$$RNO_2 + e^- \longrightarrow R\dot{N}O_2^- \xrightarrow{H_3O^+} H_2O + R\dot{N}O_2H \qquad (2)$$

is involved.

Figure 2a implies that in the case of 0.5 molar NMP in H_2SO_4/H_2O glass, there is a small contribution from the direct effect of γ irradiation to the formation of the $NO_2^{\cdot}$ radical which is detected by its high-field line. The other lines together with the spectrum of the radical $(CH_3)_2=\dot{C}-CH_2OH$, which are expected to be formed simultaneously, must be hidden under the much more intense spectra of the $R\dot{N}O_2H$ and $SO_4^{\cdot-}$ radicals.

In the case of CH_3NO_2 irradiated at 77 K, the ESR spectrum of CH_3NO_2 with $A_{//}^N=48$ G and $A_{\perp}^N=18$ G is observed and the coupling $a_{\beta}^H=22$ G of only one proton of the methyl group is resolved (Fig. 3). The rotation of the methyl group about the C–N bond is therefore hindered and the equilibrium positions of

Table 1. Radiochemical yields of radicals and molecular hydrogen

each proton correspond to the angles $\theta_1=0$ ($a_\beta^H=22.5$ G) and $\theta_2=\theta_3=\pm120°$ ($a_\beta^H=5.5$ G) where θ is the angle between the H_β–C–N plane and the axis of the nitrogen centered $2P\pi$ orbital of the unpaired electron. The spectrum of Fig. 3b was computed with these values of a_β^H, values of the $\tilde{A}^N$ and $\tilde{g}$ tensors which are given above and $\lambda=7$ G. The corresponding second moment is $\langle\Delta H^2\rangle=820$ G^2. The experimental spectrum of $CH_3\dot{N}O_2H$ recorded at 77 K is partially superposed on that of SO_4^{-} (Fig. 3a). Upon warming, the former shows a complex structure due to the release of the intermolecular rotation about the C–N bond, as previously reported for the same radical trapped in alcohol matrices.[3]

Determination of Radiochemical Yields. Measurements of radical and molecular hydrogen yields were carried out as a function of the concentration of nitroalkanes up to 0.5 mol and of irradiation doses up to 2.5×10^{20} eV ml^{-1}, as summarized in Figs. 4, 5, 6 and in Table 1. In the absence of nitroalkanes, the radiochemical yields for trapped hydrogen atoms and molecular hydrogen were $G(H_t)_0=1.8\pm0.4$ and $G(H_2)_0=0.7\pm0.02$, respectively. These values are in agreement with those given by Livingston and Weinberger,[11]

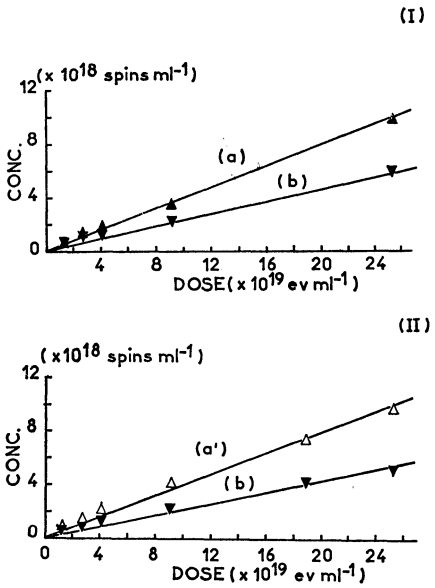

Fig. 5. Concentration of radicals as a function of irradiation dose. (I) and (II) correspond respectievly to NMP and to CH_3NO_2H 0.5 mol dm^{-3} in H_2SO_4/H_2O glassy solutions.

(a): ▲ $(CH_3)_2=C\overset{CH_2OH}{\underset{NO_2H}{\cdot}}$

(a'): △ $CH_3\dot{N}O_2H$, (b): ▼ SO_4^{-} ($HSO_4\cdot$).

$G(H_t)_0=1.5$ and $G(H_2)_0=0.6$, for an identical sulfuric acid concentration of 6.4 mol dm^{-3}. on the other hand, the sum of the G values of the SO^{-} and $OH\cdot$ radicals was found to be 2.2±0.5 and is in satisfactory agreement with the data of Henriksen and Köhnlein.[12,13] Taking into account the probable mechanisms of formation of atomic and molecular hydrogen, as well as that of $OH\cdot$ and SO_4^{-} radicals,[2] it may be assumed that $G(H_t)\sim G(SO_4^{-}+OH\cdot)\simeq2$ within the limits of experimental errors.

In the case of nitroalkane glassy solutions, the central part of the ESR spectra corresponds to SO_4^{-}, $R\dot{N}O_2H$ and $OH\cdot$. The relative yield of the $R\dot{N}O_2H$ radicals is estimated from the additivity rule of the second moments setting $\langle\Delta H^2\rangle=335$ G^2 for the composite spectrum of $SO_4^{-}+OH\cdot$ (Fig. 1b) and $\langle\Delta H^2\rangle=694$ G^2 and 820 G^2 for the $R\dot{N}O_2H$ radicals from NMP and CH_3NO_2, respectively (calculated values). Figure 5 shows that the concentration of free radicals

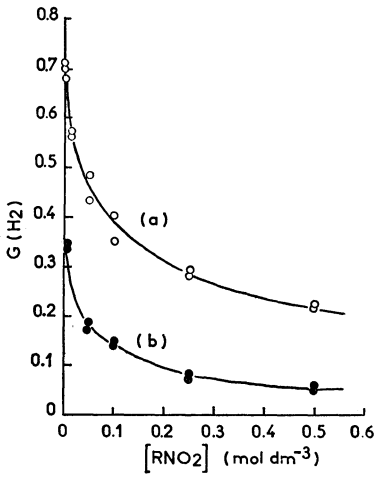

Fig. 6. G value of hydrogen molecules as a function of the concentration of nitroalkanes.

induced by γ rays increases linearly with the irradiation dose and that no saturation tendency is observed under the present experimental conditions.

As shown in Fig. 4, the yield of $CH_3\dot{N}O_2H$ radicals increases rapidly with the nitromethane concentration up to 0.2 molar with a concomitant decay of hydrogen atoms which is no longer observed above $[CH_3NO_2]=0.25$ mol dm^{-3}. The yield of $CH_3\dot{N}O_2H$ reaches a limiting value of $G(CH_3\dot{N}O_2H)\simeq3.9$. It may be pointed out that the total limiting radical yield obtained in the presence of nitromethane is $G(R\cdot)\simeq6$, whereas in the absence of scavengers $G(R\cdot)\simeq4$. NMP is quite similar to CH_3NO_3 in following the trend that the trapped hydrogen atoms disappear completely when the concentration of the nitrocompound exceeds 0.25—0.3 mol dm^{-3}. However, NMP behaves as a less efficient electron and hydrogen atom scavenger than CH_3NO_2 since the total radical yield is $G(R\cdot)\simeq4$ at a maximum concentration of 0.5 mol dm^{-3}. The limiting yield of the $R\dot{N}O_2H$ radical from NMP could not be evaluated on account of the direct effect giving rise to $NO_2\cdot$ at higher concentrations of NMP. An important point is that the yield of $SO_4^{\cdot-}+OH\cdot$ is always of the order of 2 and independent of the concentration of added nitrocompounds (Fig. 4).

Chromatographic analysis of the molecular hydrogen yields shows that $G(H_2)$ is more efficiently reduced by CH_3NO_2 than by NMP and that it becomes negligibly small as $[CH_3NO_2]$ exceeds 0.3 mol dm^{-3}.

Discussion. It is interesting to point out that $G(H_t\cdot)\simeq G(SO_4^{\cdot-}+OH\cdot)\simeq2$ is just as in the case of alkaline glasses where $G(e^-_{solv.})\simeq G(O^{\cdot-})\simeq2$.[12] This suggests that the precursor of $H_t\cdot$ is the solvated electron and that the contribution of reaction 3 is unimportant:

$$H_2O \xrightarrow{\gamma} (H_2O)^* \longrightarrow H\cdot + OH\cdot \qquad (3)$$

The fact that $G(H_2)$ becomes negligibly small at nitroalkane high concentrations suggests that there is no direct formation of molecular hydrogen during γ radiolysis. On the other hand, the limiting yield of $G(CH_3\dot{N}O_2H)\simeq4$—5 obtained for nitromethane glassy solutions cannot be explained by assuming that this compound reacts directly with electrons before hydration (dry electrons). Otherwise, a concomitant increase of $G(SO_4^{\cdot-}+OH\cdot)$ which is produced by the precursor $(H_2O)^+$ should be observed. As in the case of nitroalkanes in alkaline glass,[6] we are led to the conclusion that the yield of $CH_3\dot{N}O_2H$ radicals which exceeds 2 may be due to the scavenging of hydrogen atoms from the entity ($H\cdot$, $H\cdot$, $OH\cdot$, $OH\cdot$) resulting from the energetic recombination of non-hydrated primary species.[14] The $R\dot{N}O_2H$ yield is actually the same as the total yield of the hydrated and dry electrons determined in previous work on the radiolysis of water.[14]

The Electronic Spectra of Some Phenylthiophenes. A Molecular Orbital Treatment

R. ABU-EITTAH† and R. HILAL*

**Department of Chemistry, Faculty of Science, Cairo University, Giza, Egypt*

(Received December 2, 1975)

The electronic absorption spectra of the thiophene derivatives: mono, di-, and poly-phenylthiophenes are studied in both polar and non-polar solvents. The interaction between thienyl and phenyl chromophores is investigated both experimentally and theoretically. Assuming planar and perpendicular conformers, molecular orbital calculations are carried out on 2-phenylthiophene and on 3-phenylthiophene using the Localized-Orbital Model. The results show: (i) the planar conformer is more adquate than the perpendicular one, (ii) the near UV spectra of the two isomers are similar though their degree of conjugation is different, and (iii) excited states arise from substantial configuration interaction. There is a good agreement between the observed and calculated spectra of the two isomers.

The electronic structures of the studied compounds are of interest since though aryl thiophenes are of chemical and biological importance, yet their chemistry has made no remarkable progress. Substitution in the thiophene ring affects the spectrum in a way which depends on the type of the substituent and position of substitution. Ostman[1] used the ω technique and the "p" and "d" models for the "π" orbitals and showed that α-position in thiophene is more active than the β-position. It is found that the position of the longest wavelength band of 2-substituted thiophenes is lineary related to the ^1L_a band of monosubstituted benzenes.[2]

Many molecular orbital calculations have been reported on the π-electron system of thiophene and related compounds.[3-6] The electronic spectra of some thiophene derivatives are interpreted *via* SCFMO calculations,[7-9] and the results agree with the experiment. It has been shown that d-orbital participation is considered trivial in correlation with the spectra of thiophene[4-10] as well as the spectra of composite molecules containing thiophene.[11,12]

The spectra and theoretical treatment of arylthiophenes are not thoroughly studied in the literature. The extended Hückel theory has been applied to 2- and 3-phenylthiophenes and showed that the molecules have an equilibrium conformation twisted by 37° from the planar conformer.[13] Elpern and Nachod[14] reported the spectra of 2- and 3-phenylthiophenes and interpreted them on the basis of linear and cross conjugated systems.

In this work, the electronic spectra of some phenylthiophenes are investigated. Results (experimental and theoretical) show that differentiation of phenylthiophene to linear and cross conjugated systems cannot be done on the basis of their spectra. The LOM has been applied successfully to conjugated hydrocarbons made up of two unsaturated residues joined by a single bond.[15]

Experimental

The studied phenylthiophenes were prepared by the methods reported in the literature,[16-18] the products were purified by repeated crystallization and the melting points correspond well with the reported values. The compounds, 2,4- and 3,4-diphenylthiophenes, were kindly provided by Prof. El-Gindy.

Solvents were purified as given before[19] and the spectra were scanned on a Beckman DK Spectrophotometer using 1.0 cm fused silica cells.

Results and Discussion

Interpretation of the Spectra. The electronic absorption spectra of 2-phenylthiophene are given in Fig. 1 using ethanol, 1- and 2-propanol as solvents. The shift in band maxima depends on both dipole moment and refractive index of the solvent as shown by Bayliss and McRae.[20] The spectrum in the 330—200 nm region includes three electronic transitions identified as I, II, and III (starting from lowest energy). Two transitions (I and II) are overlapping and appear as a broad asymmetric band in the 300—240 nm region and the third transition appears as an intense shoulder in the region of 220 nm. That the broad asymmetric band consists of two overlapping transi-

† To whom all correspondences should be addressed.

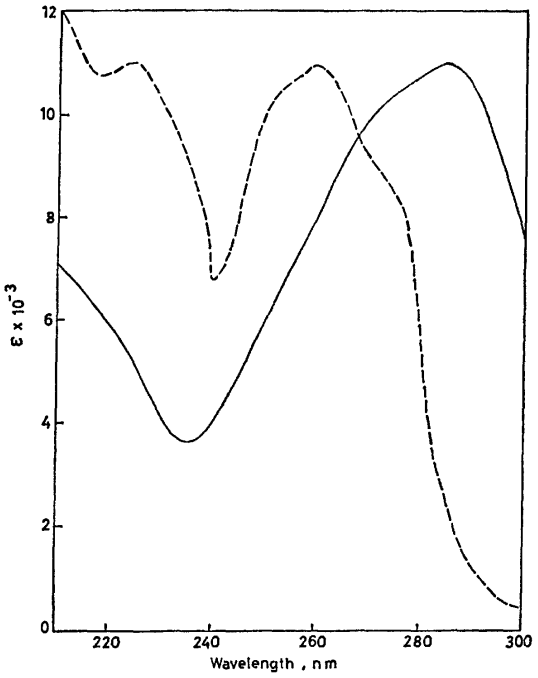

Fig. 2. Electronic absorption spectra of 2-phenylthiophene (——) and 3-phenylthiophene in ethanol (----).

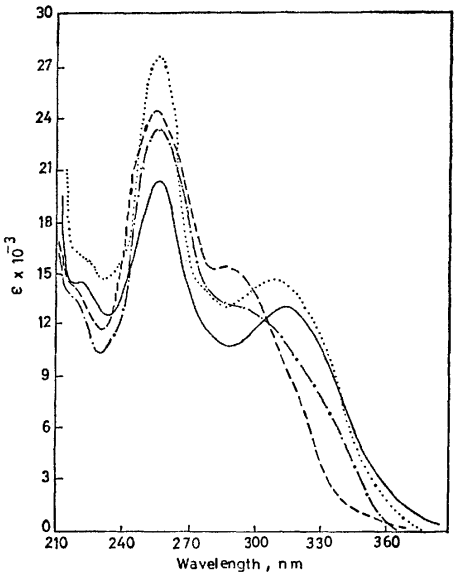

Fig. 3. Electronic absorption spectra of 2,4-diphenylthiophene in ethanol (——), 2,4-diphenylthiophene in cyclohexane (·····), 2,5-diphenylthiophene in ethanol (—·—), and 2,5-diphenylthiophene in cyclohexane (----).

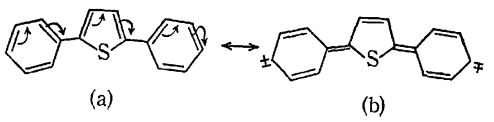
tions is seen when comparing the spectra in ethanol and 1-propanol (Fig. 1). In the latter, the extent of overlap is decreased and transition II is easily traced. In ethanol and 2-propanol the extent of overlap of the first two electronic transitions is appreciable, yet careful examination of the band indicates that it comprises two overlapping transitions. Confirmation of this conclusion will be obtained *via* MO calculations.

The composite molecule, 2-phenylthiophene, can be considered to consist of two subsystems: thiophene and benzene. Since the two subsystems are separated by one single bond, interaction between the excited states of the two subsystems will be extensive. As a result, the excited states of the composite molecule will differ appreciably from the excited states of the separate subsystems. Hence it is not adequate to assign the transitions in 2-phenylthiophene to ones localized over the thiophene nucleus and others localized over the benzene nucleus especially if coplanarity of the molecule is not significantly distorted.

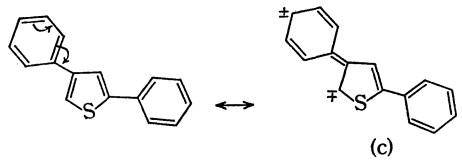
According to the resonance theory, the spectrum of 3-phenylthiophene should be different from that of the 2-phenyl derivative. However, this is not the case as Fig. 2 shows, and the two phenyl derivatives of thiophene have comparable spectra. The spectrum of the 3-phenyl derivative shows a broad band (300—240 nm) which also consists of two overlapping transitions (I and II) and the third transition appears as a shoulder. The dipole moments of 2- and 3-phenylthiophenes are 0.8 and 0.81 D respectively.[21] This shows that charge distribution in the two compounds are similar and consequently their spectra are expected to be similar. Substitution in the α-position of thiophene affects the spectrum but slightly and the resonance theory cannot adequately interpret the spectra of compounds as phenylthiophenes. The spectra of nitroanilines cannot be interpreted on the basis of the resonance theory. Contrary to the prediction of this theory, *ortho*- and *meta*-derivatives have similar spectra which differ from that of the *para*-derivative.[18,22]

Elpern and Nachod[14] reported the spectra of 2- and 3-phenylthiophene. They assigned the first transition of the two compounds to bands with λ_{max}=280 and 260 nm respectively and overlooked the fact that the first band in the spectra of the two compounds consists of two overlapping transitions. They attributed the difference in band maxima of the two compounds to the fact that the 3-phenyl isomer is cross conjugated. The results of this work indicate that 2-phenylthiophene has the first two electronic transitions at 282 and 264 nm whereas 3-phenylthiophene has the first two transitions at 275 and 260 nm which is quite comparable. The difference in transition energies of the two compounds is much less than that expected according to the resonance theory.

To confirm the above conclusion the spectra of 2,4-, 3,4-, and 2,5-diphenylthiophenes are investigated and shown in Figs. 3 and 4. The spectra of all diphenylthiophenes show three electronic transitions in the accessible ultraviolet region. In case of 2,5-diphenylthiophene the lowest energy transition (294 nm) appears as a shoulder at the long wavelength tail of the strong ~250 nm transition. The highest energy transition appears as a shoulder in the region of 220 nm. Band maxima are of the same value when the solvent is cyclohexane or ethanol, indicating that the bands are due to π–π^* transitions and charge transfer character is not apparent in the observed transitions.

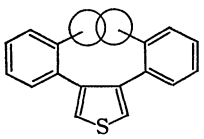


A comparison of the spectra of 2,5-diphenylthiophene and 2,4-diphenylthiophene is worthy. The extent of coplanarity is expected to be the same in the two compounds yet both have different sturctures (b) and (c).



(c)

Accordingly, the two compounds ought to have different spectra and that the 2,5-diphenylthiophene absorbs light at longer wavelength than the 2,4-diphenyl derivative due to contribution of forms as (b) to the excited state. Experimentally, the spectra of the two compounds are comparable and 2,4-diphenylthiophene absorbs light at wavelength longer than the 2,5-diphenyl derivative. The bands observed for the studied compounds are assigned to excited states of the composite molecule and not to excited states of any of the subsystems (benzene and thiophene).



In case of 3,4-diphenylthiophene steric hindrance is significant and the spectrum of the composite molecule will be the additive spectra of the subsystems. This is seen in Fig. 4. The two benzene rings are not in one plane and probably not in the plane of thiophene

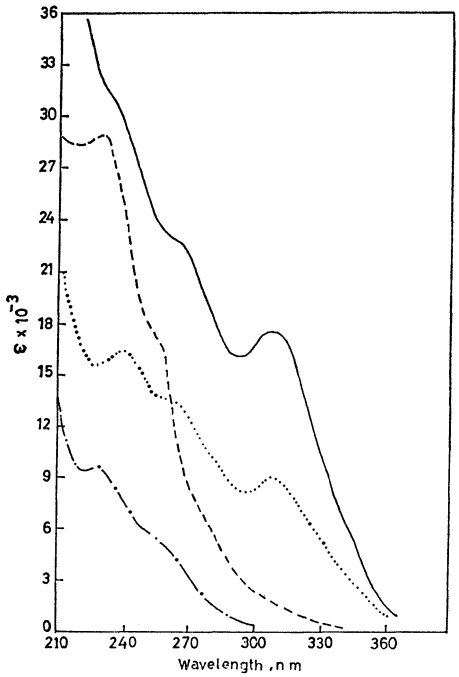


Fig. 4. Electronic absorption spectra of tetraphenylthiophene in ethanol (——), tetraphenylthiophene in cyclohexane (·····), 3,4-diphenylthiophene in ethanol (—·—), and 3,4-diphenylthiophene in cyclohexane (----).

Table 1. Band maxima and intensities of the studied phenylthiophenes in ethanol

Compound	λ_{max}, nm	ε M^{-1} cm^{-1}	f

	258	23 280	1.05
	230	30 652	1.80

ring. If one benzene ring is coplanar with the thiophene ring the spectrum of 3,4-diphenylthiophene would be similar to that of 3-phenylthiophene, this is not the case.

The spectrum of tetraphenylthiophene is shown in Fig. 4. If one considers unsymmetric twist of the phenyl groups, the spectrum of tetraphenylthiophene will be that of the 2,4- and 3,4-isomers.

Table 1 gives the numerical values of band maximum, molar absorptivity and oscillator strength.

Molecular Orbital Calculations. The self-consistent molecular orbitals of the composite molecule A–B are those of the separate constituents A and B. If the subsystems are joined through atom u in A and atom v in B, then their extent of interaction is determined by the value of the resonance integral β_{uv}. If $\beta_{uv}=0$, the electronic excited states will be the locally excited ones A*, and B*, in addition to the charge transfer ones. The general expression for the interaction between two different singly excited configurations $^1\psi_{a-b}$ and $^1\psi_{c-d}$ is given by[23]:

$$\langle {}^1\psi_{a-b}|\hat{H}|{}^1\psi_{c-d}\rangle = 2(cd|ab) - (ca|bd)$$

where $\hat{H}$ is the Hamiltonian for the system for which $\beta_{uv}=0$

Application to Perpendicular Conformers. 2-Phenylthiophene: The effect of steric hindrance in 2-phenylthiophene will cause the rings of the constituents to be non-coplanar. The value of β will be small and in the case the two rings are perpendicular will be zero. The self consistent orbitals of benzene (θ's) and of thiophene (y's) subsystems are shown in Fig. 5, and a schematic energy level diagram is shown in Fig. 6. In case of thiophene, the d-orbitals are not included since its participation is considered trivial when dealing with the UV spectrum. The singly excited states of benzene are:

$$\theta_{\beta'} = (1/2^{1/2})(\theta_3^{-1}\theta_4 - \theta_2^{-1}\theta_5);\ \theta_{\beta} = (1/2^{1/2})(\theta_3^{-1}\theta_5 + \theta_2^{-1}\theta_4)$$

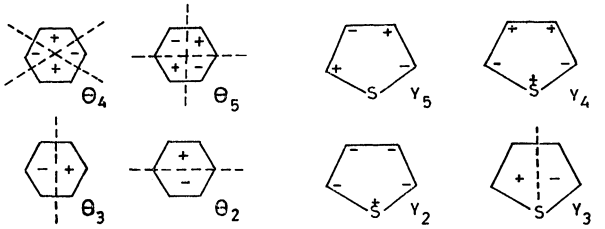

Fig. 5. The self consistent orbitals of benzene (θ) and thiophene (Y).

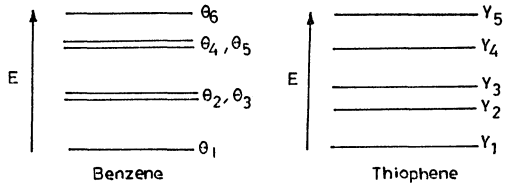

Fig. 6. A non scale energy level diagram for benzene and thiophene molecules.

$$\theta_p = (1/2^{1/2})(\theta_3^{-1}\theta_4 + \theta_2^{-1}\theta_5);\ \theta_\alpha = (1/2^{1/2})(\theta_3^{-1}\theta_5 - \theta_2^{-1}\theta_4)$$

The singly excited states of thiophene ring are constructed from the interaction between configurations of the same symmetry. The energy of the different configurations: $y_3^{-1}y_4$, $y_3^{-1}y_5$, $y_2^{-1}y_4$, $y_2^{-1}y_5$ are computed by the usual procedure,[24] and the configuration interaction matrix of thiophene is solved. The form of the first four singly excited states of thiophene are:

$$Y_I = (0.999y_3^{-1}y_4 - 0.009y_2^{-1}y_5);$$
$$Y_{II} = (0.893y_2^{-1}y_4 - 0.449y_3^{-1}y_5);$$
$$Y_{III} = (0.449y_2^{-1}y_4 + 0.893y_3^{-1}y_5);$$
$$Y_{IV} = (0.009y_3^{-1}y_4 + 0.999y_2^{-1}y_4).$$

Since orbitals θ and y are self consistent, the ground state will not interact with any of the singly excited configurations. There will be, however, interaction between the locally excited states of the thiophene and benzene rings. The molecule, 2-phenylthiophene, is not symmetric and as a result we consider interaction between all the excited states of the two subsystems. The matrix elements of the Hamiltonian between the locally excited states Y's and θ's are computed as follows:

$$\langle Y_I|\hat{H}|\theta_\alpha\rangle = \langle(0.999y_3^{-1}y_4 - 0.009y_2^{-1}y_5)|\hat{H}|(1/2^{1/2})(\theta_3^{-1}\theta_5 - \theta_2^{-1}\theta_4)\rangle \quad (1)$$

$$\langle y_3^{-1}y_4|\hat{H}|\theta_3^{-1}\theta_5\rangle = 2(\theta_3\theta_5|y_3y_4) - (\theta_3y_3|\theta_5y_5). \quad (2)$$

The second term in integral 2 is zero and to evaluate the first term of this integral, one expands[15] the MO in terms of the AO functions and using the ZDO approximation,

$$2(\theta_3\theta_5|y_3y_4) = 2(\sum_{u,\nu} C_{\theta_{3u}}C_{\theta_{5u}}C_{y_{4\nu}}C_{y_{3\nu}}\gamma_{u\nu}).$$

For the perpendicular conformers, only, electron repulsion integrals are considered between atom (1) in benzene (u), and atom (2) of thiophene (ν), and the terms $\gamma_{u\nu}$ are evaluated using the Nishimoto-Mataga[25] equation. Proceeding in this way the matrix elements of the Hamiltonian are computed between the eight states of 2-phenylthiophene. Solving this matrix, the energies and state wave finctions are obtained. The first three are:

(1) $0.765Y_I - 0.116Y_{II} + 0.182Y_{III} - 0.495\theta_\beta - 0.292\theta_p + 0.191\theta_\alpha$ ·····4.78 eV

(2) $\theta_{\beta'}$ ·····4.91 eV

(3) $0.184Y_I + 0.981Y_{II} - 0.022Y_{III} + 0.068\theta_p$ ···5.92 eV.

Comparison with experiment is postponed till we consider the planar conformer.

3-Phenylthiophene: Before considering the effect of conjugation between benzene and thiophene nuclei in 2-phenylthiophene it would be interesting to consider the perpendicular conformer of 3-phenylthiophene, computations are analogous to those of the 2-isomer. The matrix elements of the Hamiltonian between the locally excited states of the two subsystems are calculated as is done with the 2-phenyl isomer. The numerical values of these elements are much less than the corresponding ones of the 2-phenyl isomer. To this reason we attribute the difference in transition energies of the two isomers. Solving the interaction matrix of 3-phenylthiophene one gets the state functions and energies, of which:

(1) $\theta_{\beta'}$ ·····4.91 eV

(2) $0.726Y_I + 0.116Y_{II} + 0.229Y_{III} + 0.172\,Y_{IV} + 0.527\theta_\beta + 0.274\theta_p - 0.158\theta_\alpha$ ·····5.19 eV

(3) $0.343Y_I - 0.914Y_{II} - 0.089Y_{III} - 0.064Y_{IV} - 0.177\theta_\beta - 0.052\theta_p$ ·····6.91 eV.

Application to Planar Conformers. When considering the perpendicular conformers, interaction between singly excited configurations arises from electron repulsion alone. When considering the planar structures, resonance integrals, $\beta_{u\nu}$, between the two subsystems will not be zero. The resonance integral will mix together configurations which differ by the position of just one electron. The integrals to be evaluated are:

$$\int \psi_0 \hat{H}^{core} \psi_a^{-1}\psi_b d\tau = (2^{1/2}) \int \psi_a(i)\hat{H}_i^{core}\psi_b(i)d\tau_i \quad (3)$$

$$\int \psi_c^{-1}\psi_a \hat{H}^{core}\psi_c^{-1}\psi_b d\tau = \int \psi_a(i)\hat{H}_i^{core}\psi_b(i)d\tau_j \quad (4)$$

$$\int \psi_a^{-1}\psi_c \hat{H}^{core}\psi_b^{-1}\psi_c d\tau = -\int \psi_a(i)\hat{H}_i^{core}\psi_b(i)d\tau_i. \quad (5)$$

The three integrals 3—5 will be zero unless ψ_a belongs to one subsystem and ψ_b to the other.

2-Phenylthiophene: Following the above rules one has to consider the interaction between: (1) Ground state ψ_0, and charge transfer states, (2) charge transfer states to produce "charge resonance" wave functions, (3) locally excited configurations and charge resonance, and (4) locally excited configurations of the two subsystems.

To begin with, the charge transfer states: $\theta_2^{-1}y_4$, $y_3^{-1}\theta_5$, $\theta_3^{-1}y_4$, $y_3^{-1}\theta_4$ are combined to produce the following charge resonance wave functions:

$$CR_I = (1/2^{1/2})(\theta_2^{-1}y_4 + y_3^{-1}\theta_5)$$
$$CR_{II} = (1/2^{1/2})(\theta_2^{-1}y_4 - y_3^{-1}\theta_5)$$

$$CR_{III} = (1/2^{1/2})(\theta_3^{-1}y_4 + y_3^{-1}\theta_4)$$
$$CR_{IV} = (1/2^{1/2})(\theta_3^{-1}y_4 - y_3^{-1}\theta_4).$$

Since, 2-phenylthiophene is not symmetric we computed the interaction terms between thirteen different states, namely, the ground state, four charge resonance states, and eight locally excited states of the two subsystems (θ and Y's). Interaction integrals between the ground state and the charge resonance wave functions reduce to terms including the resonance integral β_{12} (between atom 1 in benzene and atom 2 in thiophene). The same thing applies to interaction integrals between the locally excited configurations of each subsystem and the charge resonance wave functions. The energies of "CR" are computed as such:

$$\langle\theta_2^{-1}y_4|\hat{H}|\theta_2^{-1}y_4\rangle = E_4 - E_2 - (y_4y_4|\theta_2\theta_2)$$

where E_4 is the ionization potential of the fourth MO of thiophene and is calculated by.[26]

$$E_4 = \sum_{u,\nu} C_{4u}C_{4\nu}F_{u\nu}$$

and

$$F_{u\nu} = \beta_{u\nu} - 1/2P_{u\nu}\gamma_{u\nu}.$$

The resonance integral, $\beta_{u\nu}$, between carbon atoms, in the benzene ring, is taken as -2.4 eV whereas that between carbon and sulfur atoms, in the thiophene ring, is taken as -1.63 eV. Other values of $\beta_{u\nu}$ are calculated using the relation[27]

$$\beta_{u\nu} = [S_{u\nu}/(1+S_{u\nu})][(I_u+I_\nu)/2].$$

The computed value of E_4 is 1.406 eV. The values of $E_2(E_{\theta_2})$ is considered equal to $E_3(E_{\theta_3})$ *i.e.* the ionization potential of benzene (9.76 eV). Also, (E_{y_3}) is taken as the ionization potential of thiophene (9.1 eV). The electron repulsion integrals are considered between all atoms (p π atomic orbitals) of benzene and all atoms of thiophene and calculated using the ZDO approximation The energies computed for the charge resonance wave functions and interaction terms are (eV):

$CR_I = 5.93$; $CR_{II} = 5.03$; $CR_{III} = CR_{IV} = 5.92$;

and

$(CR_I|CR_{II}) = -0.360$; $(CR_{III}|CR_{IV}) = -0.263$

$(CR_I|CR_{III}) = (CR_I|CR_{IV}) = (CR_{III}|CR_{IV}) =$ Zero.

The elements of the interaction matrix for the planar conformer of 2-phenylthiophene are thus calculated. Solving this martix (13×13) the energies and state wave functions of the compound are obtained. Those of the ground state and of the first three excited states are:

(1) $0.984\phi_0 - 0.103CR_I - 0.141CR_{III}$ ·····-0.2 eV

(2) $0.225\theta_{\beta'} + 0.341\theta_\beta + 0.162\theta_p - 0.07\theta_\alpha$
$- 0.608Y_I + 0.081Y_{II} - 0.091Y_{III}$
$- 0.211CR_I - 0.352CR_{II} - 0.498CR_{IV}$ ···4.46 eV

(3) $0.107\theta_\beta - 0.852\theta_{\beta'} - 0.111Y_I - 0.167Y_{III}$
$- 0.391CR_{II} + 0.160CR_{III} + 0.179CR_{IV}$ ···4.53 eV

(4) $0.175Y_{II} - 0.086Y_I - 0.293\theta_{\beta'} + 0.226\theta_p + 0.324\theta_\alpha$
$+ 0.611CR_I + 0.109CR_{II} + -0.481CR_{III}$
$- 0.320CR_{IV}$ ·····5.52 eV.

3-Phenylthiophene: Computations for this molecule are carried out similar to those of the 2-phenyl derivative. Interaction elements are of different values for the two isomers. On the other hand, β_{12} is taken equal to β_{13} (between atom 1 to benzene and atom 3 of thiophene). The following are the wave functions and the corresponding energies of the ground state and the first three excited states (covered by the spectrum in the 350—200 nm region):

(1) $0.993\phi_0 + 0.075CR_{II} + 0.094CR_{IV}$ ·····-0.097 eV

(2) $0.137Y_I - 0.138Y_{III} + 0.110Y_{IV} - 0.917\theta_{\beta'}$
$+ 0.076\theta_\beta + 0.292CR_I - 0.080CR_{II}$ ·····4.695 eV

(3) $0.141\theta_\alpha - 0.188\theta_p - 0.189\theta_\beta - 0.280\theta_{\beta'} - 0.424Y_{II}$
$- 0.475Y_I - 0.431CR_I - 0.388CR_{II}$
$- 0.291CR_{III}$ ·····4.87 eV

(4) $0.742Y_I - 0.528Y_{II} - 0.209\theta_\beta - 0.112\theta_p$
$- 0.300CR_{II}$ ·····5.61 eV.

Band Intensity. The intensity of a band is calculated by the equation

$$f = 1.085\times10^{-5}M^2\nu$$

where M is the transition moment and ν (cm^{-1}) the frequency. In the LOM, the ground state is described by the wave function $\psi_0 = a\Gamma + \sum_n b_n T_n$ and the excited state is described by:

$$\psi_{Ex} = \sum_n C_n \Lambda_n + \sum_{n'} d_{n'}T_{n'} + e\Gamma$$

then the transition moment, whithin the limits of zero overlap approximation, is calculated from:

$$\langle\psi_0|\hat{M}|\psi_{Ex}\rangle = a\sum_n C_n\langle\Gamma|\hat{M}|\Lambda_n\rangle + \sum_n\sum_{n'} b_nd_{n'}\langle T_n|\hat{M}|T_{n'}\rangle.$$

The first term reduces to the transition moment between two molecular orbitals and the second term is zero unless the charge transfer states (T_n and $T_{n'}$) are identical. It is calculated by expanding the wave function of the charge transfer state and considering integrals as $\langle y_i|y_j\rangle$, $\langle\theta_i|\theta_j\rangle$, and $\langle y_i|\theta_j\rangle$ to be zero. Also, the operator $\hat{M}$ is a one electron operator which does not depend on the electron spin.

Band intensities were calculated for the planar conformers. The origin of coordinates was assumed to be in midpoint of the bond joining the two subsystems.

Results are given in Table 2.

Comparison with Experiment. A comparison of the experimental and computed transition energies and band intensity is given in Table 2.

Discussion and Conclusions

According to the resonance theory, 2-phenylthiophene is expected to possess a spectrum different from that of the 3-phenyl isomer. The two compounds have different resonating structures and different resonance energy. Consequently, Elpern[14] assigned the first band in the spectra of the two compounds to one electronic transition with λ_{max} at 282 nm for 2-phenylthiophene and at 260 nm for 3-phenylthiophene.

Table 2. Calculated and experimental transition energies of 2- and 3-phenylthiophenes

Compound	Transition energy, eV			f	
	Perpendicular	Planar	Expt	Expt	Calcd
2-Phenylthiophene	4.78	4.66	4.40	0.40	0.40
	4.91	4.73	4.63	0.19	0.06
	5.92	5.72	5.64	—	0.14
3-Phenylthiophene	4.91	4.79	4.51	0.07	0.02
	5.19	4.97	4.77	0.24	0.10
	5.91	5.71	5.54	—	0.16

However, careful examination of the spectra (Fig. 2) shows that the first band comprises two electronic transitions whose energies are not widely separated. Calculation of band intensity confirms this conclusion. The calculated "f" for bands II in 2-phenylthiophene and I in 3-phenylthiophene is not zero. The calculated values are less than the experimental ones since they borrow some of their intensity from the stronger transitions with which they overlap. The resonance theory could not correlate the spectra of nitroanilines.

The results of computation of this work verify the following:

(1) The long wavelength band in the spectra of 2- and 3-phenylthiophene consists of two electronic transitions.

(2) The numerical values of the elements of the interaction matrix of 3-phenylthiophene are less than the corresponding ones of the 2-phenyl isomer. Due to this, we attribute the difference in transition energies of the two isomers.

(3) Contribution of the charge transfer wave function to the excited states of 2-phenylthiophene is more pronounced than in case of the 3-phenyl isomer. That is, dipolar resonating structures contribute substantially to the excited states of the 2-phenylthiophene.

(4) Results of the LOM treatment are reliable and correspondence between them and the experiment is quite satisfactory (Table 2).

(5) Excited states of phenylthiophenes arise from extensive interaction between the states of benzene and thiophene.

Semiempirical Molecular Orbital Considerations of the Electronic Structures of Transition Metal Complexes. I. Dioxygen Nickel Complexes

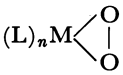
Kazuyuki TATSUMI, Takayuki FUENO,* Akira NAKAMURA, and Sei OTSUKA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received October 28, 1975)

The electronic structure of $Ni(O_2)(HNC)_2$ as a model of "side-on" coordinated dioxygen nickel complexes has been investigated by the INDO method. Calculations show that the square-planar geometry is more stable than the pseudotetrahedral form in accord with the observed structure of $Ni(O_2)(t\text{-BuNC})_2$. The central nickel atom possesses an approximately zerovalent configuration: $(3d)^{8.5}$ $(4s)^{0.5}$ $(4p)^{1.0}$. The dioxygen–nickel bonding is effected primarily through the donation and back-donation of electrons in which the O_2 π_u and π_g^* orbitals parallel to the molecular plane participate. It is predicted that *both* the Ni–O and O–O bondings tend to have greater covalent bond strengths as the electron-attracting ability of the ligand isocyanide increases. Attempts are made to assign the electronic spectra.

A number of dioxygen complexes of transition metals have recently been isolated and characterized.[1–4] In connection with possible biochemical significance of these complexes, much of the current interest in this field is directed toward the understanding of the nature of the dioxygen–transition metal bondings.[5–8] The effect of such bondings upon the electronic structure of the dioxygen moiety is also receiving attention.[5]



Molecular orbital theory has given several useful suggestions to these problems. Thus, the dioxygen–metal bond in "side-on" complexes has been described in terms of the Dewar-Chatt-Duncanson model,[9,10] in which the donation and back-donation of electrons between metal d orbitals and dioxygen are considered to be essential.[11] Ohkubo and co-workers[12] investigated the interaction between onium compounds and molecular oxygen; the catalytic activity of onium compounds in oxidation reactions was ascribed to an effective interaction of oxygen with the partially occupied d orbitals of the central atom in onium compounds. Recently, Norman[13] has dealt with $Pt(O)_2(PH_3)_2$ by the SCF-X_α scattered wave method to show that a building-up of an extra electron density in the antibonding $1\pi_g$ orbitals of dioxygen is not necessarily due to the direct Pt $d\pi \rightarrow O_2$ $1\pi_g$ back-donation. Apparently, however, characteristics of molecular oxygen coordinated to transition metal are still debatable.

The purpose of the present study is to discuss the nature of the dioxygen–nickel bonding of a "side-on" coordination complex $Ni(O_2)(t\text{-BuNC})_2$[14] in terms of an ASMO-SCF-MO method in the INDO approximation. Specifically, we examine the electronic structure of a model compound $Ni(O_2)(HNC)_2$ and the effects of its geometry and ligand structure on the dioxygen–nickel bonding as well as oxygen–oxygen bond. Assignment of the electronic spectra has also been attempted.

Method of Calculation

INDO Formalism. The approximation used in this work is basically that of the INDO method suggested by Pople *et al.*[15] Thus, all the two-electron integrals involving differential overlap are neglected, except for one-center exchange integrals of the type $(\mu\nu|\mu\nu)$.

However, our method differs somewhat from the original INDO method[15] in the evaluation of atomic integrals. First, both the one-center electron repulsion integrals $(\mu\mu|\nu\nu)$ and the one-center core attraction integrals $U_{\mu\mu}$ are obtained from the table by Oleari *et al.*[16–18] Second, the two-center repulsion integrals are approximated as:[19]

$$(\mu\mu|\nu\nu) = 14.3986/(R+a) \tag{1}$$

with

$$a = 28.7972/[(\mu\mu|\mu\mu)+(\nu\nu|\nu\nu)] \tag{2}$$

μ, on atom A; ν on atom B

where R is the distance (Å) between atoms A and B and $(\mu\mu|\mu\mu)$ *etc.* are represented in units of eV. The integrals $(\mu\mu|\nu\nu)$ for a given pair of atoms A and B may take on different values, depending on the type of the atomic orbitals, μ and ν. Third, the core resonance integrals $\beta_{\mu\nu}$ are evaluated by the Wolfsberg-Helmholtz expression:[20]

$$\beta_{\mu\nu} = -(\kappa/2)S_{\mu\nu}(I_\mu^{A}+I_\nu^{B}) \tag{3}$$

where I_μ^{A} and I_ν^{B} are the valence-state ionization potentials, $S_{\mu\nu}$ is the overlap integral between μ and ν, and the parameter κ is assumed to be 1.1.[21]

The attraction between an electron in atomic orbital μ of atom A and a core of atom B is assumed to be

$$(\mu|V_B|\mu) = -\sum_{\nu}^{B} N_\nu(\mu\mu|\nu\nu) \tag{4}$$

where N_ν refers to the number of valence electrons occupying ν. The elements of the Hartree-Fock matrix for a closed shell of electrons are then given by[22]

$$F_{\mu\mu}^{A,A} = U_{\mu\mu} + \sum_{\nu}^{A} P_{\nu\nu}\left[(\mu\mu|\nu\nu)-\frac{1}{2}(\mu\nu|\mu\nu)\right] + \sum_{\nu}^{B}(P_{\nu\nu}-N_\nu)(\mu\mu|\nu\nu) \tag{5}$$

$$F_{\mu\nu}^{A,A} = P_{\mu\nu}\left[\frac{3}{2}(\mu\nu|\mu\nu)-\frac{1}{2}(\mu\mu|\nu\nu)\right] \tag{6}$$

$$F_{\mu\nu}^{A,B} = \beta_{\mu\nu} - \frac{1}{2}P_{\mu\nu}(\mu\mu|\nu\nu) \tag{7}$$

where $P_{\mu\nu}$ *etc.* denote the bond orders.

The basis set of atomic orbitals used includes the following: 3d, 4s, and 4p of Ni; 2s and 2p of C, N,

* To whom correspondence should be addressed.

and O; and 1s of H. The initial electronic configurations of atoms assumed in the evaluation of the matrix elements (5)—(7) are $(3d)^{10}$ for Ni and $(2s)^2(2p)^m$ for C, N, and O, where m is 2, 3, and 4, respectively.

Evaluation of Integral Parameters. The one-center integrals appropriate to the present calculations are (i) core-electron attraction integrals U_{ss}, U_{pp}, and U_{dd}, (ii) Coulomb integrals $(\mu\mu|\nu\nu)$, and (iii) exchange integrals $(\mu\nu|\mu\nu)$. Oleari *et al.*[16,17] determined the one-center integrals by the least-squares fits of the total valence-state energies calculated therefrom for atoms as a function of their orbital occupation number. The calculations were based on the valence state energies taken from Moore's table.[23] The results are tabulated[18] for various valence-state quantities:[24]

U_{ss}, U_{pp}, U_{dd}, g_{ss}, g_{pp}, g_{dd}, g'_{sp}, $g'_{pp'}$, g'_{pd}, and $g'_{dd'}$

where

$$g_{\mu\mu} = (\mu\mu|\mu\mu) = J_{\mu\mu} \tag{8}$$

and

$$g'_{\mu\nu} = (\mu\mu|\nu\nu) - \frac{1}{2}(\mu\nu|\mu\nu) = J_{\mu\nu} - \frac{1}{2}K_{\mu\nu} . \tag{9}$$

In evaluating the individual one-center two-electron integrals, one must resolve $g'_{\mu\nu}$ into the components. We have made the resolution using the theoretical relationships between the individual integrals and the Slater-Condon parameters. The expressions for the Coulomb and exchange integrals in terms of the Slater-Condon parameters have been given by Clack.[25] The resolutions of g'_{sp}, g'_{sd}, and g'_{pd} necessitate evaluations of the Slater-Condon parameters G^1(sp), G^2(sd), G^1(pd), and G^3(pd). These parameters were taken from the data compiled by Hinze and Jaffé[26] for ligand atoms and by Oleari *et al.*[17] for the metal atom. The various two-electron integral values finally adopted for C, N, O, and Ni are summarized in Table 1.

The valence-state ionization potentials necessary for the evaluation of $\beta_{\mu\nu}$ were obtained from Oleari's $U_{\mu\mu}$ data and relevant Slater-Condon parameters. They are listed also in Table 1. The overlap integrals

Table 1. Atomic parameters[a] (eV)

	Ni	C	N	O	H
I_s	7.19	19.39	25.00	32.37	13.60
I_p	3.10	10.83	13.84	16.39

$J_{xz,yz}$	15.225				

a) The other parameters, $U_{\mu\mu}$ and $g_{\mu\mu}$, are tabulated in Ref. 18. The $K_{\mu\nu}$ values can be obtained from Eq. 9.

Table 2. Orbital exponents of the basis set used

	s	p	d
H	1.0000		
C	1.6083	1.5679	
N	1.9237	1.9170	
O	2.2458	2.2266	
Ni	1.4730	1.4730	2.960

were calculated using single Slater orbitals. The orbital exponents were chosen from the data by Zerner and Gouterman[27] for nickel and from those by Clementi and Raimond[28] for ligand atoms. They are given in Table 2.

Electronic Excitation. The energies and moments for singlet excitations were calculated by the conventional virtual orbital approximation without configuration interaction. The configurational energy corresponding to one-electron excitation from molecular orbital i to virtual orbital j is given by

$$\Delta^1E = \varepsilon_j - \varepsilon_i - J_{ij} + 2K_{ij} \tag{10}$$

where ε_j and ε_i respectively denote the energies of orbitals j and i, and J_{ij} and K_{ij} are the molecular Coulomb and exchange integrals, respectively. The dipole moment length is given by

$$M_{i\to j} = \sqrt{2}\sum_{A}^{\text{atoms}}\sum_{\mu}^{A}\sum_{\nu}^{A} C_{i\mu}C_{j\nu}(\mu|\boldsymbol{r}_A|\nu) \tag{11}$$

where $\boldsymbol{r}_A$ is the coordinate vector operator of atom A and $C_{i\mu}$ *etc.* are the LCAO coefficients. In evaluating $M_{i\to j}$, a contribution from atomic polarization was taken into account. This latter contribution is denoted by $M'_{i\to j}$.

Results and Discussion

Geometry of $Ni(O_2)(HNC)_2$. Detailed X-ray structual information is available for $Ni(O_2)(t\text{-BuNC})_2$.[29] The two oxygen atoms lie on the plane containing the nickel and the two isocyanide groups.

To begin with, we have calculated the total energy of our model compound $Ni(O_2)(HNC)_2$ for two extreme geometries, in which the dihedral angle θ (Fig. 1) is 0 and 90°. The results are given in Table 3, together with the net charge on the oxygen atoms Q_O as well as the bond indices W[30] for the O–O and Ni–O bonds.

Table 3 indicates that the square-planar structure (θ=0°) is more stable than the pseudotetrahedral

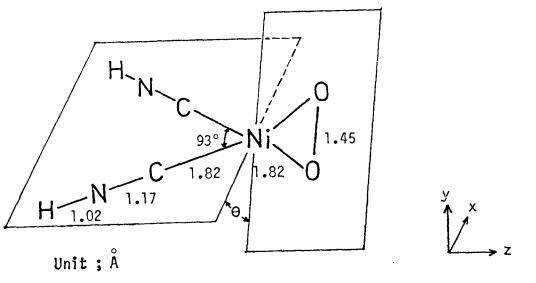

Fig. 1. Coordinate systems and structure for $Ni(O_2)(HNC)_2$.

Table 3. Total energy (E)[a], net charge on oxygen (Q), and bond indices (W) for the square-planar and pseudotetrahedral conformations of $Ni(O_2)(HNC)_2$

	Square-Planar	Pseudotetrahedral
E(eV)	−2201.2126	−2200.6274
Q_O	−0.4367	−0.4781
W_{O-O}	1.0495	1.0193
W_{Ni-O}	0.8346	0.7391

a) In calculating the total energy, the total core-core repulsion energy was approximated as

$$\sum_A \sum_B \sum_\nu^A \sum_\mu^B N_\mu N_\nu (\mu\mu|\nu\nu).$$

one ($\theta=90°$), a result compatible with the X-ray structure of $Ni(O_2)(t\text{-BuNC})_2$. Both the bond indices W_{O-O} and W_{Ni-O} are greater in the former geometry. Because the bond index can be regarded as a measure of the covalency of the bond in question,[30] the greater stability of the square-planar form can be ascribed to the greater covalent character of *both* the Ni–O and O–O bonds involved. The net charge Q_O, on the other hand, is smaller for the square-planar structure, implying a lesser extent of back-donation of electrons from Ni to O_2 as compared with the pseudotetrahedral structure. These two indications together suggest that the back-donation tends to reduce the covalency of the Ni–O as well as the O–O bond in the complex.

Electronic Structure. We have examined the electronic structure of $Ni(O_2)(HNC)_2$ of the square-planar form in detail. The magnetic susceptibility measurements of $Ni(O_2)(t\text{-BuNC})_2$ revealed a feeble magnetic moment of 0.13 BM.[14b] The PMR spectrum of the complex was also measured; the chemical shift falls in the range for diamagnetic isocyanide complexes. On the basis of these observations, we may assume that this complex is in a closed electronic structure.

The upper portion of the occupied molecular orbitals is diagrammatically shown in Fig. 2, together with low-lying vacant orbitals. Appended to the orbital levels are their numberings and symmetry representations for the C_{2v} point group instead of the higher symmetry D_{2h}. The omitted lower portion of the diagram consists merely of the essentially unperturbed O_2 $2\sigma_g$ and $2\sigma_u$ and isocyanide σ_g, σ_u, and π_u orbitals in the range from −45.4 to −16.5 eV.

The highest occupied level, $\phi_{21}(a_2)$, consists of 100% O_2 $\pi_g^*(\perp)$ orbital,[31] virtually no mixing between the Ni $3d_{xy}$ and O_2 $\pi_g^*(\perp)$ orbitals being involved. Thus, the back-donation to the O_2 $\pi_g^*(\perp)$ orbitals can be ignored. A similar conclusion was reached by the SCF-X_α scattered-wave calculation for $Pt(PH_3)_2(O_2)$.[13] The overlap integral between Ni $3d_{xy}$ and O p_y is considerably small (0.016). The lowest unoccupied level, ϕ_{22} (b_2), consists of Ni $4p_y$ and isocyanide $\pi^*(\perp)$ with an appreciable O_2 $\pi_u(\perp)$ character. The Ni–O_2 bonding is accomplished mainly through extensive mixings of the O_2 $\pi_u(\parallel)$ and σ_g orbitals with the Ni $3d_{z^2}$ and $3d_{x^2-y^2}$ orbitals, and of the O_2 $\pi_g^*(\parallel)$ with Ni $3d_{xz}$ orbital. The levels $\phi_{19}(a_1)$, $\phi_{17}(a_1)$, $\phi_{16}(a_1)$, and $\phi_{13}(a_1)$ involve the mixing

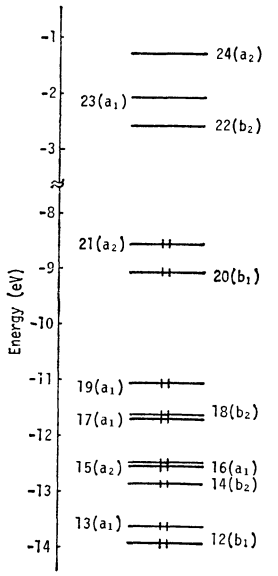

Fig. 2. Upper portion of the molecular orbital level diagram for $Ni(O_2)(HNC)_2$. The highest occupied level is $21(a_2)$.

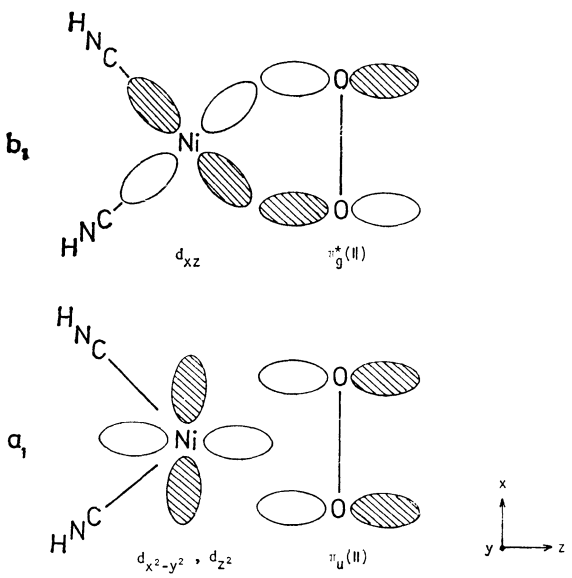

Fig. 3. Orbitals participating in the Ni–O_2 bonding of $Ni(O_2)(HNC)_2$.
b_1, the back-donation type; a_1, the donation type from O_2 to Ni.

of the former type while the level $\phi_{20}(b_1)$ is due to that of the latter. The two types of mixings, schematically shown in Fig. 3, are analogous to the donation and back-donation scheme in the Dewar-Chatt-Duncanson model.

The calculated valence-electron distributions over the atomic orbitals as well as the atoms present in the complex are summarized in Table 4. We see that the final electronic configuration of nickel is $(3d)^{8.49}$ $(4s)^{0.54}$ $(4p)^{0.98}$. Most of the d-orbital population resides in the d_{xy}, d_{yz}, $d_{x^2-y^2}$, and d_{z^2} orbitals. The 4p orbital is appreciably occupied. The net charge on nickel is nearly zero, even though its d-orbital occupation number is between 8 and 9. The isocyanide

ligands assume overall positive charges, as would be expected from the nature of isocyanide as a donating ligand. The net charge on each oxygen atom is *ca.* −0.44. The charge transfer from $Ni(HNC)_2$ to O_2 thus amounts to about one electron equivalent.

In order to gain a deeper insight into the O–O bonding nature, we calculated individual π orbital populations in the O_2 moiety as follows:

$$q(\pi_u(\perp)) = 4\sum_{i(a_2)}^{occ} C^2_{iO(p_y)} \quad (12)$$

$$q(\pi_u(\parallel)) = 4\sum_{i(a_1)}^{occ} C^2_{iO(p_z)} \quad (13)$$

$$q(\pi_g^*(\perp)) = 4\sum_{i(b_2)}^{occ} C^2_{iO(p_y)} \quad (14)$$

$$q(\pi_g^*(\parallel)) = 4\sum_{i(b_1)}^{occ} C^2_{iO(p_z)} \quad (15)$$

where $C_{iO(p_y)}$ *etc.* denote the LCAO coefficients of the i-th MO for the oxygen p orbitals specified, the summations extending over the MO's of a given symmetry a_1, a_2, b_1, or b_2. The various π orbital populations calculated for the $Ni(O_2)(HNC)_2$ complex are summarized in Table 5, together with the O–O bond length and the O–O stretching force constant.[32] For the sake of comparison, the corresponding values for molecular $O_2(^3\Sigma_g^-, {}^3\Sigma_u^\pm)$, superoxide O_2^-, and peroxide O_2^{2-} are also listed in Table 5.

The O–O bondings in dioxygen complexes have often been discussed on the basis of their analogy in bond length with those in O_2^{n-} anions ($n=1$ and 2) and excited-state O_2.[5,7,32,33] The electronic configuration of O_2 in the complex here calculated certainly reflects the effects of both the charge transfer to O_2 and the local excitation of O_2. Thus, the sum of the π^* orbital populations exceeds 3, indicative of a partial O_2^{2-} character while that of the π orbitals is less than 4, a result which would be expected if the coordinated dioxygen is assumed to partake of the character of excited $O_2(^3\Sigma_u^+$ or $^3\Sigma_u^-)$. The results can best be understood in terms of the intermolecular configuration interaction[34]; the ground state of the complex is represented by a superposition of the ground, charge-transfer, and locally-excited configurations made up of the molecular orbitals of the component molecules, $Ni(HNC)_2$ and $O_2(^3\Sigma_g^-)$.

Taking a step further, we will discuss the relative strengths of the O–O bondings of coordinated dioxygen, free oxygen anions, and various states of molecular oxygen. Since the π_u and π_g^* orbitals are, respectively, bonding and antibonding in nature, the population in the former orbitals should tend to strengthen the bond while the latter to weaken it. The O–O bond strength may be related, to a first approximation, with the differential population between them, defined as

$$\Delta q = q(\pi_u(\perp)) + q(\pi_u(\parallel)) - q(\pi_g^*(\perp)) - q(\pi_g^*(\parallel)) . \quad (16)$$

The values of Δq thus calculated for the various types of dioxygens are included in Table 5. They decrease in the order: $O_2(^3\Sigma_g^-) > O_2^- > Ni(O_2)(HNC)_2 > O_2^{2-} = O_2(^3\Sigma_u^\pm)$, in rough agreement with the decreasing order of the observed force constant f_{O-O} and the increasing order of bond length R_{O-O}. The f_{O-O} value used herewith for O_2^{2-} appears to be somewhat too large. Perhaps, dioxygen in Na_2O_2 is not adequate as a model for a free O_2^{2-}.

Polar Effect of Isocyanide Substituent. The strengths of the M–O and O–O bonds in the dioxygen complexes vary depending on the identity of the metal and auxiliary

ligands. The O–O bond length ranges from 1.30 to 1.63 Å, while the M–O bond length from 1.82 to 2.09 Å. Also, the force constants of the O–O and M–O stretchings, determined by IR spectroscopy, range from 3.0 to 3.5 mdyn/Å and from 2.1 to 3.2 mdyn/Å, respectively.

In an attempt to elucidate the effect of the substituent of the isocyanide ligand on the O–O and M–O bond strengths, we have carried out model calculations by varying the ionization potential $I_s^H(=-U_{ss}^H)$ for the hydrogen atom of isocyanide, with the other parameters being fixed. When I_s^H is smaller than 13.6 eV, the hypothetical isocyanide ligand (CNH′) should be more electron-releasing than CNH, and *vice versa*.

The net charges on oxygen Q_O calculated with various I_s^H values are listed in the first line of Table 6. It can be seen that Q_O increases in magnitude as the isocyanide ligand becomes more electron-releasing. Thus, electropositive ligands tend to enhance the back-donation of electrons from nickel to dioxygen.

Also listed in Table 6 are the bond indices W_{O-O} and W_{Ni-O}, together with the values for q as well as Δq. The quantities Δq and W_{O-O}, both of which are the measures of the O–O covalent bond strength, decrease with decreasing I_s^H. The results indicate that the substitution of electron-releasing ligands leads to a decrease in the O–O bond strength. The trend can easily be accounted for in terms of the increasing back-donation from nickel to O_2 π_g^* orbital; $q(\pi_g^*(\parallel))$ increases considerably as I_s^H decreases. Similar situations are encountered in olefin and acetylene complexes.[35]

As for the strength of the nickel–oxygen bond, the W_{Ni-O} also decreases with the increasing electron-releasing character of the isocyanide ligand. The result might appear strange. With olefin and acetylene complexes, the relative strengths of metal–olefin (or metal–acetylene) π-bonding interaction reflect the amount of back-donation; a weaker C–C bond is usually accompained by a stronger metal–olefin bond.[35,36]

The most important difference between dioxygen and olefin (or acetylene) is that the former is much more electronegative than the latter, the half-occupied π_g^* orbital of the former being much lower in energy than the lowest vacant orbital of the latter. The nickel orbitals of the isocyanide complex may lie as high as or even higher than the π_g^* orbitals of dioxygen. In order to ascertain this possibility, the UHF-INDO calculations were performed for two isolated molecules, O_2 and $Ni(HNC)_2$. The latter molecule was assumed to be in the lowest triplet state, its geometry being assumed to be the same as in Fig. 1. The resulting HOMO (degenerate) of the α-spin orbital for O_2 is at −12.05 eV, while that for $Ni(HNC)_2$, at −6.21 eV. The former is significantly lower than the latter, indicative of the higher electronegativity of O_2. Indeed, the dioxygen–nickel bonding orbital $\psi_{20}(b_1)$ possesses a large dioxygen character, in harmony with the lower O_2 π_g^* orbital as compared with the HOMO of $Ni(HNC)_2$.

Under these circumstances, the covalency of the Ni–O bond and, hence, its bond strength should decrease as the nickel atom becomes more electron-releasing. The view is supported by the IR spectra, which show that the frequency of the rhodium–oxygen stretching ν_{Rh-O} for various dioxygen rhodium complexes[32] tends to increase in the order of electron-attracting ability of the substituents. This is in contrast with the results for Vaska's dioxygen complexes, where the reversibility of oxygen coordination was realized in the presence of electron-attracting ligands.[33] However, the reversibility may not necessarily be correlated with the dioxygen–metal bond strength.

Transition Energies and Dipole Moment Lengths. Ultraviolet and visible absorption spectra have been reported for $Ni(O_2)(t\text{-BuNC})_2$ both in a $CHCl_3$ solution and in the solid state.[14b] Assignment of the greatest wavelength absorption band was also given,[14b] where the ground electronic state of the complex was assumed to be $^3A_2$. However, the assumption is probably not valid in view of the data of magnetic susceptibility and PMR spectrum, as has already been

Table 7. Transition energies (Δ^1E) and transition moment lengths (M) for $Ni(O_2)(HNC)_2$

Transition	Symmetry	Calcd			Obsd[b]	
		Δ^1E(eV)	M(Å)	M'(Å)[a]	Δ^1E(eV)	ε
$\psi_{15}\rightarrow\psi_{26}$	$^1B_2$	1.80	0.008	0.008	2.07	38
$\psi_{16}\rightarrow\psi_{26}$	$^1B_1$	2.80	0.244	0.033		
$\psi_{21}\rightarrow\psi_{26}$	$^1B_2$	2.81	0.023	0.023		
$\psi_{21}\rightarrow\psi_{22}$	$^1B_1$	2.94	0.170	0.004	3.26[c]	316
$\psi_{13}\rightarrow\psi_{26}$	$^1B_1$	3.18	0.007	0.004		
$\psi_{20}\rightarrow\psi_{23}$	$^1B_1$	3.49	0.124	0.009		

a) Contribution from atomic polarization. b) Observed in $CHCl_3$ solution. See Ref. 13. c) Observed as a superposition of many peaks.

mentioned. Thus, we here attempt reassignments of the electronic spectra, assuming that the replacement of *t*-BuNC by HNC does not affect the spectra significantly.

Table 7 gives the energies Δ^1E and dipole moment lengths M calculated for the singlet transitions in the low-energy region, together with the experimental data. Considering the observed extinction coefficients ε and the calculated M, we may ascribe the band observed at 2.07 eV to the $\psi_{15}\rightarrow\psi_{26}$ ($^1A_1\rightarrow{}^1B_2$) transition. The transition has an appreciable d-d band character with a slight charge-transfer from nickel d orbitals to ligand π_g* orbitals. The band appearing at 3.26 eV can be ascribed primarily to the three $^1A_1\rightarrow{}^1B_1$ transitions, $\psi_{16}\rightarrow\psi_{26}$, $\psi_{21}\rightarrow\psi_{22}$, and $\psi_{20}\rightarrow\psi_{23}$. The $\psi_{16}\rightarrow\psi_{26}$ transition reveals a considerable mixing of the d-d excitation with charge-transfer from the oxygen $\pi_u(\parallel)$ orbital to the isocyanide $\pi^*(\parallel)$ orbital, the resulting M being large as compared with that for a d-d transition. On the other hand, the latter two transitions are almost completely of charge-transfer type. The $\psi_{21}\rightarrow\psi_{22}$ transition corresponds to the charge-transfer from the oxygen $\pi_g^*(\perp)$ orbital to the nickel p_z and the isocyanide $\pi^*(\perp)$ orbitals, while the $\psi_{20}\rightarrow\psi_{23}$ transition from the oxygen $\pi_g^*(\parallel)$ and the nickel d orbitals to the isocyanide $\pi^*(\parallel)$ orbitals.

It should be noted that the energies calculated for the $\psi_{15}\rightarrow\psi_{26}$ and $\psi_{16}\rightarrow\psi_{26}$ transitions are relatively small (1.80 and 2.80 eV, respectively) despite their large orbital energy gaps (12.01 and 11.89 eV, respectively). Apparently, this is a consequence of their interorbital Coulomb repulsions J_{ij} being relatively large (11.14 and 10.19 eV, respectively). That these particular transitions have large J_{ij} is not surprising, since both of them possess an appreciable d-d (and hence largely local) excitation character to which the contribution of one-center Coulombic repulsions should be dominant. It is also noteworthy that for these two transitions the contribution M' of atomic polarization to dipole moment length is not negligible.

Concluding Remarks

The results given above indicate that our modified INDO method can satisfactorily account for the structure of the nickel dioxygen complex studied. It can well serve as a tool in illuminating the nature of the chemical bondings involved.

One point that may be raised against the present treatment will be the accuracy of the INDO theory itself when extended to include d orbitals. However, recent success[37,38] of the theory in quantitative interpretation of the photoelectron spectra for several transition metal complexes does appear to warrant its reliability. Description of the ground-state properties of the nickel dioxygen complex studied herein is probably reliable enough at least qualitatively.

Semiempirical Molecular Orbital Considerations of the Electronic Structures of Transition Metal Complexes. II. Acetylene- and Azo-Nickel Complexes

Kazuyuki TATSUMI, Takayuki FUENO, Akira NAKAMURA, and Sei OTSUKA
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received December 22, 1976)

The electronic structures of zerovalent nickel π complexes, Ni(HC≡CH)$(HNC)_2$ and Ni(*trans*-HN=NH)$(HNC)_2$, have been investigated by the INDO method. Both complexes are found to favor the square-planar geometry, in accord with the observed structures of Ni($C_6H_5C{\equiv}CC_6H_5$)(*t*-BuNC)$_2$ and Ni($C_6H_5N{=}NC_6H_5$)(*t*-BuNC)$_2$. Ni(*trans*-HN=NH)$(HNC)_2$ is predicted to be more stable than Ni(*cis*-HN=NH)$(HNC)_2$. The increment in the C–C and N–N bond lengths effected by the complexation seems to well reflect the net effects of σ donation and π back-donation. For the isocyanide N–C bond, an approximately linear relationship is found to hold between the calculated bond index and the observed force constant. It is suggested that both the Ni–C(of acetylene) and Ni–N(of diimide) bondings tend to have greater covalent bond strengths as the electron-releasing ability of the isocyanide ligand increases.

Since the discovery of Zeise's salt, transition metal π complexes have constituted an enormous, diversified field of chemistry.[1] Although the chemistry is well developed, theoretical inquiries to the field have still been limited to olefin complexes.[2] There have been very few attempts at coherent quantum-mechanical description of other π complexes.[3]

In our previous work,[4] we investigated the electronic structure of side-on coordinated nickel dioxygen complex Ni$(O_2)(HNC)_2$ by a modified INDO method. It was found that the greater the extent of back-donation of electrons from Ni to O_2, the weaker is the Ni–O_2 covalent bond strength. A unique substituent effect was predicted that *both* the Ni–O_2 and O–O bondings tend to have greater covalent bond strengths as the electron-attracting ability of the ligand isocyanide increases.

In this paper we will deal with the side-on isocyanide nickel complexes Ni(HC≡CH)$(HNC)_2$ and Ni(HN=NH)$(HNC)_2$ as model compounds for Ni($C_6H_5C{\equiv}CC_6H_5$)(*t*-BuNC)$_2$,[5] and Ni($C_6H_5N{=}NC_6H_5$)(*t*-BuNC)$_2$,[6] respectively. The purpose of the present study is to clarify the nature of the bondings involved in these complexes and the effects of their geometry and ligand structure on the bondings. A particular attention will be directed to comparisons between these complexes with a dioxygen nickel isocyanide complex, Ni$(O_2)(HNC)_2$.

Method of Calculation

The same ASMO SCF method at the level of the INDO approximation as described previously[4,7] was used. The basis set of atomic orbitals adopted in the calculation is: 3d, 4s, and 4p for Ni; 2s and 2p for both C and N; and 1s for H. The single-parameter functions of Zerner and Gouterman[8] have been used for the nickel atom while Clementi's functions[9] for ligand atoms. All the one-center integral parameters involved are the same as those used in our earlier paper.[4]

In calculating the core-core repulsion energy E_{AB}(core) between atoms A and B, we have used the following function:

$$E_{AB}(\text{core}) = (1-c)\sum_A\sum_B\sum_\mu^A\sum_\nu^B N_\mu N_\nu(\mu\mu|\nu\nu) + c\sum_A\sum_B\frac{14.399Z_AZ_B}{R_{AB}} \quad (1)$$

where N_μ and N_ν refer to the numbers of the valence electrons occupying AO's μ and ν, respectively; $(\mu\mu|\nu\nu)$ is the two-center repulsion integral; Z_A and Z_B are the core charge on atoms; and R_{AB} is the internuclear distance between A and B in units of Å. The parameter c has been determined to reproduce the experimental C–C bond length of acetylene (1.203 Å).[10] The resulting c value was 0.353.

Results and Discussion

A. Structure of Complexes. Precise structural information based on the X-ray data is available for Ni($C_6H_5C{\equiv}CC_6H_5$)(*t*-BuNC)$_2$[11] and Ni(*trans*-$C_6H_5N{=}NC_6H_5$)(*t*-BuNC)$_2$.[12] The dihedral angles θ between the bisisocyanide-nickel plane and the Ni–C–C (of acetylne) and Ni–N–N (of azobenzene) planes are 2.6°(7) and 1.2°(3), respectively, so that the complexes possess essentially the C_{2v} or C_2 symmetry. Acetylene, which is linear in the free state, takes a *cis*-bent structure (δ=31.4°) in the complex. Similarly, for the π-bonded azobenzene complex, there is a dihedral angle of 2ω= 26.8° between the two N–N–C (of phenyl) planes. This angle would be 0° if the C–N–N–C portion of the complex were coplanar as it is in free *trans*-azobenzene.

Conformation of the Complexes. In the first place, we will consider the conformations of our model compounds Ni(HC≡CH)$(HNC)_2$ and Ni(HN=NH)$(HNC)_2$. Calculations were carried out for a few extreme geometries of each compound. Figure 1 illustrates such geometries which can be characterized by two angles, θ and either δ or ω.

The total energies of Ni(HC≡CH)$(HNC)_2$ for three distinct conformations characterized by the symbol (θ, δ) are presented in Table 1, together with the bond indices W[13] for the Ni–C (of acetylene) and C–C bonds, the net charge Q on the acetylene moiety, and the electron populations q[4] in the acetylene π and π^* orbitals perpendicular ($\perp$) and parallel ($\parallel$) to the

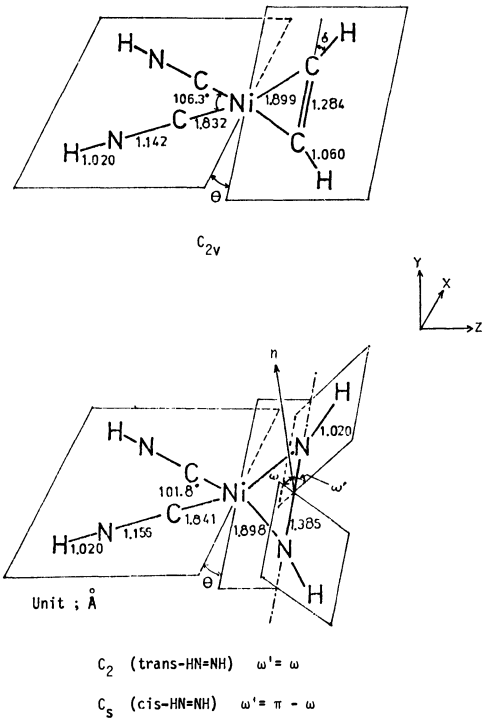

Fig. 1. Coordinate system and structures for Ni(HC≡CH)(HNC)$_2$ and Ni(HN=NH)(HNC)$_2$. The arrow n indicates the direction of the normal line on the plane which the nickel and diimide nitrogens are placed on.

Ni-acetylene plane.[14] Similar sets of data for conformations (θ, ω) of Ni(*trans*-HN=NH)(HNC)$_2$ are given in Table 2.

As can be seen in Tables 1 and 2, the square-planar bent ($\theta=0°$, $\delta>0°$) or twisted ($\theta=0°$, $\omega>0°$) form is more stable than either of the square-planar nonbent ($\theta=\delta=0°$) or untwisted ($\theta=\omega=0°$) structure and the pseudotetrahedral conformation ($\theta=90°$). The results agree well with the X-ray structures of Ni($C_6H_5C{\equiv}CC_6H_5$)-(*t*-BuNC)$_2$ and Ni(*trans*-$C_6H_5N{=}NC_6H_5$)(*t*-BuNC)$_2$.

The bond indices W for the Ni–C (of acetylene) and Ni–N (of diimide) bonds are the greatest for the square-planar bent (or twisted) structure. Since W can be regarded as a measure of covalent bond strength of the bond in question,[15] the greatest stability of the form may be ascribable to the greatest covalent character of the Ni–C or Ni–N bond. On the other hand, both W_{C-C} and W_{N-N} are the smallest for the square-planar bent and twisted structures. A stronger nickel-acetylene (or diimide) bonding is thus accompanied by a weaker C–C (or N–N) bond. A similar trend is noted in olefin complexes.[16]

Table 1. Total energy (E), bond indices (W), net charge on acetylene (Q), and various orbital populations (q) for Ni(HC≡CH)(HNC)$_2$

(θ, δ)	Square-Planar		Pseudo-tetrahedral
	Bent (0°, 31.4°)	Nonbent (0°, 0°)	Bent (90°, 31.4°)

$q(\pi_u(\parallel))$	1.6987	1.8618	1.6839
$q(\pi_g^*(\parallel))$	0.6329	0.4865	0.6313

We now attempt a more detailed analysis of the covalent bond strength of the Ni–C (of acetylene) and Ni–N (of diimide) bonds. Let us first discuss the problem of square-planar *vs.* pseudotetrahedral orientations of acetylene (bent) and diimide (twisted). As shown in Table 1, the net charge on the acetylene $Q_{HC\equiv CH}$ is smaller for the former structure. This has arisen primarily from the smaller value of $q(\pi_u(\perp))$, which implies a greater extent of electron donation from acetylene to nickel. To the contrary, the net charge on the diimide $Q_{HN=NH}$ is greater for the square-planar bent structure (Table 2). The increment of $Q_{HN=NH}$ has resulted mainly from the greater $q(\pi_g^*(\parallel))$ value,

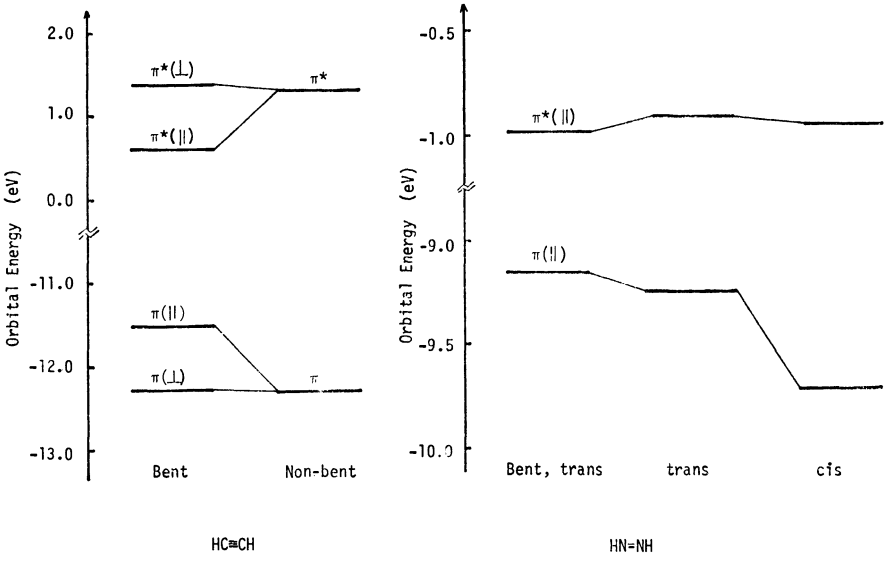

Fig. 2. Computed π and π^* energy levels for various geometries of HC≡CH and HN=NH. Bond lengths and angles are the same as those in the complexes.

Table 2. Total energy (E), bond indices (W), net charge on diimide (Q), and π orbital populations (q) for Ni(*trans*-HN=NH)$(HNC)_2$ and Ni(*cis*-HN=NH)$(HNC)_2$

(θ, ω)	*trans*-HN=NH			*cis*-HN=NH
	Square-Planar		Pseudo-tetrahedral	Square-Planar

W_{Ni-N}	0.8547	0.8338	0.8382	0.8476
W_{N-N}	1.1735	1.2059	1.1854	1.1762
$Q_{HN=NH}$	−0.3982	−0.3637	−0.3888	−0.3974
$q(\pi_u(\|\|))$	1.8057	1.8493	1.8023	1.8131
$q(\pi_g^*(\|\|))$	0.9367	0.9021	0.9078	0.9293

indicative of a greater extent of back-donation from nickel to diimide. Since a metal-unsaturated ligand bonding is accomplished by two independent interactions, σ donation and π back-donation, the greater extent of either process would strengthen the bond. Thus, the covalency of both the Ni–(HC≡CH) and Ni–(HN=NH) bonds is greater for the square-planar bent form as has been concluded on the basis of the bond index. However, it is noteworthy here that the origins of the greater stabilities for the square-planar forms differ between the acetylene- and azo-nickel complexes.

Next, we examine the bending (δ) and twisting (ω) effects of acetylene and diimide on the metal–π ligand bondings. Comparisons are now made between two extreme geometries, the square-planar bent ($\delta,\omega>0°$) and the square-planar nonbent ($\delta,\omega=0°$) structures. Both $q(\pi_u(\perp))$ and $q(\pi_u(\|))$ of the acetylene complex decrease in magnitude as the acetylene bends, while $q(\pi_g^*(\|))$ increases (Table 1). These results indicate greater extents of both σ donation and π back-donation for the bent form. The greater interaction means a greater Ni–(HC≡CH) bond strengthening. A change in the negligibly small $q(\pi_g^*(\perp))$ value need not be taken into account. In the diimide complex, $q(\pi_u(\|))$ is smaller for the twisted form, while $q(\pi_g^*(\|))$ is larger (Table 2). Thus the nickel–diimide bonding is also strengthened by the twisting of the diimide skeleton.

What brings about the increases in both the σ donation and π back-donation in the bent form? A possible answer can be obtained from the comparisons of the π and π^* orbital energy levels for the isolated HC≡CH and HN=NH fragments between the bent and nonbent structures (Fig. 2). In the case of acetylene, both occupied orbitals $\pi_u(\perp)$ and $\pi_u(\|)$ are more or less destabilized by the distortion while the unoccupied $\pi_g^*(\|)$ orbital lowers in energy. The destabilization of the occupied orbitals leads to a greater donor ability of the bent form while the stabilization of $\pi_g^*(\|)$ results in the greater acceptor ability. Contrary to this, the $\pi_g^*(\perp)$ orbital rises in energy as acetylene bends. However, this effect hardly exerts influence on the Ni–C (of acetylene) bonding because of the small overlap between Ni d_{xy} and C p_y orbitals (0.019). The diimide $\pi_u(\|)$ and $\pi_g^*(\|)$ orbitals show the same tendency as those of acetylene. The greater σ donor and π acceptor abilities of the twisted diimide can thus likewise be accounted for.

Configuration of HN=NH. For azo compounds two possible geometrical isomers, *cis* and *trans*, exist. We will focus our attention on the relative stabilities of the azo nickel complexes formed from the *cis* and *trans* isomers of HN=NH. We have calculated the total energy of our model compound Ni(*cis*-HN=NH)$(HNC)_2$, in which the bond lengths and angles are taken to be the same as those in *trans*-HN=NH complex. The result is given in the final column of Table 2, together with the bond indices W for the Ni–N and N–N bonds as well as the π and π^* orbital populations.

As Table 2 shows, the *trans* azo complex (square-planar bent) is more stable than the *cis*. The result may endorse the fact that the catalysis with low-valent diamagnetic metal complexes leads only to the *cis*→*trans* isomerization of *cis*-azobenzene; the reverse catalytic process hardly takes place.[17]

The greater stability of the *trans*-diimide complex as compared with the complex of the *cis* isomer is wholly compatible with the foregoing arguments on the effects of ligand deformation. Thus, the bond index W_{Ni-N} is larger in the *trans* isomer, indicative of a greater covalent character of the Ni–N bond. The π orbital population $q(\pi_u(\|))$ of the *trans*-diimide complex is smaller than that of the *cis* complex, while $q(\pi_g^*(\|))$ is greater in the former. The greater stability of the *trans* isomer would thus be a consequence of the greater extents of σ donation and π back-donation, which could immediately be rationalized from the π orbital level diagram shown in Fig. 2.

B. Ni-Ligand Bondings in the Square-Planar Conformer.

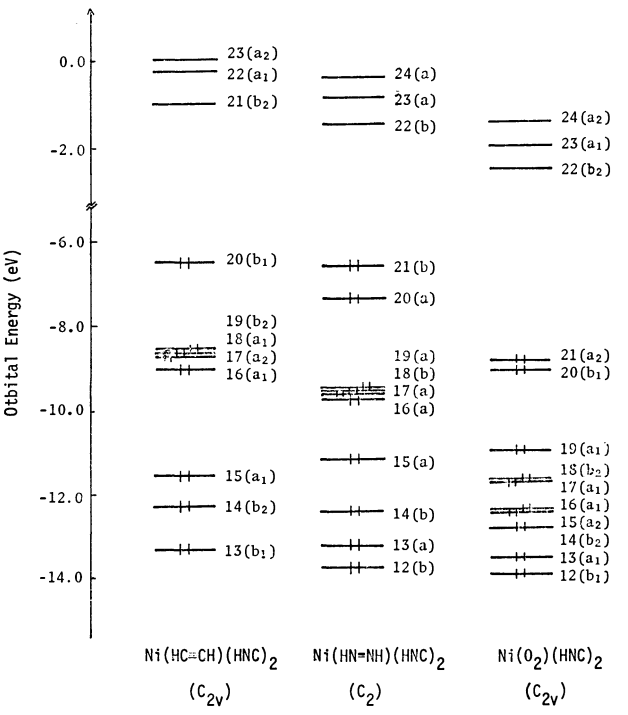

Fig. 3. Upper portions of the molecular orbital level diagrams for Ni(HC≡CH)$(HNC)_2$, Ni(HN=NH)$(HNC)_2$, and Ni$(O_2)(HNC)_2$. The highest occupied levels are 20 (b_1), 21(b), and 21(a_2), respectively.

In this section, we will describe the electronic structure of $Ni(HC{\equiv}CH)(HNC)_2$ and $Ni(trans\text{-}HN{=}NH)(HNC)_2$[18] for the square-planar form in detail. The level height and form of the bonding molecular orbitals are our specific concern here.

Molecular Orbitals. The molecular orbital energy levels are diagrammatically shown in Fig. 3, where those for the dioxygen complex $Ni(O_2)(HNC)_2$ are also shown for the sake of comparison. The levels are labeled according to the irreducible representations of the C_{2v} point group, except for the *trans*-diimide complex of the C_2 point group. Only the low-lying vacant orbitals and the upper portion of the occupied orbitals are included in the diagrams; lower orbitals which have been omitted in the diagrams consist merely of the essentially unperturbed ligand orbitals lying in the range -44.8 to -15.5 eV.

The lowest unoccupied levels, $\phi_{21}(b_2)$ for the acetylene complex and $\phi_{22}(b)$ for the azo complex, consist primarily of the isocyanide $\pi^*(\perp)$ orbital with an appreciable Ni $4p_y$ character. The highest occupied level $\phi_{20}(b_1)$ for the former complex is an admixture of the Ni $3d_{xz}$ with the $HC{\equiv}CH$ $\pi_g^*(\parallel)$ orbital. Similarly, $\phi_{21}(b)$ for the latter involves the mixing between the Ni $3d_{xz}$ and $HN{=}NH$ $\pi_g^*(\parallel)$ orbitals. These two bonding orbitals are of back-donation type which contribute to the Ni–$(HC{\equiv}CH)$ or Ni–$(HN{=}NH)$ bonding, corresponding to $\phi_{20}(b_1)$ for the dioxygen complex. Incidentally, the orbital $\phi_{21}(a_2)$ of the dioxygen complex is the lone-pair orbital $\pi_g^*(\perp)$ of O_2.

It is clear from Fig. 3 that the π-type bonding orbitals ascribable to the back-donation are more stabilized with the increase in the π acceptor ability of the unsaturated ligands. Figure 4 shows the contour maps of these back-donation type orbitals. The maps clearly show the delocalization of electrons from the Ni $3d_{xz}$ into the ligand $\pi_g^*(\parallel)$ orbital, which increases in the order $HC{\equiv}CH<HN{=}NH<O_2$, in harmony with the decreasing order of the π^* energy levels of the free molecules; 1.910 eV $(HC{\equiv}CH)$, 0.014 eV $(HN{=}NH)$, and -12.05 eV (O_2).[19]

The Ni–$(HC{\equiv}CH)$ and Ni–$(HN{=}NH)$ σ-type bondings are accomplished through donation type orbitals such as $\phi_{15}(a_1)$, $\phi_{16}(a_1)$, and $\phi_{18}(a_1)$ for the former complex and $\phi_{15}(a)$, $\phi_{16}(a)$, and $\phi_{19}(a)$ for the latter. However, each level is found to involve relatively small mixings between the Ni $d_{x^2-y^2}$ and d_{z^2} orbitals with the ligand $\pi_u(\parallel)$ orbital as compared to the back-donation type orbital.

All these results imply the relative importance of the π-type bonding in such basic zerovalent nickel complexes. Consistently, chemical and spectroscopic informations of zerovalent nickel olefin complexes show a considerable back-donation from nickel d to olefin π^* orbital.[21–24] The stability of the complexes is even governed entirely by the amount of back-donation.[23c,25] The trend forms a sharp contrast with the relative importance of σ donation in Zeise's anion $[Pt(C_2H_4)Cl_3]^-$ [26] as well as silver(I)-olefin complexes.[27]

Another type of Ni–$(HC{\equiv}CH)$ bonding is accomplished through the mixing of the $HC{\equiv}CH$ $\pi_u(\perp)$ orbital with the Ni d_{yz} orbital in $\phi_{14}(b_2)$. This is

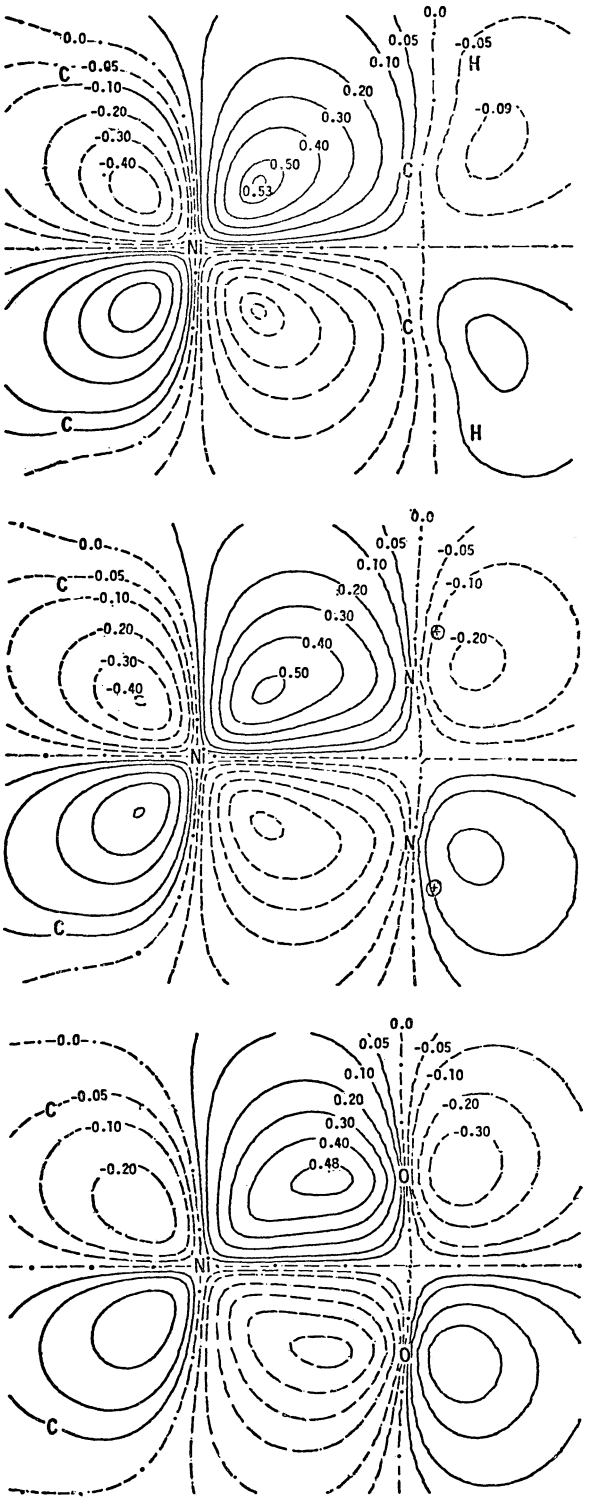

Fig. 4. Contour plots of the π-like bonding orbitals of (A) $Ni(HC{\equiv}CH)(HNC)_2$ [$20b_1$], (B) $Ni(HN{=}NH)(HNC)_2$ [21b], and (C) $Ni(O_2)(HNC)_2$ [$20b_1$]. The nitrogen and hydrogen atoms of the isocyanide ligand are excluded in the plots. The points marked with ⊕ are the projections of the hydrogen atoms onto the xz plane.

compatible with the model presented for platinum acetylene complexes by Nelson *et al.*[3a] A similar identification can be made for the dioxygen complex in the level $\phi_{14}(b_2)$.[4] The corresponding levels for the

azo complex are ψ_{20}(a) and ψ_{14}(b), which are the combinations of the two lone-pair orbitals on diimide. The mixing of the lone-pair with Ni d orbitals is practically zero.

Charge Distribution. Table 3 summarizes the calculated distributions of valence electrons over the nickel s, p, and d orbitals as well as the ligand atoms in the complexes. According to these results, the apparent electronic configurations of nickel are $(3d)^{8.90}(4s)^{0.52}(4p)^{1.07}$, $(3d)^{8.80}(4s)^{0.53}(4p)^{0.99}$, and $(3d)^{8.49}(4s)^{0.54}(4p)^{0.98}$ for Ni(HC≡CH)$(HNC)_2$, Ni(HN=NH)-$(HNC)_2$, and Ni$(O_2)(HNC)_2$, respectively. The net charge density on the nickel atom ranges from −0.49 to −0.01, increasing in the order Ni(HC≡CH)$(HNC)_2$< Ni(HN=NH)$(HNC)_2$<Ni$(O_2)(HNC)_2$. Their total d orbital occupation numbers lie between 8 and 9 and tend to increase in the reverse order. These trends are governed almost exclusively by the population on the d_{xz} orbital; nearly two electrons keep residing in each of the remaining four d orbitals. The above-mentioned order can be anticipated from the electronegativities of acetylene, diimide, and dioxygen. By a similar reasoning, positive charges on the donating isocyanide ligands should increase in the order Ni(HC≡CH)$(HNC)_2$< Ni(HN=NH)$(HNC)_2$<Ni$(O_2)(HNC)_2$. The charge transfer from the Ni$(HNC)_2$ identity to each unsaturated ligand amounts to 0.14 (acetylene), 0.41 (diimide), or 0.88 (dioxygen) of an electron.

C. Bondings within the Ligands. The activation of unsaturated ligands by metal complexes has received considerable attention because of possible catalytic applications.[28,29] We will elaborate, in this section, on the properties of C≡C and N=N bondings as well as the isocyanide C≡N bond in the complexes.

The C≡C and N=N Bondings. In Table 4, the various π orbital populations for the acetylene and diimide complexes in the most stable forms are compared with those for free acetylene and diimide. The electron donation from nickel to the organic moiety upon complexation is reflected in the diminution in $q(\pi_u(\perp))$ or $q(\pi_u(\parallel))$ while the back-donation, in the increment in $q(\pi_g^*(\parallel))$. The following points are noteworthy in Table 4: (1) The back-donation to the acetylene $\pi_g^*(\perp)$ orbital is almost zero, in contrast to an appreciable donation from the acetylene $\pi_u(\perp)$ orbital; (2) despite the presence of the filled lone-pair orbitals, diimide acts as a fairly efficient π acceptor toward zerovalent nickel; and (3) the total π population in each complex is greater than that in the corresponding free unsaturated ligand. At any rate, both the diminution in $q(\pi_u)$ and the enhancement in $q(\pi_g^*)$ should lead to loosening of the C≡C and N=N bonds.

TABLE 4. CALCULATED ORBITAL POPULATIONS (q) AND OBSERVED BOND LENGTH (R)

	Ni(C_2H_2)-$(HNC)_2$	C_2H_2	Ni(N_2H_2)-$(HNC)_2$	N_2H_2
$q(\pi_u(\perp))$	1.86	2.00	—	—

R_{L-L}(Å)	1.284[a]	1.19[b]	1.385[c]	1.243[d]

a) For Ni$(C_6H_5C{\equiv}CC_6H_5)(t\text{-BuNC})_2$, Ref. 11. b) For $C_6H_5C{\equiv}CC_6H_5$, J.M. Robertson and I. Woodward, *Proc. R. Soc., Ser. A*, **164**, 436 (1938). c) For Ni-$(C_6H_5N{=}NC_6H_5)(t\text{-BuNC})_2$, Ref. 12. d) For $C_6H_5N{=}NC_6H_5$, C. J. Brown, *Acta Crystallogr.*, **21**, 146 (1966).

We have previously introduced the quantity[4]

$$\Delta q = q(\pi_u(\perp)) + q(\pi_u(\parallel)) - q(\pi_g^*(\perp)) - q(\pi_g^*(\parallel)) \quad (2)$$

as a measure of the strength of the O–O π bond in the nickel dioxygen complex. The values of Δq calculated for HC≡CH and HN=NH, both complexed and uncomplexed, are included in Table 4. For either of the acetylene and azo complexes studied, Δq is much smaller than that for the corresponding free substrate. This would effect a considerable increase in the C≡C as well as N=N bond length R, as is actually the case.

The above-stated trend could be cast into a more quantitative generalization,[30,31] since conceptually our Δq is twice the π-bond order of the unsaturated ligand. Thus we consider the ratio of the increase in R upon complexation to that brought about on going from an unsaturated bond to a saturated one:[32]

$$r = \frac{R_{L=L}(\text{complex}) - R_{L=L}(\text{free})}{R_{L-L}(\text{saturated}) - R_{L=L}(\text{free})} \quad (3)$$

L = C, N, and O

The ratio r is now to be compared with the change in Δq effected by complexation:

$$\Delta(\Delta q) = \Delta q(\text{complex}) - \Delta q(\text{free}) \quad (4)$$

The $\Delta(\Delta q)$ takes on a value −2 when complexation involves a complete destruction of a π bond of the ligand. Needless to say, $\Delta(\Delta q)=0$ when complexation does not take place. The ratio r should respectively be 1 and 0 in these extreme cases.

Figure 5 is the plots of r against $\Delta(\Delta q)$ for the nickel isocyanide complexes of acetylene, diimide, dioxygen,

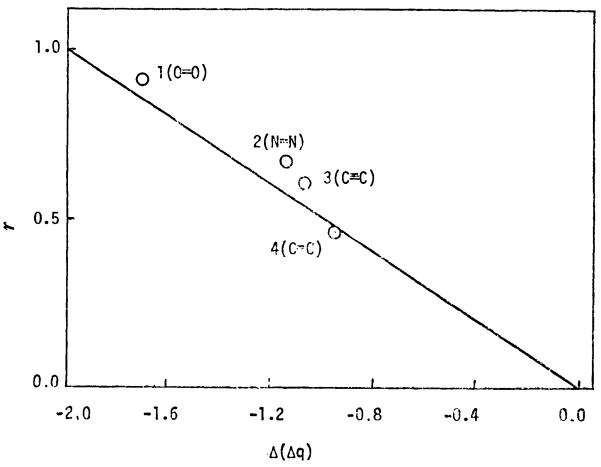

Fig. 5. Plots of the bond length ratio r of nickel complexes against the $\Delta(\Delta q)$ values calculated for the corresponding model compounds:
(1) $Ni(O_2)(t\text{-}BuNC)_2$
(2) $Ni(trans\text{-}C_6H_5N{=}NC_6H_5)(t\text{-}BuNC)_2$
(3) $Ni(C_6H_5C{\equiv}CC_6H_5)(t\text{-}BuNC)_2$
(4) $Ni(H_2C{=}CH_2)(P(C_6H_5)_3)_2$
The model compounds assumed are $Ni(O_2)(HNC)_2$, $Ni(trans\text{-}HN{=}NH)(HNC)_2$, $Ni(HC{\equiv}CH)(HNC)_2$, and $Ni(H_2C{=}CH_2)(PH_3)_2$, respectively. The bond length of O_2 in $Ni(O_2)(t\text{-}BuNC)_2$ was taken from M. Matsumoto and K. Nakatsu, *Acta Crystallogr.*, **B31**, 2711 (1975); for $Ni(H_2C{=}CH_2)(P(C_6H_5)_3)_2$, P.-T. Cheng, C. D. Cook, C. H. Koo, S. C. Nyburg, and M. T. Shimoni, *Acta Crystallogr.*, **B27**, 1904 (1971).

and ethylene. All the plots fall in the vicinity of the straight line which connects the two extreme points mentioned above. The results would make such plots for different atomic pairs meaningful.

N≡C Bonding. Infrared study[33] of a series of *cis*-planar nickel bisisocyanide complexes concludes that they possess two N≡C stretching bands assignable to the a and b modes with respect to the C_2 point group. We have applied the method of Cotton and Kraihanzel[34,35] to the two stretching frequencies observed, to derive a set of approximate force constants f_{N-C} and f_i. The former is the N≡C stretching force constant while the latter represents the *cis*-type (N≡C stretch)-(N≡C stretch) vibrational interaction force constant. Although there are several well-founded criticisms of the method,[36,37] it still seems to be useful for a comparative study of a family of analogous compounds.[38]

We here consider the N≡C stretching force constant f_{N-C}. Plotted in Fig. 6 are the f_{N-C} values for $Ni(C_6H_5C{\equiv}CC_6H_5)(t\text{-}BuNC)_2$, $Ni(C_6H_5N{=}NC_6H_5)(t\text{-}BuNC)_2$, and $Ni(O_2)(t\text{-}BuNC)_2$ against the bond indices W_{N-C} calculated for the N≡C bond of the corresponding model compounds. As can be seen in Fig. 6, there is a reasonably good linearity between f_{N-C} and W_{N-C} with a positive slope.

D. Polar Effect of Isocyanide Substituent. In dealing with the effects of substituent in isocyanide on the strengths of nickel-ligand bonds and the ligand C≡C and N=N bonds, we employ a similar model as has been

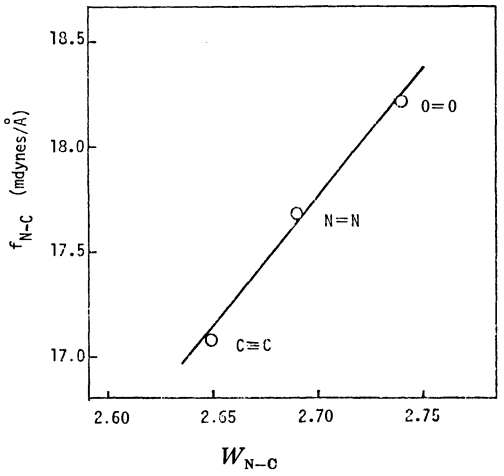

Fig. 6. Plots of the N≡C stretching force constants (f_{N-C}) *vs.* calculated bond indices (W_{N-C}) of the corresponding model compounds.

used previously.[4] That is, we assume a hypothetical isocyanide ligand (CNH′, for which the valence-state ionization potential I_S^H for the hydrogen atom H′ is allowed to vary, with the other parameters being fixed. When I_S^H is greater than 13.6 eV, CNH′ should be more electronegative than CNH, and *vice versa*. The differen-

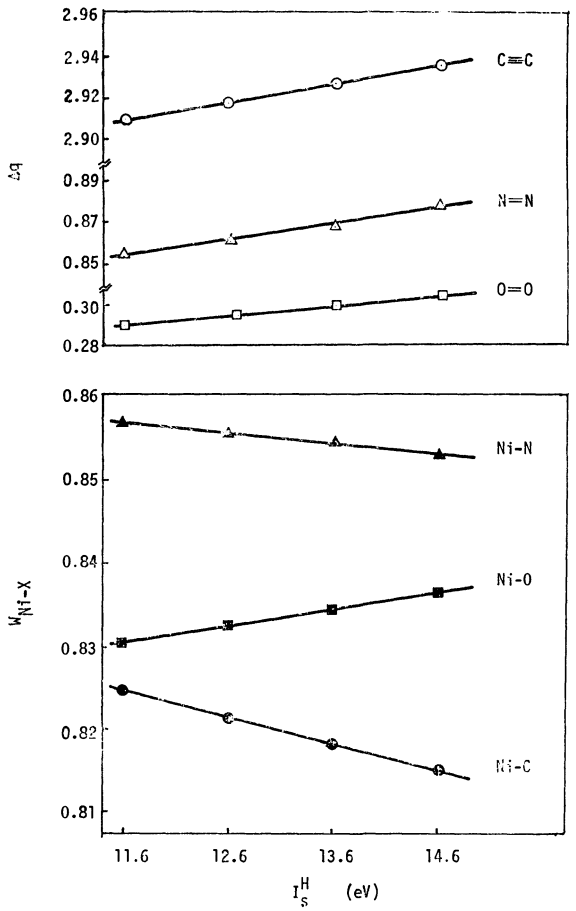

Fig. 7. Variations of the Δq values (top) and bond indices W (bottom) as the functions of I_S^H.
○, ●: $Ni(HC{\equiv}CH)(HNC)_2$, △, ▲: $Ni(HN{=}NH)(HNC)_2$, □, ■: $Ni(O_2)(HNC)_2$.

tial π orbital population Δq and bond indices W for the hypothetical complexes $Ni(HC{\equiv}CH)(H'NC)_2$ and $Ni(HN{=}NH)(H'NC)_2$ were calculated by varying I_S^H from 11.6 to 14.6 eV.

Figure 7 shows the variations in Δq and W_{Ni-L} as the functions of I_S^H. For the purpose of comparison, the calculated data for dioxygen complex $Ni(O_2)(H'NC)_2$ are also plotted. As Fig. 7 shows, the Δq-values for these three complexes altogether increase with the increasing I_S^H. Thus, as the isocyanide ligand becomes more electronegative, all the C≡C, N=N, and O=O bondings should be more and more strengthened. The trend can easily be accounted for in terms of the decreasing back-donation from nickel to the π^* orbital(s) of the unsaturated ligands.

As for the strength of the nickel–ligand bonds, both W_{Ni-C} and W_{Ni-N} decrease as the isocyanide ligand becomes more electron-withdrawing. The situation is analogous to the substitution effect on the metal–olefin π-bonding interaction in various olefin complexes.[16] By contrast, the W_{Ni-O} increases as I_S^H increases. That is, substitution of electronegative ligands tend to increase the nickel–oxygen bond strength.

The unique electronic effects of isocyanide substituents on the Ni–O bond strength can be rationalized from the type of orbital interactions involved. Figure 8 is a schematic level diagram for the highest occupied b_1 orbital of $Ni(HNC)_2(C_{2v})$ and the frontier π and π^* orbitals of the three isolated molecules, HC≡CH, HN=NH, and O_2. For the sake of convenience, the $Ni(HNC)_2$ b_1 and O_2 π levels are depicted as doubly occupied orbitals, although in reality calculations were performed by the UHF-INDO method. Note that the b_1 orbital in question lies below the π^* orbitals of HC≡CH and HN=NH but certainly above the π^* level of O_2.

The b_1 orbital which consists mainly of the Ni $3d_{xz}$ orbital interacts with the π^* levels, and this interaction contributes most dominantly to the back-donation. As the CNH is replaced by a more electron-releasing ligand, the b_1 level will be destabilized accordingly. This destabilization in turn should enhance the above-mentioned type of orbital interactions for the cases of HC≡CH and HN=NH whereas it should lead to a diminution in interaction in the case of O_2, as will be readily understood by a simple perturbation theory. The situations are wholly compatible with the trends noted in Fig. 7.

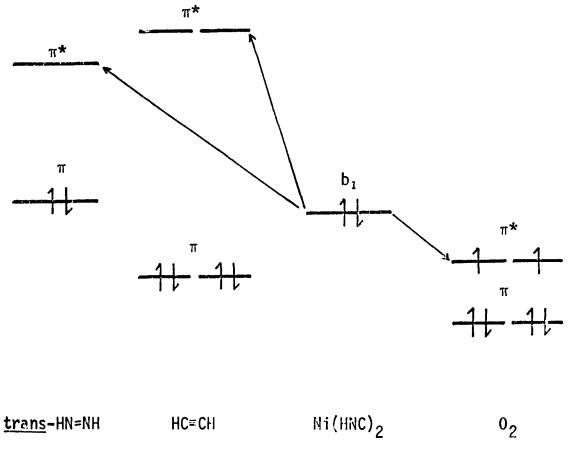

Fig. 8. Schematical level diagrams for the π and π^* orbitals of *trans*-HN=NH, HC≡CH, and O_2 as well as the highest b_1 orbitals of $Ni(HNC)_2$. The back-donation of electrons occurs in the direction of the arrows.

The Reaction of Singlet Methylene with Methane

Kazuhiko SHIBUYA, Kin-ichi OBI, and Ikuzo TANAKA
Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received December 23, 1975)

Cyclopropane in an excess of methane was photolyzed at 1470 and 1634 Å. The decomposition rate constants of the resultant vibrationally excited ethane into methyl radicals were found to be 6.0×10^9 s^{-1} and 5.0×10^9 s^{-1} at 1470 and 1634 Å respectively. The following procedure was used in treating the results obtained in our and the other researchers' systems. The statistical calculation was made to estimate the internal energy of singlet methylene, $\bar{\varepsilon}_i$, which is initially acquired in the primary decomposition process. The RRKM theory was then used to estimate the internal energy of the excited ethane. According to these calculations, the fraction of excess photon energy carried into ethane decreases as the energy, $\bar{\varepsilon}_i$, increases.

The chemistry of methylene has received much attention in recent years. The difference in reactivity of the singlet and triplet species is well-known,[1] and the insertion of singlet methylene into C–H bonds of hydrocarbons has been extensively applied to chemical activation techniques.[2] The vibrationally excited ethane is formed by the insertion reaction of singlet methylene with methane;[3-7] it either decomposes into methyl radicals or is deactivated by collision. Ketene,[4,5] diazomethane,[3,7] and methane[6] have been used as the source of methylene.

We have previously reported that cyclopropane is the most suitable molecule to produce methylene in the vacuum ultraviolet region.[8] In this study, we carried out the photolysis of cyclopropane with methane and oxygen (or nitrogen oxide) (cyclo-C_3H_6/CH_4/O_2 or NO=1/10/0.1) at 1470 and 1634 Å. The decomposition rate constants of the vibrationally excited ethane were determined and compared with the results obtained from the experiments in which the other molecules were photolyzed to produce singlet methylene with different wavelengths.

Experimenta

Most of the experimental procedures used in the present study have been described previously.[8] A synthetic sapphire plate was used as the window of the xenon lamp to cut off the weak 1295 Å line. After irradiation, the products and the remaining reactants were vacuum-distilled at the temperature of solid nitrogen to rid the reaction cell of the excess methane and subsequently collected in a sample tube by means of a Toepler pump. Analyses were made by means of gas chromatography using a 3-m-long charcoal column.

Results and Discussion

In our system, the reaction scheme relating to singlet methylene is as follows:

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow {}^1CH_2 + C_2H_4, \quad \Delta H = 101 \text{ kcal mol}^{-1}, \tag{1}$$

$${}^1CH_2 + CH_4 \longrightarrow C_2H_6{}^*, \quad \Delta H = -100 \text{ kcal mol}^{-1}, \tag{2}$$

$$\longrightarrow {}^3CH_2 + CH_4, \tag{3}$$

$${}^1CH_2 + \text{cyclo-}C_3H_6 \longrightarrow \text{removal of } {}^1CH_2, \tag{4}$$

$$C_2H_6{}^* \xrightarrow{k_d} CH_3 + CH_3, \tag{5}$$

$$\xrightarrow{\sum k_s^i(M_i)} C_2H_6. \tag{6}$$

Reaction 1 is the major primary process in the photolysis of cyclopropane.[8] Singlet methylene reacts with methane to form vibrationally excited ethane, Reaction 2, or to be deactivated to the triplet, Reaction 3. The rate constants for Reactions 2 and 3 were found to be $(1.9\pm0.5)\times10^{-12}$ and $(1.6\pm0.5)\times10^{-12}$ cm^3 molecule^{-1} s^{-1} respectively from a flash photolysis study.[5] The energized ethane should be accompanied by decomposition to methyl radicals, Reaction 5, unless it is collisionally deactivated to a stable ethane molecule, Reaction 6. Both triplet methylene and methyl radicals will be removed by the added radical scavenger, oxygen or nitrogen oxide.[9]

A steady-state treatment of Reaction 1—6 leads to:

$$\frac{(C_2H_4)}{(C_2H_6)} = C \times (1+k_d\omega^{-1}), \tag{I}$$

$$C = 1 + \frac{k_3}{k_2} + \frac{k_4}{k_2}\frac{(\text{cyclo-}C_3H_6)}{(CH_4)}, \tag{II}$$

and

$$\omega = \sum_i k_s^i(M_i), \tag{III}$$

where C is constant under our experimental conditions of (cyclo-C_3H_6)/(CH_4)=1/10, and ω is the effective collision frequency of bath gas with the energized ethane. The collisional deactivation efficiencies (β) were taken to be 0.61 and 0.83 for methane and cyclopropane respectively.[10] The collision diameters of $\sigma_{C_2H_6}$=4.38 Å, σ_{CH_4}=3.81 Å, and $\sigma_{\text{cyclo-}C_3H_6}$=4.92 Å were used to calculate the collision frequencies (Z). The effective collision frequencies of bath gases in units of s^{-1}, $\omega=\beta Z$, are as follows: $\omega_{CH_4}=0.90\times10^7\ P_{CH_4}$ (Torr) and $\omega_{\text{cyclo-}C_3H_6}=1.20\times10^7\ P_{\text{cyclo-}C_3H_6}$ (Torr). The k_d values were determined from plots of $(C_2H_4)/(C_2H_6)$ *vs.* ω^{-1} at both wavelengths; these plots are illustrated in Fig. 1. We obtained $k_d=6.0\times10^9$ s^{-1} and C=3.2 at 1470 Å photolysis and $k_d=5.0\times10^9$ s^{-1} and C=3.2 at 1634 Å photolysis. The high-pressure intercept of 3.2, combined with k_3/k_2=0.8,[5] gives k_4/k_2=14 and leads to a value for the relative reactivity of methane and cyclopropane of $k_4/(k_2+k_3)$=7.8.

The k_d values are listed in Table 1, together with those obtained from the experiments in which ketene, diazomethane, and methane were used as the source of methylene. The variation in k_d apparently reflects the internal energy of methylene which is originally acquired in the primary decomposition process to form methylene. We tentatively used the following procedure to elucidate the dependence of k_d on the

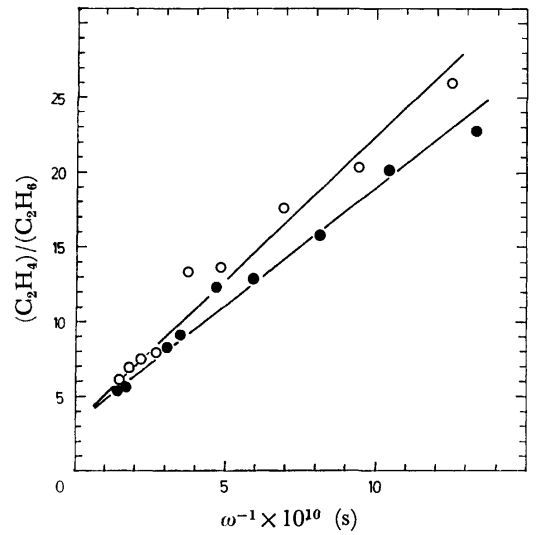

Fig. 1. Plot of $(C_2H_4)/(C_2H_6)$ *vs.* ω^{-1} at the 1470 and 1634 Å photolysis of cyclo-$C_3H_6/CH_4/O_2$ (or NO) mixtures.

Table 1. Decomposition rate constants of C_2H_6* formed by the $^1CH_2 + CH_4$ reaction[a]

Source of methylene	$P_{1/2}$[c] (Torr)	k_d (s^{-1})	Ref.
CH_2CO (3130Å)[b]	240	2.6×10^9	4)
CH_2N_2 (4358Å)[b]	320	4.2×10^9	7)
cyclo-C_3H_6 (1634Å)	560	5.0×10^9	This work
cyclo-C_3H_6 (1470Å)	670	6.0×10^9	This work
CH_4 (1236 and 1048—1067Å)[b]	770	6.9×10^9	6)

a) Bell and Kistiakowsky[3] photolyzed CH_2N_2/CD_4 mixtures, from which a value for k_d of $\sim2\times10^9$ s^{-1} was deduced by Setser and Rabinovitch[11] after correcting for isotope effects, and Braun *et al.* flash-photolyzed CH_2CO/CH_4 mixtures, from which $k_d=4\times10^9$ s^{-1} was obtained. However, these values are not listed because their photolytic lamp was not monoenergetic. b) The following effective collision frequencies in units of s^{-1}, $\omega=\beta Z$, were used: $\omega_{CH_4}=0.90\times10^7$ P_{CH_4} (Torr), $\omega_{C_3H_8}=1.22\times10^7$ $P_{C_3H_8}$ (Torr), $\omega_{CH_2N_2}=1.61\times10^7$ $P_{CH_2N_2}$ (Torr), and $\omega_{iso\text{-}C_4H_{10}}=1.90\times10^7$ $P_{iso\text{-}C_4H_{10}}$ (Torr). c) The pressure at which the half of C_2H_6* is stabilized.

internal energy of methylene. First, the average internal energy of methylene, $\bar{\varepsilon}_i$, which is initially present in the primary decomposition process was estimated on the basis of the statistical model proposed by Campbell and Schlag.[12] Second, the average internal energy of methylene, $\bar{\varepsilon}_f$, which is carried into the insertion product (ethane) was calculated from the ordinary RRKM model.

Estimation of $\bar{\varepsilon}_i$. The methylene-forming processes besides Reaction 1 in Table 1 are:

$$CH_2CO + h\nu \rightarrow {}^1CH_2 + CO,\ \Delta H = 86\ \text{kcal mol}^{-1}, \quad (7)$$

$$CH_2N_2 + h\nu \rightarrow {}^1CH_2 + N_2,\ \Delta H = 52\ \text{kcal mol}^{-1}, \quad (8)$$

$$CH_4 + h\nu \rightarrow {}^1CH_2 + H_2,\ \Delta H = 117\ \text{kcal mol}^{-1}. \quad (9)$$

The maximum energy available for methylene can be obtained by means of:

$$\varepsilon_{max} = E_p - \Delta H, \quad (IV)$$

where E_p is the energy of the photon and ΔH, the heat of the reaction of each methylene-forming process. The energy, ε_{max}, may either be partitioned among each degree of freedom of methylene and the partner fragment more or less statistically or appear as the non-statistical kinetic energy of fragments.[13] To simplify the treatment, we neglected the non-statistical energy and assumed all the vibrational modes to be active. The fraction of methylene which retains a vibrational energy, ε, out of the maximum available energy, ε_{max}, can be written[12] as:

$$f(\varepsilon) = \frac{N_{CH_2}(\varepsilon)N_R(\varepsilon_{max}-\varepsilon)}{\sum N_{CH_2}(\varepsilon_j)N_R(\varepsilon_{max}-\varepsilon_j)}, \quad (V)$$

where $N_{CH_2}(\varepsilon)$ is the energy-level density of the methylene part of the molecule used as the source of methylene, and $N_R(\varepsilon_{max}-\varepsilon)$, that of the remaining part. The energy-level densities were calculated by means of Eq. IX; all the vibrational frequencies for ethylene and methylene are given in the Appendix. The average energy, $\bar{\varepsilon}_i$, was derived from:

$$\bar{\varepsilon}_i = \int \varepsilon f(\varepsilon)d\varepsilon. \quad (VI)$$

The resultant values are listed in Table 2. If methylene, with the internal energy of $\bar{\varepsilon}$, is inserted into the C–H bond of methane, the average internal energy of energized ethane, $\bar{E}$, is:

$$\bar{E} = \bar{\varepsilon} + \varepsilon_{thermal} - \Delta H \quad (VII)$$

where $\varepsilon_{thermal}$ is the thermal energy (≈2 kcal mol^{-1}) and ΔH, the heat of reaction of Reaction 2. The experimental values for k_d are plotted as a function of $\bar{E}(=\bar{\varepsilon}_i+\varepsilon_{thermal}-\Delta H)$ is Fig. 2. This plot may represent the dependence of k_d on the internal energy of ethane, assuming that all of $\bar{\varepsilon}_i$ is carried into the insertion product without any energy loss. In case singlet methylene without any internal energy is inserted into methane, the energized ethane possesses internal energies of 102 kcal mol^{-1}, corresponding to $\bar{\varepsilon}=0$ in Eq. VII. We obtained $k_d=1.7\times10^9$ s^{-1} at $E=102$ kcal mol^{-1} in Fig. 2.

Estimation of $\bar{\varepsilon}_f$. The specific rate constant, k_E, of the decomposition of ethane with an internal energy of E can be given by the RRKM theory[14,15]

Table 2. Internal energy of singlet methylene[a]

Source of methylene	ε_{max}[b] (kcal mol^{-1})	$\bar{\varepsilon}_i$[c] (kcal mol^{-1})	$\bar{\varepsilon}_f$[d] (kcal mol^{-1})	$\bar{\varepsilon}_f/\bar{\varepsilon}_i$
CH_2CO (3130 Å)	5	3	2	0.67
CH_2N_2 (4358 Å)	13	8	4	0.50
cyclo-C_3H_6 (1634)	74	14	5	0.37
cyclo-C_3H_6 (1470 Å)	93	17	6	0.35
CH_4 (1236 Å)	114	83	7	0.08
CH_4 (1048—1067 Å)	≈153	≈113	7	0.06

a) $\Delta H_f^\circ(^1CH_2)=101$ kcal mol^{-1} was assumed. b) Maximum energy carried by methylene to form C_2H_6*. c) Average energy of methylene calculated by means of $f(E)$. d) Calculated from the RRKM model.

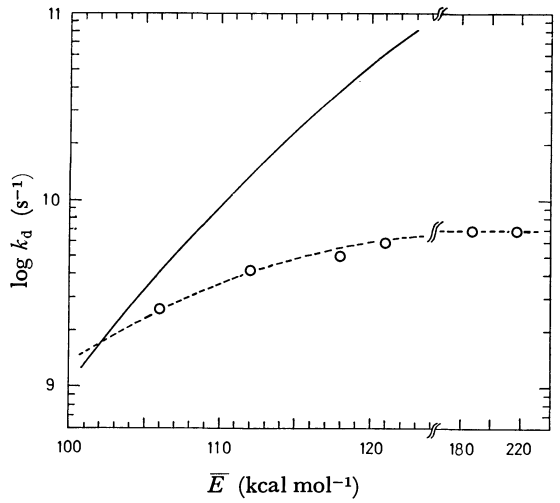

Fig. 2. Variation of k_d with $\bar{E}(=\bar{\varepsilon}_i+\varepsilon_{thermal}-\Delta H)$. Solid line represents the specific rate constant calculated from the RRKM treatment.

as follows:

$$k_E = \frac{1}{h}\frac{\sigma}{\sigma^\dagger}\left(\frac{I_A^\dagger I_B^\dagger I_C^\dagger}{I_A I_B I_C}\right)^{1/2}\frac{\sum P(E-E_0)}{N(E)}, \qquad \text{(VIII)}$$

where σ and $\sigma^\dagger$ are the symmetry numbers of the ethane molecule and the activated complex respectively. $N(E)$ is the energy level density for the ethane molecule at the energy of E, $\sum P(E-E_0)$, the energy-level sum for the activated complex, and E_0, the critical energy required for the decomposition of energized ethane into methyl radicals (85 kcal mol^{-1}).[15] In the absence of an internal free rotation, $N(E)$ and $\sum P(E-E_0)$ can be approximated by:

$$N(E) = \frac{(E+aE_z)^{s-1}}{\Gamma(s)\prod h\nu_i}, \qquad \text{(IX)}$$

and:

$$\sum P(E-E_0) = \frac{(E-E_0+a^\dagger E_z^\dagger)^{s^\dagger}}{\Gamma(s^\dagger+1)h\nu_i^\dagger}, \qquad \text{(X)}$$

as proposed by Whitten and Robinovitch.[16] In Eqs. IX and X, s and $s^\dagger$ are the numbers of the vibrational degrees of freedom, E_z and $E_z^\dagger$ are the zero point energies, and ν_i and $\nu_i^\dagger$ are the vibrational frequencies of ethane and the activated complex respectively. We assumed that $a=1$ and $a^\dagger=0.8$.[17] Our structural parameters for ethane are given in Table 3. The model used was similar to that adopted by Hase[18] except that we did not set the torsional mode (ν_4) at a free rotor in the activated complex. The frequency for $\nu_4^\dagger$ was taken to be 39 cm^{-1} because the model gave $k_E=1.7\times10^9$ s^{-1} at $E=102$ kcal mol^{-1} corresponding to $\varepsilon=0$. The calculated values for k_E are plotted as a function of the internal energy of ethane in Fig. 2 (solid line). The two curves in the figure apparently show different dependences on the energy, which implies that the internal energy, $\bar{\varepsilon}_f$, carried by methylene into the insertion product differs to a great extent from the energy, $\bar{\varepsilon}_i$, originally acquired in the methylene-forming process. We estimated the value for $\bar{E}(=\bar{\varepsilon}_f+\varepsilon_{thermal}-\Delta H)$ corresponding to each k_d value by virtue of the calculated curve for k_E. The average internal energy of singlet methylene which is carried into ethane, $\bar{\varepsilon}_f$, was calculated by introducing the average internal energy of energized ethane, $\bar{E}(=\bar{\varepsilon}_f+\varepsilon_{thermal}-\Delta H)$, into Eq. VII; the values for $\bar{\varepsilon}_f$ are listed in Table 2.

The ratios of $\bar{\varepsilon}_f$ to $\bar{\varepsilon}_i$ are also given in Table 2. The results show that only a fraction of $\bar{\varepsilon}_i$ (or ε_{max}) is carried into chemically activated ethane and that this fraction rapidly decreases as $\bar{\varepsilon}_i$ (or ε_{max}) becomes larger. The most likely explanation of this result is that singlet methylene suffers a number of inelastic collisions before reacting with methane and loses a considerable amount of the internal energy originally acquired in the primary decomposition process. In fact, a flash photolysis study[5] suggested that singlet methylene would undergo hundreds of collisions prior to insertion. The probability of the insertion reaction occurring, however, would be large to such an extent that the internal energy of singlet methylene is not fully thermalized before insertion.

TABLE 3. STRUCTURE PARAMETERS FOR ETHANE

	Molecule	Activated complex

Appendix

The vibrational frequencies of ethylene are taken[19] to be 3000, 1600, 1350, 1000, 3100, 1250, 950, 950, 3100, 800, 3000, and 1450 cm^{-1} for ν_1 to ν_{12}.

The vibrational frequencies of methylene are estimated to be 2850, 1450, and 2925 cm^{-1} for ν_1, ν_2, and ν_3, respectively.

A Study of Metal-Ligand Vibrations in Nickelocene and Ferrocene

Kenji YOKOYAMA, Shunsuke KOBINATA, and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received January 21, 1976)

Raman and infrared spectra of nickelocene and ferrocene were studied as regards metal-ligand vibrations. It was found that the C_5H_5-ring tilt vibration, $\nu_{16}(e_{1g})$, of nickelocene has considerably low frequency. This was discussed in view of metal-ligand binding between both metallocenes.

Nickelocene is a member of the ferrocene homologues but is thermally more unstable than ferrocene.[1] The Ni–cyclopentadienyl (Cp for short) distance is known to be greater than the Fe–Cp beyond the difference in covalent metallic radii of Ni and Fe.[2] This was accounted for by the difference in outer shell electron configurations, since $Ni(Cp)_2$ has two anti-bonding electrons in addition to the closed shell of $Fe(Cp)_2$ in MO representations.[3] In accordance with this, the infrared and Raman spectra[4,5] show that the metal–ligand vibrations of $Ni(Cp)_2$ have in general considerably lower frequencies than those of $Fe(Cp)_2$. Most striking is the difference observed for the Cp-ring tilt vibration $\nu_{16}(e_{1g})$[a], whose frequency is reduced as much as to half from $Fe(Cp)_2$ to $Ni(Cp)_2$, resulting in a reversed frequency order of ν_{16} and ν_4 (a_{1g} metal–Cp stretching) between both compounds. Since such behavior is evidently anomalous among other metal–ligand vibrations, a special mechanical condition associated with the ν_{16} mode of $Ni(Cp)_2$ may be found. As was suggested by Gächter *et al.*,[5] the antibonding electrons of $Ni(Cp)_2$ can be considered to be responsible for the anomaly. Since the problem is closely related to the nature of metal–Cp bindings, we have carried out a comparative study of the metal–ligand vibrations of $Fe(Cp)_2$ and $Ni(Cp)_2$ with particular attention to the behavior of ν_{16}.

The difference in metal–Cp bindings as above is expected to appear in the infrared and Raman intensities. The effect may be remarkable not only in the metal–Cp vibrations but also for such internal modes of Cp as appreciably perturb the electronic interaction between the metal and Cp-ring. These intensity features are also presented and discussed.

Experimental

Raman spectra were obtained for cyclohexane solutions of metallocenes, with 632.8 nm (He-Ne) exciting radiation for $Fe(Cp)_2$ and 514.5 nm (Ar^+) for $Ni(Cp)_2$. Since $Ni(Cp)_2$ slightly absorbs the latter radiation ($\varepsilon \approx 10$), the solution was prepared with a completely degassed solvent and irradiated in a vacuum sealed cell with a somewhat defocussed laser beam. Relative Raman intensity was determined by comparing the recorded band area with a solvent band at 426 cm^{-1}. Infrared intensities were determined in carbon tetrachloride, cyclohexane, and tetrahydrofuran solutions by means of Beer's law plots for integrated band area.

a) D_{5d} symmetry is assumed on the basis of crystalline data (J. D. Dunitz, L. E. Orgel, and A. Rich, *Acta Crystallogr.*, **9**, 373 (1956)). No essential change is necessary in the following considerations for D_{5h} or D_5 symmetries.

Results and Discussion

The observed Raman and infrared frequencies are given in Table 1 together with the frequencies and assignments previously given. Although Gächter *et al.*[5] tentatively assigned considerably higher frequencies than those of Lippincott and Nelson[4] to ν_{11} and ν_{21} of $Ni(Cp)_2$, it remains unexplained why they preferred these extremely weak Raman lines to the intense 355 cm^{-1} infrared band. On the other hand, the broad and asymmetric profile of 355 cm^{-1} absorption suggests a possibility of overlapping ν_{11} and ν_{21} which lie very close to each other in $Fe(Cp)_2$. Thus the assignment by Lippincott and Nelson[4] seems to be more reasonable, and can be adopted in the following discussion. The parenthesized frequencies of $Ni(Cp)_2$ in Table 1 are their estimated values based on the infrared frequencies and simple valence force field.

It is notable that the observed ν_{16} frquency of $Ni(Cp)_2$ is remarkably deviated from the above estimation, suggesting the presence of a special mechanical condition associated with the vibration of $Ni(Cp)_2$. Table 2 shows the ratios of force constants between $Ni(Cp)_2$ and $Fe(Cp)_2$ for some metal–ligand modes. Each vibration was assumed to be of an entirely metal–Cp character with no contribution of Cp-internal motions. Such an approximation may be sufficient for the present semi-quantitative discussion, since the changes of these metal–Cp frequencies from $Fe(Cp)_2$ to $Fe(C_5D_5)_2$ are generally as small as expected from the change of mass.

A number of theoretical studies have been devoted to the electronic structure of metallocenes.[6] They generally give the outer shell MO configurations:

$\cdots\cdots(e_{1g})^4(e_{2g})^4(a_{1g})^2$, $^1A_{1g}$ for $Fe(Cp)_2$

$\cdots\cdots(e_{1g})^4(e_{2g})^4(a_{1g})^2(e_{1g}^*)^2$, $^3A_{2g}$ for $Ni(Cp)_2$

where (e_{1g}) and (e_{1g}^*) are the metal–Cp bonding and anti-bonding orbitals, respectively, both of which are composed of the metal 3d(xz,yz) AO's and Cp-ring $\pi(e_1'')$ MO's. On the other hand, the (e_{2g}) and the (a_{1g}) orbitals are essentially non-bonding and represented by the metal $3d(x^2-y^2,xy)$ and $3d(z^2)$, respectively. A recent study by electron spectroscopy showed that the order of orbital energies in $Fe(Cp)_2$ is $(a_{1g})<(e_{2g})$.[7]

The perturbation theory gives the following expression for vibrational force constant[8]

$$k = k_1 - k_2$$

$$k_1 = \int \psi_o^{\circ *}(\partial^2 H/\partial Q^2)_o \psi_o^\circ d\tau$$

$$k_2 = 2\sum_{i \neq 0} |\int \psi_o^{\circ *}(\partial H/\partial Q)_o \psi_i^\circ d\tau|^2/(E_i^\circ - E_o^\circ).$$

k_1 is determined by the electronic wavefunction of the ground state at equilibrium configuration ϕ_0^0, so that its value for the Ni–Cp may be considerably smaller than that of the Fe–Cp owing to the anti-bonding electrons occupying (e_{ig}^*) orbitals. k_2 represents the relaxation of vibrational potential due to the vibronic mixing of excited state wavefunctions ϕ_i^0 into the ground state. k_2 may not be very important for other metal–Cp vibrations than $\nu_{16}(e_{1g})$, since the electronic spectra as well as theoretical studies[6,9,11] show that the excited states with a_{1g}, a_{2u}, e_{1u}, and e_{2u} symmetries, which can couple with the ground state through those vibrational perturbations, are all located at high energy, *viz.*, >40000 cm^{-1} in $Fe(Cp)_2$ and >30000 cm^{-1} in $Ni(Cp)_2$. On the other hand, there are several low-lying excited states of e_{1g} symmetry in both metallocenes, which have been assigned to the $(a_{1g})\rightarrow(e_{ig}^*)$ and $(e_{2g})\rightarrow(e_{ig}^*)$ excitations and are located at 22000 cm^{-1}—30000 cm^{-1} in $Fe(Cp)_2$ and at 14000 cm^{-1}—23000 cm^{-1} in $Ni(Cp)_2$, respectively. Thus the force constant of $\nu_{16}(e_{1g})$ may be considerably reduced from the k_1 value, which approximately corresponds to the classical valence force field, due to a large k_2 term involving these lower e_{1g} states. This is supported by the observation that the ν_{16} frequency is always considerably smaller than the related $\nu_{21}(e_{1u})$ ring tilt frequency.

The above fact is equally described as the vibrationally induced mixing of the (e_{ig}^*) orbital into the (e_{2g}) and (a_{1g}) orbitals. Such a mixing may modify the latter non-bonding orbitals so as to relieve the strain energy of the molecule (Fig. 1). This effect may be enhanced further on the (a_{1g}) orbital by the presence of $3d(z^2)$-4s hybridization, shown to be appreciable by an ESR study.[12] In $Ni(Cp)_2$, the above vibronic

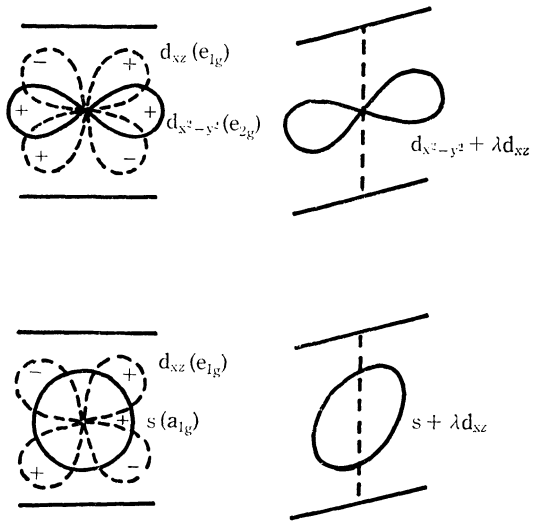

Fig. 1. Changes of the $3d(x^2-y^2)$ and the 4s orbital lobes due to a mixing 3d(xz) caused by $\nu_{16}(e_{1g})$ Cp-tilt vibration.

mixing effect on the force field may be partly cancelled by the opposite behavior of half-filled (e_{ig}^*) orbitals, but the $k_2[Ni(Cp)_2]$ may still be comparable to or even greater than that of $Fe(Cp)_2$ since the mixing orbitals are much closer to each other in energy than in $Fe(Cp)_2$.[10] On the other hand, the outer electron shell may be much less flexible for other modes, since each occupied MO can find partners of mixing only at very high energy.

In order to have an approximate idea, we consider a very simplified case in which k_2 is deliberately assumed to be significant only for the ν_{16} mode with equal values in both metallocenes. Then, k_1 of $Ni(Cp)_2$ may be

TABLE 2. RATIO OF FORCE CONSTANTS BETWEEN $Ni(Cp)_2$ AND $Fe(Cp)_2$ FOR METAL–Cp MODES

Mode[a]	$\nu_4(a_{1g})$	$\nu_{11}(a_{2u})$[b]	$\nu_{16}(e_{1g})$	$\nu_{21}(e_{1u})$[b]
$\frac{k[Ni(Cp)_2]}{k[Fe(Cp)_2]}$	0.64	0.57	0.26	0.53

a) Each mode was assumed to be of entirely metal-Cp character without the contribution of Cp-internal motions. b) Considerably higher $Ni(Cp)_2$ frequencies chosen in Ref. 5 give the ratios close to unity.

	ν_{16}	0.2	1.5

a) Relative intensities.

estimated at about 60% of the $Fe(Cp)_2$ value from Table 2. Subsequently, we get the small $k[Ni(Cp)_2]/k[Fe(Cp)_2]$ value for ν_{16} in the table if we assume the common k_2 to be equal to 0.45 times of $k_1[Fe(Cp)_2]$. The essential fact is that the negative contribution from vibronic mixing, $-k_2$, affects the force constant of $Ni(Cp)_2$ more profoundly, since k_1 of $Ni(Cp)_2$, the minuend of the above equation, is considerably smaller than $k_1[Fe(Cp)_2]$.

A few remarks should be added to the results shown in Table 3. Most striking in the infrared is the extreme difference of ν_{10} (a_{2u} ring breathing) intensities between both metallocenes. The transition moment of this mode may mostly originate from the electron vibration[13] between Cp-rings *via* metal. Therefore, the observed difference indicates a much greater importance of charge transfer effect in the Fe–Cp bindings than in the Ni–Cp. As for Raman intensities, $Ni(Cp)_2$ is by far surpassing as far as the measured bands are concerned. On the basis of Raman intensity theory,[14] it may be understood as due to the fact that the allowed excited states of $Ni(Cp)_2$ are located at considerably lower energy than $Fe(Cp)_2$.

The authors are indebted to Professor M. Sato of Tokyo Institute of Technology for the gift of nickelocene crystals.

A Systematic Study of the Yields of γ-Radiolysis Products in C_1, C_2, and C_3-Chlorofluorocarbons

Takeshi TOMINAGA, Takefumi FUKUMIZU, Takashi AOYAMA, Akihiko OKUDA, and Yoshihiro MAKIDE

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received March 19, 1976)

In the presence of bromine as a scavenger, the yields of the radiolysis products in eleven kinds of C_1—C_3 chlorofluorocarbons were investigated by means of gas chromatography. The *G*-values for the rupture of bonds in radiolysis were found to correlate with the halogen composition and the structure of their molecules. The *G*-values for the C–Cl (or C–F) bond rupture generally appear to increase with the number of chlorine (or fluorine) atoms in the chlorofluorocarbons; there was a marked difference between the *G*-values for the C–Cl rupture in each pair of structural isomers of chlorofluoroethanes. A striking selectivity in bond rupture was observed between the two C–C bonds in the chlorofluoropropanes.

Although the chlorofluorocarbons with three different types of bonds are interesting sytsems in radiation chemistry, only one work on the radiolysis of $CF_2ClCFCl_2$ (without scavengers) had been reported[1] before we initiated a systematic investigation of the radiolysis of chlorofluorocarbons as a preliminary step to the study of the radiolysis and radiation synthesis of various inorganic mixed halides. Our previous work on CF_2Cl_2, $CFCl_3$, CF_2ClCF_2Cl, and $CF_2ClCFCl_2$ with bromine as the scavenger, has revealed that the C–Cl and C–C bonds are generally more reactive than the C–F bond in the radiolysis reactions.[2,3] Recently we have studied the yields of the radiolysis products in C_1—C_3 chlorofluorocarbons and found that the reactivities of such bonds are largely influenced by the number of chlorine atoms and the structure concerning the C–Cl bonding in the molecule.[4,5] The object of the present article is to report the systematics in the reactivities of such bonds, derived from a detailed analysis of our recent data on the *G*-values of radiolysis products in the C_1, C_2, and C_3-chlorofluorocarbons, since the knowledge of the reactivities of the bonds in these compounds appears to be useful for elucidation of the mechanisms of radiolytic reactions and for the selection of procedures for the radiation synthesis of mixed halocarbons.

Experimental

Materials. Eleven kinds of chlorofluorocarbons were studied in the present work. Of these, CCl_4, $CFCl_3$, CF_2Cl_2, CF_2ClCF_2Cl, $CF_2ClCFCl_2$, and $CFCl_2CFCl_2$ were purchased from the Tokyo Chemical Industry Co., and CF_3CFCl_2, CF_3CCl_3, CF_2ClCCl_3, $CF_3CFClCF_2Cl$, and $CF_3CF_2CCl_3$, from P C R, Inc., U.S.A.; all were of a guaranteed reagent grade. These chlorofluorocarbons were purified three times by trap-to-trap distillation before use. The samples for γ-irradiation (all as liquid) were prepared by condensing mixtures of a chlorofluorocarbon and bromine into quartz capillary ampoules on a greaseless vacuum system equipped with Teflon needle valves. The bromine in the mixtures was determined by radioactivation analysis with thermal neutrons (15-s irradiation at a flux of 5×10^{11} n/cm^2 s).[6]

Gamma-ray Irradiation. The γ-irradiations were performed in a 16000-Ci ^{60}Co source for 5 to 25 h at an ambient temperature. The dose rates at the irradiation site were in the range of 2.27×10^{18}—2.73×10^{18} eV/g min, and the total energy absorbed in the system (0.82×10^{21}—3.40×10^{21} eV/g) was estimated on the basis of the electron densities of these compounds.

Gas Chromatographic Analysis of the γ-Irradiated Samples. The γ-irradiated samples were directly introduced into a gas chromatograph equipped with a thermal conductivity detector. The inorganic halogen in the mixtures was removed by means of a short stripping column packed with dehydrated potassium ferrocyanide powder, and then the organic species were analyzed on a 5-m Silicone DC 550 column. The unknown peaks on the gas chromatogram were mainly identified by (1) comparing their retention times with those of known compounds, or (2) by utilizing the known correlation between the logarithm of the retention volume and the composition of halogen atoms in mixed halocarbons.[7-9] Whenever it became necessary to confirm the identity of peaks of bromine-containing organic species, the γ-irradiated samples were further activated with thermal neutrons and their radiogas chromatograms were obtained by means of counting the ^{82}Br activities with an external γ-ray detector (NaI scintillation counter) placed after the thermal conductivity detector. The quantities of the products were determined from the TCD peak areas corrected for the detector sensitivities which had been obtained experimentally.[10]

Results and Discussion

Radiolysis of $CF_2ClCFCl_2$. Of the eleven chlorofluorocarbons studied in the present work, the radiolysis of $CF_2ClCFCl_2$ will be described here in detail as a typical example. In the presence of bromine, the major radiolysis products from $CF_2ClCFCl_2$ are $C_2F_3Cl_2Br$, CF_2ClBr, $CFCl_2Br$, and $C_2F_3ClBr_2$, which may be derived from the C–Cl and C–C bond rupture of the parent compound, followed by scavenging with bromine. The concentrations of the major products show a linear dose-dependence for the irradiation conditions used in this work (Fig. 1). The conversion of the parent compound was about 5% for a 10-h irradiation. As is illustrated in Fig. 2, the yields (in terms of *G*-values) of the bromine-scavenged products increase sharply with the increase in the bromine concentration and nearly level off at 0.1—0.2 mole fraction bromine. Table 1 summarizes the *G*-values for the formation of the major radiolysis products obtained from the plateau values of such scavenger curves. We can estimate, for example, the *G*-values for the rupture of the C–Cl or C–C bond on the assumption that the plateau *G*-value of $C_2F_3Cl_2Br$ or CF_2-

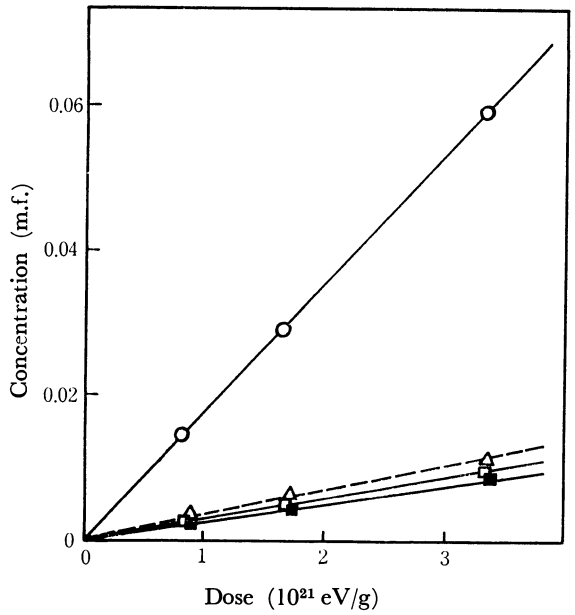

Fig. 1. The dose-dependence of the major radiolysis products from $CF_2ClCFCl_2$ containing 0.1 m. f. Br_2.

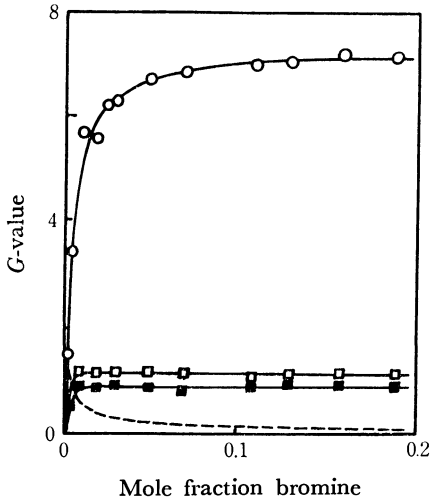

Fig. 2. The *G*-values for formation of major radiolysis products in the $CF_2ClCFCl_2$-Br_2 system as a function of bromine concentration.
—○— $C_2F_3Cl_2Br$; —□— CF_2ClBr; —■— $CFCl_2Br$; ---- CF_2Cl_2, $CFCl_3$

ClBr (or $CFCl_2Br$) corresponds to the *G*-value for the formation of the $C_2F_3Cl_2$ or CF_2Cl (or $CFCl_2$) radical (Table 1). Although the C_3 and C_4-chlorofluorocarbons resulting from the recombination or cross-combination of such radicals disappear quickly in the presence of bromine, the yields of CF_2Cl_2 and $CFCl_3$ decrease somewhat slowly with the increase in the bromine concentration (Fig. 2). The latter observation indicates that the chlorine accumulated in the system as the result of the C–Cl rupture during radiolysis may possibly compete with bromine for combination with the CF_2Cl and $CFCl_2$ radicals, thereby slightly reducing the bromine-scavenging effect

Table 1. *G*-values for the formation of the major radiolysis products in liquid $CF_2ClCFCl_2$ containing bromine

Product	Bond ruptured	*G*-value[a,b]
$C_2F_3Cl_2Br$	C–Cl	7.0 ±0.3
$CFCl_2Br$[c]	C–C	1.0 ±0.1
CF_2ClBr[c]	C–C	
$C_2F_3ClBr_2$	two C–Cl	1.3 ±0.1
$C_2F_2Cl_3Br$	C–F	0.16±0.01

a) *G*-value obtained at the plateau of the bromine-scavenger cure. b) Small amounts (*G*-value<0.1) of CF_2Br_2 and $CFClBr_2$, possibly derived from the rupture of both C–C and C–Cl bonds were also observed. c) The *G*-values for the formation of $CFCl_2Br$ and CF_2ClBr were 0.9 and 1.1 respectively.

on the formation of CF_2Cl_2 and $CFCl_3$.

The rupture of the single C–Cl bond in $CF_2ClCFCl_2$ can produce either of two isomers of $C_2F_3Cl_2Br$, *i.e.*, $CF_2ClCFClBr$ or $CF_2BrCFCl_2$. Although they could not be separated from each other by gas chromatography, the comparison of the yields of radiolysis products obtained from the re-irradiation of the $C_2F_3Cl_2Br$ fraction implies that the C(1)–Cl bond rupture was preferred by a factor of 3—4 to the C(2)–Cl bond rupture (the positions of carbon atoms are defined in the footnote to Table 2).

The product, $C_2F_3ClBr_2$, corresponding to the rupture of the two C–Cl bonds may not arise from the successive radiolysis process: $C_2F_3Cl_3+Br_2 \rightsquigarrow C_2F_3Cl_2Br$ and $C_2F_3Cl_2Br+Br_2 \rightsquigarrow C_2F_3ClBr_2$, since the *G*-value estimated for such a process can account for only a minor fraction of the observed *G*-value. It is likely that this product is mainly formed through the nearly simultaneous elimination of two chlorine atoms from adjacent carbon atoms (leading to the formation of an olefinic bond) and combination with bromine.[11]

Systematic Comparison of the G-values in C_1—C_3 Chlorofluorocarbons. Similar types of reactions and scavenging effects were observed for all the C_1—C_3 chlorofluorocarbons studied in the present work. In Table 2 are summarized the *G*-values for the rupture of various bonds, as estimated from the plateau *G*-values of the corresponding bromine-scavenged products, as has been described above.

The intra- and intermolecular comparison of the results listed in Table 2 indicates that the *G*-values for bond rupture in the C_1—C_3 chlorofluorocarbons tend to increase in the order: C–F<C–C<C–Cl, which is in accordance with the decreasing order of the bond dissociation energies of such bonds. Hence, we may consider that, in general, the weaker bond is more reactive. However, a more detailed analysis indicates that the *G*-values depend on the halogen composition and the structure of the parent molecules, as will be discussed below.

C–F Bond Rupture: For the compounds containing the same number of carbon atoms, the *G*-value for the C–F rupture tends to increase with the number of fluorine atoms in the molecule (Fig. 3). While there

10	$CF_3CFClCF_2Cl$ (1,2-dichloro-)	4.8	0.6_4	0.6_2	1.4	0.16
11	$CF_3CF_2CCl_3$ (1,1,1-trichloro-)	8.5	0.17	0.18	0.9	0·08

a) The positions of the carbon atoms are defined in the present article as follows: $CF_3CFClCF_2Cl$ as 1,2-dichlorohexafluropropane, and $CF_3CF_2CCl_3$ as 1,1,1-trichloropentafluoropropane. b) The *G*-values for the formation of the C-C scission products are as follows: CF_3Br (1.4) and $CFCl_2Br$ (0.6) from CF_3CFCl_2; CF_2ClBr (1.5) from CF_2ClCF_2Cl; CF_3Br (0.8) and CCl_3Br (1.0) from CF_3CCl_3; CF_2ClBr (1.1) and $CFCl_2Br$ (0.9) from $CF_2ClCFCl_2$; CF_2ClBr (1.2) and CCl_3Br (1.3) from CF_2ClCCl_3; $CFCl_2Br$ (2.6) from $CFCl_2CFCl_2$; $CF_3CFClBr$ (1.4) and $CF_2ClCFClBr$ (0.16) from $CF_3CFClCF_2Cl$; CCl_3Br (0.9) and CCl_3CF_2Br (0.08) from $CF_3CF_2CCl_3$. The values for the other products (CF_3Br, CF_2ClBr, and CF_3CF_2Br) from chlorofluoropropanes were omitted because, for analytical reasons, they could not be determined accurately.

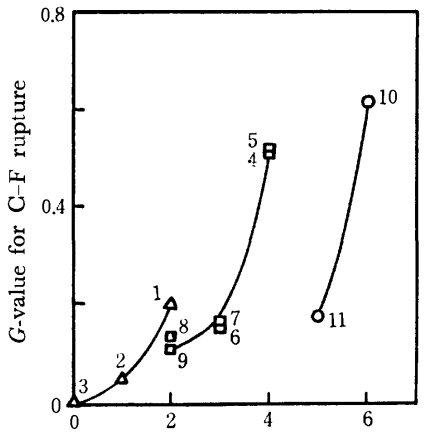

Fig. 3. The *G*-values for the C–F rupture as a function of the number of fluorine atoms in chlorofluoromethanes(△), chlorofluoroethanes(□), and chlorofluoropropanes(○).
(Keys to the numbers denoting compounds in Figs. 3—5 are given in Table 2).

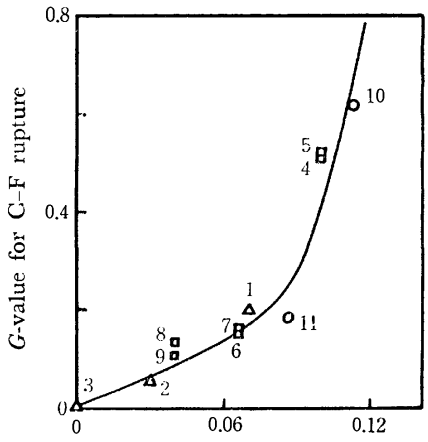

Fig. 4. The *G*-values for the C–F rupture as a function of the ratio of the number of electrons involved in the C–F bonding to the total number of electrons in the molecules of chlorofluoromethanes(△), chlorofluoroethanes(□), and chlorofluoropropanes(○).

are three isomeric pairs of chlorofluoroethanes, no significant difference was observed between the *G*-values for each pair of isomers. In Fig. 4, the *G*-value for the C–F rupture appears to correlate with the ratio of the number of electrons involved in the C–F bonding to the total number of electrons in the molecule. Thus, it is likely that the mechanism for the rupture of stable C–F bonds is possibly governed by a direct process, irrespective of small differences in the bond dissociation energies or structures of the molecules.

C–Cl Bond Rupture: As may be seen in Fig. 5, the *G*-value for the C–Cl rupture tends to increase slightly

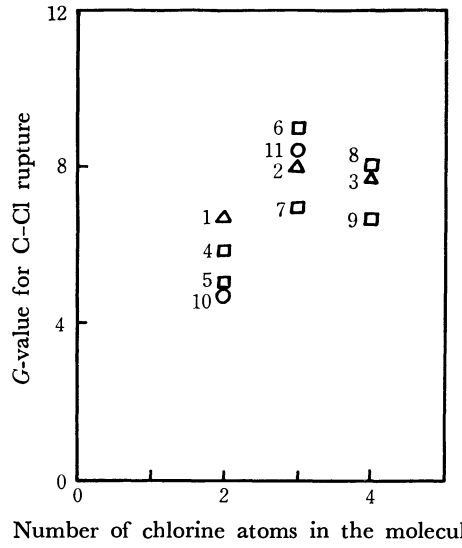

Fig. 5. The *G*-values for the C–Cl rupture as a function of the number of chlorine atoms in chlorofluoromethanes(△), chlorofluoroethanes(□), and chlorofluoropropanes(○).

with the number of chlorine atoms in the molecules containing the same number of carbon atoms, except for $CFCl_2CFCl_2$ and CF_2ClCCl_3. The difference between the *G*-values for each pair of isomers is large, and the isomer with a more asymmetrical structure concerning the C–Cl bonding (in which all or most chlorine atoms are bonded to one carbon atom) always gives a higher *G*-value for the C–Cl rupture. Such a trend may be accounted for tentatively by assuming that (1) the C–Cl bond dissociation energy may be slightly decreased with the increase in the total number of chlorine atoms in the molecule,[12] and that (2) the instability of the C–Cl bonding may be increased with the number of chlorine atoms attached to the same carbon atom as a result of the increased strain. When the *G*-value for the C–Cl rupture was plotted against the ratio of the number of electrons involved in the C–Cl bonding to the total number of electrons in the molecule, the correlation was not clear and was quite different from that observed for the C–F rupture in Fig. 4. Hence, the mechanism leading to the C–Cl rupture may be possibly controlled by processes which can be affected by small differences in the bond dissociation energies and structures of the molecules. While the radiolysis products in these systems are generally accountable in terms of the free radical processes, at least as intermediate steps, we should also examine the possibility that the dissociative electron attachment process involving electrons at low energies may contribute to the formation of such radicals (R):

$$RCl + e^- \longrightarrow R + Cl^-$$

However, only a few data on the dissociative attachment cross sections in the gas phase are available,[13] and the correlation between the *G*-value for the C–Cl rupture and the cross section for such a process in the liquid phase is still ambiguous.[14]

Besides the rupture of the single C–Cl bond, two C–Cl bonds in a molecule were often found to break, although the *G*-values for such a double C–Cl rupture were much smaller than for the single C–Cl rupture. For the chlorofluoroethanes, there is a marked difference between the *G*-values for each pair of isomers: in contrast to the single C–Cl rupture, the *G*-value is always larger for the symmetrical or less asymmetrical isomer (*i.e.*, 1,2-dichloro-, 1,1,2-trichloro-, and 1,1,2,2-tetrachloro-) than for the more asymmetrical counterpart (*i.e.*, 1,1-dichloro-, 1,1,1-trichloro-, and 1,1,1,2-tetrachloro-). Thus, the difference in the *G*-values for the single C–Cl rupture between the pair of isomers may be partly accounted for by the inverse difference in the *G*-values for the double C–Cl rupture. While the *G*-value for the double C–Cl rupture increases with the number of chlorine atoms in the series of the symmetrical or less asymmetrical isomers, it remains at low values in the series of the more asymmetrical isomers, except for the case of CF_2ClCCl_3. As has been indicated earlier, the large *G*-values for the double C–Cl rupture of the symmetrical and less asymmetrical isomers may be mainly ascribed to the nearly simultaneous elimination of two chlorine atoms from the adjacent carbon atoms, whereas the origin of the products corresponding to the double C–Cl rupture in the more asymmetrical isomers can be explained in terms of the successive radiolysis processes *via* monobromo compounds as intermediates (the simultaneous elimination process can also take place in CF_2ClCCl_3). These observations indicate that the *G*-values for the rupture of one or two C–Cl bonds in the chlorofluorocarbons are influenced by the number of chlorine atoms and the structure in the molecule: for the chlorofluorethanes and chlorofluoropropanes, the single C–Cl rupture occurs predominantly in the more asymmetrical isomers, while the double C–Cl rupture takes place appreciably in the symmetrical and less asymmetrical isomers.

C–C Bond Rupture: The *G*-values for the C(1)–C(2) rupture in the chlorofluoroethanes remain almost unchanged, or they increase only slightly with the increase in the number of chlorine atoms in the molecule; yet no significant difference is observed between the pair of isomers.

However, a striking selectivity in bond rupture is observed between the two C–C bonds in the chlorofluoropropanes: the *G*-values for the C(1)–C(2) rupture are about ten times those for the C(2)–C(3) rupture. Such a marked weakness of the C(1)–C(2) bond may be tentatively accounted for by the greater resonance stabilization obtainable in the formation of the C(1)–C(2) scission products than the C(2)–C(3) scission products.

a) In the case of $CF_3CF_2CCl_3$, the C(1)–C(2) rupture eventually yields CF_3CF_2 and CCl_3 radicals, while the C(2)–C(3) rupture produces CCl_3CF_2 and CF_3 radicals. The CCl_3 radical is near planar,[15] while the CF_3 radical has a deep pyramidal structure.[16] Thus, the strain energy in the ground state due to the proximity of halogen atoms in trihalomethyl groups may be more released in the formation of $\cdot CCl_3$ than in the formation of $\cdot CF_3$. This difference in shape between the two radicals may also lead to the larger interaction between the lone pair on halogen and the

p-orbital of carbon in the CCl_3 radical than in the CF_3 radical. Accordingly, a greater resonance stabilization may be acquired in the formation of $\cdot CCl_3$; thus, the C(1)–C(2) rupture will be favored. In addition, the steric interaction between the Cl atoms on C(1) and the F atoms on C(2) may elongate the C(1)–C(2) bond length and somewhat weaken the bond strength as compared with that of the C(2)–C(3) bond.

b) In $CF_3CFClCF_2Cl$, the C(1)–C(2) scission produces $CF_3CFCl\cdot$ and $\cdot CF_2Cl$, while the C(2)–C(3) scission yields $CF_2ClCFCl\cdot$ and $\cdot CF_3$. Since a greater resonance stabilization may be expected for the $\cdot CF_2Cl$ formation than for the $\cdot CF_3$ formation, the C(1)–C(2) rupture is favored. The elongation of the C(1)–C(2) bond as a result of the steric interaction between the Cl atoms on C(1) and C(2) atoms also tends to weaken the C(1)–C(2) bond.

In conclusion, the *G*-values for the rupture of various bonds in the chlorofluorocarbons are generally influenced by the halogen composition and the structure of the molecule. The systematic investigation of the *G*-values and the selectivity in bond rupture may provide us with important clues to an understanding of the mechanisms of radiolytic reactions as well as to establishing the systematics in radiation synthesis. Moreover, the present results may afford useful knowledge on the chemical reactivities of chlorofluorocarbons, which have not been fully studied in organic chemistry.

The present authors wish to express their thanks to Professor Nobufusa Saito, the University of Tokyo, for his encouragement and support. They are also greatly indebted to Dr. Masayuki Yoshida, the University of Tokyo, for many helpful discussions.

10) Since the sensitivity in the thermal conductivity detector appeared to correlate with the molecular weight for some chlorofluorocarbons, the sensitivities of most radiolysis products were estimated in our previous work by extrapolation based on such a correlation.[3-5] However, more extensive measurements of a number of bromochlorofluorocarbons have recently been carried out in our laboratory, and most bromine-containing compounds have been found to deviate appreciably from the above correlation (the details will be published elsewhere). Accordingly, the new sensitivity data determined experimentally have been used in the present work to re-calculate the *G*-values of the radiolysis products instead of the previous data mainly estimated by extrapolation.
11) The ^{19}F NMR spectrum of the $C_2F_3ClBr_2$ fraction revealed that $CF_2BrCFClBr$ was the predominant species.

14) On a hypothetical assumption that the ratio of the cross sections of the two chlorofluorocarbons in the liquid phase is similar to that in the gas phase, the dissociative attachment cross section of $CFCl_3$ may be about 100 times as large as that of CF_2Cl_2, whereas the difference in the *G*-values for the C–Cl rupture between these compounds is relatively small (1.4). Thus it seems unlikely that the dissociative electron attachment is the major process controlling the C–Cl bond rupture.

Donor–Acceptor Interactions in the Ground State of the Systems Forming Heteroexcimers in the Excited State

Tadashi OKADA and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 22, 1976)

Several systems which form heteroexcimers in the excited state were forced to aggregate in low temperature rigid matrices, and their absorption, fluorescence excitation and emission as well as fluorescence rise and decay curves were determined. The results indicate the existence of several kinds of donor-acceptor pairs emitting heteroexcimer fluorescence at different wavelengths. Temperature dependence of absorption spectra of those systems in liquid solutions were examined, and collisional enhancement of the absorption intensity was observed.

Numerous investigations have been carried on the heteroexcimer formation between excited singlet aromatic hydrocarbons and various ground state amines or cyano compounds. However, spectroscopic studies of the charge transfer (CT) interaction in the ground state of the heteroexcimer forming systems are scarce. Since there is no observable absorption corresponding to the excimer or heteroexcimer emission, studies on these systems have been made nearly always in a liquid state where the exciplexes are formed by diffusional encounter between the excited and ground state partners.

For a study of the electronic processes in exciplexes at low temperatures, it would be advantageous to find a matrix of a saturated hydrocarbon having adjacent sites with orientations favorable for the formation of excimer or heteroexcimer. The phenomenon of association of pyrene or anthracene molecules was found first in a cyclohexane matrix and in 3 : 1 softened glasses of isopentane and methylcyclohexane (MP) by Ferguson,[1,2] detailed spectral studies on the dimer aggregates of aromatic hydrocarbons in the rigid matrices at low temperature being carried out.[2,3] By using the same technique, we found for the first time that the solutions of pyrene and aromatic amines in cyclohexane matrix show heteroexcimer fluorescence in addition to that of pyrene monomer at various temperatures.[4]

Concerning the ground state interactions of heteroexcimer forming systems, Itoh *et al.* have recently reported their studies on dicyanoanthracene–naphthalene system at various temperatures,[5] while Yoshihara *et al.* have examined the ground state absorption spectra of concentrated solutions of pyrene–*N,N*-dimethylaniline (DMA) system.[6] Ishida and Tsubomura suggested the existence of the CT absorption band due to the interaction between anthracene and various aliphatic amines adsorbed on a porous glass.[7]

In order to elucidate the CT interactions in the ground state of heteroexcimer forming systems, we have made detailed studies on the absorption, excitation, and emission spectra as well as fluorescence rise and decay curves of some systems in low temperature matrices. We have also measured the absorption spectra at various temperatures in liquid solution in order to examine the collisional CT interactions in these systems. The results are given in the following.

Experimental

Absorption spectra of rigid solutions at low temperature were measured with a Shimadzu MPS-50L spectrophotometer and those of liquid solutions with a Cary 15 spectrophotometer. Fluorescence spectra were measured with an Aminco-Bowman spectrophotofluorometer calibrated by means of a standard tungsten lamp. Excitation spectra were measured with a Nalumi RM 20-G spectrometer equipped with a 600 grooves/mm grating and a 500 W xenon lamp as a light source. Fluorescence was passed through a Bausch & Lomb high intensity monochromator and detected with a 1P28 photomultiplier. The fluorescence rise and decay curves were determined on an apparatus composed of a Bausch & Lomb high intensity monochromator, 1P28 or HTV-R213 photomultiplier, Tektronix 661 sampling oscilloscope, and a pulsed nitrogen gas laser.

Pyrene, anthracene, perylene, DMA, *N,N*-diethylaniline (DEA) and *N,N*-dimethyl-*p*-toluidine (*p*-DMT) were purified by the same method as reported.[8] Tributylamine[9] and 1,2,4,5-tetracyanobenzene (TCNB)[10] were also the same as before. 1-(2-or 9-anthryl)-3-(*p*-*N,N*-dimethylaminophenyl)-propane(2-or 9-A-$(CH_2)_3$–DMA) was supplied by Professor S. Misumi of this University. Spectrograde hexane, cyclohexane, methylcyclohexane, toluene and tetrahydrofuran (THF) were used without further purification. Isopentane and chlorobenzene were purified by the usual method.[11] All the solutions were carefully deareated by freeze-pump-thaw cycles.

The temperature of the sample was measured with a thermocouple placed on the sample tube. A thin quartz cell with 1 mm optical path was used for measuring the absorption spectra in cyclohexane matrix.

Results and Discussion

Interactions between Electron Donor and Acceptor in Low Temperature Matrices. The temperature dependence of the absorption spectrum of perylene (5×10^{-5} M)–DMA (2×10^{-3} M) system in cyclohexane is shown in Fig. 1. The dotted curve gives the absorption spectrum of perylene dimer observed in the cyclohexane matrix at 173 K, agreeing with that reported by Ferguson.[2] The absorption spectrum shows a gradual red shift and broadening with the lowering in temperature. A similar temperature dependence of the absorption spectrum was observed in the system of pyrene (2×10^{-5} M)–DEA (1×10^{-4} M) in cyclohexane (Fig. 2).

On the other hand, the absorption spectra of pyrene–aliphatic amine (triethylamine or tributylamine) systems in cyclohexane matrix were essentially the same as those of solution at room temperature, *i.e.* of pyrene. In the case of anthracene–DMA and DEA systems, no appreciable change of absorption band arising from the interaction between donor and acceptor was observed but the absorption spectra of stable dimer and higher aggregates of anthracene[3] were detected.

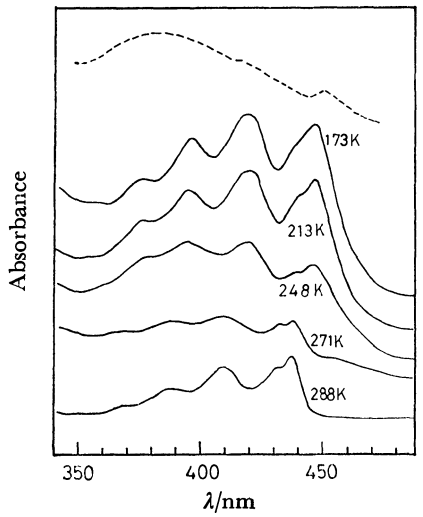

Fig. 1. Temperature dependence of the absorption spectrum of perylene (5×10^{-5} M)−DMA (2×10^{-3} M) system in cyclohexane. The dotted spectrum represents the absorption spectrum of perylene dimer observed at 173 K.

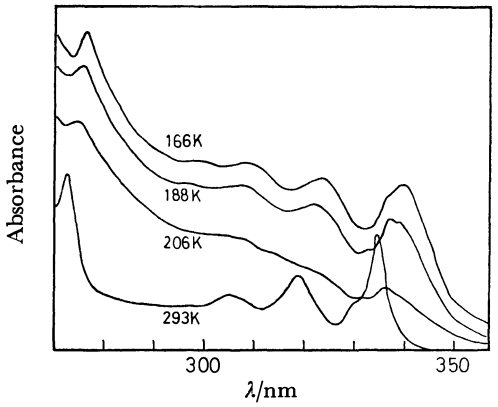

Fig. 2. Temperature dependence of the absorption spectrum of pyrene (2×10^{-5} M)-DEA (1×10^{-4} M) system in cyclohexane.

It was found that the dimer formation was a dominant process even in the case of pyrene or perylene solution with concentrations greater than 10^{-4} M in cyclohexane.

The excitation spectrum of the heteroexcimer fluorescence of the pyrene–DEA system monitored at 460 nm and that of the pyrene fluorescence monitored at 400 nm are shown in Fig. 3. The former is broadened and shifted to red as compared with the latter, similar to the absorption spectrum at low temperatures. The excitation spectrum of pyrene fluorescence is essentially the same as the absorption spectrum in solution at room temperature. In the system of high concentration of DEA (1×10^{-2} M), only the heteroexcimer fluorescence was observed throughout from room temperature to 77 K, the maximum of the excitation spectrum being observed at 342 nm in low temperature matrix as shown in Fig. 3. The same result was obtained in the case of the pyrene–DMA system. The broad excitation spectrum cannot be ascribed to the pyrene dimer since it differs notably from that of the pyrene excimer in low temperature cyclohexane matrix,[12]

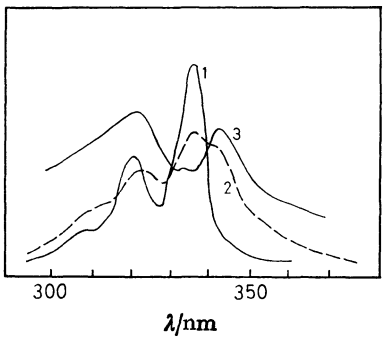

Fig. 3. Excitation spectra of pyrene-DEA system in cyclohexane matrix.
(1): [Pyrene]$=2\times10^{-5}$ M, [DEA]$=10^{-4}$ M, monitored at 400 nm.
(2): [Pyrene]$=2\times10^{-5}$ M, [DEA]$=10^{-4}$ M, monitored at 460 nm.
(3): [Pyrene]$=2\times10^{-5}$ M, [DEA]$=10^{-2}$ M, monitored at 460 nm.

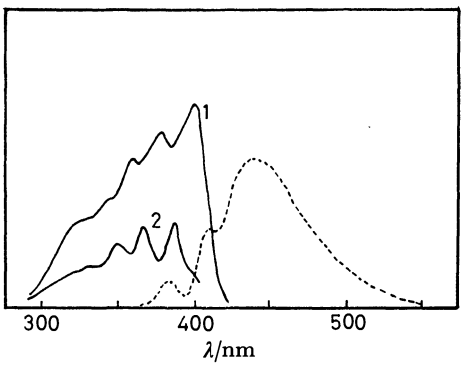

Fig. 4. Fluorescence (dotted) and excitation spectra of 2-A-$(CH_2)_3$-DMA in MP at 77 K monitored at 470 nm (1) and 400 nm (2).

Another clear-cut example of the ground state donor–acceptor interaction is the system of 2-A-$(CH_2)_3$–DMA in MP solution. The fluorescence and excitation spectra at 77 K are shown in Fig. 4. The excitation spectrum of the heteroexcimer fluorescence and that of the fluorescence from the anthracene part showed good correspondence with the absorption spectra at 77 K and room temperature, respectively.

The nature of the electronic transition responsibe for the excitation spectrum of the heteroexcimer fluorescence is not very clear at the present stage of the investigation. However, it seems that a loosely bound pair of donor and acceptor is formed in the low temperature matrix, the red shift of the absorption spectrum of which might be ascribed to the interaction between the locally excited state of the acceptor and the CT state which is situated higher than the former. When this donor–acceptor pair is excited by light absorption there occur some displacements of molecules in the pair leading to the heteroexcimer (CT state) formation.

Rise and Decay Curves of Heteroexcimer Fluorescence. In the systems described above, the rise curve of the heteroexcimer fluorescence in low temperature matrix was the same as the time-integrated function of exciting ns light pulse. This suggests that some stable

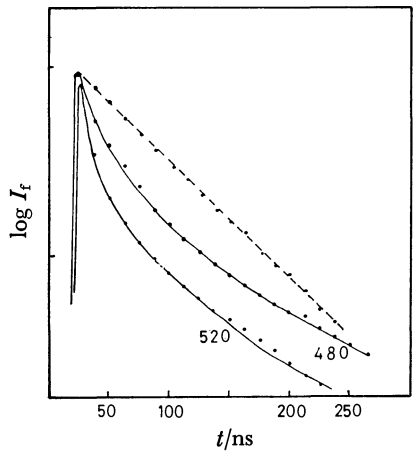

Fig. 5. Fluorescence decay curves of pyrene (1×10^{-5} M)—DEA (1×10^{-4} M) system in cyclohexane matrix at 196 K. See text.

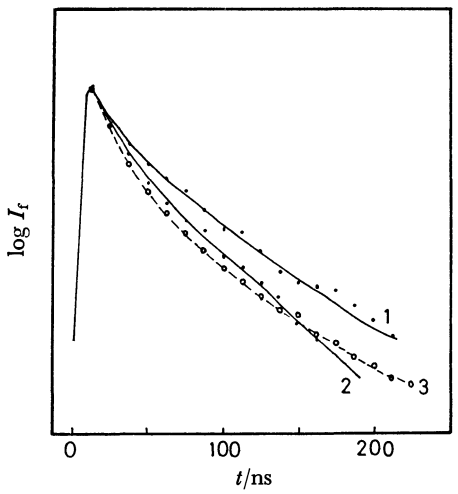

Fig. 6. Fluorescence decay curves of 9-A-$(CH_2)_3$-DMA in cyclohexane matrix at 196 K.
(1) Observed at 450 nm, (2) observed at 520 nm, (3) observed by detecting the whole emission band of heteroexcimer using a Toshiba VY-42 filter.

complex is already formed in the ground state, which agrees with the above results of absorption and excitation spectral measurements. However, it has been confirmed that the decay curve of the heteroexcimer fluorescence depends on the wavelength at which it is observed and shows a deviation from the simple exponential decay. The degree of deviation from exponential decay changes to some extent with temperature, depending also on the rate of heating or cooling. Roughly speaking, the longer the wavelength of observation, the greater the amount of the shorter decay component. This might be ascribed to the fact that there are several kinds of associated pairs emitting at different wavelengths. This phenomenon was observed in all the systems we studied but not in the case of excimer fluorescence band. As an example, the decay curves of some heteroexcimer systems are shown in Figs. 5 and 6. In the case of the pyrene–DMA or DEA system, the decay curve observed by detecting the whole emission band of heteroexcimer using an appropriate filter was accidentally single exponential (dotted line, Fig. 5). The apparent single exponential decay might represent the mean lifetime $\bar{\tau}_f$ if various kinds of heteroexcimers of the pyrene–DMA or DEA system. In the case of the pyrene (1×10^{-5} M)–DMA (1×10^{-2} M)–cyclohexane system, when the temperature is lowered, the band maximum of the heteroexcimer fluorescence shifts to red accompanied by a decrease both in the relative fluorescence intensity I_f and the mean lifetime at first, and then makes a blue shift, accompanied by increase in I_f and $\bar{\tau}_f$, to approximately the same position as it has at 300 K. The results of the temperature effects on the heteroexcimer fluoroscence are summarized in Table 1. It seems that some distribution of the associated donor–acceptor states differing with temperature might be forced to arise in the cyclohexane matrix. When the DMA concentration is small (1×10^{-4} M), the heteroexcimer fluorescence can be observed only in the wavelength region of 440—450 nm. One of the possible mechanisms for the appearance of the long wavelength fluorescence might be the formation of a more highly aggregated state than the 1 : 1 donor–aceptor pair.

Table 1. Temperature dependence of heteroexcimer fluorescence of pyrene (1×10^{-5} M)-DMA (1×10^{-2} M)-cyclohexane system

T/K	300	273	240	230—210	190-100
λ_{max}/nm	440	450	465	480	440
I_f	100	85	15	≈6	90
$\bar{\tau}_f$/ns	140	120	85	80	≈110

Absorption Spectra in Liquid Solutions. Yoshihara *et al.* studied the absorption spectra of the pyrene–DMA system in chlorobenzene, changing the DMA concentration in the range 0—7.89 M.[6] The absorption intensity in the wavelength region of 350—400 nm increases with an increase in concentration of DMA, the equilibrium constant of complex formation in the ground state being determined to be 0.2 M^{-1} with the aid of the Ketelaar plot. We also examined the anthracene–DMA system and obtained similar results.

In order to elucidate the electron donor–acceptor interactions in solution, it is worthwhile to measure the temperature dependence of the ultraviolet absorption spectra of donor–acceptor systems. The observed values of absorbance d for the THF solution of TCNB are plotted against the reciprocal of the temperature in Fig. 7. The value of d decreased at first with a rise in temperature from 298 K to 313 K, increasing with a further rise in temperature. A similar result was obtained for the system of perylene in *p*-DMT. The temperature dependence of $(d-d_0)$ of the pyrene (1×10^{-2} M)–DMA (1×10^{-2} M) system in hexane is shown in Fig. 8, where d and d_0 are the absorbance values observed for the ternary solution containing pyrene and DMA in hexane and for the equimolar hexane solution of pyrene, respectively. All of the d values are corrected for the volume change caused by temperature variation.

The observed increment of the absorption intensity at low temperatures can be explained by the very

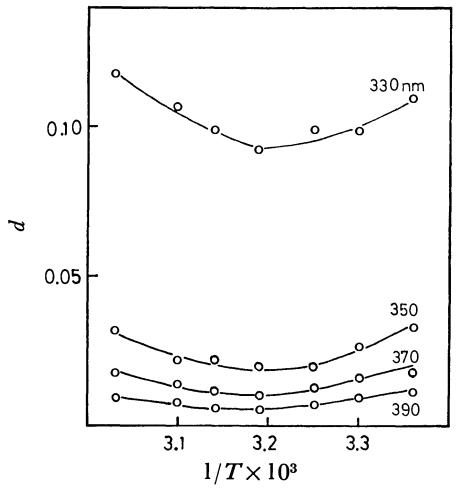

Fig. 7. Temperature dependence of d at various wavelengths in the TCNB-THF system.

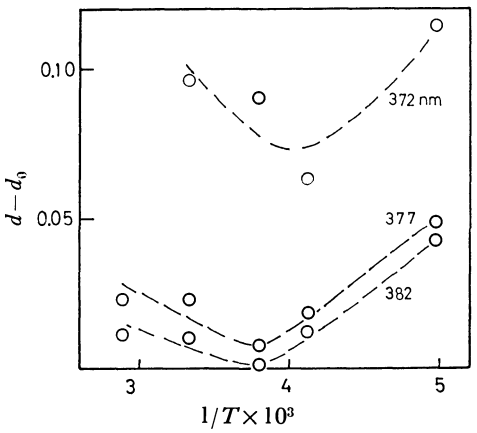

Fig. 8. Temperature dependence of $(d-d_0)$ at various wavelengths in the pyrene (1×10^{-2} M)-DMA (1×10^{2} M)-hexane system.

weak complex formation between donor and acceptor in the ground state which leads to the broadening and red shift of absorption band.

A collision induced CT interaction may arise at a high temperature leading to the enhancement of the absorption intensity, as it is actually observed in pyrene–DMA as well as TCNB–THF systems. Measurements of the collision induced absorption band would be difficult in the stable CT complex systems as compared with the heteroexcimer systems. Actually, in the case

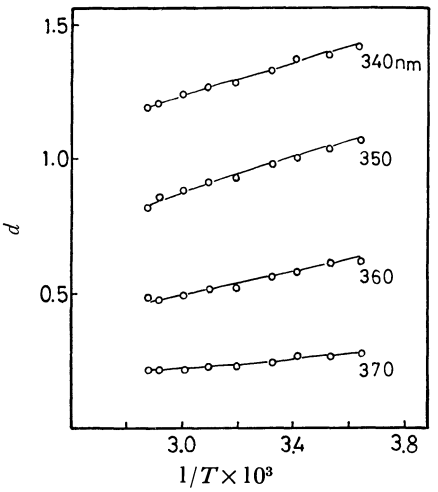

Fig. 9. Temperature dependence of d at various wavelengths in the TCNB-toluene system.

of the TCNB–toluene system, the intensity of the CT absorption band decreases monotonically with an increase in temperature up to 348 K (Fig. 9).

