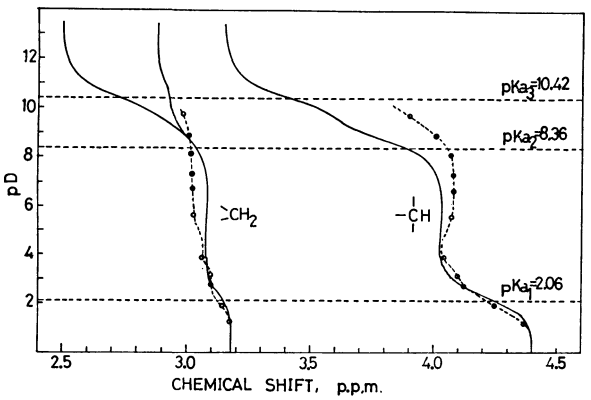

Fig. 1. Chemical shift data for cysteine (0.1 M) with (dashed lines) or without (solid lines) In(III) (0.052 M) at various pD values.

tion of the amino group indicates that the complex is not a non-charged protonated complex. In addition, the In(III) complex and the In(III) hydrolysate showed absorptions near 1100 cm^{-1}, which are assigned to the M–O–H bending mode.[4]

PMR Spectra of the 1.9: 1 Cysteine-In(III) System. Figure 1 shows the chemical-shift values of the CH and CH_2 protons of cysteine *versus* pD.[5] The dashed lines represent the titration curves of the 1.9: 1 cysteine-In(III) system. The constant chemical-shift values in the pD region from 5.5 to 8 reflect the $\widehat{SNO}$ coordination of the InL_2 complex species. In the higher pD region, the chemical-shift data suggest that some coordinated groups are released from the coordination sphere. The values of the chemical shift at about pD 4, obtained from the supernatant of the sample, are similar to those of the ligand. This indicates that the free ligand is present predominantly in the supernatant.

Potentiometric Titrations of the Cysteine-In(III) Systems. The acid dissociation constant for the carboxyl group of cysteine was obtained from the potentiometric titration data on the 0.05 M cysteine hydrochloride solution. The two remaining ionization constants, $pK_{a2}=8.36$ and $pK_{a3}=10.42$, were determined from the titration data for the 0.0015 M ligand solution by the usual linear least-squares method. These three constants were then refined by the non-linear FORTRAN IV computer program. The final values, with the standard deviations, are $\log \beta_{01-1}=10.42\pm0.01$, $\log \beta_{01-2}=18.78\pm0.01$, and $\log \beta_{01-3}=20.84\pm0.01$, at 21 °C and $I=0.1(KNO_3)$. The standard deviation in titre was 0.0029 ml. The pK_{a1} value of 2.06 was obtained from the $\log \beta_{01-3}$ and $\log \beta_{01-2}$ values. These constants are in good agreement with the reported values of $\log \beta_{01-1}=10.498$ and $\log \beta_{01-2}=18.833$ at 20 °C and $I=0.1(NaClO_4)$[6] and $pK_{a1}=1.96$ at 20 °C and $I=0.01$.[7]

The titration curve of the 4: 1 cysteine·HCl-In(III) system shows two distinct pH inflections, at $a=2$ and $a=2.75$, reflecting the formations of the InL_2 species and another species (probably InL_3) respectively; the latter was not observed in the penicillamine-In(III) system. Calculations of the stability constants for two simple species, InL and InL_2, were attempted by the Irving-Rossotti method,[8] but the consistency of the values obtained at each point was unsatisfactory. The pH titrations were carried out in the systems with various metal concentrations and metal-to-ligand ratios. The total metal concentrations $[In]_T$ were 0.00025, 0.0005, 0.0025, and 0.005 M, and the total ligand concentrations $[L]_T$ were 0.001, 0.001, 0.01, and 0.01 M respectively. The titration curves are shown in Fig. 2. Table 2 contains some data (94 points) relating to the four titration curves. The formation curves calculated in the usual manner, without assuming any hydroxo and protonated complexes, failed to be superimposed, and were not parallel to one another. The formations of the mononuclear hydroxo and protonated species were thus considered on the basis of the similarity to the penicillamine systems. These species were InL, InL_2, InLH, InL(LH), InL(OH), and $InL(OH)_2$. The best fit to the experimental results was sought for by the use of a non-linear computer program with an automatic

a) Standard deviations in parentheses.

refinement of the stability constants. The approximate estimates, 14.92 and 28.12, obtained from the Irving-Rossotti method were used as the initial values of the unknown constants for the InL and InL_2 complexes respectively. The other estimates were obtained from the values of the corresponding penicillamine-In(III) complexes. The calculation was started in the system of 0.005 M In(III) and 0.01 M cysteine hydrochloride, assuming that three species, InL, InL_2, and InLH (Table 3, Trial 1), were formed. The agreement

between the experimental and calculated values is fairly good, as compared to the non-convergence in the chemical model of InL and InL_2. The fit was further improved by the introduction of InL(OH) into Trial 1 (Trial 2). However, the introduction of InL(OH) into the chemical model of InL and InL_2 was non-converged. The system was not consistent with the non-chelating complex, $InLH_2$. The further inclusion of the $InL(OH)_2$ species (Trial 3) increased the standard deviation of the log β_{120} value. The standard deviation in titre was appreciably improved by the introduction of the InL(LH) into Trial 1 (Trial 4). The further inclusion of the $In(LH)_2$ species in Trial 4, however, led to non-convergence, as had been expected. Trials 5, 6, and 7 gave good results, in agreement with the experimental and calculated values. The presence of the InL(OH) species was doubtful, because the constants obtained from Trials 2, 3, 6, and 7 varied considerably. Trial 5 gave a slight improvement over Trial 4. Under the condition of $[In]_T=0.05$ M (see Fig. 6), Trial 4 became non-converged. A similar investigation was carried out with various other polynuclear and hydrolyzed species: In_2L_2, $In_2L_2(LH)_2$, $InL_2(OH)$, $InL_2(OH)_2$, $In_2L_2(OH)$, $In_2L_2(OH)_2$, $In_2(LH)_4(OH)_2$, $In_3L_4(OH)$, $In_3L_4(OH)_2$, *etc.*, but the results showed the absence of these species. The same treatments on the other three curves indicated that the InL(LH) and $In(LH)_2$ species became negligible, and that the InL, InL_2, and InLH species were predominant, as the concentration of the metal ion decreased. A final refinement of all these constants over the range of experimental data (4 experiments, 166 points, <pH 6) yielded the constants listed in Table 4. The calculated and experimental titres agreed with each other within a standard deviation of 0.0059 ml. The constant of the InL_3 species is also shown in the table. This value was obtained from the higher pH regions (>pH 7) of the two 4: 1 (ligand-to-metal) titration curves (2 experiments, 26 points). In these regions, the $InL_2(OH)$ species was not detected. The calculated titres are listed in Table 2. Figure 3 shows the distribution diagram of the InL_2, InL_3, InLH, InL(LH), and $In(LH)_2$ species, which was obtained from the system of 0.0025 M In(III) and 0.01 M cysteine hydrochloride.

TABLE 4. STABILITY CONSTANTS OF In(III) COMPLEXES WITH CYSTEINE HYDROCHLORIDE AT 21°C AND I=0.1 (KNO_3)[a]

InL	Log β_{110} =14.12±0.06
InL_2	Log β_{120} =27.26±0.02
InLH	Log β_{11-1}=18.46±0.02
InL(LH)	Log β_{12-1}=31.78±0.05
$In(LH)_2$	Log β_{12-2}=35.74±0.06
InL_3	Log β_{130} =32.20±0.09

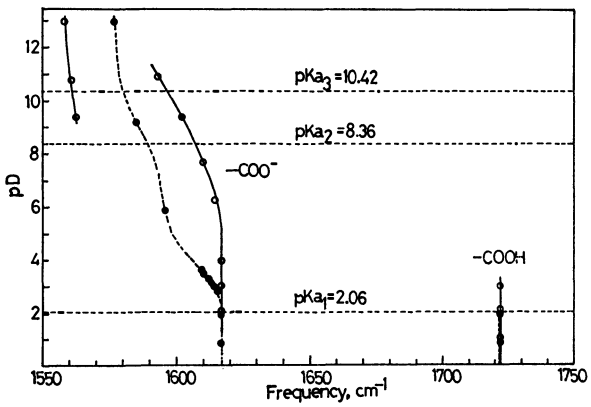

Fig. 4. IR data for cysteine (0.1 M) with (dashed line) or without (solid lines) In(III) (0.05 M) for various pD values.

IR and UV Spectra of the 2: 1 Cysteine–In(III) System. Figure 4 shows the carboxylate absorption bands of cysteine (0.1 M) in a D_2O solution in the absence (solid lines) and in the presence (dashed lines) of In(III) (0.05 M). In the lower pD region, the free ligand gives two bands, at 1617 and 1722 cm^{-1}, which are assigned to dissociated and undissociated carboxyl groups respectively. The carboxylate band shifts from 1617 to 1560 cm^{-1} with an increase in the pD, and a splitting of the band at about pD 10.5 was observed. The shift ($\Delta\nu$=57 cm^{-1}) is attributed to the electrostatic effect on the basis of the dissociation of the amino ($\Delta\nu$=42 cm^{-1}) and thiol groups ($\Delta\nu$=15 cm^{-1}), as deduced from Table 5. The electron delocalization of the carboxylate ion, $-C\overset{O}{\underset{O}{\langle}}\ominus$, could be more accelerated by the dissociation of these groups. In the solution containing the ligand and the metal ion, the carboxylate band appears

TABLE 5. CARBOXYLATE BANDS IN THE INFRARED ABSORPTION SPECTRA OF THE VARIOUS COMPOUNDS AT pD 7 AND 10 IN THE D_2O SOLUTION (cm^{-1})

Compounds	pD 7	pD 10	$\Delta\nu$[a]
α-Alanine[b]	1618	1570	48
β-Alanine[b]	1567	1567	0
S-Methyl-L-cysteine	1615	1573	42
N-Acetyl-L-cysteine	1592	1577	15
Cysteine	1617	1559	58

a) $\Delta\nu=\nu_{pD7}-\nu_{pD10}$. b) Ref. 16.

in a lower pD region in comparison with that of the ligand, indicating the coordination of the carboxyl group. The shift of the carboxylate band occurred at about pD 3, whereas about 40% of the ligand was already coordinated to the metal at pH 2, as is shown in Fig. 6. Consequently, the shift suggests the coordination of the amino group. In the pD region lower than 3, therefore, the presence of the $\widehat{S\ O}$-type complex is taken into account. The shift reaches its maximum at pD 6—7, where the InL_2 species is formed predominantly. The shift of the carboxylate band in the higher pD region (>pD 8) reveals the elimination of the carboxyl group from the coordination sphere, which is consistent with the PMR results.

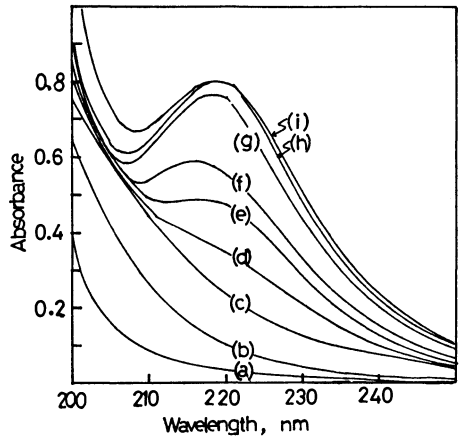

Fig. 5. Absorption spectra of the cysteine (0.00016 M)-In(III) (0.00008 M) system at various pH values: (a) pH 2.12; (b) pH 3.10; (c) pH 4.04; (d) pH 4.40; (e) pH 4.69; (f) pH 4.83; (g) pH 5.97; (h) 7.48; (i) pH 9.58.

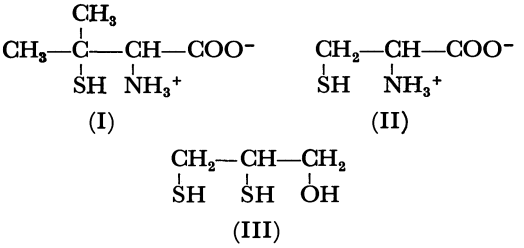
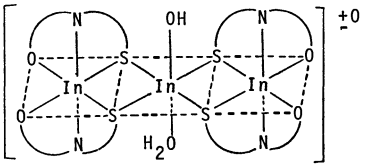
The UV absorption of cysteine in the 228—229 nm region is based on the form of the RS^- ion.[9] The absorption spectra of the cysteine-In(III) complex as a function of the pH (Fig. 5) exhibit a maximum at 217 nm, and they are quite different from those of the ligand. On the other hand, the In(III) ion(d^{10}) shows no absorption bands. The absorption band of the complex is attributed to $d\pi$ back-donation from the d^{10} metal ion to the empty d orbitals of the sulfur. In the pH region lower than 4.5, the absorption band at 217 nm does not appear, although the absorbance at about 200 nm increases with an increase in the pH. The absorption spectra of the In(III)-cysteine methyl-ester complex ($\widehat{S\ N}$ type) exhibit a maximum in the 214—219 nm region, whereas the absorption band of the In(III)-*N*-acetyl-L-cysteine complex ($\widehat{S\ O}$ type) appears in the wavelength region lower than 200 nm. Accordingly, the protonated cysteine complex InLH ($\widehat{S\ O}$ type) is formed in the pH region lower than 4.5. These findings also indicate that the charge-transfer bands based on the $In\begin{matrix}S\\N\end{matrix}$ and $In\begin{matrix}S\\O\end{matrix}$ bonds appear at about 217 nm and in the wavelength region lower than 200 nm respectively.

Discussion

The white precipitate which was not observed in the case of penicillamine(I) was formed during titration when the cysteine(II): metal ratio was smaller than 2: 1, as in 2,3-dimercapto-1-propanol(III).



The steric effect on the thiol group may be the cause of the difference among these ligands. Some sulfur-bridged polynuclear metal complexes have been reported[6,10-12] in the (II) and (III) ligands. The IR spectra suggest that the isolated cysteine-In(III) complex is hydrolyzed, but not protonated. The elemental analysis indicates that the ligand: metal ratio of the complex is 4: 3 and that the total charge of the complex is zero. The following structure can reasonably be postulated from these results:



A little excess of the metal ion causes the disruption of the equilibrium established because of the insolubility of the trimeric complex. Consequently, about 30% of the ligand will remain in the supernatant of the solution. In fact, the PMR spectra of the supernatant were similar to that of the ligand. When more of the base was added, the coordination of another hydroxide ion causes a change of the charge from zero to −1. Accordingly, the trimer is dissolved, and then the free ligand in the solution coordinates to the central metal in the trimer to form InL_2, together with the small amount of the metal hydrolysate. Based on this postulate, the sulfur-bridged trimer should have a *cis*-form. The In–S bond is stabilized by the $d\pi$ back-donation.[6,10,13-15] The higher stability constant of the sulfur-containing ligand than those of the corresponding oxygen- and nitrogen-containing ligands may be regarded as a reflection of this stabilization (cf. β-hydroxypropionic acid: log K_1=3.75, log K_2=3.04; β-aminopropionic acid: log K_1=2.72, log K_2=2.54, at 25 °C and I=0.1[13]). For the first molecule of the ligand which coordinates to In(III), the d_{xy} and d_{yz} orbitals of In(III) are used for the π bonding with the d orbital of the sulfur on the x coordinate. These orbitals of the metal ion may become less available for the bonding with the second molecule of the ligand on the $-x$ coordinate. Consequently, a *trans*-form may be unfavorable for the complex.

In the 2: 1 cysteine-In(III) system, the $In_3L_4(OH)$

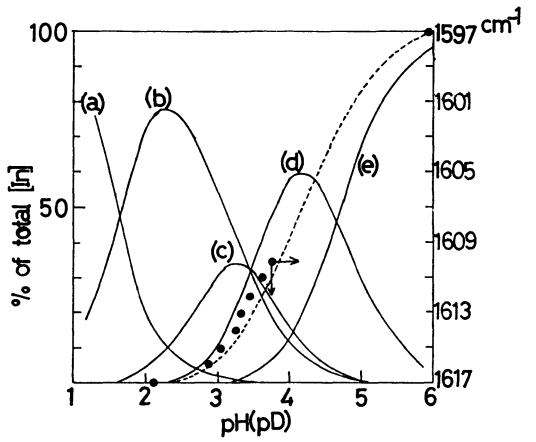


Fig. 6. Distribution diagram and IR data (●, in D_2O) for the cysteine hydrochloride (0.1 M)-In(III) (0.05M) system. Dashed line is given by $(1/2[InL(LH)]+[InL_2])/[In]_T$. (a) In^{3+}; (b) InLH; (c) $In(LH)_2$; (d) InL(LH); (e) InL_2.

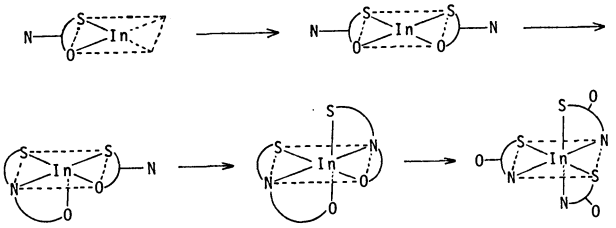
and $In_3L_4(OH)_2$ trimer were not detected by the caluclation, as had been predicted. In the cysteine-In(III) system, the protonated complexes are more readily formed than in the penicillamine system, where the $In(LH)_2$ species is absent and InLH is not always formed. At the higher metal concentrations, therefore, the InL species is negligible in the cysteine system. These differences are due to the higher stability constants of the penicillamine complexes, *e.g.*, $\log \beta_{110}=15.330$ and $\log \beta_{120}=29.789$.

The results of the potentiometric and IR measurements support the formation of the three protonated species, InLH, InL(LH), and $In(LH)_2$. Figure 6 shows the distribution diagram of the solution containing 0.1 M cysteine hydrochloride and 0.05 M In(III). The dashed line represents the sum of the distribution ratios for the two species, InL(LH) and InL_2. This is obtained by $(1/2[InL(LH)]+[InL_2])/[In]_T$. The line reflects the coordination ratio of the amino group of the ligand to the metal. Each point in the figure is a plot of the absorption frequency of the carboxylate group against the pD obtained under the same conditions, assuming the complete formation of the InL_2 species at 1597 cm^{-1}. The shift of the absorption band is considered to be caused mainly by the coordination of the amino group. Each absorption point is approximately superimposable on the dashed line. The slight deviation is probably due to the small effect on the shift of the coordination of the thiol group. This finding indicates the presence of $In(LH)_2$ and the absence of InL under these conditions. The presence of the InLH species, and the conclusion that the amino group of the coordinating cysteine is protonated, are supported by the following observations: (1) the absence of the shift of the IR band in the pD region lower than 2.5 and (2) the absence of the band of the UV absorption based on the $In\begin{pmatrix}S\\N\end{pmatrix}$ bond in the pH region lower than 4.5. In the higher pH region, the final species, InL_3, is detected by the calculation. The IR and PMR spectra indicate that the carboxyl group does not coordinate to the metal in the complex. In the case of the penicillamine complex, the steric effect of the methyl groups of the ligand prevents the attack of the third ligand molecule. At the higher metal concentrations, the following coordination process is proposed:



The authors wish to thank Dr. H. Aiba of the School of Medicine, Kyoto University, for his helpful advice, the staff of the Data Processing Center, Kyoto University, for the use of a FACOM 230-75 computer, and Dr. Y. Kuroda and Mrs. M. Uobe for their PMR measurements.

Spectrophotometric Study of the Zirconium-Pyrocatechol Violet-Tridodecylethylammonium Ternary Complex

Yoshio SHIJO

Department of Industrial Chemistry, Faculty of Engineering, University of Utsunomiya, Ishii-machi, Utsunomiya 321-21

(Received March 25, 1976)

The zirconium-pyrocatechol violet chelate anion is extracted with tridodecylethylammonium bromide in butyl acetate to form a ternary complex. The ternary complex has an absorption maximum at 586 nm in the organic layer. The optimum pH range for the extraction is from 5 to 6. Beer's law holds for 0.4—9 μg of zirconium in 5 ml of the organic phase. The molar absorptivity of the ternary complex is 3.9×10^4 cm^{-1} mol^{-1} l at 586 nm. The composition of the ternary complex is estimated to be $Zr(pv)_2(R-\overset{\overset{R}{|}}{N}-R')_3$.

The ternary complexes formed by the ionic association of the metal-Pyrocatechol Violet (PV) chelate anions and the bulky organic cations such as diphenylguanidine and quaternary ammonium salt have been studied by many workers. Kohara *et al.*[1] extracted ion pairs such as molybdenum-Pyrocatechol Violet(PV)-dialkylmethylbenzylammonium. Extraction of the indium-PV-hexadecylpyridinium system was reported by Ishito and Tonosaki.[2] The gallium-PV-diphenylguanidine system was studied by Akhmedli *et al.*[3] The gallium-PV-hexadecylpyridinium system was extracted in 1-butanol by Ishito.[4] The iron(III)-PV-diphenylguanidine system was studied by Yuryavichus and Valyukyavichyus.[5] Moreover, studies of the ternary complexes of the aluminum-PV-diphenylguanidine,[6] the bismuth-PV-diphenylguanidine,[7] and the titanium-PV-diphenylguanidine[8] systems have been reported. The water soluble metal-PV-quaternary ammonium ternary complexes in the micelle solution have been applied to the spectrophotometric determination of aluminum,[9] antimony and molybdenum,[10] niobium,[11] and tantalum.[12]

In the process of investigating the extraction of the metal chelate anions with an oleophilic quaternary ammonium salt such as tridodecylethylammonium bromide (TDEA), we reported an extraction spectrophotometric method for scandium[13] and yttrium[14] as Xylenol Orange chelate and for iron[15] as Eriochrome Cyanine R chelate and for copper,[16] tin,[17] and aluminum[18] as Pyrocatechol Violet chelate. In this paper, the fundamental conditions for the extraction of zirconium as the zirconium-PV-TDEA ternary complex with tridodecylethylammonium bromide in butyl acetate and the composition of the ternary complex will be discussed.

Experimental

Reagent. A 2.5×10^{-3} M zirconium solution was prepared by the following procedure. 0.1140 g of zirconium was placed in a platinum crucible and to this was added 6 ml of hydrofluoric acid (1+1). After the zirconium had been dissolved, 2 ml of sulfuric acid was added and evaporated to fuming sufur trioxide on a hot plate. Ater cooling, 137 ml of sulfuric acid was added and diluted to 500 ml with de-ionized water. A working standard solution was prepared as needed by the dilution of the 2.5×10^{-3} M solution with de-ionized water to each desired concentration. A 5×10^{-4} M PV solution was prepared by dissolving the Dotite PV in de-ionized water without any further purification. TDEA was prepared by the reflux to ethanolic solution of tridodecylamine and ethyl bromide for 4 h. After evaporation of the solvent, the salt was recrystallized two times from butyl acetate. A 6×10^{-4} M TDEA solution was prepared by dissolving the above TDEA in butyl acetate. All the other chemicals used were of a guaranteed reagent quality.

Apparatus. All the measurements of the absorbance were made with a Hitachi manual spectrophotometer, mode Epu-2A. Matched 10-mm absorption cells were used. The pH measurements were made with a Hitachi-Horiba model M-5 glass electrode pH meter.

Standard Procedure. Up to 9 μg of zirconium were placed in a 50 ml polyethylene beaker to which were added a definite amount of 0.1 M sulfuric acid and 2 ml of 5×10^{-4}M PV solution. pH of the solution was adjusted to 5 by the addition of 2 ml of 2 M sodium acetate solution and then the solution was diluted to 25 ml with de-ionized water. The solution was transferred into a 35 ml test tube and 5 ml of 6×10^{-4} M TDEA in butyl acetate was added. The extraction was carried out for 5 min by turning the test tube upside down at two times per 5 s. After the complete phase separation, the organic layer was taken out and centrifuged for 2 min at 3000 rpm. The extract was transferred into an absorption cell and the absorbance at 586 nm was measured against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. Absorption spectra of the ternary complex extracted into butyl acetate and of the zirconium-PV chelate anion in an aqueous solution are given in Fig. 1, along with that of the reagent blank. The ternary complex and the zirconium-PV chelate anion have an absorption maximum at 586 and 595 nm respectively.

Effect of pH. The aqueous solution was adjusted to various pH values with the acetate buffer solution and the extraction was carried out by the above procedure. Although formation of the zirconium-PV chelate should occur at a lower pH, about 2, the optimum pH range for the extraction of the ternary complex is found to be from 5 to 6. It is thought that the extractable higher cordination chelate anion forms at pH values from 5 to 6. The absorbance of the reagent blank

(2) Zr–PV in aq. soln. $[Zr]_w=10^{-5}$ M.
(3) PV–TDEA in butyl acetate $[PV]_w=4\times10^{-5}$ M
(4) PV in aq. soln. $[PV]_w=2\times10^{-4}$ M.

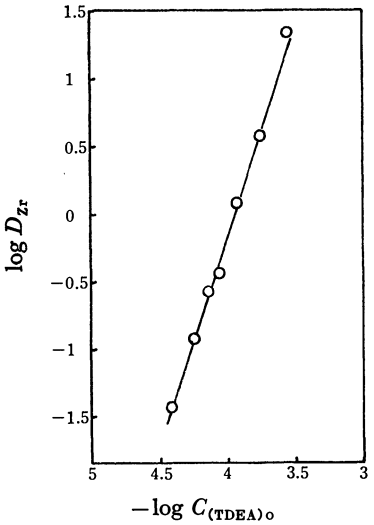

Fig. 2. Equilibrium-shift method applied to the Zr–PV–TDEA system.
$[Zr]_w=2\times10^{-6}$ M, $[PV]_w=2\times10^{-4}$ M, $[Br^-]_w=5\times10^{-4}$ M, pH=5, $V_w=25$ ml, $V_o=5$ ml, 586 nm.

in the organic layer increases very much with an increase in the pH value.

Organic Solvents. Several kind of organic solvents were tested in order to achieve a quantitative extraction of zirconium. The ternary complex can be extracted in such solvents as butyl acetate, carbon tetrachloride, benzene, toluene, xylene, and carbon disulfide. Absorbances of the ternary complex are much the same in these solvents. But the lowest absorbance of reagent blank is obtained in butyl acetate. The ternary complex can not be extracted in such solvents as 1-butanol, methyl isobutyl ketone, nitrobenzene, and chloroform.

The Effect of the PV Concentration. The effect of the PV concentration in the aqueous phase on the extraction of the ternary complex was examined by varying the PV concentration while other variables were held constant. The absorbance of the extract is constant when the PV in the initial aqueous phase is in the concentration range from 2×10^{-5}—6×10^{-5} M. The absorbance of the extract gradually decreases upon further addition of PV.

The Effect of the TDEA Concentration. The effect of the concentration of TDEA in butyl acetate on the extraction of the ternary complex was examined. The constant and maximum absorbance of the extract is obtained with a concentration higher than 4×10^{-4} M.

The Effect of the Mixing Time. The mixing time was varied from 10 sec to 15 min. The absorbance of the extract is constant for the mixing times from 3 to 15 min.

Extractability and Molar Absorptivity. The extractability of the ternary complex under the optimum conditions was examined by spectrophotometric determination of zirconium with Xylenol Orange in the extract after evaporating the organic layer. When a 250 ml portion of an aqueous layer containing 45.6 μg of zirconium is mixed with 50 ml of butyl acetate solution of TDEA, 97.8% of the zirconium is extracted by one extraction. The distribution ratio and the molar absorptivity are 2.22×10^2 and 3.9×10^4 cm^{-1} mol^{-1} l respectively.

Calibration Curve. A calibration curve for the determination of zirconium was made under the optimum conditions. A good linear relationship is obtained over the concentration range from 0.45 to 9 μg of zirconium per 5 ml of butyl acetate.

The Composition of the Ternary Complex. The molar ratio of PV to zirconium in the ternary complex was estimated to be 1 : 2 by the continuous-variation method. The molar ratio of zirconium to TDEA in the ternary complex was established by the equilibrium-shift method. All the equilibrium concentration and distribution ratios were estimated by measuring the absorbances of the organic or aqueous phase. The plot of log D_{Zr} against log $[TDEA]_o$ gives the number of TDEA which are involved in forming the ternary complex. The number is given by the slope. The slope of the straight line shows that the ratio of zirconium to TDEA is 1 : 3, as is shown in Fig. 2. According to these results, the composition of the ternary complex is estimated to be

$$Zr\,(pv)_2\left(R-\underset{\displaystyle R}{\overset{\displaystyle R}{N}}-R'\right)_3.$$

Glass Formation and Crystallization in Ternary Phosphate Systems Containing Al_2O_3

Akira KISHIOKA, Masao HAYASHI,* and Makio KINOSHITA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received April 9, 1976)

Glass formation and crystallization were investigated in two types of three-component systems, M_2O–Al_2O_3–P_2O_5 (M=Li, Na, and K) and MO–Al_2O_3–P_2O_5 (M=Mg, Ca, and Ba). In the Li_2O–Al_2O_3–P_2O_5 and MO–Al_2O_3–P_2O_5 systems, wide regions of glass formation were found in compositions containing more than 50 mol% of P_2O_5. In the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems, the two peaks in Al_2O_3 content were found in the regions of glass formation corresponding to about 35 and 65 mol% of P_2O_5. In the devitrified products of the glasses with 60 and 70 mol% of P_2O_5, $AlPO_4$, $Al(PO_3)_3$, and alkaline earth metaphosphate (in the MO–Al_2O_3–P_2O_5 system) were found by X-ray powder diffractometry. The crystalline phases in the samples obtained as mixtures of glass and crystal consisted of $AlPO_4$ in the composition containing 60 mol% of P_2O_5, while those with a P_2O_5 composition of 70 mol% consisted of $Al(PO_3)_3$. By heating those samples at 700—900 °C, the X-ray diffractions of $AlPO_4$ and $Al(PO_3)_3$ were intensified. On the other hand, in the samples with 37.5, 40, and 50 mol% of P_2O_5, all the crystalline phases consisted of $AlPO_4$, and the intensities of these X-ray diffractions decreased after the samples were heated at 600—700 °C. Thus, there is a marked structural difference between the two peak-regions in the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems.

The addition of Al_2O_3 to phosphate glass results in an improvement in the chemical durability, a decrease in the thermal expansion coefficient, and an increase in the deformation temperature of the glass, that is, the stabilization of the glass structure.[1] It has been suggested that these changes in properties are due to the formation of a ($AlPO_4$) group in the glass. There have been many investigations of the role of the Al^{3+} ion in silicate glass. On the Al^{3+} ion in phosphate glass, however, only a few investigations have been reported. Recently, Sakka investigated the coordination number of the Al^{3+} ion in silicate, phosphate, borate, and other glasses on the basis of measurements of the chemical shift of the Al $K\alpha$ line by X-ray emission spectroscopy,[2] while Watanabe *et al.* proposed the existence of –P–O–Al– linkage in the glass of the $NaPO_3$–Al_2O_3 system.[3]

In a previous paper, the authors reported the regions of glass formation in multicomponent phosphate systems containing TiO_2.[4] However, no investigations of those in aluminophosphate systems have been reported. The glass-forming region in a three-component diagram is important in the investigation of the glass structure, because it is determined by the role of cations in the glass. Therefore, it may be worthwhile to determine the glass-forming regions in ternary phosphate systems containing Al_2O_3.

In this paper, the regions of glass formation in three-component diagrams were determined for six kinds of phosphate systems containing Al_2O_3—the M_2O–Al_2O_3–P_2O_5 (M=Li, Na, and K) and MO–Al_2O_3–P_2O_5 (M=Mg, Ca, and Ba) systems. In addition, the devitrified products of the glasses and the crystalline phases in these systems were investigated by X-ray powder diffractometry. From the results obtained, the glass structure and the action of Al^{3+} ion in it were discussed in connection with the P_2O_5 content in the glass.

Experimental

Preparation of Glass. The materials used were the following reagents. Aluminum oxide and orthophosphoric acid (85%) were used in all the systems, lithium hydroxide monohydrate was used in the Li_2O–Al_2O_3–P_2O_5 system, sodium dihydrogenphosphate dihydrate, sodium triphosphate, and anhydrous sodium carbonate in the Na_2O–Al_2O_3–P_2O_5 system, potassium dihydrogenphosphate and anhydrous potassium carbonate in the K_2O–Al_2O_3–P_2O_5 system, magnesium oxide in the MgO–Al_2O_3–P_2O_5 system, calcium hydrogenphosphate dihydrate in the CaO–Al_2O_3–P_2O_5 system, and barium hydroxide octahydrate in the BaO–Al_2O_3–P_2O_5 system. All the chemicals except sodium triphosphate were of a reagent grade. Commercial reagent-grade sodium triphosphate was purified by recrystallization and dehydrated.[5] A mixture obtained by mixing the necessary amounts of compounds selected from the compounds listed above was placed in platinum dishes or alumina crucibles. The former were used in the case of P_2O_5 contents up to 50 mol%, the latter, in the case of more than 50 mol%. In the case of a Na_2O/P_2O_5 or K_2O/P_2O_5 ratio of 1 as in the Na_2O–P_2O_5 or K_2O–P_2O_5 two-component system, $NaH_2PO_4 \cdot 2H_2O$ or KH_2PO_4 was used respectively. The weight of each batch was about 20 g.

Samples were heated in a Siliconit electric furnace BSH-1530 (Siliconit Konetsukogyo Co.) equipped with a platinum platinum-rhodium thermocouple with an automatic thermoelectric regulator. The temperature was slowly raised to 1350 °C over about a 7-h period and then kept at this temperature for 1 h. The melts of batches containing up to 55 mol% of P_2O_5 were poured out and quenched by pressing them with copper plate cooled with water. The other melts of a high viscosity were taken out from the furnace together with the alumina crucible and rapidly cooled by cold air flow generated by an electric fan. The homogeneity of the formed glass was immediately observed by the naked eye and also under a microscope or a polarizing microscope.

Because of the loss of P_2O_5 by vaporization during heating, the final copomistoin of the phosphate glass usually deviates to some extent from the initial composition, where the deviation depends on the condition of preparation. Therefore, all the diagrams for the glass formation were expressed in terms of the initial composition. In order to measure the volatiliza-

tion loss of P_2O_5, the three components in the MgO–Al_2O_3–P_2O_5 glasses in the range from 50 to 80 mol% of P_2O_5 in the batch composition were determined gravimetrically—MgO and P_2O_5 as $Mg_2P_2O_7$ and Al_2O_3 as $AlPO_4$.

Devitrification of Glass. Glass grains (0.25—1 mm in diameter) of about 2 g placed in a small porcelain crucible were heated for 10 h at the temperatures given in Tables 1—7. The temperature at which the glass in each system was devitrified was in the range from 600 to 900 °C; this temperature increased with the increase in the P_2O_5 content.

X-Ray Powder Diffractometry. The obtained samples were finely pulverized with an alumina mortar and their diffraction patterns were taken by a Rigaku Denki Geigerflex diffractometer with nickel-filtered Cu $K\alpha$ radiation. The identification of the crystalline products was carried out by comparing the X-ray diffraction peaks of the sample with those of the ASTM data file.

Results and Discussion

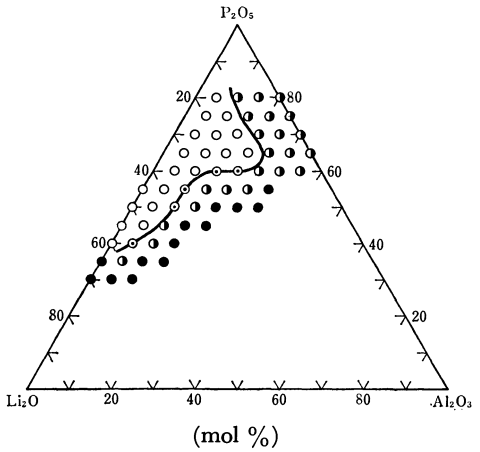
The experimetal results for the glass formation in each system are given in Figs. 1—6. The ranges of the glass formation in the M_2O–P_2O_5 and MO–P_2O_5 two-component systems were in agreement with the data presented by Takahashi,[6] except for the K_2O–P_2O_5 system, in which the glass formation was found in the composition containing less than 50 mol % of P_2O_5. In the composition at which the transparent homogeneous glass was not formed, the following three types of products were obtained; (1) a mixture of glass and crystal (when the melt was partly devitrified and when the crystalline substance was separated out in the melt), (2) a crystalline product (when the melt was devitrified and when the sample was not melted), and (3) the fused mass consisting of a crystal and glassy substance. No liquid-liquid-phase separation in the melt was found in any system.

In the MgO–Al_2O_3–P_2O_5 glasses with 50 to 80 mol % of P_2O_5, the amount of the loss of P_2O_5 by the volatilization was in the range from 1.0 to 16.5 mol %; it increased with an increase in the P_2O_5 content in the batch composition. The results of the gravimetric determination of three components in the glass of this system showed that the contents of water in the glasses were in the range from 0.5 to 1.5 wt %. Similar results may also be affirmed in the other systems.

The chemical formula of the crystalline products in the M_2O–Al_2O_3–P_2O_5 and MO–Al_2O_3–P_2O_5 systems, as identified by X-ray diffractometry, are listed in Tables 1—6, while those of the Al_2O_3–P_2O_5 two-component system are listed in Table 7.

Glass Formation in M_2O–Al_2O_3–P_2O_5 System. In the Li_2O–Al_2O_3–P_2O_5 system (Fig. 1), Al_2O_3 was incorporated into the glass composition when the P_2O_5 content exceeded about 35 mol %; the peak of the Al_2O_3 content appeared in the range from 60 to 70 mol % of P_2O_5. As can be seen from Figs. 1 and 4—6, the shape of the glass-forming region in this system is analogous to that in the MO–Al_2O_3–P_2O_5 system. As the properties of the Li^+ ion are similar to those of the alkaline earth ions, and as the electrostatic-bond strength of the Li^+ ion is larger than that of the Na^+ or K^+ ion, it may be considered that the Li^+ ion plays a role similar to that of the alkaline earth ion in the phosphate glass.

On the other hand, as is shown in Figs. 2 and 3, a large amount of Al_2O_3 was incorporated into the glass in composition of both about 35 as well as 65 mol %



(mol %)

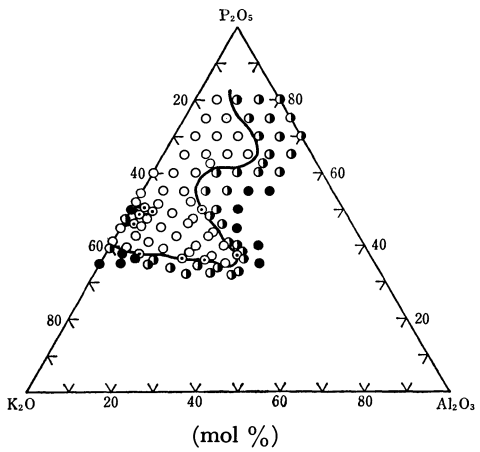
(mol %)

Fig. 2. Glass-forming region in Na_2O–Al_2O_3–P_2O_5 system.



(mol %)

Fig. 3. Glass-forming region in K_2O–Al_2O_3–P_2O_5 system.

of P_2O_5 in the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems. This is a marked difference from the Na_2O–TiO_2–P_2O_5 and K_2O–TiO_2–P_2O_5 systems,[4] where only a small amount of TiO_2 is introduced into the glass even when the content of P_2O_5 exceeds 50 mol %. This fact indicates a difference between Al^{3+} and Ti^{4+} ions in their behavior in the phosphate glass. Since the Al^{3+} ion has been regarded as an intermediate ion, it is able to act as a network modifier as well as a network former in the glass structure. According to Sakka,[2] most of the Al^{3+} ions in the glass with a higher P_2O_5 content ($P/O \approx 0.33$) are 6-fold coordinated, while those with a lower P_2O_5 content ($P/O \lesssim 0.25$) are 4-fold coordinated. The existence of two peaks of Al_2O_3 content of the glass region in both the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems suggests the above-noted change in the coordination number of the Al^{3+} ion with the P_2O_5 content in the phosphate glass.

In the K_2O–P_2O_5 two-component system, the glass was not formed at $K_2O/P_2O_5=1$ (50 mol % of P_2O_5 in Fig. 3), but at $K_2O/P_2O_5>1$. Presumably a break in the long –P–O–P– straight-chain of potassium metaphosphate ($K_2O/P_2O_5=1$) by the excess K^+ ion favored the glass formation. The glass formation in the composition along the line of $K_2O/P_2O_5=1$ in the K_2O–Al_2O_3–P_2O_5 system was more extensive than that in the same composition in the K_2O–TiO_2–P_2O_5 system.[4] This fact also suggests that the network-forming and glass-forming abilities of the Al^{3+} ion differ in some degree from those of the Ti^{4+} ion in the phosphate glass.

Glass Formation in MO–Al_2O_3–P_2O_5 System. In the systems of MgO–Al_2O_3–P_2O_5, CaO–Al_2O_3–P_2O_5, and BaO–Al_2O_3–P_2O_5 (Figs. 4, 5, and 6), the content of Al_2O_3 incorporated into the glass increased with an increase in the P_2O_5 content, and the peak of Al_2O_3 content was found in the range from 60 to 70 mol % of P_2O_5. As has been described above, the glass-forming regions in these systems were similar to that in the Li_2O–Al_2O_3–P_2O_5 system. The difference between Al_2O_3 and TiO_2 in the glass formation was observed also in the BaO–Al_2O_3–P_2O_5 and BaO–TiO_2–P_2O_5 systems, because in the latter system the amount of TiO_2 within the composition limits of glass formation decreased with an increase in the P_2O_5 content.[4]

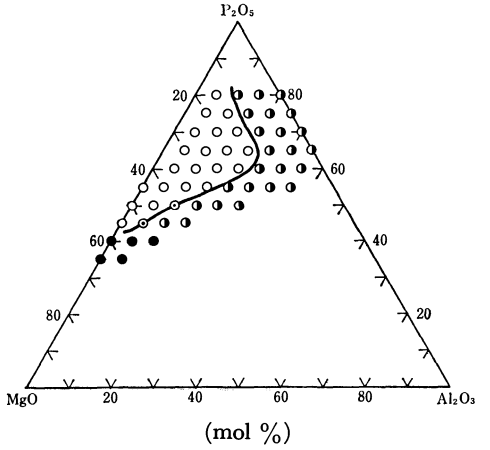


Fig. 4. Glass-forming region in MgO–Al_2O_3–P_2O_5 system.

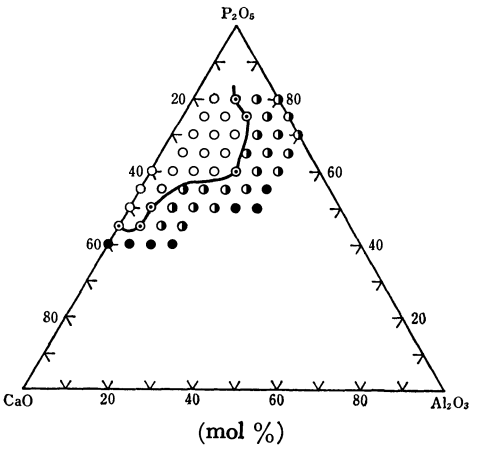

Fig. 5. Glass-forming region in CaO–Al_2O_3–P_2O_5 system.

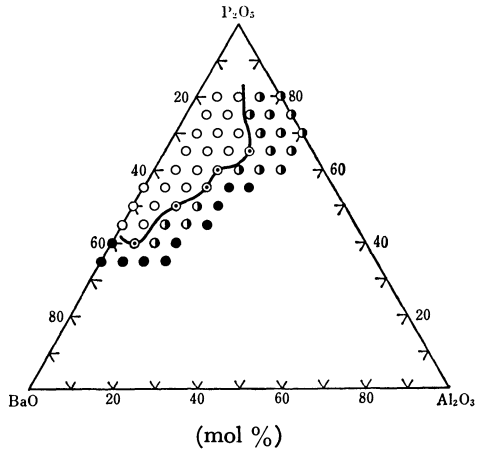

Fig. 6. Glass-forming region in BaO–Al_2O_3–P_2O_5 system.

X-Ray Powder Diffractometry. The devitrified products of the glasses obtained in the glass-forming region of the M_2O–Al_2O_3–P_2O_5 system were mainly aluminum metaphosphate in the composition containing 70 mol % of P_2O_5, aluminum metaphosphate and aluminum orthophosphate in 60 mol % of P_2O_5, and alkali metaphosphate (sodium trimetaphosphate in the Na_2O–Al_2O_3–P_2O_5 system) and aluminum orthophosphate in 50 mol % of P_2O_5 (Tables 1, 2, and 3). In each of the MO–Al_2O_3–P_2O_5 systems, alkaline earth metaphosphate as well as aluminum orthophosphate or aluminum metaphosphate was found in the compositions containing 50, 60, and 70 mol % of P_2O_5 (Tables 4, 5, and 6).

The crystalline phases in the samples outside the boundary for the glass formation in the M_2O–Al_2O_3–P_2O_5 and MO–Al_2O_3–P_2O_5 systems consisted mainly of aluminum metaphosphate in the composition containing 70 mol % of P_2O_5, aluminum orthophosphate and aluminum metaphosphate in 60 mol % of P_2O_5, and aluminum orthophosphate in 50 mol % of P_2O_5 (Tables 1—6). In the Na_2O–Al_2O_3–P_2O_5 system containing 37.5 mol % of P_2O_5 and the K_2O–Al_2O_3–P_2O_5 system containing 40 mol % of P_2O_5, the crystalline phases consisted mainly of aluminum orthophosphate (Tables 2 and 3).

As is marked with (+) sign in Tables 1—7, in all the samples outside the glass-forming range of 70 mol % of P_2O_5, the X-ray diffraction patterns of aluminum metaphosphate increased in intensity upon heating at 800—900 °C, while in the composition containing 60 mol % of P_2O_5 the crystallization of aluminum orthophosphate was promoted by heating at 700—900 °C. The same phenomena were also observed in the Al_2O_3–P_2O_5 two-component system (Table 7). The devitrified product of $25Al_2O_3 \cdot 75P_2O_5$ glass consisted predominantly of aluminum metaphosphate. These facts suggest that the network consisting of aluminum, oxygen, and phosphorous ions in the M_2O–Al_2O_3–P_2O_5 and MO–Al_2O_3–P_2O_5 glasses containing 60 mol % or more P_2O_5 is analogous to that in the Al_2O_3–P_2O_5 two-component glass. According to Pauling and Sherman,[7] the alumi-

a) This glass was prepared by heating the mixture of aluminum orthophosphate and orthophosphoric acid (85%) at 1500 °C.

num metaphosphate consists of AlO_6 octahedra and rings of four PO_4 tetrahedra. Gill and Riaz reported that the ultraphosphate glasses with M/P=0.7—1.0 consisted of trimetaphosphate rings, polyphosphate chains, and branched chains.[8] Consequently, the AlO_6 octahedra seem to stabilize these glass structures by linking them to the rings of PO_4 tetrahedra and the branching points of phosphate chains.

On the other hand, the X-ray diffraction gave rather complex patterns for the devitrified samples of the Na_2O–Al_2O_3–P_2O_5 glasses with 37.5 mol % of P_2O_5 and K_2O–Al_2O_3–P_2O_5 glasses with 40 mol % of P_2O_5. In the diffraction patterns for the samples outside the glass-forming range in the systems of 37.5, 40, and 50 mol % of P_2O_5, the diffraction patterns of aluminum orthophosphate weakened upon heating at 600—700 °C. These facts suggest that the structure of the glass in the range from 37.5 to 50 mol % of P_2O_5 differs markedly from that in the composition containing more than 50 mol % of P_2O_5 (ultraphosphate). Therefore, the above results also suggest that the action of the Al^{3+} ion the glass structure varies with the P_2O_5 content in the glasses of the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems.

In the composition containing less than 50 mol % of P_2O_5 (polyphosphate), the structures of the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 glasses may be regarded as random aggregates of the –P–O–P– and –P–O–Al– chains (clusters) consisting of PO_4 and AlO_4 tetrahedra and the Na^+ or K^+ ions.

The Conformations of Copper(II) Complexes with edda-Type Optically Active Polyamino Carboxylic Acids in Aqueous Solutions

Tasuku MURAKAMI and Masahiro HATANO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, 2-1-1 Katahira, Sendai 980

(Received April 19, 1976)

A copper(II) complex with (*S,S*)-1,1′-ethylenedipyrrolidine-2,2′-dicarboxylic acid (H_2epro) was prepared, and its absorption and CD spectra were measured in an aqueous solution. A weak absorption band at 9500 cm^{-1} was indicative of the apical coordination of the carboxylate group. Furthermore, from the fact that the effect of unidentate bases, such as pyridine and ammonia, on the absorption and CD spectra of the epro complex was quite different from that of bidentate bases, the epro complex was expected to take a *Λ*-uns-*cis* conformation. In addition, the base-addition effect was measured for the complexes of (*S,S*)-α,α′-dimethyl-*N,N′*-ethylenediaminediacetic acid(H_2eddp), (*S,S*)-α,α′-diisopropyl-*N,N′*-ethylenediaminediacetic acid(H_2eddv), and (*S,S*)-α,α′-dibenzyl-*N,N′*-ethylenediaminediacetic acid(H_2eddc). The conformations of these complexes are also discussed on the basis of the information obtained for the epro complex.

In the previous paper,[1] we have reported that the copper(II) complexes with ethylenediamine-*N,N′*-diacetic acid(H_2edda)-type optically active polyamino carboxylic acids, such as (*S,S*)-α,α′-dimethyl-*N,N′*-ethylenediaminediacetic acid(H_2eddp),[2,3] (*S,S*)-α,α′-diisopropyl-*N,N′*-ethylenediaminediacetic acid(H_2eddv), and (*S,S*)-α,α′-dibenzyl-*N,N′*-ethylenediaminediacetic acid(H_2eddc), exhibited quite different circular dichroism(CD) spectra from each other and that, hence, these complexes might adopt different conformations in aqueous solutions.

In order to obtain further information on the conformations of the edda-type copper(II) complexes, we have now prepared a new edda-type complex of a copper(II) ion with (*S,S*)-1,1′-ethylenedipyrrolidine-2,2′-dicarboxylic acid (abbreviated to H_2epro). As may be seen in Fig. 1, this acid has two pyrrolidinyl groups in its inner parts and, hence, may be expected to coordinate to a metal ion with a large stereospecificity. In this paper, we wish to report the absorption and CD spectra of the epro complex of copper(II) and, in addition, the effects of unidentate and bidentate bases on the CD spectra of other edda-type complexes. The conformations of these complexes will be discussed on the basis of the behavior of the spectra.

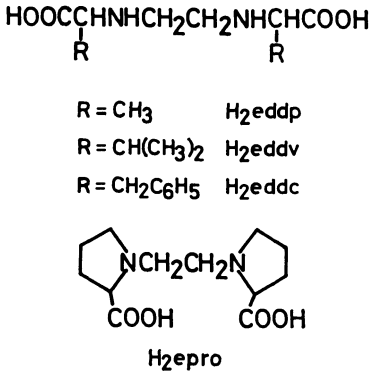

Fig. 1. Optically active edda-type polyamino carboxylic acids.

Results and Discussion

Conformation of [Cu(epro)] and Other edda-Type Complexes. Figure 2 shows the absorption and CD spectra of the epro complex in the region of 7000 to 22000 cm^{-1}, together with those of the eddp, eddv, and eddc complexes which have been reported previously.[1] The epro complex exhibited a main absorption at 15400 cm^{-1} and a weak band at about 9500 cm^{-1}. Corresponding to these two bands, two CD bands were observed with the opposite sign. The existence of this weak absorption band plays an important role when discussing the conformation of the epro complex, as will be described below.

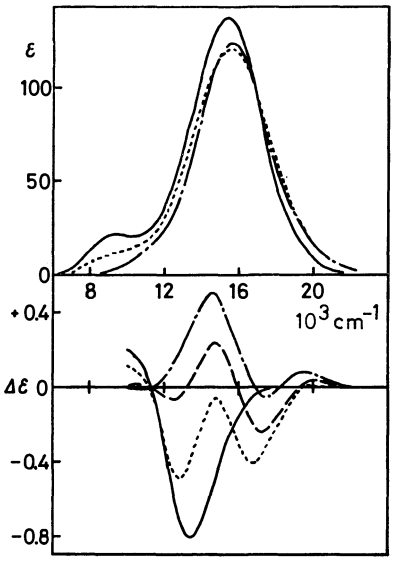

Fig. 2. Absorption and CD spectra of [Cu(epro)] (——), [Cu(eddp)] (— - —), [Cu(eddv)] (------), [Cu(eddc)] (— — —) in aqueous solutions.

In general, copper(II) complexes typically consist of four nearby donor atoms arranged approximately in a plane around the central metal ion, with the possibility of one or two more distant apical donors. A stronger ligation to the copper(II) ion along the tetragonal axis would cause the d-d absorption band to shift to a lower energy.[4-7] In many cases, a shoulder band appears at about 10000 cm^{-1} as a result of such a ligation.[7-9] Therefore, the weak band observed for the epro complex leads us to expect the apical ligation of one or two carboxylate group(s) of epro, that is, a *cis*-type coordination of epro to the copper(II) ion.[10] The chelated

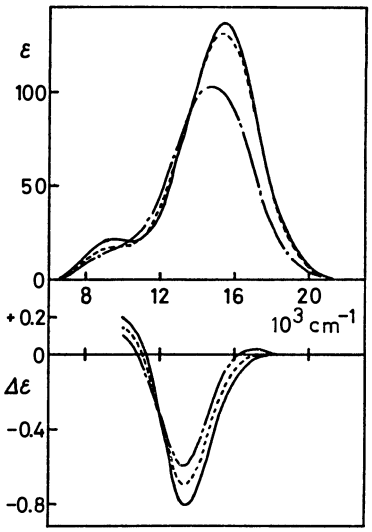

Fig. 3. The pH-dependent absorption and CD spectra of [Cu(epro)].

carboxylate group will possess a stronger ligand field than water, in spite of having the same coordination atom. Thus, the weak band is thought to become visible.

It has been observed that the optical activity of the ternary mixed complexes of copper(II) with diethylenetriamine and L-α-amino acids decreases in a high pH region.[7] This extreme decrease in the optical activity was concluded to result from the displacement of the carboxylate group coordinated at an apical position by a hydroxide ion. Therefore, if the epro complex contains an apical ligation, the intensity of the CD band is expected to decrease significantly in a high pH region. Figure 3 shows the variable-pH absorption and CD spectra of the epro complex. These spectra varied little in the pH 5 to 9 region. However, as the pH was further increased, the intensities of the absorption and CD bands appreciably decreased. Therefore, this is some evidence for the apical ligation of the carboxylate group in the epro complex. On the other hand, the absorption and CD spectra of the epro complex did not vary with the temperature (0—70 °C) and the concentration (2×10^{-3}—5×10^{-2} M) in a neutral pH region, indicating that the epro complex exists not as an equilibrium mixture, but as a single species in a neutral solution.

An examination of molecular models showed that epro hardly coordinates in a plane because of the rigid pyrrolidinyl groups. This is supported by the fact that some tetraamines, which have two pyrrolidinyl groups in their inner parts as well as epro, did not form planar species of the nickel(II) ion, but formed only octahedral ones.[11-13] Not only epro, but also other edda-type polyamino carboxylic acids seem to have primarily a certain characteristic that they hardly coordinate to a metal ion in a plane.[14] For example, as of now, no cobalt(III) complex with an edda-type acid in the planar configuration has been reported. Only s-*cis* and uns-*cis* isomers have actually been obtained.[10,15-17] Also, in the case of the edda-type complexes of the nickel(II) ion, the configuration in solution has been assigned to an s-*cis* form on the basis of NMR measurements.[18,19] Thus, the apical ligation of the one or two carboxylate group(s) which is derived from the absorption spectrum is also supported from the stereochemical point of view for epro.

In order to discriminate whether only one or both of the two carboxylate groups of epro coordinate(s) at the apical position, the effects of unidentate bases, such as pyridine and ammonia, added to the complex solution on the absorption and CD spectra were compared with those of bidentate bases, such as 2,2′-bipyridyl and ethylenediamine.

When a great excess of pyridine or ammonia was added to a solution of the epro complex, the absorption and CD bands became appreciably intense, but, in particular, the CD shape varied only to a lesser extent, as is shown in Fig. 4. However, when excess 2,2′-bipyridyl or ethylenediamine was added, the absorption spectral shape changed entirely and the intensity of the CD band decreased considerably. These findings indicate that the conformation of the epro complex remains essentially unaltered by the coordination of the unidentate bases, but the coordination of the bidentate bases alters the conformation.

The spectral behavior observed can be reasonably explained by supposing that the epro complex takes a conformation in which only one of the two carboxylate groups coordinates at an apical position, that is, a uns-*cis* form. It is expected that the bidentate base occupies two positions in the square plane about the copper(II) ion and displaces the carboxylate group coordinated in the plane, and that, consequently, the original conformation of epro is destroyed. On the other hand, the unidentate base probably coordinates to one position in the square plane and to one apical position, neither of which is occupied by epro; hence, the unidentate base may not alter the conformation

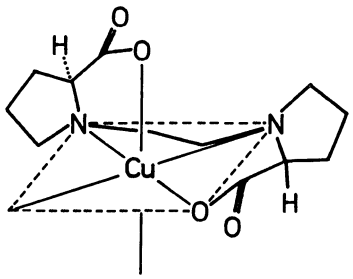

Fig. 5. Schematic drawing of a uns-*cis* structure proposed for [Cu(epro)].

of the epro complex. 2,2'-Bipyridyl or 1,10-phenanthroline act little as a unidentate base; the effect of α-methyl substituted pyridines such as α-picoline and 2,6-lutidine has been much smaller than that of pyridine.[20]

There are only two structures with apical ligation possible for the epro complex: *Λ*-uns-*cis* and Δ-s-*cis*,[21] because of the large strain originating from the pyrrolidine rings in epro. Therefore, the epro complex may be on the basis of the spectral behavior described above expected to take a *Λ*-uns-*cis* form. This structure is illustrated in Fig. 5. Each of the two tertiary nitrogen atoms in the epro complex has an *R* configuration, and the central ethylenediamine-like chelate ring seems to become an envelope.

As may be seen from Fig. 2, the eddv complex also exhibited a shoulder band at about 10000 cm^{-1} as a tailing of the main band. This implies that the apical ligation of the carboxylate group takes place to some extent in the eddv complex as well as in the epro complex. In addition, a high temperature dependence has been observed for the CD spectrum of the eddv complex.[1] This is apparently based on a binary equilibrium, as derived from the presence of isosbestic points. In the previous paper,[1] the temperature dependence observed for the eddv complex was expected to result from an equlibrium between two types of planar forms, in which the ring substituent groups are equatorial or axial. However, the contribution of the form in which the substituents are axial is probably small. The apical ligation of the carboxylate group appears to be a more plausible explanation of the weak band observed for the epro and eddv complexes.

The CD spectra of the four copper(II) complexes with optically active edda-type polyamino carboxylic acids are quite different from each other, as is shown in Fig. 2. The negative components of the CD spectra increase in this order; [Cu(eddp)]<[Cu(eddc)]<[Cu(eddv)]<[Cu(epro)]. This order is the same as that of the intensity of the shoulder band at about 10000 cm^{-1}. When excess unidentate bases, such as pyridine and ammonia, were added to the aqueous solutions of the copper(II) complexes with eddp, eddv and eddc, the intensities of these CD spectra increased extremely and their CD shapes became almost the same. In addition, the shoulder band at about 10000 cm^{-1} became very intense (see Figs. 6 and 7).[22] Furthermore, this CD shape is identical with the CD curve of the epro complex, which is affected to a lesser extent by the addition of the unidentate bases.

This spectral behavior, especially the conformity in the CD spectra, is very significant when discussing the conformations of these complexes. From these findings, the mixed complexes of eddp, eddv, and eddc with pyridine or ammonia may be expected to take the same conformation as the epro complex, that is, the *Λ*-uns-*cis* form. The remarkable augmentation of the intensity of the CD band is evidence in support of the occurrence of the dissymmetry about the metal ion. If the mixed

complexes take the *A*-uns-*cis* form, each of the two secondary nitrogen atoms has an *R* configuration as well as those of the epro complex. Thus, the unidentate base may be expected to convert the *trans*-type configuration of the edda-type acids into a uns-*cis*-type one. This conversion of the planar form into the uns-*cis* form may result from the stereospecific characteristic of the edda-type acids that they form a planar configuration only with difficulty.

The amount of unidentate bases necessary for the conversion of the eddp complex was much more than those needed for the addc and eddv complexes, as can be seen from Fig. 7. This may be a reflection on the higher stability of the planar configuration of eddp. This stability is probably related to the bulkiness of the substituent groups. Thus, the planar configuration of the edda-type acids is thought to become unstable with an increase in the bulkiness of the substituent groups. On the other hand, the effect of the bidentate bases on the spectra was entirely different from that of the unidentate bases, as is shown in Figs. 6 and 7. This finding is similar to the case of the epro complex.

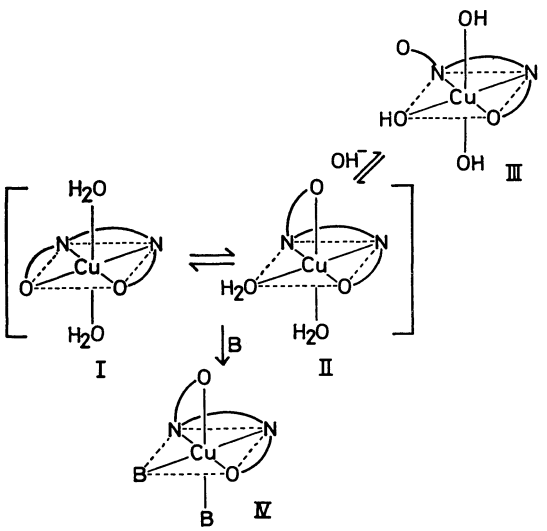

Fig. 8. Proposed equilibrium scheme for the edda-type copper(II) complexes in aqueous solutions. O–N–N–O represents edda-type ligands and B is a unidentate base. The charges on the central metal ion and coordinating groups are omitted for the simplicity.

Equilibrium Scheme. In conclusion, the equilibrium scheme for the edda-type copper(II) complexes in aqueous solutions is represented by Fig. 8, which is derived from the spectral results described above. Species (I) and (II) are predominant in a neutral pH region, which constitute an equilibrium state. In particular, however, the epro complex which exhibits the weak absorption band at 9500 cm^{-1} takes the uns-*cis* form (II) completely, and the eddp complex, almost the planar form (I). The eddv and eddc complexes may be equilibrium mixtures of these two forms. In a high pH region, the carboxylate group coordinated at the apical position is displaced by a hydroxide ion, and then Species (III) may be formed.

When an excess of the unidentate bases is added to the complex solutions, these complexes are converted from Form (I) or (II) into Form (IV). This is verified by the finding that, on the addition of unidentate bases, the CD spectra of these complexes become the same shape as that of the epro complex. Furthermore, the fact that the CD shape of the epro complex changes little on the addition of the unidentate bases is very important when introducing the above conclusion.

However, no data suitable for determining the structure of these edda-type complexes in the solid state has yet been obtained. In the near future, the structure in the solid state will be clarified in more detail.

Assignment of the CD Bands. In general, the absorption spectra observed for copper(II) complexes should consist of three d-d transitions, $d_{z^2}\rightarrow d_{x^2-y^2}$ $d_{xy}\rightarrow d_{x^2-y^2}$, and d_{xz}, $d_{yz}\rightarrow d_{x^2-y^2}$, if the molecular symmetry is taken as D_{4h}. In the case of the complexes with the stronger ligation along the tetragonal axis, the $d_{z^2}\rightarrow d_{x^2-y^2}$ transition is the lowest energy, as is well-known.[23,24] The weak band at about 10000 cm^{-1} observed for the epro complex and the mixed complexes with pyridine or ammonia apparently corresponds to the $d_{z^2}\rightarrow d_{x^2-y^2}$ transition. These complexes imposed the positive CD band for this transition, as can be seen from the figures.

On the other hand, within the main absorption band were observed a large negative CD band a very small positive band at the lower- and higher-wavenumber sides respectively. These CD bands should correspond to the other two transitions, $d_{xy}\rightarrow d_{x^2-y^2}$, and d_{xz}, $d_{yz}\rightarrow d_{x^2-y^2}$. The former transition seems to have a lower energy than the latter;[23] hence, the large negative band may be the $d_{xy}\rightarrow d_{x^2-y^2}$ transition. However, since these complexes apparently possess a molecular symmetry much lower than D_{4h}, the degenerate transition may split into two bands in practice. In this case, the main band consists of three transitions; consequently, the assignment of the two CD bands becomes more difficult. The following two descriptions may be convincing arguments: the split of the degenerate transition is probably small, or one of the three transitions may contribute little to the optical activity.

Experimental

Materials. The copper(II) complexes of eddp, eddv, and eddc were prepared as has been described in the previous paper.[1] The epro complex was isolated in the following manner. Basic copper(II) carbonate was mixed with an equimolar amount of the dimethyl ester of (*S*, *S*)-1,1′-ethylenedipyrrolidine-2 2′-dicarboxylic acid (H_2epro), which had been previously prepared,[11] in an aqueous solution. The solution was then allowed to stand at room temperature. Within a few days, a blue product was precipitated. The product was washed with ethanol and then reprecipitated from water. Found: C, 43.69; H, 5.89; N, 8.52%. Calcd for $[Cu(C_{12}H_{18}N_2O_4)]\cdot 1/2(H_2O)$: C, 44.10; H, 5.86; N, 8.57%.

The pyridine, ethylenediamine, 2,2′-bipyridyl, and 1,10-phenanthroline which were added to the complex solution were of commercial grades and were purified, if necessary, by the usual procedures. In the case of ammonia, equimolar amounts of ammonium chloride and sodium hydroxide were added to the complex solution.

Measurements. The absorption spectra were obtained by means of a Hitachi EPS-3T spectrophotometer, while the CD measurements in the region of 400 to 1000 nm were made on a Jasco J-20A spectropolarimeter. To follow the solution of the epro complex with a change in the pH, additional drops of 0.1 or 1.0 M sodium hydroxide were added. The pH of the solution was measured with a Toa HM-20B digital pH meter.

The Crystal and Molecular Structure of Chloro-α,β,γ,δ-tetraphenylporphinatocobalt(III)

Tosio SAKURAI, Kiyoko YAMAMOTO, Hirobumi NAITO,* and Nobuaki NAKAMOTO*

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351
**Department of Engineering Chemistry, College of Science and Engineering, Nihon University, Kanda, Chiyoda-ku, Tokyo 101*

(Received May 10, 1976)

The structure of the title compound, $C_{44}H_{28}N_4CoCl$, has been determined by single-crystal X-ray diffraction. The crystals are body-centered tetragonal, with $a=b=13.693(2)$, $c=9.701(2)$ Å, and $Z=2$. The space group was determined to be $I4$ from the measurement of the anomalous dispersion effect. The structure was predicted prior to the X-ray analysis from the calculation of the intermolecular van der Waals energy; the result agreed quite well with the experimentally determined structure. A tetragonal pyramidal five coordination with the chlorine atom at the apex was found for the cobalt atom. The cobalt–chlorine distance is 2.149 (6) Å, about 0.1 Å shorter than those found in ordinary octahedral coordinations.

Previously, cobalt(III) α,β,γ,δ-tetraphenylporphin complexes with a nitrogenous base, $Cl(L)_nCoTPP$ ($n=1,2$),** were prepared[1] by treating Co(II)TPP with L in an alcoholic solution containing hydrochloric acid, and the octahedral six coordination about the cobalt atom of Cl(pyridine)CoTPP was confirmed by X-ray diffraction.[2] Recently, from a solution without L investigators could isolate single crystals of chloro-α,β,γ,δ-tetraphenylporphinatocobalt(III), ClCoTPP,*** whose coordination remained ambiguous from a study of the electronic absorption spectra in various solvents and the solid state.[4] The present paper will deal with the determination of the structure of this compound by the X-ray diffraction technique. The results show a tetragonal pyramidal five coordination about the cobalt atom, with the chlorine atom at the apex.

Experimental

Preparation of Chloro-α,β,γ,δ-tetraphenylporphinatocobalt(III) (ClCoTPP). Co(II)TPP[5] (0.3 g) was suspended in methanol (297 ml) containing concentrated hydrochloric acid (3 ml). When the suspension was stirred at room temperature in an open flask for several hours, the solution gradually changed to reddish purple, and then the whole became a clear solution. The solution was filtered and concentrated under reduced pressure at about 50 °C. The separated crystalline precipitates were collected, washed with water, and then with a small amount of a methanol–water mixture (2:1), dried at room temperature, and recrystallized from methanol and then chloroform–ether (yield, 0.2 g). The crystals thus obtained were again dissolved in a small amount of chloroform, and the solvent was allowed to evaporate slowly to yield ClCoTPP as violet, lustrous, single crystals.

Found: C, 73.45; H, 4.17; N, 7.85; Co, 8.24; Cl, 5.00%. Calcd for $C_{44}H_{28}N_4CoCl$: C, 74.73; H, 3.99; N, 7.92; Co, 8.33; Cl, 5.01%.

Electronic absorption spectrum (methanol), λ/nm (ε/10³): 575_{sh} (3.8), 541_{max} (14.4), 505_{max} (3.5), 425.5_{max} (250), and 313_{max} (17.0).

Magnetic susceptibility measurements showed diamagnetism.

Measurements of X-Ray Diffraction Intensities and the Space Group Determination. The preliminary Weissenberg photographs showed that the crystals belong to the tetragonal system and that the systematic absences are $h+k+l=2n+1$. Therefore, the possible space groups are $I4$, $I\bar{4}$, or $I4/m$. The diffraction intensities were collected on a Rigaku AFC four-circle diffractometer, with graphite-monochromatized Cu $K\alpha$ radiation, within the range of $2\theta \leq 140°$. The size of the crystal was $0.6\times0.4\times0.2$ mm³. The ordinary Lorentz and polarization corrections were applied. The effect of the absorption was corrected by North, Phillips, and Mathews's experimental method.[6] The linear absorption coeffecient is 49.8 cm^{-1}. The succssive averaging of equivalent reflections yielded 855 independent reflections with $l \leq 0$. Both cobalt and chlorine atoms have considerably large $\Delta f''$ components for Cu $K\alpha$ radiation. The values of $\Delta f''$ are 3.8 and 0.7 for the cobalt and chlorine atoms respectively.[7] Therefore, in order to determine the space group, all the equivalent reflections were measured for some reflections. A few examples are shown in Table 1. These F_o values have a four-fold symmetry in the reciprocal space. Therefore, the space group is $I4$.

Crystal data $a=b=13.693(2)$, $c=9.701(2)$ Å, $V=1818.9$ (6) Å³. Space group $I4$, $Z=2$. $D_c=1.292$ g cm^{-3}.

Prediction of the Structure

The number of general equivalent positions is eight for the $I4$ space group. The number of the molecule in the cell is two. Therefore, the molecule must be located on a special position with a four-fold symmetry. From the shape of the complex, the cobalt atom was taken as the point of origin. The symmetry of the TPP group is 4. The approximate geometry of the porphinato core is well known. The most probable dihedral angle between the porphinato plane and the phenyl plane is about 72°.[2] Therefore, freedom remains in the rotation of the TPP group about the c axis. The van der Waals energy between the TPP groups was calculated in relation to the rotation angle. The energy curve showed two very sharp minima when the Co–N

** This formula represents the composition. TPP: dianion of α,β,γ,δ-tetraphenylporphin. L: nitrogenous base (example, pyridine, *p*-toluidine, *etc.*).

*** The crystal structure of ClCoTPP was previously reported, in Fleischer's review article,[3] to be $I4/m$ with $a=b=13.41$ and $c=9.82$ Å. However, as far as the present authors are aware, no written report about the structure has been published.

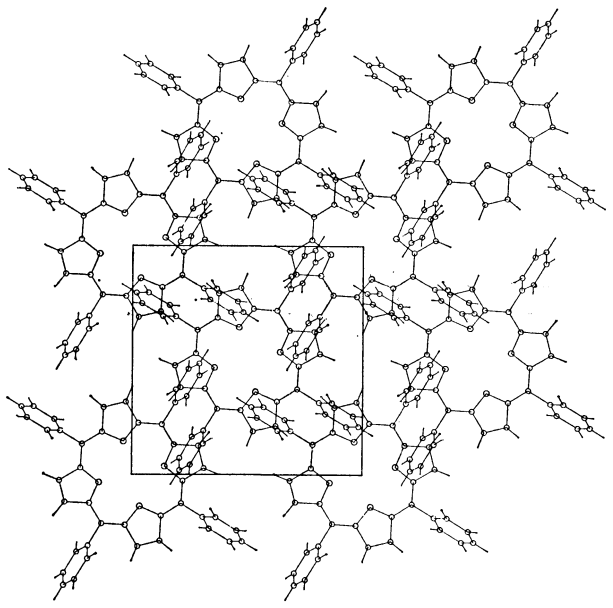

Fig. 2. The predicted structure. c axis projection.

vector makes an angle of 14° or 76° from the a axis (Fig. 1). These two orientations are energetically equivalent for the TPP group. Thus, the packing of the TPP groups in the unit cell was predicted to be as is shown in Fig. 2, or its equivalent, before the diffraction intensities were observed.

Structure Analysis

The structure was easily solved by the ordinary heavy-atom·method, independent from the predicted structure, and was refined by the block-diagonal least-squares method. In a difference Fourier map, the peaks corresponding to the hydrogen atoms were very broad; thus, the hydrogen atoms were not included in the structure-factor calculation. The refinement was performed using 855 unique reflections. The final R index, with anisotropic temperature factors, was 8.8%. In order to determine the absolute configuration and verify the space group, the structure factors of the Friedel pair reflections were also calculated. Some of the results are shown in Table 2, while the atomic parameters are given in Table 3. The structure factors

are given in Table 4.****

Discussion of the Structure

The lattice parameters of the present crystals are significantly different from those referred to by Fleischer.[3] This difference is attributable to the order and disorder structures. For the disorder structure, the chlorine atoms are distributed randomly on both +z and −z sides of the cobalt atom, so that the apparent space group is $I4/m$. We also obtained disordered crystals with $a=13.489$ and $c=9.779$ Å from the same crystallization condition. So far, all known five-coordinate structures are disordered. The only known order structure is the six-coordinate Cl_2Sn(IV)TPP.[8] Therefore, the present structure is the first example of an order structure with a five coordination. The method of distinguishing between the order and disorder structures was fully discussed by us previously.[9]

The crystal structure is shown in Fig. 3. The cobalt-nitrogen bond makes an angle of 15° from the a axis. The dihedral angle between the phenyl plane and the mean porphinato plane is 75°. These values agree quite well with the predicted structure.

The shortest intermolecular carbon–carbon distance, 3.64 Å, is between the C(2) of the pyrrole group of a molecule and the C(11) of the phenyl group of the neighbouring molecule at the body center position (Fig. 4). The rapid increase in the intermolecular energy against the rotation of the molecule from the equilibrium position is due to the repulsion between phenyl groups of the neighbouring molecules.

The bond distances and angles within the TPP group, averaged over chemically equivalent bonds, are shown in Fig. 5, while the thermal ellipsoids are shown in Fig. 6. In contrast to the previous structure,[2] the porphinato group is quite flat. The maximum deviation of the atom from the mean plane is 0.08 Å for C(3) and less than 0.03 Å for the others. The angle between the mean pyrrole plane and the mean porphinato plane is 2.1°.

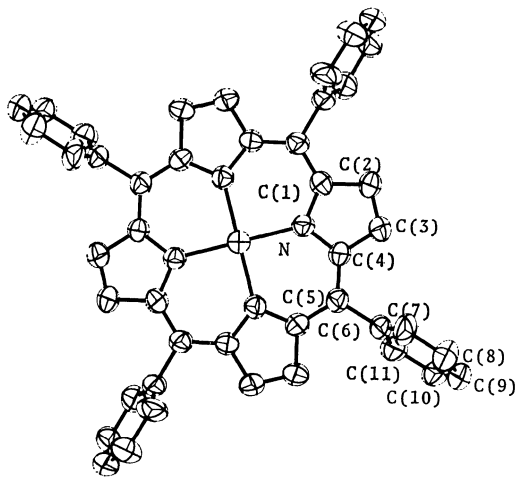

Fig. 6. Thermal ellipsoids of the molecule.

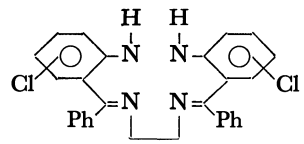
The coordination about the cobalt atom is the tetragonal pyramid, as is shown in Fig. 7. The ordinary cobalt(III) complex has been known to form an octahedral coordination. Recently, Bailey *et al.*[10] presented a tetragonal pyramidal structure for the cobalt(III) complex Co(N_4)Cl.† This complex is paramagnetic, in contrast to the present diamagnetism. Several other five-coordinate metalloporphyrins are known. The parameters of these complexes are compared in Table 5. In the present complex, the deviation of the cobalt atom from the mean plane of the nitrogen atoms is very small, and the Co–Cl distance, 2.15 Å, is shorter by about 0.1 Å than those of the ordinary six-coordinate cobalt(III) complexes.[2] Since the $d_{x^2-y^2}$ orbital of the central cobalt(III) ion is not occupied in the diamagnetic state and thus the effective radius is reduced, the cobalt ion can be in the central hole of the porphyrin. On the other hand, an occupation of $d_{x^2-y^2}$ orbital in chloro-α,β,γ,δ-tetraphenylporphinatoiron(III) gives rise to a shift of the central metal ion out of the porphinato plane.[19] The shortening of Co–Cl bond found in the present work is attributed to an enhanced donation of coordinating Cl^- ion. For an electroneutrality, the axial ligand in the five-coordinate configuration should donate much more than the one in an ordinary six-coordinate configuration. This shortening might be also due to an enhanced donation promoted by a vacancy of d_{z^2} orbital in this diamagnetic complex. In fact, the Co–Cl bond found in a paramagnetic five-coordinate cobalt(III) complex[10] is longer by about 0.25 Å than the normal bond. A similar shortening of the axial coordination in a diamagnetic d^6 five-coordinate complex has been reported on the Rh–C-

† (N_4) represents



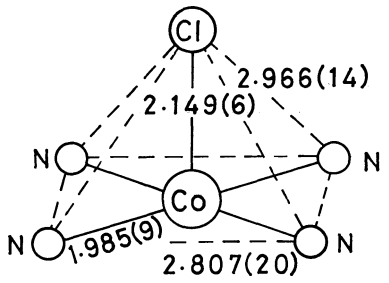


Fig. 7. Coordination about the cobalt atom.

(methyl) bond in octaethylporphinato(methyl)rhodium-(III).[18]

The structure of this complex corresponds to a geometry of an intermediate of the S_N1 substitution reaction of six-coordinate cobalt(III) complexes.

The calculations were carried out on the FACOM 230-75 computer of this Institute, using UNICS II program system.[20] The authors are grateful to Professor Hiroshi Kobayashi and Dr. Youkoh Kaizu of the Tokyo Institute of Technology for the discussion on an electronic state of this complex and the measurement of the magnetic properties. The research was supported, in part, by a Scientific Grant (034085) from the Ministry of Education.

A Potentiometric Study on Complex Formation of Cadmium(II) and Lead(II) Ions with *N*-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic Acid

Noboru OYAMA, Takehide SHIRATO, Hiroaki MATSUDA, and Hitoshi OHTAKI

Department of Electronic Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received May 13, 1976)

The complex formation of cadmium(II) and lead(II) ions with *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid (HEDTA) has been studied potentiometrically in a 1.0 M $NaClO_4$ medium at 25.0 °C by using glass and metal–amalgam electrodes. The emf data obtained over the pH range 1 to 10 were explained in terms of the formation of the following species: for the Cd–HEDTA system, CdL^- (log $\beta_{101}=13.21\pm0.04$), CdHL (log $\beta_{111}=15.61\pm0.02$) and CdH_2L^+ (log $\beta_{121}=16.68\pm0.04$); for the Pb–HEDTA system, PbL^- (log $\beta_{101}=14.83\pm0.02$), PbHL (log $\beta_{111}=16.97\pm0.02$), PbH_2L^+ (log $\beta_{121}=17.89\pm0.02$) and PbH_3L^{2+} (log $\beta_{131}=18.67\pm0.02$), where $\beta_{pqr}=[M_pH_qL_r^{(2p+q-3r)+}]/[M^{2+}]^p[H^+]^q[L^{3-}]^r$ and L denotes the unprotonated molecule of HEDTA. Protonation constants of HEDTA were determined as log $\beta_{011}=9.20\pm0.01$, log $\beta_{021}=14.72\pm0.01$, log $\beta_{031}=17.06\pm0.01$, log $\beta_{041}=18.52\pm0.01$ and log $\beta_{051}=18.65\pm0.05$.

The complex formation reaction of Cd(II) and Pb(II) ions with polyamino-*N*-polycarboxylic acids has been quantitatively studied by many investigators, and numerous results for the formation constants of unprotonated complexes have been reported.[1] Nevertheless, a relatively few attentions have been focused on the formation reactions of protonated complexes.

Earlier works on equilibrium studies of metal–HEDTA compounds have been described for systems of some divalent heavy metals and rare-earth elements.[2,3] The complexes of Cd(II) and Pb(II) ions with HEDTA have also been examined by some investigators, but formation constants of protonated complexes have scarcely been reported.[2,4,5] Although protonated complexes are expected to be present in an acidic region, most of previous experiments have only been performed in a relatively high pH region where no protonated complexes were formed.

Recently, we have studied the electrode reactions of Cd(II) and Pb(II) complexes with HEDTA and it was concluded from the d.c. polarographic behavior of the complexes in these systems that the protonated complexes MH_2L and MHL should significantly participate in the charge transfer processes.[6,7] Therefore, it is expected that such protonated complexes are also present in the bulk of the solution. The aim of the present investigation is to search the formation of protonated complexes in these systems, and thus to carry out potentiometric measurements on complex equilibrium over a wide range of pH, especially in an acidic region.

Symbols

h	Concentration of hydrogen ion at equilibrium
m	Concentration of metal ion at equilibrium
H	Analytical excess of hydrogen ion in a test solution
H_1^T	Analytical excess of hydrogen ion in the T_1 solution
c_B^T	Hydroxide ion concentration in the T_2 solution
M	Cd(II) or Pb(II)
c_M	Total concentration of M
L	*N*-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetate anion ($hedta^{3-}$)
c_L	Total concentration of L
l	Concentration of free L
X	Degree of neutralization of H_3L: $(-H+[H]-[OH])/c_L$
p	Number of metal atoms bound to complex species
q	Number of protons bound to complex species
r	Number of ligands bound to complex species
β_{pqr}	Equilibrium constant for the reaction $pM+qH+rL=M_pH_qL_r$
$\bar{n}$	Average number of protons bound to one L
y_h, y_m	Activity coefficients of hydrogen and metal ions, respectively
E_g, E_m	Emf of the cells defined by the subscripts of Eqs. 1 and 2
$E_j(h,m)$	Liquid junction potential as a function of h and m
[ ]	Concentration

All charges are omitted for the sake of convenience.

Experimental

Reagents. *N-(2-Hydroxyethyl)ethylenediamine*-N,N′,N′-*triacetic acid* was purchased from Dojindo Laboratories, recrystallized from distilled water and dried under a reduced pressure in a desiccator over silica gel. Found: C, 43.41%; H, 6.74%; N, 10.16%; O, 39.78%. Calcd for $C_{10}H_{18}N_2O_7$: C, 43.17%; H, 6.52%; N, 10.07%; O, 40.25%.

Cadmium(II) perchlorate was prepared by dissolving CdO (99.99%, Mitsuwa Pure Chemicals Co.) in a $HClO_4$ solution and was purified by recrystallizing twice from water. The stock solution contained a small amount of perchloric acid to prevent the hydrolysis of cadmium ion. The concentration of cadmium ion in the stock solution was determined by electrogravimetry. The concentration of excess $HClO_4$ in the solution was determined from the location of the end point of neutralization by means of a Gran-plot.

Lead(II) perchlorate was prepared by dissolving $PbCO_3$ in $HClO_4$ solution and purified by recrystallizing twice from water. The concentration of lead(II) ion in the stock solution was determined by electrogravimetry as PbO_2.

Sodium perchlorate was prepared according to Biedermann and Civatta.[8]

Sodium hydroxide solution was prepared by electrolysis of sodium perchlorate solution. A 1.0 M sodium perchlorate solution was taken in a polyethylene bottle and electrolyzed at about 4 mA cm^{-2} with platinum foil electrodes. The concentration of hydroxide ion was determined by titrating the stock solution with a standard perchloric acid using a bromcresol green-methyl red mixed indicator.

Perchloric acid solution was used without further purification of $HClO_4$ (E. Merck Co., reagent grade). The concentration of hydrogen ion in the stock solution was determined by means

of titration with a standard $KHCO_3$ solution using the same mixed indicator as described above. The total concentration of ClO_4^- in the $HClO_4$ solution was adjusted to 1.0 M by the addition of some $NaClO_4$ crystals.

Potassium hydrogen carbonate was prepared by recrystallizing $KHCO_3$ (reagent grade) twice from water and kept in a vessel filled with CO_2 gas.

Silver perchlorate solution used for preparation of Ag–AgCl electrodes was prepared from $HClO_4$ and Ag_2CO_3, the latter being precipitated from $AgNO_3$ solution with Na_2CO_3 and then thoroughly decanted.

Cadmium- and lead-amalgams were prepared by electrolysis of cadmium(II) perchlorate and lead(II) nitrate solution respectively, with a Metrohm E211A type coulometer. The metal content of the amalgams was about 3% (weight). Before each experiment, the tap in the amalgam delivery line was opened to supply the amalgam and an appropriate amount of the amalgam was then transferred to a separate glass tube of the J-shape. This J-type amalgam electrode was originally described by Holloway and Reilley[4] and used with slight modification. Oxidation of the amalgam was avoided by preparing and storing it in an atmosphere of nitrogen.

The measurements were performed in a paraffin-oil thermostat at 25.00±0.02 °C, which was kept in a room thermostated at 25.0±1.0 °C.

Apparatus. *Glass electrodes* (Beckman Nos. 40495 and 40498) were used.

A silver–silver chloride electrode was made according to Brown.[9] The half-cell of the "Kawai" type[10] was set for emf measurements.

A digital pH/mV meter (Orion Research, Model 801) was used for pH measurements. Potentials at each point of measurements were determined with an accuracy of±0.1 mV.

A digital voltmeter (Takeda Riken, Model TR-6656) was used for measurements of potentials of the amalgam electrodes. The potentials were determined with an accuracy of ±0.01 mV.

The titration vessel was set with a glass electrode, an amalgam electrode, an Ag–AgCl reference electrode, burets, and glass tubes for nitrogen gas inlet and outlet. Nitrogen gas was freed from O_2 and CO_2 by passing through bottles containing 10% NaOH, 10% H_2SO_4–VSO_4–Zn–amalgam and 1.0 M $NaClO_4$ solutions. The titration vessel and burets were filled with nitrogen gas before the test and titrating solutions were introduced. A stream of nitrogen gas was passed through the test solution during the course of the titration.

Methods of emf Measurements. The concentrations of hydrogen and metal (II) ions were measured with the following cell:

Indicator Electrode	Test Solution	1.00 M $NaClO_4$ aqueous solution	0.01 M $AgClO_4$ 0.99 M $NaClO_4$ aqueous solution	AgCl–Ag

where the glass or amalgam electrode was used as the indicator electrode. The emf at equilibrium can be written by the following equation at 25 °C:

$$E_g = E_g^{\circ\prime} + 59.16 \log h + 59.16 \log y_h + E_j(h, m) \quad (1)$$

$$E_m = E_m^{\circ\prime} + 29.58 \log m + 29.58 \log y_m + E_j(h, m) \quad (2)$$

where $E_g^{\circ\prime}$ and $E_m^{\circ\prime}$ are constants.

In a constant ionic medium, y_h and y_m may reasonably be assumed to be constant. The liquid junction potential $E_j(h,m)$ which is given as a function of the concentrations of hydrogen and metal ions may be independent of m, as long as the concentration of metal ion is low. Under the present experimental conditions Eqs. 1 and 2 may be rewritten, respectively, as

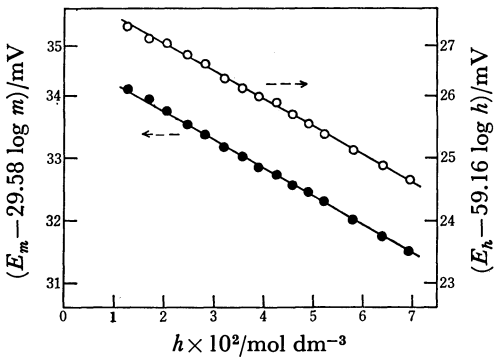

Fig. 1. Plots of $E_g - 59.16 \log h$, (○), and $E_m - 29.58 \log m$, (●), against h in 1.0 M (Na, H) ClO_4.

$$E_g = E_g^{\circ} + 59.16 \log h + E_j(h) \quad (3)$$

$$E_m = E_m^{\circ} + 29.58 \log m + E_j(h) \quad (4)$$

where $E_g^{\circ} = E_g^{\circ\prime} + 59.16 \log y_h$ and $E_m^{\circ} = E_m^{\circ\prime} + 29.58 \log y_m$. Equations 3 and 4 are transformed to

$$E_g - 59.16 \log h = E_j(h) + E_g^{\circ} \quad (5)$$

$$E_m - 29.58 \log m = E_j(h) + E_m^{\circ} \quad (6)$$

The values of $E_j(h)$, E_g° and E_m° were experimentally determined before each titration. $E_j(h)$ was estimated to be $-45\,h$ mV/mol dm^{-3}, as seen in Fig. 1, independent of the indicator electrodes used. Substituting the value of $E_j(h)$ thus obtained into Eqs. 3 and 4, the values of E_g° and E_m° were determined by means of Gran-plots. After the determination of E_g° and E_m° of the electrodes in a given solution, a suitable amount of HEDTA was added to allow to form complexes in the test solution, which has the following composition:

$$|c_M\ Cd^{2+} \text{ or } Pb^{2+},\ c_L\ HEDTA,\ H\ H^+,$$
$$(1.0 - 2c_M - H)\ NaClO_4| \quad (7)$$

During the course of the potentiometric titrations, equal volumes of T_1 and T_2 solutions,

$$T_1 = 2c_M\ Cd^{2+} \text{ or } Pb^{2+},\ 2c_L\ HEDTA,\ H_1^T\ H^+,$$
$$(1.0 - 4c_M - H_1^T)\ NaClO_4$$
$$T_2 = c_B^T\ OH^-,\ (1.0 - c_B^T)\ NaClO_4$$

were added into the test solution in order to keep constant the total concentrations of the metal ion c_M and the ligand c_L during the titration. The total concentration of perchlorate ion was also kept constant, 1.0 M. The values of h and m were obtained by using Eqs. 3 and 4, successive approximations being employed.

An emf of the amalgam electrode required about 5 min to attain a constant value after the addition of the titrants, while an emf of the glass electrode became constant within a few minutes. The potentials remained unchanged for several hours. The emf's of the amalgam electrode were determined within an accuracy of ±0.02 mV at $-\log h$ below 3.0, but at $-\log h$ above 3.5 the emf's became unstable so that the results obtained by the amalgam electrode were rather unreliable.

Results and Discussion

Evaluation of Protonation Constans of HEDTA. Overall protonation constants of the HEDTA base, β_{0q1}, were determined from the formation function $\bar{n}$. A generalized least squares method was applied to make the error squares sum $U = \sum(\bar{n} - \bar{n}_{calc})^2$ a minimum for the set of overall acid association (protonation) constants,

β_{011}, β_{021}, β_{031}, β_{041} and β_{051}. The calculation was performed with the help of an electronic computer HITAC 8700 at the Computer Center of the Tokyo Institute of Technology. $\bar{n}_{calc}$ and $\bar{n}$ denote

$$\bar{n}_{calc} = \frac{(\beta_{011}h+2\beta_{021}h^2+3\beta_{031}h^3+4\beta_{041}h^4+5\beta_{051}h^5)}{(1+\beta_{011}h+\beta_{021}h^2+\beta_{031}h^3+\beta_{041}h^4+\beta_{051}h^5)} \quad (8)$$

and

$$\bar{n} = \frac{3c_L + H - h + (K_W/h)}{c_L} \quad (9)$$

where K_W is the autoprotolysis constant of water in 1 M $NaClO_4$ solution: $10^{-13.95}$.[11] The protonation constants thus obtained were log β_{011}=9.20±0.01, log β_{021}=14.72±0.01, log β_{031}=17.06±0.01, log β_{041}=18.52±0.01 and log β_{051}=18.65±0.05. Bhat *et al.*[12] reported the values of log β_{011}=8.65, log β_{021}=13.76 and log β_{031}=16.06 in a 1.0 M $NaClO_4$ medium at 25 °C but not those of log β_{041} and log β_{051}.

Determination of the Composition and the Stability Constants of Complexes. Titration curves of the Cd(II)- and Pb(II)–HEDTA solutions are shown in Figs. 2 and 3.

From the material balance for the metal ion, we obtained Eq. 10:

$$c_M = [M] + \sum_p\sum_q\sum_r p\,[M_pH_qL_r]$$
$$= m + \sum_p\sum_q\sum_r p\beta_{pqr}m^p h^q l^r \quad (10)$$

The summation may include hydrolyzed species of the metal ion and the metal complexes ($q<0$).

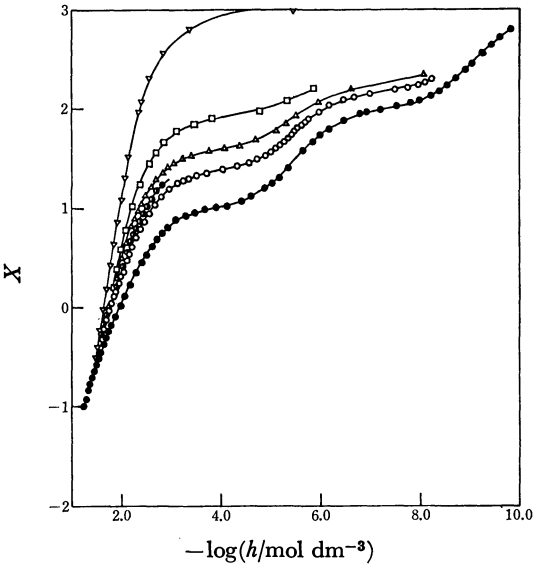

Fig. 2. Degrees of neutralization, X, of *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid (HEDTA) solutions for the Cd(II)–HEDTA system.
(●); c_M=0.0 M, c_L=0.01351 M:
(○); c_M=0.002701 M, c_L=0.01252 M:
(◑); c_M=0.003440 M*, c_L=0.012771 M*:
(△); c_M=0.002699 M, c_L=0.007508 M:
(□); c_M=0.002564 M, c_L=0.005000 M:
(▽); c_M=0.007508 M, c_L=0.007579 M.
Solid lines are the values of X calculated by the use of the stability constants in Table 1. *c_M and c_L are the initial concentrations of the metal and the ligand, and c_M and c_L are slightly changed during the course of titration by the addition of the titrants.

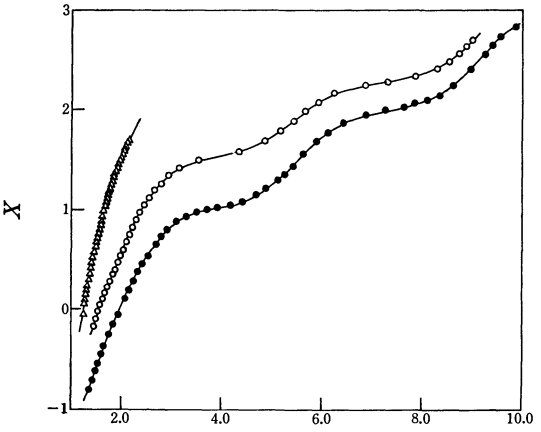

Fig. 3. Degrees of neutralization, X, of HEDTA solutions for the Pb(II)–HEDTA system.
(●); c_M=0.0 M, c_L=0.007050 M:
(○); c_M=0.002650 M, c_L=0.01008 M:
(△); c_M=0.01007 M, c_L=0.01523 M.
Solid lines are the values of X calculated by the use of the stability constants in Table 1.

Thus, we derive Eqs. 11 and 12:

$$\eta = \log(c_M/m) = \log\{1 + \sum_p\sum_q\sum_r p\beta_{pqr}m^{p-1}h^q l^r\} \quad (11)$$

and

$$\xi = \log\{(c_M - m)/m\} = \log\{\sum_p\sum_q\sum_r p[M_pH_qL_r]/[M]\}$$
$$= \log\{\sum_p\sum_q\sum_r p\beta_{pqr}m^{p-1}h^q l^r\} \quad (12)$$

The quantity η is a measure of the degree of complexation of the metal ion and $\eta>0$ at $-\log h>1.5$ (see Fig. 4). This fact shows that the complexes between the metal ions and HEDTA are formed even in an acid solution of minimum pH examined in this experiment.

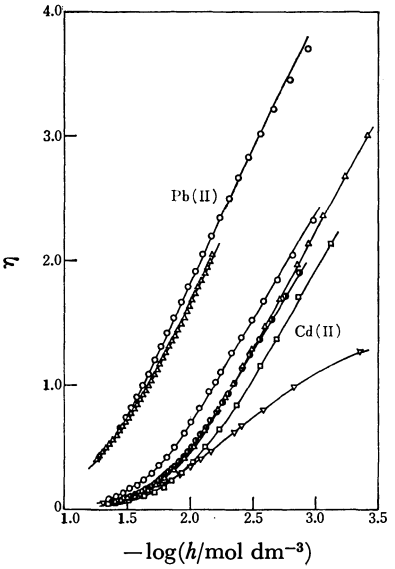

Fig. 4. Relationships between η and $-\log h$ for the Cd(II) and Pb(II) systems.
Symbols are the same as those in Figs. 2 and 3.
Solid lines are curves calculated by the use of the stability constants in Table 1.

As the first approach for analyzing data, we assume that only one kind of the complex $M_pH_qL_r$ is formed in the solution. Thus, Eq. 12 may be simplified as follows:

$$\xi = \log p\beta_{pqr} + (p-1)\log m + q\log h + r\log l \quad (13)$$

Since $c_M < c_L$ in most cases and the degree of complexation is rather small in a relatively low and narrow pH range, we can assume that l is proportional to c_L at a constant pH and inversely proportional to h^n at a given c_L; that is,

$$c_L \simeq l + \sum_{n=1}^{N}\beta_{0n1}lh^n \quad (14)$$

$$l \simeq c_L/(1+\sum_{n=1}^{N}\beta_{0n1}h^n) \simeq c_L/\beta_{0n1}h^n \quad (15)$$

From the knowledge of the association constants of the HEDTA molecules with protons, we know that most of the ligand molecules are present in the form of H_3L and H_2L^- and partially H_4L^+ in the pH range of 1.5 to 3. Therefore, the value of n may become 2—3 and may slightly change with pH. However, the assumption of an averaged constant value of n over this pH range may not introduce a serious error in the following argument at the stage of the first approximation.

Substitution of Eq. 15 into Eq. 13 leads to Eq. 16:

$$\xi \simeq \log p\beta_{pqr} + (p-1)\log m + (q-n)\log h + r\log c_L - \log\beta_{0n1} \quad (16)$$

The plots ($\xi - \log c_L$) *vs.* $-\log h$ are shown for the Cd(II)-system in Fig. 5. Points obtained at different c_L fell on an approximately single curve and the points were practically independent of c_M except for the case where $c_M = c_L$ and $-\log h > 2$. Thus, we conclude that the main species formed in this pH range has the composition of $p=1$ and $r=1$, and thus MH_qL. The slope of the line corresponds to $-(q-n)$ according to the above consideration, and we have found from Fig. 5 that the slope is about 2. Since $n=2\sim3$, q would become 0—1. Therefore, we can estimate the composition of the main species to be MHL and/or ML in the pH range discussed.

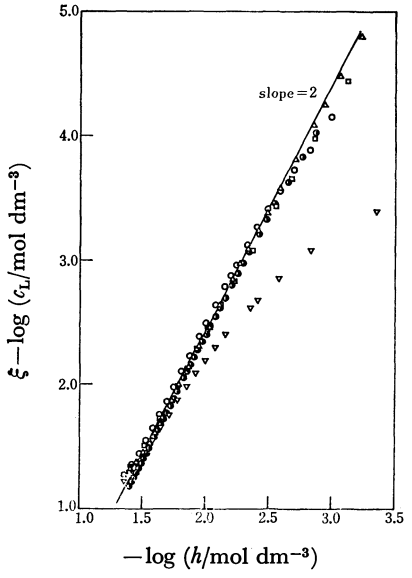

Fig. 5. Relationships between $\xi - \log c_L$ and $-\log h$ for the Cd(II)–HEDTA system.

The estimation for the compositions of the complexes formed in the solution may be made more quantitatively than in the above treatment, if the formation of mononuclear and monoligand complexes with various numbers of protons is assumed.

From the assumption, we obtained the following relationships:

$$c_M = m + \sum_{q=0}^{Q}[MH_qL] \quad (17)$$

$$c_L = l + \sum_{n=1}^{N}[H_nL] + \sum_{q=0}^{Q}[MH_qL] \quad (18)$$

Insertion of Eq. 17 into Eq. 18 and rearrangement lead to Eq. 19:

$$l = (c_L - c_M + m)/(1+\sum_{n=1}^{N}\beta_{0n1}h^n) \quad (19)$$

A function F_0 is defined as follows:

$$F_0 = (c_M - m)/ml = \sum_{q=0}^{Q}[MH_qL]/ml = \sum_{q=0}^{Q}\beta_{1q1}h^q \quad (20)$$

The plot of $\log F_0$ against $-\log h$ is shown in Fig. 6 for both systems of Cd(II)- and Pb(II)-HEDTA. In each system a single curve was obtained and the curve was independent of c_M, c_L and c_M/c_L. Therefore, the assumption of the formation of a series of MH_qL complexes is confirmed to be reasonable.

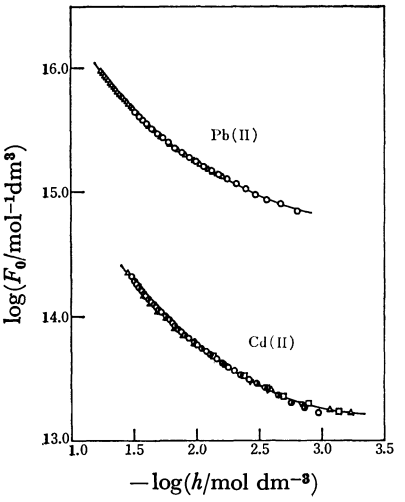

Fig. 6. Plot of $\log F_0$ against $-\log h$ for both systems. Each solid line is the curve calculated with the values of the stability constants in Table 1.

The plot of F_0 against h was extrapolated toward $h=0$ to give an intercept corresponding to β_{101}.

A new function

$$F_1 = (F_0 - \beta_{101})/h = \sum_{q=1}^{Q}\beta_{1q1}h^{q-1} \quad (21)$$

was plotted against h and then extrapolated toward $h=0$ in order to obtain β_{111}. The procedure was repeated until a horizontal line was obtained. The sets of the plots carried out to obtain β_{1q1} are shown in Figs. 7 and 8 for the Cd(II) and Pb(II) systems, respectively. The values of β_{1q1} thus found are given for the Cd(II)–HEDTA complexes as follows:

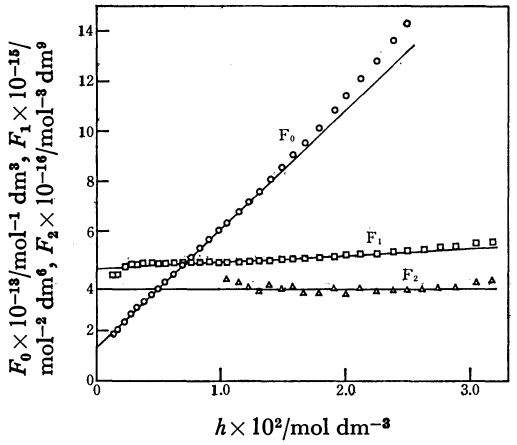

Fig. 7. A typical set of the plot of F_q *vs.* h in the system of Cd(II)–HEDTA complexes (c_M=0.002873 M, c_L= 0.01021 M). (○): F_0; (□): F_1; (△): F_2.

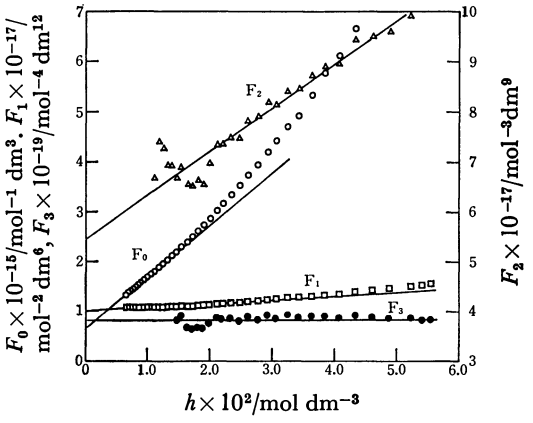

Fig. 8. A typical set of the plot of F_q *vs.* h in the system of Pb(II)–HEDTA complexes (c_M=0.01007 M, c_L= 0.01523 M). (○): F_0; (□): F_1; (△): F_2; (●): F_3.

$$\beta_{101} = 1.5\times10^{13}\ \text{mol}^{-1}\ \text{dm}^3$$
$$\beta_{111} = 4.4\times10^{15}\ \text{mol}^{-2}\ \text{dm}^6$$
$$\beta_{121} = 3.7\times10^{16}\ \text{mol}^{-3}\ \text{dm}^9$$

and for the Pb(II)–HEDTA complexes

$$\beta_{101} = 6.7\times10^{14}\ \text{mol}^{-1}\ \text{dm}^3$$
$$\beta_{111} = 1.0\times10^{17}\ \text{mol}^{-2}\ \text{dm}^6$$
$$\beta_{121} = 5.5\times10^{17}\ \text{mol}^{-3}\ \text{dm}^9$$
$$\beta_{131} = 8.0\times10^{18}\ \text{mol}^{-4}\ \text{dm}^{12}$$

The formation constants of the complexes were refined by means of a generalized least squares method. The method was applied to make the error squares sum $U=\sum\{\log F_0-\log F_{0,\text{calcd}}\}^2$ minimum for the set of the formation constants over the pH range 1.5 to 3, where $F_{0,\text{calcd}}$ denotes the value of F_0 calculated for a particular set of the formation constants. The formation constants thus determined are given in Table 1.

Since the metal amalgam electrode did not function well at a high pH range, data of X obtained in the high pH range were not analyzed by the extrapolation method described above. However, the constants reproduced the experimental results fairly well as seen from Figs. 2 and 3, and no polynuclear, polyligand and hydrolyzed species are formed.

Table 1. Stability constants of Cd(II)- and Pb(II)-HEDTA complexes (log β_{pqr})
log β_{011}=9.20±0.01, log β_{021}=14.72±0.01, log β_{031}= 17.06±0.01, log β_{041}=18.52±0.01, log β_{051}=18.65±0.05

Complexes	ML^-	MHL^0	MH_2L^+	MH_3L^{2+}
Cd(II)	13.21±0.04	15.61±0.02	16.68±0.04	—
Pb(II)	14.83±0.02	16.97±0.02	17.89±0.02	18.67±0.02

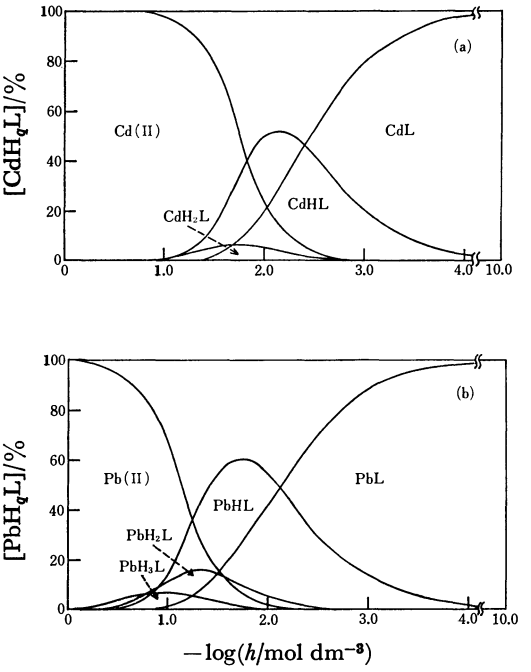

Fig. 9. The distribution of metal–HEDTA complexes *vs.* −log h (c_M=0.001M, c_L=0.01M).
(a): for the Cd(II)–HEDTA system. (b): for the Pb(II)–HEDTA system.

The distributions of the Cd(II)- and Pb(II)–HEDTA complexes are graphically represented in Fig. 9.

The Pb(II)–HEDTA complexes are stronger by 1—1.5 in log β unit than the corresponding Cd(II)–HEDTA complexes, like in other cases of the complexes of these metals with ligands containing oxygen or oxygen and nitrogen as the ligating atoms. Lead(II) ion forms the PbH_3L complex at a high concentration of hydrogen ion, whereas cadmium(II) ion does not.

The stepwise association constants of the complexes with protons are log K_H^{ML}=log {[MHL]/[ML][H]}= 2.40 and log $K_H^{MH_2L}$=log {[MH_2L]/[MHL][H]}=1.07 for the Cd(II)–HEDTA complexes and log K_H^{ML}= 2.13, log $K_H^{MH_2L}$=0.92 and log $K_H^{MH_2L}$=0.78 for the Pb(II)–HEDTA complexes. The association constants may be compared with the corresponding values of the ligand; log $K_H^{H_2L}$=log (β_{031}/β_{021})=log {[H_3L]/ [H_2L][H]}=2.34, log $K_H^{H_2L}$=log (β_{041}/β_{031})=1.46 and log $K_H^{H_2L}$=log (β_{051}/β_{041})=0.13.

The authors wish to thank Dr. Takayoshi Kawai for his kind help in potentiometric measurements.

The Crystal Structure of Bis[1-(2-thiazolylazo)-2-naphtholato]-cobalt(III) Perchlorate

Masayasu KURAHASHI

National Research Institute for Metals, 3-12, 2-Chome, Nakameguro, Meguro-ku, Tokyo 153

(Received May 14, 1976)

The crystal structure of bis[1-(2-thiazolylazo)-2-naphtholato]cobalt(III) perchlorate, $[Co^{III}(C_{13}H_8N_3OS)_2]ClO_4$ was determined from X-ray reflection data collected by counter methods. The crystals are monoclinic, space group $P2_1/c$, with $a=10.348(2)$, $b=21.066(5)$, $c=13.072(5)$ Å, $\beta=112.35(3)°$, and $Z=4$. The structure was determined by the heavy-atom method and refined by the least-squares technique to give an R value of 0.051 for 2696 observed reflections. The cobalt atom is six-coordinate and exhibits octahedral coordination. The 1-(2-thiazolylazo)-2-naphtholato group is coordinated as a terdentate ligand with the cobalt atom through the phenolic oxygen atom, the azo nitrogen atom adjacent to the naphthol ring and the thiazole nitrogen atom giving two five-membered chelate rings. Short intraligand contacts of 2.24(6) and 2.28(6) Å are observed between the azo nitrogen and naphthol hydrogen atoms.

1-(2-Thiazolylazo)-2-naphthol (Htan) was first used for the detection of metals by Boni and Hemmeler in 1958.[1] Since then, a number of applications of this dye as a spectrophotometric reagent or a complexometric indicator have been reported.[2-6] The proposed structures for some tan complexes with divalent metals were confirmed by X-ray analysis.[7-10] For the cobalt(III)–tan complex, however, there was an ambiguity concerning the structure.[3,4] X-Ray analysis was therefore carried out, a preliminary letter of the work being reported.[11]

Experimental

Single crystals of $[Co^{III}(tan)_2]ClO_4$ were grown from an ethanol solution by slow evaporation. The crystal data are given in Table 1. The unit-cell dimensions were determined by the least-squares technique using the 2θ angles of 11 reflections measured by a diffractometer. The density was determined by flotation in an aqueous solution of sodium iodide.

Table 1. Crystal data
$[Co^{III}(C_{13}H_8N_3OS)_2]ClO_4$, F.W. 667.0

Monoclinic	Space group $P2_1/c$
$a=10.348(2)$ Å	$D_m=1.67$ g cm^{-3}
$b=21.066(5)$ Å	$D_x=1.68$ g cm^{-3}
$c=13.072(5)$ Å	$Z=4$
$\beta=112.35(3)°$	$\mu=9.9$ cm^{-1} (for Mo $K\alpha$)
$V=2635.4$ Å^3	

The intensity data were collected on a Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation monochromated with a graphite plate. The dimension of the crystal was $0.2\times0.2\times0.15$ mm. The ω-2θ scan technique was employed with a scan speed of 4°/min in ω. Scan range was calculated by the formula $1.5°+0.8°\times\tan\theta$. Measurement was automatically repeated until $\sigma(|F|)/|F|$ became less than 0.03, where $\sigma(|F|)$ is the standard deviation of $|F|$ due to the counting statistics. The maximum number of repetition was limited to four. The intensities of independent reflections

with $2\theta \leq 55°$ were measured and weak reflections with $|F| < 3\sigma(|F|)$ were excluded. A total of 2696 independent reflections were obtained and used for the structure determination. The intensities were corrected for Lorentz and polarization effects, but not for absorption because of the small size of the crystal.

Solution of the Structure and Refinement

The structure was determined by the heavy-atom method. The location of the cobalt and two sulfur atoms was determined by the Patterson method. A Fourier map phased on these atoms yielded the positions of all the non-hydrogen atoms. Structural parameters were refined by the block-diagonal least-squares calculations, until $R(=\sum||F_o|-|F_c||/\sum|F_o|)$ was reduced to 0.083. The function minimized was $w(|F_o|-|F_c|)^2$, where w equals unity. 15 of 16 hydrogen atoms were clearly detected on a difference Fourier map, the remaining hydrogen position (H(7)) being evaluated by calculation. After inclusion of the hydrogen atoms, a final set of least-squares calculations was carried out, and the R value reached 0.051 for the 2696 observed reflections. Atomic scattering factors for the non-hydrogen atoms were taken from the International Tables for X-ray Crystallography,[12] and those for the hydrogen atom from Stewart, Davidson and Simpson.[13] Table 2 gives the final atomic parameters together with their estimated standard deviations. Observed and calculated structure factors are compared in Table 3.*

Description of the Structure and Discussion

The thermal ellipsoids and the numbering of atoms are given in Fig. 1. The complex cation, $[Co^{III}(tan)_2]^+$, has approximately C_2 symmetry. The cobalt atom is surrounded octahedrally by two ligand anions (referred to as A, unprimed atoms and B, primed atoms) in the mer configuration. The configuration coincides with that of $[Fe^{II}(tan)_2]$[7] and $[Ni^{II}(tan)_2]$[8] but differs from that of $[Cu^{II}(tan)(H_2O)_2]^+$,[9] or $[Pd^{II}Cl(tan)]$.[10]

The 1-(2-thiazolyazo)-2-naphtholato group (tan) acts as a terdentate ligand, being coordinated to the metal through the phenolic oxygen atom, the azo nitrogen atom adjacent to the naphthol ring and the thiazole nitrogen atom to form two five-membered chelate rings. Such mode of coordination is commonly observed in all the tan-complexes studied. No participation of the thiazole sulfur atom in metal binding has been found.

The thiazole sulfur atom is not involved in chelate ring formation because of (1) the positive charge on the thiazole sulfur atom, predicted by MO calculation for π-electron density of Htan,[14] the metal ion binding with the positively charged sulfur atom being unfavorable; and (2) the angular distortion of the chelate rings. Two possible molecular models for chelation, where the hybridization state of the ligating atoms was assumed to be sp^2, are shown in Fig. 2. The angular distortion of the chelate rings in model (a) is smaller than that in model (b). The difference arises from the fact that C(11)–S is longer than C(11)–N(3) by 0.4 Å and that C(11)–S–C(12) angle is less than C(11)–N(3)–C(13) by

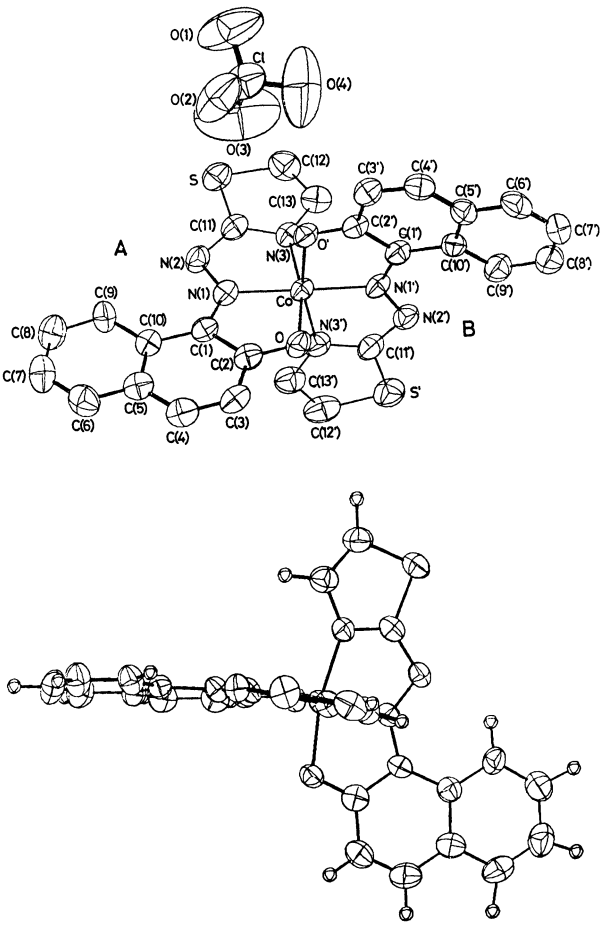

Fig. 1. (a) Thermals ellipsoids and numbering of atoms. The thermal ellipsoids are drawn at 50% probability. (b) The structure of the complex cation viewed perpendicular to the plane through Co and unprimed tan group.

* Table 3 is kept as Document No. 7633 at the Chemical Society of Japan, 1-5, Kanada-Surugadai, Chiyoda-ku, Tokyo.

11°. If the hybridization state of the sulfur atom is not sp^2 and d-electron orbitals are involved in hybridization as indicated from the observed C(11)–S–C(12) angle of 90°, a larger angular distortion will occur, or chelation will not occur.[15]

The bond lengths and angles for the complex cation and the perchlorate anions are given in Table 4 with their e.s.d.'s. The geometries of the two moieties in the complex agree within the limit of three times their corresponding e.s.d.'s. The average Co–O distance of 1.888(4) Å is acceptable. The Co–N distances range from 1.874(5) to 1.918(6) Å, being significantly shorter than the Co–NH_3 distance observed in hexaamminecobalt(III) complex (1.972(1) Å).[16] The average O–Co–N(1) and N(1)–Co–N(3) angles are 85.0(2) and 81.4(2)° respectively, being compressed from the normal valence angles. On the other hand, average N(2)–N(1)–C(1), N(1)–C(1)–C(10), S–C(11)–N(2), and Co–N(3)–C(13) angles are enlarged to 125.7(5), 128.0(5), 124.6(5) and 139.0(4)°, respectively. Such an angular distortion is usually observed in the metal-tan complexes. The average N(1)–N(2), C(1)–N(1), and C(2)–O distances of 1.301(7), 1.349(8), and 1.291(8) Å, respectively, are between the corresponding single and double bonds. This will indicate the presence of some delocalization of π-electrons.

It is of interest to see the structural changes on chelate ring formation. Figure 3 shows a comparison of the structures of Htan and $[Co^{III}(tan)_2]^+$. Since there exist two crystallographically independent tan groups in an asymmetric unit, average values for bond lengths and angles are given. There is a notable difference in the conformation about the azo group; the two ring systems attached to the central azo group are rotated

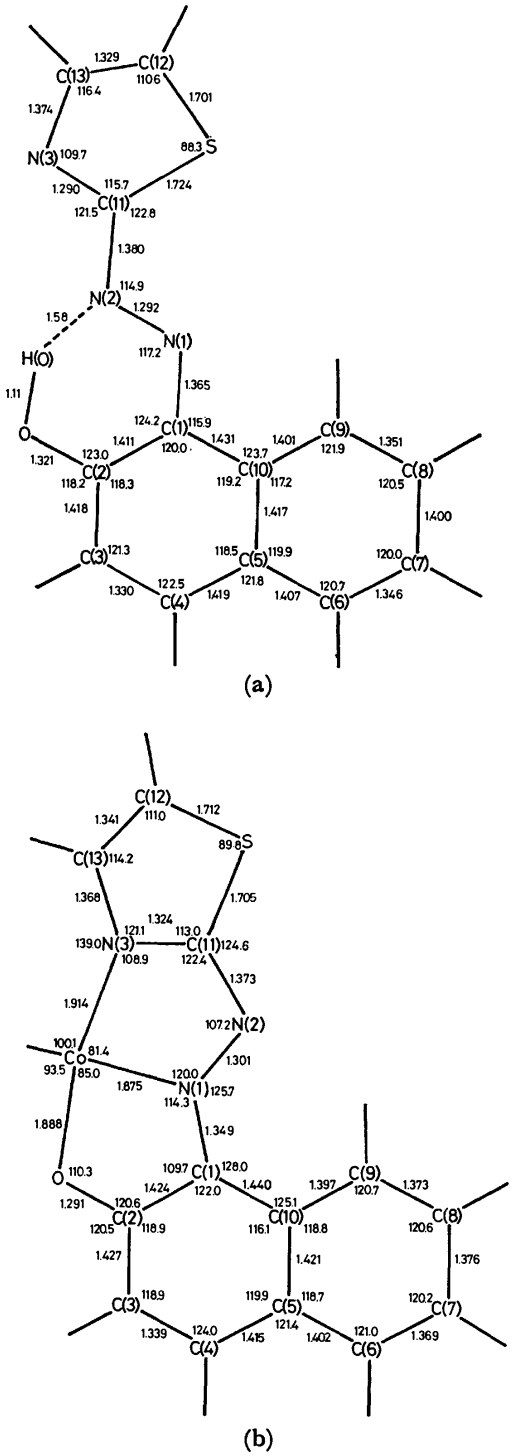

Fig. 3. Comparison of the structures between Htan and $[Co^{III}(tan)_2]^+$.
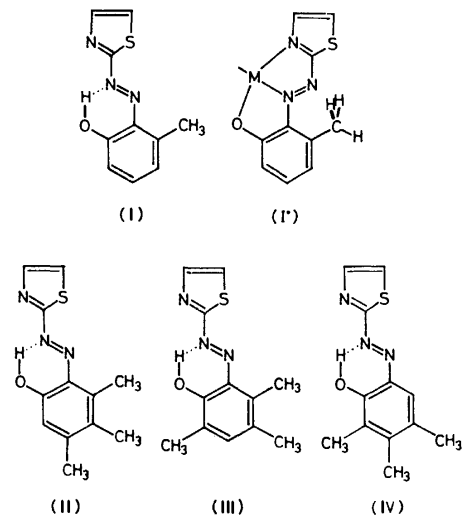
(a) Htan. (b) $[Co^{III}(tan)_2]^+$.

by 180° around the N(1)–C(1) and N(2)–C(11) bonds. As for the bond length distribution, all the corresponding distances in Htan and $[Co^{III}(tan)_2]^+$ agree within ±0.03 Å.

Comparison of N(1)–C(1)–C(10), C(1)–N(1)–N(2) and N(1)–N(2)–C(11) angles in Htan and $[Co^{III}(tan)_2]^+$ indicates that these angles are distorted by chelate ring formation. If these angles in $[Co^{III}(tan)_2]^+$ are the same as those observed in Htan, the N(2)···H(9) distance will be less than 1.8 Å. The observed distances are 2.24(6) and 2.28(6) Å for A and B, respectively. It is apparent that the tan deforms so as to relieve the N(2)···H(9) repulsion on chelate ring formation. Using the following potential function proposed by Giglio,[17]

$$V(r) = \{52100 \exp(-2.04r)\}/r^6 - 132/r^6$$

the N···H interaction energies $V(r)$ were calculated, and the values of 35.1 kcal/mol for $r=1.8$ Å and 2.3 kcal/mol for $r=2.3$ Å were obtained. This may indicate that the repulsion energy present in the complex is not too large; however, the steric effect would play an important role on chelate ring formation. A similar intraligand repulsion occurs in a complex of 2-(2-thiazolylazo)-3-methylphenol (I), as can be seen in I'.



In the course of studying the extraction of nickel(II) chelates of 2-(2-thiazolylazo)-3,4,5-trimethylphenol (II), 2-(2-thiazolylazo)-3,4,6-trimethylphenol (III) and 2-(2-thiazolylazo)-4,5,6-trimethylphenol (IV) into benzene, Fujiwara and Kawase[18,19] found that stability constants, K, for the nickel chelates of II and III are lower than the values expected from the pK_a (acid dissociation constant) *vs* $\log K$ relation.[20] This implies a steric repulsion between the azo nitrogen and the methyl group at 3-position on the phenyl group.

It is likely that the magnitudes of the N(2)···H(9)

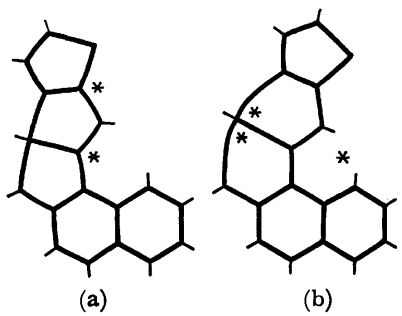


Fig. 4. Framework molecular models for the tan-complex, showing that the magnitudes of the N(2)···H(9) repulsion and the angular distortion depend on the size of the central metal atom.
(a) Small metal ion. (b) Large metal ion.

repulsion and the angular distortion depend on the size of the metal ion. Inspection of the molecular model (Fig. 4) reveals that in the complex of metal with small ionic radius the N(2)···H(9) repulsion and the angular distortion of O–M–N(1) and N(1)–M–N(3) will be small but the distortion of N(2)–N(1)–C(1) and S–C(11)–N(2) will be very large, whereas in the complex of metal with large ionic radius the former will be large and the latter small. This fact might be related to the selectivity of this reagent, that is, tan will not form a complex with metal having too small or too large ionic radius. It can be shown that the tan will not form a complex with metal whose coordination configuration is tetrahedral, so far as the tan acts as a planar terdentate ligand.[10]

A knowledge on structures may be useful for the prescription of a new analytical reagent. If one wishes to control the solubility, stability or absorbance of the complex, some functional groups are usually introduced in the ring system. In this case, it is important to take the effect of intramolecular repulsion into consideration. The present study revealed that the substitution of H(9) atom with a non-hydrogen atom or a large functional group will prevent the formation of a stable chelate ring. This means that it is unable to introduce a hydrophilic group or auxochromic group into 8-position (H(9) position) in the case of tan chelate. A similar argument holds for the substitution of H(13) atom (4-position of thiazole) with a large functional group.

and through Co and the primed tan are roughly planar (the maximum deviations being 0.08 and 0.17 Å, respectively) and these planes make an angle of 89°. The large displacements from the planes are due partly to non-bonded N(2)···H(9) repulsion and partly to intermolecular interaction. The structure of the complex cation viewed normal to the plane through the Co and the primed tan is given in Fig. 1(b).

The crystal structures projected along the a and b axes are illustrated in Fig. 5. The intermolecular distances less than 3.5 Å are listed in Table 5. There is no indication of hydrogen bonding.

The author wishes to express his sincere thanks to Professor Yoshihiko Saito of the University of Tokyo for use of the X-ray diffractometer. He is also grateful to Dr. Akira Kawase of National Chemical Laboratory for Industry for his valuable discussions. Part of the calculations was carried out on the HITAC 5020F computer at the Computer Center of the National Aerospace Laboratory, using SFR-5 and HBLS-4 programs in UNICS system.[21] The other calculations were performed on the NEAC 3100 computer of this Institute. Figures 1 and 5 were produced by DEAM-4 program.[22]

Circular Dichroism Spectra of Cobalt(III) Complexes Containing One or Two Azido, Isothiocyanato, and Nitro Ligands. I. The Bis(ethylenediamine) Complexes of *cis* Type

Kiyoshi YAMASAKI,* Jinsai HIDAKA,** and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 24, 1976)

Circular dichroism spectra have been measured for the *cis*-$[Co(X)(NH_3)(en)_2]^{2+}$, *cis*-$[Co(X)_2(en)_2]^+$, and *cis*-$[Co(X)(X')(en)_2]^+$ complexes in the visible and ultraviolet region (X and X'=N_3^-, NCS^-, or NO_2^-). The absolute configurations of the complexes have been assigned from the circular dichroism pattern in the first d-d absorption band, region and correlated with that in the near ultraviolet region of the so-called specific absorption band. The origin of the specific absorption band has been discussed.

It is well known that transition metal complexes with some particular ligands, such as azido N_3^-, isothiocyanato NCS^-, nitro NO_2^-, and sulfito SO_3^{2-}, show characteristic intense absorption bands in the near-ultraviolet region. These characteristic absorption bands were named at first "special bands,"[1,2] and later "specific bands."[3] The specific absorption bands, which are specific for the particular ligands, have been investigated by many authors, but alternative characterizations have been assigned to the origin, that is, the one attributed the bands to intraligand transitions,[1,4] and the other to charge transfer transitions.[5-9] Recently Miskowsky and Gray[10] attributed most of the specific bands of $[Co(CN)_5X]^{n-}$ or $[CoX(NH_3)_5]^{n+}$ complexes to ligand-to-metal charge transfer transitions (X= NCS^-, SCN^-, and SO_3^{2-}), but assigned the specific bands of $[Co(CN)_5(NO_2)]^{3-}$ and $[Co(NO_2)(NH_3)_5]^{2+}$ which are located at 35200 and 30700 cm^{-1}, respectively, to a metal-to-ligand charge transfer transition. The latter metal-to-ligand transition has also been assumed for the specific bands of some hexanitro metallates.[11]

The present paper deals with circular dichroism (CD) spectra of *cis*-$[Co(X)(NH_3)(en)_2]^{2+}$, *cis*-$[Co(X)_2(en)_2]^+$, and *cis*-$[Co(X)(X')(en)_2]^+$ complexes (X and X'=N_3^-, NCS^-, or NO_2^-), to find the relationship between the CD behavior in the specific band region and the absolute configuration of the complexes, and furthermore to interpret, if possible, the origin of the specific bands on the basis of the CD spectra. A preliminary letter about some of the results has been reported.[12]

Experimental

Preparation and Optical Resolution. *(1)* $(-)_{589}$-cis-$[Co(N_3)(NH_3)(en)_2]Cl_2\cdot 0.5H_2O$: To a solution containing 6.0 g of *cis*-$[CoCl(NH_3)(en)_2]Cl_2$[13] in 30 cm^3 of water were added a few drops of glacial acetic acid and 1.4 g of sodium azide. The solution was heated on a water bath and concentrated until the surface of the solution was covered with a thin crystalline product. After the resulted mixture had been allowed to stand at room temperature for an hour, the crystals were collected by filtration. 4.0 g. Recrystallization was carried out from water (60 °C). The pure crystals deposited were filtered and washed with methanol, and then acetone, and air-dried. Found: C, 15.49; H, 6.14; N, 35.75 %. Calcd for $[Co(N_3)(NH_3)(C_2H_8N_2)_2]Cl_2$: C, 15.54; H, 6.20; N, 36.25%.

The optical resolution of this complex was achieved by a modified procedure of that of Buckingham, Olsen, and Sargeson[14] using NH_4*d*-bcs as a resolving agent (*d*-bcs stands for $(+)_{589}$-(1*R*, 3*S*, 4*S*, 7*R*)-3-bromocamphor-9-sulfonate ion). The less soluble diastereomer was recrystallized from water until it showed a constant rotation. $[\alpha]_{589}=-10°$, $[\alpha]_{546}=+15°$, $[\alpha]_{467}=+371°$. Found: C, 33.34; H, 5.52; N, 12.85%. Calcd for $[Co(N_3)(NH_3)(C_2H_8N_2)_2](C_{10}H_{14}O_4BrS)_2\cdot 0.5H_2O$: C, 33.23; H, 5.58; N, 12.92%. A solution of the diastereomer was passed through a column containing Dowex 1×8 strong-base anion exchange resin (Cl^- form) and the resulted solution was evaporated to dryness below 30 °C. The deposited fine reddish-violet crystals were suspended in methanol to eliminate a contaminant, filtered, washed with methanol and acetone, and dried in a desiccator over $CaCl_2$. $[\alpha]_{589}=-210°$, $[\alpha]_{546}=-116°$. Found: C, 15.06; H, 6.35; N, 34.01%. Calcd for $[Co(N_3)(NH_3)(C_2H_8N_2)_2]Cl_2\cdot 0.5H_2O$: C, 15.10; H, 6.34; N, 35.23%.

(2) $(+)_{589}$-cis-$[Co(N_3)_2(en)_2]ClO_4$: To a solution (50 °C) of 3.0 g of *rac*-$[Co(N_3)_2(en)_2]N_3$[15] in 80 cm^3 of water was added a solution of 1.8 g of $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ in 20 cm^3 of water (*d*-tart stands for $(+)_{589}$-tartrate(4−) ion). The mixture was kept in a refrigerator for two days. The resulting dark reddish-violet prismatic crystals were filtered, washed with a little water, methanol, and then acetone, and dried in air. 2.6 g. $[\alpha]_{589}=+140°$, $[\alpha]_{546}=-539°$. The less soluble diastereomer was converted to the perchlorate by adding a large excess of solid $LiClO_4\cdot 3H_2O$ (5 g) to a suspension of the diastereomer in 80 cm^3 of water (40 °C) and stirring sufficiently (1 h). The red violet fine crystals separated were filtered, washed with a little water, methanol, and then acetone, and dried in a vacuum desiccator over $CaCl_2$. 0.5 g. Recrystallization was carried out from a minimum amount of water (40 °C). $[\alpha]_{589}=+237°$, $[\alpha]_{546}=-962°$. Found: C, 13.39; H, 4.46; N, 38.98%. Calcd for $[Co(N_3)_2(C_2H_8N_2)_2]ClO_4$: C, 13.25; H, 4.45; N, 38.62%.

The perchlorate of the $(-)_{589}$ isomer was obtained by the addition of a solution containing 0.7 g of $NaClO_4$ in 10 cm^3 of water to the above filtrate. By recrystallization from hot water this isomer gave the same rotation with the opposite sign as the $(+)_{589}$ perchlorate.

(3) $(+)_{589}$-cis-$[Co(NCS)(NH_3)(en)_2]Br_2\cdot 0.5H_2O$: $(-)_{589}$-$[CoCl(NCS)(en)_2]Cl$ (0.9 g, see below (10)) was placed in a 250 cm^3 cylinder and purged with ammonia gas in a Dry Ice–methanol bath to condense about 10 cm^3 of ammonia over the complex. The cylinder was tightly covered and allowed to stand at room temperature for about half an hour.

* Present address: Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

** Present address: Department of Chemistry, The University of Tsukuba, Ibaraki 300-31

When the color of the ammonia solution was changed from dark red to deep orange, the ammonia was evaporated by a stream of dry nitrogen. The resulted orange product (0.9 g) was dried in a vacuum desiccator over P_2O_5 to remove the remaining ammonia. A portion (0.45 g) of the dried product was dissolved in 4 cm^3 of water, and 0.9 g of NaBr was added to the solution. After it had been kept in a refrigerator overnight, the first precipitate was filtered off (this was optically almost inactive). After the filtrate had been kept in a refrigerator for another day, the second precipitate (partly resolved complex) was filtered. When the filtrate was kept in a refrigerator for further four days, the orange prisms resulted. They were filtered, washed with ethanol and acetone, and dried in a vacuum desiccator over $CaCl_2$. 37 mg. $[\alpha]_{589}=+43°$, $[\alpha]_{546}=+83°$. Found: C, 14.32; H, 4.87; N, 20.12%. Calcd for $[Co(NCS)(NH_3)(C_2H_8N_2)_2]Br_2\cdot 0.5H_2O$: C, 14.47; H, 4.86; N, 20.25%. The $(-)_{589}$ isomer was obtained from $(+)_{589}$-$[CoCl(NCS)(en)_2]Cl$.

(4) $(-)_{589}$-cis-$[Co(NCS)_2(en)_2]Cl$: The racemic chloride monohydrate[16] (3.5 g) and the resolving agent $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ (1.7 g) were dissolved in 300 cm^3 of water at 60 °C. After cooling the mixed solution to the room temperature, it was allowed to stand overnight in a refrigerator. The less soluble diastereomer deposited as red orange crystals, and it was recrystallized from hot water (300 cm^3, 60 °C). 1.1 g. $[\alpha]_{589}=-61°$, $[\alpha]_{546}=+165°$. To a suspension of 1.0 g of the recrystallized diastereomer in 80 cm^3 of water was added 200 cm^3 of aqueous solution containing 15 g of lithium chloride. The mixture was stirred for half an hour to transform the diastereomer into the reddish-orange chloride, and this was filtered, washed with 50% ethanol, ethanol and then acetone, and dried in a vacuum desiccator over $CaCl_2$. 0.5 g. $[\alpha]_{589}=-25°$, $[\alpha]_{546}=+134°$. It was confirmed that the optical rotation was not increased by recrystallization. Found: C, 21.77; H, 4.97; N, 25.44%. Calcd for $[Co(NCS)_2(C_2H_8N_2)_2]Cl$: C, 21.79; H, 4.88; N, 25.41%.

(5) $(-)_{589}$-cis-$[Co(NO_2)(NH_3)(en)_2]SO_4\cdot H_2O$: The racemic dithionate[13] was converted to the nitrate by an ion-exchange method with Dowex 2×8 resin (NO_3^- form, 50—100 mesh). The racemic nitrate, $[Co(NO_2)(NH_3)(en)_2](NO_3)_2$ (3.2 g), was dissolved in 17 cm^3 of water (40 °C), and 1.4 g of NH_4*d*-bcs was added to it.[17] The mixed solution was kept in a refrigerator for about four days. Orange yellow needles separated were filtered, washed with 50% ethanol, ethanol, and then acetone, and air-dried. 0.65 g. $[\alpha]_{589}=+44°$, $[\alpha]_{546}=+33°$, $[\alpha]_{436}=+386°$. The needles were occasionally contaminated with orange yellow prisms. The prisms were the racemic nitrate. The undesired prisms were easily removed by hand picking. The diastereomer was recrystallized from water (50 °C), and filtered, washed with a little ice-cold water, 50% ethanol, and then acetone, and dried in air. 0.5 g. $[\alpha]_{589}=+53°$, $[\alpha]_{546}=+49°$, $[\alpha]_{438}=+440°$. The diastereomer was converted to the sulfate by passing the aqueous solution through a column containing an anion-exchange resin (SO_4^{2-} form) and by evaporating the resulting solution to dryness below 30 °C. After suspending the sulfate in a methanol–water (4:1) mixture and stirring it enough, the sulfate of the $(-)_{589}$ isomer was filtered, washed with methanol and acetone, and dried in a vacuum desiccator over $CaCl_2$. $[\alpha]_{589}=-18°$, $[\alpha]_{546}=-49°$. Found: C, 13.73; H, 5.88; N, 23.21%. Calcd for $[Co(NO_2)(NH_3)(C_2H_8N_2)_2]SO_4\cdot H_2O$: C, 13.49; H, 5.94; N, 23.59%.

(6) $(-)_{589}$-cis-$[Co(NO_2)_2(en)_2]Cl$: To the solid complex, $[CoCO_3(en)_2]NO_3\cdot H_2O$[18] (32 g), was poured carefully 225 cm^3 of 4% of nitric acid. The complex was dissolved with the evolution of CO_2 gas to give a solution containing *cis*-$[Co(en)_2(OH_2)_2]^{3+}$ complex. After the solution had been stirred for a while to complete the aquation, 20.7 g of $NaNO_2$ was added, and the mixed solution was gradually heated on a water bath and stirred at 70 °C for an hour. The color of solution changed from red to dark orange, and the nitrate of the desired complex separated out. The crystals were filtered and washed with water, and then ethanol. 20 g. The nitrate was recrystallized from water (60 °C) and the fine crystals obtained were filtered, washed with water, and then ethanol, and dried in a vacuum desiccator over $CaCl_2$. Found: C, 14.74; H, 5.10; N, 29.27%. Calcd for $[Co(NO_2)_2(C_2H_8N_2)_2]NO_3$: C, 14.42; H, 4.84; N, 29.42%.

The perchlorate was obtained in a similar way from $[CoCO_3(en)_2]ClO_4$.[19] Found: C, 13.18; H, 4.23; N, 22.66%. Calcd for $[Co(NO_2)_2(C_2H_8N_2)_2]ClO_4$: C, 12.96; H, 4.35; N, 22.68%.

The nitrate was resolved in a usual way using $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ as resolving agent.[20] The less soluble diastereomer yielded the $(-)_{589}$-$[Co(NO_2)_2(en)_2]Cl$.

(7) $(+)_{589}$-cis-$[Co(N_3)(NCS)(en)_2]Cl\cdot 0.5H_2O$: To a 60 °C solution of 6.0 g of *cis*-$[CoCl(NCS)(en)_2]ClO_4$[13] in 45 cm^3 of water was added 1.2 g of NaN_3, and the resulting solution was stirred at 60 °C for about 80 min. After the solution had been diluted with an appropriate amount of water, it was poured on a column (27×800 mm) containing Dowex 50 W×8 cation-exchange resin (200—400 mesh, H^+ form). The adsorbed band was eluted first with 0.2 M LiCl solution at a rate of 1.5—2.0 cm^3/min for a week. The eluates were discarded, because it was confirmed from the absorption measurement that the eluates contained some *trans* complexes. After these operations, the remaining colored band which was placed on the upper half of the column was eluted with 0.5 M LiCl (about 13 dm^3 in total) during the next week. The broad bands eluted were fractionated by 200 cm^3 portions. The eluted ten fractions which have the first absorption band at 510—509 nm were combined and concentrated to a volume as little as possible (about 50 cm^3) in a vacuum evaporator at 35 °C. After the mixture had stood in a refrigerator overnight, the resulting precipitates, *cis*-$[Co(N_3)(NCS)(en)_2]Cl\cdot 1.5H_2O$ and LiCl, were filtered. To remove the LiCl, the mixture was suspended in 200 cm^3 of ethanol and the suspension was stirred enough. The dark reddish-violet precipitate was filtered, washed with five 20 cm^3 portions of ethanol, and then ether, and dried in a vacuum desiccator. 0.41 g. This was recrystallized from water (50 °C), and the product was washed with ethanol and ether, and dried in a vacuum desiccator over $CaCl_2$. Found: C, 17.63; H, 5.67; N, 32.28%. Calcd for $[Co(N_3)(NCS)(C_2H_8N_2)_2]Cl\cdot 1.5H_2O$: C, 17.58; H, 5.60; N, 32.79%.

The resolving agent $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ (120 mg) was dissolved in 40 cm^3 of water at 60 °C, and 220 mg of *cis*-$[Co(N_3)(NCS)(en)_2]CH_3CO_2$, which was obtained from the chloride by the usual ion-exchange method, was added to it with stirring. After cooling the mixed solution to room temperature, it was kept in a refrigerator overnight. The fine dark reddish-violet crystals separated were filtered, washed with ethanol and ether, and air-dried. 115 mg. $[\alpha]_{589}=+135°$, $[\alpha]_{546}=+60°$. The less soluble diastereomer (110 mg) was dissolved in 3 cm^3 of water at 45 °C. After the solution had stood for two weeks in a refrigerator, the resulted crystals were filtered, washed with a little water, ethanol and ether, and air-dried. 18 mg. $[\alpha]_{589}=+178°$, $[\alpha]_{546}=+50°$. The recrystallized diastereomer (18 mg) was dissolved in 10 cm^3 of water, and the solution was passed through an anion-exchange resin column (Cl^- form). The chloride solution obtained was evaporated to dryness in a vacuum desiccator over P_2O_5.

$[\alpha]_{589}=+125°$, $[\alpha]_{546}=-138°$. Found: C, 18.70; H, 5.29; N, 34.52%. Calcd for $[Co(N_3)(NCS)(C_2H_8N_2)_2]Cl\cdot 0.5H_2O$: C, 18.55; H, 5.29; N, 34.62%.

(8) $(+)_{589}$-cis-$[Co(N_3)(NO_2)(en)_2]ClO_4$: To a solution of 5.7 g of *cis*-$[CoCl(NO_2)(en)_2]Cl$ in 90 cm³ of water at 70 °C was added 1.3 g of NaN_3. The mixture was heated on a steam bath in a draft chamber. When the solution was concentrated to 10—15 cm³, a solution containing 2.4 g of $Na_2S_2O_6\cdot 2H_2O$ in 10 cm³ of water was added to it with stirring. After cooling the mixture to room temperature and then keeping it in an ice bath for an hour, the reddish-orange fine crystals precipitated were filtered, washed with a little water, and dried in air. 2.8 g. This was recrystallized twice from water (60 °C) and washed with a little water, ethanol, and then ether, and air-dried. Found: C, 13.70; H, 4.63; N, 31.87%. Calcd for $[Co(N_3)(NO_2)(C_2H_8N_2)_2]_2S_2O_6$: C, 13.84; H, 4.65; N, 32.27%.

The racemate, *cis*-$[Co(N_3)(NO_2)(en)_2]_2S_2O_6$ (6.0 g), was dissolved in 600 cm³ of water at 60 °C, and transformed into the chloride solution by an ion-exchange method. The resulted chloride solution was evaporated at 40 °C to 75 cm³ in a vacuum evaporator, and a solution of 2.6 g of NH_4*d*-bcs in 20 cm³ of water was added to it. After the mixed solution had been cooled in a refrigerator for two days, the red orange needles separated were filtered, washed with a little water, methanol and ether, and air-dried. 2.7 g. $[\alpha]_{589}=+77°$, $[\alpha]_{546}=+80°$, $[\alpha]_{472}=-542°$. The diastereomer was recrystallized from water (45 °C, 160 cm³). 0.9 g. $[\alpha]_{589}=+68°$, $[\alpha]_{546}=+72°$, $[\alpha]_{472}=-598°$. Found: C, 29.11; H, 5.26; N, 18.68%. Calcd for $[Co(N_3)(NO_2)(C_2H_8N_2)_2](C_{10}H_{14}O_4BrS)$: C, 29.13; H, 5.24; N, 19.41%. The recrystallized diastereomer (0.5 g) was dissolved in a minimum amount of water (35 cm³) at 40 °C, and 10g of $NaClO_4$ was added to it with stirring. After the mixture had stood for two hours, the resulted fine red orange lustrous prisms were filtered, washed with ethanol and ether, and air-dried. 144 mg. $[\alpha]_{589}=+32°$. $[\alpha]_{546}=+43°$. The perchlorate was recrystallized from water (40 °C, 6 cm³). 66 mg. It was confirmed that the optical rotation of this isomer was not increased by the recrystallization. Found: C, 13.27; H, 4.30; N, 30.61%. Calcd for $[Co(N_3)(NO_2)(C_2H_8N_2)_2]ClO_4$: C, 13.10; H, 4.40; N, 30.56%.

(9) $(+)_{589}$-cis-$[Co(NCS)(NO_2)(en)_2]Cl$: To a solution of 1.6 g of barium acetate in 200 cm³ of water (60 °C) was added 3.9 g of *cis*-$[Co(NCS)(NO_2)(en)_2]_2SO_4$.[13] After the mixture had been stirred for half an hour at 60 °C, the barium sulfate deposited was removed by filtration. The filtrate was evaporated to dryness with a vacuum evaporator, and the resulted fine yellow orange crystals were collected and washed with 70% ethanol, ethanol and then ether, and air-dried. 3.5 g. Found: C, 24.54; H, 5.62; N, 24.48%. Calcd for $[Co(NCS)(NO_2)(C_2H_8N_2)_2]CH_3CO_2$: C, 24.57; H, 5.60; N, 24.55%. The racemic acetate, *cis*-$[Co(NCS)(NO_2)(en)_2]CH_3CO_2$ (2.0 g), was dissolved in 10 cm³ of water at 40 °C, and a solution of 1.0 g of $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ in 10 cm³ of water at 40 °C was added to it. A large amount of yellow orange precipitate separated soon, and was filtered after an hour (the filtrate was used for separating the $(-)_{589}$-isomer), washed with ethanol and ether, and air-dried. 1.5 g. $[\alpha]_{589}=+110°$, $[\alpha]_{546}=+160°$. This was recrystallized from water (45 °C, 500 cm³). Yellow orange needles. 0.9 g. $[\alpha]_{589}=+125°$, $[\alpha]_{546}=+191°$.

The recrystallized diastereomer (0.3 g) was dissolved in 150 cm³ of water at 40 °C, and was converted into the chloride solution by an ion-exchange method. The resulted chloride solution was evaporated to dryness below 30 °C in a vacuum evaporator. After being suspended in ethanol with stirring, the fine yellow orange prisms were filtered, washed with ethanol and ether, and dried in air. 0.13 g. $[\alpha]_{589}=+87°$, $[\alpha]_{546}=+197°$. Recrystallization of the chloride caused no increase in the optical rotation. Found: C, 18.89; H, 5.05; N, 26.29%. Calcd for $[Co(NCS)(NO_2)(C_2H_8N_2)_2]Cl$: C, 18.85; H, 5.06; N, 26.37%.

The $(-)_{589}$ optical isomer appeared soon after a solution of 1.0 g of LiCl in 2 cm³ of water was added to the above mentioned filtrate freed from the diastereomer. The crystals were filtered after about 5 min, washed with ethanol and ether, and air-dried. 0.41 g. $[\alpha]_{589}=-82°$, $[\alpha]_{546}=-186°$. This was recrystallized from water (45 °C, 16 cm³). 0.22 g.

(10) $(-)_{589}$-cis-$[CoCl(NCS)(en)_2]ClO_4$: The racemic perchlorate was prepared from *trans*-$[CoCl_2(en)_2]Cl$ by the Werner's method.[13] The perchlorate obtained was contaminated with the diisothiocyanato complex, and then purified as follows. The crude perchlorate salt was fractionally extracted with water, and to each extract was added one-fourth volume of 70% $HClO_4$ and the resulted solution was cooled in an ice bath for several hours. The fine orange crystals of the contaminant, $[Co(NCS)_2(en)_2]ClO_4$, precipitated from the earlier extracts, whereas the dark red crystals of *cis*-$[CoCl(NCS)(en)_2]ClO_4$ precipitated from the later extracts. No crystallization occurred from the middle extracts. The crystals of the desired complex were recrystallized from water by the addition of perchloric acid as described above, and filtered, washed with ethanol and ether, and sucked dry. Found: C, 16.00; H, 4.18; N, 18.74%. Calcd for $[CoCl(NCS)(C_2H_8N_2)_2]ClO_4$: C, 16.14; H, 4.33; N, 18.82%.

A solution of 12 g of racemic *cis*-$[CoCl(NCS)(en)_2]ClO_4$ in 160 cm³ of water (50 °C) and a solution of 5.3 g of NH_4*d*-bcs in 30 cm³ of water (50 °C) were mixed. The mixture was allowed to stand at room temperature for an hour, and then cooled gradually to 10 °C. The dark reddish violet crystalline precipitate was filtered, washed with ethanol and ether, and dried in air. 8.6 g. The filtrate was used for obtaining the $(+)_{589}$-isomer. $[\alpha]_{589}=+11°$, $[\alpha]_{546}=+226°$. This was recrystallized from water (45 °C). $[\alpha]_{589}=+27°$, $[\alpha]_{546}=+317°$. Found: C, 30.37; H, 5.43; N, 11.57%. Calcd for $[CoCl(NCS)(C_2H_8N_2)_2](C_{10}H_{14}O_4BrS)\cdot H_2O$: C, 29.98; H, 5.37; N, 11.66%. The recrystallized diastereomer (3.5 g) was stirred with 6 cm³ of 70% $HClO_4$ for an hour. After the mixture had been stirred in an ice bath for another hour, the separated fine crystals of the perchlorate were filtered, washed with ethanol and ether. 1.2 g. $[\alpha]_{589}=-31°$, $[\alpha]_{546}=+389°$. The perchlorate was dissolved in a minimum amount of water (20 cm³), and 4 cm³ of 70% $HClO_4$ was added to it. After the mixture had stood overnight, the reddish violet crystals separated were filtered, washed with ethanol and ether, and dried in a vacuum desiccator over $CaCl_2$. 0.7 g. $[\alpha]_{589}=-39°$, $[\alpha]_{546}=+440°$. Found: C, 16.34; H, 4.31; N, 18.45%. Calcd for $[CoCl(NCS)(C_2H_8N_2)_2]ClO_4$: C, 16.14; H, 4.33; N, 18.82%.

The filtrate freed from the less soluble diastereomer was evaporated at 25 °C to 170 cm³, and after cooling the solution in an ice bath, the second crop of the diastereomer was removed. The filtrate was evaporated further to 55 cm³, and 18 cm³ of 70% $HClO_4$ was added to it. After cooling the mixture by ice, the precipitated perchlorate was filtered. This was found to be an optically impure perchlorate of the $(+)_{589}$-isomer. The filtrate was kept in a refrigerator for three days, and then the dark reddish violet needles separated. The crystals were filtered, washed with ethanol and ether, and air-dried. 0.4 g. These showed the same optical rotation with the opposite sign in comparison with the $(-)_{589}$ perchlorate.

Measurements. The absorption spectra were measured by a Shimadzu UV-200 or a Beckman DU spectrometer. The CD spectra were recorded with a Jasco Model ORD/UV-5,

J-10, or J-20 spectropolarimeter, and the optical rotation by a Yanagimoto Model 185 or a Jasco Model ORD/UV-5 spectropolarimeter. The measurements were made at room temperature in aqueous solutions. The concentration of the solution ranged from 0.005 to 0.0001 M. The cell length was 1, 2 cm, or 1 mm.

Results and Discussion

Absorption and CD Spectra. The absorption and CD data are listed in Tables 1 and 2. In Fig. 1 the CD spectra of $(-)_{589}$-$[Co(N_3)(NH_3)(en)_2]^{2+}$ and $(+)_{589}$-$[Co(N_3)_2(en)_2]^+$ complexes are shown together with their absorption spectra. In the "azido-specific band" region around 33000 cm^{-1}, the ammineazido complex shows a single CD band with its peak in almost the same position as that of the absorption peak, while the diazido complex shows two CD bands of opposite signs. This observation supports that the broadening of the specific absorption band in the diazido complex is due to the overlapping of two split components of the band. The weak negative CD band at 26100 cm^{-1} of the ammineazido complex and the positive CD band at 25800 cm^{-1} of the diazido complex correspond to the second d-d absorption band ($^1A_{1g}\rightarrow{}^1T_{2g}$ in O_h symmetry). The positive CD band of the diazido complex has the intensity comparable to the CD band in the first d-d absorption band ($^1A_{1g}\rightarrow{}^1T_{1g}$ in O_h symmetry) region. This is unusual, but this behavior should be considered to be only the result of the contiguity of the intense

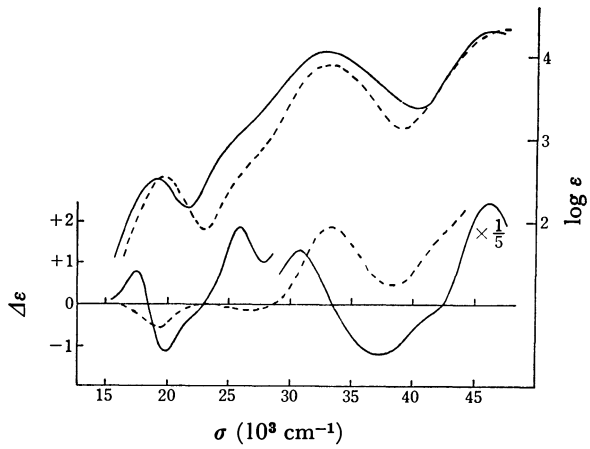

Fig. 1. Absorption and CD spectra of $(+)_{589}$-*cis*-$[Co(N_3)_2(en)_2]ClO_4$ (——) and $(-)_{589}$-*cis*-$[Co(N_3)(NH_3)(en)_2]Cl_2\cdot H_2O$ (------).

positive CD band of the specific band. In Fig. 2 the CD spectra of isothiocyanato complexes are shown with their absorption spectra. Concerning their specific bands the CD behavior similar to the azido complexes are observed; A single weal CD band is observed at 34900 cm^{-1} for the ammineisothiocyanato complex, while two CD bands of opposite signs are observed for the diisothiocyanato complex. This fact suggests the band splitting of the diisothiocyanato complex. The nagative CD band of the ammineisothiocyanato complex at 27700 cm^{-1} and the two CD bands of the diisothiocyanato complex at 25300 and 27300 cm^{-1} are assigned to the second d-d transitions.

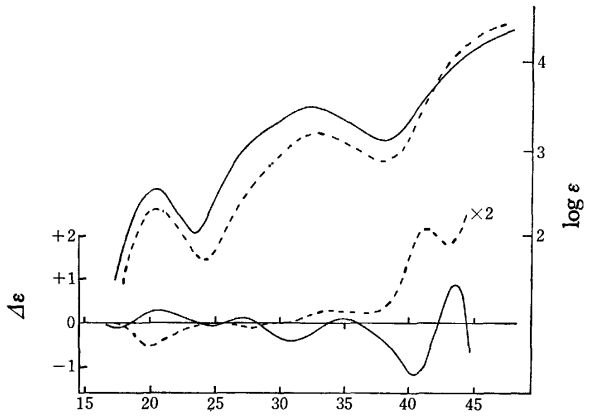

Fig. 2. Absorption and CD spectra of $(-)_{589}$-*cis*-[Co$(NCS)_2(en)_2$]Cl (——) and $(-)_{589}$-*cis*-[Co$(NCS)(NH_3)$-$(en)_2$]$Br_2 \cdot 0.5H_2O$ (------).

The azido and isothiocyanato complexes show very similar absorption curves to each other (Figs. 1 and 2). The specific absorption band at 33000 cm^{-1} of *cis*-$[Co(N_3)_2(en)_2]^+$ is 1.23 times as broad (and 1.45 times as intense) as that of *cis*-$[Co(N_3)(NH_3)(en)_2]^{2+}$. The same situation is also found for the isothiocyanato complexes, that is, the specific band at 32700 cm^{-1} of *cis*-$[Co(NCS)_2(en)_2]^+$ is 1.23 times as broad (and 1.70 times as intense) as that of *cis*-$[Co(NCS)(NH_3)(en)_2]^{2+}$. This absorption behavior concerning the band width of the azido and isothiocyanato complexes is quite a contrast to that of the corresponding nitro complexes, where the *cis* dinitro complex shows the specific band similar in width to the ammineniro one (Fig. 3). The absorption band broadening in the diazido and diisothiocyanato complexes suggests a band splitting, and this is confirmed from the CD spectra as above. It has been pointed out in earlier days for isothiocyanato complexes of chromium(III),[1] and isothiocyanato[3] and nitro[2] complexes of cobalt(III) that the specific band intensity is proportional to the number of the coordinated particular ligand, and this has been taken as an evidence for the theory that the specific band is due to the intraligand transition. As for the present complexes the (dianiono/ammineaniono) ratio of integrated intensities of the specific bands is approximately 2 for all of the azido, isothiocyanato, and nitro ligands. It is significant, however, in the case of the diazido and diisothiocyanato complexes, that the specific bands

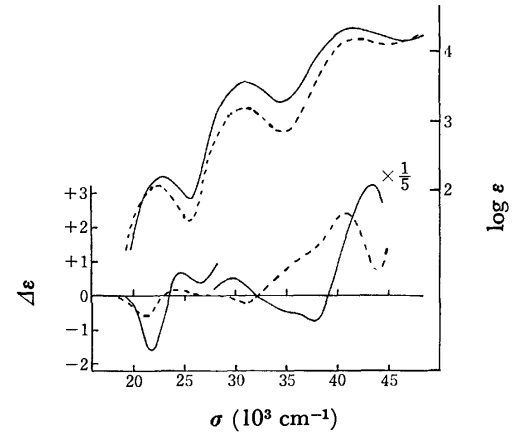

Fig. 3. Absorption and CD spectra of $(-)_{589}$-*cis*-[Co$(NO_2)_2(en)_2$]Cl (——) and $(-)_{589}$-*cis*-[Co$(NO_2)(NH_3)$-$(en)_2$]$SO_4 \cdot H_2O$ (------).

are shifted to the lower energy side than the corresponding ammineaniono complexes, and that the shift direction is the same as that of the first d-d absorption bands. The parallel shift of the specific and the first d-d bands may be taken as an evidence of the theory that the specific absorption band is due to the ligand-to-metal charge transfer transition, because the wider is the separation between the occupied d_π and the empty d_σ orbitals, the higher should be the energy of the charge transfer transition from the almost unaffected ligand orbital to the empty d_σ orbital.

Miskowsky and Gray[10] assigned the isothiocyanato specific band to the π(ligand)$\rightarrow d_{z^2}$(metal) transition as in the case of the longer wavelength charge transfer bands of amminehalogeno cobalt(III) complexes. As for the latter halogeno charge transfer bands, Yamatera[21] established the assignments that the longer and the shorter wavelength charge transfer bands are due to the p_π(ligand)$\rightarrow d_{z^2}$(metal) and p_σ(ligand)$\rightarrow d_{z^2}$(metal) transitions, respectively. The p_π(ligand)$\rightarrow d_{z^2}$(metal) transition of a C_{4v} complex such as $[CoX(NH_3)_5]^{2+}$ is expected to split into two transitions for a C_{2v} complex such as *cis*-$[CoX_2(NH_3)_4]^+$.[22] If it is presumed that the chelate ring effect of ethylenediamine is negligible, and the ligand fields of the diamine and the ammine are quite the same, the symmetry of *cis*-$[CoX(NH_3)(en)_2]^{2+}$ is approximated to C_{4v} and that of *cis*-$[CoX_2(en)_2]^+$ to C_{2v}. Then, the splitting of the specific absorption band in the diisothiocyanato complex can reasonably be explained by the theory that the isothiocyanato specific bands are due to the charge transfer transitions from π orbitals of the pseudohalogeno ligand to the lower empty d_σ orbital (d_{z^2}) of the central cobalt(III) ion. The similarity of the azido and isothiocyanato complexes in the CD and absorption spectra may be related to the fact that both the ligands are linear triatomic pseudohalide ions having sixteen valence electrons.[23] Therefore the azido specific band is also considered to be the ligand-to-metal charge transfer band.

In Fig. 3 the CD curves of the remaining pair of the mono- and dianiono type complexes, $(-)_{589}$-$[Co(NO_2)(NH_3)(en)_2]^{2+}$ and $(-)_{589}$-$[Co(NO_2)_2(en)_2]^+$, are shown with their absorption curves. In these complexes the second d-d absorption band is completely overlapped

with the nitro specific band. Both the dinitro and amminenitro complexes show two CD bands of opposite signs in the region. However, if the weak CD band of the amminenitro complex in the lower energy side is assumed to correspond to a component of the second d-d absorption band, the more intense CD band in the higher energy side corresponds to the specific band. It may be unreasonable to consider the nitro specific band in the same way as the pseudohalogeno specific band, because the NO_2^- ligand is much different from the N_3^- and NCS^- ligands, that is, the latter two ions are linear pseudohalides which have no absorption band in the near ultraviolet region,[23] while the former nonlinear ion has two weak absorption bands in this region, which have been assigned to $n\rightarrow\pi^*$ transitions.[24] Nevertheless, it is found experimentally that the CD behavior in the nitro specific band region rather resembles that in the pseudohalogeno specific band region.

For the second intense absorption band in the higher energy region (38000—45000 cm^{-1}) of the $(-)_{589}$ nitro complexes, a positive CD band is observed for the amminenitro complex and two CD bands of opposite signs, negative and positive from lower energy side, are observed for the dinitro one (Fig. 3). A similar splitting of the shorter wavelength CD band is also observed for the diisothiocyanato complex. That is, the complex has two CD bands of opposite signs in the region of 37000—44000 cm^{-1}, while the corresponding ammineisothiocyanato complex has only one CD band in this region (Fig. 2 and Table 1).

In Figs. 4—6 the absorption and CD curves of the three mixed complexes of the *cis*-$[Co(X)(X')(en)_2]^+$ type containing different two of N_3^-, NCS^-, and NO_2^- are shown together with the absorption curves of the "parent complexes," *cis*-$[Co(X)_2(en)_2]^+$ and *cis*-$[Co(X')_2(en)_2]^+$. The d-d absorption band positions of the mixed complexes are nearly intermediate between those of the parent ones, but the d-d band intensities are not necessarily intermediate. In the region of specific absorption bands, the absorption curves of the mixed complexes are nearly intermediate between those of the parent ones, but not exactly so, especially for the azidoisothiocyanato complexes. The deviation seems to suggest an interaction between two aniono ligands in the *cis* positions through the central cobalt(III) ion.

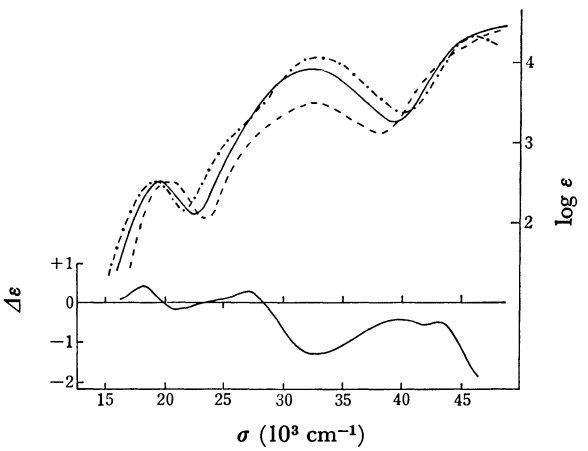

Fig. 4. Absorption and CD spectra of $(+)_{589}$-*cis*-$[Co(N_3)(NCS)(en)_2]Cl\cdot 0.5H_2O$ (——), and absorption spectra of *cis*-$[Co(N_3)_2(en)_2]ClO_4$ (-·-·-) and *cis*-$[Co(NCS)_2(en)_2]Cl\cdot H_2O$ (------).

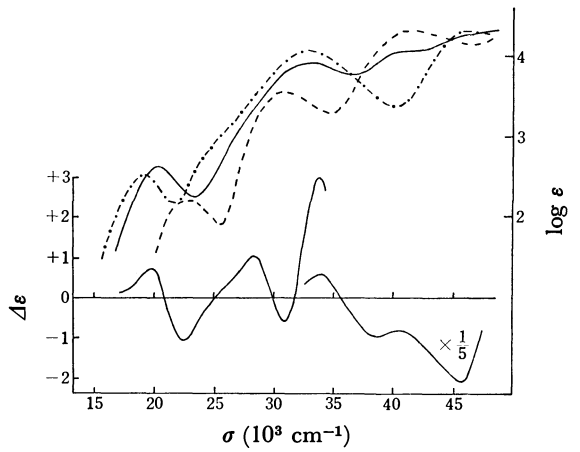

Fig. 5. Absorption and CD spectra of $(+)_{589}$-*cis*-$[Co(N_3)(NO_2)(en)_2]ClO_4$ (——), and absorption spectra of *cis*-$[Co(N_3)_2(en)_2]ClO_4$ (-·-·-) and *cis*-$[Co(NO_2)_2(en)_2]ClO_4$ (------).

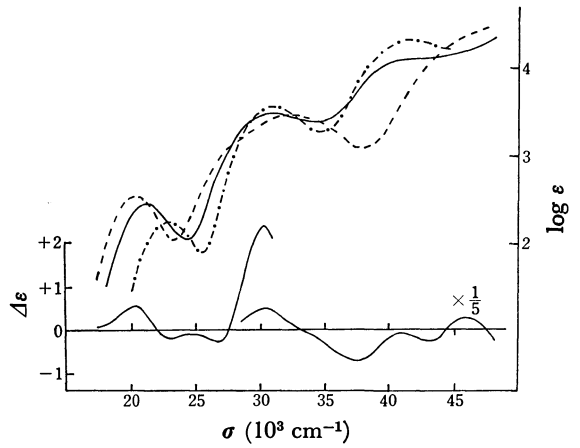

Fig. 6. Absorption and CD spectra of $(+)_{589}$-*cis*-$[Co(NCS)(NO_2)(en)_2]Cl$ (——), and absorption spectra of *cis*-$[Co(NCS)_2(en)_2]Cl\cdot H_2O$ (------) and *cis*-$[Co(NO_2)_2(en)_2]ClO_4$ (-·-·-).

The ultraviolet CD of the mixed complexes is too complicated to interpret systematically, and this may be also the reflection of the symmetry lowering and the interaction between the ligands. A comparison of the CD curves of the mixed complexes with those of the parent complexes having the same absolute configuration and further with their average CD curves was attempted on trial, but any simple regularity was not found.

Absolute Configurations of the Complexes. McCaffery *et al.*[25] have correlated the CD pattern in the first d-d absorption band of a bis(ethylenediamine) cobalt(III) complex with its absolute configuration by employing a model, in which a *cis*-$[Co(X)_2(en)_2]^+$ complex with C_2 symmetry is regarded as an intermediate between $[Co(en)_3]^{3+}$ with D_3 symmetry and *cis*-$[Co(X)_2(NH_3)_4]^+$ with C_{2v} symmetry. When the ligand X lies far above or below the ethylenediamine ligand in the spectro-

chemical series, the complex is near the C_{2v} limit, and the major one of the two CD components is observed closer in energy to the first d-d absorption band of $[Co(en)_3]^{3+}$ than the minor CD component. Then the positive major CD component is correlated to the positive E_a component of Λ-$(+)_{589}$-$[Co(en)_3]^{3+}$.[26] From this criterion and the CD data in Table 1, the absolute configuration Δ was assigned to the two present dianiono complexes, $(+)_{589}$-diazido and $(-)_{589}$-dinitro complexes, and Λ to the remaining $(-)_{589}$-diisothiocyanato complex. The absolute configuration of $(-)_{589}$-dinitro complex has been determined as Δ by an X-ray analysis.[27]

The same treatment can be applied to the mixed complexes of the *cis*-$[Co(X)(X')(en)_2]^+$ type by regarding them as the *cis*-$[Co(Z)_2(en)_2]^+$ complexes, where Z is an imaginary unidentate ligand having the average ligand strength of X and X', if X and X' are not so different in the ligand strength from each other. Thus the $(-)_{589}$ isomer of *cis*-$[CoCl(NCS)(en)_2]^+$, which has the major positive CD component at the higher energy side in the first absorption band region, was assigned to Λ. The $(+)_{589}$ isomer of *cis*-$[Co(N_3)(NCS)(en)_2]^+$ complex was assigned to Δ, because the higher energy CD component of the this isomer has a negative sign ($\Delta\varepsilon=-0.20$), though this negative component is not the major one.

As for the ammineaniono complexes, the isomers having a negative CD band in the first d-d absorption band region, that is, $(-)_{589}$-ammineazido and $(-)_{589}$-ammineisothiocyanato, were assigned to the Δ configuration according to Norman's proposal.[28] The Λ configuration of $(+)_{589}$-ammineisothiocyanato complex is consistent with the fact that this isomer was derived from the Λ-$(-)_{589}$-chloroisothiocyanato complex.

Garbett and Gillard[29] derived the $(+)_{589}$ isomer of ammineitro complex from the Λ-$(-)_{589}$-$[CoCl(NCS)(en)_2]^+$ through $(+)_{589}$-$[Co(NCS)(NO_2)(en)_2]^+$. This means that the configuration of $(-)_{589}$-ammineitro isomer in Table 1 is Δ, which has a major negative CD component at the lower energy side in the first absorption band region. It is consistent with the results for the other Δ nitro mixed complexes such as $(-)_{589}$-dinitro,[27] $(-)_{589}$-chloronitro,[29] and $(-)_{546}$-cyanonitro[30] complexes. In this relation, the present two mixed complexes, $(+)_{589}$-$[Co(N_3)(NO_2)(en)_2]^+$ and $(+)_{589}$-$[Co(NCS)(NO_2)(en)_2]^+$, were assigned to the Λ absolute configuration, because both the two complexes have a positive CD component at the lower energy side in the first absorption band region (Table 2).

Table 3. Absolute configurations of the optical isomers forming the less soluble diastereomers

Complex ion	Resolving agent	Optical rotation	Absolute configuration
(1) *cis*-$[Co(N_3)(NH_3)(en)_2]^{2+}$	a)	$(-)_{589}(-)_{546}$	Δ
(2) *cis*-$[Co(N_3)_2(en)_2]^+$	b)	$(+)_{589}(-)_{546}$	Δ
(3) *cis*-$[Co(NCS)(NH_3)(en)_2]^{2+}$	c)	$(+)_{589}(+)_{546}$	Λ
(4) *cis*-$[Co(NCS)_2(en)_2]^+$	b)	$(-)_{589}(+)_{546}$	Λ
(5) *cis*-$[Co(NO_2)(NH_3)(en)_2]^{2+}$	a)	$(-)_{589}(-)_{546}$	Δ
(6) *cis*-$[Co(NO_2)_2(en)_2]^+$	b)	$(-)_{589}(-)_{546}$	Δ
(7) *cis*-$[Co(N_3)(NCS)(en)_2]^+$	a)	$(+)_{589}(-)_{546}$	Δ
(8) *cis*-$[Co(N_3)(NO_2)(en)_2]^+$	a)	$(+)_{589}(+)_{546}$	Λ
(9) *cis*-$[Co(NCS)(NO_2)(en)_2]^+$	b)	$(+)_{589}(+)_{546}$	Λ
(10) *cis*-$[CoCl(NCS)(en)_2]^+$	a)	$(-)_{589}(+)_{546}$	Λ

a) NH_4(*d*-bcs). b) $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$. c) Derived from Λ-$(-)_{589}$-$[CoCl(NCS)(en)_2]^+$.

The assignments of absolute configurations for the present ten complexes are collected in Table 3. From this table and the CD signs of the "specific band" (Tables 1 and 2), the following relationship is obtained. In the ammineaniono complexes, all the Λ isomers show a negative CD band in the regions of the specific absorption bands, if a weak CD band of the amminenitro complex at 31000 cm^{-1} is neglected. As mentioned already, this longer-wavelength weak CD band may be due to the second d-d absorption band, which is completely overlapped with the nitro specific band. In the dianiono complexes, Λ isomers show regularly a CD pattern of negative and then positive signs in the order of increasing energy (Figs. 1—3). In the mixed type complexes, *cis*-$[Co(X)(X')(en)_2]^+$ (X and X'=N_3^-, NCS^-, or NO_2^-), the CD patterns are complicated, but the following regularity is found out for the specific band region; that is, the dominant CD band in this region is positive for all of their Λ isomers (Figs. 4—6).

The authors are grateful to Dr. Wasuke Mori of Osaka University, and Dr. Keiji Matsumoto of Osaka City University for their help in the measurements of CD spectra.

Studies of the Cobalt(III) Complexes of 8-Amino-3,6-diazaoctanate Ion. II.[1] The Preparation and Some Properties of the Complexes with a Carbonate, Oxalate, or Malonate Ligand

Kiyokatsu WATANABE

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received June 12, 1976)

The following new cobalt(III) complexes containing the quadridentate 8-amino-3,6-diazaoctanate ion (adao) have been prepared: α-[Co(adao)(ox)], α-[Co(adao)(mal)] (mal, malonate ion), *β-mer(N)*-[Co(adao)(CO_3)], *β-mer(N)*-[Co(adao)(mal)], *β-fac(N)*-[Co(adao)(CO_3)], *β-fac(N)*-[Co(adao)(ox)], and *β-fac(N)*-[Co(adao)(mal)]. The geometrical isomers have been separated by the chromatographic technique. The configurations of the complexes have been identified by means of the electronic absorption spectra and the proton NMR spectra.

The 8-amino-3,6-diazaoctanate ion (adao)* can coordinate with four coordination modes in an octahedral complex, as is shown in Fig. 1-a. These modes were designated as *α,β-mer(N)*, *β-fac(N)*, and *trans* by Schneider and Collman.[2] The two optical isomers (*Δ* and *Λ*) which arise from the contribution of a configurational chirality may exist in each of three coordination modes (*α,β-mer(N)*, and *β-fac(N)*) of their four coordination modes. When we consider the configuration of the secondary amine nitrogen atom (*s*-N) in adao, further discrimination is possible in the *β-mer(N)*, *β-fac(N)*, and *trans* forms. This is illustrated in Fig. 1-b. The configuration of the chiral *s*-N atom is described by the *R* or *S* rule proposed by Cahn, Ingold, and Prelog.[3] For the respective *β-mer(N)*, *β-fac(N)*, and *trans* racemic isomers, the existence of isomers, (*SR,RS*) and (*SS,RR*), is possible. However, such isomers are impossible to exist for the α racemic isomer. Thus, five geometrical isomers *α,β-mer(N)*-(*SR,RS*), *β-mer(N)*-(*SS, RR*), *β-fac(N)*-(*RS,SR*), and *β-fac(N)*-(*RR,SS*), are possible when a symmetrical bidentate ligand occupies the residual sites.

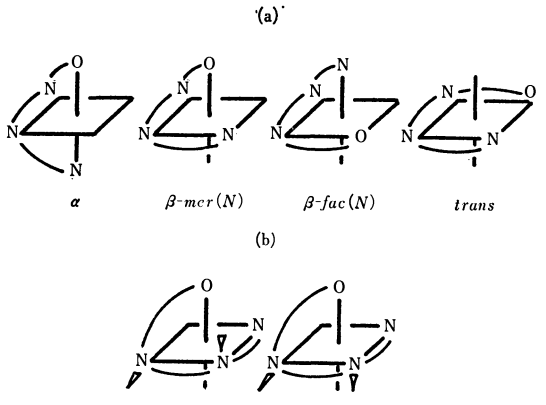

Fig. 1. Coordination modes of adao (a) and configurations around the *s*-N of adao in *Δ-β-mer(N)* coordination mode (b).

* The following abbreviations are used for the ligands: adao, 8-amino-3,6-diazaoctanate; edda, ethylenediamine-*N,N'*-diacetate; ed3a, ethylenediamine-*N,N,N'*-triacetate; *i*-dtma, 4-diethylenetriaminemonoacetate; ox, oxalate; mal, malonate.

If an unsymmetrical bidentate ligand occupies, the number of the isomers increase. Schneider *et al.*,[2] Fukuhara *et al.*,[4] and the present author[1] have studied the cobalt(III) complexes containing the quadridentate ligand. It was shown in these studies that most complexes isolated were the *β-mer(N)* isomers, although the existence of the α and the *β-fac(N)* isomers is also to be expected. In order to clarify this problem, the isolation of the isomers with a symmetrical bidentate ligand was attempted. Thus, we succeeded in isolating some of the α and *β-fac(N)* isomers for the carbonato, oxalato, and malonato complexes.

Experimental

Materials. Diethylenetriamine (Nakarai Chemicals), oxalic acid, malonic acid and all the other reagent-grade chemicals were used without further purification. Column chromatography was carried out by the use of Dowex 50 W-X8 cation-exchange resin.

Preparations. (1) *Isomers of (8-Amino-3,6-diazaoctanato)-carbonatocobalt(III)*, [*Co(adao)(CO_3)*]: The carbonato complex (5 g), which had been isolated by the method of Schneider *et al.*,[2] was dissolved in 30 cm^3 of water. The solution was then poured into a column (50 mm × 350 mm) containing Dowex 50W-X8 (200—400 mesh, sodium form). By elution with water, the adsorbed bands were gradually separated into two bands: the first was dark-red (Eluate I, ≈100 cm^3), and the second was red-violet (Eluate II, ≈300 cm^3). Eluate I was concentrated to about 15 cm^3 in a rotary evaporator below 40 °C and then kept in a refrigerator for two days. The red precipitate thus deposited (Precipitate I) was collected. Although it is possible to obtain the considerable precipitate from the mother filtrate, the precipitate does not consist of only one isomer. Precipitate I was recrystallized from warm water (≈3 cm^3, 65 °C) and subsequently washed with ethanol and ether. Yield, 0.25 g. Eluate II was reduced to about 5 cm^3 in a rotary evaporator, and then concentrated to nearly dryness over silica gel in a vacuum desiccator. The red-violet deposit was collected and recrystallized from 1 cm^3 of warm water. It was washed with ethanol and acetone. Yield, 0.12 g.

(2) *Isomers of (8-Amino-3,6-diazaoctanato)oxalatocobalt(III)*, [*Co(adao)(ox)*]: A solution of oxalic acid dihydrate (0.6 g) in 5 cm^3 of warm water (≈55 °C) was added to a suspension of Schneider's carbonato complex, [Co(adao)(CO_3)], (1.4 g) in 15 cm^3 of water, and then the mixture was heated at ≈75 °C for 4 h with continuous stirring. To the resulting product, which contained an appreciable amount of a precipitate, was added 40 cm^3 of water, and the precipitate was dissolved by

heating (≈70 °C). The solution was cooled, and then it was filtered. The red filtrate was poured into a column (20 mm × 700 mm) containing Dowex 50 W-X8 (100—200 mesh, hydrogen form), and the adsorbed sustance was eluted with water. The red band which was adsorbed at the top of the column, separated cleanly into three bands with red, pink-red, and red-violet color in the order of the elution. Each of three eluates (≈100 cm³, ≈100 cm³, and ≈120 cm³) was concentrated to about 5 cm³ in a rotary evaporator at ≈55 °C, and then cooled. Each deposit was recrystallized from hot water (5—7 cm³, ≈70 °C) and was washed with methanol and ether. The yields were 1.0 g for the red, 0.05 g for the pink-red, and 0.05 g for the red-violet isomer.

(3) *Isomers of (8-Amino-3,6-diazaoctanato)malonatocobalt(III), [Co(adao)(mal)]*: The reaction product was obtained and separated by a similar procedure to that described in (2) using malonic acid instead of oxalic acid. When three elutes (≈300 cm³, ≈250 cm³, and ≈300 cm³) were concentrated to dryness, dark-red, pink-red, and red-violet products were obtained respectively. Each product was washed with acetone. The pink-red product was hygroscopic; hence, it was difficult to handle. The yields were 1.0 g for the dark-red, 0.05 g for the pink-red, and 0.1 g for the red-violet isomer. The red-violet isomer can be obtained in a better yield by the reaction at a higher temperature (≈80 °C), but the yield of the pink-red isomer decreases.

Measurements. The visible and ultraviolet absorption spectra were measured with a Hitachi EPS-3T Recording Spectrophotometer or a Shimadzu UV-200 Recording Spectrophotometer. The proton NMR spectra were recorded with a Varian XL-100 spectrometer in deterium oxide, with *t*-butyl alcohol as the internal reference.

Results and Discussion

The analytical data for the complexes prepared are summarized in Table 1.

Electronic Spectra. The electronic spectra are shown in Figs. 2—4, while the numerical values of the absorption maxima are summarized in Table 2. If the configuration of the ligating nitrogen atom of adao is not considered, three geometrical isomers (*α,β-mer(N)*, and *β-fac(N)*) are possible for the complexes of [Co(adao)(AA)] (AA=CO_3, ox, and mal). The *α* and the *β-fac(N)* isomers belong to a *fac* type of $[CoN_3O_3]$, and the *β-mer(N)* to a *mer* one. As regards the complex of $[CoN_3O_3]$ type, it is well known that the first band of the *mer* isomer is broader than that of the *fac* isomer.[5] As may be seen in Fig. 3, which shows the spectra of the oxalato complexes, the first band of the red isomer is broader than those of the other two. From this spectral difference, the red isomer is identified as having the *β-mer(N)* structure. Although the two remaining isomers must belong to the *fac* isomer, it is difficult to determine their structures on the basis of the spectral data alone. However, it is observed that the absorption intensity of the first band of the red-violet isomer is stronger than that of the pink-red one. Similar features are observed among the spectra of the malonato com-

TABLE 2. ABSORPTION DATA OF THE adao-Co(III) COMPLEXES (Wave numbers are in 10^3 cm^{-1})

	Color	I $\bar{\nu}_{max}$ (ε)	II $\bar{\nu}_{max}$ (ε)
α-[Co(adao)(ox)]	Pink-red	19.30(142)	27.10(145)
α-[Co(adao)(mal)]	Pink-red	19.23(125)	27.06(118)
β-mer(N)-[Co(adao)-(CO_3)]	Red	19.00(162)	26.39(177)
β-mer(N)-[Co(adao)-(ox)]	Red	≈19.9 (140)	27.03(204)
β-mer(N)-[Co(adao)-(mal)]	Dark-red	≈19.9 (143)	27.00(160)
β-fac(N)-[Co(adao)-(CO_3)]	Red-violet	19.00(206)	27.10(160)
β-fac(N)-[Co(adao)-(ox)]	Red-violet	19.23(213)	27.17(196)
β-fac(N)-[Co(adao)-(mal)]	Red-violet	19.12(190)	27.17(155)

plexes (Fig. 4), and it is inferred that the dark-red isomer is the *β-mer(N)*, while the pink-red and red-violet ones are the α or the *β-fac(N)*. Among the isomers of the carbonato complex, it is found that the intensity of the first band of the red-violet isomer is stronger and narrower than that of the red one.

Proton NMR Spectra. The proton NMR spectra of the two isomers of the carbonato complex and the red isomer of the oxalato complex are shown in Fig. 5. The PMR spectra of the dark-red and red-violet isomers of the malonato complex are shown in Fig. 6. It was difficult to measure the spectra of the other two isomers of the oxalato complex because of their low solubilities. For the pink-red isomer of the malonato complex, the PMR spectrum was not obtained satisfactorily. As can be inferred from the coordination modes of adao in Fig. 1-a, these isomers may be classified into two groups from the standpoint of the disposition of adao's glycinate ring: one group consists of the isomers with out-of-plane glycinate (α and *β-mer(N)*), and the other, of those with in-plane glycinate (*β-fac(N)* and *trans*). Therefore, the PMR spectra of the former

(b): *β-fac(N)*-[Co(adao)(mal)] (red-violet).

isomers may be expected to be different from those of the latter isomers at the resonances of the glycinate protons. It has been reported that a considerable difference exists between the isomers of [Co(edda)-(AA)]$^{1\pm}$ (AA=$(NH_3)_2$, en, ox, and mal)[6] and

$[Co(adao)(AA)]^{2+}$ ($AA=(NH_3)_2$, en)[1]; that is, a AB quartet appears for the out-of-plane ring (R-ring) protons and an apparent singlet for the in-plane ring (G-ring) protons. It has also been observed in the spectra of the edda and ed3a Co(III) complexes that the value of $\delta_{AB}(=\delta_A-\delta_B)$ for the R-ring protons is in the range of 0.7 to 1.0 ppm, while that for the G-ring protons is in the range of 0.0 to 0.4 ppm.[7] As may be seen in Fig. 5, the red isomer of the oxalato complex, which has been inferred to be the *β-mer(N)* structure on the basis of the electronic spectrum, shows one AB quartet in the range of 1.96 to 3.00 ppm, although the two resonances at the lower field split into doublet. A pair of doublets in the range of 2.74 to 3.00 ppm is considered to be due to the coupling with the amine proton, which is not completely exchanged at the time of the measurement. The value of the δ_{AB} is about 0.76 ppm ($J_{AB}=18$ Hz).

The red isomer of the carbonato complex shows one clear AB quartet in the range of 1.94 to 3.00 ppm. The δ_{AB} is calculated to be 0.86 ppm. On the other hand, the red-violet isomer of the carbonato complex exhibits two resonances at 2.37 and 2.41 ppm. If it is assumed that the J_{AB} is 16 Hz,[8] the δ_{AB} is 0.12 ppm. From these spectral patterns, it can be found that the glycinate ring's disposition of the red isomer is out-of-plane, while that of the red-violet one is in-plane. Consequently, it is reasonable to assign the red isomer to the *β-mer(N)*, and the red-violet one, to the *β-fac(N)*.

The malonato isomers show more complicated spectra than those of the oxalato and carbonato isomers because of the existence of the malonate ring protons. For the dark-red isomer, it was found that the four peaks in the range of 2.77 to 3.02 ppm (Fig. 6-a) are reduced to two peaks upon the addition of Na_2CO_3 to the solution. Thus, the resonances of the dark-red malonato isomer consist of two AB quartets: one is the resonances centered at about 2.45 ppm and the other is those centered at 2.145 ppm. The δ_{AB} and J_{AB} of the quartet with the center at 2.45 ppm are 0.80 ppm and 18 Hz respectively. From the similarity of these values (δ_{AB} and J_{AB}) between the dark-red isomer and the *β-mer(N)*-ox isomer, this AB quartet is attributed to the glycinate protons of adao. The other quartet may be considered to be due to the methylene protons of the malonate ring. Therefore, the dark-red isomer is assigned to the *β-mer(N)*. The PMR spectrum of the red-violet isomer consists, in the lower field, of a doublet with the center at 2.32 ppm and a quartet with the center at 2.18 ppm. The δ_{AB} of the former is about 0.16 ppm and that of the latter, 0.48 ppm. The chemical shift and the δ_{AB} of the doublet of this isomer are similar to those of the *β-fac(N)* isomer of the carbonato complex. The quartet is obviously due to the malonate ring protons. From these facts, the red-violet isomer is assigned to the *β-fac(N)* structure.

The cobalt-malonate ring is six-membered and is necessarily conformationally bent: three conformations, chair, boat, and skew-boat, are possible. Buckingham *et al.*[9] proposed that the boat and skew-boat conformations are more stable than the chair one, on the basis of the theory in which the dipole interaction between electron pairs on the ligating oxygen and on the adjacent carbonyl oxygen is more important in the chair form. Moreover, they suggested that the skew-boat conformation is more stable than the boat one, when there is interaction between the malonate hydrogen atom and another ligating group. The theory and the results of the PMR spectra indicated that the malonate rings in the complex ions such as $[Co(mal)(en)_2]^+$ and $[Co(mal)_2(en)]^-$ take the skew-boat conformation. On the other hand, when the absolute configuration of $(-)_{589}$-Na$[Co(mal)_2(en)]$ was studied by Butler and Snow by the X-ray method, they showed that the malonate rings in the complex ion adopt the boat conformation.[10] Furthermore, Matsumoto and Kuroya, in investigating the crystal structure of $(-)_{589}$-$[Co(NO_2)_2(en)_2]\cdot(+)_{589}$-$[Co(mal)_2(en)]$ by the X-ray method, showed that the two malonate rings are nearly planar.[11] From these facts and the theory proposed by Buckingham *et al.*, the existence of the chair conformers seems to be impossible for the Co(III)-complex with the malonate ring. When the molecular models of the *β-mer(N)*-[Co(adao)(mal)] isomer are examined, it seems to be impossible that the malonate ring takes the boat conformation because of the interactions between the malonate hydrogen atoms and the adao's NH and NH_2 hydrogen atoms.

Three conformations, boat, skew-boat, and planar, are possible for the *β-fac(N)*-[Co(adao)(mal)]. When the symmetry of only the malonate ring is considered, the chemical environments of two malonate hydrogen atoms are equivalent in the skew-boat and the planar conformation, but not in the boat one. Therefore, it may be expected that the δ_{AB}'s of the malonate protons for the formers are smaller than that for the latter. As may be seen in Fig. 6, the δ_{AB} of the malonate protons of the *β-fac(N)* isomer is larger than that of the *β-mer(N)* isomer. Consequently, it may be inferred that the malonate chelate ring in the *β-mer(N)* isomer adopts the skew-boat or the planar conformation and that in the *β-fac(N)* isomer the boat one.

The possible existence of the two *β-mer(N)* isomers arising from the configuration of *s*-N atom of adao is shown in Fig. 1-b. From the examination of molecular models, it may be expected that the PMR spectrum of *β-mer(N)*-(*SR,RS*) isomer is different from that of the *β-mer(N)*-(*SS,RR*) at the resonances of the glycinate ring protons. Thus, if the *β-mer(N)* complex isolated is a mixture, a pair of doublet at the high field portion of the AB quartet pattern may be observed in the PMR spectrum. However, the PMR spectrum with a pair of doublet at the region mentioned above, is not obtained. Thus, the PMR evidences indicate that the respective *β-mer(N)* complexes isolated consist of one configuration for *s*-N atom of adao. However, it is difficult to assign the configuration of the *s*-N on the basis of the PMR spectra. On the other hand, the examination of molecular models for the two possible *β-fac(N)* isomers shows that the *β-fac(N)*-(*RS,SR*) configuration is more favoured than the *β-fac(N)*-(*RR,SS*), because the latter configuration exhibits the interaction between the hydrogen atom of the glycinate ring and the terminal amino hydrogen atom of adao. Furthermore, the PMR

spectrum shows only one clear doublet pattern. Thus, it may be inferred that the *β-fac(N)* isomers prefer the (*RS,SR*) configuration.

Besides the well-known *β-mer(N)* coordination mode, the α and the *β-fac(N)* modes are established for the oxalato and malonato complexes. Although the configuration (whether (*SR,RS*) or (*SS,RR*)) of the *s*-N in the *β-mer(N)* isomers can not be decided, it is found that the *β-mer(N)* complex isolated in this work adopts only one of the two configurations. For the malonate complexes, it is difficult to decide the ring conformation exactly. It has been inferred, however, that the conformation is the skew-boat in the *β-mer(N)* isomer and the chair in the *β-fac(N)* one. From Table 2, it may be seen that the apparent maximum of the first absorption band in the *β-mer(N)* isomer is at the same or a higher wave number than those in the corresponding α and *β-fac(N)* isomers. It was found that there are some differences in the absorption and PMR spectra between the author's *β-mer(N)*-carbonato complex and Collman's. Also, the carbonato complex isolated by Collman's method was separated cleanly into two bands by the chromatography. These facts suggest that Collman's *β-mer(N)*-carbonato complex contained another species. It is noticeable that the second band maximum of the author's *β-mer(N)* carbonato isomer is at considerably the lower wave number than that of the *β-fac(N)* one. Such difference in the second band maxima between isomers of $[CoN_3O_3]$ type have not been recognized previously,[5,12] although it has been reported that the second band of the *mer(trans)*-$[Co(CO_3)(gly)(NH_3)_2]$[13] or *mer(N)*-[Co(*i*-dtma)(CO_3)][14] exhibits a splitting.

The author expresses sincere thanks to Professor Yoichi Shimura of Osaka University for his kind guidance and to Professor Kashiro Kuroda of Ehime University for his encouragement during the course of this work.

Effects of the Anion on the Extraction of Cobalt with 8-Quinolinol into Chloroform

Eiichi SEKIDO and Kazuhiko FUJITA

Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657

(Received June 14, 1976)

The effects of the anions, especially the perchlorate ion, on the extraction of cobalt into chloroform with 8-quinolinol (Hql) were examined. Two kinds of cobalt(II) 8-quinolinol complexes, species A and B, are extracted into the chloroform phase from the aqueous cobalt(II) solution containing perchlorate ions. Species A contains no perchlorate ion and is extracted above pH 7.7; species B is an ion-pair complex containing a perchlorate ion and is predominantly extracted below pH 5.1. The compositions of species A and B were estimated to be $Co_2ql_4(Hql)_2$ and $Co_2ql_3(Hql)_3ClO_4$, respectively. These dimer complexes are related by the following equilibrium, with $\log K_{AB} = -7.2$:

$$[Co_2ql_3(Hql)_3]^+ClO_{4(o)}^- \rightleftharpoons Co_2ql_4(Hql)_{2(o)} + ClO_4^- + H^+$$

The species extracted into the chloroform phase from the aqueous cobalt(II) solution containing sulfate ions does not contain any sulfate ions. The formation of the species containing anions increases in the order: $ClO_4^- > NO_3^- > Cl^- > SO_4^{2-}$, which is also the general order of the extent of forming the ion-pair compounds. The ion-pair complex tends to prevent the oxidation from cobalt(II) 8-quinolinol complex to cobalt(III) 8-quinolinol complex.

The stoichiometric behavior of the extraction of cobalt into chloroform containing 8-quinolinol (Hql) has been studied by several investigators.[1-4] In these studies it was reported that the species extracted into chloroform is not the simple cobalt 8-quinolinol chelate, $Coql_2$, but the self-adduct, such as $Coql_2(Hql)_2$,[1,2] or $Coql_2Hql$.[3,4] These stoichiometric studies, of course, were carried out under the condition of a constant ionic strength, which was adjusted by the addition of a salt such as sodium perchlorate or potassium chloride. On the other hand, Ōki *et al.* recently reported that an ion-pair complex is extracted into chloroform when a zinc solution containing perchlorate ions is shaken with a chloroform solution containing 8-quinolinol.[5] They suggested the formation of an ion-pair complex for nickel as well as for zinc.[6] Moreover, Sekido *et al.* studied the effects of various kinds of anions on the extraction of zinc with the chloroform solution of 8-quinolinol;[7] the compositions of the zinc 8-quinolinol complexes extracted were also determined.[8] Consequently, it will be assumed that the extraction of cobalt with chloroform containing 8-quinolinol may also be affected by the kind of anion contained in the aqueous solution. Thus, in this study, the extraction behavior of the cobalt with the chloroform solution of 8-quinolinol from an aqueous solution containing one of such anions as the perchlorate, nitrate, sulfate, or chloride ion have been reexamined.

Experimental

Reagents. 8-Quinolinol was recrystallized twice from ethanol (mp 73—73.5 °C). The chloroform was shaken with dilute hydrochloric acid solution, sodium hydroxide solution, and demineralized water, dried with anhydrous sodium sulfate, and then distilled twice. Cobalt perchlorate and nitrate in analytical-reagent grade were used to prepare stock solutions of cobalt; their concentrations were determined by chelatometric titrations. Carrier-free ^{60}Co radiotracer was added to the stock solutions when the distribution ratio of cobalt was determined. The sodium salts of perchlorate, nitrate, sulfate, and chloride and the buffer components were all of analytical-reagent grade.

Apparatus. Extraction was carried out in a Taiyo M incubator at 25±0.1 °C. A Japan Radio well-type NaI(Tl) scintillation detector connected with a Toshiba UDS-24202 B universal scalar was used for the radioactivity counting. Ultraviolet and visible absorption spectra of the chloroform phase were taken with a Hitachi 124 double beam spectrophotometer and the pH of the aqueous phase was measured with a Hitachi-Horiba M-5 pH meter.

Extraction of Cobalt. Into a 50 ml glass cylindrical tube with a glass stopper was introduced 1.00 ml of 1×10^{-3} M cobalt(II) perchlorate or nitrate solution, adjusted to the desired pH with a small amount of a buffer solution. Then the sodium salt solution of the appropriate anion, whose effect was to be examined, was added, so that 10.00 ml of the final cobalt solution could be kept at the ionic strength of 0.1 or 1.0. The buffer solution was made with the mineral acid having the appropriate anion, sodium hydroxide, or such a small amount of acetic acid or boric acid that we could ignore the effect of the acetate or borate anion. After the addition of 10 ml of 0.1 M chloroform solution of 8-quinolinol, the mixture was completely equilibrated by shaking for 10 min at 200 strokes/min at 25±0.1 °C. After the mixture was centrifuged for 2 min, 5 ml of the aqueous and of the chloroform phases were taken in order to measure the radioactivity. The residual aqueous phase was used for the measurement of pH. The absorption spectra of the chloroform phase, which was extracted by the procedure described above using the cobalt solution which does not contain ^{60}Co, were measured in the range of 300 to 500 nm.

Determination of the Perchlorate Ion in the Chloroform Extract. The extracted chloroform phase was shaken for 2 min with 8 ml of 0.01 M EDTA solution adjusted to pH 5.8 and then the amount of perchlorate ion back-extracted in the aqueous solution was absorptiometrically determined by Uchikawa's method.[9]

Estimation of Cobalt(II) and (III) 8-Quinolinol Complexes in the Chloroform Phase. It is important to determine the oxidation state of cobalt in the cobalt 8-quinolinol complexes extracted into the chloroform phase. The oxidation state of cobalt was judged by the following manner as proposed by Ōki.[3] 1) Cobalt(II) 8-quinolinol complexes in the chloroform solution are readily back-extracted into aqueous EDTA solution, while cobalt(III) complexes are not. 2) The absorption spectrum of cobalt(III) 8-quinolinol complex in the

chloroform solution has an absorption maximum at 420 nm. The practical procedure is as follows: Cobalt(II) and (III) 8-quinolinol complexes which might be contained in a chloroform phase are shaken for one min with 0.001 M EDTA solution at a pH in the range of 4.0 to 5.0. The cobalt(II) 8-quinolinol complexes are completely back-extracted into the aqueous solution, whereas cobalt(III) 8-quinolinol complex remains in the chloroform phase. The absorbance of the chloroform phase back-extracted at 420 nm is measured by using the calibration curve made from the chloroform solutions of known amounts of cobalt(III) 8-quinolinol complex.

Results and Discussion

Extraction of Cobalt into Chloroform with 8-Quinolinol from an Aqueous Solution Containing Perchlorate, Nitrate, or Sulfate Ions. The relationship between the logarithm of the distribution ratio, log D, and the pH of the aqueous phase containing 0.1 M perchlorate, nitrate, or sulfate ion is shown in Fig. 1. In the part where $D<K_{Dc}$ in the acidic region (K_{Dc}: distribution coefficient of cobalt 8-quinolinol complexes), the distribution curve for sulfate ion gives a straight line with the slope +2, but for perchlorate or nitrate ions, especially for perchlorate ions, the data do not give a linear relationship. Furthermore, it is observed that their distribution ratios decrease in the order of $ClO_4^->NO_3^->SO_4^{2-}$ at an arbitrary pH below 5. On the other hand, the distribution curves for the three anions start to overlap in the region above pH 8.

Values of the absorbance at 410 nm of the extracted chloroform phase as a function of pH of the aqueous phase containing 0.1 M perchlorate, nitrate, or sulfate ion are shown in Fig. 2. The absorbance change in the range of pH 4 to 7 for perchlorate ion shows significant differences from those for sulfate and nitrate ions, although the total concentrations of cobalt in the chloroform phase for three anions are not so appreciably different in this pH range, as seen in Fig. 1. Actually, the apparent molar absorptivity at 410 nm of the species extracted at various pH values can be calculated from the values of the distribution ratio and the absorbance. The results are shown in Table 1. The values of the

c) Absorbance at 410 nm. d) Apparent molar absorptivity at 410 nm $\left(=\frac{Abs}{[Co]_0}\right)$.

apparent molar absorptivity for perchlorate ion seem to vary in two steps with pH. These facts suggest that two species of cobalt 8-quinolinol complexes exist in the chloroform phase: one is species A with $\varepsilon=4.1—4.2\times10^3$ extracted in the range of pH 7.0 to 9.0, and the other is species B with $\varepsilon=\approx2.4\times10^3$, extracted in the range of pH 4.0 to 9.0 for sulfate ions and in the range of pH 5.0 to 9.0 for nitrate ions, this species may be identical to species A extracted into the chloroform in the range of pH 7.0 to 9.0 for perchlorate ions. It was confirmed that no cobalt(III) 8-quinolinol complex, $Coql_3$, exists in the chloroform phase immediately after the extraction from an aqueous cobalt(II) solution below pH 7.0 containing 0.1 M perchlorate, nitrate, or sulfate ion, although several percents of cobalt are also extracted as a cobalt(III) 8-quinolinol complex at a pH above 7.0.

Absorption Spectra of Cobalt 8-Quinolinol Complexes Extracted into Chloroform. When the chloroform phase, which has been separated with a centrifuge from the aqueous phase, is allowed to stand in the dark at room temperature, its absorption maximum around 380 nm shifts to longer wavelengths and finally reaches 420 nm. The changes of the absorption spectra with time at pH 5.5 and 8.1 are shown Figs. 3a and 3b respectively. It is considered that the shift to the longer wavelength is due to the oxidation of the cobalt(II) 8-quinolinol complex to the cobalt(III) 8-quinolinol complex for the following reasons: 1) the wavelength of the finally reached absorption maximum, 420 nm is in accord with that for the cobalt(III) 8-quinolinol complex oxidized by hydrogen peroxide; 2) when the chloroform extracts were allowed to stand for an appropriate time, followed by back-extraction with the EDTA solution, the absorption maximum of the back-extracted chloroform phase was located at 420 nm; and 3) when nitrogen gas is passed through the chloroform phase, the shift to longer wavelengths is prolonged with time. The solid lines in Figs. 3a and 3b show absorption spectra of the chloroform phase immediately after the extraction at pH 5.5 and 8.1 from the cobalt(II) solution containing 0.1 M perchlorate or nitrate ion. These absorption spectra have their absorption maxima at 380 nm or below. This fact indicates that species A and species B extracted into the chloroform phase are not the normal 1:2 cobalt(II) 8-quinolinol complex, $Coql_2$, because its absorption maximum is located at 400 nm in chloroform.[10,11] The broken lines in Figs, 3a and 3b indicate the absorption spectra after the chloroform extracts were allowed to stand for a fixed time. When the chloroform phase extracted at pH 5.5 for perchlorate ions is allowed to stand for 20 h, no appreciable shift to longer wavelengths is observed. On the other hand, an appreciable shift to longer wavelengths is observed for nitrate ions at pH 5.5 as well as for perchlorate and nitrate ions at pH 8.1. These results lead to the conclusion that species A is apt to be oxidized in air, while species B is difficult to oxidize.

Tendency of the Formation of Species A or Species B with the Kind of Anions. The effect of the anion on the formation of species A and species B in the chloroform phase was examined by using various kinds of anions, such as perchlorate, nitrate, chloride, and sulfate ions, in 1.0 M solutions. The relationships of the standing time and the change of the absorption spectra of the chloroform phases extracted at pH 6.5 and 8.1 from the cobalt solution containing an anion in 1.0 M concentration are shown in Figs. 4 and 5 respectively. The

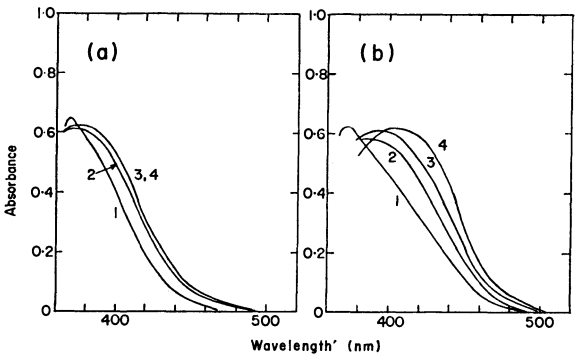

Fig. 4. Absorption spectra of the chloroform extracts from the aqueous solutions containing 1 M anion at pH 6.5.

(*a*); Immediately after extraction. (*b*); After standing for 20 h. 1; ClO_4^-, 2; NO_3^-, 3; Cl^-, 4; SO_4^{2-}.

absorption spectra after standing for 20 h for the extracts at pH 6.5 are located at longer wavelengths, in the order of $ClO_4^- < NO_3^- < Cl^- < SO_4^{2-}$ (Figs. 4a and 4b). This is the order for the rate of the oxidation to cobalt(III) 8-quinolinol complex, in other words, the order of the increase of species A, and the decrease of species B in the chloroform phase. On the other hand, for the extraction at pH 8.1, the absorption curves immediately after extraction are similar to those obtained 20 h after extraction, regardless of the kind of anion, and the oxidation seems to occur rapidly in all cases (Figs. 5a and 5b). These results indicate that species A is probably formed in the chloroform phase.

a) pH of the aqueous phase after extraction. b) Concentration of cobalt in the chloroform extracts. c) Concentration of perchlorate ion in the chloroform extracts.

Compositions of Species A and Species B. The perchlorate ion in species A and species B extracted into chloroform from the aqueous cobalt solution containing perchlorate ions was determined. The results are shown in Table 2. The chloroform phases extracted below pH 5.1 contain cobalt and perchlorate ions in the ratio of 2 to 1, but the concentration of perchlorate ions decreases gradually with increasing pH and becomes very low above pH 7.7, although the concentration of cobalt remains constant above pH 5.1. Therefore, the species extracted below pH 5.1, species B, might be an ion-pair complex, similar to that for zinc described in a previous report.[8] On the other hand, the species extracted above pH 7.7, species A, may be a complex containing no perchlorate ions. The prediction that the species extracted into chloroform to form the cobalt solution containing 1.0 M sulfate ion may be not species B but species A was confirmed by the follow. The aqueous solution containing 3.05×10^{-4} M cobalt and 1.0 M sulfate ions is extracted with 0.1 M 8-quinolinol chloroform solution at pH 3.7. The extracts in the chloroform phase can be back-extracted with 1.0 M hydrochloric acid, and then 0.1 M barium sulfate solution is added into the aqueous phase. No turbid material and no precipitate forms, so the extracts contain no sulfate ions.

On the basis of the above mentioned results, the compositions of species A and species B extracted from the cobalt solution containing perchlorate ions are represented by the formulae, $Co_nql_m(Hql)_l$ and $Co_{2s}ql_t(Hql)_u(ClO_4)_s$ respectively; then the reactions of extraction for species A and species B will be represented by the following equations:

$$nCo^{2+} + (m+l)Hql_{(o)} \rightleftarrows Co_nql_m(Hql)_{l(o)} + mH^+ \quad (1)$$

$$2sCo^{2+} + (t+u)Hql_{(o)} + sClO_4^- \rightleftarrows Co_{2s}ql_t(Hql)_u(ClO_4^-)_{s(o)} + tH^+ \quad (2)$$

where l, m, n, s, t, and u are integers. The equilibrium constants of Eqs. 1 and 2, that is, the exraction constants, K_{ex}^A and K_{ex}^B are represented as follows:

$$K_{ex}^A = \frac{[Co_nql_m(Hql)_l]_o[H]^m}{[Co]^n[Hql]_o^{m+l}} \quad (3)$$

$$K_{ex}^B = \frac{[Co_{2s}ql_t(Hql)_u(ClO_4^-)_s]_o[H]^t}{[Co]^{2s}[Hql]^{t+u}[ClO_4^-]^s} \quad (4)$$

where the charge of the chemical species was abbreviated. The distribution ratios of species A and species B, D_A and D_B, are represented by Eqs. 5 and 6 respectively:

$$D_A = \frac{n[Co_nql_m(Hql)_l]_o}{[Co]_T} \quad (5)$$

$$D_B = \frac{2s[Co_{2s}ql_t(Hql)_u(ClO_4^-)_s]_o}{[Co]_T} \quad (6)$$

Here $[Co]_T$ represents the analytical concentration of cobalt(II) in the aqueous phase. If the hydrolysis of cobalt ions and the complex formation of cobalt ions with other anions can be neglected in the aqueous phase, Eq. 7 is obtained:

$$[Co]_T = [Co](1+\sum_{i,j}\beta_{i,j}[ql]^i[Hql]^j) + [Co]\sum_{p,q}\beta_{p,q}[ql]^p[Hql]^q = [Co](1+N) \quad (7)$$

Here, $\beta_{i,j}$ and $\beta_{p,q}$ represent the formation constants of the mononuclear cobalt 8-quinolinol complex and the binuclear complex respectively, and N represents the sum of the second and third terms in the parentheses on the right-hand side of Eq. 7. When Eqs. 3 and 4 are replaced by Eqs. 5, 6, and 7 and both sides of the equations are made logarithmic, Eqs. 8 and 9 can be deduced.

$$\log D_A = (n-1)\log[Co]_T + m\mathrm{pH} + (m+l)\log[Hql]_o - n\log(1+N) + \log n + \log K_{ex}^A \quad (8)$$

$$\log D_B = (2s-1)\log[Co]_T + t\mathrm{pH} + (t+u)\log[Hql]_o - 2s\log(1+N) + s\log[ClO_4^-] + \log 2s + \log K_{ex}^B \quad (9)$$

Under the conditions that the terms except for $\log[Co]_T$ on the right-hand side of Eqs. 8 and 9 are constant, the plots of $\log D$ *vs.* $\log[Co]_T$ should give a straight line having the slope $n-1$ or $2s-1$. When $[Co]_T=[Co]_{int.}/(1+D)$, where $[Co]_{int.}$ is the initial concentration of cobalt, is placed Eqs. 8 and 9, the following Eqs. 10 and 11, which are into convenient for obtaining the values of m, l and t, u, can be deduced.

$$\log D_A + (n-1)\log(1+D_A) = m\mathrm{pH} + (m+l)\log[Hql]_o + (n-1)\log[Co]_{int.} - n\log(1+N) + \log n + \log K_{ex}^A \quad (10)$$

$$\log D_B + (2s-1)\log(1+D_B) = t\,\mathrm{pH} + (t+u)\log[\mathrm{Hql}]_o + s\log[ClO_4^-] + (2s-1)\log[\mathrm{Co}]_{int.} - 2s\log(1+N) + \log 2s + \log K_{ex}^B \quad (11)$$

The following three conditions are selected in order to determine the compositions of the extracted species A and species B: 1) the condition under which only one of species A and species B is extracted 2) the hydrolysis and the complex formation with the other anions for the cobalt ion can be neglected; 3) N can be neglected in comparison with 1 in Eq. 7. For condition 1), the extraction in the presence of sulfate ions was selected as a condition in which only species A is extracted, and the extraction in the presence of perchlorate ions at a low pH was selected as a condition in which only species B is extracted. For condition 2), the hydrolysis of cobalt ions can be neglected at low pH and the use of a low concentration of the buffer($<1\times10^{-3}$ M acetate) allows us to neglect the effect of the complex formation. For condition 3), the extraction at a pH below 3.6 satisfies the the condition of 3), according to the calculation of the concentrations of cobalt 8-quinolinol complexes.

The plots of log D *vs.* log[Co]$_T$ from Eqs. 8 and 9 are shown in Figs. 6a and 6b respectively. Both curves give straight lines with the slope of +1 in the vicinity of $[\mathrm{Co}]_{int.}=10^{-4}-10^{-5}$ M. The plots in Fig. 6a, however, seem to deviate from a straight line. Perhaps the condition of 3) is less satisfied at the higher pH in the extraction, 3.8, than at 3.6. It is suggested that both species A and species B may be dimer complexes, because $n=2$ for species A and $s=1$ for species B. In the regions of high and low concentrations of cobalt, the slopes are close to zero, which suggests that a mononuclear complex is extracted. This suggestion was supported by Table 3, which gives the data for the absorption spectra of the chloroform extracts from the cobalt solutions of various concentrations corresponding to Fig. 6a. As the concentration of cobalt becomes higher, the absorption maximum shifts to longer wavelengths. For the concentration of $[\mathrm{Co}]_{int.}=1.15\times10^{-3}$ M, the absorption maximum is located at 400 nm and the apparent molar absorptivity at 410 nm is 2000. It was confirmed that the shift to longer wavelengths can not be attributed to the oxidation to a cobalt(III) 8-quinolinol complex, because of the fact that the chloroform phase back-extracted with 1.0 M hydrochloric acid is clolorless. It is well-known that the absorption maximum of the chloroform solution of 1:2 cobalt 8-quinolinol complex is located at 395 nm and its molar absorptivity is 2200 at 410 nm, which agrees with the above results, so that the species extracted at 1×10^{-3} M of $[\mathrm{Co}]_{int.}$ may be the normal 1:2 cobalt 8-quinolinol complex.

The relationships of log $D(1+D)$ and log$[\mathrm{Hql}]_o$, according to Eqs. 10 and 11, are plotted in Figs. 7a and 7b. Straight lines with the slope +6 are obtained for both species A and B, so that $m+l=6$ for species A, and $t+u=6$ for species B. The plot of log D *vs.* pH for species A, and the plot of log $D(1+D)$ *vs.* log[ClO$_4$] for

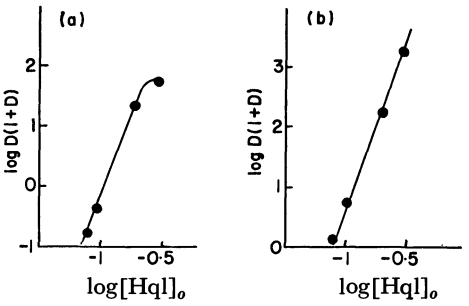

Fig. 7. Plot of log $D(1+D)$ *vs.* log[Hql].
(a); For species A, pH 3.50, Initial concentration; cobalt 1.02×10^{-4} M, SO_4^{2-} 0.1 M.
(b); For species B, pH 2.90, Initial concentration; cobalt 1.15×10^{-4} M, ClO_4^- 0.1 M.

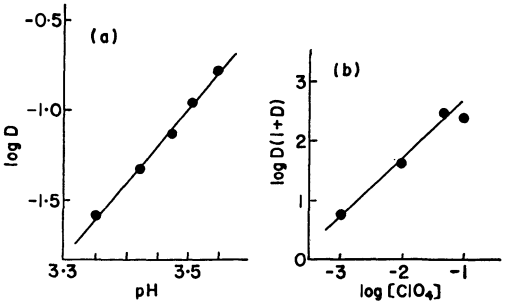

Fig. 8(a). Plot of log D *vs.* pH for species A. Initial concentration; cobalt 1.02×10^{-4} M, 8-quinolinol 0.1 M and SO_4^{2-} 0.1 M.
Fig. 8(b). Plot of log D *vs.* log $[ClO_4^-]$ for the species B. Initial concentration; cobalt 1.15×10^{-4} M, 8-quinolinol 0.1 M. Ionic strength; 0.1(ClO_4^- and SO_4^{2-}).

species B are also shown in Figs. 8a and 8b, respectively. Straight lines were obtained with the slope +2 for the former and +1 for the latter. From these results it is concluded that $n=2$, $m=4$, and $l=2$ for species A and $s=1$, $t=3$, and $u=3$ for species B, so that the composition of species A and species B can be represented by $Co_2ql_4(Hql)_2$ and $Co_2ql_3(Hql)_3ClO_4$, respectively.

Equilibrium between Species A and Species B. The following equilibrium can be considered between species A, $Co_2ql_4(Hql)_2$, and species B, $Co_2ql_3(Hql)_3ClO_4$, in the chloroform phase.

$$B_{(o)} \rightleftarrows A_{(o)} + H^+ + ClO_4^- \qquad (12)$$

$A_{(o)}$ and $B_{(o)}$ represent species A and species B in the chloroform phase. The equilibrium constant, K_{AB}, for Eq. 12 is shown in Eq. 13.

$$K_{AB} = \frac{[A]_o[H^+][ClO_4^-]}{[B]_o} \qquad (13)$$

$[A]_o$ and $[B]_o$ represent the concentrations of species A and species B in the chloroform phase. As species A and species B are both assumed to be dimer complexes, their molar absorptivities at 410 nm, ε^A_{410}, and ε^B_{410}, can be estimated to be double the values of the apparent molar absorptivities of the species which are extracted at pH 4.0 and 7.0, respectively, in the presence of of 0.1 M perchlorate ions, that is, $\varepsilon^A_{410}=8140$ and $\varepsilon^B_{410}=4620$.

The analytical concentration of cobalt in the chloroform phase, $[Co]_o$, is represented by Eq. 14 and the apparent molar absorptivity at a particular pH, ε_{410}, is represented by Eq. 15.

$$[A]_o + [B]_o = \frac{1}{2}[Co]_o \qquad (14)$$

$$[A]_o\varepsilon^A_{410} + [B]_o\varepsilon^B_{410} = \varepsilon_{410}[Co]_o \qquad (15)$$

When the values of $[A]_o$ and $[B]_o$ obtained from Eqs. 14 and 15 are placed in Eq. 13 and both sides of the equation are made logarithmic, Eq. 16 is obtained.

$$\log\frac{2\varepsilon_{410}-\varepsilon^B_{410}}{\varepsilon^A_{410}-2\varepsilon_{410}} = pH + p[ClO_4^-] + \log K_{AB} \qquad (16)$$

The plots of $\log\{(2\varepsilon_{410}-\varepsilon^B_{410})/(\varepsilon^A_{410}-2\varepsilon_{410})\}$ against $p[ClO_4^-]$ at pH=5.50 and against pH at $p[ClO_4^-]=1$ are shown in Figs. 9a and 9b, respectively. A straight line with the slope +1 was obtained in each figure, which indicates that the equilibrium represented by Eq. 12 is valid. $\log K_{AB}=-7.2$ was obtained as the average of −7.1 and −7.3, which were derived from the intercepts in Figs. 9a and 9b.

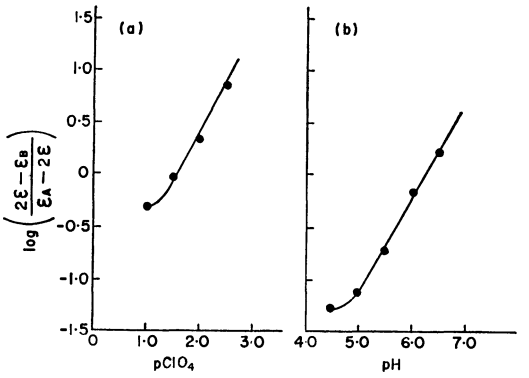

Fig. 9(a). Plot of $\log\{(2\varepsilon-\varepsilon_B)/(\varepsilon_A-2\varepsilon)\}$ *vs.* pH. Initial concentration; cobalt 1.02×10^{-4} M, 8-quinolinol 0.1 M, and ClO_4^- 0.1 M.

Fig. 9(b). Plot of $\log\{(2\varepsilon-\varepsilon_B)/(\varepsilon_A-2\varepsilon)\}$ *vs.* $p[ClO_4^-]$ a pH 5.50. Initial concentration; cobalt 1.15×10^{-4} M, 8-quinolinol 0.1 M. Ionic strength; 0.1 (ClO_4^- and NO_3^-).

The equilibrium constant, K_{AB} was also derived from the ratio of the extraction constants K^A_{ex} to K^B_{ex}. The extraction constant of species A, $K^A_{ex}=10^{-4.61}$ was obtained by using the intercept of Fig. 7a and Eq. 10, and that of species B, $K^B_{ex}=10^{2.60}$ by Fig. 7b and Eq. 11. Therefore, $\log K_{AB}=\log K^A_{ex}-\log K^B_{ex}=-4.61-2.60=-7.21$. This value is in good accord with the value obtained absorptiometrically, −7.2.

Preparation and Ligand Isotopic Exchange of Tris(acetylacetonato)-tin(IV) Perchlorate in Acetonitrile

Akira NAGASAWA and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received June 19, 1976)

Tris(acetylacetonato)tin(IV) perchlorate $[Sn(acac)_3]ClO_4$ was prepared in crystalline state in acetylacetone (Hacac) and its structure was verified. It is stable in dehydrated acetonitrile (AN) at room temperature. It undergoes hydrolysis in the presence of a large amount of water (*e.g.*, 10^{-4} mol dm^{-3} complex against 10^{-1} mol dm^{-3} water) in two steps: The first, fast step gives a product $[Sn(acac)_2(OH)(H_2O)]ClO_4$, which slowly undergoes further hydrolysis or polymerization to give eventually a gelatinous precipitate. The ligand isotopic exchange with Hacac[^{14}C] can be measured in $\simeq 10^{-2}$ mol dm^{-3} complex solution in AN containing 0.03—0.12 mol dm^{-3} water below −20 °C. The rate is independent of free Hacac concentration. The dependence of the rates of the hydrolysis and the ligand isotopic exchange on water concentration is expressed by: rate$=A$[complex][H_2O]^2/(1+B[H_2O]), where the A values are 0.15 and 0.30 dm^6 mol^{-2} s^{-1} at −20 °C, ΔH^* and ΔS^* being (50±8) and (36±20) kJ mol^{-1}, and (−60±20) and (111±40) J mol^{-1}K^{-1}, respectively. There seems to be a common rate-determining step in which one acac$^-$ ligand dissociates with the action of water. The intermediate gives rapidly the original complex in the presence of excess Hacac. Otherwise it undergoes further hydrolysis in the presence of an overwhelming amount of water. The large ionic radius of tin(IV) should be responsible for the rapid water substitution as compared with the corresponding octahedral silicon(IV) and germanium(IV).

Tris(β-diketonato) complexes are common for a wide variety of transition and non-transition metal ions, and their structures and properties have been studied intensively.[1] Several workers[2] including ourselves[3,4] have investigated the kinetics of ligand substitution (including racemization and isomerization) of tris(β-diketonato) complex cations of Group 4 elements, *i.e.* silicon(IV), germanium(IV) and titanium(IV). It seems interesting to compare their properties with those of tin(IV) analogue, for which tris-bidentate octahedral complexes of β-diketonates are left unknown.

The tin(IV) complex containing acetylacetonate (acac$^-$) was first prepared by Dilthey,[5] and it was formulated as a salt of the cation $[Sn(acac)_3]^+$. However, Rosenheim *et al.*[6] gave the formula $[Sn(acac)_2Cl_2]$ to the complex, and this form was confirmed by White.[7] Similar complexes of the type $[Sn(acac)_2X_2]$ (X=halide, methyl, and phenyl) were synthesized and their rapid site-exchange was examined by NMR.[8] Tropolonate (trop$^-$), one of the related diketonates, gave chargeless complexes with coordination numbers 7 and 8, $[Sn(trop)_3X]$ (X=chloride and phenyl) and $[Sn(trop)_4]$.[9]

We have synthesized a new compound tris(acetylacetonato)tin(IV) perchlorate $[Sn(acac)_3]ClO_4$ in crystalline state and studied its hydrolysis and ligand isotopic exchange in acetonitrile.

Experimental

Materials. *Tris(acetylacetonato)tin(IV) Perchlorate*: Dichlorobis(acetylacetonato)tin(IV) (4.1 g, 0.011 mol) prepared by the method of Morgan and Drew[10] was dissolved in Hacac (60 cm^3) and treated with silver perchlorate (4.3 g, 0.021 mol) in Hacac (50 cm^3). The precipitate (silver chloride) was filtered off, and diethyl ether (120 cm^3) was added to the filtrate to give colorless needles. They were filtered off, washed with diethyl ether, dried, and recrystallized from Hacac solution (110 cm^3) by adding diethyl ether (250 cm^3). Yield, 50% on the basis of $[Sn(acac)_2Cl_2]$. The colorless crystals melt at 221—223 °C with decomposition. Found: C, 34.94; H, 4.11; Sn, 23.3%. Calcd for $C_{15}H_{21}O_{10}ClSn$: C, 34.95; H, 4.10; Sn, 23.0%. This compound contained no chloride ions.

The complex is insoluble in diethyl ether, tetrahydrofuran, chlorobenzene, acetic acid, and hexane. It is soluble in Hacac and was recrystallized from it. It is also soluble in the following solvents: easily in acetone, acetonitrile (AN), nitromethane, and dichloromethane; slightly in ethanol, ethyl acetate, and 1,1,2,2-tetrachloroethane. In all the seven solvents the recrystallization was unsuccessful, presumably owing to water contained as an impurity. Water, chloroform, and dimethyl sulfoxide rapidly decomposed the complex to give white precipitate and Hacac.

Hydrolysis Product: An AN solution (20 cm^3, containing *ca.* 0.1 M water; M=mol dm^{-3}) of the complex ($\simeq 10^{-2}$ M) was mixed with diethyl ether (60 cm^3) and set aside for 1 h. Colorless precipitate appeared gradually. They were filtered off, washed with diethyl ether, and dried *in vacuo*. This product (Product A) absorbed the moisture from air and decomposed into Hacac and brownish white solid.

Other Reagents: Acetonitrile was refluxed with diphosphorus pentoxide and distilled. The procedure was repeated until the water content fell to *ca.* 0.005 M. Commercially available pure hexane was used without further purification. The labeled compound Hacac[^{14}C] was prepared as in reference.[11] The specific activity was 0.01 mCi/g.

Kinetic Procedure. *Hydrolysis in Acetonitrile*: Kinetic runs were carried out in a quartz cell in a thermostated jacket, which was placed in a spectrophotometer Hitachi 124. A co-necked glass tube with two branched bottoms containing the complex solution ($\simeq 10^{-4}$ M, 5 cm^3) and AN (containing 0.01 to 0.6 M water, 5 cm^3) was cooled to −25 °C and both liquids were mixed. The solution was pippeted into the quartz cell at given temperatures (−11.8, −13.7, −17.3, and −20.0 °C). Methanol was used as coolant which was circulated through the jacket from HAAKE KT 33 thermostat. Dry nitrogen was blown on the surface of the cell to avoid freezing. The change in absorption was followed at 315 or 250 nm.

Ligand Isotopic Exchange: The complex solution in AN (0.05 to 0.1 M, 5 cm^3) containing 0.05 M Hacac and the radioactive Hacac solution in AN (0.01 to 0.1 M, 5 cm^3) were introduced separately into the two branched bottoms of a co-necked flask with a stopper, and cooled in a thermostat. Both solutions were mixed after *ca.* 30 min to let the exchange reaction start.

At appropriate time intervals, portions (*ca.* 1 cm³ each) were pippeted quickly into chilled hexane (*ca.* 5 cm³) in a thin glass tube at −55 °C. (Only the enol tautomer is partly extracted into the hexane phase.[4]) After 30 to 40 s, the hexane layer (*ca.* 3 cm³) was separated and allowed to stand for 24 h at room temperature until the keto-enol equilibrium was reached. One cm³ portion was diluted 10 folds with hexane and the extinction measured at 273 nm to find the concentration of Hacac. Another 1 cm³ portion was mixed with anisole containing 0.4% *p*-terphenyl and 0.01% *p*-bis(5-phenyl-2-oxazolyl)benzene (POPOP) to be submitted to *β*-activity counting. The specific activity (x) of the extracted Hacac was known from these data.

Calculation of the Exchange Rate. The rate of isotopic exchange was calculated according to McKay's formula (Eq. 1).

$$R = -[3ab/(3a+b)][\ln(1-F)]/t \quad (1)$$

where a and b are the complex and the ligand concentration, respectively, and t and F are the lapse of time and the extent of reaction at time t, respectively. The F values were calculated by $(x_0-x_t)/(x_0-x_\infty)$ where the suffixes denote the time lapse until the quenching of reaction.

Acetylacetone is present in tautomeric enol-keto equilibrium in AN, and the percentages of enol form are 62 and 67 in AN, at room temperature and −10 °C, respectively. The interconversion rate constant between enol and keto is *ca.* 10^{-5} s^{-1} at −10 °C, being much slower than the present isotopic exchange.[12] The experimental x_∞ coincided with the value calculated on the assumption that only the enol form of free Hacac participates in the exchange. All the calculations were therefore made on this assumption, the b values being set to be equal to 0.62 time of the gross free Hacac concentration. This factor is based upon the enol percentage of Hacac in AN at room temperature. (The Hacac solution for kinetic runs were prepared, set aside for more than 24 h at room temperature, and cooled immediately before use.) The log $(1-F)$ *vs.* t diagrams are linear until *ca.* half exchange time, and seems to concave on further progress of the reaction. The R values used in the following discussion are those obtained at the initial linear part of McKay plots.

Apparatuses. Hitachi 124 Spectrophotometer with a low temperature jacket and Hitachi 323 were used for recording the UV absorption spectra at −10 to −20 °C, and at room temperature, respectively. Nuclear Chicago Unilux II-A Liquid Scintillation Counter was employed for recording the *β*-activity of ^{14}C. The water content was measured by Karl Fischer titration. Metrohm E 365 B Konduktoskop with EA 608 bright platinum electrodes was used for conductivity measurements. Hitachi EPI-2G Infrared Spectrophotometer and Varian A-60 Spectrometer were used for recording the IR absorption and NMR spectra, respectively.

Results and Discussion

Structure and Ultraviolet Absorption. The properties of the complex are summarized in Table 1. The relation between molar conductivity and concentration showed that the tin(IV) complex was a 1:1 electrolyte as those of silicon(IV), germanium(IV) and titanium(IV). The IR absorption (KBr disk) was very similar to those of the corresponding silicon(IV) and germanium(IV) complexes, with C=O stretching and ClO_4^- bands in 1500—1570 cm^{-1} region and at 1100 cm^{-1}, respectively. Proton NMR spectrum in acetonitrile[$^2H_3$] (CD_3CN) gave two singlets at 2.32 and 6.18 ppm (*vs.* TMS), corresponding to methyl and methylidyne protons of the coordinated acetylacetonates. These properties suggest

a) Complex concentration: 5×10^{-4} M, at 25 °C. b) In acetonitrile, at 25 °C. c) In KBr disk.
d) Tetramethylsilane: δ=0.0 ppm. e) Ref. 3. f) In benzene. g) Ref. 13.

that the tin(IV) complex has a common octahedral tris-chelate type structure.

The UV absorption spectrum is shown in Fig. 1. The pattern of a freshly prepared AN solution is very similar to those of silicon(IV) and germanium(IV) analogues in the absence of water (<0.01 M). There is an absorption peak at 34700 cm^{-1} (288 nm) with a shoulder at 32500 cm^{-1} (305 nm). In a complex solution ($\simeq 10^{-4}$ M) containing >0.1 M water at room temperature, the extinction coefficient decreased with time in the wavelength range 280—330 nm, and increased at 250—275 nm. Such a change seems to be due to hydrolysis of the complex cation. An isosbestic point at 278 nm was observed only in the initial period.

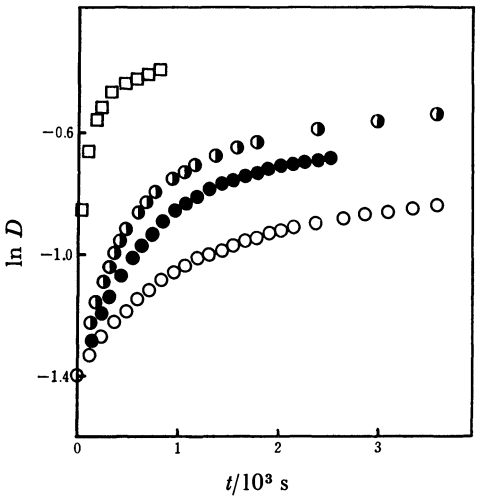

Fig. 2. Increase in extinction at 250 nm in acetonitrile at −17.3 °C. Complex, 7.4×10^{-5} M; water, 0.070 M (○), 0.094 M (●), 0.106 M (◑), 0.267 M (□).