The Viscosity of Tetraphenylphosphonium and -arsonium Halides in Water

Katsuko TAKAIZUMI and Toshiki WAKABAYASHI
The College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received March 23, 1976)

A viscometer, the inside of which was thoroughly coated by silicon grease, was prepared because it is difficult to measure precisely the viscosities of aqueous solutions of tetraphenylonium salts by means of a usual flow-type viscometer because of the characteristic peculiar to these solutions, that they make the glass wall water-repellent and water droplets tend to adhere to it. By comparing the relative viscosities on sucrose and $LaCl_3$ in water obtained by the coated viscometer with those found in the literature, it was confirmed that the viscometer operates adequately. The viscosities of Ph_4PCl, Ph_4PBr, Ph_4PNO_3, Ph_4AsCl, and Ph_4AsBr in water have been measured at 15, 25, and 35 °C. The ionic *B*-coefficients determined at 25 °C are 1.09 mol^{-1} for both cations, while the ionic activation energies for viscous flow are +4.98 and +5.02 kJ/mol for Ph_4P^+ and Ph_4As^+ respectively.

The viscosity measurement of electrolyte solutions has been widely used as an important experimental method to provide information concerning the nature of ion–solvent interactions. Although no satisfactory interpretation for the viscosity *B*-coefficient has yet been established, its sign and magnitude and its temperature dependence are usually regarded as measures of the effects arising from the size of the ion and ion–solvent interactions.[1-3] Especially with aqueous solutions which are recognized as partly structured liquids, the *B*-coefficient has been discussed in connection with the water structure and the effects of ions or of neutral solutes upon it.[4-11]

On the other hand, in the studies of aqueous solutions of hydrophobic solutes, differences between the water-solute interactions of alkyl- and aryl-substituted ions have been illustrated. In these studies, tetraphenyl ions, such as Ph_4P^+, Ph_4As^+, and BPh^-_4, have often been examined as typical and important ions containing phenyl groups.[12-19] Furthermore, some indications that BPh^-_4 and Ph_4P^+ or Ph_4As^+ interact differently with water have been obtained.[14b-19]

However, it should be noted that no studies of the viscosity of aqueous solutions of tetraphenylphosphonium and -arsonium salts have appeared, except one[17] which dealt with Ph_4AsCl only at 25 °C, and concerning the temperature dependence no data are available. This may be attributed to the peculiar characteristics of the aqueous solutions of these salts that the solutions make the glass surface water-repellent, presumably because of the preferential adhesion[20] of these large cations on the glass surface, and that the solution tends to form droplets on the glass surface.[21] Thus, in this case it is difficult to measure the viscosity precisely by means of a usual flow viscometer.

The basic conditions for assuring the precise measurement of the viscosity of fluid by means of a flow viscometer are that the flow rate on the boundary surface of the capillary be zero and the flow in the capillary be laminar. As is well known, the former is fulfilled in the case of the mercury-glass surface though the angle of contact is larger than 90°, *i.e.*, *ca.* 140° at room temperature. It can, therefore, be expected that the viscosity measurement for an aqueous solution of Ph_4MX may be possible provided that a viscometer is available which is coated by a suitable hydrophobic substance to prevent the adhesion of water droplets on the surface.

The purposes of this work are the preparation of such a viscometer, the examination of its properties as a viscometer, and the determination of the viscosities and the temperature dependence of aqueous solutions of tetraphenylphosphonium and -arsonium halides.

Experimental

Viscometer. The outline of the viscometer is shown in Fig. 1. The inside of the viscometer and all the paths for sample solutions are thoroughly coated by silicon grease film. The coating procedure is as follows: a hexane solution containing silicon grease (Dow Corning Co., Ltd.) (about 2 ppm) was filtered several times by a glass filter; each part of the viscometer was then filled up with the solution and was dried at room temperature after the solution has been removed. This procedure was repeated ten times or more. Finally the apparatus was dried at 120 °C for 24 h. The inner wall thus prepared is completely water-repellent, and the water introduced in the apparatus flows out thoroughly without leaving any droplets on the wall.

The sample solution is introduced into the bulb, B, from B_1 through three filters and the B_2 and B_3 bulbs. The B_3 bulb is an automatic buret, with a volume of about 40 cm^3; it is used to measure out a constant volume of the solution. It was confirmed that the reproducibility of the measured volume was within an error of ±5 mg by the weight of water,

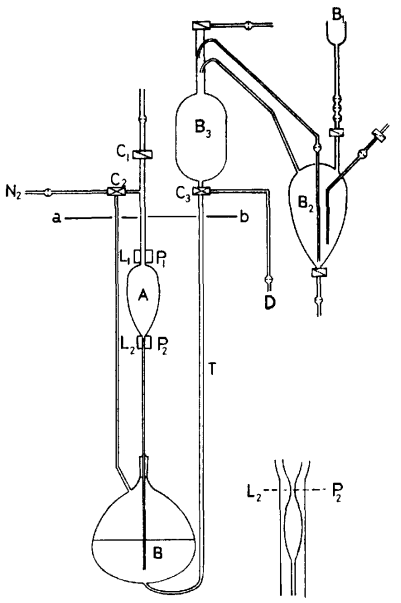

Fig. 1. The outline of the viscometer.

or 0.013%. The volume of the upper bulb, A, is about 20 cm^3; the length of the capillary, 18 cm; the diameter of the capillary, 0.06 cm.

The transit of the meniscus at each of the fixed points, P_1 and P_2 was detected as an electric pulse by means of a detector consisting of a small electric light (about 20 mW), a slit, and a phototransistor, PD 32H (NEC Co., Ltd.). The light was turned on for only a few seconds before and after the passing of the meniscus to minimize the heating. The pulse was introduced into a Takeda Riken universal counter, TR 5103, by which the flow time was recorded to the order of ms.

The viscometer was fixed in a stout frame made of brass, and, the main part was immersed in a thermostat maintaining its temperature within $\pm$0.0005 °C. The whole of the apparatus was mounted in air room, the temperature of which was controlled to within 0.1 °C. The thermostat consisted of inner and outer parts arranged concentrically. In the latter a cooling tube and a wire heater controlled automatically by a thermistor-regulator system were set, while in the former there was no heat source. The water in the bath was circulated between the two parts. Glass filters were set at all of the ends of the tubes of the apparatus opening to the atmosphere in order to keep the inside from dust.

The measured-out portion of the sample solution in B_3 is introduced slowly through the tube, T, into the bulb, B; the cock, C_3, is closed just when the meniscus passes C_3. The flow time was about 440 s for water at 25 °C. The reproducibility of the flow time is 10 ms, provided the variation in the bath temperature is kept within 0.0005 °C. After the timing, the inner solution is taken out thoroughly from an end, D, of the tube by suction. Since the removal of the solution is complete, there is no need to dry the inside after washing.

Density Measurements. The densities of the solutions at each temperature were measured by means of a pycnometer with a volume of 50 cm^3.

Chemicals. The tetraphenylphosphonium bromide was prepared by dissolving Ph_4PCl(Dotite TPPC) in dichloromethane and by shaking the solution with a 2 M aqueous solution of potassium bromide to change the chloride ion in the dichloromethane phase to the bromide ion. This extraction procedure was repeated with a fresh aqueous phase eight or more times. It was confirmed that the change of the anion from chloride to nitrate was completed by the time the process has been done five times. Considering the fact that the distribution ratio of Ph_4PBr is comparable to that of Ph_4PNO_3(200 or more) under the present conditions, the anion exchange is believed to be satisfactory. The organic phase was filtered with filter paper to remove the water, and then a small amount of ether was added to the filtrate to precipitate a small amount of a salt. The salt was filtered off from the organic solution. A crude Ph_4PBr was obtained from the solution by adding ether. The salt was recrystallized several times from dichloromethane by adding absolute ether to the solution. Ph_4AsBr was also prepared by a similar procedure. Ph_4PCl and Ph_4AsCl were purified by recrystallization.

The salts thus obtained were dried over P_2O_5 under atmospheric pressure because the aqueous solutions prepared from the salts dried for several days under a reduced pressure at 50 °C, or even at room temperature, have sometimes shown turbidity, though these drying processes are found in the literature. Also, the drying of the salts at a high temparature, 120 °C or more, should be avoided because it produces a substance which abnormally enhances the conductivity of the aqueous solution at a low concentration range, as was confirmed by conductivity measurements.[22]

Potentiometric titration with a standard iodine solution[23] to form Ph_4MI_3 showed a purity of 99.9% with respect to the tetraphenylonium ion in Ph_4PCl, Ph_4PBr, Ph_4PNO_3, Ph_4AsBr, and Ph_4AsCl, while potentiometric titration with silver nitrate showed a purity of 99.99% for the chlorides and bromides. No halide was found with Ph_4PNO_3.

The potassium chloride used in this study was of a Merck Suprapur. The sucrose was a specially prepared reagent grade for density gradient determination (Nakarai Kagaku Co.), and the aqueous solution was used within a day after preparation. Lanthanum chloride of a reagent grade (Wako Pure Chemical Ind.) was used with no further purification, and the concentration of the aqueous solution was determined by titration with a standard EDTA solution.

All of the solutions were prepared by weight with conductivity water.

Results and Discussion

The Nature of the Coated Viscometer. The viscometer was calibrated by the use of the equation: $\eta/d = at - b/t$, where a and b are regarded as instrumental constants of the viscometer. These constants were determined from the known densities and viscosities of aqueous solutions of potassium chloride[24] in the concentration range from 0.01 to 0.2 M. Although water is usually employed as a standard liquid, the potassium chloride solution was chosen here for the reason to be described below. The kinetic energy term can be connected with a and b by this relation:[3]

$$\frac{b}{a} = \frac{mV^2}{\pi^2 R^4 h_m g} \tag{1}$$

where V is the volume of liquid in the bulb, A, in Fig. 1, h_m is the mean height of the liquid column, R is the radius of the capillary, and m is a numerical coefficient introduced to take account of the particular shape of the capillary ends. For the present viscometer, m was estimated to be about 1.7, which is somewhat larger than usual values,[26] 0.5 to 1.2, for conventional flow viscometers.

It should be noted that the flow time of pure water, t_0, was longer by about 50 ms than that extrapolated to a zero concentration of potassium chloride. This suggests the presence of some interfacial effect due to the silicon grease film. For the flow time for water, therefore, we preferred the extrapolated one, which was determined by a quadratic equation of the molal concentration, to the observed one.

The relative viscosities of aqueous solutions of potassium chloride were reproduced with a standard deviation of 0.000023, which amounts to 0.002% of the relative viscosities, by means of the Jones and Dole equation;

$$\eta_r = 1 + Ac^{1/2} + Bc \tag{2}$$

with $A=0.0052_0$ and $B=0.014$.[24] A plot of $(\eta_r-1)/c^{1/2}$ against $c^{1/2}$ is shown in Fig. 2.

As a check, the viscosities of aqueous solutions of sucrose and lanthanum chloride were measured at 25 °C in the concentration region of 0.001 to 0.01 molar. The A- and B-coefficients determined by Eq. 2 are shown in Table 1, together with the values found in

the literature. The probable errors expected in the *B*-coefficients, which are designated as P_B in the table, are 0.004 and 0.003 for sucrose and lanthanum chloride respectively. The agreement is fairly well, although with sucrose the present *B*-coefficient is slightly larger, beyond the probable error, than that found in the literature.[25]

Thus, it may be concluded that the coated viscometer can be used to determine the viscosities of aqueous solutions, provided that the extrapolated value for t_0 is used. One advantage of the present viscometer over the usual ones is that, since the sample solutions can be exchanged without removing the viscometer from the support, as has been described above, this viscometer is free from any error arising from the removal and resetting.

The Viscosities of Ph_4MX. The densities of aqueous solutions were calculated by Eq. 3, assuming a linearity of the density against the molal concentration of the salts;

$$d = d_0 + \alpha m \qquad (3)$$

where m is the molality and α is a constant for a given salt at a given temperature. The linearity was confirmed for Ph_4AsCl and Ph_4AsBr at 25 °C, at least in the low concentration range below 0.015 *m*, which was the highest concentration for the viscosity measurement. Table 2 lists the values of α for all of the salts and temperatures examined. The molar concentrations of the solutions were calculated from the molality and the density.

The vscosities of the aqueous solutions of Ph_4PCl, Ph_4PBr, Ph_4PNO_3, Ph_4AsBr, and Ph_4AsCl were measured at 15, 25, and 35 °C in the concentration range from 0.0005 to 0.012 M. The relative viscosities of aqueous solutions of these bromides are given in Table 3. Recently, it was stressed[20] that an extra term in c^2 should be added to the Jones and Dole equation in order to determine the *B*-coefficient precisely. In the present study, however, the Jones and Dole equation was employed to analyze the viscosity data. Taking account of the facts that the tetraphenyl ions have considerably large *B*-coefficients and that the measurement was carried out in a low concentration range below 0.012 M, no significant error will be introduced into the results by neglecting the extra term. As an example, the plots for Ph_4PBr at three temperatures are shown in Fig. 3. The *A*- and *B*-coefficients of Eq. 2 are obtainable from the intercept and the slope, as usual.

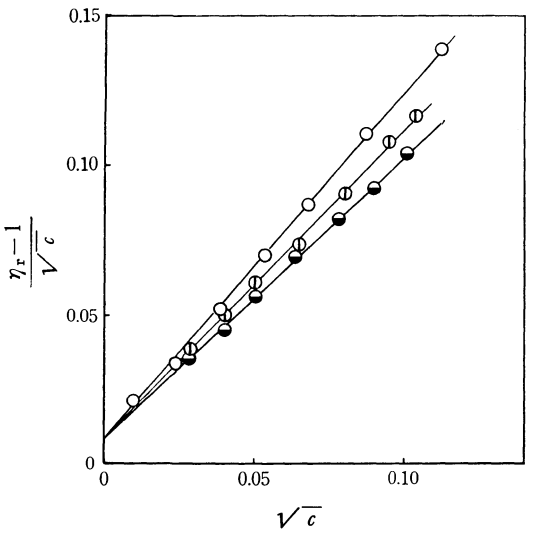

Fig. 3. Evaluation of the limiting slopes for relative viscosity of Ph_4PBr in water at 15°, 25°, and 35 °C. ○: 15 °C, ◑: 25 °C, ◒: 35 °C.

These coefficients were determined by the method of least squares and are listed in Table 3. The uncertainty in the B-coefficients is expected to be less than 0.02 mol^{-1}, as is shown in the column headed by p_B, which is the probable error. The A-coefficients found agree fairly well with the predicted ones, which are given in terms of the ionic equivalent conductivities by means of the relation derived by Falkenhagen and Vernon.[27] The splitting of the B-coefficient into the ionic components was carried out by the use of the scales introduced by Gurney[1] and by Kaminsky.[2] The ionic B-coefficients for the bromide ion at some temperatures were taken from the data by Kay, Vituccio, Zawoyski and Evans.[7] The ionic B-coefficients, B_i, thus obtained are given in the last column of Table 4. The consistency among the values of B_i for each cation obtained from different salts is satisfactory. No previous data to be compared with the present results are found in the literature except for one on Ph_4AsCl at 25 °C reported by Jolicoeur, Philip, Perron, Leduc, and Desnoyers,[17] this value is 1.08 mol^{-1}, the same as the value obtained here, though their value is based on a somewhat different equation, as has been mentioned above.

The temperature dependence of the viscosity can reasonably be expressed in terms of the activation energy for viscous flow, ΔE^*.[9,28] Assuming that the contribution of the salt to the ΔE^* is the sum of the activation energies for ionic components, it is possible to determine the ionic values for the 1 : 1 electrolyte by this equation:[9,28]

$$\Delta E^* - \Delta E_0^* = \Delta E_+^* + \Delta E_-^* \quad (4)$$

where ΔE_+^* and ΔE_-^* stand for the cationic and anionic activation energies respectively, and where ΔE_0^* is that for a pure solvent. With chloride and bromide ions,[9,28] values of −0.92 and −1.00 kJ/mol respectively for ΔE_-^* at a concentration of 1 M are assigned. The ionic activation energies thus obtained are listed in Table 5, together with those for other cations found in the literature, for comparison.

A widely accepted explanation for the viscosity B-coefficient of electrolytes, as summarized by Stokes and Mills,[3] is that the B-coefficient is a measure of the effects of (a) the size and shape of the ions, (b) the ordering of solvent molecules in the vicinity of ions as a result of the ionic field, and (c) the distortion of the solvent structure, leading to greater fluidity. The first two effects result in increasing the viscosity. One more effect is added with large hydrophobic ions such as tetraalkylammonium ions; that is, the "ice-like" structure of water at a distance from these ions is increased by their presence.[4,5] The size and sign of the B-coefficient can be determined as a result of the competition of these factors. Although the evaluation of each contribution of these effects is impossible at present, the effect of ionic size is usually estimated by the Einstein equation,[29] which was derived in the case of rigid spheres suspended in a viscous continuum. This effect results in a positive contribution to the B-coefficient by an amount of 0.0025 V,[3] where V is the hydrodynamic volume of the ion which may be equated with the standard partial molal volume of the ion, V_i^0($cm^3\,mol^{-1}$), at lower concentrations. The ionic

Table 5. Ionic activation energies of some tetra-substituted ions for viscous flow in water at 25 °C

difference[20], $B_i - 0.0025\ V_i^0$, is considered as a measure of the effects arising from ion–solvent interactions other than the size effect, provided that it is reasonable to assume the ions to be spheres. These differences for tetraphenyl ions and some tetraalkylammonium ions are listed in the column designated as ΔB_i in Table 5. The ΔB_i values decrease in this order: $Bu_4N^+ > BPh^-_4 > Ph_4P^+ > Ph_4As^+ > Pr_4N^+$.

The ionic activation energies of tetraphenylonium ions for the viscous flow at 25 °C are given in Table 5, together with other tetrasubstituted ions. The ΔE_i^* values are all positive, since the sign of dB_i/dT is opposite to that of ΔE_i^*; this means that the dB_i/dT are all negative, and fairly large compared with most of the simple inorganic ions[9]. The order of the temperature dependence of the B-coefficient is somewhat uncertain because of the experimental errors, and more acculate data are required, but it is probably safe to speculate that the order is $Bu_4N^+ > Ph_4M^\pm > Pr_4N^+$.

The conclusion is reached that tetraphenyl ions, independent of the sign of the ionic charge, are classified into net "structure-makers" in water by reason of their positive and large values for ΔB_i[20] and the negative dependence of the B-coefficients on the temperature.[7–10] However, it will be necessary here to refer to the concept of the "structure" being made or broken by the solutes introduced in the water. The information found in the literature is contradictory if an attempt is made to classify the solutes into "structure-maker" and "-breaker" based on only the results obtained from a specific experimental technique. With respect to Ph_4P^+ and Ph_4As^+, a structure-breaking effect for the water structure has been inferred from osmotic coefficient measurements[13], while the reverse was suggested by a NMR study[15] and by an inspection of the partial molal heat capacities in water.[17] A marked effect on the water structure by Ph_4AsCl was not found in the near IR spectra.[16] Also, for the tetraphenylborate ion a similar situation holds. By the criterion[30] of the classification of solutes which is based on a thermodynamic relation, $(\partial \bar{C}_p/\partial p)_T = -T(\partial^2 \bar{V}_2/\partial T^2)_p$, both Ph_4AsCl and $NaBPh_4$ are "structure-breakers" because of the negative sign[32] of $(\partial^2 \bar{V}_2^0/\partial T^2)_p$ for them.

This inconsistency is not strange; as has already been mentioned by some authors,[30,31,33,34] it arises because we are still unable to define the structure as being either made or broken by solutes or to measure quantitatively the degree of the structure; also, the ion-water interactions are too complicated to explain in terms of structure-making or -breaking, though the concept has proven to be useful in some cases. Thus, it is inadequate to classify the tetraphenyl ions as either structure-makers or -breakers; at least the "structure" assumed in the present case should be different from the "iceberg" which is considered to be promoted by larger tetraalkylammonium ions.

To apply the Einstein equation to tetraphenyl ions (and also probably to R_4N^+ with long-chain alkyl groups) seems to be of doubtful value because tetraphenyl ions have a fairly open structure[15]; to regard them as a sphere can be only a very rough approximation. The specific interactions of water molecules with phenyl groups in Ph_4As^+, Ph_4P^+ and BPh^-_4 were indicated by a NMR study[15], and those with Ph_4As^+, by a laser-Raman study.[35] The authors of the latter pointed out the possibility that this ion is pentacordinate in water, with water entering the fifth coordination site, while in methanol it is tetracoordinate. Also by this coordination model the viscosity behavior of the tetraphenyl ions in water appears to be explicable, although it will be necessary to accumulate more precise and varied information in order to understand their states in water wholly.

Proton Magnetic Resonance Study of Poly(*p*-chlorostyrene) of Low Molecular Weight

Yoshiyuki HIRAI, Yoshio NUNOMURA, and Yoshio IMAMURA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 31, 1976)

Poly(*p*-chlorostyrne) samples of relatively low molecular weight (average degrees of polymerization($\overline{DP}$): 15, 24, and 46) were prepared by radical polymerization and their PMR spectra were observed in the temperature range 5—88 °C. When the temperature was elevated, the absorption of the methyne proton moved to lower field and the half height width for the absorption of the *ortho* proton decreased more remarkably than that of the *meta* proton. The absorption of the *ortho* proton of one polymer sample ($\overline{DP}$: 15) showed an anomalous broadening. These features of the observed spectra were interpreted in terms of ring current shielding by aromatic side groups, and the conformations of the polymer are discussed.

Many studies of proton magnetic resonance (PMR) spectra and proton relaxation times of polymers of low molecular weight have been made by various authors.[1-4] In many cases reported in the literature, the spectral patterns or spin-lattice relaxation times change with chain length in the region of short chains, and they become less sensitive to chain length as the chain becomes longer (*e.g.* average degrees of polymerization ($\overline{DP}$) : 20 for polystyrene).[2,5] These observations have been interpreted in terms of a so-called "polymeric effect". However, more precise discussion based on the viewpoint of conformations or internal motions of polymer chains has not been sufficiently developed. The present paper is concerned with the discussion of the conformations of polymers (poly(*p*-chlorostyrene)) of such low degrees of polymerization.

PMR spectra of polymers which contain aromatic side groups are always deformed by the ring current effect of the side groups. The extent of the ring current effect on each proton of the polymer would be influenced by the polymer conformation. Therefore, the PMR spectra of these polymers are accessible for conformational consideration. Poly(*p*-chlorostyrene) is one of the most favorable samples to this purpose, because this polymer gives well-resolved spectra in comparison with other polymers containing aromatic side groups, such as polystyrene and its *ortho* or *meta* derivatives.

The PMR spectra of poly(*p*-chlorostyrne)s ($\overline{DP}$: 15, 24, and 46) were observed in the temperature range 5—88 °C. The observed spectra were compared with each other in chemical shifts and in half height width, and the conformations are discussed in terms of the ring current shielding.

Experimental

p-Chlorostyrene was prepared by the procedure described in "Organic Syntheses".[6] Samples of poly(*p*-chlorostyrene) were obtained by polymerization of 10 ml of monomer in 50 ml of carbon tetrachloride for 5 h at 80 °C, using α,α'-azobisisobutyronitrile as an initiator. To obtain polymer samples of various molecular weights, the amount of the initiator was changed over the range from 0.5 g to 3 g. The polymers were precipitated in about 10 volumes of methanol in order to free them from any residual monomer and initiator, and were dried *in vacuo*. The number-average molecular weights of these polymers were determined using "KUNAUAR's Vapor Pressure Osmometer" in chloroform solution at 37 °C. The average degrees of polymerization of polymer samples were 14.8, 24.0, and 46.4 (they are denoted as 15-, 24-, and 46-polymer).

Polymer solutions for PMR spectral measurements were prepared by dissolving 0.1 g of the polymer in 1.0 ml carbon tetrachloride (spectral grade). Tetramethylsilane was added to each solution as an internal reference. The polymer solutions were transferred to 5 mm o.d. NMR tubes, which were sealed after the atmosphere was replaced with nitrogen gas. The PMR spectra of each polymer were observed over the range from 5 °C to 88 °C. These spectra were measured using a Japan Electric Optics Laboratory "JNM PS-100 Spectrometer" operated at 100 MHz.

Results and Discussion

Temperature Dependence of Chemical Shift. Figure 1 shows the PMR spectra of the phenyl protons of 24-polymer in carbon tetrachloride at 5 and 70 °C. The peaks at 2.95 τ and 3.59 τ are assigned to *meta* protons (*m*-H) and *ortho* protons (*o*-H) respectively. Figure 2 shows the spectra of aliphatic protons at various temperatures. The weak absorption near 7 τ corresponds

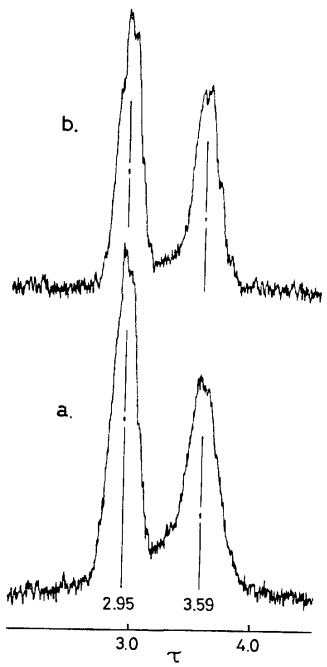

Fig. 1. PMR spectra of phenyl protons of poly(*p*-chlorostyrene) in carbon tetrachloride(0.1 g/ml). (a) 5 °C, (b) 70 °C.

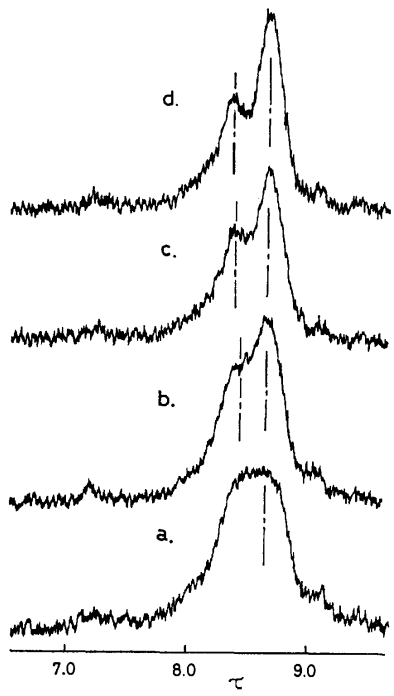

Fig. 2. PMR spectra of aliphatic protons of poly(*p*-chlorostyrene) in carbon tetrachloride(0.1 g/ml). (a) 5 °C, (b) 30 °C, (c) 50 °C, (d) 70 °C.

to the protons in terminal monomer units. The absorptions of the methyne proton (CH) and the methylene proton(CH_2) in nonterminal monomer units appear at about 8—9 τ. Figures 1 and 2 show that the peaks of the absorption of *o*-H, *m*-H, and CH_2 do not move, while that of CH moves to lower field as the temperature is raised.

The movement of peaks suggests a change of conformations. Indeed, chemical shifts are often influenced by conformations: for a change of conformations causes a change of environment at the position of the resonating proton, while the environment is governed by the effects of magnetic anisotropy or of electric field, *etc.* For poly(*p*-chlorostyrene), the effect of magnetic anisotropy is the most important factor. The magnetic anisotropy of the phenyl ring is significantly larger than that of the carbon–carbon (C–C) or carbon–chlorine (C–Cl) bond ($\chi_{//}-\chi_{\perp}$: 3.3×10^{-6} cm^3 mol^{-1} for C–C,[7] 3×10^{-7} cm^3 mol^{-1} for C–Cl[8] bond). Therefore, in this case, the changes of chemical shift caused by the conformational changes should be mainly governed by the effect of magnetic anisotropy (ring current effect) of the phenyl rings.

The extent of ring current shielding produced at the positions of CH_2, CH, *o*-H, and *m*-H was calculated for preferred conformations. The effects from the phenyl rings on either side of these protons were taken into account in this calculation. Phenyl-ring planes are assumed to be perpendicular to the plane defined by adjoining skeletal bonds. This assumption seems to be reasonable, as reported by Abe *et al.*[9,10] The ring current shieldings were estimated by the following equation:[11]

$$\Delta\sigma=\frac{\chi_{//}-\chi_{\perp}}{3R^3}(1-3\cos^2\theta)$$

where $\chi_{//}-\chi_{\perp}$ is the anisotropy of the magnetic susceptibility, R is the distance of the resonating proton from the center of the phenyl ring, and θ is the angular displacement from the symmetry axis. The bond length and bond angle are shown in Fig. 3. The value of $\chi_{//}-\chi_{\perp}$ for a *p*-chlorophenyl group would be somewhat different from the value for benzene. However, only a qualitative estimation is required in the present case: we used -59.7×10^{-6} cm^3 mol^{-1} [12] (benzene) as the value of $\chi_{//}-\chi_{\perp}$ for the *p*-chlorophenyl ring.

a) Conformational energies (kcal/mol): Ref. 17.

The calculated results are given in Table 1, where the minus and plus signs represent paramagnetic and diamagnetic shielding, respectively. The results obtained from Table 1 follow: (a) Methylene protons experience approximately constant paramagnetic shelding, and *meta* protons experience only small paramagnetic shielding. (b) *Ortho* protons experience and indefinite amount of shielding, and the correlation to conformations is found to be irregular. (c) A methyne proton experiences diamagnetic shielding in any conformation, and the shielding was remarkably effective in the stable conformations in syndiotactic and heterotactic sequences (TTTT, GTTT, and TGTT).

Evidently, polymer chains occupy more stable conformations at low temperatures, and the rise of the temperature enables polymer chains to occupy conformations of higher energy. Table 1 demonstrates that such changes in conformations reduced the diamagnetic shielding produced at the position of CH in syndiotactic and heterotactic sequences, and cause the downfield shift of the peak of the methyne proton. Polystyrene or ring-substituted polystyrene by radical polymeri-

zation is known from NMR studies[13-15] to be syndio-rich. Therefore, the spectra of samples examined in this investigation should also reflect the characteristics of the ring current effect in syndiotactic and heterotactic sequences.

On the basis of a comparison of the observed results with the calculated ones, the following reasonable conclusions are drawn: (a) When the temperature is elevated, the fractions of the stable conformations (TTTT, GTTT, and TGTT) decrease. That decrease results in the decrease of diamagnetic shelding at the position of CH; consequently, the peak of CH moves to lower field. (b) The shielding produced at the positions of CH_2, *o*-H, and *m*-H is less sensitive to conformations, and the peaks of these protons do not move, even though the temperature is elevated and the fractions of stable conformations decrease.

Temperature Dependence of Half Height Width. Table 2 represents half height widths ($\Delta H_{1/2}$) for the absorptions of *o*-H and *m*-H of 24-polymer at various temperatures.

TABLE 2. HALF HEIGHT WIDTHS OF PMR PEAKS OF PHENYL PROTONS

Temp (°C)		5	20	30	40
$\Delta H_{1/2}$ (Hz)	*o*-H	31.3	29.3	28.3	27.3
	m-H	23.7	22.5	22.5	21.8
Temp (°C)		50	60	70	88
$\Delta H_{1/2}$ (Hz)	*o*-H	25.3	25.3	24.8	25.3
	m-H	21.5	21.3	20.5	20.0

The temperature dependence of the $\Delta H_{1/2}$ is shown in Fig. 4, together with those of 15- and 46-polymer. The $\Delta H_{1/2}$ for *o*-H absorption is apparently large at low temperatures, and decreases sharply up to 50 °C, and then decreases gradually with further rise in temperature. The abrupt small decrease between 40 °C and 50 °C may reflect an increase of the tortional oscillation of nonrotating phenyl rings, as Liu *et al.*[16] pointed out in the study of polystyrene. The $\Delta H_{1/2}$ for *m*-H absorption is small at low temperatures, and decreases gradually with the rise of temperature.

In general, the widths of spectra of polymers are caused by unresolved spin-spin splitting and by the time dependence of magnetic dipole interaction. However, this strong broadening observed only in *o*-H absorption at low temperatures cannot be interpreted in terms of these factors.

Table 3 represents the differences ($\Delta\sigma'$) of the ring current shielding on ortho protons and on meta protons: $\Delta\sigma' = |\Delta\sigma(H_2) - \Delta\sigma(H_6)|$ or $|\Delta\sigma(H_3) - \Delta\sigma(H_5)|$. The differences indicate the degree of difference in the chemical shifts of *ortho* protons or *meta* protons. The $\Delta\sigma'$ for *o*-H is great in any conformation, and it is particularly great at stable conformations (TTTT in syndiotactic, GTTT and TGTT in heterotactic sequence). On the other hand, the $\Delta\sigma'$ for *m*-H is relatively small in any conformation, and is less sensitive to conformations. The $\Delta\sigma'$ for *o*-H indicates that the *o*-H spectra consist of two absorptions (absorptions of H_2 and H_6) with different chemical shifts as the chains occupy the stable conformations.

TABLE 3. CONFORMATIONS AND DIFFERENCES ($\Delta\sigma'$) OF RING CURRENT SHIELDING (ppm unit)

Chain conform		$\Delta\sigma'$ $\lvert\Delta\sigma_{H_2}-\Delta\sigma_{H_6}\rvert$	$\lvert\Delta\sigma_{H_3}-\Delta\sigma_{H_5}\rvert$
Iso	TGTG	0.18	0.01
	GTGT	0.81	0.08
	GTTG	0.46	0.12
Betero	TTTG	1.03	0.03
	TTGT	1.30	0.16
	GGTG	0.11	0.24
Syndio	TTTT	1.03	0.03
	GGTT	0.78	0.04
	TTGG	0.11	0.24

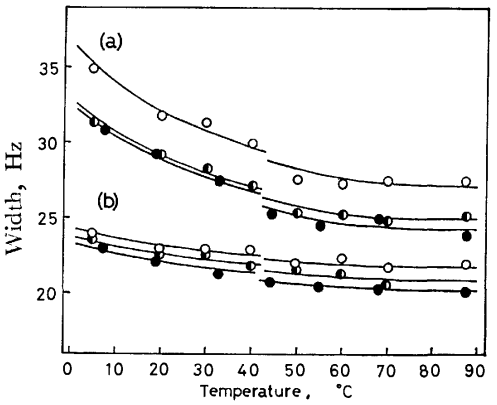

Fig. 4. Half height widths of Peaks of *ortho* protons(a) and *meta* protons(b) as a function of temperature. ○: 15-Polymer, ◐: 24-polymer, ●: 46-polymer.

From the above considerations, some interpretations for the temperature dependence of the width for phenyl absorptions can be drawn: (a) The polymer chains occupy stable conformations (TTTT, GTTT, and TGTT) at low temperatures; in these conformations the proton (H_2) has a different chemical shift from that of the proton (H_6). The overlap of the absorptions of H_2 and H_6 results in a broader absorption. (b) When the temperature is raised, the fractions of these conformations decrease, and the line widths decrease steeply. (c) The difference in the chemical shifts of *m*-H in any conformation is small, and such strong broadening as appeared in *o*-H is not observed.

These interpretations for the temperature dependence of the width are compatible with the conclusions drawn from the temperature dependence of chemical shifts.

Line Width and Molecular Weight. Figure 4 shows $\Delta H_{1/2}$ for phenyl absorptions of 15-, 24-, and 46-polymer as a function of temperature. The molecular weight dependence of $\Delta H_{1/2}$ for *m*-H absorption is small. While the $\Delta H_{1/2}$ values for *o*-H absorption of 24-polymer are similar to those of 46-polymer, those of 15-polymer are considerably different from those of 24- and 46-polymer and are anomalously large (the anomalous broadening was also observed in spectra of a polymer of lower molecular weight, $\overline{DP}$: 9.9). This phenome-

non is contrary to the well-known fact that line widths of spectra of polymers generally increase with the increase of molecular weights.

If the molecular weight distribution of 15-polymer sample is assumed to be broader than those of other samples, the sample would give a broader absorption. As shown in the absorption of aliphatic protons, if the chemical shift of phenyl protons in terminal monomer units differs from that of nonterminal monomer units and if these absorptions overlap, then the absorption of aromatic protons may become broad. This effect would be effective in the sample of low molecular weight (15-polymer). However, the anomalous broadening cannot be attributed to such effects as described above, because the anomalous broadening is observed only in *o*-H absorption and is not observed in *m*-H absorption.

As described in preceding sections, the ring current effect played an important role in understanding the PMR spectra of poly(*p*-chlorostyrene). The anomalous broadening observed in 15-polymer may also be related to the shielding effect. The temperature dependence of the chemical shift and the half height width was interpreted in terms of the preferred conformations listed in Table 1. The molecular weight dependence of the widths (the anomalous broadening) cannot be interpreted in terms of these conformations. The conformations listed in Table 1 are preferred conformations for polymers of low or high molecular weight; however, short chains could also occupy other conformations than these. For example, in shoft chains side groups are able to escape from each other, whereas in long chains such conformations are limited by steric restrictions. Since shielding is a function of conformations, the conformations which are permissible only in short chains ("permissible conformation"), produce somewhat different shielding from the shielding for the conformations listed in Table 1, and the existence of the permissible conformations must result in a broadening of spectra. As described in the preceding section, the ring current effect is effective for *o*-H and almost without effect for *m*-H; therefore, the broadening should be observed in the absorption of *o*-H.

On the basis of the above considerations, we can draw some reasonable interpretations for the PMR spectra of 15-, 24-, and 46-polymer. (a) The 15-polymer can occupy some conformations which are not permissible in polymers of higher molecular weight, and its *o*-H absorption shows the anomalous broadening owing to the absorptions arising from the so-called "permissible conformations"; the anomalous broadening can be interpreted only by the assumption of such conformations. (b) On the other hand, in the cases of 24- and 46-polymer, the conformations of the chains are just about limited to those listed in Table 1, and the anomalous broadening is not observed in the spectra of these polymers. The limitation of conformations in polymer chains might correspond to the phenomena called the "polymeric effect" cited at the beginning of this paper.

The assumption of permissible conformations does not disturb the interpretations for the temperature dependence of chemical shifts and half height widths given in preceding sections.

Far Infrared Spectra of Solid 1,2-Dihalogenoethane

Jiro HIRAISHI

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received April 7, 1976)

Far infrared spectra are measured for solid 1,2-dichloro-, dibromo-, and diiodoethane at several temperatures. The translational lattice vibrations of the crystals are observed for both high and low temperature phases. The observed frequencies of the low temperature phase of 1,2-dichloroethane agreed with the frequencies calculated by Mizushima *et al.* (Ref. 5). The nature of the phase transition is discussed on the basis of the temperature dependence of the spectra. The low frequency Raman spectrum of 1,2-diiodoethane is also reported.

Solid 1,2-dichloroethane and 1,2-dibromoethane undergo phase transitions at 177.0 and 249.49 K, respectively.[1] Lipscomb *et al.*[2] studied the X-ray diffraction of the high temperature phase (α phase) as well as the low temperature phase (β phase) of 1,2-dichloroethane and concluded that in the α phase either the molecule rotates freely or the orientation of the molecule around its Cl–Cl axis is disordered. The nature of the phase transition has been discussed in terms of Raman spectroscopy by several investigators.[3–6] For 1,2-dichloroethane, Ozora, *et al.* observed the low frequency Raman bands at several temperatures and concluded that the molecule rotates freely in the α phase.

For 1,2-dibromoethane, we reported the temperature dependence of the low frequeycy Raman bands due to the rotational lattice vibrations and showed that the nature of its phase transition is similar to that of 1,2-dichloroethane, although the crystal structure of its α phase is probably different from that of the β phase of 1,2-dichloroethane.[6]

The space group of the β phase of 1,2-dichloroethane is $C_{2h}{}^5$—$P2_1/c$; a unit cell contains two molecules.[2] The lattice vibrations at the center of the Brillouin zone are classified into $3a_g+3b_g+2a_u+b_u$. The vibrations of the a_g and b_g species are rotational modes and are Raman active, while those of the a_u and b_u species are translational modes and are infrared active. Ozora *et al.*[4] and Mizushima *et al.*[5] calculated the optically active lattice vibrations on the basis of Buckingham-type potentials between intermolecular atoms. They used the frequencies of the rotational lattice vibrations. No infrared study of the translational modes has been made in detail. Durig *et al.*[3] reported a very weak band at 50 cm^{-1} for 1,2-dichloroethane in the far infrared spectrum.

Hassel and Hveding[7] reported that solid 1,2-diiodoethane undergoes a rotational phase transition at 25.8 °C. However, no vibrational spectroscopic study has been made of the lattice vibrations of the crystal. In the present paper the far infrared spectra of solid 1,2-dichloroethane, 1,2-dibromoethane, their deuterated compounds, and 1,2-diiodoethane were studied at several temperatures in order to obtain information about the relation between translational lattice vibrations and the phase transition.

Experimental

Far infrared spectra were measured by use of a Hitachi model 070 interferometer. A cryostat equipped with a small refrigerator, Cryomech model GB03, was used for the measurements at low temperatures. Liquid samples were sealed into polyethylene cells of about 1 mm thickness. The translational lattice vibrations are very weak in the infrared spectra, because 1,2-dihalogenoethane molecules have a *trans* form in the solid state and have no dipole moment. For this cell thickness the bands due to intramolecular vibrations were completely saturated. The resolution used for the measurements was 0.65, 1.3, or 2.6 cm^{-1}, depending on the width of the bands. The temperature at the polyethylene cell was measured by use of an Au (with 0.07 atomic % Fe) chromel thermocouple obtained from Osaka Sanso Inc., which was calibrated by the calibrated GaAs thermometer of Lake Shore Cryogenics Inc. The temperature was kept constant within 0.5 K during the measurement of one interferogram. Although it reached approximately 13 K at the sample holder (made of copper), the temperature at the cell was about 65 K, because of the low thermal conductivity of the polyethylene plates.

The spectra of 1,2-diiodoethane was measured by use of a silicon plate with the cell thickness of about 0.5 mm. Commercially available 1,2-diiodoethane powder was used for the measurements, after subliming several times.

Results and Discussion

1,2-Dibromoethane. Figure 1 shows the far infrared spectra of 1,2-dibromoethane at several temperatures. At 69 K three bands at 51.1, 42.8, and 37.0 cm^{-1} were observed. The crystal structure of 1,2-dibromoethane has not yet been studied in detail. Reeds and and Lipscomb[2b] quoted the work by Meerman and

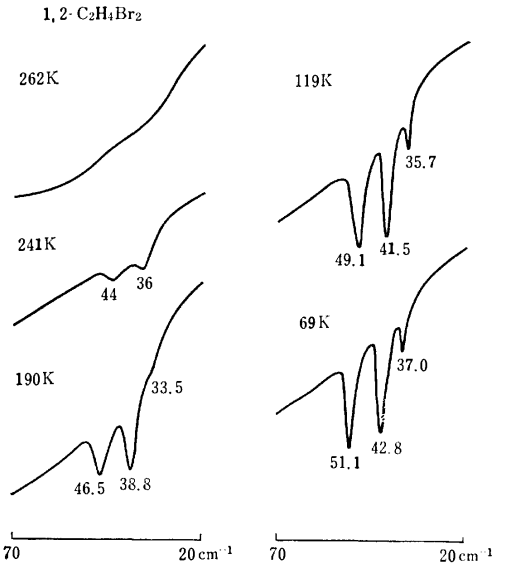

Fig. 1. Far infrared spectra of solid 1,2-$C_2H_4Br_2$.

stated that the crystal structure of the β phase of 1,2-dibromoethane was similar to that of 1,2-dichloroethane. Three bands owing to the translational lattice vibrations are expected to appear in the infrared spectra in the space group of C_{2h}^5 with two molecules in a unit cell. The present result does not contradict the statement by Reeds and Lipscomb. The spectra of 1,2-$C_2D_4Br_2$ were also measured and three bands at 50.8, 42.6, and 37.0 cm^{-1} were observed at 70 K. The small isotopic shifts are consistent with the assignments of the bands to translational lattice vibrations. The spectra of 1,2-dichloroethane show only two bands below 100 cm^{-1}, as will be seen later. The very weak band at 37.0 cm^{-1} may be assigned to an impurity. However, it did not decrease in intensity after the sample was purified by means of a spinning band fractional distillation column made by Tokyo Kagakuseiki Co., Ltd.

1,2-Dichloroethane. Two bands at 62.8 and 51.1 cm^{-1} were observed for 1,2-dichloroethane at 67 K (62.3 and 50.3 cm^{-1} for 1,2-$C_2D_4Cl_2$), as shown in Fig. 2, although three bands were expected, as noted above. Since the band of the lowest frequency of 1,2-dibromoethane is very much weaker than the others, it can be assumed, in the case of 1,2-dichloroethane, that the lowest frequency band is too weak to be observed.

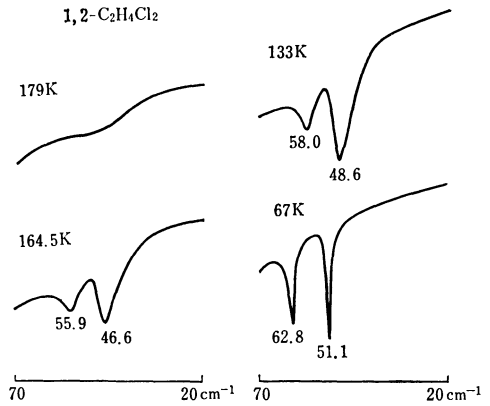

Fig. 2. Far infrared spectra of solid 1,2-$C_2H_4Cl_2$.

Ozora, *et al.*,[4] and Mizushima *et al.*[5] calculated the optically active lattice vibrations of 1,2-dichloroethane on the basis of the crystal structure at 133 K. According to their calculations, the third missing band may appear in the frequency region higher than 70 cm^{-1}. We could not detect the band in the frequency region lower than 150 cm^{-1}; here silicon plates were used instead of polyethylene sheets for the cell and windows, with the cell thickness of about 2 mm, to eliminate the interference of the band at 72 cm^{-1} from the polyethylene plates. In these calculations, the first derivatives of potential functions are neglected. Pomposiello *et al.* calculated the effect of the first derivatives on lattice vibrations of several molecular crystals including *trans*-1,2-dichloroethane.[8] Their result indicates that the frequencies of the translational lattice vibrations are not affected significantly by the first derivatives in the case of 1,2-dichloroethane and thus cannot eliminate the apparent discrepancy between the two possibilities concerning the assignment of the third missing band. In Table 1 the observed frequencies are assigned, tentatively, according to the calculation by Mizushima *et al.*

1,2-Diiodoethane. Four bands (176, 136, 41.5, and 33.5 cm^{-1}) were observed below 200 cm^{-1} at 288.5 K. The bands at 176 and 136 cm^{-1} are assigned to the CCl bending (b_u species) and the torsional vibrations (a_u species), respectively. The other bands are very weak and are assigned to the intermolecular vibrations. The space group of solid 1,2-diiodoethane is C_{2h}^5 [7,9] and three translational lattice vibrations are infrared active. The spectra at various temperatures are shown in Fig. 3. Only two bands were observed

at the low temperature phase, as in the case of 1,2-dichloroethane.

Phase Transition and Translational Lattice Vibrations. Table 2 shows the frequencies of the lattice vibrations of 1,2-dibromoethane at several temperatures. The frequencies of the translational lattice vibrations in the β phase decrease upon approaching the transition temperature. Their behavior is similar to that of the lower frequency rotational modes. The highest frequency rotational mode is the libration around the Br–Br axis; this is the most unharmonic among the observed optically active lattice vibrations.

Above the transition temperature the absorption band is very broad for 1,2-dichloroethane as well as for 1,2-dibromoethane. As the crystal structure of the α phase of 1,2-dichloroethane is similar to that of the β phase, three translational lattice vibrations are also expected in the infrared spectra for the α phase, if the molecules rotate freely in the α phase. Figure 1 indicates that the spectra are not continuous at the transition temperature, which can be explained more plausibly in terms of the orientational disorder in the α phase. As Bertie and Whally discussed,[10] the $k=0$ selection rule is not applicable to an orientationally disordered crystal. Schwartz and Ron reported a similar discontinuity in the far infrared spectra at the transition temperature for acetylene[11] and cyclohexane crystals.[12] Chlorocyclopentane crystal also exhibits a very broad band in the disordered phase.[13]

1,2-diiodoethane crystal shows a continuous spectral change near the transition temperature, as given in Fig. 3. The transition temperature was confirmed to be 298.6 K, using DTA equipment from Rigaku Denki Co., Ltd.; this agreed well with the value reported by Hassel and Hveding.[7] The result of Fig. 3 is different from those of other crystals near the order-disorder transition, as discussed above; this can be explained in terms of free rotation of molecules in the high temperature phase of 1,2-diiodoethane.

Raman Spectrum of 1,2-Diiodoethane. The Raman spectrum of 1,2-diiodoethane was also measured by use of a Cary 82 spectrophotometer, with the 647.1 nm line of a Kr^+ laser as a source. Three bands at 43.5, 36.7, and 17 cm^{-1} were observed at approximately 290 K, as is shown in Fig. 4. 1,2-Dibromoethane and 1,2-dichloroethane[4] crystals show three rotational

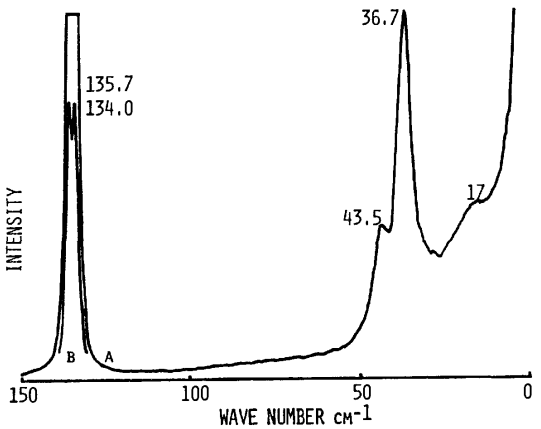

Fig. 4. Raman spectra of solid 1,2-$C_2H_4I_2$.
(A) $\Delta\nu=0.5\ cm^{-1}$. 5000 counts/full scale. (B) $\Delta\nu=0.2\ cm^{-1}$. 1000 counts/full scale. 134.0 and 135.7 cm^{-1} bands are assigned to the intramolecular CCI deformation vibrations (a_g and b_g species).

lattice vibrations in the Raman spectra, except for the rotational band around the halogen–halogen axis. Considering the results of 1,2-dichloro- and 1,2-dibromoethane crystals, the rotational band around the I–I axis is expected to be too weak and too broad to be observed at this temperature.

The author greatly acknowledges the measurement of the Raman spectrum of 1,2-diiodoethane by Dr. J. Shimada of Central Research Laboratory, Hitachi, Ltd. The author also acknowledges the help with the DTA measurement given by Dr. K. Hayamizu of National Chemical Laboratory for Industry.

Magnetic Circular Dichroism Studies on *o*-, *m*-, and *p*-Nitroanilines and *o*-, *m*-, and *p*-Aminobenzoic Acids

Akira KAITO, Akio TAJIRI, and Masahiro HATANO

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received April 9, 1976)

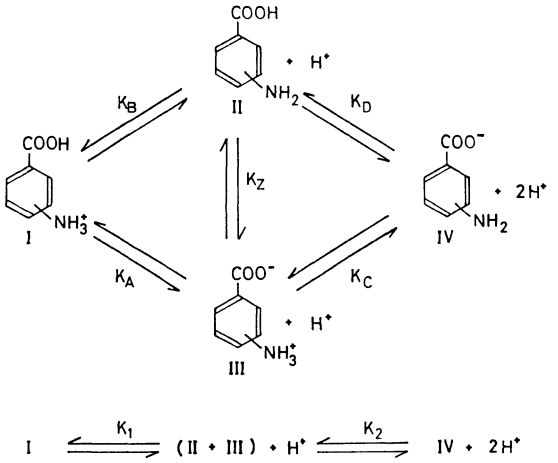
The MCD and UV spectra of *o*-, *m*-, and *p*-nitroanilines and *o*-, *m*-, and *p*-aminobenzoic acids were measured. Some ambiguous absorption bands, which strongly overlap each other, can be separated in the MCD spectra. The Faraday *B* terms were calculated using wave functions obtained from the Pariser-Parr-Pople (PPP) method; the values are in good agreement with the experimental values derived from the MCD spectra. The spectral assignments are discussed not only by comparing the excited states of nitroanilines and aminobenzoic acids with those of benzene itself, but also by taking account of the electron migration between the benzene ring and the substituent groups. On the other hand, it turns out from the measurements of the MCD spectra that the zwitterion, $C_6H_4(NH_3^+)CO_2^-$, exists in aqueous solutions of *o*- and *m*-aminobenzoic acids.

The magnetic circular dichroism (MCD) technique has been shown to be useful for elucidating the magnetic moments in the degenerate electronic states and for analyzing the electronic spectra.[1-4] For highly symmetrical molecules, we can expect the Faraday *A* and *C* terms originating from the Zeeman splitting of the degenerate ground and excited states. On the other hand, only the Faraday *B* term, due to the mixing of the electronic states by the external magnetic field, is present for the molecules of lower symmetry.

The MCD spectra of substituted benzenes have been extensively investigated,[5-11] because the experimental results are sensitive to the substituents' effects. However, only slight attention has been paid to the MCD of the benzenes containing both electron-donating and electron-accepting substituents, whose electronic spectra are characterized by the appearance of an intense absorption band in the lower wave number region (25000—40000 cm^{-1}). The dissimilarity of the electronic spectra of these benzene derivatives from that of benzene itself is considered to be based on the fact that some intramolecular charge-transfer transitions have been found in the former along with the $\pi \rightarrow \pi^*$ transitions of the benzene ring. Tanaka[12] has given the spectral assignments of *p*-nitroaniline by measuring the polarized absorption spectrum of single crystals of *p*-nitroaniline. Some bands which are ambiguous and hidden in solution become evident in the crystalline spectrum.

On the other hand, the MCD technique is occasionally used for elucidating the complicated electronic spectra of ions and molecules. The strongly overlapping absorption bands of some aromatic organic compounds[13] have been separated, and the hidden transitions of substituted biphenyls[14] have been detected in the MCD spectra. It is one of the purposes of this work to apply the MCD technique to clarification of the ambiguous and complicated electronic spectra of *o*-, *m*-, and *p*-nitroanilines and *o*-, *m*-, and *p*-aminobenzoic acids.

In aqueous solutions of *o*-, *m*-, and *p*-aminobenzoic acids, there seem to exist four chemical species in equilibria, as shown in the diagram below.



The ionization constants, K_1 and K_2, have been determined experimentally by the titration method.[15] Some investigators[15,16] have estimated the equilibrium constant, K_z, for ionization of neutral aminobenzoic acid (II) to the zwitterion (III). However, it is difficult to recognize the existence of the zwitterion (III) with the aid of the usual spectroscopic methods, such as absorption spectroscopy. This is because the absorption spectra of aminobenzoic acids are so complicated that the bands characteristic of the zwitterion (III) are hidden behind the bands due to other species of aminobenzoic acids. Another purpose of this work is to analyze the complicated electronic spectra of aminobenzoic acids in aqueous solutions in various pH ranges on the basis of the signs of the MCD spectra, and to show the existence of the zwitterion (III) in aqueous solutions.

Experimental

o-, *m*-, and *p*-Nitroanilines and *o*- and *p*-aminobenzoic acids were purified by recrystallization from water-ethanol. *m*-Aminobenzoic acid was sublimed after recrystallization from water. The MCD and UV spectra were measured with a JASCO J-20A recording spectropolarimeter equipped with a 12.5 kG electromagnet and with a Hitachi EPS-3T recording spectrophotometer, respectively. The experimental Faraday *B* terms were obtained by the use of the following equation:

$$B = -(1/33.53\nu_{max}) \int_{band} [\theta]_M d\nu \qquad (1)$$

Theoretical

The electronic transition energies and the Faraday *B* terms of nitroanilines and aminobenzoic acids were

calculated by the Pariser-Parr-Pople (PPP) approximation,[17] including configuration interactions (CI) among all singly excited configurations. One-center electron repulsion integrals and one-center core integrals were evaluated from valence state ionization potentials and electron affinities. The Nishimoto-Mataga[18] method was used for the estimation of two-center electron repulsion integrals. The resonance integrals were calculated in accordance with the Wolfsberg-Helmholtz equation.[19]

The Faraday B terms of a transition $j \leftarrow a$ is given by[1-4]

$$B_{a\to j} = \mathrm{Im}\{\sum_{k\neq a} (\langle k|\boldsymbol{\mu}|a\rangle/(E_k - E_a)) \cdot \langle a|\boldsymbol{m}|j\rangle \times \langle j|\boldsymbol{m}|k\rangle + \sum_{k\neq j} (\langle j|\boldsymbol{\mu}|k\rangle/(E_k - E_j)) \cdot \langle a|\boldsymbol{m}|j\rangle \times \langle k|\boldsymbol{m}|a\rangle\}, \quad (2)$$

where $\boldsymbol{m}$ and $\boldsymbol{\mu}$ stand for the magnetic and electric dipole moment operators, respectively, and E_a, E_j, and E_k are the energies of states, a, j, and k, respectively. The electric transition moments in Eq. 2 were evaluated by the use of the dipole length operator, $\boldsymbol{r}$, and the dipole velocity operator, $\boldsymbol{\nabla}$. The orthogonalized atomic orbital obtained by the Löwdin procedure[20] was used for the calculation of the magnetic and electric moments in Eq. 2.

It is known that the Faraday B terms calculated for a noncentric molecule using a limited basis set are origin dependent.[7,21] Caldwell and Eyring[7] have suggested that the error introduced by employing a limited basis set is minimized at the center of charge density. Accordingly, the origin is chosen at the center of charge of the ground state in this work.

Calculations were carried out using the NEAC 2200 computer in the computer center of Tohoku University.

Results and Discussion

The MCD (A) and UV (B) spectra of o- and m-nitroanilines are shown in Figs. 1 and 2. The single absorption band of m-nitroaniline observed in the higher wave number region (38000—48000 cm^{-1}) is split into two in the MCD spectrum, whereas the MCD spectrum of o-nitroaniline is weak and ambiguous in this spectral region.

The MCD and UV spectra of p-nitroaniline are shown in Fig. 3. In the region of 33000—39000 cm^{-1}, one can see a positive MCD band originating from the second $\pi\to\pi^*$ transition, which is obscured by the first intense $\pi\to\pi^*$ transition in the absorption spectrum. Two MCD bands appear with opposite signs in the higher wavenumber region (39000—48000 cm^{-1}), although these transitions are strongly overlapping in the absorption spectrum.

Figures 4—6 show the MCD and UV spectra of o-, m-, and p-aminobenzoic acids in heptane–dioxane (9 : 1 in volume) solution, in which only the neutral aminobenzoic acid (II) may be stable. p-Aminobenzoic acid exhibits negative and positive MCD bands at 33800 and at 36800 cm^{-1}, respectively, while a single absorption band appears in this spectral region. Each sign of the MCD spectra of o- and m-aminobenzoic acids is the same as that of p-aminobenzoic acid.

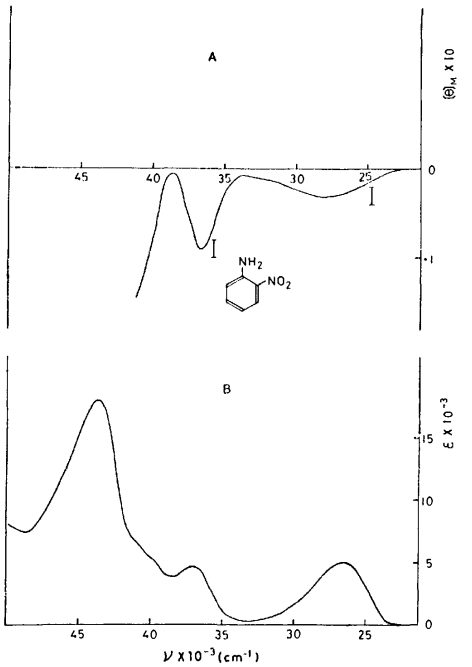


Fig. 1. MCD (A) and UV (B) spectra of o-nitroaniline in heptane solution at room temperature.

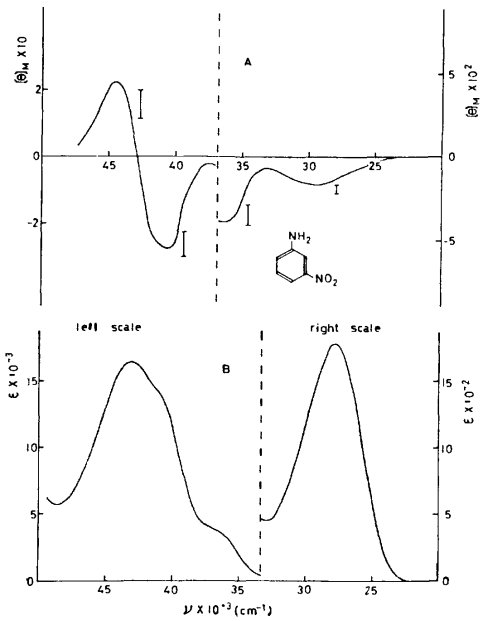

Fig. 2. MCD (A) and UV (B) spectra of m-nitroaniline in heptane-dioxane (9 : 1 in volume) solution at room temperature.

Thus, the MCD technique can be said to be a useful tool for elucidating the ambiguous absorption bands which are strongly overlapping in the absorption spectra. Three or four electronic transition scan be identified in the MCD and absorption spectra of nitroanilines and aminobenzoic acids.

The observed and calculated transition energies and Faraday B terms are summarized in Table 1, where

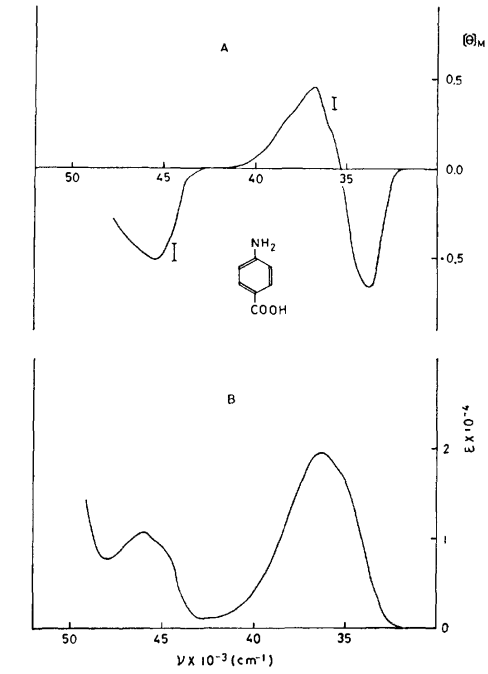

Fig. 6. MCD (A) and UV (B) spectra of *p*-aminobenzoic acid in heptane-dioxane (9 : 1 in volume) solution at room temperature.

$B_{\text{calcd}}(\boldsymbol{r})$ and $B_{\text{calcd}}(\boldsymbol{\nabla})$ denote the calculated Faraday B terms whose electric moment matrices are evaluated by the use of the dipole length and dipole velocity operators, respectively. The calculated transition energies are in good agreement with the observed values. The theoretical Faraday B terms also show fairly good agreement with the experimental values both in sign and in magnitude, except for the second $\pi \rightarrow \pi^*$ transitions of *o*- and *m*-nitroanilines. For these Faraday B terms of *o*- and *m*-nitroanilines, a large negative contribution from the mixing with the fourth excited state and a large positive contribution from the mixing with the first, third, and other higher excited states cancel each other. Therefore, it seems to be difficult to predict accurately the signs of these Faraday B terms of *o*- and *m*-nitroanilines.

It may be interesting to relate the excited states of nitroanilines and aminobenzoic acids to those of benzene

itself. The lowest four excited states of benzene are expressed as

$$|^1B_{2u}\rangle = (1/\sqrt{2})[\Psi(\phi_x\rightarrow\phi_\xi) - \Psi(\phi_y\rightarrow\phi_\eta)], \quad (3)$$

$$|^1B_{1u}\rangle = (1/\sqrt{2})[\Psi(\phi_x\rightarrow\phi_\eta) + \Psi(\phi_y\rightarrow\phi_\xi)], \quad (4)$$

$$|^1E_{lux}\rangle = (1/\sqrt{2})[\Psi(\phi_x\rightarrow\phi_\xi) + \Psi(\phi_y\rightarrow\phi_\eta)], \quad (5)$$

$$|^1E_{luy}\rangle = (1/\sqrt{2})[\Psi(\phi_x\rightarrow\phi_\eta) - \Psi(\phi_y\rightarrow\phi_\xi)], \quad (6)$$

where $\Psi(\phi_x\rightarrow\phi_\xi)$ is a configuration in which one electron is excited from the molecular orbital, ϕ_x to ϕ_ξ, and ϕ_x, ϕ_y, ϕ_ξ, and ϕ_η stand for the highest occupied and the lowest vacant orbitals and transform like X, Y, $(X^2-Y^2)/2$, and XY, respectively. Nitroanilines and aminobenzoic acids have six occupied orbitals $\phi_1,\cdots,\phi_6$, and four vacant orbita ls$\phi_7,\cdots,\phi_{10}$. As shown in Fig. 7, the highest occupied orbital ϕ_6 consists of ϕ_y and the nonbonding orbital of the amino group. The molecular orbitals ϕ_5 and ϕ_8, correspond to ϕ_x and ϕ_η of benzene itself. The molecular orbitals ϕ_7 and ϕ_9, are expressed as linear combinations of ϕ_ξ and the lowest vacant orbital of the nitro or carboxyl group. Coefficients of the main configurations in each excited state are given in the third column of Table 2.

On the other hand, the displacement of the charge distribution associated with each transition should be taken into account. If the magnitude of the net charge density on a substituent group or on the benzene ring is larger than 0.5, the intramolecular charge-transfer configuration between the benzene ring and the substituent group is considered to be predominant. The calculated net charge densities on the phenyl, amino, and nitro or carboxyl groups in each excited state are listed in the fourth column of Table 2.

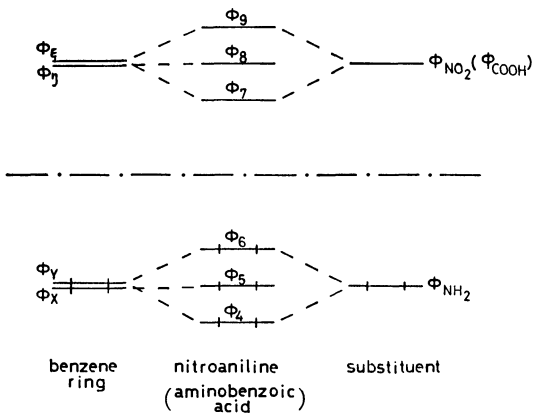

Fig. 7. Interaction of the highest occupied and the lowest vacant molecular orbitals of the benzene ring with the orbitals of the substituent groups.

The first $\pi\rightarrow\pi^*$ transitions of *o*-, *m*-, and *p*-nitroanilines can be assigned to the intramolecular charge-transfer band between the anilino and nitro groups; this can be also verified by the fact that large solvent effects are observed for these transitions. The first excited states of *o*- and *m*-aminobenzoic acids and the second excited state of *p*-aminobenzoic acid consist of the $^1B_{1u}$ state of benzene and the intramolecular charge-transfer state between the amino and carboxyphenyl groups. The first excited state of *p*-aminobenzoic acid and the second excited states of other compounds are said to be the $^1B_{2u}$ state of benzene with an appreciable contribution from the intramolecular charge-transfer configuration. The fourth excited state

a) The coefficients of the most important configurations. $\Psi_{i\to k}$ is a configuration in which one electron is excited from ϕ_i to ϕ_k.

of *o*-aminobenzoic acid, and the third excited states of *m*- and *p*-aminobenzoic acids and *m*- and *p*-nitroanilines are composed of the $^1E_{lux}$ state of benzene and the intramolecular charge-transfer state. The former is predominant in *o*-, *m*-, and *p*-aminobenzoic acids, the latter in *m*- and *p*-nitroanilines.

The present assignment for *p*-nitroaniline is consistent with the results reported by Tanaka.[12] However, the second transition observed at about 37000 cm^{-1} in the crystalline spectrum is shifted to 34600 cm^{-1} in heptane–dioxane (9 : 1 in volume) solution.

As mentioned before, four ionic and molecular species are expected to be present in aqueous solutions of *o*-, *m*-, and *p*-aminobenzoic acids. The values of the experimental ionization constants,[15] K_1 and K_2, are listed in Table 3. The MCD and UV spectra of *o*- and *m*- aminobenzoic acids in aqueous solutions are presented in Figs. 8 and 9. As seen from Table 3, the MCD and UV spectra of aminobenzoic acids at pH 13 are due to aminobenzoate ion (IV), while the spectra at pH 0 or 1 correspond to those of protonated aminobenzoic acid (I). The solid lines in Figs. 8 and 9 express the MCD and UV spectra of *o*- and *m*-aminobenzoic acids, respectively, in acetic acid–sodium

acetate buffer solutions (pH's 4.1, 4.7), where neutral aminobenzoic acid (II), the zwitterion (III), and aminobenzoate ion (IV) are expected to coexist. Since the MCD and UV spectra of neutral aminobenzoic acid (II) and aminobenzoate ion (IV) are known and the MCD and UV spectra of the zwitterion (III) are expected to be analogous to those of benzoate ion (Fig. 10), it is possible to analyze the complicated MCD and UV spectra of *o*- and *m*-aminobenzoic acids in acetic acid–sodium acetate buffer solutions. The first positive MCD band observed in the region of 27000—36000 cm^{-1} is induced by the first $\pi \rightarrow \pi^*$ transitions of neutral aminobenzoic acid (II) and aminobenzoate ion (IV). The positive MCD band observed at about 37300 cm^{-1} is considered to be due to the first $\pi \rightarrow \pi^*$ transitions of the zwitterion (III), because of the resemblance to the MCD band of benzoate ion (Fig. 10). Thus, the electronic transitions of the zwitterion (III) of *o*- and *m*-aminobenzoic acids were detected in the MCD spectra. However, it is difficult to see from the MCD spectra whether the zwitterion (III) exists in an aqueous solution of *p*-aminobenzoic acid or not, because the MCD of neutral aminobenzoic acid (II) and aminobenzoate ion (IV) may be much stronger than that of the zwitterion (III) in *p*-aminobenzoic acid.

We conclude that the magnetic circular dichroism technique can be a useful tool for separating the overlapping absorption bands and for detecting the hidden transitions. An analysis of the MCD spectrum assisted by the PPP method allows us to elucidate the spectroscopic assignments. It is also concluded, from a detailed analysis of the MCD spectra of aminobenzoic acids in aqueous solutions, that the second positive MCD bands of *o*- and *m*-aminobenzoic acids in acetic acid–sodium acetate buffer solutions provide spectroscopic evidence for the existence of the zwitterion (III).

Reactions of Recoil ^{80}Br Activated by the (n, γ) Process with Some Gaseous Cyclanes (C_4—C_6)

Masakatsu SAEKI and Enzo TACHIKAWA

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki 319-11

(Received April 12, 1976)

The reactions of ^{80}Br from the (n,γ) process with cyclanes (C_4—C_6) have been systematically investigated. The primary products formed by the ^{80}Br-for-H reaction were excited and underwent at least two modes of unimolecular decomposition. One was the elimination of the H^{80}Br molecule, and the other was the cleavage of the ring, giving the corresponding bromo-olefin and olefin. The former process was important particularly in the lower-pressure end. Thus, the reaction was easily suppressed by increasing the pressure. However, the latter process showed a different feature; that is, the yields of the decomposition products stayed at an almost constant level over the whole pressure range studied. This indicates that a highly excited product decomposes preferentially through a ring-cleavage reaction. When the total organic yield from each reaction system was plotted against the carbon number of the reactant molecules, a linear correlation was obtained. After some possible consideration, it was concluded that the life of the intermediate complex might play a more important role in the reaction of ^{80}Br with cyclanes than the other factors. Some considerations about the radiolysis of the reactant molecule are also mentioned.

The primary products formed by hot atom reactions are usually excited by the kinetic energy introduced by the recoil atoms and undergo a subsequent decomposition. Studies of these decomposition processes are one of the methods which can be used to obtain information on the energetics of hot atom reactions.

In a previous paper[1] we investigated the unimolecular decomposition of excited (c-$C_3H_5{}^{80}Br$)* formed by the reaction of ^{80}Br from the (n, γ) process with cyclopropane (c-C_3H_6) and with bromocyclopropane (c-$C_3H_5{}^{80}Br$). The results showed that the median excitation energy of the primary product from the ^{80}Br-for-H reaction was higher than that from the ^{80}Br-for-Br reaction. It was also deduced that the rupture of the C–Br bond as part of the decomposition processes of the excited primary products is more important in the ^{80}Br-for-Br reaction than in the ^{80}Br-for-H reaction.

In the present work we investigated the reactions of ^{80}Br from the (n, γ) process with gaseous cyclanes of cyclobutane, cyclopentane, and cyclohexane (c-C_4H_8, c-C_5H_{10}, and c-C_6H_{12}); the stability of the ring increases in that order. The work has two prime objects. One is the determination of the relative importance of the ring-cleavage and the HBr-elimination in the decomposition of the primary products from these reactant molecules. The other is to clarify the systematics in the reactivities of cyclanes with the recoil bromine. For these purposes, the total organic yields at high pressures were carefully investigated.

Experimental

Materials. The target chemicals, c-C_4H_8, c-C_5H_{10}, and c-C_6H_{12}, were supplied by the Merck Sharp Co., the Tokyo Chem. Co., and the Nippon Rikagakuyakuhin Co. respectively. Their nominal purities are more than 99% for c-C_4H_8 and c-C_5H_{10} and more than 95% for c-C_6H_{12}. They were purified by means of an ordinary vacuum distillation method before use. The source molecules of the hot bromine atom, CF_3Br and CH_3Br, were purchased from the Matheson Co. and the Tokyo Chem. Co. The other reagents used, H_2S, O_2, Br_2, and I_2 were all of the highest purity available.

Sample Processing A quartz ampoule with a breakable seal was used as the reaction vessel. The required gases were placed in the ampoule utilizing a vacuum line. The CF_3Br was used as the source molecule for the c-C_4H_8 and c-C_5H_{10} systems, whereas CH_3Br was used for the c-C_6H_{12} system.

The JRR-4 reactor in JAERI was used as the neutron source. Samples were irradiated for 10—40 s in the T pipe, where the thermal neutron flux was 3×10^{12} n cm^{-2} s^{-1}.

Within 15 min after the end of irradiation, the irradiated samples were injected directly into a radio-gas chromatograph by the help of a vacuum line. The separation columns used were DOP column, Neopak 1A of 60/80 mesh coated with 15% dioctyl phthalate, and a silicone column, Shimalite C of 30/80 mesh coated with silicone DC 550+stearic acid. The DOP and silicone columns, both 5 m long, were used for the c-C_4H_8 and c-C_5H_{10} systems and a short DOP column, 2.8 m, for the c-C_6H_{12} system. In the operation, the temperature of the columns was raised from room temperature to 115 °C at the rate of 8 °C min^{-1}.

The products were usually identified by comparing their retention times with those of commercial bromides. When the compounds will not be commercially available, the products were identified by applying a relationship between the boiling points and the retention times previously established[1] Furthermore, the unsaturated products, such as CH_2-$CHCH_2Br$ and C_4H_7Br, were assigned on the basis of the vanishing of their radioactivities in the radiochromatogram upon the addition of inactive Br_2 to the sample after its irradiation.

The absolute yields of the products were determined by a comparative method, using Ar as the internal standard; the details of the method were described elsewhere.[1]

Results

c-C_4H_8 System. In the reactions of ^{80}Br with c-C_4H_8, we added as a scavenger O_2, H_2S, I_2, or a mixture of H_2S+O_2. The chief products were c-$C_4H_7{}^{80}Br$, $CH_2CH^{80}Br$, $CH_3{}^{80}Br$ and $C_4H_7{}^{80}Br$.[2] As minor products, $C_2H_5{}^{80}Br$, i-$C_3H_7{}^{80}Br$, n-$C_3H_7{}^{80}Br$, and others were also detected. When the scavenger was changed from the above substances to Br_2, however, the unsaturated products disappeared and some polybromo-products, such as $CH_2BrCH_2{}^{80}Br$, $CH_2{}^{80}BrBr$, and $CH^{80}BrBr_2$, became detectable.

From careful studies of the scavenger effects of O_2, H_2S, I_2, H_2S+O_2 or Br_2, it was concluded that the 2 : 3 mixture of H_2S and O_2 was the most suitable additive to suppress the thermal reaction of ^{80}Br. The scavenger of Br_2 made the unsaturated products undetectable. In the I_2 scavenging experiments, the identification of the products became difficult, because some products labelled by ^{128}I were also produced. The amount of O_2 or H_2S sufficient for the complete suppression of thermal reactions far exceeded 10 mol % of the reaction system. Thus, in the subsequent experiments, the mixture of H_2S and O_2 was used as the scavenger.

Table 1 shows the percent yields of the products at the system pressure of 600 Torr (1 Torr=133.3 Pa); the compositions of the gases are also given in the table. The products have been grouped into two different categories; one, the scavenger-insensitive group, includes $CH_2CH^{80}Br$, $C_4H_7{}^{80}Br$, i-$C_4H_9{}^{80}Br$, and c-$C_4H_7{}^{80}Br$, while the other, the scavenger-sensitive group, includes $CH_3{}^{80}Br$, $C_2H_5{}^{80}Br$, i-$C_3H_7{}^{80}Br$, and n-$C_3H_7{}^{80}Br$. The yields of the products in the latter group and that of $CH_2CH^{80}Br$ showed no clear pressure-dependence and were constant at the values shown in Table 1 within an experimental uncertainty from 151 to 798 Torr. On the contrary, the yields of all the products in the former group except $CH_2CH^{80}Br$ showed a rather significant dependence on the system pressure from 151 to 798 Torr: from 0.27 to 0.6% for $C_4H_7{}^{80}Br$, from 0.05 to 0.15% for i-$C_4H_7{}^{80}Br$, and from 1.84 to 2.42% for c-$C_4H_7{}^{80}Br$.

Due to the limitation of the vapor pressure of c-C_4H_8, the system pressure above 800 Torr was only attained by adding ethane as a pressure-builder; *e.g.*, four times as much ethane as c-C_4H_8 were added to the reaction system. Figure 1 shows the dependences of the c-$C_4H_7{}^{80}Br$ and $CH_2CH^{80}Br$ yields on the system pressure with and without a pressure-builder. In the presence of ethane, the $CH_2CH^{80}Br$ yield was already corrected for the small amount of that from ethane according to the method to be described in the next section.

Table 1. Absolute yields of products in the c-C_4H_8 system

Product	Yield (%)
$CH_2CH^{80}Br$	0.93±0.04
$C_4H_7{}^{80}Br$	0.66±0.12
i-$C_4H_9{}^{80}Br$	0.19±0.04
c-$C_4H_7{}^{80}Br$	2.24±0.03
$CH_3{}^{80}Br$	0.31±0.02
$C_2H_5{}^{80}Br$	0.09±0.01
i-$C_3H_7{}^{80}Br$	0.06±0.01
n-$C_3H_7{}^{80}Br$	0.10±0.02

Composition of gases
c-C_4H_8 : 520 Torr
CF_3Br : 10 Torr
$H_2S + O_2(2 : 3)$: 60 Torr
Ar : 10 Torr
Total pressure : 600 Torr.

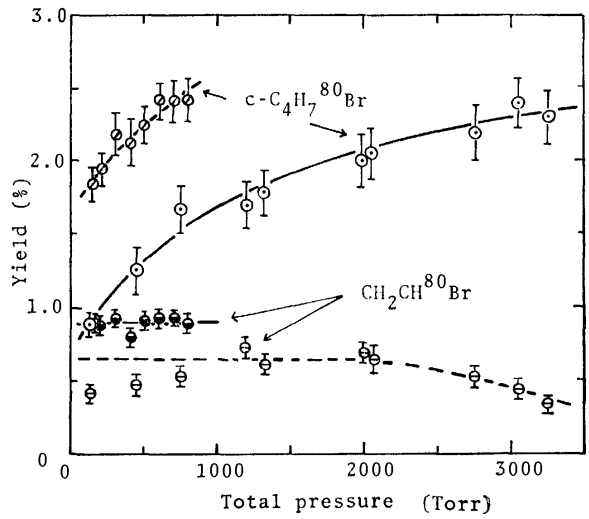

Fig. 1. Pressure-dependences of main products in c-C_4H_8 system.
In the presence of ethane; ⊙: c-$C_4H_7{}^{80}Br$, ⊖: $CH_2CH^{80}Br$.
In the absence of ethane; ∅: c-$C_4H_7{}^{80}Br$, ◒: $CH_2CH^{80}Br$.

c-C_5H_{10} System. In the c-C_5H_{10} system, the mixture of H_2S and O_2 was also used as a scavenger. The products in this system are c-$C_5H_9{}^{80}Br$, $CH_2CH^{80}Br$, $CH_2CHCH_2{}^{80}Br$, $CH_3{}^{80}Br$, and $C_4H_7{}^{80}Br$.[2] The percentage yields of these products at 400 Torr are listed in Table 2, along with the experimental conditions. Figure 2 shows the yield variations in c-$C_5H_9{}^{80}Br$, $CH_2CHCH_2{}^{80}Br$, and $CH_2CH^{80}Br$ as a function of the pressure. Ethane was also added to the reaction system as a pressure-builder in the proportion of 4 to 1. Among these products, c-$C_5H_9{}^{80}Br$ is the only product showing a pressure dependence; the yield increases significantly with the pressure at the beginning and then tends to level off.

c-C_6H_{12} System. In order for one of the main products, c-$C_6H_{11}{}^{80}Br$, to elute with a reasonable retention time, a short DOP column (2.8 m) was used for this system. Unfortunately, this column did not provide a quantitative separation of Ar and CF_3Br. Thus, the source molecule was converted from CF_3Br

Table 2. Absolute yields of products in the c-C_5H_{10} system

Product	Yield (%)
c-$C_5H_9{}^{80}Br$	0.76±0 10
$CH_2CH^{80}Br$	0.23±0.03
$CH_2CHCH_2{}^{80}Br$	0.30±0.03
$CH_3{}^{80}Br$	0.16±0.02
$C_2H_5{}^{80}Br$	0.03±0.01
$C_4H_7{}^{80}Br$	0.06±0.01

Composition of gases
c-C_5H_{10} : 300 Torr
CF_3Br : 30 Torr
$H_2S + O_2(2 : 3)$: 40 Torr
Ar : 30 Torr
Total pressure : 400 Torr.

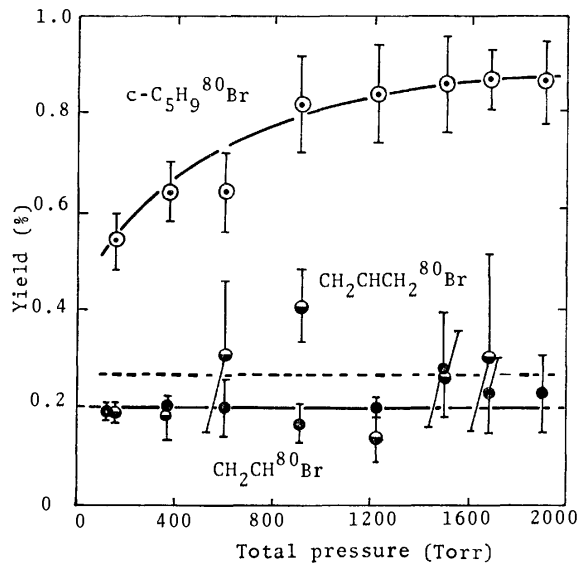

Fig. 2. Pressure-dependences of main products in *c*-C_5H_{10} system.
⊙: *c*-$C_5H_9{}^{80}Br$, ◒: $CH_2CHCH_2{}^{80}Br$, ●: $CH_2CH^{80}Br$.

to CH_3Br, on the basis of the fact that the change in the source molecule causes no significant difference in the results of the reaction of ^{80}Br from the (n, γ) process.[1]

The major products were *c*-$C_6H_{11}{}^{80}Br$, $CH_2CH^{80}Br$, and $C_4H_7{}^{80}Br$[2]; their relative yields were 1.0 : 06±0.2 : 0.6±0.2 at the system pressure of 120 Torr. Although $CH_3{}^{80}Br$ was also observed as a minor product, most of it resulted from the reaction of ^{80}Br with the source molecule. Thus, the quantitative determination of $CH_3{}^{80}Br$ from *c*-C_6H_{12} was not successful.

Discussion

Decomposition Pathways of Primary Products. When one considers the unimolecular decomposition of a primary product from a hot atom reaction, a knowledge of the decomposition mechanisms of the same compound in thermolysis and/or photolysis is very helpful. From the reported results,[3-8] the following decomposition pathways can be expected for the excited (*c*-$C_4H_7{}^{80}Br$)* and (*c*-$C_5H_9{}^{80}Br$)*:

$$(c\text{-}C_4H_7{}^{80}Br)^* \xrightarrow{S} c\text{-}C_4H_7{}^{80}Br \quad (1)$$
$$(c\text{-}C_4H_7{}^{80}Br)^* \xrightarrow{D_1} CH_2CH^{80}Br + C_2H_4 \quad (2)$$
$$(c\text{-}C_4H_7{}^{80}Br)^* \xrightarrow{D_2} H^{80}Br + C_4H_6(\diagup\!\!\diagdown) \quad (3)$$
$$(c\text{-}C_5H_9{}^{80}Br)^* \xrightarrow{S} c\text{-}C_5H_9{}^{80}Br \quad (4)$$
$$(c\text{-}C_5H_9{}^{80}Br)^* \xrightarrow{D_1} CH_2CH^{80}Br + C_2H_6 \text{ or } CH_2CHCH_2{}^{80}Br + C_2H_4 \quad (5)$$
$$(c\text{-}C_5H_9{}^{80}Br)^* \xrightarrow{D_2} H^{80}Br + c\text{-}C_5H_8 \quad (6)$$

Su *et al.* have studied the reactions of $^{80,82}Br$ from isomeric transitions with bromocyclobutane and cyclobutane.[9] However, their experimental measurements were limited to only two systems, in the gaseous phase at 800 Torr and in the liquid phase. Furthermore, they used O_2 as a scavenger and added O_2 to the reaction system in order to constitute 4 mol% of the total pressure. According to the present results, however, 4% of O_2 is not enough to reduce the non-energetic processes down to the limits of experimental uncertainty. Thus, very possibly, their results are contaminated to a significant extent by the thermal reactions.

In Fig. 1, the yield of $CH_2CH^{80}Br$ in the absence of ethane is constant within the limits of experimental uncertainties, at least up to the pressure of 800 Torr. In the presence of ethane, the $CH_2CH^{80}Br$ must be corrected for its formation from ethane. The separate experiments show that the $C_2H_5{}^{8}Br/CH_2CH^{80}Br$ ratio from ethane increases with the pressure from 6.9 at 100 Torr to 9.9 at 800 Torr. Above 800 Torr, this ratio stays constant at 9.9. Thus, the present correction is based on the assumption that these ratios are also maintained in the C_2H_6–*c*-C_4H_8 binary system. The corrected yield shows a broad maximum in the pressure range of 1000—2000 Torr. However, there is a tendency to decrease at pressures less than 1000 Torr, largely because of the uncertainty involved in the correction for the yield of $CH_2CH^{80}Br$ from ethane. Consequently, it can be considered that the yield of $CH_2CH^{80}Br$ is almost constant at pressures less than 2000 Torr, while above that point it seems to decrease slightly with the pressure.

On the other hand, the yield of *c*-$C_4H_7{}^{80}Br$ increases rapidly with an increase in the pressure at the beginning, followed by a gradual increase in the reaction systems both with and without ethane.

In the previous paper,[1] a correlation was found between the excitation energy of a primary product and the dissociation energy of a reacting bond. From the correlation, the excitation energy of the primary product formed by the ^{80}Br-for-H reaction is estimated to be around 5 eV. (The authors express the excitation energy in units of eV throughout this paper, 1 eV= 96.49 kJ mol^{-1}.) If the (*c*-$C_4H_7{}^{80}Br$)* either decomposes through Reaction 2 or stabilizes collisionally as Reaction 1, the ratio of the decomposition product and the stabilized one is calculated by applying the Kassel theory.[10] However, without any thermodynamic data for Reaction 2 available, we attempted to calculate the yield ratio using the values of A and E reported for *c*-C_4H_7Cl[3] with a value for the classical oscillators, S, of either $1/2(3N-6)$ or $2/3(3N-6)$. In these calculations, where the correct values are not used, the calculated results do not always agree quantitatively with the experimental results, but they can furnish qualitative view of the features of the decomposition-stabilization processes. The results obtained, however, are far from explaining the results shown in Fig. 1. This suggests the existence of decomposition processes other than Reaction 2.

On the thermolysis of *c*-C_4H_7Cl, Cocks and Frey reported that the activation energy of Reaction 7 was higher than that of Reaction 8:[3]

$$c\text{-}C_4H_7Cl \longrightarrow CH_2CH_2 + CH_2CHCl \quad (7)$$
$$E_a = 60.07 \pm 0.30 \text{ kcal mol}^{-1}$$
$$c\text{-}C_4H_7Cl \longrightarrow C_4H_6(\diagup\!\!\diagdown) + HCl \quad (8)$$
$$E_a = 55.24 \pm 0.19 \text{ kcal mol}^{-1}$$
$$(1 \text{ kcal mol}^{-1} = 4.184 \text{ kJ mol}^{-1})$$

They also investigated the pyrolysis of *t*-butylcyclobutane and reached the conclusion that this substrate is decomposed to ethylene and 3,3-dimethyl-1-butene.[7] Thomas *et al.* reported, in connection with thermal decomposition of methylcyclobutene, that the principal products were ethylene and propylene, and that the isomerization to 1-pentene accounted for 0.5—1.8% of the reaction.[6]

In the present case, therefore, the ring-opening reactions of the excited $(c\text{-}C_4H_7{}^{80}Br)^*$ to $C_4H_7{}^{80}Br$'s are not an important decomposition process. This consistent with the fact that the $C_4H_7{}^{80}Br$ yield has a positive dependence on the pressure. This means that the $C_4H_7{}^{80}Br$ is not a decomposition product of the excited $(c\text{-}C_4H_7{}^{80}Br)^*$, but, rather, a primary product resulting from an attack of the incident ^{80}Br on a C–C bond:

$$^{80}Br^* + c\text{-}C_4H_8 \rightarrow (C_4H_7{}^{80}Br)^*[\text{Bromobutene}] \quad (9)$$

Thus, the main decomposition process of $(c\text{-}C_4H_7{}^{80}Br)^*$ are limited in Reaction 2 or 3. No definite conclusion can be drawn as to the relative importances of these decomposition processes without adequate thermodynamic data. However, by analogy with the case of $c\text{-}C_4H_7Cl$, it is considered that the activation energy of Reaction 3 is lower than that of Reaction 2. Thus, a plausible explanation for the present results is as follows: the excited products formed by the ^{80}Br-for-H reaction with $c\text{-}C_4H_8$ decompose competitively through Reactions 2 and 3. Reaction 3 predominantly occurs with less excited primary products and is easily suppressed by an increase in the pressure. The decomposition mode of Reaction 2 giving $CH_2CH^{80}Br$ occurs with highly excited products and can only be suppressed at pressures above 2000 Torr.

As is shown in Table 2, the spectrum of the reaction products in the $c\text{-}C_5H_{10}$ system is more simple than that in the $c\text{-}C_4H_8$ system. There exists no organic product to compensate for the increase in the yield of $c\text{-}C_5H_9{}^{80}Br$ with an increase in the pressure. Thus, by analogy with the case of $c\text{-}C_4H_8$, it can be deduced, as for the decomposition processes of the excited $(c\text{-}C_5H_9{}^{80}Br)^*$, that they decompose through Reaction 5 or 6, and that Reaction 6 occurs significantly on the lower-pressure side, as can easily be understood from Fig. 2. One support for this consideration comes from the fact that the main decomposition pathway in the pyrolysis of $c\text{-}C_5H_9Br$ is Reaction 6.[4,5]

Even though the activation energy of Reaction 11 is slightly higher than that of Reaction 6,[11] the HBr-elimination-mode may still play a rather important role in the decomposition of the excited $(c\text{-}C_6H_{11}{}^{80}Br)^*$. The yields of $CH_2CH^{80}Br$ and $C_4H_7{}^{80}Br$, relative to $c\text{-}C_6H_{11}{}^{80}Br$, are high; thus, Reaction 12 must be another decomposition pathway:

$$(c\text{-}C_6H_{11}{}^{80}Br)^* \begin{cases} \xrightarrow{S} c\text{-}C_6H_{11}{}^{80}Br & (10) \\ \xrightarrow{D_1} H^{80}Br + c\text{-}C_6H_{10} & (11) \\ \xrightarrow{D_2} CH_2CH^{80}Br + C_4H_8 \text{ or } C_4H_7{}^{80}Br + C_2H_4 & (12) \end{cases}$$

The excitation energy of a primary product from a hot atom reaction spreads over an extremely wide range.[12] Thus, it can be thought that $CH_2CH^{80}Br$ in the $c\text{-}C_4H_8$ system, $CH_2CH^{80}Br$ and $CH_2CHCH_2{}^{80}Br$ in the $c\text{-}C_5H_{10}$ system, $CH_2CH^{80}Br$ and $C_4H_7{}^{80}Br$ in the $c\text{-}C_6H_{12}$ system are decomposition products from highly excited primary products. However, the greater part of the primary products is not excited enough to cleave the ring and will release $H^{80}Br$ or stabilize in collision with other molecules. However, in the present systems, no products with a negative pressure dependence were found in the pressure range studied. Thus, the experimental justification of the above consideration must rely on the measurement of $H^{80}Br$ as a function of the pressure, this has not yet suceeded.

Systematics of Total Organic Yield. It is very interesting and worth while to study the systematics in the reaction of a hot atom with various reactants in order to obtain more information about the hot atom reaction. Thus far, a number of systematic studies have been reported for the reaction of hot tritium. Rowland *et al.* have found that the yields of the tritiated alkanes and haloalkanes formed by the T-for-H reaction have a linear relationship with the NMR proton chemical shift.[13] On the other hand, Williams *et al.* have reported that the yields of CH_3T from the hot tritium abstraction of end methyl groups show no obvious effect on the electron density around the reaction site, but are correlated inversely with the $R\text{–}CH_3$ bond dissociation energy.[14]

Such discussions as have been given as examples must be based on the yield of a primary product. Unfortunately, in the present reaction system, it is rather difficult to estimate the primary yields from the ^{80}Br-for-H reactions, since not all the decomposition products can be determined experimentally, as was mentioned in the preceding section. Thus, the total organic yields found at the higher system pressure are chosen as the second-best values.

Table 3 shows the total organic yields obtained at two different system pressures, 600 and 1600 Torr, along with the experimental conditions. An excess portion of ethane which was added as a pressure-builder to the reaction system also served as a kinetic moderator to obtain identical kinetic spectra of the recoil ^{80}Br for all samples. For the $c\text{-}C_6H_{12}$ system, the experiment at 1600 Torr cannot be performed simply because the vapor pressure of $c\text{-}C_6H_{12}$ is much less than 400 Torr.

Table 3. Total organic yields at system pressures of 600 and 1600 Torr

Reactant	Total organic yield		Ratio
	600 Torr[a]	1600 Torr[b]	
$c\text{-}C_3H_6$	1.7±0.3%	2.8±0.1%	1.7±0.3
$c\text{-}C_4H_8$	1.4±0.2	2.5±0.3	1.8±0.3
$c\text{-}C_5H_{10}$	1.3±0.2	1.9±0.2	1.5±0.3
$c\text{-}C_6H_{12}$	1.0±0.1	···	···
Composition of gases	a)	b)	
Reactant	100 Torr	400 Torr	
CH_3Br	10 Torr	10 Torr	
$H_2S + O_2$ (2 : 3)	60 Torr	160 Torr	
C_2H_6	430 Torr	1030 Torr	

As may be seen in Figs. 1 and 2, at around 600 Torr the yields of the parent products are very sensitive to, and increase with, the pressure. However, the yields at the pressure of 1600 Torr are very close to the plateau values. In all cases, the ratio of the total organic yields obtained at these two different pressures stays almost constant within the limits of experimental uncertainty, as is shown in the last column of Table 3. This means that, in a qualitative sense, the excitation energies of these primary products are in a similar range. Thus, their decomposition is equally suppressed by increasing the pressure.

Consequently, the results shown in Table 3 can be compared with each other without any further adjustment. In the present case, the yields show no clear correlation with either the dissociation energy of a C–H bond[15,16] or the electron density around the hydrogen replaced.[17] On the other hand, the plots of the yields against the strain energy of the ring[18] seem to show a certain correlation; the yields decrease with the strain energy. If the total organic yield is correlated directly with the probability of the ring-opening reaction, as in Reaction 9, the most believable explanation for this results will be as follows: when the substrate is attacked by an energetic ^{80}Br, the possibility of the ring-cleavage is inversely proportional to the strain energy of the ring. Thus, a higher organic yield results from the substrate having a higher strain energy. However, it has already been confirmed that the ring-opening reaction plays a minor role in the reaction of hot atoms with cyclanes.[1,12] This is also the case in the present systems, as has already been discussed in the preceding section. Thus, all the features of the experimental results can not be interpreted only in terms of the strain of the ring.

When the total organic yields were plotted against the number of carbon atoms, a linear relationship was obtained; the yields decreased with the carbon numbers, as is shown in Fig. 3. A similar trend is also noticed in the reactions of ^{80}Br with simple alkanes;[19–24] the yields of the products resulting from the ^{80}Br-for-H reactions decrease with the carbon numbers, as is also shown in Fig. 3 as a reference. In these cases, however, the trend is not clearly seen in the total organic yields simply because, in the reactions with alkanes, the yields of the products from the ^{80}Br-for-(alkyl group) reactions constitute a greater part of the total organic yields.

There seem to exist several factors consistent with the present findings. Among them, the most conceivable ones are: 1) the elimination of $H^{80}Br$ as a decomposition process of the primary products, 2) the competition between the abstraction and substitution reactions in the primary reactions of ^{80}Br with a reactant molecule, and 3) the inherently possessed reaction probability of cyclanes toward the recoil ^{80}Br. The first factor will be ignored because of the following consideration. The elimination of $H^{80}Br$ as a decomposition process of the excited product is important only in the lower-pressure end and will be essentially suppressed at the pressure of 1600 Torr. As for the second determinant, by analogy with the reaction of recoil T,[25,26] the ^{80}Br-to-$H^{80}Br$ reaction may also be sensitive to the C–H bond strength. All the reactants

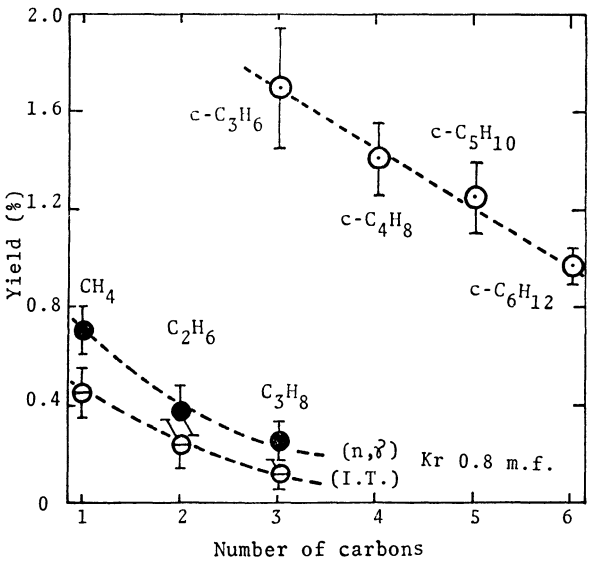

Fig. 3. Correlations between total organic yield and carbon-numbers.
⊙: Cyclane+$^{79}Br(n, \gamma)^{80}Br$, (moderator; ethane, total pressure; 600 Torr).
●: Alkane+$^{79}Br(n, \gamma)^{80}Br$, (moderator; Kr, total pressure; 700 Torr).

chosen in the present work except *c*-C_3H_6 have a C–H bond strength in the range from 93 to 95 kcal mol^{-1}. This small variation in the bond energy is rather far from the explanation of the above correlation, suggesting the insignificance of the second factor.

Thus, with reasonably confidence, the relationship may be explained in connection with the reaction probability itself; the probability decreases with an increase in the carbon numbers. As the complexity of a molecule increases, the vibration modes available also increase. As a result, the life of a intermediate complex[27,28] will become longer, because the internal excitation energy spreads over the bonds involved. In these circumstances, the probability of the rupture of any particular bond rapidly decreases with an increase in its bond strength. In the present cases, the C–Br bond in the intermediate complex will have the weakest energy and will be broken with a high probability, ejecting the incident ^{80}Br with a reduced energy. This explanation is also consistent with the following consideration.

In the reaction of recoil T with cyclanes,[29,30] the yields of the parent products seem to stay within a certain range or seem to increase very slightly with the carbon numbers. This observation may be understood as follows: the difference in the bond energy between the C–H and C–T is very small, and the relative probability of the rupture of these bonds in the intermediate complex will hardly be influenced at all by the life of the complex.

Thus, it can be concluded that the life of the intermediate complex may play a more important role than the strain energy of the ring in the reaction of ^{80}Br with cyclanes.

Appendix

Product-Distribution and Radiolysis. As is shown in Tables 1 and 2, the numbers of the products are 8 for the *c*-C_4H_8 system and 6 for the *c*-C_5H_{10} system. In the *c*-C_6H_{12} system, this decreases to only 4. This tendency seems somewhat strange, because it is the opposite of the increase in the carbon numbers of the reacting substrate.

In the radiolysis of cyclanes, the *G* values of H_2 increase with the number of carbons. However, those of hydrocarbons, especially those resulting from the cleavage of the ring, decrease with an increase in stability of the ring.[31,23] Thus, in the present case, the variation in the number of the products from different cyclanes will be considered in connection with the stability of the reactant in radiolysis.

As was described in the chapter on "Results", the products from the *c*-C_4H_8 system were divided into two groups, scavenger-sensitive and scavenger-insensitive. The products belonging to the former group may originate from the radiolysis of the parent molecule, because they have no pressure dependence and always have low yields, particularly in highly scavenged systems.

In the experiments on *c*-C_4H_8 scavenged by Br_2, some polybromoalkanes which have a smaller carbon-skeleton than C_4 were formed. These products also resulted from the reaction of the fragments from the radiolysis. The $CH_2BrCH_2{}^{80}Br$ can be chosen as a typical example among these products. This product shows a steep scavenger curve at the beginning of the Br_2 concentration. In the system of 2% Br_2, the yield of $CH_2BrCH_2{}^{80}Br$ increased linearly with the irradiation period. This may be explained according to the following reactions initiated by the radiolysis of *c*-C_4H_8:

$$c\text{-}C_4H_8 \overset{\gamma}{\sim\!\!\sim\!\!\longrightarrow} \cdot CH_2CH_2CH_2\dot{C}H_2 \quad (13)$$

$$\cdot CH_2CH_2CH_2\dot{C}H_2 \overset{Br_2}{\longrightarrow} \cdot CH_2CH_2CH_2CH_2Br \quad (14)$$

$$\cdot CH_2CH_2CH_2CH_2Br \longrightarrow \cdot CH_2CH_2Br + C_2H_4 \quad (15)$$

$$\cdot CH_2CH_2Br \overset{Br_2}{\longrightarrow} CH_2BrCH_2Br \quad (16)$$

The butylene biradical formed by Reaction 13 may decompose to $\cdot CH_2\dot{C}H_2$ or ethylene. However, Horváth *et al.* have reported that the *G* value of C_4 products from *c*-C_4H_8 is about 2 times higher than that of C_2 products.[31] Thus, $CH_2BrCH_2{}^{80}Br$ should be chiefly formed through Reactions 13—16.

If we use Br_2 as a scavenger in the reaction with a substrate having a lower radiation-resistance, its radiolysis will, sometimes, make a hot atom reaction complex. In such cases, it is advisable to chose another reagent, such as H_2S or a mixture of H_2S and O_2, as a scavenger, because H_2S will allow the radicals from radiolysis to convert saturated hydrocarbons by abstracting the H-atom.

In the present case, a mixture of H_2S and O_2 was used as the scavenger and the irradiation length of the sample was limited as short as possible. Thus, it is certain that the contribution of radiolysis to the data dealt with in this paper is not significant.

Photocyclization of Diphenylmaleonitrile in the Crystalline State

Kunihiro ICHIMURA and Shoji WATANABE

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received August 25, 1975)

Diphenylmaleonitrile shows polymorphism. The crystals are photochromic and afford 9,10-dicyanophenanthrene and 9,10-dihydro-9,10-dicyanophenanthrene after prolonged irradiation. The rates of photodecomposition and properties such as photochromism, absorption and fluorescence spectra depend upon the crystal form. Photochromism results from the formation of the 4a,4b-dihydrophenanthrene which is successively converted into the photoproducts.

We described the photocyclization of diarylfumaro- and maleonitrile in solution in a previous paper.[1] Since then we have observed the photochromism of the maleonitrile in the crystalline state. This prompted us to examine photochemistry in the crystalline state in connection with solution photochemistry.[2] In this paper we report on the solid state photocyclization of diphenylmaleonitrile,[3] pointing out that the photocyclization proceeds from an electronically excited state.

Results

Sargent and Timmons obtained diphenylmaleonitrile (I) for the first time as prisms of mp 134 °C in a small yield by the action of ammonia upon α-cyanobenzyl thiocyanate.[2a] We have found that I crystallizes in two forms; when I is recrystallized from cyclohexane, needle-like crystals are formed, while in contrast, when a solution of I in a mixture of dichloromethane and cyclohexane (*ca.* 1 : 1) is condensed very slowly, pale yellow prisms are deposited. The recrystallization of I from benzene–cyclohexane mixture afforded two types of crystals simultaneously. According to the differential scanning calorimetry measurement, the endothermic point of prisms appeared at 136 °C and that of needles at 137 °C due to melting point. The IR spectra of these crystals differ especially in the finger-print region. The IR spectroscopic data reported by the English authors[2a] are essentially identical with those of our prisms. Ultraviolet absorption maximum of these crystals undergoes the red shift in comparison with that in solution, prisms possessing the absorption band at a wavelength slightly higher than that of needles. The physical properties of the crystals are summarized in Table 1. The results indicate the polymorphism of I. The X-ray reflection patterns of these crystals differ a great deal, confirming the polymorphism (Fig. 1).

We found a different photochemical behavior depending on the crystal form. We happened to observe a pale red coloration of crystals when they were placed in a sunny place. The coloration was distinct when the crystals were irradiated with a mercury arc filtered through a band path filter (340—400 nm). The color tone differed with the two crystal forms. The reflection spectra of the irradiated crystals in KBr showed a difference of 20 nm in wavelength of absorption maxima between these crystals (Table 1). The first order decay time was also dependent on the crystal form. The color of the prisms faded more rapidly than that of the needles. The former had a half lifetime of 180 s at room temperature, the latter one of 700 s.

TABLE 1. PHYSICAL PROPERTIES OF CRYSTALS OF DIPHENYLMALEONITRILE

Appearance	Prism	Needles	Solution[1]
Mp (°C)	136.0	137.5	
Recryst. from	CH_2Cl_2–Cyclohexane	Cyclohexane	
UV spectrum; λ_{max}(nm)	286, 338	286, 336	281, 323[a]
Fluorescence (nm)	Non-fluor.	450 (25 °C) 472 (77 K)	Non-fluor.
λ_{max} of intermediate (nm)	520	500	480[b]
Half lifetime of intermediate (s)	160	700	100[b]
Photolysis	Faster	Slower	

a) In ethanol. b) In toluene.

The crystal forms also differed in fluorescence behavior; whereas the prisms were not fluorescent at all, and the exciting light produced coloration immediately, the needles were slightly fluorescent and soon turned red as the fluorescence weakened. At liquid nitrogen temperature only blue fluorescence was observed, but no red coloration of the needles. The blue fluorescence decreased sharply at −185 °C when the temperature of the crystals rose gradually.

The solid state photochemical reaction of these cystals in KBr disks was followed qualitatively by IR spectroscopy. The bands at 1308 cm^{-1} (needles) and 1301

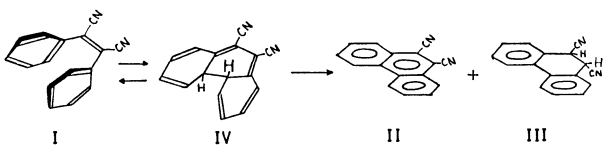

Scheme 1.

cm^{-1} (prisms) were chosen as a key band which almost disappeared after one day of irradiation with UV light from a 450 W high pressure mercury arc passed through a Corning C. S. Filter 7-60. Figure 2 shows time-conversion curves of photolysis of the two crystal forms. It is noteworthy that the rate was also affected by the crystal form; the prisms underwent photodecomposition faster than the needles. The IR spectra of these crystals after one day of irradiation were essentially identical. The characteristic bands, especially nitrile band, indicate that 9,10-dicyanophenanthrene (II) and 9,10-dihydro-9,10-dicyanophenanthrene (III) are the photoproducts.

A suspension of powdered I in water was irradiated for two days with a 100 W mercury lamp using a glass filter. The photoproducts were isolated by fractional recrystallization from methyl ethyl ketone and characterized and identified by means of IR, UV, and NMR spectra. The irradiated solid was found to consist of I, II, and III, the yields of II and III being 60% and 22%, respectively.

It is of interest to see how the excitation of the colored intermediate affects solid state photolysis. As shown in Fig. 3, the absorption maximum of the colored intermediate lies sufficiently at longer wavelength for separate excitation. The crystals dispersed in a KBr disk were simultaneously illuminated with a 450 W high pressure mercury lamp filtered with a Corning C. S. 7-60 and another 450 W lamp filtered with a Corning C. S. 3-72. The transmittances of the filteres are sketched in Fig. 3. Simultaneous irradiation resulted in very weak coloration of the crystals. However, the rate of photolysis in the early stage (within *ca.* 30%) was only slightly affected by the co-excitation; the needles underwent photodecomposition somewhat faster than in the absence of simultaneous irradiation of the colored intermediate whereas the prisms showed no effect of the co-excitation upon the rate of photolysis (Fig. 2). The IR spectra of the irradiated solids indicate that the photoproducts and the product ratio were not changed by simultaneous irradiation.

Discussion

Interest in the photocyclization of stilbenes has been focused on the nature of the intermediate and the excited state of the precursor to give phenanthrenes. Moore and co-workers proposed the 4a,4b-dihydrophenanthrene as the intermediate based on the observation of the intermediary yellow coloration (λ_{max}= 447 nm) of stilbene on UV irradiation in solution.[4] Muszkat and Fischer investigated in detail the nature of the intermediate and confirmed the hexaene system spectroscopically.[5] The excited singlet state has been recognized to play a key role in photocyclization,[6] while an alternative mechanism through a hot molecule has been proposed.[7] Evidently, the configuration of hydrogens at 4a and 4b positions of the intermediate gives a clue to whether the photocyclization proceeds *via* an electronically excited state or a higher vibrational level of the ground state. The stereochemistry of the intermediate has been discussed in connection with the rule of Woodward-Hoffmann.[5,11] However, no direct evidence for the configuration of hydrogens at 4a and 4b positions has been obtained.[8]

We have observed red coloration at λ_{max}=480 nm when diphenylfumaronitrile or maleonitrile is irradiated in certain organic solvents and ascribed this transient absorption to 9,10-dicyano-4a,4b-dihydrophenanthrene (IV).[1] It is concluded therefore that the solid state photochromism of diphenylmaleonitrile is caused by the formation and the disappearance of the colored 4a,4b-dihydrophenanthrene (IV). The solid state photocyclization could thus be interpreted to belong to the isomerization of this intermediate to III and the oxidation to II, in the same way as proposed in the solution photocyclization.[1]

It has been emphasized that the distance between

both atoms forming a covalent bond by irradiation plays a critical role to give photoproducts in the solid state.[9] Although the refined crystal structure of *cis*-stilbene derivatives is scarcely known, the result of X-ray analysis of *cis*-α-bromo-β-(2-pyridyl)styrene shows that the *ortho*-carbon of the phenyl and α-carbon of the pyridyl group are 3.42 Å apart from each other.[10] It is very likely that two phenyl groups of I are spacially arranged in a similar fashion to the case of the bromostyrene and the distance between both *ortho*-carbon atoms of two phenyl groups is sufficient to form a covalent bond in the rigid crystalline state since the critical distance which is able to form a covalent bond in the solid state photoreaction has been reported to be about 4 Å in the case of intermolecular dimerization of cinnamic acid and its related compounds.[9] From a consideration of the molecular shape in the crystalline state and the ease of solid state photocyclization to the colored intermediate of diphenylmaleonitrile, the 4a,4b-hydrogens of IV are shown to be in the *trans* configuration. It is concluded that the photocyclization of I to give IV proceeds *via* an electronically excited state. Other stilbenes, including stilbene itself, have the same hexaene system and photocyclize most probably from an electronically excited state.

The experiments of simultaneous irradiation throw light upon the subsequent reaction mechanism of the intermediate. If the process to give II and III proceeds thermally, simultaneous excitation of the colored intermediate would suppress the formation of the cyclized products (II+III), since the recovery of I from IV is photochemically allowed.[11] The results were not the case and suggest that the colored intermediate (IV) is converted either into the starting material or into the photoproducts at least partially photochemically. The formation of the 9,10-dihydrophenanthrene bearing the *trans* configuration[2b] is in line with this conclusion; the conversion of IV having *trans* hydrogens into the 9,10-dihydrophenanthrene is regarded as photochemically allowed 1,3- or 1,7-sigmatropic reaction without any considerable change of the molecular arrangement.

Although the effect of polymorphism on the photochemical behavior cannot yet be fully understood unless the refined molecular structure of both crystal forms are known, the spectroscopic data give us insight into the solid state photoreaction. The relatively large red shift of absorption maximum of the intermediate of prisms in comparison with that of needles suggests that the hexaene system of IV in prismatic crystals is more planar than that in needle-like crystals. The planar structure of IV is less favorable for stability, since two sp^3 orbitals of the intermediate force the π-electron system to be distorted. This explains the shorter half lifetime of IV in prisms.

The difference in the longest wavelength of absorption maximum between two crystal forms, though small, suggests that the molecular shape of I is dependent on the crystal form; the structure of I in prisms may be more planar than that in needles since the absorption maximum of prisms undergoes a slightly larger red shift than does that of needles. The planar structure brings about the reduction of the distance between two carbon atoms forming a covalent bond upon irradiation so that the electro-cyclization to give IV may occur more efficiently in prisms than in needles. The observation of fluorescence in needles also supports the dependence of the efficiency of photocyclization upon the crystal form. The efficiency of the cyclization to give IV in prisms could be larger than that in needles, since the prisms show no fluorescence. The dependence of the rate of photolysis upon the crystal forms therefore reflects the difference in the efficiency of photocylization to give IV.

Experimental

Measurement of Physical Properties. Infrared spectra were recorded on a Hitachi EPI-G3 type IR spectrophotometer, and UV spectra and reflection spectra of the crystals dispersed in KBr disks on a Hitachi EPS-3T spectrometer and Hitachi recording spectrophotometer type EPR-2, respectively. Fluorescence was measured with a Hitachi fluorescence spectrophotometer MPF-2A. The thermal behavior of the crystals was recorded on a Perkin-Elmer Model DSC-1B at 16 °C/min. X-Ray reflection diagrams were recorded on a Rikagaku Denki X-ray diffraction apparatus Model D-3F. Monochromatic light was obtained from JASCO CRM-FA spectro-irradiator composed of a 2 kW xenon lamp. A 450 W high pressure mercury lamp was used as the light source in other experiments.

Preparation of the Crystals of Diphenylmaleonitrile. Diphenylmaleonitrile was synthesized according to the method reported previously.[1b] The nitrile was recrystallized from cyclohexane to afford needle-like crystals which were collected and washed with cyclohexane. To a solution of the nitrile (3 g) in *ca.* 30 ml dichloromethane in an Erlenmeyer flask was added 50 ml cyclohexane, and the solution was kept to stand in the dark for a while to cultivate the prismatic crystals. The mouth of the flask was covered with a filter paper. The solvent was decanted and the crystals were treated with cyclohexane and collected by filteration. When the nitrile was recrystallized from a benzene–cyclohexane mixture, formation of two crystal forms was observed. Slower crystallization seems to favor the formation of the prisms. ν_{max} of needles (KBr); 3060, 2222, 1598, 1588, 1492, 1449, 1322, 1308, 1283, 1228, 1157, 1070, 1031, 1002, 960, 925, 862 w, 851 w, 843 w, 778, 759, 700, and 692 cm^{-1}. ν_{max} of prisms (KBr); 3060, 2222, 1596, 1587, 1499, 1445, 1321, 1301, 1280, 1221, 1180, 1160, 1070, 1027, 1000, 955, 920, 862 w, 840 w, 770, 758, and 690 cm^{-1}.

Measurement of the Colored Intermediate. KBr disks containing diphenylmaleonitrile (1 mg/150 mg) were irradiated with UV light, the reflection spectra of the colored disks being recorded at intervals. The intensity of the absorption maxima was found to decay in the first order, the half lifetime being then obtained (Table 1).

Photolysis of Diphenylmaleonitrile in KBr Disks. Diphenylmaleonitrile (0.96 mg) in KBr (150 mg) was pressed under 200 kg/cm^2, the KBr disk being held in a cell containing calcium chloride as a drying agent. Two lamp houses composed of a 450 W mercury arc were so placed that both blue (through a Corning C. S. 7-60 filter) and yellow (through a Corning C. S. 3-72 filter) beams illuminate the disk through a glass window. The IR spectra were recorded at intervals, and the amount of diphenylmaleonitrile was estimated by the decrease in intensity of the band at 1301 cm^{-1} for prisms or 1308 cm^{-1} for needles according to the calibration line. Two new peaks at 2230 and 2250 cm^{-1} due to 9,10-dihydrophenanthrene and 9,10-dicyanophenan-

threne, respectively, appear with a decrease in the nitrile band of starting material at 2222 cm^{-1}. The final spectra of both crystals were in all cases essentially identical.

Estimation of the Yields of Solid State Photoproducts. The yields of the photoproducts were estimated by UV spectroscopy as follows. The irradiation of diphenylfumaro- or maleonitrile in acidic media has been found to give 9,10-dihydro-9,10-dicyanophenanthrene as the sole product.[1] The irradiated crystals were dissolved in ethanol containing a trace amount of sulfuric acid, and the solution was illuminated with 357 nm light to convert the unreacted diphenylmaleonitrile specifically into the 9,10-dihydro derivative (III). Since I and II have absorptions above 300 nm, but not III, the difference between the spectra of solid state photoproduct above 300 nm before and after irradiation in acidic media indicates the absorbance of unreacted I. From the absorbance of the irradiated solution at 327 nm or 336 nm we obtain the quality of 9,10-dicyanophenanthrene as a solid state photoproduct. The differential spectrum was obtained by subtraction of spectrum before irradiation in acidic ethanol from that of I and III estimated as mentioned above, and was found to be essentially identical with that of II. Thus we see that the photodecomposed solid consists of only I, II, and III. The yields of II and III are found to be 60% and 22%, respectively.

The authors wish to express their thanks to Dr. H. C. Steinmetzer, University of Frankfurt am Main, for his valuable suggestions.

pH-Dependency of Photocyclization of Diarylfumaronitriles

Kunihiro ICHIMURA and Shoji WATANABE

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received August 25, 1975)

The photocyclization of diarylfumaronitriles in aqueous ethanol is influenced by pH. The product ratio of 9,10-dihydro-9,10-dicyanophenanthrenes (IV) decreases with decrease in pH. Discussion is given on the acid-catalyzed isomerization of the 4a,4b-dihydrophenanthrenes to IV from results of observation of the colored intermediate.

Some stilbenes substituted by electron-withdrawing groups at the olefinic double bond give 9,10-dihydrophenanthrenes along with the phenanthrenes on UV irradiation,[1] while stilbene yields only phenanthrene but no 9,10-dihydro derivative as a photoproduct.[2-5] The product ratio of the 9,10-dihydrophenanthrenes to the phenanthrenes in the former case depends on the reaction conditions.[1] We confirmed that the yield of 9,10-dicyanophenanthrene (IIIa) undergoes a solvent effect when diphenylfumaronitrile (Ia) is irradiated in solution (Table 1). 9,10-Dihydro-9,10-dicyanophenanthrene (IVa) is formed almost exclusively in acetic acid. This indicates that the formation of dihydro derivative (IVa) is influenced specifically by the acidic nature of the solvent. This was confirmed by the sole production of IVa when Ia was irradiated in ethanol containing a trace of sulfuric acid. These observations led us to investigate the pH-dependency of the photoproduct distribution. In this paper we report the pH-dependency of several diarylfumaro- and maleonitriles (I and II) and propose a cyclization mechanism *via* 4a,4b-dihydrophenanthrenes,[6] in contrast to the free-radical mechanism proposed recently by Srinivasan and Hsu.[7]

Results

Since diarylfumaronitriles (I) are practically insoluble in water, buffered aqueous ethanol (50 w/w%) was employed as a solvent. Although all the UV absorption spectra of Ia at pH less than *ca.* 10 were identical and remained unchanged on standing in the dark, the absorbance at the longest wavelength in more alkaline solutions (*ca.* 0.1 M NaOH) decreased gradually on standing at room temperature. The electron-withdrawing group at the phenyl ring of the fumaronitrile makes the double bond so sensitive toward the alkaline medium that the absorption bands at the greatest wavelength of α-(*p*-chloro- and cyanophenyl)-α′-phenylfumaronitriles (Ib and Ic) disappear gradually even at pH *ca.* 8. The decrease of the absorbance may occur as a result of the alkali catalyzed hydration on the olefinic double bond of the fumaronitrile, as in the case of α-arylcinnamonitrile.[8] We have employed buffered solutions (pH<8) for studies on the pH-dependency of the photolysis.

In order to obtain some information on the pH effect on the photolysis of diarylfumaronitrile, aerated solutions at various pH were irradiated with light of 330 nm, and the UV spectra were recorded at intervals. Typical examples for Ia are illustrated in Fig. 1. A family of the absorption curves changed at various pH; 9,10-dihydro-9,10-dicyanophenanthrene (IVa) forms predominantly in a weakly acidic solution whereas the formation of 9,10-dicyanophenanthrene (IIIa) is observed in neutral or alkaline solutions.

It has been emphasized that diagrams of quotients of extinction differences (EDQ diagrams) can be utilized to distinguish complicated photoreactions followed UV-spectroscopically.[9] Examination of the EDQ diagrams for Ia at various pH revealed that the elementary reactions depend also on the pH of the solution; both EDQ diagrams at pH 7.0 and 5.0 are linear but that at pH 9.0 is non-linear (Fig. 1). It is therefore concluded that two elementary reactions take part in the photoreaction of Ia at pH 7.0 and 5.0, while more complex reactions occur at pH 9.0. The photolysis of the fumaronitrile (Ia) at pH less than *ca.* 7.0 thus consists of the initial photoisomerization to the maleonitrile (IIa) and the photoinduced transformation of IIa to the phenanthrenes (IIIa+IVa).[10] Similar results were obtained when α-(*p*-methoxyphenyl)-α′-phenylfumaronitrile (Id) was used. The EDQ diagram of the photoreaction of α-(*p*-cyanophenyl)-α′-phenylfumaronitrile (Ic) was found to be non-linear even at pH 7.0, while a linear EDQ diagram was obtained when the photolysis was carried out at pH 4.0.

TABLE 1. SOLVENT EFFECT ON THE YIELD OF 9,10-DICYANOPHENANTHRENE

Solv.	Yield of 9,10-dicyano-phenanthrene (%)
Cyclohexane	80
Chloroform	10—20
Toluene	70
EtOH	30
AcOH	Trace[a]
EtOH–H_2SO_4	0[b]

a) The remaining product is 9,10-dihydro-9,10-dicyanophenanthrene. b) The 9,10-dihydro compound forms exclusively.

The pH-dependency of the photocyclized product distribution was determined by the UV spectra of the photolyzed solutions at various pH where linear EDQ diagrams were obtained. The results for Ia are given in Table 2. The UV spectra of the solutions irradiated at pH less than 4 are identical with that of the dihydro compound (IVa). A family of the absorption curves for Ia intersect at 265 and 295 nm. The peaks at 326 and 339 nm due to the phenanthrene (IIIa) increase with increase in the pH of the solutions at the same ratio. It is concluded that only IIIa and IVa

are concerned in the product distribution. The product distribution from diphenylmaleonitrile was found to be practically identical with that from the fumaronitrile (Fig. 3). The absorption spectra of the irradiated solutions in alkaline medium deviated from the isosbestic points at 265 and 295 nm. This is in

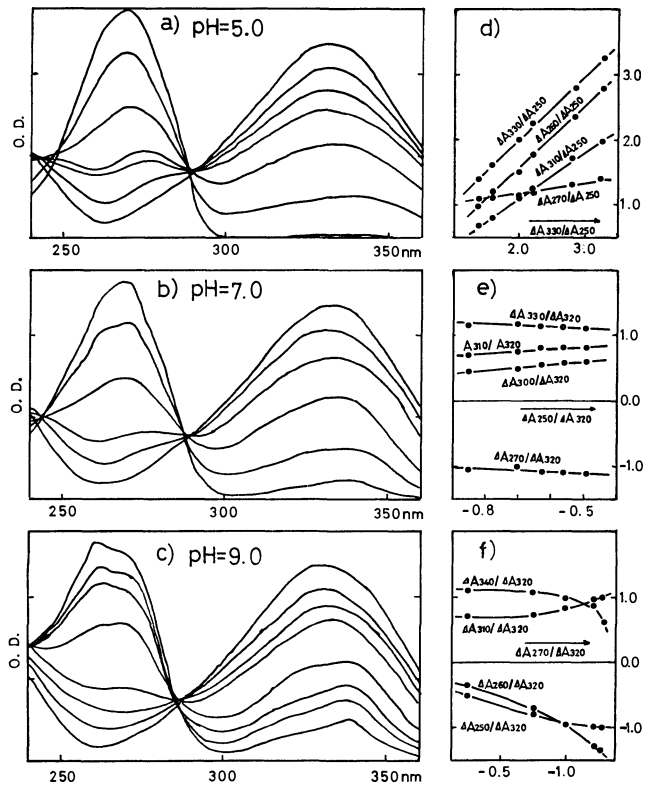

Fig. 1. The electronic absorption spectra recorded at intervals for the UV irradiation of diphenylfumaronitrile in aq. ethanol at various pH ((a): pH=5.0, (b): pH=7.0, and (c): pH=9.0) and the corresponding EDQ diagrams ((d): pH=5.0, (e): pH=7.0, and (f): pH=9.0).

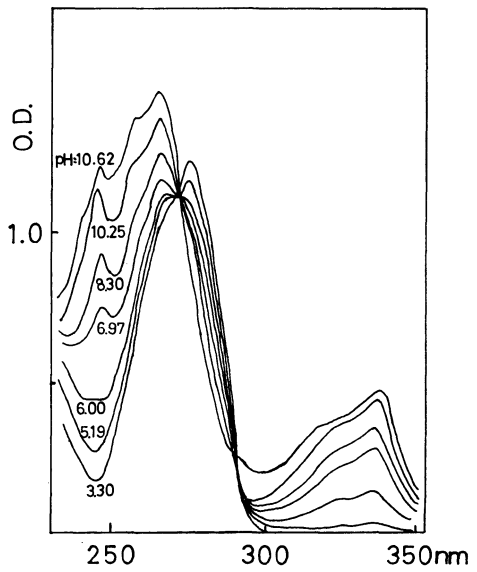

Fig. 2. The electronic absorption spectra of photoproducts from diphenylfumaronitrile irradiated in aq. ethanol at various pH.

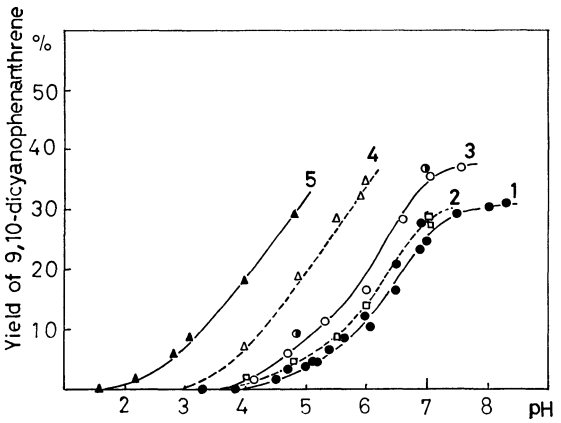

Fig. 3. pH-Dependency of the yield of 9,10-dicyanophenanthrenes; (1) 9,10-dicyanophenanthrene at 20 °C (—●—), (2) 3-methoxy-9,10-dicyanophenanthrene at 2 °C(--□--), (3) 9,10-dicyanophenanthrene at 2 °C (—○— from the fumaronitrile, —◑— from the maleonitrile), (4) 3-chloro-9,10-dicyanophenanthrene at 2 °C (--△--), (5) 3,9,10-tricyanophenanthrene at 2 °C (—▲—).

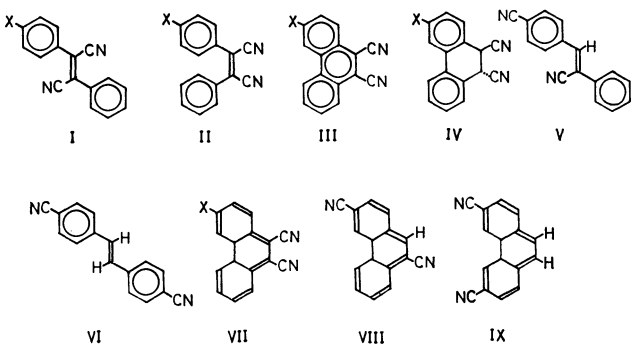
line with the anomalous photochemical behavior of this compound in alkaline region as revealed by an examination of the EDQ diagram. The other *p*-substituted diphenylfumaronitriles undergo a similar pH effect on the product distribution. The yields of the 9,10-dicyanophenanthrenes (III) at various pH were estimated by the absorbance at the longest wavelength and plotted against pH as shown in Fig. 3. The yield of phenanthrene at a given pH value increases with an increase in the electron-withdrawing power of the substituent.

As regards the effect of nitrile groups on the pH-dependency, two isomeric stilbenes, α-phenyl-β-(*p*-cyanophenyl)acrylonitrile (V) and *p,p'*-dicyanostilbene (VI), were irradiated in acidic solutions. The former underwent a pH effect similar to that of Ia, giving no 3,9-dicyanophenanthrene in acidic solutions of pH less than *ca.* 4. However, the photoreaction of the latter was not affected by the pH. The photocyclization of stilbene itself in ethanol was not influenced by addition of sulfuric acid.

We found that red coloration (λ_{max}=480 nm in toluene) occurs at room temperature on the excitation of Ia with 330 nm light in some solvents such as aromatic hydrocarbons and chloroalkanes. Although there was



no observation of such coloration in ethanol at room temperature, the solution of Ia was found to be faintly colored at −77 °C. Bleaching of the red color was accelerated by irradiation with visible light (*ca.* 480 nm), but retarded by the lowering in temperature. The bleaching corresponds to the first order decay with a half lifetime of 100 s in toluene at room temperature.

Discussion

Stilbene photocyclizes to phenanthrene through unstable yellow colored 4a,4b-dihydrophenanthrene.[2-5,11] Sargent and Timmons have suggested that the photocyclization mechanism for Ia is similar to that of stilbene, although no experimental evidence has been presented.[1] During the course of our investigation, Srinivasan and Hsu proposed an alternative free-radical chain mechanism for this type of photocyclization.[7] They observed the incorporation of deuterium from deuterated solvents into 9,10-dihydro compounds and the dependency of quantum yield on light intensity, and concluded that the abstraction of solvent hydrogen by the excited stilbene initiates the free-radical chain reaction to afford the 9,10-dihydrophenanthrenes. The mechanism can not fully explain the pH effect of the present work.

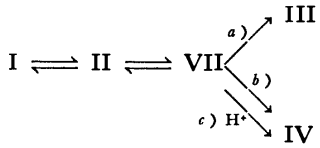
Our observation of the transient coloration on irradiation of Ia suggests the formation of 4a,4b-dihydro-9,10-dicyanophenanthrene (VIIa) as the intermediate like that in the case of stilbene.[5] The failure to observe the intermediate (VIIa) in aqueous ethanol UV-spectroscopically may be due to the shorter half life-time. The pH-dependency of the product distribution is thus explained by the acid catalyzed isomerization of the short-lived 4a,4b-dihydrophenanthrene (VII) to the 9,10-dihydro derivative (IV) as follows: The intermediate could be protonated at the cyano group to aromatize one of the ring, followed by the further migration of proton to give IV. The exclusive formation of the 9,10-dihydrophenanthrene on irradiation of α-phenyl-β-(*p*-cyanophenyl)acrylonitrile (V) in acidic solution seems to be in line with the reaction pathway. Protonation on the cyano group at the 9-position of the 4a,4b-dihydro compound (VIII) may promote the formation of the corresponding 9,10-dihydro compound in the same way. The insensibility of the photocyclization of isomeric *p,p'*-dicyanostilbene (VI) toward acid is in line with the processes; the proton catalyzed isomerization of the 4a,4b-dihydro (IX) to the 9,10-dihydro derivative can hardly occur since proton catalyzed aromatization is unfavorable in this case.

TABLE 2. THE KINETIC PARAMETERS (see Eq. 3).

X	Temp (°C)	log (k_3/k_1)	k_2/k_1
H	20	6.5	2.8
H	2	6.0	2.4
OMe	2	6.2	2.6
Cl	2	5.2	2.3[a]
CN	2	4.2	1.7[a]

a) The values were estimated so that a straight line with a gradient −1 was obtained according to Eq. 3.

The following kinetic aspects confirm the cyclization mechanism *via* VII. As shown in Fig. 1, the 9,10-dihydrocompounds (IV) are formed even in neutral or alkaline solutions, the yield being scarcely influenced by pH at pH 7—8 (Fig. 3). The results indicate that hydroxide ion plays a minor catalytic role in the process giving the photoproducts, and that the isomerization of VII to IV involves also the process irrespective of acid.



(1)

The reaction of the intermediate (VII) to give products thus consists of the following three paths as illustrated in Eq. 1 : *a*) oxidative formation of III, *b*) spontaneous isomerization to IV, and *c*) acid catalyzed isomerization to IV. We thus obtain the following equation in the region pH< 7.:

$$[D]/[P] = k_2/k_1 + k_3/k_1 \cdot [H^+] \quad (2)$$

and then

$$\log ([D]/[P] - k_2/k_1) = \log (k_3/k_1) - \mathrm{pH} \quad (3)$$

where [D] and [P] are the yields of IV and III, respectively, k_1, k_2, and k_3 corresponding to the rate constant of paths *a*, *b*, and *c*, respectively. According to Eq. 2, the ratio of the rate constants k_2/k_1 is assumed to be [D]/[P] at pH=7. The plot log ([D]/[P]−k_2/k_1) against pH gives a straight line with a gradient −1 in agreement with Eq. 3 when the estimated values for k_2/k_1 were used in the cases of Ia and Id (Fig. 4). Since the photolysis of Ib and Ic afforded non-linear EDQ diagrams even in a neutral solution, the k_2/k_1 values for these derivatives are uncertain. We have estimated them to give a straight line with a gradient −1 against pH (Table 2).

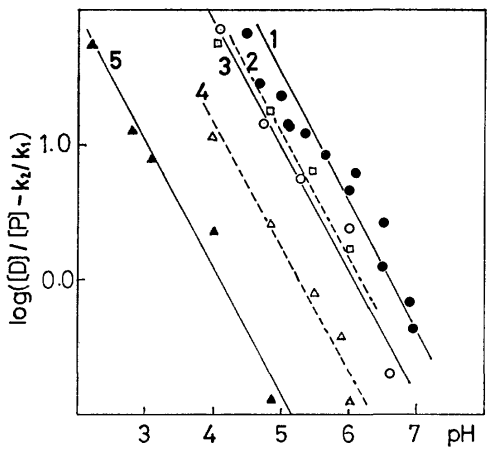


Fig. 4. pH-Dependency of photocyclization of diarylfumaronitriles; (1) diphenylfumaronitrile at 20 °C (—●—), (2) α-(*p*-anisyl)-α'-phenylfumaronitrile at 2 °C (--□--), (3) diphenylfumaronitrile at 2 °C (—○—), (4) α-(*p*-chlorophenyl)-α'-phenylfumaronitrile at 2 °C (--△--), (5) α-(*p*-cyanophenyl)-α'-phenylfumaronitrile at 2 °C (—▲—).

The spontaneous isomerization of VII to IV (path *b*) may involve an intramolecular process at least partially since the incorporation of solvent deuterium into the 9,10-dihydro compound occurs only partially.[7] From the solid state photocyclization we have concluded that VII is a *trans* isomer.[13] It is very likely that the intramolecular process occurs *via* the 1,3- or 1,7-sigmatropic shift of hydrogens of VII to afford the 9,10-dihydro derivative, which is a *trans* isomer.[1]

Experimental

All the melting points are not corrected. Ultraviolet spectra were recorded on a Hitachi EPS-3T spectrometer, and monochromatic light was obtained on a JASCO CRM-FA Spectro Irradiator consisting of a 2 kW xenon lamp.

Solvents were distilled before use.

α,β-Diarylacrylonitriles. The preparative method for α,β-diphenylacrylonitrile was employed.[14)] The results are given in Table 3.

α,α′-Diarylsuccinonitrils. (α,α′-Diphenylsuccinonitrile as a Typical Procedure): 90 g of potassium cyanide and 65 g of ammonium chloride were dissolved in 350 ml of water. The solution was added in one portion to a warm solution of 230 g of α,β-diphenylacrylonitrile in 750 ml DMF with shaking, and the mixture was allowed to stand for 1 h. Sufficient water was added to the mixture, the precipitate was filtered, washed with water and then with alcohol and dried. The crude product 268 g, mp 230—235 °C (lit,[17)] mp 238—239 °C as *meso*-isomer), was satisfactory for further use. Results for diarylsuccinonitriles synthesized by this method are given in Table 4. The hydrocyanation of α-phenyl-β-(2,4,6-trimethylphenyl)acrylonitrile by this procedure was unsuccessful.

Diphenylfumaro- and Maleonitrile. A sodium methoxide solution prepared by dissolving 37.5 g sodium in 300 ml methanol was added dropwise under vigorous stirring to 197 g iodine and 180 g crude α,α′-diphenylsuccinonitrile in 500 ml THF. At the end of the addition the color of iodine faded with a rise of temperature of the mixture. After stirring for 1 h the solvent was evaporated, and the reaction mixture was treated with a large amount of water. The precipitated crystals were filtered, washed with water, twice with cold methanol and dried. The crude product weighed 132 g and were recrystallized from ethanol to yield 84 g crude diphenylfumaronitrile which was recrystallized once more from ethanol. Mp 159—160 °C (lit,[18)] mp 161 °C). The combined ethanol filtrates were condensed to give 25 g crude diphenylmaleonitrile of mp 112—130 °C which was repeatedly recrystallized from ethanol until the mp became constant. The maleonitrile of mp 133—134 °C (lit,[19)] mp 135 °C) weighed 16 g. α-Phenyl-α′-(*p*-substituted phenyl)-succinonitriles were oxidized in a similar manner to the procedure mentioned above. The crude products showed a wide range of mp, but the isolation of diarylmaleonitriles was not attempted. The results are summarized in Table 5. The UV spectra of diarylfumaronitriles obtained are given in Table 8.

p,p′-*Dicyanostilbene.* The compound was synthesized according to the method of Fu and Sah.[20)] Mp 277—279 °C.

9,10-Dicyanophenanthrenes. A solution of 250 mg of diarylfumaronitrile in 100 ml of dichloromethane in a Pyrex flask was irradiated in the presence of 10 mg of iodine with a 450 W high pressure mercury lamp for 8 h. After the solvent had been evaporated, the crude product was chromatographed on alumina by means of dichloromethane as an eluent. The phenanthrenes were then recrystallized from methyl ethyl ketone. The results are given in Tables 6 and 9.

9,10-Dihydro-9,10-dicyanophenanthrenes. An ethanol (100 ml) solution of 250 mg diarylfumaronitrile was irradiated in a Pyrex flask with a 450 W high pressure mercury lamp under argon stream for 14 h. After the solvent had been evaporated, the residual crystalline product was recrystallized several times from ethanol. The dihydro compounds obtained are given in Table 7. The UV data are given in Table 10.

grams of diphenylfumaronitrile was dissolved in 150 ml 1,2-dichloroethane in a Pyrex flask and irradiated for 3 h with a mercury lamp. The solvent was evaporated to dryness, and the residue was recrystallized from ethanol to give crude starting material of mp 140—158 °C as needles. The filtrate was evaporated, the crystalline residue of mp 114—132 °C was recrystallized repeatedly from benzene-hexane to yield needle-like crystals of mp 132—134 °C. Identification was performed by mixture mp and UV absorption spectra.

Solvent Effect on the Yield of 9,10-Dicyanophenanthrene. Solutions of diphenylfumaronitrile in various solvents (5×10^{-5} M) were irradiated with 330 nm light until no more spectral change took place. The yield of 9,10-dicyanophenanthrene was calculated from the absorbance at 325 nm. The spectrum of the photoproduct in acidic solution was practically identical with that of 9,10-dihydro-9,10-dicyanophenanthrene.

Irradiation of 9,10-Dihydro-9,10-dicyanophenanthrene with Light of 270 nm. When an aerated solution of 9,10-dihydro compound in ethanol (5×10^{-5} M) was excited with 270 nm light, the absorbance at 269 nm decreased slowly with increase in the absorbance at 321 and 334 nm. The latter peaks are due to 9,10-dicyanophenanthrene.

Examination of EDQ diagrams[9] of the Photolysis of Diarylfumaronitrile at Various pH. The buffered solutions employed consist of citrate-phosphate-borate system. To a 25 ml buffer solution (0.01 M) was added *ca.* 10 ml ethanol with shaking, and then 5 ml 8×10^{-4} M ethanol solution of diarylfumaronitrile and finally ethanol in order to adjust the volume of the solution to 50 ml. A solution (4 ml) placed in a quartz cell (10×10 mm) was irradiated with 330 nm light at room temperature, and the UV spectrum was measured at intervals. The remaining sample solutions were subjected to pH measurement. Examination of EDQ diagram was carried out at pH 4.0, 5.0, 7.0, and 9.0.

Measurement of pH-Dependency of the Photoproduct Distribution. A cylindrical Pyrex cell containing 10 ml of the buffered solution was immersed in a thermostatted bath and irradiated through a quartz widnow with a 450 W mercury lamp until no more spectral change was observed. The irradiation time was *ca.* 5 min. The absorption spectra of the products at various pH showed isosbestic points. Since the prolonged irradiation caused gradual disappearance of 3,9,10-tricyanophenanthrene in aqueous ethanol, its yield was estimated by extrapolation. When buffered solutions of α-phenyl-β-(*p*-cyanophenyl)acrylonitrile (4.3×10^{-5} M) in aqueous ethanol were irradiated in a similar manner the absorption maxima at 313 and 324 nm due to 3,9-dicyanophenanthrene decreased and those at 272 and 241 nm due to 9,10-dihydro-3,9-dicyanophenanthrene increased with decrease in the pH of solutions. No isosbestic point appeared in the spectra of the irradiated solutions at various pH, the composition of the products being more complicated. No maxima due to the phenanthrene was observed at pH less than 4.

Observation of Colored Intermediate. A solution of diphenylfumaro- or maleonitrile (*ca.* 10^{-3} M) was irradiated with 320 nm light. Coloration was observed in chloroform, carbon tetrachloride, ethyl acetate, benzene, and toluene. The absorbance of the intermediate at 480 nm in toluene was recorded at intervals and found to decay following first order kinetics. The half lifetime was 100 s at room temperature.

The authors are indebted to Prof. Dr. G. Quinkert and Dr. H. C. Steinmetzer, University of Frankfurt am Main, for their valuable suggestions and discussions.

Ring-enlargement of Methoxynaphthalenes with Dichlorocarbene to Benzotropone Derivatives

Masaru SATO, Josuke TSUNETSUGU, and Seiji EBINE

Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama 338

(Received December 5, 1975)

The dichlorocarbene addition to various di- and trimethoxynaphthalenes has been investigated systematically. It has been found that the carbene addition is oriented by the 1-methoxyl group to the 3,4-double bond and by the 2-methoxyl group to the 1,2-double bond of naphthalene nucleus, and that the spontaneous cyclopropane ring-opening of the intermediate carbene-adducts leads to the preferencial formation of 2,3-benzotropone over 4,5-benzotropone derivatives. The steric effects by methoxyl group seem not to be significant in either the carbene-addition or ring-opening reaction.

There are several reports on the ring-enlargement reactions of benzenoid aromatic system with dihalocarbene to seven-membered or larger ring non-benzenoid aromatic systems. For example, azulene[1] was obtained from indene, bromotropone was formed from anisole,[2] and chlorobenzotropone derivatives were prepared from methoxynaphthalenes[2,3] by ring-enlargement reactions with dihalocarbene. Recently, benzocyclooctatrienedione derivatives were synthesized by the reaction of tetramethoxynaphthalene or tetramethylpurpurogallin with dichlorocarbene.[4] A benzo[3,4]cyclobuta[1,2-*c*]tropone derivative was obtained through the ring-enlargement of methoxybiphenylene with dichlorocarbene.[5] However, scarcely no systematic investigations of dichlorocarbene addition to substituted benzenoid compounds, in contrast with that to olefinic compounds,[6] have been reported. This paper will deal with a systematic examination of the ring-enlargement of methoxynaphthalenes with dichlorocarbene and with the orientation effect of the methoxyl group on the methoxynaphthalene-dichlorocarbene addition.

Results

1,2-Dimethoxynaphthalene was treated with one equivalent amount of the dichlorocarbene source, according to Makosza's method,[7] to give three kinds of products, **1**, **2**, and **3**. The IR and NMR spectra of **1** were superimposable upon those of an authentic sample of 7-chloro-6-methoxy-2,3-benzotropone,[8] and no temperature-depression was observed on their admixture.

Compound **2** showed an NMR spectrum with two doublets at δ 6.93 and 7.51 ppm (J=12.6 Hz). The electronic spectrum of **2** was closely similar to that of 2-chloro-4,5-benzotropone.[3] These spectral data are in accordance with the structure of 2-chloro-3-methoxy-4,5-benzotropone (Fig. 1).

Compound **3** showed, in its NMR spectrum, two doublets at δ 6.62 and 7.73 ppm with a small coupling constant (J=2.0 Hz), indicating the presence of two protons in the allylic positions each other of the seven-membered ring, so suggesting that the product is identifiable as 5-chloro-7-methoxy-2,3-benzotropone. Curiously enough, **3** was not necessarily reproduced in repeated experiments. The use of a large excess of carbene source failed to improve the yield of the tropone derivatives; it resulted only in the formation of a considerable amount of an intractable substance.

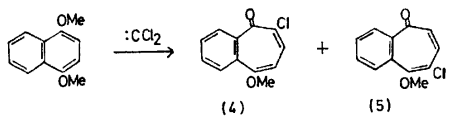
(1) (2) (3)

The reaction of 1,4-dimethoxynaphthalene with one equivalent amount of the dichlorocarbene source gave the product **4**. Its NMR spectrum showed two characteristic doublets (J=10.0 Hz), at δ 6.01 and 7.58 ppm, for H-5 and H-6, and a pair of multiplets for benzenoid 2H deshielded and benzenoid 2H not deshielded by either the carbonyl or methoxyl group. From the NMR spectra, **4** was assigned to 7-chloro-4-methoxy-2,3-benzotropone. The structure was further confirmed by conversion to the Diels-Alder adduct (**6**), whose NMR spectrum showed two olefinic doublets, at δ 6.34 and 7.08 ppm (J=9.5 Hz), indicating that **4** is unsubstituted at C-5 and C-6.

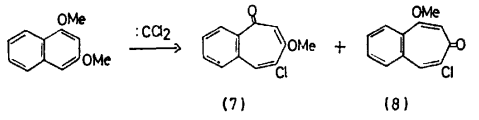
The use of three molar amounts of the dichlorocarbene source afforded an additional, thermally unstable product (**5**), which showed IR and mass spectra closely similar to those of **4**. The NMR spectrum showed two olefinic doublets (J=12.0 Hz), at δ 6.68 and 7.22 ppm. Thus, **5** was proved to be 5-chloro-4-methoxy-2,3-benzotropone.

1,3-Dimethoxynaphthalene reacted with dichloro-



(4) (5)

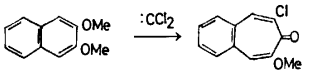
carbene to give two products, **7** in an 8.0% yield and **8** in a 2.9% yield, their UV and NMR spectra were quite similar to those of 5-bromo-6-methoxy-2,3-benzotropone and 2-bromo-6-methoxy-4,5-benzotropone respectively.[9] Therefore, **7** and **8** can be said to be 5-chloro-6-methoxy-2,3-benzotropone and 2-chloro-6-methoxy-4,5-benzotropone respectively.



(7) (8)

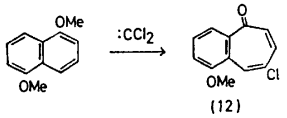
Further structural evidence was obtained by the hydrolysis of **7** and **8** with concentrated hydrochloric acid in boiling ethanol to give the same product, 5-chloro-6-hydroxy-2,3-benzotropone (**9**), whose NMR spectrum showed no methoxyl proton and two olefinic protons as two singlets at δ 6.74 and 8.31 ppm, the former disappearing on the addition of deuterated water. **7** gave the Diels-Alder adduct (**10**), but **8** gave no adduct, on heating with maleic anhydride, affording an additional proof of their structures.

The reaction of 2,3-dimethoxynaphthalene with dichlorocarbene afforded a scanty yield of 7-chloro-2-methoxy-4,5-benzotropne (**11**). The structural assignment is based on the electronic (Fig. 1) and NMR spectra : methoxyl singlet at δ 4.01 ppm, two deshielded olefinic singlets at δ 7.19 and 8.32 ppm for H-3 and H-6, and a narrow multiplet at δ 7.6—7.9 ppm for four benzenoid protons.



(11)

The reaction of 1,5-dimethoxynaphthalene with dichlorocarbene gave a product (**12**), in a poor yield, which was conclusively identified as 5-chloro-3'-methoxy-2,3-benzotropone by the following NMR spectrum: a doublet (J=2.0 Hz) at δ 8.27 ppm, deshielded by both methoxyl and chloro substituents, for H-4, a doublet (J=13 Hz) at δ 6.78 ppm for H-7, a doublet at δ 7.17 ppm for H-6, and an ABC-type three-proton system at δ 7.1—8.0 ppm for benzene-ring protons.



(12)

1,6-Dimethoxynapnthalene reacted with dichlorocarbene to give two products, **13** in a 9.9% yield and **14** in a 4.9% yield. The electronic spectrum of **13** was similar to that of 5-chloro-2,3-benzotropone (Fig. 2). The NMR spectrum of **13** showed an olefinic doublet (J=13.0 Hz) at δ 6.81 ppm, meaning that the

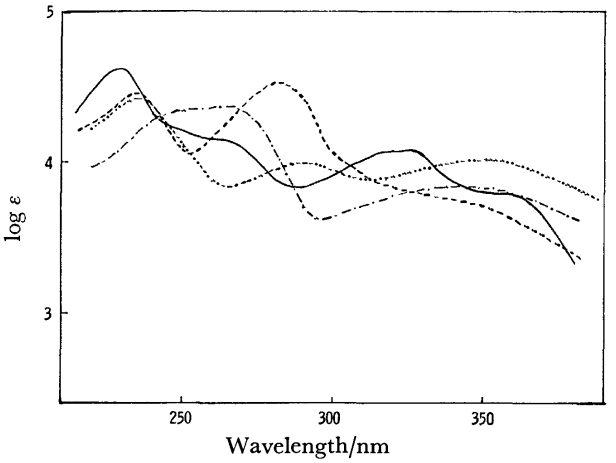


Fig. 2. The UV spectra of 2,3-benzotropones.
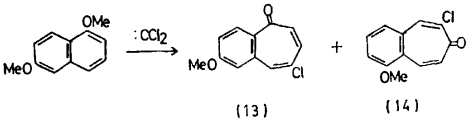
——: 5-Chloro-2,3-benzotropone, ·····: 5-chloro-3'-methoxy-2,3-benzotropone(**12**), ----: 5-chloro-4'-methoxy-2,3-benzotropone(**13**), —·—·: 5-chloro-6,7-dimethoxy-2,3-benzotropone(**15**).

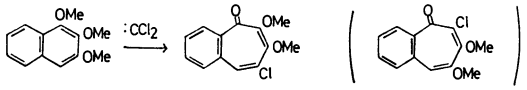
chloro substituent is at C-5 rather than at C-7, since the chemical shift of the doublet is very similar to those of 5-chloro-2,3-benzotropone (δ 6.83 ppm) and **12** (δ 6.78 ppm). Therefore, **13** is identified as 5-chloro-4'-methoxy-2,3-benzotropone. The peri-position of the benzene ring, deshielded by the carbonyl group, appeared as a doublet (J=9.0 Hz) in the lower region (δ 8.47 ppm), indicating that the methoxyl group is situated at C-4'.

The other product (**14**) showed an NMR spectral olefinic singlet (δ 8.17 ppm) and doublet (δ 8.35 ppm, J=13.5 Hz) in a remarkably lower field; they are probably due to the anisotropy of the methoxyl group and the inductive effect of the chloro substituent. The electronic spectrum showed that **14** has a chromophore of 2-chloro-4,5-benzotropone (Fig. 1). These observations can be satisfactorily explained by assigning **14** to 2-chloro-3'-methoxy-4,5-benzotropone.



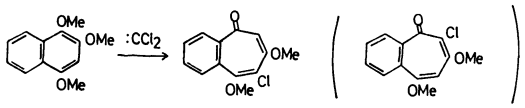
(13) (14)

1,2,3-Trimethoxynaphthalene, on treatment with dichlorocarbene, gave a sole isolable product (**15**). The electronic spectrum showed the presence of a 2,3-benzotropone structure (Fig. 2), and the NMR spectrum showed an olefinic proton signal of the seven-membered ring overlapped with benzenoid protons in a region similar to that of the H-4 of 5-chloro-2,3-benzotropone derivatives [δ 7.37 in **3** and 7.55—7.85 ppm in **7**]. Moreover, if the compound has the **16** structure, the H-4 resonance should appear in a higher field than that of 7-chloro-6-methoxy-2,3-benzotropone(**1**) (δ 7.15 ppm). This does, however, not happen. In the mass spectrum, methyl elimination preceded carbon dioxide elimination, unlike as in other benzotropone derivatives. These spectral data agree with the structure of 5-chloro-6,7-dimethoxy-2,3-benzotropone rather than with the **16** structure.



(15) (16)

1,2,4-Trimethoxynaphthalene reacted with dichlorocarbene to afford only one benzotropone derivative, in an 18% yield. The product **18** showed an NMR signal of the olefinic proton as a singlet at a fairly high field (δ 6.29 ppm) and four benzenoid protons as a pair of multiplets similar to those in 4-methoxy-2,3-benzotropones (**4** and **5**). The olefinic proton is not situated at the 6-position, since the resonance of the H-6 of 2,3-benzotropone derivatives should appear in a lower field because of the electronic effect of the carbonyl group [*e.g.*, δ 6.62 ppm in **3** and δ 7.58 ppm in **4**]. The product gave the Diels-Alder adduct (**20**) with maleic anhydride, whose NMR spectrum showed no resonance in the olefinic region, indicating that **18** has no proton at the 5- and 6-positions. Consequently, **18** proved to be 5-chloro-4,6-dimethoxy-2,3-benzotropone, excluding the **19** structure.



(18) (19)

The reaction of 1,2,3,4-tetramethoxynaphthalene with dichlorocarbene failed to give a difinite isolable product, but the NMR spectrum indicated the formation of a benzotropone derivative with no olefinic proton and three methoxyl proton signals, and the mass spectrum showed a molecular ion at *m/e* 280.

Discussion

It is known that two types of benzenoid aromatic compounds are susceptible to the attack of dichlorocarbene. One type includes fused-ring aromatic compounds, such as naphthalene,[10,11] phenanthrene,[10,11] and anthracene,[11,12] which have a small loss of resonance energy in the formation of the dihalocarbene adduct. The other type includes the aromatic compounds carrying an electron-donating substituent, such as methylnaphthalene[13] and methoxynaphthalenes,[2,3a,3b] in which the substituent not only facilitates the dichlorocarbene addition, but also might influence the orientation of the dichlorocarbene attack. The reaction of anisole with dibromocarbene affords 4-bromotropone,[2] and the reaction of 1-methoxynaphthalene gives 5-halo-2,3-benzotropone[3c-3e] exclusively, no other isomeric tropones being obtained.* 1,5- And 1,6-dimethoxynaphthalenes also reacted with dichlorocarbene to give exclusively 5-chloro-2,3-benzotropone derivatives **12** and **13** respectively. On the other hand, the reaction of 2-methoxynaphthalene with dihalocarbene afforded 2-halo-4,5-benzotropone. 2,3- And 1,6-dimethoxynaphthalenes reacted with dichlorocarbene to give 2-chloro-4,5-benzotropone derivatives, **11** and **14** respectively. These results suggest that dichlorocarbene adds regioselectively to the 3,4-double bond of 1-methoxynaphthalene derivatives and to the 1,2-double bond of 2-methoxynaphthalene derivatives. This selective carbene addition orientated by the methoxyl group was found to be consistent throughout the di- and trimethoxynaphthalenes (that is, the additivity of the effect from methoxyl groups was observed).

1,3-Dimethoxynaphthalene, in which both the methoxyl groups accelerate carbene addition to the 3,4-double bond, gave, as expected, the **7** and **8** products, which must have been derived *via* an intermediate 3,4-double bond adduct. 1,2,3- And 1,2,4-trimethoxynaphthalenes also gave a single product, **15** and **18** respectively. Carbene addition to 1,2,3-trimethoxynaphthalene occurs exclusively at the 3,4-double bond because of the orientation effect by the 1-methoxyl group, where the orientation to the 1,2-double bond by the 2-methoxyl group is cancelled by that to the 3,4-double bond by the 3-methoxyl group. Similarly, addition to 1,2,4-trimethoxynaphthalene takes place at the 1,2-double bond in terms of the 2-methoxyl group because the orientation effects by the 1- and 4-methoxyl groups cancel each other. 1,2-Dimethoxynaphthalene reacted with dichlorocarbene both at the 3,4-double bond, oriented by the 1-methoxyl group, to give **3** and at the 1,2-double bond, oriented by the 2-methoxyl group, to give **1** and **2** [although **3** was not necessarily reproduced in repeated experiments, as has been described above].

The ^{13}C-NMR spectra of methoxynaphthalenes[14] afford information about their ground-state electronic state, and may be expected to elucidate the regioselectivity of dichlorocarbene addition to the methoxynaphthalenes. In fact, a good correlation was observed between the orientation of carbene addition and the electron density deduced from the ^{13}C-NMR chemical shift of the 2-methoxynaphthalene derivatives. However, no such correlation was observed in 1-methoxynaphthalene or its derivatives. In 1-methoxy- and 1,3-dimethoxynaphthalene, for example, the electron density of C-4, as deduced from ^{13}C-NMR spectra, was lower than that of C-2, whereas the dichlorocarbene addition took place at the 3,4-double bond exclusively. The regiospecific addition observed in the dichlorocarbene addition to methoxynaphthalene derivatives might be explained in the following manner: the approach of dichlorocarbene to 1-methoxynaphthalene or its derivatives induces a dynamic polarization of electrons on the naphthalene nucleus by the methoxyl group and accumulates a negative charge at C-4 rather than at C-2, as in the electrophilic substitution of naphthalene derivatives, so that the electrophilic dichlorocarbene approaches asymmetrically to the 3,4-double bond from the direction of the electron-rich C-4 to form dihalocyclopropano-dihydronaphthalene intermediates.

The cyclopropane ring-opening of the intermediate carbene-adducts is largely facilitated by aromatization, leading to benzotropone derivatives, since the dichlorocarbene adduct of 1-ethoxy-3,4-dihydronaphthalene

* The reaction of 1-methoxynaphthalene with dichlorocarbene generated by Makosza's method gave 5-chloro-2,3-benzotropone exclusively in our experiment also.

was not affected even by silver(I) salt at room temperature.[15] The ring-enlargement of the intermediates led to the preferential formation of 2,3-benzotropone derivatives over 4,5-benzotropone derivatives. Thus, the intermediate adduct from 1,3-dimethoxynaphthalene with dichlorocarbene gave **7** more predominantly than **8**. A similar trend was observed in 1,2-dimethoxynaphthalene. 1,2,3- And 1,2,4-trimethoxynaphthalenes also gave only the 2,3-benzotropone derivatives, **15** and **18** respectively. Furthermore, it should be noted that the direction of the ring opening of the intermediate 1,2,3- and 1,2,4-trimethoxynaphthalene-carbene adducts to **15** and **18** respectively is comparable with that of an intermediate 1,4-dimethoxynaphthalene-carbene adduct to **5**.

Finally, the steric effect by the methoxyl group seems not to be significant in either the addition of dichlorocarbene to methoxynaphthalenes or the ring opening of the intermediate carbene adducts, because the carbene adds exclusively to the most hindered 1,2-double bond of 1,2,4-trimethoxynaphthalene and the ring opening of the adduct gives a more hindered product **18** rather than a less hindred **19**.

Experimental

Material. The 1- and 2-methoxynaphthalenes were commercially available. The 1,2-dimethoxynaphthalene was prepared by the reduction and methylation of commercially available 1,2-naphthoquinone. The 1,4-, 1,5-, 1,6-, and 2,3-dimethoxynaphthalenes were prepared by the methylation of the corresponding commercially available diols with dimethyl sulfate. The 1,3-,[16] 1,2,3-,[17] and 1,2,4-trimethoxynaphthalenes[18] were prepared according to the literature.

The *1,2,3,4-tetramethoxynaphthalene*[19] was prepared in the following manner. Dimethylisonaphthazalin[20] (3.7 g, 17 mmol) was stirred, portion by portion, into a mixture of ether (30 ml) and aqueous sodium dithionite (6.0 g in 30 ml of water). After 20 min, the mixture was transferred into a separable funnel and shaken vigorously. The ethereal layer was separated, and the aqueous layer was extracted with ether. The combined organic solution was dried over magnesium sulfate, filtered, and evaporated. The pale red residual oil was added to a solution of dimethyl sulfate (4.8 ml, 51 mmol) in ethanol (15 ml), and to this was added, drop by drop, 50% aqueous sodium hydroxide (5.1 ml) under an atmosphere of nitrogen. After it had then stood overnight, the solution was diluted with water, and the colorless needles which were thus precipitated were collected, washed with water, and dried. Yield: 3.6 g (86%); mp 49—53 °C, which rose to 52—53 °C upon chromatographic purification and recrystallization from hexane. Found: C, 67.75; H, 6.58%. Calcd for $C_{14}H_{16}O_4$: C, 67.72; H, 6.50%. NMR($CDCl_3$): δ 4.05 (s, 12H), 7.43 (q, 2H, J=3.2 Hz), and 8.09 (q, 2H, J=3.2 Hz).

Standard Procedure. Methoxynaphthalenes (0.03 mol), chloroform (3 ml, 0.037 mol), 50% aqueous sodium hydroxide (6 ml), and triethylbenzylammonium chloride (0.12 g) were placed in a 50-ml Erlenmeyer flask equipped with a potassium hydroxide tube, after which the mixture was stirred at room temperature for 15 to 16 h. The reaction mixture was then diluted with water and extracted with dichloromethane. The extract was washed with water and dried over anhydrous sodium sulfate. After the solvent had been removed, the residue was chromatographed on a silica gel column, with the elution of the benzene-ether mixture. Each fraction separated was purified by fractional chromatography or sublimation.

*7-Chloro-6-methoxy-2,3-benzotropone (**1**), 2-Chloro-3-methoxy-4,5-benzotropone (**2**), and 5-Chloro-7-methoxy-2,3-benzotropone (**3**).* 1,2-Dimethoxynaphthalene was submitted to the reaction with dichlorocarbene; after a standard work-up, the reaction mixture was chromatographed to give a dark red oil containing crystals. Rechromatography on a silica gel column and sublimation gave three crystalline products. One was 7-chloro-6-methoxy-2,3-benzotropone (**1**) (1.8%); yellow needles; mp 135—136 °C, which showed no depression on admixture with an authentic sample.[6] NMR($CDCl_3$): δ 4.05 (s, 3H), 6.85 (d, 1H, J=13.0 Hz), 7.45 (d, 1H, J=13.0 Hz), 7.5—7.9 (m, 3H), and 8.6 (m, 1H) ppm. The second (1.5%) is assigned to 2-chloro-3-methoxy-4,5-benzotropone (**2**); colorless needles; mp 95—96 °C. Found: C, 65.23; H, 4.16%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 238 (log ε 4.39), 274.5 (4.59), 340 (3.52), and 357 nm (3.11). IR(KBr): 1641 (s), 1610 (sh), 1594(s), and 1572 (m) cm^{-1}. NMR($CDCl_3$): δ 3.95 (s, 3H), 6.93 (d, 1H, J=12.6 Hz), 7.51 (d, 1H, J=12.6 Hz), 7.65—7.85 (m, 3H), and 8.2—8.4 (m, 1H). The third product, 5-chloro-7-methoxy-2,3-benzotropone (**3**), which, curiously could not be reproduced, in repeated experiments, was eluted faster than the above two. After sublimation and recrystallization from cyclohexane, it formed nearly colorless needles; mp 100 °C. Found: C, 65.25; H, 4.05%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 237 (log ε 4.38), 260sh (4.16), 330 (3.90), and 368 nm (3.14). IR(KBr): 1625 (s), 1610 (s), 1593 (s), and 1570 (m) cm^{-1}. NMR($CDCl_3$): δ 3.93 (s, 3H), 6.62 (d, 1H, J=2.0 Hz), 7.37 (d, 1H, J=2.0 Hz), 7.5—7.85 (m, 3H), and 8.5 (m, 1H).

*7-Chloro-4-methoxy-2,3-benzotropone (**4**) and 5-Chloro-4-methoxy-2,3-benzotropone (**5**).* The reaction of 1,4-dimethoxynaphthalene with dichlorocarbene was run using the standard procedure, and the product was chromatographed on silica gel to give two crystalline fractions. The yellow orange crystals obtained from the first elute (4.28 g, 76%) were the starting material. The second was a dark red oil which was then heated *in vacuo* to give 7-chloro-4-methoxy-2,3-benzotropone (**4**) as pale yellow crystals (0.68 g, 10.2%). Recrystallization from methanol gave an analytical sample; mp 133—133.5 °C. Found: C, 65.24; H, 4.04%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 236.5 (log ε 4.36), 256.5 (4.24), 332 (3.81), and 382 nm (3.92). IR (KBr): 1612 (s), 1593 (s), and 1565 (s) cm^{-1}. NMR ($CDCl_3$): δ 3.97 (s, 3H), 6.01 (d, 1H, J=10.0 Hz), 7.58 (d, 1H, J=10.0 Hz), 7.6—7.9 (m, 2H), and 8.3—8.6 (m, 2H). Diels-Alder adduct with maleic anhydride (**7**): colorless crystals; mp 241—242 °C. Found: C, 60.09; H, 3.52%. Calcd for $C_{18}H_{11}O_5Cl$: C, 60.29; H, 3.48%. NMR(DMSO-d_6): δ 3.65 (s, 3H), 4.26 (d, 1H, J=10.8 Hz), 4.76 (d, 1H, J=10.8 Hz), 6.34 (d, 1H, J=9.5 Hz), 7.08 (d, 1H, J=9.5 Hz), 7.5—7.85 (m, 3H), and 7.95—8.2 (m, 1H).

The reaction with three molar amounts of the dichlorocarbene source was run and the crude product was chromatographed on silica gel to give an orange semi-solid besides the recovered substance (4.2 g, 75%). The semi-solid was recrystallized from ether to give (**4**) (0.88 g, 12.4%). The mother liguor gave an additional crop of crystals (**5**), which recrystallized from cyclohexane (0.19 g, 2.9%); mp 55.5—56.5 °C. Found: C, 65.29; H, 4.03%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 231 (log ε 4.39), 312 (3.92), and 355 nm (3.83). IR(KBr): 1628 (s), 1608 (s), 1590 (s), 1570 (s), and 1530 (s) cm^{-1}. NMR-($CDCl_3$): δ 3.80 (s, 3H), 6.68 (d, 1H, J=12.0 Hz), 7.22 (d, 1H, J=12.0 Hz), 7.5—7.9 (m, 3H), and 8.1—8.5 (m, 2H).

*5-Chloro-6-methoxy-2,3-benzotropone (**7**) and 2-Chloro-6-methoxy-4,5-benzotropone (**8**).* The reaction of 1,3-dimethoxynaphthalene with dichlorocarbene was carried out by means of the standard procedure, and the reaction product was chromatographed on silica gel to give three fractions. The first fraction was the starting material (4.3 g, 76%). The second was recrystallized from ethanol to give 5-chloro-6-methoxy-2,3-benzotropone (**7**) (0.53 g, 8.0%); colorless needles; mp 149—151 °C. Found C, 65.10; H, 4.26%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 252 (log ε 4.78), 261 (4.76), 270sh (4.60), 335 (4.00), and 368sh nm (3.26). IR(KBr): 1620(w), 1607(w), 1580(m), 1566(s), and 1560(s) cm^{-1}. NMR($CDCl_3$): δ 3.82 (s, 3H), 6.54 (s, 1H), 7.55—7.85 (m, 4H), and 8.55 (m, 1H). Diels-Alder adduct with maleic anhydride (**10**): colorless crystals, mp 251—253 °C. Found: C, 60.48; H, 3.47%. Calcd for $C_{16}H_{11}O_5Cl$: C, 60.29; H, 3.48%. NMR (DMSO-d_6): δ 3.68 (s, 3H), 4.0—4.45 (m, 4H), 7.5—7.8 (m, 3H), and 8.0—8.2 (m, 1H). The third was recrystallized from hexane-benzene to give 2-chloro-6-methoxy-4,5-benzotropone (**8**) (0.19 g, 2.9%); colorless crystals; mp 125—126.5 °C. Found: C, 65.14; H, 4.04%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 256 (log ε 4.58), 263 (4.60), 273 (4.68), 288sh (4.22), and 312sh nm (3.92). IR (KBr): 1622(s), 1609(m), 1596(m), 1587(s), and 1522(m) cm^{-1}. NMR($CDCl_3$): δ 4.13 (s, 3H), 6.76 (s, 1H), 7.7—7.95 (m, 3H), 8.16 (s, 1H), and 8.55 (m, 1H).

*5-Chloro-6-hydroxy-2,3-benzotropone (**9**).* 5-Chloro-6-methoxy-2,3-benzotropone (**7**) (0.13 g, 0.6 mmol) and concentrated hydrochloric acid (1 ml) in ethanol (10 ml) were refluxed for 2.5 h. After evaporation, the residue was recrystallized from ethanol to give 5-chloro-6-hydroxy-2,3-benzotropone (**9**); colorless needles (0.10 g, 85%); mp 251 °C (dec). Found: C, 64.30; H, 3.66%. Calcd for $C_{11}H_7O_2Cl$: C, 63.94; H, 3.41%. IR(KBr): 3075—2300 (broad), 1620, 1590, 1557, and 1523 cm^{-1}. NMR (DMSO-d_6): δ 3.5 (broad, 1H), 6.74 (s, 1H), 7.8—8.1 (m, 3H), 8.31 (s, 1H), and 8.35—8.5 (m, 1H). UV(EtOH): 266 (log ε 4.48), 274.9 (4.60). 283.7 (4.54), 306 (3.72), 331 (3.78), and 350 nm (3.78).

*2-Chloro-6-methoxy-4,5-benzotropone (**8**)* (34 mg, 0.15 mmol) was similarly heated for 2 h with concentrated hydrochloric acid (0.3 ml) in ethanol (3 ml), giving the same product as described above (31 mg, 97%).

*2-Chloro-7-methoxy-4,5-benzotropone (**11**).* To a solution of 2,3-dimethoxynaphthalene (5.64 g, 0.03 mol) in chloroform (6 ml) and benzene (10 ml) were added triethylbenzylammonium chloride (0.12 g) and 40% aqueous potassium hydroxide (8 ml). After it had been stirred for 20 h at room temperature, the reaction mixture was worked-up as usual and the product was recrystallized from methanol to give 3.33 g of unchanged dimethoxynaphthalene. The filtrate was chromatographed on silica gel. The elute gave again 2.25 g of the starting material. The total recovery was 99%. The subsequent dichloromethane elute gave a yellow-brown crystalline product which, on sublimation (110 °C/2Torr) and recrystallization from methanol, afforded **11** as pale yellow needles (25 mg, 0.4%); mp 138—140 °C. The melting point was raised to 144—145 °C by repeated recrystallizations from methanol. Found: C, 65.10; H, 4.02%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 244 (log ε 4.54), 250 (4.56), 286 (4.76), and 316 nm (4.06). IR(KBr): 1620(s), 1603sh, and 1538(w) cm^{-1}. NMR($CDCl_3$): δ 4.03 (s, 3H), 7.19 (s, 1H), 8.37 (s, 1H), and 7.6—7.9 (m, 4H).

*5-Chloro-3'-methoxy-2,3-benzotropone (**12**).* A mixture of 1,5-dimethoxynaphthalene, chloroform (twice the standard amount), 50% aqueous sodium hydroxide, and triethylbenzylammonium chloride was treated as usual. Benzene was added to the reaction mixture, and the crystals which precipitated were collected by filtration and extracted with ether by means of Soxhlet extractor, giving the starting material (2.85 g). The filtrate was evaporated and the brown residue was recrystallized from benzene to give a further amount of the starting substance (1.04 g). The mother liquor from recrystallization was charged on a silica gel-column chromatograph. The first fraction was the starting material (0.44 g), while the second was a yellow crystalline product which was rechromatographed and recrystallized to give 5-chloro-3'-methoxy-2,3-benzotropone (**12**) as yellow needles (93 mg, 1.4%); mp 123—124 °C. Found: C, 64.92; H, 4.05%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 235 (log ε 4.42), 290 (3.99), and 348 nm (4.01). IR(KBr): 1630(w), 1586(s), and 1573(s) cm^{-1}. NMR($CDCl_3$): δ 3.99 (s, 3H), 6.78 (d, 1H, J= 13.0 Hz), 7.17 (dd, 1H, 13.0 and 2.0 Hz), 7.19 (dd, 1H, J=8.0 and 1.5 Hz), 7.63 (t, 1H, J=8.0 Hz), 8.01 (dd, 1H, J=8.0 and 1.5 Hz), and 8.27 (d, 1H, J=2.0 Hz).

*5-Chloro-4'-methoxy-2,3-benzotropone (**13**) and 2-Chloro-3'-methoxy-4,5-benzotropone (**14**).* The residue from the standard work-up in the reaction of 1,6-dimethoxynaphthalene was chromatographed on silica gel. The first elute was the recovered starting meterial (3.03 g, 55%). The second eluate (brown crystals) was rechromatographed on silica gel to give two crystalline fractions. One was recrystallized from benzene to give 5-chloro-4'-methoxy-2,3-benzotropone (**13**) as colorless leaflets (0.65 g, 9.9%); mp 144—144.5 °C. Found: C, 65.28; H, 4.03%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 234.3 (log ε 4.26), 282 (4.53), and 340 sh nm (3.74). IR(KBr): 1624(w), 1583(s), and 1573(s) cm^{-1}. NMR($CDCl_3$): δ 3.96 (s, 3H), 6.81 (d, 1H, J=13.0 Hz), 6.9—7.5 (m, 4H), and 8.47 (d, 1H, J=9.0 Hz). The other was recrystallized from ethanol to give 2-chloro-3'-methoxy-4,5-benzotropone (**14**) as pale yellow needles (0.33 g, 4.9%); mp 198—199 °C. Found: C, 65.40; H, 4.36%. Calcd for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.12%. UV(EtOH): 228 (log ε 4.41), 235 (4.40), and 294.8 nm (4.59). NMR($CDCl_3$): δ 4.02 (s, 3H), 7.16 (d, 1H, J=13.5 Hz), 8.35 (d, 1H, J=13.5 Hz), 8.17 (s, 1H), and 7.2—7.8 (m, 3H).

*5-Chloro-6,7-dimethoxy-2,3-benzotropone (**15**).* The mixture of 1,2,3-trimethoxynaphthalene (1.19 g, 5.5 mmol), chloroform (2 ml, 25 mmol), 50% aqueous sodium hydroxide (2 ml), and triethylbenzylammonium chloride (60 mg) was stirred for 16 h at room temperature. After the usual work-up, the red oily product was chromatographed on silica gel to give two fractions. The first was the recovered starting material (0.13 g, 11%). The second (yellow-orange crystals) was recrystallized from cyclohexane to give 5-chloro-6,7-dimethoxy-2,3-benzortopone (**15**) as yellow needles (0.38 g, 27.5%); mp 79—84 °C. Recrystallization from cyclohexane gave an analytical sample; mp 83.5—85 °C. Found: C, 62.62; H, 4.62%. Calcd for $C_{13}H_{11}O_3Cl$: C, 62.29; H, 4.42%. UV(EtOH): 250 sh (log ε 4.95), 265 (4.38), and 340 nm (3.83). IR(KBr): 1621(s), 1593(s), 1544(w), and 1519(m) cm^{-1}. NMR($CDCl_3$): δ 3.92 (s, 3H), 3.99 (s, 3H), 7.6—7.8 (m, 4H), and 8.4—8.6 (m, 1H). Diels-Alder adduct (**17**) with maleic anhydride: colorless crystals, mp 183—184 °C. Found: C, 58.25; H, 3.64%. Calcd for $C_{17}H_{13}O_6Cl$: C, 58.55; H, 3.76%. NMR($CDCl_3$): δ 3.73 (s, 3H), 3.85 (s, 4H), 4.05 (d, 1H, J=9.6 Hz), 4.29 (d, 1H, J=2.0 Hz), 7.4—7.7 (m, 3H), and 8.1—8.3 (m, 1H).

*5-Chloro-4,6-dimethoxy-2,3-benzotropone (**18**).* A reaction mixture obtained from the standard work-up in the

reaction of 1,2,4-trimethoxynaphthalene was chromatographed on silica gel to give the starting material (4.27 g, 81.3%), as well as 5-chloro-4,6-dimethoxy-2,3-benzotropone (**18**) as straw-colored crystals (1.15 g, 17.8%), the recrystallization of which from cyclohexane gave an analytical sample, mp 98—99 °C. Found: C, 62.47; H, 4.54%. Calcd for $C_{13}H_{11}O_3Cl$: C, 62.29; H, 4.42%. IR(KBr): 1620(s), 1590(s), 1561(s), and 1540(w) cm^{-1}. NMR($CDCl_3$): δ 3.74 (s, 3H), 3.87 (s, 3H), 6.29 (s, 1H), 7.6—7.85 (m, 2H), and 8.0—8.35 (m, 2H). Diels-Alder adduct (**20**) with maleic anhydride: colorless crystals; mp 215—216 °C. Found: C, 58.60; H, 3.80%. Calcd for $C_{17}H_{13}O_6Cl$: C, 58.55; H, 3.76%. NMR($CDCl_3$): δ 3.71 (s, 3H), 2.72 (dd, 1H, J=9.6 and 1.6 Hz), 3.94 (s, 3H), 4.22 (d, 1H, J=9.6 Hz), 4.42 (d, 1H, J=1.6 Hz), 7.4—7.7 (m, 3H), and 8.1—8.4 (m, 1H).

The authors are indebted to Professor Masamatsu Hoshino of this university for providing some of the authentic samples of benzotropone derivatives for the mixed melting point determination.

Studies on 1,2,4-Thiadiazolidine Derivatives. I. The Synthesis and Structural Determination of 2,4-Disubstituted 3,5-Disubstituted Imino-1,2,4-thiadiazolidines

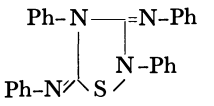
Takeshi KINOSHITA, Sadao SATO, and Chihiro TAMURA

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi Shinagawa-ku, Tokyo 140

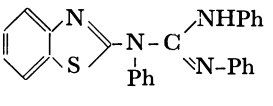
(Received December 9, 1975)

The reaction of symmetrical thiourea derivatives, RNHCSNHR, with benzoyl peroxide (BPO) gave only one isomer of 2,4-disubstituted 3,5-disubstituted imino-1,2,4-thiadiazolidines, and that of nonsymmetrical thiourea derivatives, RNHCSNHR′, with BPO yielded a mixture of some of the possible isomeric derivatives. The structures of these compounds were determined by means of NMR, mass spectra, and X-ray analyses. The steric effects of peripheral groups around the thiadiazolidine ring and some reaction mechanism are discussed.

In the past years, we have studied the oxidation reactions of thiourea derivatives with benzoyl peroxide (BPO). As reported in a preliminary paper, the oxidation of 1,3-dimethylthiourea with BPO was found to afford 2,4-dimethyl-3,5-bis(methylimino)-1,2,4-thiadiazolidine (**1a**). This reaction was initially discovered in a mass spectrometer, wherein both reagents were made to react in a sample tube and we called this a mass spectrometry reaction.[1] Later on, substance **1a** was synthesized on a laboratory scale in a good yield. In 1890 Hector[2] reported the oxidation of 1,3-diphenylthiourea by use of hydrogen peroxide and assigned, without sufficient evidence, the structure **1k** (mp 136 °C) to the product of the reaction. However, IR ane UV spectral data[3] have shown that the assignment is erroneous and the structure represented by **2** is correct. This assignment has also been confirmed by an independent synthesis from 2-anilinobenzothiazole with diphenylcarbodiimide.[4]



1k

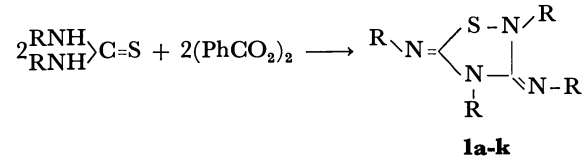


2

However, under our experimental conditions, the oxidation of 1,3-diphenylthiourea afforded 2,4-diphenyl-3,5-bis(phenylimino)-1,2,4-thiadiazolidine (**1k**, mp 51—52 °C) along with 1-benzoyl-1,3-diphenylurea. Many homologous derivatives could be synthesized under similar reaction conditions. The present paper describes these oxidation reactions and structural evidences for the related products.

Results and Discussion

Various types of thiourea derivatives have been examined as substrates for the BPO oxidation. The overall reaction may be represented in the following scheme, wherein the major by-products were benzoic acid and sulfur. The same reaction conditions were employed throughout this work, *i.e.*, the reactions were carried out by stirring the dichloromethane solution of thiourea derivatives with 1.15 equivalents of BPO for one hour at 5—10 °C. Most of the structures of the reaction products have been established by means of NMR, IR, and mass spectra and the final structural assignments of some isomers required X-ray analyses.



1a-k

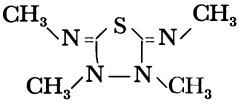
+ $4PhCO_2H$ + $1/8\ S_8$

The first choice as the substrate for the reaction was symmetrical thiourea derivatives, RNHCSNHR, which gave 1,2,4-thiadiazolidines, **1a—k**. The fundamental reaction product of **1a** ($C_6H_{12}N_4S$, *m/e* 172) was obtained from 1,3-dimethylthiourea. The NMR spectrum showed four singlet peaks at 2.49, 3.00, 3.11, and 3.28 (δ, ppm, C_6D_6). The IR absorption at 1650 cm^{-1} and the UV spectrum, λ_{max} 229 nm (EtOH), indicate that none of the C=N bonds in this molecule are conjugated. The data including the major mass fragment ions of *m/e* 102 ($M^+ - CH_3NCNCH_3$), 73 (CH_3NCS), 70 (CH_3NCNCH_3), and 61 (CH_3NS), strongly suggest that the product **1a** should be 2,4-dimethyl-3,5-bis-(methylimino)-1,2,4-thiadiazolidine.* The formation of such a thiadiazolidine ring system has also been established by an independent X-ray analysis of an other derivative as described in a later section.

Other 1,2,4-thiadiazolidine derivatives were synthesized by similar reactions (Table 1). Boiling points of some products (**1e—i**) were difficult to measure since they easily decomposed even under reduced pressure (*ca.* 2 mmHg). The yields of **1a—k** were determined by weighing the product directly after isolation by column chromatography. The mass spectrum of one of these derivatives, **1k**, is shown Fig. 1.

Four structural isomers are possible in this series of compounds as shown in Fig. 2, but in fact only one isomer could be isolated. The three isomers, **1a′**, **1a″**, and **1a‴** might be unstable, since their molecular models are considerably sterically hindered; the methyl group at the 4-position in each structure can be but-

* There is another possibility of producing the mirror symmetrical derivative, *i.e.*,



but in the NMR spectrum of **1a**, the chemical shifts of the four methyl groups have quite different values indicating that they are each situated in a different intramolecular environment. This homologue can therefore be excluded.

TABLE 1. PHYSICAL PROPERTIES AND ANALYTICAL DATA OF 1,2,4-THIADIAZOLIDINES (**1**)

Compd	R	Yield (%)	Bp °C/mmHg (Mp °C)	GLC[a] Time	GLC[a] Temp	IR[b] (cm^{-1}) C=N	Molecular[c] formula	Found (Calcd) C%	H%	N%	S%

a) 2% Silicone OV-17 on Gas Chrom Q (80—100 mesh), 1 m×2 mm i. d. glass column, flow rate: 30 ml/min He, retention time in min. b) Measured in liq. film (**1a—i**) and Nujol mulls (**1j—k**). c) Molecular formula were determined by high resolution mass spectrometry. d) Decomposed at 170—200 °C (bath temp)/2—3 mmHg.

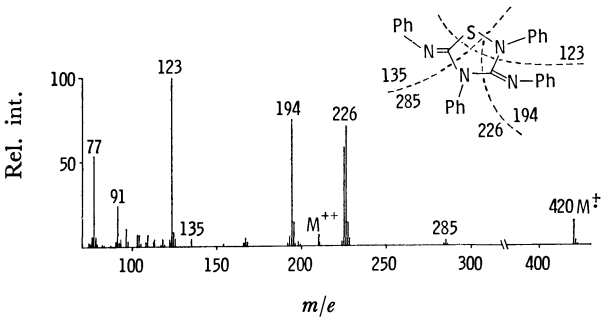

Fig. 1. Mass spectrum of **1k**.

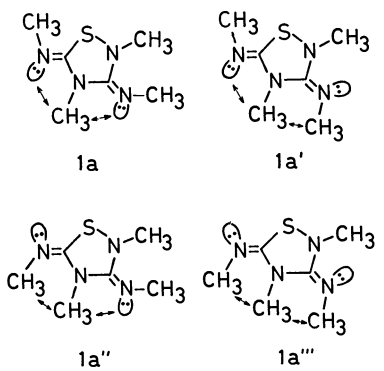

Fig. 2. Geometrical isomers of 2,4-dimethyl-3,5-bis-(methylimino)-1,2,4-thiadiazolidine.

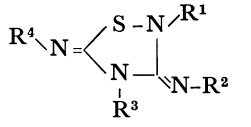
tressed either by one or two adjacent methyl groups.[5] The lone pair electrons on the imino nitrogen atoms attached to the 3- and 5-positions might affect neighbouring substituents to a smaller extent than methyl groups. The hindrances are shown by the double headed arrows in Fig. 2.

Structurally interesting molecules could be synthesized from the nonsymmetrical thiourea derivatives ($R^1NHCSNHR^2$; R^1=aryl, R^2=alkyl). There are sixteen possible different isomeric 1,2,4-thiadiazolidine derivatives through these reactions. Even if we neglect the three labile isomers such as **1a'**, **1a''**, and **1a'''**, and the four possible isomers of each (Fig. 2), there are still four isomers, **A**, **B**, **C**, and **D** left:

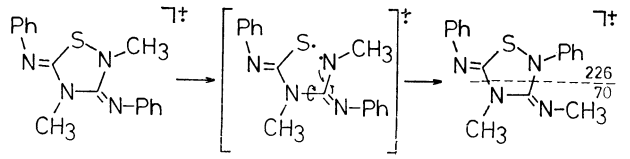


A; $R^1=R^3$=alkyl, $R^2=R^4$=aryl
B; $R^1=R^4$=aryl, $R^2=R^3$=alkyl
C; $R^1=R^4$=alkyl, $R^2=R^3$=aryl
D; $R^1=R^3$=aryl, $R^2=R^4$=alkyl

Three of these isomers could be obtained from the derivatives of 1-alkyl-3-arylthiourea. They were isolated by means of column chromatography or solubility differences in ethanol. The molecular structure of **3a** (**A**-type) was determined by X-ray analysis. The NMR spectrum of **3a** gave upfield (δ, 2.68) and down field (δ, 3.44) absorptions which were assigned to the N2 and N4 methyl groups, respectively. The assignments could be made by considering the shielding effects exerted by the diamagnetic anisotropy of the phenyl groups.

The mass spectrum of **3a** (Fig. 3) shows an ion at

m/e 226 ($C_{13}H_{10}N_2S$, MW. obsd=226.057, MW. calcd=226.056) which corresponds to the ($M^+-C_3H_6N_2$) ion. This should arise from the transannular cleavage of **3a-B** ion. Thus, the results of the mass spectrum and X-ray analysis for **3a** are apparently inconsistent. Such conflicting evidence can be explained by an intramolecular rearrangement induced by electron bombardment when the mass spectral measurement is taken.[6] Such a reaction is shown in the following scheme:

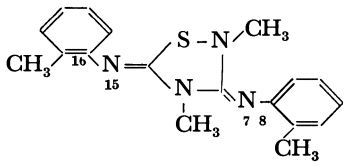


3a 3a-B

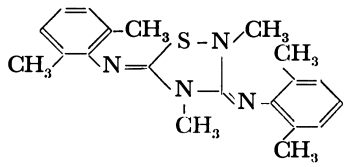
The analytical data of some **A**-type isomers are summarized in Tables 2 and 3. Their structures were established by comparison of the chemical shifts in the NMR spectra and the mass fragmentation patterns with those of **3a**.

The same reactions for thiourea derivatives containing more bulky groups at the *ortho* position in the phenyl group, such as 1-methyl-3-*o*-tolylthiourea or 1-methyl-3-(2,6-xylyl)thiourea, were carried out. These thiourea derivatives reacted with BPO to give the corresponding 1,2,4-thiadiazolidine derivatives which are sterically more hindered around the 1,2,4-thiadiazolidine ring system.

These structures were also assigned to **5** and **6** by the same procedure.



5



6

Table 4 shows the chemical shifts of the N2 and N4 methyl groups of **3a**, **5**, and **6**, in which the diamagnetic shift of the N2-methyl protons induced by virture of the benzene rings increases in the order of **6**>**5**>**3a**. Thus, the rotational angles about N7–C8 and N15–C16 bonds seem to parallel the increasing degree of steric hindrance.

On the other hand, it is noteworthy that 1-*t*-butyl-3-methylthiourea is oxidized to the corresponding urea and benzoic anhydride but not to a 1,2,4-thiadiazolidine derivative. In view of these results we propose the reaction mechanism as shown in Scheme 1.

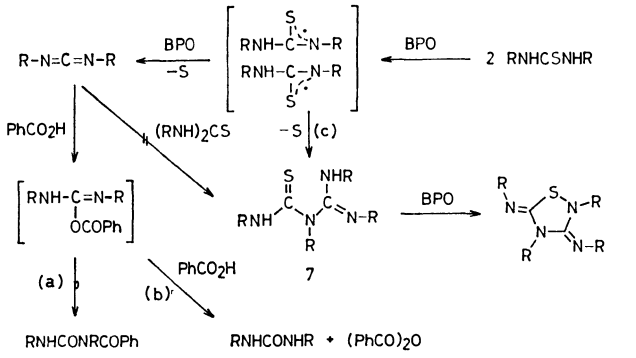

Scheme 1.

Zetzsche and his collaborators studied the reactions of carbodiimides with carboxylic acids,[7] wherein two reaction paths were reported: (a) the formation of *N*-acylureas and (b) the formation of acid anhydrides and ureas. As a general rule, aromatic carbodiimides react through route (a), but aliphatic carbodiimides give mainly acid anhydrides through route (b).[8]

Free rotation about the N-C(phenyl) bond in such a thiourea derivative as 1-methyl-3-(2,6-xylyl)thiourea may act to minimize steric hindrance when the reactants are brought closely together. However, 1-*t*-butyl-3-methylthiourea which has an even more bulky substituent may resist passing through route (c). Consequently, the latter reacts to produce a carbodiimide as a transient intermediate through route (b).

There are other reasons to support the mechanism of the formation of 1,2,4-thiadiazolidines through route (c) in Scheme 1.

1) No additional product was obtained when the mixture of 1,3-dimethylthiourea and 1,3-diisopropylcarbodiimide was brought to react in CH_2Cl_2 at room temperature for a long period. Thus the corresponding carbodiimide is not an intermediate for the formation of 1,2,4-thiadiazolidines.

2) Using a smaller amount of BPO with 1,3-diethylthiourea, the intermediate **7a** (R=Et in Scheme 1) could be isolated. Further reaction of **7a** with BPO yielded 2,4-diethyl-3,5-bis(ethylimino)-1,2,4-thiadiazolidine (**1b**). The structures of **7a** and **1b** were confirmed by their mass spectra as shown in Figs. 4 and 5,

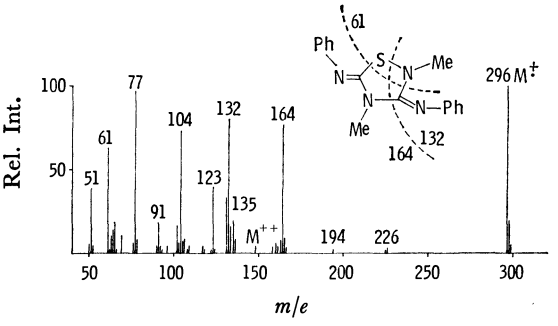

Fig. 3. Mass spectrum of **3a**.

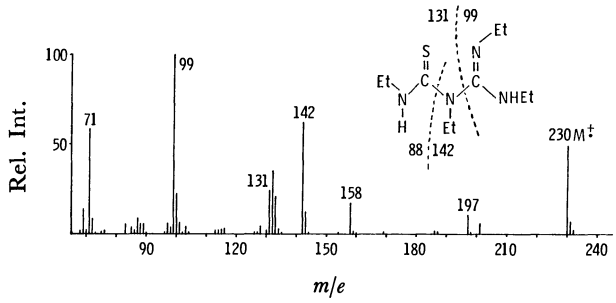

Fig. 4. Mass spectrum of **7a**.

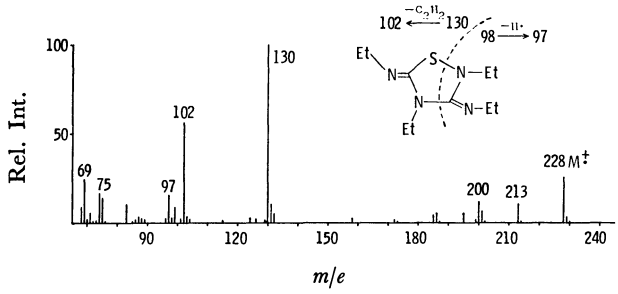

Fig. 5. Mass spectrum of **1b**.

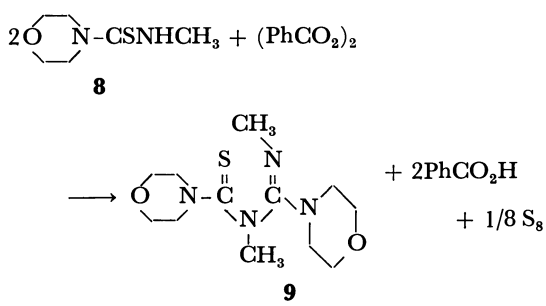
respectively.

3) Treatment of *N*-methyl-4-morpholinethiocarboxamide(**8**) with BPO gave N^1,N^2-dimethyl-N^1-morpholinothiocarbonyl-4-morpholinecarboxamidine(**9**) which is an analog of the intermediate **7** *via* route (c). The molecular structure of **9** was determined by X-ray analysis.



The investigation of the **B**, **C**, and **D** isomers of 1,2,4-thiadiazolidine derivatives is currently under progress.[9]

Experimental

All the melting points were measured on a Mitamura Riken micromelting point apparatus and are uncorrected. The IR spectra were obtained on a JASCO IRA-2 spectrophotometer and the UV spectra on a Cary 14 spectrophotometer. The NMR spectra were taken on a Varian A-60D spectrometer, using tetramethylsilane as an internal standard, and the mass spectra on a JEOL JMS-O1SG mass spectrometer, using a direct inlet and an ionization energy of 75 eV. The GLC analyses were carried out on a JEOL JGC-20KFP gas chromatograph equipped with a flame-ionization detector.

Materials. Commercial methyl, ethyl, *p*-nitrophenyl, phenyl isothiocyanates, benzoyl peroxide, and amines of the purest grade were used. Thiourea derivatives were prepared according to methods in literatures.[10-12]

Reaction of Symmetric Thioureas with BPO. To a solution of 1,3-dimethylthiourea (10.4 g, 0.1 mol) in dichloromethane (200 ml) was added dropwise a solution of BPO (27.8 g, 0.115 mol) in dichloromethane (200 ml) at 5—10 °C. After addition was over, the resulting slurry was stirred at the same temperature for one hour. The solution was then washed with an aqueous solution of sodium hydroxide (10 g, 0.25 mol) to remove benzoic acid.

The solvent was removed under reduced pressure and the resulting residue was chromatographed with petroleum ether–AcOEt (6 : 1) on a silica gel column to give **1a** (3.44 g). The physical properties and analytical data of **1a** are summarized in Table 1 along with the other derivatives (**1b-k**).

Reaction of Nonsymmetric Thioureas with BPO. From a dropping funnel, a solution of BPO (14 g, 0.058 mol) in CH_2Cl_2 (200 ml) was added to a solution of 1-methyl-3-phenylthiourea (8.3 g, 0.05 mol) in CH_2Cl_2 (200 ml) at 5—10 °C, and the reaction mixture was stirred at the same temperature for 1 h. Benzoic acid was removed with an aqueous solution of NaOH, and the solvent was removed under reduced pressure. The resulting residue was dissolved in cold acetone and filtered to remove the insoluble sulfur. After evaporation of the solvent, the residue was triturated with a small amount of cold ethanol and filtered to give **3a** (2.8 g). The filtrate was separated on a silica gel column using petroleum ether–AcOET (6 : 1) as an eluent to give **3a** (1.5 g). The physical properties and analytical data for the thiadiazolidine (**3a-i**, and **4a-g**) are summarized in Tables 2 and 3. Compounds **5** and **6** were obtained in a similar manner: **5** (in a 62% yield) oil. GLC: Retention Time 3.0 min, 2% Silicone OV-17 on Gas Chrom Q (80—100 mesh), 1 m×2 mm i. d. glass column, He flow rate 30 ml/min. Found: C, 66.69; H, 6.24; N, 17.22; S, 9.94%. Calcd for $C_{18}H_{20}N_4S$: C, 66.64; H, 6.21; N, 17.27; S, 9.88%. IR (Nujol): 1628 cm^{-1} (ν C=N). NMR (CCl_4): δ 2.19 (s, 3H), 2.23 (s, 3H), 2.60 (s, 3H), 3.48 (s, 3H), and 6.7—7.3 (m, 8H). **6** (in a 32% yield): mp 133.5 °C (from ethanol). Found: C, 68.23; H, 6.85; N, 15.68; S, 9.13%. Calcd for $C_{20}H_{24}N_4S$: C, 68.15; H, 6.86; N, 15.89; S, 9.10%. IR(Nujol): 1630 cm^{-1} (ν C=N). NMR (CCl_4): δ 2.12 (s, 6H), 2.48 (s, 3H), 3.47 (s, 3H), and 6.7—7.0 (m, 6H).

Reaction of 1-t-Butyl-3-methylthiourea with BPO. To a solution of 1-*t*-butyl-3-methylthiourea (0.05 mol) in CH_2Cl_2 was added a solution of BPO (0.06 mol) in CH_2Cl_2 with stirring under ice-cooling. The reaction is exothermic and started at once. After stirring for 1 h, the solvent was removed under reduced pressure and the residue was chromatographed over silica gel to give 1-*t*-butyl-3-methylurea, 1-*t*-butyl-3-benzoyl-3-methylurea and other by-products. None of 1,2,4-thiadiazolidine derivatives could be isolated under these conditions.

Isolation of the Intermediary Compound 7a. A solution of BPO (12.1 g, 0.05 mol) in CH_2Cl_2 was added dropwise to a solution of 1,3-diethylthiourea (13.2 g, 0.1 mol) in CH_2Cl_2 (200 ml) during 10 min with stirring under ice-cooling. The reaction mixture was kept at 5—10 °C for 30 min, and then washed with a solution of NaOH to remove the benzoic acid. After removal of CH_2Cl_2, the residue was separated on a silica gel column using ether as an eluent, and **7a** was isolated in a 2% yield (230 mg) along with the main product **1b**. Upon recrystallization from ether **7a** was obtained as colorless needles, mp 76.5 °C. Found: C, 52.23; H, 9.65; N, 24.28; S, 13.97%. Calcd for $C_{10}H_{22}N_4S$: C, 52.14; H, 9.63; N, 24.32; S, 13.92%. IR (Nujol): 3200, 1650, and 1560 cm^{-1}. NMR (CCl_4): δ 1.13 (t, 6H, J=7 Hz), 1.16 (t, 3H, J=7 Hz), 1.18 (t, 3H, J=7 Hz), 3.10 (q, 4H, J=7 Hz), 3.55 (q, 2H, J=7 Hz), and 3.88 (q, 2H, J=7 Hz).

Reaction of N-Methyl-4-morpholinethiocarboxamide 8 with BPO.

According to the usual procedure for the synthesis of thioureas, **8** was prepared from morpholine and methyl isothiocyanate. To a solution of **8** (3.2 g, 0.02 mol) in CH_2Cl_2 (200 ml) was added BPO (2.76 g, 0.0115 mol) portionwise at 5 °C. Separation was carried out in the same way as in the case of symmetric thioureas to give N^1,N^3-dimethyl-N^1-morpholinothiocarbonyl-4-morpholinecarboxamidine **9** (2.4 g, 84%), mp 151.5 °C (from benzene). Found: C, 50.37; H, 7.72; N, 19.50; S, 11.22%. Calcd for $C_{12}H_{22}N_4O_2S$: C, 50.32; H, 7.74; N, 19.50; S, 11.19%. IR (Nujol): 1645, 1470, 1300, and 1115 cm^{-1}. NMR (CCl_4): δ 2.94 (s, 3H), 3.22 (s, 3H), and 3.0—4.2 (m, 16H). Mass: *m/e* (rel. intensity) 286 (13, M^+), 271 (7, $M^+ - CH_3$), 253 (6, $M^+ - HS$), 200 (17, $M^+ - C_4H_8NO$), 127 (100, $M^+ - C_6H_{11}N_2OS$), 86 (12), and 83 (26).

Structure Determination by Means of X-Ray Analysis

Compounds **3a** and **9** were recrystallized from ethanol and from benzene, respectively. Intensity data of **3a** were obtained on a Rigaku four-circle automatic diffractometer with $\omega/2\theta$ scan technique up to $2\theta \leq 55°$ using Mo$K\alpha$ radiation, and those of **9** were collected from the equi-inclination Weissenberg photographs (*hk*0—*hk*6) with Cu$K\alpha$ radiation. They were corrected as regards Lorentz and polarization factors. No absorption correction was applied. Reflections of 1478 and 2439 were used for **3a** and **9**, respectively. The crystal data are given in Table 5.

3a: The structure of **3a** was solved by the symbolic addition technique. Nine atoms involving the thiadiazolidine ring system were revealed on the first E-map. Subsequent Fourier synthesis gave the position of all non-hydrogen atoms. Refinement of this structure was carried out by the block diagonal least-squares method to give the final *R*-factor of 0.082 including hydrogen atoms which are obtained from the difference map.

9: The structure of **9** was determined by the Patterson method. Several cycles of a block-diagonal least-squares refinement for all the atoms except hydrogen atoms gave the final *R*-factor of 0.133.

The fractional coordinates and anisotropic thermal parameters for **3a** and **9** are given in Tables 6 and 7, respectively, together with their standard deviations.

Results and Discussion

3a:[13] The bond lengths and angles are given in Fig. 6. The estimated standard deviations in the bond lengths range from 0.009 to 0.016 Å; those for the bond angles range from 0.5 to 0.9°. A stereoscopic view of the molecule projected along the b-axis is shown in Fig. 7. The deviations from various least-squares planes are given in Table 8.

The S(1)–N(2) and S(1)–C(5) bond lengths of 1.731 and 1.750 Å are comparable with those found in the S(II)–Nsp^3 and S(II)–Csp^2 single bonds. The mean

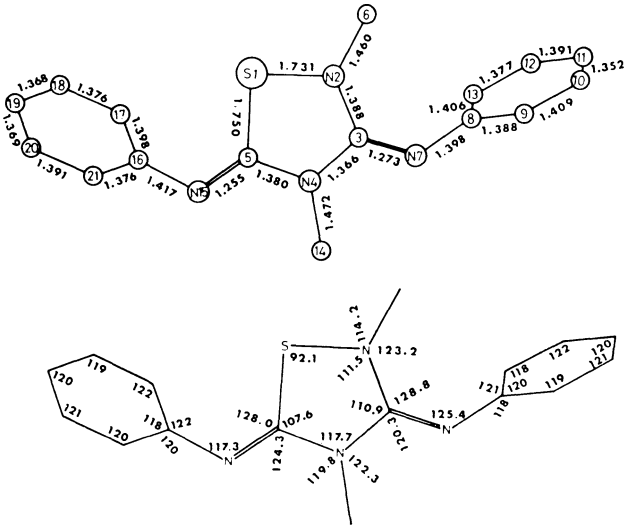

Fig. 6. Bond lengths (Å) and angles (°) of **3a**.
The mean estimated standard deviation of bond lengths is 0.011 Å, and that of bond angles is 0.7°.

value of C–N bond lengths in the thiadiazolidine ring is 1.378 Å which is compatible with those found in conjugated C–N bonds.[14] The sums of bond angles around the nitrogen atoms, N(2) and N(4), are 348.9 and 359.8° and the deviations of N(2) and N(4) from the plane consisting of the three adjacent atoms are 0.292 and 0.034 Å, respectively. The values suggest that the atomic configuration of N(4) is sp^2 hybridized, whereas the N(2) atom is sp^3 hybridized. Furthermore, there is no double bond in the thiadiazolidine ring system, only a small ring current may be expected. However, this ring system is almost planar and the maximum deviation from the mean plane is 0.035 Å. The two phenyl groups are *trans* with respect to C(3)–N(4) and the C(5)–N(4) bonds, respectively. The intramolecular non-bonded distances for N(2) ... C(8) and S(1) ... C(16) are 2.963 and 2.985 Å. The dihedral angles between the thiadiazolidine ring and these phenyl groups are 118.2 and 67.7° for planes B and C, respectively, and that between the two phenyl groups is 69.7°. The C(3)–N(7)–C(8) bond angle is 125.4° which is much greater than C(5)–N(15)–C(16) of 117.3°. This may be due to the steric hindrance between the phenyl group attached to N(7) and the

in the sp^2 hybridized form due to participation with π-electrons from the neighboring double bond. In this molecule, there are three such bonds, C(2)–N(3), C(2)–N(6), and C(4)–N(13), wherein the distances are reasonable except the N(3)–C(4) distance of 1.44 Å. Lengthening of the N(3)–C(4) bond may be due to the reduction of π-bond character at this bond by twisting. The torsional angles, C(2)–N(3)–C(4)–N(5) and C(12)–N(3)–C(4)–N(13) are 41.6 and 60.8°. The dihedral angle between the mean planes consisting of C(2)–N(3)–C(12)–C(4) and N(3)–C(4)–N(13)–N(5) is 127.6°. The sums of the bond angles around nitrogen atom are 355.3, 359.9, and 353.3° for N(3), N(6), and N(13) respectively, indicating that the N(6) atom has more sp^2 character, and the other two nitrogen atoms have sp^3 character owing to the intramolecular atomic repulsion between C(12) and C(18) The interatomic distance between these atoms is 3.24 Å. A noticeably short intermolecular atomic contact is at C(19) related by a center of symmetry with a value of 3.27 Å (Table 12).

We wish to thank Mr. Hayao Shinozaki for the IR and UV spectra, Mr. Yoji Furukawa for the NMR spectra, and Mr. Kikushige Ono for the microanalyses.

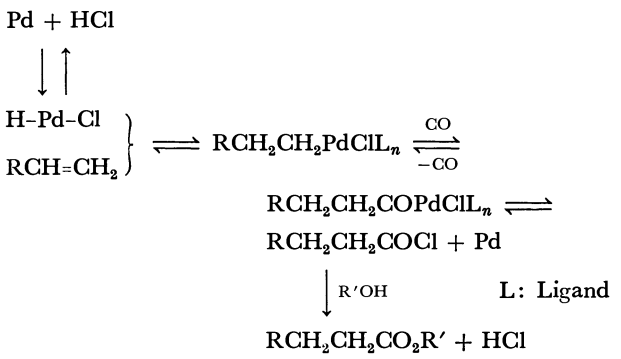
(Received December 24, 1975)

Methyl cyclohexanecarboxylate was obtained in high yields by the carbonylation of cyclohexene in a methanol solution using palladium(II) chloride-triphenylphosphine as the catalyst. The effects of variables, such as initial concentration of palladium(II) chloride, pressure of carbon monoxide, and temperature, upon the rate of carbonylation were examined kinetically. A probable reaction mechanism is proposed.

The synthesis of saturated esters from olefins, carbon monoxide and alcohol according to Eq. 1, has been described[1–6] using palladium complexes as catalysts.

$$RCH{=}CH_2 + CO + R'OH \rightarrow RCH(CO_2R')CH_3 + RCH_2CH_2CO_2R' \quad (1)$$

If water is used in place of alcohol, carboxylic acids are produced.[7] Tsuji *et al.*[8,9] proposed the mechanism shown in Scheme 1 for this reaction.



Scheme 1.

Fenton[7] considered the addition of alkoxycarbonyl or carboxyl complexes to olefins. However, very few kinetic studies have been reported on this reaction.

Methyl cyclohexanecarboxylate was obtained in high yields from cyclohexene, carbon monoxide, and methanol according to Eq. 2,

(2)

using palladium(II) chloride–triphenylphosphine as the catalyst. This paper gives the result and a discussion on the mechanism of the reaction.

Results

Preliminary Investigation. Cyclohexene was chosen as the olefin substrate since it gives no isomer. The results of carbonylation of cyclohexene under various conditions are given in Table 1. When methanol was used as the solvent, methyl cyclohexanecarboxylate was obtained in *ca.* 50% yield, a significant amount of colloidal palladium metal being found in the resulting solution. Since the palladium metal recovered was inactive for the carbonylation of cyclohexene, the low yield is attributable to the deactivation of the palladium species. In the solution containing 20% (vol.) of methanol in benzene the yield of ester increased up to 96%, no palladium metal being found during the course of reaction. Deactivation of the palladium species was negligiable.

In addition to methyl cyclohexanecarboxylate, small amounts of cyclohexyl chloride, methyl 2-chlorocyclohexanecarboxylate, and a few unidentified compounds were obtained under the conditions (Table 1). However, the sum of amounts of the remaining cyclohexene and the ester produced accounted for over 98% of the charged cyclohexene. Thus, the amounts of the by-products were neglected.

The solubility of carbon monoxide in the reaction solution was measured, the result being shown in Fig. 1. Henry's constants which were determined from the slopes of linear plots in Fig. 1 are summarized in Table 3.

The effect of stirring speed on the rate of carbonylation was examined to eliminate the effect of diffusion of carbon monoxide into the reaction solution. The yields of ester were independent of the stirring speeds

between 600 and 1000 rpm. Thus, all the kinetic experiments were carried out at about 750 rpm.

Kinetics. The following variables were examined kinetically: initial concentrations of palladium(II) chloride, cyclohexene, and methanol, pressure of carbon monoxide, temperature, and molar ratio of triphenylphosphine to palladium(II) chloride.

A typical time *vs.* yield curve is shown in Fig. 2. The plot of time *vs.* $X=\ln[(CHE)_0/\{(CHE)_0-(MCC)\}]$, where $(CHE)_0$ and (MCC) represent the concentrations of initial cyclohexene and ester produced, gives a straight line after the induction period of 30—60 min as shown in Fig. 3. Thus, except for the induction period of 30—60 min, the empirical formula $X=X_c(t-t_0)$ can be used, where t is reaction time and X_c and t_0 are constants characteristic of the observed straight line. All the

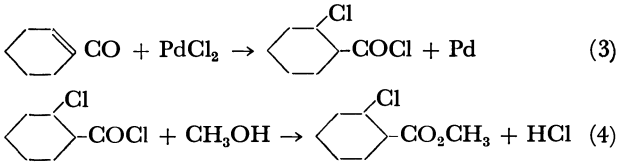
kinetic results given in terms of empirical formulas are summarized in Table 2.

When the initial concentration of methanol was reduced to half, both X_c and t_0 remained unchanged,

indicating that the rate is independent of the concentration of methanol. Variation of the molar ratio of triphenylphosphine to palladium(II) chloride from 3 to 8 had no effect on either X_c or t_0, indicating that the rate is also independent of the molar ratio. A decrease in the initial concentration of cyclohexene had no effect, indicating that the rate is of first order with respect to the concentration of cyclohexene. In contrast, X_c increased as the initial concentration of palladium(II) chloride increased, while t_0 changed irregularly. An increase in the pressure of carbon monoxide caused X_c to increase, while it changed t_0 irregularly at each temperature. The rise in temperature caused an increase in X_c but hardly any in t_0.

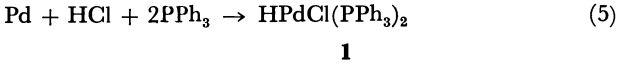
Discussion

Reaction Mechanism. Methyl 2-chlorocyclohexanecarboxylate obtained as a by-product was reported[5] to be produced in the carbonylation of cyclohexene–palladium(II) chloride complex, (cyclohexene–$PdCl_2)_2$, in a methanol solution, but the complex, prepared by the method described by Kharasch *et al.*,[10] decomposed even at room temperature in the methanol–benzene solution, giving the precipitate of palladium metal. It thus appears to be absent under the present reaction conditions. The rapid reaction from 3 to 5, which affords methyl 2-chlorocyclohexanecarboxylate and hydride–palladium intermediate **1**, probably proceeds before the catalytic carbonylation proceeds.



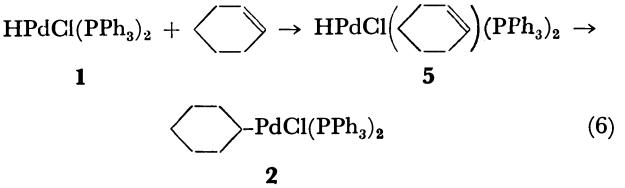
(3)

(4)

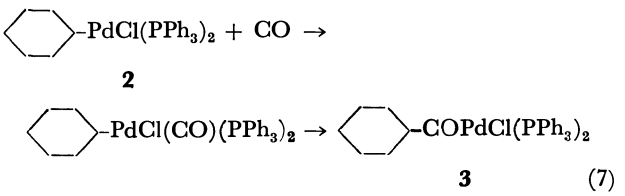


(5)

Reactions 3 and 4 have been reported[5] to proceed smoothly even at room temperature. Reaction 5 is also known[11] and complex **1** was prepared[12] from palladium(0) complex and hydrogen chloride. Insertion of the coordinated cyclohexene into the hydrogen–palladium bond in intermediate **1** would give cyclohexyl–palladium intermediate **2** (Reaction 6), which is the converted into cyclohexylcarbonyl–palladium intermediate **3** by the insertion of carbon monoxide (Reaction 7).

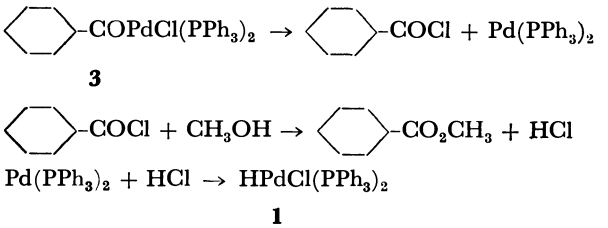


(6)

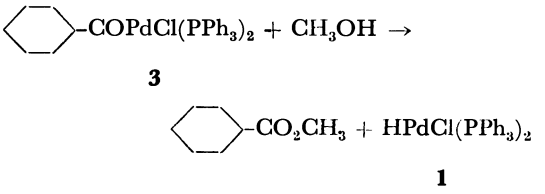


(7)

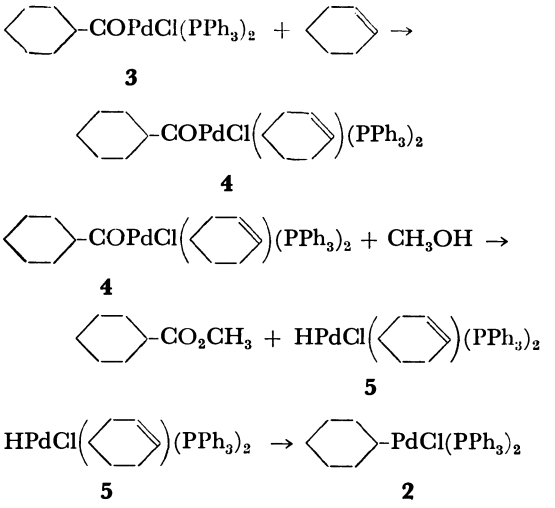
Reactions 6 and 7 have the same mechanisms as in Scheme 1. The following three mechanisms (Schemes 2, 3, and 4) can be inferred as the final process which affords methyl cyclohexanecarboxylate and regenerates the catalyst from intermediate **3**.



Scheme 2.



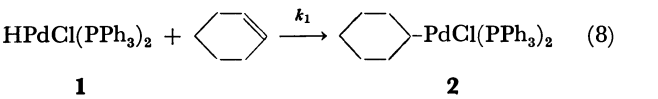
Scheme 3.



Scheme 4.

Scheme 2 is the mechanism shown in Scheme 1. Scheme 3 is deduced from the fact[13] that the alcoholysis of an acyl–palladium complex affords ester and regenerates a palladium(0) complex in the presence of a base. Scheme 4 is analogous to the mechanism of carbonylation of an allyl compound: the final product was formed by the coordination of another allyl compound.[14,15] In these three mechanisms, Scheme 4 seems to be the most probable mechanism to explain the kinetic result in which the rate of carbonylation is proportional to the concentration of cyclohexene.

Thus, the following mechanism is assumed on the basis of the reaction path described above.



(8)

$$\mathrm{CO(Gas)} \overset{H}{\rightleftharpoons}$$

$$\mathbf{2} + \mathrm{CO(Liq.)} \overset{K_2}{\rightleftharpoons} \text{C}_6\text{H}_{11}\text{-COPdCl(PPh}_3\text{)}_2 \quad (9)$$

3

$$\mathbf{3} + \text{C}_6\text{H}_6 \xrightarrow{k_3} \text{C}_6\text{H}_{11}\text{-COPdCl(C}_6\text{H}_5\text{)(PPh}_3\text{)}_2 \quad (10)$$

4

$$\mathbf{4} + \mathrm{CH_3OH} \xrightarrow{\text{Fast}} \text{C}_6\text{H}_{11}\text{-CO}_2\text{CH}_3 + \mathbf{2} \quad (11)$$

In this mechanism, k_1 and k_3 are the rate constants of Reactions 8 and 10 respectively, and K_2 and H the equilibrium constant of Reaction 9 and Henry's constant of carbon monoxide respectively. The non-catalyzed reaction from 3 to 5, which affords intermediate **1**, is assumed to proceed rapidly. The rate of Reaction 11 is also assumed to proceed rapidly, since the rate of carbonylation was independent of the concentration of methanol.

Rate Equation. The rate equation expressing the production of methyl cyclohexanecarboxylate is derived as follows.

The material balances for palladium species and cyclohexene can be given by,

$$C_1 + C_2 + C_3 \fallingdotseq (\mathrm{PdCl_2})_0 \quad (12)$$

$$(\mathrm{CHE}) + (\mathrm{MCC}) \fallingdotseq (\mathrm{CHE})_0 \quad (13)$$

where C_n is the concentration of intermediate n, and $(\mathrm{PdCl_2})_0$ and (CHE) are the concentrations of palladium(II) chloride charged and remaining cyclohexene, respectively. The equilibrium constant K_2 can be given by,

$$K_2 = \frac{C_3}{C_2 HP} \quad (14)$$

where P is the pressure of carbon monoxide. The rate of decreasing concentration of intermediate **1** can be expressed from Reaction 8 as

$$-\frac{dC_1}{dt} = k_1 C_1(\mathrm{CHE}) \quad (15)$$

where (CHE) should be nearly equal to $(\mathrm{CHE})_0$, since Reaction 8 proceeds as an elementary process of non-catalyzed reaction before the catalytic cycle from Reaction 9 to Reaction 11 proceeds. Thus, Eq. 15 can be written as

$$C_1 = (\mathrm{PdCl_2})_0 e^{-k_1(\mathrm{CHE})_0 t} \quad (16)$$

By using Eqs. 12, 14, and 16, the rate of producing methyl cyclohexanecarboxylate is given as follows.

$$\frac{d(\mathrm{MCC})}{dt} = k_3 C_3(\mathrm{CHE})$$

$$= \frac{k_3 K_2 HP(\mathrm{PdCl_2})_0(\mathrm{CHE})}{1+K_2 HP}\{1-e^{-k_1(\mathrm{CHE})_0 t}\} \quad (17)$$

By substituting Eq. 13 into Eq. 17, the following equation is derived.

$$\ln \frac{(\mathrm{CHE})_0}{(\mathrm{CHE})_0-(\mathrm{MCC})}$$

$$= \frac{k_3 K_2 HP(\mathrm{PdCl_2})_0}{1+K_2 HP}\left\{t - \frac{1-e^{-k_1(\mathrm{CHE})_0 t}}{k_1(\mathrm{CHE})_0}\right\} \quad (18)$$

Thus, the relationship between time and the concentration of methyl cyclohexanecarboxylate is given by

$$(\mathrm{MCC}) = (\mathrm{CHE})_0(1-e^{-Z}) \quad (19)$$

where

$$Z = \frac{k_3 K_2 HP(\mathrm{PdCl_2})_0}{1+K_2 HP}\left\{t - \frac{1-e^{-k_1(\mathrm{CHE})_0 t}}{k_1(\mathrm{CHE})_0}\right\}$$

Analysis of Kinetic Data. Equation 18 is compared with the kinetic results represented by the empirical formula which gives the relationship between time and X after 30—60 min. The following correlations are obtained by comparison between Eq. 18 and the empirical formula $X=X_c(t-t_0)$.

$$X_c = \frac{k_3 K_2 HP(\mathrm{PdCl_2})_0}{1+K_2 HP} \quad (20)$$

$$t_0 = \frac{1-e^{-k_1(\mathrm{CHE})_0 t}}{k_1(\mathrm{CHE})_0} \quad (21)$$

X_c should be independent of $(\mathrm{CHE})_0$. This is actually the case (Table 2). X_c should be of the

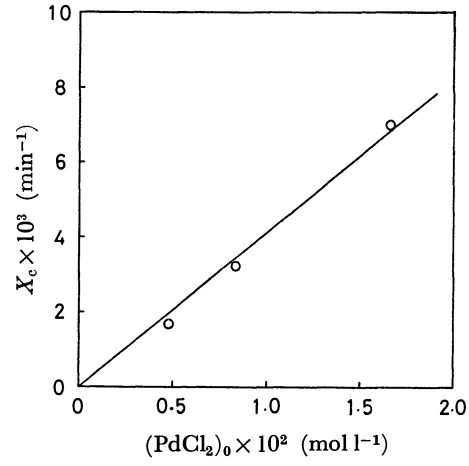


Fig. 4. Relation between $(\mathrm{PdCl_2})_0$ and X_c.
Conditions were shown in Table 2.

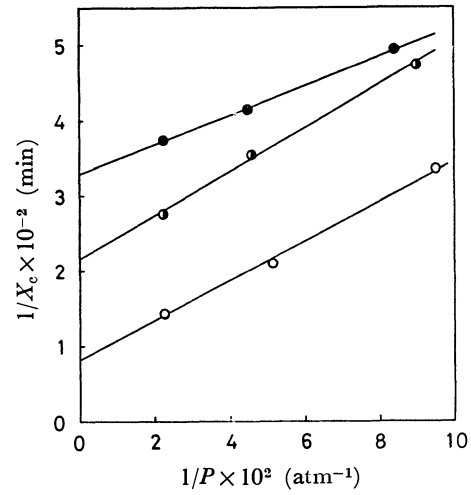

Fig. 5. Relation between $1/P$ and $1/X_c$.
Temp: ○ 120, ◑ 108, ● 100 °C.
Other conditions were shown in Table 2.

first order with respect to $(PdCl_2)_0$. The kinetic result is in line with the correlation as shown in Fig. 4. If Eq. 20 is written as Eq. 22, the reciprocal of X_c should increase linearly with increasing reciprocal of P.

$$\frac{1}{X_c} = \frac{1}{k_3K_2H(PdCl_2)_0} \cdot \frac{1}{P} + \frac{1}{k_3(PdCl_2)_0} \quad (22)$$

The kinetic result is satisfied with the correlation of Eq. 22 as shown in Fig. 5. On the other hand, the observed values of t_0 is independent of $(CHE)_0$, changing irregularly with the change in $(PdCl_2)_0$, P and temperature (Table 2). The irregularity of observed value of t_0 is related to the assumption that t_0 is constant in the empirical formula, since t_0 is in fact a function containing time as seen in Eq. 21. However, t_0 can be regarded to be constant except for the induction period of 30—60 min, since $\exp\{-k_1(CHE)_0t\}$ in Eq. 21 approaches zero with the elapse of time.

Determination of Constants. The values of k_3 and K_2H can be determined from the linear plots in Fig. 5 by means of Eq. 22. If $\exp\{-k_1(CHE)_0t\}$ is zero, Eq. 21 can be written as

$$t_0 = \frac{1}{k_1(CHE)_0} \quad (23)$$

and the value of k_1 can be estimated from the observed value of t_0. The constants obtained are summarized in Table 3. Their temperature coefficients determined from their Arrhenius plots were obtained as follows: $H=1.26$, $K_2=-18$, and $k_3=22$ kcal mol^{-1}. The value of k_1 was estimated only at 120 °C from the average of t_0 in all the data at 120 °C. From the value of k_1 obtained, $\exp\{-k_1(CHE)_0\}$ is 0.165 at 60 min when $(CHE)_0$ is 0.822 mol l^{-1}. This indicates that t_0 can be regarded to be constant at and after 60 min.

Table 3. Rate and equilibrium constants

Temp (°C)	H (mol l^{-1} atm^{-1})	K_2 (mol l^{-1})	k_1 (mol^{-1} l min^{-1})	k_3 (mol^{-1} l min^{-1})
120	1.26×10^{-2}	2.5	3.5×10^{-2}	0.75
108	1.21×10^{-2} a)	6.3		0.28
100	1.14×10^{-2}	12		0.18

a) At 110 °C.

Calculated Time-Yield Curve. Equation 18 is compared with the observed values in Fig. 2. By using the constants given in Table 3, theoretical time *vs.* yield curve was calculated by means of Eq. 19. The calculated curves (Fig. 2) are in line with the observed values including the values within 30—60 min. Other calculated curves were also consistent with the observed values over the range of the kinetic experiments at 120 °C.

The proposed mechanism sufficiently satisfies the kinetic results, but the mechanism by way of a methoxycarbonyl intermediate mentioned before does not explain them.

Experimental

Materials. Commercial palladium(II) chloride, triphenylphosphine, methyl cyclohexanecarboxylate, methyl 2-chlorocyclohexanecarboxylate, and cyclohexyl chloride were used without further purification. Cyclohexene, methanol, benzene, and mesitylene were distilled by the usual methods. Carbon monoxide was prepared by decomposing formic acid in hot sulfuric acid, *ca.* 98% purity.

Procedure. Reactions were carried out in a glass-tube placed in a stainless-steel autoclave (*ca.* 200 cm^3) equipped with a Teflon stirrer and a Teflon sampling line.

Palladium(II) chloride(0.2—1 mmol), triphenylphosphine-(3—8 mmol), cyclohexene(1—5 ml), methanol(5—10 ml), benzene(40—45 ml) and mesitylene(5 ml) were placed in the autoclave, which was then purged with nitrogen three or four times. The autoclave was heated up to 100—120 °C within 60 min and then maintained over 20 min at the desired temperature. Immediately after carbon monoxide had been pressured to 11—45 atm, stirring (600—1000 rpm) was started, this time being taken as zero time. Stirring was stopped from time to time and a sample (*ca.* 1 ml) was withdrawn through the sampling line into a trap chilled in an ice-bath within 30 s. In order to keep the pressure constant, carbon monoxide was supplied from a reservoir from time to time.

The solubility of carbon monoxide in the reaction medium was measured on the assumption that the solubility in the reaction medium is equal to that in the reaction solution without palladium(II) chloride and triphenylphosphine.

Analysis of Products. The products were identified by comparison of their retention times in gas chromatography with those of authentic samples. A PEG column (2 m, 3 mmø) with a nitrogen carrier was used at 180 °C for the determination of amounts of methyl cyclohexanecarboxylate and cyclohexene with mesitylene as an internal standard.

Reaction of 1-Alkylpyridinium Salts Carrying a Methyl or an Amino Group at the 2- or 4-Position with Activated Ethoxymethylene Compounds in the Presence of Alkali

Akikazu KAKEHI, Suketaka ITO, Takahisa FUNAHASHI, and Norio OGASAWARA

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received January 20, 1976)

It was found that various 1-alkyl-2-(**1a**—**d**) and 4-picolinium salts(**5a**,**b**) react smoothly with ethoxymethylene compounds(**2a**—**c**) activated by electron-withdrawing substituents in the presence of alkali to give the corresponding 1-alkyl-2-(**4a**—**i**) and 4-allylidenedihydropyridine derivatives(**6a**—**d**) in fairly good yields. 1-Methyl-2-(vinylimino)dihydropyridine(**8a**) and pyrimidine(**8b**) were obtained by the reactions of 1-methyl-2-aminopyridinium(**7a**) and pyrimidinium iodide(**7b**) with ethyl ethoxymethylenecyanoacetate(**2a**) under similar reaction conditions.

The reactions of 1-alkylpyridinium salts carrying a 2- or 4-methyl group with ethoxymethylene compounds in the presence of alkali afford the corresponding 2- or 4-allylidenedihydropyridine derivatives in fairly good yields rather than initially expected pyridinio-2-propen-1-ides.[1] The simplicity of the reaction procedure and the facile formation of allylidenedihydropyridines prompted us to extend the studies to aza-analogs, and we found that the reaction can be highly utilized for the preparation of this kind of compound.

This paper deals with the preparation of 2- or 4-allylidenedihydropyridines and the aza-analogs by the reactions of various 1-alkylpyridinium and pyrimidinium salts with activated ethoxymethylene compounds in the presence of an alkali.

Results and Discussion

*Reactions of 1-(Ethoxycarbonylmethyl)-2,6-lutidinium Bromide(**1a**) with Ethoxymethylene Compounds(**2a**—**c**).* A mixture of 1-(ethoxycarbonylmethyl)-2,6-lutidinium bromide(**1a**) and ethyl ethoxymethylenecyanoacetate(**2a**) was treated with potassium carbonate in chloroform at room temperature to give a new crystalline compound(**4a**) in 57% yield. A similar treatment of salt(**1a**) with 3-ethoxymethylenepentane-2,4-dione(**2b**) and ethyl ethoxymethyleneacetoacetate(**2c**) afforded the corresponding products(**4b**,**c**) in 47 and 55% yields, respectively.

Although the structures of the compounds(**4a**—**c**) were expected to be 2,6-lutidino-2-propen-1-ides(**3a**—**c**) by their elemental analyses and by comparison with similar reaction examples reported by Tamura *et al.*,[2]

their spectral data were not compatible with the proposed structures: *e.g.*, the values (1735—1743 cm^{-1}) of each one carbonyl absorption in the IR spectra differ from those of the carbonyl group conjugated with carbon-carbon double bond or ylidic carbanion; the absence of one methyl group on the 2,6-lutidine ring and the presence of new olefinic AB-type protons in the NMR spectra (Table 1) show that these compounds (**4a**—**c**) are not 2,6-lutidino-2-propen-1-ides(**3a**—**c**), but the condensation products of ethoxymethylene compounds(**2a**—**c**) with a 2-methyl group on the 2,6-lutidine ring. The results are given below.

*Preparation of Other 1-Alkyl-2-(**4d**—**i**) and 4-Allylidenedihydropyridines(**6a**—**b**) and the Aza-analogs(**8a**—**b**).* From the fact that the 1-ethoxycarbonylmethyl group in the pyridinium salt(**1a**) remains intact during the course of reaction, we attempted an extension of this reaction to other 1-alkylpyridinium salts.

As expected, 1-methyl-2-picolinium(**1b**), 1-methyl-2,6-lutidinium(**1c**), and 1-allyl-2-picolinium salts(**1d**) reacted smoothly with compounds(**2a**,**b**) in the presence of potassium carbonate to yield the corresponding 2-allylidenedihydropyridine derivatives(**4d**—**i**) in over 63% yields, the reactions with 1-methyl(**5a**) and 1-allyl-4-picolinium salts(**5b**) giving similarly the corresponding 4-allylidene derivatives(**6a**—**d**) in 85, 65, 80, and 56% yields, respectively. Vinyliminodihydropyridine derivatives(**8a**, **b**) were obtained in 87 and 58% yields by the reactions of compound(**2a**) with 1-methyl-2-aminopyridinium(**7a**) and pyrimidinium iodide(**7b**). The results are given in Schemes 2, 3 and 4. On the other hand, 1-methylpyridinium and 1-methyl-3-picolinium iodides did not react with ethoxymethylene compound(**2a**) under the same conditions, nor did pyridinium salts(**1a**, **b**) react with ethyl β-ethoxyatropate and ethyl β-bromomethacrylate.

Structural elucidation of the compounds(**4d**—**i**, **6a**—**d**, and **8a**, **b**) was achieved by means of elemental analyses (Table 3) and spectroscopic investigations. The chemical shifts of skeletal protons in the NMR spectra (Table 1) of these products are as a whole similar to each other and also to those of known allylidenedihydropyridines reported recently by Acheson and Woollard.[3]

Mechanism. The reactions should be initiated by proton abstraction from the 2-, 4-methyl or 2-amino group rather than the 1-methylene group in the corresponding pyridinium(**1a**—**d**, **5a**, **b**, and **7a**) and

pyrimidinium salt(**7b**) followed by the nucleophilic addition-elimination of the resulting dihydropyridine or dihydropyrimidine intermediates(**9** and **9'**) onto the β-carbon of ethoxymethylene compounds(**2a—c**), as shown in Scheme 5. A similar mechanism was proposed by Severin and Böhme.[4] In these reactions, the presence of an appropriate removing group in ethoxymethylene compounds and high electrophilicity are necessary, since the reactions between enamines and electrophilic olefins generally afford cyclobutane derivatives,[5] and ethyl β-ethoxyatropate and ethyl β-bromomethacrylate, which are activated by only one electron-withdrawing group, did not react with pyridinium salt under basic condition. Although there are some methods for the preparation of allylidene-

were carried out on a Perkin-Elmer 240 Elemental Analyzer. The NMR spectra were determined with a JEOL JNM-100 spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values. The IR spectra were taken with a JASCO DS-301 spectrophotometer.

*Preparation of Pyridinium (**1a—d**, **5a**, **b**, and **7a**) and Pyrimidinium Salt(**7b**).* Pyridinium salts (**1a—d** and **5a**, **b**) were prepared by the treatment of alkylating agents such as ethyl bromoacetate, methyl iodide, and allyl bromide with the corresponding pyridine derivatives without solvent, and 2-aminopyridinium(**7a**) and pyrimidinium salt(**7b**) were obtained by the reactions of 2-aminopyridine and 2-aminopyrimidine with methyl iodide in chloroform. These salts were filtered off, washed several times with ether to remove unchanged materials and used for the reactions without further purification.

*Preparation of Allylidenedihydropyridines (**4a—i** and **6a—d**) and the Aza-analogs(**8a**, **b**).* *General Procedure*: A solution of salt(2.1 mmol) and ethoxymethylene compound(2 mmol) in 50 ml of chloroform or theanol was stirred with potassium carbonate(5 g) at room temperature for 3—4 days. The reaction mixture was then filtered to remove insoluble substances and the filtrate was concentrated *in vacuo*. The residue was separated by column chromatography(alumina) using chloroform as an eluent. Recrystallization from chloroform–hexane gave yellow to red colored crystalline products.

Although the compounds(**4a—i** and **6a—d**) were formed both in chloroform or ethanol, vinyliminodihydropyridine derivatives(**8a**, **b**) were obtained only in chloroform. The latter reactions in ethanol gave only polymeric substances. Neither 1-methylpyridinium nor 1-methyl-3-picolinium iodides which have no 2- or 4-methyl group on the pyridine ring react with ethyl ethoxymethylenecyanoacetate(**2a**); pyridinium salts(**1a**, **b**) also do not react with ethyl β-ethoxyatropate or ethyl β-bromomethacrylate.

The results and some properties are summarized in Tables 1, 2, and 3.

The Reaction of 3,5-Dimethylisoxazole with Carbonyl Compounds

Choji KASHIMA,* Masakazu UEMORI, Yoshihiko TSUDA, and Yoshimori OMOTE*

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

**Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31*

(Received January 22, 1976)

The reaction product of 3,5-dimethylisoxazole (**1**) with methyl benzoate was found to be 3-methyl-5-(benzoylmethyl)isoxazole in the presence of sodium amide in liquid ammonia. On the other hand, the reaction of **1** with ethyl acetate did not give 3-methyl-5-acetonylisoxazole under similar conditions. The latter reaction product was, however, obtained in a good yield in the presence of lithium amide in liquid ammonia. The reaction of **1** with ketones and aldehydes was proved to give 3-methyl-5-(2-hydroxyalkyl)isoxazoles regiospecifically in the presence of alkali amide. In the above reactions, further alkylation gave 3-methyl-5-(2-alkoxyalkyl)-isoxazoles in moderate yields. Compound **1** reacted with acrylaldehyde, crotonaldehyde, and cinnamaldehyde to give 1,2-addition products, 3-methyl-5-(2-hydroxyalkenyl)isoxazoles, exclusively, but methyl cinnamate and cinnamic acid gave only Michael addition products, 4-(3-methyl-5-isoxazolyl)butanoic acid derivatives.

It is well known that some aminoalkylisoxazole derivatives are antipyretic, analgesic, antitussive, anti-inflammatory, and antispasmodic drugs,[1] that some 3-alkyl-5-(alkoxymethyl)isoxazole derivatives exhibit blood-sugar-reducing activity,[2] and that some others can also be used as intermediates for the synthesis of terpenes and steroids.[3] Therefore, we were much interested in synthesizing various kinds of isoxazole derivatives. In the previous papers, we have reported the regiospecific reaction of 3,5-dimethylisoxazole (**1**) with such electrophiles as alkyl halides,[4] Schiff bases,[5] benzonitrile,[5] and ethyl cyanoformate,[6] affording 5-alkyl, 5-(2-aminoalkyl)-, 5-(2-amino-2-phenylvinyl)-3-methylisoxazoles, and diethyl (3-methyl-5-isoxazolyl)-malonate respectively. In this paper we wish to report the reaction of **1** with carbonyl compounds in the presence of alkali amide in liquid ammonia.

3,5-Dimethylisoxazole (**1**) was treated with an equimolar amount of methyl benzoate in the presence of an equimolar amount of sodium amide in liquid ammonia. 3-Methyl-5-(benzoylmethyl)isoxazole (**2**) was obtained, it was identified by a direct comparison with an authentic sample.[5] Under similar conditions, **1** was treated with ethyl acetate. However, 3-methyl-5-acetonylisoxazole (**3**) could not be detected by the GLC analysis of the reaction product. The sole product was identified with ethyl acetoacetate. This result suggested that sodium-hydrogen exchange occurred between the sodium salt (**4**) of **1** and an active methyl of ethyl acetate. From the fact that lithium-hydrogen exchange is much slower than that of sodium-hydrogen,[7] it is expected that the lithium salt (**5**) of **1** reacts ethyl acetate to give **3**. Actually, a trace of **3** was obtained when **1** was treated with ethyl acetate in the presence of butyllithium in THF. On the other hand, when lithium amide was used in liquid ammonia, **3** was obtained in a 40% yield. No isomers of **3** could be detected by the GLC and NMR analyses of the reaction product. Also, 4-pentanolide with an active methylene, reacted with **1** to give 3-methyl-5-(5-hydroxy-2-oxohexyl)isoxazole (**6**).

In the case of benzaldehyde, **1** gave 3-methyl-5-(2-hydroxy-2-phenylethyl)isoxazole (**7**) in the presence of sodium amide, its structure was confirmed by dehydration to 3-methyl-5-styrylisoxazole (**8**).[5] The similar treatment of **1** with *p*-tolualdehyde, *p*-anisaldehyde, and benzophenone gave the corresponding 2-hydroxy products, **9**, **10**, and **11**[8] respectively. In the presence of lithium amide, acetone, acetophenone, and cyclohexanone were also treated with **1** to produce the corresponding products, **12**, **13**, and **14**. However aliphatic aldehydes, such as butyraldehyde and acetaldehyde, did not still react with **1** in the presence of sodium or lithium amide in liquid ammonia.

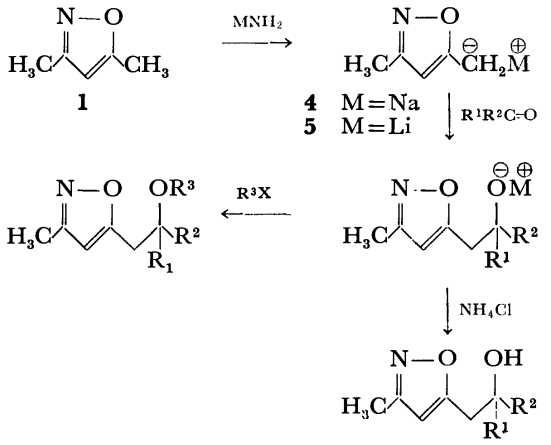
Fig. 1.

The mechanism of these reactions is speculated to be as is shown in the Scheme, that is, the salt (**4** or **5**) of **1** attacks a carbonyl group, and an oxide anion (**15**) is formed. This intermediate, **15**, is neutralized with ammonium chloride to give a hydroxy derivative. If **15** is treated with alkyl halides before neutralization, alkoxy derivatives are formed. Thus, the addition of methyl iodide to the mixture of **1**, benzaldehyde, and sodium amide gave two products, namely, the expected alkoxy derivative, 3-methyl-5-(2-methoxy-2-phenyl-



Scheme.

ethyl)isoxazole (**16**), and **7**. Also, the alkylation with ethyl bromide, allyl bromide, and benzyl bromide gave the corresponding 2-alkoxy products, **17**, **18**, and **19**. Similarly, compounds **20**, **21**, and **22** were prepared from *p*-tolualdehyde, *p*-anisaldehyde, and benzophenone respectively.

As an α,β-unsaturated carbonyl compound, chalcone was treated with **1**. Two 1 : 1 addition products were thus obtained a 1,2-addition product, 1,3-diphenyl-3-hydroxy-4-(3-methyl-5-isoxazolyl)-1-butene (**23**), and a Michael addition product, 4-(3-methyl-5-isoxazolyl)-1,3-diphenyl-1-butanone (**24**). The treatment of methyl vinyl ketone with **1** in the presence of lithium amide also gave two products, **25** and **26**. When **1** was treated with cinnamaldehyde, an 1,2-addition product, 1-(3-methyl-5-isoxazolyl)-4-phenyl-3-buten-2-ol (**27**), was obtained as well as trace amounts of a Michael addition product, 4-(3-methyl-5-isoxazolyl)-3-phenylbutanal (**28**). Similarly, **1** was treated with acrylaldehyde and crotonaldehyde to give the corresponding 1,2-addition products, **29** and **30**. On the other hand, **1** was treated with methyl cinnamate under similar conditions to give a Michael addition product **31**. 1,2-Addition products could not be detected by the IR and NMR spectral analyses of the reaction product. Furthermore, **1** was treated with an equimolar amount of cinnamic acid in the presence of two molar amounts of lithium amide to afford only a Michael addition product, 4-(3-methyl-5-isoxazolyl)-3-phenylbutanoic acid (**32**), in a poor yield. In the presence of sodium amide, the starting materials were recovered.

Additionally, some chemical reactions of these products were examined. Under the nitration condition of **1** on the C-4 position,[9] **16** was nitrated not on the C-4 position, but on the phenyl group, to give two nitro derivatives, **33** and **34**. On the other hand, **16** was iodinated on the C-4 position of the isoxazole ring to give **35**. The hydrogenations of **7**, **16**, and **22** gave the corresponding β-aminoenones, **36**, **37**, and **38** respectively.

Experimental

All the melting points and boiling points are uncorrected. The IR spectra were recorded on a Hitachi EST-3T spectrometer, and the NMR spectra, on a Hitachi H-60 or a JEOL H-100 spectrometer. The chemical shifts are expressed in ppm, with TMS as the internal standard. The GLC analyses were performed using a Hitachi KGL-2A gas chromatograph on a 1-m column packed with Apiezon grease L.

General Procedure for the Preparation of 3-Methyl-5-(2-oxoalkyl, 2-hydroxyalkyl, and 2-hydroxyalkenyl)isoxazoles and 4-(3-Methyl-5-isoxazolyl)butanoic Acid Derivatives. To a Dry Ice cooling suspension of alkali amide (0.01 mol) in liquid ammonia (80 ml), we added, drop by drop, **1** (0.01 mol) in anhydrous ether (15 ml). After stirring for 1.5 h under a nitrogen stream, a carbonyl compound (0.01 mol) was added to the colored solution and stirring was continued for another 2 h (17 h when lithium amide was used) at −78 °C. To the reaction mixture we then added ammonium chloride (6 g), and the ammonia was removed at room temperature. The residue was decanted with dichloromethane several times. The dichloromethane solution was washed with aqueous sodium chloride and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was purified by silica gel chromatography and distillation or recrystallization. The yields and physical properties of the products are collected in Tables 1 and 3.

General Procedure for the Preparation of 3-Methyl-5-(2-alkoxyalkyl)isoxazoles. To a Dry Ice cooling suspension of sodium amide (0.01 mol) in liquid ammonia (80 ml), an anhydrous ether (15 ml) solution of **1** (0.01 mol) was added. After stirring for 1.5 h at −78 °C, a carbonyl compound (0.01 mol) was added to the colored solution and stirring was continued for another 2 h. An alkyl halide (0.01 mol) in anhydrous ether (15 ml) was then added to the mixture and stirring was continued for 2 h. The following work-up and purification were done in the manner described in *General Procedure for the Preparation of 3-Methyl-5-(2-oxoalkyl, 2-hydroxyalkyl, and 2-hydroxylalkenyl)isoxazoles and 4-(3-Methyl-5-isoxazolyl)butanoic Acid Derivatives.* The yields and the physical properties of the products are collected in Tables 2 and 3.

Dehydration of 7 to 3-Methyl-5-styrylisoxazole (8). Compound **7** (0.50 g) was added to concentrated, ice-cooled sulfuric acid (5 ml) at 0 °C. The mixture was stirred for

15 min and then poured onto crushed ice. Extractive work-up with ether and subsequent purification by recrystallization from hexane afforded **8** (24% yield), whose mp and spectral data were identical with those of an authentic sample.[5]

Nitration of ***16***. Compound **16** (0.34 g) was treated with concentrated sulfuric acid (1.84 g) and nitric acid (d=1.38, 0.22 g) in a manner similar to that in the literature.[9] Work-up and column chromatography (silical gel, chloroform) afforded **33** and **34**.

*3-Methyl-5-[(2-methoxy-2-(*p*-nitrophenyl)ethyl)]isoxazole(**33**)*. Yield, 10%, mp 93.5—950 °C (carbon tetrachloride). IR (KBr): 1611, 1516, 1349, 1104, 1009, 839 cm^{-1}, NMR ($CDCl_3$): δ 2.25 (s, 3H), 3.0—3.2 (m, 2H), 3.27 (s, 3H), 4.63 (t, 1H, J=7.2 Hz), 5.80 (s, 1H), 7.82 (ABq, 4H, J_{AB}=9.0 Hz, $\Delta\nu_{AB}$=44.7 Hz). Found: C, 59.74; H, 5.57; N, 10.67%. Calcd for $C_{13}H_{14}N_2O_4$: C, 59.53; H, 5.38; N, 10.68%.

*3-Methyl-5-(*p*-nitrostyryl)isoxazole (**34**)*. Yield, 42%, mp 175—177 °C (carbon tetrachloride). IR (KBr): 1593, 1510, 1336, 1008, 833 cm^{-1}, NMR ($CDCl_3$): δ 2.35 (s, 3H), 6.20 (s, 1H), 7.19 (ABq, 2H, J_{AB}=16.8 Hz, $\Delta\nu_{AB}$=18.0 Hz), 7.91 (ABq, 4H, J_{AB}=9.0 Hz, $\Delta\nu_{AB}$=35.5 Hz). Found: C, 62.84; H, 4.38; N, 12.09%. Calcd for $C_{12}H_{10}N_2O_3$: C, 62.60; H, 4.38; N, 12.17%.

Iodination of ***16*** *to 3-Methyl-4-iodo-5-(2-methoxy-2-phenylethyl)isoxazole (**35**)*. A mixture of **16** (0.22 g), iodine (0.12 g), and nitric acid (d=1.38, 2 drops) was stirred at 80 °C for 30 min. The resulting mixture was extracted with ether. The ether solution was washed with aqueous sodium thiosulfate and water. Work-up and column chromatography (silica gel, benzene) gave **35**. Yield, 70%, bp 156—161 °C/2 mmHg. IR (neat): 1605, 1501, 1407, 1101, 1060, 748 cm^{-1}, NMR ($CDCl_3$): δ 2.20 (s, 3H), 2.7—3.5 (m, 2H), 3.17 (s, 3H), 4.56 (dd, 1H, J=6.0, 7.2 Hz), 7.27 (s, 5H). Found: C, 45.69; H, 4.23; N, 4.25%. Calcd for $C_{13}H_{14}INO_2$: C, 45.50; H, 4.12; N, 4.08%.

Catalytic Hydrogenation of Isoxazoles ***7***, ***16***, *and* ***22***. The catalytic hydrogenation of an isoxazole (1 mmol) in ethanol (15 ml) was carried out over platinum oxide (15 mg) at room temperature, then it was filtered to remove the catalyst. The filtrate was concentrated and purified by recrystallization or distillation.

*5-Amino-1-hydroxy-1-phenyl-4-hexen-3-one (**36**)*. Yield, 70%, mp 124—126 °C (benzene-ethyl acetate). IR (KBr): 3300, 3180, 1600, 1528, 1410, 1053 cm^{-1}, NMR ($CDCl_3$): δ 1.89 (s, 3H), 2.63 (d, 2H, J=6.6 Hz), 4.8 (br. s, 1H), 4.97 (s, 1H), 5.08 (t, 1H, J=6.6 Hz), 5.5 (br. s, 1H), 7.1—7.5 (m, 5H), 9.7 (br. s, 1H). Found: C, 70.31; H, 7.28; N, 6.85%. Calcd for $C_{12}H_{15}NO_2$: C, 70.22; H, 7.37; N, 6.82%.

*5-Amino-1-methoxy-1-phenyl-4-hexen-3-one (**37**)*. Yield, 90%, bp 155—160 °C/2 mmHg. IR (neat): 3350, 3170, 1619, 1527, 1142, 1097 cm^{-1}, NMR ($CDCl_3$): δ 1.90 (s, 3H), 2.3—3.1 (m, 2H), 3.21 (s, 3H), 4.69 (dd, 1H, J=4.8, 8.4 Hz), 5.00 (s, 1H), 5.3 (br. s, 1H), 7.30 (s, 5H), 9.7 (br. s, 1H). Found: C, 71.26; H, 7.86; N, 6.14%. Calcd for $C_{13}H_{17}NO_2$: C, 71.20; H, 7.82; N, 6.39%.

*5-Amino-1,1-diphenyl-1-methoxy-4-hexen-3-one (**38**)*. Yield, 60%, mp 133—134 °C (hexane-benzene). IR (KBr): 3300, 3170, 1600, 1525, 1070, 740 cm^{-1}, NMR ($CDCl_3$): δ 1.63 (s, 3H), 3.20 (s, 3H), 3.29 (s, 2H), 4.35 (s, 1H), 4.9 (br. s, 1H), 7.1—7.5 (m, 10H), 9.6 (br. s, 1H). Found: C, 77.75; H, 7.26; N, 4.74%. Calcd for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%.

(Received January 23, 1976)

Solid phase peptide synthesis by oxidation-reduction condensation *via* fragment condensation at the carboxyl end was established by a new monitoring method based on high pressure liquid chromatography. The merit of the method was demonstrated through the synthesis of ACTH (1—24). A resin-tetracosapeptide with quantitative amino acid ratios was easily prepared by coupling 6 fragments of 1—2, 3—7, 8—10, 11—14, 15—19, and 20—24 sequences. ACTH (1—24) with a full activity was obtained in 25% yield from the initial resin-dipeptide by hydrogen fluoride treatment and purification with carboxymethyl-cellulose chromatography.

The oxidation-reduction condensation reaction forming peptide linkage with use of triphenylphosphine (Ph_3P) and di-2-pyridyl disulfide ($(PyS)_2$) proceeds under mild conditions without basic or acidic catalysts. It has the advantage of minimizing the racemization of a carboxyl component and the side reactions of amino acids.[1] The condensation reaction has been successfully employed not only to syntheses of peptides,[2] nucleotides,[3] and coenzymes[4] but also to syntheses of various macrolides[5] *via* 2-pyridinethiol ester.[1,6] The active dehydrating agent in the reaction, phosphorane, is generated by mixing the carboxyl component with Ph_3P and $(PyS)_2$ whose melting points are 82 and 58 °C, respectively. Peptide bond formation would proceed through a cyclic transition state.[1] The high reactivity with high selectivity depends upon the stability of the intermediate of acyloxyphosphonium salt in which phosphorus atom exists largely in the pentacovalent form. This being the case, some modification is possible by changing the nature of the trivalent phosphorus compounds. As an example, the use of tris(*p*-bromophenyl)phosphite[7] in place of the triphenylphosphine increases the stability of the intermediate in polar solvents such as *N*,*N*-dimethylformamide. On the other hand, tributylphosphine decreases the stability of the intermediate which results in the decrease of selectivity in spite of the increase of reactivity.[8]

We have shown that the oxidation-reduction condensation can be successfully applied to the synthesis of LH-RH *via* fragment condensation on solid support by employing two types of chain elongation, from *C*-terminal amino acid to *N*-terminal amino acid and from *N*-terminal amino acid to *C*-terminal amino acid.[9]

The latter approach was further extended to a synthesis of ACTH(1—24).[10] This paper[11] contains a full report of the synthesis of ACTH(1—24) by a new technique to monitor the amount of amino component in solution based on high pressure liquid chromatography (HPLC). The general procedures for this approach are shown in Fig. 1.

The synthesis of ACTH(1—24) was carried out by coupling 6 fragments of 1—2, 3—7, 8—10, 11—14, 15—19, and 20—24 as shown in the following scheme.

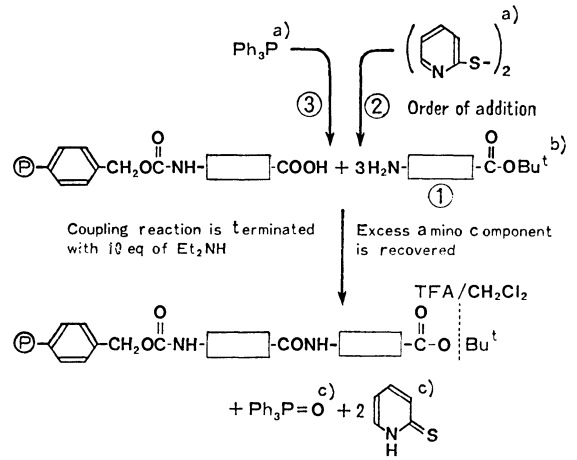

Fig. 1. General procedure for solid phase peptide synthesis by oxidation-reduction condensation.
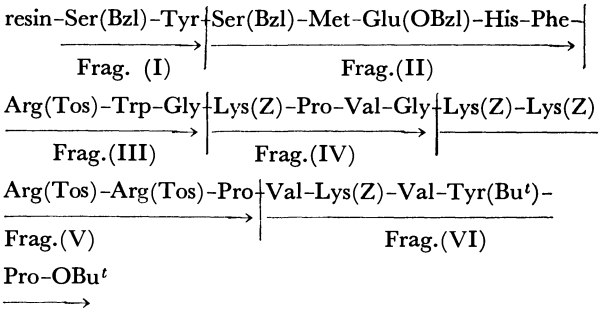
Abbreviations, Ⓟ: copolymer of styrene-2% divinylbenzene, TFA : trifluoroacetic acid and -OBu^t : *t*-butyl ester.
a) The reagents are individually stable and safely stored but should not be mixed before addition.
b) Coupling reaction is monitored by measuring the amount of amino component in solution by means of high pressure liquid chromatography.
c) Very soluble in organic solvents and easily washed out with methylene chloride, ethanol, *etc.*



The following precautions were taken: 1) the number of amino acid residue in one fragment was chosen to be less than 5, considering the easiness of the syntheses of fragments, 2) each fragment contains a unique amino acid residue which makes it possible

to check the chain elongation by amino acid analysis, 3) each fragment has a UV absorbing moiety in order to monitor the coupling reaction by HPLC, 4) the biologically active center is included in one fragment V in order to ensure the incorporation of this fragment which could be proved by the activity. The *t*-butyl ester was selected for α-carboxyl protection since it is easily deprotected with trifluoroacetic acid. The protecting groups of side chains were benzyloxycarbonyl for ε-amino function of lysine, benzyl ester for γ-carboxyl function of glutamic acid, tosyl group for guanido function of arginine and benzyl ether for hydroxyl function of serine. In the syntheses of the fragments having these protecting groups, an α-amino protecting group must be removed without influencing the other groups. *o*-Nitrophenylsulfenyl(Nps-) protecting group was chosen for this purpose. Nps-protecting group was selectively removed under neutral conditions[10] by mixing the Nps-protected fragment with 5 fold excess each of Ph_3P and pentachlorophenol in methanol at room temperature. The pure fragment with the free amino function was quantitatively obtained by gel filtration on Sephadex LH-20 in methanol and drying *in vacuo* after evaporation of the solvent.

The syntheses of protected fragments were achieved stepwise in solution by oxidation-reduction condensation using the readily available benzyloxycarbonylamino acids except in cases of incorporation of Nps-amino acid residues which were coupled with dicyclohexylcarbodiimide (DCC) or by active ester and mixed anhydride method (M.A.) (Fig. 2). The physical properties of these intermediates are given in Table 1.

Starting with 1.5 g of 2% cross-linked resin containing 0.046 mmol of *O*-benzylseryltyrosine,[9] coupling steps of the incorporation of fragment II and III were carried out with a three-fold excess fragment and a 30 fold excess each of Ph_3P, $(PyS)_2$ and 2-pyridinethiol in methylene chloride, 6 h at −15 °C and overnight at room temperature. The steps of incorporation of fragments IV, V, and VI were carried out at room temperature in the absence of 2-pyridinethiol since carboxyl ends such as glycine and proline are free from racemization. Excess fragments were recovered in washing solvents since they did not change in the coupling reaction. They were easily purified by gel filtration on Sephadex LH-20 in methanol in 80—90% recovery yield. A successive coupling of 1 g of new resin–dipeptide with recovered fragments gave resin–tetracosapeptide with nearly quantitative amino acid ratios.

During the course of the synthesis, coupling rates were easily monitored by measuring the amount of fragment in solution by HPLC. Conditions suitable for effective separation have been found through the use of porous polymer Hitachi Gel 3010, a styrene-divinylbenzene polymer which is useful packing material for HPLC.[12]

With the use of aminated Hitachi Gel 3010,[13] eluting conditions were so chosen that the remaining fragment has a constant retention time irrespective of the fragment used for elongation, since it would not be practical to select eluting conditions in each coupling cycle with a different fragment. The problem was solved by elution with an acidic mobile phase by which each fragment was eluted always at or near the void volume separated from the other components in the coupling reaction. Taking these factors into consideration, analytical conditions were established as follows: column; aminated Hitachi Gel 3010 (5 mm i.d. × 50 cm length, Pyrex glass), mobile phase; 0.2 M hydrochloric acid, 0.1 M potassium chloride/methanol (1 : 9), flow rate; 2.0 ml/min, temperature; ambient, detector; UV (240 nm). A sample solution was prepared as follows: Add 20 μl of 0.2 M potassium hydroxide/80% methanol to 20 μl of reaction solution, and then neutralize with 20 μl of 0.2 M monopotassium citrate/80% MeOH. A definite volume (5—20 μl) of each solution was injected. For the

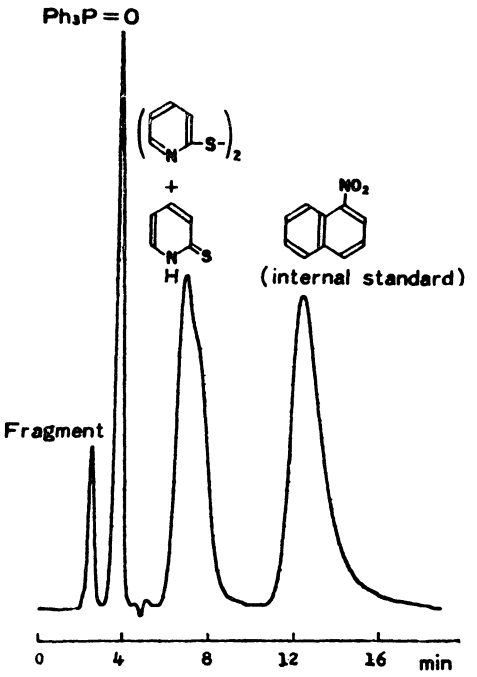


Fig. 3. A typical chromatogram by high pressure liquid chromatography.

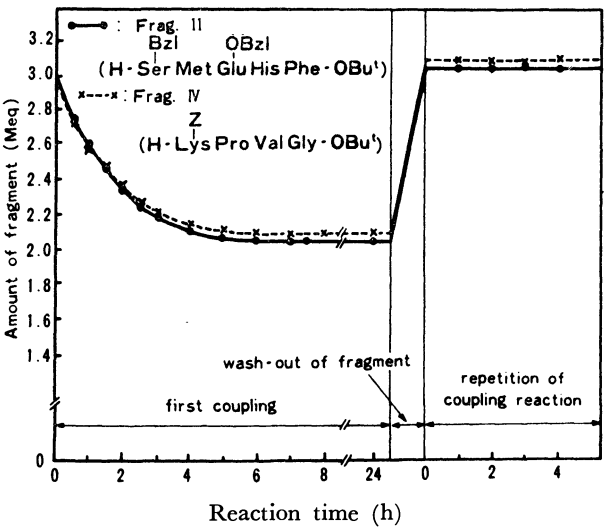

Fig. 4. Monitoring of coupling reaction by high pressure liquid chromatography.

sake of accurate determination and easy sampling, 1-nitronaphthalene was added to the reaction mixture as an internal standard. Each sample was analyzed within 15 min with an accuracy of ±1.0%.[14] A typical chromatogram is shown in Fig. 3. The remaining amino component was plotted against reaction time. Typical examples of monitoring results are shown in Fig. 4, one for the coupling of Frag. (II) and the other for that of Frag. (IV), wherein the coupling was carried out at −15 °C and room temperature, respectively. Reaction completion was principally determined by recording the time at which the curve indicates no further consumption of the fragment. Coupling was repeated until no fragment uptake was detected. It was also confirmed by determination of the amino acid ratios of the resulting peptide resin after the hydrolysis of a small portion of the resin with propionic acid–12 M hydrochloric acid (1 : 1 v/v).[15] The results at each step are given in Table 2. They indicate that fragment condensation proceeds efficiently with partial protection of side chains of amino acids.

The resin–tetracosapeptide was treated with hydrogen fluoride[16] for 30 min at 0 °C in the presence of anisole and 2-pyridinethiol. The yield of this cleavage step was 83%. The peptide was converted into acetate form and chromatographed on carboxymethyl-cellulose[17] after gel filtration on Sephadex G-25 in 1 M acetic acid. The pure ACTH(1—24)·7AcOH·$9H_2O$ which gave a single spot on thin layer chromatography and electrophoresis detected by Ehrlich, Pauly, Cl-tolidine, and ninhydrin reactions was obtained by precipitation from methanol–ethyl acetate–petroleum ether: dried *in vacuo* over phosphorus pentoxide; 41 mg, 25% yield from the initial resin–Ser(Bzl)–Tyr–OH, 43% yield from the liberated peptide from the resin. $[\alpha]_D^{20}$ −86.8° (*c* 0.5, 1% acetic acid) (lit,[18] $[\alpha]_D^{23}$ −88.6 ±2° (*c* 0.51, 1% acetic acid). Amino acid ratios after complete enzymatic digestion and acid hydrolysis[15] were in good agreement (Table 3). This shows that no detectable racemization occurred during the course of fragment condensation by oxidation-reduction process.

The ACTH activity of this purified peptide was assayed[19] by the ascorbic acid depletion test according to U.S.P. XVIII, and compared with the 2nd international standard: 96 (83—128) IU/mg identical with the value in literature.[18]

The new approach indicates that an oligopeptide as ACTH(1—24) is prepared in good yield by a simple purification procedure since the contamination of similar peptides with small difference in sequence is eliminated.

Particular merits of the method are as follows: 1) unreacted amino components can be recovered intact and recycled in the chain elongation procedure, 2) the number of protecting groups of the side chains can be reduced, 3) fragments are synthesized by the classical method from readily available Z-amino acid, 4) diacylation is avoided since excess amino components are used in solution, 5) the end peptide is homogeneous since similar contaminations are eliminated, 6) the number of acidolysis can be reduced, suitable for the acid sensitive tryptophan residue, 7) the progress and the completeness of each coupling reaction is easily analyzed by high pressure liquid chromatography.

The versatility of this approach, along with a combination of the classical synthesis in solution, promises a new possibility of facile preparation of pure peptides with long sequence, widening the extent of the usual solid phase peptide synthesis.

Experimental

All the melting points are uncorrected. Optical rotations were determined with a Perkin-Elmer Model 141 Polarimeter. Amino acid analyses were carried out on a Hitachi Amino Acid Analyzer, Model KLB-3B. High pressure liquid chromatography was performed on a Hitachi Chromatograph, Model 635 equipped with a variable UV detector. Solid phase peptide synthesis was carried out by shaking with a manual apparatus. Thin layer chromatography was

carried out on precoated plates of silica gel G (E. Merck) at 5 °C.

Nps-Ser(Bzl)-Tyr(Bu^t)-OBu^t (I. Fragment I). Z-Tyr(Bu^t)-OBu^t (4.70 g, 11 mmol) was hydrogenated in 300 ml of methanol over 10% Pd/C (0.5 g) as a catalyst; the solvent was removed after filtration of the catalyst and dried *in vacuo* over phosphorus pentoxide. The residue was used as H-Tyr(Bu^t)-OBu^t. Nps-Ser(Bzl)-OH·DCHA (5.29 g, 10 mmol) was suspended in 200 ml of ethyl acetate and washed with 10% citric acid in water. Ethyl acetate layer was separated and washed with water. After drying over magnesium sulfate, ethyl acetate was evaporated and the residue was used as Nps-Ser(Bzl)-OH. Ethyl chloroformate (1.08 g, 10 mmol) was added to a stirred mixture of Nps-Ser(Bzl)-OH, *N*-methylmorpholine (1.01 g, 10 mmol) in 200 ml of tetrahydrofuran at −15 °C. After stirring for 5 min, H-Tyr(Bu^t)-OBu^t in 50 ml of tetrahydrofuran was added at −15 °C and the reaction mixture was stirred at −15 °C for 30 min and at room temperature for 5 h. After filtration of the reaction mixture, the filtrate was evaporated and dissolved in 300 ml of ethyl acetate and washed successively with 10% citric acid, water, 5% sodium bicarbonate and water. After being dried over sodium sulfate, the solvent was evaporated *in vacuo* and Nps-Ser(Bzl)-Tyr(Bu^t)-OBu^t was obtained as an oil: yield 4.42 g (69.8%), R_f 0.89 on silica gel in *n*-BuOH : AcOH : H_2O (4 : 1 : 1) and R_f 0.85 in *n*-BuOH : AcOH : H_2O; pyridine (30 : 6 : 24 : 20). Amino acid ratios (propionic acid-12 M hydrochloric acid hydrolysis)[15]: Ser, 0.98; Tyr, 1.00 Nps-protecting group of this peptide was cleaved according to the following procedure: the above dipeptide (1.74 g, 2.8 mmol) was dissolved in 100 ml of methanol and 5 fold excess each of triphenylphosphine (3.66 g, 14 mmol), pentachlorophenol (3.72 g, 14 mmol) being added and stirred at room temperature for 30 min. The mixture was condensed after filtration of the precipitate and applied to Sephadex LH-20 column (2.5×60 cm) in methanol. H-Ser(Bzl)-Tyr(Bu^t)-OBu^t was eluted in the first fraction. The peptide was dried *in vacuo* over phosphorus pentoxide after evaporation of solvent and used for an attachment to the resin.

Z-His(Z)-Pro-OBu^t (II). To a stirred mixture of Z-His(Z)-OH with one molecule of methanol (9.11 g, 20 mmol) and di-2-pyridyl disulfide (5.28 g, 24 mmol) in 100 ml of dry methylene chloride was added triphenylphosphine (6.29 g, 24 mmol) and H-Phe-OBu^t (4.43 g, 20 mmol) in 30 ml of dry methylene chloride. The mixture was stirred at room temperature overnight and washed successively with 10% citric acid, water, 5% sodium bicarbonate and water and dried over magnesium sulfate. The solvent was evaporated after addition of silica gel (100 g) and coated residue was subjected to dry column chromatography[20] on silica gel and the peptide was eluted with diethyl ether and crystallized from ethyl acetate-diethyl ether-petroleum ether: yield 10.78 g (86.0%); mp 104—105 °C; $[\alpha]_D^{20}$ 1.7° (*c* 1, methanol).

Found: C, 66.55; H, 6.13; N, 9.09%. Calcd for $C_{35}H_{38}O_7N_4 \cdot 1/2\ H_2O$: C, 66,12; H, 6.11; N, 8.82%.

Nps-Glu(OBzl)-His-Phe-OBu^t (III). Nps-Glu(OBzl)-OH·DCHA (11.74 g, 20 mmol) was converted into a free form with citric acid as in the preparation of I and used as Nps-Glu(OBzl)-OH. To a stirred mixture of Nps-Glu(OBzl)-OH, pentachlorophenol (5.32 g, 20 mmol) in 200 ml of ethyl acetate was added dicyclohexylcarbodiimide (4.12 g, 20 mmol) with ice-cooling and the mixture was stirred at 0 °C for 1 h and kept stirring overnight. The precipitated dicyclohexylurea was filtered off and the filtrate washed with 10% citric acid, water, 5% sodium bicarbonate, water and dried over sodium sulfate. The solvent was evaporated *in vacuo* and the active ester was obtained as foam and used as Nps-Glu(OBzl)-OPcp. Compound II (6.26 g, 10 mmol) was hydrogenated over 10% Pd/C as in the preparation of I and used as H-His-Phe-OBu^t. To a stirred solution of H-His-Phe-OBu^t in 200 ml of *N,N*-dimethylformamide was added 6.54 g (10 mmol) of Nps-Glu(OBzl)-OPcp and stirred at room temperature for 48 h. The solvent was removed *in vacuo* and the residue was dissolved in ethyl acetate and washed successively with 10% citric acid, water, 5% sodium bicarbonate and water. The solvent was condensed after drying over sodium sulfate and the tripeptide was obtained by precipitation with the addition of diethyl ether: yield 5.31 g (72.4%); mp 78—80 °C, $[\alpha]_D^{20}$ −18.0° (*c* 1, methanol).

Found: C, 60.69; H, 6.10; N, 11.43; S, 4.38%. Calcd for $C_{37}H_{42}N_6O_8S$: C, 60.80; H, 5.79; N, 11.50; S, 4.39%.

Nps-Met-Glu(OBzl)-His-Phe-OBu^t (IV). Nps-Met-OPcp (2.99 g, 52.8%) was obtained as foam by the same procedure as for the preparation of Nps-Glu(OBzl)-OPcp from Nps-Met-OH·DCHA (4.38 g, 10 mmol), pentachlorophenol (2.66 g, 10 mmol) and dicyclohexylcarbodiimide (2.27 g, 11 mmol). Compound III (4.0 g, 5.48 mmol) was converted into amino free form as in the preparation of H-Ser(Bzl)-Tyr(Bu^t)-OBu^t of Fragment I. To a stirred solution of this amino free peptide in 150 ml of *N,N*-dimethylformamide was added the above Nps-Met-OPcp (3.10 g, 5.48 mmol) and kept stirring at room temperature for 48 h. After working up as in the preparation of Compound III, evaporation of the solvent gave a crude peptide. This was further purified by gel filtration on Sephadex LH-20 (2.5× 60 cm) in methanol, the tetrapeptide being obtained by crystallization from ethyl acetate-petroleum ether: yield 2.98 g (62.0%); mp 160—164 °C; $[\alpha]_D^{20}$ −42.3° (*c* 1, methanol).

Nps-Ser(Bzl)-Met-Glu(OBzl)-His-Phe-OBu^t (V, Fragment II). Nps-Ser(Bzl)-OPcp was prepared by the same procedure as for Nps-Glu(OBzl)-OPcp in the preparation of III starting from Nps-Ser(Bzl)-OH·DCHA (5.30 g, 10 mmol), pentachlorophenol (2.66 g, 10 mmol) and dicyclohexylcarbodiimide (2.27 g, 11 mmol): yield 3.85 g (64.6%); mp 117—118 °C; $[\alpha]_D^{20}$ −1.85° (*c* 1, methanol).

Found: C, 44.54; H, 2.74; N, 4.87; S, 5.45; Cl ,29.35%. Calcd for $C_{22}H_{15}N_2O_5SCl_5$: C, 44.28; H, 2.53; N, 4.70; S, 5.37; Cl, 29.71%.

Compound IV (2.06 g, 2.4 mmol) was converted into amino free form as in the preparation of H-Ser(Bzl)-Tyr(Bu^t)-OBu^t of Fragment I. To a stirred solution of this amino free peptide in 100 ml of *N,N*-dimethylformamide was added the above Nps-Ser(Bzl)-OPcp (1.43 g, 2.4 mmol) and the mixture was stirred at room temperature for 48 h. After working up as in the preparation of Compound IV, crystallization from ethyl acetate-petroleum ether gave the pentapeptide: yield 1.77 g (70.8%); mp 158—160 °C; $[\alpha]_D^{20}$ −25.6° (*c* 1, methanol).

Found: C, 59.96; H, 5.89; N, 10.49; S, 6.23%. Calcd for $C_{52}H_{62}N_8O_{11}S_2$: C, 60.10; H, 6.01; N, 10.73; S, 6.17%. R_f 0.84 on silica gel in *n*-BuOH : AcOH : H_2O (4 : 1 : 1) and R_f 0.88 in *n*-BuOH : AcOH : H_2O : pyridine (36 : 6 : 20 : 24). Amino acid ratios (propionic acid-12 M hydrochloric acid (1 : 1) hydrolysis): Ser, 0.97; Met, 0.92; Glu, 1.01; His, 1.00; Phe, 0.99. Nps-protecting group of this peptide was cleaved as in the preparation of I, the resulting amino free peptide being used for the chain elongation on the resin.

Z-Trp-Gly-OBu^t (VI). To a stirred mixture of Z-Trp-OH (33.8 g, 0.1 M), H-Gly-OBu^t (14.4 g, 0.11 M) and di-2-pyridyl disulfide (25.5 g, 0.12 M) in 300 ml of

ethyl acetate was added triphenylphosphine (31.4 g, 0.12 M) with ice-cooling and stirred at room temperature for 5 h. The mixture was worked up as in the preparation of II and the peptide was crystallized from ethyl acetate-petroleum ether: yield 37.5 g (83.2%); mp 60—70 °C (lit,[21] mp 60—70 °C); $[\alpha]_D^{20}$ −20.8° (*c* 1, methanol) (lit,[21] $[\alpha]_D^{20}$ −19.6° (*c* 1, methanol)).

Z-Arg(Tos)-Trp-Gly-OBu^t (VII, Fragment III). Compound VI (9.95 g, 22 mmol) was hydrogenated over 10% Pd/C as in the preparation of I and used as H-Trp-Gly-OBu^t. To a stirred mixture of Z-Arg(Tos)-OH (9.24 g, 20 mmol), the above H-Trp-Gly-OBu^t and di-2-pyridyl disulfide (5.10 g, 24 mmol) in 300 ml of ethyl acetate was added triphenylphosphine (6.28 g, 24 mmol) with ice-cooling and stirred at room temperature for 6 h. After working up as in the preparation of II, the coated residue was subjected to dry column chromatography. On being washed with diethyl ether, the coated layer was separated and the peptide was eluted with methanol-chloroform (1 : 2 v/v). After the solvent was removed, the residue was dissolved in ethyl acetate and washed with water. After being dried over sodium sulfate, the solution was condensed and the tripeptide was obtained by precipitation with the addition of petroleum ether: yield 13.57 g (89.3%); mp 137—140 °C; $[\alpha]_D^{20}$ −24.5° (*c* 1, methanol) (lit,[21] $[\alpha]_D^{20}$ −25.1° (*c* 1, methanol)). Amino acid ratios (3 M *p*-toluenesulfonic acid hydrolysis[22]): Arg. 0.99; Trp, 0.81; Gly, 1.00. The peptide was hydrogenated over 10% Pd/C as in the preparation of H-Tyr(Bu^t)-OBu^t of Fragment I and used for chain elongation on the resin.

Z-Val-Gly-OBu^t (VIII). To a stirred mixture of Z-Val-OH (6.30 g, 25 mmol), H-Gly-OBu^t (3.60 g, 27.5 mmol) and di-2-pyridyl disulfide (6.55 g, 30 mmol) in 250 ml of benzene was added triphenylphosphine (7.90 g, 30 mmol) in 100 ml of benzene with ice-cooling and stirred at room temperature overnight and worked up as in the preparation of II, the dipeptide being obtained by crystallization from methanol-diethyl ether: yield 6.85 g (75.2%); mp 147.3 °C; $[\alpha]_D^{20}$ −27.2° (*c* 1, methanol).

Found: C, 62.42; H, 7.63; N, 7.67%. Calcd for $C_{19}H_{28}N_2O_5$: C, 62.62; H, 7.74; N, 7.69%.

Z-Pro-Val-Gly-OBu^t (IX). Compound VIII (5.10 g 14 mmol) was hydrogenated over Pd/C as in the preparation of I and used as H-Val-Gly-OBu^t. To a stirred mixture of H-Val-Gly-OBu^t, Z-Pro-OH (4.72 g, 12.9 mmol) and di-2-pyridyl disulfide (4.17 g, 18.9 mmol) in 100 ml of methylene chloride was added triphenylphosphine (4.97 g, 18.9 mmol) in 20 ml of methylene chloride with ice-cooling and stirred at room temperature overnight. The solvent was removed and the residue was dissolved in 100 ml of ethyl acetate and worked up as in the preparation of II. The peptide was crystallized from methanol-petroleum ether after being subjected to dry column chromatography with chloroform-methanol (19 : 1 v/v): yield 5.30 g (91.2%); mp 120 °C; $[\alpha]^{20}$ −90.8° (*c* 1, methanol).

Found: C, 62.57; H, 7.67; N, 8.88%. Calcd for $C_{24}H_{35}N_3O_6$: C, 62.45; H, 7.64; N, 9.10%.

Nps-Lys(Z)-Pro-Val-Gly-OBu^t (X, Fragment IV). Compound IX (1.38 g, 3.0 m mol) was hydrogenated in methanol and Nps-Lys(Z)-OH·DCHA (1.80 g, 2.93 mmol) was converted into free form as in the preparation of I. To a stirred mixture of H-Pro-Val-Gly-OBu^t, Nps-Lys(Z)-OH in 100 ml of ethyl acetate was added dicyclohexylcarbodiimide (2.0 g, 10 mmol) with ice-cooling and stirred at room temperature overnight. The dicyclohexylurea was filtered off and the filtrate was worked up as in the preparation of II. The coated residue was subjected to dry column chromatography and eluted with ethyl acetate. The solution was washed with water, dried over sodium sulfate and condensed. Addition of petroleum ether precipitates the tetrapeptide: 1.66 g (76.2%); mp 85.6 °C; $[\alpha]_D^{20}$ −101.5° (*c* 1, methanol).

Found: C, 58.25; H, 6.75; N, 11.17; S, 4.60%. Calcd for $C_{36}H_{51}N_6O_9S$: C, 58.13; H, 6.91; N, 11.30; S, 4.31%. R_f 0.87 on silica gel in *n*-BuOH : AcOH : H_2O (4 : 1 : 1) and R_f 0.89 in *n*-BuOH : AcOH : H_2O : pyridine (30 : 6 : 24 : 20). Amino acid ratios (propionic acid-12 M hydrochloric acid hydrolysis): Lys, 1.05; Pro, 0.96; Val, 0.96; Gly, 1.00. The peptide was converted into amino free form as in the preparation of fragment I and used for chain elongation on the resin.

Z-Arg(Tos)-Pro-OBu^t (XI). To a stirred mixture of Z-Arg(Tos)-OH (13.92 g, 30 mmol), H-Pro-OBu^t (5.13 g, 30 mmol) and di-2-pyridyl disulfide (6.60 g, 30 mmol) in 100 ml of methylene chloride was added triphenylphosphine (7.86 g, 30 mmol) with ice-cooling and stirred at room temperature overnight. The mixture was worked up as in the preparation of VII and the peptide was crystallized from ethyl acetate-petroleum ether: yield 13.92 g (75%); mp 114—115 °C (lit,[23] 115—118 °C); $[\alpha]_D^{25}$ −42.5° (*c* 1, methanol) (lit,[23] −42.5°).

Z-Arg(Tos)-Arg(Tos)-Pro-OBu^t (XII). Compound XI (9.30 g, 15 mmol) was hydrogenated in methanol as in the preparation of I. To a stirred mixture of H-Arg(Tos)-Pro-OBu^t, Z-Arg(Tos)-OH (6.60 g, 14 mmol) and di-2-pyridyl disulfide (3.30 g, 15 mmol) in 50 ml of methylene chloride was added triphenylphosphine (3.94 g, 15 mmol) with ice-cooling and stirred at room temperature overnight. The mixture was worked up as in the preparation of VII, the peptide being eluted with methanol on dry column chromatography. The peptide was crystallized from methanol-diethyl ether after further filtration on Sephadex LH-20 in methanol: yield 12.41 g (89%); mp 100—102 °C (lit,[23] 100—120 °C); $[\alpha]_D^{25}$ −33.3° (*c* 1, methanol) (lit,[23] −33.3°).

Nps-Lys(Z)-Arg(Tos)-Arg(Tos)-Pro-OBu^t (XIII). Compound XII (10.20 g, 11 mmol) was hydrogenated in methanol and Nps-Lys(Z)-OH·DCHA (6.14 g, 10 mmol) was converted into free form as in the preparation of I. A mixed anhydride was prepared as in the preparation of I from Nps-Lys(Z)-OH, *N*-methylmorpholine (1.01 g, 10 mmol) and ethyl chloroformate (1.08 g, 10 mmol) in 50 ml of tetrahydrofuran. To this solution was added H-Arg(Tos)-Arg(Tos)-Pro-OBu^t in 30 ml of chloroform with stirring for 1 h with ice-cooling and kept standing overnight at room temperature. The mixture was evaporated and dissolved in 100 ml of ethyl acetate and washed successively with 2 M sodium hydroxide, water, 10% citric acid and water. After drying over magnesium sulfate, the solvent was removed and the residue was subjected to Sephadex LH-20 column (2.5×60 cm) in methanol. The first fraction was pooled and the peptide was precipitated by addition of petroleum ether after condensation of methanol: yield 10.90 g (90%); mp 88—92 °C; $[\alpha]_D^{20}$ −49.1° (*c* 1, methanol).

Found: C, 54.66; H, 6.43; N, 13.88; S, 7.84%. Calcd for $C_{55}H_{74}O_{13}N_{12}S_3$: C, 54.71; H, 6.19; N, 13.92; S, 7.97%.

Nps-Lys(Z)-Lys(Z)-Arg(Tos)-Arg(Tos)-Pro-OBu^t (XIV Fragment V). Compound XIII (8.10 g, 5.5 mmol) was converted into amino free form with triphenylphosphine (7.21 g, 27.5 mmol) and pentachlorophenol (7.30 g, 27.5 mmol) in 150 ml of methanol and 150 ml of methylene chloride as in the preparation of I. The H-Lys(Z)-Arg(Tos)-Arg(Tos)-Pro-OBu^t, Nps-Lys(Z)-OH·DCHA (3.07 g, 5 mmol), *N*-methylmorpholine (0.50 g, 5 mmol) and ethyl chloroformate (0.54 g, 5 mmol) were allowed to react in 50 ml of tetrahydrofuran and 50 ml of methylene chloride and

worked up as in the preparation of XII: yield 5.30 g (74%); mp 130—135 °C; $[\alpha]_D^{20}$ −38.3° (*c* 1, methanol).

Found: C, 56.46; H, 6.58; N, 13.44; S, 6.59%. Calcd for $C_{69}H_{92}O_{16}N_{14}S_3$: C, 56.38; H, 6.32; N, 13.35; S, 6.54%. R_f 0.96 on silica gel in *n*-BuOH : AcOH : H_2O (4 : 1 : 1) and R_f 0.89 in *n*-BuOH : AcOH : H_2O : pyridine (30 : 6 : 24 : 20). Amino acid ratios (propionic acid-12 M hydrochloric acid hydrolysis): Lys, 2.00; Arg, 1.96; Pro, 0.96. Nps-protecting group of the peptide was cleaved by the same procedure as in the preparation of I and the amino free peptide was used for chain elongation on the resin.

Z-Tyr(Bu^t)-Pro-OBu^t (XV). Z-Tyr(Bu^t)-OH·DCHA (5.52 g, 10 mmol) was converted into free form as in the preparation of I. To a stirred mixture of Z-Tyr(Bu^t)-OH, H-Pro-OBu^t (1.88 g, 11 mmol) and di-2-pyridyl disulfide (2.64 g, 12 mmol) in 100 ml of ethyl acetate was added triphenylphosphine (3.14 g, 12 mmol) with ice-cooling and stirred at room temperature for 8 h. The mixture was worked up as in the preparation of II, the peptide being obtained as an oil: yield 4.60 g (87.7%).

Z-Val-Tyr(Bu^t)-Pro-OBu^t (XVI). Compound XV (4.60 g, 8.77 mmol) was hydrogenated to H-Tyr(Bu^t)-Pro-OBu^t as in the preparation of I. To a stirred mixture of Z-Val-OH (2.0 g, 8 mmol), H-Tyr(Bu^t)-Pro-OBu^t and di-2-pyridyl disulfide (2.11 g, 9.6 mmol) in 200 ml of ethyl acetate was added triphenylphosphine (2.52 g, 9.6 mmol) with ice-cooling and stirred at room temperature overnight. The mixture was worked up as in the preparation of II, the peptide being obtained by the evaporation of diethyl ether: yield 4.30 g (86.3%); mp 45—49 °C.

Nps-Lys(Z)-Val-Tyr(Bu^t)-Pro-OBu^t (XIIV). Compound XVI (4.09 g, 6.57 mmol) was hydrogenated to H-Val-Tyr(Bu^t)-Pro-OBu^t and Nps-Lys(Z)-OH·DCHA (4.07 g, 6.57 mmol) was converted into a free form. To a stirred mixture of Nps-Lys(Z)-OH and H-Val-Tyr(Bu^t)-Pro-OBu^t in 200 ml of ethyl acetate was added dicyclohexylcarbodiimide (2.71 g, 13.1 mmol) and stirred for 2 h with ice-cooling and overnight at room temperature. Dicyclohexylurea was filtered off and the filtrate was worked up as in the preparation of X. Crystallization from ethyl acetate-petroleum ether gave the tetrapeptide: yield 3.92 g (72.8%); mp 155—156 °C; $[\alpha]_D^{20}$ −56.3° (*c* 1, methanol).

Found: C, 62.13; H, 7.16; N, 9.38; S, 3.42%. Calcd for $C_{47}H_{64}N_6O_{10}S$: C, 62.37; H, 7.13; N, 9.29; S, 3.54%.

Nps-Val-Lys(Z)-Val-Tyr(Bu^t)-Pro-OBu^t (XVIII, Fragment VI). Compound XVII (2.50 g, 2.76 mmol) and Nps-Val-OH·DCHA (1.49 g, 3.32 mmol) was converted into free form as in the preparation of I. H-Lys(Z)-Val-Tyr(Bu^t)-Pro-OBu^t, Nps-Val-OH and dicyclohexylcarbodiimide (1.14 g, 5.52 mmol) were allowed to react in 100 ml of ethyl acetate and worked up as in the preparation of X. The peptide was obtained by crystallization from ethyl acetate-petroleum ether: yield 2.08 g (72.3%); mp 206—209 °C (decomp.); $[\alpha]_D^{20}$ −105.5° (*c* 1, methanol).

Found: C, 61.87; H, 7.27; N, 9.41; S, 3.11%. Calcd for $C_{52}H_{73}N_7O_{11}S \cdot 1/2H_2O$: C, 61.64; H, 7.36; N, 9.68; S, 3.16%. R_f 0.95 on silica gel in *n*-BuOH : AcOH : H_2O (4 : 1 : 1) and R_f 0.88 in *n*-BuOH : AcOH : H_2O : pyridine (30 : 6 : 24 : 20). Amino acid ratios (propionic acid -12 M hydrochloric acid hydrolysis): Lys, 0.96; Val, 1.96; Tyr, 1.00; Pro, 1.03. Nps-protecting group of this peptide was cleaved by the same procedure as in the preparation of I and was used for chain elongation on the resin.

Attachment of H-Ser(Bzl)-Tyr(Bu^t)-OBu^t to the Methylchloroformylated Resin. The methylchloroformylated resin[9] (3 g, Cl: 1.87 mmol/g) was shaken 8 h at room temperature with 1.315 g (2.8 mmol) of H-Ser(Bzl)-Tyr(Bu^t)-OBu^t, triethylamine (0.28 g, 2.80 mmol) and 30 ml of chloroform in a vessel for solid phase peptide synthesis and washed with chloroform. The unreacted peptide was recovered in washing chloroform (2.24 mmol, 83% of the theoretical value). The remaining chloroformyl groups on the resin were covered by shaking with diethylamine (4.1 g, 56.1 mmol) and 30 ml of chloroform for 8 h and washed successively with chloroform (30 ml×3), ethanol (30 ml×3), and methylene chloride (30 ml×3). The resin was washed with trifluoroacetic acid-methylene chloride (1 : 1 v/v) and *t*-butyl group was deprotected by shaking for 30 min with 30 ml of trifluoroacetic acid-methylene chloride (1 : 1 v/v). The resulting resin was washed with methylene chloride (30 ml×3), chloroform (30 ml×3), and neutralized with 30 ml of triethylamine-chloroform (1 : 10 v/v) for 10 min. The resin was washed successively with chloroform (30 ml×3), ethanol (30 ml×3), and methylene chloride and dried *in vacuo*. An aliquot of the resin was hydrolyzed in propionic acid-12 M hydrochloric acid, the peptide content being determined by amino acid analyzer to be 0.031 mmol/g of the resin.

Chain Elongation. The resin-Ser(Bzl)-Tyr-OH prepared in the above experiment (1.5 g, 0.0465 mmol of dipeptide) was placed in a vessel for solid phase peptide synthesis. The following steps were used to couple each peptide fragment: 1) washing with methylene chloride (15 ml×3), 2) addition of 3 fold excess (0.1395 mmol) of amino free peptide fragment, 30 fold excess (1.395 mmol) of di-2-pyridyl disulfide (0.307 g) and 1-nitronaphthalene (internal standard for monitoring by HPLC) in 10 ml of methylene chloride followed by shaking for 5 min, 3) addition of 30 fold excess (1.395 mmol) of triphenylphosphine (0.366 g) in 5 ml of methylene chloride followed by a reaction period, 4) washing with methylene chloride (15 ml×3), 5) washing with ethanol (15 ml×3), 6) washing with methylene chloride (15 ml×3), 7) addition of 10 fold excess (0.465 mmol) of diethylamine (0.034 g) and 30 fold excess (1.395 mmol) each of di-2-pyridyl disulfide (0.307 g) and triphenylphosphine (0.366 g) in 15 ml of methylene chloride followed by shaking for 6 h, 8) washing with methylene chloride (15 ml×3), 9) washing with ethanol (15 ml×3), 10) washing with methylene chloride (15 ml×3), 11) wash with 15 ml of trifluoroacetic acid-methylene chloride (1 : 1 v/v) containing 5% of 2-mercaptoethanol, 12) removal of butyl ester with 15 ml of trifluoroacetic acid-methylene chloride (1:1 v/v) containing 5% of 2-mercaptoethanol for 30 min, 13) washing with methylene chloride (15 ml×3), 14) washing with chloroform (15 ml×3), 15) neutralization with 15 ml of triethylamine-chloroform (1 : 10 v/v) for 10 min, 16) washing with chloroform (15 ml×3), 17) washing with ethanol (15 ml×3), 18) washing with methylene chloride (15 ml×3). The first coupling of the initial resin-Ser(Bzl)-Tyr-OH with H-Ser(Bzl)-Met-Glu(OBzl)-His-Phe-OBu^t (fragment II) and second coupling with H-Arg(Tos)-Trp-Gly-OBu^t (fragment III) were carried out at −15 °C for 6 h and overnight at room temperature in the presence of 30 eq (1.395 mmol) of 2-pyridinethiol (0.155 g). Successive coupling of H-Lys(Z)-Pro-Val-Gly-OBu^t (fragment IV), H-Lys(Z)-Lys(Z)-Arg(Tos)-Arg(Tos)-Pro-OBu^t (fragment V) and H-Val-Lys(Z)-Val-Tyr(Bu^t)-Pro-OBu^t (fragment VI) were carried out at room temperature in the absence of 2-pyridinethiol. In each coupling step, an aliquot of the resulting resin-peptide was hydrolyzed in propionic acid-12 M hydrochloric acid (1 : 1 v/v).[15] The results of amino acid analyses are given in Table 2. The unreacted fragments were recovered in washing solvents of procedures 4), 5), and 6) and the quantities of fragments were determined by amino acid analyses of the

hydrolyzate of the portion of washing solvents: Fragment II, 0.075 mmol (recovery yield 81% of the theoretical value); Fragment III, 0.081 mmol (87%); Fragment IV, 0.084 mmol (90%); Fragment V, 0.076 mmol (82%); Fragment VI, 0.085 mmol (91%). These fragments were easily isolated by means of gel filtration on Sephadex LH-20 in methanol and complete evaporation of solvent *in vacuo*. With use of these recovered fragments, peptide chain was elongated by starting with 1 g of new resin-Ser(Bzl)-Tyr-OH (0.031 mmol) according to the procedure in the above chain elongation. Coupling reaction was continued until a monitoring curve by high pressure liquid chromatography showed no consumption of the fragment (*ca.* 6—8 h); repeated until no fragment uptake was detected. Amino acid analysis of the hydrolyzate of a portion of the resulting resin-tetracosapeptide by propionic acid–12 M hydrochloric acid showed nearly quantitative coupling reaction in each step: Ser, 2.11; Tyr, 2.02; Met, 0.91; Glu, 1.01; His, 1.00; Phe 0.97; Arg, 2.79; Gly, 1.94; Lys, 3.97; Pro, 2.75; Val, 2.93.

Monitoring of Coupling Reaction by High Pressure Liquid Chromatography. With the use of aminated Hitachi Gel 3010,[13] styrene-divinylbenzene polymer, the elution conditions were so established that each fragment has a constant retention time: column, 0.5×50 cm, Pyrex glass; mobile phase, 0.2 M hydrochloric acid, 0.1 M potassium chloride-methanol (1 : 9); flow rate, 2.0 ml/min; temperature, ambient; detector, UV (240 nm). Active dehydrating agent, phosphorane, in the reaction solution should be decomposed before injection to the column, since phosphorane is eluted near the fragment. A sample solution was prepared as follows: Add 20 μl of 0.2 M potassium hydroxide-80% methanol to 20 μl of the solution and then neutralize with 20 μl of 0.2 M monopotassium citrate-80% methanol. For the sake of accurate determination and easy sampling, 1-nitronaphthalene was added to the reaction mixture as an internal standard. A definite volume (5—20 μl) of each solution was injected, each sample being analyzed within 15 min with the accuracy of ±1.0%.[14] A typical chromatogram and examples of monitoring results are shown in Figs. 3 and 4, respectively. The amount of the consumed fragment (Fig. 4) was generally smaller than the actual amount consumed in chain elongation, since the initial peak height after shaking the resin with the fragment was arbitrarily scaled as 3 meq neglecting the small amount of adsorbed fragment on the resin. This small amount of the adsorbed fragment incorporated into the peptide chain makes up the difference in the quantity consumed as shown in the graph and the required value of 1 meq.

H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val-Lys-Val-Tyr-Pro-OH (ACTH(1—24)). The resin-tetracosapeptide started from 1.5 g of resin-dipeptide was treated with 40 ml of dry hydrogen fluoride[16] at 0° for 30 min in the presence of 2 ml of anisole and 2-pyridinethiol[9] (0.300 g). The yield of this cleavage step was 83%. After removal of hydrogen fluoride, the residue was dried over potassium hydroxide *in vacuo*. The resin was stirred in 30 ml of trifluoroacetic acid, filtered and washed with 30 ml of trifluoroacetic acid. The combined filtrate was evaporated and the residue was dissolved in 50 ml of acetic acid and evaporated *in vacuo*. The residue was dissolved in 30 ml of water, washed with diethyl ether and passed through a Dowex 1×2 (acetate form, 2.5×10 cm) with 300 ml of water to be converted into acetate form. The solution was condensed to 20 ml and stirred at 50 °C for 12 h after addition of 1 ml of mercaptoacetic acid. The solution was evaporated *in vacuo* and subjected to gel filtration on Sephadex G-25 (2×125 cm) in 1 M acetic acid in order to separate the peptide from 2-pyridinethiol and anisole. After evaporation of the Ehrlich and Pauly positive fractions of main peak, the peptide was purified on carboxymethylcellulose column (1×55 cm) by continuous gradient elution with ammonium acetate buffer at pH 6.7[17]: 0.01 M ammonium acetate (150 ml), 0.01—0.2 M ammonium acetate (270 ml), 0.2—0.4 M ammonium acetate (600 ml), 0.4 M ammonium acetate (330 ml). The main peak in 0.2—0.4 M ammonium acetate was proceeded by a small peak in 0.01—0.2 M ammonium acetate and followed by a very small peak in 0.4 M ammonium acetate. The fractions of the main peak were condensed and purified again on carboxymethylcellulose in the same manner after gel filtration on Sephadex G-25 in 1 M acetic acid. The fractions containing a single component were pooled and condensed *in vacuo*. Desalting was achieved by gel filtration on Sephadex G-25 in 1 M acetic acid and the peptide was precipitated from methanol containing 1% of acetic acid–ethyl acetate–petroleum ether after evaporation of solvent. The pure tetracosapeptide was obtained after drying *in vacuo* for 12 h at 40 °C over phosphorus pentoxide: yield 41 mg (25.2% yield based on Ser-Tyr attached on the resin and 42.8% yield from the liberated peptide from the resin); $[\alpha]^{20}$ −86.8° (*c* 0,5. 1% acetic acid) (lit,[18] $[\alpha]_D^{22}$ −88.6° ±2° (*c* 0.51, 1% acetic acid)); UV in 0.1 M sodium hydroxide, λ_{max} 283 mμ (ε=8640) and λ_{max} 289 mμ (ε=8880) (lit,[18] λ_{max} 283 mμ (ε=8550) and λ_{max} 289 mμ (ε=8810)). Thin layer chromatography gave a single spot detected by Ehrlich, Pauly, Cl-tolidine, and ninhydrin reactions: R_f 0.28 on silica gel in *n*-BuOH : AcOH : H_2O : pyridine (30 : 6 : 24 : 20) and R_f 0 in *n*-BuOH : AcOH : H_2O (4 : 1 : 1). Paper electrophoresis with lysine as reference also gave a single ninhydrin, Pauly, Ehrlich, and Cl-tolidine positive spot: R_m 0.72 in 0.5 M formic acid–2 M acetic acid (1 : 1 v/v), 60×10 cm, 900 V, 1.5 h and R_m 0.77 in pyridine-AcOH-H_2O (10 : 0.4 : 90 v/v), 60×10 cm, 1500 V, 1 h. The peptide was characterized as heptaacetate and nonahydrate by elemental analysis. Found: C, 51.19; H, 7.05; N, 15.93; S, 0.93%. Calcd for $C_{136}H_{210}O_{31}N_{40}S \cdot 7CH_3COOH \cdot 9H_2O$: C, 51.24; H, 7.33; N, 15.94; S, 0.91%. Two mg of the peptide dissolved in 0.5 ml of Tris buffer of pH 8.5 containing 0.01 M Mg^{2+} was incubated with 50γ of trypsin (Worthington Biochemical Co., TRL 100S) and 50 γ of chymotrypsin (Worthington Biochemical Co., CDI 2LX) at 37 °C for 24 h. The solution was boiled for 15 min, cooled and then incubated with 80 γ of aminopeptidase M (Rohm & Haas) and 80 γ of prolidase (Miles Laboratories Ltd., UK8) for 48 h at 37 °C. The results of amino acid analyses of the digestion mixture and propionic acid–12 M hydrochloric acid hydrolyzate of the peptide are shown in Table 3.

Bioassay. ACTH activity of the tetracosapeptide was assayed by the ascorbic acid depletion test according to USP XVIII, and compared with the 2nd international standard. The dose response regression lines for the synthetic peptide and the standard were parallel. The activity was calculated as 96 (83—128) IU/mg, identical with the value in literature.[18]

Studies of Sulfonyl Radicals. II.[1] Relative Reactivities of Addition Reactions of Sulfonyl Free Radicals to Vinyl Monomers

Yoshiyuki TAKAHARA, Masashi IINO, and Minoru MATSUDA

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira 2-Chome, Sendai 980

(Received February 6, 1976)

Addition reactions of various vinyl monomers towards the free methanesulfonyl and arenesulfonyl radicals have been investigated. Relative reactivities of *p*-methylstyrene (M_2) to styrene (M_1) towards methane- and *para*-substituted benzenesulfonyl radicals are hardly affected by the kind of sulfonyl radical, suggesting that an unpaired electron of methanesulfonyl and arenesulfonyl radicals is localized mainly on sulfonyl groups. Relative reactivities obtained with vinyl monomers were correlated to Hammett's σ_p values with $\rho_p = -3.6$ and also to Alfrey-Price's *e* values, indicating that sulfonyl radicals are strongly electrophilic. The highest selectivity of the benzenesulfonyl radical, obtained in the comparison of the selectivity of a number of radicals in addition reactions towards three representative monomers (Table 5), also supports the above conclusion.

In previous papers concerning radical copolymerization of sulfur dioxide and styrene emphasis has been laid on two aspects of the growing sulfonyl radicals ($\sim SO_2-CH_2CH(C_6H_5)-\dot{S}O_2$ and $\sim CH_2CH(C_6H_5)-CH_2CH(C_6H_5)-\dot{S}O_2$), *viz.*, their reactivity and their relationship to the compositions of poly(styrene sulfone).[2]

In this paper we report the reactivities relative to styrene of addition reactions of various vinyl monomers towards benzenesulfonyl and other sulfonyl radicals, giving a discussion on the nature of sulfonyl radicals. The formations of sulfonyl radicals from sulfonyl iodides have been studied by many investigators.[3-5] Corrêa and Waters[3] showed that addition of sulfonyl iodide to styrene occurs with very little polymerization. They have investigated on the addition reaction of *p*-toluenesulfonyl radical to *para*- or *meta*-substituted styrenes, showing that sulfonyl radical has an electrophilic character from the values of ρ ($\rho = -0.55$ or $\rho^+ = -0.50$) in the Hammett plot.[6] Truce and his co-workers have studied addition reaction to allenes and acetylene.[4,7]

We have investigated the same type of addition reaction of various vinyl monomers such as styrene, methyl methacrylate, acrylonitrile, and 1-hexene, by using sulfonyl iodides.

Experimental

Materials. Benzene, toluene, chlorobenzene, decane, and vinyl monomers were purified in the usual way. *p*-Methylstyrene was prepared from 1-(*p*-tolyl)ethanol by $KHSO_4$ dehydration and distilled twice under reduced pressure. Vinyl monomers were stored at temperature below −20 °C after purification.

Benzene-, *p*-toluene-, *p*-chlorobenzene-, and methane-sulfonyl iodide were synthesized from the corresponding sulfonyl chlorides.[21,22] *p*-Methoxybenzenesulfonyl iodide was synthesized from anisole and chlorosulfuric acid by means of the corresponding chloride.[23] All the sulfonyl iodides except methanesulfonyl iodide were recrystallized at least twice from carbon tetrachloride and dried under reduced pressure at temperatures below −20 °C in order to prevent decomposition.

Found: C, 26.57; H, 2.05%. Calcd for $C_6H_5IO_2S$ (benzenesulfonyl iodide): C, 26.87; H, 1.87%.

Found; C, 29.88; H, 2.33%. Calcd for $C_7H_7IO_2S$ (*p*-toluenesulfonyl iodide): C, 29.79; H, 2.48%.

Found: C, 28.03; H, 2.68%. Calcd for $C_7H_7IO_3S$ (*p*-methoxybenzenesulfonyl iodide): C, 28.29; H, 2.35%.

Found: C, 23.84; H, 1.48%. Calcd for $C_6H_4ClIO_2S$ (*p*-chlorobenzenesulfonyl iodide): C, 23.82; H, 1.32%.

Competitive Addition of Styrene and p-Methylstyrene towards Benzenesulfonyl Iodide. Toluene solution containing a definite amount of styrene (0.84 to 3.22 mmol), *p*-methylstyrene (0.94 to 3.15 mmol), and benzenesulfonyl iodide (0.55 to 2.14 mmol) was placed in a Pyrex glass reaction tube covered with an aluminum foil to intercept the light. The reaction tube thus prepared was connected to a vacuum system, the solution was frozen, and then the system was degassed in the usual way at least three times. After the last freeze-pump-thaw cycle, the system was closed and disconnected from the vacuum system. The reaction tube was placed in an ice-water mixture and the reaction was initiated with daylight by removing the aluminum foil. In the dark, the reaction did not occur even after 24 h. Under our experimental conditions, benzenesulfonyl iodide charged was almost completely consumed within 30 min and the yellow reaction solution became colorless at the end of the reaction. The reaction mixture was then washed with 10% aqueous $Na_2S_2O_3$ to remove any trace of sulfonyl iodide and iodine, and the products were isolated from *ca.* 75 ml petroleum ether (bp, 40—60 °C) at −60——70 °C. After a few mg of 4-*t*-butylcatechol had been added to the petroleum ether solution to prevent polymerization, the quantities of unreacted styrene and *p*-methylstyrene were determined by GLC analysis (diethylene glycol adipate polyester column) using chlorobenzene as an internal standard. We also determined the quantities of products by NMR analysis in $CDCl_3$ using tetramethylsilane as an internal standard; relative reactivities determined by both methods were almost the same (Table 3). In the competitive addition of styrene and *p*-methylstyrene towards benzenesulfonyl iodide the ratio of the reacting monomers to initial sulfonyl iodide was nearly unity, indicating the formation of 1 : 1 adducts.

Results and Discussion

Reliability of Our Relative Rate Constants. Our first intention in this study was to confirm the fact that no reverse reaction of addition of sulfonyl radicals to vinyl monomers takes place. The free radical addition of sulfonyl iodides to olefinic double bonds has been studied extensively and the following chain mechanism is generally accepted.

$$RSO_2I \longrightarrow RSO_2\cdot + I\cdot \quad (1)$$

$$RSO_2\cdot + CH_2{=}C(R')R'' \xrightarrow{k_1} RSO_2CH_2\dot{C}(R')R'' \quad (2)$$

$$RSO_2CH_2\dot{C}(R')R'' + RSO_2I \xrightarrow{k_a}$$

$$RSO_2CH_2C(R')R''I + R\dot{S}O_2 \quad (3)$$

If we use two monomers (M_1 and M_2), then we obtain

$$\frac{\log(M_{2,0}/M_2)}{\log(M_{1,0}/M_1)} = \frac{k_2}{k_1}$$

where k_1 and k_2 are the rate constants for competitive addition reaction (Eq. 2) of M_1 (styrene) and M_2 monomer towards sulfonyl radicals, respectively, and $M_{1,0}$ (and $M_{2,0}$) and M_1 (and M_2) the initial and final concentrations, respectively, of styrene (and those of monomers which are able to compete in addition reaction with styrene).

The relative reactivities of vinyl monomers to styrene (k_2/k_1) have been determined by means of Eq. 4. If a reverse reaction of Eq. 2 occurs to a great extent, our k_2/k_1 values obtained from Eq. 4 should vary with the concentration of RSO_2I. In the competitive addition reaction of styrene and *p*-methylstyrene (M_2) towards benzenesulfonyl iodide, we have confirmed the reverse reaction does not take place, namely in Table 1 the k_2/k_1 values show no significant variation with the concentration change of benzenesulfonyl iodide. For other monomer pairs we have also checked the constancy of k_2/k_1 with varying concentrations of RSO_2I (Table 2). Skell and McNamara[8] observed in the addition of benzenesulfonyl iodide to *cis*- and *trans*-2-butene at 0°C that from either olefin, neither was isomerized during the course of reaction, indicating also the absence of the reverse reaction of Eq. 2.

Table 2. Relative reactivities of various pairs of M_1 and M_2 towards benzenesulfonyl radical in toluene at 0 °C

M_1	M_2	Runs[a]	k_2/k_1
Styrene	α-Methylstyrene	3	3.21±0.29[b]
	p-Methylstyrene	9	1.72±0.10
	t-Butyl methacrylate	3	0.14±0.02
	Isopropyl methacrylate	4	0.10±0.01
Methyl methacrylate	*t*-Butyl methacrylate	2	2.01±0.05
	Isopropyl methacrylate	3	1.20±0.10
Vinyl acetate	Methyl methacrylate	3	9.83±0.37
	Methyl acrylate	3	1.57±0.08
	Acrylonitrile	2	0.73±0.08
	1-Hexene	3	2.49±0.17

a) $[PhSO_2I]_0$ was varied from 0.046 to 0.302 mol/l. b) Standard deviation.

GLC analyses of the resulting solutions indicate that within experimental error, quantitative amounts of $RSO_2CH_2C(R')R''I$ were obtained in each experiment; it is strongly suggested that the polymerization process of the vinyl monomers, $RSO_2CH_2\dot{C}(R')R'' + CH_2=C(R')R'' \rightarrow RSO_2CH_2C(R')R''-CH_2\dot{C}(R')R''$, hardly occurs in accordance with the results of Corrêa and Waters.[3] Table 1 also indicates that the k_2/k_1 values are neither affected by the ratios of the concentration of styrene and *p*-methylstyrene, nor by the kind of light initiating the reactions, nor by converstion of the reaction, suggesting that our relative reactivities are reliable.

Effects of the Structure of Sulfonyl Iodides on the Relative Reactivities of p-*Methylstyrene to Styrene.* The relative rates for the addition reactions of *p*-methylstyrene to styrene towards methane- and *para*-substituted arenesulfonyl radicals are summarized in Table 3; the k_2/k_1 values of arenesulfonyl radicals are hardly affected by the kind of *para*-substituent and are almost the same as in the case of methanesulfonyl radical, suggesting that an unpaired electron of arenesulfonyl radicals is localized mainly on sulfonyl groups and that the conjugation of an unpaired electron with π-electron of phenyl rings is small since the relative rates would be affected by the stability and polarity of a radical. The results are in line with the conclusions obtained from ESR studies carried out by McMillan and Waters[9] and Davies and Roberts;[10] in spectra for the benzenesulfonyl radical, the *ortho*-hydrogen hyperfine constant [a(*o*-H)] was larger than a(*p*-H) and a relatively large value was obtained from a(*m*-H). This may be also supported by the fact that $CH_3SO_2N{=}NC_6H_5$ can

Table 3. Relative reactivities of *p*-methylstyrene to styrene towards arenesulfonyl and methanesulfonyl radicals in toluene at 0 °C

Sulfonyl radical	Runs	k_2/k_1
Cl-C$_6$H$_4$-$\dot{S}O_2$	4	1.80±0.06[a]
CH_3-C$_6$H$_4$-$\dot{S}O_2$	6	1.63±0.08 (1.53)[b]
CH_3O-C$_6$H$_4$-$\dot{S}O_2$	4	1.73±0.08 (1.78)[b]
C$_6$H$_5$-$\dot{S}O_2$	9	1.72±0.10
$CH_3\dot{S}O_2$	3	1.79±0.06

a) Standard deviation. b) Values obtained from product analyses with 60 MHz NMR.

decompose thermally into $CH_3\dot{S}O_2$ and $\dot{C}_6H_5$ at the similar rate as $C_6H_5SO_2N{=}NC_6H_5$.[11-13]

Relative Reactivities among Vinyl Monomers. Styrene, α-methylstyrene, *p*-methylstyrene, *t*-butyl methacrylate, isopropyl methacrylate, methyl methacrylate, methyl acrylate, acrylonitrile, 1-hexene, and vinyl acetate were used for competitive addition reactions. Three kinds of relative reactivities for addition of various vinyl monomers towards benzenesulfonyl radical have been determined (Table 4). Since the relative reactivities of these vinyl monomers are spread over a wide range of *ca.* 500 fold, we have used three monomers having different reactivity, styrene, methyl methacrylate, and vinyl acetate, as a reference monomer. This was found to be reasonable from the experimental results: we obtained $k_{t\text{-BuMA}}/k_{Sty}=0.138$, $k_{i\text{-PrMA}}/k_{Sty}=0.097$, $k_{t\text{-BuMA}}/k_{MMA}=2.01$, and $k_{i\text{-PrMA}}/k_{MMA}=1.20$, thus we can calculate the two k_{MMA}/k_{Sty} values from different combinations, *i.e.*, one based on *t*-BuMA and the other on *i*-PrMA. The former gave 0.069 and the latter 0.081, which agree with the value obtained from direct competitive addition reaction, $k_{MMA}/k_{Sty}=0.077$. The relative reactivity between MMA and vinyl acetate has been calculated by the analysis of NMR data.

TABLE 4. RELATIVE REACTIVITIES ON VINYL MONOMERS TOWARDS BENZENESULFONYL RADICAL IN TOLUENE AT 0 °C

Vinyl monomer	Q[a]	e[a]	σ_p[b]	k_2/k_1
α-Methylstyrene	0.98	−1.27	−0.18	3.21
p-Methylstyrene	1.27	−0.98		1.72
Styrene	1.00	−0.80	−0.01	(1.00)
t-Butyl methacrylate	1.18	−0.35		0.14
Isopropyl methacrylate	1.20	−0.15		0.10
Methyl methacrylate	0.74	0.40	0.28	0.08
Methyl acrylate	0.42	0.60	0.45	0.012
Acrylonitrile	0.60	1.20	0.66	0.006
1-Hexene	0.019	−0.28		0.02
Vinyl acetate	0.026	−0.22		0.008

a) Alfrey-Price's Q and e values, see Ref. 14. b) Hammett's *para*-substituent constants.

The relative rates based on the styrene monomer, calculated from the results in Table 2, are shown in Table 4 together with Alfrey-Price Q and e values.[14] These relative rates can be correlated with both e values and Hammett σ_p values (Fig. 1); they are divided into two groups, one (the upper line in Fig. 1) containing conjugated monomers ($Q\geq0.42$) and the other unconjugated monomers ($Q\leq0.026$). The fact that the linear relationship with a steep slope ($\rho_p=-3.6$) exists between e values (or σ_p values) and the relative rates suggests that the benzenesulfonyl radical and also other sulfonyl radicals are highly polar and electrophilic in accordance with the result of Corrêa and Waters[6] that the *p*-toluenesulfonyl radical is electrophilic.

Selectivities for addition reaction of a number of free radicals towards three representative vinyl monomers are given in Table 5. The sulfonyl radical shows the highest selectivity. This is attributable to a strong electrophilic character[20] of the benzenesulfonyl radical since the e value of monomers is an important factor for addition reactions among conjugated vinyl monomers (Fig. 1).

(Received February 6, 1976)

The first-order rate constants for thermal decomposition of benzyl phenylazo sulfone (BPA, **1**) have been determined spectrophotometrically in six solvents using the free radical scavenging technique with a stable Koelsch free radical. Activation parameters in the non-polar solvents such as benzene, toluene, anisole and chlorobenzene were almost the same, but in the two polar solvents, pyridine and nitrobenzene, activation entropies decreased significantly as compared with those in the non-polar solvents. This can be explained by the solvation of the polar solvent in the transition state leading to a phenyldiazenyl and α-toluenesulfonyl radical pair.

Although well established studies of solvent effects have been reported on many ionic reactions, definite information is still lacking as to free radical reactions, because of a weak interaction between free radical and solvent.

In connection with the studies on sulfonyl radicals[1,2a] and the propagation mechanism of free radical copolymerization of sulfur dioxide and styrene,[2b-d] we became interested in solvent effects on the thermal decomposition of benzyl phenylazo sulfone (BPA, $C_6H_5CH_2SO_2$–N=N–C_6H_5), since sulfonyl radicals ($RSO_2\cdot$) have a strong electrophilic character[1,3] and an unpaired electron is localized on the sulfonyl groups.[1] Sulfonyl radicals are thus expected to behave as an electron acceptor[4] and to interact with polar or electron donating solvents. Activation parameters for the decomposition of *p*-tolyl phenylazo sulfone (TPA), which forms[6] *p*-toluenesulfonyl and phenyl radicals, are found[5] to change with solvents remarkably; in ethylbenzene $\Delta H^{\ddagger}=30.8$ kcal/mol, $\Delta S^{\ddagger}=10.7$ e.u. and in *N*,*N*-dimethylformamide $\Delta H^{\ddagger}=39.6$ kcal/mol, $\Delta S^{\ddagger}=34.4$ e.u. This is in striking contrast to the results reported on the thermal decomposition of 2,2′-azobisisobutyronitrile, *i.e.*, the maximum difference among the activation parameters determined in several solvents is found to be $\Delta\Delta H^{\ddagger}=1.78$ kcal/mol and $\Delta\Delta S^{\ddagger}=4.96$ e.u.[7]

We have determined the rate constants for BPA decomposition by using the radical scavenging technique with a stable radical, α,γ-bisdiphenylene-β-phenylallyl (Koelsch radical). The existence of radical-induced decomposition sometimes makes it difficult to determine a rate constant of unimolecular decomposition.[8] The unimolecular rate constsnt in BPA thermal decomposition, however, can be exclusively determined by the use of Koelsch radical (by capturing the radicals formed in the decomposition).[9]

Experimental

Materials. Benzyl phenylazo sulfone (BPA) was prepared by the reaction of benzene diazonium salt with sodium α-toluenesulfinate prepared[10] by treatment of α-toluenesulfonyl chloride with sodium sulfite and sodium hydrogencarbonate in water. Crude BPA was recrystallized several times from ethanol: mp 90—92 °C (dec) (lit,[9] 97—99 °C). (Found: C, 60.27; H, 4.60; N, 11.16%. Calcd for $C_{13}H_{12}N_2O_2S$: C, 59.98; H, 4.65; N, 10.76%.). The Koelsch radical was prepared according to the method of Kuhn and Neugebauer,[11] and recrystallized several times from benzene. Since Koelsch radical is known to crystallize from benzene in a 1 : 1 ratio with the solvent, the benzenated radical was pumped at 100 °C to constant weight (70 h). Found: C, 94.19; H, 5.06%. Calcd for $C_{33}H_{21}$: C, 94.93; H, 5.07%.). Galvinoxyl was prepared from 2,6-di-*t*-butylphenol.[12] Purity of this compound was given as 97.3% by a comparison of molar extinction coefficient with the reference value.[12] All the solvents were purified by distillation in the presence of Koelsch radical or DPPH just before use.

General Procedure. The rate at which BPA decomposes to give radicals scavenged by Koelsch radical was measured in the UV cell (1 cm path length). The cell, containing BPA, Koelsch radical and the solvent, was connected to a vacuum system through a stopcock, the solution being degassed by freeze-pump-thaw cycles. After the fourth freeze-pump-thaw cycle, the system was closed and disconnected from the vacuum system. The absorbance was then measured at 780 nm for Koelsch radical (shoulder) and at 769 nm for galvinoxyl (absorption maximum). The cell set in a Cary 14 UV spectrophotometer was thermostated at a definite temperature by the circulation of thermostated water into the cell holder. The temperature of the solution in the cell was determined by measuring the temperature of an identical solvent in another cell with a copper-constantan thermocouple.

Results and Discussion

Rate Constants for the Unimolecular Thermal Decomposition of BPA. The rate constants obtained by varying the concentration of BPA at 60 °C (Table 1) are considered to be of the real first-order, since each rate constant is not dependent upon the concentration of BPA. If Koelsch radical is highly effective in capturing all the radicals produced and if BPA is in large excess, a plot of time *vs.* absorbance of the Koelsch radical should follow zero-order kinetics with respect to the disappearance of Koelsch radical. A typical plot for the benzene solution is shown in Fig. 1. It follows that the first-order rate constants for the BPA decomposition can be calculated by

$$2k[\mathrm{BPA}]_0=k_0 \qquad (1)$$

where k_0 and k are the zero-order rate constant (slope of Fig. 1) for the disappearance of Koelsch radical and the first-order rate constant for the thermal decomposition of BPA (it should be noted that the first-order rate constants obtained here include the efficiency of diffusion from solvent cage).

In the case of nitrobenzene, however, a plot of time *vs.* absorbance did not give a straight line; the rate of

a) Galvinoxyl used as stable free radical. b) Values obtained by extrapolating to zero concentration of Koelsch radical.

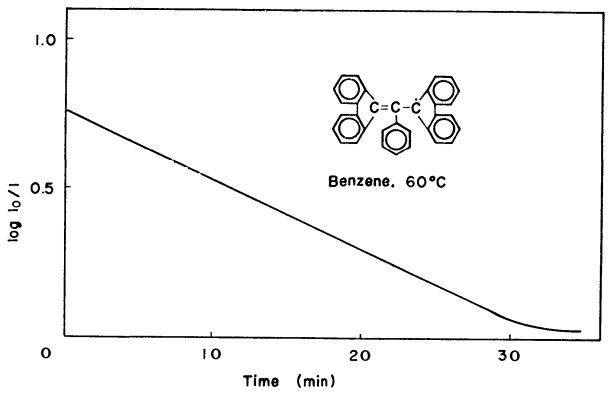

Fig. 1. Plot of absorbance at 785 nm *vs.* time for the thermal decomposition of BPA (5.83×10^{-3} mol/l) in the presence of the Koelsch radical (9.40×10^{-4} mol/l) in benzene at 60 °C.

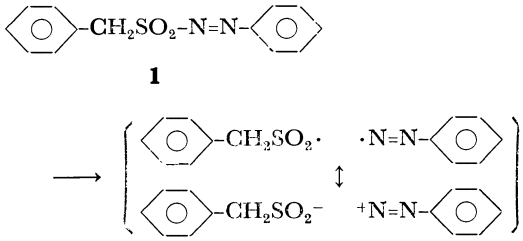
the disappearance of Koelsch radical diminished with decreasing concentration, suggesting the occurrence of an induced decomposition by Koelsch radical in nitrobenzene. Thus, the first-order rate constant in this solvent was determined by extrapolation of the disappearance rates to zero concentration of Koelsch radical.

For BPA decomposition in benzene galvinoxyl has also been used as a stable radical (Table 1). Almost the same values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ as those in the case of Koelsch radical are obtained (Table 2), supporting the above conclusion, *viz.*, the values obtained are the real first-order rate constants. The rate constant in benzene solution using Koelsch radical (1.79×10^{-5} s^{-1} at 60 °C) is approximately the same as the value reported by Kice and Gabrielsen (1.3×10^{-5} s^{-1} at 60 °C).[9)]

Strong Solvation of Polar Solvents in the Transition State. The rate constants obtained at 45—70 °C and the activation parameters in six solvents are shown in Table 2. The activation parameters in four non-polar solvents, benzene, toluene, anisole, and chlorobenzene, are almost the same within experimental error, but those obtained in two polar solvents, pyridine and nitrobenzene, decrease as compared with the values in non-polar solvents, indicating a strong solvation of pyridine or nitrobenzene in the transition state. Since BPA decomposition reaction is endothermic (Table 2), the transition state resembles products (in this case the sulfonyl and the diazenyl radicals) more than starting material, according to Hammond postulate. The contribution of the charge transferred resonance form shown below would be a possible explanation for the polar character of the transition state, in which the polar solvents solvate.



The radical pair may be stabilized by the contribution of the charge transfer between α-toluenesulfonyl radical and phenyldiazenyl radical due to the strong electron accepting nature of the former. In the thermal decomposition of alkyl arylazo sulfide (alkyl-S-N=N-Ar) the significant changes in activation parameters with solvents have been explained by the formation of ion-pair, alkyl-S^- $^+$N=N-Ar.[13)]

The isokinetic relation was plotted to give a straight line with an isokinetic temperature of 30 °C (Fig. 2, $\Delta H^{\neq}$ (34.1±2.1 kcal/mol) and $\Delta S^{\neq}$ (21.7±6.3 e.u.), obtained in the cyclohexane-benzene mixed solvent (5 : 1, vol. ratio), were also plotted).

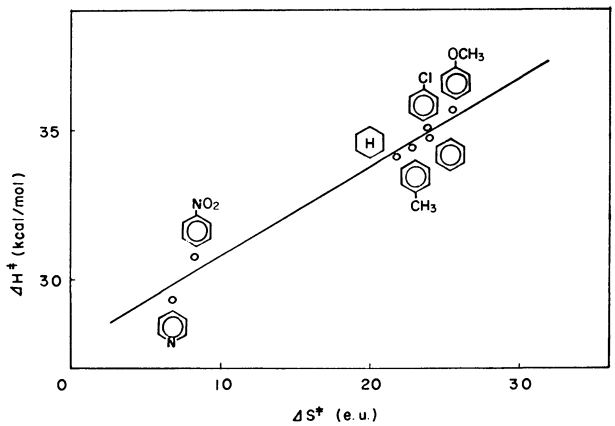


Fig. 2. Plot of isokinetic relation.

a) Measurements carried out with varying concentration of BPA. b) By the least-square method.
c) Standard deviation. d) Galvinoxyl used as stable free radical.

The rate constants obtained here include the efficiency in cage effect (f). A preliminary experiment gave f= 0.56 for the benzene solution at 80 °C. It seems that the change in f with the solvents gives little effect on the activation parameters.

The Reaction of Organoboranes with *d*-Carvone and *l*-Perillaldehyde in the Presence of Oxygen. Evidence for a Coordination between Organoboranes and α,β-Unsaturated Carbonyl Oxygens in Their Oxygen-Induced Free Radical Reaction Process

Akira ARASE, Yuzuru MASUDA, and Akira SUZUKI*

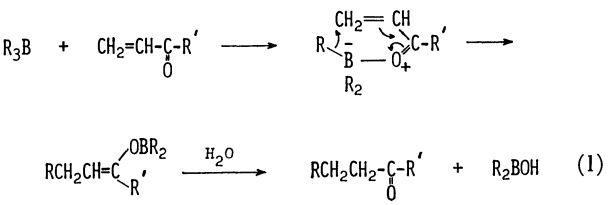
Kitami Institute of Technology, Kitami, Hokkaido 090

**Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received February 20, 1976)

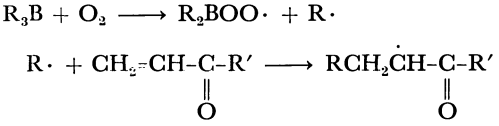
Oxygen-induced 1,4-addition reactions of trialkylboranes with cyclic α,β-unsaturated carbonyl compounds were studied. Stereoselective 1,4-additions of the alkyl groups of trialkylboranes were observed in the reactions of *d*-carvone and L-perillaldehyde. Namely, it was shown that the alkyl group adds to *d*-carvone from the *trans* side with respect to isopropenyl group to give the corresponding saturated ketones. The same type of one side attack of the alkyl group to *l*-perillaldehyde was also observed. The evidence seems to strongly support the hypothesis that coordination of boron atoms of trialkylboranes to carbonyl oxygens plays an important role, even in the oxygen-induced free radical chain reaction of organoboranes with α,β-unsaturated carbonyl compounds.

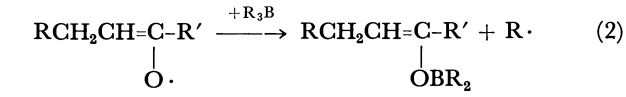
It has been previously reported by us that trialkylboranes undergo rapid 1,4-addition reactions with methyl vinyl ketone[1] to give vinyloxyboranes, which undergo hydrolysis on treatment with water to form corresponding saturated ketones (Eq. 1).



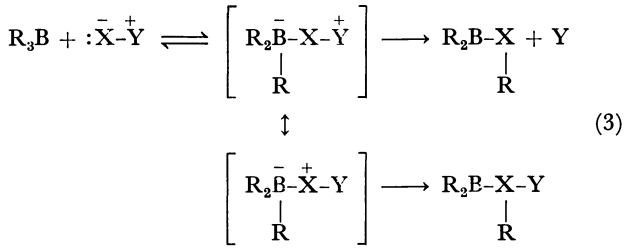
The reaction was initially considered to proceed *via* a cyclic transition state,[1] (co-ordination mechanism). The same type of reaction was shown to occur readily with other α,β-unsaturated carbonyl compounds, such as acrylaldehyde,[2] methacrylaldelyde,[3] α-bromoacrylaldelyde,[3] 2-methylcycloalkanones,[3] and isopropenyl methyl ketone.[4] However, the reaction failed when an alkyl substituent is present in the 3-position as in the cases of *trans*-crotonaldehyde and *trans*-3-penten-2-one.[4] Furthermore, it was discovered that galvinoxyl inhibits the reaction between trialkylboranes and acrylaldehyde or methyl vinyl ketone,[4] and that the reaction with 3-substituted enone systems is effectively promoted by an addition of acyl peroxide[5] or air,[6] or by photochemical means.[5] These reactions therefore were concluded to proceed by a radical chain mechanism as shown in Eq. 2.[4]

The nature of the chain propapagation step may be associated with the formation of the strong boron–oxygen bond in the vinyloxyborane, and is similar to the reaction of alkoxy radicals with trialkylboranes.[7] The failure of the reaction of 3-substituted enone systems in the absence of air or radical initiators may possibly be the result of the relatively short chain length of radical addition to these systems compared to the addition to unsubstituted systems.





On the other hand, there are many examples which suggest that reactions of organoboranes seem to proceed *via* co-ordination mechanisms, including carbonylation reactions,[8] and reactions between organoboranes and α-halocarbanions,[9] ylids,[10] diazo compounds,[11] carbenes,[12] 2-furyllithium,[13] alkyl azides,[14] and α-azidostyrene.[15] The reaction which is considered to proceed by a coordination mechanism usually involves initial Lewis acid–Lewis base interaction between the organoborane and the substrate to form an adduct, which subsequently undergoes rearrangement with migration of an alkyl group from boron to carbon (Eq. 3).



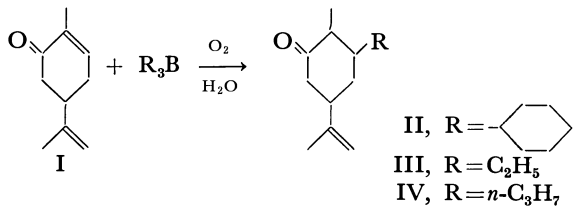
In order to know if such a Lewis acid–Lewis base interaction is involved even in the radical chain process, we conducted the reaction of trialkylboranes with *d*-carvone and *l*-perillaldehyde in the presence of oxygen.

Results and Discussion

The reaction of *d*-carvone (I) with tricyclohexylborane was carried out in aqueous tetrahydrofuran solution. During the initial stage of the reaction, a 50 mol % oxygen for tricyclohexylborane was bubbled into the solution for 1 h. Although two products, A and B, were detected by GLPC, these were not isolated by preparative GLPC or by preparative TLC. Consequently, the products, A and B, were collected as a mixture by preparative GLPC.

The elemental analysis of the mixture consisting of A and B, coincided with $C_{16}H_{26}O$. The IR spectrum

showed an absorption band at 1700 cm^{-1} due to saturated carbonyl group and the PMR spectrum in carbon tetrachloride indicated the following absorptions: 0.93 (d, J=7.0 Hz, $-CH_3$), 0.97 (d, J=7.0 Hz, $-CH_3$), 0.80—2.70 ($-CH_2-$ and $-\dot{C}H-$), 1.68 ($CH_3-\dot{C}=$), and 4.76 ($CH_2=\dot{C}-$). The mass spectra, obtained by GC-mass spectrometry, included the following peaks: *m/e* (relative intensity) 234 (29), 151 (32), 137 (100), 95 (52), 69 (32), and 55 (38) for the product A, and 234 (30), 151 (32), 137 (100), 95 (46), 69 (30), and 55 (34) for the product B. These data suggest that the products are 2-methyl-5-isopropenyl-3-cyclohexyl-1-cyclohexanones (II). The composition of the mixture was estimated by GLPC and the major product, A and the minor one, B, were 63 and 37%, respectively.



(4)

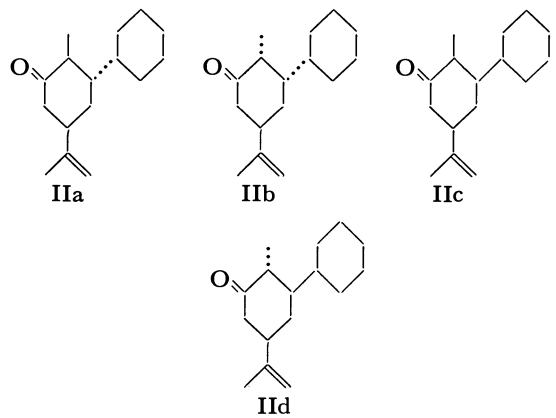
Similarly, 2-methyl-5-isopropenyl-3-ethyl-1-cyclohexanone (III) and 2-methyl-5-isopropenyl-3-propyl-1-cyclohexanone (IV) were obtained from corresponding trialkylboranes under the same reaction conditions. The results are shown in Table 1.

Table 1. Reaction of cyclic α,β-unsaturated carbonyl compounds with trialkylboranes in the presence of oxygen

α,β-Unsaturated carbonyl compound	Trialkylborane R_3B	Product	Yield,[a] %
I	Triethylborane	III	55
I	Tripropylborane	IV	60
I	Tricyclohexylborane	II	82
VII	Tricyclohexylborane	VIII	70

a) Based on the trialkylborane used.

Four stereoisomers, IIa, IIb, IIc, and IId, are considered for II. Namely, the introduction of the cyclohexyl group from the *trans* side against the isopropenyl group affords IIa or IIb, whereas the attack of the cyclohexyl group from *cis* side gives IIc or IId.



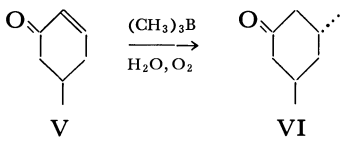
In an attempt to determine the stereochemistry, an epimerization reaction was carried out on the mixture of A and B. Thus, a mixture of A (63%) and B (37%) was treated with sodium methoxide in tetrahydrofuran at 40 °C. The reaction mixture was sampled periodically and analyzed by GLPC. The results are summarized in Table 2.

Table 2. Epimerization of IIa and IIb in the presence of sodium methoxide at 40 °C

Reaction time, h	Percent composition of IIa	and IIb	Total amount of IIa and IIb
0	63	37	100
1	72	28	100
2	74	26	99
3	74	26	100
4	74	26	99

The equilibrium distribution, 74% A to 26% B, was obtained after 2 h, and the total amount of the compounds A and B was not changed during the reaction, demonstrating that they are epimers with one another. Consequently, it was concluded that the cyclohexyl group was introduced from one side to the cyclohexenone ring of *d*-carvone.

In order to clarify whether the attack of alkyl group of organoboranes occurs *trans* or *cis* to 5-alkyl group of cyclohexenone derivatives, the reaction of 5-methyl-2-cyclohexen-1-one (V) with trimethylborane was examined as a model case of the reaction. From the experimental evidence that the reaction gave only *trans*-3,5-dimethyl-1-cyclohexanone (VI) which was identified by direct comparison of its 2,4-dinitrophenylhydrazone with that of the authentic sample prepared by House and Fischer,[16] it was decided that the methyl group of trimethylborane attacked exclusively from *trans* side to 5-methyl group (Eq. 5).

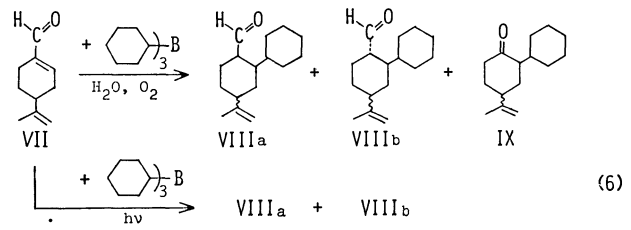


(5)

From the analogy of the above reaction and the epimerization reaction, reasonable structures for the products, A and B in the reaction of tricyclohexylborane with *d*-carvone, are assigned to IIa and IIb, respectively. These facts seem to indicate that the cyclohexyl attack occurs *trans* to isopropenyl group in *d*-carvone.

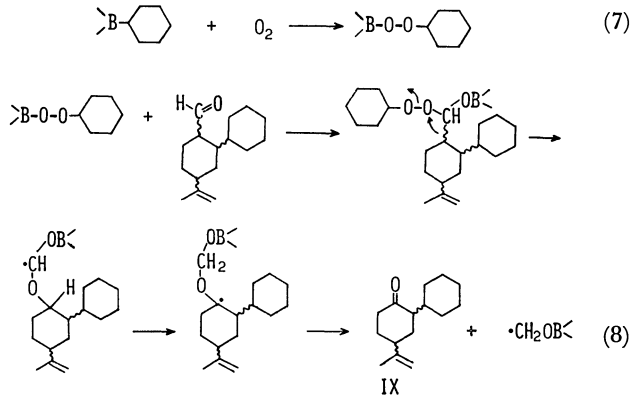
The stereoselective addition of the alkyl group of trialkylborane to 5-alkyl-2-cyclohexen-1-one derivatives mentioned above led us to examine the stereochemistry in the reaction of trialkylborane with other types of cyclic α,β-unsaturated carbonyl compounds. Thus the reaction between tricyclohexylborane and *l*-perillaldehyde (VII) was carried out under the same conditions. In the reaction, three compounds, C, D, and E were obtained. Although by preparative GLPC and by preparative TLC, the compounds C and D could not be isolated purely, the IR spectrum of the mixture consisting of 60% C and 40% D, collected by preparative

GLPC showed absorptions at 2700 and 1730 cm^{-1} due to saturated aldehyde structure. The PMR spectrum in carbon tetrachloride solution showed the following absorptions in ppm: 0.70—2.50 ($-CH_2-$ and $-\underset{|}{C}-H$); 1.73 ($CH_3-\underset{|}{C}=$); 4.71 ($CH_2=\underset{|}{C}-$); 9.70 (s, -CHO); 9.73 (S, -CHO). The mass spectra, obtained by GC-mass spectrometry, included the following peaks: m/e (relative intensity) 234 (41), 216 (12), 151 (64), 109 (100), and 83 (50) for the product C, and 234 (67), 216 (23), 151 (67), 109 (100), and 83 (99) for the product D. The elemental analysis of the mixture coincided with $C_{16}H_{26}O$. These data were all consistent with 2-cyclohexyl-4-isopropenyl-1-cyclohexanecarbaldehydes (VIIIa and VIIIb). On the other hand, the product, E, was determined from its spectroscopic data and its elemental analysis to be 2-cyclohexyl-4-isopropenyl-1-cyclohexanone (IX). Namely, it has an IR absorption peak at 1710 cm^{-1} caused by ketonic carbonyl and PMR peaks in carbon tetrachloride at 0.70—2.60 ($-CH_2-$ and $-\underset{|}{C}-H$), 1.70 ($CH_3-\underset{|}{C}=$), and 4.71 ppm ($CH_2=\underset{|}{C}-$). Addition to these data, it gave the following mass peaks: *m/e* (relative intensity) 220 (2), 138 (100), 97 (67), and 95 (46).



(6)

Since our efforts were mainly directed toward learning if a Lewis acid–Lewis base interaction is involved even in the radical chain process of organoborane reaction, a detailed discussion on formation of the abnormal product (IX) was not a main purpose in this paper. The reaction, however, should be considered to proceed through the following path. It is well known that alkyldioxydialkylborane is formed by air-oxidation of trialkylborane.[17]



(7)

(8)

Accordingly, it appears to be possible to obtain cyclohexyldioxydicyclohexylborane from tricyclohexylborane and oxygen (Eq. 7). Such a dioxyborane reacts with *l*-perillaldehyde in a similar manner which is postulated in Baeyer-Villiger reaction as depicted in Eq. 8.[18]

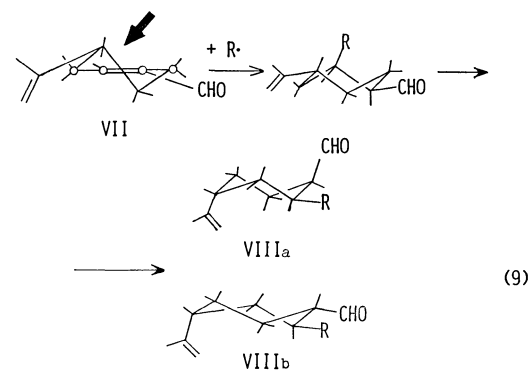
If the above-mentioned mechanism is correct, the formation of such a cyclohexanone derivative (IX) should be excluded by the photochemically induced reaction[5] of tricyclohexylborane with perillaldehyde, because oxygen is not used as a radical initiator. As expected, when the reaction was carried out under UV irradiation in the absence of air, the products were shown to be VIIIa and VIIIb, and no unusual product (IX) was detected.

Table 3. Epimerization of VIIIa and VIIIb in the presence of sodium methoxide at 40 °C

Reaction time, h	Percent composition of VIIIa and VIIIb		Total amount of VIIIa and VIIIb
0	40	60	100
1	41	59	94
3.5	46	54	97
15	46	54	97

In an attempt to know the structure relationship between VIIIa and VIIIb, epimerization reaction was carried out. Thus, after a mixture of VIIIa (40%) and VIIIb (60%) was treated with sodium methoxide in tetrahydrofuran under the same reaction conditions conducted in a mixture of IIa and IIb, the reaction products were analyzed by GLPC. The results are summarized in Table 3. This evidence shows that VIIIa and VIIIb are epimers with one another, and the equilibrium ratio is 46 : 54. It is reasonable to consider that in both VIIIa and VIIIb, cyclohexyl group, the most bulky substituent on the parent cyclohexane ring, is located in the equatorial position, and that VIIIa in which the aldehyde group is in axial, is less stable than VIIIb having an aldehyde group in the equatorial position. On the other hand, it is known that protons situated in equatorial of cyclohexane ring give rise to resonances downfield from their axial counterparts.[19] In the PMR spectrum of the mixture, 40% VIIIa and 60% VIIIb, two singlet peaks due to the aldehydic protons are observed at δ=9.70 and 9.73 ppm, and their peak ratio is 2 : 3. This fact supports the structures assigned to VIIIa and VIIIb.

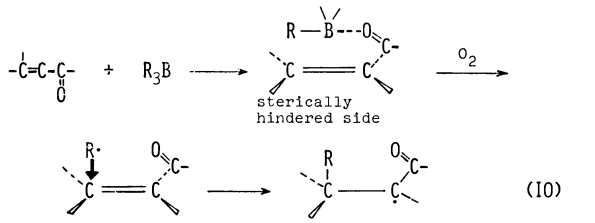
Although the stereochemistry of the isopropenyl group has not been fully clarified, it is considered that the cyclohexyl group of tricyclohexylborane was introduced from one side of cyclohexene ring of *l*-perillaldehyde (Eq. 9).



(9)

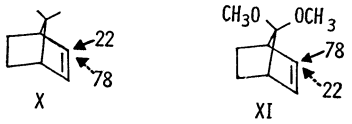
According to an analogous consideration for *d*-carvone mentioned above, it is tentatively concluded that in the products, VIIIa and VIIIb, the cyclohexyl group is located in *trans* with respect to 4-isopropenyl group (Eq. 9).

The highly stereoselective results obtained in this work seem to suggest that even when the reaction of organoboranes with α,β-unsaturated carbonyl compounds proceeds *via* a radical chain process, such a trialkylborane first approaches the carbonyl oxygen from the less hindered side of the molecule because of a Lewis acid–Lewis base intraction, and then the alkyl radical formed from the trialkylborane attacks the β-carbon from the same side of the unsaturated carbonyl derivative (Eq. 10).



(10)

There are reports which show Lewis base–Lewis acid interactions between boron and oxygen atoms in hydroboration of olefins. For example, in the hydroboration of 7,7-dimethylnorbornene (X)[20], *endo*-attack is favored, 22% *exo*- and 78% *endo*-, while *exo*-attack is predominant in the 7,7-dimethoxy derivative (XI).[21] This result is not explained by means of steric hindrance in hydroboration, but may be rationalized in terms of a more predominant approach of borane to the methoxy side. Consequently, the present proposal is not singular.



Recently, there has been an increased interest in methods for effecting 1,4-addition to α,β-unsaturated carbonyl compounds using organometallic compounds.[22–29] Although in such cases of reactions with cyclic α,β-unsaturated carbonyl compounds with substituent, mixtures containing major *trans*-1,4-addition products and minor *cis*-isomers have been reported to be obtained.[22,28,29] We did not detect corresponding *cis*-1,4-addition products in the present experiment.

Experimental

Instruments. Analytical GLPC and preparative GLPC were performed using a Hitachi Model K-53 Gaschromatograph and Varian Aerograph Model-920, respectively. PMR spectra were obtained on Hitachi Model R-20A spectrometer. Chemical shifts are reported in δ unit using TMS as the internal standard. Infra red spectra were recorded on Shimadzu 27G spectrometer. Mass spectra were obtained on Hitachi Model M-52 mass spectrometer. The light source of UV irradiation was 400W Rikosha High Pressure Mercury Lamp.

Materials. *d*-Carvone and l-perillaldehyde were distilled before use.

Reaction of Tricyclohexylborane with d-*Carvone.* Into a 25-ml round bottomed flask, equipped with a gas inlet, a septum inlet, a reflux condenser and a magnetic stirring bar, 4 mmol of tricyclohexylborane in 4 ml of THF, prepared by hydroboration of cyclohexene, under nitrogen atmosphere and 1 ml of water were charged. To the stirred solution 0.6 g (4 mmol) of *d*-carvone was added at 40 °C, and then 224 ml of air (2 mmol of oxygen) was bubbled for 1 h. After stirring for 12 h at the same temperature, the solution was saturated with sodium chloride, and the upper organic layer was analysed by GLPC. A column, packed with PEG 20 M (15%) on Diasolid M was used at 200 °C. It was indicated that the cyclohexylated products had been obtained in an 82% yield in a ratio of IIa : IIb=63 : 37. In the preparative experiment, the scale of the reaction was enlarged 10 times. After completion of the reaction, the organic layer was separated by decantation and then the lower layer was extracted with ethyl ether several times. The combined organic layer and extracts were dried over anhydrous magnesium sulfate. After removal of the solvent, the products were collected by preparative GLPC.

Anal. Found: C, 81.70; H, 11.40%. Calcd for $C_{16}H_{26}O$: C, 81.99; H, 11.18%.

Reaction of Triethylborane with d-*Carvone.* The reaction was carried out under the same conditions described above. The product, III, (yield, 55%) was collected. The IR spectrum showed an absorption at 1708 cm^{-1}. The PMR (CCl_4) spectrum showed the following absorptions: 0.80—1.05 ($-CH_3$), 1.05—2.70 ($-CH_2-$ and $-\overset{|}{C}H$), 1.72 ($CH_3-\overset{|}{C}=$), and 4.76 ($CH_2=\overset{|}{C}-$). The mass spectra (70 eV) included the following peaks: *m/e* (relative intensity) 180 (43), 151 (18), 97 (73), 95 (73), 83 (100), 69 (75), and 55 (50) for the major product, and 180 (38), 151 (8), 97 (44), 95 (64), 83 (100), 69 (56), and 55 (40) for the minor product.

Anal. Found: C, 80.10; H 11.21%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

Reaction of Tripropylborane with d-*Carvone.* A small scale reaction and preparative scale reaction were carried out in the same manner with that of tricyclohexylborane with *d*-carvone. The product IV (yield, 60%) was collected by GLPC. The IR spectrum showed an absorption at 1710 cm^{-1}. PMR (CCl_4) spectrum: 0.85—1.15 ($-CH_3$), 1.15—2.70 ($-CH_2-$ and $-\overset{|}{C}H$), 1.75 ($CH_3-\overset{|}{C}=$), and 4.70 ($CH_2=\overset{|}{C}-$). The mass spectra (70 eV) included the following peaks: *m/e* (relative intensity) 194 (24), 151 (14), 97 (100), 95 (56), 69 (46), and 55 (44) for the major product, and 194 (28), 151 (13), 97 (100), 95 (60), 69 (34), and 55 (48) for the minor product.

Anal. Found: C, 80.72; H, 11.63%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

Epimerization of IIa and IIb. The mixture (47 mg) of IIa (63%) and IIb (37%), and 0.1 ml of 0.1M-sodium methoxide in THF and diphenyl ether (internal standard for GLPC) were added into 1.9 ml of THF. The solution was stirred at 40 °C and 0.1 ml portions of the solution were periodically sampled. They were neutralized with 0.01 M-HCl, saturated with sodium chloride and then extracted with petroleum ether. The extracts were analysed by GLPC. PEG 20 M (15%) supported on Diasolid M was used as the packing materials for GLPC.

Reaction of Trimethylborane with 5-Methyl-2-cyclohexen-1-one. The reaction appratus was composed essentially of two parts. flask A and flask B. The flask A was a 100 ml-three necked flask fitted with a magnetic stirring bar, a gas inlet glass

tube, a septum inlet and an efficient condenser. Flask B was a 25 ml-flask equipped with a septum inlet and a condenser. The top of the condenser of a flask A was connected with a Tygon tube which had a syringe needle at the end. The needle was inserted into the bottom of flask B through the septum inlet.

In the flask A 1.62 g (60 mmol) of magnesium turning was placed. The entire reaction apparatus was flushed with nitrogen, and then 8.52 g (60 mmol) of methyl iodide in 20 ml of ethyl ether was added slowly to maintain a gentle reflux. After addition of methyl iodide, the mixture was stirred at 25 °C for 1 h. On the other hand, in flask B were charged 0.66 g (6 mmol) of 5-methyl-2-cyclohexen-1-one prepared by the Crossley's procedure[30] and 2 ml of THF, and the flask was cooled down to −25 °C. Then 8.5 g of boron trifluoride etherate was added dropwise to the Grignard reagent solution in flask A, and the resulting trimethylborane was introduced into flask B. A smooth dissolution of trimethylborane was observed. After generation of the trimethylborane ceased, flask A was flushed with nitrogen to sweep the remained trimethylborane in the flask into the flask B. Then the colling bath was removed, and 1 ml of water was added to the reaction mixture in B. Into the solution in flask B, 400 ml of air was bubbled slowly. After 12 h, the reaction mixture was saturated with sodium chloride, and the organic layer separated was dried over anhydrous magnesium sulfate. Thus, *trans*-3,5-dimethyl-1-cyclohexanone was isolated in a yield of 51% by GLPC at 150 °C (PEG 20 M(15%) supported on Diasolid M). 2,4-Dinitrophenylhydrazone of the ketone, recrystallized twice from ethyl alcohol, melts at 108.0—109.5 °C (literature,[16] 108.4—110 °C).

Reaction of Tricyclohexylborane with 1-Perillaldehyde. A small scale and preparative scale experiments were carried out in the same manner as described in the reaction of tricyclohexylborane with *d*-carvone. GLPC analysis (Apiezon glease L (15%) on Diasolid M at 180 °C) indicated that the products, VIII and IX, had been obtained in yields of 70% and 18%, respectively.

Anal. Found: C, 81.80; H, 11.38%. Calcd for $C_{16}H_{26}O$: C, 81.99; H, 11.18%.

Spectroscopic data of IX were as follows: IR, 1710 cm^{-1}; PMR (CCl_4), 0.70—2.60 ($-CH_2-$ and $-\overset{|}{C}H$), 1.70 ($CH_3-\overset{|}{C}=$), and 4.71 ($CH_2=\overset{|}{C}-$); mass spectrum (70 eV), m/e (relative intensity) 220 (2), 138 (100), 97 (67), and 95 (46).

Anal. Found: C, 81.80; H, 11.18%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

Epimerization Reaction of VIIIa and VIIIb. A reaction was carried out under the same conditions as mentioned in the epimerization of IIa and IIb.

The Bromination and the Mercuration of Bis(dimethylglyoximato)-(styryl)pyridinecobalts(III), Styryl-type Cobaloximes

Hiraku SHINOZAKI, Minoru KUBOTA, Osamu YAGI, and Masaru TADA*

Department of Chemistry, School of Science and Engineering, Waseda University, Shinju-ku, Tokyo 160

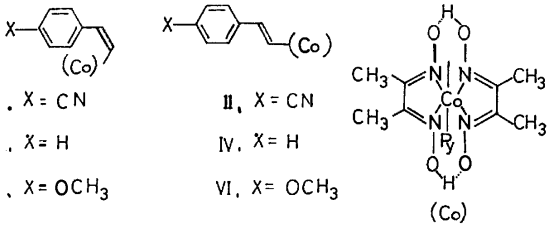
(Received February 20, 1976)

cis and *trans-p*-Cyanostyryl(pyridine)cobaloximes (I and II) and *cis* and *trans-p*-methoxystyryl(pyridine)-cobaloximes (V and VI) were prepared by the reaction of the reduced form of cobaloxime, bis(dimethylglyoximato)-(pyridine)cobalt(I), with *cis* and *trans-p*-cyanostyryl bromides and with *cis* and *trans-p*-methoxystyryl bromides, respectively. The styryl-type cobaloximes thus obtained retained the stereochemistry, *cis* or *trans*, of the starting bromides. The bromination of these styryl-type cobaloximes (I, II, V, and VI) and of the *cis* and *trans*-styryl-(pyridine)cobaloximes (III and IV) in polar or non-polar solvents gave styryl-type bromides with the retention of configuration. The mercuration of these cobaloximes with mercury(II) acetate in DMF gave styryl-type mercurials, again retaining the original configuration.

In recent years much attention has been paid to the stereochemistry of the electrophilic substitution of alkylmetal complexes,[1] especially bis(dimethylglyoximato)-(alkyl)pyridinecobalt(III) (its conventional name, alkyl-(pyridine)cobaloxime, will be used hereafter). Little is known, however, about the stereochemistry of the electrophilic fission of vinyl-type cobalt complexes, though Johnson and Meeks[2] reported the halogenation of styryl(pyridine)cobaloxime in acetic acid and we reported the bromination and the mercuration of 1-octenyl(pyridine)cobaloxime in several solvents,[3] The halogenation of *cis* and *trans*-styryl(pyridine)cobaloxime takes place with the retention of configuration in acetic acid[2] and the bromination of *cis* and *trans*-1-octenyl-(pyridine)cobaloxime takes place with the retention and the inversion of the configuration[3] (Eq. 1).

$$\text{R-CH=CH-(Co)} \xrightarrow{Br_2} \text{R-CH=CH-Br} + \text{Br-(Co)} \quad (1)$$

We examined the steric course of the bromination and the mercuration of *para*-substituted and non-substituted styryl(pyridine)cobaloximes in varying reaction conditions to get a deeper insight into the reaction mechanism, referring to the electronic effect of the substituent on the benzene ring.



I, X = CN II, X = CN
III, X = H IV, X = H
V, X = OCH_3 VI, X = OCH_3

Syntheses of Styryl-type Cobaloximes. *cis* and *trans-p*-Cyanostyryl(pyridine)cobaloxime (I and II) were synthesized by the reaction of *p*-cyanostyryl bromides with the reduced form of pyridinecobaloxime,[4] prepared *in situ* from a dimeric bis(dimethylglyoximato)(pyridine)-cobalt(II), by a reduction using zinc powder in methanol. The similar reactions of *cis* and *trans-p*-methoxystyryl bromides were sluggish and did not give *p*-methoxystyryl(pyridine)cobaloximes (V and VI) in a reasonable yield. *p*-Methoxystyryl(pyridine)cobaloximes (V and VI), therefore, were synthesized by the action of the cobaloxime anion, bis(dimethylglyoximate)(pyridine)cobalt(I), prepared *in situ* from dimethylglyoxime, cobalt(II) chloride, pyridine, sodium hydroxide, and sodium tetrahydroborate in methanol. *cis* and *trans*-Styryl(pyridine)cobaloximes (III and IV)[5] were prepared similarly, by the reaction of *cis* and *trans*-styryl bromides with the cobaloxime anion.

The stereochemistry of the styryl-type cobaloximes is easily assigned from the coupling constants of the olefinic protons in the NMR spectra of these cobaloximes; 10 Hz, 9 Hz, and 9 Hz for I, III, and V, and 15 Hz, 15 Hz, and 14 Hz for II, IV, and VI, respectively. The steric course of the reactions of styryl bromides has been reported to be completely stereospecific with retention of configuration,[5] and the reactions with *p*-cyanostyryl bromides or *p*-methoxystyryl bromides also took the stereospecific course with retention. The rate of the displacement reaction of these bromides with cobaloxime anions is much faster at the *trans*-bromide than at its *cis*-isomer, and we needed the pure *cis para*-substituted styryl bromides for the preparations of *cis* styryl-type cobaloximes. The base treatment of *erythro*-2,3-dibromo-3-(*p*-methoxyphenyl)-propionic acid gave only *trans-p*-methoxystyryl bromide under various conditions. The base treatment of *erythro*-2,3-dibromo-3-(*p*-acetoxyphenyl)propionic acid[6] gave stereoselectively *cis-p*-acetoxystyryl bromide or its *trans*-isomer, depending upon the reaction conditions. The treatment of the dibromide with triethylamine in a non-polar solvent such as benzene gave *cis-p*-acetoxystyryl bromide exclusively. On the other hand, the treatment of the dibromide with sodium acetate in water afforded only *trans-p*-acetoxystyryl bromide. *cis-p*-Acetoxystyryl bromide was converted into *cis-p*-methoxystyryl bromide by hydrolysis of the acetoxy group followed by methylation.

Electrophilic Reaction of Styryl-type Cobaloximes. Bromination of the styryl-type cobaloximes was carried out with an equivalent amount of bromine; the reaction took place smoothly at room temperature and almost instantly in polar solvents to give the corresponding styryl-type bromides in high or quantitative yields. The compositions of the styryl bromides from each reaction are collected in Table 1. The bromination of *p*-cyanostyryl(pyridine)cobaloximes (I and II) and styryl(pyridine)cobaloximes (III and IV) in methanol gave bromides retaining the original configurational most exclusively, though the bromination of

* To whom correspondence should be addressed.

p-methoxystyryl(pyridine)cobaloximes (V and VI) gave 1,1-dibromo-2-methoxy-2-(*p*-methoxyphenyl)ethane, due to the facile methoxybromination of the resulting *p*-methoxystyryl bromides. The bromination of all six cobaloximes in dichloromethane or benzene proceeded with retention. In carbon disulfide, the reaction of *cis*-cobaloximes (I, III, or V) with an equivalent amount of bromine gave products with extensive inversion (I, 45%; III, 12%, V; 20% inversion respectively). These results were proved to be due to the isomerization of the *cis*-bromides to their *trans*-isomers under the reaction conditions from the following experimental findings. The composition of the bromides from *cis*-cobaloximes (I, III, or V) depends upon the amount of bromine used and approaches the limiting values (Fig. 1).