Hydrolysis. The increase in extinction at 250 nm is illustrated in Fig. 2. At least two steps should be involved. The rate of the first fast step, which is apparent up to *ca.* 15 min in the diagram (−17.3 °C), increases with increase in water content, while the second step seems to be rather insensitive to it under the given conditions. Electrolytic conductivity of the solution remained unchanged throughout these periods.

Product of the First Step of Hydrolysis: Product A (see Experimental) seems to be a salt of hydrolysis product in the first step. This colorless solid deteriorated in atmosphere and its properties were not correctly known. The UV absorption spectrum in AN gave a peak at 34100 cm^{-1} (293 nm) with a shoulder around 33000 cm^{-1} (305 nm). The overall pattern is similar to that of the original complex, but the location and the intensity of the peak (ε=*ca.* 15000 M^{-1} cm^{-1} respect to the metal)are obviously different. The IR absorption in Nujol mull and KBr pellet indicated the presence of OH and/or H_2O, coordinated C=O of acetylacetonate, and perchlorate.

The proton NMR spectrum in CD_3CN (*ca.* 0.05 M) gave a group of peaks at *ca.* 2.2, and apparently broad peaks at *ca.* 3.7 and 6.1 ppm *vs.* TMS at room temperature. The signals at *ca.* 2.2 and 6.1 ppm seem to come from methyl and methylidyne of coordinated acac⁻, respectively. These chemical shifts are similar to those of *cis*-$[Sn(acac)_2Cl_2]$.[13]

One sample of Product A gave an analytical result, C, 25.10; H, 3.85; and ash 38.7%. (Calcd for $[Sn(OH)(acac)_2(H_2O)]ClO_4$, $C_{10}H_{17}O_{10}ClSn$: C, 26.6; H, 3.8; ash as SnO_2, 33.4%). There seems to be an overall trend that the carbon content decreases but the hydrogen and the ash percentages increase with increase in time lapse between the initiation of reaction and precipitation of Product A from AN solution. These results and constant electrolytic conductivity seem to indicate that the hydrolysis proceeds as Eq. 2 at the initial stage.

$$[Sn(acac)_3]^+ + 2H_2O \rightleftharpoons [Sn(OH)(acac)_2(H_2O)]^+ + Hacac \quad (2)$$

Product A should consist mainly of the perchlorate salt of this cation or its hydrate and contains small amounts of the products of further hydrolysis.

Reverse Reaction of the First Step: When the solution of Product A in CD_3CN ($\simeq$0.05 M) was treated with Hacac to produce *ca.* 1 M solution at room temperature, six sharp proton peaks appeared immediately in NMR spectrum. Four of them, at 2.05, 2.18, 3.65 and 5.61 ppm, correspond to the signals of free Hacac, and two remaining singlets coincided with the coordinated $acac^-$ in the original complex $[Sn(acac)_3]^+$ (Table 1). When Product A (*ca.* 2 g) was dissolved in Hacac (*ca.* 5 cm^3) at room temperature and immediately treated with diethyl ether (20 cm^3), crystalline $[Sn(acac)_3]ClO_4$ was obtained.

All these facts tell that the reverse reaction of Eq. 2 is very rapid in the presence of a large excess of Hacac. (UV absorption spectroscopy is not useful, because excessive Hacac gives an intense absorption in $\simeq$300 nm region).

Kinetics of the First Step: Apparent rate constants of the first "fast step," k_h, were obtained by the Guggenheim plot of the absorbance at 250 or 315 nm in AN. When the water concentration was less than 0.05 M in the presence of *ca.* 10^{-4} M complex, the hydrolysis was very slow below −10 °C, and the rate was measured

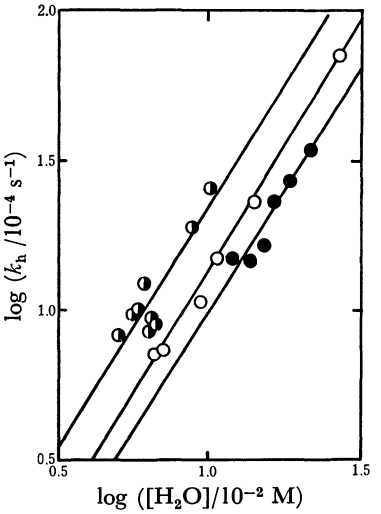

Fig. 3. Apparent hydrolysis rate constant k_h *vs.* water content in acetonitrile in log-log scale.
● −20.0 °C, ○ −17.3 °C, ◑ −11.8 °C.

in AN containing more than 0.05 M water at −10 to −20 °C. First order rate law was obeyed with respect to the complex concentration; rate=k_h[complex].

The observed k_h increases with increase in water content, as illustrated in the log-log plot of Fig. 3. The overall gradient is *ca.* 1.7 in the water concentration range 0.05 to 0.3 M. Various attempts were made to find an appropriate formula which fits the observed data. Linear plot of $[H_2O]/k_h$ *vs.* $1/[H_2O]$ indicated that Eq. 3 is a good approximation for the kinetic data in the given water concentration region.

$$k_h = A[H_2O]^2/(1+B[H_2O]) \quad (3)$$

The A values were calculated to be 0.15, 0.20, 0.27 and 0.34 $M^{-2}\,s^{-1}$ at −20.0, −17.3, −13.7 and −11.8 °C, respectively, and ΔH^* and ΔS^* therefore (50±8) kJ mol^{-1} and (60±20) J $mol^{-1}\,K^{-1}$, respectively. The observed deviation from 2 in the gradient of Fig. 3 seems to be due to the contribution of $B[H_2O]$ term in the denominator, which remains in the vicinity of unity.

The Second Step: The "slow step" of the hydrolysis was not investigated in detail. Since the electrolytic conductivity remained unchanged in this step, either further hydrolysis to give *e. g.* $[Sn(OH)_2(acac)(H_2O)_2]^+$ or polymerization to give *e.g.* $[(acac)_2Sn(\mu\text{-}OH)_2Sn(acac)_2]^{2+}$ may take place. The apparent rate constant which was rather insensitive to the water concentration (Fig. 2) was *ca.* $1\times10^{-5}\,s^{-1}$ at −20 °C. When the complex solution (≃10^{-2} M) was set aside in atmosphere for 24 h or treated with a large amount of water, gelatinous precipitate appeared, which were found to be hydrated tin(IV) hydroxide, *i.e.* olation product of tin(IV). Hence the product of the second step can be a binuclear tin(IV) complex.

Ligand Isotopic Exchange. Figure 4 gives log $(1-F)$ *vs.* t diagrams, in which Hacac in enol form is reckoned to participate in the exchange (see Experimental). These diagrams are linear without intercepts for at least $F<0.7$. The UV absorption of the reaction mixture remained unchanged during these periods. Therefore isotopic exchange must take place exclusively whenever the water concentration is of the same order with the complex concentration (≃10^{-2} M).

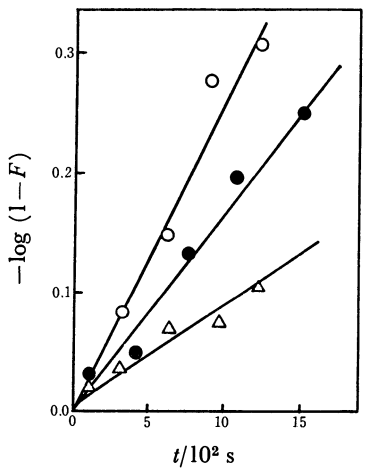

Fig. 4. McKay plots for ligand isotopic exchange of $[Sn(acac)_3]ClO_4$ in acetonitrile at −20.4 °C. Complex, 0.03 M; Hacac (enol), 0.06 M; water, 0.027 M (△), 0.045 M (●), 0.058 M (○).

a) Concentration: complex, [Sn]; enol form of Hacac, [L]; water, [H_2O]; acid, [Acid]. b) Acetic acid. c) Trichloroacetic acid.

Adjustment of water concentration was extremely difficult at a low temperature, and the experimental error is larger than the ordinary kinetic studies. Table 2 gives McKay's R values obtained in the presence of varying concentration of the complex, Hacac and water, at −20.4 °C. They are proportional to the complex concentration, and first order rate constant k_x is expressed by Eq. 4.

$$k_x = R/a \quad (4)$$

The ligand concentration gives only a small influence on the rate constant. On the other hand, the water concentration gives greater effect on k_x than others do; Fig. 5 shows the plot of k_x *vs.* the water concentration on log-log scale. The overall gradient calculated by the method of least squares is *ca.* 1.7 in the range from 0.03 to 0.12 M water. A similar plot at −28.1 °C gave a similar pattern.

There seems to be a remarkable trend, however, that the gradient becomes greater than unity in <0.05 M water. This tendency can be more clearly expressed by the plot of $k_x/[H_2O]$ *vs.* [H_2O] in Fig. 6. The $k_x/[H_2O]$ values increase almost linearly with increase in water concentration in <0.05 M solution, and seem to approach a limiting value in the range >0.05 M. Such an observation leads to two possible interpretations of participation of water as in the following.

If the original complex interacts with one mole of water to give an encounter complex, which undergoes isotopic exchange with the aid of another mole of water, the rate formula can be written as Eq. 5.

$$k_x = A'[H_2O]^2/(1+B'[H_2O]) \quad (5)$$

When the water concentration is small, Eq. 5 is reduced

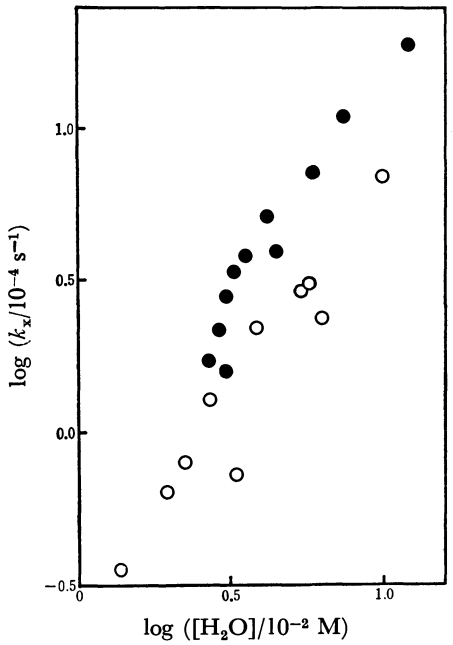

Fig. 5. Influence of water concentration on ligand isotopic exchange rate constant k_x at −28.1 (○) and − 0.4 °C (●). Complex, 0.03 M: Hacac (enol), 0.06 M.

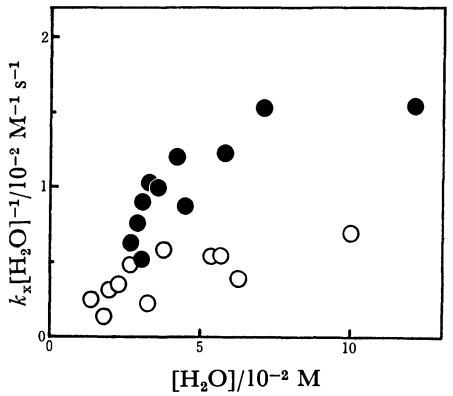

Dig. 6. Plots of $k_x/[H_2O]$ against $[H_2O]$ at −28.1 (○), and −20.4 °C (●). Complex, 0.03 M; Hacac (enol), 0.06 M.

to a second order rate formula as Eq. 6.

$$k_x = A'[H_2O]^2 \quad (6)$$

On the other hand, when the water concentration becomes >0.05 M, the term $B'[H_2O]$ in the denominator becomes sufficiently large and the $k_x/[H_2O]$ approaches a limiting value.

$$k_x/[H_2O] = (A'/B') \quad (7)$$

Equation 5 has the same pattern as Eq. 3 for the hydrolysis of the present complex. The A' value is *ca.* 0.3 M^{-2} s^{-1} in the water concentration range 0.05 to 0.12 M at −20.4 °C. (*cf.* A=0.15 M^{-2} s^{-1} for the hydrolysis). The activation enthalpies and entropies for the A' are $\Delta H^{\ddagger}=(36\pm20)$ kJ mol^{-1} and $\Delta S^{\ddagger}=(111\pm40)$ J mol^{-1} K^{-1}, respectively. They have rather large experimental errors since the data were obtained only at −28.1 and −20.4 °C.

Another interpretation can be encountered by assuming significant change in activity coefficient of water in AN.[14] Nevertheless we tend to favor the first consideration on the basis of the discussions given below.

Acetic and trichloroacetic acid enhance the isotopic exchange as seen in Table 2. The extent of the catalytic action of these weak and strong acids does not differ much from each other, and does not depend on their concentration. It seems the acid catalysis has reached almost saturation under the given conditions.

The Reaction Mechanism. The isotopic exchange does not proceed appreciably in the absence of water below 0 °C, and the original complex itself does not seem to undergo ligand isotopic exchange. The hydrolysis and the isotopic exchange were studied in different concentration regions of the complex and water in AN. However, the apparent exchange rate constant A' is only twice as large as the apparent hydrolysis rate A at −20 °C, and the activation parameters are similar to each other within the experimental errors. These facts suggest that these two reactions might proceed *via* a common route. A plausible mechanism is visualized in Fig. 7.

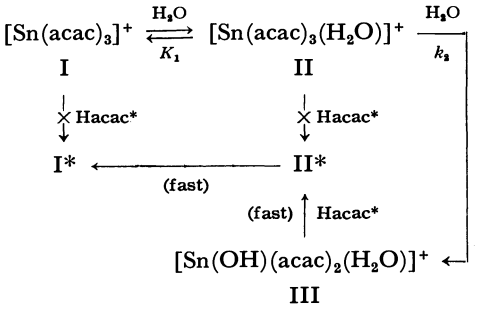

Fig. 7. Plausible mechanism of hydrolysis and ligand isotopic exchange of $[Sn(acac)_3]^+$ ion in acetonitrile. I* and II* are the same species with I and II respectively with labeled $acac^-$.

The original complex interacts rapidly with water to give an intermediate (II, for the structure, *vide infra*). Then II undergoes reaction with another molecule of water to give III, the main component of Product A (see Experimental). In the isotopic exchange reaction, excessive free Hacac rapidly reacts with III to restore II*. In the absence of free Hacac and in the presence of a large excess of water (experimental condition for the hydrolysis), III is subject to further reaction with water or to polymerization, to make the hydrolysis irreversible. Thus the isotopic exchange and hydrolysis seem to have a common intermediate and a common rate-determining step ($A=k_2K_1=A'$).

The rate-determining step II→III should involve the break of a metal-ligand bond with the aid of water. The water molecule should play a unique role, because the solvent AN brings about neither solvolysis nor isotopic exchange.

Structure and Role of Intermediate II: Intermediate II can be either a six-coordinated species with one unidentate and two bidentate $acac^-$ and a water molecule as ligands, or a seven-coordinated species with three bidentates and a water molecule. In the former case the break of the remaining bond with the aid of water would be the rate-determining step. If II were seven-coordinated, water-assisted break of a metal-ligand bond

followed by rapid break of another Sn–O bond of the same acac$^-$ would be rate-controlling. Alternatively, the seven-coordinated species can be in rapid equilibrium to give a small amount of the six-coordinated species with one unidentate acac$^-$ which can behave similarly as in the former case.

Present experimental data cannot discriminate these possible mechanisms, and we can only discuss the most probable route by analogie. Seven- and eight-coordinated tin(IV) complexes with oxygen donors are known in crystalline state,[9] and the presence of a seven-coordinated intermediate is not unlikely. Homologous complexes $[Si(acac)_3]^+$ and $[Ge(acac)_3]^+$ are claimed to produce intermediates with a unidentate acac$^-$ on racemization and isotopic exchange. It was discussed that unidentate acac$^-$ is stabilized in the complexes with highly charged central metal ions such as aluminium(III), gallium(III), silicon(IV), and germanium(IV).[3,15] Thus we tend to consider that intermediate II would be mostly present as seven-coordinated species and produce a small amount of unidentate acac$^-$ by rapid equilibrium, and that the break of the remaining Sn–O bond of the unidentate acac$^-$ would be responsible in determining the rate of hydrolysis and isotopic exchange. Assistance of water at this step can be substantiated either by attacking the intermediate as nucleophile or by blocking the vacant coordination site of the intermediate to retard the recombination of Sn–O.

Comparison with Related Complexes. Other members of 4B family, silicon(IV) and germanium(IV), give homologous complexes $[M(acac)_3]^+$ with acetylacetonate, and the structures are very similar to $[Sn(acac)_3]^+$. However, those two complexes are much more inert than the corresponding tin(IV) complex, and the ligand isotopic exchange is measurable over 100 °C in AN. The dependence of their rates upon various factors is significantly different from the present complex, and they are resistive against hydrolysis even at elevated temperatures.[3] They were resolved into enantiomers, and their racemizations were found to proceed similarly at a measurable rate without the assistance of water between 40 and 60 °C, presumably *via* an intermediate with a unidentate acac$^-$.

Frazer and Haines found that the related tin(IV) complexes $[Sn(acac)_2X_2]$ (X=Cl, Br, and I) undergo hydrolysis below 0 °C to liberate acac$^-$ in chloroform. The rate law was:

$$\text{rate} = k[H_2O][Sn(acac)_2X_2] \quad (8)$$

where the complex and water concentration were $\simeq 5\times10^{-5}$ and 0.005—0.01 M, respectively. They proposed a mechanism involving an association pre-equilibrium between the complex and water, and a rate-determining attack of this water molecule to break Sn–O bond.[16] The role of water molecule seems to be different from that in the present reactions, but the labile interaction with water is common. The large octahedral ionic radius of tin(IV) ion may be responsible for the difference among silicon(IV), germanium(IV), and tin(IV).

Titanium(IV), a member of 4A family, also gives a tris(acetylacetonato) complex $[Ti(acac)_3]^+$ with a similar structure, which readily undergoes hydrolysis in hydrous solvents. The rate of ligand isotopic exchange is measurable in the same temperature region as the tin(IV) complex, although details of the kinetic behavior remains unknown.[4] The similar lability towards hydrolysis and isotopic exchange seems to owe to the similarity in the octahedral ionic radius.

An iso-electronic cation indium(III) also gives a complex $[In(acac)_3]$, which is very sensitive to hydrolysis. Its ligand isotopic exchange is immeasurably fast at −20 °C in tetrahydrofuran.[17] Another d^{10} cation, gallium(III) gives also $[Ga(acac)_3]$ and the ligand isotopic exchange rate is measurable at $\simeq$0 °C. However, the dependence on various factors is different from the present case.[18] It seems as if the charge and the ionic radius of the central metal ion is very important in determining the kinetic behavior of non-transition metal complexes.

The authors wish to thank the Ministry of Education for Grant-in-Aid.

14) If the exchange proceeds *via* an entirely different route involving only one mol of water, the rate formula can be written as: $k_x=k_f\gamma[H_2O]$ where γ stands for the activity coefficient of water in AN. If γ decreases in $<$0.05 M solution, k_x *vs.* $[H_2O]$ diagrams can assume apparently second order dependence as shown in Fig. 5. No information is available concerning the activity coefficient of a very small concentration of water in AN at −20 °C. However, such a solution may be approximated to an AN solution of ice and a significant decrease in activity coefficient cannot be necessarily unreasonable.

Keto-Enol Tautomerism. I. The Calorimetrical Determination of the Equilibrium Constant for Keto-Enol Tautomerism for Cyclopentanone

Jack HINE and Kazushi ARATA*

The Evans Laboratory of Chemistry, The Ohio State University, Columbus, Ohio, U.S.A.

(Received May 31, 1975)

The enol content of cyclopentanone was determined by calorimetrical measurement of the enthalpy of hydrolysis of cyclopentenyl methyl ether to cyclopentanone with the assumption that the thermodynamics of hydrolysis of any ROMe to ROH is the same as that for any other ROMe. The enthalpy of the ketonization of cyclopentenol was determined to be -7.87 kcal/mol in the liquid phase and -11.66 kcal/mol in the gas phase, at 25 °C. The enol content of cyclopentanone in the gas phase at 25 °C was found to be 2.5×10^{-7}%.

The equilibrium enol content of simple ketones (RR'HC·COR": R, R', and R"=H or allyl groups) is known to be very low, both in the neat substances and in aqueous solution. The enol content has been determined by several methods. Most of the measurements were based on the classical method in which the enol content was estimated by the rapid reaction of enol with bromine.

Schwarzenbach and Wittwer determined the enol content of cyclopentanone, cyclohexanone and acetone to be 0.0048, 0.02, and 0.00025%, respectively, by running a ketone solution of known concentration and a bromine solution of steadily increasing concentration at controlled rates through a reaction vessel and determining potentiometrically the moment at which excess bromine appears.[1]

Gero improved the bromine titration by the use of the most polar halogen available (iodine monochloride) instead of bromine, because the rate of the addition reaction is essential in order to obtain accurate information on the enol content. His values for cyclopentanone, cyclohexanone and acetone were 0.088, 1.2, and 0.00015 %, respectively.[2]

A careful work by Bell and Smith on the bromine titration[3] shows what large errors the method can lead to when the proper precautions are not taken. They found that the enol contents for cyclopentanone and cyclohexanone are, respectively, 0.0013 and 0.00041%, of which the latter is 3000 times as small as that reported by Gero.

Ultraviolet[4] and infrared[5] spectroscopy were also used as a mean of studying the keto-enol equilibria.

Calorimetry for Determining Equilibrium Constants for Keto-Enol Tautomerism. For simple ketones whose enol contents are relatively small, we planned to use an indirect method based on thermochemical measurements. This method is similar to that used by Sunner, who measured the heats of hydrolysis of *iso*-propenyl acetate and *m*-cresyl acetate.[6] He assumed that the heats of hydrolysis are identical for both of the esters and therefore claimed that the extra heat liberated in the hydrolysis of isopropenyl acetate is due to the subsequent ketonization of the initially formed enol. He got a value of the enthalpy change of 7 kcal/mol for ketonization in the liquid phase.

Jencks and co-workers have shown that the free energy of hydrolysis of ROAc's changes by 14.0±0.5 kcal/mol as R is changed from ethyl through phenyl and *p*-nitrophenyl to acetyl.[7] We believe that this method could be improved upon by eliminating the assumption that the heat of hydrolysis of one ROAc to ROH is the same as that of another. It is better to assume that the thermodynamic parameters of hydrolysis of any ROMe (or ROEt or ROPr-n, *etc.*) to ROH are approximately the same whether R is changed. In support of this assumption is the fact that as R is changed from methyl through phenyl to acetyl[8] the free energy of hydrolysis of ROMe changes by 1.7 kcal/mol.[9] Therefore, we shall measure the heats of hydrolysis of various enol methyl ethers and assume the heat of hydrolysis to ROH is the same as that for some ROMe for which the heat of hydrolysis is known reliably (and if possible for an ROMe that is structurally as closely related as possible to the enol methyl ether in question), *e.g.*,

$$CH_2{=}CROMe + H_2O \longrightarrow CH_3CRO + MeOH \quad \Delta H_1 \quad (1)$$

$$R'OMe + H_2O \longrightarrow R'OH + MeOH \quad \Delta H_2 \quad (2)$$

$$CH_2{=}CROMe + H_2O \longrightarrow CH_2{=}CROH + MeOH \quad \Delta H_3 \quad (3)$$

$$CH_2{=}CROH \longrightarrow CH_3CRO \quad \Delta H_4\ (\text{Ketonization}) \quad (4)$$

obviously

$$\Delta H_1 = \Delta H_3 + \Delta H_4\ (\text{Ketonization})$$

Since it is assumed that ΔH_3 is equal to ΔH_2

$$\Delta H_4\ (\text{Ketonization}) = \Delta H_1 - \Delta H_2$$

Both ΔH_1 and ΔH_2 can be determined experimentally and therefore ΔH_4 (Ketonization) may be calculated.

The following four values are experimentally determined in order to get ΔH_1 in the liquid phase;

$$CH_2{=}CROMe(liq) + H_2O{\cdot}S + S \longrightarrow CH_3CRO{\cdot}S + CH_3OH{\cdot}S \quad \Delta H_5 \quad (5)$$

$$H_2O(liq) + S \longrightarrow H_2O{\cdot}S \quad \Delta H_6 \quad (6)$$

$$CH_3CRO(liq) + S \longrightarrow CH_3CRO{\cdot}S \quad \Delta H_7 \quad (7)$$

$$CH_3OH(liq) + S \longrightarrow CH_3OH{\cdot}S \quad \Delta H_8 \quad (8)$$

where S's are solvents. The actual reaction taking place in the calorimeter is represented by Eq. 5. In order to obtain the isothermal ideal hydrolysis reaction, as defined by Eq. 9 or 1, it is necessary to calculate as follows:

* Present address: Hokkaido University of Education, Hachiman-cho 1-2, Hakodate 040.

Eq. 5+Eq. 6−Eq. 7−Eq. 8

$$CH_2{=}CROMe(liq) + H_2O(liq) \longrightarrow CH_3CRO(liq) + CH_3OH(liq) \quad \Delta H_9 = \Delta H_1 \qquad (9)$$

Experimental

Water used in making up solutions in this study was double-distilled. Traces of potassium permanganate and potassium hydroxide were added to the distilled water before the second distillation. Baker Analyzed reagent grade tetrahydrofuran was distilled over ferrous sulfate.[10]

Cyclopentenyl Methyl Ether. The preparation of cyclopentanone dimethyl ketal was based on the method of Arbuzov and Mikhailova.[11] Cyclopentanone (168 g) and trimethyl orthoformate (212 g) were placed into a 1 l round-bottomed flask fitted with a magnetic stirrer, a condenser, and an ice bath. Six drops of concentrated sulfuric acid were added, and the reaction proved to be exothermic, causing the colorless mixture to become brown. The ice bath was removed after an hour, and the reaction allowed to continue overnight. After the reaction mixture was allowed to stir for an hour with solid potassium bisulfite (80 g) and then filtered, the product was fractionally distilled to give 204.3 g (78.5% yield) of cyclopentanone dimethyl ketal, bp 60—63 °C at 50 mmHg. Cyclopentenyl methyl ether was prepared by pyrolysis of cyclopentanone dimethyl ketal. The dimethyl ketal (108 g) was boiled overnight while resulting methanol collected, and the product was fractionated to give 52.3 g (64%) of cyclopentenyl methyl ether, bp 108—109 °C, which was found by gas chromatographic (GLC) analysis to be 90.5% pure. The purer product, 99.5%, was obtained by preparative GLC. The NMR spectrum showed at τ 5.77, a singlet (1H), assigned to the olefinic proton: τ 6.62, a singlet (3H), assigned to methoxy protons, τ 7.88, a multiplet (4H), assigned to allylic methylene protons; τ 8.22, a multiplet (2H), assigned to homoallylic methylene protons.

Calorimetric Measurements. The Bunsen ice calorimeter was used. The apparatus and the experimental procedure were similar to those described previously[12] with the following exception: the outer jacket (chamber C) was evacuated to insulate internal chambers A and B from the surrounding medium after draining of water.

In order to confirm its reliability, the apparatus was first used to determine the enthalpy of neutralization of sodium hydroxide with hydrochloric acid. Three determinations gave values of 14.45, 14.62, and 14.50 kcal/mol. The average value, 14.52±0.09 kcal/mol, is in good agreement with the reported values,[13-15] and is 5.6% smaller than the value that should have been obtained as calculated from the calorimetrically determined heat of dissociation of water at 0 °C and infinite dilution[16] and the heats of dilution[17] of sodium hydroxide, hydrochloric acid, and sodium chloride.

Determination of Heats of Hydrolysis for Cyclopentenyl Methyl Ether. In these studies an ampoule containing about 1 g of enol methyl ether was broken in a solution of 1.817 g of distilled water and 0.411 g of 96.5% sulfuric acid in 24.747 g of tetrahydrofuran [30 ml of 91.67% THF–H_2O (0.15 mol/l H_2SO_4)]. Five determinations of heat evolved gave values of 4367, 4417, 4521, 4380, and 4404 cal/mol. The average value was 4418±61 cal/mol.

The reaction solution was analyzed by GLC. The reaction solution of 0.175 g (1.78×10^{-3} mol) cyclopentenyl methyl ether in 5 ml of 91.67% THF–H_2O (0.15 M H_2SO_4), which is almost the same concentration as that used in the calorimetrical measurements, was analyzed on a 10% Carbowax and 2% KOH column (2 m). From the ratios of the area of cyclopentanone to that of THF and area of methanol to that of THF, concentrations of the products, methanol and cyclopentanone, were obtained as 1.82×10^{-3} mol and 1.72×10^{-3} mol which were 102 and 96.7%, respectively, compared with the theoretical yields.

The reaction solution of 0.146 g (1.49×10^{-3} mol) cyclopentenyl methyl ether in 25 ml of 91.67% THF–H_2O (0.15 M H_2SO_4) was also analyzed on a 5% Carbowax 20 M on Chromosorb P column (2 m). The ratio of the area of methanol to that of cyclopentanone gave 1: 1.18 as the mole ratio calculated from the estimated standard values.

The reaction solution was analyzed by UV spectrometry. From the absorbance at 281 nm of 0.042 M solution of cyclopentenyl methyl ether in THF–H_2O (0.15 M H_2SO_4), the conversion was calculated to be 106, 97.7, and 107% (103% in the average).

Determination of Heats of Solution for Cyclopentanone. In these studies an ampoule containing about 1—2 g of ketone was broken in a solution of 30 ml of 91.67% THF–H_2O (0.15 M H_2SO_4). Four determinations of heat absorbed gave values of 232, 319, 405, and 294 cal/mol. The average value was 312±72 cal/mol.

Determination of Heats of Solution for Methanol. In these studies an ampoule containing about 1 g of methanol was broken in a solution of 30 ml of 91.67% THF–H_2O (0.15 M H_2SO_4). Five determinations of heat evolved gave values of 21, 16, −8, 27, and 13 cal/mol. The average value was 14±13 cal/mol.

Determination of Heats of Solution for Water. In these studies an ampoule containing about 1 g of water was broken in a solution of 30 ml of 91.67% THF–H_2O (0.15 M H_2SO_4). Five determinations of heat evolved gave values of 198, 204, 190, 197, and 238 cal/mol. The average value was 206±19 cal/mol.

Discussion

All values determined calorimetrically are as follows,

$$\Delta H_{10} = -4418 \pm 61 \text{ cal/mol} \qquad (10)$$

$$H_2O + S \longrightarrow H_2O{\cdot}S$$

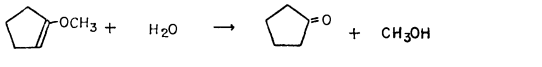
$$\Delta H_{11} = -206 \pm 19 \text{ cal/mol} \qquad (11)$$

$$\Delta H_{12} = +312 \pm 72 \text{ cal/mol} \qquad (12)$$

$$CH_3OH + S \longrightarrow CH_3OH{\cdot}S$$

$$\Delta H_{13} = +14 \pm 13 \text{ cal/mol} \qquad (13)$$

where S's are solvents, and the ± figures are standard deviations. The actual reaction taking place in the calorimeter is represented by Eq. 10. In order to obtain the isothermal, ideal hydrolysis reaction (defined by Eq. 14) it is necessary to subtract Eq. 12 and 13 from 10 and to add 11. The following result is obtained.



$$\Delta H_{14} = -4950 \pm 165 \text{ cal/mol} \qquad (14)$$

This value, −4950±165 cal/mol, is the heat of hydrolysis of the idealized reaction at 0 °C.

In order to obtain the heats of reaction at 25 °C, the

Kirchhoff's thermodynamic equation is used. The difference in the mean heat capacities at constant pressure of the products and reactants, ΔC_p, was estimated to be -4.9 cal/mol K.[18] Therefore, $\Delta H'_{14}$ (liq) $=-5072\pm165$ cal/mol, which is the heat of hydrolysis of the idealized reaction at 25 °C in the liquid phase for cyclopentenyl methyl ether, was obtained.

In order to calculate the heat of hydrolysis when both reactants and reaction are in the gaseous state it is necessary to know the heats of vaporization for all the compounds at 25 °C. The heat of vaporization of water, methanol,[20] cyclopentanone[22] and cyclopentenyl methyl ether[23] have been determined to be 10.47, 8.91, 9.67, and 9.4 kcal/mol, respectively.

The following five equations were used to calculate the heat of hydrolysis for cyclopentenyl methyl ether in the gas phase;

$$H_2O(liq) \longrightarrow H_2O(g)$$
$$\Delta H_{15} = +10.47 \text{ kcal/mol} \quad (15)$$
$$CH_3OH(liq) \longrightarrow CH_3OH(g)$$
$$\Delta H_{16} = +8.91 \text{ cal/mol} \quad (16)$$

$$\Delta H_{17} = +9.67 \text{ kcal/mol} \quad (17)$$

$$\Delta H_{18} = +9.4 \text{ kcal/mol} \quad (18)$$

$$\Delta H_{19} = -5.07 \text{ kcal/mol} \quad (19)$$

Then, $-(15)+(16)+(17)-(18)+(19)$ gives the equation in the gaseous state. Therefore, $\Delta H'_{19}(g)=-6.36$ kcal/mol, which is the heat of hydrolysis for cyclopentenyl methyl ether at 25 °C in the gas phase, is obtained.

Heats of Ketonization. The hydrolysis of enol methyl ethers to ketones may be split into two consecutive steps, *viz.* the hydrolysis to enols, and the prototropic isomerization of enols to ketones:

$$R'R''C{=}CR'''OMe + H_2O \longrightarrow R'R''CHCOR''' + MeOH \quad \Delta H_{20} \quad (20)$$
$$R'R''C{=}CR'''OMe + H_2O \longrightarrow R'R''C{=}CR'''OH + MeOH \quad \Delta H_{21} \quad (21)$$
$$R'R''C{=}CR'''OH \longrightarrow R'R''CHCOR''' \quad \Delta H_{22}\text{ (Ketonization)} \quad (22)$$

A knowledge of the value of ΔH_{21} makes it possible to obtain a value of ΔH_{22} (ketonization), which is the reverse of the enolization reaction of ketones. The reaction for ΔH_{21} is of course not experimentally accessible; it is therefore necessary to estimate the accompanying change in enthalpy indirectly from the following reaction;

$$ROMe + H_2O \longrightarrow ROH + MeOH \quad \Delta H_{23} \quad (23)$$

When R is methyl ΔH_{23} is 5.6 kcal/mol and when R is phenyl ΔH_{23} is 5.3 kcal/mol in the gas phase at 25 °C.[9] These two values were estimated to be 2.80 kcal/mol in the liquid phase.[24] Therefore, ΔH_{22} (Ketonization) can be obtained by $\Delta H_{20}-\Delta H_{23}$. In the liquid phase, value of ΔH_{22}(Ketonization) for cyclopentanone is -7.87 kcal/mol. In the gas phase, ΔH_{22} (Ketonization) for cyclopentanone can be estimated to be -11.66 kcal/mol, by taking the value of ΔH_{23} for phenyl which structurally resembles cyclopentenyl more than methyl does.

Free Energies for Ketonization. Benson and Buss have pointed out that entropies of compounds may be calculated reliably from structural contributions. Calculations, using the first-order approximation to the law of additivity of bond properties, gave $+0.13$ e.u. for the entropy of ketonization of cyclopentenol in the gas phase at 25 °C.[26,27] Therefore, free energy for the ketonization of cyclopentenol in the gas phase was -11.70 kcal/mol, which made the calculation of the equilibrium constant for the ketonization, K, and its reverse, $1/K$, which is the equilibrium constant for the enolization. They were 4.0×10^{8} and 2.5×10^{-9}, respectively. Thus, the enol content of cyclopentanone was obtained to be 2.5×10^{-7}% in the gas phase at 25 °C.

18) Mean heat capacities of water, methanol, and cyclo-

hexanone are 75.7, 78.2, and 177.8 J/K mol, respectively in the liquid phase.[19] Mean heat capacity of phenyl methyl ether, 200.8 J/K mol, was used instead of the value of cyclopentenyl methyl ether, and the value for cyclopentanone was taken as that cyclohexanone. To use the heat capacity of phenyl methyl ether for cyclopentenyl methyl ether may cause a large error, however, we believe that to take the value of cyclohexanone for cyclopentanone make this error minimized.

27) The value of −2.5 for C_{vi}–O bond was estimated from values of −16.4 and −14.3 for C–C and C_{vi}–C, 12.9 and 13.8 for C–H and C_{vi}–H, and −4.0 for C–O, respectively.

Keto-Enol Tautomerism. II.[1] The Calorimetrical Determination of the Equilibrium Constants for Keto-Enol Tautomerism for Cyclohexanone and Acetone

Jack HINE and Kazushi ARATA*

The Evans Laboratory of Chemistry, The Ohio State University, Columbus, Ohio, U.S.A.

(Received May 31, 1975)

The vapor phase enol contents of cyclohexanone and acetone were determined by calorimetric measurements of the enthalpies of hydrolysis of their corresponding enol methyl ethers to ketones and methanol in 91.67% THF-H_2O (0.15 M H_2SO_4). The relative order of enol content, together with cyclopentanone in our previous study, was cyclohexanone>cyclopentanone≧acetone, which was the same as that reported by Gero and by Schwarzenbach, but different from Bell's observed order (cyclopentanone>cyclohexanone>acetone). The enthalpies calculated from Benson's correlation of thermodynamic properties for the enolization reactions of these ketones and for the hydrolysis reactions of enol methyl ethers agreed with our relative ordering. Furthermore, data on reactions of compounds with 5- and 6-membered rings lead to the prediction that cyclohexanone contains more enol than cyclopentanone does. The kinetics of hydrolysis of enol methyl ethers was also discussed.

In an earlier paper[1] we described methods for determining the equilibrium enol content of simple ketones (RR'HC·COR": R, R', and R"=H or allyl groups) by calorimetric measurements of the enthalpies of hydrolysis of their corresponding enol methyl ethers to ketones and methanol, and by assuming that the thermodynamic parameters of hydrolysis of any ROMe to ROH are approximately the same whether R is changed. The enol content of cyclopentanone was obtained to be 2.5×10^{-7}% in the vapor phase at 25 °C.

The same method has been applied to cyclohexanone and acetone, and the relative order of enol content of these three ketone is discussed.

Experimental

Experiments which do not overlap with those reported in our previous paper[1] are described here.

Cyclohexenyl Methyl Ether. The preparation of cyclohexenyl methyl ether was analogous to that of cyclopentenyl methyl ether.[1] Pyrolysis of 43 g of cyclohexanone dimethyl ketal, bp 63—67 °C at 40 mmHg, gave 28.0 g (83% yield) of cyclohexenyl methyl ether, bp 140 °C, which was found by GLC analysis to be 92.2% pure. The purer product, 99.6%, was obtained by preparative GLC. Its NMR spectrum was identical with the reported spectra;[2] τ 5.5, a triplet (1H), assigned to the olefinic proton: τ 6.6, a singlet (3H), assigned to methoxy protons; τ 8.1, a multiplet (4H), assigned to allylic methylene protons; τ 8.5, a multiplet (4H), assigned to homoallylic methylene protons.

Isopropenyl Methyl Ether. The preparation of isopropenyl methyl ether was based on Kaufmann's method of preparation of propyl isopropenyl ether.[3] A mixture of 107 g of 2,2-dimethoxypropane, 7 g of quinoline, and 0.4 g of *p*-toluenesulfonic acid was allowed to reflux under a nitrogen blanket in a Todd distillation column and 34 g of the fraction boiling 34—52 °C was collected. This reaction was repeated in order to get more product. These mixtures were placed in a reflux set-up equipped with magnetic stirrer, condenser, and drying tube, and excess potassium metal carefully added through the condenser. After 2 h, the mixture was again distilled with the fraction boiling at 33.0—33.5 °C collected. This procedure was repeated to get the sufficiently pure (99.9%) isopropenyl methyl ether, bp 35.5 °C; [lit,[4] bp 35.2—35.6 °C/752 Torr, n_D^{20} 1.3824, d_4^{20} 0.7645]. NMR spectrum: τ 6.88, a singlet (2H), assigned to olefinic protons; 7.23, a singlet (3H), assigned to methoxy protons; τ 8.93, a singlet (2H), assigned to methyl protons.

Determination of Enthalpies of Hydrolysis for Enol Methyl Ethers. In these studies an ampoule containing about 1 g of enol methyl ether was broken in a solution of 1.817 g of distilled water and 0.411 g of 96.5% sulfuric acid in 24.847 g of tetrahydrofuran [30 ml of 91.67% THF-H_2O (0.15 mol/l H_2SO_4)].

Enthalpy of Hydrolysis of Cyclohexenyl Methyl Ether: Five determinations of heat evolved gave values of 2686, 2629, 2695, 2884, and 2888 cal/mol. The average value was 2756±121 cal/mol.

Ethalpy of Hydrolysis of Isopropenyl Methyl Ether: four determinations of heat evolved gave values of 5127, 5077, 5166, and 5174 cal/mol. The average value was 5136±44 cal/mol.

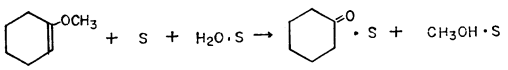
Determination of Heats of Solution for Ketones. In these studies an ampoule containing about 1—2 g of ketone was broken in a solution of 30 ml of 91.67% THF-H_2O (0.15 M H_2SO_4).

Enthalpy of Solution of Cyclohexanone: three determinations of heat absorbed gave values of 145, 170, and 162 cal/mol. The average value was 159±13 cal/mol.

Enthalpy of Solution of Acetone: five determinations of heat absorbed gave values of 162, 114, 145, 188, and 202 cal/mol. The average value was 162±35 cal/mol.

Results and Discussion

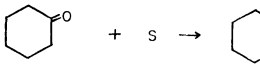
All values determined calorimetrically are as follows,



$$\Delta H_{1a} = -2756 \pm 121 \text{ cal/mol} \quad (1a)$$

$$CH_2{=}C(OCH_3)CH_3 + S + H_2O{\cdot}S \longrightarrow CH_3\overset{\overset{O}{\|}}{C}CH_3{\cdot}S + CH_3OH{\cdot}S$$

$$\Delta H_{1b} = -5136 \pm 44 \text{ cal/mol} \quad (1b)$$



$$\Delta H_{2a} = +159 \pm 13 \text{ cal/mol} \quad (2a)$$

* Present address: Hokkaido University of Education, Hachiman-cho 1-2, Hakodate 040.

$$CH_3\overset{O}{\overset{\|}{C}}CH_3 + S \longrightarrow CH_3\overset{O}{\overset{\|}{C}}CH_3\cdot S$$

$$\Delta H_{2b} = +162 \pm 35 \text{ cal/mol} \quad (2b)$$

$$H_2O + S \longrightarrow H_2O\cdot S$$

$$\Delta H_3 = -206 \pm 19 \text{ cal/mol}^{1)} \quad (3)$$

$$CH_3OH + S \longrightarrow CH_3OH\cdot S$$

$$\Delta H_4 = +14 \pm 13 \text{ cal/mol}^{1)} \quad (4)$$

where S's are solvents, and the ± figures are standard deviations. In order to obtain the isothermal, ideal hydrolysis reaction it is necessary to subtract Eq. 2 and 4 from 1 and to add 3. Thus, the heats of hydrolysis of the idealized reaction in the liquid phase at 0 °C are −3135±166 and −5518±111 cal/mol for cyclohexenyl methyl ether and isopropenyl methyl ether, respectively.

These two values were corrected to those at 25 °C by following thermodynamic equation. Calculations[5] gave −3257±166 and −5745±111 cal/mol for cyclohexenyl and isopropenyl methyl ethers, respectively. These values are the heats of hydrolysis of the idealized reaction at 25 °C in the liquid phase.

In order to calculate the enthalpy of hydrolysis when both reactants and reaction are in the gaseous state it is necessary to know the heats of vaporization for all the compounds at 25 °C. Those of water, methanol, cyclohexanone, acetone, cyclohexenyl methyl ether and isopropenyl methyl ether were 10.47, 8.91,[1] 10.61,[7] 7.61,[8] 10.62, and 6.68[9] kcal/mol, respectively. Therefore, the heats of hydrolysis for cyclohexenyl methyl ether and that for isopropenyl methyl ether at 25 °C in the gas phase were obtained to be −4.83 and −6.38 kcal/mol, respectively.

The hydrolysis of enol methyl ethers to ketones may be split into two consecutive steps, *viz.* the hydrolysis to enols, and the prototropic isomerization of enols to ketones. The heat of ketonization of RR'C=CR"OH can be estimated by assuming that, as carried out in the previous paper,[1] the heat of hydrolysis of RR'C=CR"-OMe to RR'C=CR"OH is the same as that of ROMe for which the heat of hydrolysis is known reliably to be 5.6 and 5.3 kcal/mol in gas phase when R is methyl and phenyl, respectively.[11] The heat of hydrolysis of ROMe was estimated to be 2.80 kcal/mol in the liquid phase.[1] Therefore, enthalpies of ketonization were −6.06 and −8.54 kcal/mol in the liquid phase for cyclohexanone and acetone, respectively. In the gas phase, depending on whether R is taken as methyl which is reasonable for isopropenyl, or phenyl which seems structurally a better model for cyclohexenyl, they were −10.13 and −11.98 kcal/mol for cyclohexanone and acetone, respectively.

The entropies of ketonization of cyclohexenol and isopropenol were estimated to be +0.13 and −0.87 e.u., respectively, in the gas phase at 25 °C by calculations using the first-order approximation to the law of additivity of bond properties by Benson and Buss.[1,12] Therefore, free energies for the ketonization of cyclohexenol and isopropenol at 25 °C in the gas phase were −10.17 and −11.72 kcal/mol, respectively, which made the calculation of the equilibrium constant for the ketonization, K, and its reverse, $1/K$, which is the equilibrium constant for the enolization. They are summarized in Table 1, together with our previous study for cyclopentanone.[1]

Table 1. Equilibrium constant of ketonization, K, and enolization, $1/K$, in the gas phase at 25 °C

	K	$1/K$
Cyclopentanone[1]	4.0×10^{8}	2.5×10^{-9}
Cyclohexanone	3.0×10^{7}	3.3×10^{-8}
Acetone	4.2×10^{8}	2.4×10^{-9}

Kinetics of Reactions. It is interesting to note that one can find data from the literature to suggest that the reaction we studied should have been very rapid under our conditions. The hydrolysis of isopropenyl methyl ether was studied by Salomaa *et al.*[10] From their second-order rate constant at 25 and 35 °C in water, a second-order rate constant of 120 $M^{-1}\,s^{-1}$ may be calculated (from the Arrhenius equation) at 0 °C. In the presence of 0.15 M H_2SO_4 it would hydrolyze with a first-order rate constant of about 18 s^{-1} if the solvent was water. If the rate of protonation of the ether is the same in water and in 91.67% THF-8.33% water, then the half-life of the reaction we studied would be 0.04 s. Even if the real half-life is 1000 times as long as this, the reaction should be fast enough to study satisfactorily by the method we used. In the case of cyclohexenyl methyl ether, Lienhard and Wang have determined the second-order rate constant as 2810 $M^{-1}\,min^{-1}$ in water at 25 °C.[13] Similarly, it would give about 0.098 s for the half-life of the reaction in the presence of 0.15 M H_2SO_4 at 25 °C.

We must also be concerned as to whether there is any ketal present at the end of the reaction, due to the establishment of the following equilibrium. This

equilibrium was studied in aqueous methanol by Bell *et al.*[14] From their values of K at 10 and 25 °C, a value of 8.6×10^{-4} M^{-1} at 0 °C may be calculated. Starting with 0.35 M ether and 3.3 M water, $8.6\times10^{-4}=[\text{ketal}]\cdot[H_2O]/[\text{ketone}][MeOH]^2=[\text{ketal}]\cdot3/[0.35]^3$. Thus about 0.003% of the ketone would be in the form of ketal at equilibrium. This is certainly negligible. Similarly, in the cases of cyclohexanone and acetone, equilibrium constants of 2.14×10^{-2} for cyclohexanone and 9.3×10^{-4} for acetone at 0 °C were calculated from their values of K at 10 and 25 °C. These led to calculations that 0.058% and 0.0001%, respectively, would be in ketal forms at equilibrium.

Enol Contents of Ketones. Enol contents of cyclopentanone, cyclohexanone and acetone investigated by the auther are assembled in Table 2, together with the results by other workers for comparison. The most interesting phenomenon is the relative ordering of enol contents of cyclohexanone>cyclopentanone>acetone in the data by Schwarzenbach, Gero, and the author, which is the opposite tendency to that found by Bell, who reported that cyclopentanone contains more enol than does cyclohexanone.

Shechter and his co-workers have found that the rate

Table 2. Enol contents of ketones at 25 °C

for enolization of cycloalkanones as a function of ring size is 6>8>5>7>4, and interpreted the rate order for acid-catalyzed enolization of cycloalkanones primarily on the basis of differences in steric requirements in conversion of the ketones to transition states having endocyclic unsaturated character.[20] If the rates of acid-catalyzed enolization of alkanones are related to the enol contents at equilibrium, cyclohexanone is considered to contain more enol than cyclopentanone.

Brown *et al.*[21] have reported that exocyclic double bonds stabilize a 5-membered ring and destabilize a 6-membered ring, and they made the generalization that reactions will proceed in such a manner as to favor the formation or retention of an exocyclic double bond in a 5-membered ring and to avoid the formation or retention of an exocyclic double bond in a 6-membered ring. It was also pointed out that reactions involving a change in coordination number from three to four proceed slowly in 5-membered and rapidly in 6-membered rings.

The proposal that an exocyclic double bond in 5-membered ring systems is more stable toward changes involving loss of the exocyclic double bond than the corresponding exocyclic double bond in 6-membered ring systems was supported by the higher heat of hydrogenation of cyclohexanone as compared to cyclopentanone; $\Delta H=-12.50$ kcal/mol for cyclopentanone and −15.42 for cyclohexanone.[22]

The generalization may be further illustrated by a consideration of the structures of the stable forms of the carbethoxy derivatives of cyclopentanone and cyclohexanone. The cyclopentanone derivative exists primarily in the form of the Keto derivative (5% enol) whereas the cyclohexanone compound exists primarily as the enol (57%) in 95% ethanol.[23]

In conclusion it may be reasonable to state that cyclohexanone contains more enol than cyclopentanone does. Heats of formation of three ketones and their enol forms in the gas phase at 25 °C were calculated by use of Benson and co-workers' second-order approximation which is the law of additivity of group properties. They were −53.10 kcal/mol for cyclohexanone, −45.50 for cyclopentanone, and −51.70 for acetone, and the values of their enol forms were −37.01, −27.56 and −31.40 kcal/mol, respectively. The differences for the reactions of enolization, $\Delta\Delta H°_f$, were +16.1 kcal/mol for cyclohexanone, +17.94 for cyclopentanone and +20.30 for acetone, while our observed values were 10.13, 11.66 and 11.98 kcal/mol, respectively.[24]

Heats of formation of three enol ethers, their corresponding ketones and methanol in the gas phase at 25 °C were calculated by use of Benson and co-workers' group property approach. They were −40.50 kcal/mol for cyclohexenyl methyl ether, −31.09 for cyclopentenyl methyl ether, −34.90 for isopropenyl methyl ether, −53.10 for cyclohexanone, −45.50 for cyclopentanone, −51.70 for acetone, and −48.0 for methanol. From these values, heats of hydrolysis for the enol ethers were obtained. The calculated values, $\Delta\Delta H°_f$, were −2.8 kcal/mol for cyclohexenyl methyl ether, −4.4 for cyclopentenyl methyl ether and −7.0 for isopropenyl methyl ether, while our observed values were −4.83, −6.36, and −6.38, respectively.[25] Heats of formation of enol ethers were also obtained from our values of ΔH for hydrolysis and other observed values.[24] They were −38.47 kcal/mol for cyclohexenyl methyl ether, −29.14 for cyclopentenyl methyl ether, and −35.52 for isopropenyl methyl ether in the gas phase at 25 °C.

Preparation and Properties of 7-Formyl-8-hydroxy-5-quinolinesulfonic Acid

Konomu MATSUMURA, Shin-ichi SASAKI, and Eiko TADA

Department of Chemistry, Kitasato University, Sagamihara, Kanagawa

(Received October 21, 1975)

8-Hydroxy-5-quinolinesulfonic acid (I), on condensation with formaldehyde in aqueous ammonia, produced 8-hydroxy-7-hydroxymethyl-5-quinolinesulfonic acid (IV), which, on oxidation with manganese (IV) oxide, gave 7-formyl-8-hydroxy-5-quinolinesulfonic acid (V). On treatment with boiling 6 M hydrochloric acid, V produced bis[α-hydroxy-(8-hydroxy-5-sulfo-7-quinolyl)methyl] ether (VIII).

It is known that 8-hydroxy-5-quinolinesulfonic acid (I), on condensation with formaldehyde and secondary amine, produces the corresponding Mannich base.[1] In the present study, it was found that 8-hydroxy-5-quinolinesulfonic acid (I), on heating at 90 °C for 3 h with formaldehyde in aqueous ammonia, afforded 8-hydroxy-7-hydroxymethyl-5-quinolinesulfonic acid (IV) in a 60% yield. In the course of our investigation, it was found that when this reaction was allowed to proceed at 90 °C for 40 min instead of 3 h, the major product was bis(8-hydroxy-5-sulfo-7-quinolylmethyl)amine (VII), admixed with a minute amount of IV, showing that the hydroxymethylation proceeded by way of the intermediate formation of the Mannich base (VII), which subsequently underwent hydrolysis on further heating at 90 °C. When the reaction of I with hexamethylenetetramine in aqueous ammonia was allowed to proceed at 90 °C for 3 h, a result similar to that of the formaldehyde–aqueous ammonia method was obtained.

On the other hand, when this reaction was allowed to proceed at 36 °C for 2 weeks, a mixture of IV and the Mannich base (VII), which was predominant, was formed. IV was converted to 7-formyl-8-hydroxy-5-quinolinesulfonic acid (V)[2] by oxidation with manganese(IV) oxide. The presence of a formyl group in V was confirmed by its infrared spectrum, which displayed two bands, at 2650 and 2800 cm^{-1}, indicating the characteristic carbon-hydrogen stretching frequency associated with the C–H of the formyl group. On the other hand, when a solution of I and formaldehyde in aqueous sodium hydroxide was heated at 90 °C for 3 h, contrary to our expectation of obtaining IV, 8,8′-dihydroxy-7,7′-methylenedi(5-quinolinesulfonic acid) (II) was produced in a 97% yield.

As was expected, on heating II with 50% sulfuric acid 7,7′-methylenedi(8-quinolinol) (III) was formed; on the same treatment IV also afforded III, the identity having been established by mixed mp and IR. The preparation of III by another route has already been reported by Ozawa and Shibuya.[3] The identity of the two compounds was proved by the mp and IR and mp of the diacetyl derivatives.

On heating V with 6 M hydrochloric acid at 100 °C for several minutes, a paste of well-defined crystal was formed in a good yield. This product was inferred to possess the (VIII) structure in consideration of its elemental composition and a mass-spectrometric examination.

The PMR spectrum of VIII showed no –CH(OH)– signals, perhaps because of deuteration during the examination.

VIII would be formed upon the elimination of water between two molecules of the aldehyde hydrate. Such a dimerization is not unusual with formaldehyde or chloral. The tendency of V to form aldehyde anhydride (VIII) in a 6 M hydrochloric acid solution may be due to the fact that the electron-attracting character of sulfo group may favor the formation of a hydrate form.

Mass Spectrometry. The characteristic features are that all the compounds examined underwent thermolyses prior to ionization. The mass-spectral data are listed in Table 1.

Experimental*

8,8'-Dihydroxy-7,7'-methylenedi(5-quinolinesulfonic Acid) (II). A solution of 5-sulfo-8-quinolinol dihydrate (10.44 g, 0.04 mol) and 36% formalin (30 g, 0.36 mol) in a 2.5 M sodium hydroxide solution (26 ml, 0.065 mol) was heated at 90 °C for 2 h. After cooling, the solution was acidified (T.B. 1.4) with hydrochloric acid; the crystals thus separated were filtered after the solution had stood for 2 days and then been dried at room temperature, yield, 9.3 g (97%) as monohydrate. Recrystallization from three hundred times its weight of boiling water yielded prismatic needles; mp 290—292 °C (foaming). It gives a dark green color with iron (III) chloride. IR (cm^{-1}, KBr), 3400 ($-SO_3H$), 3100 (-OH), 2950 ($-CH_2-$).

Found**: C, 47.44; H, 3.39; N, 5.76%. Calcd for $C_{19}H_{14}O_8N_2S_2\cdot H_2O$: C, 47.50; H, 3.33; N, 5.83%.

Found: C, 48.72; H, 3.35; N, 5.77%. Calcd for $C_{19}H_{14}O_8N_2S_2\cdot 0.5H_2O$: C, 48.41; H, 3.18; 5.94%.

8-Hydroxy-7-hydroxymethyl-5-quinolinesulfonic Acid (IV). (**A**) A solution of 5-sulfo-8-quinolinol dihydrate (10.44 g, 0.04 mol) and 36% formaldehyde (3.7 ml, 0.044 mol) in 7% aqueous ammonia (40 ml, 0.08 mol) was heated at 90 °C for 3 h and acidified (T.B. 1.4) while hot with 6 M hydrochloric acid; the crystals thus separated were filtered after the solution had stood for 4 days. The suspension of this crude product in 3 M hydrochloric acid (30 ml) was triturated at 90 °C for several minutes, filtered hot (filtrate F), washed with water and dried at 80 °C; yield, 6.12 g (60%). It forms as yellow thick plates (mp 289 °C(foaming)) and gives a deep green color with iron (III) chloride. For analysis, it was recrystallized from 300 times its weight of hot water. IR (cm^{-1}, KBr), 3450 ($-CH_2OH$), 3400 ($-SO_3H$), 3100 (-OH).

Found: C, 46.99; H, 3.36; N, 5.75%. Calcd for $C_{10}H_9O_5NS$: C, 47.06; H, 3.53; N, 5.49%.

Diacetyl Derivative of IV. This was made by heating a mixture of IV (260 mg), acetic anhydride (1 ml), and pyridine (1 ml) at 135 °C for 3 h, evaporating it *in vacuo* to dryness, acidifying with hydrochloric acid in cold, and washing with cold water; yield, 270 mg; mp 300 °C (foaming). It forms short needles.

Found***: C, 45.99; H, 3.97; N, 4.13%. Calcd for $C_{14}H_{13}O_7NS\cdot 1.5H_2O$: C, 45.90; H, 4.37; N, 3.83%.

Dibenzoyl Derivative of IV. A mixture of IV (260 mg), benzoyl chloride (420 mg), and pyridine (0.5 ml) was triturated at an ice-cold temperature for 0.5 h, allowed to stand at room temperature overnight, and then acidified (T.B. 1.8) with hydrochloric acid. The separated solid was filtered and treated with ethanol to give colorless prisms (300 mg), mp 288—290 °C (dec).

Found***: C, 57.58; H, 3.56; N, 3.35%. Calcd for $C_{24}H_{17}O_7NS\cdot 2H_2O$: C, 57.71; H, 4.21; N, 2.80%.

The filtrate, F, on concentration afforded fine needles (20 mg) mp 312 °C. It gives a dark violet color with iron(III) chloride and was identified as the Mannich base (VII) by IR.

(**B**) A solution of I dihydrate (5.22 g, 0.00 mol) and hexamethylenetetramine (0.51 g, $1/6\times 0.02$ mol) in 7% aqueous ammonia (20 ml) was heated at 90 °C for 2 h. The further treatment was similar to that used for (**A**). IV; yield, 2.92 g (57%); mp 289 °C (foaming). VII; yield, 50 mg; mp 312 °C. The two products were identified as IV and VII respectively by IR.

7,7'-Methylenedi(8-quinolinol) (III). A solution of II (200 mg) in 50% sulfuric acid (0.4 ml) was heated at 140 °C for one h. After cooling, on alkalifying with ammonia, the product was obtained as colorless, soft, thin plates; yield, 120 mg (86%).

On recrystallization from methanol, it formed compact prismatic needles; mp 185 °C; lit,[3] mp 170—180 °C, IR (cm^{-1}, KBr), 3100 (-OH), 2950, 1440 ($-CH_2-$).

Found: C, 75.26; H, 4.67; N, 9.04%. Calcd for $C_{19}H_{14}O_2N_2$: C, 75.50; H, 4.64; N, 9.27%.

Diacetyl Derivative of III. This crystallized as prisms from benzene; mp 170—172 °C; Lit,[3] mp 170—220 °C.

Found: C, 71.76; H, 4.81; N, 7.17%. Calcd for $C_{23}H_{17}O_4N_2$: C, 71.69; H, 4.42; N, 7.27%.

Monopicrate of III. This crystallized as rectangular thick plates from methanol; mp 245—246 °C (foaming).

Found: C, 56.30; H, 3.21; N, 12.88%. Calcd for $C_{19}H_{14}O_2N_2\cdot C_6H_3O_7N_3$: C, 56.50; H, 3.20; N, 13.18%.

A solution of IV (500 mg) in 50% soufuric acid (1 ml) was heated at 140—145 °C for 2.5 h. On further working, the product (310 mg) was obtained as prisms (mp 185 °C) and identified as III by a mixed mp and by IR.

Bis(8-hydroxy-5-sulfo-7-quinolylmethyl)amine (VII). (**A**) On heating a mixture of I dihydrate (5.22 g, 0.02 mol), hexamethylenetetramine (0.51 g, $1/6\times 0.022$ mol), and 7% aqueous ammonia (20 ml) at 80 °C for a few minutes, a clear solution was obtained. It was allowed to stand at 36 °C for 2 weeks. When the reaction mixture was then acidified (T.B. 1.4) with hydrochloric acid, soft precipitates with a gelatinous appearance were separated. The precipitates were filtered with suction, washed with water, and dried at 80 °C; yield, 3.76 g. On recrystallization from one thousand times its weight of boiling water, 2.17 g. (44.2%) of fine needles (mp 312 °C) were obtained. VII gives a dark violet color with iron (III) chloride. IR (cm^{-1}, KBr), 3400 ($-SO_3H$), 3200, 2850 (O–H), 1540, 1140 ($-CH_2-NH-CH_2-$).

Found: C, 48.52; H, 3.53; N, 8.38%. Calcd for $C_{20}H_{17}O_8N_3S_2$: C, 48.88; H, 3.46; N, 8.55%.

From the filtrate of the recrystallization, thick plates (1.16 g) were isolated on concentrating. They were after further recrystallization, identified as IV by IR and mp.

(**B**) A solution of I dihydrate (10.44 g, 0.04 mol) and 36% formalin (3.7 g, 0.044 mol) in 7% aqueous ammonia (40 ml, 0.08 mol) was heated at 90 °C for 40 min and acidified (T.B. 1.4) with 6 M hydrochloric acid; a yellow gelatinous solid thus separated was filtered after standing overnight in a refrigerator, washed well with water, and dried on a plate; yield, 5.9 g.

A portion of it, on recrystallization from hot water, yielded fine yellow needles; mp 312 °C. It gives a dark violet color with iron (III) chloride and was identified as VII by IR and mp.

7-Formyl-8-hydroxy-5-quinolinesulfonic Acid (V). To a hot solution of IV (4.1 g, 0.016 mol) and sodium acetate hydrate (2.2 g, 0.016 mol) in water (300 ml), commercial manganese dioxide (16 g) was added; the mixture was then heated at 95 °C for 2 h with vigorous stirring and filtered hot (charcoal). From the filtrate, the product was obtained as colorless thin plates on concentrating up to 150 ml, acidifying (T.B. 1.4) with hydrochloric acid, and standing overnight. It was recrystallized from fifty times its weight of hot water; yield,

* All the elemental analyses, unless stated otherwise, were performed after the material had been dried at 120 °C *in vacuo* over P_2O_5.

** Dried at room temperature over potassium hydroxide *in vacuo*.

*** Vacuum-dried at room temperature over potassium hydroxide.

1.96 g (48.2%). It turned to a black solid at 317 °C with preliminary darkening. It gives no color† reaction with iron(III) chloride; however, the mixture gradually developed a light green color after standing for 3 h at room temperature. IR (cm^{-1}, KBr), 2400 (-SO_3H), 3100 (OH), 2800, 2650 (H-CO-), 1740 (HC-O).

Found***: H_2O, 12.41; C, 41.63; H, 3.69; N, 5.06%. Calcd for $C_{10}H_7O_5NS \cdot 2H_2O$: H_2O, 12.46; C, 41.52; H, 3.81; N, 4.84%. Found: C, 47.20; H, 2.95; N, 5.76%. Calcd for $C_{10}H_7O_5NS$: C, 47.43; H, 2.77; N, 5.53%.

Mono-sodium salt of V. This was crystallized from water as colorless, soft, fine needles.

Found: C, 43.53; H, 2.66; N, 5.29%. Calcd for $C_{10}H_6O_5NSNa$: C, 43.64; H, 2.18; N, 5.09%.

3-(8-Hydroxy-5-sulfo-7-quinolyl)acrylic Acid (VI). A solution of V (0.5 g, 0.002 mol), malonic acid (0.32 g, 0.003 mol), and potassium hydroxide (0.5 g) in water (8 ml) was heated at 80 °C for 12 h and then at 95 °C for 5 h, thereafter it was acidified with hydrochloric acid; yield, 0.3 g (51%). Recrystallization from 300 times its weight of hot water afforded glistening thick plates; mp 287 °C (with foaming). VI gives a deep green color with iron(III) chloride.

Found***: C, 47.01; H, 3.36; N, 4.54%. Calcd for $C_{12}H_9O_6NS \cdot 0.5H_2O$: C, 47.37; H, 3.29; N, 4.64%.

Bis[α-hydroxy-(8-hydroxy-5-sulfo-7-quinolyl)methyl] Ether (VIII). A mixture of V dihydrate (1.16 g, 0.004 mol) and 6 M hydrochloric acid (8 ml), on heating with stirring at 100 °C, soon turned to a clear solution; it began to become turbid after 6 min and became a crystal paste after 10 min further heating.

It was diluted with water (8 ml), filtered after standing in a refrigerator overnight, washed with water, and dried at room temperature; yield, 0.96 g (80%).

Recrystallization from 55 times its weight of hot water, with the addition of a small amount of 3 M hydrochloric acid, afforded stout prismatic needles; mp 250—255 °C (foaming).

† A very concentrated solution gives a faint brownish yellow color.

VIII gives a deep green color with iron(III) chloride. It is unaltered when the solution in 1% sodium hydroxide is heated over free flame for a few min.

Water-Participation in the Crystalline-State Photodimerization of Cinnamic Acid Derivatives. A New Type of Organic Photoreaction

Fusae NAKANISHI, Hachiro NAKANISHI, Michio TSUCHIYA, and Masaki HASEGAWA

Research Institute for Polymers and Textiles, 4-Sawatari, Kanagawa-ku, Yokohama 221

(Received November 21, 1975)

A new type of organic photoreaction, a water-participation reaction in the crystalline state, has been investigated. The photoirradiation of *p*-formylcinnamic acid (*p*-FCA) crystals in the presence of water leads to 4,4′-diformyl-*β*-truxinic acid (*p*-FCA dimer) which has one molecule of crystal water. A comparison of the photodimerization carried out in the presence/absence of water revealed the effects of the water molecule on the reaction. That is, the water molecule is incorporated into the *p*-FCA dimer during the photodimerization process. Furthermore, the water accelerates the reaction rate of photodimerization, leading to the formation of the crystalline dimer, whereas only the water-free amorphous dimer results in the absence of water. In addition, by heating at 100—110 °C, the *p*-FCA dimer with a water molecule is converted into a water-free crystalline dimer, which is not attainable from a water-free amorphous dimer. The photodimerization of several *β*-form crystals of cinnamic acid derivatives has been examined from the viewpoint of water-participation: *p*-nitro, *p*-chloro, and 3,4-dichlorocinnamic acid were found to photodimerize in the same manner as *p*-FCA.

Schmidt and his co-workers[1] studied extensively the photodimerization of cinnamic acid in the crystalline state and established the field of a typical topochemical reaction in which the crystal structure of the compound plays a decisive role in the reactivity. In preparation for preparing the dimer of the *p*-phenylenediacrylic acid diethyl ester,[2] we have attempted the photodimerization of *p*-formylcinnamic acid (*p*-FCA) in the crystalline state and found that it was converted into the dimer with one molecule of crystal water if it was irradiated in the presence of water.[3]

Although a few dimers from cinnamic acid derivatives, for example α-truxillic acid, and its dichloride have been reported[4] to include a solvent molecule by the procedure of crystallization, the reaction is a new type of photoreaction in which water is incorporated into the dimer during the photodimerization process.

In this paper, further details of the reaction will be presented in order to reveal the overall view of characteristics of the crystalline-state water-participation reaction.

Experimental

Preparation of Cinnamic Acid Derivatives. *p*-FCA[5] was prepared by the condensation of terephthalaldehyde and malonic acid in the presence of piperidine and was separated from its by-product, *p*-phenylenediacrylic acid, by the extraction of crude product with acetone.

Other cinnamic acid derivatives were prepared according to the Reference.[1] All these compounds were recrystallized from the suitable solvents for preparing *β*-form crystals and were confirmed not to include any water in the original crystals.

Photodimerization. As a typical experiment, the photodimerization of *p*-FCA will be described.

Photodimerization in the Presence of Water. *p*-FCA crystals (0.3 g) were dispersed in water (100 ml) in a Pyrex flask. The flask was then irradiated with a 450-W high pressure mercury lamp at room temperature. Upon 60 minutes' irradiation the absorpotion maximum of *p*-FCA (295 nm) shifted to 254 nm and *p*-FCA was converted into the dimer quantitatively. NMR (DMSO-d_6) ppm: 3.8—4.5 (m 4, CH) 7.1—7.7 (m 8, C_6H_4) 9.8 (s 2, CHO). Found: C, 64.76; H, 4.76%. Calcd for $C_{20}H_{18}O_6+H_2O$: C, 64.86; H, 4.90%.

When the dimer was heated at 100—110 °C *in vacuo* for 10 h its elemental analysis changed as follows. Found: C, 68.48 H, 4.25%. Calcd for $C_{20}H_{18}O_6$: C, 68.18; H, 4.58%. The dimer can be recrystallized from ethanol–water.

Photodimerization in the Absence of Water. Method 1: *p*-FCA crystals were placed over phosphorus pentoxide in a petri dish with a glass cover. The dish was then irradiated with sun-light or a 450-W high-pressure mercury lamp until no further change was observed in the UV spectrum. Found: C, 67.71; H, 4.44%. Calcd for $C_{20}H_{18}O_6$: C, 68.18; H, 4.58%. *Method 2*: *p*-FCA crystals (0.3 g) were dispersed in thoroughly dried hexane (100 ml) and irradiated for 2 h in the way described above.

Identification and Quantitative Analysis of Water in the Dimer. All the crude dimers, which has been prepared in the presence of water and has been confirmed to be free from monomers by a study of their UV spectra, were dried in a dessicator over phosphorus pentoxide for 2 days at room temperature *in vacuo*. Differential scanning calorimetry (DSC) and thermogravimetric (TG) analysis were carried out with a Rigaku Standard DSC-TGA instrument at the heating rate of 10 °C/min under nitrogen.

The amounts of water in the dimer were determined by titration with Karl Fischer reagent (Mitsubishi Kasei). An accurately weighed dimer was dissolved in a dehydrated solvent (Mitsubishi Kasei) and titrated with a Karl Fischer reagent. The amounts of water in the dimer were calculated by means of the following equation:

$$\text{Weight (\%) of water in the dimer} = \text{ml of Karl Fischer reagent consumed } x \text{ factor of Karl Fischer reagent/weight of the dimer}$$

Formation of Anhydride Dimer. The dimer (0.3 g) was refluxed in acetic anhydride for 5 h. After removal of acetic anhydride, the residue was washed with ethanol and dried. The obtained product showed the absorption peaks at 1880 and 1790 cm^{-1} on the IR spectrum.

Results and Discussion

Crystalline Modification of p-*FCA.* Two crystalline modifications were found in *p*-FCA crystals, depending on the crystallization procedure. From an ethanol solution, photo-active crystals (*β*-form) are obtained, while photostable crystals (*γ*-form) are obtained from an

acetone solution. The two crystals give different intensities of absorption peaks (940, 990, and 1210—1230 cm^{-1}) in the IR spectra which are due to a carboxylic acid residue. The X-ray diffraction patterns are also different from each other (β-form, 17.2, 26.6°, γ-form, 16.9, 19.3, 23.6, 25.4, 26.8, 28.7°). However, both crystals show the same melting point (249 °C) and no phase-transition points have been observed by DSC analysis over the temperature range from room temperature to melting point.

Photodimerization of p-*FCA.* The product obtained by the irradiation of *p*-FCA crystals in the presence of water was identified as its dimer on the basis of the following data.

1. The IR spectrum of the product (Fig. 1) shows the disappearance of double bonds (1640 cm^{-1}, νC=C aliphatic).

2. In the NMR spectrum of the product, cyclobutane ring protons appear at 3.8—4.5 ppm.

However, the results of the elemental analysis of the product do not agree with the calculated value of the dimer and suggest the presence of one molecule of water in each dimer. The DSC diagram (Fig. 2-A) of the dimer shows three endothermic peaks at 105, 178, and 180 °C. The 105 °C peak which is broad and is accompanied by a weight loss, is considered to be the elimination of water from the dimer since the results of the elemental analysis of heat-treated dimer show that it has no water molecule and the DSC diagram shows two peaks at 178 and 180 °C, and no peak at 105 °C. The amounts of water in the dimer was determined to be 4.9% by means of the Karl Fischer reagent. This value indicates that each dimer has one molecule of water (Calcd 4.8%). Thus the presence of water in the *p*-FCA dimer was concluded. The peak at 178 °C was found to be due to the formation of cyclic anhydride from carboxylic acid residues; this was confirmed by the IR spectrum of the dimer heated up to 178 °C. The peak at 180 °C is its melting point. The IR spectrum of the water-free dimer is given in Fig. 1-B. The difference in the peaks at 3500, 1730, and 1350 cm^{-1} from those of the dimer with water (Fig. 1-A) is concluded to be due to the elimination of water. The X-ray diffraction patterns of the water-free dimer become different from those of the dimer with water.

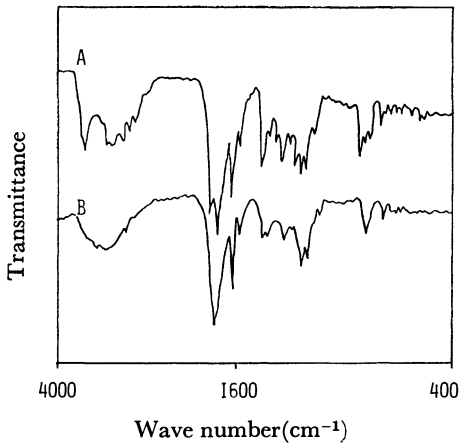

Fig. 1. IR spectra of *p*-FCA dimers.
A: The dimer obtained in the presence of water,
B: the water-free dimer obtained by heating above dimer.

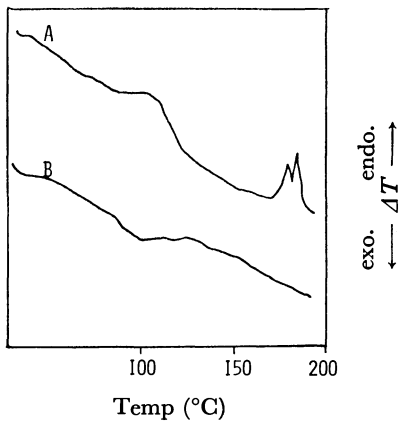

Fig. 2. DSC diagrams of *p*-FCA dimers.
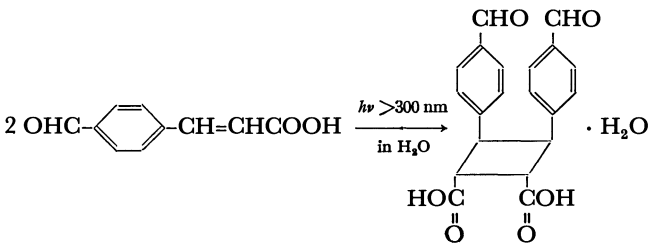
A: The dimer obtained in the presence of water,
B: the dimer obtained in the absence of water.

The structure of the dimer was dertermined by anhydride formation from carboxylic acid residues. The IR spectrum of anhydride dimer indicates the formation of five-membered-ring anhydride and the NMR spectrum of its cyclobutane-ring protons is symmetrical. These data indicate the formation of a β-truxinic acid type dimer (4,4'-diformyl-β-truxinic acid).



When the dimer in an ethanol or a dimethyl sulfoxide solution was irradiated with light (251 nm), it decomposed into *p*-FCA with cyclobutane-ring cleavage (Fig. 3).

The photodimerization of *p*-FCA crystals in the absence of water proceeds very differently in several points. The product obtained in the absence of water shows almost the same IR spectrum as that of the water-free dimer (Fig. 1-B) and the same NMR spectrum as that obtained in the presence of water.

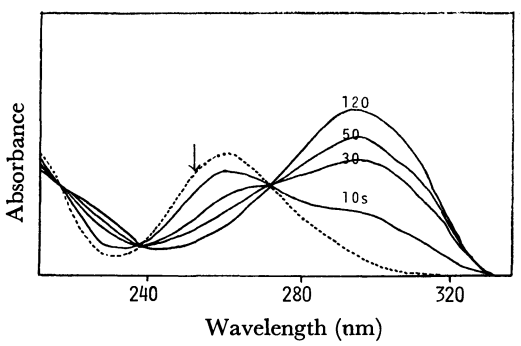


Fig. 3. Change in UV spectrum on irradiation of *p*-FCA dimer in ethanol solution.
------: Before irradiation, ——: after irradiation.

In the DSC diagram (Fig. 2-B) only the exothermic peak (100—110 °C) was observed, and there was no weight loss. The elemental analysis of the product agreed with the calculated value of the dimer without water molecule. From these data it may be concluded that the product obtained in the absence of water is the same β-truxinic acid-type dimer, but without water.

Remarkable differences connected with both dimers were found in the rates of photodimerization and crystallinity. It is interesting to note that photodimerization proceeds very rapidly, forcibly taking up the surrounding water. For example, *p*-FCA crystals embedded in the KBr pellet photodimerize in about 10 min, with the incorporation of the water which is absorbed in KBr.

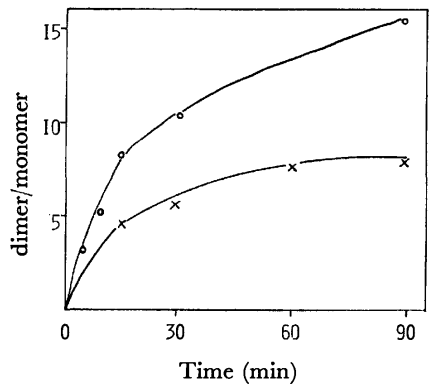

Fig. 4. Plot of dimer/monomer *vs.* time.
—○—: In water, —×—: in hexane.

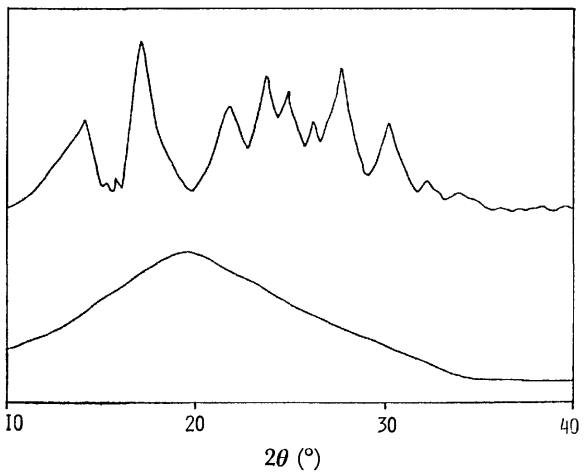

Fig. 5. X-Ray diffraction patterns of *p*-FCA dimers.
A: The dimer obtained in the presence of water,
B: the dimer obtained in the absence of water.

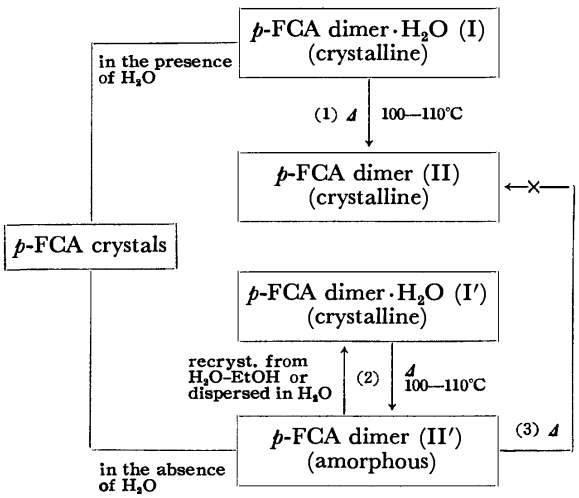
The plot of the dimer/monomer rate *vs.* the reaction time in water and hexane is shown in Fig. 4. The presence of water apparently accelerates the reaction. With respect to the crystallinity there is a prominent difference between two dimers (Fig. 5). The crystalline dimer was obtained in the presence of water, while amorphous one was obtained in the absence of water. It seems that the water molecule assists to crystallize the dimer, as is often observed in protein molecules.

The relationship of these two kinds of dimers is shown in Scheme 1.

(1) The dimer with one molecule of water (I) can be converted into the water-free crystalline dimer (II) by heating 100—110 °C *in vacuo*.

(2) The water-free amorphous dimer (II′) becomes the crystalline dimer with water (I′) by dispersing it in water as long as the irradiation time or by recrystallization from a water–ethanol solution. This process is not affected by light. The IR spectrum and X-ray diffraction patterns of the dimer (I) and the dimer (I′) are nearly identical; however, their thermal behavior is peculiarly different. The DSC diagram of the dimer (I′) shows only an endothermic peak at 100—110 °C, and it is dehydrated at that temperature not into the dimer (II) but into the water-free amorphous dimer (II′). In this point, the dimer (I′) is different from the dimer (I).

(3) The DSC diagram (Fig. 2-B) of the water-free amorphous dimer (II′) shows only an exothermic peak at 100—110 °C, which may be due to crystallization. However, it could not be converted into the water-free crystalline dimer (II) by heating at that temperature.



Scheme 1.

The observation (2) and the fact that a water solution saturated with *p*-FCA does not yield the dimer on irradiation imply that water molecule is incorporated into the dimer not after the formation of the dimer but during the photodimerization process.

Though the details of the reaction mechanism are not established yet, it is probably similar to that proposed for the solid-gas reaction of carboxylic acid and ammonia.[6] That is, if *p*-FCA crystals are exposed to light in an atmosphere of water, a dimer would be formed with the incorporation of the water molecule; at the same time, the disorientation of the crystal layer occurs sufficiently to permit the water molecule to diffuse into the next layer of *p*-FCA crystals, where the process is repeated.

Survey of Water Participation Crystalline Photodimerization of Other Cinnamic Acid Derivatives. In order to extend this new type of photodimerization of *p*-FCA to other compounds, the photodimerization of several other cinnamic acid derivatives was reinvestigated from the

viewpoint of water participation. Since the 1,2-*cis* conformation of carboxylic acid residues on a cyclobutane ring seems to be important factor in the incorporation of water, the photodimerization of several β-form crystals of cinnamic acid derivatives has been attempted in a water dispersant. The water participation was checked by the method described before. The results are given in Table 1. *p*-Nitro, *p*-chloro, and 3,4-dichlorocinnamic acid were found photodimerize in essensially the same way as *p*-FCA. The dimers from these monomers have more or less the same properties as those described in Scheme 1. However, the amounts of water incorporated into the dimer are different depending on the dimer. The dimers from β-form crystals of cinnamic acid, *o*-chloro, *m*-nitro, *p*-bromo, 2,4-, and 2,6-dichlorocinnamic acid did not incorporated any water during the photodimerization process.

Summarizing the results of the survey on the compounds which photodimerize with water participation, it can reasonablly be suggested that there is a possibility that the β-form crystals of *para*-substituted cinnamic acids photodimerize in this manner.

The Finkelstein Reaction in Acetonitrile-Glycol Mixtures.* An Approach by a Concurrent Monodentate and Bidentate Solvation Model of the Halide Ion

Yasuhiko KONDO, Kazuo TANAKA, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received February 23, 1976)

The rate constant of the reaction of methyl iodide with the bromide ion showed a characteristic dependence on the composition of solvent mixtures. In five solvent mixtures, *i.e.*, acetonitrile–ethylene glycol, –1,2-propanediol, –1,3-butanediol, –1,4-butanediol, and –2,3-butanediol, its dependence was fairly well reproduced by the theoretical equations derived on the basis of the concept of the concurrent monodentate and bidentate solvation of the halide ion by glycol. In contrast, the rate constants in acetonitrile–diethylene glycol and –triethylene glycol mixtures were better reproduced by the modified theoretical equations allowing for a self-association of glycol.

In the previous paper[1] the behavior of the rate constant of the Finkelstein reaction in acetonitrile–alcohol mixtures was discussed in terms of the multi-step solvation of anions in solvent mixtures. Several properties of the solvent which might influence the solvation energy of the anion changed simultaneously from one system to another, and this introduced extracomplexities into the treatment. In the present work, in order to understand better the concept of the multi-step solvation of anions, we intended to reduce the number of exposed parameters involved in the treatment as far as possible and to set up a visualized model of the solvation of anions in solvent mixtures.

In this paper the rate of the reaction of methyl iodide with the bromide ion in acetonitrile–glycol mixtures will be discussed on the basis of the concept of the concurrent monodentate and bidentate solvation of the anion.

Experimental

The tetrabutylammonium bromide, methyl iodide, and acetonitrile were treated as has been described elsewhere.[1] Commercial ethylene glycol, 1,2-propanediol, 1,3-butanediol, 1,4-butanediol, and diethylene glycol (all of purity>99% by GLPC) were dried over anhydrous sodium sulfate and distilled twice under reduced pressure. Commercial 2,3-butanediol (*dl*: 52.3%, *meso*: 46.6% by GLPC) and triethylene glycol (>96% by GLPC) were treated similarly.

The densities of the solvent mixtures were measured with a single-stem pycnometer with a capacity of *ca.* 30 ml; the interpolated values are summarized in Table 1.

The rate measurements were performed as has been described elsewhere.[1]

The experimental uncertainties of the rate constant were estimated to be less than ±2% from duplicate or triplicate runs. The average values are summarized in Table 2.

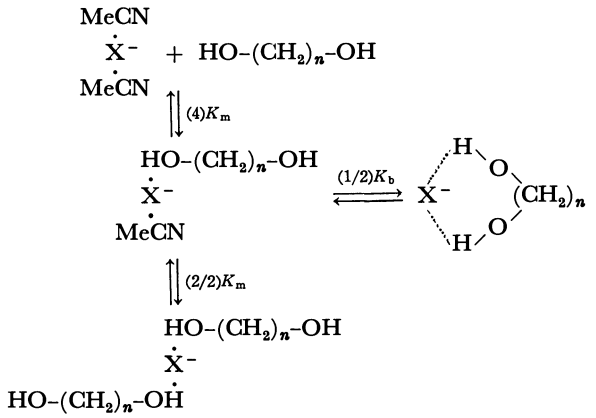
Results and Discussion

Rate Constants in Acetonitrile–Glycol Mixtures. In acetonitrile–glycol mixtures the logarithmic rate constants show a marked negative deviation from the line connecting the values in pure solvents, *i.e.*, $x_1 \ln k_1 + x_4 \ln k_4$, where k_1 and k_4 stand for the rate constant in Solvents 1 and 4, while x_1 and x_4 correspond to the mole fractions of Solvents 1 and 4. This type of behavior can be ascribed to the specific solvation of a reactant by the solvent, tending to lower the rate of reaction.[1,2]

For the purpose of reducing the complexity of the derived final equations, we set up the following scheme for the solvation of the halide ion in acetonitrile–glycol mixtures:



Scheme 1.

where K_m and K_b stand for the parameters corresponding to a monodentate and bidentate interaction of the glycol molecule with the halide ion and where the numbers in parentheses are the statistical factors of the reaction. Two such factors are combined to give the equilibrium constant of the reaction.

According to the same line of treatment as has been described in the previous papers,[1,3] the rate constants of

$$CH_3I + Br^- \longrightarrow CH_3Br + I^-$$

the reaction in mixed solvents, k_{mix}, are given by these equations:

$$\ln k_{mix} = \ln k_1 + \ln\{2K_m(2K_m+K_b)\} - \ln\{(x_4+2K_m x_1)^2+2K_m K_b x_1\} + \ln(V_{mix}/V_1) \quad (1)$$

$$(k_4/k_1) = 2K_m(2K_m+K_b)(V_4/V_1) \quad (2)$$

where V_1, V_4, and V_{mix} stand for the molar volumes of pure Solvent 1, of pure Solvent 4, and of a mixed solvent respectively. In the present series of solvent mixtures, k_4 is always the rate constant in acetonitrile.

Two parameters are included in these equations as a consequence of the proposed model. Since Eq. 2 serves as a boundary condition for the parameters, there is only one parameter left to be adjusted in reproducing the data. In Figs. 1 and 2 the theoretical values are compared with the experimental values.

One noticeable trend shown in Table 3 is that, as the distance between the hydroxyl groups gets larger and as the hydrocarbon moiety around the hydroxyl group becomes more bulky, the unidentate solvation mode takes the place of a bidentate solvation mode. This

feature is in accord with our chemical intuitions.

Rate Constants in Acetonitrile–Diethylene Glycol and –Triethylene Glycol Mixtures. In contrast to the results shown above, the rate constants in diethylene glycol and triethylene glycol–acetonitrile mixtures exhibit marked negative deviations from the values estimated on the basis of the above treatment (Fig. 3).

One of the factors not taken into account in the above treatment, but which is likely to be operating in the present systems, is a self-association of the glycol through the hydrogen bonding of a hydroxyl group to an ether linkage.

For the system in which a glycol forms acyclic long-chain polymers through self-association,[4] the mole fractions of a monomer glycol and of acetonitrile, defined in terms of moles in solution, *i.e.*, y_1 and y_4, are related to the stoichiometric mole fractions of glycol and of acetonitrile, *i.e.*, x_1 and x_4, by the following equations, as will be described in the Appendix:

$$y_1 = \frac{1}{2K(1+K)x_1}\{2Kx_1+1-(4Kx_1x_4+1)^{1/2}\} \quad (3)$$

$$y_4 = \frac{1-(K+1)y_1}{1-Ky_1} \quad (4)$$

where K stands for the equilibrium constant of the self-association.

$$[HO\text{-}(CH_2CH_2O)_m\text{-}H]_{n-1} + HO\text{-}(CH_2CH_2O)_m\text{-}H \rightleftarrows [HO\text{-}(CH_2CH_2O)_m\text{-}H]_n$$

According to a line of treatment described elsewhere,[1,3] except for the additional assumption that only a monomer glycol, and not polymers, can participate in the specific solvation of the halide ion, the activity coefficient of a halide ion in a solvent mixture, $\beta_{2,\mathrm{mix}}$ is given by Eq. 5 (see Appendix). The rate constant in these mixtures, k_{mix}, is given by Eq. 6, and the k_4/k_1 ratio is now defined by Eq. 7:

$$\beta_{2,\mathrm{mix}} = \frac{1+\frac{Ky_1^2}{(1-Ky_1)^2}}{[1+K_0\{(y_4+2K_my_1)^2+2K_mK_by_1\}]}\left(\frac{f_2^\circ V_{\mathrm{mix}}}{RT}\right) \quad (5)$$

$$\ln k_{\mathrm{mix}} = \ln k_1 + \ln [2K_m\{2K_m+K_b(1+K)\}/(1+K)^3] - \ln \{(y_4+2K_my_1)^2+2K_mK_by_1\}/[1+\{Ky_1^2/(1-Ky_1)^2\}] + \ln (V_{\mathrm{mix}}/V_1) \quad (6)$$

$$(k_4/k_1) = \frac{2K_m\{2K_m+K_b(1+K)\}}{(1+K)^3}(V_4/V_1) \quad (7)$$

The calculations were performed as follows: (1) the values of y_1 and y_4 were calculated as functions of x_1 and x_4 from Eqs. 3 and 4, using an assumed value of K; (2) making use of these values, the rate constants were calculated by means of Eqs. 6 and 7 for an assumed value of (K_b/K_m), and (3) the procedures were repeated until the optimum fit to the experimental results was obtained.

The value found for the equilibrium constant, *i.e.*, $K=1.2$, is not unexpected, since, for the hydrogen bonding between ethanol and ether, an equilibrium constant of the same order of magnitude can be estimated from the pK_{Hb} values after correcting for its solvent dependence.[5–7]

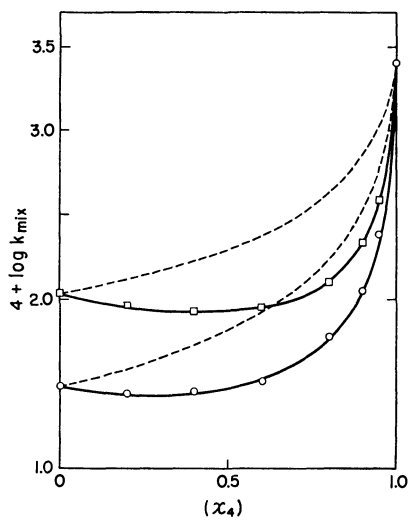

Fig. 3. Comparison of experimental and calculated data. ----; estimated values on the basis of Eqs. (1) and (2) assuming $(K_b/K_m)=0.7$, ——; calculated, ○; MeCN–diethylene glycol, □; MeCN–triethylene glycol.

As has been shown above, the values of the rate constant derived theoretically, on the basis of the solvation of the halide ion and the self-association of glycol, are in good agreement with the values observed in the various solvent mixtures. Even the phenomenon of a shallow minimum in the rate plots given in Fig. 3 is accounted for. However, although such features can be reproduced using the particular model, this does not constitute proof of the model. We feel, though, that the model is useful in accounting for the general trends observed.

We wish to thank Dr. M. H. Abraham, University of Surrey, for his discussions and for his comments on the manuscript.

Appendix

The material balances, mole fractions and equilibrium constants used in the treatment are given by these equations.

(1). Material balances,

$$N_1 = M_1 + \sum_{j=0}^{2} jM_{j2} + M_{b2} + \sum_{k=2}^{n} kM_{Ak} \quad (A\text{-}1)$$

$$N_2 = M_2 + \sum_{j=0}^{2} M_{j2} + M_{b2} \quad (A\text{-}2)$$

$$N_4 = M_4 + \sum_{j=0}^{2} (2-j)M_{j2} \quad (A\text{-}3)$$

where N_i, M_i, M_{j2}, M_{b2}, and M_{Ak} stand for the number of moles of species i before mixing, of species i in solution, of the

halide ion solvated by j mol of glycol in a monodentate way, of the halide ion solvated by glycol in a bidentate way, and of acyclic k-mer of glycol respectively.

(2). Mole fractions.

$$x_i = N_i/(N_1+N_2+N_4) \quad \text{(A-4)}$$

$$y_i = M_i/M_t \quad \text{(A-5)}$$

$$y_{j2} = M_{j2}/M_t \quad \text{(A-6)}$$

$$y_{b2} = M_{b2}/M_t \quad \text{(A-7)}$$

$$y_{Ak} = M_{Ak}/M_t \quad \text{(A-8)}$$

$$M_t = M_1 + M_2 + M_4 + M_{b2} + \sum_{j=0}^{2} M_{j2} + \sum_{k=2}^{n} M_{Ak} \quad \text{(A-9)}$$

(3). Equilibrium constants.

$$K_0 = y_{02}/(y_2 y_4^2) \quad \text{(A-10)}$$

$$4K_m = y_{12}y_4/(y_{02}y_1) \quad \text{(A-11)}$$

$$(2/2)K_m = y_{22}y_4/(y_{12}y_1) \quad \text{(A-12)}$$

$$(1/2)K_b = y_{b2}y_4/(y_{12}) \quad \text{(A-13)}$$

$$K = y_{Ak}/(y_1 y_{Ak-1}) \quad \text{(A-14)}$$

When $N_2=0$, the following relations are obtained:

$$\sum_{k=2}^{n}(k-1)y_{Ak} = Ky_1^2/(1-Ky_1)^2 \quad (\because n\to\infty) \quad \text{(A-15)}$$

$$y_1 + \sum_{k=2}^{n} k y_{Ak} = y_1/(1-Ky_1)^2 \quad (\because n\to\infty) \quad \text{(A-16)}$$

Combining Eqs. A-1, A-3, A-4, A-5, A-9, A-14, A-15, and A-16, two kinds of mole fraction are related to each other by these equations:

$$x_1 = N_1/(N_1+N_4) = y_1/\{(1-Ky_1)^2+Ky_1^2\} \quad \text{(A-17)}$$

$$x_4 = N_4/(N_1+N_4) = y_4(1-Ky_1)^2/\{(1-Ky_1)^2+Ky_1^2\} \quad \text{(A-18)}$$

Solving Eqs. A-17, and A-18 under the condition $x_1+x_4=1$, y_1 and y_4 are given by:

$$y_1 = \frac{1}{2K(1+K)x_1}\{2Kx_1+1-(4Kx_1x_4+1)^{1/2}\} \quad \text{(A-19)}$$

$$y_4 = \{1-(K+1)y_1\}/(1-Ky_1) \quad \text{(A-20)}$$

From Eqs. A-2, A-5, A-9, A-10, A-11, A-12, A-13, and A-15, we obtain:

$$\lim_{x_2\to 0}(y_2/x_2) = \{1+\sum_{k=2}^{n}(k-1)y_{Ak}\}/\{1+\sum_{j=0}^{2}(y_{j2}/y_2)+(y_{b2}/y_2)\} = \frac{1+\dfrac{Ky_1^2}{(1-Ky_1)^2}}{1+K_0\{(y_4+2K_m y_1)^2+2K_m K_b y_1\}} \quad \text{(A-21)}$$

According to the definition of $\beta_{2,\mathrm{mix}}$ previously described,[3] the activity coefficient of a solute in a solvent mixture is given by:

$$\beta_{2,\mathrm{mix}} = \lim_{x_2\to 0}(y_2/x_2)(f_2^\circ V_{\mathrm{mix}}/RT) = \frac{1+\dfrac{Ky_1^2}{(1-Ky_1)^2}}{1+K_0\{(y_4+2K_m y_1)^2+2K_m K_b y_1\}}\left(\frac{f_2^\circ V_{\mathrm{mix}}}{RT}\right) \quad \text{(A-22)}$$

Studies on Reactions of the *N*-Phosphonium Salts of Pyridines. XIX. Carbonylation of Amines with Carbon Dioxide by Means of Phosphorus Chlorides in Tertiary Amines

Noboru YAMAZAKI, Tatsuya TOMIOKA, and Fukuji HIGASHI

Department of Polymer Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 2, 1976)

Reactions of carbon dioxide and disulfide with primary amines in the presence of phosphorus chlorides gave the corresponding symmetrically disubstituted ureas and thioureas in high yields under atmospheric conditions. Phosphorus trichloride and di- and mono-chlorophosphites were remarkably effective for the reactions, whereas phosphorus pentachloride and phosphoryl chloride were ineffective. The presence of tertiary amines such as pyridine satisfactorily favored the reactions. The reaction seems to proceed *via* the *N*-phosphonium salts of pyridines as those obtained from diphenyl and triaryl phosphites, on the basis of their IR spectroscopic analyses, stoichiometric relationship between reactants and the steric effect of tertiary amines.

Phosphorous acid hexaalkyltriamide (**1**) prepared from phosphorus trichloride and secondary amines afforded the corresponding carbamoyloxy compounds (**2**) by inserting carbon dioxide.[1] **2** was aminolysed with primary amines into ureas, but not with secondary amines.[2]

$$PCl_3 + 6R_2NH \longrightarrow \underset{(\mathbf{1})}{P(NR_2)_3} \xrightarrow{CO_2} \underset{(\mathbf{2})}{P(OCONR_2)_x(NR_2)_{3-x}}\ (x=1, 2)$$

$$\xrightarrow{R_2NH} R_2NCONR_2 \qquad \xrightarrow{RNH_2} RNHCONR_2$$

Some primary amines also reacted with phosphorus trichloride to give the phosphorus–nitrogen compounds such as phosphenimidous amide derivatives (RNH–P=NR) from the aromatic amines,[3] and the amides (P-(NHR)$_3$) from the alkylamines.[4] However, these phosphorus–nitrogen compounds have not been fully investigated, nor has the insertion reaction of carbon dioxide been reported.

The phosphorus–nitrogen bonds in these phosphorous amides and imides were expected to bring about the reaction with carbon dioxide, yielding ureas by aminolysis with amines as those in **1**. Ureas were, in fact, obtained in high yields using PCl_3 and chlorophosphites ($RO-PCl_2$, $(RO)_2-PCl$) in pyridine,[5] and the reaction was successfully applied to the preparation of polyureas under mild conditions.[6]

This paper gives detailed results of the reactions of phosphorus chloride and primary amines with carbon dioxide and disulfide in the presence of tertiary amines.

$$CX_2 + 2RNH_2 + \begin{cases} PCl_3 \\ RO-PCl_2 \\ (RO)_2-PCl \end{cases} \longrightarrow RNHC(X)NHR \quad (X=O, S)$$

Results and Discussion

When carbon dioxide was passed at 60 °C for 6 h into a cylindrical flask[7] containing phosphorus trichloride and aniline (4 equiv.) in pyridine, *N,N'*-diphenylurea was obtained in 93% yield based on aniline. The yield was lowered to 21%, when the reaction was carried out in the absence of pyridine by using 7 equivalents of aniline (3 equivalent excess as HCl scavenger) in toluene, suggesting that pyridine significantly facilitates the reaction.

Table 1. *N,N'*-Diphenylurea from carbon dioxide and aniline by use of phosphorus trichloride in various tertiary amines at 60 °C for 6 h

Tertiary amine	pK_a	Yield, %[a]
None	—	21[b]

β-Picoline	5.52	85
α-Picoline	6.20	73
2,4-Lutidine	6.99	77
2,6-Lutidine	6.99	28
Triethylamine	10.87	50[c]

a) Based on aniline used. b) In toluene.
c) In an autoclave at 20 atm of CO_2.

In order to elucidate the favorable effect of tertiary amines on the reaction, the reaction of carbon dioxide with aniline was investigated in several tertiary amines (Table 1). The presence of tertiary amines favored the reaction; of the tested amines, pyridine and β- and γ-picolines with smaller steric hindrance around the nitrogen atom gave satisfactory yields, whereas the yield was lowered in sterically hindered amines such as α-picoline and 2,4-lutidine, and strikingly low in 2,6-lutidine with the largest hindrance in pyridine derivatives. The unsatisfactory result in highly basic triethylamine even under severe reaction conditions indicated that the steric hindrance was more influential than the basicity.

Various ureas were prepared using phosphorus trichloride in pyridine (Table 2). In the reactions of amines more basic than pyridine, 7 equivalents of the amines were used, since 3 equivalents were consumed as HCl scavenger. Primary amines afforded the corresponding *N,N'*-disubstituted ureas, whereas secondary amines gave no ureas.

a) Yield (%) based on aniline used.

Other phosphorus chlorides were tested in the reaction of carbon dioxide with aniline in pyridine (Table 3). Phenyl dichlorophosphite gave the best results, giving a nearly quantitative yield of *N,N'*-diphenylurea from both 2 and 4 equivalents of aniline. Monochlorophosphites gave moderate results. On the other hand, phosphorus(V) chlorides afforded no urea, but the corresponding phosphorus amides; phosphoryl chloride and phenylphosphinylidene dichloride yielded phosphoric trianilide and phenylphosphinic dianilide in 69 and 60% yields, respectively. These anilides unreactive to carbon dioxide gave no urea.

Similar to the reaction of carbon dioxide, carbon disulfide reacted with aniline in pyridine with use of phosphorus trichloride and phenyl dichlorophosphite, yielding thioureas in high yields (Table 4).

The reaction of carbon dioxide with aniline was carried out by varying the molar ratios of aniline to phosphorus chlorides, in order to examine how many mols of aniline can be converted into urea by one mol of phosphorus chloride. Figure 1 shows the variation of the produced amount of *N,N'*-diphenylurea with the ratio, indicating an increase of amount until a limiting value of *ca.* 4. Above this value, no substantial increase was found by additional aniline.

The results are represented in another way in terms of the yields based on phosphorus chloride (Fig. 2). Nearly quantitative yields were obtained at the ratio of 4 for phosphorus trichloride, and at both ratios of 2 and 4 for phenyl dichlorophosphite.

The results in Figs. 1 and 2 indicate that the trichloride can transform 4 mol of aniline into 2 mol of *N,N'*-diphenylurea, whereas the dichlorophosphite can react with 2 mol of aniline into 1 mol of the urea, and also with 4 mol of aniline into 2 mol of the urea.

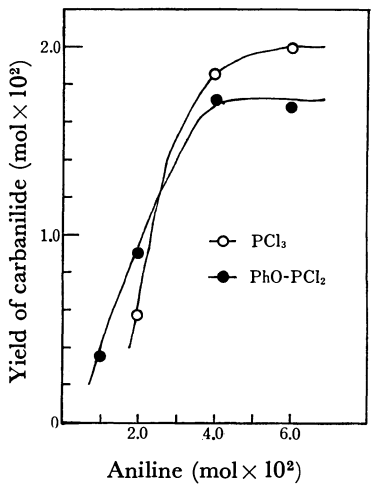

Fig. 1. Variation of urea yield with the amount of aniline employed: PCl_3=$PhO-PCl_2$=0.01 mol; temperature=60 °C; time=6 h.

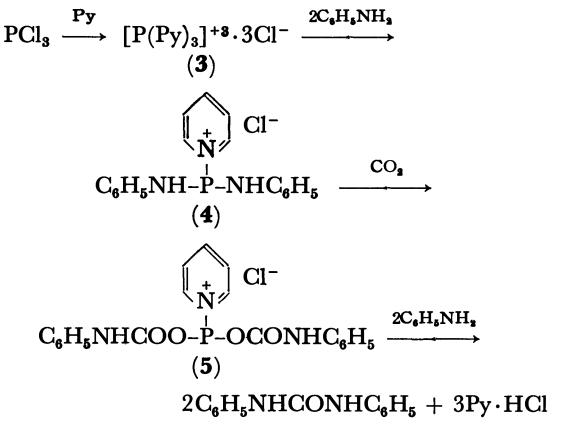


Scheme 1.

The results can explain the reaction with phosphorus trichloride in the following way (Scheme 1). The chloride in pyridine first forms a phosphonium salt (**3**), which then reacts with aniline to give **4**. The salt is also called *N*-phosphonium salt of pyridine[7] but it could be named pyridinium salt. Insertion of carbon dioxide into the phosphorus-nitrogen bonds in **4** results in a carbamoyloxy *N*-phosphonium salt (**5**) which is similar to that obtained from diphenyl phosphite.[8] Aminolysis of **5** with additional aniline gives urea.

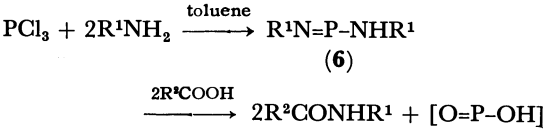
In order to confirm the proposed mechanism, **4** was obtained as a syrup contaminated with pyridine hydrochloride, after the reaction mixture of phosphorus trichloride and aniline in pyridine had been extracted with ether until no detectable amounts of pyridine and aniline were found in the ether layer.

In the IR spectrum of the syrup, a peak at 1630 cm^{-1} is due to ν C=N+ of the *N*-phosphonium salt of pyridine, and is in good agreement with that of the phosphonium salts[7] given by the oxidation of phosphites in pyridine followed by aminolysis. Although the band is overlapped with that of pyridine hydrochloride, the latter intensity contained in the band is less than half, judging from the medium intensity of a couple of other peaks due to hydrochloride.

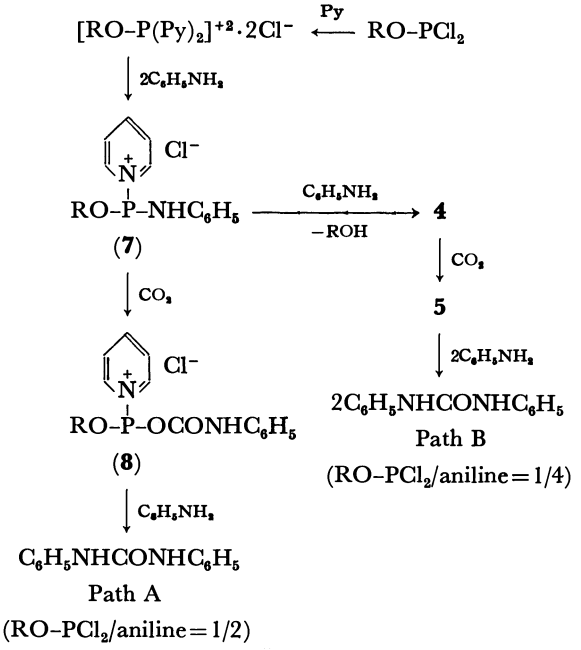
The syrup was decomposed in 1 M-sodium hydroxide, and the liberated pyridine and aniline were extracted with ether. The results of GLC analyses of the extract indicate that 3 mol of pyridine and 2 mol of aniline are present in the syrup. According to Scheme 1, **4** was contaminated with 2 mol of pyridine hydrochloride. Thus 1 mol of pyridine and 2 mol of aniline are involved in **4**.

In the reaction with amines more basic than pyridine such as cyclohexylamine, 3 mol of pyridine of **3** may be replaced by the amines to form triamide, and the amine hydrochloride, and 7 mol of the amine added can theoretically produce only 1 mol of the urea. However, better yield (1.64 mol) of the urea excluded the involvement of the triamide intermediate, although it is not clear why **3** did not react with 3 mol of the amine.

Another possible intermediate is a phosphenimidous derivative (**6**), which was proposed in amidation of carboxylic acids as shown before:[9]



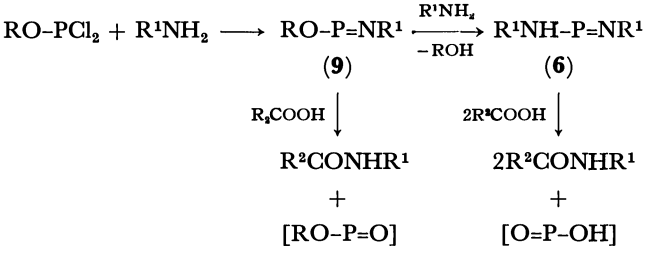
However, it can not be a dominant one in the reaction of carbon dioxide, since only a small amount (12% yield based on aniline) of **6** was obtained from the reaction mixture of phosphorus trichloride and aniline in pyridine. A separate reaction of **6** with carbon dioxide and aniline gave *N*,*N*′-diphenylurea in 38% yield as compared to 93% in the standard procedure in this study.



Scheme 2.

Similarly, dichlorophosphites might bring about two different reactions involving 2 and 4 equivalents of aniline (Scheme 2). In Path A phosphites react initially with 1 equivalent of aniline to give the *N*-phosphonium

salt (**7**) like **4**, which is converted into *N,N'*-diphenylurea by treating with carbon dioxide and then with aniline (RO–PCl_2/aniline=1/2). In Path B (RO–PCl_2/aniline=1/4), **7** reacts further with additional aniline to afford **4** by releasing phenol or alcohols. Insertion of carbon dioxide into the P–N bonds of **4** followed by aminolysis yields *N,N'*-diphenylurea. Actually, phenol (R=C_6H_5–) was obtained in 42% yield in the reaction by Path B. Better results with phenyl dichlorophosphite than with ethyl dichlorophosphite in Path B (Table 3) may be due to easier dephenoxylation than deethylation which promotes the formation of **4**.



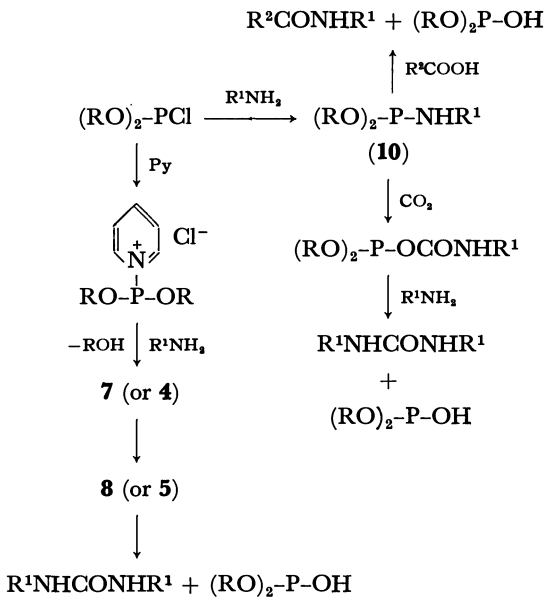
Scheme 3.

An alternative mechanism[11] *via* a phosphinimidite **6** and **9** proposed for amidation of carboxylic acids may not be reasonable, because of the lower reactivity of **6** to carbon dioxide (Scheme 3).

Similarly, the reaction with monochlorophosphites may proceed *via* the *N*-phosphonium salts of pyridine (**7** and **8**, or **4** and **5**) by releasing alcohols and phenol. Phenol was found in 47% yield (about a half of two phenoxy groups in the phosphite) in the reaction mixture with diphenyl monochlorophosphite.

An amidophosphite[11] also can be considered as an intermediate. In a separate experiment, diethyl anilidophosphite (**10**) gave the urea in 25% yield which is comparable to 29% obtained by the reaction with diethyl chlorophosphite.

Thus the reaction with monochlorophosphites may involve two paths as above (Scheme 4).



Scheme 4.

Experimental

N,N'-Diphenylurea from Carbon Dioxide and Aniline by Use of Phosphorus Trichloride in Various Tertiary Amines. Gaseous carbon dioxide was introduced at 60 °C for 6 h into a cylindrical flask containing a mixture of phosphorus trichloride (0.01 mol) and aniline (0.04 mol) in 30 ml of tertiary amines. In volatile triethylamine, the reaction was carried out in an autoclave at the pressure (20 atm) of carbon dioxide. The reaction was also carried out in 40 ml of toluene by using phosphorus trichloride (0.01 mol) and aniline (0.04 mol). The reaction mixture was condensed to a syrup under reduced pressure, and then treated with 20 ml of 50% aqueous ethanol, yielding *N,N'*-diphenylurea in high yields (Table 1).

Separation and Decomposition of **4**. A mixture of phosphorus trichloride (0.01 mol) and aniline (0.04 mol) in 30 ml of pyridine was heated at 40 °C for 1 h, and the mixture was extracted with dry ether until no pyridine and aniline were detected in the ether solution. **4** was separated as an ether-insoluble syrup, and was decomposed in 20 ml of 1 M-sodium hydroxide at ambient temperature for 1 h. The aqueous solution was extracted well with ether, and the combined ether solution was subjected to gas-liquid chromatographic analyses.

N,N'-Disubstituted Ureas from Carbon Dioxide and Various Amines by Use of Phosphorus Trichloride in Pyridine. Similarly, carbonylation of amines (0.04 mol) or amines (0.07 mol) more basic than pyridine was carried out at 60 °C for 6 h by adding the amines in pyridine to a mixture of phosphorus trichloride (0.01 mol) and pyridine (30 ml). Ureas were obtained by working up as above.

N,N'-Diphenylurea from Aniline and Carbon Dioxide by Use of Various Phosphorus Chlorides in Pyridine. The urea was obtained by the reaction at 60 °C for 6 h in 30 ml of pyridine with use of phosphorus chlorides (0.01 mol) and aniline (0.02—0.05 mol).

Thioureas from Carbon Disulfide and Amines by Use of Phosphorus Chlorides in Pyridine. A mixture of amines (0.02—0.07 mol) and phosphorus chlorides (0.01 mol) in 30 ml of pyridine was heated at 40 °C for 6 h. The resulting mixture was evaporated to a syrup under reduced pressure. Thioureas were obtained by treating the syrup with 20 ml of 50% aqueous ethanol.

(Received March 13, 1976)

Reactions of 2-guanidino-1-cyclohexanols (**1**, $\mathbf{1}_d$, $\mathbf{1}_l$) with 1,1-dimethoxycyclohexane in *N,N*-dimethylformamide in the presence of *p*-toluenesulfonic acid gave the *N,O*-cyclohexylidene derivatives (**5**, $\mathbf{5}_d$, $\mathbf{5}_l$), respectively. Similar reactions of $\mathbf{1}_l$ with 2,2-dimethoxypropane and with dimethyl acetals of *p*-tolualdehyde and *p*-bromobenzaldehyde also gave an *N,O*-isopropylindene, *N,O*-(*p*-methylbenzylidene) and *N,O*-(*p*-bromobenzylidene) derivative ($\mathbf{8}_l$, $\mathbf{9}_l$, $\mathbf{10}_l$), respectively. From IR and PMR spectral studies of $\mathbf{9}_l$ *p*-toluenesulfonate, seven-membered structures as exemplified by **9A** were assigned. The *N,O*-blocked derivatives (**5**,**9**) are stable in weakly acidic or alkaline media, but in stronger media, they are cleaved to **1**. The usefulness of the protective groups was also examined. **9** was found to resist tosylation or mesylation in pyridine but not acylation. The numerical values of optical rotations of the guanidinocyclohexanols were greatly enhanced by *N,O*-blocking.

During the course of synthetic studies on dihydrostreptomycin and related compounds, we undertook to protect the hydroxyl groups of the antibiotic by conversion into acetals or ketals. When 2″-*N*-benzyloxycarbonyldihydrostreptomycin[1] was treated with 1,1-dimethoxycyclohexane, a ketal reagent, in *N,N*-dimethylformamide (DMF) in the presence of acid catalyst, we obtained a tetracyclohexylidenated derivative. The product was found to contain no *O*-(1-methoxycyclohexyl) group[6] as judged by the PMR spectrum, although it was not isolated in crystalline state. This fact was unusual, since the starting material has only three sets of hydroxyl groups for the ketal formation. The fourth cyclohexylidene group might be formed between the guanidino and hydroxyl groups in the streptidine moiety of the dihydrostreptomycin. In order to clarify the above structure, we chose *trans*-2-guanidino-1-cyclohexanol (**1**) as a model compound and treated it with 1,1-dimethoxycyclohexane in the presence of acid catalyst. Since the compound has *trans*-diequatorial guanidino and hydroxyl groups attached to a cyclohexane ring, the compound can be deemed as a model compound for the streptidine portion of dihydrostreptomycin.

The *dl-trans*-2-guanidino-1-cyclohexanol (**1**) was prepared from *dl-trans*-2-amino-1-cyclohexanol by the reaction with *S*-methylisothiourea as described by Bannard *et al.*[2] The optically active isomers ($\mathbf{1}_d$, $\mathbf{1}_l$) were also prepared from *d*- and *l*-2-amino-1-cyclohexanol,[3,4] respectively. Since the guanidino compounds were scarcely soluble in common organic solvents, they were converted into the salts of *p*-toluenesulfonic acid which are fairly soluble in organic solvents. These *p*-toluenesulfonates were treated with 1,1-dimethoxycyclohexane in DMF in the presence of *p*-toluenesulfonic acid. The reaction was carried out to completion[5] under reduced pressure in order to remove the generated methanol. The products ($\mathbf{5}_d$, $\mathbf{5}_l$, and **5**) obtained in good yields were confirmed to have a cyclohexylidene group by elementary analyses and PMR spectral studies. Absence of the methoxyl group shown by PMR spectra ruled out the presence of the 1-methoxycyclohexyl group which is often formed[6] in the reaction between a single hydroxyl group and 1,1-dimethoxycyclohexane. These results show that the cyclohexylidene group is bifunctionally coupled to the hydroxyl and guanidine groups, or to the amino and imino groups of the guanidine portion. The presumption is also supported[7] by the difference of the color reactions of **5** and **1** for Sakaguchi reagent; **5** was negative, whereas **1** was positive, suggesting that compound **5** is a di- or tri-*N*-substituted guanidine.

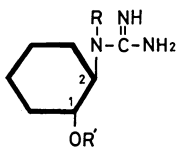
As control experiments, the *p*-toluenesulfonates of guanidinocyclohexane,[2] 2-amino-1-cyclohexanol, and 2-methylamino-1-cyclohexanol[8] were each treated with 1,1-dimethoxycyclohexane. However, no reaction took place.

In order to confirm the absence of a free hydroxyl group in **5**, **5** *p*-toluenesulfonate was treated with acetic anhydride in pyridine in the presence of triethylamine. A mixture of two products, which could not be separated by silica gel column chromatography due to their unstable nature, was obtained. However, the IR spectrum of the mixture showed no absorption peaks between 1700—1800 cm^{-1} indicating the absence of the *O*-acetyl group. On the other hand, a similar acetylation of **1** *p*-toluenesulfonate gave a triacetyl derivative (**4**), which showed an absorption peak at 1730 cm^{-1}. When the salt of **1** was acetylated with acetic anhydride in pyridine without addition of triethylamine, a mono-*O*-acetyl derivative (**3**) was formed. These results and the aforementioned result that no reaction occurs between 1-guanidinocyclohexane and 1,1-dimethoxycyclohexane indicated that **5** has a cyclohexylidene group attached to N and O, but not to N and N.

Methoxycarbonylation of **5** *p*-toluenesulfonate with methyl chloroformate and sodium hydride afforded an *N*-methoxycarbonyl derivative (**6**) in a 29% yield. Acetylation of **6** with acetic anhydride in pyridine readily gave an *N*(or *N*′**)-acetyl-*N*(or *N*′)-methoxycarbonyl derivative (**7**) as judged from their IR spectra.

$\mathbf{1}_l$ *p*-Toluenesulfonate was treated with another ketal, 2,2-dimethoxypropane in a similar manner to that for **5** to give an *N,O*-isopropylidene derivative ($\mathbf{8}_l$) in a low yield. This may be ascribed[5] to the closeness of the

** For the sake of convenience the nitrogen directly attached to the cyclohexane ring is denoted by N and the other nitrogens by N′.



1 R = H R' = H
2 = CH_3 = H
3 = H = Ac

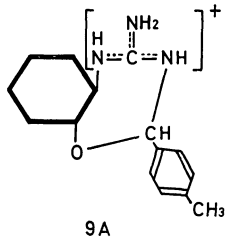
7

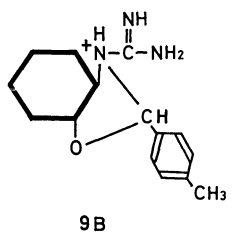
boiling points of 2,2-dimethoxypropane and methanol liberated. The structure of $\mathbf{8}_l$ was also confirmed by the acetylation of $\mathbf{8}_l$ as for **5**.

Determination of the position of nitrogen attached to the cyclohexylidene group was attempted. For this purpose, *p*-methylbenzylidene and *p*-bromobenzylidene derivatives ($\mathbf{9}_l$, $\mathbf{10}_l$)*** of $\mathbf{1}_l$ were prepared, since they were expected to have a structure similar to the cyclohexylidene derivatives (**5**, $\mathbf{5}_d$, and $\mathbf{5}_l$), and the benzylidene methine protons of the derivatives were expected to couple, in the PMR spectra, with the NH protons of the guanidine groups attached to the methine, thus revealing the position of the nitrogen in question. In the PMR spectrum of $\mathbf{9}_l$ *p*-toluenesulfonate in deuteriochloroform, the methine proton appeared as a doublet at δ 5.50. On irradiation at δ 8.34, or on deuteration, the doublet collapsed to a singlet. This suggests that the *p*-methylbenzylidene group is attached to a nitrogen bearing one hydrogen atom. However, it is still not possible to decide which one of the three nitrogens of the guanidine group is the nitrogen in question, since both **9A** and **9B** satisfy the above PMR spectral results.

Successful result was obtained from further PMR study on $\mathbf{9}_l$. Nuclear Overhauser effect was observed between the benzylidene methine proton (δ 5.50) and one of the methine protons (δ 3.2) of the cyclohexane ring. Examination of the stereomodels of **9A** and **9B** showed that only the structure **9A** can take the structure in which H-1 or H-2 of the cyclohexane ring and the methine hydrogen of the benzylidene group approach near enough for interaction. These observations suggest the structure **9A** for **9**. The IR spectra of $\mathbf{5}_d$, $\mathbf{8}_l$, $\mathbf{9}_l$, and $\mathbf{10}_l$ also supported the seven-membered structure as depicted in **9A** by the differences (75—95 cm^{-1}) in wavelength of two kinds of peaks at $\approx$1670 and $\approx$1590 cm^{-1} assignable to guanidinium ions as reported by Goto *et al.*[9]



9A



9B

In order to further confirm the structure, we prepared 2-(1-methylguanidino)-1-cyclohexanol (**2**, racemic), which has no hydrogen atom at N-1 of the guanidine portion, from 2-methylamino-1-cyclohexanol (racemic), and the **2** *p*-toluenesulfonate was treated with 1,1-dimethoxycyclohexane in a similar manner to that described above. However, this experiment was unsuccessful since no reaction occurred, suggesting that the 1-*N*-methyl group sterically hinders the ring formation or that the presence of the methyl group reduces the resonance stabilization of the guanidinium ion.

X-Ray crystallographic analysis[10] of $\mathbf{5}_d$ *p*-toluenesulfonate has been carried out and the result also supports the seven-membered structure.

In order to see if the above mentioned cyclohexylidenation, isopropylidenation, and benzylidenation can provide novel instances for *N,O*-protection, we first examined the stability of the protective groups in acidic or alkaline media. The compounds were fairly stable in weak acidic or weak alkaline media, but in moderately acidic or alkaline media, they were cleaved to the starting material (**1**) in a fairly short period.

In order to examine the usefulness of protection in synthesis, $\mathbf{9}_l$, selected as a model compound, was treated in pyridine with *p*-toluenesulfonyl or methanesulfonyl chlorides. The starting material ($\mathbf{9}_l$) was recovered in good yields showing that the *p*-methylbenzylidene group, as well as the guanidine portion, can resist the reaction. However, when $\mathbf{9}_l$ was treated in pyridine with acetic anhydride or benzoyl chloride at room temperature overnight, $\mathbf{9}_l$ was found to change, although the product was not identified. In the reaction of $\mathbf{9}_l$ with 50% sodium iodide in DMF at 100 °C, $\mathbf{9}_l$ resisted for 5 min, but gradually changed to **1** in a longer period. On the catalytic hydrogenation with palladium black or Raney nickel at room temperature, **5** and $\mathbf{9}_l$ were found to be stable at least for 10 h.

The *N,O*-blocked derivatives show high enhancement of the rotational value in magnitude as compared with **1**

Table 1.

Compound as *p*-toluenesulfonate	$[\alpha]_D$ (in methanol)
$\mathbf{1}_d$	−14°

$\mathbf{5}_d$	−88°
$\mathbf{5}_l$	+84°
$\mathbf{8}_l$	+114°
$\mathbf{9}_l$	+123°
$\mathbf{10}_l$	+121°

*** By acetal formation, an asymmetric center is produced at the benzylidene methine carbon. However, in the present case, we can discuss the structures ($\mathbf{9}_l$ and $\mathbf{10}_l$) without taking the configuration of the methine into consideration.

(Table 1). This could be utilized for assigning the absolute configurations of compounds related to **1**.

Experimental

PMR spectra were recorded at 60 and 100 MHz on Hitachi R-24A and Varian XL-100 spectrometers. Thin-layer chromatography (TLC) was performed on plates of Wakogel B-5 with sulfuric acid spray for detection. For column chromatography, silica gel (Wakogel C-200) was used. When the solvent system of chloroform–methanol–28% ammonia was used with varying the ratio, the lower layers were used.

1-Guanidinocyclohexane p-*Toluenesulfonate.* A mixture of cyclohexylamine (4.75 g), *S*-methylisothiouronium sulfate (6.65 g), and water (19 ml) was treated in a similar way to that described by Bannard *et al.*,[2] and worked up as follows: After concentration to approximately two-thirds of the original volume, the reaction mixture was charged on a column of Dowex 1×2 resin (OH form, 250 ml) and developed with water. The strongly alkaline fractions were neutralized with *p*-toluenesulfonic acid and concentrated to give a solid, which was recrystallized from water to give needles, 6.65 g (44%), mp 67—69 °C. IR (KBr): 1670, 1640 cm^{-1}.

Found: C, 53.84; H, 7.35; N, 13.55; S, 10.18%. Calcd for $C_7H_{15}N_3 \cdot C_7H_7SO_3H$: C, 53.65; H, 7.40; N, 13.41; S, 10.23%.

d-, l-, *and* dl-trans-*2-Guanidino-1-cyclohexanol (**1**$_d$, **1**$_l$, and **1**)* p-*Toluenesulfonates.* These were prepared from *d*-, *l*-, and *dl-trans*-2-aminocyclohexanols and *S*-methylisothiouronium sulfate according to the method of Bannard *et al.*[2] The reaction mixture was concentrated, and the residue was boiled with methanol. The methanol solution was filtered and the filtrate was concentrated to give a solid. The solid was chromatographed on a column of Dowex resin as described above. The products, *p*-toluenesulfonates of **1**$_d$, **1**$_l$, and **1** were obtained in approximately 40% yield. They were recrystallized from methanol–ether to give plates. Each compound is soluble in water, methanol, pyridine, DMF, hot chloroform and hot acetone, but sparingly soluble in benzene, ether, and ethyl acetate. IR (KBr): 1660 and 1635 cm^{-1} (monosubstituted guanidinium[9]). **1**$_d$ *p*-Toluenesulfonate: mp 138—139 °C; $[\alpha]_D^{17}$ +6° (*c* 1, water), −14° (*c* 0.3, methanol), −6° (*c* 0.3, aqueous pyridine 1: 1). Found: C, 51.16; H, 7.06; N, 12.96; S, 9.58%. Calcd for $C_{14}H_{23}N_3O_4S$: C, 51.05; H, 7.04; N, 12.76; S, 9.73%.

1$_l$ *p*-Toluenesulfonate: mp 138—140 °C; $[\alpha]_D^{12}$ −7° (*c* 1, water), +14° (*c* 0.3, methanol), +3° (*c* 0.3, aqueous pyridine 1: 1). Found: C, 51.12; H, 6.98; N, 12.64; S, 9.64%.

1 *p*-Toluenesulfonate: mp 151—153.5 °C; $[\alpha]_D^{17}$ 0° (*c* 1, water).

dl-trans-*2-(1-Methylguanidino)-1-cyclohexanol (**2**)* p-*Toluenesulfonate.* *dl-trans*-2-Methylamino-1-cyclohexanol (2 g) prepared from cyclohexene oxide and methylamine according to the method reported[8] was dissolved in water (20 ml) and the solution was partially neutralized with *p*-toluenesulfonic acid to pH 9. Cyanamide (1.05 g) was added and the solution was heated at 60 °C for 3 h. After neutralization with *p*-toluenesulfonic acid to pH ≈7, the reaction mixture was concentrated by evaporating with ethanol and benzene. The residue was dissolved in ethanol and the solution was filtered, and evaporated. The residue was dissolved in a mixture of chloroform–methanol–28% ammonia (2: 1: 1) and the insoluble matter was removed by filtration and discarded. The filtrate was evaporated to give a residue, which was washed with water to afford a solid (2.02 g, 38%). The solid was recrystallized from chloroform–methanol–ether to give **2** *p*-toluenesulfonate as plates. It was positive to biacetyl but negative to Sakaguchi reagent. Mp 210—211 °C; IR(KBr): 1670, 1620 cm^{-1}; PMR (dimethyl-d_6 sulfoxide) δ: 2.85 (3H s, NCH_3).

Found: C, 52.38; H, 7.10; N, 12.38; S, 9.14%. Calcd for $C_8H_{17}N_3O \cdot C_7H_7SO_3H$: C, 52.46; H, 7.34; N, 12.23; S, 9.33%.

dl-trans-*1-Acetoxy-2-guanidinocyclohexane (**3**)* p-*Toluenesulfonate.* Acetic anhydride (0.17 ml) was added to a solution of **1** (305 mg) in pyridine–DMF (1: 1, 18 ml) which was then allowed to stand at room temperature for 40 h. On being subjected to TLC with chloroform–methanol–28% ammonia (1: 1: 1), the solution showed a spot at R_f 0.43. After addition of water (0.1 ml), the solution was concentrated by evaporation with toluene under reduced pressure to give a syrup. The syrup was chromatographed on a short column of silica gel with chloroform–methanol (10: 1) to give a solid of **3** *p*-toluenesulfonate, 283 mg (82%). IR (KBr): 1745 (OAc); 1680 and 1630 cm^{-1} (monosubstituted guanidinium[9]); PMR ($CDCl_3$) δ: 1.97 (3H s, OAc), 2.36 (3H s, Ts (CH_3)), 3.1—3.6 (1H m, H-2), 4.2—4.8 (1H m, H-1).

Found: C, 51.52; H, 6.68; N, 11.13; S, 8.66%. Calcd for $C_9H_{17}N_3O_2 \cdot C_7H_7SO_3H$: C, 51.74; H, 6.78; N, 11.31; S, 8.63%.

dl-trans-*1-Acetoxy-2-*[N,N′ *(or* N′,N′*)-diacetylguanidino]-cyclohexane (**4**).* Acetic anhydride (0.57 ml) and triethylamine (0.84 ml) were added to a solution of **1** *p*-toluenesulfonate (101 mg) in pyridine (2 ml), and the resulting solution was kept at room temperature for 18 h. On being subjected to TLC with benzene–ethanol (10: 1), the solution showed a spot at R_f 0.57 (**1**: R_f 0). The solution was poured into an ice-cold mixture of chloroform (25 ml) and water (25 ml) with stirring and the organic layer separated was washed with cold water, dried over magnesium sulfate and evaporated to dryness under reduced pressure. The residue was dissolved in benzene–ethanol (10: 1) and the solution was chromatographed as described above to give slightly brown crystals, 79 mg (93%), mp 66—68 °C. IR (KBr): 1730 (OAc), 1700, 1620 (s), 1560 cm^{-1}; PMR ($CDCl_3$) δ: 2.03, 2.14, and 2.18 (each 3H s, Ac), 4—4.5 (1H m, H-1?), 4.6—5.1 (1H m, H-2?), 9.15 (1H? m, broad; disappeared on deuteration).

Found: C, 54.86; H, 7.39; N, 14.65%. Calcd for $C_{13}H_{21}N_3O_4$: C, 55.11; H, 7.47; N, 14.83%.

d-, l-, *and* dl-trans-N′, O-*Cyclohexylidene-2-guanidino-1-cyclohexanol (**5**$_d$, **5**$_l$, and **5**)* p-*Toluenesulfonates.* *p*-Toluenesulfonic acid (175 mg) and 1,1-dimethoxycyclohexane (3.34 ml) were added to a solution of **1**$_d$ *p*-toluenesulfonate (1.53 g) in DMF (12 ml). The solution was heated at 50 °C for 2 h under reduced pressure (25 Torr). During this period, some solvent (≈1 ml) of the reaction mixture was distilled off. On being subjected to TLC with chloroform–methanol–28% ammonia (3: 1: 1), the solution gave a single spot at R_f 0.25. After triethylamine (3 ml) had been added, ether was gradually added until precipitation ceased. The precipitate was filtered, washed thoroughly with ether and with water to give colorless needles of **5**$_d$ *p*-toluenesulfonate (1.70 g), which were recrystallized from ethanol, 1.47 g (77%). It is soluble in aqueous pyridine (1: 1), pyridine–DMF (1: 2), chloroform–methanol (1: 1), hot pyridine, hot DMF, and hot ethanol but sparingly soluble in water even at reflux temperature. It was positive to biacetyl but negative to Sakaguchi reagent. Mp 203—205 °C, $[\alpha]_D^{21}$ −88° (*c* 0.16, methanol), $[\alpha]_D^{16}$ −110° (*c* 0.25, aqueous pyridine 1: 1). IR (KBr): 1675 and 1580 (disubstituted guanidinium[9]), 1650, 1505 cm^{-1}; PMR (pyridine-d_5–D_2O 1: 1) δ: 1.0—2.5 (≈18H), 2.30 (3H s, Ts(CH_3)), 2.5—3.2 (1H), 3.2—3.8 (1H), one AB q (4H) centered at 7.72 ($SO_2C_6H_4CH_3$).

Found: C, 58.46; H, 7.60; N, 10.43; S, 7.68%. Calcd for

$C_{13}H_{23}N_3O \cdot C_7H_7SO_3H$: C, 58.65; H, 7.63; N, 10.26; S, 7.83%.

l-Isomer, **5**$_l$ *p*-toluenesulfonate, was similarly prepared starting from **1**$_l$ *p*-toluenesulfonate. Mp 203—205 °C; $[\alpha]_D^{22}$ +84° (*c* 0.13, methanol); $[\alpha]_D^{16}$ +101° (*c* 0.25, aqueous pyridine 1:1). Other characteristics were the same as those of **5**$_d$.

Found: C, 58.47; H, 7.50; N, 10.52; S, 7.95%.

dl-Isomer, **5** *p*-toluenesulfonate, was similarly prepared from **1** *p*-toluenesulfonate, $[\alpha]_D^{22}$ 0° (*c* 0.1, methanol). Mp 196—200 °C.

Found: C, 58.81; H, 7.51; N, 10.03; S, 7.52%.

dl-trans-N′, O-*Cyclohexylidene-2*-[N *(or* N′*)-methoxycarbonylguanidino*]-*1-cyclohexanol* (**6**). To a solution of **5** *p*-toluenesulfonate (501 mg) in dry pyridine–DMF (1:1, 30 ml) was added 50% oily sodium hydride (130 mg) at room temperature under a nitrogen atmosphere. After stirring for 1 h, methyl chloroformate (0.12 ml) was added and the stirring was continued for 30 min. The reaction mixture was then similarly treated as above twice with the hydride (60 mg×2) and methyl chloroformate (0.1 ml×2; added 5 min after the addition of the hydride). Chloroform (300 ml) was added with stirring to the resulting mixture, and the organic layer was washed thoroughly with water, dried over magnesium sulfate and the solvent was removed by co-evaporation with toluene. The brown syrup was chromatographed on a column of silica gel (45 g) with chloroform–ethyl acetate (2:1) as a developer. The fractions containing the main product (R_f 0.14 with the above solvent mixture) were concentrated to give a pale-yellow syrup (106 mg, 29%), which crystallized on standing. It was recrystallized from ethyl acetate to give prisms of **6**, mp 166.5—167 °C. An additional minor product (R_f 0.4, 64 mg) was also obtained. This product was presumed to be a trimethoxycarbonyl derivative as judged by its PMR spectrum, but no further study was carried out. Compound **6** was negative to biacetyl and Sakaguchi reagents. IR(KBr): 1630, 1500 cm^{-1}; PMR ($CDCl_3$) δ: 3.70 (3H s, CO_2CH_3).

Found: C, 60.83; H, 8.36; N, 13.97%. Calcd for $C_{15}H_{25}N_3O_3$: C, 60.99; H, 8.53; N, 14.23%.

dl-trans-N′, O-*Cyclohexylidene-2*-[N *(or* N′*)-acetyl*-N *(or* N′*)-methoxycarbonylguanidino*]-*1-cyclohexanol* (**7**). Acetic anhydride (0.13 ml) was added to a solution of **6** (82 mg) in pyridine (1.6 ml), and the resulting solution was kept at room temperature for 30 h. This was poured into a mixture of chloroform and saturated sodium hydrogencarbonate solution with stirring and the organic layer was washed thoroughly with water, dried over magnesium sulfate and concentrated to give a syrup, 73 mg (79%). It is soluble in most of organic solvents including hexane. IR (KBr): 1690 (shoulder), 1655, 1615 cm^{-1}; PMR ($CDCl_3$) δ: 2.25 (3H s, Ac), 3.81 (3H s, CO_2CH_3).

Found: C, 60.26; H, 8.13; N, 12.75%. Calcd for $C_{17}H_{27}N_3O_4$: C, 60.51; H, 8.07; N, 12.45%.

l-trans-*2-Guanidino*-N′, O-*isopropylidene-1-cyclohexanol* (**8**$_l$) p-*Toluenesulfonate*. *p*-Toluenesulfonic acid (23 mg) and 2,2-dimethoxypropane (0.32 ml) were added to a solution of **1**$_l$ *p*-toluenesulfonate (204 mg) in DMF (1.6 ml) which was heated at 50 °C for 1 h under reduced pressure (100 Torr). A few drops of the reaction mixture were taken and were poured into a mixture of triethylamine and methanol. TLC of the solution with chloroform–methanol–28% ammonia (3:1:1) showed a weak spot at R_f 0.2 (**8**$_l$). Repeated addition of 2,2-dimethoxypropane (0.32 ml) to the above reaction mixture every 30 min and working up as above did not raise the yield of **8**$_l$ as judged by TLC. Application of a higher reduced pressure (25 Torr) also did not improve the yield. After addition of triethylamine (0.3 ml), the reaction mixture was evaporated to give a syrup, which was chromatographed on a column of silica gel with chloroform–methanol–28% ammonia (3:2:2) to give a syrup (38 mg) containing **8**$_l$. Repetition of the chromatography as above gave a pure solid of **8**$_l$ (10 mg). It is soluble in methanol, benzene, chloroform, acetone, and ethyl acetate, but sparingly soluble in ether and water $[\alpha]_D^{15}$ +114° (*c* 1, methanol). IR (KBr): 1670, 1590 (disubstituted guanidinium[9]); 1510 cm^{-1}; PMR ($CDCl_3$) δ: 1.50 (6H s, $(CH_3)_2C$), 2.40 (3H s, Ts(CH_3)).

Found: C, 54.91; H, 7.25; N, 11.22; S, 8.39%. Calcd for $C_{10}H_{19}N_3O \cdot C_7H_7SO_3H$: C, 55.26; H, 7.37; N, 11.37; S, 8.68%.

l-trans-*2-Guanidino*-N′, O-p-*methylbenzylidene-1-cyclohexanol* (**9**$_l$) p-*Toluenesulfonate*. *p*-Toluenesulfonic acid (116 mg) and *p*-tolualdehyde dimethyl acetal (2.53 ml) were added to a solution of **1**$_l$ *p*-toluenesulfonate (1.02 g) in DMF (8 ml), and the resulting solution was heated at 50 °C for 2 h under reduced pressure (25 Torr). After addition of triethylamine (2 ml), the solution was concentrated. Addition of ether gave precipitates, which were washed successively with ether containing triethylamine and water to give a solid of **9**$_l$ *p*-toluenesulfonate, 911 mg (66%). The solid was recrystallized from methanol–ether to give needles. It is soluble in methanol, chloroform, and pyridine, but sparingly soluble in benzene, acetone, ethyl acetate, ether, and water. It was positive to biacetyl but negative to Sakaguchi reagent. Mp 195.5—197 °C, $[\alpha]_D^{15}$ +123° (*c* 0.2, methanol). IR (KBr): 1670, 1595 (disubstituted guanidinium), 1510 cm^{-1}; PMR ($CDCl_3$) δ: 2.33 and 2.37 (each 3H s, $C\underline{H}_3C_6H_4SO_3H$ and $C\underline{H}_3C_6H_4CH$=), 3.0—3.3 (2H, broad, H-1,2), 5.50 (1H d, $CH_3C_6H_4C\underline{H}$; J= 3 Hz; collapsed to a sharp singlet on deuteration); two AB q (each 4H) centered at 7.27 and 7.30 (J=≈8.5 Hz); 7.73 (1H incomplete d, NH; J=≈2.5 Hz; disappeared on deuteration), 8.00 (2H s, NH; disappeared on deuteration), 8.34 (1H incomplete t, NH; J=2—3 Hz, disappeared on deuteration).

Irradiation at δ 5.50 collapsed the triplet at δ 8.34 to an incomplete doublet. Irradiation at δ 8.34 collapsed the doublets at δ 5.50 and 7.73 to a singlet, respectively.

Irradiation of the solution, after introducing nitrogen, at δ 3.15 (H-1,2) caused a 5% increase in the area of the signals at δ 5.50 ($CH_3C_6H_4C\underline{H}$).

Found: C, 61.42; H, 6.88; N, 9.56; S, 7.49%. Calcd for $C_{15}H_{21}N_3O \cdot C_7H_7SO_3H$: C, 61.23; H, 6.77; N, 9.74; S, 7.43%.

l-trans-N′, O-p-*Bromobenzylidene-2-guanidino-1-cyclohexanol* (**10**$_l$) p-*Toluenesulfonate*. *p*-Toluenesulfonic acid (42 mg) and *p*-bromobenzaldehyde dimethyl acetal (1.4 ml) were added to a solution of **1**$_l$ *p*-toluenesulfonate (402 mg) in DMF (3.2 ml), and the resulting solution was heated at 50 °C for 2 h under reduced pressure (25 Torr). On being subjected to TLC with chloroform–methanol–28% ammonia (1:1:1), the solution showed main spot at R_f 0.45 but **1**$_l$ still remained. Above acetal (0.7 ml) was further added and the reaction was continued for 3 h. After addition of triethylamine (0.1 ml), the solution was processed as described for **9** to give a solid of **10**$_l$ *p*-toluenesulfonate, 379 mg (62%). The solid was recrystallized from chloroform–methanol (1:1) to give needles. It is soluble in methanol, pyridine, DMF, but sparingly soluble in chloroform, benzene, acetone, ethyl acetate, ether, and water. It was positive to Beilstein's test for halogen. Mp 224—226 °C, $[\alpha]_D^{24}$ +121° (*c* 0.2, methanol). IR (KBr): 1670, 1595 (disubstituted guanidinium); 1520 cm^{-1}; PMR (DMSO-d_6) δ: 1.0—2.2 (8H), 2.29 (3H s, Ts(CH_3)), 5.66 (1H s, $BrC_6H_4C\underline{H}$=), 7.0—8.2 (12H, $CH_3C_6\underline{H}_4SO_3$, $BrC_6\underline{H}_4CH$=, and NH (4H), the last disappeared on deuteration).

Found: C, 51.02; H, 5.33; N, 8.20%. Calcd for $C_{14}H_{18}BrN_3O \cdot C_7H_7SO_3H$: C, 50.81; H, 5.28; N, 8.46%.

Stability of **5** *and* **9**$_l$ *in Acidic and Alkaline Media*. Com-

pound $\mathbf{9}_l$ was found stable on treating its chloroform solution with saturated sodium hydrogencarbonate or 5% *p*-toluenesulfonic acid at room temperature for 5 min, as judged by TLC with chloroform–methanol–28% ammonia (1: 1: 1). Compound **5** could not be examined under the same conditions since it is scarcely soluble in chloroform. When solutions of **5** and of $\mathbf{9}_l$ in aqueous pyridine (1: 1) were kept at room temperature for 48 h, a slight conversion of $\mathbf{9}_l$ to **1** occurred, whereas **5** remained unchanged. Complete conversion of $\mathbf{9}_l$ was found to occur by keeping its aqueous methanol (1: 10) solution saturated with sodium carbonate at room temperature for 30 min, whereas, by the same treatment, less than half the amount of **5** turned to **1**. When 1.5% solutions of **5** and $\mathbf{9}_l$ in chloroform–methanol (1:1) containing 1.1 molecular equivalents (based on **5** and $\mathbf{9}_l$) of *p*-toluenesulfonic acid were kept at room temperature for 2 h, **5** completely turned to **1**, while the conversion of $\mathbf{9}_l$ to **1** was about 50%.

Reactions of $\mathbf{9}_l$ *with* p-*Toluenesulfonyl and Methanesulfonyl Chlorides.* To a solution of $\mathbf{9}_l$ *p*-toluenesulfonate (49 mg) in dry pyridine (1 ml) was added *p*-toluenesulfonyl chloride (69 mg) or methanesulfonyl chloride (45 mg) and the solution was kept at room temperature overnight. On being subjected to TLC with chloroform–methanol–28% ammonia (3: 1: 1) and chloroform-ethanol (4: 1), the solution showed a single spot (R_f 0.25 and 0.4, respectively) of $\mathbf{9}_l$. After addition of water (0.1 ml), the solution was concentrated and the resulting syrup was dissolved in chloroform. The solution was washed successively with aqueous sodium hydrogencarbonate, saturated sodium *p*-toluenesulfonate solution, water, dried over sodium sulfate and concentrated to give $\mathbf{9}_l$ *p*-toluenesulfonate, 36 mg (74%) and 36 mg (74%), respectively. Their PMR and IR spectra were indistinguishable from those of $\mathbf{9}_l$ *p*-toluenesulfonate.

The authors are grateful to Dr. Hamao Umezawa, Director of the Institute of Microbial Chemistry, for his support and encouragement, to Dr. Hiroshi Naganawa of the Institute for carrying out the NOE experiment and for his kind discussions, and to Mr. Saburo Nakada of Keio University for carrying out elementary analysis.

Studies of Peptide Antibiotics. XXXIII.[1] Syntheses of Gramicidin S Analogs Containing *N*-Methyl-L-valine in Place of L-Valine

Hayao ABE,* Kazuki SATO, Tetsuo KATO, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 29, 1976)

Two analogs of gramicidin S, [1-*N*-methyl-L-valine]-gramicidin S and [1,1'-di-*N*-methyl-L-valine]-gramicidin S, were prepared for the purpose of investigating the contribution of NH group of L-valyl residue in gramicidin S to antibacterial activity. They exhibit weak activity as compared with gramicidin S in the antibacterial test toward microorganisms. The optical rotatory dispersions of these analogs and gramicidin S were measured in ethanol and 8 M urea. It was suggested that both analogs have a different molecular conformation from that of gramicidin S, and that the NH group of valyl residues is necessary for stabilizing the conformation to exhibit biological activity.

Several models have been proposed[2] for the conformation of gramicidin S (GS) in solid state and solution. The most favorable model is the intramolecular antiparallel β-form with four hydrogen bondings between the valyl and the leucyl residues.[3] A simplified structure of the model is shown in Fig. 1. In studies of the structure-activity relationship of GS, it has been proposed that the specific conformation is necessary for molecules of GS and its analogs to exhibit biological activity.[2]

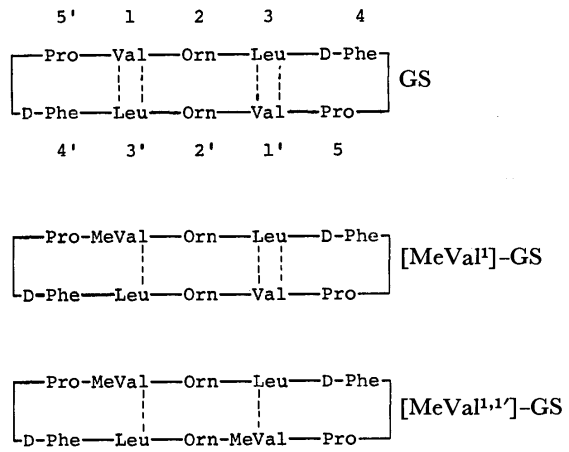

Fig. 1. Structure of GS and its analogs.

[3-*N*-Methyl-L-leucine]-gramicidin S ([MeLeu³]-GS) and [MeLeu³,³']-GS which lack some of the four hydrogen bondings in GS were synthesized in order to investigate to what extent the changes in the number of these hydrogen bondings vary the level of antibacterial activity and influence the conformations.[4] It was observed that the antibacterial activity of [MeLeu³]-GS and [MeLeu³,³']-GS is identical with that of GS and the optical rotatory dispersion (ORD) curves are similar to the curve of GS. Recent studies on the two analogs by proton magnetic resonance spectroscopy showed that the analogs might have a different conformation from that of GS in spite of the apparent resemblance between GS and the analogs in their ORD curves.[5] In other words, similarity of ORD patterns do not always guarantee similar conformation. The results led us to investigate other analogs which contain *N*-methylamino acid residue other than *N*-methyl-L-leucyl.

The present paper deals with the syntheses, antibacterial properties, and ORD measurements of [MeVal¹]-GS and [MeVal¹,¹']-GS, in which the L-valyl residues in positions 1 and 1' are replaced, singly or together, by *N*-methyl-L-valyl residues. These analogs lack one or two of the four hydrogen bondings in GS as shown in Fig. 1.

The syntheses of [MeVal¹]-GS and [MeVal¹,¹']-GS are outlined in Schemes 1 and 2.[6] The principle of the synthesis was to locate the leucyl residue at the C-terminal in order to achieve the cyclization in a good yield. In *B. brevis*, GS is synthesized enzymatically with the cyclization of a pentapeptide (H-D-Phe-Pro-Val-Orn-Leu-OH).[7] According to this finding, Tanaka *et al.* synthesized the protected GS chemically with a protected pentapeptide azide of the same amino acid sequence in a high yield of 30—36%.[8] Furthermore, the results of recent studies in this laboratory on the cyclization reaction of a pentapeptide *via* several active esters show that an *N*-hydroxysuccinimide method is excellent because of high yield, experimental simplicity, and no racemization.[1]

In order to avoid racemization of *N*-methyl-L-valyl residue, the stepwise elongation procedure was employed for the synthesis of X and XII for the following reason. McDermott and Benoiton observed that *N*-methyl-L-leucyl residue in Z-L-Ala-L-MeLeu-OH partially racemized in a coupling reaction with an amine-component by the DCC-HONSu method in spite of no racemization of Z-L-Ala-L-Leu-OH under the same conditions.[9] They reported absence of racemization of alkyloxycarbonyl-*N*-methyl-L-amino acid during the course of coupling reactions.[9]

For the synthesis of protected [MeVal¹]-GS (XIX), Boc-pentapeptide-ONSu (IX) and pentapeptide (XVI) were prepared by the stepwise elongation from the carboxyl toward the amino end as shown in Scheme 1. Coupling of these IX and XVI afforded Boc-decapeptide acid (XVII) which was converted into a decapeptide-ONSu. A key intermediate (XIX) was derived by the cyclization of the decapeptide-ONSu in a satisfactory yield of 56%. As shown in Scheme 2, Boc-decapeptide acid (XXII) was converted into the corresponding decapeptide-ONSu. A Z-substituted intermediate (XXIV) was derived by the cyclization of the decapep-

* Present address: Institute of Biological Science, Mitsui-Toatsu Chemicals, Inc., Mobara 297

Table 1. Antibacterial activity of GS and its analogs
(Minimum inhibitory concentration, μg/ml)

Strain	GS·2HC	[MeVal[1]]-GS·2HCl	[MeVal[1,1']]-GS·2HCl
Staphylococcus aureus 209p	12.5	25	50
Staphylococcus aureus Terajima	1.56	12.5	25
Enterococcus hemolyticus Hoshi	6.25	50	50
Bacillus subtillis ATCC 6633	1.56	25	50
Escherichia coli K 12	50	50	50
Proteus vulgaris OX 19	50	50	50

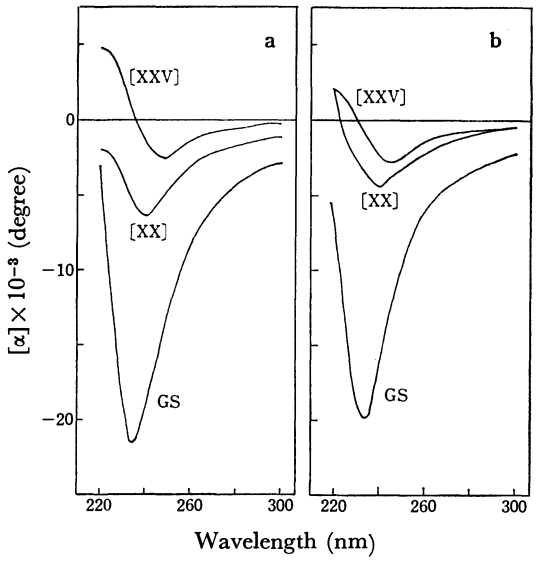

Fig. 2. ORD curves of [MeVal[1]]-GS (XX), [MeVal[1,1']]-GS (XXV), and GS.
Solvent: a, ethanol; b, 8 M aqueous urea.

analog (Table 1). The results indicate the importance of the NH's of L-valyl residues in GS for exhibiting the activity.

The ORD curves of the two analogs in ethanol as well as of GS are shown in Fig. 2-a. The trough of [MeVal[1]]-GS and of [MeVal[1,1']]-GS is at 240 and 248 nm, respectively, whereas that of GS is at 236 nm. The troughs of the analogs are shallower than the trough of GS. [MeVal[1,1']]-GS shows a greater shift in position and a shallower trough than [MeVal[1]]-GS. In 8 M aqueous urea which causes denaturation of various polypeptides, the position of the trough of [MeVal[1,1']]-GS shifts from 248 to 245 nm, but that of [MeVal[1]]-GS at 240 nm remains unchanged as in the case of GS (Fig. 2-b). The results of ORD measurements indicate that the conformation of the analogs differs from that of GS, and the stability of the analogs decreases as the number of *N*-methylvalyl residues increases. The tendency is comparable with the biological activity. We proposed that the biologically active analogs of GS show a similar ORD curve to that of GS.[10] The two analogs containing *N*-methylvalyl residues show a different ORD curve from that of GS and exhibit weak biological activity as had been expected. These results indicate that the destruction of intramolecular hydrogen bondings by substitution of valyl residues for *N*-methylvalyl residues cause the change and instabilization of conformation and decrease the biological activity consequently.

Experimental

Melting points are uncorrected. Thin-layer chromatography (TLC) was carried out on silica gel G (Merck) with the solvent system: chloroform–methanol (5: 1, v/v). The NMR spectra were recorded on a Hitachi R-20B spectrometer at 60 MHz with tetramethylsilane as an internal standard. The optical rotations were measured on a Yanagimoto polarimeter, OR-20.

Boc-Orn(Z)-Leu-OEt (I). To a solution of Boc-Orn(Z)-OH[11] (10.99 g, 30 mmol) and TEA (4.20 ml, 30 mmol) in THF (30 ml) was added isobutyl chloroformate (3.93 ml, 30 mmol) at −5 °C. After 15 min, a mixture of H-Leu-OEt·HCl (5.87 g, 30 mmol) and TEA (30 mmol) in chloroform (30 ml) was added. The mixture was left to stand overnight at room temperature, evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate. The solution was washed successively with 4% sodium hydrogencarbonate, 10% citric acid and water, and then dried over sodium sulfate. The solvent was evaporated under reduced pressure. The residual oil was solidified by the addition of ether and petroleum ether. The product was recrystallized from methanol–ether–petroleum ether; yield, 13.15 g (86%); mp 100—101 °C, $[\alpha]_D^{20}$ −21.6° (*c* 1, ethanol).

Found: C, 61.65; H, 8.02; N, 8.32%. Calcd for $C_{26}H_{41}O_7N_3$: C, 61.52; H, 8.14; N, 8.28%.

H-Orn(Z)-Leu-OEt·HCl (II). Compound I (12.69 g, 20 mmol) was dissolved in 96 ml of 2.6 M hydrogen chloride in ethyl acetate. The solution was allowed to stand for 1 h at room temperature and then evaporated. The oily residue was solidified by the addition of ether and petroleum ether, and the crude product was recrystallized from ethanol–ether–petroleum ether; yield, 10.66 g (96%); mp 126—129 °C; $[\alpha]_D^{20}$ −1.4° (*c* 1, ethanol).

Found: C, 57.13; H, 7.69; N, 9.43%. Calcd for $C_{21}H_{34}O_5N_3Cl$: C, 56.81; H, 7.72; N, 9.47%.

Boc-Val-Orn(Z)-Leu·OEt (III). A reaction mixture of Boc-Val-OH (1.87 g, 8.6 mmol), TEA (8.6 mmol) and isobutyl chloroformate (8.6 mmol) in THF (9 ml) was treated with a solution of II (3.84 g, 8.6 mmol) and TEA (8.6 mmol) in chloroform (9 ml) as described for I. The crude product was recrystallized from methanol–ether–petroleum ether; yield, 4.80 g (92%); mp 152—154 °C; $[\alpha]_D^{20}$ −38.6° (*c* 1, ethanol).

Found: C, 60.65; H, 8.13; N, 9.41%. Calcd for $C_{31}H_{50}O_8N_4\cdot1/2H_2O$: C, 60.46; H, 8.35; N, 9.10%.

H-Val-Orn(Z)-Leu-OEt·HCl (IV). Compound III (4.41 g, 7.3 mmol) was dissolved in 2.6 M hydrogen chloride in ethyl acetate (28 ml) and treated as described for II. The product was recrystallized from ethanol–ether–petroleum ether; yield, 3.57 g (90%); mp 205—207 °C; $[\alpha]_D^{20}$ −19.6° (*c* 0.5, ethanol).

Found: C, 56.72; H, 7.88; N, 10.27%. Calcd for $C_{26}H_{43}O_6N_4\cdot1/2H_2O$: C, 56.56; H, 8.03; N, 10.15%.

Boc-Pro-Val-Orn(Z)-Leu-OEt (V). A mixture of Boc-Pro-OH (1.29 g, 6 mmol), TEA (6 mmol) and isobutyl chloroformate (6 mmol) in THF (6 ml) was treated with IV (3.26 g, 6 mmol) and TEA (6 mmol) in chloroform (6 ml) as described for I. The product was recrystallized from

methanol–ether–petroleum ether; yield, 3.65 g (90%); mp 158—160 °C; $[\alpha]_D^{20}$ −69.0° (*c* 1, ethanol).

Found: C, 61.12; H, 8.04; N, 10.00%. Calcd for $C_{36}H_{57}O_9N_5$: C, 61.43; H, 8.16; N, 9.95%.

H–Pro–Val–Orn(Z)–Leu–OEt·HCl (VI). Compound V (3.52 g, 5 mmol) was treated with 2.6 M hydrogen chloride in ethyl acetate (19 ml) as described for II. The product was recrystallized from ethanol–ether–petroleum ether; yield, 3.07 g (96%); mp 187—189 °C; $[\alpha]_D^{20}$ −60.0° (*c* 0.5, ethanol).

Found: C, 57.58; H, 8.04; N, 11.01%. Calcd for $C_{31}H_{50}O_7N_5Cl$: C, 58.15; H, 7.87; N, 10.94%.

Boc–D–Phe–Pro–Val–Orn(Z)–Leu–OEt (VII). A mixture of Boc–D–Phe–OH (1.19 g, 4.5 mmol), TEA (4.5 mmol) and isobutyl chloroformate (4.5 mmol) in THF (4.5 ml) was treated with VI (2.88 g, 4.5 mmol) and TEA (4.5 mmol) in chloroform (4.5 ml) as described for I. The product was recrystallized from methanol–ether–petroleum ether; yield, 3.25 g (84%); mp 94—98 °C; $[\alpha]_D^{20}$ −76.0° (*c* 0.5, ethanol).

Found: C, 62.75; H, 8.05; N, 9.65%. Calcd for $C_{45}H_{66}O_{10}N_6\cdot 1/2H_2O$: C, 62.84; H, 7.85; N, 9.77%.

Boc–D–Phe–Pro–Val–Orn(Z)–Leu–OH (VIII). To a solution of VII (1.72 g, 2 mmol) in a mixture of methanol (10 ml) and dioxane (5 ml) was added 1 M sodium hydroxide (3.4 ml) and the solution was allowed to stand for 3 h at room temperature. After the addition of water (30 ml), the solution was concentrated *in vacuo* at a low temperature, and the residual solution was acidified with 10% citric acid and extracted with ethyl acetate. The organic layer was washed with water, dried over sodium sulfate, and evaporated. The residual oil was triturated with a mixture of ether and petroleum ether, and the powder was recrystallized from methanol–ether–petroleum ether; yield, 1.50 g (90%); mp 120—123 °C; $[\alpha]_D^{20}$ −80.1° (*c* 1, methanol).

Found: C, 61.96; H, 7.67; N, 9.98%. Calcd for $C_{43}H_{62}O_{10}N_6\cdot 1/2H_2O$: C, 62.07; H, 7.63; N, 10.10%.

Boc–D–Phe–Pro–Val–Orn(Z)–Leu–ONSu (IX). To a solution of VIII (832 mg, 1 mmol) in dioxane (5 ml) were added HONSu (115 mg, 1 mmol) and DCC (206 mg, 1 mmol) at 0 °C. After being left to stand at room temperature for 12 h, dicyclohexylurea formed was filtered off, the filtrate was evaporated, and the residual oil was solidified by the addition of ether. The product was recrystallized from dioxane–ether; yield, 643 mg (69%); mp 136—138 °C; $[\alpha]_D^{20}$ −74.1° (*c* 0.54, ethyl acetate).

Found: C, 60.83; H, 7.18; N, 10.50%. Calcd for $C_{47}H_{65}O_{12}H_7\cdot 1/2H_2O$: C, 60.76; H, 7.16; N, 10.55%.

Boc–MeVal–Orn(Z)–Leu–OEt (X). A reaction mixture of Boc–MeVal–OH[12] (4.63 g, 20 mmol), *N*-methylmorpholine (2.20 ml, 20 mmol) and isobutyl chloroformate (20 mmol) in THF (20 ml) was treated with II (8.88 g, 20 mmol) and *N*-methylmorpholine (20 mmol) in THF (20 ml) as described for I. The product was obtained as an oil; yield, 11.42 g (92%).

H–MeVal–Orn(Z)–Leu–OEt·HCl (XI). Compound X (11.17 g, 18 mmol) was treated with 2.6 M hydrogen chloride in ethyl acetate (139 ml) as described for II. The product was recrystallized from methanol–ether; yield, 7.42 g (74%); mp 174—175 °C; $[\alpha]_D^{20}$ −29.0° (*c* 0.52, methanol).

Found: C, 57.87; H, 8.15; N, 10.13%. Calcd for $C_{27}H_{45}O_6N_4Cl$: C, 58.20; H, 8.14; N, 10.06%.

Boc–Pro–MeVal–Orn(Z)–Leu–OEt (XII). To a solution of Boc–Pro–OH (2.80 g, 13 mmol), HOBt (1.76 g, 13 mmol), XI(7.24 g, 13 mmol) and TEA (13 mmol) in DMF (40 ml) was added WSCI (2.49 g, 13 mmol) at −5 °C. After stirring had been continued at −5—0 °C for 2 h, the mixture was left to stand overnight at room temperature. It was then evaporated and the residue was diluted with ethyl acetate (300 ml). The solution was washed with 4% sodium hydrogencarbonate, 10% citric acid and water, and dried over sodium sulfate. The solvent was evaporated to leave an oil; yield, 3.64 g (39%). Amino acid ratios in acid hydrolyzate; Pro 1.06, Orn 0.96, Leu 1.00.

H–Pro–MeVal–Orn(Z)–Leu–OEt·HCl (XIII) Compound XII (2.52 g, 3.5 mmol) was treated with 2.6 M hydrogen chloride in ethyl acetate (27 ml) as described for II. The oily product was purified with a column (4.9×33 cm) with silica gel 60 (Merck) as follows. The oily product was applied on the column, and the column was washed with ethyl acetate (1000 ml) and eluted with a mixture of ethyl acetate and ethanol (1: 1, v/v) (500 ml). Each fraction was assayed by TLC, and the fractions containing the desired product were evaporated to leave an oil which was crystallized by the addition of ether and petroleum ether; yield, 1.75 g (76%); mp 85—90 °C; $[\alpha]_D^{20}$ −86.6° (*c* 1.1, methanol).

Found: C, 58.28; H, 8.00; N, 10.55%. Calcd for $C_{32}H_{52}O_7N_5Cl$: C, 58.74; H, 8.01; N, 10.71%.

Boc–D–Phe–Pro–MeVal–Orn(Z)–Leu–OEt (XIV). To a solution of XIII (1.64 g, 2.5 mmol) and TEA (2.5 mmol) in dioxane (15 ml) at 5 °C was added Boc–D–Phe–ONSu[13] (1.09 g, 3 mmol) in dioxane (5 ml). The mixture was left to stand for 30 min at 5 °C and overnight at room temperature, and a few drops of 1-(2-aminoethyl)piperazine were added. After 30 min, the solution was evaporated and the residue was diluted with ethyl acetate (100 ml). The solution was washed with 4% sodium hydrogencarbonate, 10% citric acid and water, and dried over sodium sulfate. The solvent was evaporated to leave an oil; yield, 1.99 g (92%). Amino acid ratios in acid hydrolyzate; Phe 1.02, Pro 1.05, Orn 0.93, Leu 1.00.

Boc–D–Phe–Pro–MeVal–Orn(Z)–Leu–OH (XV). A solution of XIV (1.73 g, 2 mmol) in methanol (12 ml) was treated with 1 M sodium hydroxide (2.4 ml) as described for VIII. The product was recrystallized from methanol–ether–petroleum ether; yield, 1.37 g (82%); mp 95—97 °C; $[\alpha]_D^{20}$ −97.4° (*c* 0.51, methanol).

Found: C, 62.85; H, 7.72; N, 10.14%. Calcd for $C_{44}H_{64}O_{10}N_6$: C, 63.13; H, 7.71; N, 10.01%. NMR ($CDCl_3$); 1.36 (s, 9H, $(CH_3)_3C$–), 2.78 (s, 3H, CH_3N–), 5.06 (s, 2H, –O–CH_2–C_6H_5), 7.18—7.28 (m, 10H, phenyl protons).

H–D–Phe–Pro–MeVal–Orn(Z)–Leu–OH·HCl (XVI). Compound XV (840 mg, 1 mmol) was treated with 2.6 M hydrogen chloride in ethyl acetate (8 ml) as described for II. The oily product was purified with a column (4.9×38 cm) with silica gel 60 (Merck) as follows. The oily product was applied on the column, and the column was washed with a mixture of chloroform and methanol (19: 1, v/v) (500 ml) and eluted with a mixture of chloroform and methanol (9: 1, v/v) (1000 ml). The fraction with the desired product were evaporated and the residual oil was crystallized by the addition of ether; yield, 557 mg (72%); mp 136—140 °C; $[\alpha]_D^{20}$ −48.4° (*c* 0.49, methanol).

Found: C, 59.59; H, 7.32; N, 10.61%. Calcd for $C_{39}H_{57}O_8N_6Cl\cdot H_2O$: C, 59.19; H, 7.51; N, 10.62%.

Boc–D–Phe–Pro–Val–Orn(Z)–Leu–D–Phe–Pro–MeVal–Orn(Z)–Leu–OH (XVII). To a solution of XVI (162 mg, 0.21 mmol) and TEA (0.42 mmol) in DMF (1 ml) at 0 °C was added IX (195 mg, 0.21 mmol) in DMF (1 ml). The mixture was left to stand for 30 min at 0 °C and overnight at room temperature, a few drops of 1-(2-aminoethyl)piperazine were added, the solution was evaporated, and the residue was diluted with ethyl acetate (100 ml). The solution was washed with 4% sodium hydrogencarbonate, 10% citric acid and

water, dried over sodium sulfate, and the solvent was evaporated to leave an oil, which was solidified by the addition of ether. The product was recrystallized from methanol–ether; yield, 215 mg (66%); mp 133—134 °C; $[\alpha]_D^{20}$ −118° (*c* 0.33, methanol). Amino acid ratios in acid hydrolyzate; Phe 1.96, Pro 2.02; Val 0.98; Orn 1.98; Leu 2.00.

Found: C, 62.92; H, 7.54; N, 10.80%. Calcd for $C_{82}H_{116}O_{17}N_{12}\cdot H_2O$: C, 63.13; H, 7.63; N, 10.78%.

Boc–D–Phe–Pro–Val–Orn(Z)–Leu–D–Phe–Pro–MeVal–Orn(Z)–Leu–ONSu (XVIII). To a solution of XVII (185 mg, 0.12 mmol) in DMF (2 ml) were added HONSu (28 mg, 0.24 mmol) and WSCI (46 mg, 0.24 mmol) at 0 °C. After being left to stand at room temperature for 12 h, ethyl acetate (50 ml) was added, and the solution was washed with 4% sodium hydrogencarbonate, 10% citric acid and water. After drying over sodium sulfate, the solvent was evaporated to leave an oil which was solidified by the addition of ether. The product was reprecipitated from ethyl acetate–ether; yield, 186 mg (95%); mp 130—132 °C; $[\alpha]_D^{20}$ −146° (*c* 0.13, ethyl acetate).

Found: C, 61.93; H, 7.34; N, 10.95%. Calcd for $C_{86}H_{119}O_{19}N_{13}\cdot 2H_2O$: C, 61.66; H, 7.40; N, 10.87%.

cyclo(–D–*Phe–Pro–Val–Orn(Z)–Leu–D–Phe–Pro–MeVal–Orn(Z)–Leu–*) *(XIX).* Compound XVIII (164 mg, 0.1 mmol) was dissolved in TFA (3 ml) at 0 °C. After 20 min, the solution was evaporated, the residual oil was triturated with ether, and the precipitate was collected by filtration (yield, 160 mg). The *N*-hydroxysuccinimide ester trifluoroacetate thus obtained was dissolved in DMF (2 ml), the solution was added drop by drop to pyridine (50 ml) at room temperature, and the mixture was stirred for 12 h and evaporated. The residual oil was dissolved in a mixture (25 ml) of methanol and water (5: 1, v/v), and the solution was passed through columns (1.8×20 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (500 ml), and the combined effluent was evaporated to leave an oily product which was precipitated by the addition of water (yield, 98 mg). A part (63 mg) of the precipitate dissolved in methanol (1 ml) was applied on a column (1.8×110 cm) with Sephadex LH-20 and the developing was continued with methanol. The fractions with the desired product were evaporated and the residual solid was recrystallized from methanol–ether–petroleum ether; yield, 51 mg (56% from XVIII); mp 218—219 °C; $[\alpha]_D^{20}$ −211° (*c* 0.17, methanol).

Found: C, 63.19; H, 7.45; N, 11.39%; mol wt, 1455.[14] Calcd for $C_{77}H_{106}O_{14}N_{12}\cdot 2H_2O$: C, 63.35; H, 7.60; N, 11.52%; mol wt, 1460.

cyclo(–D–*Phe–Pro–Val–Orn–Leu–D–Phe–Pro–MeVal–Orn–Leu–*)·2*HCl ([MeVal*[1]*]-GS·2HCl) (XX).* Compound XIX (40 mg, 0.028 mmol) dissolved in 0.01 M hydrogen chloride in methanol (7 ml) was hydrogenated using palladium black as a catalyst. After removal of the catalyst, the filtrate was evaporated and the residual oil was precipitated by the addition of 1 M hydrochloric acid (1 ml). The product was recrystallized from ethanol–1 M hydrochloric acid; yield, 24 mg (70%); 226—228 °C; $[\alpha]_D^{20}$ −141° (*c* 0.12, ethanol). Amino acid ratios in acid hydrolyzate; Phe 2.06, Pro 2.10, Val 1.08, Orn 1.92, Leu 2.00.

Found: C, 57.75; H, 7.85; N, 13.21%. Calcd for $C_{61}H_{94}O_{10}N_{12}\cdot 2HCl\cdot 2H_2O$: C, 57.94; H, 7.97; N, 13.30%.

Boc–D–Phe–Pro–MeVal–Orn(Z)–Leu–ONSu (XXI). Compound XV (670 mg, 0.8 mmol) in dioxane (4 ml) was treated with HONSu 184 mg, 1.6 mmol) and WSCI (307 mg, 1.6 mmol) as described for XVIII. The product was reprecipitated from ethyl acetate–ether–petroleum ether; yield, 677 mg (91%); mp 105—107 °C; $[\alpha]_D^{20}$ −67.8° (*c* 0.26, ethyl acetate).

Found: C, 61.33; H, 7.17; N, 10.47%. Calcd for $C_{18}H_{67}O_{12}N_7$: C, 61.72; H, 7.23; N, 10.50%.

Boc–(D–Phe–Pro–MeVal–Orn(Z)–Leu)$_2$–OH (XXII). A solution of XVI (600 mg, 0.78 mmol) and TEA (1.56 mmol) in DMF (3 ml) was treated with XXI (654 mg, 0.7 mmol) in DMF (3 ml) as described for XVII. The product was recrystallized from methanol–ether–petroleum ether; yield, 943 mg (87%); mp 125—127 °C; $[\alpha]_D^{20}$ −46.8° (*c* 0.80, methanol). Amino acid ratios in acid hydrolyzate; Phe 1.02, Pro 1.01, Orn 1.12, Leu 1.00.

Found: C, 63.13; H, 7.73; N, 10.71%. Calcd for $C_{83}H_{118}O_{17}N_{12}\cdot H_2O$: C, 63.33; H, 7.69; N, 10.68%.

Boc–(D–Phe–Pro–MeVal–Orn(Z)–Leu)$_2$–ONSu (XXIII). Compound XXII (902 mg, 0.58 mmol) was converted into the active ester (XXIII) by the method described for XVIII; yield, 865 mg (90%); mp 115—117 °C $[\alpha]_D^{20}$ −70.6° (*c* 0.28, ethyl acetate).

Found: C, 63.00; H, 7.42; N, 10.92%. Calcd for $C_{87}H_{121}O_{19}N_{13}$: C, 63.21; H, 7.38; N, 11.02%.

cyclo(–(D–*Phe–Pro–MeVal–Orn(Z)–Leu)$_2$–*) *(XXIV).* Compound XXIII (826 mg, 0.5 mmol) was treated with TFA (10 ml) and pyridine (500 ml), successively, as described for XIX. The crude product dissolved in a mixture of methanol and water (5: 1, v/v) was treated with Dowex 1 and 50, and an oily product was precipitated by the addition of water (yield, 552 mg). A part (100 mg) of the precipitate dissolved in methanol (20 ml) was purified by column chromatography using Sephadex LH-20 (2.8×158 cm) and the residual solid was recrystallized from methanol–ether–petroleum ether; yield, 86 mg (66% from XXIII); mp 280—285 °C; $[\alpha]_D^{20}$ −50.6° (*c* 0.29, methanol).

Found: C, 64.32; H, 7.56; N, 11.51%; mol wt, 1427.[14] Calcd for $C_{78}H_{108}O_{14}N_{12}\cdot H_2O$: C, 64.35; H, 7.62; N, 11.55%; mol wt, 1438.

cyclo(–(D–*Phe–Pro–MeVal–Orn–Leu)$_2$–*)·2*HCl ([MeVal*[1,1']*-GS·2HCl) (XXV).* Compound XXIV (50 mg, 0.035 mmol) was hydrogenated as in the case of XX; yield, 41 mg (95%); mp 218—220 °C; $[\alpha]_D^{20}$ −51.9° (*c* 0.18, ethanol). Amino acid ratios in acid hydrolyzate; Phe 1.00, Pro 1.05, Orn 1.10, Leu 1.00.

Found: C, 54.25; H, 7.74; N, 11.92%. Calcd for $C_{62}H_{96}O_{10}N_{12}\cdot 2HCl\cdot 7H_2O$: C, 54.40; H, 8.25; N, 12.28%.

Paper Electrophoresis. In order to confirm the purity of the analogs of gramicidin S synthesized, paper electrophoresis was carried out.[15] The peptide (XX and XXV) revealed a single spot, and their mobility were comparable with that of GS·2HCl.

Microbiological Assays. The minimum amount of the compounds necessary for the complete inhibition of growth of several microorganisms was determined by a dilution method using a nutrient agar, the results being shown in Table 1.

ORD Measurements. The measurements were performed on a JASCO spectropolarimeter model ORD/UV-5 over the wavelength range 220—300 nm at an ambient temperature. A cell of path length 0.1 cm was used. Patterns in ethanol and 8 M urea are shown in Figs. 2-a and 2-b, respectively.

The authors wish to express their thanks to Drs. M. Miyoshi and H. Sugano of Tanabe Seiyaku Co. Ltd., Osaka, for their helpful discussions. Thanks are also due to the staff of Institute of Biological Science, Mitsui-Toatsu Chemicals, Inc., Chiba, for the biological assays.

Substrate Specificity in the Cyclodextrin-catalyzed Cleavage of Organic Phosphates and Monothiophosphates in Alkaline Solutions

Kazuo MOCHIDA, Yoshihisa MATSUI, Yoshio OTA, Koji ARAKAWA, and Yoshio DATE

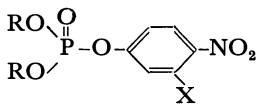
Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue 690

(Received April 10, 1976)

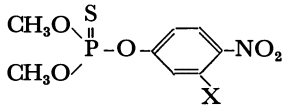
Cyclodextrin accelerates the phenol release from organic phosphates such as dialkyl 4-nitrophenyl phosphates, but it decelerates the reactions of the corresponding monothiophosphates in alkaline solutions. Each reaction proceeds *via* the prior formation of a cyclodextrin–substrate inclusion complex, followed by the nucleophilic attack of the cyclodextrin alkoxide ion or the hydroxide ion on the reaction site of the included substrate. The equilibrium and kinetic parameters involved in the reaction processes were determined and discussed in connection with the geometry of a cyclodextrin–substrate complex.

Substrate specificity is one of the most important characteristics of enzyme-catalyzed reactions. A little modification in the structure of substrates results in pronounced changes in both the binding and catalytic processes of an enzymatic reaction. A similar feature has been observed in relatively simple enzyme-model systems such as cyclodextrin.[1] For example, the cyclodextrin-induced rate acceleration of the phenol release from *meta*-substituted phenyl acetates is much greater than that from the corresponding *para*-substituted phenyl acetates.[2] The process includes the prior complexation of a substrate with cyclodextrin, and the specific spatial orientation of a substrate in a cyclodextrin complex causes a marked substrate specificity.

During the course of an investigation of the catalytic action of cyclodextrin, we found that the cyclodextrin-catalyzed cleavage of some organophosphorus pesticides in alkaline solutions reveals a characteristic substrate specificity: cyclodextrin accelerates the phenol release from the phosphates, **1a**, **1b**, and **1c**, but decelerates the release from the corresponding monothiophosphates, **2a** and **2b**.



1a: R=CH_3, X=CH_3
1b: R=CH_3, X=H
1c: R=C_2H_5, X=H



2a: X=CH_3
2b: X=H

The present study was undertaken in order to elucidate the catalytic modes of the cyclodextrin and the hydroxide ion by means of a close determination of the equilibrium and kinetic parameters involved in the reaction processes. The rate effect of cyclodextrin was also examined on the alkaline hydrolysis of a few phenyl acetates, such as *o*- and *m*-acetoxybenzoic acids (**3a** and **3b** respectively), in order to compare the equilibrium and kinetic parameters with those of the organophosphorus compounds.

Experimental

Materials. The α- and β-cyclodextrins were prepared by the method of Lane and Pirt.[3] They were separated and purified according to the directions of Cramer and Henglein.[4] Methyl α-D-glucopyranoside of a reagent grade was used without further purification. 3-Methyl-4-nitrophenol (**4**) was prepared by the method of Koelsch[5] and was purified by means of chromatography on an activated alumina column with benzene, ether, and ether–ethanol (4: 1, v/v) as eluants. The ether and ether–ethanol fractions were collected and concentrated by evaporation. The residue was recrystallized from water. Mp 127—129 °C (lit, mp 128 °C[6]). **1a** was prepared by the reaction of **4** with dimethyl chlorophosphate.[7] Crude **1a** was purified by chromatography on a silica gel column, with hexane, benzene, and ether as eluants. The ether fractions were collected and concentrated by evaporation. The residue was distilled *in vacuo*. **1b** was prepared by the reaction of sodium 4-nitrophenoxide with dimethyl chlorophosphate.[8] The **1c**, **2a**, and **2b** were provided by Sumitomo Chemical Co. and were used without further purification. The purity of these organophosphorus compounds was estimated to be 95% for **1a**, 100% for **1b**, 95% for **1c**, 97% for **2a**, and 94% for **2b** by the spectrophotometric determination at 400 nm of the phenolate anions afforded by the alkaline hydrolysis of the compounds. **3a** of a reagent grade was used without purification. **3b** was prepared by the reaction of *m*-hydroxybenzoic acid with acetic anhydride in dry pyridine and was recrystallized from chloroform.

Kinetics. The reaction rates of the esters were measured by following the appearance of the absorption of the corresponding phenoxide anions at 410 nm for the phosphates and monothiophosphates and at 300 and 310 nm for **3a** and **3b** respectively in aqueous NaOH solutions, the ionic strength (I_c) of which was maintained at 0.65 M with Na_2SO_4. In a typical run, 3.00 ml of a base solution was pipetted into a pair of 1.00-cm quartz cells, one of which was used as a reference cell and the other, as a sample cell in a Hitachi spectrophotometer, Model 124. After thermal equilibrium at 25.0±0.1 °C had been reached, 5 to 15 μl of a 8 to 55 mM ester in ethanol or methanol was added to the sample cell and the change in absorbance was followed. The results for various reaction times were treated according to the ordinary first-order rate equation. The rate constants were graphically determined. All the reactions examined obeyed good first-order kinetics with respect to substrates in both the absence and presence of cyclodextrin.

Determination of the Dissociation Constants and Rate Constants of Cyclodextrin–Substrate Complexes. As is shown in Table 1 as an example, the observed pseudo first-order rate constant (k_{obsd}) for each substrate examined approached a maximum or minimum value as the cyclodextrin concentration ([CD]) is increased. This saturation behavior, as well as the fact that methyl α-D-glucopyranoside had only a slight effect on the reaction rate, suggests that the rate process involves the prior formation of the inclusion complex of cyclodextrin with each substrate. Upon the assumption of the formation of an 1: 1

Table 1. Pseudo-first-order rate constants for the phenol release from **1a** and **2a** in alkaline solutions containing carbohydrates at 25.0 °C and I_c=0.65 M

Carbohydrate	Concn. (mM)	$k_{obsd} \times 10^2$, min^{-1}	
		1a[a]	**2a**[b]
None	—	1.33	3.14
Methyl α-D-glucopyranoside	35.0	1.30	3.06
α-Cyclodextrin	1.00	1.30	2.77
	10.0	1.15	2.65
β-Cyclodextrin	1.00	1.58	2.22
	2.50	1.74	1.64
	5.00	1.96	1.22
	7.50	2.07	1.01
	10.0	2.19	0.87

a) 0.0094 M NaOH. b) 0.20 M NaOH.

cyclodextrin–substrate complex, k_{obsd} is represented by Eq. 1[1,2] if [CD] is much higher than that of a substrate ([S]):

$$k_{obsd} = K_{diss}(k_{un}-k_{obsd})/[CD] + k_c \quad (1)$$

In this equation, K_{diss} is the dissociation constant of an inclusion complex, and k_{un} and k_c, the rate constants for free and complexed substrates respectively. The plot of k_{obsd} *vs.* $(k_{un}-k_{obsd})/[CD]$ was virtually linear for each cyclodextrin–substrate system, and the values of K_{diss} and k_c were calculated from the slope and the intercept of the line respectively.

Calculation of Equilibrium and Kinetic Parameters from the pH Dependence of the Cyclodextrin-rate Effects. We postulated the reaction scheme shown below in order to explain the pH dependence of the cyclodextrin-rate effect:

Equilibrium Processes:

$$\begin{array}{ccc} \text{CDOH} + \text{S} & \overset{K_{diss}}{\rightleftharpoons} & \text{CDOH}\cdot\text{S} \\ K_a \uparrow\downarrow \text{OH}^- & & K_a \uparrow\downarrow \text{OH}^- \\ \text{CDO}^- + \text{S} & \overset{K_{diss}}{\rightleftharpoons} & \text{CDO}^-\cdot\text{S} \end{array}$$

Reaction Processes:

$$\text{S} + \text{OH}^- \xrightarrow{k_f} \text{P}$$

$$\text{CDO}^-\cdot\text{S} \xrightarrow{k_s} \text{P}$$

$$\text{CDOH}\cdot\text{S} + \text{OH}^- \xrightarrow{k_b} \text{P}$$

$$\text{CDO}^-\cdot\text{S} + \text{OH}^- \xrightarrow{k_b} \text{P}$$

where CDOH and CDO^- represent the unionized and ionized cyclodextrins respectively; S, a substrate; P, products; K_a, the first ionization constant of cyclodextrin; k_s, the first-order rate constant for the reaction of a completed substrate with the cyclodextrin alkoxide ion, and k_f and k_b, the second-order rate constants for the reactions of free and complexed substrates respectively with OH^-. We assumed that (1) the ionization of cyclodextrin has approximately no effect on the K_{diss} and k_b values; (2) the inclusion of a substrate also has little effect on the K_s value, and (3) the reaction of a substrate with the unionized cyclodextrin is negligible. Then, the rate constants, k_{un} and k_c, may be represented as is shown below:

$$k_{un} = k_f[OH^-] \quad (2)$$

$$k_c = k_s\{K_a[OH^-]/(K_a[OH^-]+K_w)\} + k_b[OH^-] \quad (3)$$

where K_w is the ion product of water and where the term, $K_a[OH^-]/(K_a[OH^-]+K_w)$, corresponds to the fraction of the ionized cyclodextrin. To calculate the values of k_s, k_b, and K_s in Eq. 3 from the $[OH^-]$ dependence of k_c observed, we used a computerized statistical technique of regression analysis. The calculated values excellently well explained the measured values of k_c at various OH^- concentrations with the correlation coefficients of 0.986 to 0.999, as is illustrated in Figs. 1 and 2.

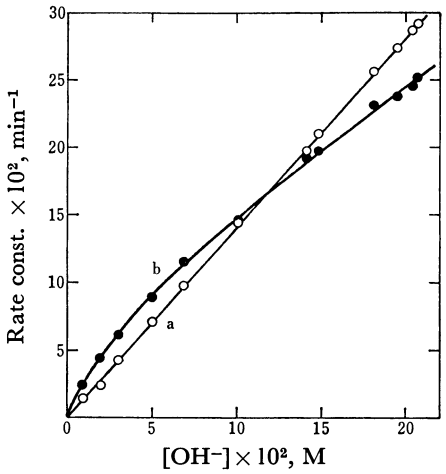


Fig. 1. Plots of k_{un} (a) and k_c (b) *vs.* $[OH^-]$ for **1a** at 25 °C and I_c=0.65 M. The solid lines were computed using the parameters in Table 3 and correspond to the best fit.

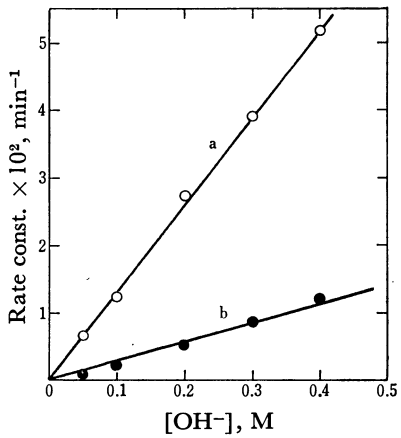

Fig. 2. Plots of k_{un} (a) and k_c (b) *vs.* $[OH^-]$ for **2a** at 25 °C and I_c=0.65 M. The solid lines were computed using the parameters in Table 3 and correspond to the best fit.

Determination of the Dissociation Constant of a Cyclodextrin–4 Complex. A 0.20 M NaOH solution (I_c=0.65 M) containing 1.33×10^{-5} M **4** and 0.0, 1.0, 2.5, 5.0, 7.5, or 10.0 mM α- or β-cyclodextrin was added to a 1.00-cm quartz cell. After the cell had been maintained at 25.0±0.1 °C, the absorption spectrum of each solution was measured by means of a Hitachi Model 124 spectrophotometer. The K_{diss} value was determined on the basis of the well-known equation:[9]

$$[CD][S]/\Delta Abs = K_{diss}/\Delta\varepsilon + [CD]/\Delta\varepsilon \quad (4)$$

where ΔAbs is the decrease in the absorbance at 380 nm of a **4** solution on the addition of cyclodextrin, and $\Delta\varepsilon$, the difference in the molar absorption coefficient at 380 nm between the free and the complexed **4** anions. The plot of $[CD][S]/\Delta Abs$ *vs.* [CD] gave an approximately straight line for a β-cyclodextrin–**4**

system, and the $\Delta\varepsilon$ and K_{diss} values were determined to be 2.8×10^{3} $M^{-1}cm^{-1}$ and 6.5×10^{-3} M respectively from the slope and the intercept of the line. The spectrum of **4** was not changed by the addition of α-cyclodextrin up to 10.0 mM.

Results

The dissociation constants (K_{diss}) of cyclodextrin–substrate-inclusion complexes and the first-order rate constants, k_{un} and k_c, of the free and included substrates respectively were measured or evaluated by the use of Eq. 1; they are summarized in Table 2. The rate effect of α-cyclodextrin on the reactions of **1a**, **2a**, and **2b** was not large enough for the corresponding k_c and K_{diss} values to be determined.

Table 2. Rate constants and dissociation constants for cyclodextrin–organic ester systems at 25.0 °C and I_c=0.65 M

To learn the role of OH^- in the reactions of the esters, the reaction rates were measured at various alkaline concentrations in the absence and in the presence of cyclodextrin. The resulting rate constants, k_{un} and k_{obsd}, as well as the K_{diss} values given in Table 2, were used to calculate the k_c values at various OH^- concentrations on the basis of Eq. 1. The rate constants, k_c, thus obtained, together with the k_{un} values, were then plotted against [OH^-], as is illustrated in Figs. 1 and 2 for the β-cyclodextrin-**1a** and -**2a** systems respectively. The plot of k_{un} *vs.* [OH^-] for each substrate gave a good straight line through the point of origin. On the other hand, the plot of k_c *vs.* [OH^-] gave a hyperbolic curve for each phosphate or acetate system: The k_c values at lower OH^- concentrations were larger than the corresponding k_{un} values, but the slope of the curve decreased with an increase in the OH^- concentration until it reached a constant value. In some cases, the k_c value became smaller than the corresponding k_{un} value in a high OH^- concentration region (Fig. 1). The k_c values for the monothiophosphates were always smaller than the corresponding k_{un} values and increased linearly with an increase in the OH^- concentration over the whole [OH^-] range studied.

It is impossible to explain these [OH^-] dependencies of k_c in terms of the reaction scheme proposed by Van-Etten *et al.*[10] for cyclodextrin–phenyl benzoate systems. They neglected the contribution of the k_b term to k_c in Eq. 3 and thought $k_c=k_a\{K_a[OH^-]/(K_a[OH^-]+K_w)\}$. Then, k_c should asymptotically approach a constant value of k_a with an increase in the OH^- concentration. This is not the case at present. On the contrary, the [OH^-] dependencies of k_c observed can be well explained by the use of Eq. 3 which involves the k_b term, too. Thus, when [OH^-] is low enough to be $K_a[OH^-]\ll K_w$, k_c in Eq. 3 becomes proportional to [OH^-]:

$$k_c = [(k_aK_a/K_w)+k_b]\cdot[OH^-] \quad (5)$$

When [OH^-] is high enough to be $K_a[OH^-]\gg K_w$,

$$k_c = k_a + k_b[OH^-] \quad (6)$$

This may be the case for the phosphate and acetate systems. If the k_a term is negligibly small compared with the k_b term in Eq. 3, k_c is given by:

$$k_c = k_b[OH^-] \quad (7)$$

This may be the case for the monothiophosphate systems. The actual values of K_a, k_a, and k_b for each reaction system were calculated by means of regression analysis with a computer (Table 3). The solid lines in Figs. 1 and 2 were drawn on the basis of the values in Table 3. They are in excellent agreement with the experimental values with correlation coefficients above 0.999.

Discussion

The rates of the phenol release from the phosphates, monothiophosphates, and acetates in the absence of cyclodextrin showed a first-order dependence on the substrates and also on OH^-. The reactions may involve a nucleophilic attack of OH^- at the phosphorus atoms of the phosphates and monothiophosphates or at the carbonyl carbon atoms of the acetates. The water-catalyzed hydrolysis of the esters may be negligible under the present reaction conditions.

Both α- and β-cyclodextrins significantly affected the reaction rates of the esters, while methyl α-D-glucopyranoside did not. This fact, as well as the fact that the rate effect is saturated with an increase in the cyclodextrin concentration, indicates that the prior formation of an inclusion compound between cyclodextrin and a substrate is essential to the rate effect.

A marked substrate specificity was found for the cyclodextrin-catalyzed cleavage of the esters studied. Thus, β-cyclodextrin accelerates the phenol release from the **1a**, **1b**, and **1c** phosphates and the **3a** and **3b** acetates at low OH^- concentrations, while it decelerates the corresponding reactions of the monothiophosphates, **2a** and **2b**. α-Cyclodextrin also accelerates the phenol release from the **1b** and **1c** phosphates and the **3a** and **3b** acetates, whereas it only slightly decelerates the corresponding reactions of **1a**, **2a**, and **2b**.

These specific rate effects of α- and β-cyclodextrins may be related to the stereochemistry of cyclodextrin–substrate complexes.[1,2] Thus, a spectrophotometric study (see the Experimental section), together with a study with the Corey-Pauling-Koltum scale molecular models, suggests that the 3-methyl-4-nitrophenyl moiety of **1a** or **2a** is too large to be included in the α-cyclodextrin cavity, but it is small enough to be included in the β-cyclodextrin cavity. The 4-nitrophenyl moiety of **1b**, **1c**, or **2b** and the carboxyphenyl moiety of **3a** or **3b** are small enough to be included in both the α- and β-cyclodextrin cavities.[2] Therefore, the relatively small effect of α-cyclodextrin on the rates of the reactions of **1a** and **2a** may be due to the binding to the α-cyclodextrin cavity of the parts other than the 3-methyl-4-nitrophenyl moiety of the substrate molecules. In such cases, the reaction sites of the substrates may be located too far from the catalytic site of α-cyclodextrin for them to react with each other.

The kinetic and equilibrium parameters determined by the regression analysis of the $[OH^-]$ dependency of k_c also serve as a basis for speculation about the geometry of a cyclodextrin-substrate complex. As VanEtten *et al.*[2] suggested, the ratio of k_a/k_f may be a measure of the proximity between the reaction site of a substrate and the catalytic site (the alkoxide ion) of cyclodextrin in a cyclodextrin-substrate complex. Furthermore, the ratio of k_b/k_f may depend on how much the reaction site of an included substrate is protected from the nucleophilic attack of OH^- compared with the free substrate.

The k_a/k_f values for β-cyclodextrin–monothiophosphate systems are virtually zero, and the k_b/k_f values for these systems are significantly smaller than those for β-cyclodextrin–phosphate systems. This fact suggests that the phosphorus atoms of the monothiophosphates are located in the middle of the cyclodextrin cavity. The electronegativity of sulfur (2.44[11]) is less than that of oxygen (3.50[11]), and the atomic radius of sulfur (1.27 Å[11]) is larger than that of oxygen (0.6 Å[11]). Therefore, the monothiophosphate group may be more hydrophobic than the corresponding phosphate group, and the former may be included more deeply in the β-cyclodextrin cavity than the latter. This presumption is supported by the fact that the inclusion complexes of β-cyclodextrin with monothiophosphates are more stable than those with the corresponding phosphates (compare the K_{diss} values in Table 2). On the other hand, the phosphorus atoms of the phosphates or the carbonyl carbon atoms of the acetates may be located in the vicinity of the secondary hydroxyl groups which are arranged around one edge of the torus of cyclodextrin. Hence, the k_a/k_f values are appreciably large for the phosphates and the acetates. The k_a/k_f values for α-cyclodextrin–phosphate and –acetate systems are generally larger than those for the corresponding β-cyclodextrin systems. This fact may be a result of the size of α-cyclodextrin being smaller than that of β-cyclodextrin.[2]

The pK_a values determined for various cyclodextrin–organic ester systems varied within a relatively small range of 12.1 to 12.7, with the one exception of pK_a= 11.4 for an α-cyclodextrin–**1b** system. VanEtten *et al.*[10] and Van Hooidonk and Groos[12] also estimated the pK_a value of α-cyclodextrin to be 12.1 and 12.6 respectively. The small variation in the pK_a value may be due either to experimental error or to a substrate-induced pK_a change, such as has often been observed for enzyme systems. Further accurate experiments may be necessary to determine which of them is the case.

Only in the case of an α-cyclodextrin–**1b** system is the pK_a value unusually small and the k_b/k_f value unusually large. A study with the scale molecular models suggested the possibility that the phosphonyl oxygen (>P→O) of **1b** included in α-cyclodextrin is located in the vicinity of one of the secondary hydroxyl groups of α-cyclodextrin close enough to form the hydrogen bonding between them. Upon the formation of such bonding, the acid dissociation of the cyclodextrin hydroxyl group may be facilitated, and at the same time the ester linkage of the substrate may be weakened to make it susceptible to the nucleophilic attack of OH^-. Cramer *et al.*[13,14] have also postulated the formation of hydrogen bonding between cyclodextrin and a substrate to explain the catalytic effect of cyclodextrin. However, the definite meaning of k_b/k_f remains to be ascertained.

The authors wish to acknowledge the technical assistance afforded by Messrs. Yoriyoshi Asano, Takashi Doi, and Tamotsu Shimizu.

The Thermal Decomposition of *N*-Thiocarbonyl Diphenylsulfimides

Hiroshi Yoshida, Hitoshi Taketani, Tsuyoshi Ogata, and Saburo Inokawa

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received April 19, 1976)

N-Thiocarbonyl diphenylsulfimides, Ia—i (R = Ph, *p*- and *m*-MeC_6H_4, *p*- and *m*-$MeOC_6H_4$, MeO, EtO, MeNH, and Me_2N), were prepared, and their thermal decomposition were studied. At 70 °C, Ia—h decomposed easily to give nitriles (or their derivatives), together with diphenyl sulfide and sulfur. Contrary to these results, the oxygen analog of Ia, g showed no decomposition even upon heating at 140 °C. The thermolysis of Ia—e in the presence of excess acetylenes(III) gave isothiazoles(IV) in moderate yields. Thiazirine(V) and nitrile sulfide(VI) may be supposed, on the basis of the kinetic experiments, to be possible intermediates for the thermal decomposition of Ib—e.

Recently a number of workers have reported on the preparation and reactions of free sulfimides[1-3] and their *N*-substituted derivatives, such as *N*-acetyl,[2,4,5] and *N*-tosyl.[3,6,7] In the course of our studies of the thiocarbonyl-stabilized *P*- and *S*-ylides and imides, we have found an interesting thermal decomposition of *N*-thiocarbonyl diphenylsulfimides(I):

$$Ph_2S{=}N{-}C(=S)R$$

I

We wish to report here on the thermal decomposition of I in the presence and in the absence of acetylenes(III).

Results and Discussion

It has been reported that free diphenylsulfimide reacts with acylating reagents, such as acid chloride and acid anhydride, to give *N*-acylsulfimides.[1,2] Here we have found the reactions of free diphenylsulfimide with methyl dithiobenzoates and xanthates to give *N*-thiocarbonyl substituted sulfimide(I) in moderate yields. The results are shown in Table 1. The sulfimides, Ia—e, decomposed slowly, even at room temperature.

The thermal decomposition of some sulfimides which have α- or β-hydrogen has been studied.[4-6] The thermolysis of *N*-acetyl dialkylsulfimide having β-hydrogen gives olefin and *N*-(alkylthio)acetamide.[4,5] However, *N*-acetyl dimethylsulfimide gives dimethyl sulfide, bis-(methylthio)methane, *N*,*N*′-methylenebisacetamide, and *N*,*N*′,*N*″-methylenetrisacetamide, which are formed by a mechanism involving a Pummerer-type rearrangement.[4,5]

N-Benzoyl and ethoxycarbonyl diphenylsulfimides (oxygen analogs of Ia and Ig) were highly stable, and did not decompose even under heating at 140 °C for 10 h. Contrary to these results, *N*-thiocarbonyl sulfimides(I) were thermally unstable, as is shown in Table 1. All the reaction products were identified by comparing their NMR and IR spectra with those of the authentic samples. Generally *N*-thiocarbonyl sulfimides(I) decomposed to give nitriles(II) (or their derivatives), together with diphenyl sulfide and sulfur. The thermolysis of If and Ig gave methyl and ethyl cyanates respectively as the initial products (NMR observation),

$$Ph_2S{=}N{-}C(=S)R \longrightarrow RCN + Ph_2S + (1/8)S_8$$

I II

but they easily rearranged to isocyanates and trimerized to tri(alkyl isocyanates). The instability of alkyl cyanates is well known.[8]

The thermolysis of Ia—e in the presence of excess acetylenes(III) gave isothiazoles(IV), together with nitrile(II), diphenyl sulfide, and sulfur. The structure of IV was confirmed by comparing the NMR and IR spectra with those of the authentically prepared samples and by elemental analyses (Table 2).

Tables 3 and 4 show the effects of the concentrations and the substituents of I and III on the product compositions, II: IV, as determined by means of the NMR spectrum. The total yields(II+IV) were quantitative, and the II: IV ratios were independent of the concentration of III.

On ultraviolet irradiation in the presence of acetylenedicarboxylate, 4-aryl-1,3,2-oxathiazoline 5-oxides give isothiazole derivatives, together with nitrile and sulfur.[9] Thiazirine and nitrile sulfide are supposed to be intermediates for this photolysis. It has also been reported that benzonitrile sulfide is a possible intermediate for the thermolysis of 5-phenyl-1,3,4-oxathiazol-2-one in the presence of dimethyl acetylenedicarboxylate to give an isothiazole derivative.[10] We similarly supposed that nitrile sulfide was a probable intermediate for the thermolysis of Ia—e.

We have performed kinetic experiments to find a possible mechanism for the thermal decomposition of I. The decomposition of I gave a good first-order rate constant(k_1), as followed by NMR spectroscopy, and k_1 was independent of the concentration of I(0.08—0.25 mol/l). The results are summarized in Table 5. The effects of solvents and substituents ($\rho=+0.22$ to Hammett's σ in benzene at 50 °C) are very small, and positive activation entropies are observed.

a) Errors are within 5%.

When the reaction of Ib with III(R′=COPh) was carried out in a benzene solution, and followed by NMR spectroscopy, the product ratio, IIb/IVb (R′=COPh), was nearly constant while the reaction proceeded. Two representative kinetic runs are shown in Table 6, and the results are collected in Table 7. The results in the table indicate that k_{disapp}(I) is equal to k_{app}(II)+k_{app}(IV), that k_{app}(II) is constant in either the presence orabsence of III, and that, moreover, k_{app}(IV) is unaffected by the concentration of III, but highly de-

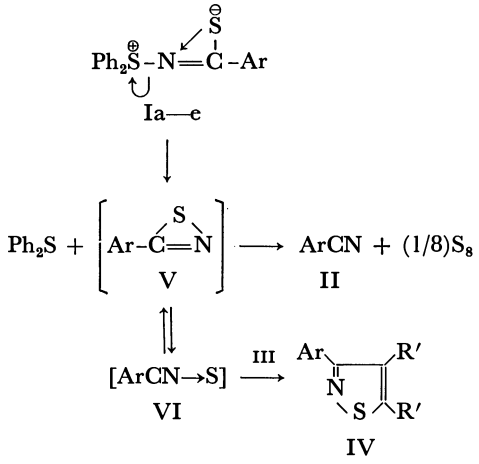
Ia—e

$$ArCN + Ph_2S{=}S \longrightarrow Ph_2S + (1/8)S_8$$

II

The explanation that II is formed by a simple four-membered cyclic transition state seems improbable,

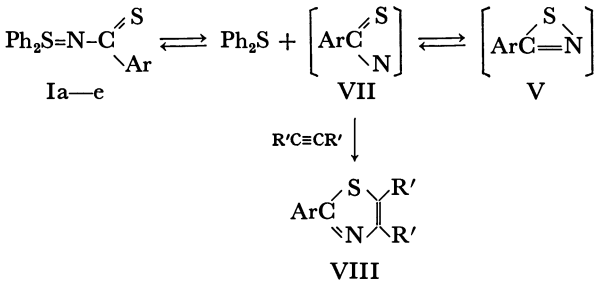


Scheme 1.

since the thermolysis of I showed positive activation entropies (Table 5) and I gave IV in the presence of III.

The mechanism we suggest is shown in Scheme 1: the initial formation of thiazirine(V), followed by two reaction paths. One is a rate-limiting cheletropic reaction of V to give II and sulfur, while the other is the ring opening of V to afford nitrile sulfide(VI), which then undergoes 1,3-dipolar cycloaddition to acetylene(III). A direct path from VI to yield II seems improbable, since rate for the appearance of II(k_{app} (II)) was unaffected by the III added (Table 7). Thus, we propose a rapid equilibrium between V and VI.

Another possible mechanism or intermediate is the formation of thiocarbonyl nitrene(VII), followed by the formation of thiazirine(V):



Ia—e VII V

VIII

Acyl nitrenes have proposed as intermediates in the Curtius rearrangement of carbonyl azides to isocyanates.[11] Some addition reactions of acyl nitrenes with sulfoxides, olefins, and acetylenes have been reported.[11] At present we have no positive evidence for the existence of the intermediate(VII). In the thermolysis of Ia—e, no isothiocyanate was observed. No addition product was isolated from the attempted reaction of Ib with dimethyl sulfoxide, cyclohexene, dimethyl fumarate, and maleate. Moreover, the result that the reaction of Ia—e with acetylenes gave isothiazoles, not thiazoles-(VIII), seems to show an intermediate(VII) having no possibility of existence or any significant lifetime.

Experimental

Preparation of Ia—i. Free diphenylsulfimide was prepared according to the literature.[3] A general procedure for the preparation of I is as follows: a mixture of diphenylsulfi-

mide (2.01 g (0.01 mol)) and methyl dithiobenzoate (2.02 g (0.012 mol)) in 50 ml of dry benzene was stirred for 3 h at room temperature. The resulting solution was treated with charcoal, and condensed *in vacuo* to give an oil, which gave needles Ia from benzene–hexane (without heat). Similarly, Ia—h were prepared in moderate yields.

Ii was prepared as follows: to a solution of diphenylsulfimide (2.01 g (0.01 mol)) and 0.9 g (0.012 mol) of pyridine in dry ether (30 ml), we slowly added 1.23 g (0.01 mol) of dimethylthiocarbamoyl chloride in ether (30 ml) at room temperature. After the mixture was stand for 4 h, the oily precipitate was separated and the resulting solution was dried *in vacuo* to give a crystalline mass, which afforded needles (Ii) from ethyl acetate–petroleum ether. The physical properties are shown in Table 1.

Thermal Decomposition of I. All the reactions were followed by NMR spectroscopy and TLC. The reaction products were identified by comparing their NMR and IR spectra with those of the authentic samples. The yields of the products were determined by VPC (IIa—e) or NMR (IIf—h), using mesityrene as the internal standard. The thermal decomposition of If, g in benzene was followed by NMR spectroscopy. The methyl signal of If, which appeared at δ 4.14, decreased in its intensity, giving new three peaks at 2.25 (MeNCO), 2.56 (MeOCN), and 3.08 [$(MeNCO)_3$]. Finally, the signals at 4.14 and 2.56 disappeared entirely. Similarly, on the thermolysis of Ig a methylene quartet (J=7 Hz) at 4.14 for Ig gave methylene quartets at 2.20(EtNCO), 3.31 (EtOCN), and 3.74 [$(EtNCO)_3$].

The yields of the products are collected in Table 1.

Thermal Decomposition of Ia—e in the Presence of Acetylene-(III). All the reactions were followed by means of the NMR spectral changes. The product compositions, II: IV were obtained by NMR spectroscopy. The isothiazoles were separated as follows: the resulting mixture was condensed *in vacuo*, and elemental sulfur was precipitated by the addition of petroleum ether. The subsequent condensation of the petroleum ether solution *in vacuo* (100 °C/1 Torr) afforded an oil which gave crystals upon the addition of a small amount of petroleum ether. The physical properties and analytical results of isothiazoles (IV) are collected in Tables 2 and 3.

Attempted Reactions of Ib with Olefins and DMSO. The reactions were followed by means of the NMR spectral changes. A solution of Ib (15 mg) and dimethyl fumarate or maleate or cyclohexene (30 mg) in benzene (0.4 ml) was heated in an oil bath at 70 °C for 15 min. The product was *p*-tolunitrile.

A solution of Ib (20 mg) in DMSO (0.5 ml) was heated at 70 °C for 20 min. Then the solution was quenched in 5 ml of water and extracted with 1 ml of chloroform. The extract was dried over sodium carbonate, and the product was found by NMR and VPC analyses to be a mixture of *p*-tolunitrile and diphenyl sulfide.

Kinetic Studies. A solution of I (0.05—0.25 mol/l) and III (0.0—0.45 mol/l) in dry benzene (or other solvents) was sealed in an NMR sample tube; the rate was followed at suitable time intervals by analyzing the NMR spectra of the methyl groups of I, II, and IV. The results are summarized Tables 5—7.

The Preparation and Reactions of α-Thiocarbonyl Dimethyloxosulfonium Ylides

Hiroshi YOSHIDA, Terutaka YAO, Tsuyoshi OGATA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received April 19, 1976)

α-Thiocarbonyl dimethyloxosulfonium ylides IIIa—e were prepared in moderate yields. The ester-stabilized ylides, IIIa—c, were mixtures of *E* and *Z* isomers, and IIIe was *Z*. The methylation of III with methyl iodide gave *S*-methylated products, IV, in quantitative yields. The thermal decomposition of IVa and IVe gave I(R=Me) and V respectively in good yields. The treatment of IIIb—e with carbon disulfide afforded 1,2-dithiole-3-thiones VIIIb—e in moderate yields.

The physical and chemical properties of carbonyl-stabilized sulfur ylides, such as I and II, have been widely studied in recent years.

I II

In the course of our studies of α-thiocarbonyl-stabilized[1] *P*- and *S*-ylides and imines, we have found interesting results on α-thiocarbonyl-stabilized dimethyloxosulfonium ylides, III. Here we will report our experimental observations of the structure and reactions of III. Some α-thiocarbonyl-stabilized sulfonium ylides are isolated as unstable compounds.[2]

Results and Discussion

Preparation of Ylides, III. A number of carbonyl-stabilized ylides, I, have previously been prepared from dimethyloxosulfonium methylide with such acylating reagents as acid chloride, acid anhydride, and alkyl carboxylate.[3] However, the reaction of dimethyloxosulfonium methylide with such thionoesters as dimethyl trithiocarbonate or methyl dithiobenzoate gives olefinic products.[4] We also could not isolate any ylide from the reaction of dimethyloxosulfonium methylide with alkyl xanthates. However, the action of the methylide with thioacylating reagents, such as xanthic anhydride, tetramethylthiuram monosulfide, and thiobenzoyl chloride, afforded α-thiocarbonyl dimethyloxosulfonium methylides, IIIa—e, in moderate yields (Table 1). The use of good leaving groups may give the expected products.

X=RCS_2 or Cl

Structure and Methylation of IIIa—e. Evidence for the resonance interaction of ylide carbanion with a thiocarbonyl group can be obtained by an examination of the infrared spectra of thioacyl ylides, III. The S=O and C=S streching frequencies of III occurred at 1020—1030 and 1160—1190 cm^{-1} respectively, as is shown in Table 1. Considering the C=S stretching frequencies of the model compounds (*O*-ethyl thioacetate (1250—1260 cm^{-1}),[5] diaryl thioketone (≈1220 cm^{-1}),[6] dialkyl thioketones (≈1260 cm^{-1}),[7] *N*,*N*-dimethylthioacetamide(1122 cm^{-1})[8]], the shift of 50—100 cm^{-1} for IIIa—c,e may be attributed to the increased single-bond character to the delocalization of the carbanion electrons through the thiocarbonyl groups (*i.e.*, betain forms). A shift to the higher frequency for IIId may diminish the

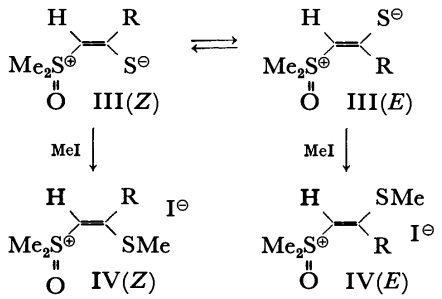
double-bond character of the thioamide resonance form, $^{\ominus}S\rangle C{=}\overset{\oplus}{N}Me_2$. This observation accords with the appearance of only one peak for two *N*-methyl groups in the NMR spectrum of IIId.[9]

The structure of the III ylide was confirmed on the basis of NMR spectroscopic studies and methylation reaction. These ylides, IIIa—e, reacted easily with methyl iodide to give only *S*-methylation products, IVa—e, in good yields. IIIa—c were mixtures of *E* and *Z* isomers, while IIId,e were composed of only *Z* isomers.



The NMR spectra of the carbonyl-stabilized sulfur ylides, I and II, have been widely studied in recent years. Much of this interest has involved the observation of geometrical isomers in these compounds.[4] Ester-stabilized ylides, I(R=alkyl–O)[10] and II(R=alkyl–O),[11] are known to be mixtures of *E* and *Z* isomers at lower temperatures.

The NMR spectra of ester-stabilized ylides, IIIa—c, at 34.5 °C showed peaks of two groups corresponding to the *E* and *Z* isomers. The stereochemistry of IIIa—c was assigned on the assumption that the methine proton *cis* to the thiolate sulfur may appear at a higher field than the methine proton *trans* to the thiolate sulfur as a result of the anisotropic shielding by the thiolate sulfur.[12] The results are shown in Table 1. The *E* isomers are much more favored than the *Z* isomers in $CDCl_3$. The methylation reactions of IIIa—c with methyl iodide to give IVa—c also support the structure determination of IIIa—c. The stereochemistry of the methylation products, IVa—c, was assigned on the basis of the chemical shifts of the vinyl protons using the values of Pascuel, Meier, and Simon.[13] Table 2 indicates that the *Z*/*E* ratio for IVc agrees well with that for IIIc. The marked deviation of the *Z*/*E* value for IVa, b from that of IIIa, b is caused by the partial decomposition of IVa, b during the methylation reaction, since IVa, b decomposes much faster than does IVc (the thermal decomposition of IVa—c will be described later). As a result, IIIa—c and IVa—c exist mainly in *E* forms.

Table 3. Solvent effects on the *Z*:*E* isomer ratios in IIIa-c at 34.5 °C

Solvent (ε)	IIIa *Z*:*E*	IIIb *Z*:*E*	IIIc *Z*:*E*
PhH (2.27)	16:84	15:85	16:84
$CDCl_3$ (4.7)	33:67	30:70	28:72
PhCl (5.61)	16:84	18:82	21:79
PhCN (25.2)	33:67	34:66	36:64
$PhNO_2$ (34.8)	28:72	32:68	38:62

The *Z*/*E* isomer ratios for IIIa—c in a variety of solvents at 34.5 °C are summarized in Table 3.

The solvent effect on the isomer ratios for ester-stabilized *P*-ylides has been widely studied.[14] The population of the *E* isomer increases consistently with an increase in the solvent polarity and with the bulkiness of the alkoxyl group; also, the *Z*/*E* ratio is governed by the dipole interaction between $P^{\oplus}$ and $O^{\ominus}$, and by the solvation of the carbonyl group.

Unlike the ester-stabilized *P*-ylides, the oxosulfonium ylides, IIIa—c, show no solvent dependence (Table 3), and *E* isomers were favoured in all the solvent used. Some keto-stabilized *S*-ylides have been shown to be mixtures of *E* and *Z* isomers.[10] Simple *keto*-stabilized ylides, such as I (R=Me, Ph)[10] and II(R=Ph),[15] show no evidence of the restricted rotation on the NMR spectra; however, they are believed to be *Z* isomers, since the following reasons may favor the *Z* form: i) steric repulsion between the sulfonium and R groups, and ii) electrostatic attraction between the positive sulfur and the negative enolate oxygen. Moreover, the alkylation of *keto*-stabilized sulfur-ylides[15,16] with trialkyloxonium tetrafluoroborate gives a mixture of *E* and *Z* *O*-alkylation products. This result indicates that the alkylation reaction does not necessarily support the presence of rotational isomers.

The methylation of IIId, e with methyl iodide gave only one isomer in quantitative yields (Table 2). The isomer was supposed to be *Z* on the basis of the following two results.

Some reports[17] show the good correlation between the chemical shifts of olefinic protons situated at the *cis* position to R and Hammett's σ_p for R: $\begin{matrix} H & R \\ \rangle{=}\langle \end{matrix}$ Similar treatments for IIIa—e and IVa—e (Figs. 1 and 2) gave straight lines for IIIa—c (*Z*), and IIId,e and for IVa—c (*Z*), and IVd,e respectively.

the conjugate acids of ylide carbanions.[19] Thus, the reaction of III with carbon disulfide may proceed as is shown below to give stable 6π compounds, VII.

Experimental

Preparation of III. Method A (in a mixture of DMSO and THF). Dimethyloxosulfonium methylide (0.15 mol) in DMSO (25 ml) was prepared from DMSO, NaH (0.15 mol), and trimethyloxosulfonium iodide (0.15 mol) according to the literature.[3] To a solution diluted with 70 ml of dry THF, we added methylxanthic anhydride (0.075 mol) in 15 ml of THF, portion by portion, for 15 min in an ice-water bath; stirring was then kept up for 2 h. The resulting mixture was quenched in ice water and extracted with 200 ml of chloroform. The chloroform extract was dried over magnesium sulfate and condenced *in vacuo* to give an oily product, which gave crystals (IIIa) from chloroform–petroleum ether. The yield and physical properties are shown in Table 1.

IIIb—e were prepared similarly.

Method B(in THF). Dimethyloxosulfonium methylide (0.15 mol) in THF (250 ml) was prepared from trimethyloxosulfonium chloride and NaH according to the literature.[3] To the solution we added tetramethylthiuram monosulfide (0.075 mol) in benzene (50 ml), portion by portion, at room temperature. The reaction mixture was stirred for 24 h, and then the precipitates were filtered off. The filtrate was condensed and chromatographed over silica gel with benzene–ethyl acetate (2: 1 v/v) to give IIId.

Reaction of III with Methyl Iodide. A solution of III in chloroform was treated with an excess of methyl iodide at room temperature for a few hours. The addition of benzene to the solution afforded IV in good yields (Table 2).

The decomposition of IV was run in $CDCl_3$ at 34.5 °C, the process being followed by NMR spectroscopy. IVa gave ylide I(R=SMe) and methyl iodide in quantitative yields after one day. I(R=SMe): Mp 109—110 °C (chloroform–ether). NMR (δ in $CDCl_3$): 2.30 (s, 3H, MeS), 3.42 (s, 6H, Me_2S), and 4.54 (s, 1H, C<u>H</u>-CO). Found: C, 36.01; H, 5.92%. Calcd for $C_5H_{10}O_2S_2$: C, 36.12; H, 6.06%.

IVe gave V in about a 90% yield and methyl iodide in a quantitative yield. V: Mp 68.5—70 °C (ether). NMR (δ in $CDCl_3$): 2.06 (s, 3H, SMe), 2.76 (s, 3H, SOMe), and 6.61 (s, 1H, C<u>H</u>=C). Found: C, 56.03; H, 5.97%. Calcd for $C_{10}H_{12}OS_2$: C, 56.57; H, 5.70%.

Photoisomerization was run in $CDCl_3$, with the NMR spectral change being followed. On irradiation with a high-pressure mercury lamp, V gave an equilibrium mixture of V and VI (1: 2) after 18—20 h. Subsequent condensation and the addition of a small amount of petroleum ether afforded VI. VI: Mp 138—140.5 °C. NMR (δ in $CDCl_3$): 2.41 (s, 3H, SMe), 2.66 (s, 3H, SOMe), and 6.15 (s, 1H, C<u>H</u>=C). Found: C, 56.43; H, 5.57%. Calcd for $C_{10}H_{12}OS_2$: C, 56.57; H, 5.70%.

A similar irradiation of VI in $CDCl_3$ afforded again a mixture of V and VI (1: 2).

The Reaction of III with Carbon Disulfide. A solution of IIIb (1.0 g) and carbon disulfide (2.0 g) in chloroform (20 ml) was refluxed for 3 h in a stream of nitrogen. The resulting mixture was condensed and chlomatographed over silica gel with hexane–ethyl acetate (6: 1). VIIb was isolated and crystallized from benzene–ether. Yield, 0.27 g; Mp 82—82.5 °C. Ms: 178(M^+).

VIIc was similarly isolated. VIIc: Mp 59.5—60.5 °C. MS: 192 (M^+). Found: C, 37.56; H, 4.22%. Calcd for $C_6H_8OS_3$: C, 37.50; H, 4.17%.

VIId, e were isolated from a crude reaction mixture and confirmed by comparison with known samples.[20,21] The results are collected in Table 4.

The Photochemical Reaction of 1,1,4,4-Tetramethyl-2,3-tetralindione with Hydrogen Donors

Kazuhiro MARUYAMA and Tomoji TAKAHASHI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received April 23, 1976)

The photochemical reaction of 1,1,4,4-tetramethyl-2,3-tetralindione, **1**, with hydrogen donors, such as xanthene and aldehyde, in the liquid phase has been investigated. When xanthene was selected as the hydrogen donor, the main products were the "1,2-adduct," photo-reduced α-keto alcohol, and 9,9′-bixanthenyl. The photolysis of **1** and an aldehyde gave the mixture of the "1,2-adduct" and the "1,4-adduct." However, in the reaction with isobutyraldehyde another type of "1,2-adduct" was obtained, *i.e.*, a combination product between the semidione radical and the isopropyl radical resulting from the decarbonylation of the isobutyryl radical, together with propene and carbon monoxide. The usual type of "1,2-adduct," the "1,4-adduct," and the photo-reduced product (α-keto alcohol) were the minor products in the reaction. It was also confirmed that the original "1,4-adduct" obtained from **1** and acetaldehyde rearranged photochemically to a different type of "1,2-adduct," but no reverse rearrangement was observed under the present conditions. The mechanisms of the reactions were discussed on the basis of product analysis and the examination of the reaction by means of CIDNP.

The photo-excited α-diketone abstract the hydrogen atom from the suitable hydrogen donor, giving the semidione radical.[1] In our previous study,[2] it was reported that 3,3-dimethyl-1,2-indandione also abstracts the hydrogen atom from aldehydes. However, no appreciable amounts of products were obtained in most cases because of the occurrence of a back reaction from the unstable intermediates produced by the attack of the acyl radicals on the aromatic ring of the conjugated semidione radical. This paper will deal with the photochemistry of 1,1,4,4-tetramethyl-2,3-tetralindione **1** as a non-enolizable α-diketone whose dicarbonyl group can not conjugate with aromatic π-electrons.

A few papers have appeared on the photochemical reaction of 1,1,4,4-tetramethyl-2,3-tetralindione, **1**, with some hydrogen donors.[3,4] However, the mechanism of the reaction has not yet been discussed. In order to understand the characteristics of the photochemical reaction, the mechanism of the reaction has now been investigated by means of the CIDNP technique.

Results and Discussion

In all of the photochemical reactions described below, a benzene solution of **1** and a hydrogen donor in a usual glass tube was irradiated from the outer side by means of a 300W high-pressure mercury arc lamp at room temperature.

The irradiation of **1** and xanthene gave a "1,2-adduct," 3-hydroxy-1,1,4,4-tetramethyl-3-xanthenyl-2-tetralone, **2**; as a photo-reduced product, 3-hydroxy-1,1,4,4-tetramethyl-2-tetralone, **3**, and 9,9′-bixanthenyl, **4**, in yields of 42, 50, and 45% respectively. As Fig. 1 shows, the polarized absorption signals which were

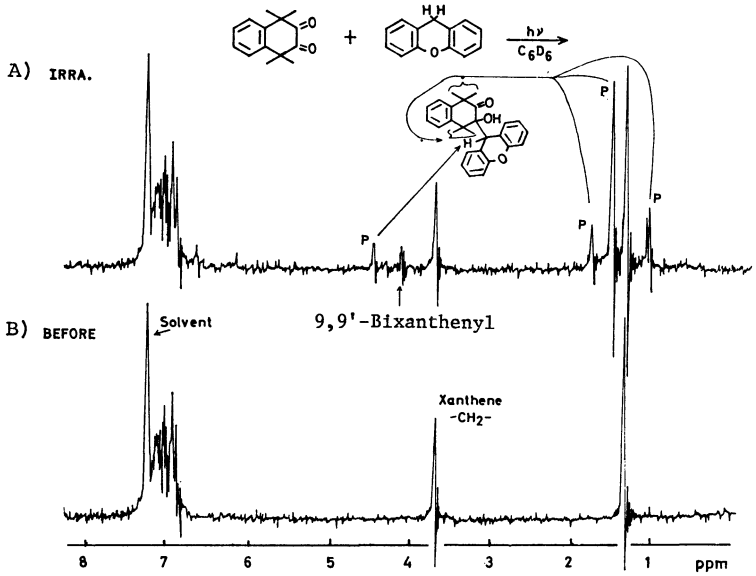

Fig. 1. A): PMR signals observed in the course of the photochemical reaction of 1,1,4,4-tetramethyl-2,3-tetralindione with xanthene during irradiation. P, polarized signals.
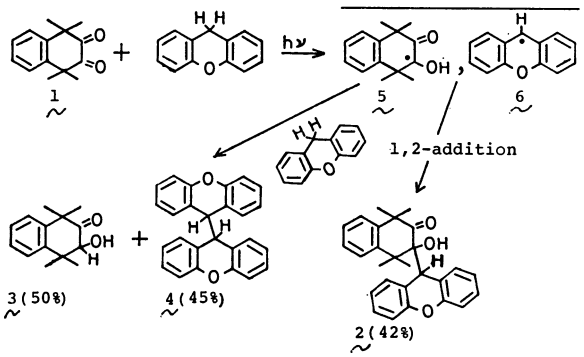
B): PMR signals observed before irradiation.

assigned to protons of the "1,2-adduct," **2**, were observed in the course of the photochemical reaction. It can be explained by Kaptein's simple rule[5] that the "1,2-adduct," **2**, results from the in-cage combination of the semidione radical, **5** ($g\simeq2.0046$[6]), and the xanthenyl radical, **6** ($g\simeq2.0057$[7]), from the triplet pair.[8] However, the semidione radical, **5**, and the xanthenyl radical, **6**, might partly escape from the cage and encounter another xanthene molecule, giving the reduced product, **3**, and 9,9'-bixanthenyl.



Scheme 1. Proton written with Gothic letter showed polarization.

When acetaldehyde was used as the hydrogen donor, a "1,2-adduct," 3-acetyl-3-hydroxy-1,1,4,4-tetramethyl-2-tetralone, **7a**, and a ketonization product after 1,4-addition, 3-acetoxy-1,1,4,4-tetramethyl-2-tetralone, **8a**, were obtained in yields of 32 and 34% respectively. The "1,2-adduct," **7a**, was identified by means of its spectral properties and by an iodoform test. The last procedure changed **7a** to 2-hydroxy-1,1,3,3-tetramethylindan-2-carboxylic acid, **9** (mp 181—184 °C[9]), quantitatively *via* the formation of 3-hydroxy-2-oxo-1,1,4,4-tetramethyl-2-tetralin-3-carboxylic acid, **10**, which was then easily decarboxylated to give **1**.[10] In fact, a benzilic-acid rearrangement converted **1** to **9** quantitatively under the same conditions. The product, **9**, was esterified with diazomethane, giving methyl 2-hydroxy-1,1,3,3-tetramethylindan-2-carboxylate, **11** (mp 77.5—78.5 °C[11]), quantitatively. The other product, **8a**, was identified by means of its spectral properties and by comparison with an authentic sample prepared by the acetylation of 3-hydroxy-1,1,4,4-tetramethyl-2-tetralone, **3**, in the presence of pyridine.

On irradiation for two days, 3-acetoxy-1,1,4,4-tetramethyl-2-tetralone, **8a**, was slowly changed to **7a** in a 17% yield, whereas no reverse conversion could be observed. A filter solution[12] was employed to cut the light of the wavelengths shorter than 330 nm. On irradiation with the light through the filter solution, **8a** remained unchanged. This is similar to the case with **7a**. Under the same conditions, **1** and acetaldehyde reacted photochemically to give **7a** and **8a** in yields of 34 and 41% respectively. In the course of the photochemical reaction of **1** and acetaldehyde, the CIDNP technique gave a only limited information because of the contingent coincidence of the acetyl protons of **7a** and **8a** in their chemical shifts in benzene-d_6. On irradiation with the light through the filter solution, **1** and other

aldehydes, propionaldehyde, *p*-anisaldehyde, *p*-tolualdehyde, *p*-isopropylbenzaldehyde, benzaldehyde, and *p*-chlorobenzaldehyde, reacted photochemically, giving the corresponding "1,2-adducts," 3-acyl-3-hydroxy-1,1,4,4-tetramethyl-2-tetralone, **7b**—**g**, and the respective "1,4-adducts," 3-acyloxy-1,1,4,4-tetramethyl-2-tetralone, **8b**—**g**. The yields of **7a**—**g** and **8a**—**g** are

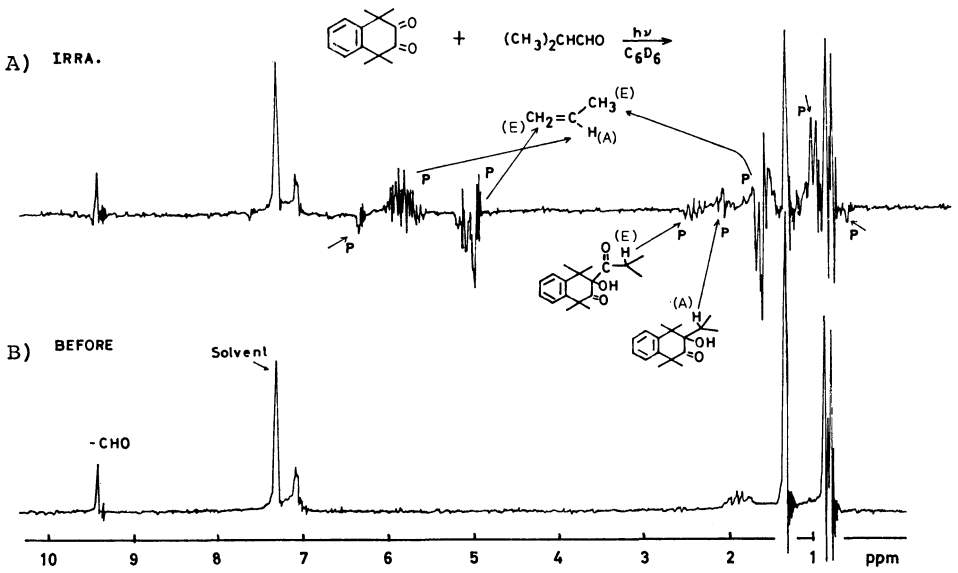

Fig. 2. A): PMR signals observed in the course of the photochemical reaction of 1,1,4,4-tetramethyl-2,3-tetralindione with isobutyraldehyde during irradiation. P, polarized signals.
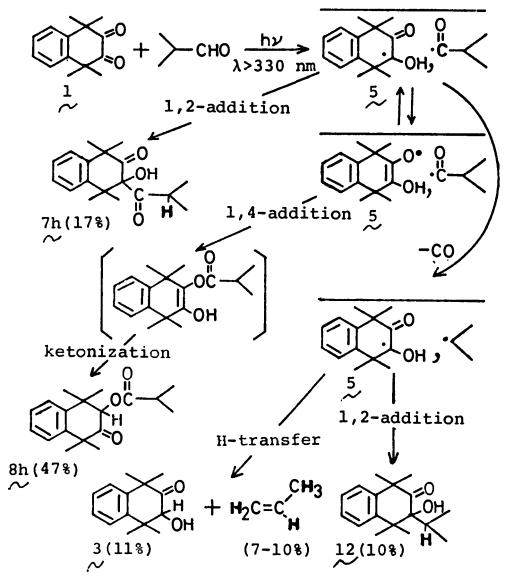
B): PMR signals observed before irradiation.

summarized in Table 1. In conclusion, the photochemical reactions of **1** with aldehydes can be described as are shown in Scheme 3.

On the other hand, the irradiation of **1** with isobutyraldehyde gave a "1,2-adduct"; 3-hydroxy-3-isobutyryl-1,1,4,4-tetramethyl-2-tetralone, **7h** (17%), a "1,4-adduct"; 3-isobutyryloxy-1,1,4,4-tetramethyl-2-tetralone, **8h** (47%), a 1,2-addition product resulting from the decarbonylation, **12** (10%), a reduced product, **3** (11%), an oxidized product; α,α,α',α'-tetramethyl-*o*-phenylenediacetic anhydride **13** (5%), and propene (7—10%), accompanied by the evolution of carbon monoxide (45—63%). Carbon monoxide was identified by the use of palladium chloride-test paper. The product, **13**, could be formed by the reaction of the semidione radical, **5**, with oxygen.[11] As Fig. 2 shows, in the course of the photochemical reaction of **1** with isobutyraldehyde, a multiplet emission signal was observed in the region corresponding to the methine proton of the "1,2-adduct,' **7h**. In addition, a multiplet absorption signal was observed corresponding to the methine proton of the other "1,2-adduct," **12**, accompanied by the other strongly polarized signals corresponding to the signals of propene;[13] these signals assigned by comparison with the signals of the synthesized authentic sample. Thus, the "1,2-adduct," **7h**, might result from the in-cage combination of the semidione radical, **5**, and the isobutyryl radical *via* the triplet pair. Similarly, **12** may be formed from the in-cage combination of the semidione radical, **5**, with the isopropyl radical ($g \cong 2.0032$[14]) *via* the triplet pair. Propene and the reduced product, **3**, might result from the dehydrogenation of the isopropyl radical by **5** *via* the triplet pair. The reaction mechanism is shown in Scheme 4. The decarbonylation and 1,2-addition reactions may be competitive, and the relative rates may depend on the stabilities of the related radicals.[15] Although the combination, disproportionation, or escape of the related radicals may occur competitively, depending on the stability of the radicals concerned, the steric repulsion between the related radicals in the radical pair could be another controlling factor. The combination of the semidione radical, **5**, with the isopropyl radical or xanthenyl radical would be more hindered sterically than that of **5** with acyl radicals. This is the reason for the formation of the reduction product, **3**, in the reactions with isobutyraldehyde and with xanthene.



Scheme 4. Protons written with Gothic letter showed polalization.

Experimental

The melting points described are uncorrected. The infrared spectra (KBr disk or a liquid film) were taken with a JASCO

IR-G spectrometer. The PMR spectra were measured with a JEOL PS-100 MHz spectrometer, using TMS as the internal standard. The ultraviolet and visible spectra were recorded by means of a Shimadzu UV-200 spectrometer. The CIDNP spectra were observed using a JEOL PS-100 MHz spectrometer, equipped with a modified NMR probe for irradiation.[16]

Materials. 1,1,4,4-Tetramethyl-2,3-tetralindione, **1**, was prepared by the oxidation of 1,1,4,4-tetramethyl-2-tetralone with selenium dioxide[17] and was purified by sublimation; mp 59—61 °C (lit,61—62 °C[17]). IR(KBr): 1710 cm^{-1} (C=O). PMR (CCl_4): δ; 1.24 (s, 12H), 7.12 ppm (s, 4H). UV_{max} (EtOH): 286 nm (ε: 443), 387 (10), 396 (15). The xanthene was commercially obtained and was purified by recrystallization from ethanol. The acetaldehyde was prepared by the depolymerization of paraldehyde. The other aldehydes were commercially obtained and were distilled before use.

General Procedure. **1** (0.5—1.0 mmol) and 2—6 equivalents of a hydrogen donor were dissolved in 20 ml of dry benzene, and then the solution was irradiated from the outer side by means of a 300W high-pressure mercury arc lamp through a water layer 5 cm thick or a filter solution 1 cm thick at room temperature. After the solution had become colorless, irradiation was stopped. After the removal of the solvent, the total product was separated by TLC, using a benzene and hexane mixture as the developing solvent. The filter solution used for light-cutting was an aqueous solution (50 ml) of sodium bromide (24.45 g) and lead nitrate (0.15 g).

Photochemical Reaction of 1 with Xanthene. A benzene solution of **1** (244 mg, 1.1 mmol) and two equivalents of xanthene was irradiated for about 5 h. 9,9'-Bixanthenyl, **4** (363 mg, 45%), 3-hydroxy-1,1,4,4-tetramethyl-3-xanthenyl-2-tetralone, **2** (486 mg, 42%), and 3-hydroxy-1,1,4,4-tetramethyl-2-tetralone, **3** (180 mg, 50%), were thus obtained. **2**; white plates; mp 149 °C. IR (KBr): 3450 (OH), 1695 cm^{-1} (C=O). PMR (CCl_4): δ; 0.75 (s, 3H), 0.94 (s, 3H), 1.48 (s, 3H), 1.84 (s, 3H), 3.02 (s, 1H; OH), 4.12 (s, 1H), 5.8—7.1 ppm (m, 12H). Found: C, 81.52; H, 6.64%. Calcd for $C_{27}H_{26}O_3$: C, 81.38; H, 6.58%. **3**; white crystals; mp 39.0—41.0 °C (lit, 40—42 °C[3]). IR (KBr): 3450 (OH), 1710 cm^{-1} (C=O). PMR (CCl_4): δ; 0.87 (s, 3H), 1.40 (s, 3H), 1.44 (s, 3H), 1.49 (s, 3H), 3.52 (d, 1H; OH), 4.20 (d, 1H), 6.9—7.2 ppm (m, 4H). **4**; white crystals; mp 211 °C.

Photochemical Reaction of 1 with Acetaldehyde. A solution of **1** (82 mg, 0.4 mmol) and acetaldehyde (77 mg, 1.8 mmol) was irradiated for about 6 h. 3-Acetyl-3-hydroxy-1,1,4,4-tetramethyl-2-tetralone, **7a** (34 mg, 34%), and 3-acetoxy-1,1,4,4-tetramethyl-2-tetralone, **8a** (32 mg, 32%), were thus obtained. **7a**; white plates; mp 80.5—81.0 °C. IR (KBr): 3400 (OH), 1700 cm^{-1} (C=O). PMR (CCl_4): δ; 0.91 (s, 3H), 1.33 (s, 3H), 1.40 (s, 3H), 1.43 (s, 3H), 2.00 (s, 3H), 4.63 (s, 1H; OH), 6.9—7.1 ppm (m, 4H). UV_{max} (EtOH): 315 nm (ε; 150). Found: C, 73.77; H, 7.77%. Calcd for $C_{16}H_{20}O_3$: C, 73.86; H, 7.76%. **8a**; white plates; mp 106.5—107.0 °C. IR (KBr): 1735, 1716 cm^{-1} (C=O). PMR (CCl_4): δ; 1.03 (s, 3H), 1.36 (s, 3H), 1.44 (s, 3H), 1.48 (s, 3H), 2.13 (s, 3H), 5.24 (s, 1H), 6.9—7.1 ppm (m. 4H). UV_{max} (EtOH): 285 nm (ε: 38), 300 (23). Found: C, 73.69; H, 7.91%. Calcd for $C_{16}H_{20}O_3$: C, 73.86; H, 7.76%.

Iodoform Reaction of 7a. To a solution of iodine (77 mg) and sodium hydroxide (141 mg) in water (10 ml), we added a solution of **7a** (24 mg) in ether (3 ml). After stirring at room temperature for 24 h, the solution was acidified with hydrochloric acid and extracted with ether. The ethereal solution was dried over sodium sulfate and evaporated, giving white crystals of 2-hydroxy-1,1,3,3-tetramethylindan-2-carboxylic acid, **9** (21 mg); mp 181—184 °C (lit, 188—189 °C[9]). IR-(KBr): 3450 (OH), 1690 cm^{-1} (C=O). PMR ($CDCl_3$): δ; 1.34 (s, 6H), 1.68 (s, 6H), 7.0—7.4 ppm (m, 4H).

Esterification of 9 with Diazomethane. A ethereal solution of diazomethane was added to a solution of **9** (13 mg) in ether at room temperature. After the removal of the solvent, white crystals of methyl 2-hydroxy-1,1,3,3-tetramethylindan-2-carboxylate, **11** (14 mg), were obtained; mp 72.0—74.0 °C (lit, 77.5—78.5 °C[11]). IR(KBr): 3450 (OH), 1705 cm^{-1} (C=O). PMR (CCl_4): δ; 1.16 (s, 6H), 1.30 (s, 6H), 3.52 (s, 3H), 6.9—7.1 ppm (m, 4H). Mass: *m/e*; 248 (M^+), 189 ($M^+ - COOCH_3$, base), 171 ($M^+ - COOCH_3 \cdot H_2O$).

Benzilic Acid Rearrangement of 1. **1** (22 mg) was converted to **9** (24 mg) under the conditions described in "*Iodoform Reaction of 7a.*"

Acetylation of 3. A mixture of **3** (26 mg), acetic anhydride (10 ml), and pyridine (10 ml) was warmed for 3 h at 80 °C. After the subsequent evaporation of the liquid phase, white crystals of **8a** (29 mg) were obtained; mp 107 °C.

Irradiation of 7a and 8a. The irradiation of a benzene solution of **8a** (13 mg) for 2 days gave a mixture of the starting material, **8a** (8 mg, 60%), and **7a** (2 mg, 17%). However, the irradiation of **7a** under the same conditions gave no reaction. On irradiation through the filter solution[13] (transmitting the light $\geq$330 nm) for 4 days, **8a** remained unchanged. **7a** was also recovered unchanged.

Photochemical Reaction of 1 with Acetaldehyde with the Use of the Filter Solution. On irradiation through the filter solution, **1** (108 mg, 0.5 mmol) and acetaldehyde (75 mg, 1.7 mmol) reacted to give **7a** (96 mg, 34%) and **8a** (102 mg, 41%).

Photochemical Reaction of 1 with Propionaldehyde. A benzene solution of **1** (119 mg, 0.6 mmol) and propionaldehyde (166 mg, 2.9 mmol) was irradiated through the filter solution to give 3-hydroxy-3-propionyl-1,1,4,4-tetramethyl-2-tetralone, **7b** (52 mg, 34%), and 3-propionyloxy-1,1,4,4-tetramethyl-2-tetralone, **8b** (59 mg, 39%). **7b**; white plates; mp 116.0—118.0 °C. IR (KBr): 3400 (OH), 1695 cm^{-1} (C=O). PMR (CCl_4): δ; 0.84 (t, 3H), 0.92 (s, 3H), 1.31 (s, 3H), 1.36 (s, 3H), 1.44 (s, 3H), 2.24 (q, 2H), 4.64 (s, 1H; OH), 6.9—7.1 ppm (m, 4H). Found: C, 74.41; H, 7.82%. Calcd for $C_{17}H_{22}O_3$: C, 74.42; H, 8.08%. **8b**; white plates; mp 67.0—68.0 °C. IR(KBr): 1745, 1725 cm^{-1} (C=O). PMR (CCl_4): δ; 1.07 (s, 3H), 1.24 (t, 3H), 1.40 (s, 3H), 1.48 (s, 3H), 1.53 (s, 3H), 2.49 (q, 2H), 5.36 (s, 1H), 7.0—7.4 ppm (m, 4H). Found: C, 74.13; H, 8.31%. Calcd for $C_{17}H_{22}O_3$: C, 74.42; H, 8.08%.

Photochemical Reaction of 1 with p-*Anisaldehyde.* A benzene solution of **1** (146 mg, 0.7 mmol) and *p*-anisaldehyde (341 mg, 2.5 mmol) was irradiated through the filter solution to give 3-hydroxy-3-*p*-methoxybenzoyl-1,1,4,4-tetramethyl-2-tetralone, **7c** (41 mg, 17%), and 3-*p*-methoxybenzoyloxy-1,1,4,4-tetramethyl-2-tetralone, **8c** (190 mg, 77%). **7c**; white needles; mp 153.5—154.5 °C. IR (KBr): 3350 (OH), 1703 cm^{-1} (C=O). PMR (CCl_4): δ; 0.96 (s, 3H), 1.23 (s, 3H), 1.52 (s, 3H), 1.57 (s, 3H), 3.77 (s, 3H), 4.64 (s, 1H; OH), 6.64—7.64 (dd, 4H), 6.9—7.1 ppm (m, 4H). Found: C, 74.69; H, 7.04%. Calcd for $C_{22}H_{24}O_4$: C, 74.97; H, 6.86%. **8c**; white prisms; mp 132.5—133.0 °C. IR (KBr); 1735, 1705 cm^{-1} (C=O). PMR (CCl_4): δ; 1.16 (s, 3H), 1.40 (s, 3H), 1.52 (s, 3H), 1.56 (s, 3H), 3.76 (s, 3H), 5.52 (s, 1H), 6.74—7.86 (dd, 4H), 6.9—7.1 ppm (m, 4H). Found: C, 74.73; H, 6.87%. Calcd for $C_{22}H_{24}O_4$: C, 74.97; H, 6.86%.

Photochemical Reaction of 1 with p-*Tolualdehyde.* The irradiation of **1** (124 mg, 0.6 mmol) and *p*-tolualdehyde (321 mg, 2.7 mmol) in benzene by the use of the filter solution gave 3-hydroxy-3-*p*-toluoyl-1,1,4,4-tetramethyl-2-tetralone, **7d** (79 mg, 41%), and 3-*p*-toluoyloxy-1,1,4,4-tetramethyl-2-tetralone, **8d** (39 mg, 20%). **7d**; white needles; mp 171.5—173.0 °C.

Biogenetic Model Reactions of Epoxygermacrones

Masatake NIWA, Masanobu IGUCHI, and Shosuke YAMAMURA*

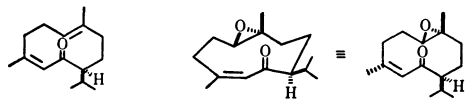
Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468

(Received April 21, 1976)

From a biogenetic point of view, acid- or base-catalyzed cyclizations of epoxygermacrones (**2**, **23**, and **33**) were carried out. In most cases, the stereospecific cyclizations of these epoxygermacrones took place to give many compounds with an 11-oxabicyclo[5.3.1]undecane system, cadinane-type, selinane-type or guaiane-type compounds depending on the kinds of reagents and solvents. The formation process of each cyclization product will be discussed in detail.

In the preceding paper,[1] we described the regio- and stereo-specific cyclizations of the germacrones in detail. Our interests are also focused on the biogenetic model reactions of the epoxygermacrones. In the present paper, we describe the acid-catalyzed cyclizations of three different kinds of epoxygermacrones leading to the formation of various cyclization products depending on the kinds of reagents and solvents. In addition, the base-catalyzed cyclizations of these epoxygermacrones are also discussed.

When treated with *m*-chloroperbenzoic acid (1.06 equiv.) (0 °C, 20 h), isoacoragermacrone (**1**)[2] was readily converted into the expected monoepoxide (**2**) (mp 55 °C; $C_{15}H_{24}O_2$; λ_{max} 243 nm), in a quantitative yield, which has an *E*-epoxide ring at the position corresponding to the isolated trisubstituted double bond of the original ketone (**1**). Epoxyisoacoragermacrone (**2**) thus obtained is used for the biogentic model reactions, as follows.[3]

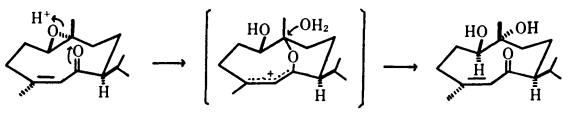


1 2

Fig. 1.

Acid-catalyzed Cyclizations of Epoxyisoacoragermacrone (2)

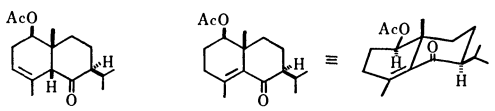
On treatment with 80% aq. HCOOH (−20 °C, 10 min), **2** was converted into a dihydroxy ketone (**3**) and a *cis*-selinate-type compound (**4**) in 47.5 and 34.2% yields, respectively. Of these two products, the structure of the former is based on its spectral data, which indicate the presence of a $-CH_2CH(OH)-\overset{Me}{\overset{|}{C}}(OH)-$grouping [$\nu_{max}$ 3400 br. cm^{-1}; δ 1.22 (3H, s) and 3.48 (1H, dd, J=4.0 and 6.0 Hz) ppm] in addition to the original α,β-unsaturated carbonyl system [ν_{max} 1685 and 1645 cm^{-1}; λ_{max} 238 nm (ε, 4200); δ 1.87 (3H, d, J=1.2 Hz) and 5.98 (1H, br.s) ppm]. The configuration of the tertiary OH group remains unsolved from the spectral data of **3**. However, this hydroxyl group must be in an α-configuration from a stereochemical aspect, as shown in Scheme 1.



2 3

Scheme 1. Formation process of the dihydroxy compound (**3**).

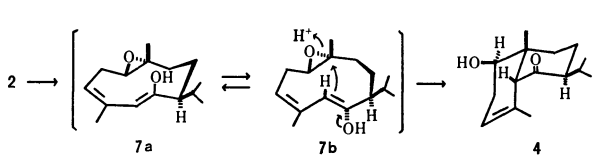
* To whom all correspondence should be addressed.



5 6

Fig. 2.

The structure of the *cis*-selinane-type compound (**4**) is unambiguously determined by its spectral data and the chemical evidences, as follows. The cyclization product (**4**) as a colorless liquid [$C_{15}H_{24}O_2$ (*m/e* 236 (M^+))] has each one of OH and CO groups (ν_{max} 3430 br. and 1705 cm^{-1}), the NMR spectrum of which indicates the presence of a $MeC(OH)=CH-$ grouping [δ 1.58 (3H, br.s) and 5.44 (1H, br.s) ppm] in addition to a tertiary methyl group [δ 1.02 (3H, s) ppm]. Acetylation of **4** with Ac_2O-pyridine (room temp, overnight) afforded the corresponding acetoxy compound (**5**) ($C_{17}H_{26}O_3$; ν_{max} 1740 and 1710 cm^{-1}). In its NMR spectrum, the triplet at δ 3.53 (1H, J=5.0 Hz) ppm in **4** is observed at δ 4.80 (1H, t, J=4.5 Hz) ppm. The remaining signals are nearly identical in both compounds. Furthermore, the ORD curve of **5** showed a negative Cotton effect ($[\phi]^T_{318nm}$ $-72°\times10^2$; $[\phi]^P_{276nm}+63°\times10^2$; $A=-135$), strongly suggesting that the acetate **5** is a *cis*-selinane-type ketone. This is further confirmed by the following acid-catalyzed isomerization with 100% HCOOH: when treated with 100% HCOOH under reflux for 10 h, the acetoxy compound **5** was converted into a fully substituted α,β-unsaturated ketone (**6**) [$C_{17}H_{26}O_3$; λ_{max} 246 nm (ε, 4800); δ 1.71 (3H, br.s) ppm], whose ORD curve has a strong positive peak ($[\phi]^P_{264nm}+150°\times10^2$) as seen in that of cholest-4-en-6-one. Finally, in comparison of the NMR spectra between **5** and **6**, the coupling constant for the proton attached to the carbon atom bearing the acetoxyl group in the latter [δ 4.85 (1H, dd, J=6.2 and 9.0 Hz) ppm] is different from that of **5** [δ 4.80 (1H, t, J=4.5 Hz) ppm]. Clearly, the configuration of the acetoxyl group should be axial in **5** and equatorial in **6**. Therefore, the stereostructures of the cyclization product and the acid-isomerization compound can be represented by **4**



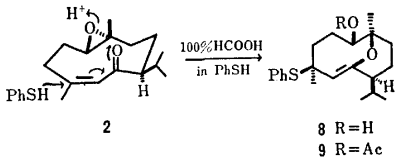
7a 7b 4

Scheme 2. Possible pathway from epoxyisoacoragermacrone (**2**) to the *cis*-selinane-type compound (**4**).

and **6**, respectively. In the above acid-catalyzed cyclization, a conjugated dienol (**7**) is a possible intermediate as shown is Scheme 2, and the stereochemistry of the cyclization product (**4**) must be led by the more favorable conformation of **7b** than that of **7a**.

We further examined the acid-catalyzed reactions of epoxyisoacoragermacrone (**2**) using 100% HCOOH in thiophenol. When treated with 100% HCOOH in thiophenol (room temp, 40 min) instead of 80% aq. HCOOH, epoxyisoacoragermacrone (**2**) was readily converted into an enol ether (**8**) with an 11-oxabicyclo-[5.3.1]undec-1-ene system, in a 65.5% yield. This compound has two tertiary methyl groups (δ 1.21 and 1.35 ppm) and the original isopropyl group (δ 0.86 and 0.88 ppm). Furthermore, the compound **8** has a PhS group [δ 7.30 (5H, complex) ppm] as well as an enol ether system (–Ċ–CH=Ċ–O–) [ν_{max} 1665 cm^{-1} and δ 4.75 (1H, s) ppm], in addition to one secondary OH group [ν_{max} 3420 br. cm^{-1} and δ 4.25 (1H, br.t, $J\simeq$6.0 Hz) ppm] which can be easily acetylated with Ac_2O–pyridine to give the corresponding acetate [**9**; ν_{max} 1735 cm^{-1} and δ 5.57 (1H, br.t, $J\simeq$6.8 Hz) ppm].

In the above reaction, the regio- and stereospecific cyclization of **2** takes place in a concerted mechanism, leading to the formation of **8**, as shown in Scheme 3.



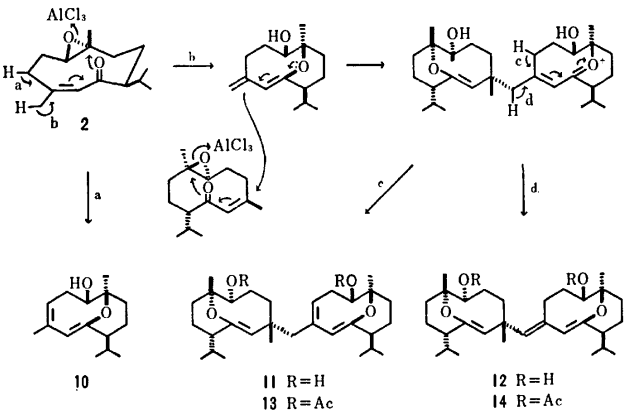
2 8 R=H 9 R=Ac

Scheme 3. Reaction of epoxyisoacoragermacrone (**2**) with 100% HCOOH in thiophenol.

Furthermore, the acid-catalyzed cyclization of **2** with $AlCl_3$ in absolute ether were carried out at −18 °C for 20 min to give three products **10**, **11**, and **12** in 18, 47, and 33% yields, respectively.

The compound **10** is a colorless liquid [$C_{15}H_{24}O_2$ (*m/e* 236 (M^+))] with a conjugated diene system [–CH_2–CH=C(Me)–CH=Ċ–O–] [ν_{max} 1650 cm^{-1}; λ_{max} 243 nm (ε, 7500); δ 1.79 (3H, br.s), 5.15 (1H, s) and 5.34 (1H, t, J=6.8 Hz) ppm]. The presence of each one of secondary OH and tertiary methyl groups is also confirmed by its spectral data [ν_{max} 3430 br. cm^{-1} and δ 3.45 (1H, dd, J=5.8 and 3.7 Hz) ppm; δ 1.35 (3H, s) ppm]. Other two compounds (**11**, mp 159.5—160.5 °C; **12**, mp 143.5—144.5 °C) with the same molecular formula ($C_{30}H_{48}O_4$) are dimeric and regarded as double bond isomers to each other, which are converted into the corresponding acetates **13** and **14**, respectively, on acetylation with Ac_2O–pyridine. The results indicate the presence of two secondary OH groups. The structures of these two dimeric compounds are also determined on the basis of their spectral data, as follows. Similarly, the NMR spectra of both compounds have three methyl singlets in addition to signals due to two isopropyl groups. However, a remarkable difference is seen in the NMR signals assigned to three olefinic protons: **11** has two singlets at δ 4.46 and 5.15 ppm and one triplet at δ 5.41 (1H, t, J=7.0 Hz) ppm, while **12** has three singlets at δ 4.79, 5.33 and 5.96 ppm. In addition, the UV spectra of these two compounds show different chromophores [**11**, λ_{max} 247 nm (ε, 6670); **12**, λ_{max} 254 nm (ε, 22400)]. From these data, the structures **11** and **12** should be given to the two dimeric compounds with mp 159.5—160.5 and 143.5—144.5 °C, respectively.

In the case of $AlCl_3$, clearly, the acid-catalyzed reaction of **2** must be initiated by cleavage of the epoxide ring with $AlCl_3$ followed by simultaneous participation of the carbonyl group, as shown in Scheme 4.

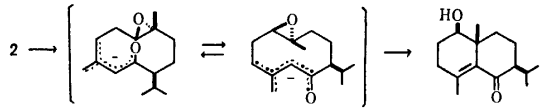


10 11 R=H 13 R=Ac 12 R=H 14 R=Ac

Scheme 4. Reaction of epoxyisoacoragermacrone (**2**) with $AlCl_3$.

Base-catalyzed Cyclizations of Epoxyisoacoragermacrone (2). In the case of the acid-catalyzed cyclization with $AlCl_3$, the driving force of the intramolecular cyclization at the initial step may be attributable to the epoxide ring openning. In contrast, the different results were obtained in the case of the base-catalyzed reactions, as described below.

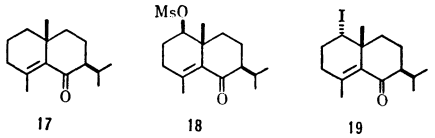
When treated with *t*-BuOK in *t*-BuOH (1.1 equiv.) under a nitrogen atmosphere (room temp, 2 h), the epoxide (**2**) was readily converted into an α,β-unsaturated ketone **15** ($C_{15}H_{24}O_2$) in a 75% yield, which was further converted into the known acetate (**6**) on acetylation with Ac_2O–pyridine. In the above cyclization using *t*-BuOK, **16** is regarded as a possible intermediate, and the stereochemistry of **15** must be led by the corresponding conformation **16b**, as shown in Scheme 5.



16a 16b 15

Scheme 5. Chemical conversion of **2** into the selinane-type compound **15**.

In connection with acolamone and isoacolamone,[2,4] both of which are included in the plant together with acoragermacrone,[2] this α,β-unsaturated ketone (**15**) was converted into the thermal isomerization product (**17**) of acolamone, in three steps, as follows. On treatment with mesyl chloride–pyridine (room temp, 2 h), the compound **15** was converted into the corresponding mesylate (**18**) [δ 3.07 (3H, s) and 4.21 (1H, t, J=7.5 Hz) ppm] in an almost quantitative yield. Further treatment of **18** with NaI in methyl ethyl ketone (under



17 18 19

Fig. 3.

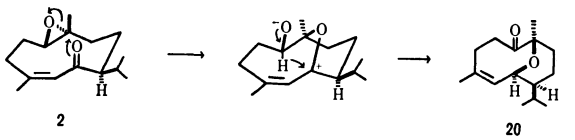
reflux, 15 h) afforded the corresponding iodide (**19**) [δ 4.31 (1H, dd, J=7.0 and 2.0 Hz) ppm]. which was directly reduced with n-Bu_3SnH in toluene (under reflux, 4 h) to give the compound **17**.

We further examined the base-catalyzed cyclization of **2** using basic alumina, as follows. Epoxyisoacoragermacrone (**2**) was directly absorbed on basic alumina (150—250 mesh), and then eluted with hexane-benzene (1 : 3) to give an isomer **20** with a CO group (ν_{max} 1715 cm^{-1}), in a 34% yield. Further elution with ether gave a fairly unstable isomer **21**, which has a secondary OH group [ν_{max} 3400 br. cm^{-1}; δ 4.32 (1H, dd, J=6.5 and 9.5 Hz) ppm], in a 46% yield. The structures of these two reaction products are based on their spectral data and the chemical evidences, as follows. Either of these compounds has a tertiary methyl group (δ 1.18 ppm in **20**; δ 1.27 ppm in **21**) in addition to the original isopropyl group. However, the former has a MeC=CH–CH–O– grouping [δ 1.86 (3H, br.s), 3.77 (1H, br.d, J=7.9 Hz) and 5.88 (1H, br.d, J=7.9 Hz) ppm], which was hydrogenated over 5% Pd-C to give the corresponding dihydro-compound **22**, mp 37—40 °C; $C_{15}H_{26}O_2$: δ 1.08 (3H, d, J=6.5 Hz) and 3.27 (1H, m) ppm. On the other hand, the alcohol **21** has a conjugated diene system (CH_2=C–CH=C–O–), as judged by its IR, UV and NMR spectra: ν_{max} 1650 and 1600 cm^{-1}; λ_{max} 240 nm (ε, 16160); δ 4.67 (1H, br.m), 4.79 (1H, d, J=2.4 Hz) and 5.58 (1H, s) ppm.

21 22

Fig. 4.

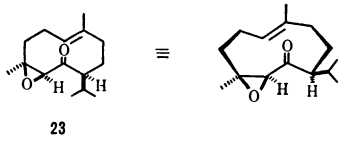
In the above reaction using basic alumina, an intramolecular H^- transfer may take place, leading to the formation of **20**, as shown in Scheme 6.



2 20

Scheme 6. Formation process of the keto compound (**20**).

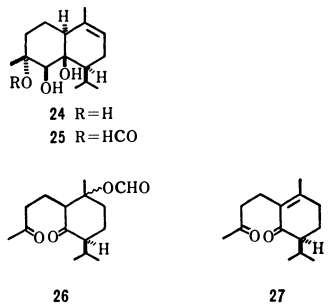
In the next experiment, epoxidation of isoacoragermacrone (**1**) was carried out using 30% H_2O_2–5% NaOH aq. solution (room temp, overnight) to afford an epoxygermacrone (**23**) in a 92% yield (mp 85.5—86 °C; $C_{15}H_{24}O_2$; ν_{max} 1720 cm^{-1}: δ 1.42 (3H, s) and 3.43 (1H, s) ppm], which has an epoxide ring[5] at the position corresponding to the conjugated double bond of isoacoragermacrone (**1**). This epoxide (**23**) was also submitted to the biogenetic model reactions,[6] as seen in the case of **2**.



23

Fig. 5.

Acid-catalyzed Cyclizations of the Epoxygermacrone (23). This epoxide (**23**) is quite stable to 80% aq. AcOH at room temperature. However, when heated at 60 °C for 3 h, **23** was converted into a cadinane-type compound **24** [mp 195 °C (decomp.); $C_{15}H_{26}O_3$] in a 48% yield. This cyclization product **24** was also obtained in an 8% yield together with the corresponding formate (**25**) [ν_{max} 1720 cm^{-1}; δ 8.04 (1H, s) ppm] in a 15% yield, on treatment of **23** with 80% aq. HCOOH (room temp, 10 min). The latter (**25**) was readily converted into **24** on hydrolysis with 10% methanolic KOH. The structure of the cadinate-type compound (**24**) was determined by its spectral data [ν_{max} 3400 br. cm^{-1}; δ 1.32 (3H, s), 1.73 (3H, br.s), 3.90 (1H, br.s) and 5.64 (1H, m) ppm] and the following chemical evidence. When treated with $NaIO_4$ in aq. MeOH (room temp, overnight), the compound **24** was converted into a diketone (**26**) as a colorless liquid [ν_{max} 1720 br. cm^{-1} and no OH band; δ 1.26 (3H, s), 2.12 (3H, s) and 8.00 (1H, s) ppm]. This oxidation product (**26**) was further treated with NaOMe–MeOH (under reflux, 4 h) to give an α,β-unsaturated ketone in a high yield, whose structure was proved to be **27** by its spectral data: ν_{max} 1710 and 1660 cm^{-1}; λ_{max} 243 nm (ε, 10300); δ (C_6D_6) 1.56 (3H, s), 1.72 (3H, s), 2.30 (2H, t, J=7.8 Hz), and 2.65 (2H, t, J=7.8 Hz) ppm.



24 R=H
25 R=HCO

26 27

Fig. 6.

Probably, the intramolecular cyclization of **23** takes place after cleavage of the epoxide ring. From a biogenetic point of view, the formation of the trisubstituted olefins (**24** and **25**) is interesting. The further acid-catalyzed cyclization of the epoxygermacrone (**23**) was carried out using $AlCl_3$ in absolute ether.

On treatment with $AlCl_3$ in absolute ether (0 °C, 10 min), the epoxide (**23**) afforded a mixture of several compounds, from which two cyclization products **28** and **29** were isolated in 27 and 32% yields, respectively. The former (**28**) is an aldehyde [$C_{15}H_{24}O_2$ (m/e 236 (M^+)); ν_{max} 2700 and 1720 cm^{-1}; δ 9.75 (1H, s) ppm], and has no OH group. The NMR spectrum of **28** indicates the presence of two tertiary methyl groups (δ 1.25 and 1.52 ppm)[7] in addition to the original isopropyl group. On reduction with $LiAlH_4$ in THF (room temp, overnight). the aldehyde (**28**) was converted

into the corresponding alcohol **30** ($C_{15}H_{26}O_2$) which was a tertiary hydroxymethyl group [ν_{max} 3400 cm^{-1}: δ 3.56 (1H, d, J=12 Hz) and 3.76 (1H, d, J=12 Hz) ppm]. It was acetylated with Ac_2O–pyridine to give an acetate (**31**); $C_{17}H_{28}O_3$; ν_{max} 1740 cm^{-1}; δ 2.07 (3H, s) and 4.10 (2H, br.s) ppm. This alcohol was easily reconverted into the original aldehyde (**28**), in a 52% yield, on oxidation with Jones reagent (room temp, 1.5 h). From the above spectral and chemical data, the structure of the aldehyde can be represented by **28**.

The compound **29** has the same molecular formula as that of **28**. However, the former has no CO group, but instead a hydroxyl group (ν_{max} 3560 cm^{-1}). As described above, the aldehyde (**28**) has two tertiary methyl groups, while **29** has one methyl group [δ 1.67 (3H, s) ppm] and one exocyclic double bond [δ 4.66 (1H, br.s) and 4.86 (1H, br.s) ppm] that can be converted into a secondary methyl group on catalytic hydrogenation leading to the formation of the corresponding dihydro-compound (**32**); $C_{15}H_{26}O_2$ [m/e 238 (M^+)]; δ 1.10 (3H, d, J=8 Hz) and 2.85 (1H, m) ppm. From a structural point of view, particularly, it is important that the NMR spectra of **29** and **32** both have the two sharp doublets with a geminal coupling constant (J= 12 Hz) which can be assigned to the isolated methylene group (δ 2.90 and 3.31 ppm in **29**; δ 2.86 and 3.18 ppm in **32**). From these data, the structure of the alcohol may be represented by **29**.

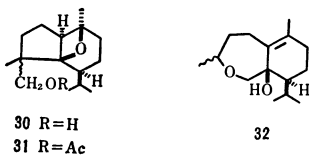


Fig. 7.

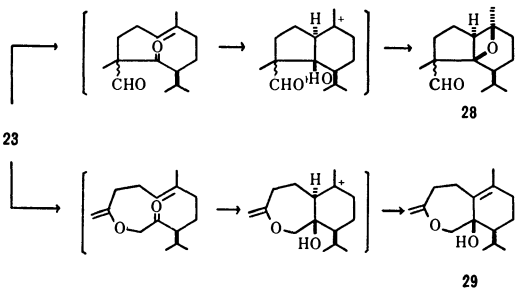
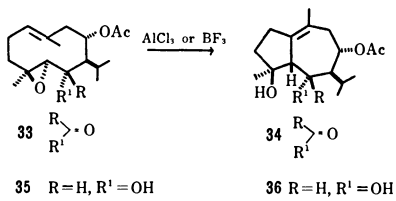
In the above reaction of the epoxygermacrone (**23**) with $AlCl_3$, these two cyclization compounds **28** and **29** may be produced according to the following pathways, as shown in Scheme 7.



Scheme 7. Possible pathways from **23** to the compounds **28** and **29**.

Finally, we used the oxidation product (**33**) of shiromodiolmonoacetate[8] as an (*E*,*E*)-epoxygermacrone, as will be described below. This epoxide (**33**) is also stable to 80% aq. AcOH at room temperature, as seen in the case of the (*Z*,*E*)-epoxygermacrone (**23**). However, when heated at 80 °C for 4 h, the epoxide (**33**) was converted into a mixture of many products, from which a guaiane-type compound (**34**) was isolated in a low yield (*ca.* 15%). The structure of **34** is based on its mass, IR and NMR spectra: $C_{17}H_{26}O_4$ [m/e 276 (M^+-18) and 234 (M^+-60)]; ν_{max} 3420, 1735 and 1710 cm^{-1}; δ 0.98 (3H, d, J=7 Hz) and 1.05 (3H, d, J= 7 Hz) [*i*-Pr], 1.36 (3H, s) [Me–C(OH)–], 1.71 (3H, br.s) [Me–C=C–], 2.05 (3H, s) and 5.30 (1H, m) [AcO–CH–] and 3.54 (1H, br.s) ppm [=C–CH–C=O]. This guaiane-type compound (**34**) was also produced in a 40% yield on treatment with $AlCl_3$ in absolute ether (−5 °C, 15 min). These results are quite similar to that of shiromodiol monoacetate (**35**), the acid-catalysed cyclization of which has afforded the corresponding guaiane-type compound (**36**).[8]



Scheme 8. Acid-catalyzed cyclization of the (*E*,*E*)-epoxygermacrone or -germacrene.

Experimental

All the mps are uncorrected. GLC were recorded on a Shimadzu GC-1C gas chromatograph with a flame-ionizer detector (stationary phase: 5% PEG 20 M on Celite 545 (100 mesh); column (ϕ 3 mm × 1.5 m (stainless steel)] temp: 90 °C; carrier gas: nitrogen (85 ml/min); inlet pressure: 1.2 Kg/cm^2], unless otherwise stated. IR spectra were recorded on a Hitachi-215 spectrophotometer. UV spectra were taken on a Hitachi-124 spectrophotometer, using MeOH as the solvent. NMR spectra were recorded on a Varian Associate A-60 (60 MHz), a Nihondenshi JNM-C60H (60 MHz) or JNM-PS 100 (100 MHz), using $CDCl_3$ as the solvent, unless otherwise stated. The chemical shifts are given in ppm relative to the internal TMS, and only prominent signals are cited (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). Mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating at an ionization energy of 70 eV. ORD curves were recorded on a JASCO ORD/UV spectrophotometer, using MeOH as the solvent. Preparative TLC were carried out on Kieselgel PF_{254} (E. Merck, A. G.), unless otherwise stated.

Epoxidation of Isoacoragermacrone (1) with m-*Chloroperbenzoic Acid.* To a solution of **1** (1.10 g) in ether (40 ml) was added, with stirring, *m*-chloroperbenzoic acid (920 mg) at 0 °C. The resulting solution was further stirred at 0 °C for 20 h, and then washed successively with sat. Na_2SO_3, sat. $NaHCO_3$ and sat. NaCl aq. solutions, and then dried over anhydrous Na_2SO_4. Removal of the solvent afforded a crystalline solid of **2** (1.18 g), which was recrystallized from hexane to give colorless columns; mp 55 °C; ν_{max} (KBr) 1675 and 1620 cm^{-1}; λ_{max} 243 nm (ε, 6400); δ 0.93 (3H, d, J=6.5 Hz), 0.97 (3H, d, J=6.5 Hz), 1.21 (3H, s), 1.91 (3H, d, J=1.3 Hz) and 6.20 (1H, br.s) ppm; m/e 236 (M^+), 193 and 175 (Found: C, 76.30; H, 10.47%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%).

Reaction of 2 with 80% aq. HCOOH. The compound **2** (260 mg) was dissolved, with stirring, in 80% aq. HCOOH (8 ml) at −18—−20 °C. The resulting solution was further stirred at the same temperature for 10 min, and then diluted with ice water (*ca.* 40 ml) and extracted with CH_2Cl_2. The extract was washed successively with a sat. $NaHCO_3$ aq. solu-

tion and water, and then dried over anhydrous $MgSO_4$. Evaporation of the solvent under reduced pressure afforded crude crystals, which were washed with ether to leave insoluble crystals of the dihydroxy ketone **3** (94 mg). The ethereal solution was concentrated under reduced pressure to give an oil, which was separated by preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and hexane–ether (2: 1) to give **3** (39 mg) and the *cis*-selinane-type compound **4** (89 mg).

3: mp 155—157 °C (from Et_2O–MeOH); ν_{max} (KBr) 3400 br., 1680 and 1645 cm^{-1}; λ_{max} 238 nm (ε, 4200); δ 0.93 (6H, d, J=6.5 Hz), 1.22 (3H, s), 1.87 (3H, d, J=1.2 Hz), 3.48 (1H, dd, J=4.0 and 6.0 Hz), and 5.98 (1H, br. s) ppm; *m/e* 236 (M^+-18) and 210 (Found: C, 70.81; H, 10.57%. Calcd for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30%).

4 as a colorless viscous liquid: ν_{max} (film) 3430 br. and 1705 cm^{-1}; δ 0.91 (6H, d, J=5.0 Hz), 1.02 (3H, s), 1.58 (3H, br. s), 3.53 (1H, t, J=5.0 Hz), and 5.44 (1H, br. s) ppm; *m/e* 236 (M^+) and 193 (Found: *m/e* 236.17726. Calcd for $C_{15}H_{24}O_2$: *m/e* 236.17762).

Acetylation of the Selinane-type Compound (4). A solution of **4** (85 mg) in Ac_2O–pyridine (2: 5) (7 ml) was stirred at room temperature overnight, and then poured into a cooled 5% HCl aq. solution, and extracted with ether. The ethereal extract was washed successively with water, 5% $NaHCO_3$ aq. solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent under reduced pressure gave an oil, which was purified by preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and hexane–ether (5: 1) to afford **5** (53 mg) as a colorless viscous liquid; ν_{max} (film) 1740, 1710, and 1245 cm^{-1}; δ 0.90 (6H, d, J=5.1 Hz), 0.98 (3H, s), 1.62 (3H, br. s), 2.03 (3H, s), 4.80 (1H, t, J=4.5 Hz), and 5.45 (1H, br. s) ppm; *m/e* 278 (M^+), 237, and 219 (Found: 278.18864. Calcd for $C_{17}H_{26}O_3$: *m/e* 278.18818).

Acid-catalyzed Isomerization of the Acetate (5) with 100% HCOOH. A solution of **5** (50 mg) in 100% HCOOH (3 ml) was refluxed for 10 h under a nitrogen atmosphere, and then slowly poured into a sat. $NaHCO_3$ aq. solution and extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous $MgSO_4$. Removal of the solvent left a brown oil (42 mg) which was separated by preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and hexane–ether (4: 1) to give the starting material **5** (8 mg) and the α,β-unsaturated ketone **6** (10 mg) as a colorless viscous liquid; ν_{max} (film) 1745, 1690, 1630, and 1250 cm^{-1}; λ_{max} 246 nm (ε, 4800); δ 0.89 (3H, d, J=6.8 Hz), 0.95 (3H, d, J=6.8 Hz), 1.01 (3H, s), 1.71 (3H, br. s), 2.07 (3H, s). and 4.85 (1H, dd, J=6.2 and 9.0 Hz) ppm; *m/e* 278 (M^+), 237, and 219 (Found: *m/e* 278.18670. Calcd for $C_{17}H_{26}O_3$: *m/e* 278.18818).

Acid-catalyzed Reaction of Epoxyisoacoragermacrone (2) in Thiophenol. To a solution of **2** (160 mg) in thiophenol (2 ml) was added, with stirring, 5 drops of 100% HCOOH at room temperature. The resulting solution was further stirred at room temperature, and then diluted with a cooled 10% NaOH aq. solution (20 ml) and extracted with ether. The ethereal extract was washed successively with a cooled 10% NaOH aq. solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded an almost colorless liquid, which was purified by preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and hexane–benzene (1: 1) to give the enol ether **8** (165 mg) as a colorless viscous liquid; ν_{max} (film) 3420 br., 3060 sh., 3950, 1665, 1580, 745, and 690 cm^{-1}: δ 0.86 (3H, d, J=6.0 Hz), 0.88 (3H, d, J=6.0 Hz), 1.21 (3H, s), 1.35 (3H, s), 1.49 (1H, s, OH), 4.25 (1H, br. t, $J\simeq$6.0 Hz), 4.75 (1H, s), and 7.30 (5H, complex) ppm; *m/e* 236 (M^+-PhSH) and 221 (Found: *m/e* 236.17410. Calcd for $C_{15}H_{24}O_2$ ($C_{21}H_{30}O_2S-C_6H_6S$)*: *m/e* 236.17762).

Acetylation of 8 with Ac_2O–Pyridine. To a solution of **8** (60 mg) in pyridine (2 ml) was added Ac_2O (0.5 ml) at 0 °C. The solution was allowed to stand at the same temperature overnight, and then diluted with ice water (*ca.* 20 ml) and extracted with ether. The ethereal extract was washed successively with a cooled 10% HCl aq. solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent under reduced pressure left a colorless viscous liquid (61 mg) in an almost pure state, which was further purified by preparative TLC using benzene to give **9** (58 mg) as a colorless viscous liquid; ν_{max} (film) 3050, 1735, 1665, 1580, 1240, 745, and 690 cm^{-1}; δ 0.87 (6H, d, J=6.0 Hz), 1.25 (3H, s), 1.37 (3H, s), 2.00 (3H, s), 4.82 (1H, s), 5.57 (1H, br. t, $J\simeq$6.8 Hz), and 7.35 (5H, complex) ppm; *m/e* 279 (M^+-109) and 278 (M^+-110) (Found: *m/e* 279.19579. Calcd for $C_{17}H_{27}O_3$ ($C_{23}H_{32}O_3S-C_6H_5S$)*: *m/e* 279.19601).

Reaction of 2 with $AlCl_3$ in Absolute Ether. To a solution of **2** (325 mg) in absolute ether (15 ml) was added, with stirring, a solution of $AlCl_3$ (200 mg) in absolute ether (4 ml) at −18 °C. The solution was further stirred at −18—−20 °C for 20 min, and then diluted with ether saturated with water. The ethereal solution was washed successively with a sat. potassium sodium tartarate aq. solution and a sat. NaCl aq. solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent afforded a residue, which was dissolved in ether (2 ml). Precipitated colorless crystals of the dimer **11** (95 mg) was collected by filtration. The filtrate was concentrated, and the residue was subjected to preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and hexane–ether (1: 1) giving two fractions. From the less polar fraction, the compound **10** (60 mg) was isolated as a colorless liquid; ν_{max} (film) 3430 br., 3030 sh. and 1650 cm^{-1}; λ_{max} 243 nm (ε, 7500); δ 0.95 (6H, d, J=5.3 Hz), 1.35 (3H, s), 1.79 (3H, br. s), 1.69 (1H, s, OH), 3.45 (1H, dd, J=3.7 and 5.8 Hz), 5.15 (1H, s) and 5.34 (1H, t, J=6.8 Hz) ppm: *m/e* 236 (M^+ for $C_{15}H_{24}O_2$), 221, 218, and 175. Elemental analysis of **10** was not carried out because of its instability, but its structure was supported by the above-mentioned physical data.

From the more polar fraction, a colorless oil was obtained, which was further separated by preparative TLC using $CHCl_3$–MeOH (100: 5) to give two dimers **11** (59 mg) and **12** (107 mg). Their physical data are shown below.

11: mp 159.5—160.5 °C (from hexane–ether); ν_{max} (KBr) 3450 br., 1680 and 1660 cm^{-1}; λ_{max} 247 and 205 nm (ε, 6670 and 13680, respectively); δ 0.96 (12H, complex), 1.01 (3H, s), 1.28 (3H, s), 1.39 (3H, s), 3.21 (1H, t, J=4.0 Hz), 3.93 (1H, t, J=6.1 Hz), 4.46 (1H, s), 5.15 (1H, s), and 5.41 (1H, t, J=7.0 Hz) ppm; *m/e* 472 (M^+), 238, 237, 236, and 219 (Found: *m/e* 472.35658. Calcd for $C_{30}H_{48}O_4$: *m/e* 472.35524).

12: mp 143.5—144.5 °C (from hexane–ether); ν_{max} (KBr) 3390 br., 1680, and 1650 cm^{-1}; λ_{max} 254 and 203 nm (ε, 22400 and 11800, respectively); δ 0.90 (12H, complex), 1.08 (3H, s), 1.18 (3H, s), 1.23 (3H, s), 1.51 (2H, s, OH), 3.32 (1H, br. m), 4.26 (2H, br. m), 4.79 (1H, s), 5.33 (1H, s), and 5.96 (1H, s) ppm; *m/e* 472 (M^+), 238, 237, 236, and 219 (Found: *m/e* 472.35714. Calcd for $C_{30}H_{48}O_4$: *m/e* 472.35524).

Acetylation of the Dimer 11. To a solution of **11** (100 mg) in pyridine (5 ml) was added Ac_2O (2 ml) at 0 °C. The resulting solution was further stirred at 0 °C overnight, and then poured into ice water and extracted with ether. The ethereal extract was washed successively with a cooled 5% HCl aq. solution, a cooled sat. $NaHCO_3$ aq. solution, and water, and then dried over anhydrous Na_2SO_4. After evaporation of the solvent, the residue was purified by preparative TLC using

* No molecular ion peak was observed.

alumina [GF_{254} (type E), E. Merck, A. G.] and benzene to give **13** (62 mg) as a colorless viscous liquid; ν_{max} (film) 3040, 1740, 1670, and 1250 cm^{-1}; δ 0.83—1.00 (12H, complex), 1.00 (3H, s), 1.27 (6H, s), 2.00 (3H, s), 2.06 (3H, s), 4.64 (1H, s), 5.26 (1H, s), and 4.87—5.74 (3H, complex) ppm (Found: *m/e* 556.37888. Calcd for $C_{34}H_{52}O_6$: *m/e* 556.37637).

Acetylation of the Dimer ***12***. To a solution of **12** (90 mg) in pyridine (5 ml) was added Ac_2O (2 ml) at 0 °C. The resulting solution was stirred at 0 °C overnight, and then treated according to the same procedure as that for **11** to give an oil, which was purified by preparative TLC using AcOEt–benzene (1: 10) to give **14** (61 mg) as a colorless viscous liquid; ν_{max} (film) 1740, 1680, 1650, and 1240 cm^{-1}; δ 0.90 (12H, complex), 1.11 (3H, s), 1.22 (3H, s), 1.28 (3H, s), 2.02 (6H, s), 3.48 (1H, m), 4.87 (1H, s), 5.38 (1H, s), 5.31—5.67 (2H, m), and 5.99 (1H, s) ppm (Found: *m/e* 556.37982. Calcd for $C_{34}H_{52}O_6$: *m/e* 556.37637).

Base-catalyzed Reaction of ***2*** *with* t-*BuOK*. To a solution of potassium metal (25 mg) in *t*-BuOH (4 ml) was added, with stirring, a solution of **2** (137 mg) in *t*-BuOH (1 ml) at 25 °C under a nitrogen atmosphere. The solution was further stirred at 25 °C for 2 h, and then diluted with water (10 ml) and extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous Na_2SO_4. Removal of the solvent gave an oil which was purified by preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and hexane–ether (1: 1) to give a colorless viscous liquid of **15** (103 mg); ν_{max} (film) 3450 br., 1680, and 1630 cm^{-1}; λ_{max} 248 nm (ε, 4600); δ 0.90 (3H, d, J=6.9 Hz), 0.95 (3H, d, J=6.9 Hz), 0.94 (3H, s), 1.69 (3H, br. s) and 3.61 (1H, dd, J=6.5 and 9.0 Hz) ppm; *m/e* 236 (M^+) and 193 (Found: *m/e* 236.17911. Calcd for $C_{15}H_{24}O_2$: *m/e* 236.17762).

Acetylation of the α,β-Unsaturated Ketone ***(15)***. A solution of **15** (84 mg) in pyridine (5 ml) and Ac_2O (1 ml) was allowed to stand at room temperature overnight, and then poured into a cooled 5% HCl aq. solution and extracted with ether. The ethereal extract was washed successively with water, 5% $NaHCO_3$ aq. solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded an oil, which was purified by preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and hexane–ether (5: 1) to give a colorless viscous liquid (69 mg), which was completely identical with the acetoxy compound **6** (TLC and IR spectrum).

Mesylation of ***15***. To a solution of **15** (93 mg) in pyridine (3 ml) was added dropwise, with stirring, mesyl chloride (50 mg) at 0 °C. The resulting solution was further stirred at 0 °C for 1 h, and then at room temperature for 2 h. After addition of ice–water (*ca.* 10 ml), the solution was extracted with ether. The extract was washed successively with a cooled 5% HCl aq. solution, water and a sat. NaCl aq. solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure afforded the mesylate **18** (124 mg) in a pure state as a colorless viscous liquid; ν_{max} (film) 1690, 1630, 1350, and 1170 cm^{-1}; λ_{max} 246 nm (ε, 4200); δ 0.89 (3H, d, J=6.5 Hz), 0.95 (3H, d, J=6.5 Hz), 1.00 (3H, s), 1.70 (3H, s), 3.07 (3H, s), and 4.21 (1H, t, J=7.5 Hz) ppm; *m/e* 314 (M^+), 218 and 175 (Found: *m/e* 314.15690. Calcd for $C_{16}H_{26}O_4S$: *m/e* 314.15517).

Reaction of the Mesylate ***18*** *with NaI*. A mixture of **18** (112 mg) and NaI (530 mg) in methyl ethyl ketone (7 ml) was refluxed, with stirring, for 15 h under a nitrogen atmosphere, and then concentrated under reduced pressure to leave a reddish residue, which was diluted with water (30 ml) and then extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous Na_2SO_4. Removal of the solvent left a reddish oil (120 mg) which was purified by preparative TLC using hexane–benzene (1: 3) to give **19** (36 mg) as a colorless liquid; ν_{max} (film) 1690 and 1630 cm^{-1}; δ 0.88 (3H, d, J=6.3 Hz), 0.93 (3H, d, J=6.3 Hz), 1.11 (3H, s), 1.67 (3H, s), and 4.31 (1H, dd, J=7.0 and 2.0 Hz) ppm; *m/e* 346 (M^+ for $C_{15}H_{23}IO$) and 219 (M^+—I). This iodide was directly used for the next experiment.

Reduction of the Iodide ***19*** *with* n-Bu_3SnH. To a solution of **19** (36 mg) in toluene (3 ml) was added *n*-Bu_3SnH (26 mg) under a nitrogen atmosphere. The solution was refluxed for 4 h, and then concentrated under reduced pressure to give a yellow oil, which was purified by preparative TLC using hexane–benzene (1: 1) to give a pale yellow liquid (22 mg) which was completely identical with an authentic sample of the isomerization product (**17**) of acolamone[4] (GLC, TLC, and IR spectrum).

Reaction of Epoxyisoacoragermacrone ***(2)*** *with Basic Alumina*. The compound **2** (980 mg) was dissolved in hexane–benzene (1: 3), and directly chromatographed on basic alumina (Katayama Chemical Co., Ltd., 150—250 mesh) (50 g). Elution with the same solvent system afforded **20** (330 mg) in a pure state as a colorless oil; ν_{max} (film) 3030, 1715, and 1650 cm^{-1}; δ 0.99 (6H, d, J=6.9 Hz), 1.18 (3H, s), 1.86 (3H, br. s), 3.33 (1H, m), 3.77 (1H, br. d, J=7.9 Hz) and 5.88 (1H, br. d, J=7.9 Hz) ppm; *m/e* 436 (M^+), 193, 175, and 165 (Found: *m/e* 236.17941. Calcd for $C_{15}H_{24}O_2$: *m/e* 236.17762).

Further elution with ether afforded a pale yellow oil (450 mg) in an almost pure state, which was further purified by preparative TLC using alumina [GF_{254} (type E), E. Merck, A. G.] and benzene to give **21** in a pure state as a colorless viscous liquid; λ_{max} (film) 3400 br., 3080, 1650, 1600, 915, and 880 cm^{-1}; λ_{max} 240 nm (ε, 16160); δ 0.89 (3H, d, J=6.3 Hz), 0.92 (3H, d, J=6.3 Hz), 1.27 (3H, s), 3.38 (1H, br. m), 4.32 (1H, dd, J=6.5 and 9.5 Hz), 4.67 (1H, br. m), 4.79 (1H, d, J=2.4 Hz), and 5.58 (1H, s) ppm; *m/e* 236 (M^+ for $C_{15}H_{24}O_2$), 221 and 193. Elemental analysis of **21** was not carried out because of its instability, but its structure may be supported by the above-mentioned physical data.

Catalytic Hydrogenation of ***20***. Catalytic hydrogenation of **20** (45 mg) in MeOH (10 ml) was carried out over 5% Pd–C (150 mg) at room temperature for 40 min, and then filtered to remove the catalyst. The filtrate was concentrated under reduced pressure to give a colorless viscous liquid which was chromatographed on alumina and eluted with ether to give the dihydro compound **22** (38 mg) as colorless crystals; mp 37—40 °C (by sublimation); ν_{max} (KBr) 1705 cm^{-1}; δ 0.94 (6H, d, J=7.1 Hz), 1.08 (3H, d, J=6.5 Hz), 1.23 (3H, s), and 3.27 (1H, m) ppm; *m/e* 238 (M^+), 210, 195, 182, and 167 (found: *m/e* 238.19233. Calcd for $C_{15}H_{26}O_2$: *m/e* 238.19327).

Epoxidation of Isoacoragermacrone ***(1)*** *with 30% H_2O_2–5% aq. NaOH*. To a solution of **1** (440 mg) in MeOH (30 ml) was slowly added a mixed solution of 30% H_2O_2 (2 ml) and 5% NaOH aq. solution (10 ml) at 0 °C, and then the reaction temperature was gradually elevated to room temperature. The solution was further stirred at room temperature overnight, and then diluted with water (60 ml) and extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded a colorless viscous liquid (436 mg), which was crystallized from hexane to give colorless prisms of **23**; mp 85.5—86 °C; ν_{max} (KBr) 1720 cm^{-1}; δ 0.90 (3H, d, J=7 Hz), 1.04 (3H, d, J=7 Hz), 1.42 (3H, s), 1.44 (3H, s), 3.43 (1H, s) and 5.20 (1H, t, J=7 Hz) ppm (Found: *m/e* 236.17474. Calcd for $C_{15}H_{24}O_2$: *m/e* 236.17762).

Reaction of ***23*** *with 80% aq. AcOH*. A solution of **23** (23 mg) in 80% aq. AcOH (0.5 ml) was heated at 60 °C for 3 h,

with stirring. After addition of ether (20 ml), the solution was washed successively with a sat. $NaHCO_3$ aq. solution and a sat. NaCl aq. solution, and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded a colorless liquid (25 mg), which was recrystallized from ether to give colorless crystals (10 mg). The remaining ethereal solution was concentrated, and then separated by preparative TLC to give colorless crystals (2 mg). Recrystallization from $CHCl_3$ afforded colorless prisms of **24**; mp 195 °C (decomp.); ν_{max} (KBr) 3400 cm^{-1}; δ 0.92 (3H, d, J=7 Hz), 0.94 (3H, d, J=7 Hz), 1.32 (3H, s), 1.56 (1H, s, OH), 1.73 (3H, br. s), 2.16 (2H, s, OH), 3.90 (1H, br. s) and 5.64 (1H, m) ppm; *m/e* 254 (M^+) and 236 (Found: C, 70.27; H, 10.50%. Calcd for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30%).

*Reaction of **23** with 80% aq. HCOOH.* A solution of **23** (120 mg) in 80% aq. HCOOH (2 ml) was stirred at room temperature for 10 min, and then diluted with ether (40 ml). The ethereal solution was washed successively with water, a sat. $NaHCO_3$ aq. solution and a sat. NaCl aq. solution, and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded a colorless viscous liquid which was dissolved in ether (0.5 ml) to give the triol **24** (10 mg) as colorless crystals. After filtration of the crystals, the filtrate was subjected to preparative TLC using $CHCl_3$ to give the formate **25** (22 mg) as a colorless viscous liquid; ν_{max} (film) 3470 and 1720 cm^{-1}; δ 0.93 (3H, d, J=7 Hz), 0.96 (3H, d, J=7 Hz), 1.66 (3H, s), 1.74 (3H, br.s), 2.49 (1H, s, OH), 3.96 (1H, d, J=5.4 Hz), 5.65 (1H, m), and 8.04 (1H, s) ppm; *m/e* 236 (M^+−HCOOH), 218, and 200. Without purification this formate was used for the next experiment.

*Hydrolysis of the Formate (**25**) with 10% Methanolic KOH.* A solution of **25** (22 mg) in 10% methanolic KOH (5 ml) was stirred at room temperature overnight, and then diluted with ether (30 ml). The ethereal solution was washed with water, and then dried over anhydrous Na_2SO_4. Removal of the solvent gave colorless crystals of **24** (mp and IR spectrum).

*Oxidation of the Triol (**24**) with $NaIO_4$.* To a solution of **24** (90 mg) in MeOH (6 ml) was added, with stirring, a solution of $NaIO_4$ (230 mg) in water (3 ml). The resulting solution was further stirred at room temperature overnight, and then diluted with water (20 ml) and extracted with ether. The ethereal extract was washed successively with water and a sat. NaCl aq. solution, and then dried over anhydrous $MgSO_4$. After evaporation of the solvent, the oily residue was separated by preparative TLC using $CHCl_3$ to give the oxidation product **26** (18 mg) in addition to the starting material (20 mg) (TLC and IR spectrum).

26. A colorless viscous liquid: ν_{max} (film) 1720 br.cm^{-1}; δ 0.86 (3H, d, J=6.5 Hz), 0.93 (3H, d, J=6.5 Hz), 1.26 (3H, s), 2.12 (3H, s), 3.03 (1H, dd, J=10 and 2 Hz) and 8.00 (1H, s) ppm; *m/e* 222 [M^+($C_{15}H_{24}O_4$)−HCOOH]. This compound was further used for the next experiment.

*Formation of an α,β-Unsaturated Ketone **27**.* A solution of **26** (18 mg) in MeOH (4 ml) containing NaOMe (10 mg) was refluxed for 4 h under a nitrogen atmosphere, and then diluted with water (10 ml) and extracted with ether. The ethereal solution was washed with water, and then dried over anhydrous $MgSO_4$. Evaporation of the solvent gave a colorless oil, which was purified by preparative TLC using $CHCl_3$ to afford **27** (14 mg) in a pure state as a colorless liquid; δ (C_6D_6) 0.86 (3H, d, J=7.0 Hz), 0.91 (3H, d, J=7.0 Hz), 1.56 (3H, s), 1.72 (3H, s), 2.30 (2H, t, J=7.8 Hz), and 2.65 (2H, t, J=7.8 Hz) ppm (Found: *m/e* 222.16433. Calcd for $C_{14}H_{22}O_2$: *m/e* 222.16197).

*Reaction of **23** with $AlCl_3$.* To a solution of **23** (190 mg) in absolute ether (10 ml) was added, with stirring, a solution of $AlCl_3$ (118 mg) in absolute ether (2 ml) at 0 °C. The solution was further stirred at 0 °C for 10 min, and then the reaction was quenched by addition of ice-water (0.5 ml). After addition of a sat. potassium sodium tartarate aq. solution (10 ml), the ethereal layer was separated. The aqueous solution was further extracted with ether. The combined ethereal extracts were washed with water, and then dried over anhydrous $MgSO_4$. Evaporation of the solvent afforded a colorless viscous liquid, which was separated by preparative TLC using benzene to give **28** (52 mg) and **29** (60 mg).

28. A colorless viscous liquid: ν_{max} (film) 2700 and 1720 cm^{-1}; δ 0.91 (3H, d, J=7 Hz), 0.98 (3H, d, J=7 Hz), 1.25 (3H, s), 1.52 (3H, s), and 9.75 (1H, s) ppm (Found: *m/e* 236.17748. Calcd for $C_{15}H_{24}O_2$: *m/e* 236.17762).

29. A colorless viscous liquid: ν_{max} (film) 3560, 3090, and 1650 cm^{-1}; δ 0.87 (3H, d, J=7 Hz), 0.90 (3H, d, J=7 Hz), 1.67 (3H, s), 2.90 (1H, d, J=12 Hz), 3.31 (1H, d, J=12 Hz), 4.66 (1H, br. s), and 4.86 (1H, br. s) ppm (Found: *m/e* 236.17253. Calcd for $C_{15}H_{24}O_2$: *m/e* 236.17762).

*Reduction of the Aldehyde (**28**) with $LiAlH_4$.* To a solution of **28** (55 mg) in absolute THF (5 ml) was added, with stirring, $LiAlH_4$ (20 mg) at room temperature. The reaction mixture was further stirred at room temperature overnight. After decomposition of an excess of the reagent with water, the reaction mixture was diluted with 5% HCl aq. solution, and then extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous $MgSO_4$. After evaporation of the solvent, a colorless oil was purified by preparative TLC using $CHCl_3$ to give **30** (35 mg) as a colorless viscous liquid; ν_{max} (film) 3400 cm^{-1}; δ 0.98 (3H, d, J=6 Hz), 1.03 (3H, d, J=6 Hz), 1.24 (6H, s), 3.56 (1H, d, J=12 Hz), and 3.76 (1H, d, J=12 Hz) ppm (Found: *m/e* 238.19307. Calcd for $C_{15}H_{26}O_2$: *m/e* 238.19327).

*Acetylation of the Alcohol (**30**).* A solution of **30** (35 mg) in pyridine (3 ml) and Ac_2O (1 ml) was stirred at room temperature overnight, and then treated as usual to give a pale yellow oil, which was purified by preparative TLC using $CHCl_3$ to give **31** (25 mg) as a colorless viscous liquid; ν_{max} (film) 1740 and 1240 cm^{-1}; δ 0.94 (3H, d, J=7 Hz), 0.97 (3H, d, J=7 Hz), 1.24 (3H, s), 1.28 (3H, s), 2.07 (3H, s), and 4.10 (2H, br. s) ppm (Found: *m/e* 280.20383. Calcd for $C_{17}H_{28}O_3$: *m/e* 280.20433).

*Hydrolysis of the Acetate (**31**).* A solution of **31** (25 mg) in 5% methanolic KOH (2 ml) was stirred at room temperature overnight, and then diluted with water (10 ml) and extracted with ether. The ethereal extract was washed with water and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded the original alcohol (**30**) (TLC and IR spectrum) as a colorless liquid.

*Oxidation of **30**.* Jones' reagent was carefully added to a solution of **30** (25 mg) in acetone (4 ml) until a brown color appeared persistently. The mixture was stirred at room temperature for 1.5 h, and then diluted with water (10 ml) after decomposition of an excess of the reagent with 30% ascorbic acid aq. solution. The aqueous solution was extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous $MgSO_4$. Removal of the solvent gave an almost colorless oil, which was purified by preparative TLC using benzene to afford **28** (13 mg) (TLC and IR spectrum) as a colorless viscous liquid.

*Catalytic Hydrogenation of **29**.* Catalytic hydrogenation of **29** (28 mg) in AcOEt (3 ml) was carried out over PtO_2 at room temperature for 1.5 h, and then filtered to remove the catalyst. The filtrate was concentrated under reduced pressure to give a colorless viscous liquid, which was purified by preparative TLC using hexane–benzene (1: 1) to give the

dihydro compound (**32**) as a colorless viscous liquid; ν_{max} (film) 3560 cm^{-1}; δ 0.90 (3H, d, J=7 Hz), 0.92 (3H, d, J=7 Hz), 1.10 (3H, d, J=8 Hz), 1.64 (3H, s), 2.85 (1H, m), 2.86 (1H, d, J=12 Hz), and 3.18 (1H, d, J=12 Hz) ppm (Found: *m/e* 238.19088. Calcd for $C_{15}H_{26}O_2$: *m/e* 238.19327).

*Reaction of **33** with 80% aq. AcOH.* A solution of **33** (60 mg) in 80% aq. AcOH (1 ml) was heated, with stirring, at 80 °C for 4 h, and then diluted with water (15 ml) and extracted with $CHCl_3$. The extract was washed successively with water, a sat. $NaHCO_3$ aq. solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded a pale brown oil, which was separated by preparative TLC using benzene–ether (3: 1) to give **34** (9 mg) as a colorless viscous liquid; *m/e* 276 (M^+-H_2O), 234 (M^+—AcOH), and 216 (Found: *m/e* 234.16179. Calcd for $C_{15}H_{22}O_2$ ($C_{17}H_{26}O_4$–AcOH): *m/e* 234.16197).

*Reaction of **33** with $AlCl_3$ in Absolute Ether.* To a solution of **33** (120 mg) in absolute ether (20 ml) was added, with stirring, a solution of $AlCl_3$ (60 mg) in absolute ether (10 ml) at −5 °C. The solution was further stirred at −5 °C, and then the reaction was quenched by addition of ice–water (*ca.* 1 ml). The ethereal layer was separated, and dried over anhydrous $MgSO_4$. After evaporation of the solvent, an oily residue was separated by preparative TLC using benzene–ether (3: 1) to give **34** (48 mg) (TLC and IR spectrum) as a colorless viscous liquid.

The authors wish to thank Prof. Y. Hirata (Nagoya University) for his invaluable suggestions. Thanks are also due to Prof. K. Munakata and Dr. K. Wada (Nagoya University) for the sample and IR spectrum of shiromodiol diacetate, and Prof. M. Noro (Meijo University) for collection of the plant *Parabenzoinn trilobum* Nakai. They are also indebted to Drs. M. Kurono and M. Toda (Ono Pharmaceutical Co., Ltd.) for measurements of high resolution mass spectra. This research has been supported in part by grants from the Ministry of Education, to which greatful acknowledgement is made.

Chemical Correlations of α-Santonin with (+)-Junenol and Acolamone

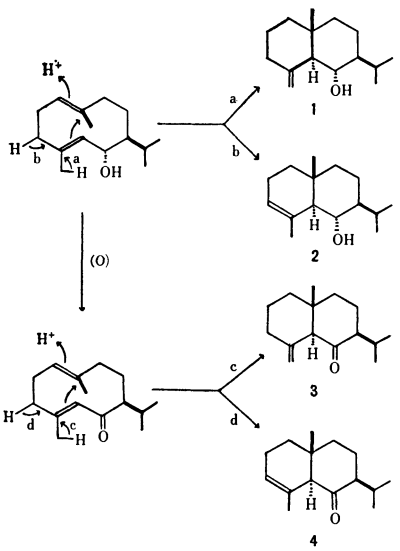
Masatake NIWA, Masanobu IGUCHI, and Shosuke YAMAMURA*

Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468

(Received April 21, 1976)

The chemical transformation of the acetoxy ketone (**5**), which has previously been obtained from α-santonin, to (+)-junenol (**1**) and acolamone (**3**) has been carried out. In addition, isojunenol (**2**) was also derived from **5** *via* the trisubstituted olefin (**9**) which was obtained as the main product from the α- and β-oriented mesylates (**8** and **11**) on treatment with NaI in HMPA.

From a biogenetic point of view, the selinane-type sesquiterpenes [(+)-junenol (**1**),[1] isojunenol (**2**), acolamone (**3**) and isoacolamone (**4**)[2]] should be produced from such a common intermediate as a ten-membered ring compound with an (*E,E*)-1,5-cyclodecadiene system, as is shown in Scheme 1.[2] Of these four selinane-type compounds, isojunenol (**3**) has not yet been found. In the present paper, we describe the chemical transformation of the known acetoxy ketone (**5**)[3] to these selinane-type sesquiterpenes. The results indicate that they have the same absolute configuration as α-santonin.



Scheme 1.

The acetoxy ketone (**5**) was reduced with $NaBH_4$ in EtOH (room temp, overnight) to give a mixture of α- and β-hydroxy compounds in a 98% yield (**6**, 27%; **7**, 71%). The further treatment of the latter with mesyl chloride-pyridine afforded the corresponding mesylate (**8**) in a 98% yield; it was directly converted into a trisubstituted olefin (**9**) and a disubstituted olefin (**10**), in 65 and 22% yields respectively, on treatment with NaI in HMPA (80 °C, 3 h) under a nitrogen atmosphere [**9**, δ 1.65 (3H, br.s) and 5.32 (1H, br.s) ppm; **10**, δ 1.01 (3H, d, J=6.5 Hz) and 5.45 (2H, complex) ppm]. Furthermore, the mesylate (**11**) obtainable from **6** in a 92% yield was also treated with NaI in HMPA to give **9** and **10** in 54 and 20% yields respectively. The trisubstituted olefin (**9**) which was obtained from **5** in a 56% overall yield was used for the next experiment, as will be described below.

* To whom all correspondence should be addressed.

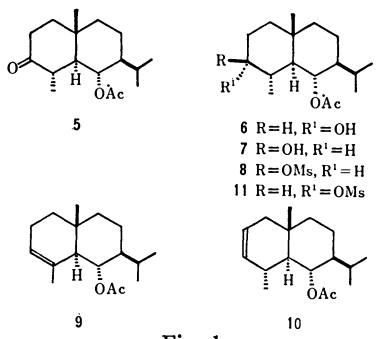


Fig. 1.

The epoxidation of **9** with *m*-chloroperbenzoic acid (under reflux, 3 h), followed by $LiAlH_4$ reduction, afforded a dihydroxy compound (**12**) *via* an epoxide (**13**); the compound was further converted into an acetate (**14**) in an 87.4% overall yield on acetylation with Ac_2O-pyridine (100 °C, overnight).

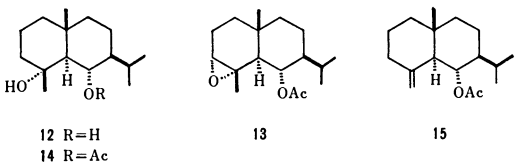

Fig. 2.

Finally, compound **14** was converted into (+)-junenol (**1**) and then into acolamone (**3**) as follows. When treated with $POCl_3$-pyridine at 0 °C for 1 h and then at room temperature overnight, **14** was converted into the corresponding dehydration product, (**15**) [δ 4.45 (1H, br.s) and 4.73 (1H, br.s)ppm], in a 94% yield; it was then reduced with $LiAlH_4$ in ether (under reflux, 2 h) to give, in a quantitative yield, (+)-junenol (**1**); mp 61—61.5 °C (lit, mp 60 °C); $[\alpha]_D^{23}$ +53.1 ° (c=1.07 MeOH) (lit, +52°).[1] The further oxidation of **1** with pyridinium chlorochromate in CH_2Cl_2 (room temp, 30 h) afforded acolamone (**3**) as a colorless, viscous liquid in a 78% yield.

The chemical correlation between acolamone (**3**) and isoacolamone (**4**) has already been established.[2] Surprisingly, though, isojunenol (**2**) has not been isolated from any source. However, on treatment with $LiAlH_4$ in ether (under reflux, 2 h), the olefin (**9**) was readily converted, in a quantitative yield, into isojunenol (**2**); mp 77—78.5 °C; $C_{15}H_{26}O$; ν_{max} 3380 br. cm^{-1}; δ 1.91 (3H, br.s), 3.51 (1H, br.t, J=10.0 Hz), and 5.36 (1H, br.s) ppm.

Experimental

All the mps are uncorrected. IR spectra were recorded on a Hitachi-215 spectrophotometer. NMR spectra were obtained on a Nihondenshi JNM-PS 100 (100 MHz) NMR spectrometer, using $CDCl_3$ as the solvent, unless otherwise stated. The chemical shifts are given in ppm relative to the internal TMS, and only prominent signals are cited (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). Mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating at an ionization energy of 70 eV. Preparative TLC were carried out on Kieselgel PF_{254} (E. Merck, A. G., Germany), unless otherwise stated.

Reduction of the Acetoxy Ketone (5) with $NaBH_4$. Into a solution of **5** (140 mg) in EtOH (4 ml) we stirred $NaBH_4$ (20 mg). The resulting solution was further stirred at room temperature overnight, and then diluted with ether (30 ml) and washed with water. After having been dried over anhydrous Na_2SO_4, the ethereal solution was concentrated under reduced pressure to give a crystalline solid (140 mg), which was subsequently separated by preparative TLC using 5% Et_2O–$CHCl_3$ to give an α-hydroxy acetate, **6** (38 mg), and a β-hydroxy acetate, **7** (100 mg).

6 as colorless prisms: mp 115—116 °C (from hexane); ν_{max} (KBr) 3510, 1720, and 1270 cm^{-1}; δ 0.81 (3H, d, J=6.5 Hz), 0.87 (3H, s), 0.88 (3H, d, J=6.5 Hz), 1.98 (3H, s), 2.14 (1H, br. s, OH), 3.66 (1H, br. s), and 4.86 (1H, br. t, J=9.0 Hz) ppm (Found: C, 72.31; H, 10.95%. Calcd for $C_{17}H_{30}O_3$: C, 72.30; H, 10.71%).

7 as colorless needles: mp 126—126.5 °C (from hexane); ν_{max} (KBr) 3220 br., 1735, and 1250 cm^{-1}; δ 0.82 (3H, d, J=7.0 Hz), 0.89 (3H, d, J=7.0 Hz), 0.90 (3H, s), 0.98 (3H, d, J=6.5 Hz), 2.01 (3H, s), 3.03 (1H, dt, J=5.2 and 10.0 Hz), and 4.92 (1H, t, J=9.5 Hz) ppm (Found: C, 72.09; H, 11.06%. Calcd for $C_{17}H_{30}O_3$: C, 72.30; H, 10.71%).

Reaction of the β-Hydroxy Acetate (7) with Mesyl Chloride–Pyridine. Into a solution of **7** (150 mg) in pyridine (1 ml) we stirred mesyl chloride (67 mg), and then the solution was further stirred at room temperature for 3 h and diluted with ether (30 ml). The ethereal solution was washed successively with 10% aq. HCl, water, and a sat. NaCl aq. solution, and then dried over anhydrous Na_2SO_4. The removal of the solvent under reduced pressure afforded colorless prisms of **8** (182 mg); mp 97—100 °C (from hexane); δ 0.82 (3H, d, J=7.0 Hz), 0.89 (3H, d, J=7.0 Hz), 0.92 (3H, s), 0.98 (3H, d, J=6.5 Hz), 1.99 (3H, s), 2.98 (3H, s), 4.16 (1H, dt, J=6.0 and 10.0 Hz), and 4.88 (1H, br. t, J=9.0 Hz) ppm (Found: C, 59.91; H, 9.30%. Calcd for $C_{18}H_{32}O_5S$: C, 59.97; H, 8.95%).

Reaction of the α-Hydroxy Acetate (6) with Mesyl Chloride–Pyridine. Using the same procedure as that used for **7**, the **6** acetate (170 mg) was treated with mesyl chloride (76 mg)-pyridine (2 ml) (room temp, 3 h) to afford colorless prisms of **11** (200 mg); mp 102—103 °C (from hexane–ether); ν_{max} (KBr) 1730, 1250, and 1185 cm^{-1}; δ 0.82 (3H, d, J=7.5 Hz), 0.89 (3H, d, J=7.5 Hz), 0.90 (3H, s), 1.01 (3H, d, J=6.0 Hz), 2.00 (3H, s), 3.02 (3H, s), 4.20 (1H, br. q, J=2.0 Hz), and 4.89 (1H, br. t, J=9.5 Hz) ppm (Found: C, 59.73; H, 9.13%. Calcd for $C_{18}H_{32}O_5S$: C, 59.97; H, 8.95%).

Formation of Two Olefins, 9 and 10. Into a solution of the **8** mesylate (400 mg) in HMPA (5 ml) we stirred NaI (330 mg) under a nitrogen atmosphere. The reaction mixture was further stirred at 80 °C for 3 h and then diluted with AcOEt. The solution was washed with water, and then dried over anhydrous Na_2SO_4. The removal of the solvent under reduced pressure afforded a reddish oil (290 mg), which was separated by preparative TLC [10% $AgNO_3$–SiO_2; hexane–benzene (3:2)] to give **9** (185 mg) and **10** (63 mg).

9 as a colorless viscous liquid: ν_{max} (film) 1740, 1640, and 1250 cm^{-1}; δ 0.82 (3H, s), 0.85 (3H, d, J=5.5 Hz), 0.92 (3H, d, J=5.5 Hz), 1.65 (3H, br. s), 2.04 (3H, s), 4.95 (1H, br. t, J=9.5 Hz), and 5.32 (1H, br. s) ppm; *m/e* 204 (M^+—AcOH), 198 and 161. No elemental analysis of this oil has been carried out, but its structure must be supported by the above-mentioned spectral data, coupled with those of the next experiment, as will be described below.

10 as colorless needles: mp 35—36 °C (by sublimation); ν_{max} (KBr) 1730, 1660, and 1255 cm^{-1}; δ 0.81 (3H, d, J=7.0 Hz), 0.90 (3H, d, J=7.0 Hz), 0.91 (3H, s), 1.01 (3H, d, J=6.5 Hz), 2.06 (3H, s), 5.01 (1H, br. t, J=10.0 Hz), and 5.45 (2H, complex) ppm (Found: C, 76.67; H, 10.93%. Calcd for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67%).

Reaction of 11 with NaI in HMPA. Using the same procedure as that used for **8**, a solution of **11** (180 mg) and NaI (150 mg) in HMPA (3 ml) was heated at 80 °C for 3 h with stirring, and then treated as usual to give **9** (71 mg) and **10** (27 mg).

Epoxidation of the Trisubstituted Olefin (9). To a solution of **9** (70 mg) in CH_2Cl_2 (5 ml) we added *m*-chloroperbenzoic acid (50 mg). The resulting solution was refluxed for 3 h, then washed successively with 10% aq. Na_2SO_3, 10% aq. $NaHCO_3$, and sat. NaCl aq. solutions, and then dried over anhydrous Na_2SO_4. The removal of the solvent under reduced pressure gave white crystals (70 mg), the sublimation of which afforded colorless prisms of **13**; mp 81—82 °C; ν_{max} (KBr) 1735 and 1250 cm^{-1}; δ 0.84 (3H, s), 0.85 (3H, d, J=5.0 Hz), 0.92 (3H, d, J=5.0 Hz), 1.22 (3H, s), 2.08 (3H, s), 2.87 (1H, br. t, J=2.0 Hz) and 4.92 (1H, dd, J=11.0 and 9.0 Hz) ppm (Found: C, 72.57; H, 10.18%. Calcd for $C_{17}H_{28}O_3$: C, 72.82; H, 10.06%).

Reduction of the Epoxide (13) with $LiAlH_4$. A mixture of **13** (140 mg) and $LiAlH_4$ (10 mg) in ether (10 ml) was refluxed for 2 h with stirring. After decomposition with ether saturated with water, the reaction mixture was filtered. The filtrate was concentrated under reduced pressure to give colorless needles of **12**; mp 142.5—143 °C; ν_{max} (KBr) 3200 br. cm^{-1}; δ 0.86 (3H, s), 0.87 (3H, d, J=7.0 Hz), 0.94 (3H, d, J=7.0 Hz), 1.34 (3H, s), 3.61 (1H, br. t, J=8.5 Hz), and 4.19 (2H, br. s, OH) ppm (Found: C, 74.96; H, 12.06%. Calcd for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%).

Acetylation of the Diol (12). A solution of **12** (94 mg) in Ac_2O (0.5 ml) and pyridine (1 ml) was stirred at 100 °C overnight, and then diluted with water (10 ml) and extracted with ether. The ethereal extract was washed successively with 10% aq. HCl, 10% aq. NaOH, water, and a sat. NaCl aq. solution, and then dried over anhydrous Na_2SO_4. The removal of the solvent under reduced pressure gave white crystals (102 mg), which were recrystallized from hexane to give colorless needles of **14**; mp 85—86 °C; ν_{max} (KBr) 3330 br., 1735, and 1250 cm^{-1}; δ 0.85 (3H, d, J=7.0 Hz), 0.90 (3H, d, J=7.0 Hz), 0.91 (3H, s), 1.19 (3H, s), 2.06 (3H, s), 2.91 (1H, br. s, OH), and 5.19 (1H, br. t, J=10.0 Hz) ppm (Found: C, 71.95; H, 10.63%. Calcd for $C_{17}H_{30}O_3$: C, 72.30; H, 10.71%).

Dehydration of the Monoacetate (14). Into a solution of **14** (85 mg) in pyridine (2 ml), we stirred $POCl_3$ (0.5 ml) at 0 °C. The resulting solution was further stirred at 0 °C for 1 h, and at room temperature overnight, and then slowly poured into ice-water and extracted with ether. The ethereal extract was washed successively with 10% aq. HCl and water, and then dried over anhydrous Na_2SO_4. The removal of the solvent under reduced pressure afforded a crystalline solid, which was subsequently purified by preparative TLC using benzene to give white crystals of **15** (75 mg); mp 37—40 °C

(by sublimation); ν_{max} (KBr) 1730, 1655, and 1255 cm^{-1}; δ 0.76 (3H, s), 0.87 (3H, d, J=7.0 Hz), 0.92 (3H, d, J=7.0 Hz), 2.02 (3H, s), 4.45 (1H, br. s), 4.73 (1H, br. s), and 5.00 (1H, br. t, J=9.5 Hz) ppm (Found: C, 76.73; H, 10.88%. Calcd for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67%).

Formation of (+)-Junenol (1). A mixture of **15** (125 mg) and $LiAlH_4$ (10 mg) in absolute ether (10 ml) was refluxed for 2 h with stirring. After the decomposition of the excess amounts of the reagent with ether saturated with water, the reaction mixture was filtered. The filtrate was concentrated under reduced pressure to give white crystals (104 mg), the sublimation of which afforded colorless needles of (+)-junenol (mp, optical rotation, and IR spectrum)[1]; δ 0.73 (3H, s), 0.87 (3H, d, J=7.5 Hz), 0.94 (3H, d, J=7.5 Hz), 1.95 (1H, s, OH), 3.63 (1H, br. t, J=10.0 Hz), 4.63 (1H, br. s), and 4.93 (1H, br. s) ppm (Found: C, 80.72; H, 12.03%. Calcd for $C_{15}H_{26}O$: C, 81.02; H, 11.79%).

Oxidation of (+)-Junenol (1). Into a suspension of pyridinium chlorochromate (680 mg) in CH_2Cl_2 (7 ml) we stirred a solution of **1** (70 mg) in CH_2Cl_2 (3 ml) at room temperature. The reaction mixture was further stirred at room temperature for 30 h, and then diluted with absolute ether and filtered. The filtrate was concentrated under reduced pressure to give a brown liquid, which was subsequently separated by preparative TLC using hexane–benzene (1:2) to afford a colorless liquid of acolamone (31 mg) (TLC and IR spectrum) and white crystals of the starting material (30 mg) (mp and IR spectrum).

Reduction of the Acetoxy Olefin (9) with $LiAlH_4$. Into a solution of **9** (112 mg) in absolute ether (10 ml) we stirred $LiAlH_4$ (10 mg), and then the reaction mixture was refluxed for 2 h. After the decomposition of the excess amounts of the reagent with ether saturated with water, the reaction mixture was filtered. The filtrate was concentrated under reduced pressure to give white crystals (93 mg), the sublimation of which afforded colorless prisms of isojunenol (**2**); mp 77—78.5 °C; ν_{max} (KBr) 3380 br. cm^{-1}; δ 0.78 (3H, s), 0.87 (3H, d, J=7.0 Hz), 0.96 (3H, d, J=7.0 Hz), 1.91 (3H, br. s), 3.51 (1H, br. t, J=10.0 Hz), and 5.36 (1H, br. s) ppm (Found: C, 80.50; H, 12.11%. Calcd for $C_{15}H_{26}O$: C, 81.02; H, 11.79%).

Regio- and Stereospecific Cyclizations of Germacrones

Masatake NIWA, Masanobu IGUCHI, and Shosuke YAMAMURA*

Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468

(Received April 21, 1976)

From a biogenetic point of view, the acid-catalyzed cyclizations of germacrones (**1**, **2**, and **3**) were carried out, using several kinds of reagents and solvents (80% aq AcOH, 80% aq HCOOH, $AlCl_3$ in absolute ether, AcOH in PhSH, 100% HCOOH in PhSH, and concd H_2SO_4 in PhSH). In all cases, the stereospecific cyclizations of these germacrones took place to give cadinane-type, selinane-type or guaiane-type compounds depending on the kinds of reagents and solvents. The formation process of each compound will be presented in detail.

From a biogentic point of view, many sesquiterpenes are known to be derived from germacrenes or germacrones, which are regarded as an important precursor. Our interests are focused on the biogenetic-type reactions of these ten-membered ring sesquiterpenes and their derivatives. In the present paper, we describe the regio- and stereospecific cyclizations of these germacrones with some acids, leading to the formation of cadinane-type, selinane-type or guaiane-type compounds. In addition, some naturally occurring sesquiterpenes were synthesized from these germacrones.

As described in the previous papers,[1,2] many sesquiterpenes have been isolated from the plant *Acorus calamus* L. and their structures also been established. Of these sesquiterpenes, acoragermacrone (**1**) is regarded as the most important compound, which has been chemically converted into isoacoragermacrone (**2**), preisocalamendiol (**3**) and other sesquiterpenes.[2] In our experiments, mainly, three germacrones **1**, **2** and **3** were used for the biogenetic-type reactions.

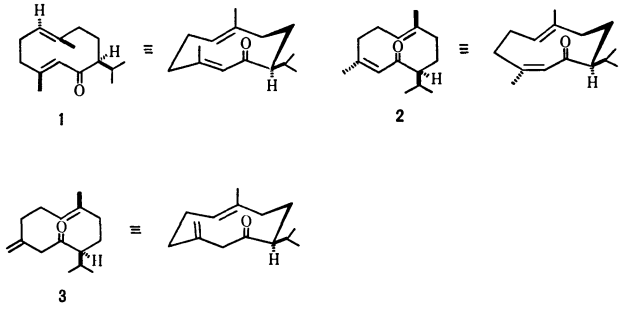

Fig. 1.

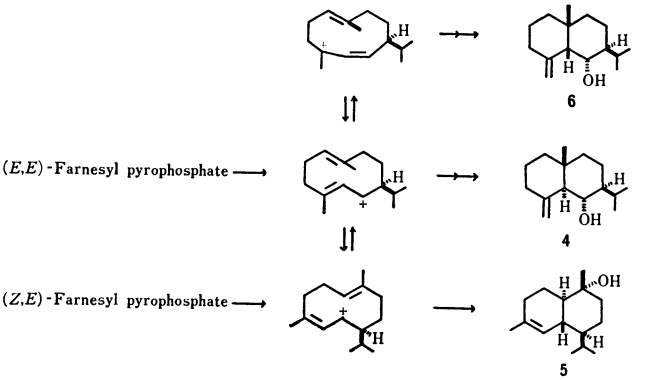
Acid-catalyzed Cyclizations of Acoragermacrone (1). Biogenetically, *trans*-selinane-type sesquiterpenes are produced from the corresponding germacrenes with an (*E*,*E*)-1,5-cyclodecadiene system, while cadinane-type compounds must be stereochemically produced from the corresponding ten-membered ring compounds with an (*E*,*Z*)-1,5-cyclodecadiene system which may be directly derived from a (*Z*,*E*)-farnesyl pyrophosphate or produced on *cis-trans* isomerization of the corresponding (*E*,*E*)-1,5-cyclodecadienes: the formation process of junenol (**4**)[3] as well as of α-cadinol (**5**)[4] is demonstrated in Scheme 1. Quite recently, 5-epi-junenol (**6**) was isolated from *Ferula galbaniflua*.[5] Probably, this sesquiterpene is produced on double-bond isomerization of the (*E*,*E*)-1,5-cyclodecadienyl cation, followed by acid-catalyzed cyclization together with simultaneous hydration, as shown in Scheme 1.



Scheme 1. Biogenesis of *cis*- and *trans*-selinane-type and cadinane-type sesquiterpenes.

It is interesting to examine the acid-catalyzed cyclization of acoragermacrone (**1**), because the protonated form (A) of **1** is expected to show the same behavior as that of the (*E*,*E*)-1,5-cyclodecadienyl cation (B), as shown in Scheme 1. Thus, the acid-catalyzed reactions of acoragermacrone (**1**) were carried out under various conditions.[6]

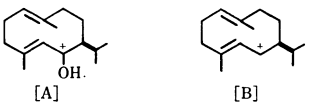


Fig. 2.

As described earlier,[2] $AlCl_3$ converted **1** into two *trans*-selinane-type sesquiterpenes, acolamone (**7**) and isoacolamone (**8**), in 55 and 23% yields, respectively. Both of them are included in the plant together with acoragermacrone (**1**).

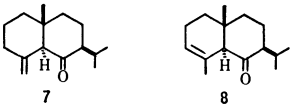

Fig. 3.

Acoragermacrone (**1**) is fairly stable toward 80% aq AcOH at room temperature. However, when heated at 75°C for 50 min, the compound **1** afforded isocalamendiol (**9**),[1] in a 28% yield. Clearly, acoragermacrone with an (*E*,*E*)-1,5-cyclodecadiene system must be converted into preisocalamendiol (**3**) which is further subjected to the regio- and stereospecific cyclization giving the

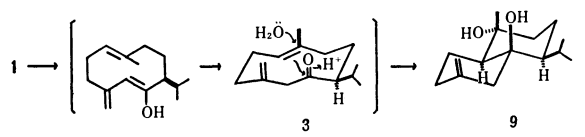
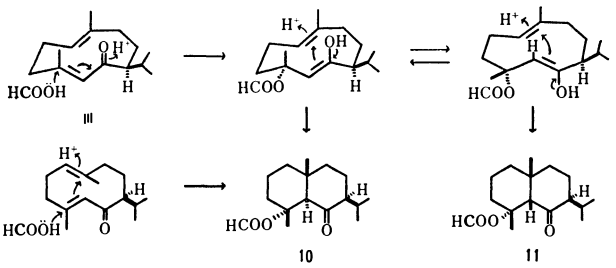


Scheme 2. Conversion of acoragermacrone into isocalamendiol.

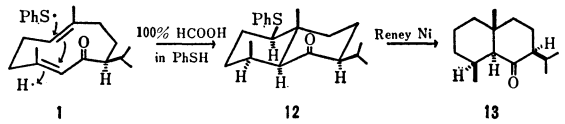
cadinane-type compound (**9**), as shown in Scheme 2.

Furthermore, the acid-catalyzed cyclization of acoragermacrone (**1**) was carried out using 80% aq HCOOH instead of 80% aq AcOH. In this case, the cyclization reaction takes place under much milder conditions (room temp, 10 min) to give three cyclization products **9**, **10** and **11**, in 19, 17 and 17% yields, respectively, one of which is identical with isocalamendiol (mp and IR spectrum). Other two compounds both are selinane-type compounds (**10**, mp 45—48 °C; **11**, mp 83—85 °C) with the same molecular formula ($C_{16}H_{26}O_3$), whose structures are based on their spectral data, as will be discussed below. Both cyclization compounds show an IR absorption band at 1720 cm^{-1}, and an intense fragment peak at *m/e* 220 (M^+—HCOOH). The NMR spectra of both compounds are also quite similar to each other: they have two methyl singlets (δ 0.90 and 1.88 ppm in **10**; δ 0.96 and 1.91 ppm in **11**) in addition to one isopropyl group. Furthermore, these compounds have two singlets due to a C_5-methine proton and a HCOO–grouping (δ 2.87 and 8.04 ppm in **10**; δ 2.93 and 8.03 ppm in **11**). From the above data, these two products must be selinane-type compounds and stereoisomers to each other. In fact, a remarkable difference is observed in their ORD curves: the *trans*-selinane-type compound (**10**) has a positive Cotton effect ($[\phi]^{P}_{320nm}$ $+14°\times10^2$, $[\phi]^{T}_{277nm}$ $-28°\times10^2$, $A=+42$), while the *cis*-isomer (**11**) has a negative Cotton effect $[(\phi]^{T}_{324nm}$ $-56°\times10^2$, $[\phi]^{P}_{278nm}$ $+61°\times10^2$, $A=-117$). In particular, the formation of the *cis*-selinane-type compound (**11**)is interesting in connection with Scheme 1. As seen in Scheme 3, two possible pathways from **1** to the *trans*-isomer (**10**) are suggested, and any of them can not be ruled out. The *cis*-isomer (**11**) seems to be derived directly from one of the ten-membered ring conformers, since these two selinane-type compounds are not interconvertible under mild reaction conditions. We further examined the acid-catalysed cyclization of acoragermacrone (**1**) using 100% HCOOH in thiophenol, as follows.



Scheme 3. Acid-catalyzed cyclization of acoragermacrone with 80% aq HCOOH.

When treated with 100% HCOOH in thiophenol (room temp, 1 h), the compound **1** was readily converted into a selinne-tyape compound (**12**), in *ca.* 60% yield. This compound (**12**) is a colorless oil with molecular formula $C_{21}H_{30}OS$, whose structure has been elucidated on the basis of its spectral data and chemical evidence: desulfurization of **12** with Raney Ni(W-4) gave dihydroacolamone (**13**)[2] in a 26% yield. In particular, the NMR signal at δ 3.01 (1H, dd, J=6.5 and 8.8 Hz) ppm indicates that the PhS group should be in an equatorial configuration. As shown in Scheme 4, the regio- and stereospecific cyclization of **1** may not take place in an ionic mechanism, but probably in a radical manner.[7]



Scheme 4. Regio- and sterespecific cyclization of acoragermacrone with 100% HCOOH in thiophenol.

Acid-catalyzed Cyclization of Isoacoragermacrone (2). It is quite reasonable to suppose that the protonated form(C) of isoacoragemacrone (**2**) is equivalent to the (*Z,E*)-1,5-cyclodecadienyl cation (D) in their chemical behavior. Furthermore, from a stereochemical aspect, isoacoragermacrone, which has been obtained from acoragermacrone (**1**) as well as from preisocalamendiol (**3**),[2] seems to be converted into cadinane-type compounds, as shown in Scheme 1. In fact, when treated with 80% aq AcOH at room temperature for 5 min, **2** was readily converted into two dienes **14** and **15**, in 43 and 23% yields, respectively.[8] The structures of these products are based on their spectral data [**14**,

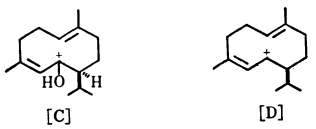


Fig. 4.

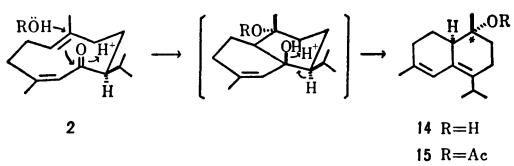
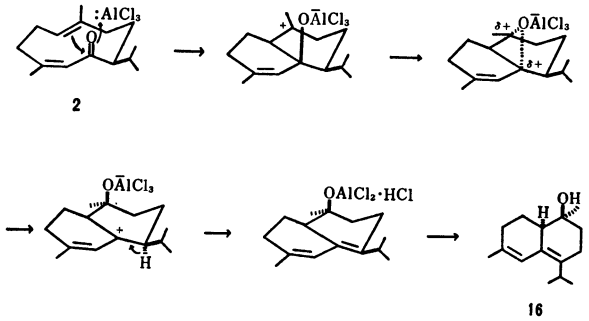
$C_{15}H_{24}O$; ν_{max} 3350 (br) cm^{-1}; λ_{max} 247 and 241 nm (ε, 11100 and 10900, respectively); δ 1.06 (3H, s), 1.80 (3H, br.s) and 6.24 (1H, br.s) ppm. **15**, $C_{17}H_{26}O_2$; ν_{max} 1730 cm^{-1}; λ_{max} 247 and 241 nm (ε, 10500 and 10300, respectively); δ 1.35 (3H, s), 1.79 (3H, br.s), 1.99 (3H, s) and 6.25 (1H, br.s) ppm], in which the configuration of the asterisked carbon atom will be discussed later. The different point between **14** and **15** is that the former has a hydroxyl group, while an acetoxyl group is present in **15**. Thus, treatment of the latter with $LiAlH_4$ afforded **14** in a high yield. In the above experiment, the regio- and stereospecific cyclization of isoacoragermacrone (**2**) takes place in a concerted



Scheme 5. Reaction of isoacoragermacrone (**2**) with 80% aq AcOH.

manner, leading to the formation of **14** and **15**, as shown in Scheme 5.

On the other hand, when treated with $AlCl_3$ in absolute ether (0 °C, 10 mil), isoacoragermacrone (**2**) was converted into an isomer of **14** in a 72% yield. The spectral data of this isomer (**16**) are quite similar to those of **14** except for the chemical shift of the tertiary methyl signal (δ 1.06 ppm in **14**; δ 1.28 ppm in **16**). Clearly, the axial methyl signal in the former should be observed in higher magnetic field than that of the equatorial isomer.[8,9] In the case of $AlCl_3$, the stereospecific reaction of **2** takes place in a stepwise manner, as demonstrated in Scheme 6, which includes an intramolecular oxygen-transfer.[8]



Scheme 6. Reaction of isoacoragermacrone (**2**) with $AlCl_3$.

We further examined the acid-catalyzed cyclization of isoacoragermacrone (**2**) in thiophenol.[10] Interestingly, when treated with AcOH in thiophenol (room temp, 24 h), isoacoragermacrone (**2**) was converted into a guaiane-type compound (**17**, mp 90—91 °C; $C_{21}H_{30}OS$), in a 50% yield, whose structure was determined by its spectral data and the following chemical evidence. This compound has a CO group (ν_{max} 1700 cm^{-1}) and each one of secondary and tertiary methyl groups [δ (CCl_4) 0.95 (3H, d, J=7.5 Hz) and 1.22 (3H, s) ppm] in addition to the original isopropyl group. Treatment of **17** with MeI in acetone (under reflux, 8 h) afforded an α,β-unsaturated ketone in a 66% yield [**18**, $C_{15}H_{24}O$; ν_{max} 1670 and 1610 cm^{-1}; λ_{max} 256 nm (ε, 8270); δ 2.05 (3H, s) ppm]. On desulfurization with Raney Ni (W-4) in EtOH, the guaiane-type compound **17** was readily converted, in an 86% yield, into the corresponding reduction product (**19**, mp 55—57.5 °C; $C_{15}H_{26}O$) which has a newly formed secondary methyl group in addition to the three secondary methyl groups (δ 0.83, 0.87, 0.92 and 1.13 ppm). In addition, a methine doublet at δ 2.92 (1H, d, J= 8.5 Hz) ppm in **17** became double doublets at δ 2.86 (1H, dd, J=7.8 and 4.8 Hz) ppm in **19**. Finally, this reduction product **19** was converted into the more stable *trans*-isomer (**20**) on treatment with NaOMe–MeOH (under reflux, 3 h).[11] The stereostructures of these two isomers (**19** and **20**) are also supported by measurements of their ORD curves: the *cis*-isomer (**19**) has a positive Cotton effect ($[\phi]^{P}_{321nm}$ +14°×10², $[\phi]^{P}_{276nm}$ −39°×10², A=+53), while the *trans*-isomer (**20**) has a negative Cotton effect ($[\phi]^{T}_{312nm}$ −46°×10², $[\phi]^{P}_{272nm}$ +57°×10², A=−103).

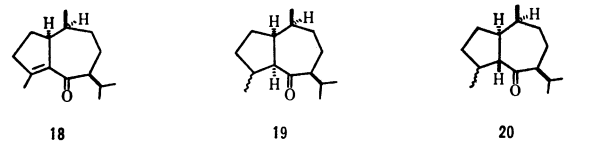


Fig. 5.

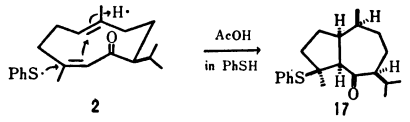
The formation process of the guaiane-type compound (**17**) is shown in Scheme 7, indicating that the regio- and stereospecific cyclization of **2** takes place in a radical mechanism.

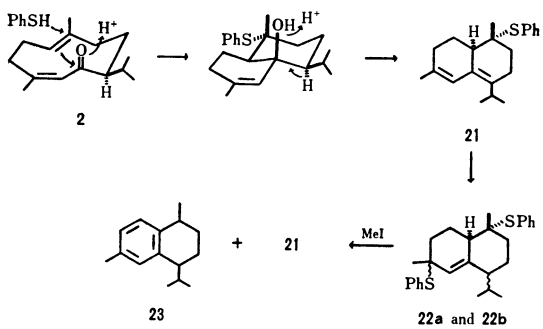


Scheme 7. Reaction of isoacoragermacrone with AcOH in thiophenol.

In the case of 100% HCOOH in thiophenol (room temp, 15 h), four cyclization products were obtained from isoacoragermacrone (**2**), in low yields (**17**, 15%; **21**, 5%; **22a**+**22b**, 12%). One of them is completely identical with the guaiane-type compound (**17**) which has been already obtained in the case of AcOH in thiophenol, as described earlier (mp and IR spectrum). The other three products (**21**, **22a** and **22b**) are cadinane-type compounds, whose structures are based on their spectral data and chemical evidences. The compound **21** is a colorless viscous liquid ($C_{21}H_{28}S$) and has two methyl groups [δ 1.09 (3H, s) and 1.76 (3H, br.s) ppm] in addition to the original isopropyl group. In addition, one broad singlet at δ 6.13 ppm due to an olefinic proton is observed in the NMR spectrum of **21**.

The compound **22**, a colorless viscous liquid, is an inseparable mixture consisting of two epimers (**22a** and **22b**), both of which have two PhS groups [δ 7.10—7.70 (10H, complex) ppm] and one olefinic proton (δ 5.35 and 5.43 ppm). Finally, these compounds (**21**, **22a** and **22b**) were chemically interconvertible, as follows.

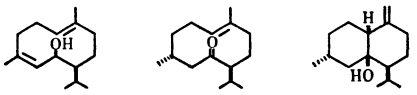
When treated with conc. H_2SO_4 in thiophenol (0 °C, 30 min), the compound **21** was readily converted into the mixture of **22a** and **22b**, in a 75% yield. On the other hand, the mixture (**22a** and **22b**) reacted with excess amounts of MeI (under reflux, 4 h) to give **21** and calamenene (**23**), in 45 and 29% yields, respectively.



Scheme 8. The formation of cadinane-type compounds (**21**, **22a** and **22b**) from isoacoragermacrone (**2**).

We further examined the acid-catalyzed cyclization of isoacoragermacrone (**2**) in thiophenol using concd H_2SO_4 instead of 100% HCOOH (0 °C, 30 min). In this case, the cadinane-type compounds were only isolated from the reaction mixture (**21**, 4%; **22a**+**22b**, 67%). In the above experiment using such a strong acid as concd H_2SO_4, clearly, the regio- and stereospecific cyclization of **2** giving these cadinane-type compounds must take place in an ionic mechanism (see Scheme 8) in contrast to the formation process of the guaiane-type compound (**17**).

From a biogenetic point of view, such an allyl alcohol as **24** is also attractive to us for the biogenetic model reactions (see Scheme 1). However, reduction of isoacoragermacrone (**2**) with diisobutylaluminium hydride (0—5 °C, 2 h) did not afford the desired alcohol (**24**), but a saturated ketone (**25**) in a 72% yield, which could be converted into the known cadinane-type compound (**26**)[1] in a 20% yield on treatment with 80% aq AcOH (room temp, 5 min).



24 25 26

Fig. 6.

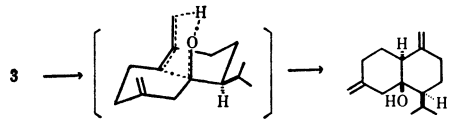
Regio- and Stereospecificity in the Cyclizations of Preisocalamendiol (3) and its Derivatives. As reported in the previous paper,[1] action of 80% aq AcOH on preisocalamendiol (**3**) converted it into isocalamendiol (**9**) in a good yield. However, any amount of calamendiol (**27**), an isomer of **9**, has not been obtained.[8] We further examined the acid-catalyzed cyclization of **3** with $AlCl_3$ in absolute ether, which was carried out at 0 °C for 10 min to give the dienol (**28**)[1] in a 54% yield. The compound **28** was also obtained, in a high yield, by thermal reaction of **3** at 180 °C, as described in Table 1. Probably, a chair-like transition state must be included in the course of the stereospecific cyclization, as demonstrated in Scheme 9.[12]

Table 1. Thermal isomerization of preisocalamendiol (**3**)

Time (min)	**3** (%)	**28** (%)	Other products (%)
0	100	0	0
7.5	99	1	0
22	83	17	0
42	48	46	6
90	3	86	11

Peak-heights in gas chromatogram (PEG 20 M, N_2, 115 °C, flame-ionizer detector) were served as approximate values of the content (%)

The Formation of ε-Cadinene. Preisocalamendiol (**3**) is quite stable toward $NaBH_4$. However, when treated with excess amounts of $LiAlH_4$ (room temp, 30 h), **3** was converted into the corresponding hydroxy compound in a quantitative yield [**29**, $C_{15}H_{26}O$; ν_{max} 3360 br·cm^{-1}; δ 3.60—3.92 (1H, m) ppm]. Further



28

Scheme 9. Thermal isomerization of preisocalamendiol (**3**) to the dienol (**28**).

treatment of **29** with 80% aq HCOOH (0 °C, 2 h) did not afford any cyclization product, but the corresponding formate in a high yield [**30**, ν_{max} 1720 cm^{-1}; δ 3.66—3.90 (1H, m) and 8.11 (1H, s) ppm]. On reduction with $LiAlH_4$, this formate was reconverted into the original alcohol (**29**).

Finally, dehydration of **29** with mesyl chloride-pyridine (room temp, 7 h) afforded ε-cadinene (**31**) in a 35% yield, which was further subjected to catalytic hydrogenation (PtO_2 in AcOEt) giving the corresponding tetrahydro compound (**32**).[13] The IR spectrum of **32** was completely identical with that of an authentic sample of tetrahydrocadinene.[14]

Experimental

All the mps are uncorrected. GLC were recorded on a Shimadzu GC-1C gas chromatograph with a flame-ionizer detector [stationary phase: 5% PEG 20M on Celite 545 (100 mesh); column [ϕ 3 mm × 1.5 m (stainless steel)] temp: 90 °C; carrier gas: nitrogen (85 ml/min); inlet pressure: 1.2 kg/cm^2], unless otherwise stated. IR spectra were recorded on a Hitachi-215 spectrophotometer. UV spectra were taken on a Hitachi-124 spectrophotometer, using MeOH as the solvent. NMR spectra were recorded on a Varian Associate A-60 (60 MHz), a JEOL JNM-C60H (60 MHz) or JNM-PS 100 (100 MHz), using $CDCl_3$ as the solvent, unless otherwise stated. The chemical shifts are given in ppm relative to the internal TMS, and only prominent signals are recorded (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). Mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating at an ionization energy of 70 eV. ORD curves were recorded on a JASCO ORD/UV-5 spectrophotometer, using MeOH as the solvent. Preparative TLC were carried out on Kieselgel PF_{254} (E. Merck, A. G.), unless otherwise stated.

Reaction of Acoragermacrone (1) with 80% aq AcOH. A solution of **1** (27 mg) in 80% aq AcOH (0.5 ml) was heated at 75 °C for 50 min with stirring, and then diluted with water (2 ml). The solution was neutralized with a dil. $NaHCO_3$aq solution, and then extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous Na_2SO_4. Removal of the solvent gave a colorless viscous liquid, which was subsequently separated by preparative TLC using benzene–ether (4: 1) to give isocalamendiol (**9**) (8 mg) (mp and IR spectrum).

Reaction of Acoragermacrone (1) with 80% aq HCOOH. A solution of **1** (90 mg) in 80% aq HCOOH (0.9 ml) was

stirred at room temperature for 10 min, and then diluted with water (5 ml). The solution was neutralized with a sat. $NaHCO_3$ aq solution, and then extracted with ether. The ethereal extract was washed with water and dried over anhydrous Na_2SO_4. The solvent was evaporated under reduced pressure to give a pale yellow liquid (106 mg), which was separated by preparative TLC using benzene–ether (4: 1) to give three main fractions in the following order: **9** (18 mg), **10** (19 mg), and **11** (19 mg). The compound **9** was identical with an authentic sample of isocalamendiol (mp and IR spectrum). The physical data of the other two products are shown below.

trans-*Selinane-type Compound (10)*: mp 45—48 °C (from hexane); ν_{max} (film) 1720 cm^{-1}; δ 0.88 (3H, d, J=6.5 Hz), 0.92 (3H, d, J=6.5 Hz), 0.90 (3H, s), 1.88 (3H, s), 2.87 (1H, s) and 8.04 (1H, s) ppm; *m/e* 266 (M^+) and 220 (Found: *m/e* 266.18862. Calcd for $C_{16}H_{26}O_3$: *m/e* 266.18818).

cis-*Selinane-type Compound (11)*: mp 83—85 °C (from hexane); ν_{max} (film) 1720 cm^{-1}; δ 0.85 (3H, d, J=6.0 Hz), 0.98 (3H, d, J=6.0 Hz), 0.96 (3H, s), 1.91 (3H, s), 2.93 (1H, s), and 8.03 (1H, s) ppm; *m/e* 266 (M^+) and 220 (Found: *m/e* 266.19067. Calcd for $C_{16}H_{26}O_3$: *m/e* 266.18818).

Reaction of Acoragemacrone (1) with 100% HCOOH in Thiophenol. To a solution of **1** (125 mg) in thiophenol (2 ml) was added 5 drops of 100% HCOOH with stirring. The resulting solution was further stirred at room temperature for 1 h, and then diluted with a lot of ether. The ethereal solution was washed successively with 10% NaOH aq solution and water, and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure left a pale yellow liquid (190 mg), which was purified by preparative TLC using hexane–benzene (1: 1) to give a pale yellow liquid of **12** (109 mg), ν_{max} (film) 3060, 1710, 1580, 735, and 690 cm^{-1}; δ 0.83 (3H, s), 0.85—1.00 (9H, complex), 3.01 (1H, dd, J=6.5 and 8.8 Hz) and 7.18—7.69 (5H, complex) ppm; *m/e* 330 (M^+) and 220 (Found: *m/e* 330.20388. Calcd for $C_{21}H_{30}OS$: *m/e* 330.20173).

Desulfurization of 12. To a solution of **12** (80 mg) in EtOH (3 ml) was added Raney Ni (W-4) (100 mg), and then the reaction mixture was refluxed for 3 h under a nitrogen atmosphere. After removal of the catalyst, the filtrate was concentrated under reduced pressure to give a colorless viscous liquid (51 mg) which was purified by preparative GLC at 120 °C to give a colorless liquid of dihydroacolamone (14 mg) (GLC, TLC and IR spectrum).

Reaction of Isoacoragermacrone (2) with 80% aq AcOH. Isoacoragermacrone (40 mg) was dissolved in 80% aq AcOH (5 ml) with stirring. The resulting solution was further stirred at room temperature for 5 min, and then diluted with ice-water (*ca.* 10 ml). After neutralization with $NaHCO_3$ powder, the solution was extracted with ether. The ethereal extract was washed with a sat. NaCl aq solution and dried over anhydrous Na_2SO_4, and then concentrated under reduced pressure to give a colorless oil, which was separated by preparative TLC using petroleum ether–ether (1: 3) to give two fractions. From the more polar fraction, the alcohol **14** (17 mg) was isolated as a colorless viscous liquid. From the less polar fraction, the acetate **15** (11 mg) was also obtained as a colorless viscous liquid.

14: ν_{max} (film) 3350 br. and 1640 br. cm^{-1}; λ_{max} 247 and 241 nm (ε, 11100 and 10900, respectively); δ 0.96 (3H, d, J=7.0 Hz), 0.98 (3H, d, J=7.0 Hz), 1.06 (3H, s), 1.80 (3H, br. s) and 6.24 (1H, br. s) ppm; *m/e* 220 (M^+), 187 and 159 (Found: *m/e* 220.18096. Calcd for $C_{15}H_{24}O$: *m/e*220.18270).

15: ν_{max} (film) 1730 and 1660 br. cm^{-1}; λ_{max} 247 and 241 nm (ε, 10500 and 10300, respectively); δ 0.96 (3H, d, J=7.0 Hz), 0.98 (3H, d, J=7.0 Hz), 1.35 (3H, s), 1.79 (3H, br. s), 1.99 (3H, s), 4.77 (1H, br. s) and 6.25 (1H, br. s) ppm; *m/e* 262 (M^+), 220, 202, 187, 177, and 159 (Found: *m/e* 262.19634. Calcd for $C_{17}H_{26}O_2$: *m/e* 262.19327).

Reduction of the Acetate 15 with $LiAlH_4$. To a solution of **15** (18 mg) in anhydrous ether (5 ml) was added $LiAlH_4$ (4 mg) with stirring, and then the reaction mixture was heated under reflux for 4 h. After decomposition of an excess of the reagent with water, 20% potassium sodium tartarate aq solution was added to the reaction mixture, which was extracted with ether. The ethereal extract was dried over anhydrous Na_2SO_4, and then concentrated under reduced pressure to give a colorless oil (14 mg), which was purified by preparative TLC using petroleum ether–ether (1: 3) to give the alcohol **14** (GLC, TLC, and IR spectrum).

Reaction of Isoacoragermacrone (2) with $AlCl_3$. To a solution of **2** (39 mg) in absolute ether (5 ml) was added a solution of $AlCl_3$ (24 mg) in absolute ether (1.5 ml) at 0 °C, with stirring. The resulting solution was further stirred at 0 °C for 10 min, and then poured into ice water and extracted with ether several times. The combined ethereal extracts were washed with a sat. NaCl aq solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure afforded a colorless oil,* which was purified by preparative TLC using alumina [GF_{254} (type E), E. Merck A. G.] and benzene to give **16** as a colorless viscous liquid (20 mg); ν_{max} (film) 3570 sh., 3450 and 1640 cm^{-1}; λ_{max} 246 and 241 nm (ε, 16300 and 16200, respectively); δ 1.00 (6H, d, J=7.0 Hz), 1.28 (3H, s), 1.77 (3H, br. s) and 6.27 (1H, br. s) ppm; *m/e* 220 (M^+), 202, 187, and 159 (Found: *m/e* 220.18247. Calcd for $C_{15}H_{24}O$: *m/e* 220.18271).

The Formation of the Guaiane-type Compound (17). To a solution of isoacoragermacrone (245 mg) in thiophenol (2 ml) was added, with stirring, 10 drops of AcOH at room temperature, and then the resulting solution was further stirred at room temperature for 24 h. After addition of a cooled 10% NaOH aq solution, the solution was extracted with ether. The ethereal extract was washed successively with a cooled 10% NaOH aq solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent under reduced pressure gave an almost colorless liquid, which was chromatographed on silica gel (20 g) and eluted with benzene to give **17** as colorless crystals (184 mg); mp 90—91 °C (from hexane); ν_{max} (KBr) 3060, 1700, 1580, 745, and 690 cm^{-1}; δ (CCl_4) 0.91 (3H, d, J=6.4 Hz), 0.95 (3H, d, $J\simeq$7.5 Hz), 0.96 (3H, d, J=6.4 Hz), 1.22 (3H, s), 2.92 (1H, d, J=8.5 Hz) and 7.08—7.57 (5H, m) ppm; *m/e* 330 (M^+) and 221 (Found: C, 76.53; H, 9.26%. Calcd for $C_{21}H_{30}OS$: C, 76.31; H, 9.15%).

Formation of the α,β-Unsaturated Ketone (18). A solution of **17** (100 mg) and freshly distilled MeI (1 ml) in acetone (4 ml) was refluxed under a nitrogen atmosphere for 8 h, and then concentrated under reduced pressure to give a crude residue which was purified by preparative TLC using hexane–benzene (1: 1) to give **18** as a colorless liquid (44 mg); ν_{max} (film) 1670 and 1610 cm^{-1}; λ_{max} 256 nm (ε, 8270); δ 0.72 (3H, d, J=6.5 Hz), 0.88 (3H, d, J=6.4 Hz), 0.92 (3H, d, J=6.4 Hz), 2.05 (3H, br. s) and 3.24 (1H, m) ppm; *m/e* 220 (M^+) and 215 (Found: 220.18108. Calcd for $C_{15}H_{24}O$: *m/e* 220.18271).

Desulfurization of 17. To a solution of **17** (137 mg) in absolute EtOH (5 ml) was added, with stirring, Raney Ni (W-4) (*ca.* 1 g) at room temperature, and then the reaction mixture was refluxed under a nitrogen atmosphere for 6 h. After filtration of the catalyst, the filtrate was concentrated

* Peak-area of analytical GLC was served as approximate values of the content (%), indicating that this oil contained the alcohol **16** (28.2 mg).

under reduced pressure to give a crystalline solid (79 mg), the sublimation of which afforded **19** as colorless needles; mp 55—57.5 °C; ν_{max} (KBr) 1700 cm^{-1}; δ 0.83 (3H, d, J=6.7 Hz), 0.87 (3H, d, J=6.5 Hz), 0.92 (3H, d, J=6.5 Hz), 1.13 (3H, d, J=6.3 Hz) and 2.86 (1H, dd, J=7.8 and 4.8 Hz) ppm; *m/e* 222 (M^+), 207 and 166 (Found: *m/e* 222.19849. Calcd for $C_{15}H_{26}O$: *m/e* 222.19836).

Epimerization of ***19***. A solution of **19** (44 mg) and NaOMe (27 mg) in absolute MeOH (3 ml) was refluxed for 3 h under a nitrogen atmosphere, and then concentrated under reduced pressure. After addition of water (5 ml), the reaction mixture was extracted with ether. The ethereal extract was dried over anhydrous $MgSO_4$. Evaporation of the solvent afforded a colorless liquid (39 mg), which was separated by preparative TLC using hexane–benzene (1: 1) to give two fractions. From the less polar fraction, the starting material of **19** (8 mg) was recovered (mp and IR spectrum). From the polar fraction, a colorless viscous liquid **20** (28 mg) was isolated; ν_{max} (film) 1695 cm^{-1}; δ 0.84—1.06 (12H, complex) ppm; *m/e* 222 (M^+), 207 and 166 (Found: *m/e* 222.19846. Calcd for $C_{15}H_{26}O$: *m/e* 222.19836).

Reaction of Isoacoragermacrone (2) with 100% HCOOH in Thiophenol. To a solution of **2** (480 mg) in thiophenol–benzene [30 ml (1: 1)] was added, with stirring, 20 drops of 100% HCOOH at room temperature. The resulting solution was further stirred at room temperature for 15 h, and then washed successively with 10% NaOH aq solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent under reduced pressure afforded a viscous liquid which was chromatographed on silica gel. Elution with hexane–benzene (1: 1) gave a colorless oil (347 mg), which was rechromatographed on silica gel and eluted with hexane and then with hexane–benzene (9: 1) to give **21** (33 mg) and **22** (110 mg), respectively.

Further elution of the above viscous liquid with hexane–benzene (1: 1) gave a colorless viscous liquid (179 mg) of undetermined structure. Continuous elution with the same solvent system afforded the guaiane-type compound **17** (110 mg) (mp and IR spectrum).

21. A colorless viscous liquid; ν_{max} (film) 3070 sh., 3060, 1580 br., 745 and 690 cm^{-1}; δ (CCl_4) 0.93 (6H, d, J=7.0 Hz), 1.09 (3H, s), 1.76 (3H, br. s), 2.99 (1H, m, J=7.0 Hz), 6.13 (1H, br. s) and 7.30 (5H, complex) ppm; *m/e* 312 (M^+), 202, 187, and 159 (Found: *m/e* 312.19197. Calcd for $C_{21}H_{28}S$: *m/e* 312.19116).

22. A colorless viscous liquid; ν_{max} (film) 3070, 1585 br., 750 and 695 cm^{-1}; δ (CCl_4) 0.76—0.98 (6H, complex), 1.12 (3H, s), 1.24 and 1.26 (total 3H), 5.35 and 5.43 (total 1H) and 7.10—7.70 (10H, complex) ppm; *m/e* 312 (M^+—110), 202 and 159 (Found: *m/e* 312.19105. Calcd for $C_{27}H_{34}S_2$–C_6H_6S; *m/e* 312.19116).

Reaction of Isoacoragermacrone (2) with concd H_2SO_4 in Thiophenal. To a solution of **2** (380 mg) in thiophenol (12 ml) was added, with stirring, 10 drops of conc. H_2SO_4 at 0 °C, and the solution was further stirred at 0 °C for 30 min, and then extracted with ether after addition of a cooled 10% NaOH aq. solution (40 ml). The ethereal extract was washed successively with 10% NaOH aq solution and water, and then dried over anhydrous $MgSO_4$. Removal of the solvent afforded a pale yellow liquid, which was chromatographed on silica gel (15 g) and eluted with hexane to give a colorless viscous liquid of **21** (22 mg) (TLC and IR spectrum). Further elution with hexane–benzene (9: 1) also gave a colorless viscous liquid **22** (491 mg) (TLC and IR spectrum).

Formation of the Dithio Compounds (22a and 22b) from the Conjugated Diene (21). To a solution of **21** (12 mg) in thiophenol (1 ml) was added, with stirring, one drop of concd H_2SO_4 at 0 °C. The solution was further stirred at 0 °C for 30 min, and then extracted with hexane after addition of a cooled 10% NaOH aq solution. The extract was washed successively with a cooled 10% NaOH aq solution and water, and then dried over anhydrous $MgSO_4$. After evaporation of the solvent, the residue was purified by preparative TLC using hexane to give a mixture of dithio compounds (**22a** and **22b**) as a colorless viscous liquid (9 mg) (TLC and IR spectrum).

Conversion of the Dithio Compounds (22a and 22b) into the Conjugated Diene (21). A solution of the dithio compounds (100 mg) in acetone containing MeI (2 ml) was refluxed for 4 h under a nitrogen atmosphere, and then concentrated under reduced pressure to give a pale yellow liquid which was separated by preparative TLC using hexane to give two fractions. From the first fraction, calamenene (14 mg) was isolated (GLC, TLC, and IR spectrum). From the second fraction, **21** (39 mg) was obtained (TLC and IR spectrum) as a colorless viscous liquid.

Reduction of Isoacoragermacrone (2) with Diisobutylaluminium Hydride (DBAH). To a solution of **2** (27 mg) in absolute benzene (2 ml) was added, with stirring, a solution of DBAH (100 mg) in heptane at 0 °C under a nitrogen atmosphere. The solution was further stirred at 0 °C for 1.5 h and at 5 °C for 30 min, and then cooled to 0 °C again. After addition of MeOH–benzene (1: 1) (5 ml), the solution was concentrated under reduced pressure to dryness. The residue was diluted with benzene with shaking, and then filtered. The filtrate was concentrated under reduced pressure to give a colorless oil (26 mg),** which was purified by preparative TLC using alumina [GF_{254} (type E), E. Merck A. G.] and benzene to give the corresponding dihydro compound **25** (7.5 mg) as a colorless viscous liquid; ν_{max} (film) 1700 cm^{-1}; δ 0.87 (3H, d, J=6.9 Hz), 0.92 (3H, d, J=6.9 Hz), 0.96 (3H, d, J=6.9 Hz), 1.45 (3H, br. s) and 5.16 (1H, t, J=6.5 Hz) ppm; *m/e* 222 (M^+) and 207 (Found: *m/e* 222.19837. Calcd for $C_{15}H_{26}O$: *m/e* 222.19836).

Reaction of the Dihydro Compound (25) with 80% aq AcOH. A solution of **25** (54 mg) in 80% aq AcOH (4 ml) was stirred at room temperature for 5 min, and then diluted with ice–water (*ca.* 10 ml). After neutralization with $NaHCO_3$ powder, the solution was extracted with ether. The ethereal extract was washed with a sat. NaCl aq solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent afforded a colorless oil which was separated by preparative TLC using alumina [GF_{254} (type E), E. Merck A. G.] and benzene to give **26** (11 mg) as a colorless viscous liquid, which was identical with an authentic sample of dihydro-dehydroisocalamendiol.[1]

Reaction of Preisocalamendiol (3) with $AlCl_3$. To a solution of **3** (27 mg) in absolute ether (5 ml) was added, with stirring, a solution of $AlCl_3$ (23 mg) in absolute ether (1.5 ml) at 0 °C. The resulting solution was further stirred at 0 °C for 10 min, and then poured into ice–water. After separation of the ethereal layer, the aqueous solution was extracted with ether. The combined extracts were washed with a sat. NaCl aq. solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent afforded a yellow oil***, which was subjected to preparative TLC using alumina [GF_{254} (type E), E. Merck A. G.] and benzene, giving a colorless viscous liquid, the dienol **28** (6.6 mg) (GLC, TLC, and IR spectrum).[1]

** Peak-area of analytical GLC was served as approximate values of the content (%), indicating that this oil contained the dihydro compound (19.6 mg).

*** Peak-area of analytical GLC was served as an approximate value of the content (%), indicating that this oil contained the dienol (14.6 mg).

Thermal Isomerization of Preisocalamendiol (3). A colorless viscous liquid of **3** (*ca.* 10 mg) in a sealed tube was heated at 180 °C, and the composition of the reaction mixture was checked by analytical GLC, as already described in Table 1.

Reduction of Preisocalamendiol (3) with $LiAlH_4$. To a solution of **3** (220 mg) in absolute ether (20 ml) was slowly added, with stirring, $LiAlH_4$ (40 mg) at room temperature, and then the reaction mixture was further stirred at room temperature for 30 h. After decomposition of an excess of the reagent with water, 20% potassium sodium tartarate aq solution was added to the reaction mixture, which was extracted with ether. The ethereal extract was washed with a sat. NaCl aq solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure afforded **29** (220 mg)† as a colorless liquid; ν_{max} (film) 3360 br. and 1640 cm^{-1}; δ 0.95 (6H, d, J=6.8 Hz), 1.60 (3H, br. s), 3.60—3.92 (1H, m), 4.92 (2H, br. s) and 5.25 (1H, m) ppm; *m/e* 222 (M^+), 204 and 161 (Found: *m/e* 222.19700. Calcd for $C_{15}H_{26}O$: *m/e* 222.19836).

Reaction of 29 with 80% aq HCOOH. The alcohol **29** (36 mg) was dissolved in 80% aq HCOOH (1 ml) at 0 °C. The resulting solution was stirred at 0 °C for 2 h, and then poured into a cooled sat. $NaHCO_3$ aq solution and extracted with ether. The ethereal extract was washed with a sat. NaCl aq solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent gave a colorless oil (39 mg) in an almost pure state, which was purified by preparative GLC at 110 °C to afford a pure sample of the formate **30** (13 mg); ν_{max} (film 1720 and 1645 cm^{-1}; δ 0.93 (3H, d, J=6.9 Hz), 0.98 (3H, d, J=6.9 Hz), 1.66 (3H, d, J=1.3 Hz), 3.66—3.90 (1H, m), 4.97 (2H, br. s), 5.28 (1H, br. m) and 8.11 (1H, s) ppm; *m/e* 204 (M^+-46) and 161. Elemental analysis of this formate has not been carried out, but its structure (**30**) is supported by the above-mentioned spectral data coupled with the next experimental results.

Recoversion of the Formate (30) into the Alcohol (29). To a solution of **30** (13 mg) in absolute ether (3 ml) was added, with stirring, $LiAlH_4$ (4 mg). The reaction mixture was further stirred at room temperature for 3 h, and then an excess of the reagent was decomposed by addition of ether saturated with water. The reaction mixture was diluted with 20% potassium sodium tartarate aq solution (5 ml), and then extracted with ether. The ethereal extract was washed with a sat. NaCl aq solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent afforded a colorless oil (11 mg) which was purified by preparative TLC using petroleum ether–ether (5:3) to give **29** (6 mg) in a pure state (GLC and IR spectrum).

Formation of ε-Cadinene (31). To a solution of **29** (164 mg) in absolute pyridine (10 ml) was slowly added, with stirring, a solution of mesyl chloride (100 mg) in pyridine (5 ml) at 0 °C. The resulting solution was further stirred at 0 °C for 1 h, and then at room temperature for 7 h. The solution was poured into ice water, and then extracted with ether. The ethereal extract was washed throughly with a sat. NaCl aq solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure gave an almost colorless oil (135 mg), which was purified by preparative TLC using hexane to give ε-cadinene (51 mg) as a colorless viscous liquid; ν_{max} (film) 3070 and 1645 cm^{-1}; δ 0.71 (3H, d, J=6.7 Hz), 0.91 (3H, d, J=6.7 Hz) and 4.72—4.48 (4H, complex) ppm; *m/e* 204 (M^+ for $C_{15}H_{24}$), 176 and 161.

Catalytic Hydrogenation of ε-Cadinene (31). Catalytic hydrogenation of **31** (10 mg) in AcOEt (1 ml) was carried out over PtO_2 (3 mg) at room temperature for 2 h. After filtration of the catalyst, the solvent was evaporated under reduced pressure to give a colorless oil (10.1 mg) in a pure state; δ 0.73 (3H, d, J=6.6 Hz), 0.82 (6H, d, J=7.0 Hz) and 0.97 (3H, d, J=6.6 Hz) ppm; *m/e* 208 (M^+ for $C_{15}H_{28}$), 165 and 109. The IR spectrum of this oil was completely identical with that of an authentic sample of tetrahydrocadinene.[14]

† GLC of this liquid showed only one peak.

The authors wish to thank Professor Yoshimasa Hirata (Nagoya University) for his invaluable suggestion. Thanks are also due to Drs. Masayasu Kurono and Masaaki Toda (Ono Pharmaceutical Co. Ltd.) for measurements of high resolution mass spectra. This research has been supported in part by grants from the Ministry of Education, to which greatful acknowledgement is made.

A Single-step Synthesis of 2-Substituted 2-Thiazolines[1)]

Nobutaka SUZUKI and Yasuji IZAWA*

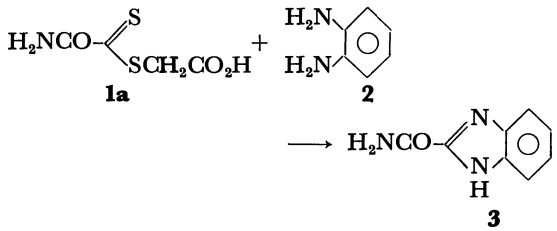
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu 514

(Received April 23, 1976)

2-Phenyl-2-thiazoline (**4b**) and its derivatives: [4-carboxylic acid (**4c**), 4-carboxylic acid methyl ester (**4d**), and 5,5-dimethyl-4-carboxylic acid (**4e**)], 2-(*p*-chlorophenyl)-2-thiazoline (**4f**) and its 4-carboxylic acid (**4g**), and 2-methyl-2-thiazoline (**4h**) were obtained by treating $RCS_2CH_2CO_2H$ [R=Phenyl (**1b**), *p*-chlorophenyl (**1d**), or methyl (**1e**)] or $MeCS_2Et$ (**1f**) with the corresponding 2-aminoethane thiols, *i.e.*, cysteamine (**6a**), cysteine (**6b**), cysteine methy ester (**6c**), and/or penicillamine (**6d**). **4b** was also obtained from $PhCS_2Et$ (**1c**) and **6a** with a rate approximately equal to that from **1b** and **6a**. The attempted synthesis of 2-methyl-2-thiazoline-4-carboxylic acid (**4i**) using a similar method gave only *N*-acetylcysteine (**7**).

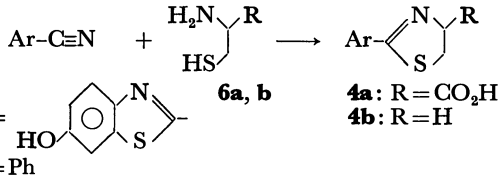
There have been numerous reports concerning the synthesis of 2-aryl- and 2-alkyl-2-thiazolines. The known synthetic methods can be classified as follows: (a) condensation of nitriles (R–C≡N)[2-4)] or isonitriles (R–N=C:)[5a)] with 2-aminoethane thiols (H_2N–CH_2CH_2–SH), or intramolecular cyclization of 2-mercapto isonitriles [R–CH(SH)CHR′–N=C:];[5b)] (b) dehydration of *N*-acyl-2-aminoethane thiols (R–$CONHCH_2CH_2$–SH)[2,6)] or *N*-thioacyl-2-aminoethanols (R–$CSNHCH_2$–CH_2–OH);[7)] and (c) condensation of thioamides or imino thiols [R–(C=NH)SH] with 1,2-dihalides (X–CH_2CH_2–X) or 2-haloethylamines (H_2N–CH_2CH_2–X),[8)] where R and R′=alkyl, aryl, or H, and X=Br or Cl. However, most of these require several steps and/or drastic conditions, such as high temperature and strongly acidic or basic media, to synthesize relatively unstable thiazolines.

Suzuki and Goto have found in the course of the studies on the firefly bioluminescence[9)] that (carbamoylthiocarbonylthio)acetic acid (**1a**)[10)] readily condensed with *o*-phenylenediamine (**2**) at room temperature and pH *ca.* 8 to give 2-carbamoylbenzimidazole (**3**); similar reactions were expected to be applicable to the preparation of other five-membered heterocycles.



1a **2** **3**

White *et al.* reported an effective synthesis of an unstable thiazoline, firefly luciferin (**4a**), by condensation of 2-cyano-6-hydroxybenzothiazole (**5a**) with cysteine (**6b**) under mild conditions, *i.e.*, at room temperature at pH *ca.* 8.[4)] However, we found that although 2-phenyl-2-thiazoline (**4b**) could be prepared by treating benzonitrile (**5b**) with cysteamine (**6a**)



6a, b **4a**: R=CO_2H **4b**: R=H

5a: Ar=

5b: Ar=Ph

* To whom all correspondence should be addressed.

according to the above method (required reflux in EtOH), attempted condensation of the nitrile (**5b**) with other 2-aminoethane thiols (**6b**, **6c**, and **6d**) under similar conditions did not give the corresponding thiazolines (**4c**, **4d**, and **4e**).

In the present paper we wish to report on a convenient preparation of 2-substituted 2-thiazolines and their derivatives (**4b—4h**),[1)] which were obtained by the condensation of dithioates (**1b—1f**) with the corresponding 2-aminoethane thiols (**6a—6d**) under slightly alkaline conditions; a probable reaction pathway is also discussed.

Methods and Results

Syntheses of the 2-phenyl-2-thiazolines (**4b—4e**) which gave good yields were performed by the condensation of the dithioate (**1b**)[11)] with the corresponding 2-aminoethane thiols (**6a—6d**) at room temperature in slightly alkaline media. **4b** was also obtained by the condensation of **6a** with **1c**[12)] in place of **1b**.

Similarly, **4f** and **4g** were obtained from **1d**[13)] and the corresponding 2-aminoethane thiols (**6a** and **6b**). Although 2-methyl-2-thiazoline (**4h**) was obtained in an unsatisfactory yield by the similar condensation of **1e**[11)] or **1f**[12)] with **6a**, the attempted synthesis of the 4-carboxylic acid (**4i**) by treating **1e** or **1f** with **6b** was unsuccessful; *N*-acetylcysteine (**7**), mp 106 °C,[14)] as

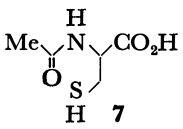
colorless crystals was however obtained in moderate yields (44% for **1e** and 65% for **1f**).

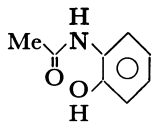


7

The results and the physical properties of the products are summarized in Table 1 and 2.

Discussion

To account for the observed products, especially *N*-acetylcysteine (**7**), a stepwise reaction pathway may be considered as the possible reaction scheme rather than a concerted reaction pathway. The product (**7**) is regarded as a rearrangement product of *S*-acetylcysteine derived from a hydrolysis of *S*-thioacetylcysteine;[14] this is supported by the moderate stability of **4e** reported by Smith and Gorin.[14] The production of *N*-acetyl-*o*-aminophenol (**8**) in the synthesis of 2-methylbenzoxazole (**9**)[15] may also support the stepwise reaction pathway.



8

The first step in this reaction should be a nucleophilic attack of one of two nucleophiles, *i.e.*, the amino group or the sulfide anion.

$-SCH_2CO_2H$ **10** $-SEt$ **11**

It is well known that the carboxymethylthio group (**10**) is an effective leaving group in aqueous alkaline

media. We expected to get some mechanistic information about the first step of the present reaction when the group **10** was replaced by the ethylthio group (**11**), which is supposed to be a less effective leaving group than **10**.[16,17] When **1b** and **1c** were treated with **6a**, the disappearance rates of **1b** and **1c** were almost identical and the products were identified by GLC and IR spectra to be **4b**. This fact implies that there is little effect from the leaving groups on this reaction (see Fig. 1), and also that the sulfide anion is so strong a nucleophile that no significant effect from the leaving group could be determined.

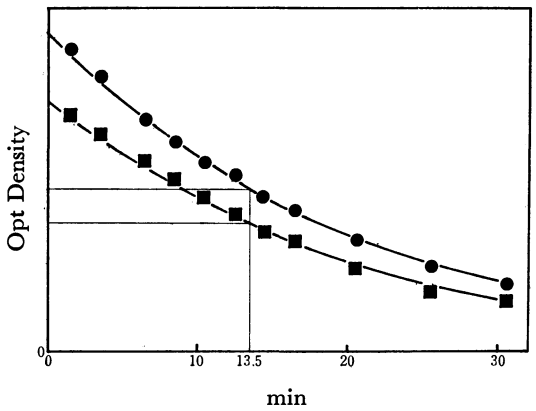


Fig. 1. Optical densities of **1b** and **1c** on treatments with **6a** at λ_{max} 488 nm in aqueous EtOH (1: 1).
—●—: **1b**, —■—: **1c**.

Lawson and Searle have shown that in the absence of any steric hindrance to the approach of the amino-nitrogen atom to the thion-carbon atom of **1b**, the ease of thiobenzoylation of amino compounds depends largely on the nucleophilicity of the amino-nitrogen atom.[7b] Thus, the lower yield of 2-methyl derivative (**4h**) and the unsuccessful attempt to prepare **4i** may be explained by the lowering of the electrophilicity of the thion-carbon atom caused by an electronic effect of the methyl substituent in the second step of the present reaction.

Some of the cyclizations to yield 2-thiazolines were reported to be acid catalysed.[2,5b,7a-c,12] The cyclization in the present reaction, however, occurs in basic conditions.

Provided that the present reaction proceeds through a stepwise mechanism, and since the acidities of –SH and $-NH_2$ are

$$-SH \gg -NH_2,^{18)}$$

we suggest that the cyclization may proceed as follows:

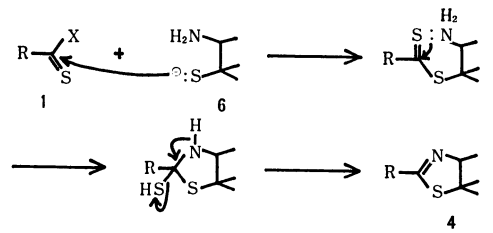

Chart 1.

Experimental

All mps and bps were uncorrected. The following spectrometers were used for spectral measurements: UV: Shimadzu UV-200; IR: JASCO IR-G; NMR: JEOL JNM-MH-100 (100 MHz); MS: JEOL JMS-D-100. The spectral data are presented as follows: UV: in nm and ε in parentheses; IR in cm^{-1}; NMR: chemical shifts (δ) in ppm from int. TMS and coupling constants (J) in Hz (accuracy $\pm$0.5 Hz); the solvents used are given in parentheses. GLC conditions used were as follows: Yanagimoto Yanaco G-1800F; Silicone SE-GE-31 (10%) on Diasolid L (60—80 mesh), in stainless steel column (2 m $\times$ ϕ 2.25 mm); col. temp 215 °C, inj. temp 170 °C, carrier gas (N_2) 20 ml/min. TLC conditions used were as follows: Silica gel PF_{254}-gipshaltig (E. Merck A. G.); thickness: 2.2 mm, 20 cm $\times$ 20 cm, hexane.

Benzonitrile (**5b**), acetonitrile, cysteine (**6b**), cysteine methyl ester (**6c**), penicillamine (**6d**), and *N*-acetyl-L-cysteine (**7**) were purchased from Nakarai Chem. Co., and cysteamine (**6a**) was from Tokyo Kasei Chem. Co.

*Carboxymethyl dithiobenzoate (**1b**)*[11] and *carboxymethyl p-chlorodithiobenzoate (**1d**)*[13] were prepared according to the method of Kurzer *et al.*[11] **1b**: Red fine prisms; mp 121—123 °C [lit,[11] 125 °C], λ_{max} [EtOH–H_2O (1: 1)] 487 nm (ε 120), 294 (12000), no change occurred after the addition of 1 M NaOH. **1d**: Reddish orange leaflets; mp 120—121 °C [lit,[13] 115—117 °C]; Found: C, 44.09; H, 2.76%. Calcd for $C_9H_7ClO_2S_2$: C, 43.81; H, 2.86%.

*Ethyl dithioacetate (**1f**)*,[12] *ethyl dithiobenzoate (**1c**)*,[12] and *carboxymethyl dithioacetate (**1e**)*[13] were prepared according to the methods of Meijer *et al.*[12] **1c**: Red liq.; bp 113—118 °C/1.2 mmHg [lit,[13] 164 °C/12 Torr], λ_{max} [EtOH–H_2O (1: 1)] 488 nm (100), 298 (10800), no change occurred after the addition of 1 M NaOH. **1e**: Yellow needles; mp 76—79 °C [lit,[7a] 80—81 °C]. **1f**: Orange-yellow liq.; bp 47—50 °C/12 mm [lit,[12] 52 °C/12 mm].

Authentic samples of **4c**, **4d**, **4h** were prepared by the methods described in the lit. **4c**: Colorless needles; mp 116—117 °C [lit,[7a] mp 122 °C]. **4d**: Colorless fine needles; mp 112—114 °C [as HCl salt; lit,[7a] mp 113—114 °C]. **4h**: Pale-yellow liq. bp 142—144 °C [lit,[19] bp 143—145 °C].

General Synthetic Procedure of the Thiazolines. The dithioate (**1b—f**) (1.0 mmol) and the aminothiol (**6a—d**) (1.1 mmol) were dissolved in aqueous MeOH or aqueous EtOH (1: 1; 25 ml); the pH was adjusted to *ca.* 8 with aqueous 1 M NaOH. The mixture was stirred at room temp under slightly reduced pressure (aspirator) to remove H_2S generated until the red color of the dithioate disappeared. The reaction was also monitored by TLC (E. Merck A. G.; Silica gel PF_{254}-gipshaltig, *ca.* 0.25 mm, hexane–acetone, 3: 1). The pH of the mixture was checked occasionally and kept *ca.* 8 by intermittent additions of the aqueous alkali. After the mixture was acidified (pH *ca.* 3) with aqueous 1 M HCl and concentrated *in vacuo* below 40 °C, the resulting aqueous mixture was extracted with $CHCl_3$ or EtOAc. Evaporation of the extracts and/or crystallization gave a liquid (**4b** or **4h**) or crystalline product (**4c**, **4d**, **4e**, **4f**, or **4g**) in good yield. The results and their properties are shown in Tables 1 and 2. The products of each condensation were checked with GLC and/or TLC before and after the acidification of the reaction mixtures. The products were identical before and after the work-up.

The thiazoline (**4b**) synthesized was identical with that from **5b** and **6a** (IR and NMR), and its bp was identical with that which appears in the lit.[11] The carboxylic acid (**4c**) and its methyl ester (**4d**) were identified by comparing with mp, IR, and NMR of the authentic samples.[7a] 2-Methyl-2-thiazoline

(**4h**) synthesized was identical with that of the authentic sample.[19] The *N*-acetylcysteine (**7**) obtained was assigned by comparing its mp, IR, and NMR with the authentic sample.[14]

*2-Phenyl-5,5-dimethyl-2-thiazoline-4-carboxylic Acid (**4e**).* Found: C, 61.39; H, 5.58%. Calcd for $C_{12}H_{13}NO_2S$: C, 61.25; H, 5.57%. Its IR spectrum was very similar to that of **4c**; MS showed a molecular peak at *m/e* 235 and NMR spectral data showed two methyls (1.44s and 1.72s), a methine (4.81s), and monosubstituted benzene protons (7.50 m and 7.78 m), which support the structure assignment (**4e**).

*2-(p-Chlorophenyl)-2-thiazoline (**4f**).* Found: C,54.44; H, 3.79%. Calcd for C_9H_8ClNS: C, 54.68; H, 4.08%. Its IR spectrum was very similar to that of **4b**; MS showed a molecular peak at *m/e* 197 and its NMR spectrum showed two methylenes (3.44 t and 4.46 t), and *p*-disubstituted benzene protons (7.39 d and 7.79 d), which support the structure assignment (**4f**).

*2-(p-Chlorophenyl)-2-thiazoline-4-carboxylic Acid (**4g**).* Found: C, 49.82; H, 3.23; N, 5.64%. Calcd for $C_{10}H_8ClNO_2S$: C, 49.70; H, 3.34; N, 5.80%. Its IR spectrum was very similar to that of **4c**; MS showed a molecular peak at *m/e* 241 and its NMR spectrum showed two methylene protons (3.65 d and 3.68 d), a methine (5.32 t), and *p*-disubstituted benzene protons (7.56 d and 7.82 d), which support the structure assignment (**4g**).

*Relative Rate of Reaction of **1b** or **1c** with **6d**.* Into the aqueous ethanolic (1:1; 3 ml) solutions of **1b** or **1c** (0.1 mmol/15 ml) were added an aqueous 1 M NaOH (60 μl) and then an aqueous ethanolic solution (2 ml) of **6a** (0.11 mmol/10 ml). Their optical densities at *ca.* 488 nm were measured at intervals (16 °C). The relative reaction rate was calculated based on the results to be about unity ($\tau_{1/2}$=13.5 min). The generation of **4b** was confirmed by GLC. (See Fig. 1).

We thank Professor Toshio Goto and his co-laborators of Nagoya University for the measurements of Mass spectra.

Hetera-*p*-carbophane. VIII. The Change in Binding Sites of NMR Shift Reagents in Polyoxadioxo[*n*]paracyclophanes and Their Open-chain Analogs[1)]

Kazuhiko SAKAMOTO and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 7, 1976)

A series of polyoxadioxo[*n*]paracyclophanes were prepared by condensation of polyethylene glycols with the corresponding 2,5-disubstituted *p*-phenylenediacetyl dichlorides under high dilution conditions. ^{1}H NMR spectra of these compounds were recorded in the presence and absence of lanthanoid shift reagents and the results are compared with those of the open-chain analogs. The change in binding sites of the shift reagents is observed as the number of ethylenedioxy units increases, and the result is discussed from the standpoint of electronic and steric effects.

The usefulness of NMR shift reagents for the determination of the ester conformations, *s-cis* and *s-trans*, has been reported from this laboratory.[2)] As a combined extension of this and other studies on hetera-*p*-carbophanes, it was of interest to investigate the binding sites of the shift reagent for polyoxadioxo[*n*]paracyclophanes.

A literature search revealed that, although ether oxygen is usually a very weak binding site for the shift reagent,[3)] polyglyme does form a complex at the end of the chain[4)] and several aromatic compounds which possess two ether groups *ortho* to each other bind more strongly to the shift reagent at the ethers than to the ester groups.[5)] Therefore, if an ansa chain contains ethylenedioxy units there is a possibility that competition takes place among the binding sites including the ethylenedioxy and the ester groups.

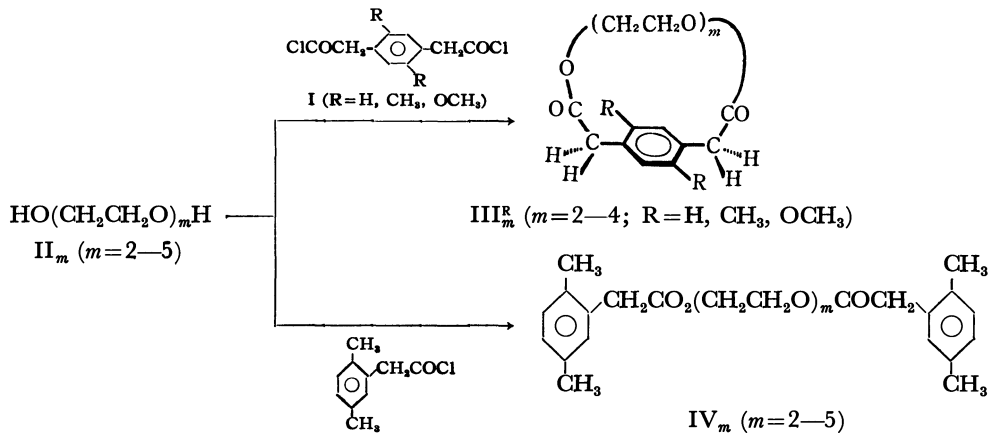
Therefore, a series of polyoxadioxo[*n*]paracyclophanes and open-chain analogs were prepared and their ^{1}H NMR spectra were observed in the presence of the shift reagents. This paper describes an interesting result which suggests that a change in the binding sites occurs according to the chain length of the polyoxyethylene compounds.

Experimental

The syntheses of a series of disubstituted polyoxadioxo[*n*]-paracyclophanes (III^R_m, where *m* is the number of oxyethylene units and R the substituent) and open-chain analogs (IV_m, where *m* is the number of oxyethylene units) were accomplished by the condensation of polyoxaalkane-α,ω-diols (polyethylene glycols) with the corresponding acyl chlorides (Scheme 1). The polyoxaalkane-α,ω-diols were of commercial origin except for 3,6,9,12-tetraoxatetradecane-1,14-diol (II_5) which was prepared according to a method described in the literature.[6)] The acid chlorides were synthesized in a manner reported previously.[7)]

Syntheses of Polyoxadioxo[n]*paracyclophanes (III^R_m) and Bis(*2,5-*dimethylphenylacetate)s (IV_m) of Polyoxaalkane-α,ω-diols.* The condensation between the chlorides (I) and the diols (II_m) was carried out in essentially the same manner as that reported previously,[8)] except for the omission of the base. A chromatograph of the crude products on silica gel using a hexane–ether mixture as the eluent gave pure compounds. Esterification of II with 2,5-dimethylphenylacetyl chloride proceeded normally. Analytical and other pertinent data are summarized in Table 1.

Measurement of Spectra. The infrared spectra were recorded on a Hitachi EPI-G2 infrared spectrometer with KBr discs for III^R_m and with a neat liquid for IV_m. The ^{1}H NMR spectra were measured at 34 °C on a Hitachi R-20B spectrometer operating at 60 MHz. Samples were dissolved in deuteriochloroform for conventional measurements and the chemical shifts were recorded relative to an internal TMS. Lanthanoid [Eu(dpm)$_3$ and Eu(fod)$_3$-d_{27}] induced shifts were measured with deuteriochloroform solutions in a manner analogous to that reported previously.[2)] The mass spectra were recorded on a Hitachi RMU-6L spectrometer.



Scheme 1.

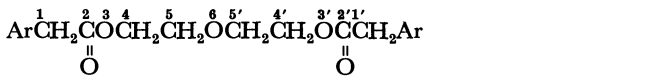
a) s=singlet, AB-q=AB-quartet, m=multiplet, AA′=AA′ part of AA′BB′ type signal, BB′=BB′ part of AA′BB′ type signal, and bs=broad signal. b) J_{AB}=14.0 Hz, $\Delta\delta_{AB}$=16.8 Hz. c) J_{AB}=14.5 Hz, $\Delta\delta_{AB}$=14.5 Hz. *) Since there was so much overlapping of the methylene protons at δ 3.4—3.7 in III^R_m and IV_m that it was difficult to estimate the intensities separately, the intensity of all protons contributing to the overlapped signals was shown.

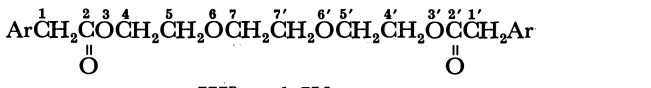
Results and Discussion

Peak Assignments of Bridge Methylene Protons. The ^1H NMR spectral data of polyoxadioxo[n]paracyclophanes (III^R_m) and bis(2,5-dimethylphenylacetate)s (IV_m) of polyoxaalkane-α,ω-diols are summarized in Table 2.

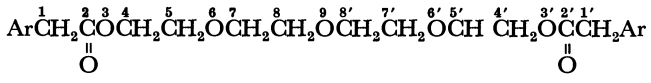
The benzylic protons of III^{Me}_2 and III^{Me}_3 give signals of the AB type at δ *ca.* 3.60, suggesting a slow internal rotation of the aromatic ring on the NMR time scale, whereas those of III^R_m other than III^{Me}_2 and III^{Me}_3 and IV_m give signals of the A_2 type at δ 3.52—3.65. AA'BB' signals appearing at δ 4.0—4.3 and 3.2—3.7 for III^R_m and IV_m are assigned to 4- and 5-methylene protons,



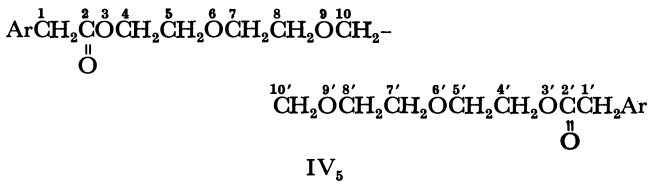
III^R_2 and IV_2



III^R_3 and IV_3



III^R_4 and IV_4



IV_5

respectively, from a comparison of the chemical shifts with those for α-methylene protons of the corresponding dioxadioxo[n]paracyclophanes (V_n, where n is the number of atoms in the ansa chain) and open-chain analogs,[8] and by taking advantage of a known chemical shift rule.[9] The singlets observed at δ *ca.* 3.15 for III^R_3 and at δ 3.54 for IV_3 were then assigned to 7-methylene protons. Similarly, the multiplets centered at δ *ca.* 3.5 for III^R_4 and the broad singlet at δ *ca.* 3.6 for IV_4 were attributed to 7- and 8-methylene protons. IV_5 has a singlet signal for 7-, 8-, and 10-methylene protons.

a) For the numbering of the bridge methylene, see text.

On the basis of the above assignments, the difference in chemical shifts of the corresponding methylene protons can be calculated, as $\Delta\delta_{CH_2}=\delta_{CH_2}(IV_m)-\delta_{CH_2}(III^{Me}_m)$, and the results are shown in Table 3. The results are believed to be a reflection of the ring current effect of the benzene ring and, indeed, are in close agreement with the expected values from a calculation using the Johnson-Bovey method.[10] An increase in the number of oxyethylene units causes a decrease in $\Delta\delta_{CH_2}$ indicating that the mobility of the ansa chain is increased and the ring current effect is increasingly cancelled out.

Lanthanoid-induced Shifts [LIS] and Assignment of the Binding Site. The shift reagents, Eu(dpm)$_3$ and Eu(fod)$_3$-d_{27}, were added to solutions containing the substrate and the molar ratios were changed from 0 to 0.5. The LIS was plotted against [L]/[S], where [L] and [S] have their usual meanings,[3] indicating proper linearity. Relative slopes of the straight lines were obtained by taking the slope of the straight line due to methylene protons in the α-position of the carbonyl group as a reference and are shown in Table 4.

The assignment of straight lines obtained by plotting

Table 4. Relative slopes of LIS vs. [L]/[S] lines obtained for polyoxadioxo[n]paracyclophanes (III^R_m) and bis(2,5-dimethylphenylacetate)s (IV_m) of polyoxaalkane-α,ω-diols[a]

a) Values in parentheses are those obtained using Eu(fod)$_3$-d_{27} while the others were obtained using Eu(dpm)$_3$.

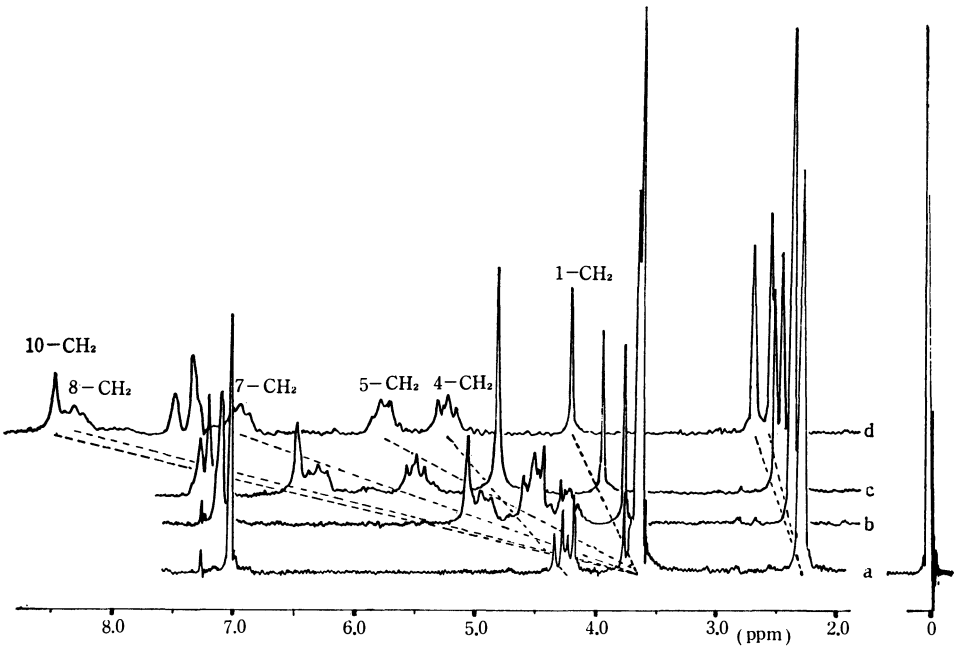

Fig. 1. ^{1}H NMR spectra of IV_5 with various amounts of Eu(fod)$_3$-d_{27} in $CDCl_3$ at 34 °C. Curves a, b, c, and d correspond to [L]/[S] of 0, 0.17, 0.29, and 0.52, respectively.

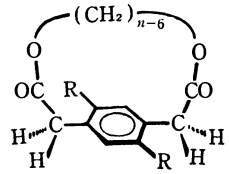
LIS *vs.* [L]/[S] is straightforward when the number of oxyethylene groups is 2 or 3, because they result in a set of independent signals for each pair of protons. However, it is necessary to carefully assign those signals which appear separately after the addition of the shift reagent, but which overlap in the absence of the reagent.

The ^{1}H NMR spectra of IV_5 for varying amounts of Eu(fod)$_3$-d_{27} in deuteriochloroform at 34 °C are shown in Fig. 1. The apparent singlet at δ 3.60 in the absence of the reagent separates into a singlet and two multiplets with an increase in the value of [L]/[S]. The singlet at the lowest field is necessarily assigned to 10-methylene protons because the neighboring methylene group is equivalent and no coupling with other protons is expected. From the 7- and 8-methylene protons, the latter produces the lower field signal because the 10-methylene protons give the signal at the lowest field and the shift reagent must be coordinated closer to the 8-methylene than to the 7-methylene protons.

The assignments of signals due to III_2^R and IV_4 were carried out analogously. The chemical shifts of 4- and 5-methylene protons are known even in the absence of the shift reagent. For the 7- and 8-protons, it must be the 8-protons that result in the lower field signals for the addition of the shift reagent, because if a complex is formed using the 6′- and 9-oxygens, the 8-protons are closer to the shift reagent than the 7-protons. Although the binding site may change as discussed later, the situation still holds because if the binding sites are 6- and 9-oxygens, the effect should be equal for the 7- and 8-protons.

The relative slopes of 1-methylene protons in III_2^R are in good agreement with the data for 13,16-dimethyl-3,9-dioxa-2,10-dioxo[11]paracyclophane (V_{11})[5] which has an ansa chain with the same number of atoms and is known to form a complex with the shift reagent at the oxygen of the ester carbonyl. IV_2 showed a similar tendency. Thus, it may be concluded that the reagent binds to the ester carbonyl in III_2^R and IV_2.



V_{11}: n=11, R=CH_3
V_{14}: n=14, R=CH_3

In contrast, the relative slopes of 1-methylene protons in III_3^R are different from those of V_{14} to a great extent, although similar values are expected if III_3^R binds at the carbonyl oxygen, as does V_{14}.[8] IV_3 behaves similarly to III_3^R. Therefore, the results must be attributed to the presence of (a) binding site(s) other than the carbonyl.

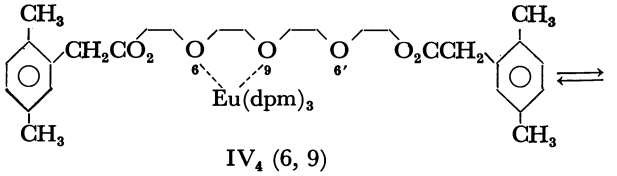
Although lactarorufin is known to bind preferentially to the shift reagent at an ether oxygen rather than at an ester carbonyl,[11] this anomaly is caused because of steric blocking of the carbonyl oxygen and such a steric factor is not expected in these compounds (III_m^R). Rather, it is reasonably assumed that the ethylenedioxy unit is a preferred binding site for the shift reagent, because two ether oxygens *ortho* to each other in the aromatic system are known to bind as a bidentate ligand to the shift reagent more readily than the ester group,[5] and because polyglyme binds to the shift reagent.[4]

Judging from the failure of complex formation at the ethylenedioxy units in III_2^R and IV_2, it is concluded that the ethylenedioxy unit, one oxygen of which is a part of the ester moiety, is inferior to the ester carbonyl for complexation. Thus the order of binding ease is $ROCH_2CH_2OR > RCOOR > ROCH_2CH_2OCOR$.

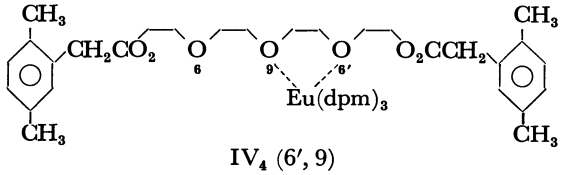
Since the slopes of LIS *vs.* [L]/[S] for the methylenes

in III_3^R and IV_3 become steeper as the methylene becomes closer to the center of the chain, it is reasonable to assume that the shift reagent forms a complex at the 6,6′-positions. Indeed, it is generally accepted that in ^1H NMR an LIS results by complexation to an oxygen function of an organic compound predominantly from the pseudocontact interaction.[3]

The data for III_4^R may be interpreted as the result of rapid equilibrium between the two equivalent complexes as has been pointed out for polyglyme,[4] because there are two equally good binding sites. The LIS values observed for a compound with only one strong binding site may be taken to represent "intrinsic" shifts for protons of such complexes. Then the observed shifts in a molecule with two or more good complexing sites can be taken as weighted means of the "intrinsic" shifts, and are determined by the populations of the complexes. Since IV_4 has two equivalent binding sites, it may be assumed that two complexes exist in equal populations and exchange rapidly on the NMR time scale. By analogy to the cases of III_3^R and IV_3, these two complexes are shown by $IV_4(6,9)$ and $IV_4(6',9)$.

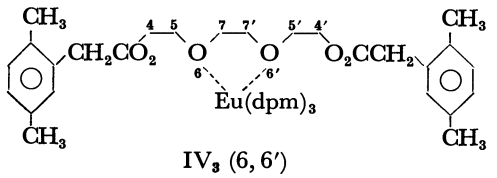


IV_4 (6, 9)



IV_4 (6′, 9)

According to the above assumption, the relative slopes of the LIS *vs.* [L]/[S] lines for $IV_4(6,9)$ and $IV_4(6',9)$ can be taken as almost the same as those in the IV_3–lathanoid complex $IV_3(6,6')$; the 7- and 8-methylenes in $IV_4(6,9)$ give a slope of 5.8, since these are equivalent to the 7- and 7′-methylenes in $IV_3(6,6')$. Then 5- and 8′-methylenes in $IV_4(6,9)$ will give a slope of 2.2, since these are equivalent to the 5- and 5′-methylenes in $IV_3(6,6')$, *etc.* Using the above assumption, we can calculate the relative slopes as shown in Fig. 2. The calculated values are in good agreement with those observed.



IV_3 (6, 6′)

Similarly, the observed values of IV_5 are reasonably well reproduced by the assumption of equal populations of complexes $IV_5(6,9)$, $IV_5(9,9')$, and $IV_5(6',9')$ (see Fig. 2). Since, if we assume that there is only one complex $IV_5(9,9')$ or only two complexes, $IV_5(6,9)$ and $IV_5(6',9')$, we obtain much less satisfactorily calculated values, it may be assumed that the three complexing

It is concluded, by taking advantage of the results with open-chain analogs, that the polyoxadioxo[n]-paracyclophanes with long ansa chains behave similarly

* Although the above simple calculation gives satisfactory results for flexible molecule, it appears that the method is not applicable to less mobile molecules. Thus, application of the method to the cyclophanes (III_m^R) gives results far from satisfactory.

toward the shift reagent. The binding sites in these compounds are changing rapidly among the favored ethylenedioxy units. The chemical shifts of the methylene protons and the slopes of LIS *vs.* [L]/[S] lines are in agreement with this conclusion.

Origin for the Change in Binding Sites. It is clear from the above discussion that the ester carbonyl is an inferior binding site for the shift reagent with respect to the ethylenedioxy unit, unless one of the oxygens in the latter is a part of the ester moiety. The inferiority of the $ROCH_2CH_2O_2CR$ moiety can be attributed to the low electron density of the ether oxygen in the ester group.

Among the ethylenedioxy units referred to in this paper, the binding ability appears to be invariant irrespective of the position of the unit. This is in sharp contrast to the fact that polyglymes bind to the shift reagent at the terminal ethylenedioxy units. It is proposed that this difference be ascribed to steric and electronic effects for the following reasons. Firstly, the methyl group is known to be smaller than the ethyl group and other long chain alkyls, the most noted example being the reactivity of the carbonyl group in ketones toward hydrogen sulfite.[12] In complex formation also, the heat of formation and the entropy term will be unfavorable when the chain becomes longer. Secondly, the oxygen in position 2 of polyoxaalkanes will have the highest basicity, since the oxygens in the inner positions are substituted by an "ethyl" group which carries an oxygen atom in the β-position. In fact, 3-methoxypropionic acid is known to be a stronger acid than acetic acid by an order of magnitude, indicating that the $CH_3OCH_2CH_2$ group is electron-withdrawing relative to the CH_3.[13]

N-Halogen Compounds of Cyanamide Derivatives. VI.[1] The Preparation and Reaction of 2-Carbonimidoyl-3-imino-Δ^4-1,2,4-thiadiazolines

Toshio FUCHIGAMI and Keijiro ODO

Department of Electronic Chemistry, The Graduate School, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 11, 1976)

The reactions of potassium methyl cyanoiminodithiocarbonate (I), potassium methoxy and ethoxythiocarbonylcyanamide (IIa and IIb) with *N*-chloroamidines in various solvents were investigated. Δ^4-1,2,4-Thiadiazolines (TDZ), IIIa—d, were obtained from I in good yields, whereas the 1,3,5-triazines obtained as by-products in addition to TDZ were formed from II and *N*-chlorobenzamidine (NCB) in chloroform and dichloromethane. In the latter reaction, desulfrization occurred completely to give 1,3,5-triazine and/or a chain intermediate to 1,3,5-triazine in dipolar solvents. The TDZ were readily cleft at the N-S link by hydrogen sulfide and recyclized to 1,3,5-triazines. By alkaline hydrolysis, the TDZ were transformed to 2-amino-1,3,5-triazin-4-ols.

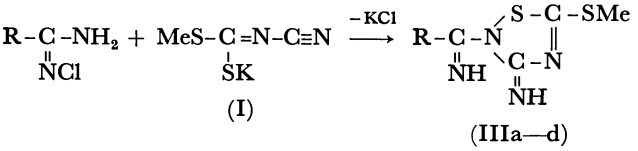
1,2,4-Thiadiazole derivatives have been known since 1821,[2] and many of them are important compounds as dyes, medicines, and agricultural chemicals. However, there have been few reports on the preparation of 1,2,4-thiadiazolines, especially on that of Δ^4-1,2,4-thiadiazolines. In our previous works,[3,4] we found that 2-carbonimidoyl-3-imino-5-methylthio-Δ^4-1,2,4-thiadiazolines could easily be prepared by the reaction of *N*-chloroamidino compounds with I and clarified their properties.

In this paper, we wish to describe the preparation of TDZ using *N*-chloroamidines, I, and II, and the desulfurization in the reaction of II with NCB, together with the reactivities of TDZ in alkaline solutions.

Results and Discussion

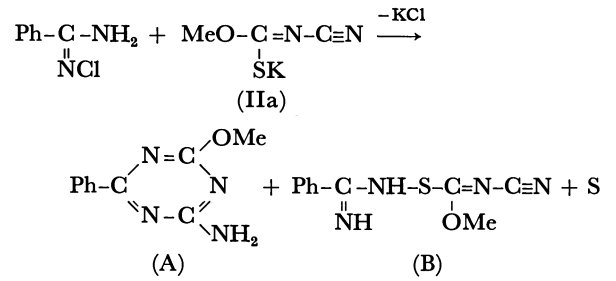
Preparation of Potassium Methoxythiocarbonylcyanamide (IIa). According to the method of preparing IIb,[5] IIa was prepared by the reaction of cyanamide with *O,S*-dimethyl dithiocarbonate in the presence of potassium hydroxide in ethanol. The yield was 40%, and the melting point was 192—195 °C (dp).

Reaction of I with N-*Chloroamidines.* *N*-Chloroamidine reacted exothermically with I in chloroform below 5 °C. After 1—2 h, an active chlorine disappeared and TDZ were formed. In the case of NCB, the yield of the TDZ increased when the solvent was acetonitrile. The structures of the TDZ, IIIa—d, were confirmed by means of elemental analyses and by studies of the IR and mass spectra. The results are summarized in Table 1.



(I) (IIIa—d)

Reaction of IIa and IIb with N-*Chloroamidines.* NCB and IIa reacted readily in chloroform at 10—15 °C. After about 1 h, the active chlorine disappeared and an oily material was obtained instead of the TDZ. A small amount of a crystal (A), the oily material (B), and sulfur could be separated from it.



(IIa) (A) (B)

The A product was 2-amino-4-methoxy-6-phenyl-1,3,5-triazine, whose structure was determined by the elemental analysis and by a study of its IR spectrum, in which the characteristic absorption of 1,3,5-triazine ring was observed at 830 cm^{-1}. The other product, B, which contained sulfur and showed a strong absorption of a nitrile group at 2200 cm^{-1} in the IR spectrum, was supposed to be the open-chain intermediate to the TDZ, the ring closure of B was attempted by acid catalysis. Expectedly, TDZ (IV) could be obtained as corresponding salts by the treatment of B at room temperature using hydrochloric acid, picric acid, and copper (II) chloride.

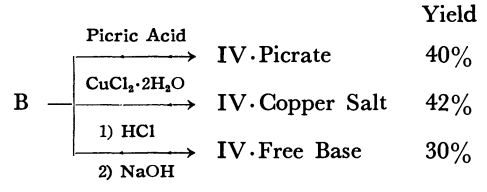


Table 1. PREPARATION OF TDZ FROM I AND *N*-CHLQOOAMIDINES

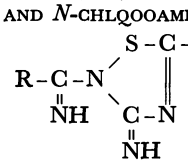
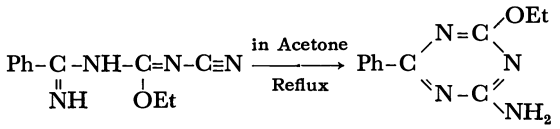


TDZ No	TDZ R	Solvent	Reaction time (min)	Yield (%)
IIIa	Ph	$CHCl_3$	100	64
IIIa	Ph	MeCN	50	76
IIIb	*p*-tol	$CHCl_3$	120	58
IIIc	Bzl	$CHCl_3$	110	57
IIId	Me	$CHCl_3$	180	58

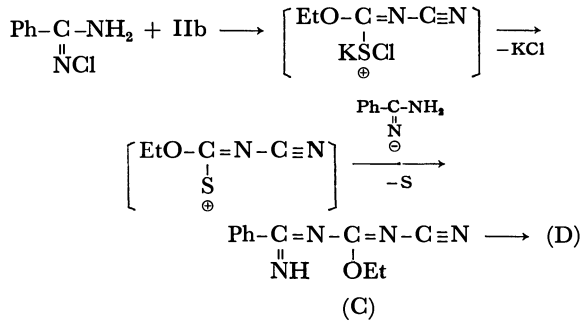
The reaction of NCB with IIb was likewise examined

using various kinds of solvents. As is shown in Table 2, a remarkable solvent effect was observed. In dichloromethane, the products were a TDZ (Va) and C, whose IR spectrum showed the absorption of a nitrile group at 2200 cm^{-1}. Only 2-amino-4-ethoxy-6-phenyl-1,3,5-triazine (D) was formed in acetonitrile and ethyl acetate, while C was the sole product in acetone. C was *N*-benzimidoyl-*N'*-cyano-*O*-ethylisourea, whose structure was confirmed by means of elemental analysis, by studies of the IR and mass spectra, and also by the following reaction. C, which was stable at room temperature, was converted into 1,3,5-triazine under reflux in acetone.



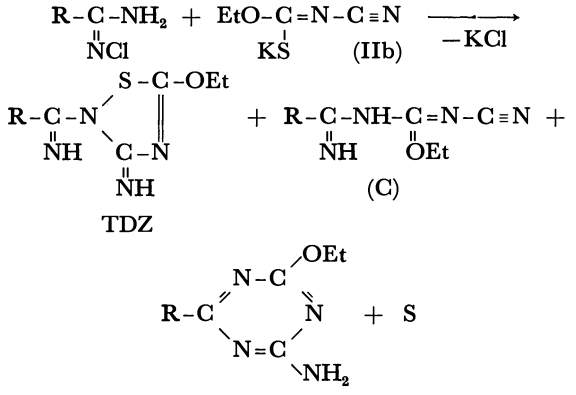
(C) (D) quant.

Thus, it was found that desulfurization took place completely in the above three solvents. On the other hand, no desulfurization was observed in the case of *N*-chloroacetamidine, and the corresponding TDZ (Vb) was obtained in a low yield. This desulfurization may occur by means of the oxidation with a positive chlorine from NCB and may be accelerated in polar solvents.



(C)

Table 2. Reaction of IIb with *N*-chloroamidines



TDZ (C)

(D)

R	Solvent	Reaction time (min)[a]	Product (%) TDZ	C	D	S
Ph	CH_2Cl_2	60(40)	47	18	—	+
	AcOEt	90(60)	—	—	62	++
	MeCN	35(15)	—	—	78	++
	Me_2CO	60(40)	—	98	—	++
Me	MeCN	270	38	—	—	—

a) Active chlorine disappeared.

The decay time of an active chlorine decreased considerably in acetonitrile, as is shown in Table 2.

The TDZ derivatives thus prepared are mono acidic bases, and their basicity is weaker than that of the starting compounds, amidino compounds. Therefore, a TDZ ring seems to be an electron-withdrawing group. A copper salt, whose color is blue or green, is formed from TDZ and copper (II) chloride, but its structure has not yet been established. The physical properties and analytical data of TDZ and the copper salts are summarized in Tables 3 and 4.

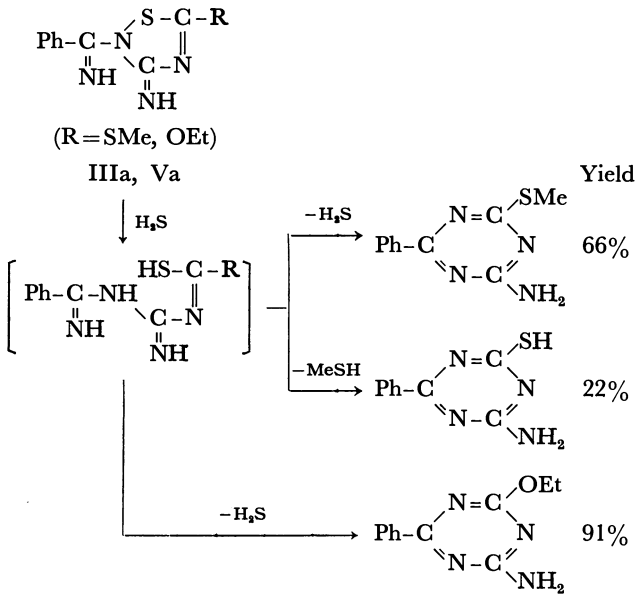
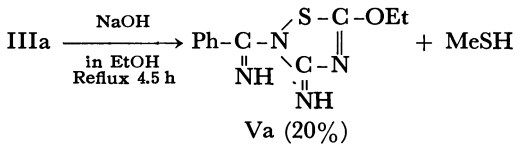
TDZ was readily cleft at the N–S link by hydrogen sulfide, and the elimination of methanethiol or hydrogen sulfide from the intermediate gave 1,3,5-triazines. Although 5-methylthio-TDZ gave two kinds of 1,3,5-triazines, 5-ethoxy-TDZ gave only one kind of 1,3,5-triazine.

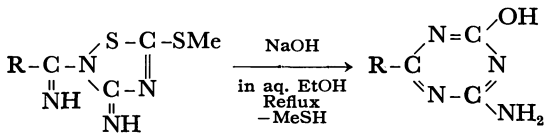


The low stability of TDZ seems to be related to its structure, in which the aromatic character is absent.

5-Methylthio-TDZ, IIIa was treated with ethanolic sodium hydroxide to give 5-ethoxy-TDZ, Va in a low yield.



We found that the ring cleavage of TDZ by alkaline hydrolysis gave rise to 1,3,5-triazine, also. The TDZ were refluxed with sodium hydroxide in aqueous alcohol to give 2-amino-1,3,5-triazin-ol in high yields.



(IIIa, b)

	Yield
R=Ph	85%
R=*p*-tol	64%

However, the detailed mechanism of the transformation has not yet been made clear.

The physical properties and analytical data of 1,3,5-triazines are summarized in Table 5.

Experimental

Materials. Potassium Methyl Cyanoiminodithiocarbonate (I): To a stirred solution of cyanamide (8.40 g, 20 mmol) and potassium hydroxide (22.40 g, 40 mmol) in water–acetone (60—30 ml), we gradually added, drop by drop, carbon disulfide (15.20 g, 20 mmol) at 0—5 °C. After the addition, the mixture was stirred at room temperature for 1.5 h; it was cooled below 5 °C again, and then methyl iodide was added, drop by drop. After the addition, the mixture was stirred at room temperature for 2 h. The residue obtained by the removal of the solvent was extracted with hot ethanol (80 ml). After the extract had been concentrated under reduced pressure, the crude product of I was obtained (24 g, 71%). Re-

crystallization from ethanol gave pure I; mp 213—214 °C (214—216 °C).[7]

Potassium Methoxythiocarbonylcyanamide (IIa): According to the method of preparing potassium ethoxythiocarbonylcyanamide (IIb),[5] IIa was prepared by the reaction of cyanamide with *O,S*-dimethyl dithiocarbonate and potassium hydroxide in ethanol. Two recrystallizations from ethanol gave pure IIa (yield 40%, dp 192—195 °C). Found: C, 23.30; H, 1.96; N, 18.14%. Calcd for $C_3H_3N_2OSK$: C, 23.36; H, 1.96; N, 18.16%.

The *N*-chloroamidines were prepared by a previously described method.[8]

Reaction of I with N-Chloroamidines. 2-Benzimidoyl-3-imino-5-methylthio-TDZ (IIIa): To a stirred suspension of I (3.40 g, 20 mmol) in acetonitrile (20 ml), we gradually added a solution of NCB (3.09 g, 20 mmol) in acetonitrile (20 ml), the temperature being kept below 10 °C. After about 50 min of continued stirring, the solvent was removed by distillation under reduced pressure. The titled compound was obtained by washing the residue with water to remove potassium chloride; 3.78 g, 76%, mp 129—135 °C. Pure IIIa: mp 138—139 °C (from acetone). The above reaction, when carried out in chloroform by a similar method, gave IIIa in a 64% yield.

2-p-Toluimidoyl-3-imino-5-methylthio-TDZ (IIIb): To a stirred mixture of I (5.95 g, 35 mmol) and chloroform (55 ml) we gradually added, drop by drop, a solution of *N*-chloro-*p*-toluamidine (5.90 g, 35 mmol) in chloroform (55 ml). After about 2 h of continued stirring, the active chlorine disappeared and potassium chloride was precipitated. After the salt had been removed by filtration, the filtrate was concentrated. When the residue was washed with a small amount of acetone, 4.90 g of crude IIIb remained; 53%, mp 181—182 °C. Recrystallization from acetone gave pure IIIb; mp 181—182 °C. To the washings, we added a methanolic solution of copper (II) chloride. The copper salt of IIIb thus precipitated was collected by filtration; dp 253 °C. The yield was 5%.

Similarly, reactions with other *N*-chloroamidines were carried out.

Reaction of IIa with NCB. Cyclization by Picric Acid: To a stirred suspension of IIa (4.62 g, 30 mmol) in chloroform (40 ml), we added, drop by drop, a solution of NCB (4.62 g, 30 mmol) in chloroform (20 ml). After 1 h of stirring, the reaction mixture was poured into water (25 ml). The organic layer was separated, and then the aqueous layer was extracted twice with 5 ml portions of chloroform. After the combined chloroform extracts had been dried over sodium sulfate, filtered off, and concentrated under reduced pressure, an oily material remained. On standing for 5 days at room temperature, part of 2-amino-4-methoxy-6-phenyl-1,3,5-triazine (A) crystallized out of the oil. On the addition of a small amount of ethyl acetate, the resulting A was separated by filtration (0.83 g, 13%). The oily product (B) obtained by the concentration of the filtrate was dissolved in ether, and a saturated ethereal solution of picric acid was added. The picrate of 2-benzimidoyl-3-imino-5-methoxy-TDZ (IV) thus precipitated was collected and recrystallized from water; mp 183—185 °C. The yield was 5.53 g (40%). When A was recrystallized from methanol, a small amount of sulfur was separated. Purified A; mp 161—164 °C.

Cyclization by Copper(II) Chloride: A (0.80 g, 13%) and B were obtained by the same procedure as above. The copper salt of IV was precipitated on the addition of a methanolic solution of copper(II) chloride ($CuCl_2 \cdot 3H_2O$) to a methanolic solution of B. The yield was 4.83 g (42%); dp 266 °C.

Cyclization by Hydrochloric Acid: To a methanolic solution of A, we added 15 ml of 2 M hydrochloric acid, and then the mixture was stirred for 20 min at room temperature. After the addition of 2 M sodium hydroxide to make the reaction mixture neutral, the methanol was almost entirely removed by concentration. The oily material thus obtained was left for a while, whereupon, crystals (IV) were obtained as a free base. The yield was 2.11 g (30%); mp 124—128 °C (from acetone–water).

Reaction of IIb with NCB. The Reaction in Dichloromethane: To a stirred suspension of IIb (10.08 g, 60 mmol) in dichloromethane (60 ml), we added, drop by drop, a solution of NCB (9.27 g, 60 mmol) in dichloromethane (60 ml) below 10 °C. After about 1 h of continued stirring, the reaction mixture was poured into 30 ml of water; then sulfur was separated. The organic layer was separated, and the aqueous layer was extracted twice with 10 ml portions of dichloromethane. The combined extracts were dried over sodium sulfate, filtered, and concentrated. To the residual oily material, we added a small amount of ethyl acetate and rubbed the sirup with a grass rod. The resulting crystals were filtered off and recrystallized from ethanol to give 2-benzimidoyl-3-imino-5-ethoxy-TDZ (Va); mp 138—139 °C. The yield was 6.16 g (41%). The filtrate and mother liquor were then combined, and an ethanolic solution of copper(II) chloride was added. The copper salt of Va thus precipitated was collected by filtration (1.50 g, 6%, dp 270 °C). By removing the copper from the filtrate, 2-amino-4-ethoxy-6-phenyl-1,3,5-triazine (D) was obtained; 2.34 g (18%); mp 153—154 °C (from ethanol).

The Reaction in Acetonitrile: The reaction (15 mmol scale) in 30 ml of acetonitrile was carried out according to the same procedure. Desulfurization occurred at the time of the addition of NCB, and after about 15 min the active chlorine disappeared. The insoluble matter was removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. D was obtained by washing the residual crystals with ether: 2.37 g, 73%, mp 153—156 °C. To the washings, we added a saturated ethereal solution of picric acid. The picrate of D was thus precipitated; 0.37 g (5%), dp 193 °C. The total yield was 78%.

The reaction in ethyl acetate was carried out similarly.

The Reaction in Acetone-Formation of N-Benzimidoyl-N′-cyano-O-ethylisourea (C): According to the same procedure, the reaction (17 mmol scale) in acetone (34 ml) was carried out. The insoluble matter was removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The residue, C, was washed with petroleum ether and a small amount of ether. The yield of C was 3.60 g (98%); mp 120 °C. Recrystallization from ethanol gave pure C; mp 125—126 °C. IR spectrum (cm^{-1}): 3200, 3300 (νNH); 2200 (νC≡N); 1600 (νC=N). Found: C, 60.93; H, 5.58; N, 25.41%. Calcd for $C_{11}H_{12}N_4O$: C, 61.10; H, 5.59; N, 25.91%.

Reaction of IIb with N-Chloroacetamidine. According to the same procedure, a reddish brown reaction mixture was obtained. The insoluble matter was removed by filtration, and the concentration of the filtrate afforded a reddish brown oily material, which was then dissolved in hot water and treated with charcoal. The addition of a saturated aqueous solution of picric acid to it afforded the picrate of 2-acetimidoyl-3-imino-5-ethoxy-TDZ (Vb). The yield was 7.93 g (38%); mp 144—148 °C. Recrystallization from water gave pure Vb; mp 148—149 °C. The free base of Vb was obtained by the treatment of the picrate with concd hydrochloric acid; mp 80—81 °C (from dichloromethane–petroleum ether).

Reduction of TDZ by Hydrogen Sulfide. Reduction of IIIa: Hydrogen sulfide was passed through a solution of IIIa (2.00

g, 8 mmol) in ethanol–chloroform (40—40 ml). The solution was left at room temperature for about 1 h and the resulting precipitate (P-1) was separated by filtration. After the filtrate had been evaporated to dryness, the residual yellowish crystals were dissolved in 5% ammonium hydroxide (20 ml), and then the insoluble matter was removed by filtration. The filtrate was neutralized with 3 M acetic acid, and the precipitate (P-1) was separated by filtration. The matter insoluble in ammonium hydroxide was extracted with hot ethanol (20 ml), and the residual sulfur was removed by filtration. After cooling, the precipitate (P-2) was obtained. P-1 was 2-amino-4-mercapto-6-phenyl-1,3,5-triazine; yield 0.36 g (22%); dp 278 °C (from DMF–water). P-2 was 2-amino-4-methylthio-6-phenyl-1,3,5-triazine; 1.15 g, 66%, mp 170—172 °C (from acetone).

Reduction of Va: In the same way, hydrogen sulfide was passed through. The precipitated sulfur was removed by filtration, and the filtrate was evaporated to dryness. The recrystallization of the residue from ethanol gave pure D; 91%, mp 153—154 °C.

Reaction of IIIa with Potassium Hydroxide in Ethanol. IIIa (2.50 g, 10 mmol) and potassium hydroxide were refluxed in ethanol (20 ml) for 4.5 h. Methanethiol was evolved and an insoluble matter was precipitated after about 1 h of reflux. The unidentified precipitate was removed by filtration, and the concentration of the filtrate gave an oily material. It was dissolved in chloroform; the subsequent removal of an insoluble matter by filtration and the concentration of the filtrate gave a sirup. It was solidified by treatment with a small amount of ether, and the solid was collected by filtration. Two recrystallizations from ethanol gave Va; 0.23 g (9%). The addition of a saturated ethereal solution of picric acid to an ethereal solution of the filtrate gave the picrate of Va; 0.51 g (11%). The total yield of Va was 20%. A mixed-melting-point determination with the authentic sample prepared from IIb and NCB showed no depression.

Reaction of IIIa with Sodium Hydroxide in Aqueous Ethanol. A mixture of IIIa (2.50 g, 10 mmol) and 3 M sodium hydroxide (30 ml)–ethanol (30 ml) was refluxed for 1.5 h. TDZ, IIIa was thus gradually dissolved, with the evolution of methanethiol. When the reaction mixture was evaporated under reduced pressure to remove almost all the ethanol and was neutralized with 3 M hydrochloric acid, the resulting precipitate, 2-amino-4-hydroxy-6-phenyl-1,3,5-triazine, was filtered out; yield, 1.60 g (85%): dp 327—328 °C (from DMF–ethanol).

Reaction of IIIb with Sodium Hydroxide in Aqueous Ethanol. 2-Amino-4-hydroxy-6-*p*-tolyl-1,3,5-triazine was obtained by a similar method. The yield was 64%, dp 327—329 °C (from DMF–water).

N-Halogen Compounds of Cyanamide Derivatives. VII.[1] The Preparation and Amidination of 5-Ethoxy-Δ^4-1,2,4-thiadiazolines

Toshio FUCHIGAMI, Tsutomu NONAKA, and Keijiro ODO

Department of Electronic Chemistry, The Graduate School, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 11, 1976)

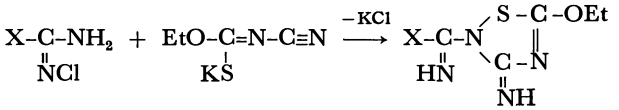
2-Methoxycarbonimidoyl and 2-amidino-3-imino-5-ethoxy-Δ^4-1,2,4-thiadiazolines (I and II) were prepared by the reaction of potassium ethoxythiocarbonylcyanamide (III) with *N*-chloro compounds of *O*-methylisourea and guanidine. Δ^4-1,2,4-Thiadiazoline, I reacted with aliphatic amine to give 2-amidino-Δ^4-1,2,4-thiadiazolines and 1,3,5-triazines in the presence of both the free amines and amine hydrochlorides. The ring opening of Δ^4-1,2,4-thiadiazoline, which finally results in the formation of 1,3,5-triazine, was found to be catalyzed mainly by a base and also by an acid.

Our previous papers[2-4] described that 2-imidoyl-3-imino-5-methylthio and 5-alkoxy-Δ^4-1,2,4-thiadiazolines were prepared in good yields by the reaction of *N*-chloroamidino compounds; we also described their reactivities for sodium hydroxide, amine, hydrogen chloride, and hydrogen sulfide.

In this paper, we wish to report on the preparation of two new Δ^4-1,2,4-thiadiazolines (TDZ), I and IIa, from III[4] and *N*-chloro compounds of *O*-methylisourea and guanidine, and on the amidination of I, together with the ring opening of TDZ, catalyzed by the amine, to give 1,3,5-triazine (IV).

Results and Discussion

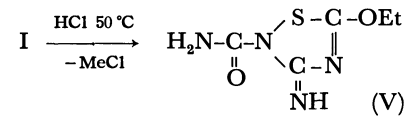
Preparation of 5-Ethoxy-TDZ (I and II). *N*-Chloro compounds of *O*-methylisourea and guanidine readily reacted with III in acetonitrile to form I and IIa. The structures of I and IIa were confirmed by means of elemental analysis and by a study of the IR spectrum.



(III)

X	Yield (%)
MeO	I (80)
H_2N	IIa (60)

Amidination of I. Since compound I can be regarded as *N,N*-disubstituted *O*-alkylisourea with a reactive imidate group, the amidination of I was examined using various kinds of amines. The amidination of I proceeded under reflux in ethanol in the presence of both amine and its hydrochloride to give 2-amidino-TDZ and 1,3,5-triazine (IV). 1,3,5-Triazine, IV has a composition in which sulfur can be excepted from TDZ. In the case of methylamine, desulfurization occurred almost completely, so IV and an unidentified product were obtained instead of 2-amidino-TDZ. In the case of benzylamine, when the amount of free amine was reduced by half, desulfurization was considerably inhibited. Therefore, free amine seemed to participate in the conversion of 2-amidino-TDZ to IV. In the case of a weak base such as aniline, neither the amidination nor ring opening of TDZ occurred, and 2-carbamoyl-TDZ (V) was obtained. Compound V was also obtained quantitatively by the treatment of I with excess dry hydrogen chloride in methanol.



As is shown in Table 1, the ethoxyl group of I was found not to be reactive.

The physical properties and analytical data of TDZ are summarized in Table 2.

TABLE 1. AMIDINATION OF I

Conversion of TDZ into 1,3,5-Triazine. Since the above results suggest that free amine participates in the ring opening of TDZ, the conversion of TDZ into 1,3,5-triazine was examined using various kinds of TDZ and amines. Methylamine reacted with I under reflux in ethanol to give IV, as expected, in a good yield. In the case of a bulky amine such as diethylamine, traces of IV were obtained in the presence of an equivalent of the base, and, finally, four equivalents of the base were needed for the quantitative conversion. In the case of triethylamine, no ring opening occurred, and the starting TDZ was recovered. The result may be due to the steric hindrance of triethylamine. Ammonium chloride reacted also with I to give V in about a 50% yield. In the reaction with a weak base such as aniline, no reaction occurred. TDZ (IIc) did not react with free benzylamine, while in the presence of the hydrochloride the reaction occurred to give IVc quantitatively. Amine was found to act as a catalyzer, because the amine used as a neucleophile is not included in IV. The above results showed that the conversion of TDZ to IV depends on the bulkiness and basicity of the amine and on the presence of acid.

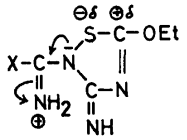

Fig. 1.

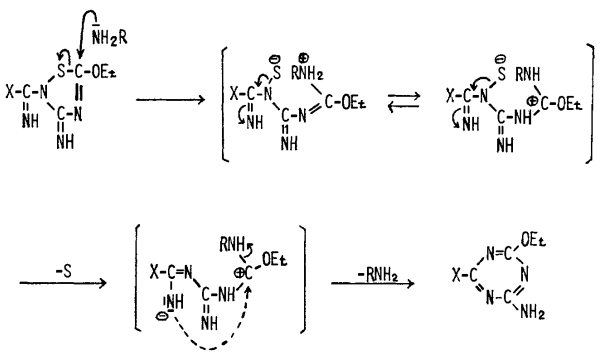
The conversion may be initiated by the attack of the free amine on the 5-carbon. The cleavage of the C–S bond, the loss of sulfur from the resulting intermediate, and the recyclization take place to give IV. In the presence of acid, protonation may occur at the imino group. The electron density at the 5-carbon may be



Scheme 1. Conversion of TDZ to 1,3,5-triazine.

reduced by the effect of the protonated imino group, and so the attack of the amine may be easier (Fig. 1).

Experimental

2-Methoxycarbonimidoyl-3-imino-5-ethoxy-Δ^4-1,2,4-thiadiazoline (I). To a stirred mixture of III[4] (6.27 g, 40 mmol) and acetonitrile (40 ml), we added a solution of *N*-chloro-*O*-methylisourea (4.34 g, 40 mmol) in acetonitrile (20 ml). The temperature was maintained below 5 °C during the reaction. After 1.75 h of continued stirring, the reaction mixture was evaporated to dryness under reduced pressure. The title compound was obtained by washing the residue with water 6.45 g; 80%; mp 138—143 °C. Recrystallization from ethanol gave a pure product; mp 143 °C. Picrate: mp 137 °C (from water). Found: C, 33.32; H, 2.97; N, 22.78%. Calcd for $C_{12}H_{13}N_7SO_9$: C, 33.42; H, 3.04; N, 22.73%.

2-Amidino-3-imino-5-ethoxy-Δ^4-1,2,4-thiadiazoline (IIa). The title compound was prepared according to approximately the same procedure as that described previously.[3] Recrystallization from methanol–water gave pure IIa; mp 177—180 °C. Picrate: mp 288 °C (from water). Found: C, 31.77; H, 2.93; N, 26.80%. Calcd for $C_{11}H_{12}N_8SO_8$: C, 31.74; H, 2.91; N, 26.92%.

Amidination of I. *Amidination of I with Benzylamine*: A solution of I (2.02 g, 10 mmol), benzylamine (2.14 g, 20 mmol), and benzylamine hydrochloride (1.44 g, 10 mmol) in ethanol (25 ml) was refluxed for 3 h. After the reaction mixture had been evaporated to dryness under reduced pressure, the residue was washed with ether (10 ml). TDZ, IIc containing sulfur was obtained by washing the residue with water: 1.39 g; 50%; mp 137—140 °C (from MeOH). The addition of petroleum ether to the ethereal washings afforded 2-amino-4-benzylamino-6-ethoxy-1,3,5-triazine (IVc) (0.47 g; 19%; mp 181—183 °C (from DMF). Found: C, 58.61; H, 6.26; N, 28.45%. Calcd for $C_{12}H_{15}N_5O$: C, 58.76; H, 6.16; N, 28.55%. Picrate: mp 174—175 °C (from EtOH). Found: C, 45.45; H, 3.83; N, 23.51%. Calcd for $C_{18}H_{18}N_8O_8$: C 45.57; H, 3.82; N, 23.62%.

Amidination of I with n-*Propylamine*: Using the same procedure as above (20 mmol scale), after the sulfur had been removed, the filtrate was concentrated. The residual oily material was crystallized from water (20 ml), subsequent recrystallization from ethanol (15 ml) afforded two kinds of products. IIb: 0.92 g; 20%; mp 162—163 °C (from EtOH). 2-Amino-4-ethoxy-6-*n*-propylamino-1,3,5-triazine (IVb): 1.53 g; 39%; mp 132—134 °C (from aq MeOH). Found: C, 48.59; H, 7.45; N, 35.31%. Calcd for $C_8H_{15}N_5O$: C, 48.72; H, 7.67; N, 35.51%.

2-Amino-4-ethoxy-6-methylamino-1,3,5-triazine (IVd) was obtained in a similar manner by the reaction of I with methylamine: 10%; mp 171—172 °C (170—171 °C)[6] (from water). Picrate: dp 202—203 °C (from water). Found: C, 36.26; H, 3.74; N, 27.70%. Calcd for $C_{12}H_{14}N_8O_8$: C, 36.19; H, 3.54; N, 28.13%.

2-Carbamoyl-3-imino-5-ethoxy-Δ^4-1,2,4-thiadiazoline (V). A slow stream of dry hydrogen chloride was passed through a solution of I (2.02 g, 10 mmol) in methanol (30 ml) at 50 °C for 40 min. A small amount of a brown precipitate was removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The title compound was obtained by washing the residue with ether; 1.84 g, 98%; dp> 300 °C (from DMF–EtOH).

Reaction of TDZ with Free Amines. *Reaction of I with Aqueous Ammonia*: A solution of I (1.01 g, 5 mmol) and 5% ammonium hydroxide (8 ml, 20 mmol) in ethanol (15 ml) was refluxed for 3 h. After the precipitated sulfur had been filtered off, the filtrate was cooled and I was precipitated; 0.46 g, 46%. After the filtration of I, the concentration of the filtrate afforded 2-amino-4-ethoxy-6-methoxy-1,3,5-triazine (IVe): 0.46 g, 54%; mp 102—103 °C. Found: C, 41.92; H, 6.03; N, 32.62%. Calcd for $C_6H_{10}N_4O_2$: C, 42.35; H, 5.92; N, 32.92%.

Reaction of IIc with Benzylamine: A mixture of IIb (0.55 g 2 mmol), benzylamine (0.72 g, 4 mmol), and benzylamine hydrochloride (0.29 g, 2 mmol) was refluxed in ethanol (6 ml) for 3 h. After the reaction mixture had been concentrated, the residue was washed with ether and water; 1,3,5-triazine (IVc) was thus obtained; 0.49 g; quant.

The Wolff Rearrangement and 1,3-Dipolar Cycloaddition of 2-Diazo-3,4-bis(diphenylmethylene)cyclobutanone[1]

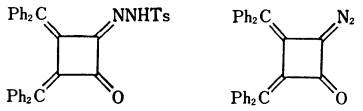
Kozaburo UEDA, Masanori IGAKI, and Fumio TODA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received May 12, 1976)

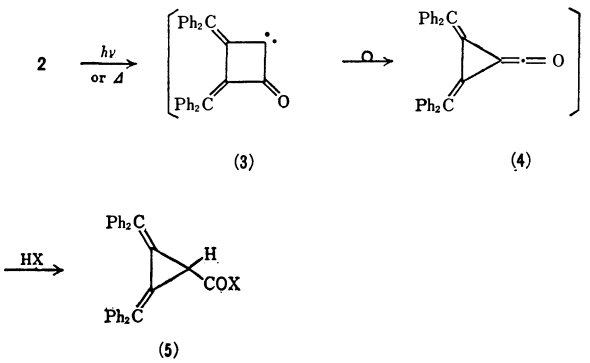
The first example of the Wolff rearrangement of α-diazocyclobutanone, the title diazo ketone (**2**), into the three-membered cyclic ketene (**4**) was observed. The ketene intermediate (**4**) could be trapped by its reaction with alcohols, aniline, azobenzene, and *N*-benzylideneaniline to afford 1-alkoxycarbonyl- (**5a**—**c**) and 1-phenylcarbamoyl-2,3-bis(diphenylmethylene)cyclopropane (**5e**), and 1,2-bis(diphenylmethylene)-5,6-diphenyl-5,6-diaza- (**9**) and 1,2-bis(diphenylmethylene)-5,6-diphenyl-5-azaspiro[2,3]hexan-4-one (**10a**), respectively. In contrast to the rearrangement, **2** directly reacted with *p*-benzoquinone and nitrosobenzene, affording the corresponding 1,3-dipolar cycloadducts (**14** and **15**).

The Wolff rearrangements of six- and five-membered α-diazocycloalkanones have been extensively applied to the synthesis of highly strained compounds.[2] However, no such rearrangement of α-diazocyclobutanone has yet been reported, because the synthesis of the α-diazocyclobutanone is difficult.[3] We wish now to report the first synthesis of the α-diazocyclobutanone, 2-diazo-3,4-bis-(diphenylmethylene)cyclobutanone (**2**), and its Wolf rearrangement into the three-membered cyclic ketene (**4**).



1 **2**

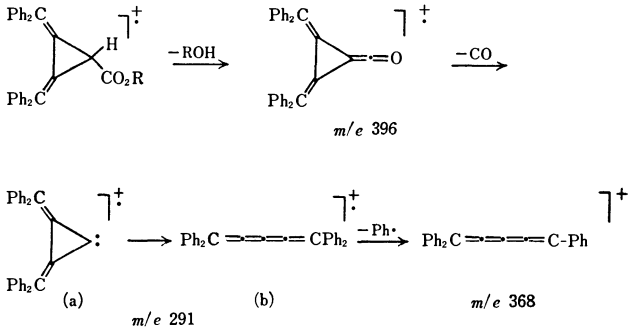
Diazo ketone (**2**) was prepared by the treatment of 3,4-bis(diphenylmethylene)cyclobutanedione tosylhydrazone (**1**), which had been derived from 3,4-bis-(diphenylmethylene)cyclobutanedione[4] and tosylhydrazine, with basic aluminum oxide; the overall yield was 95%. The irradiation of **2** in the presence of water, ROH, and an aniline afforded 1-carboxy-(**5d**), 1-alkoxycarbonyl-(**5a**—**c**), and 1-phenylcarbamoyl-2,3-bis(diphenylmethylene)cyclopropane (**5e**) respectively in the yields summarized in Table 1. Although the photolysis of **2** in the presence of water afforded **5d** in a very low yield, the thermal decomposition of **2** in aqueous dioxane afforded **5d** in a relatively high yield (52%). The above trapping reactions support the intermediacy of **4** in both the photolysis and thermolysis of **2**.



(3) (4) (5)

Scheme 1.

The structures of all the rearrangement products (**5a**—**e**) were elucidated on the basis of their spectral data (Table 1). In the mass spectra, all the esters (**5a**—**c**) showed a fragment ion ($C_{23}H_{15}^+$, *m/e* 291) as the base peak; a reasonable fragment pattern of **5** is as follows: The rearrangement of the cation radical (**a**) into **b** is similar to the cyclopropylidene-allene rearrangement.[5] In the UV spectra, the absorption bands of **5a**—**e** (λ_{max} 370—374 nm) appeared at a longer wavelength region than that of **8**[6] (λ_{max} 357 nm). This bathochromic shift is probably due to a ring strain of **5**.



m/e 396

(a) *m/e* 291 (b) *m/e* 368

Scheme 2.

The treatment of 2,3-bis(diphenylmethylene)-cyclopropylmethanol (**6**), which had been obtained by the reduction of **5a** with $LiAlH_4$, with thionyl chloride afforded 3-chloro-1,2-bis(diphenylmethylene)cyclobutane (**7**). The formation of **7** can be interpreted by a ring expansion accompanied by chlorination.[7]

The photolysis of **2** in the presence of azobenzene gave 1,2-bis(diphenylmethylene)-5,6-diphenyl-5,6-diazaspiro-[2.3]hexan-4-one (**9**) in a 75% yield. The photolysis and thermolysis of **2** in the presence of benzylideneaniline and *N*-(diphenylmethylene)aniline afforded 5,6-

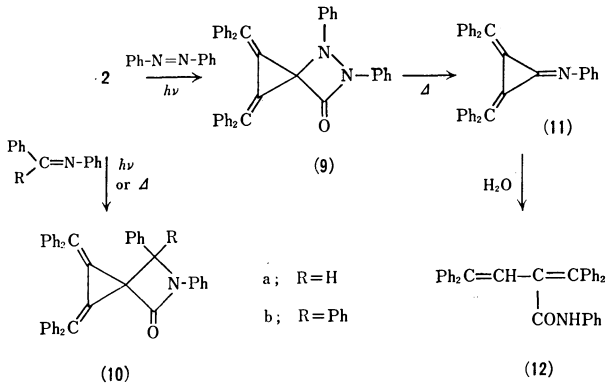
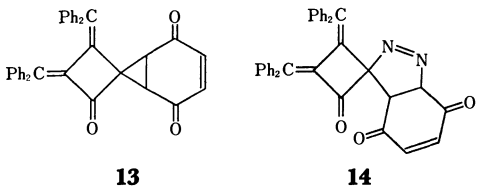
a) Yield obtained by thermolysis in aq dioxane. b) Chemical shift of the ring proton.

diphenyl- (**10a**) and 5,6,6-triphenyl-1,2-bis(diphenylmethylene)-5-azaspiro[2.3]hexan-4-one (**10b**) respectively. These reactions can be interpreted in terms of the cycloaddition of the ketene (**4**) with azobenzene and imines, because it has been known that the reaction of ketene with N=N or C=N bonds affords the corresponding cycloaddition product.[8] The thermolysis of diazetidinone (**9**) easily afforded 1,2-bis(diphenylmethylene)-3-phenyliminocyclopropane (**11**) quantitatively; on hydrolysis, this afforded 1,1,4,4-tetraphenyl-2-phenylcarbamoyl-1,3-butadiene (**12**, 75%).



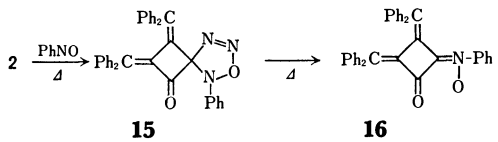
Scheme 3

On the contrary, the photolysis and thermolysis of **2** in the presence of *p*-benzoquinone afforded 2,3-bis(diphenylmethylene)-4,4-(3,6-dioxo-4-cyclohexen-1,2-ylene)cyclobutanone (**13**) in 45 and 59% yields respectively. However, when a mixture of **2** and *p*-benzoquinone in benzene was kept at room temperature, 5,6-diaza-7,8-(1,4-dioxo-2-butylene)-2,3-bis(diphenylmethylene)spiro[3,4]octan-1-one (**14**) was obtained in an 80% yield. The heating of **14** easily afforded **13** quantitatively. Finally, it is clear that the conversion of **2** into **13** proceeds *via* **14**. Similarly, the reaction of **2** with nitrosobenzene afforded 2,3-bis(diphenylmethylene)-8-phenyl-5,6,8-triaza-7-oxaspiro[3.4]oct-5-en-1-one (**15**) and 2,3-bis(diphenylmethylene)-4-phenyliminocyclobutan-1-one *N*-oxide (**16**) in 15 and 50% yields respectively. The 1,3-dipolar cycloadduct (**15**) was thermally unstable and was easily converted into



13 **14**

16 at room temperature. To our best knowledge, no such 1,3-cycloadduct as **15** has yet been isolated in any reaction of diazoketone with nitrosobenzene.[9]



15 **16**

Experimental

All the melting points are uncorrected. Photolysis was carried out at room temperature under a nitrogen atmosphere, using light from a 100-W high-pressure mercury lamp (Riko Kagaku Sangyo Co), with filtered Pyrex glass. The IR, UV, and NMR spectra were measured in a KBr disk, $CHCl_3$, and $CDCl_3$ respectively, unless otherwise stated. The mass spectra were obtained with an ionization energy of 75 eV.

Preparation of Diazo Ketone (2). A mixture of 3,4-bis(diphenylmethylene)cyclobutanedione[3] (4.12 g, 10 mmol), tosylhydrazine (2.05 g, 11 mmol), and concd HCl (1 ml) in CH_2Cl_2–MeOH (1: 1, 200 ml) was kept at room temperature for 4 h. The crude crystals thus formed were recrystallized from AcOEt to give **1** as red needles; 5.80 g (100%); mp 145—146 °C. IR (Nujol): 3240 (NH), 1750 (C=O), 1170 (SO_2), 755 cm^{-1} (Ph); λ_{max}: 281 (28000), 398 (24000), 440 sh (8400), 515 nm (ε, 10000); NMR: 0.10 (s, 1H, NH), 2.35—2.9 (m, 14H), 3.17 (s, 5H), 3.24 (s, 5H), 7.62 τ (s, 3H).

Found: C, 76.46; H, 4.53%. Calcd for $C_{37}H_{28}O_3N_2S$: C, 76.54; H, 4.86%.

To a stirred solution of **1** (1.16 g, 2 mmol) in $CHCl_3$ (50 ml), we added aluminum oxide (20 g, Woelm, basic activity I) at 0 °C over a period of 30 min; the stirring was continued for a further hour. The mixture was then passed through the short column packed with basic aluminum oxide (30 g) described above, using $CHCl_3$ (200 ml) as the eluent. The crude crystals left after the evaporation of the solvent were recrystal-

lized from ether–light petroleum to afford **2** as orange prisms; 0.81 g (95%); mp 123—124 °C. IR: 2050 (N_2), 1745 cm^{-1} (C=O); λ_{max}: 262 (10000), 271 (11000), 338 (6700), 420 nm (ε, 5100).

Found: C, 84.65; H, 4.60%. Calcd for $C_{30}H_{20}ON_2$: C, 84.88; H, 4.75%.

*Photolysis of **2** in the Presence of Alcohols, Aniline, and Water.* A mixture of **2** (424 mg, 1 mmol) and MeOH (20 ml) in benzene (150 ml) was irradiated for 2 h. The oily material left after the evaporation of the solvent was chromatographed on silica gel, using benzene as the eluent, to afford crude crystals. The recrystallization from EtOH afforded **5a** as colorless prisms; 372 mg (87%). The photochemical reactions of **2** with EtOH, *i*-PrOH, and aniline, according to the same procedure as above, afforded **5b**, **5c**, and **5e** respectively. The photochemical reaction of **2** with water was carried out in dioxane for 12 h. The oily material left after the evaporation of the solvent was taken up in ether, from which **5d** was extracted with an aqueous Na_2CO_3 solution. The physical properties, yields, and analytical data of **5a**—**e** are summarized in Table 1.

*Thermal Reaction of **2** in Aqueous Dioxane.* A solution of **2** (424 mg, 1 mmol) in 10%-aqueous dioxane (30 ml) was refluxed for 1 h. The reaction mixture was then treated by the procedure used for the reaction mixture of the photolysis of **2** in aqueous dioxane to afford **5d**; 215 mg (52%).

*Reduction of **5a** with $LiAlH_4$.* To a stirred solution of **5a** (200 mg, 0.47 mmol) in ether (20 ml), we added an excess of $LiAlH_4$. The reaction mixture was stirred for a further hour, decomposed with dil-HCl, and then extracted with ether. The crude crystals left after the evaporation of the solvent were recrystallized from CH_2Cl_2–EtOH to give **6** as colorless prisms; 180 mg (95%); mp 141—142 °C. IR (Nujol): 3400 and 1070 cm^{-1} (OH); λ_{max} 260 (23700), 375 nm (ε, 28600); NMR; 2.48 (s, 10H), 3.05 (s, 5H), 3.12 (s, 5H), 6.03 (d, J=9 Hz, 2H), 7.13 (t, J=9 Hz, 1H), 8.75 τ (br s, 1H, OH).

Found: C, 89.65; H, 5.88%. Calcd for $C_{30}H_{24}O$: C, 89.96; H, 6.04%.

*Chlorination of **6** with $SOCl_2$.* To a solution of 6 (100 mg, 0.25 mmol) in ether (10 ml), we added an excess of $SOCl_2$, after which the mixture was refluxed for 1 h. The oily material left after the evaporation of the solvent was chromatographed on silica gel, using benzene as the eluent, to give **7** as orange prisms; 42 mg (40%); mp 183—184 °C. NMR: 2.60 (s, 5H), 2.65 (s, 5H), 3.07 (s, 10H), 4.83 (t, J=5.5 Hz, 1H), 6.55—67.5 τ (m, 2H).

Found: C, 85.87; H, 5.42%. Calcd for $C_{30}H_{23}Cl$: C, 86.00; H, 5.53%. The spectral data of **7** were identical with those of an authentic sample prepared by the addition of HCl to 3,4-bis(diphenylmethylene)-1-cyclobutene.[4]

*Preparation of **9**.* A solution of **2** (424 mg, 1 mmol) and azobenzene (200 mg, 1.1 mmol) in benzene (150 ml) was irradiated for 10 h. The oily material left after the evaporation of the solvent was chromatographed on silica gel. Elution with benzene afforded **9** as yellow prisms; 435 mg (75%); mp 186.5—187 °C. IR: 1760 cm^{-1} (C=O); λ_{max}: 270 (27200), 404 nm (ε, 28000); NMR: 2.30—3.40 (m); MS: *m/e* (rel intensity) 578 (M^+, 91), 501 (80), 459 (M^+—PhNCO, 34), 167 (100).

Found: C, 86.88; H, 5.15%. Calcd for $C_{42}H_{30}ON_2$: C, 87.17; H, 5.23%.

*Preparation of **11** and Its Hydrolysis.* A solution of **9** (580 mg, 1 mmol) in xylene (30 ml) was refluxed for 4 h. The subsequent evaporation of the solvent under reduced pressure afforded **11** as a red liquid; 460 mg (100%). IR (neat): 1600 and 1030 cm^{-1} (C–N); λ_{max}: 272 (37500), 395 nm (ε, 32000); NMR: 2.45—3.30 (m). **11** is very sensitive to water and is easily hydrolyzed. For example, when a solution of **11** (230 mg, 0.5 mmol) in AcOEt (10 ml) was kept at room temperature for 1 day, **12** was obtained as colorless prisms after recrystallization from AcOEt; 180 mg (75%); mp 224—225 °C. IR (Nujol): 3330, 1655, and 1520 cm^{-1} (CONH); λ_{max}: 245 (21200), 337 nm (ε, 14000); NMR: 2.30—2.95 (m, 25H), 3.32 τ (br s, 2H); MS: *m/e* (rel intensity) 477 (M^+, 56), 385 (M^+—PhNH, 76), 357 (M^+—PhNHCO, 74), 279 (100).

Found: C, 87.85; H, 5.70%. Calcd for $C_{35}H_{27}ON$: C, 88.02; H, 5.70%.

*Preparation of **10a**. By Photolysis*: A solution of **2** (424 mg, 1 mmol) and *N*-benzylideneaniline (200 mg, 1.1 mmol) in benzene (150 ml) was irradiated for 8 h. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **10a** as yellow prisms; 376 mg (65%); mp 190—191 °C. IR: 1750 and 1260 (C=O), 1170 cm^{-1} (C–N); 2.35—3.7 (m, 30H), 4.68 τ (s, 1H); λ_{max}: 260 (36200), 383 nm (ε, 29500); MS: *m/e* (rel intensity) 578 (M^+, 20), 459 (M^+—PhNCO, 20), 397 (M^+—PhCH=NPh, 80), 396 (100).

Found: C, 89.10; H, 5.22%. Calcd for $C_{43}H_{31}ON$: C, 89.40; H, 5.41%.

By Thermolysis: A solution of **2** (424 mg, 1 mmol) and *N*-benzylideneaniline (200 mg, 1.1 mmol) in dioxane (30 ml) was heated under reflux for 1 h; thereafter it was worked up in a manner similar to that described above to afford **10a**; 237 mg (41%).

*Preparation of **10b**. By Photolysis*: A solution of **2** (424 mg, 1 mmol) and *N*-(diphenylmethylene)aniline (314 mg, 1.1 mmol) in benzne (150 ml) was irradiated for 10 h. The oily material left after the evaporation of the solvent was chromatographed on silica gel, using benzene as the eluent, to give **10b** as yellow prisms; 530 mg (81%); mp 242—246 °C. IR: 1740 and 1250 (C=O), 1170 (C–N), 740 cm^{-1} (Ph); λ_{max}: 263 (30000), 383 nm (ε, 23900); MS: *m/e* 653 (M^+, 100), 396 (M^+—Ph_2C–NPh, 30), 291 (70).

Found: C, 89.75; H, 5.38%. Calcd for $C_{49}H_{35}ON$: C, 90.01; H, 5.40%.

By Thermolysis: A solution of 2 (424 mg, 1 mmol) and *N*-(diphenylmethylene)aniline (314 mg, 1.1 mmol) in dioxane (30 ml) was refluxed for 1 h. The oily material left after the evaporation of the solvent was chromatographed on silica gel, using benzene as the eluent, to afford **10b**, 260 mg (40%).

*Preparation of **13**. By Photolysis*: A solution of **2** (424 mg, 1 mmol) and *p*-benzoquinone (126 mg, 1.1 mmol) in benzene (150 ml) was irradiated for 6 h. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to give **13** as yellow prisms; 227 mg (45%); mp 218.5—220 °C. IR: 1760 and 1670 cm^{-1} (C=O); λ_{max}: 246 (25400), 265 (22600), 350 (14000), 455 nm (ε, 7400)0 NMR: 2.54 (s, 10H), 3.00 (s, 5H), 3.17 (s, 5H), 3.35 (s, 2H), 7.13 τ (s, 2H); MS; *m/e* (rel intensity) 504 (M^+, 100), 427 (M^+—Ph, 20).

Found: C, 85.49; H, 4.98%. Calcd for $C_{36}H_{24}O_3$: C, 85.69; H, 4.79%.

By Thermolysis: A solution of **2** (424 mg, 1 mmol) and *p*-benzoquinone (126 mg, 1.1 mmol) in dioxane (30 ml) was refluxed for 2 h. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **13**; 298 mg (59%).

*Preparation of **14** and Its Thermal Decomposition.* A solution of 2 (424 mg, 1 mmol) and *p*-benzoquinone (126 mg, 1.2 mmol) in benzene (30 ml) was kept for 12 h at 0 °C. The crude crystals left after the evapotation of the solvent were recrystallized from CH_2Cl_2–EtOH to afford **14** as orange prisms; 425 mg (80%); mp 290 °C. IR: 1760 and 1695 cm^{-1} (C=O); λ_{max}: 283 (26000), 362 (17000), 450 nm (ε, 10000);

NMR: 2.25—3.7 (m, 22H), 7.40 τ(s, 2H).

Found: C, 80.94; H, 4.28%. Calcd for $C_{36}H_{24}O_3N_2$: C, 81.18; H, 4.54%.

A solution of **14** (200 mg, 0.38 mmol) in xylene (50 ml) was heated at reflux for 4 h. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **13**; 180 mg (95%).

*Preparation of **15** and **16**.* A solution of **2** (848 mg, 2 mmol) and nitrosobenzene (630 mg, 4 mmol) in benzene (50 ml) was kept for 10 h at room temperature. The crude crystals left after the evaporation of the solvent were recrystallized from CH_2Cl_2–EtOH to afford a mixture of pale yellow (**15**; 160 mg (15%); mp 120 °C dec) and brilliant black crystals (**16**; 475 mg (50%); mp 211—213 °C), which were separated mechanically. When a solution of the former (**15**, 100 mg, 0.19 mmol) in AcOEt was heated at reflux for 10 min and then kept for 12 h, the latter crystals were obtained; they were subsequently recrystallized from AcOEt to afford **16**; 76 mg (80%) **15**. IR: 1780 (C=O), 1195 cm^{-1} (C–N); λ_{max}: 242 (27000), 315 nm (ε, 14500); NMR: 2.35—2.75 (m, 10H), 2.85—2.95 (m, 5H), 3.0—3.4 τ (m, 10H).

Found: C, 80.92; H, 4.48%. Calcd for $C_{36}H_{25}O_2N_3$: C, 81.33; H, 4.74%.

16. IR: 1750 (C=O), 1290 cm^{-1} (N-O); λ_{max} 241 (17200), 280 (16300), 408 (10000), 505 (11700), 585 sh (3700), 640 nm (ε, 2300); MS: *m/e* (rel intensity) 503 (M^+, 9), 487 (M^+—O, 28), 382 (67), 189 (100).

Found: C, 85.60; H, 5.12%. Calcd for $C_{36}H_{25}O_2N$: C, 85.86; H, 5.00%.

Nucleophilic Displacement Catalyzed by Transition Metal. III.[1] Kinetic Investigation of the Cyanation of Iodobenzene Catalyzed by Palladium(II)

Kentaro TAKAGI, Tadashi OKAMOTO,* Yasumasa SAKAKIBARA,** Atsuyoshi OHNO,* Shinzaburo OKA,* and Naomi HAYAMA

(Received May 26, 1976)

The nucleophilic displacement of iodobenzene with potassium cyanide was carried out in HMPA in the presence of palladium(II) acetate. The reaction obeys the following kinetics;

$$d[C_6H_5CN]/dt = k[Pd(OAc)_2]_0(M_{KCN})^{2/3}$$

A reaction scheme composed of two cycles has been proposed: in one cycle Pd^0 activates iodobenzene and in the other cycle Pd^{2+} assists the dissolution of potassium cyanide.

In a previous paper,[2] we reported that the nucleophilic displacement of non-activated aryl halides by cyanide anions takes place in the presence of palladium-

$$ArX + KCN \xrightarrow{Pd(II)} ArCN + KX$$

(II) salts. The scope of the reaction revealed that the palladium(II) salt is initially reduced to a lower-valent species, which plays the role of an active catalyst, and that the cyanide ligand retards the reduction. It is particularly interesting to note that a cyanide anion in the solution is a retarder of the reaction. In order to obtain an insight into the mechanism of the reaction, we studied the reaction from the kinetic viewpoint. The results and the most plausible scheme for the reaction will be presented in this paper.

Results and Discussion

The reaction of iodobenzene with potassium cyanide

was carried out in hexamethylphosphoric triamide (HMPA) at 102 °C using palladium(II) acetate as a catalyst. Benzonitrile was obtained in a quantitative yield, and by-products such as biphenyl were not detected on GLC. Since the reaction system is heterogeneous and there remains an undetermined variable (*vide infra*), we resigned to calculate numerical values for the rate constants.

Effect of Concentrations of Reactants. As is shown in Fig. 1, the initial rate for the appearance of benzonitrile was independent of the initial concentration of iodobenzene, which ranged from 2.36×10^{-2} M to 7.07×10^{-2} M. On the other hand, the rate increased non-linearly with the amount (weight) of potassium cyanide, as illustrated in Fig. 2. The analysis of the order with the method of integration[3] revealed that the kinetics obeys a two-thirds-order (r=0.992) for the amount of potassium cyanide. A linear relationship directed at the origin was observed between the rate and the concentration of palladium(II) acetate, provided that the concentration was greater than 1.04×10^{-3} M (Fig. 3).

Thus, Eq. 1 shows the rate expression determined experimentally, where $[Pd(OAc)_2]_0$ stands for the initial concentration of palladium(II) acetate and M_{KCN}

means the amount of potassium cyanide in the reaction mixture.

$$d[C_6H_5CN]/dt = k[Pd(OAc)_2]_0(M_{KCN})^{2/3}$$
$$[Pd(OAc)_2]_0 \geq 1.04 \times 10^{-3}M$$

Rate of Dissolution of Potassium Cyanide into HMPA. Concentrations of potassium cyanide in HMPA at 102 °C were measured at appropriate time intervals after mixing both materials; the result is shown in Fig. 4. It is noteworthy that the concentration-time profile has an asymptote of about 1×10^{-3} M, which is almost identical to the minimum concentration of palladium(II) acetate necessary for the catalytic reaction. This observation seems to reveal that the cyanide anion in the solution[4] is trapped rapidly by a palladium(II) acetate at the very initial stage of the reaction to form the cyanide salt, which is inactive for initiation of the reaction.

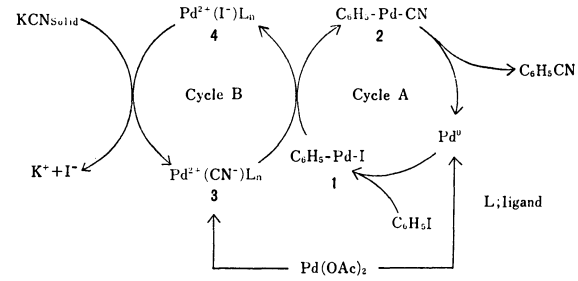
$$Pd(OAc)_2 + CN^- \xrightarrow[\text{fast}]{} Pd^{2+}(CN^-)L_n \not\rightarrow Pd^0$$
$$\downarrow \qquad\qquad \uparrow$$
$$Pd^0 \qquad KCN_{solid}$$

L; ligand(OAc^-, solvent, *etc.*)

The fact that potassium tetracyanopalladate(II) or palladium(II) cyanide is an inactive catalyst under the present conditions[2,5] supports this idea. Thus, in order to have a catalytic reaction, the initial concentration of palladium(II) acetate must exceed that of potassium cyanide in the solution.

The initial rate of dissolution of potassium cyanide into HMPA can be calculated to be 6×10^{-5} M·min^{-1}, which is far smaller (1/30—1/100) than the rates of the appearance of benzonitrile (2×10^{-3}—6×10^{-3} M·min^{-1}, *cf.* Figs. 1—3). This result suggests that the cyanide anions which contribute to the reaction comes directly from the potassium cyanide in the solid state, if not all.

Reaction Scheme. The results and discussion presented above leads to the following scheme as the most plausible mechanism for the reaction:



The low-valent palladium species (Pd^0) which comes from palladium(II) acetate[6] reacts with iodobenzene to give an oxidative-addition adduct (**1**). A methathesis of **1** with the cyanopalladium complex (**3**) produces the phenylcyanopalladium(II) complex (**2**), which subsequently yields benzonitrile and regenerates Pd^0 to ensure the catalytic cycle A. This is the well-known sequence of oxidative addition, methathesis, and reductive elimination in transition metal catalysis.[7] Supporting evidence for this is presented by the reaction of arylmercury(II) compound with potassium cyanide in the presence of palladium(II) chloride.

$$p\text{-}CH_3\text{-}C_6H_4\text{-}HgCl + KCN + PdCl_2 \longrightarrow$$
$$p\text{-}CH_3\text{-}C_6H_4\text{-}CN\ (+\ KCl + HgCl_2 + Pd)$$

In this case *p*-methylbenzonitrile was obtained quantitatively based on palladium(II) chloride.[8]

The cycle B represents a cyanide-carrier. Palladium-(II) species draws the cyanide anion away from solid potassium cyanide and transfers it to **1** in methathesis.

The fact that the overall reaction rate is independent of the concentration of iodobenzene implies that the rate-determining step is the process for the abstraction of cyanide anions from the solid surface by palladium(II) species. Under such a circumstance the reaction rate is proportional to the stoichiometric concentration of

palladium(II) acetate and to the surface area of potassium cyanide in solid state, that is, the two-thirds-order of the amount of potassium cyanide; thus the experimentally derived Eq. 1 is consistent with the reaction scheme.

It should be noted that, in constructing the reaction scheme, we have assumed that almost all the palladium species in the reaction mixture is used as a cyanide-carrier (cycle B) and that the steady-state concentration of palladium species in cycle A is quite low.

That a cyano-complex such as **3** can provide the cyanide anions to form another complex, **2**, has been confirmed with a control experiment: when palladium(II) acetate ($[Pd(OAc)_2]/[KCN]=1/4$) was added into a homogeneous solution of iodobenzene and potassium cyanide in HMPA containing a small amount of water and the solution was heated at 102 °C for 30 min, no reaction took place. However, when additional palladium(II) acetate (half the amount to the initial palladium(II) acetate) was added to this reaction solution and the solution was kept at 102 °C for 30 min, benzonitrile was obtained in a 86% yield (based on potassium cyanide used). Since all palladium(II) cations initially added were consumed to form tetracyanopalladate(II) anions, there remained no species to yield Pd^0, whereas Pd^0 could be produced from the second portion of palladium(II) acetate because there remained scarcely any cyanide anions in the solution.