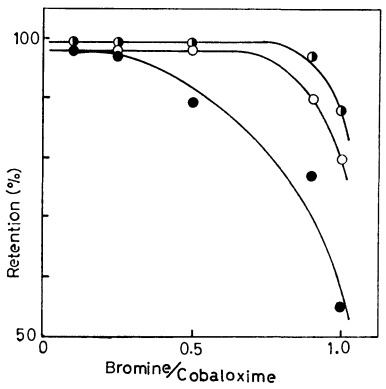


Fig. 1. Stereospecificity in the bromination of cobaloximes with varying amount of bromine.
a) ● (I), ◑ (III), ○ (V).
b) In carbon disulfide at room temperature.

These limiting values were obtained by extrapolation of the curves to an infinite amount of the bromine used, and are collected in Table 1. Brominations of the cobaloximes, therefore, are proved to proceed with retention even in carbon disulfide. This feature is in sharp contrast with the bromination of *cis* and *trans*-1-octenyl(pyridine)cobaloxime, which gives products with a preferential inversion in carbon disulfide.[3] We reexamined the bromination of 1-octenyl(pyridine)-cobaloxime with varying amounts of bromine, but no significant difference from the earlier results was observed. A temperature-effect upon the product composition was found in the case of the bromination of 1-octenyl(pyridine)cobaloxime[3] and we found that the bromination of styryl-type cobaloximes in refluxing carbon disulfide (46 °C) gave the styryl-type bromides with inversion to some extent. The compositions in Table 1 are again the limiting values from the reaction with 0.25 equivalent amount of bromine. These data show that the bromination itself takes place with a complete retention in carbon disulfide even at a higher temperature. Next, we examined the relative reactivities of the *trans*-cobaloximes (II, IV, and VI) and *trans*-1-octenyl(pyridine)cobaloxime to bromine by carrying out a competitive reaction. The relative reactivities thus obtained are 1.0 (II), 2.3 (1-octenyl(pyridine)-cobaloxime), 3.1 (IV), and 4.7 (VI); this sequence of the reactivity is accounted for by the electrophilic nature of the reaction, though a more profound difference in the reactivity, in general, can be expected for a typical electrophilic reaction of *para*-substituted styrenes.[7]

One of the possible explanations of the stereochemical consequence of the bromination is the hindered rotation of the bond between the benzylic carbon and the carbon-bearing cobaloxime moiety in an intermediate (B), which either formed in concert with the attack of bromine or formed stepwise *via* an intermediate (A) (Eq. 2). This inhibition of rotation must be due to the stereoelectronic stabilization of the benzylic cation by either a vertical stabilization,[8] originating from the conjugation between the vacant *p*-orbital and the σ-bond of carbon–cobalt, or a d-π conjugation between the vacant *p*-orbital and a filled d-orbital of the cobalt ion.[9] The rupture of the cobaloxime moiety from the cation (B) is expected to afford styryl-type bromides which retain the original configuration of the starting cobaloximes.

Dodd and Johnson[10] have described briefly, in a review article, the mercuration of the cobaloximes III and IV in acetic acid; they pointed out that inconsistent results were obtained depending on the purity of the solvent. Our mercuration of the cobaloximes (I—VI) with mercury(II) acetate in DMF, followed by the treatment with sodium chloride, gave the styryl-type mercurials. NMR analysis of the resulting mercurials dissolved in DMSO showed that the product retained the original stereochemistry of the cobaloximes. No stereochemical consequence is further altered, regardless of whether the *para*-substituent is electron

donating ($-OCH_3$) or electron withdrawing (-CN), and the mercuration must take the same steric course as the bromination.

In conclusion the bromination and the mercuration of *para*-substituted styryl(pyridine)cobaloximes take place with the retention of configuration to give styryl-type bromides and styrylmercury(II) chlorides in high yields; these results can be accounted for by the intervention of the benzylic cation stabilized by neighboring group participation of a cobaloxime moiety.

Experimental

Styryl-type Bromides. *cis* and *trans*-Styryl bromide,[11,12] *cis* and *trans-p*-cyanostyryl bromides,[13] and *trans-p*-methoxystyryl bromide[14] were prepared by the reported methods. *cis-p*-Methoxystyryl bromide was prepared from *erythro*-2,3-dibromo-3-(*p*-acetoxyphenyl)propionic acid, mp 187—189 °C, which was prepared by the same procedure as that used for the prepartion of *erythro*-2,3-dibromo-3-(phenyl)propionic acid.[6]

The mixture of *erythro*-2,3-dibromo-3-(*p*-acetoxyphenyl)-propionic acid (50 g, 0.137 mol), 35 ml of triethylamine, and 250 ml of benzene was refluxed for 2 h, then the mixture was filtered to remove the triethylamine hydrobromide. The filtrate was washed successively with water, saturated aqueous $NaHCO_3$, and 2M HCl, and was dried over Na_2SO_4. The condensation of the solution gave a mixture of *cis* and *trans-p*-acetoxystyryl bromides (*cis*/*trans*=84/16) as an oil (22 g). The solution of these *p*-acetoxystyryl bromides (22 g) in ethanol (80 ml) and water (20 ml) was mixed with 4 ml of concd HCl and then refluxed for 2 h. Most of the ethanol was evaporated under reduced pressure and the aqueous solution thus obtained was extracted with benzene after the addition of more water. The benzene extract was wased with saturated aqueous $NaHCO_3$ and was dried over Na_2SO_4. Evaporation of benzene from the solution gave a light yellow solid, which was purified by passing through a silica gel column (2.5×25 cm) with hexane–ether (1 : 1) to give *p*-hydroxystyryl bromides (15.7 g). For the purification of *cis-p*-hydroxystyryl bromide, the *p*-hydroxystyryl bromides were esterified with benzoyl chloride–pyridine, and the recrystallization of the benzoates from hexane–carbon tetrachloride gave *cis-p*-benzoyloxystyryl bromide. Mp 93 °C, IR(KBr): 1730 and 700 cm^{-1}. NMR($CDCl_3$): 6.36 (1H, d, J=8 Hz) and 6.98 ppm (δ) (1H, d, J=8 Hz).

Hydrolysis of the *cis-p*-benzoyloxystyryl bromide (8.2 g) with sodium hydroxide (2.7 g) in ethanol–water (6 : 1) gave *cis-p*-hydroxystyryl bromide in quantitative yield. The methylation of the bromide by dimethyl sulfate in dry acetone in the presence of K_2CO_3 gave *cis-p*-methoxystyryl bromide (3.5 g, 71%). Bp 128—134 °C/15—16 mmHg. IR(neat): 1600, 1505, 1250, 1175, 1015, 830, and 705 cm^{-1}. NMR (CCl_4): 3.58 (3H, s), 5.96 (1H, d, J=8 Hz), 6.50 (2H, d, J=9 Hz), 6.62 (1H, d, J=8 Hz), 7.26 ppm (δ) (2H, d, J=9 Hz).

Syntheses of Styryl-type Cobaloximes. *cis* and *trans*-Styryl(pyridine)cobaloximes (III and IV) were prepared by the reaction of *cis* and *trans*-styryl bromides with the cobaloxime anion, as reported earlier.[5]

a) *cis* and *trans-p*-Cyanostyryl(pyridine)cobaloximes (I and II). To a mixture of *cis-p*-cyanostyryl bromide (2.1 g, 10 mmol) and dimeric pyridinecobaloxime, $(Co(dmgH)_2py)_2$,[4] (7.3 g, 10 mmol) in 80 ml of methanol was added under nitrogen 2.0 g of zinc powder; the mixture was stirred for 18 h at room temperature. The reaction mixture was filtered and the filtrate was condensed. The residue was dissolved in 70 ml of chloroform, and the chloroform extract was washed with water and dried over Na_2SO_4. The chloroform solution was condensed under reduced pressure and the condensate was passed through a Florisil column (2.7× 18 cm) with chloroform–ethylacetate (1 : 1) to remove impurities. Evaporation of the solvent from the eluate gave essentially pure *cis-p*-cyanostyryl(pyridine)cobaloxime (I) in the yield of 48%. Recrystallization of I from acetonitrile–benzene gave pure cobaloxime (I).

The same procedure starting with *trans-p*-cyanostyryl bromide gave *trans-p*-cyanostyryl(pyridine)cobaloxime (II) in the yield of 66%.

cis-Cobaloxime (I), mp 208—210 °C (decomp). Found: C, 53.15; H, 4.98; N, 16.92%. Calcd for $C_{22}H_{25}N_6O_4Co$: C, 53.23; H, 5.08; N, 16.93%. IR (KBr): 2230, 1600, 1560, 1440, 700, 550, 520 cm^{-1}. NMR ($CDCl_3$): 1.92 (12H, s), 5.99 (1H, d, J=10 Hz), 6.39 (1H, d, J=10 Hz), 7.06—7.86 (7H, m), 8.42—8.60 ppm (δ) (2H, m).

trans-Cobaloxime (II), mp 216—224 °C (decomp). Found: C, 53.24; H, 5.07; N, 17.10%. Calcd for $C_{22}H_{25}N_6O_4Co$: C, 53.23; H, 5.08; N, 16.93%. IR (KBr): 2230, 1605, 1565, 1450, 975, 700, 550, 520 cm^{-1}. NMR ($CDCl_3$): 2.14 (12H, s), 6.30 (1H, d, J=15 Hz), 7.40—8.00 (8H, m), 8.60—8.85 ppm (δ) (2H, m).

b) *cis* and *trans*-Methoxystyryl(pyridine)cobaloximes (V) and (VI). *cis*-Cobaloxime (V) was synthesized by the reaction of *cis-p*-methoxystyryl bromide (1.0 g, 4.7 mmol) with the cobaloxime anion prepared *in situ* from $CoCl_2 \cdot 6H_2O$ (0.95 g, 4 mmol), dimethylglyoxime (0.93 g, 8 mmol), 8 ml of 10 M-sodium hydroxide, pyridine (0.5 g), and sodium tetrahydroborate (200 mg) under nitrogen in methanol (40 ml) at 0 °C for 1 h and at room temperature for 1.5 h. The reaction mixture was extracted with benzene (50 ml× 2) after the addition of water (100 ml). The condensation of the extract after drying over Na_2SO_4 gave the residue containing *cis*-cobaloxime (V). This residue was passed through a Florisil column (2.5×20 cm) with dichloromethane and dichloromethane–ethyl acetate (2 : 1). Evaporation of the solvent from the latter fraction gave *cis*-cobaloxime (V). Recrystallization of the cobaloxime (V) from acetonitrile gave pure V in the yield of 39%.

The same procedure starting with *trans-p*-methoxystyryl bromide gave *trans-p*-methoxystyryl(pyridine)cobaloxime (VI) in the yield of 45% after recrystallization.

cis-Cobaloxime (V), mp 198—204 °C (decomp). Found: C, 52.63; H, 5.44; N, 14.00%. Calcd for $C_{22}H_{28}N_5O_5Co$:

C, 52.70; H, 5.63; N, 13.97%. IR (KBr): 1610, 1595, 1510, 1450, 1240, 850, 770, 705, 530 cm^{-1}. NMR ($CDCl_3$): 1.84 (12H, s), 3.60 (3H, s), 5.24 (1H, d, J=9 Hz), 6.10 (1H, d, J=9 Hz), 6.46 (2H, d, J=9 Hz), 6.66 (2H, d, J=9 Hz), 6.86—8.22 ppm (δ) (5H, pyridine).

trans-Cobaloxime (VI), mp 215—218 °C (decomp). Found: C, 52.49; H, 5.51; N, 14.26%. Calcd for $C_{22}H_{28}N_5O_5Co$: C, 52.70; H, 5.63; N, 13.97%. IR (KBr): 1600, 1500, 1440, 1230, 950, 830, 750, 510 cm^{-1}. NMR ($CDCl_3$): 2.00 (12H, s), 3.58 (3H, s), 5.86 (1H, d, J=14 Hz), 6.46 (2H, d, J=8 Hz), 6.59 (1H, d, J=14 Hz), 6.88 (2H, d, J=8 Hz), 7.00—8.44 ppm (δ) (5H, pyridine).

Reaction of Cobaloximes (I—VI) with Bromine. The solution of one of the cobaloximes (I—VI) (0.2 mmol) in one of the solvents (15 ml) depicted in Table 1 was treated with an equivalent amount of bromine in 1 ml of the same solvent, and the mixture was stirred for 30 min at room temperature under nitrogen. When carbon disulfide was used as a solvent, the volume of the solution was increased to 40 ml and the reaction at 46 °C was carried out by boiling the reaction mixture. The reactions with smaller equivalents of bromine were carried out in the same manner to get the limiting values listed in Table 1. After the reaction the mixture was filtered, the filtrate was condensed, and the residue was dissolved in hexane–ether (1 : 1). Passing of the solution through an alumina column (Merck II-III, 0.8×5 cm) with hexane–ether (1 : 1) gave the corresponding styryl-type bromides. The product composition was determined by a GLC analysis (2.1 m, 5%-PEG-Succinate on Chromosorb P, N_2). Identification of the bromides as *cis* and *trans*-styryl-type bromides was made by the comparison of GLC and NMR spectra of the products with those of authentic samples.

Competitive Reaction. A solution containing equal amounts (0.2 mmol) of cobaloximes II, IV, and VI was treated with 0.02 mmol of bromine and stirred for 20 min at room temperature under nitrogen. The reaction mixture was worked up as described above and the relative amounts of styryl-type bromides were determined by GLC analyses. For this purpose the relative sensitivity of the bromides in GLC analyses was determined by analyzing a mixture of the bromides with known composition. The mixture of 0.2 mmol of *trans*-styryl(pyridine)cobaloxime and *trans*-1-octenyl(pyridine)cobaloxime was subjected to the same treatment.

Mercuration of Cobaloximes (I—VI). The solution of one of the cobaloximes (I—VI, 0.2 mmol) in DMF (10 ml) was treated with 1.2 equivalents of mercuric acetate and the mixture was stirred for 30 min at room temperature. The mixture was further stirred for 10 min after addition of 2 ml of saturated aqueous solution of sodium chloride and was extracted with chloroform after further addition of water (10 ml). The extract was washed with water and dried over Na_2SO_4. Evaporation of chloroform and DMF at reduced pressure gave a styryl-type mercurial. The crude product thus obtained was passed through a silica gel column (1.0× 10 cm) with chloroform and evaporation of the solvent gave styryl-type mercury(II) chloride with retention in the yield listed in Table 2. The product composition was determined by the relative intensities of the NMR signals of the olefinic hydrogens of the product. The structure of the mercurials was confirmed by transforming these organomercury(II) chlorides into the corresponding styryl-type bromides with bromine in pyridine. *cis*-Cyanostyrylmercury(II) chloride, mp 184—185 °C. IR (KBr): 2220, 1405, 850, 540 cm^{-1}. NMR (DMSO): 6.53 (1H, d, J=12 Hz), 7.56 (1H, d, J=12 Hz), 7.95 ppm (δ) (4H, s).

trans-Cyanostyrylmercury(II) chloride, mp 232—233 °C. IR (KBr): 2230, 1500, 1170, 970, 850, 780, 550 cm^{-1}. NMR (DMSO): 6.92 (2H, s), 7.63, 7.85 ppm (δ) (4H, AB-type, J=8 Hz).

cis-Styrylmercury(II) chloride, mp 106.5—107 °C. IR (KBr): 1580, 1560, 1480, 1440, 1325, 770, 680 cm^{-1}. NMR (DMSO-d_6): 6.30 (1H, d, J=12 Hz), 7.30—7.90 ppm (δ) (6H, m).

trans-Styrylmercury(II) chloride, mp 210—211 °C. IR (KBr): 1590, 1560, 1490, 1440, 965, 720 cm^{-1}. NMR (DMSO-d_6): 6.60, 6.85 (2H, AB-type, J=18 Hz), 7.05—7.50 ppm (δ) (5H, m).

cis-Methoxystyrylmercury(II) chloride, mp 97—98 °C. IR (KBr): 1610, 1510, 1260, 1170, 830 cm^{-1}. NMR (DMSO-d_6): 3.80 (3H, s), 6.15 (1H, d, J=11 Hz), 7.20 (2H, d, J=9 Hz), 7.43 (1H, d, J=11 Hz), 7.65 ppm (δ) (2H, d, J=9 Hz).

trans-Methoxymercury(II) chloride, mp 220—222 °C. IR (KBr): 1600, 1510, 1250, 1170, 1020, 960, 830, 770 cm^{-1}. NMR (DMSO-d_6): 3.80 (3H, s), 6.50, 6.85 (2H, AB-type, J=19 Hz), 6.96 (2H, d, J=9 Hz), 7.40 ppm (δ) (2H, d, J=9 Hz).

New Cross Aldol Reactions. Titanium Tetrachloride-promoted Reactions of Silyl Enol Ethers with Carbonyl Compounds Containing A Functional Group

Kazuo BANNO

The First Research Institute, Tokushima Factory,
Otsuka Pharmaceutical Co., Ltd., Kagasuno, Kawauchi-cho Tokushima 771-01

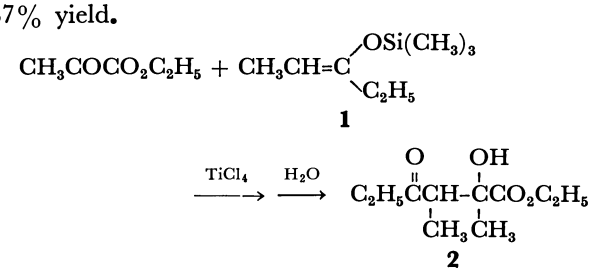
(Received March 8, 1976)

It was found that, in the presence of titanium tetrachloride, silyl enol ethers selectively react with aldehyde or ketone function of various carbonyl compounds containing another functional group giving the corresponding cross aldols in good yields. The present cross aldol reaction was successfully applied to the synthesis of ar-turmerone, one of the volatile principles of turmeric oil.

In previous paper,[1-3] it was reported that the reactions of silyl enol ethers with various simple carbonyl compounds in the presence of titanium tetrachloride proceed under mild conditions giving the desired cross aldols in good yields. According to this procedure, it was established that cross aldols are exclusively produced in most cases and no by-products, such as the di-, poly-, and self-condensation products, and α,β-unsaturated carbonyl compounds formed in the usual base-promoted aldol condensation, are produced. Therefore, it is recognized that this reaction is one of the most useful cross aldol processes among the methods reported by House[4] *et al.* and Wittig[5] *et al.*

In the present paper, the titanium tetrachloride-promoted reaction of silyl enol ethers with a variety of carbonyl compounds containing an additional functional will be described.

In the first experiment, the reaction of ethyl pyruvate with silyl enol ether (**1**) in the presence of an equimolar amount of titanium tetrachloride was attempted at room temperature. After hydrolysis, ethyl 2-hydroxy-2,3-dimethyl-4-oxohexanoate (**2**) was obtained in an 87% yield.



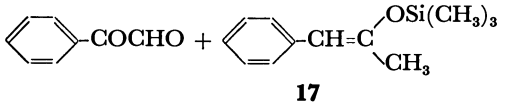
1

2

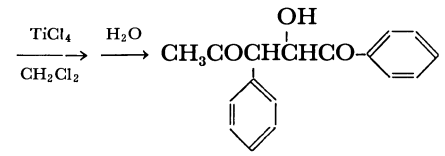
The effect of the amount of titanium tetrachloride upon the yield of **2** was investigated using the reaction of ethyl pyruvate with **1** as a model and **2** was obtained in the highest yield when an equimolar amount of titanium tetrachloride was employed.

The reactions of various silyl enol ethers with a variety of keto esters were attempted in the presence of an equimolar amount of titanium tetrachloride. These results are given in Table 1. Of these keto esters, it was found that ethyl acetoacetate did not react with silyl enol ethers under the same conditions and was recovered quantitatively.

In the next experiment, the reaction of silyl enol ethers with various dicarbonyl compounds was studied. For example, when silyl enol ether (**17**) was allowed to react with an equimolar amount of phenylglyoxal at −78 °C for 2 h, 2-hydroxy-1,3-diphenyl-1,4-pentanedione (**18**) was obtained exclusively in an 83% yield, and none of the product added to the ketone function was detected.

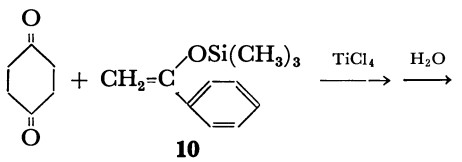


17

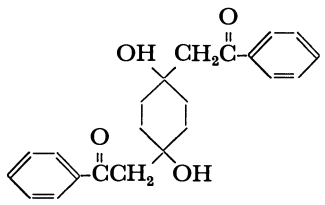


18

Unexpectedly, in the case of the reaction of 1,4-cyclohexanedione with an equimolar amount of the silyl enol ether (**10**), 1,4-bis(benzoylmethyl)-1,4-cyclohexanediol (**19**) was obtained in an 86% yield (based on **10**), and no 4-hydroxy-4-(benzoylmethyl)-1-cyclohexanone was detected by NMR and TLC analyses.



10



19

As described above, it should be noted that the silyl enol ether reacted only with the aldehyde function of the keto aldehyde in the presence of titanium tetrachloride at −78 °C giving the corresponding hydroxy diketone, and the silyl enol ether selectively reacted with the ketone function of the keto ester at room temperature to give the corresponding hydroxy keto ester. However, when the diketone was treated with an equimolar amount of the silyl enol ether, the latter reacted with both the ketone functions of the diketone.

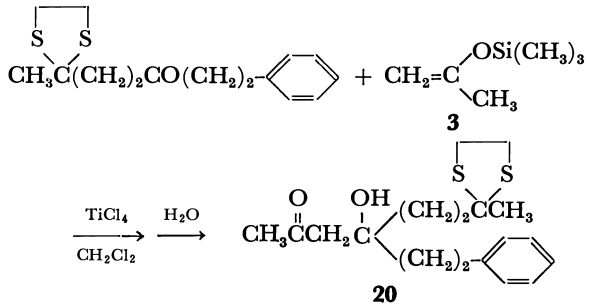
Of the usual protecting groups of the carbonyl function examined,[6] it was found that only thioacetal[7] was stable and useful in the present reaction. Thus,

TABLE 1. SYNTHESIS OF HYDROXY KETO ESTERS FROM SILYL ENOL ETHERS AND KETO ESTERS

Reagents		Product	
Keto ester	Silyl enol ether	Hydroxy keto ester	Yield (%)
$CH_3COCO_2C_2H_5$	$CH_2=C(OSi(CH_3)_3)CH_3$ (**3**)	$CH_3C(=O)CH(OH)CH_2CO_2C_2H_5$, CH_3 (**4**)	55
	 (**5**)	 (**6**)	76
	 (**7**)	 (**8**)	88
$CH_3CO-C(CH_3)(CH_3)-CO_2C_2H_5$	**7**	 (**9**)	52
	 (**10**)	 (**11**)	38
$CH_3CO(CH_2)_2CO_2C_2H_5$	**1**	$C_2H_5C(=O)CH(CH_3)-C(OH)(CH_3)-(CH_2)_2CO_2C_2H_5$ (**12**)	86
$CH_3CO(CH_2)_2CO_2C_2H_5$	**5**	 (**13**)	73
	10	 (**14**)	41
$CH_3CO(CH_2)_3CO_2CH_3$	**1**	$C_2H_5C(=O)CH(CH_3)-C(OH)(CH_3)-(CH_2)_3CO_2CH_3$ (**15**)	71
	7	 (**16**)	69

aldol formation at one of the keto groups in a diketone was performed after converting the other keto groups into its thioacetal. For example, when silyl enol ether (**3**) was allowed to react with 6,6-ethylenedithio-1-phenyl-3-heptanone in the presence of titanium tetrachloride, 7,7-ethylenedithio-4-hydroxy-4-phenethyl-2-octanone (**20**) was obtained in a 76% yield.

Next, in order to examine the influence of various functional groups on the titanium tetrachloride-promoted reaction of silyly enol ethers with carbonyl



20

Table 2. Synthesis of aldols from silyl enol ethers and carbonyl compounds having a functional group

Reagents: Carbonyl compound	Reagents: Silyl enol ether	Reaction conditions: temp (°C) / time (h)	Product: Aldol	Product: Yield (%)

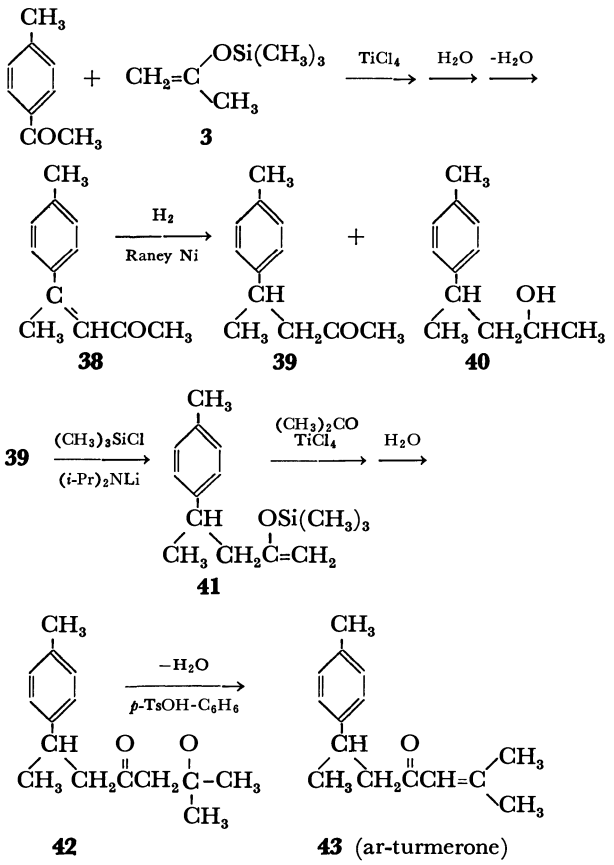
compounds, the reaction of silyl enol ethers with a variety of aliphatic and aromatic carbonyl compounds having, acyloxy, alkoxy, carboxy, amino, cyano, halogeno, hydroxy, and nitro substituents was investigated. The results are summarized in Table 2.

As shown is in Table 2, it is apparent that the titanium tetrachloride-promoted aldol reaction using silyl enol ethers is not influenced by groups such as acyloxy, alkoxyl, cyano, dialkylamino, halogeno, nitro, and thioacetal groups. However, in the cases of the carbonyl compounds containing active hydrogen, such as carboxyl, hydroxyl, primary amino, and secondary amino groups, no aldols were obtained and the silyl enol ethers were decomposed into the original carbonyl compounds. In these cases, it is believed that, at first, the carbonyl compound with active hydrogen reacted with titanium tetrachrloride to produce hydrogen chloride, which in turn rapidly reacted with the silyl enol ether to form the original carbonyl compound.

It was also established that the aldols were obtained by reactions of silyl enol ethers with various substituted aromatic aldehydes. In the cases of substituted aromatic ketones having an electron-attracting group, aldols were produced, but aromatic ketones having an electron-releasing group did not afford aldols for the same reaction procedure.

The utility of this new procedure was demonstrated by the synthesis of ar-turmerone,[8,9] 2-methy-6-*p*-tolyl-2-heptene-4-one, one of the volatile principles of turmeric oil.[10,11]

By dehydration of the reaction product of 4-methylacetophenone with the silyl enol ether (**3**) in the presence



38 **39** **40** **41** **42** **43** (ar-turmerone)

of titanium tetrachloride, the α,β-unsaturated ketone (**38**) was obtained in a 53% yield, and the catalytic reduction of **38** over Raney nickel afforded the ketone

(**39**) and the alcohol (**40**) in 77% and 16% yields, respectively. The silyl enol ether (**41**), prepared from **39** according to the method of House *et al.*[12] was treated with acetone and titanium tetrachloride giving the aldol (**42**) in a 88% yield. This was dehydrated with *p*-toluenesulfonic acid–benzene to give racemic ar-turmerone (**43**) in a 92% yield. In summary, it is concluded that, in the presence of titanium tetrachloride, various silyl enol ethers react with a variety of aliphatic and aromatic carbonyl compounds containing an additional functional group, except for functional groups having active hydrogen, affording the corresponding aldols in good yields. The selective reaction forming an aldol in one of the carbonyl groups of a dialdehyde or a diketone occurs after converting the other carbonyl group into its thioacetal.

Experimental

Materials. Commercially available carbonyl compounds having the functional group, $TiCl_4$ and chlorotrimethylsilane were purified by the conventional procedures, recrystallization or distillation, before use. A commercial hexane solution of *n*-BuLi was used after standarization and commercially produced Raney nickel was thoroughly washed with methanol. 6,6-Ethylenedithio-1-phenyl-3-heptanone was prepared by the method of Araki *et al.*[13]

Methyl 6-oxohexanoate and 5-oxohexanenitril were prepared from ethyl acetoacetate and acrylonitrile according to a procedure in the literature.[14]

Trimethylsilyl enol ethers of ketones have been described in a previous paper.[3]

*Reaction of Ethyl Pyruvate with 3-Trimethylsiloxy-2-pentene (**1**)* To a dichloromethane (15 ml) solution of ethyl pyruvate (0.390 g, 3 mmol) and $TiCl_4$ (0.567 g, 3 mmol) was added a dichloromethane (30 ml) solution of silyl enol ether (**1**) (0.468 g, 3 mmol) at room temperature in an argon atmosphere, and the mixture was kept at room temperature for 3 h with stirring. After hydrolysis with cold water (30 ml), the resulting organic layer was extracted with ether (70 ml). The extract was washed with a saturated NaCl solution and dried over anhydrous Na_2SO_4. The ethereal solution was concentrated under reduced pressure. The aldol, ethyl 2-hydroxy-2,3-dimethyl-4-oxohexanoate (**2**), was obtained in an 87% (0.527 g) yield from the residue after purification by column chromatography (silica gel). The physical properties and analytic data of the product (**2**) are shown in Table. 3.

*Reaction of 6,6-Ethylenedithio-1-phenyl-3-heptanone with 2-Trimethylsiloxypropene (**3**).* As in the same procedure described above, 6,6-ethylenedithio-1-phenyl-3-heptanone (0.843 g, 3 mmol) reacted with silyl enol ether (**3**) (0.390 g, 3 mmol) in dichloromethane (40 ml) in the presence of $TiCl_4$ (0.567 g, 3 mmol) at 0 °C for 3 h. The reaction mixture was worked up as in the preparation of **2** to give a crude oil. It was purified by preparative TLC (silica gel) using dichloromethane to give 0.767 g (76%) of 7,7-ethylenedithio-4-hydroxy-4-phenethyl-2-octanone (**20**). The physical properties and analytical data of **20** are shown in Table 3.

Reaction of p-*Dimethylaminobenzaldehyde with 3-Trimethylsiloxy-2-pentene (**1**).* In a procedure similar to that described above, p-dimethylaminobenzaldehyde (0.450 g, 3 mmol) reacted with silyl enol ether (**1**) (0.474 g, 3 mmol) in dichloromethane (40 ml) in the presence of $TiCl_4$ (0.567 g, 3 mmol) at −10 °C for 3 h. The reaction mixture was quenched with aq. 5% K_2CO_3 (30 ml) at 0 °C, and the suspension was kept standing at room temperature for 10 min. After filtration, the filtrate was extracted with ether (100 ml). The organic layer was separated, dried over anhydrous Na_2SO_4 and concentrated under reduced pressure. The residue was purified by column chromatography (aluminium oxide active, neutral) to give 1-(*p*-dimethylaminophenyl)-1-hydroxyl-2-methyl-3-pentanone (**27**) in a 65% (0.458 g) yield. The physical properties and analytical data of **27** are listed in Table 3.

Reaction of p-*Acetoxyacetophenone with 1-Phenyl-1-trimethylsiloxyethylene (**10**).* A dichloromethane (10 ml) solution of 0.576 g (3 mmol) of silyl enol ether (**10**) was added dropwise into a refluxing mixture or 0.434 g (3 mmol) of *p*-acetoxyacetophenone and 0.567 g (3 mmol) of $TiCl_4$ in dichloromethane (30 ml) in an argon atmosphere within 10 min, and the reaction mixture was refluxed for 30 min. After cooling to room temperature, the reaction mixture was quenched with water (10 ml) and extracted with ether (100 ml). The resulting crude product was analyzed by chromatography on silica gel. Elution with benzene and dichloromethane (1 : 1) gave 0.098 g (11%) of 3-hydroxy-1-phenyl-3-(p-acetoxyphenyl)-1-butanone (**35**).

*Synthesis of ar-Turmerone. Preparation of 4-*p*-Tolyl-3-pentene-2-one (**38**):* A dichloromethane (40 ml) solution of 5.20 g (40 mmol) of silyl enol ether (**3**) was added to a refluxing mixture of 2.68 g (20 mmol) of *p*-methylacetophenone and 3.78 g (20 mmol) of $TiCl_4$ in dichloromethane (50 ml) in an argon atmosphere over a period of 10 min, and the reaction mixture was refluxed for 3 h. After a similar work-up, a benzene solution (50 ml) of the resulting crude was refluxed for 1 h in the presence of *p*-TsOH (0.2 g). After removal of the solvent and the unreacted starting material by distillation, **38** was isolated in a 53% (1.84 g) yield by column chromatography (silica gel) [bp 150—154 °C/25 mmHg. IR (neat): 1680, 1600 cm^{-1}. NMR (CCl_4): δ 2.20 (s, 3H), 2.37 (s, 3H), 2.50 (s, 3H), 6.45 (s, 1H), 7.0—7.7 (m, 4H)].

*Reduction of 4-*p*-Tolyl-3-pentene-2-one (**38**).* A methanol (50 ml) solution of 3.48 g (20 mmol) of **38** was treated with hydrogen for 2 h at −10 °C in the presence of commercially produced Raney nickel. About 490 ml of hydrogen was adsorbed. After filtering off the Raney nickel, the filtrate was evaporated and the residual oil was purified by column chromatography (silica gel) using dichloromethane as a developer to give 2.71 g (77%) of 4-*p*-tolyl-2-pentanone (**39**). [Found: C, 81.93; H, 9.18%. Calcd for $C_{12}H_{16}O$: C, 81,77; H, 9.15%. IR (neat): 1720 cm^{-1}. NMR (CCl_4): δ 1.25 (d, J=7 Hz, 3H), 2.01 (s, 3H), 2.38 (s, 3H), 2.68 (d, J=7 Hz, 2H), 3.0—3.5 (m, 1H), 7.15 (s, 4H)], and 0.56 g (16%) of 4-*p*-tolyl-2-pentanol (**40**) [IR (neat): 3400 cm^{-1}. NMR ($CDCl_3$): δ 1.0—1.4 (m, 6H), 1.5—2.1 (m, 2H), 2.33 (s, 3H), 2.5—4.0 (m, 2H), 7.17 (s, 4H)].

*Silylation of 4-*p*-Tolyl-2-pentanone (**39**).* A hexane solution (30.8 ml) containing 55 mmol of *n*-BuLi was mixed with 500 ml of THF. The resulting solution was cooled to −10 °C and treated with 5.5 g (55 mmol) of diisopropylamine. To this solution, 8.8 g (50 mmol) of 4-*p*-tolyl-2-pentanone (**39**) was added dropwise over a 20 min period with stirring. After stirring the mixture at the same temperature for 30 min, 6.0 g (55 mmol) of chlorotrimethylsilane was added. The reaction mixture was stirred for 30 min, diluted with 300 ml of ether, and washed rapidly with two 100 ml portions of cold aqueous 10% $KHSO_4$ and then cold aqueous 5% $NaHCO_3$. The organic layer was dried and concentrated. Fractional distillation of the residue through a spinning Teflon-band column gave fraction 1, 9.4 g (76%), bp 152—155/3.2 mmHg, containing pure 4-*p*-tolyl-2-trimethyl-

A Synthesis of Diosphenols[1]

Masao ŌHASHI†, Seiichi INOUE, and Kikumasa SATO*

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 233

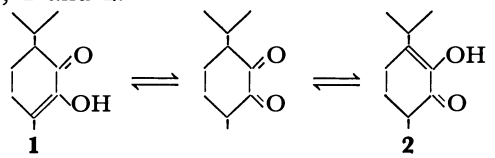
†*Chemical Laboratory, Seimi Chemical Co., Ltd., Chigasaki, Chigasaki-shi, Kanagawa 253*

(Received February 21, 1976)

A new synthesis of diosphenols (**1** and **2**) is described. The oxidation of 2-isopropylcyclohexanone with copper(II) chloride gave the corresponding α-diketone (**8**), which was then methylated to afford diosphenol (**1**) together with a considerable amount of isodiosphenol (**2**). In particular, pure **2** has been isolated and the characteristics of **2** are also presented.

The monoterpenoid diosphenol(*buccocamphor*)(2-hydroxy-1-*p*-menthen-3-one) (**1**) has been found in the essential oil of various *Barosma* or *Mentha* species.[2] **1** has been synthesized from many terpenoid derivatives: l-menthone,[3,4] carvomenthone,[4] piperitone,[4] and piperitone oxide [5]

Diosphenol seems to exist as a mixture of two enolate forms, **1** and **2**.

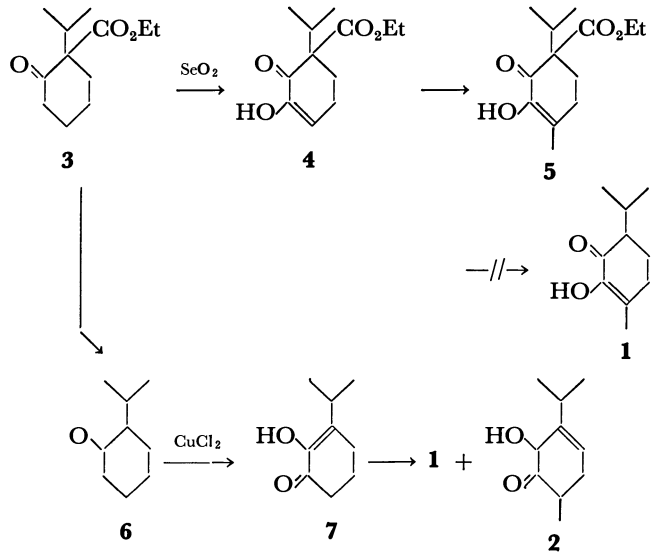


1 **2**

Recently, Shibata *et al.*[6] reexamined the method of Macbeth and Robertson[3d] and isolated the reverse enol form; isodiosphenol (3-hydroxy-3-*p*-menthen-2-one) (**2**). But the details of **2** have not yet been reported.

Now we wish to report a convenient synthesis of **1** and **2** from ethyl 1-isopropyl-2-oxocyclohexanecarboxylate (**3**)[7] which is easily obtained by the condensation of ethyl cyclohexanecarboxylate with isopropyl iodide.

When **3** was refluxed with selenium dioxide in aqueous dioxane for 35 h, 6-ethoxycarbonyl-6-isopropyl-2-hydroxy-2-cyclohexen-1-one (**4**) was obtained. Compound **4** easily reacted with morpholine and formalin in dioxane at room temperature to afford a Mannich base, which was then hydrogenolyzed with zinc powder in acetic acid to give 6-ethoxycarbonyl-6-isopropyl-2-hydroxy-3-methyl-2-cyclohexen-1-one (**5**). In order to get **1**, we examined the deethoxycarbonylization of **5**



3 **4** **5** **1** **6** **7** **2**

* To whom all correspondence should be addressed.

with aqueous sulfuric acid, hydrochloric acid, or with lithium iodide dihydrate. However, in no case could **1** be obtained. The difficulty in hydrolysis of **5** is supposed to be due to the steric hindrance of the isopropyl group.[8] Then we examined the hydrolysis of **3**.

Although the attempted deethoxycarbonylization of **3** with sulfuric acid, barium hydroxide, or potassium hydroxide[9] was unfavorable, the refluxing of **3** with lithium iodide dihydrate in dimethylformamide gave 2-isopropylcyclohexanone (**6**) in excellent yield(91%).

Treatment of **6** with 4 molar amounts of copper(II) chloride in 50% acetic acid under reflux for 3 h afforded 2-hydroxy-3-isopropyl-2-cyclohexen-1-one (**7**) in moderate yield(61%). The structure of **7** was assigned on the basis of its IR, NMR, and UV spectra, and by elemental analysis. Then we examined the methylation[10] of **7** for the synthesis of **1** and **2**.

3-Alkyl-2-hydroxy-2-cycloalkenones easily reacted with morpholine and formalin in dioxane at room temperature to give corresponding bis-Mannich base.[11] Under the same conditions, compound **7** failed to react even when warmed at reflux, apparently because of the steric hindrance of the isopropyl group. However, **7** reacted with both morpholine hydrochloride and formalin in water under reflux to give the Mannich base, which was then hydrogenolyzed with zinc powder in acetic acid at 75—80 °C for 7 h, and gave a mixture of **1** and **2** in 31% yield. The ratio of the two components was **1**/**2**=62/38. Pure **1** and **2** can be isolated by crystallization or preparative GLC. The UV spectra of these two isomers in 95% ethanol slightly differ from each other: namely, **2** is bathochromic by *ca.* 1.0 nm. This result is parallel to the observations on 2-hydroxy-3-methyl-2-cyclohexen-1-one[11] and **7**. In the NMR spectra of **1** and **2**, the characteristic signals due to the methine proton in the isopropyl group and the methyl protons clearly differ from each other and are consistent with the assigned structures **1** and **2**, respectively. In mass spectra, a distinct difference between **1** and **2** is observed at *m/e* 125 (M^+—isopropyl) and 126 (association of the hydrogen shift with 125): the intensities of the two fragments are the reverse of each other. (see Experimental Section)

Finally, it should be noted that a fair amount of isodiosphenol (**2**) is formed along with **1** in the present reaction conditions and pure **2** is comparatively stable[12] at room temperature.

Experimental

All the points are uncorrected. The IR spectra were recorded with a Hitachi Model 215 spectrophotometer, and the UV spectra with a Hitachi Model EPS-3T spectro-

photometer. The NMR spactra were obtained on a JEOL Model C-60H spectrometer, with tetramethylsilane as the internal reference. The mass spectra were determined on a Hitachi RMU-6E spectrometer.

*Ethyl 1-Isopropyl-2-oxocyclohexanecarboxylate (**3**).* This substance was prepared in 74% yield according to Ref. 7.

*6-Ethoxycarbonyl-2-hydroxy-6-isopropyl-2-cyclohexen-1-one (**4**).* A mixture of **3** (8.48 g, 40 mmol), selenium dioxide (8.8 g, 80 mmol), dioxane (100 ml), and water (30 ml) was stirred for 35 h under reflux. After cooling, the deposited selenium was filtered off, the solvent was distilled, and the residue was extracted with chloroform. After drying, the extract was concentrated and the residue was distilled to give the crude product **4** (3.1 g); bp 99—130 °C/0.4 mmHg. Redistillation afforded 1.60 g (17.7%) of pure **4**; bp 99—103 °C/0.3 mmHg. IR (neat) 3420 (O–H), 1730, w. 1710, 1675 (C=O), 1620 cm^{-1} (C=C). NMR (CCl_4) δ 0.78 (3H, d, J=7.0 Hz), 0.86 (3H, d, J=7.0 Hz), 1.26 (3H, t, J=7.0 Hz), 1.6—2.7 (5H, m), 4.16 (2H, q, J=7.0 Hz), 5.60 (1H, broad s), 6.95 (1H, m); mass *m/e*; 226 (M^+), 41 (100%).

*6-Ethoxycarbonyl-2-hydroxy-6-isopropyl-3-methyl-2-cyclohexen-1-one (**5**).* To a mixture of **4** (1.30 g, 5.75 mmol), dioxane (5 ml), and morpholine (0.50 g, 5.75 mmol), formalin (0.464 g, 5.75 mmol) in dioxane (1 ml) was added at 3—4 °C and the mixture was then stirred for 20 h at room temperature. After removal of the dioxane *in vacuo*, curde Mannich base (2.0 g) was obtained. To this Mannich base, acetic acid (18 ml) and zinc powder (1.9 g) were added, and the mixture was then stirred for 7 h at 72—74 °C. After the zinc had been filtered off and the acetic acid had been removed under reduced pressure, water (10 ml) was added. After extraction with chloroform and drying with magnesium sulfate, the solvent was evaporated and the residue was chromatographed on a silica gel column. Elution with benzene–ethyl acetate (10 : 1) yielded 0.345 g (Y=25%) of **5**; which was distilled at 100—110 °C/0.3 mmHg. IR (neat) 3370 (O–H), 1740, w. 1710, 1660 (C=O), 1643 cm^{-1} (C=C); NMR (CCl_4) δ 0.75 (3H, d, J=7.0 Hz), 0.88 (3H, d, J=7.0 Hz), 1.25 (3H, t, J=7.0 Hz), 2.02 (3H, s), 2.3—3.0 (5H, m), 4.13 (2H, q, J=7.0 Hz); mass *m/e*; 240 (M^+), 41 (100%).

*2-Isopropylcyclohexanone (**6**).* To a stirred, slightly boiling solution of lithium iodide dihydrate (16.7 g, 0.099 mol) in dimethylformamide (40 ml) was added ethyl 1-isopropyl-2-oxocyclohexanecarboxylate (7.0 g, 0.033 mol) dissolved in dimethylformamide (5 ml) over a period of 5 min under nitrogen atmosphere. The mixture was then refluxed for 45 h. The resulting mixture was diluted with aqueous hydrochloric acid and extracted with ether. The extract, after washing with water and drying over magnesium sulfate, was concentrated and the residual oil was distilled to give 4.2 g (Y=91%) of **6**; bp 81—85 °C/16 mmHg (lit,[8] bp 80 °C/10 mmHg).

*2-Hydroxy-3-isopropyl-2-cyclohexen-1-one (**7**).* A mixture of **6** (1.95 g, 14 mmol), copper(II) chloride (7.53 g, 56 mmol), acetic acid (15.3 ml), and water (17.4 ml) was stirred for 3 h under reflux. After cooling, the mixture was saturated with ammonium chloride and extracted with ether. The extract was washed with aqueous ammonium chloride, dried over magnesium sulfate, and concentrated. The residual oil was distilled to give 1.30 g (Y=61%) of **7**; bp 71—73 °C/0.6 mmHg, n_D^{25}=1.4994. IR (neat) 3420 (O–H), 1665 (C=O), 1640 cm^{-1} (C=C); NMR (CCl_4) δ 1.06 (6H, d, J=7.0 Hz), 1.7—2.6 (6H, m), 3.16 (1H, heptet, J=7.0 Hz), 6.14 (1H, s); UV_{max} (95% EtOH) 275.5 nm (ε 9500). Found: C, 70.57; H, 9.24%. Calcd for $C_9H_{14}O_2$: C, 70.10; H, 9.15%. 2,4-Dinitrophenylhydrazone: mp 147—149 °C. Found: C, 54.14; H, 5.34; N, 16.77%. Calcd for $C_{15}H_{18}N_4O_5$: C, 53.89; H, 5.43; N, 16.76%.

*Methylation of **7**: 2-Hydroxy-1-*p*-menthen-3-one (**1**) and 3-Hydroxy-3-*p*-menthen-2-one (**2**).* A mixture of **7** (0.924 g, 6 mmol), morpholine (1.04 g, 12 mmol), concentrated hydrochloric acid (1.25 g, 12 mmol), water (13.8 ml), and formalin (0.973 g, 12 mmol) was stirred for 8 h under reflux. Evaporation of water *in vacuo* gave the crude Mannich base. To this Mannich base, acetic acid (18 ml) and zinc powder (3.2 g) were added, and the mixture was then stirred for 7 h at 75—80 °C. After the zinc had been filtered off and the acetic acid had been removed under reduced pressure, a small amount of water was added. After extraction with ether, washing with saturated aqueous ammonium chloride, and drying with magnesium sulfate, the solvent was evaporated and the residue (647 mg) was chromatographed on a silica gel column (elution with benzene) to give a mixture of **1** and **2** (312 mg, Y=31%, **1** : **2**=62 : 38); these give rise to 6.4 and 5.7 min retention times. (DC-200 column 3 m, 150 °C, He, 1.5 kg/cm^2). When the mixture was allowed to stand in an ice box, **1** precipitated. After filtration and recrystallization from petroleum ether, pure diosphenol (**1**) (82 mg) was obtained. Mp 82—83 °C (lit,[3d] mp 82 °C): IR (KBr) 3400 (O–H), 1665 (C=O), 1640 cm^{-1} (C=O); NMR (CCl_4) δ 0.86 (3H, d, J=7.0 Hz), 0.97 (3H, d, J=7.0 Hz), 1.80 (3H, broad s), 1.8—2.5 (6H, m), 5.99 (1H, s); UV_{max} (95% EtOH) 274 nm (ε 9600); mass *m/e* (%) 168 (M^+, 14), 126 (42), 125 (32), 43 (74), and 41 (100). The filtrate was subjected to the preparative GLC (DC-200 column 1 cm × 2 m, 150 °C, He, 150 ml/min) and pure **2** (50 mg) was obtained as a colorless oil, which boiled at 67—70 °C/0.4 mmHg, n_D^{25}=1.4925. IR (neat) 3420 (O–H), 1665 (C=O), 1640 cm^{-1} (C=C); NMR (CCl_4) δ 1.05 (3H, d, J=7.0 Hz), 1.06 (3H, d, J=7.0 Hz), 1.15 (3H, d, J=7.0 Hz), 1.6—2.5 (5H, m), 3.15 (1H, heptet, J=7.0 Hz), 6.07 (1H, broad s); UV_{max} (95% EtOH) 275 nm (ε 10000); mass *m/e* (%) 168 (M^+, 15), 126 (25), 125 (53), 43 (85), and 41 (100). Found: C, 71.80; H, 9.73%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

The Abnormal Wallach Rearrangements of 4,4'-Dialkylazoxybenzenes

Ichiro SHIMAO and Shigenori MATSUMURA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi, Toyama 933

(Received February 26, 1976)

The reactions of 4,4'-dialkylazoxybenzenes (**1**) with sulfuric acid afforded 2-alkyl-5-(*p*-alkylphenylazo)phenols (**2**) and 2-alkyl-4-(*p*-alkylphenylazo)phenols (**3**) as novel rearrangement products; in certain cases 4-(*p*-alkylphenylazo)phenols (**4**) were also obtained. The ratios of these azophenols were greatly affected by the alkyl group type. In addition, the reactions gave a very small amount of 5-alkyl-2-(*p*-alkylphenylazo)phenols (**5**), which were considered as normal Wallach rearrangement products.

In 1880, Wallach and Belli[1] found that heating azoxybenzene with sulfuric acid converted it to azobenzene and 4-hydroxyazobenzene. Later, in 1900, Bamberger[2] found that a small amount of 2-hydroxyazobenzene was also formed as a by-product in the reaction. Thereafter, many mechanistic investigations about the Wallach rearrangement have been carried out.[3] But only a few studies have been reported on the Wallach rearrangement of disubstituted azoxybenzenes.[4,5]

The rearrangement reaction of *p,p'*-azoxytoluene (**1a**) with sulfuric acid has been anomalous. Bamberger[6] found that **1a** gave a substance having a melting point of 204 °C in this reaction. In 1936, Parsons and Bailar[7] reported that this reaction afforded some alkali soluble (mp 210—212 °C) and alkali insoluble materials (mp 208—210 °C) which both contained a hydroxyl group; they suggested without any sure evidence that the alkali soluble material was 3-hydroxy-4,4'-dimethylazobenzene and the alkali insoluble material was 4-methyl-4'-hydroxymethylazobenzene. Subsequently, Gore and Hughes[4] reported the isolation of a substance having the same melting point in this reaction, and they showed that the two products obtained by Parsons and Bailar[7] were identical. They also proposed, carelessly, that this substance was 2-hydroxy-4,4'-dimethylazobenzene. The result of Gore and Hughes has been widely accepted and cited.[8]

On the other hand, Cumming and Ferrier[9] reported that the irradiation of **1a** gave 5-methyl-2-(*p*-tolylazo)-phenol (**5a**) (mp 150 —151 °C). It is generally recognized that 2-hydroxyazobenzenes are exclusively obtained by the photorearrangement of azoxybenzenes. Consequently, on the basis of the substantial difference of their melting points, it appears to be extremely doubtful that the reaction of **1a** with sulfuric acid gave **5a** as the main product.

In the present investigation, we confirm the structure of the rearrangement product of **1a**, and deal with the reactions of some 4,4'-dialkylazoxybenzenes (**1**) and some other disubstituted azoxybenzenes with sulfuric acid.

Results and Discussion

The investigation of the Wallach rearrangement of disubstituted azoxybenzenes have been insufficient. Thus, in order to compare with the reaction of **1**, some examples of the normal Wallach rearrangement were carried out; the results are shown in Table 1. The unsubstituted and 3,3'-disubstituted azoxybenzenes (**6**) gave 4-hydroxyazobenzenes (**7**) as the major products and 2-hydroxyazobenzenes (**8**) as by-products, and 4,4'-dihaloazoxybenzenes (**9**) gave **8**. The azoxybenzenes were reduced to a considerable extent to yield the corresponding azobenzenes (**10**), and some resinous meterial was also found.

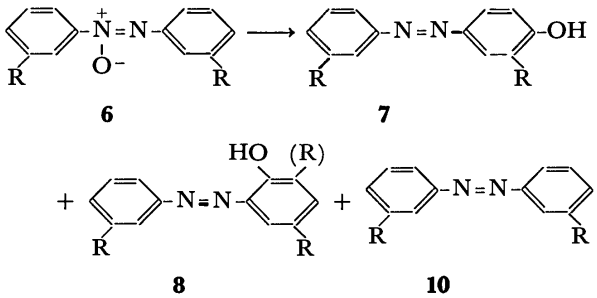
c) 4-Chloro-2-(*m*-chlorophenylazo)phenol.



6 **7**

8 **10**

The 2-hydroxyazo compound **8** obtained from *m,m'*-azoxytoluene (**6a**) was a mixture of 4-methyl-2-(*m*-tolylazo)phenol (**8a**) and 6-methyl-2-(*m*-tolylazo)pnenol (**8b**). The ratio of **8a** to **8b** was determined by gas chromatography to be 2.5 : 1. On the other hand, the compound **8** obtained from 3,3'-dichloroazoxybenzene (**6b**) was 4-chloro-2-(*m*-chlorophenylazo)phenol.

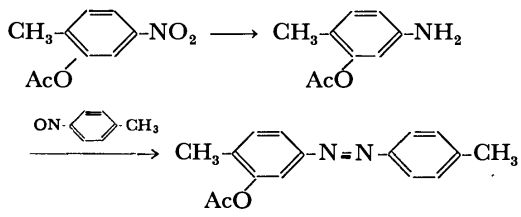
Unlike the photorearrangement,[10] in the reaction with sulfuric acid the isomer ratios of **8** were affected by the substituents of **6**.

The compounds **1** were treated with 85% sulfuric acid at 50 °C and the reaction products were separated by column chromatography. The results are shown in Table 2.

As in the reactions of 3,3'- and 4,4'-dichloroazoxybenzenes, **1a** reacted faster than the *meta* isomer **6a**. Such results can probably be attributed to the stabilization effect of these *p*-substituents on the cationic intermediate.

The main rearrangement product of **1a** was 2-methyl-5-(*p*-tolylazo)phenol (**2a**). This compound **2a** was acetylated with acetic anhydride; then the structure of **2a** acetate was confirmed by a comparison with the sample obtained by the following synthesis:

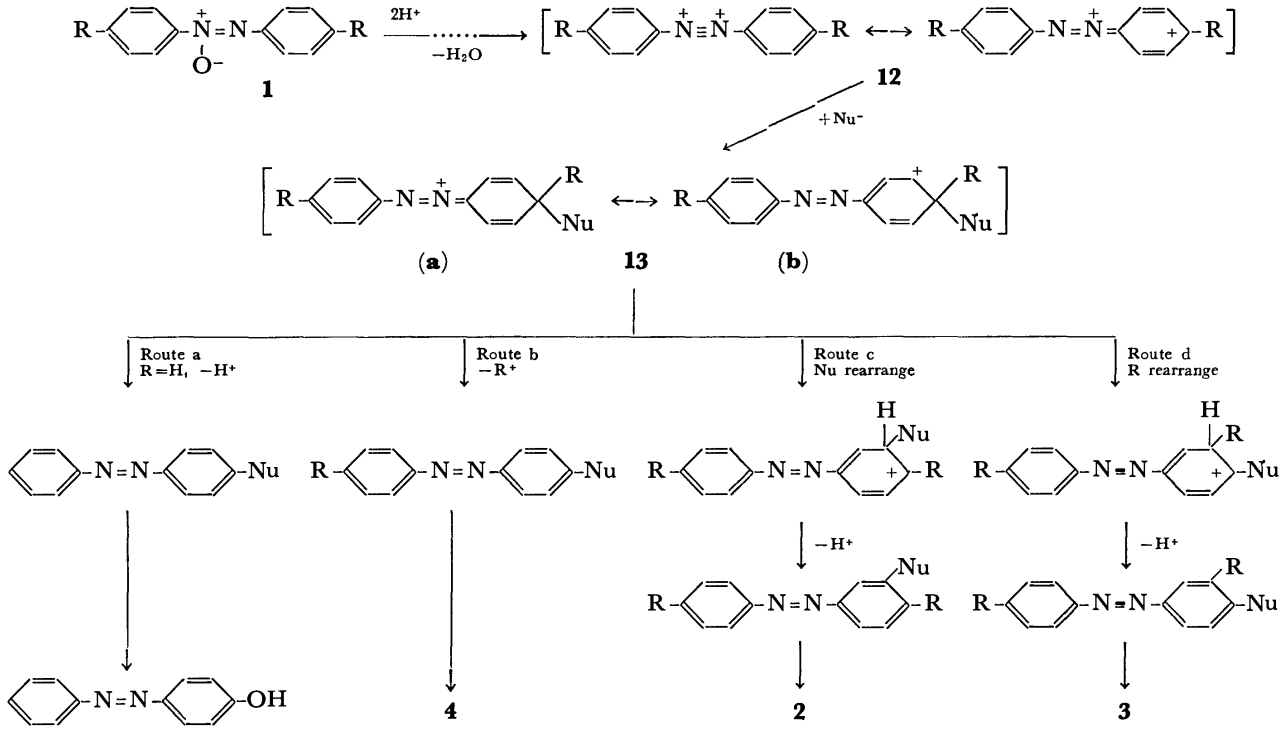


2a acetate

The melting point(211—212 °C) of **2a** was close to those[4,7] reported previously for the main product of the Wallach rearrangement of **1a**. Therefore it is evident that the conclusion of Gore and Hughes[4] is incorrect.[11] Although 5-alkyl-2-(*p*-alkylphenylazo)-phenols (**5**) appear to be the normal Wallach rearrangement products of **1**, **5a** was formed in only 0.2% yield. It is well-known that an irradiation of **1a** gives **5a**.[9,10] In order to conform the structure of **5a**, it was independently prepared by the condensation of 4-methyl-2-benzyloxyaniline and *p*-nitrosotoluene and then the debenzylation with hydrobromic acid. The gas chromatographic analysis showed that a trace amount of **5** was formed in the reaction of **1b—e**.

The 4,4'-diethylazoxybenzene (**1b**) and 4,4'-dipropylazoxybenzene (**1c**) afforded the corresponding 3-hydroxyazo compounds, **2b** and **2c**, respectively. Furthermore, **1b** and **1c** rearranged peculiarly to the 2-alkyl-4-(*p*-alkylphenylazo)phenols, **3b** and **3c**, respectively. The propyl group did not rearrange to an isopropyl group in this rearrangement.

The reactions of **1d** and **1e** yielded 4-(*p*-alkylphenylazo)phenols, **4d** and **4e**, respectively as the main products. Recently, Cox and Buncel[3] briefly communicated the formation of the same products. The rearrangement accompanied by the dealkylation was also ob-



Scheme 1.

served in the reaction of **1b** and **1c**. In the reaction of **1d**, **3d** was formed as a by-product.

The mechanism shown in Scheme 1 accounts nicely for the formation of the various azophenols, except **5**: First, **1** undergoes diprotonation and then dehydration to yield the dicationic intermediate (**12**). Subsequently the nucleophile, probably HSO_4^-, attacks the dication to form the complex (**13**). When R=H, the deprotonation occurs to afford the 4-hydroxyazobenzenes (Route a). This mechanism has been proposed as a pathway of the Wallach rearrangement.[3]

On the other hand, the compounds **4** were formed by the separation of a alkyl carbonium ion from the complex **13** (Route b). When the carbonium ion is more stable, such as an isopropyl or *tert*-butyl group, the reaction proceeds preferentially by this route. In route c, the nucleophile group migrates to its *ortho* position in the complex **13** and then the deprotonation occurs to yield **2**. The compound **1a** rearranges mostly by this route. In Route d, the alkyl group migrates to its *ortho* position in **13** and then the deprotonation occurs. The compounds, **1b**, **1c**, and **1d**, which have the primary or secondary alkyl groups, rearrange by this route to form **3**.

The nucleophile attacks mostly the carbon atom attached the alkyl group. Thus the 2-hydroxyazo compounds **5** were only slightly formed. This can probably be attributed to the fact that the electron-releasing effect of the alkyl group accelerates the formation of the dicationic intermediate **12** and therefore the formation of **5** is hindered. Shemyakin and coworkers showed that the formation of 2-hydroxyazobenzenes appears to proceed by an intramolecular pathway different from that in the formation of 4-hydroxyazobenzenes.[12]

The migration of the alkyl group or the nucleophile group may be caused by the positive charge on the *ortho* carbon atom of complex **13b**. Although the methyl group does not migrate, the ethyl and propyl groups do. This is probably due to the increasing electron density on the α-carbon atom by the electron-releasing effect of the alkyl group. The secondary and tertiary alkyl groups, in which the effect of the alkyl group is larger than that of the primary alkyl group, leave as the carbonium ion (Route b). It is of interest that the reaction route is greatly affected by the type of the alkyl group. These reactions appear to be explained by the monocationic mechanism[3] proposed for the Wallach rearrangement; however, the formation of **2** and **3** may be more reasonably interpreted by the dicationic mechanism.

In analogy with the usual Wallach rearrangement, considerable amounts of azobenzenes were formed in these reactions. The formation of azobenzenes has been known for a long time; however, the mechanism is still not elucidated.[13] In addition, the reaction afforded a small amount of some unidentified products. Further work is under way to isolate and identify these products and to determine the mechanism of the formation of azobenzenes.

Experimental

The IR spectra were recorded with a JASCO IRA-1 spectrophotometer. The NMR spectra were obtained with a JEOL MH-100 spectrometer using TMS as the internal standard. The gas chromatographic analysis was carried out using a Shimadzu GC-2C apparatus on a 0.75 m×3 mm column packed with 2% Silicone OV-225. The melting points are uncorrected.

Materials. 4,4′-Dipropyl- and diisopropylazoxybenzenes (**1c** and **1d**) were prepared by the oxidation of the corresponding azo compounds. **1c** mp 63—64 °C. Found: C, 76.56; H, 7.90; N, 9.97%. Calcd for $C_{18}H_{22}N_2O$: C, 76.56; H, 7.85; N, 9.92%. **1d** mp 62—63 °C (lit,[14] 62—63 °C). The other azoxybenzenes were prepared according to the method given in the previous work.[14]

Reaction of 4,4′-Dialkylazoxybenzenes (1) with Sulfuric Acid. A solution of **1** (0.02 mol) in 85% sulfuric acid (12 ml) was heated for 30 min at 50 °C. The reaction mixture was poured into cold water, and then extracted with chloroform

a) Lit,[15] 125 °C.

or benzene. The extract was washed with water. After removal of the solvent, the residue was chromatographed on a silica gel column using benzene as a solvent. Unless otherwise noted, all the products were identified by a comparison of these mp and IR spectra with those of authentic samples.

The first fraction gave the crude **11**, contaminated by **1** and **5**, as analyzed by gas chromatography. In the reaction of **1a**, this fraction was again chromatographed on alumina using benzene as a solvent, and the residue on the column was extracted with methanol. The extract gave **5a** mp 150—151 °C (yield 0.2%).

The second fraction gave **2**, which was recrystallized from benzene. **2a** mp 211—212 °C. Found: C, 74.38; H, 5.95; N, 12.26%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%. **2b** mp 152.5—153 °C. Found: C, 75.35; H, 7.06; N, 11.25%. Calcd for $C_{16}H_{18}N_2O$: C, 75.56; H, 7.13; N, 11.02%. **2c** mp 126.5—127 °C. Found: C, 76.55; H, 8.01; N, 9.92%. Calcd for $C_{18}H_{22}N_2O$: C, 76.56; H, 7.85; N, 9.92%.

The azophenols, **2a**, **2b**, and **2c**, were acetylated with acetic anhydride and pyridine. The products were recrystallized from hexane. Acetate of **2a** mp 105—106 °C. Acetate of **2b** mp 78.5—80 °C. Acetate of **2c** mp 46—47 °C. Found: C, 74.27; H, 7.34; N, 8.46%. Calcd for $C_{20}H_{24}N_2O_2$: C, 74.04; H, 7.46; N, 8.64%. The mp and the IR and NMR spectra of the acetates of **2a** and **2b** were identical with those of an authentic sample prepared independently. The **2c** acetate was identified by a comparison of its IR and NMR spectra (particularly, the characteristic signals due to aryl protons) with those of the **2a** and **2b** acetates. **2c** acetate: IR (KBr): 1750 (C-O), 1220 cm^{-1} (CO-O-Ar); NMR ($CDCl_3$): δ 1.00 (t, $2CH_3$), 1.68 (m, $2CH_2$), 2.35 (s, CH_3-COO), 2.58, 2.68 (t, $2CH_2Ar$), 7.3—8.0 (m, ArH).

The third fraction gave **3**. These products were recrystallized from hexane or ethanol-water. **3b** mp 116—117 °C. **3c** mp 55—56 °C. **3d** mp 86—88 °C.

The fourth fraction gave **4**, which was recrystallized from hexane. **4b** mp 122—123 °C. **4d** mp 115—116 °C. **4e** mp 127—128 °C. Since **4c** was impure, the crude **4c** was acetylated by the usual method. After purification by column chromatography (silica gel, benzene), recrystallization from hexane afforded **4c** acetate mp 80—81 °C.

The other fractions gave a small amount of unidentified substances.

*Preparation of the Authentic Samples. (A) 2-Alkyl-4-(*p-*alkylphenylazo)phenols (3) and 4-(*p-*Alkylphenylazo)phenols (4):* These azophenols were prepared by diazocoupling of the corresponding phenols and diazonium salts. These were purified by the use of column chromatography on silica gel and recrystallization from hexane or hexane-benzene. The results are shown in Table 3.

*(B) 5-Methyl-2-(*p-*tolylazo)phenol (5a):* The azophenol **5a** was obtained by the irradiation of the ethanolic solution of **1a**, and **5a** was also prepared by the method previously reported for 6-chloro-2-(3-chlorophenylazo)phenol.[16] 4,4′-Dimethyl-2-benzyloxyazobenzene, mp 95—96 °C (yield, 20%), Found: C, 79.90; H, 6.60; N, 8.85%. Calcd for $C_{21}H_{20}N_2O$: C, 79.71; H, 6.37; N, 8.85%. The **5a** mp 151—152 °C (yield, 69%).

(C) Acetate of 2a: 3-Acetoxy-4-methylaniline was prepared by catalytic hydrogenation of 2-acetoxy-4-nitrotoluene. Mp 78—79 °C. Found: C, 65.53; H, 6.85; N, 8.63%. Calcd for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48%.

A solution of the acetoxyaniline (0.67 g) and *p*-nitrosotoluene (0.49 g) in acetic acid was allowed to stand overnight at room temperature. The reaction mixture was poured into water, and extracted with benzene. After removal of the solvent, the extract was chromatographed on silica gel (solvent: benzene). The third fraction was recrystallized from hexane to give 3-acetoxy-4,4′-dimethylazobenzene (**2a** acetate) mp 104—105 °C. Found: C, 71.44; H, 5.79; N, 10.82%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44%.

2b acetate was prepared by the same method. Mp 78—79 °C. Found: C, 72.82; H, 6.86; N, 9.38%. Calcd for $C_{18}H_{20}N_2O_2$: C, 72.95; H, 6.80; N, 9.45%.

The Formation and Reaction of Carbonyl Ylide. The Copper Chelate-catalyzed Decomposition of 1-(Diazoacetyl)fluorenone in the Presence of Ethylenic and Acetylenic Compounds

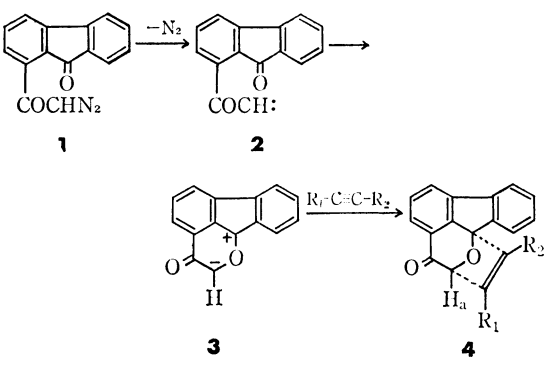
Toshikazu IBATA,* Tadayuki MOTOYAMA, and Masashi HAMAGUCHI
Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received March 15, 1976)

1,3-Dipolar cycloadducts were obtained by the copper chelate-catalyzed decomposition of 1-(diazoacetyl)-fluorenone in the presence of acetylenic and ethylenic dipolarophiles. The reaction proceeded *via* intermediate carbonyl ylide (**3**), which has been generated by the carbene-carbonyl reaction of **2**. The cycloaddition of **3** with ethylenic dipolarophiles was determined to proce d stereospecifically.

The thermolysis[1] and photolysis[2] of epoxides with electron-withdrawing groups, the thermolysis of 1,3,4-oxadiazolines,[3] and the reaction of carbenes with carbonyl compounds[4,5] have been known to be the general method of the formation of carbonyl ylides. In particular, the intramolecular carbene-carbonyl reaction has been recognized as one of the most convenient methods of the formation of cyclic carbonyl ylides.[5-7] For example, as the first stable five-membered cyclic carbonyl ylide, isomünchnon was obtained by the $Cu(acac)_2$ catalyzed decomposition of *N*-methyl-*N*-(diazo-*p*-nitrophenylacetyl)benzamide.[6] As a result of a continuing study of the intramolecular carbene-carbonyl reaction, we wish now to report the formation of carbonyl ylide by the copper chelate-catalyzed decomposition of 1-(diazoacetyl)fluorenone (**1**) and its cycloaddition with acetylenic and ethylenic dipolarophiles.

Results and Discussion

Cycloaddition with Acetylenic Dipolarophiles. When 1-(diazoacetyl)fluorenone (**1**) was decomposed in the presence of a 1.5 molar amount of dibenzoylacetylene and a catalytic amount of $Cu(acac)_2$ in absolute benzene at 80 °C, a cycloadduct (**4a**; $R_1=R_2=COPh$) was obtained in an 89% yield. The IR spectrum of **4a** shows a carbonyl band of cyclic ketone at 1704 cm^{-1} besides that of the benzoyl absorption at 1659 cm^{-1}, as is shown in Table 1. The methine proton, H_a, of **4a** shows a singlet at 4.22 τ which is at a field higher by 0.5 τ than those of other adducts with acetylenic dipolarophiles because of the shielding effect of the benzoyl group at the adjacent carbon. Dimethyl acetylenedicarboxylate also afforded an adduct (**4b**: $R_1=R_2=COOCH_3$) in a quantitative yield.



Although there are two possibilities in the direction of the cycloaddition of asymmetric acetylenes, methyl propiolate gave only one adduct (**4c**: $R_1=H$, $R_2=COOCH_3$, 80%), which exhibited a doublet methine signal of H_a at 4.78 τ and that of H_b at 2.48 τ coupled with one another ($J_{ab}=2.5$ Hz). This means that H_a and H_b are in a vicinal position and that R_2 is the methoxycarbonyl group. The NMR signal of methoxycarbonyl of **4c** at 6.51 τ is comparable to that of one OCH_3 (at 6.56 τ) of the adduct of dimethyl acetylenedicarboxylate (**4b**). Phenylacetylene yielded an adduct with a similar direction of cycloaddition (**4d**: $R_1=H$, $R_2=Ph$) in an 86% yield.

On the other hand, methyl phenylpropiolate yielded two cycloadducts, **4e** (24%) and **4f** (30%). The similarity of their IR spectra demonstrates that they are isomers different in the direction of cycloaddition. The singlet of **4e** at 6.69 τ was assigned to the methoxycarbonyl group at the R_2 position in comparison with that of **4c** (at 6.51 τ). Therefore, the singlet of **4f** at 6.30 τ was assigned to methoxycarbonyl at R_1. In general, the methoxycarbonyl group at R_2 has a methyl signal at a higher field than that of R_1 because of the

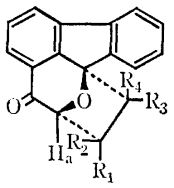
a) $J_{ab}=2.5$ Hz. b) $J_{ab}=2.4$ Hz. c) A broad absorption was observed.

anisotropy of the fluorene ring.

Because of the contribution of a resonance formula $H-\overset{+}{C}=\overset{-}{C}-COOCH_3$ in methyl propiolate, the α-carbon with an increased electron density attacks the positively charged C_9 of the fluorene ring of carbonyl ylide (**3**) to give **4c**. In the case of phenylacetylene, π-π interaction[11] between the phenyl group and the fluorene ring regulates the direction of cycloaddtition, affording **4d**. In the addition of methyl phenylpropiolate, electronic interaction and π-π interaction compete; two products, **4e** and **4f**, are thus formed.

*Cycloaddition of **3** with Ethylenic Dipolarophiles.* Ethylenic dipolarophiles also gave cycloadducts (**5**) in high yields (Table 3). The configuration of the adducts were determined on the basis of their NMR properties. The reaction with *trans*-1,2-dibenzoylethylene gave a single adduct (**5a**), which showed doublet methine signals of H_a and H_c at 4.88 τ and 4.46 τ, and a double doublet of H_b at 5.10 τ. From the small value of the coupling constant between H_a and H_b (J_{ab}=1.6 Hz), H_a and H_b are decided to be in the *trans* configuration. The coupling constant, J_{bc}, (=4.9 Hz) also indicates that H_b and H_c are *trans*. Therefore, the structure of **5a** was determined to be as is shown in Table 2.

In general, the *cis* coupling constants of methine protons in **5** have larger values (8.0—10.6 Hz) than those of *trans* protons (1.6—6.9 Hz) in this ring system.[8-10] For example, in the two adducts of dimethyl fumarate, the minor adduct, mp 142—144 °C, was assigned to **5b**, in which H_a and H_b are *trans* (J_{ab}= 1.4 Hz) and H_b and H_c are *trans* (J_{bc}=5.6 Hz).[10] On



(**5**)

the contrary, in the major adduct, mp 210—213 °C, the large coupling constant of J_{ab}=8.0 Hz indicates that H_a and H_b are *cis*, while the small value of J_{bc} (=5.8 Hz) shows H_b and H_c are *trans*. An inspection of the Dreiding model of these adducts indicates that the newly formed tetrahydrofuran ring is perpendicular to the fluorene ring and that R_4 is situated under the plane of the fluorene ring. Therefore, when R_4 is the methoxycarbonyl group, the ring current of the fluorene ring causes an upper-field shift of the methyl signals, as may be seen in the NMR spectrum of **4b**.

In the reactions with asymmetric olefins, such as methyl cinnamate or methyl *p*-bromocinnamate, a single adduct was obtained; it was assigned the structure shown in Table 2 (R_1=$COOCH_3$ and R_4=Ar) on the basis of the values of the coupling constants (see Table 2) and the chemical shift of methoxycarbonyl (6.20 and 6.23 τ).

trans-Stilbene gave an adudct with a structure similar to **5a** in a 26% yield, besides a dimer(**6**) of the carbonyl ylide (70%). However, *cis*-stilbene did not form an adduct, but yielded the dimer in an 84% yield and 1-(hydroxyacetyl)fluorenone (**7**) in a 3% yield. The formation of the dimer suggests that the dipolarophilicity of *trans*-stilbene and *cis*-stilbene is lower than that of the other dipolarophiles cited above.

Styrene is much more reactive than stilbenes and affords an adduct (**5g**) which shows an H_a resonance as a double doublet coupling with both H_b and H_b' (J_{ab}=1.7 (*trans*) and $J_{ab'}$=8.5 Hz (*cis*)). Thus, R_4 is decided to be phenyl in **5g**. Methyl methacrylate gave an adduct (**5h**) in which R_3 was assigned to methoxycarbonyl, because the methoxy signal was at 6.28 τ and H_a was a double doublet. The configuration of these adducts reveals that the phenyl (or *p*-bromophenyl) group is located at the R_4 position in the adducts of phenyl-substituted ethylenic dipolarophiles, such as methyl cinnamate, methyl *p*-bromocinnamate, *trans*-stilbene, and styrene. This directing effect seems to be caused by the π-π interaction[11] between the phenyl ring of dipolarophiles and the fluorene ring of the carbonyl ylide (**3**), which might be parallel in the transition state.

When the diazo compound (**1**) was catalytically decomposed without dipolarophile, the reaction mixture turned red[12] and was then decolorized after a few ten minutes. The treatment of the reaction mixture gave, quantitatively, a white crystalline product of the head-to-tail dimer of the carbonyl ylide.[5] Since, the attempt at the isolation of the carbonyl ylide (**2**) was unsuccessful, further studies to synthesize a stable carbonyl ylide of this type are now in progress.

Experimental[13]

Materials. Fluorenone-1-carboxylic acid was prepared by the CrO_3 oxidation of fluoranthene,[14] and was treated with thionyl chloride to give the corresponding acid chloride.

*1-(Diazoacetyl)fluorenone (**1**)* was prepared by the reaction of excess diazomethane with the corresponding acid chloride according to the usual method;[15] yellow plates, mp 149—151 °C; IR(KBr), 2120 (C=N_2), 1698 (C=O), and 1600 cm^{-1} (carbonyl of diazoketone). Found: C, 72.67; H, 3.39; N, 11.35%. Calcd for $C_{15}H_8O_2N_2$: C, 72.57; H, 3.25; N, 11.29%.

Dipolarophiles. Dibenzoylacetylene,[16] dimethyl acetylenedicarboxylate,[17] methyl phenylpropiolate,[18] methyl *p*-bromocinnamate,[19] and *trans*-dibenzoylethylene[20] were prepared by the procedure described in the literature. Other crystalline dipolarophiles, such as dimethyl fumarate, methyl cinnamate, and *trans*-stilbene, were used after the purification of commercial reagents by recrystallization. Liquid dipolarophiles, methyl propiolate, phenylacetylene, styrene, and methyl methacrylate, were purified by distillation im-

a) In this reaction the dimer (**6**) was obtained in a 70% yield.

mediately before use.

*General Procedure of the Decomposition of 1-(Diazoacetyl)-fluorenone (**1**) in the Presence of Dipolarophiles.* 1-(Diazoacetyl)fluorenone (0.25 g, 1 mmol) was added, in small portions, to a benzene solution (30 ml) of a 1.5—3.0 molar amount of dipolarophile and a catalytic amount (0.02 g, 0.08 mmol) of $Cu(acac)_2$ at 80 °C. A vigorous evolution of nitrogen gas was observed immediately after the addition. The reaction mixture was separated by column chromatography on silica gel, using benzene as the eluent. The physical properties of the cycloadducts obtained are listed in Tables 1 and 2, while the yields, melting point, and results of elemental analyses are shown in Table 3.

*Formation of Dimer (**6**).* 1-(Diazoacetyl)fluorenone (0.25 g, 1 mmol) was decomposed in a benzene solution of a catalytic amount of $Cu(acac)_2$ by adding it in small portions. During the course of the addition, a vigorous evolution of nitrogen was observed and the reaction mixture turned red. After the red color has disappeared, the solvent was evaporated under reduced pressure. A white crystalline product was thus obtained in a quantitative yield; 0.22 g, mp>360 °C; IR (KBr), 1698 cm^{-1} (C=O). Found: C, 81.56; H, 3.69%. Calcd for $C_{30}H_{16}O_4$: C, 81.81; H, 3.66%.

The Facile Synthesis of *N*-Substituted Piperidines from Glutaraldehyde and Primary Amines with Tetracarbonylhydridoferrate

Yoshihisa WATANABE, Sang Chul SHIM, Take-aki MITSUDO,
Masakazu YAMASHITA, and Yoshinobu TAKEGAMI
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received April 10, 1976)

Ethanolic tetracarbonylhydridoferrate solution combined with glutaraldehyde is very efficient for the selective transformation of an amino group into a piperidine ring. A large variety of both aliphatic and aromatic amines react with the ferrate-glutaraldehyde at room temperature under carbon monoxide to give the corresponding *N*-alkyl- and *N*-arylpiperidines in good to excellent yields.

A large variety of methods are available for building up the piperidine ring.[1] Most of these feature the closing of the piperidine ring at the nitrogen atom. In these methods, 1,5-dihalids, 1,5-halogeno amine, 1,5-amino alcohol, 1,5-diamine, 1,3-dinitrile, pyridines, tetrahydropyran, and *N*-arylglutarimide are used as the starting materials. The major portion of the synthetic problem is the preparation of a suitable starting material. The double Mannich condensation of glutaraldehyde, amine, and acetonedicarboxylic acid provides an elegant classical synthesis of tropinone.[1b] Little attention, however, has been paid to the normal reductive amination of glutaraldehyde. Recently, sodium cyanohydroborate has been shown to be effective to be a selective reducing reagent in the preparation of *N*-heterocycles with 5- and 6-membered rings by the reductive amination of dicarbonyl compounds.[2]

The present paper will deal with the facile synthesis of a variety of *N*-alkyl- and *N*-arylpiperidines by the reductive amination of glutaraldehyde with tetracarbonylhydridoferrate as a highly selective reducing reagent; this reagent has been shown to be efficient for the reductive alkylation of amines, ketones, and indole.[3] A preliminary report of this work was published elsewhere.[3c]

Experimental

The potassium tetracarbonylhydridoferrate was prepared according to the method described in a previous paper;[4] 11—22 mmol of the ferrate was used in each run. The pentacarbonyliron, amines, aqueous glutaraldehyde (45%), and the other compounds employed were all commercial products.

Reaction Procedure. To a mixture of pentacarbonyliron (11—22 mmol), a 1 M-potassium hydroxide (33—66 mmol) solution in ethanol, and a primary amine (11—22 mmol), we added, drop by drop, 45% aqueous glutaraldehyde (11—22 mmol) for 5—10 min; the mixture was then stirred for 5—72 h at room temperature under carbon monoxide.

a) At room temperature under carbon monoxide. Molar ratio: ferrate-glutaraldehyde-amine, 1.0 : 1.0 : 1.0.
b) Mol/mol-ferrate. c) Isolate yield. Based on the amount of the ferrate used.

The reaction was readily monitored by the GLPC analysis of the primary amine used. When all of the amine had been consumed, the reaction was stopped and the potassium carbonate formed in the reaction was filtered off. The filtrate was concentrated to 3—5 ml on a rotary evaporator and/or with a Kugelrohr apparatus, and the products were separated and purified by careful vacuum distillation, and submitted to analysis.

Analytical Procedure. The GLPC analysis was made using internal standards: a column (0.3 cm ø, 3 m) packed with 10% Versamid on Neopak 60—80 mesh. The measurements of the PMR and IR spectra were made on a JOEL Model 3H 60-NMR spectrometer and a Varian HR 220 spectrometer, and on a 215 Hitachi grating spectrometer, respectively.

Results and Discussion

N-Substituted Piperidines from Primary Amines. A large variety of primary amines were converted into the corresponding *N*-substituted piperidines in good to excellent yields with tetracarbonylhydridoferrate–glutaraldehyde under mild conditions, at room temperature and under carbon monoxide. The results are listed in Tables 1 and 2.

When aqueous glutaraldehyde (45%) is mixed with a primary amine in ethanol, an intractable condensation material is obtained after evaporating the solvents, but the ferrate–glutaraldehyde–amine system gives *N*-

23	105/0.1	8.40(m, 12H), 7.00(t, 8H), 3.17(s, 4H, Ar)	78.37 (78.64)	9.77 (9.90)	11.69 (11.46)

a) IR(Neat), ν_{-NH_2} 3340 and 3440 cm^{-1}.

substituted piperidines: the ferrate acts as an efficient and highly selective reducing reagent to give the *N*-heterocycles as the only reaction products.

$$OHC(CH_2)_3CHO + RNH_2 \xrightarrow{KHFe(CO)_4} \overbrace{(CH_2)_5\,N\text{-}R}$$

The reaction proceeds smoothly with an absorption of carbon monoxide and with a color change from pale yellow brown to red.

This reaction has a great tendency to undergo a heterocyclization at the nitrogen atom of the amines, even at the ferrate–glutaraldehyde–amine molar ratio of 1.0 : 1.0 : 2.0; at this ratio *N*,*N*′-disubstituted pentanediamines are expected to be formed, but the *N*-heterocycles and the unconsumed primary amines are identified.

$$OHC(CH_2)_3CHO + 2RNH_2 \begin{cases} \xrightarrow{KHFe(CO)_4} \overbrace{(CH_2)_5\,N\text{-}R} + RNH_2 \\ \not\longrightarrow\ RNH(CH_2)_5HNR \end{cases}$$

This method can be applied to both aromatic and aliphatic amines with different functional groups. In the cases of substituted anilines, such substituents as the methyl, methoxyl, and chloro groups have almost no effect on the formation of the heterocycles when located at the *para* position, but they have some inhibitory effect when located at the *ortho* position. *o*-Methyl- and *o*-methoxyanilines require longer reaction times for completion, and from *o*-chloroaniline the corresponding piperidine could not be isolated even after a reaction time of 72 h. Such influence of the *ortho* substituents seems to be due to steric hindrance. Usual aliphatic amines, 1-butanamine and 1-octanamine, give the *N*-heterocyles, but this type of compound, simple *N*-alkylpiperidines, are somwhat unstable to be gradually oxidized under air with a color change from colorless to brown. Different aliphatic amines with such functional groups as the phenyl, hydroxyl, and carboxyl groups are also converted into the heterocycles with no difficulty. The successful results with the glycine methyl ester clearly indicate that this method can be applied to amino acids and their derivatives. This reaction seems to proceed *via* Schiff bases and immonium salts and seems to include the reduction of carbon-nitrogen double bonds.[3f]

$$OHC(CH_2)_3CHO + RNH_2 \longrightarrow \left[OHC(CH_2)_3\text{-}CH{=}N\text{-}R \longrightarrow OHC(CH_2)_4\text{-}NH\text{-}R \longrightarrow \overbrace{(CH_2)_4\,\underset{\backslash\!-\!CH^{/}}{N^+}\text{-}R} \right] \longrightarrow \overbrace{(CH_2)_5\,N\text{-}R}$$

N-Substituted Piperidines from Phenylenediamines. The results for phenylenediamines are listed in Tables 3 and 4. This reaction also proceeds readily under mild conditions. In the reaction of *o*- and *p*-phenylenediamines with the ferrate–glutaraldehyde system, two types of products, *N*-(aminophenyl)piperidines and dipiperidinobenzenes, are obtainable. The types of the products sharply depend on the ferrate–glutaraldehyde–amine molar ratio. The molar ratio of 1.0 : 1.0 : 1.0 gives the *N*-(aminophenyl)piperidines selectively.

$$C_6H_4(NH_2)_2 + OHC(CH_2)_3CHO \xrightarrow{KHFe(CO)_4} C_6H_4(NH_2)[N(CH_2)_5]$$

This results also shows that this reaction has a great tendency to undergo heterocyclization at the nitrogen atom; one of the two amino groups is selectively alkylated to the piperidine ring. The molar ratio of 2.0 : 2.0 : 1.0 gives dipiperidinobenzenes; two amino groups are derived into two piperidine rings, but *o*-phenylenediamine requires a much longer reaction time than the *p*-derivative. (Exps. 21 and 23).

The results obtained here show that this method is widely applicable for the selective transformation of the amino group into the piperidine ring.

Dehydroannulenes. V. Synthesis and Properties of 1,6,12,17-Tetra-*t*-butyl-2,4,13,15-tetrakisdehydro[22]annulene

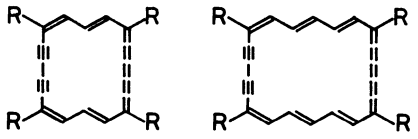
Masahiko IYODA, Hideaki MIYAZAKI, and Masazumi NAKAGAWA*

Department of Chemistry, Faculty of Science, Osaka University Toyonaka, Osaka 560

(Received April 23, 1976)

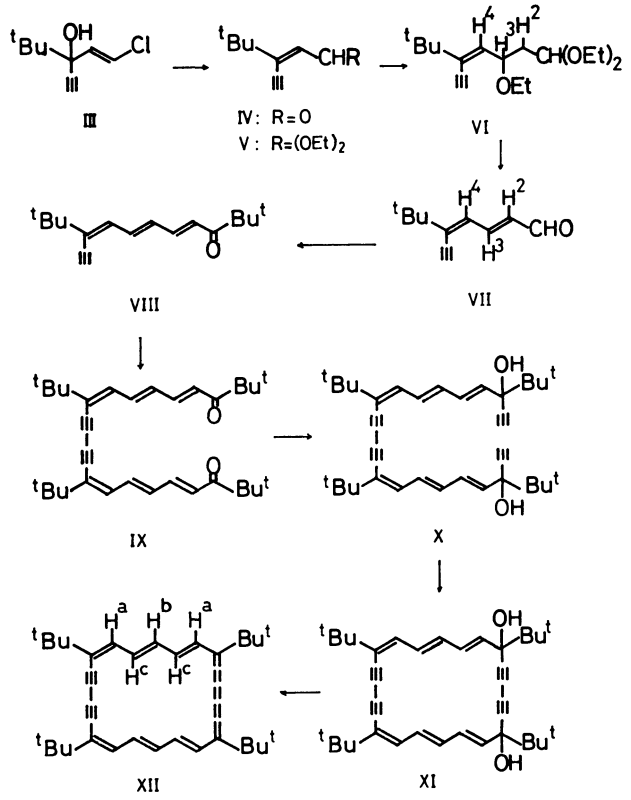
The synthesis of 1,6,12,17-tetra-*t*-butyl-2,4-13,15-tetrakisdehydro[22]annulene has been performed. The tetrakisdehydro[22]annulene was found to be strongly diatropic having high conformational stability.

In view of strong diatropicity and high conformational stability of tetrasubstituted tetrakisdehydro[18]-annulene (I)[1-4] synthesis of higher analogue of I, tetrakisdehydro[22]annulene (II), seemed to be of considerable interest for the purpose gaining further insight into the aromaticity of macrocyclic $[4n+2]\pi$-electron system. The present paper is concerned with the synthesis and properties of tetra-*t*-butyltetrakis-dehydro[22]annulene (XII=II, R=*t*-Bu).[5]



I II

3-*t*-Butyl-2-penten-4-ynal (IV) obtained from III[3] was converted into diethyl acetal (V) in the usual way. Condensation of ethyl vinyl ether[6] with V in benzene in the presence of boron trifluoride etherate yielded ethoxy acetal (VI) in a high yield. Unstable 5-*t*-butyl-2,4-heptadien-6-ynal (VII) obtained on treatment of VI with hydrogen chloride in aqueous dioxane was condensed with pinacolone to give trienyne ketone (VIII). Oxidative coupling of the trienyne ketone (VIII) with copper(II) acetate monohydrate in pyridine–methanol[7] yielded hexaendiyne diketone (IX). Bis-ethynylation of the diketone (IX) could be achieved by lithium acetylide–ethylenediamine complex[8] in tetrahydrofuran saturated with acetylene. Bis-ethynyl alcohol (X) obtained in a high yield was oxidatively coupled with copper(II) acetate in pyridine–methanol under high dilution conditions using ether as an entraining solvent to give cyclic glycol (XI). The fact that the 22-membered cyclic glycol (XI) could be obtained in 77.5% yield seems to be attributable to the molecular geometry of X favorable for intramolecular oxidative coupling.



III IV: R=O V: R=(OEt)$_2$ VI VII VIII IX X XI XII

Finely powdered tin(II) chloride dehydrate was added at −60 °C under nitrogen atmosphere to a stirred solution of the cyclic glycol (XI) in ether saturated with hydrogen chloride. Resulting deep blue violet reaction mixture was worked up rapidly at a low temperature. Chromatography of the product on alumina at −20 °C followed by elution with dichloromethane–pentane gave tetra-*t*-butyltetrakisdehydro[22]-annulene (XII) as unstable dark violet crystals in a yield of 85%. The crystals of XII changed quickly to colorless solid at *ca.* 100 °C on attempted melting point determination. Full hydrogenation of XII over platinum catalyst gave tetra-*t*-butylcyclodocosane.

As illustrated in Fig. 1, XII showed closely related electronic spectrum to that of tetra-*t*-butyltetrakisde-hydro[18]annulane (I, R=*t*-Bu)[3] except for considerable bathochromic shift in XII. The NMR spectrum of XII is shown in Fig. 2. The fact that the outer protons (H^a and H^b) resonate at unusually low field and the inner protons (H^c) exhibit signals at fairly high field clearly demonstrates the induction of diamagnetic ring current indicating the aromatic nature of the tetrakisdehydro[22]annulene (XII). The fact that the NMR spectra of XII obtained at 30 °C and −40 °C exhibit no essential change (Table 1) indicates the conformational stability of the 22-membered ring with delocalized π-electron system containing formal diacetylene and hexapentaene units. The coalescence temperature of XII could not be determined owing rather rapid decomposition of XII at temperature higher than 30 °C.

The difference in chemical shifts between the signal of inner protons (τ_i) and the lowest field signal of outer protons (τ_o) can be regarded as an approximate measure of ring current. The τ_i—τ_o-value ($\Delta\tau$) for tetra-*t*-butyltetrakisdehydro[18]annulene (I, R=*t*-Bu) has

* Author to whom inquiries should be addressed.

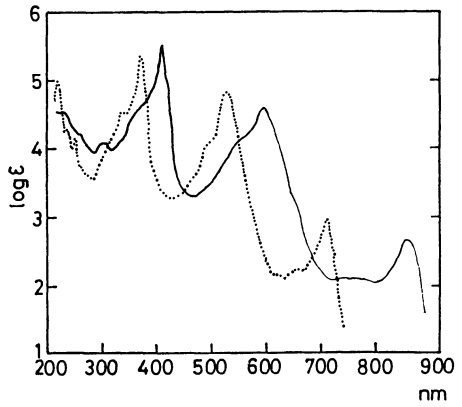


Fig. 1. Electronic spectra in THF of tetra-*t*-butyltetrakisdehydro[18]annulene (I, R=*t*-Bu) (·····) and tetra-*t*-butyltetrakisdehydro[22]annulene (XII) (——).

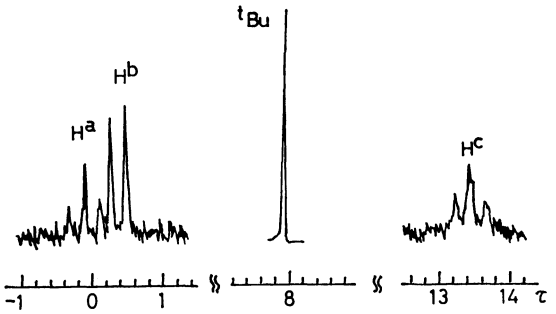

Fig. 2. NMR spectrum of tetra-*t*-butyltetrakisdehydro-[22]annulene (XII).
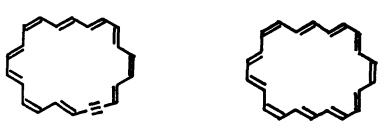
60 MHz, in $CDCl_3$, at 30 °C.

Table 1. NMR Parameters of tetra-*t*-butyltetrakisdehydro[22]annulene (XII), 60 MHz, $CDCl_3$

Temperature	H_b	H^a	*t*-Bu	H^c
−40 °C	−0.43 t	0.09 d	7.88 s	13.71 t
	J=13	J=13		J=13
+30 °C	−0.16 t	0.33 d	7.93 s	13.44 t
	J=13	J=13		J=13

been found to be $\Delta\tau$=14.83,[3] whereas an appreciable decrease in the value, $\Delta\tau$=13.44−(−0.16)=13.60, was observed for tetra-*t*-butyltetrakisdehydro[22]annulene (XII). The $\Delta\tau$-values for I and XII can be compared reasonably well, since these compounds have similar geometries and planarities. Therefore, the marked decrease in the $\Delta\tau$-value for XII as compared with that for I(R=*t*-Bu) can be regarded as an evidence for theoretically predicted decrease of resonance energy[9] or ring-current intensity[10] along with increase of ring size.



XIII XIV

It has been reported that monodehydro[22]annulene (XIII) exhibits signals of outer protons at τ1.55—3.75 and these of inner protons at τ6.55—9.30.[11] The NMR spectrum of [22]annulene (XIV) has been found to be temperature dependent indicating conformational mobility of the molecule (coalescence temperature, *ca.* 20 °C). At −90 °C, XIV showed outer proton signals at τ 0.35—0.7 and 0.9—1.5, and inner proton signals at τ 10.4—11.2.[12] A much higher diatropicity and conformational stability of XII as compared with XIII and XIV indicate that symmetrical 'acetylene-cumulene'-dehydroannulenes containing equalized acetylenic and cumulenic linkages in the cyclic system are one of the most adequate structure for the study of aromaticity of macrocyclic system.

Experimental

All melting and boiling points are not corrected. The IR spectra were measured with a Hitachi EPI-2 or EPI-G3 spectrometer, and strong; medium and weak bands were indicated by s, m and w, respectively. The UV spectra, obtained on a Hitachi EPS-3T spectrophotometer, were recorded in nm and the ε-values were given in parentheses. Shoulder was denoted by sh. The mass spectra were measured with a Hitachi RM-50 spectrometer. The NMR spectra obtained on a Varian A-60 spectrometer were given in τ-values with respect to TMS as an internal standard, and the coupling constants (J) are recorded in Hz. Silica gel (Merck, Kiesel Gel 60) or alumina (Merck, Act. II-III) was used for column chromatography, unless otherwise stated.

3-t-Butyl-2-penten-4-ynal Diethyl Acetal (V). To a mixture of slightly crude IV (63.70 g, bp 47—50 °C/400 Pa) obtained from III (88.0 g)[3] and ethyl orthoformate (160 ml) was added a solution of *p*-toluenesulfonic acid monohydrate (6.00 g, 0.968 mmol). The mixture was stirred at 30 °C for 24 h under nitrogen atmosphere, and then chilled on an ice-bath. The cooled reaction mixture was poured onto ice-water containing sodium hydrogencarbonate. The organic layer was separated and the aqueous layer was extracted with ether (100 ml×2). The combined organic layer was washed successively with sodium hydrogencarbonate and sodium chloride solutions, dried (K_2CO_3), concentrated *in vacuo*, and distilled, yielding V: 84.11 g, 78.5% based on III; bp 78–79 °C/400 Pa; MS: *m/e* 210 (M^+); IR (CCl_4): 3320 m (C≡CH), 2085 w (C≡C), 1628 w (C=C), 1200–1000 s (C–O–C) cm^{-1}; NMR (CCl_4): 4.24 (d, 1, J=7.5, olefinic), 4.78 (d, 1, J=7.5, acetal), 6.48 (m, 4, $-CH_2-$), 6.89 (s, 1, C≡CH), 8.83 (t, 6, J=7.0. CH_3), 8.83 (s, 9, *t*-Bu). Elemental analyses gave unstisfactory results presumably owing to extremely facile hydrolysis of V.

5-t-Butyl-3-ethoxy-4-hepten-6-ynal Diethyl Acetal (VI). A solution of boron trifluoride etherate (20 mg) in benzene (1 ml) was added to a solution of V (7.40 g, 0.0352 mol) in the same solvent (20 ml) at 40 °C, and then a solution of ethyl vinyl ether (2.79 g, 0.0387 mol) in the same solvent (5 ml) was slowly added. After the mixture had been kept at the same temperature for further 2 h. Finely powdered potassium carbonate was added to the cooled reaction mixture resulting in a yellow solution. The inorganic material was removed by filtration and washed with ether. The combined organic layer and washings were concentrated under reduced pressure, and distilled *in vacuo*, giving VI: 8.98 g, 90.4%; bp 110—111 °C/400 Pa; MS: *m/e* 282 (M^+); IR (CCl_4): 3320 m (C≡CH), 2070 w (C≡C), 1620 w (C=C), 1150—1050 s (C–O–C) cm^{-1}; NMR (CCl_4): 4.36 (d, 1, J=9.0, H^4), 5.42 (m, 1, H^1), 5.64 (m, 1, H^3), 6.56 (m, 6, $O-CH_2-$), 6.83 (s, 1, C≡CH), 8.30 (m, 2, H^2), 8.85

(t, 9, J=7.0, CH_3).

Found: C, 71.89; H, 10.61%. Calcd for $C_{17}H_{30}O_3$: C, 72.30; H, 10.71%.

Although VI gave rather unsatisfactory elemental analysis, it was used without further purification in the following reaction.

5-t-Butyl-2,4-heptadien-6-ynal (VII). A mixture of VI (10.00 g, 0.0354 mol), dioxane (60 ml) and 3M hydrochloric acid (50 ml) was vigorously stirred under nitrogen atmosphere at 50 °C for 3 h, and then at 40 °C for 18 h. The reaction mixture was chilled and the organic layer was separated. The aqueous layer was extracted with ether. The combined organic layer was washed successively with saturated sodium hydrogen carbonate and sodium chloride solutions, dried (Na_2SO_4), concentrated under reduced pressure, and rapidly distilled *in vacuo* under nitrogen atmosphere using short neck distilling flask to give VII: yellow liquid; 4.06 g, 70.7%; bp 60—70 °C/200 Pa; IR (CCl_4): 3300 m (C≡CH), 2810 w, 2730 w (CHO), 1687 s (C=O), 1616 s (C=C), 977 s (*trans* CH=CH) cm^{-1}; NMR (CCl_4): 0.56 (d, 1, J=7.5, CHO), 2.47 (dd, 1, J=11, 15, H^3), 3.46 (d, 1, J=11, H^4), 3.87 (dd, 1, J=7.5, 11, H^2), 8.81 (s, 9, *t*-Bu).

VII was found to be unstable changing to a red viscous liquid on standing at room-temperature for 1 h, but could be kept for several days at −20 °C under nitrogen atmosphere, and was best stored as an ether solution at 0 °C. VII gave no satisfactory elemental analyses.

Since the aldehyde (VII) decomposed partly during distillation, the reaction product was passed through a short column of alumina, and the slightly crude VII obtained on concentrating the filtrate was used without purification for further reaction.

2,4-Dinitrophenylhydrazone of VII. The crude hydrazone was obtained from VII (88 mg, 0.54 mmol), ethanol (7.4 ml), phosphoric acid (0.6 ml) and 2,4-dinitrophenylhydrazine (100 mg, 0.50 mmol), and was purified by chromatography on silica gel. Elution with petroleum ether–benzene yielded pure 2,4-dinitrophenylhydrazone: red crystals; 160 mg, 93%; mp 194.0–194.9 °C (from petroleum ether–benzene).

Found: C, 59.39; H, 5.35; N, 16.59%. Calcd for $C_{17}H_{18}N_4O_4$: C, 59.64; H, 5.30; N, 16.37%.

9-t-Butyl-2,2-dimethyl-4,6,8-undecatrien-10-yn-3-one (VIII). VI (12.2 g, 0.0433 mol) was converted into VII according to the above procedure, and the crude product dissolved in carbon tetrachloride was passed through a short column of alumina. Elution with the same solvent yielded slightly crude VII (4.91 g, light brown liquid). A solution of sodium hydroxide (2.00 g, 50.0 mmol) in ethanol (5 ml) and water (5 ml) was added under nitrogen atmosphere to a solution of the crude VII (4.91 g) and pinacolone (5.00 g, 50.0 mmol) in ethanol (60 ml) maintained at 0 °C. After being kept at 22 °C for 36 h, the reaction mixture was poured onto ice-cooled 3 M hydrochloric acid (50 ml), and extracted with ether (20 ml×3). The extract was washed successively with water and saturated sodium chloride solution, dried (Na_2SO_4), and concentrated under reduced pressure. The residue was chromatographed on alumina to give VIII: pale yellow crystals (from methanol); 3.20 g, The mother liquor of crystallization was chromatographed on silica gel, yielding further crop of VIII: 2.08 g (total yield, 5.28 g, 50.0%). An analytical specimen of VIII was obtained on further recrystallization from pentane: mp 92.5—93.5 °C; IR (CCl_4): 3300 m (C≡CH), 1678 s (C=O), 1591 s (C=C), 999 s (*trans* CH=CH) cm^{-1}; NMR (CCl_4): 2.40—3.85 (m, 5, olefinic), 6.69 (s, 1, C≡CH), 8.83 (s, 9, *t*-Bu), 8.88 (s, 9, *t*-Bu); UV (99% EtOH): λ_{max} 230 sh (5520), 239 (6670), 336 (37900) nm.

Found: C, 83.80; H, 9.97%. Calcd for $C_{17}H_{24}O$: C, 83.55; H, 9.90%.

9,14-Di-t-butyl-2,2,21,21-tetramethyl-4,6,8,14,16,18-docosahexaen-10,12-diyn-3,20-dione (IX). A solution of VIII (3.00 g, 0.0123 mol) in pyridine (15 ml) and methanol (15 ml) was added to a stirred mixture of copper(II) acetate monohydrate (15.00 g, 0.0752 mol), pyridine (50 ml) and methanol (50 ml) at 30 °C. The mixture, after being stirred for 15 h at 30—35 °C, was poured onto ice-cooled 2 M hydrochloric acid, and extracted with ether (100 ml×4). The extract was washed successively with diluted hydrochloric acid, saturated sodium hydrogencarbonate and saturated sodium chloride solutions, and dried ($MgSO_4$). Crystalline residue obtained on concentrating the extract *in vacuo* was chromatographed on alumina and eluted with benzene to give IX: yellow crystals (washed with methanol); 2.49 g, 83.3%. An analytical sample was obtained on recrystallization from methanol: yellow crystals; mp 171.5—172.5 °C; MS: *m/e* 486 (M^+), 429 (M−57); IR (CCl_4): 1678 m (C=O), 1592 s (C=C), 999s (*trans* CH=CH) cm^{-1}; NMR ($CDCl_3$): 2.40—3.81 (m, 10, olefinic), 8.78 (s, 18, *t*-Bu), 8.84 (s, 18, *t*-Bu); UV (99% EtOH): λ_{max} 246.5 (23100), 288 sh (22300), 325 sh (39800), 343 (46200), 385 (41200), 425 sh (24300) nm.

Found: C, 83.73; H, 9.41%. Calcd for $C_{34}H_{46}O_2$: C, 83.90; H, 9.53%.

9,14-Di-t-butyl-2,2,21,21-tetramethyl-3,20-diethynyl-4,6,8,14,16,18-docosahexaen-10,12-diyne-3,20-diol (X). To a stirred mixture of lithium acetylide-ethylenediamine complex[8] (3.00 g, 0.0326 mol) in THF (60 ml) saturated with acetylene was added at 30 °C a solution of IX (1.60 g, 0.00329 mol) in THF (15 ml). After being stirred for further 2 h at 30 °C under bubbling of acetylene, the reaction mixture was chilled in an ice-salt-bath, and saturated ammonium chloride solution was added dropwise at a rate to maintain the internal temperature at −5—0 °C. Then water was added to the mixture, and the organic layer was separated. The aqueous layer was extracted with ether (30 ml×3), and the extract was combined with the organic layer. The combined organic layer was washed with diluted hydrochloric acid and saturated brine, successively, dried ($MgSO_4$), and concentrated under reduced pressure. Chromatography of the residue on alumina followed by elution with benzene yielded an amorphous solid (1.71 g, 96.6%) which was washed thoroughly with pentane to give X: pale yellow crystalline powder; mp 148—150 °C; MS: *m/e* 538 (M^+), 481 (M−57), 436 (M−57—18); IR ($CHCl_3$): 3590 m (OH), 3317 m (C≡CH), 2193 w, 2106 w (C≡C), 1600 w (C=C), 995 s (*trans* CH=CH) cm^{-1}; UV (99% EtOH): λ_{max} 223.5 (29500), 262.5 (27500), 280 sh (31900), 293 (4300), 305 (49100), 327 (39300), 347 (38300), 369 (31500), 397.5 (22600) nm.

Found: C, 84.38; H, 9.34%. Calcd for $C_{38}H_{50}O_2$: C, 84.71; H, 9.35%.

1,6,12,17-Tetra-t-butyl-7,9,11,17,19,21-cyclodocosahexaen-2,4,13,15-tetrayn-1,6-diol (XI). A solution of X (1.710 g) in ether (90 ml), pyridine (90 ml) and methanol (60 ml) was added over a period of 12 h to a stirred and refluxing solution (internal temperature, 50 °C) of copper(II) acetate monohydrate (18.0 g, 0.0902 mol) in ether (180 ml), pyridine (180 ml) and methanol (40 ml) using a high-dilution apparatus. After being refluxed for further 2 h, the reaction mixture was concentrated under reduced pressure to *ca.* 200 ml, and poured onto ice-cooled 2 M hydrochloric acid (600 ml). The mixture was extracted with ether (100 ml×4), and the extract was washed successively with 2 M hydrochloric acid, saturated sodium hydrogencarbonate solution and saturated brine, dried ($MgSO_4$), and the solution was con-

centrated under reduced pressure, yielding a crystalline residue. Chromatography of the residue on alumina followed by elution with benzene gave XI (1.32 g, 77%), which was recrystallized from dichloromethane–pentane to yield pure XI: yellowish crystals, turned to dark brown soild at *ca.* 240 °C; MS: *m/e* 536 (M^+), 479 (M−57); IR (KBr-disk): 3340 m br. (OH), (988 s *trans* CH=CH) cm^{-1}; NMR ($CDCl_3$): 2.64—4.28 (m, 10, olefinic), 7.91 (br. s, 2, OH, disappeared on addition of D_2O), 8.81 (s, 18, *t*-Bu), 8.89 (s, 18, *t*-Bu); UV (99% EtOH): λ_{max} 279 sh (45400), 292 (83400), 302 (102000), 323.5 sh (12700), 360 sh (12500), 385 (17200), 409 (16200) nm.

Found: C, 84.92; H, 9.03%. Calcd for $C_{38}H_{48}O_2$: C, 85.02; H, 9.01%.

*1,6,12,17-Tetra-*t*-butyl-2,4,13,15-tetrakisdehydro[22]annulene (XII).* To a solution of XI (150 mg, 0.279 mmol) in ether saturated with hydrogen chloride (10 ml) was added under nitrogen atmosphere finely powdered tin(II) chloride dihydrate (450 mg, 1.99 mmol) at −60 °C. After being stirred for 30 min at the same temperature, resulting deep blue violet reaction mixture was mixed with ether (30 ml). The organic layer was washed successively with cold water and cold saturated sodium hydrogencarbonate solution, dried ($MgSO_4$), and concentrated under reduced pressure at a temperature below 0 °C. The dark violet residue was immediately chromatographed on alumina at −20 °C. Elution with dichloromethane–pentane (3 : 7) gave XII: 119 mg, 85%; dark violet crystals, turned to colorless solid at *ca.* 100 °C; IR (Nujol mull, measured at a low temperature): 988 (*trans* CH=CH) cm^{-1}; UV (THF): λ_{max} 222 (37000), 231 (37000), 263.5 (16000), 299 (13000), 311 (11000), 369 sh (41000), 382 (47000), 414 (35000), 552 sh (14000), 596 (46000), 732 (130), 768 (130), 858 (490) nm (*cf.*, Fig. 1); NMR: see, Table 1 and Fig. 2.

The crystals of XII decomposed rapidly on exposure to diffused daylight and air at room-temperature. Solutions of XII in pentane, ether or dichloromethane turned gradually to yellow on standing at 0 °C. TLC examination reveals that the product is a complex mixture. XII could be kept with slight decomposition at −78 °C in a diluted dichloromethane solution or crystalline state. XII gave poor elemental analysis and it would seem that the instability of XII is to blame.

Found: C, 89.92; H, 9.32%. Calcd for $C_{38}H_{46}$: C, 90.78; H, 9.22%.

Catalytic Hydrogenation of XII. A cold solution of XII (46 mg) in ethyl acetate (10 ml) was added at −20 °C to a mixture of acetic acid (20 ml) and ethyl acetate (10 ml) containing platinum catalyst (200 mg of platinum oxide was prereduced). The mixture was stirred under hydrogen atmosphere at −15——20 °C for 3 h. After the mixture had been stirred overnight at room temperature, the catalyst was removed by filtration. The filtrate was mixed with ether and washed successively with water, saturated sodium hydrogencarbonate solution and saturated brine, dried ($MgSO_4$), and the solvent was removed under reduced pressure. Yellow oily residue, which crystallized on standing, was chromatographed on alumina, and eluted with pentane to give tetra-*t*-butylcyclodocosane: 42 mg, 86%; Colorless crystals (from ethyl acetate–methanol); mp 97—101 °C; MS: *m/e* 532 (M^+), 477 (M−57), 57 (base peak); IR (CCl_4): 2940 s, 2860 s, 1476 m, 1393 w, 1365 m cm^{-1}; NMR (CCl_4): 8.32 (m, CH_2, −CH=), 9.15 (s, CH_3).

Found: C, 85.81; H, 14.36%. Calcd for $C_{38}H_{76}$: C, 85.63; H, 14.37%.

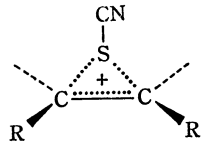
Pseudohalogen Chemistry. III.[1] Orientation of Heterolytic Addition of Thiocyanogen Chloride to Some Unsymmetrical Alkenes

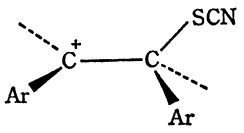
Robert G. Guy* and Ian Pearson
School of Natural Sciences, The Hatfield Polytechnic, P.O. Box 109, Hatfield, Hertfordshire, England
(Received January 26, 1976)

Thiocyanogen chloride reacts with various unsymmetrical alkenes, cycloalkenes, and α-arylalkenes in the presence of a radical inhibitor in acetic acid in the dark at 25 °C to yield α-chloro-β-thiocyanates, α-acetoxy-β-thiocyanates, α-hydroxy-β-thiocyanates, vinylic thiocyanates or allylic isothiocyanates in various combinations. The additions to the α-arylalkenes are regiospecific, yielding the Markownikov-orientated products, but the regiospecificity of the additions to the aliphatic alkenes depends on the structure of the alkene. The orientation of addition is discussed in terms of open carbonium ions, *e.g.* **17**, for the α-arylalkenes and cyano-sulfonium ions, *e.g.* **18**, for the aliphatic alkenes.

In Parts I[2] and II,[1] it was shown that thiocyanogen chloride, ClSCN, reacts readiiy at 25 °C with symmetrical alkenes, cycloalkenes and α-arylalkenes, *e.g.* *cis*- and *trans*-2-butene, *trans*-Δ^2-octalin, *cis*- and *trans*-stilbene, and acenaphthylene, in the presence of a radical inhibitor in acetic acid in the dark, to yield α-chloro-β-thiocyanates and α-acetoxy-β-thiocyanates. A heterolytic mechanism involving a two-step, kinetically controlled addition was postulated. For the aliphatic alkenes, the formation of a symmetrical cyanosulfonium ion, *e.g.* **1**, was proposed to account for the *trans*-stereospecific additions observed;[2] for the α-arylalkenes, the formation of an open carbonium ion, *e.g.* **2**, which exists as an ion-pair, and steric control of reaction by the thiocyanato group of the carbonium ion were proposed to account for the observed *trans*- stereoselectivity.[1]



1



2

Here we describe the orientation of addition of thiocyanogen chloride under heterolytic conditions in acetic acid to some unsymmetrical alkenes, cycloalkenes, and α-arylalkenes.

Results

The alkenes investigated, reaction times, products, and yields are recorded in the Table 1. Constitutionally different products of the reactions were readily separated by column chromatography on silica gel, but regioisomers and stereoisomers were not completely resolved, as indicated by TLC and by IR and ^{1}H NMR spectroscopy. Structural assignments were made as before[1,2] using published IR and NMR data,[1-6] and isomer ratios were determined from the integral traces of appropriate absorption bands in the ^{1}H NMR spectra of the mixtures (see Experimental section for details).

Control experiments showed that the products listed in the Table 1 were stable under the conditions used in the reactions. No reaction occurred with *trans*-cinnamic acid, *trans*-crotonic acid, methyl *trans*-cinnamate, methyl acrylate, vinyl chloride, vinylidene chloride, trichloroethylene or vinyl bromide during 48—164 h. No isomerisation of the alkenes was observed.

Discussion

The heterolytic addition of thiocyanogen chloride, which is polarised in the manner Cl(δ−)–SCN(δ+)[7], to an unsymmetrical alkene RCH=CH_2 (R=alkyl or aryl) may yield the Markownikov-orientated adduct RCHClCH_2SCN and/or the regioisomer RCH(SCN)-CH_2Cl.

α-Arylalkenes. The data for the α-arylalkenes examined show that the addition reaction is regiospecific, yielding the Markownikov-orientated products **3**—**6** and **8** exclusively. Other data, *e.g.* the *trans*-stereoselectivity of the addition to indene (see products **4** and **5**), and the low chlorothiocyanate : acetoxythiocyanate ratios observed for the additions to styrene and indene (see Table 1) resemble those obtained for the corresponding additions to symmetrical α-arylalkenes.[1] Consequently, a similar mechanism is postulated, *i.e.* a two-step, kinetically controlled, electrophilic reaction in which the first step is the formation, as an ion-pair, of the more stable of the two possible open thiocyanato-carbonium ions, *e.g.* **17**, due to the stabilising effect of the α-aryl group. Nucleophilic attack on **17** by chloride ions or acetic acid solvent molecules, and steric control of reaction by the thiocyanato group, leads to the observed α-chloro-β-thiocyanates and α-acetoxy-β-thiocyanates which, in the case of 1,1-diphenylethylene and triphenylethylene, are readily hydrolysed to the corresponding α-hydroxy-β-thiocyanates **6** and **8** during the aqueous work-up procedure. Concomitant loss of a β-proton from **17** leads to the observed substitution products, *i.e.*, the vinyl thiocyanates **7** and **9** (*cf.* the formation of vinyl sulfides in the corresponding additions of 2,4-dinitrobenzenesulfenyl chloride to α-arylalkenes).[15] This substitution reaction becomes progressively more important as the number of stabilising aryl groups on the vinylic product increases (*cf.* the products from styrene, 1,1-diphenylethylene and triphenylethylene).

a) Time for 100% reaction as indicated by titration. b) Chlorothiocyanate: acetoxythiocyanate ratio. c) Could not be determined due to hydrolysis (see text). d) Partial structure only.

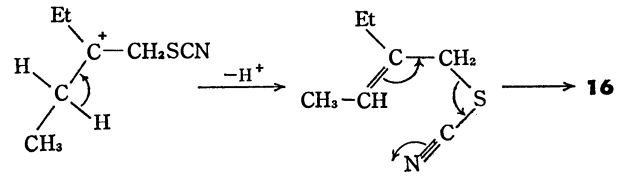
Aliphatic Alkenes. The data for the aliphatic alkenes examined show that the regiospecificity of the addition reaction varies with the structure of the alkene and the nature of the nucleophile (see products **10**—**15**). Since other data, *e.g.* the stereospecific *trans*-addition to 4-*t*-butylcyclohexene, 4-methylcyclohexene, and 5α-cholest-2-ene (see products **12**—**14**), and the high chlorothiocyanate : acetoxythiocyanate ratios observed for these alkenes (see Table 1) resemble those obtained for the corresponding additions to symmetrical alkenes and cycloalkenes,[2] a similar mechanism, but with an unsymmetrical cyano-sulfonium ion intermediate, *e.g.* **18**, is postulated.

For the terminal alkenes, propene and 1-hexene, the electron-donating alkyl substituent in **18** (R= Me, *n*-Bu) allows a greater share of the positive charge to be available at C_α than at C_β, thus permitting preferential nucleophilic attack by chloride ion at C_α and formation of the Markownikov-orientated products **10a** and **11a**. Similar non-regiospecificity and isomer ratios have been observed in the corresponding additions of bromine chloride, iodine chloride, and 2,4-dinitrobenzenesulfenyl chloride.[15] The exclusive formation of the Markownikov-orientated acetoxythiocyanates **10c** and **11c** in these cases may be due to acetic acid being a weaker nucleophile than chloride ion, and thus more selective in its attack. Similar effects have been noted in additions of sulfenyl halides to alkenes.[8]

In the cases of 4-*t*-butyl- and 4-methyl-cyclohexene, the equatorial *t*-butyl and methyl groups are too remote from the reaction centre (a) to affect the ease with which the episulfonium bridge is formed on either side of the ring, and (b) to make the bridge significantly asymmetric. Consequently diaxial ring-opening, in the manner described for Δ^2-octalin and cyclohexene,[2] can occur with equal ease at C_α and C_β leading in each case to equal amounts of regioisomers (see products **12** and **14**). Similar results have been obtained in the heterolytic addition of bromine chloride to these alkenes.[9] For 5α-cholest-2-ene, steric shielding of the β-side of the molecule by the axial C_{10} methyl group leads to exclusive formation of the 2α, 3α-sulfonium ion which, on diaxial ring opening at C_2, leads to the observed 2β-chloro-3α-thiocyanate (**13a**) and 2β-acetoxy-3α-thiocyanate (**13b**). Similar regiospecificity and stereospecificity have been noted in the heterolytic addition of iodine azide[10] and iodine isocyanate[11] to this alkene.

The disubstituted terminal alkene, 2-ethylbut-1-ene,

differs from the previous alkenes in giving (a) the Markownikov-orientated adducts **15a** and **15b** exclusively (*cf.* the exclusive Markownikov addition of iodine isocyanate to 2-methylpropene)[11] and (b) the unsaturated isothiocyanate **16**. Furthermore, the chlorothiocyanate : acetoxythiocyanate ratio (see Table 1) is in the range shown by the α-arylalkenes rather than that shown by the aliphatic alkenes. It is suggested that this alkene reacts *via* the open carbonium ion **19** rather than a cyano-sulfonium ion, due to the second ethyl group conferring stability comparable to that of a single phenyl group. Concomitant proton loss from an ethyl group of the carbonium ion (*cf.* the α-arylalkenes), followed by allylic rearrangement,[12] readily accounts for the formation of the isothiocyanate **16** as shown below.



19

Reactivity of Thiocyanogen Chloride. The presence of one electron-withdrawing group deactivates the double bond sufficiently to prevent addition of thiocyanogen chloride to these alkenes. This pseudohalogen chloride is therefore comparable in reactivity to the arenesulfenyl chlorides (ArSCl), but less reactive than iodine chloride and bromine chloride.[15]

Experimental

Alkenes. 4-*t*-Butylcyclohexene (bp 64—65 °C/15 mmHg, n_D^{25} 1.4567) was prepared by dehydration of 4-*t*-butylcyclohexanol with potassium hydrogensulfate. 5α-Cholest-2-ene (mp 74—75 °C) was prepared as described.[13] The other alkenes used were commercial samples purified until their physical constants agreed with those recorded in the literature.

General Procedure. This has been described in Parts I[2] and II.[1]

Propene. Propene gave (a) a mixture of 2-chloro-1-thiocyanatopropane (**10a**) and 1-chloro-2-thiocyanatopropane (**10b**) as a colourless liquid; bp 35—37 °C/0.1 mmHg; n_D^{22} 1.5010; ν 2165(SCN)cm^{-1}; τ (in CCl_4) 5.74 (sext, *J* 6.5 Hz, CHCl), 6.08 to 6.63 (m, CHSCN and CH_2Cl), 6.75 (d, *J* 6.5 Hz, CH_2SCN), 8.30 (d, *J* 6.5 Hz, CH_3CHCl), 8.40 (d, *J* 6.5 Hz, CH_3CHSCN) (Found: C, 35.2; H, 4.7; N, 10.25%. Calcd for C_4H_6ClNS: C, 35.45; H, 4.45; N, 10.35%), and (b) 2-*acetoxy*-1-*thiocyanatopropane* (**10c**) as a colourless liquid; bp 56—57 °C/0.1 mmHg; n_D^{22} 1.4700; ν 2165(SCN), 1740 (C=O) cm^{-1}; τ (in CCl_4) 4.86 (1H, p of d, *J* 6.5 and 4.5 Hz, CHOAc), 6.87 (1H, d, *J* 4.5 Hz, one H of CH_2SCN), 6.90 (1H, d, *J* 6.5 Hz, second H of CH_2SCN), 7.93 (3H, s, $OCOCH_3$), 8.61 (3H, d, *J* 6.5 Hz, CH_3) (Found: C, 45.15; H, 5.8; N, 8.9%. $C_6H_9NO_2S$ requires C, 45.3; H, 5.7; N, 8.8%). The isomer ratio for the mixture of chlorothiocyanates was determined from the integral traces of the CHX and CH_2X (X=Cl, SCN) proton signals.

1-Hexene. 1-Hexene gave (a) a mixture of 2-chloro-1-thiocyanatohexane (**11a**) and 1-chloro-2-thiocyanatohexane (**11b**) as a colourless liquid; bp 65—67 °C/0.05 mmHg n_D^{25} 1.4891; ν 2165(SCN)cm^{-1}; τ (in $CDCl_3$) 5.84 (p, *J* 6 Hz, CHCl), 6.08 to 6.55 (m, CHSCN and CH_2Cl), 6.69 (d, *J* 6 Hz, CH_2SCN), 7.80 to 9.30 (m, C_4H_9) (Found: C, 47.6; H, 7.0; Cl, 19.85; N, 7.9%. Calcd for $C_7H_{12}ClNS$: C, 47.3; H, 6.8; Cl, 19.95; N, 7.9%), and (b) 2-*acetoxy*-1-*thiocyanatohexane* (**11c**) as a colourless liquid; bp 76 °C/0.05 mmHg; n_D^{25} 1.4684; ν 2165 (SCN), 1740 (C=O)cm^{-1}; τ (in $CDCl_3$) 4.85 (1H, q of d, *J* 6.5 and 4.5 Hz, CHOAc), 6.78 (1H, d, *J* 4.5 Hz, one H of CH_2SCN), 6.85 (1H, d, *J* 6.5 Hz, second H of CH_2SCN), 7.89 (3H, s, $OCOCH_3$), 7.95 to 9.30 (9H, m, C_4H_9) (Found: C, 53.3; H, 7.45; N, 7.3; S, 15.8%. $C_9H_{15}NO_2S$ requires C, 53.7; H, 7.5; N, 6.95; S, 15.95%). The isomer ratio for the mixture of chlorothiocyanates was determined as described for propene.

4-t-Butylcyclohexene. 4-*t*-Butylcyclohexene gave (a) a mixture of 2*ax*-chloro-1*ax*-thiocyanate-4*eq*-*t*-butylcyclohexane (**12a**) and 1*ax*-chloro-2*ax*-thiocyanato-4*eq*-*t*-butylcyclohexane (**12b**) as a pale yellow liquid; bp 78—79 °C/0.05 mmHg; n_D^{25} 1.5132; ν 2165(SCN)cm^{-1}; τ (in $CDCl_3$ at 100 MHz) 5.44 and 5.77 (each 1H, distorted q, band-width 9Hz, *J*~3 Hz, CHCl), 5.96 and 6.10 (each 1H, distorted q, band-width 9 Hz, *J*~3 Hz, CHSCN), 7.50 to 9.00 (14 H, m, CH_2 and $CHBu^t$), 9.10 (18H, s, C_3H_9) (Found: C, 57.3; H, 7.7; Cl, 15.0; N, 5.9%. Calcd for $C_{11}H_{18}ClNS$: C, 57.0; H, 7.85; Cl, 15.3; N, 6.05%), and (b) a mixture of 2*ax*-acetoxy-1*ax*-thiocyanato-4*eq*-*t*-butylcyclohexane (**12c**) and 1*ax*-acetoxy-2*ax*-thiocyanato-4*eq*-*t*-butylcyclohexane (**12d**) as a colourless liquid; bp 96 °C/0.05 mmHg n_D^{25} 1.4195; ν 2165 (SCN), 1740 (C=O)cm^{-1}; τ (in $CDCl_3$ at 100 MHz) 4.87 and 5.00 (each 1H, distorted q, band-width 10 Hz, *J*~3 Hz, CHOAc), 6.12 and 6.25 (each 1H, distorted q, band-width 10 Hz, *J*~3 Hz, CHSCN), 7.50 to 9.00 (14H, m, CH_2 and $CHBu^t$), 9.10 (18H, s, C_3H_9) (Found: C, 60.9; H, 8.25; N, 5.6; S, 12.65%. Calcd for $C_{13}H_{21}NO_2S$: C, 61.15; H, 8.3; N, 5.5; S, 12.55%). The isomer ratio for each mixture was determined from the integral traces of the CHX (X=SCN, Cl or OAc) proton signals.

5α-Cholest-2-ene. 5α-Cholest-2-ene gave (a) 2β-*chloro*-3α-*thiocyanato*-5α-*cholestane* (**13a**) as colourless needles; mp 90—92 °C after crystallization from methanol; ν 2165(SCN) cm^{-1}; τ (in $CDCl_3$ at 100 MHZ) 5.49 (1H, distorted q, band-width 9 Hz, *J*~3 Hz, CHCl) 5.95 (1H, distorted q, band-width 9 Hz, *J*~3 Hz, CHSCN), 7.50 to 9.20 (44H, m, residual H) (Found: C, 72.2; H, 10.3; N, 3.25%. $C_{28}H_{46}ClNS$ requires C, 72.45; H, 10.0; N, 3.0%), and (b) 2β-acetoxy-3α-thiocyanato-5α-cholrestane (**13b**) as colourless needles, mp 110—112 °C after crystallization from methanol, identical in physical and spectral properties with the compound described by Takeda *et al.*[4] (Found: C, 73.6; H, 10.25; N, 2.8%. Calcd for $C_{30}H_{49}NO_2S$: C, 73.9; H, 10.15; N, 2.85%).

The effect of a 3α- and a 2β-thiocyanato group on the chemical shift of a 2α- and a 3β-CHCl proton respectively was calculated using a chemical shift value of τ 5.55 for the equatorial 2α- and 3β-CHCl protons,[14] and shift values of −0.03 and −0.13 τ for the 3α- and the 2β-thiocyanato groups respectively.[5]

4-Methylcyclohexene. 4-Methylcyclohexene gave (a) a mixture of 4-methyl-*trans*-1-chloro-2-thiocyanatocyclohexane (**14b**) and 4-methyl-*trans*-2-chloro-1-thiocyanatocyclohexane (**14a**) as a colourless liquid; bp 60—62 °C/0.05 mmHg; n_D^{20} 1.5224; ν 2165(SCN)cm^{-1}; τ (in $CDCl_3$ at 100 MHz) 5.45 to 5.90 (1H, 10-line m, band-width 40 Hz, overlapping CHCl), 6.10 to 6.50 (1H, 9-line m, band-width 37 Hz, overlapping CHSCN), 7.50 to 9.10 (10 H, m, residual H) (Found: C, 50.6; H, 6.55; N, 7.35%. Calcd for $C_8H_{12}ClNS$: C, 50.65; H, 6.4; N, 7.4%), and (b) a mixture of 4-methyl-

trans-1-acetoxy-2-thiocyanatocyclohexane (**14d**) and 4-methyl-*trans*-2-acetoxy-1-thiocyanatocyclohexane (**14c**) as a colourless liquid; bp 76—78 °C/0.05 mmHg; n_D^{20} 1.4960; ν 2165(SCN), 1740 (C=O) cm^{-1}; τ (in $CDCl_3$ at 100 MHz) 4.80 to 5.30 (1H, 13-line m, band-width 44 Hz, overlapping CHOAc), 6.25 to 6.65 (1H, 14-line m, band-width 35 Hz, overlapping CHSCN), 7.50 to 9.20 (10H, m, residual H) (Found: C, 56.65; H, 7.25; N, 6.35%. Calcd for $C_{10}H_{15}NO_2S$: C, 56.35; H, 7.1; N, 6.55%). Due to overlapping, the isomer ratio for each mixture could not be determined from the integral traces of the CHX (X=SCN, Cl or OAc) proton signals; the symmetry of these signals, however, indicated that the positional isomers were present in equal amounts in both cases.

2-Ethylbut-1-ene. 2-Ethylbut-1-ene gave, in order of elution from the column, (a) *2-ethyl-3-isothiocyanatobut-1-ene* (**16**) as a colourless liquid; bp 30 °C/0.1 mmHg; n_D^{21} 1.5112; ν 3100 (=C–H), 2200 to 1980(NCS), 1640(C=C) cm^{-1}; τ (in CCl_4), 4.91 and 5.08 (each 1H, d, J 1.5 Hz, vinyl H), 5.72 (1H, q, J 7 Hz, CHNCS), 7.87 (2H, q, J 7 Hz, CH_2), 8.51 (3H, d, J 7 Hz, CH_3CHNCS), 8.87 (3H, t, J 7 Hz, CH_3CH_2) (Found: C, 59.7; H, 8.0; N, 9.55; S, 22.25%. $C_7H_{11}NS$ requires C, 59.55; H, 7.85; N, 9.9; S, 22.65%), (b) *2-chloro-2-ethyl-1-thiocyanatobutane* (**15a**) as a colourless liquid; bp 50 °C/0.1 mmHg; n_D^{21} 1.4990; ν 2165(SCN) cm^{-1}; τ (in CCl_4) 6.61 (2H, s, CH_2SCN), 8.19 (4H, q, J 7 Hz, CH_2), 8.94 (6H, t, J 7 Hz, CH_3) (Found: C, 47,3; H, 6.8; N, 7.65%. $C_7H_{12}ClNS$ requires C, 47.3; H, 6.8; N, 7.9%), and (c) *2-acetoxy-2-ethyl-1-thiocyanatobutane* (**15b**) as a colourless liquid; bp 64 °C/0.1 mmHg; n_D^{23} 1.4775; ν 2165 (SCN), 1740 (C=O) cm^{-1}; τ (in CCl_4) 6.50 (2H, s, CH_2SCN), 8.01 (3H, s, $OCOCH_3$), 8.08 (4H, q, J 7 Hz, CH_2), 9.12 (6H, t, J 7 Hz, CH_3) (Found:,C, 53.9; H, 7.25; N, 6.8%. $C_9H_{15}NO_2S$ requires C, 53.7; H, 7.5; N, 6.95%).

Styrene. Styrene gave (a) *1-chloro-1-phenyl-2-thiocyanatoethane* (**3a**) as a colourless liquid; bp 79 °C/0.05 mmHg; n_D^{23} 1.5802; ν 2165(SCN) cm^{-1}; τ (in $CDCl_3$) 2.61 (5H, s, aromatic H), 4.90 (1H, t, J 7.5 Hz, CHCl), 6.50 (2H, d, J 7.5 Hz, CH_2SCN) (Found: C, 54.7; H, 4.25; Cl, 17.65; N, 7.2; S, 16.1%. C_9H_8ClNS requires C, 54.7; H, 4.1; Cl, 17.95; N, 7.1; S, 16.15%), and (b) 1-*acetoxy*-1-*phenyl*-2-*thiocyanatoethane* (**3b**) as a colourless liquid; bp 107 °C/0.05 mmHg; n_D^{20} 1.5412; ν 2165(SCN), 1740(C=O) cm^{-1}; τ (in $CDCl_3$) 2.63 (5H, s, aromatic H), 3.96 (1H, t, J 7 Hz, CHOAc), 6.67 (2H, d, J 7 Hz, CH_2SCN), 7.85 (3H, s, $OCOCH_3$) (Found: C, 59.5; H, 5.25; N, 6.25%. $C_{11}H_{11}NO_2S$ requires C, 59.7; H, 5.0; N, 6.35%).

1-Chloro-1-phenyl-2-thiocyanatoethane (1 g) was heated under reflux with triethylamine (1 g) in toluene (25 ml) for 12 h. After cooling triethylamine hydrochloride was filtered off, and the filtrate was washed with dilute sulfuric acid and then water. Drying ($MgSO_4$) and removal of solvent gave *trans-β-thiocyanatostyrene* (0.7 g, 86%) as a colourless liquid; bp 89 °C/0.2 mmHg, n_D^{24} 1.6178; ν 2170(SCN) cm^{-1}; τ (in $CDCl_3$) 2.70 (5H, s, aromatic H), 3.06 (1H, d, J 15 Hz, *trans*-C=CHSCN), 3.60 (1H, d, J 15 Hz, *trans*-C=CHPh) (Found: C, 67.1; H, 4.25; N, 8.75%. C_9H_7NS requires C, 67.05; H, 4.4; N, 8.7%)

Indene. Indene gave (a) a mixture of *cis*- and *trans*-1-chloro-2-thiocyanatoindane (**4a** and **5a**) as a colourless liquid; bp 105—107 °C/0.05 mmHg; n_D^{27} 1.6015; ν 2165 (SCN) cm^{-1}; τ (in CCl_4) 2.50 to 3.10 (m, aromatic H) 4.63 (d, J 5.5 Hz, *cis*-CHCl), 4.73 (d, J 4.5 Hz, *trans*-CHCl), 5.65 to 6.50 (m, *cis*- and *trans*-CHSCN and one H of *trans*-CH_2), 6.65 (d, J 7.5 Hz, *cis*-CH_2), 7.00 (d of d, J 17 Hz and 5 Hz, second H of *trans*-CH_2) (Found: C, 57.4; H, 4.05; Cl, 16.5; N, 6.65%. Calcd for $C_{10}H_8ClNS$: C, 57.25; H, 3.85; Cl, 16.9; N, 6.7%), and (b) a mixture of *cis*- and *trans*-1-acetoxy-2-thiocyanatoindane (**4b** and **5b**) as a colourless liquid; bp 123—125 °C/0.05 mmHg; n_D^{25} 1.5585; ν 2165(SCN), 1740 (C=O); τ (in CCl_4) 2.60—2.90 (m, aromatic H), 3.82 (d, J 5 Hz, coincidental *cis*- and *trans*-CHOAc), 5.65 to 6.20 (m, *cis*- and *trans*-CHSCN), 6.40 (d of d, J 15.5 Hz and 7.5 Hz, one H of *trans*-CH_2): 6.60 (d, J 7 Hz, *cis*-CH_2), 7.00 (d of d, J 15.5 Hz and 6.5 Hz, second H of *trans*-CH_2), 7.96 (s, $OCOCH_3$) (Found: C, 61.45; H, 4.9; N, 6.25%. Calcd for $C_{12}H_{11}NO_2S$: C, 61.80; H, 4.75; N, 6.0%). The isomer ratio for each mixture was determined from the integral traces of the *cis*-CH_2 and the high-field *trans*-CH_2 proton signals. The *cis*- and *trans*-CHX (X=Cl, OAc) proton signals were more clearly resolved in dimethyl sulfoxide solvent [τ 4.23 (d, J 5.5 Hz, *cis*-CHCl), 4.37 (d, J 4.5 Hz, *trans*-CHCl), 3.70 (d, J 5.5 Hz, *cis*-CHOAc), 3.75 (d, J 5 Hz, *trans*-CHOAc)].

1,1-Diphenylethylene. 1,1-Diphenylethylene gave (a) 1,1-diphenyl-2-thiocyanatoethylene (**2**) as a waxy solid; ν 2165 (SCN), 1600(C=C) cm^{-1}; τ (in CCl_4) 2.40 to 2.85 (10H, m, aromatic H), 3.47 (1H, s, CHSCN). This product, on treatment with lithium aluminium hydride and then 2,4-dinitrochlorobenzene,[7] gave 1,1-*diphenyl*-2-*(2,4-dinitrophenylthio)ethylene* as yellow needles; mp 138—141 °C after crystallisation from acetic acid (Found: C, 63.1; H, 3.7; N, 7.45%. $C_{20}H_{14}N_2O_4S$ requires C, 63.5; H, 3.75; N, 7.4%), and (b) 1-*hydroxy*-1,1-*diphenyl*-2-*thiocyanatoethane* (**6**) as colourless needles; mp 99—100 °C after crystallisation from benzene–light petroleum; ν 2165 (SCN), 3350(OH) cm^{-1}; τ (in CCl_4) 2.62 (10H, s, aromatic H), 6.11 (2H, s, CH_2SCN), 7.12 (1H, s, OH); (Found: C, 70.8, H, 5.1; N, 5.5%. $C_{15}H_{13}NOS$ requires C, 70.6; H, 5.15; N, 5.5%).

Triphenylethylene. Triphenylethylene gave (a) *triphenylthiocyanatoethylene* (**9**) as colourless plates; mp 103—104 °C after crystallisation from carbon tetrachloride; ν 2165(SCN), 1530(C=C) cm^{-1}; τ (in $CDCl_3$) 2.60 to 2.98 (m, phenyl H) (Found: C, 80.5; H, 4.8; N, 4.4. $C_{21}N_{15}NS$ requires C, 80.5; H, 4.85; N, 4.45%), and (b) 1-*hydroxy*-1,1,2-*triphenyl*-2-*thiocyanatoethane* (**8**) as colourless needles; mp 165—168 °C after crystallisation from carbon tetrachloride; ν 2165(SCN), 3350(OH) cm^{-1}; τ (in $CDCl_3$) 2.65 to 3.05 (15H, m, aromatic H), 4.49 (1H, s, CHSCN), 7.04 (1H, s, OH) (Found: C, 76.5; H, 5.1, N, 4.1%. $C_{21}H_{17}NOS$ requires C, 76.1; H, 5.15; N, 4.25%).

Control Experiments. These were carried out as described in Part I.[2]

Unreactive Alkenes. *trans*-Cinnamic acid, *trans*-crotonic acid, and methyl *trans*-cinnamate were recovered quantitively from the reaction mixtures after 48—140 h, and identified by their IR spectra. Methyl acrylate, vinyl chloride, vinylidene chloride, trichloroethylene, and vinyl bromide yielded no product after 48—126 h, but were not recovered due to their loss by volatilisation during the isolation procedure.

Spectra. IR spectra were recorded with a Perkin-Elmer 237 spectrometer, and were taken for films of liquid products and for Nujol mulls of solid products. ^1H NMR spectra were recorded with Varian A60A and HA100 spectrometers, using tetramethylsilane as internal standard. In the NMR data given above, s=singlet, d=doublet t=triplet, q=quartet, p=pentet, sext=sextet, m=multiplet; band-widths are separations of outer lines.[3]

We thank Hertfordshire County Council for the award of a Research Assistantship to one of us (I.P.), and the Chemical Society for the award of a Research Grant.

Reflection Spectra of Acenaphthene Crystals

Masashi TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received February 10, 1976)

Synopsis. The reflection spectra have been measured for acenaphthene crystals. The excited states of the acenaphthene molecule are similar to those of the naphthalene molecule; the lower $\pi\rightarrow\pi^*$ excited states are observed at 31100 (α), 32600 (p), 43700 (β), and 47400 (β') cm^{-1}. In the reflection spectra of the crystal, the α and β states polarized along the b axis are observed at 30900 and 41800 cm^{-1}, respectively. The p and β' states are found at 32100 and 44000 cm^{-1} in the a axis spectrum and at 31400 and 45000 cm^{-1} in the c axis spectrum.

Four lower $\pi\rightarrow\pi^*$ excited state (α, p, β, and β' bands) of the naphthalene molecule were found to be located at 32000, 34500, 45500, and 60000 cm^{-1} respectively by the study of UV spectra in solution. The α and β bands are reported to be polarized along the long molecular axis (B_{2u} symmetry) and the p and β' along the short axis (B_{1u} symmetry).

McClure[1] succeeded in obtaining the polarization direction of the first $\pi\rightarrow\pi^*$ state (α band) with the mixed crystal of naphthalene in durene. Bree[2] observed the α, p, and β' bands of acenaphthene crystal by the polarized absorption method. However, he could not find the intense β band, although the dipole-dipole approximation predicted this band would lie at 58730 and 48230 cm^{-1}, with all the intensity effectively concentrated in the higher energy component.

We have determined the band position of the β state by measuring the reflection spectra of acenaphthene crystal and have theoretically explained the difference between the observed and predicted values.

Experimental

Single crystals of acenaphthene were grown by slow evaporation from ethyl acetate solution. The crystals showed well-developed (010), (100), (101), and (111) faces. These faces were identified by a morphological examination.

Reflection spectra at normal incidence were measured over a wavelength range 650—192 nm with a reflection spectrophotometer made in our laboratory. Reflection spectra for the (010) and (100) faces are shown in Fig. 1 and the corresponding absorption spectra obtained by the Kramers-Kronig transformation[3] are shown in Fig. 2.

Results and Discussion

The acenaphthene crystal has four molecules in an orthorhombic unit cell of space group $Pcm2_1$ (C_{2v}^2)[4] in which a molecular and a crystallographic mirror plane coincide. Therefore, the B_{1u} states (p and β' bands) are polarized in the ac plane, while the B_{2u} states (α and β bands) appear only in the b polarization.

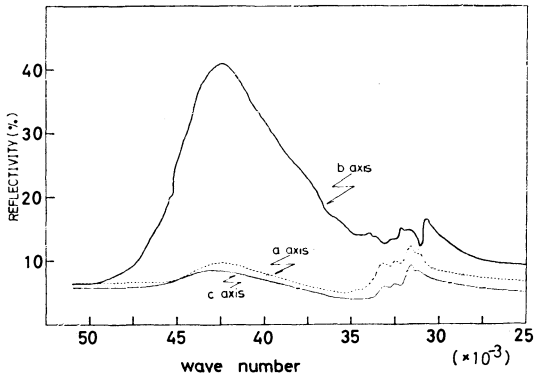

Fig. 1. The reflection spectra of the acenaphthene crystal on the ac and bc planes.

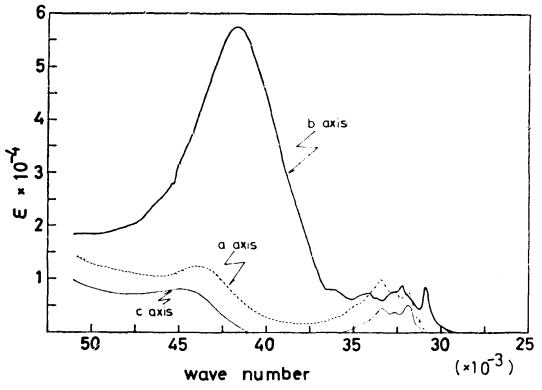

Fig. 2. The absorption spectra obtained by the Kramers-Kronig transformation of the reflection spectra of the acenaphthene crystal.

Two bands in the b axis spectrum are observed, at 30900 and 41800 cm^{-1}. The weak band at 30900 cm^{-1} corresponds to the α band at 31100 cm^{-1} in solution and is assigned to the α state of B_{2u} symmetry in the free molecule. Bree[2] observed this band at 31020 cm^{-1}. However, the intense band at 41800 cm^{-1} was not observed by Bree and can be obtained only by the reflection method. This band corresponds to the β band at 43700 cm^{-1} in solution and is assigned to the B_{2u} state of the molecule. The spectra for the ac plane has two bands. The one band in the region of 3200 cm^{-1} has a vibronic structure and the other, at about 45000 cm^{-1}, is broad; these bands correspond to the p and β' states in the free molecule, respectively. The band positions of these bands are consistent with those obtained by Bree.

In Table 1 are given the calculated exciton state energies and oscillator strengths, obtained by the CI[5]

TABLE 1. CALCULATED AND OBSERVED TRANSITION ENERGIES (E IN 1000 cm^{-1}) AND OSCILLATOR STRENGTHS (f) OF EXCITON STATES OF THE ACENAPHTHENE CRYSTAL

		p	35.4	(0.05)	34.7	(0.25)	34.7	(0.26)		
		β'	49.4	(0.68)	48.8	(0.46)	48.9	(0.40)	44.0	(0.4)
		β'	50.6	(0.54)	49.8	(0.56)	49.9	(0.63)		
B_2	b axis	α[a]	34.1	(0)	34.0	(0)	34.0	(0)	30.9	(0.18)
		β	49.0	(6.34)	46.6	(4.39)	46.4	(4.39)	41.8	(2.0)
		β	65.2	(0)	57.0	(0)	57.0	(0)		

a) The α band in the B_2 exciton state is doublet. b) Calculation by the exciton CI method[4] when the inner zone radius is 50 Å. c) Calculations by the exciton RPA method[5] where the inner zone radii are 50 and 100 Å, respectively.

and RPA[6] methods; where the intermolecular interactions were estimated for two inner zone radii, 50 and 100 Å. The calculated values for the two inner zone radii are nearly equal; hence, convergence of the summation of intermolecular interactions has been achieved. Table 1 shows that the exciton state energies and oscillator strengths decrease more and are closer to the observed values in the RPA method than in the CI method.

The intense β band was predicted to lie at 58700 cm^{-1} by Bree, while the observed value is 41800 cm^{-1}. Using the CI and RPA methods, this band was calculated to be located at 49000 and 46600 cm^{-1}, respectively. The difference between these three calculated values can be explained by the fact that the RPA method includes the polarization effect by taking account of the double excitation, by comparison with the CI and dipole-dipole approximations. That is, the polarization effect has a strong influence on the Davydov splitting and band shift of the intense band.

The other band system (α state) at 30900 cm^{-1} is theoretically forbidden, but seems to be allowed by the mixing of higher excited states than the states taken into account in this calculation. The p band at 32000 cm^{-1} is expected to arise from a short axis transition. The calculated exciton state energies are 34400 and 35200 cm^{-1} for the A_1 exciton state and 33700 and 34700 cm^{-1} for the B_1 exciton state; these are supported by the observed values. The measured polarization ratio (f^a/f^c) is 1.5, comparable to the calculated value of 1.7. The oscillator strengths of two p states in the B_1 exciton state show different values: (0.69/0.05) in the CI method and (0.21/0.26) in the RPA method. This can be explained by the difference in the CI and RPA methods of the mixing of the nearly degenerate exciton configurations belonging to crystallographically non-equivelent sites.

Dielectric Transition in a Solution of Linear Poly(vinyl acetate)

Satoru MASHIMO, Yasuo IWASA,* Akio CHIBA,* and Keniti HIGASI*

Department of Physics, Tokai University, Hiratsuka, Kanagawa 259-12

**School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160*

(Received March 10, 1976)

Synopsis. The dielectric constants and losses of linear poly(vinyl acetate) (PVAc) in carbon tetrachloride were measured at various temperatures and frequencies. The results provide proof that dielectric transition in solution occurs for PVAc, irrespective of its sources.

The interesting phenomenon of dielectric transition in solution was first discovered for poly(vinyl acetate) (PVAc) in toluene.[1] Later the same phenomenon was found also for PVAc in carbon tetrachloride,[2] poly(vinyl chloride) in dioxane[3] and poly(*p*-chlorostyrene) in carbon tetrachloride.[3] One interpretation[3] of this transition is that the transition indicates the change in conformation from globular chain molecules (lower temperature) to loosely coiled chain molecules (higher temperature). This new type of transition has also been discussed by several theoreticians, such as Ptitsyn *et al.*,[4] Lifshitz,[5] Edwards,[6] Domb,[7] and Saito.[8]

The purpose of this note is to clear up doubts regarding the polymer samples employed. The samples of PVAc and poly(vinyl chloride) used previously were all from commercial sources, and commercial PVAc is believed to have branched chains. A sample of linear PVAc chains was prepared for this work by the acetylation of linear poly(vinyl alcohol),[9] and its purity was checked by means of the infra-red absorption spectra. The viscosity-average molecular weight of the sample was 6.1×10^4. The carbon tetrachloride was dehydrated and distilled before use. The dielectric measurements[1-3] were carried out by the use of the apparatus described in previous reports.[2,3]

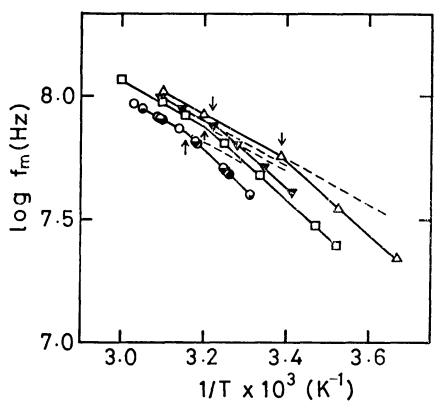

Fig. 1. Plot of $\log f_m$ against $1/T$ for PVAc in carbon tetrachloride.
△: 2.66 wt%, $\overline{M}_n=0.97\times10^4$, $\overline{M}_v=1.7\times10^4$;
▼: 1.93 wt%, $\overline{M}_n=3.0\times10^4$, $\overline{M}_v=4.3\times10^4$;
□: 2.68 wt%, linear PVAc, $\overline{M}_v=6.1\times10^4$;
●: 1.00 wt%, $\overline{M}_n=1.1\times10^5$, $\overline{M}_v=3.9\times10^5$;
○: 2.04 wt%; ◒: 3.20 wt%.

The results of the dielectric measurements are shown in Figs. 1 and 2, together with those for the commercial ones.[2,3] A dielectric transition is observed in the linear PVAc in carbon tetrachloride, too. The plot of $\log f_m$ against $1/T$ gives two straight lines. The transition temperatures (T_t) are obtained from the points at which two lines intersect. The apparent activation energy above T_t is calculated to be 4.2 kcal/mol, while it is 6.9 kcal/mol below T_t. These values

△: 40.0 and 50.0 °C; ▼: 1.93 wt%, $\overline{M}_n=3.0\times10^4$, 19.7 and 25.5 °C; ▽: 44.1 and 50.3 °C; ■: 2.68 wt% linear PVAc, 11.0 and 15.0 °C; □: 50.0 and 60.0 °C; ●: 3.20 wt%, $\overline{M}_n=1.1\times10^5$, 29.0 and 35.0 °C; ○: 50.0 and 55.0 °C.

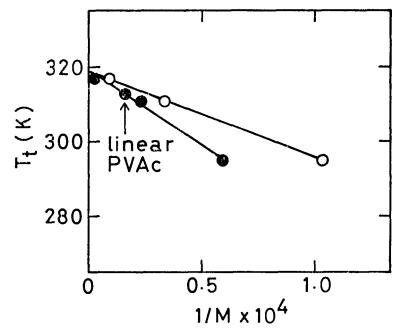

Fig. 3. Plot of T_t against the reciprocal of the molecular weight of PVAc. Open circles refer to the number-average molecular weight and closed circles the viscosity-average molecular weight.

are in complete agreement with those for the commercial PVAc. A slight change in the shape of the two loss curves at T_t is observed, and there is no difference in these curves with the sort of sample, *i.e.*, whether commercial and linear. The temperature, T_t, depends on the molecular weight of PVAc, as is shown in Fig. 3. In conclusion, the effects of the branched chains, and, possibly, of the source of the sample do not appear to play an important role in this kind of transition phenomenon.

Benzene Induced Shift for Some Organometallic 8-Quinolinolato Complexes: A New Criterion for the Interaction of Nitrogen with Metal

Yoshikane KAWASAKI

Department of Petroleum Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

(Received March 19, 1976)

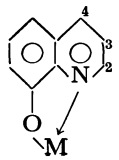
Synopsis. The benzene induced shift was measured for some organometallic 8-quinolinolato complexes. A large upfield shift (0.5—0.7 ppm) of the 2-proton of the 8-quinolinolato ligand was found in benzene when the nitrogen in the 8-quinolinolato ligand coordinated to the metal. But the shift was small (0—0.3 ppm) in the absence of nitrogen coordination.

The striking chemical shift difference of the proton resonance of molecules having polar sites caused by changing the solvent from an inert solvent such as carbon tetrachloride to benzene has been applied in many configurational studies[1-3] since the phenomenon was discovered by Bothner-By and Click[4] and Reeves and Schneider.[5] Various explanations have been put forward to interpret the phenomenon.[4,6-13] The phenomenon has been expressed by a large anisotropy of the benzene ring. Ronayne and Williams[8] have pointed out that the benzene induced shift, $\Delta=\delta'-\delta_{\text{benzene}}$ (δ' is the chemical shift of protons in inert solvents such as carbon tetrachloride, chloroform, cyclohexane, or in the pure liquid, and δ_{benzene} is the value in benzene), is positive for the protons in the neighborhood of the positively polarized sites of the molecule and negative for the protons near the negatively polarized sites. In fact, they have shown that in 4-methylpyridine, the 3-proton and the 4-methyl protons give positive Δ values and the 2-proton gives a negative Δ value. Ford and Hart[14] have shown that in tetraalkylammonium tetraalkylborates the alkyl groups of tetraalkylammonium cation give positive Δ values and the tetraalkylborate anion shows a negative Δ value.

In the present paper the benzene induced shift has been measured for some organometallic 8-quinolinolato complexes to study the coordination of the nitrogen in the 8-quinolinolato ligand to the metal.

Results and Discussion

As can be seen from Table 1, the 3- and 4-protons of the 8-quinolinolato ligand of 8-methoxyquinoline, 8-quinolinol, and all organometallic 8-quinolinolato complexes were found to show large positive Δ values. The Δ value of the 2-proton of 8-methoxyquinoline, in which the nitrogen is free from coordination or hydrogen bonding, was very small. Trimethyl(8-quinolinolato)-silane and -germane also gave rather small Δ values for the 2-proton. The value is almost the same as that of 8-quinolinol. These compounds have shown the absorption maximum at around 320 nm and, therefore, have been considered to have a non-chelated 8-quinolinolato ligand.[15] On the other hand, in the complexes with a chelated 8-quinolinolato ligand, such as trimethyl-(8-quinolinolato)tin, and in the protonated 8-methoxyquinoline, the Δ value of the 2-proton was positive and large. The amount of upfield shift is almost the same as those of the 3- and 4-portons. Other organometallic complexes with a chelated 8-quinolinolato ligand, which show the absorption maximum at about 350 nm, gave similar results. The Δ value of the 2-proton of the 8-quinolinolato ligand, therefore, may be used as a new criterion of coordination of nitrogen. The interaction of the lone pair of nitrogen in the 8-quinolinolato ligand with the metal may remove the negatively polarized charges from the nitrogen. The result leads to large positive Δ values of the 2-proton, in accordance with an empirical rule that Δ value is positive when the protons are in the neighborhood of a positively polarized site of a molecule.[7,8]



Meinema and Noltes[16] have reported that in trimethyl(8-quinolinolato)antimony chloride, the nitrogen in the 8-quinolinolato ligand does not coordinate to antimony, on the basis of the UV spectra of this complex. We[17] have, on the other hand, expected a weak interaction of nitrogen with antimony for the corresponding bromide. One of complications in these trimethyl(8-quinolinolato)antimony halides is that the UV spectra of these complexes depend on the concentration.[18] If the Δ value criterion can be applicable to these 8-quinolinolato complexes, the data in Table 1 indicate that these complexes belong to the complexes with the chelated 8-quinolinolato ligand.

In trimethyl(8-quinolinolato)antimony carboxylates, the chemical shift of the 2-proton appears at a rather low magnetic field, as compared with that of trimethyl-(8-quinolinolato)antimony halides and 8-quinolinol, although the values of the 3- and 4-protons are almost the same as other 8-quinolinolato complexes. The Δ values of the 2-proton of these trimethyl(8-quinolinolato)antimony carboxylates is small and in some cases negative. One of possible reasons for these results is that the magnetic anisotropy of the carbonyl group in the carboxylato ligand affects the intramolecular 2-proton.* In these complexes, the absorption maximum appears in the region between that of typically chelated complexes and that of non-chelated compounds.[18] Therefore, the coordination of nitrogen to antimony is probably weak, if present at all.

* The chemical shift of the 2-proton was not affected even if the concentration of these complexes was changed.

a) Value in parentheses is the Δ value. b) Chemical shift of the carboxylato group. c) 8-Methoxyquinoline. d) Ref. 17. e) 8-Methoxyquinoline in 0.1 ml CF_3COOH and 0.5 ml CH_2Cl_2 or C_6H_6. f) Obscured by other signals. g) Not measured. h) Ref. 19. i) Ref. 15. j) Ref. 20. k) Ref. 21. l) Ref. 16. m) Ref. 18.

Experimental

The UV spectra were recorded on a Hitachi model 124 spectrometer with 1 mm quartz cells. The PMR measurements were made with a JEOL JNM-PS-100 spectrometer operating at 100 MHz. The chemical shift (δ) was measured relative to tetramethylsilane as the internal standard. Solvents were purified by distillation.

We wish to express our hearty thanks to Professor Rokuro Okawara for his continuous encouragement throughout this study.

Studies of the Surface of Titanium Dioxide. III. The Electrical Conduction and the Hydrogen Uptake

Toru IWAKI and Masaji MIURA

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received April 1, 1976)

Synopsis. The changes in the electrical conductance and the hydrogen uptake of titanium dioxide were examined with the introduction of hydrogen at 250—500 °C. The former was found to approach the equilibrium rapidly, compared with the latter above 350 °C.

In a previous paper,[1] it has been suggested that hydrogen atoms adsorbed on the surface of titanium dioxide, during the hydrogen reduction, form hydroxyl groups before the weight of titanium dioxide begins to decrease. Adsorbed hydrogen atoms are well known to influence the electrical conductivity remarkably.[2] In the present study, simultaneous measurements of the electrical conductance and the hydrogen uptake were performed in order to clarify the initial stage of the hydrogen reduction by comparison with the previous results.[1]

Experimental

Materials. The rutile sample was prepared by the hydrolysis of titanium tetrachloride in an aqueous medium, followed by the calcination at 600 °C for 6 h in a stream of oxygen. The surface area obtained from the nitrogen adsorption at 77 K was 11.7 $m^2 g^{-1}$. The average grain size was about 1μ.[3] Hydrogen was purified by passing it through platinum asbestos and a liquid nitrogen trap.

Procedure. The sample was placed in contact with oxygen gas at 600 °C for 30 min and then outgassed at 500 °C and 10^{-5} Torr for 3 h. Hydrogen gas was introduced at temperatures between 250 and 500 °C. A liquid nitrogen trap was installed just before the sample in order to protect it from contamination due to organic substances[4] and to condense the water vapor produced by the hydrogen reduction of the sample. The dc-electrical conductance was measured on the following two kinds of samples. One was an unpressed sample, in which four platinum electrodes were buried, while the other was pressed at 8 t cm^{-2} into a pellet, both sides of which were covered with evaporated platinum films. The hydrogen uptake and electrical conductance were measured simultaneously for the unpressed sample, the former being determined volumetrically. No appreciable hydrogen uptake of the pressed sample could be detected because of an insufficient amount of the sample and probably also because of the slow reaction rate. All experiments were carried out in a static gas system.

Results and Discussion

The electrical conductance of the unpressed sample prior to the introduction of hydrogen ranged from 10^{-9} to 10^{-8} A V^{-1} between 250 and 500 °C. The obtained activation energy is 0.35 eV, indicating that the conduction electrons are provided from the impurity levels, which are composed of oxygen vacancies produced on the surface of titanium dioxide during the activation at 500 °C.[5] Figure 1 shows the change in the electrical conductance of the unpressed sample after the introduction of hydrogen. The electrical conductance increased greatly with a rise in the temperature. The electron mobility in a rutile single crystal in the presence of hydrogen was found to be small, 0.15 $cm^2 V^{-1} s^{-1}$ at 360 °C.[6] The rate of increase in the electrical conductance at the initial stage above 350 °C obeyed the Elovich equation, which had been found to be applicable to the rate of the reduction reaction.[1] Below 350 °C it obeyed t^n partly, where t is the time and n= 0.5—0.7.

Figure 2 shows the change in the electrical con-

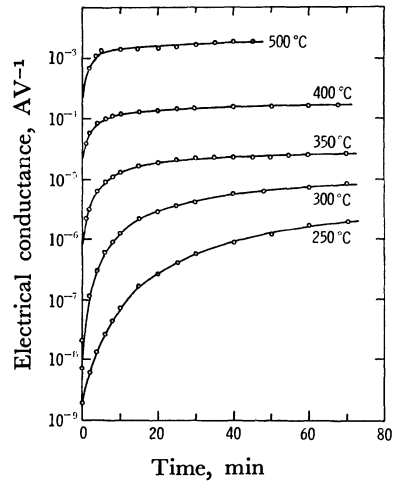

Fig. 1. Electrical conductance of the unpressed sample as a function of time after the introduction of hydrogen at 0.5 atm and several temperatures.

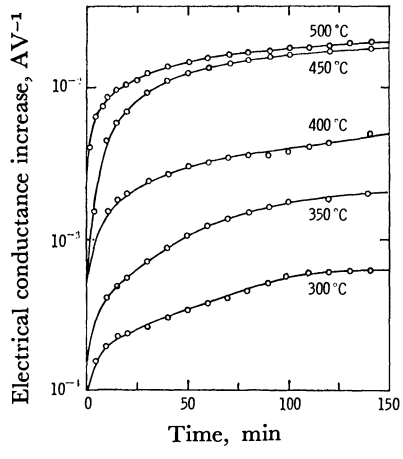

Fig. 2. Electrical conductance of the pressed sample as a function of time after the introduction of hydrogen at 0.5 atm and several temperatures.

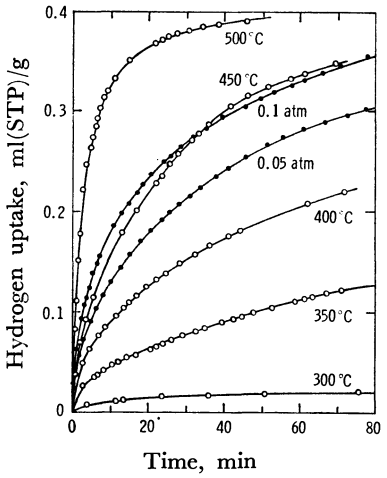

Fig. 3. Hydrogen uptake as a function of time after the introduction of hydrogen at several temperatures. The open circles indicate that the hydrogen pressure is 0.5 atm and the closed circles other hydrogen pressures at 500 °C.

ductance of the pressed sample, where the electrical conductance before the introduction of hydrogen ranged from 10^{-4} to 10^{-3} A V^{-1}. The kinetics was found to obey t^n above 350 °C, where $n=0.3$—0.6. The remarkable difference between the results in Figs. 1 and 2 may be attributable to the contacts between particles and between electrode and particles and to the mobility of the gas molecules migrating through the opening of the titanium dioxide particles.

Figure 3 shows the hydrogen uptake as a function of the time. The hydrogen uptake increased with an increase in the temperature, analogously to the electrical conductance. The rate of hydrogen uptake was found to obey the parabolic rate law. The activation energy obtained was 26 kcal mol^{-1}, indicating the chemisorption of hydrogen, followed by diffusion through the surface region into the bulk. The time required for the attainment of the equilibrium of the hydrogen uptake was short, compared with that of the weight decrease reported in the previous study.[1] The amount of the hydrogen uptake at 500 °C corresponds to a one percent surface coverage if one hydrogen atom is held to one surface oxygen atom. The differences between these findings and the previous ones may result from differences in the experimental conditions, between the static gas system and the circulating one. Nevertheless, at the initial stage, the rates of changes in both the electrical conductance and the hydrogen uptake were quite large, compared with that in the weight decrease. In the previous study, the rate-determining step in the initial stage of the hydrogen reduction was presumed to be the formation of the hydroxyl groups on the surface. The present results support the previous finding concerning the presence of adsorbed hydrogen atoms before the reduction reaction begins.

A comparison of Fig. 1 with Fig. 3 makes it clear that the electrical conductance approaches the equilibrium more rapidly than the hydrogen uptake, especially above 350 °C. The appreciable changes in both the electrical conductance and the hydrogen uptake below 350 °C are also to be noted, because the weight decrease could not be observed below 350 °C.[1] This implies that adsorbed hydrogen atoms which can not take part in the reduction reaction exist on the surface. This hydrogen may adsorb reversibly because the electrical conductance is restored to the original one by outgassing the sample after a run. Above 400 °C, the oxygen vacancies formed by the hydrogen reduction as well as the adsorbed hydrogen atoms contribute remarkably to the electrical conduction.[5]

Rapid Qualitative and Quantitative Microanalysis of Organic Substances by Means of a Glass-ring Oven Technique. III. Determination of a Trace Amount of Brucine in Strychnine Nitrate

Atsushi CHIBA

Department of Electrochemistry, Faculty of Engineering, Yokohama National University, Ohka, Minami-ku, Yokohama 233

(Received August 28, 1975)

Synopsis. A rapid and highly selective method for the microdetermination of brucine in strychnine nitrate by the ring oven technique is presented. Nitric acid was used as a developing solution and color reagent. The detection limit was 0.2 μg, and the time needed for the determination about 5 min.

The spot test and the ring oven technique, among others, have been proposed in the literature for the simple determination of an alkaloid. The trace of brucine has been adulterated by strychnine production. It was determined in various alkaloids from 10 to 15 μg by use of the ring oven technique.[1] This work deals with a new simplified procedure, in which the detection limit and the determination range have been improved.

Experimental

Apparatus. A glass ring oven[2] was used. As the bath liquid 100 ml of water was used, the analytical procedure being carried out at 90 °C.

Brucine Standard Stock Solution. Brucine (Tokyo Chemical Industry Co., Ltd.) was recrystallized from water and ethanol. After it had been dried for 48 h in a sulfuric acid desiccator, a 100-mg portion of brucine was dissolved in 100 ml of 10 vol% ethanol. This standard stock solution was diluted as required.

Color Reagent. (1.0 M) Nitric acid was used both as color reagent and as developing solution.

Filter Paper. Toyo No. 54 filter paper, diam. 55 mm, was used. The other reagents were of analytical reagent grade.

Procedure. A filter paper was set upon a ring oven maintained at 90 °C. The sample solution was dropped in the center of the filter paper. After the spot had dried, the developing solution was dropped on the same place. Brucine was removed to the ring zone with 15 μl of 1.0 M nitric acid. After the developing solution had dried, brucine was removed with 20 μl of 1.0 M nitric acid. After the developing solution had dried, the amount of brucine was determined by comparing the color intensities of all the standard rings. We used 20, 30, and 50 μl for the sample solutions. The procedure was repeated three times. The amount of brucine was obtained by averaging the values of the three measurements.

Standard Rings. A filter paper was set upon the ring oven at 90 °C. Ten microliters of the brucine standard solution containing 0.2—1.0 μg per ml was dropped in the center of the paper. After the standard solution had dried out, 15 μl of a 1.0 M nitric acid solution was dropped in the center of the paper. After this solution had dried, 20 μl of a 1.0 M nitric acid solution was then dropped. Standard ring scales containing 0.2—2.0 μg of brucine were prepared at an interval of 0.02 or 0.05 μg.

Results and Discussion

Clear rings were not formed below 90 °C. The paper sometimes burned when heating was carried out above 100 °C. Well defined rings were obtained at 90 °C. Filter paper No. 54 was found to be the best of six kinds of chromatography paper.

NO_2 gas, which gives immediate coloration, was used. Brucine was concentrated by the use of water, ammonia and hydrochloric acid. When there was not enough to concentrate in the ring zone, the concentration ring was wide and spreading.

Nitric acid was used since it can be concentrated and thus conveniently serves both as developing solution and color reagent. The ring was wide and spreading when 0.1—0.2 M nitric acid was used, but clear ring formed when 0.5—8 M nitric acid was used. Strychnine showed identical results. The ring zone often burned when nitric acid concentration exceeded 2.0 M. Thus 1.0 M solution was used. No thin and clear ring could be obtained by a single developing procedure, the error being large. A good ring could, however, be obtained by repeating the procedure twice. When the amounts of the developing solution were 15 and 20 μl, the results were better than when 10 and 10 μl, or 10 and 15 μl were used. Fifteen and 20 μl of 1.0 M

Table 2. Determination of brucine in strychnine nitrate

Sample	Brucine detected[a)]	Concentration of brucine (μg/l g-strychnine nitrate)
A	1.5	75
B	2.0	100
C	1.0	50

a) In 100 μl.

nitric acid were used. Brucine was concentrated in the ring zone perfectly. Concentration was determined according to color intensity and width of the ring as observed under a microscope.

The ring zone was 20 mm in diameter and 0.2 mm wide, the detection limit 0.2 μg, and the determination range 0.2—20 μg. The average relative error for this technique is 5% over the whole range of concentration of brucine, 0.2—20 μg. When the developing solution dried, the concentration ring turned blood-red, then to yellow-red with the elapse of time. The coloration remained unchanged for some years.

The results are given in Table 1. When the amount of brucine is small, strychnine nitrate has little or no effect on the results. When the standard solution is added to the sample, the error becomes a little greater.

One gram of strychnine nitrate was recrystallized from water and ethanol, and mother liquor was concentrated to 5.0 ml. Brucine was determined with the use of 20, 30, and 50 μl of the mother liquor. The results are given in Table 2. Commercial strychnine nitrate contains a trace of brucine. The analytical procedure took about five minutes, the accuracy being unsatisfactory.

The sample was concentrated with 10 μl of water and its quality was determined by NO_2 gas. The method can also be applied to the analysis of medicine.

The author thanks Prof. T. Ogawa, Yokohama National University, for his suggestion.

Adduct-Formation Constants of Bis(3-trifluoroacetyl-*d*-camphorato)copper(II) with Lewis Bases

Tsunenobu SHIGEMATSU, Masakazu MATSUI, Yoshihiro SASAKI, and Matsujiro SAKURADA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received February 5, 1976)

Synopsis. The formation constants of the mono-adducts of bis(3-trifluoroacetyl-*d*-camphorato)copper(II) with the Lewis bases, such as pyridine, α-picoline, β-picoline, γ-picoline, isopropylamine, and *d*- and *l*-α-methylbenzylamine, were determined spectrophotometrically.

Some metal complexes of β-diketones react further with heterocyclic bases, amines, and phosphorate esters,[1-4] and this adduct formation reaction plays an important role in the synergistic effect for solvent extraction.[5-9]

We investigated the adduct-formation between bis-(3-trifluoroacetyl-*d*-comphorate)copper(II) and heterocyclic bases and amines, including chiral amines, because this β-diketone is chiral and bulky, and determined spectrophotometrically the formation constants.

Experimental

3-Trifluoroacetyl-*d*-camphor (Hfacam) was synthesized from ethyl trifluoroacetate and *d*-camphor using a procedure similar to that described by Hammond.[10] The copper complex, $Cu(facam)_2$, was prepared by adding an ethanol solution of the ligand to an aqueous solution of copper acetate at 60 °C. After cooling, the green crystals which precipitated were filtered off. This product was recrystallized from benzene and then sublimed three times *in vacuo* at 160 °C. (Found: C, 51.54; H, 5.14; F, 20.37%. Calcd for $C_{24}H_{28}O_4F_6Cu$: C, 51.66; H, 5.06; F, 20.43%)

The absorption spectra in benzene at 25 °C were recorded on a Hitachi 323 automatic recording spectrophotometer.

The formation constant K_1 of the mono-adduct was calculated by an equation similar to that of Rose-Drago.[11,12]

$$Cu(facam)_2 + B(\text{Lewis base}) \underset{K_1}{\rightleftharpoons} Cu(facam)_2B \qquad (1)$$

$$\frac{C_A C_B}{A-A_0} = \left[C_A + C_B - \frac{A-A_0}{\varepsilon_3-\varepsilon_1}\right]\frac{1}{\varepsilon_3-\varepsilon_1} + \frac{1}{(\varepsilon_3-\varepsilon_1)K_1} \qquad (2)$$

where A and A_0 are the absorbances at a chosen wavelength in the presence and absence of B, and C_A and C_B are the initial concentrations of $Cu(facam)_2$ and B, respectively. ε_1 and ε_3 are the extinction coefficients of $Cu(facam)_2$ and $Cu(facam)_2B$, respectively. The least-squares method was applied to obtain the best K_1 and ε_3 values.

Results and Discussion

The spectrum of $Cu(facam)_2$ in benzene (*cf.* Fig. 1-(a)) exhibited two maxima at 574 and 680 nm; it resembles those of bis(acetylacetonato)copper(II), $Cu(acac)_2$, and bis(trifluoroacetylacetonato)copper(II), $Cu(tfa)_2$, with a square-planar symmetry.[3,13] When the concentration ratio of pyridine to $Cu(facam)_2$ was in the range 0—0.6, two clear isosbestic points were present, indicating the formation of a mono-adduct. The isosbestic points vanished with increase of the pyridine concentration, and a maximum appeared at 800 nm in the pyridine solution. Moreover, the analytical results of the crystals isolated from the pyridine solution agreed with the calculated values for $Cu(facam)_2(Py)_2$. Therefore, the spectrum in the pyridine solution may be due to $Cu(facam)_2(Py)_2$. Similar spectral changes of $Cu(facam)_2$ caused by the addition of β- and γ-picolines and the analytical results of the crystals isolated from the β- and γ-picoline solutions proved the existence of the bis-adducts, $Cu(facam)_2(\beta\text{-pic})_2$ and $Cu(facam)_2(\gamma\text{-pic})_2$. With α-picoline, two isosbestic points were observed in the concentration-ratio range smaller than 1.0, suggesting a mono-adduct formation.

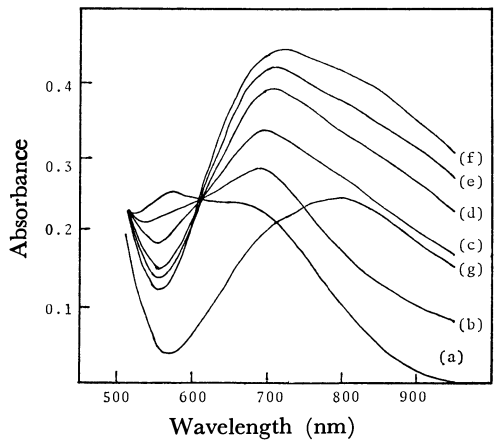

Fig. 1. Spectral change of $Cu(facam)_2$ in benzene caused by the addition of pyridine. $C_A = 4.3 \times 10^{-3}$ M, ratio of C_B/C_A; (a) 0.0; (b) 0.2; (c) 0.4; (d); 0.6; (e) 0.8; (f) 1.0; (g) pyridine.

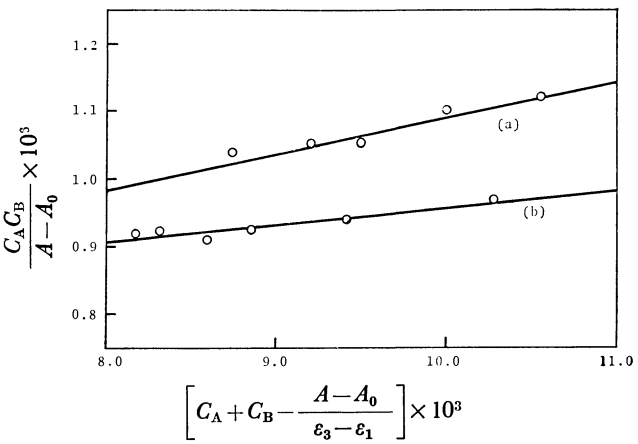

Fig. 2. Plots of $C_A C_B/(A-A_0)$ *vs.* $\left[C_A + C_B - \frac{A-A_0}{\varepsilon_3-\varepsilon_1}\right]$ for α-methylbenzylamine at 700 nm. (a) *l*-α-Methylbenzylamine, (b) *d*-α-methylbenzylamine.

Table 1. Formation constants of mono-adducts between $Cu(facam)_2$ and bases at 25±1 °C

Base	K_1 (M^{-1})
Pyridine	31.1± 4.5
α-Picoline	83.3±24.6
β-Picoline	30.9± 6.4
γ-Picoline	21.9± 5.6
Isopropylamine	26.4± 6.7
d-α-Methylbenzylamine	33.2±12.9
l-α-Methylbenzylamine	84.3±21.0

These isosbestic points vanished with the increase of the α-picoline concentration, and the spectrum in the α-picoline solution exhibited a maximum at 750 nm, with a shoulder at 850 nm. For isopropylamine, two isosbestic points at 520 and 610 nm were found in the concentration ratio range smaller than 1.0. For *d*- and *l*-α-methylbenzylamines, a dull isosbestic point at 600 nm was observed in the region smaller than 0.8, suggesting the formation of a mono-adduct.

An example of the calculation of formation constants is given in Fig. 2, and the K_1 values are summarized in Table 1. The solid lines are drawn on the basis of the calculated ε_3 and K_1 values. The agreement of the plots with the solid lines confirms the plausibility of the calculated ε_3 and K_1 values.