The existence of an appreciable amount of an iodo-complex, **4**, in the reacting solution can be shown from the absorption spectra. A pale-yellow reaction solution turns to reddish brown during the reaction, then comes back to pale-yellow at the end of the reaction. The reddish brown solution exhibits absorption similar to that of palladium(II) iodide solution at 500 nm or higher wavelengths, as is illustrated in Fig. 5.[9]

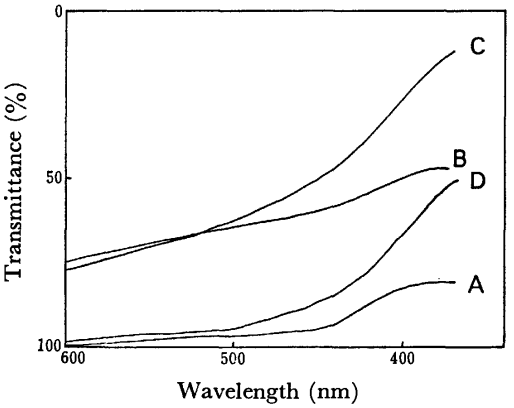


Fig. 5. Electronic spectra.
(A) $Pd(OAc)_2$, (B) PdI_2, (C) Reaction solution-in progress, (D) Reaction solution-terminate.
The concentrations of palladium(II) salts and other reaction conditions (C,D) are identical with those of Fig. 2.

Experimental

Materials. Palladium(II) acetate was prepared according to the literature.[10] HMPA and iodobenzene were commercial reagents and were dried over Molecular Sieves-(3A). Potassium cyanide was recrystallized from water and was ground by the use of a mortar.

Procedure. All reactions were performed in a 30-ml flask equipped with a magnetic stirrer and a three-way trap under a nitrogen stream. A mixture composed of potassium cyanide, iodobenzene, naphthalene (internal standard), and HMPA was stirred for 30 min at 102±1 °C. Then, a HMPA solution of palladium(II) acetate was added at once to start the reaction. Each aliquot (0.4 ml) taken out at appropriate time intervals was quenched with 5 ml of 12.5% aqueous sodium chloride, and the organic materials were extracted with 3 ml of ether. The ether layer was washed with 5 ml of 12.5% aqueous sodium chloride, dried over sodium sulfate, and subjected to the analysis on GLC (Hitachi Perkin-Elmer F6D, 35% silicon DC 200 on celite 545, 2 m, 140 °C, 0.8 kg·cm^{-2} of N_2).

The standard reaction mixture was composed of 1.01 mmol of potassium cyanide, 0.34 mmol of iodobenzene, 0.011 mmol of palladium(II) acetate, and 7.7 ml of HMPA. The concentration of each reagent was changed as indicated in Figs. 1—3.

The reaction rates were computed based on the amount of benzonitrile yielded at 2 min after the initiation.

Reaction of Arylmercury(II) Compound with Potassium Cyanide in the Presence of Palladium(II) Chloride. Into a solution of 65.8 mg (0.2 mmol) of *p*-chloromercuritoluene and 13.0 mg (0.2 mmol) of potassium cyanide in DMF (2.5 ml) was added 2.5 ml of 0.02 M solution of palladium(II) chloride in DMF. The mixture was kept at 50 °C for 1 h. The analysis by GLC revealed 5.8 mg (0.05 mmol) of *p*-methylbenzonitrile (a 99% yield based on $PdCl_2$) and a small amount of *p,p'*-bitolyl.

Solubility of Potassium Cyanide. To 2.02 mmol of potassium cyanide kept at 102 °C under nitrogen was added 15.4 ml of HMPA preheated to 102 °C; the concentrations of cyanide anions in the stirred mixture were measured at appropriate time intervals by the aid of a cyanide-ion electrode (Toa Electronic Ltd., CN-125).

Absorption Spectra. The spectra were recorded on a Hitachi Spectrophotometer 124. The reaction mixture was diluted with HMPA by a factor of 3 when it was submitted to the spectroscopy.

One of the authors (K. T.) wishes to thank the Ministry of Education for the support of this work with Grant No. 074167.

The Synthetic Reactions of Aliphatic Nitro Compounds. XI. The Synthesis of β-Amino-α-hydroxycarboxylic Acids and γ-Aminocarboxylic Acids[1]

Eisuke KAJI, Akira IGARASHI, and Shonosuke ZEN

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received May 31, 1976)

The *O*-alkylation of some nitroparaffins, 2-nitropropane, 2-nitrobutane, 1-nitropropane, and phenylnitromethane, with methyl bromoacetate in dipolar aprotic solvent led to α-hydroxy-β-nitrocarboxylates, which were converted into β-amino-α-hydroxycarboxylic acids. Several γ-aminocarboxylic acids were synthesized from the corresponding γ-nitrocarboxylates which were obtained *via* *C*-alkylation of the nitroparaffins with methyl β-bromopropionate.

The ambident reactivity of aliphatic nitro compounds has been known to undergo unique reactions with several electrophiles.[2-4] We have found that alkylation of α-carbon atom in nitroparaffins is useful for the formation of a C–C bond, considering that carbon alkylation is applicable to a rather limited case where some nitroparaffins are alkylated with α-halonitroparaffins or some benzyl halides.[5-7]

It has been already reported by Hass *et al.*[8] that oxygen alkylation is available for the synthesis of aldehydes. However, practical investigation of the ambident nitronate anion is limited to the field of a reaction involving radical anion intermediates.[9,10]

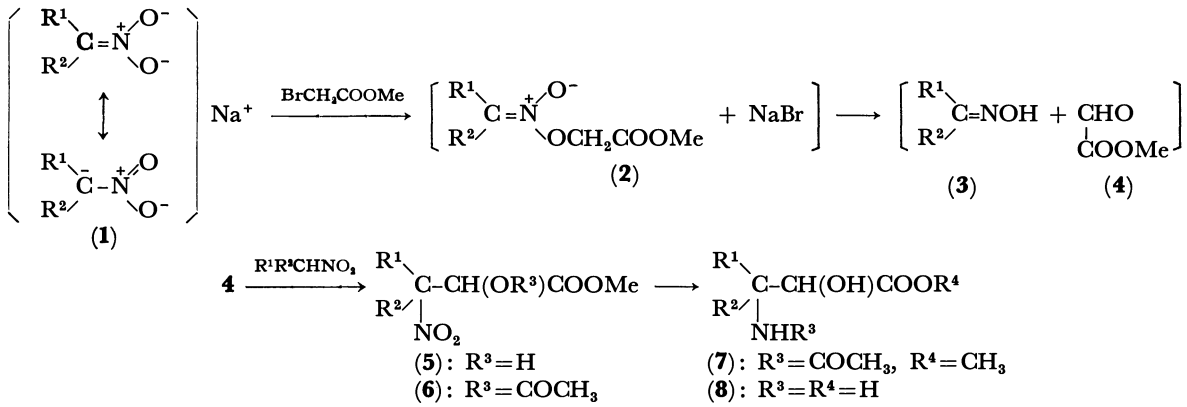
Recently we have found that the use of dipolar aprotic solvents such as *N,N*-dimethylacetamide in this reaction promotes carbon alkylation of nitroacetate anion, and that the orientation of alkylation depends on the kind of the electrophiles used. We have reported that several α-amino acids[11,12] and 4-substituted isoxazoline *N*-oxides[13] can be synthesized *via* alkylation of nitroacetate. Recent developments on amino acids of β- or γ-series which are themselves biologically active or the important components of several antibiotics[14-16] prompted us to explore new and general syntheses of these series of amino acids *via* alkylation of nitroparaffins.

For our purposes, attempted alkylation of several nitroparaffins, 2-nitropropane (**1a**), 2-nitrobutane (**1b**), 1-nitropropane (**1c**), and phenylnitromethane (**1d**), with bromoacetic ester and β-bromopropionic ester was carried out. The reaction of two equivalents of the aci-nitro compounds with methyl bromoacetate in a dipolar aprotic solvent produced α-hydroxy-β-nitroesters (**5**) which would be produced by the condensation of excess nitroparaffin with methyl glyoxylate (**4**) formed by the initial *O*-alkylation followed by degradation, as illustrated in Chart 1. This scheme was supported by the isolation of α-benzaldoxime (**3d**, $R^1=C_6H_5$, $R^2=H$) from the reaction mixture of **5d**, which was identified with an authentic sample. The structure of **5** was confirmed from the IR and NMR spectra and elemental analyses (Tables 1 and 2).

It seems that this reaction is well suited for secondary rather than primary nitroparaffins except for phenylnitromethane. In the alkylation of nitromethane or nitroethane with methyl bromoacetate, similar products that were expected were not obtained under analogous conditions, since the products from primary nitro compounds would still have an active hydrogen which would undergo subsequent alkylation or side reaction.

The compound **5b** or **5c** was confirmed by NMR to be a diastereomeric mixture consisting of *erythro* and *threo* isomers in a ratio of *ca.* 1 : 1, as shown in Table 2. This result agreed well with a previous report on the ethyl ester of **5c**.[17]

Catalytic hydrogenation of **5** in methanol usually gave a mixture of products which could not be purified further. Subsequently *O*-acetyl derivatives (**6**) of **5** were prepared and subjected to hydrogenation over a Raney nickel catalyst to yield the corresponding β-amino-esters (**7**). From the spectroscopic data of **7**, *O*→*N* migration of acetyl group seems to be occurred to give



a: $R^1=R^2=CH_3$; **b**: $R^1=C_2H_5$, $R^2=CH_3$; **c**: $R^1=C_2H_5$, $R^2=H$; **d**: $R^1=C_6H_5$, $R^2=H$

methyl β-acetamido-α-hydroxycarboxylates (**7**). The IR spectra of **7** showed a strong absorption at 1640—1650 cm^{-1}, typical of an amide, and a broad NH peak appeared at δ 5.8—6.1 region in its NMR spectra. **7** was readily hydrolyzed by treatment with 6 M hydrochloric acid under refluxing for 16 h, giving β-amino-α-hydroxycarboxylic acid hydrochloride as a viscous oil. Deionization through an ion-exchange resin (IR-45, OH form or Dowex 50 W, Na form) column followed by recrystallization gave free amino acids (**8**) as colorless crystals.

The composition of the isomers of **8b** and **8c** was observed to be almost one isomer on the basis of NMR signals for β-CH_3 proton (δ 1.27) for **8b** and α-proton (δ 4.08) for **8c**, whereas crude products (**8b** and **8c**) consist of a mixture of two diastereomers in which β-CH_3 proton was observed at δ 1.27 and 1.23 for **8b** and α-proton at δ 4.08 and 4.16 for **8c**. β-Phenylisoserine (**8d**) was separated into two isomers under ion-

Experimental

All boiling and melting points are uncorrected. The IR spectra were measured on a JASCO Model IRA-1 spectrometer. The NMR spectra were recorded with a 100 MHz JEOL PS-100 spectrometer. Tetramethylsilane was used as an internal standard for deuteriochloroform and tetradeuteriomethanol solution and sodium 2,2-dimethyl-2-silapentane-5-sulfonate was used in deuterium oxide solution. The peak positions are given in δ value.

Typical Procedure. *Methyl α-Hydroxy-β-nitroisovalerate (5a)*: 1 M sodium methoxide (10 ml) was added to a stirred solution of 2-nitropropane (1.73 g, 20 mmol) and methyl bromoacetate (1.53 g, 10 mmol) in 30 ml of *N,N*-dimethylacetamide. After agitation at room temperature overnight, the reaction mixture was poured into 150 ml of ice-cold water covered with 50 ml of benzene. The aqueous phase was extracted four more times with 50 ml portions of benzene. After the benzene extract had been washed with four 50 ml portions of water, benzene layer was dried over anhydrous sodium sulfate. The benzene was removed under reduced pressure. Rectification of the residue yielded 0.85 g of **5a** in 48% yield. Bp, elemental analysis, and spectroscopic data were shown in Table 1 and 2. **5b—5d** were also obtained in a similar procedure. **5c** and **5d** were purified by column chromatography on silica gel (hexane/ethyl acetate as eluant) before distillation.

Methyl α-Acetoxy-β-nitroisovalerate (6a). Concds ulfuric acid (0.05 ml) was added to a stirred solution of **5a** (1 g, 5.65 mmol) in 10 ml of acetic anhydride under ice-cooling. When stirring was continued for an additional 1 h, all the starting material was consumed as shown by silica gel TLC (hexane–ethyl acetate, 2: 1). The reaction mixture was poured into 50 ml of water and extracted with diethyl ether (3×25 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and solvent was evaporated. Recrystallization or sublimation of the resultant solid-residue gave 0.78 g (63%) of colorless crystals. **6b—6d** were also obtained under analogous conditions. The results are summarized in Table 1 and 2.

β-Amino-α-hydroxyisovaleric Acid (8a). A methanolic slurry of Raney nickel T-1 catalyst (1.5 ml) was added to a solution of **6a** (0.73 g, 3.33 mmol) in 40 ml of methanol. The mixture was hydrogenated at room temperature under 3.5 kg/cm² of hydrogen atmosphere in a Parr low-pressure hydrogenator. The catalyst was filtered and the filtrate was evaporated to afford 0.73 g of deep yellow oil (**7a**). **7a** was subjected to next step without further purification except **7b** and **7c** which were passed through ion-exchange resin (Dowex 50 W, H form).

A 0.5 g (2.64 mmol) portion of **7a** was refluxed with 6 M hydrochloric acid (8 ml) for 16 h. After evaporation of the solvent the residual oil was dissolved in water and deionized through a column of basic resin (IR-45, OH form, water as an eluant). Concentration of the eluant gave 0.4 g of amorphous solid. The crude solid was recrystallized from aqueous ethanol to yield 0.15 g of colorless crystals in 42% yield. **8b—8d** were prepared in a similar way as **8a** from the corresponding α-acetoxy-β-nitro esters (**6b—6d**). The results are summarized in Table 4.

Methyl γ-Nitroisocaproate (10a) To a stirred solution of 2-nitropropane (1.0 g, 11.24 mmol) and methyl β-bromopropionate (1.88 g, 11.24 mmol) in 20 ml of anhydrous *N,N*-dimethylacetamide, was added 11.24 ml of 1 M sodium methoxide. The mixture was stirred at room temperature overnight. The resultant yellow liquid was worked up as in the procedure for **5a**. The crude yellow oil was purified by distillation to yield 1.67 g (85%) of colorless oil (**10a**). **10b—10d** were also obtained in analogous way. The results are summarized in Table 3.

γ-Aminoisocaproic Acid (11a). **10a** (1.5 g, 8.57 mmol) was hydrogenated in 80 ml of methanol in the presence of Raney nickel T-1 (2 ml of methanolic slurry) with a low pressure hydrogen (3.5 kg/cm²) for 1.5 h at room temperature. The catalyst was filtered off and the solvent was removed. The residue was subsequently hydrolyzed without further purification. Hydrolysis was carried out by refluxing with 6 M hydrochloric acid for 16 h. After evaporation the residual solid was washed with anhydrous ether and acetone. Recrystallization from methanol–ether afforded 0.73 g (51%) of analytically pure **11a**. **11b—11c** were also obtained in a similar way. The results are summarized in Table 4.

The authors are indebted to Miss Kazuko Shibuya, Messrs. Kazuo Yamaji and Toshihide Kamiya for their technical assistance.

Conformationally Stable 1-Substituted 1-Methyl-4-*t*-butyl-1-silacyclohexanes, a New Organosilicon System Suitable for Stereochemical Studies

Hideki SAKURAI and Masashi MURAKAMI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received June 7, 1976)

Ten 1-methyl-4-*t*-butyl-1-silacyclohexyl derivatives ($C_{10}H_{21}Si$–X, X=H, Cl, $OCH(CH_3)_2$, OCH_3, $OC(CH_3)_3$, C_6H_5, *p*-Br–C_6H_4, *p*-Cl–C_6H_4, $Si(CH_3)_2H$, F) were synthesized and separated into conformationally stable *cis* and *trans* isomers. The stereochemistry of these compounds has been determined on the basis of NMR and GLC. They were found to behave stereochemically like acyclic optically active silanes.

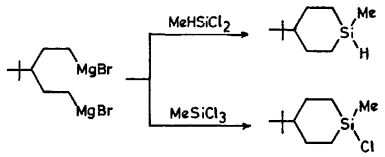
Sommer and Frye prepared the first optically active organosilicon compounds, 1-naphthylphenylmethylsilane derivatives (1-NaPhMeSi*X) in 1959.[1]

Since then several reports have been made on other optically active organosilicon compounds.[2–5] They are of importance for the study of the stereochemical behavior of reactions at silicon centers. Several other types of optically active ring compounds are also known.[6,7] However, the majority of optically active organosilicon compounds so far prepared have at least one bond between an aromatic moiety and silicon. Such a structure is often inconvenient for a certain stereochemical research of reactions in which the bond of silicon to aromatic groups cleaves or forms. Cleavage of the bond of silicon to aromatic groups with electrophiles (desilylation)[8] and substitution reactions of silyl radicals on an aromatic nucleus (homolytic aromatic silylation)[9] are examples of such reactions. Moreover, accurate measurement of optical activity requires a large amount of pure sample. In some cases, separation of optically active product(s) from a reaction mixture is infeasible because of extensive racemization.[10]

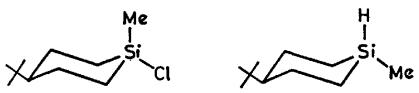
Conformationally stable compound such as *t*-butylcyclohexane derivatives are also useful in stereochemical investigations. However, no silicon analog of such a class of compounds has been prepared. During the course of a study on the stereochemistry of unstable organosilicon intermediates such as silyl radicals and silylenes,[11] it became necessary to find aliphatic silicon compounds suitable for the stereochemical study. This paper describes the synthesis and reactions of new 4-*t*-butyl-1-methyl-1-silacyclohexane derivatives.[12] Numerous stereochemical studies on the corresponding carbon analogs, 4-*t*-butylcyclohexanes, have been published since the first proposal of the *t*-butyl function as a holding group.[13] The conformationally stable organosilicon compounds are also proved to be useful in the stereochemical study of almost all kinds of reactions on silicon.

Results and Discussion

Preparation and Stereochemistry. The reaction of the di-Grignard reagent from 3-*t*-butyl-1,5-dibromopentane (**1**)[14] with methyldichlorosilane and with methyltrichlorosilane afforded 4-*t*-butyl-1-methyl-1-silacyclohexane (**2**, *cis*/*trans*=1.0) and 4-*t*-butyl-1-methyl-1-chloro-1-silacyclohexane (**3**, *cis*/*trans*=1/2.3), respectively.



Since all the compounds so far prepared have a methyl group on silicon, 4-*t*-butyl and 1-methyl groups are referred to as *cis* and *trans* respectively, throughout this paper. Suffix a is added to the *cis* compounds and b to the *trans*, as illustrated in the following.



3a (*cis*) 2b (*trans*)

By reduction of **3** (*cis*/*trans*=1/2.3) with lithium aluminum hydride, **2** (*cis*/*trans*=2.8/1) was obtained. The *cis* and *trans* mixtures of **2** and **3** could not be separated into individual isomers by means of GLC. However, alkoxy derivatives, prepared by the direct alcoholysis of **3** or alcoholysis of **2** catalyzed by palladium on charcoal, can be used for separation. The isopropoxysilane (**4**) was the most convenient for separation of *cis* and *trans* isomers by preparative TLC. These isomeric alkoxysilanes can be reduced to **2** with lithium aluminum hydride with retention of configuration as in reduction of optically active alkoxysilanes.[2] Several derivatives were prepared from **2** and **3** the usual organosilicon transformations (Table 1).

The *cis* and *trans* structures of hydrosilanes (**2**) can be identified unequivocally even as a mixture by NMR, and spectral assignment done with the mixture was confirmed again with pure isomers, **2a** and **2b**. Figure 1 shows the NMR spectra of **2**. Figures 2 and 3 show Si–H region of NMR spectra of **2b**, and **2a**, respectively.

The structures of **2a** and **2b** were assigned as follows from SiH–CH_2 coupling constants. Irradiation of the $SiCH_3$ signal of **2b** revealed $J_{SiH(ax)CH(ax)}$ and $J_{SiH(ax)CH(eq)}$ to be 6.5 and 1.7 Hz, respectively, and $J_{SiH(ax)CH(ax)}$ to be *ca.* 1.0 Hz for **2a**. The value of $J_{SiH(ax)CH(ax)}$ observed in the present compound is relatively smaller than the $J_{SiH(ax)CH(ax)}$ values (8—13 Hz) observed for carbon analogs. It should be noted that the present analysis of the coupling constants may not be accurate for complex systems such as AA'BB'X. Thus, we do not claim accuracy of the absolute values of the coupling constant. However, the relative values are sufficient to

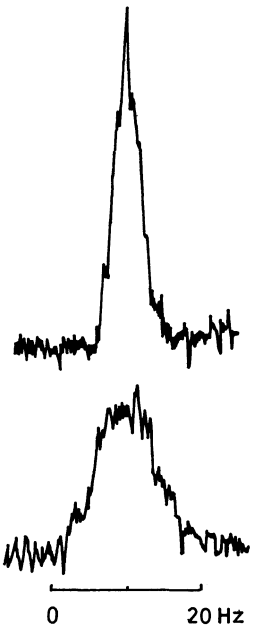


Fig. 3. SiH signal of **2a** (lower) and SiH signal irradiated at the $SiCH_3$ signal of **2a** (upper).

Table 2. Chemical shifts and configuration of functional group attached to six-membered ring in the chair conformation

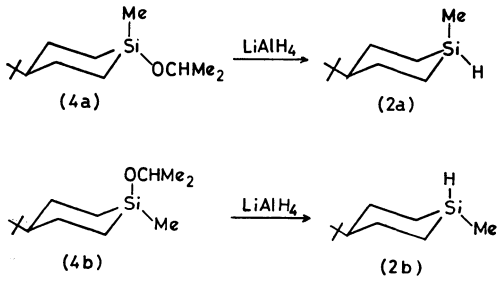
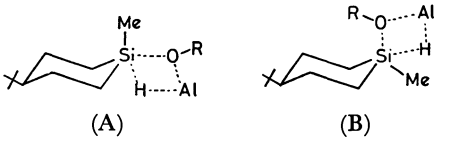
Group	Relationship in 	Relationship in Me	Equatorial upfield	Equatorial upfield
OMe	Equatorial upfield[a]	Equatorial upfield
H	Axial upfield	Axial upfield
	$J_{CHax-CHax}$ 8—13 Hz	$J_{SiHax-CHax}$ 6.5 Hz
	$J_{CHax-CHeq}$ 2—6 Hz	$J_{SiHax-CHeq}$ 1.7 Hz
		$J_{SiHeq-CHax}$ 1 Hz

a) Some exceptions have been given.[16]

field is the *cis* isomer.

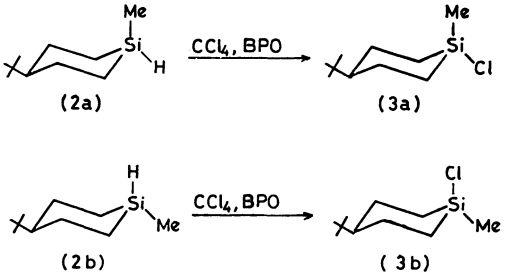
Reaction. The isomeric alkoxy derivatives were reduced to **2** with lithium aluminum hydride with retention of configuration. It seems of interest that the *cis* isopropoxysilane, **4a**, was more reactive than the *trans* one, **4b**, toward reduction. Thus, **4a** was reduced easily with lithium aluminum hydride by reflux for a few hours in ether. However, **4b** could not be reduced completely at the temperature of refluxing ether even





after 10 h, and was only reduced in refluxing tetrahydrofuran. To this type of reaction, Sommer and coworkers[17] suggested a four-centered mechanism. The present result on the silacyclohexane series can also be explained in terms of such a four-centered mechanism. The reaction intermediate or the transition state (B) leading to **2b** should be much more crowded than (A) which should lead to **2a**. Thus it is reasonable to consider that **4b** is less reactive than **4a** toward reduction.

The free radical chlorination of **2** with carbon tetrachloride in the presence of benzoyl peroxide gave **3** in almost quantitative yields with retention of configuration.



Since the free-radical chlorination in this reaction has been shown to go through a silyl radical intermediate with retention of configuration,[18] the chlorosilane (**3**) should have the same configuration as **2**.[7] This is a strong indication that the stereochemical assignments based on NMR are valid.

Reactions of **3** (*cis*/*trans*=1/2.3) with lithium aluminum hydride gave **2** (*cis*/*trans*=2.8/1), namely, an inversion of configuration. 4-*t*-Butyl-1-methyl-1-phenyl-1-silacyclohexane (**7**, *cis*/*trans*=1.6/1) was also prepared from **3** (*cis*/*trans*=1/2.3) by phenylation with phenyllithium. Methanolysis of **3** (*cis*/*trans*=1/2.3) gave 4-*t*-butyl-1-methyl-1-methoxy-1-silacyclohexane (**5**, *cis*/*trans*=1.7/1), with inversion of configuration in both reactions. Thus, the stereochemical courses of these three reactions were in good agreement with the results studied by using optically active silicon compounds.[2] Recently it has been demonstrated that the angle-strained asymmetric silicon center shows remarkable stereochemical crossover to retention of configuration.[7] However, it can be concluded that the strainless silicon centers in six-membered rings behave stereochemically like acyclic organosilicon compounds.

Several derivatives listed in Table 4 were prepared and separated by preparative GLC. As an example, phenyl derivatives **7a** and **7b** could be separated by GLC, typical examples of GLC and NMR spectra being shown in Fig. 4. The ratio of **7a** and **7b** determined by GLC agreed completely with that obtained by NMR. Silacyclohexyl derivatives which have bulky groups attached to silicon at the equatorial position, *i.e. cis* compounds, were separated systematically from

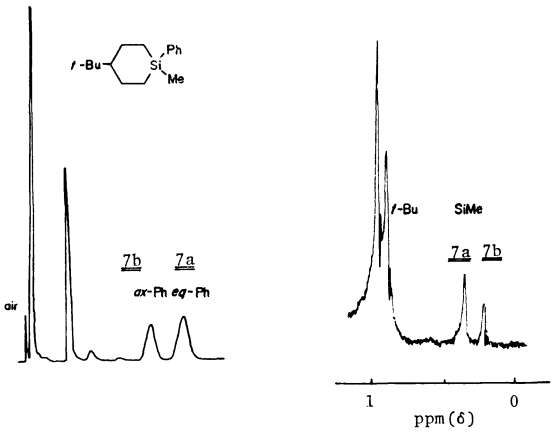


Fig. 4. GLC chart (left) and NMR spectrum (right) of 4-*t*-butyl-1-methyl-1-phenyl-1-silacyclohexane (**7**).

their *trans* compounds on GLC with a longer retention time as observed for carbon analogs.[12]

It should be noted that the compounds possess some advantages as substrates in the stereochemical study; (a) separation of *cis* and *trans* isomer is relatively easy: (b) the stereochemical course can be monitored by NMR and/or GLC; hence each reaction requires only a small amount of reactant: (c) a mixture simply enriched with either of the two isomers can be used satisfactorily: (d) absence of the phenyl or naphthyl group makes some reactions, such as photolysis in the presence of **2** and halodesilylation of **7**, possible.

Experimental

Materials. Reduction of *t*-butylphenol followed by chromic acid oxidation was employed for the preparation of 4-*t*-butylcyclohexanone according to the literature.[19] Preparation of 1,5-dibromo-3-*t*-butylpentane (**1**) has been described elsewhere.[20] Other materials were commercially available and were used without further purification.

NMR spectra were obtained at 100 MHz using a Varian HA-100 spectrometer. IR spectra were taken with a Hitachi EPI spectrometer.

Preparation of 4-t-Butyl-1-methyl-1-silacyclohexane (2). *Method A*: A mixture of 5 g (0.2 g-atom) of magnesium and 100 ml of tetrahydrofuran (THF) was placed in a 500 ml three-necked flask. Then 28.6 g (0.10 mol) of **1** and 11.5 g (0.10 mol) of methyldichlorosilane in 100 ml of THF were added over a period of 1 h. The mixture was stirred with reflux for several hours to complete the reaction. The mixture was then hydrolyzed and extracted with petroleum ether. After the solvent was removed, fractional distillation gave 5 g (0.03 mol, 29% yield) of **2** (*cis*/*trans*=1) as a colorless oil, bp 95 °C (35 mmHg); n_D^{20} 0.8424; IR (neat, cm^{-1}): 2120 (ν_{SiH}), 1250 (δ_{SiMe}) 800 (ν_{Si-Me}). Found: C, 70.37; H, 12.89%. Calcd for $C_{10}H_{22}Si$: C, 70.50; H, 13.01%.

Method B: Reduction of 1 g (4 mmol) of **3** (*cis*/*trans*=1/2.3) with 1 g (26.3 mmol) of lithium aluminum hydride gave **2** (*cis*/*trans*=2.8/1) in an almost quantitative yield (by GLC). The compound was identified by comparing its NMR and IR spectra and GLC with those of **2** prepared by method A.

Preparation of 4-t-Butyl-1-methyl-1-chloro-1-silacyclohexane (3). A mixture of 4 g (0.2 g-atom) of magnesium and 100 ml of THF was placed in a 500 ml three-necked flask. Then 28.5 g (0.10 mol) of **1** and 15 g (0.10 mol) of methyltrichlorosilane in 100 ml of THF were added in a period of 1 h. After the reaction was completed, THF was distilled as completely as possible and 200 ml of diethyl ether was added. The precipitated magnesium salts were filtered from the ethereal solution. After the solvent was removed, fractional distillation gave 10 g (0.148 mol, 48% yield) of **3** (*cis*/*trans*=1/2.3) as a colorless oil, bp 103 °C (20 mmHg). Found: C, 58.32; H, 10.6%. Calcd for $C_{10}H_{21}SiCl$: C, 58.64; H, 10.33%.

Preparation of 4-t-Butyl-1-methyl-1-fluoro-1-silacyclohexane (11). A volatile residue in the preparation of **3** [5.8 g bp ≈120 °C (3 mmHg)] was added drop by drop to 50 ml of concd sulfuric acid at −10 °C with vigorous stirring over a period of 30 min. After additional stirring for 1 h, 4 g (0.07 mol) of ammonium hydrogen fluoride was added several portions. The organic layer was extracted with petroleum ether. Evaporation of the solvent gave 5.1 g of a residue. Fractional distillation of the residue gave 3.7 g of **11** (*cis*/*trans*=1) as a colorless oil, bp 98 °C (55 mmHg); n_D^{20} 0.9127. IR (neat cm^{-1}): 1260 (ν_{SiMe}), 800 (ν_{SiMe}). Found: F, 10.3%. Calcd for $C_{10}H_{21}SiF$: F, 10.1%.

Preparation and Separation of 4-t-Butyl-1-methyl-1-methoxy-1-silacyclohexane (5). *Method A*: Methanolysis of 0.99 g (4.9 mmol) of **3** (*cis*/*trans*=1/2.3) with 10 ml (0.25 mol) of methanol in the presence of 20 ml (0.2 mol) of cyclohexylamine in 50 ml of petroleum ether gave 1.03 g of a crude product. This was purified by chromatography on a silica gel column to yield 0.65 g (3.3 mmol, 67% yield) of **5** (*cis*/*trans*=1.7/1). The *cis* and *trans* mixture can be separated into each isomer by preparative GLC (PEG 20 M, ratio of the retention times: *cis*/*trans*=1.14). Physical data are: **5a**, n_D^{20} 1.4530; d_4^{20} 0.8891 and **5b**, n_D^{20} 1.4520; d_4^{20} 0.8908. IR (neat, cm^{-1}): 1090 (ν_{SiO}), 1255 (ν_{SiMe}), 820 (ν_{SiMe}). Found **5a**: C, 66.14; H, 12.25%. **5b**: C, 66.18; H, 11.86%. Calcd for $C_{11}H_{24}SiO$: 65.93; H, 12.07%.

Method B: Methanolysis of 1.39 g (8.19 mmol) of **2** (*cis*/*trans*=1) with 0.35 ml (8.7 mmol) of methanol in dry pentane in the presence of 0.09 g of 10% palladium on charcoal (10% Pd-C) gave **5** (1.7 g) as a crude product, which was subsequently treated with a silica gel column. Fractional distillation gave 0.89 g (4.5 mmol, 54% yield) of pure **5**, bp 120 °C (70 mmHg). The substance was identified by comparing its NMR, IR, and GLC with those of **5** prepared by method A.

Preparation and Separation of 4-t-Butyl-1-methyl-1-isopropoxy-1-silacyclohexane (4). 3.69 g (21.6 mmol) of **2** (*cis*/*trans*=1) was treated with 2 g (*ca.* 20 mmol) of isopropyl alcohol in 50 ml of dry pentane in the presence of 0.5 g of 10% Pd-C. After further work-up as described above, fractional distillation gave 2.60 g (10.7 mmol, 49.5% yield) of **4**, bp 108 °C (24 mmHg). The product was isolated and purified by preparative GLC (Apiezon L, ratio of retention times: **4a**/**4b**=1.25) to give 0.49 g of **4b**, n_D^{20} 1.4483; d_4^{20} 0.8714 and 0.57 g of **4a**, n_D^{20} 1.4486; d_4^{20} 0.8710, IR (neat cm^{-1}) 1030 (ν_{SiO}), 1255 (ν_{SiMe}), 815 (ν_{SiMe}). Found **4a**: C, 68.14; H, 12.25%. **4b**: C, 68.32; H, 12.25%. Calcd for $C_{13}H_{23}SiO$: C, 68.35; H, 12.35%.

Preparation and Separation of 4-t-Butyl-1-methyl-1-t-butoxy-1-silacyclohexane (6). 25 ml of pentane, 0.4 ml (2.5 mmol) of triethylsilane and 3 ml (30 mmol) of *t*-butyl alcohol were treated with 0.5 g of 10% Pd-C. When vigorous evolution of hydrogen ceased 1.7 g (9.8 mmol) of **2** (*cis*/*trans*=1) was added to the mixture which was kept standing overnight under nitrogen. After a similar work-up, fractional distillation gave 2.1 g (8.7 mmol, 85% yield) of **6**, bp 145 °C (70 mmHg). This was separated to each isomer with preparative GLC (Apiezon L, ratio of retention times: **6a**/**6b**=1.22), giving 0.41 g of **6a**, n_D^{20} 1.4484, d_4^{20} 0.8680; and 0.22 g of **6b**, n_D^{20} 1.4510, d_4^{20} 0.8727.

IR (neat cm^{-1}) 1050 (ν_{Si-O}), 1250 (ν_{SiMe}), 820 (ν_{SiMe}). Found: **6a**: C, 69.69, H, 12.56%. **6b**: C, 69.14; H, 12.45%. Calcd for $C_{14}H_{30}SiO$: C, 69.35; H, 12.47%.

Preparation and Separation of 4-t-Butyl-1-methyl-1-phenyl-1-silacyclohexane (7). *Method A*: Phenylation of 3.1 g (16.4 mmol) of **11** with 25 ml (0.87 M, 20.1 m eq.) of phenyllithium in ether, followed by fractional distillation, gave 2.5 g (9.5 mmol, 58% yield) of **7**, bp 145 °C (35 mmHg). This was further purified by preparative GLC (Apiezon L, ratio of retention times: **7a**/**7b**=1.26) to give 0.78 g of **7a**: n_D^{20} 1.5173; d_4^{20} 0.9345, and 0.36 g of **7b**: n_D^{20} 1.5174; d_4^{20} 0.9333, IR (neat, cm^{-1}): 1436, 1115 (SiPh); 1250 (ν_{SiMe}), 800 (ν_{SiMe}). Found **7a**: C, 77.79, H, 10.72%. **7b**: C, 77.72; H, 10.92%. Calcd for $C_{16}H_{26}Si$: C, 77.97; H, 10.63%.

Preparation and Separation of 4-t-Butyl-1-methyl-1-(p-bromophenyl)-1-silacyclohexane (8). *p*-Bromophenyllithium was prepared from 10.5 g (10.5 mmol) of 1,4-dibromobenzene and 10 m eq. of butyllithium in ether by Gilman's method.[21] To the ethereal solution of *p*-bromophenyllithium was added 1.5 g (8.0 mmol) of **11**. The reaction mixture was refluxed overnight under nitrogen. Further work-up and evaporation of the solvent gave 3.3 g of a residual material. This was purified with a silica gel column to give 2.6 g (8.0 mmol, 100% yield) of **8** (*cis*/*trans*=1.86/1) as a pale yellow oil which solidified readily. Further purification of 1.2 g of **8** by preparative GLC (Apiezon L, ratio of retention times: **8a**/**8b**=1.24) gave 176 mg of **8a** (mp 39—40 °C after recrystallization from ethanol) and 77 mg of **8b** (mp 84—85 °C, after recrystallization from ethanol). Found **8a**: C, 59.24; H, 7.78%. **8b**: C, 59.31; H, 8.01%. Calcd for $C_{16}H_{25}SiBr$; C, 59.06; H, 7.74%.

Preparation and Separation of 4-t-Butyl-1-p-Chlorophenyl-1-methyl-1-silacyclohexane (9). *p*-Chlorophenylmagnesium chloride in THF was prepared from 7 g (47.5 mmol) of 1,4-dichlorobenzene and 1 g (40 mg-atom) of magnesium. By a similar procedure to that given above, followed by purification by preparative GLC (Apiezon L, ratio of retention times: **9a**/**9b**=1.20), 0.85 g (4.5 mmol) of **11** gave *ca.* 40 mg of **9a** (mp 30 °C) and 10 mg of mixture of **9a** and **9b**. Calcd for $C_{16}H_{25}SiCl$: C, 68.41; H, 9.06%. Mixture of **8a** and **8b**; C, 68.49; H, 9.20%.

Preparation of cis-*4-t-Butyl-1-methyl-1-silacyclohexane (2a).* A mixture of 0.56 g (2.26 mmol) of **4a** and 1 g (26.4 mmol) of lithium aluminum hydride in 100 ml of ether was refluxed for 10 h and hydrolyzed. After work-up, 0.26 g (1.54 mmol, 68% yield) of pure **2a** was obtained. The structure of **2a** was confirmed by its IR and NMR spectra, and retention time of GLC.

Preparation of trans-*4-t-Butyl-1-methyl-1-silacyclohexane (2b).* Reduction of 0.44 g (1.8 mmol) of **4b** with 1 g (26.4 mmol) of lithium aluminum hydride by refluxing in THF for 10 h gave 0.23 g (1.3 mmol 75% yield) of pure **2b**. The structure of **2b** was confirmed by its IR and NMR spectra, and retention time of GLC.

The authors are grateful to Toshiba Silicone Co. Ltd., for a gift of chlorosilanes.

(Received June 10, 1976)

2-Amino-2,3-dideoxy-L- and -D-ribohexose ($\mathbf{1}_L$ and $\mathbf{1}_D$) were synthesized from 2-amino-2-deoxy-L- and -D-glucose, respectively, through a reaction sequence which involves 3-O→2-N acetyl migration of methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-L- and -D-glucopyranoside ($\mathbf{3}_L$ and $\mathbf{3}_D$). A preparative method of methyl 4,6-di-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside ($\mathbf{11}_D$) is given.

In a program directed towards the synthesis of deoxy variants of streptomycin, Sano *et al.*[1] reported a novel method for the preparation of 2-amino-2,3-dideoxy-L-ribohexose ($\mathbf{1}_L$) from 2-amino-2-deoxy-L-glucose achieved without protection of the anomeric hydroxyl group throughout the reaction sequence. In the present paper we wish to report an alternative method for the preparation of $\mathbf{1}_L$ from 2-amino-2-deoxy-L-glucose by utilizing O→N acetyl migration. The same synthesis for the D-sugar ($\mathbf{1}_D$) is also described.

Results and Discussion

2-Amino-2-deoxy-L-glucose ($\mathbf{2}_L$) was prepared from L-arabinose by the method of Kuhn and Kirschenlohr.[2] Treatment of the hydrochloride of $\mathbf{2}_L$ with acetyl bromide followed by treatment with methanol according to the method for the corresponding D-sugar described by Irvine *et al.*[3] and Wolfrom and Shen Han[4] gave methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-L-glucopyranoside ($\mathbf{3}_L$) hydrobromide. Treatment of the hydrobromide with 5% aqueous sodium carbonate gave the free base ($\mathbf{3}_L$) in 93% yield, O→N acetyl migration being successfully avoided. Fodor and Oetvoes[5] obtained the corresponding D-sugar base from its hydrobromide by treatment with sodium methoxide in chloroform in 97% yield.

The regiospecific removal of the acetyl group at C-3 of $\mathbf{3}_L$ by utilizing O→N acetyl migration was studied in detail. Fodor *et al.*[5,6] reported that the behavior of ethyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucoside in organic solvents (methanol, ethanol, and acetone) is complicated and that O→N acetyl migration or deacetylation occurs as the main reaction, depending on the reaction conditions (solvents, their dryness, and temperature). We further attempted the O→N acetyl migration of $\mathbf{3}_L$ in pyridine,[7] toluene, and diglyme, but without success. However, we found that, with *N,N*-dimethylformamide (DMF) at reflux temperature, $\mathbf{3}_L$ was converted into the migration product, methyl 2-acetamido-4,6-di-*O*-acetyl-2-deoxy-β-L-glucopyranoside ($\mathbf{4}_L$) in a high yield (72%).

It should be noted that, in ethanol at room temperature, deacetylation at C-3 of methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside ($\mathbf{3}_D$) takes place almost completely to afford methyl 4,6-di-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside ($\mathbf{11}_D$) in a 93% yield, in accord with the result reported by Fodor and Oetvoes.[5]

Tosylation or mesylation of $\mathbf{4}_L$ was readily achieved by the conventional method to give the 3-*O*-tosylate ($\mathbf{5}_L$) or 3-*O*-mesylate ($\mathbf{6}_L$). Iodination with sodium iodide in DMF gave the 3-iodo derivative ($\mathbf{7}_L$), which was then hydrogenolyzed with Raney nickel to afford methyl 2-acetamido-4,6-di-*O*-acetyl-2,3-dideoxy-β-L-ribohexopyranoside ($\mathbf{8}_L$). To confirm the structure, $\mathbf{8}_L$ was de-*O*-acetylated and the *N*-acetyl derivative ($\mathbf{9}_L$) was acetonated with 2,2-dimethoxypropane to give $\mathbf{10}_L$. The position of the isopropylidene group in the derivative was determined by PMR studies; the large coupling constants of H-3_{ax} ($J=\approx 11$ Hz) indicated the 3-deoxy-4,6-*O*-isopropylidene, not 4-deoxy-3,6-*O*-isopropylidene, structure.

Finally acid hydrolysis of $\mathbf{8}_L$ was carried out in 1 M hydrochloric acid at 110 °C to afford 2-amino-2,3-dideoxy-L-ribohexose ($\mathbf{1}_L$), which shows a specific rotation numerically compatible with that of D-isomer[8] but opposite in direction.

2-Amino-2,3-dideoxy-D-ribohexose ($\mathbf{1}_D$) and the intermediates of D-series were prepared in a similar manner to that described in the preparation of the corresponding L-series.

Experimental

General. Melting points were determined on a Kofler block and are uncorrected. Infrared spectra were recorded for potassium bromide pellets with a Hitachi Model 285 grating

infrared spectrophotometer. PMR spectra were recorded a 60 and 100 MHz with Hitachi R-24A and Varian XL-100 spectrometers. Thin layer chromatography was performed on Wakogel B-5 with sulfuric acid spray for detection. For column chromatography, silica gel (Wakogel C-200) was used.

*Methyl 3,4,6-Tri-*O*-acetyl-2-amino-2-deoxy-β-*L*- and* D*-glucopyranoside (**3**$_L$ and **3**$_D$).* Acetyl bromide (15.4 ml) was added to a well dried (dried *in vacuo* at 60 °C for 2 h in the presence of P_2O_5) 2-amino-2-deoxy-L-glucose (**2**$_L$) hydrochloride (4.8 g), and the mixture in a sealed tube was allowed to stand at room temperature for 3 days. Deposition of deep-brown needles was observed. The reaction mixture was concentrated *in vacuo*. To the resulting solid were added methanol (200 ml) and pyridine (20 ml) and the solution was allowed to stand for 30 min at room temperature. After concentration of the solution, the residue hydrobromide was suspended in chloroform (250 ml) and the mixture was washed with 5% aqueous sodium carbonate and water. The chloroform layer was dried over sodium sulfate, and concentrated to give crystals (6.3 g, 93%). Recrystallization from hexane–chloroform gave needles of **3**$_L$; mp 152.5—153 °C, $[\alpha]_D^{24}$ −17.5° (*c* 1, methanol). IR: 1750 (OAc), 1605 (NH_2) cm^{-1}. PMR ($CDCl_3$): δ 1.40 (2H s, disappeared on deuteration), 2.05 (3H s, Ac), 2.10 (6H s, Ac), 2.95 (1H q, *J*=8 and 10.5 Hz, H-2), 3.61 (3H s, OCH_3), 4.0—4.55 (2H double q, *J*=3, 4.5, and 12 Hz, H-6,6′), 4.21 (1H d, *J*=8 Hz, H-1), 4.99—5.17 (2H m, H-3, 4). Irradiation at δ 5.1 caused the quartet at 2.95 to collapse to a doublet. Irradiation at δ 2.95 caused the doublet at δ 4.21 to collapse to a singlet.

Found: C, 48.84; H, 6.56; N, 4.29%. Calcd for $C_{13}H_{21}NO_8$: C, 48.90; H, 6.63; N, 4.39%.

3$_D$: mp 151—152 °C (lit,[5] 152 °C), $[\alpha]_D^{27}$ +15° (*c* 1, methanol) (lit,[5] +10° (methanol)).

Found: C, 49.20; H, 6.58; N, 4.14%.

*Methyl 2-Acetamido-4,6-di-*O*-acetyl-2-deoxy-β-*L*- and* D*-glucopyranoside (**4**$_L$ and **4**$_D$).* A solution of **3**$_L$ (4.30 g) in dry DMF (86 ml) was refluxed for 4 h. On being subjected to TLC with chloroform–acetone (1: 1), **3**$_L$ (R_f 0.5) almost disappeared and **4**$_L$ (R_f 0.25) appeared. Concentration of the solution under reduced pressure gave a residue, which was dissolved in methanol (200 ml). The solution was decolorized with charcoal and concentrated to give a solid, which was recrystallized from hexane–chloroform to give needles (2.36g). Concentration of the mother liquor gave a syrup, which was chromatographed on a silica gel column with chloroform–acetone (2: 1) as a developer to give **4**$_L$ (720 mg) and **3**$_L$ (111 mg). Total yield of **4**$_L$ was 72%. Mp 172.5—173 °C, $[\alpha]_D^{24}$ +35° (*c* 1, methanol). IR: 3430 (OH), 1740 (OCO); 1620, 1560 (NHCO) cm^{-1}. PMR ($(CD_3)_2SO$): δ 1.81 (3H s, Ac), 2.02 and 2.03 (each 3H s, Ac), 3.33 (3H s, OCH_3), 3.35—3.75 (3H m, H-2,3,5), 3.85—4.25 (2H double q, *J*=3, 5, and 12 Hz, H-6,6), 4.35 (1H d, *J*=8 Hz, H-1), 4.63 (1H q, *J*=8 and 10 Hz, H-4), 5.28 (1H d, *J*=5 Hz, disappeared on deuteration), 7.75 (1H d, *J*=8 Hz, disappeared on deuteration). Irradiation at δ 3.5 caused the doublets at δ 4.35, 5.28, and 7.75 collapsed to singlets, respectively.

Found: C, 48.93; H, 6.58; N, 4.25%. Calcd for $C_{13}H_{21}NO_8$: C, 48.89; H, 6.64; N, 4.39%.

4$_D$: mp 173—173.5 °C, $[\alpha]_D^{27}$ −38° (*c* 1, methanol).

Found: C, 48.98; H, 6.50; N, 4.33%.

*Methyl 2-Acetamido-4,6-di-*O*-acetyl-2-deoxy-3-*O*-tosyl-β-*L*- and* D*-glucopyranoside (**5**$_L$ and **5**$_D$).* *p*-Toluenesulfonyl chloride (840 mg) was added to a cold solution of well dried **4**$_L$ (700 mg) in dry pyridine (14 ml), and the solution was allowed to stand at −10 °C overnight. The solution showed a single spot at R_f 0.57 on being subjected to TLC with chloroform–tacetone (2: 1). After addition of water (0.2 ml), the mixture was concertrated and coevaporated with toluene. The residue was extracted with ethyl acetate. The solution was washed successively with 0.4 M potassium hydrogensulfate, aqueous sodium hydrogencarbonate, and water, dried over sodium sulfate and concentrated. The residue was recrystallized from hexane–ethyl acetate to give needles, 638 mg (61%); mp 137—138.5 °C (dec), $[\alpha]_D^{24}$ +18° (*c* 1, methanol). PMR ($CDCl_3$): δ 1.91 (6H s, Ac), 2.06 (3H s, Ac), 2.46 (3H s, $C_6H_4CH_3$), 3.54 (3H s, OCH_3), 4.90 (1H d, *J*=8.5 Hz, H-1). 5—5.5 (2H m, H-3,4).

Found: C, 50.57; H, 5.73; N, 2.71; S, 6.91%. Calcd for $C_{20}H_{27}NO_{10}S$: C, 50.73; H, 5.75; N, 2.96; S, 6.77%.

5$_D$: mp 138—139 °C (dec), $[\alpha]_D^{27}$ −22° (*c* 1, methanol).

Found: C, 50.87; H, 5.79; N, 2.74; S, 6.61%.

*Methyl 2-Acetamido-4,6-di-*O*-acetyl-2-deoxy-3-*O*-mesyl-β-*L*- and* D*-glucopyranoside (**6**$_L$ and **6**$_D$).* Compounds **4**$_L$ and **4**$_D$ were treated as described above for **5**$_L$ using methanesulfonyl chlororide instead of *p*-toluenesulfonyl chloride to give **6**$_L$ and **6**$_D$ (~80%), respectively.

6$_L$: mp 157—158 °C (dec), $[\alpha]_D^{23}$ +20° (*c* 1, methanol).

Found: C, 42.47; H, 5.65; N, 3.23; S, 8.17%. Calcd for $C_{14}H_{23}NO_{10}S$: C, 42.31; H, 5.83; N, 3.52; S, 8.07%.

6$_D$: mp 158—159.5°C (dec), $[\alpha]_D^{27}$ −20° (*c* 1, methanol).

Found: C, 42.25; H, 5.65; N, 3.35; S, 8.24%.

*Methyl 2-Acetamido-4,6-di-*O*-acetyl-2,3-dideoxy-3-iodo-β-*L*- and* D*-gluco and/or allopyranoside (**7**$_L$ and **7**$_D$).* To a solution of **5**$_L$ (1.01 g) in dry DMF (20 ml) was added dry sodium iodide (10 g) and after displacement of the air in the reaction vessel with nitrogen, the mixture was heated in a tightly stoppered vessel at 100 °C for 2 h. Chloroform (200 ml) was added and the mixture was filtered. The organic layer was washed successively with water, aqueous 20% sodium thiosulfate, and water, and dried over sodium sulfate. The solution showed, on being subjected to TLC with chloform–ether (1: 1), a single spot at R_f 0.15 (*cf.* **5**$_L$: R_f 0.1). Concentration of the solution gave a solid of **7**$_L$, 677 mg (74%); mp 186—188 °C (dec), $[\alpha]_D^{24}$ +5° (*c* 1, methanol).

Found: C, 36.35; H, 4.63; N, 3.20; I, 29.20%. Calcd for $C_{13}H_{20}INO_7$: C, 36.38; H, 4.70; N, 3.26; I, 29.51%.

7$_D$: mp 184—186 °C (dec), $[\alpha]_D^{26}$ −7.5° (*c* 1, methanol).

Found: C, 36.75; H, 4.80; N, 2.95; I, 29.24%.

*Methyl 2-Acetamido-4,6-di-*O*-acetyl-2,3-dideoxy-β-*L*- and* D*-ribohexopyranoside (**8**$_L$ and **8**$_D$).* To a solution of **7**$_L$ (582 mg) in aqueous dioxane (1: 9, 10 ml) was added sodium hydrogencarbonate (40 mg) and the mixture was hydrogenated over Raney nickel under pressure (50 lb/in²) at room temperature for 3 h. Filtration followed by evaporation gave a syrup, which was chromatographed on a silica gel column with ethyl acetate to give a solid of **8**$_L$, 298 mg (72%), mp 150—150.5 °C, $[\alpha]_D^{24}$ +43° (*c* 1, methanol). PMR (DMF-d_7): δ 1.60 (1H q, *J*=≈11.5 Hz, H-3_{ax}), 1.88 (3H s, Ac), 2.07 (6H s, AcO), 2.37 (1H double t, *J*=5 and 12 Hz, H-3_{eq}), 3.43 (3H s, OCH_3), octet centered at 4.22 (q in higher field, *J*=3 and 12 Hz; q in lower field, *J*=5 and 12 Hz, H-6,6′), 4.49 (1H d, *J*=8 Hz, H-1), 4.72 (1H octet, *J*=5, 10, and 11 Hz, H-4), 7.97 (1H broad d, *J*=≈8 Hz, NH). Irradiation of H-4 caused the signal of H-3_{ax} and H-3_{eq} to collapse to a triplet (*J*=≈11 Hz) and a quartet (*J*=5 and 12 Hz), respectively.

Found: C, 51.65; H, 6.92; N, 4.53%. Calcd for $C_{13}H_{21}NO_7$: C, 51.48; H, 6.98; N, 4.62%.

8$_D$: mp 149—149.5 °C, $[\alpha]_D^{27}$ −44° (*c* 1, methanol).

Found: C, 51.41; H, 6.91; N, 4.53%.

*Methyl 2-Acetamido-2,3-dideoxy-β-*L*-ribohexopyranoside (**9**$_L$).* To a solution of **8**$_L$ (64 mg) in dry methanol (2 ml) was added a piece of sodium metal. After 5 min, the solution was

neutralized with Amberlite CG 50 (H form, pretreated with methanol) and concentrated. The residue was recrystallized from ethanol–ether to give needles of $\mathbf{9}_L$, 39 mg (85%); mp 152—153 °C, $[\alpha]_D^{23}$ +58° (*c* 1, methanol). IR: 1560, 1650 cm^{-1}. PMR ($CDCl_3$): δ 1.92 (3H s, Ac), 4.28 (1H d, J=8 Hz, H-1).

Found: C, 49.09; H, 7.73; N, 6.16%. Calcd for $C_9H_{17}NO_5$: C, 49.31; H, 7.82; N, 6.39%.

*Methyl 2-Acetamino-2,3-dideoxy-4,6-O-isopropylidene-β-L-ribo-hexopyranoside (**10**$_L$).* To a solution of $\mathbf{9}_L$ (27 mg) in DMF (1 ml) were added 2,2-dimethoxypropane (0.1 ml), molecular sieves 5A, and a trace amount of *p*-toluenesulfonic acid and the solution was allowed to stand at 25 °C for 3 h. The solution showed, on being subjected to TLC with chloroform–methanol (5: 1), a single spot at R_f 0.42 (*cf.* $\mathbf{7}_L$: R_f 0.1). After addition of triethylamine (0.1 ml), the mixture was filtered and concentrated. The residue was purified by passing through a short column of silica gel with chloroform–methanol (15: 1) to give a syrup, which, on standing, crystallized into prisms, 30 mg (95%); mp 148—149 °C, $[\alpha]_D^{23}$ +81° (*c* 1, methanol). PMR ($CDCl_3$): δ 1.41 and 1.50 (each 3H s, $C(CH_3)_2$), 1.54 (1H q, J=12 Hz, H-3_{ax}), 1.99 (3H s, Ac), 2.36 (1H double t, J=≈4.5×2 and 12 Hz, H-3_{eq}), 3.48 (3H s, OCH_3), 4.34 (1H d, J=8 Hz, H-1).

Found: C, 55.31; H, 7.97; N, 5.30%. Calcd for $C_{12}H_{21}NO_5$: C, 55.58; H, 8.16; N, 5.40%.

*2-Amino-2,3-dideoxy-L- and D-ribohexose (**1**$_L$ and **1**$_D$) Hydrochloride.* A solution of $\mathbf{8}_L$ (100 mg) in 1 M hydrochloric acid (2 ml) was heated at 110 °C for 2 h in the atmosphere of nitrogen in a sealed tube. Water (20 ml×2) was added to the reaction mixture which was then concentrated. To the concentrate (~0.5 ml) were added methanol and acetone to give a syrup, which was dissolved in methanol and decolorized with charcoal. The solution was concentrated to give a residue which was recrystallized from methanol–acetone to give needles of $\mathbf{1}_L$ hydrochloride, 31 mg. Another crop (15 mg) was obtained from the mother liquor. Total yield was 72%, mp 150—160 °C (gradually decomposes), $[\alpha]_D^{23}$ −49° (*c* 1, water, final value). R_f 0.30 (TLC with ethyl acetate–pyridine–acetic acid–water 5: 5: 1: 3) (*cf.* 2-amino-2-deoxy-L-glucose hydrochloride: R_f 0.27).

Found: C, 36.32; H, 6.94; N, 6.89; Cl, 17.81%. Calcd for $C_6H_{13}NO_4 \cdot HCl$: C, 36.10; H, 7.07; N, 7.02; Cl, 17.76%.

$\mathbf{1}_D$: $[\alpha]_D^{23}$ +43° (*c* 0.3, water, final value) (lit,[8] +43.9° (water)).

*Methyl 4,6-Di-O-acetyl-2-amino-2-deoxy-β-D-glucopyranoside (**11**$_D$).* A solution of $\mathbf{3}_D$ (1.83 g) in ethanol (200 ml) was kept at room temperature for 2 days. Concentration of the solution gave a residue, which was recrystallized from hexane–chloroform to give plates, 1.71 g (93%), mp 138—139 °C, $[\alpha]_D^{23}$ −37° (*c* 1, methanol). PMR ($CDCl_3$): δ 2.08 and 2.13 (each 3H s, Ac), 2.35 (3H s, disappeared on deuteration, NH_2 and OH), 2.75 (1H q, J=8 and 10 Hz, H-2), 3.48 (1H t, J=10 Hz, H-3), 3.55 (3H s, OCH_3), 3.65 (1H m, H-5), 4.12 (1H d, J=8 Hz, H-1), 4—4.55 (2H double q, J=3, 4.5 and 12 Hz, H-6,6′), 4.87 (1H t, J=10 Hz, H-4). Irradiation of H-2 caused the signals of H-1 (δ 4.12) and H-3 (δ 3.48) to collapse to a singlet and a doublet, respectively, but the signals of H-4 (δ 4.87) remained unchanged.

Found: C, 47.35; H, 6.62; N, 4.76%. Calcd for $C_{11}H_{19}NO_7$: C, 47.65; H, 6.91; N, 5.05%.

Aminocyclitols. 34. Synthesis of Inosadiamine-1,4 Derivatives

Kinnichi TADANO, Takaaki SHIRATORI, and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received June 19, 1976)

Three new inosadiamine-1,4 derivatives have been prepared by nitromethane cyclization of a dialdehyde obtained by periodate oxidation of 1,4-di-*O*-methyl-(1,2,3,4,5/0)-5-acetamido-1,2,3,4-cyclopentanetetrol. The cyclization product was catalytically hydrogenated and subsequently acetylated to give three inosadiamine derivatives. Their structures were established by PMR spectra as *myo*-2,5, *epi*-1,4, and *cis*-inosadiamine-1,4 derivatives.

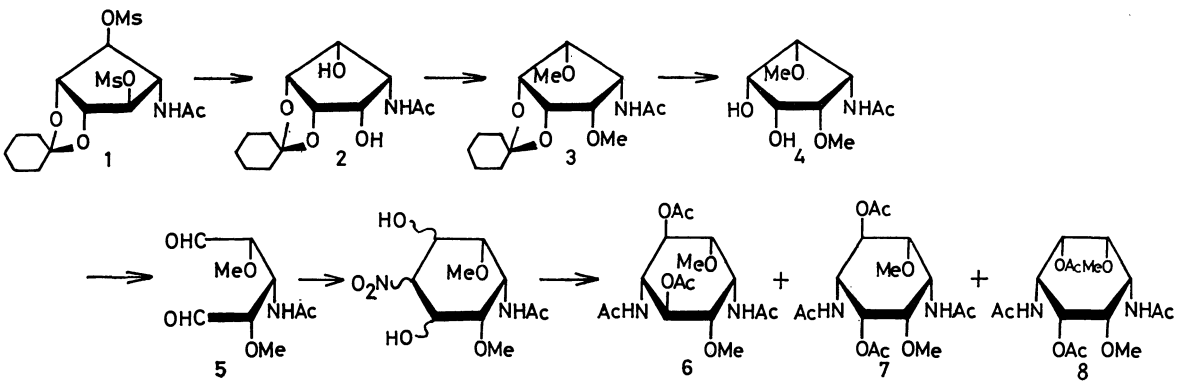
In connection with the results given in the preceding paper,[1] we have prepared three inosadiamine-1,4-derivatives: 1,3-di-*O*-methyl-*myo*-inosadiamine-2,5 (**6**), 3,5-di-*O*-methyl-*epi*-inosadiamine-1,4 (**7**) and 3,5-di-*O*-methyl-*cis*-inosadiamine-1,4 derivatives (**8**), by the nitromethane cyclization of dialdehyde (**5**).

When the starting material 2,3-*O*-cyclohexylidene-1,4-di-*O*-mesyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol[2] (**1**) was subjected to displacement of the sulfonyloxy groups by heating in water in the presence of sodium acetate, 2,3-*O*-cyclohexylidene-(1,2,3,4,5/0)-5-acetamido-1,2,3,4-cyclopentanetetrol (**2**) was obtained in 72% yield. *O*-Methylation of **2** afforded the 1,4-di-*O*-methyl derivative (**3**), which was further converted to 1,4-di-*O*-methyl-(1,2,3,4,5/0)-5-acetamido-1,2,3,4-cyclopentanetetrol (**4**) by hydrolysis. Oxidation of **4** by sodium metaperiodate yielded the dialdehyde (**5**) as a syrup. Cyclization of **5** with nitromethane in the presence of sodium methoxide gave deoxynitroinosamine derivatives, which were catalytically hydrogenated and subsequently acetylated. The product was purified by column chromatography to give the three products **6**, **7**, and **8**.

Results and Discussion

Since three new chiral centers are introduced in the products, it is possible for six diastereomers to occur in the reaction: *allo*-2,5, *cis*-1,4, *epi*-1,4, *epi*-3,6, *myo*-2,5 and *neo*-inosadiamine-2,5 derivative.

The PMR spectrum of **6** revealed three signals due to the four acetyl groups. Unequivocal distinction between the signal of an acetoxyl and that of an acetamido group was established by means of deuterioacetylation technique.[3] The two signals at δ 1.85 and 2.00 are attributable to the two acetamido groups and the signal at δ 2.04 is ascribed to the two equatorial acetoxyl groups.[4] The results are summarized in Table 1. The two methoxyl groups revealed their signal at δ 3.38 as a singlet. This indicates that these



Scheme 1.

TABLE 1. CHEMICAL SHIFTS OF METHYL PROTONS IN DMSO-d_6

Compound	Acetamido		Acetoxyl		Methoxyl
	equatorial	axial	equatorial	axial	
6: *myo*-2,5	1.85 (3H)[a]	2.00 (3H)	2.04 (6H)		3.38 (6H)
12	1.84 (3H)	2.00 (3H)			3.34 (6H)
7: *epi*-1,4	1.87 (3H)	2.02 (3H)	2.05 (3H)	2.23 (3H)	3.38 (3H), 3.39 (3H)
13	1.87 (3H)	2.03 (3H)			3.40 (3H), 3.42 (3H)
8: *cis*-1,4	1.85 (3H)	2.02 (3H)	2.09 (6H)		3.51 (6H)
14	1.85 (3H)	2.02 (3H)			3.51 (6H)

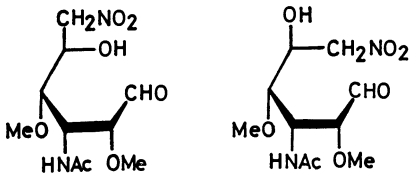
a) Peak positions are given in δ values, the number of protons being given in parentheses.

* To whom correspondence should be addressed.

methoxyl groups are located in an equivalent state. Hence, *myo*-2,5 and *cis*-1,4 configurations are conceivable. The signal of the two ring protons on the carbons which bear the acetoxyl groups appeared at δ 5.35 (J=10 Hz) as a triplet, indicating that *trans* configurations exsist between the acetoxyl and the methoxyl groups, and between the acetoxyl and the newly introduced acetamido groups. Furthermore, the two ring protons on the carbons which bear the methoxyl groups revealed their signal at δ 3.62 as double doublet (J=10 and 3 Hz), suggesting a *cis*-configuration between the methoxyl and another acetamido group. Thus, the configuration of *myo*-inosadiamine-2,5 was established for **6**.

The PMR spectrum of **7** revealed four signal at δ 1.87, 2.02, 2.05, and 2.23 for the four acetyl groups. The first two peaks are attributed to an equatorial and an axial acetamido group, respectively, the last two peaks to an equatorial and an axial acetoxyl group, respectively. The two methoxyl groups showed their signals at δ 3.38 and 3.39, indicating a nonequivalent conformation of the surroundings. Thus, **7** was assigned to be *epi*-inosadiamine-1,4 derivative.

The PMR spectrum of **8** revealed two signals at δ 1.85 and 2.02 for the two acetamido groups, and a signal at δ 2.09 for the two acetoxyl groups. The signal of the two methoxyl groups appeared at δ 3.51. These data indicate a symmetrical structure of **8**, *cis*-inosadiamine-1,4 being proposed for the configuration.



D-*allo* L-*talo*

Scheme 2.

The analogous reaction mechanism[1,5] is proposed for the present nitromethane cyclization. That is the initial step of the reaction is an addition between nitromethane and one of the two aldehyde groups of **5**, giving two diastereomers: D-*allo* and L-*talo* type intermediates. The second step of the reaction is an intramolecular cyclization of the intermediates to give *cis*-1,4 and *epi*-1,4 from the D-*allo*, and *epi*-1,4 and *myo*-2,5 from the L-*talo* intermediate.

Experimental

All the melting points were determined in capillary tubes, and are uncorrected. Solutions were evaporated under reduced pressure. De-*O*-acetylation was carried out in methanolic ammonia at ambient temperature. PMR spectra were measured at 60 MHz on a Varian A-60D spectrometer in dimethyl-d_6 sulfoxide with tetramethylsilane as an internal standard. The peak positions are given in δ values.

2,3-O-Cyclohexylidene-(1,2,3,4,5/0)-5-acetamido-1,2,3,4-cyclopentanetetrol (2). 2,3-*O*-Cyclohexylidene-1,4-di-*O*-mesyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol[2] (**1**, 20.0 g) and sodium acetate (97.0 g) were heated in boiling water (300 ml) under reflux for 16 h. After cooling to ambient temperature, the solution was repeatedly extracted with chloroform. The resulting solution was dried over anhydrous sodium sulfate and evaporated. The residue was recrystallized from ethyl acetate to give 9.20 g (72%) of **2**, mp 170—171 °C.

Found: C, 57.80; H, 7.81; N, 5.11%. Calcd for $C_{13}H_{21}NO_5$: C, 57.55; H, 7.80; N, 5.16%.

1,4-Di-O-methyl-(1,2,3,4,5/0)-5-acetamido-1,2,3,4-cyclopentanetetrol (4). A mixture of **2** (10.8 g), methyl iodide (11.0 ml) and silver oxide (22.0 g) in *N,N*-dimethylformamide (100 ml) was stirred for 10 h in the dark, and an insoluble matter was removed by filtration. The filtrate was evaporated to give 2,3-*O*-cyclohexylidene-1,4-di-*O*-methyl-(1,2,3,4,5/0)-5-acetamido-1,2,3,4-cyclopentanetetrol (**3**) as a syrup (13.4 g). PMR ($CDCl_3$) δ 1.99 (s, 3, NAc), 3.40 (s, 6, $2OCH_3$).

Compound **3** (13.4 g) was heated under reflux for 2 h in 0.1 M hydrochloric acid (105 ml), and the solution was evaporated to give a crystalline residue (10.1 g). Recrystallization from benzene afforded 6.28 g (72% from **2**) of **4**, mp 123—125 °C.

Found: C, 49.03; H, 7.60; N, 6.17%. Calcd for $C_9H_{17}NO_5$: C, 49.30; H, 7.82; N, 6.39%.

*3-Acetamido-2,4-di-O-methyl-3-deoxy-*ribo*-pentodialdose (5).* Compound **4** (1.50 g) was added with mechanical agitation under ice cooling to a solution of sodium metaperiodate (1.61 g) in cold water (20 ml). The solution was left to settle overnight at ambient temperature. After being neutralized with sodium hydrogen carbonate, the solution was filtered. The filtrate was evaporated to give **5** as a crude residue. The product was used for a successive reaction without purification.

Nitromethane Cyclization of 5. To a solution of **5** (1.48 g) and nitromethane (0.74 ml) in methanol (6.0 ml), 1.4 M methanolic sodium methoxide (10 ml) was added under ice cooling with agitation. After being left to settle in a refrigerator overnight, the solution was evaporated. The residue was hydrogenated in 20% aqueous acetic acid (12 ml) in the presence of Raney nickel T-4[6] at 3.4 kg/cm^2 of hydrogen atmosphere with a Parr apparatus for 16 h. After the catalyst was removed by filtration, the filtrate was evaporated. The residue was acetylated with acetic anhydride in pyridine in the usual manner. The product was dissolved in 10 ml of benzene–ethanol (4: 1, v/v), and the solution was stored in a refrigerator for a few days to give 244 mg of tetra-*N,O*-acetyl-3,5-di-*O*-methyl-*cis*-inosadiamine-1,4 (**8**) as crystals.

The mother liquor was evaporated, and the residue was fractionated on a silica gel column (28×380 mm) in benzene–ethanol (5: 1, v/v). Each aliquot was monitored on TLC with the same solvent. The fractions (R_f 0.37 on TLC) were combined and evaporated to give 309 mg (12% from **4**) of tetra-*N,O*-acetyl-1,3-di-*O*-methyl-*myo*-inosadiamine-2,5 (**6**). A part of the product was recrystallized from ethanol to give an analytical sample, mp 203—205 °C.

Found: C, 51.50; H, 6.93; N. 7.35%. Calcd for $C_{16}H_{26}N_2O_8$: C, 51.33; H, 7.00; N, 7.48%.

The fractions (R_f 0.30 on TLC) gave 417 mg (16% from **4**) of tetra-*N,O*-acetyl-3,5-di-*O*-methyl-*epi*-inosadiamine-1,4 (**7**) as a syrup.

Found: C, 51.14; H, 6.88; N, 7.34%. Calcd for $C_{16}H_{26}N_2O_8$: C, 51.33; H, 7.00; N, 7.48%.

The fractions (R_f 0.22 on TLC) gave another crop (202 mg) of **8**. The total yield (446 mg) was 17% from **4**. A part of the product was recrystallized from benzene–ethanol (4: 1, v/v) to give an analytical sample, mp 290—292 °C.

Found: C, 51.06; H, 6.91; N, 7.33%. Calcd for $C_{16}H_{26}N_2O_8$: C, 51.33; H, 7.00; N, 7.48%.

*2,5-Di-*N*-acetyl-1,3-di-*O*-methyl-*myo*-inosadiamine-2,5 (9).*

Compound **6** (180 mg) was de-*O*-acetylated, and the product was recrystallized from ethanol to give 76 mg (54%) of **9**, mp 240—242 °C.

Found: C, 49.76; H, 7.57; N, 9.48%. Calcd for $C_{12}H_{22}N_2O_6$: C, 49.65; H, 7.64; N, 9.65%.

A 50 mg portion of **9** was acylated with acetic anhydride-d_6 (0.2 ml) in pyridine (1 ml), and the product was recrystallized from ethyl acetate to give 35 mg (53%) of 4,6-di-*O*-acetyl-d_3 derivative (**12**), mp 203—205 °C.

1,4-Di-N-*acetyl-3,5-di*-O-*methyl*-epi-*inosadiamine-1,4 (**10**).* Compound **7** (340 mg) was de-*O*-acetylated, and the product was recrystallized from ethyl acetate–ethanol (10: 1, v/v) to give 210 mg (80%) of **10**, mp 207—208°C.

Found: C, 49.45; H, 7.42; N, 9.76%. Calcd for $C_{12}H_{22}N_2O_6$: C, 49.65; H, 7.64; N, 9.65%.

An 80 mg portion of **10** was acylated with acetic anhydride-d_6 in pyridine, and the product was purified on a silica gel column in benzene–ethanol (5: 1, v/v) to give 83 mg (79%) of 2,6-di-*O*-acetyl-d_3 derivative (**13**) as a syrup.

1,4-Di-N-*acetyl-3,5-di*-O-*methyl*-cis-*inosadiamine-1,4 (**11**).* Compound **8** (400 mg) was de-*O*-acetylated, and the product was recrystallized from methanol to give 188 mg (61%) of **11**, mp above 295 °C.

Found: C, 49.40; H, 7.54; N, 9.48%. Calcd for $C_{12}H_{22}N_2O_6$: C, 49.65; H, 7.64; N, 9.65%.

A 50 mg portion of **11** was acylated with acetic anhydride-d_6 in pyridine, and the product was recrystallized from ethanol to give 32 mg (49%) of 2,6-di-*O*-acetyl-d_6 derivative (**14**), mp 290—292 °C.

New Sesquiterpene Lactones of Eremophilane-Type from *Ligularia Fauriei* (Fr.) Koidz.[1]

Yoshihiko Moriyama and Takeyoshi Takahashi

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 21, 1976)

Two new sesquiterpene lactones of eremophilane-type were isolated from *Ligularia Fauriei* (Fr.) Koidz., and their structures including absolute stereochemistry were shown to be 8β-hydroxyeremophil-7(11)-ene-12,8α;14β,6α-diolide (**1**) and eremophil-7(11)-ene-12,8α;14β,6α-diolide (**2**), respectively. The isolation of the two known lactones, 6β,8β-dihydroxyeremophil-7(11)-en-12,8α-olide (**3**) and 6β-hydroxyeremophil-7(11)-en-12,8α-olide (**4**), is also described. The photosensitized autoxidation of the known furanoeremophilan-14β,6α-olide (**5**) gave **1** and 8β-methoxyeremophil-7(11)-ene-12,8α;14β,6α-diolide (**18**).

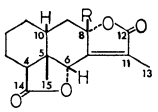
During chemical investigation on plants of the genus *Ligularia* (Compositae) and related plants,[2] two new sesquiterpene lactones were isolated from *Ligularia Fauriei* (Fr.) Koidz. In the present communication, the structure determination leading to 8β-hydroxyeremophil-7(11)-ene-12,8α; 14β,6α-diolide (**1**) and eremophil-7(11)-ene-12,8α; 14β,6α-diolide (**2**) for these sesquiterpenes is described.

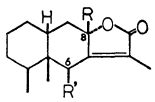
A benzene extract of the roots of the plant was subjected to separation by column chromatography on silica gel to give four sesquiterpene lactones (**1**, **2**, **3**, and **4**) in addition to the previously reported furanoeremophilan-14β,6α-olide (**5**).[3,4]

The lactone (**1**), mp 253.5—254 °C (dec), $[\alpha]_D$ +94° ($CHCl_3$), crystallized from a mixture of benzene and chloroform as colorless needles. The molecular formula of $C_{15}H_{18}O_5$ was determined by elemental analysis and the appearance of the molecular ion peak at *m/e* 278 in the mass spectrum. The IR, UV, and PMR spectra indicated the presence of a tertiary methyl, an olefinic methyl, an α,β-unsaturated γ-lactone,[5,6] a γ-lactone, and a hydroxyl group; signals due to a secondary methyl were absent (*cf.* Experimental). Acetylation of the lactone (**1**) with acetic anhydride in pyridine gave a monoacetate (**6**) showing no hydroxyl absorption in its IR spectrum. Based on these spectral data, the structure (**1**) is suggested for this lactone (**1**), providing that the lactone belongs to a sesquiterpene of eremophilane-type. The following evidence provides support for the proposed structure (**1**).

It has been reported that the autoxidation of atractylon (**7**) gives a lactone (**8**) and a hydroxylactone (**9**), and that the latter compound (**9**) in turn affords an unsaturated enol lactone (**10**) by dehydration.[7] Oxidation of atractylon (**7**) with dichlorodicyanobenzoquinone (DDQ) to yield **10** has also been described.[8] Furanoeremophilan-14β,6α-olide (**5**) with the known absolute stereochemistry[3] was treated with DDQ in dioxane to give an unsaturated enol lactone (**11**). The same compound (**11**) was obtained by dehydration of the lactone (**1**) with phosphorus oxychloride in pyridine. Irradiation of **5** in methanol with a high pressure mercury lamp under an oxygen atmosphere in the presence of Rose Bengal gave a compound identical with the lactone (**1**). The observation described above shows that the lactone (**1**) can be formulated as 8ξ-hydroxyeremophil-7(11)-ene-12,8α; 14β,6α-diolide. The β-configuration of the hydroxyl group at $C_{(8)}$ was suggested by the presence in the lactone (**1**) of a long-range spin-coupling (J=2 Hz) between the olefinic methyl ($C_{(11)}$–CH_3) protons and the allylic proton ($C_{(6\beta)}$)–H) at the lactone terminus. An examination of the stereostructure of **1** with 8β-OH by the use of Dreiding model shows that the angle between $C_{(6\beta)}$–H and $C_{(11)}$–CH_3 is around 90°, in agreement with the observed homoallylic spin-coupling constant.[9] In an alternative structure with 8α-OH, the angle lies around 30° and the corresponding homoallylic spin-coupling would be negligible.[9] This received support from the following observation.[10] Naya *et al.*[10] reported the presence of a homoallylic spin-coupling (J=1.0—1.5 Hz) between $C_{(6\alpha)}$–H and $C_{(11)}$–CH_3 in 6β-hydroxy-8α-methoxyeremophil-7(11)-en-12,8β-olide (**12**) and 6β-acetoxy-8α-methoxyeremophil-7(11)-en-12,8β-olide (**13**) whose structures were firmly established, while the absence of this long-range spin-coupling in 6β-hydroxy-8β-methoxyeremophil-7(11)-en-12,8α-olide (**14**) and 6β-acetoxy-8β-methoxyeremophil-7(11)-en-12,8α-olide(**15**). The angles between $C_{(6\alpha)}$–H and $C_{(11)}$–CH_3 were reported to be 90° and 20° for the 8α- (**12** and **13**) and 8β-methoxy (**14** and **15**) derivatives, respectively. Therefore, the structure including absolute stereochemistry of the lactone (**1**) should be represented by 8β-hydroxyeremophil-7(11)-ene-12,8α;14β,6α-diolide (**1**).

The molecular formula of $C_{15}H_{18}O_4$ was given for the lactone (**2**), mp 186—186.5 °C (dec.), $[\alpha]_D$+93°





1 R = OH

2 R = H

6 R = OAc

18 R = OMe

3 R = OH, R' = OH

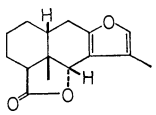
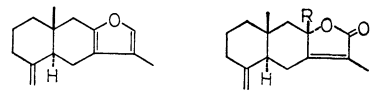
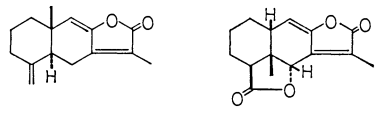
17 R = H, R' = H



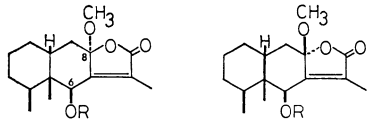
5



7 8 R = H 9 R = OH



10 11



12 R=H 13 R=Ac 14 R=H 15 R=Ac

($CHCl_3$). The spectral data suggested the presence of a tertiary methyl, an olefinic methyl, an α,β-unsaturated γ-lactone, and a γ-lactone grouping (*cf.* Experimental). No hydroxyl absorption was observed in the IR spectrum. In the PMR spectrum of the lactone (**2**) the signals due to the proton ($C_{(8)}$–H) at the unsaturated lactone terminus appeared at δ 4.75 as a multiplet, while the corresponding signals were absent in the spectrum of the lactone (**1**). Treatment of the lactone (**1**) with sodium borohydride in methanol containing sodium hydroxide gave the lactone (**2**). These results show that the lactone (**1**) contains one hydroxyl group more than the lactone (**2**), and that the hydroxyl group at $C_{(8)}$ of **1** must be replaced by a hydrogen atom in the case of the lactone (**2**). PMDR experiments revealed the presence in the lactone (**2**) of long-range spin-couplings of the olefinic methyl ($C_{(11)}$–CH_3) protons to the allylic proton ($C_{(6\beta)}$–H; J=2 Hz) and to the other allylic proton ($C_{(8)}$–H; J=2 Hz). This observation leads to the 8β-H configuration for the lactone (**2**).[9] Thus, the structure including absolute stereochemistry of the lactone (**2**) is shown to be eremophil-7(11)-ene-12,8α; 14β,6α-diolide (**2**).

The lactone (**3**), mp 217—218 °C (dec), $[\alpha]_D$ +82° (EtOH), gave a diacetate (**16**), mp 120.5—121 °C, by acetylation with acetic anhydride in pyridine. This lactone (**3**) proved to be identical with 6β,8β-dihydroxyeremophil-7(11)-en-12,8α-olide (**3**),[10] recently reported by Naya *et al.* The lactone (**4**), mp 207—207.5 °C, $[\alpha]_D$ +213° ($CHCl_3$), was found to be identical with 6β-hydroxyeremophil-7(11)-en-12,8α-olide (**4**).[6,10,11] The lactone (**3**) was treated with sodium borohydride in methanol containing sodium hydroxide to yield two products, which were shown to be **4** and eremophil-7(11)-en-12,8α-olide (**17**),[12,13] respectively. The similar treatment of **4** gave **17**.

The photosensitized autoxidation of **5** in methanol gave a compound (**18**), $C_{16}H_{20}O_5$, mp 184.5—185 °C, besides the lactone (**1**). The PMR spectrum of **18** indicated the presence of a methoxyl group. The multiplet due to 8β-H appeared in the spectrum of **2** is absent in that of **18**. The other spectral data of **2** and **18** were almost identical, showing the presence of the common groupings: a tertiary methyl, an olefinic methyl, an α,β-unsaturated γ-lactone, and a γ-lactone grouping (*cf.* Experimental). The extra methoxyl group of **18** must be located on $C_{(8)}$ of the structure moiety of **2**. The presence of a long-range spin-coupling (J=2 Hz) of the olefinic methyl ($C_{(11)}$–CH_3) protons to the allylic proton ($C_{(6\beta)}$–H) at the lactone terminus was observed for **18**.[9] Therefore, the structure of the photoproduct (**18**) should be represented by 8β-methoxyeremophil-7(11)-ene-12,8α; 14β,6α-diolide (**18**).

The two lactones (**1** and **2**)[14] represent the first examples of eremophilane-type sesquiterpenes with two lactone rings in their molecules.

Experimental

All mps were determined on a hot block and reported uncorrected. IR, UV, and mass spectra were recorded on Hitachi EPI-G2, Hitachi EPS-3, and Hitachi RMU-6 spectrometers, respectively. Measurements of optical rotation were carried out using a JASCO DIP-SL polarimeter. PMR spectra were taken on a Hitachi R-20 or a JEOL JNM-PS-100 spectrometer, using TMS as internal standard. Kieselgel G nach Stahl and Kieselgel 60 PF_{254} (Merck) were used for analytical and preparative TLC, respectively. For column chromatography Wakogel C-200 (Wako Pure Chemicals) was used.

Isolation of the Lactones (1, 2, 3, and 4). Dried roots (900 g) of *L. Fauriei* were extracted twice with hot benzene (2 l). The residue obtained after removal of the solvent was chromatographed on a column of silica gel (180 g). Elution with petroleum ether–ether (20: 1, 1 l) gave furanoeremophilan-14β, 6α-olide (**5**)[3,4] (5.40 g). After elution of **5**, more polar constituents were eluted with ether. The residue obtained after evaporation of the solvent was subjected to chromatographic separation on a column of silica gel (100 g).

Elution with benzene (1.2 l) gave, on removal of the solvent, a solid, which was crystallized from ether to afford eremophil-7(11)-ene-12, 8α; 14β, 6α-diolide (**2**; 204 mg) as needles, mp 186—186.5 °C (dec.); $[\alpha]_D$ +93° (*c* 0.91, $CHCl_3$); UV (EtOH) λ_{max} 217 nm (ε 19300); IR (Nujol) 1786, 1739, and 1684 (sh) cm^{-1}; PMR ($CDCl_3$) δ 1.29 (3H, s; $C_{(5)}$–CH_3), δ 2.00 (3H, t, $J_{6\beta,13}$=2 and $J_{8\beta,13}$=2 Hz; $C_{(11)}$–CH_3), δ 4.75 (1H, m, $J_{8\beta,13}$=2, $J_{8\beta,9\alpha}$=13, and $J_{8\beta,9\beta}$=5 Hz (by PMDR experiments); $C_{(8\beta)}$–H), and δ 5.05 (1H, q, $J_{6\beta,13}$=2 Hz (confirmed by PMDR experiments); $C_{(6\beta)}$–H); mass spectrum *m/e* 262 (relative intensity 73%; M^+), *m/e* 152 (100%). Found: C, 69.13; H, 7.14%. Calcd for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92%.

Subsequent elution with benzene–ether (10: 1, 400 ml) and evaporation of the solvents gave a residue, which was crystallized from benzene to yield 6β-hydroxyeremophil-7(11)-en-12, 8α-olide[6,10,11] (**4**; 40 mg) as needles, mp 207—207.5 °C (lit, mp 208 °C[6,11] and mp 204—205 °C[10]); $[\alpha]_D$ +213° (*c* 1.19, $CHCl_3$) (lit, $[\alpha]_D$ +205.8° ($CHCl_3$),[6] $[\alpha]_D$ +203° ($CHCl_3$),[10] and $[\alpha]_D$ −35.4° ($CHCl_3$)[11,15]); UV (EtOH) λ_{max} 218 nm (ε 14400) [lit, λ_{max} 218.5 nm (ε 13700) (EtOH)[6] and λ_{max} 220 nm (log ε 4.12)[11]]; IR (Nujol) 3440, 1739, 1709 (sh), and 1690 cm^{-1}; PMR ($CDCl_3$) δ 0.80 (3H, d-like; $C_{(4)}$–CH_3), δ 1.13 (3H, s; $C_{(5)}$–CH_3), δ 1.85 (3H, d, $J_{8\beta,13}$=2 Hz; $C_{(11)}$–CH_3), δ 4.80 (1H, s; $C_{(6\alpha)}$–H), δ *ca.* 5.1 (1H, m; $C_{(8\beta)}$–H), and

δ 2.23 (1H, s, disappeared on addition of D_2O; $C_{(6\beta)}$-OH); mass spectrum *m/e* 250 (7%, M^+), *m/e* 126 (100%). Found: C, 72.00; H, 8.90%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%. This lactone was found to be identical (mp, mixed mp, $[\alpha]_D$, IR, UV, PMR, and mass spectra) with an authentic specimen of **4**.[6]

Fractions eluted with benzene–ether (5: 1, 400 mg) gave, on removal of the solvents, a solid, which was crystallized from chloroform–benzene to afford 8β-hydroxyeremophil-7(11)-ene-12, 8α; 14β, 6α-diolide (**1**; 250 mg) as needles, mp 253.5—254 °C (dec); $[\alpha]_D$ +94° (*c* 0.88, $CHCl_3$); UV (EtOH) λ_{max} 214 nm (ε 12400); IR (Nujol) 3260, 1787, and 1710 cm^{-1}; PMR (acetone-d_6) δ 1.28 (3H, s; $C_{(5)}$-CH_3), δ 1.86 (3H, d, $J_{6\beta,13}$=2 Hz; $C_{(11)}$-CH_3), δ 5.18 (1H, q, $J_{6\beta,13}$=2 Hz (confirmed by PMDR experiments); $C_{(6\beta)}$-H), and δ 6.51 (1H, s, disappeared on addition of D_2O; $C_{(8\beta)}$-OH); mass spectrum *m/e* 278 (44%, M^+), *m/e* 109 (100%). Found: C, 65.08; H, 6.42%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

Successive elution with the same solvents [benzene–ether (5: 1), 500 ml] and the evaporation of the solvents gave a residue. This was crystallized from chloroform–benzene to yield 6β,8β-dihydroxyeremophil-7(11)-en-12, 8α-olide (**3**; 567 mg)[10] as plates, mp 217—218 °C (dec) (lit, mp 211—212 °C); $[\alpha]_D$ +82° (*c* 0.98, EtOH) [lit, $[\alpha]_D$ +169° ($CHCl_3$)[10]]; UV (EtOH) λ_{max} 219 nm (ε 11800); IR (Nujol) 3480, 3230, and 1721 cm^{-1}; ($CHCl_3$) 3530, 1761, 998, and 980 (sh) cm^{-1} (lit, ($CHCl_3$) 3525, 3250, 1760, 1005, and 990 cm^{-1} [10]); PMR (acetone-d_6) δ 0.80 (3H, d-like; $C_{(4)}$-CH_3), δ 1.12 (3H, s; $C_{(5)}$-CH_3), δ 1.83 (3H, s, $C_{(11)}$-CH_3), and δ 4.64 (1H, br. s; $C_{(6\alpha)}$-H); ($CDCl_3$) δ 0.82 (3H, unresolved signals; $C_{(4)}$-CH_3), δ 1.13 (3H, s, $C_{(5)}$-CH_3), δ 1.88 (3H, s; $C_{(11)}$-CH_3), δ 2.09 (2H, s; $C_{(9)}$-H_2), δ 2.96 and δ 3.10 (each 1H, s, disappeared on addition of D_2O; $C_{(6\beta)}$-OH and $C_{(8\beta)}$-OH), and δ 4.62 (1H, s; $C_{(6\alpha)}$-H); [lit, ($CDCl_3$) δ 0.78 (3H, unresolved signals; $C_{(4)}$-CH_3), δ 1.11 (3H, s; $C_{(5)}$-CH_3), δ 1.87 (3H, s; $C_{(11)}$-CH_3), δ 2.07 (2H, s; $C_{(9)}$-H_2), δ 2.70 (2H, br. s; $C_{(6\beta)}$-OH and $C_{(8\beta)}$-OH), and δ 4.60 (1H, s; $C_{(6\alpha)}$-H)[10]]; mass spectrum *m/e* 248 (6%, $(M-18)^+$], *m/e* 109 (100%) (no molecular ion peak was observed). Found: C, 67.89; H, 8.53%. Calcd for $C_{15}H_{22}O_4$: C, 67.65; H, 8.33%. This lactone proved to be identical with **3**, recently reported by Naya *et al.*[10]

Acetylation of the Lactone (1). The lactone (**1**; 36 mg) was acetylated with acetic anhydride (2 ml) in pyridine (3 ml) at room temperature. Treatment as usual gave a residue, which was chromatographed on a column of silica gel (5 g). Fractions eluted with benzene (14 ml) gave an oil, which was purified by preparative TLC. Crystallization of the oil from petroleum ether afforded a monoacetate (**6**; 17 mg) as needles, mp 183—184 °C; IR (Nujol) 1800, 1784, 1773, and 1707 cm^{-1}; PMR ($CDCl_3$) δ 1.32 (3H, s; $C_{(5)}$-CH_3), δ 2.06 (3H, d, $J_{6\beta,13}$=2 Hz; $C_{(11)}$-CH_3), δ 2.13 (3H, s; -$COCH_3$), and δ 5.04 (1H, q, $J_{6\beta,13}$=2 Hz; $C_{(6\beta)}$-H); mass spectrum *m/e* 320 (3%, M^+), *m/e* 278 [100%, $(M-42)^+$]. Found: C, 63.66; H, 6.26%. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%.

Acetylation of the Lactone (3). To a solution of **3** (30 mg) in pyridine (2 ml) was added acetic anhydride (1 ml), and the solution was left for 3 days at room temperature. After working up in the usual manner, a crystalline product was obtained. Recrystallization from petroleum ether gave a diacetate (**16**; 38 mg), as needles, mp 120.5—121 °C (lit, 119.5—120.5 °C[10]); IR (Nujol) 1770, 1751, 1733, and 1248 cm^{-1}; PMR ($CDCl_3$) δ 0.82 (3H, unresolved signals; $C_{(4)}$-CH_3), δ 1.00 (3H, s; $C_{(5)}$-CH_3), δ 1.96 (3H, s; $C_{(11)}$-CH_3), δ 1.98 (3H, s; -$COCH_3$), δ 2.02 (3H, s; -$COCH_3$), and δ 5.88 (1H, s; $C_{(6\alpha)}$-H); mass spectrum *m/e* 308 [3%, $(M-42)^+$], *m/e* 109 (100%) (no molecular ion peak was observed). Found: C, 65.24; H, 7.45%. Calcd for $C_{19}H_{26}O_6$: C, 65.12; H, 7.48%.

Oxidation of the Lactone (5) with DDQ. A mixture of furanoeremophilan-14β,6α-olide (**5**; 500 mg) and DDQ (1.2 g) in dioxane (10 ml) was heated at 80 °C for 1 h, and then the solvent was evaporated under reduced pressure. The residue was extracted with hot benzene. The reaction mixture obtained after removal of the benzene was chromatographed on a column of silica gel (50 g). Elution with benzene–ether (5: 1, 1 l) gave a mixture of crystalline products (227 mg, recrystallized from benzene), which was subjected to sublimation. From the sublimated material (119 mg), a product (34 mg) with R_f value 0.62 (benzene–ether, 1: 1) on TLC (silica gel) was collected by repeated preparative TLC. Crystallization of the product from ether gave an unsaturated enol lactone (**11**; 23 mg) as an amorphous solid, IR (neat) 1785 and 1665 cm^{-1}; PMR ($CDCl_3$) δ 1.38 (3H, s; $C_{(5)}$-CH_3), δ 2.12 (3H, br. s; $C_{(11)}$-CH_3), δ 2.65 (1H, dd, $J_{3\alpha,4\alpha}$=2 and $J_{3\beta,4\alpha}$= 12 Hz; $C_{(4\alpha)}$-H), δ 2.96 (1H, m; $C_{(10\beta)}$-H), δ 5.28 (1H, q, $J_{6\beta,13}$=1.5 Hz; $C_{(6\beta)}$-H), and δ 5.65 (1H, d, $J_{9,10\beta}$=3 Hz; $C_{(9)}$-H) (the presence of these spin-couplings was confirmed by PMDR experiments); mass spectrum *m/e* 260 (9%, M^+ related to a molecular formula of $C_{15}H_{16}O_4$], *m/e* 67 (100%). This compound is very unstable and most of the compound decomposed within 1 day on leaving it in a solution. The purity was checked before and after the measurement of these spectra. The UV (EtOH) spectra showed the absorption maximum at 280 nm.[7,8] However, the ε value could not be determined precisely due to fragility of the compound. Appearance of the maximum at 222 nm during the measurement would be due to the decomposition of the compound. Elemental analysis gave an unsatisfactory result probably due to the unstability of the compound.

Dehydration of the Lactone (1). To a stirred solution of **1** (51 mg) in pyridine (2 ml), phosphorus oxychloride (0.2 ml) was added at 0 °C, and the stirring was continued for 1 h at 0 °C, then for 4 h at room temperature. After addition of crushed ice, the reaction mixture was extracted with chloroform (50 ml). The extract was dried over anhydrous sodium sulfate, and the solvent was evaporated under reduced pressure. From the reaction mixture, the unsaturated enol lactone (**11**; 9 mg) was obtained by preparative TLC, which was found to be identical (TLC, IR, PMR, and mass spectra) with the sample (**11**) prepared by oxidation of **5**.

Photosensitized Autoxidation of the Lactone (5) in Methanol. Rose Bengal (53 mg) was added to a solution of **5** (308 mg) in methanol (600 ml), and the resulting solution was irradiated with a high pressure mercury lamp (100W, Rikosha) under oxygen atmosphere at 0 °C for 1 h. The residue obtained after removal of the methanol under reduced pressure, was chromatographed on a column of silica gel (50 g). Elution with benzene–ether (10: 1) gave two principal fractions: the less polar fraction (269 mg) and the more polar fraction (21 mg). From the more polar fraction, a crystalline product (9.5 mg) was obtained after recrystallization from benzene–chloroform, which was found to be identical (mp, TLC, IR, and PMR spectra) with 8β-hydroxyeremophil-7(11)-ene-12, 8α;14β,6α-diolide (**1**).

The less polar fraction was repeatedly chromatographed on a column of silica gel (50 g). Elution with benzene–ether (20: 1, 200 ml) gave 8β-methoxyeremophil-7(11)-ene-12,8α;14β,6α-diolide (**18**; 111 mg, recrystallized from petroleum ether), mp 184.5—185 °C; UV (EtOH) λ_{max} 216 nm (ε 14700); IR (Nujol) 1790, 1765, and 1690 cm^{-1}; PMR ($CDCl_3$) δ 1.29 (3H, s; $C_{(5)}$-CH_3), δ 2.01 (3H, d, $J_{6\beta,13}$=2 Hz; $C_{(11)}$-CH_3), δ 3.21 (3H, s; -OCH_3), and δ 4.88 (1H, q, $J_{6\beta,13}$=2 Hz; $C_{(6\beta)}$-H); mass spectrum *m/e* 292 (35%, M^+), *m/e* 67 (100%). Found: C, 65.67; H, 6.66%. Calcd for $C_{16}H_{20}O_5$: C, 65.74; H,

6.90%.

When the lactone (**5**) in methanol was either left for 3 days under bubbling of oxygen or irradiated with ultraviolet rays for 5 h under oxygen atmosphere, **5** suffered no change.

Reduction of the Lactone (1) with Sodium Borohydride. To a mixture of **1** (30 mg) and aqueous sodium hydroxide (10%, 0.3 ml) in methanol (3 ml), sodium borohydride (51 mg) was added at 0 °C with stirring, and the stirring was continued for 1 h at 0 °C, then for 2 h at room temperature. After evaporation of the methanol under reduced pressure, the residue was acidified with sulfuric acid (0.5 M), and extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and the solvent was removed to give a residue, which was chromatographed on a column of silica gel (7 g), using benzene–ether (10:1) as eluent. A crystalline product (5 mg) was obtained, which was purified by crystallization from ether. This compound (2 mg) was found to be identical (mp, TLC, IR, PMR, and mass spectra) with eremophil-7(11)-ene-12,8α; 14β,6α-diolide (**2**).

Reduction of the Lactone (3) with Sodium Borohydride. The lactone (**3**; 30 mg) was treated with sodium borohydride (50 mg) in methanol containing sodium hydroxide according to the procedures described in the reduction of **1**. The residue was chromatographed on a column of silica gel (20 g). Elution with benzene (120 ml) gave an oily product, which then solidified (10 mg). This compound proved to be identical with eremophil-7(11)-en-12,8α-olide (**17**),[12,13] mp 107—111 °C; IR (Nujol) 1740, 1687, and 1035 cm^{-1}; PMR ($CDCl_3$) δ 0.80 (3H, d-like; $C_{(4)}$–CH_3), δ 1.05 (3H, s; $C_{(5)}$–CH_3), δ 1.80 (3H, t, $J_{6\beta,13}$=2 Hz and $J_{8\beta,13}$=2 Hz; $C_{(11)}$–CH_3), δ 2.90 (1H, d, $J_{6\alpha,6\beta}$=15 Hz; $C_{(6\alpha)}$–H) (signals due to $C_{(6\beta)}$–H is overlapped with other signals), and δ 4.61 (1H, m; $C_{(8\beta)}$–H); mass spectrum *m/e* 234 (8%, M^+ related to a molecular formula of $C_{15}H_{22}O_3$), *m/e* 123 (100%).

Successive elution with benzene–ether (5: 1, 90 ml) gave a product (3 mg), mp 207—207.5 °C, whose IR, PMR, and mass spectra were found to be identical with those of 6β-hydroxyeremophil-7(11)-en-12,8α-olide (**4**).[6]

Reduction of the Lactone (4) with Sodium Borohydride. Treatment of the lactone (**4**; 13 mg) with sodium borohydride (55 mg) in methanol containing sodium hydroxide, according to the procedures described in the reduction of **3**, gave a residue, which was chromatographed on a column of silica gel (5 g). Elution with benzene (150 ml) gave a crystalline compound (3 mg). This compound was found to be identical (mp, TLC, IR, and PMR spectra) with **17** described above. Further elution with ether (30 ml) afforded the unchanged starting material (**4**; 10 mg).

The authors wish to thank Prof. K. Naya, Kwansei Gakuin University, for a generous gift of authentic samples of 6β,8β-dihydroxyeremophil-7(11)-en-12,8α-olide (**3**) and the diacetate (**16**), together with their PMR and IR spectra. The authors are also grateful to Dr. H. Ishii, Shionogi Research Laboratory, for a kind supply of an authentic sample of 6β-hydroxyeremophil-7(11)-en-12,8α-olide (**4**).

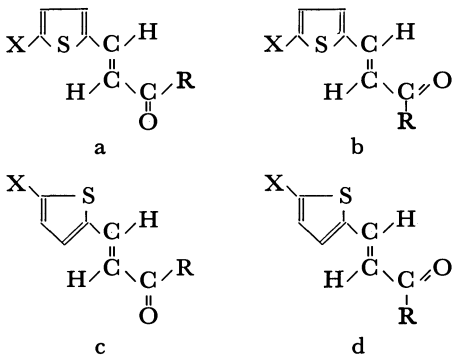
(Received June 23, 1976)

The most predominant conformation of 4-(2-thienyl)-3-butene-2-one and methyl β-(2-thienyl)acrylates were determined by the analysis of their LIS's. The LIS's toward higher fields were observed with some ring protons (H_3's and some of H_4's), and were best interpreted by assuming that about 20% of the shift reagent coordinates on the methoxyl oxygen atom and the rest on the carbonyl oxygen atom.

β-(2-Thienyl)acrylic esters are considered to take a planar conformation in order to minimize pi-electronic energy of the whole conjugated system. However, the rotation about the two C(sp^2)–C(sp^2) single bonds (C_β–C_2 and C_α–$C_{carbonyl}$) produces the possibility to exist as the four conformers **1**a—**1**b. As the rotational barriers around these essential single bonds are relatively low,[1] the interconversion among these occurs rapidly, and the ester exists as an equilibrium mixture in which the most stable conformer predominates over the others. Thus, it is of considerable significance to determine which of the four is the most predominant conformer. The stereochemistry of conjugated unsaturated ketones have been discussed by several authors,[2,3] and it is concluded that the *s-trans* conformation is, in general, more stable than *s-cis* one from the ultraviolet spectroscopic evidences. However, the conformation around the other essential single bond is less certain. The molecular models and the molecular diagrams[2] suggest that the conformer (a or b) in which the C_2–C_3 bond of the thiophene ring is *s-trans* with respect to the ethylenic bond of the enone system is considerably less hindered than the *s-cis* one (c or d), since the H_α–H_3 repulsion operating in the *s-cis* conformer is substituted by much less H_β–H_3 repulsion in the former conformer.



a b c d

Thus, the stereochemistry of some *trans*-β-(2-thienyl)-acrylic esters (**1**) and *trans*-4-(2-thienyl)-3-buten-2-one (**2**) has been investigated by measuring the LIS (lanthanoid induced shift) values of their proton NMR spectra.

Experimental

Materials used in this investigation were synthesized according to the methods previously reported,[10] or obtained by purification of commercially available materials. Proton NMR spectra were measured in carbon tetrachloride employing a JNM C-60H spectrometer operating at 60 MHz. The concentrations of the solutions were adjusted approximately at 0.3 mol l^{-1} with respect to substrates. Tris(dipivaloylmethanato)europium [=Eu(dpm)$_3$] was used as a shift reagent throughout this investigation, and it was added in small portions to a solution containing an excess of the substrate in order to obtain the $\Delta\delta$ *vs.* [shift reagent]/[substrate] plots.

Results and Discussion

The LIS values and their proportions to the largest were given in Table 1. In order to determine the privileged conformation of *trans*-4-(5-bromo-2-thienyl)-3-buten-2-one, the most probable locations of the Eu(III) ion to reproduce the observed LIS values of 2 were calculated with all of four conformations **2**a—**2**d (where X is Br) by evaluating the agreement factors (*R*-values) defined by Eq. 1,[4] where $(S_{obsd})_i$ and $(S_{calcd})_i$ are the observed and the calculated LIS's of proton *i*, respectively.

$$R = \left\{ \frac{[(S_{obsd})_i - (S_{calcd})_i]^2}{(S_{obsd})_i^2} \right\}^{1/2} \quad (1)$$

Reasonable results given in Fig. 1 were obtained only when the substrate molecule takes the *s-trans*, *s-trans* conformation (**2**a). As shown in Fig. 1, the location of Eu(III) in the enone–Eu(dpm)$_3$ complex is 2.3 Å apart from the carbonyl oxygen atom and not so far from the C=O axis.

The relative values of the LIS's of the thienylacrylic esters, as a whole, are similar to those of the thienylbutenone (**2**). However, a remarkable differences are observed with the signs of the LIS's of some ring protons (H_3's and some H_4's in Table 1) and with the relative magnitudes of the LIS's of α- and β-protons. The difference is interpreted by assuming that the complexation of Eu(dpm)$_3$ also occurs on the methoxyl oxygen atom to some extent. To estimate roughly the relative abundances of the complexes in which the Eu(III) ions are bonded to the carbonyl and the alkoxyl oxygen atoms, the LIS's of the equimolar mixture of acetone and diethyl ether is measured and, by comparing with the LIS's of each component under the same conditions, the 80% of the shift reagent is shown to coordinate to the carbonyl oxygen atom of acetone.[5] Employing the results of the intermolecular competition, the LIS's of the thienylacrylic ester (**1**) were estimated as

TABLE 1. THE LIS'S OF METHYL β-(5-SUBSTITUTED-2-THIENYL)-ACRYLATES AND RELATED COMPOUNDS

Compounds		(O)CH_3	H_α	H_β	H_3	H_4	5-CH_3

a) S_i refers to the LIS value of proton i, which is defined as $S_i = \Delta\delta/([Eu(dpm)_3]/[Substrate])$.
b) See text.

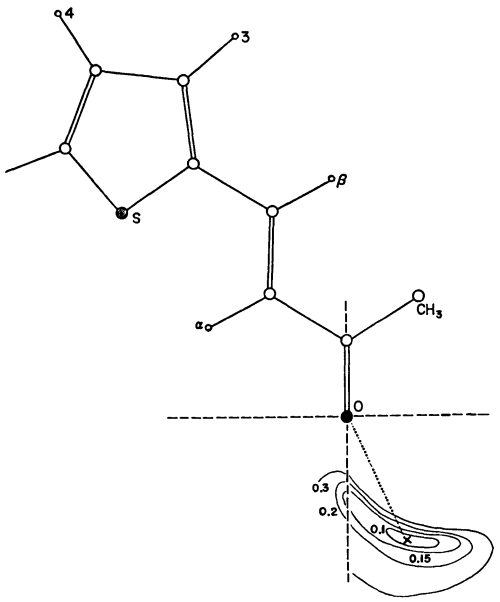

Fig. 1. The most probable position of the Eu(III) ion (x) determined by evaluating the R-values from Eq. 1 for 4-(2-thienyl)-3-buten-2-one.
(The figures show the R-values.)

the weighted sums of the contribution of the Eu(III) ions in two sites calculated by the McConnell Robertson equation,[6] $\Delta\delta = K(1-3\cos^2\theta)r^{-3}$, by assuming (i) that the shift reagent coordinates to the carbonyl and the methoxyl oxygen atoms of the ester in the ratio of 4: 1, (ii) that the Eu(III) ion is located on the extension of the C=O bond or on the bisector of the C–O–C angle of the methoxyl group, and (iii) that the Eu–O distance is 2.5 Å for the carbonyl oxygen and 3.0 Å for the methoxyl oxygen of the ester group. A conformation in which the two alkyl groups are antiperiplanar, termed "*trans*", is demonstrated to be the most favorable conformation of the carboxylic ester,[7] and the same conformation is also assumed in the calculation. As the location of the second Eu(III) ion coordinating on the methoxyl oxygen atoms is too close (about 1.9 Å) to realize, its location is modified to be on a line 19° out side from the bisector line and 3.0 Å distant from the oxygen atom (so as to keep the nearest Eu···H distance farther than 2.5 Å). This modification gives a reasonable set of the calculated LIS's of **1** showns together with the observed values, in Table 1. The position of the methoxyl protons are chosen to be the center of gravity of its three protons. In spite of this oversimplification and uncertainty of the position of the methyl group, the agreement between the relative values of the observed and the calculated LIS's are good, and the LIS's of the thienylacrylic esters can be explained by taking into accounts the participation of the alkoxyl oxygen atom in the formation of the shift reagent–substrate complex. The β-(5-bromo-2-furyl)-acrylic esters behave quite similarly with their thia-analogs towards the shift-reagent, and, in consequence with the previous reports,[8,9] the intra-ring oxygen atom does not participate in the complex formation with the shift-reagent. The LIS's of cinnamic esters are also similar and the participation of the alkoxyl-oxygen atom might be quite general in esters.

Layered Compounds. XXXVI.[1] Structure and Properties of Triple-layered Metaparacyclophanes

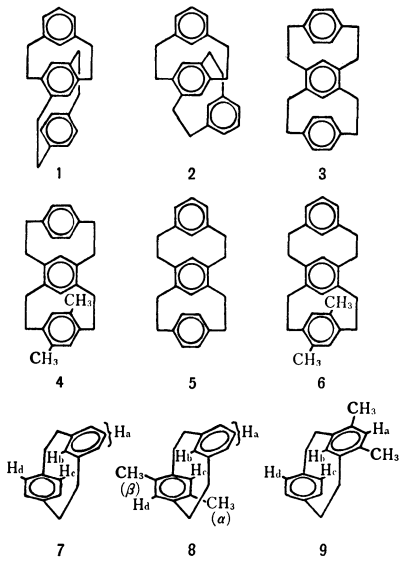
Naoki KANNEN, Tetsuo OTSUBO, Yoshiteru SAKATA, and Soichi MISUMI*

The Institute of Scientific Industrial Research, Osaka University, Suita, Osaka 565

(Received June 7, 1976)

The geometrical structures of triple-layered metaparacyclophanes are discussed on the basis of the chemical shifts of the NMR spectra and their temperature dependence. [2.2]Metacyclo(4,7)[2.2]paracyclophane **1** and [2.2]metacyclo(12,15)[2.2]metaparacyclophane **2** proved to be mixtures of conformational isomers due to arrangement of meta-substituted ring. [2.2]Paracyclo(4,6)[2.2]metaparacyclophane **3** was confirmed to be a staircase-shape (*anti*-form), in contrast to a platform-shape (*syn*-form) of [2.2]metacyclo(4,6)[2.2]metaparacyclophane **5**. In their electronic spectra, **1** and **2** exhibit a transannular electronic interaction between the benzene rings similar to that of multilayered [2.2]paracyclophanes; **3** and **5** show one similar to that of multilayered [2.2]metacyclophanes. The difference between the former and the latter groups seems to arise from the substitution modes of methylene bridges attached to the inside benzene of triple-layered metaparacyclophanes.

In the preceding paper we reported the syntheses of triple-layered [2.2]metaparacyclophanes **1**—**6**.[1] The compounds are expected to consist of mixtures of conformational isomers due to fixation of meta-substituted benzene rings. In compounds **3**—**6** there seem to be two types of stacking which characterize either a staircase-shape (*anti*-form) or a platform-shape (*syn*-form) conformer. In this paper we discuss the assignment of the structures in detail and the conformational flipping of the meta ring at high temperature on the basis of NMR study. The transannular electronic interactions between benzene rings are considered in comparison with the electronic spectra of multilayered paracyclophane or metacyclophane.



Scheme 1.

Results and Discussion

Structure and NMR Spectra. The NMR spectra of layered metaparacyclophanes **1**—**9** are summarized in Table 1. The high field shift of the inner aromatic proton Hb of [2.2]metaparacyclophane **7** suggests that the proton is situated just above the faced para-substituted ring. The aromatic protons, Hc and Hd, of the para ring are nonequivalent at room temperature, becoming equivalent at higher temperature (T_c, *ca.* 140 °C). The behavior is interpreted in terms of conformational flipping of the meta ring which is fixed at room temperature.[2] The activation energy calculated is about 21 kcal/mol. Similarly two dimethyl derivatives **8** and **9** show the fixation of the meta ring at room temperature.

The triple-layered metaparacyclophane **1** exhibits a NMR pattern similar to those of **7**—**9** except high field shifts of the protons, Hb, Hc, and Hd, due to the anisotropy of the additional third benzene ring. Figure 1

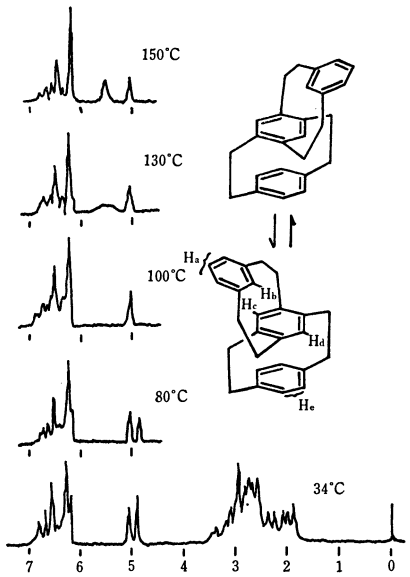

Fig. 1. NMR spectra of **1** in hexachlorobutadiene at various temperatures.

shows NMR spectra at various temperatures. The conformational flipping of meta ring occurs at 100 °C, a relatively low temperature which corresponds to 18 kcal/mol of activation energy. The difference in 3 kcal/mol as compared with [2.2]metaparacyclophane **7** is considered to arise from twisting of the inside ring, which is pulled up and down by two pairs of methylene bridges, to lower the steric energy barrier to the flipping of the meta ring.

For **2**, fixation of the meta ring is expected to give two conformational isomers, **2a** and **2b**, which should show quite different NMR spectra. In fact **2** reveals the NMR spectrum corresponding to 1 : 1 equilibrium mixture of the two isomers at room temperature (Fig. 2). Thus the inner aromatic protons, Hb and Hb', of meta rings appear at slightly different positions (δ 5.28 and 5.37 ppm) with equal integral intensity. Also, as expected from the structures in Fig. 2, the aromatic protons Hc at the inside ring of **2a** are equivalent (δ 5.60), but not those (Hc' and Hd') of **2b** (δ 4.39 and 6.87). The extraordinary upfield shift of the proton Hd' is explained in terms of an additive shielding effect of two meta rings, between which the proton is sandwiched. The energy barrier for the conformational flipping of the meta rings is relatively low (19 kcal/mol). Above the coalescence temperature (116 °C) the inner aromatic protons of meta rings and the aromatic protons of the inside ring appear as a singlet at δ 5.63 and 5.30, respectively.

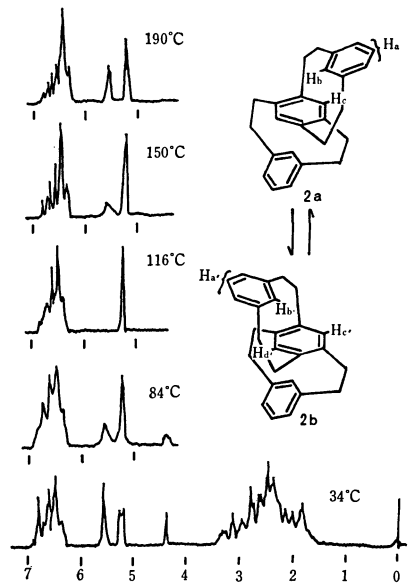

Fig. 2. NMR spectra of **2** in hexachlorobutadiene at various temperatures.

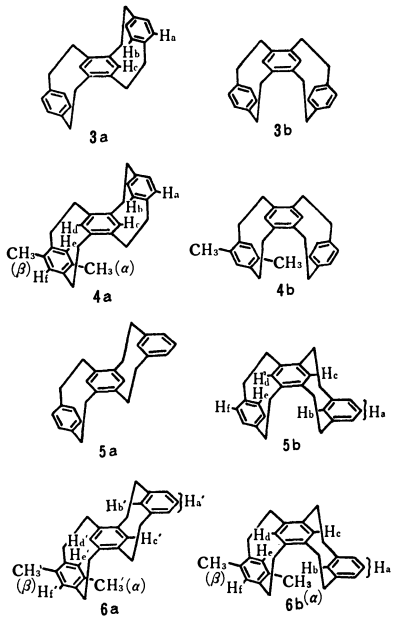

Scheme 2.

Two conformations, **3a** and **3b**, are possible for the structure of **3**. However, the NMR spectrum of **3** is very simple, suggesting that the compound consists of a symmetrical isomer. Dimethyl derivative **4** was prepared in order to facilitate the structure assignment of the parent compound **3**. Examination of the *syn*-form **3b** with a molecular model indicates that the *endo* aromatic protons of the two para rings are sterically crowded. When methyl groups are substituted to **3b**, more severe crowding is expected in the resulting *syn*-form **4b**. On the other hand, such methyl substitution in *anti*-form **3a** does not seem to influence the parent structure. The actual compound **4** is also composed of a single isomer and should have the same geometry as **3** since the aromatic protons, Ha and Hb, of nonsubstituted para ring of **4** show chemical shifts very close to those of **3**. *endo* Methyl protons CH_3-α (δ 1.44) of **4** appear at a slightly higher field than the corresponding protons (δ 1.65) of 12,15-dimethyl[2.2]metaparacyclophane **8**. If the geometry is of *syn*-form, the methyl signal should shift to downfield due to the deshielding effect of the third benzene ring or nonsubstituted para ring. Consequently, the staircase-shape (*anti*-form) structure is assigned to both **3** and **4**. Recently the validity of this assignment has been confirmed by X-ray crystallo-

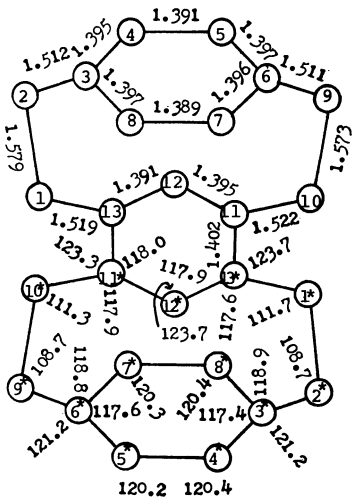

Fig. 3. Profile of triple-layered metaparacyclophane **3**. Bond lengths and angles.

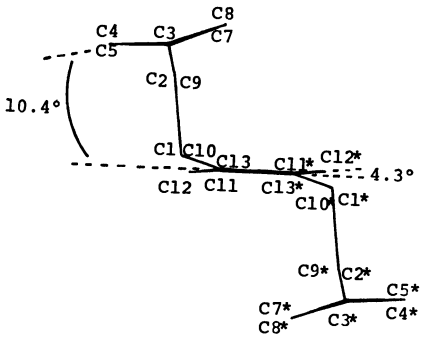

Fig. 4. Projection viewed down the vector C(1)–C(10).

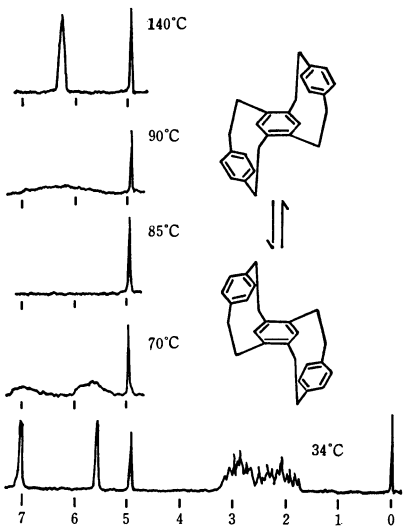

Fig. 5. NMR spectra of **3** in hexachlorobutadiene at various temperatures.

graphic analysis.[3] The inside benzene is slightly overlapped with two para rings at *ca.* 10° angle, as shown in Figs. 3 and 4. By steric repulsion with the two para rings arranged in *anti*-form, the inside benzene ring is bent into a chair shape. This is the first example of a chair-shape benzene. There is a conformational flipping at elevated temperature also for compound **3** (Fig. 5). The nonequivalent aromatic protons, Ha and Hb, of para rings coalesce at 85 °C and appear as a singlet just in the middle of their initial positions at higher temperature. This spectrum indicates that the conformational change occurs between two *anti*-forms by means of double flipping of the two para rings, but not between *anti*- and *syn*-forms by one ring flipping.

A different conformational behavior was observed in the case of **5**. Two conformational isomers, *anti*-form **5a** and *syn*-form **5b**, are also possible for **5**. However, compound **5** shows no temperature dependence in its NMR spectrum, suggesting that it is composed of a single isomer, **5a** or **5b**. Methyl substitution makes the *syn*-form structure unstable as in the case of **3**. Actually the dimethyl derivative **6** was obtained as a mixture of two conformational isomers, **6a** and **6b**, in a 1 : 1 ratio (Table 1). The results may be explained by assuming that the *syn*-form conformer **5b** is assigned to the structure of compound **5** and the methyl substitution equalizes the stabilities of *syn*- and *anti*-forms by lowering the stability of the former. The assumption was confirmed by X-ray crystal analysis of **5** (Figs. 6 and 7).[3] Differing from **3**, the inside benzene of **5** is bent into a boat shape.

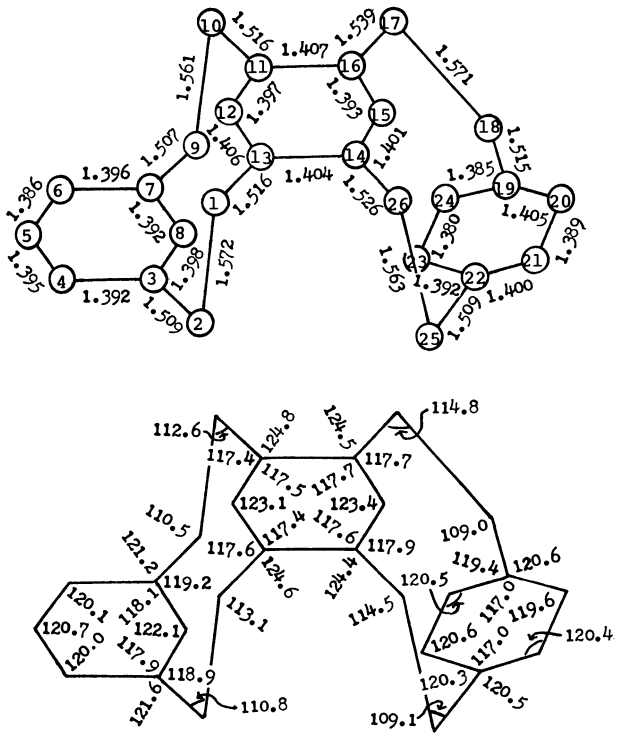

Fig. 6. Profile of triple-layered metaparacyclophane **5**. Bond lengths and angles.

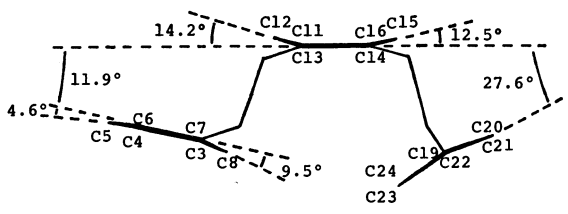

Fig. 7. Projection viewed down the vector C(3)–C(7).

Let us discuss the stereochemical difference between the two triple-layered metaparacyclophanes **3** and **5**. In a series of multilayered [2.2]metacyclophanes, the platform conformer is thermally more stable than the staircase one.[4] This seems to be related to the strained structure of the inside benzene ring. Thus the inside ring is bent into a boat form in the former and into a chair form in the latter. Molecular orbital calculation revealed that the boat-shape benzene is much more stable than the chair-shape one, mainly due to the difference in the resonance integral term.[5] The stability of *syn*-form **5b** can be explained in the same manner. On the other hand, molecular model examination of *syn*-form **3b** indicates that steric crowding between two para benzenes should be considerably large. The steric overcrowding energy presumably overcomes the energy difference between boat and chair forms of the inside benzene, making the *anti*-form geometry favorable for compound **3**.

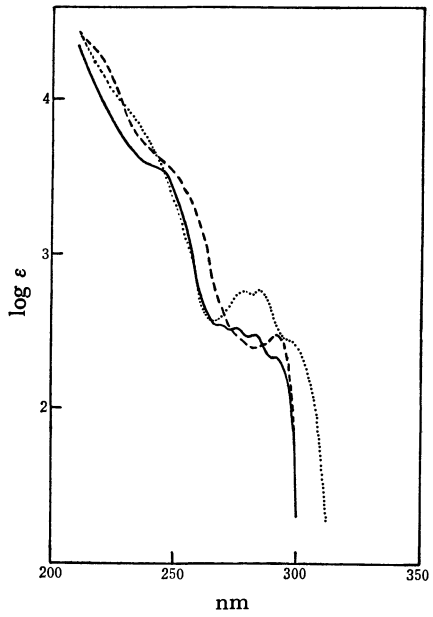

Fig. 8. Electronic spectra of [2.2]metaparacyclophane **7** (—) and the dimethyl derivatives **8**(···) and **9** (---) in cyclohexane.

Electronic Spectra. Electronic spectra of [2.2]-metaparacyclophane **7** and its dimethyl derivatives **8** and **9** are shown in Fig. 8. The most marked features are broadening and bathochromic shift of the absorption bands associated with B_{1u} and B_{2u} transitions of benzene. Such features were generally observed in the spectra of layered cyclophanes and mainly explained by π-electronic interaction between benzene rings.[6] In addition, bending of the benzene ring is responsible to some extent.[7] This is also the case for [2.2]metapara-cyclophane, since its para ring is severely bent into a boat shape as demonstrated by X-ray crystal analyses.[3,8] Although [2.2]paracyclophane shows strong π-electron interaction due to sufficient overlapping of two faced benzenes, such a strong interaction can not be expected for the parent compound **7** of [2.2]metaparacyclophane series because of partial overlapping. However, the interaction in this cyclophane system is evidently realized by methyl substitution. Thus, two dimethyl derivatives **8** and **9** show rather different spectra from that of **7** besides the normal substituent effect. It is especially remarkable in the long wavelength region of **8**, *viz.*, the substitution at para ring is more effective than that at meta ring. This suggests that the transition of the para ring makes relatively large contribution to the transannular electronic interaction of [2.2]meta-paracyclophane.

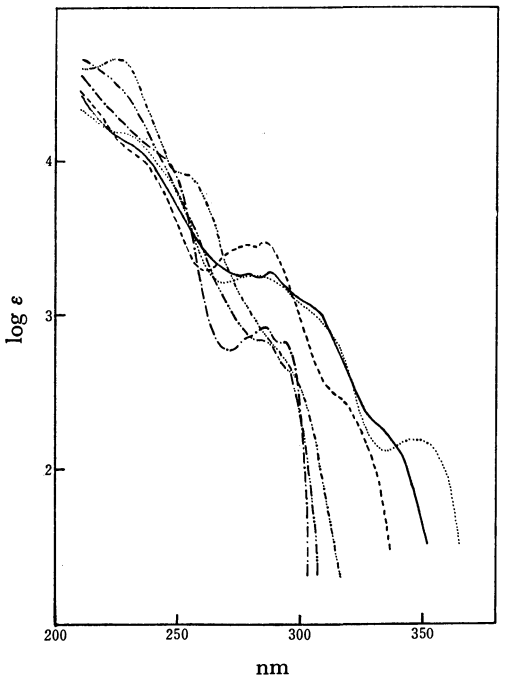

Fig. 9. Electronic spectra of triple-layered [2.2]meta-paracyclophanes **1** (——), **2** (----), **3** (-·-·-), and **5** (-··-), together with triple-layered [2.2]paracyc-lophane **10** (·····) and metacyclophane **11** (-·-·-) in cyclohexane.

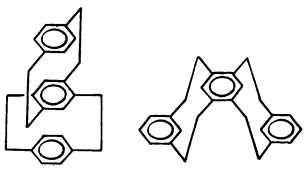

10 **11**

Scheme 3.

A similar consideration can be extended to the present triple-layered metaparacyclophanes. As seen in Fig. 9, the electronic spectra of **1** and **2** show new bands around 330 and 315 nm, respectively, and an increase of intensity of the bands in the 260—310 nm region as compared with that of [2.2]paracyclophane or [2.2]-metaparacyclophane. Thus their absorption curves are similar to the curve of triple-layered [2.2]paracyclophane **10**,[9] indicating that a marked transannular electronic interaction also exists between the meta and para rings. On the other hand, the electronic spectra of **3** and **5** are similar to that of triple-layered [2.2]metacyclophane **11**[10] indicative of a weak electronic interaction. This is in marked contrast to the phenomenon of **1** and **2**.

There is no essential difference in the spectra due to conformational difference between *anti*- and *syn*-forms. Substitution modes of methylene bridges attached to the inside ring of triple-layered [2.2]metaparacyclophane serve as an important factor on overlapping of benzene rings and hence, on the electronic interaction.

The present work was partially supported by a Grant-in-Aid (754096, 1972) for Scientific Research from the Ministry of Education.

Layered Compounds. XXXVII.[1] Syntheses and Properties of Quadruple-layered Metaparacyclophanes

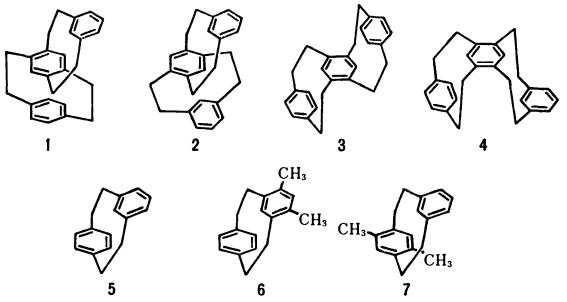
Naoki KANNEN, Tetsuo OTSUBO, and Soichi MISUMI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received June 24, 1976)

Six quadruple-layered [2.2]metaparacyclophanes have been synthesized by photo-induced desulfurization or the Hofmann elimination method. Their electronic spectra exhibit stronger transannular electronic interactions than those of the corresponding triple-layered [2.2]metaparacyclophanes and considerable dependence on the bridge substitution mode of the inside ring. The absorption spectra of the charge transfer complexes of a series of layered metaparacyclophanes and tetracyanoethylene have been studied with regard to the donor characters. It is concluded that the electron release from meta to para ring is significant, while the reverse is less effective.

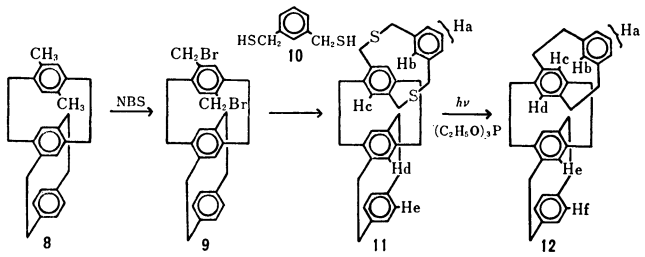
In preceding papers we reported the syntheses, structures, and properties of triple-layered [2.2]metaparacyclophanes **1**—**4**.[1] Although double-layered [2.2]-metaparacyclophanes **5**—**7** show no remarkable transannular electronic interaction between benzene rings,[1] compounds **1** and **2**, the inside ring of which is doubly *para*-substituted with two pairs of methylene brigdes, exhibit strong interaction as in the case of multilayered [2.2]paracyclophanes. On the other hand, compounds **3** and **4** with doubly *meta*-substituted benzene reveal weak interaction as in the case of multilayered [2.2]-metacyclophanes. In this paper we report the syntheses and properties of some quadruple-layered [2.2]metaparacyclophanes. The compounds are expected to give us further information on the relationship between structures and spectra.



Scheme 1.

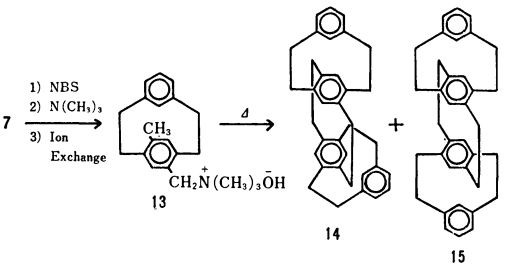
Results and Discussion

Syntheses and Structures. Dimethyl derivative **8**[2] of triple-layered [2.2]paracyclophane was brominated with *N*-bromosuccinimide and the resulting dibromide **9** was coupled with 1,3-bis(mercaptomethyl)benzene **10** to afford dithia compound **11** in 16% overall yield.



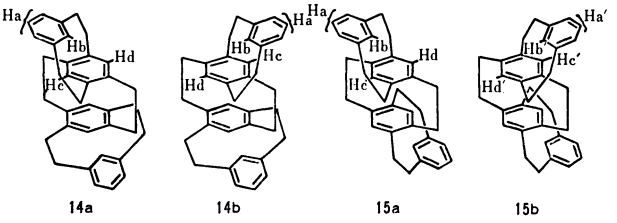
Scheme 2.

Compound **11** was then converted into the desired quadruple-layered metaparacyclophane **12** in an excellent yield (81%) using photodesulfurization developed by Bruhin *et al.*[3] The structure of **12** was determined by its NMR spectrum. Most of the aromatic protons appear at high field due to the shielding effect of the other benzene rings. Hc and Hd protons are not equivalent, indicating fixation of meta ring as in the case of [2.2]metaparacyclophane **5**.[4]



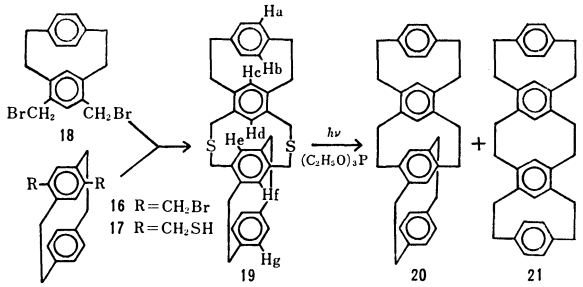
Scheme 3.

Hofmann elimination reaction, a convenient method for approach of multilayered [2.2]paracyclophanes,[2,5] was applied to the syntheses of quadruple-layered metaparacyclophanes **14** and **15**. 12,15-Dimethyl[2.2]-metaparacyclophane **7**[1] was brominated with *N*-bromosuccinimide followed by treatment with trimethylamine and then ion exchange resin to give the quaternary ammonium hydroxide **13**. Pyrolysis of **13** in boiling xylene afforded a mixture of the desired cyclophanes **14** and **15**, which could be separated by utilizing the large difference in their solubility. In the same manner as for quadruple-layered [2.2]paracyclophanes,[2] the more soluble isomer was assigned to the structure **14**, and the less soluble one to the structure **15**. The eclipse of methylene bridges at two inside rings of **15** may be responsible for the lower yield (2.7%) than that of **14** (12%). Fixation of the meta rings of **14** gives two possible conformational structures **14a** and **14b**. They



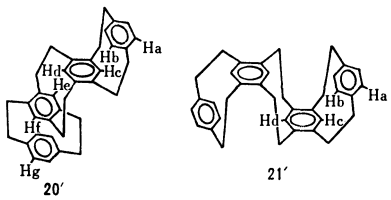
Scheme 4.

are not enantiometric with each other, but can not be distinguished on NMR analysis due to the equivalence of the corresponding aromatic protons. Two conformational structures are expected also for **15**. In this case the NMR spectrum demonstrates two sets of signals for aromatic protons, which correspond to **15a** and **15b**. The ratio was evaluated to be 1 : 1 on the basis of the integral intensities.



Scheme 5.

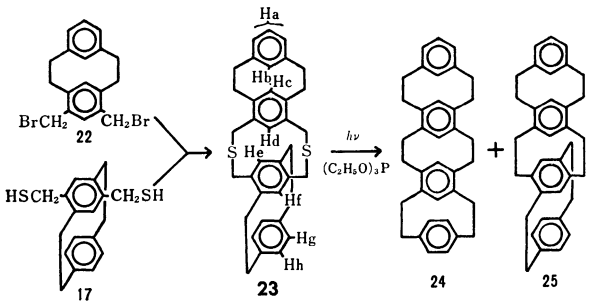
4,7-Bis(bromomethyl)[2.2]paracyclophane **16**[1] was led to the corresponding dithiol **17** in 74% yield. Condensation of **17** with 4,6-bis(bromomethyl)[2.2]-metaparacyclophane **18**[1] gave dithia compound **19** in 25% yield. Photodesulfurization of **19** in triethyl phosphite afforded the desired quadruple-layered metaparacyclophane **20** in 40% yield and its isomer **21** in 33% yield. From the fact that triple-layered metaparacyclophane **1** is easily photo-isomerized to **4**,[1] **20** seems to isomerize to **21** during the photolysis.



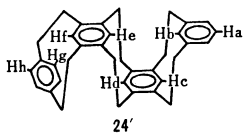
Scheme 6.

The geometry of **3** was confirmed to be a staircase-shape on the basis of NMR analysis[1] and X-ray crystallographic analysis.[6] Similarly, the structure of **20** is expected to have a staircase-shape as shown in **20′**. The NMR spectrum is in good accord with the present structure **20′**. In the same manner as in the case of multilayered[2.2]paracyclophanes,[7] the chemical shifts of the aromatic protons in **20** can be successfully evaluated by considering the anisotropy of the stacked rings. Three stereoisomers are possible for **21**. However, its NMR spectrum is simple and suggests that there is only one conformational isomer having a symmetrical structure. The structure was determined to be **21′** by comparison of the NMR spectrum with that of **4** which has a platform-shape differing from **3**.[1]

Condensation of 4,6-bis(bromomethyl)[2.2]metacyclophane **22**[8] with 4,7-bis(mercaptomethyl)[2.2]-paracyclophane **17** gave coupling compound **23** in 29% yield. Photodesulfurization of **23** afforded **24** in 30% yield. The product **24** is considered to be derived from **25** which was initially desired. Unfortunately **25**



Seheme 7.



Scheme 8.

could not be isolated because of contamination with oily by-products. Four conformational isomers are possible for **24**, but the NMR spectrum can be explained on a single isomer of zigzag structure **24′**. The assignment is consistent with the fact that in multilayered metacyclophanes, the structure of platform-shape is thermodynamically stable.[9]

Electronic Spectra. The electronic spectra of quadruple-layered [2.2]metaparacyclophanes are shown in Fig. 1. The explanation that bridge substitution mode is important for transannular electronic interaction of triple-layered metaparacyclophane[5] is also applicable to the present case. Compounds **12**, **14**, and **15** are formally regarded as if they are given by stacking another meta or para substituted benzene on the outside para ring of triple-layered metaparacyclophane **1**. As expected, their spectra exhibit much more bathochromic

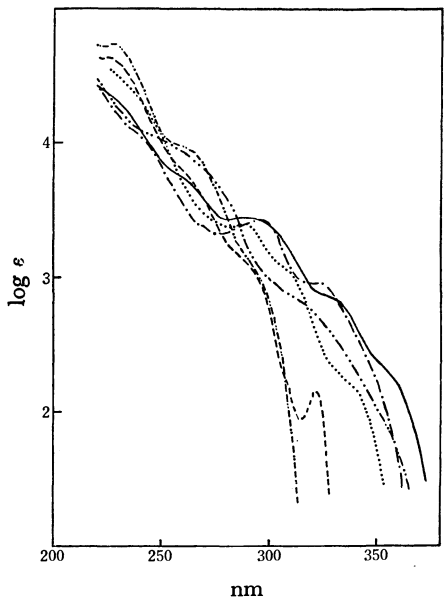


Fig. 1. Electronic spectra of quadruple-layered metaparacyclophanes **12** (——), **14** (-·-·-) in cyclohexane and **15** (-···-), **20** (·····), **21** (– – –), **24** (------) in tetrahydrofuran.

shifts and stronger transannular electronic interactions than that of **1**. On the other hand, stacking of another *para*-substituted benzene on the outside meta ring of **1** gives the structure **20**, which is expected to provide spectral properties of both meta and para bridged types. In fact, the electronic spectrum of **20** is, in a short wavelength region, similar to that of **3** (meta type) and, in a long wavelength region, identical with that of **1** (para type). Compounds **21** and **24** are classified as a meta bridged type. Their spectra exhibit just a weak transannular electronic interaction as seen in multilayered [2.2]metacyclophanes.[8]

Charge Transfer Spectra. It is well-known that an aromatic hydrocarbon forms a charge transfer complex with tetracyanoethylene (TCNE) and that absorption maximum of its charge transfer band gives information on π-basicity of the donor.[10] The increased transannular electronic interaction of multilayered [2.2]paracyclophanes was observed to be reflected in the increase of π-basicity.[2,5] Thus with increasing number of layers, the donor character of the cyclophanes increases and the absorption maximum of the charge transfer complex with TCNE shifts to longer wavelength.

It is interesting to study which of the two benzene rings in [2.2]metaparacyclophane **5** tends to more easily form a complex with TCNE and which of two types of transannular electron release in TCNE complexes is more effective, *viz.*, from the non-complexed meta or para ring to the complexed face ring. Absorption maximum wavelengths of layered metaparacyclophane–TCNE complexes are summarized in Table 1. The charge transfer complex of *m*-xylene with TCNE shows a CT absorption maximum at 440 nm in dichloromethane, and the complex of *p*-xylene two absorption maxima at 420 nm and 465 nm.[2] The CT absorption maximum of [2.2]metaparacyclophane **5** with TCNE is at 457 nm which is situated between the above values of *m*-xylene and *p*-xylene. This suggests that both the meta and para benzenes form complexes with TCNE. The CT complexes of dimethyl derivatives **6** and **7** give us further information. Their absorption maxima appear around 490 nm, with an additional shoulder at 570 nm for **7**. This is considered to arise from the complex of the durene moiety with TCNE. Since durene–TCNE complex shows a CT band at 480 nm,[2] the transannular electron release from the meta ring to the complexed durene moiety is more significant, whereas that from the para ring is less effective.

Table 1. Absorption maxima of layered [2.2]-metaparacyclophane–TCNE complexes in dichloromethane

Compound	λ_{max} (nm)

20	545
MPC[a] having a para- and a meta-rings at both outsides	
1	483, 585[b]
4	428, 520[b]
12	486, 710

a) Metaparacyclophanes. b) Shoulder.

In the case of multilayered metaparacyclophanes having meta rings on both outsides, TCNE exclusively forms a complex with the outside meta ring since TCNE is sterically unable to face the inside ring. Evidently these compounds have very weak π-basicity although their own electronic spectra exhibit remarkable transannular electronic interactions. It can be concluded that electron release from the para ring to the meta ring is less effective.

On the other hand, compounds **3** and **20** have para rings at both ends which exclusively face TCNE. The two absorption maxima of **3** at 451 and 547 nm exhibit outstanding bathochromic shifts as compared with the corresponding peaks of *p*-xylene–TCNE complex. Evidently there is reasonable electron release from the meta to the para ring as described in dimethyl[2.2]-metaparacyclophanes. In the case of **20**, the [2.2]-paracyclophane moiety is considered to form TCNE complex with relative ease. Comparing the CT absorption maximum (545 nm) with that (521 nm) of [2.2]-paracyclophane itself,[2] we might expect some contribution of electron release from the third stacked benzene ring to the complexed face ring of the [2.2]paracyclophane moiety in TCNE complex of **20**.

Compounds **1** and **12** contain double- and triple-layered [2.2]paracyclophane moieties, respectively, which have more increased donor character than [2.2]-metaparacyclophane. In fact, the long wavelength maxima of the TCNE complexes shift to longer wavelength like multilayered [2.2]paracyclophanes[2] and the donor characters of these cyclophanes increase progressively. The transannular electron release of **12** is particularly significant. The case of **4** seems to be more complicated because its structure is a platform-shape and the inside ring is also capable of forming a complex. Probably its CT spectrum appears as a mixture of all possible complexes.

Experimental

Mps are uncorrected. All the solvents are of reagent grade unless otherwise specified. NMR spectra were taken with a Hitachi-Perkin Elmer R-20 spectrometer (60 MHz) using tetramethylsilane as an internal std, electronic spectra with a Hitachi EPS-3T spectrophotometer, and mass spectra with a Hitachi RMU-7 spectrometer at 70 eV using a direct insertion technique.

Bis(bromomethyl)triple-layered[2.2]paracyclophane (9). A mixture of dimethyl derivative **8**[2] (1.00 g, 2.7 mmol) of triple-layered [2.2]paracyclophane, *N*-bromosuccinimide (0.97 g, 5.4 mmol), and a small amount of benzoyl peroxide in 20 ml of carbon tetrachloride was refluxed for 3 h. After removal of insoluble succinimide by filtration, the soln was washed with water and dried over anhyd sodium sulfate. The solvent was evaporated to give the desired product as an oil (1.65 g). This was used in the next step without purification.

*Dithia Compound (**11**).* A soln of the above dibromide **9** in 35 ml of benzene and a soln of 1,3-bis(mercaptomethyl)-benzene **10** (0.54 g, 3 mmol) and sodium hydroxide (0.26 g, 6.5 mmol) in water (2 ml) and ethanol (33 ml) were added dropwise and simultaneously over a period of 2.5 h to a refluxing ethanol (100 ml) in a nitrogen atmosphere. After the solvent was removed, the residue was taken up in benzene and chromatographed on alumina (40 g) using benzene–hexane (1:1) for elution. The initial fraction gave the desired coupling compd **11** (0.23 g, 16% based on **8**), colorless needles from 1:1 benzene–ethanol, mp 217—218 °C.

Found: C, 81.29; H, 6.67; S, 12.16%. Calcd for $C_{36}H_{36}S_2$: C, 81.14; H, 6.87; S, 12.03%. NMR ($CDCl_3$, δ) 2.0—3.9 (m, 24H, CH_2), 5.29 (bs, 1H, Hb), 5.48 (s, 2H, Hd), 5.64 (s, 2H, Hc), 6.17 (s, 4H, He), 6.82 (m, 3H, Ha). MS *m/e* 532 (M^+), 104.

*Quadruple-layered Metaparacyclophane (*m-p,p-p,p-p*) (**12**).* The above coupling compd **11** (100 mg, 0.19 mmol) in 13 ml of purified triethyl phosphite was irradiated through a quartz tube with a high pressure mercury lamp for 3 h under a nitrogen atmosphere. The solvent was evaporated and the residue was chromatographed over silica gel (20 g) using 1:4 benzene–hexane for elution. The first fraction gave the desired product **12** (71 mg, 81%), colorless plates from 1:1 benzene–ethanol, mp 117—118 °C.

Found: C, 92.10; H, 7.60%. Calcd for $C_{36}H_{36}$: C, 92.24; H, 7.76%. NMR ($CDCl_3$, δ) 1.5—3.4 (m, 24H, CH_2), 4.67 (s, 1H, Hc), 5.05 (bs, 1H, Hb), 5.27 (s, 2H, He), 5.90 (s, 1H, Hd), 6.15 (s, 4H, Hf), 6.5 (m, 3H, Ha). MS *m/e* 468 (M^+), 234.

*Quadruple-layered Metaparacyclophane (*m-p,p-p,p-m*) (**14** and **15**).* A mixture of 12,15-dimethyl[2.2]metaparacyclophane **7**[1] (2.98 g, 13 mmol), *N*-bromosuccinimide (2.24 g, 13 mmol), and a small amount of benzoyl peroxide in 20 ml of carbon tetrachloride was refluxed for 5 h. After removal of succinimide by filtration, the soln was washed with water, dried over anhyd sodium sulfate, and then mixed with excess trimethylamine in ether. The mixture was stirred with ice cooling overnight. The resulting white ppt of quaternary ammonium bromide was extracted with a small amount of water. The aq soln was filtered, washed with xylene, and passed through a column containing strongly basic anion exchange resin, Dowex I-X8, 50—100 mesh. The aq soln of the quaternary ammonium hydroxide **13** was mixed with phenothiazine (100 mg) and xylene (50 ml). The mixture was heated with stirring under a nitrogen atmosphere, and water was removed by azeotropic distillation using a Dean-Stark type of water separator. After removal of water, the reflux was continued for additional 6 h. The solvent was removed and the residue was chromatographed over silica gel using 1:4 benzene–hexane for elution. The first fraction gave a mixture of **14** and **15**, which then separated by treatment with carbon tetrachloride. The more soluble isomer **14** (366 mg, 12%) was recrystd from toluene, colorless fine crystals, mp 191—192 °C.

Found: C, 92.27; H, 7.88%. Calcd for $C_{36}H_{36}$: C, 92.24; H, 7.76%. NMR ($CDCl_3$, δ) 1.2—3.4 (m, 24H, CH_2), 4.73 (s, 2H, Hc), 5.06 (bs, 2H, Hb), 5.94 (s, 2H, Hd), 6.4—7.0 (m, 6H, Ha). MS *m/e* 468 (M^+), 234, 104.

The less soluble isomer **15** (82 mg, 2.7%) was recrystd from toluene, colorless fine crystals, mp 265 °C (dec).

Found: C, 92.36; H, 7.61%. Calcd for $C_{36}H_{36}$: C, 92.24; H, 7.76%. NMR ($CDCl_3$, δ) 1.0—3.0 (m, 48H, CH_2), 4.68 (s, 2H, Hc′), 4.79 (s, 2H, Hc), 5.10 (bs, 4H, Hb, and Hb′), 5.94 (s, 2H, Hd), 6.07 (s, 2H, Hd′), 6.4—6.9 (m, 12H, Ha and Ha′). MS *m/e* 468 (M^+), 234.

*4,7-Bis(mercaptomethyl)[2.2]paracyclophane (**17**).* 4,7-Bis(bromomethyl)[2.2]paracyclophane **16**[1] (11.82 g, 30 mmol) was added portionwise to a boiling soln of thiourea (4.60 g, 61 mmol) in 50 ml of ethanol. The mixture was refluxed for 2 h and concd to dryness. The crude thiouronium salt was refluxed with potassium hydroxide (20 g) in 50 ml of water for 15 h. After filtration, the soln was acidified with dil sulfuric acid and the resulting solid was extracted with chloroform. The extract was washed with water, dried over anhyd sodium sulfate, and subjected to alumina column chromatography. Elution with 1:1 benzene–hexane gave the desired mercaptan **17** (6.70 g, 74%), colorless prisms from benzene–hexane, mp 92—93 °C.

Found: C, 72.23; H, 6.79; S, 21.03%. Calcd for $C_{18}H_{20}S_2$: C, 71.94; H, 6.72; S, 21.34%. NMR ($CDCl_3$, δ) 1.53 (t, J=8 Hz, 2H, SH), 2.6—4.0 (m, 12H, bridged CH_2 and CH_2-S), 6.25 (s, 2H, ArH), 6.40 and 6.63 (A_2B_2, J=8 Hz, 4H, ArH). MS *m/e* 300 (M^+).

*Dithia Compound (**19**).* A soln of 4,6-bis(bromomethyl)-[2.2]metaparacyclophane **18**[1] (1.30 g, 3.3 mmol) in 35 ml of benzene and a soln of 4,7-bis(mercaptomethyl)[2.2]paracyclophane **17** (0.99 g, 3.3 mmol) and potassium hydroxide (0.38 g, 5.8 mmol as 85% content) in water (7 ml) and ethanol (28 ml) were added dropwise and simultaneously over a period of 3 h to boiling ethanol (100 ml) in a nitrogen atmosphere. Reflux was continued for additional 12 h and the solvent was removed. The residue was taken up in benzene and chromatographed over alumina using 1:1 benzene–hexane for elution. The first fraction gave the desired product **19** (0.44 g, 25%), colorless fine crystals from toluene, mp 260 °C (with dec).

Found: C, 81.24; H, 6.67; S, 11.90%. Calcd for $C_{36}H_{36}S_2$: C, 81.14; H, 6.82; S, 12.03%. NMR ($CDCl_3$, δ) 1.8—4.2 (m, 24H, CH_2), 4.86 (s, 1H, Hc or Hd), 5.06 (s, 1H, Hd or Hc), 6.03 (bs, 2H, Hb), 6.15 (s, 1H, He or Hf), 6.43 (s, 1H, Hf or He), 6.3—6.7 (m, 4H, Hg), 7.13 (bs, 2H, Ha). MS *m/e* 532 (M^+).

*Quadruple-layered Metaparacyclophane (*p-m,m-p,p-p*) (**20**) and (*p-m,m-m,m-p*) (**21**).* The dithia compd **19** (100 mg, 0.19 mmol) and triethyl phosphite (14 ml) were placed in a quartz tube and irradiated with a high pressure mercury lamp for 3 h under bubbling nitrogen. The solvent was evaporated and the residue was treated with 1:4 benzene–hexane. The insoluble solid was filtered and washed with hexane to give the pure isomer **21** (29 mg, 33%), colorless plates from toluene, mp$>$300 °C.

Found: C, 91.99; H, 7.48%. Calcd for $C_{36}H_{36}$: C, 92.24; H, 7.76%. NMR ($CDCl_3$, δ) 1.5—3.5 (m, 24H, CH_2), 5.26 (s, 2H, Hd), 5.72 (s, 2H, Hc), 6.35 (bs, 4H, Hb), 7.47 (bs, 4H, Ha). MS *m/e* 468 (M^+).

The filtrate was subjected to silica gel column chromatography. Elution with 1:4 benzene–hexane afforded the other isomer **20** (35 mg, 40%), colorless plates from 1:1 benzene–hexane, mp 242—243 °C.

Found: C, 91.99; H, 7.54%. Calcd for $C_{36}H_{36}$: C, 92.24; H, 7.76%. NMR ($CDCl_3$, δ) 1.5—3.5 (m, 24H, CH_2), 4.62 (s, 1H, Hd), 4.69 (s, 1H, He), 4.75 (s, 1H, Hc), 5.55 (bs, 2H, Hb), 6.11 (s, 1H, Hf), 6.29 (bs, 4H, Hg), 7.09 (bs, 2H, Ha). MS *m/e* 468 (M^+), 364, 104.

*Dithia Compound (**23**).* A soln of 4,6-bis(bromomethyl)-[2.2]metacyclophane **22**[8] (1.36 g, 3.5 mmol) in 40 ml of benzene and a soln of 4,7-bis(mercaptomethyl)[2.2]paracyclophane **17** (1.04 g, 3.5 mmol) and potassium hydroxide (0.55 g, 8.3 mmol as 85% content) in water (10 ml) and ethanol (30 ml) were added dropwise and simultaneously over a period of 3.5 h to boiling ethanol (100 ml) in a nitrogen atmosphere.

Reflux was continued for additional 12 h. The solvent was removed, and the residue was taken up in benzene and subjected to alumina column chromatography. Elution with 1:1 benzene–hexane gave an oil which was then treated with hexane to solidify. The product **23** was filtered and washed with hexane (0.52 g, 29%), colorless fine crystals from toluene, mp 230—231 °C.

Found: C, 81.26; H, 6.68; S, 11.94%. Calcd for $C_{36}H_{36}S_2$: C, 81.14; H, 6.82; S, 12.03%. NMR ($CDCl_3$, δ) 2.5—4.1 (m, 25H, CH_2 and Hc), 4.52 (bs, 1H, Hb), 5.23 (s, 1H, Hd), 6.20 (s, 2H, He and Hf), 6.40 and 6.60 (A_2B_2, J=7 Hz, 4H, Hh, and Hg, respectively), 7.1 (m, 3H, Ha). MS *m/e* 532 (M^+).

Quadruple-layered Metaparacyclophane (m-m,m-m,m-p) ***(24)***. The dithia compd **23** (50 mg, 0.09 mmol) and triethyl phosphite (13 ml) was placed in a quartz tube and irradiated with a high pressure mercury lamp (400 W) for 2 h under nitrogen. The solvent was evaporated and the residue was chromatographed over silica gel using 1:4 benzene–hexane for elution. After a mixture of **25** and an unknown oily compd, the desired product **24** was eluted (13 mg, 30%), colorless fine crystals from toluene, mp>300 °C.

Found: C, 92.23; H, 7.50%. Calcd for $C_{36}H_{36}$: C, 92.24; H, 7.76%. NMR ($CDCl_3$, δ) 1.5—3.7 (m, 24H, CH_2), 4.19 (s, 1H, Hc), 4.58 (s, 1H, He), 5.01 (bs, 1H, Hb), 5.62 (s, 1H, Hd), 5.71 (s, 1H, Hf), 6.50 (d, J=2 Hz, 2H, Hg), 7.1—7.4 (m, 3H, Ha), 7.50 (d, J=2 Hz, 2H, Hh). MS *m/e* 468 (M^+).

Arjungenin, Arjunglucoside I, and Arjunglucoside II. A New Triterpene and New Triterpene Glucosides from *Terminalia arjuna*[1]

Tadashi HONDA, Tatsushi MURAE, Takahiko TSUYUKI, Takeyoshi TAKAHASHI, and Masanobu SAWAI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
**Chemical Research Laboratory, Teikoku Hormon Manufacturing Co., Ltd., Shimosakunobe, Kawasaki 213*

(Received June 25, 1976)

Arjungenin, a new triterpene isolated from *Terminalia arjuna*, is shown to be 2α,3β,19α,23-tetrahydroxyolean-12-en-28-oic acid (**1**). The structures of two new triterpene glucosides, arjunglucoside I and arjunglucoside II, isolated from the same plant, were determined to be β-D-glucopyranosyl 2α,3β,19α,23-tetrahydroxyolean-12-en-28-oate (**2**) and β-D-glucopyranosyl arjunolate (**3**), respectively.

It has been reported that *Terminalia arjuna* (Combretaceae) contains ellagic acid, D(+)-mannitol, (+)-leucocyanidin, (+)-leucodelphinidin, β-sitosterol, oleanolic acid, arjunic acid, arjunolic acid, arjunetin, and a saponin ($C_{42}H_{68}O_{15}\cdot 2H_2O$).[2,3] The methanol extract of the bark of the plant was recently examined, and a new sapogenin which we named arjungenin was isolated. In the present communication, we wish to report the structure determination leading to the structure **1** for arjungenin. An isolation of two new saponins named arjunglucoside I (**2**) and arjunglucoside II (**3**) from the same plant is also described.

The molecular formula of $C_{30}H_{48}O_6$ was given for arjungenin (**1**), mp 293—294 °C (dec), $[\alpha]_D$ +29° (EtOH), based on its elemental analysis and mass spectral data. Arjungenin was treated with diazomethane to give a methyl ester (**4**), mp 162—165 °C, which on acetylation with acetic anhydride in pyridine afforded an ester triacetate (**5**), mp 137—138 °C. Treatment of **5** with acetic anhydride in the presence of perchloric acid gave an ester tetraacetate (**6**), an amorphous solid, which shows no IR absorption due to a hydroxyl group. Therefore, the nature of all six oxygen atoms involved in arjungenin is characterized. Arjungenin is a tetrahydroxy carboxylic acid.

In the mass spectra of arjungenin (**1**), **4**, **5**, and of **6**, characteristic peaks due to a retro-Diels-Alder-type cleavage of the olean-12-ene skeleton[4,5] appear at *m/e* 264, *m/e* 278, *m/e* 278, and *m/e* 320, respectively, showing the presence of a hydroxyl group at the D/E ring of arjungenin. The ester triacetate (**5**) was heated under reflux with phosphoryl chloride in pyridine to give a mixture of dienes (**7** and **8**), which was then treated with dry hydrogen chloride in chloroform to afford a single product (**8**), mp 115—118 °C (UV and PMR spectral data: *cf.* Experimental). This product (**8**) was found to be identical with the diene (**8**) derived from methyl tri-*O*-acetylarjunolate (**9**)[6] according to the procedures described by King *et al.*[3] The Collins oxidation of **5** gave a ketone (**10**), an amorphous solid, whose ORD curve (a=+102) was almost identical with that (a=+102) of a 19-keto derivative (**11**)[2a] prepared from arjunic acid (**12**).[2a] Arjungenin is thus suggested to be 2α,3β,19ξ,23-tetrahydroxyolean-12-en-28-oic acid.

The structure of tomentosic acid has been determined to be 2α,3β,19β(equatorial), 23-tetrahydroxyolean-12-en-28-oic acid (**13**).[7] As the physical constants of arjungenin and its methyl ester are not identical with those[7] of **13** and its methyl ester, respectively, the hydroxyl group at C-19 of arjungenin (**1**) is considered to be in an α(axial) configuration. This received support from the following evidence.

Reduction of a ketone (**14**) with sodium borohydride has been reported to yield a 19α(axial)-ol (**15**; methyl arjunate) almost quantitatively.[2a] On reduction with sodium borohydride, the ketone (**10**) gave arjungenin ester triacetate (**5**) as a sole product. The PMR spectrum

of **5** shows a broad signal ($W_{1/2}$=6 Hz) at δ 3.10 due to a proton on C-18 (β, axial) and a multiplet at δ 3.35 due to a proton on C-19 (Table 1). When deuterium oxide was added, this multiplet changed into a doublet ($J_{18\beta,19\beta}$=4 Hz) suggesting an equatorial (β) nature for the proton on C-19. The presence of the same coupling constant ($J_{18\beta,19\beta}$=4 Hz) was observed in the spectrum of arjungenin ester tetraacetate (**6**) (Table 1). The ketone (**10**) was reduced with sodium borodeuteride (in dioxane, room temperature) to give a 19β-deuterated product (**16**). In the PMR spectrum of **16**, the signal at δ 3.10 due to a proton on C-18 appears as a broad singlet ($W_{1/2}$=3 Hz), while the multiplet at δ 3.35 is absent. When treated with acetic anhydride in the presence of perchloric acid, **16** yielded a 19β-deuterated tetraacetate (**17**). The signal due to a proton on C-18 of **17** is shifted and appears at δ 3.30 The evidence described above confirms the assignment for signals due to the protons on C-18 and C-19, and leads to an α(axial)-configuration for the hydroxyl group at C-19. The structure including absolute configuration of arjungenin should be represented by 2α,3β,19α,23-tetrahydroxyolean-12-en-28-oic acid (**1**).

Siaresinolic acid (**18**),[8,9] arjunic acid (**12**),[2a] and sericic acid (**19**)[10] are triterpene acids which have the same structure moiety (19α-hydroxyolean-12-en-28-oic acid structure) around the C/D/E rings as that of arjungenin (**1**). The assignments hitherto reported for the PMR signals due to the protons on C-18β and C-19β of methyl di-*O*-acetylarjunate (**20**) and of methyl tri-*O*-acetylsericate (**21**) seem to be erroneous. In the PMR spectrum of **20**, a triplet at δ 3.35 and a broad signal at δ 3.10 were described to be due to a proton on C-19β and a hydroxyl group on C-19α, respectively.[2a] However, we found that the latter signal (δ 3.10) remained unchanged after addition of deuterium oxide. The signal at δ 3.10 must be due to the proton on C-18β in accordance with our spectral data for arjungenin ester triacetate (**5**) (*cf.* Table 1). Bombardelli *et al.* reported that in the PMR spectrum of **21** a broad doublet at δ 3.16 (J=3 Hz) and a doublet at δ 3.34 (J=3 Hz) are due to the protons on C-19β and C-18β, respectively.[10] These assignments are considered to be reversed based on the observation described for **5** (*cf.*

a) Determined in $CDCl_3$ at 60 MHz. Coupling constants are expressed in Hz. s: singlet; d: doublet; br. d: broad doublet; t: triplet; m: multiplet. b) Determined in $CDCl_3$ at 100 MHz. c) Broad signal. d) On addition of D_2O, this multiplet changes into a doublet (J=4 Hz). e) Unresolved signal. f) A-part of AB-type quartet (J_{AB}=12 Hz). g) B-part of AB-type quartet. h) A-part of ABX-spin system (J_{AB}=12 Hz; J_{AX}=2 Hz). i) B-part of ABX-spin system (J_{AB}=12 Hz; J_{BX}=4 Hz). j) These signals are overlapped. k) These signals are overlapped and appear at δ 4.96—δ 5.30.

Table 1).

Arjunglucoside I (**2**) crystallized from aqueous methanol as colorless needles, mp 231 °C, $[\alpha]_D$ +17° (EtOH). Elemental analysis indicates the formula $C_{36}H_{58}O_{11}\cdot 2H_2O$. Acid-catalyzed methanolysis of **2** afforded arjungenin (**1**) and methyl D-glucoside. An alkaline hydrolysis of **2** yielded **1** and D-glucose. The IR spectrum of **2** shows an ester carbonyl absorption at 1730 cm^{-1} and no carbonyl absorption due to a free carboxylic acid. Therefore the presence of an ester glucoside linkage is suggested for **2**. Acetylation of **2** with acetic anhydride and pyridine gave a heptaacetate (**22**). The mass spectrum of **22** shows a peak at *m/e* 331 due to a fragment ion (**23**)[11] formed by cleavage of

the glucoside linkage; the appearance of a series of peaks at *m/e* 331, *m/e* 211, *m/e* 169, and *m/e* 109[11] suggests the presence of a tetra-*O*-acetylglucopyranosyl group for **22**. As the tetra-*O*-acetyl-D-glucopyranosyl group preferentially exists as a Cl form, the PMR spectrum of **22** ($J_{1',2'}$=8 Hz; Table 1) indicates the presence of a β-glucosyl linkage in the molecule.[12] The presence of an ester glucoside linkage in **22** received support from the appearance of signals due to a proton on C-1′ at δ 5.60 (Table 1). The structure of arjunglucoside I is thus shown to be β-D-glucopyranosyl 2α,3β,19α,-23-tetrahydroxyolean-12-en-28-oate (**2**).

The elemental analysis of arjunglucoside II (**3**; crystallized from aqueous methanol), mp 252 °C, $[\alpha]_D$ +37° (EtOH), fitted best for the molecular formula $C_{36}H_{58}O_{10}\cdot H_2O$.[13] On acid-catalyzed methanolysis, **3** yielded arjunolic acid (**24**) and methyl D-glucoside. An alkaline hydrolysis of **3** gave **24** and D-glucose. The IR spectrum of **3** shows the presence of an ester carbonyl group (1730 cm^{-1}) and the absence of a free carboxylic acid. Acetylation of **3** with acetic anhydride and pyridine gave a heptaacetate (**25**). When treated with methyl iodide in *N,N*-dimethylformamide in the presence of silver oxide, **3** gave a heptamethyl ether (**26**). On hydrolysis of **26**, arjunolic acid trimethyl ether (**27**) was obtained. Therefore, the presence of an ester glucoside linkage is suggested for **3**. The mass spectrum of **25** shows a series of peaks at *m/e* 331, *m/e* 211, *m/e* 169, and *m/e* 109[11] characteristic for the presence of a tetra-*O*-acetylglucopyranosyl group. The presence of a β-glucosyl linkage is suggested from the PMR spectrum of **25** ($J_{1',2'}$=8 Hz; Table 1). The structure of β-D-glucopyranosyl 2α,3β,23-trihydroxy-olean-12-en-28-oate (**3**; β-D-glucopyranosyl arjunolate) is thus given for arjunglucoside II.

Experimental

IR spectra were measured using a Hitachi EPI-G2 spectrometer. UV spectra were determined on a Hitachi EPS-3 spectrophotometer. ORD measurements were carried out on a JASCO Model J-20 spectrometer. Optical rotations were measured on a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV. PMR spectra were measured using a JEOL 4H-100 (100 MHz) or a Hitachi R-20 (60 MHz) spectrometer. Chemical shifts were expressed in δ downfield from TMS as an internal standard, and coupling constants in Hz. Thin layer chromatography (TLC) was carried out on Kieselgel G nach Stahl, Kieselgel GF_{254} nach Stahl, and Kieselgel 60 PF_{254} (E. Merck, Darmstadt). For column chromatography Wakogel C-200 (Wako Pure Chemical Ind.) was used. All mps were determined on a hot block and reported uncorrected.

Isolation. The bark (1.3 kg) of *Terminalia arjuna* were sliced and ground into powder and extracted with methanol (total 4 l) at room temperature. To the extract was added lead acetate (100 g) and a precipitated material then formed was filtered off. Water (*ca.* 12 l) was added to the filtrate to give a greenish-yellow precipitate which was separated by filtration. The mother liquor was concentrated under reduced pressure to give another crop of the greenish-yellow precipitate. The combined greenish-yellow material (material A; total 4 g) showed six spots on TLC and was subjected to separation on a column of silica gel (450 g). Eluted fractions were examined by TLC (silica gel).

Elution with chloroform–methanol (47: 3) gave *arjunic acid*[2a] (**12**; 260 mg), mp >280 °C (dec), $[\alpha]_D$ +28° (*c* 3.1, EtOH), characterized as its methyl ester diacetate[2a] (**20**), mp 234—235 °C (crystallized from methanol), $[\alpha]_D$ +4° (*c* 1.6, EtOH); IR (Nujol) 3540, 1740, and 1640 cm^{-1}; PMR ($CDCl_3$) δ 0.69, δ 1.06, and δ 1.25 (each 3H, s; *t*-CH_3), δ 0.91 and δ 0.99 (each 6H, s; 2×*t*-CH_3), δ 1.98 and δ 2.05 (each 3H, s; 2×$OCOCH_3$), δ 3.62 (3H, s; CO_2CH_3), δ 3.10 (1H, m; $C_{(18\beta)}$-H), δ 3.35 (1H, d, J=4 Hz; $C_{(19\beta)}$-H), δ 4.75 (1H, d, J=11 Hz; $C_{(3\alpha)}$-H), δ 5.15 (1H, ddd, J=11, J=11, and J=4 Hz; $C_{(2\beta)}$-H), and δ 5.45 (1H, t; $C_{(12)}$-H); mass spectrum *m/e* 586 (M^+), *m/e* 568, *m/e* 527, *m/e* 278, *m/e* 260, *m/e* 245, *m/e* 219, and *m/e* 201 (base peak).

Found: C, 71.69; H, 9.54%. Calcd for $C_{35}H_{54}O_7$: C, 71.64; H, 9.28%.

Subsequent elution with chloroform–methanol (23: 2) yielded *arjunolic acid*[6,14] (**24**; 230 mg), mp 296—297 °C (dec.) (from aqueous methanol), $[\alpha]_D$ +61° (*c* 2.9, EtOH), characterized as its methyl ester,[6] mp 210—213 °C, $[\alpha]_D$ +61° (*c* 1.3, EtOH); IR (KBr) 3430, 1730, and 1640 cm^{-1}; PMR ($CDCl_3$) δ 0.73, δ 0.85, δ 1.03, and δ 1.15 (each 3H, s; *t*-CH_3), δ 0.95 (6H, s; 2×*t*-CH_3), δ 3.63 (3H s; CO_2CH_3), and δ 5.30 (1H, m; $C_{(12)}$-H); mass spectrum *m/e* 502 (M^+), *m/e* 484, *m/e* 466, *m/e* 262, *m/e* 249, *m/e* 203 (base peak), *m/e* 189, and *m/e* 133.

Found: C, 74.19; H, 10.12%. Calcd for $C_{31}H_{50}O_5$: C, 74.06; H, 10.03%. This methyl ester was found to be identical (mp, $[\alpha]_D$, IR, PMR, and mass spectrum) with an authentic sample of methyl arjunolate.[14]

Successive elution with chloroform–methanol (9: 1) gave *arjungenin* (**1**; 20 mg), mp 293—294 °C (dec.)(from aqueous methanol), $[\alpha]_D$ +29° (*c* 2.6, EtOH), IR (KBr) 3400, 1690, and 1630 cm^{-1}; PMR (pyridine-d_5) δ 1.08 and δ 1.11 (each 6H, s; 2×*t*-CH_3), δ 1.19 and δ 2.09 (each 3H, s; *t*-CH_3), δ 3.59 (2H, s), δ 3.76 (1H, s), δ 4.15 (2H, m), and δ 5.52 (1H, s; $C_{(12)}$-H); mass spectrum *m/e* 504 (M^+), *m/e* 486, *m/e* 468, *m/e* 264, *m/e* 246, *m/e* 231, and *m/e* 201 (base peak).

Found: C, 71.41; H, 9.56%. Calcd for $C_{30}H_{48}O_6$: C, 71.39; H, 9.59%.

Elution with chloroform–methanol (43: 7) yielded *arjunetin*[2b] (**28**; β-D-glucopyranosyl arjunate; 1.8 g), mp 232—234 °C (from aqueous methanol), $[\alpha]_D$ +15° (*c* 1.3, EtOH); IR (Nujol) 3370, 1730, and 1640 cm^{-1}; mass spectrum *m/e* 488, *m/e* 470, *m/e* 452, *m/e* 264, *m/e* 246, *m/e* 231, and *m/e* 201 (base peak) (no molecular ion peak was observed), characterized as its hexaacetate (**29**)[2b], mp 235—237 °C (from ethanol), $[\alpha]_D$ +1° (*c* 1.5, $CHCl_3$); IR (Nujol) 3510, 1760, 1730, and 1710 cm^{-1}; PMR ($CDCl_3$) δ 0.69, δ 0.90, δ 0.92, δ 0.95, δ 0.98, δ 1.06, and δ 1.25 (each 3H, s; *t*-CH_3), δ 1.99 (3H, s; $OCOCH_3$), δ 2.02 (9H, s; 3×$OCOCH_3$), δ 2.07 (6H, s; 2×$OCOCH_3$), δ 3.06 (1H, br. signal; $C_{(18\beta)}$-H), δ 3.34 (1H, br. signal; $C_{(19\beta)}$-H), δ 3.80 (1H, m; $C_{(5')}$-H), δ 4.06 (1H, as A part of ABX-system: $J_{6',6'}$=12 and $J_{5',6'}$=2 Hz; $C_{(6')}$-H), δ 4.28 (1H, as B part of ABX-system: $J_{6',6'}$=12 and $J_{5',6'}$=4 Hz; $C_{(6')}$-H), δ 4.74 (1H, d, $J_{2\beta,3\alpha}$=10 Hz; $C_{(3\alpha)}$-H), δ 5.44 (1H, m; $C_{(12)}$-H), and δ 5.60 (1H, d, $J_{1',2'}$=8 Hz; $C_{(1')}$-H); mass spectrum *m/e* 570, *m/e* 554, *m/e* 526, *m/e* 331, *m/e* 271, *m/e* 264, *m/e* 246, *m/e* 231, *m/e* 211, *m/e* 169, *m/e* 109, and *m/e* 43 (base peak) (no molecular ion peak was observed).

Found: C, 64.07; H, 8.06%. Calcd for $C_{48}H_{70}O_{16}$: C, 63.85; H, 7.76%. Alkaline hydrolysis (4% KOH–EtOH, reflux, 5 h) of **28** gave arjunic acid (**12**) and D-glucose.

Subsequent elution with chloroform–methanol (21: 4) gave *arjunglucoside II* (**3**; β-D-glucopyranosyl arjunolate; 1 g), mp 252 °C (from aqueous methanol), $[\alpha]_D$ +37° (*c* 2.3, EtOH); IR (KBr) 3400, 1730, and 1630 cm^{-1}; mass spectrum *m/e* 488,

m/e 470, *m/e* 452, *m/e* 248 (base peak), *m/e* 233, *m/e* 203, *m/e* 189, and *m/e* 133 (no molecular ion peak was observed).

Found: C, 61.13; H, 8.83%. Calcd for $C_{36}H_{58}O_{10}\cdot 3H_2O$: C, 61.34; H, 9.15%.

Five among six constituents contained in material A were thus separated. The sixth constituent corresponding to the most polar spot on the TLC could be obtained from material B, rather than from material A, as described below. The mother liquor after separation of material A was treated with hydrogen sulfide to precipitate lead sulfide which was removed by filtration. The resulting filtrate gave, on evaporation of the solvent, a residue (material B; 3.2 g), containing the sixth constituent mentioned above as a main constituent (examined by TLC). Material B was subjected to separation on a column of silica gel (250 g). Elution with chloroform–methanol (83: 17) gave *arjunglucoside I* (**2**; 450 mg), mp 231 °C (from aqueous methanol), $[\alpha]_D$ +17° (*c* 2.8 EtOH); IR (KBr) 3410, 1730, and 1640 cm^{-1}; mass spectrum *m/e* 504, *m/e* 486, *m/e* 468, *m/e* 264, *m/e* 246, *m/e* 231, and *m/e* 201 (base peak) (no molecular ion peak was observed). Found: C, 63.16; H, 9.13%. Calcd for $C_{36}H_{58}O_{11}\cdot H_2O$: C, 63.14; H, 8.83%.

Methylation of Arjungenin (1). To arjungenin (**1**, 217 mg) in ether was added diazomethane in ether. The reaction mixture was treated as usual to give a residue (215 mg), which was crystallized from ether to yield arjungenin methyl ester (**4**), mp 162—165 °C; IR (KBr) 3430, 1720, and 1640 cm^{-1}; mass spectrum *m/e* 518 (M^+), *m/e* 500, *m/e* 482, *m/e* 278, *m/e* 260, *m/e* 245, *m/e* 219, and *m/e* 201 (base peak). Found: *m/e* 518.3503 (M^+). Calcd for $C_{31}H_{50}O_6$: *m/e* 518.3604.

Acetylation of Arjungenin Methyl Ester (4). Arjungenin methyl ester (**4**; 100 mg) dissolved in pyridine (1 ml) was treated with acetic anhydride (1 ml) overnight at room temperature. After the usual work-up, acetylated product (100 mg) was obtained and purified by column chromatography to give arjungenin methyl ester triacetate (**5**) mp 137—138 °C, $[\alpha]_D$ +8° (*c* 1.8, EtOH); IR (Nujol) 3520, 1740, and 1630 cm^{-1}, PMR (Table 1); mass spectrum *m/e* 644 (M^+), *m/e* 626, *m/e* 585, *m/e* 278, *m/e* 260, *m/e* 245, *m/e* 219, and *m/e* 201 (base peak). Found: C, 68.73; H, 8.89%. Calcd for $C_{37}H_{56}O_9$: C, 68.91; H, 8.75%.

Acetylation of Arjungenin Methyl Ester Triacetate (5). To arjungenin methyl ester triacetate (**5**; 23 mg) in acetic anhydride (2 ml) was added a drop of perchloric acid at −10 °C. The reaction mixture was kept at room temperature for 15 min, and poured into water. Extraction with ether and removal of the solvent gave a residue (22 mg), which was purified by preparative TLC to yield arjungenin methyl ester tetraacetate (**6**; 9 mg), an amorphous solid, IR (Nujol) 1730, and 1230 cm^{-1}, PMR (Table 1; signals due to four acetoxyl groups were observed); mass spectrum *m/e* 626 [(M−AcOH)$^+$], *m/e* 567, *m/e* 507, *m/e* 320, *m/e* 260, *m/e* 245, and *m/e* 201 (base peak)(no molecular ion peak was observed). Found: *m/e* 626.3820 [(M−AcOH)$^+$]. Calcd for ($C_{39}H_{58}O_{10}-C_2H_4O_2$): *m/e* 626.3815.

Dehydration of Arjungenin Methyl Ester Triacetate (5). Arjungenin methyl ester triacetate (**5**; 30 mg) in pyridine (0.5 ml) was treated with phosphoryl chloride (0.2 ml) under reflux for 6 h. The reaction mixture was treated in the usual manner to give a residue which was chromatographed to afford a mixture (24 mg) of dienes (**7** and **8**), an amorphous solid, UV (EtOH) λ_{max} 243, 252, and 261 nm, mass spectrum *m/e* 626 and *m/e* 201 (base peak). The fact that the product was a mixture of dienes (**7** and **8**) is suggested by the PMR spectrum. There appear signals at δ 5.40 (s; $C_{(19)}$–H) and δ 5.48 (m; $C_{(12)}$–H) due to olefinic protons of a 12,18-diene[2a] system, besides those at δ 5.53 (d, J=11 Hz; $C_{(12)}$–H) and δ 6.43 (dd, J=11 and J=2 Hz; $C_{(11)}$–H) due to olefinic protons of the 11,13(18)-diene (**8**) (*vide infra*).

Treatment of the Mixture of Dienes (7 and 8) with Dry Hydrogen Chloride. Dry hydrogen chloride was passed through a solution of the mixture (24 mg) of dienes (**7** and **8**) in chloroform (3 ml) at room temperature for 1 h. After the usual work-up, a residue was obtained and purified by preparative TLC to give methyl 2α,3β,23-triacetoxyoleana-11,13(18)-dien-28-oate (**8**; 15 mg), mp 115—118 °C, $[\alpha]_D$ −120° (*c* 0.2, EtOH); UV (EtOH) λ_{max} 243.5 nm (log ε 4.41), 251.5 (4.47), 260.5 (4.27); IR (KBr) 1735 and 1630 cm^{-1}, PMR ($CDCl_3$) δ 0.80 (6H, s; 2×*t*-CH_3), δ 0.90, δ 0.94, δ 0.97, and δ 1.10 (each 3H, s; *t*-CH_3), δ 2.00, δ 2.01, and δ 2.10 (each 3H, s; $OCOCH_3$), δ 3.66 (3H, s; CO_2CH_3), δ 3.60 and δ 3.80 (each 1H, d, J=12 Hz; $C_{(23)}$–H_2), δ 5.15 (2H, m; $C_{(2\beta)}$–H and $C_{(3\alpha)}$–H), δ 5.53 (1H, d, J=11 Hz; $C_{(12)}$–H), and δ 6.43 (1H, dd, J=11 and J=2 Hz; $C_{(11)}$–H); mass spectrum *m/e* 626 (M^+), *m/e* 567, *m/e* 507, *m/e* 447, *m/e* 387, and *m/e* 187 (base peak). Found: C, 70.75; H, 8.81%. Calcd for $C_{37}H_{54}O_8$: C, 70.90; H, 8.68%.

Oxidation of Methyl Tri-O-acetylarjunolate (9) with Selenium Dioxide. This oxidation was effected according to the procedures described by King *et al.*,[3] which include alkaline hydrolysis at the final stage to give methyl 2α,3β,23-trihydroxyoleana-11,13(18)-dien-28-oate (**30**). Methyl tri-*O*-acetylarjunolate[6] (**9**; 51 mg) in acetic acid (2 ml) was heated with selenium dioxide (9 mg) under reflux for 17 h. After cooling, the reaction mixture was poured into water and extracted with ether. Removal of the solvent gave a residue (42 mg), which was purified by preparative TLC to afford 2α,3β,23-triacetoxyoleana-11,13(18)-dien-28-oate (**8**; 18 mg). This compound proved to be identical (mp, $[\alpha]_D$, IR, UV, PMR, TLC, and mass spectrum) with the diene (**8**) obtained from **5** by dehydration and by subsequent treatment with dry hydrogen chloride.

The Collins Oxidation of Arjungenin Methyl Ester Triacetate (5). To a solution prepared from chromium trioxide (260 mg), pyridine (0.5 ml), and dichloromethane (4 ml), was added a solution of arjungenin methyl ester triacetate (**5**; 220 mg) in dichloromethane (2 ml), and the whole was stirred at room temperature for 30 min. After the usual work-up a residue (200 mg) was obtained. The residue was purified by preparative TLC to yield methyl 2α,3β,23-triacetoxy-19-oxo-olean-12-en-28-oate (**10**, 150 mg), an amorphous solid; IR (Nujol) 1745 and 1710 (sh) cm^{-1}; PMR ($CDCl_3$) δ 0.74, δ 0.88, δ 0.98, and δ 1.19 (each 3H, s; *t*-CH_3), δ 1.09 (6H, s; 2×*t*-CH_3), δ 1.98, δ 2.00, and δ 2.07 (each 3H, s; $OCOCH_3$), δ 3.68 (3H, s; CO_2CH_3), δ 3.58 and δ 3.90 (each 1H, d, J=12 Hz; $C_{(23)}$–H_2), δ 5.10 (2H, m, $C_{(2\beta)}$–H and $C_{(3\alpha)}$–H), and δ 5.30 (1H, m; $C_{(12)}$–H); ORD (*c* 0.06, EtOH) $[\phi]_{315}$ +5300° and $[\phi]_{265}$ −4900° (a=+102); mass spectrum *m/e* 642 (M^+), *m/e* 582, *m/e* 522, *m/e* 462, *m/e* 276, and *m/e* 217 (base peak). Found: C, 69.11; H, 8.58%. Calcd for $C_{37}H_{54}O_9$: C, 69.13; H, 8.47%.

The Jones Oxidation of Methyl Di-O-acetylarjunate (20). To a solution of methyl di-*O*-acetylarjunate (**20**; 200 mg) in acetone (15 ml) was added the Jones reagent (2.2 ml), and the mixture was stirred at 0 °C for 20 min. After the usual treatment, a residue was crystallized from methanol to afford methyl 2α,3β-diacetoxy-19-oxo-olean-12-en-28-oate[2a] (**11**; 120 mg), mp 200—201 °C; IR (KBr) 1720, 1440, 1360, and 1240 cm^{-1}; PMR ($CDCl_3$) δ 0.78, δ 1.00, and δ 1.20 (each 3H, s; *t*-CH_3), δ 0.91 and δ 1.10 (each 6H, s; 2×*t*-CH_3), δ 2.00 and δ 2.05 (each 3H, s; $OCOCH_3$), δ 3.70 (3H, s; CO_2CH_3), δ 4.77 (1H, d; J=11 Hz; $C_{(3\alpha)}$–H), δ 5.05 (1H, ddd; J=11, J=11, and J=4 Hz; $C_{(2\beta)}$–H), and δ 5.28 (1H, m; $C_{(12)}$–H); ORD (*c* 0.04, EtOH) $[\phi]_{315}$ +4900° and $[\phi]_{265}$ −5300° (a=+102); mass spectrum *m/e* 584 (M^+), *m/e* 525, *m/e* 464, *m/e* 405, *m/e* 276,

and *m/e* 217 (base peak). Found: C, 71.69; H, 9.23%. Calcd for $C_{35}H_{52}O_7$: C, 71.88; H, 8.96%.

*Reduction of the Ketone (**10**) with Sodium Borohydride.* The ketone (**10**; 16 mg) in dioxane (1.5 ml) was treated with sodium borohydride (76 mg) under stirring at room temperature for 2 h. The reaction mixture was diluted with water, acidified with diluted sulfuric acid, and extracted with ether. Removal of the solvent gave a residue (11 mg), showing one spot (on TLC) corresponding to the 19α-ol (**5**). This residue was passed through a column of silica gel [elution with benzene–acetone (47: 3)] to afford arjungenin methyl ester triacetate (**5**; 8 mg) (identified by mp, mixed mp, $[\alpha]_D$, IR, PMR, and mass spectra).

Similar reduction of the ketone (**10**; 20 mg) in dioxane (1.2 ml) with sodium borodeuteride (102 mg) gave a residue (16 mg), which was purified by preparative TLC to yield 19β-deuterated arjungenin methyl ester triacetate (**16**; 13 mg). The IR spectrum of **16** is almost superimposable with that of **5**.

In the PMR spectrum ($CDCl_3$) of **16**, a broad singlet (1H, $W_{1/2}$=3 Hz; $C_{(18\beta)}$-H) appears at δ 3.10. The multiplet signal at δ 3.35 (1H; $C_{(19\beta)}$-H) observed for **5** is absent in the spectrum of **16**. The other PMR spectral data of **16** and **5** are identical. The mass spectrum of **16** shows the following peaks: *m/e* 645 (M^+), *m/e* 627, *m/e* 586, *m/e* 279, *m/e* 261, *m/e* 246, *m/e* 220, and *m/e* 202 (base peak).

*Acetylation of the 19β-Deuterated Product (**16**).* The 19β-deuterated product (**16**; 11 mg) was acetylated according to the procedures described for the acetylation of **5**. 19β-Deuterated arjungenin methyl ester tetraacetate (**17**; 6 mg) was obtained as an oil. The IR spectra of **17** and arjungenin methyl ester tetraacetate (**6**) are almost identical. The PMR spectrum ($CDCl_3$) of **17** shows a broad singlet (1H) at δ 3.30 due to $C_{(18\beta)}$-H; no signal due to $C_{(19\beta)}$-H was observed. The other PMR spectral data of **17** and **6** are the same. The mass spectrum of **17** shows the following peaks: *m/e* 627 [(M−AcOH)$^+$], *m/e* 568, *m/e* 508, *m/e* 321, *m/e* 261, *m/e* 246, and *m/e* 202 (base peak) (no molecular ion peak was observed).

*Methanolysis of Arjunglucoside I (**2**).* To a solution prepared from methanol (6 ml), water (2 ml) and sulfuric acid (0.3 ml), was added arjunglucoside I (**2**; 77 mg), and the resulting mixture was heated under reflux for 4 h. The reaction mixture was poured into water and extracted with ether. The ethereal layer was treated as usual to give a residue, which was crystallized from aqueous methanol to afford arjungenin (**1**; 45 mg) (identified by mp, mixed mp, $[\alpha]_D$, IR, PMR, TLC, and mass spectrometry). The aqueous layer was passed through a column of Dowex 1-X2 (OH^-) and a column of Dowex 50W-X8 (H^+), successively, and concentrated under reduced pressure to give a residue. The residue (methyl D-glucoside) was trimethylsilylated and subjected to examination by GLC [column: 2% Silicone OV 17 on Chromosorb WAW, 4(mm)×1.5(m), column temperature: 160 °C; detection: FID, detector temperature: 190 °C, carrier gas: N_2 45 ml/min; instrument: Shimadzu GC-4A PF] to identify the silylated product as methyl tetra-*O*-trimethylsilyl-D-glucoside (retention time: 8.6 min).

*Alkaline Hydrolysis of Arjunglucoside I (**2**).* To a solution prepared from methanol (5 ml), water (3 ml) and potassium hydroxide (0.3 g), was added arjunglucoside I (**2**; 170 mg). The resulting mixture was heated under reflux for 5 h, poured into water, acidified by addition of hydrochloric acid, and extracted with ether. From the ethereal layer arjungenin (**1**; 100 mg) (identified by mp, mixed mp, $[\alpha]_D$, IR, PMR, TLC, and mass spectrometry) was obtained. The aqueous layer was passed through a column of Dowex 1-X2 (OH^-) and then a column of Dowex 50W-X8 (H^+), and concentrated under reduced pressure to give a residue, which was identified to be D-glucose (R_f=0.52) [on Avicel plate (Funakoshi Pharmaceutical Co., Ltd.), developing with pyridine–ethyl acetate–acetic acid–water (5: 5: 1: 3), visualized by aniline hydrogen phthalate at 80 °C].

*Acetylation of Arjunglucoside I (**2**).* Arjunglucoside I (**2**; 38 mg) in pyridine was treated with acetic anhydride overnight at room temperature. The reaction mixture was treated as usual to give a residue, which was purified by column chromatography to afford arjunglucoside I heptaacetate (**22**; 30 mg), mp 147—149 °C, $[\alpha]_D$ −7° (*c* 1.4, EtOH); IR (KBr) 3520, 1740, and 1630 cm^{-1}; PMR (Table 1); mass spectrum *m/e* 331, *m/e* 271, *m/e* 264, *m/e* 246, *m/e* 231, *m/e* 211, *m/e* 201, *m/e* 169, *m/e* 109, and *m/e* 43 (base peak) (no molecular ion peak was observed). Found: C, 62.08; H, 7.59%. Calcd for $C_{50}H_{72}O_{18}$: C, 62.49; H, 7.55%.

*Methanolysis of Arjunglucoside II (**3**).* A mixture of arjunglucoside II (**3**; 130 mg), methanol (5 ml), water (1 ml), and sulfuric acid (0.2 ml), was heated under reflux for 4 h. Water was added to the reaction mixture and the resulting mixture was extracted with ether. From the ethereal layer arjunolic acid[6] (**24**; 85 mg) was obtained (identified by mp, $[\alpha]_D$, IR, TLC, and mass spectrometry). The aqueous layer was treated as described in the methanolysis of **2** to give a residue, which proved to be methyl D-glucoside (identified by its conversion to methyl tetra-*O*-trimethylsilyl-D-glucoside; detection by GLC).

*Alkaline Hydrolysis of Arjunglucoside II (**3**).* A mixture of arjunglucoside II (**3**; 100 mg), methanol (4 ml), water (2 ml), and potassium hydroxide (0.2 g), was heated under reflux for 4 h. The reaction mixture was poured into water, acidified by addition of hydrochloric acid, and extracted with ether. The ethereal layer gave, after the usual work-up, arjunolic acid[6] (**24**; 60 mg) (identified by mp, $[\alpha]_D$, IR, TLC, and mass spectrometry). The aqueous layer was treated as described in the alkaline hydrolysis of **2** to give a residue, which proved to be identical with D-glucose.

*Acetylation of Arjunglucoside II (**3**).* Arjunglucoside II (**3**; 40 mg) in pyridine was acetylated with acetic anhydride overnight at room temperature. After the usual work-up, a residue was obtained. The residue was chromatographed to yield arjunglucoside II heptaacetate (**25**; 46 mg), mp 136—140 °C, $[\alpha]_D$ +26° (*c* 2.0, $CHCl_3$); IR (Nujol) 1740 and 1630 cm^{-1}; PMR (Table 1), mass spectrum *m/e* 331, *m/e* 271, *m/e* 248, *m/e* 233, *m/e* 211, *m/e* 203, *m/e* 189, *m/e* 169, *m/e* 133, *m/e* 109, and *m/e* 43 (base peak) (no molecular ion peak was observed). Found: C, 62.33; H, 7.54%. Calcd for $C_{50}H_{72}O_{17}\cdot H_2O$: C, 62.35; H, 7.74%.

*Methylation of Arjunglucoside II (**3**).* To a solution of arjunglucoside II (**3**; 110 mg) in *N*,*N*-dimethylformamide (3 ml), were added methyl iodide (4 ml) and silver oxide (1.2 g), and the whole was stirred at 60 °C for 24 h. After cooling, the reaction mixture was filtered to remove insoluble material, which was washed several times with chloroform. The washings were combined with the filtrate. Evaporation of the solvents gave a residue, which was dissolved in chloroform. This chloroform solution was washed successively with water, aqueous sodium thiosulfate solution, and with brine, and dried over calcium chloride. Removal of the solvent gave a residue, which was chromatographed to give arjunglucoside II heptamethyl ether (**26**; 30 mg), an amorphous solid, IR (KBr) 1740 and 1635 cm^{-1}; PMR ($CDCl_3$) δ 0.68, δ 0.78, δ 0.98, and δ 1.16 (each 3H, s; *t*-CH_3), δ 0.94 (6H, s; 2×*t*-CH_3), δ 3.33, δ 3.38, δ 3.43, and δ 3.65 (each 3H, s; OCH_3), δ 3.54 (9H, s; 3×OCH_3), δ 5.32 (2H, m; $C_{(12)}$-H and $C_{(1')}$-H); mass spectrum *m/e* 748 (M^+), *m/e* 704, *m/e* 584, *m/e* 530, *m/e* 528, *m/e* 498, *m/e* 497, *m/e* 248, *m/e* 219, *m/e* 203, *m/e* 187 (base peak), and *m/e* 155. Found: C, 67.53; H, 9.79%. Calcd for $C_{43}H_{72}O_{10}\cdot H_2O$: C,

67.33; H, 9.72%.

*Acid Hydrolysis of Arjunglucoside II Heptamethyl Ether (**26**).* A mixture of the heptamethyl ether (**26**; 100 mg), methanol (8 ml), and hydrochloric acid (0.3 ml), was heated under reflux for 7 h. The reaction mixture was poured into water and extracted with ether. Evaporation of the solvent gave a residue, which was chromatographed to afford arjunolic acid trimethyl ether (**27**; 43 mg), mp 140—150 °C (dec); IR (Nujol) 1690 cm^{-1}; PMR ($CDCl_3$) δ 0.65, δ 0.72, and δ 1.12 (each 3H, s; t-CH_3), δ 0.94 (9H, s; $3\times t$-CH_3), δ 3.31, δ 3.42, and δ 3.52 (each 3H, s; OCH_3), δ 5.27 (1H, br. signal; $C_{(12)}$–H); mass spectrum *m/e* 530 (M^+), *m/e* 528, *m/e* 498, *m/e* 466, *m/e* 453, *m/e* 248 (base peak), *m/e* 233, *m/e* 203, *m/e* 189, and *m/e* 133. Found; *m/e* 530.3887. Calcd for $C_{33}H_{54}O_5$: *m/e* 530.3968.

Micellar Activation of Nucleophilic Reactivity of Coenzyme A and Glutathione toward *p*-Nitrophenyl Acetate*

Seiji SHINKAI and Toyoki KUNITAKE

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received June 26, 1976)

The reaction of coenzyme A(CoASH) and glutathione (GSH) with *p*-nitrophenyl acetate was studied in aqueous media at 30 °C. The reaction is highly accelerated in the presence of hydrophobic aggregates such as hydrophobic oligocations and CTABr micelles. Nonionic and anionic micelles were ineffective. The pK_a of CoASH is lowered by 0.5 pK_a unit in 2 mM of CTABr, while that of GSH is hardly affected. The second-order rate constant for CoASH is improved (290-fold) more than that of GSH(100-fold), relative to the nonmicellar system. Enhanced reactivities are efficiently suppressed by addition of KCl. These results are the first example of the marked activation of sulfhydryl coenzymes by the micellar microenvironment, and explicable by the concept of *hydrophobic ion pairs*: the coenzymes are bound onto the cationic micelle and the thiol anions form ion pairs with surfactant cations at the relatively hydrophobic environment of the micelle.

The reactivity of thiol groups has been of much concern in relation to functions of some sulfhydryl enzymes and enzymes requiring coenzyme A(CoASH) or glutathione (GSH).[1,2]

Nucleophilic reactions of thiol anions toward *p*-nitrophenyl acetate (NpAc: Eq. 1) have been evaluated by several investigators. Schonbaum and Bender[3] reported the hydrolysis of NpAc by *o*-mercaptobenzoic acid, and Jencks and Carriuolo[4] determined second-order rate constants (k_a) for the reaction of 2-mercaptoethanol and mercaptoacetate with NpAc. Subsequently, Whitaker[5] and Ogilvie and coworkers[6] reported the rate constants for the reaction of biologically important thiols such as cysteine and glutathione (GSH) with NpAc. However, the nucleophilic reactivity of thiol groups *in vivo* is incomparably enhanced relative to those observed *in vitro*. It is known that the active site of sulfhydryl enzymes is situated in the hydrophobic region,[7] but the essential role of the hydrophobic environment is not established. Heitmann[8] demonstrated that the nucleophilicity of *N*-dodecanoyl-DL-cysteinate mixed with a cationic micelle is appreciably improved (6—7 fold toward chloroacetamide, 100—200 fold toward NpAc). Tagaki and coworkers[9] also reported that a micellar solution of octadecyltrimethylammonium bromide markedly enhanced the reaction rate of alkanethiols and NpAc.

The possibility thus arises that the nucleophilic reactivity of a number of biological cofactors containing thiol groups is commonly affected by the micellar environment. One may anticipate that the reactions of coenzymes occurring in micelles are akin to those occurring in apoenzymes. That is, coenzymes may be activated by the micellar environment as done by apoenzymes. In this study, we examined the effect of micellar environments on the nucleophilic reactivity of coenzyme A(CoASH) and GSH toward NpAc. These coenzymes have additional anionic charges other than the thiol group and are expected to be easily bound onto the cationic micelles. We have discovered that the nucleophilicity of these biological cofactors toward NpAc (Eq. 1) is pronouncedly enhanced in the presence of a cationic micelle of hexadecyltrimethylammonium bromide (CTABr) and analogous hydrophobic aggregates (tetracationic detergents), and that the rate enhancement is attributed to the formation of *hydrophobic ion pairs*.[10-12] This is probably the first example that the nucleophilicity of coenzymes is markedly improved by the microenvironmental effect.

Experimental

Materials. Coenzyme A and glutathione were purchased from Kojin and Wako Pure Chem. Ind., respectively, and used without further purification. These cofactors were assayed by the reaction with NpAc(see Results Section). Hexadecyltrimethylammonium bromide was the product of wako Pure Chem. Ind., and recrystallized from ethanol before use. Other surfactants (sodium dodecylsulfate, polyoxyethylene ($n=10$) oleyl alcohol, trioctylmethylammonium chloride) were used without further purification. Quaternized triethylenetetramine derivatives were prepared and characterized by Mr. Y. Okahata.

Kinetics. The kinetic measurements for the reaction of coenzyme A and glutathione with NpAc were carried out in 3 vol% aqueous ethanol at 30 ± 0.1 °C at a calculated ionic strength ($\mu=0.01$ with KCl) unless otherwise stated. The buffer solutions (0.02 M borate below pH 9.3 and ammonium above pH 9.3) were prepared in twice-distilled water under nitrogen. In order to avoid air oxidation of thiols, the kinetic runs were performed under anaerobic conditions(N_2). A typical example of the reaction procedure is as follows: 2.8 ml of a buffer solution containing an appropriate surfactant were placed in a modified Thunberg cuvette, and was degassed for 15 min by bubbling N_2. An aqueous solution (0.1 ml) of coenzyme was added, and 0.1 ml of an ethanol solution of NpAc was deposited in the side-arm of the cell. Both solutions

* Nucleophilic Ion Pairs. III. Contribution No. 407 from this department.

were degassed for 15 min by passing N_2. The cell was closed and equilibrated at 30 °C, and the content of the side-arm was rapidly mixed with the buffer solution. The progress of the reaction was followed by monitoring the *p*-nitrophenolate ion released (401 nm) on a Hitachi 124 spectrophotometer equipped with a thermostated cell-housing. In runs in the presence of surfactants, excess substrates were employed in order to lower the concentration of thiols as far as possible, since addition of polyanionic species may significantly affect the catalysis of the cationic micelle. On the other hand, excess thiols were employed in the absence of the surfactant. The pseudo-first-order rate constants were calculated with a Sharp Compet 364 for up to 3—4 half-lives. The pH of the reaction mixture was confirmed not to vary before and after the reaction by pH measurements (TOA Digital pH Meter, model HM-15A).

Results

Burst Release of p-*Nitrophenolate and Stoichiometry.* The reaction under anaerobic conditions was initiated by mixing of a surfactant solution containing coenzymes and an ethanol solution of NpAc. Figure 1 gives the time course of the absorbance change at 401 nm for the reaction of GSH and NpAc in the presence of 2 mM of CTABr. The burst release of *p*-nitrophenolate at pH 9.20 almost concluded within 10 s, and the slow, linear increase in the absorbance ensued. Since the absorbance increase in the second stage of the reaction was parallel to (or, under the insufficiently anaerobic condition, slightly slower than) that observed in the absence of the coenzyme moiety, the decomposition of the thiol ester (turnover) is negligibly slow, and the second stage should correspond to the spontaneous decay of NpAc (k_{spont}).

The magnitude of the initial burst was plotted against the concentration of CoASH and GSH in Fig. 2. The slopes of Fig. 2 were evaluated by the least-squares method to be 15000 for CoASH and 16600 for GSH,

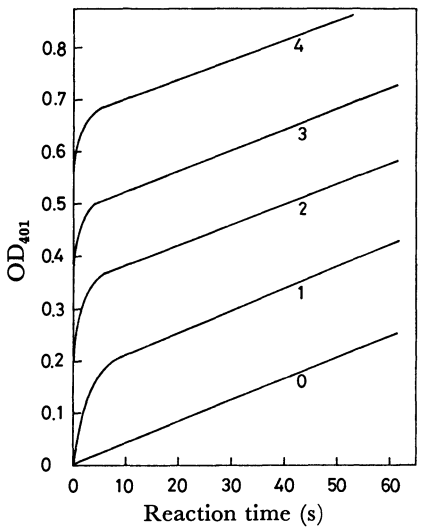

Fig. 1. Time-course of the absorption of *p*-nitrophenolate ion (401 nm) for the reaction of GSH and NpAc. pH 9.20, $[NpAc]=4.00\times10^{-4}$ M, $[CTABr]=2.0\times10^{-3}$ M. $[GSH]_T\times10^5$ M: (0) 0; (1) 1.00; (2) 2.00; (3) 3.00; (4) 4.00.

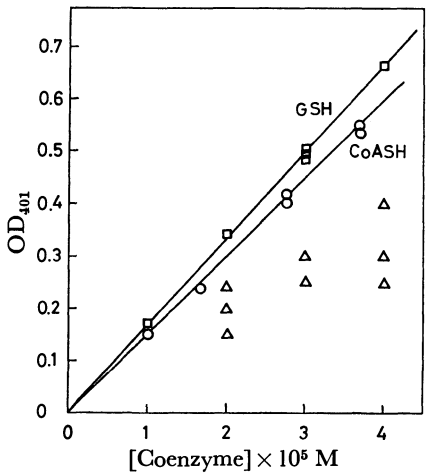

Fig. 2. $[CoASH]_T$ and $[GSH]_T$ *vs.* OD_{401} of the initial burst stage; △, N_2 was not bubbled prior to initiation of the reaction of GSH and NpAc.

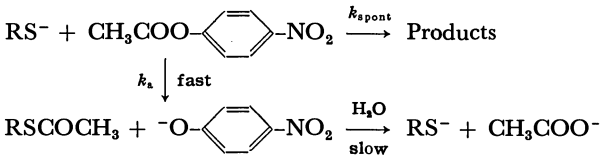
respectively. These values are close to the molar absorption coefficient of the *p*-nitrophenolate anion ($\varepsilon=17800$) in the presence of 2 mM of CTABr. Thus, the coenzymes bound onto the CTABr micelle must react quantitatively with NpAc. The slight discrespancy observed would be due to the loss of the thiol function by air oxidation. When nitrogen was not bubbled prior to the reaction, the data lacked in reproducibility and a smaller slope (*ca.* 7500) resulted (Fig. 2). The influence of cationic micelles on the oxidation of thiols will be discussed elsewhere.

Results of Figs. 1 and 2 now enable us to depict reaction scheme 1 and the corresponding rate equation (Eq. 2),

$$v_{obsd}=k_{spont}[NpAc]+v_a \quad (2)$$

where v_{obsd} is the reaction rate at the initial burst stage and v_a the reaction rate for the acyl transfer from NpAc to the coenzyme.



Scheme 1.

Determination of Second-Order Rate Constants. The rate constants for the initial burst reaction were determined at pH 8.78. The increase in absorbance at 401 nm satisfied the pseudo-first-order rate equation at least up to 3 half-lives, and the pseudo-first-order rate constants ($k_{a,obsd}$) thus evaluated were proportional to the concentration of NpAc (Fig. 3). Evidently, the reaction is first-order both in coenzyme and in substrate, giving the kinetic expressions of Eqs. 3 and 4,

$$v_a=k_{a,obs}[CoASH\text{ or }GSH]_T$$
$$=k_a'[CoASH\text{ or }GSH]_T[NpAc] \quad (3)$$

$$k_a'=k_a\left(\frac{K_a}{K_a+a_H}\right) \quad (4)$$

where K_a is the acid dissociation constant of thiol groups

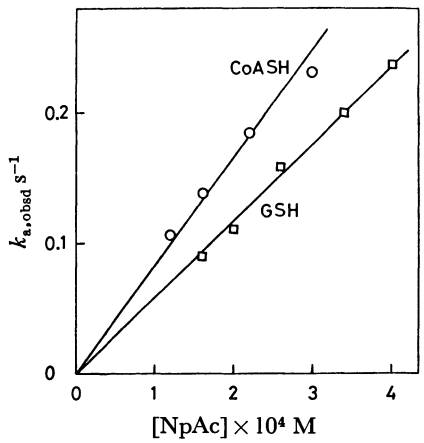


Fig. 3. [NpAc] *vs.* $k_{a,obsd}$. pH 8.78±0.03, [CTABr]= 2.0×10^{-3} M, $[CoASH]_T=2.00\times10^{-5}$ M, $[GSH]_T=2.19\times10^{-5}$ M.

Table 1. Apparent and true second-order rate constants

Surfactant	mM	k'_a at pH 8.78 $M^{-1}s^{-1}$	k_a $M^{-1}s^{-1}$	pK_a[c]

and $[CoASH]_T$ and $[GSH]_T$ are the total concentration of coenzymes. Typical examples of the apparent second-order rate constants (k_a') for the reaction of CoASH and GSH with NpAc in the presence and the absence of surfactants are recorded in Table 1.

Surfactant Concentration-Rate Profiles. In the non-micellar system, the apparent second-order rate constants at pH 8.78 were 1—8 $M^{-1}s^{-1}$ (Table 1). These values are not much different from those of alkane thiols,[5,6] indicating that the nucleophilic reactivity of biological cofactors toward NpAc is not anomalous in the nonenzymatic system.

In Figs. 4 and 5, the apparent second-order rate constants were plotted against the concentration of CTABr and quaternized triethylenetetramine derivatives. Plots of k_a' against the concentration of CTABr

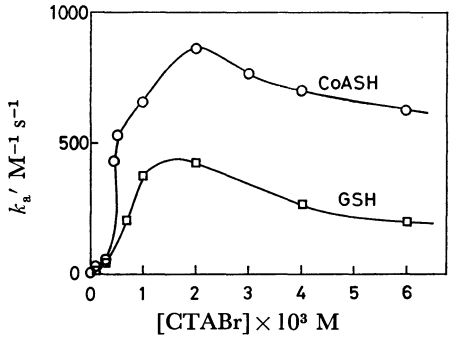

Fig. 4. Apparent second-order rate constants plotted against the concentration of CTABr. For CoASH+NpAc: $[CoASH]_T=2.00\times10^{-5}$ M, $[NpAc]=1.60\times10^{-4}$ M, pH 8.78±0.03. For GSH+NpAc: $[GSH]_T=2.05\times10^{-5}$ M, $[NpAc]=3.35\times10^{-4}$ M, pH 8.65±0.03.

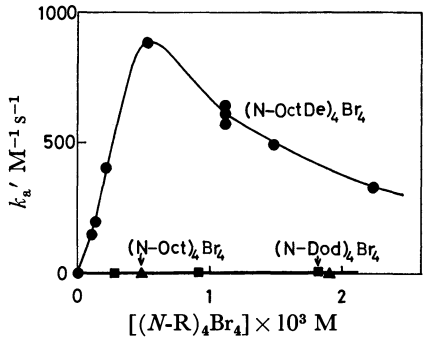

Fig. 5. Apparent second-order rate constants for the reaction of CoASH and NpAc plotted against the concentration of (N-R)$_4$Br$_4$. $[CoASH]_T=2.00\times10^{-5}$ M, $[NpAc]=2.00\times10^{-4}$ M, pH 8.78±0.03.

(Fig. 4) give multiphasic curves: around the CMC (9.2×10^{-4} M at 25 °C[13]: 8.0×10^{-4} M under the kinetic condition; Okahata, unpublished) the rate constants rise rapidly with increasing concentration of CTABr. Further increase in the CTABr concentration rather suppresses the rate constants, resulting in rate maxima at 2×10^{-3} M of CTABr. At the optimal CTABr concentration (2 mM), rate augmentations of 810-fold for CoASH and 75-fold for GSH are observed. Plots of k_a' against the concentration of (N-OctDe)$_4$ showed a similar concentration-rate profile with a rate maximum at 5×10^{-3} M, except that the reaction rates are significantly improved at very low concentration of (N-OctDe)$_4$Br$_4$ (Fig. 5). The rate augmentation in the presence of (N-OctDe)$_4$Br$_4$ for the reaction of CoASH and NpAc was 840-fold at the optimal concentration as compared with the typical non-micellar system. In contrast, the aqueous solutions of (N-Dod)$_4$ and (N-Oct)$_4$ did not accelerate this reaction (Fig. 5). Addition of anionic (SDS) and nonionic (POOA) surfactants above their CMC was also ineffective (Table 1). Addition of hydrophobic ammonium ions such as CTABr (below the CMC) and Oct_3MeNCl to the nonionic micellar system did not increase the rate, either (Table 1).

Effects of Ionic Strength and pH. The rate of micelle-catalyzed reaction is influenced by the ionic strength of the medium.[14,15] Apparent second-order rate constants (k_a') for the reaction of CoASH and GSH

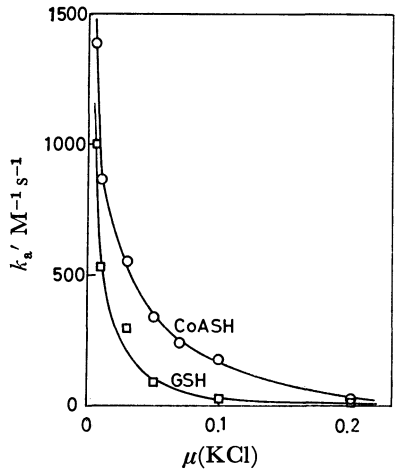

Fig. 6. Effect of ionic strength. [CTABr]$=2.0\times10^{-3}$ M, pH 8.78±0.03. Other reaction conditions are recorded under Fig. 4.

bound to the CTABr micelle were evaluated as a function of ionic strength (μ(KCl)$=0.006-0.2$; Fig. 6). The reaction rates for both coenzymes are markedly suppressed with increasing salt concentration. Fig. 6 proves that the reactivity of GSH is more susceptible to ionic strength than that of CoASH, and the rate difference amounts to 54-fold for CoASH and 110-fold for GSH. At $\mu=0.2$, the k_a' value for the reaction of GSH and NpAc is 9.05 M^{-1} s^{-1}, which is almost equal to the non-micellar value (7.60 M^{-1} s^{-1}).

The pH dependence of the rate is illustrated in Fig. 7. The acid dissociation constants (K_a) and the true second-order rate constants (k_a) were determined by fitting of the theoretical curves (Eq. 4) to the experimental plots. The solid curves in Fig. 7 were obtained

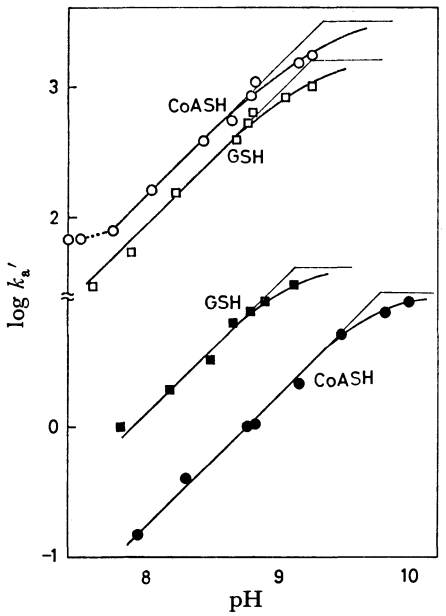

Fig. 7. pH Dependence. [CTABr]$=2.0\times10^{-3}$ M for ○ and □; other reaction conditions are recorded under Fig. 4. CTABr are not added for ● and ■; [CoASH]$_T=2.00\times10^{-4}$ M, [GSH]$_T=4.02\times10^{-4}$ M, [NpAc]$=2.00\times10^{-5}$ M.

by using Eq. 4 for k_a and pK_a values recorded in Table 1. The reactive species in this acyl transfer reaction is undoutedly the dissociated fraction of the thiol groups. The true second-order constants (k_a) in the presence of 2 mM of CTABr are thus estimated to be $(1-3)\times10^3$ M^{-1} s^{-1} (Table 1). Therefore, the cationic micelle of CTABr enhances the nucleophilicity of CoASH and GSH anions by 290-fold and 100-fold respectively. It is also worth while mentioning that the pK_a value of CoASH is considerably lowered (0.5 pK_a unit), while that of GSH is not.

As shown in Fig. 7, the rate constant for the reaction of CoASH and NpAc in the presence of CTABr deviates upwards at pH 7.4—7.6. A similar trend has been noticed in the polysoap-catalyzed reaction of CoASH with NpAc.[16] We consider that the adenine moiety of CoASH is responsible for the deviation, but the detail is not clear at present.

Discussion

It is frequently said that the micellar catalyses provide appropriate model systems of the enzymatic catalyses.[15,17] For instance, micelles significantly influence rates and equilibria of biologically important reactions. One of the recent, novel findings in the micellar catalysis is the fact that the nucleophilicity of a variety of anionic nucleophiles is unusually enhanced in cationic micelles (Ref. 10 and references cited therein) as well as in cationic polysoap.[18-20] Since this phenomenon is not limited to the conventional cationic micelle, it was proposed that the rate acceleration is largely derived from the formation of hydrophobic ion pairs between anionic species and cationic surfactant in a micellar, hydrophobic environment.[10-12] The anion included in a hydrophobic ion pair will attain its high reactivity from desolvation (dehydration), as already known for the ionic reactions in organic solvents.[21]

The apparent second-order rate constants (k_a') for CoASH and GSH at pH 8.78 were evaluated to be 863 and 530 M^{-1} s^{-1}, respectively (Table 1). On the other hand, the k_a' values for the reaction of dodecanethiol and NpAc are 417 M^{-1} s^{-1} ([octadecyltrimethylammonium bromide]$=ca.$ 10^{-3} M, pH 9.0)[9] and 462 M^{-1} s^{-1} ([partially laurylated poly(2-ethyl-1-vinylimidazole)]$=2.25\times10^{-3}$ M, pH 8.93).[20] The nucleophilicity of the micellar GSH is comparable to that of the hydrophobic ion pair of dodecanethiol, and that of CoASH is still higher. In the previous examples, some hydrophobic functions such as long alkyl chain, aromatic ring, and/or polymer backbone were indispensable for forming highly nucleophilic ion pairs.[18,22-24] In contrast, CoASH and GSH are polyanions with phosphate and carboxylate groups, and expected to be bound onto the cationic micellar surface mainly due to the electrostatic interaction. It is unlikely, by considering the poor solubility of these coenzymes in organic solvents, that the thiol groups are buried deeply in the hydrophobic core of the micelle. Therefore, the formation of reactive hydrophobic ion pairs is possible in a region fairly close to the surface of the micelle.

We previously showed that the nucleophilicity of

hydrophobic hydroxamate anions in the presence of nonionic micelles is markedly enhanced by the addition of hydrophobic ammonium salts.[10-12] As listed in Table 1, rate increases could not be observed by addition of CTABr below the CMC and Oct_3MeNCl. Supposedly, the hydrophobic interaction between these hydrophobic ammonium salts and the biological cofactors is not strong enough to bring the latter to the micellar phase of the nonionic micelle.

It is probable that the higher reactivity of CoASH relative to that of GSH is associated with the efficient binding of CoASH to the micellar phase. According to Cordes and Dunlap,[14] typical surfactant concentration-rate profiles such as Figs. 4 and 5 can be rationalized on the basis of (1) adsorption of progressively greater fractions of the nucleophile to the micellar phase until that fraction approaches unity (in the CTABr micellar system, NpAc is hardly concentrated in the micellar phase)[25] and (2) inhibition of the micellar catalysis by the counterions of the surfactant itself. Thus, Cordes and Dunlap[14] state that, when 50% of the nucleophile is associated with the micellar phase, about 50% of the maximum catalysis experienced. Figure 4 shows that the concentration of CTABr at the 50% reactivity is 0.9 mM for CoASH and 1.5 mM for GSH, so that CoASH possesses association constant several times larger than that of GSH. In a separate study, we estimated the binding constants of CoASH and GSH with 29 mol % laurylated poly(2-ethyl-1-vinylimidazole) to be 1100 and 240 M^{-1}, respectively.[16]

A similar trend is found for the effect of ionic strength (Fig. 6). The salt effect in the micellar system primarily arises from competitive occupation of the counterion site.[26] Figure 6 suggests that GSH is expelled out of the micellar phase more easily than CoASH by the counteranion binding.

In conclusion, the reactivity of sulfhydryl coenzymes can be enhanced remarkably in the presence of cationic micelles. This is explained by the formation of reactive ion pairs between CoASH and GSH anions and cationic CTABr molecules in the micellar phase. Since the coenzyme binding site of apoenzymes is said to be situated in relatively hydrophobic regions,[7] the CTABr micelle may serve as a model of apoenzymes.

The *N*-Alkylation of Xanthine Derivatives with Trialkyl Phosphates

Toshizumi TANABE, Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA

Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 26, 1976)

The *N*-alkylation of xanthine, theophylline, and theobromine with trimethyl, triethyl, and triallyl phosphates in a weak alkaline aqueous solution is described. Especially, trimethyl phosphate converted these heterocycles to the corresponding *N*-methyl derivatives in good yields.

Xanthine and its methylated derivatives, such as theophylline and theobromine, occur in living systems, especially in plants. Since these methylated purines and other alkyl analogs are biologically and physiologically important, the *N*-alkylation of this class of heterocycles has been studied actively.

Various alkylating agents, such as dialkyl sulfate,[1-3] alkyl *p*-toluenesulfonate,[3] and alkyl halide,[4,5] have been used for the *N*-alkylation of xanthine and its derivatives. Although the site of alkylation is influenced by various conditions, it has been generally established that, under alkaline conditions, alkylation takes place in the following order, that of the decreasing acidity of the replaced proton: N-3, N-7, and then N-1. Under neutral or acidic conditions, on the other hand, only imidazole ring-nitrogens are alkylated, converting the purine into quaternised or betaine forms.

In previous papers, we reported the *N*-alkylation of purines,[6] imidazoles,[7,8] and pyrimidines[9] by heating with alkyl esters of phosphoric acid at about 200 °C. Since this procedure would be too vigorous for many natural products, however, we continued our search for mild conditions, using xanthine, theophylline, and theobromine. This paper will show a facile *N*-alkylation of this class of heterocycles in a weak alkaline aqueous solution at 25—60 °C. Unlike reactions with other alkylating agents, which in most cases are insoluble in water, the present reaction can be carried out successfully in an aqueous environment because of the water-soluble property of a trialkyl phosphate.

Results and Discussion

The reactions were carried out by stirring a mixture of a purine and a 2—5 molar excess of trialkyl phosphate in water (pH 9—10) at 25—60 °C. The products were isolated through extraction and recrystallization. The results are summarized in Table 1.

The reaction of xanthine (**1**) with trimethyl phosphate (**a**) at 25 °C for 48 h afforded four ultraviolet absorbing products (**2**—**5**). The **2** and **3** products were produced mainly, and identified as caffeine and theobromine respectively through their physical constants. Compounds **4** and **5** were identified as 3-methylxanthine and 7-methylxanthine respectively according to their ultraviolet absorption spectra. With an increase in the reaction temperature and the reaction time, **1** tends to be methylated effectively at the N-1, N-3, and N-7 positions to produce 1,3,7-trimethylxanthine (**2**, caffeine), while at low temperatures and short reaction times **3** is isolated as the only product. Ethylation and allylation took place also in **1** to give 3,7-dialkyl derivatives (**6**, **7**). These results suggest that the N-1 position of **1** is less reactive than the N-3 and N-7 positions.

This trend was observed also in the alkylation of theobromine (**3**) and theophylline (**10**). Thus, although **10** was alkylated with triethyl phosphate (**b**) or triallyl phosphate (**c**) to give the corresponding 7-alkyl derivatives (**11** and **12**) quantitatively, **3** was transformed to the 1-alkyl derivatives (**8** and **9**) in only low yields.

Table 1. Reactions of purines with trialkyl phosphates[a]

Purine	R of O=P $(OR)_3$	Mole ratio (Ester/Purine)	Temp (°C)	Time (h)	Product	Yield (%)
Xanthine (**1**)	Me	6	60	48	Caffeine (**2**)	73
1	Me	6	25	48	**2**	17
					3	9
					3-Methylxanthine (**4**)	Trace
					7-Methylxanthine (**5**)	Trace
1	Et	3	80	48	3,7-Diethylxanthine (**6**)	6
1	Allyl	3	60	48	3,7-Diallylxanthine (**7**)	15

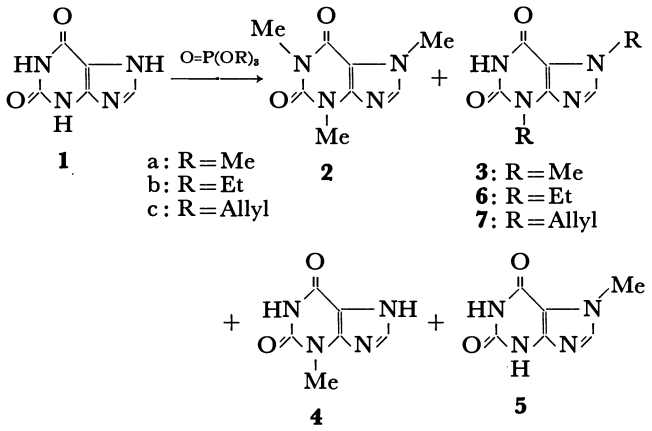
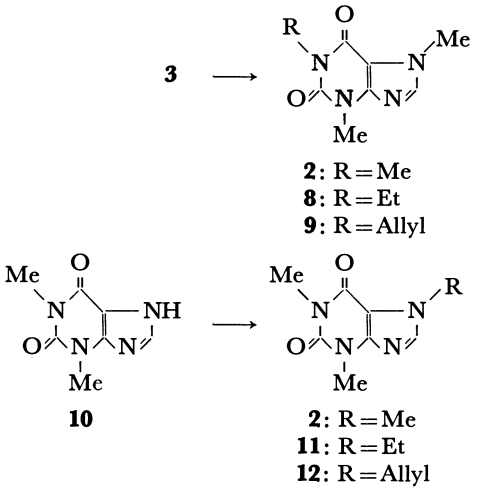
10	Me	3	60	8	**2**	92
10	Et	3	60	48	7-Ethyltheophylline (**11**)	26
10	Allyl	3	60	48	7-Allyltheophylline (**12**)	50
Theobromine (**3**)	Me	6	25	100	**2**	87
3	Me	3	60	24	**2**	93
3	Et	3	60	48	1-Ethyltheobromine (**8**)	10
3	Allyl	3	60	48	1-Allyltheobromine (**9**)	16

a) The reactions were carried out in an aqueous solution at pH 9—10.



The low reactivity of the N-1 position towards alkylation might be attributed to the decreased nucleophilicity of the N-1 nitrogen atom and the steric hindrance around the N-1 position towards the alkyl groups of phosphate esters by two adjacent carbonyl groups at the 2 and 6 positions.



The order of the reactivity of trialkyl phosphates in aqueous solutions was $O=P(OCH_3)_3$ (**a**)>$O=P(OCH_2-CH=CH_2)_3$ (**c**)>$O=P(OCH_2H_5)_3$ (**b**). The high reactivity of **a** may result partly from its low steric hindrance at the reaction site. The unexpected high reactivity of **c**, in spite of its decreased solubility in water, may originate from its conjugated structure.

The above results indicate that trialkyl phosphate, especially **a**, may be a useful alkylating agent, allowing an alkylation reaction to proceed under mild conditions.

Experimental

The UV and IR spectra were measured with Hitachi EPS-3T and Jasco IR-G spectrometers respectively. The NMR spectra were recorded on a Hitachi-Perkin Elmer R-20 spectrometer, with a dilute solution in deuteriochloroform or dimethyl-d^6 sulfoxide and tetramethylsilane as the internal and outside standards. Thin-layer chromatography was performed on silica gel [GF_{254} (type 60), Merck] using a mixture of chloroform and methanol (7: 1). Commercially available xanthine, theophylline, and theobromine, as well as trimethyl and triethyl phosphates, were used without further purification. The triallyl phosphate was prepared by the procedure of Toy and Costello.[10]

The following preparations are typical. The reaction conditions are listed in Table 1.

Alkylation of Xanthine (1). *A. With Trimethyl Phosphate (a)*: *Procedure 1*: A mixture of **1** (1.38 g, 9.1 mmol) and **a** (7.50 g, 54.0 mmol) in water (10 ml) was stirred at 60 °C. The solution was maintained at pH 9—10 throughout the reaction by the occasional addition of 4 M sodium hydroxide. After 48 h of stirring, the reaction mixture was extracted with chloroform. The subsequent evaporation of the solvent from the organic extract gave caffeine (**2**) as crystals; mp 233—234 °C (from THF–ethanol) (lit,[11] mp 235 °C), (1.28 g, 73%).

Procedure 2: A mixture of **1** (1.35 g, 8.9 mmol) and **a** (7.50 g, 54.0 mmol) in water (20 ml, pH 9—10, NaOH) was stirred at 25 °C for 48 h. Thin-layer chromatography of the reaction mixture showed four ultraviolet absorbing products; R_f: **5**= 0.27, **4**=0.31, **3**=0.46, and **2**=0.69 (chloroform–methanol 7: 1). The subsequent evaporation of the solvent from the organic layer gave **2** as crystals; (0.29 g, 17%). The aqueous layer was neutralized with concentrated hydrochloric acid and extracted with chloroform. Upon the concentration of the organic layer, **3** was obtained as a white powder and was identified as theobromine by a comparison of its physical properties with those of an authentic sample (0.14 g, 9%). The ultraviolet spectra of the aqueous extract of the corresponding spots for **5** and **4** coincided with those of 7-methyl- and 3-methylxanthine respectively; 7-methylxanthine: λ_{max} (H_2O) nm: 265 (pH 1), 269 (pH 7), 283 (pH 13) [lit,[12] 266 (pH 0.8), 268 (pH 4), 268 (pH 7), 288 (pH 13)], 3-methylxanthine: λ_{max} (H_2O) nm: 269 (pH 1), 272 (pH 7), 275 (pH 13) [lit,[11] 270 (pH 6), 274 (pH 14)].

B. With Triallyl Phosphate (c): The treatment of **1** (1.52 g, 10.0 mmol) with **c** (5.10 g, 30 mmol) in water (10 ml, pH 9—10, NaOH) gave 3,7-diallylxanthine (**7**, 0.38 g, 15%) after the reaction mixture had been stirred at 60 °C for 48 h; mp 182.5—184 °C (from ethanol); IR (KBr): 3000 (m), 2800 (w), 1680 (s), 1585 (m), 1540 (m), 1375 (m), 1295 (w), 1265 (m), 1130 (m), 990 (s), 920 (s), 840 (m), 750 (w), and 620 cm^{-1} (m); NMR (DMSO-d^6): 4.43 (complex m, 2H, $-C\mathbf{H}_2-CH=CH_2$), 4.60—5.30 (complex m, 2H, $-CH_2-CH=C\mathbf{H}_2$), 5.45—6.25 (complex m, 1H, $-CH_2-C\mathbf{H}=CH_2$), and 7.92 ppm (δ) (s, 1H, H^8); UV, λ_{max} (H_2O) nm: pH 1, 269 (log ε 4.13), pH 7, 273 (log ε 3.96), pH 13, 275 (log ε 4.00); Found: C, 56.54; H, 5.08; N, 23.74%. Calcd for $C_{11}H_{12}N_4O_2 \cdot 0.1H_2O$: C, 56.54; H, 5.22; N, 23.95%.

Alkylation of Theophylline (10). *A. With Trimethyl Phosphate (a)*: A mixture of **10** (1.54 g, 8.6 mmol) and **a** (3.75 g, 27.0 mmol) was stirred in water (10 ml, pH 9—10, NaOH) at 60 °C for 8 h. After the reaction mixture had then been allowed to stand at room temperature, **2** appeared as crystals from the solution (1.28 g, 79%). The organic layer was concentrated to give another crop of **2** (0.20 g, 12%).

B. With Triallyl Phosphate (c): A reaction of **10** (1.81 g, 10.0 mmol) with **c** (5.10 g, 30.0 mmol) in water (10 ml, pH 9—10, NaOH) at 60 °C for 48 h afforded 7-allyltheophylline (**9**, 1.11 g, 50%) after a procedure similar to that described above; mp 101—103 °C (from hexane) (lit,[13] 101—102 °C); IR (KBr): 3100 (m), 2950 (w), 1700 (s), 1655 (s), 1550 (m), 1480(m), 1370 (w), 1230 (m), 1030 (m), 940 (w), 760 (s), 750 (s), and 620 cm^{-1} (m); NMR ($CDCl_3$): 3.48 (s, 3H, $-C\mathbf{H}_3$), 3.67 (s, 3H, $-C\mathbf{H}_3$), 5.03 (complex m, 2H, $-C\mathbf{H}_2-CH=CH_2$), 5.20—5.53 (complex m, 2H, $-CH_2-CH=C\mathbf{H}_2$), 5.70—6.45 (complex m, 1H, $-CH_2-C\mathbf{H}=CH_2$), and 7.65 ppm (δ) (s, 1H, $\mathbf{H}^8$); UV, λ_{max} (H_2O) nm: pH 1, 273 (log ε 3.98), pH 7, 275 (log ε 3.94), pH 13, 275 (log ε 3.94); Found: C, 54.47; H, 5.43; N, 26.00%. Calcd for $C_8H_{10}N_4O_2$: C, 54.54;

H, 5.49; N, 25.44%.

Alkylation of Theobromine (3) with Triallyl Phosphate (c). A reaction of **3** (1.81 g, 10.0 mmol) with **c** (5.20 g, 30.0 mmol) in water (10 ml, pH 9—10, NaOH) at 60 °C for 48 h afforded 1-allyltheobromine (**9**, 0.29 g, 16%) upon the treatment of the reaction mixture in a manner similar to that described above; mp 139—142 °C (sublime); IR (KBr): 3200 (m), 2900 (w), 1700(s), 1640 (s), 1540 (m), 1450 (m), 1360 (m), 1275 (w), 1230 (m), 1100 (w), 920 (s), 860 (w), 760 (s), 740 (s), 650 (w), and 620 cm^{-1} (m); NMR ($CDCl_3$): 3.58 (s, 3H, $-CH_3$), 4.00 (s, 3H, $-CH_3$), 4.63 (complex m, 2H, $-CH_2-CH=CH_2$), 5.03—5.47 (complex m, 2H, $-CH_2-CH=CH_2$), 5.48—5.96 (complex m, 1H, $-CH_2-CH=CH_2$), and 7.53 ppm (δ) (s, 1H, H^8); UV, λ_{max} (H_2O) nm: pH 1, 274 (log ε 4.03), pH 7, 275 (log ε 4.01), pH 13, 275 (log ε 4.01); Found: C, 54.77; H, 5.40; N, 25.88%. Calcd for $C_8H_{10}N_4O_2$: C, 54.54; H, 5.49; N, 25.44%.

An Anion Radical Precursor in the Nucleophilic Substitution of *o*-Dinitrobenzene

Takehiro ABE and Yusaku IKEGAMI*

(Received July 12, 1976)

By visible and ESR spectroscopies, the appearance of *o*-dinitrobenzene anion radical has been demonstrated for the replacement of one nitro group of *o*-dinitrobenzene by hydroxide ion in aqueous dimethyl sulfoxide. Kinetic studies have supported the suggestion that the anion radical is a precursor in the substitution reaction.

According to the electron transfer theory proposed by Nagakura and Tanaka,[1,2] nucleophilic aromatic substitution should proceed *via* the anion radical resulting from one-electron transfer from the highest occupied orbital of a nucleophilic reagent to the lowest vacant orbital of an aromatic molecule. Here the energy level of the highest occupied orbital must be higher than that of the lowest vacant orbital. Recently, some anion radicals observed during the course of nucleophilic substitution have been supposed to be precursors in the substitution mechanisms.[3-10] As described by Bernasconi,[10] there has been no evidence that the anion radicals are the precursors in the nucleophilic substitution rather than the products resulting from competing side reactions. We now present the experimental results strongly supporting that an *o*-dinitrobenzene anion radical is the precursor in the replacement of one nitro group of *o*-dinitrobenzene by hydroxide ion in aqueous dimethyl sulfoxide (DMSO).