The comparison of the K_1 values reported in the literature[1,2,14-16] with the present data shows that the K_1 values, except that of α-picoline, increase in the order $Cu(tfa)_2 > Cu(facam)_2 > Cu(acac)_2$. This suggests that the rigid and bulky 3-trifluoroacetyl-*d*-camphor hinders the formation of the mono-adduct with bases, but that the electron-withdrawing property of the CF_3-group is still effective. The K_1 value of α-picoline is smaller than those of the other pyridine derivatives for $Cu(acac)_2$ and $Cu(tfa)_2$, whereas the relation is reversed for $Cu(facam)_2$. The K_1 values of *d*- and *l*-α-methylbenzylamine are remarkably different; this difference is difficult to explain, due to the lack of information on their mono-adducts.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (8), 2327—2328 (1976)

Stability Constants of the Rare Earth Complexes with 2-Ethyl-2-hydroxy-3-methylbutyric Acid*

Yasuo SUZUKI and Jack E. POWELL**

Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Ikuta, Tama-ku, Kawasaki 214

***Energy and Mineral Resources Research Institute and Department of Chemistry, Iowa State University, Ames, Iowa 50010, U.S.A.*

(Received March 23, 1976)

Synopsis. The stability constants of the rare-earth complexes with 2-ethyl-2-hydroxy-3-methylbutyric acid have been determined potentiometrically at 25.0 °C and at an ionic strength of 0.10, with sodium perchlorate as the supporting electrolyte.

The stability constants of the rare-earth complexes with some 2-hydroxymonocarboxylic acids have previously been determined by the authors and their coworkers.[1-3] The complexing agent employed in this study, 2-ethyl-2-hydroxy-3-methylbutyric acid, which will be abbreviated as Hehmb hereafter, was first prepared by Darzens.[4] This acid was expected to have properties similar to those of 2-hydroxyisobutyric or glycolic acids, though it has an apparently lower solubility in water. The stability constants of the rare earth-ehmb complexes were determined by pH measurements, and a comparison with those of the analogous acid complexes will be presented.

Experimental

Reagents and Apparatus. The rare-earth perchlorate solutions were prepared from the respective oxides with a purity of 99.9% or higher, supplied by the Ames Laboratory of the U. S. Atomic Energy Commission. The Hehmb used in this work was also prepared in the Ames Laboratory; it had a melting point of 75.0—75.5 °C, which agreed sufficiently well with Darzens' result, *e.g.*, 76 °C. The solubility of Hehmb in water is 8.11 g/100 g H_2O at 25.0 °C, which allows us to make a saturated solution of 0.56 mol/dm³.

A Beckman model 76 pH meter was used, with its expanded scale, throughout the work, together with Beckman 41263 glass and 39170 reference electrodes.

Procedures. The experimental procedures were similar to those used in the previous work.[3]

Results and Discussion

The acid dissociation constant of Hehmb at 25.0 °C and at an ionic strength of 0.10 with sodium perchlorate was determined to be 2.557×10^{-4}.

The ligand number, $\bar{n}$, and the free-ligand-ion concentration, $[A^-]$, were derived from the hydrogen-ion concentration previously determined and from the known stoichiometry of the solutions. Since the ligand number did not exceed 2 throughout the measurements, only the following two equilibria were considered here:

$$R^{3+} + A^- \rightleftharpoons RA^{2+}, \quad K_1 = [RA^{2+}]/[R^{3+}][A^-];$$

$$RA^{2+} + A^- \rightleftharpoons RA_2^+, \quad K_2 = [RA_2^+]/[RA^{2+}][A^-];$$

where R^{3+} denotes a trivalent rare-earth cation. The stability constants were computed on an IBM 7044 computer at the Tokai Research Establishment, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki. The computational programs used were the weighted least-squares ones originally patterned by Sullivan, *et al.*[5] and by Stagg and Powell,[1] adopted to the IBM 7044 computer. The constants thus obtained are shown in Table 1.

The stability constants of the lanthanum ehmb complexes are appreciably lower than those of the corresponding lanthanum complexes, such as 2-hydroxyisobutyrates or lactates. The increase in the constants with the descending periodic sequence down to gadolinium is far more remarkable compared with that in the case of the complexes of the analogous acids, but the subsequent increase in the constants along with the heavier rare earth elements is considerably reduced. The latter trend may be due to the steric effect of the relatively large molecules of the ligand on the cations of a smaller size. These facts indicate that Hehmb may be favorably used for separating lighter rare earths from each other.

Besides the gadolinium break, two more breaks are

a) The values given in this table are subject to absolute errors of as much as ±5% in the case of K_1, and ±10% in the case of K_2. The values of K_1, however, can be compared with those for the adjacent rare earths with greater confidence.

* The work was performed at the Institute for Atomic Research and Department of Chemistry, Iowa State University, Ames, Iowa.

apparently observed: one is located between neodymium and samarium, and the other, between holmium and erbium. This result coincides with the observations of some other rare earth chelates, such as ethylenediaminetetraacetates,[6] picolinates,[7] and *N'*-methylethylenediamine-*N,N,N'*-triacetates.[8] The reason for the fine structure of the stability trend remains to be considered, together with the tetrad effect.[9,10]

The authors wish to express their gratitude to Mr. J. L. Farrell of the Institute for Atomic Research, Iowa State University, for preparing the Hehmb used in the experiment, and to Mr. T. Tsutsui of the Computational Center, Tokai Research Establishment, Japan Atomic Energy Research Institute.

The Polarized Crystal Spectra of *trans*(O)-$[Co(OCOCH_3)_2(en)_2]^+$ and *trans*(O)-$[Co(OCOCH_3)_2(py)_2en]^+$

Shunji NAGASAKI and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 26, 1976)

Synopsis. The polarized crystal spectra of *trans*-(O)-$[Co(OCOCH_3)_2(en)_2]Cl$ have exhibited a dichroism which can be understood by means of a vibronic D_{4h} model. On the other hand, the spectra of a new complex, *trans*(O)-$[Co(OCOCH_3)_2(py)_2en]ClO_4$, have shown a different dichroism from that in the bis(ethylenediamine) complex.

Polarized crystal spectra are useful for the assignment of the absorption bands of complexes. The spectra of various complexes of cobalt(III),[1] chromium(III),[1,2] platinum(II),[3] *etc.* have been investigated, but interest has been particularly centered on the spectra of *trans*-dihalobis(ethylenediamine)-type cobalt(III) complexes[4-6] because of the marked splitting of the first absorption band ($^1T_{1g}$ band).

In the present work we succeeded in obtaining *trans*-bis(acetato)bis(pyridine)ethylenediaminecobalt(III) perchlorate, *trans*(O)-$[Co(OCOCH_3)_2(py)_2en]ClO_4$, whose absorption spectrum in solution exhibits a marked splitting of the $^1T_{1g}$ band. The corresponding bis-(ethylenediamine) complex, *trans*(O)-$[Co(OCOCH_3)_2(en)_2]^+$, has already been reported.[7,8] Thus, in this paper the polarized crystal spectra of the two *trans*(O) complexes will be reported. The spectra were measured with a microspectrophotometer which had been constructed by the present authors.

Experimental

Measurements. The microspectrophotometer was constructed according to the literature.[9] The assembly consists of a Hitachi 323 recording spectrophotometer and a specially designed sample compartment containing a microscope. As light sources, a tungsten filament lamp and a deuterium discharge lamp were used for the visible and near-ultraviolet regions respectively. As the microscope, an Olympus POM polarising microscope was used, together with an Olympus MO 90 reflecting objective (90 X) or a Zeiss-Jena reflecting objective (40 X). The light was polarized by a quartz Rochon prism. The photomultiplier tube was a Hamamatsu TV Co., Ltd., head-on type R376.

With this apparatus the crystal spectra were measured over the frequency range from 15000 to 30000 cm^{-1} at room temperature with incident light polarized parallel ($\parallel$) and perpendicular ($\perp$) to a suitable axis. The axis was chosen under a polarizing microscope as a direction exhibiting a remarkable dichroism. Since no attempt was made to determine the thickness of the crystal, the molar extinction was not evaluated. The reliability of this apparatus was checked with the spectra of *trans*-$[CoCl_2(en)_2]Cl\cdot HCl\cdot 2H_2O$.[4,5]

Preparation of the Complex. The known complex, *trans*(O)-$[Co(OCOCH_3)_2(en)_2]^+$, was prepared as the chloride according to the method in the literature.[8] A new complex, *trans*(O)-$[Co(OCOCH_3)_2(py)_2en]ClO_4$, was prepared according to the following procedure; to an aqueous solution of *cis*-$K[Co(CO_3)_2(py)_2]\cdot 3H_2O$[10] (21.5 g, 0.05 mol) in water (100 ml), we added ethylenediamine monohydrate (3.0 g, 0.05 mol) and 3 M acetic acid (100 ml), after which the mixture was stirred at room temperature for a few days, whereby the solution became red-violet. A portion of the resulting solution was charged on a column of an ion-exchange resin (Dowex 50 WX8, Na-form), and the complexes were eluted with a 0.3 M $NaClO_4$ aqueous solution, whereupon the desired complex was eluted first, followed by *cis*-$[CoCO_3(py)_2en]^+$ and $[CoCO_3(en)_2]^+$. By repeated chromatographic separations the desired fraction was collected. After the fraction had been concentrated to a small volume, the concentrate was kept in a refrigerator to crystallize the desired complex. The recrystallization was performed from water. Yield, *ca.* 0.5 g.

Found: C, 38.80; H, 4.85; N, 11.19%. Calcd for $[Co(OCOCH_3)_2(py)_2(en)]ClO_4 = CoC_{16}H_{24}O_4N_4\cdot ClO_4$: C, 38.84; H, 4.89; N, 11.32%.

Results and Discussion

The crystal spectra of *trans*-$[CoCl_2(en)_2]Cl\cdot HCl\cdot 2H_2O$ measured with our apparatus exhibited a peak at 1600 cm^{-1} with the $\parallel$ polarization and two peaks at 16200 and 22700 cm^{-1} with the $\perp$ polarization, which agreed with the values reported in the literature: 16000 ($\parallel$), 16200 ($\perp$) and 22700 cm^{-1} ($\perp$)[4] and 15900 ($\parallel$), 16100 ($\perp$) and 23100 cm^{-1} ($\perp$).[5] These spectral data proved the usefulness of our apparatus.

Trans*(O)*-*[Co(OCOCH$_3$)$_2$(en)$_2$]Cl.* The polarized crystal spectra are shown in Fig. 1, together with the solution spectrum. The dichroism was clearly observed in the $^1T_{1g}$ band; the $\tilde{\nu}_{Ia}$ maximum is observed at 18500 cm^{-1} with both $\parallel$ and $\perp$ polarization, and the $\tilde{\nu}_{Ib}$ maximum at 23000 cm^{-1} with the $\perp$ polarization.

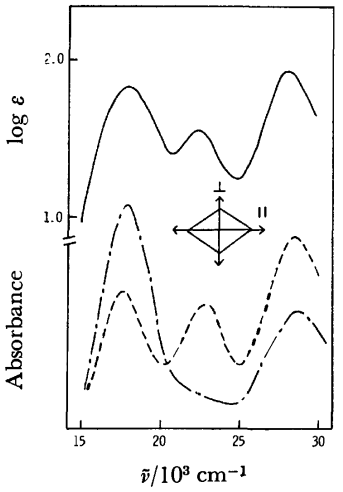

Fig. 1. Absorption spectra of *trans*(O)-$[Co(OCOCH_3)_2(en)_2]Cl$ (—— solution, ---- $\perp$, —-— $\parallel$).

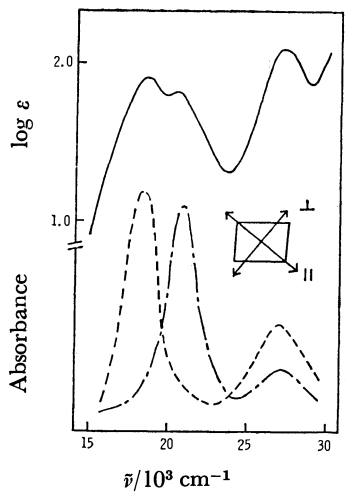

Fig. 2. Absorption spectra of *trans*(O)-[Co(OCOCH$_3$)$_2$-(py)$_2$en]ClO$_4$ (—— solution, ---- ⊥, —— ∥).

Those features are quite similar to those of the *trans*-dichloro complex. Although no crystal structure is known, the observed dichroism can be interpreted in terms of a vibronic D_{4h} model;[6] the $\tilde{\nu}_{Ia}$ is assigned to $^1E_g^a \leftarrow {}^1A_{1g}$, and the $\tilde{\nu}_{Ib}$, to $^1A_{2g} \leftarrow {}^1A_{1g}$. Concerning the second absorption band ($^1T_{2g}$ band), the maxima and intensities are different between the ∥ and ⊥ spectra. The maximum at 27600 cm^{-1} with the larger intensity may be assigned to $(^1B_{2g} + {}^1E_g^b) \leftarrow {}^1A_{1g}$, and the other maximum at 28100 cm^{-1} with the smaller intensity, to $^1E_g^b \leftarrow {}^1A_{1g}$.

trans*(O)*-[*Co(OCOCH$_3$)$_2$(py)$_2$en*]*ClO$_4$*. The solution and crystal spectra are shown in Fig. 2. This complex was identified as the *trans*(O) isomer on the basis of the splitting of the T_{1g} band. A preliminary X-ray investigation of this complex in this laboratory established that the crystal is monoclinic, with the space group C2/c, and that the O–Co–O axis makes an angle of *ca.* 45° with the crystal c axis and is on the ac plane. Thus, the ∥ polarization implies the incident light polarized along the O–Co–O axis.

In the crystal spectra, a marked dichroism is observed in the $^1T_{1g}$ band. With the ⊥ polarization, one peak is observed at 18400 and with the ∥ polarization, another peak at 21000 cm^{-1}. Those features of the dichroism differ from those of the *trans*(O)-bis(ethylenediamine) complex; hence, the vibronic D_{4h} model[6] is not applicable to the interpretation of this dichroism. Instead, a nonvibronic D_4 model may be applicable; the ⊥ band at 18400 cm^{-1} is assignable to $^1E \leftarrow {}^1A_1$, and the ∥ band at 2100 cm^{-1}, to $^1A_2 \leftarrow {}^1A_1$. As for the $^1T_{2g}$ band, the maxima and intensities are different between the ∥ and ⊥ spectra. However, the D_4 selection rule involves a forbidden $^1B_2 \leftarrow {}^1A_1$ transition.

Great thanks should be expressed to Professor Y. Kondo, Professor M. Nakahara and Dr. A. Urushiyama of Rikkyo University for their helpful guidance in the construction of the present microspectrophotometer.

The Reduction of Divalent Copper and Tetravalent Tellurium by Ascorbic Acid—Application to Copper Telluride Analysis

M. K. Joshi and Sarala Raoot

Defence Metallurgical Research Laboratory, Hyderabad, India

(Received March 26, 1975)

Synopsis. Quantitative reduction of Cu^{2+} to metal copper and Te^{4+} to metal tellurium by ascorbic acid in alkaline and acid medium respectively has been studied. Based on this a new method for easy and simultaneous determination of copper and tellurium as in copper-telluride has been developed with reproducible results.

In redox-gravimetry, ascorbic acid has been extensively employed as a metal precipitant for determining such elements as selenium,[1] silver,[2] mercury,[3] and gold.[4] In these methods, the metal ion in mineral acids is reduced to the metallic stage and weighed. Despite these applications and the versatility attained by ascorbic acid in diverse analytical methods,[5] its "reducibility" in strongly alkaline medium appears to be much less studied. And although reduction of quadrivalent selenium to metal selenium has been reported, identical observations with tellurium find a meagre mention in available literature.

Preliminary experiments revealed that when ascorbic acid was introduced separately in solutions of copper sulphate and sodium tellurite, metals copper (in strongly alkaline medium) and tellurium (in strongly acid medium) were precipitated. In NaOH solutions Cu^{2+} was reduced preferentially to metal while Te^{4+} remained in solution and a reverse phenomenon was witnessed on making the solutions acidic. Quantitative aspects of these two redox-reactions and their extension to simultaneous determination of copper and tellurium in copper telluride have been reported in this paper.

Experimental

All reagents used in these investigations were of Analytical Grade purity.

Reduction of Cu^{2+} to Metallic Copper. 2.96 g of AR copper turnings were dissolved in minimum nitric acid in a 250 ml beaker and fumed with 5 ml of sulphuric acid. The residue was dissolved in distilled water and made up to one litre. Its copper content was checked iodometrically. An aliquot portion of this solution was taken in a round bottom flask fitted with a ground glass seal condenser. 20% aqueous sodium hydroxide solution was introduced into the flask till the pale-blue gelatinous precipitate of cupric hydroxide was formed. The contents were diluted to 60—70 ml and an adequate volume of the alkali was further added to maintain its overall normality at or above 1N (a minimum volume of 60—70 ml of the reaction mixture was found to be convenient for reflux, preventing formation of a paste and facilitate observance of supernatant liquid). Crystalline ascorbic acid (a minimum of 5 to 6 times the weight of copper present in aliquot) was then added when a colloidal reddish yellow precipitate appeared almost immediately. The condenser was fitted in and the system refluxed for about 10 to 15 min on a suitable heating mantle. The reddish yellow precipitate was reduced gradually to metallic copper which settled down leaving behind a clear supernatant liquid. The system was cooled, condenser detached and the copper filtered under suction through a weighed sintered glass crucible of porosity-4. It was washed 3 to 4 times with hot 1% sodium hydroxide solution, then with hot water till free from alkali and finally with a small quantity of absolute alcohol and ether. The precipitated copper was sucked dry, heated in an air oven at 110 °C for about one hour, cooled in a desiccator and weighed to a constant weight. It was later dissolved in 1 : 1 nitric acid, diluted to about 100 ml, titrated iodometrically against 0.1 N thiosulphate solution. Results at serial nos. 1 to 7 in the table pertain to these studies. For quick routine analysis, the precipitated copper may be filtered through a Whatman 42 fitter pulp, dissolved in 1 : 1 nitric acid, washed and titrated iodometrically.

Reduction of Te^{4+} to Metallic Tellurium. 7.4 g of AR tellurium metal was dissolved in 100 ml of concentrated hydrochloric acid in a 500 ml beaker. The solution was made up to 1 liter maintaining its overall HCl normality at about 2.5 N. Tellurium content in the solution was checked gravimetrically.

A measured volume of the Te^{4+} solution was taken in a round bottom flask fitted with a ground glass seal condenser followed by an adequate volume of concentrated HCl and distilled water to achieve an overall normality at or above 2.5 N and the total volume of the reactants at 60—70 ml. Crystalline ascorbic acid (4 to 5 times the weight of tellurium in aliquot) was now added to the flask when black colloidal precipitate of tellurium was seen almost instantaneously. The system was refluxed for abour 10 min when the precipitate settles down leaving behind a clear supernatant liquid. The contents were cooled and tellurium was filtered under suction through a weighed sintered glass crucible of porosity-4. The precipitate was washed thoroughly with hot water till free from chloride ions and then with a small quantity of absolute alcohol and ether. It was sucked dry, heated in an air oven at 105 °C for about an hour, desiccated and weighed to constant weight. Results at serial nos. 8 to 14 in the table correspond to these experiments.

Separation and Estimation of Copper and Tellurium when Present Together as in Copper Telluride. Synthetic copper telluride solutions were prepared by weighing accurately electrolytic copper and high purity tellurium in weight ratios 1 : 1, 1 : 2, 2 : 1, and 2 : 3 in a 250 ml beaker and dissolving in a minimum volume of 1 : 1 nitric acid by careful heating. Excess nitric acid was removed by fuming with concentrated sulphuric acid. The residue when cooled was taken up with HCl and made up to 250 ml in a standard volumetric flask such that overall normality of HCl in the solution was maintained at about 2.5 N. In a 25 ml portion of each of these copper was first determined by ascorbic acid in alkaline medium by weighing and titration (*cf.* experimental for copper). The alkaline filtrate was transferred to a 500 ml Pyrex beaker, evaporated to 100 ml, concentrated HCl added to the prescribed normality and precipitated tellurium weighed gravimetrically (*cf.* experimental for tellurium).

Results of experiments at serial nos. 15 to 18 in the table refer to these investigations.

18	0.0500	0.0497	—	0.0750	0.0746

Ratio of Cu^{2+} to Te^{4+} in experiments at serial nos. 15, 16, 17, and 18 was respectively 1:1, 1:2, 2:1, and 2:3.

Discussion

In order to study various reaction parameters, a series of experiments were carried out and it was established that the optimum conditions for a quantitative reduction of Cu^{2+} to metallic copper are, (1) 5 to 6 folds excess of ascorbic acid, (2) overall sodium hydroxide concentration at or above 1 N, (3) duration of reflux 15 to 20 min, and those for Te^{4+} to metal tellurium, (1) 4 to 5 folds excess of the acid reagent, (2) HCl concentration at or above 2.5 N and (3) time of reflux 10 to 15 min.

The close agreement between the amount of copper and tellurium taken for investigation and that obtained gravimetrically and volumetrically (for copper only) show that the accuracy is high for a fairly wide range of the metal ion concentrations, the errors being 0.2 to 0.7% for copper and 0.1 to 1.0% for tellurium. The deviations in most of the cases are on the negative side which may be attributed to the losses occuring during transfer and washing of the precipitated metals. A special feature of the present method is that both the metal ions are determined simultaneously by just altering the medium of reaction.

Studies on tellurides of silver and bismuth on identical lines and applications of the copper-ascorbic acid redox-reaction to direct determination and/or separation of copper in brasses, bronzes and aluminium alloys have shown encouraging results and will be communicated later.

Our grateful thanks are due to Dr. R. V. Tamhankar, Director, Defence Metallurgical Research Laboratory, Hyderabad for his valuable suggestion and for permission to publish this paper.

Morpholinobenzoquinones: Synthesis and Reactions

Yoshimori OMOTE* and Toshihiko KOMATSU

Department of Chemistry, University of Tsukuba, Sakura, Niihari, Ibaraki 300-31

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo 112

(Received January 27, 1976)

Synopsis. Two 4-morpholino-1,2-benzoquinones (5-*t*-butyl- and 5-methyl-) have been prepared by the oxidation of the corresponding catechols with silver oxide. The quinones were then condensed with *o*-phenylenediamine to give phenazines.

The oxidation of aminocatechols to the corresponding quinones has been studied by Horner,[1] Iwao[2] and Jackson,[3] but few papers on the isolation and properties of the quinones have been published. We wish now to report on the synthesis of morpholinobenzoquinones as well as on their chemical properties.

The reaction of 4-*t*-butyl-1,2-benzoquinone with morpholine gave 5-*t*-butyl-4-morpholinocatechol (**1**) in a 48% yield. The structure of **1** was confirmed on the basis of the spectroscopic data and the results of elemental analysis. Aminocatechols, such as 4-aminocatechol and 4-dimethylaminocatechol, are known to be labile to atmospheric oxygen,[1] however, **1** is stable and can be isolated as colorless crystals. The reaction of 4-methyl-1,2-benzoquinone with morpholine gave **2** in only a 7.7% yield.

The catechol **1** was oxidized with silver oxide to give 5-*t*-butyl-4-morpholino-1,2-benzoquinone (**3**). The **3** quinone was then condensed with *o*-phenylenediamine to afford a phenazine, **5**. The **6** phenazine was also obtained from the labile **4** and *o*-phenylenediamine.

Experimental

5-t-Butyl-4-morpholinocatechol (1). 4-*t*-Butyl-1,2-benzoquinone was prepared by the method of Pospíšil[4] from 2 g of 4-*t*-butylcatechol. Morpholine (4 ml) in tetrahydrofuran (10 ml) was slowly stirred into a solution of the quinone in terahydrofuran (30 ml) under nitrogen at 0 °C. When white precipitates appeared after stirring at room temperature, the reaction mixture was concentrated. The precipitate (1.46 g) was then recrystallized from dioxane; colorless needles, mp 240 °C (dec). UV λ_{max}^{EtOH} (ε): 220 sh (7930) and 285 (3420) nm; NMR (DMSO-d_6): δ 1.37 (s, 9H), 2.6 (m, 4H), 3.7 (m, 4H), 6.70 (s, 1H), 6.74 (s, 1H) and 8.61 (br. s, 2H, D_2O exchangeable); IR (KBr): 3500 cm^{-1} (OH). Found: C, 66.81; H, 8.64; N, 5.58%. Calcd for $C_{14}H_{21}NO_3$: 66.90; H, 8.42; N, 5.57%.

5-Methyl-4-morpholinocatechol (2). 4-Methyl-1,2-benzoquinone was prepared by the oxidation of 4-methylcatechol (2 g) with cerium(IV) sulfate.[5] Morpholine (4 ml) in methanol (20 ml) was stirred with the resulting quinone at room temperature under nitrogen. After stirring for 10 min, the mixture was concentrated and chromatographed over silica gel (eluted with benzene–ethyl acetate 4 : 1) to give 260 mg of **2** (7.7%); colorless prisms from ethyl acetate; mp 186—188 °C. UV λ_{max}^{EtOH} (ε): 263 sh (5900) and 295 (3750) nm; NMR (DMSO-d_6): δ 2.10 (s, 3H), 2.7 (m, 4H), 3.7 (m, 4H), 6.50 (s, 1H), 6.57 (s, 1H) and 8.4 (br. s, 2H, D_2O exchangeable); IR (KBr): 3450 cm^{-1} (OH).

5-t-Butyl-4-morpholino-1,2-benzoquinone (3). Silver oxide (100 mg, freshly prepared from silver nitrate) was added, in portions, to a solution of **1** (100 mg) in dry dioxane (20 ml). After the mixture had been stirred for 30 min at room temperature under argon, the resulting precipitate was removed by filtration. The filtrate was concentrated by freeze-drying to a red-orange powder (93 mg, 93%) of **3**; sublimed at 80 °C under 10^{-6} mmHg; mp 90 °C. UV $\lambda_{max}^{CHCl_3}$ (ε): 335 (2870) and 456 (2010) nm: $\lambda_{max}^{H_2O}$ (ε): 272 (10300), 330 (2200) and 510 (2870) nm; NMR ($CDCl_3$): δ 1.38 (s, 9H), 2.93 (m, 4H), 3.83 (m, 4H), 6.08 (s, 1H) and 6.39 (s, 1H); IR (KBr): 1680, 1660 and 1650 cm^{-1} (C=O). Found: C, 67.25; H, 7.74; N, 5.82%. Calcd for $C_{14}H_{19}NO_3$: C, 67.44; H, 7.68; N, 5.62%.

5-Methyl-4-morpholino-1,2-benzoquinone (4). This quinone could not be isolated, but a solution of the quinone was obtained by the treatment of the corresponding catechol, **2** with *o*-chloranil. UV λ_{max}^{EtOH} (ε): 496 (3100) nm; NMR (DMSO-d_6): δ 2.22 (d, J=1.5 Hz, 3H), 3.2 (m, 4H), 3.75 (m, 4H), 5.63 (s, 1H) and 6.25 (q, J=1.5 Hz, 1H).

2-t-Butyl-3-morpholinophenazine (5). *o*-Phenylenediamine (100 mg) in dioxane (5 ml) was added to a dioxane solution (10 ml) of **3** (100 mg); then the mixture was stirred for 20 h at room temperature under argon. After the removal of the solvent, the residue was chromatographed over silica gel to give a yellow powder (63 mg, 45%); yellow prisms from methanol; mp 140 °C. UV λ_{max}^{EtOH} (ε): 256 (117000) and 372 (14500) nm; NMR ($CDCl_3$): δ 1.63 (s, 9H), 3.00 (m, 4H), 3.94 (m, 4H) and 7.7—8.3 (m, 6H). Found: C, 75.30; H, 7.32; N, 13.23%. Calcd for $C_{20}H_{23}N_3O$: C, 74.74; H, 7.21; N, 13.07%.

2-Methyl-3-morpholinophenazine (6). To a mixture of 310 mg of 4-methylcatechol and 0.25 ml of morpholine in 20 ml of tetrahydrofuran, silver oxide (1.16 g), in portions, was added with stirring, after which the mixture was stirred for 15 further min under argon at room temperature. When the precipitate had been removed by filtration, 270 mg of *o*-phenylenediamine in tetrahydrofuran (10 ml) was dropped into the filtrate and the mixture was stirred for 20 min. After

the removal of the solvent, 16 ml of acetic anhydride containing 1 ml of pyridine was added to the residue, and the solution was warmed at 60 °C for 5 min in a water bath. When the solvent had been evaporated under reduced pressure, the resulting crystals of the acetate of *o*-phenylenediamine were removed by filtration. The filtrate was chromatographed over silica gel to give 205 mg (29.3%) of **6**; yellow prisms from methanol; mp 131—132 °C. UV λ_{max}^{EtOH} (ε): 235 (29700), 256 (45600), 382 (12100) and 410 (8670) nm; NMR ($CDCl_3$): δ 2.59 (s, 3H), 3.1 (m, 4H), 3.9 (m, 4H) and 7.5—8.3 (m, 6H). Found: C, 73.13; H, 6.17; N, 14.99%. Calcd for $C_{17}H_{17}N_3O$; C, 73.09; H, 6.13; N, 15.04%.

Preparation of Hindered Esters from Acid Chlorides and Alcohols in the Presence of Silver Cyanide

Seiji TAKIMOTO, Junji INANAGA, Tsutomu KATSUKI, and Masaru YAMAGUCHI

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 2, 1975)

Synopsis. Sterically hindered esters were prepared from the corresponding acyl chlorides and alcohols in the presence of silver cyanide. The method is superior to the conventional acyl chloride–alcohol–pyridine method as regards yield and the rapidity of reaction.

This report describes a rapid and convenient procedure for preparing sterically very crowded esters by the reaction between acyl chlorides and alcohols in the presence of silver cyanide. The results are summarized in Table 1.

The conventional acyl chloride–alcohol–pyridine method is useful for the preparation of the usual esters but it is too slow and incomplete for preparing the hindered esters. The method in which the acyl chlorides are treated with lithium alkoxides[1] and that in which the acids and alcohols are treated with trifluoroacetic anhydride[2] appear to be the most useful ones in view of the yield and the rapidity of the reaction. However, because of the strongly alkaline or acidic reaction conditions inherent to these methods, their applicability must be made with certain restrictions: in the alkoxide method, some reservation should be given to acid chlorides having α-hydrogen atoms;[1] the trifluoroacetic anhydride method is not suitable for aliphatic tertiary alcohols.[2] The present method can be applied to a wide variety of substrates with better yields. Esters of triphenylmethanol, however, can not be prepared by this method.

The reaction seems to proceed with the help of the electrophilic catalysis of silver ion though other silver salts such as silver carbonate or silver trifluoroacetate are ineffective for the ester formation. The intermediacy of the acyl cyanide as the main reaction pass might be excluded since the acyl cyanide has been reported to be less reactive to the nucleophiles than the corresponding acyl chloride.[3] Actually, in an experiment carried out with pivaloyl cyanide and 2-methyl-2-propanol in HMPA at 80 °C for 8 h, only a trace of ester could be observed. Addition of tributylamine[4] or DBU caused no acceleration in the reaction but rather retarded it.

Copper cyanide showed a similar effect but the yield of the ester was very low and the formation of a considerable amount of acid anhydride was observed.

Experimental

Silver cyanide was precipitated by mixing a potassium cyanide solution (1.95 g in 50 ml water) with a silver nitrate

TABLE 1. PERCENT YIELD OF HINDERED ESTERS

Acid chloride (0.5 mmol)	Alcohol (mmol)		Reaction conditions: Solvent (1 ml);	Temp;	Time	Ester Yield (%)[a]
Pivaloyl	2-Butanol	(0.5)	Benzene;	r. t.;	1 h	100
	2-Methyl-2-propanol	(0.6)	HMPA;	80 °C;	10 min	94
		(1.0)	Benzene;	80 °C;	30 min	100
	3-Ethyl-3-pentanol	(1.0)	HMPA;	80 °C;	10 min	57
		(1.0)	Benzene;	80 °C;	4 h	99[b]
	2,6-Dimethylphenol	(0.7)	HMPA;	80 °C;	4 h	61
		(0.5)	Benzene;	80 °C;	30 h	83[c]
2,2-Diethylbutyryl	2-Butanol	(0.5)	Benzene;	80 °C;	1 h	94
	2-Methyl-2-propanol	(1.0)	HMPA;	80 °C;	10 min	95
		(1.0)	Benzene;	80 °C;	4.5 h	90
	3-Ethyl-3-pentanol	(1.0)	HMPA;	80 °C;	30 min	75
		(1.0)	Benzene;	80 °C;	54 h	86
	2,6-Dimethylphenol	(0.5)	HMPA;	80 °C;	30 min	80
		(0.5)	Benzene;	80 °C;	75 h	90
2,4,6-Trimethylbenzoyl	2-Methyl-2-propanol	(0.5)	Benzene;	r. t.;	10 min	92
	3-Ethyl-3-pentanol	(1.0)	HMPA;	80 °C;	30 min	92
		(0.5)	Benzene;	80 °C;	3 h	82[c]
	2,6-Dimethylphenol	(0.5)	Benzene;	r. t.;	5 min	92
2-Methylpentanoyl	3-Ethyl-3-pentanol	(0.5)	Benzene;	r. t.;	3 h	95

a) Unless otherwise stated, the yields were determined by GLPC by comparison with the appropriate internal standards. b) An experiment carried out according to the trifluoroacetic anhydride method[2] gave the ester formation (13%, r. t., 1 h) but the ester gradually disappeared in eight hours. c) The yield was that of the product distilled after the work up.

Table 2. Analytical and NMR data of new esters

Ester	Found(Calcd) C%	Found(Calcd) H%	NMR, δ
2,6-Dimethylphenyl pivalate	75.74 (75.69)	8.80 (8.80)	1.42(s, 9H), 2.14(s, 6H), 7.02(s, 3H)
2-Butyl 2,2-diethylbutyrate	72.32 (71.95)	12.19 (12.08)	0.76(t, 9H, J=7.9 Hz), 0.88(t, 3H, J=9.0 Hz), 1.19(d, 3H, J=6.0 Hz), 1.35—1.90 (m, 8H), 4.80(m, 1H)
t-Butyl 2,2-diethylbutyrate	71.67 (71.95)	12.06 (12.08)	0.77(t, 9H, J=7.2 Hz), 1.34(s, 9H), 1.55(m, 6H)
3-Ethyl-3-pentyl 2,2-diethylbutyrate	74.10 (74.32)	12.50 (12.48)	0.80(t, 9H), 0.83(t, 9H), 1.36—2.10 (m, 12H)
2,6-Dimethylphenyl 2,2-diethylbutyrate	77.34 (77.37)	9.74 (9.74)	0.93(t, 9H, J=7.1 Hz), 1.89(q, 6H), 2.16(s, 6H), 7.01(s, 3H)
3-Ethyl-3-pentyl 2,4,6-trimethylbenzoate	77.55 (77.82)	9.90 (9.99)	0.91(t, 9H, J=7.0 Hz), 1.98(q, 6H, J=7.0 Hz), 2.25(s, 3H), 2.34(s, 6H), 6.81(s, 2H)
3-Ethyl-3-pentyl 2-methylpentanoate	73.01 (72.84)	12.27 (12.23)	0.83(t, 12H, J=8.0 Hz), 1.12(q, 3H, J=7.0 Hz), 1.40(m, 4H), 1.84(q, 6H, J=8.0 Hz), 2.40(m, 1H)

solution (5.1 g in 100 ml water) at room temperature, which was then washed thoroughly with water and dried for twelve hours under 2 mmHg. Of the solvents examined, benzene and HMPA gave the best results. In HMPA, the reaction completed very rapidly but the yield was slightly reduced. The NMR spectra in $CDCl_3$ were used for identification of the esters. A typical example is given below.

t-Butyl Pivalate. Pivaloyl chloride (60 mg, 0.5 mmol) was added with use of a microsyringe to a stirred mixture of silver cyanide (134 mg, 1 mmol), 2-methyl-2-propanol (44 mg, 0.6 mmol) and HMPA (1 ml) with the exclusion of moisture, the mixture being then heated at 80 °C in an oil bath. Formation of the ester was followed by GLPC by the addition of an internal standard (xylene in this case). After ten minutes the amount of ester became constant with a 94% yield. For isolation of the ester, the reaction mixture was diluted with pentane (10 ml) without addition of xylene, filtered through a celite column, washed successively with a 10% aqueous sodium hydrogencarbonate solution and water, dried with calcium sulfate, and distilled at 150 °C (bath temperature).

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Pyrolysis of *S*-[2-(Phenylthio-, Phenylsulfinyl-, and Phenylsulfonyl)-ethyl]-*N*-*p*-tosylsulfilimine[1)]

Naomichi FURUKAWA, Toshifumi HATANAKA, Katsumasa HARADA, and Shigeru OAE

(Received February 20, 1976)

Synopsis. The β-substituent effect on the rate of Ei reaction was investigated by using *S*-[2-(phenylthio-, phenylsulfinyl-, and phenylsulfonyl)ethyl]-*N*-*p*-tosylsulfilimines. The reactivity lies in the order of β-substituents: $PhSO_2 > PhSO > PhS > Ph$. From this and the kinetic isotope effect, the rate determining step is the intramolecular β-hydrogen abstraction by the *N*-*p*-tosyl group.

In previous studies,[2)] we found that *S*-alkyl-*N*-*p*-tosylsulfilimines having a β-hydrogen atom can readily undergo pyrolysis to afford the corresponding olefins and the sulfenamide in high yields. The kinetic study revealed that the rate of the pyrolysis of *S*-1-phenyl-substitdted-*N*-*p*-tosylsulfilimine is 10^3 times faster than that of the unsubstitdted derivative. Meanwhile, the *S*-2-phenyl-substituted-derivative was found to be pyrolyzed only 2.5 times faster than the unsubstituted one. Thus, although the rates of the pyrolysis vary widely upon changing the structure of the sulfilimine, the reaction has been suggested to proceed *via* nearly an ideal concerted *cis*-elimination mechanism. In order to collect further evidence to clarify the Ei reaction and especially to examine the effect of the electron withdrawing β-substituent, *S*-[2-(phenylthio-, phenylsulfinyl-, and phenylsulfonyl)ethyl]-*N*-*p*-tosylsulfilimines were subjected to the usual pyrolysis. This paper describes the results of the kinetic study of the pyrolysis.

Results and Discussion

S-(Phenyl)ethyl-*S*-phenyl-(I), *S*-[2-(phenylthio)-ethyl]-*S*-phenyl-(II), *S*-[2-(phenylsulfinyl)ethyl]-*S*-phenyl-(III), and *S*-[2-(phenylsulfonyl)ethyl]-*S*-phenyl-(IV)-*N*-*p*-tosyl-sulfilimines were prepared in the usual manner from the corresponding sulfides with chloramine-T in methanol and subjected to the pyrolysis. The pyrolysis was carried out by heating the solution of each of these sulfilimines in chloroform. The product analyses performed by NMR spectroscopy *in situ* in $CDCl_3$, showed a mixture of the olefins and the sulfenamide.

$$\mathrm{Ph\text{-}S\text{-}CH_2CH_2X} \longrightarrow \mathrm{Ph\text{-}S\text{-}NHTs} + \mathrm{CH_2{=}CHX}$$
$$\downarrow$$
$$\mathrm{NTs}$$

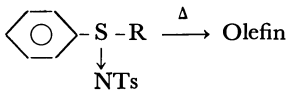
(X=Ph, PhS, PhSO, $PhSO_2$)

The kinetic data were obtained by following the IR absorption of the NH band of *N*-phenylthio-*p*-toluenesulfonamide which appears at 3310 cm^{-1}. The rates of the pyrolysis were correlated well by the first order rate equation; the data are summarized in the Table together with the relative rates of other sulfilimines obtained previously.

The data in the Table indicate that the effects of the β-substituent for the pyrolysis on the reactivity lie in the following sequence: $PhSO_2 > PhSO > PhS >$ Ph. This trend corresponds to that found in the E_2 elimination reaction which we studied previously[3)] and also to that in the base-catalyzed H-D exchange.[4)]

In order to study the nature of the transition state for the Ei reaction of the sulfilimine having a strong electron withdrawing β-substituent, *S*-phenyl-*S*-[2-(phenylsulfonyl)ethyl-2,2-d_2]-*N*-*p*-tosylsulfilimine was prepared and subjected to the pyrolysis. The kinetic study indicated the isotope effect in the pyrolysis reaction, calculated as k_H/k_D, to be 4.2. This clearly indicates that the reaction is also a concerted process that involves the rate-determining intramolecular β-hydrogen abstraction by the *N*-*p*-tosyl group. This rather large value of the kinetic isotope effect, as compared to the previous values obtained for *S*-ethyl-*S*-phenyl (3.0) and *S*-(α-methylbenzyl)-*S*-phenyl-*N*-*p*-tosylsulfilimine (2.9), and the small rate-enhancement by the β-phenyl group in the pyrolysis of *S*-2-(substituted)ethyl-*N*-*p*-tosylsulfilimine, as compared to the re-

TABLE 1. THE KINETIC RESULTS OF THE PYROLYSIS OF SULFILIMINE



Sulfilimine R	Temp °C	k $s^{-1} \times 10^5$	Rel.[b)] rate	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ e.u.

$CH_2CH_2S(O)C_6H_5$[a)]	60.0	1.12	15	26.6	−1.7
$CH_2CH_2SC_6H_5$	60.0	0.48	7	26.8	−2.4

a) In order to obtain the trend of the β-substituent, one isomer having a mp 124—127 °C was subjected to the pyrolysis. b) The relative rates are all calculated by correcting the number of available β-hydrogen atoms at 60.6 °C.

latively large acceleration by the phenyl group in the pyrolysis of *N*-ethyl-*N*-methyl-*N*-phenethylamine oxide,[5] may indicate that the transition state for the Ei reaction of *S*-(α-methylbenzyl)-*N*-*p*-tosylsulfilimine takes nearly the E_1 like process, namely S(III)–N bond cleavage is the rate-determining step, while that for the 2-phenylsulfonyl derivative corresponds to the ideal concerted Ei process, though shifting slightly to a carbanion-like state. In view of these observations in the pyrolysis of the 2-phenyl-sulfonyl derivative, the hydrogen abstraction is believed to be more important step than in the pyrolysis of the above mentioned sulfilimines. The large negative value of the activation entropy found for the 2-phenylsulfonyl compound is also in keeping with the ideal type transition state in which the large negative charge in the vicinal bulky sulfonyl group approaches the negatively charged *N*-*p*-tosyl group, thus making the transition state substantially more rigid.

Experimental

S-[*2-(Phenylthio)ethyl*]-S-*phenyl*-N-p-*tosylsulfilimine (II)*. The sulfilimine was prepared in the usual manner[6] by treating 1,2-bis(phenylthio)ethane with chloramine-T in ethanol. The yield was 84%, mp 133 °C, IR 1150, 1290 (ν_{SO_2}), 990 (ν_{SN}), NMR (δ ppm), $-CH_2CH_2-$ (s, 3.20, 4H), *p*-CH_3 (s, 2.50, 3H), Phenyl-H (m, 7.0—8.0, 14H). Found: C, 60.64; H, 4.97; N, 3.42%. Calcd for $C_{21}H_{21}S_3O_2N$: C, 60.69; H, 5.09; N, 3.37%.

S-[*2-(Phenylsulfinyl)ethyl*]-S-*phenyl*-N-p-*tosylsulfilimine (III)*. 2-(Phenylsulfinyl)ethyl phenyl sulfide (1.0 g) which was prepared from 1,2-bis(phenylthio)ethane and perbenzoic acid was dissolved in chloroform. The chloroform solution of the sulfide was treated at room temperature with chloramine-T as described above. After 30 min the solution was quenched with aqueous sodium hydroxide solution to remove *p*-toluenesulfonamide. The chloroform solution was washed with water and dried over anhyd. sodium sulfate. After the evaporation of chloroform, a solid crystalline residue was obtained in 0.7 g (70%) yield. The NMR spectra of the crude crystals indicated a broad peak at δ 2.5 ppm, suggesting that the compound (III) is a composite of two stereoisomers. The crude crystals, therefore, were separated by fractional crystallization from ethanol several times to give two different crystals; one has mp 119—120 °C, the other mp 124—127 °C. Found: C, 58.08; H, 4.79; N, 3.27%. Calcd for $C_{21}H_{21}S_3O_3N$: C, 58.44; H, 4.90; N, 3.25% (mixture).

S-[*2-(Phenylsulfonyl)ethyl*]-S-*phenyl*-N-p-*tosylsulfilimine (IV)*. A mixture of 2-(phenylthio)ethyl phenyl sulfone (2.0 g) and chloramine-T was heated in methanol solution for a few minutes in the presence of a drop of acetic acid. After the work-up, the crystalline product was isolated and recrystallized from ethanol. The yield was 1.75 g (55%) mp 87 °C. Found: C, 56.52; H, 4.74; N, 3.22%. Calcd for $C_{21}H_{21}S_3O_4N$: C, 56.35; H, 4.73; N, 3.13%.

S-[*2-(Phenylsulfonyl) ethyl*]-*2,2*-d_2-S-*phenyl*-N-p-*tosylsulfilimine*. The sulfilimine was prepared by the usual method mentinoned above from 2-(phenylthio)ethyl-2,2-d_2 phenyl sulfone, which was prepared in advance by treating the sulfone and D_2O in dioxane in the presence of sodium carbonate.

Kinetics. The kinetic study was carried out by the method reported elsewhere following the increase of the IR NH stretching band which appeared at 3310 cm^{-1}. The reaction was found to obey a good first-order kinetic equation.

Product Analysis. The olefins formed were not isolated except in the case of the phenethyl derivative. When the pyrolysis was carried out in the NMR tube until the alkyl protons of the starting sulfilimine disappeared, the NMR peaks were found to be a 1 : 1 mixture of the corresponding olefin and the sulfenamide, which corresponds to the authentic samples prepared separately.

Tri(hetero)substituted Carbonium Ions. XII. A Novel Ring Expansion of 1,3-Dithiolanylium Salts into 1,3-Dithia-4-cyclohexene (1,3-Dithiine) System

Kazuhisa HIRATANI,[1] Takeshi NAKAI,* and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 12, 1976)

Synopsis. Pyrolysis of 2-dialkylamino-4-bromomethyl-4-methyl-1,3-dithiolanylium bromides (**2**) readily prepared by bromination of the *S*-(2-methylallyl) dithiocarbamates afforded the six-membered 2-alkylimino-5-methyl-1,3-dithiines (**4**) in good yields. A reasonable mechanism for the novel ring expansion is presented.

There has been considerable interest in the ring transformations of heterocyclic systems and their synthetic applications.[2] In the preceding paper,[3] we described the pyrolysis of 2-dialkylamino-4-bromomethyl-1,3-dithiolanylium bromides (**1**) readily prepared by bromination[4] of the *S*-allyl dithiocarbamates; this affords the 2-dialkylamino-4-methyl-1,3-dithiolylium salts (**3**) with retention of the five-membered structures.

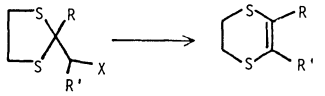
2, R=CH_3, R′=CH_3, C_2H_5

3

4a, R′=CH_3
b, R′=C_2H_5

In this note we wish to report that pyrolysis of 2-dialkylamino-4-bromomethyl-4-methyl-1,3-dithiolanylium bromides (**2**) obtained by bromination of the *S*-(2-methylallyl) dithiocarbamates takes an entirely different course to give the six-membered 2-alkylimino-5-methyl-1,3-dithia-4-cyclohexenes (2-alkylimino-5-methyl-1,3-dithiines) (**4**). This novel ring transformation is, to our knowledge, the first example of a ring expansion of 1,3-dithiolane derivatives into 1,3-dithiine systems, although ring expansions of 1,3-dithiolane derivatives such as **5** into 2,3-dihydro-1,4-dithiine systems (**6**) are well precedented.[5]



5, X=Cl, Br, OAc **6**

When the 1,3-dithiolanylium bromide **2a** (R=CH_3) was heated in bulk at the melting point (*ca.* 200 °C) for 10 min in nitrogen, **2a** was completely pyrolyzed, with the evolution of gases including methyl bromide, to afford 2-methylimino-1,3-dithiine (**4a**) and its hydrobromide salt (**4a′**) in 16% and 48% yields, respectively, along with an intractable tar. A similar pyrolysis of **2a** at 190 °C for 10 min followed by base treatment and column chromatography gave **4a** in 52%. Both **4a** and **4a′** were identified on the basis of their elemental analyses and spectroscopic properties: **4a**, IR (neat), 1592 cm^{-1} (C=N); NMR ($CDCl_3$), δ 2.05 (3H, d), 3.25 (3H, s), 3.0—3.5 (2H, m), and 6.1—6.3 (1H, m); **4a′** IR (KBr), 1580 cm^{-1} (C=N+); NMR (DMSO-d_6), δ 2.16 (3H, s), 3.33 (3H, s), 3.97 (2H, s), 6.75 (1H, s), and 7.9—9.0 (1H, br. s).

The methylimino-1,3-dithiine **4a** was allowed to react with methyl iodide to give the 2-dimethylamino-1,3-dithiinylium iodide (**7**). The UV spectrum of **7** was very similar to that of the 1,3-dithianylium salt (**8**),[6] supporting the six-membered structure for **4a**.

7 **8**, X=Br, ClO_4

A similar pyrolysis of **2b** (R′=C_2H_5) at 180—190 °C for 45 min followed by base treatment afforded the ethylimino-1,3-dithiine (**4b**) in 51% yield; **4b**, NMR (neat), δ 1.21 (3H, t), 2.04 (3H, s), 3.33 (2H, q), 3.4—3.6 (2H, m), and 6.1—6.3 (1H, m).

The tetrafluoroborate salt obtained by anion exchange of bromide **2a** with sodium tetrafluoroborate failed to undergo the ring expansion under the same conditions as in the pyrolysis of **2a** and was recovered quantitatively. This finding indicates that the thermal ring expansion is initiated by the elimination of alkyl bromide *via* the attack of the bromide anion on the *N*-alkyl carbon atoms. Therefore, the novel ring transformation is best rationalized by the following mechanism, which involves the ring expansion of the imino-1,3-dithiolane **9** formed *via* the elimination of alkyl bromide from **2**. The mechanism for the ring expansion process is analogous to the one accepted for the ring expansions[5] of **5** into **6** described above.

(PS-100 or MH-60) and a Hitachi EPI-S2 spectrometer, respectively.

1,3-Dithiolanylium Bromides (2) were prepared by bromination of the corresponding *S*-(2-methallyl) dithiocarbamate, following the procedures described in the previous paper[4]; **2a** ($R'=CH_3$), mp 202—204 °C; **2b** ($R'=C_2H_5$), mp 116—120 °C. Treatment of **2a** with sodium tetrafluoroborate gave the tetrafluoroborate of **2a**, mp 151—153 °C (from ethanol).

Pyrolysis of Salts 2. (*a*): When the bromide **2a** (1.36 g, 4.0 mmol) was heated at 210 °C under nitrogen, the bromide gradually melted and the evolution of gases was observed. After heating at that temperature for 10 min, the gas evolution ceased. A white solid and a yellowish oil were formed at the top side of the flask, and a dark-brown tar was left at the bottom of the flask. The white solid was collected, washed with ether, and recrystallized from acetone-ethanol to give 0.45 g (48%) of the hydrobromide of **4a** (**4a'**); mp 175—177 °C. The spectral data are described above.

Found: C, 29.72; H, 4.19; N, 5.68%. Calcd for $C_6H_{10}BrNS_2$: C, 30.00; H, 4.17; N, 5.83%.

The ethereal washings were freed from solvent to give 0.01 g (16%) of **4a** as an oily residue. The spectral data are described above.

Treatment of the hydrobromide **4a'** thus obtained with triethylamine in benzene afforded the free imine **4a** in 96% yield. Furthermore, **4a** thus obtained was allowed to react with methyl iodide in acetone to give the 1,3-dithiinylium iodide (**7**); UV (EtOH), λ_{max} 244 (sh.) and 269 nm; IR (KBr), 1570 cm^{-1} ($C{=}N^+$).

Found: C, 27.32; H, 4.02; N, 4.73%. Calcd for $C_7H_{12}INS_2$: C, 27.90; H, 3.99; N, 4.65%.

(*b*): The bromide **2a** (5.00 g, 14.9 mmol) was pyrolyzed at 190 °C for 10 min in a similar manner. After cooling, an aqueous solution of sodium carbonate was added to the residue with stirring and the resulting mixture was extracted twice with ether. The combined extracts were dried over anhydrous sodium sulfate and freed from solvent to give an oily residue. Purification of the oil by chromatography on silica gel, using chloroform as eluent, followed by distillation, gave 1.23 g (52%) of **4a**: bp 77—79 °C/0.07 mmHg.

(*c*): The bromide **2b** (3.15 g, 8.7 mmol) was pyrolyzed at 180—190 °C for 45 min. After cooling, the residue was subjected to the same work-ups as in the case of (*b*) yielding 0.76 g (51%) of **4b** as an oil. The spectral data are described above.

(*d*): The tetrafluoroborate of **2a** (0.51 g) was heated at 210 °C for 10 min. After cooling, 0.506 g (99%) of the starting salt was recovered.

The Photochemical Sulfenylation of Halides with Organic Disulfides

Tamotsu FUJISAWA and Hiromichi OHTA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received March 29, 1976)

Synopsis. The reaction of organic disulfides with aryl radicals photochemically generated from aryl halides was investigated. Diaryl sulfides were obtained from diaryl disulfides when the radiation was provided by a low-pressure mercury lamp, while dialkyl disulfides afforded alkyl aryl sulfides whether the radiation source was a low- or a high-pressure mercury lamp.

There have been several methods reported for the formation of an aryl-sulfur linkage; in those methods, organic disulfides occupy a fairly significant position as sulfenylation reagents. The disulfide linkage is known to be cleaved by a nucleophilic[1] or electrophilic[2] attack. In addition, disulfides are good radical-trapping reagents, and the formation of an aryl-sulfur linkage by this type of reaction has been demonstrated with phenylazotriphenylmethane[3] and *N*-nitrosoacetylarylamine[4] as radical sources.

The photolysis of aryl halides is known to generate aryl radicals.[5] Halobenzenes, because of their thermal stability and availability, have more advantages as free radical sources than do azo or *N*-nitroso compounds. Thus, if disulfides can be used as scavengers of photochemically generated carbon radicals from halobenzenes, the formation of aryl-sulfur linkages would be easily achieved under milder conditions.

This reaction, however, presents a potential problem in that organic disulfides decompose on ultraviolet irradiation to give thiyl radicals.[6] In the present experiments the photochemical sulfenylatin of halobenzenes with organic disulfides was examined, and this problem was solved by the use of a large excess of halobenzenes in the presence of an aqueous solution of sodium thiosulfate.

When a solution of diphenyl disulfide in iodobenzene was irradiated in a Vycor tube with a low-pressur mercury lamp (50 W), phenyl radicals were generated and diphenyl sulfide was obtained in a 39% yield. Iodine was simultaneously formed and colored the solution deeply, thus strongly decreasing the efficiency of the photochemical reaction. Moreover, a significant part of the phenyl radicals were considered to be trapped by the iodine to regenerate the starting material instead of reacting with the disulfide. Accordingly, if the free iodine could be removed from the reaction system as soon as it is formed,[7] a better yield of diphenyl sulfide would be expected. Thus, sodium thiosulfate was used to consume iodine. A solution of diphenyl disulfide in an excess of iodobenzene and an aqueous solution of thiosulfate were stirred vigrously and irradiated with a low-pressure lamp. The yield of diphenyl sulfide was thus raised remarkably.

$$C_6H_5I + RSSR \longrightarrow RSC_6H_5 + RS\cdot + 1/2\, I_2$$

Table 1 shows the results of the sulfenylation of iodobenzene with various diaryl disulfides. Arylthio radicals partly recombine to form diaryl disulfide, which again undergoes the reaction with phenyl radicals and probably causes the yield of monosulfide to exceed the stoichiometric amount in some cases.

Compared with experiments using a low-pressure lamp, which afforded aryl phenyl sulfides in good yields, the use of a high-pressure mercury lamp (450W) resulted in a negligible yield of monosulfides, although the consumption of diaryl disulfide was large. This observation is attributable to the rapid photodecomposition of diaryl disulfide to thiyl radicals, which leads to side reactions.[8]

Dialkyl disulfides also reacted with iodobenzene to

a) Irradiated by a low-pressure lamp (50 W). b) Based on consumed disulfide.

give alkyl phenyl sulfides on irradiation. Both low- and high-pressure lamps were effective in the formation of sulfides. An attack by a phenyl radical on the disulfide linkage rather than α-hydrogen abstruction occurred mainly, much as in the cases of thermal reactions.[3)] The yields of alkyl phenyl sulfides were influenced by steric factors. In the case of di-*t*-butyl disulfide, the consumption of the disulfide was very small and neither *t*-butyl phenyl sulfide nor *t*-butyl phenyl disulfide was obtained.

The photochemical sulfenylation by the use of disulfide was also studied with various aryl halides. The results are summarized in Table 2. The reaction effected with a low-pressure lamp afforded good yields of the expected monosulfides. *p*-Bromophenol gave diaryl sulfides by the reaction with diaryl disulfides, but the expected monosulfides could not be obtained from dialkyl disulfides.

Experimental

Reaction of Disulfides with Iodobenzene: General Procedure. Into a reaction tube (Vycor for a low-pressure lamp; Pyrex for a high-pressure lamp) were placed a disulfide (2.5 mmol), iodobenzene (5 ml), and a 1 M aqueous solution of sodium thiosulfate (5 ml). The reaction tube was degassed and sealed *in vacuo*. Irradiation was carried out with an external helical low-pressure mercury lamp (50 W) or a high-pressure mercury lamp (450 W) for 48 h with vigorous stirring. The organic layer was separated from the reaction mixture, and the aqueous layer was washed with dichloromethane. After being dried over anhydrous sodium sulfate, the combined organic layer was concentrated to exactly 10 ml. Phenyl monosulfide and recovered disulfide were identified and determined by GLPC using a standard solution of each authentic sample.

The Simulation of the ESR Spectra of the Perylene Cation on Solid Surfaces

Hisashi UEDA

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received July 2, 1975)

The simulation of the ESR spectra of the perylene cation formed on the surface of silica gel (with MoO_3), silica–alumina, and γ-alumina (with MoO_3) was studied. These oxides were pretreated in a vacuum of 10^{-5} Torr and at 300 °C, and were then brought into contact with a purified perylene solution in benzene. The main parameters which determine the shape of spectra were investigated. By comparing the experimental spectra with the simulated ones, it was concluded that unpaired electron-spin densities on the carbon atoms of the perylene cation are identical to those of the perylene cation in the H_2SO_4 solution. However, the number of γ-protons which have spin-nuclear interactions with the unpaired electron is three or less. It was found that a considerable part of the line-width is caused by g-unisotropies. If the perylene cation is bound more strongly on the surface, more g-unisotropy is observed and the half-width becomes wider. When the perylene cation is prepared in the air, O_2 and H_2O molecules coordinate to the perylene cation formed. It was found that the complex cations thus formed have different g-unisotropies and that the ESR spectrum of this cation mixture is structureless, smooth, and a continuous curve.

The perylene cation is formed when a benzene solution of perylene is added to pretreated silica gel, on which MoO_3 is supported. The pretreatment consists of heating the oxide at 300 °C and under a vacuum of 10^{-5} Torr. The ESR spectra of the perylene cations formed on those oxides which have been thus pretreated have hyperfine structures which are not found in the spectra of untreated oxides.[1-3] The present work was undertaken in order to ascertain what simulation parameters will simulate those hyperfine structures. The combinations of parameters which fit the experimental spectra well were found, and upon those parameters the probable structures of the perylene cation on oxide surfaces are discussed.

Experimental

The perylene cation is formed when a benzene solution of perylene is mixed with inorganic oxide powders which have positively charged points on their surfaces. In the present work three mixed oxides were used: (1) γ-alumina, on which 8.5% of MoO_3 was supported, (2) silica–alumina, consisting of 25% Al_2O_3 and 75% SiO_2, and (3) silica gel, on which 8.5% of MoO_3 was supported. All the oxides except the alumina sample for Fig. 4 were pretreated before mixing with a perylene solution (5 mg/ml). The pretreatment consisted of heating the mixed oxide in a Pyrex tube at 300 °C while it was evacuated to 10^{-5} Torr. After one hour the oxide was cooled and mixed with a perylene solution in benzene which had been prepared in the vacuum line. In the sample for Fig. 4 the perylene cation was prepared in the air. A benzene solution of perylene and alumina with MoO_3 were mixed and then the benzene was evaporated in the air. After the evaporation of the benzene the ESR spectra of the perylene cation (Fig. 4, solid line) were obtained. The evacuation of the sample to 10^{-5} Torr had no effect on the spectrum. After recording the spectrum, benzene was added to the sample and the ESR spectrum was taken again. Again no solvent effect was observed.

Results

In Fig. 1 the ESR spectrum of the perylene cation formed on the surface of γ-alumina (solid line) is shown. One of the simulated spectra is also shown (dotted line).

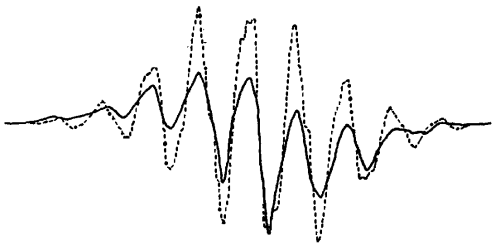

Fig. 1. ESR spectra of perylene cation on pretreated alumina (MoO_3) surfaces. The dotted curve is a simulated spectrum.

The parameters used for the simulation spectrum were $a_\alpha=4.10$, $a_\beta=3.10$, and $a_\gamma=0.46$ G, which are common through Figs. 1—5.[4,5] In the case of Fig. 1, $NA=4$, $NB=4$, $NC=3$, and $W=1.84$ G were used. NC and W could not be decided separately. $NC=3$ was selected in connection with Fig. 3, after which $W=1.84$ G was adopted.

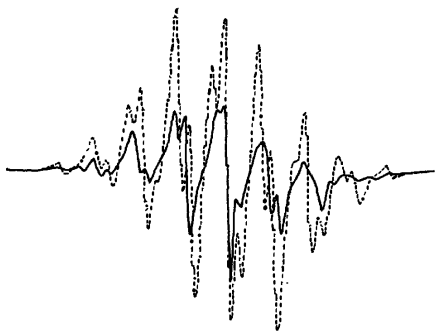

Fig. 2. ESR spectra of perylene cation on pretreated silica–alumina surfaces. The dotted curve is a simulated spectrum.

In Fig. 2 the ESR spectrum of the perylene cation formed on the surface of silica–alumina (solid line) is shown. One of the simulated spectra is also shown (dotted line). The parameters used for Fig. 2 were $NA=4$, $NB=4$, $NC=0$, and $W=2.98$ G. The further splitting of the 9-line spectrum is caused by $a_\alpha-a_\beta=1.0$ G. The line widths of the 9-line (or 18-line)

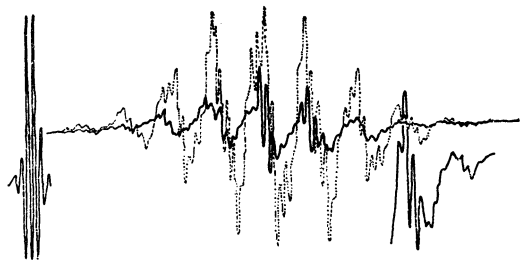

Fig. 3. ESR spectra of perylene cation on pretreated silica gel (MoO_3) surfaces. The dotted curve is a simulated spectrum.

spectrum of Fig. 2 are determined by both NC and W. Therefore, $NC=0$ and $W=2.98$ G should not be accepted with their face values.

In Fig. 3 the ESR spectrum of the perylene cation formed on the surface of silica gel (solid line) is shown. One of the simulated spectra is also shown (dotted line). The parameters used for Fig. 3 were $NA=4$, $NB=4$, $NC=3$, and $W=1.33$ G. The total number of the hyperfine lines to be obtained theoretically is $(NA+1)$-$(NB+1)(NC+1)=100$. The central part of the second derivative curve of the experimentally obtained spectrum is shown to the left of the first derivative curves. In the second derivative curve, the variations in the curvatures of the spectral line are more intensified than the first derivative curve. An important point found in the experimental spectrum is that the total number of hyperfine lines is an even number. The two equally strong, most intense lines in the center of the spectrum typically demonstrate this fact. In the case of Fig. 3, therefore, $NC=3$ is an essential parameter. Considering this fact, $NC=3$ was used in the simulation of Fig. 1. In order to see the less intense hyperfine lines, a part of the 10-times-amplified spectrum is shown to the right of the figure.

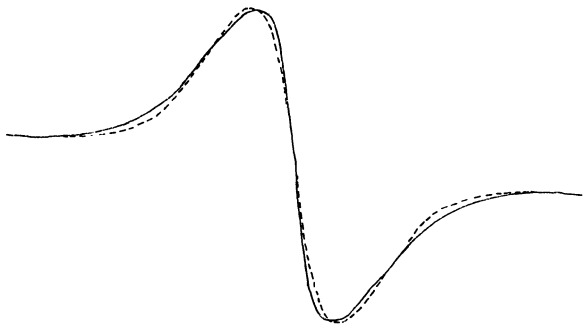

Fig. 4. ESR spectra of perylene cation prepared in the air. The dotted curve is a simulated spectrum which was calculated by assuming a half width of 8.20 G.

In Fig. 4 the ESR spectrum of the perylene cation which was prepared in the air on the alumina surface (solid line) is shown. As a mathematical problem, $NA=4$, $NB=4$, and $W=8.20$ G give a satisfactorily simulated spectrum (dotted line). However, $W=8.20$ G, considering $a_\alpha=4.10$ G, is too large to interpret. Therefore, some other simulations must be tried. For this reason the spectra in Fig. 5 were calculated.

In Fig. 5 three simulated spectra, 5A, 5B, and 5C,

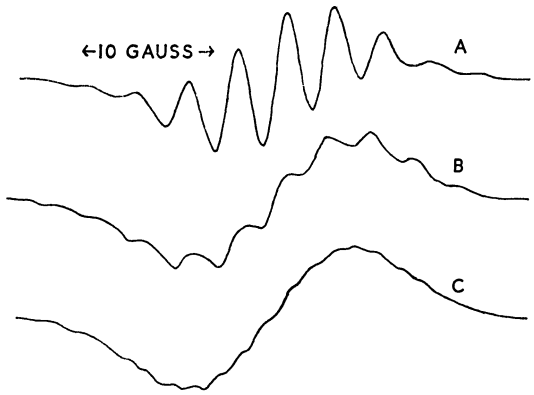

Fig. 5. The simulated ESR spectra for the perylene cation prepared in the air. A: Single g-factor with line width of 1.0 G. B: A spectrum obtained by averaging the spectrum A by a set of unisotropic g-factors. C: A spectrum obtained by averaging two of B-type spectrum different g-tensors.

are shown. The 5A spectrum was obtained by $a_\alpha=a_\beta=3.60$ G (a g-unisotropy of 1.0 G or $\delta g=0.0006$ is included in these values), $NA=4$, $NB=4$, and $W=1.82$ G. This is similar to the one in Fig. 1. On the base of 5A, the 5B spectrum was calculated assuming g-unisotropy. The unisotropic principal values of g, $g_1(2.0009)$, $g_2(2.0030)$, and $g_3(2.0051)$ were assumed. In 1800 directions uniformly distributed in the three-dimensional space, the g-factors were computed from those three principal values. The 1800 spectra obtained by these g-factors were then averaged. The 5B spectrum thus obtained shows that the assumption of only one set of unisotropic g-factors is not enough to get a smooth simulation curve in Fig. 4. If two perylene cations with different principal values of the g-factor are assumed, a smoother curve, 5C, is obtained. In the 5C spectrum, $g_{11}(2.0009)$, $g_{12}(2.0030)$, $g_{13}(2.0051)$, and $g_{21}(2.0019)$, $g_{22}(2.0040)$, and $g_{23}(2.0061)$ were assumed. In practice, the 5B′ spectrum was computed from g_{21}, g_{22}, and g_{23} in the same way as that for 5B. The 5B and 5B′ spectra were then averaged.

Discussion

The Unpaired Electron-spin-density Distribution in the Perylene Cation. One of the γ-protons of the perylene cation on the silica gel surface, as is shown by the simulation in Fig. 3, does not have a hyperfine interaction with the unpaired electron. If one of the γ-protons is removed from the perylene molecule, and if the cation becomes a $C_{20}H_{11}\cdot$ radical, the molecular symmetry changes and the a_α and a_β values should change from 4.10 G and 3.10 G respectively. In the present simulations, $a_\alpha=4.10$ and $a_\beta=3.10$ G gave satisfactory results. This suggests that the migration of the proton was not so large as to cause a great change in the π-electron orbital.

The Factors Affecting the Linewidth. There are three main sources which contribute to the magnitude of the half-width, W: (1) the magnetic dipole-dipole interactions, (2) the unaveraged unisotropic hyperfine splitting

caused by the restricted motions of the cation, and (3) the unisotropy in the *g*-factor.

The contribution of (1) is estimated from the linewidth of Fig. 3 to be about 0.2 G. The contribution from (2) will be about 2 G because it will be about 50% of a_α (4.10 G). The contribution from (3) apparently becomes quite large in some cases. In Fig. 5, if two of the principal values differ from the third value +0.0021 and −0.0021 respectively, the half-width becomes so wide that the entire spectrum looks continuous. A half-width of 8.2 G can give a simulated spectrum which resembles the experimentally obtained spectrum.

The Different States of the Perylene Cation on Three Oxides.

Silica Gel: If a completely degassed and dehydrated sample is used, the half-width can be reduced to 0.2 G and the detailed structure of the spectrum can be observed. The motions of the perylene cation are quite free in this case, and as a result the unisotropy in the *g*-factor is considerably reduced.

Silica–Alumina: In Fig. 2, $NC=0$ and $W=2.98$ G were used as simulation parameters. In the W value the width caused by $NC=3$ and $a_\gamma=0.46$ G may be hidden. The reason why a_γ is not observed is the unisotropy in the *g*-factor. If unisotropy of 0.0003 in the principal values of the *g*-factor is assumed, the resulting linewidth is 0.46 G. Therefore, a_γ becomes invisible. On silica–alumina surfaces, the motions of the perylene cation are more restricted than those on silica gel. However, the linewidth caused by the unisotropy of the *g*-factor is not so large as to submerge the 1.0 G difference between a_γ and a_β.

γ-Alumina: *In the Presence of Air and Humidity.* The perylene cation prepared in the presence of air and humidity gives the ESR spectrum shown in Fig. 4. If we assume two different states of the perylene cation, which have differently unisotropic *g*-factors, a spectrum like Fig. 5C may be obtained. This holds true if, for example, we assume (P^+O_2), a perylene cation to which O_2 is weakly bonded, and (P^+OH_2), a perylene cation to which H_2O is weakly bonded. If (P^+O_2) has the *g*-factor of (g_{11}, g_{12}, g_{13}) and (P^+OH_2) has the *g*-factor of (g_{21}, g_{22}, g_{23}) used for Fig. 5C, and if there is an equal mixture of those two species, a spectrum just like Fig. 5C is observed. It will also be possible to use alternate species, such as P^+O (an atomic oxygen is adsorbed by the cation) or P^+O_2-1 and P^+O_2-2 (two differently coordinated oxygen molecules to a perylene cation) as well as P^+O_2 and P^+OH_2. It remains for future study to determine which of them are really present.

γ-Alumina: *Cation Formation in a Vacuum.* When a perylene solution is mixed with calcined alumina with MoO_3 in a vacuum line, the effects of O_2 and H_2O will be mostly removed from the spectrum. However, even after repeating the pretreatment several times, the ESR spectrum of the perylene cation cannot be resolved any more than that in Fig. 1. The reason for this is that the motions of the perylene cation are more restricted than those on silica–alumina. If the motion of the cation is more restricted, the unisotropy of the hyperfine structure can be observed more; also, the unisotropy of the *g*-factor will be observed still more. For these reasons, the half-width value, 1.84 G, for Fig. 1 includes the width due to the *g*-factor unisotropy. Seeing that, in the case of silica–alumina, $a_\alpha-a_\beta=1.0$ G was detected in the experimental spectrum, while in the case of alumina it was almost unobservable, the half-width due to the *g*-unisotropy is 1.0 G. This corresponds to a *g*-unisotropy of 0.0006.

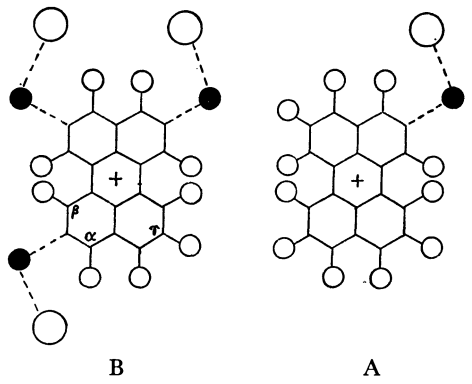

Fig. 6. Perylene cation on oxide surfaces. A: Fixed at one point and has relatively free motions. The cation on silica gel surface. B: Fixed at several points, and has restricted motions. The cation formed in the air on alumina surface. A large circle signifies an oxygen atom (anion) and a small filled circle signifies a fixed proton.

Conclusion. An oxygen atom, an oxygen ion, or molecules containing oxygen will bond weakly to the perylene cation, formed and stabilized on an oxide surface. The unpaired electron of the perylene cation migrates slightly to the atomic or molecular orbital of oxygen. The spin-orbit coupling in the oxygen orbitals affects the energy level of the unpaired electron and causes the *g*-factor to become slightly more unisotropic. The unisotropy of the *g*-tensor is averaged by the motion of the perylene cation allowed on the surface. The degree of averaging depends on the oxide carriers used. The pictures shown in Fig. 6 illustrate some aspects of the perylene cation formed on oxide surfaces.

Rotational Isomerism and Intermolecular Interaction in the Liquid Phase

Tsunetake FUJIYAMA and Masao KAKIMOTO*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158
**Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 114*

(Received September 2, 1975)

The Raman intensities of some fundamental lines of 1,2-dichloroethane and 1,2-dibromoethane and related molecules with internal rotation axes were observed at various temperatures. The observed relative intensities were corrected for some systematic errors expected in the intensity measurement. The importance of a local-field effect was emphasized. The van't Hoff plot of the observed intensity ratios of the *trans* and *gauche* isomers showed the existence of strong intermolecular interactions in the liquid phase. The intermolecular interaction energy in the liquid phase was theoretically estimated from both the macroscopic and microscopic points of view. The usefulness of a dipole-dipole interaction model was emphasized.

Rotational isomerism has been one of the major subjects in the field of physical chemistry. Many investigations have been concerned with the determination of the energy difference between rotational isomers, ΔE. In doing so, one uses the van't Hoff relation and plots the logarithms of the intensity ratio of the vibration spectra of two isomers against $1/T$, where T is the absolute temperature, and thus obtains ΔE from the slope of the plot. This method may be reasonable for the study of ΔE in the gas phase. In the case of a liquid, however, ΔE may be dependent on the temperature because of the existence of intermolecular interactions.

The present report will be concerned with the accurate measurement of the relative intensities of the Raman lines corresponding to the rotational isomers and with the determination of the interaction terms which mainly contribute to ΔE. In order to estimate the interaction energy from the microscopic point of view, it is necessary to know the relative population of the rotational isomers coexisting in the liquid phase. Detailed discussions will also be given for some experimental problems in determining relative populations from the observed Raman intensities.

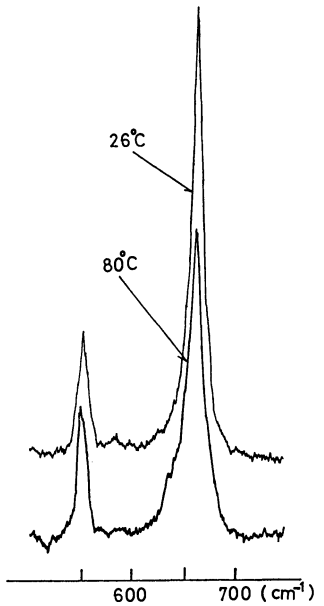

Fig. 1. Raman spectra of 1,2-dibromoethane in the region of 700—500 cm^{-1}.

Experimental

The samples used in the present work were commercial products. After fractional distillation, the purity was checked by gas chromatography.

The Raman spectra were recorded using a laser Raman spectrometer designed and constructed by the authors.[1] The instrument is composed of a He–Ne gas laser source (NEC, GLC 108, 50 mW), a Spex 1401 double monochromator, a HTV R-376 photomultiplier (S-20 response), a handmade lock-in amplifier (375 cps modulation), and a recorder. The linearity of the whole electronic system has been carefully tested. From the standard errors estimated by a linear fitting of the final output voltage against the light energy, the linearity of the whole system was claimed to be better than 1% of the full scale as long as the full scale output voltage was within 10—0.3 V[1]. Special attention was paid to the stability of the laser source.

The stability of the laser output during the spectral measurement was observed by monitoring the light energy which penetrated through the 100% reflectance mirror of the laser cavity. When the output power of the laser source drifted more than 1% during the intensity measurements, the data observed were completely discarded.

The high-temperature cell used for the measurement has been described previously.[2] The accuracy of the observed temperature is within ± 1 °C.

The 754 and 654 cm^{-1} lines of 1,2-dichloroethane were used for the relative intensity measurements. These two lines correspond to the C–Cl stretching vibrations of the *trans* and *gauche* isomers respectively. As for 1,2-dibromoethane, the, 660 cm^{-1} (of *trans*) and the 551 cm^{-1} (of *gauche*) lines were used. Those four lines have scattering cross sections large enough for their relative intensities to be observed with a high accuracy. Relative intensity measurements were repeated eight times at each temperature, the reproducibility of the observed integrated intensities was more than 99%. A typical trace of the observed spectra of 1,2-dibromoethane is illustrated in Fig. 1, which may demonstrate the actual S/N ratio of the observation. The relative intensity areas were determined by a weight method. The averaged value of the eight intensity data was taken as the observed Raman intensity. The maximum deviation of the observed intensity from the averaged value was less than 2%.

Results and Discussion

Correction of the Intensity Data for Systematic Errors. In a previous report, the apparent intensity change due to the temperature has been throughly discussed for typical liquid systems, where the importance of a local-field effect and a density effect have been emphasized.[2] According to the conclusion of the report, an appropriate factor or local-field correction for Raman scattering, L, may be expressed as:

$$L = \frac{(n^2+2)^4}{81}, \tag{1}$$

if the variation in the refractive index over the frequency range of the Raman shift can be ignored. The refractive indices for different temperatures may be estimated from the empirical Eykman equation:

$$\frac{n^2-1}{n+0.4} = \frac{d}{M} \times C, \tag{2}$$

where C is a constant characteristic for a molecule; M the molecular weight, and d, the density.[3] The density, d, as a function of temperature may be found in the International Critical Tables.[4]

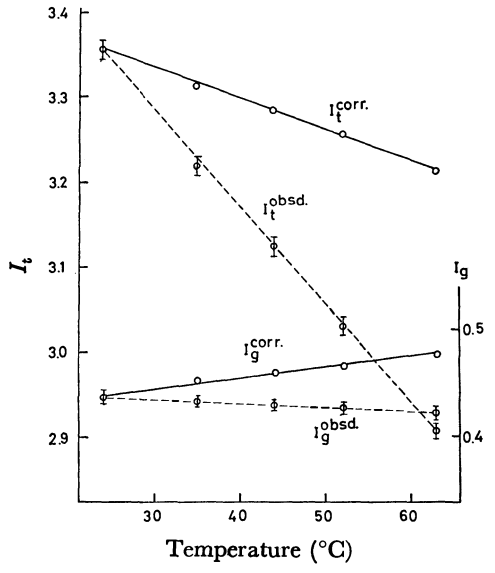

Fig. 2. Raman intensity changes due to temperature for 1,2-dibromoethane.
Observed value; ·····, corrected value; ——.

The observed relative intensities were corrected for the above two factors. The importance and the validity of those corrections are most obvious for 1,2-dibromoethane. In Fig. 2, the observed (denoted as I^{obsd}) and corrected (denoted as I^{corr}) intensities are plotted against the temperature in arbitrary units. It may be seen from the figure that both I_t^{obsd} (of the *trans* isomer) and I_g^{obsd} (of the *gauche* isomer) decrease in magnitude as the temperature increases. If the scattering cross section of the *trans* and *gauche* bands do not change in magnitude within the temperature range of the present experiment, this result is obviously strange because the *trans* and *gauche* isomers are in a thermal equilibrium. After being corrected for the effects of the density and a local-field, however, I_t^{corr} decreases in magnitude as the temperature increases, while I_g^{corr} increases in magnitude within the same temperature range.

Determination of the Relative Population of Rotational Isomers. If we know a scattering cross section of individual Raman lines, the relative population of rotational isomers can be determined from the observed intensity data. Haltman *et al.*[5] have discussed this problem in the case of an infrared absorption and proposed this relation:

$$\frac{A_1}{\alpha_1} + \frac{A_2}{\alpha_2} = C_T, \tag{3}$$

if components 1 and 2 are in thermal equilibrium. In Eq. 3, C_T is the total concentration of components 1 and 2; A, the band area, and α, the absorption coefficient. A similar relation holds for the case of a Raman scattering;

$$\frac{I_t^{obsd}}{\Omega_t} + \frac{I_g^{obsd}}{\Omega_g} = C, \tag{4}$$

or

$$I_g^{obsd} = -(\Omega_g/\Omega_t)I_t^{obsd} + \Omega_g C \tag{4'}$$

where Ω is an absolute scattering cross section, and C, a constant determined by the experimental conditions. By plotting I_g^{obsd} against I_t^{obsd} at series of temperatures, a straight line with a slope of $-(\Omega_g/\Omega_t)$ is generated as long as the scattering cross sections, Ω_g and Ω_t, are constant over the temperature range. As was emphasized in the preceding section, however, the correction of the intensity data for the systematic errors is a pivotal point for the determination of (Ω_g/Ω_t) by the use of Eq. 4.[6] Therefore, Eq. 4 should be modified to:

$$\frac{I_t^{corr}}{\Omega_t} + \frac{I_g^{corr}}{\Omega_g} = C. \tag{5}$$

The same intensity correction is also important in the case of infrared absorption, because the observed band area, A, should be corrected for the same types of systematic errors.[7,8]

Figure 3 shows the plotting of I_g^{corr} against I_t^{corr} at a series of temperatures for 1,2-dibromoethane. As is to be expected from Eq. 5, the plot gives a straight

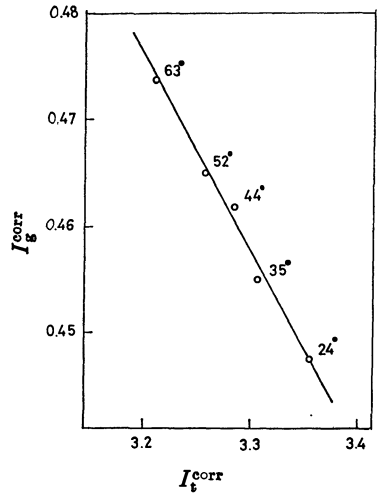

Fig. 3. $I_g^{corr} - I_t^{corr}$ plot for 1,2-dibromoethane.

line with a slope of $-(\Omega_g/\Omega_t)=-0.18$ for 1,2-dibromoethane. The number ratio of the *trans* and *gauche* isomers can, then, be calculated from this relation:

$$\frac{n_t}{n_g}=\frac{I_t^{corr}}{I_g^{corr}}\frac{\Omega_g}{\Omega_t}. \tag{6}$$

In the case of 1,2-dichloroethane, the $I_g^{corr}-I_t^{corr}$ plot was not successful, because the temperature dependence of the relative intensities of the *trans* and *gauche* bands was very small.

van't Hoff Plot and Energy Difference between Rotational Isomers. It has been widely accepted that the energy difference between the *trans* and *gauche* isomers, $\Delta E=E_g-E_t$, can be obtained by the use of the van't Hoff relation:

$$\ln\left(\frac{n_t}{n_g}\right)=A^\circ+\left(\frac{\Delta E}{kT}\right) \tag{7}$$

where A° is a constant; k, the Boltzmann constant, and T, the absolute temperature. Equation 7 claims that a straight line relation should hold between $\ln(n_t/n_g)$ and $(1/T)$. Actually, the observed $\ln(n_t/n_g)$ is plotted against $(1/T)$ in Fig. 4. We see from the figure that a

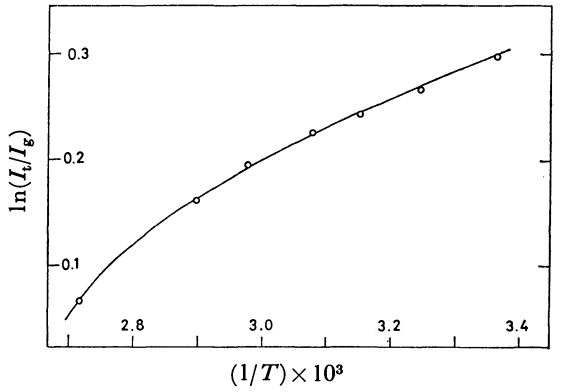

Fig. 4. Relation between $\ln(n_t/n_g)$ and $(1/T)$ for 1,2-dibromoethane.

straight line relation does not hold for the present results. This probably means that ΔE depends on the temperature in the case of liquid 1,2-dibromoethane. The effects of the entropy changes due to the temperature are included in the constant term, A°, of Eq. 7. These effects are ascertained to be negligible in the present discussion if we take into account the frequency changes in the torsional vibrations due to the temperature, and if we assume that the molecular structure is independent of the temperature within the temperature range of the present experiment. It is important to add that the absolute scattering cross sections of the *trans* and *gauche* bands are verified to be independent of the temperature from the plotting of Fig. 3.

From the $\ln(n_t/n_g)$ against $(1/T)$ plot, the ΔE values of 650—900 cal/mol are obtained according to the temperature range under consideration. If we fit the observed points to a linear function, the value of 750 cal/mol is obtained for ΔE of liquid 1,2-dibromoethane. Similar anomalous behavior for van't Hoff plot has been observed for the molecules whose *gauche* forms have large dipole moments, such as 1,2-dichloroethane and 1,1,2,2-tetrabromoethane. In the case of

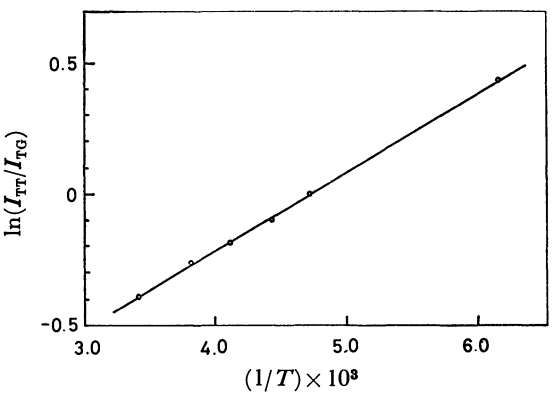

Fig. 5. van't Hoff plot for the TT- and TG-bands of pentane.

non-polar molecules, on the other hand, beautiful straight lines have been obtained for the van't Hoff plot. A typical example observed for the TT- and TG-form bands of pentane is illustrated in Fig. 5.[9] These results indicate that ΔE is dependent on the temperature and that the temperature dependency may arise from intermolecular interactions related with a dipole moment. As the *trans* isomer has no dipole moment, only the interaction between the *gauche* isomers will be considered.

Taking into account the intermolecular interactions expected in the liquid phase, we may rewrite Eq. 7 as:

$$\ln\left(\frac{n_t}{n_g}\right)=A^\circ+\left(\frac{\Delta E^\circ}{kT}\right)+\left(\frac{H}{kT}\right) \tag{8}$$

where H represents the stabilization energy of the *gauche* isomer due to the intermolecular interaction of the dipole type, and where ΔE° menas the intrinsic energy difference between rotational isomers or the energy difference in the rotational isomers when they are well isolated from other molecules. In other words, ΔE° is to be compared with the energy difference observed in the gas phase. If an interaction term, H/kT, be estimated, the $\ln(n_t/n_g)$ values for the gas phase can be estimated from those observed in the liquid phase:

$$\ln\left(\frac{n_t}{n_g}\right)_{gas}=\ln\left(\frac{n_t}{n_g}\right)_{liquid}-\left(\frac{H}{kT}\right) \tag{9}$$

Estimation of the Interaction Energy: Macroscopic. The simplest way of estimating the interaction energy, H, has been proposed by Watanabe.[10] The idea is based upon the reaction field of Onsager in a dilectric field.[11]

If we consider the dielectric field of Onsager, and consider a small cavity with a radius, a, in a continuous medium of the dielectric constant, ε, a dipole moment, μ, at the center of this cavity should cause dielectric polarization in the continuous medium. The polarization in turn exerts a field, F, upon the original dipole:

$$F=\frac{2(\varepsilon-1)}{2\varepsilon+1}\frac{\mu}{a^3} \tag{10}$$

In the present case, the *gauche* isomer can be represented by the sphere, because the *trans* isomer has no dipole moment. The *gauche* isomer in the liquid phase will then possess an excess of electrostatic energy by an amount of:

$$H = \frac{(\varepsilon-1)}{2\varepsilon+1}\frac{\mu_g}{a^3} \tag{11}$$

as compared with that of the free molecule, where, in the present case, μ_g, is the permanent dipole moment of the *gauche* isomer. The corresponding energy change in the *trans* isomer with no dipole moment is negligible. By introducing the observed μ_g, and ε values of Morino *et al.*[12] into Eq. 11, the (H/kT) values were obtained. Then the expected values of $\ln(n_t/n_g)_{gas}$ were calculated by the use of Eq. 9. The results are given in the last column of Table 1 and are illustrated on Fig. 6 (denoted as the Onsager Field). Obviously, the calculated points of $\ln(n_t/n_g)$ for different temperatures fall on a straight line, from which the $\Delta E°$ value expected for the gas phase is calculated to be 1.6 kcal/mol and the $\ln(n_t/n_g)$ value, to be 1.53 at 20 °C. The experimental $\Delta E°$ values observed by the dielectric constant measurement,[13] and the vibration spectra[14–16] are 1.4—1.78 kcal/mol. These values agree well with the calculated value of 1.6 kcal/mol. The logarithmic relative population, $\ln(n_t/n_g)$, as observed by a gas-phase electron-diffraction method, has been reported to be 1.38—1.7 at 20 °C.[17] The agreements between the expected and observed values are quite satisfactory; this indicates the validity of the way of estimating the interaction term, H, on a macroscopic base.

Table 1. Observed and calculated $\ln(n_t/n_g)$-values at various temperatures

(I) Dipole-dipole interaction, (II) dipole-dipole interaction+dipole-induced dipole interaction, (III) reaction field of Onsager.

Temperature (°C)	Observed (Liquid)	Calculated (I)	(II)	(III)
24	0.300	0.755	0.951	1.534
35	0.269	0.690	0.878	1.444
44	0.245	0.640	0.822	1.372
52	0.232	0.603	0.779	1.318
63	0.199	0.544	0.713	1.233
72	0.164	0.490[a]	0.654[a]	1.157[a]
97	0.071	0.362[a]	0.522[a]	1.018[a]

a) Density as a function of the temperature is not given in these temperature ranges (see Ref. 4).

Estimation of the Interaction Energy: Microscopic. The preceding discussion has been based upon a macroscopic point of view. As the macroscopic estimation of H was quite successful, it is of much importance to calculate the interaction term, H, on a microscopic base, also.

Consider the environments to be built up of gas-like molecules dispersed in a vacuum to give the actual density of the liquid phase, instead of looking on them as continuous dielectrics. Only the interactions between the *gauche* isomers are considered in the estimation of H, because the *gauche* isomer has a large dipole moment. Then, H is expressed as:[18,19]

$$H = H_1 + H_2 \tag{12}$$

where

$$H_1 = -\frac{4\pi^2}{27}\frac{\mu_g^4}{kT}\left(\frac{\rho}{W_m}\right)^2\frac{N_a^2}{1+(n_t/n_g)} \tag{12a}$$

$$H_2 = -\frac{4\pi^2}{27}\alpha m^2\left(\frac{\rho}{W_m}\right)^2 N_a^2 \tag{12b}$$

and

$$m = \frac{\mu_g}{1-\frac{4\pi^2}{27}\left(\frac{\rho}{W_m}\right)N_a^2\alpha\left[\frac{\mu_g^2}{kT}\frac{1}{1+(n_t/n_g)}+\alpha\right]} \tag{12c}$$

In Eqs. 12, μ_g is a dipole moment of the *gauche* isomer; ρ, the density; W_m, the molecular weight; α, the averaged polarizability of a *trans-gauche* mixture; N_a, Avogadro's number, and k, the Boltzmann constant. H_1 corresponds to the dipole-dipole interaction between the *gauche* isomers, and H_2, the dipole-induced dipole interaction. By introducing the observed values of μ_g,[12] ρ, and α[20] into Eqs. 12, we obtained the expected values, $\ln(n_t/n_g)$, by the use of Eq. 9. The results are summarized in Table 1 and are illustrated in Fig. 6. The results show that the value of 1.2 kcal/mol is obtained for $\Delta E°$ if we consider only the dipole-dipole interaction in the estimation of H (see Fig. 6, denoted as Dipole-Dipole). If we add the dipole-induced dipole interaction term, the value of 1.4 kcal/mol, is obtained for $\Delta E°$ (see Fig. 6, denoted as Dipole-Induced Dipole). As the observed $\Delta E°$'s are 1.4—1.78 kcal/mol, the agreement between the calculated and observed values seems satisfactory. On the other hand, Table 1 and Fig. 6 show that the agreement between the calculated and observed $\ln(n_t/n_g)$'s is less satisfactory than that obtained by the preceding macroscopic estimation.

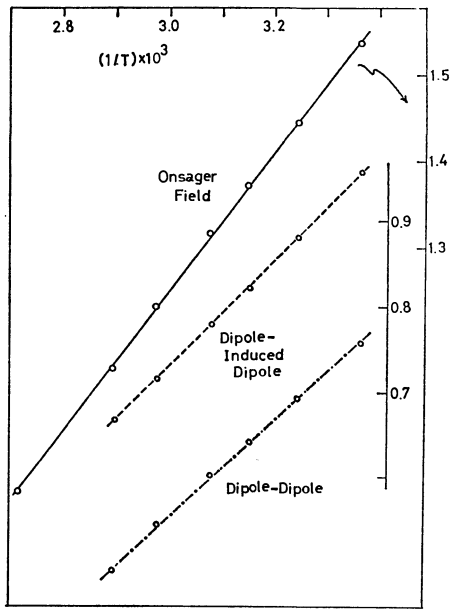

Fig. 6. Expected values for $\ln(n_t/n_g)_{gas}$ for 1,2-dibromoethane (as for the notations, see the text).

The present theoretical approach to estimating the interaction term, H, is based upon an extremely simple model. As has been described in a reference,[19] we first estimated the total interaction energy using a dipole interaction model, and then we averaged it over all possible orientations and distances of the interacting pair. In the averaging process, we assumed a distribution function of the simple Boltzmann type, and we truncated the Taylor expansion of the distribution

function at the first-order term with respect to $(1/T)$. These treatments are certainly over-simplified. The numerical results, however, suggest the possibility of estimating the thermodynamic quantities of the liquid phase by such a purely microscopic approach. Attention must be paid to the fact that the interaction term obtained by the present calculation is expressed in terms of purely molecular quantities, such as a dipole moment and polarizability, instead of a dielectric constans, a very macroscopic quantity, although the polarizability and the molecular radius are *practically* calculated from such macroscopic quantities as the refractive index and the density.

The authors are indebted to all the members of the Shimanouchi Laboratory of The University of Tokyo and to Professor Takehiko Shimanouchi for their helpful correspondence about this work.

Heterogeneous Catalysis in Liquid-Phase Oxidation of Olefin. I. Activity of Vanadium System Catalysts for Oxidation of Cyclohexene

Katsuomi TAKEHIRA and Toshio ISHIKAWA

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received October 27, 1975)

The catalytic activities of various binary oxides containing vanadium for the liquid-phase oxidation of cyclohexene have been studied, in comparison with those of one component oxides and soluble metal acetylacetonates. The reaction was carried out at 60 °C in benzene solvent. The distribution of reaction products suggests the occurrence of autoxidation and epoxidation when vanadium system catalysts are used. Among the binary catalysts, V–Cr and V–Mo systems showed relatively high specific activities, especially high activity being obtained by the former systems calcined at a low temperature. It seems that cyclohexene oxide is formed mainly by two successive catalytic processes, *i.e.*, the formation of cyclohexenyl hydroperoxide by autoxidation and the selective oxidation of cyclohexene with the hydroperoxide. The machanism of epoxidation was confirmed by the reaction of cyclohexene with *t*-butyl hydroperoxide in the presence of V–Cr catalyst.

Studies have been carried out in the field of liquid-phase oxidation of olefins with insoluble catalysts containing transition metals. Cyclohexene was often used as a model reactant.[1,2] Meyer *et al.*[1] showed the heterogeneous-homogeneous character of the reaction with MnO_2 and CoO as catalysts. Gould and Rads[2] studied the distribution of reaction products and suggested that the atomic number and oxidation state of transition metal in the catalyst are important in determining the course of the reaction. However, these studies are almost restricted to the activity of one component metal oxide, scarcely any attempts to test the catalytic activity of binary oxide system being made.

V_2O_5 was found to be comparatively active for the liquid-phase oxidation of acrylaldehyde.[3] It has been frequently used as a catalyst for vapor-phase oxidation of some hydrocarbons, many investigations being published about the high activity obtained by combining V_2O_5 and another oxide. The high activity is thought to be caused by the formation of different structures from those of original oxides.[4] A similar phenomenon is expected also in a liquid-phase oxidation. Vanadium-chromium binary oxide shows higher activity than the individual one component oxide in the liquid-phase oxidation of acrylaldehyde.[5] The catalytic activity of the binary oxide was discussed in connection with its structure, and the active species in this catalyst was thought to be phase Y which is a chromium isopolyvanadate.

On the other hand, soluble metal complexes of vanadium, as well as those of molybdenum or tungsten, catalyze the selective epoxidation of olefin with organic hydroperoxide.[6] The oxidation of cyclohexene with binary oxide catalyst containing vanadium seems to be of interest in view of the epoxidation. For the purpose of studying the effects of addition of second component to vanadium pentoxide, various binary oxides containing vanadium were prepared, and their catalytic activities for the oxidation of cyclohexene have been examined in comparison with those of one component oxides and soluble metal acetylacetonates. These results are reported in this paper.

Experimental

Catalysts. Metal acetylacetonates [$Me(acac)_n$], *i.e.*, $VO(acac)_2$, $Cr(acac)_3$, $Mn(acac)_2$, $Mn(acac)_3$, $Fe(acac)_3$, $Co(acac)_2$, $Co(acac)_3$, $Ni(acac)_2$, $Cu(acac)_2$, $Zn(acac)_2$, and $MoO_2(acac)_2$ (Tokyo Chemical Industry Co.) were used.

One component metal oxides were prepared as follows. Cr_2O_3, Mn_2O_3, Fe_2O_3, CoO, NiO, CuO, ZnO, and Bi_2O_3 were prepared by calcination of the corresponding metal hydroxides at 450 °C for 6 h in air. The hydroxide was precipitated by addition of dilute aqueous ammonia to an aqueous solution of the corresponding metal nitrate, followed by separation from the solution by filtration, sufficient washing with water, and drying at 100 °C for one day. V_2O_5 was prepared by calcining V_2O_5 hydrate precipitated by addition of concentrated nitric acid to a warm aqueous solution of NH_4VO_3 and the subsequent washing, and drying mentioned above. MoO_3 and WO_3 were similarly prepared by calcining $H_2MoO_4 \cdot H_2O$ and H_2WO_4, respectively.

In order to study the effects of addition of second component (C_{II}) to V_2O_5, 20 kinds of binary system oxides, *i.e.*, V–Li (1/1),* V–Na (1/1), V–K (1/1), V–Mg (1/1), V–Ca (1/1), V–Sr (1/1), V–Ba (1/1), V–Cr (1/0.4), V–Mn (1/0.4), V–Fe (1/0.4), V–Co (1/0.4), V–Ni (1/0.4), V–Cu (1/0.4) V–Zn (1/0.4), V–Mo (1/0.2), V–W (1/0.2), V–B (1/0.4), V–P (1/0.4), V–Sb (1/0.4), and V–Bi (1/0.4), were prepared in the following way. A mixture of V_2O_5 hydrate and raw material of second component; hydroxide of alkali or alkaline earth metal, nitrate of Cr, Mn, Fe, Co, Ni, Cu, Zn, or Bi, $H_2MoO_4 \cdot H_2O$, H_2WO_4, H_3BO_3, H_3PO_4, or Sb_2O_5, was kneaded with a small amount of water at 80 °C for 6 h.** The resulting paste was dried at 100 °C for one day, and calcined at 400 °C for 3 h in the air. Since V–Cr and V–Mo systems showed high specific activities, both systems were calcined at 600 and 800 °C in order to study the effects of calcination temperature. For the purpose of indicating the calcination temperature, catalysts are denoted by $V\text{–}C_{II(400)}$, $V\text{–}C_{II(600)}$, and $V\text{–}C_{II(800)}$, respectively.

In all cases, a particle size of metal oxide used as catalyst was smaller than 100 mesh.

Apparatus and Procedure of Reaction. The oxidation reaction was carried out at 60 °C and under 1 atm of oxygen using a gas-sealed system with an oxygen recycling unit (Fig. 1). Catalyst and benzene as a solvent were put into the reactor. Cyclohexene (20.0 ml, prepurified by passing over activated alumina to eliminate hydroperoxide) was then added, and the stirring of the reaction mixture and bubbling of oxygen (flow

* The fractional number in parentheses is the atomic ratio of V/C_{II}.

** A three component system, V–S–K (1/1/2), was also made from a mixture of V_2O_5 hydrate and K_2SO_4.

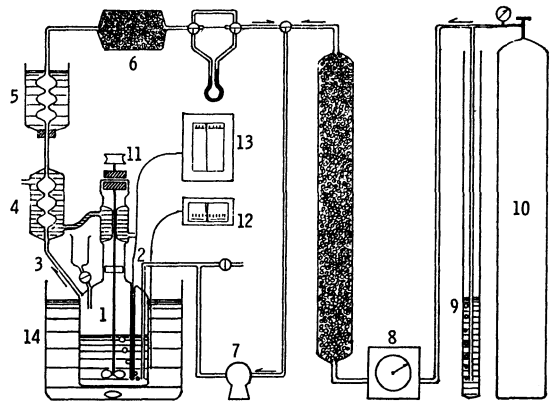

Fig. 1. Reaction apparatus.

rate; 200 ml/min) into it were started. The effluent gas mixture flowing out from the reactor was passed through the condensers and the carbon dioxide-elimination tube, and was recycled by the pump into the reactor. In order to keep the inside pressure at one atm, oxygen was supplied through a gas meter.

In order to clarify the mechanism of epoxidation the reaction of cyclohexene with *t*-butyl hydroperoxide was carried out in benzene under 1 atm of dry nitrogen using a 20 ml of glass flask. The reactor was placed on a shaker so that the catalyst was uniformly suspended.

Analyses of Reaction Products and Catalysts. The oxidation products were assayed as follows. Cyclohexenyl hydroperoxide was determined by the iodometric method described by Wagner *et al.*[7] The remaining components were determined by gas chromatography using a column of PEG 6000 after treating the sample with a sufficient amount of triphenylphosphine so as to reduce quantitatively the hydroperoxide into alcohol.[2] Solvent of benzene was used as an internal standard. Cyclohexene (unconverted), cyclohexene oxide, cyclohexenone, and cyclohexenol were determined. In the case of the reaction with *t*-butyl hydroperoxide, the unreacted hydroperoxide and cyclohexene oxide formed were determined by the iodometric method and gas chromatography, respectively.

The catalysts were analyzed by the following methods. The surface area was determined by the BET method using nitrogen. Powder-type X-ray diffraction pattern was obtained with a diffractometer of Geigerflex D-3F type (Rigaku Denki Co.) with Cu$K\alpha$ radiation. Infrared spectrum was recorded with a JASCO-DS 403 G grating spectrophotometer with samples prepared in the form of KBr pressed discs.

Results and Discussions

When an olefin is oxidized by radical chain mechanism, the peroxy radical formed has two reactivities, hydrogen abstraction from olefin and addition to olefin. It was experimentally found that both contributions change a great deal with the structure of olefin.[8,9] According to the result of cyclohexene oxidation by Mayo *et al.*,[8] the main part of the autoxidation products is cyclohexenyl hydroperoxide, and the amount of cyclohexene oxide is very small, indicating that hydrogen abstruction proceeds mainly. It might be concluded that cyclohexene oxide is scarcely formed in the radical chain reaction. Experiments with use of a radical initiator also gave similar results. As an example, by the 4 h reaction in benzene solvent with a thermal initiator of azobisisobutyronitrile (AIBN) (10^{-2} mol/l), 90.4% of cyclohexenyl hydroperoxide, 3.2% of cyclohexene oxide, 2.5% of cyclohexenone, and 3.9% of cyclohexenol were formed.***

However, it was reported that relatively large amount of cyclohexene oxide was formed in the case of using some transition metal catalysts. Gould and Rado[2] carried out the oxidation of neat cyclohexene using soluble acetylacetonates or insoluble oxides of various transition metals as a catalyst at 70 °C under the oxygen pressure of 6.5 atm. A relatively high yield of cyclohexene oxide was obtained with molybdenum or vanadium compound catalyst, such as $Mo_2(acac)_2$, VO-

$(acac)_2$, MoO_3 or V_2O_5. Therefore, in the present work, the activity of one component metal catalyst was first of all studied. The following results were obtained by use of acetylacetonates and oxides of several metals as catalysts.

Activities of One Component Metal Catalysts. The results with metal acetylacetonate catalysts are given in Table 1. Cobalt and manganese also show high activity. The activity depends on the oxidation states or coordination numbers. In the reaction with $Co(acac)_2$ catalyst, a rapid absorption of oxygen was observed after the color of reaction solution turned from pink to green, suggesting the formation of cobaltic ion. The induction period was shortened by the addition of *t*-butyl hydroperoxide, the oxygen absorption being also accompanied by a similar change of color. Hydroperoxide seemes to be decomposed by way of its coordination to cobalt. Then, the chain reaction starts. In contrast, $Co(acac)_3$ shows relatively low activity which may be ascribed to the larger stability of the six-coordinated octahedral structure.[10)] A long induction period and a low activity observed with $Mn(acac)_2$ indicate that manganous ion inhibited, as reported by Gould and Rado[2)] the autoxidation of cyclohexene by reacting with cyclohexenyl peroxy radical. $Cr(acac)_3$ was reported to have activity in the oxidation of neat cyclohexene.[2)] However, it showed no oxygen absorption in the present work. The deactivation observed especially with $Co(acac)_2$ and $Mn(acac)_3$ seems to result from the formation of the metal oxides or basic chelate. This is supported by the fact that precipitates formed during the course of reaction.

The results of the reactions with several matal oxides catalysts are given in Table 2. Mn_2O_3 shows the highest activity. In spite of the inactivity of chromium and vanadium in the chelate form, their oxides showed activity. Meyer *et al.*[1)] reported that chromium(III) oxides seem to initiate the reaction only by the decomposition of hydroperoxide, while cyclohexene itself may be the initiating agent in the reaction activated by cobalt and manganese oxides. In the present study, the long induction period observed in the reaction with chromium(III) oxide may be due to the accumulation of the hydroperoxide. Manganese oxide exhibiting a considerably short induction period is thought to initiate the reaction without decomposing the hydroperoxide.

Concerning the reaction products, the following results were obtained. The main product with the active catalysts was cyclohexenyl hydroperoxide, the amount of cyclohexene oxide being very small. The selectivity of the hydroperoxide was lower with manganese and cobalt catalysts than with the other catalysts except V_2O_5. This is thought to be caused by the formation of cyclohexenol and cyclohexenone accompanied by the radical decomposition of hydroperoxide. Contrary to the results obtained by Gould and Rado,[2)] MoO_3, $MoO_2(acac)_2$, and $VO(acac)_2$ gave no epoxide. Fairly high selectivity of the epoxide was attained only with V_2O_5. The other catalysts showed low values of selectivity which are near those obtained by using the thermal initiator AIBN.

Details of the Reaction with V_2O_5. In order to clarify the oxidation with V_2O_5 and compare the results with that with other catalysts, several reactions were carried out. The distributions of products in the reactions are given in Table 3. V_2O_5 showed a higher selectivity of cyclohexene oxide than the other catalysts. The high selectivity does not seem to be explained by the radical chain mechanism. The epoxidation with V_2O_5 seems to proceed either by the oxygen activation

(4)

Reaction 3 proceeds by a radical chain mechanism.

Various studies have been carried out on the formation and reactivity of adsorbed oxygen species on the surface of metal oxides in the field of vapor-phase oxidation. Yoshida *et al.*[11] considered that O_2^-, an adsorbed oxygen species on partially reduced V_2O_5–SiO_2 catalyst, oxidizes propylene at room temperature by a mechanism involving the intermediate of epoxide structure. In the present study, the reduced vanadium species existed also in V_2O_5 catalyst,† and the oxygen activation mechanism is therefore possible. However, in spite of this argument in favor of the oxygen activation process, the fairly large amount of hydroperoxide in the products suggests the availability of another mechanism involving the radical chain reaction 3. The hydroperoxide intermediate mechanism is also supported by the presence of a large amount of cyclohexenol.

In the reactions with cobalt and manganese catalysts, the main products were cyclohexenyl hydroperoxide, cyclohexenol, and cyclohexenone, and the formation of cyclohexene oxide was very small. Such distribution of products may be explained by an acceleration of the radical chain reaction due to the Haber-Weiss mechanism. The distribution of oxidation products with Cr_2O_3 was similar to that with cobalt and manganese catalysts. Cr_2O_3 seems to accelerate the radical chain reaction by decomposing the hydroperoxide.

Reaction Results with Binary Oxide Catalysts. V_2O_5 catalyzes the epoxidation of cyclohexene. The activity of V_2O_5 catalyst increases in acrylaldehyde oxidation when it is modified with another metal oxide, Cr_2O_3, resulting in change of catalyst structure.[5] Similar phenomena concerning the catalyst for vapor-phase oxidation have been reported.[4] The catalytic activities of various binary oxides containing vanadium were tested also in the liquid-phase oxidation of cyclohexene.

Oxygen absorption was observed for several binary oxides. The results are given in Table 4. Concerning the maximum rate of oxygen absorption (R_{max}), the activity of the catalysts can be put in the order $\text{V–Cr}_{(400)} \gg \text{V–Cr}_{(600)} \gg \text{V–Mn} > \text{V–P} > \text{V–Fe} \simeq \text{V–Bi} \simeq \text{V–Mo}_{(800)}$, the other systems showing extremely low activity. The V–Cr system in particular showed high activity. This binary system showed higher activity when calcined at lower temperature, which coincides with results observed in the study of acrylaldehyde oxidation.[5] The activity of the V–Mo system, in contrast, appeared only when calcined at 800 °C. With respect to the formation of cyclohexene oxide, most of these binary systems showed comparatively higher ability than the one component metal oxides (Table 2) or metal acetylacetonates (Table 1).

Structure and Activity of V–Cr and V–Mo Systems. In the liquid-phase oxidation with insoluble metal oxide catalysts, the reaction proceeds by a heterogeneous initiation mechanism on the surface of catalysts.[1] The specific surface area (S_s) of the catalyst having relatively high activity was measured and is given in Table 5, together with the specific activity (R_{max}/S), *i.e.*, the maximum rate of oxygen absorption per unit surface area of the catalyst. The V–Cr system calcined at a low temperature also showed higher values in specific activity.

According to the results of X-ray diffraction analysis (Fig. 2), $\text{V–Cr}_{(400)}$ and $\text{V–Cr}_{(600)}$ showed diffraction

lines of V_2O_5 and phase Y which was reported to be a chromium isopolyvanadate.[5] However, $V\text{-}Cr_{(800)}$ showed no lines of phase Y but gave the lines of V_2O_5 and chromium orthovanadate ($CrVO_4$). While $V\text{-}Cr_{(800)}$ showed the line of d=4.38 Å which is thought to be of the plane (001) in pure V_2O_5, the lines observed with $V\text{-}Cr_{(400)}$ and $V\text{-}Cr_{(600)}$ gave the values 4.43 and 4.41 Å, respectively. This indicates that the c-axis of V_2O_5 crystal was elongated in $V\text{-}Cr_{(400)}$ and $V\text{-}Cr_{(600)}$, suggesting the formation of interfacial solid solution.†† The diffraction peaks of phase Y were slightly stronger in the pattern of $V\text{-}Cr_{(600)}$ than in that of $V\text{-}Cr_{(400)}$, while the line width of the peaks was broader in the latter. Thus, it seems that the crystallinity of phase Y is lower in the catalyst calcined at lower temperature. In the IR spectra, the absorption bands of phase Y[5] were observed in both $V\text{-}Cr_{(400)}$ and $V\text{-}Cr_{(600)}$, especially sharply in the latter catalyst. However, $V\text{-}Cr_{(800)}$ showed no such absorption bands. Thus, phase Y and the solid solution were observed in the active V–Cr binary catalysts. Phase Y is mainly formed in the catalysts prepared from NH_4VO_3 and $Cr(NO_3)_3\cdot 9H_2O$.[5] On the other hand, the catalysts in the present work were prepared from V_2O_5 hydrate and $Cr(NO_3)_3\cdot 9H_2O$. In spite of the difference in the preparative method, the formation of phase Y was observed in both cases.

The specific activity of $V\text{-}Mo_{(800)}$ came next to that of $V\text{-}Cr_{(400)}$. However, $V\text{-}Mo_{(400)}$ and $V\text{-}Mo_{(600)}$ were inactive. Concerning the catalytic activity of the V–Mo system, studies have been carried out in the field of vapor-phase oxidation, and the relationship between the activity and the structure of this system was studied in detail. The activity of this system was explained either by the formation of solid solution of MoO_3 in V_2O_5,[4] or by the formation of chemical compounds.[13] Two types of compound, *i.e.*, $Mo_6V_9O_{40}$ and $Mo_4V_6O_{25}$, were formed in the catalyst used for the oxidation of benzene to maleic anhydride. The X-ray diffraction patterns of $V\text{-}Mo_{(400)}$ and $V\text{-}Mo_{(800)}$ are shown in

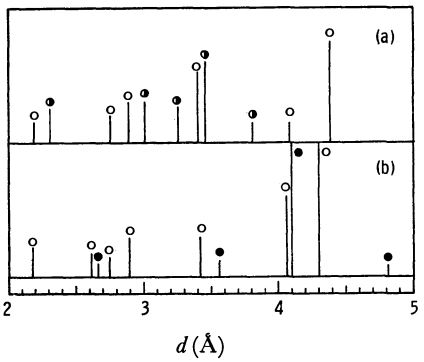

Fig. 3. X-Ray diffraction patterns of V–Mo system catalysts.*
(a): $V\text{-}Mo_{(400)}$, (b): $V\text{-}Mo_{(800)}$.
○: V_2O_5, ◑: MoO_3, ●: $Mo_6V_9O_{40}$.
* The pattern of $V\text{-}Mo_{(600)}$ was similar to of $V\text{-}Mo_{(400)}$.

Fig. 3. $V\text{-}Mo_{(400)}$ gave only the diffraction lines of V_2O_5 and MoO_3. However, in the IR spectra of $V\text{-}Mo_{(400)}$ and $V\text{-}Mo_{(600)}$, two weak absorption bands were observed at 955 and 1035 cm^{-1} together with the bands of V_2O_5 and MoO_3, suggesting the formation of some amorphous structure. On the other hand, $V\text{-}Mo_{(800)}$ showed several new lines together with the lines of V_2O_5, and the d-spacings of the new peaks were in fair agreement with the values of $Mo_6V_9O_{40}$. The diffraction data also indicate formation of solid solution. The d-spacing value of the strongest line of V_2O_5, *i.e.*, d=4.38 Å (001) in pure V_2O_5 and observed in $V\text{-}Mo_{(400)}$, was found at d=4.30 Å in $V\text{-}Mo_{(800)}$. Consequently, the lattice dimension of c-axis is shortened. According to the results of IR analysis of $V\text{-}Mo_{(800)}$, the absorption band assigned to the stretching vibration of V=O double bond was slightly displaced toward lower frequency from 1020 cm^{-1} of pure V_2O_5, broadening considerably. The results agree fairly well with those obtained by Yoshida.[4] Thus, a solid solution of MoO_3 in V_2O_5, belonging to a substitutional type, is formed in $V\text{-}Mo_{(800)}$. $V\text{-}Mo_{(400)}$ or $V\text{-}Mo_{(600)}$ is

†† It was confirmed that the interfacial solid solution is formed in the binary system. It was observed by Kurina *et al.*[12] that the solid solution is also formed in the binary oxide prepared from NH_4VO_3 and $Cr(NO_3)_3\cdot 9H_2O$. However, the existence of phase Y was not reported.

considered to be a simple mixture of V_2O_5, MoO_3 and the amorphous structure, and V–$Mo_{(800)}$ to consist of the solid solution and $Mo_6V_9O_{40}$. $Mo_6V_9O_{40}$ contains a reduced vanadium species, V^{4+}, the amount of which is one-ninth of the total vanadium.[13] The reduced vanadium species is also included in the solid solution.[4] V–$Mo_{(400)}$ and V–$Mo_{(600)}$ are inactive††† in spite of the existence of V_2O_5. Since MoO_3 initiates no oxidation, the activity of V–$Mo_{(800)}$ may be due to the reduced species. This V^{4+} ion was also considered to be contained in both Y and the solid solution observed in the V–Cr system. However, this system also contains a chromium species which is considered to be active for the decomposition of hydroperoxide in the form of Cr_2O_3. Thus, though the increase of activity caused by the addition of both chromium and molybdenum oxides seems to be correlated with change of catalyst structure, detailed discussions on this problem are necessary.

Details of the Activity of V–Cr System. The V–Cr system was found to be fairly active for cyclohexene oxidation, especially for the oxidation. In order to elucidate the mechanism of the reaction, the distribution of products in the reaction with V–$Cr_{(400)}$ was studied. The results are shown in Table 3 together with those of the V–Mn catalyst.

Both V–$Cr_{(400)}$ and V–Mn gave a product distribution similar to that with V_2O_5, fairly high selectivity of cyclohexene oxide being obtained. The epoxidation, therefore, is thought to proceed mainly by the hydroperoxide intermediate mechanism in the same way as in the reaction with V_2O_5. On the other hand, the hydroperoxide may be formed by radical chain reaction. The binary system catalysts might have two types of active site, one effective for the radical chain reaction and the other for the epoxidation with the hydroperoxide. Arzoumanian *et al.*[14] reported that the high selectivity of epoxide is obtained in the cyclohexene oxidation with soluble metallic catalyst system, and that this catalyst system is made up of two types of active component; a complex of Rh or Ir effective for the autoxidation, and that of Mo or V for the selective epoxidation. In the present study, it can be presumed that the two types of active site coexist on the surface of catalyst active for epoxidation.

Table 6. Epoxidation of cyclohexene with *t*-butyl hydroperoxide[a]

Cat.	Conv. of hydroperoxide (%)	Yield of epoxide (%)
$MoO_2(acac)_2$[c]	64.3	72.6
$VO(acac)_2$[c]	33.5	38.4
$Co(acac)_2$[c]	53.1	5.6
V–$Cr_{(400)}$[d]	26.3	35.6

a) Concentrations of cyclohexene and *t*-butyl hydroperoxide were 0.45 and 0.41 mol/l, respectively. Solvent was benzene, and the reaction temperature was 60 °C. b) Based on reacted hydroperoxide. c) Concentration of catalyst was 10^{-3} mol/l, and reaction time was 2 h. d) Concentration of catalyst was 5 g/l, and reaction time was 3 h.

$Co(acac)_2$ shows high activity at the beginning of the reaction, its activity being lowered with reaction time (Fig. 4). This seems to be due to the change of chelate into the insoluble state. Concerning the distribution of products, cyclohexeneyl hydroperoxide continued to be the main component throughout the reaction time, the amount of cyclohexene oxide remaining very small. Cyclohexene oxide is considered to be formed by the addition mechanism in radical chain reactions as recognized with AIBN. Thus, a typical autoxidation proceeds in the reaction with $Co(acac)_2$ catalyst. In contrast, the activity of V–$Cr_{(400)}$ was low at the biginning of the reaction but increased rapidly with reaction time. That is, the lowering of activity was not observed with this binary oxide. The selectivity of cyclohexenyl hydroperoxide was not so high as in the reaction with $Co(acac)_2$. The amount of both cyclohexene oxide and cyclohexenol was larger than that of cyclohexenone resulting from the decomposition of cyclohexenyl hydroperoxide. In order to clarify the mechanism of epoxidation, several reactions of cyclohexene with *t*-butyl hydroperoxide were carried out in the presence of catalyst (Table 6). $MoO_2(acac)_2$ shows high activity for epoxidation with hydroperoxide.[6] A small amount of epoxide observed in the case with $Co(acac)_2$ seems to be found by the reaction of cyclohexene with *t*-butyl peroxyradical. The yield of epoxide obtained with V–$Cr_{(400)}$ is similar to that with $VO(acac)_2$, suggesting that epoxidation by the hydroperoxide intermediate mechanism proceeds together with the radical decomposition of hydroperoxide. The successive catalytic processes concerning the formation of the epoxide (Eqs. 3 and 4) are supported; the first one consists of the hydroperoxide formation as in a typical autoxidation process, and the second, a selective olefin oxidation wherein the hydroperoxide acts as the oxidizing agent.

Electronic Spectra and Electronic Structure of TCNQ Complexes

Jiro TANAKA, Masashi TANAKA, Takashi KAWAI, Teruhiro TAKABE, and Osamu MAKI
Department of Chemistry, Faculty of Science, Nagoya University, Nagoya 464
(Received December 11, 1975)

Electronic spectra of several TCNQ complexes have been measured with single crystals by the transmission method. The assignment of electronic transitions are presented based on the electronic structure of the crystals. The molecular viewpoint is stressed in a theoretical treatment. The spectra are interpreted in terms of the charge transfer between TCNQ species and the local transitions of TCNQ and the donor molecules. It is shown that the electronic structure of the crystal may be deduced from the spectral analysis. The magnetic and electric properties of several conducting TCNQ complexes are discussed by this model with the wavefunctions determined by a theoretical calculation and the analysis of the spectral results.

Electronic absorption spectra of TCNQ complexes have been investigated for single crystals and powdered samples by many people. Although there have been many comprehensive papers and reviews on the structural, electronic and magnetic properties of these crystals,[1-5] but the interesting electronic processes of these complexes are still not satisfactorily explained in a comprehensive way.

Recently the study on optical spectra becomes more important, because the remarkable electronic properties of high conductive TCNQ salts may be elucidated by the analysis of their electronic spectra. In the present paper we will discuss the single crystal electronic absorption spectra of several TCNQ complexes, together with the discussions of the electronic structures and the intermolecular interactions. The interpretation of the electronic spectra is presented and the magnetic and electric properties are studied with the model calculation. The aim of this paper is to give an unified view on different aspects of physical properties based on the chemical constitution and electronic structure of the crystals. We try to find a reasonable concept of the characteristic properties of organic conductors from structural points of view, hoping that this analysis will be a useful guide for the design and synthesis of new conducting organic materials. It will be shown that the electronic spectrum may give a useful diagonosis on the electronic structure of TCNQ complexes.

Experimental

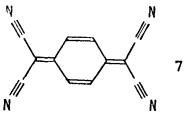
The materials were prepared by the methods of Melby *et al.*[6] and Melby.[7] Very thin crystals were prepared by recrystallization from dry acetonitrile and their absorption spectra were measured by the microspectrophotometer designed in this laboratory. The thickness of the crystals used for the transmission measurement was less than a few micron, but it was difficult to measure the thickness very accurately.

The spectrophotometer consists of a light source, a monochromator of Carl Zeiss M4Q and a detector with a PbS photocell and a HTV 446 photomultiplier tube. An Olympus microscope was used with Carl Zeiss Ultrafluar objectives of 32 and 100 magnifing power. The lenses are achromatic for 700—230 nm, but it is not guaranteed for the near infrared region, therefore we have used possibly large crystals to avoid the effect of aberration. A quartz polarizer of Rochon type was used to obtain a polarized light. The crystalline axis and the indices of the developed planes were checked and confirmed by taking X-ray photographs with crystals which were large enough for the X-ray experiment. Sometimes very thin crystals were prepared by recrystallization on a quartz slide glass, and the crystalline habit was checked by the polarizing microscope and compared with the large one determined by the X-ray method.

Crystalline Structure and Electronic Configuration of TCNQ Complexes

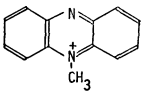
The crystals of TCNQ complexes can be classified into two groups, in one group the donor and TCNQ make a stacking pair (D^+A^-), while in the other group TCNQ makes the column by itself ($A\cdot A\cdot A\cdot \cdots$) and the donor forms their own column or take their own positions.[3] In this study we concentrate on the latter type of crystals which is more interesting than the ordinary DA complex. The complexes forming TCNQ columns show variable ratio of the donor to TCNQ; there is a variety of type of (D: A) ratio as 1: 1, 1: 2, 2: 3, and 2: 4. For complexes having TCNQ more than 1: 1 mole ratio, neutral TCNQ molecules are involved. The names and abbreviations of typical donors or cations are shown in Fig. 1.

The X-ray crystal structure analysis on these complexes revealed that there are a little but significant difference of the bond length between the neutral, negative and a half-ionized TCNQ species. Actually the crystallographic results show that these differently



7,7,8,8-Tetracyanoquinodimethane — TCNQ

Tetrathiafulvalene — TTF

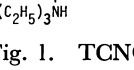


N-Methylphenazinium cation — $(NMP)^+$

Morpholinium cation — $(Mor)^+$

Quinolinium cation — Q^+

Methyltriphenylphosphonium cation — $(MTPP)^+$



Triethylammonium cation — $(TEA)^+$

Fig. 1. TCNQ and several donor molecules.

harged species are situated on different sites in the crystal.

In crystals such as $Q(TCNQ)_2$,[8] $TMPD(TCNQ)_2$,[9] and $Ac(TCNQ)_2$[10] the structure of all TCNQ is equivalent, which may imply that the negative charges may be completely delocalized all over the TCNQ columns. However, from a view of strong electron correlation effect between electrons on the same and the nearest neighbour molecules, it seems more reasonable that extra electrons may reside in alternate site to relieve the repulsion. In this case both the negative and the neutral TCNQ coexist, however, it was difficult to discern which is the anion or the neutral species, and the X-ray scattering method will give only an average structure of the charged and neutral molecules. Therefore a most plausible electron configuration of the 1 : 2 type crystal is that the excess electrons are localized on alternate TCNQ site and the neutral TCNQ is sandwiched between anions, and such a locally ordered structure may fluctuate, and a superposition of two alternative structures will give an apparently equivalent crystal structure. We may call this type of electron configuration as an alternant type.

An apparent chemical constitution of the complex does not necessarily mean an equivalence of the electronic structure, for instance, recent X-ray analyses of TTF–TCNQ[11–13] show that the bond lengths for TCNQ in this complex are close to a half-charged anion. This is in harmony with recent experiments on ESCA and IR studies of TTF–TCNQ.[14,15] These studies give evidences of incomplete charge transfer from TTF to TCNQ that the crystal is considered to contain both $(TCNQ)^0$ and $(TCNQ)^-$. For this reason, it may be more plausible that this crystal has an alternant type structure as its basic configuration rather than that all TTF and TCNQ are singly ionized. Further consideration will be given in later sections.

In crystals with 2: 4 or 2: 3 donor to TCNQ ratio, electrons are thought to be localized on particular paired sites, hence, we may call this type of configuration as an island type.[16,17]

In crystal in which all TCNQ have a negative charge, the TCNQ column forms either a linear chain or a dimeric pair, and the phase transition was observed to change the linear form to the dimeric form at low temperature.[18,19]

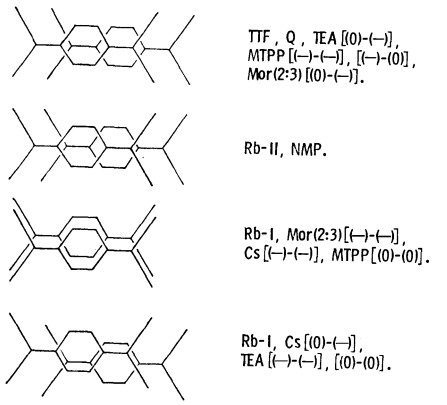


Fig. 3. Nearest neighbour overlap of TCNQ molecules.

In Fig. 2 different types of electron configuration of TCNQ column are schematically classified. The most important type from a view of good electric conduction may be an alternant type and an island type. In the following we will discuss the electron interaction between TCNQ molecules in the crystal by these basic electron configurations. The types of the interactions are the dimer type, the island type and the alternant type. For the linear chain structure, the interaction must be considered to obey the crystal symmetry of the one-dimensional lattice, however, the TCNQ complex we have treated in this paper has a dimeric structure rather than a linear chain structure, therefore our theoretical treatment may be limited to the coupled molecular model. The extension to include the exciton interaction between different cells may not be difficult, but the excited state of CT character may be easily trapped because of their large polarization effect, and empirically the magnitude of the exciton type interaction will be not so significant for such CT complexes, therefore the exciton treatment is not developed in this study.

The mode of overlapping of TCNQ molecules is shown in Fig. 3, and a tendency may be seen that a pair made of neutral and charged TCNQ takes a similar conformation, in which a direct overlap is avoided by displacing one molecule to the other.[3] A pair made of both charged TCNQ species takes several different conformations, but it shows a tendency of larger overlap than the former type.

Fig. 2. Electronic configurations of TCNQ columns and types of interactions.

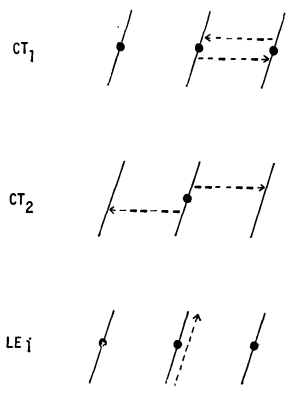

Fig. 4. Basic excited configurations in TCNQ columns.

Theoretical Analysis of Electronic Spectra

The electronic spectra of TCNQ anion in solution was studied by Boyd and Phillips[20] and the molecular orbital calculation was carried out by Lowitz.[21] For the TCNQ complex crystals, Iida[22] has pointed out that there are three types of transitions in the visible and near infrared region. The basic excited configurations are shown in Fig. 4. The LE excited level means locally excited level of TCNQ anion and we denote the lowest one of this kind as LE_1 and the second one by LE_2, and so on. The CT_1 level is the charge transfer between the TCNQ anions and the CT_2 level is the charge transfer from the anion to the neutral TCNQ. In actual crystals, these levels interact to each other, and complicated spectral patterns are observed. In the following we attempt to analyse the spectral features of the complex by calculating the intermolecular interaction between the levels of different TCNQ molecules with the modified Hubbard Hamiltonian,[23,1] which is further modified by our own recipe.

The wavefunction of the system may be described by an antisymmetrized product of the molecular orbitals of the constituent TCNQs. The Hamiltonian of the system may be given by

$$H=\sum_{pi}\sum_{qj}\sum_{\sigma}\langle\phi_{pi}|-\frac{\hbar^2}{2m}\Delta_\mu+\sum_{s\alpha}V(R_{s\alpha}-r_\mu)|\phi_{qj}\rangle a^+_{pi\sigma}a_{qj\sigma}+\frac{1}{2}\sum_{pi}\sum_{qj}\sum_{rk}\sum_{sl}\sum_{\sigma\sigma'}(\phi_{pi}\phi_{sl}|\phi_{qj}\phi_{rk})a^+_{pi\sigma}a^+_{qj\sigma'}a_{rk\sigma'}a_{sl\sigma} \quad (1)$$

where ϕ_{pi} and ϕ_{qj} denote the i-th and the j-th molecular orbitals of the p and q molecules and σ indicates spin functions. The Coulomb repulsion integral is written with a notation that

$$(\phi_{pi}\phi_{sl}|\phi_{qj}\phi_{rk})=\int\phi^*_{pi}(\mu)\phi_{sl}(\mu)\frac{e^2}{r_{\mu\nu}}\phi^*_{qj}(\nu)\phi_{rk}(\nu)dv_\mu dv_\nu. \quad (2)$$

In this calculation we restrict our attention to the higher MO of TCNQ, m and m-1, where the singly occupied highest MO in $TCNQ^-$ is written by m and the doubly occupied second highest MO by m-1.

The intermolecular interaction between p and q molecules is considered only for the nearest neighbours, and we retain the interactions which are first order to the electron overlap. Then the Hamiltonian is given by

$$H=\sum_{p,q}\sum_{i,j=m-1}^{m}\sum_{\sigma}t^{pq}_{ij}a^+_{pi\sigma}a_{qj\sigma}+\sum_{p}U^{pp}_{mm}n_{pm\alpha}n_{pm\beta}+\sum_{p,q}\sum_{\sigma\sigma'}U^{pq}_{mm}n_{pm\sigma}n_{qm\sigma'}+\sum_{p,q}\sum_{\sigma\sigma'}D_{pq}a^+_{pm\sigma}a^+_{qm-1\sigma'}a_{qm\sigma'}a_{qm\sigma} \quad (3)$$

where

$$t^{pq}_{ij}=\langle\phi_{pi}|-\frac{\hbar^2}{2m}\Delta_\mu+\sum_{s\alpha}V(R_{s\alpha}-r)|\phi_{qj}\rangle \quad (4)$$

$$U^{pp}_{mm}=(\phi_{pm}\phi_{pm}|\phi_{pm}\phi_{pm}) \quad (5)$$

$$U^{pq}_{mm}=(\phi_{pm}\phi_{pm}|\phi_{qm}\phi_{qm}) \quad (6)$$

and

$$D_{pq}=(\phi_{pm}\phi_{qm}|\phi_{qm-1}\phi_{qm}). \quad (7)$$

Here V is the neutral core potential and we evaluate the transfer integral t^{pq}_{ij} by the extended Hückel method as

$$t^{pq}_{ij}=KWS^{pq}_{ij} \quad (8)$$

where W is the orbital energy of TCNQ, and we have used the value given by the photoemission experiment of -7.5 eV[14,24] and K is set equal to 1.2. Actually this choice is rather empirical as in the extended Hückel method where K is taken in the range of 1.0—2.0. We have also attempted to evaluate each term in the integral, namely the kinetic energy and the neutral core potential energy of the electron moving between p and q molecules, and they are found to be proportional to the overlap integral S^{pq}. The transfer integral t was also shown to be proportional to the overlap integral and it was nearly the same order of magnitude with the value estimated by Eq. 4. In the latter sections it will be seen that this choice is reasonable from a view of consistency of the spectral and magnetic properties of various complexes. In the actual calculation we have used the molecular orbital of Lowitz[21] for $TCNQ^-$ and the four term SCF-AO of Clementi *et al.*[25] The calculated overlap and transfer integrals are listed in Table 1.

The Coulomb repulsion energy U^{pp}_{mm} and U^{pq}_{mm} are those for the electrons on the same and the nearest neighbour sites, and they were calculated for a typical arrangement of the crystal by using Nishimoto-Mataga potential and the results are

$$U^{pp}_{mm}=3.95\text{ eV} \text{ and } U^{pq}_{mm}=2.29\text{ eV}.$$

The former value is the same with the value given by Hiroma, Kuroda and Akamatu.[26] The difference between these two terms is 1.66 eV, but the spectral analysis shows that it may be about 1.5 eV, therefore we estimate the screening effect of the electronic polarization[27] as being a factor of 0.9, and newly define the spectroscopic U value as

$$U=\eta(U^{pp}_{mm}-U^{pq}_{mm})=1.5\text{ eV} \quad (9)$$

where η=0.9. It appears that the η value is not so different for various crystals and it seems unlikely that η is very small and U is reduced to a great extent by the polarization of large conjugated molecules.

The Coulomb energy difference between the CT_2 and the ground configurations, which is important in the island type and the alternant type systems, may be written as U', where U' will be approximately given by

$$U'=U^{pq}_{mm}-U^{pq+1}_{mm}. \quad (10)$$

The numerical estimate of this small difference of energy may be a difficult problem, because it will require an accurate calculation including the Madelung energy of the crystal for two different configurations. Actually it may be either positive or negative values depending on the structure of the complex and it will give a measure of either the island or the alternant type configuration is stable in the ground state. Here we have empirically estimated the energy values from spectroscopic results to fit the calculated energy levels with the observed spectra, instead of evaluating this term by the calculation.

The last term D^{pq} means the interaction energy between the LE_1 and CT_1 configurations, and it is approximately estimated by the dipole-dipole interaction of the two transition dipoles. The size of the transition moment of the LE_1 band was estimated with the experimental data of solution spectra as 1.46 Å. The transition length for the CT_1 band was approximated as

a) (N,N'-Dibenzyl-4,4′-bipyridylium)$_2$ (TCNQ).

S_{mm}^{pq} R^{pq} and its center was placed in the midpoint of the two TCNQ molecules.

The energy level of the LE_1 is also important in spectral analysis, and it was estimated from the solution's spectral data as 1.5 eV and we denote it as Δ in the following formula. The calculation for the crystal was carried out with the model system, in which a possibly small unit to consider the interaction was selected. We have illustrated in Fig. 2 the unit by brackets and a translation unit by the square mark on the top.

For the dimer type system the configuration interaction between the ground, CT_1 and LE_1 levels must be considered. An approximate energy level scheme and wavefunctions obtained by the perturbational calculation are shown in Fig. 5. Numerical values of energy levels are calculated by diagonalizing the secular deter-

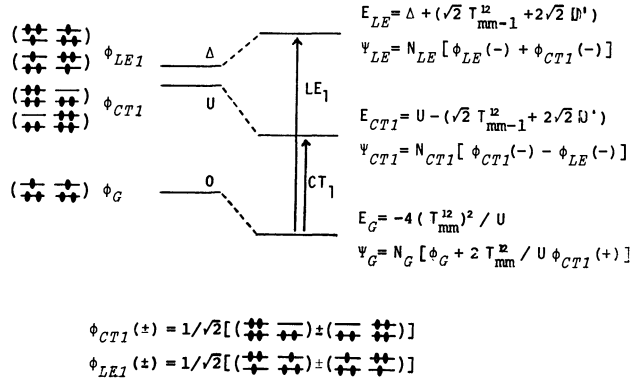

Fig. 5. Energy levels of a dimer type interaction. Actually the diagonal energy of CT_1 and LE_1 is nearly the same, namely $\Delta=U$.

minant for the symmetrical and the antisymmetrical states. The secular equations are

$$\begin{vmatrix} 0 & 2t^{12}_{m.m} & 0 & \mathrm{G} \\ & U & \sqrt{2}\,t^{12}_{m.m-1} & \mathrm{CT_1}^{(+)} \\ & & \Delta & \mathrm{LE_1}^{(+)} \\ U & \sqrt{2}\,(t^{12}_{m.m-1}+2D^{12}) & & \mathrm{CT_1}^{(-)} \\ & \Delta & & \mathrm{LE_1}^{(-)} \end{vmatrix} \quad (11)$$

where the off-diagonal energy values were estimated by the procedures mentioned above. The calculation was carried out for Rb(TCNQ)–I crystal, which has a dimer type configuration.[28] Also this model was applied for TMTTF (bis-tetramethylene-tetrathiafulvalene) because it may form dimer type crystal. The results of calculation are tabulated in Table 2 with with the observed spectral data. It is found that the agreements are fairly well for these crystals.

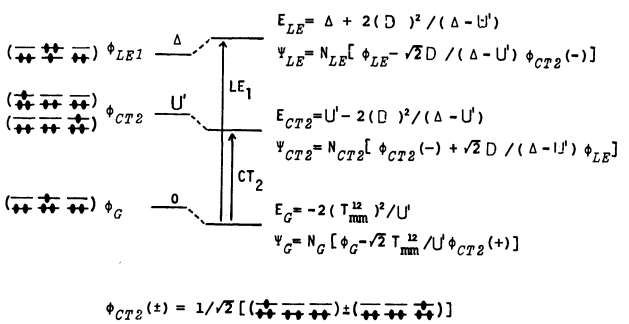

Fig. 6. Energy levels of an alternant type interaction.

For the dimer system the singlet ground state is stabilized to the triplet state, because the coupling of two neighbouring spins by the CT interaction is allowed for only the singlet state. The comparison of the calculated S–T separation energy with the magnetic susceptibility data will be given in the later section.

For the alternant system, the ground, the CT_2 and the LE_1 configurations were considered. An approximate solution by the perturbational treatment is illustrated in Fig. 6. The CT_2 level is not so close to the LE_1 level that the mixing between these configurations is not so significant. The secular determinants are as follows.

$$\begin{vmatrix} 0 & \sqrt{2}\,t^{12}_{mm} & \mathrm{G} \\ & U' & \mathrm{CT_2}^{(+)} \\ U' & -\sqrt{2}\,D^{12} & \mathrm{CT_2}^{(-)} \\ & \Delta & \mathrm{LE_1}^{(-)} \end{vmatrix} \quad (12)$$

a) ΔE in 10^3 cm^{-1}.

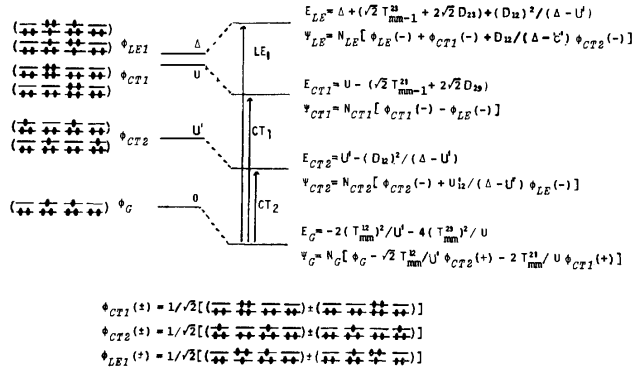

Fig. 7. Energy levels of an island type interaction. The diagonal energies are nearly the same for CT_1 and LE_1 states, namely $\Delta = U$.

The results of numerical calculation are shown for Q, TTF and the triclinic form of NMP–TCNQ crystals. The discussion on the calculated and the experimental results will be given for each crystals in the next section.

For the alternant system the spin correlation between the neighbouring sites can not be expected to be large, because the pairing scheme by the CT interaction between the nearest neighbour sites is not conceivable.

The island type system involves both the CT_1 and the CT_2 configurations and the calculation was carried out including these and LE_1 configurations. An approximate energy level scheme is given in Fig. 7. The numerical calculation was carried out with the secular equations given below.

$$\begin{vmatrix} 0 & \sqrt{2}\,t_{mm}^{12} & 2t_{mm}^{23} & 0 & \\ & U' & 0 & -D^{12} & \\ & & U & \sqrt{2}\,t_{m.m-1}^{23} & \\ & & & \Delta & \end{vmatrix} \begin{matrix} G \\ CT_2^{(+)} \\ CT_1^{(+)} \\ LE_1^{(+)} \end{matrix} \qquad (13)$$

$$\begin{vmatrix} U' & 0 & -D^{12} & \\ & U & \sqrt{2}\,(t_{m.m-1}^{23}+2D^{23}) & \\ & & \Delta & \end{vmatrix} \begin{matrix} CT_2^{(-)} \\ CT_1^{(-)} \\ LE_1^{(-)} \end{matrix}$$

The results of calculations are shown in Table 2 for Cs, Mor, TEA, and MTPP–(TCNQ) complexes. Here the oscillator strengths of the electronic transitions are estimated for each transitions with reference to the stacking axis of TCNQ columns and they are given by *f*-numbers parallel and perpendicular to the stacking axis. It is found that the mixing of the CT_1 level with the LE_1 level gives significant changes of the polarization character guessed by the oriented gas model. The comparison of the calculated results with the experimental results will be given in the later section.

All calculations were performed at the Computation Center of Nagoya University.

Interpretation of Crystalline Spectra

Rb(TCNQ)–I. The crystalline structure of Rb(TCNQ)–I was analyzed by Hoekstra, Spoelder and Vos[28] and the crystals have monoclinic symmetry with the space group $P2_1/c$. The projection of molecules onto the developed crystalline plane is shown in Fig. 8, where the TCNQ ions form rows along the a-axis and

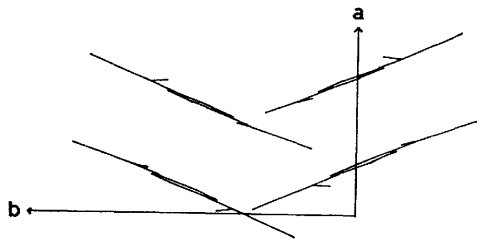

Fig. 8. Projection of Rb(TCNQ)–I onto the developed (001) plane.

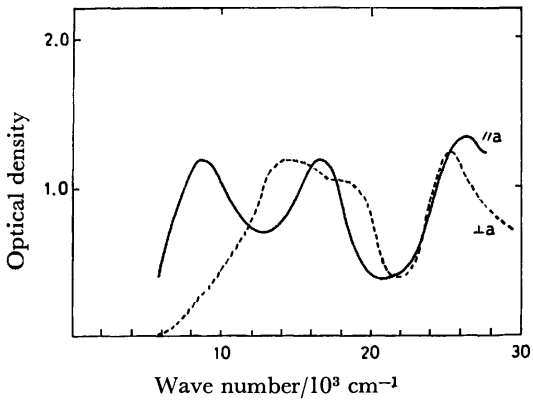

Fig. 9. Polarized absorption spectra on the (001) plane of a single crystal of Rb(TCNQ)–I.
——: a axis, ·····: b axis.

the interplanar distances show alternation of 3.159 Å and 3.484 Å, which implies that dimeric pairs are formed in the crystals. The crystalline absorption spectra were measured along the a- and b-axes of the (001) plane, and are shown in Fig. 9. The lowest energy transition is regarded as the CT_1 transition, and its energy and the polarization ratio are in fairly good agreement with the calculated results. The LE_1 band of $(TCNQ)^-$ shifts to the higher energy region by 3000—4000 cm^{-1}, and it seems that the blue shift of the LE_1 band is a characteristic of the dimer type electron configuration of TCNQ complex crystals. The calculated results of the energy and the polarization ratio of the LE_1 band are not in perfect, but in farily good agreement with the observed tendency of the spectra. The blue sflift of the LE_1 band is interpreted as the mixing of the CT_1 and the LE_1 levels. The third transition at 26000 cm^{-1} region may be reasonably assigned to the second band of $(TCNQ)^-$, namely the LE_2 band, because the second band of $(TCNQ)^-$ in acetonitrile solution appears at 24000 cm^{-1}.

The peaks of main absorption bands are in reasonable agreement with the powder spectra given by Sakai *et al.*[29] and Oohashi and Sakata,[30] and the polarized spectra presented here give an evidence of the CT character of the lowest energy transition.

Q(TCNQ)₂. The crystalline structure of Q-$(TCNQ)_2$ was analyzed by Kobayashi, Marumo and Saito[8] and the projection of molecules onto the developed (100) plane is shown in Fig. 10. The structure is disordered as regard to the orientation of quinolinium ions. The crystalline absorption spectra were measured with the (100) plane with the light polarized

parallel to the b- and c-axis and the spectra are shown in Fig. 11. The spectra are typical of the alternant type structure that the CT_2 transition is at the lowest energy region and the LE_1 band is not shifted to the higher energy region. Namely the CT_2 band is observed at about 5500 cm^{-1} and the LE_1 band is found at 12000 cm^{-1}. The LE_1 band is not shifted because the mixing of the CT_2 and the LE_1 levels is not so significant, for the diagonal energy values of the CT_2 level is much less than that of the LE_1 level. The energy of the CT_2 level is certainly smaller than that of the CT_1 level and we have estimated the U' value for this crystal at 0.8 eV, which is much smaller than the U value of 1.5 eV of the dimer system. The results of calculation are shown in Table 2 and it is seen that the observed and calculated results are in fairly good agreement. It will mean that the assumed alternant model is reasonable to interpret the electronic spectra of this crystal.

The absorption bands at above 26000 cm^{-1} region along the b-axis may be due to the LE_2 state and the first excited state of neutral TCNQ molecule and the band found at 31000 cm^{-1} may be ascribed to the local transition of the quinolinium cation. The appearance of the LE_1 band at lower energy region at about 12000 cm^{-1} implies that the electronic configuration of TCNQ column is an alternant type. This criterion may be used for the analysis of the spectra of other TCNQ complex crystals.

TTF(TCNQ). The crystal of TTF(TCNQ) is the best conducting organic complex hitherto known[4,31-34] and the optical spectra have been intensively investigated by several groups.[35-37] The present result provides a polarization measurement in the near infrared and visible region by the transmission measurement, therefore it may be interesting to compare the result with the former investigations by other methods.

The crystalline structure of the complex was analyzed by Kistenmacher, Phillips and Cowan[11] at room temperature and by Blessing and Coppens[12] at low temperature. The projection of molecules onto the (001) plane is shown in Fig. 12. Both TCNQ and TTF form independent segregated columns along the b-axis. The CT transition will be particularly polarized along this axis, and actually it is found that the absorption edge of the CT band is observed along the b-axis (Fig. 13). The maximum of this band could not be found by the transmission method, because it was in the out of the range of the present spectrophotometric system.

The peak of this transition was observed by Torrance *et al.*[37] with a powdered sample at 3000 cm^{-1}, while Jacobsen, Tarner, Garito and Heeger[36] measured the reflectivity of the single crystal from 4000 cm^{-1} down to 50 cm^{-1} and found that the maximum of conductivity lies at 1300 cm^{-1}. We also measured the single crystal reflectivity from 35000 cm^{-1} to 4000 cm^{-1}, and confirmed the result of Grant *et al.*,[35] and by combining this result with the infrared data of Jacobsen *et al.* we calculated the absorption maximum by Kramers-Kronig transformation to be at 3000 cm^{-1}.[38] The peak of absorption is located at 3000 cm^{-1}, therefore the character of this transition is assigned as the CT_2 type by the analogy with the spectra of other complexes. The CT band is observed at the lowest energy region and the LE_1 band is appeared at 12000 cm^{-1} without any blue-shift, hence the electron configuration of TTF(TCNQ) will be an alternant type, or at least an alternant type mixed with an island type. The mixing of an island type with an alternant type is an

important feature of the present crystal, and anyhow it implies that an electron transfer from TTF to TCNQ is incomplete.

The theoretical calculation of the energy level is carried out by the alternant model with the U' value of 0.35 eV and the result is in satisfactory agreement with the observed energy, the intensity and the polarization ratio of both the CT_2 and LE_1 bands. In spite of this, the spectral feature of this complex is very close to other island type crystals, therefore the basic electron configuration may involve an island type. Then, in addition to the CT_2 band, the CT_1 and LE_1 bands will be mixed, but this type of mixing could not be confirmed distinctly in the present spectra. Namely, the band at 18000 cm^{-1} region along the b-axis may be a shifted LE_1 band mixed with the CT_1 band in the island model, however, the TTF cation may absorb in this region along this direction, because it has own absorption bands at 18000, 23000, 29000, and 40000 cm^{-1}.[39] A recent unpublished result by Torrance and coworkers[40] gave absorption bands in TTF-$Br_{0.76}$ at 5000, 13000, and 18000 cm^{-1}, but the intensities were smaller than that of TCNQ anion. Therefore the band appearing at 18000 cm^{-1} along the b-axis is reasonably considered to be a mixed CT_1 and LE_1 bands. Thus the spectral results support a strong mixing of the alternant and the island type.

In addition to this, the broad absorption bands around 24000—30000 cm^{-1} region are ascribed to the negative and neutral TCNQ species, because the maximum of these absorptions are expected at 24000 and 25000 cm^{-1}, respectively. These are another reasons to assign the electron configuration of this crystal to the mixed alternant and island types.

Following the theoretical calculation the ground state is represented by $0.91\ \varphi_A + 0.41\ \varphi_I$, where the starting set is a pure alternant configuration, and it means that the electron configuration is 83% of the alternant and 17% of the island type. Then extra neutral vacant sites are produced adjacent to the island site, and if these sites were filled by further electrons from the donor molecule, then the amount of charge transfer will be 0.585. For this population, the ground state is written as 50% of the alternant and 50% of the island configurations, which is in perfect agreement with the spectral properties discussed above.

There are several evidences[12-15] that an electron transfer from TTF to TCNQ is not complete, and the present results give another evidences that both TCNQ and TTF columns are partially ionized and the excess charges may delocalize or fluctuate within or between columns. This view may give an important clue to the understanding of this particular complex.

Of course, other interpretations on the spectral propeties of TTF(TCNQ) have been presented by the metallic band model[4,36,41] or the polaron theory,[42] but our approach is based on a molecular model, which may give wide correlations with other TCNQ complexes.

TMTF(TCNQ). Ueno, *et al.*[43] have synthesized bi(4,5-tetramethylene-1,3-dithiol-2-ylidene), (TMTF), which is an analogue of TTF, and prepared its complex with TCNQ and kindly gifted us the crystals. We have

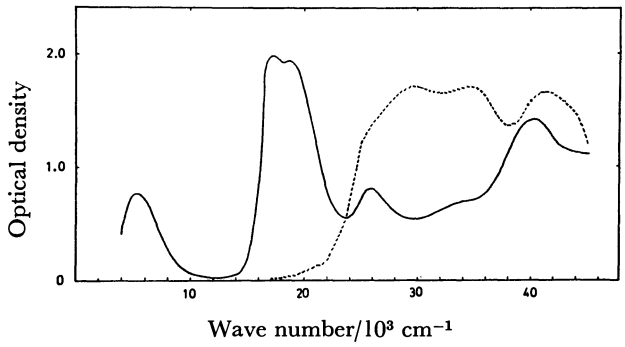

Fig. 14. Polarized absorption spectra on the (010) plane of a single crystal of (TMTF) (TCNQ).
——: a axis, ·····: c axis.

measured and compared the spectral property with that of TTF(TCNQ). The crystalline data of TMTF-(TCNQ) was examined and it was found that the crystal is triclinic and the lattice constants are $a=7.07$, $b=13.39$ and $c=6.91$ Å and $\alpha=70.9$, $\beta=105.0$ and $\gamma=93.0°$. The crystalline absorption spectra were measured along the a- and c-axis, and the CT band was found along the a-axis with a maximum at 5500 cm^{-1} (Fig. 14). The LE_1 band was also found along the a-axis with a maximum at 17400—19500 cm^{-1}. Although the crystalline structure of the complex is not yet determined, the structure of the crystal may be supposed that the stacking axis of $(TCNQ)^-$ is along the a-axis. The appearance of the LE_1 band at higher energy region indicates that the interaction between the CT_1 level and the LE_1 level in the dimer or in the linear chain structure may be very strong in this crystal. Actually the calculated values of transition energies for the dimeric system of TTF(TCNQ) are very close to the experimental values found for TMTF(TCNQ) (Table 2). From these analysis it is supposed that the electronic structure of TCNQ in this crystal will be all negatively charged with a dimeric or a linear chain structure. However, another possibility that the crystal may have a D^+A^- type structure may remain because the crystal structure is not yet determined.

NMP(TCNQ). Two crystalline forms of NMP-(TCNQ) have been reported[44] and the crystalline structure analysis have been carried out only for the good conducting triclinic system by Fritchie[45] and recently by Kobayashi.[46] It has been shown that columns of both TCNQ and NMP develop parallel to the a-axis in the triclinic crystal.

Both the monoclinic and the triclinic crystals were prepared from the same acetonitrile solution, and they were distinguished by the color on transmission or reflection. Their developed faces were confirmed by taking the X-ray photographs and they were (001) plane for the triclinic and (100) plane for the monoclinic crystals. The projection of molecules onto the (001) plane of the triclinic crystal is shown in Fig. 15. Following the crystal structure analysis, it has been presumed that the crystal contains only $(TCNQ)^-$ and $(NMP)^+$ species, but the explanation on the magnetic susceptibility of this crystal[2,47] may be difficult by a fully charged and stacked model. Soos has suggested a model that TCNQ column may contain some neutral

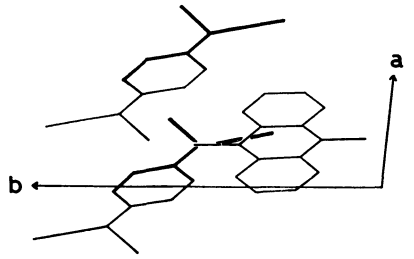

Fig. 15. Projection of triclinic (NMP) (TCNQ) onto the developed (001) plane.

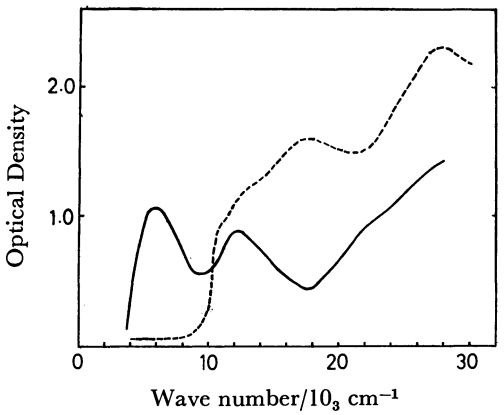

Fig. 16. Polarized absorption spectra on the (001) plane of a single crystal of triclinic (NMP)(TCNQ).
——: a axis, ·····: b axis.

species to explain several physical properties.

The spectra measured with the triclinic crystal for the (001) plane are shown in Fig. 16, and it is easily found that the CT band appears solely along the a-axis at 5500 cm^{-1}, and the LE_1 band is observed at about 12000 cm^{-1}. This result is a typical pattern of an alternant electron configuration, namely excess electrons exist on alternate TCNQ sites. It may mean that an electron transfer from $(TCNQ)^-$ to $(NMP)^+$ may occur at almost every alternate TCNQ sites. By this transfer a half of $(NMP)^+$ ions will become neutral radicals, and the absorption band at 17000 cm^{-1} region may be assigned as due to the neutral radicals, since Sakata and Nagakura[48] have found the absorption in this region with neutral radicals. It seems that NMP radicals also take alternate configurations, since if the radicals are paired another strong band should appear at 13000 cm^{-1} region, but it is not clearly found in the spectra.

The result of theoretical calculation by the alternant model with the U' value of 0.7 eV is in good agreement with the spectra of the triclinic crystal. The CT band appearing at 5500 cm^{-1} is interpreted on this basis as a CT_2 band. The dichroic intensity ratio for the CT_2 and LE_1 bands are satisfactorily explained, and the broad bands appearing at 12000 cm^{-1} region along the a- and b-axis are assigned to the LE_1 band. The absorption bands around 26000—28000 cm^{-1} region are assigned as the superposed TCNQ neutral and ionic species. A recent reflectivity measurement of this crystal provides an evidence of the presence of neutral TCNQ species.[38]

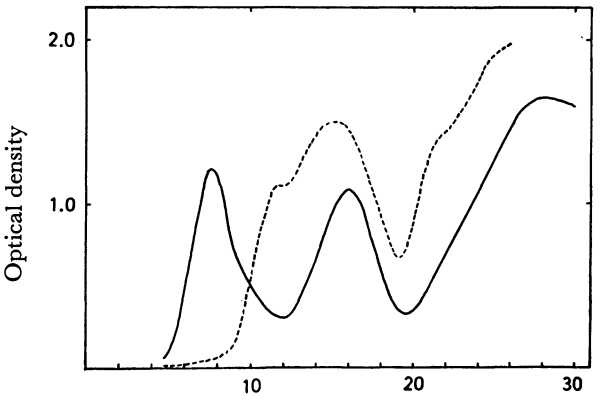

Fig. 17. Polarized absorption spectra on the (100) plane of a single crystal of monoclinic (NMP) (TCNQ).
——: b axis, ·····: a axis.

The crystalline absorption spectra of the monoclinic form were measured with the (100) plane, and the CT band was found at higher energy than for the triclinic crystal (Fig. 17). The LE_1 band is blue shifted. Although the crystalline structure of this form has not yet been published,[44] but it is suggested to be composed of D^+A^- stacks. Then the spectral result is explained in such a way that the lowest energy transition is a CT between $(TCNQ)^-$ and $(NMP)^+$, and the bands at 12000 and 16000 cm^{-1} are the LE bands of $(TCNQ)^-$ and $(NMP)^+$, respectively. A nearly diamagnetic behaviour of this crystal[44] will be also consistent with the D^+A^- model of this crystal.

Thus the variation of the physical properties of the triclinic and the monoclinic NMP(TCNQ) is reasonably explained by the change of the electron configuration of the crystals.

$Cs_2(TCNQ)_3$. The crystalline structure was determined by Fritchie and Arthur.[16] It belongs to a monoclinic system of the space group $P2_1/c$. One of the TCNQ in the unit cell is situated on the center of symmetry and is considered as neutral, and other two non-centric TCNQ are analyzed to have negative charges. The localization of the charge is also confirmed by the photoemission spectroscopy.[49] The projection of molecules onto the developed crystalline plane is shown in Fig. 18. The TCNQ column elongates along the b-axis with interplanar spacings of 3.22 Å for adjacent charged molecules. In Fig. 3 the overlap for charged species is shown to be larger than for the mixed species.[3] Since the center of TCNQ molecules are lined along the b-axis, the CT bands may be observed particularly along the b-axis, if the mixing of the CT and LE_1 levels is not significant. Also the long-axis of TCNQ is inclined 45° to the b-axis, therefore the LE type bands are expected to give the dichroic intensity ratio of 1 : 1 for the b- and a-axis.

The crystalline absorption spectra have been measured before by Hiroma *et al.*,[26] but we have measured again to extend into near infrared and the spectra with the (001) plane are shown in Fig. 19. Two CT bands found at 6000 and 11000 cm^{-1} mainly along the b-axis. The lower energy band is considered as the CT_2 type

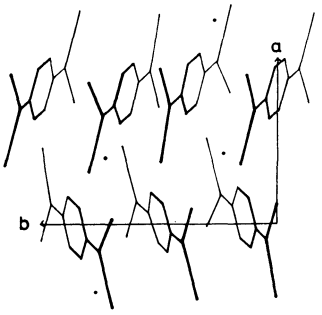

Fig. 18. Projection of $Cs_2(TCNQ)_3$ into the developed (001) plane.

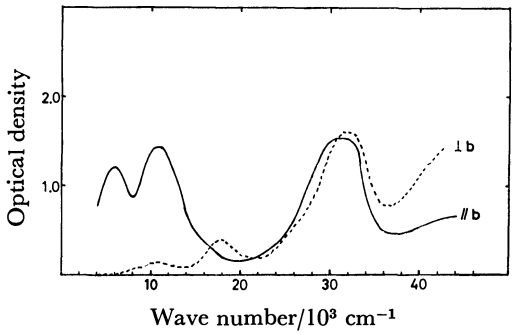

Fig. 19. Polarized absorption spectra on the (001) plane of a single crystal of $Cs_2(TCNQ)_3$.
——: b axis, ……: a axis.

between the neutral and charged TCNQ molecules, and the higher energy one is the CT_1 band mixed to some extent with the LE_1 band. The mixing between these two transitions is verified by a theoretical calculation. The blue shift of the LE_1 band is as much as 5000 cm^{-1}, and the change of the intensity is very remarkable, and these characteristics are reasonably explained by the interaction of the CT_1 and LE_1 levels. The deviation of the observed intensity ratio (3.5) from the oriented gas model (1.0) is also accounted for by this calculation as the effect of the mixing of the CT_1 and LE_1 levels. The observed dichroic ratio for the LE_2 band (1.06) is in good agreement with the oriented gas model (1.0) because the LE_2 level is not significantly influenced by other levels except that the band is blue shifted by 2000 cm^{-1}.

The characteristic of the island type electron configuration is exemplified with these spectra that both the CT_2 and CT_1 bands are observed along the stacking axis of TCNQ columns; the LE_1 band is blue shifted and the dichroic intensity ratio are changed from the oriented gas model by the interaction of the CT_1 and LE_1 levels.

(Mor)$_2$(TCNQ)$_3$. The crystal structure of (morpholinium)$_2$(TCNQ)$_3$ was determined by Sundaresan and Wallwork[50]; the crystals are monoclinic, belonging to the space group $P2_1/c$. Two of three TCNQ species in the unit cell are negatively charged, while the other TCNQ is neutral. The overlapping of the charged molecules and the charged and neutral molecules are shown in Fig. 3, and the patterns are similar to other systems having the same charge distributions.[3]

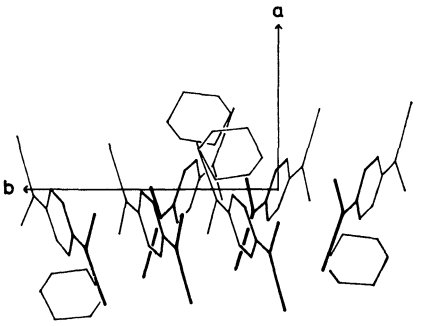

Fig. 20. Projection of $(Mor)_2(TCNQ)_3$ onto the developed plane.

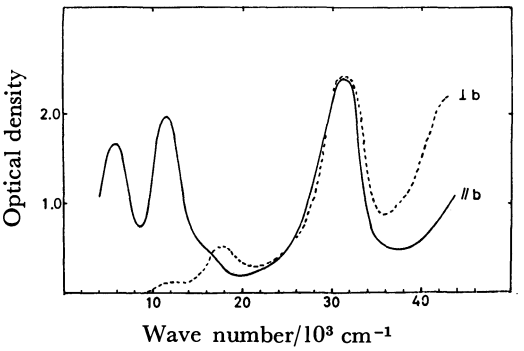

Fig. 21. Polarized absorption spectra on the (001) plane of a single crystal of $(Mor)_2(TCNQ)_3$.
——: b axis, ……: a axis.

The crystalline absorption spectra were measured with the (001) plane and the projection of molecules onto this plane is shown in Fig. 20. The column of TCNQ elongates along the b-axis, and the long-axis of TCNQ molecule is inclined to the b-axis by 45°. The spectra are shown in Fig. 21 and two CT bands are clearly observed along the b-axis with maximum at 6000 and 11500 cm^{-1}. The band at 6000 cm^{-1} is assigned to the CT_2 band, the band at 11500 cm^{-1} is the CT_1 mixed with the LE_1 band. The LE_1 band is found at 17500 cm^{-1}; it is blue shifted as much as 5000 cm^{-1}. The dichroic intensity ratio of the LE_1 band is also changed from the oriented gas model of 1.0 to 3.0. On the other hand the LE_2 band shows the same intensity for the b- and a-axis in accordance with the oriented gas model.

The observed energies and the polarization characteristics are well explained by a theoretical calculation with an island model, and it is very interesting that a gross feature of the spectra is very close to the spectra of $Cs_2(TCNQ)_3$ in spite of a great difference in chemical nature of the cationic group. It will mean that the crystalline spectra reflect the electron configuration of the crystal.

(TEA)$_2$(TCNQ)$_4$. The crystal structure of triethylammonium TCNQ complex was determined by Kobayashi, Ohashi, Marumo and Saito;[17] the crystal is triclinic with space group $P\bar{1}$, and four TCNQ molecules form a repeating unit in the column. Two of four TCNQ molecules in the centrosymmetric inside pair are considered to have negative charges and two

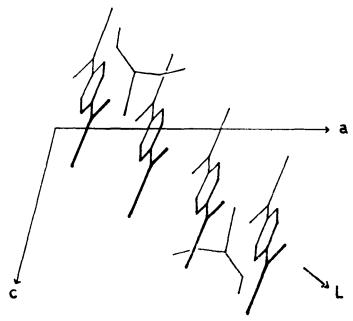

Fig. 22. Projection of $(TEA)_2(TCNQ)_4$ onto the developed (010) plane.

——: Parallel to the stacking axis, L,
……: perpendicular to the stacking axis.

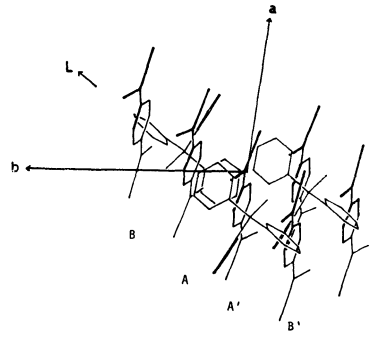

Fig. 24. Projection of $(MTPP)_2(TCNQ)_4$ onto the developed (001) plane.

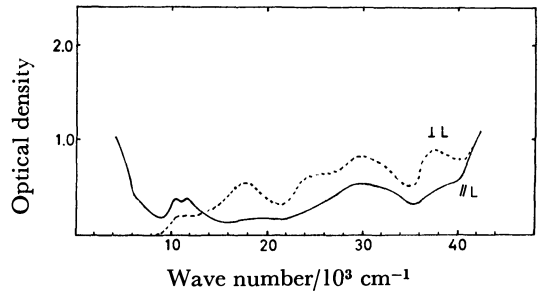

Fig. 25. Polarized absorption spectra on the (001) plane of a single crystal of $(MTPP)_2(TCNQ)_4$.
——: Parallel to the stacking axis, L,
……: perpendicular to the stacking axis.

outer TCNQ molecules are thought to be neutral. Thus the structure is typical of an island type configuration. The stacking axis of TCNQ column makes about 40° to the a-axis in the (010) projection, and the long-axis of the TCNQ molecule makes 50° to the stacking axis (Fig. 22). On this projection the LE_1 and LE_2 bands are expected to give a dichroic intensity ratio of 1.4 with the stacking axis ($I_\perp/I_{//}$).

The crystalline absorption spectra measured with the (010) plane in the direction parallel and perpendicular to the stacking-axis are shown in Fig. 23. Along the stacking axis prominent absorptions are found at around 4000 and at 11000 cm^{-1}, and two bands are observed at 17700 and 29000 cm^{-1}. Although the maximum of the lowest energy band is not found, but it is unambiguously assigned to the CT_2 band because of its polarization, and the next band at 11000 cm^{-1} is a transition to the coupled LE_1 and CT_1 states. Another coupled transition of the CT_1 and LE_1 states is found at 17700 cm^{-1}. The energy levels, the intensities and the dichroic ratio of these transitions are well explained by the theoretical calculation as a consequence of the mxing of the LE_1 and CT_1 levels. The distribution of intensities between these two bands and the change of the dichroic ratio suggests that the mixing is very efficient between these two levels. The pattern of the spectra may be typical of 2: 4 type island electron configuration, in which negatively charged TCNQ species are surrounded by neutral TCNQ molecules. The CT_2 band may have lower energy than that of 2: 3 type system, because the electron correlation between the neighbour sites is much reduced by a presence of the extra neutral TCNQ molecule. The absorption bands at 28000—30000 cm^{-1} are assigned to the LE_2 bands of $(TCNQ)^-$ and $(TCNQ)_2$, and the dichroic ratio is about 2.0, which is in fairly good agreement with the oriented gas ratio.

$(MTPP)_2(TCNQ)_4$. The crystalline structure of methyltriphenylphosphonium TCNQ was determined by McPhail, Semeniuk and Chesnut,[51] and by Konno and Saito.[52] The crystal belongs to a triclinic system with the space group of $P\bar{1}$. The tetrad structure was found for TCNQ column, but the standard deviation for the bond distances are larger than the difference of bond distances of $(TCNQ)^0$ and $(TCNQ)^-$. The crystalline absorption spectra were measured with the (001) plane, and the projection of molecules onto this plane is shown in Fig. 24. The stacking axis of TCNQ makes about 45° to the b-axis on this projection, and the long-axis of the TCNQ molecule is inclined about 50° to the stacking axis of TCNQ column.

The spectra shown in Fig. 25 are very close to that of $(TEA)_2(TCNQ)_4$, therefore it seems more probable that the electrons are localized within two TCNQ molecules rather than that they delocalize over the column. The lowest energy absorption was found around 4000 cm^{-1} region along the stacking axis, and it is assigned to the CT_2 band. Two prominent peaks were observed at 11000 and 17700 cm^{-1} region and these are regarded as the transitions to the mixed LE_1 and CT_1 states. The observed energy values and the dichroic intensity ratios are well accounted for by the theoretical calculation based on the island model. The LE_2 band appears at 25000 and 30000 cm^{-1} region, and this

splitting will imply that the TCNQ species exist as negative and neutral ones in the crystal.

The spectral similarity between $(TEA)_2$- and $(MTPP)_2(TCNQ)_4$ is very striking that a similar electron configuration of TCNQ column is supposed for these chemically different crystals. Among four TCNQ molecules labelled by A, A', B and B' in Fig. 24,[51] the spectral, magnetic and a slight variation of bond length support that electrons may be localized on A and A' sites, but the mode of overlapping may not be in favour of this assignment.

Energy Separation of the Triplet and Singlet States

The magnetic susceptibilities of TCNQ complexes have been measured for various crystals by many people, and experimental data of the energy separations for the triplet and singlet states have been accumulated.[1,5] The singlet state of the coupled TCNQ dimers will be stabilized by the CT interaction as compared to the triplet state, because the CT interaction could not be expected for the triplet state because of Pauli principle.[52] Following the perturbational calculation given in the previous section, the singlet state of the dimer will be stabilized to the triplet state approximately by

$$J = \frac{4t_{mm}^2}{U} \tag{14}$$

where U is the spectroscopic electron correlation energy, and t_{mm} is the transfer integral between the half-filled highest occupied orbitals. Although there may be a slight change of U values depending on the crystalline structure and the electron configuration, but we may take it as a constant value of 1.5 eV. The J values are calculated by Eq. 14 for several complexes which have TCNQ pairs and the results are shown in Table 3. The experimental J values are estimated by the temperature dependence of the magnetic susceptibility. It is seen that the agreement between the experimental and the calculated J values is reasonably good in spite of a simple model used for the calculation. Although the structure of the alkaline salts of TCNQ are not dimeric in a rigorous sense,[5] as in their low temperature phase another neighbour site is found close to the dimer pair.[18,19] In spite of this the magnitude of the second transfer integral t_2 is one third of the dimer pair, so we have ignored this effect in this treatment.

Table 3. Calculated and observed magnetic J values

For the alternant type crystal the stabilization by the charge transfer effect may be small since the CT interaction can not be expected as the first order effect. In fact very small J values were found NMP, Q and Ac–TCNQ complexes.[2] These results may be well explained by the model that these crystals have the alternant electron configuration, and the CT type stabilization may not occur significantly.

The susceptibility of the TTF–TCNQ crystal behaves differently from other good conducting crystals; it shows a distinct temperature dependence even in the metallic state.[53,54] In view of an importance of accurate susceptibility data[53] for the analysis of the electronic structure of the crystal, we have attempted to fit the calculated susceptibility by our model with the observed one, although there remain several parameters which may be checked by other methods. The susceptibility will be particularly dependent on the number of active spins, therefore the number of electron transfer may be guessed by this work.

The calculation of transfer integrals in and between the TTF and TCNQ chains were carried out by Berlinsky *et al.*,[24] and by using their values we may estimate the CT interaction between the chains as being negligible and that within the TTF chain is 0.007 or 0.086 eV depending on either sulphur 3p or 3d orbitals being used. For the TCNQ chain, we have used our own integral values, and the S–T separation is estimated as 0.052 eV. In order to simplify the calculation, the dimeric state in TTF chain is also assumed to have the same activation energy of 0.052 eV. Then the spins on the TCNQ and TTF chains are divided into the island and alternant type and the number of the transferred electron and their distributions are adjusted to fit the calculated curve with the observed one. The susceptibility was calculated by using the dimer model for the island system and Heisenberg model[55] for the alternant system. The best fits were obtained by using the following set of parameters: Case 1. TCNQ chain, alternant 0.25 (J=0.024 eV), island 0.335 (J=0.052 eV); TTF chain, alternant 0.17 (J=0.008 eV), island 0.415 (J=0.052 eV), the number of electron transfer is 0.585; Case 2. TCNQ chain, alternant 0.48 (J=0.021 eV), island 0.11 (J=0.052 eV); TTF chain, alternant 0.10 (J=0.010 eV), island 0.49 (J=0.052 eV), the number of electron transfer is 0.59. By these parameters the observed curve was reproduced with the error less than 10%.

We have completely ignored the interaction between the spins on the island and alternant system within the chain, and actually the interaction of these clusters may not be simple enough to allow such a simple treatment. The ratio of the alternant and the island system were not exactly the same in TCNQ chain by both parameters, but it is roughly in agreement with the analysis presented in the previous section. Moreover the number of charge transfer is in good agreement with the X-ray

result of Coppens (0.48—0.60).[13] The number of charge transfer may vary with temperature, but such a consideration was not included in this calculation.

Electrical Conductivity and Electronic Structure

Variety of TCNQ complexes may be classified into several groups from the electrical conductivity[2,67]; (a) the low conductive group which are nearly insulating or semiconducting with high activation energies, (b) the intermediate case which are semiconducting with small activation energies, and (c) the good conducting ones which behave like metal.

Alkaline salts of 1:1 composition, which may form the dimer type crystals, and several island type crystals which have localized electrons belong to class (a).[67] Following the one-electron band theory[5] the high resistivity will be explained by the band gap produced by the Peierls transition at low temperatures.

According to Ovchinikov,[68] the band gap in the one-dimensional Hubbard model is given by $U-4t$, and we may compare the observed activation energies of various crystals with the estimated activation energies given by

$$\Delta E = \frac{1}{2}(U-4t) \tag{15}$$

Here t values are given in Table 1 and we take an average of two nearest neighbour values and the results of the calculation are tabulated in Table 4. The agreement between the calculated and the experimental values is not so bad for these crystals. From a view of the Mott theory[69] on the metal to insulator transition, we may compare $4t$ values for several crystals with U values. It gives $U>4t$ for most crystals, therefore the metallic state will not be easily realized. The smallest U' values is 0.35 eV of TTF(TCNQ), therefore the small U' is apparently in favour of the metallic state, but still the inter- and intra-site Coulomb energies are by no means negligible. The transfer integrals are in the range of 0.35—0.10 eV, and it is larger for the dimer type configuration than the alternant or the island type, but U is larger again for the dimer type.

Suezaki[70] has calculated the conductivity of TCNQ complexes by the Hubbard Hamiltonian, and has proposed a formula that

$$\sigma = \sigma_0 e^{-\Delta E/kT}$$

$$\sigma_0 = \frac{1}{12\pi}\frac{e^2 n\delta^2}{\hbar}\frac{t}{U} \tag{16}$$

where δ is the vector connecting between two TCNQ molecules. We have evaluated by using our t and U values for $(TEA)_2(TCNQ)_4$, and σ_0 is estimated as

Table 4. Activation energies for semiconductivity

	ΔE(eV) Calcd	ΔE(eV) Obsd	References
Na	0.33	0.33	67
K	0.35	0.35	67
Rb-I	0.35	0.49	82
Rb-II	0.60	0.17	82

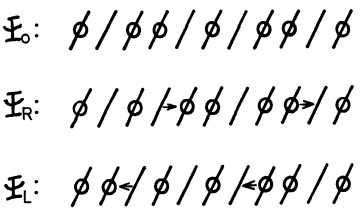

Fig. 26. Basic electron configurations of TTF(TCNQ). The top row represents the ground state without field (Ψ_0). The middle row shows an electron flowed into the right (Ψ_R), and the bottom row exhibits a flow into the opposite direct on (Ψ_L).

$8\,\Omega^{-1}\,cm^{-1}$ for the b-axis, which is a reasonable fit as compared to the observed value of $4\,\Omega^{-1}\,cm^{-1}$.[67] However, the same formula applied to $(MTPP)_2(TCNQ)_4$ and $Cs_2(TCNQ)_3$[67] gives the results which are two or three orders of magnitudes larger than the experimental values. For $Q(TCNQ)_2$ the calculated one is one or two orders of magnitudes smaller than the observed values,[67,71] therefore this formula may be limited for explaining the electrical properties of these complexes.

All good conducting TCNQ complexes like Q, NMP, Ac and TTF(TCNQ) have alternant electron configuration as a basic unit; in addition, they have a common characteristic that the cation groups are stacked to form their own columns. It seems certain that the cation stack also plays an important role in the conduction mechanism. For example, the TTF column may be even more conductive than TCNQ column,[54] however, not all TTF complexes show good conductivity,[72] therefore the correlation of motion of electrons and holes on both chains may be very significant. Bloch *et al.*[73] discussed this point from a band theory, and suggested that the overlapping of the energy levels of the donor and the acceptor bands is important. A partial electron transfer from the donor to acceptor column may be realized by such a band scheme.

We have tried to estimate the conductivity based on our model of TTF(TCNQ). The basic electron configuration of TCNQ column in this particular crystal is written by an admixture of an island and an alternant type as is explained in the previous section. The ground state wavefunction for the column will be given by

$$\psi_0 = a\varphi_A + b\varphi_I \tag{17}$$

and the basic electron configurations are depicted in Fig. 26. The coefficients a and b may be estimated from the spectral and structural analyses as mentioned before.