Experimental

o-Dinitrobenzene was obtained commercially and purified by recrystallization. DMSO was kept in contact with barium oxide for a week and fractionated two times under reduced pressure. *N,N*-Dimethylformamide was treated with sodium hydroxide pellets and barium oxide, and distilled at 1 Torr. This solvent was kept with Molecular Sieves 4A after degassed.

Unless otherwise stated, all the mixings of degassed solutions of *o*-dinitrobenzene with degassed solutions of sodium hydroxide were carried out in sealed cells in order to obtain the electronic and ESR spectra. Electronic-spectral changes were recorded with a Cary 14 recording spectrophotometer equipped with a thermostated cell compartment. ESR spectra were recorded with a Varian E-4 EPR spectrometer.

Results and Discussion

When a DMSO solution of *o*-dinitrobenzene was mixed with an aqueous DMSO solution of sodium hydroxide, the resultant reaction system showed absorption spectral changes shown in Figs. 1 and 2. Curve e in Fig. 1 is obtained by correcting curve a for the absorption of DMSO, because DMSO absorbs above 700 nm as shown in Fig. 1. The reaction system, therefore, shows the absorption curve of e in the region 800—1200 nm. The bands at 325 and 800—1200 nm increased in intensity and gradually disappeared later on.

The initial 420 nm band (curve a in Fig. 2) differs from the final 430 nm band (curve f) in peak position. In the case of the similar reaction system open to the air, it was distinctly observed with a Hitachi rapid scan spectrophotometer RSP-2 that at the initial stage the 420 nm band increased in intensity in the same way as the 325 nm band. The time courses of absorption-coefficient changes at 900 and 430 nm are shown in Fig. 3. Curve b in Fig. 3 indicates that the whole course of increasing absorption coefficient at 430 nm is not due to one species, since the increase in the coefficient is abruptly slow down at *ca.* 5 min after mixing. Accordingly, the initial 420 nm band is assigned to the labile

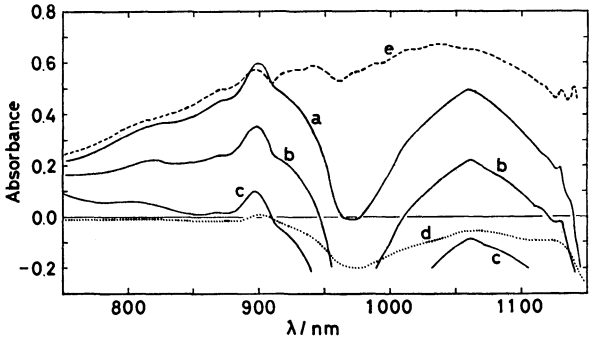

Fig. 1. Spectral change of the DMSO solution containing *o*-dinitrobenzene (3.30×10^{-4} M), sodium hydroxide (1.00×10^{-2} M) and 4% (v/v) water (25 °C). Time after mixing: a, 4.4 min; b, 15 min; c, 41 min. Curve e is obtained by correcting curve a for the absorption of DMSO (curve d). Path length was 2.87 cm except the case of d, whose path length was 1.00 cm.

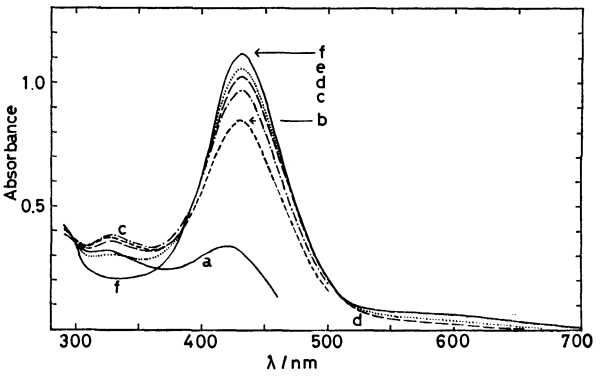

Fig. 2. Spectral change of the same solution as in Fig. 1 (25 °C). Time after mixing: a, 15 s; b, 1.3 min; c, 4.6 min; d, 11 min; e, 30 min; f, 100 min. Path length was 0.390 cm.

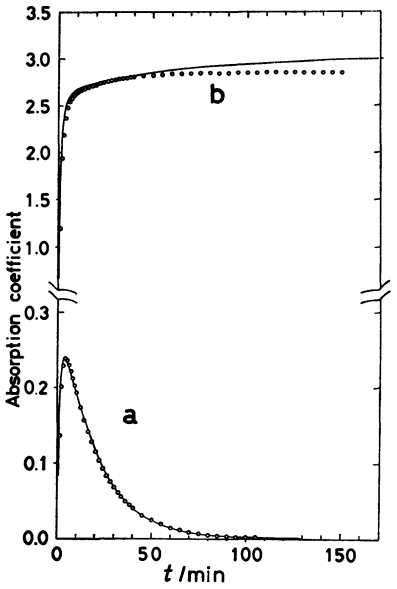

Fig. 3. Time course (full lines) of absorption coefficient of the same solution as in Fig. 1 (25.0 °C). a, 900 nm; b, 430 nm. Circles show the values calculated according to Eqs. 1 and 2 or to Eqs. 3 and 4.

species showing the bands at 325 and 800—1200 nm.

The bands at 325 and 420 nm do not correspond to the 430 and 455 nm bands, respectively, of the π-electronic structure (*i.e.*, 1-nitropentadienate) of 1-amino-1-methoxy-2-nitrocyclohexadienate formed from *o*-nitroaniline and methoxide ion in dichloromethane.[11] The bands at 325, 420, and 800—1200 nm correspond to those at 350, 440, and 1090 nm, respectively, assigned to the *o*-dinitrobenzene anion radical in a γ-irradiated rigid solution in 2-methyltetrahydrofuran at 77 K.[12] We, therefore, assign the labile species showing these bands to the anion radical.

It is well-known that the reaction of *o*-dinitrobenzene with hydroxide ion yields *o*-nitrophenol and nitrite ion.[13] Sodium nitrite (4.5×10^{-4} M) in DMSO containing 4% (v/v) water and sodium hydroxide (1.00×10^{-2} M) absorbed very weakly in the region above 400 nm. The final 430 nm band of the reaction system (curve f in Fig. 2) differed in peak position from the 450 nm band of the similar solution of *o*-nitrophenol, while the similar DMSO solution of *p*-dinitrobenzene finally showed the band identical with that of the similar solution of *p*-nitrophenol in the peak position and shape.[8] When the reaction system containing *o*-dinitrobenzene (0.3 M) and sodium hydroxide (0.7 M) in aqueous DMSO-d_6 was stood for 4 h in the dark at room temperature, the system showed the ^{1}H NMR spectrum of *o*-nitrophenoxide ion at the range δ 5—8 ppm.[14] The reaction of *o*-dinitrobenzene (0.745 g, 0.12 M) with sodium hydroxide (0.26 M) in DMSO containing 19% (v/v) water at room temperature afforded a yellowish-orange crude substance (0.485 g) after dilution with water, neutralization, and extraction with diethyl ether. The IR spectrum of the crude substance exhibited the absorption bands corresponding to *o*-nitrophenol. The results of thin-layer chromatography for the aqueous DMSO solution of *o*-dinitrobenzene (7.2×10^{-2} M) and sodium hydroxide (1.8×10^{-1} M), allowed to stand overnight in the dark at room temperature, showed the major product of *o*-nitrophenol and the absence of unaltered *o*-dinitrobenzene, though there was the small spot which could not be eluted with benzene containing a small amount of methanol. From the above results, the final species showing the 430 nm band was identified as *o*-nitrophenoxide ion. The production of nitrite ion was confirmed by the brown ring test.

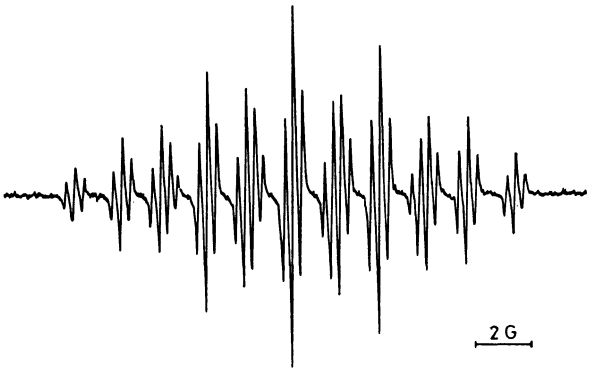

Fig. 4. ESR Spectrum of the same solution as in Fig. 1 (*ca.* 21 °C).

The formation of the labile *o*-dinitrobenzene anion radical in the reaction system was confirmed by ESR spectroscopy. The reaction system showed a strong ESR signal. Hyperfine structure of the ESR spectrum (Fig. 4) is consistent with that of the *o*-dinitrobenzene anion radical having the two equivalent nitrogen atoms. The splitting constants, $a_N=3.02$, $a_H(3,6)=0.30$, and $a_H(4,5)=1.64$ gauss, agreed well with the reference values.[15] The time course of relative ESR-signal intensity of the anion radical in the reaction system at *ca.* 21 °C resembled that of the absorption coefficient change at 900 nm in Fig. 3.

No other radical species was found in the ESR spectrum of the reaction system, even if the system kept at 19 °C for 3 min after mixing was suddenly cooled to −130 °C and then warmed gradually over recording the spectrum. This result indicates that any long-lived radical other than the *o*-dinitrobenzene anion radical was not present in the reaction system, and eliminates any mechanism including persisting radicals other than the *o*-dinitrobenzene anion radical. Thus, the result eliminates the following schemes in which the hydroxyl radical produced reversibly should long live together with the anion radical.

o-Dinitrobenzene

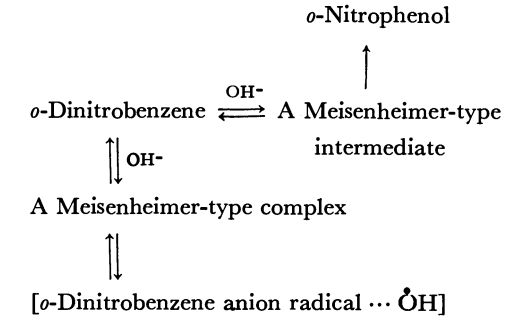
$\uparrow\downarrow$ OH^-

A Meisenheimer-type intermediate $\longrightarrow$ *o*-Nitrophenol

$\uparrow\downarrow$

[*o*-Dinitrobenzene anion radical ··· $\dot{O}H$]

The formation of the *o*-dinitrobenzene anion radical in DMSO is not due to electron transfer from methylsulfinyl methanide[16] to *o*-dinitrobenzene, because the



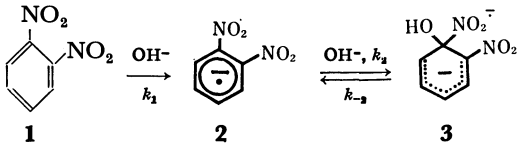
mixture obtained by mixing two drops of aqueous solution of sodium hydroxide (5 M) with an *N*,*N*-dimethylformamide solution of *o*-dinitrobenzene (1×10^{-2} M) also showed the ESR spectrum of the *o*-dinitrobenzene anion radical with $a_N=3.25$, $a_{H3}=0.40$, and $a_{H4}=1.68$ gauss.

The mixture of *o*-dinitrobenzene (1.00×10^{-2} M) and sodium 1,1-dimethoxy-2,4,6-trinitrocyclohexadienate (9.21×10^{-3} M)[17] in DMSO did not show any ESR signal at the temperatures of 0° and 25 °C. This fact suggests that an electron transfer does not occur between *o*-dinitrobenzene and the Meisenheimer-type intermediate in the reaction system under study. Since the Meisenheimer intermediate has the stable π-electronic structure of pentadienate, the highest-occupied energy level of the intermediate would be lower than the lowest-vacant energy level of *o*-dinitrobenzene, so that the electron transfer can not occur.[1,2]

Thus, the formation of *o*-dinitrobenzene anion radical is probably due to the direct electron transfer from hydroxide ion to *o*-dinitrobenzene. The lowest-vacant energy level of *o*-dinitrobenzene can be estimated to be −5.84 eV from the values[18] of the lowest π-π^* transition energy (4.43 eV) and ionization potential (10.27 eV) of *o*-dinitrobenzene. The energy level is sufficiently lower than the occupied energy level of OH^- (−2.1 eV[1]). According to Nagakura and Tanaka's theory, therefore, the anion radical can be formed as a result of the direct electron transfer from hydroxide ion to *o*-dinitrobenzene. In the case of the aqueous DMSO solution of *p*-dinitrobenzene and hydroxide ion, the production of the short-lived hydroxyl radical has been confirmed by spin-trapping with 2-nitroso-2-methylpropane.[9]

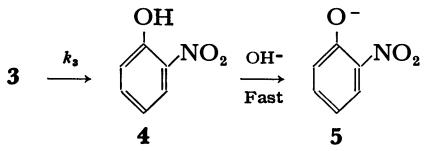
Here we denote the initial concentrations of *o*-dinitrobenzene and sodium hydroxide by $[o\text{-DNB}]_0$ and $[NaOH]_0$, respectively. The rate of decrease in the 900 nm absorption coefficient of the DMSO solution containing 4% (v/v) water, $[o\text{-DNB}]_0=3.31\times10^{-4}$ M, and $[NaOH]_0=1.00\times10^{-2}$ M was faster than that for the same solution except for $[NaOH]_0=5.0\times10^{-3}$ M at 25 °C. When $3\times[o\text{-DNB}]_0<[NaOH]_0=1.00\times10^{-2}$ M, the decrease in the 900 nm absorption coefficient obeyed the pseudo-first order kinetics and was relatively fast. In the case of $[o\text{-DNB}]_0:[NaOH]_0=1:2$ where $[NaOH]_0=1.00\times10^{-2}$ M, the decrease in the 900 nm absorption coefficient was extremely slow. The radical species in this solution lived for a few days at room temperature after mixing. The thin-layer chromatography of the reaction system, stood overnight in the dark at room temperature, distinctly showed the presence of unaltered *o*-dinitrobenzene for the case of $2.5\times[o\text{-DNB}]_0>[NaOH]_0$. All these facts mean that the relatively fast decomposition of the anion radical requires hydroxide ion. The further reaction of the anion radical with hydroxide ion is possibly the formation of a dianion radical such as proposed by Shein *et al.*[4,10] The question, however, remains, since the formation of the dianion radical is unfamiliar. Hydroxide ion will be further consumed for ionizing *o*-nitrophenol, because *o*-nitrophenol in the DMSO solution containing 4% (v/v) water in the absence of sodium hydroxide did not show any absorption band above 400 nm.

In view of the above results, the reaction scheme for the present reaction may be written below under the condition of $3\times[o\text{-DNB}]_0<[NaOH]_0$.

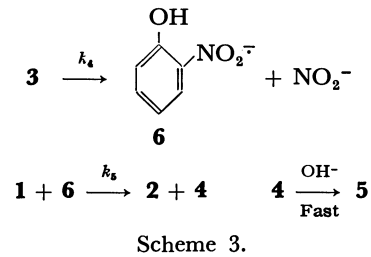


Scheme 1.

Here k_i denotes the rate constant for the ith step. The first-order rate constants of k_1 and k_2 contain $[NaOH]_0$. The authors propose Scheme 2 or 3 for the further reactions of **3**.

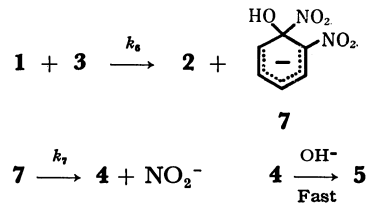


Scheme 2.



Scheme 3.

According to one of the mechanisms proposed by Schein *et al.*,[4,10] **3** should undergo the reaction indicated in Scheme 4.



Scheme 4.

Dianion radical **3** seems very labile, because any Meisenheimer-type complex, in which the nucleophilic reagent attacks the carbon atom carrying a nitro group, has never been observed. Dianion radical **3** is,

therefore, likely to decompose rather than to exchange an electron with *o*-dinitrobenzene. Moreover, Scheme 4 would give the concentration changes different from those for Schemes 2 and 3, which can explain the experimental data shown in Fig. 3, as described below. Accordingly, Scheme 4 is ignored here.

Since no band other than those of **2** and **5** is found in Fig. 2, we can assume the restrictions of $k_2 \ll k_3$ and $k_2 \ll k_4$ or k_5 in Schemes 2 and 3, respectively. Then, the steady state treatment was applied for the concentrations of **3** and **6**. The absorption-coefficient changes for 900 and 430 nm with time t are expressed below. For Schemes 1 and 2,

$$a(900\,\text{nm}) = \frac{k_1}{k_1-k_2'}\varepsilon_R[o\text{-DNB}]_0\{\exp(-k_2't)-\exp(-k_1t)\} \quad (1)$$

$$a(430\,\text{nm}) = \varepsilon_{NP}[o\text{-DNB}]_0-\frac{k_1}{k_1-k_2'}(\varepsilon_{NP}-\varepsilon_R')[o\text{-DNB}]_0 \times\exp(-k_2't)-\frac{k_1\varepsilon_R'-k_2'\varepsilon_{NP}}{k_1-k_2'}[o\text{-DNB}]_0\exp(-k_1t) \quad (2)$$

where $k_2'=k_2\{1-k_{-2}/(k_3+k_{-2})\}$. Here ε_R and ε_{NP} are molar absorption coefficients of **2** and **5**, respectively. For Schemes 1 and 3,

$$a(900\,\text{nm}) = \frac{k_1}{r_1-r_2}\varepsilon_R[o\text{-DNB}]_0\{\exp(-r_2t)-\exp(-r_1t)\} \quad (3)$$

$$a(430\,\text{nm}) = \varepsilon_{NP}[o\text{-DNB}]_0-\frac{r_1\varepsilon_{NP}-k_1\varepsilon_R'}{r_1-r_2}[o\text{-DNB}]_0\exp(-r_2t) -\frac{k_1\varepsilon_R'-r_2\varepsilon_{NP}}{r_1-r_2}[o\text{-DNB}]_0\exp(-r_1t) \quad (4)$$

where $r_1=k_1/2+\{(k_1/2)^2-k_1k_2k_3/(k_{-2}+k_3)\}^{1/2}$ and $r_2=k_1/2-\{(k_{1/2})^2-k_1k_2k_3/(k_{-2}+k_3)\}^{1/2}$. Instead of the last two steps in Scheme 3, the following steps are also possible and give the same results.

$$\mathbf{6} + OH^- \xrightarrow{\text{Fast}} \mathbf{8} + H_2O$$

$$\mathbf{1} + \mathbf{8} \xrightarrow{k_5} \mathbf{2} + \mathbf{5}$$

The values calculated for the absorption coefficients according to Eqs. 1 and 2, are plotted in Fig. 3 by assuming the following values: $k_1=0.638\ \text{min}^{-1}$, $k_2'=0.0519\ \text{min}^{-1}$, $\varepsilon_R(900\,\text{nm})=9.05\times10^2$, $\varepsilon_R'(430\,\text{nm})=7.63\times10^3$, and $\varepsilon_{NP}(430\,\text{nm})=8.62\times10^3$. Equations 3 and 4 also give the identical plot by assuming the following values: $k_1=0.690\ \text{min}^{-1}$, $r_1=0.638\ \text{min}^{-1}$, $r_2=0.0519\ \text{min}^{-1}$, $\varepsilon_R(900\,\text{nm})=8.37\times10^2$, $\varepsilon_R'(430\,\text{nm})=7.05\times10^3$, and $\varepsilon_{NP}(430\,\text{nm})=8.62\times10^3$.

The calculated values of absorption coefficients for 430 nm are somewhat lower than the found ones after 50 min. The values finally found may be made up by the small superposition of absorption coefficients of nitrite ion and a minor by-product upon that of *o*-nitrophenoxide ion at 430 nm. The molar absorption coefficients of 440 and 1090 nm bands of the anion radical in the rigid solution at 77 K are 6×10^3 and 4×10^3, respectively.[12] The values of $\varepsilon_R'(430\,\text{nm})$ are comparable to 6×10^3, while the values of $\varepsilon_R(900\,\text{nm})$ are considerably smaller than 4×10^3.

Now we can not select one of Schemes 2 and 3. In Scheme 2, the decomposition of **3** should yield the dianion radical $NO_2\cdot^{2-}$. The formation $NO_2\cdot^{2-}$ is unfamiliar, though it has been identified by ESR spectroscopy in KCl crystals dropped with KNO_2.[19] As shown in Fig. 3, the two sets of Eqs. 1 and 2 and of Eqs. 3 and 4 can well reproduce the experimental data to the same extent. In conclusion, the kinetic results strongly support that the *o*-dinitrobenzene anion radical is the precursor in the reaction under study, though the further reaction of the anion radical is not established.

It is unlikely that the primary step of formation of **2** in Scheme 1 is an elementary reaction. The step may be accounted for below. In the case of photosubstitution reaction of 3,5-dinitroanisole with hydroxide ion to produce 3,5-dinitrophenol, a primary reaction step is the formation of intermediate [3,5-dinitroanisole···ȮH] owing to an electron transfer from hydroxide ion to the π-π^* triplet state of 3,5-dinitroanisole.[20,21] The half-lifetime of the intermediate is *ca.* 5×10^{-7} s.[20] Therefore, the corresponding intermediate (**9**) is reasonably supposed to be formed in the present reaction. On the other hand, the rate constant for the reaction of hydroxyl radical with DMSO in aqueous DMSO ($HO\cdot + CH_3SOCH_3 \rightarrow CH_3\cdot + CH_3SO\cdot OH$) is $5\times10^9\ M^{-1}\,s^{-1}$ (25 °C).[22] The reaction between DMSO and hydroxyl radical in **9** is probably faster than that of **9**. Thus, the persisting *o*-dinitrobenzene anion radical in the present reaction system may be generated as follows:

$$\mathbf{1} + OH^- \rightleftharpoons \mathbf{9}$$

$$\mathbf{9} + CH_3SOCH_3 \longrightarrow \mathbf{2} + CH_3\cdot + CH_3SO\cdot OH$$

The methyl radical will undergo a rapid reaction.

A Simple Method for the Synthesis of Lignan Skeleton.[1] Syntheses of (±)-Parabenzlactone and (±)-Hinokinin

Yuzo Asano, Tadao Kamikawa, and Takashi Tokoroyama

Faculty of Science, Osaka City University, Sugimotocho, Sumiyoshiku, Osaka 558

(Received July 14, 1976)

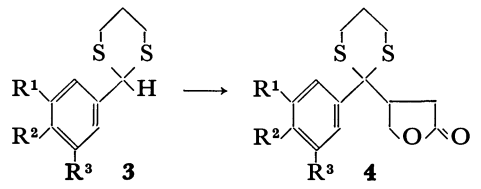
The reaction of 2-aryl-2-lithio-1,3-dithianes with 2-butenolide followed by quenching with benzyl halides gave lignan skeleton in fairly good yield.

In connection with the total synthesis of a novel class of antileukemic lignan lactone, steganacin (**1**),[2] we needed the efficient synthetic method for constructing the *seco*-lactone skeleton (**2**). We have studied the addition of 2-aryl-2-lithio-1,3-dithianes to 2-butenolide, hoping to find a new method leading to **2**. Although synthetic applications of 2-lithio-1,3-dithianes as an acyl anion equivalent had been widely explored,[3] little investigation existed for the Michael addition of it to α,β-unsaturated lactones, when we started on this project. Since then Ziegler and Schwartz[4] reported the synthesis of lignans by means of a conjugate addition of aryl dithiane anion to 2-butenolide. In this paper we wish to report on the results of our own independent studies which based on the essentially the same idea as theirs.

Results and Discussion

Treatment of 2-aryl-1,3-dithianes (**3**)[5] in THF with butyllithium at −40 °C followed by addition of 2-butenolide at −78 °C gave the Michael addition products (**4**). Concerning the effect of substituents, it was shown that the addition was facilitated by the presence of electron-releasing groups **4b**—**4e**, as shown in Table 1. Neither 2-lithio-1,3-dithiane nor 2-lithio-2-aryl-1,3-dithiolane added to 2-butenolide. Desulfurization of **4** with *N*-chlorosuccinimide and silver nitrate gave β-aroyl-γ-lactones (**5**), as shown in Table 2.

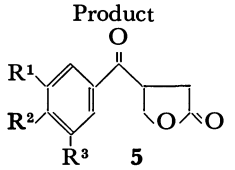
Table 1. Formation of dithiane lactones



Dithiane **3**	Product Mp (°C)	Yield (%)[a]
a ; $R^1=R^2=R^3=H$	109 —110	13
b ; $R^1=R^3=H$; $R^2=OMe$	98.5—100	88
c ; $R^1=R^2=OMe$; $R^3=H$	130 —131	71
d ; $R^1=R^2=-OCH_2O-$; $R^3=H$	158.5—160	78
(lit,[4])	154 —155)	
e ; $R^1=R^2=R^3=OMe$	161 —163	68
f ; $R^1=OBz$; $R^2=OMe$; $R^3=H$	130 —131.5	79

a) Isolated yield.

Table 2. Desulfurization of dithiane lactones



Product **5**	Condition Temp (°C)	Time (min)	Mp (°C)	Yield (%)
b ; $R^1=R^3=H$; $R^2=OMe$	rt	60	68.5— 69.5	80
c ; $R^1=R^2=OMe$; $R^3=H$	40	30	118 —119.5	67
d ; $R^1=R^2=-OCH_2O-$; $R^3=H$	50	30	118 —119	100

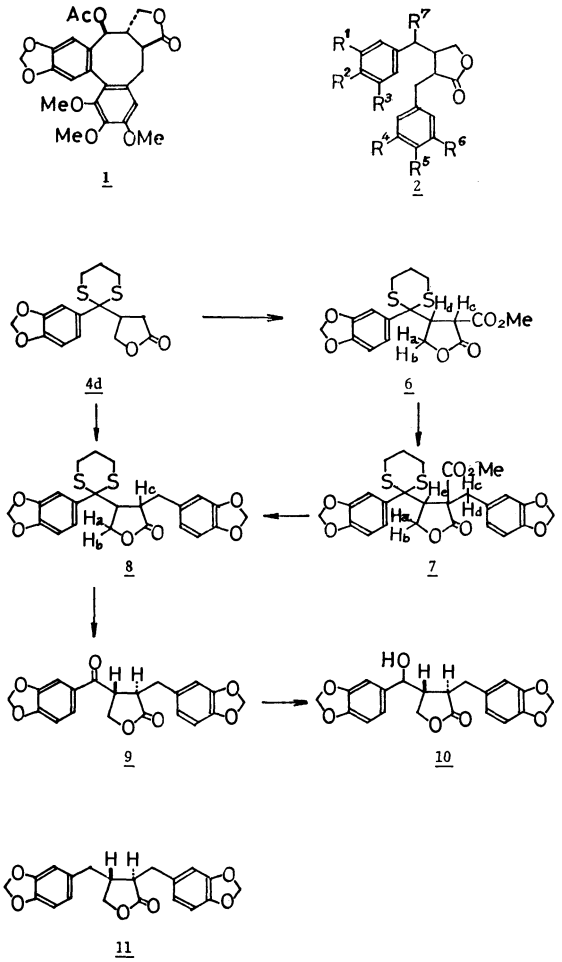
Attempted alkylation of **4d** with lithium cyclohexylisopropylamide and piperonyl bromide (THF–HMPA, −78 °C, 2 h) led to the recovery of the starting material.* We then carried out indirect alkylation. Treatment of the lactone **4d** with dimethyl carbonate and sodium hydride without solvent gave the α-carbomethoxy lactone (**6**). The NMR spectrum showed peaks at 3.94 ppm (d, J=9.0 Hz) due to $-CO-\underline{CH}-CO_2Me$, suggesting the *trans* configuration of substituents. This was alkylated with piperonyl bromide to give the trisubstituted lactone (**7**) in 74% yield from **4d**. The IR spectrum of **7** showed the presence of a γ-lactone (1780 cm^{-1}) and an ester group (1750 cm^{-1}). The NMR spectrum of **7** showed signals at 3.00 (H_e, dd, J=8.2 and 11.3 Hz), 3.31 (H_c, H_d, AB_q, J=16.1 Hz), 3.92 (H_b, t, J=8.2 and 10.2 Hz) and 4.55 ppm (H_a, dd, J=10.2 and 11.3 Hz). Hydrolysis of the ester **7** with ethanolic potassium hydroxide followed by acidification gave the bis-benzyl-substituted lactone (**8**) in 80% yield. The IR spectrum of **8** showed a characteristic band at 1770 cm^{-1}. The NMR spectrum of **8** showed signals at 2.91 (H_c, m), 3.86 (H_b, q, J=8.2 and 9.8 Hz), 4.54 (H_a, q, J=4.2 and 9.8 Hz), 5.86 ($-OCH_2O-$, q, J=2 Hz) and 5.96 ppm ($-OCH_2O-$, q, J=2 Hz). The characteristic feature of the NMR spectrum is the non-equivalence of both methylenedioxy groups, probably due to the stretched and rather rigid *trans* orientation[6] of the two methylenedioxy benzyl residue to avoid the steric repulsion of large 1,3-dithiane group and to the presence of hindered rotation.

We have also observed that the intermediate lactone enolate generated by the Michael addition can be

* Ziegler and Schwartz[4] alkylated **4d** with lithium diisopropylamide and 3,4,5-trimethoxybenzyl chloride in THF–HMPA at −78 °C for 3 h and then at room temperature for 18 h.



trapped with piperonyl bromide to give **8** in 78% yield. Cleavage of the dithioketal group of **8** gave the keto lactone **9**. The NMR spectrum ($CDCl_3$–C_6D_6 1: 1) of **9** showed three protons multiplet between 2.52—3.36 ppm (Fig. 1). The multiplets centered at 2.76 and 3.30 ppm were assigned as H_A and H_B, and H_X, respectively. Two benzylic protons forming the AB part of an ABXY system with $J_{AY}=J_{BY}=0$ Hz and the proton α to the lactone carbonyl forming the X part. Analysis of the spectrum revealed the following coupling constants: $|J_{AB}|=14.2$ Hz; $|J_{AX}|=3.4$ Hz; $|J_{BX}|=9.0$ Hz; and $|J_{XY}|=8.5$ Hz. As the coupling constants of flexible five-membered ring might be of little diagnostic value, we then carried out equilibration experiments. Equilibration of **9** with potassium *t*-butoxide in *t*-butyl alcohol gave unchanged material, suggesting the thermodynamically more stable, *trans* stereochemistry of the two substituents at the lactone ring. The keto lactone **9** was identical with oxo-parabenzlactone[7] (IR, UV, NMR, and TLC) derived from natural (—)-parabenzlactone by means of Jones' oxidation.

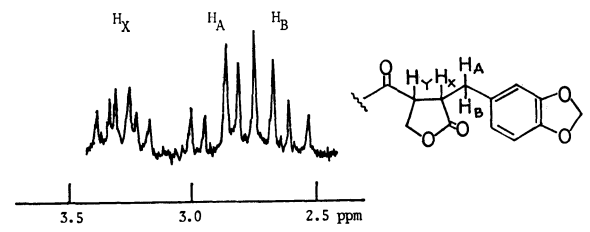


Fig. 1 The NMR spectrum of 9 in $CDCl_3$-C_6D_6 (1:1).

Fig. 1. The NMR spectrum of **9** in $CDCl_3$–C_6D_6 (1: 1).

Reduction of **9** with $NaBH_4$ or $Zn(BH_4)_2$ gave (±)-parabenzlactone (**10**), which was identical with the natural product[7] (IR, UV, NMR, and TLC). Since it has been known that the reduction with $Zn(BH_4)_2$ does not change the configuration at the lactone ring,[8] the synthetic parabenzlactone also takes the *trans* stereochemistry. Thus the synthesis unambiguously established the *trans* stereochemistry of (—)-parabenzlactone which accords with the conclusion derived from CD experiments.[9]

Reductive desulfurization of **8** with Raney Ni gave the amorphous lactone (**11**), whose IR and NMR spectra were superimposable with those of (—)-hinokinin.[9]

Experimental

All the melting points are uncorrected. The IR spectra were measured with JASCO IRA-1 spectrophotometer. The NMR spectra were recorded in $CDCl_3$, with TMS as the internal standard, using JEOL PS-100 spectrophotometer.

General Procedure for the Preparation of Dithiane Lactones **4**. Butyllithium (6.5 ml of a 15% hexane solution, 0.0105 mol) was added to a solution of 2-aryl-1,3-dithiane **3** (0.01 mol) in THF (30 ml) and HMPA (0.01 mol) at −75 °C under nitrogen atmosphere. The mixture was stirred for an additional hour at −40 °C. After cooling at −75 °C, the mixture was treated with 2-butenolide (1.26 g; 0.015 mol) in 3 ml of THF, stirred for two hours at −75 °C, and then treated with 10% hydrochloric acid. Extractive work-up and chromatography on silicic acid gave pure dithiane lactone.

Dithiane Lactone **4a**. IR (Nujol) 1780, 1770 (sh), 1600, 1490, 1180, 770, and 710 cm^{-1}; NMR ($CDCl_3$) 1.84 (m, 2), 2.16—3.12 (m, 6), 4.0—4.42 (m, 2), 7.2—7.48 (m, 3), and 7.84—7.94 (m, 2); Found: C, 60.05; H, 5.82%. Calcd for $C_{14}H_{16}O_2S_2$: C, 59.97; H, 5.75%.

Dithiane Lactone **4b**. IR ($CHCl_3$) 1775, 1605, and 1025 cm^{-1}; NMR ($CDCl_3$) 1.7—2.0 (m, 2), 2.21—3.16 (m, 7), 3.84 (s, 3), 4.04—4.44 (m, 2), 6.90 (m, 2), and 7.82 ppm (m, 2); Found: C, 58.06; H, 5.84%. Calcd for $C_{15}H_{18}O_3S_2$: C, 58.03; H, 5.84%.

Dithiane Lactone **4c**. IR ($CHCl_3$) 1775, 1600, 1590, and 1025 cm^{-1}; NMR ($CDCl_3$) 1.8—2.04 (m, 2), 2.29—3.24 (m, 7), 3.97 (s, 6), 4.10—4.52 (m, 2), 6.94 (d, 1, J=9 Hz) and 7.49—7.60 ppm (m, 2); Found: C, 56.55; H, 5.94%. Calcd for $C_{16}H_{20}O_4S_2$: C, 56.44; H, 5.92%.

Dithiane Lactone **4d**. IR (Nujol) 1775, 1500, 1040, and 930 cm^{-1}; NMR ($CDCl_3$–DMSO-d_6) 1.8—2.01 (m,2), 2.24—3.16 (m, 7), 4.06—4.46 (m, 2), 6.02 (s, 2), 6.80 (d, 1, J=9 Hz), and 7.31—7.48 ppm (m, 2); Found: C, 55.51; H, 4.95%. Calcd for $C_{15}H_{16}O_4S_2$: C, 55.53; H, 4.97%.

Dithiane Lactone **4e**. IR (Nujol) 1780, 1500, 1585, and 1130 cm^{-1}; NMR ($CDCl_3$) 1.96 (m, 2), 2.28—3.22 (m, 7), 3.91 (s, 9), 4.11—4.61 (m, 2), and 7.28 (s, 2); Found: C, 55.06; H, 5.99%. Calcd for $C_{17}H_{22}O_5S_2$: C, 55.11; H, 5.99%.

Dithiane Lactone **4f**. IR ($CHCl_3$) 1770, 1600, 1585, and 1020 cm^{-1}; NMR ($CDCl_3$) 1.80—2.02 (m, 2), 2.26—3.20 (m, 7), 3.90 (s, 3), 4.08—4.50 (m, 2), 5.17 (s, 2), 6.92 (d, 1, J=8 Hz), and 7.30—7.56 (m, 8).

General Procedure for the Desulfurization of Dithiane Lactones **4**. To a mixture of NCS (0.004 mol) and silver nitrate (0.0045 mol) in 4 ml of CH_3CN and 2 ml of water was added a solution of **4** (0.001 mol) in CH_3CN. The mixture was stirred under

the condition shown in Table 2, then poured into sat NaCl soln and extracted with ether. The extract was washed with $NaHSO_3$ soln and NaCl soln and dried. Evaporation and chromatography gave pure β-aroyl-γ-lactone **5**.

β-(4-Methoxybenzoyl)butyrolactone ***5b***. IR ($CHCl_3$) 1770, 1670, 1595, 1570, 1210, and 1025 cm^{-1}; NMR ($CDCl_3$) 2.56—3.10 (m, 2), 3.86 (s, 3), 4.12—4.64 (m, 3), 6.94 (m, 2), and 7.87 ppm (m, 2); Found: C, 65.46; H, 5.49%. Calcd for $C_{11}H_{12}O_4$: C, 65.44; H, 5.49%.

β-(3,4-Dimethoxybenzoyl)butyrolactone ***5c***. IR ($CHCl_3$) 1775, 1670, 1590, 1585, 1260, and 1020 cm^{-1}; NMR ($CDCl_3$) 2.60—3.15 (m, 2), 3.93 (s, 3), 3.96 (s, 3), 4.27—4.70 (m, 3), 6.94 (d, 1, J=9 Hz), and 7.44—7.61 (m, 2); Found: C, 62.37; H, 5.68%. Calcd for $C_{13}H_{14}O_5$: C, 62.39; H, 5.64%.

β-(3,4-Methylenedioxybenzoyl)butyrolactone ***5d***. IR (Nujol) 1780, 1680, 1620, and 1040 cm^{-1}; NMR ($CDCl_3$) 2.57—3.12 (m, 2), 4.08—4.64 (m, 3), 6.04 (s, 2), 6.84 (d, 1, J=8 Hz) and 7.35—7.50 ppm (m, 2); Found: C, 61.40; H, 4.28%. Calcd for $C_{12}H_{10}O_5$: C, 61.54; H, 4.30%.

β-(3,4,5-Trimethoxybenzoyl)butyrolactone ***5e***. IR ($CHCl_3$) 1780, 1680, 1590, 1030, and 1000 cm^{-1}; NMR ($CDCl_3$) 2.90 (m, 2), 3.93 (s, 9), 4.48 (m, 3), and 7.16 ppm (s, 2).

β-(3-Benzyloxy-4-methoxybenzoyl)butyrolactone ***5f***. IR ($CHCl_3$) 1775, 1670, 1590, 1580, 1260, and 1020 cm^{-1}; NMR ($CDCl_3$) 2.55—3.12 (m, 2), 3.91 (s, 3), 4.20—4.62 (m, 3), 5.20 (s, 2), 6.89 (d, 1, J=9 Hz), 7.27—7.42 (m, 6), and 7.46 ppm (d, 1, J=9 Hz); Found: C, 69.84; H, 5.49%. Calcd for $C_{19}H_{18}O_5$: C, 69.93; H, 5.56%.

Carbomethoxylation of ***4***. To 0.275 g (0.0057 mol) of 50% mineral oil dispersion of NaH (twice washed with anhyd. hexane) suspended in 5 ml of dry Me_2CO_3 was added 713 mg of **4** in 11 ml of Me_2CO_3 and 5 ml of anhyd. THF, and the mixture was refluxed for 10 h. After the excess reagent had been destroyed with MeOH, the mixture was poured into water and extracted with $CHCl_3$. The organic layer was washed with $NaHCO_3$ soln, dried and evaporated to give 813 mg (97%) of the carbomethoxy lactone **6**, mp 168—170 °C (from EtOH), IR (Nujol) 1770 and 1735 cm^{-1}; NMR ($CDCl_3$) 1.94 (m, 2), 2.72 (m, 4), 3.58 (m, 1, H_d), 3.68 (s, 3), 3.94 (d, 1, J=9 Hz, H_c), 4.32 (q, 1, J=8 and 10 Hz), 6.82 (d, 1, J=9 Hz), and 7.44 ppm (m, 2); Found: C, 53.35; H, 4.72%. Calcd for $C_{17}H_{18}O_6S_2$: C, 53.39; H, 4.74%.

Alkylation of ***6***. To a soln of 654 mg (0.00171 mol) of **6** in 30 ml of DME was added 115 mg (0.00239 mol) of NaH mineral oil dispersion (50%) under a nitrogen atmosphere. Several drops of dried *t*-BuOH were added, the mixture was stirred for 40 min at room temp, then a soln of 386 mg (0.00171 mol) of piperonyl bromide in 7 ml of DME was added and the resulting mixture was refluxed for 3 h. After removal of the solvent under reduced pressure, water was added to this mixture and extracted with ether. The crude product was chromatographed over neutral Al_2O_3 (Act II), and elution with C_6H_6–ether (95: 5) afforded 674 mg (76%) of **7**, mp 206—208 °C (from EtOH), IR ($CHCl_3$) 1780, 1750, 1610, and 940 cm^{-1}; NMR ($CDCl_3$) 1.91 (m, 2), 2.64 (m, 4), 3.00 (q, 1, J=8.2 and 8.5 Hz, H_e), 3.31 (q, 2, J=15 Hz, H_c, H_d), 3.81 (s, 3), 3.92 (q, 1, J=8.2 and 10 Hz, H_b), 4.55 (q, 1, J=8.5 and 10 Hz, H_a), 5.91 (s, 2), 6.06 (s, 2), and 6.74—7.56 ppm (m, 6); Found: C, 58.04; H, 4.67%. Calcd for $C_{25}H_{24}O_8S_2$: C, 58.12; H, 4.68%.

Decarboxylation of ***7***. Hydrolysis of **7** (260 mg) with 1 M ethanolic KOH (15 ml) at 50 °C for an hour followed by acidification with acetic acid gave **8** (205 mg; 80%), mp 153—155 °C (from EtOH); IR ($CHCl_3$) 1770, 1610, and 940 cm^{-1}; NMR ($CDCl_3$) 1.84 (m, 2), 2.56 (m, 7), 2.96 (m, 1, H_c), 3.86 (q, 1, J=8.2 and 10 Hz, H_b), 4.54 (q, 1, J=4.2 and 10 Hz, H_a), 5.86 (q, 2, J=2.0 Hz) and 5.96 ppm (q, 2, J=2.0 Hz); Found: C, 60.12; H, 4.83%. Calcd for $C_{23}H_{22}O_6S_2$: C, 60.24; H, 4.84%.

One-pot Synthesis of ***8***. Butyllithium (3.3 ml of a 15% hexane soln, 5.29×10^{-3} mol) was added to a soln of **3d** (1.211 g; 5.04×10^{-3} mol) in THF (25 ml) at −78 °C under nitrogen atmosphere. The mixture was stirred for 1.5 h at −40 °C. After cooling at −78 °C, the mixture was treated with 2-butenolide (0.423 g; 5.04×10^{-3} mol) in 5 ml of abs. THF. After stirring for 2 h at −60 °C, the mixture was treated with 10% HCl. Extractive work-up and chromatography on silicic acid and elution with C_6H_6–AcOEt (95: 5) gave pure **8** in 77% yield.

Equilibration of ***8***. The lactone **8** (50 mg) was added to a 3% soln of *t*-BuOK in *t*-BuOH (10 ml). The mixture was stirred for 5 h at 60 °C and then for 12 h at room temp. After quenching the reaction with dil HCl, extractive work-up gave the starting material (TLC, NMR, and IR).

Desulfurization of ***8***. To a mixture of NCS (0.567 g; 97%; 4.12×10^{-3} mol) and silver nitrate (0.787 g; 4.63×10^{-3} mol) in 4 ml of CH_3CN and 2 ml of water was added a soln of **8** (474 mg; 1.03×10^{-3} mol) in 6 ml of CH_3CN. The mixture was heated for 30 min at 50 °C, then poured into sat. NaCl soln and extracted with ether. The extract was washed with $NaHSO_3$ soln and NaCl soln and dried. Evaporation of the solvent gave the keto lactone **9**, (370 mg; 100%), mp 140—142 °C (from EtOH); IR ($CHCl_3$) 1780, 1675, 1610, and 940 cm^{-1}; NMR ($CDCl_3$) 2.92 (m, 2, AB part of ABXY system), 3.38 (m, 1, X part of ABXY system), 3.79—4.40 (m, 3), 5.84 (s, 2), and 6.01 ppm (s, 2). This compound was identical with the oxo-parabenzlactone derived from natural (−)-parabenzlactone[7] by oxidation with Jones' reagent (IR, NMR, UV and TLC).

Reduction of ***9***. (a) To a chilled (0 °C) soln of **9** (36 mg; 9.78×10^{-5} mol) in 5 ml of MeOH and 5 ml of THF was added 4 mg (9.78×10^{-5} mol) of $NaBH_4$. The mixture was stirred for 40 min and then the excess reagent was destroyed with few drops of acetic acid. The solvent was removed *in vacuo* (50 °C), the residue was diluted with water and worked up by extraction with $CHCl_3$ giving **10** (16 mg), mp 156—158 °C (from MeOH). This was identical with natural parabenzlactone[7] (IR, NMR, and TLC).

(b) To a soln of **9** (60 mg; 1.63×10^{-4} mol) in 2.5 ml of dry C_6H_6 was added 1.63×10^{-4} mol of zinc borohydride[8] in 11.2 ml of abs ether. After 24 h at room temp the mixture was treated with water and then with dil acetic acid. Extractive work-up gave an oil (65 mg), which was purified by chromatography on silicic acid. Elution with AcOEt–C_6H_6 (1: 4) gave pure **10** (50 mg).

Reductive Desulfurization of ***8***. The mixture of **8** (150 mg) and 2 g of Raney Ni (W-2) in 50 ml of abs EtOH was refluxed overnight. Filtration of the catalyst and evaporation of the solvent gave **11** as a viscous oil. The IR and NMR spectra of **11** were superimposable with those of (−)-hinokinin.[9]

The authors wish to express their thanks to Dr. K. Wada, Nagoya University, for provinding the sample of (−)-parabenzlactone and to Dr. S. Nishibe, Higashinippon Gakuen University, for informing us the stereochemistry of (−)-parabenzlactone, and for kindly supplying the IR and NMR spectra of (−)-hinokinin.

Studies of the Removal of Oily Soil by Rolling-up in Detergency. II. On Binary Soil Systems Consisting of Oleic Acid and Liquid Paraffin

Keizo OGINO and Ken-ichi SHIGEMURA

Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received February 28, 1976)

The rolling-up mechanism of oily soil from the surface of a polypropylene (PP) sheet in an aqueous solution of sodium dodecylbenzenesulfonate (LAS) was studied by the observation of the contact angle (θ). A binary system consisting of *cis*-9-octadecenoic acid (oleic acid)–liquid paraffin (Nujol) was used as an example of oily soil. The time required for the removal of the oily soil mixture from the PP sheet by rolling-up became shorter with the increase in the liquid paraffin content of the mixture. The oily soil with binary components was more easily removed from the substrate than a single-component oily soil.

Although the mechanism of the practical cleaning of oily soil is extremely complicated, it is well known that the cleaning consists of three basic processes that may occur simultaneously or in succession: rolling-up, solubilization, and emulsification.[1]

The process of rolling-up may be explained as follows. As soon as the soil-substrate system of air is purged and the solution/soil/substrate interfaces become stable, the contact angle at the soil/substrate interface begins to increase and attains the intrinsic equilibrium state. At the same time, the force acting between the oily soil and the substrate decreases; when the contact angle reaches 180°, the oily soil is completely removed from the substrate.

Smith *et al.*[2] have reported a change in the contact angle of an oily soil/substrate system in detergent solutions of various concentrations in the course of time, using mineral oil as the oily soil and fiber as the substrate. On the other hand, Stevenson[3] found that polar oil was far more easily removed from fiber than was mineral oil and that the addition of polar substances to mineral oil greatly facilitated the removal. However, their studies were only presented qualitatively by photographs; the inter-relations of the changes among the components of the soil, the concentration of the detergent in the solution, and other factors were not described.

In the previous report, we studied the removal of single-component oily soil from a low-energy surface.[4] In this study, the rolling-up process of oily soil on a polypropylene surface in a detergent solution was examined in terms of the change in the contact angle with time, using mixtures of polar and non-polar soils in certain proportions (by weight), and the interaction between the oily soil and surfactant was speculated upon.

Experimental

Materials. *Substrate*: A polypropylene (PP) sheet from Mitsui Noblene J. H. G. was used as the substrate. The preparation of the specimen from the obtained sheet was described in the previous report.[4] The sheet was cut into specimens of $10\times10\times1.2$ mm, and the surface was cleaned several times with a commercial detergent solution at 35 °C, rinsed with distilled water for 60 min, soaked into absolute ethanol for 5 min, dried in a vacuum for 3 h, and stored in a dessicator at room temperature till use.

Surface-active Agents: The sodium dodecylbenzenesulfonate (LAS) was of commercial grade from the Wako Chemical Co., Ltd.

Oily Soil: Oily soil of a binary system was prepared by mixing oleic acid (reagent grade from Tokyo Kasei Co.) and liquid paraffin (reagent grade from Wako Pure Chemical Co., Ltd.) in the ratios of 1:0, 3:1, 1:1, 1:3, and 0:1 (by weight).

Apparatus. The contact angle and its change with the time were measured by means of a Goniometer (Erma Kogaku Co., Ltd., M 2010, A-a, G-type), while the surface tension of the oily soil was measured by means of a Wilhelmy-type Surface Tensionmeter ST-1 (Shimadzu Seisakusho).

Procedure. A volume of 1.5×10^{-3} ml of the oily soil was dropped on a PP sheet by means of a microsyringe connected with a micrometer. Then the sheet with a drop of the soil on it was set in a glass cell ($40\times25\times15$ mm). The glass cell was placed on the table of the Goniometer, and then the surfactant solution was poured slowly onto it. The change in the contact angle with the time and the time required for the removal of the oily soil from the surface by rolling-up were measured as in the previous report.[4]

Results and Discussion

Wetting of the Polypropylene Sheet with Organic Liquids. Figure 1 shows the contact angle and the surface tension of the binary oily soil on a PP sheet in the air. Both the contact angle and the surface tension decreased with an increase in the proportion of liquid paraffin in the soil and reached the highest value at 100 per cent oleic acid. This result is consistent with that of Zisman[5] that the contact angle of organic liquid on a low-energy

●: Contact angle,
○: Surface tension.

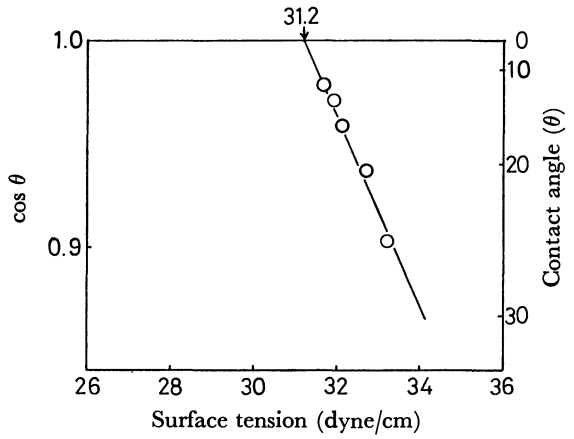

Fig. 2. Surface tension *vs.* cosine of the contact angle of the same mixed liquids as Fig. 1 on polypropylene.

surface tends to decrease with a decrease in the surface tension for a homologous series of liquids.

From the results shown in Fig. 1, the relation between the contact angle and the surface tension was derived; it is plotted in Fig. 2, which indicates a linear relationship between the two properties; the critical surface tension of PP, γ_c, is 31.2 dyne/cm, a calculated from the relationship extrapolated to $\cos\theta=1$.

Change in the Appearance of Oily Soil in a Detergent Solution. The change in the appearance of oily soil which had been dropped onto the PP sheet was observed in accordance with the time-course of the change in the contact angle in LAS solutions of various concentrations. The results for the binary oily soil systems are shown in Figs. 3, 4, and 5. Similar results have been obtained for the single-component systems of oleic acid or liquid paraffin, as has been described in the previous paper.[4] The change in the appearance of oily soils of various compositions in LAS solutions is illustrated in Fig. 6.

As may be seen in Figs. 3, 4, and 5, the contact angle changed with the time in oleic acid–liquid paraffin binary systems; the cause of this change is considered

to be the adsorption of a surface-active agent on the oily soil surface. When the droplet of oleic acid on the substrate was brought into the surfactant solution, the contact angle rapidly increased and rolled back, as was shown in the previous paper.[4] After about 20 min in the 0.150 per cent LAS solution, the droplet was constricted and floated away.

For a mixture of oleic acid and liquid paraffin in the proportion of 3: 1, the addition of a 0.115 per cent LAS solution causes the roll back of the droplet, much as with oleic acid alone; necking begins after about 22 min of rolling-up, but a portion of the soil remains intact on the PP sheet after the removal of the droplet (Figs. 3 and 6). In contrast to the soil of oleic acid alone, the binary soil of oleic acid and liquid paraffin rolls up in a more dilute solution of LAS; for example, the time required for rolling-up was 114.9 min in 0.100 per cent, 22.3 min in 0.115 per cent, and 8.7 min in 0.125 per cent solutions of LAS.

Similarly, the rolling-up phenomena were observed for the mixtures of oleic acid and liquid paraffin in the ratios of 1: 1 (Figs. 4 and 6) and 1: 3 (Figs. 5 and 6). Both mixed soils were removed incompletely from the PP surface; the time for the removal was 27.6 min for the former and about 30 s for the latter in an LAS

solution at a 0.100 per cent concentration.

As presented in the previous study and in Fig. 6, non-polar liquid paraffin was the only material which showed no appreciable changes in the contact angle in the detergent solutions.

In Table 1, the values of the contact angle and the time required to remove the mixed oily soil from the PP sheet by rolling-up in an LAS solution are shown. It is apparent from these results that the rolling-up phenomenon occurs for the mixed oily soil, but not for the liquid paraffin alone. On the other hand, both the value of the final contact angle of the oily soil to the PP sheet in a LAS solution and the time required to remove oily soil by rolling-up decrease with an increase in the proportion of liquid paraffin in the soil. Besides, it is confirmed that the addition of paraffin to oleic acid facilitates the rolling-up of the droplets.

For the mixture of oleic acid-liquid paraffin placed as an oily soil on a low-energy surface such as polypropylene, the rolling-up occurs at the contact angle of $0°<\theta<90°$. It is noteworthy that, on a high-energy surface, rolling-up occurs only when $\theta=180°$.[6]

From Fig. 6, the adsorbed concentration of LAS molecules at the solution/oily soil interface seems to be larger than that at the solution–substrate interface. On the other hand, in the mixed oily soil systems, the contact angle in a LAS solution decreases, while the contact area does not decrease, with the increase in the proportion of liquid paraffin. These differences between the soils of the binary components and oleic acid alone are presumed to be due to the difference in the orientation of the oleic acid and liquid paraffin molecules.

The intermolecular force in the bulk of liquid oily soil is strongly exerted by the polar molecules, and the intervention of non-polar molecules with the polar molecules causes a decrease in the intermolecular forces. As a result, the reduction of the cohesive force of the molecules in the oily soil gives rise to rolling-up in spite of the small contact angle in the LAS solution. It was clarified in the previous paper[4] that polar oils interact with a surfactant more strongly than non-polar substances. This must be the reason for the easier rolling-up of the polar soils.

When a drop of oily soil placed onto a substrate was immersed into a solution of the surface-active agent, the contact angle increased and approached equilibrium, and the oily soil underwent necking and rolling-up depends on three forces: the cohesive force of the oily soil itself, the buoyancy, and the adhesive force between the substrate and the oily soil. For instance, a droplet of oleic acid rolls up because the horizontal tension nearly disappears at a contact angle, θ of 86.5° (nearly 90°).[4] It is presumed that the balance of the above three forces is shifted in a solution of a surface-active agent by the adsorption and desorption of LAS molecules at the oil/solution/substrate triple interfaces.

From these results, it may be speculated that, in all oily-soil systems of multiple components except those of paraffin alone, one of the three forces which exert influence on the oily soil, buoyancy, exceeds the other two forces; the reduction of cohesive force between the molecules in the soil is considered to be the inherent reason for the rolling-up process. Also, on a low-energy surface such as polypropylene, oily soil including polar components tends to roll up. The presence of polar components in the soil is one of the factor controlling the rolling-up.

Sulfoxonium Ylide Chemistry. VII.[1] Reductive Cleavage of Dimethylsulfoxonium Allylides

Junya IDE and Yukichi KISHIDA

Central Research Laboratories, Sankyo Co., Ltd., 1-2-58 Hiromachi, Shinagawa-ku, Tokyo 140

(Received June 14, 1976)

Reductive cleavage of dimethylsulfoxonium allylides with zinc in acetic acid or by hydrogenation over platinum at high pressure (120 atm) has been investigated. Reduction of dimethylsulfoxonium 3-ethoxycarbonyl-2-phenylallylide (**1**) with zinc gave predominantly ethyl 3-phenyl-3-butenoate (**2**) together with ethyl (*E*)-3-phenyl-2-butenoate (**3**) (90: 10). However, under the more acidic conditions (pH 2), **3** was the exclusive product. Hydrogenation of **1** over platinum afforded a mixture of **3** and ethyl 3-phenylbutanoate (**4**). Reduction of dimethylsulfoxonium 3-ethoxycarbonyl-2-phenyl-1-(phenylcarbamoyl)allylide (**6**) either with zinc or by hydrogenation gave ethyl (*Z*)-3-phenyl-4-phenylcarbamoyl-2-butenoate (**7**). Hydrogenation of dimethylsulfoxonium 1-benzoyl-3-ethoxycarbonyl-2-phenylallylide (**9**) at room temperature provided ethyl (*Z*)-3,5-diphenyl-5-oxo-2-pentenoate (**10**) and 4,6-diphenyl-2-pyrone (**11**), and at 80 °C **11** and ethyl 3,5-diphenyl-5-oxopentanoate (**12**).

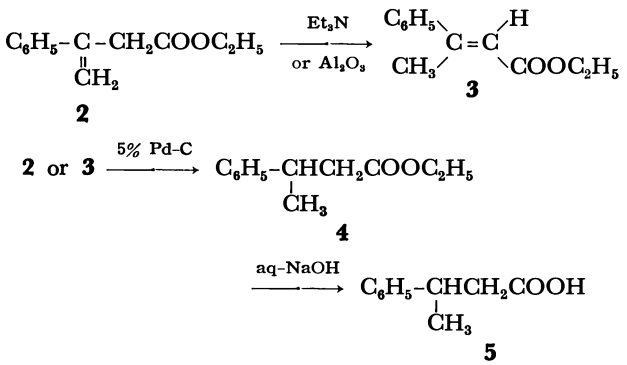
In the continuation of our studies on sulfoxonium ylides to clarify the chemical behavior of carbon–sulfur ylide bond, the reduction of sulfoxonium ylides by a dissolving metal or catalytic hydrogenation is of interest from a synthetic view point. It is already known that desulfurizations of allyl sulfide and thioacetals are effected by dissolving metal such as Raney-Ni or sodium. Additionally, dissolving metal reduction either in the presence of a proton donor or followed by treatment with a proton donor offers the advantage of selectivity in reduction or of stereoselectivity. There has been, however, only one report on the reduction of a sulfoxonium ylide reported by Corey and Chaykovsky.[2]

In the present paper, we would like to describe the reduction of sulfoxonium allylides with zinc in acetic acid and by catalytic reduction over platinum in acetic acid at high pressure, along with certain mechanistic aspects of these processes.

Results and Discussion

Treatment of dimethylsulfoxonium 3-ethoxycarbonyl-2-phenylallylide (**1**) with zinc powder in acetic acid (pH 4.7) at 16—18 °C under an argon atmosphere gave ethyl 3-phenyl-3-butenoate (**2**) and ethyl (*E*)-3-phenyl-2-butenoate (**3**) in a ratio of 90: 10 (by GLC analysis) in 92% yield. On the contrary, under more acidic conditions using a small amount of hydrochloric acid (pH 2), **1** afforded **3** exclusively. Reduction of **1** over platinum in acetic acid at 120 atm of hydrogen at room temperature gave a mixture of **3** and ethyl 3-phenylbutanoate (**4**) in 88% yield. However, under atmospheric pressure the reduction was not effected and the starting material (**1**) was recovered.

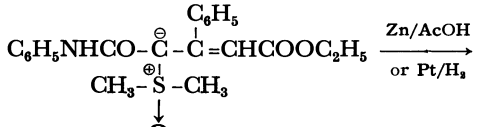
Base-catalysed isomerization of **2** was readily effected with alumina or triethylamine to give the more stable isomer (**3**). Catalytic hydrogenation of **2** or **3** over 5% palladium–charcoal afforded **4**, which was hydrolysed to the corresponding acid (**5**).



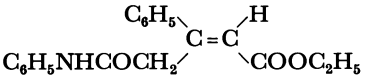
The NMR, UV, and IR spectral data of **2**, **3**, and **4** also support their structures. Terminal methylene protons of **2** appeared at δ 5.21 and 5.48 ppm (J=1.2 Hz). The UV spectrum of **2** showed λ_{max} (EtOH) 243 nm (ε 10600), which was very similar to that of α-methylstyrene (λ_{max} (EtOH) 240 nm (ε 12000)),[3] and its IR spectrum exhibited a band at 909 cm^{-1} characteristic of terminal methylene group. The *E*-configuration was assigned to **3** based on the UV spectrum showing its absorption maximum at 265 nm (ε 15860).[4] From a synthetic view point this method seems to be preferable for the preparation of the unconjugated ester (**2**) which is hardly accessible because of its chemical instability.

Reduction of dimethylsulfoxonium 3-ethoxycarbonyl-2-phenyl-1-(phenylcarbamoyl)allylide (**6**) either with zinc in acetic acid or over platinum in acetic acid under

120 atm of hydrogen at room temperature afforded ethyl β-(phenylcarbamoylmethyl)cinnamate (**7**), mp 169—170 °C, in 66% and 73% yield, respectively.



6

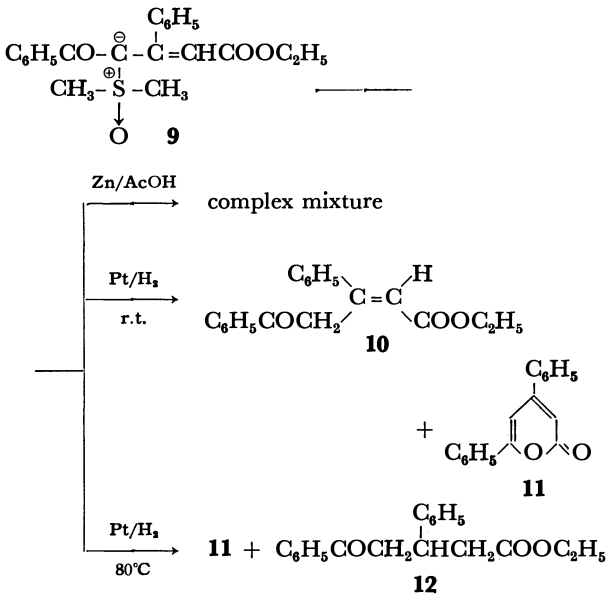


7

In the NMR spectrum of **7**, methylene and vinyl protons appeared as singlets at δ 4.16 and 6.57 ppm, respectively. The UV spectrum of **7** showed λ_{max} (EtOH) 224 (ε 13880), 247 (ε 22200), and 270 nm (ε 15850) which was similar to the additive chromophore of ethyl (*E*)-phenyl-2-butenoate (**3**) and acetanilide (λ_{max} (EtOH) 242 nm (ε 13200)),[5] whereas the UV spectrum of *trans*-cinnamanilide (**8**) showed λ_{max} (EtOH) 221 (ε 18600), 240 (ε 4800), and 295 nm (ε 25800),[6] which would be appropriate for that of the other double bond isomer (**7'**).

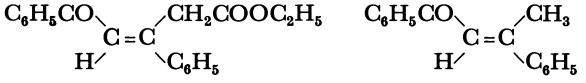
7' **8**

Treatment of dimethylsulfoxonium 1-benzoyl-3-ethoxycarbonyl-2-phenylallylide (**9**) with zinc in acetic acid at 16—18 °C resulted in a complex mixture, whereas its reduction over platinum in acetic acid under 120 atm at room temperature afforded ethyl *(Z)*-β-(benzoylmethyl)cinnamate (**10**), mp 85—86 °C and 4,6-diphenyl-2-pyrone (**11**), mp 136—137 °C (lit, mp 142 °C)[7] in 20 and 13% yield, respectively. However, in the reduction of **9** at 80 °C, the pyrone (**11**) and ethyl 3,5-diphenyl-5-oxobutanoate (**12**), mp 61—62 °C, were obtained in 60 and 9% yield, respectively.



9 **10** **11** **12**

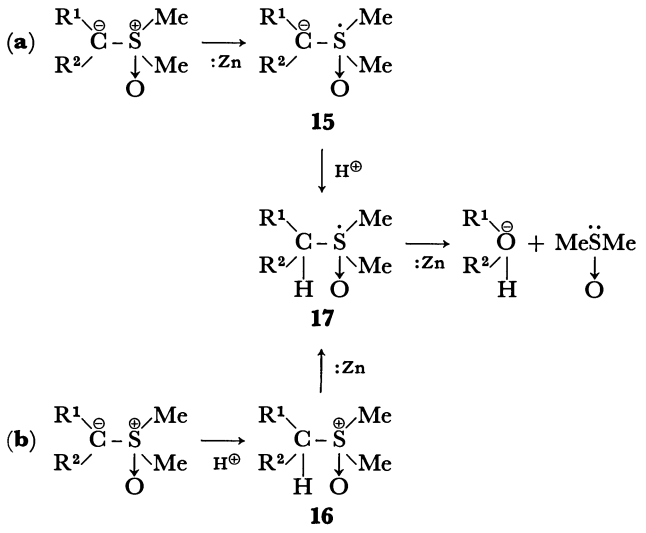
The assignment of the position of the double bond and *Z*-configuration to **10** was based on the NMR and UV spectral data. In the NMR spectrum of **10** methylene and vinyl protons appeared at δ 4.87 (singlet) and 6.40 ppm (singlet), respectively. Its UV spectrum showed λ_{max} (EtOH) 246 (ε 21750) and 268 nm (ε 16630), which is in good agreement with the chromophore bearing acetophenone (λ_{max} (EtOH) 243 nm (ε 13200)[8]) and ethyl (*E*)-3-phenyl-2-butenoate (**3**). Another possible structure (**13**) which should have a similar chromophore with (*E*)-1,3-diphenyl-2-buten-1-one (**14**) (λ_{max} (EtOH) 227.5 (ε 9600), 262.5 (ε 10500) (sh), and 295 nm (ε 16000)),[9] can be excluded by comparing with that of **10**. Its IR spectrum revealed the carbonyl band at 1715 cm^{-1} which is appropriate for an α,β-unsaturated ester, but not for an α,β-unsaturated benzoyl group.



13 **14**

The NMR spectrum of **11** showed two vinyl protons as AB quartet with a small coupling constant at δ 6.48 and 6.98 ppm (J=1.3 Hz) and its UV spectrum exhibited λ_{max} (EtOH) 229 (ε 10880), 236 (ε 11200), 262 (ε 23100), and 344 nm (ε 10200).[10] The pyrone (**11**) was directly compared with an authentic sample prepared according to the method of Schulte *et al.*[7] The structure of **12** was determined by the examination of its UV and NMR spectra (see Experimental) and elemental analysis. The UV spectrum of **12** showed λ_{max} (EtOH) 243 nm (ε 12930), which was very close to that of acetophenone (*vide supra*),[8] supporting the existence of $C_6H_5COCH_2$ moiety.

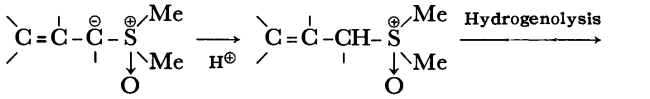
Reduction of a sulfoxonium ylide with zinc in acetic acid could be well interpreted as proceeding through an anion radical (**15**) produced by electron transfer from the metal surface to sulfur of ylide (type "**a**"), or radical (**17**) produced by electron transfer to the sulfoxonium ion (**16**) fromed by protonation to ylide in acidic conditions (type "**b**").[11] A further electron transfer to the resulting radical (**17**) leads to the cleavage of carbon–sulfur bond. This reductive cleavage reaction



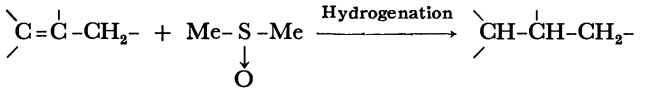
15 **17** **16**

of type "**b**" by dissolving metal has been found in ammonium, sulfonium, and phosphonium salts.[11]

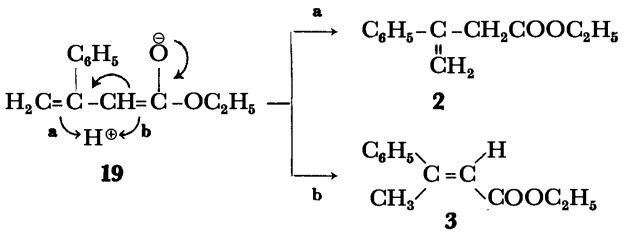
On the other hand, the sulfoxonium allylide over platinum in acidic medium at high pressure of hydrogen is likely to undergo hydrogenolysis of allylsulfoxonium salt (**18**) produced by protonation to the ylide, and the resulting allyl group could be further hydrogenated partially to the saturated product depending upon the reaction conditions and/or the character of the substituents on the double bond.



18



It is noteworthy that in the reduction of **1** with zinc the non-conjugated ester (**2**) and the conjugated ester (**3**) are obtained selectively depending on the acidity of reaction medium. This would be attributed to the mode of protonation of the plausible reaction intermediate (**19**), in which weak acids lead to the kinetically-controlled product (**2**) by proton attack at the central position of the enolate anion, and strong acids or equilibrating conditions give the thermodynamically-controlled one (**3**) by attack of the proton at the terminal position according to the Ingold's theory.[12]



19

2

3

Experimental

All the melting points were uncorrected. NMR spectra were recorded on a Varian A-60 and HA-100 spectrometers using TMS as an internal standard, IR spectra were taken on a Hitachi EPI-G3, and UV spectra were obtained with Beckman DK-2 spectrophotometer.

Reduction of Dimethylsulfoxonium 3-Ethoxycarbonyl-2-phenylallylide (1) with Zinc in Acetic Acid. *a) At pH 4.7*: To a solution of **1** (15 g, 57 mmol) in glacial acetic acid (160 ml) was added zinc powder (39 g, 570 mmol) in many portions so as to control the inner temperature at 16—18 °C with external cooling, and the reaction mixture was stirred at room temperature for 8 h. The inorganic substances were filtered and washed with ether. The filtrate was concentrated under reduced pressure. The residue was dissolved in ether (500 ml), and the ethereal solution was washed successively with 5% $NaHCO_3$ solution, water and saturated NaCl solution, and dried over anhydrous Na_2SO_4. After the evaporation of the solvent under reduced pressure, the residue was chromatographed on silica gel (220 g). Elution with hexane–benzene (5: 1) gave ethyl (*E*)-3-phenyl-2-butenoate (**3**) (990 mg; 9.2% yield), bp 105—106 °C/1 Torr; IR (Liquid): ν 1710, 1625, and 1170 cm^{-1}; NMR ($CDCl_3$): δ 1.15 (3H, t, J=7 Hz; $COOCH_2$-$C\underline{H}_3$), 4.05 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 2.54 (3H, d, J=1.2 Hz; =C–CH_3), 6.07 (1H, q, J=1.2 Hz; =C–H), 7.3 ppm (5H, m; C_6H_5–); UV (EtOH): λ_{max} 265 nm (ε 15860); Found: C, 75.84; H, 7.54%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%. Elution with hexane–benzene (3: 1) gave ethyl 3-phenyl-3-butenoate (**2**) (9.84 g, 90.8% yield), bp 98—100 °C/1 Torr; IR (Liquid): ν 1735 (–$COOC_2H_5$) and 909 cm^{-1} (=CH_2); NMR ($CDCl_3$): δ 1.15 (3H, t, J=7 Hz; $COOCH_2$-$C\underline{H}_3$), 4.08 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 3.41 (3H, d, J_{AX}=1.2 Hz, =C–$C\underline{H}_{2X}$–$COOC_2H_5$), 5.21 (1H, q, J_{AB}=J_{AX}=1.2 Hz; =C–H_A (*trans* to phenyl group)), 5.48 (1H, d, J_{AB}=1.2 Hz; =C–H_B (*cis* to phenyl group)), and 7.3 ppm (5H, m; C_6H_5); UV (EtOH): λ_{max} 243 nm (ε 10600); Found: C, 75.60; H, 7.55%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

b) At pH 2 Containing Hydrogenchloride: The Ylide (**1**) (5 g, 19 mmol) was dissolved in glacial acetic acid (70 ml), and pH value was adjusted at 1.8—2.0 by adding small amount of concd HCl (*ca.* 2 ml). To the solution was added zinc powder (13 g, 200 mmol) in many portions so as to control the inner temperature at 16—18 °C with external cooling and the reaction mixture was stirred at room temperature for 8 h. After the same work-up as described in **a**), the residue was distilled *in vacuo* to give **3**, bp 105—106 °C/1 Torr (3.2 g, 90% yield).

Catalytic Hydrogenolysis of Dimethylsulfoxonium 3-Ethoxycarbonyl-2-phenylallylide (1) over Platinum in Acetic Acid. A solution of **1** (8.8 g, 33 mmol) in glacial acetic acid (60 ml) was hydrogenated over PtO_2 (1.8 g) in an autoclave at 120 atm of hydrogen at room temperature for 10 h. The catalyst was removed by filtration and the filtrate was concentrated under reduced pressure. The residue was chromatographed on silica gel (140 g). Elution with hexane–benzene (5: 1) afforded **3** (4.04 g, 64.4% yield) and elution with hexane–benzene (3: 1) gave ethyl 3-phenylbutanoate (**4**) (1.52 g, 24% yield), bp 95—97 °C/2 Torr; IR (Liquid): ν 1735 cm^{-1} ($COOC_2H_5$); NMR ($CDCl_3$): δ 1.14 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.06 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 1.3 (3H, d, J=7 Hz; H_X in C_6H_5–$\underset{H_Y}{\overset{CH_{3X}}{C}}$–$\underset{H_B}{\overset{H_A}{C}}$–), 2.41 (1H, dd, J_{AY}=2 Hz, J_{AB}=15.5 Hz; H_A), 2.71 (1H, d, J_{AB}=15.5 Hz; H_B), 3.30 (1H, dq, J_{AY}=2 Hz, J_{XY}=7 Hz; H_Y), 7.25 ppm (5H, m; $C_6\underline{H}_5$); Found: C, 75.41; H, 8.32%. Calcd for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39%.

Isomerization of Ethyl 3-Phenyl-3-butenoate (2) to Ethyl (E)-3-Phenyl-2-butenoate (3). *a) With Alumina*: A solution of **2** (2.5 g) in hexane (10 ml) was placed on Al_2O_3 (Woelm grade I) (50 g) and eluted with hexane–benzene (1: 1) to give 2.3 g of **3**.

b) With Triethylamine: A solution of **2** (2.5 g) and triethylamine (500 mg) in benzene (10 ml) was heated under reflux for 1 h. After evaporation under reduced pressure, the residue was distilled *in vacuo* to give 2.2 g of **3**, bp 105—106 °C/1 Torr.

Hydrogenation of Ethyl 3-Phenyl-3-butenoate (2) or Ethyl (E)-3-Phenyl-2-butenoate (3). A solution of **2** or **3** (1.4 g) and Pd-charcoal (5%) (500 mg) in ethyl acetate (10 ml) was hydrogenated in hydrogen atmosphere under ordinary pressure. After removal of the catalyst, the solution was concentrated under reduced pressure. The residue was distilled *in vacuo* to afford **4**, bp 95—97 °C/2 Torr.

Hydrolysis of Ethyl 3-Phenylbutanoate (4). The ester (**4**) (1.2 g) was dissolved in ethanol (10 ml) and 10% NaOH (6 ml), and the solution was heated at 50 °C for 3 h. The reaction mixture was neutralized with acetic acid and concentrated under reduced pressure. After the addition of water (10 ml) and extraction with ethyl acetate, the organic layer was dried over anhydrous Na_2SO_4 and evaporated under reduced pres-

sure. The residue was distilled *in vacuo* to give 850 mg of the corresponding acid (**5**), bp 132—136 °C/2 Torr (bath temp); Found: C, 73.45; H, 7.41%. Calcd for $C_{10}H_{12}O_2$: C, 73.14; H, 7.36%.

*Reduction of Dimethylsulfoxonium 3-Ethoxycarbonyl-2-phenyl-1-(phenylcarbamoyl)allylide (**6**) with Zinc in Acetic Acid.* To a solution of **6** (15.6 mmol, 6 g) in glacial acetic acid (60 ml) was added zinc powder (10 g, 160 mmol) in many portions so as to control the inner temperature at 16—18 °C with external cooling. The reaction mixture was stirred at room temperature for 15 h. The inorganic substances were filtered and washed with CH_2Cl_2 (100 ml). The filtrate was concentrated under reduced pressure. The residue was dissolved in chloroform (400 ml), and the solution was washed successively with 5% $NaHCO_3$ solution, water and saturated NaCl solution, and dried over Na_2SO_4. After the evaporation of the solvent under reduced pressure, the residue was chromatographed on silica gel (50 g). Elution with benzene gave ethyl β-(phenylcarbamoylmethyl)cinnamate (**7**; 3.18 g, 66% yield), mp 169—170 °C (from EtOH); IR (Nujol): ν 3100—3300 (NH), 1700, 1650, 1620, and 1600 cm^{-1} (CONH, $=CCOOC_2H_5$); NMR ($CDCl_3$): δ 1.37 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.41 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 4.15 (2H, s; $COC\underline{H}_2C=$), 6.56 (1H, s; =CH–), and 7.65 ppm (10H, m; C_6H_5); UV (EtOH): λ_{max} 224 (ε 13880), 247 (ε 22200), and 270 nm (ε 15850) (shoulder); Found: C, 73.48; H, 6.18; N, 4.53%. Calcd for $C_{19}H_{19}NO_3$: C, 73.76; H, 6.19; N, 4.53%.

*Catalytic Hydrogenolysis of Dimethylsulfoxonium 3-Ethoxycarbonyl-2-(phenylcarbamoyl)allylide (**6**) over Platinum in Acetic Acid.* A solution of **6** (2.1 g, 5.4 mmol) and PtO_2 (500 mg) in glacial acetic acid (20 ml) was hydrogenated in an autoclave at 125 atm of hydrogen at room temperature for 12 h. The catalyst was removed by filtration and the filtrate was concentrated under reduced pressure. The residue was chromatographed on silica gel (20 g). Elution with benzene gave **7** (1.22 g, 73% yield), mp 169—170 °C (from EtOH).

*Catalytic Hydrogenolysis of Dimethylsulfoxonium 1-Benzoyl-3-ethoxycarbonyl-2-phenylallylide (**9**).* *a) At Room Temperature*: A solution of **9** (4 g, 11 mmol) in glacial acetic acid (45 ml) was hydrogenated over PtO_2 (800 mg) in an autoclave at 125 atm of hydrogen at room temperature for 10 h. The catalyst was removed by filtration and the solvent was evaporated under reduced pressure. The residue was chromatographed on silica gel (70 g). Elution with hexane–benzene (2: 1) gave ethyl (*Z*)-β-(benzoylmethyl)cinnamate (**10**, 0.64 g, 20.2% yield), mp 85—86 °C (colorless needles, from EtOH); IR (Nujol): ν 1715 cm^{-1} ($C_6H_5C=CHCOOC_2H_5$); NMR ($CDCl_3$) δ 1.26 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.18 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 4.87 (2H, s; $COCH_2C=$), 6.40 (1H, s; =CH–), 7.4 (8H, m; aromatic protons), and 8.1 ppm (2H, m; aromatic protons); UV (EtOH): λ_{max} 246 (ε 21750), and 268 nm (ε 16630); Found: C, 77.21; H, 7.21%. Calcd for $C_{19}H_{18}O_3$: C, 77.52; H, 7.16%. Elution with hexane–benzene (1: 1) afforded 4,6-diphenyl-2-pyrone (**11**, 350 mg, 13% yield), mp 137—138 °C (lit, mp 142 °C;[7] 138—139 °C;[10b] IR (Nujol): ν 1702 cm^{-1} (pyrone CO); NMR ($CDCl_3$): δ 6.47 (1H, d, J=1.5 Hz; =CH), 6.97 (1H, d, J=1.5 Hz; =CH), and 7.4—8.0 ppm (10H, m); UV (EtOH): λ_{max} 229 (ε 10880), 236 (ε 11200), 262 (ε 23100), and 344 nm (ε 10200); Found: C, 82.17; H, 4.80%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%. The mixed melting point of **11** with the authentic sample prepared by the method[7] showed no depression.

b) At 80 °C: A solution of **9** (7.1 g 19.2 mmol) in glacial acetic acid (50 ml) was hydrogenated over PtO_2 (1.2 g) in an autoclave at 125 atm of hydrogen at 80 °C for 10 h. The catalyst was removed by filtration and the solvent was concentrated under reduced pressure. The residue was chromatographed on silica gel (120 g). Elution with hexane–benzene (3: 1) gave ethyl 3,5-diphenyl-5-oxobutanoate (**12**, 500 mg, 8.8% yield), mp 61—62 °C (colorless crystals, from hexane–EtOH): IR (Nujol): ν 1745 ($COOC_2H_5$) and 1680 cm^{-1} (CO); NMR (100 Mc. $CDCl_3$); for $PhCO-\overset{H_A}{\underset{H_B}{C}}-\overset{H_X}{\underset{Ph}{C}}-\overset{H_C}{\underset{H_D}{C}}-COOEt$: δ 1.10 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.0 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 2.80 (H_C, q, J_{CD}=15 Hz, J_{CX}=7 Hz), 2.61 (H_D, q, J_{CD}=15 Hz, J_{DX}=8 Hz), 3.39 (H_A, q, J_{AB}=15 Hz, J_{AX}=6.5 Hz), 3.24 (H_B, q, J_{AB}=15 Hz, J_{BX}=8 Hz), 3.86 (H_X, m: about 9 lines containing splittings matching J_{AX}, J_{BX}, J_{CX}, and J_{DX}), 7.22 (5H, s; C_6H_5), and 7.9 and 7.5 ppm (5H, m: C_6H_5CO); UV (EtOH): λ_{max} 243 nm (ε 12930); Found: C, 77.46; H, 6.66%. Calcd for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80%.

The authors are very grateful to Dr. M. C. Woods of Varian Associates at Tohoku University for measuring 100 Mc NMR spectra and for his valuable comments, and to Dr. T. Hiraoka of our Laboratories for his helpful suggestions. Thanks are also due to Mr. M. Ishida for his technical assistance.

Sulfoxonium Ylide Chemistry. VIII.[1] A Novel Rearrangement of Dimethylsulfoxonium Ylides

Junya IDE, Tetsuo HIRAOKA, and Yukichi KISHIDA

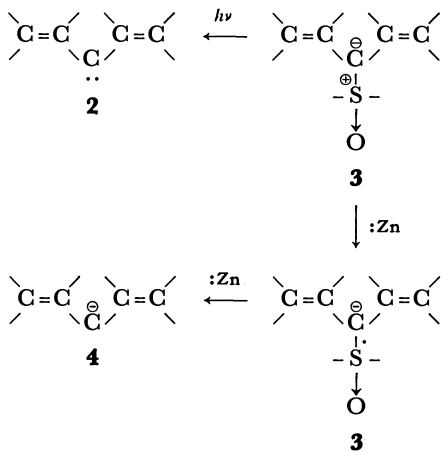
Central Research Laboratories, Sankyo Co., Ltd., 1-2-58 Hiromachi, Shinagawa-ku, Tokyo 140

(Received June 14, 1976)

Reduction of dimethylsulfoxonium 3-ethoxycarbonyl-1-[1,2-bis(methoxycarbonyl)vinyl]-2-phenylallylide (**1**) and dimethylsulfoxonium 3-ethoxycarbonyl-1-[2-(ethoxycarbonyl)vinyl]-2-phenylallylide (**5**) with zinc in acetic acid gave (*Z*)- and (*E*)-3-methoxycarbonyl-4-ethoxycarbonyl-5-phenyl-3,5-hexadienoic acid methyl ester (**6a** and **6b**), and (*Z*)- and (*E*)-4-ethoxycarbonyl-5-phenyl-3,5-hexadienoic acid ethyl ester (**7a** and **7b**), respectively, whose structures were determined by the NMR spectral data and further chemical transformations. The reaction mechanism of the reductive rearrangement was proposed to proceed through an anion radical to form a four membered intermediate (**11**), which cleaved to non-conjugated dienes leading to *Z* and *E* conjugated products.

In the preceding paper,[1] we have reported that the reductive cleavage of sulfoxonium allylides with dissolving metal such as zinc in acetic acid proceeds through an anion radical produced by electron transfer from the metal surface to the sulfur atom of ylides followed by cleavage of carbon–sulfur bond to produce a carbanion. Furthermore, we reported on the photolysis of several dimethylsulfoxonium allylides,[2] in which the vinylallylide (**1**) afforded naphthalene derivatives supposedly produced through a carbene intermediate (**2**) followed by complex rearrangement.

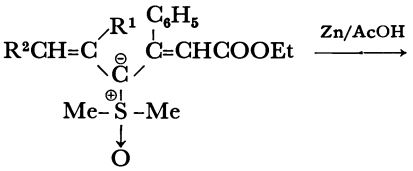
In the continuation of our studies on sulfoxonium ylides to clarify the chemical character of the carbon–sulfur ylide bond, it would be of interest to compare the chemical behavior of divinyl carbene (**2**) presumably generated by photolysis of the corresponding ylide (**3**) with divinyl carbanion (**4**) produced by dissolving metal reduction of **3**.



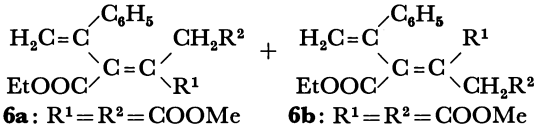
In the present paper we wish to describe a novel type of rearrangement of sulfoxonium vinylallylides *via* divinyl carbanion by dissolving metal reduction.

Results and Discussion

Treatment of dimethylsulfoxonium 3-ethoxycarbonyl-1-[1,2-bis(methoxycarbonyl)vinyl]-2-phenylallylide (**1**)[3] and dimethylsulfoxonium 3-ethoxycarbonyl-1-[2-(ethoxycarbonyl)vinyl]-2-phenylallylide (**5**)[3] with zinc in acetic acid at room temperature afforded a mixture of two geometrical isomers, (**6a** and **6b**) in 74% and (**7a** and **7b**) in 51% yield, respectively. The products obtained from **1** were successfully separated by silica gel column chromatography into **6a** and **6b** with a ratio of 88: 12 which was determined by the NMR spectroscopy. However, the separation of the mixture obtained from **5** was unsuccessful even by repeated column chromatography on silica gel or alumina. The ratio of two geometrical isomers (**7a** and **7b**) consisted of 40: 60 determined by the NMR spectroscopy.



1: $R^1=R^2=COOMe$
5: $R^1=H$, $R^2=COOEt$



6a: $R^1=R^2=COOMe$ **6b**: $R^1=R^2=COOMe$
7a: $R^1=H$, $R^2=COOEt$ **7b**: $R^1=H$, $R^2=COOEt$

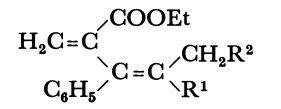
In the NMR spectra of **6a** and **6b**, terminal methylene protons were observed characteristically as AB quartet at δ 5.43 and 5.83 ppm (J=0.4 Hz), and δ 5.25 and 5.62 ppm (J=0.8 Hz), respectively. Likewise, terminal methylene protons of **7a** and **7b** appeared as AB quartet at δ 5.13 and 5.74 ppm (J=1.5 Hz), and δ 5.27 and 5.36 ppm (J=1.5 Hz), respectively. These terminal methylenes in **6a**, **b** and **7a**, **b** were chemically identified as 2,4-dinitrophenylhydrazone of formaldehyde liberated by ozonolysis.

The methylene protons (=C–$\underline{CH_2}$–COOMe) of **6a** and **6b** appeared at δ 3.39 and 3.78 ppm as sharp singlet, respectively. The fact that the chemical shift of the methylene protons of **6b** appeared at lower field than that of **6a**, is apparently caused by anisotropic effects of the ethoxycarbonyl group at the β-position. Therefore, the geometry between the methoxycarbonylmethyl (–CH_2COOMe) and ethoxycarbonyl group in **6b** is assignable to *Z*-configuration, and in **6a** to *E*-configuration. The *E*-isomer (**6a**) is likely to be thermodynamically more stable than the *Z*-isomer (**6b**) because of less interraction between methoxycarbonyl methyl and ethoxycarbonyl group. This observation

reflects the product distribution of **7**.

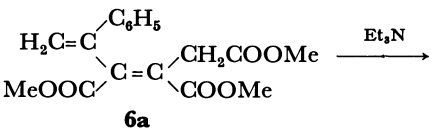
For **7a** the methylene (-$\underline{CH_2}$COOEt) and vinyl protons exhibited doublet at δ 3.19 ppm (J=7.5 Hz) and triplet at δ 7.1 ppm (J=7.5 Hz), respectively, and for **7b** doublet at δ 3.55 ppm (J=7 Hz) and triplet at δ 6.37 ppm (J=7 Hz), respectively. The chemical shifts of the vinyl proton of **7a** and the methylene protons (=C-$\underline{CH_2}$-COOMe) of **7b** appeared at lower field than those of **7b** and **7a**, respectively, due to the anisotropic effect of the ethoxycarbonyl group at the β-position. These observations indicate that the geometry between the methoxycarbonylmethyl (-CH_2COOMe) and ethoxycarbonyl group of **7a** is assigned to E-, and that of **7b** to Z-configuration.

Another possible structures (**6a'** and **6b'**) and (**7a'** and **7b'**) could be written for the reduction products obtained from sulfoxonium ylides (**1**) and (**5**), respectively. However, further chemical transformations and mechanistic consideration definitely excluded this possibility (*vide infra*).

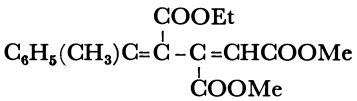


6a': R^1=R^2=COOMe **6b'**: R^1=R^2=COOMe
7a': R^1=H, R^2=COOEt **7b'**: R^1=H, R^2=COOEt

Treatment of the pure E-isomer (**6a**) with triethylamine in benzene furnished stereospecifically only one isomerized product (**8**), whose geometrical configuration was not clear. In its NMR spectrum, methyl and one vinyl protons appeared at δ 2.58 ppm (sharp singlet) and at δ 6.61 ppm (singlet), respectively, in addition to the peaks due to the two methoxycarbonyl and ethoxycarbonyl groups.



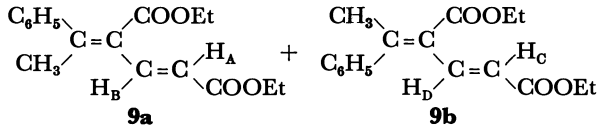
6a



8

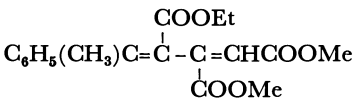
Analogously, base-catalysed isomerization of a mixture of **7a** and **7b** (36: 65) with triethylamine gave a mixture of two geometrical isomers (**9a**, and **9b**) in a ratio of 76: 24, which was determined by the NMR spectroscopy. In the NMR spectrum of **9a**, methyl protons appeared at δ 2.24 ppm as doublet (J=1 Hz), vinyl proton (H_A) at δ 5.88 ppm as doublet (J=16 Hz) and vinyl proton (H_B) at δ 7.30 ppm as quartet (J=16 and 1 Hz), and in that of **9b**, methyl protons appeared at δ 2.33 ppm as singlet, vinyl proton (H_C) at δ 6.07 ppm as doublet (J=16 Hz) and vinyl proton (H_D) at δ 7.76 ppm as doublet (J=16 Hz). The geometry of two vinyl protons in both **9a** and **9b** should be assigned to E-configuration from their coupling constant of J=16 Hz. The chemical shifts of the methyl (δ 2.33 ppm) and vinyl proton (H_D at δ 7.76 ppm) of **9b** appeared at lower field than that of **9a** (2.23 and 7.30 (H_B), respectively) due to the anisotropic effects of the ethoxycarbonyl and phenyl groups of **9b**. These facts indicate that the methyl group of **9b** preserves Z-configuration to the β-ethoxycarbonylgroup, and that of **9a** E-configuration.

7a+**7b**

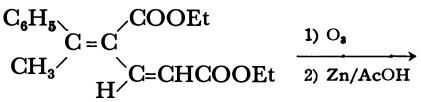


9a **9b**

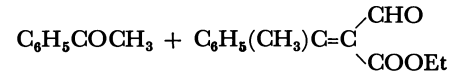
Ozonolysis of **8** in dichloromethane followed by treatment with zinc liberated acetophenone, which was identified as 2,4-dinitrophenylhydrazone, together with acetaldehyde,[4] whereas a mixture of **9** (a mixture of Z



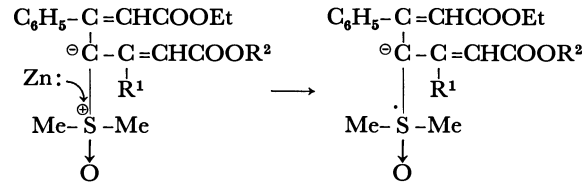
8

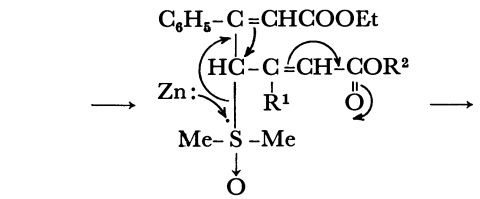


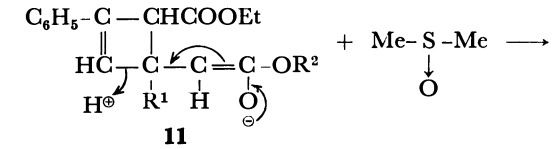
9



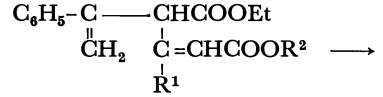
10

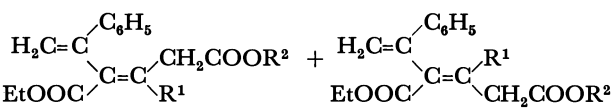






11





6: R^1=COOMe, R_2=Me; **7**: R^1=H, R^2=Et

and *E* (76: 24)) by ozonolysis yielded acetophenone and 2-formyl-3-phenyl-2-butenoate (**10**), which was confirmed as 2,4-dinitrophenylhydrazone (mp 194—195 °C). Thus, other possible structures (**6a'**, **6b'**, **7a'**, and **7b'**) as reduction products from **1** and **5** were firmly excluded.

The reaction pathway for the present reductive cleavage of dimethylsulfoxonium vinylallylides is likely to proceed through an anion radical to form a four membered intermediate (**11**), which would be cleaved to an unstable non-conjugated diene leading finally to conjugated products. On these novel and complex reactions the proposed mechanism can only be viewed tentatively. The mechanistic investigation in detail is under continuation.

It seems to be quite interesting that divinyl carbanion and carbene system derived by dissolving metal reduction and photolysis from the corresponding sulfoxonium ylides, respectively, possess remarkably outstanding chemical bihavior, which are now under studying.

Experimental

All the melting points were uncorrected. NMR spectra were recorded on a Varian A-60 and HA-100 spectrometers using TMS as an internal standard, IR spectra were taken on a Hitachi EPI-G3 and UV spectra were obtained with Beckman DK-2 spectrophotometer.

*Reduction of Dimethylsulfoxonium 3-Ethoxycarbonyl-1-[1,2-bis-(methoxycarbonyl)vinyl]-2-phenylallylide (**1**).* To a solution of **1** (15.5 g, 38 mmol) in acetic acid (150 ml) was added zinc powder (25 g, 380 mmol) in many portions under controlling inner temperature at 18—20 °C with cold water, and the reaction mixture was stirred at room temperature for 10 h. The inorganic substrance was filtered and washed with ether. The filtrate was concentrated under reduced pressure. The residue was dissolved in ether (*ca.* 500 ml), and the ethereal solution was washed successively with 5% $NaHCO_3$ solution, water and saturated NaCl solution, and dried over anhydrous Na_2SO_4. After the evaporation of the solvent under reduced pressure, the residue was chromatographed on silica gel (80 g). Elution with hexane–benzene (3: 1) gave 1.11 g (8.8% yield) of methyl (*Z*)-4-ethoxycarbonyl-3-methoxycarbonyl-5-phenyl-3,5-hexadienoate (**6b**), bp 140—143 °C/10^{-4} Torr (bath temp); IR (liquid): ν 1745, 1720, 1718, and 905 cm^{-1} (=CH_2); NMR ($CDCl_3$): δ 1.03 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.10 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 3.56 (3H, s; $COOCH_3$), 3.74 (3H, s; $COOCH_3$), 3.78 (2H, s; CH_2COOMe), 5.25 (1H, d, J=0.8 Hz; -CH), 5.62 (1H, d, J=0.8 Hz; =CH) and 7.4 ppm (5H, m; C_6H_5); Found: C, 65.21; H, 6.03%. Calcd for $C_{18}H_{20}O_6$: C, 65.02; H, 6.07%. Elution with hexane–benzene (1: 1—1: 3) afforded 7.99 g (63.3% yield) of methyl (*E*)-3-ethoxycarbonyl-4-methoxycarbonyl-5-phenyl-3,5-hexadienoate (**6a**), bp 140—141 °C/10^{-4} Torr (bath temp); IR (Liquid): ν1745, 1720, 1705, and 905 cm^{-1} (=CH_2); NMR ($CDCl_3$): δ 1.18 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.22 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 3.60 (3H, s; $COOCH_3$), 3.81 (3H, s; $COOCH_3$), 5.43 (1H, d, J=0.4 Hz; -CH), 5.83 (1H, d, J=0.4 Hz; =CH) and 7.4 ppm (5H, m; C_6H_5); Found: C, 64.78; H, 6.11%. Calcd for $C_{18}H_{20}O_6$: C, 65.02; H, 6.07%.

*Reduction of Dimethylsulfoxonium 3-Ethoxycarbonyl-1-[2-(ethoxycarbonyl)vinyl]-2-phenylallylide (**5**).* To a solution of **5** (8.4 g, 23 mmol) in acetic acid (100 ml) was added zinc powder (15 g, 230 mmol) in many portions under controlling inner temperature at 18—20 °C with cold water, and the reaction mixture was stirred over night (13 h). The inorganic substance was filtered and washed with ether. The filtrate was concentrated under reduced pressure. The residue was dissolved in ether (*ca.* 300 ml), and the ethereal solution was washed successively with 5% $NaHCO_3$ solution, water, and saturated NaCl solution, and dried over anhydrous Na_2SO_4. After the evaporation of the solvent under reduced pressure, the residue was distilled *in vacuo* to give 3.4 g (51.2% yield) of a mixture of ethyl (*Z*)- and (*E*)-4-ethoxycarbonyl-5-phenyl-3,5-hexadienoate (**7a** and **7b**) in a ratio of 40: 60, bp 120—121 °C/10^{-4} Torr; IR (Liquid): ν 1745, 1720, and 903 cm^{-1} (=CH_2); UV (EtOH): λ_{max} 238 nm (ε 12440); NMR (100 Mc, $CDCl_3$): For *Z*-isomer (7a): δ 1.10 and 1.23 (6H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.08 and 4.21 (4H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 3.19 (2H, d, J=7.5 Hz; =C-$C\underline{H}_2$COOEt), 7.10 (1H, t, J=7.5 Hz; =C$\underline{H}$-CH_2-), 5.13 (1H, d, J=1.5 Hz; =CH), 5.74 (1H, d, J=1.5 Hz; =CH), and 7.25 ppm (5H, s; C_6H_5); For *E*-isomer (**7b**): δ 1.01 and 1.27 (6H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.12 and 4.17 (4H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 3.55 (2H, d, J=7 Hz; =C-CH_2COOEt), 6.37 (1H, t, J=7 Hz; =C$\underline{H}$-CH_2), 5.27 (1H, d, J=1.5 Hz; =CH), 5.36 (1H, d, J=1.5 Hz; =CH), and 7.25 ppm (5H, s; C_6H_5); Found: C, 70.69; H, 7.15%. Calcd for $C_{17}H_{20}O_4$: C, 70.81; H, 6.99%.

*Ozonolysis of a Mixture of Methyl(Z)- and (E)-4-Ethoxycarbonyl-3-methoxycarbonyl-5-phenyl-3,5-hexadienoate (**6a** and **6b**).* Into a solution of **6** (a mixture of **6a** and **6b** (88: 12)) (1.5 g, 4.5 mmol) in acetic acid (50 ml) containing small amount of KI freshly generated ozone was passed under cooling at 15—18 °C with cold water until iodine deposited. To the reaction mixture was added zinc (1 g) and water (20 ml), and stirred at room temperature for 2 h. The reaction mixture was submitted to steam-distillation, and the distilate was passed into a saturated solution of 2,4-dinitrophenylhydrazine in 2 M-HCl (150 ml). Deposited yellow precipitate was collected by filtration, and recrystallized from ethyl acetate to give 250 mg (26.5% yield) of 2,4-dinitrophenylhydrazone of formaldehyde, mp 162—163 °C, which was identified with an authentic sample in the mixed melting point and in their IR spectra.

*Ozonolysis of a Mixture of Ethyl (Z)- and (E)-4-Ethoxycarbonyl-5-phenyl-3,5-hexadienoate (**7a** and **7b**).* Into a solution of **7** (a mixture of **7a** and **7b** (40: 60)) (1 g, 3.46 mmol) in acetic acid (40 ml) containing small amount of KI, freshly generated ozone was passed under cooling at 15—18 °C with cold water until iodine deposited. The same work-up as described above afforded 240 mg (33% yield) of 2,4-dinitrophenylhydrazone of formaldehyde, mp 162—163 °C.

*Isomerization of Methyl (E)4-Ethoxycarbonyl-3-methoxycarbonyl-5-phenyl-3,5-hexadienoate (**6a**) to Methyl 4-Ethoxycarbonyl-3-methoxycarbonyl-5-phenyl-2,4-hexadienoate (**8**).* A solution of **6a** (3.0 g, 9 mmol) and triethylamine (9 ml) in benzene (75 ml) was heated under reflux for 30 h. After the evaporation of the solvent, the residue was chromatographed on silica gel (100 g). Elution with benzene afforded 1.15 g (38.3% yield) of **8**, bp 142—143 °C/10^{-4} Torr (bath temp); IR (Liquid): ν 1720, 1718, and 1715 cm^{-1}; NMR ($CDCl_3$): δ 1.24 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.22 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 2.58 (3H, s; =CCH_3), 3.60 (3H, s; $COOCH_3$), 3.69 (3H, s, $COOCH_3$), 6.61 (1H, s; =CH), and 7.25 (5H, m; C_6H_5); Found: C, 64.78; H, 6.26%. Calcd for $C_{18}H_{20}O_6$: C, 65.02; H, 6.07%. Further elution with benzene–ethyl acetate (3: 1) gave a mixture of **6a** and **8** (1.12 g).

*Isomerization of a Mixture of Ethyl (Z)- and (E)-4-Ethoxycarbonyl-5-phenyl-3,5-hexadienoate (**7a** and **7b**) to a Mixture of Ethyl (Z)- and (E)-4-Ethoxycarbonyl-5-phenyl-2,4-hexadienoate (**9a** and **9b**).* A solution of **7** (a mixture of **7a** and **7b** (40: 60)) (1.6 g, 5.5 mmol) and triethylamine (5 g, 50 mmol)

in benzene (25 ml) was heated under reflux for 2 h. After the evaporation of the solvent, the residue was distilled *in vacuo* to give 1.2 g (75% yield) of a mixture of **9a** and **9b**, bp 140—141 °C/10^{-4} Torr; IR (liquid): ν 1720, 1718 cm^{-1}; NMR ($CDCl_3$): For *E*-isomer (**9a**): δ 1.22 and 1.38 (6H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.14 and 4.40 (4H, q, J=7 Hz; $CO\text{-}OC\underline{H}_2CH_3$), 2.24 (3H, s; CH_3), 5.88 (1H, d, J=16 Hz; =CHCOOEt), 7.30 (1H, d, J=16 Hz; =CH), and 7.35 ppm (5H, m; C_6H_5); For *Z*-isomer (**9b**): δ 0.87 and 1.30 (6H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 3.94 and 4.27 (4H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 2.33 (3H, s; CH_3), 6.07 (1H, d, J=16 Hz; =CHCOOEt), 7.76 (1H, d, J=16 Hz; =CH), and 7.25 ppm (5H, m; C_6H_5); UV (EtOH) λ_{max} 234 (ε 11160), and 285 nm (ε 14660); Found: C, 70.86; H, 7.02%. Calcd for $C_{17}H_{20}O_4$: C, 70.81; H, 6.99%.

Ozonolysis of Methyl 4-Ethoxycarbonyl-3-methoxycarbonyl-5-phenyl-2,4-hexadienoate (8). Into a solution of **8** (800 mg, 2.4 mmol) in dichloromethane (12 ml) was passed freshly generated ozone (250 mg, 5.2 mmol) at −50 °C. To the reaction mixture was added zinc powder (800 mg), acetic acid (0.4 ml) and water (0.2 ml), and stirred at room temperature for 2 h. After filtration of the inorganic substance, the filtrate was concentrated under reduced pressure. To the residue was added a solution of 2,4-dinitrophenylhydrazine (2.4 g in H_2SO_4 (12 ml), H_2O (18 ml) and EtOH (150 ml)), and heated under reflux for 30 min. After addition of water (200 ml) and extraction with ethyl acetate, the organic layer was washed with water and dried over anhydrous Na_2SO_4. After evaporation of the solvent under reduced pressure, the residue was chromatographed on silica gel (30 g). Elution with benzene gave 2,4-dinitrophenylhydrazone of acetophenone (110 mg, 15.2% yield), mp 253—255 °C, which showed no depression in mixed melting point with an authentic specimen. Further elution with benzene gave 2,4-dinitrophenylhydrazone of acetaldehyde (400 mg, 74% yield),[4] mp 159—161 °C (from EtOH), which showed no depression in mixed melting point with an authentic samples; NMR ($CDCl_3$): δ 2.16 (3H, d, J=6 Hz; N=CH-$C\underline{H}_3$), 7.69 (1H, q, J=6 Hz; N=CH-CH_3), 8.01 (1H, d, J=10 Hz; -NH-N=), 8.40 (1H, dd, J=2.5 and J=10 Hz; -NH-N=), 9.19 (1H, d, J=2.5 Hz: -NH-N=), and 11.16 (1H, m, NH); Found: C, 42.62; H, 3.70; N, 24.89%. Calcd for $C_8H_8N_4O_4$: C, 42.86; H, 3.59; N 24.99%.

Ozonolysis of a Mixture of Ethyl (Z)- and (E)-4-Ethoxycarbonyl-5-phenyl-2,4-hexadienoate (9a and 9b). Into a solution of **9** (a mixture of **9a** and **9b** (76: 24)) (1.0 g, 3.5 mmol) in dichloromethane (55 ml) was passed freshly generated ozone (*ca.* 8 mmol) at −50 °C. To the reaction mixture was added zinc powder (840 mg, 14 mmol), acetic acid (0.5 ml) and water (0.1 ml), and stirred at room temperature for 2 h. After the same procedure as described above, the crude hydrazone was chromatographed on silica gel (30 g). Elution with benzene gave 36 mg of 2,4-dinitrophenylhydrazone of acetophenone, mp 253—255 °C (from EtOH), which showed no depression with an authentic sample in mixed melting point; Further elution with benzene gave 148 mg (10.7% yield) of orange crystals of 2,4-dinitrophenylhydrazone of ethyl 2-formyl-3-phenyl-2-butenoate (**10**), mp 194—195 °C (decomp) (from ethyl acetate): NMR ($CDCl_3$): δ 1.48 (3H, t, J=7 Hz; $COOCH_2C\underline{H}_3$), 4.50 (2H, q, J=7 Hz; $COOC\underline{H}_2CH_3$), 2.30 (3H, s; $=CCH_3$), 7.42 (5H, m; C_6H_5), 7.69 (1H, s; =CH-), 7.80 (1H, d, J=9 Hz; -NHN=), 8.32 (1H, dd, J=9 and J=3 Hz; -NHN=), 9.07 (1H, d, J=3 Hz; -NHN=), and 10.98 ppm (1H, m; NH); Found: C, 57.64; H, 4.53; N, 13.93%. Calcd for $C_{19}H_{18}N_4O_6$: C, 57.28; H, 4.55; N, 14.07%.

The authors wish to thank Messrs. N. Ishida and T. Miyamura for their technical assistance.

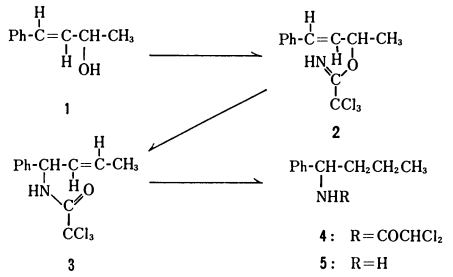
(Received May 26, 1976)

The [3,3]sigmatropic rearrangement of (2*E*)-(1*R*)-1-methyl-3-phenyl-2-propenyl trichloroacetimidate to give *N*-[(2*E*)-(1*R*)-1-phenyl-2-butenyl]trichloroacetamide was effected thermally with nearly complete transfer of chirality *via* a doubly suprafacial transition state. The application of the self-immolative asymmetric synthesis to optically active carveols afforded carveylamines of the predicted configuration.

In the previous papers, we reported transfer of chirality from tetracoordinate nitrogen to trigonal carbon[1] and from tetrahedral carbon to trigonal carbon[2] with nearly quantitative conservation of chirality. These findings not only indicate that the reaction proceeds *via* [2,3]sigmatropic rearrangement but also offer a novel method for stereo-specific synthesis of alcohols from amine oxides with allylic inversion. The reverse transformation, allylic alcohols to amines with allylic inversion, can be achieved by the Chapman-type rearrangements,[3] which are classified as [3,3]sigmatropic rearrangement according to the Woodward-Hoffmann rule. The conversion of an allylic phenylurethane into an *N*-phenylallylamine by Hill was the sole precedent in which the stereochemistry was thoroughly elucidated.[4] In spite of the reasonable stereochemical outcome in favor of a doubly suprafacial mode, the optical yield obtained (65%) was rather moderate in view of the general observations in this type of rearrangements.[5] This may presumably be due to the radical by-path. Recently, the rearrangement of allylic trichloroacetimidates to trichloroacetamides was reported by Overman.[6] This process would be advantageous in enabling one to ensure high yields of primary amines over those which are limited by substituents on nitrogen.

We now present another self-immolative asymmetric synthesis of amines from chiral allylic alcohols by the use of trichloroacetimidic ester as an intermediary. The substrate used in the present study was the chiral trichloroacetimidate, (*E*)-(+)-1-methyl-3-phenyl-2-propenyl trichloroacetimidate [(+)-2].

By the treatment with sodium hydride and trichloroacetonitrile, (*E*)-(+)-4-phenyl-3-buten-2-ol [(+)-**1**, $[\alpha]_D^{20}$ 17.3°][7a,b] was converted to (+)-**2** having $[\alpha]_D^{20}$ 34.7° in 94% yield, whose purity proved to be 85% as assessed by NMR. The trichloroacetimidate (+)-**2** was heated in toluene under reflux to give the [3,3] shift product, (+)-*N*-[(*E*)-1-phenyl-2-butenyl]trichloroacetamide [(+)-**3**, $[\alpha]_D^{20}$ 15.1°] in 74% yield. The *E*-geometry of double bond in resulting (+)-**3** was established by IR and NMR spectra. Neither *Z*-isomer nor [1,3] shift product was detected in the reaction mixture. Hydrogenation of (+)-**3** over palladium charcoal resulted in the formation of the saturated dichloroacetamide [(+)-**4**, $[\alpha]_D^{20}$ 32.7°], one of the 3 chlorine atoms having been simultaneously replaced by hydrogen during the reaction process.

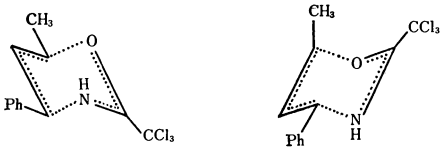


Scheme 1.

The absolute configuration as well as the enantiomeric purity of **4**, crucial to the mechanistic picture of the present rearrangement, were obtained by the conversion of optically pure (−)-1-phenyl-1-aminobutane [(−)-**5**, $[\alpha]_D^{25}$ −22.2°] of the well-defined *S*-configuration[8] into (−)-**4**, $[\alpha]_D^{25}$ −71.7°. Consequently, the end product (+)-**4** and the parent rearrangement product (+)-**3** can be safely assigned the *R*-configuration and should be of 45.6% optical purity.

Since the *R*-configuration of the starting (+)-**1** has been unambiguously established by the correlation to (*R*)-(−)-4-phenyl-2-butanol,[7a,c] and the NMR spectroscopy with the use of a chiral shift reagent showed the chiral alcohol (+)-**1** to be of 45±2% enantiomeric purity, the present thermal rearrangement proceeded with complete retention of chirality.

The finding that the complete transfer of chirality was achieved during the [3,3] shift and that the [1,3] shift product was not detected at all corroborates the concertedness of the process and excludes radical dissociation-recombination. Two transition states would be conceivable for doubly suprafacial fasion in thermally allowed [3,3]sigmatropic rearrangement: 4-centered chair-form and 6-centered boat-form. In view of the Cope[5a,9] and the Claisen[5b,10] rearrangements attained so far, we can reasonably formulate the transition state topology of choice for the allylic rearrangement of trichloroacetimidate as the former in agreement with Overman. Furthermore, the finding that the *R-E* trichloroacetimidate (+)-**2** rearranged to give the *R-E* trichloroacetamide (+)-**3** cogently supports the fashion **6**. The *S-Z* product, which would be expected from the alternative 4-centered mode **7**, was not detected at all in the present rearrangement. The preference of fashion **6** to **7** could be rationalized by the unfavorable non-bonded interaction between methyl group and hydrogen atom which orient *syn*-axial in the latter,

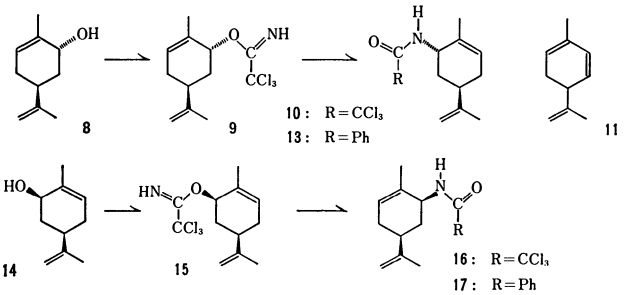


6 7

Fig. 1. Transition state topology predicted for the rearrangement of (2*E*)-(1*R*)-1-methyl-3-phenyl-2-propenyl trichloroacetimidate [(+)-**2**].

while both methyl and phenyl groups orient equatorial in the former, therefore thermodynamically more favorable.

As a probe of synthetic utility, the present rearrangement was successfully applied to the naturally derived allylic alcohols whose configurations have been known. According to Scheme 2, (+)-*trans*-carveol [(+)-**8**, α_D^{20} 172°][11] was converted into the corresponding trichloroacetimidate [(+)-**9**, $[\alpha]_D^{22}$ 72°] in 85% yield. It is noted in this system that the allylic group is tied back in a 6-membered ring, which *a priori* compels the transition state topology to assume nothing but a doubly suprafacial mode.



Scheme 2.

Upon heating, (+)-**9** gave (−)-*N*-carveyl trichloroacetamide [(−)-**10**, $[\alpha]_D^{23}$ −117°] in 44% yield. The observed lowering in the yield of rearrangement product may be attributed to the elimination side process, as actually indicated by the formation of the triene (**11**, 18%) and trichloroacetamide (**12**, 41%).[12] The transformation of (−)-**10** by the consecutive alkaline hydrolysis and benzoylation gave (−)-*N*-*trans*-carveylbenzamide [(−)-**13**, $[\alpha]_D^{18}$ −245°, mp 112—113 °C]. The absolute configuration of (−)-**13** can be safely assigned as depicted in Scheme 2 by the comparison of physical constants in agreement with those in the literature.[13]

In the case of the (−)-*cis* counterpart [(−)-**15**, $[\alpha]_D^{23}$ −48 °], (−)-*N*-carveyltrichloroacetamide [(−)-**16**,$[\alpha]_D^{23}$ −43.6°] was obtained in 42% yield along with **12** (35%). By exactly the same work-up as for (−)-*trans* isomer, (−)-**16**, was transformed into (−)-*N*-*cis*-carveylbenzamide [(−)-**17**, $[\alpha]_D^{20}$ −95.2°, mp 169 °C].[13]

In both cases, the absolute configurations of the rearrangement products coincided with those predicted from the doubly suprafacial transition state. The stereospecific 1,3-transposition of alcohol and amine functions was thus achieved by the present self-immolative asymmetric synthesis.

Experimental

All melting and boiling points were uncorrected. IR spectra were recorded with a Hitachi 215 and NMR spectra on a Varian EM-360. Elemental analyses were carried out with a Yanagimoto CHN-corder TM-1. Optical rotations were observed with a Yanagimoto OR-50 or a Perkin Elmer R-241.

Assessment of the Enantiomeric Purity of (E)-(+)-4-Phenyl-3-buten-2-ol [(+)-1]. Chemical shift non-equivalence of the enantiomers was observed on the following conditions; carbon tetrachloride solution of (+)-**1** (0.45 M, $[\alpha]_D^{20}$ 17.3°)[7a,b] and tris-[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]-europium (III) (**18**, 0.06 M) using JEOL MH-100 (100 MHz). Methyl doublets of enantiomers appeared at (δ 2.31, 2.37) and (δ 2.34, 2.40) respectively. The enantiomeric purity of (+)-**1** proved to be 45±2% by the calculation from peak heights and areas.

(E)-(+)-1-Methyl-3-phenyl-2-propenyl Trichloroacetimidate [(+)-2]. A solution of (+)-**1** [1.8 g, 12 mmol, $[\alpha]_D^{20}$ 17.3° (*c* 5.1, $CHCl_3$)] in dry ether (20 ml) was treated with sodium hydride (110 mg, 47% in mineral oil, 2.1 mmol) which had been previously washed 3 times with dry hexane. The resulting mixture was added to trichloroacetonitrile (1.8 g, 12 mmol) in dry ether (10 ml) at −15 °C in nitrogen atmosphere. After stirring at 0 °C for 1.5 h, the solution was concentrated under reduced pressure. Pentane (40 ml) containing methanol (0.8 ml, 2.1 mmol) was added and the mixture was shaken for 1 min. Successive filtration and evaporation gave (+)-**2** (3.3 g, 94%) whose purity proved to be 85% as assessed by NMR; $[\alpha]_D^{20}$ 34.7° (*c* 5.0, $CHCl_3$); IR (liquid): NH 3350, C=N 1650, =CH (*E*) 960 cm^{-1}; NMR (CCl_4): δ 1.63 (d, 3H, CH_3), 5.77—6.28 (m, 1H, CH), 6.39—7.33 (m, 2H, CH=CH), 7.57—8.00 (m, 5H, phenyl), 8.70—9.00 (broad, 1H, NH).

[3,3] Rearrangement of (+)-2. The trichloroacetimidate (+)-**2** (3.2 g, purity 85%) in toluene (35 ml) was heated under reflux for 4 h. Distillation gave (+)-*N*-[(*E*)-1-phenyl-2-butenyl]trichloroacetamide [(+)-**3**, 2.0 g, 74%]; bp 121—124 °C/0.06 Torr; mp 62—64 °C; $[\alpha]_D^{20}$ 15.1° (*c* 2.7, $CHCl_3$); IR (KBr): NH 3400, C=O 1680, =CH (*E*) 962 cm^{-1}; NMR (CCl_4): δ 1.70—1.91 (m, 3H, CH_3), 5.28—5.87 (m, 3H, CH, and CH=CH), 6.44—7.00 (broad, 1H, NH), 7.31 (s, 5H, phenyl).

Found: C, 49.30; H, 4.18; N, 4.76%. Calcd for $C_{12}H_{12}NOCl_3$: C, 49.26; H, 4.13; N, 4.79%.

Hydrogenation of (+)-3. The trichloroacetamide (+)-**3** (1.0 g, 3.4 mmol) was hydrogenated over 5% palladium-charcoal (200 mg) in ethanol (100 ml) and 2 equivalent amounts of hydrogen (170 ml at room temperature) were absorbed. The reaction mixture was neutralized with aqueous potassium carbonate. Distillation gave (+)-*N*-(1-phenylbutyl)dichloroacetamide [(+)-**4**, 740 mg, 83%]; bp 116 °C/0.03 Torr; mp 92—93.5 °C; $[\alpha]_D^{20}$ 32.7° (*c* 3.0, $CHCl_3$); IR (KBr): NH 3280, C=O 1660 cm^{-1}; NMR ($CDCl_3$): δ 0.78—1.12 (m, 3H, CH_3), 1.13—2.08 (m, 4H, CH_2CH_2), 4.78—5.20 (m, 1H, CH), 5.98 (s, 1H, $CHCl_2$), 7.41 (s, 5H, phenyl).

Found: C, 55.34; H, 6.07; N, 5.39%. Calcd for $C_{12}H_{15}NOCl_2$: C, 55.40; H, 5.81; N, 5.38%.

(−)-1-Phenyl-1-aminobutane [(−)-5]. The racemic amine[14] (136 g, 0.91 mol) was added to (−)-*N*-acetylleucine (158 g, 0.91 mol) in methanol (1200 ml) and the salt formed was recrystallized 4 times from methanol to yield colorless fine needles (4.6 g); mp 196—198 °C; $[\alpha]_D^{25}$ −1.8° (*c* 5.0, methanol). The physical constants did not alter on further recrystallizations. The amine liberated from the salt had bp 105—107 °C/20 Torr, $[\alpha]_D^{25}$ −22.2° (*c* 5.1, $CHCl_3$). The racemic **5** exhibited an apparent chemical shift non-equiva-

lence for the methine proton in carbon tetrachloride solution of (±)-**5** (0.4 M) and **18** (0.02 M), whereas no separation of the same signal was observed with the resolved amine under the same conditions.

(−)-N-(1-Phenylbutyl)dichloroacetamide [*(−)-4*]. To the solution of dichloroacetyl chloride (1.5 g, 10 mmol) in benzene (10 ml), the mixture of (−)-**5** (1.5 g, 10 mmol) and pyridine (1.6 g, 20 mmol) in benzene (10 ml) was added dropwise at 0 °C. After stirring at room temperature overnight, the resulting dichloroacetamide was extracted with benzene. Distillation gave (−)-**4** (1.7 g, 56%); $[\alpha]_D^{25}$ −71.7° (*c* 3.1, $CHCl_3$).

*(+)-*trans*-Carveyltrichloroacetimidate* [*(+)-9*]. The reaction of (+)-*trans*-carveol [(+)-**8**, 1.5 g, 10 mmol, α_D^{20} 172° (neat) (lit,[11] α_D^{20} 185.8°)] and trichloroacetonitrile (1.4 g, 10 mmol) was conducted with potassium hydride (500 mg, 23.8% in mineral oil, 2 mmol) in place of sodium hydride. The subsequent work-up in exactly the same manner as described for (+)-**2** yielded (+)-**9** (2.5 g, 85%). In this case, the unreacted (+)-**8** was not detected in NMR spectrum; $[\alpha]_D^{22}$ 72° (*c* 3.0, $CHCl_3$); IR (liquid): NH 3350, C=N 1650 cm^{-1}; NMR (CCl_4): δ 0.68—2.75 (m, 5H, ring protons), 1.78 (s, 3H, CH_3), 1.82 (s, 3H, CH_3), 4.78—4.99 (m, 2H, $=CH_2$), 5.41—5.66 (m, 1H, CH–O), 5.77—6.07 (m, 1H, =CH–), 8.33—8.63 (broad, 1H, NH).

[3,3] Rearrangement of (+)-9. The trichloroacetimidate (+)-**9** (2.5 g) in toluene (25 g) was heated under reflux for 10 h. The reaction mixture was concentrated and treated with warm hexane. After removal of the insoluble material, trichloroacetamide (**12**, 560 mg, 41%), the solution was evaporated. After 1,5,8(9)-*p*-menthatriene (**11**, 200 mg, 18%) was removed, (−)-*N*-carveyltrichloroacetamide [(−)-**10**, 1.1 g, 44%] distilled at 114—115 °C/0.15 Torr. The analytical sample was obtained by recrystallization from hexane; mp 91—93 °C; $[\alpha]_D^{23}$ −117° (*c* 3.0, $CHCl_3$); IR (KBr): NH 3310, C=O 1690 cm^{-1}; NMR (CCl_4): δ 1.20—2.58 (m, 5H, ring protons), 1.80 (s, 6H, $2CH_3$), 4.28—4.66 (m, 1H, CH–N), 4.85—5.00 (m, 2H, $=CH_2$), 5.79—6.01 (m, 1H, =CH–), 6.40—6.83 (broad, 1H, NH).

Found: C, 48.55; H, 5.58; N, 4.69%. Calcd for $C_{12}H_{16}NOCl_3$: C, 48.59; H, 5.44; N, 4.72%.

*(−)-N-*trans*-Carveylbenzamide* [*(−)-13*]. Sodium hydroxide (1.6 g, 40 mmol) in water (8 ml) was added to (−)-**10** (400 mg, 1.4 mmol) in ethanol (13 ml). The reaction mixture was stirred in nitrogen atmosphere at room temperature for 40 h. The amine extracted with ether was treated with benzoyl chloride (420 mg, 3 mmol) in pyridine (3 ml). The resulting benzamide (−)-**13** was extracted with chloroform and recrystallized from methanol-water; mp 112—113 °C; $[\alpha]_D^{18}$ −245° (*c* 3.0, $CHCl_3$) (lit,[13a] mp 103 °C; $[\alpha]_D^{21}$ −175.4°, lit,[13b] 114 °C; $[\alpha]_D$ −250°).

Found: C, 79.76; H, 8.36; N, 5.41%. Calcd for $C_{17}H_{21}NO$: C, 79.96; H, 8.29; N, 5.49%.

*(−)-*cis*-Carveyltrichloroacetimidate* [*(−)-15*]. By the same procedure as described for the (+)-*trans* counterpart, (−)-*cis*-carveol [(−)-**14**, α_D^{24} −22° (neat) (lit,[15a] α_D^{25} −22.8°)] was converted to (−)-**15** (99%); $[\alpha]_D^{23}$ −48° (*c* 3.0, $CHCl_3$); IR (liquid): NH 3350, C=N 1660 cm^{-1}; NMR (CCl_4): δ 0.87—2.80 (m, 5H, ring protons), 1.85 (s, 6H, $2CH_3$), 4.97—5.18 (m, 2H, $=CH_2$), 5.71—6.19 (m, 2H, CH–O and =CH–), 8.71—8.95 (broad, 1H, NH).

[3,3] Rearrangement of (−)-15. The trichloroacetimidate (−)-**15** (2.6 g) in xylene (26 ml) was heated under reflux for 8 h. The reaction mixture was worked up in exactly the same manner as described for (−)-**10**. Along with **12** (500 mg, 35%), (−)-*N*-carveyltrichloroacetamide [(−)-**16**] was obtained (1.1 g, 42%); bp 109—110 °C/0.1 Torr; mp 87—89° C; $[\alpha]_D^{23}$ −43.6° (*c* 3.0, $CHCl_3$); IR (KBr): NH 3270, C=O 1680 cm^{-1}; NMR (CCl_4): δ 1.05—2.63 (m, 5H, ring protons), 1.73 (s, 3H, CH_3), 1.77 (s, 3H, CH_3), 4.26—4.75 (m, 1H, CH–N), 4.73—4.93 (m, 2H, $=CH_2$), 5.52—5.87 (m, 1H, =CH–), 6.35—6.93 (broad, 1H, NH).

Found: C, 48.82; H, 5.54; N, 4.77%. Calcd for $C_{12}H_{16}NOCl_3$: C, 48.59; H, 5.44; N, 4.72%.

*(−)-N-*cis*-Carveylbenzamide* [*(−)-17*]. By the same procedure as described for (−)-**14**, (−)-**16** was converted to (−)-**17**; mp 169 °C; $[\alpha]_D^{20}$ −95.2° (*c* 4.7, $CHCl_3$) (lit,[13a] mp 169 °C; $[\alpha]_D^{19}$ −91.9°, lit,[13b] mp 169 °C; $[\alpha]_D$ −96°).

Found: C, 79.97; H, 8.24; N, 5.66%. Calcd for $C_{17}H_{21}NO$: C, 79.96; H, 8.29; N, 5.49%.

The authors are indebted to Dr. Larry E. Overman of the University of California for his valuable suggestion to this work.

Studies on the Reactions of Bis(acetylacetonato)platinum(II) with Lewis Bases. I. Reactions with Tertiary Phosphines Leading to a Complex Containing Carbon-Bonded Unidetate Acetylacetonato Ligand and Preparation of New Alkylplatinum Complexes

Takashi Ito, Takashi Kiriyama, and Akio Yamamoto

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 23, 1976)

Addition of tertiary phosphines (PR_3) to [Pt(acac)$_2$] (acac=acetylacetonato-*O,O'*) causes the rearrangement of one of the O-bonded chelate acac ligands to a C-bonded form giving [Pt(acac)(γ-acac)PR_3] (γ-acac=acetylacetonato-*C*[3]) (PR_3=PPh_3, **1a**, and $P(C_6H_{11})_3$, **2a**). Complexes **1a** and **2a** were isolated and characterized by means of elemental analysis, infrared and ^{1}H- and ^{13}C-NMR spectroscopy. Some reactions involving complex **1** were investigated. The mechanism of formation of a diethylplatinum complex in the reaction of [Pt(acac)$_2$] with Al(OEt)Et_2 and PPh_3 is discussed taking into account the rearrangement of the acac ligand from the O-bonded chelate to a C-bonded form.

Various alkyl-transition metal complexes have been isolated from the systems consisted of transition metal acetylacetonates, [M(acac)$_n$],[1] alkylaluminium compounds and ligand molecules such as tertiary phosphines or amines.[2] Some of these systems also afford hydrido complexes or zero-valent complexes by decomposition of intermediate unstable alkyltransition metal complexes. The mechanism of formation of the carbon-to-metal σ bond in these systems, however, has not been studied extensively. In the course of our study on the syntheses of alkyl complexes of palladium(II) and platinum(II) from systems consisted of [M(acac)$_2$] (M=Pd and Pt), alkylaluminium compound, and Lewis bases,[3] we found that [Pt(acac)$_2$] itself reacts with a tertiary phosphine to yield the complexes **1a** and **2a** in which acetylacetonato ligand is coordinated with platinum in a unidentate form *via* central (γ-) carbon atom.

Several kinds of ionic platinum(II) complexes with a central carbon bonded acetylacetonato ligand[4-6] have been reported by Lewis *et al.* More recently, Baba *et al.* reported the preparation of palladium(II) analog of **1a** by the reaction of [Pd(acac)$_2$] with Lewis bases such as PPh_3, pyridine, and secondary amines.[7] Here we report isolation, characterization, and some reactions of complexes **1a**, **2a**, and **2b** with special reference to the alkylation reaction mentioned above.

[M(acac)$_2$][1] [M(acac)(γ-acac)PR_3][1]

{M=Pt; PR_3=PPh_3 (**1a**), $P(C_6H_{11})_3$ (**2a**)
{M=Pd; PR_3=PPh_3 (**1b**)[7], $P(C_6H_{11})_3$ (**2b**)

Results and Discussion

Reaction of [Pt(acac)$_2$] with Triphenylphosphine, PPh_3.

The reaction of [Pt(acac)$_2$] with an equimolar amount of triphenylphosphine in toluene at room temperature afforded a diamagnetic pale yellow compound, which was identified as (2,4-pentanedionato-*C*[3])(2,4-pentanedionato-*O,O'*)triphenylphosphineplatinum(II), [Pt(acac)(γ-acac)PPh_3],[1] **1a**, on the basis of its infrared and NMR spectra and elemental analysis. The product is soluble in most aromatic solvents, chlorinated organic solvents, and ethers, and can be recrystallized from these solvents. As is shown in Table 1, complex **1a** possesses intense infrared bands which are characteristic of an enol-type bidentate acac ligand (1575, 1550, and 1525 cm^{-1}) and diketo-type γ-acac ligand (1685 and 1650 cm^{-1}),[5,8,9] and are very similar to the analogous palladium complex, [Pd(acac)(γ-acac)PPh_3], **1b**. A medium band at 445 cm^{-1} was assigned to ν(Pt–C) since the band lacks in the spectra of [PtX(acac)PPh_3] (X= Cl, Br and I) and [Pt(acac)$(PPh_3)_2$]BPh_4 which are derived from complex **1a** (*vide post*).

The ^{1}H-NMR spectral data of complex **1a** are listed in Table 2 together with **1b** and **2a**. Fig. 1a shows the ^{1}H-NMR spectrum of **1a** as a typical spectrum of this type of complexes. Assignment of each signal has been achieved by comparing it with the one reported for anionic Pt(II) complexes,[5,8] Pt(IV) complexes,[9] and analogous Pd(II) complexes[7] with γ-acac ligands. Of the two singlets due to methyl protons in the chelate acac ligand, the lower field signal was assigned to that trans to the phosphorus ligand according to the assign-

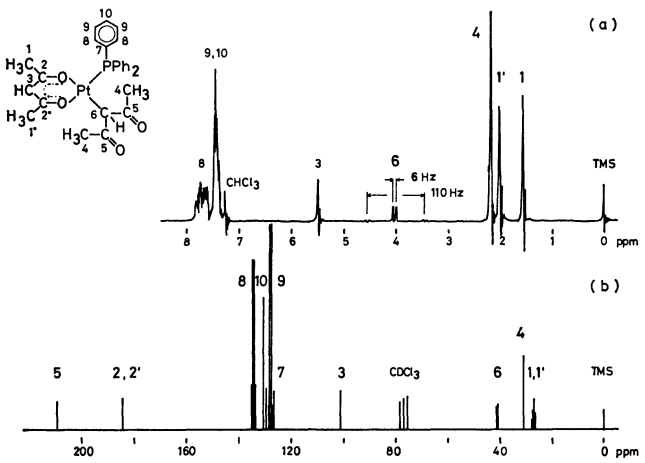

Fig. 1. ^{1}H- and ^{13}C-NMR spectra of [Pt(acac)(γ-acac)-PPh_3], **1a**, in $CDCl_3$, at room temperature.

a) In $CDCl_3$ unless otherwise stated, 100 MHz, at 25 °C. Chemical shifts are in δ values (ppm) with respect to tetramethylsilane as internal standard. Coupling constants are in Hz. In the parentheses are multiplicity and number of protons. Multiplicity symbols are as follows: s, singlet; ss, singlet with satellites due to ^{195}Pt; d, doublet; ds, doublet with satellites due to ^{195}Pt; q, quintet; sex, sextet; m, multiplet; br, broad. b) In C_5H_5N. c) In C_6D_6. d) The compound was prepared by the method described in the literature.[7] e) $|^3J(PH)|$. f) $|^2J(^{195}PtH)|$. g) ^{195}Pt-Satellites were not obtained due to low S/N ratio. h) L corresponds to tertiary phosphine ligand. i) Not observable due to overlapping with solvent signals.

ment by Baba *et al.*[7] Protons in the chelate acac ligand in complex **1a** exhibit upfield shift when the solvent was changed from $CDCl_3$ through pyridine to benzene, whereas those in the C-bonded γ-acac ligand shift towards downfield. The chemical shift of the methine proton in the γ-acac ligand in **1a** is somewhat lower than in the corresponding palladium complex, **1b** (δ=3.54 ppm[7]). The phosphorus–hydrogen coupling constant for this proton ($|^3J(P-H)|$=6 Hz) is almost the same as the reported value of 6.1 Hz for *trans*-[Pt(CH$_3$)Cl(PEt$_3$)$_2$][10] and 6.3 Hz for **1b**.[7] The methine proton attached to the platinum-bonded carbon atom in γ-acac ligand is known to accompany satellite signals due to ^{195}Pt. The fairly large coupling constant of $|^2J(^{195}Pt-H)|$=110 Hz for complex **1a** is similar to the reported values for K$^+$[Pt(acac)(γ-acac)-Cl]$^-$ (120 Hz) and K$^+$[Pt(acac)(γ-acac)$_2$]$^-$ (123 Hz).[5]

The ^{31}P{^{1}H}-NMR spectrum of **1a** in $CDCl_3$ showed a singlet at 11.8 ppm (downfield from the external reference of PPh$_3$ in C_6D_6/C_6H_5Cl) with the satellite bands due to ^{195}Pt. The analogous Pd complex, **1b**, showed the ^{31}P resonance at 37.8 ppm. The coupling constant, $|^1J(^{195}Pt-P)|$, of 4490 Hz for **1a** does not greatly differ from reported values of 3875 Hz for *cis*-[PtCl$_2$(PPh$_3$)$_2$][11] and of 3500—3600 Hz for *cis*-[PtCl$_2$(PR$_3$)$_2$],[12] and much larger than those of *ca.* 2400 Hz for *trans*-[PtCl$_2$(PR$_3$)$_2$].[12]

Table 3 summarizes the ^{13}C-NMR data of complex **1a** and its palladium analog, **1b**, together with those of [Pd(acac)$_2$], which were used to assist the assignment of the phosphine complexes. Fig. 1b compares the ^{13}C-NMR spectrum with ^{1}H-NMR spectrum for the typical complex **1a**. Although satellite bands due to ^{195}Pt could not be observed except for *ortho*-carbons (C^8) (as for the carbon numbering, refer to Fig. 1) of PPh$_3$ in the spectrum of complex **1a**, the assignment was made with the aid of supplementary information on the ^{13}C-NMR of [Pt(acac)(γ-acac)py] (py=pyridine)[13] which shows varying magnitudes of $|J(^{195}Pt-^{13}C)|$ values corresponding to the positions of the carbon atoms with respect to the central platinum. As is seen in Table 3, carbon signals due to the bidentate enol-acac ligand (C^1–C^3) are almost unchanged from those of [Pd(acac)$_2$] and their chemical shifts are very similar to those reported for acetylacetonato complexes of Be,[14] Al,[14] Co,[14,15] Ir,[16] and Ni.[17] Two methyl- and two keto-carbons of the bidentate acac ligand (C^1 and $C^{1'}$, and C^2 and $C^{2'}$, respectively) in **1b** are observed as non-equivalent carbons on coordination of PPh$_3$ as in the case for methyl protons in the ^{1}H-NMR spectrum. Resolution of the

a) In $CDCl_3$ at room temperature. 25.2 MHz, Chemical shifts are in ppm, downfield positive, from tetramethylsilane as an internal reference. Coupling constants $|^nJ(^{31}P-^{13}C)|$ in Hz are in parentheses. Multiplicity abbreviations are: s, singlet; d, doublet; ds, doublet with satellite bands due to ^{195}Pt; c, complex pattern. b) See Fig. 1 for numbering of the carbon atoms. c) $|^3J(^{195}Pt-^{13}C)|=35.1$ Hz.

fine structure of the NMR spectrum for these carbons in complex **1a** was not sufficient and a complicated pattern due to the coupling with ^{195}Pt resulted. A large upfield shift is observed for the methine carbon in the γ-acac ligand (C^6) compared to that in the bidentate enol-acac ligand (C^3), and the C^6 carbon in the Pt complex resonates at a higher field than in its Pd analog. All these features parallel with those of the ^{1}H-NMR spectra. Appearance of a single C^5 signal at a lower field than for C^2 indicates that C^5 carbons belong to intact keto groups which are free from coordination to the central metal. Cheney *et al.* reported that ^{31}P–^{13}C coupling constants of the Pt-bonded methyl carbon in *cis*-[$PtMe_2(PMe_2Ph)_2$] are 104 and 9 Hz for mutually trans and cis ^{31}P and ^{13}C nuclei, respectively.[18] The small $|^2J(^{31}P-^{13}C)|$ values (5—9 Hz) of the methyl carbon cis to the phosphorus ligands were also reported for the cationic *trans*-monomethylbis(tertiaryl phosphine)-platinum(II) complexes.[19] A small value of the ^{31}P–^{13}C coupling constants for C^6 methine carbon suggests that γ-acac ligand occupies the cis position with respect to PPh_3 in complexes **1a** and **1b**. Furthermore, fairly large values of $|J(^{31}P-^{13}C)|$ observed for $C^{1'}$ and $C^{2'}$-carbons in **1b** indicate the presence of a large trans effect of PPh_3, the fact in accord with the observation in dimethylplatinum complex mentioned above. Chemical shifts and ^{31}P–^{13}C coupling constants of the *ortho*-, *meta*-, and *para*-carbons (C^8, C^9, and C^{10}) of the coordinated PPh_3 are similar to those of free PPh_3.[20] On the other hand, the carbon atom (C^7) attached to phosphorus moves upfield considerably (*ca.* 10 ppm) upon coordination accompanying an increase in the magnitude of the ^{31}P–^{13}C coupling constant (from 21 Hz for free PPh_3[20] to 62.6 Hz for **1a**). These facts may reflect an increase in M→P back donation in complexes **1a** and **1b**.

When more than one mole equivalent of PPh_3 was allowed to react with [$Pt(acac)_2$] at an elevated temperature in tetrahydrofuran, a creamy white compound was isolated, whose infrared spectrum shows ν(C=O) bands at 1653 and 1600 cm^{-1}. The ^{1}H-NMR spectrum and elemental analysis of this diamagnetic compound suggest the composition of [$Pt(CH_2COCHCOCH_3)(PPh_3)_2$]. The detailed study of this unusual complex will be reported elsewhere.

Reaction of [*Pt(acac)$_2$*] *and* [*Pd(acac)$_2$*] *with Tricyclohexylphosphine, PCy$_3$.* Tricyclohexylphosphine reacted with an equimolar amount of [$Pt(acac)_2$] in diethyl ether at room temperature to yield a white compound which was identified as (2,4-pentanedionato-C^3)(2,4-pentanedionato-O,O')tricyclohexylphosphineplatinum(II), [Pt(acac)(γ-acac)PCy_3], **2a**, on the basis of its infrared and ^{1}H-NMR spectra. Similarly obtained was its Pd-analog, [Pd(acac)(γ-acac)PCy_3], **2b**, by the reaction in benzene. Both complexes **2a** and **2b** are quite soluble in most common organic solvents to render the purification by recrystallization somewhat difficult. The infrared absorptions of **2a** and **2b** in the region of 1500 1700 cm^{-1}, listed in Table 1, indicate the presence of both acac and γ-acac ligands. Detection of the metal–carbon stretching bands for these complexes failed due to the complicated absorptions in the low frequency region.

The ^{1}H-NMR spectral data for complexes **2a** and **2b** are listed in Table 2. Signals due to the acac and γ-acac ligands are essentially the same as those of the analogous PPh_3 complexes **1a** and **1b**. Differences of the chemical shifts between two acac-CH_3 protons are less in PCy_3 complexes (0.08 ppm in **2a** and 0.10 ppm in **2b**) than in the PPh_3 complexes (0.46 ppm in **1a** and 0.50 ppm[7] in **1b**) indicating a weaker trans effect of PCy_3 as compared with PPh_3. The chemical shift of the γ-acac methine proton is lower by 0.55 ppm in Pt complex, **2a**, than in the corresponding Pd complex, **2b**, as was the case in the PPh_3 complexes, **1a** and **1b**. Unlike the Pt–PPh_3 complex, **1a**, no satellite bands due to ^{195}Pt were observed for the methine proton of γ-acac ligand in the PCy_3 complex **2a**. This may be attributable to a low S/N ratio encountered in the spectrum of **2a**.

The reaction of [$Pt(acac)_2$] with an excess amount of PCy_3 also yielded complex **2a** and the complex

analogous to [Pt($CH_2COCHCOCH_3$)(PPh_3)$_2$] was not obtained.

Some Reactions of the Complexes [M(acac)(γ-acac)PPh$_3$] (M=Pt, 1a and Pd, 1b). In order to get some information on chemical properties of the C-bonded acetylacetonato ligand, several reactions were carried out on complexes **1a** and **1b**. The reaction of **1a** with an excess amount of acetyl or benzoyl chloride afforded the known complex [PtCl(acac)(PPh_3)];[21] the similar reaction has been reported for the Pd analog, **1b**.[7] Methyl iodide reacted with **1a** and **1b** at ambient temperature to give [MI(acac)(PPh_3)] (M=Pt, **3a**; Pd, **3b**) whose characteristic infrared absorptions are included in Table 1. Similarly was obtained [PtBr(acac)(PPh_3)] by the reaction between **1a** and ethyl bromide. A cationic complex of the type [M(acac)(PPh_3)$_2$]$^+BPh_4^-$ (M=Pt, **4a**; Pd, **4b**) was obtained upon treatment of **1a** or **1b** with $NaBPh_4$ in the presence of an equimolar amount of PPh_3 in tetrahydrofuran at room temperature. These reactions accompany formation of sodium salt of acetylacetonate which was isolated and identified by means of its infrared spectrum and elemental analysis.

$$[M(acac)(\gamma\text{-acac})(PPh_3)] + PPh_3 + NaBPh_4 \longrightarrow [M(acac)(PPh_3)_2]^+BPh_4^- + \text{Na-acac}$$

1a (M=Pt), **1b** (M=Pd); **4a** (M=Pt), **4b** (M=Pd)

Absence of bands at 1600—1700 cm^{-1} in the infrared spectra of **4a** and **4b** (Table 1) indicates that the C-bonded acac ligand in **1a** and **1b** is replaced by PPh_3. The ^{1}H-NMR spectrum of **4b** in $CDCl_3$ at room temperature shows a single methyl resonance at δ 1.51 ppm (6H) and the methine resonance at δ 5.41 ppm (singlet, 1H). Complex **4b** was also obtained by a successive reaction of [Pd(acac)$_2$] with 2 molar equivalents of PPh_3 followed by $NaBPh_4$ treatment in refluxing EtOH.

Preparation of Alkyl Complexes from the System of [Pt(acac)$_2$], Alkylaluminium Compounds, and Tertiary Phosphines. A variety of mono- or di-alkyl complexes of Pt(II) or Pd(II) have been prepared by the use of alkyllithium compounds or Grignard reagents.[22,23] However, application of alkylaluminium compounds for such synthesis has been relatively limited. Formation of hydrido complexes has been reported when [M(acac)$_2$] (M=Pd or Pt) was treated with $AlEt_3$ in the presence of $P(C_6H_{11})_3$.[24] A zero-valent ethylene complex, [Pd(C_2H_4)(PR_3)$_2$], and a σ-diethyl complex, [$PdEt_2$($R_2PCH_2CH_2PR_2$)], have been prepared by the reaction of Al(OEt)Et_2 with [Pd(acac)$_2$] in the presence of an appropriate tertiary phosphine.[25] In our attempts to obtain new alkyl complexes of Pt(II) and Pd(II) using alkylaluminium compound as an alkylating agent, we succeeded in the isolation of a series of dialkylpalladium complexes[3] and some alkylplatinum complexes.

The reaction of [Pt(acac)$_2$] with a large excess of diethylmonoethoxyaluminium in the presence of 2 mol of PPh_3 in diethyl ether at room temperature yielded a white solid whose elemental analysis was close to the value for [$PtEt_2$(PPh_3)$_2$], **5a**. The infrared spectrum of the product shows aliphatic C–H stretching bands at 2800—2940 cm^{-1} in a complicated pattern and no bands due to acetylacetonato ligand were observed. There are two relatively strong bands at 460 and 425 cm^{-1} which disappear on thermolysis of the complex. These bands are absent in the spectrum of *cis*-[$PtCl_2$(PPh_3)$_2$]. Hence either one of the two or both bands may be assignable to ν(Pt–C). The ^{1}H-NMR spectrum of **5a** in toluene-d_8 at room temperature showed a complicated multiplet at δ 0.4—1.8 ppm assignable to the ethyl group together with signals at 7—8 ppm due to the phenyl protons. Upon thermolysis *in vacuo* at 160 °C, the complex evolved quantitative amounts of ethylene and ethane in a ratio of 1 : 1. Although a diethyl complex of the type [$PtEt_2L_2$] has been reported for L=PMe_3 and PEt_3,[22] this is the first example of the isolation of the ethylplatinum complex with L=PPh_3.

$$[Pt(acac)_2] + 2PPh_3 \xrightarrow{10\,Al(OEt)Et_2} [PtEt_2(PPh_3)_2]\ \mathbf{5a}$$

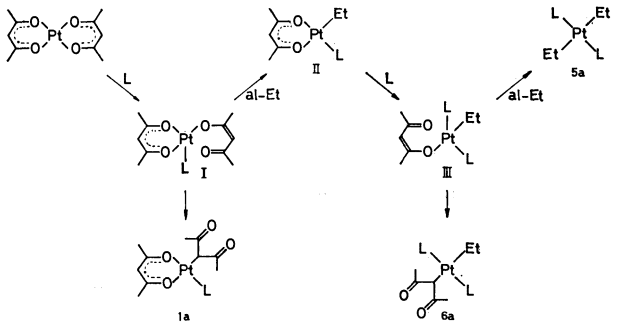
$$[Pt(acac)_2] + 2PPh_3 \xrightarrow{2\,Al(OEt)Et_2} [PtEt(\gamma\text{-acac})(PPh_3)_2]\ \mathbf{6a}$$

$$\mathbf{6a} \xrightarrow[-C_2H_6]{\text{recrystallized from THF}} [Pt(CH_2COCHCOCH_3)(PPh_3)_2]$$

When a smaller amount of Al(OEt)Et_2 (2—6 mol per mol of [Pt(acac)$_2$]) was employed, a pale yellow solid of **6a** precipitated. The solid evolved ethylene and ethane (0.5: 1) on thermolysis at 145 °C, the total amount of which was 105% on the basis of the formula, [$PtEt(\gamma$-acac)(PPh_3)$_2$]. Its infrared spectrum shows strong bands at 1670 and 1635 cm^{-1} indicating the acetylacetonato ligand coordinated *via* the central carbon atom. Interestingly, attempted crystallization of this monoethyl complex from tetrahydrofuran at room temperature yielded the afore-mentioned unique acetylacetonato complex, [Pt($CH_2COCHCOCH_3$)(PPh_3)$_2$], as supported by infrared and ^{1}H-NMR spectra and elemental analysis.

In alkylations of nickel(II) acetylacetonate, with alkylaluminium compounds in the presence of appropriate tertiary phosphine ligands, intermediate alkylation products having both acac and alkyl ligands have been isolated.[26,27] Therefore, it is evident that the acac ligands in the starting complexes can be replaced with alkyl ligands in a stepwise manner. In considering the replacement mechanism of the acac ligand by an alkyl group, it is natural to assume that the acac ligand in a unidentate form may be replaced more easily than the chelated acac ligand. We have observed that the methyl groups in acac ligand of [NiEt(acac)(PPh_3)],[17b] [Ni(COEt)(acac)(PPh_3)],[28] and [Pd(acac)(γ-acac)(py)][13] give rise to a singlet ^{1}H-NMR resonance in some solvents and accounted for the results by assuming an exchange process proceeding through partial dissociation of the acac ligand to give an O-bonded unidentate form. Furthermore, we have recently isolated a platinum complex, [Pt(2,4-pentanedionato-*O*)$_2$(PEt_3)$_2$], which possesses two unidentate O-bonded acetylacetonato ligands.[29]

On the basis of these results we propose the processes



Scheme.
L=PPh_3, al-Et=Al(OEt)Et_2

as represented in the Scheme as the likely alkylation mechanism of [Pt(acac)$_2$] by an alkylaluminium compound. [Pt(acac)$_2$] may be converted to a unidentate O-bonded form I in the presence of a tertiary phosphine ligand. The intermediate I may give the [Pt(acac)(γ-acac)L] type complex **1a** in the absence of an alkylating agent, but the alkylating agent such as diethylmonoethoxyaluminium may replace the unidentate O-bonded acac ligand by the ethyl group to afford II. Although the intermediate II was not isolated in the present case, the corresponding nickel analogs were isolated and fully characterized.[17,26,27,30] The intermediate complex II may further rearrange by attack of another tertiary phosphine ligand to the isolated complex, [PtEt(γ-acac)(PPh_3)$_2$] **6a** by a process as shown in the Scheme.[31] The presence of a larger amount of the alkylating agent gives rise to the dialkylplatinum complex **5a**. In view of the isolation of complexes **1a** and **6a** an alternative line of alkylation processes involving the replacement of the γ-acac ligand by an alkyl group is also conceivable, although such a mechanism seems less straightforward as compared with the one presented in the Scheme.

Experimental

All manipulations were carried out under an atmosphere of deoxygenated nitrogen or argon, or *in vacuo*. Solvents were dried in the usual manner, distilled, and stored under a nitrogen atmosphere.

Infrared spectra were recorded on Hitachi EPI-G3 and 295 spectrometers using KBr pellets prepared under an inert atmosphere. NMR spectra were measured on a JEOL PS-100 spectrometer by Mr. Y. Nakamura of our research laboratory to whom we are indebted. Measurements of ^{1}H-NMR spectra (100 MHz) were carried out in deuteriochloroform at 25 °C unless otherwise stated and ^{1}H chemical shifts are reported with tetramethylsilane as the internal standard. Proton noise decoupled ^{31}P- and ^{13}C-NMR spectra were measured on the same spectrometer operating in the Fourier transform mode at 40.5 (^{31}P) and 25.2 MHz (^{13}C), respectively. Using 10 mm sample tubes, the spectra were taken on deuteriochloroform solutions and were calibrated with triphenylphosphine (in a mixture of C_6D_6 and C_6H_5Cl) as the external reference (for ^{31}P spectra) and with tetramethylsilane as the internal reference (for ^{13}C spectra). Microanalyses were carried out by Mr. T. Saito of our research laboratory.

Bis(2,4-pentanedionato)platinum(II)[32] and -palladium (II),[33] and (2,4-pentanedionato-*C*^{3}) (2,4-pentanedionato-*O*,*O*′)triphenylphosphinepalladium(II)[7] were prepared according to the reported method. Triphenylphosphine was kindly donated by Ihara Chemical Industry Co. Ltd., and used without further purification. Tricyclohexylphosphine was prepared as described in the literature.[34] Commercially available methyl iodide, benzoyl chloride, acetyl chloride, ethyl bromide and sodium tetraphenylborate were used without further purification. Diethylmonoethoxyaluminium was prepared from triethylaluminium and ethanol by the usual method.

Analytical data of new compounds prepared in this report are listed in Table 4.

*Preparation of (2,4-Pentanedionato-*C^3*)(2,4-pentanedionato-O,O′)triphenylphosphineplatinum(II)*, **1a**. On stirring the mixture of [Pt(acac)$_2$] (0.41 g, 1.05 mmol), PPh_3 (0.29 g, 1.09 mmol) and toluene (5 cm^3) at room temperature, the initial pale yellow suspension turned to a pale yellow clear solution in 1 h. The system was stirred for another 1.5 h. Then, the solution was concentrated to 2 cm^3 to leave a yellow oily solution, from which a creamy white precipitate was yielded on digestion with hexane. The precipitate was filtered off, washed with hexane and dried *in vacuo* to give 0.61 g (89%) of crude product. Recrystallization of the creamy white powder from diethyl ether afforded 0.40 g (58%) of [Pt(acac)(γ-acac)PPh_3] as a white microcrystalline solid. The reaction could be carried out similarly in diethyl ether, but in this case much longer reaction period (*ca.* 40 h) was necessary to complete the reaction.

*Preparation of (2,4-Pentanedionato-*C^3*)(2,4-pentanedionato-O,O′)tricyclohexylphosphineplatinum(II)*, **2a**. On stirring the heterogeneous pale yellow mixture of [Pt(acac)$_2$] (0.37 g, 0.95 mmol), tricyclohexylphosphine (0.27 g, 0.95 mmol), and diethyl ether (20 cm^3) at room temperature, the amount of precipitate gradually decreased, and in 21 h of stirring, an almost clear yellow solution resulted. Then, the solvent was

Table 4. Melting points and analytical results of some new acetylacetonato complexes

Complexes		Appearance	Mp, °C[a]	Analysis[b], % C	H
[Pt(acac)(γ-acac)PPh_3]	**1a**	white crystals	148—153	51.3 (51.3)	5.3 (4.5)
[Pt(acac)(γ-acac)PCy_3]	**2a**	creamy white crystals	180—182	48.9 (49.9)	7.1 (7.0)
[Pd(acac)(γ-acac)PCy_3]	**2b**	pale yellow crystals	178—181	56.5 (57.5)	8.6 (8.1)
[PtI(acac)PPh_3]	**3a**	orange-yellow powder[c]	—	—	—
[PdI(acac)PPh_3]	**3b**	orange needles	184—188	47.4 (46.5)	3.9 (3.7)[d]
[Pt(acac)(PPh_3)$_2$]BPh_4	**4a**	white crystals	183—187	68.1 (67.6)	5.6 (5.2)
[Pd(acac)(PPh_3)$_2$]BPh_4	**4b**	yellow crystals	160—164	74.4 (74.4)	5.9 (5.5)

a) Melting points (with decomposition) were measured on a hot stage with a sample in a small capillary sealed under vacuum and are uncorrected. b) Calculated values are in parentheses. c) Not obtained pure. d) I, 20.3% (21.3%).

partially evaporated in the stream of nitrogen with stirring, which caused precipitation of a white powder. The precipitate was filtered off at about −20 °C, washed with diethyl ether at the same temperature and dried *in vacuo* at room temperature to give 0.49 g (76%) of crude product. Recrystallization of a white powder from CH_2Cl_2–hexane at low temperature yielded 0.17 g (26.5%) of pure [Pt(acac)(γ-acac)PCy_3] as a creamy white crystalline solid. The yield of recrystallization was low due to too high solubility of the product in the common organic solvents.

Similarly obtained is its Pd-analog, (2,4-pentanedionato-C^3)-(2,4-pentanedionato-*O*, *O'*) tricyclohexylphosphinepalladium-(II), **2b**, from [Pd(acac)$_2$] (0.38 g, 1.23 mmol) and PCy_3 (0.35 g, 1.25 mmol). The reaction was carried out in benzene (5 cm^3) and completed in 1 h to give, on working up, 0.42 g (58%) of the product as a pale yellow microcrystalline solid.

*Reactions of [Pt(acac)(γ-acac)PPh_3], **1a**. With Benzoyl Chloride*: Complex **1a** (0.21 g, 0.32 mmol) was allowed to react with 2.0 cm^3 (17.1 mmol) of PhCOCl in benzene (2 cm^3) at room temperature for 4 h. The initial clear yellow solution turned to heterogeneous. The amount of the precipitate was increased on addition of hexane to the system. The precipitate was filtered off, washed with hexane and dried *in vacuo*. The yellowish brown powder thus obtained was crystallized from benzene and was identified as [PtCl(acac)PPh_3] on the basis of the infrared spectrum and elemental analysis. Similarly carried out was the reaction of **1a** with neat acetyl chloride to give the same product.

With Methyl Iodide: To the flask containing 0.20 g (0.31 mmol) of complex **1a** was added 5 cm^3 of methyl iodide by means of trap-to-trap method in a vacuum. The yellow solution was stirred at room temperature for 10 days. The unreacted methyl iodide was evaporated off *in vacuo* to leave an orange solid, which was reprecipitated from toluene–hexane. The orange-yellow powder of [PtI(acac)PPh_3], **3a**, thus obtained weighed 0.11 g (58%). The reaction of **1a** with ethyl bromide was similarly carried out to give an orange-yellow powder of [PtBr(acac)PPh_3].

With Sodium Tetraphenylborate: To the yellow solution of complex **1a** (0.46 g, 0.70 mmol) and PPh_3 (0.19 g, 0.70 mmol) in tetrahydrofuran (7 cm^3), 0.24 g (0.70 mmol) of $NaBPh_4$ was added. On stirring the mixture at room temperature for a day, a white fine powder, possibly of sodium acetylacetonate, was yielded. The solvent was evaporated off *in vacuo* to leave an off-white solid, which was washed with ethanol and dried *in vacuo*. The crude white powder thus obtained was recrystallized from THF–EtOH to give white microcrystals of [Pt(acac)$(PPh_3)_2$]$^+BPh_4^-$ **4a** (0.46 g, 58%).

*Reaction of [Pd(acac)(γ-acac)PPh_3], **1b**. With Methyl Iodide*: Into the yellow suspension of **1b** (0.30 g, 0.53 mmol) in toluene (5 cm^3), 0.114 g (0.803 mmol) of methyl iodide was added by means of a microsyringe. The mixture was stirred at room temperature for 6 h to yield a pale red solution. The solvent was evaporated *in vacuo* into almost dryness. The residual orange-yellow solid was washed with hexane and dried *in vacuo*. The crude product, weighed 0.18 g (57%), was crystallized from CH_2Cl_2–hexane to afford orange needles of [PdI(acac)PPh_3], **3b**, (0.07 g, 22%).

With Sodium Tetraphenylborate: Into a clear yellow solution of **1b** (0.22 g, 0.39 mmol) and PPh_3 (0.11 g, 0.39 mmol) in tetrahydrofuran, was added 0.14 g (0.39 mmol) of $NaBPh_4$. On stirring the solution at room temperature the system became turbid in about one minute and a colorless precipitate gradually came out. After being stirred for 1.5 h, the white precipitate was removed by filtration and was identified as sodium 2,4-pentanedionate (0.04 g, 84%) on the basis of infrared spectrum and microanalysis. Found: C, 49.1; H, 6.5%. Calcd for $C_5H_7O_2Na$: C, 49.2; H, 5.8%. From the yellow filtrate, the solvent was evaporated off *in vacuo* to leave a pale yellow mass, which was washed with ethanol and hexane, and dried *in vacuo*. The crude product (0.38 g, 93%) was recrystallized from tetrahydrofuran to give a yellow crystalline solid of [Pd(acac)$(PPh_3)_2$]$^+BPh_4^-$, **4b** (0.22 g, 84%). Compound **4b** was also obtained by the direct reaction of [Pd(acac)$_2$] (0.20 g, 0.65 mmol) and PPh_3 (0.34 g, 1.31 mmol) in the presence of $NaBPh_4$ (0.23 g, 0.67 mmol) in refluxing ethanol (8 cm^3) for 2 h. The crude product of **4b** weighed 0.62 g (90%).

*Preparation of Diethylbis(triphenylphosphine)platinum(II), **5a**.* Into a cooled (−60 °C) mixture of [Pt(acac)$_2$] (1.0 g, 2.6 mmol), PPh_3 (1.35 g, 5.2 mmol) and diethyl ether (40 cm^3), 3.9 cm^3 (26 mmol) of Al(OEt)Et_2 was added by means of a syringe. The temperature of the mixture was allowed to raise gradually and the system was stirred at room temperature for 75 h, to yield a white precipitate with an accompanying evolution of ethane. The precipitate was filtered off, washed with hexane and crystallized from toluene to afford a colorless microcrystalline powder. (0.50 g, 25% based on [Pt(acac)$_2$] used.) (Found: C, 60.4; H, 5.3%. Calcd for $C_{40}H_{40}P_2Pt$: C, 61.8; H, 5.2%). A low stability of the product in solution prevented from obtaining an analytically pure compound.

Thermolysis of 0.1398 g (0.1798 mmol) of the product *in vacuo* at 160 °C evolved 0.360 mmole of gas (as measured with a Toepler pump) which consists of equimolar amounts of ethylene and ethane as analyzed by GLC.

*Preparation of Ethyl(2,4-pentanedionato-C^3)bis(triphenylphosphine)platinum(II), **6a**.* To a mixture of [Pt(acac)$_2$] (1.89 g, 4.80 mmol), PPh_3 (2.52 g, 9.63 mmol) and 50 cm^3 of diethyl ether, Al(OEt)Et_2 (3.76 g, 8.79 mmol) was added at −70 °C. The mixture was stirred at room temperature for 74 h to yield a white precipitate, which was filtered off, washed with hexane and dried *in vacuo*. The pale yellow powder thus obtained had an analytical value close to that for [PtEt(γ-acac)$(PPh_3)_2$] (0.92 g, 23%). (Found: C, 62.0; H, 5.1%. Calcd for $C_{43}H_{42}O_2P_2Pt$: C, 60.9; H, 5.0%). On thermolysis of the product (115.1 mg, 0.1358 mmol) at 145 °C, evolution of ethylene and ethane (0.5: 1), the total amount of which was 0.143 mmol (105%), was observed.

We thank the Kawakami Foundation for support.

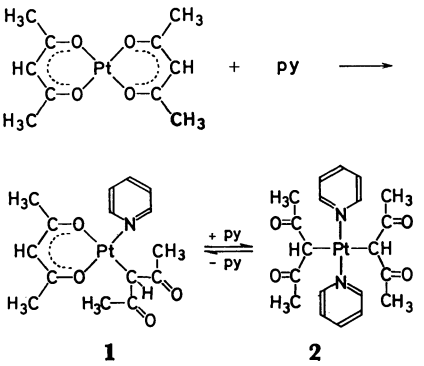
(Received June 23, 1976)

Heating a pyridine solution of [Pt(acac)$_2$] (acac=2,4-pentanedionato-*O,O'*) at 100 °C afforded central C-bonded complexes, [Pt(acac)(γ-acac)py], **1**, and [Pt(γ-acac)$_2$py$_2$], **2** (γ-acac=2,4-pentanedionato-*C*^{3}). Complexes **1** and **2** were isolated and characterized by means of elemental analysis, infrared and ^{1}H- and ^{13}C-NMR spectroscopy. Heating **1** in pyridine yielded **2**, and conversely, heating **2** in $CDCl_3$ yielded **1**. All these reactions were monitored by ^{1}H-NMR spectroscopy and were found to obey the first-order rate law. From the rate constants at various temperatures, activation parameters were calculated for each reaction. Existence of isokinetic relationship among these three reactions suggests the presence of a common reaction intermediate. Observation of the variable temperature ^{1}H-NMR spectra of [Pd(acac)(γ-acac)py] in pyridine suggests that the activated intermediate may be a species having an oxygen-bonded unidentate acac ligand ("dangling" enolate ligand).

Participation of a central(γ-) carbon atom in an acetylacetonato ligand in coordination to the metal was disclosed for the first time by Hazell *et al.* in 1959 for a dimeric β-diketonato complex of platinum(IV).[1] Soon after, Mason *et al.*[2] reported that Werner's K[Pt(acac)$_2$Cl][3,4] was in fact K[Pt(acac)(γ-acac)Cl][4] in which one of two acetylacetonato ligands is coordinated to Pt(II) *via* the central(γ-) carbon atom. Since then several kinds of γ-acac complexes of platinum(II) have been reported including $Na_2[Pt(\gamma\text{-acac})_2X_2]$ (X= halogen),[5] K[Pt(acac)(γ-acac)$_2$],[5] and [(acac)ClPt(γ-acac)M(II)(γ-acac)PtCl(acac)] where M(II) stands for a divalent metal ion,[6,7] as well as those of Pt(IV) such as [Pt(CH$_3$)$_3$(γ-acac)(L-L)] where L-L is 2,2'-bipyridine (bpy),[8,9] and 1,10-phenanthroline (phen).[9] However, non-ionic Pt(II) complex with a carbon-bonded acetylacetonato ligand has not been known except for poorly soluble [Pt(γ-acac)X(L-L)] where L-L is a bidentate ligand such as bpy, phen, ethylenediamine (en) and 1,2-bis(diphenylphosphino)ethane (dpe).[10] In a preceding paper, we described the isolation and characterization of new, non-ionic γ-acac complexes of the type [Pt(acac)(γ-acac)L] (L=PPh_3 and $P(C_6H_{11})_3$), which are formed by the reaction of bis(acetylacetonato)platinum with an equimolar amount of the tertiary phosphine.[11] The reaction of [Pt(acac)$_2$] with an excess of pyridine, on the other hand, yielded the complex in which both acetylacetonato ligands are coordinated to platinum *via* central carbon atoms, *i.e.*, [Pt(γ-acac)$_2$(py)$_2$)], **2**, together with a mono-γ-acac complex, [Pt(acac)(γ-acac)(py)], **1**, which exist as an equilibrium mixture. There is no precedent of the observation of a direct rearrangement of the acetylacetonato ligand coordinated to platinum metal from the bidentate enol type mode of coordination (acac) to the diketo type (γ-acac), although such a rearrangement has been reported for mercury(II)[12,13] and palladium(II).[14] The present report describes isolation and characterization of γ-acac complexes **1** and **2** and some results of mechanistic study on their rearrangement reaction observed by means of the ^{1}H-NMR spectroscopy.

Results and Discussion

Reaction of Bis(acetylacetonato)platinum with Pyridine. When [Pt(acac)$_2$] was heated at 100 °C in pyridine (py), a homogeneous brown solution resulted, from which colorless prisms were produced on allowing it to stand still at room temperature. The prisms were characterized as bis(2,4-pentanedionato-*C*^{3})bispyridineplatinum(II), [Pt(γ-acac)$_2$(py)$_2$], **2**, on the basis of microanalysis, and infrared and NMR spectral results. Although a steric configuration of **2** is uncertain, the fact that 2,2'-bipyridine does not react with [Pt(acac)$_2$] is in favor of the *trans*-configuration as is shown in the following equation.



1 **2**

From the solution part of the reaction mixture, an off-white crystalline powder of (2,4-pentanedionato-*C*^{3})-(2,4-pentanedionato-*O,O'*)pyridineplatinum(II), [Pt(acac)(γ-acac)py], **1**, was precipitated on addition of hexane. If the solution is heated again at 100 °C after removal of the prisms, instead of precipitating out **1**, a further crop of prisms of **2** was obtained. Thus, repetition of these procedures for 5 times or more makes the total yield of **2** to be almost quantitative. This fact indicates that complexes **1** and **2** exist in equilibrium in a pyridine solution in agreement with the result obtained by a ^{1}H-NMR spectral study (*vide infra*).

The complexes analogous to **1**, but having tertiary phosphines with a formula of [Pt(acac)(γ-acac)L] (L=

a) Melting points (with decomposition) were measured on a hot stage with a sample in a small capillary sealed under vacuum and are uncorrected. b) Calculated values are in parentheses.

PPh_3 and $P(C_6H_{11})_3$) have been obtained by the reaction of [Pt(acac)$_2$] with an equimolar amount of the corresponding tertiary phosphine.[11] It is interesting to note, however, that the reaction with an excess amount of triphenylphosphine at an elevated temperature resulted in the formation of another type of platinum(II) complex of a composition [Pt($CH_2COCHCOCH_3$)(PPh_3)$_2$],[11] instead of yielding the bis-γ-acac complex analogous to **2**. Complex **2** is the first example of a neutral Pt(II) complex in which two acetylacetonato ligands are coordinated to the metal *via* central (γ-) carbon atoms. The reaction of bis(acetylacetonato)-palladium with pyridine is known to afford only the complex analogous to **1**, *i.e.*, [Pd(acac)(γ-acac)py].[14] The formation of the palladium complex similar to **2**, [Pd(1-ethoxy-1,3-dioxobut-2-yl)$_2$L$_2$] was reported quite recently, where L stands for a substituted or unsubstituted p ridine.[15]

Infrared and ^1H- and ^{13}C-NMR Spectra of the Complexes. In Table 1, characteristic infrared absorptions due to the acetylacetonato ligands in complexes **1** and **2** are listed together with melting points and analytical data. A pattern of the spectrum of complex **1** in the region of 1500—1700 cm^{-1} is very similar to those reported for [Pt(acac)(γ-acac)PPh_3][11] and K[PtCl(acac)(γ-acac)].[16] In addition to bands listed in Table 1, there is an extra band in the spectrum of complex **1** at 1615 cm^{-1} which is assignable to the coordinated pyridine moiety. Two bands due to the γ-acac ligand in **1** appeared at a higher wave number by 15—20 cm^{-1} than in palladium analog of **1**, [Pd(acac)(γ-acac)py].[14] Absence of a band in the region of 1500—1600 cm^{-1} in complex **2** strongly suggests that it has no O-bonded chelate acac ligand. Two bands at 1650 and 1610 cm^{-1} can be assigned to ν(C=O) of the carbon bonded γ-acac ligand by comparing them with the reported values of 1652 and 1626 cm^{-1} for $Na_2[PtCl_2(\gamma\text{-acac})_2]$.[16] These lines of infrared spectral evidence are in accord with the bis(γ-acac) type of structure proposed for **2**.

The ^{1}H-NMR parametrs of complexes **1** and **2** are listed in Table 2. Assignments of their signals have been made simply by comparing them with those reported for the similar complexes.[5,9,11,14] Two methyl groups in the chelated enol acac ligand in **1** appear as non-equivalent signals owing to difference in the influence of the ligands *trans* to the chelate oxygen, as is the case reported for [MX(acac)L] (M=Pt[10] and Pd[14]) and [M(acac)(γ-acac)L] (M=Pd[14] and Pt[11]). According to the assignment made by Baba *et al.* for [Pd(acac)(γ-acac)-L] (L=PPh_3, py, and *N*-methylbenzylamine),[14] the signal at higher field (δ=1.87 ppm) is tentatively assigned to the methyl group *cis* to the pyridine ligand. The methine proton of the γ-acac ligand in complex **1** resonates at a lower field than that in [Pt(acac)(γ-acac)-

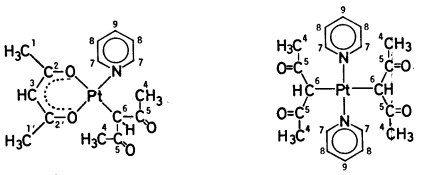
a) In $CDCl_3$ at room temperature, 25.1 MHz. Tetramethylsilane as an internal standard.
b) Numbering for the carbon atoms is as follows:



c) Multiplicity abbreviations: s, singlet; ss, singlet with satellite bands due to ^{195}Pt.

PPh_3] (4.04 ppm[11]) by *ca.* 1 ppm whereas that in **2** resonates at the similar field. These methine protons accompanied satellite bands due to ^{195}Pt with a larger coupling constant for **1** than for **2**. Although no data are available for the ^{195}Pt–H coupling constant of the methine proton of the mutually *trans* bis(γ-acac) ligands, the $|^2J(^{195}\text{Pt–H})|$ values for **1** and **2** listed in Table 2 are similar to those reported for K[Pt(acac)(γ-acac)Cl] (120 Hz) and K[Pt(acac)(γ-acac)$_2$] (123 Hz).[5] Assignments of the signals due to the pyridine ligand(s) were achieved by examination of their relative intensities and multiplicities. A doublet assignable to the α-proton in the coordinated pyridine accompanied satellite bands due to a coupling with ^{195}Pt.

The structures of complexes **1** and **2** are further supported by their ^{13}C-NMR spectra which are summarized in Table 3. The spectrum of complex **1** is similar to that of the analogous complex [Pt(acac)-(γ-acac)PPh_3].[11] Absence of the phosphorus nucleus in **1** made the spectrum more simplified than the PPh_3 analog. Assignment of each signal was further confirmed by recording a half decoupled spectrum,[17] in which the signals assigned to C^3, C^6, C^7, C^8, and C^9 split into doublets while those to C^2, $C^{2'}$, and C^5 remained as singlets. (As for the numbering of the carbon atoms, refer to the foot note of Table 3). A singlet signal due to C^4 split into a quartet on half decoupling and those of C^1 and $C^{1'}$ changed to a complex pattern which is consisted of basically 8 lines. The $|^1J(^{195}\text{Pt–}^{13}\text{C})|$ value of 619 Hz for the methine carbon of the γ-acac ligand in complex **1** is similar to the reported values for *cis*-[Pt(CH_3)$_2$L$_2$] (594 Hz for L=PMe_2Ph,[18] 689 Hz for L=$AsMe_3$,[19] and 685 Hz for L=$AsMe_2Ph$.[18] On the other hand, an exceptionally small $|^1J(^{195}\text{Pt–}^{13}\text{C})|$ value (369 Hz) was observed for complex **2**. Such a small ^{195}Pt–^{13}C coupling constant has been reported only for the methyl carbon attached to platinum atom at a *trans* position with respect to the carbene ligand, *i.e.*, *trans*-[Pt(CH_3)(cb)($AsMe_3$)$_2$][PF_6], where cb stands for carbene ligands (385 Hz for cb=:CMe(NMe_2), 381 Hz for cb=:CMe(NHMe), 380 Hz for cb=:CMe(NH_2), and 360 Hz for cb=:CMe(OMe)).[19,20] This decrease in $|^1J(\text{Pt–C})|$ value when going from **1** to **2** parallels a decrease in $|^2J(\text{Pt–H})|$ value suggesting a stronger Pt–C bond in complex **1** than in **2**. Interestingly, the slope of the line connecting two points plotted for $|^1J(\text{Pt–C})|$ *vs* $|^2J(\text{Pt–H})|$ coincided fairly well with those reported for serieses of platinum–methyl complexes.[20,21] The keto-carbon (C^5) in the γ-acac ligand in **1** and **2** showed ^{195}Pt-satellite bands with $|^2J(\text{Pt–C}^5)|=65$ and 49 Hz, respectively. Although there are no available data on the ^{13}C-NMR spectral parameters for this type of ligand, these values are within the range of values reported for $|^2J(\text{Pt–C})|$, *e.g.*, 50 and 86 Hz have been reported for $|^2J(\text{Pt–As–C})|$ and $|^2J(\text{Pt–C–C})|$, respectively, in the carbene complex, *trans*-[PtMe{C(OMe)-Me}($AsMe_3$)$_2$][PF_6].[20,21] Furthermore, ^{195}Pt-satellite bands are observed for the methine carbon (C^3) of acac ligand with $|^3J(\text{Pt–C}^3)|=68$ Hz, which is larger than $|^2J(\text{Pt–C}^5)|$. This effect may reflect the conjugate character of the chelate acac ligand. Intensities of unequivalent C^2 and $C^{2'}$ signals were reduced considerably as compared with that of the C^3 signal due to the absence of NOE effect (C^3 being tertiary carbon), hence a discernment of its satellite bands from the noise signals might have become impossible. Among three signals due to the pyridine ligand, the signal with the smallest intensity at *ca.* 138 ppm was assigned to the

γ-carbon. Assignments of the other two signals were made by comparing their chemical shifts with those of free pyridine (149.6, 123.5 and 135.6 ppm for α, β, and γ-carbons, respectively in $CDCl_3$).[22] It should be noticed that the α-carbon signal does not accompany satellite bands due to ^{195}Pt in spite of the presence of the distinct satellite bands for β- (in **1** and **2**) and γ- (in **1**) carbon atoms. This fact may be correlated to the reported data on the phenylplatinum complex, *cis*-$[PtPh_2(PEt_3)_2]$, where the ^{195}Pt–C coupling constant due to the phenyl *ortho* carbon is less than that for *meta* carbon (36 and 64 Hz, respectively).[21] A poor resolution of the spectrum of **2** prevented the accurate measurement of the coupling constant for the γ-carbon satellite bands.

Kinetic Study on the Formation of 1 and 2. Kinetic studies on the formation of **1** and **2** and their interconversions were achieved by following the ^1H-NMR spectral change in either pyridine or chloroform at various temperatures.

The ^1H-NMR spectrum of $[Pt(acac)_2]$ in pyridine at 60 °C consists of a single methyl resonance at 1.79 ppm and a methine resonance at 5.48 ppm. (Fig. 1A). On keeping the sample at this temperature, several new signals which are assignable to the protons of γ-acac ligand(s) in **1** and **2** appeared at the expense of the initial two singlets and they grew gradually with time. Figure 1B illustrates the spectrum of the system taken after 9 h at 60 °C. Assignments of the signals were confirmed by comparing them with the spectra of the isolated complexes **1** and **2**. The rate of conversion of $[Pt(acac)_2]$ into **1** (reaction (i) in Eq. 2) obeyed the first-order rate law with respect to $[Pt(acac)_2]$. The first-order rate constants (k_1) thus obtained for reaction (i) at various temperatures are listed in Table 4. Similarly were obtained the first-order rate relationship for reactions (ii) and (iii) in Eq. 2. For reaction (ii) the

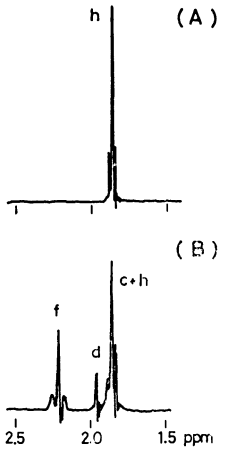

Fig. 3. Change of the ^{1}H-NMR spectrum (methyl region) of [Pt(γ-acac)$_2$py$_2$] in $CDCl_3$ at 60 °C. (A) Initial spectrum. (B) After 4.5 h. Proton notations are as shown in Fig. 1.

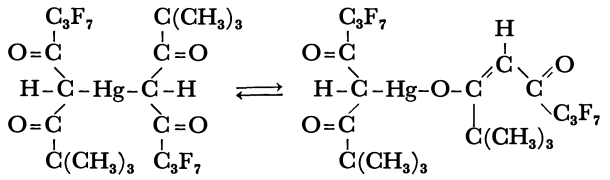
illustrated in Fig. 3. Deuteriochloroform was used as a reaction solvent in reaction (iii) because of a poor solubility of **2** in pyridine. The first-order rate law was again observed and the rate constants, k_3, obtained at various temperatures, are also included in Table 4. Arrhenius activation energies, E_a, and frequency factors, A, for reactions (i), (ii), and (iii) were obtained from the slopes and intercepts, respectively, of the least-square straight lines of log k *vs.* $1/T$ plots. Activation enthalpies, ΔH^*, and activation entropies, ΔS^*, were obtained similarly from the least-square treatment for the Eyring plots of log k/T *vs.* $1/T$. The free energy of activation, ΔG^*, was calculated from the equation $\Delta G^* = \Delta H^* - T\Delta S^*$. The activation parameters are liested in Table 5.

In spite of numerous studies concerning the configurational rearrangement of octahedral enolate acetylacetonato complexes of transition and non-transition metals,[23-27] scarcely has been reported the mechanistic study of the ligand exchange in the square planar acetylacetonato complex.[28] This may be ascribed to the slow rate of exchange in the latter compared to the six-coordinate complex, which renders the study of dynamic behavior of these complexes by NMR measurement inapplicable. Furthermore, little has been studied on the rearrangement of acetylacetonato complex between a chelated enol form and a central carbon bonded diketo form. Fish has made an NMR study on the dynamic behavior of bis(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-dioxooctan-5-yl)mercury in acetone-d_6, in which the following exchange has been observed.[13] The Arrhenius activation energy, E_a, and the free



energy of activation, ΔG^*, for this process were estimated as 9.90 and 10.35 (at 25 °C) kcal/mol*, respectively, which are much lower than the values of, respectively, 16—27 and *ca.* 26 kcal/mol for the present system, indicating a less labile character of the acac ligand in the present platinum complexes in the keto-enol exchange as compared to the mercury complex in agreement with the prediction by Fish.[13]

Observation that the reactions (i), (ii), and (iii) obey the first-order rate law suggests that these reactions proceed *via* unimolecular processes with respect to the complexes involved. Furthermore, observation of constant ΔG^* values for the three reactions, despite the considerable variance of ΔH^* and ΔS^* values, suggests the presence of an isokinetic relationship. Figure 4 demonstrates the presence of the compensation effect between ΔH^* and ΔS^* values in the three reactions. In a strict sense, comparison of the reactions (i) and (ii) with reaction (iii) may not be quite adequate because of the difference in the solvent employed. (Employment of $CDCl_3$ in reactions (i) and (ii) was not feasible because of occurence of unexpected, not fully studied reaction

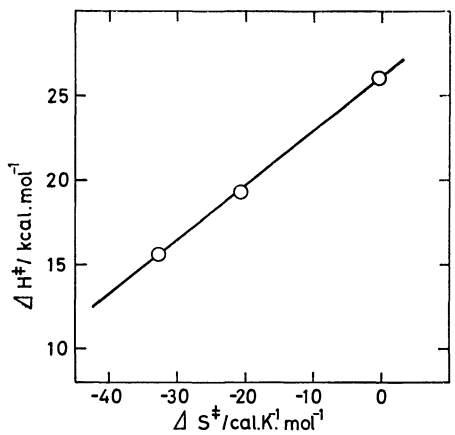


Fig. 4. Isokinetic relationship for the reactions, [Pt(acac)$_2$] $\xrightarrow{py}$ [Pt(acac)(γ-acac)py] $\underset{-py}{\overset{py}{\rightleftharpoons}}$ [Pt(γ-acac)$_2$(py)$_2$].

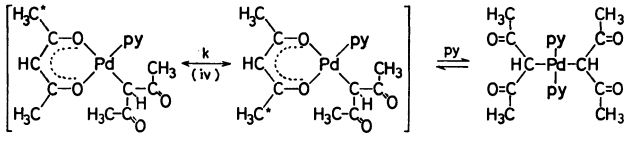
* Throughout this paper 1 cal=4.184 J.

between $CDCl_3$ and pyridine in the presence of the platinum complex.) However, the results suggest that, in spite of the difference in solvents, the three reactions proceed through a similar activated species in the rearrangement reactions from the acac form to the γ-acac form and *vice versa*. The isokinetic temperature, the temperature at which the rates of three processes become equal, was estimated as 323 K (50 °C).

In contrast to the platinum complex, the reaction of bis(acetylacetonato)palladium with pyridine has been reported to give only [Pd(acac)(γ-acac)py] even under rigorous conditions.[14] No bis(γ-acac) complex of palladium, analogous to **2**, has been isolated. The variable temperature ^{1}H-NMR measument of [Pd(acac)(γ-acac)py], **3**, in pyridine, however, revealed the presence of equilibria as follows:



A **3** B **4** (3)

Two singlets at 2.08 and 1.94 ppm at −20 °C due to the two methyl groups of the chelated acetylacetonato ligand in **3** broaden on raising the temperature and coalesce at 46 °C. Above the temperature, the coalesced singlet signal sharpens with temperature increase. This spectra change may be interpreted by assuming the acceleration of the exchange rate between species A and B on raising the temperature (Eq. 3). In Fig. 5, the relevant spectra in the temperature range of 20—46 °C are reproduced, together with the one at −20 °C. The rate constants k, for the exchange were calculated from the separation of two singlets as are recorded in Figure 5. An Arrhenius plot of these k values leads to activation parameters which are included in Table 5. A very small peak is observed at 1.99 ppm at −20 °C and it grows gradually on raising the temperature (Figure 5). This may be due to the methyl protons of bis(γ-acac) type complex **4**, which is in equilibrium with **3** (Eq. 3). All attempts to isolate **4** from the equilibrium mixture were unsuccessful.

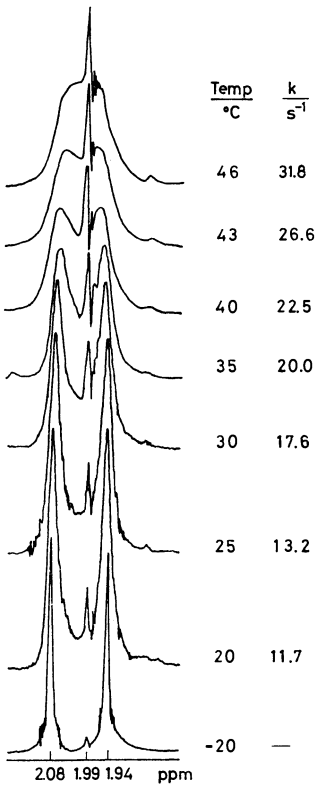


Fig. 5. Temperature dependence of the ^{1}H-NMR spectra (methyl proton region) of [Pd(acac)(γ-acac)py] in pyridine-d_5.

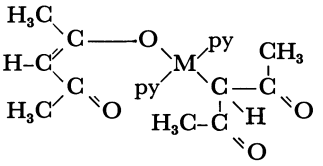
Saito and Takahashi have reported the Arrhenius activation energy E_a of 23 kcal/mol for the palladium–oxygen bond rupture in the exchange reaction of $[Pd(acac)_2]$ and ^{14}C-labelled acetylacetone in anisole.[28] Much smaller value (6.2 kcal/mol) obtained in the present study implies that the presence of a large excess of pyridine may facilitate the palladium–oxygen bond rupture. The presence of large negative $\Delta S^{\ddagger}$ values for the forward (bidentate enol→unidentate diketo) transformations and a very small $\Delta S^{\ddagger}$ value for the reverse process with regards to platinum complexes also may be taken as an indication of the solvent participation in the forward processes. The mechanism of the interchange may involve the solvent assisted partial M–O bond rupture as shown below, rotation of the unidentate acac around the M–O bond and recoordination *via* the carbonyl group to the metal.

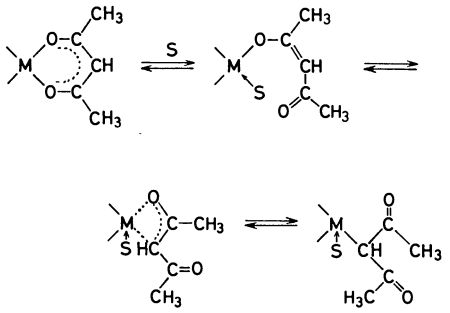


M=Pd, Pt

The similar value of E_a, *ca.* 10 kcal/mol, has been reported for the exchange of a bidentate enol acac ligand in [NiEt(acac)PPh_3][29] and in the various six-coordinate acac complexes.[23,24]

In a separate reaction of $[Pt(acac)_2]$ with triethylphosphine we have isolated another type of a complex, bis(2,4-pentanedionato-*O*)bis(triethylphosphine)platinum(II) containing two unidentate acac ligands, which are singly bonded to platinum through enol oxygen atoms.[30]

In view of these results it is tempting to speculate on the rearrangement mechanisms of the acac ligand. In the forward reaction starting from the bidentate enol type complex to the γ-acac type complex three reaction pathways are conceivable. A bimolecular mechanism involving the direct transfer of the chelate acac ligand to another platinum complex is unlikely on the basis of the observed first-order rate law. The second mechanism where a unimolecular "flipping" of the bidentate enol ligand to the γ-acac ligand takes place seems less likely than the third mechanism which involves the partial dissociation of the bidentate enol ligand to a singly bonded form with participation of the solvent. The further process might involve an oxoallyl intermediate through which a new M–C bond is formed as shown below in the following scheme:



(S=solvent molecule)

The reverse process starting from the γ-diketo form leading to the enol chelate could be accounted for by assuming common intermediates presented above.

Although the evidence supporting this mechanism is circumstantial at best, it is compatible with various features of the rearrangement reaction.

Formation of a γ-acac type complex also may have implications related to the polymerization activities of various transition metal acetylacetonates for some vinyl monomers.[31,32] A typical initiator [Mn(acac)$_3$] can be reduced to [Mn(acac)$_2$] in the presence of a vinyl monomer which is polymerized by a radical $CH_3CO\dot{C}HCOCH_3$[31-33] liberated by homolytic splitting of Mn–C bond from a possible intermediate complex such as [Mn(acac)$_2$(γ-acac)·S]. In fact, the reduction of [Mn(acac)$_3$] in the presence of 1,10-phenanthroline gave a phen-complex [Mn(acac)$_2$(phen)].[33,34] Another implication of the partial dissociation of the enol chelate concerning the alkylation mechanism of transition metal acetylacetonates has been discussed in the previous paper.[11]

Experimental

Procedures, materials, and instruments used are as reported in a preceding paper.[11] Guaranteed grade pyridine was used for the reaction without further purification.

Reaction of Bis(acetylacetonato)platinum(II) with Pyridine. The pale yellow suspension of [Pt(acac)$_2$] (0.60 g, 1.53 mmol) in pyridine (3.4 cm^3) was heated at 100—110 °C under nitrogen for 1 h resulting in a brown solution. After cooling, 20 cm^3 of hexane was added to the solution to yield a creamy white precipitate, which was filtered off, washed with hexane and dried *in vacuo*. The crude product (0.54 g) thus obtained is a mixture of [Pt(acac)(γ-acac)py], **1**, and [Pt(γ-acac)$_2$(py)$_2$], **2**, which can be separated from each other by extraction with diethyl ether (20 cm^3×5). The extract was concentrated to *ca.* 10 cm^3 *in vacuo*. To the concentrated solution was added hexane (20 cm^3) to give a creamy white precipitate which was filtered off, washed with hexane and dried *in vacuo*. The off-white powder thus obtained (0.34 g, 40%) was identified as [Pt(acac)(γ-acac)py], **1**, on the basis of infrared and NMR spectroscopy (see text). The product thus obtained is analytically pure, but can be recrystallized from toluene.

The white residue of extraction was found to be analytically pure [Pt(γ-acac)$_2$(py)$_2$], **2** (0.12 g, 17%). The results of micro analysis for complexes **1** and **2** are listed in Table 1.

In order to obtain **2** in a much higher yield, the following procedure is recommendable. The yellow solution of [Pt(acac)$_2$] (0.90 g, 2.29 mmol) in pyridine (10 cm^3) was heated at 100—110 °C under nitrogen for 6 h. The system was cooled down to room temperature and kept at the temperature overnight. The colorless prisms of **2** thus yielded were isolated by decantation, washed with diethyl ether and dried *in vacuo*. (0.16 g). The supernatant was again heated at 110 °C for 3 h. On working up as above, 0.20 g of the prisms of **2** were obtained. Repetition of this procedure 5 times gave the total amount of 0.91 g (72%) of **2** obtained as colorless prisms; the procedure may be continued further until the quantitative yield of **2** is attained.

Kinetic Measurements. The kinetic measurements of the rearrangement of acetylacetonato ligand were made using a JEOL PS-100 NMR spectrometer equipped with a JES-VT-3 variable-temperature controller. The temperature of the probe was calibrated (±0.5 °C) by measuring the reading of the thermometer inserted directly into a probe. The sample solution made up with the concentration of 0.18—0.27 M was used for each run.

The extent of conversion (x) of the reactions (i), (ii), and (iii) (Eq. 2 in the text) was calculated by the equations, $x_{\mathrm{i}}=\{2[f]+[h]\}/\{[a+c]+[d]+[f]+[h]\}$, $x_{\mathrm{ii}}=[h]/\{[c]+[d]+[f]+[h]\}$, and $x_{\mathrm{iii}}=2[f]/\{[c]+[d]+[f]+[h]\}$, respectively, where an alphabet in a square blacket means the relative intensity of the corresponding signal shown in Figs. 1—3. First-order rate constants were obtained from the slope of the linear plots of $\ln 1/(1-x)$ *vs.* t.

The rates of the interchange of the enol acetylacetonato ligand in [Pd(acac)(γ-acac)py] in pyridine-d_5 were calculated from the differences in the chemical shifts of two methyl singlets below the coalescence temperature using Gutowsky and Holm's equation.[35] The singlet signal above the coalescence temperature could not be used for the purpose of the kinetic analyses because of the overlapping of the signal in question with that ascribable to the methyl proton of [Pd(γ-acac)$_2$(py)$_2$] (see text).

We thank the Kawakami Foundation for support.

(Received May 8, 1976)

Glassy and crystalline thermal products were made by heating a mixture of sodium metaphosphate glass and chromium(III) oxide with P/Cr ratios in the range from 1.0 to 300 at 1000 °C for 3 h in a platinum crucible and by then rapidly quenching the resulting melt. The crystalline substances were present in the products with P/Cr ratios smaller than 50 and were, except for chromium(III) oxide, an unknown substance and chromium(III) tripolyphosphate. The colorimetric determination and the measurement of the average chain length of polyphosphate anions present in the water-soluble parts of the products with P/Cr ratios larger than 50 showed that chromium(III) oxide reacts with sodium metaphosphate glass to make Cr–O–P linkages. Assuming that the glass has P–O–P, P–O^-, Cr–O–P, and Cr–O^- linkages, a theoretical treatment of the degree of polymerization of condensed phosphates were made and compared with the data. It was concluded that the most reasonable chemical structure of the glassy thermal products of the $NaPO_3$–Cr_2O_3 system is $Cr(OP)_3$.

Several attempts to prepare condensed phosphates containing oxoacid anions of some elements other than phosphorus have been made. The investigated systems were arsenate–phosphates,[1] silicate–phosphates,[2] vanadate–phosphates,[3] and borate–phosphates.[4,5] It was reported that condensed compounds of this type have P–O–As, P–O–Si, P–O–V, and P–O–B linkages, respectively. The authors also have studied thermal products in antimonate–phosphate,[6–8] molybdate–phosphate,[9] tungstate–phosphate,[9] and aluminate–phosphate[10] systems. It was concluded that they have P–O–Sb, P–O–Mo, P–O–W, and P–O–Al linkages, respectively, and the most reasonable chemical structure of the glassy products is proposed.

In the present paper, glassy and crystalline substances of the $NaPO_3$–Cr_2O_3 system with various P/Cr ratios were prepared by heating a mixture of Graham's salt and chromium(III) oxide at 1000 °C for 3 h in order to obtain some information on the chemical composition and structure of the system. The compositions of condensed phosphates were determined by the paper-chromatographic analysis of their aqueous solutions. The identification of the crystalline products was made by X-ray diffractometry and the chemical structure of the glassy products was studied by the theoretical treatment of the degree of polymerization of the condensed phosphates contained in the glassy products.

Experimental

Materials and Procedure. Sodium metaphosphate glass was prepared by heating monosodium orthophosphate dihydrate in a platinum crucible at 1000 °C for 3 h and then by quenching the melt by placing the crucible in ice water. The chromium(III) oxide was of a commercial grade. A mixture of sodium metaphosphate glass and chromium(III) oxide with P/Cr ratios in the range from 1.0 to 300 was heated in a platinum crucible at 1000 °C for 3 h. The resulting product was quenched by the same method as that for the preparation of sodium metaphosphate.

Chromium(III) Pyro- and Tripolyphosphates. The X-ray diffraction data for chromium(III) orthophosphate are listed in the "A. S. T. M. Diffraction Data File," while those for chromium(III) pyro- and tripolyphosphates are not. Chromium(III) pyro- and tripolyphosphates were prepared by the following method for the purpose of referring the X-ray diffraction data for chromium(III) pyro- and tripolyphosphates with those for the thermal products. Chromium(III) pyro- and tripolyphosphates were made by adding chromium(III) nitrate to an aqueous solution of sodium pyro- and tripolyphosphates. The precipitate was filtered off and washed with water.[11] The hydrated compound was heated first at 500 °C for 1 h and then at 1000 °C for 1 h. The X-ray diffraction patterns of the dehydrated compounds were taken with a powder method. The determination of the chemical compositions of the compounds were made by paper-chromatographic analysis of the phosphates present in the precipitates and the quantitative analysis of chromium and phosphorus of the dehydrated compounds. The dehydrated compounds were insoluble in water. About one gram of these water-insoluble compounds was mixed completely with 10 g of potassium carbonate and then heated at 800 °C for 20 min in a platinum crucible. Chromium is oxidized to chromate and these water-insoluble compounds are converted to water-soluble compounds. The chromate and phosphate ions in the aqueous solution of the water-soluble compounds were determined by the colorimetric method of analysis;[12] for chromate, the diphenylcarbazide method was used and for phosphate the molybdenum blue method. In the case of the colorimetric analysis of phosphates, 2 ml of the Mo reagent and 1 ml of the reducing solution were used because this method is more suitable than that described in textbooks for the colorimetric analysis of the phosphates contained in water-soluble compounds. Accordingly, the colorimetric measurement of phosphorus must be made under the condition that the concentration of phosphorus is less than 10 γ/50 ml.

The crystalline thermal products of the $NaPO_3$–Cr_2O_3 system were also insoluble in water. The determination of chromium and phosphorus of the crystalline thermal products were made by using the same method as that for chromium(III) pyro- and tripolyphosphates. The quantitative analysis of the phosphates present in the water-soluble thermal products was made as follows.

Paper Chromatography and Colorimetric Determination of Phosphates in the Water-soluble Thermal Products. One-dimensional paper chromatography was used for the separation of the phosphate species contained in the water-soluble thermal products by using the solvents described in a previous paper.[10] About one gram of the product was placed in 50 ml of water and the mixture was stirred for one hour at room temperature. The insoluble part was then filtered off, dried, and weighed for

the purpose of measuring the solubility of the product. About 8 μl of the sample solution was placed on the starting point of Toyo No. 51A filter paper (2 by 50 cm) and developed for 40 h at 5 °C. The identifications and determinations of each phosphate spot on a chromatogram were carried out by using the same method as that described in a previous paper.[6]

The Measurement of the Average Chain Length of Phosphates in Glassy Thermal Products. The method used in a previous paper[6] was adopted for the measurement of the average chain length of polyphosphates contained in the thermal products. The measurement of the average chain length of polyphosphates was achieved for sample solutions of the thermal products with P/Cr ratios larger than 80 and no appreciable effect of chromium ions on the measurement of the average chain length of polyphosphates was observed.

X-Ray Diffractometry. The samples were ground to powder which could pass through a 150 mesh sieve. Their X-ray diffraction patterns were taken by using a powder method on a Toshiba X-ray diffractometer, ADG-102.

Infrared Spectral Measurement. The infrared spectra of the products were recorded on a JASCO infrared spectrophotometer, model IR-G, by using a KBr tablet method.

Results and Discussion

Chromium(III) Pyro- and Tripolyphosphates. The P/Cr ratios of the chromium(III) pyro- and tripolyphosphates obtained by adding chromium(III) nitrate to an aqueous sodium pyro- or tripolyphosphate solution were 1.5 and 1.8, respectively. The values of the P/Cr ratios correspond to the theoretical values of the P/Cr ratios of $Cr_4(P_2O_7)_3$ and $Cr_5(P_3O_{10})_3$. The X-ray diffraction diagrams of the dehydrated chromium(III) pyro- and tripolyphosphates are shown in Fig. 1.

Amount of the Water-soluble Parts in the Thermal Products and Identification of the Thermal Products by X-Ray Diffractometry. The thermal products with P/Cr ratios larger than 80 were amorphous, while those with P/Cr ratios in the range from 1.0 to 50 contained crystalline substances. The X-ray diffraction diagrams of the crystalline thermal products with P/Cr ratios in the range from 1.0 to 3.0 are shown in Fig. 1. The X-ray diffraction diagrams of the thermal products with P/Cr ratios of 1.0 and 2.0 contain peaks of chromium(III) oxide and an unknown crystalline substance. The peaks due to chromium(III) oxide and chromium(III) tripolyphosphate appear in the X-ray diffraction pattern of the thermal product with a P/Cr ratio of 3.0. The X-ray diffraction diagrams for the products with P/Cr ratios in the range from 5.0 to 50 were the same as that for chromium(III) tripolyphosphate and hence chromium(III) tripolyphosphate is the only crystalline substance contained in the thermal products with P/Cr ratios in the range from 5.0 to 50. Accordingly, it could be concluded that the P–O–P linkages of high-polyphosphate in this system are broken to make chromium(III) tripolyphosphate. It is noteworthy that chromium(III) oxide reacts with $NaPO_3$ glass to produce chromium(III) tripolyphosphate and not to make chromium(III) ortho- and pyrophosphates. The unknown crystalline substance and chromium(III) tripolyphosphate present in the thermal products were insoluble in water. The amount of water-soluble parts in the products are listed in Table 1. The results of identification of the crystalline products by X-ray diffractometry are also shown in Table 1.

20—300				2—4	1—3	93—97

phosphates decrease with an increase in the P/Cr ratio, while those of high-polyphosphates increase with an increase in the P/Cr ratio. This result is in good agreement with those of the other systems described in previous papers.[6-10] By the same considerations as in previous papers, it can reasonably be concluded that chromium(III) oxide reacts with sodium metaphosphate to make a Cr–O–P linkage at 1000 °C and that the Cr–O–P linkage of the water-soluble products is readily hydrolyzed to produce chromium and phosphate ions in water solutions. The contents of trimeta- and tetrametaphosphates do not change much with the variation in the P/Cr ratio and hence the formation of trimeta- and tetrametaphosphates may be little affected by chromium.

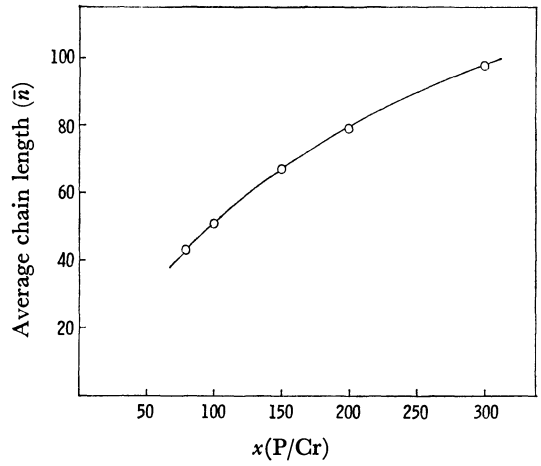

Fig. 2. Variation of average chain length of polyphosphates present in the thermal products with P/Cr ratios larger than 80.

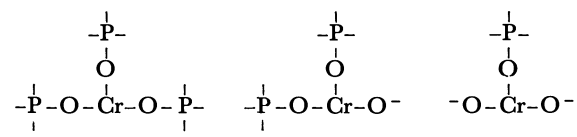
Average Chain Length of Polyphosphates and the Chemical Structure of Glassy Products. The behavior of chromium contained in the glassy and water-soluble thermal products can be examined by measuring the correlation between the average chain length of polyphosphates and the P/Cr ratio of the products,[2,6-10] because the chain length of the polyphosphates present in the thermal products is affected by the coordination number of chromium. To obtain the correlation, it is necessary that the thermal product dissolves completely in water. Therefore, the average chain length of the polyphosphates present in the glassy products with P/Cr ratios larger than 80 was measured. The result is shown in Fig. 2 and indicates that the average chain length of the polyphosphates contained in the glassy products increases with an increase in the P/Cr ratio. This tendency is the same as that of the distribution of polyphosphates obtained by quantitative analysis. Accordingly, it can be concluded that this result is one proof of the presence of the Cr–O–P linkage in the glassy products. The correlation between the chromium coordination number and the average chain length of polyphosphates in the glassy products can be discussed theoretically employing the method described in previous papers.[2,6-10] Depending upon the method, the average chain length, $\bar{n}$, of the polyphosphates in the glass of the $NaPO_3$-Cr_2O_3 system is given by the following equation:

$$(\bar{n}+2)/\bar{n} = (x+y-z+fx)/x \quad (1)$$

where, x, y, and z are respectively the number of phosphorus atoms, P–O–Cr linkages, and Cr–O^- linkages per atom of chromium and where f is the factor shortening the chain length of the polyphosphates, given with respect to an atom of phosphorus. The previous results[2,6-10] indicate that the value of f is in the range from 0.01 to 0.025 under the conditions employed in this experiment. There are three possible structures containing P–O–Cr and Cr–O^- linkages, which are as follows:



The average chain length of the polyphosphates present in the glassy products can be calculated on the basis of these chemical structures. The calculated values are listed in Table 3. When the f factor is 0.01, the calculated values of $\bar{n}$ based on Structure A are very close to the measured ones throughout the range of P/Cr ratios from 80 to 300. From these results, it may be reasonably concluded that the chemical structure of the glassy thermal products of the Cr_2O_3–$NaPO_3$ system with P/Cr ratios larger than 80 is the Structure A and hence the valence of chromium which contributes to the shortening of the chain length of polyphosphates is three. The chromium coordination number in the glassy products may be larger than three (in general, the coordination number of chromium is six or four). The coordination numbers which do not contribute to the shortening of the chain length of polyphsophates cannot be discussed by using the method described above. The P–O–Cr linkage which does not affect the average chain length of polyphosphates may be produced by the interaction between chromium and the oxygen atom of a P=O bond.

Table 3. Average chain length of polyphosphates of the $NaPO_3$-Cr_2O_3 system with P/Cr ratios larger than 80

x (P/Cr)	$\bar{n}$ Found	$\bar{n}$ calcd by Eq. 1 (f=0.01) Structure A (y=3, z=0)	Structure B (y=2, z=1)	Structure C (y=1, z=2)
80	43	42	89	—
100	51	50	100	∞
150	67	67	120	600
200	79	80	133	400
300	98	100	150	300

Infrared Spectra. The infrared spectra of sodium metaphosphate glass, chromium(III) oxide, chromium(III) tripolyphosphate, and the thermal products with P/Cr ratios in the range from 1.0 to 15 are shown in Fig. 3. Since the infrared spectra of the thermal products with P/Cr ratios larger than 20 are the same as that of sodium metaphosphate glass, the existence of the absorptions of the Cr–O–P linkage in the glassy products

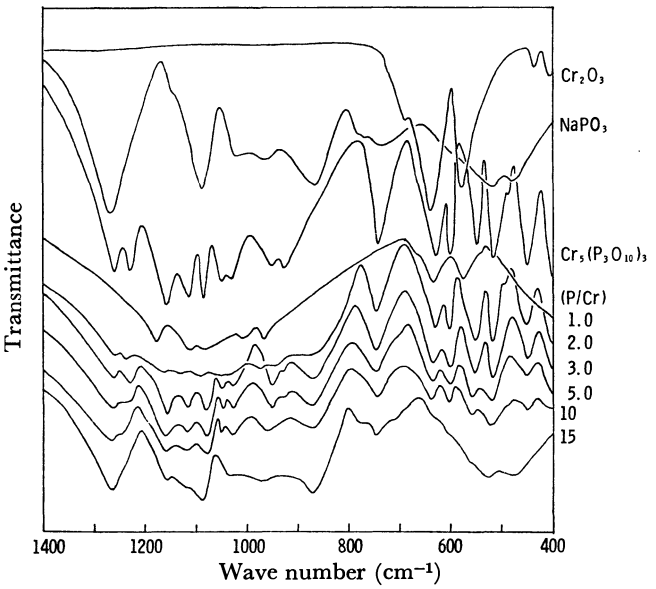


Fig. 3. IR spectra of Cr_2O_3, $NaPO_3$, $Cr_5(P_3O_{10})_3$, and the products with P/Cr ratios from 1.0 to 15.

cannot be discussed. The infrared spectrum of the thermal product with a P/Cr ratio of 1.0 contains the absorptions due to chromium(III) oxide (absorptions at 640 and 580 cm^{-1}) and does not contain an absorption due to chromium(III) tripolyphosphate, while the infrared spectra of the thermal products with P/Cr ratios larger than 2.0 exhibit an absorption attributable to chromium(III) tripolyphosphate. The absorption of chromium(III) tripolyphosphate becomes gradually ambiguous with an increase in the P/Cr ratio from 3.0 to 15. The infrared spectra of the water-insoluble parts which were obtained by treating with water the thermal products with P/Cr ratios of 5.0—50 are the same as that of chromium(III) tripolyphosphate. These results agree well with those obtained above.

Photoinduced One-Electron Reduction of 1-Benzyl-3-carbamoylpyridinium Chloride and 3,5-Bis(ethoxycarbonyl)-2,6-dimethylpyridine[1)]

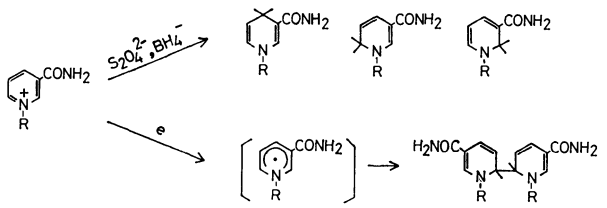
Koji KANO and Taku MATSUO*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 7, 1976)

Photolysis of 1-benzyl-3-carbamoylpyridinium chloride (BNA^+) in aqueous solution in the presence of diethylamine and/or ethylenediaminetetraacetate gives the 6,6′-dimer (**1**), a coupled product of the pyridyl radicals generated by one-electron transfer from alkylamine to photoexcited BNA^+. Thermal one-electron reduction of BNA^+ either with zinc dust/copper sulfate or with magnesium powder in aqueous alkaline medium yields the 4,6′-dimer (**2**) together with a small amount of **1**. In the case of 3,5-bis(ethoxycarbonyl)-2,6-dimethylpyridine (HE_{ox}), the 2,2′-dimer (**3**) is formed as an initial photoreduction product, which is converted into the 4,4′-dimer (**4**) and 1,2-dihydropyridine (**5**) upon prolonged irradiation.

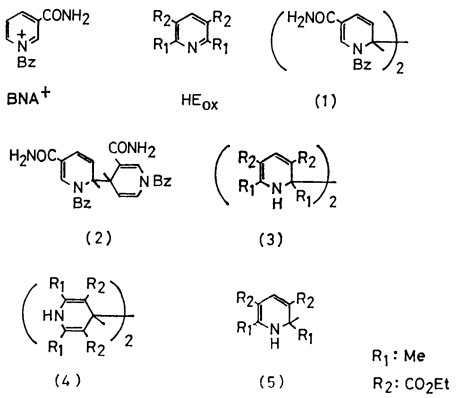
The non-enzymatic reduction of NAD^+ and its analogues is classified into one- and two-electron reductions.[2)] Sodium dithionite and hydroborate are two-electron reducing agents, the former affording 1,4-dihydronicotinamides and the latter 1,2- and 1,6-isomers.[3,4)] On the other hand, the one-electron reduced species (pyridyl radicals) of 1-substituted 3-carbamoylpyridinium ions are obtained either by electrolysis in DMSO[5)] or radiolysis in aqueous 2-propanol,[6,7)] The pyridyl radicals give 6,6′-dimers (Scheme 1) as the final product.[5)] From a synthetic



Scheme 1.

viewpoint, however, neither electrolysis nor radiolysis is a convenient method for preparing the reduced pyridines. In 1959, Wallenfels and Gellrich reported that the reduction of 1-benzyl- and 1-(2,6-dichlorobenzyl)-3-carbamoylpyridinium chlorides either with magnesium powder or with zinc dust/copper sulfate in aqueous alkaline solution gave the 6,6′-dimers in 20—26% yields.[8)]

In the present paper, a new type of one-electron reduction of pyridinium and pyridine compounds is reported.[9)] The compounds investigated are 1-benzyl-3-carbamoylpyridinium chloride (BNA^+) and 3,5-bis(ethoxycarbonyl)-2,6-dimethylpyridine (HE_{ox}), which are also useful as NAD^+ models. Diethylamine (DEA) and ethylenediaminetetraacetate (EDTA) were used as the reducing agents under photo-irradiation. The thermal reduction of BNA^+ was also carried out according to the method of Wallenfels and Gellrich. 4,6′-Dimer (**2**) was obtained as the main reduction product accompanied by a small amount of 6,6′-dimer (**1**). This result differs from that reported by Wallenfels and Gellrich.[8)]



Yellow solid materials adhered to the surface of the lamp upon irradiation of a solution of BNA^+ in water

a) Fluorescence maximum.

containing DEA with a high-pressure mercury lamp. Based on spectroscopic data, the solid material was identified to be the 6,6′-dimer (**1**) as obtained by the coupling of the pyridyl radicals generated by the one-electron reduction of BNA$^+$. The yield of **1** was 50% as calculated on the basis of consumed BNA$^+$. 6,6′-Dimer (**1**) was synthesized by Wallenfels and Gellrich,[8] its UV and NMR spectroscopic data being reported.[8,10] The UV and NMR spectra of **1** obtained in the present experiment are in good agreement with those reported,[8,10] although the mp (164—165 °C (dec)) of **1** we obtained differs distinctly from that given by Wallenfels and Gellrich (mp 191—193 °C (dec)).[11] An attempt was made to prepare the 6,6′-dimer (**1**) by the receipe of Wallenfels and Gellrich.[8] Reduction was carried out either with zinc dust/copper sulfate or with magnesium powder in aqueous ammonia solution, the main product with mp 169 °C (dec) being obtained (yield, 6—20%) in both cases.[11] The UV and NMR spectra (Table 1) suggest that the thermal reduction product is not the 6,6′-dimer (**1**). By means of NMR spectroscopy, the compound was confirmed to be the 4,6′-dimer (**2**) (see Experimental). As in the case of 6,6′-dimer (**1**), 4,6′-dimer (**2**) was rapidly oxidized by methyl viologen in methanol. In the case of Zn/Cu system, a small amount of byproduct (mp 164—165.5 °C (dec), 0.3%) was also isolated together with **2** (20%). Both the spectroscopic data and mp (dec) proved that the byproduct is the same 6,6′-dimer (**1**) as obtained by photoreduction. In spite of the fact that experiment was carried out very carefully, **1** was obtained only in a low yield.

DEA could be replaced with EDTA. In this case, the solution should be made slightly alkaline since **1** decomposes to an unknown compound either in neutral or in acidic medium.

Benzyl and methyl viologens were analogously photoreduced to the corresponding cation radicals in the Ar-flushed aqueous solution (pH 7.9) containing EDTA:

R: CH_2Ph λ_{max} 371, 388, 400, 550, 560, 599, and 660 (sh) nm.
R: CH_3 λ_{max} 367, 384, 395, 570 (sh), 600, and 660 nm.[12]

The pyridine ring itself could also be photoreduced by the above method devised for pyridinium ions. Upon irradiation of a mixture of HE_{ox}, EDTA, and potassium carbonate in 40% (v/v) aqueous acetonitrile, the 2,2′-dimer (**3**) precipitated as very pure, lemon yellow crystals, its yield being 51% as calculated on the basis of consumed HE_{ox}. The 2,2′-dimer (**3**) is hardly soluble in organic solvents, such as acetonitrile, dimethyl sulfoxide, carbon tetrachloride, chloroform, ethanol, methanol, acetone, and benzene, but easily soluble in basic solvents such as pyridine and DEA. Its structure was deduced from the following spectroscopic data. In the NMR spectrum of **3** in pyridine-d_5, the proton signals due to methyl groups at the 6,6′- and

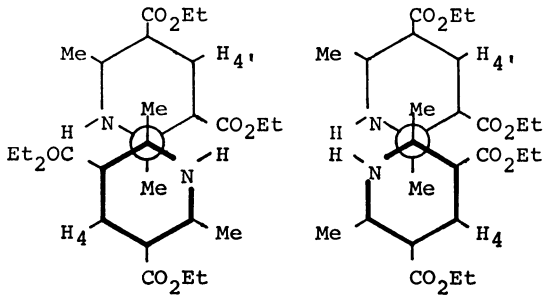

Fig. 1. Steric isomers of the 2,2′-dimer (**3**).

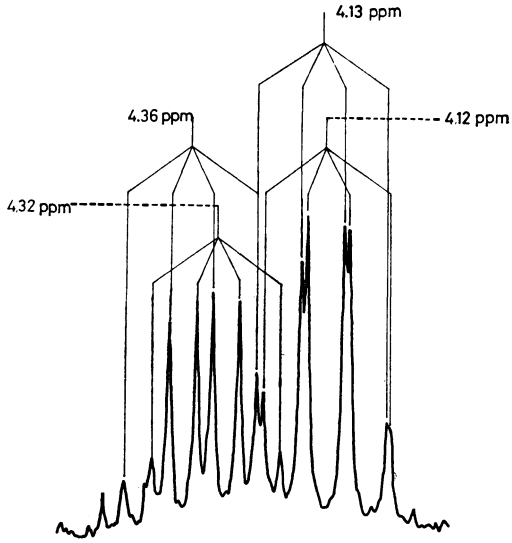

Fig. 2. NMR spectrum of $CO_2CH_2CH_3$ of the 2,2′-dimer(**3**) in DMSO-d_6 (90 MHz).

2,2′-positions are observed at δ 2.11 and 2.58 ppm, respectively, and those due to the ethoxycarbonyl groups at 1.03 and 1.26 ppm. The proton at the 4-position can not be detected because the signal overlaps with that of non-deuterated pyridine (7.68 ppm) in the solvent. As to the methylene protons of the ethoxycarbonyl group, the four quartet signals were observed (Fig. 1). Since **3** contains two asymmetric carbon atoms, it is expected that *meso* and racemic isomers are present (Fig. 2) and that the chemical shift of the methylene protons of the ethoxycarbonyl groups in the two isomers differs. Judging from the distance between the asymmetric center and the protons in question, the difference in the chemical shift for the ethoxycarbonyl groups at 5- and 5′-positions should be less than that for the 3- and 3′-positions. Therefore, the two quartet signals at δ 4.12 and 4.13 ppm should be assigned to the methylene protons at 5(5′)-positions of the *meso* and racemic isomers. The ones at lower magnetic field (δ 4.32 and 4.36 ppm) are thus ascribed to the methylene protons at 3(3′)-positions of these isomers. In agreement with the assignment of the NMR spectra, four different carbonyl absorptions are observed for **3** (Table 1).

2,2′-Dimer (**3**) could not be isolated by the photolysis of HE_{ox} in aqueous acetonitrile containing large

Table 2. Effects of irradiation time on yields of 4 and 5[a)]

Run No.	Irradiation time, h	4, %[b)]	5, %[b)]
1	3	14	12
2	6	19	13
3	6.25	19	17
4	14	3	27

a) A mixture of HE_{ox} (1.0 g) and DEA (20 ml) in 50% (v/v) aqueous acetonitrile (200 ml) was irradiated with a 30W low-pressure mercury lamp under nitrogen atmosphere. b) Except for Run No. 3, the yields of **4** and **5** were determined by NMR spectra of the mixture of **4** and **5** which were obtained by the evaporation of acetonitrile from the photolyzed solution. In Run No. 3, the yields were calculated from the weight of **4** and **5** isolated.

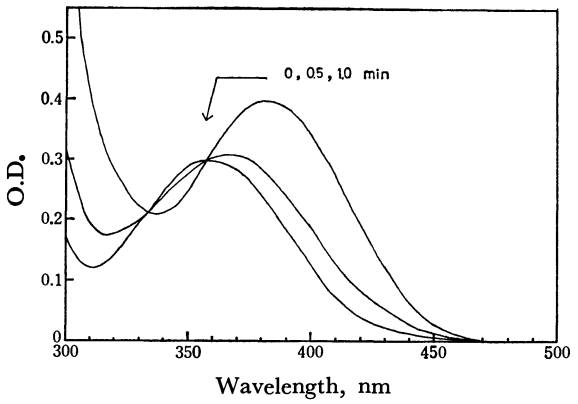

Fig. 3. Photoisomerization of the 2,2′-dimer (**3**) to the 4,4′-dimer (**4**). The 2,2′-dimer (**3**) in methanol was flushed with argon gas and irradiated with beams of light (>420 nm, a Toshiba V-Y42 filter) obtained from a Ushio 500 W super high-pressure mercury lamp.

excess of DEA. Instead, the 4,4′-dimer (**4**) and 3,5-bis(ethoxycarbonyl)-2,6-dimethyl-1,2-dihydropyridine (**5**) were obtained in 19 and 17% yields, respectively. It should be noted that dihydropyridine (**5**) is a two-electron reduced product. The effect of irradiation time on the yield of **4** and **5** is given in Table 2. It is seen that prolonged irradiation increases the yield of **5** at the expense of **4**. This suggests that **5** is formed *via* **4**. 4,4′-Dimer (**4**) (λ_{max} 360 nm) was verified to be almost quantitatively converted to **5** (λ_{max} 373 nm) upon irradiation of the aqueous acetonitrile solution in the presence of DEA, although **5** was not obtained in the absence of DEA.

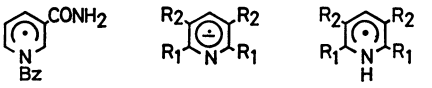
2,2′-Dimer (**3**) precipitated during irradiation (17%) when the photoreaction of HE_{ox} was carried out in the presence of low concentration of DEA. It is suggested that **3** is an intermediate of the photochemical reactions. Figure 3 shows the spectral change along the photolysis of **3** in methanol. Upon irradiation (>420 nm, Ar), the absorption maximum at 382 nm due to **3** shifts to 358 nm which is ascribed to **4**. This is a 1,3-sigmatropic rearrangement, which is considered to proceed quantitatively since isosbestic points are observed at 257, 333, and 358 nm. The scheme of the photoreduction of HE_{ox} in the presence of DEA can be summarized as follows (Scheme 2):

$$HE_{ox} \xrightarrow[DEA]{h\nu} [HE_{ox}H\cdot] \longrightarrow \mathbf{3} \xrightarrow{h\nu} \mathbf{4} \xrightarrow[DEA]{h\nu} \mathbf{5}$$

Scheme 2.

No photoreduction products of HE_{ox} (**3**, **4**, and **5**) in methanol are oxidized by methyl viologen.

The photolysis of either BNA^+ or HE_{ox} in aqueous media containing DEA and/or EDTA afforded the corresponding dimers of one-electron reduced species. In the case of BNA^+, the one-electron transfer from alkylamine to photoexcited BNA^+ should yield a radical **6**. On the basis of both quantum mechanical calculation[13)] and stereochemical consideration, it seems that coupling of the radical takes place at the 6-position.



(6) (7) (8)

In the case of HE_{ox}, on the other hand, a pyridyl radical anion **7** should be a primary photoproduct. According to Brühlmann and Hayon, the pK_a-values for radical anions of nicotinamide analogues are generally larger than 13.[7)] The radical anion **7** can be immediately protonated to yield a free radical **8** under the present experimental conditions. The free radical **8** will afford the dimer **3** as the final product. The pyridyl radicals are thus proposed as the common intermediates in the photoreduction of both BNA^+ and HE_{ox}. The presence of the pyridyl radicals has also been verified by the kinetic study of the reduction of the Hemin pyridine complex (one-electron acceptor) coupled with the photoreduction of BNA^+, HE_{ox}, and other related compounds in the presence of *N,N,N′,N′*-tetramethylethylenediamine.[14)]

In connection with the redox property of the pyridine derivatives, it should be mentioned that the Hemin complex was also reduced by all the above-described dimers (**1**, **2**, **3**, and **4**) although the rates were somewhat lower than those with the pyridyl radicals. On the other hand, the Hemin complex was hardly reduced by two-electron reduced NAD^+-model compounds such as 1-benzyl-1,4-dihydronicotinamide[15)] and 3,5-bis(ethoxycarbonyl)-2,6-dimethyl-1,4-dihydropyridine (Hantzsch ester). This difference may be useful in elucidating the mechanism of redox-systems where pyridine derivatives play important roles.

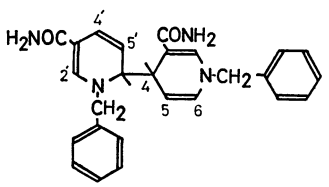
Experimental

Melting points were determined on a hot-stage apparatus and are corrected. Spectroscopic measurements were made with Shimadzu UV-200 and Hitachi 124 recording spectrophotometers, Varian A-60 and Bruker WH-90 FT NMR spectrometers, a Hitachi RML-6E mass spectrometer, and a JASCO DS-403 G grating IR spectrophotometer. A Shimadzu Baush & Lomb Spectronic 505 recording spectro-

photometer was modified for the fluorescence measurements. BNA^{+}[16] and HE_{ox}[17] were prepared according to the procedures given in the literature. Reagent grade DEA (Wako Pure Chem.) and disodium ethylenediaminetetraacetate dihydrate (Dohzin Pharm. Co.), DMSO-d_6 (Stohler Isotope Chem., 99.5%), and pyridine-d_5 (Merck, 99.5%) were used. Water was distilled and deionized with a column of ion-exchange resin. The photolysis in a preparative scale was carried out by the use of Riko immersion-type 100W high-pressure and 30W low-pressure mercury lamps.

Reduction of 1-Benzyl-3-carbamoylpyridinium Chloride with Zinc Dust-Copper Sulfate in Aqueous Ammonia.[8] A solution of 2.5 g copper sulfate pentahydrate in 20 ml of water was gradually poured into water containg 6 g of zinc dust under vigorous stirring at room tempreature. A mixture of 10 ml of 28% aqueous ammonia and 50 ml of methanol was added to it and then 5 g (20 mmol) of BNA^{+} in 20 ml of water was poured into the solution. At this time, the reaction mixture turned yellow. After stirring was continued for 20 min at room temperature, the yellow precipitates and inorganic materials were collected by filtration. The residue was extracted with 20 ml of boiling methanol in nitrogen atmosphere and the insoluble matter was filtered. The residue was further extracted with 30 ml of boiling methanol. The former extract was kept in a refrigerator (*ca.* −5 °C) overnight to give lemon yellow crystals (0.85 g), which was identified to be 4,6′-dimer (**2**) (yield, 20%); mp 168.5—169 °C (dec); NMR (DMSO-d_6): δ 7.38 (s, aromatic ring), 7.18 (s, 2,2′H), 6.78 and 6.38 (broad s, $CONH_2$), 6.36 (d, 4′H or 6H, $J_{4',5'}$ or $J_{5,6}$ 8.0 Hz), 6.20 (d, 6H or 4′H, $J_{5,6}$ or $J_{4',5'}$ 8.0 Hz), 4.79 (q, 5′H, $J_{5',6'}$ 5.0 Hz), 4.66 (q, 5H, $J_{4,5}$ 4.4 Hz), 4.42 (s, NCH_2), 4.00 (d, 4H), and 3.28 ppm (d, 6′H). The NMR spectrum (5 mg/1 ml of DMSO-d_6) was obtained after 100 scans with the Bruker WH-90 FT NMR spectrometer.

When nitrogen was bubbled into a methanolic solution of the latter extract, 13 mg (0.3%) of the 6,6′-dimer (**1**) separated out of the solution; mp 164—165.5 °C (dec). The analytical date are given in Table 1 and in the photochemical section (*vide infra*).



Reduction of 1-Benzyl-3-carbamoylpyridinium Chloride with Magnesium Powder in Aqueous Ammonia.[8] Magnesium powder (3 g) was gradually added into a 1.1% aqueous ammonia solution (100 ml) of BNA^{+} (5 g, 20 mmol) and ammonium chloride (9 g) under vigorous stirring at 48—50 °C, about 1.5 h being required for the addition. Stirring was continued for additional 30 min at 48—50 °C after all of magnesium powder had been consumed. When the reaction was completed, the reaction mixture was cooled with an ice-bath and the yellow precipitates and colorless inorganic solid were collected by filtration. The residue was dissolved into 100 ml of methanol in order to remove inorganic matter and the methanolic layer was concentrated to *ca.* 50 ml. The residue was gradually poured into 200 ml of 2.8% aqueous ammonia under cooling with an ice-bath. The pale yellow precipitates (3 g) were filtered and recrystallized from acetonitrile to give crude 4,6′-dimer (**2**) (mp 144—145.5 °C (dec)). Further recrystallization from methanol afforded the pure 4,6′-dimer (**2**) (0.27 g, 6%); mp 168.7—169 °C (dec).

Photoreduction of 1-Benzyl-3-carbamoylpyridinium Chloride in the Presence of Diethylamine. A solution of BNA^{+} (2 g, 8.0 mmol) and DEA (10 ml, *ca.* 96 mmol) in 140 ml of water was irradiated with a 100W high-pressure immersion lamp under nitrogen bubbling for 2 h. Orange yellow precipiates (119 mg) were collected by filtration. The filtrate was further irradiated for 2 h after the solid covering the lamp wall had been removed. The second precipitates (212 mg) were collected and combined with the former. The NMR spectrum indicated that the precipitates were mainly 6,6′-dimer (**1**) (19%). The crude **1** (67 mg) was recrystallized from methanol and the pale yellow plates obtained were dried at 50 °C overnight to give 42 mg of pure **1**; mp 164—165 °C (dec); NMR (DMSO-d_6): δ 7.29 (s, aromatic ring), 7.18 (s, 2H), 6.97 (broad s, $CONH_2$), 6.04 (d, 4H, $J_{4,5}$ 7.6 Hz), 4.34 (s, NCH_2), 4.33 (q, 5H), and 3.18 ppm (d, 6H, $J_{5,6}$ 5.0 Hz). The NMR spectrum was measured with the Bruker WH-90 FT NMR spectrometer. After the second photolysis, unreacted BNA^{+} was recovered (1.23 g, 61%) from the filtrate.

Photoreduction of 1-Benzyl-3-carbamoylpyridinium Chloride in the Presence of Ethylenediaminetetraacetate. A solution of BNA^{+} (0.5 g, 2 mmol), disodium ethylenediaminetetraacetate dihydrate (1.1 g, 3 mmol), and potassium carbonate (2 g) in 200 ml of water was irradiated with a 30W low-pressure mercury lamp under argon bubbling for 10 h. The precipitates (63 mg, 15%) were filtered and recrystallized from methanol to give the 6,6′-dimer (**1**).

Photoreduction of 3,5-Bis(ethoxycarbonyl)-2,6-dimethylpyridine in the Presence of Ethylenediaminetetraacetate. A solution of HE_{ox} (0.5 g, 2 mmol), disodium ethylenediaminetetraacetate dihydrate (2.25 g, 6 mmol), and potassium carbonate (2 g) in 40% (v/v) aqueous acetonitrile (250 ml) was irradiated with a 30W low-pressure mercury lamp under nitrogen bubbling and stirring for 9.5 h. The lemon yellow precipitates of the 2,2′-dimer (**3**) (171 mg, 34%) were collected by filtration; mp 178—179 °C (dec). HE_{ox} (166 mg, 33%) was recovered by the evaporation of acetonitrile from the filtrate. 2,2′-Dimer (**3**) can be recrystallized from pyridine; mp 175.8—176 °C (dec); NMR (pyridine-d_5): δ 8.98 (braod s, NH), 7.68 (s, 4H?), 4.36 and 4.32 (q, 3,3′-$CO_2CH_2CH_3$), 4.13 and 4.12 (q, 5,5′-$CO_2CH_2CH_3$), 2.58 (s, 2,2′-CH_3), 2.11 (s, 6,6′-CH_3), 1.26 (t, 3,3′-$CO_2CH_2CH_3$, J 7.0 Hz), and 1.03 ppm (t, 5,5′-$CO_2CH_2CH_3$, J 7.0 Hz). The NMR spectrum (10 mg/0.6 ml of pyridine-d_5) was obtained after 35 scans with the Bruker WH-90 FT NMR spectrometer.

Photoreduction of 3,5-Bis(ethoxycarbonyl)-2,6-dimethylpyridine in the Presence of Diethylamine. a) A solution of HE_{ox} (1 g, 4 mmol) and DEA (20 ml, 192 mmol) in 50%(v/v) aqueous acetonitrile (120 ml) was irradiated with a 30W low-pressure mercury lamp under nitrogen bubbling for 6.25 h. The reaction mixture was concentrated *in vacuo* to *ca.* 50 ml. Yellow precipitates were collected by filtration. Unreacted HE_{ox} was recovered from the filtrate as brown oil, which was purified by silica gel column chromatography with ethyl acetate and recrystallized from acetonitrile (284 mg, 28%). The yellow precipitates were recrystallized from acetonitrile to give 193 mg of the 4,4′-dimer (**4**) (19%); mp>200 °C (sublim.). The filtrate was concentrated and the residue obtained was purified by silica gel column chromatography with ethyl acetate to give 172 mg of 3,5-bis(ethoxycarbonyl)-2,6-dimethyl-1,2-dihydropyridine (**5**) (17%); mp 149—153 °C (dec).

The 4,4′-dimer (**4**); NMR (DMSO-d_6): δ 8.35 (broad s, NH), 3.97 (s, 4,4′H), 3.97 (q, $CO_2CH_2CH_3$, J 7.0 Hz), 2.05 (s, CH_3), and 1.18 ppm (t, $CO_2CH_2CH_3$).

3,5-Bis(ethoxycarbonyl)-2,6-dimethyl-1,2-dihydropyridine (**5**); Mass: 253 (M^{+}); UV: λ_{max}^{MeOH} 212, 283, and 373.5

nm; fluorescence: F^{MeOH}_{max} 490 nm; NMR (DMSO-d_6): δ 7.70 (s, 4H), 6.93 (broad s, NH), 4.52 (q, 2H, $J_{2,Me}$ 6.5 Hz), 4.18 (q, $CO_2CH_2CH_3$, J 7.0 Hz), 2.39 (s, $6CH_3$), 1.30 (t, $CO_2CH_2CH_3$), and 1.18 ppm (d, $2CH_3$). The NMR spectrum of **4** and **5** were measured with the Varian A-60 spectrometer.

b) A mixture of HE_{ox} (0.5 g, 2 mmol), DEA (1 g, 14 mmol), and 100 ml of a phosphate buffer solution (1/15 M, pH 8.0) was disolved into 150 ml of 67%(v/v) aqueous acetonitrile. The HE_{ox} solution was irradiated with a 30W low-pressure mercury lamp under nitrogen bubbling and stirring for 4 h. The lemon yellow precipitates were collected by filtration and washed with water and acetonitrile to give pure 2,2′-dimer (**3**) (84 mg, 17%); mp 176—176.5 °C (dec).

11) The melting points (decomposition points) of **1** (164—165.5 °C) and **2** (169 °C) were reproducible as far as the measurement was made on a hot-stage apparatus. However, **1** and **2** decomposed at >187 °C and 180—182 °C, respectively, and turned into brown resins when the measurement was carried out with degassed samples in capillary tubes and a heating bath. Both resins gradually melted at 210—220 °C. **1** and **2** might have been oxidized by air during the course of mesurement on the hot-stage, the resulting oxidation products decomposing at 164—165.5 °C (**1**) and 169 °C (**2**). The difference in the mp (dec) of **1** between the present experiment and that by Wallenfels and Gellrich seems to be due to the difference in the method of measurement.

Synthesis of Dihalogenobis(2-pyridinethiolato)tin(IV) by the Oxidative Addition of Disulfide to Tin(II) Halides—Consideration on the Coordination Structure[1]

Mitsuo MASAKI and Satoshi MATSUNAMI

Polymer Research Laboratory, Ube Industries, Ltd., Minami-Kaigan, Goi, Ichihara, Chiba 290

(Received May 11, 1976)

The reaction of di-2-pyridyl disulfide with tin(II) halides was found to give dihalogenobis(2-pyridinethiolato)-tin(IV). The oxidative addition reaction was successfully extended to the preparation of other dihalogenodithiolatotin(IV) complexes. Dichlorobis(2-pyridinethiolato)tin(IV) was also prepared by the reaction of 2(1*H*)-pyridinethione with tin(IV) chloride and proposed to be a monomeric, octahedral complex with a four-membered (Sn, S, C, and N) chelate ring from its molecular weight and IR spectral data. Dichlorobis(2-quinolinethiolato)tin(IV) could be isolated similarly as a stable complex. However, attempts to isolate the dichlorodithiolatotin(IV) in which an intramolecular chelation seems hardly possible were unsuccessful. The great stability of bis(2-pyridinethiolato)- and bis(2-quinolinethiolato)-dihalogenotin(IV) could be ascribed to the intramolecular four-membered chelate ring formation for the six-coordination of tin atom.

In a previous paper, an isolation of a stable complex, dichlorobis(2-pyridinethiolato)tin(IV) (**1**) was reported.[2] Several types of stable dihalogenodithiolatotin(IV) complexes, formed with dithiocarbamato,[3] phosphinodithionito,[4] alkoxycarbonylmethanethiolato,[5] 1,3-diphenyl-3-thioxo-1-propanonato[6] and 2-pyridinethiolato *N*-oxide[7] are known. These ligands act as a bidentate in the complexes and allow the intramolecular chelation for six-coordination of tin atom. Six-membered(Sn, S, 3 C, and O), five-membered (Sn, S, C, C or N, and O) and four-membered (Sn, S, C or P, and S) chelate ring structures have been proposed for the complexes. Six-coordination of the tin atom seems possible for the complex **1** by a coordination of the pyridine nucleus through nitrogen. Such a coordination, however, would lead to the formation of a new type four-membered (Sn, S, C, and N) chelate ring.

This paper deals with the synthesis of dihalogenobis-(2-pyridinethiolato)tin(IV) by the oxidative addition reaction of di-2-pyridyl disulfide to tin(II) halides, an extension of the reaction to prepare other dihalogenodithiolatotin(IV) complexes, and an observation on the structure of **1**, as well as a consideration on a relationship between the stability of dihalogenodithiolatotin-(IV) complex and its coordination structure.

Results and Discussion

Synthesis. When tin(II) chloride was mixed with an equimolar or excess amount of di-2-pyridyl disulfide in an organic solvent such as 1,2-dichloroethane or benzene at room temperature, an exothermic reaction occurred and dichlorobis(2-pyridinethiolato)-tin(IV) (**1**) was produced in a high yield. The product was identified by IR spectrum with the specimen prepared from the reaction of 2(1*H*)-pyridinethione with tin(IV) compounds. Analogous reactions of the disulfide with tin(II) bromide and tin(II) iodide afforded dibromobis(2-pyridinethiolato)tin(IV) and diiodobis(2-pyridinethiolato)tin(IV) in high yields. The reactions of bis(substituted 2-pyridyl) disulfides with tin(II) chloride proceeded in a similar way to give the corresponding dichlorodithiolatotin(IV) complexes. The results are given in Table 1.

Treatment of di-2-pyridyl disulfide *N,N'*-dioxide with tin(II) chloride or fluoride in an aqueous hydrohalogenic acid gives the complex of the dioxide with the tin(II) halide.[8] Dihalogenobis(2-pyridinethiolato *N*-oxide)-tin(IV) was prepared from 2-pyridinethiol *N*-oxide and tin(IV) halide.[7] In contrast, the treatment of di-2-pyridyl disulfide with tin(II) chloride in an aqueous hydrochloric acid afforded neither the tin(II) complex nor **1**, but 2(1*H*)-pyridinethione in 75% yield. No report seems to have appeared on such an oxidative addition of disulfide to tin(II) halide.[9]

The reaction was successfully extended to the preparation of other dihalogenodithiolatotin(IV) complexes. Dichlorobis(ethoxycarbonylmethanethiolato)tin(IV) was obtained from the reaction of bis(ethoxycarbonylmethyl) disulfide with tin(II) chloride in refluxing ethanol. The reaction of bis(dialkylthiocarbamoyl) disulfide with tin(II) chloride or fluoride in 1,2-dichloroethane afforded the corresponding dihalogenobis(dialkyldithiocarbamato)tin(IV), respectively. Since tin(II) halides are almost insoluble in 1,2-dichloroethane or benzene, the use of a soluble complex of tin(II) halide with an inert organic ligand such as triphenylphosphine oxide or hexahydro-2*H*-azepin-2-one was attempted with successful results. The advantage of this method lies in the fact that the reaction can be carried out smoothly in a homogeneous system affording a highly pure product in a good yield without purification process. Dichlorobis(2-pyridinethiolato *N*-oxide)-tin(IV) was prepared readily from the corresponding disulfide and the complex of tin(II) chloride with the ligand mentioned above. The results are given in Table 1.

Complex **1** can be obtained from the reaction of 2(1*H*)-pyridinethione with dichlorobis(organo-oxy)tin-(IV) such as bis(acetylacetonato)dichlorotin(IV).[2] It was also prepared either by the reaction of 2(1*H*)-pyridinethione with tin(IV) chloride in the presence of base, or by the treatment of tetrachlorobis[2(1*H*)-pyridinethione]tin(IV) with a large excess of water. The treatment of **1** with hydrogen chloride under anhydrous conditions afforded tetrachlorobis[2(1*H*)-pyridinethione]tin(IV). The results are illustrated in Scheme 1.

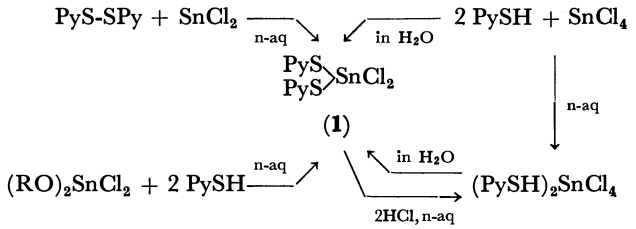
a) A and B indicate procedures similar to methods *a*) and *b*) for **1**, respectively, C indicates a procedure similar to the method reported for **1**.[2] b) Mol wt: Found: 481; Calcd: 466. c) refl.: refluxing temperature. d) The solvent in parentheses was used for separation of the products after termination of the reaction. e) The product could be confirmed only by mass spectrum; *m/e* 522(M^+).

Observation on Structure. Complex **1** is monomeric in dilute methyl isobutyl ketone (osmometry) at ambient temperature. The mass spectrum of **1** exhibits the monotin-containing, polyisotopic molecular ion (*m/e* 410) as the highest mass feature, which corresponds to the parent peak of the monomer. The remaining major peaks (*m/e* 375, 340, 300, 265, and 230) in the spectrum can be assigned to species resulting from the loss of one or two chlorine and/or a pyridinethiolato group from the parent molecular ion. However, no molecular ion corresponding to ditin-containing species was observed. This suggests that **1** is the monomeric tin(IV) complex.

The IR spectrum of **1** exhibits four bands due to



Py: pyridyl, n-aq: in non-aqueous organic solvent

Scheme 1.

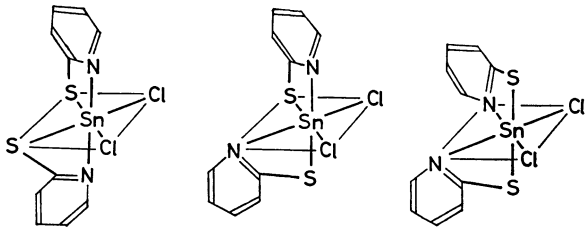


Fig. 1. Three possible structures for **1**. The enantiomers are possible for the respective structures.

ring vibration (C=C/C=N stretching) at 1580(s), 1550 (m), 1435(s), and 1420 cm^{-1}(s) in the 1600—1400 cm^{-1} region. This absorption pattern corresponds to that of di-2-pyridyl disulfide [1570(s), 1555(m), 1440(s), and 1410 cm^{-1} (s)], rather than to that of 2(1*H*)-pyridinethione [1610(m), 1575 (s; N–H bending), 1500(w), and 1435 cm^{-1} (m)]. The spectrum of **1** exhibits no remarkable band in C=S stretching spectral region, while a very strong intensity absorption band at 1136 cm^{-1} is observed in the spectrum of 2(1*H*)-pyridinethione. This indicates that the two 2-pyridinethiolato ligands in **1** exist not in an unequivocal thione form but rather in the thiol form like di-2-pyridyl disulfide. On the other hand, a difference in the spectra between **1** and di-2-pyridyl disulfide is observed in the absorption bands due to ring vibrations and C–H bending vibrations. The ring vibration frequencies which are present at 990 and 610 cm^{-1} in di-2-pyridyl disulfide shift to 1010 and 650 cm^{-1} in **1**, respectively. The shift to higher frequency region confirms the coordination of pyridine nucleus through nitrogen to tin atom.[10] The C–H out of plane bending vibration bands in **1** are at 770(m), 755(m), and 720 cm^{-1} (m), while the absorptions are at 750 (s; doublet) and 710 cm^{-1} (m) in the disulfide. The shift to higher frequency region in **1** can be interpreted again by the coordination of pyridine nucleus through nitrogen, which are likely to cause a depletion of π-electron density on the pyridine ring.[11] Additional information is available in the 500—200 cm^{-1} spectral region. Since a decisive assignment of all the bands in this region is difficult, dimethylbis(2-pyridinethiolato)tin(IV) was synthesized for comparison from dichlorodimethyltin(IV) and 2(1*H*)-pyridinethione. It was found that the three strong absorption bands at 310, 300, and 270 cm^{-1} are characteristic of **1**. The former two bands can be assigned to the Sn–Cl vibrations, since the frequency range is quite close to that of six-coordinated octahedral tin(VI) complexes[10,12–14] and absorption due to Sn–N vibration should be in a lower frequency region.[14] Two Sn–Cl stretching bands suggest *cis* configuration for the chlorine atoms in this complex, since only one Sn–Cl stretching band is expected for the *trans* configuration.[2,12]

Thus, six possible structures can be envisaged for **1**, *cis* Sn–S and *trans* Sn–N, *cis* Sn–S and *cis* Sn–N, and *trans* Sn–S and *cis* Sn–N, and their respective enantiomers. Three possible structures are shown in Fig. 1. However, it is not clear which structure is favorable, since no decisive information is available as to whether the two sulfur–tin bonds are *cis* or *trans*.

Consideration on Stability. Dihalogenobis(2-pyridinethiolato)tin(IV) is not sensitive to hydrolysis, being energetically so stable that it can be readily obtained under mild conditions from various starting materials including highly stable bis(acetylacetonato)dichlorotin(IV).[15] All the monomeric, octahedral dihalogenodithiolatotin(IV) complexes reported hitherto[3–7] are similarly stable. However, there has been no report on the dihalogenodithiolatotin(IV) complexes in which an intramolecular chelation is absent, except bis(benzenethiolato)dichlorotin(IV). Klages *et al.* reported that bis(benzenethiolato)dichlorotin(IV) can be obtained by the thermal dehydrochlorination of the complex prepared from 2 equiv of benzenethiol and tin(IV) chloride.[16]

In the course of repeated experiments on the reaction of benzenethiol with tin(IV) chloride in molar ratio 2 : 1 under several conditions, we could not isolate bis(benzenethiolato)dichlorotin(IV) but obtained diphenyl disulfide and tin(II) chloride together with tetrakis(benzenethiolato)tin(IV). This suggests that bis(benzenethiolato)dichlorotin(IV) is so unstable as to decompose giving diphenyl disulfide and tin(II) chloride or to disproportionate to tetrakis(benzenethiolato)-tin(IV) and tin(IV) chloride.

The stability of the dihalogenobis(2-pyridinethiolato)-tin(IV) could be ascribed to the octahedral structure with the four-membered chelate ring condensed with pyridine ring. In order to confirm this, syntheses of several dichlorodithiolatotin(IV) were attempted.

The reaction of bis(acetylacetonato)dichlorotin(IV) with 2(1*H*)-quinolinethione or 4-methyl-2(1*H*)-quinolinethione gave dichlorobis(2-quinolinethiolato)tin(IV) or its 4-methyl homolog as a stable complex in a good yield, as expected. Attempts to prepare dichlorotin-(IV) derivatives of five-membered heterocyclethiol[17] were then made by reactions of bis(acetylacetonato)-dichlorotin(IV) or dichlorobis(hexahydro-2*H*-azepin-2-onato)tin(IV) with the various thiols or by reactions of tin(II) chloride with the corresponding disulfides. However, all the attempts were unsuccessful except for dichlorobis(2-benzothiazolethiolato)tin(IV), which could be obtained from either of the reactions as a very unstable product.

The unsuccessful syntheses can be ascribed to the unstability of the desired products. Dichlorotin(IV) derivative of the five-membered heterocyclethiols would not take an octahedral structure, since an intramolecular chelation would be hardly possible owing to the strain of four-membered chelate ring condensed with the five-membered cycle.[18] The unstability of a dichlorodi-

Table 2. Substituted dipyridyldisulfides [RSSR]

thiolatotin(IV) which is not octahedral was also supported by an unsuccessful preparation of dichlorotin(IV) derivative of ethanethiol or phenylmethanethiol.

The results suggest that six-coordination with an intramolecular chelation is of considerable importance for stabilization of a monomeric dihalogenodithiolatotin(IV) complex.

Experimental

All the melting points were determined in a liquid bath and are uncorrected. The products were identified, unless otherwise stated, by comparison of the melting points and IR spectra with those of authentic samples as well as elemental analyses. The IR spectra were measured in KBr disk with a Hitachi Perkin-Elmer 225 Grating Infrared Spectrometer and a JASCO IR-G Grating Infrared Spectrometer. The molecular weight was determined in methyl isobutyl ketone with a Hitachi 115 Vapor Pressure Osmometer.

Materials. Commercial anhydrous $SnCl_2$ was used after drying over sulfuric acid. Substituted pyridyl disulfides were prepared from the corresponding substituted pyridinethiol by a procedure midified from that described for the preparation of di-2-pyridyl disulfides.[19] Appropriate thiol (0.1 mol) was dissolved in a solution of sodium ethoxide (0.1 mol) in ethanol (80—160 ml). To the resulting solution was added dropwise a solution of iodine (0.05 mol) in ethanol (90—190 ml). The precipitated product was collected and recrystallized. When the reaction mixture was homogeneous, it was concentrated under reduced pressure, and the residue was treated with water (120 ml) to give the crude disulfide, which was recrystallized. The results for new compounds are given in Table 2.

Dichlorobis(2-pyridinethiolato)tin(IV) **1**. *a) Reaction of Di-2-pyridyl Disulfide with $SnCl_2$*: A solution of di-2-pyridyl disulfide (19.40 g, 88.1 mmol) in 1,2-dichloroethane (EDC, 70 ml) was added drop by drop to a suspension of $SnCl_2$ (13.76 g, 72.6 mmol) in EDC (50 ml) at 10 °C and the mixture was stirred at room temperature for 12 h. The precipitate was collected by filtration, washed with EDC(200 ml), and dried to give 28.86 g of a slightly pale yellow powdery solid; mp 275—277 °C (dec). The solid (6 g) was recrystallized from methyl isobutyl ketone (650 ml) to give slightly pale yellow prisms (4.33 g); mp 275—277 °C (dec). The product was identified with the specimen reported previously.[2] Yield, 97%. Mol wt: Found: 385; Calcd: 410.

The use of a solution of triphenylphosphine oxide–tin(II) chloride (41.22 g, 88.1 mmol) complex or hexahydro-2*H*-azepin-2-one–tin(II) chloride (36.64 g, 88.1 mmol) complex in EDC in place of the suspension of $SnCl_2$ gave a similar result.

b) Treatment of Tetrachlorobis[2(1H)-pyridinethione]tin(IV) with Triethylenediamine: A solution of trietylenediamine (2.81 g, 25 mmol) in benzene (30 ml) was added drop by drop to a suspension of tetrachlorobis[2(1*H*)-pyridinethione]tin(IV) (12.07 g, 25 mmol) in benzene (120 ml) at room temperature. After completion of the addition, the mixture was refluxed by heating for 2 h. The reaction mixture was filtered to give 14.69 g of a mixture of **1** and triethylenediamine dihydrochloride. The mixture was washed repeatedly with ice-water and then dried to give 10.04 g (98%) of **1**; mp 275—277 °C (dec).

c) Treatment of Tetrachlorobis[2(1H)-pyridinethione]tin(IV) with Water: Tetrachlorobis[2(1*H*)-pyridinethione]tin(IV) (4.83 g 10 mmol) was suspended in water (100 ml) and the mixture was stirred vigorously at room temperature for 20 min. The suspension was filtered, washed with water, and dried to give 3.45 g (84%) of **1**; mp 275—277 °C (dec).

Dichloro(triphenylphosphine oxide)tin(II). To a solution of triphenylphosphine oxide (5.56 g, 20 mmol) in benzene (40 ml) was added $SnCl_2$ (3.78 g, 20 mmol), and the mixture was heated with stirring to the refluxing temperature. The resulting solution was filtered and left to stand at room temperature under nitrogen atmosphere. The precipitated crystals were collected and washed with a small amount of benzene to give 9.92 g of dichloro(triphenylphosphine oxide)tin(II)–benzene adduct (1 : 1) as colorless crystals; mp 81—84 °C (sinter at 67 °C). Found: C, 52.97; H, 3.89; Cl, 12.91%. Calcd for $C_{30}H_{26}Cl_2OPSn$; C, 52.89; H, 3.70; Cl, 13.01%.

The adduct was dried at 50 °C under reduced pressure to give the benzene free adduct; mp 96—97 °C.

Found: C, 46.13; H, 3.37; Cl, 15.14%. Calcd for $C_{24}H_{20}Cl_2OPSn$: C, 46.16; H, 3.21; Cl, 15.18%.

4,6-Dimethyl-2-pyridinethiol. A suspension of 3-cyano-4,6-dimethyl-2-pyridinethiol[20] (48.21 g, 294 mmol) in 250 ml of aqueous hydrobromic acid (48%) was heated with refluxing for 4 h and left to stand at room temperature for several hours. The resulting precipitate was filtered and recrystallized from ethanol (1700 ml) to give 9.31 g (17%) of 2-mercapto-4,6-dimethyl-3-pyridinecarboxylic acid; mp 253—254 °C (dec). Found: C, 52.40; H, 4.99; N, 7.57; S, 17.70%. Calcd for $C_8H_9NO_2S$: C, 52.44; H, 4.95; N, 7.64; S, 17.50%.

The filtrate separated from the carboxylic acid was diluted with water (1500 ml) and allowed to stand overnight at room temperature to give 11.64 g of yellow precipitate. Recrystallization from acetonitrile (800 ml) gave 7.50 g (18%) of the title compound as yellow prisms; mp 239—241 °C. Found: C, 60.42; H, 6.52; N, 10.18; S, 22.74%. Calcd for C_7H_9NS: C, 60.39; H, 6.52; N, 10.06; S, 23.03%.

Ethyl 2-Mercapto-6-methyl-3-pyridinecarboxylate. Into a suspension of 2-mercapto-6-methyl-3-pyridinecarboxylic acid[21] (14.44 g, 85.3 mmol) and ethanol (200 ml) was passed dry hydrogen chloride with refluxing by heating for

5 h and the mixture was allowed to stand at room temperature overnight. The resulting crystalline precipitate was collected (9.60 g) and neutrallized by treating with an aqueous solution of sodium hydrogen carbonate. Recrystallization from diisopropyl ether (1500 ml) gave 5.41 g (32%) of yellowish prisms; mp 129—131 °C. Found: C, 54.69; H, 5.40; N, 7.11; S, 16.23%. Calcd for $C_9H_{11}NO_2S$: C, 54.80; H, 5.62; N, 7.10; S, 16.22%.

Ethyl 2-Mercapto-4,6-dimethyl-3-pyridinecarboxylate. Into a homogeneous mixture of ethyl cyanoacetate (80 g, 0.7 mol), pyridine (80 ml) and triethylamine (50 ml) was passed dry hydrogen sulfide at room temperature for 7 h. The reaction mixture was poured into water (250 ml) and extracted three times with diisopropyl ether. The combined extracts were concentrated and the residue was chromatographed on a silica gel (Wakogel C-200) column, immersed in benzene. Elution with benzene–1-butanol (4 :1) afforded ethyl thiocarbamoylacetate (55.33 g) as the first running substance. A mixture of the thiocarbamoylacetate (40.22 g, 0.27 mol), acetylacetone (54.7 g, 0.55 mol) and triethylamine (10 g) was heated at 50 °C for 5 h, and then treated with diisopropyl ether (100 ml). The crystalline product was recrystallized twice from isopropyl alcohol (350 ml)–diisopropyl ether (150 ml) to give 35 g (61%) of pale brown needles; mp 154.5—155.5 °C. Found: C, 57.05; H, 6.25; N, 6.76; S, 15.00%. Calcd for $C_{10}H_{13}NO_2S$: C, 56.85; H, 6.20; N, 6.63; S, 15.17%.

Reaction of **1** *with Hydrogen Chloride.* Into a suspension of **1** (4.10 g, 10 mmol) in EDC (100 ml) was passed dry hydrogen chloride (400 ml) below −20 °C. The reaction mixture was concentrated under reduced pressure, and the residue was treated with EDC (100 ml). Filtration followed by drying at 100 °C under reduced pressure for 5 h gave 4.83 g (100%) of tetrachlorobis[2(1*H*)-pyridinethione]tin(IV), which was identified with the authentic specimen described below.

Tetrachlorobis[2(1H)-pyridinethione]tin(IV). A solution of tin(IV) chloride (3.13 g, 12 mmol) in EDC (20 ml) was added drop by drop to a solution of 2(1*H*)-pyridinethione (2.67 g, 24 mmol) in EDC (80 ml) with stirring at room temperature. After the addition, the mixture was stirred for 15 h. The resulting solid was collected by filtration, washed with EDC (30 ml), and dried to give 5.79 g (100%) of yellow crystalline powder; mp 224—226 °C. Found: C, 25.22; H, 2.12; N, 6.11; S, 13.34; Cl, 29.10%. Calcd for $C_{10}H_{10}Cl_4N_2S_2Sn$: C, 24.87; H, 2.09; N, 5.80; S, 13.28; Cl, 29.37%.

Dimethylbis(2-pyridinethiolato)tin(IV). To a solution of sodium ethoxide (30.4 mmol) in ethanol (150 ml) was added 2(1*H*)-pyridinethione (3.38 g, 30.4 mmol) and then dimethyldichlorotin(IV) (1.82 g, 15.2 mmol). After being stirred at room temperature for 2 h, the mixture was concentrated and the residue was treated with water (200 ml). The insoluble substance was collected by filtration, washed with water (30 ml) and dried to give 2.96 g of crude product, which was recrystallized from isopropyl alcohol (40 ml) to give 2.62 g (47%) of colorless needles; mp 139 °C. IR (KBr): 1570, 1550, 1445, 1410, 990, 740, 720, 620, 395, and 360 cm^{-1}. Found: C, 39.00; H, 3.77; N, 7.39; S, 17.41%. Calcd for $C_{12}H_{14}N_2S_2Sn$: C, 39.05; H, 3.82; N, 7.59; S, 17.38%.

An Attempted Synthesis of Bis(benzenethiolato)dichlorotin(IV). A solution of bis(benzenethiol)tetrachlorotin(IV),[16] prepared by adding a solution of tin(IV) chloride (10.42 g, 40 mmol) in EDC (50 ml) to a solution of benzenethiol (8.82 g, 80 mmol) in EDC (100 ml) below −20 °C, was refluxed by heating for 8 h, during which dry nitrogen gas was passed through a capillary in the mixture, in order to remove hydrogen chloride formed. Eighty percent of hydrogen chloride based on benzenethiol was trapped in 0.5 M aqueous sodium hydroxide solution from the exhaust nitrogen gas. The product precipitated in the reaction mixture was collected by filtration and confirmed to be $SnCl_2$ (1.20 g, 16% based on $SnCl_4$) by being converted into dichloro(triphenylphosphine oxide)tin(II), which was identified with the authentic sample. To the filtrate was added triphenylphosphine oxide (9.39 g, 33.7 mmol), and the mixture was stirred for 0.5 h. The mixture was then concentrated and the residue was treated with benzene (150 ml). The resulting precipitate was collected by filtration, washed with benzene (70 ml), and dried to give 13.72 g (42% based on $SnCl_4$ used) of tetrachlorobis(triphenylphosphine oxide)tin(IV); mp 330—332 °C (lit,[22] mp 323 °C). The filtrate separated from the tin(IV) complex and the washing were combined and concentrated, and to the residue was added hexane (30 ml). The insoluble yellow crystals were collected by filtration and washed with hexane (15 ml×2). Crude tetrakis(benzenethiolato)-tin(IV) (**2**) was obtained: 6.40 g. The combined filtrate and washings were concentrated and the residue was chromatographed on a silica gel column (Wakogel C-300) immersed in hexane. Elution with hexane afforded 1.35 g (7.7% based on benzenethiol) of diphenyl disulfide; mp 58—60 °C (lit,[23] mp 60—62 °C). Subsequent elution with benzene gave 1.26 g of **2**, which was identified by its IR spectrum. Two crops of **2** were combined and recrystallized from isopropyl alcohol (220 ml). Pale yellow needles, 4.06 g (18% based on $SnCl_4$); mp 65—66.5 °C (lit,[24] 63—64 °C).

The authors wish to express their gratitude to Dr. Masao Horio, Prof. Emeritus, Kyoto University, and Dr. Shotaro Sugiura, President, Polymer Research Laboratory, Ube Industries, for their encouragement.

Resolution of Amino Acids. XII. Preparation of L-2-Amino-5-arylpentanoic Acids, Constituent Amino Acids in AM-Toxins[1,2]

Yasuyuki SHIMOHIGASHI, Sannamu LEE, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 13, 1976)

The L-forms of 2-amino-5-(*p*-methoxyphenyl)pentanoic acid (Amp), 2-amino-5-phenylpentanoic acid (App), and 2-amino-5-(*p*-hydroxyphenyl)pentanoic acid (Ahp) are constituent amino acids in AM-toxins. The *O*-methyl linkage of L-Amp was hydrolyzed gradually by heating with hydrochloric acid. A procedure without drastic acid treatment is given for the synthesis and resolution of Amp. Diethyl [3-(*p*-methoxyphenyl)propyl]acetamidomalonate (**3a**) was saponified to the corresponding malonic acid (**5a**), and **5a** was converted into acetyl-DL-Amp (DL-**6a**) by decarboxylation. The DL-**6a** and acetyl-DL-App were resolved by acylase to afford L-Amp and L-App, respectively. The L-Ahp was prepared from L-Amp by acid treatment.

A toxic substance isolated from *Alternaria mali* was named alternariolide by Okuno *et al.*[3] and AM-toxin I by Ueno *et al.*[4] They confirmed the structure to be a cyclic tetradepsipeptide which contains L-2-amino-5-(*p*-methoxyphenyl)pentanoic acid (L-Amp, L-**1a**) as a constituent.[3,4] Later Ueno *et al.* clarified the structures of AM-toxin II[4] and III,[5] indicating that II contains L-2-amino-5-phenylpentanoic acid (L-App, L-**1b**) and III L-2-amino-5-(*p*-hydroxyphenyl)pentanoic acid (L-Ahp, L-**1c**).[6] We

App (**1b**)	H
Ahp (**1c**)	OH

undertook to synthesize AM-toxin I, II, and III with the intention of preparing three L-amino acids (L-**1a, b, c**). This paper deals with the synthesis of acetyl-DL-Amp and acetyl-DL-App, their subsequent optical resolution by acylase to afford L-Amp and L-App, and the preparation of L-Ahp from L-Amp by demethylation.

Okuno *et al.* reported the synthesis of DL-Amp by Strecker method which involves heating with hydrochloric acid.[7] There has been no report on the synthesis of L-Amp. Ueno *et al.*[4] and Okuno *et al.*[7] described the isolation of L-Amp by heating AM-toxin I with 6 M hydrochloric acid at 110 °C for 20 h, but they reported neither occurrence nor isolation of Ahp in the acid hydrolysate. The results indicate that *O*-methyl linkage in Amp is quite stable during the course of acid treatment. Izumiya and Nagamatsu prepared D-tyrosine from *O*-methyl-D-tyrosine (*O*-Me-D-Tyr) by refluxing in 48% hydrobromic acid.[8] Hirota *et al.* also isolated D-tyrosine together with *O*-Me-D-Tyr by heating Cyl-2, a cyclic tetrapeptide containing *O*-Me-D-Tyr residue as a constituent,[9] with 6 M hydrochloric acid at 115 °C for 15 h. These reports stimulated us to study the stability of *O*-methyl group of Amp against acid treatment. Both L-Amp and *O*-Me-L-Tyr were heated with 6 M hydrochloric acid at 110 °C for certain intervals, and the resulting solution was subjected to an amino acid analysis for determination of the amount of Ahp or tyrosine. The result is shown in Fig. 1. Unexpectedly the rate of demethylation of L-Amp was slightly greater than that of *O*-Me-L-Tyr.

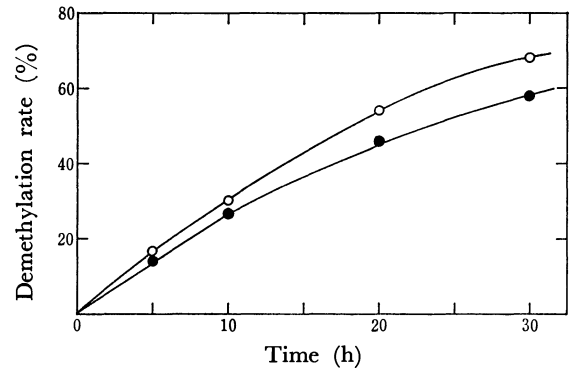

Fig. 1. Time course of demethylation of *O*-methyl-α-amino acids with 6 M HCl at 110 °C.
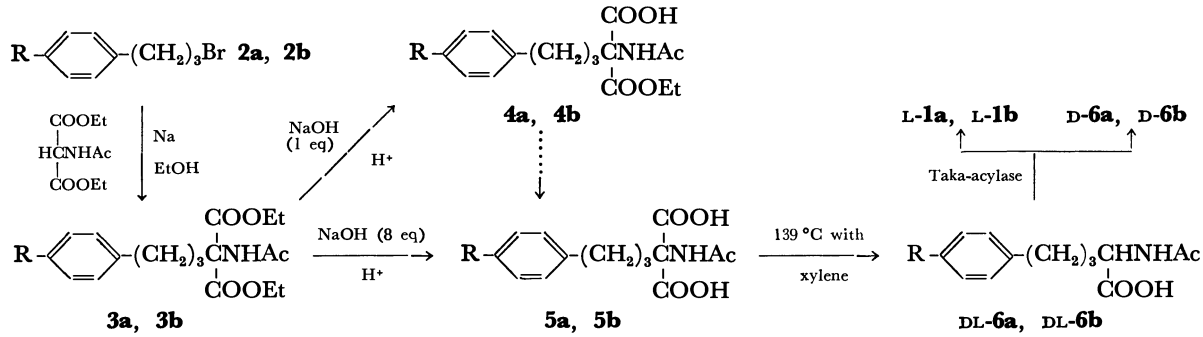
○: L-Amp, ●: *O*-Me-L-Tyr.



Scheme 1. Synthesis and resolution of acetyl-DL-amino acids (DL-**6a**, DL-**6b**).

Table 1. Proteolytic coefficients (C_0) of acetylamino acids by Taka-acylase

Substrate	C_0[a]	
	0.05M[b]	0.01M[b]
Ac-DL-Phe	1.21	2.26
Ac-DL-Amp (DL-**6a**)	0.32	1.19
Ac-DL-App (DL-**6b**)	0.23	1.70

a) $C_0 = K_0/E$ where K_0 = % hydrolysis × min^{-1} and E = mg protein $N \times ml^{-1}$; pH 7.3, temp 38 °C. b) Concentration of L-form of substrate.

For the synthesis and optical resolution of Amp, we designed a route which involves no heating with a mineral acid. As shown in Scheme 1, diethyl [3-(*p*-methoxyphenyl)propyl]acetamidomalonate (**3a**) was prepared from alkyl bromide (**2a**) and diethyl acetamidomalonate in a yield of 64%. When **3a** was subjected to saponification with excess sodium hydroxide at 38 °C, TLC indicated that **3a** rapidly turned to **4a**, and that **3a** or **4a** finally turned to [3-(*p*-methoxyphenyl)propyl]acetamidomalonic acid (**5a**) after ten days; **5a** was obtained from **3a** in a yield of 95%. Pure **4a** was easily prepared from **3a** by the use of one equivalent of sodium hydroxide. Acetyl-DL-Amp (DL-**6a**) was obtained from **5a** by heating in xylene in a yield of 95%. Andrako *et al.* prepared a series of alkylacetamidomalonic acids (**7**) from the corresponding diethyl malonates with sodium hydroxide at 100 °C. They used it for the next step without isolating **7**; a suspension of **7** in water was heated to give the corresponging acetyl-DL-amino acid.[10] When we applied the procedure of Andrako *et al.* to **3a**, we could only isolate DL-**6a** in poor yield because of high hydrophobicity of a series of compounds (**3a**, **5a**, DL-**6a**).

Acetyl-DL-App (DL-**6b**) was also prepared in good yield by decarboxylation of **5b** (Scheme 1). Nakashima *et al.* reported the preparation of DL-**6b** by acetylation of DL-App which was synthesized from **3b** with refluxing hydrochloric acid.[11]

Prior to the preparative resolution of DL-**6a** and DL-**6b** by Taka-acylase, the rates of hydrolysis of two substrates were determined using acetyl-DL-Phe as a reference substrate. The results are given in Table 1. For the preparation of Taka-acylase from Takadiastase powder,[12] the procedure of Masaki *et al.*[13] was slightly modified. Although both L-**6a** and L-**6b** were less susceptible than Ac-L-Phe, the results indicate that optical resolution of DL-**6a** and DL-**6b** is achieved with a slightly increased amount of Taka-acylase. DL-**6a** or DL-**6b** was subjected to the action of Taka-acylase, the desired L-amino acid (L-**1a** or L-**1b**) being obtained in a yield of 83% or 82% (Scheme 1). Acetyl-D-amino acid (D-**6a** or D-**6b**) was isolated from the mother liquor after removal of L-amino acid. Nakashima *et al.* also isolated L-App from the reaction mixture of Ac-DL-App and aminoacylase.[11]

For the preparation of L-Ahp, the L-Amp was heated with 6 M hydrochloric acid for 80 h (Fig. 1), L-Ahp being isolated in a yield of 82%. We suspected the occurrence of partial racemization in Ahp during prolonged heating with hydrochloric acid. For the detection of possible racemate in L-Ahp isolated, the method of Manning and Moore[14] was applied with slight modification; benzyloxycarbonyl-L-leucine succinimide ester (Z-L-Leu-OSu) was used instead of L-leucine *N*-carboxyanhydride. DL-Ahp prepared from Ac-DL-Amp was coupled with Z-L-Leu-OSu, and the resulting Z-L-Leu-DL-Ahp was hydrogenated to afford L-Leu-DL-Ahp substance (**8**). In a similar manner, L-Leu-L-Ahp substance (**9**) was prepared from Z-L-Leu-OSu and the L-Ahp. A chromatogram of an amino acid analyzer is shown in Fig. 2. We assumed that a peptide showing peak C is L-Leu-L-Ahp while the one showing peak D is L-Leu-D-Ahp. Since **9** afforded peak C but no D, the L-Ahp is optically pure. In contrast, Manning and Moore reported that L-Leu-L-Tyr, which is a homolog of L-Leu-L-Ahp, is eluted more slowly than L-Leu-D-Tyr.[14] We obtained the same results[14] in the preparation of L-Leu-L-Tyr substance and L-Leu-DL-Tyr substance using Z-L-Leu-OSu, and subsequent chromatographic studies.

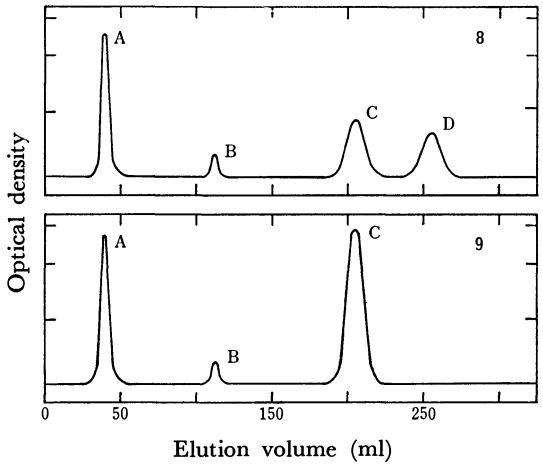

Fig. 2. Chromatogram of L-Leu-DL-Ahp substance (**8**) and L-Leu-L-Ahp substance (**9**). Buffer: pH 5.28 throughout. A: Leu, B: Ahp, C: L-Leu-L-Ahp, D: L-Leu-D-Ahp.

The synthesis of AM-toxin I by utilization of L-Amp has been reported.[2]

Experimental

All the melting points are uncorrected. TLC was carried out on silica gel G (Merck) with the solvent system; R_f^1, *n*-BuOH(1-butanol)–AcOH–pyridine–H_2O (4:1:1:2,v/v). Paper chromatography was carried out on Toyo Roshi No. 51 with the solvent system: R_f^2, the same solvent as that used for TLC; R_f^3, *n*-BuOH–AcOH–H_2O (4:1:2, v/v). Amino acids and peptides were determined with a Hitachi amino acid analyzer KLA-5 with spherical resin under the following conditions: flow rate, 60 ml/h; jacket temperature, 55 °C. Specific rotation was measured with a Union high sensitivity polarimeter PM-71.

*3-(p-Methoxyphenyl)propyl Bromide (**2a**).* The procedure of Catch *et al.*[15] was slightly modified as follows. Ethyl *p*-methoxycinnamate (65 g)[15] in EtOH (300 ml) was treated with hydrogen in the presence of Pd black (5 g). Absorption of hydrogen (7.1 l) ceased after about 18 h.

The catalyst was removed and the filtrate was distilled under reduced pressure to afford ethyl 3-(*p*-methoxyphenyl)propionate (**10**) (59.7 g, 91%), bp 148—149 °C/8 mmHg. The **10** (59.3 g) was reduced with $LiAlH_4$ (6.88 g), and the resulting 3-(*p*-methoxyphenyl)-1-propanol (48.2 g, 90%) was treated with PBr_3 (33.1 g) and **2a** was distilled (bp 117—119 °C/5 mmHg).[15] Yield of **2a**, 49.8 g (75%).

*3-Phenylpropyl Bromide (**2b**).* The procedure of Norris *et al.*[16] was slightly modified as follows. A mixture of 3-phenyl-1-propanol (54.8 g) and 48% hydrobromic acid (192 ml) was refluxed for 36 h. After being cooled the solution was diluted with water, and extracted with ether. The extract was washed successively with 4% Na_2CO_3 solution and water, and then dried (Na_2SO_4). After removal of the solvent, distillation under reduced pressure gave **2b** (71.5 g, 89%), bp 84—85 °C/5 mmHg.

*Diethyl [3-(p-Methoxyphenyl)propyl]acetamidomalonate (**3a**).* To a solution of Na (2.08 g, 90.4 mmol) in absolute EtOH (70 ml) was added diethyl acetamidomalonate (16.4 g, 75.5 mmol) under stirring. A solution of **2a** (17.3 g, 75.5 mmol) in absolute EtOH (30 ml) was added within 30 min. The brown solution was stirred under reflux for 8 h. The precipitate filtered off was washed with EtOH. The combined filtrates were evaporated *in vacuo* to give an oil which crystallized with the addition of water. The crystals collected were washed successively with water and ether–petroleum ether (1:1, v/v); yield, 17.6 g (64%); mp 97—99 °C; R_f^1 0.94.

Found: C, 62.44; H, 7.33; N, 3.89%. Calcd for $C_{19}H_{27}O_6N$: C, 62.45; H, 7.45; N, 3.83%.

*Diethyl (3-Phenylpropyl)acetamidomalonate (**3b**).* This was prepared from **2b** (50 g, 251 mmol) as described for **3a**; yield, 65.0 g (77%); mp 86—87 °C; R_f^1 0.95 (Found: C, 64.47; H, 7.56; N, 4.18%). Andrako *et al.* synthesized **3b** with mp 87—88 °C in 14% yield by the same method.[10]

*2-Acetamido-2-ethoxycarbonyl-5-(p-methoxyphenyl)pentanoic Acid (**4a**).* To a solution of **3a** (730 mg, 2 mmol) in EtOH (8 ml) was added 1 M NaOH (2 ml) at 0 °C. After being left to stand for 18 h at room temperature, the solution was evaporated and acidified with 1 M HCl (2.2 ml). The oil separated was extracted with AcOEt. The extract was washed with water, dried and evaporated. The residual solid was recrystallized from AcOEt–ether–petroleum ether; yield, 517 mg (77%); mp 126 °C; R_f^1 0.73.

Found: C, 60.37; H, 6.93; N, 4.11%. Calcd for $C_{17}H_{23}O_6N$: C, 60.52; H, 6.87; N, 4.15%.

*2-Acetamido-2-ethoxycarbonyl-5-phenylpentanoic Acid (**4b**).* This was prepared from **3b** (1.68 g, 5 mmol) as described for **4a**; yield, 1.09 g (71%); mp 129—130 °C; R_f^1 0.79.

Found: C, 62.30; H, 6.88; N, 4.68%. Calcd for $C_{16}H_{21}O_5N$: C, 62.52; H, 6.88; N, 4.56%.

*[3-(p-Methoxyphenyl)propyl]acetamidomalonic Acid (**5a**).* To a solution of **3a** (14.2 g, 38.9 mmol) in MeOH (350 ml) was added 2 M NaOH (160 ml). The solution was allowed to stand at 38 °C for 10 days until no **3a** or **4a** was detected in the reaction mixture; TLC was used as a monitor. The solution was evaporated, and acidified with 6 M HCl (55 ml). The liberated oil was extracted with AcOEt. The extract was washed with water, dried and evaporated. The residual solid was recrystallized from AcOEt–ether–petroleum ether; yield, 11.4 g (95%); mp 109—110 °C; R_f^1 0.61. Compound **5a** is less stable than **5b**; on being left to stand at room temperature for several days, purified crystals of **5a** gave a small amount of decarboxylated material (DL-**6a**) as detected by TLC. The values of elemental analysis of **5a** deviated from the calculated ones.

*(3-Phenylpropyl)acetamidomalonic Acid (**5b**).* This was prepared from **3b** (16.8 g, 50 mmol) with 2 M NaOH (200 ml) as described for the preparation of **5a**. The rate of saponification of **3b** was slightly greater than that of **3a**. Yield, 12.6 g (90%); mp 119—120 °C; R_f^1 0.64.

Found: C, 60.19; H, 6.16; N, 5.03%. Calcd for $C_{14}H_{17}O_5N$: C, 60.20; H, 6.14; N, 5.02%.

*Ac-DL-Amp (DL-**6a**).* Compound **5a** (8.47 g, 27.4 mmol) suspended in *p*-xylene (100 ml) was refluxed for 2 h. After being cooled at 0 °C, crystals were collected and washed with petroleum ether; yield, 6.91 g (95%); mp 132—133 °C; R_f^1 0.79.

Found: C, 63.45; H, 7.24; N, 5.19%. Calcd for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28%.

*Ac-DL-App (DL-**6b**).* This was prepared from **5b** (12.0 g, 42.9 mmol) as described for DL-**6a**; yield, 9.10 g (90%); mp 148—149 °C; R_f^1 0.80 (Found: C, 66.47; H, 7.40; N, 5.82%). Reported value, mp 147—148 °C.[10]

Partially Purified Enzyme (Taka-acylase). Preparation of Taka-acylase: Takadiastase powder (100 g) was suspended in water (550 ml) and the insoluble material was filtered off at 0 °C. The filtrate was treated with $(NH_4)_2SO_4$ (92 g, 0.26 saturation) and centrifuged (10000 rpm, 20 min) at 0 °C. The supernatant phase was brought to 0.85 saturation with $(NH_4)_2SO_4$ (209 g) and centrifuged (10000 rpm, 20 min) at 0 °C. The sediment was suspended in 30% acetone (200 ml) at −5 °C and the suspension was centrifuged (12000 rpm, 30 min). The sediment was dissolved in a small amount of water, dialyzed and lyophilized; yield of powder(Taka-acylase), 397 mg.

Determination of Proteolytic Coefficient (C_0) *by Taka-acylase*: In a 2-ml flask, an acetyl-DL-amino acid and one equivalent of 0.5 M NaOH were added. Further 0.1 M sodium barbital buffer (1 ml) of pH 7.3, 1/80 M $CoCl_2$ (0.2 ml), and an aqueous enzyme solution (0.2 ml) containing Taka-acylase (4 mg) were added. The solution was made up to 2.0 ml with water. The reaction mixture was incubated at 38 °C, aliquots being withdrawn at selected intervals. The rate of appearance of free amino acid was followed by the amino acid analyzer: column, 0.9×10 cm; buffer, standard 0.2 M sodium citrate at pH 5.28. It was found that the hydrolysis of substrates follows zero-order kinetics within experimental error. The result is shown in Table 1.

*Resolution of Ac-DL-Amp (DL-**6a**). L-Amp (L-**1a**)*: DL-**6a** (5.31 g, 20 mmol) was dissolved in 0.2 M NaOH (110 ml), the pH being adjusted to 7.3 with AcOH. To the solution were added 128 mg of Taka-acylase in 0.2 M sodium acetate (20 ml) and 20 ml of 1/80 M $CoCl_2$. Water was added to bring the volume to 200 ml. After a few drops of toluene had been added, the solution was left to stand at 38 °C for 10 days. The precipitate formed was collected by filtration and washed with 100 ml of water (the precipitate was dissolved in a small amount of 1 M HCl and the solution was subjected to column chromatography). The pH of the combined filtrates was adjusted to 5 with 6 M HCl, a small amount of Norit was added, and the mixture was maintained at 50—60 °C for 10 min. The filtrate was evaporated to a small volume, its pH being adjusted to 3. The mixture was extracted with AcOEt, and the extract was washed with water (the extract was used for the preparation of Ac-D-Amp). The combined aqueous layers and the solution of the above precipitate in 1 M HCl were put on a column (2.2×20 cm) of Dowex 50×8 (H^+ form). The column was washed with water and eluted with 2 M NH_4OH (300 ml). The eluate was evaporated, and the residue was recrystallized from dilute HCl–Et_3N; yield, 1.85 g (83%); mp 232—234 °C (dec); $[\alpha]_D^{21}$ +31.8° (*c* 2.0, 5 M HCl–DMF);[17] R_f^2 0.88, R_f^3 0.76.

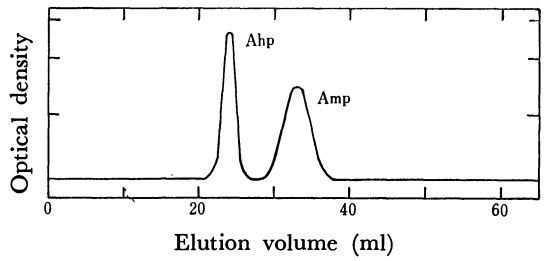

Fig. 3. Chromatogram of a solution after 20 h heating at 110 °C with 6 M HCl of L-Amp.

Found: C, 64.45; H, 7.60; N, 6.05%. Calcd for $C_{12}H_{17}O_3N$: C, 64.55; H, 7.68; N, 6.27%.

Ac-D-Amp (D-**6a**): The extract obtained above was dried (Na_2SO_4) and evaporated. Residual solid was recrystallized from EtOH–water; yield, 2.50 g (94%); mp 145 °C; $[\alpha]_D^{21}$ −16.1 ° (*c* 2.0, EtOH); R_f^1 0.79.

Found: C, 63.27; H, 7.18; N, 5.24%. Calcd for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28%.

Resolution of Ac-DL-App (DL-**6b**). L-*App* (L-**1b**): DL-**6b** (5.88 g, 25 mmol) was treated with Taka-acylase as mentioned above. L-App was obtained from the reaction mixture, and an extract with AcOEt was set aside for the next step. Yield, 1.98 g (82%); mp 227—229 °C (dec); $[\alpha]_D^{21}$ +33.5 ° (*c* 2.0, 5 M HCl–DMF); R_f^2 0.91, R_f^3 0.77 (Found: C, 68.29; H, 7.79; N, 7.24%). Reported value, $[\alpha]_D^{21}$ +25.7 ° (1 M HCl).[11]

Ac-D-App (D-**6b**): The extract obtained above was treated as described for Ac-D-Amp; yield, 2.54 g (86%); mp 148—149 °C; $[\alpha]_D^{21}$ −11.0 ° (*c* 2.0, EtOH); R_f^1 0.80.

Found: C, 66.34; H, 7.29; N, 5.97%. Calcd for $C_{13}H_{17}O_3N$: C, 66.36; H, 7.28; N, 5.95%.

Demethylation of L-*Amp and* O-*Me*-L-*Tyr*. L-Amp (1.12 mg, 5 μmol) and O-Me-L-Tyr (0.98 mg, 5 μmol)[8] were each heated in a sealed tube with 6 M HCl (1 ml) at 110 °C for certain intervals. A solution in the tube was subjected to amino acid analysis. Determination of the two components in the solution was carried out under the following conditions: column, 0.9×10 cm; buffer, standard 0.2 M citrate buffer at pH 5.28; effluent volume, 24 ml (Ahp) and 33 ml (Amp), 18 ml (Tyr) and 22 ml (*O*-Me-Tyr). The percentage of demethylation of these *O*-methyl-α-amino acids is plotted against time (Fig. 1), and the chromatogam of a solution after 20 h heating of L-Amp is shown in Fig. 3. Amp was converted completely into Ahp after heating for 70—80 h.

DL-*Ahp* (DL-**1c**). A suspension of DL-**6a** (220 mg, 0.83 mmol) in 6 M HCl (20 ml) was refluxed on an oil bath at 110 °C for 80 h. The solution was evaporated *in vacuo* several times by the addition of water. The residual solid was recrystallized from dilute HCl–Et_3N–EtOH; yield, 134 mg (77%); mp 272—273 °C (dec); R_f^2 0.78, R_f^3 0.66.

Found: C, 62.66; H, 7.21; N, 6.63%. Calcd for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69%.

L-*Ahp* (L-**1c**). This was prepared from L-Amp (1.12 g, 5 mmol) as described above; yield, 0.86 g (82%); mp 242—243 °C (dec); $[\alpha]_D^{21}$ +36.1 ° (*c* 2.0, 5 M HCl–DMF); R_f^2 0.78, R_f^3 0.66.

Found: C, 62.65; H, 7.22; N, 6.50%. Calcd for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69%.

Racemization Test of L-*Ahp*. L-*Leu*-DL-*Ahp Substance* (**8**): To a solution of DL-Ahp (10 mg, 48 μmol), dioxane (1 ml), water (1 ml), and Et_3N (6.7 μl, 48 μmol) was added Z-L-Leu-OSu[18] (26 mg, 72 μmol) in dioxane (1 ml) at 0 °C. The mixture was allowed to stand overnight at room temperature and then evaporated. The residue dissolved in MeOH–AcOH–H_2O (5:1:1, v/v) was hydrogenated in the presence of Pd black, and the filtrate was evaporated to dryness. The residue was designated **8**.

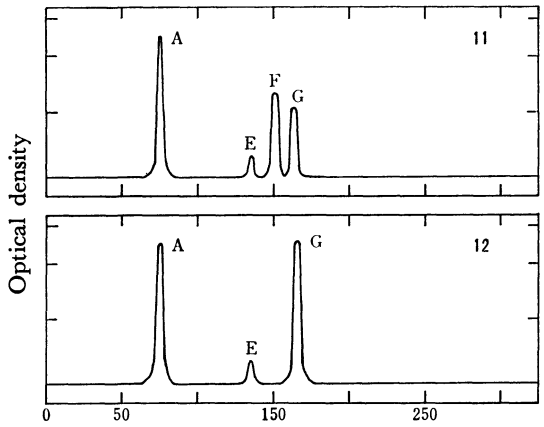

Fig. 4. Chromatogram of L-Leu-DL-Tyr substance (**11**) and L-Leu-L-Tyr substance (**12**). Buffer: pH 4.25 for 0—40 ml and pH 5.28 after 40 ml. A: Leu, E: Tyr, F: L-Leu-D-Tyr, G: L-Leu-L-Tyr.

L-*Leu*-L-*Ahp Substance* (**9**): This was obtained from L-Ahp (10 mg, 48 μmol) as described above.

Chromatography with Amino Acid Analyzer: **8** and **9** were each dissolved in 0.2 M citrate buffer of pH 2.2, and an aliquot (1 μmol) of the solution was subjected to amino acid analysis. The following conditions were sufficient to permit the separation of two diastereomers; column, 0.9× 55 cm; buffer, the standard citrate at pH 5.28. The chromatograms are shown in Fig. 2.

Chromatography of L-*Leu-Tyr*. The L-Leu-DL-Tyr substance (**11**) and L-Leu-L-Tyr substance (**12**) were prepared as described for the preparation of **8** and **9**. **11** was eluted as one peak (effluent volume, 75 ml) which was faster than L-Leu-L-Ahp (effluent volume, 203 ml) when analysis was carried out under the same conditions for the separation of **8**. It was possible under the following conditions to separate two diastereomers in **11**; **11** was eluted with pH 4.25 buffer for 40 min, thereafter with pH 5.28 buffer. As shown in Fig. 4, L-Leu-L-Tyr substance (**12**) showed a peak of G, but the view that a peptide showing G might be *O*-leucyl peptide was not excluded. The possibility was eliminated by the following experiment. Z-L-Leu-OSu was coupled with *O*-benzyl-L-Tyr[19] and the peptide substance obtained by hydrogenation gave a peak identical with that of G.

Oxidation of Olefins with Thallium(III) Acetate in Diols[1)]

Sakae UEMURA,* Haruo MIYOSHI, Akio TOSHIMITSU, and Masaya OKANO

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

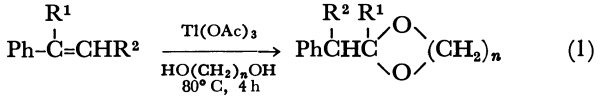
(Received May 19, 1976)

The oxidation of styrene, α- and β-methylstyrene, and 1-octene with thallium(III) acetate in diols, $HO(CH_2)_nOH$ (n=2, 3, and 4), has been investigated. From styrene the derivatives of 1,3-dioxolane, 1,3-dioxane, and 1,3-dioxepane were mainly obtained for n=2, 3, and 4 respectively, while the reaction of 1-octene in 1,2-ethanediol afforded 1-acetoxy-2-(2-hydroxyethoxy)octane as the main product. A new alkoxythallate of styrene, $C_6H_5CH(OCH_2CH_2OH)CH_2Tl(OAc)_2$, has been isolated under milder conditions.

Extensive data are available on the oxidation of olefins with metal salts in alcohols. However, there are only a few reports[2)] on the reaction with the use of a diol as an alcohol component. As an extension of studies on the alkoxythallation of olefins[3)] we now report the first example of the oxidation of olefins with thallium(III) acetate in various diols, $HO(CH_2)_nOH$ (n=2, 3, and 4), where an intramolecular substitution of thallium moiety by hydroxy oxygen may be expected in the intermediate ω-hydroxyalkoxythallate of olefins. Isolation of a new alkoxythallate of styrene and its reactions are also reported.

Results and Discussion

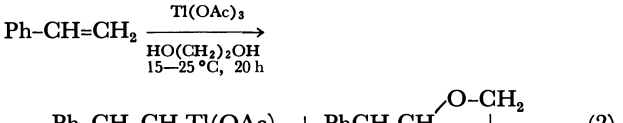
Reaction of styrene (**1a**) with thallium(III) acetate in 1,2-ethanediol, 1,3-propanediol, and 1,4-butanediol at 80 °C for 4 h gave 2-benzyl-1,3-dioxolane (**2a**, 36% yield), 2-benzyl-1,3-dioxane (**2d**, 33% yield), and 2-benzyl-1,3-dioxepane (**2e**, 17% yield) respectively, together with small amounts of phenylacetaldehyde and acetophenone in each case. Similarly, 2-methyl-2-benzyl-1,3-dioxolane (**2b**, 81% yield) and 2-(α-methylbenzyl)-1,3-dioxolane (**2c**, 23% yield) were formed from α- (**1b**) and β-methylstyrene (**1c**) respectively, by the use of 1,2-ethanediol as solvent. The ring products clearly arise from phenyl migration (Scheme 1). When the reaction of styrene with thallium(III)



(1)

1a(R^1=R^2=H) **2a**(R^1=R^2=H, n=2)
b(R^1=Me, R^2=H) **b**(R^1=Me, R^2=H, n=2)
c(R^1=H, R^2=Me) **c**(R^1=H, R^2=Me, n=2)
d(R^1=R^2=H, n=3)
e(R^1=R^2=H, n=4)

acetate in 1,2-ethanediol was carried out at room temperature, a new organothallium(III) compound (**3**) was isolated together with **2a** (Scheme 2). In



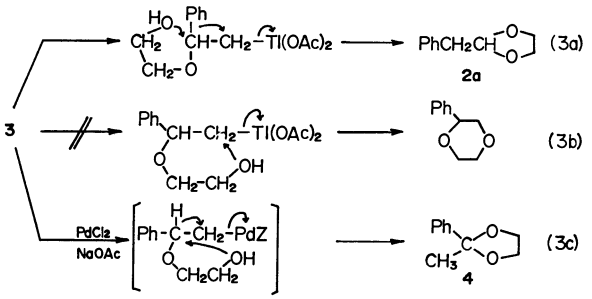
(2)

3 **2a**

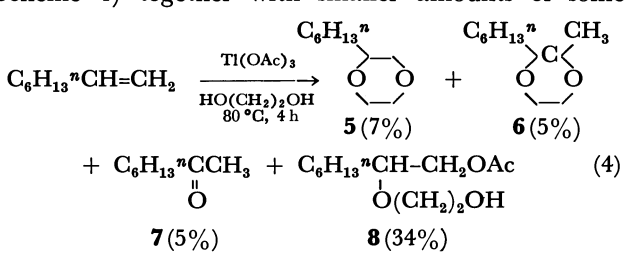
order to ascertain **3** to be the intermediate for **2a**, the isolated **3** was heated in 1,2-ethanediol at 80 °C for 4 h. As expected, **2a** was obtained as the sole product.

*To whom correspondence should be addressed.

This indicates that **2a** was formed through a 1,2-shift of the phenyl group with dethallation and a simultaneous or successive nucleophilic attack of hydroxy oxygen on the carbon bearing alkoxyl group (Scheme 3a) as was noted in thermal decomposition of methoxythallate of styrene in methanol,[3c)] with no intramolecular attack of oxygen on carbon bearing thallium moiety to give 2-phenyl-1,4-dioxane (Scheme 3b) taking place at all. Formation of **2b—e** can also be explained by a similar scheme. On the other hand, when **3** was heated in 1,2-ethanediol in the presence of palladium(II) salt, 2-methyl-2-phenyl-1,3-dioxolane (**4**) was readily obtained almost quantitatively. Formation of **4** can be explained by Scheme 3c which involves hydride shift instead of phenyl migration as has been proposed in the reactions of alkoxymercurials[2b)] and alkoxythallates[3a)] of olefins with palladium(II) salts.



If the phenyl group which easily migrates to give **2a—e** is replaced by the alkyl group, the formation of the reaction product by Scheme 3b can be expected since the alkyl group does not migrate as easily as the phenyl group. We chose 1-octene as a substrate and carried out its oxidation in 1,2-ethanediol at 80 °C for 4 h, the oxidation with thallium(III) acetate in methanol having been reported in detail.[4)] As a result one major product and three minor ones were identified (Scheme 4) together with smaller amounts of some



(4)

7(5%) **8**(34%)

unidentified compounds. 2-Heptyl-1,3-dioxolane or 1-octanal which arises from hexyl group migration was not formed in the reaction products. Formation of 2-hexyl-1,4-dioxane (**5**) shows that the reaction corresponding to Scheme 3b is partly operative in this case. A similar reaction in 1,3-propanediol gave no compound corresponding to **5**.

Although thallium(III) was almost completely reduced to thallium(I) in these reactions, the yields of the products were generally low. This may be due to the consumption of thallium(III) for the oxidation of diols as was noted by Kabbe in the case of some 1,2-diols.[5] We also confirmed that when thallium(III) acetate (10 mmol) is heated in 1,2-ethanediol (7.5 ml) at 82 °C for 4 h, 65% of thallium(III) is reduced to thallium(I) (by iodometry).

Experimental

Commercial organic and inorganic materials were used. The IR and NMR spectra were recorded with a Hitachi EPI-S2 and a Varian EM-360 apparatus, respectively. Gas chromatography was carried out on Shimadzu 4BMPF and 5APTF apparatus using EGSS-X(15%)-Chromosorb-W (1 m and 3 m) and PEG-6000(25%)-Chromosorb-W (3 m) columns (N_2 as a carrier gas).

Oxidation of Olefin with $Tl(OAc)_3$ in Diol. A typical experimental procedure is as follows. A mixture of styrene (4.1 g, 40 mmol), $Tl(OAc)_3$ (7.7 g, 20 mmol), and 1,2-ethanediol (15 ml) was heated at 80 °C for 4 h under stirring. After the usual work-up, GLC analysis of benzene extract revealed the presence of 7.2 mmol (36% yield based on Tl^{3+} charged) of 2-benzyl-1,3-dioxolane (**2a**) and small amounts of phenylacetaldehyde and acetophenone as the products, butyrophenone being used as an internal standard. Distillation gave 0.5 g of pure **2a**. Thallium(III) was almost completely reduced to thallium(I). Authentic samples of **2a—e**, **4**, and **6** were prepared by the acetalization or ketalization of phenylacetaldehyde, 2-phenylpropionaldehyde, acetophenone and 2-octanone in the corresponding diols[6] and their structures were confirmed by NMR; **2a** bp 80—93 °C/2 Torr, **2b** bp 81 °C/2 Torr, **2c** bp 93—95 °C/4 Torr, **2d** bp 100—104.5 °C/4 Torr, **2e** bp 106—110 °C/4 Torr, **4** bp 83—84 °C/15 Torr, **6** bp 78—79°C/15 Torr. **5** was prepared by the alkaline dehydrobromination of 1-bromo-2-(2-hydroxyethoxy)octane which was synthesized from 1-octene, 1,2-ethanediol, and *N*-bromosuccinimide.[7] **8** was prepared by the reaction of 1-bromo-2-(2-hydroxyethoxy)octane with KOAc in DMSO; bp 120—123 °C/5 Torr, NMR (CCl_4) δ 0.67—1.07 (m. 3H), 1.07—1.73 (m. 10H), 1.98(s. 3H), 2.3(br. 1H), 3.23—3.67(m. 5H), and 3.67—4.23(m. 2H). No 2-acetoxy-1-(2-hydroxyethoxy)octane (positional isomer of **8**) was detected by NMR in the oxidation products of 1-octene.

*Isolation of **3**.* A mixture of styrene (4.1 g, 40 mmol), $Tl(OAc)_3$ (7.7 g, 20 mmol), and 1,2-ethanediol (15 ml) was stirred at 15—25 °C for 20 h. To this was added 500 ml of petroleum ether and the mixture was then left to stand for 3 days in a refrigerator to give a white crystal of **3** as a precipitate. **3** was collected by filtration [4.2 g, 43% yield; mp 133—135 °C(dec)]. The treatment of organic filtrate as described above revealed the presence of 28% yield of **2a**. **3** is soluble in pyridine, DMSO, DMF, hot $CHCl_3$, and hot ethanol, but insoluble in water, THF, ether, benzene, CCl_4, acetonitrile, and acetic acid. IR(hexachlorobutadiene and paraffin mulls): 3250(s), 2950(m), 2920(m), 2860(m), 1625(sh), 1610(s), 1530(s), 1430(s), 1360(s), 1320(s), 1110(m), 1090(m), 1067(m), 974(m), 762(m), 695(m), and 685(m) cm^{-1}. NMR(pyridine-d_5): δ 2.09(s. 6H), 3.10(d. 1H, J_{Tl-H} = 732 Hz), 3.14(d. 1H, J_{Tl-H} = 875 Hz), 3.53(t. 2H), 3.76 (t. 2H), 5.01(d. 1H, J_{Tl-H} = 739 Hz), 5.76(s. 1H), and 6.9—7.6 (m. 5H). Found: C, 34.48; H, 4.11; Tl, 41.28%. Calcd for $C_{14}H_{19}O_6Tl$: C, 34.48; H, 3.93; Tl, 41.91%.

*Reaction of **3** with Palladium(II) Salt.* **3** (0.98 g, 2 mmol) was added to a hot mixture (75—80 °C) of $PdCl_2$ (0.36 g, 2.03 mmol), NaOAc (0.33 g, 4.02 mmol), and 1,2-ethanediol (10 ml) and the resulting mixture was stirred for 20 min. A black precipitate formed was filtered off. Saturated aq. NaCl was added to the filtrate which was then extracted with benzene. GLC analysis of the benzene extract revealed the presence of acetophenone (0.19 mmol) and 2-methyl-2-phenyl-1,3-dioxolane (**4**, 1.81 mmol) together with a trace amount of **2a**, *p*-methylacetophenone being used as an internal standard.

The Stereoselective Synthesis of *threo*-3-Hydroxy-4-amino Acids

Tsutomu KATSUKI and Masaru YAMAGUCHI

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received May 31, 1976)

Two *threo*-3-hydroxy-4-amino acids, *dl*-4-amino-3-hydroxy-6-methylheptanoic acid (**1**) and *dl*-4-amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic acid (**2**), the optically active forms of which had been isolated by the acid hydrolysis of some antibiotics, were synthesized stereoselectively from L-leucine and DL-3-(3-pyridyl)-alanine respectively through 2-pyrrolidinone intermediates.

Two unusual *threo*-type hydroxy amino acids, (3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid (**1**) and (2*R*,3*S*,4*S*)-4-amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic acid (**2**), have been isolated by the acid hydrolysis of various pepstatins[1a-e] and pyridomycin[2] respectively. The first synthesis of **1** was carried out by Morishima *et al.* in a *non*-stereoselective way.[3] Kinoshita *et al.* recently synthesized **1** and **2** in a highly stereospecific manner starting from the appropriate optically active deoxy-sugar derivatives.[4,5]

The present authors have now attempted the synthesis of this type of hydroxy amino acid according to a general plan starting from common amino acids and involving the stereoselective reduction of 4-hydroxy-3-pyrrolin-2-one intermediates, such as **6** (Scheme 1) or **13** (Scheme 2). The *dl*-**1** could be synthesized smoothly along those lines. In the case of **2**, the reduction of the 4-hydroxy-3-pyrrolin-2-one (**13**) proceeded in the desired manner, but the subsequent steps led to a mixture of two *dl*-hydroxy amino acids, epimeric at the C-2 carbon atom. The major (90%) *non*-natural-type isomer (**23**) could easily be obtained in a pure form, but the isolation of the minor (10%) natural-type isomer (**2**) was so tedious that no crystalline sample could be obtained.

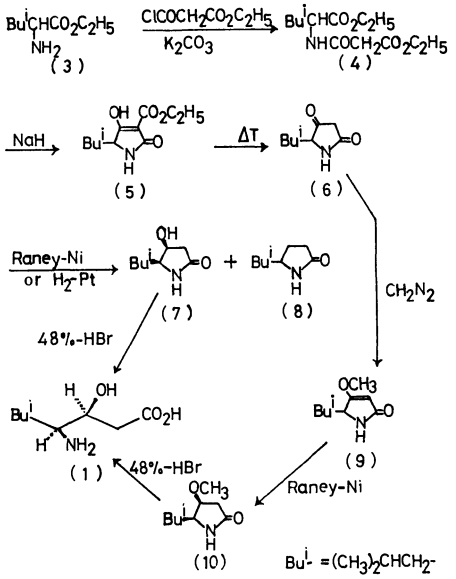
Results and Discussion

dl-*4-Amino-3-hydroxy-6-methylheptanoic Acid (1) (Scheme 1).* The *N*-(ethoxycarbonylacetyl)leucine ethyl ester (**4**) derived from **3** was subjected to Dieckmann condensation in a usual way[6] to give 3-ethoxycarbonyl-4-hydroxy-5-isobutyl-3-pyrrolin-2-one (**5**), which was then decarboxylated to 5-isobutyl-2,4-pyrrolidinedione (**6**) in an 87.7% overall yield from **4**. The pyrrolidinedione (**6**) thus obtained was a racemate, and it was used without resolution.

When **6** was hydrogenated with Raney nickel, it gave a mixture of 4-hydroxy-5-isobutyl-2-pyrrolidinone (**7**) and 5-isobutyl-2-pyrrolidinone (**8**). Compound (**7**) could be separated from **8** by crystallization and was proved, from the results of the subsequent hydrolysis, to be the *cis*-compound with regard to the two substituents at C-4 and C-5.

The hydrogenation of **6** in the presence of platinum oxide in ethyl acetate gave mostly **7**, but in a mixture of ethanol and acetic acid, it led to the hydrogenolyzed product (**8**) quantitatively. Alternatively, **6** was converted into 4-methoxy-5-isobutyl-3-pyrrolin-2-one (**9**) by diazomethane and was hydrogenated with Raney nickel to give *cis*-4-methoxy-5-isobutyl-2-pyrrolidinone (**10**) in an 87% yield.

The hydrolysis of **7** or **10** with 48% hydrobromic acid, followed by chromatographic purification on a Dowex 50 column, gave the *dl*-**1**[7] in a fair yield (74% from **10**). The NMR spectrum of synthetic *dl*-**1** agreed with that of the natural specimen.[3]



Scheme 1.

dl-*4-Amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic Acid (2) (Scheme 2).* DL-3-(3-Pyridyl)alanine[8] was converted to its methyl ester (**11**), which was then condensed with 2-ethoxycarbonylpropionyl chloride. The *N*-(2-ethoxycarbonylpropionyl)-3-(3-pyridyl)alanine methyl ester (**12**) thus obtained was subjected to Dieckmann condensation with sodium methoxide to afford 4-hydroxy-3-methyl-5-(3-pyridylmethyl)-3-pyrrolin-2-one (**13**) in a 32% overall yield from pyridylalanine.

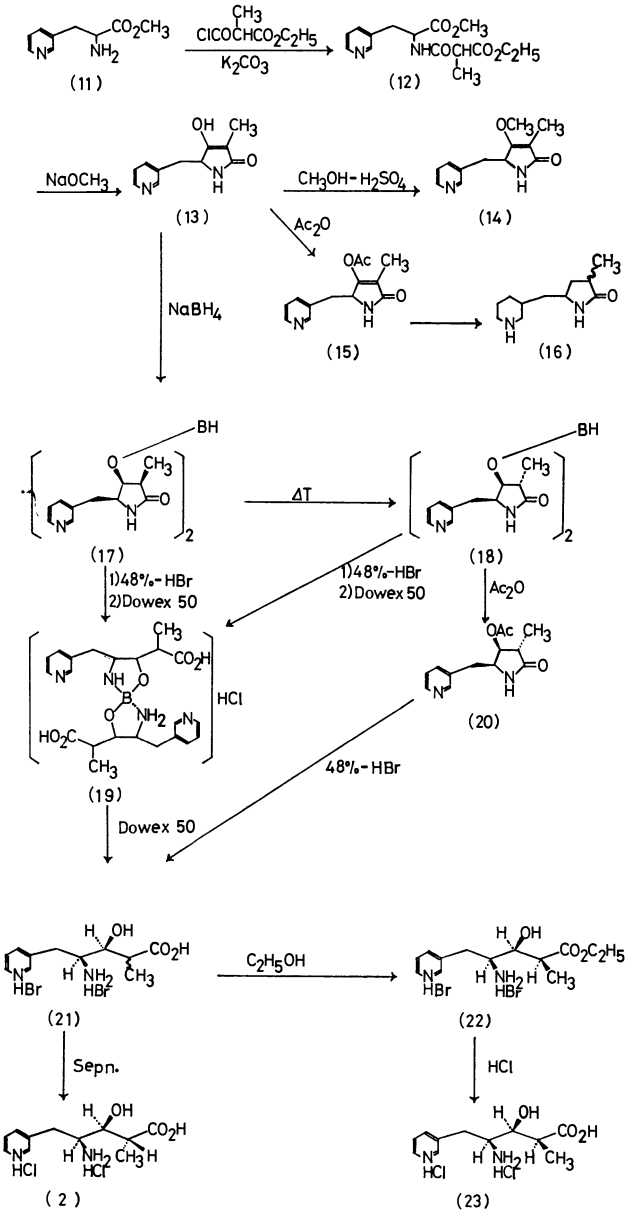
The catalytic hydrogenation of **13**, its methyl ether (**14**), or its acetate (**15**) was, however, unsuccessful because of the hydrogenolysis of the *O*-function at C-4 and/or of the reduction of the pyridine nucleus, leading to the formation of **16**, for example. Compound (**13**) was then reduced with sodium borohydride in 2-propanol to give, stereoselectively, a single compound, bis[4-methyl-5-oxo-2-(3-pyridylmethyl)-3-pyrrolidinyl]-boronate, which was considered to have the desired *cis*-configuration, as represented by **17**. Unfortunately, the compound was unstable to heat, and, on recrystallization from a mixture of chloroform and ethyl acetate, it isomerized into the more stable isomer (**18**).

The compound (**17** or **18**) was hydrolyzed with

48% hydrobromic acid at 50 °C. The product obtained was a mixture of the boron complexes of the two isomeric hydroxy amino acids with the composition represented by **19**.

The elimination of boric acid from **19** was effected by treatment with 48% hydrobromic acid, followed by ion-exchange chromatography, thus giving a mixture of two racemic hydroxy amino acids (**21**, a mixture of **2** and **23**, 30% from **13**). The isomer with the configuration corresponding to the natural amino acid (**2**) in the mixture was the minor component (10% from NMR). Alternatively, boron was removed by the acetylation of **18** with acetic anhydride and pyridine, and the acetate (**20**) was hydrolyzed by hydrobromic acid to give **21** with the same isomeric ratio as above in a 40% overall yield from **13**.

The *non*-natural-type major isomer (**23**) could be easily separated from the minor counterpart by the recrystallization of the mixture from ethanol, whereupon



Scheme 2.

the isomer crystallized out as its ethyl ester (**22**);[9] the hydrolysis of the ester gave pure **23**. The isolation of the natural-type isomer (**2**) was, however, very tedious. The above hydroxy amino acid mixture (**21**) was repeatedly chromatographed on the Dowex-50 column, and finally a small amount of an almost pure sample was obtained in the form of a *non*-crystalline concentrate, which gave the same NMR spectrum as that of authentic natural amino acid (**2**).

Experimental

The melting points are uncorrected. The IR spectra were taken on a Hitachi R-215 spectrometer. The NMR spectra were recorded on Hitachi R-20B and Hitachi R-22 spectrometers.

N-(Ethoxycarbonylacetyl)leucine Ethyl Ester (4), 3-Ethoxycarbonyl-4-hydroxy-5-isobutyl-3-pyrrolin-2-one (5), and 5-Isobutyl-2,4-pyrrolidinedione (6). Compounds (**4** and **5**) were prepared from the L-leucine ethyl ester in a way similar to that described by Achiwa and Yamada for the preparation of 5-ethyl-5-methyl-2,4-pyrrolidinedione.[6] **4** (60% from **3**); bp 145 °C/2 mmHg. **5** (87% from **4**), NMR (CD_3OD): δ 0.96(d, 6H), 1.31(t, 3H), 1.40—2.05 (m, 3H), 4.08(t, 1H), 4.3(q, 2H). The recrystallization of **5** from a mixture of ethyl acetate and ligroin gave **6** as colorless needles. Mp 124 °C. IR: ν_{max} 3180, 2960, 1765, 1680, 1384, 1290, 1240, 853, 800, 682 cm^{-1}. NMR ($CDCl_3$):[10] δ 0.96(d, 6H), 1.45—2.10(m, 3H), 3.03(s, 2H), 4.06(m, 1H), 7.85 (broad s, 1H). Found: C, 61.57; H, 8.42; N, 8.86%. Calcd for $C_8H_{13}NO_2$: C, 61.91; H, 8.44; N, 9.03%.

4,5-cis-4-Hydroxy-5-isobutyl-2-pyrrolidinone (7). a) A mixture of **6** (97 mg), excess Raney nickel, and ethanol (10 ml) was refluxed for 3 h. The Raney nickel was then removed by filtration, and the solvent was removed *in vacuo* to give a colorless solid. Subsequent recrystallization from a mixture of dichloromethane and hexane gave **7** as colorless prisms (48 mg, 48%). Mp 131—132 °C. NMR ($CDCl_3$): δ 0.96(d, 6H), 1.58(m, 3H), 2.51(m, 2H), 3.70 (m, 1H), 4.40(m, 1H), 6.28(broad s, 1H). Found: C, 60.95; H, 9.62; N, 8.76%. Calcd for $C_8H_{15}NO_2$: C, 61.12; H, 9.62; N, 8.91%.

b) Compound (**6**, 32 mg) was dissolved in ethyl acetate (20 ml) and hydrogenated over the platinum oxide catalyst. After the removal of the catalyst, the solution was concentrated and the residue was crystallized from a mixture of dichloromethane and hexane to give **7** as colorless prisms (31 mg, 94%).

5-Isobutyl-2-pyrrolidinone (8). Compound (**6**, 29 mg) was dissolved in a mixture of ethanol(9 ml) and acetic acid (1 ml) and then hydrogenated over the platinum oxide catalyst. After the removal of the catalyst and the solvent, the residue was sublimed at 80 °C/20 mmHg to afford **8** as colorless needles (26 mg, quantitative). Mp 74.5—75°C. NMR ($CDCl_3$): δ 0.94 (d, 6H), 1.29—1.85 (m, 3H), 2.18—2.52(m, 4H), 3.70(m, 1H), 6.60(1H). Found: C, 67.88; H, 10.65; N, 9.83%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92%.

4-Methoxy-5-isobutyl-3-pyrrolin-2-one (9) and 4,5-cis-4-Methoxy-5-isobutyl-2-pyrrolidinone (10). The ethereal diazomethane was added to a solution of **6** in methanol at 0 °C. After the removal of the excess diazomethane and the solvent, **9** was obtained as colorless needles quantitatively. NMR ($CDCl_3$): δ 0.96(d, 6H), 1.32—1.95 (m, 3H), 3.78(s, 3H), 4.05 (m, 1H), 5.00 (d, 1H), 6.95 (broad s, 1H). The ether (**9**) was used without purification in the following reaction. A mixture of **9** (139 mg) and excess Raney nickel

in ethanol was refluxed for 5 h. The mixture was then filtered and concentrated under reduced pressure. The residue was recrystallized from a mixture of dichloromethane and hexane to give **10** as colorless needles (120 mg, 86%). Mp 87—88 °C. NMR ($CDCl_3$): δ 0.95(6H), 1.35—1.70 (m, 3H), 2.44 (d, 2H), 3.32 (s, 3H), 3.69—4.10 (m, 2H), 7.35(broad s, 1H). Found: C, 62.97; H, 10.03; N, 8.04%. Calcd for $C_9H_{17}NO_2$: C, 63.13; H, 10.00; N, 8.18%.

dl-*4-Amino-3-hydroxy-6-methylheptanoic Acid (1).*

a) A mixture of **10** (60 mg) and 48% hydrobromic acid (5 ml) was stirred for 10 h at 78 °C. The mixture was then concentrated to dryness under reduced pressure, redissolved in water (5 ml), and applied to a column of Dowex 50(0.8 cm × 25 cm). The column was washed with water until the eluent became neutral, and then the amino acid was eluted with 2 M-ammonia. The eluate was concentrated under reduced pressure, and the residue was recrystallized from a mixture of methanol and ethanol to afford *dl*-**1** as colorless crystals (45 mg, 74%). Mp 211.5—213.5 °C (dec). NMR (D_2O): δ 0.98 (d, 6H), 1.38—1.72 (m, 3H), 2.44—2.62(m, 2H), 3.13—3.47(m, 1H), 3.88—4.22(m, 1H). The NMR spectrum ($J_{3,4}$=5.5 Hz) of *dl*-**1** agreed with that ($J_{3,4}$=5.5 Hz)[3] of natural amino acid. Found: C, 54.66; H, 9.68; N, 7.99%. Calcd for $C_8H_{17}NO_3$: C, 54.83; H, 9.68; N, 7.99%.

b) By the same procedure as was used in the hydrolysis of **10**, **7** was hydrolyzed to give *dl*-**1** (80%).

N-*(2-Ethoxycarbonylpropionyl)-3-(3-pyridyl)alanine Methyl Ester (12).* By the same procedure as was described for the preparation of **4**, **11** (2.8 g) was *N*-acylated with 2-ethoxycarbonylpropionyl chloride. The crude product was purified by chromatography (silica gel, ethyl acetate) to give **12** (3.99 g, 88%). It was then recrystallized from diisopropyl ether. Colorless needles; mp 70.5—71.5 °C. IR: ν_{max} 3300, 3100, 3000, 2940, 1740, 1640, 1550, 1200, 1100, 1045, 1000, 960, 830, 810, 770, 715 cm^{-1}. NMR ($CDCl_3$): δ 1.22(t, 3H), 1.35(d, 3H), 3.05—3.43(m, 3H), 3.72(s, 3H), 4.14(q, 2H), 4.87(m, 1H), 7.15—7.70 and 8.30—8.60(m, 4H), 9.42(brosd s, 1H). Found: C, 58.43; H, 6.67; N, 8.80%. Calcd for $C_{15}H_{20}N_2O_5$: C, 58.43; H, 6.54; N, 9.09%.

4-Hydroxy-3-methyl-5-(3-pyridylmethyl)-3-pyrrolin-2-one (13). Sodium (3 g) was dissolved in absolute methanol (100 ml). To this solution, **12** (3 g) was added, after which the whole mixture was refluxed for 10 h. After the removal of the solvent under reduced pressure, the residue was dissolved in water (10 ml) and applied to a column of Dowex 50 (3 cm × 40 cm). After the column had then been washed with water, the **13** was eluted with 2 M-ammonia. Fractions containing **13** were concentrated, and the residue was recrystallized from methanol to give **13** as colorless prisms (1.1 g, 41%). Mp 172—174 °C. IR: ν_{max} 1665, 1600, 1580, 1490, 1225, 760, 700 cm^{-1}. NMR (CD_3SOCD_3): δ 1.39(s, 3H), 2.87—3.05(m, 2H), 4.13(m, 1H), 7.24—7.75 and 8.32—8.55 (m, 4H). Found: C, 64.52; H, 5.90; N, 14.10%. Calcd for $C_{11}H_{12}N_2O_2$: C, 64.69; H, 5.92; N, 13.72%.

4-Methoxy-3-methyl-5-(3-pyridylmethyl)-3-pyrrolin-2-one (14). A mixture of **13** (67 mg) and concentrated sulfuric acid (0.1 ml) in anhydrous methanol was refluxed for 30 h. This solution was then neutralized with dry Dowex 1 (OH-type). After filtration, the whole solution was concentrated to an oil (47 mg, 76%). NMR ($CDCl_3$): δ 1.78(s, 3H), 2.75—3.01(m, 2H), 3.90—4.20(m, 1H), 3.97(s, 3H), 6.80—7.56 and 8.20—8.50(m, 4H).

4-Acetoxy-3-methyl-5-(3-pyridylmethyl)-3-pyrrlolin-2-one (15). A mixture of **13** (45 mg) and acetic anhydride (0.4 ml) was stirred for 3 h. The solution was then concentrated, and the residue was recrystallized from a mixture of chloroform and diisopropyl ether to give colorless needles (50 mg, 89%). Mp 134—134.5 °C. IR: ν_{max} 3180, 3080, 1780, 1700, 1575, 1480, 1420, 1200, 760, 705 cm^{-1}. NMR ($CDCl_3$): δ 1.57 (d, 3H), 2.16(s, 3H), 2.73—2.96(m, 2H), 4.40—4.68(m, 1H), 5.65(broad s, 1H), 7.05—7.65 and 8.22—8.48(m, 4H). Found: C, 63.16; H, 5.83; N, 11.45%. Calcd for $C_{13}H_{14}N_2O_3$: C, 63.40; H, 5.73; N, 11.38%.

*Bis[4-methyl-5-oxo-2-(3-pyridylmethyl)-3-pyrrolidinyl]boronate (17, 3,4-*cis*-4,5-*cis*) and (18, 3,4-*trans*-4,5-*cis*).* Sodium borohydride (200 mg) was added to a solution of **13** (200 mg) in 2-propanol (20 ml), after which the mixture was stirred at room temperature for 48 h. The mixture was then diluted with water and extracted with chloroform. The extract was washed with water, dried over anhydrous sodium sulfate, and concentrated under a vacuum to give **17** as colorless oil (165 mg, 82%). NMR (CD_3OD): δ 1.16(d, 3H, J= 6.5 Hz), 2.30(m, 1H), 2.79—3.15 (m, 2H), 3.70—4.18 (m, 2H), 7.20—7.90 and 8.26—8.60(m, 4H). The recrystallization of **17** from a mixture of methanol and diisopropyl ether afforded a stable isomer, **18**, as colorless prisms. Mp 210—218 °C. IR: ν_{max} 1710, 1585, 1485, 1115, 780, 720, 710 cm^{-1}. NMR (CD_3OD): δ1.15(d, 3H, J=7.5 Hz), 2.29 (m, 1H), 2.80—3.10(m, 2H), 3.53—4.20(m, 2H), 7.24—7.90 and 8.25—8.57(m, 4H). Found: C, 62.45; H, 6.67; N, 13.21%. Calcd for $C_{22}H_{27}N_4O_4B$: C, 62.57; H, 6.44; N, 13.27%.

Boron Complex of 4-Amino-3-hydroxy-2-methyl-5-(3-pyridyl)-pentanoic Acid (19). Compound (**18**, 100 mg) was dissolved in 48% hydrobromic acid, and the solution was stirred at 70 °C for 72 h. The solution was then concentrated and applied to an ion-exchange column of Dowex 50 (0.8 cm × 25 cm). The amino acid was eluted by 3 M-hydrochloric acid, and the residue of the eluate was recrystallized from a mixture of ethanol and 2-propanol to give **19** as colorless needles (70 mg, 60%). Mp 211.5—212 °C. IR: ν_{max} 1700, 1575, 1475, 1105, 1040, 773, 720, 700 cm^{-1}. Found: C, 53.78; H, 6.20; N, 11.49%. Calcd for $C_{22}H_{30}N_4O_6$-BCl: C, 53.62; H, 6.14; N, 11.37%.

*3,4-*trans*-4,5-*cis*-4-Acetoxy-3-methyl-5-(3-pyridylmethyl)-2-pyrrolidinone (20).* A mixture of **18** (125 mg), pyridine (2 ml), and acetic anhydride (2 ml) was stirred at room temperature for 24 h, diluted with water, and extracted with chloroform. The extract was dried over anhydrous sodium sulfate and concentrated to give a residue which was then recrystallized from a mixture of methanol and diisopropyl ether. Colorless needles (80 mg, 54.5%); mp 143.5—144 °C. IR: ν_{max} 1730, 1710, 1580, 1485, 1218, 785, 710 cm^{-1}. NMR (CD_3OD): δ 1.17 (d, 3H), 2.10 (s, 3H), 2.46 (m, 1H), 2.82 (d, 2H), 4.20 (q, 1H), 5.01 (t, 1H), 7.25—7.88 and 8.30—8.60 (m, 4H). Found: C, 62.91; H, 6.52; N, 11.33%. Calcd for $C_{13}H_{16}N_2O_3$: C, 62.89; H, 6.50; N, 11.28%.

4-Amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic Acid Dihydrochloride (21, a Mixture of 2 and 23). a) The complex (**19**, 120 mg) was dissolved in 48% hydrobromic acid in the presence of ion-exchange resin (Dowex 50, 5 g). The mixture was stirred for 10 h, and the solvent was removed under reduced pressure. The resin was washed with water, and the amino acid was eluted with 3 M-hydrochloric acid. The concentration of the eluate gave **21**, an isomeric mixture of the dihydrochlorides of **2** and **23**, in the form of a viscous syrup (90 mg, 62%). The NMR spectrum of the sample gave an approximate ratio of **23** : **2**=9 : 1.

b) The acetate (**20**, 200 mg) was dissolved in 48% hydrobromic acid. The mixture was stirred at 70 °C for 40 h and then concentrated to a viscous syrup in the form of

dihydrobromide, with the same isomeric ratio as above (280 mg, 90%).

*Ethyl 4-Amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoate Dihydrobromide (**22**).* The above dihydrobromide (**21**, 250 mg) was crystallized from ethanol to give **22** as colorless needles (150 mg, 56%). Mp 191 °C (dec). IR: ν_{max} 1725, 1610, 1590, 1510, 1204, 1095, 790, 675 cm^{-1}. NMR (CD_3OD): δ 1.24 (t, 3H), 1.25 (d, 3H), 2.85 (m, 1H), 3.25—3.50 (m, 2H), 3.65—4.20 (m, 2H), 4.14 (q, 2H), 8.00—8.30 and 8.61—9.10 (m, 4H). Found: C, 37.41; H, 5.30; N, 6.75%. Calcd for $C_{13}H_{20}N_2O_3 \cdot 2HBr$: C, 37.70; H, 5.35; N, 6.76%.

*4-Amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic Acid Dihydrochloride (**23**).* The ethyl ester (**22**, 100 mg) was stirred with 4 M-hydrochloric acid (25 ml) at room temperature for 10 h; then the mixture was concentrated, and the residue was treated with dioxane. As the precipitate was very hygroscopic, it was filtered with the exclusion of moisture, washed with dioxane, and dried to yield **23** (68.5 mg, 90%). IR: ν_{max} 1710, 1605, 1548, 1466, 1185, 780, 673 cm^{-1}. NMR (D_2O): δ 1.14 (d, 3H, J=7.0 Hz), 2.80 (m, 1H), 3.18—3.42 (m, 2H), 3.58—3.94 (m, 2H), 7.91—8.21 and 8.44—8.84 (m, 4H). Found: C, 42.21; H, 6.21; N, 8.87%. Calcd for $C_{11}H_{16}N_2O_3 \cdot 2HCl \cdot H_2O$: C, 41.92; H, 6.40; N, 8.89%.

*4-Amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic Acid Dihydrochloride (**2**).* A hydroxy amino acid mixture (**21**, 185 mg) which contained *dl*-**2** (10%) and its diastereomer (**23**, 90%) was applied to a column of Dowex 50 (H-form, 100—200 mesh, 0.8 cm × 50 cm). The column was washed with water, and then the amino acid was eluted with 2M-hydrochloric acid. The diastereomer (**23**) was eluted a little faster than **2**. The fractions containing *dl*-**2** were combined and concentrated. The concentrate was, again, applied to the column; this process was repeated five times. The glassy concentrate thus obtained (4 mg) gave an NMR spectrum identical with that of natural (−)-**2**. NMR (D_2O): δ 1.13 (d, 3H, J=7.0 Hz), 2.80 (quintet, 1H), 3.18—3.44 (m, 2H), 3.67—3.91 (m, 2H), 7.95—8.25 (m, 1H), 8.50—8.85 (m, 3H).

The authors wish to express their thanks to Dr. Hiroshi Ogawara, National Institute of Health of Japan, and Professor Mitsuhiro Kinoshita, Keio University, who kindly offered the NMR spectrum of (−)-**2**. This work was supported in part by a grant from the Ministry of Education.

Carbonylation of Dienes and Diols in the Presence of Copper(I) Carbonyl Catalysts

Yoshie SOUMA, Jun IYODA, and Hiroshi SANO

Government Industrial Research Institute, Osaka Midorigaoka, Ikeda, Osaka 563

(Received May 4, 1976)

Dienes and diols having carbon numbers of 6 to 12 reacted with carbon monoxide to give mixtures of lactones, dicarboxylic acids and monocarboxylic acids in the presence of copper(I) carbonyl catalysts at room temperature and at 1 atm of carbon monoxide. Dienes and diols having carbon numbers larger than 10 gave isomers of dicarboxylic acid, the main component of which was tetramethyl-substituted tertiary carboxylic acid. The yield increased for an increase of the carbon number. All starting materials gave mixtures of 1,4- and 1,5-lactones. Larger amounts of the lactones were obtained from diols than from dienes. Cyclic monocarboxylic acid and saturated monocarboxylic acid were obtained by the carbonylation of 1,7-octadiene. The appropriate reaction temperature of the dienes and diols was 0—10 and 20—30 °C, respectively.

Several results of carbonylation catalyzed by copper(I) carbonyl ion giving tertiary-carboxylic acids in high yields from olefins and alcohols at room temperature and in pure carbon monoxide at 1 atm were described in previous paper.[1-5]

For the carbonylation of dienes and diols, strong acid catalysts and metal carbonyl catalysts were used. Schauerte and Koch have studied the carbonylation of dienes and diols in concd H_2SO_4 and $BF_3 \cdot H_2O$, and obtained mixtures of dicarboxylic acids, monocarboxylic acids and lactones.[6,7] On the other hand, Kuvaev *et al.* have studied the carbonylation of butadiene in the presence of a $Co_2(CO)_8$ catalyst at 160—220 °C at 250 atm of carbon monoxide, and obtained mixtures of adipic, methylglutaric and alkylsuccinic acids.[8] Paulik has also synthesized C_5—C_{22} dicarboxylic acids by the carbonylation of C_3—C_{20} non-vicinal glycols in the presence of rhodium and iridium complex catalysts at 200 °C at 70 atm of carbon monoxide.[9] In all these reactions, the carbonylation was carried out at elevated pressures of carbon monoxide.

In this paper, carbonylation of dienes and diols in the presence of copper(I) carbonyl catalysts in strong acids at room temperature and at 1 atom of carbon monoxide are described. The effect of the carbon number of the starting materials upon the formation of the dicarboxylic acid or lactone was studied using C_6—C_{12} dienes and diols. The reaction mechanisms are briefly discussed.

Results and Discussion

An unstable copper(I) carbonyl ion $Cu(CO)_n^+$ is formed by the absorption of carbon monoxide in an H_2SO_4 or H_2SO_4–FSO_3H solution of cuprous oxide.[10] Dienes and diols easily react with carbon monoxide at atmospheric pressure in the presence of copper(I) carbonyl ions.

$$Cu^+ + CO \rightarrow Cu(CO)^+ \xrightarrow{CO} Cu(CO)_n^+ \quad n=3, 4$$

$$Cu(CO)_n^+ \rightleftharpoons Cu(CO)^+ + (n-1)CO$$

The copper(I) carbonyl ion behaves as a CO carrier from the gas phase to the H_2SO_4 solution, and has the same effect on the carbonylation as for elevated pressures of carbon monoxide. In general, the carbonylation of dienes in acid solutions is difficult because of their strong tendency to polymerization. However, the application of copper(I) carbonyl catalysts renders possible the carbonylation of diene in high yields even in strong acid solutions.

Dienes and diols having carbon numbers from 6 to 12 react with carbon monoxide and gave mixtures of monocarboxylic acids, dicarboxylic acids and lactones. The ratio of these components in the mixture varied with the carbon number of the starting material. The results are shown in Table 1. Dicarboxylic acids were obtained from starting materials having carbon numbers larger than 10. Lactones were obtained from all compounds. In general, larger amounts of lactones were obtained from diols than from dienes. Cyclic monocarboxylic acid and saturated monocarboxylic acid were obtained by the carbonylation of 1,7-octadiene. No hydroxycarboxylic acid and unsaturated carboxylic acid were identified in the strong acid solution. The carbonylation of diols was carried out at 20—30 °C, on the other hand, the carbonylation of dienes was carried out at 0—10 °C in order to prevent polymerization.

The reaction schemes are explained as follows. The reaction pathways of the dienes and diols are almost the same. A carbonium ion (I) is formed by protonation to the double bond of the diene, or by protonation and successive dehydration of the diol.

$$CH_2{=}CH{-}(CH_2)_n{-}CH{=}CH_2 \xrightarrow{H^+} CH_3{-}\overset{+}{C}H{-}(CH_2)_n{-}\overset{+}{C}H{-}CH_3$$

$$HO{-}(CH_2)_{n+4}{-}OH \xrightarrow{H^+} H_2\overset{+}{O}{-}(CH_2)_{n+4}{-}\overset{+}{O}H_2 \xrightarrow{-H_2O} CH_2{-}(CH_2)_{n+2}{-}\overset{+}{C}H_2$$

(I)

When the carbon number of I is larger than 10, the carbonium ion (I) isomerizes to the more stable *t*-carbonium ion (II) by Wagner-Meerwein rearrangement, and reacts with carbon monoxide. By this mechanism, *t*-dicarboxylic acid is obtained from a diene or diol having a carbon number larger than 10. In this case, the carbon number for the two tertiary carbonium ions is larger than 4. The yield of *t*-dicarboxylic acid increases when the carbon numbers of the starting materials increases to between

Table 1. Carbonylation products of dienes and diols[a)]

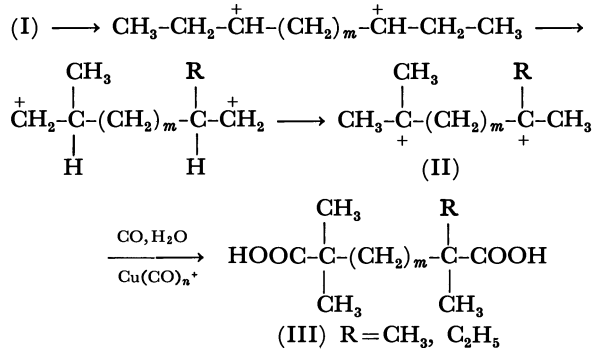
a) Reactions were carried out using 30 ml of 98% H_2SO_4, 1.144 g of Cu_2O and 30 mmol of dienes or diols.
b) During the carbonylation, 10 ml of FSO_3H was added. c) The structure of this substance was not determined.

C_{10} and C_{12}. The dicarboxylic acids obtained consist of structural isomers of which the main product is tetramethyl-substituted dicarboxylic acid and the by-product is ethyl-substituted dicarboxylic acid.



Lactone was always obtained for the carbonylation of the dienes or diols. The lactone obtained is a mixture of five-membered 1,4-lactones and six-membered 1,5-lactone derivatives. No four-membered lactones or large-ring lactones were obtained. In the formation of stable 1,4-lactone derivatives, the carbonium ions (I) rearrange to resonance-stabilized allyl cation intermediates (V′). The carbonium ions (V) undergo carbonylation and hydration, and subsequently 1,4-lactones are formed by intramolecular esterification. During the isomerization process to V, carbonium ions (IV) react with carbon monoxide, and then stable 1,5-lactone derivatives are obtained. Generally, the amount of 1,4-lactone is larger than the quantity of 1,5-lactone. Lactonization to five- and six-membered rings is fast, however ring-closure reactions to seven- and eight-membered rings are slow. Furthermore, the isomerization rate is higher than the ring-closure rate to large-ring lactones. For these reasons, it is understood that no large-ring lactones or four-membered lactone are obtained. In all lactones, the α-carbon of the carbonyl group has two alkyl substituents, and the carbon atom adjacent to the oxygen atom has one alkyl substituent.

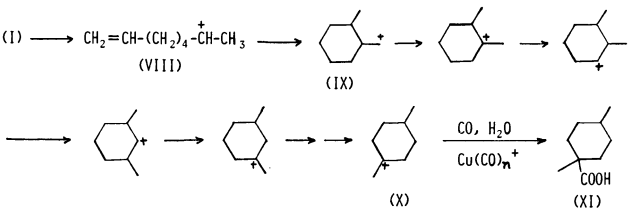
R_1=CH_3, C_2H_5, C_3H_7, C_4H_9
R_2=CH_3, C_2H_5

Cyclic monocarboxylic acid and *t*-monocarboxylic acid are obtained by the carbonylation of 1,7-octadiene. In the formation of cyclic monocarboxylic acid, the carbonium ion (VIII) undergoes a ring-closure reaction by means of the intramolecular attack of the cation on the double bond. After rearrangement from IX to X, the carbonium ion (X) reacts with carbon monoxide producing 1,4-dimethylcyclohexanecarboxylic acid.



To form saturated *t*-monocarboxylic acid, some of the carbonium ions (I) are saturated by hydride abstraction from other molecules. It appears that the secondary carbonium ions are more susceptible to saturation than *t*-carbonium ions.

Actually, the main alkyl chain of the carboxylic acid obtained is linear.

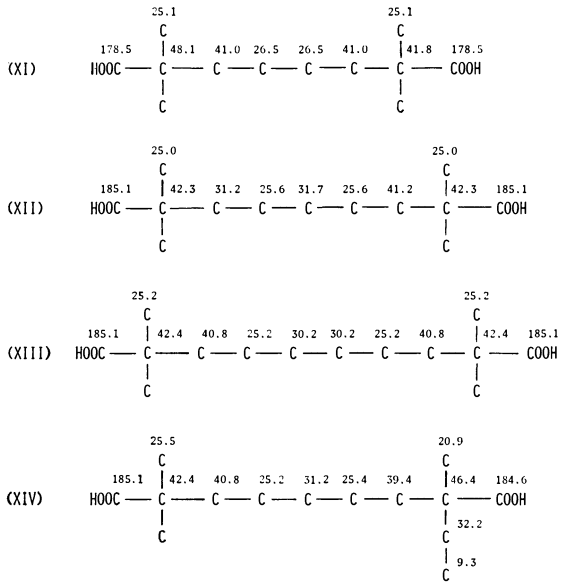

Chart 1. ^{13}C NMR chemical shifts of tertiary-dicarboxylic acids.

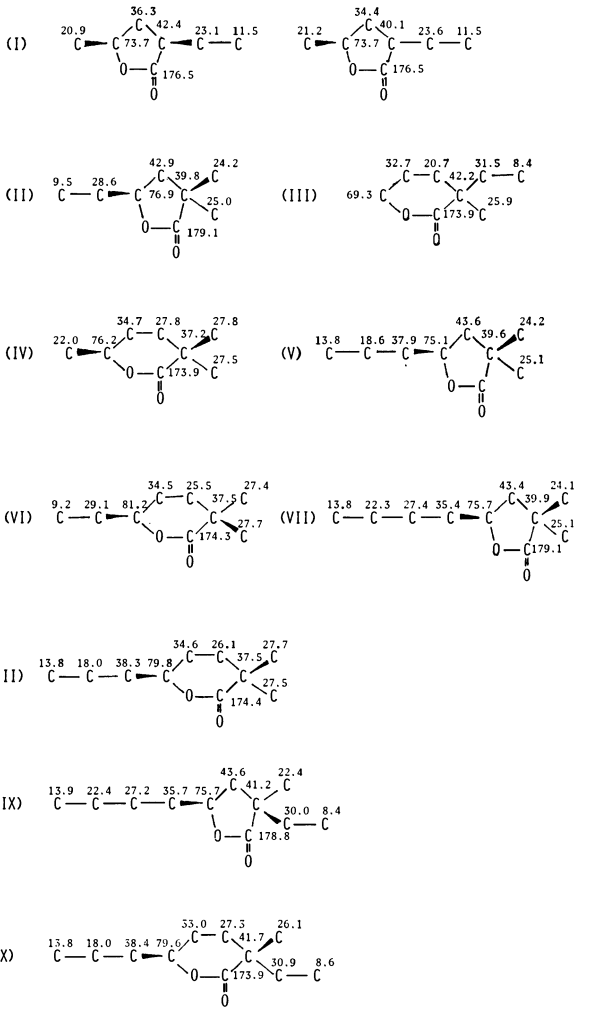

Chart 2. ^{13}C NMR chemical shifts of lactones.

Dicarboxylic acid was separated as crystals from lactone and recrystallized from a mixed solvent of petroleum ether and acetone. Since the isomers of

the dicarboxylic acids could not be separated, the mixtures were analyzed by ^{13}C NMR. Lactone and monocarboxylic acid were isolated by preparative GLPC, and the structures were determined by ^{1}H NMR, ^{13}C NMR, IR, GC-MS and elemental analysis. The ^{13}C NMR chemical-shift assignments of the dicarboxylic acids and lactones are shown in Charts 1 and 2. From the ^{13}C NMR analysis, other isomers coexisted with the compound shown in Charts 1 and 2, however, the amount of other isomers was so few that the determination of their structures was not successful.

Several characteristics are clarified by the results of the analysis of the lactones. On the GLPC chromatogram, two large peaks were observed for every sample. The first peak corresponds to the 1,4-lactone derivatives, and the second peak to the 1,5-lactone derivatives. In the IR spectra, the $\nu_{C=O}$ of 1,4-lactone and 1,5-lactone were observed at 1775 and 1725 cm^{-1}, respectively. In the ^{1}H NMR chemical shifts of 1,4-lactones, characteristic signals for methylene of the lactone ring were observed at 2.0—2.3 ppm as the AB part of the ABX spin system. From ^{13}C NMR analysis, the chemical shifts for the carbonyl carbons of 1,4-lactone and 1,5-lactone were determined to be at 176—179 ppm and at *ca.* 174 ppm, respectively.

Using silver carbonyl ions instead of copper(I) carbonyl ions as catalysts, the same catalytic effect was observed and the same reaction products were obtained.

Experimental

GLPC analysis was performed using a 3-m Free Fatty Acid Polyester column. The infrared spectra were taken with neat samples using a JASCO IRA-1 spectrophotometer. The ^{1}H NMR spectra were taken using a JEOL PS-100 at 100 MHz with CCl_4 as the solvent. Chemical shifts are given in δ units (ppm) downfield from the tetramethylsilane internal standard. The ^{13}C NMR spectra were measured using the pulsed Fourier-transform technique with a JEOL PS-100 instrument, an FT-100 FT unit, a DP-1 pulse programmer, and an EC-100 computer, at a resonance frequency of 25.15 MHz. Proton noise decoupling was normally used. Mass spectra were obtained using a JEOL JMS-06 gas chromatograph-mass spectrometer with a 20-eV ionizing voltage.

Preparation of the Cu(I) Carbonyl Catalysts. In a 300-ml three-necked flask equipped with a thermometer and a carbon monoxide gas burette, 1.144 g of Cu_2O and 30 ml of 98% H_2SO_4 were placed: The apparatus was evacuated by a rotary pump, and then carbon monoxide was introduced from the gas burette. The mixture was stirred vigorously and a heterogeneous solution of $Cu(CO)_n^+$ was prepared.

Carbonylation of Dienes and Diols. From a syringe, 30 mmol of dienes or diols were added dropwise to the Cu(I) carbonyl catalyst solution for 2 h. Absorption of the carbon monoxide was completed within 2 — 3 h, and the reaction mixture was poured over ice-water. The mixture was shaken with hexane, and the reaction products were isolated by preparative GLPC or by recrystallization. The structures of the products were determined by ^{1}H NMR, ^{13}C NMR, IR and mass spectra and by elemental analysis.

In order to determine the monocarboxylic acid, dicarboxylic acid and lactone yield in the mixture, first the total amount of the carboxylic acids was determined by titrating a 1/10 volume of hexane extract with a 1/10 M NaOH ethanol solution. The monocarboxylic acid yield was determined using gas chromatography by adding a known amount of an internal standard. The dicarboxylic acid yield was calculated from the difference between the total carboxylic acid yield and the monocarboxylic acid yield. The lactone yield was determined by measuring the saponification value. The excess of the 1/10 M NaOH ethanol solution was added to the hexane extract, and the mixture was refluxed for 3 h, then titrated with a standard 1/10 M HCl solution. The lactone yield was found from the difference between saponification value and the total amount of carboxylic acids.

2,2-Dimethyl-4-hexanolide was obtained from 1,7-heptanediol. IR: 2960, 1760 (C=O), 1460, 1205 cm^{-1}. NMR δ 0.98 (3H, t, J=7Hz, $-CH_2-CH_3$), 1.20 (6H, s, $-\overset{|}{\underset{|}{C}}-CH_3$) 1.43—1.80 (2H, m, $-CH_2-CH_2$), 2.00—2.30 (2H, m, $-OCH-CH_2-$), 4.25(1H, m, $-O-CH-CH_2-$). Found: C, 67.23; H, 9.78%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.92%.

2-Methyl-2-ethyl-5-heptanolide was obtained from 1,7-heptanediol. IR: 2980, 1735 (C=O), 1380, 1260, 1140 cm^{-1}. NMR (CCl_4) δ 0.90 (3H, t, J=7Hz, $-CH_2-CH_3$), 1.20 (3H, s, $-\overset{|}{\underset{|}{C}}-CH_3$), 1.40—2.00 (6H, m, $-CH_2-$), 4.28 (2H, m, $-O-CH_2-$). Mass spectrum *m/e* (%) 142 (M^+, 8) 127(9), 113(100), 55(46). Found: C, 67.11; H, 9.89%. Calcd for $C_8H_{14}O_2$; C, 67.57; H, 9.92%.

2,2-Dimethyl-4-heptanolide was obtained from 1,7-octadiene and 1,8-octanediol. IR: 2970, 1770 (C=O), 1460, 1385, 1205, 1115 cm^{-1}. NMR (CCl_4) δ 1.00 (3H, t, J=7 Hz, $-CH_2-CH_3$), 1.20 (6H, s, $CH_3-\overset{|}{\underset{|}{C}}-CH_3$), 1.36—2.20 (6H, m, $-CH_2-$), 4.35 (1H, m, $-CH-O-$). Mass spectrum *m/e* (%) 156 (M^+, 21), 113(100), 85(82), 69(86). Found: C, 69.07; H, 10.64%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

2,2-Dimethyl-5-heptanolide was obtained from 1,7-octadiene and 1,8-octanediol. IR: 2970, 1725(C=O), 1385, 1280, 1120 cm^{-1}. NMR (CCl_4) δ 1.02 (3H, t, J=7 Hz, $-CH_2-CH_3$), 1.22 (6H, s, $CH_3-\overset{|}{\underset{|}{C}}-CH_3$), 1.40—1.95 (6H, m, $-CH_2-$), 4.14 (1H, m, $-CH-O-$). Mass spectrum *m/e* (%) 156 (M^+, 9), 127(14), 81(28) 70(25), 56(100). Found: C, 69.22; H, 10.73%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

2,2-Dimethyl-4-octanolide was obtained from 1,9-nonanediol. IR: 2960, 1765 (C=O), 1460, 1200, 1115 cm^{-1}. NMR (CCl_4) δ 0.94 (3H, t, J=6Hz, $-CH_2-CH_3$), 1.20 (6H, s, $CH-\overset{|}{\underset{|}{C}}-CH_3$), 1.40—2.40 (8H, m, $-CH_2-$), (1H, m, $-CH-O-$). Mass spectrum *m/e* (%) 170(M^+, 14), 140(13), 112 (76), 70(100). Found: C, 70.35; H, 10.46%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65%.

2,2-Dimethyl-5-octanolide was obtained from 1,9-nonanediol. IR: 2960, 1725 (C=O), 1380, 1120 cm^{-1}. NMR (CCl_4) δ 0.98 (3H, t, J=7 Hz, $-CH_2-CH_3$), 1.20 (6H, s, $CH_3-\overset{|}{\underset{|}{C}}-CH_3$), 1.40—1.80 (8H, $-CH_2-$), 4.20 (1H, m, $-CH-O-$). Mass spectrum *m/e* (%) 170 (M^+, 10), 126 (33), 70 (55), 56(100). Found: C, 70.48; H, 10.49%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65%.

C_{12} t-Dicarboxylic Acids (a mixture of 2,2,7,7-tetramethyloctanedioic acid and 2-ethyl-2,6,6-trimethylheptanedioic acid) were obtained from 1,9-decadiene. Mp 152—156 °C. IR (KBr): 2970, 1680 (C=O), 1465, 1380, 1250, 1170 cm^{-1}. NMR (CCl_4) δ 0.88 (t, J=7 Hz, CH_3-CH_2-), 1.08, 1.12, 1.16 (s, $\overset{|}{\underset{|}{C}}-CH_3$), 1.20—1.95 (m, $-CH_2-$), 12.5

(br. s, -COOH). Found: C, 62.28; H, 9.75%. Calcd for $C_{12}H_{22}O_4$: C, 62.58; H, 9.63%.

C_{13} t-Dicarboxylic Acids (a mixture of 2,2,8,8-tetramethylnonanedioic acid and 2-ethyl-2,7,7-trimethyloctanedioic acid) were obtained from 1,10-undecadiene. Mp 132—134°C. IR(KBr): 2970, 1680 (C=O), 1400, 1250, 1193, 920 cm^{-1}. NMR (CCl_4) δ 0.84 (t, J=7Hz, CH_3-CH_2-), 1.04 (s, CH_3-C-), 1.14 (s, CH_3-C-CH_3), 1.26—1.88 (m, -CH_2-), 11.2 (br. s, -COOH). Found: C, 64.29; H, 10.38%. Calcd for $C_{13}H_{24}O_4$: C, 63.91; H, 9.90%.

C_{14} t-Dicarboxylic Acids (a mixture of 2,2,9,9-tetramethyldecanedioic acid and 2-ethyl-2,8,8-trimethylnonanedioic acid) were obtained from 1,12-dodecanediol. Mp 114—118°C. IR(KBr): 2970, 1680 (C=O), 1460, 1250, 1180, 920 cm^{-1}. NMR (CCl_4) δ 0.86 (t, J=7Hz, CH_3-CH_2-), 1.08, 1.14 (s, CH_3-C-), 1.20—1.80 (m, -CH_2-), 12.2 (br. s, -COOH). Found: C, 65.47; H, 10.57%. Calcd for $C_{14}H_{26}O_4$: C, 65.09; H, 10.14%.

2-Ethyl-4-pentanolide, *2,2-Dimethylheptanoic Acid*, *2-Methyl-2-ethylhexanoic Acid* and *1,4-Dimethylcyclohexanecarboxylic Acid* were identified using authentic samples obtained by the carbonylation of 1,5-hexadiene, 1-octene and 1,4-dimethylcyclohexane, respectively.[1,3]

Carbonylation of Olefins, Alcohols, and Saturated Hydrocarbons Using $Cu(CO)_n^+$ and $Ag(CO)_2^+$ Catalysts in BF_3–H_2O

Yoshie Souma and Hiroshi Sano

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received May 4, 1976)

Olefins, alcohols, and saturated hydrocarbons reacted with carbon monoxide to give *t*-carboxylic acids in high yields using copper carbonyl and silver carbonyl catalysts at room temperature and in carbon monoxide at atmospheric pressure in BF_3–H_2O solutions. Dienes and diols also reacted with carbon monoxide to give mixtures of monocarboxylic acids, dicarboxylic acids and lactones. The concentration ratio of H_2O/BF_3 was maintained between 1 and 2 during the carbonylation reaction. There was no difference between the catalytic behavior of $Cu(CO)_n^+$ and that of $Ag(CO)_2^+$. The reaction rates for primary alcohols were very low in BF_3–H_2O, although they increased with the addition of H_2SO_4. The reaction rates for *s*-alcohol, *t*-alcohol and olefins in BF_3–H_2O remained unchanged upon the addition of H_2SO_4.

In previous papers, the authors have reported that olefins, alcohols, and saturated hydrocarbons reacted with carbon monoxide and produced *t*-carboxylic acids in the presence of $Cu(CO)_n^+$ catalysts in H_2SO_4 at room temperature and at atmospheric pressure.[1-4] Similarly, carbonylation reactions of diisobutylene and 1-octene have been reported by Yoneda *et al.* using $Cu(CO)_n^+$ catalysts in BF_3–H_2O.[5] It has been reported that Ag_2O was not effective in the carbonylation.[6] In this case, no silver carbonyl ions appear to be formed, because silver compounds are easily reduced to metal silver when BF_3–H_2O is added to Ag_2O in a CO atmosphere at room temperature. However, the formation of $Ag(CO)_2^+$ was possible by adding Ag_2O to cold BF_3–H_2O.[7] Therefore, it was clarified that the catalysis of $Ag(CO)_2^+$ was the same as that of $Cu(CO)_n^+$ in BF_3–H_2O. This paper describes the carbonylation of olefins, alcohols, and saturated hydrocarbons using $Ag(CO)_2^+$ and $Cu(CO)_n^+$ catalysts in BF_3–H_2O.

Results and Discussion

Cu(I) compounds absorb carbon monoxide and form unstable copper carbonyl ions $Cu(CO)_4^+$, in BF_3–H_2O, as described in a preceding paper.[7]

$$Cu^+ + CO \rightleftharpoons Cu(CO)_4^+ \quad (1)$$

$$Cu(CO)_4^+ \rightleftharpoons Cu(CO)^+ + 3CO \quad (2)$$

In BF_3–H_2O, $Cu(CO)_4^+$, and $Cu(CO)^+$ coexist in equilibrium. The effect of temperature and BF_3 concentration on the formation of $Cu(CO)_4^+$ has been reported by Matsushima *et al.*[8] As the temperature decreases, the equilibruim is shifted toward the left hand side of Reaction 2.

As has been described previously, Ag carbonyl ions are also formed by the absorption of carbon monoxide by silver compounds in cold BF_3–H_2O solutions.[7]

$$Ag^+ + CO \rightleftharpoons Ag(CO)_2^+ \quad (3)$$

$Ag(CO)_2^+$ and Ag^+ also coexist in equilibrium. The effect of the temperature and concentration of BF_3–H_2O on the formation of $Ag(CO)_2^+$ is shown in Fig. 1. Silver carbonyl ions are formed in concentrated BF_3–H_2O solutions, when the H_2O/BF_3 molar ratio of the solution is between 1 and 2. The equilibirum is shifted toward the right hand side of Reaction 3 as the temperature decreases. IR absorption ($\nu_{C=O}$) of $Cu(CO)_4^+$, $Cu(CO)^+$, and $Ag(CO)_2^+$, in BF_3–H_2O occur at 2185, 2160, and 2193 cm^{-1}, respectively.[7] The ^{13}C NMR chemical shifts of $Cu(CO)_4^+$, $Cu(CO)^+$, and $Ag(CO)_2$ are 169.5, 169.0, and 173.4 ppm, respectively.[7]

Table 1. Carbonylation of 1-octene catalyzed by $Cu(CO)_n^+$ and $Ag(CO)_2^+$ in BF_3–H_2O[a]

H_2O/BF_3 mole ratio	$Cu(CO)_n^+/Cu^+$	Yield of C_9-*t*-acid	$Ag(CO)_2^+/Ag^+$	Yield of C_9-*t*-acid
1.0	2.8	92	1.2	93
1.2	2.5	95	1.1	96
1.5	1.8	68	0.7	80
1.7	1.4	50	0.6	55
2.0	1.1	7	0.4	5

a) In all cases, 20 ml of BF_3–H_2O, 572 mg of Cu_2O, 928 mg of Ag_2O and 3.15 ml of 1-octene were used. The reaction was carried out at 20°C in 1 atm of carbon monoxide. b) The product was a 4 : 2 : 1 mixture of 2,2-dimethylheptanoic acid, 2-methyl-2-ethylhexanoic acid and 2-methyl-2-propylpentanoic acid.

The results of the carbonylation reaction of 1-octene in various concentrations of BF_3–H_2O using $Cu(CO)_n^+$ and $Ag(CO)_2^+$ catalysts are shown in Table 1.

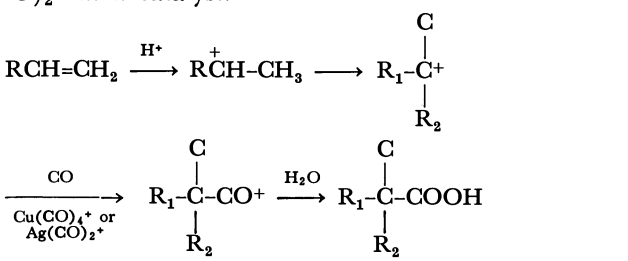
Table 2. The carbonylation of olefins, alcohols, and saturated hydrocarbons[a)]

Compound	Catalyst	Time	Products	Yield	(total)
1-Hexene	$Cu(CO)_4^+$	1 h	2,2-Dimethylpentanoic acid	60	80
			2-Methyl-2-ethylbutanoic acid	20	
1-Octene	$Ag(CO)_2^+$	1 h	2,2-Dimethylheptanoic acid	55	92
			2-Methyl-2-ethylhexanoic acid	26	
			2-Methyl-2-propylpentanoic acid	13	
1-Decene	$Ag(CO)_2^+$	1 h	2,2-Dimethylnonanoic acid	47	86
			2-Methyl-2-ethyloctanoic acid	23	
			2-Methyl-2-propylheptanoic acid	11	
			2-Methyl-2-buthylhexanoic acid	5	
Cyclohexene	$Cu(CO)_4^+$	1 h	1-Methylcyclopentanecarboxylic acid		75
2-Propanol	$Cu(CO)_4^+$	3 d	2-Methylpropionic acid		15
2-Methyl-2-propanol	$Cu(CO)_4^+$	2 h	2,2-Dimethylpropionic acid		94
1-Hexanol	$Ag(CO)_2^+$	1 d	2,2-Dimethylpentanoic acid	12	16
			2-Methyl-2-ethylbutanoic acid	4	
2-Hexanol	$Ag(CO)_2^+$	2 h	2,2-dimethylpentanoic acid	72	95
			2-Methyl-2-ethylbutanoic acid	23	
3-Methyl-3-pentanol	$Ag(CO)_2^+$	2 h	2,2-Dimethylpentanoic acid	16	95
			2-Methyl-2-ethylbutanoic acid	79	
1-Octanol	$Ag(CO)_2^+$	7 d	2,2-Dimethylheptanoic acid	20	35
			2-Methyl-2-ethylhexanoic acid	10	
			2-Methyl-2-propylpentanoic acid	5	
		1 d	same as above		16
Methylcyclohexane (Coexist. with 1-octene)	$Cu(CO)_4^+$	2 h	1-Methylcyclohexanecarboxylic acid		30
			C_9 *t*-carboxylic acid		60
Methylcyclopentane (Coexist. with 2-hexanol)	$Ag(CO)_2^+$	2 h	1-Methylcyclopentanecarboxylic acid		30
			C_7 *t*-carboxylic acid		50

a) The reaction was carried out using 20 ml of BF_3–H_2O, 572 mg of Cu_2O, 928 mg of Ag_2O, and 20 mmol of the compound, at 25 °C in carbon monoxide, at 1 atm.

The yield of *t*-carboxylic acids and the reaction rate decrease with a decrease in the BF_3 concentration. This tendency of the yield to decrease corresponds to the decrease of the amount of $Cu(CO)_4^+$ or $Ag(CO)_2^+$ present in the BF_3–H_2O solution. The carbonylation does not proceed at H_2O/BF_3 molar ratio larger than 2. The best results were obtained at H_2O/BF_3 molar ratios of 1.0—1.2.

The reaction scheme is the same as that for H_2SO_4. The olefin is protonated in the BF_3–H_2O solution and is rearranged to a tertiary carbonium ion with the migration of an alkyl group. The tertiary carbonium ion reacts with carbon monoxide and forms *t*-carboxylic acid in the presence of $Cu(CO)_4^+$ or $Ag(CO)_2^+$ as a catalyst.



$R_1 = CH_3$, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, *n*-C_5H_{11}, *n*-C_6H_{13}, *n*-C_7H_{15}
$R_2 = CH_3$, C_2H_5, *n*-C_3H_7

The results of the carbonylation of olefins, alcohols, and saturated hydrocarbons are shown in Table 2.

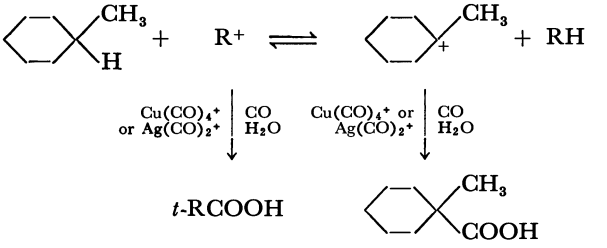
The rate and the conversion of the reaction with primary alcohols were low, and most of the primary alcohol was recovered. The dehydration of primary alcohol appears to be difficult.

Table 3. The influence of the BF_3–H_2O concentration on the carbonylation of saturated hydrocarbons[a)]

Yield of carboxylic acid	H_2O/BF_3 molar ratio			
	1.0	1.2	1.5	1.7
1-Methylcyclohexane-carboxylic acid	30	8	1	0
C_9 *t*-carboxylic acid	60	84	65	57

a) The reactions were carried out using 20 ml of BF_3–H_2O, 527 mg of Cu_2O, 2.56 ml of methylcyclohexane, and 3.14 ml of 1-octene at 20 °C.

Saturated hydrocarbons react with carbon monoxide in the presence of olefins and alcohols. The hydride ion is abstracted from the saturated hydrocarbon by the carbonium ion formed from the olefin or alcohol. Then the carbonium ion forms *t*-carboxylic acid. Saturated hydrocarbons which have no tertiary hydrogens do not react with carbon monoxide.

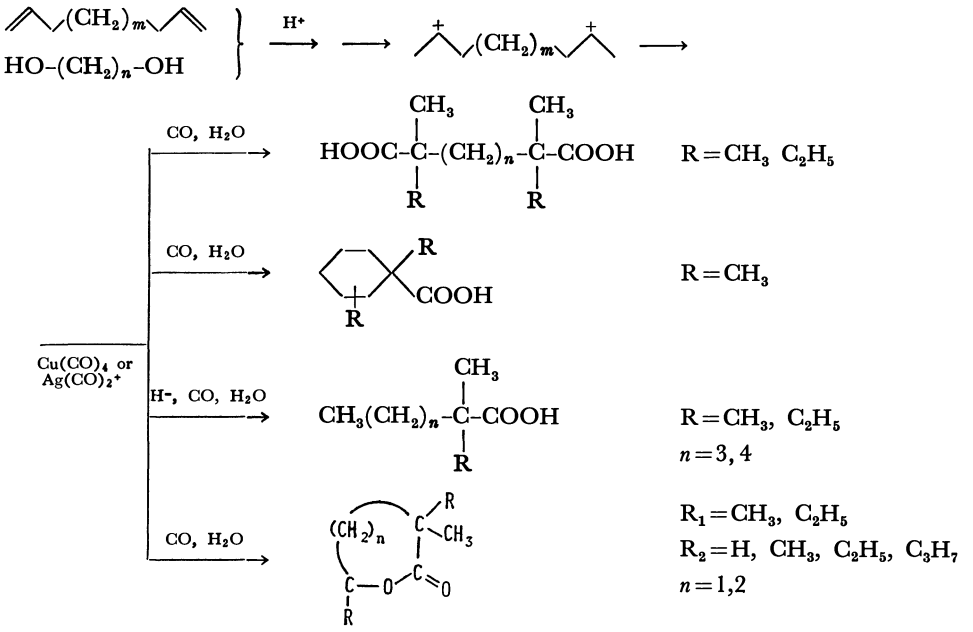


Hydride transfer takes place only in concentrated BF_3–H_2O solutions. The results of the carbonylation

of 1-methylcyclohexane in the presence of 1-octene in various concentrations of BF_3–H_2O are shown in Table 3.

The results of carbonylation reactions of diene and diol are shown in Table 4. Mixtures of *t*-monocarboxylic acids or *t*-dicarboxylic acids and lactones were obtained. The lactones have alkyl branches on α-carbon. The structural analysis of each compound will be reported elsewhere.[9]

The reaction scheme proposed is as follows.



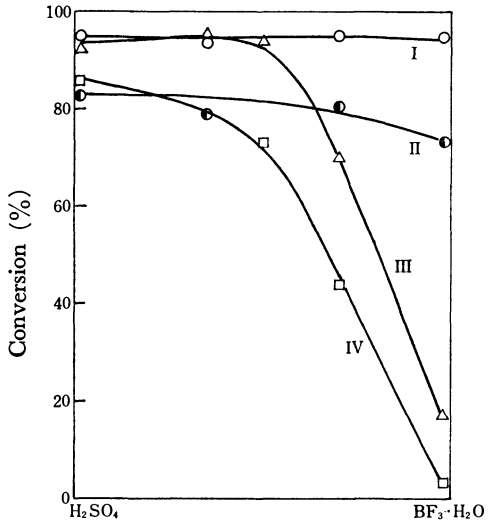


Fig. 2. Carbonylation in BF_3–H_2O~H_2SO_4 system. I: 1-Octene, II: 1,9-decadiene, III: 1-octanol, IV: 1,2-dodecanediol.

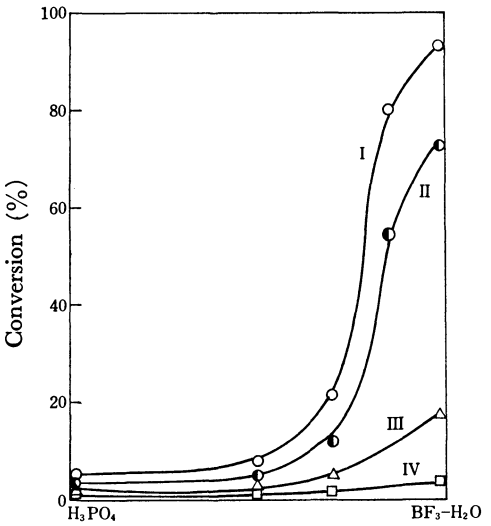

Fig. 3. Carbonylation in BF_3–H_2O~H_3PO_4 system. I: 1-Octene, II: 1,9-decadiene, III: 1-octanol, IV: 1,12-dodecanediol.

The effect of the addition of H_2SO_4 or H_3PO_4 to the BF_3–H_2O solution is shown in Figs. 2 and 3. The addition of H_2SO_4 accelerates the carbonylation reaction of primary alcohols such as 1-octanol and 1,12-dodecanediol, but is not effective in the reactions of olefins and *s*- or *t*-alcohols. The addition of H_2SO_4 appears to promote the dehydration of primary alcohols. The addition of H_3PO_4 decreases the carboxylic acid yield and the reaction rate.

The catalytic behavior of $Ag(CO)_2^+$ and $Cu(CO)_4^+$ are the same for the carbonylation reactions in BF_3–H_2O.

Experimental

Preparation of $Cu(CO)_n^+$ and $Ag(CO)_2^+$ in BF_3–H_2O. The BF_3–H_2O solution was preparared by introducing BF_3 gas into water.

In a 300 ml three-necked flask, equipped with a thermometer and a CO gas burette, 572 mg of Cu_2O were placed. The apparatus was evacuated by a vacuum pump and CO was introduced from the gas burette. The mixture was stirred after the addition of BF_3–H_2O. Colorless copper(I) carbonyl ions were formed by the absorption of CO by the Cu_2O.

Table 4. Carbonylation of dienes and diols[a)]

Compound	Catalyst	Temp, °C	Time, h	Products	Yield, %
1,5-Hexadiene	$Cu(CO)_4^+$	5—10	2	2-Ethyl-4-pentanolide	35
1,7-Octadiene	$Ag(CO)_2^+$	20—30	2	1,4-Dimethylcyclohexanecarboxylic acid	30
				2,2-Dimethyl-4-heptanolide	35
				2,2-Dimethyl-5-heptanolide	8
1,9-Decadiene	$Cu(CO)_4^+$	6—10	2	2,2,7,7-Tetramethyloctanedioic acid	30
				2-Ethyl-2,6,6-trimethylheptanedioic acid	5
				2-Methyl-2-ethyl-4-octanolide	40
				2-Methyl-2-ethyl-5-octanolide	20
1,12-Dodecanediol	$Cu(CO)_4^+$	20—30	3	No reaction	
1,12-Dodecanediol	$Cu(CO)_4^+$	20—25	3	2,2,9,9-Tetramethyldecanedioic acid	30
				2-Ethyl-2,8,8-trimethylnonanedioic acid	10
				1,4- and 1,5-Lactone	45

a) The reactions were carried out using 30 ml of BF_3–H_2O, 6 mmol of Cu_2O or Ag_2O, and 30 mmol of the compound. b) An additional 30 ml of 98% H_2SO_4 were used.

For the preparation of silver carbonyl ions, 928 mg of Ag_2O were placed in a three-necked flask containing ice-cold BF_3–H_2O. Colorless silver carbonyl ions were formed by the absorption of CO by the Ag_2O for a period of 10 min.

Carbonylation of Olefins, Alcohols, and Saturated Hydrocarbons. From a syringe, 20 mmol of an olefin (an alcohols or an equimolar mixture consisting of saturated hydrocarbons and an alkyl cation source) were added drop by drop to the copper(I) carbonyl (or silver carbonyl) catalyst solution. Immediately, carbon monoxide reacted with these compounds. The reaction mixture was poured into ice-water, and the product was extracted with hexane.

The yields of monocarboxylic acid, dicarboxylic acid and lactone in the mixtures were determined as follows. First, a 1/5 volume of an hexane extract of the mixture was titrated with a 1/10 N NaOH ethanol solution to determine the total amount of carboxylic acid. The amount of monocarboxylic acid was determined by gas chromatography in the presence of a known amount of prim-carboxylic acid as an internal standard. The amount of dicarboxylic acid was found from the difference between the total amount of carboxylic acids and the amount of monocarboxylic acid. The amount of lactone was determined by measuring the saponification value as follows. The excess of the 1/10 N NaOH ethanol solution was added to the hexane extract, and the mixture was refluxed for 3 h and then titrated using a standard 1/10 N HCl solution. The amount of lactone was calculated from the difference between the saponification value and the total amount of carboxylic acid. GLPC analysis was performed using a 3-m FFAP column (10% on chromosorb WAW).

All identifications were carried out using authentic samples obtained and characterized previously by the carbonylation of olefins, alcohols, and saturated hydrocarbons in H_2SO_4 systems.[1-3,9)]

Layered Compounds. XXXIV.[1] Molecular and Crystal Structure of a Polycyclic Compound from Novel Cycloaddition Reaction of Triple-layered Anthracenophane

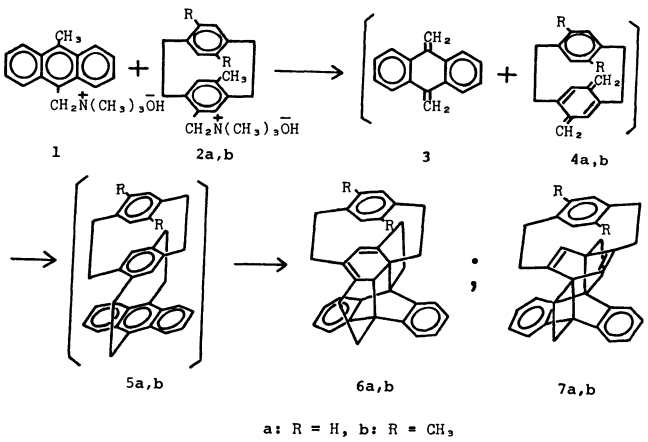
Toshihiro TOYODA, Akio IWAMA, Tetsuo OTSUBO, and Soichi MISUMI*

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received May 15, 1976)

An unusual Diels-Alder reaction was observed to give intramolecular cycloadducts during the syntheses of triple-layered cyclophanes containing anthracene nucleus. The structure of the product was determined by spectral and X-ray crystal analyses. The crystal is monoclinic, $P2_1/c$, with $a=15.896$, $b=8.937$, $c=18.575$ Å, $\beta=120.31°$, $Z=4$. The crystal structure was determined by the direct method using the MULTAN program and refined by the block-diagonal least-squares method to an R index of 0.081. The structure of the molecule is fairly strained.

Layered cyclophanes in which benzene rings are closely fixed face-to-face by methylene bridges have been studied as suitable models for examining transannular π-electron interactions.[2] Reports appeared on the double-layered compounds containing anthracene nuclei as carbophanes of extended aromatic π-system, and their anomalous physical and chemical behaviors.[3] In order to study further the transannular π-electron interaction anthracenophanes, we have undertaken the syntheses of triple-layered compounds (**5**) containing anthracene nucleus. In this paper we report on an unusual reaction which takes place to give cycloadducts (**6**) in place of the desired anthracenophanes. The structures of the products were determined by spectroscopic and X-ray crystallographic analyses.



Scheme 1.

Syntheses and Properties. A quaternary ammonium hydroxide (**1**) was obtained by treatment of 9-chloromethyl-10-methylanthracene[4] with trimethylamine in ether followed by anion exchange with a resin IRA-400. Pyrolysis of an equimolar mixture of the ammonium hydroxide (**1**) and (7-methyl-4-[2.2]-paracyclophanylmethyl)trimethylammonium hydroxide (**2a**)[5] was carried out in boiling xylene in the presence of a catalytic amount of phenothiazine. After removal of water by azeotropic distillation, and separation of solid material by filtration, the reaction mixture was chromatographed twice on alumina to afford pure colorless product in 7.8% yield along with quadruple-layered cyclophanes[5] derived by self-coupling of an intermediate quinodimethane derivative **4a**. The recrystallized product showed a molecular formula $C_{34}H_{30}$ coinciding with the structure **5a** from elemental analysis, mass spectrum, and osmometric molecular weight determination. However, its electronic spectrum shows only a tailing absorption in a wavelength region longer than 350 nm, indicating the absence of anthracene nucleus (Fig. 1). Its PMR spectrum reveals an olefinic proton at δ 4.36 and an increase of aliphatic protons at the expense of two aromatic protons as compared with the proton ratio expected from formula **5a** (Table 1). The spectral data indicate that the intermediate **5a** undergoes a certain intramolecular reaction to give a structural isomer.

Two structures (**6a** and **7a**) are possible for the product on the basis of spectral data and examination with molecular models. Structure **6a** is regarded as a $(4\pi+2\pi)$ cycloadduct of the anthracene and the inner benzene moieties of **5a**, and structure **7a** as a $(4\pi+4\pi)$ one. The PMR data (Table 1) is not consistent with **7a** having C_2 symmetry. Consequently, the remaining **6a** is presumed as the structure of intramolecular cycloadduct. Similarly, the product $C_{36}H_{34}$ which was obtained by cross-breeding pyrolysis of a mixture of **1** and **2b** shows spectra consistent with **6b** (Fig. 1 and

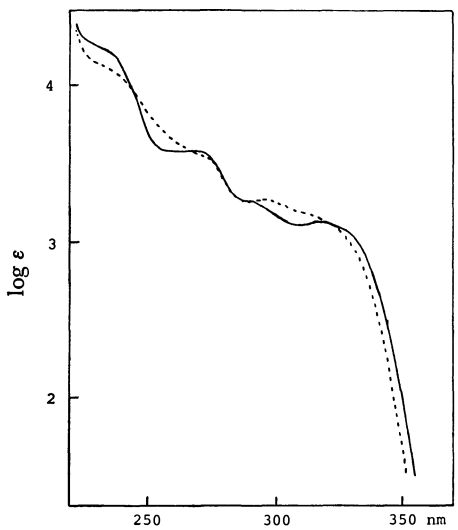


Fig. 1. Electronic spectra of the compounds **6a** (——) and **6b** (----) in tetrahydrofuran.

Table 1. PMR spectra of pyrolysis products

1+**2a** → $C_{34}H_{30}$			**1**+**2b** → $C_{36}H_{34}$		
Chemical shift ppm	Number of protons		Chemical shift ppm	Number of protons	
1.0—3.0 (m)	17	CH_2, CH	0.9—3.3 (m)	23	CH_3, CH_2, CH
4.36 (bs)	1	=CH	4.52 (bs)	1	=CH
6.7—7.4 (m)	12	ArH	6.42 (s)	1	ArH
			6.55 (s)	1	ArH
			6.7—7.2 (m)	8	ArH

Table 1). Two singlets at δ 6.42 and 6.55 on its PMR spectrum are assigned to the aromatic protons of paracyclophane moiety. A considerable high-field shift of the protons as compared to the corresponding ones of **6a** is attributed to the enhanced ortho shift σ_{OE}.[6]

Attempts to prepare the triple-layered anthracenophane **5** by retro-Diels-Alder reaction of **6** under various thermal and photochemical conditions were unsuccessful.

Experimental

Physical Methods. Melting points are uncorrected. PMR spectra were taken on Hitachi Perkin-Elmer R-20 (60 MHz) and JEOL JNM-TS-100 (100 MHz) spectrometers on dilute solution in deuteriochloroform using tetramethylsilane as an internal standard. UV spectra were measured on Hitachi EPS-3T spectrometer, MS on Hitachi RMU-7 spectrometer, and molecular weights on Knauer vapor pressure osmometer using methylene chloride.

(9-Methyl-10-anthrylmethyl)trimethylammonium Chloride. An excess of trimethylamine (4 g) in ether (50 ml) was added with stirring to a solution of 9-chloromethyl-10-methylanthracene (6.5 g, 27 mmol), obtained by chloromethylation of 9-methylanthracene,[4] in benzene (800 ml) at room temp. After prolonged stirring, the resulting yellow ppt was filtered, washed with benzene and dried *in vacuo*. The yield of quaternary ammonium chloride was 7.3 g (90%).

*Cross-breeding Pyrolysis of Ammonium Bases, **1** and **2**. Compound **6a**.* An aq solution (1.5 l) of equimolar mixture of (9-methyl-10-anthrylmethyl)trimethylammonium chloride (4.0 g, 13.3 mmol) and (7-methyl-4-[2.2]paracyclophanylmethyl)trimethylammonium bromide[5] (4.6 g, 13.3 mmol) was passed through a column of anion exchange resin IRA-400 to give aq solution of two ammonium bases, **1** and **2a**. The aq soln was added dropwise for 15 h to a boiling solution of phenothiazine (100 mg) in xylene (200 ml) placed in a three-necked, pear-shaped flask fitted with a mechanical stirrer and a Dean-Stark type water separator. After complete removal of water, insoluble solid was filtered and the filtrate was condensed to *ca.* 5 ml *in vacuo*. Precipitated solid was filtered and the filtrate was chromatographed on neutral alumina (Sumitomo KCG-30). Elution with benzene–hexane (1 : 9) gave 0.51 g (8.7% yield) of **6a**. Compound **6a** was recrystallized from benzene, colorless prisms, mp 238.0—240.5 °C with decomposition near 240 °C.

MS (*m/e*) 438 [M+], 334, 234, 204. Found: C, 92.98; H, 6.81%; mol wt 428 (vapor pressure osmometry). Calcd for $C_{34}H_{30}$: C, 93.12; H, 6.90%; mol wt 438.6.

*Compound **6b**.* Pyrolysis of two ammonium bases, **1** and **2b**, derived from an equimolar solution (1.5 l) of (9-methyl-10-anthrylmethyl)trimethylammonium chloride (3.35 g, 11.2 mmol) and (4,7,12-trimethyl-15-[2.2]paracyclophanylmethyl)trimethylammonium bromide[5] (5.0 g, 12.4 mmol), was carried out in the same manner as that for **6a** to afford a 1.5% yield (78 mg) of **6b**. Compound **6b** was recrystallized from benzene to give colorless prisms, mp 220—235 °C with decomposition over 180 °C.

MS (*m/e*) 466 [M+], 334, 262, 204, 132. Found: C, 92.65; H, 7.23%; mol wt 458 (vapor pressure osmometry). Calcd for $C_{36}H_{34}$: C, 92.66; H, 7.35%; mol wt 466.7.

X-Ray Structure Determination

The crystal of compound **6a** crystallized in colorless prisms from benzene was used for the measurement of intensities. The space group was determined to be $P2_1/c$ from oscillation and Weissenberg photographs. The cell constant was determined by the least-squares method (Sakurai, 1967)[7] based on the Bragg angles of 30 reflections. The density was measured by floatation in aq zinc bromide at room temperature.

Crystal Data. $C_{34}H_{30}$ MW=438.61; monoclinic, space group $P2_1/c$, a=15.896(3), b=8.937(2), c=18.575(3) Å, β=120.31 °(1), V=2278.0(6) Å^3), Mo $K\alpha$ radiation λ=0.71069 Å, D_m=1.275 g/cm^3, Z=8, D_x=1.279 g/cm^3.

Systematic absences $h0l$ when l is odd
$0k0$ when k is odd

Three-dimensional intensity data were collected on a Rigakudenki automatic four-circle diffractometer with Mo $K\alpha$ radiation. The crystal selected for the data collection was 0.33×0.17×0.20 mm in size. The relative intensities were measured with the θ-2θ scan technique (scan speed 2 °/min(2θ)) in a range from $\{2\theta(\alpha_1)-1.0\ °\}$ to $\{2\theta(\alpha_2)+1.0\ °\}$. During the course of data collection, the three standard reflections were monitored at every 50 reflections in order to examine the stability of the electronics and the crystal. A total of 5669 independent reflections were measured in the range $0<\sin\theta/\lambda<0.7$, of which 3054 were recorded as observed. The intensities were corrected for Lorentz and polarization factors, but not for absorption. Background intensities were measured for ten seconds at both ends of a scan.

Structure Refinement. The structure was determined by the direct method using the MULTAN program[8] with 494 reflections having E's>1.5. The sets of phases selected by the program were:

h	k	l	Phase	
4	1	$\bar{1}$	0	origin fixing
4	1	$\bar{2}$	0	
5	4	$\overline{23}$	0	

Table 2. Atomic fractional coordinates and anisotropic thermal parameters ($\times 10^4$) of the carbon atoms
Anisotropic thermal parameters are expressed in the form of $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$.
The estimated standard deviation, given in parentheses, refers to the last significant figure.

by Σ_1 formula

Of the 16 possible solutions, one set of phases (12,1, $\overline{15}$ and 1,5,$\overline{12}=0$;12,4,$\bar{2}$ and $18\bar{1}=\pi$) giving the figure of merit of 1.23 seemed to be correct. An E map generated from this set of phases gave starting positions for all carbon atoms which gave an initial $R=0.27$. After refinement with the block-diagonal least-squares method ($R=0.17$), a difference synthesis revealed the positions of all the hydrogen atoms. The refinement with isotropic thermal parameters for all the atoms, followed by further cycles of refinement using the block-diagonal least-squares method[9] with carbon atoms anisotropic and hydrogen atoms isotropic temperature factors, yielded the final residual R of 0.081. The final atomic coordinates, thermal parameters, and the corresponding standard deviations are listed in Tables 2 and 3.* Computation was done on a NEAC 2200-700 computer at Osaka University. Atomic scattering factors were taken from those of Suzuki.[10]

Results and Discussion

The molecular geometry is shown in Fig. 2. The structure obtained is in complete agreement with that of **6a** determined by spectroscopy. For the dimethyl derivative $C_{36}H_{34}$, structure **6b** can be assigned on the basis of the fact that it shows electronic and PMR spectra similar to those of **6a** and that the cell constant and the reflection pattern of the crystal of **6b** (space group $P2_1/c$) closely resemble those of **6a**.

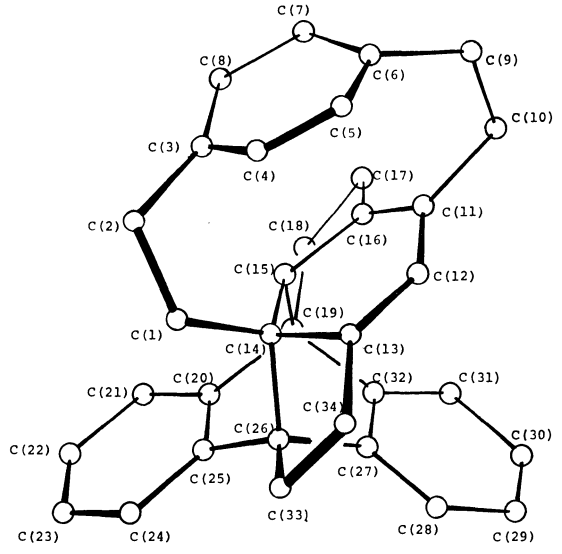

Fig. 2. Projection of the molecular structure along the b-axis.

* A list of structure factors has been deposited with the Chemical Society of Japan, 1-5 Kanda-Surugadai, Chiyoda-ku, Tokyo 101 (Document No. 7630).

The bond distances and angles for the molecule of **6a** are given in Tables 4 and 5 with their estimated standard deviations. The C–C bond lengths of the benzene ring, C(3)—C(8), are normal. On the other hand, the two aromatic C–C bonds, C(22)–C(23) and C(29)–C(30), are slightly shorter, which is probably attributable to intermolecular repulsions and/or the inaccuracy of the present crystal analysis.

In the cyclohexadiene moiety C(11)—C(16), the bond lengths of the double bonds, C(11)–C(16) and C(12)–C(13), and the single bond C(11)–C(12) are normal as compared to the common butadiene system (C=C 1.31—1.34 Å and C–C 1.37—1.53 Å), whereas the single bonds, C(14)–C(15) and C(15)–C(16), are appreciably shorter than the normal values (C–C 1.54 Å and C–C= 1.51 Å). As shown in Fig. 3 and Table 6, the marked steric compressions of C(15) and H(15) by benzene C(3)—C(8) and the bridged methylene, C(2) and C(18), are responsible for the shortening of these two single bonds. Other two single bonds,

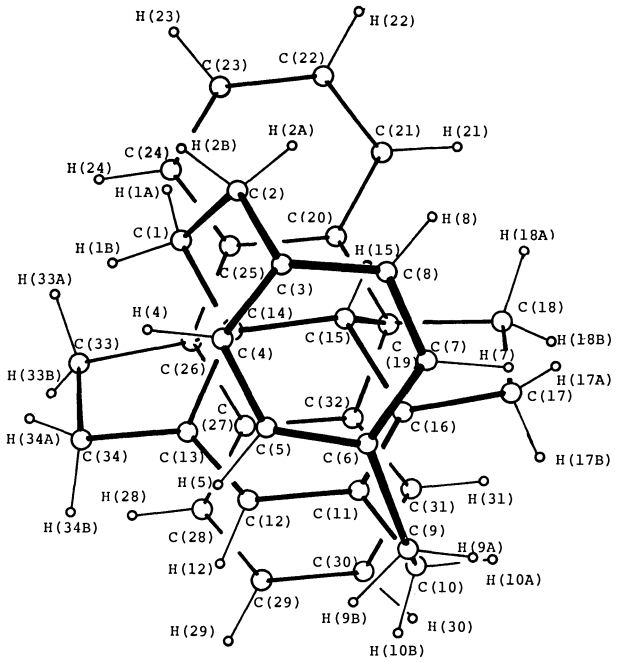

Fig. 3. A view of the molecule along the normal to the plane defined by four carbon atoms, C(20), C(25), C(27), and C(32).

C(14)–C(26) and C(15)–C(19), formed by the intramolecular Diels-Alder reaction are considerably elongated to 1.600 and 1.567 Å, respectively, from the normal value. This may be caused by the steric repulsions acting on methylene C(1) and the cyclohexadiene moiety C(11)—C(16) from the dihydroanthracene moiety C(19)—C(32) (Table 7). As shown in Fig. 4, the cyclohexadiene moiety has a nearly planar structure in spite of a severe overlapping of the π-electron cloud with that of the benzene ring C(3)—C(8). Intramolecular nonbonding distances are given in

TABLE 7. SOME INTRAMOLECULAR NONBONDING DISTANCES AROUND C(1) AND BETWEEN CYCLOHEXADIENE C(11)—C(16) AND TWO BENZENE RINGS, C(20)—C(25) AND C(27)—C(32), WITH e.s.d.'s

		C(16)...C(32)	2.829(6)

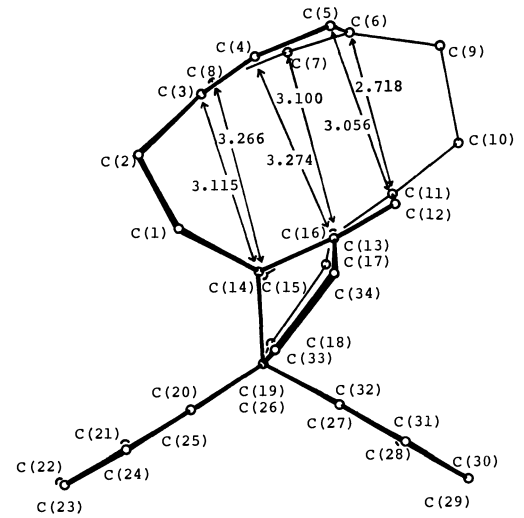

Fig. 4. A view of the molecule along the bond C(19)–C(26).

Table 8. Such unexpected planarity of the cyclohexadiene moiety can be explained by a compensation of the repulsions acting on both upper and lower sides of the diene moiety. An unsymmetrical boat-shape deformation of the para-substituted benzene ring C(3)—C(8) is observed (Fig. 5), which may result from the π-electron repulsion between the benzene ring and the diene moiety (Table 8). The repulsion would also affect the bond lengths of the

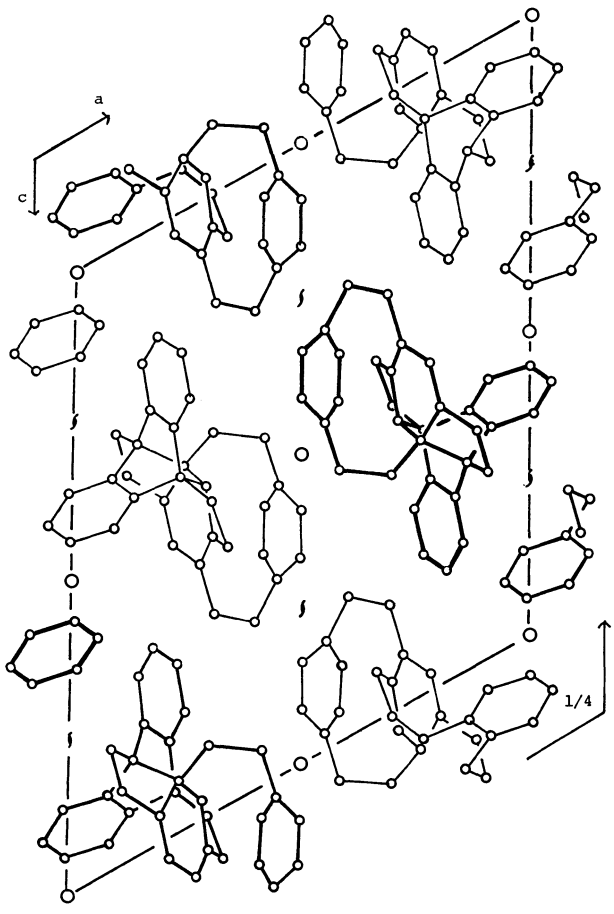

Fig. 6. Molecular arrangement in the crystal.

two bridged single bonds, C(1)–C(2) and C(9)–C(10), both of them, especially the latter, being longer than the normal C–C bond length.

The molecular arrangement in the crystal is shown in Fig. 6. Some intermolecular nonbonding distances are so short that will cause the strain of the molecule.

In conclusion, it is shown from spectral and X-ray crystal analyses that the unexpected cycloadducts **6** were formed in place of the desired triple-layered anthracenophane **5** by cross-breeding pyrolysis of the ammonium bases **1** and **2**. The formation of **6** is explainable by the intramolecular Diels-Alder addition of the inner benzene ring as a dienophile to the 9,10-positions of the anthracene moiety in the intermediate **5**. Recently, Korte and his co-workers[11] reported the first example of benzene and its derivatives being allowed to react as dienophile with hexachlorobutadiene under the high pressure of 10 kbar to afford 1:2 adducts. The unusual cycloaddition reaction of the intermediate **5** under ordinary conditions can be explained by the close fixing of the anthracene against the inner benzene moieties with short methylene bridges, and by the severe molecular strain of the intermediate as seen in the structures of triple-[12] and quadruple-layered cyclophanes.[13] In other words, strain releasing forces would act as a driving force for the unusual reaction.

The authors are greatly indebted to Professors M. Kakudo and N. Kasai of Osaka University for the X-ray crystallographic analysis. The research was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Layered Compounds. XXXV.[1] Syntheses of Triple-layered Metaparacyclophanes

Naoki KANNEN, Tetsuo OTSUBO, Yoshiteru SAKATA, and Soichi MISUMI*
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received June 7, 1976)

Six triple-layered [2.2]metaparacyclophanes have been prepared using general synthetic methods such as the Stevens rearrangement-Raney nickel desulfurization method, pyrolysis of bissulfone, and photo-induced desulfurization. The pyrolysis of bissulfone has turned out to be the most useful and convenient method for preparation of the intermediate double-layered [2.2]metaparacyclophanes because of simple experimental process and excellent yields. The unexpected formation of compound **9** during the photo-induced desulfurization of **7** was explained by a unique skeletal rearrangement of the intermediate **8** on irradiation.

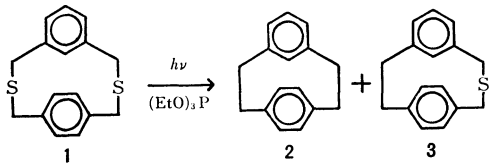
Since [2.2]metaparacyclophane **2** in which meta-substituted benzene is stacked at some angle on the para-substituted benzene by double methylene bridges was first synthesized in 1966,[2] its unique structure has become of great interest. Earlier efforts were made to study the NMR spectrum which showed temperature-dependence due to the flipping of the meta-ring.[2-5] On the other hand, as observed in the electronic spectra, there are few unambiguous evidences supporting the originally expected transannular electronic interaction between two benzene rings. In earlier papers of this series, multilayered para- and meta-cyclophanes were reported to exhibit stronger electronic interactions in their physical and chemical properties than the corresponding double-layered cyclophanes.[6]

One may expect that, in the same manner as multilayered meta- and para-series, multilayered metaparacyclophanes should offer further informations concerning the interaction between meta- and para-rings. However, there are a number of possible structual isomers according to the combination modes of meta- and para-rings in this series of multilayered cyclophanes. The present paper describes the syntheses of six triple-layered metaparacyclophanes containing a durene ring as the inner benzene nucleus along with several [2.2]metaparacyclophane derivatives.[7]

The nomenclature of cyclophanes proposed by Hirayama[8] is very useful also for the present series of multilayered cyclophanes, but not so familiar with us. Therfore, in this paper, we tentatively call the triple-layered cyclophanes as derivatives of double-layered one. For example, the compound **8** is regarded as a metacyclo derivative of [2.2]paracyclophane. In addition, we use a brief and convenient notation affixed after the name of compounds, *e.g.*, m-p,p-p for **8**, where m and p indicate meta and para bridging of methylene chains, respectively.

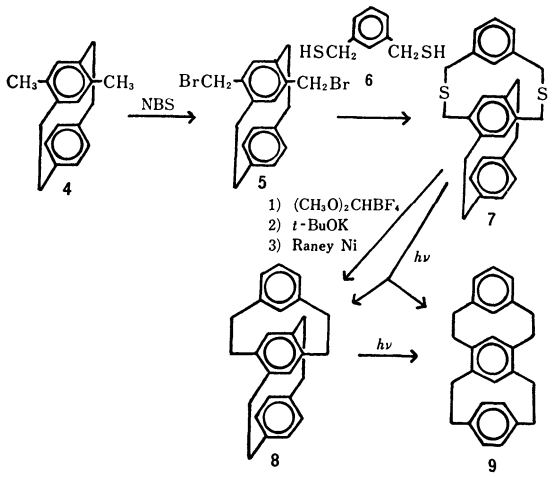
Results and Discussion

Synthesis: *[2.2]Metaparacyclophane (2).* From acid-catalyzed rearrangement of [2.2]paracyclophane, [2.2]-metaparacyclophane **2** was first prepared by Cram and his co-workers.[2] As alternate routes, Boekelheide and his co-workers developed the Stevens rearrangement-Hofmann elimination method and dithiane alkylation-Raney nickel desulfurization method.[9] Also Vögtle obtained the same compound **2** by pyrolysis of bissulfone.[3] We investigated photo-induced desulfurization according to Jenny and his co-workers[10] as an alternate synthetic method of **2**. On irradiation of 2,11-dithia-[3.3]metaparacyclophane **1**[9] in triethyl phosphite with a 400w high pressure mercury lamp, **2** was obtained in 40% yield together with a by-product, 2-thia[3.2]metaparacyclophane **3** in 9% yield.



Scheme 1.

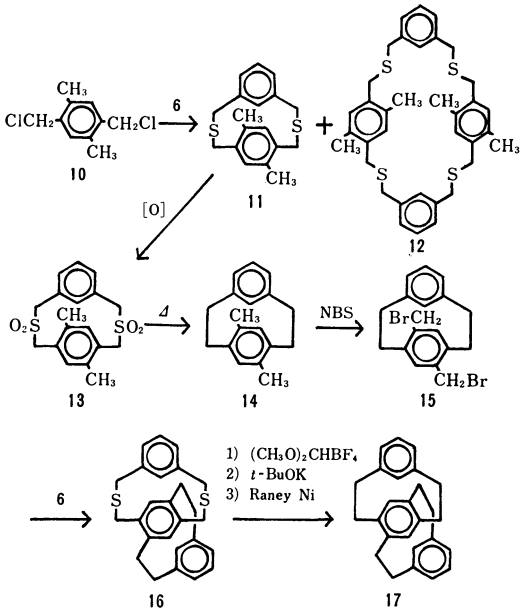
[2.2]Metacyclo(4,7)[2.2]paracyclophane (m-p,p-p) *(8).* Treatment of 4,7-dimethyl[2.2]paracyclophane **4**[6a] with *N*-bromosuccinimide (NBS) gave the corresponding bis(bromomethyl) compound **5** in 76% yield. Condensation of **5** with 1,3-bis(mercaptomethyl)benzene **6** smoothly afforded 18,27-dithia[3.3]metacyclo(4,7)[2.2]-paracyclophane **7** in 56% yield. The desired triple-layered metaparacyclophane (m-p,p-p) **8** was obtained in only 12% yield by the Stevens rearrangement of **7** followed by desulfurization with Raney nickel. On the other hand, direct photodesulfurization of **7** in triethyl phosphite gave **8** in 26% yield together with a small amount of another isomer (m-m,m-p) **9**. The structure of **9** was confirmed by comparison with the authentic sample synthesized by alternate routes as described later. The unexpected formation of **9** provides an interesting problem whether **9** is formed



Scheme 2.

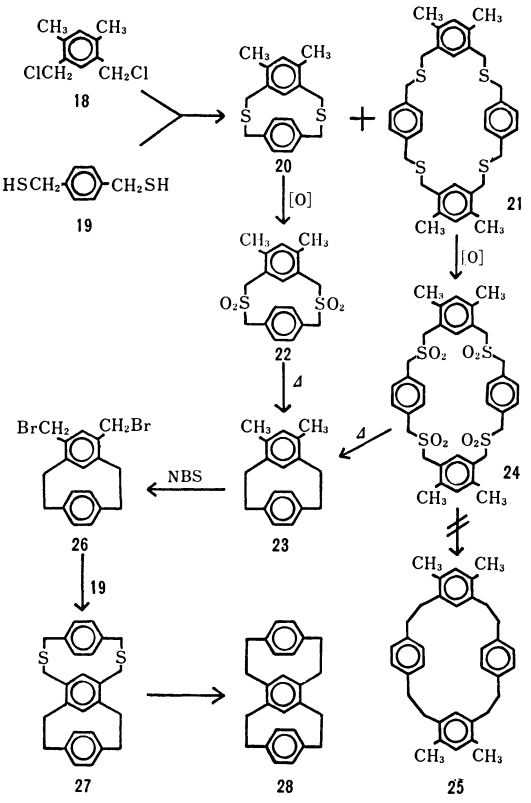
directly from **7** or through the main product **8**. A plausible mechanism is that the initially produced **8** isomerizes to **9** by exchanging the bridge positions at the inside benzene ring during irradiation. This assumption was supported by the facts that prolonged irradiation of **7** resulted in an increased yield (23%) of **9** with a decreased yield of **8** and that irradiation of **8** in degassed cyclohexane produced the isomer **9**.

[2.2]Metacyclo(12,15)[2.2]metaparacyclophane (m-p,p-m) ***(17)***. Condensation of 2,5-bis(chloromethyl)-*p*-xylene **10** with **6** gave 14,17-dimethyl-2,11-dithia[3.3]metaparacyclophane **11** in a good yield (71%) together with its dimer **12** in 6% yield. Pyrolysis of bissulfone **13** at about 900 °C, which was derived by oxidation of the dithiacyclophane **11** in a quantitative yield, afforded 12,15-dimethyl[2.2]metaparacyclophane **14** in an excellent yield (86%). Treatment of **14** with NBS gave the corresponding bis(bromomethyl) compound **15** in 88% yield. As usual, 18,27-dithia[3.3]metacyclo(12,15)[2.2]metaparacyclophane **16** was obtained by condensation of **15** with **6** in 32% yield and then converted to the desired cyclophane (m-p,p-m) **17** in a low yield (9.4%) by the Stevens rearrangement-Raney nickel desulfurization method. Direct photodesulfurization of **16** to **17** was unsuccessful.



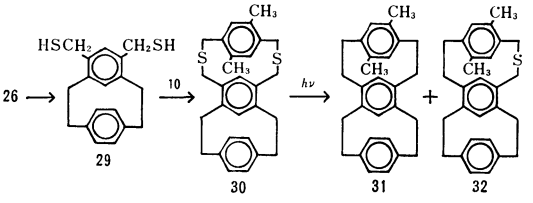
Scheme 3.

[2.2]Paracyclo(4,6)[2.2]metaparacyclophane (p-m,m-p) ***(28)***. Condensation of 4,6-bis(chloromethyl)-*m*-xylene **18** with 1,4-bis(mercaptomethyl)benzene **19** gave 5,6-dimethyl-2,11-dithia[3.3]metaparacyclophane **20** and its cyclic dimer **21** in 68 and 18% yields, respectively. Oxidation of **20** and pyrolysis of the resulting bissulfone **22** afforded 4,6-dimethyl[2.2]metaparacyclophane **23** in a satisfactory yield (91%). Surprisingly, pyrolysis of tetrakissulfone **24** derived from **21** produced rather strained metaparacyclophane **23** in 74% yield instead of the expected [2.2.2.2]metaparametaparacyclophane **25**. 4,6-Bis(bromomethyl)[2.2]metaparacyclophane **26**, which was derived from bromination of **23** with NBS in 78% yield, was coupled with dimercaptan **19** to give 18,27-dithia[3.3]paracyclo(4,6)[2.2]metaparacyclophane **27** in 35% yield. The Stevens rearrangement-Raney nickel desulfurization treatment of **27** afforded the desired cyclophane (p-m,m-p) **28** in only 6.8% yield. On the other hand, direct photodesulfurization of **27** in triethyl phosphite under a nitrogen atmosphere provided the same cyclophane **28** in a better yield of 55%.



Scheme 4.

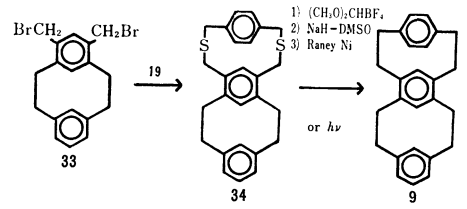
12,15-Dimethyl[2.2]paracyclo(4,6)[2.2]metaparacyclophane (dimethyl p-m,m-p) ***(31)***. 4,6-Bis(bromomethyl)[2.2]-metaparacyclophane **26** was converted to the corresponding bis(mercaptomethyl) compound **29** in 96% yield in the usual way. The reaction of **29** with **10** gave dimethyl dithia compound **30** in 70% yield. Irradiation of **30** in triethyl phosphite under bubbling nitrogen afforded the desired dimethylcyclophane **31** in 60% yield and half-desulfurized cyclophane **32** in 24% yield.



Scheme 5.

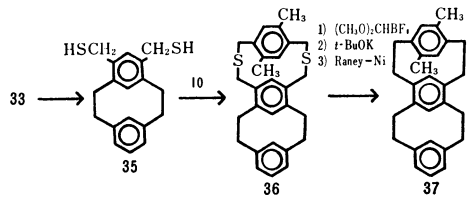
[2.2]Metacyclo(4,6)[2.2]metaparacyclophane (m-m,m-p) ***(9)***. Treatment of 4,6-bis(bromomethyl)[2.2]metacyclophane **33**[6b] with dimercaptan **19** gave 18,27-dithia-[3.3]paracyclo(4,6)[2.2]metacyclophane **34** in 34%

yield. Then **34** was led to the desired cyclophane **9** by the Stevens rearrangement-Raney nickel method (19%) or the photochemical method (35%).



Scheme 6.

12,15-Dimethyl[2.2]metacyclo(4,6)[2.2]metaparacyclophane (dimethyl m-m,m-p*)* (**37**). The above dibromide **33** was transformed to the corresponding dimercaptan **35** in 85% yield. As usual, the reaction of **35** with **10** smoothly gave dimethyl dithia compound **36** in 74% yield. Desulfurization of **36** was carried out using the Stevens rearrangement-Raney nickel reaction to prepare the desired cyclophane **36** in 15% yield, while photochemical desulfurization of **35** failed to provide **37** because of a large amount of oily contaminant.



Scheme 7.

Experimental

Mps are uncorrected. All solvents are of reagent grade unless otherwise specified. Photodesulfurizations were carried out in triethyl phosphite degassed or under nitrogen bubbling at room temp using a quartz tube and a 400 W high pressure mercury lamp. PMR spectra were taken with a Hitachi-Perkin Elmer R-20 spectrometer (60 MHz) using TMS as an internal std, and MS with a Hitachi RMU-7 spectrometer at 70 eV using a direct insertion technique.

*Photodesulfurization of 2,11-Dithia[3.3]metaparacyclophane (**1**).* A soln of 250 mg (0.93 mmol) of 2,11-dithia[3.3]metaparacyclophane **1** in 6 ml of triethyl phosphite purified by distillation over sodium metal was degassed by the freeze-pump-thaw method in a quartz tube and then the tube was sealed. The soln was irradiated with a 400 W high pressure mercury lamp for 7 days at room temp. The solvent was evaporated and the residue was chromatographed on neutral alumina (40 g, Woelm activity I-II). First elution with hexane gave [2.2]metaparacyclophane **2** (79 mg, 40%), then with hexane-benzene (1 : 1) a mixture of 2-thia[3.2]metaparacyclophane **3** and *O,O,O*-triethyl phosphorothioate, and finally with benzene **1** (20 mg) was recovered. [2.2]Metaparacyclophane was recrystd from methanol to give colorless fine crystals, mp 79—80 °C [lit, 79—81 °C (Cram,[2] Vögtle[3]), 81—81.5 °C (Boekelheide[9])]. The compd **3** was purified by rechromatography on silica gel (30 g, Merck activity I-II) using hexane-benzene (4 : 1) (20 mg, 9%). Recrystallization from ethanol gave colorless plates, mp 224—224.5 °C.

Found: C, 80.22; H, 6.66; S, 13.19%. Calcd for $C_{16}H_{16}S$: C, 79.95; H, 6.71; S, 13.34%. PMR (CCl_4, δ) 2.67 (A_2B_2, 4H, CH_2), 3.26 (s, 2H, CH_2), 3.70 (s, 2H, CH_2), 5.32 (bs, 1H, meta internal ArH), 6.34 (d, J=9 Hz, 2H, para ArH), 6.82 (d, J=9 Hz, 2H, para ArH). MS *m/e* 240 (M^+), 104.

*4,7-Bis(bromomethyl)[2.2]paracyclophane (**5**).* A mixture of 4,7-dimethyl[2.2]paracyclophane **4** (4.72 g, 20 mmol) and *N*-bromosuccinimide (7.12 g, 40 mmol) was refluxed in 100 ml of carbon tetrachloride for 4 h. After removal of succinimide by filtration, the filtrate was evaporated and the residue was recrystd from carbon tetrachloride to give the desired dibromide **5** (5.95 g, 76%), colorless prisms, mp 166—168 °C.

Found: C, 54.62; H, 4.67; Br, 40.23%. Calcd for $C_{18}H_{18}Br_2$: C, 54.85; H, 4.60; Br, 40.55%. PMR (CCl_4, δ) 2.6—3.6 (m, 8H, bridged CH_2), 4.16 and 4.40 (A_2B_2, 4H, CH_2Br), 6.29 (s, 2H, ArH). MS *m/e* 396, 394, 392 (M^+), 315, 313, 234, 104.

*18,27-Dithia[3.3]metacyclo(4,7)[2.2]paracyclophane (**7**).* A soln of 1,3-bis(mercaptomethyl)benzene **6** (0.90 g, 5.3 mmol) and sodium hydroxide (0.43 g, 11 mmol) in 35 ml of 95% ethanol, and a soln of the dibromide **5** (1.97 g, 5 mmol) in 35 ml of benzene were added dropwise and simultaneously over a period of 4 h to refluxing and stirring abs ethanol (100 ml) placed in a 300 ml three necked flask under a nitrogen atmosphere. Refluxing was continued for additional 12 h. The mixture was concd and the residue was extracted with chloroform. The extract was washed, dried, and evaporated. The residual solid was chromatographed on neutral alumina (Woelm act. II) with hexane-benzene (1 : 1) to give the dithia compd (1.12 g, 56%). Recrystallization from benzene-ethanol (1 : 1) afforded colorless fine crystals, mp 163—164 °C.

Found: C, 77.49; H, 6.37; S, 15.74%. Calcd for $C_{26}H_{26}S_2$: C, 77.55; H, 6.52; S, 15.92%. PMR ($CDCl_3$, δ) 2.1—4.0 (m, 16H, CH_2) 5.39 (bs, 1H, meta inner ArH), 5.89 (s, 2H, ArH of inner benzene), 6.34 and 6.50 (A_2B_2, 4H, para ArH), 6.9 (m, 3H, meta ArH). MS *m/e* 402 (M^+), 104.

[2.2]Metacyclo(4,7)[2.2]paracyclophane (m-p,p-p) *(**8**).*

a) By the Stevens Rearrangement-Raney Nickel Desulfurization. A mixture of the above dithia compd **7** (0.40 g, 1 mmol) and dimethoxycarbonium fluoroborate[11] (0.65 g, 4 mmol) was refluxed with magnetic stirring in 30 ml of dichloromethane for 6 h. After evaporation of the solvent and decomposition of the excess reagent, the residual solid was powdered and then refluxed with potassium *t*-butoxide (1.1 g, 10 mmol) in 30 ml of dry tetrahydrofuran for 16 h. The mixture was filtered and the filtrate was evaporated. The resulting rearrangement product was refluxed with Raney nickel (6 ml) in 50 ml of abs ethanol for 19 h. Raney nickel was removed by filtration and washed with benzene. The filtrate and the washings were combined and evaporated. The residue was chromatographed on neutral alumina (50 g, Woelm act. II) eluted with hexane-benzene (9 : 1) to give the desired triple-layered metaparacyclophane **8** (40 mg, 12%). For analysis, **8** was recrystd from ethanol, colorless plates, mp 144—145 °C.

Found: C, 92.40; H, 7.68%. Calcd for $C_{26}H_{26}$: C, 92.24; H, 7.76%. PMR ($CDCl_3$, δ) 1.5—3.6 (m, 16H, CH_2), 4.90 (s, 1H, ArH of inner benzene), 5.12 (bs, 1H, meta inner ArH), 6.17 (s, 1H, ArH of inner benzene), 6.30 (bs, 4H, para benzene), 6.6 (m, 3H, meta benzene). MS *m/e* 338 (M^+), 234, 104.

b) By Photodesulfurization. The dithia compd **7** (95 mg, 0.24 mmol) was dissolved in 10 ml of freshly distd triethyl phosphite in a quartz tube and the tube was externally irradiated for an hour bubbling a slow stream of nitrogen

through the soln. The solvent was evaporated and the residue was chromatographed over silica gel (40 g, Merck act. II-III) with hexane–benzene (4 : 1) to give 23 mg (28%) of **8**. When the irradiation was continued for 15 h, an isomeric triple-layered metaparacyclophane **9** was obtained in 23% yield, accompanied with **8** and an unknown oily substance. A 98 h irradiation produced **9** in the highest yield (34%). A soln of **8** (43 mg) in 10 ml of freshly purified cyclohexane was irradiated in a quartz tube for 28 h under an argon atmosphere and worked up in the usual way to give a mixture of **8** and **9** (26 mg).

*14,17-Dimethyl-2,11-dithia[3.3]metaparacyclophane (**11**) and 14,-17,32,35-Tetramethyl-2,11,20,29-tetrathia[3.3.3.3]metaparametaparacyclophane (**12**).* A soln of 1,3-bis(mercaptomethyl)-benzene **6** (3.40 g, 20 mmol) and sodium hydroxide (1.60 g, 40 mmol) in a mixture of water (5 ml) and ethanol (245 ml) and a soln of 2,5-bis(chloromethyl)-*p*-xylene **10** (4.06 g, 20 mmol) in 250 ml of benzene–ethanol (1 : 1) were added dropwise and simultaneously over a period of 4 h with stirring to refluxing alcohol (1 l) in a nitrogen atmosphere. Refluxing was continued for additional 12 h. The solvent was evaporated and the residue was extracted with benzene. The benzene extract was condensed and chromatographed over silica gel (100 g, Merck act. II-III). Elution with hexane–benzene (1 : 1) gave the dithia compd **11** (4.72 g, 71%), colorless columns from benzene–ethanol (1 : 1), mp 130—131 °C.

Found: C, 71.84; H, 6.79; S, 20.94%. Calcd for $C_{18}H_{20}S_2$: C, 71.94; H, 6.72; S, 21.34%. PMR ($CDCl_3$, δ) 2.16 (s, 6H, CH_3), 3.48 (s, 4H, CH_2), 3.71 and 3.96 (A_2B_2, 4H, CH_2), 5.63 (bs, 1H, ArH), 6.69 (s, 2H, ArH), 7.03 (m, 3H, ArH). MS *m/e* 300 (M^+).

Then elution with benzene gave the tetrathia compd **12** (0.36 g, 5.5%), which was recrystd from hexane–benzene (1 : 1), colorless fine crystals, mp 206—207 °C.

Found: C, 71.77; H, 6.60; S, 21.05%. Calcd for $C_{36}H_{40}S_4$: C, 71.94; H, 6.70; S, 21.34%. PMR ($CDCl_3$, δ) 2.13 (s, 12H, CH_3), 3.59 (s, 8H, CH_2), 3.61 (s, 8H, CH_2), 6.89 (bs, 4H, ArH), 7.08 (bs, 2H, ArH), 7.32 (m, 6H, ArH). MS *m/e* 600 (M^+), 132.

*12,15-Dimethyl[2.2]metaparacyclophane (**14**).* To a suspension of 15 g (50 mmol) of the above dithia compd **11** in 100 ml of acetic acid was added slowly an excess (30 ml, 0.34 mol) of hydrogen peroxide (35%) with stirring and then the soln was warmed at 100 °C for 5 h. The resulting ppt was filtered, washed repeatedly with water, and dried to give a quantitative yield of the corresponding bissulfone **13**. Pyrolysis of the bissulfone **13** to the corresponding [2.2]cyclophane **14** was carried out according to the general method described below. The bissulfone **13** (2.0 g) was placed into a Pyrex bulb and plugged lightly with glass wool. In order to prevent a loss of the product, some absorbent cotton was placed near the end of a glass tube which was connected to an aspirator to absorb sulfur dioxide generated. The Pyrex bulb was inserted into a furnance pre-heated at 900 °C and the reaction was completed within 1 min. The trapped product **14** was chromatographed over neutral alumina (10 g, Woelm act. II) with hexane (1.12 g, 86% based on **11**), colorless plates from pentane, mp 65—66 °C.

Found: C, 91.25; H, 8.68%. Calcd for $C_{18}H_{20}$: C, 91.45; H, 8.55%. PMR ($CDCl_3$, δ) 1.65 (s, 3H, CH_3), 1.9—3.4 (m, 8H, CH_2), 2.43 (s, 3H, CH_3), 5.51 (s, 1H, meta inner ArH), 5.69 (s, 1H, para ArH), 6.78 (s, 1H, para ArH), 6.86 (m, 3H, meta ArH). MS *m/e* 236 (M^+), 104.

*12,15-Bis(bromomethyl)[2.2]metaparacyclophane (**15**).* By the usual way from **14** (1.00 g, 4 mmol), *N*-bromosuccinimide (1.51 g, 8 mmol), and a small amount of benzoyl peroxide in 20 ml of carbon tetrachloride, 1.46 g (88%) of **15** was obtained as an yellow oil. The dibromide was used in the next coupling reaction without purification.

PMR ($CDCl_3$, δ) 2.0—4.5 (m, 8H, CH_2), 4.60 (s, 4H, CH_2), 5.55 (bs, 1H, meta ArH), 5.82 (s, 1H, para ArH), 6.9 (m, 3H, meta ArH), 7.22 (s, 1H, para ArH). MS *m/e* 396, 394, 392 (M^+), 315, 313.

*18,27-Dithia[3,3]metacyclo(12,15)[2.2]metaparacyclophane (**16**).* A soln of the dibromide **15** (1.46 g, 3.7 mmol) in 35 ml of benzene and a soln of 1,3-bis(mercaptomethyl)-benzene **6** (0.63 g, 3.7 mmol) and sodium hydroxide (0.30 g, 7.5 mmol) in a mixture of 2 ml of water and 33 ml of ethanol were added dropwise and simultaneously to 100 ml of refluxing ethanol for 4 h in a nitrogen atmosphere and refluxing was continued for additional 12 h. The solvent was evaporated and the residue was chromatographed on neutral alumina (60 g, Woelm act. II) with hexane–benzene (1 : 1). The initial eluate gave 0.47 g (32%) of **16** as an oil.

PMR ($CDCl_3$, δ) 1.5—4.3 (m, 16H, CH_2), 5.22 (bs, 1H, ArH of [2.2]bridged *m*-xylene moiety), 5.42 (s, 1H, ArH of durene moiety), 5.53 (bs, 1H, ArH of S-bridged *m*-xylene moiety), 6.54 (s, 1H, ArH of durene moiety), 6.5—7.2 (m, 6H, ArH of both *m*-xylene moieties). MS *m/e* 402 (M^+).

[2.2]Metacyclo(12,15)[2.2]metaparacyclophane (m-p,p-m) *(**17**).* The synthesis of **17** was carried out in the same manner as that of **8**. The reaction conditions were as follows; methylation of the dithia compd **16** (1.10 g, 2.7 mmol) with the Borch reagent[11] (2.30 g, 14 mmol) in dichloromethane (20 ml) under reflux for 15 h; the Stevens rearrangement with potassium *t*-butoxide (3.50 g, 31 mmol) in 25 ml of dry tetrahydrofuran under reflux for 4 h; desulfurization with Raney nickel (6 ml) in 60 ml of benzene–ethanol (1 : 5) under reflux for 15 h. The desired cyclophane **17** was purified by column chromatography over silica gel (50 g, Merck act. II) using hexane–benzene (9 : 1) (87 mg, 9.4%) and recrystd from benzene–ethanol (1 : 1), colorless plates, mp 170—171 °C.

Found: C, 92.04; H, 7.67%. Calcd for $C_{26}H_{26}$: C, 92.24; H, 7.76%. PMR ($CDCl_3$, δ) 1.5—3.5 (m, 32H, CH_2), 4.39 (s, 1H, ArH of durene moiety), 5.28 (bs, 1H, meta ArH), 5.37 (bs, 1H, meta ArH), 5.60 (s, 2H, ArH of durene moiety), 6.4—7.1 (m, 12H, meta ArH), 6.87 (s, 1H, ArH of durene moiety). MS *m/e* 338 (M^+).

*5,7-Dimethyl-2,11-dithia[3.3]metaparacyclophane (**20**) and 5,7,-23,25-Tetramethyl-2,11,20,29-tetrathia[3.3.3.3]metaparametaparacyclophane (**21**).* A soln of 4,6-bis(chloromethyl)-*m*-xylene **18** (10.15 g, 50 mmol) in 250 ml of benzene–alcohol (1 : 4) and a soln of 1,4-bis(mercaptomethyl)benzene **19** (8.50 g, 50 mmol) in 10 ml of water and 240 ml of alcohol were added dropwise and simultaneously over a period of 4 h to boiling ethanol (1 l) with stirring under a nitrogen atmosphere and refluxing was continued for additional 12 h. After removal of the solvent the residue was extracted with chloroform and the extract was evaporated to dryness. The resulting solid was chromatographed over silica gel (200 g, Merck act. II). Elution with benzene–hexane (1 : 1) gave the dithia compd **20** (10.14 g, 68%), which was recrystd from benzene, colorless columns, mp 215—216 °C.

Found: C, 71.90; H, 6.85; S, 21.08%. Calcd for $C_{18}H_{20}S_2$: C, 71.94; H, 6.72; S, 21.34%. PMR ($CDCl_3$, δ) 2.15 (s, 6H, CH_3), 3.42 (s, 4H, CH_2), 3.86 (s, 4H, CH_2), 5.30 (s, 1H, ArH of durene moiety), 6.92 (bs, 1H, ArH of durene moiety), 7.00 (s, 4H, ArH of *p*-xylene moiety). MS *m/e* 300 (M^+).

Elution with benzene gave the tetrathia compd **21** (2.76 g, 18%) which was recrystallized from toluene, colorless needles, mp 235—236 °C.

Found: C, 72.02; H, 6.69; S, 21.08%. Calcd for $C_{36}H_{40}S_4$: C, 71.94; H, 6.72; S, 21.34%. PMR ($CDCl_3$, δ) 2.37 (s, 12H, CH_3), 3.55 (s, 8H, CH_2), 3.63 (s, 8H, CH_2), 6.87 (bs, 2H, ArH), 7.04 (bs, 2H, ArH). MS *m/e* 600 (M^+).

*4,6-Dimethyl[2.2]metaparacyclophane (**23**).* The cyclophane **23** was synthesized from **20** by the same method as **14**. Thus a suspension of the dithiacyclophane **20** (3.0 g, 10 mmol) in 20 ml of acetic acid was oxidized with 10 ml of hydrogen peroxide (35%) at 100 °C for 5 h with stirring to give the bissulfone **22** in a quantitative yield. Pyrolysis of the bissulfone **22** at 900 °C under 0.1 mmHg followed by chromatography gave **23** (91% based on **20**), colorless plates from pentane, mp 63—64 °C. On the other hand, the same cyclophane **23** was obtained in a good yield of 74% by oxidation-pyrolysis of the tetrathiacyclophane **21**.

Found: C, 91.25; H, 8.63%. Calcd for $C_{18}H_{20}$: C, 91.45; H, 8.55%. PMR ($CDCl_3$, δ) 2.22 (s, 6H, CH_3), 1.7—3.3 (m, 8H, CH_2), 5.22 (s, 1H, ArH of durene moiety), 5.83 (d, J=1 Hz, 2H, ArH of *p*-xylene moiety), 6.65 (bs, 1H, ArH of durene moiety), 7.16 (d, J=1 Hz, 2H, ArH of *p*-xylene moiety). MS *m/e* 236 (M^+), 132, 104.

*4,6-Bis(bromomethyl)[2.2]metaparacyclophane (**26**).* A mixture of **23** (0.50 g, 2 mmol), *N*-bromosuccinimide (0.76 g, 4 mmol), and a small amount of benzoyl peroxide in 20 ml of carbon tetrachloride was refluxed for 3.5 h and worked up in the usual way. The resulting crystals were washed with methanol to give 0.65 g (78% yield) of **26**, colorless plates from carbon tetrachloride, mp 151—152 °C.

Found: C, 55.02; H, 4.51; Br, 40.14%. Calcd for $C_{18}H_{18}Br_2$: C, 54.85; H, 4.60; Br, 40.55%. PMR ($CDCl_3$, δ) 1.8—3.4 (m, 8H, CH_2), 4.46 (s, 4H, CH_2Br), 5.45 (s, 1H, ArH of durene moiety), 6.14 (d, J=2 Hz, 2H, ArH of *p*-xylene moiety), 7.12 (s, 1H, ArH of durene moiety), 7.24 (d, J=2 Hz, 2H, ArH of *p*-xylene moiety). MS *m/e* 396, 394, 392 (M^+), 315, 313, 104.

*18,27-Dithia[3.3]paracyclo(4,6)[2.2]metaparacyclophane (**27**).* A soln of the dibromide **26** (0.6 g, 1.7 mmol) in 35 ml of benzene and a soln of 1,4-bis(mercaptomethyl)benzene **19** (0.28 g, 1.6 mmol) and sodium hydroxide (0.14 g, 3.5 mmol) in water (2 ml) and alcohol (35 ml) were added dropwise and simultaneously to 100 ml of boiling ethanol for 4 h under a nitrogen atmosphere. The mixture was refluxed for 12 h and worked up in the usual way. The desired dithiacyclophane **27** was purified by column chromatography (0.30 g, 35%) and recrystd from benzene, colorless prisms, mp 265—266 °C (sealed tube).

Found: C, 77.71; H, 6.35; S, 15.74%. Calcd for $C_{26}H_{26}S_2$: C, 77.55; H, 6.52; S, 15.92%. PMR ($CDCl_3$, δ) 1.0—4.0 (m, 16H, CH_2), 5.01 (s, 1H, ArH of durene moiety), 5.14 (s, 1H, ArH of durene moiety), 5.91 (bs, 2H, ArH of [2.2]bridged *p*-xylene moiety), 7.02 (bs, 2H, ArH of S-bridged *p*-xylene moiety), 7.14 (bs, 2H, ArH of [2.2]-bridged *p*-xylene moiety), 7.30 (bs, 2H, ArH of S-bridged *p*-xylene moiety). MS *m/e* 402 (M^+), 104.

[2.2]Paracyclo(4,6)[2.2]metaparacyclophane (p-m,m-p) *(**28**).*
a) By the Stevens Rearrangement-Raney Nickel Desulfurization. In the same manner as the synthesis of **8**, 1.53 g (3.8 mmol) of the dithiacyclophane **27** and 1.50 g (9.3 mmol) of the Borch reagent[11] in 20 ml of dichloromethane were refluxed with stirring for 15 h. The resulting ppt was filtered and then refluxed with 2.0 g (18 mmol) of potassium *t*-butoxide in 30 ml of dry tetrahydrofuran for 5 h. The mixture was filtered and the filtrate was condensed. The residue was refluxed with Raney nickel (10 ml) in benzene (5 ml) and ethanol (60 ml) for 17 h. After removal of Raney nickel the soln was worked up in the usual way. Chromatography over silica gel (50 g, Merck act. II) gave **28** (87 mg, 6.8%) from hexane–benzene (9 : 1) eluate. The cyclophane **28** was recrystd from toluene, colorless plates, mp 259—260 °C (sealed tube).

Found: C, 92.20; H, 7.73%. Calcd for $C_{26}H_{26}$: C, 92.24; H, 7.76%. PMR ($CDCl_3$, δ) 1.5—3.3 (m, 16H, CH_2), 4.94 (s, 2H, ArH of durene moiety), 5.66 (bs, 4H, ArH of *p*-xylene moiety), 7.12 (bs, 4H, *p*-xylene moiety). MS *m/e* 338 (M^+), 104.

b) By Photodesulfurization. A suspension of the dithiacyclophane **27** (30 mg, 0.075 mmol) in 15 ml of freshly distd triethyl phosphite was placed in a quartz tube and the tube was externally irradiated with a 400 W high pressure mercury lamp under bubbling of nitrogen for 13 h. After removal of the solvent the residue was adsorbed on silica gel (15 g, Merck act. II) and eluted with hexane–benzene (4 : 1) to give **27** (15 mg, 55%).

*4,6-Bis(mercaptomethyl)[2.2]metaparacyclophane (**29**).* 4,6-Bis(bromomethyl)[2.2]metaparacyclophane **26** (6.61 g, 17 mmol) was added portionwise to a warm soln of thiourea (2.60 g, 34 mmol) dissolved in 50 ml of ethanol and then the mixture was refluxed for 3 h. The solvent was evaporated and the residual thiouronium salt was refluxed with 85% potassium hydroxide (18 g) in 50 ml of water for 8 h. The cold soln was filtered and acidified with hydrochloric acid to ppt the dithiol **29**. The mixture was extracted with chloroform and the extract was washed with water, dried over anhyd sodium sulfate, and evaporated to dryness. The resulting solid was chromatographed on neutral alumina (20 g) using hexane–benzene (1 : 1) to give the desired thiol **29** (4.83 g, 96%), colorless fine crystals from hexane–benzene (1 : 1), mp 112—113 °C.

Found: C, 72.23; H, 6.68; S, 21.08%. Calcd for $C_{18}H_{20}S_2$: C, 71.94; H, 6.72; S, 21.34%. PMR ($CDCl_3$, δ) 1.78 (t, J=8 Hz, 2H, SH), 1.7—3.3 (m, 8H, CH_2), 3.70 (d, J=8 Hz, 4H, CH_2), 5.36 (s, 1H, ArH of durene moiety), 6.03 (d, 2H, ArH of *p*-xylene moiety), 6.97 (s, 1H, ArH of durene moiety), 7.23 (d, 2H, ArH of *p*-xylene moiety). MS *m/e* 300 (M^+).

*21,24-Dimethyl-18,27-dithia[3.3]paracyclo(4,6)[2.2]metaparacyclophane (**30**).* A soln of 2,5-bis(chloromethyl)-*p*-xylene **10** (1.02 g, 5 mmol) in 40 ml of benzene and a soln of the above dithiol **29** (1.50 g, 5 mmol) and 85% potassium hydroxide (0.66 g, 10 mmol) in 40 ml of 80% aq ethanol were added dropwise and simultaneously over a period of 3 h to 300 ml of boiling ethanol under a nitrogen atmosphere. The mixture was refluxed for additional 12 h and worked up in the same manner as the synthesis of **7**. Chromatography of the product over silica gel (50 g, Merck act. II) with hexane–benzene (1 : 1) gave the dithiacyclophane **30** (1.44 g, 70%), colorless plates from ethanol, mp 201—202 °C.

Found: C, 78.14; H, 6.91; S, 14.84%. Calcd for $C_{28}H_{30}S_2$: C, 78.23; H, 6.98; S, 14.90%. PMR ($CDCl_3$, δ) 1.96 (s, 3H, CH_3), 2.45 (s, 3H, CH_3), 2.5—4.4 (m, 16H, CH_2), 4.89 (s, 1H, ArH), 5.08 (s, 1H, ArH), 5.76 (bs, 2H, ArH of *p*-xylene moiety), 6.76 (s, 1H, ArH), 7.00 (s, 1H, ArH), 7.10 (bs, 2H, ArH of *p*-xylene moiety). MS *m/e* 430 (M^+).

*12,15-Dimethyl[2.2]paracyclo(4,6)[2.2]metaparacyclophane (**31**) and 21,24-Dimethyl-18-thia[3.2]paracyclo(4,6)[2.2]metaparacyclophane (**32**).* A suspension of the above dithiacyclophane **30** (100 mg, 0.2 mmol) in 14 ml of purified triethyl phosphite was externally irradiated in a quartz tube under bubbling of nitrogen at room temp for 8.5 h. The solvent was evaporated and the residue was chromatographed over silica gel (20 g, Merck act. II) with hexane–benzene (4 : 1). The initial eluate gave the desired product **31** (55 mg, 63%), colorless fine crystals from toluene, mp 192—193 °C.

Heterocycles by Cycloaddition. IV.[1] Cycloaddition Reactions of Mesoionic Compounds with a 7-Azabicyclo[2.2.1]heptadiene, and Double Fragmentation of the Adducts

Hiroshi MATSUKUBO* and Hiroshi KATO

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received May 29, 1976)

Cycloaddition of some five-membered mesoionic compounds with dimethyl 7-tosyl-7-azabicyclo[2.2.1]-hepta-2,5-diene-2,3-dicarboxylate occurs only across the unsubstituted double bond. Pyrolysis of the adducts resulted in a double fragmentation reaction to give two five-membered aromatic heterocycles. A dithiolone adduct gave the *S*-oxide, which was pyrolyzed to the corresponding thiopyran-2-one.

In an effort to extend the synthetic value of mesoionic compounds, we have reported that the cycloaddition-double fragmentation reactions of mesoionic compounds (**1**) with a 7-oxabicyclo[2.2.1]heptadiene (**2**) provides an attractive route for the preparation of many five- and six-membered aromatic heterocycles.[2] In these reactions, some mesoionic compounds gave adducts (or fragmentation products) with a high periselectivity, while others gave products resulting from cycloaddition across both the two double bonds of **2**. Since it was established that the approach of mesoionic compounds to **2** occurs from above the surface of the oxygen bridge,[2-4] a bulky substituent at the 7-position may be expected to cause a higher periselectivity than with **2** due to the steric effect of the substituent. With this in mind, we studied the reactions of mesoionic compounds with dimethyl 7-*p*-toluenesulfonyl-7-azabicyclo[2.2.1]hepta-2,5-diene-2,3-dicarboxylate (**3**), and report here the results.

The reaction of mesoionic 3-methyl-2,4-diphenyl-5-oxazolone (**4**) with the azabicycloheptadiene **3** proceeded at a slower rate than with the oxabicycloheptadiene **2**, and gave 1-methyl-2,5-diphenylpyrrole (**6**) and dimethyl 1-(*p*-toluenesulfonyl)pyrrole-3,4-dicarboxylate (**7**). This result shows that the cycloaddition of the oxazolone **4** took place selectively across the unsubstituted double bond to give an intermediate adduct (**5**), which spontaneously underwent double fragmentation under the reaction conditions to carbon dioxide, **6**, and **7**. This behavior is in contrast to the reaction of **4** with the oxa analog **2**, which afforded products resulting from addition of **4** on both the substituted and the unsubstituted double bonds.

The reaction of mesoionic 2,5-diphenyl-1,3-dithiol-4-one (**8a**) with **3** in benzene under reflux gave the 1 : 1 adduct, dimethyl 9-oxo-1,8-diphenyl-12-*p*-toluenesulfonyl-12-aza-10,11-dithiatetracyclo-[6.2.1.1.^{3,6}-0^{2,7}]dodec-4-ene-4,5-dicarboxylate (**9a**). The base peak of the mass spectrum of the adduct at *m/e* 236, and the lack of NMR signal assignable to olefinic protons show that the addition took place across the unsubstituted double bond of **3**. Assignment of the *exo*, *exo* configuration among the four possible stereoisomers (**9a** and **ixa--ixc**) is based on the NMR spectrum: the lack of coupling between the bridgehead and the angular protons (H_a and H_c; H_b and H_d) eliminates structures **ixb** and **ixc**, and small or no chemical shift difference of the two methoxycarbonyl (0.03 ppm) and two bridgehead protons (H_a and H_b; 0 ppm) as well as a considerable one between the two angular protons (H_c and H_d; 0.45 ppm) are compatible only with the *exo*, *exo* configuration **9a**. A larger chemical shift difference of the two bridgehead protons than that of the two angular methine protons would be expected for configuration **ixa**. Pyrolysis of the adduct **9a** in toluene under reflux afforded 2,5-diphenylthiophene (**10**) and the pyrrole **7**. The treatment of the dithiolone adduct **9** with *m*-chloroperbenzoic acid gave the corresponding *S*-oxide (**11a**). The oxide oxygen was probably introduced anti to the aza bridge because it exerted only a small effect on the chemical shift values of the angular and the bridgehead protons. The *S*-oxide was fairly stable thermally, but was pyrolyzed in refluxing diethylbenzene with an extrusion of SO to give 3,6-diphenylthiopyran-2-one (**12a**) and the pyrrole **7**. The *S*-oxide **11a** was only partly decomposed after refluxing in xylene for a long time though the yield of the thiopyranone **12a** was higher (70%) than that in diethylbenzene (29%) when based on con-

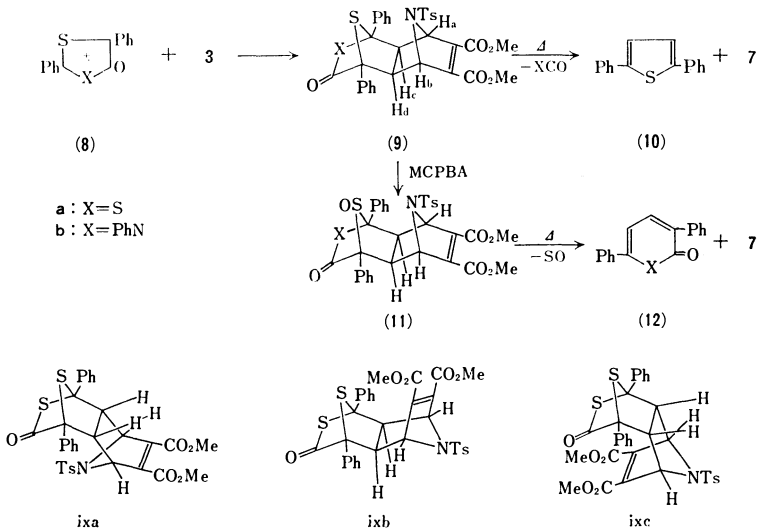

Scheme 2.

sumed *S*-oxide.

As previously reported,[2] the reaction of mesoionic 2,3,5-triphenyl-4-thiazolone (**8b**) with the oxabicycloheptadiene **2** gave adducts resulting from addition across both the substituted and the unsubstituted double bonds as well as other minor products. The reaction of **8a** with the aza analog **3** proceeded sluggishly in benzene under reflux, but afforded the cycloadduct, dimethyl *exo,exo*-9-oxo-1,8,10-triphenyl-12-*p*-toluenesulfonyl-10,12-diaza-11-thiatetracyclo[6.2.1.1.^{3,6}0^{2,7}]-dodec-4-ene-4,5-dicarboxylate (**9b**) resulting from the addition only on the unsubstituted double bond. The proposed structure and configuration of **9a** are based on spectral data (See Experimental). When the thiazolone adduct **9b** was pyrolyzed in diphenyl ether under reflux, the thiophene **10** and the pyrrole **7** were formed. The thiazolone adduct **9b** gave the corresponding (*anti*-) *S*-oxide (**11b**) on treatment with *m*-chloroperbenzoic acid. The mass spectrum of **11b** was rather complex although it showed weak peaks expected for double fragmentation products (*m/e* 337 and 323). The pyrolysis of **11b** in xylene under reflux gave complex products, from which neither the expected pyridone (**12b**) nor the pyrrole **7** could be isolated.

The above survey shows that the periselectivity of the mesoionic compounds to a bicycloheptadiene system is improved as expected by introducing a bulky substituent into the 7-position. At the outset of the present work, it was also anticipated that the double fragmentation of the adduct with **3** might be more facilitated than that of the adduct with **2** due to the pronounced aromaticity of the pyrrole ring and to the repulsive acceleration between the two bridge groups.[5] This expectation was not realized. This is probably due to the fact that the double fragmentation steps are not concerted but rather are two consecutive processes consisting of the initial extrusion of X=C=O or SO to give an unstable intermediate ylide, and its fragmentation to stable products.[6] Since the main purpose of the present work was improvement of the periselectivity, reaction conditions were not optimized. However, the high yields of products based on consumed starting materials suggest that this cycloaddition-double fragmentation reaction should constitute an attractive synthetic method of many heterocycles by appropriate selection of reaction partners.

Experimental

Mps were determined on a hot stage and are not corrected. UV and IR (KBr) spectra were recorded on a Hitachi EPS-3T and a Hitachi EPI-G3 spectrophotometer. PMR ($CDCl_3$, TMS internal standard) and mass (70 eV, direct inlet) spectra were measured with a JEOL JNM-4H-100 (100 MHz) and a Hitachi RMU-6 spectrometer. Solvents were concentrated *in vacuo*. The identity of a compound was established on the basis of mp, mixed mp, and IR and NMR spectral determinations.

*Reaction of the Oxazolone **4** with the Diene **3**.* A mixture of the diene **3**[7] (1.4 mmol) and the oxazolone **4**[8] (1.4 mmol) in benzene (50 cm^3) was stirred at 40 °C under a nitrogen atmosphere for 28 h. The solvent was concd and the residue was chromatographed (silica gel/$CHCl_3$) to give, besides the unreacted diene **3** (27%), 1-methyl-2,5-diphenylpyrrole **6** (55%), mp 206—207 °C, lit,[9] 204—205 °C, identical with an authentic specimen,[2] and dimethyl 1-tosylpyrrole-3,4-dicarboxylate **7** (56%), mp 116.5—117.5 °C; UV_{max} (MeOH) 237 (log ε 4.35) and 275^{sh} nm (2.98); IR 1747, 1730, 1720, 1709, 1378, 1275, 1192, 1176, and 1160 cm^{-1}; PMR δ=7.74 and 7.27 (AA'BB', each 2, J=8 Hz, ArH), 7.58 (s, 2, =CH), 3.80 (s, 6, OMe), and 2.41 ppm (s, 3, CMe); MS *m/e* (rel intensity), 337 (38, M$^+$), 306 (23, M$^+$—OMe), 155 (68, Ts$^+$), 151 (25, M$^+$—Ts—OMe), and 91 (100, $MeC_6H_4^+$). Found: C, 53.50; H, 4.46; N, 4.00%. Calcd for $C_{15}H_{15}NO_6S$: C, 53.41; H, 4.48; N, 4.15%.

*Adduct (**9a**) of the Dithiolone **8a** and the Diene **3**.* A soln of the diene **3** (1.1 mmol) and the dithiolone **8a**[10] (1.1 mmol) in benzene (50 cm^3) was refluxed under nitrogen for 11 h. The solvent was concd and the residue was recrystd (MeOH) to give needles of the adduct **9a** (95%), mp 154—155 °C (dec); UV (MeOH) end absorption; IR 1748, 1714, 1350, and 1165 cm^{-1}; PMR δ=7.52—7.14 (m, 14, ArH), 4.67 (s, 2, bridgehead H), 3.76 and 3.73 (s, each 3, OMe), 3.66 and 3.21 (d, each 1, J=6.5 Hz, angular H), and 2.41 ppm (s, 3, CMe); MS *m/e* (rel intensity) 337 (12, **7**$^+$), 236

(100, **10**$^+$), 155 (23, Ts$^+$), 121 (22, PhCS$^+$), 91 (48, $MeC_6H_4^+$), and 60 (37, COS$^+$). Found: C, 60.54; H, 4.21; N, 2.14%. Calcd for $C_{32}H_{27}NO_7S_3$: C, 60.65; H, 4.29; N, 2.21%.

Pyrolysis of the Adduct ***9a***. A suspension of the adduct **9a** (160 mg) in toluene (25 cm^3) was heated under reflux for 100 h. The soln was concd and the residue was chromatographed (silica gel/acetone : cyclohexane : ligroin = 1 : 3 : 6) to give 2,5-diphenylthiophene (**10**)[2] (67%), mp 154—155 °C, lit,[11] 152—153 °C, the pyrrole **7** (64%), and unchanged adduct **9a** (31%), all identical with authentic specimens.

S-*Oxide* (***11a***). A soln of the adduct **9a** (0.28 mmol) and *m*-chloroperbenzoic acid (80% purity, 0.32 mmol) in dichloromethane (20 cm^3) was stirred at room temp for 23 h. The soln was washed (aq NaOH; water), dried (Na_2SO_4), and concd, and the residue was recrystd ($CHCl_3$-Et_2O) to give prisms of the *S*-oxide **11a** (87%), mp 238—239 °C (dec); UV (MeOH) end absorption; IR 1750^{sh}, 1716, 1706^{sh}, 1350, 1164, and 1086 cm^{-1}; PMR δ=7.70—7.38 (m, 12, ArH), 7.25 (AA′ part of AA′BB′, 2, J=8 Hz, ArH), 4.78 and 4.57 (d, each 1, J=1.7 Hz, bridgehead H), 3.72 (s, 6, OMe), 3.65 and 3.05 (d, each 1, J=8 Hz, angular H), and 2.42 ppm (s, 3, CMe); MS *m/e* (rel intensity) 337 (19, **7**$^+$), 264 (27, **12a**$^+$), 236 (100, **10**$^+$), 155 (36, Ts$^+$), 121 (19, PhCS$^+$), and 91 (81, $MeC_6H_4^+$). Found: C, 59.19; H, 4.13; N, 2.03%. Calcd for $C_{32}H_{27}NO_8S_3$: C, 59.15; H, 4.19; N, 2.16%.

Pyrolysis of the S-*Oxide* ***11a***. The *S*-oxide **11a** (85 mg) was heated in diethylbenzene (10 cm^3) under reflux for 10 h. The soln was concd, and the residue was chromatographed (silica gel/$CHCl_3$) to give 3,6-diphenylthiopyran-2-one (**12a**)[2] (29%), mp 187—187.5 °C, lit,[12] 183.5—184 °C, the pyrrole **7** (23%), and unchanged **11a** (24%), all identical with authentic specimens. When the *S*-oxide **11a** was heated in xylene under reflux for 95 h, **12a** (18%), **7** (4%), and **11a** (75%) were isolated.

Adduct (***9b***) *of the Thiazolone* ***8b*** *and the Diene* ***3***. A soln of the thiazolone **8b**[13] (1.1 mmol) and the diene **3** (1.1 mmol) in benzene (50 cm^3) was refluxed for 98 h. The soln was concd and the residue was recrystd (PhH-hexane) to give prisms of **9b** (52%), mp 215—216 °C; UV (MeOH) end absorption; IR 1737, 1715, 1699^{sh}, 1350, and 1166 cm^{-1}; PMR δ=7.58—7.03 (m, 17, ArH), 6.82—6.65 (m, 2, ArH), 4.95 and 4.67 (d, each 1, J=1.7 Hz, bridgehead H), 3.81 and 3.76 (s, each 3, OMe), 3.66 and 3.16 (d, each 1, J=7 Hz, angular H), and 2.40 ppm (s, 3, CMe); MS *m/e* (rel intensity) 355 (8, M$^+$—**7**), 337 (27, **7**$^+$), 263 (23, M$^+$—**7**—PhNH), 236 (92, **10**$^+$), 155 (49, Ts$^+$), 121 (19, PhCS$^+$) 119 (47, PhNCO$^+$), and 91 (100, $MeC_6H_4^+$). Found: C, 67.50; H, 4.63; N, 3.62%. Calcd for $C_{41}H_{35}N_2O_7S_2$ (**9b**+1/2 PhH): C, 67.28; H, 4.82; N, 3.83%. Found (after prolonged heating *in vacuo*): C, 66.45; H, 4.60; N, 3.77%. Calcd for $C_{38}H_{32}N_2O_7S_2$: C, 65.88; H, 4.66; N, 4.04%.[14] From the mother liquor of recrystallization, the unchanged diene **3** (35%) was recovered.

Pyrolysis of the Adduct ***9b***. A suspension of the adduct **9b** (0.1 g) in diphenyl ether (20 cm^3) was heated under reflux for 30 min. The solvent was removed and the residue was chromatographed (silica gel/$CHCl_3$) to give the thiophene **10** (88%) and the pyrrole **7** (82%), both identical with authentic specimens.

S-*Oxide* (***11b***). A soln of the adduct **9b** (0.29 mmol) and *m*-chloroperbenzoic acid (0.32 mmol) in dichloromethane (10 cm^3) was stirred overnight at room temp. The soln was washed (aq NaOH; water), dried (Na_2SO_4), concd, and the residue was recrystd ($CHCl_3$-Et_2O) to give the *S*-oxide **11b** (83%) as prisms, mp 182—184 °C (dec); UV (MeOH) 225 nm^{sh} (log ε 4.505); IR 1722, 1713^{sh}, 1350, 1166, and 1087 cm^{-1}; PMR δ=7.68—6.92 (m, 19, ArH), 4.98 and 4.65 (d, each 1, J=1.7 Hz, bridgehead H), 3.80 and 3.72 (s, each 3, OMe), 3.67 and 3.15 (d, each 1, J=8 Hz, angular H), and 2.41 ppm (s, 3, CMe); MS *m/e* (rel intensity) 506 (21), 431 (16), 337 (7, **7**$^+$), 323 (13, **12b**$^+$), 180 (21, PhCNPh$^+$), 155 (34, Ts$^+$), 119 (12, PhNCO$^+$), 91 (100, $MeC_6H_4^+$), and 77 (43, Ph$^+$). Found: C, 64.20; H, 4.49; N, 3.73%. Calcd for $C_{38}H_{32}N_2O_8S_2$: C, 64.39; H, 4.55; N, 3.95%.

We are indebted to Kyorin Chemical Laboratories for elemental analyses and mass spectral measurements, and to Mr. Naomi Takagi for experimental assistance.

Determination of the Solubility of Oxygen in Copper by the Coulometric Method

Tetsuya WADA, Kazuo FUEKI,* and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

** Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113*

(Received February 6, 1976)

Synopsis. The solubility of oxygen in copper was determined at 800—1000 °C by means of the coulometric method. The data obtained is represented by the following equation: $\log N(\text{atom fraction}) = -2.164 - 1820/T$

At high temperatures, the oxidation rate of alloys is significantly affected by the formation of an internal oxidation layer. Since this internal oxidation is a phenomenon of oxygen diffusion into the alloy from the oxide-alloy interface, resulting in the formation of an oxide with the less noble constituent, the data of solubilities and diffusion coefficients of oxygen in the alloy are required in order to analyze the rate of alloy oxidation. The solubility of oxygen can be determined directly by the vacuum fusion method, the inert gas fusion method, the method of reduction of a metal saturated with oxygen, and the neutron or proton activation analysis. The solubility can also be determined indirectly by electric resistance measurements, lattice parameter measurements, and E. M. F. measurements by means of solid electrolytes. On the whole the direct methods are rather complicated. Since the coulometric method allows the precise determination of the thickness of thin oxide films, such as passive films, it can be applied to the estimation of the solubility of oxygen in metals and alloys. The purpose of this note is to report the determination of the oxygen solubility in copper by means of coulometric analysis.

Experimental

Rectangular slices, 20 mm × 7 mm in area and 0.2—0.8 mm in thickness, were cut from an ingot of electrolytic copper, 99.999% pure; they were polished with alumina powders, washed with soap and water, and dried in a desiccator. The polished specimens were treated in a pure hydrogen gas flow at 500 °C for 3 h to remove strains and surface oxides. Spectroscopic analysis revealed that the copper specimen contained Pb, As, Sb, Fe, and Ni, 1 ppm each, and 6 ppm of S as impurities.

Two specimens were oxidized simultaneously at 200—240 °C in air for a definite time to obtain copper(I) oxide films, 1500—2500 Å thick. One of these two specimens was used to determine the oxide film thickness by the coulometric method. It was placed in a cell as a cathode and two platinum anodes were placed to face either side of the cathodic plate. An aqueous solution of 0.1 M KCl was used as an electrolytic solution and a saturated calomel electrode as a reference electrode. Nitrogen gas was bubbled through the solution for 20 min to remove the dissolved oxygen; then the electrolysis was carried out with a current density of 67 $\mu A/cm^2$. The time variation of the potential difference between the cathode and the reference electrode was recorded. The oxide film thickness was calculated from the total amount of charge passed.[1,2]

The second specimen was sealed in a 10 mmϕ Vycor tube *in vacuo*, annealed in an electric furnace kept at each desired temperature within ±1 °C, and quenched as soon as possible after the annealing. The thickness of the remaining oxide film was then determined by the coulometric method. During the annealing, surface copper(I) oxide decomposes into copper and oxygen at the metal-oxide interface, and the oxygen diffuses inward. Therefore, the amount of dissolved oxygen was calculated from the decrease in the oxide film thickness. The amount of dissolved oxygen was plotted against t/l,[2] where t is the annealing time and $2l$ is the thickness of the copper specimen. The solubility of oxygen was determind from the saturated value.

Results and Discussion

Preliminary experiments showed that a faint red-colored deposit of copper(I) oxide appeared on the inner wall of the Vycor tube in the case of prolonged annealing. Therefore, sufficiently thin copper specimens were used so that the saturation could be completed in a short annealing period.

Table 1 gives the oxygen solubility, N, expressed in terms of atomic fraction. The standard deviation of N was less than 34%. Figure 1 gives the temperature dependence of the averaged N as a plot of log N *vs.*

TABLE 1. SOLUBILITY OF OXYGEN IN COPPER

Temp T(°C)	Thickness of Cu specimen $2l \times 10^2$(cm)	Annealing time t(min)	$t/l^2 \times 10^{-6}$ (s/cm²)	Solubility of oxygen (ppm)
1000	2.49	10.0	3.84	273
1000	2.52	15.0	5.67	245
950	5.01	30.0	2.86	229

$1/T$. The relationship is represented by the equation:

$$\log N = -2.164 - 1820/T \quad (1)$$

The data obtained by the previous investigators are also plotted in the same figure. Rhines and Mathewson[3] and Phillips and Skinner[4] determined the solubility from the weight decrease of copper saturated with oxygen by reduction. Bouillon and Orszagh[5] used the mass spectroscopic analysis coupled with the vacuum fusion technique. Pastrek and Rapp[6] studied the solubility using a solid electrolyte cell. The data of the present work agree well with those from Phillips and Bouillon.

From Eq. 1, the enthalpy change, the entropy change and the free energy change for the dissolution of oxygen in copper can be derived . They are

$$\Delta H = 8330 \text{ cal/mol},$$
$$\Delta S = -9.90 \text{ cal/mol deg},$$
$$\Delta F = 8330 + 9.90\,T \text{ cal/mol}$$

respectively.

X-Ray Photoelectron Spectroscopy of Aminobenzoic Acids and Anthranilic Acid Chelates

Tooru YOSHIDA and Shigemasa SAWADA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received September 30, 1975)

Synopsis. Photoelectron spectra of three isomers of aminobenzoic acid and several metal chelates of *o*-isomer were measured. It was confirmed that *o*- and *p*-isomers exist in the non-polar form and *m*-isomer in the dipolar. In the chelates the trend was for the N(1s) chemical shifts to increase in parallel with the metal electronegativities.

It has been derived[1] from IR spectroscopy that *m*-amino-benzoic acid in the solid state exists in the dipolar form, while *o*- and *p*-isomers exist in the non-polar form. The *o*-isomer(anthranilic acid) exhibits a polymorphic transition;[2] its crystal structure for the form stable at room temperature has been determined from the X-ray diffraction data. It was found that there are two non-equivalent molecules per unit cell in the space group $P2_1cn$.[3]

Khan and Srivastava[4] deduced from X-ray and IR studies of the molecular stucture of *o*-isomer that the unit cell contains two equivalent molecules.

The purpose of this paper is to report the results by X-ray photoelectron spectroscopy (XPS) for the molecular structure of *o*-, *m*-, and *p*-isomers and for the chemical shift, the change in the N(1s) electron binding energy of anthranilic acid on complex formation.

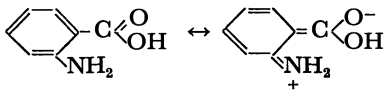
The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. Al $K\alpha$ (1486.6 eV) X-ray radiation was used as the excitation source. The samples were ground to powder and then dusted onto a double-backed adhesive tape. The measurements were run at room temperature under a vacuum of about 10^{-7} Torr. The binding energy of the C(1s) peak was used as the energy standard throughout the present experiments; it was taken to be 285.0 eV. All the compounds measured are given in Table 1. Three isomers of aminobenzoic acid of an analytical grade were used after recrystallization from ethanol, and in the case of *o*-isomer after recrystallization from acetic acid,[2] which was employed to obtain the form stable at room temperature. All the anthranilic acid chelates with a ligand–metal ratio of 2 : 1 were prepared based upon the literature methods.[5]

The O(1s), N(1s), and C(1s) electron spectra of *o*-, *m*-, and *p*-aminobenzoic acids are shown in Fig. 1; their measured binding energies are given in Table 1. Two peaks were observed in the C(1s) electron spectra for all the isomers. It was determined that the one with higher binding energy corresponds to the carbon of the substituent group, and the other to the carbon of the benzene ring. The N(1s) electron binding energies of *o*- and *p*-isomers were about 2 eV lower than that of *m*-isomer. The O(1s) electron peak of *m*-isomer was narrower in full-width at half-maximum height (FWHM) and about 1—2 eV lower in binding energy, compared with those of *o*- and *p*-isomers. The O(1s) spectra of *o*- and *p*-isomers both have a broad peak, which suggests the presence of at least two kinds of oxygen atoms. The two peaks, a and b, with the different binding energies shown by the broken lines in the figure, were obtained by a graphical resolution of the peak of *p*-isomer.

In view of the stuctures[4,6] of *o*- and *p*-isomers determined from X-ray and IR analyses, it seems that the two peaks, a and b, in Fig. 1 correspond to the oxygen atoms of C–OH and C=O, respectively.

The FWHMs (2.9—3.1 eV) of the O(1s) peaks of *o*- and *p*-isomers are larger than that(2.7 eV) of benzoic acid, which is the same value as acetic acid[7] in the solid state. Such an increase of the FWHM in *o*- and *p*-isomers may be attributable to the contribution of a resonance structure, as shown below: This con-

and



tribution has the possibility of increasing the difference between the electron densities on the two oxygens of the carboxylate group, which would give rise to the broadening of the O(1s) peak. Benzoic acid can not reasonably have the above resonance. That the FWHM of *o*-isomer is about 0.2 eV smaller than that of *p*-isomer may be attributable to the decrease of such resonance due to steric hindrance in the former, which has been suggested from IR.[8]

In the zwitterion structure of *m*-isomer,[1] the N(1s) and O(1s) peaks may correspond to the positively charged nitrogen atom and the negatively charged oxygen atoms of the carboxylate group. The C(1s) binding energy of the carboxylate group of the *m*-isomer is about 1 eV lower than those of the other two isomers. This can be explained by arguing that the electron density on the carbon atom of the carboxylate group in the former becomes larger than those of the carboxyl group in the latter, because of the delocalization of a unit negative charge within a carboxylate group.

Although *o*-isomer crystallized from acetic acid has been reported to have in part a zwitterion structure,[3] this was not confirmed by this XPS study at all.

The N(1s) and O(1s) electron spectra of all the anthranilic acid metal chelates and sodium salt were single peaks with the FWHMs of 1.6—1.8 eV and 1.7—1.9 eV, respectively, except that the FWHMs of the O(1s) peaks of Pd and Pt chelates were 2.1—2.2 eV.

In the charge-potential model,[6] the chemical shift can be expressed in terms of the charge on the atom

Table 1. Measured binding energies and frequencies

Samples		Binding energy (eV)[a] C(1s)[b]	N(1s)	ΔE[c]	O(1s)	χ[d]	ν_{N-H}[e]	ν_{COO^-}[f]

and the Coulomb potential energy of an electron due to the other atoms in the molecule. In this study, however, it was assumed that the chemical shift is dominated by the charge on the atom concerned, since the compounds studied here are covalent and their structures are similar. Therefore, the N(1s) chemical shifts in all the chelates are considered to be due to the decrease in the electron density on the nitrogen atoms caused by the coordination of lone-pair electrons of the nitrogen atoms to the metal.

The N(1s) chemical shifts tended to increase in parallel with the metal electronegativities. This can be explained by arguing that the covalent character of the bonds between the metal ions and the ligand increases with the metal electronegativity. A more covalent coordinate bond is considered to decrease the electron density on the donor atoms, which would appear in the increase of the binding energies.

It has previously been demonstrated by IR that the coordination of amino groups to metals results in appreciable decreases in the frequencies of the N–H stretching vibrations. These changes become larger with increasing covalent character of the N–M bonds.[9] There seems to be a certain reasonable relation between the N(1s) chemical shift and the N–H frequency, the N(1s) chemical shift increasing with decreasing N–H frequency.

All the binding energies and the FWHMs of the O(1s) peaks of the metal chelates were similar to those of sodium salt rather than those of free anthranilic acid. The C(1s) binding energies of the carboxylate group for the chelates (288.3—288.6 eV) were also similar to that of sodium salt (288.4 eV).

It has been concluded from the IR study that as the bonding of the carboxylate groups with a metal atom becomes more covalent the absorption peak for the antisymmetrical vibration of the COO^- groups shifts to higher frequencies.[10] All the frequencies of the chelates are larger than that of sodium salt, as shown in Table 1. Furthermore, the O(1s) binding energies of almost all chelates are slightly larger than that of sodium salt.

These results suggest that the COO^-–M^{2+} bonds in anthranilic acid chelates are not so essentially ionic as in the case of sodium salt.

Sandhu *et al.*[11] have proposed a polymeric structure for the anthranilic acid metal chelates from IR and magnetic susceptibility measurements, and suggested that the stereochemistry around the metal ion is that of a distorted octahedron, with both oxygens of carboxylate bonded to two different metal atoms, though unequally. This inequality of the two oxygens of carboxylate may be associated with the present result that the FWHMs of the O(1s) peaks of the chelates are 0.1—0.5 eV larger than that of the sodium salt, as is shown in Table 1.

An MO-theoretical Study on the Hydration of Simple Olefins

Ichiro HIRONO, Osamu KIKUCHI, and Keizo SUZUKI

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

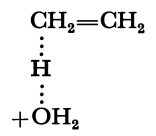
(Received February 21, 1976)

Synopsis. The acid-catalyzed hydration of simple olefins was studied on the basis of a semi-empirical SCF NDDO method. The substituent effect on the activation energy agreed well with experimental result.

Olefins can be hydrated by treatment with water and an acid catalyst. Though several mechanisms[1-3] have been proposed for the acid-catalyzed hydration of olefins, they may be written simply as:

$$CH_2{=}CH_2 + H_3O^+ \xrightarrow{\text{slow}} CH_3{-}\overset{+}{C}H_2 \xrightarrow{\text{fast}} CH_3{-}CH_2OH + H_3O$$

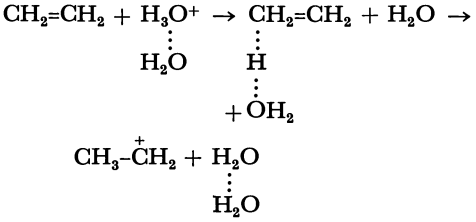
The rate-determining step, which is the first step, is slow proton transfer from H_3O^+ to the olefin, *via* I. This step is followed by the rapid addition of water.[1,2]



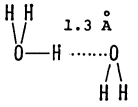
I

The hydration of simple olefins is a simple example of a catalytic reaction and a fundamental process for the preparation of alcohol from petroleum by-products. This note reports the results of an MO-theoretical study of this reaction mechanism and the substituent effect on the activation energy of the reaction. The MO method employed here is a semi-empirical NDDO method[4] which gives well-balanced molecular geometries and reaction energies.

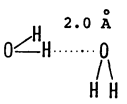
Though the solvent effect must be considered in this reaction, it is difficult to introduce it in a precise form since this effect has very complex aspects. Here the solvent effect was introduced simply by adding one more water molecule to the system. It is assumed that



the solvent water molecule, which bonds weakly to H_3O^+, leaves the H_3O^+ ion when a new bond is formed between the H_3O^+ and an olefin. The interaction energies for II and III, where each H···O distance was optimized, are 1.79 and 0.50 eV, respectively.



II



III

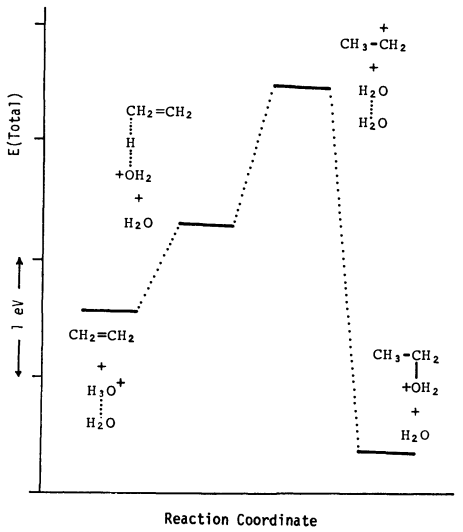


Fig. 1. Energy variation along the hydration of ethylene.

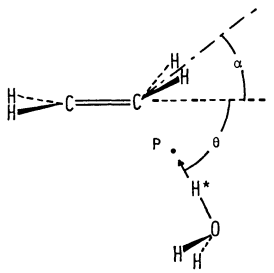
The energy diagram for this process is shown in Fig. 1. In Fig. 1, the energy of the carbonium ion, which is considered to be an intermediate of the process, is higher than that of I. In an actual water medium, the carbonium ion is stabilized by the solvent. This effect, however, is not considered in Fig. 1. The detailed calculation on the attack of H_3O^+ on ethylene from the direction shown in IV[5] was performed to examine the most favorable path for the above process.



IV

The energy map of this process for $\theta=45°$ is shown in Fig. 2. It was found from Fig. 2 and from the calculated results that (1) H_3O^+ approaches the point P (the position of the H atom in the tetrahedral $-CH_3$ group) without any appreciable change in the H*–O bond length until the P–O distance becomes 1.5 Å, (2) the geometry of ethylene at P–O=1.5 Å is: C–C =1.30 Å, and $\alpha=10°$, (3) after the proton transfer from H_3O^+ to ethylene, H_2O leaves the carbonium ion, and (4) no appreciable change was observed in the energy maps for $45° < \theta < 90°$. In the calculation of the energy maps, the solvent effects of II and III

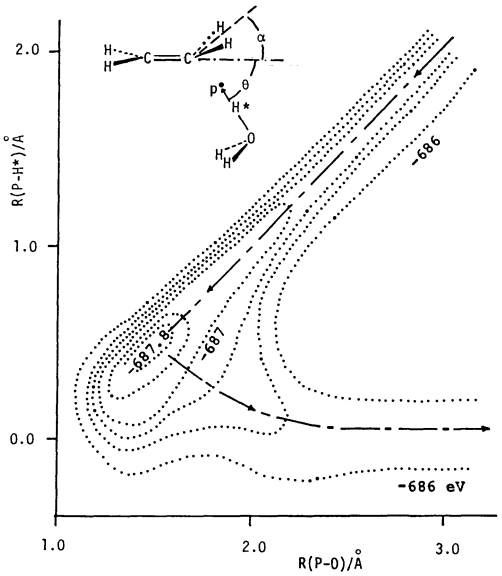


Fig. 2. Energy contours for the ethylene-H_3O^+ system. The C-C bond length and the angle α were optimized in the calculation.

were excluded. This is the reason why I is stable in Fig. 2.

The formation of the carbonium ion is followed by the rapid addition of water producing an oxonium ion (Fig. 1), and the carbonium ion does not correspond to the transition state. Nevertheless, it is expected that the transition state resembles the carbonium ion and I, and that the activation energy of the present process correlates with the difference between the energy of the carbonium ion and that of the initial state. The activation energies estimated under this assumption are listed in Table 1 as well as available experimental values.[1] The discrepancy between the calculated and experimetal activation energies is 20—30%. The activation energy for isobutene is very large, because the geometries of substituted carbonium ions were estimated from that of $CH_3-\overset{+}{C}H_2$ and this value reflects the overestimation of the steric interaction between the two CH_3 groups. The calculated values reproduce satisfactory the experimentally observed

Table 1. Activation energies for the hydration of simple olefins

Olefins[a]	E_a (kcal/mol)	
	Calcd	Exptl[1]
$CH_2=\overset{*}{C}H_2$	44.5	32.4
$CH_2=\overset{*}{C}H-Me$	35.1	26.4
$Me-CH=\overset{*}{C}H_2$	63.4	—
$CH_2=\overset{*}{C}(Me)_2$	25.7	21.1
$(Me)_2C=\overset{*}{C}H_2$	169.8	—
$Me-CH=\overset{*}{C}H-Me$	48.4	—
$CH_2=\overset{*}{C}H-Et$	34.6	—
$Et-CH=\overset{*}{C}H_2$	45.0	—

a) The asterisk indicates the carbon atom which is attacked by the hydroxyl group.

substituent effect on the activation energy. The Markownikoff rule is also reflected in the olefins listed in Table 1. The present authors thus feel that the present treatment correctly describes the reaction to some extent.