By applying the electric field $\boldsymbol{E}$, one of the electron in the island cluster may flow into the right or the left sites and the newly produced states are described as Ψ_R and Ψ_L. The difference of population of these two states are statistically estimated by the Boltzmann distribution as

$$\omega(\boldsymbol{E}) = \frac{e^{e\boldsymbol{r}_0\cdot\boldsymbol{E}/kT} - e^{-e\boldsymbol{r}_0\cdot\boldsymbol{E}/kT}}{e^{e\boldsymbol{r}_0\cdot\boldsymbol{E}/kT} + e^{-e\boldsymbol{r}_0\cdot\boldsymbol{E}/kT}} = \frac{e\boldsymbol{r}_0\cdot\boldsymbol{E}}{kT} \tag{18}$$

where $\boldsymbol{r}_0$ is the distance between the center of two TCNQs. Here we have assumed that the positive charges on the cation site are fixed.

The crystalline structure analysis on TTF(TCNQ) showed that the lattice spacing is uniform for one unit translation, and it implies that electrons and holes are delocalized over more than several lattice sites but not fixed at particular sites without any activation energy at high temperature phase.

The probability of electron transfer between the island and alternant sites may be evaluated by the Fermi golden rule assuming that the transition is isoenergetic. Namely the transition rates are given by

$$W_R = \frac{2\pi}{\hbar}|\langle\psi_R|H|\psi_0\rangle|^2\rho_R(\varepsilon, \boldsymbol{E}) \tag{19}$$

or

$$W_L = \frac{2\pi}{\hbar}|\langle\psi_L|H|\psi_0\rangle|^2\rho_L(\varepsilon, \boldsymbol{E})$$

where $\rho(\varepsilon, \boldsymbol{E})$ is the state density under the field, which is approximated by the reciprocal of the band width $2t$ multiplied by the field factor, and $\rho_R(\varepsilon, \boldsymbol{E})$ and $\rho_L(\varepsilon, \boldsymbol{E})$ are differently populated when the field is applied, say into the right direction, as

$$\rho_R(\varepsilon, \boldsymbol{E}) - \rho_L(\varepsilon, \boldsymbol{E}) = \omega(\boldsymbol{E})/2t \tag{20}$$

The fluctuation time of electron, τ_R and τ_L, are related to these probabilities as $\tau_R = 1/W_R$ and $\tau_L = 1/W_L$. The flow of electron along the applied field will be given by

$$\begin{aligned} \boldsymbol{J}_R &= er_0\left(\frac{1}{\tau_R} - \frac{1}{\tau_L}\right) \\ &= \frac{\pi}{\hbar}t\cdot er_0\cdot\omega(\boldsymbol{E}) \end{aligned} \tag{21}$$

where t is the transfer integral evaluated in the previous section. The conductivity σ per unit length is given by $\boldsymbol{J}/\boldsymbol{E}$ multiplied by n, the number of mobile electron along the chain in an unit volume, as

$$\sigma = \frac{\pi}{\hbar}t\cdot(er_0)^2\frac{n}{kT} \tag{22}$$

and the numerical value is easily evaluated as 2950 Ω^{-1}cm^{-1} for the case of equal mixing of the island and the alternant configurations with an electron transfer of 0.585 from TTF to TCNQ, and it is 1231 Ω^{-1} cm^{-1} for an electron transfer of 0.50 at 300 K. The observed values are in the range of 500—1000 Ω^{-1} cm^{-1} according to Cohen, Coleman, Garito and Heeger.[32] The temperature dependence of the conductivity is T^{-1} by Eq. 22, however, Groff, Suna and Merrifield[34] reported $T^{-2.3}$ behaviour in this crystal. If the number of electron transfer or back transfer from TTF to TCNQ has T^{-1} dependence, then n in Eq. 22 may also shows T^{-1} dependence, and the observed tendency may be qualitatively explained.

Here we have localized the cation charges on particular sites, but it may fluctuate also, and this fluctuation will be essential for good conductivity as mentioned before. If we suppose that a similar electron configuration exists for the cation column and count the contribution of both chain independently, the value of conductivity may be approximately doubled and the expected maximum value at 58 K may be 3×10^4 Ω^{-1}cm^{-1}. The ideally coherent motion of electron in both chains may be involved in the giant conduction[31] particularly observed in this crystal. As another example, a recent measurement of the highest organic conductivity at room temperature by Bloch, Cowan, Bechgaard, Pyle, Banks and Poehler[74] on (HMTSF)(TCNQ) showed the value as large as 1391 to 2178 Ω^{-1} cm^{-1}, which are nearly the same magnitude with the maximum value of the above mentioned mechanism.

For other alternant type crystals like NMP and Q(TCNQ), the mixing of the island configuration is smaller than for TTF(TCNQ), and a similar calculation is carried out by assuming that the electron transfer occurs at the island site and its population is determined from the spectral analysis. The results are as follows; NMP(TCNQ), $\sigma_{calcd}=220$ Ω^{-1} cm^{-1}, $\sigma_{obsd}=180$[2]—200[47] Ω^{-1} cm^{-1}; Q(TCNQ), $\sigma_{calcd}=410$ Ω^{-1} cm^{-1}, $\sigma_{obsd}=100$[67]—70[71] Ω^{-1} cm^{-1}. These results are in fairly good agreement to each other.

As regard to the giant conductivity of TTF(TCNQ) at low temperature, Anderson, Lee, and Saitoh[75] have presented a view that the activation energy may be the coupling energy of Josephson junction. Interestingly, these authors and Lee, Rice, and Anderson [76,77] thought that the Peierls transition occurs already at room temperature. Our viewpoint on this system is that the longer period than the short period of normal lattice is already mixed in at room temperature, and an apparent lattice constant may represent the averaged period, hence our view may involve the same content as Anderson *et al.*[75-77] With TTF(TCNQ) the diffuse X-ray lines were observed by Denoyer, Comes, Garito, and Heeger[78] and Kagoshima, Anzai, Kajinuma, and Ishiguro[79] even at room temperature which indicated that the longer period than the normal lattice might be mixed. Although these authors explained it by the Kohn anomaly in the one-dimensional metallic lattice, but we may explain it by a partial mixing of the island type structure, which may have nearly triple lattice period.

Next we may try to estimate the polarizability and hence the dielectric constant in the static field for the mixed alternant and island type crystals. The polarizability α and the dielectric constant ε of the TCNQ chain may be given by

$$\alpha = \bar{m}(\boldsymbol{E})/\boldsymbol{E} = \langle\psi_R|er|\psi_R\rangle\omega(\boldsymbol{E})/\boldsymbol{E}$$

and

$$\simeq b^2\frac{(er_0)^2}{kT}$$

$$\varepsilon = 1 + 4\pi N\alpha \tag{23}$$

where Nb^2 is the number of active site in an unit volume of the crystal. The calculated results are $\varepsilon=3400$ for TTF(TCNQ) and $\varepsilon=330$ for NMP(TCNQ) at 4.2 K. The observed values are $\varepsilon=(3.2\pm0.7)\times10^3$ for TTF(TCNQ)[80] and $\varepsilon=350\pm50$[81] for NMP(TCNQ). The agreement between the observed and calculated results is quite satisfactory in spite of our simple model used for the calculation. Although our calculation on TTF(TCNQ) is based on the structure determined at room temperature, but we believe that the basic electronic structure is the same even at 4.2 K. In the low temperature phase below 54 K, the correlation of electronic motion may be lost within and between chains, presumably because a 3D regularity inhibits a labile electron motion as in other island type crystals.

Finally we must comment on the design of good conducting organic molecules. First of all good conducting TCNQ complexes which we have studied have an alternant electron configuration as the basic unit and the admixture of an island type configuration increases the conductivity significantly. In this respect a perfectly charged chain is not suitable, and a column with some vacancies will be essential.

A good overlap between TCNQ molecules will be, undoubtedly, very important in the intermolecular interaction, but the size of the transfer integral is limited as large as 0.15 eV between $TCNQ^0$ and $TCNQ^-$. Hence a small U' value for the alternant system may be significant to increase the mixing of the island type, and it may drop even to nearly zero value for some particular crystals by the balance of Coulomb forces within and between columns. The good overlap and the formation of the one-dimensional column of the donor (cation) group is also a necessary condition, because our experience shows that all good conducting crystals have both TCNQ and cation columns. It will imply that a nice balance of charges and a coherent motion of electrons and holes will be possible or facilitated by the interaction between two columns through the variable electron transfer mechanism and a correlation of Coulombic interaction. Anyway the fluctuation of the charges in the chain and the fractional charge transfer between the donor and the acceptor columns are most important for the good conductivity. It necessarily imposes a critical condition for the donor and the acceptor molecules to have a peculiar character that their radicals must be stable enough to form a complex chain with their parent molecules. It means that excess charges must be shared between several molecules, and this condition is actually satisfied in TCNQ complexes as well as TTF complexes.[81]

In concluding this paper the importance of the optical studies of these complexes must be emphasized, particularly in the infrared region, because it will give fundamental information of the electronic structure of these crystals. Although our treatment is concentrated on the molecular approach, but the physical parameters found in this study will be useful even for the band theoretical investigations.

The authors are grateful to Professors Makoto Okawara and Dwaine O. Cowan for the kind gifts of TTF(TCNQ) crystals, and to Dr. Jerry B. Torrance for kind information and comment. They also thank to Professor Yoshihiko Saito for many crystallograpflic information, and to Drs. Motomichi Inoue and Hitosi Sumi for helpful discussions. One of the authors (J. T.) thanks to Professors Takehiko Shimanouchi and Takeo Yamamoto of the University of Tokyo for the use of the Tool-IR system of the Computation Center of the University of Tokyo.

(Received January 5, 1976)

The applicability of flow micro-calorimetry to the measurement of ion exchange heat was investigated by use of H-form resin of Dowex 50W×4 having a low degree of cross-linking. It was found that: accurate measurement of ion exchange heat can be performed by means of flow micro-calorimetry; the data obtained include additional heat effects such as heats of invasion and dilution; the effects can be exactly analyzed experimentally and eliminated for calibrating the data of pure ion exchange heat. The ion exchange heat thus obtained for the H-form resin and alkali metal ions was found to agree with the results obtained by means of heat of immersion measurements.

A number of fundamental studies have been carried out on ion exchange phenomena as regards the origin of selectivity of ion exchangers.[1-3] Combining the calorimetric data and the selectivity coefficients on ion exchange phenomena, Cruickshank and Meares,[4] Myers and Boyd,[5] and Boyd *et al.*[6] developed the thermodynamics of ion exchange reactions and attempted to elucidate the exchange phenomena in terms of the properties of ions and the structure of resins. In order to measure the ion exchange heat, they adopted the same calorimetric technique as that used for the measurement of immersion heat. The heat of ion exchange reaction can be measured step by step over the whole range of loading on one kind of ion.

A report has been given on flow micro-calorimetry[7] for the measurement of heat of adsorption from solution, which makes it possible to measure sensitively a small amount of heat evolved in a solid-liquid system.

The present paper deals with the applicability of flow micro-calorimetry to the measurement of ion exchange heat of alkali metal ions with H^+ ions, by use of a cation exchange resin, Dowex 50 W×4, made of poly(styrene sulfonate) and having relatively homogeneous sites for the exchange of alkali metal ions.

Experimental

Materials. Poly(styrene sulfonate) type resin, Dowex 50W×4 was used as a cation exchanger. The resin was washed with dilute hydrochloric acid until the well-defined H-form was ensured, followed by washing with distilled water. The total exchange capacity of the resin thus treated was 4.35 meq/g for alkali metal ions. Alkali metal chlorides of guaranteed grade were employed for the preparation of electrolyte solutions.

Ion Exchange Calorimetry. The apparatus was essentially the same as that used for the measurement of heat of adsorption from solution.[7] Figure 1 shows a diagram of the flow micro-calorimeter. The main part of this apparatus consists of a liquid column chromatograph, JLC-2A (Japan Electron Optics Laboratory Co., Ltd.). The resin (0.1 ml in apparent volume) was sandwiched by glass beads (65—100 mesh) and placed in a bed in the same position as that of both detection and reference columns. A coiled platinum resistance wire of 0.1 mm in diameter and 25 cm in length was embedded in the sample bed of the detection column, used for the calibration of the heat evolved by ion-exchanging. Change in temperature caused by ion exchange reaction or passage of electrical current through the platinum wire was detected with a thermistor connected by copper leads to a Wheatstone bridge, another arm of which was constructed by a similar thermistor placed in the reference column so that the calorimeter operates as a type of twin calorimeter. All the reacting solutions or water were forced to flow through the sample bed with a constant rate, 0.36 ml/min, by use of a constant flow pump.

The procedure for ion exchange calorimetry was carried out as follows. After the attainment of thermal equilibrium, the H-form resin set in the columns was washed with distilled water by passing through with the flow pump, until a constant base line was attained. Then, a certain amount of electrical energy was supplied to the platinum heater, the temperature rise being recorded. The calibration measurements were repeated by supplying various amounts of electrical energy. Next, the flowing liquid was converted from water into an electrolyte solution by means of exchange valves (Fig. 1). The heat

† Present address: Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662.

liberated by the exchange of alkali metal ions with H^+ ions in the resin was recorded. All the measurements of ion exchange heat were carried out at 30 °C and within a reproducibility of ±5%. The amount of ions which underwent exchange was determined by titrating the eluted solution with a standard 0.01 M NaOH solution.

Results and Discussion

Figure 2 shows the peaks corresponding to the heats generated when various amounts of electrical energy were supplied under a flow rate, 0.36 ml/min, of water. Here, the rate of heat generation was 0.076 J/min. The relation between the peak area (Fig. 2) and the electrical energy supplied is shown in Fig. 3. We see that the peak area is proportional to the electrical energy supplied, and that the straight line passes the origin of the co-ordinates. A preliminary test[7] showed that the slope of the calibration curves does not depend upon the rate of heat generation, but varies with the flow rate of liquid. Thus, the flow rate of liquid was kept constant during the course of the experiment.

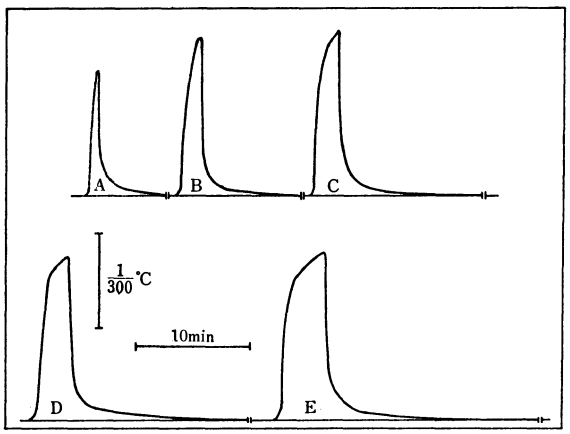

Fig. 2. Calibration peaks at 30 °C.
Peaks, A, B, C, D, and E were obtained by supplying electrical energy of 0.1515, 0.3063, 0.4690, 0.6188, and 0.7653 J respectively.

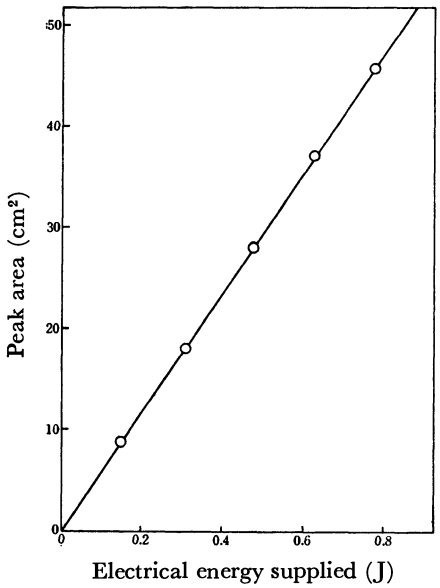

Fig. 3. Relation between peak area and electrical energy supplied.

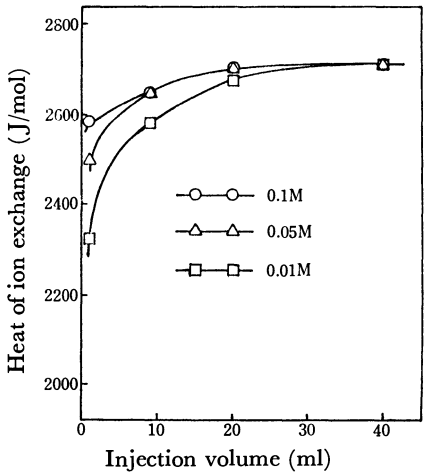

Fig. 4. Dependence of heat of ion exchange (Na^+) upon injection volume.

Figure 4 shows the molar heat of ion exchange (J/mol) as a function of the injected volume of 0.05 M solution to a constant amount (0.1 ml) of the resin. The heat evolution due to ion exchange reaction increases with increasing amount of solution injected and reaches a constant value when the volume of injected solution exceeds 10 ml. Such a slight heat evolution at the initial stage of injection may be due to partial exchange of ions at a slightly greater distance from the position of thermistor as compared to the cases where the volume of injected solution exceeds 10 ml. Thus, the measurement on the molar heats of ion exchange reaction was carried out by injecting 40 ml solution.

Figure 5 shows a few peaks obtained when the flowing liquids were exchanged successively by means of the exchange valves in the order: water, electrolyte solution, water. Preliminary tests showed that the higher the concentration of the solution and the greater the atomic weight of the ions injected, the steeper the peaks, whereas the peak area, obtained on a given alkali ion species are the same irrespective of the concentration of the solution. The peaks were obtained by injecting 40 ml of 0.05 M solution of Li^+, Na^+, and K^+ ions, and 60 ml of 0.035 M solution of Rb^+ and Cs^+ ions, respectively. The results show that the exchange reaction of alkali metal ions with H^+ ions in the H-form resin is exothermic except for the case of Li^+ ions. A small endothermic peak appeared after the flowing liquid was changed from an electrolyte solution to water except for the case of Li^+ ions.

Concerning these phenomena, the following experiment was carried out. The H-form resin set in the detection column of the calorimeter was converted to the Na-form by flowing a sufficient amount of NaCl solution, washed with water completely, and subjected to the injection of 40 ml of 0.05 M NaCl solution. When washing with water and injection of NaCl solution were repeated, the same recording was obtained as shown in each underlying curve in Fig. 5. The results show that a pair of small peaks appear, exothermic at the initial

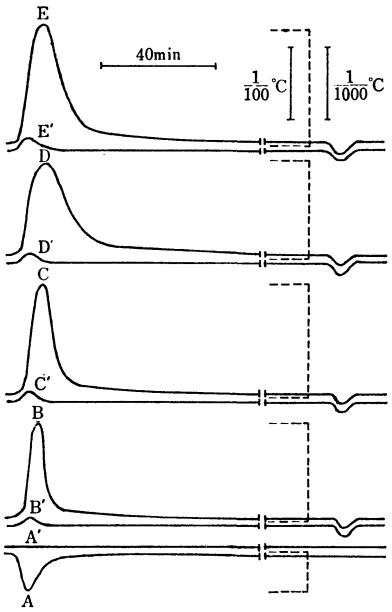

Fig. 5. Heat of ion exchange reaction of alkali metal ions with H^+ ions in resin. A, Li^+; B, Na^+; C, K^+; D, Rb^+; E, Cs^+. Curves A′, B′, C′, D′, and E′ (sensitivity 1/1000 °C) show the heat generation when a solution was injected to the resin containing the same cation species. Peaks directed upward mean "exothermic" and directed downward "endothermic".

stage just after the injection of a solution, and endothermic at the initial stage of washing, except for the case of Li^+-loading, where a nearly straight line appears. The areas of both peaks appearing in a curve are almost the same, being also lose to the area of endothemic peaks appearing at the latter part of the corresponding main run. The heat evolution which took place was too small to be detected. However, it appeared when the concentration was high, the sign being the same as that of heat of ion exchange reaction. The same phenomenon was also found when a solution of H^+ ions was injected into the H-form resin, the sign of heat generation being the same as that in the case of Li^+ ions. It is not easy to find the cause of the occurrence of such small peaks. The ion exchange reaction might be accompanied by a weak interaction of ions in solution with the field of exchanging sites such as invasion or adsorption which may involve hydration and dehydration of ions concerned. We could infer that the small endothermic peaks appearing in the process of washing with water are due to physical interaction such as desorption of ions from the network of resin. The main peak of exchange reaction might be determined by exchange reaction and physical interaction. In order to obtain the energy of pure exchange reaction, we should subtract the contribution of the weak interaction from the total heat effects.

In the present system, the boundaries between water and electrolyte solution would be formed every time the exchange valves are operated, moving in the detection column through the position of the temperature sensing element. Since the diffusion of ions or dilution of the solution would gradually take place near the boundaries during the course of liquid flow, a small amount of heat generation can be expected when a moving boundary layer passes through the position of the thermistor. In order to test the heat generation by dilution, the layer of resin was replaced by glass beads which are considered not to act upon neutral alkali chloride solution. The exchange operation of the valves was carried out as before. No visible peaks appeared when the concentration of the solution was 0.05 M.

Table 1. Ion exchange heat of alkali metal ions with Dowex 50WX4, H-form cation exchange resin

Metal ion	Quantity exchanged (meq)	Heat evolved (J)	Ion exchange heat (J/mol)
Li^+	0.1558	−0.196	−1260 (−920.5)
Na^+	0.1549	0.432	2790 (3598.2)
K^+	0.1589	0.730	4590 (5313.7)
Rb^+	0.1546	0.815	5270 (—)
Cs^+	0.1524	0.876	5750 (6192.3)

Ion exchange heats in parenthesis were calculated from those by Boyd *et al.*,[6] which were obtained by exchanging any alkali metal ions for Na^+ ions in Na-form Dowex 50 WX4.

The molar heat of ion exchange of alkali metal ions with H^+ ions in the H-form resin was obtained by calibrating the heat of invasion. The results are listed in Table 1 together with those reported by Boyd *et al.*[6] The molar heats agree with those obtained by the other method. The ion exchange heat depends strongly upon the extent of ion loading particularly in highly cross-linked resin. In the latter case, the heat of ion exchange is high at the initial loading of ions, decreases gradually with increasing loading of ions and sharply near 60—80 % loading. On the other hand, the exchanger, Dowex 50 W×4, is of relatively low extent of cross-linking, representing only a small dependence of the exchange heat upon ion loading. This makes us convince the coincidence of two kinds of data on ion exchange heat, *i.e.* of differential heats reported by Boyd *et al.* and intergral heats.

Electronic Configuration Analysis of Molecular Deformations

Takashi OKADA, Shigeru NAGASE, Kizashi YAMAGUCHI, and Takayuki FUENO
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received January 20, 1976)

A procedure is described which enables to trace the variations of electronic configuration of molecular systems undergoing structural deformation. The mapping operator proposed by Trindle is used to derive a reference set of molecular orbitals which is suitable to the analysis of the wave functions for deformed molecules. The method has been applied to the twisting of ethylene as well as the electrocyclic reactions of butadiene. The results corroborate Bader's symmetry requirement for the electronic excitations accompanying nuclear displacements.

The method of configuration analysis[1] has made it possible to disclose the electronic-structural features of a transient molecular system in comparison with a pertinent reference system. In this method, any configuration Ψ_σ^P of a given system P is expressed as a linear combination of configurations Ψ_λ^Q which are constructed of the molecular orbitals (MO) for the reference system Q:

$$\Psi_\sigma^P = \sum_\lambda l_{\sigma\lambda}\Psi_\lambda^Q \quad (1)$$

The coefficients $l_{\sigma\lambda}$ are evaluated through calculations of appropriate minor determinants of the matrix $\boldsymbol{B}$ such that

$$\boldsymbol{\phi}^P = \boldsymbol{\phi}^Q\boldsymbol{B} \quad (2)$$

where the row vactor $\boldsymbol{\phi}$ represents a set of orthonormal MO's for each system. The matrix $\boldsymbol{B}$ can be expressed as

$$\boldsymbol{B} = (\boldsymbol{C}^Q)^\dagger\boldsymbol{C}^P \quad (3)$$

where $\boldsymbol{C}^P$ and $\boldsymbol{C}^Q$ denote the relevant LCAO matrices for $\boldsymbol{\phi}^P$ and $\boldsymbol{\phi}^Q$, respectively.

The foregoing procedure may be applied to the interpretations of nuclear displacement processes such as molecular vibrations and chemical reactions. However, the method as it stands is based on the assumption that the AO basis set $\boldsymbol{\chi}$ has the same implication for both systems P and Q. Consider two equivalent wave functions expressed in different coordinate systems. These functions can be identified with each other by means of configuration analysis, only if the two coordinate systems are superposed by translation alone. That is to say, the invariance for the rotation of coordinate systems does not hold in this method of configuration analysis. Therefore, there appears a difficulty in its applications to the processes accompanied by molecular deformations. In such cases, different meanings must be given to the AO basis sets $\boldsymbol{\chi}^P$ and $\boldsymbol{\chi}^Q$, on which the MO's ϕ_i^P and ϕ_i^Q are to be based, respectively.

To cope with the situation delineated above, it is advantageous to introduce the mapping procedure which has been proposed by Trindle.[2-4] By making use of the mapping operator which projects the MO's ϕ_i^Q defined in the $\boldsymbol{\chi}^Q$ space onto the $\boldsymbol{\chi}^P$ space, we obtain a set of mapped orbitals ϕ_i^R:

$$\boldsymbol{\phi}^R = \boldsymbol{\phi}^Q\boldsymbol{R} \quad (4)$$

where $\boldsymbol{R}$ is the mapping operator in the matrix representation. Use of the mapped orbitals as reference orbitals renders the configuration analysis meaningful.[5] Thus, the configurations mixed in this way correspond only to the charge reorganization during the nuclear displacement. The weight of the ground configuration so calculated for the ground electronic state is equivalent to the state overlap which Trindle defined in his mapping analysis as a criterion of the orbital-symmetry allowedness of thermal reactions.[2]

It should be noted that an analogous multi-configurational representation has been proposed by Trindle and Collins in their energy-based mapping analysis.[4] Practically, however, their method could hardly be applied to problems involving a large number of configurations. There one would inevitably encounter with too numerous degrees of freedom to determine simultaneously the mapping operator and the configurational mixing coefficients with confidence.

Applications and Discussion

To illustrate the use of the present method we here apply it to two processes, the twisting of ethylene and the ring-closure of butadiene to cyclobutene. The molecular geometries were all taken from the literature.[6] Use was made of the CNDO/2 wave functions[7] in a single-determinant approximation. The mapping operators were obtained by the original overlap-based formalism.[2]

(A) Twisting of Ethylene. We have examined the wave function of a twisted ethylene molecule, for which the dihedral angle between the two CH_2 planes is assumed to be 45°. The SCF MO's calculated for the planar ethylene were projected onto the AO basis set of the twisted ethylene. The mapped orbitals $\boldsymbol{\phi}^R$ thus obtained are used as the reference orbitals in the configuration analysis. Given in Table 1 are the absolute values of the configurational coefficients which are larger than 0.01. Each excited singlet configuration is designated by the pair of occupied and unoccupied MO's which are specified according to the irreducible representations of the D_{2h} point group. The symmetries of configurations are indicated in the second column.

As Table 1 shows, the coefficients for the excited configurations are relatively small, indicating that the

Table 1. Absolute values of the configurational coefficients for the twisting of ethylene[a]

Configuration	Symmetry	Coefficient
Ground	A_g	0.998
$1b_{1u} \rightarrow 2b_{1g}^*$	A_u	0.039
$1b_{2u} \rightarrow 1b_{2g}^*$	A_u	0.039
$1b_{1g} \rightarrow 2b_{1g}^*$	A_g	0.010

a) At the twisting angle of 45°.

charge distribution in ethylene suffers relaxation only slightly if the nuclear motion takes place. The effect of charge redistribution on the height of rotational barrier is, therefore, expected to be small.

More important in Table 1 is the trend that, aside from the totally symmetric excited configuration, the ground configuration mixes only with those configurations of the A_u symmetry. The twisting motion of ethylene also possesses the A_u symmetry. Thus, the excited configurations to be mixed, if slightly, with the ground configuration upon nuclear displacement have the same symmetry as the normal coordinate which is responsible for the displacement. The results are in agreement with the generalization first put forth by Bader.[8]

(B) Ring-closure of Butadiene. Two stereochemical courses, conrotatory and disrotatory, are investigated. Since butadiene (*s-cis*) possesses the C_{2v} symmetry, the corresponding representations will be used throughout this section. Thus, the conrotatory and disrotatory reaction modes may be characterized by the A_2 and B_2 representations, respectively. Two intermediate structures I and II as well as the product structure F have been examined for each reaction. The distance between the terminal carbon atoms was assumed to change linearly with the CH_2 rotation angles θ in the course of reaction. The structures I and II correspond to $\theta=50$ and 80°, respectively.

The results of calculations are shown in Tables 2 and 3, where the absolute values of the coefficients for dominantly contributing configurations only are listed. It can be seen here also that Bader's rule is fulfilled. That is, except for the A_1 configurations, only the excited configurations having the A_2 and B_2 symmetries are mixed with the ground configuration in the conrotatory(A_2) and disrotatory(B_2) reactions, respectively.

Comparison of Table 2 with Table 3 shows that the two stereochemical courses have quite contrasting features. Thus, in the conrotatory reaction (Table 2) the configurational coefficients change continuously throughout, whereas in the disrotatory reaction mode (Table 3) there is no composite configuration at all

a) I, intermediate I for which $\theta=50°$; II, intermediate II for which $\theta=80°$; P, product (cyclobutene).

that is common to structures I and II. In the former reaction, therefore, the nuclear motion is accompanied by a smooth development in relaxation in charge distribution, thus rendering the molecular deformation energetically favorable. The discontinuity of the configurational mixing in the latter reaction is obviously due to the interchange between the highest occupied and lowest unoccupied MO's in the course of reaction, a characteristic which inheres in orbital-symmetry forbidden reactions.

As can be seen from Tables 2 and 3, the mixing of the excited A_1 configurations is especially small in the disrotatory reaction. In this reaction, therefore, the electronic relaxation due to the approach of the terminal CH_2 groups, which should be characterized as a motion with the A_1 symmetry, must be by far less efficient than in the conrotatory reaction. This may be taken as an indication that the steric course of ring closure is governed by the ease of the approaching motion of the two CH_2 groups rather than the ease of thier rotational motions. The interpretation is compatible with the potential energy surfaces calculated by van der Lugt and Oosterhoff[10] for the two steric courses of reaction.

The Thermodynamics of Nonstoichiometric $Pr_{1-y}Gd_yO_{1.5+\delta}$

Kazuhiro ENDO,** Shigeru YAMAUCHI, Kazuo FUEKI,* and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

**Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received February 2, 1976)

In order to contribute to the study of the thermodynamics of point defects in ionic crystals, the nonstoichiometry, δ, of $Pr_{1-y}Gd_yO_{1.5+\delta}$ ($y=0$, 0.1, 0.2, and 0.4) with a wide nonstoichiometric composition range was measured as a function of the oxygen partial pressure. Assuming that excess oxygen ions preferentially occupy Z-sites of the bixbyite structure and that the Pr^{3+} and Pr^{4+} ions are distributed on cationic sites at random, the equilibrium constant, K, was calculated for

$$2Pr^{4+} + O_z^{2-} = 2Pr^{3+} + V_z + \frac{1}{2}O_2$$

It was found that $\ln K$ changes with δ in the relation;

$$\ln K = A + B\delta + C\delta^2$$

The parabolic dependence of $\ln K$ on δ is interpreted in terms of the changes in the energy of the defect formation and in the interaction energy between defects with the volume.

As transport phenomena in solids are closely related to point defects, the elucidation of a transport mechanism necessitates detailed studies of its defects. Since the pioneering works by Wagner and Schottky,[1] many studies have been made of point defects and nonstoichiomitry in ionic crystals. In early thermodynamic treatments the ideal solution approximation was employed to deal with point defects.[2] Although the approximation was experimentally proved to be applicable to many cases, some difficulties arose in the interpretation of the thermodynamic and transport properties of ionic crystals, which have wide nonstoichiometric composition ranges.[3] Several models, *e.g.*, the blocking model,[4-7] the microdomain model,[8,9] and the cluster model,[10-14] have been proposed for picturing the structure of point defects in such nonstoichiometric crystals. However, scarcely no experimental verification of these models has been undertaken.

In order to elucidate the relation between the defect structure and the thermodynamic or transport properties of nonstoichiometric oxides, the present authors have carried out a series of studies of the $Pr_{1-y}Gd_yO_{1.5+\delta}$ system.

There are several phases between $PrO_{1.5}$ and $PrO_{2.0}$.[15,16] At high temperatures, $PrO_{1.5}$ takes the hexagonal structure (A-type) called the θ-phase, whereas it takes the cubic structure (C-type) at low temperatures. The fluorite structure oxide, $PrO_{2+\delta}$, is called the α-phase. Between the fluorite structure oxide and the C-type one, there are several phases, such as the ι and β phases. Above 900 °C, a relatively wide nonstoichiometric phase called the σ-phase appears. The structure of the σ-phase is substantially the bixbyite one, which is regarded as a distorted fluorite structure regularly lacking one fourth of its anions. Anionic vacant sites are characteristic of the bixbyite structure and were named "Z-sites" by Anderson.[17] Hyde *et al.*[15] have pointed out that excess anions in the bixbyite structure oxide may occupy the Z-sites. The preferential occupancy of the Z-sites by excess oxygen ions in a bixbyite structure was experimentally verified from the relationship between the lattice parameter of Y_2O_3 doped with ZrO_2 and its density.[18] It was also previously shown by the present authors[19] that the X-ray peak intensity due to the superstructure of $Pr_{1-y}Gd_yO_{1.5+\delta}$ decreases with the increase in δ.

The present work aims to contribute to the thermodynamics of nonstoichiometric solids containing high-concentration-point defects, using σ-phase solid solutions of $Pr_{1-y}Gd_yO_{1.5+\delta}$ as samples.

Experimental

Praseodymium oxide and gadolinium oxide of a 99.99% purity, supplied by the Shin-etsu Chemical Company, were used as the starting materials. These oxides were dissolved in G. R. grade nitric acid, and the two solutions were mixed in the desired proportions. The mixed solution was then added to a solution of G. R. grade oxalic acid to obtain the coprecipitate of praseodymium gadolinium oxalate, which was then converted into an oxide solid solution, $Pr_{1-y}Gd_yO_{1.5+\delta}$, by calcination, followed by heating at 1550 °C for homogenization.

About 1.5 g of the oxide sample was weighed in a quartz basket, suspended from a Cahn RG Electrobalance with a quartz fibre and placed in a reaction tube heated by an electric furnance. The oxygen partial pressure in the tube was controlled by gas mixtures of argon and oxygen. The circulation of the gas mixtures was carried out by means of an electromagnetic piston pump. The nonstoichiometry was determined gravimetrically, assuming that the $Pr_{1-y}Gd_yO_{1.5+\delta}$ solid solutions were stoichiometric in a pure CO atmosphere.

Results and Discussion

Figures 1 to 4 give the nonstoichiometry δ of σ-phase oxide, $Pr_{1-y}Gd_yO_{1.5+\delta}$, as a function of the oxygen partial pressure and the temperature. As may be seen in these figures, the stability region of the σ-phase extends upon the formation of solid solutions between praseodymium oxide and gadolinium oxide. If point defects in the nonstoichiometric σ-phase oxide tend to form a local or long-range ordering, the stability region of the σ-phase will be narrowed by the addition of gadolinium oxide to praseodymium oxide, because the ordering is

** Present address, Electrotechnical Laboratory, Tanashi, Tokyo 188

prevented by the formation of a solid solution. The results of the present work, therefore, suggest that point defects in the σ-phase oxide are distributed at random. The dependence of the electronic conductivity on δ was well interpreted in terms of the random distribution of Pr^{3+} and Pr^{4+} in the $Pr_{1-y}Gd_yO_{1.5+\delta}$ solid solution.[20]

Accordingly, the equilibrium between σ-phase oxide and oxygen can be expressed by;

$$2Pr^{4+} + O_z^{2-} = 2Pr^{3+} + V_z + \frac{1}{2}O_2 \qquad (1)$$

where O_z^{2-} denotes oxygen ions occupying the Z-site

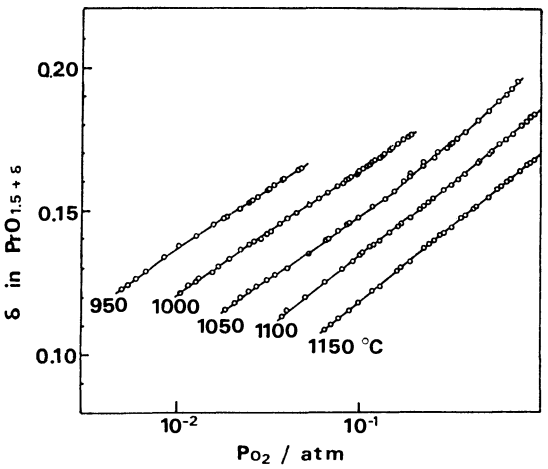

Fig. 1. The dependence of δ on P_{O_2} for $PrO_{1.5+\delta}$.

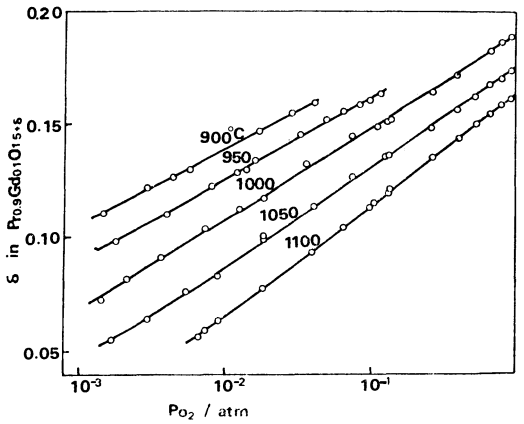

Fig. 2. The dependence of δ on P_{O_2} for $Pr_{0.9}Gd_{0.1}O_{1.5+\delta}$.

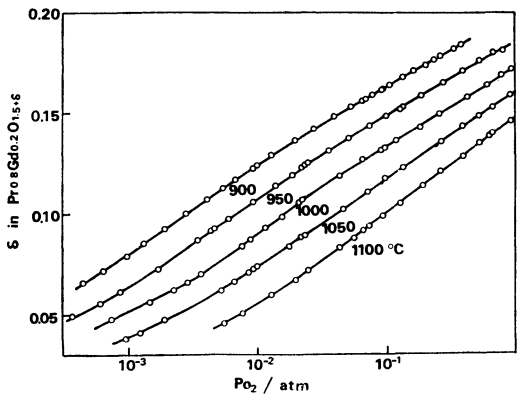

Fig. 3. The dependence of δ on P_{O_2} for $Pr_{0.8}Gd_{0.2}O_{1.5+\delta}$.

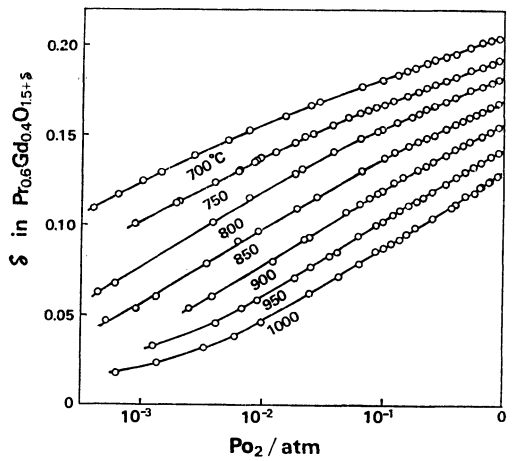

Fig. 4. The dependence of δ on P_{O_2} for $Pr_{0.6}Gd_{0.4}O_{1.5+\delta}$.

and where V_z represents the vacant Z-site. The mass action law for (1) is;

$$K = \frac{[Pr^{3+}]^2[V_z]P_{O_2}^{1/2}}{[Pr^{4+}]^2[O_z^{2-}]} = \frac{(0.5-\delta)(1-y-2\delta)^2P_{O_2}^{1/2}}{4\delta^3}. \qquad (2)$$

If the interaction between defects is extremely weak, the value of K should be constant, as is shown by Eq. 2. It may be seen, however, that $\ln K$ is not constant, but parabolically changes with the increase in δ.

In order to examine whether or not the relation between $\ln K$ and δ is well expressed by;

$$\ln K = A + B\delta + C\delta^2 \qquad (3)$$

the values of A, B, and C were determined by the least-squares method. The solid lines in Fig. 5 represent the least-squares curves, which are in good coincidence with the open circles.

The dependence of $\ln K$ on δ indicates that the energy required for the formation of point defects is a function of the concentration of oxygen ions occupying Z-sites.

The dependence of $\ln K$ on δ might be interpreted by other models, *e.g.*, a model wherein $V_O^{\cdot}$, $V_O^{\cdot\cdot}$, V_{Pr}'', and V_{Pr}''' vacancies are taken into consideration; the blocking model, wherein defects of the same kind do not occupy two neighboring sites, or the Bragg-Williams approximation, wherein the bixbyite structure is regarded as an ordered phase consisting of an O_I sublattice and an O_z sublattice. However, the results of calculation did not agree with the observed ones.

A similar dependence of $\ln K$ on δ, given in Fig. 5 and Eq. 3, has been reported for a few hydride systems.[21,22] As to the other oxide systems, preliminary experiments by the present authors have shown that the $TbO_{1.5+\delta}$ of the bixbyite structure and the $CeO_{2-\delta}$ of the fluorite structure have wide nonstoichiometric composition ranges and that $\ln K$ changes parabolically with δ.

Harashima *et al*[21] have interpreted the dependence of the composition of hydrides on the hydrogen pressure, assuming that the energy of the formation of defects and the interaction energy between defects depends on the molar volume of the crystal. Below, Harashima's treatment will be extended to the present system in

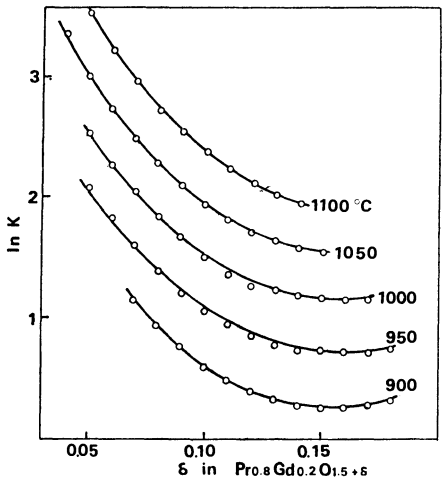

Fig. 5. The dependence of ln K on δ for $Pr_{0.8}Gd_{0.2}O_{1.5+\delta}$.

order to interpret the relation between ln$K$ and δ.

Let us denote the number of cationic sites in $Pr_{1-y}Gd_yO_{1.5+\delta}$ of the bixbyite structure by $2N$, the number of total praseodymium ions by $2N(1-y)$, and the number of Z-sites by N. Assuming the random distribution of O_z^{2-} ions on Z-sites and that of Pr^{3+} and Pr^{4+} ions on cationic sites, we obtain the following expression for the Gibbs free energy of a crystal;

$$G(N_z) = G_0(T) + H(N_z) - kT\ln\left\{\frac{N!}{N_z!(N-N_z)!}\times\frac{[2N(1-y)]!}{(2N_z)![2N(1-y)-2N_z]!}\right\} \quad (4)$$

where N_z is the number of O_z^{2-} ions, $G_0(T)$ is the Gibbs free energy at a constant T for the stoichiometric oxide ($\delta=0$, $N_z=0$), and $H(N_z)$ is the difference in enthalpy between the nonstoichiometric oxide (δ, N_z) and the stoichiometric oxide.

N_z is independent of the content of Gd^{3+} ions, y; therefore, the contribution of Gd^{3+} ions to the Gibbs free energy is included in $G_0(T)$. By differentiating Eq. 4 with N_z and replacing $N_z/2N$ by δ, one obtains;

$$\ln[\lambda_{O_2}]^{1/2} = \ln\left[\frac{4\delta^3}{(0.5-\delta)(1-y-2\delta)^2}\right] + \frac{\partial H(\delta)/\partial\delta}{2NkT} \quad (5)$$

where λ_{O_2} is the absolute activity of the oxygen molecule. The relation between the absolute activity and the oxygen partial pressure is;

$$\ln[\lambda_{O_2}] = \ln P_{O_2} - \frac{\chi_{O_2}}{kT} + \frac{\Psi}{N_0kT} \quad (6)$$

where χ_{O_2} is the dissociation energy of the molecular oxygen, Ψ is the free energy function $(G_T^\circ - H_0^\circ)/T$, and N_0 is Avogadro's number. From Eqs. 2, 5, and 6, we obtain:

$$\ln K = \frac{1}{kT}\left[\frac{1}{2N}\cdot\frac{\partial H(\delta)}{\partial\delta} + \frac{\chi_{O_2}}{2}\right] - \frac{\Psi}{2N_0k} \quad (7)$$

In Eq. 7, χ_{O_2} is constant and Ψ is independent of δ. If ε is the energy required for introducing an atomic oxygen into the bixbyite lattice to form an O_z^{2-} ion and two Pr^{4+} ions converted from Pr^{3+} ions, ω is the interaction energy between two adjacent O_z^{2-} ions, and z is the number of neighboring sites of an O_z^{2-} ion, the enthalpy changes, $H(N_z)$ and $H(\delta)$, are expressed by;

$$H(N_z) = -N_z\varepsilon - \frac{z}{2}N_z\left(\frac{N_z}{2N}\right)\omega \quad (8)$$

$$H(\delta) = -2N(\varepsilon\delta + z\omega\delta^2) \quad (9)$$

When ε and ω are constant, these equations give the enthalpy changes for the regular solution.

According to Harashima, ε and ω change with the volume of the crystal, V;

$$\varepsilon = \varepsilon_0 + \left(\frac{\partial\varepsilon}{\partial V}\right)(V-V_0) \quad (10)$$

$$\omega = \omega_0 + \left(\frac{\partial\omega}{\partial V}\right)(V-V_0) \quad (11)$$

where ε_0, ω_0, and V_0 represent ε, ω, and V respectively at $\delta=0$. The insertion of Eqs. 10 and 11 into Eq. 9 yields;

$$H(\delta) = -2N\left\{\delta\left[\varepsilon_0 + \left(\frac{\partial\varepsilon}{\partial V}\right)(V-V_0)\right] + z\delta^2\left[\omega_0 + \left(\frac{\partial\omega}{\partial V}\right)(V-V_0)\right]\right\} \quad (12)$$

Since the volume of a crystal can be determined by the condition $(\partial G/\partial V)_T=0$, it follows from Eqs. 4 and 9 that;

$$\left(\frac{\partial G}{\partial V}\right)_{T,\delta} = \left(\frac{\partial G_0}{\partial V}\right)_T - 2N\delta\left(\frac{\partial\varepsilon}{\partial V}\right)_{T,\delta} - 2Nz\delta^2\left(\frac{\partial\omega}{\partial V}\right)_{T,\delta} = 0 \quad (13)$$

Taylor's expansion of $(\partial G_0/\partial V)_T$ at V_0 gives;

$$\left(\frac{\partial G_0}{\partial V}\right)_{T,\delta} \fallingdotseq \left(\frac{\partial G_0}{\partial V}\right)_{T,V_0} + \left(\frac{\partial^2 G_0}{\partial V^2}\right)_{T,V_0}(V-V_0) \fallingdotseq -\left(\frac{\partial P}{\partial V}\right)_{V_0}(V-V_0)$$

Therefore,

$$\left(\frac{\partial G_0}{\partial V}\right)_T = \frac{V-V_0}{\kappa V_0} \quad (14)$$

where κ is the compressibility. From Eqs. 13 and 14, we obtain:

$$V - V_0 = 2N\kappa V_0\left[\delta\left(\frac{\partial\varepsilon}{\partial V}\right) + z\delta^2\left(\frac{\partial\omega}{\partial V}\right)\right] \quad (15)$$

By inserting Eq. 15 into Eq. 12 and omitting the term of δ^4, one obtains;

$$H(\delta) = -2N\left\{\varepsilon_0\delta + \left[z\omega_0 + 2N\kappa V_0\left(\frac{\partial\varepsilon}{\partial V}\right)^2\right]\delta^2 + 4N\kappa V_0 z\left(\frac{\partial\varepsilon}{\partial V}\right)\left(\frac{\partial\omega}{\partial V}\right)\delta^3\right\}$$

By putting v as the molecular volume and replacing V by $2Nv$, one obtains;

$$H(\delta) = -2N\left\{\varepsilon_0\delta + \left[z\omega_0 + \kappa v_0\left(\frac{\partial\varepsilon}{\partial v}\right)^2\right]\delta^2 + 2\kappa z v_0\left(\frac{\partial\varepsilon}{\partial v}\right)\left(\frac{\partial\omega}{\partial v}\right)\delta^3\right\} \quad (16)$$

where v_0 is the value of v at $\delta=0$. From Eqs. 7 and 16, one obtains;

$$\ln K = -\frac{1}{kT}\left\{\varepsilon_0 + 2\left[z\omega_0 + \kappa v_0\left(\frac{\partial\varepsilon}{\partial v}\right)^2\right]\delta + 6z\kappa v_0\left(\frac{\partial\varepsilon}{\partial v}\right)\left(\frac{\partial\omega}{\partial v}\right)\delta^2 - \frac{\chi_{O_2}}{2}\right\} - \frac{\Psi}{2N_0k} \quad (17)$$

By a comparison of Eq. 17 with Eq. 3, one obtains;

$$A = -\frac{1}{kT}\left(\varepsilon_0 - \frac{\chi_{O_2}}{2}\right) - \frac{\Psi}{2N_0k} \quad (18)$$

$$B = -\frac{2}{kT}\left[z\omega_0 + \kappa v_0\left(\frac{\partial\varepsilon}{\partial v}\right)^2\right] \quad (19)$$

$$C = -\frac{6z\kappa v_0}{kT}\left(\frac{\partial\varepsilon}{\partial v}\right)\left(\frac{\partial\omega}{\partial v}\right) \quad (20)$$

As may be seen in Eqs. 18, 19, and 20, A, B, and C depend on the temperature. Therefore, the values of ε_0, RTB and RTC were calculated for various temperatures and averaged, instead of the values of A, B, and C. Those values are expected to be less dependent on the temperature. The results are summarized in Table 1.

Table 1. Estimated energy parameter for $Pr_{1-y}Gd_yO_{1.5+\delta}$[a]

y	ε_0 kcal mol^{-1}	RTB kcal mol^{-1}	RTC kcal mol^{-1}	$\partial\varepsilon/\partial v$ cm^{-3}	$\partial\omega/\partial v$ kcal cm^{-3}	ω_0 kcal mol^{-1}
0.0	87.2 (±0.7)	−45 (±10)	110 (±25)	−0.95	1.2	5.9
0.1	85.9 (±2)	−60 (±25)	180 (±30)	−0.95	1.9	8.4
0.2	83.1 (±0.4)	−92 (± 3)	290 (± 5)	−0.96	3.1	14
0.4	81.4 (±1.4)	−94 (± 9)	310 (±50)	−0.96	3.4	14

a) The values in parentheses are the standard deviations.

The values of χ_{O_2} and Ψ were taken from the JANAF Thermochemical Tables.[23] Since ε_0 is the energy required for introducing one atomic oxygen into a crystal to form one O_z^{2-} ion and two Pr^{4+} ions converted from Pr^{3+} ions, it is expected to be independent of the gadolinium content. As may be seen in Table 1, ε_0 is nearly independent of the temperature and the gadolinium content as expected.

The values of RTB and RTC are much scattered and depend on y and the temperature. These results may be attributed to the temperature dependence of κ, $(\partial\varepsilon/\partial v)$, and $(\partial\omega/\partial v)$. Because of the lack of compressibility data available for the calculation, it is difficult to calculate accurate values of B and C, but a rough estimation is possible.

Provided that the second term of the right hand side of Eq. 15 can be omitted, one obtains;

$$\frac{\partial\varepsilon}{\partial v} \fallingdotseq \frac{V - V_0}{\kappa V_0\delta} \quad (21)$$

From the compressibility data of Sm_2O_3 and Gd_2O_3,[24] the reciprocal of the compressibility of σ-phase $PrO_{1.5+\delta}$, $(1/\kappa)$, is estimated as 2×10^{11} dyn cm^{-2}. The $(V-V_0)/V_0\delta$ ratio can be calculated from the lattice parameter of $Pr_{1-y}Gd_yO_{1.5+\delta}$.

If $Pr_{1-y}Gd_yO_{1.5+\delta}$ is regarded as an solid solution consisting of $(1-y-2\delta)$ mol of $PrO_{1.5}$, 2δ mol of PrO_2, and y mol of $GdO_{1.5}$, Vegard's law holds, as is shown in Fig. 6, and the lattice parameter of $Pr_{1-y}Gd_yO_{1.5+\delta}$ is represented by;

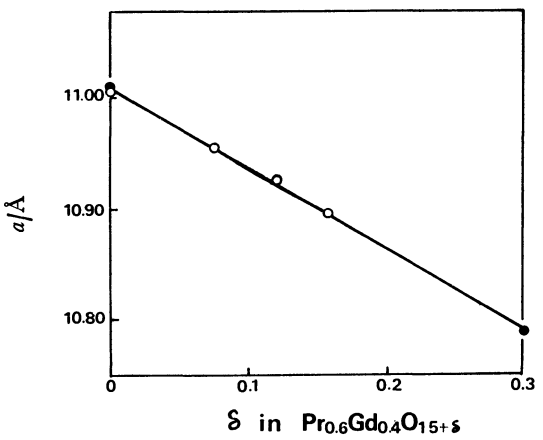

Fig. 6. The relationship between a and δ in $Pr_{0.6}Gd_{0.4}O_{1.5+\delta}$.
○: Observed, ●: calculated.

$$a = (1-y-2\delta)a_{PrO_{1.5}} + 2\delta a_{PrO_2} + y a_{GdO_{1.5}}$$

Therefore,

$$\frac{V - V_0}{V_0\delta} = \frac{a^3 - a_0^3}{\delta a_0^3} \fallingdotseq \frac{(da^3/d\delta)}{a_0^3} = \frac{6(a_{PrO_2} - a_{PrO_{1.5}})}{a_0} \quad (22)$$

The values of $(\partial\varepsilon/\partial v)$ calculated by means of Eqs. 21 and 22, and the values of ω_0 and $(\partial\omega/\partial v)$ calculated with the help of Eqs. 19 and 20 and $(\partial\varepsilon/\partial v)$ are listed in Table 1. Since the lattice parameter of $Pr_{1-y}Gd_yO_{1.5+\delta}$ decreases with an increase in y, ω_0 will be increased as y increases. Because of the lack of accuracy of κ, the values of $(\partial\varepsilon/\partial v)$ and $(\partial\omega/\partial v)$ are less accurate than those of ω_0.

Conclusion

In order to effect a thermodynamic study of bixbyite-type oxides, the nonstoichiometry δ in $Pr_{1-y}Gd_yO_{1.5+\delta}$ was determined as a function of the oxygen partial pressure. It was found that the nonstoichiometric region is extended upon the addition of gadolinium oxide and that, when $y=0.4$, δ can be increased until more than half of the praseodymium ions become tetravalent. The equilibrium between oxygen and nonstoichiometric oxide was calculated based on the random distribution of excess oxygen ions on Z-sites and of Pr^{3+} and Pr^{4+} ions on cationic sites. The parabolic dependence of $\ln K$ on δ was found.

Assuming that the energy of defect formation and the interaction energy between defects change with the molar volume of oxide, the dependence of $\ln K$ on δ was interpreted.

Photochemistry of Cyclobutanes. I. Photolysis of Naphthalene *peri*-Fused Cyclobutanes in Rigid Media. Photocleavage from an Upper Triplet State

Koichi HONDA, Akira YABE, and Hideaki TANAKA

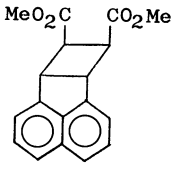
National Chemical Laboratory for Industry, Nishiyawata, Hiratsuka-shi, Kanagawa 254

(Received February 12, 1976)

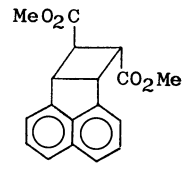
The photocleavage reaction of naphthalene *peri*-fused cyclobutanes (I—IV) in rigid media is found to proceed from one (or several) of the upper triplet states. Nearly planar cyclobutanes (I—III), which were photocleaved in fluid solutions to yield acenaphthylene and 1,2-ethylenedicarboxylic acid derivatives, afford 1,8-naphthalenediacrylic acid derivatives in addition to the above products by irradiation in rigid media. Twisted cyclobutane (IV), which is considerably stable to irradiation in fluid solutions, was also photocleaved in rigid media to give dimethyl 1,8-naphthalenediacrylate. An NMR study shows that the formation of these diacrylic acid derivatives from I—IV in rigid media is considerably stereospecific. The yield ratio of diacrylic acid derivatives to acenaphthylene formed in the photolysis of I—III is independent of the viscosity of the solvents, *i.e.*, of the matrix rigidity, but depends on other properties of the rigid solvents. A concerted mechanism is proposed for the photocleavage reaction of I—IV in rigid media in order to explain the photochemistry different from that in fluid solutions.

There are two possible modes for the photocleavage of four-membered rings of cyclobutane compounds. In the case of cyclobutanes formed from the photocycloaddition of two olefins, one mode of cleavage corresponds to the photoreverse reaction and another leads to the formation of new olefins, if the two modes are not equivalent. However, the photolysis of cyclobutane derivatives frequently shows cleavage-mode selectivity in spite of the energetic possibility of both cleavage modes. It is important to find the factors determining this selectivity. One of the factors must be the steric strain of the cyclobutane ring caused by the interaction of substituent groups. This is supported by the fact that highly-twisted strain-free cyclobutanes are remarkably stable to irradiation.

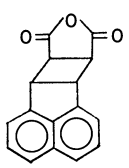
The present authors studied the photolysis of some naphthalene *peri*-fused cyclobutanes (I—IV) to elucidate the factors influencing the cleavage mode. In fluid solutions, the photocleavage of I—III having nearly planar cyclobutane rings takes place from S_1 and T_1, affording only one mode of cleavage products, acenaphthylene and 1,2-ethylenedicarboxylic acid derivatives, but twisted strain-free cyclobutane IV is not photocleaved. In contrast, the irradiation of I—III in rigid media results in two possible modes of cleavage, giving 1,8-naphthalenediacrylic acid derivatives (the valence isomers of I—III) in addition to the photocleavage products observed in fluid solutions. Moreover, IV, for which two photocleavage modes are equivalent, is also photolyzed in rigid media to yield a diacrylate.



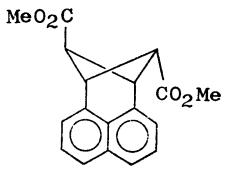
I



II



III



IV

In the present paper, the present authors report that the photocleavage reaction of I—IV in rigid glassy matrices proceeds from higher triplet state(s) by a concerted mechanism, and that this causes a photochemical reaction different from that in fluid solutions.

Experimental

Cyclobutanes I—IV were prepared by a method described elesewhere.[1] All the compounds were purified by repeated recrystallization and the purity was checked by GLC. Low-temperature photolysis was performed in EPA (5: 5: 2) prepared by mixing diethyl ether, isopentane and ethanol, in MP by mixing 3-methylpentane and isopentane, and in glycerol. The solvents except for glycerol were used after purification using alumina column chromatography. A spectrally-pure grade glycerol was used without further purification.

Electronic absorption spectra were obtained using a Shimadzu D-40R spectrometer, emission spectra using a Hitachi MPF-2 spectrometer, and NMR spectra using a Hitachi R-24A instrument.

Two different cell-Dewar arrangements (the cell was immersed in a Dewar containing a coolant) were used. One arrangement consisted of a small cylindrical quartz cell (with a 10-mm pathlength and a 10-mm diameter) and a quartz Dewar equipped with two large flat windows (parallel each other, 20 mm in diameter). This arrangement was used in order to achieve complete photochemical conversion of all sample in the cell. The completely converted samples were used to study the photochemical reaction of the photoproducts. The other arrangement consisted of a cubic quartz cell (with a 10-mm pathlength) and a quartz Dewar equipped with three flat windows (two are parallel and one is at right angles to the other two, 10 mm in diameter). This arrangement was used for following photochemical changes simultaneously using absorption and emission spectroscopy. Generally, liquid nitrogen was used as the coolant, and Dry Ice–ethanol or ice water–sodium chloride was used for glycerol solvent.

A 500-W high-pressure mercury arc lamp with quartz optics (Ushio-501C), a water heat filter (with a 10-mm pathlength), and Toshiba glass filters UV D25 and UV 29 (transparent between 270 and 400 nm) were used for ordinary irradiation. A neutral filter (50% transparency) was added to the lamp system for changing the light intensity. Simultaneous irradiation with two light beams was obtained using the following

light sources: a 10-W low pressure mercury lamp with the Toshiba UV D25 filter (to cut out the 185 nm radiation) for excitation, and the 500-W mercury arc system with Toshiba glass filters VV 40 and UV 39 (transparent between 370 and 470 nm) for long-wavelength light irradiation.

The concentration of samples for photochemistry and spectroscopy was usually about 10^{-4} M. Almost all experiments were performed in an aerated system, since the photochemical reactions were confirmed to be unaffected by air after a comparison between aerated and degassed samples.

An immersion photoreactor consisting of a quartz reaction vessel (doughnut type with a 10-mm pathlength and a 250-ml volume), a quartz Dewar jacket, a quartz jacket for lamp cooling (using circulating water) and a 100-W high-pressure mercury arc lamp was used for the preparative work. The reactor was the most satisfactory one of the several reactors tested. Solutions of I—IV (50 mg in 500 ml EPA) were divided into two 250-ml portions and each was irradiated in the reactor. Irradiation and thawing was repeated to achieve as large a degree of conversion as possible. After the irradiation of each portion for a total of 3 h, the solutions were added and the solvent was evaporated off under reduced pressure. NMR spectra of the residue were obtained without further isolation and the formation of 1,8-naphthalenediacrylic acid derivatives were confirmed, but isolation of the products by preparative GLC was unsuccessful.

Results

Identification of the Products. The photochemical reaction of cyclobutanes I—IV in an EPA rigid glassy matrix at liquid nitrogen temperature was followed using UV spectroscopy; the cyclobutane bands gradually disappeared while the bands of the products grew at longer wavelengths. The starting and the fully-converted spectra of I are shown in Fig. 1, as an example of the spectral changes of the cylobutanes. The photochemical reactions of I—III in fluid solutions were cleavage into acenaphthylene and 1,2-ethylenedicarboxylic acid derivatives,[2] and IV was found to be rather stable to irradiation in fluid solutions.[3] The frozen-state spectrum of acenaphthylene obtained by the photolysis of I in an EPA solution at room temperature under otherwise similar conditions is also shown in Fig. 1. A comparison of the final spectra resulting from the photolysis of I in rigid and fluid states of EPA solutions (Fig. 1) suggests the formation of acenaphthylene and unidentified product(s) resulting in a broad band at about 340—350 nm in EPA at 77 K under the irradiation of I in an EPA matrix. The spectral changes of II and III were similar to that of I, and the final spectra were a superposition of the spectra of acenaphthylene and unidentified products. The irradiation of IV in the rigid matrix also caused spectral changes and gave product(s) having a broad band at about 340 nm, but no acenaphthylene was formed. The conversion efficiency of the highly-twisted cyclobutane, IV, was lower than that of the nearly planar cyclobutanes, I—III.

The unidentified products characteristic of the rigid-state photolysis of I—IV, P_I—P_{IV}, respectively, were identified to be 1,8-naphthalenediacrylic acid derivatives which were formed by the photocleavage of the cyclobutane rings of I—IV, on the basis of their photochemical behavior and absorption, fluorescence and NMR spectra.

Photochemical Behavior of P_I—P_{IV}: The products from the photolysis of I—IV in an EPA glassy matrix did not undergo any more photochemical reactions in the matrix due to selective irradiation. However, after the matrix was melted by warming to room temperature, P_I—P_{IV} reacted easily under the same irradiation to give products whose spectra closely resembled those of the starting cyclobutanes I—IV. Since the irradiation of these products from P_I—P_{IV} at room temperature no

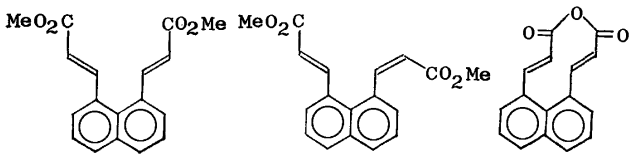
longer gave acenaphthylene as did I—III,[4] most of them are considered to be twisted cyclobutanes like IV, if they are indeed cyclobutanes. Acenaphthylene coexisting with P_I—P_{III} remained almost unchanged throughout these photochemical procedures. Thus, the net absorption spectra of P_I—P_{III} could be respectively obtained as the differences between the superposed spectra and that of the remaining acenaphthylene. The spectral change of P_I and its net absorption spectrum obtained in these procedures are shown in Fig. 2. The net spectra of P_I—P_{III} and the spectrum of P_{IV} resemble each other and their maximum peaks occur at about 330—340 nm in EPA solutions at room temperature.

The net absorption spectra and the photochemical behavior of P_I—P_{IV} agreed well with those of 1,8-naphthalenediacrylic acid derivatives, which was expected from our previous study of the photochemistry of dimethyl 1,8-naphthalenediacrylate (V).[1] The irradiation of V in fluid solutions gave predominantly intramolecular head-to-tail adducts (the main product is IV), while V is photochemically unreactive in rigid matrices. The photochemistry of 1,8-naphthalenediacrylic anhydride (VI) was not studied but was inferred to be almost the same as that of V except for the formation of larger amounts of head-to-head adducts like III due to the fixed structure of VI. This was consistent with the photochemical behavior observed with respect to P_{III}.[4]



trans, trans V *trans, cis* V VI

Fluorescence Spectra of P_I—P_{IV}: Absorption and fluorescence spectral changes of I—IV due to irradiation in EPA at 77 K were observed simultaneously. The fluorescence was measured using 290, 340, or 365 nm radiation for excitation. The fluorescence of both the starting cyclobutanes and the products were observed using 290 nm light for excitation, while using 340 or 365 nm light, only product fluorescence was observed. Intense fluorescence bands due to the products from I—IV appeared and increased with irradiation time in parallel with the growth of the absorption bands of the products, while the intensity of the fluorescence of I—IV decreased at the same time. Since acenaphthylene does not fluoresce,[5] the observed fluorescence of the products was attributed to P_I—P_{IV} even in the case of I—III. The excitation spectra of the fluorescence of the products from I—IV agreed well with the absorption spectra of P_I—P_{IV}, respectively.

The shape and the position of the fluorescence spectra of P_I—P_{IV} agree well with those of V and probably VI, as is shown in Fig. 3. No phosphorescence of P_I—P_{IV} was observed and the intensity of the fluorescence was lowered remarkably upon melting the matrix. This is in accord with the observation with respect to V (non-phosphorescent, with a fluorescence quantum yield in

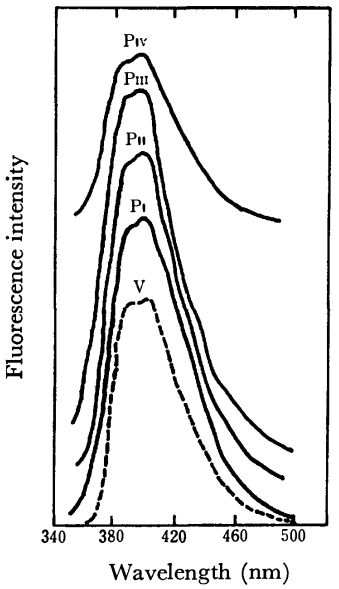


Fig. 3. Fluorescence spectra of P_I—P_{IV} observed after 1 min-irradiation of I—IV in EPA at 77K respectively, and that of *trans, trans* V in EPA matrix (excited with 340 nm light).

EPA of *ca.* 0.9 at 77 K and *ca.* 0.03 at room temperature).[1] These emission spectral observations also suggest that P_I—P_{IV} are 1,8-naphthalenediacrylic acid derivatives.

NMR Spectra of P_I—P_{IV}: Preparatory work on the photolysis of I—IV in EPA at 77 K was performed in order to confirm the formation of the diacrylic acid derivatives. Since the isolation of P_I—P_{IV} from the reaction mixtures by means of preparative GLC was unsuccessful because of the thermal high-reactivity of these substances, an attempt was made to detect them by means of proton NMR spectroscopy. The formation of the dialkenes could be confirmed clearly, since their NMR peaks (of vinyl and/or methyl protons) are not interrupted by the peaks of compounds coexisting with them.[6]

The NMR spectrum of P_I agreed with that of authentic *trans, trans* V, while those of P_{II} and P_{IV} were identical with each other and agreed with that of authentic *trans, cis* V.[7] The spectrum of P_{III} was

TABLE 1. NMR SPECTRAL DATA OF P_I—P_{IV}

Compound	NMR ($CDCl_3$) δ ppm	Assignment

considered to be reasonable for that of VI, although the authentic spectrum of this substance could not be obtained.[8] The observed NMR spectral data of P_I—P_{IV} and their assignments are shown in Table 1. The NMR study suggests that the formation of diacrylic acid derivatives from I—IV in rigid matrices is stereospecific to within the sensitivity of the NMR spectrometer.[6]

Product Yield. The yield of the photocleavage products upon the photolysis of I—IV in an EPA rigid matrix was estimated on the basis of the UV spectra resulting from irradiation to the point of complete conversion. In the case of I—III, the spectral separation of two olefinic products was effected by the photochemical procedures described above. The amount of the products was calculated from the intensity of their spectra using ε at λ_{max}: 4900 (340 nm) for acenaphthylene, 17400 (335 nm) for *trans, trans* V and VI, and 13000 (332 nm) for *trans, cis* V.[9] The quantum yields for the photocleavage of I—IV in rigid matrices were remarkably small and actually zero, since prolonged irradiation with monochromatic light (290 or 313 nm light from the 500 W Hg lamp) which is strong enough for reactions at room temperature scarcely caused any reaction in EPA at 77 K. Thus, the relative disappearance rates of the starting cyclobutanes for irradiation with strong filtered light were determined spectrally in order to compare their photochemical reactivity. The product yield and relative disappearance rate are summarized in Table 2. The total yield of the photocleavage products is much smaller than 100% with respect to all the cyclobutanes studied, and reactions other than photocleavage reach about 60% of the total reactions, as is shown in Table 2.

Table 2. Product yields in the photolysis of I—IV in EPA at 77 K

Compound	R[a]	Product yield (%)		
		Acenaphthylene	1,8-Naphthalenedialkene	Others

II	2.0	44	12	44
III	2.3	20	20	60
IV	0.5	—	43	57

a) Relative disappearance rate.

Fluorescence and Phosphorescence of I—IV. Remarkably intense fluorescence and fairly intense phosphorescence were observed for I—IV in rigid media. The fluorescence and phosphorescence spectra of I—IV in EPA solutions at 77 K were similar to those of naphthalene except that the former was located at a wavelength about 10 nm longer than the latter. The quantum yields for fluorescence and phosphorescence were determined using naphthalene as a standard (ϕ_f=0.55, ϕ_p=0.10 in EPA at 77 K).[10] Phosphorescence lifetimes were also measured by the usual method. The results, summarized in Table 3, show that the cyclobutanes have almost the same emission spectral characteristics as naphthalene, and possess considerably long phosphorescence lifetimes.

Contribution of Upper Triplet State(s). Photocleavage into 1,8-naphthalenedialkenes proceeds only in those instances in which solvents are changed into rigid glasses and the long-lived phosphorescence of the cyclobutanes is observed. This was confirmed using glycerol as a solvent at several reaction temperatures (0 to −80 °C) where the solvent was convertible from a cooled viscous fluid into a rigid glass. Thus, it is suggested that the actual substrates of the photochemical reaction in rigid media are the lowest triplets of the cyclobutanes and the reaction proceeds from upper triplet states which are populated when the metastable triplet absorbs another photon of sufficient energy. In order to verify this, two standard experiments were performed with respect to the cyclobutanes in EPA at 77 K.

Table 3. Quantum yields for fluorescence and phosphorescence, and the phosphorescence lifetime of I—IV in EPA at 77 K[a]

Compound	φ_f	φ_p	τ_p(s)
I	0.58	0.05	2.54
II	0.61	0.07	2.47
III	0.46	0.05	2.40
IV	0.13	0.10	2.54

a) φ_f, φ_p, and τ_p denote the quantum yields for fluorescence (excited with 290 nm light) and phosphorescence (excited with 313 nm light), and the phosphorescence lifetime derived from the decay at the 490 nm and 520 nm peaks, respectively. Naphthalene (φ_f=0.55, φ_p=0.10 in EPA at 77 K)[10] was used as a standard.

Table 4. Dependence of the primary rate of formation of photocleavage products on the light intensity

Rate (full intensity)/Rate (50% intensity)

Compound	Acenaphthylene	1,8-Naphthalenedialkene
I	4.0	3.9
II	3.8	3.9
III	4.0	4.0
IV	—	4.0

(1) The dependence of the primary rate of formation of the photocleavage products on the light intensity was determined. When the intensity of the incident light was decreased to one half using the neutral filter of 50% transparency, the rate was decreased to about a fourth with respect to the formation of both acenaphthylene and dialkenes. The ratio of the rate at full intensity to that at a one-half intensity is shown in Table 4. The fact that the rate is approximately proportional to the square of the light intensity suggests that almost all the photocleavage products are formed by a two-photon mechanism.

(2) The effect of simultaneous irradiation with strong long-wavelength light on the product forming rate was measured. The rate due to a weak source of 254 nm light increased seven- to eight-fold when the samples were irradiated simultaneously with intense light (370—470 nm) which itself had no effect on the cyclobutanes.[11] The effective wavelengths of the second beam

corresponded to those at which the intense bands of the triplet-triplet absorption spectra of naphthalene and alkylnaphthalenes are located.[12] In the case of I—III, the product ratio of acenaphthylene and 1,8-dialkenylnaphthalene was almost independent of irradiation with the long-wavelength light. These results also show that the photocleavage reaction of I—IV in rigid matrices proceeds from upper triplet state(s) formed by the subsequent absorption of two photons.

Table 5. Solvent effect on the photocleavage of I

Solvent	Viscosity (p)[13]	Cleavage ratio (A : N)[a]

IP-3MP (50:50)[b]	5.9×10^8	62 : 38
IP-3MP (0:100)[b]	9.4×10^{11}	69 : 31

a) A=acenaphthylene, N=dimethyl 1,8-naphthalenediacrylate. b) At 77 K (liq. nitrogen). c) At 196 K (Dry Ice–ethanol).

Solvent Effect. In order to examine the effect of the solvents used as matrices on the cleavage mode of the cyclobutanes I—III, the photocleavage of I was studied in some rigid solvents. The yield ratio of the acenaphthylene and *trans, trans* V formed from I according to the two photocleavage modes is shown in Table 5. The ratios are nearly equal to within the experimental errors for the hydrocarbon solvents IP-3-MP, which have remarkably different viscosity but are otherwise similar in nature,[13] while the ratio varies for solvents of different nature. Thus, the ratio of the two modes of cleavage is found to be independent of solvent viscosity, *i.e.*, the rigidity of the matrix, but is found to depend on some other solvent characteristics.

Discussion

Reaction from the Upper Triplet State(s). The photocleavage reaction of I—IV in rigid matrices is found to proceed from the upper triplet state(s) formed by the subsequent absorption of two photons. Since the photoexciting moiety of the cyclobutane compounds is the naphthalene ring, the cleavage is expected to occur in one (or several) of the upper triplet states of the naphthalene chromophore. The triplet state energies (10^3 cm^{-1}) of naphthalene itself, and probably of I—IV, are as follows: T_1=21.3, T_2=30.8, T_3=38.7, T_4=45.5, T_5=58.9, and T_6=63.7.[14] The T_1-T_4 and T_1-T_6 absorption transitions have remarkably large extinction coefficients (33000 and 55000, respectively), but only the former transition is possible energetically under the present conditions. Furthermore, the energy of the T_1-T_4 transition is in accord with the second-photon energy which is effective in causing the reaction. Thus, the photocleavage reaction may be occuring in any of the states T_2-T_4 of the cyclobutanes.

The contribution of the upper triplet state(s) has been reported by Kolc and Michl[15] for a photochemical study of the ring-opening of naphthalene-fused cyclobutenes into the pleiadene family in rigid matrices. Furthermore, it was found that the *cis* dimer of acenaphthylene is also photocleaved to acenaphthylene from the upper triplet state(s) in rigid matrices.[16] It seems to be noteworthy that the long-lived T_1 state of naphthalene chromophore acts as a second-photon receiver in all the reactions described above.

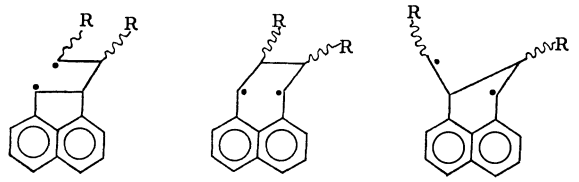
The photochemical reactions of I—III in fluid media take place from the S_1 and T_1 states rather efficiently at room temperature, whereas the reactions of I—IV in rigid matrices occur almost exclusively from the upper triplet state(s). This shows that the S_1 and T_1 states of I—III become unreactive in rigid matrices, although those of IV are inactive even in fluid solutions. In other words, thanks to the unreactivity of the S_1 and T_1 states and the long lifetime of the T_1 state, the reaction from the upper triplet becomes noticeable in rigid matrices. The difference of the reactivities in fluid and in rigid media suggests that the reaction from the S_1 and T_1 states requires some activation energy. The activation energy of I—III may be so small that the reaction can proceed in fluid solutions. Since the reaction from the S_1 and T_1 states is stopped in rigid matrices, the S_1 and T_1 states of I—III should dissipate most of their energy as emission (and as heat). In fact, the fluorescence yields for I—III in EPA matrices at 77 K are about two times larger than those at room temperature, although the yield of IV does not change so much.

Side Reactions. In fluid media, reactions other than photocleavage are unimportant in I—III and IV is stable under the usual conditions, while in rigid media, side reactions become about 60% of the total photochemical reactions (Table 2). Therefore, most of the side reactions in rigid media seem to be related to the upper triplet states. However, photoionization and photosensitized solvent decomposition are excluded from the side reactions because these high-energy processes are energetically impossible in such low upper triplet states as T_2-T_4. Moreover, secondary photolysis of the primary olefinic products is also excluded, since the products are considerably stable to irradiation in rigid matrices. Hence, the side reactions are expected to be fragmentations of I—IV in upper triplet states except for the cleavage of the cyclobutane ring.

In view of the fact that absorption bands based on the naphthalene rings of I—IV disappear almost completely, but that no long-wavelength bands other than those due to the cleavage products appear, the destruction of the naphthalene rings seems to be involved in the side reactions, though the details are not known. In fact, naphthalene itself undergoes photolysis under similar conditions, and its spectrum is gradually changed to an ambiguous one having bands at shorter wavelengths.

Reaction Mechanism. The primary products in fluid solutions show that the photocleavage proceeds preferentially through biradical intermediates (VII).[2] Nonformation of naphthalenedialkenes demonstrates that biradicals (VIII), which are expected to lead, at least partly, to the dialkenes even in rigid media,[17] are energetically unfavorable intermediates.[18] If the reaction in the upper triplet states proceeds by a biradical mechanism, the predominant formation of acenaphth-

ylene must hold for the photolysis in rigid glassy matrices. The occurence of two modes of cleavage in rigid matrices must be explained in terms of a change in the reaction mechanism. The difference in the photochemistries in fluid solutions and in rigid matrices is attributable to the difference in the reaction mechanism for the S_1 and T_1 states and that for the upper triplet states. Therefore, a concerted mechanism is proposed for the photocleavage reactions of I—III in rigid media.



VII VIII IX

R=CO_2Me or 2R=$(CO)_2O$ R=CO_2Me

In contrast to I—III, IV is inactive in the S_1 and T_1 states. The cleavage of its strain-free cyclobutane ring may require much a higher energy than in the cases of I—III. For the upper triplet states, the energetic requirement is satisfied and the cleavage can proceed. It is also supposed that a concerted mechanisms for the reaction of IV in rigid media, without rationalization by the MO theory, from an analogy with naphthalene-fused cyclobutene compounds which are inert in the S_1 and T_1 states and reactive in upper triplet states.[15]

A concerted mechanism for the cleavage reactions for I—IV in rigid matrices is supported by the stereospecific formation of naphthalenedialkenes. If the formation is through the biradical VIII (in the case of I—III) or IX (in the case of IV), geometrical isomers of the diolefinic products must be observed except for the case of II, since the inversion of the cycloheptane ring of VIII and the cyclohexane ring of IX is possible even in rigid media. In fact, Pagni *et al.*[17] reported that biradicals of the IX type are highly flexible and ring inversion occurs easily in an ethanol matrix at liquid nitrogen temperature.

The ineffectiveness of matrix rigidity on the yield ratio of the two photocleavage products from I and probably from II and III (Table 5) also supports the concerted cleavage mechanism. If the reaction is nonconcerted, biradicals VII and VIII must be affected differently by solvent rigidity when they change their geometries at the product forming stage, and consequentely, the ratio must vary with matrix rigidity. The dependence of the yield ratio on the solvent may be explained in terms of a solvent-induced shift of the relative positions of the crossing points of the potential curves for the upper triplet cyclobutanes and of those for some excited states of the olefinic products.

Substituent and Structual Effects. A comparison of the photolysis of isomers I and II shows that II always gives a greater amount of acenaphthylene and has a higher reactivity than I (Table 2). In a glycerol matrix, II gives only acenaphthylene. This is obviously due to the higher ring strain of II caused by the interaction of the naphthalene ring with the substituent at its *cis* position. Kaupp[19] has reported in a study of the photocleavage of some phenyl-substituted cyclobutanes that the cleavage of the *cis*-disubstituted bond is particularly favored due to the relief of a large part of the steric strain in the cyclobutane ring. The relative reactivity (Table 2) shows that IV is less reactive than I—III even in reactions from the upper triplet states in spite of its higher phosphorescence yield.

Therefore, ring strain is an important factor for determining the cleavage mode and the reactivity even in reactions from the upper triplet states.

The authors are grateful to Mr. Kazuhiro Kashiwagi for his assistance during the experiments.

Hydrogen Bonding Systems Containing Hydrogen Fluoride. III.* Infrared Frequency Shifts and CNDO/2 Calculations on HF-Carbonyl Compound Complexes

Mitsunori TSUDA, Hidekazu TOUHARA, Koichiro NAKANISHI,** and Nobuatsu WATANABE

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received February 14, 1976)

CNDO/2 calculations were carried out for the hydrogen bonded complexes between hydrogen fluoride (HF) and a series of organic compounds having a carbonyl group as a proton acceptor. Infrared spectral measurements were also made to obtain the frequency shifts of H–F stretching vibration, $\Delta\nu_{HF}$, for the same complexes in dilute carbon tetrachloride solution. Optimum geometry was obtained on the assumption of planar complex. For all the carbonyl compounds used, the interatomic angles, $\angle$C–O···H, were 120°—123° for the most stable conformation. The changes in the distance between H atom and F atom, ΔR_{HF}, were in good correlation with $\Delta\nu_{HF}$ obtained from IR spectra. Calculated hydrogen bond energies were also in good correlation with $\Delta\nu_{HF}$, though their absolute values were somewhat larger than those derived from experimental observations. This indicates that the CNDO/2 calculations give relatively correct enthalpy values for the hydrogen bond complexes of a given donor with a series of molecules having a common acceptor group. Other correlations of $\Delta\nu_{HF}$ with properties expected to change with the hydrogen bond formation were also confirmed. These include the energies of each bond obtained by the partitioning of the total energy and the force constant of H–F bond. The electron population on the oxygen atom and other atoms participating in the hydrogen bond formation, the charge transfer, ionization potentials and dipole moment enhancements were also calculated and discussed in terms of the measure of hydrogen bond strength.

One of the unique physico-chemical properties of hydrogen fluoride (HF) is a strong tendency to form the hydrogen bonding complexes with various organic molecules. It has been recognized experimentally that the frequency shift of H–F stretching mode due to hydrogen bond formation, $\Delta\nu_{HF}$, and the hydrogen bond energy, ΔH, are unusually larger than the corresponding quantities for any other hydrogen bonding systems.[1-4] On the other hand, HF has a simple geometrical structure and its electronic structure is also relatively simple. To date, many molecular orbital calculations for HF hydrogen bonding systems have been carried out by both non-empirical and semi-empirical methods.[5,6] The results of these calculations give theoretical insight into the nature of hydrogen bonding interactions of HF. However, reliable experimental evidence is often missing and no attempt has been made to compare the well-established experimental data with the calculated results for a series of hydrogen bond complexes consisting of a fixed proton donor (HF) and various proton acceptors.

In the present study, a series of organic compounds which have a carbonyl group were chosen as proton acceptor and the nature of their HF complexes was examined. Reasons for our choice of acceptors are: since the carbonyl group is found in organic molecules such as ketones, aldehydes and amides, their proton accepting ability is distributed over a wide range, making it possible for us to deal with molecules having largely differing pK_a values; the geometry of carbonyl compounds is usually simple and well-defined. The following carbonyl compounds were chosen: formaldehyde, acetaldehyde, propionaldehyde, butyraldehyde, acetone, methyl ethyl ketone, methyl propyl-ketone and *N*,*N*′-dimethylformamide (DMF). CNDO/2 calculations were carried out on the hydrogen bonded structure of HF. Optimized geometry and the corresponding hydrogen bond energy were obtained. The values of $\Delta\nu_{HF}$ were also determined for the same acceptors in dilute carbon tetrachloride solution by the method described previously.[4]

Experimental

The experimental procedures and apparatus used to obtain infrared frequency shift were the same as those reported previously.[3,4] The solubility of aldehydes in CCl_4 was so small that determination of equilibrium constant of complex formation was impossible. Only the $\Delta\nu_{HF}$ could be determined (Table 1).

Method of Calculation

The CNDO/2 calculations were carried out by means of the original parameterization of Pople, Segel and Santry.[7,8] Throughout the calculations, the standard geometries were used and kept constant for all the proton acceptor monomers, and the geometry of proton donor (HF) was fully optimized with respect to the total energy. Figure 1 shows the specifications of geometry for hydrogen bonding complexes.

The optimum geometries and corresponding total energies were obtained by the following procedure.

(1) The HF molecule is first placed on the x-axis in xy-plane. As shown in Fig. 1, the xy-plane is one of the planes of symmetry for the acceptor molecule and the x-axis is the extension line of C=O bond of the acceptor molecule. The distance between fluorine and oxygen atoms, R(F–O), was optimized with respect to the total energy.

(2) On the xy-plane, angular orientation of the HF molecule with respect to C=O bond was optimized by rotating the HF molecule around the origin toward the smaller alkyl group of acceptor molecule by an angle θ.

(3) Keeping R(F–O) and θ constant, the atomic distance R(H–F) is optimized.

(4) Finally R(F–O) is again optimized by keeping R(H–F) and θ constant.

The above procedures seem to be sufficient for obtaining optimum geometries, since the values obtained remain unchanged even when both R(H–F) and θ were again optimized in the same manner. The following comment is given as regards the calculated optimum geometry and energy for each HF complex. The angle ϕ (Fig. 1) was assumed to be zero. For HF–formaldehyde complex, a CNDO/2 calculation has been reported by Schuster.[9] Both θ and ϕ were optimized in his calculation. However, as pointed out by Morokuma[10] and by Kollman and Allen,[5] the angular dependence of hydrogen bond energy was estimated to be very small in CNDO/2 and other empirical calculations, which is in contrast with the results of more refined *ab initio* calculations for the same complex. Optimization with respect to ϕ in the CNDO/2 calculations may not be justified. The structure of hydrogen bonding complex can well be described by means of a general hybridization model.[11,12] Since there should be a trigonal hybrid orbital on the oxygen atom of carbonyl group in the molecular plane, the assumption that $\phi=0$ may be sufficiently reasonable.

According to Schuster's calculation, the hydrogen bond energy, ΔE, for HF–formaldehyde complex is insensitive to ϕ. Our calculated ΔE value was −14.48 kcal/mol for HF–formaldehyde complex. This is almost comparable with those of Schuster[9] for the case that $\phi=0$, a minor discrepancy being due to the difference in the geometry used for formaldehyde monomer.

Results and Discussion

Geometry of HF Hydrogen Bonding Complexes. The optimum geometries calculated for the complexes between HF and a series of carbonyl compounds are summarized in Table 1. The optimum values of θ are 57—60° for all the complexes studied. This is consistent with the general hybridization model for the hydrogen bonds. Since there is a trigonal hybridization on the

oxygen atom of the carbonyl group, the values of θ seem to meet our expectation. It is interesting to examine the possible correlation between the change in atomic distances accompanied by hydrogen bond formation and the infrared frequency shift. As shown in Fig. 2, the change in H–F distance, ΔR(H–F), was found to increase linearly with $\Delta\nu_{HF}$.

Hydrogen Bonding Energy and the Badger-Bauer Relationship. The hydrogen bonding energy ΔE we obtained are given in Table 1. The partitioning of total molecular energy was also carried out, the results and the force constants of H–F bond also being summarized in Table 1.

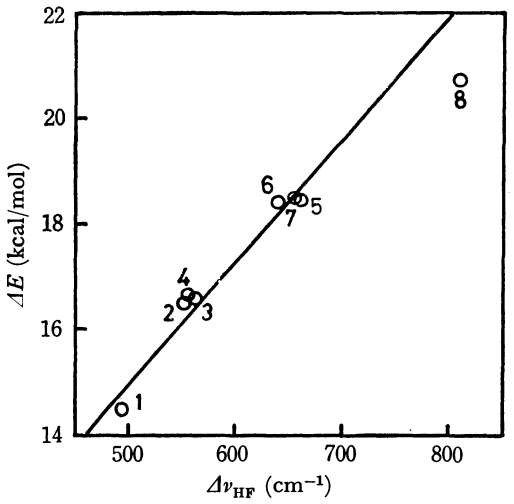

Fig. 3. Plots of ΔE *vs.* $\Delta\nu_{HF}$. The number of points is the same as that in Fig. 2.

Badger-Bauer Relationship: A linear correlation, called the Badger-Bauer relationship, is known to exist between the hydrogen bond energy and the frequency shift.[13–16] A linear correlation could also be recognized between the calculated hydrogen bond energy ΔE and experimental frequency shift, $\Delta\nu_{HF}$, except for the case of HF–DMF complex (Fig. 3). The results indicate that relative values of ΔE can be reasonably estimated from the present calculations for HF–aldehyde and HF–ketone complexes. The deviation for HF–DMF complex will not be due to the fact that the relative value for this complex is unjustifiable.

This will be confirmed from the following discussion. The ΔE values for HF–acetone and HF–DMF complexes were calculated to be -18.44 and -20.73 kcal/mol, respectively (Table 1), while the enthalpy of complex formation values, ΔH, for the above two in carbon tetrachloride solution have been estimated to be -6.9 and -7.6 kcal/mol, respectively, from infrared spectroscopic measurement.[4] However, the ratio, $\Delta E/\Delta H$, for HF–acetone complex agrees fairly well with that for HF–DMF complex within experimental error.[17] This indicates that the relative value of ΔE for HF–DMF complex is also as reasonable as those for other complexes. The discrepancy found for HF–DMF complex may be due to the fact that the nature of the hydrogen bond differs from the other since DMF monomer has a conjugated system and its highest occupied orbital is not σ- but π-orbital. The anomaly for HF–DMF complex was observed in all the correlations tested.

It is recognized that semi-empirical calculations such as CNDO/2 overestimate the hydrogen bond energy.[5] The discrepancy between ΔE and ΔH is seriously large, even when the difference between experimental environment and the assumption in theoretical calculation is taken into considerations. However, since the calculated ΔE values are relatively valid, we may define a corrected ΔE value which is normalized so as to satisfy the experimental ΔH values both for HF–acetone and HF–DMF complexes. These normalized energy values (denoted by ΔE_{corr}) are also given in Table 1.

Semi-empirical methods such as CNDO/2 calculation involve optional parameters and the problem of which parameterization is the most suitable for representing such delicate interactions as the hydrogen bond remains.[18] However, the present calculations for the hydrogen bond complexes between a fixed proton donor and a series of proton acceptors with a fixed functional group should provide fairly reasonable (relative) values of hydrogen bond energy probably because of the compensation of various factors concerning parameterization. It is concluded that the present treatment is useful for estimating the hydrogen bond energy which cannot be obtained due to experimental difficulty (*e.g.*, in the case of HF–aldehyde complexes).

Partitioning of Total Energy: The total molecular energy E may be decomposed into one and two center terms;[7]

$$E = \sum_{A} E_A + \sum_{A}\sum_{B} E_{AB} \qquad (1)$$

The two center term, E_{AB}, can be interpreted as a measure of the strength of A–B bond and written as[19]

$$E_{AB} = E^R_{AB} + E^V_{AB} + E^J_{AB} + E^K_{AB} + E^N_{AB}. \qquad (2)$$

The leading term of the RHS of Eq. 2, E^R_{AB}, represents the contribution of resonance integral to E_{AB}[20] and is given by[19]

$$E^R_{AB} = 2\sum_{\mu\in A}\sum_{\nu\in B} P_{\mu\nu}\beta_{\mu\nu}S_{\mu\nu}. \qquad (3)$$

An analysis of E^R_{AB} is equivalent to a population analysis in which the individual terms are weighted with an energy factor $\beta_{\mu\nu}$. The amounts of change in E_{AB} and E^R_{AB} for H–F bond,

$$\Delta E_{HF} = E_{HF}(\text{monomer}) - E_{HF}(\text{complex}) \qquad (4)$$

$$\Delta E^R_{HF} = E^R_{HF}(\text{monomer}) - E^R_{HF}(\text{complex}) \qquad (5)$$

were expected to be more directly correlated with $\Delta\nu_{HF}$. As shown in Fig. 4, both ΔE_{HF} and ΔE^R_{HF} are in good correlation with $\Delta\nu_{HF}$ values.

Force Constant of H–F Bonds: The force constant K(H–F) of H–F bond can be approximately evaluated from the second derivative of the total energy with respect to H–F distance at an equilibrium geometry (Table 1). It decreases with an increase in the strength of hydrogen bond. A linear correlation holds with ν_{HF} (Fig. 5).

Electron Populations and Charge Transfer. The electron populations on the atoms participating in the formation of hydrogen bond or the charge transfer due to the hydrogen bond formation may be utilized as a measure of hydrogen bond strength. The electron

populations on F, H, O and C atoms for monomers and complexes and the amount of charge transfer from the proton acceptors to the proton donor, ΔQ, are summarized (in Table 2).

Correlations with Hydrogen Bond Energy: Del Bene[11,21] pointed out from the results of *ab initio* calculations that the net electron population on the proton accepting sites (atoms) is a good measure of the hydrogen bond strength. In accordance with this suggestion, the electron population on the oxygen atoms of proton acceptor and ΔQ are plotted against ΔE_{corr}. Good linear correlations have been obtained except for the HF–DMF complex (Fig. 6).

Electron Population on Oxygen Atom: Although the above correlations are successful, more detailed analysis on the electron population on the oxygen atom will give

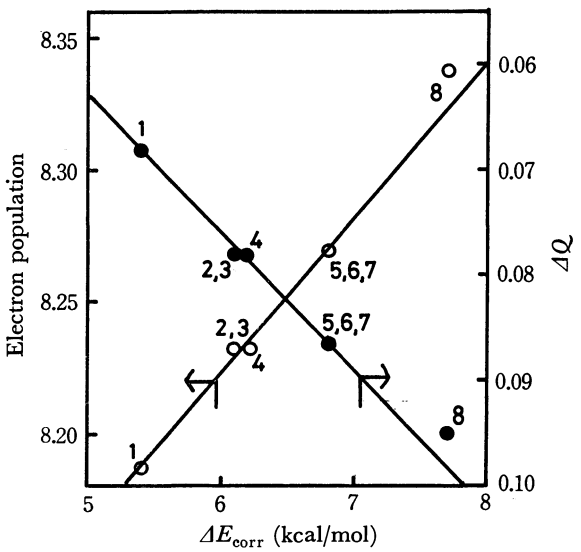

Fig. 6. Plots of electron population on O atom of proton acceptor monomer and the amount of charge transfer by hydrogen bond against ΔE_{corr}. The number of points is the same as that in Fig. 2.

further insight into the nature of the present hydrogen bond systems. First, let us examine the changes in the electron populations on each atom participating F–H···O=C hydrogen bond. The following changes were observed on the electron populations when the hydrogen bonding complex was formed (Table 2): For all the complexes studied, there were an increase in the electron population on the fluorine atom and a decrease in the electron population both on the hydrogen and carbon atoms. On the other hand, a decrease in the electron population on the oxygen atom was observed only for the cases of HF–DMF and HF–formaldehyde complexes. This led us to calculate the contributions of σ- and π-electrons to the total electron population. Table 3 shows, as an example, the amounts of change in the electron populations on the O and C atoms for HF–formaldehyde and HF–acetaldehyde complexes. It is seen that there is a decrease in the σ-electron population and an increase in the π-electron population for each complex, and that the sign of the change in total electron population depends on the relative magnitude of both contributions.

It is thus concluded that, for all the complexes other than HF–formaldehyde and HF–DMF, there are some

more transfers of π-electrons from methyl-, ethyl-, or propyl group into carbonyl group by the hyperconjugation effect which is accompanied by hydrogen bond formation. The increase in the electron population on the oxygen atom for these complexes should be due to the fact that the increase in the π-electron population by this effect exceeds the decrease in the σ-electron population. The lack of hyperconjugation effect in the HF–formaldehyde and HF–DMF complexes might be responsible for the decrease in the total electron population on the oxygen atom.

Ionization Potential and Dipole Moment Enhancement. The proton accepting abilities of the carbonyl group have been discussed in detail by Cook.[22] It is of interest to calculate the energy, $E_{C=O}$, of the carbonyl group for monomer and complex and the first ionization potential (IP) and to examine possible correlations of the frequency of the C=O stretching vibration, $\nu_{C=O}$, with them. The results of calculation for $E_{C=O}$ and IP are given in Table 4. We see that the calculated $E_{C=O}$ values are parallel with the $\nu_{C=O}$ values given by Cook.[22] A similar parallelism can be confirmed for any pairs from ΔE_{corr}, $\Delta\nu_{HF}$, and $\Delta E_{C=O}$ (the change in the amount of $E_{C=O}$ by the hydrogen bond formation).

IP as a Measure of Hydrogen Bond Strength: The calculated IP values for proton acceptor monomers are compared with those obtained experimentally in Fig. 7.[22,23] A satisfactory correspondence holds between them, though the calculated values are always somewhat larger than the observed ones (DMF is an exception). Cook has pointed out that there is a linear relationship between IP and $\nu_{C=O}$ and the latter can be used as a measure of the hydrogen bond strength. The $\nu_{C=O}$ will exhibit a shift due to the hydrogen bond formation and can also be used as a measure of hydrogen bond strength, though the shift, $\Delta\nu_{C=O}$, could not be detected for HF-complexes.[24] Careful examination of the IP values (Table 4) leads to the conclusion that they cannot always be used as a measure of hydrogen bond strength. The values for $\Delta\nu_{HF}$, $\nu_{C=O}$, $E_{C=O}$, and ΔE_{corr} are almost constant for three aldehydes except formaldehyde and for three ketones, whereas the values of both observed and calculated IP decrease continuously from acetaldehyde to methyl propyl ketone.

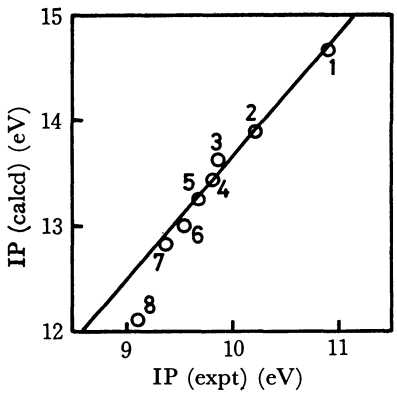

Fig. 7. Plots of calculated ionization potential *vs.* experimental ionization potential for all acceptor monomers. The number of points is the same as that in Fig. 2.

The failure of correlation may be interpreted as follows. The first ionization potential of proton acceptor monomer depends on the properties of the highest occupied orbital. This is considered to be a measure of the charge transfer and/or of the proton accepting ability. However, since various kinds of interactions other than the charge transfer (*e.g.*, electrostatic, dispersion, and repulsive) may contribute to the hydrogen bond energy, one cannot always discuss the strength of hydrogen bond in terms of the facility of charge transfer and accordingly the first ionization potential. It is important to evaluate how much the ionization potential of proton acceptor monomer reflects the properties of electrons available for hydrogen bonding.[21,11]

Anomaly in HF–DMF Complex: For all the acceptor monomers except DMF, the highest occupied orbitals are σ-orbital. It consists almost exclusively of the lone pair orbital. In contrast, the highest occupied orbital of DMF monomer is π-orbital. Since the highest

occupied orbital would take the main part in hydrogen bond, calculations on HF–DMF complex were performed for two models, a π-hydrogen bond model in which the HF molecule approaches perpendicular to the molecular plane of acceptor molecule, and a σ-hydrogen bond model which is the same as that for other complexes. The π-hydrogen bond model was found to have less hydrogen bond energy than the σ-hydrogen bond model. Similar results have been recognized in the *ab initio* calculations on HF–HCN and HF–formaldehyde hydrogen bonds.[11,25] This was ascribed to the fact that the energy of electrons in π-orbital is considered to be more favorable for the charge transfer in hydrogen bond than that in σ-orbital. However, the σ-orbital has a higher electron density on the site of hydrogen bonding and accordingly has a higher probability of interaction with proton donor than the π-orbital. Thus the electrons in the σ-orbital seem to give greater contribution to hydrogen bonding. This may explain the anomaly of HF–DMF complex.

Dipole Moment Enhancement: It is well-known for typical hydrogen bonding that the dipole moment of hydrogen bond complex becomes larger than the sum of the dipole moments of its components.[26] The calculated values for the increase in dipole moment $\Delta\mu$ are given in Table 4. No correlations were recognized between $\Delta\mu$ and ΔE_{corr}. For the HF–aldehyde complexes, with HF–formaldehyde as an exception, the $\Delta\mu$ values increase in the order, acetaldehyde$<$ propionaldehyde$<$butyraldehyde, while the ΔE_{corr} values remain almost constant. The $\Delta\mu$ can be divided into two contributions, one due to induced dipole moment, $\Delta\mu_{ind}$, and the other to charge transfer, $\Delta\mu_{ct}$.[26] Since the $\Delta\mu_{ct}$ for these HF–aldehyde complexes would be almost the same, the behavior of overall $\Delta\mu$ can be interpreted as the increase of contributions of $\Delta\mu_{ind}$ in the order given above.

In conclusion, the present CNDO/2 calculations could give, though semi-quantitative, a fairly good description of the properties of HF hydrogen bond complexes. Correlations with experimental $\Delta\nu_{HF}$ would serve to overcome the lack of energetic information due to experimental difficulties. Success and failure of correlations with the quantities used as a measure of hydrogen bond strength may furnish further insight to the understanding of HF hydrogen bonds.

The authors thank Dr. Shigeo Yoneda for his kind guidance and suggestions. They are also grateful for permission to use the facilities at the Computer Center of Kyoto University.

An INDO-MO Study of the Conformations and Electronic Structures of $HCHOH^+$, CH_3CHOH^+, $(CH_3)_2COH^+$, $HCO_2H_2^+$, $CH_3CO_2H_2^+$, and $CH_3OH_2^+$

Katsutoshi OHKUBO, Toshiaki YOSHIDA, and Katsumi TOMIYOSHI

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received February 14, 1976)

INDO-SCF calculations were performed on several protonated compounds, $HCHOH^+$ CH_3CHOH^+, $(CH_3)_2COH^+$, $HCO_2H_2^+$, $CH_3CO_2H_2^+$, and $CH_3OH_2^+$, and also on the corresponding parent molecules in order to investigate their conformations and electronic structures. Geometric optimization resulted in reasonable conformations as compared with the previous *ab initio* calculations and in sufficient magnitudes of the energy differences between the rotational isomers in comparison with the NMR observations. The change in the electronic structures of the parent molecules due to protonation is also discussed by paying attention to the polarization caused by electron delocalization, hybridization at the proton-bound oxygen atom, the protonation energy, and the ionization potentials.

Protonated weak bases formed quantitatively in low-temperature "magic acid" solutions have hitherto received considerable attention, because such cations are important as intermediates in acid-catalyzed hydrolysis reactions and in the determination of Brønsted base strengths. Concerning the structures of tautomers or rotational isomers of the protonated species, Olah *et al.*[1] have extensively studied the low-temperature NMR spectra of these substances.

However, the structures of protonated aldehydes, ketones, acids, and alcohols, which were investigated in the present work, have been the object of only limited investigations as regards their molecular orbital treatments. Only protonated formaldehyde, acetaldehyde, and formic acid have been studied in detail in a few *ab initio* calculations. The geometric optimization of CH_3CHOH^+ and $HCO_2H_2^+$ by Ros[2] with small Gaussian basis set (32/2) brought about an incorrect relative stability of their rotational isomers, and large Gaussian basis set (73/3) calculations performed by Csizmadia *et al.*[3,4] improved the discrepancy of this relative stability on the base of results obtained under geometric assumptions.

Recently, the present authors have undertaken a semi-empirical INDO-MO study of several protonated compounds with particular attention being paid to their optimized conformations, electronic structures, and the magnitude of the energy difference between tautomers or rotational isomers. The present INDO calculations with sufficient geometric optimization were almost successfully carried out so that the above subjects may be discussed without any need to consider the solvent effect on the protonated species in super-acid solutions.

Method of Calculation

The semi-empirical calculations of HCHO, CH_3CHO, $(CH_3)_2CO$, HCO_2H, CH_3CO_2H, CH_3OH, and their protonated species (unstable alkoxy-protonated species were neglected in the protonated acids) were carried out using the INDO-SCF method[5] which is considered to be reliable for bond angles, but less so for bond lengths.[6]

The bond lengths and angles which are to be optimized are shown in Fig. 1 in which most of the fixed lengths and angles were taken from the standard tables,[7] except for those of HCHO and CH_3CHO (which were taken from Ref. 2). The optimization of geometric parameters was carried out by means of a repeated SCF-procedure. This was performed first on the bond lengths for fixed bond angles, then in turn on the angles until the most

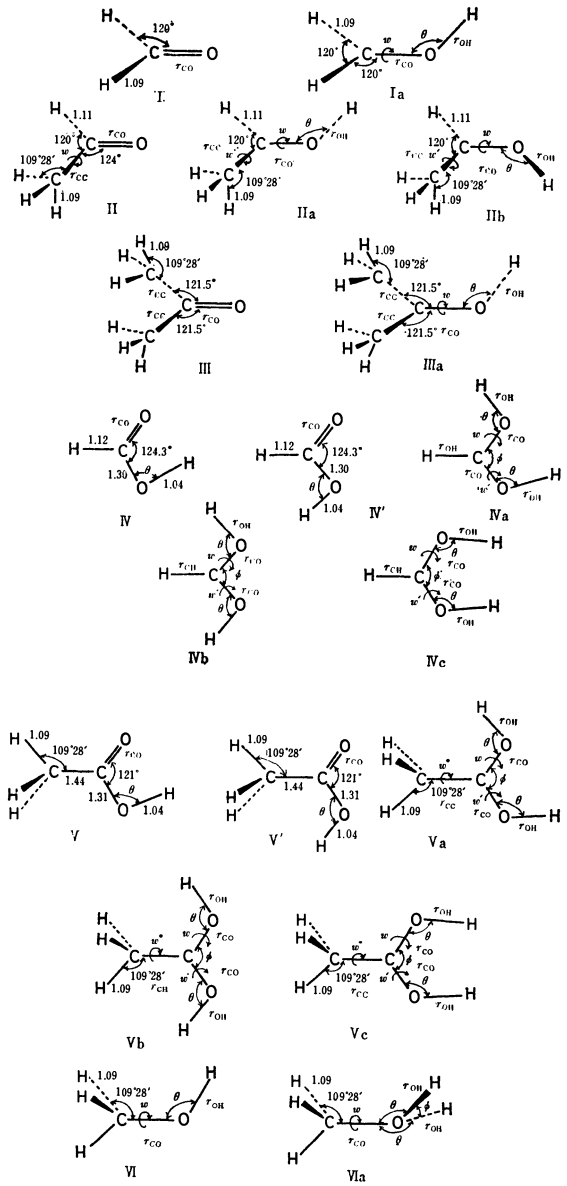

Fig. 1. Geometric parameters for parent molecules and protonated species.

stable conformations had identical bond lengths and angles, and finally the optimized geometries were recalculated by changing all their bond lengths and angles by the amounts of ± 0.02 Å and $\pm 2°$, respectively, as a check on the reliability of the optimization results. In the cases of $HCO_2H_2^+$ and $CH_3CO_2H_2^+$, the optimized r_{CO}, r_{OH}, and r_{HC} (or r_{CC}) values in the energetically most stable *cis-trans* isomer (IVa or Va in Fig. 1) were commonly used for the other unstable isomers.

Results and Discussion

Optimized Conformations. Let us first examine the optimized conformations of the parent molecules before discussing those of the protonated species. The bond length of the C=O bond was calculated to be slightly longer than the experimental value by 0.02—0.04 Å for all the molecules, except CH_3OH, with an overestimation of the θ values for the acids to the extent of *ca.* 4°, while the value (1.36 Å) for CH_3OH was shorter by 0.074 Å than the experimental value (1.434 Å[8]) with $r_{OH}=1.04$ Å (expt.[8])$=0.937$ Å) and $\theta=107°$ (expt.[8])$=105°56'$). Some parent molecules such as CH_3OH and HCHO have already been calculated by the INDO method without any geometric assumptions,[5] but the geometric assumptions used here did not show as serious defects in comparison with the complete optimization results,[5] so that the protonated species may be treated under same geometric assumptions as the parent molecules.

In regard to the rotations of the CH_3 group about the C–C bond (CH_3CHO) and about the C–O bond (CH_3OH), the rotational barriers obtained from the energy difference between the most stable staggered conformations (SII and SVI) and the most unstable eclipsed conformers (EII and EVI) were estimated to be 0.35 kcal/mol (expt.[9])$=1.16$ kcal/mol) for CH_3-CHO and 0.83 kcal/mol (expt.[8])$=1.07$ kcal/mol; *ab initio*[10])$=1.59$ kcal/mol) for CH_3OH (see Fig. 2). The INDO calculations resulted in smaller rotational barriers than those obtained from the experimental results, probably because the approximations involved in the INDO method neglect multiple-center (more than two-center) repulsion integrals.

Concerning two possible isomers of HCO_2H and CH_3CO_2H (Fig. 1), the *trans* forms (IV and V) of both the acids, which have smaller bond angles (θ) than the *cis* form by 1° were found to be more stable by 1.69

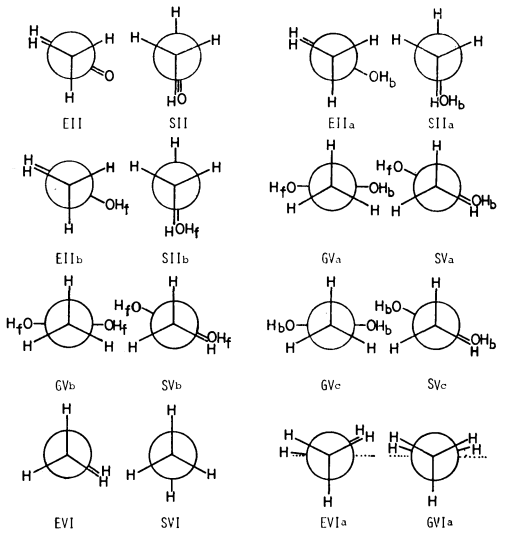

Fig. 2. Energetically most stable and unstable conformations of the protonated species during the CH_3 rotation around the C–C or C–O bond. (The subscripts of b and f mean the back and the front respectively.)

TABLE 1. OPTIMIZED VALUES FOR THE GEOMETRIC PARAMETERS

Species	$r_{C=O}$	r_{CO}	r_{OH}	r_{CC}	θ	ϕ	ω	ω'	ω''	r_{HC}
I	1.25(1.21)

VI		1.36(1.434)	1.04(0.937)		107°(105°56′)		0°			
VIa		1.39	1.04		121°	65°	0°			

Bond lengths are in Å units. Values in parentheses are experimental,[7] optimized[2] (underlined), and assumed values[2] (doubly underlined). a) 116° has been given for the other C–O–H angle.

kcal/mol for HCO_2H or by 5.33 kcal/mol for CH_3CO_2H than the other forms. The experimentally determined energy difference between *trans* (IV) and *cis* (IV') HCO_2H (IV is more stable than IV'), 2.0 kcal/mol, is well reflected in the computed value of 1.63 kcal/mol, even though previous *ab initio* calculations of IV and IV' gave overestimated energy differences of 8.1 kcal/mol (for (32/2) basis sets)[2] and 9.46 kcal/mol (for (73/3) basis sets).[3] The energy difference (1.69 kcal/mol) between IV and IV' of $H_aC(=O_a)OH_b$ can be roughly explained using the Coulomb attraction or repulsion energy estimated from $0.5292Q_AQ_B/r_{AB}$ (Q_A and Q_B=formal charges of A and B atoms; r_{AB}=nuclear distance between A and B). As a result, the difference in the Coulomb attractions (IV—IV'=3.34 kcal/mol for the O_a–H_b and −1.29 kcal/mol for the negatively charged H_a-positively charged H_b attractions) makes IV more stable than IV' by 2.05 kcal/mol. The energy difference between V and V' for $CH_3C(=O_a)OH_a$ was also explained similarly by the O_a–H_a attraction and the CH_3–H_a repulsion. It is noteworthy here that, in the *trans* isomers of both the acids, hydrogen bonding cannot be expected between the O_a and H_b (or H_a) atoms (overlap populations were negative).

Now, let us focus on the optimized conformations of the protonated species (Table 1). Protonation on the oxygen atom resulted the C–O bond length being increased by 0.03—0.04 Å with respect to the r_{CO} of the parent molecule. The magnitude of the C–O bond stretching was in good agreement with that expected from *ab initio* calculations of $HCO_2H_2^+$ and $CH_3CO_2H_2^+$,[2] but the r_{OH} value of 1.04 Å given consistently for all the protonated species except $HCHOH^+$ (r_{OH}=1.05 Å) appears to be considerably overestimated in comparison with r_{OH}=0.985 Å of $HCO_2H_2^+$ calculated by Ros.[2]

In regard to the bond angles, the C–O–H bond angle (θ) fell in the range from 117° (Va) to 121° (VIa), and those of Ia and Va, b, c, were found to be almost identical for both the INDO and *ab initio*[2] calculation results. Interestingly, the O–C–O bond angles (ϕ) which were assumed to be 124°[2] or 120°[3] in the previous *ab initio* calculations are different for the three isomers of the protonated acids. They increased systematically for a decrease in the distance between the two hydrogen atoms of the O–H bonds, that is, with increasing H–H repulsion. However, the magnitude of the change in the ϕ value (11°) appears to be too large, nevertheless the INDO calculation tends to underestimate the electron-electron repulsions.[5,11]

Here, we will discuss the CH_3 rotation about the C–C bond for the two isomers of CH_3CHOH^+ and the three isomers of $CH_3CO_2H_2^+$ and about the C–O bond for $CH_3OH_2^+$. As can be seen from Fig. 2, the staggered (SIIa, SIIb, SVa, SVb, and SVc) and gauche-like (GVIa) conformations having minimum H–H repulsions or maximum H–O attractions were found to be the most stable, while the eclipsed (EIIa, EIIb, and EVIa) structures possessing maximum H–H repulsion and the gauche structures (GVa, GVb, and GVc) having minimum H–O attraction were the most unstable. The rotational barriers falling in the range of 0.005—0.48 kcal/mol indicate free CH_3 rotations in the above protonated species except for *trans*-CH_3CHOH^+ (barrier=0.86 kcal/mol). Therefore, the CH_3 rotation, especially that in $CH_3CO_2H_2^+$, does not appear to play an important role in the determination of the relative stability of the protonated isomers.

Charge Densities, Protonation Energies, Dipole Moments, and Ionization Potentials. The change in the electron distributions for protonation will be discussed first by noticing the charge densities of the parent molecules and the energetically most stable protonated conformers

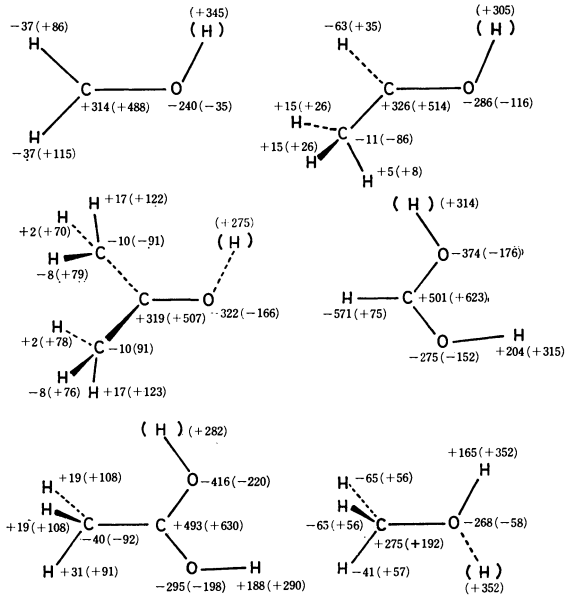

Fig. 3. Change in the charge distribution on the protonation. (Values in parentheses are those of the most stable protonated conformers, and all the values are in units of 10^{-3} electrons.)

(Fig. 3). Ros[2] has already pointed out on the basis of the results of his *ab initio* calculation that there is a general shift (polarization) of electrons from the terminal carbon-bound hydrogens (but not from the proton-bound oxygen) towards the incoming proton. This trend was also observed from the change in the charge distributions estimated by the present INDO calculations. The computed charge distributions appear reliable in view of the fact that the computed dipole moments of the parent molecules (those of the protonated species are unknown) are in satisfactory agreement with the experimental values.[12–16]

The protonation also brought about a change in the electronic properties of the parent molecule, especially in the bond between the carbon and the proton-bound oxygen. The protonation decreased the overlap population of the above C–O bond by from 7.9% (HCHO) to 12.4% (CH_3CO_2H). The decrease in the π-type overlap population (16.8% for HCHO–35.5% for CH_3CO_2H) was found to be more marked than for the σ-type (5.0% for CH_3CHO–6.8% for CH_3CO_2H). The remarkable change in the π-conjugation of the C–O bond on the protonation is ascribed not only to the stretching of the C–O bond but also to the change in the hybridization at the proton-bound oxygen atom,

TABLE 2. ELECTRONIC PROPERTIES OF THE PARENT AND PROTONATED SPECIES

Values in parentheses are those for the *trans* C–O bond with respect to the H–C bond. a) Ref. 12. b) Ref. 13. c) Ref. 14. d) Ref. 15. e) Ref. 16. f) Ref. 18. g) Ref. 19. h) Ref. 20. i) Ref. 21.

because the magnitude of the decrease in the π-type overlap population for a simple expansion of the C–O bond length without the incoming proton is markedly different from that for protonation. For example, the simple stretching of r_{CO} in HCHO from 1.25 Å (the optimized r_{CO} for HCHO) to 1.28 Å (the r_{CO} for $HCHOH^+$) decreased the π overlap population from 0.198 to 0.187, while protonation decreased it from 0.198 to 0.165. This trend can also be recognized in the other species, even in CH_3OH which has a pseudo π-conjugation at the C–O bond (π bond-orders=0.223 in CH_3OH and 0.139 in $CH_3OH_2^+$). The change in the hybridization at the oxygen atom upon protonation results in a protonation energy (proton affinity), because hybridization of the oxygen lone-pairs (defined by the %s or %p character) correlates linearly with the proton affinity (PA).[17] In this sense, the incoming proton predominantly interacts not only with the highest-occupied (HO), nonbonding oxygen-lone-pair-orbital expanding perpendicularly to the C–O bond axis, but also with the oxygen lone-pair orbital conjugating with the carbon pi-orbital at the lower MO (next to the HOMO). In this respect, the order of the computed *PA* values which correspond consistently to one half of the magnitude of the observed results[18,19] was well reflected in that of the observed *PA* values (Table 2). Protonation at the oxygen atom also decreased the electron density predominantly on the HO oxygen-lone-pair orbital and lowered the ionization potential (*IP*) of the parent molecule. As can be seen from Table 2, the IP values of the parent molecules became markedly large due to the protonation, and the computed *IP* values, IP_{calcd}, were found to be systematically overestimated in comparison with the observed *IP* values,[20,21] IP_{obsd}, ($IP_{obsd}/IP_{calcd}\approx 0.8$).

Relative Stability between the Rotational Isomers. In CH_3CHOH^+, $HCO_2H_2^+$, and $CH_3CO_2H_2^+$, two keto-protonated isomers have been proposed for each species as the result of NMR spectroscopic investigations:[1] IIa and IIb, IVa and IVb, and Va and Vb in Fig. 1. The relative stabilities determined using the present INDO calculations, the previous *ab initio* computations,[2–4] and by the NMR spectra[1] are summarized in Fig. 4. In regard to the energy difference (1.85 kcal/mol) between IIa and IIb, the present INDO result is in good agreement with the experimental value (about 1 kcal/mol) and with the *ab initio* calculations for large Gaussian basis sets[3] (1.15 kcal/mol), although small basis sets of Gaussian exponents (32/2)[2] failed in the estimation of the relative stability between IIa and IIb (IIa was computed to be less stable than IIb). The Coulomb repulsion of H_a–H_b in $CH_3CH_aOH_b^+$ (1.55 and 2.41 kcal/mol for IIa and IIb, respectively) and of CH_3–H_b (6.29 and 6.98 kcal/mol for IIa and IIb, respectively) makes the *cis* isomer (IIa) more favorable energetically than the other isomer (IIb) by 1.55 kcal/mol, a value which roughly corresponds to the energy difference between IIa and IIb. A remark should be made about the H_a–H_b repulsion: a value (2.41 kcal/mol for IIb) larger than this value (1.55 kcal/mol for IIa) was given by the larger positive charge of H_a (0.074) in IIb ($Q_{H_b}=+0.303$; $r_{H_a-H_a}=2.976$ Å) as compared with that of H_a (0.035) in IIa ($Q_{H_b}=+0.305$; $r_{H_a-H_a}=2.284$ Å). In this respect, the energy contribution terms listed in Table 3 indicate that IIa has smaller nuclear repulsions and larger one-electron attractions than IIb.

The relative stabilities of the protonated isomers of $HCO_2H_2^+$, IVa>IVb>IVc, was in agreement with the

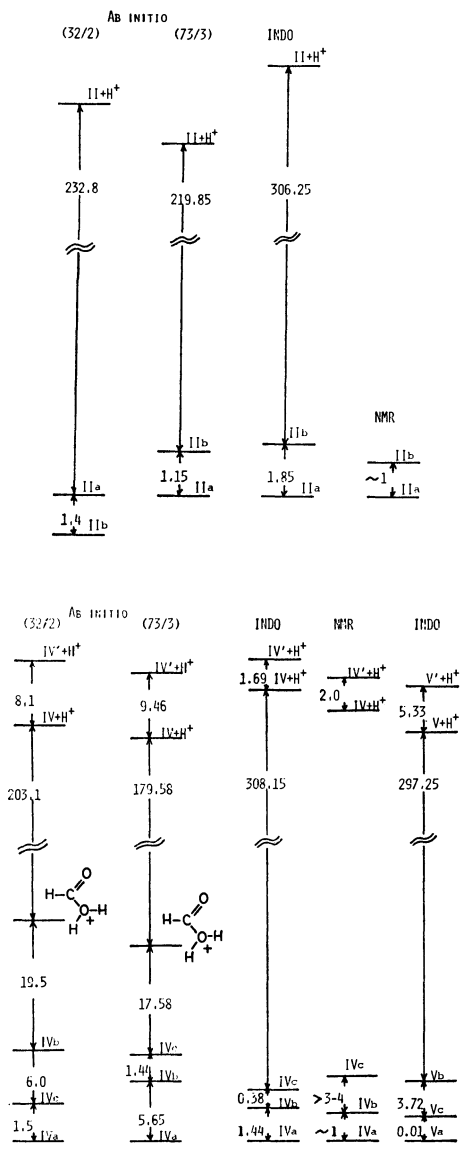

Fig. 4. Energy difference between the protonated isomers. (Values are in units of kcal/mol.)

Table 3. Energy contribution terms for parent and protonated species

Species	Total energy a.u.	One-electron energy a.u.	Inter-electronic repulsion a.u.	Nuclear repulsion a.u.

NMR results[1] and with the results of the *ab initio* calculation obtained by Csizmadia *et al.*[3] (Ros's data: IVa>IVc>IVb). Although the energy difference (1.44 kcal/mol) between IVa and IVb corresponds approximately to that (about 1 kcal/mol) of the NMR results, the difference (0.38 kcal/mol) between IVb and IVc is too small for comparison with the experiment (3—4 kcal/mol).[1] This may be attributable to an underestimation of the electron-electron repulsions. As can be seen from Table 3, the small repulsion terms, especially the electron repulsions, which favor IVc and IVb rather than IVa, were overcome by the one-electron energy term, and the relative stabilities follow the order: IVa>IVb>IVc.

Concerning the isomers of $CH_3CO_2H_2^+$, a discrepancy between the order of relative stabilities calculated by the INDO calculations (Va>Vc>Vb) and that found from the NMR spectra (Va>Vb≫Vc)[1] was observed. This discrepancy may also be ascribed to an underestimation of the electron repulsion in view of the fact that the electron repulsion, in addition to the nuclear repulsion, makes Vc most favorable, even though a reasonable order (Va>Vb>Vc) can be obtained from the attraction term. It should be stressed here that the *cis-trans* conformers (IVa and Va) in both the acids were not stabilized by the hydrogen bonding between the *cis*-oxygen and the *trans*-hydrogen atoms because the appreciable long distances between the two atoms (about 2.40 Å in IVa and about 3.31 Å in Va) brought about negative overlap populations (−0.0008 for IVa and −0.0002 for Va), even though the effect of the hydrogen bonding has been demonstrated on the basis of the IR spectroscopic investigation of protonated carboxylic acids.[22]

At any rate, the present INDO calculations of the protonated isomers brought about sufficient results for the determination of their relative stabilities in contrast with the previous *ab initio* calculation results.[2-4]

The calculations were carried out on a FACOM 230-75 computer at the Data Processing Center of Kyushu University.

Thermal Decomposition of Dimethyl Ether in the Presence of Nitrogen Oxide

Kohji TADASA,* Naomi IMAI, Tetsuo INABA, and Yutaka KUBOKAWA**
Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Sakai, Osaka 591
(Received March 19, 1976)

The effect of NO addition on the thermal decomposition of CH_3OCH_3 has been studied at 500 °C. The rate of pyrolysis decreases markedly when the amount of NO is small, but increases linearly with increase in amount. Acceleration of pyrolysis was studied. Major reaction products are CH_4, CH_2O, CO, H_2O, and N_2, the minor ones being H_2, N_2O, and C_2H_6. The quantities of all the products were determined under different conditions except CH_2O and H_2O. It was found that the rate of formation is nearly of first order with respect to both NO and CH_3OCH_3. A reaction scheme is proposed. It is suggested that the rate of decomposition is nearly equal to that of the second order reaction $NO+CH_3OCH_3 \rightarrow HNO+CH_3OCH_2$.

The thermal decompositions of lower hydrocarbons, aldehydes, ketones, ethers *etc.* proceed *via* free radical chain reactions in the gas phase. Nitrogen oxide has been used as an effective inhibitor for these free-radical reactions, since it combines readily with free radicals. Nitrogen oxide, however, reacts easily with the molecules of these organic compounds, forming free radicals. Thus, the two effects of nitrogen oxide, inhibitive and accelerative, make the reaction mechanism very complicated.

When nitrogen oxide is added in a free-radical thermal decomposition of an organic substance, the rate of the reaction first decreases and then increases with the amount of addition, giving rise to a minimum rate. The minimum rate is not sufficiently small as compared with the uninhibited rate to suggest that the free-radical reaction is completely surpressed, even at the minimum rate, owing to the accelerating action of nitrogen oxide. In the case of dimethyl ether, however, the minimum rate is very small as compared with the uninhibited rate, and the inhibitive and the accelerative parts are distinctly separated in the nitrogen oxide pressure-rate curve. Thus, dimethyl ether is thought to be suitable for the study of the effects of nitrogen oxide on pyrolysis.

Investigations[1–3] has been carried out on the nitrogen oxide inhibited pyrolysis of dimethyl ether mainly following the total pressure change. We have measured the quantities of the reaction products under different conditions and derived a reaction scheme.

Experimental

Commercial dimethyl ether and nitrogen oxide were purified by repeated bulb-to-bulb distillation.

The reaction was studied at 500 °C in a conventional static system. The products of the pyrolysis were separated by means of cold traps and a Toepler pump, and analyzed quantitatively by gas chromatography. The apparatus, techniques of separation and analysis are similar to those described previously.[4]

Results

All the runs were carried out at 500 °C. The quantitative analyses were made for CH_4, CO, N_2, N_2O, H_2, and C_2H_6, among the products of pyrolysis. CH_2O and H_2O were formed in large amounts, but these were not determined because of inaccuracy of the measurements.

Fig. 2. Plot of rate of formation *vs.* NO pressure for the pyrol sis of 100 Torr CH_3OCH_3 at 500 °C.
(a) ◇: CH_4, ○: CO, ⓘ: N_2,
(b) △: H_2, ▽: N_2O, □: C_2H_6 (×10).

No CH_3OH was observed in detectable amount, although it is an important pyrolysis product of CH_2O.

The yields of the products were determined at different times during the course of uninhibited and inhibited pyrolyses. Some results are shown in Fig. 1. For most products the yields increase linearly with time from the beginning of the reaction. The rate of CH_4 formation, however, is higher in the initial period of the pyrolysis than after 5 min, as is often the case in pyrolysis. The rate of CH_4 formation was obtained from intercept of the slope in the yield-time plot.

The dependence of the rate of product formation on the pressure of NO added to the reaction mixture is shown in Fig. 2 for the pyrolysis of CH_3OCH_3 at 100 Torr pressure and 500 °C. In the uninhibited pyrolysis, the rates of formation are 1.04, 0.63, and 0.40 Torr min^{-1} for CH_4, CO, and H_2 respectively, addition of 10 Torr of NO reducing them to 0.095 (9% of uninhibited rate), 0.015 (2%), and 0.0025 (0.6%), respectively. The addition of an increased amount of NO causes a linear increase in the rates of formation of all products analyzed. The extrapolated straight lines pass through the origin except for CH_4 which has a small intercept on the vertical axis.

Figure 3 shows the relation between the rates of product formation and the CH_3OCH_3 pressure in the pyrolysis with 50 Torr of NO. The plots show linearity except for CH_4, for which the plot gives a curve slightly concave downwards.

Discussion

The thermal decomposition of CH_3OCH_3 has been established by a number of workers to proceed by a free-radical chain process, which is as follows.[5-7]

$$CH_3 + CH_3OCH_3 \longrightarrow CH_4 + CH_3OCH_2$$
$$CH_3OCH_2 \longrightarrow CH_2O + CH_3$$

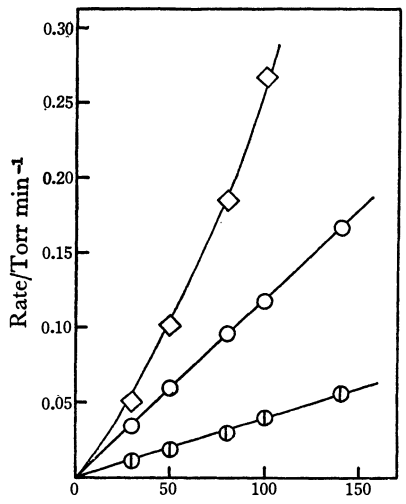

Fig. 3(a).

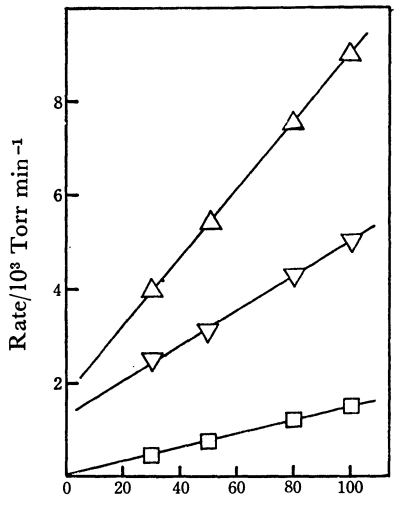

Fig. 3(b).

Fig. 3. Plot of rate of formation *vs.* CH_3OCH_3 pressure for the pyrolysis of 50 Torr NO at 500 °C.
(a) ◇: CH_4, ○: CO, ⓘ: N_2,
(b) △: H_2, ▽: N_2O, □: C_2H_6 (×10).

It has been established that CH_2O once produced also undergoes free-radical chain decomposition.[6,8]

$$CH_3 + CH_2O \longrightarrow CH_4 + CHO$$
$$H + CH_2O \longrightarrow H_2 + CHO$$
$$CHO + M \longrightarrow CO + H + M$$

Thus CH_3OCH_3 decomposes by two stoichiometric steps:

$$CH_3OCH_3 \longrightarrow CH_4 + CH_2O \quad (I)$$
$$CH_2O \longrightarrow CO + H_2 \quad (II)$$

Accordingly the rates of CO and H_2 formation increase with time in the early period. In Fig. 1(b) (NO=0 Torr) a concave curve is shown for the CO yield.

In the pyrolysis with NO, however, the CO yield increases linearly with time, suggesting that CO is not a secondary product. Stoichiometric relation (II) does not hold in the inhibited pyrolysis, since the H_2 yield is much smaller than that of CO.

In this work, the major products analyzed are CH_4, CO, and N_2, the N_2 yield being about half that of CO. The same ratio of CO and N_2 is also observed in the CH_2O–NO pyrolysis, where the following stoichimetry holds approximately.

$$CH_2O + NO \longrightarrow CO + H_2O + (1/2)N_2$$

A similar ratio of CO and N_2 found in the CH_3OCH_3–NO pyrolysis seems to suggest that they are formed by processes similar to the CH_2O–NO pyrolysis. By the addition of NO, CH_3OCH_3 seems to decompose according to two stoichiometric relations:

$$CH_3OCH_3 \longrightarrow CH_4 + CH_2O \quad (I)$$
$$CH_3OCH_3 + NO \longrightarrow CH_4 + CO + H_2O + (1/2)N_2 \quad (II)$$

Thus the following relation is expected to hold between the rates of product formation.

$$R_{CH_2O} = R_{CH_4} - R_{CO}$$
$$R_{H_2O} = R_{CO} = 2R_{N_2}$$

McKenney *et al.*[3] studied the NO inhibited pyrolysis of CH_3OCH_3 over the temperature range 500—600 °C and proposed a reaction mechanism, which indicates that NO inhibits the reaction by

$$CH_3 + NO \rightleftharpoons CH_3NO \rightleftharpoons CH_2NOH \longrightarrow \text{products}$$

and

$$CH_3 + CH_2NOH \longrightarrow CH_3CH_2\text{–}NOH \longrightarrow C_2H_6 + NO$$

while it accelerates the reaction by

$$NO + CH_3OCH_3 \longrightarrow HNO + CH_3OCH_2$$

According to their scheme, CH_3 and H, the latter being formed by the decomposition of HNO,

$$HNO + M \longrightarrow H + NO + M$$

take part in the chain decomposition of CH_3OCH_3, even when a sufficient amount of NO is added. According to their argument, R_{CH_4} is expressed by

$$R_{CH_4} \propto [CH_3OCH_3]^{3/2}$$

being independent of [NO]. R_{H_2} should be equal to a half of the NO accelerated part of the rate of CH_3OCH_3 decomposition. Their prediction concerning R_{CH_4} and R_{H_2} is not consistent with the results we obtained at 500 °C.

The results we obtained show kinetics and stoichiometry which lead to the following scheme.

$$NO + CH_3OCH_3 \longrightarrow HNO + CH_3OCH_2 \quad (1)$$
$$NO + CH_3OCH_2 \longrightarrow HNO + CH_3 + CHO \quad (2)$$
$$NO + CH_3OCH_2 \longrightarrow CH_3NO + CH_2O \quad (3)$$
$$NO + CH_3 \longrightarrow CH_3NO \quad (4)$$
$$NO + CHO \longrightarrow HNO + CO \quad (5)$$
$$CH_3NO + HNO \longrightarrow CH_4 + NO + NO \quad (6)$$
$$HNO + HNO \longrightarrow OH + OH + N_2 \quad (7)$$
$$OH + HNO \longrightarrow H_2O + NO \quad (8)$$
$$CH_3OCH_3 + M \longrightarrow CH_3 + CH_3O + M \quad (9)$$
$$NO + CH_3O \longrightarrow HNO + CH_2O \quad (10)$$

In contrast to that of McKenny *et al.*, the scheme indicates that HNO and CH_3NO do not decompose, but they react with each other or react with radicals, *i.e.*, Eqs. 6—8.

The above reaction Schemes (1—10) give the following relations with regard to the reaction rates.

$$R_{CH_4} = R_6 = R_1 + R_9 = k_1[NO][CH_3OCH_3] + k_9[CH_3OCH_3][M] \quad (i)$$

$$R_2 = \{k_2/(k_2+k_3)\}R_1$$

$$R_3 = \{k_3/(k_2+k_3)\}R_1$$

$$R_5 = R_2 = 2R_7 = R_8$$

$$R_{CO} = R_5,\ R_{N_2} = R_7,\ R_{H_2O} = R_8$$

hence

$$R_{CO} = R_{H_2O} = 2R_{N_2} = \{k_1k_2/(k_2+k_3)\}[NO][CH_3OCH_3] \quad (ii)$$

$$R_{CH_2O} = R_3 + R_{10} = R_3 + R_9 = \{k_1k_3/(k_2+k_3)\}[NO][CH_3OCH_3] + k_9[CH_3OCH_3][M] \quad (iii)$$

The experimental results satisfy the reaction orders in Eqs. i, ii, and iii. In Eq. i the first term represents the rate of the reaction between NO and CH_3OCH_3 (1), and the second one represents that of the initiating step in the thermal chain decomposition of CH_3OCH_3 alone (9). This might be due to the fact that the second term is very small compared with the first term in Eq. i, the CH_4 line intersects the Y axis just above the origin in Fig. 2(a), and the CH_4-curve is slightly concave in Fig. 3(a). The reaction orders of the CO and N_2 formation in Eq. ii are satisfied by the results in Figs. 2(a) and 3(a). Eqs. i, ii, and iii give the relation

$$R_{CH_2O} = R_{CH_4} - R_{CO}$$

which is also supported by the results.

The following reactions are proposed for the formation of minor products H_2, N_2O, and C_2H_6.

$$HNO + HNO \longrightarrow H_2 + NO + NO \quad (11)$$

$$HNO + HNO \longrightarrow H_2O + N_2O \quad (12)$$

$$CH_3NO + CH_3NO \longrightarrow C_2H_6 + NO + NO \quad (13)$$

When the rates of Eqs. 11, 12, and 13 are much smaller than those of Eqs. 6, 7, and 8, the following rate equations result from Schemes 1—13.

$$R_{H_2} = R_{11} = (k_{11}/k_7)R_7 = (k_{11}/2k_7)R_2 = \{k_1k_2k_{11}/2k_7(k_2+k_3)\}[NO][CH_3OCH_3]$$

$$R_{N_2O} = R_{12} = (k_{12}/k_7)R_7 = (k_{12}/2k_7)R_2 = \{k_1k_2k_{12}/2k_7(k_2+k_3)\}[NO][CH_3OCH_3]$$

$$R_{C_2H_6} = \{2k_1(k_2+k_3)k_7k_{13}/k_2k_6^2\}[NO][CH_3OCH_3]$$

These rate equations coincide with the reaction orders found experimentally (Fig. 2(b) and Fig. 3(b)). Since Eqs. 11, 12, and 13 are much slower than Eqs. 1—8, the addition of Eqs. 11, 12, and 13 to Schemes 1—10 does not cause any serious change in the rate equations (Eqs. i, ii, and iii).

The following ratios of the rate constants are obtained from the results.

$$k_2/k_3 = 1.5$$

$$k_{11}/k_7 = 0.017$$

and

$$k_{12}/k_7 = 0.011$$

It is well-known that HNO reacts with itself by Eq. 12,[9] but Eq. 7 has been suggested to take place more quickly at about 500 °C.[4,10] Both reactions (Eqs. 7 and 11) involve the internal rearrangement of $(HNO)_2$, while, in Reactions 6, 8, 11, and 13, HNO or CH_3NO release H or CH_3 when they react with each other or react with radicals. Reactions of the latter type have been proposed by Szabó.[11]

In the reaction schemes proposed above, radicals, CH_3OCH_2, CHO, and CH_3O are attached by NO before they decompose. Even if these radicals decompose first and then the fragment radicals or atoms combine with NO, the above rate equation does not change. As an example, replacement of Eq. 5 by the following two steps

$$CHO + M \longrightarrow CO + H + M$$

and

$$H + NO + M \longrightarrow HNO + M$$

does not alter the rate of the CO formation (Eq. iii).

NO undergoes disproportionation to N_2 and NO_2 in the presence of free radicals, according to the following mechanism.[12]

$$NO + R \longrightarrow RNO$$

$$RNO + 2NO \longrightarrow RNO(NO)_2 \longrightarrow RN_2ONO_2 \longrightarrow R + N_2 + NO_3$$

$$NO_3 + NO \longrightarrow NO_2 + NO_2$$

The reactions do not seem to be important since they cannot explain the reaction order of N_2 formation. No NO_2 was observed amongst the pyrolysis products.

Solid-state Properties of Evaporated Methyl Viologen

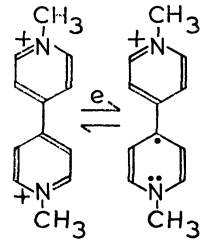
Kentaro MURANO, Yusuke KAMURA,* and Hiroo INOKUCHI**
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received March 22, 1976)

The methyl viologen film evaporated at about 250 °C has a violet color, and its electronic absorption spectrum resembles that of the enzymatically reduced methyl viologen. The evaporated film becomes colorless upon the introduction of air. By means of the photoemission spectroscopical method, a very low ionization potential, 3.6 eV, was obtained for the evaporated methyl viologen film. The character of the evaporated methyl viologen is a free-radical one, and its specific resistivity is very low as compared with other organic radicals.

Methyl viologen (abbreviated as MV hereafter) was found to be a good oxidation-reduction indicator by Michaelis and Hill in 1933.[1] This compound has been widely used in the research field of biochemistry, for the oxidation-reduction reaction is conducted by the transfer of one electron and its redox potential is independent of the hydrogen-ion concentration of the solution. For example, the enzymatic reduction of MV in the presence of hydrogenase is as follows:

$$1/2H_2 + MV^{2+} \xrightarrow{\text{hydrogenase}} H^+ + MV^+$$

where MV^{2+} and MV^+ represent oxidized and reduced methyl viologen respectively; the structures of the reduced and oxidized MV are shown below.



Oxidized-MV Reduced-MV

MV could be evaporated *in vacuo* at about 250 °C. The color of the evaporated film was violet, and the electronic spectrum resembled that of the enzymatically reduced MV. This evaporated film will be denoted as "reduc-MV." When the evaporated film was exposed to air, the violet color of the film vanished and the electronic spectrum changed to that of the oxidized MV (denoted as "oxi-MV").

In order to ascertain the reduc-MV, we measured the solid-state properties of these two species of MV, reduc-MV and oxi-MV. The vacuum ultraviolet photoemission spectrum of the reduc-MV, which is stable only in a vacuum, and that of the oxi-MV were observed, and the difference in the ionization potentials (*IP*) of the two species, as estimated from their photoemission spectra, is discussed.

Moreover, in order to understand the electron transport in the organic radical, the electrical conductivity of these MV films was observed.

** Present address: Institute for Molecular Science, Okazaki 444.

Experimental

The electronic absorption spectrum of the 'oxidized MV' in an aqueous solution and that of the enzymatically 'reduced MV,' which was reduced by a hydrogen gas in the presence of hydrogenase, were obtained by an ordinary method. The film was obtained on a quartz plate by evaporation at about 250 °C under a vacuum of 10^{-4} Torr. The absorption spectra of the evaporated film and that exposed to air were measured.

The measurements of the vacuum ultraviolet-photoemission spectroscopy were carried out using a vacuum ultraviolet monochromator combined with a hydrogen-discharge lamp. The photoemission measurement was done by the ac modulated retarding potential method described earlier,[2] but with a little modification of the collector-cell housing. The energy distribution curves (EDCs) of the reduc-MV and oxi-MV were thus obtained. The spectral dependence of the quantum yield (SDQY) was also found for oxi-MV. These measurements were carried out at about 3×10^{-6} Torr because the reduc-MV was easily changed to the oxi-MV under a low vacuum.

The electrical conductivity of these species was measured at 8×10^{-7} Torr in a high-vacuum bell-jar system by the two-probe method. The aluminum metal for the electrodes and the MV were successively evaporated on a clean quartz substrate as a surface-type arrangement; the details of the experimental procedure have been reported in a previous paper.[3]

In order to introduce a dry oxygen gas into the bell-jar, oxygen gas from a commercial cylinder was flowed to the bell-jar *via* a molecular sieve trap cooled with liquid nitrogen, and the change in the conductivity was examined. To observe the temperature dependence of the conductivity, the sample was heated by an outside-mantle heater.

Results and Discussion

Electronic Absorption Spectra. Figure 1 shows the electronic absorption spectra. The spectrum of the

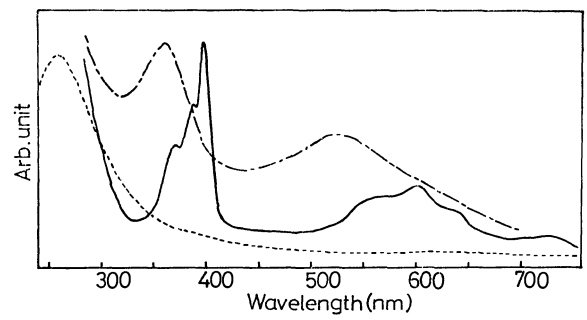

Fig. 1. The electronic spectra of MV.
---: Oxidized MV, —: enzymatically reduced MV (in aqueous solution), -·-: reduc-MV (in solid state).

oxidized MV reveals the absorbance maximum at 260 nm. The spectrum of enzymatically reduced MV has its vibrational structures at 367, 384, and 394 nm and another peak at 605 nm. The electronic spectrum of the reduced MV was investigated by Michaelis and Hill.[1] They proposed that the one excess electron belongs to the reduced form and is shared by the two nitrogen atoms, and that the blue color is explained by their resonance.

On the other hand, the spectrum of the evaporated film of MV shows the absorbance maxima at 358 and 520 nm. This spectrum resembles that of the enzymatically reduced MV, and the energy differences between the 358 nm peak of the film and 394 nm peak of the reduced MV, and also between the former's 520 nm and the later's 605 nm peak, are about 8700 cm^{-1}. When the evaporated film of MV was exposed to air, the violet color of the film disappeared and the spectrum coincided with that of the oxidized MV.

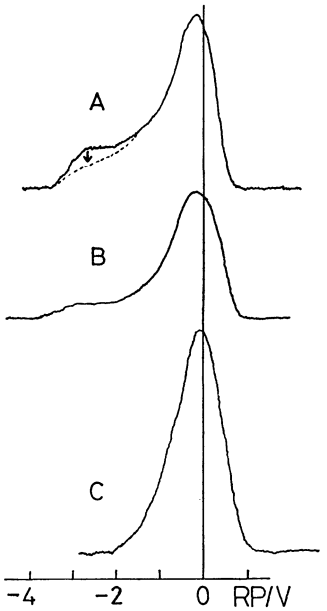

Fig. 2. The EDCs of reduc- and oxi-MV as a function of incident photon energy. A, B; reduc-MV. C; oxi-MV. Incident photon energy. A; 7.75 eV. B; 8.16 eV. C; 7.75 eV. ↓ shows the change of EDC from reduc-MV to oxi-MV.

Vacuum Ultraviolet Photoemission Spectroscopy. The EDCs of the photoelectron emitted by vacuum ultraviolet-light radiation are shown in Fig. 2. The EDCs of the reduc-MV produced by the incident-light energies of 7.75 and 8.16 eV are the two upper curves, while that of the oxi-MV irradiated by a photon energy of 7.75 eV is the bottom curve. A low-energy stationary peak was observed in all spectra, while a shoulder was obviously observed in the two upper spectra.

The values of the stopping voltage, V_0, and the saturation voltage, V_s, of the retarding potential for photoemission are obtained from the EDCs; they are listed in Table 1. The *IP* was calculated from V_0 and V_s by means of the following equation;

$$IP = h\nu - e(V_s - V_0)$$

Table 1. The incident photon energy, V_0, V_s, and the *IP* of the reduc- and oxi-MV

	EDC				$Y^{1/3}$
	$h\nu$(eV)	V_0(V)	V_s(V)	*IP*(eV)	*IP*(eV)
Reduc-MV	7.75	−3.5	0.7	3.6	
	8.16	−3.8	0.7	3.7	
Oxi-MV	7.75	−2.1	0.9	4.8	4.8—4.9

The calculated ionization potentials are also listed in Table 1. The stopping voltage of the oxi-MV was low compared with that of the reduc-MV, and the energy difference between them reached more than 1 eV.

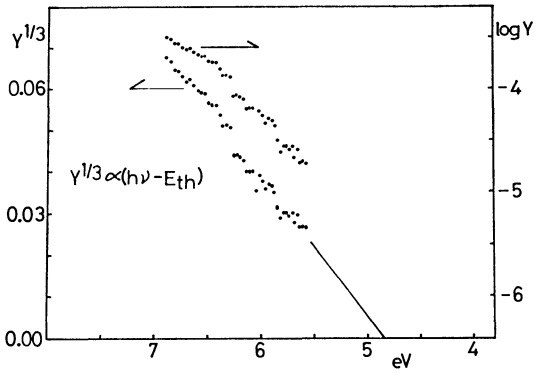

Fig. 3. The SDQY plots and cube root plots of the photoemission yield for oxi-MV.

Figure 3 shows SDQY near the threshold-energy region. Considering the experimental error, the small ripples of the plots are meaningless. The quantum yield decreased gradually with a decrease in the photon energy. The quantum yield in organic crystals and charge-transfer complexes near the threshold energy is subject to the conventional power law:

$$Y^{1/3} \propto (h\nu - E_{th})$$

where E_{th} is the threshold energy.[4]

The threshold energy value of 4.8—4.9 eV was obtained for oxi-MV from the above equation. This value was nearly equal to the *IP* calculated from the EDC of the oxi-MV. The threshold energy of the reduc-MV was not obtained accurately, because the photoemission is sensitive to surface conditions. The EDC of the reduc-MV changed gradually to that of the oxi-MV, as is shown by ↓ in Fig. 2. The phenomenon results because the surface of the reduc-MV gradually changes to the oxi-MV.

From Table 1, the difference of *IP* between the reduc- and oxi-MV can be seen to be more than 1 eV. This finding is consistent with the concept that the reduced form has one excess electron, which may occupy the lowest vacant molecular orbital of the oxi-MV.

The *IP* of the reduc-MV is very low compared with those of other organic substances. Only the organic dyes, crystal violet and malachite green have comparably low *IP* values.[5] Crystal violet and malachite green have a dimethyl amino group, which is constructed of four-valencies nitrogen atoms. The resonance may be

expected to occur over the whole molecule, and this resonance reduces the value of *IP*. Taking into account the low *IP* of the substance containing the dimethyl amino group measured by Nakato *et al.*, we consider that the same behavior can be expected in the reduc-MV.[6]

Electrical Conductivity. From the voltage dependence of the electrical conductivity for the two species of MV, there exists an ohmic contact. The electrical conductivity was held to be constant during the long observation period; also, the observation was carried out under a high vacuum, 8×10^{-7} Torr, so the predominant contribution to the conductivity is electronic, not ionic.

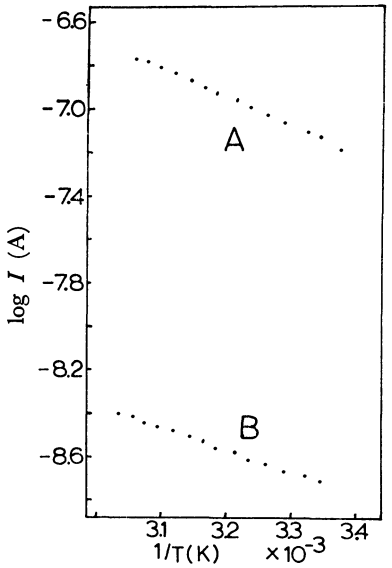

Fig. 4. The temperature dependence of the electrical current of the reduc- and oxi-MV. A; reduc-MV. B; oxi-MV.

The temperature dependence of the electrical conductivity is shown in Fig. 4. From the plot of log I *vs.* $1/T$, the activation energies of 0.2_6 and 0.2_0 eV were obtained for the reduc-MV and oxi-MV respectively by means of the following equation;

$$\sigma = \sigma_0 \exp(-\Delta E/kT)$$

where σ is the electrical conductivity; ΔE, the apparent activation energy, k, the Boltzmann constant, and T, the absolute temperature. The activation energy and the electrical current are summarized in Table 2. The difference in the activation energies of the reduc- and oxi-MV is so small that it is meaningless.

The specific resistance of the reduc-MV was estimated to be 10^5—10^6 Ωcm, for the thickness of the sample was estimated to be 10^3—10^4 Å. This value, 10^5—10^6 Ωcm, is extraordinary small compared with those of the polycyclic aromatics, polymer and organic dyes; it is in the range of the inorganic semiconductors.

Table 2. The electrical current of some species of MV[a]

State	T(°C)	ΔE(eV)	I(A)
Reduc-MV	17	0.26	1.5×10^{-13}
	17		6.3×10^{-8}
	28		7.7×10^{-8}
	54		1.7×10^{-7}
Reduc-MV+O_2	23		4.7×10^{-8}
	15		4.3×10^{-8}
Reduc-MV+O_2+H_2O	17		2.5×10^{-6}
Oxi-MV	17	0.20	2.2×10^{-9}
	54		3.8×10^{-9}

a) Applied voltage: 20V.

The color of the reduc-MV did not change upon the introduction of water-free oxygen, while the electrical conductivity decreased a little. The high conductivity of the reduc-MV was not, therefore, attributed to the oxygen. The electrical conductivity increased extraordinarily when the reduc-MV was exposed to the atmosphere, and the maximum current reached 2.5×10^{-6} A. In this procedure, the color of the reduc-MV vanished, so the coexistence of oxygen and water is shown to be necessary for the change from reduc-MV to oxi-MV. When the oxygen and water were excluded to measure the conductivity of oxi-MV, the oxi-MV was less conductive than reduc-MV. The reduc-MV exists as a radical, so it is reasonable to ascertain its high conduction by its having excess electrons.

The authors wish to express their gratitude to Yoshio Kohno for his operation of the high-vacuum electrical-conductivity-measurement system and Dr. Tomohiko Hirooka for his helpful discussions.

The Pressure and Temperature Dependences of the Second Virial Coefficients and the Chain Dimensions of Polydimethylsiloxane Solutions

Kenji KUBOTA, Kenji KUBO, and Kazuyoshi OGINO

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received April 8, 1976)

A new light-scattering optical cell was designed in order to perform light-scattering measurements at various temperatures and under pressures up to 400 kg/cm^2. The second virial coefficients and the radii of gyration were determined at high polymer dilutions for polydimethylsiloxane in cyclohexyl bromide at 27.0, 36.5, 47.2, and 56.2 °C, in benzene and toluene at 27.0 °C, and in chlorobenzene at 30.0 °C. The method employed to determine the dimensions of the polymer is described. By a series of measurements of polydimethylsiloxane solutions, it is shown that the second virial coefficients, the radii of gyration, and the fundamental thermodynamic properties of the solutions depend on the pressure. The correlation between values of A_2 and $\langle S^2 \rangle^{1/2}$ shows that pressure influences these quantities through its effect on the polymer-solvent interaction parameter, χ or z. The values of the relative partial molar excess volume were calculated directly from the data. The obtained data were compared with the excluded volume theories and the corresponding state theories; the agreement was fair.

The most important thermodynamic variables of the systems are the composition, the temperature, and the pressure. For polymer solutions, a very extensive literature exists on the dependence of the chemical potential upon the composition and the temperature, but the pressure was generally held constant. Solution theories have traditionally emphasized an energetic difference in the chemical nature and intermolecular force. However, recent works[1-3] in polymer solution thermodynamics have shown the importance of a difference in free volume, or in degrees of thermal expansion and isothermal compressibility, between the polymer and the solvent.

By mixing the polymer and the solvent, the free volumes change towards an intermediate value characteristic of the mixture. These changes contribute strongly to the thermodynamic functions of the mixture: ΔH_M, ΔS_M, ΔG_M as well as ΔV_M. In particular, the free volume contribution to the interaction parameter, χ, is remarkable. Accordingly, a large difference in the free volume between the polymer and the solvent will influence the χ parameter strongly. This accounts for the existence of the lower critical solution temperature.[4]

The application of pressure will cause a change in the difference in the free volume through the difference of the compressibility between the polymer and the solvent and the corresponding effect on the χ parameter. Then, the effect of the pressure is remarkable. It is evident that the pressure effect on $\langle S^2 \rangle$ and A_2 should be large. The pressure dependence of the critical solution temperature is negative near the upper critical solution temperature in the case of a negative value of ΔV_M. This predicts that the Flory temperature will decrease with the pressure. The solvent becomes better for the polymer with an increase in the pressure, and A_2 and $\langle S^2 \rangle$ should increase. Besides, the pressure dependence of the lower critical solution, where the free volume contribution is dominant, is particularly large.

Accordingly, a complete knowledge of the systems requires a knowledge of the effect of the pressure,[5] and the pressure should be included as an available independent variable.

Schulz and Lechner[5-7] studied the effect of the pressure on light scattering for polystyrene solutions. They measured up to 800 atm. The results are in semiquantitative agreement with a theoretical treatment of the pressure effects. An interesting change in the A_2 of polystyrene in *trans*-decalin with the pressure was observed.

Gaeckle and Patterson[8] studied the second virial coefficients and the radii of the gyration of polyisobutylene in 2-methylbutane and polystyrene in 2-butanone up to 110 atm. They showed that the corresponding state theories are good representations of the pressure effects.

McDonald and Claesson[9] examined the light-scattering properties of various pure solvents and the second virial coefficients of polystyrene in 4-methyl-2-pentanone up to 5000 atm. The polymer solution showed a limiting behavior above 2000 atm in terms of the magnitude of both the second virial coefficient and the radius of gyration.

In this work, polydimethylsiloxane in cyclohexyl bromide (theta solvant), benzene, toluene, and chlorobenzene (good solvents) were examined, using a modified Shimadzu light scattering photometer (PG-21) and a high-pressure optical cell which had been designed for this work. Polydimethylsiloxane was chosen since it has a very large thermal expansion coefficient and isothermal compressibility compared with other polymers.

Thermodynamic Considerations

Pressure and Temperature Dependence of A_2. At low concentrations the following equation is valid:

$$-\Delta\mu_1/RT = cV_1/M + A_2c^2V_1 \quad (1)$$

Here, V_1 is the molar volume of the pure solvent at the experimental temperature and pressure and c is the usual concentration, *i.e.*, the weight of the polymer per volume of the solution. The second virial coefficient is related to the excess chemical potential of the solvent:

$$A_2 = -\Delta\mu_1^E/RTc^2V_1 \quad (2)$$

According to the Gibbs-Helmholtz equation, the excess chemical potential of the solvent is split into an enthalpy term, $\Delta\bar{H}_1$, and an entropy term, $\Delta\bar{S}_1^E$. Thus, two corresponding terms are obtained for the second virial coefficient:

$$A_2 = A_{2,H} + A_{2,S} \quad (3)$$

$$A_{2,H} = -\Delta\bar{H}_1/RTc^2V_1 \quad (4)$$

$$A_{2,S} = \Delta\bar{S}_1^E/Rc^2V_1 \quad (5)$$

Then, from the temperature dependence of A_2 at a constant pressure and weight fraction, the values of $A_{2,H}$ and $A_{2,S}$ can be calculated:

$$A_{2,H} = \alpha TA_2 - T(\partial A_2/\partial T)_P \quad (6)$$

$$A_{2,S} = A_2(1-\alpha T) + T(\partial A_2/\partial T)_P \quad (7)$$

By combining Eqs. 4 and 5 with Eqs. 6 and 7, we obtain:

$$\Delta\bar{H}_1/RT = c^2V_1T((\partial A_2/\partial T)_P - \alpha A_2) \quad (8)$$

$$\Delta\bar{S}_1^E/R = c^2V_1((1-\alpha T)A_2 + T(\partial A_2/\partial T)_P) \quad (9)$$

On the other hand, from the pressure dependence of A_2 at a constant temperature and weight fraction, the relative partical molar excess volume is obtained:

$$\Delta\bar{V}_1/V_1 = c^2RT(-(\partial A_2/\partial P)_T - \beta A_2) \quad (10)$$

Here, α and β are the thermal expansion coefficient and the isothermal compressibility of the solvent respectively.

Excluded Volume Effects and the χ Parameter. Equations 8 and 10 give $\Delta\bar{H}_1$ and $\Delta\bar{V}_1$ in the dilute region where the solution is nonuniform according to the excluded volume effect. These values cannot be directly compared with the usual heat and volume measurements made at higher concentrations where the polymer molecules interpenetrate and the solution is uniform. Consequently, in order to estimate the free energy parameter, χ, from the value of A_2 obtained from the light-scattering measurements, the evaluation of the excluded volume effect is necessary.

According to the dilute solution theories, the nonuniformity of the solution gives rise to the penetrating function, $\Phi(z)$, in the expression of A_2:[10]

$$A_2 = 4\pi^{3/2}N_A\langle S^2\rangle^{3/2}\Phi(z)/M^2 = 4\pi^{3/2}N_A\langle S^2\rangle^{3/2}zh(z)/M^2 \quad (11)$$

$$z = (1/4\pi)^{3/2}(v_{2,sp}^2/N_AV_1)M^2(1-2\chi)/\langle S^2\rangle_0^{3/2} \quad (12)$$

Here z is the excluded volume parameter, while $v_{2,sp}$ and $\langle S^2\rangle_0^{1/2}$ are the specific volume of the polymer and the unperturbed mean-square radius of the gyration of the polymer.

Direct thermodynamic measurements of the heats and volumes of mixing leading to the values of $\Delta\bar{V}_1$ and $\Delta\bar{H}_1$ have been made between 20—80% of a polymer in general. If the values of A_2 of dilute polymer solutions were available for use in finding the chemical potential of the solvent for high concentrations, the values of $\Delta\bar{V}_1$ and $\Delta\bar{H}_1$ could be predicted from Eqs. 8 and 10.[8,11] In comparison with the Flory-Huggins equation, the theoretical expression of A_2 at a sufficiently high concentration is written as follows:

$$A_2^c = v_{2,sp}^2(1/2-\chi)/V_1 \quad (13)$$

In this equation, the excluded volume effect function $h(z)$ is absent. Therefore, A_2^c, the second virial coefficient at a high concentration, can be obtained from the experimental values of a dilute solution through division by $h(z)$:

$$A_2^c = A_2/h(z) \quad (14)$$

Moreover, $h(z)$ can be evaluated from $\langle S^2\rangle$ using excluded volume effect theories, and then A_2^c or χ can be estimated. Transforming the concentration into volume fraction, we obtain:

$$\phi_2 = cv_{2,sp} \quad (15)$$

A change in the volume on mixing, ΔV_M, is symmetrical in the volume fractions of the components, *i.e.*:

$$\Delta V_M/V = D\phi_1\phi_2 \quad (16)$$

By differentiating Eq. 16 with the number of the solvent, we obtain:

$$\Delta\bar{V}_1/V_1 = D\phi_2^2 \quad (17)$$

Consequently, from Eqs. 10 and 17 we obtain:

$$D = (RT/v_{2,sp}^2)(-(\partial A_2^c/\partial P)_T - \beta A_2^c) \quad (18)$$

On the other hand, by combining Eqs. 13 and 14 we obtain:

$$\chi_{1,H} = -T(\partial\chi/\partial T)_P = T(\partial(V_1TA_2^c/v_{2,sp}^2)/\partial T)_P = (V_1T/v_{2,sp}^2)((\partial A_2^c/\partial T)_P - \alpha A_2^c) \quad (19)$$

Thus, the pressure dependence of the parameters can be obtained from the second virial coefficients for dilute solutions.

Experimental

Materials. The polydimethylsiloxane is from the Shinetsu Chemical Co., with 50×10^4 CS and 10×10^4 CS. The M_V values of these polymers are 14.6×10^4 (1) and 10.6×10^4 (2) respectively.[12] The polydimethylsiloxane (PDMS)-(1) was fractionated by means of the fractional solution method into 13 fractions, using benzene (good solvent) and methanol (poor solvent). The 12th fraction (1F12) of $M_W=57.8\times10^4$ ($M_W/M_N<1.02$) was used in this work. The PDMS-(2) was fractionated in the same way into 8 fractions, and the 3rd fraction (2F3) of $M_W=7.30\times10^4$ was used. All the solvents (cyclohexyl bromide, benzene, toluene, and chlorobenzene) were reagent-grade and were further purified before use.

Apparatus. A high pressure optical cell was constructed. The cell, of a cylindrical form, was made of brass (Fig. 1). The windows were made of quartz (12 mm×5 mm) and were

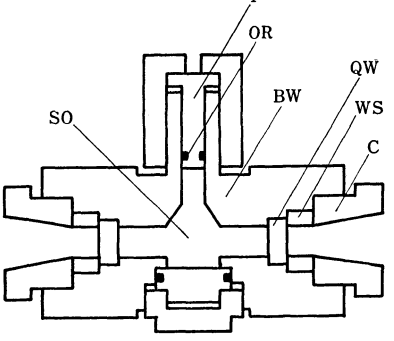

Fig. 1. High pressure optical cell (side view): (P) piston; (B) body; (CP) cap; (OR) O-ring gasket; (QW) quartz window; (WS) window spacer; (SO) solution.

tightened using the conventional unsupported area technique.[13] The capacity of the cell was *ca.* 5 cm³. All the O-rings were of Teflon, were stored in pure solvents for about 1 month prior to use, and were cleaned with an ultrasonic cleaner before measurement. The dimensions of the cell were designed so that the cell could be used for the Shimadzu light-scattering photometer (PG-21) without any modification. The pressure was generated by compressing the polymer solu tions directly. The pressure was determined by a solid-front pressure gauge (Heise Bourdon Gauge).

Procedure. The polymer solution was made up to approximately the required concentration and was cleared of dust by ultracentrifugation. The optical cell was connected to the pressure tube (1/16″ o.d. and 0.5 mm i.d.) and heated to the required temperature, and the solution was compressed to the required pressure. About one hour was necessary for the solution to become homogeneous and for the pressure gradient to be got rid of before measurements. The concentration of the solution was determined by weighing the solution and the polymer after measurements. The scattered light intensity was measured at the angle of 90°.

Determination of the Optical Constant, K, *at High Pressures.* In order to determine the absolute scattered intensity, a relative method was employed. The intensity of the solution was measured under the same conditions as those of the solvent.

The radius of the gyration of the polymer is determined by measurements of the wavelength dependence or the scattering-angle dependence or disymmetry of the scattered intensity. In this work, the following method was employed in order to determine $P(90)$, the value of the scattering function at the angle of 90°. It is assumed that the molecular weight of the polymer is constant as a function of the pressure; that is, no aggregation or decomposition happens.

According to Debye,[14] the following equation in terms of the Rayleigh ratio is yielded:

$$Kc/R_{90} = 1/MP(90) + 2A_2c \tag{20}$$

As this relation is still valid at high pressure,

$$K^*c/R_{90} = 1/MP(90) + 2A_2c \tag{21}$$

where $K^*=Kf$. K is the optical constant at 0 kg/cm². The factor, f, which indicates the change in K with the pressure has a magnitude less than unity.

Substitution and rearrangement give:

$$Kc/R_{90} = 1/MP(90)f + 2A_2c/f \tag{22}$$

Here, the direct measurable quantities as a function of the pressure are R_{90} and c. Plotting Kc/R_{90} *vs.* c gives an intercept value which is $1/MP(90)f$ and a slope of $2A_2/f$. In the case of $\langle S^2\rangle^{1/2} \ll \lambda$, $P(90)$ is unity, and as the optical constant, K, does not vary with the molecular weight of the polymer, by measuring the scattered intensity of the solution of the polymer with the radius of gyration, which is much smaller than the wavelength of the light, f is determined from the intercept value to be as is expressed in Eq. 23:

$$Kc/R_{90} = 1/Mf + 2A_2c/f \tag{23}$$

Using this value of f, $P(90)$ can be determined from the intercept and A_2 can be determined from the slope obtained from Eq. 22. With this value of $P(90)$, $\langle S^2\rangle$ is determined. PDMS (2F3) is used in order to determine f. The radius of the gyration of 2F3 is obtained by extrapolating the data given by Schulz and Haug;[15] it gives *ca.* 60Å for $\langle S^2\rangle_0^{1/2}$. This is much smaller than the wavelength of the light, and the assumption $P(90)=1$ is reasonable.

Results

The absolute Rayleigh ratio of cyclohexyl bromide as a function of the pressure is shown in Fig. 2 as an example, while the f-factor of PDMS in cyclohexyl bromide are shown in Fig. 3. The Rayleigh ratio decreases linearly with the pressure. This can be intuitively expected, for an increase in the pressure tends to produce a more ordered state.[9] The magnitude of the decrease is variable, depending on the solvents. The changes in the Rayleigh ratio of the solvents, $(\partial \ln R_{90}^{\circ}/\partial P)_T$, are 2.76×10^{-4}, 3.81×10^{-4}, 3.38×10^{-4}, and 1.01×10^{-4} l/kg cm^{-2} for cyclohexyl bromide, benzene, toluene, and chlorobenzene respectively. It seems that there is a correlation between the magnitude of compressibility and that of the decrease in the Rayleigh ratio for the solvents.

The values of A_2 obtained for each solvent are summarized in Table 1. The values of A_2 are shown in Figs. 4 and 5 as a function of the pressure for PDMS (1F12) and of $\langle S^2\rangle^{1/2}$ in Fig. 6 as a function of the temperature under various pressures for 1F12 in cyclohexyl bromide. These values under 0 kg/cm² agree well with the results obtained by Schulz and Haug.[15] The unperturbed dimensions of the polymer were

increases. θ-Temperature seems to have a tendency to reach a limiting value at high pressures. Both A_2 and $<S^2>^{1/2}$ increases with the pressure, in accord with negative values of ΔV_m. The change in $<S^2>^{1/2}$ with the pressure is more rapid than that of A_2. The dimension increases about 20% under 400 kg/cm^2. Accordingly, the effect of the pressure makes the solvent better for the polymer.

Using Eqs. 6 and 7, A_2 can be separated into $A_{2,H}$ and $A_{2,S}$. These values are summarized in Table 2. At θ-temperature $-A_{2,H}$ and $A_{2,S}$ (these cancel each other out) increase considerably with the pressure and the solvent becomes more endothermal. At higher temperatures, however, $-A_{2,H}$ decreases with the pressure and the solvent becomes less endothermal. From this fact and from the fact that A_2 increases with the pressure, it is evident that the contribution of the entropy term is larger than the enthalpy term.

In polar solvents, cyclohexyl bromide and chlorobenzene, the extent of the change in A_2 with the pressure is larger than in good solvents, benzene and toluene. In particular, A_2 in benzene seems to be independent of the pressure.

From the pressure dependence of A_2 and Eq. 10, the values of the relative partial molar excess volume were obtained; they are tabulated in Table 3. It is evident from this table that the volume contracts on mixing for all solvents.

Discussion

Absolute Rayleigh Ratio of the Solvents. The values in Fig. 2 are the absolute Rayleigh ratios of the solvents obtained in the manner described above. The experimental values of this ratio were reproducible within the limit of experimental error. The isotropic Rayleigh ratio is defined as follows:[16]

$$R_{iso} = (2\pi^2/\lambda_0^4)kT(\tilde{n}(\partial\tilde{n}/\partial P))^2/\beta \quad (24)$$

By experiments, the total Rayleigh ratio is measured. Since a statistical independence is assumed for the assorted fluctuation phenomena,

$$R_{total} = R_{iso} + R_{aniso} \quad (25)$$

The anisotropic component of the Rayleigh ratio is defined using the degree of depolarization, ρ_u, and R_{total} is written as follows:

$$R_{total} = R_{iso}(6+6\rho_u)/(6-7\rho_u) \quad (26)$$

According to McDonald and Claesson,[9] R_{aniso} is nearly independent of the pressure. The change in R_{total} with the pressure is determined by the contribution of the R_{iso} term in Eq. 25; therefore, the degree of depolarization increases with the pressure, and the contribution of R_{aniso} to R_{total} increases. This means that the refractive index of the solvent increases with the pressure, but the $(\partial\tilde{n}/\partial P)_T$ term decreases more rapidly with the pressure. Since the anisotropic characteristics are related to the structural properties of the liquids, a further examination is warranted. The refractive index of benzene under high pressures is available,[17] and the calculation of the depolarization can be done. The pressure dependence of the Rayleigh ratio of benzene was examined by McDonald and Claesson.[9] Their results are in good agreement with the above.

The Pressure Dependence of the θ-Temperature. In the PDMS+cyclohexyl bromide solution, the θ-temperature decreases with the pressure. At the θ-temperature, A_2 becomes zero and $d\theta/dP$ is expressed by the following equation:

$$d\theta/dP = -(\partial A_2/\partial P)_T/(\partial A_2/\partial T)_P \quad (27)$$

From the values of A_2 tabulated in Table 1, $(\partial A_2/\partial T)_P$ and $(\partial A_2/\partial P)_T$ are obtained. Under 0 kg/cm² the θ-temperature is 27.6 °C. The value of $(\partial A_2/\partial T)_P$ at 27.6 °C and under 0 kg/cm² is 4.72×10^{-6}, while that of $(\partial A_2/\partial P)_T$ is 4.5×10^{-8}, which gives $d\theta/dP=-0.95\times10^{-2}$ deg/kg cm^{-2}. The value of the corresponding $d\theta/dP$ obtained from the experiments (Fig. 7) is -0.96×10^{-2} deg/kg cm^{-2}. These values are consistent.

The pressure coefficient of a critical solution temperature is given by the relation:[18]

$$dT_c/dP = T(\partial\Delta\bar{V}_1/\partial\phi_2)_c/(\partial\Delta\bar{H}_1/\partial\phi_2)_c \quad (28)$$

In the vicinity of the upper critical solution temperature, the process of mixing is endothermal, and $(\partial\Delta\bar{H}_1/\partial\phi_2)_c$ must be negative. A negative value of the volume change on mixing is obtained (see Table 3), so $(\partial\Delta\bar{V}_1/\partial\phi_2)_c$ is positive. Consequently, dT_c/dP must be negative. This is in good agreement with the negative value of $d\theta/dP$. The pressure coefficient of the upper critical solution temperature of PDMS in cyclohexyl bromide must be small, of the order of 10^{-2}. According to Gaeckle and Patterson,[8] the pressure dependence of A_2 in the vicinity of the lower critical solution temperature, polyisobutylene in 2-methylbutane, is very large, and $(\partial A_2/\partial P)_T$ is 2.2×10^{-6} cm³ mol g^{-2} bar^{-1}. The dT_c/dP of the lower critical solution temperature is 0.44 deg/bar, in contrast to PDMS in cyclohexyl bromide. This behavior is due to the difference in the pressure contribution. At the lower critical solution temperature, the free volume contribution is dominant and the pressure dependence is large. At the upper critical solution temperature, polystyrene in cyclohexane,[19] dT_c/dP is in the order of 10^{-3} and changes in sign depending on the molecular weight. These are reflected in the extent of $(\partial A_2/\partial P)_T$.

Pressure and Temperature Dependence of $\langle S^2\rangle_0$. The values of $\langle S^2\rangle^{1/2}$ at the θ-temperature give the unperturbed chain dimensions of the polymer. The radius of gyration is related to the coil expansion coefficient, α:

$$\langle S^2\rangle = \langle S^2\rangle_0\alpha^2 \quad (29)$$

The coil expansion coefficient, α, is changed through pressure and temperature. For PDMS in cyclohexyl bromide at different temperatures and pressures, the α's were plotted against the corresponding values of A_2, as is shown in Fig. 8. A single curve was obtained. This shows that the effect of the pressure on the chain dimension is not at all different from that of the temperature and that $\langle S^2\rangle_0$ is a function of the pressure. According to Schulz and Lechner,[5-7] the radius of gyration changes with the pressure, although A_2 remains

nearly constant, and the unperturbed dimensions are influenced by the pressure. Moreover, if the pressure dependence of the unperturbed dimension is not included in the estimation of α, the plot of α against A_2 does not give a single curve.[8] Therefore, it must be concluded that $\langle S^2\rangle_0$ is influenced by the pressure.

For the same value of A_2 under various pressures, $\langle S^2\rangle^{1/2}$ for PDMS in cyclohexyl bromide increases with the pressure. This indicates that the unperturbed dimension is an increasing function of the pressure. The unperturbed chain dimension, $\langle S^2\rangle_0^{1/2}$, was determined by interpolating the θ-temperature in the $\langle S^2\rangle^{1/2}$ plot against the temperature under various pressures, as is shown in Fig. 6. These values were 191, 193, 200, 216, and 227 Å for 0, 100, 200, 300, and 400 kg/cm^2 respectively. The increase in the dimensions with the pressure reaches *ca.* 20% at 400 kg/cm^2. On the other hand, the temperature dependence of the unperturved chain dimension $(\partial \ln\langle R^2\rangle_0/\partial T)_P$ of PDMS is 0.75×10^{-3} l/deg. Since θ-temperature decreases with the pressure, the increase in the unperturbed chain dimension is directly due to the pressure. As Gaeckle and Patterson have shown, this result indicates the pressure effect of the solvent packing on the population of conformations or rotational isomers of polymer. It is usually believed that the solvent has little effect on the unperturbed dimensions of a polymer, but in the present case it should not be disregarded. Even a small effect of solvent packing on the rotational isomer equilibrium would have important consequences in the polymer solution thermodynamics. In the case of PDMS, this effect is large. PDMS has, as an irregular form, pendant CH_3 groups spaced by comparatively long Si–O and Si–C bonds. The irregularity in the cross section of the chain will make the effect of the solvent packing large.[20]

These results show that α should be determined considering the pressure effect on the unperturbed chain dimension and that the excluded volume effect should be examined by including the pressure effect as well as the temperature.