Infrared Spectra of Tribromochloro-*p*-benzoquinone and Its Anion Radical

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 4, 1976)

Synopsis. A chemically-stable anion radical salt of tribromochloro-*p*-benzoquinone was synthesized. The infrared spectrum of the anion radical was examined together with its neutral molecule.

The vibrational spectrum of an ion radical is known to differ distinctly from that of its neutral molecule.[1-8] So far, few quantitative studies have been made on such a difference. The infrared spectra of *p*-chloranil (*p*-QCl_4), *p*-bromanil (*p*-QBr_4), 2,5-dibromo-3,6-dichloro-*p*-benzoquinone (*p*-QBr_2Cl_2) and their corresponding anion radicals were previously examined.[3-6] In order to explain the frequency difference in fundamental vibration between the neutral molecule and its anion radical, the fundamental frequencies were assigned, and the simple Urey-Bradley force fields were determined for both the neutral and anion radical molecules. We are able to understand these frequency differences on the basis of the difference in the intramolecular force fields of the two molecules. It was found that the force constants of *p*-QBr_2Cl_2 and its anion radical can be transferred from those of *p*-QX_4, (X= Cl or Br), and its anion radical, respectively.[6] Measurements of the infrared spectra (400—4000 cm^{-1}) of tribromochloro-*p*-benzoquinone (*p*-QBr_3Cl) and its anion radical have been carried out in order to observe the difference in the spectra of these neutral and anion radical molecules. The fundamental vibrations were assigned by comparison with those of *p*-QX_4, (X=Cl or Br), *p*-QBr_2Cl_2 and their anion radicals.

The neutral *p*-QBr_3Cl was prepared by the oxidation of tribromochlorohydroquinone and purified by recrystallization from benzene or gracial acetic acid. The anion radical salt with the potassium cation (K^+ *p*-$QBr_3Cl^{\cdot-}$), which is stable at room temperature, was synthesized by the method of Torrey and Hunter.[9] The infrared spectra of these solid compounds were measured as Nujol mulls in the range 400—4000 cm^{-1} with an IR-G infrared spectrophotometer (Japan Spectroscopic Co., Ltd.). The infrared spectra in the regions where the absorption due to Nujol appears were measured using hexachlorobutadiene mulls.

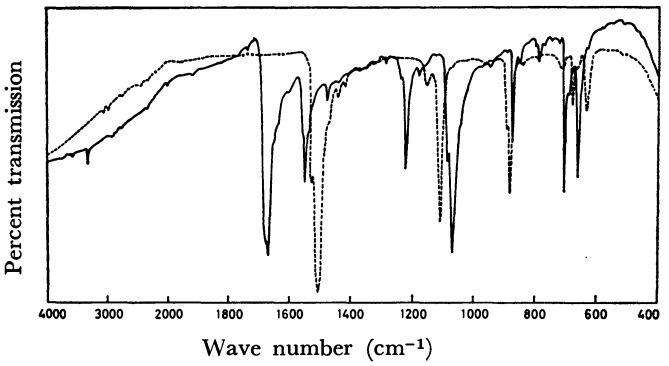

Fig. 1. The infrared spectra of neutral tribromochloro-*p*-benzoquinone (*p*-QBr_3Cl, ——) and its anion radical salt with the potassium cation (K^+ *p*-$QBr_3Cl^{\cdot-}$, ----).

The spectra obtained for these compounds are reproduced in Fig. 1. Since the counter cation of the anion radical salt is a simple alkali metal cation, the observed spectrum of K^+ *p*-$QBr_3Cl^{\cdot-}$ in the region under investigation would be due to that of the *p*-QBr_3Cl anion radical itself. In the infrared spectra of the neutral *p*-QBr_3Cl and its anion radical, we can also observe appreciable frequency shifts between their corresponding bands. Although the point groups of these molecules are degraded into C_s, their spectroscopic features are found to be close to those of *p*-QX_4, (X=Cl or Br), *p*-QBr_2Cl_2 and their anion radicals,[3-6] where *p*-QX_4 and *p*-QBr_2Cl_2 have D_{2h} and C_{2h} point groups, respectively. Thus, the assignments of the fundamental vibrations of *p*-QBr_3Cl and its anion radical were made in comparison with those of symmetrical *p*-benzoquinones.

For the neutral *p*-QBr_3Cl, two strong absorptions at 1678 and 1671 cm^{-1} can definitely be assigned to the C=O bond stretching modes. For the anion radical, however, we could observe only one fundamental absorption due to the C=O mode at 1509 cm^{-1}, although there may appear two fundamentals from the symmetry property of the molecule. We note a remarkable red shift of 166 cm^{-1} upon introduction of an extra electron to the neutral *p*-QBr_3Cl. Such a large red shift has also been found in the cases of *p*-QX_4, (X=Cl or Br), *p*-QBr_2Cl_2 and their corresponding anion radicals.[3-6]

The strong absorption at 1551 cm^{-1} with shoulders for the neutral *p*-QBr_3Cl arises from the C=C bond stretching mode, the corresponding band for the anion radical being found at 1530 cm^{-1}. Thus, the fundamental absorption due to the C=C mode is red-shifted by 21 cm^{-1} when the neutral *p*-QBr_3Cl changes into its anion radical. On the other hand, the absorption at 1222 cm^{-1} of the neutral *p*-QBr_3Cl is attributable to the C–C bond stretching mode. The band at 1069 cm^{-1} with a shoulder at 1085 cm^{-1} of the same molecule may arise from the major contribution of the C–C bond stretching mode and the minor contribution of the C–Cl bond stretching mode. In comparison with the spectroscopic data of *p*-QX_4 (X=Cl or Br),[4,5] the bands at 1222 and 1069 cm^{-1} come mostly from the B_{3u} and B_{2u} modes of *p*-QX_4, respectively. This also implies the similarity of the spectroscopic features of *p*-QBr_3Cl and *p*-QX_4 (X=Cl or Br). As regards the corresponding absorption of the *p*-QBr_3Cl anion radical, only one fundamental absorption was observed at 1109 cm^{-1}. The band is attributable to a shifted band of 1069 cm^{-1} of the neutral *p*-QBr_3Cl, indicating an

appreciable blue shift by 40 cm^{-1} upon introduction of the extra electron to the neutral *p*-QBr_3Cl. According to previous experimental and theoretical investigations,[3-6] the C=C bond-stretching force constant decreases, while the C-C bond-stretching force constant increases, in going from the neutral *p*-QX_4 (X=Cl or Br) and *p*-QBr_2Cl_2 to their corresponding anion radicals. Such an increase of the C–C bond-stretching force constant leads to the blue shift of the 1109 cm^{-1} band of the *p*-QBr_3Cl anion radical. Although the 1222 cm^{-1} band of the neutral *p*-QBr_3Cl can also be expected to shift to higher energy region in its anion radical, no such absorption was observed in the anion radical presumably because of its weak intensity. The lack of this absorption of the C–C stretching mode has also been found in the series of the *p*-QX_4 (X=Cl or Br) and *p*-QBr_2Cl_2 anion radicals.[3-6]

In the wave number region 1000—400 cm^{-1}, the spectrum of the neutral *p*-QBr_3Cl has three strong absorptions at 876, 706, and 660 cm^{-1}, respectively. By referring to the assignments of *p*-QBr_4 and *p*-QBr_2Cl_2,[5,6] the 876 cm^{-1} band seems to arise from the mixing of the C–C, C–Cl, and C–Br bond-stretching modes, and the 660 cm^{-1} band from the mixing of the C–Cl and C–Br stretching modes.[10] On the other hand, the spectrum of the *p*-QBr_3Cl anion radical has three corresponding absorptions at 881 cm^{-1} with a shoulder around 891, at 682 and at 638, respectively.[10] The 881 cm^{-1} band shows a slight blue-shift, and the 638 cm^{-1} band a red-shift as compared to the corresponding 876 and 660 cm^{-1} absorptions of the neutral molecule. The C–Cl and C–Br bond-stretching force constants are known to be weakened by the formation of the anion radicals,[5,6] so that the appreciable red-shift of the 638 cm^{-1} band can be explained in terms of the mixing of the C–Cl and C–Br stretching modes. The reason for the slight blue-shift of the 881 cm^{-1} band is that it arises from the mixing of the C–C, C–Cl and C–Br stretching modes, and the C–C stretching force constant is strengthened by forming the anion radical.

In view of these results, although the molecular symmetries of the neutral *p*-QBr_3Cl and its anion radical are degraded from those symmetrical *p*-QX_4 (X=Cl or Br), *p*-QBr_2Cl_2 and their anion radicals, the spectroscopic features of *p*-QBr_3Cl and its anion radical can be understood on the basis of the infrared spectra reported on the symmetrical *p*-benzoquinones and their anion radicals.[3-6]

NMR Studies of the Pyridine Exchange Reaction in the Pyridine Adduct of Bis(salicylaldehydato)nickel(II)

Masamoto IWAIZUMI, Kouto MIGITA, and Taro ISOBE
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980
(Received March 8, 1976)

Synopsis. The pyridine exchange reaction in the pyridine adduct of bis(salicylaldehydato)nickel(II) becomes appreciably slower and its activation energy increases with the decrease of the electron donor properties of the in-plane ligand. However, changes in the spin delocalization onto the coordinated pyridine by the in-plane ligand appear small.

Spin delocalization onto bases interacting with bis(acetylacetonato)nickel(II), $Ni(acac)_2$, has been one of the subjects investigated in great detail through isotropic paramagnetic shifts in NMR.[1] In this system the spin distributions in the bases are directly evaluated from the observed isotropic shifts, since the pseudocontact interaction is negligible and the exchange reaction of the bases which coordinate to $Ni(acac)_2$ is in the limit of the fast exchange rate region. However, whether or not the exchange reaction is in the fast rate region seems to have a critical dependence on the ligands already bound to the nickel. We observed that when bis(salicylaldehydato)nickel(II), $Ni(sal)_2$, is used in place of $Ni(acac)_2$, the relative ratio of contact shifts for the α, β, and γ protons in pyridine appreciably differs from that in the $Ni(acac)_2$ system. This deviation becomes much larger when the nitro derivative of salicylaldehydate ion is used as an in-plane ligand.[2] As is shown later, these changes can be related to the fact that the pyridine exchange reactions in $Ni(sal)_2$ and its derivatives are not in the fast exchange rate region at the measurement temperature, and the observed shifts are not exactly the weighted average between the free and associated forms of pyridine. The main purpose of this note is to show how the exchange reaction of pyridine at the apical position in six-coordinated nickel complexes is affected by the in-plane ligands already bound to the nickel.

Experimental

The nickel(II) complexes used were those with salicylaldehyde and its 5-methyl, 5-chloro, 5-bromo, and 5-nitro derivatives [$Ni(sal)_2$ and $Ni(5X\text{-}sal)_2$, X=Me, Cl, Br, and NO_2]. These complexes were dried at 110°C *in vacuo* before use. NMR spectra of the bulk solvent protons in pyridine solutions of these complexes were measured with a Jeol JNM PS 100 NMR spectrometer at various temperatures.

The magnetic susceptibilities of the complexes in pyridine were determined by the Evans method,[3] using TMS for a reference signal.

Results and Discussion

It was observed that the isotropic shifts and the line widths of pyridine protons change markedly with temperature. Though the ratio of the isotropic shifts of α, β, and γ protons for each nickel complex system at an ambient temperature differs, each approaches the ratio observed for pyridine interacting with $Ni(acac)_2$[1a] and all become the same as the temperature increases. The features of the changes in the line width and in the isotropic shifts are those seen typically in exchanging ligands of transition metal complex solutions.[4] In Fig. 1, the line width changes are shown by the plot of the observed transverse relaxation rates *vs.* $1/T$. It is seen that the pyridine exchange reaction is appreciably affected by the in-plane ligands, and at the ambient temperature ($1/T \approx 3.3 \times 10^{-3}$) the pyridine exchange reaction is in the slow exchange rate region. To consider quantitatively the line width changes in the present system, one needs to take into account effects of spin-spin decoupling as well as effects of changes in the quadrupole relaxation of nitrogen caused by paramagnetic

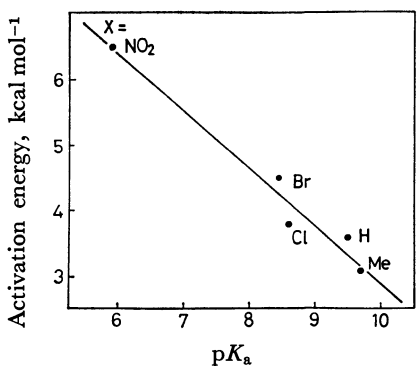

Fig. 2. Relation between the Arrhenius activation energies of pyridine exchange reaction and pK_a values of the in-plane ligands of $Ni(5X\text{-}sal)_2$.

pulses due to the presence of the nickel complexes. We assume here that the spin-spin interaction is completely decoupled and the broadening due to the quadrupole relaxation of nitrogen does not contribute any more. As a crude approximation, we further regard the observed line width as arising from only the pyridine exchange reaction.[5] The observed relaxation rate, $1/T_2$ for the case satisfying the condition $\Delta\omega_M^2 \gg (1/T_{2M})^2$ or $(1/\tau_M)^2$, is hence put equal to P_M/τ_M,[4,6] where $\Delta\omega_M$ and $1/T_{2M}$ are the chemical shift and the transverse relaxation rate of the proton in the coordinating pyridine, P_M is the ratio of the solvent bound to the Ni(II) complexes to the free-solvent concentration, and $1/\tau_M$ is the pyridine exchange rate. In Fig. 1 the region where the plots show negative slope satisfies the above rate condition. By the Arrhenius relation, these negative slopes are proportional to the activation energies of the pyridine exchange reactions. The slopes show that the activation energies increase in the order of Ni(5Me-sal)$_2$, Ni(sal)$_2$, Ni(5Cl-sal)$_2$, Ni(5Br-sal)$_2$, and Ni(5NO$_2$-sal)$_2$; their reaction rates at a given temperature also decrease in this order of the complexes. Figure 2 shows that there is a good correlation between the activation energies of the pyridine exchange reactions and the pK_a values[7] of the in-plane ligands. Here, the activation energies were evaluated from the slopes of the curves in the slow exchange rate region in Fig. 1, with the approximation $1/T_2 \approx P_M/\tau_M$.[5] The results of Fig. 2 suggest that the activation energy of the pyridine exchange reaction decreases with the increase of the electron donor property of the in-plane ligands, since pK_a values may be regarded as a measure of the electron donor properties.

In view of the above result and the fact that acetylacetone has a pK_a value, 9.50,[7] larger than salicylaldehyde and its derivatives, it can be understood that the pyridine exchange reaction in the Ni(acac)$_2$ system is much faster than the Ni(sal)$_2$ system.

The hyperfine coupling constants of pyridine protons, $A_H/\hbar$, are obtained from the isotropic shifts in the fast exchange rate region by the relation:

$$\frac{\Delta\omega_{obsd}}{P_M} = -\left(\frac{A_H}{\hbar}\right)\frac{\omega_0\mu_e\beta\sqrt{S(S+1)}}{3kT\gamma_H}$$

where $\Delta\omega_{obsd}$ is the observed isotropic shift, ω_0 is the resonant frequency, and μ_e is the effective magnetic moment of nickel in the complexes. The values obtained for the α proton are 10.1 ± 0.5 rad s^{-1} (μ_e=3.1 BM), 9.0 ± 0.5 rad s^{-1} (3.0 BM), 10.1 ± 0.5 rad s^{-1} (2.9 BM), 10.1 ± 0.5 rad s^{-1} (2.8 BM), and 9.7 ± 0.5 rad s^{-1} (2.8BM) for Ni(5Me-sal)$_2$, Ni(sal)$_2$, Ni(5Cl-sal)$_2$, Ni(5Br-sal)$_2$, and Ni(5NO$_2$-sal)$_2$, respectively. Significant changes could not be detected in the hyperfine coupling constants of these complex systems. However, it may be worth noting that the delocalized spin densities on the coordinated pyridine were estimated to be about 0.03 from the comparison with the spin density distribution estimated by the INDO calculation using a phenyl radical as a model compound for pyridine coordinated to nickel.[1d]

2) The relative ratio of the isotropic shifts for α, β, and γ protons of pyridine was 10 : 4.8 : 1.2 in the system of Ni(sal)$_2$-pyridine at 30°C, but the ratio for the α and β protons in the Ni(5NO$_2$-sal)$_2$-pyridine system was 10 : 19. In the latter case, the isotropic shift of γ proton could not be determined with confidence because of the overlap of its signal with that of the β proton. The ratio reported for the Ni(acac)$_2$-pyridine system is 10.0 : 2.94 : 0.77.[1a]

Reaction of Mercury(II)–Ethylenediaminetetraacetate–Capriquat Complex with Potassium Iodide in 1,2-Dichloroethane and Its Application to the Spectrophotometric Determination of Mercury(II)

Akira SHIMAZAKI, Masao SUGAWARA, and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 12, 1976)

Synopsis. A mercury(II)–ethylenediaminetetraacetate–methyltrioctylammonium chloride (Capriquat) complex in 1,2-dichloroethane reacts quantitatively with potassium iodide and forms an ion-pair of tetraiodomercurate(II) with a capriquat cation. The composition of the extracted species was determined to be $[Hg(edta)(Cq)_2]$. The reaction was applied to the spectrophotometric determination of mercury(II).

Irving and Al-Jarrah[1] have developed a useful method for separating mercury(II) from many metal ions, based on the extraction of several edta complexes with a methyltrioctylammonium chloride (Aliquat 336) solution in 1,2-dichloroethane.

The spectrophotometric determination of mercury(II) as a tetraiodo complex has been carried out by several authors.[2-4]

In the present work, it is reported that the mercury(II)–edta–methyltrioctylammonium chloride (Capriquat, abbreviated Cq^+Cl^-) complex in the dichloroethane extract reacts quantitatively with potassium iodide forming an ion-pair consisting of a tetraiodomer-curate(II) and a capriquat cation. The present methodhas the advantage that the determination is possible with a part of the extract needed.

Experimental

Reagents. A capriquat solution (0.1 mol dm^{-3}) was prepared by dissolving 12.5 g of capriquat (Dojindo Pharmaceutical Co.) in 250 cm^3 of 1,2-dichloroethane. All other chemicals used were of analytical reagent grade. A stock solution of mercury(II) was prepared from mercury(II) nitrate (Wako Chemicals Co.) and standardized volumetrically.[5] A stock solution of ethylenediaminetetraacetic acid (H_4edta) was prepared from its disodium salts.

A stock solution of potassium iodide (Wako Chemicals Co.) was prepared and stored in a subdued light environment.

Deionized water was used.

Apparatus. A Hitachi 356 two-wavelength and double-beam spectrophotometer and a Shimadzu QV-50 spectrophotometer with 10-mm quartz cells were used for the absorptiometric measurements. An Iwaki Shaker, model KM, was used for the extraction.

Established Procedure. Into a 100-cm^3 separatory funnel were placed an aliquot of a mercury(II) solution containing less than 80 μg, 0.4 cm^3 of a 0.01 mol dm^{-3} Na_2H_2-edta solution and 10 cm^3 of a phosphate buffer solution (pH 7.0) in the sequence. The mixture was diluted to 30 cm^3 with water. After the addition of 20 cm^3 of a 0.01 mol dm^{-3} capriquat solution, two layers were shaken for 10 min and allowed to stand for 10 min. The organic layer was drained into a beaker containing anhydrous sodium sulfate and dehydrated. A 10-cm^3 portion of the extract was placed into another separatory funnel and shaken with 10 cm^3 of a 0.03 mol dm^{-3} potassium iodide solution. The organic layer was transferred into a beaker, dehydrated as above and then subjected to optical measurements.

Results and Discussion

Extraction of the Mercury(II)–edta Complex with a Capriquat Solution. As shown by Irving and Al-Jarrah,[1] the mercury(II)–edta complex in the presence of a 10% excess of Na_2H_2edta is quantitatively extractable in the pH range from 3.5 to 11 by an equal volume of a 0.2 mol dm^{-3} Aliquat 336 solution in dichloroethane.

The results of present investigation, in which the extractability of mercury(II) was determined from the absorbance measurements according to the above procedure, were almost in accordance with those of Irving and Al-Jarrah. However, it is important to note that when the Na_2H_2edta concentration was increased above 0.01 mol dm^{-3}, a decrease in extractability of mercury(II) was observed, probably because of a competitive reaction between the $Hg(edta)^{2-}$ complex and the H_2edta^{2-} ions with the capriquat cations.

The extractability of mercury(II), as determined by repeatedly shaking the separated aqueous layer with a fresh capriquat solution in dichloroethane was found to be 93.3% for a single extraction at as aqueous-to-organic volume ratio of 3 : 2. At volume ratios higher than twice the aqueous layer up to the ratio of the organic layer, the extractability decreased.

Composition of Extracted Species. The distribution ratio D is evaluated to be

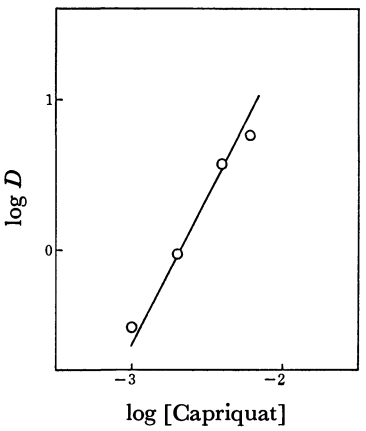

Fig. 1. A plot of log D *vs.* log [Capriquat] at pH 7.01 in the presence of 15 μmol dm^{-3} mercury(II) and 0.13 mmol dm^{-3} Na_2H_2edta.
The straight line was drawn based on the results of the method of least squares.

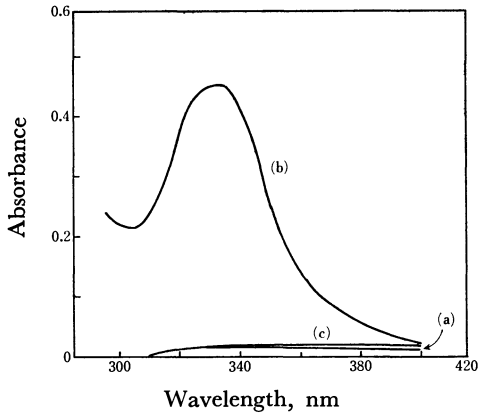

Fig. 2. Absorption spectra of dichloroethane extracts obtained from aqueous media buffered at pH 7.0 and containing 15 μmol dm^{-3} mercury(II) and 0.13 mmol dm^{-3} Na_2H_2edta.
Capriquat concentration in dichloroethane: 0.01 mol dm^{-3}.
a) $(Cq^+)_2[Hg(edta)^{2-}]$ ion-pair *vs.* dichloroethane, b) $(Cq^+)_2(HgI_4^{2-})$ ion-pair obtained by shaking with 0.03 mol dm^{-3} potassium iodide solution *vs.* dichloroethane, c) the reagent blank corresponding to curve (b).

$$D = \frac{(A/\varepsilon)}{C_1 - (A/\varepsilon)} \quad (1)$$

where C_1 is the initial concentration of $Hg(edta)^{2-}$ in the aqueous phase and ε is the molar absorption coefficient of the capriquat tetraiodomercurate(II) ion-pair. In an aqueous medium of pH 7.0 containing a large excess of Na_2H_2edta, mercury(II) exists in the form of $Hg(edta)^{2-}$. Hence, the slope of the plot of log D *vs.* log [Capriquat] should correspond to the molar ratio of the capriquat cation to the $Hg(edta)^{2-}$ anion. As is shown in Fig. 1, the plot has a slope of 1.99, clearly indicating that the composition of the extracted species *is estimated to be* $[Hg(edta)^{2-}(Cq^+)_2]$.

Absorption Spectra of Mercury(II) Complexes. The absorption spectra of the extract obtained according to the above procedure are given in Fig. 2. The ternary complex has an absorption maximum at 333 nm.

Effect of Potassium Iodide Concentration. A 10-cm^3 portion of the separated extract was shaken with an equal volume of an aqueous potassium iodide solution. It was found that a constant and maximum absorbance was obtained for potassium iodide concentration above 0.01 mol dm^{-3}. With various volumes of the potassium iodide solution, it was found that the maximum absorbance was obtained with 5—20 cm^3 of the 0.03 mol dm^{-3} potassium iodide solution.

Calibration Curve. Beer's law was obeyed in the concentration range from 1.1 to 8.8 μg cm^{-3} of Hg(II) in the extract. The molar absorption coefficient is 2.12×10^4 cm^{-1} mol^{-1} dm^3 and the Sandell sensitivity is 9.28×10^{-3} μg Hg(II) per cm^2.

Effect of Diverse Ions. The interference of diverse ions was investigated. Setting the tolerance limit for interfering ions causing an error at ±2.5% for mercury(II) recovery, the results summarized in Table 1 were found.

Table 1. Effect of diverse ions

Mercury(II) taken: 88.8 μg

Interfering ion added	Tolerance limit, mg
Mg(II), Zn(II), NO_3^-, SO_4^{2-}	10

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (11), 3329—3330 (1976)

Preparation and Circular Dichroism of Cyanoamminebis[(R)-propylenediamine]cobalt(III) Complexes

Kazuo KASHIWABARA* and Shoichi SUZUKI

Department of Chemistry, Faculty of Science, Tohoku Universisy, Aramaki, Sendai 980

(Received June 7, 1976)

Synopsis. Three new complexes, *trans*-, *cis*-Λ-, and *cis*-Λ-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$(pn=propylenediamine) were prepared. The geometrical structure was determined on the basis of ^1H NMR spectra. The optical isomers were characterized from the circular dichroism spectra.

The normal character of cyanide as a ligand has been reported in the splitting of the first and second absorption bands of cobalt(III) complexes.[1] A different case was reported [2] in which the splitting of the first absorption band in *trans*-$[Co(CN)_2(NH_3)_4]^+$ is small for the one expected from Yamatera's theory.[3] This indicates that more spectral data are necessary for cyanide complexes.

The circular dichroism (CD) spectra of dicyanobis(diamine)cobalt(III) complexes were discussed in a previous paper.[4] The CD spectra of $[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ complexes are discussed herewith.

Experimental

Preparation and Separation of the Isomers. $[Co(CN)(NH_3)_5]Cl_2$[5] (2g, 8.3mmol) was dissolved in a 50 cm^3 aqueous solution of R-pn(27mmol). The solution was kept at 60—70°C for 3 h with active charcoal (0.5 g). The orange red solution was filtered. The filtrate was cooled to room temperature and poured into a column (2.5 × 50 cm) of a Dowex 50W-X8 (200—400 mesh) ion exchange resin of sodium form. After the column had been washed with water, the adsorbed band was eluted with a 1M aqueous sodium chloride solution at a 15 cm^3/h rate. A small amount of the first light yellow eluate was found to be *cis*-$[Co(CN)_2(R\text{-}pn)_2]^+$ from the visible and ultraviolet absorption spectra.[4] The second orange yellow eluate was concentrated to a small volume at 40°C in a rotary evaporator under reduced pressure. Ethanol was added to the concentrate to precipitate sodium chloride. This was repeated several times in order to remove sodium chloride as far as possible. Finally, the filtrate was passed through a column (2.5×50 cm) of Sephadex LH-20 with an eluent of ethanol-water (4 : 1) for complete removal of the sodium choride. The eluate evaporated to dryness to afford an orange yellow product which was obtained in a *ca.* 100 mg yield. The product (FI) is very soluble in water, but not in organic solvents. Found : C, 22.99 ; H, 7.47 ; N, 24.00%. Calcd for $[Co(CN)(NH_3)(R\text{-}pn)_2]Cl_2\cdot 2H_2O$:C, 23.54; H, 7.62; N, 23.53%.

The third and fourth orange yellow eluates from the Dowex 50W-X8 column were treated in the same way as for the first eluate, orange yellow products FII and FIII, respectively, being obtained. The products are very soluble in water, but not in organic solvents. Yield, *ca.* 150 mg for FII and *ca.* 250 mg for FIII. Found for FII: C, 25.19; H, 7.60; N, 24.35%. Calcd for $[Co(CN)(NH_3)(R\text{-}pn)_2]Cl_2\cdot H_2O$: C, 24.79; H, 7.43; N, 24.78%. Found for FIII: C, 23.67; H, 7.47; N, 24.08%. Calcd for $[Co(CN)(NH_3)(R\text{-}pn)_2]Cl_2\cdot 2H_2O$: C, 23.54; H, 7.62; N, 23.53%.

Another orange band was observed near the top of the column, but was not characterized.

Measurements. The electronic absorption spectra were obtained with a Hitachi 323 recording spectrophotometer. The CD spectra were recorded on a Jasco Model ORD/UV-5 spectropolarimeter and the ^1H NMR spectra on a Varian A-60 spectrometer in deuterium oxide using sodium trimethylsilylpropanesulfonate (DSS) as an internal standard.

Results and Discussion

Three isomers, *trans*(CN-NH_3) and two *cis*(CN-NH_3), are possible for $[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ if the location of the methyl group in the pn chelate is not considered. They were isolated with a Dowex 50W-X8 ion exchange resin. No more isomers due to the location of the methyl group were obtained.

The ^1H NMR spectra of FI exhibits a doublet (J= 5.8 Hz) due to a CH_3 group of R-pn at 1.31 ppm. FII and FIII isomers showed two doublets with J=5.9 Hz and 6.3 Hz at 1.32 and 1.46 ppm, respectively. Thus, we have assigned FI to the *trans*(CN-NH_3) isomer and FII and FIII to the *cis*(CN-NH_3) isomer.

The visible and ultraviolet absorption spectra of FI, FII, and FIII are almost the same as each other and are very similar to the spectrum of $[Co(CN)(NH_3)_5]^{2+}$. The absorption data in the d-d transition region are shown in the Table together with the CD data.

Figure 1 shows the CD spectra of *trans*-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ and *trans*-$[Co(CN)_2(R\text{-}pn)_2]^+$ in water. If the electronic state in the complex *trans*-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ can be approximated to the C_{4v} form, the two CD peaks in the first absorption band might be assigned to the A_2 and E components. The apparent energy difference of these two peaks (2.9×10^3 cm^{-1}) is smaller than that (3.7×10^3 cm^{-1}) of *trans*-

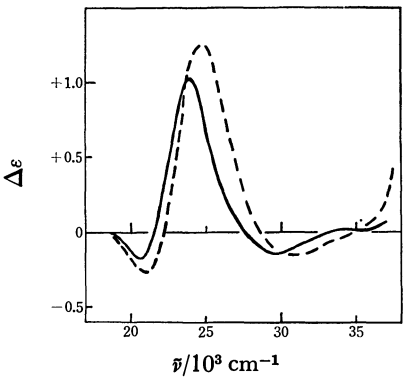

Fig. 1. CD spectra of *trans*-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ (——) and *trans*-$[Co(CN)_2(R\text{-}pn)_2]^+$(---) in water.

* Present address: Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464.

Table 1. Absorption and CD spectral data for $[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ ($\tilde{\nu}$ in 10^3 cm^{-1})

Complex	I Band		II Band	
	$\tilde{\nu}_{max}$ (log ε)	$\tilde{\nu}^{cd}_{ext}$ ($\Delta\varepsilon_{ext}$)	$\tilde{\nu}_{max}$ (log ε)	$\tilde{\nu}^{cd}_{ext}$ ($\Delta\varepsilon_{ext}$)
FI	23.09(1.88)	20.62(−0.19)	31.10(1.90)	29.41(−0.14)
		23.53(+1.05)		
FII	23.04(1.88)	22.99(+1.11)	30.91(1.90)	29.50(−0.08)
FIII	22.94(1.94)	20.83(−0.67)	30.77(1.97)	30.30(−0.11)
		23.64(+0.69)		

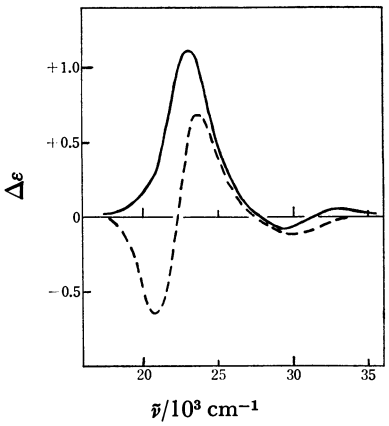

Fig. 2 CD spectra of *cis*-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ in water, FII (——) and FIII(- - - -).

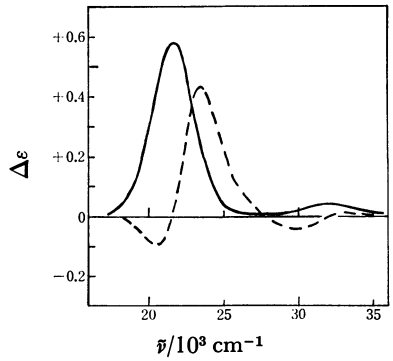

Fig. 3 Calculated configurational (——) and vicinal (- - - -) CD curves of *cis*-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$.

$[Co(CN)_2(R\text{-}pn)_2]^+$ as expected from Yamatera's theory.

Figure 2 shows the CD spectra of FII and FIII. The CD spectrum of FII gives a very strong positive band in the first absorption band region, suggesting a *Λ* configuration on the basis of the empirical rule.[6] FIII can be assigned to *Δ* isomer although the spectrum shows a negative and a positive band, since the CD spectral patterns of *cis*-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ correspond to those of *cis*-*Λ*-$[Co(CN)_2(R\text{-}pn)_2]^+$.[4]

Figure 3 shows the configurational and vicinal curves of *cis*-$[Co(CN)(NH_3)(R\text{-}pn)_2]^{2+}$ which were derived by the method reported previously.[4] The pattern of the derived vicinal CD curves is similar to the observed CD spectrum of FI. The configurational CD curve of FII confirms a *Λ* configuration for the isomer. The spectral pattern of the configurational effect is similar to that of *cis*-$[Co(CN)(NH_3)(en)_2]Br_2$,[7] indicating the validity of the additivity of CD to these complexes.

The encouragement and helpful discussions of Professor Kazuo Saito are gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (11), 3331—3332 (1976)

Asymmetric Oxidation of Benzyl *p*-Tolyl Sulfide with Active Halogeno Compounds in the Presence of Optically-Active Alcohols

Yoshiyasu SATO, Norio KUNIEDA, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received April 12, 1976)

Synopsis. The oxidation of benzyl *p*-tolyl sulfide with active halogeno compounds such as *N*-bromosuccinimide, *N*-chlorosuccinimide and *t*-butyl hypochlorite, affords optically-active benzyl *p*-tolyl sulfoxide. The absolute configuration of the sulfoxide obtained depends on the chirality of the alcohols used.

In previous papers,[1,2] the authors have reported that *N*-bromo-ε-caprolactam (NBC) or *N*-chloro-nylon-66 (NCN-66) oxidizes sulfides to the corresponding sulfoxides in the presence of water or alcohols. During the course of the study of the oxidation, a novel asymmetric induction was found in the presence of optically-active alcohols.[3,4] But the dependence of the absolute configuration of the sulfoxides on the chirality of alcohols used is different for NBC and for NCN-66. Accordingly, in the present note, the asymmetric oxidation of benzyl *p*-tolyl sulfide (I) with various other reagents in the presence of optically-active alcohols is reported.

Experimental

The chemical reagents and procedure are essentially the same as those described previously.[3]

The assignments of the reaction products were performed on the basis of NMR and IR spectra and elemental analysis.

The optical purity of the benzyl *p*-tolyl sulfoxide obtained was calculated from published data: (*R*)-(+)-benzyl *p*-tolyl sulfoxide, $[\alpha]_D$ +252° (acetone).[5]

Results and Discussion

Optically-active benzyl *p*-tolyl sulfoxide was formed by all the active halogeno compounds used in the presence of optically-active alcohols.

In the case of alcohols listed in Table 1, the absolute configuration of I obtained depends on the chirality of the alcohols used.

It is generally assumed that the oxidation of sulfides with active halogeno compounds in the presnece of alcohols results in the formation of alkoxysulfonium salts.[6] And the alkoxysulfonium salts can either form sulfoxides by the elimination of alkyl halides, followed by the retention of the configuration at the sulfur atom,[7] or yield sulfoxides by hydrolysis, followed by an inversion of the configuration.[8]

Thus, the oxidation of I with NBC in the presence of an (*R*)-alcohol forms more of the (*S*)-alkoxysulfonium salt than the (*R*)-alkoxysulfonium salt, and the hydrolysis of a mixture of the salts leads to larger amounts of the corresponding (*R*)-sulfoxide than that of the (*S*)-sulfoxide.

In the case of other oxidation reagents, the predominantly formed (*S*)-alkoxysulfonium salt leads to the corresponding (*S*)-sulfoxide with the elimination of an alkyl halide.

On the other hand, the results using (—)-menthol as the alcohol differ from those described above. As shown in Table 2, the oxidation of I with *N*-halogeno compounds in the presence of (—)-menthol preferentially produces the corresponding (*R*)-sulfoxide, but the oxidation of I with *t*-butyl hypochlorite gives the (*S*)-sulfoxide dominantly. Accordingly, the mechanism for the oxidation of I with *t*-butyl hypochlorite differs from that for the oxidation with *N*-halogeno compounds.

On the basis of these results, it is postulated that the

TABLE 1. ASYMMETRIC OXIDATION OF BENZYL *p*-TOLYL SULFIDE WITH ACTIVE HALOGENO COMPOUNDS IN THE PRESENCE OF OPTICALLY-ACTIVE ALCOHOLS AT −20 °C

Halogeno compound	Alcohol	Solvent	Time (h)	Sulfoxide

oxidation of sulfides with active halogeno compounds in the presence of potically-active alcohols affords the corresponding optically-active sulfoxides. The absolute configuration of the sulfoxides obtained depends on the chirality of the alcohols used, and the oxidation reagents affect the route of oxidation of the sulfides.

Heterocycles by Cycloaddition. III.[1] Dihydroisoindolequinone, the Correct Structure of the Proposed Azatetracyclononanedione

Hiroshi MATSUKUBO* and Hiroshi KATO**

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

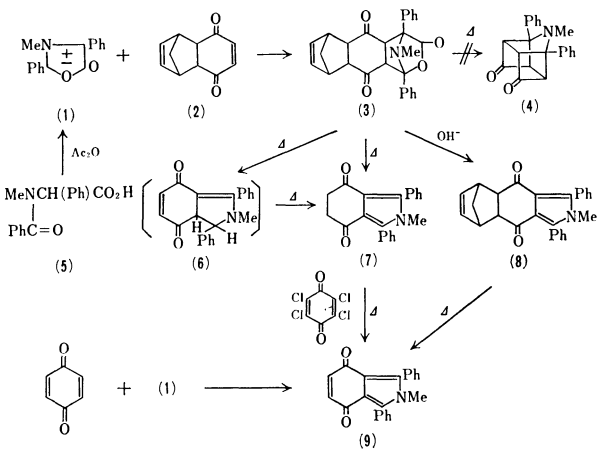
(Received May 6, 1976)

Synopsis. Pyrolysis of a cyclopentadienequinone–oxazolone adduct (**3**) gives a 5,6-dihydro-4,7-isoindolequinone (**7**) and not an azatetracyclic cage compound (**4**). The dihydroquinone (**7**) was dehydrogenated to the corresponding isoindolequinone (**9**), which was synthesized *via* alternative routes.

The cycloaddition–extrusion of five-membered mesoionic compounds has been utilized for the preparation of a wide variety of heterocyclic systems.[2] The reaction with an olefin usually gives a dihydro heterocyclic compound by migration of a substituent, but with some dipolarophiles, the transient ylide formed by the cycloaddition–extrusion reaction, is trapped by the dipolarophile to give a 1 : 2 adduct.[3] When a dipolarophile has two double bonds within the molecule with a suitable framework, the initially formed ylide can be trapped intramolecularly to give a cage compound. Such cage compounds have been prepared by the reactions of a sydnone with cyclooctadiene[4] and butadienes.[5]

As an extreme case of such a double intramolecular cycloaddition, Myers *et al.*[6] recently claimed the formation of 8-aza-7,9-diphenyl-8-methyltetracyclo-[4.3.0.^{3,9}0^{4,7}]nonane-2,5-dione (**4**) by pyrolysis of 1,3,3a,4,4a,5,8,8a,9,9a-decahydro-5,8-methano-2-methyl-4,9-dioxo-1,3-diphenyl-2*H*-benz[*f*]isoindole-1,3-carbolactone (**3**),[7] the adduct of the mesoionic 3-methyl-2,4-diphenyl-5-oxazolone (**1**) and cyclopentadienequinone (**2**).

The spectral data of the product (**A**), however, do not appear to be in agreement with the proposed structure **4**. For example, the reported infrared carbonyl band of **A** at 1665 cm^{-1} is too low for a strained cyclobutanone system,[8] and the ultraviolet absorption maximum at 308 nm suggests an aromatic or a conjugated chromophor. We thought that these data are more compatible with 5,6-dihydro-2-methyl-1,3-diphenyl-4,7-isoindolequinone (**7**) than with **4**. It was found that the NMR singlet at δ 2.88 disappeared by base-catalyzed treatment of **A** with deuterium oxide. This shows that the carbonyl group of the product **A** is enolizable, and it cannot reconcile with the proposed structure **4**. Dehydrogenation of the product **A** with chloranil gave 2-methyl-1,3-diphenyl-4,7-isoindolequinone (**9**). The structure of the quinone **9** was established by an independent synthesis by pyrolysis of 4,4a,5,8,8a,9-hexahydro-5,8-methano-2-methyl-1,3-diphenyl-2*H*-benz[*f*]isoindole-4,9-dione (**8**),[6] or alternatively, by the cycloaddition–extrusion–dehydrogenation reaction of the mesoionic oxazolone **1** with



p-benzoquinone.[9]

The above results show that the pyrolysis of the adduct **3** proceeds normally to give the dihydroisoindolequinone (**6**) by extrusion of carbon dioxide and cyclopentadiene, which isomerizes under the reaction conditions to **7** with an aromatic pyrrole ring. The ease and high yields of those reactions, however, should be considered as an indirect and yet an attractive synthetic method of many benzoquinones condensed with a heterocyclic ring, and their dihydro derivatives; because it has been known that the reactions of quinones and five-membered mesoionic compounds always give fully unsaturated systems by dehydrogenation with the quinones present in the reaction system,[9,10] and that the yields of such adducts are sometimes low due to the formation of by-products including the 1 : 2 adduct of benzoquinone and a mesoionic compound. Thus, we isolated **9** only in 8% yield by the reaction of benzoquinone with the mesoionic oxazolone **1**, and the formation in 17% yield of **9** by the same reaction under slightly different (*in situ*?) conditions is reported.[9]

Experimental

Mps were determined on a Yanagimoto hot-stage apparatus and are not corrected. UV and IR spectra were recorded on Hitachi EPS-3T and Hitachi EPI-G3 spectrophotometers. NMR and mass spectra were measured with JEOL JNM-4H-100 (100 MHz) and Hitachi RMU-6 spectrometers.

Cyclopentadienequinone–Oxazolone Adduct (3). This could conveniently be prepared by the *in situ* reaction: A soln of cyclopentadienequinone **2** (10 mmol) and 2-(*N*-methylbenzamido)-2-phenylacetic acid (**5**) (10 mmol) in acetic anhydride (30 ml) was stirred at 55—60 °C for 2 h under nitrogen. The crystals which separated out were collected and washed with benzene to give pure **3** (92%), mp 160—

** To whom inquiries should be addressed.

161 °C (dec) (lit,[6] 158—160 °C). Spectral data were identical with those reported.

Base-Catalyzed Deuteration of Dihydroisoindolequinone (7). A soln of **7** and a small amount of anhyd potassium carbonate in a mixture of dioxane and deuterium oxide was heated under reflux for 1 h. The soln was concd *in vacuo*, the residue was extracted with deuteriochloroform, and the extract was dried ($MgSO_4$) and was used for NMR measurement. The spectral pattern was identical with **7** except that the singlet peak at δ 2.88 disappeared completely.

2-Methyl-1,3-diphenyl-4,7-isoindolequinone (9). *(a)* A soln of **7** (0.2 g; 0.64 mmol) and chloranil (0.19 g; 0.78 mmol) in xylene (10 ml) was refluxed for 4 h. The solvent was removed *in vacuo*, the residue was extracted with chloroform, and the extract was washed with aq sodium hydroxide and water, dried ($MgSO_4$), and concd. The residue was recrystd from methanol to give orange prisms of **9** (0.2 g, 100%), mp 186—187 °C. UV_{max} (MeOH) 229 (log ε 4.42), 276 (4.13), and 418 nm (3.64); IR (KBr) 1655^{sh} and 1646 cm^{-1} (C=O); NMR ($CDCl_3$; TMS) 3.27 (s, 3, Me), 6.50 (s, 2, CH=), and 7.40 ppm (br s, 10, Ph); MS (70 eV; direct inlet) *m/e* (rel intensity) 313 (M^+, 100), 312 (69), and 118 (31). Found: C, 80.22; H, 4.65; N, 4.37%. Calcd for $C_{21}H_{15}NO_2$: C, 80.50; H, 4.83; N, 4.47%.

(b) A suspension of the methanobenz[*f*]isoindoledione **8**[6] (75 mg) in xylene (10 ml) was refluxed for 18 h. The solvent was removed *in vacuo* and the residue was chromatographed (silica gel/chloroform) and recrystd from methanol to give **9** (50 mg, 81%), identical with the specimen prepared by procedure (a).

(c) A soln of *p*-benzoquinone (0.43 g; 4 mmol) and the oxazolone **1** (0.5 g; 2 mmol) in benzene (20 ml) was stirred at room temperature for 3 h under nitrogen, and was then warmed for 3 h at 60 °C. The benzene extract of the reaction mixture was chromatographed (silica gel/chloroform) to give **9** (50 mg, 8%), identical with the specimen prepared by procedure (a).

We are indebted to Kyorin Chemical Laboratories for elemental and mass spectral analyses.

Carbonylation of Saturated Hydrocarbons Catalyzed by Copper(I) Carbonyls in FSO_3H–Sb_5F

Yoshie Souma and Hiroshi Sano

Government Industrial Research Institute, Osaka Midorigaoka, Ikeda, Osaka 563

(Received May 4, 1976)

Synopsis. Saturated hydrocarbons react with carbon monoxide in the presence of copper(I) carbonyl catalysts in FSO_3H–SbF_5. Tertiary-carboxylic acid and secondary-carboxylic acid were obtained in high yields at −2 to +2 °C and at 1 atm of carbon monoxide. For the isomerization process of intermediate carbonium ions, the cleavage of the C–C bond was recognized, and stable *t*-butyl cations were formed.

Several results on carbonylation catalyzed by copper(I) carbonyl ions have been described in previous papers.[1-5] The copper(I) carbonyl ions play an important role enriching the carbon monoxide concentration in strong acid solutions, and promotes the carbonylation rate to give tertiary-carboxylic acid in a high yield.

Olah has investigated the formation of alkyl cations from alkanes *via* hydride abstraction in FSO_3H–SbF_5, and presented the following equation.[6,7]

$$R_3CH \xrightarrow{FSO_3H\text{-}SbF_5} R_3C^+SbF_5FSO_3^- + H_2$$

Olah has reported that the alkyl cations rearranged to tertiary carbonium ions, and furthermore, stable *t*-butyl cations were formed from hydrocarbons of C_5—C_{16} by the cleavage of the C–C bond.

Paatz has studied the carbonylation of saturated hydrocarbons in HF–SbF_5 solutions, and obtained carboxylic acids and ketones.[8] However, the conversion of saturated hydrocarbons to carbonyl compounds was less than 30%, due to the low solubility of carbon monoxide in strong acids. Suzuki has also studied the carbonylation of 2,2,4-trimethylpentane and alcohol in HF–SbF_5 and obtained carboxylic acid.[9,10]

In this paper, the carbonylation of saturated hydrocarbons catalyzed by copper(I) carbonyl ions to give secondary-carboxylic acids and tertiary-carboxylic acids in high yields is described.

Table 1. The amount of carbon monoxide absorbed by Cu^+ in FSO_3H–SbF_5[a]

Temp °C	Absorbed CO n in $Cu(CO)_n^+$
−45	4.0
−30	4.0
−20	4.0
−10	3.95
0	3.80
10	3.60
20	3.50
30	3.35

a) The amount of absorbed carbon monoxide was measured using 0.858 g of Cu_2O, 20 ml of FSO_3H and 10 ml of SbF_5.

Results and Discussion

Cuprous oxide absorbs carbon monoxide in FSO_3H–SbF_5 solutions to form a homogeneous catalyst solution containing copper(I) carbonyl ions. The amount of absorbed carbon monoxide increases when the temperature is lowered, as is shown in Table 1. In FSO_3H–SbF_5 solutions, $Cu(CO)_4^+$ exists in a mixture in equilibrium with $Cu(CO)^+$. The $\nu_{C=O}$ absorptions of $Cu(CO)_4^+$ and $Cu(CO)^+$ in FSO_3H–SbF_5 solutions were observed at 2183 and 2152 cm^{-1} respectively on the other hand, that of gaseous carbon monoxide occured at 2143 cm^{-1}.[11,12] The $\nu_{C=O}$ absorptions for $Cu(CO)_4^+$ and $Cu(CO)^+$ increased more than that for gaseous carbon monoxide. This indicates that the C–O bonding order becomes higher when the carbon monoxide coordinates to the cuprous ion.

Table 2. Carbonylation of saturated hydrocarbons[a]

Substrate	Product	Yield %
Methylcyclopentane	1-Methylcyclopentanecarboxylic acid	45
	Cyclohexanecarboxylic acid	40
Methylcyclohexane	1-Methylcyclohexanecarboxylic acid	5
	Mixture of methylcyclohexanecarboxylic acid and ethylcyclopentanecarboxylic acid	90
Cyclohexane	Cyclohexanecarboxylic acid	45
Hexane	2,2-Dimethylpentanoic acid	55
	2-Methyl-2-ethylbutanoic acid	35
	2,2-Dimethylbutanoic acid	11
	2,2-Dimethylpropionic acid	17
	Cyclohexanecarboxylic acid	25
2-Methylpentane	2,2-Dimethylpentanoic acid	45
	2-Methyl-2-ethylbutanoic acid	30
2-Methylbutane	2,2-Dimethylbutanoic acid	20
	Mixture of 2,3-dimethylbutanoic acid and 4-methylpentanoic acid	40
Octane	2,2-Dimethylpropionic acid	195
Decane	2,2-Dimethylpropionic acid	102
	2,2-Dimethylbutanoic acid	20
	Mixture of 2-pentanecarboxylic acid and 3-pentanecarboxylic acid	30
	2,2-Dimethylpentanoic acid	30
	2-Methyl-2-ethylbutanoic acid	10

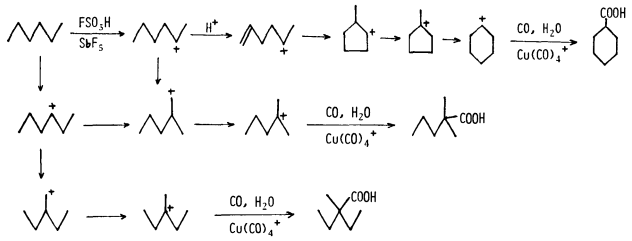
a) The reaction was carried out using 20 ml of FSO_3H, 10 ml of SbF_5, 0.858 g of Cu_2O and 30 mmol of saturated hydrocarbons at −2 to 2 °C for 2 h at 1 atm of CO.

In addition, ^{13}C NMR chemical shifts of $Cu(CO)_4^+$, $Cu(CO)^+$, and CO were observed at 171.1, 169.2, and 181.5 ppm, respectively.[12] The absorptions of $Cu(CO)_4^+$ and $Cu(CO)^+$ were chemically shifted to fields higher than that of gaseous carbon monoxide.

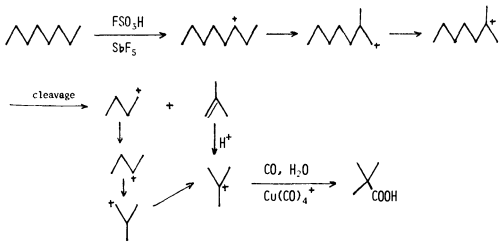
The significance of employing the copper(I) carbonyl catalysts in carbonylation reactions in FSO_3H–SbF_5 is the promotion of the rate of carbonylation, and at the same time, the increase in the yield of carbonylated products. The results are shown in Table 2. The reaction proceeded rapidly for temperatures −2 to 2 °C. Olah has stated that hydride abstraction tends to proceed in the order: primary hydrogen<secondary hydrogen<tertiary hydrogen.[7] The same tendency was observed for the carbonylation listed in Table 2.

Methylcyclopentane gave methylcyclopentanecarboxylic acid and cyclohexanecarboxylic acid.

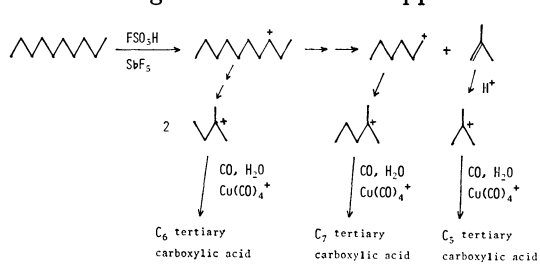
From hexane, C_5 and C_6 carboxylic acids such as 2,2-dimethylpropionic acid and 2,2-dimethylbutanoic acid were obtained together with C_7 carboxylic acids. This may be due to the formation of tertiary-butyl cations and tertiary pentyl cations by the β-scission of C_6 tertiary carbonium ions.



Octane gave only C_5 tertiary carboxylic acid, *i.e.*, 2,2-dimethylpropionic acid. It means that two *t*-butyl cations were formed by the cleavage of a C–C bond of octane.



Decane gave 2,2-dimethylpropionic acid as the main product, and at the same time, C_6 tertiary and C_7 tertiary carboxylic acids were obtained. A complicated cleavage of C–C bond appears to occur.



Experimental

The products were separated by preparative GLPC and analyzed by ^1H NMR, ^{13}C NMR, and IR spectroscopy, as described in a previous paper.[1] FSO_3H and SbF_5 were obtained from the Cationic Co.

Preparation of Copper(I) Carbonyl Catalysts. In a 300 ml three-necked flask equipped with a thermometer and a carbon monoxide gas burette, 0.858 g of Cu_2O was placed. The apparatus was evacuated using a rotary pump, and carbon monoxide was introduced from the gas burette. The mixture was stirred vigorously after 20 ml of FSO_3H and 10 ml of SbF_5 had been added. A colorless copper(I) carbonyl solution was formed by the absorption of carbon monoxide by Cu_2O.

Carbonylation of Saturated Hydrocarbons. From a syringe, 30 mmol of saturated hydrocarbons were added dropwise to the catalyst solution at −2 to 2 °C. Immediately carbon monoxide was absorbed. After the reaction was completed, the mixture was poured over ice. The mixture was shaken with hexane, and the total yield of carboxylic acids was determined by titrating the hexane extract with a 1/10 M NaOH ethanol solution. Each product was identified using authetic samples.[1]

The ^{13}C NMR Spectra of Several 4-Amino-3-penten-2-ones and Their Palladium Complexes

Yasuhisa SENDA, Akira KASAHARA,* Akio SUZUKI,* and Taeko IZUMI*

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Sendai 980

** Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992*

(Received May 13, 1976)

Synopsis. A ^{13}C NMR study of several 4-amino-3-penten-2-ones and their palladium chelate complexes is presented. The resonances of the carbonyl carbons of these complexed molecules moved upfield by about 20 ppm relative to the free ligands, while no significant shifts were observed for those of carbons bearing the amino groups.

Three kinds of structures—I, II, and III—are possible for α,β-unsaturated β-amino ketones. In an infrared study a tautomeric equilibrium has been reported to exist between those corresponding to I and II, with the III structure ruled out.[1] Cromwell *et al.*[2] have presented convincing evidence for the II structure in the infrared study of various α,β-unsaturated β-amino ketones. It was also indicated in the ^1H NMR spectra that these tautomers are present predominantly in the II form.[3] We wish to report here a ^{13}C NMR study of several 4-amino-3-penten-2-ones and their palladium chelate complexes.

The natural-abundance 25.15 MHz ^{13}C FT-NMR spectra were obtained using the ^1H noise-decoupling technique. The assignment of the resonances to the specific carbon atoms was made with the aid of ^1H off-resonance experiments. The chemical shifts thus obtained are listed in Tables 1 and 2.

The chemical shifts for the carbonyl carbons of alkyl methyl ketones are usually more than δ; 200.[4] The resonances for the α,β-unsaturated carbonyl carbons move upfield at around δ; 190,[5] while the imino carbons in the II structure are supposed to appear at less than δ; 170.[6] The resonances around δ; 190 are, therefore, assigned to the carbonyl carbons (C-2). The signal at δ; 95.13, which is assigned to the sp^2 hybridized carbon (C-3) of 4-methylamino-3-penten-2-one is split into a doublet in the off-resonance spectra. This evidence suggests that significant portions of these compounds are present in the α,β-unsaturated amino ketone structure, II. The methyl carbon signals (C-1 and C-5) appear separately depending on the structural environments. It has been reported that the methyl carbon resonances of the alkyl methyl ketones usually appear around δ; 28—30,[7] while those of the enol ethers appear around δ; 20.[8] Consequently, the methyl carbon signals at δ; 28.63—29.60 and δ; 18.56—21.90 may correspond to C-1 and C-5 respectively. These assignments are supported by the findings that the signals which are provided by C-5 experience a large upfield shift when the hydrogen on the nitrogen atom is replaced by the methyl group. This shift may be due to the γ-effect between C-5 and the *N*-methyl group. The resonances of the carbonyl carbons of acetylacetone, which is a fifty-fifty mixture of the I and II structures, appear at a field slightly higher than those of the α,β-unsaturated β-amino ketones.

The structures of the palladium complexes are represented as IV or V and VI. The carbonyl carbon resonances of the palladium complexes appear at around δ; 170, at a field about 20 ppm higher than those of the free ligands. The resonances for the methyl carbon next to the carbonyl carbon (C-1) also move upfield, whereas the C-5 resonances move downfield compared with those of the corresponding free ligands. These results indicate the increasing contribution to the enol imine form, V, by the chelate com-

plex formation. Similarly to the case of α,β-unsaturated β-amino ketones, the upfield shift of the C-5 resonances was observed upon the replacement of the hydrogen on the nitrogen atom with the methyl, the methylene, or the phenyl groups. When the hydrogen of C-3 is replaced by the halogen, the carbon resonances of the substituents on the nitrogen atoms as well as those of the skeletal carbons usually move downfield, with the exception of those of C-2, which reveal the opposite trend.

Experimental

NMR Spectra. The ^{13}C FT-NMR spectra were obtained at 25.15 MHz with a JEOL JNM-MH-100 instrument equipped with a JNM-MFT-100 Fourier transform accessory; the instrument was controlled with a JEC-6 spectrum computer. Samples were observed in 5-mm spinning tubes at 15±5% solutions in $CDCl_3$ at 28 °C. The solvent provided the internal lock signal. The measurement conditions were as follows: pulse width, 27.5 μs (*ca.* 45°); repetition time, 4 s; spectral width, 6.25 kHz; data point, 8192; acquisition time, 0.65 s. Noise modulated proton decoupling was carried out at a nominal power of 20 W. All the chemical shifts are expressed in δ (ppm downfield from internal Me_4Si). Each observed chemical shift is estimated to be accurate to δ ±0.06.

Materials. The compounds employed in this work have been previously prepared except **5**, which was commercially available; **1**,[9] **2**,[1]**3**,[10]**4**,[10]**6**—**13**,[11] **14**,[12] and **15**.[13]

Studies on Heterocyclic Chemistry. XX.[1] Photo-reactions of 5-Benzylideneamino-3-arylisoxazoles in Trialkylamine

Tarozaemon NISHIWAKI

Department of Chemistry, Yamaguchi University, Yamaguchi 753

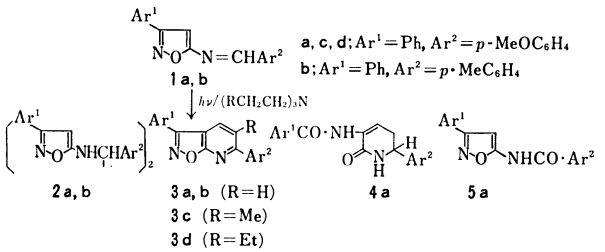
(Received May 31, 1976)

Synopsis. Irradiation of 5-benzylideneamino-3-arylisoxazoles at 254 nm in a mixture of trialkylamine and nitrile gives diaminoethanes (reduction), benzamides (oxidation), and isoxazolo[5,4-*b*]pyridine (cyclization).

From a growing interest in the photo-reactions of organic compounds in amines,[2] studies were carried out on 5-benzylideneamino-3-arylisoxazoles (**1**) which undergo photo-reduction, photo-oxidation, and photo-cyclization in trialkylamine.

Irradiation of **1a** in a mixture of triethylamine and benzonitrile (2:13) at 254 nm afforded *N*,*N*′-bis-(3-phenyl-5-isoxazolyl)-1,2-*p*-anisyl-1,2-ethanediamine (**2a**) and 3-phenyl-6-*p*-anisylisoxazolo[5,4-*b*]pyridine (**3a**) in low yields. The structure of **2a** was confirmed by synthesis, and that of **3a** rests on its spectral data. The high resolution mass spectrum displays M^+ as the base peak and the NMR spectrum two sets of one-proton doublets at δ 8.10 (J=8 Hz) and 8.67 ppm (J=8 Hz) besides methyl and phenyl protons. The β,γ-unsubstituted pyridine structure is established from their J value,[3] the lower-field doublet being assigned to the γ-proton by virtue of its remarkable downfield shift (0.46 ppm) in deuteriotrifluoroacetic acid. Absence of a benzoyl ion in its mass spectrum[4] rules out the corresponding oxazolo[5,4-*b*]pyridine structure. Photolysis of **1b** likewise produced the corresponding **2b** and **3b** in low yields.

Acetonitrile may be used as a solvent, but the reaction is far less clean. Thus, **1a** afforded 3-benzoylamino-6-*p*-anisyl-5,6-dihydro-2(1*H*)-pyridone (**4a**), *N*-(3-phenyl-5-isoxazolyl)-*p*-anisamide (**5a**), *p*-methoxybenzyl alcohol,[5] and 5-amino-3-phenylisoxazole in addition to **2a** and **3a**. The NMR spectrum (see Experimental) and mass spectral fragmentations [major ions: M^+, $Ar^2CH{=}NH_2^+$ (base peak), $Ar^1C{\equiv}O^+$, $(M\text{-}Ar^1CO)^+$, and $(M\text{-}Ar^2CH{=}NH)^+$] of **4a** are consistent with the assigned structure, whereas the structure of **5a** was confirmed by synthesis.



The two carbon fragment at positions 4 and 5 of the isoxazolopyridine ring arises from the amine, as supported by the regioselective formation of the 5-methyl and 5-ethyl derivatives (**3c**) and (**3d**) when **1a** was photolyzed in tripropylamine and tributyamine, respectively. It was found that **3c** and **3d** are obtained again in low yields by photolyzing **1a** in triethylamine in the presence of propionaldehyde and butyraldehyde, respectively.[6] This suggests the intermediacy of an aldehyde in the cyclization step leading to **3**, which may be formed by the photo-oxidation of the amine.[7] Isolation of butyric acid from the photolyzate in tributylamine supports the occurrence of the oxidation of amine.

Besides the occurrence of photo-reduction to **2** and photo-oxidation to **5**, photo-cyclization of **1** to **3**, which bears a marked resemblance to the photo-cyclization of some of the Schiff bases with ethanol,[8,9] is interesting because the related systems (*e.g.*, 5-benzylideneaminopyrazoles and *N*-benzylideneanilines) were photo-unreactive in amine[10] and relatively few studies[11] have been made on the isoxazolo[5,4-*b*] pyridine ring system. Attempts to obtain **3** in a moderate yield were unsuccessful. It may be relevant, however, to note some findings on the conditions to give **3**. Photolysis of a $(2\text{—}3)\times10^{-2}$ mol l^{-1} solution of **1** in a nitrile in the presence of *ca.* 50 molar excess of the amine was found to give **3** in 2—7% yield. Use of a solvent other than a nitrile (*e.g.*, ethanol and tetrahydrofuran) and >300 nm light was ineffective and use of dialkylamine (*e.g.*, diethylamine) slowed down the reaction

Experimental

NMR spectra were measured at 100 MHz using a Varian HA-100 spectrometer. The assignments were confirmed by decoupling techniques when necessary. The light source was a Riko low pressure mercury lamp (30 W) immersed in a quartz well.

*N,N′-Bis(3-aryl-5-isoxazolyl)-1,2-diaryl-1,2-ethanediamines (**2**).* The compounds were prepared in 20—48% yield as described[12] using wet tetrahydrofuran and crystallized from ethanol, for which satisfactory spectral data have been obtained. **2a**: mp 237—238 °C (dec). Found: C, 72.88; H, 5.13; N, 9.87%. Calcd for $C_{34}H_{30}N_4O_4$: C, 73.10; H, 5.41; N, 10.03%. **2b**: mp 260 °C (dec). Found: C, 77.34; H, 6.01; N, 10.75%. Calcd for $C_{34}H_{30}N_4O_2$: C, 77.54; H, 5.74; N, 10.64%.

*N-(3-Phenyl-5-isoxazolyl)-p-anisamide (**5a**).* The compound was prepared in 75% yield by the Schotten-Baumann procedure and crystallized from ethanol, mp 186—187 °C. Found: C, 69.20; H, 4.82%. Calcd for $C_{17}H_{14}N_2O_3$: C, 69.37; H, 4.80%.

Photolysis in Benzonitrile. A mixture of **1**, triethylamine (20 ml), and benzonitrile (130 ml) was irradiated under the conditions given in Table 1. Evaporation *in vacuo* and chromatography[5] of the residue with ether gave **3**, which crystallized from ethanol. **3a**: mp 170—171 °C, NMR (DMSO-d_6): δ 3.88 (s, 3H), 7.10 (d, J=9, 2H), 7.64 (m, 3H), 8.07 (m, 2H), 8.10 (d, J=8, 1H), 8.22 (d, J=9, 2H), 8.67 ppm (d, J=8, 1H); UV (EtOH) λ_{max} (log ε): 243 nm (4.12), 332

(4.43). Found: C, 75.75; H, 4.73; N, 9.42%. Calcd for $C_{19}H_{14}N_2O_2$: C, 75.48; H, 4.67; N, 9.27%. **3b**: mp 170—171 °C, NMR: δ 2.38 (s, 3H), 7.32 (d, J=9, 2H), 7.60 (m, 3H), 8.08 (m, 5H), 8.67 ppm (d, J=8, 1H); UV (EtOH) λ_{max} (log ε): 247 nm (3.96), 320 (4.12). Found: C, 79.56; H, 5.10; N, 9.64%. Calcd for $C_{19}H_{14}N_2O$: C, 79.70; H, 4.93; N, 9.78%. Elution with acetone gave **2**, identical with authentic specimens.

Table 1. Photolysis of **1** in benzonitrile

Compound	Irradiation time: Weight (g)	Irradiation time: h	Products Weights (g)
1a	(0.83)	20	**2a** (0.04) + **3a** (0.02)
2b	(1.00)	7	**2b** (0.12) + **3b** (0.01)

Photolysis in Acetonitrile. (a) A mixture of **1a** (2.78 g), triethylamine (40 ml), and acetonitrile (260 ml) was irradiated for 20 h. Evaporation *in vacuo* and chromatography of the residue with chloroform gave the starting material (0.57 g) and **3a** (0.01 g). GLC of the filtrate revealed the presence of *p*-methoxybenzyl alcohol. Elution with ether–ethyl acetate (5 : 1) gave an oil, which was triturated with ethanol to give an additional amount of **3a** (0.06 g). Evaporation of its filtrate and re-chromatography of the residue with ether–ethyl acetate (5 : 1) gave 5-amino-3-phenylisoxazole (0.10 g) and **5a** (0.10 g), identical with an authentic specimen. Elution with acetone gave **4a** (0.009 g), which was crystallized from ethanol, mp 199—200 °C, NMR: δ 2.70 (m, 2H), 3.72 (s, 3H), 4.64 (t, J=7, 1H), 6.88 (d, J=9, 2H), 7.11 (t, J=4, 1H), 7.28 (d, J=9, 2H), 7.52 (m, 3H), 7.81 (m, 2H), 8.28 (s, exchangeable, 1H), 9.04 ppm (s, exchangeable, 1H). Found: C, 70.97, H, 5.70; N, 8.76%. Calcd for $C_{19}H_{18}N_2O_3$: C, 70.79; H, 5.63; N, 8.69%. TLC of its filtrate revealed the presence of **2a**. (b) A mixture of **1a** (1.00 g), tripropylamine (or tributylamine) (20 ml), and acetonitrile (130 ml) was irradiated for 20 h and worked up as before. Elution with ether gave the corresponding 5-alkylisoxazolopyridines, which crystallized from ethanol. **3c**: mp 192—193 °C, NMR: δ 2.50 (s, 3H), 3.83 (s, 3H), 7.04 (d, J=9, 2H), 7.64 (m, 5H), 8.09 (m, 2H), 8.58 (s, 1H): UV (EtOH) λ_{max} (log ε): 236 nm (4.19), 321 (4.15). Found: C, 76.17; H, 4.96; N, 8.81%. Calcd for $C_{20}H_{16}N_2O_2$: C, 75.93; H, 5.10; N, 8.86%. **3d**: mp 144—145 °C, NMR: δ 1.16 (t, 3H), 2.84 (q, 2H), 3.83 (s, 3H), 7.04 (d, J=9, 2H), 7.53 (d, J=9, 2H), 7.62 (m, 3H), 8.08 (m, 2H), 8.57 ppm (s, 1H); UV (EtOH) λ_{max} (log ε) 234 nm (4.19), 318 (4.08). Found: C, 76.05; H, 5.51; N, 8.66%. Calcd for $C_{21}H_{18}N_2O_2$: C, 76.34; H, 5.49; N, 8.48%. (c) A mixture of **1a** (1.00 g), propionaldehyde (or butyraldehyde) (10 ml), triethylamine (10 ml), and acetonitrile (150 ml) was irradiated for 20 h. Work-up gave the corresponding 5-alkylisoxazolopyridines [**3c** (0.025 g); **3d** (0.046 g)].

Sulfoxonium Ylide Chemistry. VI.[1] A Convenient Method for Synthesizing 1-Substituted 4-Phenyl-3-pyrrolin-2-ones

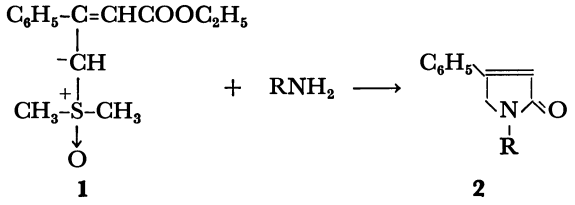
Junya IDE and Yasuo YURA
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received June 6, 1976)

Synopsis. Synthesis of 1-substituted 4-phenyl-3-pyrrolin-2-ones (**2**) from dimethylsulfoxonium 3-ethoxycarbonyl-2-phenylallylide (**1**) and various primary amines is described.

In the continuation of our studies on sulfoxonium ylide chemistry, we have found a convenient method for synthesizing 1-substituted 4-phenyl-3-pyrrolin-2-ones from dimethylsulfoxonium 3-ethoxycarbonyl-2-phenylallylide (**1**)[2] and primary amines in fairly good yield. There have been only a few reports on the synthesis of substituted 3-pyrrolin-2-ones.[3]

Treatment of ylide **1** with aniline in tetrahydrofuran containing a small amount of 10% HCl under reflux for 3.5 h afforded 1,4-diphenyl-3-pyrrolin-2-one (**2a**) in 75% yield. The structure of **2a** was confirmed with the spectral and elemental analysis data. Its IR spectrum showed bands at 1686, 1629, and 1608 cm^{-1} due to the α,β-unsaturated lactam. In the NMR spectrum of **2a** in $CDCl_3$, methylene protons appeared at δ 4.72 (doublet, J=2 Hz), a vinyl proton at 6.48 (triplet, J=2 Hz) and aromatic protons at 7.5 ppm (multiplet).



1 **2**

Speckamp *et al.*[3c] reported 1-methyl-4-phenyl-3-pyrrolin-2-one (**3**) and 1-methyl-3-phenyl-3-pyrrolin-2-one (**4**) in which vinyl protons appeared at δ 6.45 and 7.17 ppm, respectively. These data also could support the structure of **2**.

3 **4**

The 1-substituted 4-phenyl-3-pyrrolin-2-ones (**2**) prepared by this method using various primary amines are listed in Table 1.

Experimental

All the melting points are uncorrected. The NMR spectra were recorded on a Varian A-60 instrument, using TMS as the internal standard. The IR spectra were obtained on a Hitachi EPI-G3 spectrophotometer.

General Procedure for Synthesis of 1-Substituted 4-Phenyl-3-pyrrolin-2-one (2). A solution of **1** (5 mmol) and an amine (15 mmol) in 10% HCl (1.6 ml) and THF (20 ml) was heated under reflux for 2—4 h. The reaction mixture was diluted with ether and washed successively with 2% HCl solution, H_2O and sat. NaCl solution, and dried over Na_2SO_4. Evaporation of the solvent *in vacuo* gave a crude product, which was purified by column chromatography on silica gel or recrystallization from ethanol.

1-n-Butyl-4-phenyl-3-pyrrolin-2-one (2h). A solution of **1** (1.33 g) and butylamine (1.09 g) in 10% HCl (1.6 ml) and THF (20 ml) was heated under reflux for 3.5 h. The reaction mixture was diluted with ether (100 ml) and successively washed with 2% HCl solution, H_2O and sat. NaCl solution, and dried over Na_2SO_4. Evaporation of the solvent gave 1.19 g of an oily residue, which was chromatographed on silica gel (10 g) to afford 380 mg of **2h** (35% yield) by eluting with benzene.

1-Allyl-4-phenyl-3-pyrrolin-2-one (2j). A solution of **1** (1.33 g) and allylamine (855 mg) in 10% HCl (1.6 ml) and THF (20 ml) was heated under reflux for 3.5 h. The reaction mixture was treated as described above to give 1.02 g of an

Luminescence of Pyridinols and Related Molecules

Ko KIMURA and Ryo NAGAI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received March 24, 1976)

Synopsis. Quantum yields of fluorescence and phosphorescence together with lifetimes at 77 K suggest that 2-pyridinol exists in the keto form in the excited states as well as in the ground state, and the lowest excited singlet and triplet states for 2-, 3-pyridinol, 2-methoxypyridine, and *N*-methyl-2-pyridone are ($\pi\pi^*$) states. The lowest triplet state for 4-pyridinol takes the keto form, and is assigned to ($\pi\pi^*$).

Studies on tautomerism of pyridinols in the ground state carried out by Mason and others[1] show that 2- and 4-pyridinol exist as the tautomeric pyridones in aqueous solutions, whereas 3-pyridinol exists as an equilibrium mixture of the enol and keto form in the same solvent. Closely related compounds such as 2-methoxypyridine and *N*-methyl-2-pyridone correspond to the enol and keto forms of 2-pyridinol, respectively. Quantum yields of fluorescence Φ_f and phosphorescence Φ_p for these compounds in an alcohol (ethanol containing 10% methanol) mixture (A), an acidic (1 N sulfuric acid) alcohol mixture (H^+), and an alcohol mixture containing 0.1 N sodium hydroxide (B) at 77 K and at 300 K are given in Table 1, together with lifetimes of fluorescence τ_f and phosphorescence τ_p. Temperature dependence and/or protonation effect of Φ_f's, which are characteristic of some nitrogen heterocyclics, clearly show the contribution of the close $^1(n\pi^*)$ or $^3(n\pi^*)$ state in energy[2] to radiative and/or radiationless transitions from the lowest excited singlet state. The lowest excited singlet and triplet states for 2-pyridinol and its derivatives in protic solvents are assigned to ($\pi\pi^*$) from ϕ_f's and τ_p's. Fluorescence spectra of 2-pyridinol do not resemble those of 2-methoxypyridine. From a comparison of these spectra and quantum yields it is evident that 2-pyridinol takes the keto form (pyridone) even in the excited state just as in the ground state.

The temperature dependence and protonation effect of Φ_f's and Φ_p's for 3-pyridinol closely resemble those for 2-methoxypyridine. In solvent (B), the formation of the 3-pyridinolate anion[3] may partly be responsible for the temperature independence of Φ_f's. These observations together with τ_p's suggest that 3-pyridinol takes the enol form in the excited state in the solvents

(B)	357	0.06	326	0.06	1.2*	449	0.34	0.92		

2PL, 2MOP, NM2P, and 3PL are abbreviations for 2-pyridinol, 2-methoxypyridine, *N*-methyl-2-pyridone, and 3-pyridinol, respectively. The symbol * means the calculated lifetimes obtained from integrations of absorption and fluorescence spectra together with the observed Φ_f's.[8]

The character k_f and k_{nr} are transition rates of fluorescence and radiationless processes from the lowest excited singlet state, respectively.

used in this work, and that the lowest excited singlet and triplet states are assigned to ($\pi\pi^*$).

Φ_f's and Φ_p's for 4-pyridinol at 77 K are smaller than 0.01 irrespective of solvents, except Φ_p in solvent (A), in which Φ_p is 0.15. τ_p's for 4-pyridinol at 77 K vary from 0.3 to 1 s, depending on solvents. The phosphorescence spectra for 4-pyridinol in solvent (A) show the well defined vibrational structure, in which a characteristic vibration indicative of the keto form may be found,[4] as in the fluorescence spectra for 2-pyridinol in the same solvent. These observations lead to the conclusion that 4-pyridinol takes the keto form in the lowest triplet state which is assigned to ($\pi\pi^*$). Calculations[2] suggest the ($n\pi^*$) assignment for the lowest excited singlet state of 4-pyridinol in the keto and enol forms, but it is difficult to make conclusive assignment from observation of the small Φ_f values only.

Experimental

2-, 3-, and 4-pyridinol were recrystallized five times from ethanol and/or acetone, then purified by zone melting, and finally sublimed *in vacuo*. 2-methoxypyridine and *N*-methyl-2-pyridone were distilled through a spinning band column at reduced pressure, then purified through a basic alumina column, and finally distilled *in vacuo*. Ethanol (Wako pure chemicals, analytical grade) was refluxed over silver nitrate and potassium hydroxide, and then distilled through a glass packed column. Methanol (Wako pure chemicals, analytical grade) was distilled through a glass packed column. Sulfuric acid and sodium hydroxide were of analytical grade (Wako pure chemicals and Yashima chemicals, respectively).

Φ_f's and/or Φ_p's for luminescence were determined by comparison with those of quinine hydrogensulfate (5×10^{-3} M, $\Phi_f=0.51$ at 300 K),[5] and not corrected for change in refractive indices of solvents. The optical arrangement used in measurements of Φ_f's and Φ_p's was of surface type, which allows for the exciting light to be absorbed completely through the first 1—2 mm optical path (concentration 10^{-2}—5×10^{-4} M). The concentration quenching was negligibly small for these molecules, as is estimated by Stern-Volmer's plot (not given). The sensitivity correction of the combination of monochromator with photomultiplier was made with the use of a standard lamp.[6] The lifetime measurements for fluorescence were carried out by the stroboscopic technique,[7] and those for phosphorescence with a Tektronix 454A oscilloscope with manually operated shutter. Concentrations used in lifetime measurements were 10^{-4}—10^{-5} M. All the samples were evacuated by repeated cycles of freezing, pumping, and thawing. The sample cells were then sealed off from the evacuation system.

Phase Diagram of the Pyrene-Picryl Chloride System

Masaki BANDO and Yoshio MATSUNAGA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 19, 1976)

Synopsis. A differential scanning calorimetric study of the pyrene–picryl chloride system has revealed five molecular compounds with mole ratios of 1: 1, 4: 3, 2: 1, 3: 1, and 4: 1 respectively.

Most molecular compounds are equimolar in composition. Therefore, the phase diagrams of organic binary systems are generally simple. The pyrene-pyromellitic dianhydride system which forms three molecular compounds with ratios of 3: 1 or 2: 1, 1: 1, and 1: 3 respectively is known to be rather exceptional.[1] Such simplicity may be characteristic of organic systems but may be, at least in part, connected with the thaw-point-melting-point method employed in the determination of phase diagrams.[2] While solid–liquid equilibria give valuable information regarding the state of a system within the temperature limits of the diagram, the information obtained does not necessarily remain valid at lower temperatures. When solid-solid transitions, if any, are included in the examinations, the phase relations might be more complicated than previously reported. Studies of the anthracene–carbazole and naphthalene–2-naphthol systems made by Robinson and Scott seem to support such a postulate; however, neither of the systems gives a molecular compound.[3,4] The pyrene–picryl chloride system, which has been reported to form only an equimolar compound,[5] has been studied as our first choice along this line because of the following reasons. First, a solid-solid transition is known to occur in the molecular compound near 80 °C.[6] Secondly, the closely-related pyrene-picryl bromide system has been found to form two compounds with ratios of 1: 1 and 3: 2 respectively.[7]

Samples were prepared by melting mixtures with known ratios of the parent compounds. The composition is quoted in the mole percentage of the hydrocarbon. The melting points and transition temperatures were determined using a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C. X-Ray measurements on powdered samples were made at room temperature with a Toshiba recording diffractometer, Model ADG-301, using filtered copper radiation.

As is shown in Fig. 1, the phase relations in the region from 0 to 50 mol % are simple. A eutectic occurs at 12 mol % and 75 °C; these values are to be compared with 8 mol % and 73.5 °C reported by Shinomiya.[5] All the samples in the region from this point to 50 mol % show an endothermic peak due to the appearance of the liquid phase and also one at 81 °C due to a solid-solid transition in the equimolar molecular compound. Four more distinct compounds are formed in the region from 50 to 80 mol %. If the 1: 1 molecular compound melting at 154 °C were the only compound formed in this system, the endothermic peak due to the transition should be observed in the entire region from 50 to 100 mol %. As a matter of fact, the peak is observable only up to 57 mol %. Between 58 and 75 mol %, a new endothermic peak appears at 82—83 °C. Above 67 mol % an additional peak is found at 77 °C. This disappears by 80 mol %. These observations lead to the conclusion that the peak at 82—83 °C is due to a solid-solid transition in the 2: 1 compound (66.7 mol %) and that at 77 °C is due to a solid-solid transition in the 3: 1 compound (75 mol %). Two more phase boundaries are located at 57—58 mol % and at 80 mol % respectively, on the basis of the discontinuity of the transitions. These compositions correspond to molecular compounds with ratios of 4: 3 and 4: 1. Neither of them show solid-solid transitions near 80 °C.

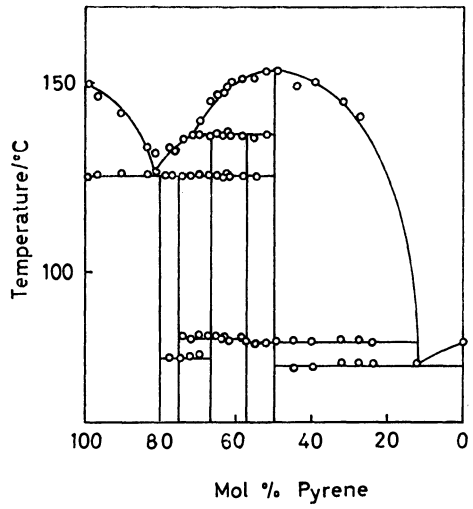

Fig. 1. The pyrene–picryl chloride phase diagram.

Turning to the solid-liquid equilibria in the region from 50 to 100 mol %, we see that only the equimolar molecular compound melts congruently. All the other four cease to be stable before their congruent melting points are reached. In the equilibrium diagram a eutectic point is cleary observed at about 81 mol % and 126 °C, and a peritectic point at about 71 mol % and 136 °C. It is evident that a eutectic conglomerate of pyrene and the 4: 1 molecular compound coexist in contact with the liquid at the former point. Shinomiya has assumed the eutectic point to be at 77 mol % and 125 °C.[5] Because of the formation of the 4: 1 compound this point cannot be at such a low percentage of the hydrocarbon. By visual examination, the thaw point in the region from 58 to 66 mol % was located not at 126 °C but at 136 °C; therefore, the molecular compound which undergoes decomposition into another compound and the liquid at the latter point was identified as the 2: 1 compound. The incongruent melting

* To whom inquiries may be addressed.

points of the 4: 1 and 3: 1 compounds are supposed to be slightly higher than the eutectic, but they are practically not distinguishable from each other. The endothermic peak observed at about 126 °C in the region from 50 to 66 mol % is nearly at the eutectic temperature. However, this must be attributed to a solid-solid transition in the 4: 3 compound, since the peak is not accompanied with liquefaction. This molecular compound also melts incongruently. Its peritectic point is located presumably very close to that of the 2: 1 compound. This conclusion is in accordance with Shinomiya's finding that the formation of liquid occurred at 135 °C in his 57.4 mol % sample.[5] If this observation was seriously taken into consideration, he could easily find the peritectic point in this system. Nevertheless, it should be emphasized that only two molecular compounds among the five may be found using the thaw-point-melting-point method.

The differences in the X-ray diffraction patterns between the equimolar molecular compound and the other four are appreciable. The crystal data of the 1: 1 compound have been determined by Herbstein and Kaftory.[8] The peak with a spacing of $a \sin\beta = 17.13$ Å is seen only in this compound. On the other hand, a spacing of about 10.6 Å, which is absent in the 1: 1 compound, is the longest in all the other compounds. The patterns of the compounds with stoichiometries other than 1: 1 are not very different from each other; however, the observed minor but definite difference is consistent with the existence of distinct compounds. The crystal structure of the stable red prisms of 3 pyrene: 2 picryl bromide has been described in terms of equimolar mixed stacks with alternating pyrene and picryl bromide molecules and interstial pyrene molecules steeply inclined to the stack axis.[7] It is likely that the hydrocarbon in the new phases of the present system also fills two different structural roles.

The authors wish to express their thanks to Professor Toshio Yokokawa for letting them use the X-ray diffractometer.

Charge-carrier Drift Mobility in Pyrene Single Crystals

Akira SUZUKI, Hiroo INOKUCHI,* and Yusei MARUYAMA**

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
***Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112*

(Received July 12, 1976)

Synopsis. The charge-carrier drift mobility in highly pure pyrene single crystals was measured. Observed values were $(3.8\pm0.1)\times10^{-3}$ cm^2 V^{-1} s^{-1} for electrons and $(3.3\pm0.4)\times10^{-3}$ cm^2 V^{-1} s^{-1} for holes at 345 K. The mobilities increased with the temperature between 333—374 K with an activation energy of 0.43 ± 0.01 eV for electrons.

Measurements of charge-carrier drift mobility in organic crystals have given the most important information in the studies of their electrical conduction processes. A few years ago, we observed rather small carrier mobilities in perylene single crystals and analyzed the obtained results taking the excimer-like excess electron state into consideration.[1)]

In this note, we will report the behavior of carrier drift mobility in pyrene single crystals in which the "dimeric structure" in an unit cell is also realized and in which its effect results in a pronounced excimer emission. In order to confirm the hypothetical transport model based on the "dimeric structure" in a perylene crystal,[1)] a similar type of measurement should be done using a dimeric pyrene crystal.

Highly pure pyrene was obtained by a careful zone-refining technique after conventional chemical and physical treatments. A single crystal ingot was grown using a pulling-down method in a Bridgman furnace from which disk-like, single crystals were carefully cleavaged out in a size of ≈10 mm $\times10$ mm $\times0.5$ mm (in thickness). Electron and hole drift mobility in the c'-direction were measured using the previously reported measuring system,[1)] but with the air-gap-discharge light pulser replaced by a xenon flash tube (Ushio Denki) as an exciting light source. Since the photocurrent sensitivity was not high enough at room temperature, the drift mobilities were observed in the temperature range of 333—374 K.

The typical photocurrent pulses observed are shown in Fig. 1 under the conditions specified in the caption. The observed electron or hole mobility was almost independent of the electric field between 1×10^4—2×10^4 V cm^{-1}, the mean value in the c'-direction was $(3.8\pm0.1)\times10^{-3}$ cm^2 V^{-1} s^{-1} for electrons and $(3.3\pm0.4)\times10^{-3}$ cm^2 V^{-1} s^{-1} for holes at 345 K. These

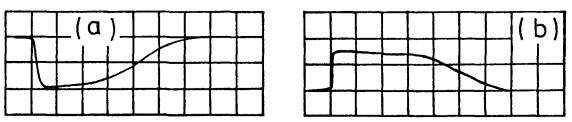

Fig. 1. Typical photocurrent *vs.* time curves.

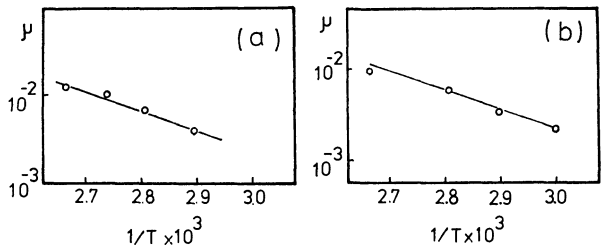

Fig. 2. Temperature dependence of drift mobility.
(a) Electron, (b) hole.

values are smaller by about one order than those in a perylene crystal.[1)] The electron mobility increased with the temperature between 345—374 K. Plots of the logarithm of the mobility *vs.* T^{-1} in Fig. 2 show an almost straight line of 0.4 eV in this temperature range. The hole mobility also showed a similar temperature dependence.

In order to elucidate the experimentally obtained characteristic of the electron drift mobility in the c'-direction, we display the relevant transfer integral values in Table 2, comparing them with the corresponding ones in a perylene crystal[1)] and an anthracene crystal.[3)]

TABLE 2. A COMPARISON OF THE ELECTRON-TRANSFER INTEGRALS IN THE c'-DIRECTION IN A PYRENE CRYSTAL WITH THOSE IN A PERYLENE OR AN ANTHRACENE CRYSTAL IN UNITS OF 10^{-4} eV

Molecule-pairs	Pyrene	Perylene	Anthracene
1— 8	74.3	3.57	0.38
1—11	— 0.60	0.84	0.67
1—13	—13.4	0.13	0.38

The physical situation in a pyrene crystal seems to be qualitatively similar to the case of perylene when we compare the values indicatied in Table 2 with the observed mobility. In the pyrene crystal, an excess electron on a dimeric point may be somewhile localized. through the formation of an excimer-like electronic state between two molecules. The excimer state in pyrene crystals is known to be located 0.4 eV below the mutually independent molecular lowest excited state.[4)] The relative displacement between dimeric molecules due to an excimer formation was estimated by Birks to be ~0.2 A.[4)] These two effects may cause the fluctuation in the transfer integrals and also the activation process in the electron-transport procedure. This type of fluctuation should be significant in determining the drift mobility value in this case.

The drift behavior of the charge carriers in organic

* Present address: Institute for Molecular Science, Okazaki-shi, Aichi 444.

molecular crystals may be determined mainly by means of the intermolecular resonance integrals or transfer integrals, which can be evaluated from the molecular wavefunctions, taking the crystal structure into consideration. The crystal structure of pyrene was analyzed by Robertson and White.[2]

The transfer integrals for each pair of molecules in a pyrene crystal were calculated using Hückel-type molecular orbitals, in which a single Slater orbital exponent, 3.08×10^8 cm^{-1}, was employed. Only the two center integrals were considered, the other procedures in the calculation were almost the same as those reported by Katz *et al.*[3]

In Table 1 we display the transfer integrals calculated between the molecule at Position 1 and the several neighboring molecules, the numbering of which is shown in Fig. 3. The same formalism as that shown in Ref. 1 will lead to the drift mobility in the c'-direction, 1.4×10^{-4} cm^2 V^{-1} s^{-1} at 345 K, using the formulae deduced by Gosar and Choi[5] and the activation energy of 0.44 eV.

Although the agreement between the calculated value, 1.4×10^{-4} cm^2 V^{-1} s^{-1}, and the observed value, 3.9×10^{-3} cm^2 V^{-1} s^{-1}, at 345 K is not so good as in the perylene crystal (0.015 cm^2 V^{-1} s^{-1} and 0.017 cm^2 V^{-1} s^{-1} respectively), the validity of the proposed electron-transfer mechanism may seem to be confirmed.

Table 1. Intermolecule transfer integrals in units of 10^{-4} eV

Molecule number	Electron	Hole
2	99.5	76.7
3	−13.5	38.1
4	− 4.07	1.06
5	−13.5	38.1
6	3.58	14.2
7	− 4.07	1.06
8	74.3	−79.6
9	0.30	0.0
10	− 0.31	0.33
11	− 0.60	−1.03
12	74.3	0.16
13	−13.4	0.14

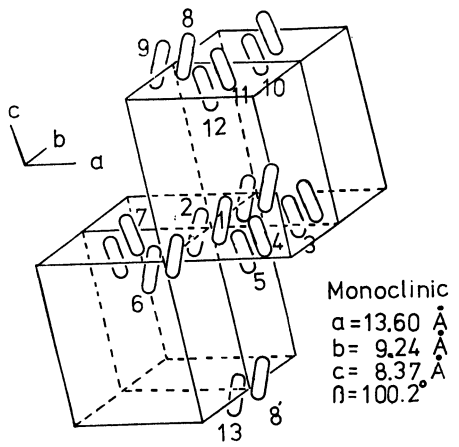

Fig. 3. Schematic representation of the pyrene unit cells, showing the numbering of the molecules used in this paper.

The large discrepancy between the previously reported value[6] and the present one may be partly due to the difference in the purity of the specimen and also partly to that in the crystal growth method. The former crystals were grown from a solution.

We wish greatly to acknowledge Professor Takaaki Danno's kind cooperation in the crystal-growth procedure.

Observation of the Scale Formed on Nickel in Nitrogen Oxide

Yoshio TAKASU, Shun-ichi MARU, and Yoshiharu MATSUDA

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube, Yamaguchi 755

(Received May 4, 1976)

Synopsis. The state of the scale formed on nickel in nitrogen oxide was examined. Its characteristics are summarized as follows: (1) remarkable oxidation of the grain boundary, (2) the formation of a large amount of lattice defects, and (3) unequal oxidation behaviors for the various crystal planes.

Concerning reactions of metals with nitrogen oxide, some previous work has been reported.[1,2] Recently, the oxidation of nickel in nitrogen oxide has been found to obey the linear rate law with a faster reaction rate than that in oxygen.[3] In this study, the state of these scales was observed.

Measurements of oxidation rates or sample preparation were carried out with a high vacuum apparatus. Nitrogen oxide of a high purity in a glass cylinder from the *Takachiho Co.* was used without further purification. The oxygen was prepared by bulb-to-bulb distillation from a commercial cylinder at liquid nitrogen temperature. Test sample (99.98% Ni) were 1.0×1.0 cm^2 in area and have a thickness of 0.0050 cm. They were annealed *in vacuo* at 800 °C for 2 h, electropolished in a mixed acid (H_2SO_4–H_3PO_4–H_2O),[4] and rinsed in distilled water. The mean size of the grains was 20 μm.

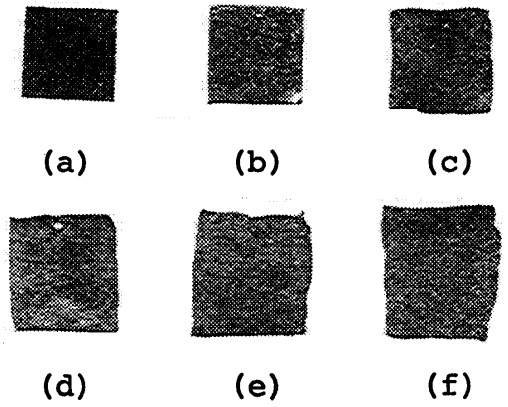

Fig. 1. Photographs of the specimens oxidized in nitrogen oxide,
where, (a): non-oxidized (electropolished), (b), (c), (d), (e), and (f): oxidized in 10 Torr of NO at 700 °C for 5, 10, 25, 40, and 90 min, respectively.

Figure 1 shows the size and shape of the specimens oxidized in nitrogen oxide, where (a) is a non-oxidized specimen and (b), (c), (d), (e), and (f) are specimens oxidized in 10 Torr of nitrogen oxide at 700 °C for 5, 10, 25, 40, and 90 min, respectively. As shown in this figure, the specimen increased in size and changed shape during the oxidation. The relation between the size of the specimen and the oxidation time was shown in Fig. 2. Since the specimens were curled or warped a little by the oxidation, the value r, the ratio of the mean length of each side of the specimen to that of a non-oxidized one, contained a noticeable error. Obviously, the r value increased rapidly during the oxidation. That is, the specimen oxidized in nitrogen oxide was very coarse and bulky. Moreover, even specimens oxidized to about 14 percent (P_{NO}=10 Torr, 700 °C, 10 min) at the early stage of the oxidation process were very brittle. These findings should suggest that preferential oxidation occured along grain boundary and the entire grain boundary was oxidized within less than 10 min. Then, all the scales oxidized in nitrogen oxide in this study were identified to be NiO using X-ray diffractometry. No nitrogen peak was found in the IMA (Ion-Micro-Analysis) spectra of these scales.[3] However, their color was grayish black, so that a large quantity of lattice defects, probably cation vacancies,[5] should be present in them. On the other hand, the scale formed in an oxygen atmosphere was greenish and dense. For example, even specimens oxidized at about 14 percent (P_{O_2}=10 Torr, 700 °C, 180 min) were not brittle and their size did not change in comparison with that prior to oxidation.

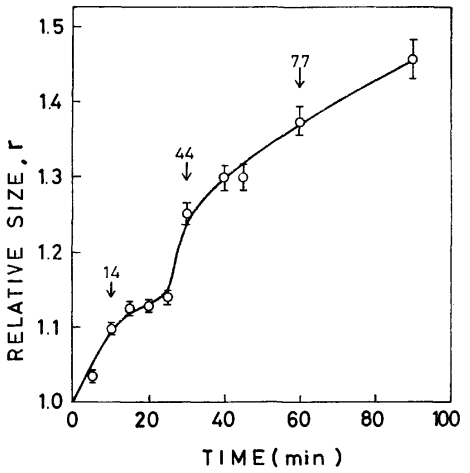

Fig. 2. Relation between the size of specimen and oxidation time.
The numerical values shown in this figure signify the percent of nickel oxidized.

Figure 3 represents the optical metallographs of scales formed in nitrogen oxide and oxygen, where (a) is a non-oxidized specimen, (b) is a specimen oxidized in 10 Torr of oxygen at 700 °C for 180 min, and (c), (d), and (e) are specimens oxidized in 10 Toor of nitrogen oxide at 700 °C for 5, 10, and 40 min, respectively. The surface oxidized in oxygen, (b), was relatively uniform in this photograph, while those in nitrogen oxide (c, d, and e) were not uniform. Namely, in the latter case, the grain boundaries were extremely swollen

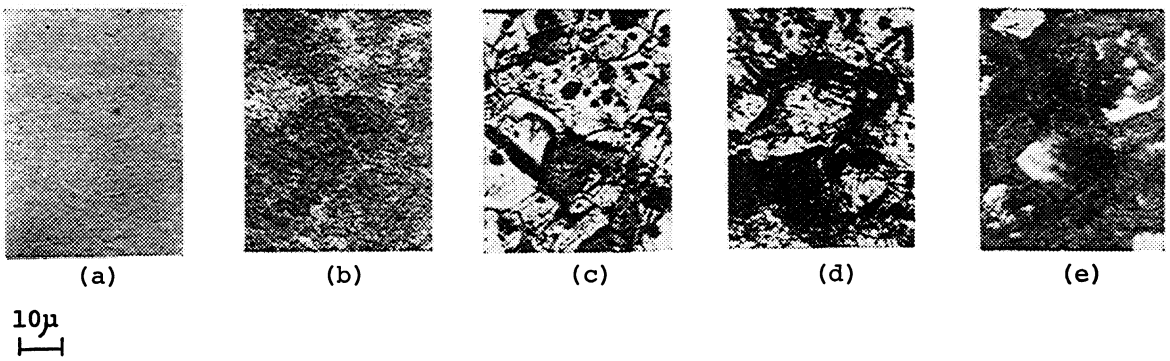

Fig. 3. Optical metallographs of the specimen oxidized in nitrogen oxide or oxygen, where, (a): non-oxidized (electropolished),
(b): oxidized in 10 Torr of O_2 at 700 °C for 180 min,
(c), (d), (e), and (f): oxidized in 10 Torr of NO at 700 °C for 5, 10, and 40 min, respectively.

during the oxidation. Moreover, the state of a few grains became very coarse (black in the photograph), while others did not. As described above, the main characteristics of the state of the scale formed on nickel in nitrogen oxide can be summarized as follows: (1) remarkable oxidation of the grain boundary, which caused the specimen to become coarse, bulky, and brittle, (2) the formation of a large amount of lattice defects, and (3) unequal oxidation behavior among the various crystal planes.

These findings appeared in the rapid diffusion rate of nickel ions through the bulky oxide layer with a large amount of lattice defects and, at the same time, agree with previous results and estimations[3] that the oxidation of nickel in nitrogen oxide was governed by a surface reaction in spite of its rapid oxidation obeying the linear rate law.

A New Synthesis of α-Santalol

Kikumasa SATO, Seiichi INOUE, Yoshihiro TAKAGI,* and Shigeki MORII

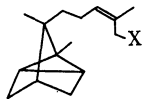
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Ooka, Minami-ku, Yokohama 233

**Nippon Terpene Chemical Co., Ltd., Wakinohama-cho, Fukiai-ku, Kobe 651*

(Received February 6, 1976)

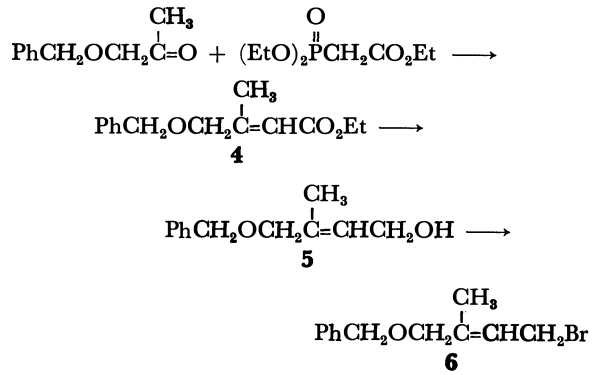
Synopsis. A new synthesis of α-santalol (**1**) is described. 1-Benzyloxy-4-bromo-2-methyl-2-butene (**6**) was converted by the reaction with nickel carbonyl to the π-allylic nickel bromide complex (**7**), which reacted with (−)-π-bromotricyclene (**8**) to afford benzyl ether (**2**). The benzyl ether (**2**) was led to (**1**) (cis: trans=40: 60) by reductive cleavage of the benzyloxy group.

α-Santalol (**1**), which is one of the main constituents of East Indian sandalwood oil, is highly prized in perfumery. Thus, many synthetic approaches have been studied.[1-7]

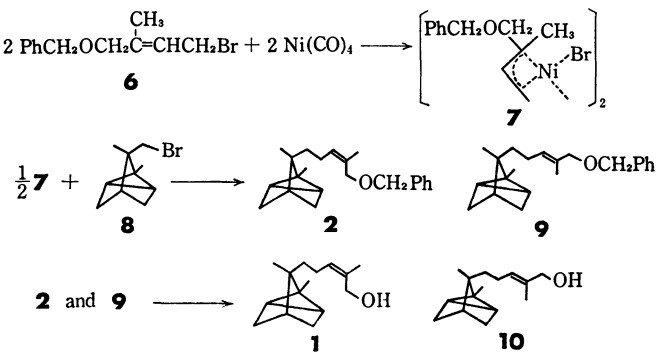


1, X=OH
2, X=OCH_2Ph
3, X=H

It is known that the π-allylnickel halide complex reacts with alkyl halides to afford allylalkanes.[8] Corey reported that α-santalene (**3**) was synthesized by the reaction of π-iodotricyclene with π-1,1-dimethylallylnickel bromide.[8] Sathe reported that the transformation of α-santalene to α-santalol was carried out by the selenium dioxide oxidation of (**3**), followed by reduction of the resulting aldehyde.[2] However, in the literature the stereochemistry of the product was not described. We reinvestigated Sathe's method and showed that the resulting alcohol was *trans*-α-santalol, isomeric to natural α-santalol, which has a *cis* configuration at the trisubstituted olefin moiety in the side chain.[9] We attempted to synthesize α-santalol by the crosscoupling reaction of a functionalized prenyl fragment with a tricyclene component.



(−)-π-Bromotricyclene (**8**) was prepared by the method of Corey.[10] Ethyl 4-benzyloxy-3-methyl-2-butenoate (**4**), which was prepared by the Wittig reaction of benzyloxyacetone with diethyl (ethoxycarbonylmethyl)phosphonate, was converted to 4-benzyloxy-3-methyl-2-buten-1-ol (**5**) by lithium aluminum hydride reduction. Bromination of alcohol (**5**) was carried out by the reaction with phosphorus tribromide and pyridine in petroleum ether to give 1-benzyloxy-4-bromo-2-methyl-2-butene (**6**). Bromide (**6**) was a *cis* and *trans* mixture (32: 68). The cross-coupling reaction of π-3-(benzyloxymethyl)-2-butenylnickel bromide (**7**), which was transformed from **6** (*cis*: *trans*=32: 68) and nickel carbonyl, with (−)-π-bromotricyclene (**8**) in hexamethylphosphoric triamide (HMPT) afforded benzyl ethers of α-santalol (**2**: **9**=40: 60). The *cis* (**2**) and *trans* (**9**) mixture of benzyl ethers was led to α-santalol (**1**: **10**=40: 60) by reductive cleavage of the benzyl ether function with lithium in ethylamine at −78 °C. Efforts to increase its selectivity in dimethylformamide or *N*-methylpyrolidone were unsuccessful. Stereoisomers of α-santalol were separated by means of column chromatography over silica gel (benzene–ethyl acetate). The isolated *cis*-α-santalol (**1**) was completely identical with natural α-santalol.



Experimental

All the boiling points are uncorrected. The IR spectra were recorded on a Hitachi Model 215 spectrophotometer. The NMR spectra were recorded on a JEOL Model C-60 spectrometer using tetramethylsilane as an internal standard.

Ethyl 4-Benzyloxy-3-methyl-2-butenoate (4). Diethyl (ethoxycarbonylmethyl)phosphonate (13.4 g) in tetrahydrofuran (THF) (20 ml) was added to sodium hydride (2.6 g) in THF (80 ml) at 22—35 °C and the mixture was stirred for 1.5 h at room temperature. Benzyloxyacetone (8.2 g) in THF (20 ml) was added dropwise to this mixture during 2.5 h at 22—35 °C with additional stirring for 1 h under reflux. After the usual work-up, distillation gave ethyl 4-benzyloxy-3-methyl-2-butenoate (**4**) (9.9 g; 74%), bp 120—129 °C/0.4 mmHg. *cis*: *trans*=37: 63. IR: 1700, 1650 cm^{-1}. NMR (CCl_4): δ 1.25 (t, 3H), 1.99 and 2.08 (*cis* and *trans* each s, 3H), 3.90 (s, 2H), 4.10 (q, 2H), 4.46 (s, 2H), 5.65 and 5.89 (*cis* and *trans* each t, 1H), 7.21 (s, 5H). Found: C, 71.80; H, 7.92%. Calcd for $C_{14}H_{18}O_3$: C, 71.77; H, 7.74%.

4-Benzyloxy-3-methyl-2-buten-1-ol (5). A solution of

ethyl 4-benzyloxy-3-methyl-2-butenoate (**4**) (18.7 g) in diethyl ether (50 ml) was added dropwise to a stirred slurry of lithium aluminum hydride (3.8 g) in diethyl ether (100 ml) for 1.5 h at 22—35 °C, and then stirred for 2 h. The mixture was neutralized with hydrochloric acid and extracted with ether. After drying over Na_2SO_4, distillation gave 4-benzyloxy-3-methyl-2-buten-1-ol(**5**) (15.3 g; quantitative), bp 125—134 °C/0.2 mmHg. *cis*: *trans*=37: 63. IR: 3350, 1070 cm^{-1}. NMR (CCl_4): δ 1.65 and 1.77 (*trans* and *cis* each s, 3H), 2.8 (br, 1H), 3.81 and 3.93 (*trans* and *cis* each s, 2H), 4.05 (d, 2H), 4.39 (s, 2H), 5.57 (t, 1H), 7.20 (s, 5H). Found: C, 74.49; H, 8.41%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

1-Benzyloxy-4-bromo-2-methyl-2-butene (6). To a solution of 4-benzyloxy-3-methyl-2-buten-1-ol (**5**) (7.0 g) and pyridine (1 ml) in petroleum ether (50 ml) was added phosphorus tribromide (4.3 g) in petroleum ether (10 ml) dropwise for 2.5 h at −15——5 °C. After the addition was complete, the reaction mixture was stirred for 1 h at −11——7 °C. After work-up, crude 1-benzyloxy-4-bromo-2-methyl-2-butene (**6**) (7.8 g; 84%) was obtained as a pale yellow oil. This bromide was used without further purification. *cis*: *trans*= 32: 68. n_D^{20} 1.5455. IR: 2850, 1660 cm^{-1}. NMR (CCl_4): δ 1.73 and 1.85 (*trans* and *cis* each s, 3H), 3.90 (s, 2H), 3.95 (d, 2H), 4.45 (s, 2H), 5.80 (s, 1H), 7.30 (s, 5H).

Benzyl Ether of α-Santalol (2 and 9). 1-Benzyloxy-4-bromo-2-methyl-2-butene (**6**) (*cis*: *trans*=32: 68, 14 g) in benzene (90 ml) was added dropwise to a solution of nickel carbonyl (14 g) in benzene (90 ml) for 1.5 h at 49—51 °C under an argon atmosphere. After the addition was complete, the reaction mixture was stirred for 3.5 h under the same conditions. Then the excess nickel carbonyl and the benzene were removed under reduced pressure, and to the residue HMPT (90 ml) was added. (−)-π-Bromotricyclene (**8**) (3.9 g) in HMPT (40 ml) was added dropwise to the solution of the nickel complex for 1 h at 40—45 °C, and stirred for 21 h. After work-up, the distillation gave benzyl ethers of α-santalol (**2** and **9**) (2.5 g; 45%), bp 138—142 °C/0.2 mmHg. *cis*: *trans*=40: 60. IR: 2920, 1080 cm^{-1}. NMR (CCl_4): δ 0.80 (s, 3H), 0.95 (s, 3H), 0.80—2.10 (m, 11H), 1.63 and 1.70 (*trans* and *cis* each s, 3H), 3.76 and 3.89 (*trans* and *cis* each s, 2H), 4.34 (d, 2H), 5.30 (m, 1H), 7.23 (s, 5H). Found: C, 85.00; H, 9.67%. Calcd for $C_{22}H_{30}O$: C, 85.11; H, 9.74%.

α-Santalol (1). Small pieces of lithium (0.3 g) were added to the stirred ethylamine (75 ml) at −10—0 °C until all the lithium was dissolved. After cooling to −78 °C, benzyl ethers of α-santalol (**2**: **9**=48: 52, 2.9 g) in petroleum ethers (10 ml) was added. After stirring for 2.5 h at −78 °C, ammonium chloride (2.0 g) was added and the ethylamine was distilled out. After work-up, the distillation gave α-santalol (**1** and **10**) (1.9 g; 90%), bp 98−102 °C/0.17 mmHg. *cis*: *trans*=48: 52. *cis*- and *trans*- α-Santalol were each isolated by means of column chromatography over silica gel (10: 1 benzene ethyl acetate as eluent). *cis*-α-Santalol (**1**): n_D^{20} 1.5018, $[\alpha]_D^{20}$ +17.20 (c=0.8, $CHCl_3$). IR: 3300, 2950, 1005 cm^{-1}. NMR ($CDCl_3$): δ 0.82 (s, 3H), 0.82—2.20 (m, 12H), 0.98 (s, 3H), 1.80 (s, 3H), 4.13 (s, 2H), 5.33 (t, 1H). *trans*-α-Santalol (**10**): n_D^{20} 1.5013, $[\alpha]_D^{20}$ +17.22 (c=1.5, $CHCl_3$). IR: 3300, 2940, 1005 cm^{-1}. NMR ($CDCl_3$): δ 0.85 (s, 3H), 0.85—2.20 (m, 12H), 1.00 (s, 3H), 1.68 (s, 3H), 3.99 (s, 2H), 5.40 (t, 1H).

Oxidative Ring Cleavage of 3,5-Di-*t*-butyl-catechol and -*o*-benzoquinone by Base-Catalyzed Oxygenation

Akira NISHINAGA, Toshio ITAHARA, and Teruo MATSUURA

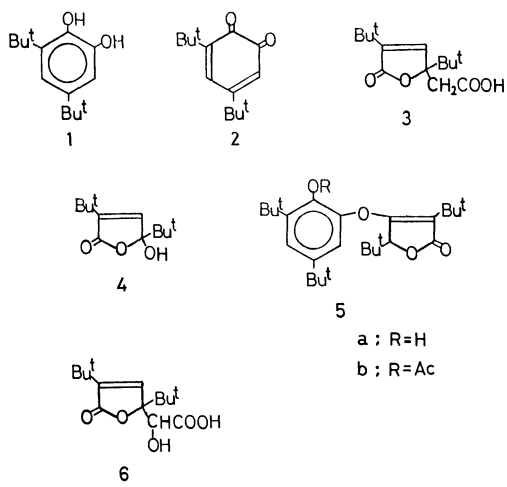
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received May 8, 1976)

Synopsis. The oxygenation of 3,5-di-*t*-butyl-catechol and -*o*-benzoquinone in *t*-BuOH with *t*-BuOK leads to the direct oxidative cleavage of the C_1–C_2 bond affording 2,4-di-*t*-butyl-4-carboxymethyl-2-buten-4-olide, a muconic acid derivative. The reaction is rationalized by assuming the reaction of 3,5-di-*t*-butyl-*o*-benzosemiquinone with oxygen.

Oxidative ring cleavage of catechols by molecular oxygen is of interest in connection with the biological oxygenation of catechols.[1-4] It has been shown that photooxygenation[1] and oxygenation with copper(I) chloride–pyridine complex[2] lead to the direct oxidative cleavage of the C_1–C_2 bond of catechols giving rise to muconic acid derivatives. No such direct cleavage has been observed in the base-catalyzed oxygenation of 3,5-di-*t*-butylcatechol in MeOH[3] or in DMF,[4] where products were always accompained by further introduction of oxygen function to the molecules.

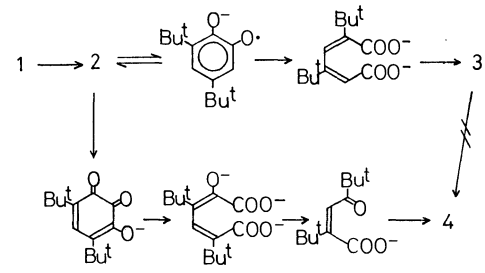
In the present paper it is reported that the oxygenation of 3,5-di-*t*-butylcatechol (**1**) or 3,5-di-*t*-butyl-*o*-benzoquinone (**2**) in *t*-BuOH containing *t*-BuOK causes the direct oxidative cleavage of the C_1–C_2 bond to give 2,4-di-*t*-butyl-4-carboxymethyl-2-buten-4-olide (**3**), a muconic acid derivative. When oxygen was bubbled through a solution of **1** in *t*-BuOH containing *t*-BuOK at room temperature for 8 h, compound **3**, 2,4-di-*t*-butyl-4-hydroxy-2-buten-4-olide (**4**), and 2,4-di-*t*-butyl-3-(3,5-di-*t*-butyl-2-hydroxyphenoxy)-2-buten-4-olide (**5a**) were obtained in 41, 14, and 21% yields, respectively.[5] The structure of **5a** was determined from its elemental analysis and spectral data, and also by the fact that the acetylation of **5a** gave 2,4-di-*t*-butyl-3-(2-acetoxy-3,5-di-*t*-butylphenoxy)-2-buten-4-olide (**5b**). Since compound **3** is quite stable under the reaction conditions, it should not be an intermediate for the formation of **4**. These products, therefore, must be formed *via* different reaction path.



Scheme 1.

Oxygenation of 3,5-di-*t*-butyl-*o*-benzoquinone (**2**), on the other hand, in *t*-BuOH with *t*-BuOK resulted in the preferential formation of **3** (Table 1). Since the quinone **2** gave the corresponding semiquinone anion under the reaction conditions and oxygen was not significantly reduced in *t*-BuOH containing *t*-BuOK, it is believed that the formation of **3** results from the reaction of the semiquinone anion with molecular oxygen. On the other hand, 2,4-di-*t*-butyl-4-(carboxyhydroxymethyl)-2-buten-4-olide (**6**) has been found to be the sole product on the oxidation of the quinone **2** by H_2O_2[3] and compound **4** is easily obtained on the *t*-BuOK-catalyzed oxygenation of **6**.[4]

It is therefore concluded that the reaction of the *o*-benzosemiquinone with molecular oxygen leads to the direct oxidative cleavage of the C_1–C_2 bond, whereas the reaction of **2** with hydrogen peroxide or its anionic species gives rise to the formation of **4** as depicted in the following scheme.



Scheme 2.

The formation of a small amount of **4** in the oxygenation of **2** may be attributed to the reduction of oxygen by an anionic species of **1** resulting from disproportionation of the semiquinone.

Table 1. Base-catalyzed oxygenation of **2** in various solvents at room tempeoature

Solvent	*t*-BuOK/2 (mol ratio)	Reaction time (h)	Conversion (%)	Product (%)[a]	
				3	**4**
MeOH	4.5	8	100	—	41
t-BuOH	4.5	8	100	64	7
$NHEt_2$	4.5	8	100	62	6
NEt_3	4.5	8	100	51	18
DMF	4.5	8	100	24	36
DMSO	4.5	8	100	35	25
HMPA	4.5	8	100	58	7
DME	4.5	8	100	62	6

a) Yields were determined by NMR.

The dimeric compound **5a** was not formed on the oxygenation of **2**, suggesting that the formation of **5a** in the oxygenation of **1** is considered to result from the combination of the phenolate anion of **1** with **2** but not from the coupling of the semiquinone with each other.

Similar results were obtained in other solvents (Table 1). Compound **3** was not isolable on the reaction in MeOH, where only **4** was isolated. In this system the reaction of **2** with H_2O_2 takes place predominantly because the quinone **2** is reduced to **1** in MeOH in the presence of base. Comparable amounts of **3** and **4** were obtained in DMF and in DMSO.[6] When luminol is added to a solution of *t*-BuOK in DMF or DMSO under O_2 bubbling, chemiluminescence is observed. This is indicative of the formation of superoxide anion.[7] Superoxide anion is well-known to form O_2 and H_2O_2 through its dismutation.[8] Therefore, the results in the oxygenation of **2** in DMF and DMSO indicate that there is a competition between the reaction of the semiquinone with O_2 and that of the quinone **2** with H_2O_2 in these solvents. A similar competition reaction has been reported for the oxidation of **1** with KO_2, where compounds **3** and **6** are main products.[9] It is suggested by Moro-oka and Foote[9] that the formation of **3** and **6** is attributed to the different type of decomposition of a common peroxide intermediate resulting from the combination of the semiquinone and superoxide anion. This mechanism is also possible for the formation of **3** and **4** in the present oxygenation.

Experimental

Oxygenation of 1 in t-*BuOH–*t-*BuOK.* Oxygen was bubbled through a soln of **1** (0.274 g) in *t*-BuOH (15 ml) containing *t*-BuOK (0.5 g) at 40 °C for 8 h. The reaction mixture was acidified with dil. HCl and extracted with ether. The extract was washed with water, dried (Na_2SO_4), and evaporated. The residue was triturated with hexane to give **3** (0.14 g, 41%), identical with the product in the photooxygenation[1] of **1** (IR, NMR, and mp). The organic soln. after removal of **3** was chromatographed on a silica gel plate (developed by $CHCl_3$) to give **4** (0.03 g, 14%), identical with the reported product[4] (IR, NMR, mp), and **5a** (0.05 g, 21%), colorless needles (hexane), mp 199—200 °C; IR (Nujol): 3380 (OH), 1715 (C=O) cm^{-1}; NMR ($CDCl_3$): δ 1.07 (*t*-Bu), 1.28 (*t*-Bu), 1.35 (*t*-Bu), 1.43 (*t*-Bu), 5.30 (1H, s, =C–CH–O), 5.74 (OH), 6.90 (1H, s, ArH), 7.21 (1H, s, ArH).

Found: C, 74.93; H, 9.58%. Calcd for $C_{26}H_{40}O_4$: C, 74.96; H, 9.68%.

Acetylation of 5a. A soln of **5a** (0.1 g) in acetic anhydride (10 ml) containing pyridine (4 ml) was allowed to stand at room temperature for 3 h. The reaction mixture was poured into a large excess of water to afford **5b** (0.11 g), colorless needles (hexane), mp 190—191 °C; IR (Nujol): 1780 (AcO), 1740 (C=O) cm^{-1}; NMR ($CDCl_3$): δ 1.07 (*t*-Bu), 1.28 (*t*-Bu), 1.38 (*t*-Bu), 1.44 (*t*-Bu), 2.35 (AcO), 5.05 (1H, s, =C–CH–O–), 6.90 (1H, d, J=2.0 Hz, ArH), 6.97 (1H, d, J=2.0 Hz, ArH).

Found: C, 73.24; H, 8.97%. Calcd for $C_{28}H_{42}O_5$: C, 73.32; H, 9.23%.

Oxygenation of 2. A procedure similar to that in the oxygenation of **1** described above was applied: **2** (1 mmol) in various solvents (15 ml). The results are summarized in Table 1.

The present work was financially supported by the Ministry of Education.

Photoreactions of Flavanones[1]

Ruka NAKASHIMA, Kazuaki OKAMOTO, and Teruo MATSUURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received May 24, 1976)

Synopsis. On irradiation in benzene, 5,7-dimethyl-4′-methoxyflavanone gave a bis-flavanone V, while in 2-propanol it was largely recovered. Irradiation of 4′-methoxyflavanone in benzene and 2-propanol yielded the corresponding chalcone and pinacols, respectively. 5,7,4′-Trimethoxyflavanone was relatively inert to photolysis in benzene, but gave a complex mixture of products in 2-propanol.

In a series of our investigation on flavonoid photochemistry,[2-5] it has been found that the presence of the 5-hydroxyl group causes photo-resistance to flavonoids such as 3-methoxyflavones,[4,5] 3-hydroxyflavones,[5] and flavanones,[5] possibly due to the loss of its excitation energy. Among these flavonoids, the photoreaction of flavanones had remained unknown until Kishimoto *et al.*[6] and Mack and Pinhey[7] reported that flavanones underwent photoreduction in 2-propanol and photoisomerization to chalcones and 4-phenyl-3,4-dihydrocoumarines in benzene. These reports prompted us to communicate our independent results on the photoreactions of a few flavanone derivatives.

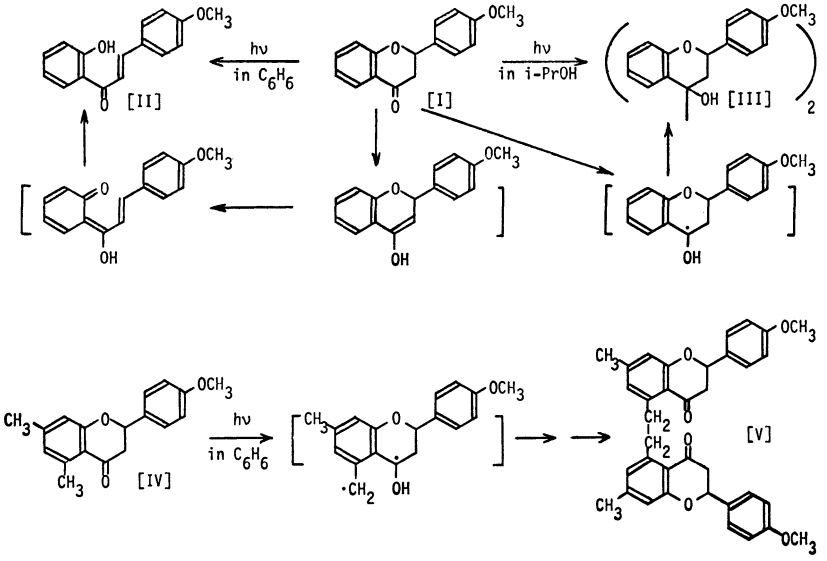
Irradiation of 4′-methoxyflavanone (I) with a high-pressure mercury lamp (Pyrex) in benzene and 2-propanol gave 4-methoxy-2′-hydroxychalcone (II; 14%) with the recovered I (18%) and a mixture of pinacols III[8] in 23% yield, respectively, similarly to the other flavanones.[6] In both solvents, the remaining part of products was intractable polymers. The formation of II may be recognized as a 6π-electrocyclic reaction of the enolic form of I. A similar type of photochemical electrocyclic reaction has been observed for 2*H*-pyrans.[9] The reverse reaction of 2′-hydroxychalcone to flavanone is known to occur photochemically.[10] Under similar photolysis conditions, 5,7,4′-trimethoxyflavone was largely recovered under the formation of some resinous material in benzene, while it underwent faster photodecomposition in 2-propanol to give a complex mixture of at least six products.

5,7-Dimethyl-4′-methoxyflavanone (IV), which was photochemically rather unreactive in 2-propanol underwent oxidative coupling by irradiation in benzene to give V in 8% yield. The structure of V was assigned by elemental and NMR (with decoupling) spectral analyses. On longer irradiation, V suffered further photodecomposition to give a resinous material. It may be reasonable to assume that the formation of V involves an intramolecular hydrogen abstraction of the excited IV, similar to that of *o*-alkylphenyl ketone.[11] A similar dehydrodimerization has been reported to occur in the photolysis of 5,8-dimethyltetralone.[12]

Experimental

All the melting points are uncorrected. NMR, IR, and mass spectra were measured on an NEVA T-60 or a Varian HA-100 spectrometer with TMS as the internal standard, on a Hitachi EPI-G3 spectrophotometer, and on a Hitachi RMS-4 spectrometer, respectively.

Materials. 4-Methoxy-2′-hydroxychalcone (II) was prepared from *o*-hydroxyacetophenone and *p*-anisaldehyde by the method for the preparation of chalcone.[13] The product was cyclized by refluxing in a mixture of 1: 1: 1 ethanol, acetic acid, and water for 10 h[14] to 4′-methoxyflavanone (I); mp 89—90 °C (lit,[15] mp 97 °C); NMR ($CDCl_3$), δ 2.8—3.2 (m, 2H), 3.80 (s, 3H), an ABX at 2.80, 3.18, and 5.45 (J_{AB}=17 Hz), J_{AX}=5 Hz, J_{BX}=11 Hz, $-CH_2-\underset{|}{C}H-$), 6.8—8.0 (m, 8H). 4′,5,7-Trimethoxyflavanone, mp 125—126 °C (lit,[16] mp 123 °C), was prepared by the similar method *via* 4,4′,6′-trimethoxy-2′-hydroxychalcone, mp 112.5—114 °C (lit,[17] mp 113



°C), which was prepared from 2-hydroxy-4,6-dimethoxyacetophenone[18] and *p*-anisaldehyde.

4′-Methoxy-5,7-dimethylflavanone (IV) was prepared by the following sequence of reactions applying the known method[14]: 3,5-xylenol→3,5-xylyl acetate→2-hydroxy-4,6-dimethylacetophenone→4-methoxy-2′-hydroxy-4′,6′-dimethylchalcone→IV. Recrystallization from ethanol gave IV as colorless crystals; mp 77—79 °C; IR (KBr), 1680, 1620, 1520 cm^{-1}; *m/e*, 282 (M^+); NMR ($CDCl_3$), δ 2.35 (s, 3H, 7-Me); 2.65 (s, 3H, 5-Me), 3.85 (s, 3H, 4′-OMe), 2.8—3.2 (m, 2H, 3-CH_2), 5.40 (dd, 1H, J=4 and 11 Hz, 2-CH), 6.30 (broad s, 1H, aromatic H), 6.36 (broad s, 1H, aromatic H), an AB at 7.00 and 7.44 (J_{AB}=9 Hz).

Found: C, 76.10; H, 6.58%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43%.

Photolysis of 4′-Methoxyflavanone (I). *(a) In Benzene*: A solution of I (500 mg) in benzene (130 ml) was irradiated with a 100-W high-pressure mercury lamp through Pyrex glass under nitrogen for 8 h. After removal of the solvent, the residue was submitted to preparative TLC (silica gel; chloroform) to give I (90 mg) and 4-methoxy-2′-hydroxychalcone (II; 70 mg) identical with an authentic sample (IR).

(b) In 2-Propanol: A solution of I (1 g) in 2-propanol (140 ml) was irradiated for 6 h in the same manner. After removal of the solvent, the residue was crystallized four times from ethyl acetate to give a stereoisomeric mixture of 4,4-bi(4-hydroxy-4′-methoxyflavane)s (III; 230 mg) as colorless crystals; mp 229—232 °C; IR (KBr), 3500, 3440, 1620, 1520, 1480 cm^{-1}, 510 (M^+), 492, 256; NMR (DMSO-d_6), δ 1.6—2.7 (m, 2H, 3-CH_2), 3.76 (s, 3H, 4′-OMe), 5.16 (s, 1/2 H, OH), 5.21 (diffused s, 1/2H, OH), 5.8—6.2 (m, 1H, 2-CH), 6.7—7.6 (m, 8H, aromatic H).

Found: C, 74.98; H, 5.97%. Calcd for $C_{32}H_{30}O_6$: C, 75.27; H, 5.92%.

Photolysis of 4′,5,7-Trimethoxyflavanone. *(a) In Benzene*: A solution of the flavanone (800 mg) in benzene (130 ml) was irradiated in a similar manner for 5 h. TLC analysis (silica gel; ethyl acetate) of the reaction mixture showed that it consisted of the recovered starting material with a small amount of origin substances. The starting material (450 mg) was recovered by preparative TLC.

(b) In 2-Propanol: The flavanone (500 mg) in 2-propanol (140 ml) was similarly irradiated for 5 h. The reaction mixture showed a complex TLC pattern in which the presence of at least six products were observed. No pure product was isolated by preparative TLC.

Photolysis of 4′-Methoxy-5,7-dimethylflavanone (IV). *In Benzene*: A solution of IV (800 mg) in benzene (130 ml) was irradiated similarly for 2 h. After removal of the solvent, the addition of ethanol to the residue gave insoluble crystals which on two recrystallizations from chloroform yielded 1,2-[bis(4′-methoxy-7-methyl-4-oxo-5-flavanyl)]ethane (V; 60 mg) as colorless crystals; mp 221—223 °C; IR (KBr), 1680, 1620, 1520, 1470 cm^{-1}; *m/e*, 562 (M^+), 281, 267; NMR ($CDCl_3$), δ 2.35 (s, 3H, 7-Me), and ABX at 2.80, 3.10, and 5.38 (J_{AB}=9 Hz, J_{AX}=2 Hz, J_{BX}=6 Hz, $-CH_2CH-$), 3.30 (m, 2H, $-CH_2-$), 3.81 (s, 3H, 4′-OMe), AB at 6.94 and 7.39 (4H, J_{AB}=4.5 Hz, 2′,3′,5′,6′-aromatic H), 6.74 (broad s, 1H, aromatic H), 6.90 (broad s, 1H, aromatic H).

Found: C, 75.63; H, 6.42%. Calcd for $C_{36}H_{34}O_6$: C, 76.85; H, 6.09%.

(b) In 2-Propanol: A solution of IV (300 mg) in 2-propanol (140 ml) was irradiated similarly. TLC analyses of the reaction mixture after 6 and 12 h showed that it consisted mainly of the starting material and some colored polymers.

The authors express their gratitude to Dr. Tamio Ueno, Pesticide Research Institute, Faculty of Agriculture, Kyoto University for the measurement of mass spectra.

Studies on Nucleosides and Nucleotides. V. Selective Aroylation of 5′-Hydroxyl Group of Uridine and Adenosine

Satoru SHIMOKAWA, Junji KIMURA, and Oyo MITSUNOBU

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

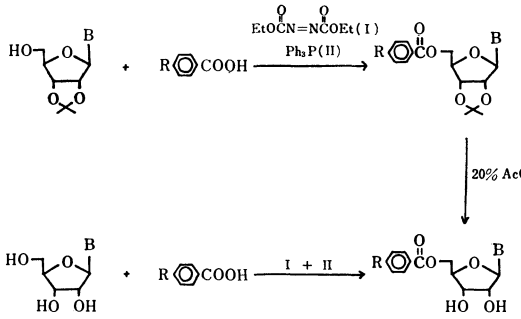
(Received May 28, 1976)

Synopsis. When uridine was allowed to react with diethyl azodicarboxylate, triphenylphosphine and either benzoic or *p*-nitrobenzoic acid at room temperature, 5′-*O*-aroyluridines were selectively obtained in good yields. Similarly, adenosine gave 5′-*O*-aroyladenosine. In this case, however, a small amount of N^3,5′-cycloadenosine was formed.

In a previous paper, the selective acylation of the 5′-hydroxyl group of thymidine by the use of diethyl azodicarboxylate (I) and triphenylphosphine (II) was described.[1] We now report selective aroylation of 5′-hydroxyl group of uridine and adenosine with a similar system.

When 2′,3′-*O*-isopropylideneuridine was allowed to react with *p*-nitrobenzoic acid, I and II in dioxane containing a small amount of hexamethylphosphoric triamide (HMPA)[2] at room temperature overnight, 2′,3′-*O*-isopropylidene-5′-*O*-(*p*-nitrobenzoyl) uridine (IIIb) was isolated in a 65% yield. Similarly, 2′,3′-*O*-isopropylidene-5′-*O*-benzoyluridine (IIIa) and 2′,3′-*O*-isopropylidene-5′-*O*-(*p*-nitrobenzoyl) adenosine (IVb) were obtained. The 2′,3′-*O*-isopropylidene group of IIIa, IIIb and IVb was removed in the usual manner giving the corresponding 5′-*O*-aroylnucleosides (IIIc, IIId and IVd).

The reaction of uridine with I, II and either benzoic or *p*-nitrobenzoic acid under the same conditions as above also led to the formation of the corresponding 5′-*O*-aroyluridines (IIIc and IIId) in good yields. Examination of the crude reaction mixture on paper chromatography in four solvent systems revealed the presence of uridine and a nucleosidic product which have the same R_f values as the corresponding 5′-*O*-aroyluridine prepared from the 2′,3′-*O*-isopropylideneuridines. In spite of an apparently clean reaction as judged by paper chromatographical analysis (IIIc, 83%; IIId, 80%), the isolated yields of the products were about 50%. Structures of the isolated IIIc and IIId were confirmed by elemental analyses, UV spectra and positive *cis*-diol test.[3] The total analysis thus gave assurance that the reaction of uridine with I, II and either benzoic or *p*-nitrobenzoic acid brings about selective aroylation of the 5′-hydroxyl group of uridine without any accompanying 2′- and/or 3′-*O*-aroylated products.



Following the method described above, 5′-*O*-(*p*-nitrobenzoyl)adenosine (IVd) was isolated in a 43% yield. The homogeneity of the isolated product was determined by paper chromatography in four solvent systems. The results are summarized in Table 1.

In the case of the aroylation of adenosine, however, the formation of a small amount of a side product was observed by examination of the reaction mixture with paper chromatography. The ultraviolet spectral characteristics of the side product indicated a chromophore similar to N^3, 5′-cycloadenosine (VI, λ_{max} 272

Table 1. Preparation of 5′-*O*-aroylnucleosides at room temperature

		B[a]	R	Yield[b] %	Mp °C	UV absorption Solvent	λ_{max} nm ($\varepsilon \times 10^{-4}$)		
	IIIa	Ur	H	43	145—146	95% EtOH	232 (1.50)	260	(1.01)
						THF		259	(1.32)

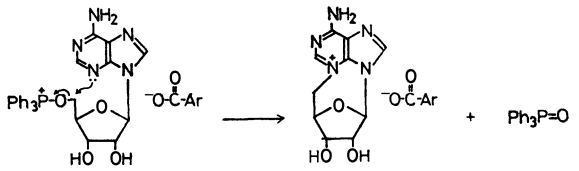
nm, lit,[4] λ_{max} 273 nm). The formation of VI may be due to intramolecular displacement of an intermediate (V) of the present reaction.[5] When the reaction was carried out in *N,N*-dimethylformamide (DMF) at room temperature, the yield of VI was found to increase to 52% by paper chromatographical analysis.



5′-*O*-Aroyluridine and 5′-*O*-aroyladenosine were treated with methanolic ammonia (saturated at room temperature) at room temperature and the reaction was monitored by paper chromatography. While *p*-nitrobenzoyl group was completely removed within 1 h, it took 8 h for the complete removal of benzoyl group.

Experimental

Method. Paper chromatography was carried out by the ascending technique using Toyo Roshi No. 51A paper. Solvent systems were A, 1-butanol: 2 M HCl (3: 1); B, ethanol: 1 M ammonium acetate (7: 3); C, 1-butanol: acetic acid: water (5: 2: 3); D, 1-butanol: water (86: 14).

Table 2. Paper chromatography of different compounds

	R_f values in solvent system			
	A	B	C	D
Uridine	0.33	0.65	0.42	0.16
5′-*O*-Benzoyluridine	0.82	0.82	0.74	0.55
5′-*O*-*p*-Nitrobenzoyluridine	0.77	0.80	0.77	0.51
Adenosine	0.10	0.57	0.42	0.19
5′-*O*-*p*-Nitrobenzoyladenosine	0.50	0.73	0.71	0.51
N^3,5′-Cycloadenosine			0.32	

5′-O-Aroyluridine. A solution of 1.5 mmol each of benzoic acid and I in dioxane (1 ml) was added to a suspension of uridine (1 mmol) and II (1.5 mmol) in dioxane (1 ml) under vigorous stirring at room temperature over a period of 1 h. In the case of *p*-nitrobenzoylation, *p*-nitrobenzoic acid and I were dissolved in a mixture of dioxane (1 ml) and HMPA (0.5 ml). The mixture became clear within 1 h. After the solution was kept stirring overnight and the solvent was removed under reduced pressure, the residue was applied to a silica gel column (Wakogel C-300, 3.2 × 100 cm). The column was eluted with ethyl acetate giving the desired product, 5′-*O*-benzoyluridine (IIIc, 291 mg, 56%) or 5′-*O*-(*p*-nitrobenzoyl)uridine (IIId, 394 mg, 50%). In a large scale reaction, the isolated yield of IIIc increased to 77%.

5′-O-(p-Nitrobenzoyl)adenosine. The reaction was carried out in the same manner as described above. After removal of the solvent, the crude product was washed with methanol, and the remaining solid was suspended in water. The suspension was heated under reflux to dissolve unchanged adenosine. 5′-*O*-(*p*-Nitrobenzoyl)adenosine was left as insoluble solid (180 mg, 43%). The product was found to be homogeneous by paper chromatography and gave satisfactory results by elemental analysis. Paper chromatography of the crude reaction mixture indicated the presence of a small amount of N^3,5′-cycloadenosine (VI).

(Received June 15, 1976)

Synopsis. Acetylparabenzlactone (**1**), an acetylation product of (−)-parabenzlactone (**2**), has been newly isolated from *Parabenzoin trilobum* Nakai, and the stereostructures of these two piperolignanolides have also been elucidated. Furthermore, the chemical conversion of **1** to a lariciresinol-type lactone (**3**) has been carried out.

In the course of our search for such an epoxygermacrene as shiromodiol,[1] which has been used for a biogenetic-type reaction,[2] we have isolated a new lignanolide, named acetylparabenzlactone (**1**), from *Parabenzoin trilobum* Nakai instead of (−)-parabenzlactone (**2**),[3] whose stereostructure remains unsettled.

Fresh leaves of the same plant[4] were extracted with hot benzene. The benzene extract was repeatedly chromatographed on silica gel, and then purified by preparative TLC to give colorless needles of acetylparabenzlactone (**1**) in a 0.017% yield.

The UV and NMR spectra of **1** indicate the presence of two methylenedioxyphenyl groups [δ 5.91 (2H, s), 5.92 (2H, s) and 6.60 (6H, complex)]. Furthermore, this lignanolide is proved to have a five-membered ring lactone and a secondary acetoxyl group [δ 2.10 (3H, s) and 5.70 (1H, d, J=6.0 Hz)]. From these data, this lignanolide (**1**) must be regarded as an acetylation product of (−)-parabenzlactone (**2**), which has previously been reported by Wada and Munakata.[3] Thus, the former was readily converted to **2** on treatment with 2% methanolic KOH (room temp, 1.5 h), giving a mixture of two hydroxyl lactones (**2** and **3**) with the same molecular formula ($C_{20}H_{18}O_7$) in 65 and 21% yields respectively. One of them is completely identical with an authentic sample of (−)-parabenzlactone (**2**) (mixed mp and IR spectrum). The structure of isoparabenzlactone (**3**) was also established (see below). In addition to the two original methylenedioxyphenyl groups, this compound has a five-membered ring lactone grouping [ν_{max} 1770 cm^{-1}; δ 5.13 (1H, d, J=8.0 Hz)]. In particular, the presence of a hydroxymethyl group in **3** can be confirmed by its NMR spectrum, which has a signal at δ 3.50 (2H, complex) which is shifted to δ 3.95 on acetylation, giving the corresponding acetate (**4**). From these data, isoparabenzlactone should be a lariciresinol-type lactone (**3**), whose stereostructure is based on those of **1** and **2**.

On hydrogenolysis over a freshly prepared palladium catalyst in EtOH containing $HClO_4$, (−)-parabenzlactone (**2**) was readily converted to (−)-hinokinin (**5**) in a 71% yield (IR and CD spectra).[5] Finally, the configuration of the remaining OH group in **2** is based on the NMR signal at δ 4.60 assignable to the proton attached to the carbon atom bearing the OH group, whose coupling constant is 6.5 Hz,[6] indicating that (−)-parabenzlactone adopts the stereostructure depicted in **2**. Thus, acetylparabenzlactone also has the **1** stereostructure.

2 X=OH
5 X=H

3 X=H
4 X=Ac

Experimental

All the mps are uncorrected. The IR spectra were recorded on a Hitachi-215 spectrophotometer. The UV spectra were taken on a Hitachi-124 spectrophotometer, using MeOH as the solvent. The NMR spectra were recorded on a JEOL JNM-PS 100 NMR spectrometer, using $CDCl_3$, unless otherwise stated. The chemical shifts are given in ppm relative to the internal TMS; only prominent signals are cited (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). The mass spectra were obtained on a Hitachi RMU-6D mass spectrometer, operating with an ionization energy of 70 eV. The optical rotation was measured on a JASCO Model DIP-SL automatic polarimeter.

Isolation of Acetylparabenzlactone (1). Fresh leaves of *Parabenzoin trilobum* Nakai (15 kg) immersed in benzene (100 l) were heated under reflux for 7 h and then filtered. The filtrates were concentrated under reduced pressure to obtain a viscous residue. After the above procedure has been repeated, the total weight of the benzene extracts thus far obtained was 430 g. The viscous residue (100 g) was chromatographed on silica gel (Mallinckrodt, 100 mesh) (900 g). After the elution of shiromodiol monoacetate[1] with hexane–AcOEt (3: 1), further elution with hexane–AcOEt (2: 1) afforded a crude oil (3.0 g), which was then rechromatographed on silica gel (Mallinckrodt, 100 mesh) (55 g) and eluted with $CHCl_3$ to give a slightly crude material (1.5 g). Further purification was carried out using preparative TLC (Kieselgel PF_{254}; $CHCl_3$) to give colorless needles of acetylparabenzlactone (**1**) (605 mg) in a pure state; mp 134—136 °C (from hexane–benzene)[7]; $[\alpha]_D^{28}$ −19.6° (c=0.82 in dioxane); λ_{max} 286 and 236 nm (ε, 7500 and 7800 respectively); ν_{max} ($CHCl_3$) 1770, 1745, 1240, and 1045 cm^{-1}; δ 2.10 (3H, s), 2.6—3.0 (4H, complex), 3.94 (2H, complex), 5.70 (1H, d, J=6.0 Hz), 5.91 (2H, s), 5.92 (2H, s), and 6.60 (6H, complex); m/e 412 (M^+), 352, 175, 151, and 135 (Found: C, 64.24; H, 4.80%. Calcd for $C_{22}H_{20}O_8$: C, 64.07; H, 4.89%).

Base-catalysed Reaction of Acetylparabenzlactone (1). A solution of **1** (150 mg) in 2% methanolic KOH (10 ml) was stirred at room temperature for 1.5 h, and then made acidic

with a dil HCl aq solution and extracted with $CHCl_3$. The extract was washed with water and then dried over anhydrous $MgSO_4$. The subsequent removal of the solvent under reduced pressure gave a pale yellow liquid, which was separated by preparative TLC (Kieselgel PF_{254}) using $CHCl_3$–Et_2O (3: 1) to give two deacetyl compounds [**2** (88 mg) and **3** (28 mg)] in a pure state. The physical data of these two compounds are shown below. Particularly, the recrystallization of the former from hexane–benzene gave (−)-parabenzlactone (**2**) with a mp of 156—158 °C (lit,[3] 159—161 °C) (mixed mp and IR spectrum); δ 1.64 (1H, br. s), 2.13 (1H, br. s, OH), 2.60 (1H, q, J=7.5 Hz), 2.95 (2H, br. s), 3.94 (2H, d, J=7.0 Hz), 4.60 (1H, d, J=6.5 Hz), 5.92 (2H, s), 5.96 (2H, s), and 6.68 (6H, complex); *m/e* 370 (M^+), 352, 175, 151, and 135 (Found: C, 65.04; H, 4.68%. Calcd for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%).

*Isoparabenzlactone (**3**) as a Colorless Viscous Liquid*: ν_{max} ($CHCl_3$) 3400 and 1770 cm^{-1}; δ 1.92 (1H, s, OH), 2.25 (1H, br. s), 3.03 (3H, complex), 3.50 (2H, complex), 5.13 (1H, d, J=8.0 Hz), 5.92 (2H, s), 5.93 (2H, s), 6.59 (1H, s), and 6.70 (5H, near s); *m/e* 370 (M^+), 178, 151, and 135 (Found: *m/e* 370.10706. Calcd for $C_{20}H_{18}O_7$: *m/e* 370.10523).

*Acetylation of (−)-Parabenzlactone (**2**).* A solution of **3** (35 mg) in Ac_2O–pyridine [1: 2 (1.5 ml)] was allowed to stand at room temperature overnight and was then diluted with $CHCl_3$ (30 ml). The chloroform solution was washed with water and then dried over anhydrous $MgSO_4$. The subsequent removal of the solvent under reduced pressure left a residue which was purified by preparative TLC (Kieselgel PF_{254}; $CHCl_3$) to give the original acetate (**1**) (33 mg) (mp, TLC and IR spectrum).[3,7]

*Acetylation of Isoparabenzlactone (**3**).* According to the same procedure as has been described above, the alcohol **3** (30 mg) was treated with Ac_2O–pyridine [1: 2 (1.5 ml)] to give a colorless viscous liquid (27 mg), which was then crystallized from hexane–benzene to afford colorless needles of acetylisoparabenzlactone (**4**); mp 56—58 °C; $[\alpha]_D^{28}$ +97.3° (*c* 1.47 in dioxane); λ_{max} 287 and 237 nm (ε, 7300 and 7700, respectively); ν_{max} ($CHCl_3$) 1770 and 1740 cm^{-1}; δ 2.00 (3H, s), 2.43 (1H, heptette, J=8.0 Hz), 2.8—3.2 (3H, complex), 3.95 (2H, m), 4.98 (1H, d, J=8.5 Hz), 5.91 (2H, s), 5.92 (2H, s), and 6.70 (6H, complex); *m/e* 412 (M^+), 220 and 135 (Found: *m/e* 412.11389. Calcd for $C_{22}H_{20}O_8$: *m/e* 412.11581).

*Hydrogenolysis of (−)-Parabenzlactone (**2**).* The catalytic hydrogenation of **2** (15 mg) in EtOH (3 ml) containing 3 drops of a 60% aq. $HClO_4$ solution was carried out over freshly prepared palladium (30 mg) at room temperature overnight. After the addition of AcOEt (20 ml), the catalyst was removed by filtration. The filtrate was washed with water and then dried over anhydrous $MgSO_4$. The subsequent removal of the solvent under reduced pressure gave a crude oil, which was purified by preparative TLC (Kieselgel PF_{254}; $CHCl_3$) to give a colorless viscous liquid (10 mg) which was completely identical with an authentic sample of (−)-hinokinin (**5**) (IR and CD spectra).

The authors wish to thank Professor Katsura Munakata and Dr. Kojiro Wada (Nagoya University) for providing them with the authentic samples of (−)-parabenzlactone and its acetate. They are also indebted to Professor Masao Noro (Meijo University) for the collection of the plant *Parabenzoin trilobum* Nakai.

The Photochemical Synthesis of 5-Aryl-7,12-benz[*a*]anthracenediones from 1,4-Naphthoquinones and 1,1-Diarylethylenes

Kazuhiro MARUYAMA, Tetsuo OTSUKI, and Kiichiro MITSUI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received June 23, 1976)

Synopsis. By the photolysis of the benzene solution of a variety of 2,3-disubstituted (halogeno, methoxy, and acetoxy) 1,4-naphthoquinones, **1**, and 1,1-diarylethylenes, **2**, 5-aryl-7,12-benz[*a*]anthracenediones, **3**, are obtained in fairly good yields (22—68%).

In a previous study[1] the photochemical reaction of 2-bromo-3-methoxy-1,4-naphthoquinone, **1a**, with 1,1-diphenylethylene has been found to give 5-phenyl-7,12-benz[*a*]anthracenedione, **3a**. As an extension of that work, we wish now to report a more facile and general route for the preparation of 5-aryl-7,12-benz[*a*]-anthracenediones, **3**.

In the photochemical reaction of 2-alkoxy-3-bromo-1,4-naphthoquinones, *e.g.*, **1a**, with 1,1-diphenylethylene, **2a**, the methoxyl group and the bromine atom were both found to be missing during the course of the photolysis to give 5-phenyl-7,12-benz[*a*]anthracenedione, **3a**. Although 2-alkoxy-3-bromo-1,4-naphthoquinones are good substrates for the preparation of **3a**, several steps are required to prepare them as starting materials.[2]

In this work the reactivities of other 2,3-disubstituted 1,4-naphthoquinones, such as 2,3-dichloro-1,4-naphthoquinone, **1b**, 2,3-dibromo-1,4-naphthoquinone, **1c**, and 2-acetoxy-3-bromo-1,4-naphthoquinone, **1d**, in the photolysis were investigated. Since 5-phenyl-7,12-benz[*a*]anthracenedione, **3a**, was obtained in a satisfactory yield in every case examined here (see Table 1), not only alkoxyl group but also halogen atoms were concluded to be good leaving groups in the photochemical reaction. Because of the accessibility of quinones, such as 2,3-dichloro-1,4-naphthoquinone **1b**, our photochemical reaction could provide a more facile synthetic route to 5-phenyl-7,12-benz[*a*]anthracenedione, **3a**. The use of other substituted 1,1-diphenylethylenes, **2b—e**, in the reaction opens the route to give 5-aryl-7,12-benz[*a*]anthracenediones. Every combination of a quinone, **1**, and a 1,1-diarylethylene, **2**, resulted in a similar, smooth photochemical reaction to yield 5-aryl-7,12-benz[*a*]anthracenediones, **3** (Table 1).[3] The photochemical reaction of monosubstituted 1,1-diarylethylenes, **2b—e**, with the quinone, **1**, produced two possible isomers, **3I** and **3II**; they were isolated separately in some cases. The differentiation of the two isomers, **3I** and **3II**, depends on their NMR spectra; that is, the presence or the absence of the spin-spin coupling of the aromatic proton at C-1 (δ: 9.40—9.97 ppm, characterized by its lower chemical shifts) is the indicator. The C-1 aromatic proton of the isomer, **3II**, invariably shows a doublet signal (J=8—12 Hz) due to the spin-spin coupling with the C-2 aromatic proton, while the C-1 aromatic proton of the isomer, 3I, appears as a singlet or a slightly split doublet signal (J=2 Hz) (Table 2). Thus, the isomer ratio, **3I**/**3II**, was estimated from the integration of the NMR signals of the mixture (Table 1).

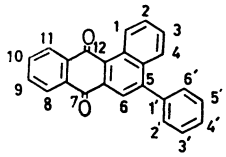
a) The IR spectrum was measured as the state of the KBr disk. b) The UV spectrum was measured as the solution of chloroform. c) The NMR spectrum was measured as the solution of deuterated chloroform, and the chemical shifts were calibrated from TMS as the internal standard. d) The data were measured as a mixture of two isomers.



irradiated by means of a high-pressure Hg arc lamp (300 W) through a 5-cm-thick water layer at room temperature. After the complete consumption of the quinone —in general, it takes about 10 h of irradiation, the solvent was distilled off under a reduced pressure. The subsequent purification of the reaction mixture by using chromatography on silica gel gave 5-aryl-7,12-benz[*a*]anthracenediones as a mixture of two isomers; this mixture was further purified by recrystallization from benzene–hexane. The yields, the isomer ratios, and the physical properties of the products are summarized in Tables 1 and 2. The general procedures for the elucidation of the structure, **3**, were given in the previous communication.[1]

Starting Materials. 2-Bromo-3-methoxy-1,4-naphthoquinone,[2] 2,3-dibromo-1,4-naphthoquinone,[4] 2-acetoxy-3-bromo-1,4-naphthoquinone,[5] 1-(*p*-methylphenyl)-1-phenylethylene,[6] 1-(*p*-methoxyphenyl)-1-phenylethylene,[6] 1-(*p*-chlorophenyl)-1-phenylethylene,[7] and 1-(*p*-bromophenyl)-1-phenylethylene[8] were all synthesized according to the usual method; the physical and spectral data were all compatible with those described in the literature.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (11), 3363—3364 (1976)

The Structure of Hamayne, a New Alkaloid from *Crinum asiaticum* L. *var. japonicum* Baker

Masamitsu Ochi, Hitoshi Otsuki, and Kosho Nagao

Faculty of Arts and Sciences, Kochi University, Asakura, Kochi 780

(Received July 2, 1976)

Synopsis. The structure of hamayne isolated from the fruit of *Crinum asiaticum* L. *var. japonicum* Baker was established to be *O*-demethylcrinamine (IV) on the basis of spectral and chemical evidence.

Kutani and Matsumoto have reported the isolation of lycorine (I) from the fruit (or seed) of *Crinum asiaticum* L. *var. japonicum* Baker.[1] Reinvestigation of the alkaloidal components in the fruit of this plant led to the isolation of three additional alkaloids, crinamine (II), *O,N*-diacetyl-*N*-demethylgalanthamine (III),[2] and a new alkaloid. In this paper, we will deal with the structural elucidation of the new alkaloid designated as hamayne.

Hamayne (IV), $C_{16}H_{17}O_4N$, mp 79—80 °C, $[\alpha]_D^{12}$ +43° (*c* 0.1, EtOH), was obtained in a 0.002% yield from fresh fruit by partitioning and careful column chromatography. IV shows a hydroxylic absorption in the IR (KBr) spectrum at 3400 cm^{-1} and forms a diacetate (V), $C_{20}H_{21}O_6N$, mp 77.5—78 °C, the IR spectrum of which no longer exhibits a hydroxyl group. The NMR spectrum of V shows signals due to two acetyl groups at δ 2.01 and 2.07 (3H each, s), a benzyl methylene group linked to a nitrogen atom at δ 3.66 and 4.32 (1H each, AB q, J=18 Hz), a methylenedioxy group at δ 5.89 (2H, s), and two aromatic protons at δ 6.46 and 6.84 (1H each, s). In addition, the NMDR data of V indicate the presence of two groupings, $-CH(OAc)-CH_2-N<$[δ 3.40 (2H, d, J=6 Hz) and 4.95 (1H, t, J=6 Hz)] and $-CH_A=CH_B-CH_C(OAc)-$[δ_A 6.21 (1H, dd), δ_B 5.87 (1H, dd), and δ_C 5.44 (1H, m); J_{AB}=10 Hz, $J_{AC}=J_{BC}$=2 Hz]. These facts suggest that IV has a structure analogous to that of crinamine (II), in which the methoxyl group is replaced by a hydroxyl group. This was confirmed by the conversion of IV into apohaemanthamine (VI).[4] Thus, the treatment of IV with 6 M hydrochloric acid gave VI, which was also obtained by a similar treatment from II.[4] The configuration at C-3 was proven as follows. In the NMR spectrum of V, the signal due to C-1 proton appears as a doublet of doublets at δ 6.21 as a result of the coupling with the C-2 and C-3 protons, the allylic coupling constant ($J_{1,3}$=2 Hz) of which corresponds to that of C-3 equatorial (α-oriented) acetate.[5] This observation indicates that IV and II have the same configuration at C-3. Therefore, hamayne (IV) must be *O*-demethylcrinamine.

VI

Experimental

All mps are uncorrected. The IR and UV spectra were recorded on a JASCO model IR-S and a Hitachi EPS-3T spectrophotometer, respectively. The NMR spectra were determined, using a JEOL PS-100 spectrometer, in $CDCl_3$ solutions with TMS as an internal standard unless otherwise stated. A Rex Optical Works apparatus, model NEP-2, was used for the measurement of the rotations.

Isolation. Fresh fruit of *Crinum asiaticum* L. *var. japonicum* Baker (19.2 kg), collected in the garden of the Usa Marine Biological Station, Kochi University, in August 1974, were chopped up and extracted with 20 l of methanol for 2 months. The methanol extract was concentrated up to about 2 l, leaving an aqueous solution. This solution, after filtration, was basified with solid Na_2CO_3 and extracted with 3 l of chloroform. The chloroform insoluble alkaloids containing lycorine were deposited between two layers. These alkaloids (16.5 g) were collected by filtration. The chloroform layer was washed with water, dried over Na_2SO_4 and evaporated to dryness. The residue (5.08 g) was repeatedly subject to chromatography over silicic acid. Elution with $CHCl_3$–AcOEt–MeOH (5: 5: 1) gave crinamine (II) (0.684 g) (mp and IR) and the fractions eluted with $CHCl_3$–AcOEt–MeOH (5: 5: 2) yielded hamayne (IV) (0.371 g): plates from acetone; mp 79—80 °C, $[\alpha]_D^{12}$ +43° (*c* 0.1, EtOH); UV (EtOH) nm (ε) 240 (4380) and 296 (7010). Found: C, 64.42; H, 6.47; N, 4.32%. Calcd for $C_{16}H_{17}O_4N \cdot 2/3H_2O$: C, 64.20; H, 6.17; N, 4.68%.

The more polar fractions eluted with $CHCl_3$–AcOEt–MeOH (1: 1: 1) were combined and evaporated to dryness. The residue (1.07 g) was acetylated with acetic anhydride (15 ml) and pyridine (30 ml) by heating under reflux for 3 h and worked up in the usual way. The resulting precipitates were chromatographed over silicic acid, with $CHCl_3$–MeOH (99: 1) as the eluent, to give *O,N*-diacetyl-*N*-demethylgalanthamine (III) (0.784 g) (mp, IR, NMR, and chemical properties).[6]

Acetylation of IV. A solution of IV (50 mg) in acetic anhydride (1 ml) and pyridine (2 ml) was refluxed for 3 h and then worked up in the usual way to afford V (34 mg): needles from methanol; mp 77.5—78 °C; IR (Nujol) 1730 cm^{-1}. Found: C, 64.70; H, 5.70; N, 3.61%. Calcd for $C_{20}H_{21}O_6N$: C, 64.88; H, 5.70; N, 3.77%.

Formation of VI. The procedure of Fales and Wildman[4] was followed: a solution of IV (76 mg) in 2.5 ml of 6 M hydrochloric acid was heated at 100 °C for 1 h. The solution was poured into 75 ml of water, basified with aqueous ammonia

and extracted with chloroform. The chloroform layer was washed with water, dried with Na_2SO_4 and concentrated. The residual oil (69 mg) was subject to chromatography over silicic acid, and the elution with benzene–AcOEt (9: 1) gave VI (28 mg) (mp, IR, and NMR).

We are grateful to Professor T. Tokoroyama of Osaka City University for the measurement of NMR and to Professor K. Yatsuzuka of Usa Marine Biological Station, Kochi University, for the providing of the plants.

A General Synthetic Method for 1-Substituted 1,4-Dihydro-3(2*H*)-isoquinolinones

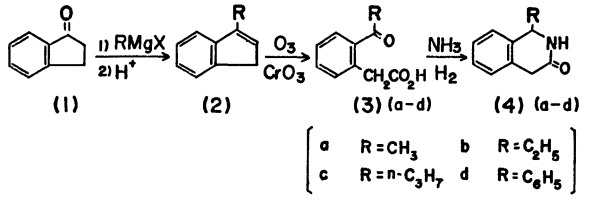
Hiroshi KOTAKE, Hideki KINOSHITA, Katsuhiko INOMATA, and Hiroshi MASUDA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received July 12, 1976)

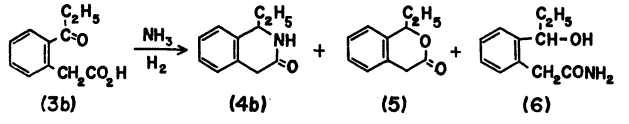
Synopsis. The reaction conditions for the conversion of **3** into **4** were investigated in some detail, and it was found that the reductive amination of *o*-acylphenylacetic acid was allowed to proceed smoothly by the use of deactivated Raney nickel.

In the previous paper[1] it was shown that the reductive amination of *o*-acetylphenylacetic acid (**3a**) afforded 1-methyl-1,4-dihydro-3(2*H*)-isoquinolinone (**4a**) in the presence of Raney nickel in good yield. From this result we were interested in the investigation of the general utility of the reductive amination of this type for synthesis of 1-alkyl or 1-aryl 1,4-dihydro-3(2*H*) isoquinolinones (**4**), which may be easily converted to the corresponding tetrahydroisoquinoline by the action of $LiAlH_4$ or B_2H_6. We report here the results of a detailed study of the reductive amination of *o*-acylphenylacetic acids and provide evidence of the generality of this method.



o-Acylphenylacetic acids (**3**) (**b**—**d**) were prepared easily by a Grignard reaction of indanone (**1**), followed by ozonolysis which was accompanied by oxidation with CrO_3.

Initially, the reaction condition was examined for the ring formation of *o*-propionylphenylacetic acid as a model. *o*-Propionylphenylacetic acid (**3b**) was treated with ammonia in the presence of Raney nickel in an autoclave to give a mixture of three compounds. After



chromatographic separation, three main compounds, **4b**, **5**, and **6**, were isolated in yields of 49, 4.4, and 34%, respectively. The structures of these compounds were confirmed by means of spectroscopic evidence and elemental analysis. This result suggested that a competing reaction took place in the reductive amination reaction. This finding showed that it was necessary to reduce the activity of Raney nickel (W-5) toward the carbonyl group in order to avoid this unfavorable competing reaction. The deactivation of Raney nickel was achieved by treatment with acetone (soaking for 1.5 h at room temperature). When the reductive amination of *o*-propionylphenylacetic acid (**3b**) was carried out under the same reaction conditions using deactivated Raney nickel, 1-ethyl-1,4-dihydro-3(2*H*)-isoquinolinone (**4b**) was obtained in high yield. 1-Propyl- and 1-phenyl-1,4-dihydro-3(2*H*)isoquinolinone (**4c** and **4c**) were also obtained in high yields, as shown in the table, by the same procedure using deactivated Raney nickel.

TABLE 1. YIELDS OF **4** (**b**–**d**) FROM **3** (**b**–**d**)

Experimental

All the melting points are uncorrected. The NMR and IR spectra were recorded on JEOL JNM-60 and JASCO IRA-1 spectrometers, respectively.

1-Ethyl-1,4-dihydro-3(2H)-isoquinolinone (4b). *Method A*: Raney nickel and a soln of *o*-propionylphenylacetic acid (**3b**) (300 mg) in ethanol (30 ml) previously saturated with ammonia were placed in an autoclave, and the reaction was carried out for 7 h at 110 °C in an atmosphere of hydrogen at 70 atm. After the reaction, the solvent was removed *in vacuo*, and the resulting residue was subjected to preparative TLC to give three compounds: 1-ethyl-1,4-dihydro-3(2*H*)-isoquinolinone (**4b**), lactone (**5**), and amide (**6**), in yields of 49% (134 mg), 4.4% (12 mg), and 34% (103 mg), respectively. Compound **4b**: mp 107 °C; IR (KBr): 3180, 3050, 1690 cm^{-1}; NMR ($CDCl_3$): δ 0.90 (t, 3H), 1.79 (pentuplet, 2H), 3.55 (s, 2H), 4.41 (t, 1H), 7.14 (s, 4H), 7.55—7.90 (b, 1H); Found: C, 75.67; H, 7.43; N, 8.21%. Calcd for $C_{11}H_{13}ON$: C, 75.40; H, 7.48; N, 7.99%. Compound **5**: colorless oily liquid; IR (Neat): 1740, 1235, 1150 cm^{-1}; NMR (CCl_4): δ 1.08 (t, 3H), 1.97 (dq, 2H), 3.57 (s, 2H), 5.14 (t, 1H), 7.15 (s, 4H). Compound **6**: mp 98—99.5 °C; IR (KBr): 3280, 3100, 1650, 1010 cm^{-1}; NMR ($CDCl_3$): δ 0.88 (t, 3H), 1.73 (pentuplet, 2H), 3.55 (s, 2H), 3.94 (bs, 1H), 4.66 (t, 1H), 6.06 (bs, 2H), 7.10—7.50 (m, 4H); Found: C, 68.07; H, 7.96; N, 7.27%. Calcd for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82; N, 7.25%.

Method B: Raney nickel (W-5) was soaked in acetone before use at room temperature in order to reduce the activity. When the reductive amination of **3b** was carried out under the same reaction conditions as described above using Raney nickel which was soaked in acetone for 90 min at room temperature, **4b** was obtained in an 86% yield accompanied by small amount of **6**. On the other hand, when the soaking time of the catalyst in acetone was shortened from 90 min to 40 min, the reductive amination gives rise to **4b**, **5**, and **6** in yields of 60%, 2.2%, and 15%, respectively.

1-Propyl-1,4-dihydro-3(2H)-isoquinolinone (4c). **4c** was

obtained in a 65% yield by the reductive amination of **3c** according to method B. Mp 97—98 °C; IR (KBr): 3180, 3050, 1680 cm^{-1}; NMR ($CDCl_3$): δ 0.91 (t, 3H), 1.14—1.90 (m, 4H), 3.52 (s, 2H), 4.20—4.60 (t, 1H), 6.80—7.32 (m, 5H); Found: C, 75.78; H, 8.03; N, 7.24%. Calcd for $C_{12}H_{15}ON$: C, 76.15; H, 7.99; N, 7.40%.

*1-Phenyl-1,4-dihydro-3(2H)-isoquinolinone (**4d**).* This compound was obtained in a 74% yield by the reductive amination of **3d** according to method B. mp 141.5—144 °C; IR (KBr): 3190, 3050, 1660 cm^{-1}; NMR ($CDCl_3$): δ 3.60 (s, 2H), 5.50 (s, 1H), 6.77—7.34 (m, 10H): Found: C, 80.36; H, 5.69; N, 6.31%. Calcd for $C_{15}H_{13}ON$: C, 80.69; H, 5.87; N, 6.27%.

Nature of Oxygen Species Incorporated into Acrylaldehyde in Vapor-Phase Oxidation of Propylene over Supported Copper Catalyst

Masamichi AKIMOTO, Masao AKIYAMA, and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 11, 1975)

The oxidation of propylene with Cu_2O as active phase for acrylaldehyde formation gave no acrylaldehyde in contrast to the fully oxidized CuO–SiC. However, CuO–SiC from which adsorbed oxygen species was eliminated gave rise to the formation of a negligible amount of acrylaldehyde. The presence of molecular oxygen species adsorbed on the CuO–SiC was shown by the desorption of oxygen and the isotopic mixing reaction of ^{16}O—^{18}O. The adsorbed oxygen (possibly molecular oxygen species) seems to be necessary as oxygen incorporated into acrylaldehyde. Agreement of the ratio of $^{18}O/^{16}O$ in acrylaldehyde formed by the oxidation with oxygen containing ^{18}O over $Cu_2{}^{16}O$ with that of $^{18}O/^{16}O$ in the reaction mixture supports the role of adsorbed oxygen species. The presence of O_2^- over Cu_2O during the course of oxidation was confirmed by the formation of furan and maleic anhydride in the co-oxidation with butadiene. The results were discussed in relation to the structure of the catalyst suitable for selective oxidation, the incorporation of oxygen atom *via* electronegative oxygen species adsorbed being proposed.

The vapor-phase oxidation of propylene to acrylaldehyde over copper(I) oxide has been investigated, some of the results being summarized.[1-3] Studies were mostly focused on the determination of intermediate hydrocarbon species *via* which acrylaldehyde is formed. The initial removal of a hydrogen atom from the methyl group to form an allylic intermediate was proposed by many workers.[4-6] However, not much attention has been paid to the form of oxygen species participating in the selective oxidation of propylene to acrylaldehyde. In this selective oxidation, oxygen plays two roles, *i.e.*, abstraction of hydrogen atoms and addition to the formed intermediate hydrocarbon species.

In general, the lattice oxygen of transition metal oxides is capable of hydrogen abstraction, differing with the type of metal-oxygen bond. However, the lattice oxygen is not always incorporated into selective oxidation products, as seen in the special role of double bond type lattice oxygen in the oxidation of butadiene to maleic anhydride.[7,8] Wood and co-workers[9] assumed in their semiconductivity studies on the oxidation of propylene over Cu_2O that electronegative oxygen species sorbed on the surface is the active species for acrylaldehyde formation. On the other hand, Callahan and Grasselli[10] showed that the lattice oxygen of copper oxide catalyst is involved in acrylaldehyde formation. The form of oxygen species incorporated into acrylaldehyde has not been sufficiently clarified. We have investigated the vapor-phase oxidation of propylene over supported copper catalyst as regards the nature of oxygen species incorporated into acrylaldehyde by means of X-ray analysis, oxygen isotope (^{18}O) and co-oxidation with butadiene or furan. The results were discussed in relation to the structure of the catalyst suitable for acrylaldehyde formation.

Experimental

Vapor-phase catalytic oxidation of propylene was performed using a conventional flow microreactor and a pulse reactor under atmospheric pressure. The microreactor was a Pyrex tube of inner diam 12 mm and length 300 mm with a concentric thermowell; the pulse reactor was a 4 mm inner diam U-type Pyrex tube. Heating was carried out with a cylindrical fluidized thermal bath. The catalyst was diluted with 30—50 mesh quartz, Raschig rings (2.5 $\times$ 2.5 mm) being used as a preheating medium.

As reacting substances, air, propylene (99% up), butadiene (99% up) and reagent grade furan were used. Nitrogen, hydrogen and helium were supplied from commercial cylinders. Gaseous oxygen containing ^{18}O (Japan-Isotope Association) was used. The air was purified by passing through silica gel and a soda-lime tower in order to remove water and CO_2. Helium was used as a carrier gas for oxidation by means of pulse technique. A trace amount of impurities such as oxygen existing in helium was removed by passing through a molecular sieve 13X column (4 mm inner diam, 1 m) cooled with liquid nitrogen.

CuO–SiC catalyst was prepared as follows. SiC (60—80 mesh) was calcined at 1000 °C for 4 h in a furnace. The precipitate obtained by the addition of an aqueous solution of Na_2CO_3 to the suspension of the calcined SiC in an aqueous solution of $Cu(NO_3)_2$ was thoroughly washed with water and then dried on a water-bath. The mass obtained was then calcined at 500 °C for 5 h in the air. The amount of CuO supported is 6.2 wt%, and the surface area is about 0.3 m^2/g. The catalyst was reduced with hydrogen current at 400 °C for 1.5 h prior to the experiment. Cu_2O was prepared according to two methods: (a) by the reduction of $Cu(AcO)_2$ with 1 N hydrazine in an aqueous media[11] (denoted by Cu_2O (I)); (b) by the addition of 10% aqueous solution of glucose to an aqueous mixture of $CuSO_4$, sodium potassium tartarate and NaOH at 100 °C[12] (denoted by Cu_2O(II)). The products were found to be pure by X-ray diffraction. The reduction of CuO–SiC was carried out by immersion into an aqueous solution of hydrazine at room temperature, the amount of nitrogen evolved being measured with a capillary glass tube.

The gaseous effluent from the reactor was analyzed by gas chromatography. PEG 20 M 20 wt% on Neopak 1A (acrylaldehyde, furan, acetaldehyde) and propylene carbonate 40 wt% on Celite 545 (CO_2) were used as separating columns. Maleic anhydride formed was absorbed in water followed by boiling of the solution in order to remove dissolved CO_2 and titration with an aqueous solution of NaOH. The structure of the catalyst was investigated by X-ray diffraction using nickel-filtered Cu $K\alpha$ radiation (30 kV, 20 mA). The isotopic mixture of gaseous oxygen or acrylaldehyde was analyzed by means of mass spectroscopy. Adsorption of

oxygen on the reduced catalyst was measured with a conventional volumetric apparatus.

Results

Active Phase for the Selective Oxidation. The oxidation of propylene (C_3' 28.0 vol%, O_2 5.0 vol%, and N_2 67.0 vol%) at W/F=0.934 g-catalyst h/g-mol became observable at 320 °C. Acrylaldehyde, CO_2 and a very small amount of CH_3CHO were formed. Above 370 °C, a gradual decrease in selectivity appeared. However, change in activity and selectivity was hardly observable at 350 °C during the course of oxidation. The selectivity is independent of the contact time below W/F=0.934 g-catalyst h/g-mol at 350 °C, as shown in Fig. 1. The steady state of the catalyst during oxidation under the reaction conditions was quenched by the introduction of helium (200 NTP ml/min) for 5 min to eliminate the reactant gas followed by a rapid decrease in temperature. X-Ray diffraction of the catalyst was observed at 2θ=36.3, 42.3, 61.4 (strong), and 38.8° (weak). The catalyst is composed of Cu_2O and a very small amount of CuO.

a) Temp: 350 °C, carrier gas: He 45 NTPml/min, pulse: C_3' 5.69 NTPml.

Oxidation of Propylene with Copper Oxides. The oxidation of propylene with various copper oxides was carried out by the pulse method. Only propylene was successively injected over the oxides (Table 1). In the case of Cu_2O (I) and Cu_2O (II), no formation of acrylaldehyde was observed even on the first injection in contrast to the case of CO_2. Use of 0.20 g Cu_2O (I) also gave the same result. In contrast, acrylaldehyde was formed in the first and second injections onto CuO–SiC which was prepared by reduction with hydrogen at 400 °C for 1.5 h followed by oxidation with air current at 350 °C. The amount of oxygen participating in acrylaldehyde formation and complete oxidation up to the second injection is 0.128 and 3.390 NTP ml/g-catalyst, respectively. However, when the CuO–SiC had been treated with 1 N NH_2–NH_2 at room temperature with evolution of 0.80 NTP ml N_2/g-catalyst, only a trace amount of acrylaldehyde was formed. X-Ray diffraction of this treated catalyst was observed at 2θ=35.7, 38.8, and 48.9° (strong). Thus the product is CuO.

Reduction of the Catalyst and Adsorption of Oxygen. Reduction of CuO–SiC with an aqueous solution of hydrazine (0.1 N) and adsorption of gaseous oxygen on the reduced one were performed in order to clarify the form of oxygen removed by treatment with the hydrazine solution. The hydrazine solution was heated at 80—90 °C for 10 min followed by cooling to room temperature. The solution was stirred for about 1 h until scarcely any evolution of nitrogen gas was observed. CuO–SiC catalyst was then introduced into the hydrazine solution and the amount of nitrogen evolved was determined (Fig. 2). CuO–SiC was prepared by the oxidation of the reduced catalyst with air current at 350 °C. An inflection point appears at 0.33 NTP ml N_2/g-catalyst (Fig. 2). No

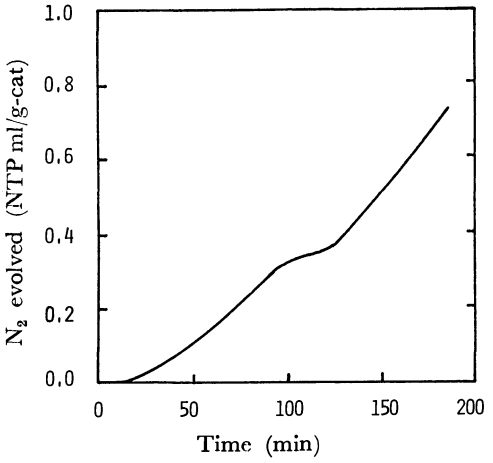

Fig. 2. Reduction of CuO–SiC catalyst with an aqueous solution of hydrazine.
CuO–SiC: 0.50 g, hydrazine: 0.1 N, temp: 18 °C.

definite inflection point was observed in the case of 1 N hydrazine. Adsorption of gaseous oxygen on the reduced catalyst was quantitatively studied. CuO–SiC reduced similarly was evacuated for 1 h at room temperature and again for 1 h at 250 °C. After determination of the dead volume of the adsorption apparatus, gaseous oxygen was introduced at room temperature and the catalyst was treated at 350 °C for 1 h. The amount of oxygen adsorbed was measured by observing the pressure drop of oxygen. When the amount of nitrogen evolved by the reduction was 0.30 or 0.60 NTP ml/g-catalyst, that of oxygen adsorbed was 0.32 or 0.63 NTP ml/g-catalyst at oxygen pressure of 137.6 or 133.6 Torr, respectively.

Isotopic Mixing Reaction of ^{18}O—^{16}O. $Cu^{16}O$–SiC was evacuated at 350 °C for 1.5 h in a vessel and then a mixture of oxygen ($^{18}O^{16}O$ 36.58, $^{16}O^{16}O$ 63.42 mol %) was introduced under 54 Torr at 20 °C. The isotopic mixing reaction was carried out at 198 °C. The gaseous oxygen was withdrawn to a small glass tube (*ca.* 1 ml) during the course of the reaction and was diluted with helium to *ca.* 5% O_2 followed by the analysis. Hardly any formation of $^{18}O^{18}O$ or change in the composition of the gaseous phase was observed (Fig. 3).

On the other hand, CuO–SiC (13.3 g) was evacuated at 525 °C under 10^{-5} Torr for 2 h. Oxygen was then adsorbed at 155 °C under $P_{O_2}=150$ Torr for 3 h. The oxygen pressure was then kept at room temperature overnight. After pumping out gaseous oxygen at room temperature, the temperature was raised and after 1 h, the amount of oxygen desorbed was determined by measuring the oxygen pressure. The amount was 0.007, 0.017, or 0.019 NTP ml/g-catalyst at 203, 350, or 448 °C, respectively.

Oxidation of Propylene with $^{18}O_2$ over $Cu_2{}^{16}O$. A pulse containing propylene and heavy oxygen was injected over $Cu_2{}^{16}O$ (I) at 350 °C and the acrylaldehyde formed was separated with a gas chromatographic column coupled with the outlet of the pulse reactor. Injection was repeated several times using new $Cu_2{}^{16}O$ (I) at each injection, and the content of ^{18}O in acrylaldehyde collected was determined (Table 2). For the sake of comparison, the result obtained by using $^{16}O_2$ is given in the Table. The relative intensity of the species was $I_{58}/I_{56}=0.213$ or $I_{57}/I_{55}=0.218$, the average being 0.215. The values were in good agreement with that of $^{18}O/^{16}O$ in the pulse.

Co-oxidation of Propylene with Furan or Butadiene over Cu_2O. In order to investigate the form of oxygen species present on Cu_2O during the course of oxidation of propylene, co-oxidation with furan or butadiene was performed with reference to the formation of maleic anhydride and furan. Oxidation of propylene was first carried out for 2 h and then furan or butadiene was supplied. The concentration of furan or butadiene in the feed was kept very low, 1.5—3.0 vol%, as com-

pared with that of propylene, so that the catalyst would not change structurally. The formation of maleic anhydride or of furan and maleic anhydride in the cooxidation with furan or butadiene, respectively, is given in Table 3. The selectivity for maleic anhydride or furan and maleic anhydride formation was 1.6—2.5 or 10.6—11.7%, respectively.

Discussion

The catalyst consists of Cu_2O and a very small amount of CuO during the oxidation of propylene. Thus, Cu_2O is the active phase for acrylaldehyde formation in line with the results reported.[9,13,14] However, the oxidation of propylene with Cu_2O gave no acrylaldehyde in accordance with the result for the CuO–SiC reduced with hydrazine (Table 1). This supports strongly the view that the lattice oxygen of Cu_2O and CuO is not incorporated into acrylaldehyde though it can abstract hydrogen atom from propylene. In contrast, the formation of acrylaldehyde in the oxidation with fully oxidized CuO–SiC suggests an important role of oxygen species adsorbed on the catalyst in acrylaldehyde formation. However, if the lattice oxygen existing on the surface of CuO could be eliminated by treatment with the hydrazine solution, the important role of the lattice oxygen can not be denied.

An inflection point appears at 0.33 NTP ml N_2/g-catalyst in the reduction of CuO–SiC with an aqueous solution of hydrazine (Fig. 2). The amount of nitrogen evolved up to this point might be equivalent to that of oxygen adsorbed on the surface, and nitrogen evolved beyond this point is due to the reduction of lattice oxygen with hydrazine and the decomposition of hydrazine by contact with copper ions. Reliability of the reduction is strongly supported by the good agreement of the amount of nitrogen evolved in the reduction of CuO–SiC with hydrazine with that of oxygen adsorbed on the reduced catalysts at $P_{O_2}=134$—138 Torr. Thus, the amount of oxygen adsorbed on the surface of CuO–SiC is 0.33 NTP ml O_2/g-catalyst or 5.32 NTP ml/g-CuO. The fact that the amount of oxygen consumed for acrylaldehyde formation up to the second injection is 0.128 NTP ml/g-catalyst or 2.065 NTP ml/g-CuO and that only a trace of acrylaldehyde was formed by the oxidation with the CuO–SiC which had been treated with the hydrazine solution (N_2 0.80 NTP ml/g-catalyst evolved) offer further evidence for the very important role of the adsorbed oxygen species or the surface lattice oxygen in the selective oxidation. As lattice oxygen of metal oxide is expected to play the role of hydrogen abstraction,[15–17] the adsorbed oxygen species or the surface lattice oxygen might be necessary for acrylaldehyde formation as the oxygen species incorporated rather than that abstracting the hydrogen atom from hydrocarbon species.

Callahan and Grasselli[10] found the formation of acrylaldehyde in the oxidation of propylene with fully oxidized CuO–SiC (0.4 wt% as CuO) at 300 °C by means of a pulse method and concluded that lattice oxygen is involved in the selective oxidation. According to our calculations based on the assumption that the volume of propylene was measured at 20 °C and 1 atm, only CO_2 and H_2O being formed by unselective oxidation, the amount of oxygen used for acrylaldehyde formation is 0.01 NTP ml/g-catalyst or 2.58 NTP ml/g-CuO. The latter value is comparable to the value previously obtained 2.065 NTP ml/g-CuO and is less than the amount of adsorbed oxygen species 5.32 NTP ml/g-CuO. Even taking account of the differences in the reaction temperature and the content of CuO supported, their result is explained by assuming the very important role of adsorbed oxygen species in acrylaldehyde formation.

Formation of acrylaldehyde in the reduction of metal oxide with propylene also takes place in the case of SnO_2, Sb_2O_4, Fe_2O_3–Sb_2O_4,[16,17] MoO_3, and bismuth molybdates.[17,18] Double bond type lattice oxygen Mo=O of MoO_3 is incorporated into furan and maleic anhydride formed in the oxidation of butadiene.[8] Incorporation of the lattice oxygen into acrylaldehyde in the oxidation of propylene over the catalysts containing MoO_3 is very likely to occur. This is supported by the formation of MoO_2 in the reduction of the catalysts with propylene.[17,18] In the case of other oxides which have no double bond type lattice oxygen, formation of acrylaldehyde might be attributed to the presence of adsorbed oxygen species or to the higher positive charge of the adsorbed hydrocarbon species. Formation of acrylaldehyde appeared with a rise in the acidity of Bi_2O_3 and SnO_2 catalysts by addition of P_2O_5.[19] However, this is not the case of the selective oxidation over Cu_2O since the amount of CuO was very small.

The form of oxygen species adsorbed on the CuO–SiC is discussed in the following. The fact that no change in the composition of gaseous oxygen was observed in the isotopic mixing reaction over the catalyst suggests non-dissociative adsorption of oxygen molecule on the surface (Fig. 3). The desorption of oxygen from the CuO–SiC with a rise in temperature provides further evidence for the existence of adsorbed oxygen species and the reversibility of some portion of oxygen adsorption. A part of adsorbed oxygen species seems to be present as diatomic species. Incorporation of the adsorbed oxygen species into acrylaldehyde was also supported in accordance with $^{18}O/^{16}O$ ratio in the formed acrylaldehyde with that in the pulse (Table 2). Oxygen species adsorbed on Cu_2O are negatively charged.[20,21] This strongly suggests formation of various oxygen species over Cu_2O during the course of oxidation of propylene as follows: O_2-(gas)$\rightarrow O_2^-\rightarrow O^-\rightarrow O^{2-}$ (lattice). We showed in our studies on the oxidation of butadiene[8] and furan[22] over supported molybdena and promoted anatase-type titania catalysts that oxygen atom of O_2^- is incorporated into maleic anhydride. Furan is an intermediate of maleic anhydride from butadiene.[23] Thus, formation of furan and maleic anhydride in the cooxidations (Table 3) gives strong evidence to the formation of O_2^- over Cu_2O during the course of oxidation of propylene. Enikeev *et al.*[21] proposed in their studies on the work function of Cu_2O upon the adsorption that adsorbed propylene and various products

have a partial positive charge in contrast with adsorbed oxygen species. Even if this positively charged hydrocarbon intermediate reacts with electronegative oxygen species such as O_2^-, there appears no special difficulty in these addition reactions.

The result given in Table 1 can not clarify whether lattice oxygen on the surface of CuO is incorporated into acrylaldehyde or not. However, the fact that CuO is not a selective phase in contrast with Cu_2O during the course of oxidation and that the catalyst consists of Cu_2O and a very small amount of CuO at the steady state suggests the incorporation of the adsorbed oxygen species rather than the surface lattice oxygen during the course of steady state oxidation. Formation of the electronegative oxygen species on CuO is very difficult in contrast with that on Cu_2O[9]. This possibly accounts for the great difference in selectivity during the oxidation of propylene over these copper oxides rather than the ability to perform hydrogen abstraction. Charge of the adsorbed oxygen species existing on the surface of CuO–SiC was not clarified. It is apparent that the oxygen species adsorbed on the surface acts as oxygen incorporated into acrylaldehyde in the pulse experiment. The results provide one possibility that acrylaldehyde can be formed even over CuO if lattice oxygen of this oxide could abstract hydrogen from propylene and electronegative oxygen species adsorbed could be present. This is the case of acrylaldehyde formation in the pulse experiment.

We have no experimental result showing which electronegative oxygen species of O_2^- or O^- is incorporated. No attention was paid to the direct incorporation of gaseous oxygen into acrylaldehyde since this mechanism could not explain the difference in selectivity during the course of oxidation over Cu_2O and CuO. Kugler and Kokes[24] presumed from IR that acrylaldehyde is formed by the reaction of O_2^- with the π-allyl. Cant and Hall[25] also proposed a very important role of diatomic oxygen species in the oxidation of propylene to acrylaldehyde over Rh or Ru–α-Al_2O_3. These observations are in line with ours and offer a greater possibility for preferential incorporation of the electronegative molecular oxygen species during the course of selective oxidation over Cu_2O. This is consistent with the fact that the amount of oxygen consumed for acrylaldehyde formation, which is equal to that of the adsorbed molecular oxygen used for the incorporation, is less than that of the adsorbed oxygen species (Table 1 and Fig. 2).

Modification of the Packed-bed Electrode and Its Potential Distribution

Shiro YOSHIZAWA, Zenichiro TAKEHARA, and Zempachi OGUMI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received February 2, 1976)

The packed-bed electrode has been investigated in order to scale up the cell capacity by introducing three-dimensional electrode. The reactions of aniline formation by cathodic reduction of nitrobenzene and Fe(II) ion formation by cathodic reduction of Fe(III) ion were studied. When bed particles with high electric conductivity were used, the effective depth of the packed-bed where the electrode reaction took place was very small. However, when particles with moderate resistance were used, the effective depth increased. This is because the potential distribution in the bed material is the same as that in the electrolyte in the bed, the potential difference between particles and electrolyte thus being maintained constant at any position in the bed. From the standpoint of scaling up the cell capacity, this type of electrode can be effectively applied.

Application of a packed-bed or porous electrode[1,2] has been investigated by many workers, in order to scale up the cell capacity by introducing three-dimensional electrode. The packed-bed electrode was also recently studied as regards application to the treatment of waste water.[3,4] The increase in cell current was not large since the effective depth of packed-bed or porous electrode where the electrode reaction took place was very small. This is ascribed to the high electronic conductivity of bed material or porous material and to the apparent low conductivity of electrolyte in the bed which is caused by small void between particles in the bed. Under these conditions, the potential of solution in the bed and that of bed particles are distributed as represented by curves $\varphi_s(P)$ and $\varphi_m(P)$. Thus the potential difference between particles and electrolyte changes in the bed (curve $\Delta\varphi(P)$, Fig. 1).[5] This shows that the potential difference between particles and electrolyte enough for an electrode reaction to proceed exists only at the part of bed nearest to the counter electrode.

Fleischman *et al.*, [5] Hiddleston and Douglas[6] and Janssen[7] introduced a fluidized-bed electrode. The apparent resistance of bed material in the bed which changes with the expansion of bed causes a potential distribution in the bed (curve $\varphi_m(f)$, Fig. 1).[5] The potential distribution of solution in the bed also changes at the same time as the change of expansion (curve $\varphi_s(f)$). The potential distribution formed thus in both sides of the solution in the bed and bed particle causes an adequate potential difference between particles and electrolyte for an electrode reaction at any position in the bed as shown by curve $\Delta\varphi(f)$. Accordingly the effective depth of bed electrode where the electrode reaction took place could be expected to become large.

If particles with moderate resistance are used as bed material of a packed-bed electrode, the same potential distribution in a packed-bed electrode as in a fluidized-bed electrode can be expected. We have examined the potential profile in a packed-bed constructed with particles having a moderate resistance and also the increase of effective depth of this type of electrode.

Experimental

Carbon particles (14—20 mesh) partly graphitized were used as bed material. The resistance of the particles was about 3.4 Ωcm. Two other kinds of particle were also used, a glass bead (1—2 mm diam) chemically plated with copper, and a carbon particle (about 0.5 mm diam), also chemically plated with copper because of high resistance. Copper deposition of the particles was carried out by the same technique as that given in a previous paper.[2]

The electrolysis cell (Fig. 2) was made of polyvinyl chrolide. The bed size was 3 cm in width and 1.5 cm in thickness. The bed depth was changeable. The bed was supported on a glass filter through which electrolyte was distributed. The bed was also covered with a glass filter. A graphite plate

was used as a counter electrode. A graphite or copper plate was used as a feeder electrode which was set at the opposite end of the bed from the counter electrode. Both electrodes were positioned parallel to each other. The electrolyte fed into the cell flowed across the bed.

Three kinds of electrolyte were used: 1 M HCl saturated with nitrobenzene, 0.02 M $FeCl_3$+1 M HCl and 0.5 M $FeCl_3$+1 M HCl.

Four graphite rods or four copper wires were inserted into the bed from one side for use as probes, with which the potential of the bed particle at each position was measured. Four glass capillaries were inserted into the bed from the other side for use as Luggin capillaries, with which the solution potential in the bed was measured. Potential distributions in the direction of depth in the bed* were measured. Two saturated calomel electrodes (SCE) were used for measuring the potential distribution in the solution. Electrolysis was carried out at room temperature.

Results and Discussion

Dissolution of copper occurred when glass beads or carbon particles plated with copper were used as bed material. This may be ascribed to the high conductivity of the bed material. In this case, most of the cell current came from the part of the bed electrode nearest to the counter electrode. The potential of the particle at a part farther from the counter electrode can become so positive to the solution potential at the same position as to make the dissolution of copper possible. These two kinds of particle are not suitable as bed material. In most of the experiments a third material, 14—20 mesh carbon particles, was used.

Reduction of Nitrobenzene. A nitrobenzene solution was reduced to aniline by a bed electrode constructed with carbon particles. A feeder electrode and probes were made of copper. Potential distribution was measured by constant current electrolysis at 500 mA/cm² (Fig. 3). A distribution of particle potential took place in the bed as expected. $\Delta\varphi$, the difference between particle potential and solution potential at the same position in the bed, becomes large near a feeder electrode, hydrogen evolution being observed in this region. The reduction of nitrobenzene takes place at fairly negative potential. On the other hand, hydrogen overvoltage of carbon is not so high. The potential region where the reduction of nitrobenzene occurs predominantly is narrow. The reduction of nitrobenzene to aniline is accompanied by many side reactions. $\Delta\varphi$ can not be set at a given potential throughout the bed (Fig. 3); we can not accurately control $\Delta\varphi$ throughout the bed. This causes the reduction of current efficiency of aniline formation, as confirmed experimentally. The current efficiency became less than 50%.

Reduction of Iron(III) Ion. The reduction of iron(III) ion was examined as an example of the reaction with a low overvoltage. The feeder electrode and probes consist of graphite. The potential distribution was measured at a high concentration of iron(III) ion, 0.5M in 1M HCl, under conditions of constant current electrolysis (Figs. 4 and 5). The solution potential, φ_s was referred to that at a position just next to the diaphragm on the side of the counter electrode. The particle potential, φ_m, was referred to the potential of feeder electrode. The value of φ_m at zero position was due to the contact

* A small moving Luggin capillary and a small probe made from graphite rod or copper wire were also used, for measuring the potential distribution of solution in bed and that of bed particles in the directions of width and thickness in the bed. In these directions, uniform potential distributions were observed.

resistance between particles and the feeder electrode.** $\Delta\varphi$ corresponds to the potential difference at each position in the bed from an equilibrium potential 650 mV (*vs.* SCE).

The fact that the change of $\Delta\varphi$ along the depth was not so large at the small cell current (Fig. 4) indicates that the packed-bed is active throughout. On the other hand, Fig. 5 shows that at a large cell current, $\Delta\varphi$ becomes larger near both ends than at the center. This means that a larger part of the cell current comes from the parts near both ends and that all the packed-bed is not used equally. However, the effective depth was remarkably improved as compared with the usual packed-bed.[8]

The packed-bed electrode was applied to the reduction of iron(III) ion under conditions of limiting current by mass transfer in a solution of 0.02M $FeCl_3$ in 1M HCl. The dependence of total cell current on the potential of probe No. 1 (*vs.* SCE) was examined at different flow rates by using packed-bed electrode of 1.5 cm depth constructed with 14—20 mesh carbon particles (Fig. 6). The cell current depending on flow rate was much larger than that at feeder electrode only. The limiting current appeared clearly at a lower flow rate at more negative potential than 0.3 V. But this became ambiguous with an increase in flow rate. This may be ascribed to the disturbance of flow path in the bed and to the change of potential distribution in the bed due to the increase in cell current. The total cell current is expected to increase when the flow rate becomes large. This was examined at different bed depths (Fig. 6). The total cell current

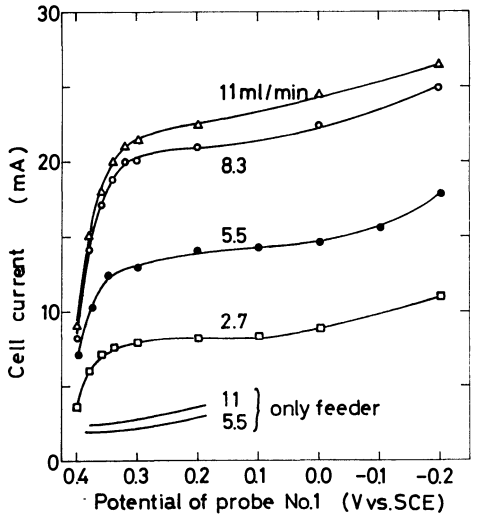

Fig. 6. Current potential relationships on a packed-bed electrode of 1.5 cm depth in 0.02 M $FeCl_3$+1 M HCl at different flow rate.
Potential of probe No. 1 was set *vs.* SCE.

** This value should be proportional to the current. However, we could not observe the proportionality and a reproducible result according to φ_m at zero position. This may be due to the small change in the surface roughness of the feeder electrode and that of film thickness of penetrated electrolyte between feeder electrode and particles.

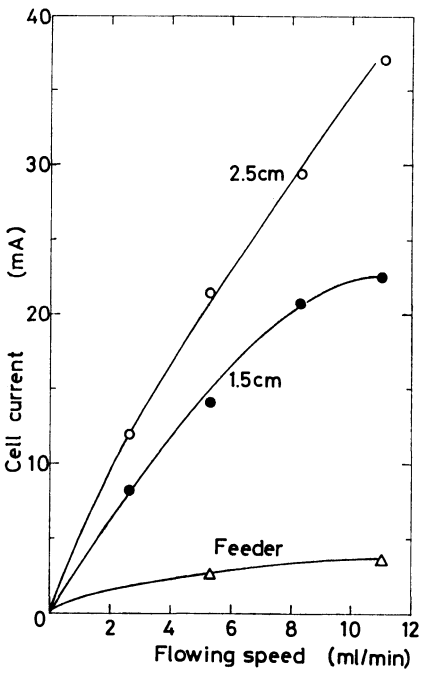

Fig. 7. The dependence of total current on flow rate in 0.02 M $FeCl_3$+1 M HCl.
Potential of probe No. 1 was set at 0.2 V (*vs.* SCE).
Bed depth, —●—: 1.5 cm, —○—: 2.5 cm, —△—: feeder electrode only.

increased with flow rate (Fig. 7). A linear relationship is expected between total cell current and flow rate under conditions of limiting mass transfer from the theory of mass or heat transfer in a packed-bed reactor.[9] However, this was not the case as shown in Fig. 7. This may also be ascribed to the disturbance of flow path in the packed-bed because of its construction.

The profile of $\Delta\varphi$ was examined under conditions of potentiostatic electrolysis where the potential of probe No.1 was set *vs.* SCE. $\Delta\varphi$ was larger than 0.4 V (Fig. 8), indicating that the particle potential throughout the bed was negative as conditions of limiting current

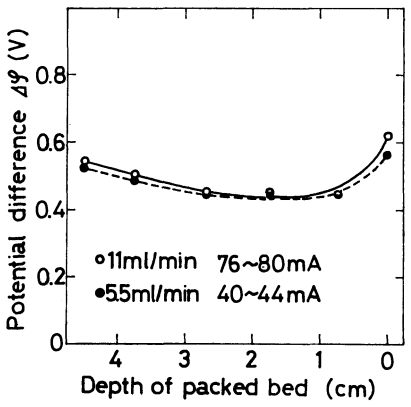

Fig. 8. The change of $\Delta\varphi$ along the bed depth in 0.02 M $FeCl_3$+1 M HCl. The potential of probe No. 1 was set at 0.2 V (*vs.* SCE).
—○—: 11 ml/min, total current 76—80 mA.
—●—: 5.5 ml/min, total current 40—44 mA.

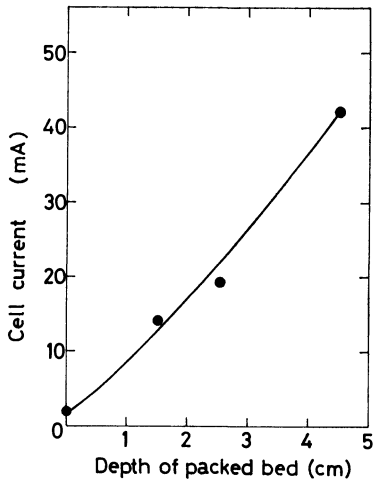

Fig. 9. Dependence of total cell current on bed depth in 0.02 M $FeCl_3$+1 M HCl at flow rate 5.5 ml/min. Potential of probe No. 1 was set at 0.2 V (*vs.* SCE).

were attained. The electrode reaction occurred almost at the same rate in the whole part of packed-bed. All the particles in the packed-bed were used effectively. This was confirmed by an experiment in which the relationship between total cell current and bed depth was examined. Total cell current increases with the bed depth (Fig. 9). The increase of cell current thus can be attained by the increase in bed depth.

The reaction ratio of reactant was small even at a low concentration because of the thinness of the bed. The reaction ratio would increase by using a thicker bed. In this case the potential distribution along the thickness might be taken into consideration. Use of this thicker bed will make this type of electrode more effective for the treatment of waste water containing harmful components in a low concentration. It is easier to control an electrode of this type than a fluidized-bed electrode.

Conclusion

The distribution of particle potential appears in the bed in a packed-bed electrode constructed with particles of moderate resistance. The distribution enables the packed-bed electrode to act in the same manner as the fluidized-bed electrode. The effective depth in the former could be improved as in the latter. As the potential in a bed can not be accurately controlled, the potential region of the desired reaction should be made wide. The electrode can be effectively applied to the solution of a low reactant concentration such as waste water.

ENDOR Studies of the Hyperfine Interaction of Phenylgalvinoxyl Radicals in Solution

Kazuo MUKAI, Takashi KAMATA, Toshiko TAMAKI, and Kazuhiko ISHIZU
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received February 12, 1976)

The ENDOR spectra of ten kinds of phenylgalvinoxyl derivatives in solution have been observed, and the hyperfine splitting constants have been determined. The formally equivalent four meta ring protons of the galvinoxyl skeleton in the phenylgalvinoxyl radical become magnetically nonequivalent in two groups of two. This behavior may be explained by assuming that splittings arising through pure spin polarization, or through mixed hyperconjugation and spin polarization, are different for *syn* and *anti* meta ring protons of the phenylgalvinoxyl radical. A similar effect has been observed in the ENDOR spectra of other phenylgalvinoxyl derivatives. In radicals with a large substitution group at the meta or para position of the phenyl ring, the galvinoxyl skeleton twists unsymmetrically on either side; thus, all or three among the four meta ring protons become magnetically nonequivalent. The solvent dependence of the ENDOR spectra of the phenylgalvinoxyl radicals constituted strong evidence for the importance of the solvent in fixing the conformation and symmetric property of the radical molecules. The proposed analyses of the ENDOR spectra were also supported by the McLachlan Molecular Orbital calculations.

The galvinoxyl radical (I) (see Fig. 1) is well known as a very stable neutral radical.[1,2] The magnetic properties of galvinoxyl in solution and in the solid state have been extensively studied using several physical methods, such as ESR,[3] NMR,[4] ENDOR,[5] magnetic susceptibility,[6] and specific heat.[7] The quinone methide radicals obtained by the replacement of *t*-butyl groups by methoxyl or methyl groups have also been studied by means of ESR and ENDOR, showing some interesting aspects of the electronic structures of these radicals.[8]

The phenylgalvinoxyl radical (II) (see Fig. 1) has an electronic structure similar to galvinoxyl, and exhibits a stability approaching that of galvinoxyl.[9] Recent studies of the magnetic susceptibility of phenylgalvinoxyl (II) and some of its derivatives (IV)—(VIII) have clarified some interesting magnetic properties in the solid state, suggesting intermolecular ferromagnetic exchange interaction in some of these radicals.[10] The magnetic property is very sensitive to both the packing of the radical molecules in the crystal and the distribution of the unpaired electron on the radical. ESR is a frequently used method for determining the distribution of the unpaired electron on radical molecules. However, the ESR spectra of the above phenylgalvinoxyl radicals are usually resolved, showing only five line-splittings ($a_m^H = 1.32$—1.35 G) due to the four meta ring protons in the galvinoxyl skeleton of the phenylgalvinoxyl radicals.[10-12] Therefore, it is not clear whether an unpaired electron spreads all over the molecular frame, since detailed analyses of the hyperfine splitting constants have never been attempted for these radicals.

Electron nuclear double resonance (ENDOR) spectroscopy is a valuable method for the determination of the proton isotropic hyperfine couplings of organic radicals in solution, since the effective resolution is much higher than for ESR. In the preliminary ENDOR experiment on phenylgalvinoxyl (II), the ENDOR line from the four meta ring protons was observed to be split, suggesting that there are two pairs of equivalent ring protons.[13] In the work, this splitting was tentatively ascribed to a restricted rotation with molecular asymmetry. On the other hand, all four meta ring protons of galvinoxyl are equivalent within the resolution of the ENDOR experiments.[5]

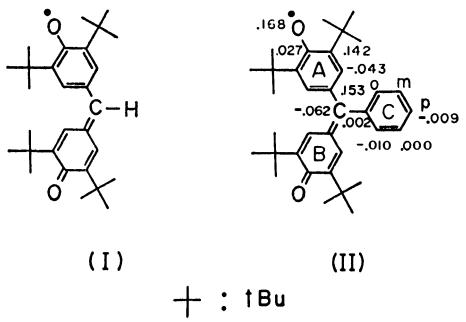

Fig. 1. Chemical structures of galvinoxyl (I) and phenylgalvinoxyl (II), showing numbering system and McLachlan unpaired spin densities.

In the present paper, proton hyperfine splitting constants measured from the solution ENDOR spectra of ten kinds of phenylgalvinoxyl radicals in toluene and, in some cases, in 2-methyltetrahydrofuran (2-MTHF) will be reported, in order to present fundamental data which are essential for a more detailed understanding of the magnetic properties of these radicals in the solid state. Even though these radicals show simple quintet ESR absorption spectra, the ENDOR experiments have yielded several notable results which, we think, could not have been obtained from the ESR spectra. Based on the ENDOR data, interesting conformational changes due to steric interactions and solvent effects for these radicals will be discussed.

Experimental

The galvinoxyl radical (I) was synthesized following the method of Kharash and Joshi[1] or Coppinger.[2] The syntheses and physical properties of the phenol precursors (P-II)—(P-X), except for the phenol (P-III), of the phenylgalvinoxyl radicals (II)—(X) (see Figs. 1 and 2) were reported previously.[10,12] The phenol (P-III) was prepared according to the method of Coffield *et al.*[14] After the condensation of 2,6-di-*t*-butylphenol with benzaldehyde-d_5 (E. Merck AG. 99%), the deuterated bisphenol (P-III) was synthesized; thereafter

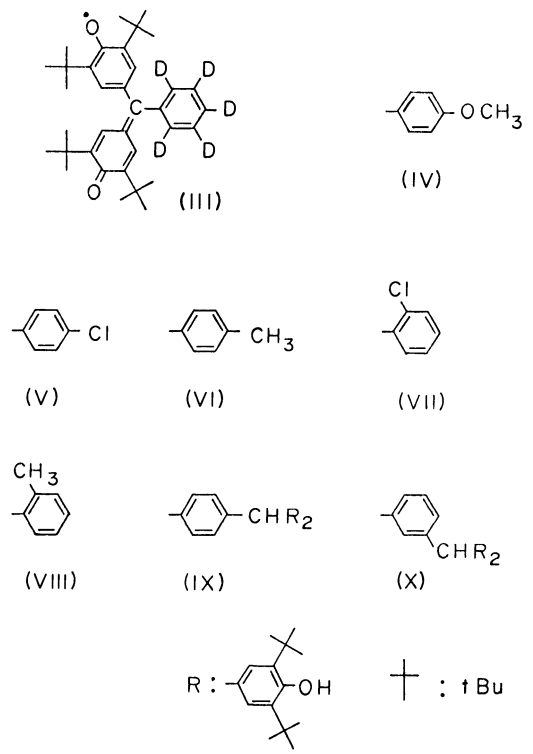

Fig. 2. Chemical structures of phenylgalvinoxyl derivatives (III)—(X).

it was recrystallized twice from ethanol. Mp 162.5—163.5 °C. Found: C, 83.44; H and D, 10.15%. Calcd for $C_{35}H_{43}D_5O_2$; C, 83.11; H and D, 10.56%. The ultraviolet absorption spectrum in ethanol with λ_{max}=279 nm (log ε=3.65) and the proton NMR spectrum in CCl_4 with $\delta_{t\text{-Bu}}$=1.38, δ_{OH}=4.92, δ_{CH}=5.28, and $\delta_{m\ H}$=6.82 ppm (TMS as the standard) are in good agreement with those of the corresponding bisphenol, except for the disappearance of the proton NMR absorption due to five phenyl protons of the undeuterated bisphenol.

The phenylgalvinoxyl radicals (II)—(X) were prepared by the oxidation of the phenols with PbO_2 in toluene or 2-MTHF under a vacuum. The initial ESR spectra resulting from the slight oxidation of the phenols with PbO_2 were a doublet of triplets.[12] After further oxidation, the phenylgalvinoxyl radical, which has the structure shown in Fig. 1, and its derivatives were formed. The ESR spectra of these phenylgalvinoxyls show five line splitting with intensities of 1 : 4 : 6 : 4 : 1.

The ENDOR spectra were recorded by means of a JEOL-type ES-EDX-1 spectrometer, operated with 80 Hz magnetic field modulation.[15] About 150 watts of the continuous radio wave frequency modulated at 6.5 kHz were running inside of the cavity for NMR excitation. The ESR measurements were carried out using a JES-ME-3X spectrometer.

Results and Discussion

The ESR spectra of the phenylgalvinoxyl (II) and some of its derivatives (III)—(X) (see Figs. 1 and 2) show only five line splittings due to four meta ring protons of the quinone methide skeleton; we were unable to resolve the splittings from the other protons. The meta ring proton hyperfine splittings, a_m^H, observed in toluene at room temperature are listed in the first column of Table 1. Figures 3 and 4 show several typical ENDOR spectra of the phenylgalvinoxyl and some of its derivatives in toluene. The ENDOR spectra of these radicals were also measured in the 2-MTHF solvent. The results of the analyses of these spectra are also tabulated in Table 1, together with the data of the galvinoxyl radical used as reference. The temperatures (T) at which the best resolved ENDOR spectra were obtained are listed in Table 1.

ENDOR Spectra of Galvinoxyl (I), Phenylgalvinoxyl (II), and Phenyl-d_5-galvinoxyl (III). The ENDOR spectrum of galvinoxyl (I) in toluene (see Fig. 3(a)) shows three different proton hyperfine splittings (5.77_4, 1.36_6, and 0.05_5 G), which are attributable, respectively, to a methide proton, four ring protons, and the 36 tertiary butyl protons. On the other hand, the ENDOR spectrum of phenylgalvinoxyl (II) in toluene (see Fig. 3(b)) clearly exhibits four different proton hyperfine splittings (1.34_7, 1.27_2, 0.20_7, and 0.05_8 G). The larger two hyperfine splittings (1.34_7 and 1.27_2 G) are easily assigned to the four meta ring protons of phenoxyl groups, taking their ESR hyperfine coupling constants (a_m^H=1.32 G) into account. This assignment

is also consistent with the known assignments for galvinoxyl (I).[3] Since, at the temperatures at which we measured the ENDOR signal, the intensities of the ENDOR transitions corresponding to the hyperfine couplings, 1.34_7 and 1.27_2 G, are equal, the four protons must be equivalent in two groups of two protons. Here, the splitting of the meta ring proton ENDOR signal at a low temperature is independent of both the microwave and radio frequency power,[5] and we are confident that it reflects a real difference in hyperfine coupling. Similar splittings are also observed in all the other radicals investigated, except for the (IX) and (X) radicals, as is shown in Figs. 3 and 4. Comparing the ENDOR spectrum of phenylgalvinoxyl with that of galvinoxyl, the hyperfine splitting of 0.20_7 G of the former, which has never been observed in the latter, can clearly be identified as the proton hyperfine splitting in the substituted phenyl ring. We confirmed that the splitting of 0.20_7 G can be assigned to the ring protons in the substituted phenyl, because it is lost in phenyl-d_5-galvinoxyl (see Fig. 3(c)). Thus, the smallest splitting of 0.05_8 G is attributable to that of tertiary butyl protons. This fact indicates that the unpaired electron spreads over the substituted phenyl ring, C, although the magnitude of the electron density is very small. Anticipating the results of the McLachlan Molecular Orbital calculations to be described later (see Fig. 1), the 0.20_7 G splitting will be assigned to the ortho and para ring protons of the substituted phenyl ring, C, in which the unpaired spin densities on meta ring carbon atoms are too small to explain the 0.20_7 G splitting or even the 0.05_8 G splitting.

As has been discussed above, the ENDOR results indicate that the four meta ring protons must be equivalent magnetically in two groups of two protons. In support of the present assumptions, one may refer to the accurate ESR and/or ENDOR data on the allyl radical[16] and 2-methylgalvinoxyl[8] (see the structure in Ref. 8), because both radicals have electronic structures (allyl skeletons) similar to that of phenylgalvinoxyl.

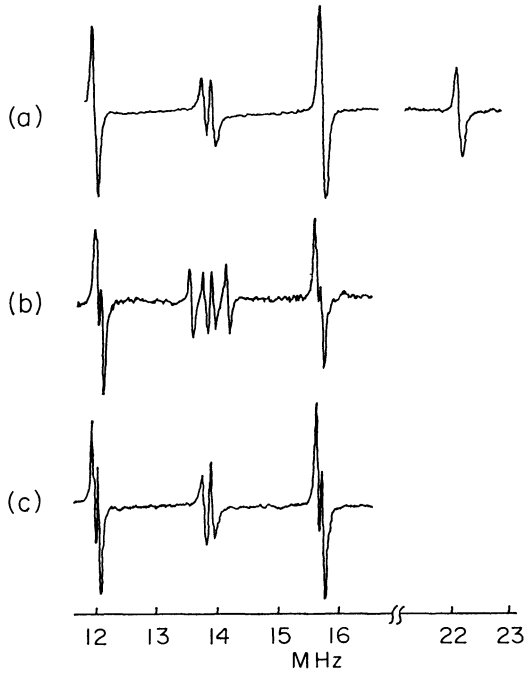

Fig. 3. ENDOR spectra of (a) galvinoxyl (I) (at −75 °C), (b) phenylgalvinoxyl (II) (at −60 °C), and (c) phenyl-d_5-galvinoxyl (III) (at −68 °C) in toluene.

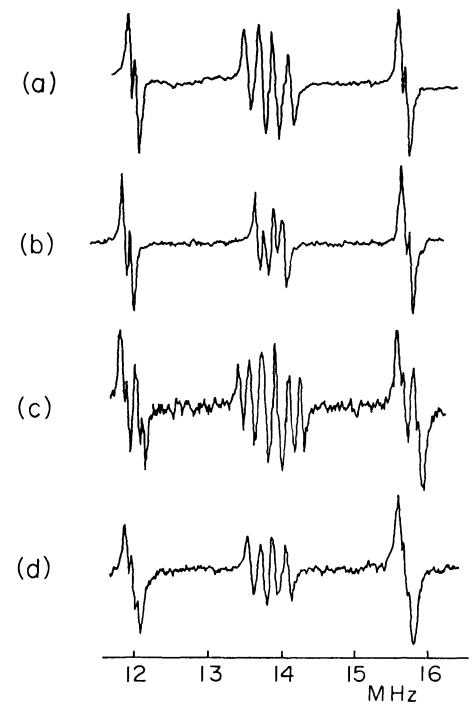

Fig. 4. ENDOR spectra of (a) radical (IV) (at −80 °C), (b) radical (VII) (at −61 °C), (c) radical (IX) (at −45 °C), and (d) radical (X) (at −73 °C) in toluene.

The low-temperature ESR spectrum of the allyl radical reveals two pairs of magnetically inequivalent *syn* and *anti* terminal protons (13.90 and 14.81 G), which give rise to a triplet-of-triplets hyperfine structure further split into doublets by the proton in the 2 position (4.06 G). The different splittings which are observed for formally equivalent methylene protons in allyl could be understood because the splitting arising through pure spin polarization, or through mixed hyperconjugation and spin polarization, is expected to be different for *syn* and *anti* terminal protons. A similar situation may be expected to explain the observed inequivalence of meta ring protons of phenylgalvinoxyl.

The non-equivalence of the methyl proton splitting has been observed in the ENDOR spectra at low temperatures of the 2-methyl-derivative of galvinoxyl by Steelink *et al.*[8] When the two *t*-butyl groups on one of the two phenyl rings of galvinoxyl are replaced by methyl groups, the two methyl groups are inequivalent, showing a splitting of the methyl proton ENDOR line. However, in this case, all four ring protons of 2-methylgalvinoxyl are equivalent within the resolution of the ENDOR experiments. The molecular structure and packing in crystalline galvinoxyl have been determined by X-ray diffraction.[17] The observed bond angle at methine carbon is 134 degrees, and the phenyl

groups are twisted by 12 degrees. On the other hand, the phenylgalvinoxyl radical may be considered rather as triphenylmethyl derivatives. The Stuart molecular model indicates that the main steric interaction in phenylgalvinoxyl works between the ring protons, although weak interactions can be seen between the substituted *t*-butyl groups. Thus, the radical most probably adopts a propeller configuration, with a bond angle of about 120° at the centered carbon and a twist angle of about 30°.[18] Therefore, the decrease in the bond angle at the centered carbon and the increase in the twist angle in phenylgalvinoxyl compared to those of galvinoxyl will induce the difference in the hyperfine splitting constants of two meta ring protons in each of two phenyl rings, A and B.

ENDOR Spectra of IV, V, and VI Radicals. The para-derivatives, (IV), (V), and (VI) (see Fig. 2), of phenylgalvinoxyl show spectra similar to that of phenylgalvinoxyl. For example, the spectrum of the IV radical clearly exhibits four different proton hyperfine splittings, as is shown in Fig. 4(a). The value of each hyperfine splitting is very close to the corresponding value of phenylgalvinoxyl. This indicates that the effects of the para-substitution of the phenyl ring C by CH_3O-, Cl-, and CH_3- groups are too small to induce any change in the unpaired spin distribution or molecular structure. The hyperfine splittings for the IV, V, and VI radicals are listed in Table 1.

ENDOR Spectra of VII and VIII Radicals. The effect of the ortho-substitution of the phenyl ring, C, by Cl- and CH_3- groups has been studied (see Fig. 2, (P-VII) and (P-VIII)). The ENDOR spectrum of the VII radical (ortho-Cl-derivative) in toluene is shown in Fig. 4(b), indicating again four different proton hyperfine splittings (1.35_8, 1.29_1, 0.11_6, and 0.05_1 G). The obvious assignments of the 1.35_8 and 1.29_1 G to two pairs of ring protons, the 0.11_6 G to the ortho and para protons of the phenyl ring, C, and the 0.05_1 G to the tertiary butyl protons, are consistent with the results for the II—VI radicals. A similar spectrum is obtained for the VIII radical (ortho-CH_3-derivative), and the hyperfine splittings observed are listed in Table 1.

As has been reported for the tris(*p*-nitrophenyl)-methyl radical from the results of X-ray analysis, three phenyl rings, A, B, and C, of the phenylgalvinoxyl are considered to be twisted with an equivalent angle, 30°. Ortho-substitution induces a strong interaction between the pendent group and the ring adjacent to the pendent group. Therefore, we can expect that the two rings, A and B, of the quinone methide skeleton will be distorted by different angles, θ_A and θ_B, respectively. If this effect is large, we can expect four kinds of ring-proton hyperfine splittings for these radicals. However, the VII and VIII radicals show two kinds of hyperfine splittings due to four meta ring protons, with values similar to that of phenylgalvinoxyl. On the other hand, the hyperfine splittings of the phenyl ring, C, are reduced to almost half of that of phenylgalvinoxyl.

Since the ring protons in the rings A and B are believed to be inequivalent, even if the steric effect by ortho-substitution is small, this perturbation might make some contribution to the width and shape of the meta ring proton absorption lines. In addition, since the steric effect of the ortho-CH_3-derivative (VIII) must, in principle, be different from that of the ortho-Cl-derivative (VII), this would also induce a difference in the width and shape of the absorption lines of these two ortho-derivatives. The surprising thing is that all of these effects are so small. These results can be understood, however, by assuming that the ring C, to which the pendent groups are attached, is twisted more than the other rings, A and B, and that the twisting angles, θ_A and θ_B, are nearly equal to each other, that is, $\theta_C > \theta_A \approx \theta_B$.

ENDOR Spectra of IX and X Radicals. The ENDOR spectrum of the IX and X radicals (see Fig. 2) in toluene at −45 and −73 °C are shown in Fig. 4(c) and (d) respectively. The spectrum of the IX radical consists of 14 lines symmetrically disposed on both sides of the free proton NMR frequency. This spectrum is very different from those of other phenylgalvinoxyls. A comparison of the present ENDOR results on IX with those of an earlier work on II suggests that one group of splittings (1.40_7, 1.35_7, 1.26_0, 1.20_7 G) should be assigned to the four meta ring protons, and the (0.05_0 G) splitting, to the *t*-butyl protons. Similarly, the (0.18_3 G) splitting is assigned to the two ortho protons, and that of 0.28_9 G, to the one remaining para-methylene proton of the phenyl ring, C. This result indicates that the galvinoxyl skeleton twists unsymmetrically on either side; thus, all four meta ring protons are magnetically inequivalent. The differences (0.05_0 and 0.05_3 G) between the two larger splittings (1.40_7, 1.35_7 G) and the two smaller splittings (1.26_0, 1.20_7 G) are similar to each other and are comparable with those of other phenylgalvinoxyls. Therefore, assuming the twist angles ($\theta_A < \theta_B$), the two larger splittings and the two smaller splittings are attributable to the two meta ring protons of the ring A and the ring B respectively of the galvinoxyl skeleton.

Figure 4(d) shows the ENDOR spectrum of the X radical in toluene at −73 °C, indicating five different hyperfine splittings. Similarly, the splitting of 0.18_1 G may be assigned to ortho and para protons of the phenyl ring C, and that of 0.05_8 G, to the *t*-butyl protons. Clearly the splittings of 1.37_1, 1.32_1, and 1.26_8 G are to be assigned to the four magnetically inequivalent meta ring protons. Again, the data may be explained tentatively by keeping in mind the fact that the galvinoxyl skeleton twists unsymmetrically on either side, but the difference in the twist angles is smaller than that in the IX radical, and thus the intermediate two splittings coincide with each other. The cause of such molecular asymmetry is steric interaction between the galvinoxyl skeleton ring and the large group substituted to the ring C. The Stuart molecular model supports the idea that such steric interaction is possible for these radicals, (IX) and (X).

Solvent Effect. The solvent dependences of the ENDOR spectra of the II, VII, VIII, IX, and X radicals were also examined. In the II, VII, and VIII radicals, the ENDOR spectra in toluene and in 2-MTHF are similar to each other, and the observed values of the hyperfine splittings show a good accordance, within

the limits of experimental error, as is shown in Table 1. On the other hand, notable solvent dependences were observed in the ENDOR spectra of the IX and X radicals. The ENDOR spectrum of the IX radical in toluene at −40°——60 °C (see Fig. 4(c)) consists of 14 lines symmetrically disposed on both sides of the free proton NMR frequency. On the other hand, the ENDOR spectrum in 2-MTHF of the same radical (IX) at −50°——70 °C consists of 10 lines. This spectrum is quite similar to that of the X radical in toluene, shown in Fig. 4(d). Clearly, in 2-MTHF, the meta ring protons show three kinds of hyperfine splittings. This result may be explained by assuming that the degree of molecular asymmetry, that is, the difference in the twist angles, θ_A and θ_B, observed for the IX radical in toluene, was decreased in 2-MTHF. The splitting of 0.28_9 G due to the para methylene proton of the phenyl ring C, also disappeared in 2-MTHF. This must be due to the change in the dihedral angle of the CH bond to the $2p_z$ orbital of the ring C. Similar solvent effects were observed for the X radical. The ENDOR spectrum of the X radical in 2-MTHF at −54 °C shows four kinds of splittings, 1.34_7 and 1.27_4 G due to meta ring protons, 0.18_9 G due to phenyl ring C protons, and 0.06_1 G due to *t*-butyl protons. This result differs from the five kinds of splittings of the same radical seen in toluene at −40°——75 °C; it implies that the molecular asymmetry of the X radical observed in toluene is eliminated in 2-MTHF.

Many investigations of the solvent effect of free radicals, including phenoxyl radicals, have been reported.[19] The effect has been explained as a redistribution of the π-electron spin density in a radical molecule induced by the electrostatic interaction and/or the hydrogen bond formation between the radical and the solvent molecules. However, in all the phenoxyl radicals studied in the present work, the variation in the hyperfine splitting constants, and thus the π-electron spin density induced by these effects, are both thought to be small because of the steric effect of tertiary butyl groups in these molecules. In fact, the observed change in the hyperfine splittings of the II, VI, and VIII radicals in toluene and 2-MTHF is negligible, as is shown in Table 1. On the other hand, the notable solvent effect in the hyperfine splitting of the IX and X radicals observed here may be explained by assuming a change in the steric structure of the radical molecules due to the solvents. Therefore, in other words, the present solvent dependences observed for the phenylgalvinoxyls serve as evidence that solvent molecules play an important role in fixing the conformations and symmetric properties of the radical molecules.

MO Calculations. Using the same parameters for the oxygen atom as those used for the galvinoxyl radical by Luckhurst,[20] the McLachlan spin density of the phenylgalvinoxyl radical was calculated. In this calculation all three phenyl groups were assumed to be twisted by 30° about the methyl carbon bonds. The choice of 30° was made on the basis of the results of the X-ray analysis of the tris(*p*-nitrophenyl)methyl radical,[18] because steric hindrance between substituted *t*-butyl groups in the phenylgalvinoxyl radical is considered to be small from the Stuart molecular model; thus, the structure of the phenylgalvinoxyl mainly depends on that of the triphenylmethyl skeleton. Spin densities are not very sensitive to the choice of this angle as long as it is small, since the resonance integral between the methyl carbon and the attached phenyl carbon varies as $\beta=\beta_0\cos\theta$. The results are given in Fig. 1. They can explain the qualitative ENDOR spectrum of phenylgalvinoxyl, assuming the Q values of 23 G for ring protons and 0.28 G[19] for tertiary butyl protons. The orbitals containing an unpaired electron of the phenylgalvinoxyls have, at least in the Hückel approximation, a node in the centered phenyl ring, C, and a carbon atom connected to the phenyl ring, giving a zero spin density on the phenyl ring. In the McLachlan approximation, the orbitals are spin-polarized so as to yield nonvanishing spin densities in the phenyl ring C of the radical. These spin densities are $\rho_{ortho}=-0.010$ and $\rho_{para}=-0.009$, and the hyperfine splitting constant ($a^H=0.20_7$ G) may be assigned to the ortho and para ring protons of the phenyl ring C. The unpaired spin densities ($\rho_{meta}=0.000$) on the meta carbon atoms are negligibly small.

Recent studies of the magnetic susceptibilities of phenylgalvinoxyl (II) and some of its derivatives (IV)—(VIII) have clarified some interesting magnetic properties in the solid states, suggesting intermolecular ferromagnetic exchange interaction in some of these radicals.[10] The sign and magnitude of the exchange interaction between the π-electron spins may depend on both the spin densities and the molecular packing.[21,22] The results of ENDOR measurements and McLachlan Molecular Orbital calculation show that there are large positive and negative atomic π-spin densities in these radicals, and it is quite possible that, in special cases, these radicals may pancake on top of one another in the crystal lattice so that atoms of a positive spin density are exchange-coupled most strongly to atoms of a negative spin density in neighboring molecules. In such a case, the apparent exchange interaction is ferromagnetic, corresponding to the results verified experimentally by magnetic susceptibility measurements.[6,10,22]

We wish to thank Professor Yasuo Deguchi and Mr. Fujito Nemoto for their helpful discussions. We also wish to express our gratitude to Drs. Osamu Takizawa and Kohji Watanabe for their McLachlan Molecular Orbital calculations. We are grateful to Messrs. Masahiro Kohno and Takamitsu Yamamoto for their kind advice on the measurements of the ENDOR spectra. We are also grateful to Mr. Taizi Itoh for his kind help in the syntheses of phenols (*p*-IX) and (*p*-X).

Electronic States of Fluorene, Carbazole and Dibenzofuran

Masashi TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received March 8, 1976)

The polarized reflection spectra of the fluorene, carbazole, and dibenzofuran crystals have been measured from 30000 to 53000 cm^{-1} and the absolute intensity of the absorption parallel to the a, b, and c axes of these crystals has been obtained by the Kramers-Kronig transformation; these data allowed an interpretation to be made for the solution spectra. Furthermore, the influence of the intermolecular interaction on each level has been examined. This analysis shows that the lowest excited state of the fluorene molecule is the B_2 state, while those of the carbazole and dibenzofuran are the A_1 states. In fluorene, the sum of the oscillator strengths of the transition to two lower excited states (α and α^* states) is 0.39 in the molecule and 0.61 in the crystal. Such hyperchromism is also observed in the α, p, and β states of carbazole and the β state of dibenzofuran. On the other hand, the α^* state of dibenzofuran is hypochromic and the oscillator strengths in the molecule (0.87) decrease to 0.36 in the crystal. However, the factor group splitting and the crystal field shift are small and a one to one correspondence can easily be obtained between the solution and crystalline spectra.

The electronic spectra of fluorene, carbazole, and dibenzofuran are of interest because of the physical and chemical properties of five-membered heterocycles; many papers concerned with an experimental or theoretical analysis of their UV spectra have been reported.

These molecules have the symmetry of point group C_{2v} and the A_1 (polarized to the short axis) and B_2 (polarized to the long axis) states can be observed in the UV measurement. According to the vapor spectra observed by Pinkham and Wait,[1] the lowest energy $\pi\rightarrow\pi^*$ transition of fluorene vapor has its origin at 33773 cm^{-1} and was assigned to $A_1\rightarrow A_1$. Two $\pi\rightarrow\pi^*$ transitions were observed for dibenzofuran vapor. The one with the origin at 31488 cm^{-1} was assigned to an $A_1\rightarrow A_1$ transition, while the one which originates at 33647 cm^{-1} was assigned to $A_1\rightarrow B_2$. The strong $\pi\rightarrow\pi^*$ transition of carbazole which originates at 36346 cm^{-1} was assigned to $A_1\rightarrow B_2$. The weaker $\pi\rightarrow\pi^*$ band system, originating at 30694 cm^{-1}, was assigned to $A_1\rightarrow A_1$.

Solution studies have been made of the absorption, fluorescence, and phosphorescence. Kanda *et al.*[2] measured the phosphorescence of fluorene and dibenzofuran in cyclohexane at 90 K. Mataga, Torihashi, and Ezumi[3] studied the solvent effects upon the fluorescence and absorption spectra of carbazole. As is cited in the paper by Dörr and Gropper,[4] Joop[5] appears to have obtained the polarization of the fluorescence excitation spectrum of fluorene and found that the *p*-values for fluorescence are positive when excitation is made to the first and second absorption bands. Schütt and Zimmerman[6] reported the fluorescence, phosphorescence, and absorption polarization ratio of carbazole and found that the *p*-values are positive for the first band at 29500 cm^{-1} and negative for the second band at 34000 cm^{-1}, Lace *et al.*[7] measured the polarized absorption of dibenzofuran in 1,2,4,5-tetramethylbenzene host and decided that the 3000 Å transition should be assigned to $A_1\rightarrow B_2$. Siegel and Judeikis[8] determined the polarization by the method of magnetophotoselection and they also demonstrated that the lowest state of fluorene has a B_2 symmetry and those of carbazole and dibenzofuran have A_1 symmetries.

In the crystal of these compounds, there are four molecules in an orthorhombic unit cell;[9-11] the long axis of the molecule lies exactly parallel to one of the crystalline axes and the short axis is perpendicular to it. Accordingly, it is possible to assign the transitions to the A_1 and B_2 states distinctly by using the polarization technique. The polarized crystalline absorption spectra were measured by the group of Bree.[12-14] The a and b axes polarized spectra of a fluorene crystal showed that the 33000 cm^{-1} system is the B_2 state, while the a and c axes spectra of a dibenzofuran crystal showed that the first band is the A_1 state. The polarized absorption spectra of carbazole in a fluorene matrix were measured by Bree and his coworkers; they made the assignment that the 30000 cm^{-1} system is the A_1 state.

The author measured the polarized reflection spectra of titled crystals with several crystalline faces and attempted to give better assignments of absorption bands for a wide spectral range. Furthermore, the influence of the intermolecular interaction on the band position and intensity of each level was examined and compared with the results calculated by the SCF-RPA exciton method.[15] This method, which takes into account the double excitation configuration, is very usefull for studying the intermolecular interaction, because the double excitation has a large effect on the hypochromism, as was shown by Tinoco[16] and Rhodes.[17]

Experimental

Single crystals of fluorene, carbazole, and dibenzofuran were grown by slow evaporation of the ethanol solution after purifying the material by column chromatography. The crystal showed well developed (001) or (010) faces.

Reflection spectra at the normal incidence have been measured over a range of 20000—53000 cm^{-1} with a reflection spectrophotometer made in our laboratory and the absorption spectra have been obtained by the Kramers-Kronig transformation.[18] The oscillator strength along the α axis of the crystal may be evaluated by using the following equation:[19]

$$f^{\alpha} = 4.32\times10^{-9} \int n_{\alpha}(\sigma)\,\varepsilon_{\alpha}(\sigma)\,d\sigma$$

where the integration is calculated over the whole band, σ is the wave number, and n_{α} and ε_{α} are the α component of the refractive index and the molar extinction coefficient.

Oscillator strengths for the three orthogonal axes in the orthorhombic crystal should be compared with that in solution:

$$f^{a} + f^{b} + f^{c} = 3f^{\text{solution}}$$

where the suffixes a, b, and c correspond to the crystal axes.

Thoeretical

The electronic states of the molecules are calculated by the RPA method.[20] This method is formulated as an eigenvalue problem for the singlet energies ΔE of a many-electron system as follows:

$$\begin{pmatrix} A & B \\ B & A \end{pmatrix}\begin{pmatrix} X \\ Y \end{pmatrix} = \Delta E \begin{pmatrix} X \\ -Y \end{pmatrix}$$

where

$$A_{ij,kl} = (\varepsilon_j - \varepsilon_i)\delta_{ik}\delta_{jl} + 2(ij|kl) - (ik|jl)$$

and

$$B_{ij,kl} = 2(ij|kl) - (il|jk)$$

The indices i, k refer to the HF orbitals occupied in the ground configuration Φ_0 and the indices j, l refer to the virtual orbitals of the HF eigenvalue problem

$$F\phi_i = \varepsilon_i\phi_i.$$

The two-electron integrals are defined by

$$(ij|kl) = \int \phi_i^*(1)\,\phi_j(1)\frac{1}{r_{12}}\phi_k^*(2)\,\phi_l(2)\,d\tau_1\,d\tau_2.$$

Then the above-mentioned equations can be evaluated with the approximations of the neglect of differential overlap[21] and of the use of two-center coulomb integrals γ_{pq} estimated by Nishimoto-Mataga's method.[22] The one-center core coulomb integrals α_p and the two-center resonance integrals β_{pq} are approximated in the following equations:

$$\alpha_p = -I_p - (n_p - 1)\gamma_{pp} - \sum_{r \neq p} n_r\gamma_{pr}$$

$$\beta_{pq} = -K(I_p + I_q)S_{pq}$$

where the constant K is taken to be 0.29. The overlap integrals S_{pq} are calculated between the nearest neighbor atoms by using the SCF-AO's[23] and neglected in other cases. The values of the ionization potentials I_p are taken from Pilcher and Skinner's table[24] and the one-center integrals γ_{pp} are estimated by the Pariser-Parr approximation.[25]

In theoretical studies of the ultraviolet spectra of five-membered rings, Momicchioli and Rasteli[26] showed that the lower excited states of these molecules have the α, α^*, p, β, β^*, and β' characters in Clar's notation, where α and β characters mean that the excited states derive mainly from the mixing of Φ (A→B′) and Φ (B→A′) configurations, and similarly α^* and β^* characters from Φ (A→C′) and Φ (C→A′) and p and β' from Φ (A→A′), Φ (B→B′), and Φ (C→C′). The letters ···C,B,A,A′,B′,C′··· are the molecular orbitals denoted according to increasing energy. In these compounds of point group C_{2v}, the molecular orbitals C, A, B′, and D′ span the a_1 representation and D, B, A′, and C′ the b_2, respectively. Therefore, the α and β states belong to the A_1 symmetry and are the short axis polarized states, and the α^*, p, β^*, and β' states belonging to the B_2 symmetry are the long axis polarized states. In addition to the above-mentioned states, two other bands can be observed in the higher energy range and may be noted as the γ and δ states of the A_1 symmetry. The γ state has the large contribution from four configurations of Φ (B→C′), Φ (C→B′), Φ (A→B′), and Φ (B→A′), and the δ state from Φ (D→C′) and Φ (C→D′).

The exciton states of the crystal are calculated according to the RPA exciton method.[15] This method takes into account the effect of the doubly excited configurations in addition to the mixing between the singly excited configurations.

All of the above-mentioned computations were carried out on a FACOM 230—60 computer at the Nagoya University computation center.

Results and Discussion

Fluorene. The solution spectrum is described in Fig. 1 and the theoretically calculated results of the molecule are given in Table 1, together with the assignment of the observed states. The first band in the region of 3000 Å has structure and consists of two electronic states. The lowest state at 33200 cm^{-1} is the long axis polarized state of B_2 symmetry (α^* state) and the short axis state (α state) is covered by the α^* state, as shown below. The third state (p state) also has structure; its origin is at 35900 cm^{-1} and other vibronic levels appear at 36900, 38100, 39200, and 40400 cm^{-1}. This state is assigned to the B_2 state. There are many other states in the higher energy region: two shoulders at 44300 cm^{-1} (β^* state) and 45500 cm^{-1} (β' state) and a stronger system (β state) beginning near 48000 cm^{-1}.

Fluorene forms orthorhombic crystals of space group Pnam (D_{2h}^{16}) having four molecules in a unit cell.[9] Projections onto the (010) and (001) faces are shown in Fig. 2. Beacuse of site symmetry (C_s), the long axis of the molecule lies exactly parallel to the c crystalline axis and the short in-plane axis is in

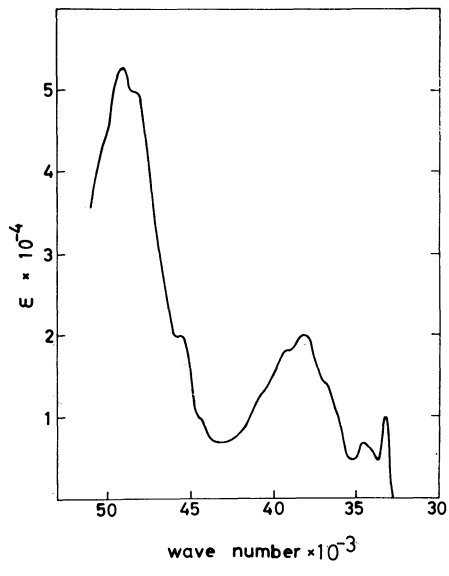

Fig. 1. The spectrum in isooctane of the fluorene molecule.

TABLE 1. THE LOWER EXCITED STATES OF THE FLUORENE MOLECULE, CALCULATED BY THE RPA METHOD
(All energy values are given in the units of $10^3\,cm^{-1}$.)

State		Obsd		Calculated Values		
		E	(f)	E	(f)	Wavefunction
A_1	α	>33.2	(0.13)	32.9	(0.00)	$0.6482\,\Phi(6\to8)-0.6482\,\Phi(5\to7)+\cdots$

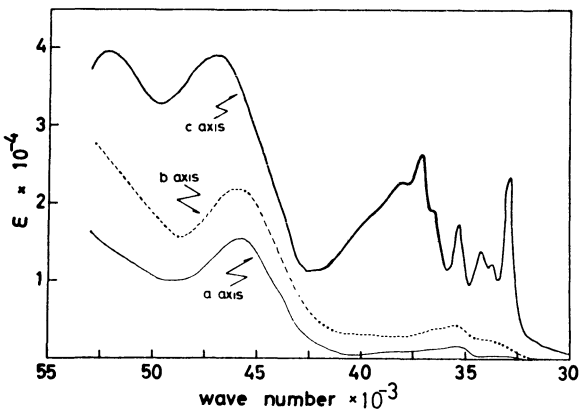

Fig. 3. The polarized absorption spectra of the fluorene crystal obtained by the K-K transformation of the reflection spectra.

the (001) plane. Thus, a long axis transition in the isolated molecule may not be observed in the (001) cleavage plane; only the short axis transition is allowed and is assigned to the $A_1\to A_1$ transition. The c axis spectrum is of the B_2 states allowed for the polarized light parallel to the long axis in the molecule. It will be expected that the A_1 and B_2 excited states can be separately measured and the absorption spectra for these crystalline axes can be obtained from the reflection spectra, as shown in Fig. 3.

In the crystalline c-axes spectrum, four transitions of α^*, p, β^*, and β' were observed at 32900, 35300, 47400, and 52600 cm^{-1}; these were assigned to the transition to the B_2 state. The a and b axes spectra have three bands (α, β, and δ) at 33500, 46000, and about 54000 cm^{-1}, which correspond to the short axis polarized bands of the molecule and are assigned to the A_1 state. The theoretical studies shown in Table 1 predict two transitions (one long and one short axis polarized) followed by a strong long axis transition. This experiment shows that the lowest excited state is the α^* state at 32900 cm^{-1} and the second state is the α state at 33500 cm^{-1}, although the first and second states obtained theoretically are reversed in order. Bree and Zwarich[12] found that 32818 cm^{-1} in fluorescence and 32910 cm^{-1} in the c axis-polarized absorption may both connect the same lowest electronic levels (B_2 state) in the crystal. Our experimental result is in good agreement with their measurement. The successive levels of the lowest α^* state are located at 33700 and 34300 cm^{-1} in the crystalline spectrum and at 34000 and 34700 cm^{-1} in the solution spectrum. The origin of the p state is assigned to the peak at 35300 cm^{-1} and higher vibronic levels appear at 36400, 37100, and 38100 cm^{-1}. The comparison of the vibronic levels between the solution and the crystalline spectra is shown in Table 2.

The excitation energies and oscillator strengths of the crystal were calculated by the RPA exciton me-

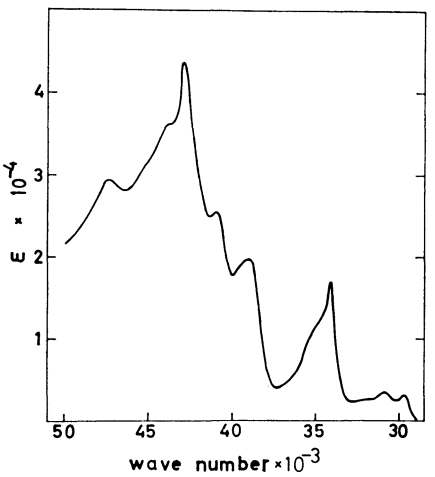

Fig. 4. The spectrum in ethanol of the carbazole molecule.

thod.[15] The results are shown in Table 3, in which the intermolecular interactions for the inner zone were calculated to 50 Å. As shown in Tables 1 and 3, the comparison between the oscillator strengths of the molecule and the crystal show that the sum of the oscillator strengths of two states (α and α^* states) is 0.39 (3 f^{solution}) in the molecule and 0.61 ($f^a+f^b+f^c$) in the crystal. In the intense p band, the absorption intensity in the molecule (3 $f^{\text{solution}}=1.29$) is comparable with 1.18 (f^c) in the crystal. The dichroic ratio($f^a/f^b=2.6$) of the α band is slightly larger than the oriented gas polarization ratio of 2.1. However, those of the higher states deviate from the values expected from the oriented gas model and can be explained by the intermolecular interaction.

Carbazole. The solution spectrum is described in Fig. 4 and the theoretically calculated results of the molecule are given in Table 4, together with the assignment of the observed states. The first band in the region of 30000 cm^{-1} has structure; the origin is located at 29700 cm^{-1} and other vibronic levels appear at 30900 and 32100 cm^{-1}. This state is assigned to the short axis polarized state of A_1 symmetry (α band). The second α^* band originating at 34100 cm^{-1} is of B_2 symmetry and a successive vibronic level appears as the shoulder at 35300 cm^{-1}. Band positions of the α and α^* states are summarized in Table 5. There are many other states in the higher energy region, the p band at 39000 cm^{-1} and a stronger and more complex system which probably contains four separate electronic transitions at 41000 cm^{-1} (β state), 43000 cm^{-1} (β' state), 45000 cm^{-1} (β^* state), and 47400 cm^{-1} (γ state).

Carbazole forms orthorhombic crystals of space group Pnma (D_{2h}^{16}) with four molecules, as shown in Fig. 5.[10] The crystal structure of carbazole resembles that of fluorene having the same space group (although the axes b and c have been interchanged) and has similar unit cell dimensions and molecular orientations. The polarized absorption spectra along three crystalline axes are obtained from the reflection spectra by the K-K transformation and are shown in Fig. 6. The excitation energies and oscillator strengths of the crystal were calculated by the SCF-RPA exciton method; the results are shown in Table 6 together with the observed values.

In the crystalline b axis spectrum, four transitions (α^*, p, β', and β^*) at 33900, 40300, 42000, and 45600 cm^{-1} must be assigned to the B_2 state. The a and c axes spectra have four bands (α, β, γ, and δ) at 29400, ≈40000, ≈44000, and 53000 cm^{-1} which should be assigned to the A_1 state. Band positions of the vibronic levels of the α and α^* states can be compared with those in the solution spectrum, as shown in Table 5. The factor group splitting and the crystal field shift are negligibly small in the a and c axes spectra,

although large shifts are observed in the b axis spectrum. Tables 4 and 6 show that the oscillator strength of the α state is 0.12 ($3\,f^{\text{solution}}$) in the molecule and 0.29 (f^a+f^c) in the crystal and the hyperchromism is observed. In the α^* state, the intensity of the molecule ($3\,f^{\text{solution}}=0.48$) is comparable with that of the crystal ($f^b=0.54$). The p and β states are hyperchromic and the intensities of the molecule increase in the crystal. The observed dichroic ratios (f^b/f^c) of the α and γ states are about 2.6, while the oriented gas polarization ratio is 3.2. Those of the other states (β and δ) deviate from the values expected from the oriented gas model and may be explained by the intermolecular interaction.

Dibenzofuran. The solution spectrum is depicted in Fig. 7 and the theoretically calculated results of the molecule are given in Table 7 together with the assignment of the observed states. The first band, extending from about 33000 to 40000 cm^{-1}, has structure and consists of both the short axis polarized state (α state) and the long axis polarized state (α^* state). The α state in the region of the lowest energy originates at 33100 cm^{-1} and the successive vibronic levels occur as the shoulders at 34600 and 36100 cm^{-1}. The α^* state is observed as sharp peaks; the principal origin is at 33600 cm^{-1} and the higher levels are located at 34800 and 35600 cm^{-1}. The assignment for these two bands is supported by comparison with the crystalline spectra, as shown below. The third state (p state) also has structure; the origin is observed at 40100 cm^{-1} and other levels appear at 40900 and 41400 cm^{-1}. This band is assigned to the B_2 state. There are many other states in the higher energy region: two shoulders at 43900 cm^{-1} (β state) and 47200 cm^{-1} (β^* state) and two intense bands at 45800 cm^{-1} (β' state) and

48300 cm^{-1} (γ state).

Dibenzofuran crystallizes with four molecules in an orthorhombic unit cell having space group Pnam (D_{2h}^{16}).[14] Each molecule is held in the lattice with the long axis exactly parallel to the c crystal axis and with the short in-plane axis in the ab plane. The dispositions of the four molecules in the unit cell are shown clearly in Fig. 8. The polarized absorption spectra along these crystal axes are given from the reflection spectra by the K-K transformation, as shown in Fig. 9.

TABLE 9. THE CALCULATED AND OBSERVED VALUES OF THE TRANSITION ENERGIES (E IN $10^3\,cm^{-1}$) AND OSCILLATOR STRENGTHS OF THE DIBENZOFURAN CRYSTAL

State		Obsd		Calcd	
		E	(f)	E	(f)
B_{3u}	α	32.6	(0.02)	33.8	(0.003)
(a axis)	β	43.5	(0.14)	44.9	(0.50)
	γ			49.6	(0.02)
	δ	≈55	(0.65)	56.9	(0.37)
B_{2u}	α	32.6	(0.06)	33.8	(0.004)
(b axis)	β	42.5	(0.60)	46.0	(0.99)
	γ			49.0	(0.04)
	δ	≈53.5	(0.76)	50.5	(0.39)
B_{1u}	α^*	33.3	(0.36)	34.8	(1.55)
(c axis)	p	39.1	(0.20)	36.0	(0.92)
	β'	≈46	(1.30)	44.4	(1.95)
	β	≈53.5	(0.27)	52.1	(0.10)

In the crystalline c axis spectrum, four transitions (α^*, p, β', and β^*) observed at 33300, 39100, 46000, and 53500 cm^{-1} must be polarized along the long axis of the molecule and may be assigned to the B_2 state. The α^* state is located at 33300 cm^{-1} and the following

levels are observed at 34500 and 35300 cm^{-1}. The p state originates at 39100 cm^{-1} and the higher level appears at 40600 cm^{-1}, while the second level at 40900 cm^{-1} in the solution spectrum can not be observed. The a and b axes spectra have three bands (α, β, and δ states) at 32600, about 43000, and 55000 cm^{-1}, corresponding to the short axis polarized band of the molecule, and can be assigned to the A_1 state. The α state has its origin at 32600 cm^{-1} and the higher successive levels are observed at 34000 and 35400 cm^{-1}.

The excitation energies and oscillator strengths of the crystal were calculated by the SCF-RPA exciton method; the results are shown in Table 9, in which the intermolecular interactions for the inner zone were calculated to be 50 Å. The factor group splitting is slightly observed for the β and δ states. However, many transitions in the crystal are red-shifted by the crystal force compared with the transitions in solution. The comparison between the observed oscillator strengths of the molecule and crystal shows that the oscillator strength of the β band is 0.51 ($3\,f^{\text{solution}}$) in the molecule and 0.74 ($f^{a}+f^{b}$) in the crystal and the hyperchromism is observed in the range of 44000 cm^{-1}. On the other hand, the α^* state is hypochromic and the intensity of the molecule ($3\,f^{\text{solution}}=0.87$) decreases to 0.36 ($f^{c}$) in the crystal. Such decreases of the intensity are also observed in all other state regions. The observed dichroic ratios (f^{b}/f^{a}) of the α and β states are 3.0 and 3.6, respectively. These values are comparable with the oriented gas polarization ratio of 3.6. However, that of the β state deviates from the values expected from the oriented gas model.

The author would like to express his deep gratitude to Professor Jiro Tanaka of this university for his kind encouragement and critical reading of the manuscript.

The Alkoxylation of Aerosil Silica with C_1–C_4 Alcohols

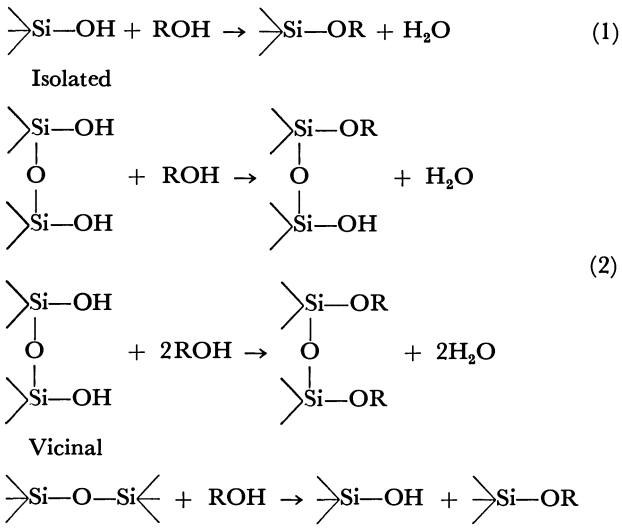
Shigeto KITAHARA

Fukuoka University of Education, Akama, Munakata, Fukuoka 811-41

(Received March 8, 1976)

The Aerosil surface was treated with C_1–C_4 alcohols under both high-pressure and low-pressure conditions. The high-pressure treatment was carried out at various temperatures up to 250 °C using an autoclave, while the low-pressure treatment was done at 280 °C under vapor pressure at room temperature. The surface changes were followed by IR spectroscopy, and the carbon content was determined. The degrees of alkoxylation (OR groups/100 Å^2) of the Aerosils treated sufficiently under low pressures were 1.3—1.6, approximately equal to the amount of OH isolated before the treatment, while the values under high pressures reached 2.3—3.4, equal or near to the amount of the total OH. The values for methoxylation were particularly higher, while those for *t*-butoxylation were quite low. These results, in addition to the observation of the IR spectra, indicate that the isolated OH groups are predominantly esterified under low pressures, while under high pressures the vicinal OH groups are esterified as well, and the opening of the siloxane bonds occurs easily in the case of methoxylation. The stability of the alkyl groups on the Aerosil against heating decreased in the order of: primary>secondary>tertiary.

It is well known that a silica gel surface is alkoxylated with alcohols and that the resulting surface is hydrophobic. It is considered[1-3] that the alkoxylation occurs through the esterification of surface hydroxyl groups and the opening of surface siloxane bonds. The surface hydroxyls consist of the isolated OH, the single OH, the vicinal OH, and the hydrogen-bonded OH.



The reaction has been studied by several workers[1-17] under both high- and low-pressure conditions; however, the investigations under the two conditions have been carried out separately by different workers. Regarding a comparison in the alkoxylations under the two conditions, only Stöber *et al.*[4] have reported comparatively the degrees of alkoxylation under the two conditions. From the values, a satisfactory discussion is impossible because of the differences in the experimental conditions other than the pressure.

In the present study, including the differences in the alkoxylations under the two conditions, the effects of the kinds of alcohols and the experimental conditions on the reaction were systematically examined by means of C_1–C_4 alcohols. The conditions under which Reactions 1, 2, and 3 take place were discussed on the base of the results. In addition, the stability against the heating of the alkoxyl groups on the Aerosil surface was examined.

Aerosil-200 (Japan Aerosil Co., Ltd.) was chosen as the sample, because the Aerosil powder was adequate for the production of a transparent disc, and the same kinds of silica have been used by many workers. The reaction was mainly carried out under high pressures using an autoclave. Some runs were carried out under low pressures, though, that is, under vapor pressures of the alcohols at room temperature. The surface changes upon the treatments were followed by infrared spectroscopy, and the carbon content was determined.

Experimental

Materials. The Aerosil powder was pressed into discs 10 mm in diameter, each weighing about 10 mg, at a pressure of about 5 ton/cm^2. All the alcohols used were the purest commercially available reagents.

The surface area of the Aerosil was determined by means of the BET method, and the cross-sectional area of nitrogen was assumed to be 16.2 Å^2. The surface area of the disc before the treatment was 217 m^2/g, while those of the discs alkoxylated sufficiently were 176—188 m^2/g.

The content of the total hydroxyl groups of the Aerosil was determined from the weight loss induced by heating the Aerosil, previously dried to a constant weight at 110 °C, for 4 h at 1100 °C. The content of the isolated hydroxyl groups was determined from the chlorine content on the surface of Aerosil allowed to react with dichlorodimethylsilane, according to the procedures reported by Armistead *et al.*[18] The chlorine content was determined as follows: the chlorine on the Aerosil was extracted with a 0.1 M-NaOH solution, and then the amount of chlorine in the solution was titrated with a 0.0141 M-$Hg(NO_3)_2$ solution according to the procedures described in JIS-K0101 of the Industrial Analysis. The amount of the total OH groups and that of the isolated OH on the surface were 2.7 and 1.5 groups per 100Å^2 respectively. The former agreed with the value of 3.0±0.3 reported by the manufacturer of the Aerosil. The latter is considered to be reasonable by comparison with the following values obtained for the Aerosils: 1.4—1.5 by Hair *et al.*,[19] 1.4±0.1 by Armistead *et al.*,[20] 1.4±0.3 by Colin *et al.*,[21] and 1.4 by Tsutsumi *et al.*[12]

Alkoxylation Processes. The autoclave used was made of stainless steel and had a volume of about 30 ml. Several discs were placed in the upper part within the autoclave,

supported with a holder and above the liquid phase of 15 ml of alcohol brought into the autoclave. Prior to use, some discs were heated for 3 h at constant temperatures over the range of 550 to 900 °C in the air. The autoclave was heated in an electric oven and was kept at a constant temperature. The reaction was carried out at temperatures over the range of 30—250 °C. The autoclave was quenched with running water immediately after it was taken out of the oven.

In the case of low-pressure treatment, the discs were allowed to stand in contact with alcohol vapor at 280 °C in a glass apparatus. Prior to use, the discs were out-gassed in the same apparatus for 3 h at 280 and 570 °C under a residual pressure of about 10^{-5} Torr.

Infrared Spectroscopy. The spectrometer used was a Hitachi EPI-G Spectrophotometer. The discs were taken out into the atmosphere after they had been out-gassed; then they were immediately subjected to the infrared measurement. The moisture in the atmosphere will have little effect on them, since the discs alkoxylated have hydrophobic surfaces.

Determination of the Alkoxyl Group Concentration on the surface. The carbon content of the discs was measured by the usual combustion method. The amount of the alkoxyl groups (mol/g) was calculated from the carbon content. The degree of alkoxylation, the surface concentration of alkoxyl groups per 100Å^2, was determined from the amount of the alkoxyl groups and the surface area of the disc. The relative amount of the alkoxyl groups was also determined by the spectroscopic method.

Results and Discussion

Effect of Reaction Temperature on the Alkoxylation. It took a few hours for the autoclave to be heated to 250 °C. In order to follow the change in the Aerosil surface during that period, the infrared spectra of the Aerosil were observed at several stages during the course of heating. Those for *n*-BuOH are illustrated in Fig. 1. The increase in the bands at 2800—3200 cm^{-1} due to butyl groups corresponding to the decrease in the band at 3750 cm^{-1} due to the isolated OH groups indicates that the isolated OH groups were esterified with *n*-BuOH.

The discs were treated with the alcohols in the autoclave for 20 h at the given temperatures. The infrared spectra of the resulting discs were then observed. The spectral changes with an increase in the reaction temperature were similar to those shown in Fig. 1. The changes were quantitatively followed by means of both the optical density for the 3750 cm^{-1} band and that for the 2960 or 2970 cm^{-1} band assigned to CH stretching. Figure 2 illustrates the results obtained for the Aerosils treated with MeOH and *n*-PrOH. In Fig. 2, the increase in the optical density of the 2960 or 2970 cm^{-1} band is attended by the decrease in that of the 3750 cm^{-1} band. This relation clearly indicates that the isolated OH groups are increasingly esterified with an increase in the reaction temperature.

Figure 3 shows the amounts of alkoxyl groups obtained from the carbon content as a function of the reaction temperature. The amounts of every alkoxyl group increased with an increase in the temperature, and each arrived at its highest value at 200—250 °C. This change corresponds to the change in the optical densities of the bands due to alkyl groups in Fig. 2.

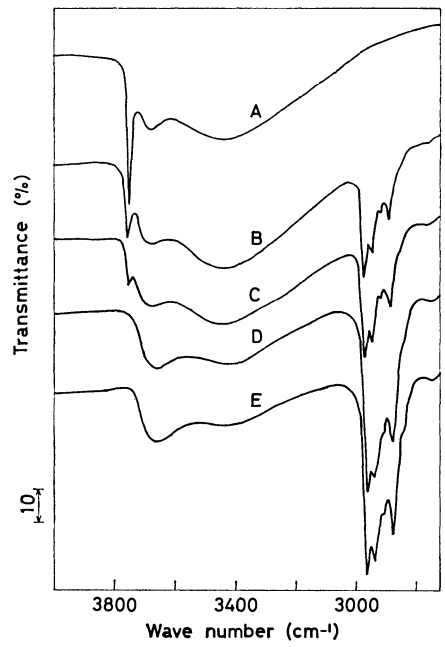


Fig. 1. Change of infrared spectra of Aerosil treated with 1-butanol during the course of reaction.
A: Original Aerosil, B: 100 °C, C: 160 °C, D: 200 °C, E: 240 °C (The numerical values indicate the temperatures at each stage during the course of heating up to 250 °C).

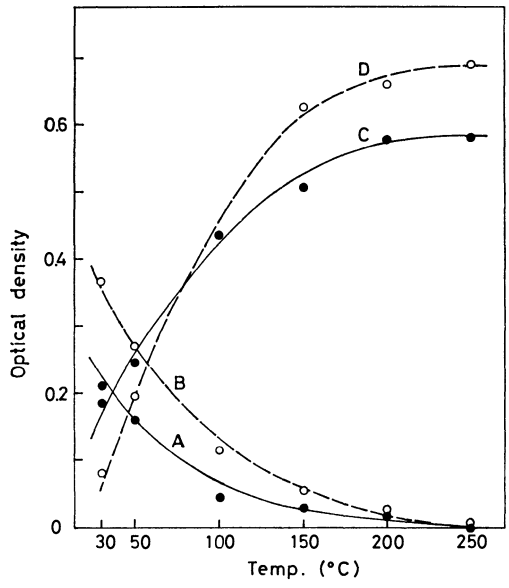

Fig. 2. Optical density for the isolated silanol band and that for the alkyl band as a function of reaction temperature.
A: OH band at 3750 cm^{-1} for the Aerosils treated with methanol, B: OH band at 3750 cm^{-1} for the Aerosils treated with 1-propanol, C: CH_3 band at 2960 cm^{-1} for the Aerosils corresponding to A, D: n-C_3H_7 band at 2970 cm^{-1} for the Aerosil corresponding to B.

The Aerosil treated with methanol had the highest values among all the alkoxylated Aerosils throughout the temperature range, the values decreased in the

order of: MeOH > EtOH > *n*-BuOH > *i*-BuOH > *s*-BuOH. The values for *n*-PrOH and *i*-PrOH are similar to those for *n*-BuOH and *i*-BuOH respectively; therefore, those values are omitted in Fig. 3.

It has previously been reported[1,9] that *t*-BuOH did not react easily with silica gel. It was found from the characteristic adsorption bands due to the *t*-butyl groups, however, that the alkoxylation was effectively carried out for 3 h at 200—240 °C. The bands were intense, but small in comparison with those due to the other alkyls, and the band at 3750 cm^{-1} still remained to a considerable extent.

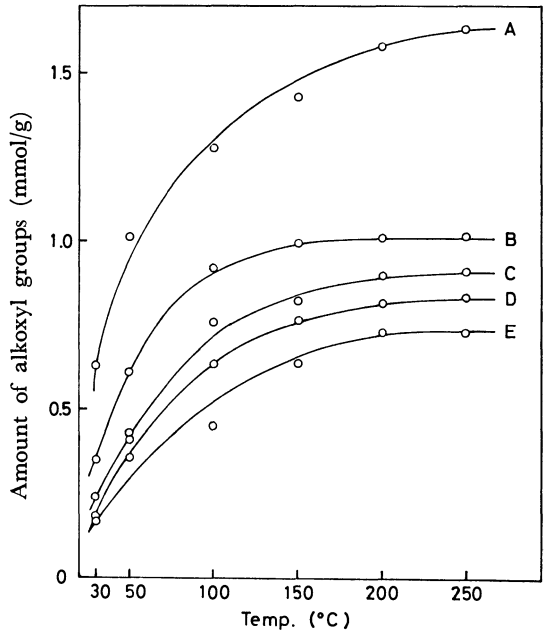

Fig. 3. Amount of alkoxyl groups as a function of reaction temperature.
A: Methoxyl, B: ethoxyl, C: butoxyl, D: isobutoxyl, E: secondary butoxyl.

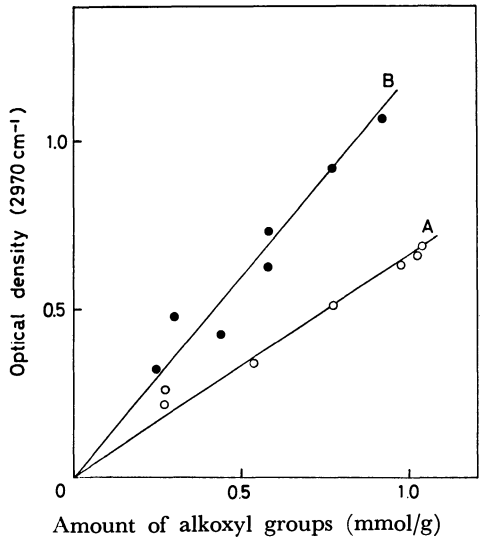

Fig. 4. Relation between amount of alkoxyl groups obtained from carbon content and optical density for the alkyl groups.
A: Ethoxyl, B: butoxyl.

The amounts of alkoxyl groups obtained by means of the carbon content were checked by means of the optical densities of the absorption bands due to the alkyl groups. Figure 4 illustrates the results for the ethoxyl and butoxyl groups. The two values bear a nearly linear relationship to each other.

Effect of Thermal Pretreatment on the Alkoxylation. The Aerosil discs were heated prior to the reaction at temperatures of 550, 700, 800, and 900 °C for 3 h in the air. The surface areas of the resulting discs corresponding to these temperatures, were 209, 167, 146, and 76 m^2/g respectively. The discs were treated with alcohols at 250 °C for 20 h in the autoclave immediately after the thermal pretreatment. Figure 5 shows the amounts of alkoxyl groups in the discs as a function of the thermal pretreatment temperature. The decrease in the amounts with the increase in the temperature must result from the decrease in both the surface area and the hydroxyl groups induced by the thermal pretreatment. The values for methoxyl were higher than those for the other alkoxyls at all pretreatment temperatures, as in the case of non-pretreatment. The infrared spectra of the Aerosils which were heated at 700, 800, and 900 °C prior to the reaction and then treated with methanol are shown in Fig. 6. The bands due to methyl groups decreased in intensity as the bands due to the isolated OH groups decreased with an increase in the pretreatment temperature.

Comparison of the Reactions under Low Pressures with Those under High Pressures. The infrared spectra of the Aerosils treated under low pressures were compared with those of the Aerosils treated under high pressures. The isolated hydroxyl band at 3750 cm^{-1} vanished almost entirely even upon the low-pressure treatment, not to mention the high-pressure treatment; however, the alkoxyl bands at 2800—3200 cm^{-1} ap-

peared with a stronger intensity in the case of the high-pressure treatment. The preliminary observations indicate that the isolated hydroxyl groups were almost completely esterified, even under low pressures, if sufficient time was available, while under high-pressures reactions other than the esterification of the isolated hydroxyl groups may have occurred simultaneously.

In order to obtain further information about the mode of the alkoxylation, the quantitative relations of the isolated OH and the alkoxyl groups on the Aerosils alkoxylated in varying degrees were examined by means of the optical densities of the two groups. The degrees of the alkoxylation were made to vary by a change in the reaction time under low-pressure conditions and by a change in the reaction temperature under high-pressure conditions. The optical densities for the methyl and propyl bands are plotted against those for the isolated OH band, in Fig. 7. The values bear a linear relationship to each other about the Aerosils with low optical densities of the alkyl bands; however, about those with higher optical densities upward deviations from the linearity were observed. These results show that the alkoxylation under low-pressure conditions is due only to the esterification of the isolated OH groups and support the above consideration that the alkoxylation under high-pressure conditions involves reactions other than esterification.

Comparison of the Degrees of Alkoxylation. Table 1 shows the degrees of alkoxylation for the completely

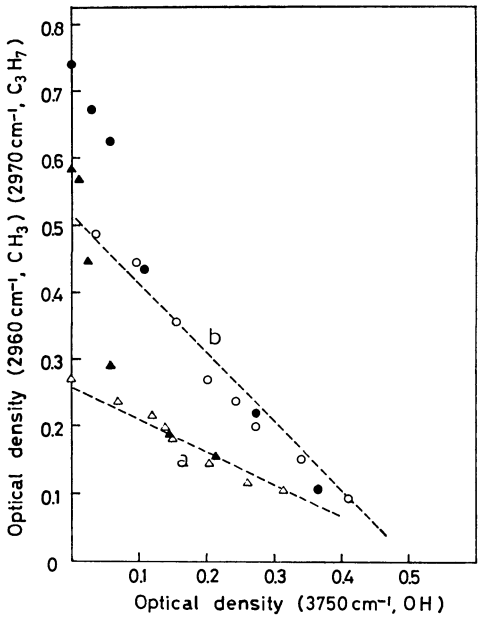

Fig. 7. Relation between optical density for the isolated silanol and that for the alkyl groups.
a △, ▲: Aerosil treated with methanol, b ○, ●: Aerosil treated with 1-propanol, △, ○: low-pressure treatment; ▲, ●: high-pressure treatment.

alkoxylated Aerosils. The values in the case of the low-pressure treatment were lower than those in the case of the high-pressure treatment. The former were approximately equal to the surface concentration of the isolated OH groups, 1.5 groups/100 Å², although the values for methoxyl groups were a little higher. The latter were in the range of 2.3—3.4 groups/100 Å², except for the much higher value for methoxyl, and were equal or near to the surface concentration of the total OH groups, 3.0 groups/100 Å². These facts indicate that, under low pressures, the alcohols react in a 1 : 1 ratio with the isolated OH groups, while under high pressures they react in a 1 : 1 with the total OH groups. However, the branched-chain alcohols can not react with all the OH groups completely because of their larger cross-sectional molecular areas. The degree of alkoxylation in the case of the high-pressure treatment decreased in the following order:

Table 1. Degrees of alkoxylation
(Alkoxyl groups/100 Å²)

Alcohols	Low-pressure		High-pressure	
	Thermal pretreatment at 280 °C	Thermal pretreatment at 570 °C	Non	Thermal pretreatment at 550 °C
MeOH	1.8	1.9	5.5	5.5
EtOH	1.6	1.8	3.4	2.5
n-PrOH	1.4	1.6	3.2	2.4
i-PrOH	1.4		2.7	
n-BuOH	1.3	1.7	3.2	2.4
i-BuOH	1.3		2.7	
s-BuOH	1.3		2.3	
t-BuOH	0.4		0.7	

MeOH> EtOH> *n*-BuOH> *i*-PrOH, *i*-BuOH> *s*-BuOH >*t*-BuOH. This order was the same as that of the amount of alkoxyl groups, since there was no considerable difference in the surface area of the alkoxylated Aerosils. Lambert *et al.*[16] have reported the same tendency for the pentanol isomers under low pressures. As they have explained, the steric factors must play an important part. That the degree of methoxylation was much larger than the concentration of the total OH groups indicates that, in addition to Reactions 1 and 2, Reaction 3 contributes in no small measure to the methoxylation. It has been concluded in a previous paper,[22] from the dissolution of silica gel in methanol methanol can easily open the siloxane bond at high temperatures and high pressures. The higher degree for the methoxylation is perhaps based on this function of methanol, in addition to the small cross sectional area of a methoxyl group.

The thermal pretreatment had an effect on the alkoxylation under low-pressure conditions, as is well known, but it was somewhat inhibitory of the alkoxylation under high-pressure conditions, as shown in Table 1. Only the methoxylation was not affected by the thermal pretreatment. In the runs under high pressures, the discs were heated in the air and then subjected to room temperature, if only for a moment, before they were sealed with an alcohol in the autoclave. During this procedure, not only the strained siloxane[2,22,23] but also the stable siloxane are caused by the dehydration of the vicinal OH groups. The stable siloxane can not easily be opened with methanol. The lowering of the degrees of alkoxylation by thermal pretreatment may be attributed to the alteration of the vicinal OH groups into the stable siloxane bonds.

Stability of Alkoxyl Groups on the Aerosil Surface against Heating. The Aerosils alkoxylated were heated at various temperatures in a vacuum of about 10^{-5} Torr, and their changes were observed by means of the infrared spectra. Morterra *et al.*[24] have observed the change about the methyl group, and Raymond *et al.*[15] have observed that about the butyl and secondary butyl groups; however, no systematic observation through various kinds of alkyls has yet been carried out. A remarkable removal of the alkyl groups occurred at the following temperatures for each alkyl group: Me: 650—750 °C, Et, *n*-Pr, *n*-Bu, *i*-Bu: 500—550 °C, *i*-Pr, *s*-Bu: 420—470 °C, *t*-Bu: about 400 °C. Methyl groups were particularly stable, and the infrared observations suggested that the removal reaction of the methyl groups is different from that of the other alkyl groups. It was found from the above results that the stability decreases in this order; primary> secondary> tertiary and that it is independent of the number of the carbon.

The author is indebted to Miss Mayumi Fukui for obtaining the IR spectra and for her carbon-content determinations.

The Photoelectrolytic Reaction of Chlorophyll–β-Carotene–Quinone Electrodes

Fujio TAKAHASHI and Ryoichi KIKUCHI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received April 7, 1976)

The NAD^+ (nicotinamide adenine dinucleotide) reduction was carried out under illumination by using a platinum electrode coated with chlorophyll and quinone. Various quinones and β-carotene were used as components of the cathode layer to obtain a higher current density. The highest current density, 13 $\mu A/cm^2$, was obtained in the case in which the cathode layer contained 0.01 $\mu mol/cm^2$ of chlorophyll and the molar ratio of chlorophyll: chloranil : β-carotene was 1 : 1 : 2. The role of quinone and β-carotene in the cathode layer was discussed.

Since the photochemical reaction in chloroplasts can be compared with an electrochemical reaction, Photosystem I and Photosystem II can be regarded as a cathode and an anode, respectively. It was reported that the photoelectrolysis was carried out by the system connecting the chlorophyll-1,4-naphthoquinone electrode and the chlorophyll-9,10-anthracenediol electrode under illumination.[1] The photoexcited chlorophyll-1,4-naphthoquinone electrode and chlorophyll-9,10-anthracenediol electrode behaved as a cathode to reduce NAD^+ (nicotinamide adenine dinucleotide) and as an anode to oxidize hexacyanoferrate(II) (The expression "chlorophyll-redox compound electrode" is used for an electrode lined with a chlorophyll/redox compound mixture. Similar expressions are used where a different compound is specified.)

The redox potentials of plastocyanin and cytochrome f in Photosystem I (+0.37 V)[2] are more positive than that of plastoquinone in Photosystem II (*ca.* 0 V).[2] Therefore, plastocyanin and cytochrome f in Photosystem I are able to oxidize the reduced plastoquinone in Photosystem II. In turn, the reduced plastocyanin and cytochrome f transfer the electron to the chlorophyll cation in Photosystem I, and plastoquinone gains the electron from the photoexcited chlorophyll in Photosystem II. It was assumed that the electron transfer from Photosystem II to Photosystem I might occur with the driving force caused by the difference of redox potentials of the redox compounds in the photosystems. Therefore it was expected that a higher potential difference between two chlorophyll electrodes could be obtained under illumination if a redox compound which exhibited a more positive redox potential than 1,4-naphthoquinone was used as a component in the cathode layer.

β-Carotene, one of carotenoids in the photosystems, is known to exhibit a photoconductive property[3] and to be utilized in the mixture of chlorophyll, albumin, and 2-methyl-1,4-naphthoquinone to make an electron transfer easier under illumination.[4] An energy transfer from β-carotene to chlorophyll is known from a study of photoexcitation with a black lipid membrane containing chlorophyll and β-carotene.[5] From these facts it was thought that the addition of β-carotene as one of components in the electrode layer might make the current density higher.

This paper will present some recent results on the photoelectrolysis by using chlorophyll electrodes and the speculation on the role of quinone and β-carotene in the electrode layer under illumination.

Experimental

Chlorophyll, which was a mixture of type a and b, was prepared from spinach leaves by the method of Jacobs *et al.*[6] Various quinones were purified by sublimation. NAD^+ used was made by the Oriental Yeast Co. The other chemicals, including β-carotene, were of reagent grade or the best commercially available grade. The conducting adhesive used was Fujikura-kasei Dotite D-362.

Catholyte (anolyte): 5 mM NAD^+ (5 mM potassium hexacyanoferrate(II) in M/30 phosphate buffer (pH 6.9).* For the photoelectrolysis 60 ml of catholyte and anolyte were used.

Chlorophyll-redox compound electrodes were prepared by the method described in the previous paper:[1] The cathode layer on a platinum plate (2 cm × 4 cm) consisted of 2.5 μmol of chlorophyll, 2.5 μmol of one of the quinones, and 0.1 g of conducting adhesive. The anode layer was prepared in the same manner as the cathode, except that 2.5 μmol of 9,10-anthracenediol was added in place of the quinone. Two-layer electrodes:** A platinum wire (1 cm long with a diameter of 0.1 cm) connected with a sealed wire was used as an electrode. Two drops (0.1 ml) of 5 mM chlorophyll solution in hexane spread on the water surface. A thin layer of chlorophyll remained after evaporation of the hexane on the water surface. The thickness of the chlorophyll layer was estimated to be *ca.* 0.05 μm because the diameter of the chlorophyll layer which remained on the water surface was about 5 cm. Two grams of conducting adhesive and 10 mg of chloranil were added into 50 ml of hexane to make a suspensoid. Two drops of the suspensoid were spread on the water surface in another beaker to make a layer containing conducting adhesive and chloranil. A two-layer electrode was prepared by the following method: The platinum wire was dipped into the chlorophyll layer spread on the water surface very quietly and then pulled up. The platinum wire was thus covered by a chlorophyll layer. In turn the platinum wire coated by the chlorophyll layer was dipped into the chloroanil layer spread on the water surface. Thus the chloranil layer was coated on the chlorophyll layer. The electrode coated with chloranil first and then with a chlorophyll layer was prepared in the same manner.

The same electric cell as reported in the previous paper was used for all the experiments. The photoelectrolytic reaction was carried out under illumination (1×10^4 lx) through a heat absorber with a photoreflector lamp (100 V, 500 W). The entire electric cell including the calomel electrode was placed in a thermostat and was controlled at 20 °C. Nitrogen gas was bubbling into the electrolyte during the

* $M = 1$ mol dm^{-3}.

** We defined "two-layer" as putting one layer upon another.

experiments.

The measurements of potential and current, and the determination of NAD^+ and hexacyanoferrate(II) were carried out in the same manner as described in the previous paper.[1)]

Results and Discussion

Various Chlorophyll–Quinone Electrodes. To make the current density of the photoelectric reaction increase, various quinones were used as a component of one layer of the chlorophyll–quinone electrode.

The photoelectrolytic reaction was carried out with the systems of chlorophyll–quinone electrode in NAD^+ solution and chlorophyll–9,10-anthracenediol electrode in hexacyanoferrate (II) solution. The photovoltage and photocurrent were determined when both electrodes were illuminated at 1×10^4 lx. The photovoltage was found to increase with quinones exhibiting a more positive redox potential, as shown in Fig. 1 (above). The cathodic potential and current were observed at the chlorophyll–quinone electrode under illumination. When the light was turned off, the chlorophyll–quinone electrode became a nanode and the chlorophyll–9,10-anthracenediol electrode became a cathode. The potential difference of the chlorophyll–quinone *vs.* the chlorophyll–9,10-anthracenediol electrode in the dark increased with a positive shift of the redox potential of quinone as shown in Fig. 1 (below). The electrode potentials of the chlorophyll–1,4-naphthoquinone electrode and the chlorophyll–chloranil electrode *vs.* calomel electrode were obtained to be +80 and +90 mV in the dark, and −46 and −93 mV under illumination.

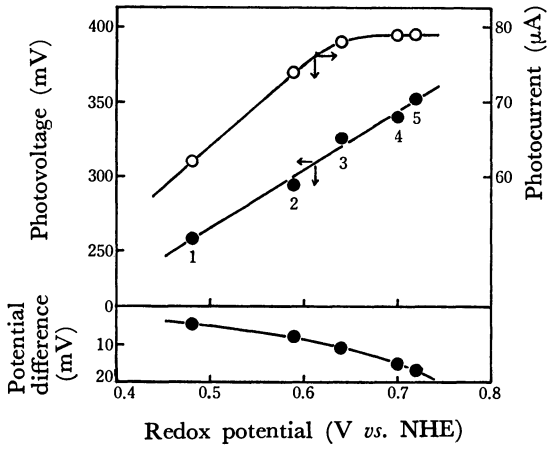

Fig. 1. Various chlorophyll–quinone electrodes.
1: 1,4-Naphthoquinone, 2: dimethyl-*p*-benzoquinone, 3: *p*-toluquinone, 4: chloranil, 5: 2,5-dichloro-*p*-benzoquinone. The values of redox potential of various quinones were cited from Ref. 7.

The value of the photocurrent reached a plateau in the case that chloranil and 2,5-dichloro-*p*-benzoquinone were used as components of the cathode layer.

The Effect of β-Carotene. To make the electric resistance of the chlorophyll electrode lower under illumination, β-carotene was added as a component of both anode and cathode layers. The chlorophyll-

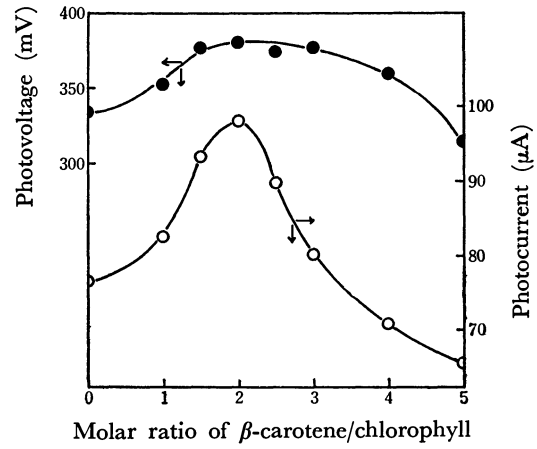

Fig. 2. The effect of β-carotene.

chloranil electrode was used as a cathode. The quantity of chlorophyll and chloranil (9,10-anthracenediol) of the electrode layer was the same as in the previous section, except for the addition of 0—12.5 μmol of β-carotene.

By using the chlorophyll–chloranil–β-carotene electrode as a cathode and the chlorophyll–9,10-anthracenediol–β-carotene electrode as an anode, the photocurrent was measured as shown in Fig. 2. The maximum photocurrent was obtained at the molar ratio of chlorophyll : chloranil (9,10-anthracenediol) : β-carotene = 1 : 1 : 2. The maximum photovoltage was about 50 mV higher than in the case where β-carotene was not included as a component of the electrode layers.

It is plausible that in the electrode layer chlorophyll, chloranil, and β-carotene may form a ternary complex which might exhibit a photoconductive property.

The Thickness of the Electrode Layer. The thickness of the electrode layer had to be considered as one of the factors which influences the electric resistance of the electrode. It was expected to obtain larger potential differences and current densities by reducing the thickness of the electrode layer.

The chlorophyll electrodes which were coated by different quantities of electrode layers were prepared with a mixture of chlorophyll, chloranil (9,10-anthracenediol), β-carotene (molar ratio of 1 : 1 : 2),

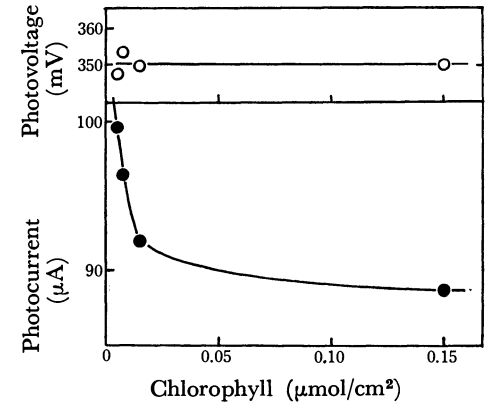

Fig. 3. The thickness of electrode layer.

and conducting adhesive (the mixing ratio: 0.1 g of conducting adhesive/2.5 μmol of chlorophyll).

The photocurrent density was found to increase by decreasing the quantity of the electrode layer from 0.16 to 0.005 μmol of chlorophyll/cm² (Fig. 3). A constant photocurrent could not be produced below 0.005 μmol/cm². The optimum thickness of the electrode layer was found to be about 0.01 μmol of chlorophyll/cm² (Fig. 3).

Photoelectrolysis. The photoelectrolysis was carried out by using the electrodes which were prepared with the optimum conditions of quantity (0.01 μmol/cm² of chlorophyll) and mixing ratio as in the previous section. The potential-time curves and the photocurrent-time curve are shown in Fig. 4. The potential difference and the current density were found to be 0.35 V and 13 μA/cm² under illumination. These values are higher than those in the case of the chlorophyll–1,4-naphthoquinone electrode (0.25 V, 8 μA/cm²) in the previous paper.[1] The quantity of electricity amounted to 5.29 C (corresponding to 54.8×10^{-6} F where F is the Faraday constant) after 12 h. This is much greater than the quantity of electricity passed for the reduction (oxidation) of chloranil (9,10-anthracenediol) in the electrode layer which contained 0.13 μmol of chloranil (9,10-anthracenediol). Meanwhile 7.4% NAD^+ was reduced and 14.2% hexacyanoferrate(II) was oxidized. The current efficiencies were 72% and 71%, respectively. When the light was turned off while the external circuit was kept closed, the reverse potential and the reverse current were observed to be 0.11 V and 10 μA/cm². The current decreased with time.

From the potential-current curves of the chlorophyll–chloranil electrode and the chlorophyll–chloranil-β-carotene electrode (Fig. 5), two reduction waves were observed, at −0.2 and −0.8 V *vs.* SCE; these were assigned to chloranil and NAD^+. The cathode potential in Fig. 4 (−0.1 V *vs.* SCE) was more positive than that obtained in Fig. 5. These results suggest that chloranil in the cathode layer could not be reduced during photoelectrolysis.

Two-layer Electrodes. To clarify the process of electron transfer on the cathode, the photoelectrolytic reaction was carried out with two-layer electrodes. The two-layer electrodes used were prepared as described in the experimental section. As the counter electrode a platinum electrode (2 cm×4 cm) was used.

In the case of the two-layer electrode coated with chloranil on a chlorophyll layer, very little current was produced, as shown in Fig. 6 (curve D). A higher current production by the two-layer electrode coated with chlorophyll on a chloranil layer in curve B was observed, as compared with curve D and with curve C, which was obtained by the single layer electrode coated with chloranil only.

It is deduced that the photoexcited chlorophyll can not, but chloranil can gain an electron from the counter electrode. It seems that the electron may

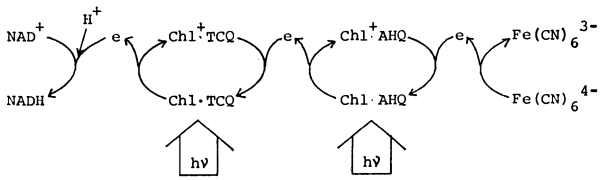
transfer from the reduced chloranil to the photoexcited chlorophyll. However, the reduced chloranil can not release an electron to NAD^+. On the other hand, the single layer electrode prepared from the mixture of chlorophyll and chloranil was able to keep producing much higher and constant current during the time tested (curve A).

The Process of Electron Transfer. It is known that the reduced plastocyanin and the reduced cytochrome f can reduce P700 under illumination.[8,9] It has been reported that a semiconductor electrode prepared by depositing chlorophyll on a single crystal of zinc oxide can exhibit an anodic behavior under illumination to transfer an electron from hydroquinone in electrolyte to zinc oxide through chlorophyll.[10] On the contrary it seems that an electron may not transfer in the order platinum, chloranil, chlorophyll, and NAD^+ in the case of a two-layer electrode. As a probable speculation, chlorophyll was thought to form a complex with chloranil in the cathode layer under illumination, and a transient state of the complex might drive the electron transfer from the layer of chlorophyll–9,10-anthracenediol in the anode to that of chlorophyll–chroanil in the cathode through platinum. A contact potential barrier, which was known to exist at the chlorophyll–metal contact,[11] might not influence the direction of current flow in the case of our chlorophyll electrodes. Because both cathode and anode were prepared in the same condition on a platinum plate, the contact potential barrier between chlorophyll and platinum at the cathode would offset that at the anode. The process of electron transfer can be expressed as the following: where Chl·TCQ and Chl·AHQ respectively represent the chlorophyll complexes of chloranil and 9,10-anthracenediol, and $Chl^+ \cdot TCQ$ and $Chl^+ \cdot AHQ$ mean the cations of these chlorophyll complexes The driving force of electron transfer from anode to cathode through the external circuit was found to increase as the redox potential of quinone in the cathode was made more positive, using the results in Fig. 1. The mechanism of electron transfer from the cathode to the catholyte will be discussed in another paper.



The authors express their sincere thanks to Professor Shuichi Suzuki of the Tokyo Institute of Technology for his encouragement.

Hydrogen Atom Transfer in the Quenching of Pyrene Fluorescence by Amines

Tadashi OKADA, Takeshi MORI, and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received April 14, 1976)

The mechanism of the quenching of pyrene fluorescence by primary and secondary amines has been studied by means of fluorescence measurements and transient absorption measurements with the use of laser photolysis as well as conventional flash photolysis methods. It has been confirmed that 1-hydro-1-pyrenyl radicals and amino radicals are produced in the course of the fluorescence quenching reaction. The relative yields of 1-hydro-1-pyrenyl radicals for various amine quenchers were estimated.

It is well known that excited pyrene forms heteroexcimers with *N,N*-dimethylaniline (DMA) and *N,N*-dimethylnaphthylamines. However, when aniline, *N*-methylaniline and naphthylamines are used as electron donors for the heteroexcimer formation with excited aromatic hydrocarbons in solution at room temperature, no heteroexcimer fluorescence can be observed, quenching of the fluorescence of aromatic hydrocarbon occurring even in nonpolar solvents.[1,2] It seems plausible that the charge transfer interaction in the encounter complex followed by some efficient radiationless processes plays an important role in the case of the quenching by primary or secondary amines.

A possible mechanism for this fluorescence quenching by amines with free N–H group might be the charge transfer followed by a rapid proton transfer from the amine to the aromatic hydrocarbon in the encounter complex. In the case of hydrogen abstraction by excited ketones, especially for the ketone–amine systems, it is frequently assumed that the photoreduction proceeds *via* the charge transfer from the amine to the triplet ketone followed by proton transfer.[3,4] In contrast to the case of carbonyl compounds, only a few studies have been carried out concerning the hydrogen abstraction reaction of excited aromatic hydrocarbons. No attempt seems to have been made dealing with direct measurements on the hydrogen abstraction process of excited hydrocarbons.

In order to elucidate the mechanism of the quenching of the aromatic hydrocarbon fluorescence by amines with free N–H group, we have made detailed studies on excited pyrene–amine systems by means of fluorescence measurements as well as transient absorption measurements.

Exprimental

Fluorescence spectra were measured with an Aminco-Bowman spectrophotofluorometer equipped with an HTV-R446S photomultiplier. An ordinary flash photolysis apparatus with photoelectric detection of the transient absorption spectrum was used. A small computer (1K) was used to analyze the time dependence of transient species. The nanosecond laser photolysis method was the same as reported elsewhere.[5]

GR-grade *N*-methylaniline (NMA), *N*-ethylaniline (NEA), *N*-butylaniline (NBA), dibutylamine (DBAm), butylamine (BAm), and diethylamine (DEAm) were carefully distilled and stored in a vacuum. GR-grade aniline (AN) was steam-distilled, dried over potassium hydroxide, distilled under reduced pressure and stored in a vacuum. GR-grade diisobutylamine (DIBAm) was distilled in a vacuum and stored. Diphenylamine (DPA) was recrystallized from ethanol and sublimed. Spectro-grade hexane was distilled over metallic sodium.

All solutions for the measurement were deaerated by freeze-pump-thaw cycles, amines being added by the method of vacuum distillation to the solution for the measurements. The concentration of pyrene was 2×10^{-5} M. A cylindrical quartz cell (10 cm long, 1 cm i. d.) was used for the flash photolysis.

Results and Discussion

Quenching Rate Constant. The fluorescence quenching rate constants, k_q, for pyrene–amine–hexane systems at room temperature were determined. The plot of $\log k_q$ *vs.* ionization potential I_p of amines is given in Fig. 1. The values of the quenching rate constant for aliphatic amine systems are considerably smaller as compared with those of aromatic ones. This seems to indicate that an additional activation energy over that for the aromatic amine system is necessary for the quenching processes in the pyrene–aliphatic amine systems. The difference in the quenching rate constant of aromatic and aliphatic amines was also observed in the case of the heteroexcimer formation of such systems as pyrene–DMA and pyrene–tributylamine (TBA) studied by Nakashima *et al.*[6] According to them, additional activation energy is necessary for the change of the structure of TBA from a pyramidal one to a planar one in the course of the electron transfer. Such a structural change may occur also in the case of the present systems.

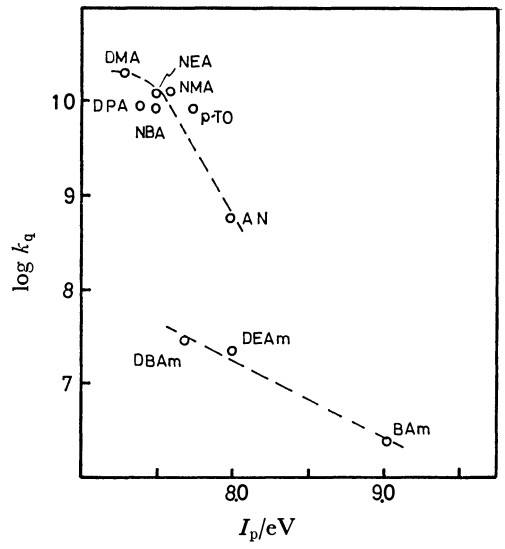

Fig. 1. Plot of $\log k_q$ *vs.* I_p for pyrene–amine–hexane systems at room temperature.

The relation between log k_q and I_p (Fig. 1) suggests that the mechanism of the quenching of the pyrene fluorescence may be charge transfer interaction in the encounter complex between excited pyrene and amine. The k_q for DMA is close to the rate constant of the diffusion-controlled reaction. Although k_q and I_p values of NMA or NEA are rather close to those of DMA, the heteroexcimer fluorescence can be observed only in the case of DMA. In view of this fact, we assume the following mechanism for the quenching by the primary or secondary amines:

$$\begin{array}{ccccccc} A^* + HD & \xrightarrow{k_q} & (A^- \cdots HD^+) & \xrightarrow{k_p} & (\dot{A}H \cdots \dot{D}) & \xrightarrow{k_d} & \dot{A}H + \dot{D} \\ & {\scriptstyle k_f'}\downarrow\ \ \downarrow{\scriptstyle k_1'} & & & \downarrow{\scriptstyle k_1''} & & \end{array} \quad (1)$$

If one assumes that the rate constants of radiative (k_f') and radiationless (k_1') transitions of the charge transfer state ($A^- \cdots HD^+$) are equal to those of the pyrene–DMA heteroexcimer in hexane, respectively, one can estimate the order of magnitude of the rate constant k_p in Eq. 1 by means of the following quantities.

$$\Phi'_{DMA} = \tau_f' k_f' = 0.66$$

$$\Phi'_{NEA} = \frac{k_f'}{k_f' + k_1' + k_p} \lesssim 10^{-4} \text{ (limit of the detection system)}$$

$$1/\tau_f' = 2.6 \times 10^6\ s^{-1}$$

where Φ'_{DMA} and Φ'_{NEA} are the fluorescence quantum yields of pyrene–DMA and pyrene–NEA heteroexcimers, respectively, and τ_f' is the lifetime of pyrene–DMA heteroexcimer. Thus, $k_p + k_1' \sim k_p \gtrsim 2 \times 10^{10}\ s^{-1}$.

A reaction mechanism similar to the above was also assumed by Yang and Libman for the primary process in photochemical addition of secondary amines to anthracene.[7]

Transient Absorption Spectra. If the reaction mechanism described above is valid, the transiently produced radicals may be detected by means of laser photolysis or conventional flash photolysis. The results of measurements for pyrene–NMA–hexane and pyrene–DBAm–hexane systems are given in Figs. 2 and 3, respectively. Absorption bands were observed in the 380—430 nm region, which could be explained as a superposition of absorption bands of pyrene triplet state and some unknown transient species. At the delay time of 50 μs, the T-T absorption band becomes much weaker while another absorption band remains fairly strong. Similar spectra were observed for all the systems of pyrene–primary and secondary amines. As an example, the transient spectra of pyrene–aniline–cyclohexane system obtained by means of the conventional flash photolysis method are shown in Fig. 4.

In order to identify the long lived transient species, 1,2-dihydropyrene in methylcyclohexane–isopentane (3 : 1) mixture was irradiated with a low pressure mercury lamp, and absorption spectra of photoproduct were measured. The spectrum obtained (Fig. 5a) might be assigned to the photoproduct radical (1-hydro-1-pyrenyl radical), being similar to the spectra shown in Figs. 2—4. As regards these results, we

made a semi-empirical open shell SCFMO calculation on the π-electronic state of the odd alternant hydrocarbon ().[8] The result indicates strong absorption bands at 3.7 and 4.9 eV, respectively, of which the lower energy one might be identified with the spectrum observed by means of the low temperature photolysis of 1,2-dihydropyrene and of the flash photolysis of the pyrene–amine systems.

On the other hand, pulse radiolysis studies on pyrene in ethanol containing 1 vol % sulfuric acid were made by Kira.[9] The reaction scheme of this system may be written as follows:

$$C_2H_5OH \rightsquigarrow e^-_{sol},\ \dot{H},\ C_2H_5OH_2^+,\ C_2H_5\dot{O},\ \text{and other neutral radicals}$$

$$e^-_{sol} + H^+ \longrightarrow \dot{H}$$

$$\dot{H} + P_y \longrightarrow P_y\dot{H}$$

where P_y and $P_y\dot{H}$ are pyrene and 1-hydro-1-pyrenyl radical, respectively. The spectrum obtained by Kira is given in Fig. 5b. The spectrum shows peaks at 405 nm and 395 nm, being essentially the same as the spectrum obtained by subtracting the T-T ab sorption band of pyrene from the transient spectra observed in pyrene–amine systems.

Since the absorption spectra of anilino radicals were observed in the wavelength region of *ca.* 400 nm and their intensities are rather weak,[10,11] we cannot distinguish these bands from the observed spectra. However, in the case of pyrene–DPA–hexane system, the absorption spectrum of the diphenylamino radical with maximum at *ca.* 770 nm[12] was observed clearly by means of flash photolysis (Fig. 6). Thus, the formation of both kinds of radicals has been confirmed exprimentally.

The decay processes of transient species were examined by analyzing precisely the time dependence of the transient absorption intensity at several wavelengths. It was found that the pyrene triplet state shows a single

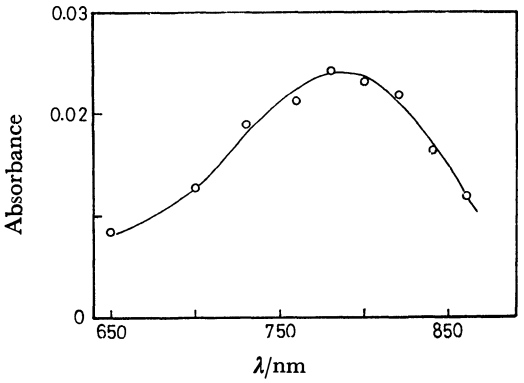

Fig. 6. Transient absorption spectrum of pyrene–DPA–hexane system at 200 μs after flash excitation. [Pyrene]$=2\times10^{-4}$ M, [DPA]$=1\times10^{-2}$ M.

exponential decay with a lifetime of *ca.* 30 μs in the case of pyrene–aniline system and that the decay of diphenylamino radical monitored at 780 nm is due to the bimolecular reaction. In contrast to the results of amino radical and pyrene triplet state, the decay process of 1-hydro-1-pyrenyl radical detected at 400 nm is rather complex. Namely, it shows an exponential decay at first over several hundred μs followed by a bimolecular decay. The two component decays in the wavelength region of the absorption band of 1-hydro-1-pyrenyl radical was observed for all pyrene-amine systems studied here. By analyzing the decay curves and time dependences of the spectra, it was established that the transient species which shows the bimolecular decay is formed from the 1-hydro-1-pyrenyl radical decaying unimolecularly. The mechanism of this two component decay process is not very clear at the present stage of investigation.

For interpretation of the fluorescence quenching mechanism in terms of the hydrogen atom transfer reaction, we assume that the reaction occurs in the singlet excited state. There is a possibility that the radicals are formed by the reaction in the triplet state. It is rather difficult to confirm this possibility since the absorption bands of the pyrene triplet state are overlapped with those of the radical. We have examined the problem by using the dilute solution of anthracene–DPA–hexane system with [anthracene]$=1\times10^{-4}$ M and [DPA]$=1\times10^{-3}$ M, since the T-T spectrum of anthracene is not overlapped with that of the hydrated radical as those of pyrene. The results of measurements by flash photolysis clearly show that no hydrogen atom transfer reaction occurs in the triplet state since no absorption of the diphenylamino radical is detected by the addition of DPA.

In order to evaluate the relative yield of 1-hydro-1-pyrenyl radical, the transient absorption due to the triplet state of the equimolar pyrene solution without amine was used as a standard. The relative yield was estimated by OD_R/OD_T, where OD_R and OD_T are absorbance extrapolated to $t=0$ of the 1-hydro-1-pyrenyl radical observed at 400 nm and that of pyrene triplet state of the standard solution observed at 415 nm, respectively. The values of OD_R/OD_T for various amines are summarized in Table 1, together with the

values of I_p of amines. Since the k_q values for an amine differ, we should make correction for the difference by changing the concentrations of amines so that the extent of fluorescence quenching by various amines is equal. However, because of the large difference between the k_q values of the aromatic and aliphatic amines, it is difficult to adjust the quenching degree to the same extent. Thus, the fluorescence of pyrene in solutions examined here was quenched more than 99% in the case of aromatic amines and 90% in the case of aliphatic amines.

We see from Table 1 that OD_R/OD_T values for AN, BAm and DEAm are small as compared with the values for the other amines though the fluorescence of pyrene is quenched almost completely. The result suggests that in the case of these amines a process of returning to the ground state from radical pair $\dot{A}H....\dot{D}$ is predominant.

The quenching process of triplet benzophenone by amine has been directly demonstrated with the laser photolysis method by Arimitsu *et al.*[4,13] It has been found that no ketyl radical formation but ionic photodissociation to benzophenone anion and amine cation occurs in a strongly polar solvent such as acetonitrile, while photoreduction due to the hydrogen atom transfer from amine to ketone occurs efficiently in a nonpolar solvent, and these processes compete with each other, depending upon the solvent polarity.

In the present system, analogous solvent effects upon the transient absorption spectra as well as those upon the quenching rate constant have been observed. The k_q values for pyrene–AN, pyrene–DEAm and pyrene–DBAm systems in various solvents of different polarity are given in Table 2. We see that k_q increases with an increase in solvent polarity. The transient spectra of pyrene–AN–acetonitrile system show strong absorption bands of solvated radical ions (Fig. 7).

The k_q values for the pyrene–aniline system are much smaller than those of the other pyrene-aromatic amine systems. This seems to indicate that a considerable additional activation energy over that for the diffusional motion is necessary not only in the case of the pyrene–aliphatic amine systems but also for the quenching process in the pyrene–aniline system. The additional activation energy necessary for the charge transfer in the encounter complex becomes smaller with a decrease in the I_p values of amines. The result for the solvent effect upon the k_q value indicates that not only the I_p value of the quencher but also the solvent polarity affect the additional activation energy. Namely, it decreases with an increase in the solvent polarity, and the k_q value in polar solvents involves both hydrogen atom transfer and ionic dissociation. These two processes compete with each other, the ionic dissociation being predominant in a strongly polar solvent such as acetonitrile.

Since the $(A^-...HD^+)$ state is stabilized in polar solvents while the energy of $(\dot{A}H\cdots\dot{D})$ is independent of solvent polarity, the heteroexcimer fluorescence may be detected in slightly polar solvents, where the ionic dissociation is not predominant.

The authors are grateful to Professor S. Kato and his co-workers for use of the apparatus for flash photolysis, and for their valuable discussions concerning the experimental technique. The authors express their

Radiotracer Studies of the Adsorption of Surface Active Substances at Aqueous Surfaces. VI. Urea Adsorption on an Adsorbed Monolayer of a Nonionic Surfactant

Kazuo TAJIMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received May 1, 1976)

The surface tension and adsorption were observed by the Wilhelmy plate and radiotracer methods at the air-solution interface of an aqueous solution of urea and α-dodecyl-ω-hydroxyhexa(oxyethylene) ($D(EO)_6$). The adsorption of $D(EO)_6$ was dependent on the concentration of urea below the CMC values, but above the values it was independent of the concentration. Urea adsorption occurs positively for low-surface packing of the poly(oxyethylene) group of $D(EO)_6$, but negatively for the closest packing of the group and high concentrations of urea. It was confirmed that $D(EO)_6$ adsorption took place at the solution surface according to the Gibbs adsorption isotherm, which was taken into account as an activity coefficient in an empirical equation for the interactions of $D(EO)_6$ and urea in solution. Urea adsorption for the adsorbed monolayer of $D(EO)_6$ above the CMC value was interpreted assuming that urea, as for the nonionic micelle, was non-penetrating, which was examined by gel permeation.

The surface tension of the aqueous urea solution is almost invariant or is slightly increased with increasing urea concentration at the air-solution interface.[1,2] When covered with stearic acid[2] or protein[3] monolayers on the urea solution, urea adsorption occurs at the monolayers due to the dipole-dipole interactions of the urea and film substances, but not at the ionic monolayer of the stearate.[4] However, the micelle formation in the aqueous solution of ionic and nonionic surfactants is markedly affected by urea present in the solution, and the CMC value is shifted to higher surfactant concentrations.[5] Also, urea decreases the surface tension lowering of the surfactant solution, and causes a change in the activity of the surfactant in the solution due not only to a reduction of the dielectric constant of water, but also to a direct interaction with the surfactant.[6]

If the activity for each kinetic unit in the urea–surfactant solution is undeterminable, the Gibbs adsorption of solutes cannot be calculated from only the relationship between the surface tension and the apparent concentration of solutes in the solution,[7] without additional experimental information about the surface adsorption. In a previous paper,[1] the surface adsorption of a nonionic surfactant at constant concentration was measured as a function of the concentration of various additives, but no additive adsorption was obtained. The surface compositions of adsorbed mixed monolayers are not easily determined in comparison with the case of insoluble monolayers.

The present report is concerned with the elucidation of urea adsorption for the adsorbed monolayer by measuring the adsorption of nonionic surfactant at the air–solution interface. Further, the micelle size will be examined by the gel permeation of the urea–surfactant solution in order to check whether or not urea has penetrated into the micelle.

Experimental

Materials. α-Dodecyl-ω-hydroxyhexa(oxyethylene) ($D(EO)_6$), α-dodecyl-2,3-$^3H_2$-ω-hydroxyhexa(oxyethylene), and urea (EP. grade, purified by recrystallization with water) were the same as those used in previous experiments.[1] The water used was distilled three times after refluxing with alkali-permanganate overnight. The experimental temperature was maintained at 30.0±0.5 °C.

Measurements of Surface Tension and Adsorption. The surface tensions of surfactant solutions with and without urea were measured by the Wilhelmy plate method. The surface tension at equilibrium was taken to be those values which no longer changed with time (usually equilibrium was established after several hours). The amount of nonionic surfactant adsorption was measured by the radiotracer method using a tritiated compound. Details of the equipment and of the experimental procedure have been presented previously.[8,9]

Gel Permeation. The apparatus and procedure used for the gel permeation of a urea–nonionic surfactant solution, are almost the same as those used by Suzuki and Sasaki.[10] The gel (Sephadex G75) was embedded in a column (diameter 1.2 cm and gel height 15.0 cm) after swelling in a urea solution of the same concentration as was eluted in the gel permeation. The nonionic surfactant in the each fraction (1 ml) was analyzed by the iodine turbidity method.[11] Constant amounts of iodine (10^{-2} M, 0.3 ml) in excess of the requirement for forming the iodine–nonionic complex, and then hydrochloric acid (1 M, 0.4 mol), were added to each fraction. After shaking the mixture for about 30 min, the turbidity of the solutions was measured at 660 mμ using a Shimadzu spectrophotometer (Spectronic 20).

Results and Discussion

The surface tensions of the $D(EO)_6$ solution with and without urea are shown in Fig. 1. Surface tension lowering is markedly dependent on the urea concentration, but independent above the CMC value to within experimental error. Quite similar observations above the CMC value have been reported by Schwuger,[12] who has measured the surface tension of a urea(3 M)–$D(EO)_6$ solution by the ring method. A weak break point is observed on each curve in Fig. 1 at some solution concentration below the CMC value. This phenomenon appears to give the possibility of a change in the solubility state of the solutes in the solution, as is discussed in detail below.

Figure 2 shows the adsorption isotherms of $D(EO)_6$ at various urea concentrations. These isotherms are

nonionic adsorbed monolayer may be expected from the isotherms in Fig. 2. Sears has reported[2] that urea adsorption for a constant molecular area of a stearic acid monolayer occurs roughly in proportion to the concentration of urea in the solution. In the case of an adsorbed monolayer, the constant molecular area (constant $D(EO)_6$ density on the surface) corresponds to a constant value of Γ_1 in Fig. 2, because of the very dilute solution for C_1. Therefore, urea adsorption in the adsorbed monolayer may be estimated using a relationship between the surface tension and bulk concentrations of urea and $D(EO)_6$ such that a constant value of Γ_1 is maintained. Differentiating Eq. 1 applied to this system with respect to the logarithmic concentration of urea, we have at constant Γ_1,

$$-\left(\frac{\partial\gamma}{RT\partial\ln C_2}\right)_{\Gamma_1} = \left\{\left(\frac{\partial\ln f_1}{\partial\ln C_2}\right)_{\Gamma_1} + \left(\frac{\partial\ln C_1}{\partial\ln C_2}\right)_{\Gamma_1}\right\}\Gamma_1 + \left\{1+\left(\frac{\partial\ln f_2}{\partial\ln C_2}\right)_{\Gamma_1}\right\}\Gamma_2. \quad (7)$$

Since $C_1/C_2 \ll 1$, $(\partial \ln f_2/\partial \ln C_2)_{\Gamma_1}$ may be replaced by that for a simple aqueous solution of urea. From the empirical data for the osmotic coefficient of a urea solution[14] and Bjerrum's equation,[15] we have

$$\frac{\partial\ln f_2}{\partial\ln C_2} = -0.046C_2.$$

Also, from the Gibbs-Duhem equation for the solutes in the bulk solution and assuming Eq. 3, we have

$$\left(\frac{\partial\ln f_1}{\partial\ln C_2}\right)_{\Gamma_1} = \left\{1-\left(\frac{\partial\ln C_1}{\partial\ln C_2}\right)_{\Gamma_1}\right\}\left(\frac{\partial\ln f_1}{\partial\ln C_2}\right)_1. \quad (9)$$

Combining Eqs. 5, 7, 8 and 9, we have

$$\Gamma_2 = \frac{1}{1-0.046C_2}\left[-\left(\frac{\partial\gamma}{RT\partial\ln C_2}\right)_{\Gamma_1} + \delta\left\{1-\left(\frac{\partial\ln C_1}{\partial\ln C_2}\right)_{\Gamma_1}\right\} - \Gamma_1\left(\frac{\partial\ln C_1}{\partial\ln C_2}\right)_{\Gamma_1}\right] \quad (10)$$

where

$$\delta = 4.5\times10^{-11}C_2^{0.15}. \quad (10')$$

The relations between the surface tension and urea concentration, and C_2 *vs.* C_1 at constant Γ_1 are shown in a and b of Fig. 3. The amount of urea adsorbed, Γ_2, calculated using Eq. 10 with 1.4×10^{-10} mol/cm^2 for Γ_1 is shown in Table 2.

The increasing urea concentration in the solution enhances the urea adsorption at the adsorbed monolayer of a nonionic surfactant, the same as in the case of a stearic acid monolayer.[2] However, there are some essential differences pertinent to urea adsorption in these monolayers. The amount of adsorbed urea for an insoluble monolayer may be the absolute amount, but this is not the case for adsorbed monolayers, as expressed by Eq. 10. Namely, the last term in Eq. 10 represents the amount of urea accompanying the Γ_1 amount in proportion to the composition ratio of solutes in the bulk phase (here $\partial C_1/\partial C_2$ is almost constant), which is similar to the concept for the Gibbs adsorption.[7] Since urea itself is a surface inactive substance, it is easily deduced that Γ_2 is the difference in amounts of urea accumulated in the poly(oxyethylene) chain of the nonionic surfactant on the surface and in the bulk phases.

TABLE 2. ADSORPTION OF UREA ONTO THE ADSORBED $D(EO)_6$ MONOLAYER UNDER VARIOUS CONDITIONS

C_1 mol/l$\times10^5$	C_2 mol/l	Area of $D(EO)_6$ A^2/molecule	Urea adsorption mol/cm^2 $\times10^{10}$
0.45	0.040	118.6	0.90
0.70	0.40	118.6	1.01
1.0	4.0	118.6	1.39
4.0	0.040	38.9	0.06
4.0	0.40	79.4	0.06
4.0	4.0	105.7	−0.61

The Γ_2 value at the saturated adsorption region of $D(EO)_6$ (C_1 is maintained constant at 4.0×10^{-5} mol/l) at various urea concentrations is cited in Table 2. The calculation of Γ_2 in this case were performed using Eq. 11, which was derived in the same manner as in a previous paper,[16] assuming $C_1/C_2 \ll 1$ and $(\partial \ln f_1/\partial \ln C_1)_2 \approx 0$, as

$$\Gamma_2 = \left(-\frac{\partial\gamma}{RT\partial\ln C_2}\right)_1 - \left(\frac{\partial\ln f_1}{\partial\ln C_2}\right)_1\left(-\frac{\partial\gamma}{RT\partial\ln C_1}\right)_2 \quad (11)$$

where $(\partial \ln f_1/\partial \ln C_2)_1$ was deduced from Eq. 5, and the value of $(\partial\gamma/\partial \log C_2)_1$ was obtained from the curve in Fig. 4. The value of Γ_2 in the saturated adsorption region is almost zero at low urea concentrations, but is negative in 4.0 mol/l urea solutions. This property of urea adsorption can be explained by that at low urea concentrations, the accumulation of urea at the poly(oxyethylene) group of adsorbed nonionic surfactant is almost the same as that in the bulk phase, however, at high urea concentrations, it decreases in comparison with that of urea in the bulk solution owing to a squeezing from the poly(oxyethylene) group with the lateral cohesive force of hydrocarbon chains of adsorbed molecules at the surface. A similar phenomenon, which occurs when the surface density of a surface active material increases at constant urea concentration, is

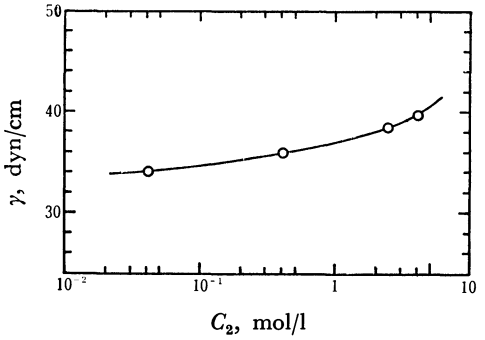

Fig. 4. Surface tension *vs.* concetration curve of urea at constant concentration of $D(EO)_6$ (4.0×10^{-5} mol/l).

observed not only in stearic acid monolayers,[2] but also in adsorbed monolayers at concentrations above the CMC value as described in the following section.

The Effect of Urea on Micelle. In the preceding section it was stated that urea adsorption occurs at adsorbed monolayers of $D(EO)_6$. However, above the CMC(0) value in the surface phase, urea appears to be forced out from inter-poly(oxyethylene) chains to below the $D(EO)_6$ monolayer as expected from the findings shown in Fig. 2. The micelle in the bulk solution is generally considered to attain the following equilibrium relation with the single species:[17]

$$\underset{\text{(single)}}{nA} \rightleftharpoons \underset{\text{(micelle)}}{A_n^M},$$

where n is the micelle aggregation number, A the single molecule and the superscript M denotes the micelle. In urea–nonionic solutions, the following processes for micellization are proposed:

$$nA + n\cdot mU \rightleftharpoons n(AUm) \rightleftharpoons [(AUm)_n^M] \rightleftharpoons A_n^M + n\cdot mU,$$

where m is conventionally constant, AUm the single molecule of nonionic surfactant ureanized, and $(AUm)_n^M$ the urea-penetrated micelle. If bound urea is squeezed out from the interior of micelle toward the outside, it may be considered to be almost the same as the $D(EO)_6$ micelle in the absence of urea. The micelle penetrated urea, which would be enclosed in either the hydrocarbon moiety and poly(oxyethylene) group or only the head group, is likely, if present, to be unstable due to the occurence of weak break points on the surface tension *vs.* concentration curves in Fig. 1 and also from the peculiar isotherms in Fig. 2. Schick *et al.*[18] have observed that the aggregation number of α-(*p*-nonylphenyl) - ω - hydroxypentadeca(oxyethylene) micelle slightly increases with the presence of urea in the solution, and suggested that the marked increments in the CMC values of α-alkyl-ω-hydroxypoly(oxyethylene) solutions are caused by a decrease in the cooperative structure of water.[5] According to Schik's suggestion, Hammes and Schimmel[6] predicted, from the results of the ultrasonic attenuation measurements in aqueous urea–poly(oxyethylene) glycol solutions, that the change in local solvent structure could involve a cooperative binding of urea to the poly(oxyethylene) group in solution. To elucidate this possibility of urea behavior in the micelle solution, the elusion volume of micelle, which is closely dependent on the micelle size,[19] was measured from the gel permeations of the micelle solution with and without urea. The results obtained are cited in Table 3. No large difference in elusion volume was observed at a urea concentration of 2.5 mol/l. Consequently, it is considered that the micelle size is not affected by the presence of urea.

TABLE 3. ELUSION VOLUMES OF MICELLE AND SINGLE SPECIES OF $D(EO)_6$ SOLUTIONS WITH AND WITHOUT UREA

(A) Water			(B) 2.5 M of urea

			22.0	6.0	17.5

Muller *et al.*, who studied the effects of additives on aqueous sodium ω,ω,ω-trifluorododecyl sulfate (F_3-SDS)[20] and α-(ω,ω,ω-trifluorododecyl)-ω-hydroxyhexa(oxyethylene)[21] solutions by the fluorine NMR method, have reported that the micelle chemical shifts with the presence and absence of urea in the solutions are about half (the R value in Ref. 20 is about 0.5), in comparison with those for single molecules. Though the aggregation number of nonionic micelle could not be determined and that of F_3SDS micelle was rather reduced with the presence of urea, they maintain that the urea, glycerol and glycine additives should be nonpenetrating in nonionic micelle. These results are in good agreement with the result for gel permeation and support the proposed mechanisms for micellization in urea–nonionic solutions.

The findings of the present studies and FNMR spectra may lead to the conclusion that the micelle of $D(EO)_6$ solutions with urea is almost the same as that of solutions without urea. If no urea entered into the micelle entity, none could be incorporated in the adsorbed monolayer, thermodynamically equilibrated with the micelle in bulk solution.

(Received May 24, 1976)

In order to reveal the formation mechanism of the active species in ethylene polymerization, the reduction of three kinds of molybdenum oxides, I, II, and III, which are insoluble in aq 10 M-NH_3, soluble in aq NH_3 but insoluble in water, and soluble in water respectively, was studied under a hydrogen pressure of 170 Torr over the temperature range 350—450 °C. The reduction rate of oxides I and II followed Elovich kinetics with a variable activation energy which increased with the progress of reduction, while that of III followed Elovich kinetics in the multiple kinetic stages and the minimum in apparent activation energy for the reduction lies at the reduction extent of $MoO_{2.7-2.6}$. The final states of reduction of I, II, and III were $MoO_{2.8-2.6}$, $MoO_{2.0}$ and $MoO_{2.2-2.1}$, respectively. The amount of Mo(V) in each oxide was determined by ESR measurements. The results indicate that Mo(V) in the II is related to the decrease of the apparent activation energy on reduction of III through their mutual interaction. A formation mechanism of the active species, Mo(V) in III, was proposed.

The polymerization over MoO_3–Al_2O_3 catalysts has been studied. The activity of the catalysts and the kinetics of the polymerization were reported.[1] The relation between the activity and chemical states in the supported molybdenum oxides, I, II and III, which are insoluble in aq 10 M-NH_3, soluble in aq NH_3 but insoluble in water, and soluble in water respectively, was reported.[2] The activity was found to be attributable to molybdenum(V) in III, $[Mo^{5+}]_w$.[3]

We have investigated the reduction mechanism of each oxide and the formation mechanism of the active species in order to clarify why the amount of $[Mo^{5+}]_w$ on alumina is greater than that on other carriers.

It is well known that in a hydro-cracking reaction[4,5] and an equilibrium reaction of H_2–D_2[6] carried out over MoO_3–Al_2O_3 catalysts, the activity is related to the chemical states of the molybdena besides polymerization. Our results might be useful for understanding the formation mechanism of the active species in the reactions.

Sontag *et al.*[7] were the first to note the extreme difficulty of reducing molybdena supported on alumina in hydrogen as compared with bulk MoO_3. They attributed this to an inhibition effect by water adsorbed on the alumina surface, which seems to raise from a localized surface equilibrium unfavorable to reduction. Kabe *et al.*[8] and Massoth[9] reported on the kinetics of reduction of MoO_3–Al_2O_3 catalysts and showed that the reduction followed the Elovich-type equation with a variable activation energy which increased with the progress of reduction. However, thier results differ as regards the final state and activation energy of the reduction. It may be pointed out that their catalysts were reduced under different conditions and that the proportion of molybdenum oxide in the three chemical states differed owing to the different conditions for the preparation of the catalysts.

Catalysts reduced under a hydrogen pressure of 170 Torr over the temperature range 350—450 °C are very active for polymerization. The kinetics of reduction of the oxide in each chemical state was studied under the same conditions. The molybdenum(V) contents were determined by ESR measurements.

The results elucidate some relations between the formation of molybdenum(V) in II and that in III. A formation mechanism of the active species, $[Mo^{5+}]_w$, is proposed.

Exprimental

Materials. Commercial hydrogen and oxygen (> 99.9%) were used without further purification. MoO_3–Al_2O_3 catalysts were prepared according to the procedure described previously.[1] Samples contained MoO_3 between 0 and 16.7 wt%. Data for the catalysts were given previously.[2] The support used was gamma alumina. X-Ray analysis gave no lines attributable to MoO_3 except for 16.7 wt% MoO_3–Al_2O_3.

Reduction of Catalysts. The apparatus was simply a closed system consisting of a furnace containing a reactor for the catalyst and a manometer made of 6-mm ID capillary tubing for measuring pressure. The system had about 160 ml capacity. Catalyst charges of 300—1000 mg were used. The catalyst was evacuated for an hour under a pressure of 10^{-3} Torr at 200 °C and then at 400 °C. The catalyst was reduced under a hydrogen pressure of 170 Torr over the temperature range 350—450 °C. The reduction was carried out in a batch system. One cycle consisted of a hydrogen reduction for a given period of 3—5, 1—2, and 1—2 min at 350, 400, and 450 °C, respectively and of an evacuation for 5 min.

The extent of reduction was determined from the amount of oxygen completely reoxidizing the catalyst. The extent shows the conversion ratio of MoO_3 to MoO_2.

ESR Measurement. The measurement was carried out as described previously.[3]

Results and Discussion

Activation Energy. The reduction of the molybdenum oxides, I, II and III, was studied in order to determine the activation energy. Since II and III can not be isolated, the following catalysts were used. (A), 16.7wt% MoO_3–Al_2O_3 consisting of I, II, and III; (B), prepared by the removal of III from (A) with water; (C), prepared by the removal of both II and III with aq 10 M-NH_3.

The reduction extent of the catalyst, θ, is given by

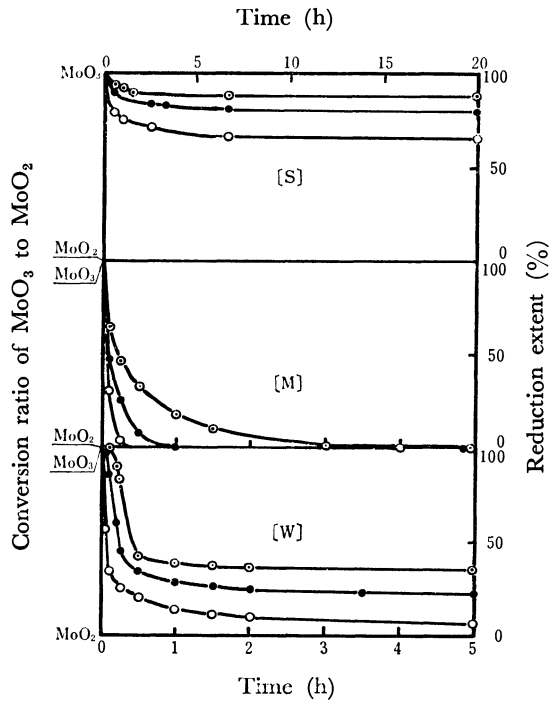

Fig. 1. Variation of the reduction extent of the oxide I, the oxide II and the oxide III with time.
⊙: 350 °C, ●: 400 °C, ○: 450 °C.

$$\theta = \frac{\theta_S[S] + \theta_M[M] + \theta_W[W]}{[S] + [M] + [W]} \quad (1)$$

where θ_S, θ_M, and θ_W denote the reduction extent of I, II, and III for given time, respectively, and [S], [M], and [W] the concentration, respectively. The reduction extent of each oxide can be determined by Eq. 1 on the basis of the reduction extents of catalysts (A), (B), and (C).

The reduction extents of the catalysts were measured at 350, 400, and 450 °C, and were evaluated as shown in Fig. 1. Catalyst(A) is the most active for the polymerization over the molybdena-content range 0—16.7 wt%. At 450 °C, I is reduced to $MoO_{2.6}$ in *ca.* 20 h and II

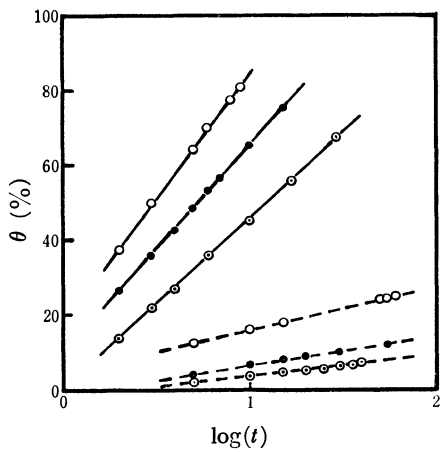

Fig. 2. Elovich plots for reduction of the oxide I and the oxide II at various temperature and 170-Torr H_2.

to $MoO_{2.0}$ in *ca.* half an hour and III to $MoO_{2.1}$ in *ca.* 5 h. These final states in each oxide varied little with further reduction. Thus the increasing order of reduction rates is: I, III, and II.

With catalysts(A), (B), and (C) reduced under the same conditions, no signal was observed except for one of molybdenum(V) by ESR measurements. In X-ray analysis, diffraction of MoO_2 was observed but not of $MoO_{1.5}$. These indicate that I, II and III are reduced to molybdenum(IV).

The reduction extents of I and II are plotted against logarithmic time in Fig. 2 on the basis of the results in Fig. 1. θ shows a linear relation with logarithmic time. Thus, the reduction follows an Elovich-type equation.[10,11]

$$\frac{d\theta}{dt} = a \cdot \exp(-b\theta) \quad (2)$$

where a and b are constants of the extent of reduction.

Figure 3 was obtained in a similar manner for the θ of III. The values of the θ show a curve with logarithmic time. The curve indicates that the reduction follows an Elovich-type equation in multiple kinetic stages.[11,12]

When the reduction follows an Elovich-type equation, the activation energy, $E(\theta)$, is expressed by an extension of Eq. 2 as follows:[8,9]

$$\frac{d\theta}{dt} = a \cdot \exp(-b\theta) = A \cdot \exp[-E(\theta)/RT] \quad (3)$$

where A is constant. Transforming Eq. 3 into logarithmic form, we obtain

$$\ln\left(\frac{d\theta}{dt}\right) = \ln(A) - E(\theta)/RT \quad (4)$$

The rates of reduction at a discrete value of θ are obtained from the slopes of θ-time recorder tracing in Fig. 1. Therefore, the activation energies at a discrete value of θ in both I and II are calculated on the basis of the plot of the rates against θ by Eq. 4. The results are shown in Fig. 4. The energy only at the θ value 10% was calculated for I owing to the difficulty of reducing I in hydrogen in the temperature range 350—450 °C. The result: $E(\theta=10\%)=42.5$ kcal/mol. This

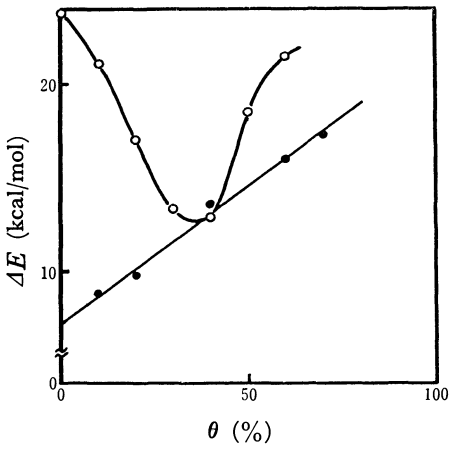

Fig. 4. Effect of reduction extent on activation energy.
●: The oxide II, ○: the oxide III.

is nearly equal to the value, $E(\theta)=30+52\theta$, reported by Kabe *et al.*[8] We see from Fig. 1. that the value of $E(\theta)$ in II is determined by

$$E(\theta) = 7.2 + 14.4\theta_M \quad (0<\theta_M<70\%) \qquad (5)$$

The value of $E(\theta)$ in II varies only 10 kcal/mol in the θ range 0—70%. This variation is smaller than that in I. This supports the conclusion[2] that as regards the strength of the interaction with alumina, the distribution in II is narrower than that in I. Extrapolation to $\theta=0$ gives $E_0=7.2$ kcal/mol. The value is smaller than 30 kcal/mol reported by Kabe *et al.*[8] and Sukeno *et al.*[13] and 9.8 kcal/mol by Massoth[9] and 27 kcal/mol for crystal MoO_3 by Kennedy *et al.*[14] The explanation for the difference is that the $E(\theta)$ in II could not be measured due to the rapid reduction of II.

The apparent activation energy of reduction in III is determined from the Arrhenius plots of the reduction rates. The results are given in Fig. 4. We see that the energy in III is minimum, 13 kcal/mol, in the θ range 30—40%, no reduction of bulk MoO_3 being observed under the present experimental conditions. MoO_3–SiO_2 catalysts (650 m^2/g) in which molybdena hardly intracts with silica support, could be reduced under a hydrogen pressure of 170 mmHg in the temperature range 400—450 °C and the apparent activation energy of reduction was determined to be constant, 39 kcal/mol, in the θ range 0—50%. These results indicate that III is reduced much more easily than the bulk MoO_3 and the MoO_3–SiO_2 catalysts.

Formation Mechanism of Active Species. MoO_3–Al_2O_3 catalysts were reduced from Mo(VI) to Mo(IV). The intermediate Mo(V) is supposed to be formed in the reduction process. In order to reveal the reduction mechanism of MoO_3–Al_2O_3 catalysts, the variation of the amount of Mo(V) in each oxide with reduction time was measured by ESR. The relation between the apparent $g'_{//}$-value and the Mo(V) content is expressed as follows.[3]

$$g'_{//} = \frac{1.9140[Mo^{5+}]_S + 1.9086[Mo^{5+}]_M + 1.8960[Mo^{5+}]_W}{[Mo^{5+}]_{total}} \qquad (6)$$

where $[Mo^{5+}]$ is a concentration of Mo(V), and S, M, and W subscripts refer to I, II, and III, respectively. The total amount of Mo(V) in the catalysts, $[Mo^{5+}]_{total}$, are expressed as follows.[3]

$$[Mo^{5+}]_{total} = [Mo^{5+}]_S + [Mo^{5+}]_M + [Mo^{5+}]_W \qquad (7)$$

In order to determine the Mo(V) content in each oxide, $[Mo^{5+}]_{total}$ and the apparent $g'_{//}$-values in catalyst(A), (B), and (C) were measured by ESR (Fig. 5). We see that $[Mo^{5+}]_{total}$ decreases within a reduction period of 50 min in the order (B)>(A)>(C). The apparent $g'_{//}$-value in (A) shows a minimum value for a reduction period of 7—10 min and that in (B) shows a nearly constant value.

$[Mo^{5+}]_M$ and $[Mo^{5+}]_S$ in (B) were calculated by substituting the apparent $g'_{//}$-values and $[Mo^{5+}]_{total}$ (Fig. 5) into Eqs. 6 and 7. The results are shown in Fig. 6. The behavior of $[Mo^{5+}]_S$ is in fair agreement with that of $[Mo^{5+}]_S$ (Fig. 5). The agreement indicates that I hardly interacts with II. $[Mo^{5+}]_M$ shows a constant value of 1.5×10^{19} spin/g-cat in the θ range 40—90%. The result supports the view that II exists in fine dispersion on the alumina surface[2] and that I

○: The oxide II, ●: the oxide III.

and II exist separately.

$[Mo^{5+}]_M$ and $[Mo^{5+}]_w$ in (A) were calculated by substituting $[Mo^{5+}]_{total}$, the apparent $g'_{//}$-value and $[Mo^{5+}]_s$ (Fig. 5), into Eqs. 6 and 7. The results are shown in Fig. 7. $[Mo^{5+}]_M$ in (A) increases remarkably within a reduction period of 4 min and decreases rapidly during further reduction time. The behavior of $[Mo^{5+}]_M$ differs from that in (B). $[Mo^{5+}]_w$ begins to form after a remarkable increase in $[Mo^{5+}]_M$, the behavior being in contrast to that of $[Mo^{5+}]_M$ (Fig. 7). This indicates that II interacts with III. The increase and decrease of $[Mo^{5+}]_M$ in Fig. 7 correspond to the decrease and increase, respectively, of activation energy for reducing III. Recently, it has been reported that the bulk MoO_3 is easily reduced in hydrogen at a lower temperature in the presence of 0.1—0.01 mol% of Pd or Ni.[15-19] The Pd- and Ni-catalyzed reduction was explained in terms of the transfer of hydrogen chemisorbed on Pd and Ni. This supports the view that $[Mo^{5+}]_M$ catalyzes the reduction of III. This is also supported by the following : As compared with III, it is difficult to reduce the bulk MoO_3 and the MoO_3–SiO_2 catalysts, in which $[Mo^{5+}]_M$ is absent. No relation between the amount of adsorbed hydrogen and the total amount of Mo(V) was observed. We reported that the amount of chemisorbed hydrogen agrees with the concentration of $[Mo^{5+}]_w$.[3] Hydrogen is chemisorbed on Mo(V) in MoO_3–Al_2O_3 catalysts[20] and the reduction of bulk MoO_3 is auto-catalytic in hydrogen.[19] In view of these facts, the formation mechanism of active species Mo(V) in III is proposed as follows: First, II is reduced in the MoO_3–Al_2O_3 catalysts and the $[Mo^{5+}]_M$ is formed and then the hydrogen to be chemisorbed on the $[Mo^{5+}]_M$ promotes the reduction of III from Mo(VI) to Mo(V); second, the hydrogen is chemisorbed on the formed $[Mo^{5+}]_w$ which also promotes the reduction of III from Mo(VI) to Mo(V). Therefore, more $[Mo^{5+}]_w$ is formed in the MoO_3–Al_2O_3 catalysts than in the MoO_3–SiO_2 catalysts and in the bulk MoO_3.

Structure of Molybdena on Alumina. The properties of molybdena supported on alumina in the content range of 0—16.7wt% and calcined over the temperature range 400—550 °C were explained in terms of a distorted octahedral structure.[3] Concerning the structure of I, we see that I interacts strongly with alumina but hardly interacts at all with II to exist on the alumina surface[2] and the crystal field is the strongest of the three oxides;[3] I is reduced only to $MoO_{2.8-2.6}$ in the temperature range 350—450 °C, the activation energy of reduction being greater than 42.5 kcal/mol. Thus, it is concluded that Mo atom of I has 6 Mo–O bondings which are nearly equal in strength and probably located inside the alumina lattice (Fig. 8).

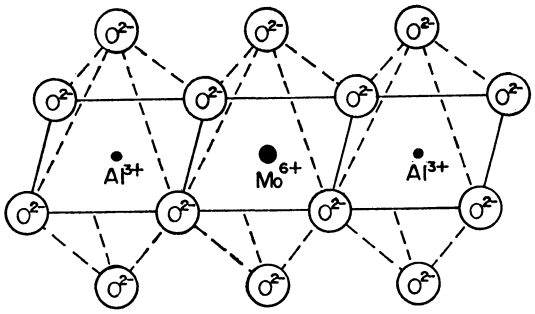

Fig. 8. Model of the oxide I.

Concerning the structures of II and III, we see that: II interacts with alumina, the interaction being weaker than that of I; the diffraction of a crystal MoO_3 is observed in the molybdena content 16.7wt%[2] II is reduced easily to MoO_2, interacts with III and promotes the reduction of III. These facts support the view that Mo atom of II has 6 Mo–O bondings, two bondings of which are weaker than the other four bondings, and that a part of III forms a crystal MoO_3 with an increase of III.

Equilibrium Spreading Pressure of the Mixed System of Normal Long Chain Fatty Acids

Kozo Fujii, Seiji Yoshino, Kinsi Motomura, Makoto Nakamura, and Ryohei Matuura

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received May 24, 1976)

Equilibrium spreading pressure were measured at various compositions and temperatures for mixed systems of tridecanoic acid-myristic acid, myristic acid-pentadecanoic acid, and pentadecanoic acid-palmitic acid, and thermodynamical treatment of these data with respect to the equilibrium between crystal and monolayer was performed. By evaluating the equilibrium composition of monolayer phase from the measured curve of equilibrium spreading pressure *vs.* composition of solid phase, the phase diagram was constructed. It was found that the equilibrium curve has a maximum point where the solid and monolayer phases have the same composition and a point where the solid phase is in equilibrium with two monolayer phases. The partial molar enthalpy change accompanied by the phase transition from solid to monolayer were found to be dependent on the composition.

It is interesting to clarify the behavior and aspect of the spreading from solid to monolayer. The equilibrium spreading pressure is related to the state of the crystal and the monolayer in equilibrium with the crystal.

Indeed the equilibrium spreading pressure (ESP) of a single component has been studied by many investigators,[1-3] but there have been much less reports about equilibrium spreading pressure of mixtures dealing with the equilibrium between the two states, namely the monolayer state and the crystal state of the mixture.[4-6]

In the present paper we intended to study the ESP of the system of tridecanoic acid-myristic acid (C_{13}–C_{14} acid system), myristic acid-pentadecanoic acid (C_{14}–C_{15} acid system), and pentadecanoic acid-palmitic acid (C_{15}–C_{16} acid system). The ESP's were measured at various compositions and temperatures, and thermodynamic treatment of the data was performed in which both the three-dimensional solid state and the two-dimensional monolayer state were taken into account on the basis of the theory in the previous paper.[7]

Experimental

Materials. The fatty acids used in the present study were purified by a fractional distillation at reduced pressure. Then they were recrystallized from petroleum ether and dried for about 24 h at room temperature under reduced pressure.

The purity was checked by differential thermal analysis (DTA), X-ray diffraction, and gas-chromatography.

Method of Measurements. A) The Measurements of Three-dimensional Solid State: Samples were prepared by melting the mixture of two acids at about 100 °C for 30 min and cooling to room temperature in a thermos bottle. Before the measurement those samples were ground in a mortor. The melting points and the transition points were measured by DTA. Long spacings of the crystal were measured by X-ray diffractometer. The details of the apparatus and method of measurements were previously described.[8]

B) The Measurements of Two-dimensional Monolayer State: Surface pressure-area measurements were performed by using a modified Wilhelmy type surface balance.

Benzene, spreading solvent, was shaken with concentrated sulfuric acid. After being washed with water to be neutral, it was refluxed with metal sodium and then carefully distilled.

The underlying solution, 0.001 M HCl, was prepared by using twice distilled water. The surface of the solution was cleaned by glass barriers coated with paraffine. The monolayer spread from benzene solution was left to stand for 10 min and then compressed continuously with a constant velocity.

C) The Measurements of ESP: Equilibrium spreading pressure measurements were performed by using an automatically recording Wilhelmy type surface balance.

Solid samples used here were the same as those described in the previous section A. After the surface of the solution was cleaned and the surface tension was held constant for more than two hours, an amount of powdered sample was deposited on it.

The pressure increased as time passed and reached a value which was held constatnt within ± 0.2 dyn/cm per hour. We took it as the ESP.

Results and Discussion

Three-dimensional Solid State. The melting points, the transition points, and the freezing points measured by DTA, and the long spacings measured by X-ray diffraction for the C_{13}–C_{14} system are plotted against the composition in Figs. 1 and 2, respectively. Similar results were also obtained for the C_{14}–C_{15} and C_{15}–C_{16} systems. From these results we assume that the solid

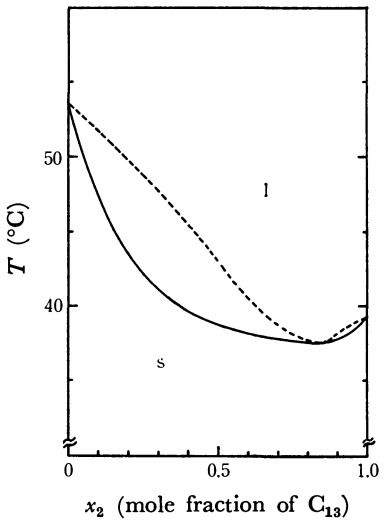

Fig. 3. Three-dimensional phase diagram of the C_{13}–C_{14} system : l, region of liquid solution; s, region of solid solution.

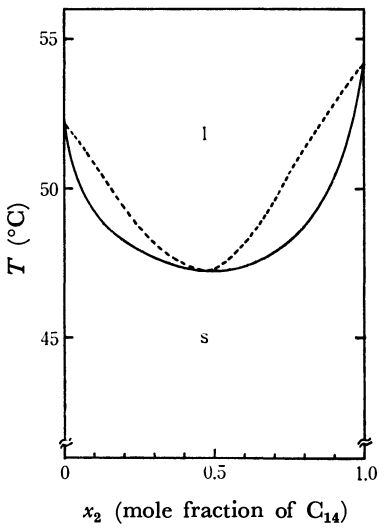

Fig. 4. Three-dimentional phase diagram of the C_{14}–C_{15} system : l, region of liquid solution; s, region of solid solution.

state is the regular solution, because the solid state deviates from ideal in such an extent that the curve representing the equilibrium between solid and liquid phases has a small minimum. And the liquid phase is assumed to be an ideal solution. Then we apply an equation similar to that for azeotropic mixture of liquid-vapor system. We have the following equations[9]

$$(\omega/RT_A)(x^s_{2,A})^2 = (\Delta h^0_1/R)(1/T_A - 1/T^0_1) \quad (1)$$

and

$$(\omega/RT_A)(x^s_{1,A})^2 = (\Delta h^0_2/R)(1/T_A - 1/T^0_2) \quad (2)$$

where Δh^0_i is the heat of fusion, T^0_i is the melting point, T_A is the temperature of minimum point, $x^s_{i,A}$, is the mole fraction of ith component at the minimum point, ω is a constant relating to the interaction energy, the superscript s denotes solid phase, and the subscripts 1 and 2 denote the fatty acids of larger and smaller carbon number, respectively. From Eqs. 1 and 2, we obtain

$$\omega = \{[\Delta h^0_1(T^0_1 - T_A)/T^0_1]^{1/2} + [\Delta h^0_2(T^0_2 - T_A)/T^0_2]^{1/2}\}^2 \quad (3)$$

The values of Δh^0_i, T^0_i, T_A, and ω for each system are listed in Table 1. Then, we can calculate the solidus and liquidus curves from the following equations;

$$x^s_2 = \{\exp[\omega(x^{s2}_2/RT) - \lambda_1] - 1\}/\{\exp[\omega(x^{s2}_2/RT) - \lambda_1] - \exp[\omega(x^{s2}_1/RT) - \lambda_2]\} \quad (4)$$

and

$$x^l_2 = \{\exp[\omega((x^{s2}_1 + x^{s2}_2)/RT) - \lambda_1 - \lambda_2] - \exp(-\lambda_2)\} / \{\exp[\omega(x^{s2}_2/RT) - \lambda_1] - \exp[\omega(x^{s2}_1/RT) - \lambda_2]\} \quad (5)$$

where

$$\lambda_1 = (\Delta h^0_1/R)(1/T - 1/T^0_1) \quad (6)$$

and

$$\lambda_2 = (\Delta h^0_2/R)(1/T^0_2 - 1/T). \quad (7)$$

So, we can depict the phase diagram, which is shown in Figs. 3 to 5 for the C_{13}–C_{14}, C_{14}–C_{15}, and C_{15}–C_{16} systems, respectively. These systems show minimum points, but there are small differences between the values of mole fraction of minimum point. It is concluded that in binary solid mixtures the different behavior is arisen from the difference in the crystalline state between an odd-numbered acid and an even-numbered acid.

Two-dimensional Monolayer State. It is impossible to perform thermodynamic analysis with respect to the ESP if we do not have information of the state of monolayer. So the surface pressure-mean molecular area (π-A) curve was measured at various compositions and temperatures. It was found that in each system the transition pressure from expanded to condensed state, π^{eq}, varied somewhat linearly with the mole fraction of component 2 referred to the fatty acids, x^π_2, over the whole range of composition.

The composition of the condensed film (c) coexisting with the expanded film (e) is calculated by using the equation [7,11]

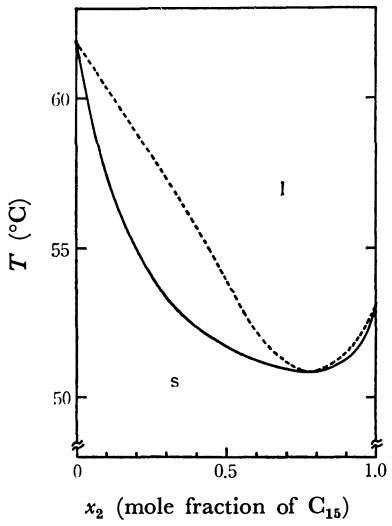

Fig. 5. Three-dimensional phase diagram of the C_{15}–C_{16} system : l, region of liquid solution; s, region of solid solution.

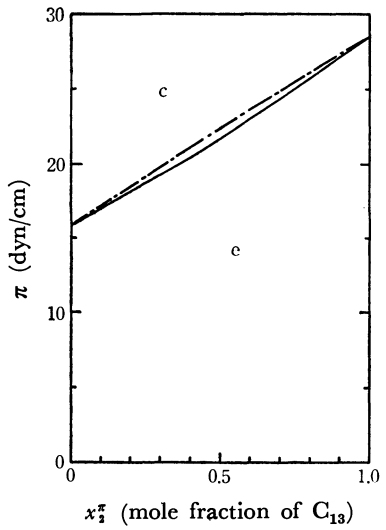

Fig. 6. Two-dimensional phase diagram of the C_{13}–C_{14} system at 20 °C : c, region of condensed monolayer; e, region of expanded monolayer.

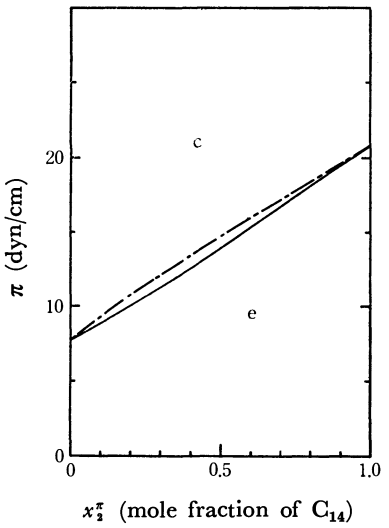

Fig. 7. Two-dimensional phase diagram of the C_{14}–C_{15} system at 25 °C : c, region of condensed monolayer; e, region of expanded monolayer.

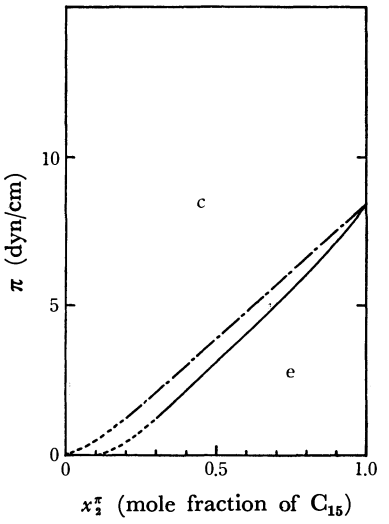

Fig. 8. Two-dimensional phase diagram of the C_{15}–C_{16} system at 25 °C : c, region of condensed monolayer; e, region of expanded monolayer.

$$x_1^{\pi,c} = x_1^{\pi,e} + [(A^c - A^e)x_1^{\pi,e}x_2^{\pi,e}/kT](\partial\pi^{eq}/\partial x_2^{\pi,e})_{p,T} \quad (8)$$

By a procedure similar to that in the previous paper,[11,12] the phase diagrams of two-dimensional monolayer state were depicted for each system in Figs. 6 to 8. The aspect of these phase diagrams is quite identical. After all, it is concluded that the two-component fatty acid system in which the number of carbon atoms is different by only one gives almost ideal mixture in monolayer state.

Equilibrium between Solid State and Monolayer State.

When a sample of fatty acid mixture is placed on the surface of water, the surface pressure increases with time as it spreads on the surface. The surface pressure-time curve is shown in Fig. 9 for the C_{14}–C_{15} system as an example.

The break point is detected at $x_2^s = 0.75$ and 0.10, but not at 0.90. The surface pressure at the break point is almost equal to that of transition from the expanded to the condensed film. So it is expected that the phase transition occurs at the break point and therefore the monolayer in equilibrium with the bulk solid forms a condensed film. Consequently it is concluded that the break point is observed if bulk solid is in equilibrium with the condensed film, but not observed if bulk solid is in equilibrium with the expanded film.

The values of ESP measured at various compositions and temperatures are plotted against the compositions of the bulk solid for the C_{14}–C_{15} system in Fig. 10. The similar curves were also obtained for other two systems. Comparing the ESP curves with the solidus curve in Fig. 4, it seems likely that the higher the melting points, the lower the ESP, and *vice versa*. We may say that the solid sample having the higher melting point is more difficult to spread because of its stronger molecular

Table 1. The calculated values of ω for each system

Fatty acid	Heat of fusion[10] (kcal/mol)	Mixture	Minimum point (°C)	ω (cal/mol)
Tridecanoic acid (C_{13})	8.02			
		C_{13}–C_{14} system	311.1	835.0

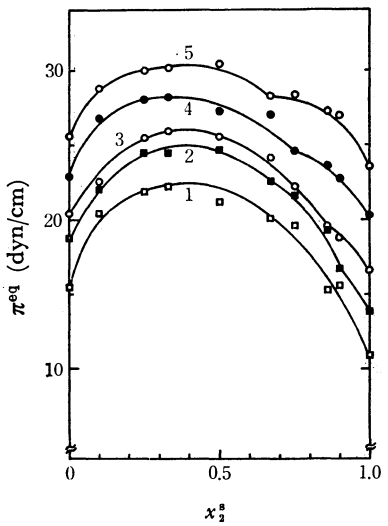

Fig. 10. Equilibrium spreading pressure *vs.* mole fraction of myristic acid curves of C_{14}–C_{15} system : 1, 15 °C; 2, 20 °C; 3, 25 °C; 4, 30 °C; 5, 35 °C.

interaction.

In Fig. 10 the break points are observed on ESP curves at 20, 25, 30, and 35 °C. For the C_{13}–C_{14} acid system the break points were observed at 25 and 30 °C, while for the C_{15}–C_{16} system the break point was not observed in the range of experimented temperatures. It might be presumed that at this break point two monolayer phases are formed by spreading from the crystal. This is understood from the fact that the curve 3 in Fig. 10 and the curves in Fig. 7 intersect in the neighborhood of that break point.

We shall consider thermodynamically the behavior of the variation of ESP with the composition shown in Fig. 10. Choosing the mole fraction x_2^s as a free variable, the variation of the ESP, π^{eq}, with x_2^s can be written in the following form[7,11]

$$(\partial\pi^{eq}/\partial x_2^s)_{T,p} = [(\partial\mu_1^s/\partial x_2^s)(\partial\mu_2^m/\partial x_2^\pi) - (\partial\mu_2^s/\partial x_2^s)(\partial\mu_1^m/\partial x_2^\pi)] / [\bar{a}_1^\pi(\partial\mu_2^m/\partial x_2^\pi) - \bar{a}_2^\pi(\partial\mu_1^m/\partial x_2^\pi)] \quad (9)$$

In Eq. 9, $\bar{a}_i^\pi$ is the apparent partial molar area related to the mean molar area, a, as

$$\bar{a}_1^\pi = a - x_2^\pi(\partial a/\partial x_2^\pi) \quad (10)$$

$$\bar{a}_2^\pi = a + x_1^\pi(\partial a/\partial x_2^\pi) \quad (11)$$

From the Gibbs-Duhem equation in the bulk phase, we have

$$x_1^s(\partial\mu_1^s/\partial x_2^s) + x_2^s(\partial\mu_2^s/\partial x_2^s) = 0 \quad (12)$$

and in the monolayer phase, we have

$$x_1^\pi(\partial\mu_1^m/\partial x_2^\pi) + x_2^\pi(\partial\mu_2^m/\partial x_2^\pi) = 0 \quad (13)$$

Substituting Eqs. 10 to 13 into Eq. 9;

$$(\partial\pi^{eq}/\partial x_2^s)_{T,p} = [(x_2^\pi - x_2^s)/x_1^s a](\partial\mu_2^s/\partial x_2^s)_{T,p} \quad (14)$$

If $(\partial\mu_2^s/\partial x_2^s)_{T,p}$ is known, the mole fraction of the equilibrium monolayer coexisting with crystal, x_2^π, can be calculated. In the previous section we have assumed the solid solution as the regular solution; *i.e.*,

$$RT\ln\gamma_1^s = \omega(x_2^s)^2 \quad (15)$$

and

$$RT\ln\gamma_2^s = \omega(x_1^s)^2 \quad (16)$$

where γ_i^s is the activity coefficient in bulk solid. The chemical potential in the bulk solid is expressed in terms of the composition as

$$\mu_2^s = \mu_2^{0,s} + RT\ln x_2^s + \omega(x_1^s)^2 \quad (17)$$

Differentiating the above equation with respect to x_2^s at constant T and p and substituting it into Eq. 14, we obtain the equation for calculating x_2^π:

$$x_2^\pi = x_2^s + [ax_1^s x_2^s/(RT - 2\omega x_1^s x_2^s)](\partial\pi^{eq}/\partial x_2^s)_{T,p} \quad (18)$$

Since it has been established that the mixed monolayers of long chain n-fatty acids have the same molar area, irrespective of the chain length, if they are in the same monolayer state, [11–13] the values of a were determined from the π-A curve of C_{14} acid when the equilibrium monolayer is the expanded film and that of C_{18} acid when the equilibrium monolayer is the condensed film.

It is now possible to make up the phase diagram of

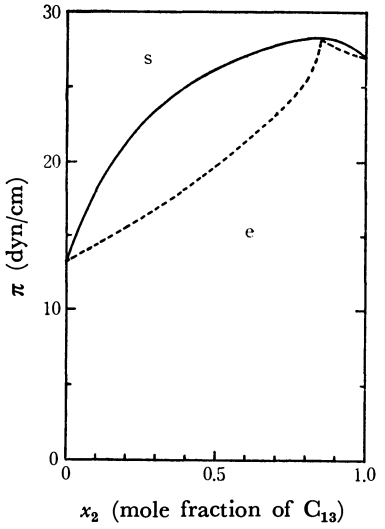

Fig. 11. Phase diagram of the C_{13}–C_{14} system at 20 °C : s, region of solid solution; e, region of expanded monolayer.

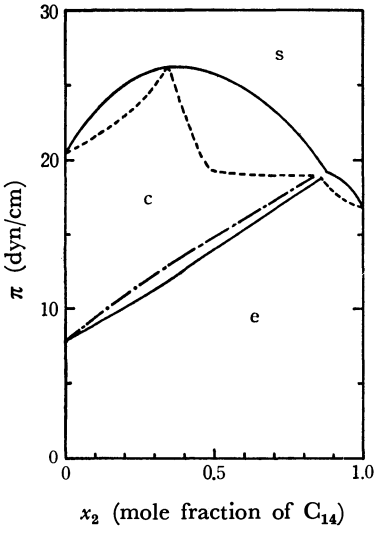

Fig. 12. Phase diagram of the C_{14}–C_{15} system at 25 °C : s, region of solid solution; c, region of condensed monolayer; e, region of expanded monolayer.

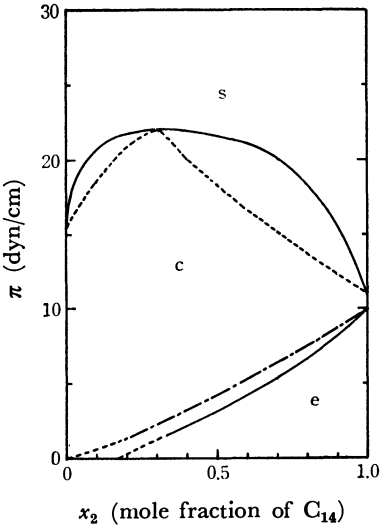

Fig. 13. Phase diagram of the C_{14}–C_{15} system at 15 °C: s, region of solid solution; c, region of condensed monolayer; e, region of expanded monolayer.

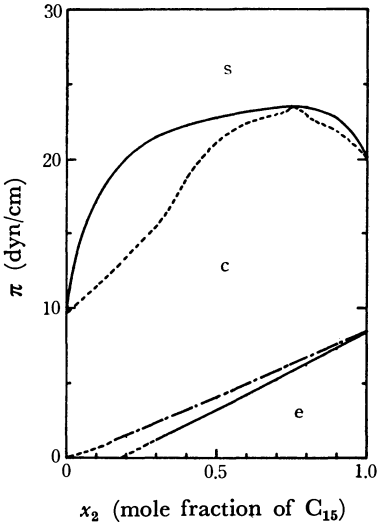

Fig. 14. Phase diagram of the C_{15}–C_{16} system at 25 °C: s, region of solid solution; c, region of condensed monolayer; e, region of expanded monolayer.

the mixed system of fatty acids representing the condition of equilibrium between phases of solid and monolayer, which is illustrated in Figs. 11 to 14 for the present three systems at different temperatures. In Fig. 11 of the C_{13}–C_{14} system it is shown that the bulk solid is in equilibrium with the expanded film at any composition, but in Fig. 14 of the C_{15}–C_{16} system the bulk solid is in equilibrium with the condensed film. In the case of the C_{14}–C_{15} system, the phase diagram at 15 °C drawn in Fig. 13 is similar to that of the C_{15}–C_{16} system. However, the phase diagram at 25 °C drawn in Fig. 12 is different from the above ones in that the bulk solid is in equilibrium with the condensed film in the portion of mole fraction from $x_2^\pi=0$ to 0.85, but in the portion of mole fraction from $x_2^\pi=0.85$ to 1.0 the bulk solid is in equilibrium with the expanded film. At this point, that is, at the mole fraction of $x_2^\pi=0.85$, the bulk solid, the condensed film, and the expanded film coexist. This is the triple point. As seen in Fig. 10, this point shifts to a higher value of x_2^s with decreasing temperature. This triple point disappears at 15 °C in the C_{14}–C_{15} system. Though there is a possibility of appearance of the triple point in the C_{15}–C_{16} system if the temperature is raised, we can not experiment at the higher temperature because of several restrictions.

Entropy and Enthalpy Changes Accompanied by the Phase Transition from Bulk Solid to Equilibrium Monolayer.

Now, from the variation of the transition pressure with temperature, the entropy changes accompanied by the phase transition from solid state to monolayer state can be calculated by using equation [7,11]

$$(\partial\pi^{eq}/\partial T)_{p,x_2^s} = [(\bar{s}_1^\pi-\bar{s}_1^s)(\partial\mu_2^m/\partial x_2^\pi) - (\bar{s}_2^\pi-\bar{s}_2^s)(\partial\mu_1^m/\partial x_2^\pi)] / [\bar{a}_1^\pi(\partial\mu_2^m/\partial x_2^\pi)-\bar{a}_2^\pi(\partial\mu_1^m/\partial x_2^\pi)] \quad (19)$$

Substituting Eqs. 10, 11, and 13 into Eq. 19, we obtain the following equation

$$a(\partial\pi^{eq}/\partial T)_{p,x_2^s} = x_1^\pi(\bar{s}_1^\pi - \bar{s}_1^s) + x_2^\pi(\bar{s}_2^\pi - \bar{s}_2^s) \quad (20)$$

The calculation of the apparent mean molar entropy change of the C_{14}–C_{15} system was carried out at 20 °C by making use of the values of $(\partial\pi^{eq}/\partial T)_{p,x_2^s}$ estimated from Fig. 10. The entropy changes plotted against the composition of the equilibrium monolayer, x_2^π, are shown in Fig. 15. It exhibits a remarkable discontinuity at the mole fraction of $x_2^\pi \approx 0.9$, and separates into two parts. It seems to be the reason for the discontinuity that the entropy of spreading to expanded film differs considerably from that to condensed film. The magnitude of this gap is fairly good agreement with the value taken at the corresponding mole fraction from Fig. 16 where the apparent mean molar entropy change, $[x_1^{\pi,c}(\bar{s}_1^{\pi,c} - \bar{s}_1^{\pi,e}) + x_2^{\pi,c}(\bar{s}_2^{\pi,c} - \bar{s}_2^{\pi,e})]$, associated with the transition from expanded to condensed monolayer is plotted against the mole fraction of the expanded monolayer, $x_2^{\pi,e}$. For the C_{15}–C_{16} system the entropy change calculated similarly indicated that the phase transition occurs from solid state to condensed film over the whole range of the composition.

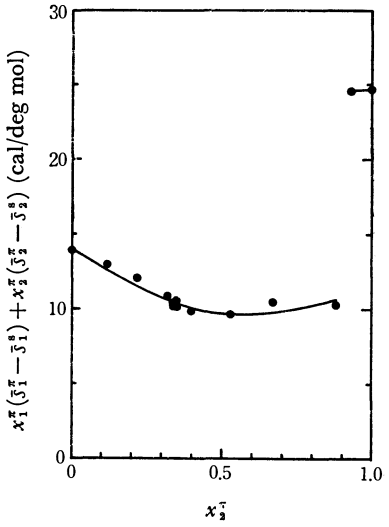

Fig. 15. Apparent mean molar entropy change *vs.* mole fraction of myristic acid curve of the C_{14}–C_{15} system at 20 °C.

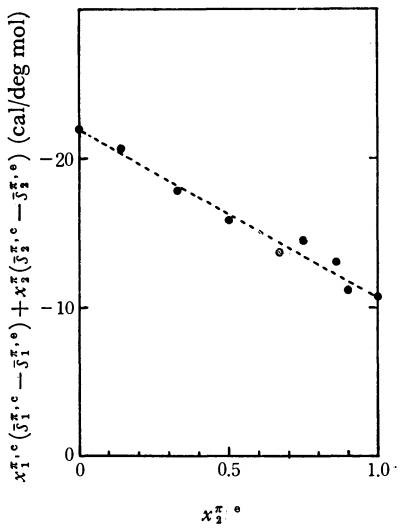

Fig. 16. Apparent mean molar entropy change *vs.* mole fraction of myristic acid curve of the C_{14}–C_{15} system at 20 °C.

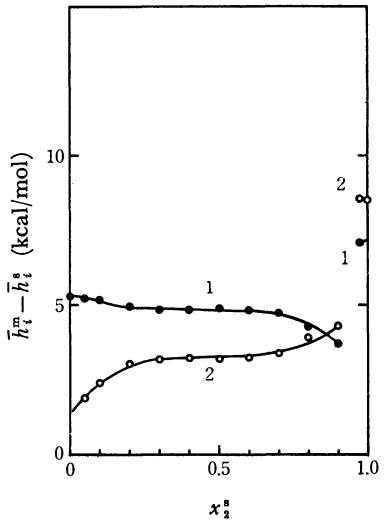

Fig. 17. Partial molar enthalpy change *vs.* mole fraction of myristic acid curve of the C_{14}–C_{15} system at 20 °C : 1, pentadecanoic acid; 2, myristic acid.

Each term of the right-hand side of Eq. 20 is the apparent partial molar entropy change of the respective component and is connected with the partial molar entropy change at the phase transition from the solid to the monolayer state, $\bar{s}_i^m - \bar{s}_i^s$, by

$$\bar{s}_1^m - \bar{s}_1^s = (\bar{s}_1^\pi - \bar{s}_1^s) - [a - x_2^\pi(\partial a/\partial x_2^\pi) - \bar{a}_1](\partial\pi/\partial T)_{p,x_w^m,x_2^\pi} - \bar{a}_1(\partial\gamma^0/\partial T)_p \quad (21)$$

and

$$\bar{s}_2^m - \bar{s}_2^s = (\bar{s}_2^\pi - \bar{s}_2^s) - [a + x_2^\pi(\partial a/\partial x_2^\pi) - \bar{a}_2](\partial\pi/\partial T)_{p,x_w^m,x_2^\pi} - \bar{a}_2(\partial\gamma^0/\partial T)_p \quad (22)$$

where $\bar{s}_i$ is partial molar entropy, $\bar{a}_i$ is the partial molar area, x_w^m is the mole fraction of water in the monolayer and γ^0 is the surface tension of pure water.[7,11] Further we can calculate the partial molar enthalpy change by

$$\bar{h}_1^m - \bar{h}_1^s = T(\bar{s}_1^m - \bar{s}_1^s) \quad (23)$$

and

$$\bar{h}_2^m - \bar{h}_2^s = T(\bar{s}_2^m - \bar{s}_2^s), \quad (24)$$

where $\mu_i^m = \mu_i^s$ has been used.

The results are shown in Fig. 17 for the C_{14}–C_{15} system at 20 °C where we have plotted it against the composition of solid state. From this figure the partial molar enthalpy change may be said to be dependent on the composition. On the other hand, the partial molar enthalpy change from expanded to condensed film, $\bar{h}_i^e - \bar{h}_i^s$, is almost independent of the composition.[12] This difference in the composition dependence of the partial molar enthalpy change seems to result from the non-ideal behavior in solid solution or from the fact that the ESP changes with the size of solid grain which is spread.[14]

Microwave Spectrum, Structure, Dipole Moment and Internal Rotation of Ethanethiol. II. *Gauche* Isomer

Jun NAKAGAWA, Kazunori KUWADA, and Michiro HAYASHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received June 2, 1976)

The microwave spectra of *gauche*-ethanethiol and its isotopic species were studied. Most of the observed spectra for the species having the plane of symmetry exhibited doublet structures with large spacings due to the internal rotation of the mercapto group. The r_s structure of the *gauche* isomer was determined from the observed moments of inertia. The *gauche* isomer whose dihedral angle τ(CCSH) is 61°45′±58′ has structural parameters close to those for the *trans* isomer except the angles around the carbon atom in the methylene group. The difference in angle values around the carbon atom in the methylene group between the *trans* and *gauche* isomers can be explained by the 3°7′ tilt of the methylene group towards the lone pair electrons on the sulfur atom. The direction of the dipole moment in the molecule was discussed on the basis of data given by Schmidt and Quade. The potential barrier of the mercapto internal rotation was obtained from splittings of the observed spectra. The Fourier coefficients of this barrier are $V_1=-207\pm67$, $V_2=-386\pm27$, and $V_3=1305\pm20$ cal/mol. The spectra due to the excited methyl and mercapto torsional states were also measured for the *trans* and *gauche* isomers. The potential barrier of the methyl internal rotation for the *trans* isomer was found to be 3260±30 cal/mol from splittings of the spectra due to the first excited methyl torsional state.

In previous paper,[1,2] (referred to as I) reports were given on the microwave spectrum of *trans*-ethanethiol in relation to the r_s structure, dipole moment and the observed microwave spectra of *gauche*-ethanethiol. In the present paper, we deal with the microwave spectrum, r_s structure, and internal rotation of both the mercapto and methyl groups of *gauche*-ethanethiol.

After publication of our papers on the *trans* isomer and rough descriptions of the spectra for the *gauche* isomer, Schmidt and Quade[3] reported an independent study on the microwave spectra of *gauche*-ethanethiol and its four deuterated species. They carried out the analysis of the internal rotation of the mercapto group and the dipole moment assuming a certain structure.

We were working on the same subject for the *gauche* isomer as theirs as a continuation of our work on *trans*-ethanethiol. However, publication of our experimental results was deliberately delayed in order to determine a reliable molecular structure[4] for the *gauche* isomer as well as that for the *trans* isomer and to find the spectra in the excited methyl torsional states both for the *trans* and *gauche* isomers. Wherever their measurements overlap ours, the agreement is very good.

Exprimental

Normal and deuterated species of ethanethiol were prepared and purified in the same manner as described in I. Two ^{13}C species were prepared from the corresponding ^{13}C enriched ethyl iodides (90 atom% ^{13}C, Merck Sharp & Dohme, Canada) by the standard method.[5] The spectra of ^{34}S species were measured with a sample containing this species in natural isotopic abundance. Measurements were carried out by the same apparatus and under the same conditions as those in I.

Microwave Spectra of *Gauche* Isomer

gauche-Ethanethiol is a slightly asymmetric prolate top molecule as is *trans*-ethanethiol. Though *a*-, *b*-, and *c*-type transitions are expected for the microwave spectra, *b*-type transitions are actually very weak.

Microwave spectra of *a*- and *c*-types belonging to the *gauche* isomer in the ground state were measured and assignments made for the normal and nine isotopically substituted species of ethanethiol. Observed frequencies with $J\leqq7$ are given in Tables 1 and 2. *s*- and *a*- (*e.g.* *s*-CH_2DCH_2SH) stand for the species whose deuterium atoms are situated in the CCS plane and out of the CCS plane, respectively, and -1 and -2 (*e.g.* *a*-CH_2DCH_2SH-2) stand for the species whose deuterium atoms are situated on the opposite side and the same side of the CCS plane as the hydrogen atom in the mercapto group, respectively.

The observed spectra for some of the species exhibit doublet structures whose components have identical Stark effects.[1,2]

The normal and nine isotopic species of *gauche*-ethanethiol can be classified into three groups by means of the fine structures of the spectra. Group I(CH_3CH_2SH, $CH_3CH_2{}^{34}SH$, $^{13}CH_3CH_2SH$, $CH_3{}^{13}CH_2SH$, and *s*-CH_2DCH_2SH) consists of the species which have the symmetry plane in the CH_3CH_2S part of the molecule. For Group I, observed *c*-type spectra are doublets with spacings of about 3500 MHz, *a*-type spectra with $K_{-1}=1$ are doublets with spacings of several MHz, and *a*-type spectra with $K_{-1}\neq1$ are singlets. For the CH_3CH_2-SD species (Group II), *c*-type spectra are doublets with spacings of about 140 MHz, while *a*-type spectra are singlets. For Group III, in which each species has an isotopically substituted atom situated out of the CCS plane, (*a*-CH_2DCH_2SH-1, *a*-CH_2DCH_2SH-2, CH_3CHDSH-1, and CH_3CHDSH-2), spectra are singlets.

For the species belonging to Groups I and II, tunnelling effect between two equivalent *gauche* minima in the internal rotation potential function of the mercapto group produces two different energy states (referred to as the + and − states). The + and − states indicate the symmetric and antisymmetric states with respect to the mercapto internal rotation angle, respectively. The energy difference between the + and − states for the SH group is greater than that for the SD group since the reduced moment of inertia around the internal rotation axis for the SD group is greater

a) Figures in parentheses indicate the uncertainty attached to the last significant figures calculated from 2.5 times the standard deviations. b) 10^3 times the coefficient of the $[J(J+1)]^2$ term in the centrifugal distortion formula in MHz. For the first six species, this term is neglected in the determination of the rotational constants. In Table 2 of the previous paper on the *trans* isomer (Ref. 2), signs of the corresponding D_J values were mistyped, that is, -4.68 in that table should read 4.68 and so on. c) Energy difference between the + and − states. d) Coefficient of $(P_xP_y+P_yP_x)$ term in Eq. 3c.

than for the SH group.

From group-theoretical considerations, the selection rules governing transitions between the rotational energy levels belonging to the + and − states are + ↔ + and − ↔ − for *a*-type transitions and + ↔ − for *c*-type transitions.

In order to obtain the rotational constants from the observed frequencies for the species belonging to Groups I and II, we must consider the effective Hamiltonian which includes not only the rigid rotor terms of the + and − states but also cross terms between the + and − states. The rotational constants obtained are given in Table 3. It is found that the rotational constants of the + and − states are essentially equal within experimental error for the species belonging to Groups I and II.

For the species belonging to Group III, splittings of the + and − states cannot occur because there are no equivalent *gauche* forms. Although the *a*-CH_2D-CH_2SH species has two equivalent *gauche* forms, tunnelling effect between these two conformers occurs through the internal rotation potential of not only the mercapto group but also the methyl group. Splittings of the + and − states are negligibly small. The rotational constatnts were obtained by a least squares analysis from all the observed frequencies so as to fit in with a modified rigid rotor expression which includes only the $D_J[J(J+1)]^2$ term of the centrifugal distortion formula. The rotational constants are given in Table 3.

Analysis of Doublet Structures of the Observed Spectra for the *Gauche* Isomer

Analysis of doublet structures of the observed spectra is necessary for the species belonging to Groups I and II. In order to derive the Hamiltonian for the coupling problem of overall rotation and internal rotation of the mercapto group, the coordinate system for the species belonging to Groups I and II is so chosen that the z-axis is parallel to the mercapto internal rotation axis, the y-axis is in the symmetry plane, and the x-axis is perpendicular to the symmetry plane. The Hamiltonian concerning overall and internal rotation is then written as the sum of the overall rotation, internal rotation, and overall-internal rotation interaction terms:[6)]

$$H = H_{\text{rot}} + H_{\text{int}} + H_{\text{rot-int}}, \tag{1}$$

$$\begin{aligned} H_{\text{rot}} = {} & \sum \mu_{xx}^{(n)} \cos n\alpha \cdot P_x^2 + \sum \mu_{yy}^{(n)} \cos n\alpha \cdot P_y^2 \\ & + \sum \mu_{zz}^{(n)} \cos n\alpha \cdot P_z^2 + \sum \mu_{yz}^{(n)} \cos n\alpha \cdot (P_yP_z + P_zP_y) \\ & + \sum \mu_{xz}^{(n)} \sin n\alpha \cdot (P_xP_z + P_zP_x) \\ & + \sum \mu_{xy}^{(n)} \sin n\alpha \cdot (P_xP_y + P_yP_x), \end{aligned} \tag{1a}$$

$$\begin{aligned} H_{\text{int}} = {} & \sum \mu_{\alpha}^{(n)} (p_\alpha^2 \cos n\alpha + \cos n\alpha \cdot p_\alpha^2) \\ & + \sum \frac{V_n}{2} (1 - \cos n\alpha), \end{aligned} \tag{1b}$$

$$\begin{aligned} H_{\text{rot-int}} = {} & \sum \mu_{\alpha x}^{(n)} (p_\alpha \sin n\alpha + \sin n\alpha \cdot p_\alpha) P_x \\ & + \sum \mu_{\alpha y}^{(n)} (p_\alpha \cos n\alpha + \cos n\alpha \cdot p_\alpha) P_y \\ & + \sum \mu_{\alpha z}^{(n)} (p_\alpha \cos n\alpha + \cos n\alpha \cdot p_\alpha) P_z, \end{aligned} \tag{1c}$$

where $\mu_{gg'}^{(n)}$, represents the n-th Fourier coefficient of the g,g'-th element of the reciprocal inertia tensor, α denotes the mercapto internal rotation angle, and P_x, P_y, P_z, and p_α represent x, y, and z components of the total angular momentum and the mercapto internal rotational angular momentum, respectively.

Assuming that the wave functions for the Hamiltonian (1) can be written as the products of overall and internal rotation wave functions and that internal rotation wave functions are obtained as the eigenfunctions of Eq. 1b, the effective Hamiltonian for the overall rotation is reduced to the following formulas.

$$\begin{aligned} \langle + |H| + \rangle = {} & A'_+P_z^2 + B'_+P_y^2 + C'_+P_x^2 + F'_+(P_yP_z + P_zP_y) \\ & + M'_+P_x, \end{aligned} \tag{2a}$$

$$\begin{aligned} \langle - |H| - \rangle = {} & A'_-P_z^2 + B'_-P_y^2 + C'_-P_x^2 + F'_-(P_yP_z + P_zP_y) \\ & + M'_+P_x + \Delta\nu, \end{aligned} \tag{2b}$$

$$\begin{aligned} \langle + |H| - \rangle = {} & D'_{\pm}(P_xP_y + P_yP_x) + E'_{\pm}(P_xP_z + P_zP_x) \\ & + N'_{\pm}P_y + Q'_{\pm}P_z, \end{aligned} \tag{2c}$$

where $\Delta\nu$ denotes the pure internal rotational energy difference between the + and − states. Coefficients A'_+, *etc.* are obtained as the matrix elements of the cor-

responding operators between the wave functions of + and +, or − and −, or + and − states. The cross term in Eq. 2c occurs from the odd functions of α, $\sin n\alpha$ and $(p_\alpha \cdot \cos n\alpha + \cos n\alpha \cdot p_\alpha)$, in Eq. 1.

After a suitable rotation about the x-axis is carried out, it is possible that Eqs. 2a and 2b are reduced to formulas containing no $(P_yP_z+P_zP_y)$ term. Furthermore, the P_x terms in Eqs. 2a and 2b can be neglected, since these terms contribute to the off-diagonal matrix elements, whose K_{-1} values are not equal. Thus the effective Hamiltonians are written as

$$\langle +|H|+\rangle = A_+P_x^2 + B_+P_y^2 + C_+P_z^2, \quad (3a)$$

$$\langle -|H|-\rangle = A_-P_x^2 + B_-P_y^2 + C_-P_z^2 + \Delta\nu \quad (3b)$$

$$\langle +|H|-\rangle = D_\pm(P_xP_y+P_yP_x) + E_\pm(P_xP_z+P_zP_x) + N_\pm P_y + Q_\pm P_z \quad (3c)$$

Taking account of the selection rules of *a*- and *c*-type transitions, it can be concluded that doublet structures of *a*-type transitions are due to the difference in the rotational constants of the + and − states or/and the cross terms of Eq. 3c, while doublet structures of *c*-type transitions arise mainly from the energy difference $\Delta\nu$ between the + and − states.

Group I. Since observed *a*-type transitions are singlets except $K_{-1}=1$ transitions, the rotational constants of the + and − states are regarded to be approximately equal to each other. Doublet structures of $K_{-1}=1$ transitions are due to the cross terms in Eq. 3c.

For the normal species, *a*-type $J=2\rightarrow3$ transitions with $K_{-1}=1$ have the largest splittings of all the *a*-type transitions.

This is understandable if the 2_{11} level of the + state is accidentally degenerate with the 2_{12} level of the − state (referred to as 2_{11}^+ and 2_{12}^-). Furthermore, the fact that the splittings of $J=1\rightarrow2$ transitions are greater than those of $J=3\rightarrow4$ transitions indicates that the

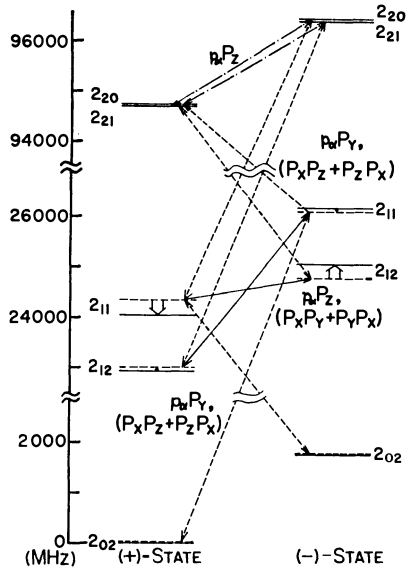

Fig. 1. The interaction scheme between the + and − states for $J=2$ levels of the normal species. Solid and dotted lines indicate perturbed and unperturbed levels, respectively.

2_{11}^+ level is slightly lower than the 2_{12}^- level.

The interaction scheme of the cross terms are shown for the normal species in Fig. 1. Since the molecule is a nearly prolate symmetric top, the P_z term connects two levels with the same K_{-1}, while the $(P_xP_y+P_yP_x)$ term connects two levels whose K_{-1} values differ by 2 from each other except $K_{-1}=1$ levels. However, the observed spectra show doublet structures only in the case of $K_{-1}=1$ transitions. Thus we cannot determine the contributions due to the P_z and $(P_xP_y+P_yP_x)$ terms independently. The determination might be possible if the transitions with $J=8$ or 9 are available, since the levels with $J=8$ or 9 would exhibit the degeneracy for $K_{-1}=2$ levels which is affected by the P_z term most sensitively. However, the corresponding transitions are expected out of our observable frequency region.

The $(P_xP_z+P_zP_x)$ and P_y terms affect the splittings only by a small amount, since the energy difference of the levels which perturb each other through these terms is ten times larger than those in the case of P_z connections so that the corresponding levels of the + and − states are equally pushed up or down. Schmidt and Quade[3] determined the coefficient of the $(P_xP_z+P_zP_x)$ term neglecting the P_y term but the error of this coefficient would be fairly large. We have analyzed the doublet structures by taking account of only the $(P_xP_y+P_yP_x)$ term of Eq. 3c.

For the *c*-type transitions, splittings are about twice the energy difference between the + and − states, *i.e.*, $2\Delta\nu$. The assignments of the *c*-type *Q* branch transitions were made taking account of the roughly estimated value of $\Delta\nu$ from the *a*-type transitions. A least squares analysis was carried out using rotational constants *A*, *B*, *C*, energy difference $\Delta\nu$, and the coefficient of the cross term $D_\pm$, as parameters. Centrifugal distortion effect was neglected since relatively low *J* transitions were used.

As is shown in Table 8 for the normal species, if a suitable choice of the components of the doublets is made, the observed *a*-type transition frequencies can be fitted with the rigid rotor expression giving the rotational constants *B* and *C* which are equal to the rotational constants obtained by the above procedures within the experimental error. This is explained as follows.

Since the rotational constants for the + and − states are approximately equal to each other, the frequencies of a given *a*-type transition for the + and − states are equal to each other if all the coupling terms are negligible. However, for the transitions with $K_{-1}=1$, the energy difference between the + and − states makes pairs of energy levels such as $(1_{10}^+, 1_{11}^-)$, $(2_{11}^+, 2_{12}^-)$, and $(3_{12}^+, 3_{13}^-)$ to be in an accidental degeneracy and the coupling term $(P_xP_y+P_yP_x)$ makes a level in a pair shift to the upper side and the other to the lower side. The frequencies of the transitions containing these levels shift from the original values. On the other hand, the coupling term makes little influence on pairs of energy levels such as $(1_{10}^-, 1_{11}^+)$, $(2_{11}^-, 2_{12}^+)$, and $(3_{12}^-, 3_{13}^+)$ which are not in degeneracy. The frequencies of the transitions containing these levels remain unchanged and they can be fitted with the rigid rotor expression as well as those of the transitions with $K_{-1}=0$ or 2.

Group II. For this group, there are no splittings for the *a*-type transitions, all the observed *c*-type transitions having splittings of about 140 MHz. The analysis of the observed spectra was carried out by a least squares technique using rotational constants and energy difference Δv as parameters neglecting centrifugal distortion contributions.

r_s Structure

Our present data are sufficient to determine the r_s structure for the *gauche* isomer by the substitutuion method. However, there are several atoms situated close to one of the principal axes for the *gauche* isomer. Solutions of the Kraitchman equations are not reliable for the coordinates having small absolute values for these atoms. These "bad" coordinates must be calculated from other reliable coordinates either with the aid of the first moment equations or by some assumptions on the structure.

There are five so-called "bad" coordinates for the *gauche* isomer: 1) x_c coodinates of the carbon atoms in the methylene and methyl groups, 2) x_b and x_c coordinates of the hydrogen atom labeled by H_s in the methyl group, and 3) x_c coodinate of the sulfur atom.

We have three first moment equations and three inertia products which should be zero in the principal axis system. Then, if desirable, some of the five "bad" coordinates can be obtained from these six relations. However, use of the inertia products makes the error of the calculated coordinates greater in general and some of three first moment equations will be useful for confirmation of the results. The following assumptions on the structure were made for the calculation of the "bad" coordinates.

The most reasonable assumptions for x_c coordinates of the carbon atoms in the methylene and methyl groups are probably $r(CH^1)=r(CH^2)$ and $r(CH_a^1)=r(CH_a^2)$, since these bond lengths are equal to each other from the symmetry for the *trans* isomer. For x_b and x_c coordinates of the H_s atom in the methyl group, assumptions $r(CH_s)=r(CH_a^1)=r(CH_a^2)$ and $r(H_sH_a^1)=r(H_sH_a^2)$ are acceptable, since $r(CH_s)$ and $r(CH_a)$ for the *trans* isomer are essentially equal to each other within experimental error. The name of each atom is shown in Fig. 2.

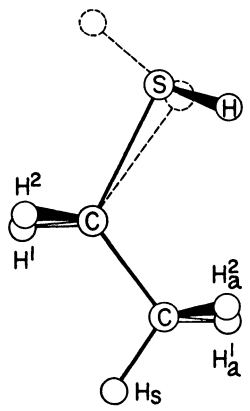

Fig. 2. Symbols of atoms in *gauche*-ethanethiol.

The x_c coordinate of the sulfur atom was solved by use of the first moment equation. The coordinates obtained are given in Table 5 where the calculated two first moments and three inertia products are also given for confirmation of the adequacy of the assumptions. Deviations of the calculated moments of inertia from the observed are also given in Table 4, for all the species. The root mean square deviation for thirty moments of inertia is 0.3938 amu Å which is satisfactorily small.

Structural parameters calculated from atom coordinates are given in Table 6, in comparison with those for the *trans* isomer.[2]

Despite many "bad" coordinates, the structural parameters for the *gauche* isomer are reliable in a similar extent to those for the *trans* isomer. Structural parameters of the CSH and CH_3C parts of the *gauche* isomer are essentially equal to those of the *trans* isomer, except slightly longer r(SH) and shorter r(CS) values (Table 6). The dihedral angle τ(CCSH) for the *gauche* isomer can also be determined satisfactorily.

Significant discrepancies are found in the six angles around the carbon atom in the methylene group. This was expected in I from the anomalous smallness of α(CCS) in the *trans* isomer. This was explained by considering the tilt of the ethyl group towards the lone pair electrons on the sulfur atom in a similar manner to the case of the methyl group in methanethiol. The

a) Figures in parentheses indicate 99% reliability intervals. Structural parameters for the *gauche* isomer were obtained by the following assumptions. $r(CH^1)=r(CH^2)$ for CH_2; $r(CH_a^1)=r(CH_a^2)=r(CH_s)$, $\alpha(CCH_a^1)=\alpha(CCH_a^2)$, $\alpha(H_sCH_a^1)=\alpha(H_sCH_a^2)$ for CH_3. b) Quoted from (Ref. 2). c) The proposed structure by Schmidt and Quade (Ref. 3). Figures in parentheses indicate the parameters derived from their parameters. The dihedral angle for the *gauche* isomer is defined as the dihedral angle around the internal rotation axis of the SH group and is not equal to our definition. d) See text.

present structural data for the *gauche* isomer are useful for the explanation.

Let us assume that 1) the methylene group is tilted $\delta°$ towords lone pair electrons on the sulfur atom, 2) the internal rotation axis of the mercapto group does not always coincide with the CS bond, 3) the dihedral angle is defined as that around the internal rotation axis of the mercapto group and is 180° for the *trans* isomer and $\tau°$ for the *gauche* isomer, and 4) α(HCH) and α(HCC) angles remain unchanged between the *trans* and the *gauche* isomers.

From these assumptions, the following relations can be derived approximately.

For the *trans* isomer,

$$\alpha(\mathrm{CCS})_{trans} = \beta - \gamma \quad (4)$$

$$\alpha(\mathrm{SCH})_{trans} = \gamma + \delta\cos\omega \quad (5)$$

For the *gauche* isomer,

$$\alpha(\mathrm{CCS})_{gauche} = \beta + \delta\cos\tau \quad (6)$$

$$\alpha(\mathrm{SCH}^1)_{gauche} = \gamma - \delta\cos(\tau-\omega) \quad (7)$$

$$\alpha(\mathrm{SCH}^2)_{gauche} = \gamma - \delta\cos(\tau+\omega) \quad (8)$$

where ω is the dihedral angle between the symmetry plane and the plane containing the CH bond and the internal rotation axis, and β and γ indicate the angles made by r(CC) and r(CH) against the internal rotation axis, respectively, *viz.*, the hypothetical unperturbed α(CCS) and α(SCH) angles which are free from the influence of the tilt and are common to the *trans* and *gauche* isomers.

In order to evaluate δ, β, and γ values from the relations (4)—(8), we must know the values of τ and ω, where ω is a function of α(HCH) and γ. Since the values of τ and ω are not far from 60°, it is reasonable as a first approximation to calculate the γ value with 60° for both the τ and δ values. The value γ=107°52′ is obtained. Though α(HCH) values for the *trans* and *gauche* isomers are not equal to each other beyond experimental error in contrast with the assumption 4), the average (107°45′) of the observed α(HCH) values for the two isomers is taken as the value in the evaluation of the ω angle. ω=57°57′ is obtained using γ=107°52′ and α(HCH)=107°45′. Though the experimentally obtained dihedral angle (61°45′) is actually the one defined around the CS bond, the value is taken as the τ value in the above relations as an approximation. In the calculation, because of experimental error, choice of three relations from the five gives slightly different values of δ, β, and γ. The average values for the different choices are δ=3°7′, β=111°55′, and γ=107°50′.

The α(HCC) value 110°45′ was obtained, which is in good agreement with the average (110°37′) of the experimentally obtained α(HCC) values for the two isomers.

It is interesting that the hypothetical unperturbed α(CCS) (=β) is close to α(CCC) in propane (112°24′)[7] and the tilt angle (=δ) is slightly larger than that of the methyl groups in methanethiol[8] and dimethyl sulfide[9] (2°30′). The tilt of the methylene group indicates that the internal rotation axis of the mercapto group does not coincide with the CS bond, a line from the carbon atom in the methylene group to the mercapto group making an angle of 3°7′ with the CS bond.

Schmidt and Quade[3] proposed a structure for ethanethiol. It was obtained so as to fit the calculated moments of inertia with those observed for four species of the *trans* isomer and five species of the *gauche* isomer.

For the structures of the two isomers, they took thirteen structural parameters, some of which have different definitions from ours. They assumed that 1) change in the structure from the *trans* to the *gauche* isomer has been explained solely in terms of the orientation of the mercapto group, 2) the internal rotation axis of the mercapto group does not always coincide with the CS bond, 3) the dihedral angle of the mercapto group is defined around the internal rotation axis, this being 180° for the *trans* isomer and 60° for the *gauche* isomer, respectively, and 4) the methyl group is axially symmetric.

From the assumptions, the following parameters are common to the *trans* and *gauche* isomers; for the skeleton, r(CC), r(CS), for the mercapto group, r(SH), α(CSH), for the methyl group, $r(\mathrm{CH_s})=r(\mathrm{CH_a})$, α(CCH), for the methylene group, r(CH), α(CCH) and the dihedral angle between the CCH and CCS planes.

They used the tilt angle of the methylene group and the angle between the CC bond and the internal rotation axis which is identical with our unperturbed α(CCS). Their proposed structure is given in Table 6, where some of the parameter values were converted from their parameter definitions into ours. For the dihedral angle of the mercapto group for the *gauche* isomer, their value is approximately comparable to ours since the definitions are different.

We see that the proposed structure is regarded as a fairly good approximate structure for ethanethiol. In particular, the agreement for the unperturbed α(CCS) and the tilt angle for the methylene group is surprisingly good. When the averages of our parameters for two isomers are taken, their other parameter values are in good agreement with ours within experimental error. However, they took r(CS) longer by *ca.* 0.01Å and α(CSH) smaller by *ca.* 1° than our r_s structural parameters.

Dipole Moment

The dipole moment of the *trans* isomer obtained by Stark effect measurements was reported in I, discussion being given on its direction in the molecule. Schmidt and Quade[3] also reported the dipole moments both for the *trans* and *gauche* isomers. Their values of the dipole moment and its component for the *trans* isomer are in good agreement with ours. We have not carried out measurements of the dipole moment for the *gauche* isomer. However, the direction of the dipole moment can be discussed from their reported values of the dipole moment, its components, and our r_s structure.

Schmidt and Quade extended their measurements of the dipole moments to the normal and four deuterated species. However, change in the dipole moment and its components by isotopic substitutions was negligible within experimental error.

They reported μ_a=1.49±0.02, μ_b=0.19±0.10, μ_c=0.59±0.02 and μ_{total}=1.61±0.05 *D* for the normal

species. It was found that the dipole moment exists along the line which makes angles of 22°35′, 83°14′, and 68°33′ with the *a*-, *b*-, and *c*-inertial axes, respectively.

From the structure, the dipole moment makes angles of 25° and 23°27′ with the CS bond and the bisector of the CSH angle, respectively. As we described in I, the dipole moments of *trans*-ethanethiol (1.560 *D*) and methanethiol (1.532 *D*) exist along lines which make angles of 28°46′ and 18°30′ with the bisector of the CSH angle in the symmetry plane inclining towards the ethyl and methyl groups, respectively. The difference in direction of the two molecules can be explained by an induced moment whose direction is from the methyl to the methylene groups in the ethyl group. When the group moment of the CH_2SH part of *trans*-ethanethiol is regarded to be equal to the dipole moment of methanethiol whose direction is from the inside of the CSH angle to the apex, the induced moment of the ethyl group is found to be 0.36 *D*. The dipole moment of *gauche*-ethanethiol is calculated to be 1.77 *D* whose direction is along the line making angles of 24°4′, 82°22′, and 67°20′ with the *a*-, *b*-, and *c*-inertial axes, respectively. Though the magnitude of the calculated dipole moment is larger than the observed by about 10%, the calculated direction is in good agreement with the observed one.

Microwave Spectra in the Excited States for *Trans* and *Gauche* Isomers

Several groups of weak spectra attributed to the excited vibrational states exist around the spectra due to the ground states of both the *trans* and *gauche* isomers.

For the *trans* isomer of the normal species, there are at least two groups of spectra whose $1_{10}\leftarrow1_{01}$ transitions are found at frequencies lower than the ground state spectra by about 410 and 480 MHz. The group of spectra whose $1_{10}\leftarrow1_{01}$ is found at 23053.85 MHz are much weaker than the other group whose $1_{10}\leftarrow1_{01}$

a) Figures in parentheses indicate the difference between the observed and calculated frequencies. b) For *b*-type transitions, A component frequencies are shown. c) $\Delta\nu$ indicates the difference between A and E component frequencies. Figures in parentheses indicate differences of the observed splittings from the calculated which were computed using the listed parameters in the table. d) E component of the doublet is hidden under a strong line. e) Overlapping with a strong line with slow Stark lobes and the frequencies were obtained by measuring the Stark lobes with sine-wave Stark modulation and D. C. bias. f) Coefficient of the $[J(J+1)]^2$ term of the centrifugal distortion. g) $P_c=(I_a+I_b-I_c)/2$. For the ground state, $P_c=3.1946$ amu Å^2. h) Moment of intertia of the CH_3 group around the internal rotation axis. i) Direction cosines of the internal rotation axis in the principal inertial axes. j) $\hbar^2/2rI_\alpha$, $r=1-\lambda^2I_\alpha/I_a-\mu^2I_\alpha/I_b$. k) Reduced barrier. l) Root mean square deviation of the observed frequencies from the calculated. For the ground state, $A=28416.89(74)$, $B=5485.77(9)$, $C=4881.92(10)$, $D_J\times10^2=0.47(41)$ and RMS=0.22 MHz.

is found at 23124.59 MHz. This group of spectra exhibits doublet structures, while the other group of spectra is singlets.

Schmidt and Quade[3] also observed the spectra belonging to the stronger group and assigned them to the spectra due to the first excited mercapto torsional state. They found no spectra belonging to the weaker group. Spectra of these two groups cannot be predicted by a modified rigid rotor expression which is applied to those for the ground state. The root mean square deviations of the observed frequencies from the calculated are 0.87 and 0.93 MHz for the stronger and weaker group, respectively, while it is 0.22 MHz for the ground state. Centrifugal distortion contributions seem to be much larger for the spectra of these two groups than for those of the ground state, though the contributions cannot be determined explicitly at present because of the lack of sufficient data of the observed frequencies with different K_{-1} values. Observed frequencies of the spectra are given in Table 7.

Quantities $P_c(=(I_a+I_b-I_c)/2)$ calculated from the observed rotational constants for the ground state and the two groups of the spectra are 3.1946, 3.7022, and 3.4241 amu Å^2, respectively. The difference in the values of the two groups and the value of the ground state $\Delta P_c(=(P_c)_{excited}-(P_c)_{ground})$ (0.5076 and 0.2295 amu Å^2) indicates that these groups are due to the excited states of out of plane vibrations.[10]

Schmidt and Quade measured the intensities of the stronger group spectra relative to those of the corresponding ground state spectra and concluded that the stronger group is due to the first excited state of an out of plane vibration having the frequency of 154±18 cm^{-1}. They presumed this vibration to be the mercapto torsion for the *trans* isomer.

For the *gauche* isomer of the normal species, two groups of weak *a*-type *R* branch spectra are also observed. Spectra of these two groups exhibit doublet structures in a similar manner to those in the ground state of the *gauche* isomer. Some of the transitions with $K_{-1}=0$ also exhibit doublet structures while the corresponding transitions in the ground state are singlets. Search for *c*-type transitions of these two groups has been unsuccessful so far. The observed frequencies are given in Table 8.

Schmidt and Quade also measured the spectra of the stronger group whose relative intensities indicate that the group is due to the excited state of a vibration having the frequency of 192±20 cm^{-1}. They presumed this vibration to be the mercapto torsion for the *gauche* isomer.

There are only two out of plane vibrations expected below 400 cm^{-1} for each of the *trans* and *gauche* isomers, the mercapto torsion around 170 cm^{-1} and the methyl torsion around 250 cm^{-1}. Inagaki *et al.*[11] and Manocha *et al.*[12] reported the far-infrared spectra of ethanethiol. For the mercapto torsion, they assigned a band at 158.0 cm^{-1} to the 0→1 transition of the *trans* isomer and the bands at 193.0 and 191.8 cm^{-1} to the $0_+\rightarrow 1_-$ and $0_-\rightarrow 1_+$ transitions, respectively, of the *gauche* isomer. The frequencies are in good agreement with those obtained from the relative intensity measurements of the microwave spectra by Schmidt and Quade for the stronger groups of the *trans* and *gauche* isomers.

For the methyl torsion, they reported only a series of bands at 247.5, 233.5, and 220.5 cm^{-1} and assigned them to $v=0\rightarrow 1$, $1\rightarrow 2$, and $2\rightarrow 3$ bands of the methyl torsion, respectively.

a) Figures in parentheses indicate the differences between the observed and calculated frequencies. b) ++ indicates the transition from the + state to the + state. For the first excited SH torsional state, tentative assignments are given in the table for the ++ and −− components of the doublets. c) Since the *gauche* isomer is very close to the prolate symmetric top, *a*-type transition frequencies can be expressed only by *B* and *C* rotational constants. Figures in parentheses indicate 99% reliability intervals calculated from 2.5 times the standard deviation. d) Root mean square deviation of the observed frequencies from the calculated. For the SH and CH_3 excited torsional states, RMS is 3.01 and 5.04 MHz, respectively if the choice of the components of the observed frequencies is reverse.

The doublet structures observed for the spectra belonging to the weaker group of the *trans* isomer indicate that the group is due to the first excited state of the methyl torsion. For the *gauche* isomer, the weaker group of the spectra may also be due to the first excited methyl torsional state, though there is no definite evidence for the assignment of the group.

For the methyl excited torsional state for the *gauche* isomer, components of doublets predictable by a rigid rotor expression are reverse in frequency to those for the ground state (Table 8). This is understood qualitatively as follows.

For the methyl excited torsional state, smallness of the splittings of the transitions with $K_{-1}=0$ indicates that the rotational constants of the + and − states are nearly equal in a similar manner to the ground state. However, the energy difference of the + and − states (estimated to be about 1300 MHz) seems to be much smaller than that for the ground state (determined to be 1750 MHz). This is obvious from the fact that the splittings of $J=1\rightarrow2$ are larger than those of $J=2\rightarrow3$, the reverse of the case for the ground state.

Schematic energy and transition diagrams for cases of no interactions, and ground and methyl excited torsional states are shown in Fig. 3. If there are no interactions between the + and − states, *a*-type transitions of both states have the same frequencies. For the ground state the interaction occurs strongly between the accidentally degenerate levels which are $K_{-1}=1$ levels for low J. Since the 2_{11}^{+} level is lower than the 2_{12}^{-} level, both levels are pushed down and up, respectively, by an amount of $\Delta\nu_2$. For the degenerate case of $(1_{10}^{+}, 1_{11}^{-})$ and $(3_{12}^{+}, 3_{13}^{-})$, 1_{10}^{+} and 1_{11}^{-} levels shift to lower and higher energy by an amount of $\Delta\nu_1$, and 3_{12}^{+} and 3_{13}^{-} levels are pushed up and down by an amount of $\Delta\nu_3$, respectively, since 1_{10}^{+} and 3_{13}^{-} levels are lower than the 1_{11}^{-} and 3_{12}^{+} levels, respectively. Thus the frequencies of the transitions concerned with $K_{-1}=1$ levels are

$$\left.\begin{aligned}
\nu(1_{10}^{+}\rightarrow2_{11}^{+}) &= \nu_2 + \Delta\nu_1 - \Delta\nu_2,\\
\nu(1_{11}^{-}\rightarrow2_{12}^{-}) &= \nu_1 - \Delta\nu_1 + \Delta\nu_2,\\
\nu(2_{11}^{+}\rightarrow3_{12}^{+}) &= \nu_4 + \Delta\nu_2 + \Delta\nu_3,\\
\nu(2_{12}^{-}\rightarrow3_{13}^{-}) &= \nu_3 - \Delta\nu_2 - \Delta\nu_3,
\end{aligned}\right\} \quad (9)$$

where ν_1, ν_2, ν_3, and ν_4 indicate the unperturbed frequencies of the corresponding transitions, whereas $\nu(1_{11}^{+}\rightarrow2_{12}^{+})$, $\nu(1_{10}^{-}\rightarrow2_{11}^{-})$, $\nu(2_{12}^{+}\rightarrow3_{13}^{+})$, and $\nu(2_{11}^{-}\rightarrow3_{12}^{-})$ are nearly unperturbed frequencies, since the levels are not in degeneracy.

On the other hand, for the methyl excited torsional state, since the 2_{11}^{+} level is higher than the 2_{12}^{-} level, the 2_{11}^{+} and 2_{12}^{-} levels are pushed up and down by an amount of $\Delta\nu_2$ as shown in Fig. 3(C). The directions of these shifts are the reverse of those for the case of the ground state. The frequencies of the transitions which are strongly affected by the interactions are

$$\left.\begin{aligned}
\nu(1_{10}^{+}\rightarrow2_{11}^{+}) &= \nu_2 + \Delta\nu_1 + \Delta\nu_2,\\
\nu(1_{11}^{-}\rightarrow2_{12}^{-}) &= \nu_1 - \Delta\nu_1 - \Delta\nu_2,\\
\nu(2_{11}^{+}\rightarrow3_{12}^{+}) &= \nu_4 - \Delta\nu_2 + \Delta\nu_3,\\
\nu(2_{12}^{-}\rightarrow3_{13}^{-}) &= \nu_3 + \Delta\nu_2 - \Delta\nu_3.
\end{aligned}\right\} \quad (10)$$

Since the $(2_{11}^{+}, 2_{12}^{-})$ couple is more degenerate than the $(3_{12}^{+}, 3_{13}^{-})$ couple, $\Delta\nu_2>\Delta\nu_3$, and then $\nu(2_{11}^{+}\rightarrow3_{12}^{+})$ is lower than $\nu(2_{11}^{-}\rightarrow3_{12}^{-})$ which is nearly equal to ν_4.

For the mercapto excited torsional state, splittings of the transitions with $K_{-1}=0$ are not small and the differences in the rotational constants of the + and − states are not negligible (Table 8).

According to the theoretical calculation, the rotational constants of the + and − states are nearly equal to each other within 0.1 MHz for the ground state, while they differ by *ca.* 5 MHz for the first excited mercapto torsional state. The observed results are in line with the calculated results. Though the coefficients of the cross terms $D_{\pm}$ and $E_{\pm}$ remain nearly unchanged between the ground and excited states, coefficients N and Q which correspond to the so-called Coriolis terms become about 25 times larger for the excited state than those for the ground state.

We see from Table 8 that the observed frequencies of *a*-type transitions for the mercapto excited torsional state cannot be fitted satisfactorily with a rigid rotor expression whatever choice of components of the doublets is used. This might be explained by the above results of the theoretical calculation.

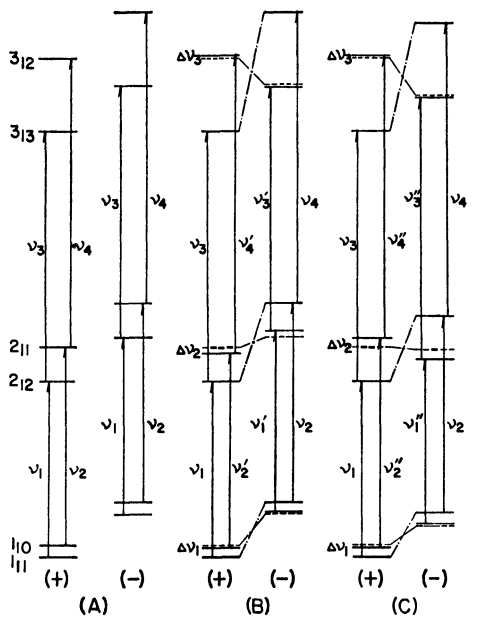

Fig. 3. Schematic energy and transition diagrams for the cases of (A) no interactions, (B) ground state and (C) methyl excited torsional state for the normal species.
Solid and dotted lines indicate perturbed and unperturbed levels, respectively.
For (B), $\nu_1'=\nu_1-\Delta\nu_1+\Delta\nu_2$, $\nu_2'=\nu_2+\Delta\nu_1-\Delta\nu_2$, $\nu_3'=\nu_3-\Delta\nu_2-\Delta\nu_3$, and $\nu_4'=\nu_4+\Delta\nu_2+\Delta\nu_3$, for (C), $\nu_1''=\nu_1-\Delta\nu_1-\Delta\nu_2$, $\nu_2''=\nu_2+\Delta\nu_1+\Delta\nu_2$, $\nu_3''=\nu_3+\Delta\nu_2-\Delta\nu_3$, and $\nu_4''=\nu_4-\Delta\nu_2+\Delta\nu_3$. See text.

Internal Rotation of the Methyl Group

As is shown in Table 7, from the observed splittings of the spectra attributed to the first excited methyl torsional state of the *trans* isomer, the barrier to internal rotation of the methyl group was determined to be $V_3=3260\pm30$ cal/mol by the principal axis method

neglecting the coupling effect of the mercapto internal rotation.

Schmidt and Quade[3] also reported the V_3 value as 3306±86 cal/mol which was obtained from very small splittings of high J, high K_{-1} transitions found in the ground state of the *trans* isomer. Their value is essentially identical with ours within experimental error.

Manocha *et al.*[12] observed only one weak series of far-infrared bands at the higher frequency wing of the strong mercapto torsion band due to the *gauche* isomer. They assigned them to the $v=0\rightarrow1$, $1\rightarrow2$, and $2\rightarrow3$ bands of the methyl torsion, though they did not confirm to which isomer these bands belong. From these bands, the barrier was calculated to be $V_3=3886\pm60$ and $V_6=-69\pm23$ cal/mol.

According to the relative intensity measurements of the microwave spectra by Schmidt and Quade, the *gauche* isomer is more stable by 406±43 cal/mol than the *trans* isomer so that populations of the *trans* and *gauche* isomers are in the ratio of *ca.* 1 : 4 at room temperature where the far-infrared spectra were observed. The barrier obtained from the far-infrared data probably belongs to the *gauche* isomer. The barrier of the methyl internal rotation for the *trans* isomer is lower by *ca.* 630 cal/mol than that for the *gauche* isomer.

Hirota[13] reported the barriers for the *trans* and *gauche* isomers of propyl fluoride which are 2690 and 2865 cal/mol, respectively. For this molecule, the barrier for the *trans* isomer is also lower by 175 cal/mol than that for the *gauche* isomer but change of the barrier is not so prominent as for ethanethiol.

Barriers to internal rotation of the CH_3–C group for a series of molecules; ethyl chloride,[14] ethyl bromide,[15] ethyl fluoride,[16] propane,[17] *trans*-ethyl methyl ether,[18] and *trans*-ethanol,[19] were reported to be 3685, 3684, 3330, 3325, 3300, and 3323 cal/mol, respectively. The barrier of *gauche*-ethanethiol is the highest among these molecules, while that of *trans*-ethanethiol is the lowest.

Internal Rotation of the Mercapto Group

The barrier to the mercapto internal rotation was determined using the Hamiltonian (1b) with the first three terms with the coefficients V_1, V_2, and V_3 of the potential function. Coefficients $\mu_\alpha^{(n)}$ of the kinetic terms were calculated on the basis of the r_s structure including the tilt angle. The first three terms of the kinetic terms were taken into consideration, though the coefficients $\mu_\alpha^{(1)}$ and $\mu_\alpha^{(3)}$ of the second and third terms were much smaller than that of the first term, $\mu_\alpha^{(0)}$.

The energy matrix was constructed from the Hamiltonian (1b) and the basis functions were chosen as $\{(1/\sqrt{2\pi}), (1/\sqrt{\pi})\cos\alpha,\cdots, (1/\sqrt{\pi})\cos 30\alpha\}$ for the symmetric states and $\{(1/\sqrt{\pi})\sin\alpha,\cdots, (1/\sqrt{\pi})\sin 30\alpha\}$ for the antisymmetric states. The torsional energy levels were obtained by a direct diagonalization of the energy matrix. A least squares analysis was carried out taking V_1, V_2, and V_3 as parameters in order to reproduce the energy differences of the + and − states of the *gauche* isomer obtained from the microwave spectra and those obtained from seven observed mercapto torsional frequencies of the *trans* and the *gauche* isomers reported

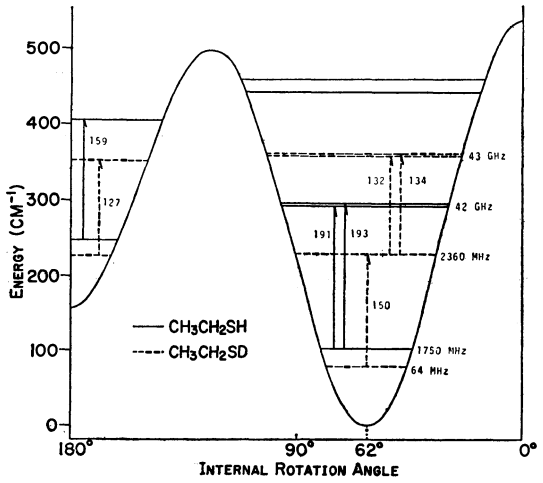

Fig. 4. Potential curve, energy levels and transition frequencies of mercapto internal rotation.

by Manocha *et al.*[12] both for the normal and CH_3CH_2SD species. The results are given in Table 9 and the resulting potential curve together with the energy levels in Fig. 4. The results reported by Schmidt and Quade and by Manocha *et al.* are also given in Table 9 for the sake of comparison.

Since the assumed structure used by Schmidt and Quade is close to our r_s structrue, the $\mu_\alpha^{(n)}$ values do not differ much between their calculation and ours. However, they disregarded the $\mu_\alpha^{(1)}$ and $\mu_\alpha^{(2)}$ terms since they were much smaller than the $\mu_\alpha^{(0)}$ term, while we included these terms in our calculation.

In order to know the influence of these terms, a calculation was made using our data neglecting these terms. It was found that the influence is negligible for the barrier values. The differences in the barrier values in our results and those by Schmidt and Quade are considered to be due to the data used in the calculations. Since their data obtained mainly from the intensity measurements have relatively large uncertainties, our results may be more reliable.

The energy differences used by us and by Manocha *et al.* are the same except for those of $g^0_+-g^0_-$ which were added to the data in our calculation. On the other hand, their assumed structure differs a great deal from our r_s structure. Actually, they used the $\mu_\alpha^{(n)}$ values calculated by Inagaki *et al.*[11] who obtained these coefficient values from a model structure. The structure is; $r(CS)=1.81$, $r(CC)=1.53$, $r(CH)=1.095$, and $r(SH)=1.329$ Å, $\alpha(CSH)=100°18'$ and other angles =tetrahedral. Not only do their structural parameters differ a great deal from the r_s structural parameters but the tilt angle was not taken into consideration. The $\mu_\alpha^{(n)}$ values of their calculations and ours greatly differ. The $\mu_\alpha^{(1)}$ and $\mu_\alpha^{(2)}$ values are much larger than ours. Furthermore, using four energy differences for the CH_3CH_2SD species, they could determine not only the V_1, V_2, and V_3 values but also the V_6 value which was neglected in our calculation.

For a comparison of our results with theirs, trial calculations were carried out with several different choices of $\mu_\alpha^{(n)}$ values and the data. It can be concluded

that 1) discrepancies found in the barrier values obtained by the present authors and by Manocha *et al.* arise form the structure used in the calculations and 2) the V_6 value cannot be determined in sufficient accuracy if the $\mu_\alpha^{(n)}$ values based on the r_s structure are used in the calculation.

Catalytic Isotope Exchange Reaction between Deuterium Gas and Water Pre-Adsorbed on Platinum/Alumina

Itsuo IIDA, Junko KATO, and Kenzi TAMARU*

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

**Department of Chemistry, Faculty of Sciense, University of Tokyo, Hongo, Tokyo 113*

(Received June 10, 1976)

The catalytic isotope exchange reaction between deuterium gas and the water pre-adsorbed on Pt/Al_2O_3 was studied. At reaction temperatures above 273 K, the exchange rate was proportional to the deuterium pressure and independent of the amount of adsorbed water, which suggests that the rate determining step is the supply of deuterium from the gas phase. Its apparent activation energy was 38 kJ mol^{-1}. Below freezing point of water, the kinetic behaviour was different from that above freezing point. At higher deuterium pressures the rate dropped abruptly at 273 K. Below the temperature the apparent activation energy was 54 kJ mol^{-1} and the exchange rate depended not on the deuterium pressure but on the amount of the pre-adsorbed water. At lower pressures, however, the kinetic behaviour was the same as that above 273 K, till the rate of the supply of deuterium from the gas phase exceeded the supply of hydrogen from adsorbed water to platinum surface.

These results suggest that below 273 K the supply of hydrogen is markedly retarded, the state of the adsorbed water differing from that above 273 K. It was also demonstrated that when the adsorbed water is in the state of capillary condensation, the exchange rate becomes very small.

The isotope exchange reaction between hydrogen and water is considered to be important in nuclear industry as a means of obtaining enriched deuterium, and the success of this process depends to a large extent upon the rate of isotope transfer between the two chemical species. The isotope separation is possible because the equilibrium constant K of the reaction, $HDO+H_2 \rightleftarrows H_2O+HD$, or the ratio of the isotope concentration in the reactants, is not equal to unity exactly, and the value of K depends upon the temperatures where equilibrium attained. In enriching the deuterium, different equilibration at different temperatures is employed. In principle, it is more effective if the temperature of the cold reactor is as low as possible, since the isotope effect is greater at lower temperatures.

Although platinum on an activated charcoal and nickel on chromium oxide were reported to be efficient catalysts for the vapour phase reaction, both catalysts lose their catalytic activities when condensed water film covers the catalyst surface at lower temperatutres,[1,2] which prevents these catalysts from being used in the lower temperature range.

The mechanism of the hydrogen exchange reaction catalyzed by transition metals at temperatures above the boiling point of water has been extensively studied.[3-5] Recently, Rolston and Goodale [6] studied the mechanism of this exchange reaction catalyzed by platinum supported on alumina and proposed that the rate determining step of the exchange reaction in the vapour phase consists of the hydrogen atom switch between chemisorbed hydrogen on platinum and physisorbed water on alumina. Sagert and Pouteau[7-9] also studied this reaction over various noble metals and reported that the exchange rate depended not on the hydrogen gas pressure but on the pressure of water vapour on platinum catalyst. They also supported the hydrogen switching mechanism proposed by Rolston and Goodale.

On the other hand, when the reaction takes place between liquid water and hydrogen gas bubble over suspended platinum charcoal catalyst at around room temperature, it was shown that the rate increases with stirring rate, which implies that the rate determining step consists of the hydrogen gas diffusion through the water to contact with the catalyst surface.[10] Since little is known of the chemical kinetic behaviour of this exchange reaction below room temperature, it is significant to examine the behaviour of each elementary step of the exchange reaction on the catalyst surface.

Experimental

The rate of exchange reaction between deuterium gas and the water adsorbed on platinum/alumina catalyst was measured in a closed circulation system, volume 340 cm^3, changing the amount of water adsorbed on the catalyst. The isotope abundance in the gas phase was determined by gas chromatography using 5% manganese chloride on an alumina column at 77 K. Prior to the measurements, the catalyst was subjected to heat-treatment *in vacuo* at 423 K, then cooled down to room temperature. The catalyst was 0.5% platinum supported on an alumina pellet (Lot No. 48-1-1 Nippon Engelhard Co., Ltd.,). Initial pretreatment of the catalyst consisted of evacuation at room temperature for 30 min, and at 398 K for 30 min. The sample was then treated with hydrogen at 623 K overnight and evacuated at the same temperature overnight. The surface area measured by the BET method was 92 m^2/g, the amount of the catalyst being 2.13 g. The adsorption isotherm of water on the catalyst in the temperature range 229—296.5 K was measured. Since the equilibrium pressure of the water at low coverage was very low, the pressure was measured with a Pirani gauge which was calibrated by a MacLeod gauge.

Results and Discussion

The adsorption isotherm of water on the catalyst at 296.5 K is shown in Fig. 1. If the area occupied by a water molecule is $1.06 \times 10^{-19} m^2$,[11] the monomolecular adsorption of water on the catalyst surface area corresponds to 0.054 g of water. In the standard run, the amount of pre-adsorbed water was fixed to 0.025 g and the pressures of the water vapour which were in equilibrium with the adsorbed water were below 40 Pa even at room temperature as given in Fig. 1. From the adsorption isotherm, the capillary condensation is considered to take place when the amount of adsorbed

water exceeds about 0.14 g.

The temperature dependence of the exchange rate between deuterium gas and the adsorbed water is given in Fig. 2 for several deuterium pressures in the Arrhenius form. Under deuterium pressures of 55 kPa and 27 kPa, the exchange rates dropped abruptly at 273 K, below which they fell to another temperature dependency. The apparent activation energies above and below 273 K correspond to 38 and 54 kJ mol^{-1}, respectively, which suggests not only an appreciable change in the rate determining step of the reaction at 273 K but also the possibility that the transport phenomena might be involved in a rate determining step which is markedly influenced by freezing the adsorbed water.

Under lower deuterium pressures such as 15 and 9.3 kPa, the Arrhenius plots exhibited no discontinuity at 273 K and the apparent activation energy was the same with 38 kJ mol^{-1}.

Consequently, the temperature dependence of the reaction rate revealed at higher deuterium pressures such as 55 and 27 kPa, the abrupt drop of exchange rate and the activation energy change could be observed, but at lower pressures such as 15 kPa and 9.3 kPa, the change of activation energy takes the form of a bent in the Arrhenius plots.

$H_2O(a)$=0.025 g.

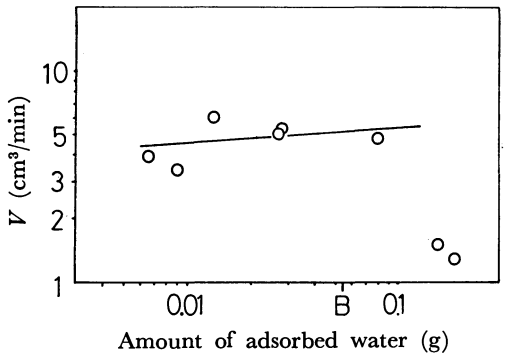

Fig. 4. Dependence of the exchange rate on the amount of adsorbed water at 273 K.
P_{D_2}=27 kPa.

The variation of the rate with deuterium pressure at 273 K is shown in Fig. 3. The reaction order with respect to deuterium pressure, given by the slope of line, is 0.9. The dependence of rate on the amount of the adsorbed water at 273 K is shown in Fig. 4. The amount of adsorbed water corresponding to that of monolayer full coverage is denoted by B. The results (Fig. 4) demonstrate that when the amount of adsorbed water does not much exceed point B, the reaction order with respect to the amount of the adsorbed water is zero. However, when the amount of the adsorbed water exceeds point B, the exchange rates decrease considerably. Judging from the results in Fig. 1, the amounts of adsorbed water in the range correspond to capillary condensation. It was accordingly suggested that when the adsorbed water is condensed in the pores of the catalyst, the diffusion of deuterium gas through the condensed water becomes the rate determining step.

The exchange rate is nearly proportional to the deuterium pressure, and is independent of the amount of the adsorbed water provided that the adsorbed water is not in the state of capillary condensation. It was suggested that the rate determining step of this exchange reaction above 273 K is the supply of deuterium from the gas phase to the active sites in the platinum surface.

In contrast to the kinetic behaviour above 273 K, the kinetic behabiour below 273 K is rather complicated. At 269 K, the order of the reaction with respect

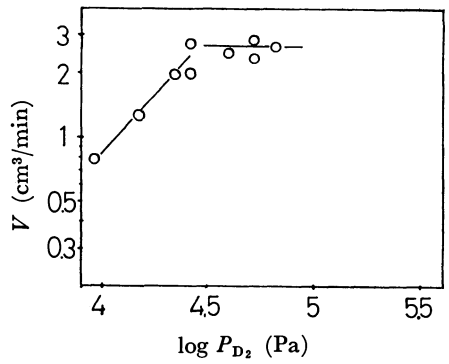

Fig. 5. Dependence of the exchange rate on D_2 pressure at 269 K.
$H_2O(a)=0.025$ g.

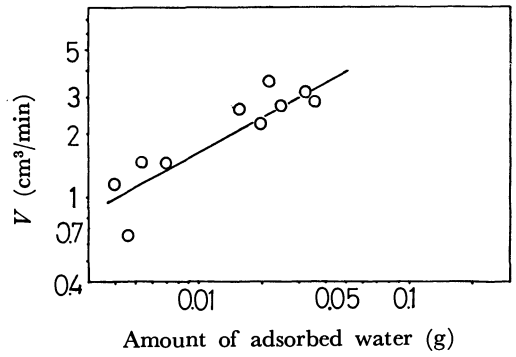

Fig. 6. Dependence of the exchange rate on the amount of adsorbed water.
$P_{D_2}=55$ kPa.

$P_{D_2}=15$ kPa.

to deuterium pressure is 1.1 under lower deuterium pressures below 27 kPa, whereas at higher pressures the rate is independent of the deuterium pressure (Fig. 5). The dependence of the rates upon the amount of adsorbed water was measured under deuterium pressures of 55 and 15 kPa at 269 K (Figs. 6 and 7, respectively). The reaction order with respect to the amount of the adsorbed water is 0.5—0.6 under the deuterium pressure of 55 kPa, and 0.2 under the deuterium pressure of 15 kPa. When the exchange rates are nearly proportional to the pressure of deuterium gas, the reaction order with respect to the amount of the adsorbed water is as low as 0.2 and when the exchange rates are independent of the pressure of deuterium gas,

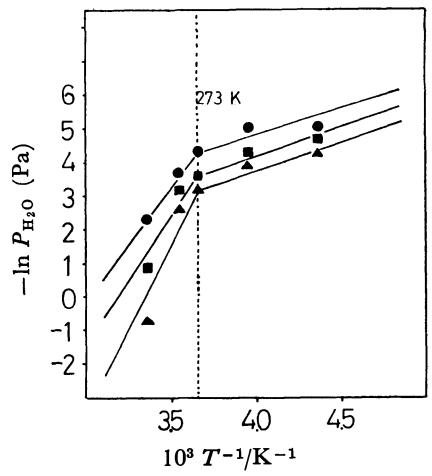

Fig. 8. Adsorption isoster of water on 9.44 g of platinum/alumina.

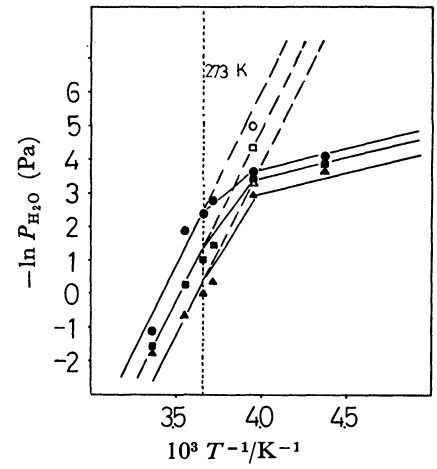

Fig. 9. Adsorption isoster of water on 9.44 g of platinum/alumina.
—●—; $H_2O(a)=7$ mmol, —■—; $H_2O(a)=8$ mmol, —▲—; $H_2O(a)=9$ mmol, --○--; $H_2O(a)=7$ mmol, --□--; $H_2O(a)=8$ mmol, --△--; $H_2O(a)=9$ mmol. Broken lines are the plots for the second adsorption after the adsorption temperature was once raised.

the order is 0.5—0.6.

Consequently, the rate determining step at 269 K shifts from the supply of deuterium from the gas phase to that of hydrogen from the adsorbed water as the pressure of the deuterium gas increases.

The adsorption isosters of water over the platinum/alumina at lower and higher coverages are shown in Fig. 8 and Fig. 9, respectively, the slope of which is proportional to the heat of adsorption. We see that the adsorption isoster bent at 273 K.

Since the phase change of the adsorbed water from liquid to solid should cause an increase in the heat of adsorption below 273 K, it was interpreted that the equilibration of the adsorption of the water below 273 K is nearly apparent. In the experiments of water adsorption below 273 K, after the apparent equilibrium, the temperature of the adsorbate rose to room tem-

perature, and after 12 h the temperature was lowered again. It was found that the additional adsorption (Fig. 9) and the plots of the equilibrium pressure of the water below 273 K come of the same line of the adsorption isoster above 273 K. The heat of adsorption of water on platinum/alumina was found to be 84 kJ mol^{-1}.

Thus, though the heat of adsorption of water on platinum/alumina is much greater than the heat of fusion of the water, the water cannot spread over the adsorbate easily and crystallizes on the surface of platinum/alumina.

Considering the results of the adsorption of water on the catalyst, it was concluded that the change in the kinetic behaviour at 273 K is due to the retardation of the supply of hydrogen from the frozen water. The apparent activation energy of the exchange reaction between deuterium and water below 273 K would be that for the transfer of adsorbed water. This activation energy might be measured above 273 K if the water coverage was very low. However, in such a case, the increase in the HD content of deuterium gas is not measurable.

This work was performed under the auspices of Power Reactor and Nuclear Fuel Development Corporation (Japan).

Stereochemical Studies of Elimination Reactions of 2-Bromobutane and 2,3-Dibromobutane over Bivalent-Ion Exchanged Silica Gels

Yukio Aoki,* Makoto Misono, and Yukio Yoneda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 17, 1976)

Elimination reactions of 2-bromobutane and 2,3-dibromobutane over silica gels in which silanol protons on the surface were exchanged with bivalent ions such as Ba(II), Ca(II), Mg(II), and Ni(II) have been investigated. Dehydrobromination of 2-bromobutane was found to proceed mainly with *syn* elimination. Debromination by *anti* mode and non-stereospecific dehydrobromination were observed for 2,3-dibromobutane. The catalytic activities of these silica gels exhibit reversed volcano-type patterns when they are plotted against the electronegativity of metal ion together with those of alkali-ion exchanged silica gels. Reaction intermediates consistent with the stereochemistry observed are a *s*-butyl cation and a bromonium ion, respectively for 2-bromobutane and 2,3-dibromobutane.

In the previous paper, we reported a remarkable effect of alkali ion exchange of silica gel on the acid-base properties and the stereochemistry of the title reactions.[1] The reactions proceeded with *anti* elimination over Cs- and K-exchanged silica gels in which basic sites play a primarily important role. However, the reaction of 2-bromobutane proceeded with *syn* mode over silica gel and Na- or Li-exchanged silica gel, all of which are weakly acidic. It was demonstrated that the acid-base properties are the prime factor determining the stereochemistry.[2] The observed dependence of the steric course of reaction on the acid-base properties was explained by the variation of the reaction mechanism from a concerted elimination over basic surfaces to a carbonium-ion like mechanism over acidic surfaces.

In the present work, we have extended the study to silica gels exchanged with bivalent metal ions which are expected to be more strongly acidic, with the aim of clarifying how the reaction rate, stereochemistry, and orientation of olefin formation vary with the acid strength of the catalyst surface. Acidic properties and catalytic activities have already been investigated for the metal ion-exchanged silica or porous glass.[3,4] The metal ion loaded on oxide surface may be regarded as a model of Lewis acid sites having a series of various acid strengths.

Experimental

Apparatus and Procedure. The procedure for the reaction study (pulse technique) and the analyses of products are the same as reported.[1] 10—50 mg of catalyst was used for the reaction of 2-bromobutane and 100—200 mg for that of 2,3-dibromobutane. Effect of pyridine adsorption on the catalytic activity was studied as follows. After ordinary pretreatment of the catalysts at 300 °C in a stream of helium, 10 μl of pyridine injected into the helium stream was passed through the catalyst bed at 150 or 160 °C. The temperature was then raised at a rate of 5 °C/min to the predetermined temprature. The reaction of 2-bromobutane was examined after the temperature had been lowered to 150 or 160 °C.

Catalysts and Reagents. The same silica gels as reported[1] were used as starting material. Ion-exchange was performed by impregnating the silica gel in aqueous solutions of metal chlorides followed by washing with water and drying at 110 °C overnight. The pH (5—7) of the solution was not intentionally controlled, a small amount of metal carbonate being added in some cases. The amount of loaded metal ion was as low as *ca.* 5 μg-ion/g. The surface area was *ca.* 500 m^2/g. The reagents used for the reactions were the same as reported.[1]

Results

Dehydrobromination of 2-Bromobutane. All the silica gels exchanged with bivalent metal ions (Mg(II), Ca(II), Ba(II), and Ni(II)) exhibited much higher activity for the dehydrobromination of 2-bromobutane than the alkali-ion exchanged silica gels.[1] Decrease in activity and change in butene composition were small during the repeated pulses. Although butene injected separately did not isomerize over these catalysts under the reaction conditions, 1-pentene pulsed together with 2-bromobutane isomerized in some cases to a small extent (*ca.* 5—10%). Hydrogen bromide formed from 2-bromobutane seemed to act as a temporary catalyst for the isomerization. The butene composition observed was probably affected by the secondary isomerization, but this influence should be small, since pentenes which are more reactive than butenes[2] did not isomerize to a great extent.

Butene compositions formed from 2-bromobutane-d_0 and the contents of d_1 species in each butene isomer formed from 2-bromobutane-3-d_1 (*erythro*: *threo*: d_0=77: 17: 6)[1] are given in Table 1. The ratios, $(trans/cis)_0/(trans/cis)_1$,[5] were 0.86—0.91, indicating that *syn* elimination was the major process over these four silica gels. The d_1 content of 1-butene which should agree with that of the starting 2-bromobutane-3-d_1 (94%) was low in some cases. This seems due partly to the secondary isomerization which may cause H–D exchange and partly to experimental error because of the small amount of 1-butene formed.

Under the same assumptions that the isotope effect and % *anti* (the fraction of reaction which proceeded by *anti* mode) are the same for *trans*- and *cis*-2-butene formation,[1] % *anti* was calculated to be *ca.* 20—30% (% *syn*: 70—80%) for these silica gels (Table 1). The elimination reaction may actually be more stereospecific than the values thus determined. Hydrogen shift in an alkyl cation intermediate was found to take place during the course of reactions of alkyl halides over solid acids.[6] This hydrogen shift as well as the H–D exchange by secondary isomerization should diminish the difference in d_1 content between

trans- and *cis*-2-butene. Thus the apparent % *anti* becomes closer to 50%.

Figure 1 shows how the catalytic activity changes with the electronegativity of metal ion[7] loaded. The results of alkali ion[1] are also given. Although the amount of metal ion loaded differs between mono- and bivalent ions, it is obvious that the activity increases from Na(I) to Ni(II) with increasing electronegativity. Since the activity increases with decreasing electronegatively from K(I) to Cs(I), a reversed volcano-type pattern exists in the activity-electronegativity correlation.

Positional and geometrical orientation of butene formation over these silica gels is shown in Fig. 2. The higher 2-/1-butene ratio (Saytzeff orientation) and the *trans*/*cis* ratio close to unity, together with the predominant *syn* elimination, are characteristic of bivalent-ion exchanged silica gels. This is in line with the view that these silica gels behave as acids like Li–SiO_2 but have much stronger acid strength. Figure 3 shows the effect of pyridine on the catalytic activity. Active sites of silica gel poisoned by pyridine were mostly regenerated at 150 °C 20 min after the addition, while only about a half was recovered in the case of Ni–SiO_2 even at 300—350 °C in a helium stream. It is seen that the strength of pyridine adsorption to active sites, which should reflect the acid strength, increases in the order Ca(II)<Mg(II)<

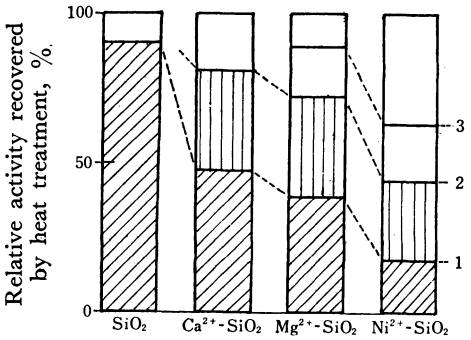

Fig. 3. Relative activity of silica gels poisoned by pyridine for dehydrobromination of 2-bromobutane. Reaction temp. : 150 °C (160 °C for Ca–SiO_2)
1: After heat treatment at the reaction temperature.
2: After heat treatment at 300 °C.
3: After heat treatment at 350 °C.

Ni(II) in accordance with electronegativity. The apparent energy of activation obtained at the state of stationary activity was 11.2 kcal/mol for Ca–SiO_2. The value is closer to that of Li–SiO_2 (9 kcal/mol) than to that Cs–SiO_2 (4—5 kcal/mol).[1] The activation energy for *trans-* and *cis*-2-butene formation was respectively 2.1 and 2.4 kcal/mol lower than that for 1-butene formation.

Reactions of 2,3-Dibromobutane. 2,3-Dibromobutane was less reactive than 2-bromobutane over bivalent-ion exchanged silica gels. Butadiene formation by the elimation of two molecules of hydrogen bromide and debromination to form 2-butene (*anti* elimination) were the major reactions. Minor reaction of dehydrobromination to form 2-bromo-2-butene was not stereospecific. No apparent difference in selectivity for these elimination reactions was observed among the bivalent ions, the fraction of debromination being 50—60% of total reactions. These elimination reactions also show a reversed volcano-type pattern when plotted against electronegativity (Fig. 1). It is to be noted that 2,3-dibromobutane is more reactive than 2-bromobutane (both with *anti* elimination) on the left branch, while the relative reactivity is the reverse on the right branch.

Discussion

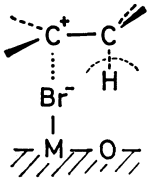
Bivalent metal ions undergo exchange with two silanol groups over the surface of silica gel when the extent of exchange is low.[3]

$$M^{2+} + 2{\equiv}Si\text{-}OH \rightarrow {\equiv}Si\text{-}O\diagdown\ \diagup M + 2H^+ \quad {\equiv}Si\text{-}O\diagup$$

The acidic sites increase in number with the amount of metal ion loaded at least at low extent of exchange, and Lewis acid sites which were proposed to be active for dehydrochlorination of isopropyl chloride are predominant after evacuation above 300 °C.[3]

The relative catalytic activity, (Ni(II)>Ca(II)≈Mg(II)≈Ba(II)≫Li(I)≈Na(I))(Fig. 1), parallels the acid strength of catalysts which can be estimated from the electronegativity of metal ion and the effect of pyridine adsorption on activity (Fig. 3). We proposed that the reaction intermediate or the transition state resembles a carbonium ion more over Li–SiO_2 than over Cs–SiO_2, since the stronger acidity of the former makes the C–Br bond breaking easier. This explanation can be applied to the present results. As the acid strength increases further by the exchange with bivalent ion, the C–Br bond breaks more readily and the rate of reaction *via* a carbonium ion will increase. Thus, the activity for elimination over metal-ion exchanged silica gels shows a reversed volcano-type pattern (Fig. 1), when the results of Cs- and K–SiO_2 are included, where the activity increases with base strength.[1]

The favored steric course over basic surface was *anti* mode.[1] On the other hand, over acidic surface *syn* elimintion is favored in the case of 2-bromobutane. 2,3-Dibromobutane is likely to form a bromine-bridged intermediate after heterolytic C–Br bond breaking. The intermediate decomposes to butene (*anti* elimination), 2-bromo-2-butene (non-stereospecific) and butadiene (−2HBr *via* CH_2=CH–CHBr–CH_3).[2b,8] Although the ionic radii are similar for Ba(II) (1.50Å) and K(I)(1.52Å),[9] the preferred steric mode of the dehydrobromination of 2-bromobutane was opposite. This suggests that the ionic radius by itself is not the prime factor determining the stereochemistry of elimination. A trend of % *syn* elimination of 2-bromobutane as Ba(II) (86%)>Ca(II) (75%)>Mg(II) (67%) was found for alkali-earth metal ions. This may be a reflection of acid strength, but factors such as the difference in metal content and the secondary isomerization (or hydrogen shift during reaction) as well as experimental error should be considered before coming to such a conclusion. However, it seems remarkable that considerable stereospecificity (*syn*>75%) was observed in case that the carbonium-ion mechanism is most probable. In order to complete dehydrobromination by *syn* mode, a proton must be transferred from *s*-butyl cation toward the direction to which a bromide ion is released, possibly by a model as proposed previously,[2a] before the "roll-over" of or the hydrogen shift in the intermediate completely takes place.



Correlations of the catalytic activity, the orientation of olefin formation, and the stereochemistry with the acid-base properties of catalyst are summarized in Table 2. We see that the stereochemistry of reaction which reflects the reaction mechanism differs for acidic and basic catalysts, their activity and selectivity definitely exhibiting different dependency on the acid–base properties. Similar changes in activity or reaction mechanism with the acid-base properties have been discussed by Noller *et al.*[10] and Mochida *et al.*[11] Trends as shown in Figs. 1 and 2 were also found in the case of metal chlorides supported on silica gel.[12] Lewis acid sites were considered to be the active sites in these catalysts. For example, they were as active as metal sulfates for dehydrobromination, but were much less active for olefin isomerization. Although the acid strength of protonic sites can increase with electroneg-

Table 2. Summary of dehydrobromination of 2-bromobutane over metal-ion exchanged silica gels

Metal ions	Cs(I), K(I)	Ca(II), Ni(II)

Microwave Spectrum of (Chloromethyl)germane

Jun NAKAGAWA and Michiro HAYASHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received June 18, 1976)

In order to determine the molecular structure and barrier to internal rotation of the GeH_3 group, the microwave spectra of (chloromethyl)germane and its deuterated species $ClCH_2GeD_3$ have been investigated. From splittings of the spectra due to the first excited GeH_3 torsional state, the barrier to internal rotation was determined to be 1740±30 cal/mol. Assuming the cylindrical symmetry of the C–Cl bond, the quadrupole coupling constant was determined to be $\chi_{zz}=-74.7$ MHz for the $^{35}ClCH_2{}^{74}GeH_3$ species.

Several papers have been published on a series of molecules containing germanium atom. In particular, the papers on (fluoromethyl)germane by Krisher *et al.*[1] and on fluoromethylgermane by Roberts[2] called our attention because of the remarkable difference of barrier heights to internal rotation between these molecules. For a comparison of the results, we dealt with (chloromethyl)germane and chloromethylgermane, two chlorine-substituted molecules of (fluoromethyl)germane and fluoromethylgermane. In the present paper, we report the results of (chloromethyl)-germane obtained by microwave spectroscopy.

Experimental

Samples of (chloromethyl)germane and its deuterated species $ClCH_2GeD_3$ were prepared by the reaction of germanium tetrachloride with diazomethane in diethyl ether and by reducing the resulting $ClCH_2GeCl_3$ with $LiAlH_4$ or $LiAlD_4$ in dibutyl ether.[3]

The sample contained ^{74}Ge, ^{72}Ge and ^{70}Ge nuclei (37, 27 and 21%) and ^{35}Cl and ^{37}Cl nuclei (75 and 25%) in natural isotopic abundance ratio.

Microwave spectra were measured with a conventional 100 kHz Stark modulation spectrometer at the National Chemical Loboratory for Industry, Tokyo. All the spectra were measured at dry ice temperature on a recording chart. The spectra of five different isotopic species could be assinged. For the sake of simplicity, we denote the species by symbols such as (35, 74)-H_3 and (35, 74)-D_3, *etc.* for $^{35}ClCH_2{}^{74}GeH_3$ and $^{35}ClCH_2{}^{74}GeD_3$, *etc.*

Microwave Spectra

(Chloromethyl)germane has a form of a nearly prolate symmetric top with an asymmetry parameter κ of about −0.987. Both *a*- and *b*-type transitions were observed. Due to the quadrupolar coupling effect, the spectra exhibit multiplet structures which can be predicted by the first order perturbation theory. Measurements of the spectra were carried out for comparatively intense hyperfine components which satisfy the relation $\Delta F=\Delta J$. The assignment was made by first considering the hyperfine splitting pattern and finally confirming it by the double resonance technique using $7_{07}\leftarrow 6_{16}$ and $7_{07}\leftarrow 6_{06}$ transitions as pumping and signal transitions, respectively. The frequencies observed are given in Table 1.

First, the quadrupole coupling constants χ_{aa} and $\eta_a\chi_{aa}$ and rough values of the rotational constants were determined by a least squares technique from several low J transitions with relatively large splittings. Frequencies of transitions were then calculated with use of the values of the quadrupole coupling constants and rotational constants. Since the observed quadrupolar splittings were predicted by these calculations (Table 2), the hypothetical unsplit frequencies were determined by comparing the observed and calculated frequencies. From the hypothetical unsplit frequencies (Table 3), the accurate rotational constants were determined by a least squares analysis so as to fit in with a modified rigid rotor expression including only the $D_J[J(J+1)]^2$ term of the centrifugal distortion formula. The rotational constants and the quadrupole coupling constants are given in Table 4.

Molecular Structure

The data of the present work are not sufficient to determine the r_s structural parameters of (chloromethyl)germane by the substitution method. For this molecule, if C_3 symmetry of the GeH_3 group around the C–Ge bond is assumed, there are eight independent structural parameters, four of which are related to the $ClCH_2$ part of the molecule and independent of the germanium atom. Schwendeman and Jacobs[4] reported the r_s structure of (chloromethyl)-silane. Thus four parameters related to the $ClCH_2$ part were assumed to be identical to those of (chloromethyl)silane. The other four parameters were so determined as to reproduce fifteen observed rotational constants by a least squares technique. The differences between the observed and calculated rotational constants are given in Table 4. The root mean square deviation of fifteen rotational constants is smaller than 0.03 %.

The atom coordinates for the chlorine and germanium atoms can be obtained by solving the Kraitchman equations with the data for suitable pairs of the species. The x_c coordinate of the out of plane hydrogen atom in the GeH_3 group can also be obtained from the data for the (35, 74)-H_3 and (35, 74)-D_3 species. The coordinates solved are given in Table 4 with the differences from the calculated coordinates from the structural parameters adjusted. The agreement between these two coordinate values is satisfactory. The structural parameters (Table 5) are compared with the reported parameters of similar molecules such as $ClCH_2SiH_3$, CH_3SiH_3[5] and CH_3GeH_3[6]. A comparison of the adjusted structural parameters of (chloromethyl)germane with those of similar molecules indicates several interesting facts.

r(CX), (X=Si or Ge) becomes longer by replacing a hydrogen atom in the methyl group with a chlorine atom, while r(XH) becomes shorter and α(HXC)

a) Since the measured components of the multiplets satisfy the rule of $\Delta F = \Delta J$, they can be labeled by the F quantum number of the lower level of the transitions shown in the table except for the components of the $1_{11} \leftarrow 0_{00}$ transitions. For the symbols for the species, see the text.

a) Figures in parentheses indicate the uncertainties calculated from 2.5 times the standard deviation attached to the last significant figures. b) These indicate the difference in the observed and calculated rotational constants. Figures in parentheses indicate quantities such as $100\times\Delta A/A$. c) Figures in parentheses indicate the experimental uncertainties attached to the last significant figures. d) Calculated from χ_{aa} and $\eta_a\chi_{aa}$ under the assumption of the coincidence of the z-axis and the C-Cl bond. e) Calculated from χ_{aa} and $\eta_a\chi_{aa}$ under the assumption of the cylindrical symmetry of the tensor ($\eta_z=0$). f) θ_{za}(st.), the angle between the z- and a-axis obtained from the structure. $\theta_{za}(\chi)$, the θ_{za} angle obtained from the χ values. g) Figures in parentheses indicate the difference of the values obtained from the solution of the Kraitchman equations and from the structure.

becomes smaller. The ratio of the changes of the parameters from CH_3XH_3 to $ClCH_2XH_3$ is close to each other for organosilane and germane. On the other hand, for α(XCCl) the germane has a larger value than the silane.

Quadrupole Coupling Constants

The principal value χ_{zz} and the asymmetry parameter $\eta_z(=\chi_{xx}-\chi_{yy})/\chi_{zz})$ of the quadrupole coupling tensor can be obtained if both the diagonal and off-diagonal values of the tensor in the principal inertial axis system are available. However, because of the lack of off-diagonal values, χ_{zz} and η_z values were calculated under an assumption of either 1) the coincidence of the z-axis and C–Cl bond or 2) the cylindrical symmetry of the tensor along the z-axis. In the former case, the angle θ_{za} between the z- and a-axes was taken as that from the structure described in the preceding section. The asymmetry parameter η_z was found to be fairly small for every species (Table 4). In the latter case where $\eta_z=0$, the angle θ_{za} can be calculated from the χ values. The calculated θ_{za} is in good agreement with that from the structure. This indicates that the structure given in the preceding section is a plausible one and the electric charge distribution around the Cl nucleus has nearly cylindrical symmetry along the C–Cl bond.

a) Components of the quadrupolar multiplets are labeled F quantum number of the lower level; components of the internal rotation doublet are labeled A or E. b) Hypothetical unsplit frequencies. Figures in parentheses indicate the difference between the observed and calculated frequencies. c) Spacing of the internal rotation doublet, $\nu_A - \nu_E$. Figures in parentheses indicate the difference between the observed and calculated values.

χ_{zz} values obtained from the above two cases are nearly equal to each other. They are -74.7 ± 0.6 and -58.5 ± 0.7 MHz, for the $^{35}ClCH_2{}^{74}GeH_3$ and $^{37}ClCH_2{}^{74}GeH_3$ species, respectively, when $\eta_z=0$ is assumed and the ratio between the ^{35}Cl and ^{37}Cl species is 1.28 which is close to the ratio of quadrupole moments of the ^{35}Cl and ^{37}Cl nuclei (1.2688).[7]

The χ_{zz} values for ethyl chloride ($^{35}ClCH_2CH_3$) and (chloromethyl)silane ($^{35}ClCH_2SiH_3$) were reported by Schwendeman and Jacobs,[4,8] to be -71.24 ± 0.19 and -72.0 ± 0.6 MHz under the same assumption as in the present work. It should be noted that the χ_{zz} value for (chloromethyl)germane is about 4% larger than that of ethyl chloride and (chloromethyl)-silane beyond experimental error.

Internal Rotation of the GeH_3 Group

Weak spectra attributed to the excited vibrational state exist around the ground state spectra. Some of them exhibit doublet structures besides the hyperfine structures due to the quadrupolar coupling effect. The assignments of the excited state spectra were made for the (34, 74)-H_3 and (35, 72)-H_3 species. They are presumably the spectra due to the first excited GeH_3 torsional state from the spacings of the doublet structures found for the b-type transitions. The observed frequencies of these spectra are given in Table 6. The χ_{aa} and $\eta_a\chi_{aa}$ values for the excited state are essentially equal to those for the ground state (Table 7).

From the splittings of the doublet structures, the barrier to internal rotation of the GeH_3 group was calculated by the principal axis method using the structure given in the preceding section. The barrier height is $V_3=1740\ \pm30$ cal/mol[10] which is much higher than that for (fluoromethyl)germane (1390 ± 40),[1] fluoromethylgermane (941 ± 5)[2] and methylgermane (1239 ± 25).[6] The ratio of the barriers for (chloromethyl)germane and (fluoromethyl)germane is calculated to be 1.25, while that for ethyl chloride (3685 ± 12)[8] and ethyl fluoride (3306 ± 100)[9] is 1.11. The increase in the barrier from the fluoride to the chloride for the germane is much larger than for the ethyl halides.

Measurements of the Interactions between Polyethylene Glycol and Organic Compounds by Gas Chromatographic Technique*

Mitsuyasu KAWAKAMI, Makoto EGASHIRA,** and Shuichi KAGAWA

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received June 21, 1976)

A gas-liquid chromatographic technique was employed to measure the thermodynamic properties of the solutions consisting of polyethylene glycol (PEG) and some organic compounds. Three kinds of PEG with different molecular weights were used as a stationary liquid, and six kinds of organic compounds as a solute. For most of the compounds examined, the retention volume varied with the sample size injected. By using the retention volume at an infinitesimal sample size, thermodynamic properties of organic compounds at infinite dilution in PEG, such as the activity coefficient based on weight fraction, Henry coefficient based on weight fraction, and the partial molar excess enthalpy, were determined. From the results it was found that the particular interactions between organic compounds and PEG such as the hydrogen bond formation is not significant, and the solutions can be regarded as a regular solution. The solubility parameters of PEG-600, -1000, and -4000 at 67.3 °C were found to be 10.0, 9.8, and 9.5, respectively.

Many investigations[1] have been carried out to measure thermodynamic properties of solution with gas-liquid chromatography (GLC). As an example, Everett and Stoddart[2] measured the infinite dilution activity coefficients of a series of hydrocarbons in dinonyl phthalate by GLC and obtained results in good agreement with those by a static method. However, the technique was not applied to the polymer–organic compound systems until quite recently. Since there exists a distribution of molecular weights in polymer, the activity coefficient based on mole fraction is not adequate for such a system.

Recently the activity coefficients based on weight fraction and molality were proposed for a polymer–organic compound system by Patterson *et al.*,[3] and Fritz and Kovats,[4] respectively. On the other hand, Newman and Prausnitz[5] used the GLC technique to obtain the volatility (based on weight fraction) of solvents in polymer coatings.

In the present work, the measurement of thermodynamic properties based on weight fraction by GLC technique was carried out for the system of polyethylene glycol (PEG) and some organic compounds. PEG is a popular column packing material in gas chromatography, several investigations having been made on its gas chromatographic properties. Adlard[6] found that the retention volume of alcohol decreases with increase in the molecular weight of PEG. The behavior of alcohol, which is opposite to that of other organic compounds, was considered to be due to hydrogen bond with PEG. Watanabe *et al.*,[7] and Yamao[8] independently found a similar behavior for formaldehyde. However, no thermodynamic properties were determined for the reason described above. In this work, the activity coefficient based on weight fraction at infinite dilution, Henry coefficient based on weight fraction, and the partial molar excess enthalpy of mixing were determined for several organic compounds. The solubility parameters of PEG were determined by the method of Takamiya *et al.*[9] The peculiar behavior of alcohol as regards the retention volume on the molecular weight of PEG could be interpreted by the solubility parameter.

Theoretical

The net retention volume V_N can be related to the partition coefficient K_d for GLC by

$$V_N = K_d V_2 \tag{1}$$

where V_2 is the total volume of stationary liquid in the column. The corrected retention volume divided by the weight of stationary liquid w_2 and converted into 0 °C is called the specific retention volume V_g, which is related to V_N by

$$V_g = \frac{V_N}{w_2}\frac{273}{T_c} \tag{2}$$

where T_c is the column temperature. From Eqs. 1 and 2 we obtain

$$K_d = V_g \frac{w_2}{V_2}\frac{T_c}{273} = V_g \rho_2 \frac{T_c}{273} \tag{3}$$

where ρ_2 is the density of stationary liquid. The value of V_g can be obtained experimentally by means of the equation

$$V_g = \frac{3}{2}\left\{\frac{(p_i/p_o)^2-1}{(p_i/p_o)^3-1}\right\}\frac{273}{T_r}\frac{1}{w_2}t_R F \tag{4}$$

where p_i and p_o are the pressures at inlet and outlet, respectively, t_R is the peak maximum retention time, and F is the flow rate of carrier gas at room temperature T_r.

If the temperature dependence of ρ_2 can be neglected, the differentiation of Eq. 3 by $1/T_c$ gives

$$\frac{d \ln K_d}{d(1/T_c)} = -\frac{\Delta H_s}{R} = \frac{d \ln V_g}{d(1/T_c)} - T_c \tag{5}$$

where ΔH_s is the heat of solution. Thus the value of ΔH_s can be determined from the temperature dependence of V_g.

Following Patterson *et al.*,[3] the infinite dilution activity coefficient $\gamma_1^\infty(w)$ based on weight fraction is expressed as

$$\ln \gamma_1^\infty(w) = \ln \frac{273R}{M_1 p_1^\circ V_g} - \frac{B_{11}-v_1^\circ}{RT_c}p_1^\circ \tag{6}$$

* A preliminary report of this work was presented at the 33rd National Meeting of the Chemical Society of Japan, Fukuoka, October 1975.

TABLE 1. SECOND VIRIAL COEFFICIENTS, VAPOR PRESSURES, AND MOLAR VOLUMES OF SOLUTES AT 67.3 °C

Solute	$-B_{11}$ / ml mol^{-1}	p_1° / Torr	v_1° / ml mol^{-1}
Ethanol	604	486	62.3
Methanol	475	839	43.4
Ethyl acetate	1052	549	104.3
Dichloromethane	611	1852	68.1
Benzene	1041	500	94.1
Hexane	1209	728	140.1

where the subscript 1 denotes the solute. The second term of the right side is a correction for the nonideality of gas phase. B_{11} is the second virial coefficient of pure solute, p_1° the saturated vapor pressure, v_1° the molar volume at column temperature, and M_1 the molecular weight. When B_{11}, p_1°, and v_1° are known, $\gamma_1^\infty(w)$ can be calculated from V_g. In the present work, B_{11} and p_1° were evaluated by the Berthelot relation and the Antoine equation, respectively, the value of v_1° being estimated from the density by using the expansion factor proposed by Watson. These values are given in Table 1.

From the temperature dependence of activity coefficient, the partial molar excess enthalpy of mixing at infinite dilution $\Delta\bar{H}_1^{E\infty}$ can be evaluated by the equation

$$\frac{d \ln \gamma_1^\infty(w)}{d(1/T_c)} = \frac{\Delta\bar{H}_1^{E\infty}}{R}, \tag{7}$$

and the Henry coefficient based on weight fraction $H_1(w)$ can be evaluated by the equation

$$H_1(w) = p_1^\circ \gamma_1^\infty(w). \tag{8}$$

The solubility parameter of stationary liquid can be determined as follows.

If the temperature dependence of gas phase imperfection term (the second term of right side of Eq. 6) can be neglected, differentiating Eq. 6 by $1/T_c$, and using the relations of Eqs. 5 and 7 and the Clausius-Clapeyron equation, $-d\ln p_1^\circ/d(1/T) = \Delta H_1^v/R$, we obtain[10]

$$-\Delta H_s = \Delta H_1^v - RT_c - \Delta\bar{H}_1^{E\infty} \tag{9}$$

where ΔH_1^v is the heat of vaporization.

The partial molar excess enthalpy in an infinitely dilute regular solution is expressed as

$$\Delta\bar{H}_1^{E\infty} = v_1^\circ(\delta_1 - \delta_2)^2 \tag{10}$$

where δ_1 and δ_2 are the solubility parameter of solute and solvent (stationary liquid), respectively. The solubility parameter of solute can be estimated by the equation

$$\delta_1 = \left(\frac{\Delta H_1^v - RT}{v_1^\circ}\right)^{1/2}. \tag{11}$$

Substitution of Eqs. 10 and 11 into Eq. 9 gives

$$-\Delta H_s/v_1^\circ = 2\delta_1\delta_2 - \delta_2^2 \tag{12}$$

which shows that there is a linear relationship between $-\Delta H_s/v_1^\circ$ and δ_1. Hence, if the plot of $-\Delta H_s/v_1^\circ$ against δ_1 is linear, the system can be regarded as a regular solution and δ_2 can be obtained from the slope and also from the intercept, independently.[9] In the present work, ΔH_1^v was estimated from the slope of the Othmer chart drawn by the vapor pressure data, and δ_1 was calculated from Eq. 11.

Experimental

Apparatus. A Yanagimoto G-80 gas chromatograph was used. The column was a copper tube of 3 mm i.d. and 2 m in length. The measurements were carried out in the range 56.5—77.1 °C. Helium was used as carrier gas. The flow rate was measured at the outlet by soap-film flowmeter and corrected for a vapor pressure of water. The flow rate was kept at 20 ml/min. The sample was injected with a 1-μl micrometer syringe and the sample size was varied below 0.1 μl. The accurate sample size was determined from the peak area in chromatogram.

Stationary Phase and Column Preparation. PEG-600, -1000, and -4000 (Gasukuro Kogyo Co.) were coated on the solid support, 60—80 mesh of Uniport B (Gasukuro Kogyo Co.) in the range of coverage ratio 0.1—0.3. The coverage ratio which was measured with the Soxhlet extractor did not change throughout the measurement.

The properties of PEG used are given in Table 2. The melting range was determined by DSC and the concentration of end hydroxyl group C_{OH} was measured by titration. The average molecular weight M_n was calculated from C_{OH}.

TABLE 2. PROPERTIES OF PEG USED

	C_{OH} / mmol g-packing^{-1}	M_n	melt. range / °C
PEG-600	3.18	670	−4—17
PEG-1000	1.52	1400	22—48
PEG-4000	0.61	3400	50—59

Solute. The following compounds were used as a solute: ethanol, methanol, ethyl acetate, dichloromethane, benzene, and hexane. They were of reagent grade and used without further treatment.

Preliminary Experiments

Effect of Sample Size on Retention Volume. For most of the solutes, especially for methanol and hexane, the specific retention volume increased with a decrease in the sample size injected. An illustration is given in Fig. 1. The retention volume at the infinitesimal sample size obtained by extrapolation was used for calculation below.

Effect of Coverage Ratio on Retention Volume. In some GLC systems, surface adsorption occurs in addition to absorption. Martin[11] proposed that the retention volume observed would be presented by the sum of two terms,

$$V_R = K_d V_2 + K_a A$$

where K_a is the adsorption coefficient and A is the surface area of stationary liquid. Assuming that A is independent of coverage ratio α and equal to the surface area of solid support, and using V_g instead of V_R, we obtain

$$V_g = \frac{273}{T_c}\frac{1}{\rho_2}K_d + \frac{273}{T_c}s\frac{1-\alpha}{\alpha}K_a$$

where s is the specific surface area of support. Therefore, when there exists a contribution of surface adsorption, V_g should vary with α.

The retention volumes were measured by varying the coverage ratio from 0.1 to 0.3. The result is shown in Fig. 2.

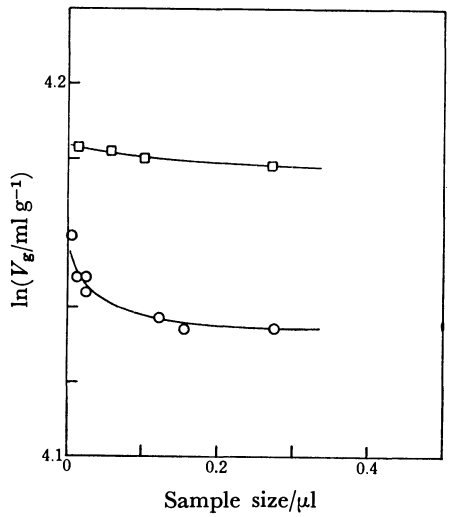

Fig. 1. An example of the variation of specific retention volumes with sample size.
□: Ethyl acetate–PEG-600 at 67.3 °C
○: Methanol–PEG-1000 at 77.1 °C

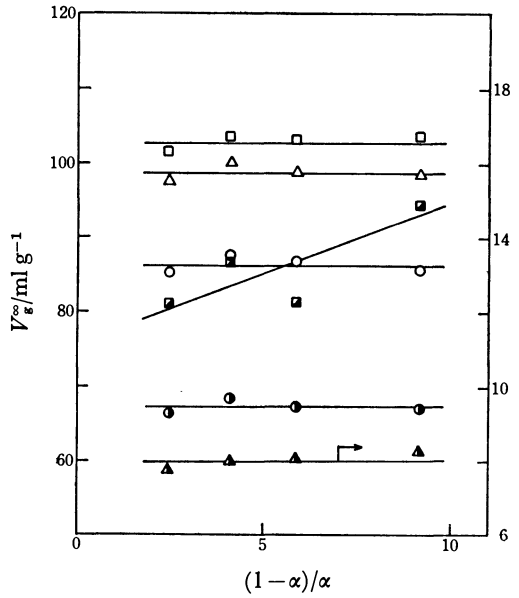

Fig. 2. The plots of V_g^∞ at 67.3 °C *vs.* $(1-\alpha)/\alpha$.
□: Ethanol, ◪: methanol, ◑: ethyl acetate, ○: dichloromethane, △: benzene, ▲: hexane.
The measure of right side is for hexane and the left for others.

Clearly the specific retention volumes are almost constant for more than 0.15 of α except for methanol. Thus the coverage ratio was kept 0.15 for each PEG, and methanol was removed from the discussion below.

Results

Thermodynamic Properties. The infinite dilution activity coefficients and Henry coefficients based on weight fraction are given in Table 3.

The partial molar heats of mixing at infinite dilution were evaluated from the slope of the plot of $\ln\gamma_1^\infty(w)$ against $1/T_c$ according to Eq. 7. An example is shown in Fig. 3.

Variations of Henry coefficients and the partial molar excess enthalpies with the concentration of hydroxyl group of PEG are shown in Figs. 4 and 5, respectively. We see that $\Delta\bar{H}_1^{E\infty}$ and $H_1(w)$ for hexane is much larger than that of other solutes. In the case of ethanol, on the other hand, the dependence of $\Delta\bar{H}_1^{E\infty}$ and $H_1(w)$ on C_{OH} is opposite that of other solutes in agreement with the result of Adlard.

Solubility Parameter of PEG. Adaptability of the thermodynamic properties we obtained to the regular solution theory will be examined. Figure

○: Ethanol, □: ethyl acetate, △: benzene, ◪: dichloromethane, ▲: hexane.

6 shows the plot of Eq. 12. There seems to be an excellently linear relationship. The straight lines are computed by least squares treatment of data of all solutes except for the one of dichloromethane which deviates a great deal. The partial molar enthalpy of dichloromethane is negative (exothermic). This is inconsistent with Eq. 10, which shows that $\Delta\bar{H}_1^{E\infty}$ is never negative in a regular solution. Since dichloromethane is electron attractive, this seems to be due to an interaction of charge-transfer type. Therefore,

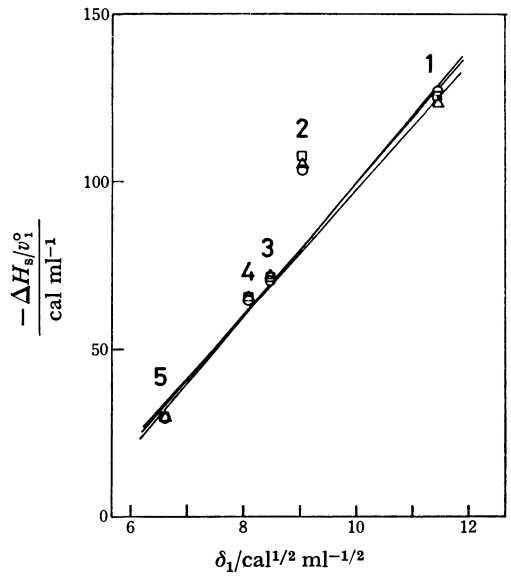

Fig. 6. The plots of $-\Delta H_s/v_1^\circ$ *vs.* δ_1.

Solute 1: ethanol, 2: dichloromethane, 3: benzene, 4: ethyl acetate, 5: hexane.

the system would not show the behavior of a regular solution.

Solubility parameters of PEG calculated from the plot of Fig. 6 are given in Table 4. The values from the slope and intercept, obtained independently, show good agreement with each other. The solubility parameter decreases with increase in the molecular weight. The value calculated by Small's method[12] is about 9.1 at 25 °C, which may be more small at the measurement temperature. This method, however, refers to high molecular weight polymer in which the contribution of the end group can be neglected.

TABLE 4. SOLUBILITY PARAMETERS OF PEG AT 67.3 °C

	PEG		
	-600	-1000	-4000
From the slope	10.0	9.7	9.4
From the intercept	10.0	9.8	9.5

The hydroxylic compounds usually have high δ values due to self-association. Thus, the values obtained experimentally seem to be reasonable by taking account of the relatively low molecular weight of 600—4000 and of the appreciable contribution of the end hydroxyl group. The order of magnitude of δ is considered to be appropriate since the effect of the hydroxyl group will decrease with increase in molecular weight.

Takamiya *et al.*[9] obtained values of 8.8 and 10.0 for δ of PEG-400 and -1500, respectively, at 100 °C. While the values are close to our results, δ increases with the molecular weight of PEG. The difference may arise from the error due to a large sample size injected or from the difference in organic compounds used as solutes.

Discussion

Organic solvents can be classified on the basis of potentialities for forming hydrogen bonds.[13] For example, ethanol and methanol belong to the class containing both active donor and acceptor atoms. Benzene is known to be electron donative. Of all the solvents used here only hexane has no active atoms.

On the other hand, PEG has ether groups and end hydroxyl groups. As the molecular weight of PEG becomes larger, its nature as an ether will become dominant. PEG is known to be a polar liquid, and the interaction between PEG and polar solvent is expected to be complicated.

Adlard[6] considered that the different behavior of alcohol from other compounds in the dependence of retention volumes on molecular weight of PEG may arise from the formation of hydrogen bond between alcohols and PEG. It seems to be necessary, however, to take account of the effect of self-association in the case of hydroxylic compounds. We see that $\Delta H_1^{E\infty}$ for ethanol is endothermic (Fig. 5). This suggests that the rupture of self-association of alcohol at infinite dilution will play an important roll as well as the formation of hydrogen bond between PEG and alcohol. These phenomena contribute to the heat of mixing conversely each other. Consequently, the influence of the hydrogen bond on $\Delta H_1^{H\infty}$ will not appear apparently. For other polar compounds except for dichloromethane, no particular interaction is observed.