Pressure and Temperature Dependence of A_2 *and* $\langle S^2\rangle$. The excluded volume effect was examined at different temperatures and pressures using Eq. 11 and the corresponding value of A_2 given in Table 1, while the values of $zh(z)$ were calculated for PDMS in cyclohexyl bromide. Figure 8 shows the relation between α and $zh(z)$; it may be seen that the points for different temperatures and pressures do approximately fall on a single curve, as expected from the theory. This is not changed even by the effects of polydispersity on the values of A_2 and $\langle S^2\rangle^{1/2}$, as has examined by Gaeckle and Patterson.[8]

A number of closed expressions for the expansion factor, α, of the polymer relating to A_2 or z are also presented. In the usual treatment, the penetrating function, Φ, is plotted against α. In this work, however, in order to estimate A_2^c or χ, α was plotted against $zh(z)$. This plot makes clear the tendency of the change in α. The abscissa in Fig. 8, $zh(z)$, was obtained from the Krigbaum-Carpenter-Kaneko-Roig (KCKR) theory[21] with three values of the ρ-parameter: 0, 0.4, and 1. The ρ-parameter depends on the ratio of the

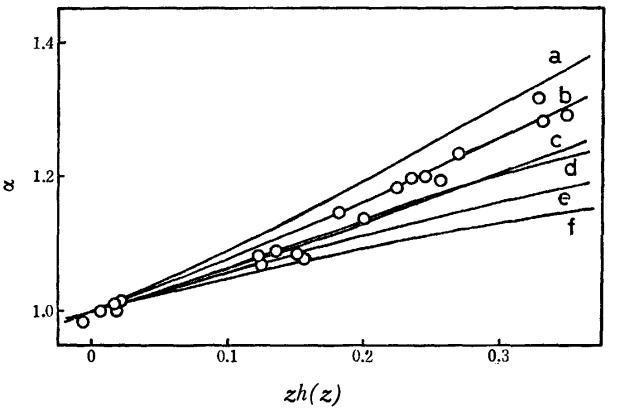

Fig. 8. The coil expansion factor, α, for PDMS (1F12) in cyclohexyl bromide at various temperatures and pressures. Curves a, b, and c are given by the Fixman-Stockmayer expression for α, Eq. 30, and the KCKR theory for A_2 with ρ equal to 0, 0.4, and 1, respectively. Curves d, e, and f are given by the Flory-Stockmayer modification, Eq. 31, and the KCKR theory for A_2 with ρ equal to 0, 0.4, and 1, respectively. The abscissa, $zh(z)$, is proportional to A_2.

total number of intramolecular contacts to the number of long-range contacts. The evaluation of z from α was obtained by using the Fixman-Stockmayer expression[22] and the Flory-Stockmayer modification[23]:

$$\alpha^3 - 1 = 2z \tag{30}$$

$$\alpha^5 - \alpha^3 = 1.276z \tag{31}$$

The resulting six curves of α against $zh(z)$ are shown in Fig. 8. It is noticeable that $zh(z)$ is equal to $\alpha^3\Phi$. The experimental data are well expressed by Eq. 30 and $\rho=0.4$.

The penetrating function, Φ, was also examined. Five conjugate closed expressions were compared with the experimental data. These were the Flory[24]-Flory, Krigbaum, Orofino:[25] Flory, Stockmayer modification[23]-Flory, Krigbaum, Orofino modification;[23] Fixman[22]-Kurata;[26] Yamakawa-Tanaka;[27] and Casassa[28] equations. The experimental points were in better agreement with the Casassa equation than the others. The Casassa equation corresponds to the KCKR theory with the ρ-parameter equal to 0. These results show that pressure effect on the excluded volume effect is quite similar to the temperature effect.

Relative Partial Molar Excess Volumes and Heats of the Solvent. In order to evaluate the volumes and heats of dilution, Eqs. 8 and 10 were used. In Table 2, $A_{2,H}$ and $A_{2,S}$ are shown, while in Table 3, the $\Delta\bar{V}_1$ values are tabulated.

For all the solvents the $\Delta\bar{V}_1$ values were negative, and the absolute value of $\Delta\bar{V}_1$ for cyclohexyl bromide decreases with the temperature. Throughout the pressure range of the experiment, $(\partial A_2/\partial P)_T$ was nearly constant, and the pressure dependence of $\Delta\bar{V}_1$ was not remarkable. However, according to McDonald and Claesson,[9] A_2 reaches a limiting value at a high pressure. Consequently, $(\partial A_2/\partial P)_T$ becomes zero and the volume of dilution at a high pressure is directly related to the limiting value of A_2. Their results show that the change in the volume on mixing at a high pressure decreases and

reaches a limiting value.

The value of $\Delta\tilde{V}_1$ varies depending on the solvent. However, the values for the polar solvents, cyclohexyl bromide and chlorobenzene, are very similar. The value of $\Delta\tilde{V}_1$ for cyclohexyl bromide depends mainly on $(\partial A_2/\partial P)_T$. On the contrary, those of the good solvents, benzene, toluene, and chlorobenzene, depend mainly on the term of βA_2 in Eq. 10. This is because the value of A_2 is about ten times larger than that for the θ-solvent. In the case of polyisobutylene in 2-methylbutane, $(\partial A_2/\partial P)_T$ term is much larger than βA_2 term. For θ-solvent the $(\partial A_2/\partial P)_T$ term is dominant over $\Delta\tilde{V}_1$.

In comparing $A_{2,S}$ with $A_{2,H}$, the contribution of $A_{2,S}$ is larger to A_2 and the pressure effect is effectively reflected in the entropy term.

The KCKR theory was used to obtain the $h(z)$ function in order to furnish values of A_2^c for use in Eqs. 18 and 19. In this theory, the values of the ρ-parameter equal to 0, 0.2, and 1 give results corresponding to the well-known Casassa,[28] Kurata-Yamakawa,[26] and Flory-Krigbaum[29] theories respectively. In accordance with the KCKR[21] and Gaeckle and Patterson,[8] and from a comparison with the experimental results shown in Fig. 8, an intermediate value of 0.4 was used for the ρ-parameter in evaluating $h(z)$. Then the $h(z)$ function was calculated from the KCKR theory, and A_2^c was obtained from the values of A_2 in a dilute solution. From Eq. 13 the χ-parameter was obtained. The χ-parameter decreases with the temperature and the pressure.

The values of D at the temperature of 27.0, 36.5, 47.2, and 56.2 °C for PDMS in cyclohexyl bromide in Eq. 18 were obtained; they were -1.08×10^{-3}, -1.26×10^{-3}, -1.00×10^{-3}, and -0.878×10^{-3} respectively.

From the change in A_2 at zero pressure, values of the enthalpic parameter, κ, were obtained for PDMS cyclohexyl bromide. They were 0.197 at 27.0 °C and 0.178 at 56.2 °C. The corresponding values of the entropic parameter, ψ, were 0.196 at 27.0 °C and 0.194 at 56.2 °C.

Comparison of the Pressure Dependence of A_2 *with the Predictions of Newer Theories.* The second virial coefficient is related to the polymer-solvent interaction parameter, χ, through Eqs. 11 and 12. The pressure dependence of χ can be predicted using a newer theory of polymer solution. The following equations were used to predict the pressure dependence of χ and that of A_2^c in the concentrated range of the polymer solution:

$$\chi_1/c_1 = -\tilde{U}_1\nu^2/\tilde{T}_1 + (1/2)\tilde{C}_{p,1}(\tau+\pi\tilde{P}_1\tilde{V}_1^2/(\tilde{P}_1\tilde{V}_1^2+1))^2 \quad (32)$$

$$\chi_1 = (P_1^*V_1^*/\tilde{V}_1RT)(A^2\alpha T/2+Y) - V_1^*Q/R(s_1/s_2)^2 \quad (33)$$

$$\chi_1/c_1 = (1/\tilde{V}_1\tilde{T}_1)(1-(P_2^*/P_1^*)^{1/2}(\tilde{V}_1/\tilde{V}_2))^2 + \delta \quad (34)$$

Equations 32, 33, and 34 are given by the Patterson theory, the Flory theory, and the solubility parameter theory respectively.

Here $\tilde{U}_1$ and $\tilde{C}_{P,1}$ are the reduced configurational energy and the heat capacity of the pure solvent. $\tilde{P}_1$, $\tilde{V}_1$, and $\tilde{T}_1$ are the reduced pressure, the volume, and the temperature of the solvent. P_1^*, V_1^*, and T_1^* are the characteristic pressure, volume, and temperature of the solvent. A and Y are defined as follows;

$$A = (1-T_1^*/T_2^*)(P_2^*/P_1^*) - (s_2/s_1)(X_{12}/P_1^*) \quad (35)$$

$$Y = (X_{12}/P_1^*)(s_2/s_1)^2 \quad (36)$$

The Flory theory essentially predicts these quantities, using a van der Waals model of the liquid state and a partition function similar to the Hirschfelder-Eyring cell partition function.[30] Then,

$$\tilde{U}_1 = -\tilde{V}_1^{-1} \quad (37)$$

$$\tilde{C}_{p,1}^{-1} = (1-(2/3)\tilde{V}_1^{-1/3}) - 2(1-\tilde{V}_1^{1/3})/(\tilde{P}_1\tilde{V}_1^2+1) \quad (38)$$

The τ-parameter is related to the difference between the thermal expansion coefficient of the solvent and the polymer, and is defined by:

$$\tau = 1 - T_1^*/T_2^* \quad (39)$$

The ν^2-parameter is related to the difference in cohesive energy and size between the solvent and the polymer segment. The π-parameter is similarly related to the difference between the reduction parameter, P^*, of the components and is defined by:

$$\pi = P_1^*/P_2^* - 1 \quad (40)$$

c_1 is the number of external degrees of freedom of the solvent molecule. This is calculated from the relation:

$$c_1 = P_1^*V_1^*/RT_1^* \quad (41)$$

In the Flory theory, the X_{12} parameter measures the interchange energy on the formation of contacts between the solvent and the polymer, Q is analogously defined to represent the entropy arising from the interchange of neighboring molecules, and s_1 and s_2 denote the number of surface sites for segments of the respective species.

In treating the thermodynamics of the PDMS solutions, the τ, π, and c_1 parameters were determined from Eqs. 39, 40, and 41. Moreover, ν^2, X_{12}, Q, and δ were decided to fit with the zero pressure data of A_2.

The pressure dependence of A_2 was predicted from Eqs. 32, 33, and 34 using the parameters decided as above. The evaluation of A_2 from χ was done by means of the KCKR theory.

The values of $(\partial A_2/\partial P)_T$ predicted by Eq. 34 were all overestimated. Equation 34 was obtained by combining the solubility parameter theory with the corresponding state theory. In the solubility parameter theory, the Berthelot relation is assumed for the energy of the (1—2) contacts relative to the (1—1) and (2—2) contacts. Also, the parameter δ expresses the correction of entropy. In PDMS solution, the contribution of the entropy is unusually large. Consequently, the error from δ may be large. Besides, as Flory has described,[31] the Berthelot relation is not a good assumption for the polymer solutions.

For cyclohexyl bromide and chlorobenzene solutions, the values of A_2 predicted by Eqs. 32 and 33 were underestimated. Also, the negative values of $(\partial A_2/\partial P)_T$ were obtained. The reason for this is that these solvents are both polar solvents, and that the configurational energy is not expressed in the form of $1/V$ which was assumed by Flory[2] for liquids. Especially, for chlorobenzene $(\partial U/\partial V)_T$ is an increasing function of the volume at a constant temperature.[32] Therefore, the equation of state defined by Flory is not in conformity with the polar solvents.

For benzene and toluene, the curves of A_2 predicted by Eq. 32 are a little underestimated compared with the experimental results. The fitted ν^2 parameter is small, corresponding to $X_{12}=4.54$ and 3.72 cal/cm^3 respectively, as obtained from the relation of $X_{12}=\nu^2 P_1^*$. The slopes predicted from Eq. 32 are -4.0×10^{-8} and -1.0×10^{-8} cm^3 mol g^{-2}/kg cm^{-2} at 27.0 °C for benzene and toluene. The predicted values of χ at 27.0 °C under zero pressure are in good agreement with the results reported by Kuwahara.[33] They are 0.48 for benzene and 0.46 for toluene at 25.0 °C; on the other hand, in this experiment 0.47 and 0.44 were found respectively.

The $c_1\nu^2$ term in Eq. 32 increases with the pressure, and the interchange energy contribution increases. However, the $\tilde{C}_{P,1}$ term decreases with the pressure, and the effect of the pressure on the free volume or the equation of state term makes the polymer more soluble to the solvent. This suggests the significance of the contribution of the free volume. Indeed, the $\chi_{1,H}$ term predicted from Eq. 32 decreases with the pressure. In the Patterson theory, the Q term in the Flory theory is neglected. For PDMS solutions the contribution of the Q term to χ is usually large;[34] consequently, the entropy term of χ in the Patterson theory was overestimated and $(\partial A_2/\partial P)_T$ was underestimated. However, this behavior of $\chi_{1,H}$ is in agreement with the behavior of $A_{2,H}$ of the cyclohexyl bromide solution at higher temperatures.

For benzene the curve of A_2 predicted from Eq. 33 was also examined. The $(\partial A_2/\partial P)_T$ predicted from Eq. 33 using values of X_{12} and Q parameter equal to 5.26 cal/cm^3 and -0.01 cal/cm^3 deg obtained by Flory and Shih[34] was underestimated and negative. The predicted value of $(\partial A_2/\partial P)_T$ was -2.5×10^{-8} cm^3 mol g^{-2}/kg cm^{-2} at 27.0 °C. $\chi_{1,H}$ which is given by the $\chi_{1,H}=-T(\partial\chi/\partial T)$ relation; χ is defined by Eq. 33 and decreases with the pressure. Also, the free volume term of χ in Eq. 33 decreases with pressure. However, for a benzene solution the free volume term or the equation of state term contribution to the free energy predicted from Eq. 33 is unusually small and the interchange energy contribution is large. PDMS has an extremely large thermal expansion coefficient and isothermal compressibility compared to the other polymers, for example, polystyrene; it corresponds to the small values of P^* and T^*. Consequently, the A parameter (Eq. 35) is small. Because of this, the contribution of X_{12} to χ is dominant.

For polyisobutylene in 2-methylbutane, which gives a θ-temperature associated with the lower critical solution temperature of 45 °C, the free volume contribution is dominant and the $(\partial A_2/\partial P)_T$ predicted from Eq. 32 is positive and large. Its value is 2.2×10^{-6} and 3.4×10^{-6} cm^3 mol g^{-2}/kg cm^{-2} at 24 and 57 °C respectively. These values are in good agreement with the results of Gaeckle and Patterson.[8] This means that the pressure effect is well explained when the free volume contribution is dominant. In the vicinity of the upper critical solution temperature, the energy contribution is predominant over the free volume contribution, and the energy contribution predicted from the corresponding state theory is overestimated.

This discrepancy in the PDMS solution may be related to the discrepancy of the excess volume predicted from the corresponding state theory against the experiment.[34] Especially the estimation of the excess volume of mixing is important in considering the pressure effect. The behavior of A_2 for polystyrene in *trans*-decalin is related to the volume change on mixing.[19] At a high pressure A_2 shows a limiting behavior and the excess volume depends on the pressure. However, the corresponding state theory gives a qualitative prediction of the pressure contribution.

Flotation of MnO_4^- and Fe^{3+} Ions by the Combined Use of Sodium Silicate and Cationic Surfactant

Isao TAKAYANAGI,* Koichi KOBAYASHI,** Keiko HACHISUKA, and Tsunetaka SASAKI***

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received April 16, 1976)

The removals of MnO_4^- and Fe^{3+} ions from an aqueous solution by the combined use of silicate ions(SiO_3^{2-}) and a cationic surfactant, hexadecyltrimethylammonium chloride (HTAC), were studied by means of ion flotation techniques. The effect of variables such as pH, the surfactant concentration, and the order of addition of the reagents on the floatability of the ions were studied. More than 98 and 97% of the MnO_4^- and Fe^{3+} ions, respectively, could be floated under the optimum conditions. The optimum composition of SiO_3^{2-} and HTAC was found to be about 0.9 in mole fraction of SiO_3^{2-} for both systems. It was also found that the order of the addition of the reagents markedly affects the floatability. Further, a schematic model of flotation was proposed, taking account of the compositions of the sublate. MnO_4^- and Fe^{3+} ion flotations differed from each other in that MnO_4^- ions combine with SiO_3^{2-} ions through the double layer of HTAC molecules, which are subsequently coagulated and floated by HTAC, while Fe^{3+} ions or polynuclear Fe^{3+} ions combine directly with SiO_3^{2-} ions, which are subsequently coagulated and floated by HTAC.

Ion flotation has been employed for the removal of inorganic anions and cations from an aqueous solution. The process involves the formation of a surface-active complex by the addition of surface-active ions opposite in charge to the ions to be separated. The complex is then floated by means of gas bubbles introduced into the solution. Various studies have been made of the reagents available for flotation and of the mechanism of flotation.[1] Among the possible processes of ion flotation, the use of a surfactant with or without a polyelectrolyte has been confirmed to be effective for the flotation of anions, cations, and particles.[2] Goto and Izumi have reported the removal of heavy metal ions from an aqueous solution by using polyethylenepolyamine.[3] Cu^{2+}, Cd^{2+}, and Co^{2+} ions have been more effectively removed from an aqueous solution by the combined use of macromolecular or polymer anions, such as bentonite, and cationic surfactants than by the simple use of an anionic surfactant.[4,5] So far, no application of ion flotation has been made to the removal of cations and anions from an aqueous solution by the combined use of silicate ions and a cationic surfactant, which also belongs to this category.

The present study is intended to establish the feasibility of ion flotation for the removal of anions and cations such as Fe^{3+} and MnO_4^- ions from an aqueous solution by the combined use of silicate ions and a cationic surfactant, hexadecyltrimethylammonium chloride (HTAC).

Experimental

Materials. The concentrated solution of about 2×10^{-3} mol/l permanganate solution was prepared by dissolving extra-pure grade potassium permanganate into triply distilled water; the solution was stocked in a dark room. The concentration of permanganate ions was determined by the usual method of titrating with a standard solution of sodium oxalate.

The iron(III) chloride used was of analytical reagent grade $FeCl_3\cdot6H_2O$, and was purified before use by recrystallization. A stock solution of 7.45×10^{-3} mol/l concentration was prepared by dissolving iron(III) chloride in triply distilled water, with the addition of a small amount of sulfuric acid to make the solution of pH 1.4. The concentration of Fe^{3+} ions was determined with an atomic absorption spectrometer (Techtron Pty., Ltd., Model-AA-100), using an aqueous solution of Mohr's salt of known concentration as a standard.

The cationic surfactant used was of pure grade hexadecyltrimethylammonium chloride (HTAC) supplied by the Kao Soap Co., Ltd.; its aqueous solution was prepared by dissolving HTAC in triply distilled water. The solution was employed after diluting just before use. The solution of silicate ions (SiO_3^{2-}) was prepared by dissolving reagent grade water glass in triply distilled water. The sodium hydroxide used for controlling pH was of extra-pure reagent grade, and was purified by precipitation from its saturated solution.

All other chemicals were of analytical reagent grade unless otherwise specified and were used without further purification.

Procedure. *MnO_4^- Ion Flotation*: In a test tube 1.65 cm in inner diameter and 16.5 cm in length, 10 ml of water, a given amount of potassium permanganate solution, and varying amounts of HTAC and sodium silicate solutions were introduced; the volume was filled with water to a total of 12 ml. The test tube of the sample solution was allowed to stand for 2 min and was slowly and repeatedly turned upside down. Then the precipitates formed with MnO_4^- were shaken for 10 s by hand and were floated with minute bubbles. After 5 min, the underlying liquid was taken out of the test tube and was centrifuged to remove the remaining precipitates. The concentration of permanganate ions in the solution was determined by a colorimeter (Bausch and Lomb, Spectronic 20) at 720 nm.

The floatability (%) of MnO_4^- ions was given by

$$F = \frac{C_i - C_f}{C_i} \times 100\%$$

where C_i and C_f denote the initial and final concentrations of MnO_4^- ions, respectively.

The concentration of HTAC and SiO_3^{2-} in the solution was determined as follows.

HTAC Concentration: Five ml of the solution without the precipitate was taken in a flask and mixed with 0.1 ml of Bromophenol Blue solution as a color indicator (a mixture of

0.08% Bromophenol Blue, 62.5% acetic acid, 10.25% Na_2SO_4, and 27.17% water). The solution was titrated with sodium octadecylsulfate solution in a water bath at 60 °C.[6] The amount of HTAC in the sublate was calculated from the difference in the amount of HTAC in the solution before and after the precipitate formation.

SiO_3^{2-} Concentration: The concentration of SiO_3^{2-} was colorimetrically determined by the color developed by the addition of ammonium molybdate.[7] The absorbance was measured at 830 nm and the amount of SiO_3^{2-} in the sublate was calculated similarly to that of HTAC mentioned above. In some cases, the amount of SiO_3^{2-} in the sublate could not be determined as a difference owing to its small content. In such a case the sublate was removed and washed with distilled water, subjected to combustion in a platinum crucibles, fused with anhydrous sodium carbonate, and dissolved in triply distilled water. The solution was adjusted to pH 2 with sulfuric acid, and the amount of SiO_3^{2-} in the solution was determined by the colorimetry.

Fe^{3+} Ion Flotation. The varying amounts of Fe^{3+}, HTAC, and SiO_3^{2-} solutions and a small amount of sodium hydroxide solution were introduced into a graduated test tube 1.0 cm in inner diameter and 17 cm in length. The total volume of the solution was increased with water to 10 ml. The solution was treated in the same manner as in the case of the MnO_4^- ion flotation. After the flotation, about 5 ml of the underlying solution was taken out of the test tube for the measurements of the pH, concentration of HTAC, SiO_3^{2-}, and Fe^{3+}, from which the floatability of Fe^{3+} and the composition of the sublate were calculated. The floatability of the Fe^{3+} ions was calculated similarly to that of MnO_4^-.

The measurements of the flotation were carried out at room temperature, about 25 °C.

Results and Discussion

MnO_4^- Ion Flotation. Figure 1 shows the floatability of MnO_4^- as a function of total molar concentration of Na_2SiO_3+HTAC and mole fraction of Na_2SiO_3 in the mixture at pH 11. The area circumscribed by the curve shows the optimum region of MnO_4^- flotation, where more than 85% of MnO_4^- is floated. The triangles show the systems of less than 85% floatability, while the circles and squares indicate the systems with floatabilities of 90 and 98%, respectively. As may be seen in Fig. 1, the mole fractions of SiO_3^{2-} in the sample solution fall in a narrow range from 0.86 to 0.94 in the region of optimum flotation. In the upper region neighboring this optimum region (system No. 6 for instance), the flotation is not so efficient, although the permanganate ions coagulate completely. In the region of excess HTAC, the solution becomes turbid and the floatability decreases. Table 1 lists the floatability (F), and the solution and sublate compositions of the representative systems No. 1, 2, and 3 in the optimum flotation region in Fig. 1. Among these systems, a maximum floatability of 98% was obtained for the No. 2 system. From Table 1, the mole ratios of SiO_3^{2-} to HTAC of the sublates are seen to be about 2 for the three systems, while the mole ratios of HTAC to MnO_4^- are about 15.9, 7.52, and 2.47 for systems No. 1, 2, and 3 respectively, these decrease with decreasing amount of the total concentration of SiO_3^{2-}+HTAC.

Table 1. Floatability of MnO_4^-, and solution and sublate compositions of the MnO_4^-–SiO_3^{2-}–HTAC system

No.	F (%)	MnO_4^- (10^{-4} mol/l)[a]	HTAC (10^{-4} mol/l)	SiO_3^{2-} (10^{-4} mol/l)
1	85	1.91 (1.61)	26.3 (25.6)	200 (50.0)
2	98	2.01 (1.98)	15.7 (14.9)	137 (28.3)
3	91	2.08 (1.89)	4.92 (4.67)	54.0 (10.5)

( ) Indicates sublate compositions.
a) Mole number of each component in the sublate produced in 1 l solution.

In agreement with these data, some models of the sublate structure are proposed for these systems, as shown in Fig. 2.† In these models the double molecules bridging HTAC between MnO_4^- and SiO_3^{2-} are

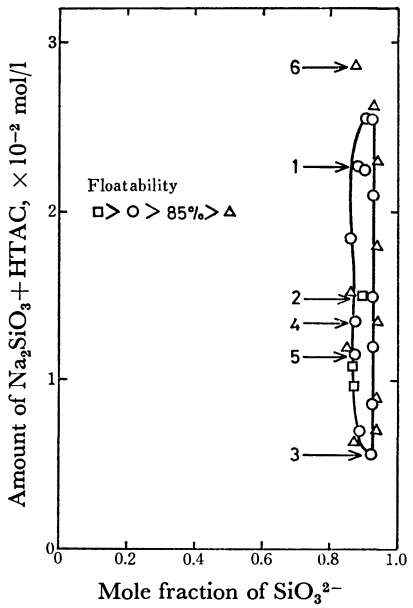

Fig. 1. Diagram of MnO_4^- ion flotation by SiO_3^{2-} and HTAC.

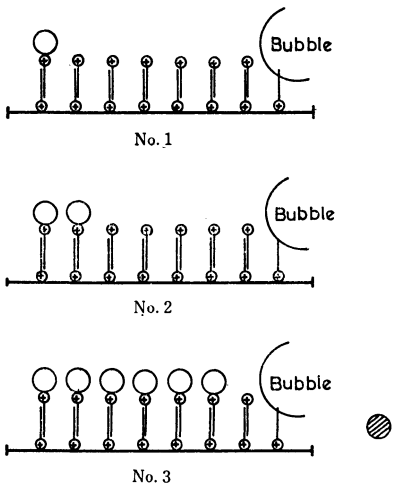

Fig. 2. A schematic drawing of sublate structure of MnO_4^-–SiO_3^{2-}–HTAC precipitate. ⊢⊣: $(SiO_3^{2-})_n$, ○: combined MnO_4^-, ◍: free MnO_4^-, ⊕—: HTAC.

† An exact agreement of the composition was not attempted, for the sake of simplicity.

indicated. HTAC also acts to float the sublates by attracting them to bubbles.

Now, in model No. 1, most MnO_4^- ions combine with silicate ions in the manner indicated in Fig. 2, but the excess positive charge due to the double molecular HTAC ions not combined with MnO_4^- increases the hydrophilicity and decreases the floatability. On the other hand, in model No. 3, nearly the full attachment of MnO_4^- ions is in equilibrium with some free MnO_4^- ions not attached to the silicate back-bone which does not float. Thus, the floatability of MnO_4^- again decreases. Therefore, a maximum of floatability is expected to appear somewhere between the two systems. System No. 2 may be considered to be such a system.

Table 2. Floatability of MnO_4^- and order of addition of reagents

No.	F(%)	
	HTAC+SiO_3^{2-}	SiO_3^{2-}+HTAC
2	98	90
4	96	91
5	91.6	88

The effect of order of the addition of reagents on the floatability of MnO_4^- was also investigated. The results are shown in Table 2. As seen, the addition of SiO_3^{2-} to systems No. 2, 4, and 5 followed by HTAC shows less floatability than the addition of the reagents in the reverse order. This effect may be explained by the fact that HTAC combines mainly with SiO_3^{2-}, as is evidenced by the white precipitate of hexadecyltrimethylammonium silicate which forms, to which MnO_4^- attaches only weakly. Thus the floatability decreases in the fomer case, while in the latter case HTAC combines with both MnO_4^- and SiO_3^{2-}, enabling MnO_4^- to float by the double molecular bridge of HTAC.

Since in the case of MnO_4^- flotation we attempted merely to confirm the possibility of flotation of the anion by the polymer and surfactant addition, the pH of the solution (about 11) was not varied to study its effect on floatability.

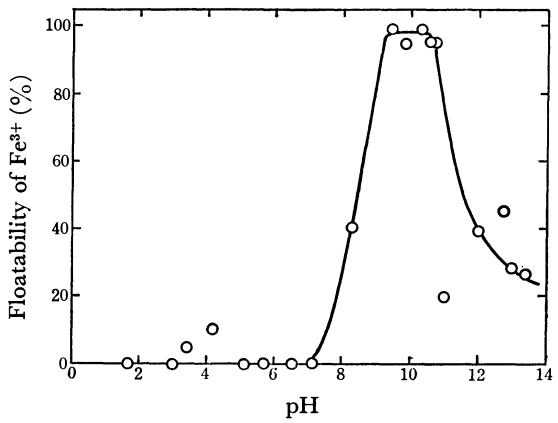

Fig. 3. Floatability *vs.* pH for Fe^{3+}–SiO_3^{2-}–HTAC system. Fe^{3+}: 7.45×10^{-5} mol/l, SiO_3^{2-}: 1.56×10^{-2} mol/l, HTAC: 2.02×10^{-3} mol/l.

Fe^{3+} Ion Flotation. In the case of Fe^{3+} ion flotation, as in the previous study,[8] the dissolved state of Fe^{3+} ions influencing the floatability was largely affected by the change in the pH, different from the case of MnO_4^-. Figure 3 shows the effect of the pH on the floatability for the Fe^{3+}–SiO_3^{2-}–HTAC system. As shown in Fig. 3, the floatability increases sharply at about pH 7 and reaches a maximum at a pH value from 9.4 to 10.7, showing an F of 97%. In the case of Fe^{3+} ion flotation by silicate ions and cationic surfactant, the Fe^{3+} ions directly combine with SiO_3^{2-}, which also combines with HTAC. At a pH value lower than 7, the floatability is practically zero for the Fe^{3+}–SiO_3^{2-}–HTAC system, presumably due to the strong adsorption of H^+ on the silicate back-bone with the exclusion of the adsorption of both Fe^{3+} and HTAC ions. In the case of Fe^{3+} ion flotation by an anionic surfactant alone and by bentonite and a cationic surfactant, the rise in floatability is seen at about pH 3 and above, as has been reported by Rubin and Johnson.[2,10] In the case of Fe^{3+} ion flotation, the iron polynuclear species forms at a certain pH, as has been reported by E. Matijevic *et al.*,[9] and then is floated by SiO_3^{2-} ions and HTAC.

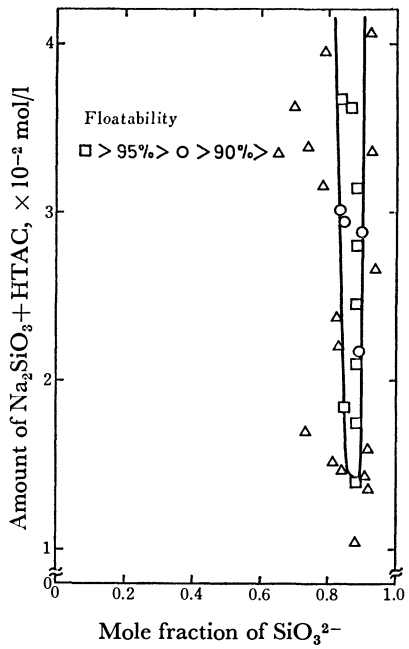

Fig. 4. Diagram of Fe^{3+} ion flotation by SiO_3^{2-} and HTAC.

Figure 4 shows the floatability diagram for Fe^{3+} at pH 9.4—10.7, similar to Fig. 1. The optimum region of Fe^{3+} ion flotation was observed in mole fractions of SiO_3^{2-} ranging from 0.85 to 0.90 and above the total concentration of 14.1×10^{-3} mol/l. In the region outside the optimum condition, the solution became turbid. In this solution the coagulation did not occur when the fraction of SiO_3^{2-} was smaller, while for a larger mole fraction of SiO_3^{2-}, it did occur, though the coagulate formed did not float. The diagram of Fig. 4 is quite similar to the case of MnO_4^-. Table 3 shows the optimum floatability and the compositions in mole of Fe^{3+}-sublate produced in 1 l solution, together with

Table 3. Sublate composition of the MnO_4^-–SiO_3^{2-}–HTAC and Fe^{3+}–SiO_3^{2-}–HTAC systems

F (%)	MnO_4^- (10^{-4} mol/l)[a)]	Fe^{3+} (10^{-4} mol/l)	HTAC (10^{-3} mol/l)	SiO_3^{2-} (10^{-3} mol/l)
97.7		0.728	1.624	8.50
98.0	1.980		1.487	2.83

a) The same as mentioned in Table 1.

those of the MnO_4^--sublate. It is seen that the SiO_3^{2-}/HTAC ratios in the sublate at optimum floatability are about 5 for the Fe^{3+}–SiO_3^{2-}–HTAC system, as shown in Table 3, while the ratio is 2 for the MnO_4^-–SiO_3^{2-}–HTAC system. This difference can be expected, since in the former system Fe^{3+} ions combine directly with SiO_3^{2-} ions, while in the latter system cationic surfactant molecules act as bridges between MnO_4^- ions and SiO_3^{2-} ions. Figure 5 shows such a difference in the structures of the MnO_4^-–SiO_3^{2-}–HTAC and Fe^{3+}–SiO_3^{2-}–HTAC systems.

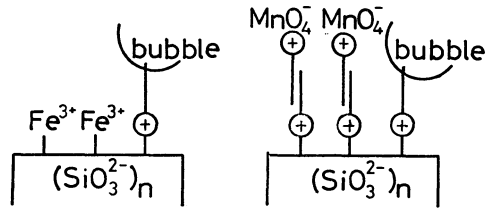

Fig. 5. Comparison of sublate structures of MnO_4^-–SiO_3^{2-}–HTAC and Fe^{3+}–SiO_3^{2-}–HTAC precipitates.

The flotation of Fe^{3+} ions was also carried out at higher Fe^{3+} concentrations near the optimum pH conditions. Thus, the effect of the order of addition of reagents upon the floatability could also be studied. The results are shown in Figs. 6, 7, and 8. As may be seen in Fig. 6, hardly any difference in the order of addition of regaents appears at the Fe^{3+} ion concentration of 6.68×10^{-5} mol/l, and the maximum floatability of 98% was obtained under the optimum conditions. In the more concentrated solution of 3.15×10^{-3} mol/l

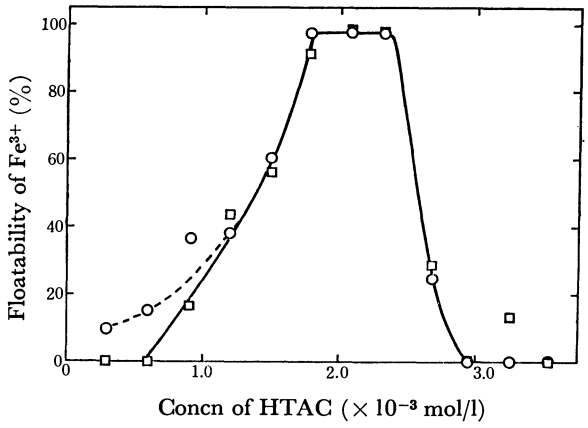

Fig. 6. Floatability *vs.* concn of HTAC for Fe^{3+}–SiO_3^{2-}–HTAC system. Fe^{3+}: 6.68×10^{-5} mol/l, SiO_3^{2-}: 1.58×10^{-2} mol/l, pH: 10.35.
—: Addition of Fe^{3+}, SiO_3^{2-}, OH^-, and HTAC in this order.
---: Addition of Fe^{3+}, OH^-, SiO_3^{2-}, and HTAC in this order.

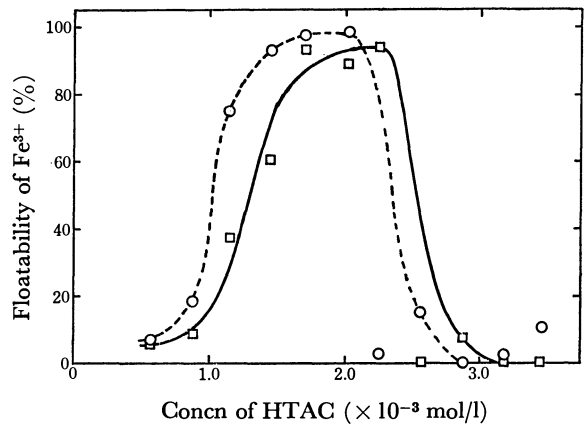

Fig. 7. Floatability *vs.* concn of HTAC for Fe^{3+}–SiO_3^{2-}–HTAC system. Fe^{3+}: 3.15×10^{-3} mol/l, SiO_3^{2-}: 1.56×10^{-2} mol/l, pH: 9.85.
—: Addition of Fe^{3+}, SiO_3^{2-}, OH^-, and HTAC in this order.
---: Addition of Fe^{3+}, OH^-, SiO_3^{2-}, and HTAC in this order.

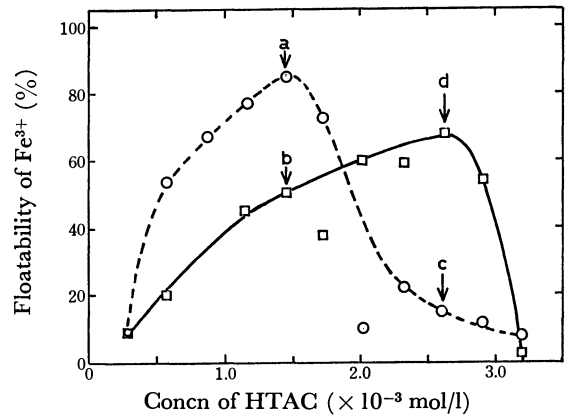

Fig. 8. Floatability *vs.* concn of HTAC for Fe^{3+}–SiO_3^{2-}–HTAC system. Fe^{3+}: 6.99×10^{-3} mol/l, SiO_3^{2-}: 1.56×10^{-2} mol/l, pH: 9.60.
—: Addition of Fe^{3+}, SiO_3^{2-}, OH^-, and HTAC in this order.
---: Addition of Fe^{3+}, OH^-, SiO_3^{2-}, and HTAC in this order.

(Fig. 7), the difference in the order of addition of reagents slightly appears. Here, in the case of the addition in the order of Fe^{3+}, OH^-, SiO_3^{2-}, and HTAC, the optimum floatability of F=98% was obtained at the HTAC concentration of 2.0×10^{-3} mol/l, while in the case of the addition in the order of Fe^{3+}, SiO_3^{2-}, OH^-, and HTAC, the optimum floatability of F=94% was obtained at the HTAC concentration of 2.0×10^{-3} mol/l. The position of peaks are the same as that of Fig. 6, but the floatability is seen to decrease slightly with the increase of Fe^{3+} ions. On further increase of Fe^{3+} ions to 6.99×10^{-3} mol/l, the floatability showed a maximum of F=85.5% at the HTAC concentration of 1.4×10^{-3} mol/l for the addition in the order of Fe^{3+}, OH^-, SiO_3^{2-}, and HTAC, while a far smaller maximum of F=67.5% was obtained at the HTAC concentration of 2.61×10^{-3} mol/l for the addition in the order of Fe^{3+}, SiO_3^{2-}, OH^-, and HTAC.

The above difference may be due to the difference in structure of the sublate formed. In order to investigate the compositions of the sublate at points *a*, *b*, *c*, and *d* in Fig. 8 and to elucidate the mechanism of flotation, the compositions of each sublate and the total precipitate were determined. These results are shown in Table 4. In the case of the addition in the order of Fe^{3+}, OH^-, SiO_3^{2-}, and HTAC, the polynuclear Fe^{3+} ions may form and combine with SiO_3^{2-}, resulting in coagulation and flotation. This may explain the effective flotation of Fe^{3+} with a smaller amount of cationic surfactant. On the other hand, each Fe^{3+} ion combines directly with a SiO_3^{2-} ion in the case of the addition in the order of Fe^{3+}, SiO_3^{2-}, OH^-, and HTAC. In this case, a larger amount of cationic surfactant is required at optimum floatability, as shown in Fig. 8. From these considerations together with the compositions given in Table 4, schematic structures of the sublate for the Fe^{3+}–SiO_3^{2-}–HTAC system have been presented in Fig. 9. As can be seen, in the case of system *a* the polynuclear Fe^{3+} ion forms, attaches to SiO_3^{2-}, and is effectively floated by HTAC, while in the case of system

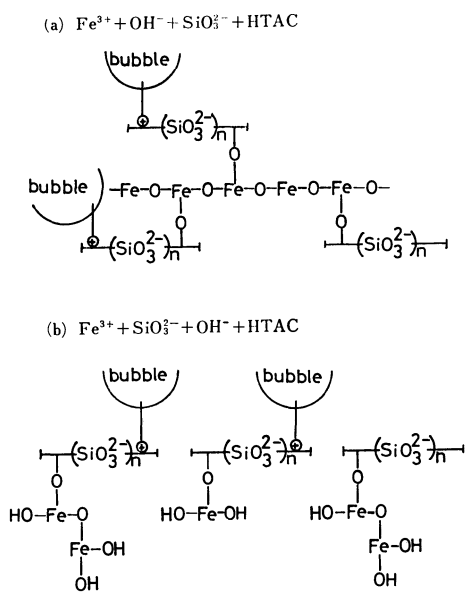

Fig. 9. Difference of sublate (precipitate) structure due to the difference of order of SiO_3^{2-} and HTAC addition.

Table 4. Sublate and precipitate compositions as affected by the order of SiO_3^{2-} and HTAC addition

No.	F (%)	Fe^{3+} (10^{-3} mol/l)[a]	HTAC (10^{-3} mol/l)	SiO_3^{2-} (10^{-3} mol/l)
a	85.6	6.89(5.98)	1.48(1.48)	13.2(12.2)
b	50.6	6.93(3.54)	1.48(1.48)	13.9(11.6)
c	15.6	6.94(1.09)	2.60(2.60)	12.8(9.60)
d	67.5	6.92(4.72)	2.60(2.60)	13.7(12.0)

( ) Indicates sublate compositions.
a) The same as mentioned in Table 1.

b, each Fe^{3+} ion combines rather directly with SiO_3^{2-} and is floated by HTAC, showing lower *F* values. In Fig. 9, the models are presented so that the numbers of moles of HTAC, Fe^{3+}, and SiO_3^{2-} in the precipitate are equal for the systems *a* and *b*. At higher concentrations of HTAC, it is evident from Fig. 9 that the increase of the composition of HTAC in the sublate *a* does not affect the wettability of the sublate (system *c*), while the increase of HTAC in the sublate *b* increases the floatability by the increase of the attachments of HTAC to the SiO_3^{2-}–Fe^{3+} complex having no HTAC (system *d*).

Equilibrium Dialysis Studies of the DNA-Acridine Complexes

Yukio KUBOTA, Yoshio EGUCHI, Kazumasa HASHIMOTO, Masaaki WAKITA, Yumi HONDA, and Yasuo FUJISAKI

Department of Chemistry, Yamaguchi University, Yamaguchi 753

(Received April 19, 1976)

The strong binding of acridine dyes with DNA was studied by means of equilibrium dialysis. Ten acridine derivatives were used to elucidate the effect of the dye structure on the nature of strong binding. In the strong binding, up to one dye molecule per 4—6 nucleotides was bound with the change of free energy in 5—9 kcal mol^{-1}. The introduction of bulky groups to the 10 or 3,6-positions of the acridine ring led to a marked decrease in both the association constant and the maximum number of binding sites per DNA phosphate. These findings suggest that, when a dye molecule is intercalated, the dye is located in such a way that the bulky groups attached to the acridine ring produce some steric hindrance to the binding.

The binding of acridine dyes to DNA has been extensively studied because of their biological activity and the general interest for the binding interaction of a macromolecule with small molecules.[1,2] It is generally believed that at least two types of binding processes are involved: weak and strong binding processes.[3] The weakly bound dye molecules are thought to be outside the double helix and stacked along the phosphate backbone.[4,5] Lerman[6,7] proposed the intercalation model for the strong binding, in which the dye molecules are inserted in a sandwich-like way between adjacent base pairs of DNA by the extension and the local unwinding of the helix. Though the general features of the model are widely accepted,[1,2] the exact location of the strongly bound dye molecules is not yet known. One of approaches to elucidate the possible location of the intercalating dye is a systematic investigation of the effects of the dye structure on the binding nature.

In the present study, the nature of strong binding was examined by means of equilibrium dialysis, using five 3,6-diaminoacridines and five 10-alkylderivatives of acridine orange. The aims of this study are: (1) to determine the thermodynamic parameters for the strong binding, (2) to reveal the effects of the dye structure on these parameters, and (3) to obtain some information on the location of the intercalative acridine dyes.

Experimental

Materials. Calf thymus DNA was purchased from Worthington Biochemical Corporation. The concentration of DNA was calculated from the absorbance at 260 nm, using the molar extinction coefficient per nucleotide residue (ε= 6600 M^{-1} cm^{-1}).[8]

Acridine orange and proflavine were obtained from Chroma and British Drug Houses, respectively. 3,6-Bis(methylamino)-acridine (Ac[NHMe]$_2$), 3,6-bis(ethylamino)acridine (Ac[NHEt]$_2$), and 3,6-bis(diethylamino)acridine (Ac[NEt_2]$_2$) were the same as previously reported.[9] 10-Alkylderivatives of acridine orange (R=methyl, propyl, pentyl, isopropyl, and benzyl) were prepared according to the method of Miethke and Zanker;[10] these are hereafter abbreviated as AO-methyl, AO-propyl, AO-pentyl, AO-isopropyl, and AO-benzyl. These dyes were purified by repeating crystallization and chromatography. Any trace of impurity was not detected by thin-layer chromatography on silica gel for each dye.

Methods. All dialysis experiments were made at ionic strengths of 0.01 and 0.11; these conditions were such that the Donnan effect could be neglected.

Both DNA and dye were dissolved in 0.005 M phosphate buffer (pH 6.9) and ionic strength was controlled by addition of NaCl solution. The DNA solutions (5 cm^3) were sealed in dialysis bags prepared from constant length (9 cm) of cellulose tubing (1.5 cm in diameter; Visking Co.) which had been cleaned by being boiled in 1% sodium hydrogencarbonate. These bags were immersed in 50 cm^3 brown flasks containing 30 cm^3 of dye solutions; the flasks had been coated with silicone to reduce the adsorption of dye. The initial dye concentrations ranged from 8×10^{-6} to 1.5×10^{-5} M except for Ac-[NEt_2]$_2$, AO-isopropyl and AO-benzyl at ionic strength of 0.11 ($(4—7)\times10^{-5}$ M). The flasks were mechanically rocked for 60 h in a thermostat.

For the determination of equilibrium dye concentration, both outer and inner solutions were analyzed because of the large adsorption of dye on the dialysis bag. The concentration of free dye (C_f) was determined from the absorbance of the outer solution at an appropriate wavelength for each system. Inner solutions were analyzed spectrophotometrically after dissociation of the DNA–dye complexes with an equal volume of 0.2 M LiCl in methanol.[11] Then the concentration of the bound dye was taken as a difference between the dye concentration of the inner solution and that of the outer solution.

All spectrophotometric measurements were made with a Shimadzu QV-50 spectrophotometer using the expanded scale whenever necessary.

For a single binding process to equivalent and independent binding sites, the following equation can be derived:[12]

$$r/C_f = K(n-r) \tag{1}$$

where r is the number of bound dye molecules per DNA phosphate, K is the association constant between a dye molecule and a binding site, and n is the maximum number of binding sites per DNA phosphate. By rearranging Eq. 1 one can obtain:

$$1/C_f = K(n/r-1). \tag{2}$$

Accordingly, a plot of $1/C_f$ against $1/r$ should give a straight line crossing the axes at $1/r=n$ and $1/C_f=-K$. If m independent binding processes are present, Eq. 2 holds for each binding and therefore one can obtain:

$$1/C_f = \sum_{i=1}^{m} K_i(n_i/r_i-1) \tag{3}$$

Then the plot of $1/C_f$ against $1/r$ cannot be linear.

Results and Discussion

Typical plots of $1/C_f$ against $1/r$ at various temperatures are shown in Figs. 1 and 2. A linear relationship

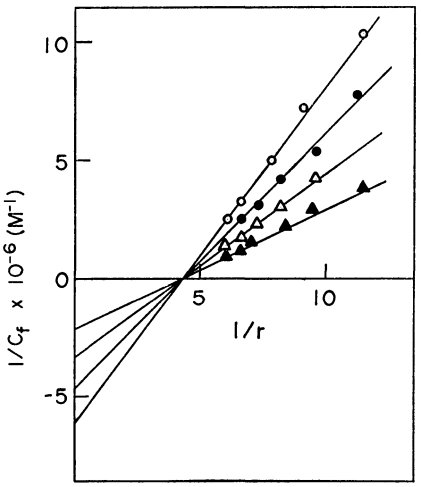

Fig. 1. Plots of $1/C_f$ against $1/r$ for the DNA–Ac[NHEt]$_2$ system at ionic strength of 0.01.
(○) 25 °C, (●) 31 °C, (△) 38 °C, (▲) 45 °C.

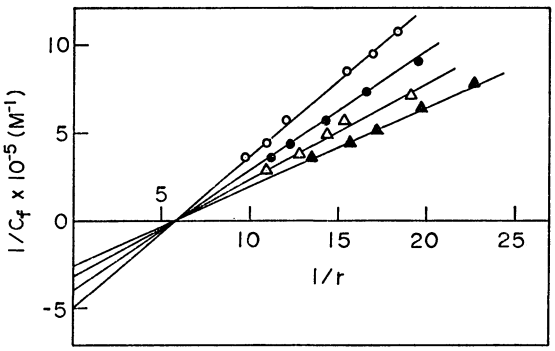

Fig. 2. Plots of $1/C_f$ against $1/r$ for the DNA–Ac[NEt$_2$]$_2$ system at ionic strength of 0.01.
(○) 25 °C, (●) 31 °C, (△) 38 °C, (▲) 45 °C.

between $1/C_f$ and $1/r$ was pretty good. From such plots, both K and n were determined by extrapolating the linear portion to $1/C_f$ and $1/r$ axes, respectively. As can be seen in Figs. 1 and 2, the K values are dependent on the temperature, while the n values seem to be constant within the experimental errors in the temperature ranges examined. In general, the $1/C_f$ *vs.* $1/r$ curves deviated from the linearity at low $1/r$ values ($r>0.2$); presumably due to the weak binding process.[4,5] Armstrong *et al.* proposed that, at low ionic strength, a binding of dye dimers takes place at high r values by binding of a second dye molecule to those already intercalated.[11] To avoid complications for the analysis of data,[11,13] we restrained our study to the range of strong binding ($r<0.15$) at relatively high ionic strengths.

Thermodynamic parameters, the change of free energy ($\Delta G°$), enthalpy ($\Delta H°$) and entropy ($\Delta S°$) were calculated using the following equations.

$$\Delta G° = -RT\ln K \quad (4)$$

$$\Delta H° = -Rd\ln K/d(1/T) \quad (5)$$

$$\Delta S° = (\Delta H° - \Delta G°)/T \quad (6)$$

A plot of log K against $1/T$ for each system gave a straight line in the temperature ranges examined (25—45 °C).

Table 1. Thermodynamic parameters at 25 °C

Dye	Ionic strength	n	$k\times10^{-5}$ (M^{-1})	$-\Delta G°$ (kcal mol^{-1})	$-\Delta H°$ (kcal mol^{-1})	$\Delta S°$ (cal deg^{-1} mol^{-1})
Proflavine	0.01	0.22	48	9.1	8.5	2.0
	0.11	0.20	3.1	7.5	8.7	−4.0

	0.11	0.20	3.4	7.5	8.8	−4.4
AO-pentyl	0.01	0.24	53	9.2	8.5	2.3
	0.11	0.20	3.7	7.6	8.6	−3.4
AO-isopropyl	0.01	0.17	15.6	8.4	6.5	6.4
	0.11	0.17	0.61	6.5	6.2	1.0
AO-benzyl	0.01	0.18	18.4	8.5	6.9	5.4
	0.11	0.18	0.63	6.5	6.5	0

The thermodynamic parameters calculated from the data of equilibrium dialysis are listed in Table 1. These results show that the thermodynamic parameters depend on the dye structure and can be summarized as follows. (1) The n values for all acridine dyes do not exceed 0.25 ($0.15<n<0.25$); this is consistent with the findings reported earlier.[13–16] (2) The value of the association constant for all 3,6-diaminoacridines, except Ac[NEt$_2$]$_2$, are of the same order of magnitude. The K and $\Delta G°$ values for the DNA–proflavine and DNA–acridine orange complexes are in good agreement with the values in the literatures.[14,15,17] (3) The thermodynamic parameters for AO-methyl, AO-propyl and AO-pentyl are almost the same as those for acridine orange. (4) The K and n values for AO-isopropyl, AO-benzyl and Ac[NEt$_2$]$_2$ are much smaller than those for the other dyes. A marked increase in the $\Delta S°$ value is observed for these dyes when compared to the $\Delta S°$ value for the other dyes. The results imply that the bulky substituents of these dyes may exert some steric effect on the binding.

Due to the presence of bulky substituents such as diethylamino and isopropyl on the acridine ring, the original intercalation model of Lerman[6,7] may be modified.[18,19] According to the model proposed by Pritchard *et al.*,[18] the positively charged nitrogen of the acridine ring associates closely with the negatively charged oxygen of the phosphate group. Therefore, it can be predicted that any substituent on the ring nitrogen strongly affects the binding. However, the results of AO-methyl, AO-propyl and AO-pentyl show no dependence on the length of the alkyl chains attached to the ring nitrogen (Table 1). On the other hand, the results of AO-isopropyl, AO-benzyl and Ac[NEt$_2$]$_2$

indicate that the introduction of the bulky groups to the 10- or 3,6-positions of the acridine ring leads to a remarkable decrease in the K and n values. Further, the smaller K value for $Ac[NEt_2]_2$ in comparison with those for AO-isopropyl and AO-benzyl (Table 1) suggests that the bulky groups attached to the 3,6-positions have more pronounced effect on the binding than the bulky groups on the ring nitrogen do. In agreement with the findings of Löber and Achtert,[20] our results may be interpreted to show that the 10-position is not so important for the strong binding and that the acridine dyes examined in this study are intercalated in such a way that the 3,6-diamino groups are directed towards the DNA phosphate groups or very close to them. In such a location, the bulky substituents at the 3,6-positions would show significant steric effect. Even in such a location, however, it is expected that the bulky groups such as isopropyl and benzyl on the ring nitrogen still produce some steric hindrance to the binding. Therefore, such bulky groups may lie in the groove of the DNA helix so as to minimize the steric hindrance. In an attempt to elucidate further the effect of the dye structure on the strong binding, flow polarized fluorescence and viscosity studies are currently in progress.

The authors are indebted to Dr. Mitsuo Zama for his valuable advice for the method of equilibrium dialysis.

Studies of Iron(II) Complexes with Several Schiff Bases: New Examples of $^5T_2$-$^1A_1$ Equilibrium

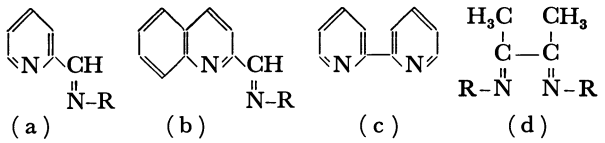
Yonezo MAEDA, Yoshimasa TAKASHIMA, and Yuzo NISHIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812

(Received September 2, 1975)

Iron complexes with the Schiff bases of quinolinecarbaldehyde and pyridinecarbaldehyde were prepared. Mössbauer spectra and magnetic susceptibilities of the compounds, $Fe(pipa)_2(NCS)_2$, $Fe(pa)_2(NCS)_2$, $Fe(pot)_2(NCS)_2 \cdot 1/2CHCl_3$, $Fe(ppt)_2(NCS)_2$, $Fe(ppca)_2(NCS)_2$, and $Fe(ppa)_2(NCS)_2$ were studied in the temperature range between 298 and 27 K. It was found that these complexes showed an incomplete $^5T_2$-$^1A_1$ transition in the solid. The compound $Fe(poca)_2(NCS)_2$ also showed a similar phenomenon. The observations of the behavior of the various complexes indicated that the magnetic changeover from spin-paired to spin-free would be closely associated with a modification of the crystal lattice. The $FeL'Cl_2$(L': the Schiff bases of quinolinecarbaldehyde) were found to have distorted tetrahedral structures.

The spectral study of a substantial series of complexes derived from the Schiff bases of 2-pyridinecarbaldehyde has already been completed.[1] The iron(II) complexes of *N*-(2-pyridylmethylene)methylamine exhibit quite similar magnetic and spectroscopic behavior to that of the iron(II) complexes of 2,2'-bipyridine and 1,10-phenanthroline. A series of iron(II) complexes with the Schiff bases of quinolinecarbaldehyde and pyridinecarbaldehyde were prepared. The spectroscopic and magnetic properties of some compounds possessing anomalous magnetic properties are reported in this work. From a structural point of view, the iron complexes with the Schiff bases of quinolinecarbaldehyde and pyridinecarbaldehyde are well correlated with those of 2,2'-bipyridine and aliphatic α,α'-diimine, *i.e.*, they all contain –N=C–C=N group which directly participates in the co-ordination. As may readily be seen in the figure, however, the Schiff bases of pyridinecarbaldehyde(a) and quinolinecarbaldehyde(b) are in an intermediate state between 2,2'-bipyridine(c), and α,α'-diimine(d) compounds with respect to the conjugated double bond.



(a) (b) (c) (d)

It has been observed that certain iron(II) complexes of 2,2'-bipyridine,[2] 1,10-phenanthroline,[3] and 2-(aminomethyl)pyridine[4] have magnetic moments which are dependent on temperature. It was suggested that the intermediate magnetic moment might be due to a thermal equilibrium between the high- and low-spin states. Recently iron(II) compounds which exhibit an incomplete $^5T_2$-$^1A_1$ transition have been reported.[5]

Experimental

Materials. Quinoline derivatives were prepared from 2-quinolinecarbaldehyde and aromatic or aliphatic amines. The preparation of the 2-quinolinecarbaldehyde was accomplished by reduction of ω,ω-dibromoquinaldine with silver nitrate.[6] 2-Pyridinecarbaldehyde was purchased from the Ishizu Pharmaceutical Co., Ltd. The ligand abbreviations used in this work are, qa for *N*-(2-quinolylmethylene)aniline, qipa for *N*-(2-quinolylmethylene)isopropylamine, qot for *N*-(2-quinolylmethylene)-*o*-toluidine, qpt for *N*-(2-quinolylmethylene)-*p*-toluidine, qea for *N*-(2-quinolylmethylene)ethylamine, qba for *N*-(2-quinolylmethylene)benzylamine, pa for *N*-(2-pyridylmethylene)aniline, pipa for *N*-(2-pyridylmethylene)isopropylamine, pot for *N*-(2-pyridylmethylene)-*o*-toluidine, ppt for *N*-(2-pyridylmethylene)-*p*-toluidine, ppna for *N*-(2-pyridylmethylene)-*p*-nitroaniline, ppca for *N*-(2-pyridylmethylene)-*p*-chloroaniline, poca for *N*-(2-pyridylmethylene)-*o*-chloroaniline, ppa for *N*-(2-pyridylmethylene)-*p*-anisidine, pba for *N*-(2-pyridylmethylene)benzylamine and ph for 2-pyridinecarbaldehyde hydrazone.

Preparations of the Complexes. The complexes were prepared by mixing iron(II) salts and the Schiff bases in an ethanolic solution.

The crystals were collected and recrystallized from water, acetone or chloroform. To avoid any possible oxidation, the procedures were carried out in a nitrogen atmosphere, using air-free ethanol. The complexes are generally stable to oxidation in the solid state. The complexes, however, were stored in a nitrogen atmosphere. The complexes prepared are listed in Table 1 together with analytical and magnetic data. Microanalyses were carried out at the Elemental Analysis Center of Kyushu University.

Measurements. Mössbauer effect measurements were made with a spectrometer described elsewhere.[7] Cobalt-57 diffused into palladium foil was used as the source. The isomer shifts, δ_N, were measured relative to the center of the spectrum of sodium nitroprusside which was used as velocity calibration. The absorbers used are very thin of approximately 0.067 mg of ^{57}Fe per cm^2 so that the saturation effect becomes negligible. The transmitted counts were stored at the rate of 60000—600000 counts per channel over a period of 18—50 h to minimize the statistical error. Magnetic susceptibilities between 77 and 295 K were measured on the polycrystalline samples by the Faraday method, while magnetic susceptibilities at 295 K were measured by the Gouy method. $HgCo(NCS)_4$ was used as the calibration substance.

Diamagnetic corrections were made for the ligands and anions. The effective magnetic moment, μ_{eff}, was obtained from the relation $\mu_{eff}=2.83\sqrt{\chi_m T}$, where χ_m is the molar susceptibility after applying diamagnetic corrections.

Reflectance and infrared spectra were obtained with apparatus described elsewhere.[8]

The conductivities of the complexes in one of solutions of acetone, chloroform and water, were measured using a Yanagimoto bridge and a cell which had been previously calibrated with aqueous KCl solutions.

TABLE 2. CONDUCTIVITY DATA OF SOME IRON COMPLEXES (10^{-3}M)

Complexes	Λ_m (mho cm^{-2} mol^{-1})	Solvent[1)]
$Fe(pa)_2Cl_2$	22.0	A
$Fe(pa)_2(NCS)_2$	4.3	A
$Fe(pot)_2(NCS)_2 \cdot 1/2CHCl_3$	0.1	A
$Fe(ppt)_2(NCS)_2$	0.1	A
$Fe(pba)_3(NCS)_2 \cdot H_2O$	149.0	W
$Fe(ph)_3(NCS)_2$	150.3	W
$Fe(poca)_2(NCS)_2$	0	C
$Fe(ppca)_2(NCS)_2$	0	C
C $Fe(ppa)_2(NCS)_2$	0	C

The measurements were performed at 25 °C. Abbreviations: A: acetone, C: chloroform, W: water.

Results and Discussion

All the complexes prepared are listed in Table 1. The results obtained by elemental analysis agreed well with the calculated values. The effective magnetic moments at 295 K are also listed in the Table 1.

Conductivities. The molar conductivities of these complexes described in Table 2 exhibit a pattern consistent with their proposed structures. The iron complexes $Fe(pa)_2Cl_2$, $Fe(pa)_2(NCS)_2$, $Fe(pot)_2(NCS)_2 \cdot 1/2CHCl_3$, $Fe(ppt)_2(NCS)_2$, $Fe(poca)_2(NCS)_2$, $Fe(ppca)_2(NCS)_2$, and $Fe(ppa)_2(NCS)_2$ were non-electrolytic in acetone or chloroform. The molar conductivities of a water solution of $Fe(pba)_3(NCS)_2 \cdot H_2O$ and $Fe(ph)_3(NCS)_2$ show that the compounds behave as uni-bivalent electrolytes. The conductivities of some of these compounds are not listed in Table 2, because they could not be determined owing to their low solubility in organic solvents.

Mössbauer Spectra. For an $Fe^{2+}(d^6)$ system, a separate Mössbauer transition could be observed for the high and low-spin states. The time of change from one spin state to the other must therefore be longer than 1×10^{-7} s, the lifetime of the ^{57}Fe excited state. The ^{57}Fe Mössbauer data obtained are given in Tables 3 and 4. The Mössbauer spectra of compounds $Fe(pipa)_2(NCS)_2$, $Fe(pa)_2(NCS)_2$, $Fe(pot)_2(NCS)_2 \cdot 1/2CHCl_3$, $Fe(ppt)_2(NCS)_2$, $Fe(ppa)_2(NCS)_2$, and $Fe(ppca)_2(NCS)_2$ at a variety of temperatures are shown in Figs. 1—6.

The values of the isomer shift and quadrupole splitting of $Fe(pa)_2(NCS)_2$ at 298 K would appear to fall in the region of those characteristic of a high-spin six-coordinated iron(II) compound. The spectrum changes to that of a low-spin iron(II) compound at 27 K, partly leaving the high-spin doublet. This result coincides well with the magnetic susceptibility data which are at intermediate values between those of high-spin and low-spin iron(II) compounds.

On the other hand, the spectrum of $Fe(pipa)_2(NCS)_2$ measured at 298 K consists of superimposed lines that are assigned to high-spin and low-spin iron(II) compounds, respectively. The spectrum changes to the spectrum characteristic of a low-spin iron(II) compound at 196 K, *i.e.*, a small isomer shift and a small quadrupole splitting are observed. The Mössbauer spectra of $Fe(pa)_2Cl_2$, $Fe(pba)_3(NCS)_2 \cdot H_2O$, and $Fe(ph)_3(NCS)_2$, which contain similar ligands, were measured for a comparison of the Mössbauer parameter. The spectrum of $Fe(ppna)_2(NCS)_2$ was also measured at 83 K and iron was found to be in the high-spin state.

In view of the strong electron acceptability of the nitro group, one would expect that the nitrogen atom of imine accepts appreciable electrons providing a strong bond with the iron atom.[9)] This expectation, however, was found to be unreasonable as can be seen from the data given in Table 3, *i.e.*, $Fe(ppna)_2(NCS)_2$ is in a high-spin state at 83 K. The differences in the field strengths were not observed for pa, and ppt. The fraction ΔS_L in Table 4 shows the ratio of the absorption

appropriate to the temperature-insensitive paramagnetism usually found for low-spin iron(II) compounds. It is concluded, therefore, that at 83 K the ground state is in the $^1A_1$ state and that this is the state populated almost exclusively. An interpretation of the magnetic data in terms of an antiferromagnetic-type exchange interaction between neighboring iron atoms is unrealistic since no reasonable fit of the curves for χ_A could be obtained for any value of the exchange coefficient J and since the Mössbauer spectra show that the population of one of the two sites increases with a decrease in temperature. On the other hand, the Mössbauer spectra of the compounds $Fe(pa)_2(NCS)_2$, $Fe(pot)_2(NCS)_2 \cdot 1/2CHCl_3$, and $Fe(ppa)_2(NCS)_2$ show that both high and low-spin states are populated at 27 K and that the transition is incomplete at 27 K (13 K for the last complex). To account for the magnetism of the cross-over compounds theoretically by applying the van Vleck approach[12] is not a good method for this system since such an attempt for systems having spin-paired and spin-free equilibria has failed.[13] For the $^1A_1$-$^5T_2$ equilibrium, the equilibrium constant K_{eq} is given by $K_{eq}=(\mu_o^2-\mu_L^2)/(\mu_H^2-\mu_o^2)$, where μ_H and μ_L are the magnetic moments of the high-spin and low-spin isomers, respectively. Plots of ln K_{eq} *vs.* $1/T$ for $Fe(pipa)_2(NCS)_2$ and $Fe(pa)_2(NCS)_2$ are given in Fig. 8. This calculation for $Fe(pa)_2(NCS)_2$ is based on the assumption that the magnetism of the high-spin state follows a normal Curie-Weiss law, $\chi_m^{corr}=3.7\times10^{-6}/(T+20)$, only over the temperature range from 250 to 300 K. Although using the limited range of temperatures available may introduce considerable uncertainties in the Weiss and Curie constants, the above equation was applied to the lower temperature and μ_H was calculated from this equation. μ_L was taken as 0.8 BM to take into account the temperature-insensitive paramagnetism. For $Fe(pipa)_2(NCS)_2$, the same equation was applied.

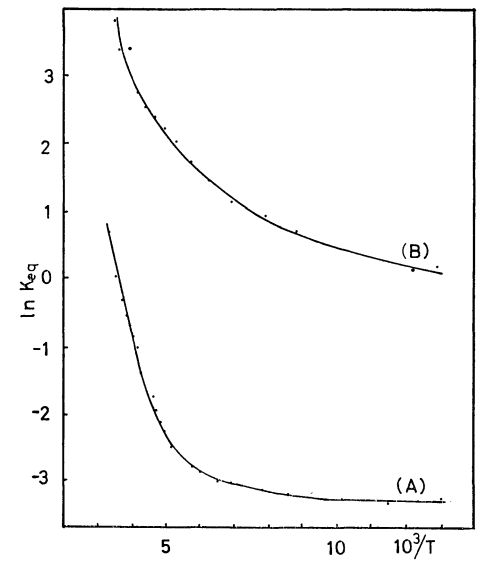

Fig. 8. Curves of ln K_{eq} against $1/T$ for (A) $Fe(pipa)_2(NCS)_2$ and (B) $Fe(pa)_2(NCS)_2$.

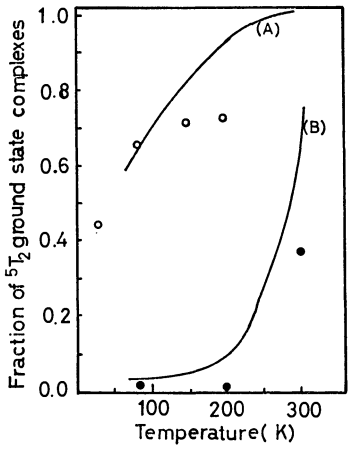

Fig. 9. Plots of the ratio of $^5T_2$ ground state complexes derived from magnetism of $Fe(pa)_2(NCS)_2$(A) and $Fe(pipa)_2(NCS)_2$(B) with temperature, and the ratio of the spectral area of the iron of high-spin state to the total area of the Mössbauer spectra of A(shown by white circle) and B(shown by black circle) at a variety of temperatures.

The fractions of the $^5T_2$ ground state complexes, n_H, derived from the magnetism of $Fe(pa)_2(NCS)_2$ and $Fe(pipa)_2(NCS)_2$, are plotted *vs.* T in Fig. 9. The ratio of the absorption area of the high-spin state to the total absorption area, ΔS_H, is also shown for various temperatures in Fig. 9. The Mössbauer spectra of $Fe(pa)_2(NCS)_2$ was also measured at 148 K using the melting point of propanol. For $Fe(pa)_2(NCS)_2$, $n_L=0.37$ was derived from the magnetic data at 83 K. On the other hand, $\Delta S_L=0.35$ was calculated from the Mössbauer absorption area under the assumption that the Debye-Waller factors, f_H and f_L, were equal. For $Fe(ppt)_2(NCS)_2$, $n_L=0.37$ and $\Delta S_L=0.34$ are calculated from the magnetic data and the Mössbauer data, respectively. It is assumed that the Debye-Waller factors, f_H and f_L, are almost equal at 83 K. Fig. 9, however, shows that at temperatures higher than 80 K, ΔS_H is less than n_H. This fact can be accounted for by the differences in the Debye-Waller factors, f_H and f_L, at higher temperatures, that is, f_H is less than f_L. The above differences would result from modifications of the crystal lattice or changes in the bond length between the central metal atom and coordinated atoms.

In the case of *N*-(2-pyridylmethylene)aniline derivatives, the fraction changed to the $^1A_1$ state at 83 K decreases in the order: ppa>pa≈ppt≈ppca>ppna. This would also be expressed by the order, $-OCH_3$> $-H\approx-CH_3\approx-Cl>-NO_2$, with respect to the substitutional group. The electron acceptor strength would be expected to increase in the order, $-OCH_3<-CH_3<$ $-H<-Cl<-NO_2$, on the basis of the sigma constant of the Hammett rule. This would seem to explain the fact that the higher electron acceptability of the functional group of the C-4 position brings about decreasing coordinating ability of the N atom in aniline.

The ΔH derived for the magnetic changes of $Fe(pipa)_2(NCS)_2$ remains constant at 3.94 kcal/mol (1380 cm^{-1}) over the temperature range of 224—273 K and is constant at 0.13 kcal/mol (45.5 cm^{-1}) between 87 and 151 K. Between 151 and 224 K ΔH changes continuously. The marked variations of ΔH of the compounds suggest a temperature dependence of the heat capacity of the compounds. Accordingly, it is conceivable that slight modifications of the crystal lattice occur in these compounds.

Electronic Spectra. The reflectance spectra of the iron complexes between 28000 and 4000 cm^{-1} were measured at 298 K. The positions of the absorption maxima are listed in Table 3. The spectra of octahedral iron(II) complexes usually show only comparatively weak bands due to the d-d transitions.[14] The $^5T_{2g}$-$^5E_{2g}$ transition band due to the high-spin form of the complexes which occurs at about 9000—12000 cm^{-1} was not observed, because of very strong charge-transfer bands. The d-d transitions for $Fe(qipa)Cl_2$ and the other substances were also not observed for the same reason, although tetrahedral iron(II) complexes are known to show usually strong band at about 5000 cm^{-1}.

Infrared Spectra. The infrared spectra of iron complexes were studied in the range between 4000 and 200 cm^{-1} at 298 K. Two strong Fe–Cl bands are observed for $Fe(qa)Cl_2$, $Fe(qipa)Cl_2$, $Fe(qot)Cl_2$ and $Fe(qpt)Cl_2$ in accordance with the IR data of $Fe(quinoline)_2Cl_2$[15] which has a tetrahedral structure. It might be assumed from this result that these complexes having $FeLCl_2$-type compositions possess a tetrahedral structure.

For N-bonded thiocyanate, the following absorption ranges are proposed:[16] ν_1 2040—2080, ν_2 465—480, and ν_3 780—860 cm^{-1}. Inspection of Table 3 indicates that in the $^5T_{2g}$ state all the thiocyanates are N-bonded. For $Fe(pipa)_2(NCS)_2$, there is another band at 2100 cm^{-1} at room temperature, which aries from the C–N stretching mode bonded to the iron atom of the $^1A_1$ state,[3] because both the high- and low-spin states are observed in $Fe(pipa)_2(NCS)_2$ at 298 K, as obtained from the Mössbauer spectra and magnetic propoerties. The splitting of the C–N stretching mode is revealed for the $^5T_2$ ground state of some of the complexes by a slight indentation of the main peak. This splitting could be considered to be a *cis*-configuration of the compound.[3] The compounds, $Fe(ppa)_2(NCS)_2$ and $Fe(poca)_2(NCS)_2$, show a sharp absorption for C–N stretching at about 2050 cm^{-1}. The compound, $Fe(pipa)_2(NCS)_2$, shows a very small splitting for C–N stretching at 2050 and 2057 cm^{-1}. This may support for the interpretation of a *trans*-configuration for the compound.

The Kinetics of the Reaction between the Chromium(III) Ion and the Ethylenediamine-*N,N,N',N'*-tetraacetate Ion in the Presence of Hydrogen Peroxide

Katsumi YAMAMOTO and Kousaburo OHASHI

Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310

(Received September 3, 1975)

The rate of the reaction between chromium(III) ion and ethylenediamine-*N,N,N',N'*-tetraacetate was found to be accelerated upon the addition of a large excess of hydrogen peroxide. Under such a condition the rate of $Cr^{III}(edta)(H_2O)^-$ formation shows a first-order dependence on the concentrations of hydrogen peroxide and chromium(III) ions, but is independent of the concentration of EDTA. The rate of $Cr^{III}(edta)(H_2O)^-$ formation catalyzed by the hydrogen peroxide increases with an increase in the pH and decreases with an increase in the acetate ion concentration. The kinetic study suggested that the initiation of the reaction takes place as follows: $Cr(III)+H_2O_2 \longrightarrow Cr(IV)+OH\cdot+OH^-$ The reaction mechanism of the hydrogen-peroxide catalysis is discussed in terms of the formation of the chromium(IV)- and /or the chronium(V)-EDTA complex in the course of the reaction. It was found that monohydroxochromium(III) is much more reactive than the chromium (III) ion toward hydrogen peroxide.

Though the reactivities of trivalent and sexavalent chromium ions with EDTA are very small at room temperature, Pribil *et al.*[1] and the present authors[2,3] have observed that $Cr^{III}(edta)(H_2O)^-$ was formed instantaneously when the chromium(VI) ion was reduced by reagents such as ascorbic acid in the presence of EDTA. This reaction was utilized for the spectrophotometric determination of the concentrations of reducing agents.[2,3]

Though the chemical properties of chromium(II), chromium(III), and chromium(VI) ions have been extensively investigated, those of chromium(IV) and chromium(V) ions are little known.[4]

Recently, Beck and Durham[5] investigated semiquantitatively the reduction of the chromium(VI) ion by hydrazine in the presence of EDTA; they suggested that chromium(IV)- and chromium(V)-EDTA complexes[6] act as intermediates in the course of the redox reaction.

The present authors found that the chromium(III) ion easily reacted with EDTA in the presence of hydrogen peroxide, as in the case of the reduction of the chromium(VI) ion by reducing agents in the presence of EDTA.

In this connection, a kinetic study of the formation of $Cr^{III}(edta)(H_2O)^-$ in the presence of hydrogen peroxide was carried out.

Experimental

Materials. A solution of chromium(III) perchlorate was prepared by the reduction of sodium dichromate in perchloric acid with hydrogen peroxide. The concentration of the chromium(III) ion was determined by the following procedure. A solution of the chromium(III) ion was heated with an excess of EDTA at 90 °C and pH 3.90 for 50 min. The concentration of the chromium(III) ion was calculated from the known molar extinction coefficient of $Cr^{III}(edta)(H_2O)^-$ at 550 nm. The stock solution of EDTA was standardized using calcium ions. The concentration of the reagent-grade hydrogen peroxide was determined by titration with a standard potassium permanganate solution. The pH and ionic strength of the reaction mixture were adjusted by the addition of an acetate buffer solution and sodium perchlorate respectively.

All the other chemicals were of a reagent grade.

Measurement of the Reaction Rate. To a chromium(III) ion solution in an Erlenmeyer flask we successively added the acetate buffer solution, the EDTA solution, and the hydrogen peroxide solution. Then this complete solution was transferred into a quartz spectrophotometer cell with a light path 1 cm in length. The temperature of the optical cells was controlled to 25±0.1 °C by circulating water through the cell holder. The kinetic measurements were carried out by recording the change in absorbance at 550 nm as a function of the time using a Hitachi EPS-3 type spectrophotometer. In every experiment hydrogen peroxide was present in a large excess relative to the concentrations of the chromium(III) ion and EDTA. The initial pH of the reaction solution was measured immediately after the initiation of the reaction with a Hitachi-Horiba F-5 pH meter. The variation in pH during the reaction was within 0.02 pH unit.

Results and Discussion

Reaction of the Chromium(III) Ion with EDTA in the Absence of Hydrogen Peroxide. The kinetics of the reaction of the chromium(III) ion with EDTA was studied by Hamm.[7] He found that the rate of the formation of $Cr^{III}(edta)(H_2O)^-$ did not depend upon the concentration of EDTA, and that it was very sensitive to the pH of the reaction mixture. Schwarzenbach and Biedermann[8] showed that one water molecule is contained in the first coordination sphere of the chromium(III)-EDTA complex. Moreover Ogino *et al.*[9,10] reported that the chromium(III)-EDTA complex was present as $Cr^{III}(edta)(H_2O)^-$ in the pH range from 3.6 to 5.3.

The dependence of the EDTA concentration on the formation rate was also examined in this work. The rate constant very slightly decreased with an increase in the EDTA concentration. The formation rate is independent of the acetate ion in the concentration range from 0.40 M to 0.05 M. Table 1 shows the first-order rate constants for the reaction between the chromium(III) ion and EDTA which were obtained in this work.

Reaction of the Chromium(III) Ion with EDTA in the Presence of Hydrogen Peroxide. The change in the absorption spectra of the chromium(III) ion solution

in the presence of EDTA upon the addition of a large excess of hydrogen peroxide is shown in Fig. 1. The change in the absorption spectra suggests that the reaction product of the chromium(III) ion is $Cr^{III}(edta)(H_2O)^-$. Curve E (45 min after the initiation of the reaction) in Fig. 1 is the absorption spectrum obtained in the absence of hydrogen peroxide. The rate of the formation of $Cr^{III}(edta)(H_2O)^-$ in the presence of

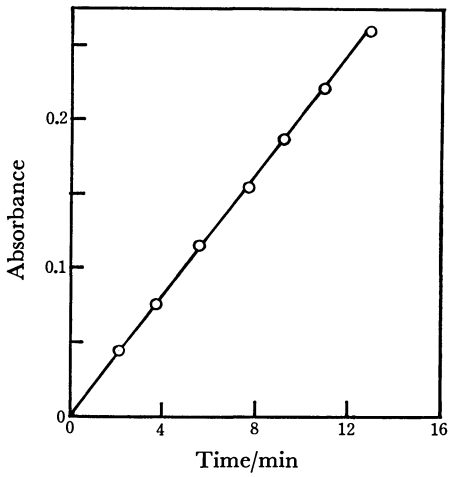

Fig. 2. Typical kinetic runs of the reaction between chromium(III) ion and EDTA in the presence of hydrogen peroxide.
$[EDTA]=2.00\times10^{-2}$ M, $[H_2O_2]=5.05$ M, $[Cr^{3+}]=7.13\times10^{-3}$ M, $[CH_3COO^-]=0.10$ M, pH 3.82, I=0.35, 25 °C, 550 nm.

hydrogen peroxide was found to be much larger than that in the absence of hydrogen peroxide.

The plot of the absorbance at 550 nm *vs.* the time were linear for at least 15% of the whole reaction (Fig. 2). Therefore, the zeroth-order rate constants of the formation of $Cr^{III}(edta)(H_2O)^-$ were determined from the initial slope of the absorbance *vs.* the time plots.

The formation rate of $Cr^{III}(edta)(H_2O)^-$ is independent of the order of the addition of the hydrogen peroxide and EDTA solutions to the chromium(III) solution.

Dependence of the Chromium(III)-ion and Hydrogen-peroxide Concentrations on the Formation Rate of $Cr^{III}(edta)(H_2O)^-$. The dependence of the concentration of the chromium(III) ion on the rate of the formation of $Cr^{III}(edta)(H_2O)^-$ was examined in the presence of a large excess of hydrogen peroxide at pH 3.82 and

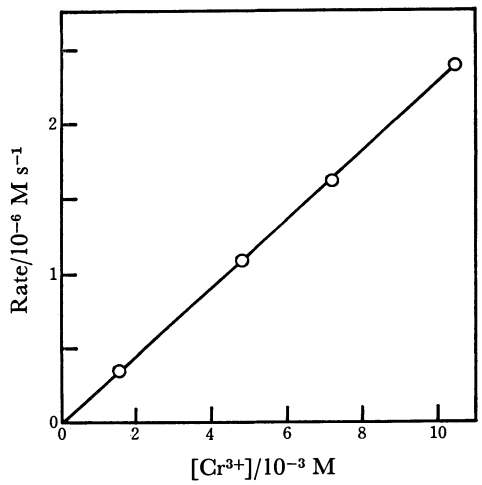

Fig. 3. The relation between the rate for the formation of $Cr^{III}(edta)(H_2O)^-$ and the concentration of chromium(III) ion.
$[EDTA]=2.00\times10^{-2}$ M, $[H_2O_2]=5.05$ M, pH 3.82, $[CH_3COO^-]=0.10$ M, I=0.35, 25 °C.

25 °C. As is shown in Fig. 3, the linear relationship between the chromium(III)-ion concentration and the formation rate indicates that the reaction rate has a first-order dependence with respect to the concentration of the chromium(III) ion. It was also found that the formation rate has a first-order dependence on the hydrogen peroxide in the concentration range 1.5 M to 5.0 M at a given pH and at a given acetate ion concentration.

Dependence of EDTA. The formation rate is independent of the EDTA concentration, as is shown in Fig. 4.

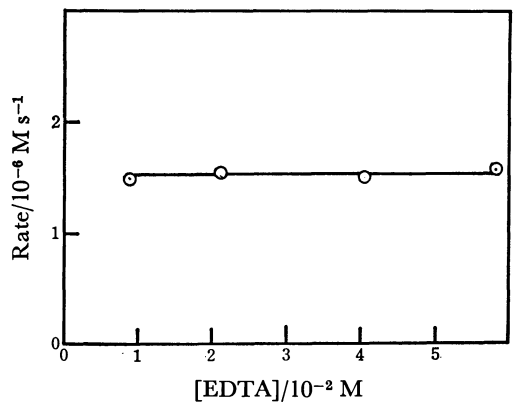

Fig. 4. The relation between the rate for the formation of $Cr^{III}(edta)(H_2O)^-$ and the concentration of hydrogen peroxide.
$[Cr^{3+}]=7.13\times10^{-3}$ M, $[EDTA]=2.00\times10^{-2}$ M, pH 3.82, $[CH_3COO^-]=0.10$ M, $I=0.35$, 25 °C.

The rate law for the hydrogen peroxide-catalyzed formation of $Cr^{III}(edta)(H_2O)^-$ is represented by Eq. 1:

$$\frac{d[Cr^{III}(edta)(H_2O)^-]}{dt} = k_{obsd}[Cr(III)][H_2O_2] \quad (1)$$

where k_{obsd} represents the observed second-order rate constant under the given conditions.

Effects of the pH and the Acetate Ion on the Formation Rate of $Cr^{III}(edta)(H_2O)^-$. The formation rate of $Cr^{III}(edta)(H_2O)^-$ in the presence of hydrogen peroxide was found to increase with an increase in the pH in the pH range from 3.30 to 4.50. It was also found that the formation rate decreases with an increase in the acetate-ion concentration. The observed second-order rate constants under various experimental conditions are listed in Table 1. These data clearly indicate a linear relationship between k_{obsd} and reciprocal concentration of the acetate ions, with an intercept at any given pH. Thus, the conditional second-order rate constant may be expressed by Eq. 2:

$$k_{obsd} = k'_{obsd} + \frac{k''_{obsd}}{[CH_3COO^-]} \quad (2)$$

The conditional rate constants, k'_{obsd} and k''_{obsd}, at the given pH are listed in Table 2.

The initiation of the reaction must take place by means of Reaction 3:

$$Cr(III) + H_2O_2 \xrightarrow{slow} Cr(IV) + OH\cdot + OH^- \quad (3)$$

For the subsequent reactions after Reaction 3 the following reaction paths are possible:

$$Cr(III) + OH\cdot \xrightarrow{fast} Cr(IV) + OH^- \quad (4)$$

the rapid complex formation step of the chromium(IV)–EDTA complex,

$$Cr(IV) + EDTA \xrightarrow{fast} Cr(IV)\text{–}EDTA \quad (5)$$

and the reduction of the chromium(IV)–EDTA complex by chromium(III) ion and/or hydrogen peroxide.

$$Cr(IV)\text{–}EDTA + Cr(III) \xrightarrow{fast} Cr^{III}(edta)(H_2O)^- + Cr(IV) \quad (6)$$

$$Cr(IV)\text{–}EDTA + \frac{1}{2}H_2O_2 \xrightarrow{fast} Cr^{III}(edta)(H_2O)^- + \frac{1}{4}O_2 + \frac{1}{2}H_2O \quad (7)$$

The possibility of the formation of chromium(V) and chromium(V)–EDTA can not be excluded. Therefore, Eqs. 8—11 may be added to Eqs. 4—7:

$$Cr(IV) + OH\cdot \xrightarrow{fast} Cr(V) + OH^- \quad (8)$$

$$Cr(V) + EDTA \xrightarrow{fast} Cr(V)\text{–}EDTA \quad (9)$$

$$Cr(V)\text{–}EDTA + Cr(III) \xrightarrow{fast} Cr(IV)\text{–}EDTA + Cr(IV) \quad (10)$$

$$Cr(V)\text{–}EDTA + \frac{1}{2}H_2O_2 \xrightarrow{fast} Cr(IV)\text{–}EDTA + \frac{1}{4}O_2 + \frac{1}{2}H_2O \quad (11)$$

No evolution of oxygen gas was observed up to about one half-life. Therefore, the possibility of Reactions 7 and 11 may be very small.

The predominant species of EDTA at pH 3.30 are H_2edta^{2-} (78%) and H_3edta^- (22%), while those at pH 4.50 are H_2edta^{2-} (97%) and $Hedta^{3-}$ (3%). Such a variation in species of EDTA does not affect the formation rate of $Cr^{III}(edta)(H_2O)^-$ in the presence of hydrogen peroxide, since the rate is independent of the EDTA concentration.

Although no detailed explanation of the effect of the acetate ion can be given, the interaction of the acetate ion with the chromium(III) ion through the formation of the hydrogen bond[11] may be one of the reasons for the retardation of the rate.

The chromium(III) ion was appreciably hydrolyzed to the monohydroxochromium(III) ion ($CrOH^{2+}$) under the present experimental conditions. Reaction 3 can be rewritten as Reaction 12:

Table 2. Conditional rate constants, k'_{obsd} and k''_{obsd} of the formation of $Cr^{III}(edta)(H_2O)^-$ at 25 °C and $I=0.35$ ($NaClO_4$)

pH	k'_{obsd} $M^{-1}\,s^{-1}$	k''_{obsd} s^{-1}
3.30	8.9×10^{-6}	6.3×10^{-7}
3.52	1.4×10^{-5}	1.5×10^{-6}
3.70	1.6×10^{-5}	2.0×10^{-6}
4.00	3.0×10^{-5}	4.0×10^{-6}
4.50	5.0×10^{-5}	1.4×10^{-5}

$$\left\{\begin{array}{c} Cr^{3+} \\ K \Big\| H^{+} \\ CrOH^{2+} \end{array}\right\} + H_2O_2 \longrightarrow Cr(IV) + OH\cdot + OH^- \quad (12)$$

Assuming the hydrolysis of the chromium(III) ion, the rate constant, k'_{obsd}, is represented by Eq. 13:

$$k'_{obsd} = \frac{k[H^+]+k_{OH}K}{[H^+]+K} \quad (13)$$

where $K(K=[CrOH^{2+}][H^+]/[Cr^{3+}])$ is the first hydrolysis constant of the chromium(III) ion and where k and k_{OH} are the second-order rate constants for the reactions involving a chromium(III) ion and a monohydroxochromium(III) ion respectively. If $k_{OH}K \gg k[H^+]$ is assumed, the reciprocal of k'_{obsd} is expressed as:

$$\frac{1}{k'_{obsd}} = \frac{[H^+]}{k_{OH}K} + \frac{1}{k_{OH}} \quad (14)$$

A plot of $1/k'_{obsd}$ *vs.* $[H^+]$ shows a linear relationship. The values of k_{OH} and K are 6.2×10^{-5} M^{-1} s^{-1} and 8.3×10^{-5} M respectively at 25 °C and $I=0.35$. The value of K has been determined to be 1.3×10^{-4} M at 15 °C.[12] The slightly smaller value of K obtained in this work compared with that in the literature may be brought about by the differences in the experimental conditions and method.

The fact that the monohydroxochromium(III) ion is much more reactive than the chromium(III) ion toward hydrogen peroxide is very similar to the observation regarding the relative reactivity of the monohydroxomanganese(III) ion and the manganese(III) ion toward $N_2H_5^+$,[13] and to that of the monohydroxocerium(IV) ion and the cerium(IV) ion toward $N_2H_5^+$.[13] The H-atom transfer mechanism was proposed for the reaction between the monohydroxocerium(IV) ion and $N_2H_5^+$.[14]

Though there is no reason for supposing that the mechanism for the reaction of the monohydroxochromium(III) ion with hydrogen peroxide is the H-atom transfer, the possibility of this mechanism can not necessarily be excluded.

Ogard and Taube[15] suggested that the chromium(IV) ion is very labile for the substitution on the basis of the kinetics of the dissociation reaction of $Cr(Cl)(H_2O)_5^{2+}$ in the presence of an oxidizing agent.

The occurrence of the hydrogen peroxide-catalyzed reaction found in this work must be ascribed to the substitution lability of chromium(IV) or chromium(V), and the large oxidizing power and stability constant of chromium(IV)–EDTA or chromium(V)–EDTA.

The authors wish to express their thanks to Mr. Shigehira Iida for his assistance in this work.

The Neutron Activation Analysis of Mercury in Soil

Souichi NAKANO,* Jukichi HONBOH, and Noriake URABE

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received October 22, 1975)

A radiochemical neutron activation procedure has been designed for the determination of mercury in soils. After the irradiation of 100 mg of soil it was decomposed with a hydrofluoric and perchloric acid mixture in a platinum crucible, and the mercury was separated radiochemically by solvent extraction from sulfuric acid·potassium iodide media into toluene, followed by precipitation as a sulfide. The radioactivity of ^{197}Hg was measured by using a Ge(Li) detector. The chemical yield, as determined by atomic absorption spectrophotometry, was high enough, and the precision was satisfactory. The detection limit is estimated to be 1—2 ppb [$(1—2)\times 10^{-10}$ g] by this method. The above procedure was applied to the determination of mercury in soils sampled in the Kumamoto and Minamata districts and in between.

The mercury contamination of soil has no less serious an influence on man and his ecosystem than do those of foodstuff, air, and water, so its detailed investigation should be pushed forward. Neutron activation analyses for mercury in various materials have been reported by a number of workers;[1] however, such analyses for mercury in soil have been few.[2]

An important step to improve the accuracy and detection limits in the activation analysis of mercury in matrices consists of radiochemical separation. Various methods have been used for separation by many investigators,—for instance, distillation or evaporation,[3-7] solvent extraction,[8,9] isotopic exchange,[5] anion exchange,[10-14] precipitation,[2,14-16] deposition,[15,17] and adsorption.[6] The present authors investigated a solvent extraction method of mercury with toluene from sulfuric acid·potassium iodide-treated samples to achieve a complete, satisfactory separation.[18] The procedure was studied in order to determine whether or not it was satisfactory in precision and detection limits. In addition, it was relatively simple and quick. The atomic absorption method was used for the determination of the chemical yield as an auxiliary means.

Because of the volatile nature of mercury and its compounds, the problem of mercury loss from a heated matrix is important; in this study it was checked by means of an atomic absorption method.

The activities of either ^{197}Hg or ^{203}Hg have generally been used for the determination. Because of the more convenient half-life, cross section, and target abundance of ^{197}Hg than ^{203}Hg (64 h, 3.1×10^3 b, 0.146% and 47 d, 4.9 b, 29.8% respectively),[19] the γ-ray of ^{197}Hg and the X-rays of ^{197}Au were measured by the present procedure.

After the method mentioned above had been established, the contents of mercury in 11 soil samples from Kumamoto and Minamata and in between were determined and discussed.

Experimental

Irradiation Facilities, Instruments, and Reagents. The samples and standards were irradiated in the S-Pipe of the JRR-4 Reactor at the Japan Atomic Energy Research Institute. The thermal neutron flux was 2×10^{13} n cm^{-2} s^{-1}. The activities were measured with a 41.5 cm^3 Ge(Li) detector (ORTEC) coupled to a 4096-channel pulse-height analyzer (Toshiba USC-1 model 10). A Perkin-Elmer model 303 atomic absorption spectrophotometer equipped with a recorder readout was used. The reagents used were of the JIS special grade from Wako Pure Chemical, unless otherwise mentioned. Doubly distilled water was used for the pre-irradiation procedure.

Procedure. Sample Preparation and Irradiation: All of the soil samples were taken from 30 cm deep, dried in the atmosphere at room temperature, ground in an agate mortar, and finally passed through a JIS 125 sieve. Into a quartz vial (5 mm$\phi\times$4 cm), 100 mg of a soil sample was placed. A standard consisted of 5.0×10^{-7} g of mercury (in the form of mercury (II) acetate in 0.1 M acetic acid), which was transferred to a quartz vial with a micropipet and absorbed onto 100 mg of silica powder (from E. Merck, Germany). All the vials were sealed with an oxygen-city gas torch. The above procedure was performed in a dustless room throughout, and the mortar, the quartz vials, and the glassware were washed with *aqua regia* and water prior to use. A standard and five samples were packed together in a polyethylene capsule; this unit was irradiated for 5 h and then left for 24 h in order to permit the short-lived nuclides to decay.

Decomposition and Radiochemical Separation: The main components of the soil seemed to be mineral granules and humus, to which mercury as a contaminant seemed to adhere *via* natural water beside that involved in the soil in nature. In any case, it was necessary to decompose the components completely for the following extraction procedure.

Irradiated vials were washed with 6 M nitric acid, water, and acetone before opening. The contents were then thoroughly transferred to a 20 ml platinum crucible. Onto the matrix 1.00 mg of mercury (in the form of mercury(II) chloride in 0.1 M hydrochloric acid) was added as a carrier. With 2 ml of 46% hydrofluoric acid and 1.5 ml of 60% perchloric acid, the sample was decomposed at 160 ± 5 °C for 45 min in an oil bath. Then 1 ml of a saturated boric acid solution was pipetted into the crucible, and the mixture was heated again for 5 min. The decomposed sample solution was transferred to a 50 ml volumetric flask, and subsequently diluted with 15 ml of 20 M sulfuric acid, 1 ml of a 5.0×10^{-2} M potassium iodide solution, and water to make 6.0 M sulfuric acid and a 1.0×10^{-3} M potassium iodide solution. The mixture was transferred to a 100 ml separatory funnel. With 10 ml of toluene added, it was shaken for 3 min by means of a mechanical shaker and then allowed to stand. After the aqueous phase had been discarded, the organic phase was washed with a 50 ml portion of the aqueous 6.0 M sulfuric acid and a 1.0×10^{-3} M potassium iodide solution. A 1 ml aliquot of the organic phase was taken for atomic absorption spectrometry in order to ascertain the recovery. With 50 ml of a 200 μg/ml mercury

* Present address: Radioisotopic Laboratory, Kumamoto University Medical School, Honjoh, Kumamoto 860.

solution (in the form of mercury(II) chloride in 0.1 M hydrochloric acid), radioactive mercury was stripped from the remaining phase, precipitated with hydrogen sulfide, and filtered by means of suction on 25 mmϕ filter paper (Toyo Roshi No. 5C).

A standard sample was processed in a manner similar to that used for soil samples.

γ-Ray Spectrometry: The filter paper with the precipitates was heat-sealed in a polyethylene sheet, and its radioactivity was measured with a Ge(Li) detector for 1000 s. For quantitations, conventional peak integration and background subtraction were applied to the 68.8 keV X-ray from ^{197}Au, and to the composite peak of the 77.6 keV γ-ray of ^{197}Hg and 78.0 keV X-ray from ^{197}Au.

Results and Discussion

The Determination of Mercury Retention after Decomposition. To determine mercury retention after decomposition process, 1 ml of a mercury(II) chloride solution (10.0 mg Hg/ml), 2 ml of 46% hydrofluoric acid, and 1.5 ml of 60% perchloric acid were added to 100 mg of soil in a 20 ml platinum crucible. Covered, it was heated in an oil bath at an appropriate temperature until the contents appeared to be transparent; then the contents were cooled to room temperature and diluted to 50 ml in a volumetric flask with water. The mercury concentration was subsequently measured by atomic absorption spectrometry.

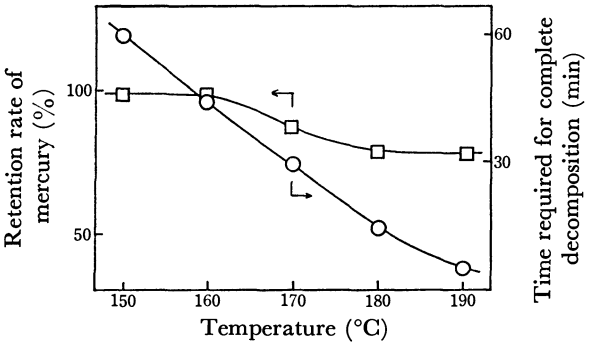

Fig. 1. Retention rate of mercury after complete decomposition of soil in a platinum crucible and the time required for *vs.* temperature. The initial contents: 100 mg of soil, 10.0 mg of mercury in the form of mercury(II) chloride, 2 ml of 46% hydrofluoric acid, and 1.5 ml of 60% perchloric acid. Determined with an atomic absorption method.

As is shown in Fig. 1, the retention rate of mercury (in the form of mercury(II) chloride) after the complete decomposition of the soil was 98% up to 160 °C and dropped toward higher temperatures, and the time required for complete decomposition became approximately 15 min shorter with each 10 °C elevation in temperature. This indicates that the optimum conditions for complete decomposition without loss were at 160 °C for 45 min.

The Determination of Extraction Curve of Mercury(II). The extractability of mercury(II) was examined as follows. To a 10 ml graduated test tube with a ground stopper, 0.5 ml of a mercury(II) chloride solution (1.00 mg Hg/ml) and appropriate volumes of 20 M sulfuric acid and either a 5.0×10^{-3} M or a 5.0×10^{-1} M potassium iodide solution were added. The contents were diluted to the 5 ml mark with water. With 5 ml of toluene added, the tube was dipped in a water bath at 20 °C for 15 min, shaken vigorously by hand for 3 min, and then allowed to stand. Each phase was then separated, centrifuged, and submitted to atomic absorption measurement.

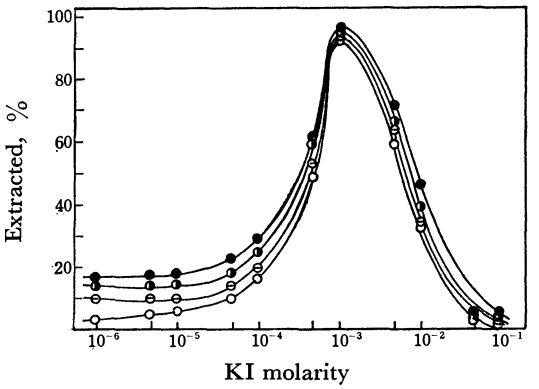

Fig. 2. Extraction curves of mercury into toluene as functions of potassium iodide and sulfuric acid concentrations. The initial mercury concentration: 100 μg/ml in the form of mercury(II) chloride in aqueous phase. Temperature: 20 °C. Determined with an atomic absorption method. ●: 8.0, ◑: 6.0, ⊖: 4.0, ○: 2.0 M sulfuric acid.

The extraction curves of mercury in Fig. 2 indicate that the maximum extraction was obtained at approximately 1×10^{-3} M potassium iodide. This concentration is somewhat higher than that reported by Byrne and Gorenc.[18] The differences in initial mercury concentration and temperature between the present method and that in the literature are 100 μg/ml, and 20 °C, and 1 μg/ml, and 25 °C, respectively.

Examples of the γ-spectra during and after the radiochemical separation procedure are given in Figs. 3 and 4 respectively. Figure 3 shows a typical spectrum of the extracted toluene phase, while Fig. 4 shows one of the final mercury sulfide precipitate. Both spectra indicate typical photopeaks of 68.8 keV (^{197}Au X-ray),

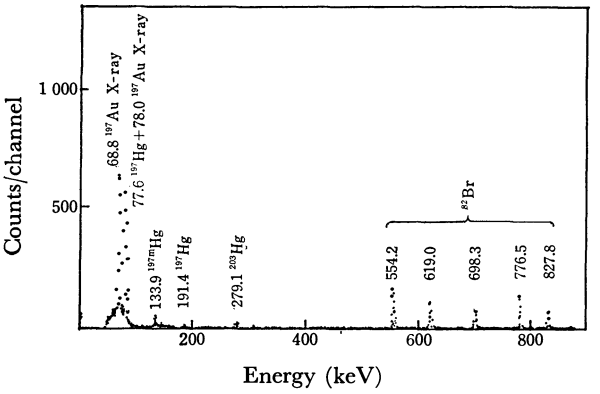

Fig. 3. An example of γ-ray spectrum of the toluene extract. Thermal neutron flux: 2×10^{13} n cm^{-2} s^{-1}, Time of irradiation: 5 h, Time of decay: 30 h, Counting time: 1000 s. Measured with a Ge(Li) detector.

TABLE 1. MERCURY CONTENTS IN SOILS COLLECTED AT 11 SPOTS BETWEEN KUMAMOTO AND MINAMATA CITIES

Spot No.	1	2	3	4	5	6	7	8	9	10	11
Mercury found (ppm)	1.87	1.01	0.74	0.84	1.03	1.32	1.25	10.3	4.9	0.36	6.6

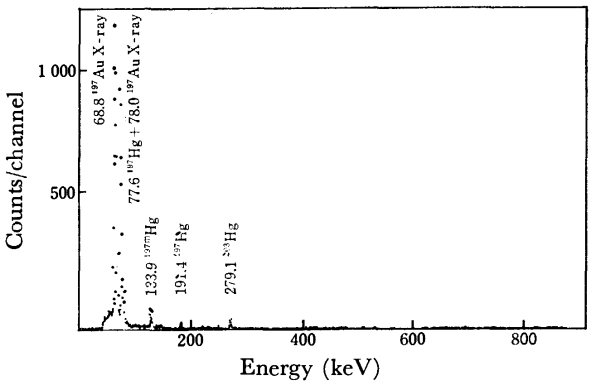

Fig. 4. An example of γ-ray spectrum of the final mercury sulfide precipitate. Time of decay: 32 h. Other conditions were the same as in Fig. 3.

77.6 keV (^{197}Hg)+, 78.0 keV (^{197}Au X-ray), and others emitted by radioactive mercuries.[20] The probable spectral overlaps of these photopeaks with those emitted by ^{169}Yb (63.5 keV), ^{182}Ta (67.7 keV), ^{153}Sm (69.6 keV), and ^{187}W (71.9 keV) were considered, but they gave no problem in this work because no others emitted by any nuclide could be detected in the spectra. In Fig. 3 there exist photopeaks emitted by ^{82}Br, which might be extracted in an oxidized form. The peak heights of radioactive mercury in Fig. 4 were about twice those in Fig. 3 as a result of the improvement in the self-shielding and geometry.

The amount of mercury in the soil was calculated by means of the following equation;

Mercury contents in soil (ppm)

$$= 5.0\times10^{2}\times\frac{1}{W_x}\cdot\frac{C_x\varepsilon_s}{C_s\varepsilon_x}\exp\{1.08\times10^{-2}\times(t_x-t_s)\}$$

where W_x is the weight of irradiated soil (mg),

C_x and C_s are the counts/1000 s of a sample and a standard respectively,

ε_x and ε_s are the absorbances of a sample and a standard with atomic absorption respectively, and

t_x and t_s are the elapsed times after the irradiation of a sample and a standard respectively (h).

The procedure described above was applied to the determination of the mercury contents in the soil sample of Spot No. 7 in Table 1, with irradiation in a capsule. The average mercury concentration, based on five replicate analyses, was 1.25 ppm, with a relative standard deviation of 3.7%. The precision was thus satisfactory. The recovery averaged 82%. The detection limit (twice the square root of the background counts under the peak of interest) is estimated at 1—2 ppb [$(1—2)\times10^{-10}$ g in 100 mg of a sample] by this method.

Furthermore, the proposed procedure was applied to the determinations of the mercury contents in 11 soil samples, which were collected on March 3, 1975, along National Route 3 between Kumamoto and Minamata cities. Duplicate analyses were made on each of the samples except for Spot No. 7; the results are summarized in Table 1. All of the procedure after irradiation was done in two days by two persons. The average of 11 determinations was 2.7 ppm, extremely high compared to those in the literature.[2] The results show that the contamination of soil with mercury has spread all over the area.

This study has been supported by a Grant-in-Aid for the Co-utilization Program of the Japan Atomic Energy Research Institute from the Ministry of Education. The authors wish to thank Mr. Takemi Takano of The University of Tokyo for his valuable technical suggestions, and Mr. Kazutoshi Mori and Mr. Yukuo Shudo of this university for their assistance during the investigation.

The Kinetic Study of the Oxidation Reaction of the Tris(2,2′-bipyridine)-cobalt(II) Ion and the Ethylenediamine-*N,N,N′,N′*-tetraacetato-cobaltate(II) Ion by the Peroxodisulfate Ion

Kousaburo OHASHI, Morito MATSUZAWA, Eichi HAMANO, and Katsumi YAMAMOTO

Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310

(Received November 26, 1975)

The kinetics of the oxidation of Co^{II}–EDTA and $Co^{II}(bpy)_3^{2+}$ by the peroxodisulfate ion ($S_2O_8^{2-}$) in acidic media have been studied spectrophotometrically; EDTA and bpy represent ethylenediamine-*N,N,N′,N′*-tetraacetic acid and 2,2′-bipyridine respectively. The stoichiometry of the reactions of Co^{II}–EDTA with the peroxodisulfate ion was $2Co^{II}\text{–EDTA}+S_2O_8^{2-}=2Co^{III}(edta)^-+2SO_4^{2-}$. The rate for the oxidation of Co^{II}–EDTA by the peroxodisulfate ion is independent of the concentration of Co^{II}–EDTA, but first-order dependent with respect to the peroxodisulfate-ion concentration. The rate law is $d[Co^{III}(edta)^-]/dt=2k[S_2O_8^{2-}]$. The rate-determining step must be the decomposition of $S_2O_8^{2-}$ into $2SO_4^{\cdot-}$. The first-order rate constant, the activation enthalpy, and the activation entropy are 5.5×10^{-8} s^{-1}, 24 kcal mol^{-1}, and -12 eu respectively at pH 3.60, 25 °C, and $I=0.50$ ($NaClO_4$). Two moles of $Co^{II}(bpy)_3^{2+}$ are oxidized by one mole of the peroxodisulfate ion. For the oxidation of $Co^{II}(bpy)_3^{2+}$, the following reaction path and rate law were proposed:

$$Co^{II}(bpy)_3^{2+}+S_3O_8^{2-}\overset{K_e}{\rightleftharpoons}[Co^{II}(bpy)_3^{2+}\cdot S_2O_8^{2-}]\overset{k}{\longrightarrow}Co^{III}(bpy)_3^{3+}+SO_4^{2-}+SO_4^{\cdot-}$$

$$Co^{II}(bpy)_3^{2+}+SO_4^{\cdot-}\overset{\text{fast}}{\longrightarrow}Co^{III}(bpy)_3^{3+}+SO_4^{2-}$$

$$\frac{d[Co^{III}(bpy)_3^{3+}]}{dt}=\left\{\frac{2k\cdot K_e}{1+K_e[S_2O_8^{2-}]}\right\}[S_2O_8^{2-}][Co^{II}(bpy)_3^{2+}]_T$$

At pH 3.60, 25 °C, and $I=0.50$ (Na_2SO_4), the rate constant, k, and the equilibrium constant, K_e, are 0.53 s^{-1} and 5.6 M^{-1} respectively. The difference in the rate law and mechanism between Co^{II}–EDTA and Co^{II}–$(bpy)_3^{2+}$ may come from the difference in charge on the cobalt(II) complexes.

A large number of investigations have been done in the field of the oxidation of metal ions,[1–3] metal complexes,[4–6] and various organic compounds[7,8] by the peroxodisulfate ion. The rate for the oxidation reactions of positively charged metal complexes such as $Fe^{II}(bpy)_3^{2+}$ [4] and $Os^{II}(bpy)_3^{2+}$ [6] by the peroxodisulfate ion is first-order dependent on the concentrations of the peroxodisulfate ion and also the metal complex. These have, however, been few of the oxidation reaction of the negatively charged metal complex by the peroxodisulfate ion. Recently, studies of the kinetics of the oxidation reaction of Co^{II}–EDTA using various oxidizing agents, for example, $Fe^{III}(CN)_6^{3-}$,[9,10] $Fe^{III}(bpy)_3^{3+}$,[11] $Fe^{III}(phen)_3^{3+}$,[11] and Mn^{III}–EDTA[11] have been carried out. Previously, the present authors have reported the kinetics of the oxidation reaction of the nitrilopolyacetate–cobalt(II) ion by chromic acid ($HCrO_4^-$) in acidic media, and suggested that the oxidation reaction proceeds through an inner-sphere mechanism.[12]

The present kinetic study of the oxidation reactions of Co^{II}–EDTA and $Co^{II}(bpy)_3^{2+}$ with the peroxodisulfate ion was carried out spectrophotometrically in order to obtain information on the behavior of the negatively and positively charged cobalt(II) complexes toward the oxidant.

Experimental

Materials. The Co^{II}–EDTA solution was prepared by adding an equivalent amount of an Na_2H_2edta solution to a cobalt(II) solution. For the preparation of the $Co^{II}(bpy)_3^{2+}$ solution, the concentration of 2,2′-bipyridine was kept at ten times that of the cobalt(II) ion.

Standard solutions of potassium peroxodisulfate were prepared by dissolving known quantities of the reagent into redistilled water. The peroxodisulfate ion solution was prepared just before use to avoid any decomposition. The adjustment of the pH of the solution was made by adding the acetate buffer solution. The ionic strengths of the solutions of Co^{II}–EDTA and $Co^{II}(bpy)_3^{2+}$ were adjusted to 0.50 by the addition of sodium perchlorate and sodium sulfate respectively.

All the other chemicals were of a reagent grade.

Measurement of the Reaction Rate. The solutions of potassium peroxodisulfate, the acetate buffer, and Co^{II}–EDTA were thermostated at a desired temperature. In each experiment, portions of these solutions were pipeted into a flask, the peroxodisulfate being added last to the solution containing Co^{II}–EDTA, and the time was counted from its addition. A portion of the solution was transferred into a 1 cm cell placed in a thermostated cell compartment of a Hitachi Model EPS-3-type spectrophotometer. The variation in the absorbance of the solution was measured at 540 nm.

The kinetic-measurements for $Co^{II}(bpy)_3^{2+}$ were performed at 420 nm by the stopped-flow technique using a Hitachi EPS-1-type rapid-scan spectrophotometer. The solution of $Co^{II}(bpy)_3^{2+}$ and the peroxodisulfate ion was thermostated at 25 °C before the initiation of the reaction.

All the kinetic experiments were carried out under the condition of a large excess of the peroxodisulfate-ion concentration with respect to the Co^{II}–EDTA and $Co^{II}(bpy)_3^{2+}$ concentration.

Results and Discussion

The Oxidation Reaction of Co^{II}–EDTA with $S_2O_8^{2-}$. Figure 1 shows the absorption spectral change of the Co^{II}–EDTA[13] solution upon the addition of a large excess of the peroxodisulfate ion under the conditions of pH 3.60 and 50 °C. The oxidation product, $Co^{III}(edta)^-$ was characterized spectrophotometrically. The stoichiometry for the oxidation of Co^{II}–EDTA by the

[Co^{II}–EDTA]=3.08×10^{-3} M.
(A) [$S_2O_8^{2-}$]=8.65×10^{-3} M, (B) [$S_2O_8^{2-}$]=2.89×10^{-2} M.

peroxodisulfate ion was confirmed spectrophotometrically as follows:

$$2Co^{II}\text{–EDTA} + S_2O_8^{2-} = 2Co^{III}(edta)^- + 2SO_4^{2-}$$

The plots of the absorbance *vs.* the time show a straight line for 80% of the whole reaction (Fig. 2). This behavior of the change in the absorbance with the time indicates that the oxidation rate is zero-order with respect to the Co^{II}–EDTA concentration. The kinetic data are shown in Table 1.

Table 1. Kinetic data for the oxidation of Co^{II}–EDTA by the peroxodisulfate ion

Concentration of Co^{II}–EDTA (10^{-3}M)	Rate[a] (10^{-6} M s^{-1})
2.0	1.2
4.0	1.2
5.0	1.2
7.4	1.3
10.0	1.2

a) [$S_2O_8^{2-}$]=8.65×10^{-2} M, pH 3.60, 50 °C, I=0.50.

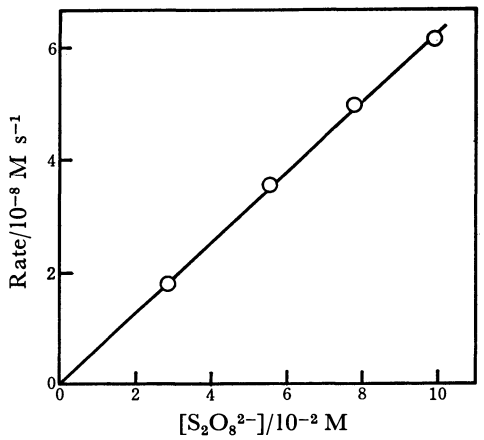

Fig. 3. Plot of the apparent rate for the peroxodisulfate oxidation of Co^{II}–EDTA *vs.* [$S_2O_8^{2-}$] at pH 3.60, 40 °C, and I=0.50 ($NaClO_4$).
[Co^{II}–EDTA]=3.02×10^{-3} M.

In order to determine the effect of the peroxodisulfate-ion concentration on the rate, the reaction was carried out at four different initial concentrations of the peroxodisulfate ion. As is shown in Fig. 3, the plot of the apparent rate *vs.* the peroxodisulfate-ion concentration shows a straight line (Fig. 3). The rate law for the oxidation reaction of Co^{II}–EDTA with the peroxodisulfate ion is represented by Eq. 1:

$$\frac{d[Co^{III}(edta)^-]}{dt} = 2k[S_2O_8^{2-}] \quad (1)$$

where k is the first-order rate constant at a given pH value. The determination of the rate constants was performed in the temperature range from 50 °C to 75 °C. The rate constant at 25 °C was obtained by the extrapolation of the Arrhenius plots. The values of the rate constant at 25 °C and 75 °C, and of the activation enthalpy and entropy, are summarized in Table 2.

The effect of the pH on the oxidation rate was investigated in the pH range from 3.50 to 5.36. Table 3

Table 2. The rate constants, equilibrium constant, and activation parameters for the peroxodisulfate oxidation of Co^{II}–EDTA and $Co^{II}(bpy)_3^{2+}$

Complex ion	Rate constant (s^{-1})	K_e (M^{-1})	ΔH^* (kcal mol^{-1})	ΔS^* (eu)
Co^{II}–EDTA	5.5×10^{-8} [a]	—	24	−12
	2.3×10^{-5} [b]			
$Co^{II}(bpy)_3^{2+}$	0.53[c]	5.6	—	—

a) pH 3.60, 25 °C, I=0.50. b) pH 3.60, 75 °C, I=0.50. c) pH 3.60, 25 °C, I=0.50.

Table 3. The rate constants for the peroxodisulfate oxidation of Co^{II}–EDTA at various pHs

pH	Rate constant[a] (s^{-1})
3.50	1.1×10^{-6}
4.10	1.0×10^{-6}
5.36	9.8×10^{-7}

a) at 50 °C and I=0.50.

shows the first-order rate constant at various pH values. The rate constant increases with a decrease in the pH value, but the variation in the rate constant is negligibly small.

The rate-determining step in the oxidation reaction of Co^{II}–EDTA with the peroxodisulfate ion must be homolytic fission into two sulfate radicals, since the oxidation rate is first-order with respect to the peroxodisulfate-ion concentration and is independent of the Co^{II}–EDTA concentration. The path for the oxidation of Co^{II}–EDTA may be represented by Eqs. 2 and 3:

$$S_2O_8^{2-} \xrightarrow{\text{slow}} 2SO_4^{\cdot-} \quad (2)$$

$$Co^{II}\text{–EDTA} + SO_4^{\cdot-} \xrightarrow{\text{fast}} Co^{III}(edta)^- + SO_4^{2-} \quad (3)$$

Kolthoff and Miller[15] investigated the kinetics of the decomposition reaction of the peroxodisulfate ion in an acidic solution. They demonstrated that the rate law for the decomposition reaction was of the form:

$$-d[S_2O_8^{2-}]/dt = k_1[S_2O_8^{2-}] + k_2[S_2O_8^{2-}][H^+]$$

and that the contribution of the second term could be neglected above pH 2.0.

The values of the rate constant and the activation parameters of the peroxodisulfate-ion oxidation of Co^{II}–EDTA are different from those of the auto-decomposition reaction.[15] No detailed explanations of the differences in the effect of the hydrogen ion, the rate constant, and the activation parameters between the peroxodisulfate-ion oxidation reaction of Co^{II}–EDTA and the auto-decomposition reaction of the peroxodisulfate ion can be given.

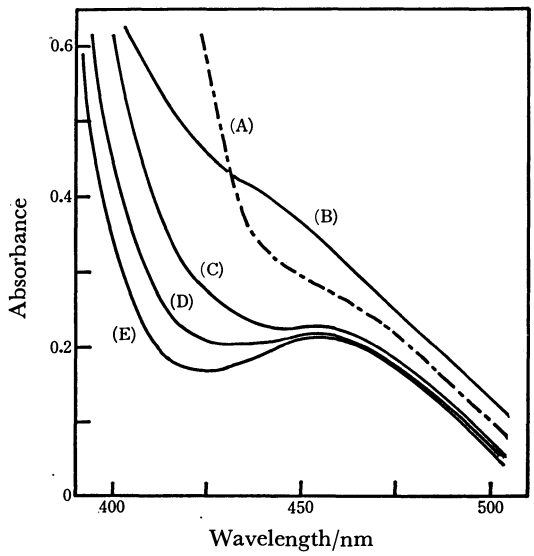

Fig. 4. Absorption spectra of the species related to the reaction of $Co^{II}(bpy)_3^{2+}$ with peroxodisulfate ion.
(A) Spectrum of $Co^{II}(bpy)_3^{2+}$ solution in the pH range from 3.10 to 6.50.
(B) Spectrum obtained for the reaction of $Co^{II}(bpy)_3^{2+}$ with peroxodisulfate ion at pH 6.50 after the completion of the reaction.
(C) Spectrum obtained for the reaction of $Co^{II}(bpy)_3^{2+}$ with peroxodisulfate ion at pH 5.50 after the completion of the reaction.
(D) Spectrum obtained for the reaction of $Co^{II}(bpy)_3^{2+}$ with peroxodisulfate ion at pH 4.03 after the completion of the reaction.
(E) Spectrum obtained for the reaction of $Co^{II}(bpy)_3^{2+}$ with peroxodisulfate ion in the pH range from 3.10 to 3.60 after the completion of the reaction.
$[Co^{II}(bpy)_3^{2+}]=3.00\times10^{-3}$ M, $[S_2O_8^{2-}]=3.00\times10^{-2}$ M.

The Oxidation of $Co^{II}(bpy)_3^{2+}$ by $S_2O_8^{2-}$. Figure 4 shows the change in the absorption spectra with the pH of the solution, which was obtained for the reaction of $Co^{II}(bpy)_3^{2+}$ with the peroxodisulfate ion. Curve E, which was obtained in the pH range from 3.10 to 3.60, coincides with the absorption spectrum of $Co^{III}(bpy)_3^{3+}$. However, the absorption spectra of the products obtained above pH 3.60 do not coincide with that of $Co^{III}(bpy)_3^{3+}$. Consequently, the kinetic measurements of the oxidation reaction were carried out at pH 3.60. The oxidation product obtained above pH 3.60 was not characterized.

The stoichiometry for the reaction of $Co^{II}(bpy)_3^{2+}$ with the peroxodisulfate ion was examined spectrophotometrically. If two moles of $Co^{II}(bpy)_3^{2+}$ are oxidized by one mol of the peroxodisulfate ion under an excess of the $Co^{II}(bpy)_3^{2+}$ concentration with respect to the peroxodisulfate-ion concentration, the absorbance (D) at a given wavelength after the completion of the reaction is shown by Eq. 4:

$$D = \varepsilon_{Co^{II}(bpy)_3^{2+}}([Co^{II}(bpy)_3^{2+}]-2[S_2O_8^{2-}]) + 2\varepsilon_{Co^{III}(bpy)_3^{3+}}[S_2O_8^{2-}] \quad (4)$$

where $\varepsilon_{Co^{III}(bpy)_3^{3+}}$ and $\varepsilon_{Co^{II}(bpy)_3^{2+}}$ denote the molar extinction coefficients of $Co^{III}(bpy)_3^{3+}$ and $Co^{II}(bpy)_3^{2+}$ respectively. At 420 nm, $\varepsilon_{Co^{III}(bpy)_3^{3+}}$ and $\varepsilon_{Co^{II}(bpy)_3^{2+}}$ are 61.0 and 157.0 respectively. At $[Co^{II}(bpy)_3^{2+}]=4.50\times10^{-3}$ M, Eq. 4 can be rewritten as Eq. 5:

$$D = 0.707 - 192[S_2O_8^{2-}] \quad (5)$$

Figure 5 shows the plots of the absorbance *vs.* $[S_2O_8^{2-}]$ at pH 3.60. The values of the intercept and slope are 0.702 and −188 respectively. This result illustrates that the overall reaction can be represented as follows:

$$2Co^{II}(bpy)_3^{2+} + S_2O_8^{2-} = 2Co^{III}(bpy)_3^{3+} + 2SO_4^{2-}$$

The plots of log (A_t-A_∞) *vs.* the time show a straight

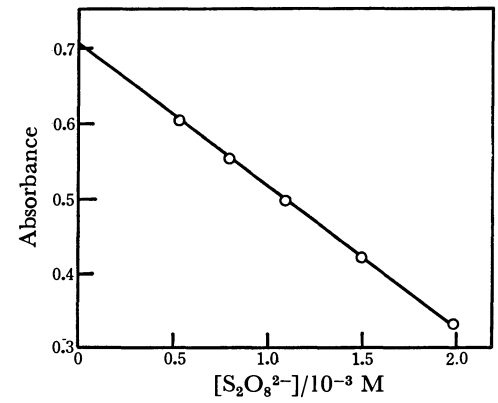

Fig. 5. Plot of the absorbance *vs.* $[S_2O_8^{2-}]$ for the reaction of $Co^{II}(bpy)_3^{2+}$ with peroxodisulfate ion. The measurements of absorbance were made at pH 3.60, 25 °C, and 420 nm.
$[Co^{II}(bpy)_3^{2+}]=4.50\times10^{-3}$ M.

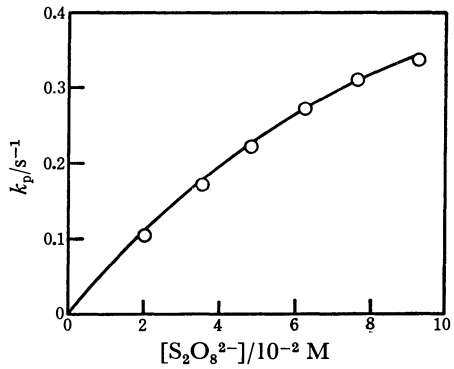

Fig. 6. Plot of the pseudo-first-order rate constant *vs.* $[S_2O_8^{2-}]$ at pH 3.60, 25 °C, and I=0.50 (Na_2SO_4). $[Co^{II}(bpy)_3^{2+}]=3.00\times10^{-3}$ M.

line for at least 80% of the whole reaction, where A_t is the absorbance at time t and A_∞, the absorbance after all the $Co^{II}(bpy)_3^{2+}$ has been oxidized to $Co^{III}(bpy)_3^{3+}$. This indicates that the rate of the oxidation of $Co^{II}(bpy)_3^{2+}$ by the peroxodisulfate ion is first-order-dependent on the concentration of $Co^{II}(bpy)_3^{2+}$. As is shown in Fig. 6, the relation between the apparent pseudo-first-order rate constants, k_p, which were evaluated from the slope of the log (A_t-A_∞) *vs.* time plots, and the concentrations of the peroxodisulfate ion is not linear. This result seems to be compatible with the existence of a pre-equilibrium between the $Co^{II}(bpy)_3^{2+}$ and $S_2O_8^{2-}$ to form an ion-pair, which then undergoes decomposition to give $Co^{III}(bpy)_3^{3+}$ and the sulfate radical ion. The reaction paths may be represented as follows:

$$Co^{II}(bpy)_3^{2+} + S_2O_8^{2-} \overset{K_e}{\rightleftharpoons} [Co^{II}(bpy)_3^{2+}\cdot S_2O_8^{2-}]$$
$$\overset{k}{\longrightarrow} Co^{III}(bpy)_3^{3+} + SO_4^{\cdot-} + SO_4^{2-} \quad (6)$$

followed by

$$Co^{II}(bpy)_3^{2+} + SO_4^{\cdot-} \overset{\text{fast}}{\longrightarrow} Co^{III}(bpy)_3^{3+} + SO_4^{2-} \quad (7)$$

No effect of the pH on the rate of the oxidation could be found in the pH range from 3.1 to 3.6. The ion-pair formation between metal complexes and the peroxodisulfate ion has been reported on the basis of the kinetic data of the oxidation reaction.[16] Furthermore, for the oxidation of $Fe^{II}(bpy)_3^{2+}$ by the peroxodisulfate ion, ion-pair formation as an intermediate was postulated.[11] The rate law for the peroxodisulfate oxidation of $Co^{II}(bpy)_3^{2+}$ is represented by Eq. 8:

$$\frac{d[Co^{III}(bpy)_3^{3+}]}{dt} = \left\{\frac{2k\cdot K_e}{1+K_e[S_2O_8^{2-}]}\right\}[S_2O_8^{2-}][Co^{II}(bpy)_3^{2+}]_T \quad (8)$$

where k and K_e are the first-order rate constant and the equilibrium constant ($K_e=[Co^{II}(bpy)_3^{2+}\cdot S_2O_8^{2-}]/[Co^{II}(bpy)_3^{2+}][S_2O_8^{2-}]$) for Reaction 6 respectively, and where $[Co^{II}(bpy)_3^{2+}]_T$ is the total concentration of the tris(2,2'-bipyridine)cobalt(II) ion. The reciprocal of the observed second-order rate constant is shown by Eq. 9:

$$\frac{1}{k_{obsd}} = \frac{1}{2k\cdot K_e} + \frac{1}{2k}[S_2O_8^{2-}] \quad (9)$$

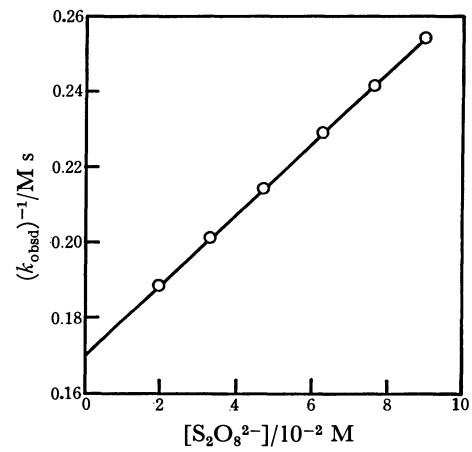

Fig. 7. Plot of the inverse of the observed second-order rate constant *vs.* $[S_2O_8^{2-}]$ at pH 3.60, 25 °C, and I= 0.50 (Na_2SO_4). $[Co^{II}(bpy)_3^{2+}]=3.00\times10^{-3}$ M.

The plot of $1/k_{obsd}$ *vs.* $[S_2O_8^{2-}]$ shows a straight line (Fig. 7). The linear plot is consistent with the occurrence of the reaction of 6 and 7. The values of k and K_e are listed in Table 2.

It seems likely that the oxidation reaction of $Co^{II}(bpy)_3^{2+}$ with the peroxodisulfate ion would proceed through an outer-sphere mechanism, since the oxidation product is $Co^{III}(bpy)_3^{3+}$.

The standard oxidation-reduction potentials for the $Co^{II}(bpy)_3^{2+}$–$Co^{III}(bpy)_3^{3+}$ couple and the $Co^{II}(edta)^{2-}$–$Co^{III}(edta)^-$ couple are 0.37 V[17] and −0.37 V[18] respectively. With regard to the standard oxidation-reduction potential, the rate for the oxidation of $Co^{II}(bpy)_3^{2+}$ by the peroxodisulfate ion is expected to be smaller than that for the oxidation of Co^{II}–EDTA by the peroxodisulfate ion. As is shown in Table 2, however, reactivity of $Co^{II}(bpy)_3^{2+}$ against the peroxodisulfate ion was found to be much larger than that of Co^{II}–EDTA. The differences in reactivity and in rate law between $Co^{II}(bpy)_3^{2+}$ and Co^{II}–EDTA may come from the difference in the charge on the cobalt(II) complexes.

Halogenation and Nitration of Some Mixed Ligand Acetylacetonatocobalt(III) Complexes

Kashiro KURODA, Kouzou YOSHITANI,* Kazufumi KUNIGITA,**
Yukiko KAMIIBA, and Kiyokatsu WATANABE
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790
(Received December 2, 1975)

In six kinds of mixed ligand acetylacetonatocobalt(III) complexes ($(NH_3)_4$-, $(en)_2$-, α-trien-, β-trien-, *fac(N)*-*i*-dtma-, and *mer(N)*-*i*-dtma-complexes†), the methine hydrogen of the coordinated acetylacetonate ion has been substituted with chlorine, bromine, and iodine, and in five of them excepting the *mer(N)*-*i*-dtma complex, it has been substituted with a nitro group. The halogenated and the nitrated complexes were isolated and identified by means of electronic absorption spectra and NMR spectra. The effects of the substitutions on the properties and the characteristics of the substitution reactions are described and discussed.

Collman and his collaborators have investigated extensively various electrophilic substitutions, such as halogenation, nitration, and acetylation at the central methine of the ligand in acetylacetonatometal complexes.[1] *N*-Halogenosuccinimides have been found to be excellent reagents for halogenation,[2] and a mixture of copper(II) nitrate and acetic anhydride for nitration.[3] However, the complexes they studied are mostly tris(acetylacetonato)metal(III) or bis(acetylacetonato)-metal(II), which are neutral and soluble in organic solvents. Only a few papers have reported that mixed ligand acetylacetonatometal complexes were substituted at the methine by electrophiles.[4] It has also been reported that the acetylacetonatobis(ethylenediamine)-cobalt(III) ion, $[Co(acac)(en)_2]^{2+}$, is not brominated even under forced conditions.[5] The present authors have recently succeeded in the bromination of *fac(N)*- and *mer(N)*-[Co(acac)(*i*-dtma)]ClO_4† with *N*-bromosuccinimide in a ethanol(50%)–water mixture.[6] Therefore, it was thought worthwhile to further examine these substitutions, using the other kinds of mixed ligand acetylacetonatocobalt(III) complexes, especially those with high positive charges. As a result, the halogenation and the nitration were accomplished without difficulty in several kinds of the cationic complexes. This report deals with the preparation and characterization of the substituted complexes and a preliminary consideration of the substitution mechanism.

Experimental

Materials, Analysis, Apparatus, and Measurements. All the chemicals used were of the reagent grade and were used without further purification. The carbon, hydrogen, and nitrogen in the synthesized complexes were analyzed by the Analytical Center of the Institute for Chemical Research of Kyoto University. The visible and ultraviolet absorption spectra were measured in aqueous solution with a Hitachi EPS-3T Recording Spectrophotometer. The optical rotations were counted with a JASCO DIP-180 Polarimeter at 589 and 405 nm. The proton NMR spectra were recorded with a Japan Electron Optics JNM-100 Spectrometer (100 MHz), using deuterium oxide as the solvent and *t*-butanol as the internal reference. The temperature of the probe was maintained at 22±1 °C.

Chlorination, Bromination, and Iodination. The halogenations were carried out using *N*-halogenosuccinimides in methanol(50%)–water or acetone(50%)–water mixtures at *ca.* 50 °C. Since the procedures of the halogenation for each acetylacetonato complex were quite similar, only a representative case will be described below.

A solution of $[Co(acac)(en)_2](ClO_4)_2$[7] (2.4 g) in 15 ml of water was mixed with a solution of *N*-chlorosuccinimide (0.8 g) in 15 ml of acetone. The mixture was stirred at *ca.* 50 °C for 30 min, and was then concentrated to *ca.* 10 ml at that temperature. A red precipitate resulted upon the addition of 1 ml of 6 M $HClO_4$ with cooling. The precipitate was recrystallized with 10 ml of warm water and the addition of a few drops of 6 M $HClO_4$. The product was washed with ethanol and ether. Yield, 1.5 g.

Nitration. The nitration was carried out in a manner similar to Collman's method for the nitration of $[Co(acac)_3]$.[8] Again, since the procedures for each complex were quite similar, only a representative case will be described.

Finely divided copper(II) nitrate trihydrate (0.7 g) was mixed into 60 ml of acetic anhydride at 0 °C and the mixture was stirred for 15 min. Into the mixture was added 1.2 g of $[Co(acac)(en)_2](ClO_4)_2$. The mixture was stirred at 0 °C for 1 h and then at room temperature for another hour. The bluish product thus obtained was poured into an ice(90 g)–water (90 g) mixture. The double liquid mixture was stirred until it became homogeneous and reddish brown (*ca.* 1 h). The solution was then concentrated to *ca.* 15 ml in a rotary evaporator below 60 °C. A brown-red precipitate resulted upon the addition of 1 ml of 6 M $HClO_4$ followed by cooling. It was recrystallized with 10 ml of warm water and the addition of a few drops of 6M $HClO_4$. The product was washed with ethanol and ether. Yield, 0.6 g.

Six kinds of mixed ligand acetylacetonatocobalt(III) complexes ($[Co(acac)(NH_3)_4](ClO_4)_2$,[7] $[Co(acac)(en)_2](ClO_4)_2$, α-$[Co(acac)(trien)](ClO_4)_2$,[7] β-$[Co(acac)(trien)]Br_2$,[7] *fac(N)*-[Co(acac)(*i*-dtma)]ClO_4,[6] and *mer(N)*-[Co(acac)(*i*-dtma)]ClO_4[6]) were attempted for their chlorination, bromination, iodination, and nitration in manners similar to that described above, and all but the nitration of *mer(N)*-[Co-

mer(*N*)-$[Co(Iacac)(i\text{-dtma})]ClO_4$	$CoC_{11}H_{20}O_8N_3ClI$	543.59	24.15	3.71	7.72	24.30	3.71	7.73

(acac)(*i*-dtma)]ClO_4 were successful. The single unsuccessful attempt at nitration was due to the insolubility of the complex in the nitration reagent. The results of the elemental analysis of the complexes obtained are shown in Table 1. (The results for the brominated species of *i*-dtma complexes have previously been reported.[6])

Preparation of $(+)_{589}$-$[Co(acac)(en)_2](ClO_4)_2$ *and Its Halogenation.* A diastereoisomer of the bis(ethylenediamine) complex, $(+)_{589}$-$[Co(acac)(en)_2][(+)_{589}$-$AsOC_4H_4O_6]_2$, was prepared by the standard method.[9] One gram of the diastereoisomer was suspended in 45 ml of ethanol and 5 ml of aqueous 2 M $NaClO_4$ was added. The mixture was stirred at *ca.* 45 °C until the solid phase changed to white (*ca.* 30 min). After the solid ($(+)_{589}$-$AsOC_4H_4O_6Na$) was removed by filtration, the orange-red filtrate was concentrated to *ca.* 10 ml, whereupon an additional white precipitate resulted, which was then removed. The filtrate was then placed overnight in a refrigerator, and the red crystals thus formed were collected and washed with ethanol and ether. Yield, 0.5 g. $[\alpha]_{589}=+478°$, $[\alpha]_{405}=-2475°$. The specific rotation was not changed by recrystallization.

The halogenation of the optical isomer was carried out in the same manner as that for the inactive complex. $[\alpha]_{589}=+506°$, $[\alpha]_{405}=-2600°$ for the chlorinated complex, $[\alpha]_{589}=+473°$, $[\alpha]_{405}=-2440°$ for the brominated complex, and $[\alpha]_{589}=+460°$, $[\alpha]_{405}=-2395°$ for the iodinated complex.

Results and Discussion

Absorption Spectra. The absorption spectra of $[Co(acac)(en)_2](ClO_4)_2$ and its halogenated and nitrated species, as well as those of $[Co(acac)_3]$ and $[Co(Xacac)_3]$ (X=Cl, Br, I, NO_2) are shown in Figs. 1 and 2. The spectra of the other set of complexes with the same ammine or amine ligand have patterns quite similar to those of the set of bis(ethylenediamine) complexes, some of which have been presented elsewhere.[6,7,10] The numerical values of the absorption maxima are summarized in Table 2.

Since the halogenation and nitration of $[Co(acac)_3]$ have been well-established, the spectral variations observed between the spectrum of $[Co(acac)_3]$ and those of $[Co(Xacac)_3]$ may be adopted as an indication of the substitutions at the methine of the ligand. Thus, as may be seen in Fig. 1 and Table 2, the wave numbers

of the first bands of $[Co(Xacac)_3]$ (X=Cl, Br, I) are nearly equal to that of $[Co(acac)_3]$, whereas the intensities of the formers are rather higher than that of the latter. The specific band arising around 30×10^3 cm^{-1} (which has been attributed to the transition of an electron from the metal t_{2g} to the ligand π^* orbitals[11]) shifts to lower wave numbers with nearly equal intensity upon halogenation. These spectral movements are observable, with a slightly modified and rather pronounced feature, between the spectra of each group containing an acetylacetonato complex and its halogenated species, as may be seen in the figure and the table.

The spectral shift of $[Co(O_2Nacac)_3]$ from $[Co(acac)_3]$ may be summarized as follows. First, the first band shifts to a higher wave number with an increase in the band intensity. Second, the specific band expands with a considerable deformation of the band feature, and no clear maximum is observable. This expansion and deformation probably comes from an overlap of the absorption of the nitro group (*ca.* 27×10^3 cm^{-1}) onto the $\pi^*\leftarrow t_{2g}$ band. These spectral variations are also observable in each spectrum of the nitrated complexes, although the increase in intensity of the first band is very small in a few cases.

Thus, the absorption spectra, together with the results of the elemental analysis and NMR spectra described

below, indicate that all the acetylacetonato complexes studied have been substituted by halogens and all but *mer*(*N*)-[Co(acac)(*i*-dtma)]ClO_4 by a nitro group at the methine of the ligand. The spectral relationships for the complexes can be summarized as follows:

(1) with respect to the first bands,

$$\bar{\nu}_{acac} \simeq \bar{\nu}_{Clacac} \simeq \bar{\nu}_{Bracac} \simeq \bar{\nu}_{Iacac} \text{ and } \bar{\nu}_{acac} < \bar{\nu}_{O_2Nacac}$$

$$\varepsilon_{acac} < \varepsilon_{Clacac} < \varepsilon_{Bracac} < \varepsilon_{Iacac} \text{ and } \varepsilon_{acac} \leqslant \varepsilon_{O_2Nacac}$$

(2) with respect to the specific bands,

$$\bar{\nu}_{acac} > \bar{\nu}_{Clacac} \simeq \bar{\nu}_{Bracac} > \bar{\nu}_{Iacac}$$

$$\varepsilon_{acac} \simeq \varepsilon_{Clacac} > \varepsilon_{Bracac} > \varepsilon_{Iacac}$$

NMR Spectra. The proton NMR spectra were measured to further verify the substitutions at the methine of the ligand. The resonances of the methine protons observed around 4.5 ppm in the spectra of the unsubstituted complexes disappeared completely in those of the substituted complexes, supporting our identification. As an illustration, a set of representative spectra is shown in Fig. 3.

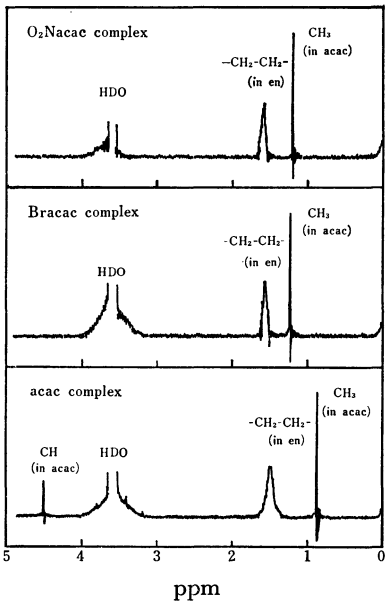

Fig. 3. NMR spectra of $[Co(acac)(en)_2](ClO_4)_2$ and its brominated and nitrated species.

Preparation. Acetylacetonatobis(ethylenediamine)-cobalt(III) is usually obtained as an iodide salt owing to its ease of isolation.[9] Bromination of the iodide salt was also attempted using *N*-bromosuccinimide. However, a redox reaction appeared to occur simultaneously, and the reaction product was too complicated to isolate the brominated species. The perchlorate salt is more soluble in water than the iodide, and is very soluble in methanol, ethanol, and acetone, especially when it is wet. Therefore, the perchlorate is a little difficult to handle in its preparation. However, this property is rather suitable for the substitutions, and no trouble was found in this regard. The property was also utilized to convert $(+)_{589}$-$[Co(acac)(en)_2][(+)_{589}$-$AsOC_4H_4O_6]_2$ into $(+)_{589}$-$[Co(acac)(en)_2](ClO_4)_2$. The lack of success in the bromination of $[Co(acac)(en)_2]^{2+}$ by Collman *et al.*,[5] although the detail of their procedure is not available, is assumed to be due simply to an unsuitable counter anion. A more or less similar situation was experienced for the other acetylacetonato complexes, and since β-$[Co(acac)(trien)](ClO_4)_2$ is especially soluble in the organic solvents, the bromide salt, which is a little easier to handle in isolation, was used as the starting substance.

The halogenated and nitrated species, in general, are less soluble in water and have better crystallizability than their parent complex. Thus, in the cases of the halogenations, the substituted complex sometimes appears as crystals during the reaction.

Characteristics of the Substitution Reactions. Because of the very similar behavior of the chelated acetylacetonate ion to that of the aromatic hydrocarbons, it is widely accepted that these substitution reactions are ionic rather than radical processes. It has therefore been argued[4a] on this assumption that, because of the electrostatic interaction between the substrates and the electrophiles, cationic acetylacetonatometal complexes are more resistant to substitutions at the methine than neutral and anionic complexes. However, our results indicate that this is not necessarily true, since the substituted complexes were obtained easily and without distinct differences in yields by similar procedures for substrates which were unipositive and dipositive. A quantitative comparison of the rate of chlorination also indicated that the charge of the complex was not a dominant factor in the substitution,[10] and rather the degree of distortion from the regular octahedron structure appeared to be more influential since the dipositive β-trien complex was the most reactive. The following is a possible explanation for this minor effect of the net charge of the complex upon the reactions.

According to the Pauling electroneutrality principle, the net charge of a complex ion is distributed among the atoms which exist on the surface of the ion. Thus, the methine hydrogen must be more positive, as the net

charge of the complex ion increases. This means that the methine carbon in the more positive ion is possibly the more negative and is the more reactive with the electrophilic reagents. It may be considered that the increase in reactivity compensates the effect of the electrostatic repulsion between the complex cation and the electrophile.

In order to examine the above consideration and to clarify the reaction pathway, some kinetic measurements were carried out on the chlorination of $[Co(acac)(en)_2]^{2+}$. A spectral change is illustrated in Fig. 4 and the concentrations of the complex during the reaction were obtained from the optical densities at 343 nm. The result of the measurements is summarized in Table 3.

In order to obtain the rate constant, it was at first assumed that the reaction was of the second order and obeyed the quation,

$$k = \frac{2.303}{(b-a)} \frac{1}{t} \log \frac{a(b-x)}{b(a-x)}$$

where a and b are the initial concentrations of the reactant complex and *N*-chlorosuccinimide (NCS), respectively. However, the values of k calculated at different times in a run are not in agreement, but decrease as the time increases. Since the isosbestic points at 290 and 333 nm were strictly maintained during the reaction, it is certain that the only reaction of the reactant complex was the chlorination. Therefore, the cause of the decrease in k with time must reside in a reaction of NCS, which consumes NCS without chlorinating the complex. This assumption was confirmed by an equimolar experiment (No. 11), in which x_∞ was not 100%, but 80.8%. Thus, the kinetic equation can be assumed to be

$$\frac{dx}{dt} = k(a-x)(b-(1+c')x) = k(a-x)(b-cx)$$

and

$$k = \frac{2.303}{(b-ac)} \frac{1}{t} \log \frac{a(b-cx)}{b(a-x)}$$

where c can be estimated from the equimolar experiment as

$$\frac{19.2}{80.8} = \frac{c'}{1} \qquad c = 1 + c' = 1.238$$

With this approximation, the values of k in a run agree to within 3% of each other and the values thus obtained are tabulated in the table.

Several characteristics can be pointed out from the table.

(1) Without NCS, the reactant complex, involving the optical active complex, is stable under the conditions of these experiments. (No. 9).

(2) The rate in the ethanol(50%)–water mixture is considerably smaller than those in aqueous solutions. (No. 6).

(3) An increase in the concentration of $HClO_4$, as well as of $NaClO_4$, hardly accelerates the velocity. (Nos. 4, 5).

(4) The optically active isomer reacts with the same velocity as the inactive complex, as expected. (No. 8).

(5) The optical rotation increases with the evolution of the reaction, and α_∞ is identical with the value calculated from the rotation of the isolated active $[Co(Clacac)(en)_2](ClO_4)_2$. (No. 10).

The kinetic equation and these characteristics of the reaction may, as a whole, indicate that the reaction proceeds with a direct attack of NCS molecule onto the substrate, for which no bond rupture between the metal and the ligands is involved as an activation process. It is also supposed that the dipolar water molecules surrounding the reactants have sufficient power to activate the reactant ions and molecules.

Studies on Pulse Polarography. IV. Normal Pulse Polarographic Behavior of Fe(II) in an Unbuffered Medium and Catalytic Wave for Fe(II)-Chlorate System

Sadayuki HIMENO

Department of Chemistry, College of General Education, Kobe University, Nada-ku, Kobe 657

(Received January 26, 1976)

The normal pulse polarogram of Fe(II) showed a double-wave behavior in an unbuffered solution containing iodate. The results of pulse polarographic and cyclic voltammetric studies indicate that colloidal $Fe(OH)_2$ formed by the reaction between aqua-Fe(II) and OH^- arising from the iodate reduction is responsible for the second wave. A catalytic wave was observed in the presence of chlorate in Tast polarography. The catalytic wave which appears to be a polarographic maximum, has an abnormal form, in which the current increases at every second or third drop because of the depletion of colloidal $Fe(OH)_2$ around the electrode. The catalytic current is due to the reaction of chlorate with colloidal $Fe(OH)_2$ formed in the vicinity of the electrode.

Pulse polarography developed for differentiating the faradaic and charging currents has a better sensitivity as compared with DC polarography and is suitable for trace analysis. In normal pulse polarography, successively increasing potential pulses are applied to the electrode, one pulse per drop with DME, from the initial (resting) potential, which is generally chosen in the potential region where no faradaic process occurs. A current-voltage curve in normal pulse polarography is quite similar to that obtained by current-sampled DC (Tast) polarography.

It has been established that dissolved oxygen is reducible at DME so that high concentration of OH^- is generated at the electrode surface in neutral, unbuffered solution. In the course of the pulse polarographic study of iron-group metals in an unbuffered solution containing dissolved oxygen, it was observed that colloidal $Ni(OH)_2$ generated around the electrode gives an unusual peak on the normal pulse polarogram.[1]

During the investigation of normal pulse polarographic behavior of Fe(II) in an unbuffered solution, it was found that in the presence of colloidal $Fe(OH)_2$, chlorate gives the current enhancement due to the catalytic process, the nature of which was quite analogous to the nitrate system.[2] Iodate was used in the case of Fe(II) since dissolved oxygen shows a marked trend to oxidize Fe(II) to Fe(III).

In order to explain the nature of chlorate catalytic wave observed on Fe(II) reduction wave in an unbuffered medium containing dissolved oxygen, Ruvinskii *et al.* postulated a catalytic reaction with participation of Fe(0) hydroxo complex deposited on the electrode surface.[3] They assumed a catalytic regeneration of Fe(II) hydroxo complex in order to explain a large increase of current.

This paper describes the normal pulse polarographic behavior of Fe(II) in unbuffered solutions containing iodate and also the characteristics of the catalytic current induced by colloidal $Fe(OH)_2$ because their mechanism is not consistent with the results obtained. The mechanism of the process is presented.

Apparatus and Reagents

Apparatus. Polarographic measurements were carried out with a Princeton Applied Research Polarographic Analyzer, Model 174 in conjunction with the Linear Sweep Module Accessory, Model 174/51. This module, which synchronizes the potential scan with DME, permits the scan to start after pre-selected interval during the growth of a drop and to be completed within the lifetime the of drop. The drop time was controlled using a Mechanical Drop Timer, Model 172-A. Polarograms were recorded on a Riken Denshi X-Y Recorder, Model D-8C. The capillary employed had a $m^{2/3} \cdot t^{1/6}$ of 1.45 $mg^{2/3}\,s^{-1/2}$ in 0.1 M KNO_3 solution in an open circuit. One mercury drop was used for HMDE and a fresh drop was suspended from the tip of a mercury plated platinum wire for each measurement unless otherwise stated. The pH of the solution was measured with a Toa Denpa pH Meter, Model HM-8. An external saturated calomel electrode (SCE) was used as a reference electrode. Nitrogen was used to remove dissolved oxygen from the solution. The cell was immersed in water bath maintained at 25 ± 0.1 °C.

Reagents. All chemicals were of reagent grade and were used without further purification. Water used for preparation of the solutions was de-ionized on an ion-exchange resin bed and then distilled twice with a quartz apparatus.

Results

Normal Pulse Polarographic Behavior of Fe(II) in Unbuffered Solutions Containing Iodate. A typical normal pulse polarogram of 0.6 mM Fe(II) in 0.1 M KCl containing iodate (pH 5.1) is shown in Fig. 1. The reduction of iodate under these conditions proceeds as follows.[4]

$$IO_3^- + 3H_2O + 6e = I^- + 6OH^- \quad (E_{1/2} = -1.1\ V)$$

When the initial potential was set at -0.70 V, more anodic than the reduction potential of iodate, the normal pulse polarogram of Fe(II) consisted of only one wave with half-wave potential of -1.41 V. However, when the initial potential was chosen in the potential region where the reduction of iodate took place, the polarogram of Fe(II) had two waves. The second wave, which had a peak at the potential of -1.58 V disappeared completely by buffering the solution, indicating that the wave was due to the effect of OH^- arising from the reduction of iodate.

The relationship between the wave heights and pH of the solution is given in Fig. 2. Only a single-step reduction wave was obtained below pH 3.8 since no local high pH values occurred at the electrode. On increasing pH, the peak height of the second wave

increased and reached its limiting value in the pH range 4.8—6.0. The second wave decreased in height above pH 7.0 because of the precipitation of $Fe(OH)_2$ ($K_{sp} = 10^{-15}$).[5] The first wave obtained when the initial potential was set at −0.70 V was always greater than that obtained at −1.20 V and decreased gradually with increasing pH in the whole pH range studied. This indicates that the concentration of aqua-Fe(II) decreases around the electrode due to hydrolysis at the initial potential.

Figure 3 shows the wave heights as a function of Fe(II) concentration. It was found that the first wave increases almost linearly with Fe(II) concentration up

to 3 mM but starts asymptotically from the origin, while the relation between the second wave and Fe(II) concentration is not linear.

With a given Fe(II) concentration, the peak current of the second wave increased almost linearly with iodate concentration up to approximately 0.25 mM. Above this concentration, the second wave went through a maximum and then decreased as shown in Fig. 4, while the first wave decreased gradually on increasing iodate concentration.

From the results, it can be assumed that the first wave corresponds to the reduction of aqua-Fe(II) and the second to that of $Fe(OH)_2$ formed chemically between aqua-Fe(II) and OH^- in the vicinity of the electrode at the initial potential. It was also found that the peak height of the second wave decreases with increase in

the concentration of the supporting electrolyte. This can be explained by the assumption that the coagulation of colloidal $Fe(OH)_2$ occurs and $Fe(OH)_2$ in the flocculated state can no longer be reduced. It can be confirmed by the fact that colloidal $Ni(OH)_2$ shows a similar behavior, its solubility being almost the same order as that of $Fe(OH)_2$.[1)]

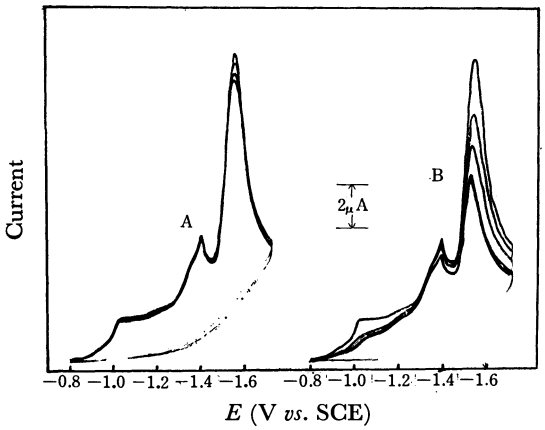

Fig. 5. Linear sweep voltammograms of 0.4 mM Fe(II) in 0.1 M KCl (pH 5.0) containing 0.08 mM iodate at DME.
A) With violent agitation of capillary. B) With mild agitation of capillary.
Pre-selected time; 1 s, Scan rate; 200 mV/s.

A periodical alternation of high and low currents appeared at every second drop with mild agitation of capillary (Fig. 1). The unusual phenomenon was also investigated by means of linear sweep voltammetry at DME. The current-voltage curve exhibited the same two peaks with peak potentials, −1.40 and −1.55 V, respectively as observed in normal pulse polarography (Fig. 5). On increasing iodate concentration, the first wave decreased with an increase of the second one. This might be ascribed to the reduction of colloidal $Fe(OH)_2$ formed in the vicinity of the electrode. Reproducible current-voltage curves were obtained in the multiple cathodic scans either when the capillary was agitated violently or when the solution was stirred with a magnetic stirrer. However, with mild agitation of the capillary, the second peak decreased gradually in the multiple scans. The results suggest that the reproducible production of colloidal $Fe(OH)_2$ at every drop cannot be obtained in a quiet solution.

In order to clarify the nature of Fe(II)–OH^- system, a number of cyclic voltammetric studies have been carried out with the use of HMDE. Table 1 gives the relationship between scan rates and peak currents of 0.4 mM Fe(II) in 0.1 M KCl containing 0.1 mM iodate. The value of $i_p/v^{1/2}$ is practically constant for the first wave, indicating that the process was diffusion controlled. However, the peak current of the second wave shows an abnormal current increase at greater scan rates.

Chlorate Catalytic Wave in Tast Polarography. Fe(II) in unbuffered solutions catalyzes the reduction of chlorate in Tast polarography (Fig. 6). This catalytic wave did not yield a limiting current but showed a

maximum (peak) on the rising portion of Fe(II) reduction wave. The average peak current obtained in DC polarography was practically independent of the height of the mercury reservoir. Its temperature coefficient was +4.9% per degree, indicating that the current was kinetically controlled.

The relationship between the catalytic currents and chlorate concentration with 0.4 mM Fe(II) in 0.1 M KCl at different concentrations of iodate is shown in Fig. 7.

The catalytic wave could be obtained in the pH range 4.1—6.5, the range agreeing closely with that at which the second wave was obtained in normal pulse polarography (Fig. 2).

The catalytic wave decreased with an increase in the concentration of the supporting electrolyte and disappeared on buffering the solution.

Figure 8 shows the effect of iodate concentration on the catalytic wave. At the same Fe(II) and chlorate concentrations, the catalytic wave first increased and then decreased gradually when the iodate concentration was increased beyond 0.25 mM. This effect is in line with the observation made on varying iodate concentration in normal pulse polarography (Fig. 4).

The current-time curves of an individual drop at various potentials for the catalytic wave were recorded. The instantaneous i-t curves show the current increase at every second or third drop. However, the current

increased at every drop when the solution was stirred. This anomalous behavior is quite similar to recent observations on the nitrate system.[2)]

Cyclic voltammetric investigations with HMDE were carried out in order to investigate more precisely the role of $Fe(OH)_2$ in the reduction of chlorate. Figure 9 shows the current-voltage curve (B) recorded in the solution 0.4 mM Fe(II) in 0.1 M KCl containing 1 mM chlorate and 0.25 mM iodate. The curve shows two peaks with peak potentials, −1.22 and −1.56 V, respectively. The first wave is ascribed to the catalytic wave, probably involving the discharge of aqua-Fe(II), the second one being responsible for the reduction of colloidal $Fe(OH)_2$. When the cathodic potential scan was carried out up to −1.4 V (more positive than the second wave), the catalytic wave continued to increase in height in the multiple cathodic scans. However, when colloidal $Fe(OH)_2$ was electroreduced in the first scan, the catalytic wave could no longer be observed in the following scans. Similarly, in the absence of iodate, the curve corresponded to the reduction of aqua-Fe(II) (curve (A) in Fig. 9). This indicates that if iron exists as colloidal $Fe(OH)_2$ around the electrode, the catalytic reaction can take place.

The heights of the peaks obtained after the initial electrolysis at various potentials are shown in Fig. 10. When the initial electrolysis was carried out at a potential between −1.05 and −1.35 V for 0.4 mM Fe(II) in 0.1 M KCl containing 1 mM chlorate, the current-voltage curve was found to be almost the same as the one obtained in the presence of both iodate and chlorate (curve (B), Fig. 9). Similar experiments were carried out for 0.4 mM Fe(II) in 0.1 M KCl containing 0.04 mM iodate. The results are also shown in Fig. 10. We see that the first wave (the reduction wave of

aqua-Fe(II)) decreases in the potential region between −1.25 V and −1.40 V, since aqua-Fe(II) is partly reduced directly to Fe(0) at the initial potential and the concentration of aqua-Fe(II) diminishes around the electrode. The second wave (the reduction wave of colloidal $Fe(OH)_2$) then appears after the initial electrolysis at potentials more positive than the reduction potential of aqua-Fe(II).

Discussion

On the basis of pulse polarographic and cyclic voltammetric experiments, we can assume that the main product of the reaction between aqua-Fe(II) and OH^- produced around the electrode is colloidal $Fe(OH)_2$, which is responsible for the second wave. This assumption is also supported by the thermodynamic data that the formal potentials of Fe(II)/Fe(0) and $Fe(OH)_2$/Fe(0) are equal to −0.44 and −0.88 V, respectively.[5]

It has been established that the initial adsorption of the depolarizer produces an unusual peak on the normal pulse polarogram.[6–9] Wopschall and Shain have also stated that a significant increase in the current function at faster scan rates is an indication of the presence of weak adsorption in cyclic voltammetry with HMDE.[10] Thus, from the shape of the normal pulse polarogram and the results in Table 1, we can conclude that colloidal $Fe(OH)_2$ is adsorbed weakly on the electrode surface at the initial potential. This is in line with the work of Dahms, who reported the presence of adsorption of $Fe(OH)_2$ on DME by means of galvanostatic charging curves.[11]

From the fact that the peak currents of the second wave are about 30 μA in both normal pulse polarography (Fig. 4) and cyclic voltammetry (Fig. 10), the second wave might be ascribed to the discharge of both adsorbed $Fe(OH)_2$ and colloidal $Fe(OH)_2$ in the neighborhood of the electrode but not to the discharge of adsorbed $Fe(OH)_2$ only.

Ruvinskii *et al.*[3] postulated that the current enhancement with chlorate is due to the chemical reaction between chlorate and Fe(0) hydroxo complex formed on the electrode surface by the reduction of Fe(II) hydroxo complex and the current drop is due to the decomposition (amalgamation) of Fe(0) hydroxo complex deposited on the electrode surface.

$$\mathrm{Fe(II)(OH)}_x \xrightarrow{2e} \mathrm{Fe(0)(OH)}_x \longrightarrow \mathrm{Fe(Hg)} + x\mathrm{OH}^- \qquad (x = 1, 2, \text{ and } 3)$$

$$\uparrow\!\!_____\!\!\downarrow \; \mathrm{ClO_3^-}$$

However, this seems to be improbable since no catalytic wave can be observed when colloidal $Fe(OH)_2$ is electroreduced (Fig. 9). It can be seen in Fig. 10 that colloidal $Fe(OH)_2$ can no longer be produced at the plateau potentials of Fe(II) reduction wave (more negative than −1.4 V) because of the direct reduction of aqua-Fe(II) to Fe(0). The potential coincides with that at which the catalytic current drops abruptly to the reduction current of Fe(II). This indicates that participation of Fe(0) hydroxo complex in the catalytic process is negligible and the nature of the catalytic process is related to the chemical reaction of colloidal $Fe(OH)_2$ with chlorate.

The mechanism for the catalytic effect might be as follows: Chlorate is chemically reduced by colloidal $Fe(OH)_2$ formed in the vicinity of the electrode; the unstable Fe(III) hydroxo complex is then reduced at the cathode, resulting in a catalytic reduction current.

Cyclic voltammetric studies with HMDE (Fig. 10) show that the catalytic wave also appears in the absence of iodate when the initial electrolysis is carried out in the potential region between −1.05 and −1.35 V. It is impossible to explain completely the occurrence of the catalytic wave under these conditions. However, this is probably because a trace of colloidal $Fe(OH)_2$ exists around the electrode. It should be noted that the second wave, whose peak potential is identical to that of the reduction of colloidal $Fe(OH)_2$ can also be observed (curve (B), Fig. 10). This suggests that OH^- is liberated in the vicinity of the electrode by the reduction of chlorate, although the reduction product of chlorate cannot be detected. This is easily realized by the fact that no second wave appears when the electrolysis is carried out in a buffered solution (pH 5.5). Since the amount of OH^- produced in this way is directly related to the formation of colloidal $Fe(OH)_2$, the process may acquire an autocatalytic character.

It can be seen that the amount of colloidal $Fe(OH)_2$ formed at every drop is not reproducible in a quiet solution (Figs. 1(C) and 5). If stirring of the solution is insufficient after detachment of the individual mercury drops, accumulation of aqua-Fe(II) in the close neighborhood of the electrode cannot be made constant at every drop. The anomalous *i-t* curves obtained for the catalytic wave may be explained in this way.

The author wishes to thank Professor Atsuyoshi Saito for his valuable advice and for helpful discussions throughout this investigation.

A Light Scattering Study of the Hydrolytic Behavior of Zirconium(IV) and Niobium(V) in a Hydrochloric Acid Solution

Yoshinobu SHIOKAWA, Akiko SATO, and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-chome, Sendai 980

(Received February 28, 1976)

The hydrolytic behavior of zirconium(IV) and niobium(V) in a hydrochloric acid solution was studied using light scattering measurements. It is found that the species of zirconium(IV) have a degree of polymerization of 3 and a charge per monomer unit of 1.5 in a 1.5 M hydrochloric acid solution with $[Cl^-]=1.7$ M. Also, it was found that for a chloride ion concentration of 11 M, the species of niobium(V) are monomeric in 8—11 M hydrochloric acid and colloidal below 8 M. The effect of standing time of the hydrochloric acid solution of niobium(V) was also investigated.

The nature of hydrolysis and polymerization of metal ions in aqueous solutions has been clarified by Sillén and his co-workers.[1] They have employed accurate potentiometric measurements for a wide range of concentrations of reacting species and for a controlled, relatively high ionic strength. Alekseeva *et al.*[2] have studied potentiometrically the hydrolytic polymerization of zirconium(IV) and hafnium(IV) in perchloric acid solutions at pH 0.3—1.5. However, the state of the metal ions, which are highly hydrolyzable and have a strong tendency to precipitate, has been investigated in strong acid solutions. At high acidities, direct potentiometric measurements of hydrogen ions set free in the hydrolytic process are not possible. Norén[3] has employed an indirect technique using a fluoride membrane electrode in his investigation of the hydrolysis of zirconium(IV) and hafnium(IV).

However, interesting aspects of these metals in aqueous solutions have been also observed in other than potentiometric measurements. Yagodin *et al.*[4] pointed out that a part of the zirconium(IV) is in a form which can not extracted by tributyl phosphate (TBP), and that the amount of non-extractable substance corresponds to the amount of zirconium which could not be determined by the usual method using pyrocatechol violet. They also observed that in nitric acid solutions of zirconium there were two types of hydrolytic species, one being complexes with mobile equilibrium and the other stable ones without equilibrium. Suzuki and Inoue[5] have studied the stability of protactinium(V) in a perchloric acid solution employing thenoyl trifluoroacetone(TTA)–benzene extraction, ion exchange, filtration, and synergism of diisobutyl carbinol on the TTA–benzene extraction. It was observed that the method of preparation and concentration of protactinium both affected the behavior of the protactinium in a perchloric acid solution, a part of the protactinium being in a form which was not adsorbed by a cation exchange resin, and that the protactinium species extracted in the TTA–benzene solution were not stable. Mitsugashira[6] has also found that, in a perchloric acid solution of protactinium(V), non-extractable species were present in a di(2-ethylhexyl)phosphoric acid–benzene extraction study.

Therefore, in aqueous solutions of metal ions which are highly hydrolyzable and have a strong tendency to precipitate, species with irreversible processes are often present. Thus it is attractive to follow an approach from a view different from equilibrium analysis such as solvent extraction. It is also interesting to compare the results of this approach with that of equilibrium analysis. In the present work, the states of zirconium(IV) and niobium(V) in hydrochloric acid solutions were studied by means of Rayleigh light scattering measurements. These measurements are basically independent of equilibrium analysis such as solvent extraction. Therefore, this is a sensitive method for weighing the species in solution, and can therefore provide observations of the polynuclear complexes formed by the hydrolytic process.

Experimental

The zirconium obtained as $ZrOCl_2 \cdot 8H_2O$ was recrystallized from concentrated hydrochloric acid. The salt was dissolved in the hydrochloric acid and finally the acidity of the zirconium solution was adjusted to 1.5 M and the chloride ion concentration to 1.7 M with sodium chloride.

A hydrochloric acid solution of niobium was prepared as follows. Niobium(V) oxide was fused with potassium bisulfate in the ratio of 1 gram of the oxide to 10 grams of the bisulfate. This melt was cooled and dissolved in a warm 4%-ammonium oxalate solution. The resulting solution was filtered and alkalized with 10% ammonia with vigorous stirring. The precipitate thus obtained was separated by centrifugation and washed with dilute hydrochloric acid solutions. This precipitate was dissolved in concentrated hydrochloric acid. Hydrogen chloride was passed through the resulting solution for several hours, initially at room temperature and finally in an ice bath. The solution was then diluted drop by drop with vigorous stirring to the desired concentration with respect to the hydrochloric acid using a hydrochloric acid solution of suitable concentration. The chloride ion concentration was adjusted to 11.0 M with lithium chloride, which was synthesized from lithium carbonate and hydrochloric acid.

The amount of zirconium was determined by EDTA utilizing back titration with copper(II) and niobium gravimetrically as an oxide, igniting niobium hydroxide precipitated by tannin. The acidity of the solution was determined by titration with a standard sodium hydroxide solution.

Light scattering measurements were made using a 4 cm semioctagonal or square cell at 436 nm with a Shimadzu PG-21 light scattering photometer modified in order to increase the sensitivity. The photometer was calibrated using benzene, so as to obtain 47.5×10^{-6} cm^{-1} for the total Rayleigh ratio. This benzene was washed with concentrated sulfuric acid, passed through an activated aluminium oxide column, and then carefully distilled prior to use. Measurements of the

redistilled water gave reasonable values for the Rayleigh ratio $(2.70—2.90)\times10^{-6}$ cm^{-1}.

Refractive index increments were determined at 436 nm and at 25 °C using a Shimadzu DR-3 photoelectric differential refractometer calibrated with sodium chloride solutions.

Each sample was filtered through a Millipore MF filter having a pore diameter of 0.22 μm or a Fluorinert filter having a pore diameter of 0.2 μm, directly into cell, which had been previously rendered dust free. This clean solution was subjected to light scattering and then the refractive index increment was measured. During these procedures, the acidity of the solution remained unchanged.

Results

In a previous paper,[7] the present authors pointed out that the cross-term including the concentration scattering and density scattering, suggested by Bullough, does not need to be taken into account. Therefore, the relation between the Rayleigh ratio and the degree of polymerization, derived by Tobias and Tyree,[8] is valid. The weight-average degree of polymerization N is associated with the excess Rayleigh ratio R^* due to the zirconium or niobium species by

$$\frac{1}{N}=\frac{H\phi\psi^2 m}{R^*}-\frac{z^2 m}{2(m_3+m_5)} \qquad (1)$$

$$H=2000\pi^2n^2/\lambda^4N_A$$

where ϕ is the volume fraction of water, N_A Avogadro's number, n the refractive index of the solution, and λ the wave length of the light. The symbols m, z, and ψ denote the molarity, the absolute value of the charge, and the differential refractive index of the monomeric zirconium or niobium, respectively. The definition of ψ is

$$\psi=\left(\frac{\partial n}{\partial m}\right)-\frac{zm_3}{2(m_3+m_5)}\left(\frac{\partial n}{\partial m_3}\right)-\frac{zm_5}{2(m_3+m_5)}\left(\frac{\partial n}{\partial m_5}\right) \qquad (2)$$

where m_3 and m_5 are the concentrations of the acid and of the supporting electrolyte, respectively. Attention should be paid to the excess Rayleigh ratio expressed as a function of the degree of polymerization and charge.

Zirconium(IV). The influence of the zirconium concentration on the total Rayleigh ratio was investigated for a 1.5 M hydrochloric acid solution with $[Cl^-]=1.7$ M, as is shown in Fig. 1. The Rayleigh ratio, obtained for a 1.5 M hydrochloric acid solution with $[Cl^-]=1.7$ M, was subtracted from the total Rayleigh ratio of the zirconium solution to give the excess Rayleigh ratio due to zirconium species. The excess Rayleigh ratio is also shown in Fig. 1. The results are reproducibile to within a few percent.

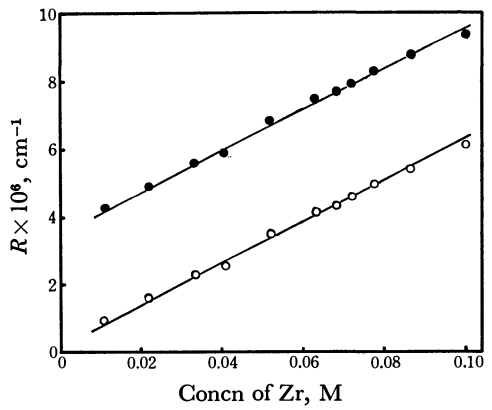

Fig. 1. Dependence of Rayleigh ratio on Zr concentration: ●, total Rayleigh ratio; ○, excess Rayleigh ratio.

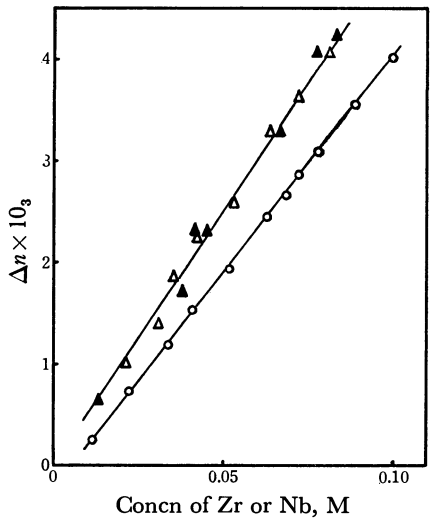

Fig. 2. Refractive index increment of Zr or Nb in HCl solutions: ○, Zr in 1.5 M HCl+0.2 M NaCl; △, Nb in 11 M HCl; ▲, Nb in 8.0 M HCl+3.0 M LiCl.

The refractive index increments of zirconium solutions were determined, as is shown in Fig. 2, where Δn is the difference of the refractive indices between the zirconium solution and a 1.5 M hydrochloric acid solution with $[Cl^-]=1.7$ M. The value found from the slope for $\partial n/\partial m$ is 4.02×10^{-2} l/M. The refractive index increments for hydrochloric acid solutions were also determined, as is shown in Fig. 3. In this figure, Δn is the difference in the refractive indices between a hydro-

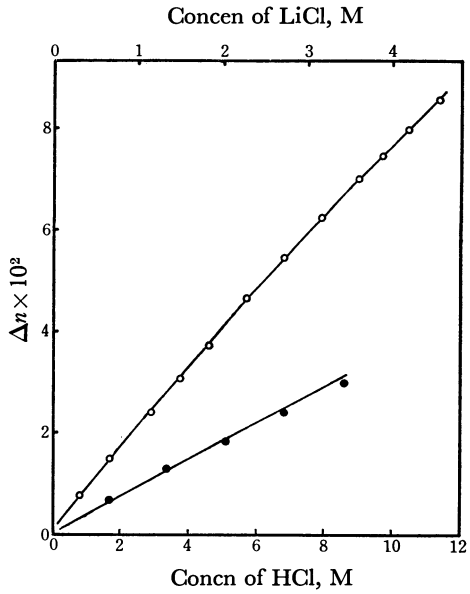

Fig. 3. Refractive index increment of HCl and LiCl solutions: ○, HCl; ●, LiCl.

chloric acid solution and redistilled water and is expressed as

$$\Delta n = -1.03\times10^{-4}m_3^2 + 8.77\times10^{-3}m_3 + 1.68\times10^{-4}. \quad (3)$$

The refractive index increments of sodium chloride solutions were taken from Ref. 9. The value found for $\partial n/\partial m_3$ is 8.46×10^{-3} l/M and that for $\partial n/\partial m_5$ is 1.01×10^{-2} l/M. The volume fraction of water in zirconium solutions was taken to be approximately that of a 1.7 M hydrochloric acid solution and was calculated from the density of the hydrochloric acid solution at 20 °C. The value found is 0.967.

The procedure[8] for applying Eq. 1 is to consider the charge z to be a parameter. A plot of the degree of polymerization, N, *vs.* the zirconium concentration, m, is made for the various values assumed for z. The value of z for which N is independent of m is the correct value for the charge, and the corresponding value of N yields the proper degree of polymerization. Figure 4 indicates that the weight-average degree of polymerization is 3 and that the average charge per zirconium atom is 1.5.

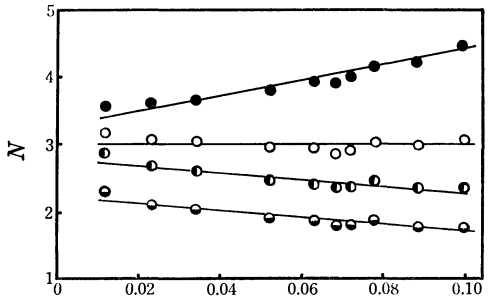

Fig. 4. Plot of the degree of polymerization *vs.* concentration of Zr with the charge as a parameter: ◒, $z=0$; ◐, $z=1$; ○, $z=1.5$; ●, $z=2$.

Niobium(V). The effect of the hydrochloric acid concentration of the niobium solutions on the excess Rayleigh ratio was examined at niobium concentrations of 0.05 M. As is shown in Fig. 5, no appreciable change could be found in the range of acidity from 8 to 11 M, whereas below 8 M a rapid increase is observed.

The effect of the niobium concentration on the total Rayleigh ratio was investigated in two series of experiments. One is for the 11 M hydrochloric acid solution of niobium and the other is for the 8 M solution. The

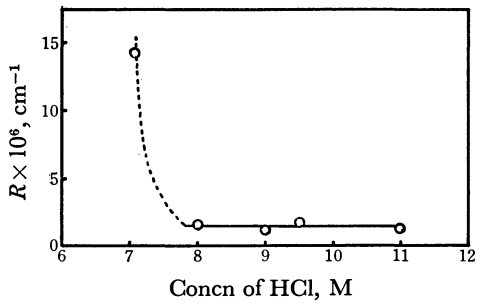

Fig. 5. Dependence of excess Rayleigh ratio on HCl concentration; [Nb(V)]=0.05 M; [Cl⁻]=11 M.

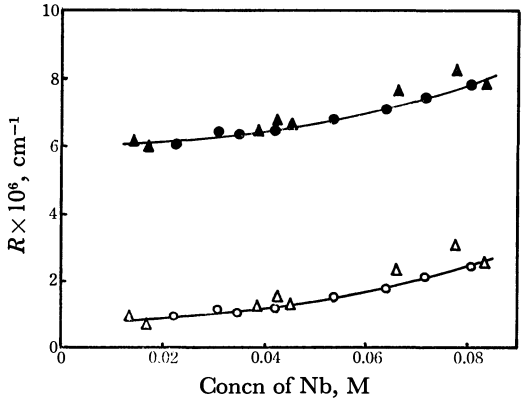

Fig. 6. Dependence of Rayleigh ratio on Nb concentration: ●, total Rayleigh ratio of Nb in 11 M HCl; ○, excess Rayleigh ratio of Nb in 11 M HCl; ▲, total Rayleigh ratio of Nb in 8.0 M HCl+3.0 M LiCl; △, excess Rayleigh ratio of Nb in 8.0 M HCl+3.0 M LiCl.

reproducibilities of these experiments were poor and thus the total Rayleigh ratio shown in Fig. 6 is approximately equal to the mean value of the measured ratio. The Rayleigh ratio obtained for the 11 M hydrochloric acid solution, or the 8 M solution with [Cl⁻]=11 M, was subtracted from the total Rayleigh ratio for a niobium solution in order to obtain the excess Rayleigh ratio due to the niobium species.

The refractive index increments of the niobium were determined in two series of experiments, as is shown in Fig. 2, where Δn is the difference in the refractive index between the niobium solutions and an 11 M hydrochloric acid solution or an 8 M solution with [Cl⁻] =11 M. The value found for $\partial n/\partial m$ is 5.18×10^{-2} l/M for both experiments. The refractive index increments of lithium chloride solutions were also determined, as is shown in Fig. 3. The value found for $\partial n/\partial m_5$ is 8.62×10^{-3} l/M and the values for $\partial n/\partial m_3$ were calculated using Eq. 3. The volume fraction were calculated from the density of the hydrochloric acid and lithium chloride solutions at 20 °C. For the 11 and 8 M series, the value found are 0.755 and 0.766, respectively.

Figure 7 shows the plots of the degree of polymerization *vs.* the concentration of niobium with the charge as a parameter in 11 and 8 M hydrochloric acid solutions

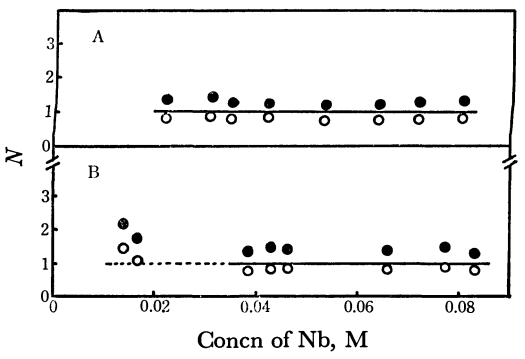

Fig. 7. Plots of the degree of polymerization *vs.* concentration of Nb with the charge as a parameter: ○, $z=0$; ●, $z=3$.
Series A, Nb in 11 M HCl.
Series B, Nb in 8.0 M HCl+3.0 M LiCl.

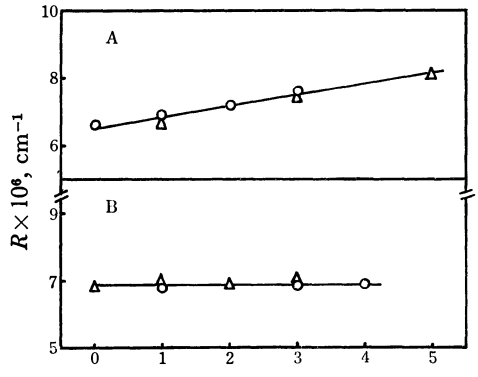

Fig. 8. The effect of standing time on the total Rayleigh ratio of Nb solutions.
Series A, Nb in 8.0 M HCl+3.0 M LiCl: ○, 0.0396 M Nb; △, 0.0430 M Nb.
Series B, Nb in 9.5 M HCl+1.5 M LiCl: ○, 0.0381 M Nb; △, 0.0409 M Nb.

of niobium. There is little difference in the degree of polymerization between the plots for $z=0$ and those for $z=3$. Considering both the poor reproducibility for the total Rayleigh ratios and the impossiblity of a species carrying four or five charges per niobium atom in the solution, we may estimate the degree of polymerization to be unity for the two series. However, it is not all possible to estimate the charge.

The relation between the total Rayleigh ratio of a niobium solution and the standing time after preparation was examined for 8 and 9.5 M hydrochloric acid solutions, as is shown in Fig. 8. At an acidity of 8 M, the total Rayleigh ratio changes appreciably, but it does not change at 9.5 M over several days. Also, the effect of a longer standing time on 8 M hydrochloric acid solutions was examined. However, no reproducible results could be obtained. In these solutions, thehydrolytic precipitation was observed within about ten days after the preparation, and thus, the poorly reproducible results may be related to the precipitation.

Discussion

Zirconium(IV). Assuming species to have constant charge, the weight-average degree of polymerization was found to be 3 and the charge per zirconium atom to be 1.5 in a 1.5 M hydrochloric acid solution. This result is qualitatively consistent with that obtained by ultracentrifugation[10] and with that obtained by spectrophotometry.[11]

From TTA–benzene extraction and spectrophotometric measurements, Zielen and Connick[12] found polynuclear complexes of $Zr_3(OH)_4^{8+}$ and $Zr_4(OH)_8^{8+}$, and also evaluated their hydrolytic constants, as is shown in a footnote to Fig. 9. In this footnote, additional data[13] for the formation of mononuclear complexes are listed. Using these constants, the distribution of these complexes at a hydrogen ion concentration of 1.5 M was calculated, as is shown in Fig. 9a, and as was the weight-average degree of polymerization and the charge per zirconium atom, which is shown in Fig. 9b. These

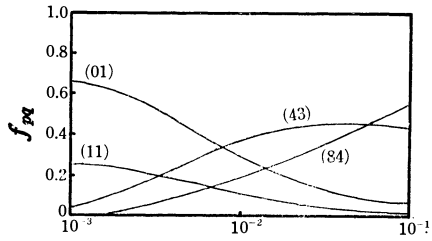

Fig. 9(a).

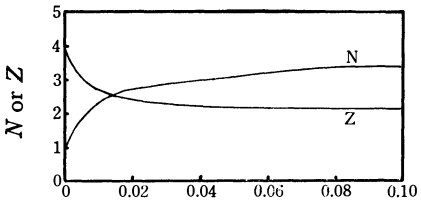

Fig. 9(b).

Fig. 9. Distribution f_{pq}, degree of polymerization N, and charge per one atom Z of Zr solution at $[H^+]=1.5$ M, which are calculated by hydrolytic constants, $\log\beta_{11}=-0.22$, $\log\beta_{21}=-0.84$, $\log\beta_{31}=-1.88$, $\log\beta_{41}=-3.05$, $\log\beta_{43}=5.39$, and $\log\beta_{84}=8.24$. In the (pq) p and q denote the composition of complex $Zr_q(OH)_p^{4q-p}$ and f_{pq}, N, and Z are defined as follow: $f_{pq}=q[Zr_q(OH)_p^{4q-p}]/[Zr]_{tot}$, $N=\sum_{p,q} q f_{pq}$, and $Z=\sum_{p,q}(4-p/q)f_{pq}$

results for a 1.7 M chloride solution are assumed to be valid, though these constants were evaluated with respect to a 2 M perchlorate solution. No appreciable error should be introduced, at least in the degree of polymerization, from this assumption, since Babko and Gridchina[14] have found that the degree of polymerization is the same in perchloric, hydrochloric and nitric acid solutions using a dialysis method. The degree of polymerization and the charge shown in Fig. 9b are consistent with the present results, except for a slight discrepancy of the charge. This discrepancy may be explained by experimental errors and/or by the diminishing charge for the coordination of chloride ions in the present chloride solutions.

The agreement between the results obtained by the solvent extraction and spectrophotometric method and that by the light scattering method is interesting from two point of view. One is concerned with the assumptions used in the experimental method and the other with the existence of species with irreversible processes. Now, the experimental methods based on different principles, such as solvent extraction and light scattering, were conducted under individual and separate assumptions. This agreement suggests that these assumptions are appropriate, at least in this case. However, in a zirconium solution there are often species with irreversible processes, as mentioned before. Thus, this agreement suggests that these species only slightly contribute to the behavior of these solutions.

Niobium(V). A hydrochloric acid solution of niobium is less stable than a solution of zirconium. Hydrolytic precipitation appears even in 10 M hydro-

chloric acid solutions with a niobium concentration of 0.01—0.1 M within a few hours after the preparation. However, maintaining the chloride ion concentration at 11 M, as is shown in Fig. 5, the precipitation does not appear for an 8 M hydrochloric acid solution of niobium. Below hydrochloric acid concentrations of 8 M, the rapid increase of excess Rayleigh ratio must be related to the formation of hydrolytic colloidal particles. The constancy of the excess Rayleigh ratio for acidities of 8—11 M suggests that monomeric species are predominant. These species may be forms of $Nb(OH)_m$-Cl_n^{5-m-n}, as has been suggested by Kanzelmeyer *et al.*[15]

It is interesting to note that a species in an 8 M hydrochloric acid solution of niobium is transformed into a colloidal particle for a 7 M solution. This transformation suggests that the intermediate polymer of niobium is unstable or that it can exist only in a narrow range of hydrochloric acid concentrations. This phenomenon is extremely different from the case of a zirconium solution, in which the polymer can exist stably over a wide range of concentrations. On the other hand, some investigations have indicated the existence of a niobium polymer.[16-18] This discrepancy may be explained by the different conditions of solutions and/or of the preparations of the solutions.

As is shown in Fig. 8, a standing effect is perceived for an 8 M hydrochloric acid solution of niobium but no effect was found for a 9.5 M solution a few days after the preparation of solution. This effect on the Rayleigh ratio must be associated with an increase in the degree of polymerization, because the Rayleigh ratio depends only slightly on the charge. The difference in the standing effect between 8 and 9.5 M solutions suggests that some species which are present in the 8 M solution and are hardly present in the 9.5 M solution, may be related to the polymerization process.

The Syntheses and Properties of Bis(3-hydroxy-2-methyl-4-pyronato) Complexes of Bivalent Metal Ions

Hideyoshi MORITA, Shigeru SHIMOMURA, and Shinichi KAWAGUCHI*

Faculty of Pharmaceutical Sciences, Tokushima University, Shomachi, Tokushima 770

**Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshiku, Osaka 558*

(Received March 13, 1976)

Bis(3-hydroxy-2-methyl-4-pyronato) complexes of cobalt(II), nickel(II), copper(II), and zinc(II) have been prepared: $CoL_2(OH_2)_2$, $NiL_2(OH_2)_2$, CuL_2, and $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$. The 2,2′-bipyridine-(bpy) and 1,10-phenanthroline(phen) adducts of these complexes were also synthesized: CoL_2(bpy), CoL_2(phen), NiL_2(bpy), ZnL_2(bpy), and ZnL_2(phen). Based on the magnetic, spectral, and thermogravimetric data, the structures of these complexes are proposed: all of the cobalt(II), nickel(II), and zinc(II) complexes are octahedral, and CuL_2 is square planar. The NMR spectra of the zinc(II) complexes are discussed.

3-Hydroxy-2-methyl-4-pyrone occurs naturally is also obtained by the alkaline hydrolysis of streptmycin salts.[1] The pyrone has a caramel-like odor, and is used as a spice in bread and cakes. However, the compound is not harmless, the oral lethal dose (LD_{50}) for rats being 1.48 g/kg.[2] On the other hand, Nickell and Gordon reported on a stimulatory effect of this pyrone on plant growth, and suggested that the effect might be brought about by its metal chelate since methoxylation of the hydroxyl group of pyrone renders it inactive.[3] Thus a detailed study of the metal complexes of the pyrone is desirable.

The stability constants have been determined for a number of metal complexes of this pyrone.[4] Several tervalent metal complexes were isolated,[5,6] but no example of the mixed ligand complex containing another base has been reported.

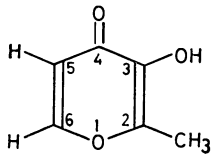

Fig. 1. 3-Hydroxy-2-methyl-4-pyrone.

This paper reports on the syntheses and structural studies of the bivalent metal complexes of 3-hydroxy-2-methyl-4-pyrone (HL, Fig. 1) and their 2,2′-bipyridine and 1,10-phenanthroline adducts.

Experimental

Syntheses of Complexes. Bis(3-hydroxy-2-methyl-4-pyronato)diaquacobalt(II), $CoL_2(OH_2)_2$: A 20 ml portion of 1 M NaOH solution was added to *ca.* 100 ml of warm aqueous ethanol (1:1 by volume) containing 2.54 g (0.02 mol) of 3-hydroxy-2-methyl-4-pyrone and 2.39 g (0.01 mol) of cobalt(II) chloride hexahydrate. The mixture was stirred for *ca.* 30 minutes and then kept standing overnight in a refrigerator. A dull yellow precipitate was obtained by filtration, washed with water and ethanol successively, and air dried. Yield: *ca.* 2.5 g, 72%.

The corresponding nickel(II), copper(II), and zinc(II) complexes, $NiL_2(OH_2)_2$, CuL_2, and $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$, were also prepared by the same method in 81, 80, and 78% Yields, respectively.

Bis(3-hydroxy-2-methyl-4-pyronato)bipyridinecobalt(II), CoL_2(bpy): A mixture containing 1.72 g (0.005 mol) of $CoL_2(OH_2)_2$ and 0.78 g (0.005 mol) of 2,2′-bipyridine in 200 ml of acetone was stirred for *ca.* 5 h and then filtered and washed with acetone. The crude complex was recrystallized from hot acetone and air dried. Yield: *ca.* 2.0 g, 86%.

In a similar fashion, NiL_2(bpy), ZnL_2(bpy), CoL_2(phen) and ZnL_2(phen) were obtained in 60, 85, 86, and 85% yields, respectively.

Analyses and Measurements. Metal contents in these complexes were determined by atomic absorption. The results of elemental analysis are shown in Table 1 together with some properties. The visible and ultraviolet absorption and reflection spectra were obtained with Hitachi EPS-3 and Shimadzu MPS-5000 recording spectrophotometers. The infrared spectra (4000—400 cm^{-1}) were obtained with a Hitachi EPI-G2 infrared spectrophotometer by the KBr disk method, and those in the 700—200 cm^{-1} region with a Jasco DS-701G infrared spectrophotometer by the CsI disk method. The magnetic susceptibility was determined at room temperature by the Faraday method with an automatically recording magnetic balance (Shimadzu Seisakusho Co., Ltd.). Mercury(II) tetraisothiocyanatocobaltate(II) was used as a reference

TABLE 1. COLOR AND ANALYTICAL DATA OF THE ISOLATED COMPLEXES

Complex	Color	Found (Calcd), %					Magnetic moment
		C	H	N	M	H_2O	B.M. (K)
$CoL_2(OH_2)_2$	dull yellow	41.44(41.76)	4.52(4.09)		16.93(17.03)	10.1(10.44)	4.74(303)
CoL_2(bpy)	orange	56.19(56.79)	3.97(3.90)	6.22(6.02)			4.56(297)

substance. Diamagnetic corrections were calculated from Pascal's constants. Thermogravimetric curves were obtained with a Rigaku Denki 8002 H/D differential thermobalance at a heating rate of 3 °C/min in the air. The NMR spectra were measured in $(CD_3)_2SO$ at 100 MHz with a JNM-PS-100 spectrometer (Japan Electron Optics Lab. Co., Ltd.) using tetramethylsilane as an internal reference.

Results and Discussion

Infrared Spectra and Thermogravimetric Data. The characteristic IR bands of the metal complexes of 3-hydroxy-2-methyl-4-pyrone and their base adducts summerized are in Table 2. They were assigned in reference to the literature.[7-11] The frequencies of the C=O and C=C stretching vibrations in all these complexes are smaller by *ca.* 50 cm^{-1} than those in the free ligand. This suggests that the 3-hydroxy-2-methyl-4-pyronate ion is coordinated to the metal ion through both oxygen atoms of the carbonyl and hydroxyl groups, and that the delocalization of the olefinic and carbonyl electrons of the 3-hydroxy-2-methyl-4-pyronate ion takes place.[12]

The OH stretching bands of $CoL_2(OH_2)_2$, $NiL_2(OH_2)_2$ and $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$ are shown in Fig. 2. The OH stretching bands of cobalt(II) and nickel(II) complexes are observed at *ca.* 3420 cm^{-1}, both being sharp. In contrast the zinc(II) complex exhibits a very broad band at 3480 cm^{-1}, which might be composed of the OH stretching bands of both the coordinated and lattice water. Thermogravimetric analysis of the three complexes shows that the zinc(II) complex begins to liberate water at around 80 °C, and the nickel(II) and cobalt(II) complexes at around 115 and 105 °C, respectively. The difference in the temperature of water liberation suggests that the zinc(II) complex may contain lattice water, although the thermogravimetric analysis can not discriminate the coordinated and lattice water.

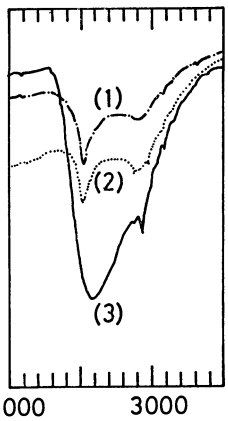

Fig. 2. The IR spectra of: (1) $CoL_2(OH_2)_2$; (2) $NiL_2(OH_2)_2$; and (3) $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$.

The IR spectra of adducts containing heterocyclic diamine (phen or bpy) consist of bands due to the 3-hydroxy-2-methyl-4-pyronate ligand and those of the coordinated diamine. The bands in the 1700—1500 cm^{-1} region are little affected by the coordination of the diamine, no new bands being observed in this region. Thus the bands around 1600 and 1570 cm^{-1} are assigned mainly to the C=O and C=C stretching vibrations, respectively, of the 3-hydroxy-2-methyl-4-pyronate ligand. The coordination of phen to the metal ion is evidenced by the new bands at around 1420, 865, and 725 cm^{-1},[9,10] and the coordination of bpy is also revealed by the shift and split of the characteristic band (751 cm^{-1}) of the free ligand into two bands around 780 and

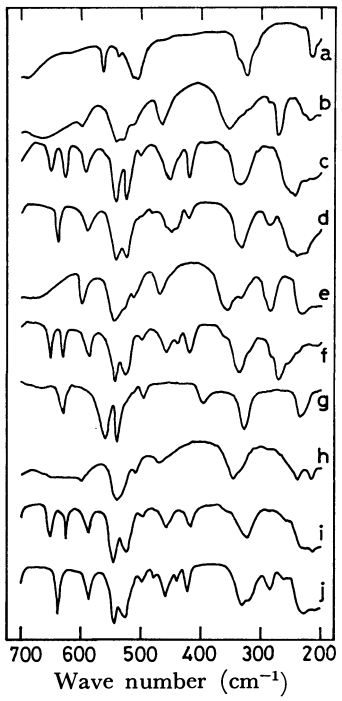

Fig. 3. The far-IR spectra of: (a) HL; (b) $CoL_2(OH_2)_2$; (c) CoL_2(bpy); (d) CoL_2(phen); (e) $NiL_2(OH_2)_2$; (f) NiL_2(bpy); (g) CuL_2; (h) $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$; (i) ZnL_2(bpy); and (j) ZnL_2(phen).

740 cm^{-1},[10,11] and by the appearance of a new band at around 1020 cm^{-1}.[10,11]

The far-IR spectra in the 700—200 cm^{-1} region of the present complexes are shown in Fig. 3. They are assigned tentatively as listed in Table 2 in reference to literature.[8] In the case of adducts containing heterocyclic diamine, the bands assigned to the metal-oxygen stretching are shifted towards the lower-frequency side (around 455 cm^{-1}), the new bands attributable to bpy or phen appearing at *ca.* 420 cm^{-1}. The above shift may be caused by the weakening of the metal-oxygen bond due to the coordination of diamine.

Electronic Spectra and Magnetic Data. Both the absorption (in ethanol) and reflection spectra of the 3-hydroxy-2-methyl-4-pyronate complexes are shown in Figs. 4 and 5, their magnetic moments being listed in Table 1. In the 20000—7000 cm^{-1} region, $CoL_2(OH_2)_2$, CoL_2(bpy) and CoL_2(phen) show absorption bands at *ca.* 18000(sh) (ε=41.8), 8600 (ε=2.6), and 7570 (ε=3.1) cm^{-1}, at *ca.* 19000(sh) (ε=67.2) and 9200 (ε=5.9)

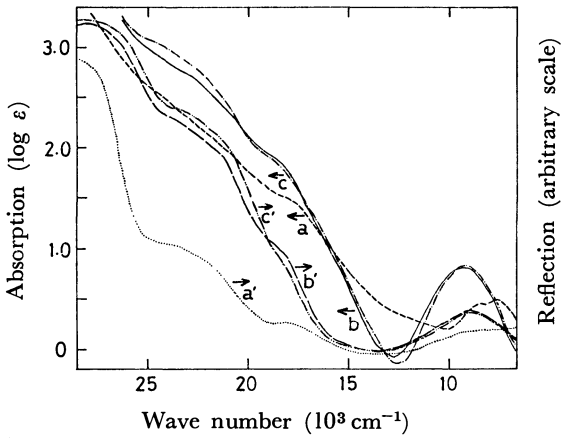

Fig. 4. The absorption and reflection spectra of: (a) and (a'), $CoL_2(OH_2)_2$; (b) and (b'), CoL_2(bpy); (c) and (c'), CoL_2(phen).

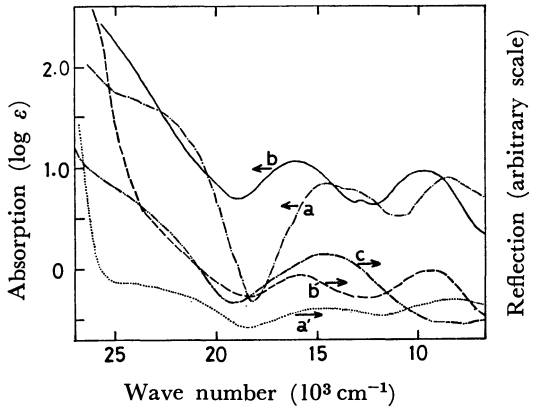

Fig. 5. The absorption and reflection spectra of: (a) and (a'), $NiL_2(OH_2)_2$; (b) and (b'), NiL_2(bpy); (c), CuL_2.

cm^{-1}, and at *ca.* 19200(sh) (ε=65.6) and 9100 (ε=6.1) cm^{-1}, respectively. The reflection spectra of these complexes are similar to the corresponding absorption spectra in solution. The results reveal that all these cobalt(II) complexes are octahedral in the two phases, although the magnetic moments of CoL_2(bpy) and CoL_2(phen) are a little lower than the value usually observed for the octahedral cobalt(II) complexes.[13]

The absorption spectra of $NiL_2(OH_2)_2$ and NiL_2(bpy) in the 20000—7000 cm^{-1} region exhibit bands at 14500 (ε=5.5), 13000 (ε=4.6), and 8500 (ε=7.0), and at 16100 (ε=11.9), 12900 (ε=2.6), and 8800 (ε=7.3) cm^{-1}, respectively. The reflection spectra of these complexes are also similar to the corresponding absorption spectra. The spectra and the observed magnetic moments of $NiL_2(OH_2)_2$ (3.21 B. M.) and NiL_2(bpy) (3.13 B. M.) suggest that both of the nickel(II) complexes are octahedral.

The observed magnetic moment (1.84 B. M.) of CuL_2 is normal, indicating that there is no copper-copper interaction. The reflection spectrum of this copper(II)

Coupling constants, J, have the unit of Hz.

complex in the 20000—8000 cm^{-1} region shows only one symmetrical d-d band at 14700 cm^{-1}. Troporone and 3-hydroxy-2-methyl-4-pyrone are very similar ligands, both coordinating to a metal ion through oxygen atoms of the hydroxy and carbonyl groups to form a five-membered chelate ring. The absorption spectrum of Cu(troporonato)$_2$ exibits a weak band at 14700 cm^{-1} ($\varepsilon \approx 100$).[14] This complex has the O_4-tetracoordinate planar structure around the copper ion, although the plane including the copper and oxygen atoms makes an angle of 4.9° with the plane of the seven membered ring.[15] The close resemblance of the reflection spectrum of CuL_2 to the absorption spectrum of Cu(troporonato)$_2$ strongly suggests the O_4-tetracoordinate planar structure for CuL_2 in solid.

NMR Spectra of Zn(II) Complexes. The NMR spectra of $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$, ZnL_2(bpy), and ZnL_2(phen) in dimethyl sulfoxide solutions are shown in Table 3. The assingments are based on integration of the peak area in comparison with the NMR spectra of InL_3,[6] 2,2′-bipyridine,[16] and 1,10-phenanthroline and its metal complexes.[17]

In the spectrum of $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$, the resonance peak at 8.81 ppm due to the OH proton of free HL is lost, the resonance peaks of protons 5 and 6 and methyl protons of this ligand being shifted downfield by 0.22, 0.12, and 0.10 ppm, respectively, due to chelation to zinc(II) ion.

In the case of ZnL_2(bpy), the downfield shifts of the protons 5, 6 and methyl protons of the pyronate ligand are much smaller, *i.e.* 0.09, 0.03 and 0.06 ppm, respectively, than those in $[ZnL_2(OH_2)_2]\cdot 1/2H_2O$. Signals of the protons 5 and 6 of this ligand in ZnL_2(phen) are shifted upfield by 0.04 and 0.08 ppm, respectively, while the peak for the methyl protons is shifted down field by 0.04 ppm. This might be caused by a decrease in the electron donation from the chelating oxygen atoms to the metal because of the coligation of bpy or phen to the zinc(II) ion, or by the magnetic anisotropy effect of the ring current of these diamines.

The resonance peaks of the protons 6 and 6′ of bpy in ZnL_2(bpy), and the protons 2 and 9 of phen in ZnL_2(phen) are shifted upfield by 0.04 and 0.25 ppm, respectively, than those of free diamines. Miller and Prince reported that an upfield shift for the 2 and 9 ring protons of phen in the tris-1,10-phenanthroline complexes of Co(III), Fe(II), Ru(II), and Zn(II) and the tetrakis-1,10-phenanthroline complexes of Ca(II) and Mg(II) is probably due to a metal-nonbonded hydrogen interaction.[17] In the present case of ZnL_2(phen), the upfield shift of the 2 and 9 protons of phen may also be due to a similar effect.

The authors are grateful to Dr. Shunji Utsuno of Shizuoka University for his mesurement of the reflcetion spectra.

Equilibria of Complex Formation in Aqueous Solution between Lead(II) and Thallium(I) Ions, and Cyclic and Linear Polyethers

Mutsuo KODAMA[1] and Eiichi KIMURA*

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036
**Institute of Pharmaceutical Sciences, Hiroshima University School of Medicine, Kasumi, Hiroshima 734*

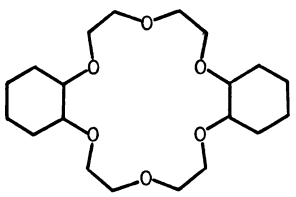
(Received March 19, 1976)

log K, ΔH and ΔS values were polarographically determined for the interaction in aqueous solution of Pb^{2+} and Tl^{+} ions with a cyclic polyether, 1,4,7,10,13,16-hexaoxacyclooctadecane(18-crown-6), and a linear polyether, tetraethylene glycol dimethyl ether(tetraglyme). The stability constant of a 1:1 Pb^{2+} complex with the macrocyclic ligand is four figures higher than that with the linear ligand. This macrocyclic effect is explained in terms of entropy.

The stability of a complex between a given cyclic polyether and a cation is dependent on the cation diameter, as illustrated by a case in which the preference of 18-membered cyclic hexaether **1** and **2** (2.6—3.2 Å macrocycle hole cavity) for divalent metal ions decreases in the order; $Pb^{2+}(2.4)>Ba^{2+}(2.7)>Sr^{2+}(2.3)>Hg^{2+}(2.2)>Ca^{2+}(2.0$ Å).[2] The size selectivity is determined by several effects such as electrostatic attraction between metal ion and ligand, ligand conformational change, changes in total particle number, dehydration of the metal ion and ligand, or hydration of the metal-ligand complex. In the thermodynamic study on the 1:1 complexes of **1** and **2** with divalent metal ions, Izatt *et al.* showed that the complexation with Sr^{2+} is more favorable entropically but less so enthalpically than with Ba^{2+}.[3] This suggests that the dominant effects in determining size selectivity are the endothermic removal of water from the hydration sheath with an accompanying gain in entropy, both of which are known more pronounced for the more strongly hydrated Sr^{2+} ion.[4] However, for the complex formation with Pb^{2+} ion which stands linking between Sr^{2+} and Ba^{2+} in terms of ionic diameter, no thermodynamic functions have been reported as yet.

A macrocyclic effect of $\approx 10^4$-fold stability enhancement was found between K^{+}(2.7 Å) complex of an open-chain hexaether, **3**, and those of the macrocyclic analogs such as **1** or **2**.[5] It was postulated that entropic forces work against complete envelopment of the cation by the non-cyclic polyether. However, recent studies on the macrocyclic tetramine system[6-8] disclosed the fact that thermodynamic parameter ΔH often plays more important role in the macrocyclic effect which is linked to ligand solvation effects.[9]

In order to investigate the complexing properties and a major source of the macrocyclic effect, the present polarographic study was undertaken on the interaction of Pb^{2+} with 1,4,7,10,13,16-hexaoxacyclooctadecane-



Dicyclohexyl-18-crown-6

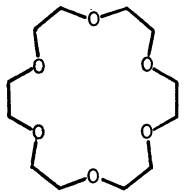
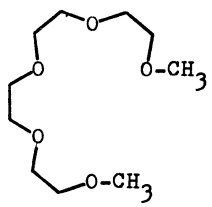
3. Pentaglyme



4. 18-Crown-6



5. Tetraglyme

(18-crown-6), **4**, and tetraethylene glycol dimethyl ether (tetraglyme), **5**, in aqueous solution. Stability constant K, ΔH and ΔS values have also been determined for Tl^{+} complex formation with **4**. The studies constitute a part of our investigations into the macrocyclic effects.[8,10,11] Similar studies have been reported on the metal ion complexes containing analogous ligands, $H_{3-n}(CH_2CH_2OCH_2CH_2OCH_2CH_2)_nNH_{3-n}$, **6**.[12-15]

Experimental

Reagents. A standard solution of thallium(I) perchlorate was prepared by dissolving pure thallium metal in a reagent grade perchloric acid. A standard lead(II) nitrate solution was prepared by dissolving pure lead(II) nitrate crystals in redistilled water. Tetraethylammonium perchlorate(TEAP) was prepared by the method given by Fujinaga, Izutsu and Takaoka,[16] and purified by recrystallization from water. 18-Crown-6, **4**, (Aldrich Chemical Company, Inc.) was recrystallized from acetonitrile. The ionic strength of the sample solutions was adjusted to 0.10 by adding an appropriate amount of TEAP. The other reagents were of analytical reagent grade and were used without further purification.

Apparatus and Experimental Procedures. The d.c. current-voltage curves were obtained by using a manual polarograph similar to that of Kolthoff and Lingane[17] or a Yanagimoto P-8 pen-recording polarograph. For all the measurements, we used a dropping mercury electrode with an m value of 0.915 mg/s and a drop time, t_d, of 5.00 s in an air-free 0.10 M $NaClO_4$ solution at the mercury height of 65 cm, with an open circuit. A saturated calomel electrode (SCE) with a large area was used as a reference electrode. All the free ligands we used gave no reduction wave. In order to prevent the precipitation of metal ions as hydroxides, the pH of the sample solutions were adjusted to 2.00 by adding $HClO_4$. The oxygen dissolved in the sample solution was removed by bubbling pure nitrogen gas through the solution.

Results

Polarographic Behavior of Pb^{2+} and Tl^{+} in Solutions Containing 4. Crown ligand **4** lowered the surface tension at the interface of a mercury-electrolyte solution, changing the electrocapillary curve considerably in the potential range from −0.30 to −1.40 V *vs.* SCE (Fig. 1).

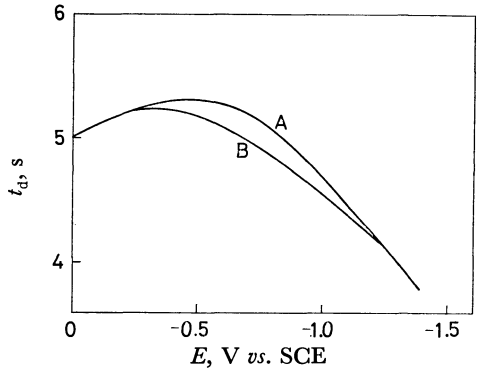


Fig. 1. Electrocapillary curves (A) without and (B) with **4** of 2.50×10^{-3} M at I=0.10 M (TEAP), pH=2.00.

The lowering was found to be independent of the solution pH and the nature of supporting electrolyte. Although no tensammetric wave was observed, the depression of the electrocapillary curve may be indicative of an adsorption of **4** at the mercury electrode surface. This was supported by the effect of the adsorbed **4** on the d.c. polarogram of cadmium(II) ion (Fig. 2). However, **4** had no depressing effect on the d.c. polarographic behavior of Pb^{2+} and Tl^{+} even at concentration above 50×10^{-3} M.

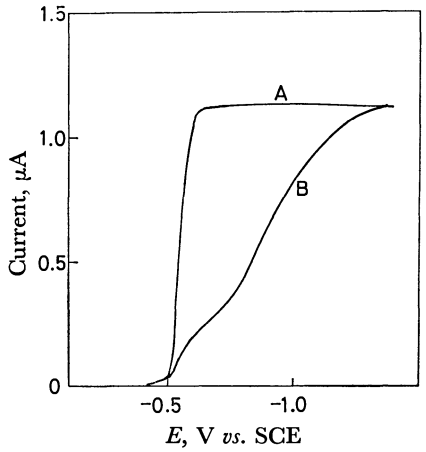

Fig. 2. Polarograms of Cd^{2+} (A) wthout and (B) with **4** of 21.8×10^{-3} M. I=0.10 M (TEAP) and pH=2.00.

The lead and thallium ions invariably gave single well-defined waves under the present experimental conditions. The plots of $\log(i/(i_1-i))$ *vs.* d.c. potential, E, gave straight lines with reciprocal slopes of −31—−32 mV and −58——61 mV for Pb^{2+} and Tl^{+}, respectively. Their limiting currents (i_1) were exactly proportional to their bulk concentrations and to the square root of the effective pressure on the dropping mercury electrode. Thus, the two electron reduction of Pb^{2+} and one electron reduction of Tl^{+} in the presence of **4** were polarographically defined to be reversible. The half-wave potential, $E_{1/2}$, and i_1 underwent little pH effect within the range 1.0—3.0. Complexation was demonstrated by the negative shift of $E_{1/2}$, $\Delta E_{1/2}$, upon increasing the ligand concentration, [**4**]. The slope in

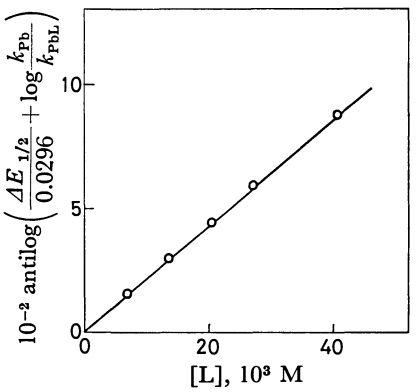

Fig. 3. Determination of the stability constant for Pb^{2+}-**4** complex. A plot of antilog $(\Delta E_{1/2}/0.0296+\log(k_{Pb}/k_{PbL}))$ *vs.* [**4**]. $[Pb^{2+}]=0.25\times10^{-3}$ M, I=0.10 M, pH=2.00, 25 °C.

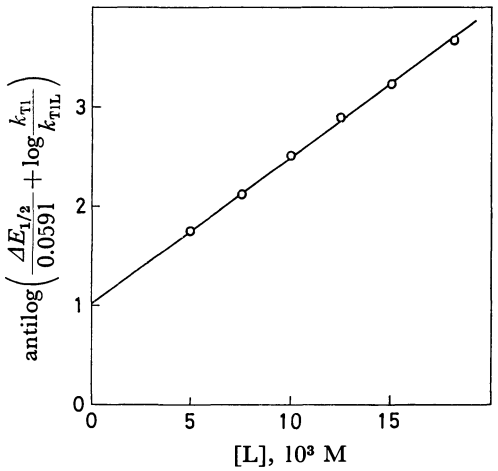

Fig. 4. Determination of the stability constant for Tl^{+}-**4** complex. A plot of antilog$(\Delta E_{1/2}/0.0591+\log(k_{Tl}/k_{TlL}))$ *vs.* [**4**]. $[Tl^{+}]=0.25\times10^{-3}$ M, I=0.10 M, pH=2.00, 25 °C.

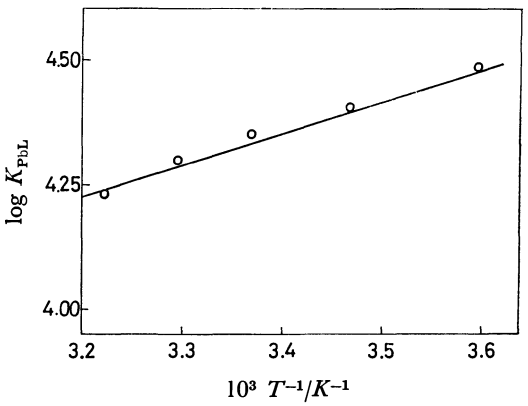

Fig. 5. Temperature dependence of the stability constant of Pb^{2+}-**4** complex.

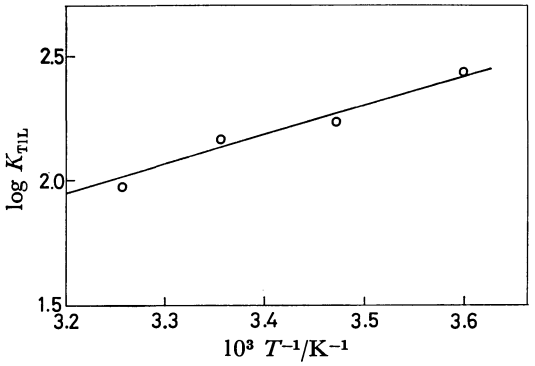

Fig. 6. Temperature dependence of the stability constant of Tl^{+}–**4** complex.

the linear relation between antilog($n\Delta E_{1/2}/0.0591 + \log(k_M/k_{ML})$) and [**4**] immediately allowed the estimation of the 1 : 1 complex stability constant for both metal ions, where logarithm of the diffusion current constant ratio, k_M/k_{ML}, was 0.06 for Pb^{2+} and 0.04 for Tl^{+} system (Figs. 3 and 4). Stability constants, K_{PbL} and K_{TlL}, were measured at various temperatures (5—35 °C) to estimate thermodynamic functions (Figs. 5 and 6). The results are summarized in Table 1.

Table 1. Stability constants (I=0.10 M. 25 °C) and thermodynamic functions

Complex	log K [a]	$-\Delta H$ [a] kcal mol^{-1}	ΔS [a] cal K^{-1} mol^{-1}
Pb^{2+}–(18-Crown-6)	4.4±0.1	3.1±0.2	9.7±1
Tl^{+}–(18-Crown-6)	2.2±0.1	5.4±0.3	−8.3±1
Pb^{2+}–Tetraglyme	0.5±0.1 (log β_1)	3.2±0.2	−8.3±1
Pb^{2+}–(Tetraglyme)$_2$	1.6±0.1 (log β_2)	6.4±0.3	−14.3±2

a) Uncertainties are the standard deviations.

Polarographic Behavior of Lead(II) in Tetraglyme **5** *Solution.* The solution containing Pb^{2+}, **5**, and 0.1 M TEAP also gave a reversible polarographic wave. As in the case of the cyclic ligand system, the increase in the concentration of **5**, [**5**], caused a negative shift of $E_{1/2}$. However, a plot of [antilog($\Delta E_{1/2}/0.0296 + \log(k_{Pb}/k_{PbL}) - 1$]/[**5**] instead of antilog($\Delta E_{1/2}/0.0296 + \log(k_{Pb}/k_{PbL})$) *vs.* [**5**] gave a straight line with an intercept of finite value (Fig. 7). The electrode reaction mechanism is thus written as

$$PbL^{2+} \rightleftharpoons Pb^{2+} + 2e^- + Hg \rightleftharpoons Pb(Hg)$$
$$\Big\Updownarrow$$
$$PbL_2^{2+}$$

and the shift of the half-wave potential is expressed in the form

$$\Delta E_{1/2} = 0.0296 \log (1 + K_{PbL}[5] + K_{PbL}K^*_{PbL_2}[5]^2) + 0.0296 \log \frac{k_{PbL}}{k_{Pb}}$$

where K_{PbL} and $K^*_{PbL_2}$ denote the first and second successive formation constants, respectively, of lead(II)-tetraglyme complex. From the intercept and slope of

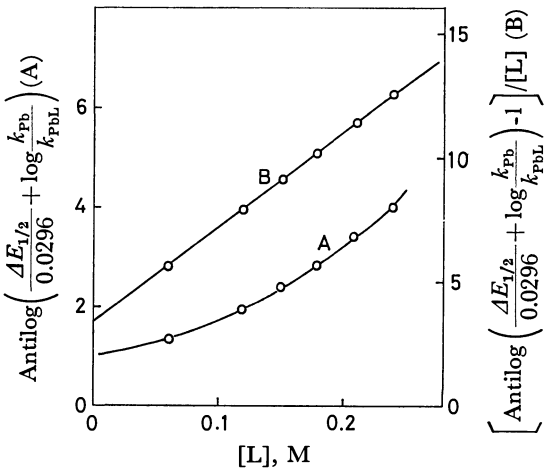

Fig. 7. Determination of the stability constants for Pb^{2+}–**5** complexes. Plots of [antilog($\Delta E_{1/2}/0.0296 + \log(k_{Pb}/k_{PbL})$) − 1]/[**5**] and antilog ($\Delta E_{1/2}/0.0296 + \log(k_{Pb}/k_{PbL})$) *vs.* [**5**]. [$Pb^{2+}$]=0.40×10^{-3} M, I=0.10 M, pH=2.00, 25 °C.

the above linear relation, $K_{PbL}(\beta_1)$ and $K_{PbL}K^*_{PbL_2}(\beta_2)$ values were determined. They were also measured at various temperatures (10—35 °C) in order to determine the thermodynamic parameters (Table 1 and Fig. 8). The polarography of Tl^{+} ion in the tetraglyme solution was also studied. However, little evidence indicating the complex formation was obtained.

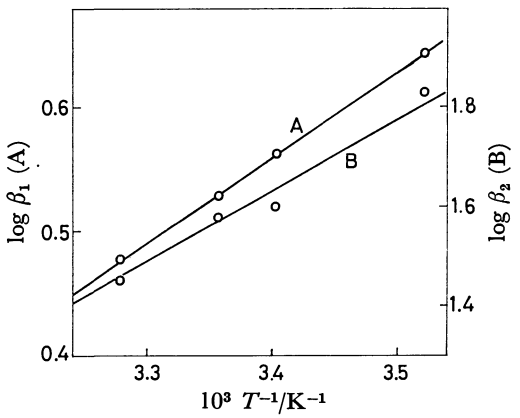

Fig. 8. Temperature dependence of stability constants for 1 : 1 (β_1) and 1 : 2 (β_2) Pb^{2+} -**5** complexes.

Discussion

Crown ether undergoes adsorption to the mercury electrode surface to block the electrochemical reactions of Cd^{2+}, but not of Pb^{2+} or Tl^{+}. This might be relevant in some way to the selective ion transport phenomena across cell membranes. The metal ions such as Pb^{2+} or Tl^{+} may pass through the artificial membrane of the 18-crown-6 in complex forms possibly by repeating dissociation and complexation before reaching the electrode surface. On the other hand, Cd^{2+} ion shows the low permeability probably because of its low affinity for **4**. We observed that the presence of **4** similarly hindered the reduction of transition metal ions like

Cu^{2+}, which is known to be incapable of forming stable complexes with **4**.[2b]

The agreement of the stability constant of $10^{4.4}$ for the 1:1 Pb^{2+}–**4** complex with those for Pb^{2+}–**1** or –**2** (log K 4—5) determined by Christensen *et al.*[2a] is noteworthy in view of the difference in side groups as well as in the methods. A comparison of the present Pb^{2+} data with those of the alkali earth metal ion[3] discloses a remarkable entropic effect contributing to the Pb^{2+} complex stability. The special affinity of the bicylic polyoxadiaza ligand, **6** (n=3), for Pb^{2+} over Ba^{2+} or Sr^{2+} is similarly accounted for by the greater entropic contribution.[12] Considering the fact that the dehydration of Pb^{2+} ion causes the least entropic increase among the three divalent metal ions,[4] the major contribution to the large positive ΔS value upon the Pb^{2+} complex formation might result from other sources.

The measurement for a linear polyoxy ligand, **5**, was conducted in the identical conditions. No complication took place as in the case of **4**. It was found that **5** forms a 1:1 and a 2:1 complex with Pb^{2+} in aqueous solution. The second successive stability constant ($K^*_{PbL_2}$) is greater than the first one. The large enthalpic gain due to small expenditure of energy for the dehydration of Pb^{2+}–**5** (1:1) complex outweighs the loss of entropy, making an overall free energy change for the additional ligation feasible.

Comparison of stability constants of 1:1 complexes for the linear (though short of one oxygen atom) and cyclic ligands allows the estimation of the macrocyclic effect of *ca.* 10^4-fold that is entirely accounted for by the favorable entropy contribution. The *macrocyclic effect* in the present case can be regarded as a synonym to *chelate effect.*

Thallium(I) ion forms with **4** a 1:1 complex having the stability constant of $10^{2.2}$ at I=0.10 and 25 °C. The high exothermicity exceeds the unfavorable entropy change. Unlike Pb^{2+} or smaller metal ions, Tl^+ is too large (2.8 Å diameter) to fit the macrocyclic cavity and has to lie above the plane of the six oxygen atoms, in analogy to Rb^+(2.9 Å).[18,19] Hence, the desolvation, a major factor contributing to positive entropy change upon complexation in some metal ions would not be sufficient for the ligand substitution of Tl^+_{aq}.

(Received March 29, 1976)

Copper(II) and nickel(II) complexes of the 3-formylsalicylic acid–diamine Schiff bases, H_4fsaen, H_4fsapn, H_4fsatn, H_4fsaph, and H_4fsach, where en, pn, tn, ph, and ch denote ethylenediamine, propylenediamine, trimethylenediamine, *o*-phenylenediamine, and 1,2-cyclohexanediamine respectively, have been obtained and characterized. Binuclear copper(II) complexes, Cu_2(fsaen)·$2H_2O$, Cu_2(fsapn)·$2H_2O$, Cu_2(fsatn)·$2H_2O$, Cu_2(fsaph)·H_2O, and Cu_2(fsach)·$2H_2O$, show a strong antiferromagnetic spin-exchange interaction between metal ions, $-2J$ values being more than 555 cm^{-1}. It was revealed that Ni_2(fsaen)·$3H_2O$, Ni_2(fsapn)·$3H_2O$, Ni_2(fsaph)·$5H_2O$, and Ni_2(fsach)·$3H_2O$ are novel binuclear complexes composed of one paramagnetic and one diamagnetic nickel(II) ions. On the other hand, Ni_2(fsatn)·$5H_2O$ is a binuclear complex of paramagnetic nickel(II) ions. Its magnetism obeys the Curie-Weiss law in the range from liquid nitrogen temperature to room temperature with the Weiss constant of −40 K.

In the previous papers of this series,[3,4] we have reported that 3-formylsalicylic acid and its Schiff bases with alkyl amines form binuclear copper(II) and nickel(II) complexes. In those complexes the phenolic oxygen operates as a bridging group, and the carboxylate oxygen and the formyl oxygen or imino nitrogen coordinate to metal ion. It is supposed that two organic moieties are constructed *trans* to each other (Fig. 1).

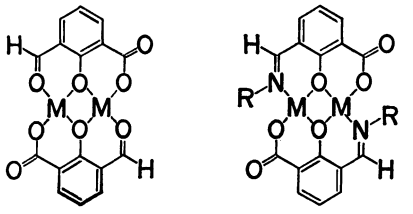

Fig. 1.

The Schiff bases derived from 3-formylsalicylic acid and diamines would form binuclear complexes bridged by the phenolic oxygens. One of the purposes of this study is synthesizing binuclear copper(II) complexes with these Schiff bases and investigating the spin-spin exchange interaction between copper(II) ions.

Geometrical requirement of the ligands results in the formation of a *cis*-configuration complex with respect to the imino nitrogens and the carboxylate oxygens. Therefore, the "inside" coordination site has N_2O_2-coordinating atoms, while the "outside" coordination site has O_4-coordinating atoms. Since there is a considerable difference in the ligand field strength between the "inside" and "outside" coordination spheres, the present ligands might form a binuclear nickel(II) complex composed of one paramagnetic and one diamagnetic metal ions. Synthesis of the binuclear nickel(II) complex of a novel spin-state is another purpose of this study.

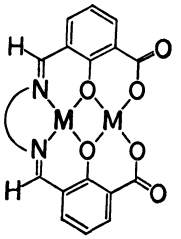

Fig. 2.

The 3-formylsalicylic acid–diamine Schiff bases utilized in this study are as follows: H_4 fsaen (Schiff base with ethylenediamine), H_4fsapn (propylenediamine), H_4fsatn (trimethylenediamine), H_4fsaph (*o*-phenylenediamine), and H_4fsach (1,2-cyclohexanediamine). The binuclear copper(II) and nickel(II) complexes with these ligands were synthesized and characterized on the basis of elemental analyses, infrared spectra, visible spectra, and magnetic measurements. The binuclear complexes are abbreviated as Cu_2(fsaen), Ni_2(fsapn), and so on. The mononuclear complexes, M(H_2fsaen)·$1/2H_2O$ and M(H_2fsapn)·$1/2H_2O$ (M=Cu(II) and Ni(II)), were also isolated and characterized.

Experimental

Syntheses. 3-Formylsalicylic acid was prepared after the method of Duff and Bills.[5] The synthetic procedures of the complexes are the same in principle. Syntheses of Cu(H_2fsaen)·$1/2H_2O$, Cu_2(fsaen)·$2H_2O$, and Ni_2(fsaen)·$3H_2O$ are represented.

Cu_2(H_2fsaen)·$1/2H_2O$. 3-Formylsalicylic acid (136 mg) was dissolved in an aqueous solution (30 ml) of sodium carbonate (55 mg), and then ethylenediamine (30 mg) was added. To this hot solution was added an aqueous solution (10 ml) of copper(II) acetate monohydrate (100 mg). Soon purple needles separated. After the reaction mixture was warmed at 60°C for a while, the product was isolated, washed with hot water and dried under reduced pressure.

Cu_2(fsaen)·$2H_2O$. An aqueous solution (30 ml) containing 3-formylsalicylic acid (136 mg), ethylenediamine (30 mg) and sodium carbonate (55 mg) was warmed at *ca.* 60°C

$Ni_2(fsach)\cdot 3H_2O$	45.35	4.33	4.66	20.68	45.72	4.19	4.85	20.32

a) $fsaen^{4-}=C_{18}H_{12}N_2O_6$, $fsapn^{4-}=fsatn^{4-}=C_{19}H_{14}N_2O_6$, $fsaph^{4-}=C_{22}H_{10}N_2O_6$, and $fsach^{4-}=C_{22}H_{18}N_2O_6$.

and to this mixture was added an aqueous solution (15 ml) of copper(II) acetate monohydrate (200 mg). This was heated at 60°C for 30 min and yellowish brown prisms which separated were collected, washed with hot water and dried under reduced pressure.

$Ni_2(fsaen)\cdot 3H_2O$. To a warm aqueous solution (30 ml) of 3-formylsalicylic acid (136 mg), ethylenediamine (30 mg) and sodium carbonate (55 mg), an aqueous solution (15 ml) of nickel(II) acetate tetrahydrate (250 mg) was added. The mixture was maintained at this temperature for 1 h. Red prisms which separated were collected, thoroughly washed with hot water, and dried under reduced pressure.

Elemental analyses of the mononuclear and binuclear metal complexes are given in Table 1.

Measurements. Infrared spectra were measured with a Hitachi 215 grating infrared spectrometer on a KBr disk. Reflectance spectra were recorded with a Shimadzu multipurpose spectrophotometer Model MPS-5000. Magnetic susceptibilities were measured by the Faraday method from liquid nitrogen temperature to room temperature. Diamagnetic correction was done using the Pascal constants.[6] Effective magnetic moment was calculated by the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$. The temperature-independent paramagnetism, $N\alpha$, for a paramagnetic nickel(II) ion is estimated at 193×10^{-6} e.m.u./mol.[7]

Results and Discussion

Mononuclear Complexes. Color and physical properties for the mononuclear complexes are tabulated in Table 2. The infrared absorption bands at 1725—1705 and at 1645—1635 cm^{-1} are tentatively assigned to the

TABLE 2. COLOR, SPECTRAL DATA, AND MAGNETIC MOMENTS OF MONONUCLEAR COMPLEXES

Complex	Color	Infrared (cm^{-1})		Visible (cm^{-1})	μ_{eff} (T(K)) (B.M.)
		C=O	C=N		
$Cu(H_2fsaen)\cdot 1/2H_2O$	purple	1705	1645	18100	1.85 (294.3)
$Cu(H_2fsapn)\cdot 1/2H_2O$	purple	1705	1645	18200	1.84 (292.9)
$Ni(H_2fsaen)\cdot 1/2H_2O$	yellow	1725	1635	18500	diamag.
$Ni(H_2fsapn)\cdot 1/2H_2O$	orange	1720	1635	18600	diamag.

C=O stretching vibration of free carboxyl group and the coordinated azomethin group respectively. The ligand field band for $Cu(H_2fsaen)\cdot 1/2H_2O$ and for $Cu(H_2fsapn)\cdot 1/2H_2O$ well corresponds to the band for *N,N'*-disalicylideneethylenediaminatocopper(II)[8-10] and for *N, N'*-disalicylidenepropylenediaminatocopper(II)[10,11] respectively. The room temperature magnetic moment for $Cu(H_2fsaen)\cdot 1/2H_2O$ and for $Cu(H_2fsapn)\cdot 1/2H_2O$ also is substantially equal to 1.84 B.M.[12] for *N,N'*-disalicylideneethylenediaminatocopper(II) and 1.81 B.M.[12] for *N,N'*-disalicylidenepropylenediaminatocopper(II) respectively. These facts imply that each of the present complexes has a similar structure to the corresponding *N,N'*-disalicylidenealkylenediaminatocopper-(II) complex.

It is clear that $Ni(H_2fsaen)\cdot 1/2H_2O$ and $Ni(H_2fsapn)\cdot$

TABLE 3. COLOR, SPECTRAL DATA AND MAGNETIC MOMENTS OF BINUCLEAR COPPER(II) COMPLEXES

Complex	Color	Infrared (cm^{-1})		Visible (cm^{-1})		$\mu_{eff}(T(K))$ (B.M.)
		C=O	C=N			
$Cu_2(fsaen)\cdot 2H_2O$	yellowish brown	1565	1640	13400	18200	0.76(295.4)
$Cu_2(fsapn)\cdot 2H_2O$	yellowish brown	1560	1630	13000	18000	0.85(299.0)
$Cu_2(fsatn)\cdot 2H_2O$	blue	1580	1630	14600	17500	0.68(295.4)
$Cu_2(fsaph)\cdot H_2O$	brown	1550	1620	15000	18000	0.89(296.7)
$Cu_2(fsach)\cdot 2H_2O$	yellowish brown	1560	1635	15100	17400	1.03(298.4)

$1/2H_2O$ have a planar configuration, since they are diamagnetic and their reflectance spectra possess only one ligand field band around 18500 cm^{-1}, which corresponds to the band for *N,N'*-disalicylideneethylenediaminatonickel(II)[10] and *N,N'*-disalicylidenepropylenediaminatonickel(II).[10]

Binuclear Copper(II) Complexes. In Table 3 color, infrared and visible absorption bands, and effective magnetic moments for the binuclear copper(II) complexes are given. No absorption band was found in the region 1750—1650 cm^{-1}. Instead a broad and strong band was found around 1550—1580 cm^{-1}. In general the $\nu_{C=O}$ mode of carboxyl shifts to lower frequency by coordination.[13] In the case of binuclear complexes of 3-formylsalicylic acid[3] and its Schiff bases,[4] the C=O stretching vibration was found around 1550 cm^{-1}. Therefore it seems reasonable to assign the band at 1580—1550 cm^{-1} to the coordinated carboxylate group.

The reflectance spectra of the complexes show two bands in the visible region. The second (higher energy) band for $Cu_2(fsaen)\cdot 2H_2O$ and for $Cu_2(fsapn)\cdot 2H_2O$ is well in accordance with the band for $Cu(H_2fsaen)\cdot 1/2H_2O$ and for $Cu(H_2fsapn)\cdot 1/2H_2O$, respectively. The position of the second band for $Cu_2(fsaph)\cdot H_2O$ is practically equal to that of the band (17900 cm^{-1}) for *N, N'*-disalicylidene-*o*-phenylenediaminatocopper(II).[10,12] Therefore, the second band was tentatively assigned to the "inside" copper(II) (CuN_2O_2-chromophor). The band at 17500 cm^{-1} for $Cu_2(fsatn)\cdot 2H_2O$ is considerably higher in energy compared with 16600 cm^{-1} [10] for *N,N'*-disalicylidenetrimethylenediaminatocopper(II). Sinn *et al.*[12,14] have found that dichloro[*N,N'*-disalicylidenetrimethylenediaminatocopper(II)]copper(II) and dichloro[*N, N'*-disalicylidenetrimethylenediaminatocopper(II)]zinc(II) have a d-d band at 17100 cm^{-1}. This fact implies that the coplanarity of the plane in *N,N'*-disalicylidenetrimethylenediaminatocopper(II) is enhanced on forming a binuclear complex bridged by the phenolic oxygen.[12,14] Therefore the band at 17500 cm^{-1} of $Cu_2(fsatn)\cdot 2H_2O$ is attributed to the $[CuN_2O_2]$-chromophor. On the other hand, the first (lower energy) band is tentatively assigned to the "outside" copper(II) ion. It is not clear if a water molecule coordinates to the "outside" copper from an apical direction.

Sub-normal magnetic moments of the complexes at room temperature suggest a partial spin-pairing between copper(II) ions. The magnetic susceptibility was measured at various temperatures (77.4—300 K). The results are shown in Fig. 3. The magnetisms were well interpreted in terms of the Bleaney-Bowers equation,[15]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha,$$

where J is the exchange integral, k the Boltzmann constant, N the Avogadro number, β the Bohr magneton, and g the Lande *g*-factor. The magnetic parameters, $-2J$, g, and $N\alpha$, obtained from the best fit of the experimental values to the theoretical values are given in Table 4.

It is well known[12,14,16,17] that the copper(II) complexes with the tetradentate Schiff bases of salicylaldehyde form binuclear copper(II) complexes bridged by the phenolic oxygens when treated with copper(II) chloride or copper(II) bromide. The magnetic properties of these complexes have been elucidated by Sinn *et al.*,[16] and the $-2J$ values, the energy separation between the singlet and triplet states, are evaluated at 98—472 cm^{-1}. It is apparent that the present complexes exhibit a stronger antiferromagnetic spin-exchange interaction compared with dihalogeno[*N,N'*-disalicylidenealkylenediaminatocopper(II)]copper(II) complexes. In these complexes it seems that the steric hindrance between the halogen and the hydrogen attached to the 3-position (next to the phenolic oxygen) of the aromatic ring is sufficiently large to deform the (X=halogen) plane to a pseudotetrahedral geometry.[16,18] In fact it was demonstrated from X-ray analysis[19] that the "outside" configuration of dichloro-[*N, N'*-disalicylideneethylenediaminatocopper(II)]copper(II) is pseudotetrahedral. On the other hand, no steric hindrance is expected in our complexes, since the carboxyl group attached to the 3-position of the salicylaldehyde moiety takes part in coordination. Thus

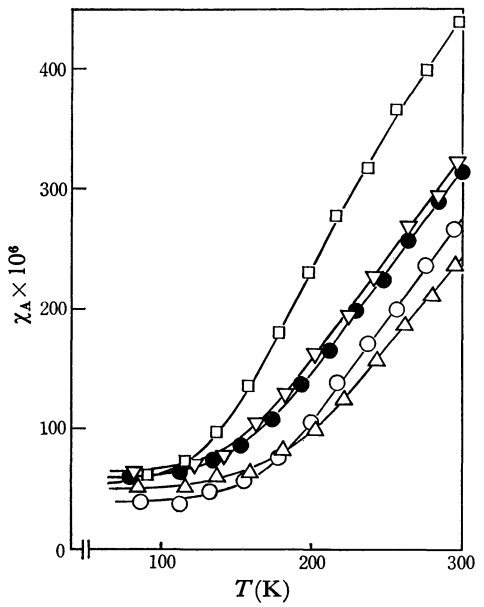

Fig. 3. Temperature variation of magnetic susceptibility of (○)$Cu_2(fsaen)\cdot 2H_2O$, (●)$Cu_2(fsapn)\cdot 2H_2O$, (△)$Cu_2(fsatn)\cdot 2H_2O$, (▽)$Cu_2(fsaph)\cdot H_2O$, and (□)$Cu_2(fsach)\cdot 2H_2O$.

Table 4. Magnetic parameters, $-2J$, g, and $N\alpha$, for binuclear copper(II) complexes

Complex	$-2J$ (cm^{-1})	g	$N\alpha\times 10^6$ (c.g.s./mol)
$Cu_2(fsaen)\cdot 2H_2O$	660	2.20	40
$Cu_2(fsapn)\cdot 2H_2O$	655	2.20	60
$Cu_2(fsatn)\cdot 2H_2O$	720	2.20	50
$Cu_2(fsaph)\cdot H_2O$	650	2.20	65
$Cu_2(fsach)\cdot 2H_2O$	555	2.20	55

TABLE 5. COLOR, SPECTRAL DATA, AND MAGNETIC MOMENTS OF BINUCLEAR NICKEL(II) COMPLEXES

Complex	Color	Infrared (cm^{-1}) C=O	C=N	Visible (cm^{-1})			$\mu_{eff}(T(K))^{a)}$ (B.M.)
$Ni_2(fsaen)\cdot 3H_2O$	red	1555	1623	9400	16000	18300	2.17(295.3) [3.14]
$Ni_2(fsapn)\cdot 3H_2O$	orange	1555	1625	9600	15000	18700	2.27(299.0) [3.23]
$Ni_2(fsatn)\cdot 5H_2O$	blue	1560	1635	8200 14500	9700 17100	12400	3.36(298.3)
$Ni_2(fsaph)\cdot 5H_2O$	reddish orange	1550	1620	9500	15500	18500	2.33(296.6) [3.28]
$Ni_2(fsach)\cdot 3H_2O$	orange	1555	1625	9100	14800	18500	2.25(294.8) [3.21]

a) Magnetic moment per nickel(II) ion. The value in a bracket is calculated on the assumption that one of nickel(II) ions is diamagnetic.

the configuration of the "outside" copper $\begin{pmatrix} O & O \\ & Cu \\ O & O \end{pmatrix}$ is substantially planar and two tetragonal planes of the "inside" and "outside" copper(II) ions form a coplane. Thereby the spin exchange between the metal ions may be efficiently caused by a super-exchange mechanism through the oxygen P_π-orbitals.[20]

Binuclear Nickel(II) Complexes. The infrared spectra of the binuclear nickel(II) complexes are similar to those of the corresponding copper(II) complexes. Each reflectance spectrum of $Ni_2(fsaen)\cdot 3H_2O$, $Ni_2(fsapn)\cdot 3H_2O$, $Ni_2(fsaph)\cdot 5H_2O$, and $Ni_2(fsach)\cdot 3H_2O$ has three d-d bands in visible region. The band around 18500 cm^{-1} seems to correspond to the band for the mononuclear nickel(II) complexes. The bands around 9500 and 15500 cm^{-1} imply that these complexes contain a nickel(II) of octahedral configuration. Accordingly, the coordination of water from apical positions was supposed for the "outside" nickel. The bands around 9500 and 15500 cm^{-1} were assigned to the $^3T_{2g}\leftarrow{}^3A_{2g}$ and $^3T_{1g}\leftarrow{}^3A_{2g}$ transitions respectively. Since the 10 Dq for hexaaquonickel(II) is estimated at 8500 cm^{-1},[21] the ligand field in the present complexes is stronger than H_2O.

The magnetic moments calculated per one nickel(II) ion are much lower than the spin-only value 2.83 B.M. This may be explained by (a) antiferromagnetic spin-pairing between paramagnetic nickel(II) ions or (b) formation of binuclear complex containing one paramagnetic and one diamagnetic nickel(II) ions. The visible spectra of the complexes seem to support the latter possibility. In order to obtain further evidence magnetic susceptibility was measured at various temperatures. In Fig. 4, $1/(\chi_A - N\alpha)$ is plotted against temperature. As is seen in Fig. 4 the magnetisms of the complexes are well interpreted in terms of the Curie-Weiss law ($\chi_A = C/(T-\theta)$). It should be noted that the Weiss constants are very small (at best 4 K). The phenolic oxygen-briged binuclear nickel(II) complexes so far reported obey the Curie-Weiss law in the range from liquid nitrogen temperature to room temperature with a relatively large Weiss constant more than 30 K.[3,4,22,23] Accordingly it is concluded that $Ni_2(fsaen)\cdot 3H_2O$, $Ni_2(fsapn)\cdot 3H_2O$, $Ni_2(fsaph)\cdot 5H_2O$, and

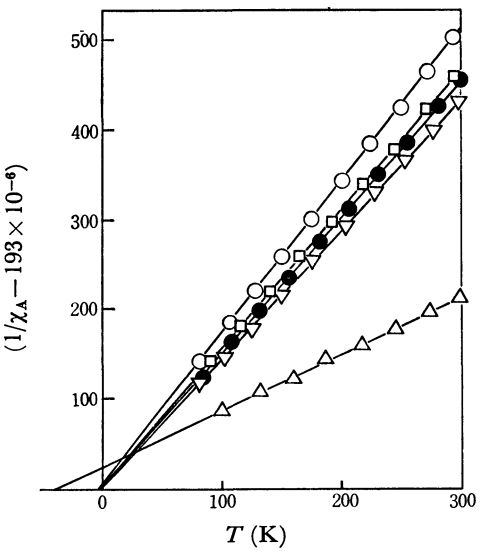

Fig 4. Plots of inverse susceptibilities as a function of temperature for (○)$Ni_2(fsaen)\cdot 3H_2O$, (●)$Ni_2(fsapn)\cdot 3H_2O$, (△)$Ni(fsatn)\cdot 5H_2O$, (▽)$Ni_2(fsaph)\cdot 5H_2O$, and (□)$Ni_2(fsach)\cdot 3H_2O$ per a nickel atom.

$Ni_2(fsach)\cdot 3H_2O$ are novel complexes composed of one paramagnetic and one diamagnetic nickel(II) ions. Thus, magnetic moments per binuclear units were calculated to give 3.14—3.28 B.M., which are quite common to a nickel(II) in an octahedral environment.

Paramagnetic-diamagnetic binuclear nickel(II) complexes are rare.[22] The success in synthesizing paramagnetic-diamagnetic binuclear nickel(II) complexes with the present ligands is obviously cocerned with a considerable difference in the ligand field strength between the "inside" and "outside" coordination sites. The coordinatively selective property of the ligands also leads to the formation of the copper(II)-paramagnetic nickel(II) complex (CuNi(fsaen))[24] and other hetero-metal binuclear complexes.[25] The Schiff bases derived from 1,3,5-triketones and diamines,[26-29] which are similar in coordinating mode to our ligands, should form paramagnetic-diamagnetic binuclear nickel(II) complexes.

The color and the visible spectrum of $Ni_2(fsatn)\cdot$

$5H_2O$ are markedly different from other nickel(II) complexes. It is known that *N,N'*-disalicylidenetrimethylenediaminatonickel(II) maintains a planar structure.[10,30] However its d-d band is fairly low in energy, demonstrating a weaker ligand field of the ligand with a 6-6-6 condensed ring system compared with the tetradentate salicylaldehyde-Schiff bases with a 6-5-6 condensed ring system. The binuclear nickel(II) complex of the macrocycle obtained from 2-hydroxy-5-methylisophthalaldehyde and 1,3-propanediamine (nickel(II) ions are bridged by the phenolic oxygens) is known to have a high-spin state, where the nickel is coordinated with chloride ion in the apical position.[23] From this fact it is likely that the "inside" ligand field strength of H_4fsatn decreases to allow the fifth (and the sixth) coordination from an apical position when the phenolic oxygen operates as a bridge. The room temperature magnetic moment of Ni_2(fsatn)·$5H_2O$ is 3.36 B.M. per one nickel(II) ion. The magnetic moment decreases with lowering of temperature to 2.97 B.M. at 87.5 K. The $1/(\chi_A - N\alpha)$ plots against temperature obey the Curie-Weiss law with the large Weiss constant −40 K. This value is quite comparable to those (−35—−41 K) found for the binuclear nickel(II) complexes of 3-formylsalicylic acid–monoamine Schiff bases.[4] Thus it is evident that Ni_2(fsatn)·$5H_2O$ is a binuclear complex composed of two paramagnetic nickel(II) ions.

The authors are grateful to the Ministry of Education for a Scientific Research Grant-in-Aid.

(Received April 15, 1976)

The hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates was run in water, aqueous ethanol, aqueous glycerol, aqueous acetonitrile, aqueous dimethyl sulfoxide, and aqueous tetrahydrofuran at various pH values and temperatures. The initial concentration of the phosphates was 0.025 mol/l. The hydrolysis of the poly- and metaphosphates followed first-order kinetics with respect to the concentration of the phosphate, under all conditions studied. The hydrolysis of sodium pyro- and tripolyphosphates was an acid-catalyzed reaction and that of sodium trimeta- and tetrametaphosphates was an acid- and base-catalyzed reaction. In acidic solutions, the rate of hydrolysis of the poly- and metaphosphates in water was slower than that in any aqueous organic solution. It is concluded that the nucleophilicity of the water molecule in the aqueous organic solutions may increase on account of the interaction of the water molecule with the organic molecules. The hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates in acidic solutions is considered to be of the S_N2 type, because the overall-reaction rate is highly dependent on the nucleophilicity of the water molecule. The solvent effect on the rate of hydrolysis of sodium tripolyphosphate in basic solutions was the same as that in acidic solutions and hence the mechanism of the hydrolysis of sodium tripolyphosphate in basic solutions may be the same as that in acidic solutions. The rate of hydrolysis of sodium trimeta- and tetrametaphosphates in a basic water solvent was much faster than that in basic aqueous ethanol and basic aqueous dimethyl sulfoxide and was largely slower than that in basic aqueous glycerol. Consequently, the mechanism of the hydrolysis of sodium trimeta- and tetrametaphosphates in basic solutions seems to differ from that in acidic solutions. The acceleration of the rate of hydrolysis of the metaphosphates by the organic molecules depends significantly upon the activation energy. The activation energy of the hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates was 17—34 kcal/mol in the pH range of 1.0—12.2 and increased with an increase in the pH value of the phosphate solution in water and aqueous ethyl alcohol solvents.

The tetrahedral phosphorus atom of organic compounds having a P=O bond is sensitive for nucleophilic attack.[1] Wieker and Thilo proposed the same mechanism for the hydrolysis of long-chain polyphosphate by examining the catalytic effect of metal cations on the hydrolytic polyphosphate degradation.[2] In previous papers by the authors,[3,4] the solvent effect on the rate of hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates was examined by running the hydrolysis in water, aqueous dioxane, aqueous formic acid, and aqueous acetic acid. According to the results, the hydrolysis of sodium pyro- and tripolyphosphates at any pH value and that of sodium trimeta- and tetrametaphosphates in acidic solutions were considered to be S_N2 reactions. The types of solvents used in our previous experiments were not numerous. Therefore, in the present paper, the solvent effect on the rate of hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates is examined by using aqueous ethanol, aqueous glycerol, aqueous acetonitrile, aqueous dimethyl sulfoxide, and aqueous tetrahydrofuran as solvents. Ethanol and glycerol are protic solvents and acetonitrile, dimethyl sulfoxide, and tetrahydrofuran are dipolar aprotic solvents. The hydrogen atom of the OH-group contained in the first group can form a hydrogen bond with the oxygen atom of a water molecule and the oxygen or the nitrogen atom present in the second group can form a hydrogen bond with the hydrogen atom of a water molecule.

Experimental

Materials and Procedure. All the materials except sodium tripoly-, trimeta-, and tetrametaphosphates were of a commercial grade. Sodium tripoly-, trimeta-, and tetrametaphosphates were produced by the method described in Refs. 5 and 6. The solvents used in this experiment and their dielectric constants are listed in Table 1. The dielectric constants were measured by using an Ando Denki TR-1C VHF material characteristics test assembly. The initial concentration of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates was 0.025 mol/l. This concentration is suitable for analysis. pH control of the phosphate solutions was made by the same method as that described in previous papers by the authors by using nitric acid and aqueous tetramethyl ammonium hydroxide.[3,4] The pH adjustment was made to within ± 0.1 unit of the desired pH value. The pH change of

TABLE 1. SOLVENTS USED FOR THE HYDROLYSIS OF PYRO-, TRIPOLY-, TRIMETA-, AND TETRAMETAPHOSPHATES AND THEIR DIELECTRIC CONSTANTS

Solvent	Dielectric constant	Symbol
Water		S_1
25 vol% aqueous ethanol	63	S_2
20 vol% aqueous ethanol	65	S_3
35 vol% aqueous glycerol	64	S_4
30 vol% aqueous acetonitrile	69	S_5
25 vol% aqueous dimethyl sulfoxide	73	S_6
20 vol% aqueous dimethyl sulfoxide	73	S_7
25 vol% aqueous tetrahydrofuran	59	S_8
20 vol% aqueous tetrahydrofuran	65	S_9

the phosphate solution of the S_5 solvent in basic media with the elapse of reaction time was very large and it was difficult to maintain the pH of the solution to within ± 0.1 unit of the desired pH value. Therefore, the hydrolysis of the phosphates in the S_5 solvent was not run in basic media. The reaction temperature was maintained at 30, 50, or 70 ± 0.05 °C by using a thermostat. The separation and determination of the phosphate species in the sample solution were carried out by using the same method as described in previous papers.[3,4] However, the separation of the hydrolysis products of trimeta- and tetrametaphosphates for all alkaline solutions was not good, and hence, after the basic sample solutions were acidified with nitric acid, the acidified solutions were spotted on filter papers. For the hydrolysis of sodium trimeta- and tetrametaphosphates in the S_4 solvent, 1 ml of a saturated aqueous sodium chloride solution was added to 10 ml of the sample solution and then the separation of the phosphate species in the solution was carried out by using one-dimensional paper chromatography. Since the boiling point of tetrahydrofuran is 65 °C, the hydrolysis of the phosphates in the S_8 and S_9 solvents was not run at 70 °C.

Results and Discussion

Order of the Reactions and the pH Dependence of the Reaction Rates. The hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates obeyed first-order kinetics with respect to the concentration of the phosphate under the conditions studied. The rate constants of the hydrolysis of the phosphates are listed in Tables 2—5. In all the solvents used in this experiment, the rate of hydrolysis of the short-chain polyphosphates (pyro- and tripolyphosphates) decreases with an increase in the pH of the solution and this tendency is the same as that found in previous experiments.[3,7] Since the hydrolytic degradation of pyrophosphate is very slow in a basic solution and the measurement of the rate of hydrolysis of pyrophosphate in basic media is difficult, only the hydrolysis of tripolyphosphate was run in basic solutions. As Tables 2 and 3 show, the hydrolysis of the short-chain polyphosphates is an acid-catalyzed reaction in all solvents. In the case of the hydrolysis of the small-ring metaphosphates (trimeta- and tetrametaphosphates), the rate of hydrolysis of the small-ring metaphosphates decreases in acidic solutions and increases in basic solutions with an increase in the pH value for all solvents.[8] Therefore, the hydrolysis of

a) For the solvents, refer to Table 1.

small-ring metaphosphates is an acid- and base-catalyzed reaction in all solvents, and this is also in good agreement with the results obtained for previous experiments.[4,7] In the course of the hydrolysis of sodium tetrametaphosphate in the acidic S_1–S_8 solvents and the basic S_2 and S_5–S_8 solvents, trimetaphosphate was detected on a paper chromatogram and the quantity of the trimetaphosphate was too small for an accurate determination. Otani, Miura, and Doi have reported that trimetaphosphate was detected as the intermediate of the hydrolytic degradation of tetrapolyphosphate in an acidic aqueous solution.[9] Tetrametaphosphate is hydrolyzed to tetrapolyphosphate in the first step of hydrolytic degradation,[10] and hence, the trimetaphosphate detected in this experiment from the hydrolysis of sodium tetrametaphosphate may be produced by the hydrolysis of the tetrapolyphosphate which is produced by the hydrolysis of tetrametaphosphate. Accordingly, it can be said that there is little difference in the hydrolytic processes for tetrametaphosphate in either the S_1 and S_4 solvents or in the S_2, S_5, S_6, and S_8 solvents. In order to obtain information concerning the mechanism of the hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates, the activation energy and log A

a) For the solvents, refer to Table 1.

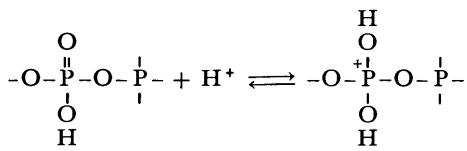
(A: frequency factor) of the hydrolysis of the phosphates were calculated by means of an Arrhenius plot and are listed in Tables 6—9. Since the activation energy and log A for the hydrolysis of sodium pyro- and tripolyphosphates in acidic solutions increase with an increase in the pH value, the decrease of the rate of hydrolysis for both the short-chain polyphosphates with increasing pH value depends highly upon the activation energy in all acidic solutions studied. The activation energy of the hydrolysis of sodium trimeta- and tetrametaphosphates increases with an increase in the pH value in all acidic solutions, while log A of the hydrolysis of both the small-ring metaphosphates decreases with an increase in the pH value. The decrease in the rate of hydrolysis with increasing pH value, therefore, depends upon both the activation energy and the frequency factor in all the acidic solutions studied. For basic solutions, the increase in the rate of hydrolysis of sodium trimetaphosphate with an increase in the pH value in

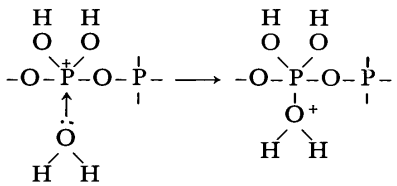
the S_1 and S_2 solvents is highly dependent upon an entropy term, while those in the S_4 and S_6 solvents depend on an energy term and on energy and entropy terms, respectively.

Difference in the Stability of the Hydrolysis of Phosphates. According to the results shown in Tables 2—5, sodium pyrophosphate is more stable against hydrolytic degradation than sodium tripolyphosphate and sodium trimetaphosphate much more subject to hydrolytic scission than is sodium tetrametaphosphate. It can be seen by comparing the results in Tables 6 and 8 with those in Tables 7 and 9, respectively, that the stability of sodium pyrophosphate against hydrolytic scission depends upon an energy term or upon both energy and entropy terms, while the stability of sodium tetrametaphosphate depends entirely on an energy term under the conditions studied. The stability of chain phosphate against hydrolytic degradation decreases, in general, with the chain length of the phosphate,[7] and it can reasonably be accepted that the longer the chain of the phosphate, the greater the probability of hydrolytic scission of a P–O–P linkage. This explanation can not be applied to the stability of small-ring metaphosphates because the chain length of tetrametaphosphate is longer than that of trimetaphosphate. The stability of tetrametaphosphate against hydrolysis is explained by Van Wazer as follows: a tetrametaphosphate ring exhibits a greater number of possible atomic configurations and modes of internal motion than does a trimetaphosphate ion, so that the latter is essentially more rigid and hence more subject to scission.[7] According to Griffith and Rutt,[11] a trimetaphosphate ion has D_{3h} symmetry (planar form) and a tetrametaphosphate ion has C_{2h} symmetry (chair form) in an aqueous solution. The former may be more rigid than the latter. By quantum-chemical consideration, the stability of a system generally proceeds with an increase in the number of obtainable states of the system. The discussion given above and the kinetic data obtained in this experiment seem to support Wazer's explanation of the stability of tetrametaphosphate against hydrolytic scission.

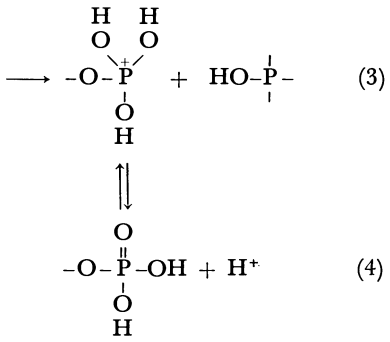
The Solvent Effect on the Rate of Hydrolysis. As is shown in Tables 2—5, in acidic media, the rate of hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates in pure water is slower than that in the ethanol–water, glycerol–water, acetonitrile–water, dimethyl sulfoxide–water, and tetrahydrofuran–water solvents at the same pH values and reaction temperatures. The solvent effect of ethanol, glycerol, and acetonitrile on the rate of hydrolysis of short-chain and small-ring phosphates in acidic media is a small, while that of dimethyl sulfoxide and tetrahydrofuran in acidic media is very marked. The rate of hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates in aqueous dimethyl sulfoxide and aqueous tetrahydrofuran is about 1.5—3.0 and 1.3—2.0 times faster, respectively, than that in pure water. In organic reactions, the effect of the dielectric constant of a solvent on a reactant has been discussed extensively.[12] The relation between the rate constant for the hydrolysis of the phosphates and the dielectric constant of the sample solutions is not parallel and is complex. The present authors have discussed the solvent effect on the rate of hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates by dioxane, formic acid, and acetic acid in previous papers.[3,4] Depending upon the same consideration of the previous papers, the solvent effect in this experiment can reasonably be explained in terms of the difference in the nucleophilicity of the water molecule in each solution as follows. (1) In the case of protic solvents, ethanol and glycerol can interact with a water molecule and hence the hydrogen bond between water molecules may be broken and a hydrogen bond may then be established between the hydrogen atom of the OH group of the protic organic molecules and the oxygen atom of a water molecule. The hydrogen bond between the protic organic molecules and a water molecule may be weaker than that between water molecules, because the polarity of a water molecule is larger than that of ethanol and glycerol molecules. Therefore, the nucleophilicity of the water molecule in aqueous ethanol and aqueous glycerol is larger than that in pure water. The nucleophilic attack by the water molecule of aqueous ethanol and aqueous glycerol on the phosphorus atom of the phosphates may be more favorable energetically than that in pure water. (2) The oxygen atom of dimethyl sulfoxide and tetrahydrofuran and the nitrogen atom of acetonitrile can form a hydrogen bond with the hydrogen atom of a water molecule, and hence the hydrogen bond between water molecules is broken. Accordingly, the nucleophilicity of the water molecule in the aqueous organic solvents may be larger than that in pure water and the nucleophilic attack of the water molecule in aqueous dimethyl sulfoxide, aqueous tetrahydrofuran, and aqueous acetonitrile may also be more favorable energetically than that in pure water. From the results listed in Tables 6—9, it can be said that the acceleration of the rate for short-chain and small-ring phosphates by the organic solvents in acidic media depends mainly upon the activation energy. This appears to support considerations (1) and (2) above. According to the above discussion, since the overall-reaction rates of the hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates in acidic media are highly dependent upon the nucleophilicity of the water molecule and the hydrolysis of the phosphates is an acid-catalyzed reaction, one can describe a series of elementary reactions for the hydrolysis of the poly- and metaphosphates as follows:



(1)



(2)



(3)

(4)

The phosphate ion on the right-hand side of reaction (1) may more readily accept the nucleophilic attack of a water molecule than the phosphate on the left-hand side of reaction (1). The rate-determining step for the hydrolysis of the poly- and metaphosphates in an acidic solution may be the second step because the overall-reaction rate is highly dependent upon the nucleophilicity of the water molecule, as mentioned above. Therefore, the hydrolysis of sodium pyro-, tripoly-, trimeta-, and tetrametaphosphates in acidic solutions may be of the S_N2 type. This conclusion is in good agreement with that of the reaction mechanism of organic phosphorus(V) compounds having P=O bonds[1] and that of the hydrolytic mechanism of long-chain polyphosphates proposed by Wieker and Thilo.[2]

In basic solutions, as is shown in Table 3, the solvent effect on the rate of hydrolysis of sodium tripolyphosphates is the same as that in acidic solutions, and the hydrolysis of the polyphosphate in basic solutions may also be of the S_N2 type. The kinetic data in Tables 4 and 5 show that the solvent effect on the rate of hydrolysis of sodium trimeta- and tetrametaphosphates in basic solutions is much different from that in acidic solutions. The rate of hydrolysis of both metaphosphates in pure water is much faster than that in the S_2 and S_6 solvents and is much slower than that in the S_4 solvent. From the results in Tables 8 and 9, the acceleration or the retardation of the rate of hydrolysis of both metaphosphates in the basic S_2, S_4, and S_6 solvents in comparison with the rate of hydrolysis in the basic S_1 solvent depends upon an energy term. This tendency is almost the same as that obtained in a previous paper by the authors.[4] The hydrolytic reaction mechanism for sodium trimeta- and tetrametaphosphates in basic solutions is not the same as that in acidic solutions. It can be concluded that there are other elementary reactions affecting the overall-reaction rate of the hydrolysis of sodium trimeta- and tetrametaphosphates in basic solutions, other than the nucleophilic attack of a water molecule on the phosphorus atom of the phosphates.

Successive Spectrophotometric Determination of Palladium and Platinum

Kingo MIZUNO and Giroku MIYATANI*

Department of Chemistry, Faculty of Liberal Arts, Iron and Steel Technical College, Nishikoya, Amagasaki-shi, Hyogo 661

**Department of Metallurgy, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka 565*

(Received April 17, 1976)

The absorbance of the water soluble red complex of palladium(II) and 4-(2-pyridylazo)resorcinol (PAR) was measured at 513 nm. Concd hydrochloric acid and tin(II) chloride were added to an aliquot of the red solution, and both the palladium complex and the excess of PAR were decolorized by the reduction of the azo radical of PAR. The absorbance of the platinum complex with tin(II) chloride was measured at 403 nm.

The photometric determination of many metals by using 4-(2-pyridylazo)resorcinol (PAR) has been described. It is known that palladium(II) reacts with PAR to form four kinds of stable 1 : 1 chelates. One of them is green at pH below 4 and the others are red at pH above 4.[1] We found that the water soluble red complex at pH 10.3—11 had an absorption maximum at about 520 nm in 0.01 M EDTA.[2] By the use of the EDTA–NaOH solution, not only a masking of many diverse ions but also a buffer action at 10.5 has been achieved, and 30 times of platinum(IV) was scarcely interfered in the determination of palladium.

The tin(II) chloride method is widely used for the spectrophotometric determination of micro amounts of platinum.[3] But in the presence of palladium it gives a positive error in the determination of platinum, so that the regions available to this method are limited.

It has been known that many azo compounds are easily reduced with tin(II) chloride in concentrated hydrochloric acid.[4,5] We found that PAR and its palladium complex were also reduced and almost completely decolorized. This reductive reaction was combined with the determination of platinum; the spectrophotometric determination of Pd-PAR complex was carried out at 513 nm and then the determination of platinum at 403 nm. By using this procedure the successive determination of palladium and platinum became possible.

Experimental

Apparatus. A Hitachi double beam spectrophotometer model 200-20 with 1 cm cuvettes, a Hitachi recorder model QPD53, and a Hitachi-Horiba pH meter model H-5 were used.

Reagents. A standard palladium stock solution was made by dissolving 500 mg of metal in aqua regia and evaporating to dryness on a water bath After evaporating to dryness three times with hydrochloric acids, the residue was dissolved with 0.1 M hydrochloric acid and made up to 500 ml with 0.1 M hydrochloric acid. This solution was standardized gravimetrically by the dimethylglyoxime method. The palladium test solution was prepared by diluting 5 ml of stock solution and 4.5 ml of 1 M hydrochloric acid and diluted to 500 ml with water. This test solution contained 9.86 μg of palladium per ml.

A standard platinum solution was made by dissolving 100 mg of pure platinum in a few ml of aqua regia and evaporating to dryness; then 5 ml of concd hydrochloric acid and 0.1 g of sodium chloride were added and the solution evaporated to dryness. The residue was dissolved in 20 ml of 6 M hydrochloric acid and the solution was diluted to exactly 1 l. This standard solution contained 100 μg of platinum per ml.

A 0.1% PAR solution was prepared by dissolving 0.25 g of PAR (free acid form, Dojin Pharmaceutical Laboratories, Kumamoto, Japan) to 2 ml of 1 M sodium hydroxide solution, and diluting to 250 ml with water. This solution was stored in a polyethylene bottle.

An EDTA buffer solution having a pH of 10.5 was prepared by adding 100 ml of 1 M sodium hydroxide to about 200 ml of EDTA aqueous solution in which was dissolved 18.6 g of EDTA (di-sodium salt) and diluting to 500 ml with water.

The tin(II) chloride solution was made by dissolving 115 g of $SnCl_2 \cdot 2H_2O$ in 170 ml of warm concd hydrochloric acid and diluting to 500 ml with water. A stick of pure tin was placed in the bottle to keep the solution in the reduced state.

All the other chemicals used were of reagent grade.

Recommended Procedure. To the sample solution containing 0—100 μg palladium and 0—300 μg platinum, 5 ml of 0.1 M EDTA buffer solution (pH 10.5) and 0.5 ml of 0.1% PAR solution were added (if needed, the pH ought to be adjusted to 10.3—10.5 by 0.1 M sodium hydroxide). Then the solution was warmed in a water bath at 80 °C for 10 min and was cooled. The solution was diluted to 50 ml with water to determine its absorbance at 513 nm. A blank was run through the whole procedure, using water.

To a 25 ml residual solution of determined palladium contents, 7 ml of concd hydrochloric acid was added and stirred, followed by the addition of 10 ml of tin(II) chloride solution. The solution was diluted to 50 ml with water to determine its absorbance at 403 nm.

The authentic absorbance of platinum was provided by substracting 0.001 for each 10 μg palladium from its observed absorbance. By these procedures palladium and platinum were successively determined.

Results and Discussion

Measurements of Absorption Spectra. Figure 1 shows the absorption spectra of PAR and Pd-PAR. In the previous paper[2] measurements were carried out at 520 nm. However, as it turned out that the absorption maximum of Pd-PAR complex was at 513 nm, in this study measurements were carried out at this wavelength at pH 10.3—10.5. Under these conditions the molar extinction coefficient was 2.6×10^4 and the sensitivity which gave the absorbance of 0.001 was 0.0041 μg-Pd^{2+}/cm^2. To the beaker containing 49.3 μg palladium, 5 ml of 0.1 M EDTA buffer solution and 0.5 ml of 0.1% PAR solution were added. The solution was heated at 80 °C for 10 min and cooled, then 7 ml of concd hydrochloric acid was added to it. In addition,

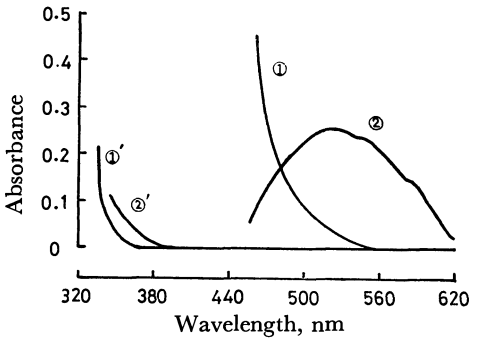

Fig. 1. Absorption curves of PAR, Pd-PAR and their decolorized.
①PAR (0.5 mg/50 ml), ② Pd-PAR (Pd: 49.3 μg/50 ml), ①′ and ②′ signify the solutions being reduced corresponding to ① and ②.

49.3	200	0.244	24.65	100	0.085	0.080
49.3	300	0.245	24.65	150	0.125	0.120

a) Total volume 50 ml, PAR 0.5 mg/50 ml.

when one drop of tin(II) chloride was added, the solution of Pd-PAR complex changed from green to colorless. As the tin(II) chloride content increased, PAR and its palladium complex were reduced and almost completely decolorized. In Fig. 1, ① and ② are the absorption curves of PAR and Pd-PAR respectively, and ①′ and ②′ are the blanks of ① and ② respectively. ①′ and ②′ have no absorption at 403 nm, which is the wavelength for platinum. For determining the platinum contents, the sensitivity of this procedure was not different from Sandell's procedure.

The Successive Determination of Palladium and Platinum. The results shown in Table 1 were obtained from the analysis of some known synthetic mixtures containing 0—49.3 μg palladium and 0—300 μg platinum. In the case of no platinum, palladium gave an absorbance as if the absorbance of platinum were 0.001. In the presence of palladium, the absorbance of platinum increased 0.001 for each 10 μg palladium (5 μg palladium in determining platinum contents). By these corrections of the absorbance of platinum, a good linear relationship was found between the platinum content and its absorbance.

The Successive Determination of Other Metals and Platinum. As the photometric determination of many metals can be carried out by using PAR,[6] other metals and platinum can be determined in succession. In place of PAR the heterocyclic azo dyestuffs will be able to be used.

The authors wish to thank Dr. Eiichi Ibuki, Professor in the Kyoto College of Pharmacy, for his advice on this work. They also thank Dr. Hiromu Imai, Professor in Kansai University, and Dr. Takeshige Oyama, Professor in the Iron and Steel Technical College, for their ardent encouragement.

Kinetics of Ligand Substitution Reaction of Some Aminopolyacetatonickel(II) Complexes with Reference to Activation Parameters

Shigenobu FUNAHASHI and Motoharu TANAKA*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received May 13, 1976)

The substitution reactions of some Ni(II)–L complexes (L: ethylenediamine-*N,N'*-diacetate, edda^{2-}; nitrilotriacetate, nta^{3-}; iminodiacetate, ida^{2-}) with 4-(2-pyridylazo)resorcinol (H_2par) have been studied spectrophotometrically at I=0.10. Rate constant k (mol dm^{-3}, s) at 25 °C, activation enthalpy ΔH^{*}/kJ mol^{-1} and activation entropy ΔS^{*}/J K^{-1} mol^{-1} are respectively: 1.7×10^{3}, 58.5 and 12.5 for k[Ni^{2+}][Hpar^{-}]; 4.0×10^{2}, 51.8 and −22 for k[Ni(nta)$^{-}$][Hpar^{-}]; 1.0×10^{3}, 41.8 and −46 for k[Ni(edda)][Hpar^{-}]; 2.7×10^{-4}, 109 and 30 for k[(par)-Ni(edda)$^{2-}$]; 5.1×10^{-3}, 88 and 17 for k[(par)Ni(Hedda)$^{-}$]; 1.7×10^{3}, 122 and 226 for k[Ni(ida)][Hpar^{-}]. In terms of activation parameters some discussions are made on the effect of coordinated ligands on the lability of leaving ligands and pre-equilibrium involving partial dissociation of leaving ligands.

Extensive investigations[1] have indicated that the ligand substitution reaction of metal chelates with multidentate ligands proceeds through an intermediate in which a central metal ion is bonded with both leaving and entering ligands and that the cleavage of the bond between the metal and leaving ligand is the rate-determining step. We have previously reported the kinetics and mechanism of ligand substitution reactions of Ni(II)–NTA and Ni(II)–EDDA complexes with PAR at 25 °C[2]**. We have pointed out on the basis of values of rate constants that the effect of ligands already present in a complex on the ease of replacement of the leaving ligand is closely related to the electron-donating properties of the ligands.[2,3] It seems worthwhile to consider the labilization of the leaving ligands by the bound ligand in terms of activation parameters.

Experimental

Preparation of all reagents except IDA, instrumentation and experimental procedure for measuring equilibria and reaction rates are the same as described previously.[2] Reagent grade IDA, obtained from Dojin-do Chemical Co., Japan, was recrystallized twice from distilled water.

Results

Ligand Substitution Reaction of the Ni(II)–EDDA Complex with PAR. The ligand substitution reaction of the ethylenediamine-*N,N'*-diacetatonickel(II) complex with 4-(2-pyridylazo)resorcinol at 17.1, 20.3, and 23.2 °C has been measured by the same method as described previously.[2] The mechanism proposed for the reaction is as follows:[2]

$$\mathrm{Ni(edda)} + \mathrm{Hpar^-} \xrightarrow{k_1} \mathrm{(par)Ni(edda)'} + \mathrm{H^+} \quad (1)$$

$$\mathrm{(par)Ni(edda)^{2-}} \xrightarrow{k_2} \mathrm{Ni(par)} + \mathrm{edda'} \quad (2)$$

$$\mathrm{(par)Ni(edda)^{2-}} + \mathrm{H^+} \rightleftharpoons \mathrm{(par)Ni(Hedda)^-} \quad K^{\mathrm{H}}_{\mathrm{(par)Ni(Hedda)}}$$

$$\mathrm{(par)Ni(Hedda)^-} \xrightarrow{k_{2,\mathrm{H}}} \mathrm{Ni(par)} + \mathrm{edda'}$$

$$\mathrm{Ni(par)} \xrightarrow[\text{fast}]{+\mathrm{Hpar^-}} \mathrm{Ni(par)_2^{2-}} \quad (2)$$

The rate constants and formation constants of the protonated complex at various temperatures, and the values of activation parameters are given in Table 1.

Ligand Substitution Reaction of the Ni(II)–NTA Complex with PAR. The ligand substitution reaction of the nitrilotriacetatonickel(II) complex with 4-(2-pyridylazo)resorcinol at 20.2 and 15.4 °C has been followed as described previously.[2] The reaction proceeds as follows:[2]

$$\mathrm{Ni(nta)^-} + \mathrm{Hpar^-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{(par)Ni(nta)^{3-}} + \mathrm{H^+} \quad (3)$$

$$\mathrm{(par)Ni(nta)^{3-}} \xrightarrow{k_2} \mathrm{Ni(par)} + \mathrm{nta'}$$

$$\mathrm{Ni(par)} \xrightarrow[\text{fast}]{+\mathrm{Hpar}} \mathrm{Ni(par)_2^{2-}} \quad (4)$$

parameters are summarized in Table 2.

Ligand Substitution Reaction of the Ni(II)–IDA Complex with PAR. We have studied the ligand substitution reaction of the bis(iminodiacetato)nickel(II) complex with PAR:

$$\text{Ni(II)–IDA} + \text{PAR} \rightleftharpoons \text{Ni(II)–PAR} + \text{IDA} \quad (5)$$

Under the present experimental conditions, the Ni(II)–IDA and Ni(II)–PAR complexes are the 1 : 2 complexes *i.e.* $Ni(ida)_2^{2-}$ and $Ni(par)_2^{2-}$, respectively. The dominant species of PAR is the monoionic species $Hpar^-$. Reaction (5) is so much favored to the right that the reaction of the Ni(II)–IDA complex with PAR goes to completion. The overall ligand substitution reaction is described as

$$Ni(ida)_2^{2-} + 2Hpar^- \longrightarrow Ni(par)_2^{2-} + 2ida' \quad (6)$$

where ida' represents IDA not combined to nickel. The initial rates were analyzed. The reaction was found to be of first-order with respect to $Ni(ida)_2^{2-}$ and $Hpar^-$. Some conditional second-order rate constants are summarized in Table 3.

5.60×10^{-4}	9.209	2.7	3.47×10^{-3}
5.60×10^{-4}	8.453	6.7	1.48×10^{-2}

a) $C_{Ni}=1.02\times10^{-5}$, $C_{PAR}=1.00\times10^{-4}$ mol dm^{-3}.
b) $C_{Ni}=5.09\times10^{-6}$, $C_{PAR}=5.00\times10^{-5}$ mol dm^{-3}.

The dependence of IDA concentration on the conditional rate constant points to predissociation of IDA in $Ni(ida)_2^{2-}$ because the values of the rate constant decrease with increasing concentration of IDA and $-\log[H^+]$. We assume the following reaction scheme:

$$Ni(ida)_2^{2-} \rightleftharpoons Ni(ida) + ida' \quad (7)$$

$$Ni(ida) + Hpar^- \xrightarrow{k_2} Ni(par) \xrightarrow[fast]{+Hpar^-} Ni(par)_2^{2-} \quad (8)$$

Then the rate equation of the formation of $Ni(par)_2^{2-}$ is given by

$$\text{Rate} = k_2[Ni(ida)][Hpar^-]$$

$$= k_2\frac{\alpha_{ida(H)}}{K^{ida}_{Ni(ida)_2}(C_{IDA}-2C_{Ni})}[Ni(ida)_2^{2-}][Hpar^-] \quad (9)$$

where C_{IDA} and C_{Ni} are the total concentrations of IDA and nickel ion, respectively, and $\alpha_{ida(H)}=1+K^{H}_{Hida}[H^+]+K^{H}_{Hida}K^{H}_{H_2ida}[H^+]^2$.* The conditional rate constants are plotted against the values of $\alpha_{ida(H)}/\{K^{ida}_{Ni(ida)_2}(C_{IDA}-2C_{Ni})\}$ in Fig. 1. The non-zero intercept in the plot indicates another reaction path not involving predissociation of IDA in $Ni(ida)_2^{2-}$. The reaction, therefore, proceeds through two parallel reaction paths for which the following rate equation can be deduced:

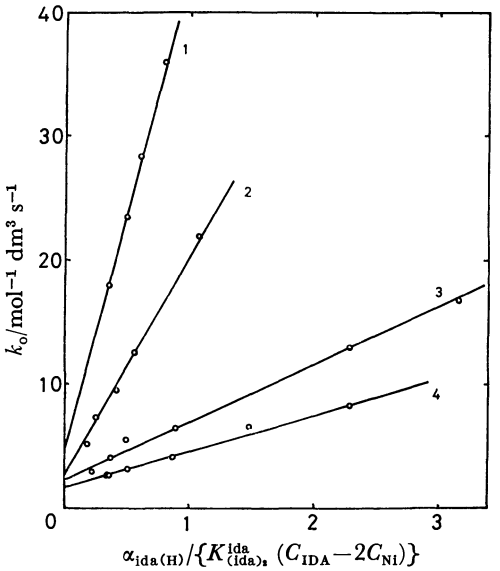

Fig. 1. Dependence of k_0 on the function $\alpha_{ida(H)}/\{K^{ida}_{Ni(ida)_2}(C_{IDA}-2C_{Ni})\}$.
Reaction temp/°C, 1: 30.0; 2: 25.0; 3: 19.3; 4: 14.1.

* $K^{ida}_{Ni(ida)_2}=[Ni(ida)_2^{2-}]/\{[Ni(ida)][ida^{2-}]\}$, $K^{H}_{Hida}=[Hida^-]/\{[ida^{2-}][H^+]\}$, $K^{H}_{H_2ida}=[H_2ida]/\{[Hida^-][H^+]\}$. The values for these stability constants at a given temperature are available (G. Anderegg *Helv. Chim. Acta*, **47**, 1801 (1964)).

$$\frac{d[Ni(par)_2^{2-}]}{dt} = k_1[Ni(ida)_2^{2-}][Hpar^-] + k_2[Ni(ida)][Hpar^-] = \left\{k_1 + \frac{k_2\alpha_{ida(H)}}{K^{ida}_{Ni(ida)_2}(C_{IDA}-2C_{Ni})}\right\} \times [Ni(ida)_2^{2-}][Hpar^-] \quad (10)$$

Thus the observed second-order rate constant k_0 is equal to $k_1+k_2\alpha_{ida(H)}/\{K^{ida}_{Ni(ida)_2}(C_{IDA}-2C_{Ni})\}$. Rate constants at various temperatures are tabulated in Table 4.

Table 4. Rate constants for ligand substitution of Ni(II)–IDA with PAR and activation parameters

Reaction temp/°C	k_1 / mol^{-1} dm^3 s^{-1}	k_2 / mol^{-1} dm^3 s^{-1}
14.1	≈1.6	2.9×10^2
19.3	≈2.1	4.8×10^2
25.0	≈3.0	1.7×10^3
30.0	≈4.5	3.8×10^3
ΔH^*/kJ mol^{-1}		122±15
ΔS^*/J K^{-1} mol^{-1}		226±50

Activation parameters for k_2 are 121±15 kJ mol^{-1} for the activation enthalpy and 226±50 J K^{-1} mol^{-1} for the activation entropy. Activation parameters for k_1 are not evaluated because of uncertainty.

Discussion

In order to estimate thermodynamic parameters for pre-equilibrium of partial dissociation preceding the rate-determining steps in substitution, we need to consider thermodynamic parameters for some nickel complexes.

Thermodynamic parameters for some nickel complexes are given in Table 5 where the data are presented in the order of numbers of available coordination sites; N_xO_y represents a ligand having x nitrogen atoms and y oxygen atoms for coordination. The data in Table 5 illustrate a striking difference between ΔH and ΔS values for nitrogen and oxygen donors. The Ni(edda) complex is formed with exothermic enthalpy similar to that of the $Ni(en)^{2+}$ complex and the stability constant of the former is larger than that of the latter due to the contribution of positive entropy for chelation of carboxylates. The ΔH values for nitrogen coordination are appreciably more exothermic and constitute the major portion of ΔH. The contribution of nickel–carboxylate bonds to the total ΔH values is very small (see values for acetate and oxalate in Table 5). Interactions with carboxylate groups, being of a more electrostatic character, would be expected to have only a small and probably endothermic effect. It is possible to estimate approximate values for the contribution made by each nickel–nitrogen bond and each nickel–oxygen bond by assuming additivity. We can deduce the ΔH and ΔS values per coordinated nitrogen atom to be about 20 kJ mol^{-1} and about 0 J K^{-1} mol^{-1}, respectively, and per coordinated oxygen atom which forms a chelate ring, about 0 kJ mol^{-1} and 40—60 J K^{-1} mol^{-1}, respectively.

Results in the present study are summarized in Table 6. The rate-determining step of reactions A, B, and C (Table 6) is the dissociation of a water molecule coordinated to nickel(II). We have previously pointed

Table 6. Activation parameters for reactions of some nickel(II) complexes

Reaction (Equation number in the text)	Rate equation	Reaction product	Rate constant at 25 °C k(mol dm^{-3}, s)	ΔH^*/kJ mol^{-1}	ΔS^*/J K^{-1} mol^{-1}
A[a]	$k[Ni^{2+}][Hpar^-]$	$Ni(par)_2^{2-}$	1.7×10^3	58.5± 2.5	12.5± 5

out that there should be the dissociation of one donor oxygen atom of the coordinated ligand in the Ni–NTA and Ni–EDDA complexes before the incoming ligand (PAR) can gain a coordination foothold.[2] The $\Delta S^{\neq}$ value for reactions B and C which is more negative than that for reaction A is attributable to the dissociation of a carboxylate at the pre-equilibrium step. On the other hand, as the contribution of such dissociation of carboxylate to $\Delta H^{\neq}$ may be regarded as about 0 kJ mol^{-1} (*vide supra*), the decrease in $\Delta H^{\neq}$ in going from reaction A to B and C supports the view that the labilization of the remaining water molecules by the bound ligands is closely related to the electron-donating properties of the latter ligands: when a ligand coordinated to the central metal ion donates electrons to the central metal to a greater extent, the bond of the central metal with the remaining coordinated water molecules will be weakened and more easily broken.

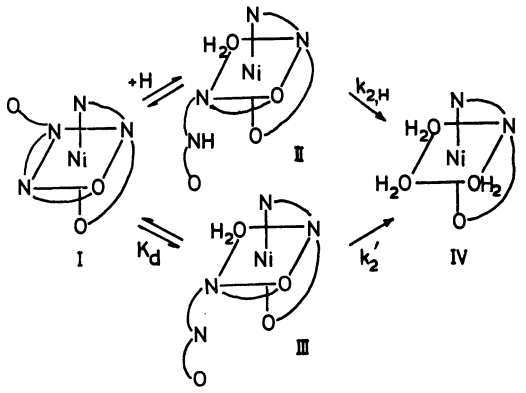

Fig. 2. Proposed reaction mechanism for the dissociation of the intermediate. EDDA and PAR are symbolized as O–N–N–O and N–N–O, respectively. Charges are omitted.

In our previous paper,[2] it was pointed out that judging from the stability constants of EDDA[4]: $[Hedda^-]/\{[edda^{2-}][H^+]\}=10^{9.57}$ and $[H_2edda]/\{[Hedda^-][H^+]\}=10^{6.48}$, the proton in the protonated complex (II in Fig. 2) should be attached to a nitrogen atom in the EDDA which is the most basic. In this work, we determined the values of the stability constants of the protonated complex at 17.1 and 20.3 °C which are the same as the value at 25.0 °C within an experimental error (Table 1). This indicates that the enthalpy for reaction I→II in Fig. 2 is zero kJ mol^{-1}. All the enthalpies for the protonation of nitrogen atoms in MIDA, NTA, and EDDA are approximately −30 kJ mol^{-1}.[5] Taking into account the fact that the contribution of nickel–carboxylate bonds to the total enthalpy values is rather small, the enthalpy for detaching a nitrogen atom in the (par)Ni(edda)$^{2-}$ complex seems to be about 30 kJ mol^{-1}. In reaction I→II in Fig. 2, the endothermic enthalpy for detaching a nitrogen–nickel bond is compensated by the exothermic enthalpy for binding a proton to a nitrogen atom, and so the net enthalpy change for reaction I→II may be nearly zero kJ mol^{-1}.

It may be of interest to examine the difference in rates between reactions D and E from kinetic and mechanistic point of view. The difference in activation parameters for k_2 (reaction D in Table 6) and $k_{2,H}$ (reaction E in Table 6) is explained on the basis of the equilibria preceding rate-determining steps. If we accept a possible mechanism given in Fig. 2, k_2 is given as follows

$$k_2 = K_d k_2'$$

where K_d is the equilibrium constant between I and III and k_2' is a rate constant for the rate-determining step (III→IV). The first Ni–N bond rupture (I→III) would require an energy corresponding to $\Delta H \approx 20$ kJ mol^{-1} and $\Delta S \approx 0$ J K^{-1} mol^{-1}. This is consistent with our experimental data of the activation parameters for $k_{2,H}$ (II→IV) and k_2' (III→IV) within error limits.

In the substitution of the Ni(II)–IDA complex with PAR, the formation of a mixed-ligand intermediate involving both IDA and PAR could not be observed. However, by analogy with the EDDA and NTA systems, it seems reasonable to speculate that the reaction for the IDA system also proceeds through an intermediate with both leaving and entering ligands. Then the k_2 process in Eq. 10 corresponds to an overall reaction involving formation of the mixed-ligand intermediate and dissociation of the leaving ligand IDA from the intermediate. The large activation enthalpy for reaction F in Table 6 is close to the sum of the activation enthalpies for reactions B (or C) and E: the intermediate is not so stable. The large enthaly of activation for reaction F is largely offset by an exceptionally large entropy of activation. But sufficient information is not available to explain such a remarkably positive entropy of activation.

Studies on Leuckart-Wallach Reaction Paths

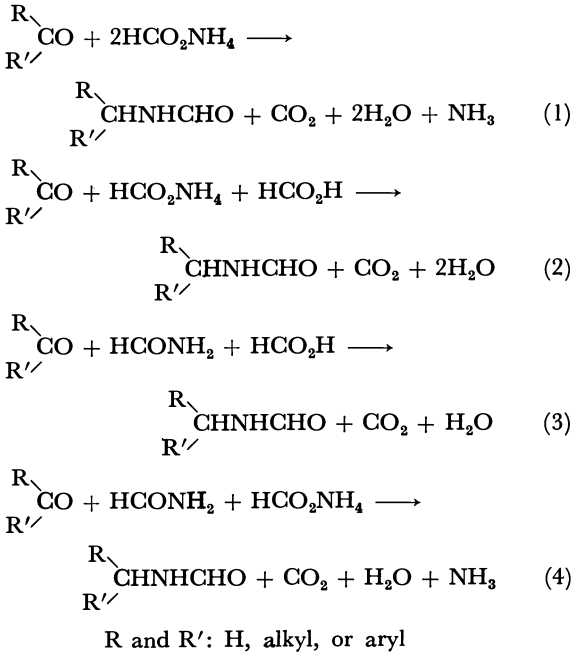
Keiichi Ito, Hitoshi Oba, and Minoru Sekiya
Shizuoka College of Pharmacy, Oshika, Shizuoka 422
(Received March 17, 1975)

The Leuckart-Wallach reaction paths were investigated by means of catalytic reduction in the Leuckart-Wallach reaction system and on the basis of analogous formic acid reductions. It was determined that, in the early stage of the Leuckart-Wallach reaction, ammonia, amine and also formamide undergo addition reactions to carbonyl compounds. The addition of formamide catalyzed by formic acid plays a significant role only for the more reactive substrates such as benzaldehyde. The behaviors of plausible intermediates for the formic acid reduction are discussed on the basis of the data of similar formic acid reductions.

The Leuckart-Wallach reaction is well known[1-4] as a process for the reductive amination of aldehydes and ketones. Many workers have been involved in experiments designed to elucidate the mechanism of the reaction. Some have commented on the ammonia- or the amine-addition mechanism of the carbonyl condensation stage and others on the formamide-addition mechanism. Furthermore, the mechanism of the second stage, reduction, is still in dispute. The present work involving catalytic reduction of the Leuckart-Wallach reaction system relating to formic acid reduction bears significantly upon the understanding of the reaction path.

Results and Discussion

Process of the Leuckart-Wallach Reaction. A number of reagents such as ammonium formate, ammonium formate–formic acid, formamide–formic acid, and formamide–ammonium formate have been used[1] for reactions with carbonyl compounds. The overall reactions with respect to the formation of *N*-formyl primary amine can be illustrated by the equations shown in Scheme 1. The formations of *N*-formyl secondary amine and tertiary amine can be similarly formulated by replacing the ammonium formate and formamide with their *N*-alkyl analogs. The carbon dioxide formation in these reactions is indicative of the participation of formic acid as the reducing agent. Several workers have conducted the reduction of carbonyl compounds with formamide alone, although no convincing determination has been made of its reducing capacity. In these cases, the actual reducing agent may be ammonium



R and R′: H, alkyl, or aryl

Scheme 1.

formate which can plausibly be derived from formamide by hydrolysis with water produced in the reaction mixture. In our trials of the reactions of benzaldehyde and cyclohexanone with formamide[5] (Table 1) almost no carbon dioxide was detected during the course of the reaction, which proceeded only at higher temperatures and required a much longer period. This diminishes the possibility of reduction with ammonium formate generated from formamide. In the reaction of benzal-

a) Carried out using C_6H_5CHO (0.1 mol) and $C_6H_{10}O$ (0.2 mol) with 10-fold amounts of the reagent, $HCONH_2$, HCO_2NH_4, and $HCONH_2$ added with HCO_2H (1.5 molar equiv. to the substrate). b) Yield is based on the product isolated. R = $C_6H_5CH_2$– and C_6H_{11}–. c) Amaron was obtained as a by-product. d) *N*,*N*′-Benzylidenebisformamide was obtained as a by-product.

dehyde with formamide amaron (2,3,5,6-tetraphenylpyrazine), in addition to the amine products, was isolated. In previous papers by the present authors the formations of amaron and lophine (2,4,5-triphenylimidazole) in the reactions of *N,N'* benzylidenebisformamide[6] and *N*-benzylideneaniline[7] with formamide are well documented and were interpreted as clues to support the idea of self oxidation-reduction reactions. In view of these papers, it is then suggested that the reaction of benzaldehyde with formamide alone appears to proceed similarly to the self oxidation-reduction course. From this abnormality of the reduction course, the reaction with formamide alone may be distinguished from others involving formic acid reduction. Accordingly, the decription hesreafter is chiefly concerned with the reactions involving formic acid reduction.

Although the Leuckart-Wallach reaction involves many elementary steps, the path of the reaction can be divided into two important stages, the formation of the C–N bond and the formic acid reduction to amine.

The Initial Condensation Stage. Two arguments have been postulated for the initial stage of the Leuckart-Wallach reaction, the addition of ammonia or amines[8–12] and the addition of formamide[12–18] to carbonyl compounds. As long as ammonium formate undergoes dehydration to formamide at the reaction temperature, the participation of ammonium formate as formamide in the reaction is possible. Conversely, the participation of formamide as ammonium formate is possible when the hydrolysis of formamide occurs with water formed in the reaction mixture. Therefore, the interconversion[1] between ammonium formate and formamide allows the participation of these two species in every fashion of the Leuckart-Wallach reaction in Scheme 1. It has been a problem to determine whether the actual participating species is ammonium formate or formamide.

Using benzaldehyde and cyclohexanone as carbonyl compounds, preliminary experiments were undertaken on the typical reactions with formamide, formic acid–formamide, and ammonium formate (Table 1). The difficulty in defining the behaviors of the reagents comes from the dual roles played by the reagents in both the initial C–N bond formation and the succeeding reduction. In order to understand how the reagents react initially with the carbonyl compounds, it is desirable, if possible, to eliminate the succeeding reduction by the same reagents.

Experiments for this purpose were carried out on the catalytic reductions of the carbonyl compounds in the presence of the Leuckart-Wallach reagents below the temperature (100 °C) at which the reagents affect the carbon dioxide formation. In this manner, formic acid reduction is eliminated and replaced by catalytic reduction. Using a palladium-on-charcoal catalyst, high-pressure hydrogenation of the Leuckart-Wallach reaction system occurred with benzaldehyde under standardized conditions at 90—100 °C.

The affinities of formamide and *N*-benzylformamide for benzaldehyde can be realized from the results of

runs 1, 2, and 3 in Table 2, although the reduction of unreacted benzaldehyde to benzyl alcohol is shown. Formamide itself was shown to be inert to benzaldehyde. On the other hand, in the presence of formic acid, formamide led to the formation of not only *N*-benzylformamide but also *N,N*-dibenzylformamide and tribenzylamine. Under the same conditions, *N*-benzylformamide affected the formation of only a small amount of *N,N*-dibenzylformamide. In consideration of the appreciable formation of *N,N*-dibenzylformamide and tribenzylamine in run 2 it was then required to know whether water, which was formed in the reaction mixture, participates in the product formation, since water hydrolyzes formamide into another reactive ammonium formate. Runs 4 and 5 in Table 2 carried out in the presence of a desiccant, boron trioxide, and of water, respectively, offered clear information on the effect of water on the reaction. In the former, the addition of boron trioxide considerably reduced the yields of *N,N*-dibenzylformamide and tribenzylamine relative to *N*-benzylformamide, whereas, in the latter, the addition of water considerably increased the yield of tribenzylamine without the formation of *N*-benzylformamide. The result of run 5 closely resembles that of run 8 carried out using ammonium formate in place of the formamide of run 2. In view of the above facts, the water added can be understood to affect an increase in the participation of ammonium formate and the desiccant to affect an increase in the participation of formamide. In such a reaction in the presence of formic acid, the interaction between formamide and benzaldehyde is actually recognized to occur, although the participation of ammonium formate also occurs. Formic acid as an additive can then be regarded as an acid catalyst for the reaction between formamide and benzaldehyde.

Next, an examination by the same hydrogenation procedure was attempted in order to observe the behavior of ammonium formate with benzaldehyde. The catalytic reductions of benzaldehyde in the presence of ammonium formate and of ammonia (ammonium carbonate was used) resulted in the formation of tribenzylamine and dibenzylamine, in free and *N*-formylated forms, in the yields given in Table 2. It is inferred that dibenzylamine is derived from the initially formed benzylamine, and tribenzylamine stepwise through dibenzylamine. This was demonstrated by carrying out the reduction in the presence of benzylamine and of dibenzylamine, where the effect of the additional presence of formic acid was also checked, as can be seen for runs 9, 11, 10, and 12 in Table 2. From the above results, it was found that in the ammonium formate medium under the hydrogenation conditions, the carbonyl addition of the amine species proceeds stepwise leading to benzylamine, dibenzylamine and finally tribenzylamine. The reaction was shifted to the formation favorable to tribenzylamine when formic acid was present.

Following the same catalytic reduction procedure, an examination was then made using cyclohexanone. Formamide was, however, inert with cyclohexanone in the hydrogenation system, probably owing to the low

Table 3.[a] Catalytic reduction[b] of cyclohexanone in the Leuckart-Wallach reaction system

Run No.	Additive[c]	Reaction time (min)	Yield (%) of the product[d]			
			ROH	RNH_2	R_2NH	Total

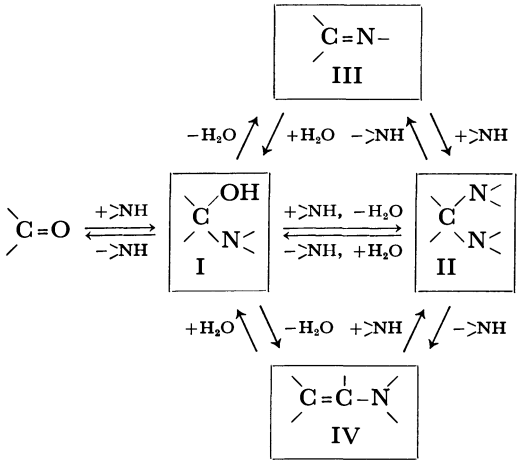
a) R=⟨H⟩–. b) Hydrogenation condition—catalyst, 10% Pd–C, 6 g; initial hydrogen pressure, 80 kg/cm² (room temp); reaction temp, 55—60 °C. c) Molar equivalents of the additives to the cyclohexanone (0.2 mol) used are given in parenthesis. d) Yield of the product isolated is calculated from the starting cyclohexanone. e) Recovery.

temperature (60 °C) which restricts the carbon dioxide formation. As can be seen in Table 3, ammonia and ammonium formate lead to the formation of cyclohexylamine and, more favorably, dicyclohexylamine. Cyclohexylamine, even in the presence of formic acid, was shown to greatly effect the formation of dicyclohexylamine in the same hydrogenation system. No formation of tricyclohexylamine from cyclohexanone was observed even for hydrogenation in the presence of dicyclohex l-amine. The lack of any tricyclohexylamine formation throughout the above runs may be due to a steric hindrance.

The Formic Acid Reduction Stage. After an understanding of the behaviors of formamide and ammonium



Relation to the reagent

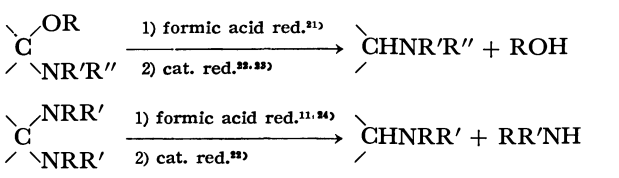
a. In the case of >NH=ammonia and amines
NH_3 and $-NH_2$ ⟶ I, II, III
>NH ⟶ I, II, IV (with >CHCO–)

b. In the case of >NH=$HCONH_2$ and HCONH–
$HCONH_2$ ⟶ I, II, III
HCONH– ⟶ I

Scheme 2.

formate toward carbonyl compounds, the formic acid reduction stage in the Leuckart-Wallach reaction encounters a problem. Plausible intermediates resulting from the addition and condensation reactions of ammonia (from ammonium formate) and of formamide with the carbonyl compounds can be described as in Scheme 2. In the Leuckart-Wallach reaction, how these intermediates participate in the formic acid reduction is a subject to be studied in relation to their catalytic reductions.

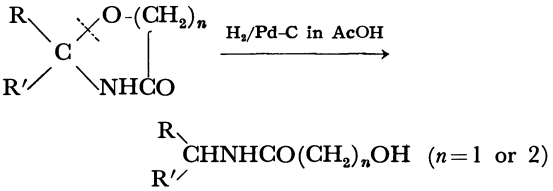
For Ammonia or Amine Condensation Intermediates: Both the formic acid and the catalytic reductions of Schiff's bases[7,19] of type III and enamine[20] of type IV in Scheme 2 are well documented to result in the reduction of their C=N and C=C double bonds, respectively. In previous work,[11,21-24] several available analogs of types I and II such as  and  (R, R', and R''≠H) have been known to undergo reductive fission of one of the two bonds to the hetero-atom to give a tertiary amine by formic acid reduction, as well as catalytic reduction, as is shown in the following schemes:

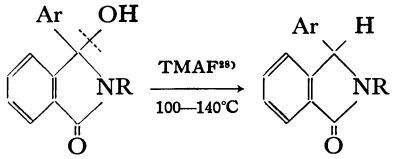


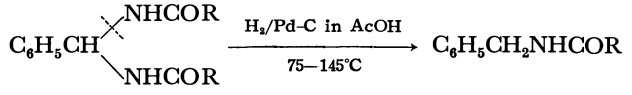
Since in these reported reduction, reductive fission has been realized to occur directly, the intermediates of types I and II  ; R, R'=H or alkyl) seem to undergo reductive fission without dehydration and deamination, respectively.

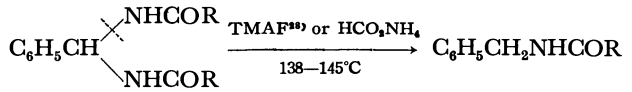
Thus, any type of intermediate shown in Scheme 2 can produce the same amine products upon reduction with formic acid, as well as upon catalytic reduction.

For Formamide Condensation Intermediates: Plausible condensation intermediates from formamide may be assumed to be of types I, II and III in Scheme 2. Previous papers appear to draw some insight relative to the formic acid and catalytic reductions of types I and II. There have been reported the catalytic reduction of 4-oxazolidinones and tetrahydro-4H-1,3-oxazin-4-ones,[25] the formic acid reduction of 3-aryl-3-hydroxyphthalimidines[26] and the catalytic[27] and the formic acid reductions[6] of *N,N'*-benzylidenebisamides. These substrates are regarded as analogs of types I and II. The reductions affect the reductive fissions, as is shown by the dotted lines in the following schemes, resulting in *N*-acylated amines. The patterns of these reactions









may not be in conflict in receiving types I and II as plausible intermediates.

In order to obtain further information about an intermediate of type I, an examination was directed to the synthesis of *N*-(α-hydroxybenzyl)amide and its formic acid reduction. The synthesis was successfully performed by the hydrolysis of *N*-(α-piperidinobenzyl)-benzamide with aqueous acetic acid. The formic acid reduction of *N*-(α-hydroxybenzyl)benzamide with TMAF[28] proceeded at 95—100 °C, while carbon dioxide was detected in a short period. Although most of the material was converted into benzaldehyde and benzamide, benzylamine was obtained even in a low yield (about 3%) through hydrolysis. Neverthless, it may be possible for the benzaldehyde reaction that *N*-(α-hydroxybenzyl)formamide exists in a certain equilibrium for the conventional use of a large excess of formamide. Type I is therefore referred to as a plausible intermediate in the reaction with formamide.

Comprehensive Aspect of the Leuckart-Wallach Reaction. In spite of the confusion in the previous arguments for the Leuckart-Wallach reaction, the present work in the catalytic reduction system has demonstrated both the ammonia- or amine-addition and the formamide-addition to the carbonyl compound in the initial stage. The latter was shown to be favorable for rather reactive carbonyl compounds such as benzaldehyde, while the presence of formic acid was necessary. *N*-Alkylformamide was nearly inert with the carbonyl compounds as demonstrated by the interaction of benzaldehyde with *N*-benzylformamide. The behaviors of plausible intermediates for formic acid reduction in the Leuckart-Wallach reaction are described in relation to their catalytic reduction which proceeded in a similar fashion giving the same amine products. Since mutual conversion between the intermediates are possible, it appears difficult to decide the actual intermediate undergoing the formic acid reduction for each of the various carbonyl compounds. In opposition to previously reported statements, clear accounts for the features of the Leuckart-Wallach reaction can be drawn from our results. In the formic acid reductions, the formamide-condensation intermediates are reduced to *N*-formyl primary amine, while the ammonia- or amine-condensation intermediates are reduced to primary, secondary and tertiary amines, the former two undergoing successive *N*-formylation or reacting competitively with the carbonyl compound. Ammonium formate as a reacting species therefore reacts to produce tertiary

amine and/or *N*-formyl secondary amine rather than *N*-formyl primary amine, particularly under conditions accelerating the carbonyl addition (the presence of formic acid is effective), whereas formamide reacts in favor of the production of *N*-formyl primary amine. The reaction with formamide as given by Eq. 3, however, involves a considerable participation of ammonium formate generated from formamide by the hydrolysis with water formed in the reaction mixture. In conformity with the above features several papers dealing with the behaviors of the Leuckart-Wallach reagents for the preparative purpose of yielding *N*-formyl primary amine have reported that a mixture of formamide and formic acid or ammonium formate is more efficient in several cases[9,13,16,29] rather than the use of ammonium formate alone. The predominant formation of *N*-formyl primary amine by the increase in the formamide participation is brought on by the reaction with formamide alone, but in this case the reduction is suggested to be caused through self oxidation-reduction of the carbonyl compound rather than by formic acid.

Experimental

Reaction of Benzaldehyde with Formamide, Formic Acid–Formamide and Ammonium Formate (Table 1). The reactions of benzaldehyde were carried out by heating with constant stirring of the reagents, *i.e.*, freshly distilled formamide (run 1), formic acid-formamide (run 2) and dried ammonium formate (run 3). The starting amounts and the reaction temperatures are listed in Table 1. In runs 2 and 3 considerable CO_2 evolution was observed, whereas in the run with formamide almost none was detected even at the high temperature given. The products were concentrated by distilling off the excess of the reagents under reduced pressure in runs 1 and 2, whereas in run 3 this was accomplished by benzene extraction since the reaction mixture solidified. In run 2, *N,N'*-benzylidenebisformamide, mp 148—149 °C [lit,[30] mp 149—150 °C], was isolated in a 24% yield from the residue as a benzene insoluble material. The concentrates were subjected to fractional distillation under reduced pressure to give two fractions, bp 134—136 °C/0.3 mmHg and bp 164—166 °C/0.3 mmHg, leaving a resinous residue only in run 1. The first solid fraction was identified as *N*-benzylformamide, mp 57—59 °C. The second fraction was shown to be composed of tribenzylamine and *N,N*-dibenzylformamide. Their separation was accomplished by passing dry HCl through the benzene solution, resulting in the precipitation of tribenzylamine hydrochloride, mp 226—228 °C. After filtration, the filtrate was freed of HCl by treating with aqueous $NaHCO_3$, dried over $MgSO_4$ and concentrated to leave crystals which were identified as *N,N*-dibenzylformamide, mp 49—50 °C. The foregoing distillation residue obtained in run 1 was chromatographed through silica gel using $CHCl_3$ as an eluent. From earlier fractions 1.5 g of amaron was obtained, mp 245—246 °C [lit,[30] mp 246—247 °C].

All the products obtained above were identified by comparison of their IR spectra with those of authentic specimens and by the mixed melting point test. Their yields are shown in Table 1.

Reactions of Cyclohexanone with Formamide, Formic Acid–Formamide and Ammonium Formate (Table 1). The reactions of cyclohexanone were carried out in a way similar to those of benzaldehyde under the conditions listed in Table 1. In the course of the reactions, considerable CO_2 was detected when formic acid–formamide and ammonium formate were used. The reaction solutions were concentrated under reduced pressure to remove excess amounts of the reagents. In every run, the resulting residue was distilled into two fractions, bp 123—125 °C/4 mmHg and bp 150—154 °C/4 mmHg, leaving a resinous residue only in the run with formamide (run 4). The former fraction was shown to be *N*-cyclohexylformamide [Found: C, 66.36; H, 10.36; N, 10.71%. Calcd for $C_7H_{13}NO$: C, 66.10; H, 10.30; N, 11.01%] and the latter *N,N*-dicyclohexylformamide, mp 53—56 °C [Found: C, 74.65; H, 10.98; N, 6.71%. Calcd for $C_{13}H_{23}NO$: C, 74.59; H, 11.08; N, 6.69%]. Their yields are recorded in Table 1.

Catalytic Reductions of Benzaldehyde in the Leuckart-Wallach Reaction System (Table 2). In the presence of the reagents indicated in Table 2, the high-pressure hydrogenation of benzaldehyde was carried out over a Pd–C catalyst under the conditions given in Table 2. The reductions were accomplished by constant shaking at 90—100 °C, for which a preliminary test showed no formation of CO_2, and were continued until the pressure drop nearly ceased. After filtration of the autoclave contents, the filtrates were concentrated, whereupon benzyl alcohol was distilled together with formamide. With the addition of water to the distillates followed by distillation, benzyl alcohol alone was steam-distilled and isolated by saturation of the resulting distillate with K_2CO_3 and then by extraction with benzene. The above concentration residues were subjected to distillation under reduced pressure. In runs 5, 7, 8, and 12, where *N,N*-dibenzylformamide and tribenzylamine were present in the residue, this product was distilled as a mixture at bp 142—160 °C/0.2 mmHg. Their separation was accomplished by the same procedure as described in the first section. In addition to *N,N*-dibenzylformamide and tribenzylamine, *N*-benzylformamide was present in the residue in runs 2, 3, and 4, and free dibenzylamine in that of run 10. For these runs all the *N*-benzylformamide and dibenzylamine were distilled separately from the other two products at bp 125—129 °C/0.2 mmHg and bp 122—127 °C/1 mmHg, respectively. In runs 6, 9, and 11, where the residue was composed of dibenzylamine and tribenzylamine, these products were simply separated as two distillates, bp 122—127 °C/1 mmHg and bp 165—171 °C/1 mmHg, respectively. All the products were identified by comparison of their IR spectra with those of authentic specimens and by mixed melting point tests. Their yields are recorded in Table 2.

Catalytic Reductions of Cyclohexanone in the Leuckart-Wallach Reaction System (Table 3). As indicated in Table 3, the high-pressure hydrogenations of cyclohexanone were carried out in the presence of the Leuckart-Wallach reagents over a Pd–C catalyst. The reduction temperature was maintained at 55—60 °C, a temperature for which formic acid reduction was not effective. After filtration of the autoclave contents, the filtrates combined with methanolic rinsings were concentrated, whereupon volatile cyclohexylamine was distilled together with MeOH. Acidification of the distillates with aqueous HCl followed by concentration gave cyclohexylamine hydrochloride. In run 4, the concentration residue was wholly solidified as crystals, while in run 6 only partly so, and the crystals were identified to be dicyclohexylammonium formate, needles from acetone–MeOH, mp 161—162 °C [lit,[15] mp 166—167 °C]. Found: C, 68.75; H, 11.08; N, 6.23%. Calcd for $C_{13}H_{25}NO_2$: C, 68.68; H, 11.08; N, 6.16%. Mixtures composed of cyclohexanol and dicyclohexylamine were obtained as the filtrate in run 6 and as the concentration residue in runs 3 and 5. The two components of these mixtures were separated by distillation under reduced pressure. During the distillation, dicyclohexylamine and cyclohexanol partly formed a crystalline sublimate, which was identified as

the adduct, $(C_6H_5)_2NH\cdot C_6H_5OH$, mp 51—54 °C [lit,[31] mp 47—48 °C]. Found: C, 76.14; H, 12.37; N, 5.02%. Calcd for $C_{18}H_{35}NO$: C, 76.80; H, 12.53; N, 4.98%. The yields of the products are recorded in Table 3.

Preparation of N-(α-Hydroxybenzyl)benzamide and its Formic Acid Reduction. A suspension of 2.9 g of powdered *N*-(α-piperidinobenzyl)benzamide[32] in 42 ml of 3% AcOH was heated at 85 °C for 10—15 min with vigorous stirring and then immediately cooled. The suspended precipitates were collected by filtration, washed with a small amount of cold water and quickly dried. Recrystallization from dry $CHCl_3$ gave needles of *N*-(α-hydroxybenzyl)benzamide, mp 100—102 °C. Yield, 0.8 g (35%). IR ν_{max} (KBr) 3265, 1640, 1520, and 1032 cm^{-1}. Found: C, 74.29; H, 5.78; N, 6.17%. Calcd for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.77; N, 6.16%.

A mixture of 4.6 g of *N*-(α-hydroxybenzyl)benzamide and 28 g of TMAF[28] was heated with stirring at 95—100 °C for about 40 min, after which the CO_2 detected was negligible. The reaction solution was concentrated under reduced pressure, whereupon benzaldehyde was distilled off together with the excess TMAF. Basification of the distillate with KOH and extraction with benzene gave benzaldehyde in a 95% yield. In order to detect *N*-benzylbenzamide in the residue, which was mostly composed of benzamide, a hydrolyzed solution of the residue with 50% ethanolic KOH was subjected to GLC using a column packed with Carbowax 20 M on 20% KOH-Chromosorb W. The benzylamine was detected in a 3% yield.

The authors wish to thank Mr. K. Narita and the other members of the Analysis Center of this college for the elemental analyses.

Preparation and Reactions of 4-Alkoxy-2,2-bis(trifluoromethyl)-thietanes and 5-Alkoxy-3,3-bis(trifluoromethyl)dithiolanes

Tomoya KITAZUME, Toru OTAKA, Ryutaro TAKEI, and Nobuo ISHIKAWA

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 27, 1975)

4-Alkoxy-2,2-bis(trifluoromethyl)thietanes, **3** (R=Me and Et), were prepared by the reactions of 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane with alkyl vinyl ethers in a KF–DMF system. A bimolecular condensation product, bis[4,4-bis(trifluoromethyl)thietan-2-yl]ether, **5**, was obtained by the treatment of **3** with concentrated sulfuric acid. On the other hand, when treated with sulfur in DMF in the presence of diethylamine, **3** gave 5-alkoxy-3,3-bis(trifluoromethyl)-1,2-dithiolanes, **8**, in rather good yields. Several reactions of these thietanes and 1,2-dithiolanes, including those with butyllithium, were examined.

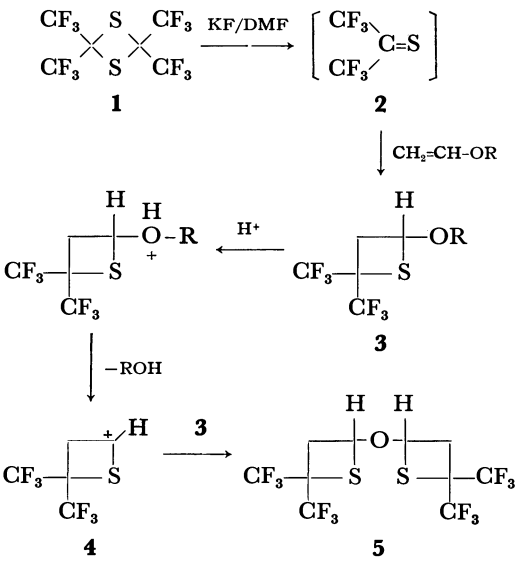
In our previous paper, it has been reported that hexafluorothioacetone (**2**) is liberated gently from its dimer, 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (**1**), in a potassium fluoride–*N*,*N*-dimethylformamide system.[1] Since the dimer is a stable liquid which can be prepared from hexafluoropropene and sulfur directly, the compound seemed to be a useful starting material for the hexafluorothioacetone derivatives. Thus, the earlier studies have been continued, and we now wish to report on the preparation of cycloadducts of hexafluorothioacetone liberated from **1**, with alkyl vinyl ethers and on several reactions of the cycloadducts, 4-alkoxy-2,2-bis(trifluoromethyl)thietanes, and its sulfurized dithiolane derivatives, 5-alkoxy-3,3-bis-(trifluoromethyl)-1,2-dithiolanes.

Results and Discussion

Preparation of 4-Alkoxy-2,2-bis(trifluoromethyl)thietanes (3). The cycloadduct of hexafluorothioacetone with ethyl vinyl ether, 3- or 4-ethoxy-2,2-bis(trifluoromethyl)-thietane, has been reported, though the structure has not been proved conclusively.[2] By the reaction of 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (**1**) with ethyl vinyl ether in the presence of potassium fluoride in *N*,*N*-dimethylformamide, we obtained the same adduct in a good yield. On the basis of its mass spectrum, the structure was established as to be 4-ethoxy-2,2-bis-(trifluoromethyl)thietane (**3**, R=Et). That is, fragment peaks corresponding to $(CF_3)_2C$–CH_2^+ (*m/e* 164) and EtO–CH=S^+ (*m/e* 90), which resulted from the cleavage of the 4-ethoxythietane ring, as well as to the M^+ 254 molecular ion, were observed. However, the fragment peak corresponding to EtO–CH=$C^+(CF_3)_2$ (*m/e* 208), which should have resulted from another isomer, the 3-ethoxy compound, was not observed. When methyl vinyl ether was used in the above reaction, a similar 4-methoxy compound, **3** (R=Me), was obtained.

Thus, in this heterolytic cycloaddition, hexafluorothioacetone behaved as being normally polarized, *e.g.*, into a negative sulfur atom and a positive carbon atom, although a few examples have appeared in the literature in which hexafluorothioacetone reacts as if the thiocarbonyl group is polarized in the "reverse" direction.[3,4]

Reactions of 4-Alkoxy-2,2-bis(trifluoromethyl)thietanes. As cyclic monothioacetals, 4-alkoxy-2,2-bis(trifluoromethyl)thietanes were presumed to be susceptible to the attack of an acid or a base.



1 **2** **3** **4** **5**

When a solution of the thietane **3** (R=Et) in concentrated sulfuric acid was kept at room temperature for several hours, a bimolecular condensation product was obtained. The structure of this compound was established from its spectral analysis as to be bis[4,4-bis(trifluoromethyl)thietan-2-yl]ether (**5**). In the IR spectrum, no absorption band due to either a OH or SH group was observed. In the ^{19}F NMR spectrum, only one multiplet signal due to CF_3 groups appeared, while in the ^1H NMR spectrum, two signals due to two unequivalent CH_2 protons and one triplet signal due to the CH proton were observed in the appropriate positions. In the mass spectrum, two fragment peaks, *m/e* 209 (base peak) and *m/e* 225, as well as the parent peak, M^+ 434, appeared; they resulted from the cleavage of the ether linkage.

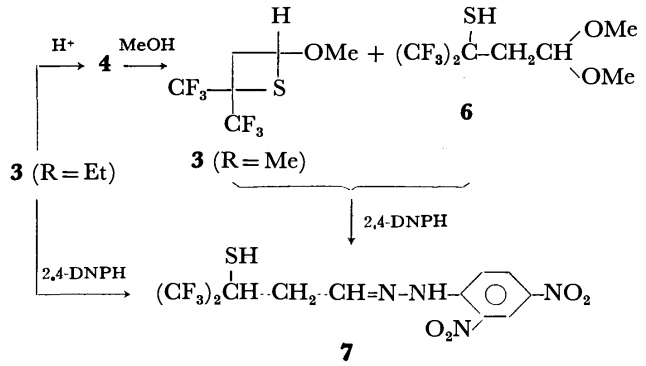
The pathway of the formation of **5** was presumed to be as is shown above. Protonation on the oxygen atom of **3**, followed by the loss of alcohol, gives a carbonium ion, **4**, which is stabilized by the adjacent sulfur atom. This carbonium ion finally attacks another molecule of **3** to give **5**. In order to confirm the formation of the cation, **4**, we carried out the following reactions.

In the presence of sulfuric acid, the ethoxythietane **3** (R=Et) was allowed to react with a large excess of methanol at room temperature. As reaction products, we thus obtained methoxythietane, **3** (R=Me), and

4,4,4-trifluoro-3-mercapto-3-(trifluoromethyl)butyraldehyde dimethyl acetal **6**, in yields of 17 and 30% respectively. The structure of **6** was elucidated from the spectral data. An absorption band due to SH appeared at 2550 cm^{-1} in its IR spectrum, and four signals due to the CH, OCH_3, SH, and CH_2 protons appeared appropriately in its NMR spectrum.

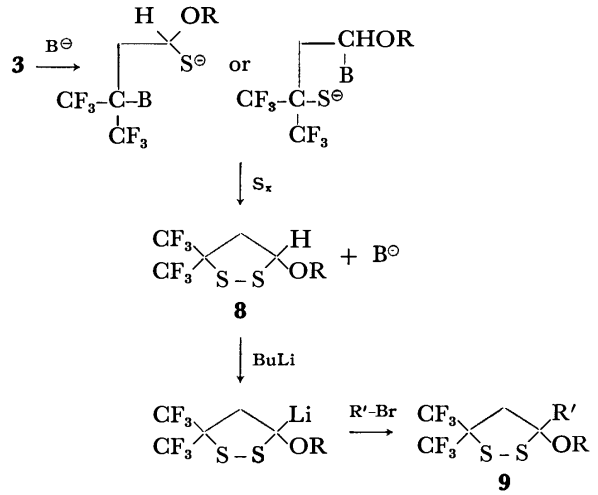
In this reaction, it was presumed that **3** (R=Me) was formed by an alkoxyl exchange *via* the carbonium ion, **4**, whereas **6** was formed by the further nucleophilic attack of a methanol molecule on **3**, which resulted in a cleavage of the thietane ring.

When the reaction mixture was treated with 2,4-dinitrophenylhydrazine and aqueous sulfuric acid, 2,4-dinitrophenylhydrazone of **6** was obtained in a 63% yield. This hydrazone, **7**, was also provided in a good yield (76%) directly from **3** (R=Et and Me) by treatment with 2,4-dinitrophenylhydrazine. These results mean that the cyclic monothioacetal **3**, as well as the dimethyl acetal **6**, behaved equivalently to an aldehyde, as had been expected.



When the ethoxythietane (**3**, R=Et) in a polar solvent was treated with diethylamine or potassium hydroxide at room temperature, 5-ethoxy-3,3-bis(trifluoromethyl)-1,2-dithiolane (**8**) was obtained as the main product. This base-catalyzed disproportionation seems to occur because the five-membered ring of 1,2-dithiolane is thermodynamically more stable than the four-membered ring of thietane.

Preparation of 5-Alkoxy-3,3-bis(trifluoromethyl)-1,2-dithiolanes. An example of the ring-expansion reaction of thietanes into 1,2-dithiolanes involving heating with sulfur has been reported.[5] This direct sulfurization was, however, applied in vain in the preparation of **8** from **3**. In the presence of a base such as diethylamine, however, the thietane, **3**, reacted with sulfur in *N,N*-dimethylformamide, and the 1,2-dithiolane **8** was obtained in a rather good yield:



The structure of this 1,2-dithiolane derivative, **8**, was evident from its ^{19}F NMR and mass spectra. The two trifluoromethyl groups of the dithiolane were nuclear-magnetically unequivalent, while those of the thietane compound, **3**, were equivalent, as has been described before. We assumed that, while the five-membered ring is not co-planar,[6] the four-membered ring is nearly co-planar or that its frequency between axial and equatorial vibrations is so quick that the NMR at room temperature is not distinguishable.

The Alkylation of Thietane, 3, and Dithiolane, 8. Because of the adjacent sulfur atom, the carbon atom of the 4-position of the thietane, **3**, and of the 5-position of the dithiolane, **8**, had been expected to be lithiated to give a carbanionic intermediate.

The five-membered 1,2-dithiolane compound, **8**, was easily lithiated with butyllithium in a hexane–tetrahydrofuran solution, and the resulting lithio compound reacted with alkyl bromides to give their 5-alkyl derivatives, **9** (Table 1).

In contrast with the above-mentioned results, the four-membered thietane compound, **3**, gave ring-opened monothioacetal, 4-alkoxy-4-butylthio-1,1-difluoro-2-(trifluoromethyl)-1-butene, **11**, by the similar reaction. The structure of this compound, **11** (R=Et), was also evident from its spectral data. In the IR spectrum, the presence of the C=C double bond was revealed by the absorption at 1748 cm^{-1}. In the ^{19}F NMR spectrum, three signals due to the CF_2=C–CF_3 group appeared. In the ^1H NMR, two noticeable signals due to methine and methylene groups appeared, in addition to those due to butyl and ethyl groups.

3 3″ 10 11 12

The reaction mechanism was presumed to be as is shown above. Thus, the thietane, **3**, did not give the expected carbanion, **3″**; instead the sulfur atom was attacked by the butyl anion. This must be ascribed to the low stability of the **3″** carbanion, which is too much strained to have a *p*-orbital occupied by two electrons at the 3-carbon atom. The attack of the butyl anion on the sulfur atom might have been promoted by the co-ordination of alkoxy oxygen on lithium, as is shown in the scheme. The reaction was terminated by the liberation of a fluoride ion from one of the trifluoromethyl groups, giving the α-olefin, (**11**).

In order to obtain a range of compounds of this type, we also carried out the reaction of alkoxythietanes (**3**) with Grignard reagents. The corresponding monothioacetals (**11′**) were obtained in good yields (Table 2).

Further, these nomothioacetals yielded a hydrazone, **12**, by a reaction with 2,4-dinitrophenylhydrazine, thus behaving like acetals,[4] as had been expected.

Experimental

4-Ethoxy-2,2-bis(trifluoromethyl)thietane (3, R=Et). A mixture of 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (36.4 g, 0.1 mol), ethyl vinyl ether (14.4 g, 0.2 mol), potassium fluoride (5.8 g, 0.1 mol) and *N,N*-dimethylformamide (70 ml) was stirred for 24 h at room temperature. The whole was poured into water, and the separated oily material was extracted with diethyl ether. The extract was dried over magnesium sulfate, and the solvent was removed. The residue was then subjected to vacuum distillation, giving **3** (R=Et) (18.3 g) (bp 78—80 °C/70 mmHg (lit,[2] bp 43 °C/10 mmHg)) in a 72% yield.

Found: F, 44.4%. Calcd for $C_7H_8F_6OS$: F, 44.9%. ^{19}F NMR*: δ −3.1 (s). MS: M$^+$ 254, *m/e* 164 ($(CF_3)_2C$–CH_2), *m/e* 90 (EtO–CH=S), *m/e* 145 (CF_2=C(CF_3)CH_2).

4-Methoxy-2,2-bis(trifluoromethyl)thietane (3, R=Me). (bp 145—148 °C/760 mmHg) was obtained in a 68% yield by using methyl vinyl ether instead of ethyl vinyl ether in the above procedure.

Found: F, 47.7%. Calcd for $C_6H_6F_6OS$: F, 47.5%. ^{19}F NMR: δ −3.0 (s).

Bis[4,4-bis(trifluoromethyl)thietan-2-yl] Ether (5). Alkoxythietane **3** (R=Et or Me) (0.04 mol) was dissolved in concd sulfuric acid (10 ml), after which the solution was allowed to stand for 1 h at room temperature. The reaction mixture was then poured into ice water and worked up as has been described above. The crude product solidified upon being stored in an ice-box; it was recrystallized from petroleum ether to give **5**, mp 91—92 °C. Yield: 76% from **3** (R=Et) and 82% from **3** (R=Me).

Found: C, 27.5; H, 1.13; F, 52.4%. Calcd for $C_{10}H_6F_{12}OS_2$: C, 27.7; H, 1.39; F, 52.2%. ^{19}F NMR (in CCl_4): δ 6.5 (m). ^{1}H NMR ($CDCl_3$): τ 6.95 and 7.28 (d of d each, $C\underline{H}_2$, J_{gem}=15.0 Hz), 4.55 (t, $C\underline{H}$, J_{vic}=9.0 Hz). MS: M$^+$ 434, *m/e* 225 ($C_5H_3F_6SO$), *m/e* 209 ($C_5H_3F_6S$).

Reaction of 3 (R=Et) with Methanolic Sulfuric Acid. A mixture of **3** (R=Et, 10.16 g, 0.04 mol), concd sulfuric acid (8 ml), and methanol (40 ml) was stirred for 11 days at room

* All the ^{19}F NMR chemical shifts throughout this article are given in δ ppm from external trifluoroacetic acid. They were measured in neat unless the solvent is indicated.

temperature. The reaction mixture was then poured into water, and a separated oily material was extracted with diethyl ether. Two products, 4-methoxy-2,2-bis(trifluoromethyl)-thietane (**3**, R=Me) and 4,4,4-trifluoro-3-mercapto-3-(trifluoromethyl)butyraldehyde dimethyl acetal, **6**, were separated from each other by means of gas chromatography. The yields, 17% for **3** (R=Me) and 30% for **6**, were determined by GLC, using nitrobenzene as the internal standard.

Thiol **6**: Found: F, 41.7%. Calcd for $C_7H_{10}F_6O_2S$: F, 41.9%. IR: 2550 (S–H), 1070, 1050 (C–O–C) cm^{-1}. ^{19}F NMR: δ −5.6 (s). ^1H NMR τ 5.45 ($CH_2C\underline{H}$, t, J=5.5 Hz), 6.80 ($2\times OC\underline{H}_3$, s), 6.89 ($S\underline{H}$, s), 7.80 ($C\underline{H}_2CH$, d).

4,4,4-Trifluoro-3-mercapto-3-(trifluoromethyl) butyraldehyde 2,4-Dinitrophenylhydrazone (**7**). 2,4-Dinitrophenylhydrazine (2.18 g, 0.011 mol) was dissolved in a mixture of ethanol (47 ml), water (14 ml), and concd sulfuric acid (10 ml). Ethoxythietane **3** (R=Et, 2.54 g, 0.01 mol) was added to this solution, and the whole was stirred for 24 h at room temperature. The precipitated product was collected by filtration and recrystallized from benzene to give the 2,4-dinitrophenylhydrazone; mp 131—132 °C (3.08 g, 76%).

Found: C, 32.4; H, 1.42; N, 13.8; F, 28.0%. Calcd for $C_{11}H_8F_6N_4O_4S$: C, 32.5; H, 1.47; N, 13.8; F, 28.1%. IR: 3305 (NH), 2570 (SH), 1615 (C=N), 1510, 1340 (NO_2) cm^{-1}. ^{19}F NMR ($CHCl_3$): δ −6.5 (s).

5-Alkoxy-3,3-bis(trifluoromethyl)-1,2-dithiolane (**8**). *a) By the Disproportionation of* **3**: Ethoxythietane **3** (R=Et, 5.08 g, 0.02 mol) was dissolved in *N,N*-dimethylformamide (15 ml), and then diethylamine (1.63 g, 0.02 mol) was added to this solution. The whole was stirred for 72 h at room temperature. The reaction mixture was worked up as usual, giving 5-ethoxy-3,3-bis(trifluoromethyl)-1,2-dithiolane (**8**, R=Et) (bp 73—75 °C/11 mmHg, 1.57 g) in a yield of 55%. In the potassium hydroxide–methanol system, the same product was obtained in a 55% yield.

Found: C, 29.5; H, 2.67; F, 39.6%. Calcd for $C_7H_8F_6OS_2$: C, 29.4; H, 2.82; F, 39.8%. ^{19}F NMR: δ −6.4 (q), −8.6 (q). J_{F-F}=10.4 Hz.

No other identifiable products were separated from the distillation residue.

b) By the Sulfurization of **3**: A mixture of ethoxy thietane (**3**, R=Et) (20.3 g, 0.08 mol), sulfur (3.07 g, 0.09 mol), diethylamine (2.92 g, 0.04 mol), and dimethylformamide (50 ml) was refluxed for 1 h. The reaction mixture was then poured into water, and the separated oily material was extracted with diethyl ether. The usual work-up gave the dithiolane (**8**, R=Et) (13.0 g) in a yield of 57%.

When methoxythietane (**3**, R=Me) was sulfurized in a similar way, methoxy dithiolane (**8**, R=Me) (bp 103—105 °C/50 mmHg) was obtained in a 46% yield.

Found: F, 42.1%. Calcd for $C_6H_6F_6OS_2$: F, 41.9%. ^{19}F NMR: δ −6.5 (q), −7.5 (q). J_{F-F}=10.2 Hz.

4-Alkoxy-4-alkyl(or phenyl)thio-1,1-difluoro-2-(trifluoromethyl)-1-butene (**11′**). *a) Reaction of Alkoxythietane* **3** *and Butyllithium*: A hexane solution of butyllithium (1.71 N, 13 ml, 0.022 mol) was stirred into a solution of ethoxythietane (**3**, R=Et) (5.08 g, 0.02 mol) in dry tetrahydrofuran (50 ml) with the temperature kept at −50—−60 °C. After 2 h of stirring at −60 °C, the reaction mixture was poured into water and worked up as usual. Vacuum distillation gave a 1-butene compound, **11** (R=Et) (3.10 g, 53%); bp 94—95 °C/19 mmHg.

Found: F, 32.3%. Calcd for $C_{11}H_{17}F_5OS$: F, 32.5%. IR: 1748 (C=C) cm^{-1}. ^1H NMR: τ 5.60 (t, $CH_2C\underline{H}<$), 6.1—6.9 (m, $S-CH_2C\underline{H}_2C\underline{H}_2$), 7.3—7.7 (m, $OC\underline{H}_2$), 8.3—8.7 (m, $SC\underline{H}_2$) 8.85 (t, $OCH_2C\underline{H}_3$), 8.98 (t, $S(CH_2)_3C\underline{H}_3$). ^{19}F NMR: (Table 2). MS: M^+ (not observed), *m/e* 203 (M^+−SBu), *m/e* 147 (EtO–CH–SBu).

The reaction with methoxythietane **3** (R=Me) gave a similar product, **11** (R=Me), in a 59% yield (Table 2).

b) Reaction of Alkoxythietane **3** *with a Grignard Reagent.* Intoa solution of a Grignard reagent prepared from phenyl bromide (6.91 g, 0.044 mol), magnesium (1.15 g, 0.04 mol), and dry tetrahydrofuran (30 ml), 4-ethoxy-2,2-bis(trifluoromethyl)-thietane **3** (R=Et) (10.16 g, 0.04 mol) was added in the course of 30 min at room temperature. After 3 h of stirring at that temperature, the reaction mixture was worked up as usual. The distillation of the crude product gave an oil, **11′** (R=Et, R′=Ph) (8.23 g, 67%); bp 130—132 °C/27 mmHg.

Found: F, 30.7%. Calcd for $C_{13}H_{13}F_5OS$: F, 30.4%. ^1H NMR: τ 2.5—2.9 (m, Ar$\underline{H}$), 5.37 (t, $CH_2C\underline{H}<$), 5.9—6.9 (d of q, $C\underline{H}_2CH_3$), 7.38 (d, $C\underline{H}_2CH<$), 8.80 (t, $CH_2C\underline{H}_3$). ^{19}F NMR: (Table 2).

Similar reactions with other Grignard reagents were also carried out (Table 2).

4,4-Difluoro-3-(trifluoromethyl)-3-butanal 2,4-Dinitrophenylhydrazone (**12**). Into a solution of 2,4-dinitrophenylhydrazine (2.18 g, 0.011 mol) in ethanol (47 ml), **11′** (R=Et, R′=Bu) (2.92 g, 0.01 mol) and dilute sulfuric acid (concd H_2SO_4 10 ml and H_2O 14 ml) were added. The whole was stirred for 24 h at room temperature, and then worked up as usual. The crude product was recrystallized from acetone to give 2,4-dinitrophenylhydrazone (3.40 g, 96%); mp 120—120.5 °C.

Found: C, 37.4; H, 1.97; N, 16.1; F, 26.9%. Calcd for $C_{11}H_7N_4O_4F_5$: C, 37.3; H, 1.99; N, 15.8; F, 26.8%. IR: 3280 (N–H), 1755 (C=C), 1505, 1365 (NO_2) cm^{-1}. ^{19}F NMR: δ −16.7 (d of d, CF_3), −1.67 (q of d, CF_2), 2.00 (d of q, CF_2).

Photolysis of Organic Azides. II.[1] The Photolysis of 2,2′-Diazidobiphenyl in Rigid Matrices at Low Temperatures

Akira YABE and Koichi HONDA

National Chemical Laboratory for Industry, Nishiyawata, Hiratsuka, Kanagawa 254

(Received January 14, 1976)

The direct, triplet-sensitized, and low-temperature photolyses of 2,2′-diazidobiphenyl have been studied. The direct irradiation afforded 4-azidocarbazole, and the triplet sensitization resulted in the predominant formation of the azo dimer, accompanied by a low yield of benzo[*c*]cinnoline. The photolysis in a rigid matrix at 77 K afforded benzo[*c*]cinnoline quantitatively. The mechanism for its preferential formation in low-temperature matrix photolysis is discussed, and we propose a biphotonic process involving a dinitrene *via* a mononitrene.

The photolysis of 2-azidobiphenyl has received considerable attention in recent years. It has been well established by Swenton and his co-workers[2] that the direct photolysis results in the predominant formation of carbazole and that the triplet sensitization leads to the predominant formation of the azo dimer (2,2′-diphenylazobenzene). In connection with studies of 2-azidobiphenyl, it became of interest to examine the photolytic reaction of 2,2′-diazidobiphenyl (I) and to determine whether the intramolecular azo compound benzo[*c*]cinnoline (II) is given by the triplet-sensitized photolysis.

In our preliminary study[1] of the photolysis of I, we found that, although the sensitized photolysis fell short of our expectations, the low-temperature photolysis in a rigid matrix led to the quantitative formation of II, suppressing other competitive reactions. The preferential intramolecular-azo-bond formation of vicinal diazido compounds under these conditions may provide a useful method for the preparation of cyclo-azo compounds. In this paper, the direct and sensitized photolyses of I and 2,2′-diazido-6,6′-dimethylbiphenyl (VII) at room temperature are examined by comparison with those of 2-azidobiphenyl. Moreover, the low-temperature photolyses in rigid matrices are studied, and we propose a mechanistic scheme involving a dinitrene, which accounts for the exclusive formation of II, on the basis of the absorption spectra at 77 K.

Results

Direct Irradiation of I. It has previously been reported[3] that the direct irradiation of I in heptane affords 4-azidocarbazole (III) in a 50% yield, together with trace amounts of II. We reinvestigated it briefly for a mechanistic study in connection with the sensitized and low-temperature photolyses. In addition to III (55—65%) as the major product, II and the bimolecular product IV were identified in trace amounts (<1%) (Table 1). In the case of I, the photochemical reaction is not simple compared with the photolysis of 2-azidobiphenyl because III and IV still have one more reactive azido group. With the increase in the irradiation time, most of the photoproducts become intractable polymeric materials. Hence, the yields of these compounds (also VI, which will be described later) are subject to experimental indefiniteness. Therefore, the following product yields were determined in an earlier stage which could be analyzed. Unless otherwise stated, the product analysis was carried out within about 20% of conversion at most. Among the final products, the azo dimer (V) of III was not detected, although the irradiation of isolated III seemed to afford the azo dimer, which was characterized by an absorption spectrum with a broad peak between 350 and 400 nm. The yield of III is rather insensitive to solvents, as is shown in Table 2.

Table 1. Products from the irradiation of I

Reactants	Solvent	Temperature	Products
I(4×10^{-4} M)[a]	Hexane	Room temp	III (65%), II & VI (trace)
I(10^{-2} M)[a]	Hexane	Room temp	III (55%), II & VI (trace)
I(10^{-2} M), Acetophenone (1.8 M)[b]	Benzene	Room temp	VI (45%), II (<5%), IV (trace)
I(10^{-2} M), Benzophenone (0.5 M)[b]	Benzene	Room temp	VI (40%), II (<5%), IV (trace)
I(6×10^{-4} M)[a]	EPA	77 K	II (98%)
I(6×10^{-4} M)[a]	3MP	77 K	II (98%)
I(5×10^{-4} M)[a]	Glycerol	201 K	II (55%), III (10%)

a) Irradiation with a 6W low-pressure mercury lamp. b) Irradiation with a 100W high-pressure mercury lamp through a filter solution of 0.13 wt% naphthalene in ethyl alcohol.

Table 2. Effect of solvents on the direct irradiation of I[a]

Solvent	Yield of III
Hexane	50—55%
Ether	48—54%
Benzene	45—52%
2-Propanol	46—52%

a) 10^{-2} M solution of I; irradiation with a 6W low-pressure mercury lamp through a UV-D25 filter.

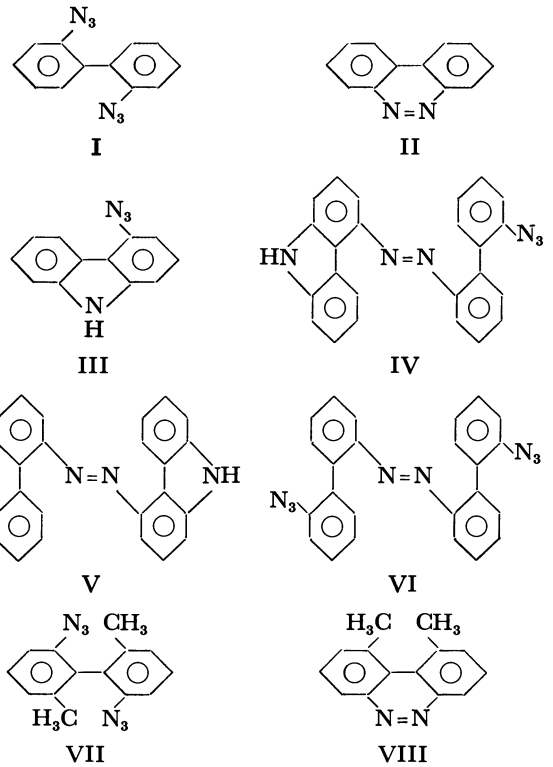
Sensitized Photolysis of I. In connection with the photolysis of 2-azidobiphenyl, where the triplet sensitizer led to the predominant formation of the azo compound, we could expect that triplet sensitizers would increase the yield of II in the photolysis of I. With this expectation, we used acetophenone and benzophenone, which are good triplet sensitizers in the case of 2-azidobiphenyl. Both sensitizations afforded the intermolecular azo compound (VI), instead of the expected II, as the major

product, although the yield of II increased relatively (<*ca.* 5%) (Table 1).

Low-temperature Photolysis of I in a Rigid Matrix. Photolyses of azido compounds at low temperatures in rigid matrices have been studied with considerable attention from the spectroscopic point of view of the nitrenes resulting from them. It is well-known that the irradiations of many aromatic azides in organic matrices at the temperature of liquid nitrogen afforded indefinitely stable intermediate nitrenes.[4] However, no study of the low-temperature photolysis of vicinal diazido compounds has been reported. It is thus of interest to examine whether both mononitrenes and dinitrenes are trapped or converted to some final products under these conditions.

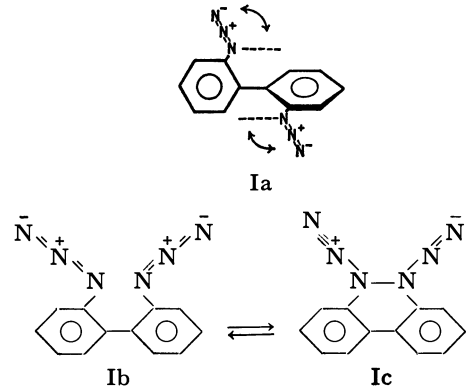
We found that the intramolecular azo compound II was formed effectively with a short irradiation of I in a rigid matrix at low temperatures. The irradiation of I in EPA (5:5:2), 3-methylpentane (3 MP), or methylcyclohexane–isopentane (1:3) at 77 K resulted in an almost quantitative formation of II. The photolysis of I in a glycerol matrix at −72 °C gave 55% of II and about 10% of III. At 77 K the dependence of the yield of II on the solvents was not observed, and there were no reactions with solvents.

Photolysis of VII. In order to study the steric effects on the reactivity of the vicinal two azido groups, the photolysis of VII was briefly examined. The first attempt at the pyrolysis and photolysis of VII by Coffin and Robbins[5] resulted in amorphous materials which could not be characterized. Our attempts to obtain the intramolecular azo compound (1,10-dimethylbenzo[*c*]-cinnoline: VIII) by the triplet-sensitized photolysis of a 10^{-3} M solution of VII in benzene with acetophenone or benzophenone gave only unidentified polymeric materials, like the direct irradiation. However, the irradiation of a 5×10^{-4} M solution of VII in EPA at 77 K afforded expected VIII in a 60% yield.



Discussion

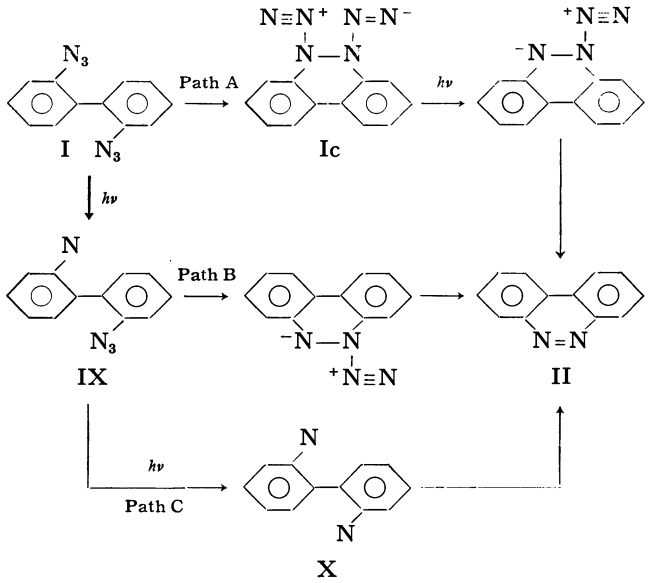
The results of the photolysis at room temperature indicate that the reaction mechanism is rather similar to that for 2-azidobiphenyl. The direct irradiation led exclusively to the inserted compound (III) in the *o'*-position of biphenyl, and the azo compound formation is almost negligible. The lower yield of III, compared with the yield of carbazole in the case of 2-azidobiphenyl, must be due to some subsequent reactions by one more azido group, resulting in polymeric materials. Also, the triplet sensitization was similar to that of 2-azidobiphenyl. The predominant formation of the intermolecular azo compound rather than the intramolecular one could be explained in terms of a structural factor of *o,o'*-disubstituted biphenyls. Although it is difficult to deduce exactly the structure of the excited triplet I, which is presumed to be the precursor for the azo bond formation,[6] the two azido groups must be situated in positions which are far apart from each other, as is shown in Ia. In view of the spectroscopic study of



hindered biphenyl compounds, the twisting about the central (1,1')bond (the angle θ between the two benzene rings) seemed to be similar to that of 2,2'-dimethylbiphenyl ($\theta=70°$), since the effective radius of an azido group is 2.04 Å,[7] compared to 2.0 Å of a methyl group. Moreover, the close similarity of the absorption spectra of 2-azidobiphenyl, I, and VII indicates that such interaction between two "vicinal" azido groups, as represented by the structures of Ib and Ic, is negligible. Thus, the bulky two azido groups are partly free to rotate about the C–N bond at room temperature, as is shown in Ia, and they must prefer the intermolecular one.

The photolysis of I in a rigid matrix at 77 K gave a clear-cut product different from that obtained at room temperature. There is no doubt that the matrix rigidity suppresses a bimolecular reaction. The intramolecular insertion in the *o'*-position, however, could be a possible reaction like the carbazole formation by the irradiation of 2-azidobiphenyl in a rigid matrix at 77 K.[8a] In what follows, we wish to discuss the low-temperature photolysis. The possible mechanisms leading to II from I may be depicted as follows.

Path A involves the azido-azido intramolecular-interacting structure Ic; Path B, the attack on an



intramolecular azido group by the nitreno group (IX); and Path C, the intramolecular recombination of the nitreno groups (2,2′-dinitrenobiphenyl: X) *via* IX. Although the Ic structure in Path A was excluded in the case of photolysis at room temperature, it must be considered a little possible in low-temperature photolysis because the rotation about the C–N bond may be locked in the plane of the ring at 77 K.[8b] If the two azido groups are locked in a rather non-hindered state, the activation energy for the rotation of benzene rings must be lowered to only a few kcal/mol. However, the observed absorption spectrum at 77 K does not shift from that at room temperature. Therefore, the twisting about the central (1,1′) bond seems to be similar to that at room temperature. Thus, Path A may be ruled out, although the mechanisms involving Ic in an excited state still remain as possibilities.

Both Paths B and C involve 2-azido-2′-nitrenobiphenyl (IX) as an intermediate, whereas Path A does not require a discrete intermediate. It seemed first that II was produced directly without being trapped as the nitrene or dinitrene intermediate upon the direct irradiation of I. However, the results from the absorption spectra which are followed with a faint irradiation indicate at least a two-step process (Fig. 1). The absorption peaks of I at 232 and 252 nm decreased slightly upon a faint irradiation. Then, with the increase in irradiation the strong peaks belonging to II appeared rapidly in the same region. When the cell which was immersed in liquid nitrogen was taken up outside at room temperature after a faint irradiation at 77 K, and after this procedure had been repeated over and over again, III was obtained, whereas it was never detected after complete irradiation at 77 K within the limits of our analytical method. These results indicate that IX is trapped as an intermediate in the initial stage of photolysis. In Fig. 1, the decrease in absorbance at about 250 nm after a faint irradiation means that only a small fraction of I is converted to IX in preference to the formation of II. The extinction coefficient of II (33000 at 250 nm) is larger than that (18400 at 252 nm) of I; consequently, that of IX near

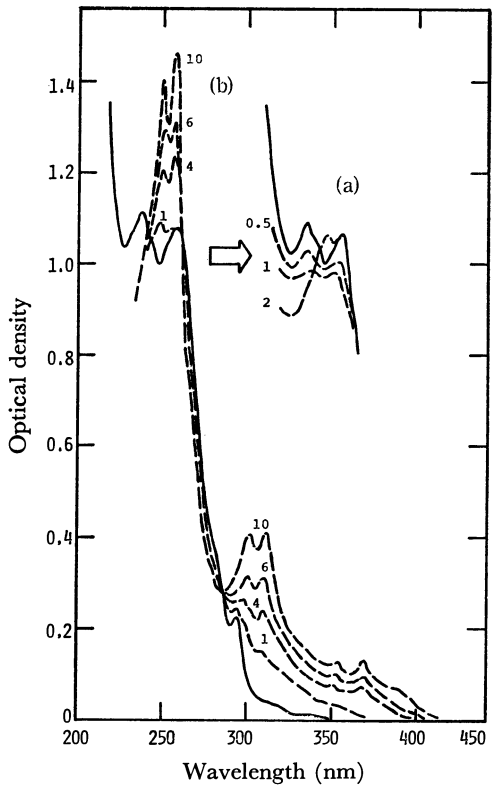


Fig. 1. Absorption spectra of I in EPA at 77 K, —: before irradiation, ---: (a) in the region at ɒ50 nm after irradiation through the 1/2 slit, (b) after irradiation through the open slit. Numbers refer to irradiation time in minutes.

250 nm is estimated to be less than that of I. When the cell with the decrease in absorbance at 250 nm was kept in the dark at 77 K, the absorbance increased very slightly (about 2—3%) for periods as long as 4 h. Although this increase in absorbance may indicate the formation of II from IX along Path B, the rate is almost negligible compared with that of the formation upon further irradiation.

Another clue to elucidating whether the mechanism is Path B or C is the dependence of the formation rate of the final product, II, on the incident-light intensity. Path C is a biphotonic process, whereas Path B is monophotonic. The yields of II *vs.* the irradiation time

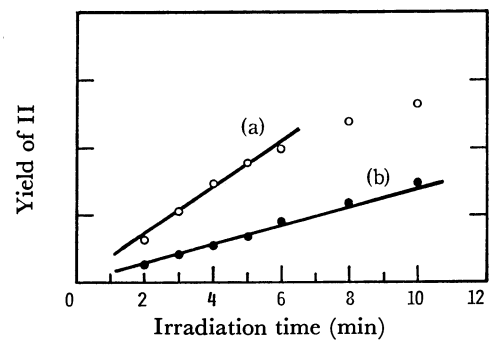

Fig. 2. Dependence of the formation rate of II from I in EPA at 77 K on the light intensity, (a) ○: I_0, (b) ●: $I_0/2$. The ratio of the formation rate is 1: 1/3.4, which is calculated from the slopes of (a) and (b).

were plotted in each case of light intensity, I_0 and $I_0/2$ (Fig. 2). The observed ratio for the formation rate of II is 1 : 1/3.4. Since the extinction coefficient of the product (II) at 253.7 nm is high, and since the diffusion rate in a glassy matrix at 77 K is remarkably low, the actual rate in the case of I_0 is deduced to be additional. Hence, the ratio must approach further to 1/4, which is a theoretical value if it is a biphotonic process.

Thus, it may be concluded that the mechanism for the formation of II in low-temperature matrix photolysis involves the dinitrene (X) *via* the mononitrene (IX). This conclusion is supported by the following observation; the formation of II is due both to the low temperature and to the rigidity of matrices. When the irradiation of I in an isopentane–methylcyclohexane (3: 1) matrix, which formed II quantitatively at 77 K, was carried out in a slightly softened matrix at a slightly increased temperature (about 90 K), the yield of II decreased remarkably, presumably to below 10% (the small amounts of the photoproduct prevented accurate yield data). At the temperature of methanol–solid carbon dioxide (−72 °C), the photolysis gave 55% of III, as at room temperature. At the same temperature, on the contrary, the irradiation in a glycerol matrix with high viscosity (about 10^{13} Poise[9]) gave III in a 55% yield, together with about 10% of II, although the yield of II decreased considerably compared with that in a rigid matrix at 77 K. These results agree with the observations in trapping aromatic nitrenes. Reiser and his co-workers[8b] have found that many aromatic nitrenes are indefinitely stable in a rigid matrix at 77 K, and that a small increase in the temperature (from 77 to 90 K) sufficient to soften slightly the matrix invariably causes the nitrenes to disappear. When 2-azidobiphenyl was irradiated in a glycerol matrix at −72 °C, 2-nitrenobiphenyl could no longer be trapped and carbazole was formed directly. At this temperature the formation of carbazole from 2-nitrenobiphenyl proceeded thermally with no photon, although the conversion of trapped 2-nitrenobiphenyl into carbazole at 77 K was a less efficient photolytic process. This activation energy was estimated to be 8 kcal/mol[8b] or 11.46 kcal/mol.[6] This must also be roughly the case for I. In the stage in which IX is generated, the insertion reaction leading to III must be competitive with the decomposition of the second azido group. Although the latter is still efficient, even at low temperatures, the former, which is an activated process, must be highly affected by the reaction temperature. That is, the formation of III from IX, which is a facile thermal reaction at room temperature or even at −72 °C, is greatly suppressed in a rigid matrix at 77 K. Thus, generated IX survives and is converted into the dinitrene (X) upon further irradiation. Although the quantum yield (Φ_2) for the decomposition of the second azido group could not be determined, we can presume it to be as follows. The quantum yields for the decomposition of I and VII at room temperature are 0.44 and 0.42 respectively, and these must be very similar to the quantum yields (Φ_1) for the decomposition of the first azido group at low temperatures. If it is assumed that the ratio of Φ_2/Φ_1 lies between 2.2 and 3.0, which was found for several *p*,*p*′-diazido compounds,[8c] then Φ_2 is estimated to be between 0.8 and 1.0. According to Reiser and his co-workers,[8a] in the case of 2-azidobiphenyl, the quantum yield of carbazole formation which is 0.44 at 25 °C lowers greatly to 0.01—0.02 in a rigid matrix at 77 K. In our cases, it is suggested that the insertion must become negligible compared with the highly efficient decomposition.

In general, the dinitrenes resulting from vicinal[10] and geminal[11] diazides have not been trapped even in a rigid matrix at low temperatures (higher than 77 K). The process to II from X must be fast. Thus, the formation of II from I (and of VIII from VII) may be regarded as a consecutive first-order reaction as follows:

$$\mathrm{I} \xrightarrow[k_1]{h\nu} \mathrm{IX} \xrightarrow[k_2]{h\nu} (\mathrm{X}) \xrightarrow[\text{fast}]{} \mathrm{II}$$

The kinetics in the photolysis of the dimethyl derivatives (VII) was obtained conveniently because the absorption peak belonging to the mononitrene was not seriously interfered with that of the final product (VIII). In Fig. 3, the absorption peaks at 308 and 330 nm belong to the intermediate mononitrene and the final product 1,10-dimethylbenzo[*c*]cinnoline (VIII) respectively. On the basis of these spectral data and the independent analysis of the decomposed diazide, the concentration-time relationship shown in Fig. 4 was obtained. Although we withhold all stoichiometric discussion because the plots for the mononitrene may have a fairly large experimental error, there is no doubt that the relationship between these three curves indicates $k_2 > k_1$ at least.

Experimental

All the melting points are uncorrected. IR and UV spectra were recorded on JASCO Model IR-S and Shimadzu Model D-40R spectrophotometers respectively. NMR spectra were recorded on a Hitachi Model R-24A spectrometer at 60 MHz using TMS as an internal standard. Mass spectra were recorded on a Hitachi Model RMU-6M spectrometer. The microanalyses were performed at the Institute of Physical and Chemical Research.

Materials. *2,2'-Diazidobiphenyl (I)* was prepared from 2,2'-diaminobiphenyl by Procedure A of Smith and Brown.[12] The crude material was purified by column chromatography on silica gel and was recrystallized twice from ether–hexane; mp 70—71 °C. IR (KBr): 2180, 2120 (N_3) cm^{-1}. UV (Ether): $\lambda_{max}(\varepsilon)$ 252 (18400), 232 (19000) nm. MS: *m/e* 236 (M^+), 208 (M^+-N_2), 180 (M^+-2N_2). Found: C, 60.81; H, 3.51; N, 36.80%. Calcd for $C_{12}H_8N_6$: C, 61.01; H, 3.41; N, 35.57%.

2,2'-Diazido-6,6'-dimethylbiphenyl (VII) was prepared by the method of Coffin and Robbins.[5] After purification by silica gel column chromatography,it was recrystallized from ethanol; mp 58—59 °C (lit, 56—57 °C[5]). IR(KBr): 3100—2950, 2250 and 2160 (N_3) cm^{-1}. UV (Hexane): 288sh (2500), 254 (19900) nm. NMR ($CDCl_3$): δ 7.5—6.8 (m, 6H), 1.95 (s, 6H). MS: *m/e* 264 (M^+), 236 (M^+-N_2), 208 (M^+-2N_2).

The solvents used in the spectroscopic study and in low-temperature photolysis were dried over sodium wire or a molecular sieve and finally passed through a column of alumina.

Irradiation of Azides. The light source for spectroscopic studies was an Ushio USH-500D 500W high-pressure mercury lamp equipped with a Nikon G-250 monochromator. Irradiations for spectroscopic studies of low-temperature photolysis were carried out with a cell which had been immersed in liquid nitrogen or solid carbon dioxide–ethanol contained in a quartz Dewar vessel equipped with optical windows on opposite sides. Irradiations on preparative scale at room temperature were carried out under nitrogen with a conventional immersion well-type reactor equipped with an Ushio UM-102 100W high-pressure mercury lamp. In a low-temperature photolysis, a cylindrical cell immersed in coolants was irradiated with the low-pressure mercury lamp protected with a transparent quartz Dewar vessel.

Product Analysis. The separation and the yield determination of the photoproducts were carried out with a preparative layer chromatograph (Merck Silicagel 60 F_{254}) and a Hitachi high-speed liquid chromatograph Model 634, followed by UV analysis. The identity of II was confirmed by comparison with an authentic sample. The other products were identified on the basis of the following microanalyses and spectral data.

4-Azidocarbazole (III): mp 118—120 °C. IR (KBr): 3480 (NH), 2170 (N_3) cm^{-1}. UV (Ether): 343 (4020), 328 (3500), 301 (7300), 292 (7300), 250 (23000) nm. MS: *m/e* 208 (M^+), 180 (M^+-N_2). Found: C, 68.99; H, 4.22; N, 26.48%. Calcd for $C_{12}H_8N_4$: C, 69.22; H, 3.87; N, 26.91%.

4-(2'-Azido-2-biphenylylazo)carbazole (IV): mp 122—124 °C. IR (KBr): 3480 (NH), 2170 (N_3) cm^{-1}. UV (Ether): 435 (9900), 306 (9700), 250 (35300) nm. MS: *m/e* 388 (M^+), 360 (M^+-N_2).

2,2'-Bis(o-azidophenyl)azobenzene (VI): mp 144—146 °C. IR (KBr): 2180, 2160 (N_3) cm^{-1}. UV (Ether): 460 (250), 325 (8200) nm. MS: *m/e* 416 (M^+), 388 (M^+-N_2), 360 (M^+-2N_2). Found: C, 69.02; H, 4.14; N, 26.04%. Calcd for $C_{24}H_{16}N_8$: C, 69.22; H, 3.87; N, 26.91%.

1,10-Dimethylbenzo[c]*cinnoline (VIII)*: mp 110—111 °C (lit, 96 °C[5]). IR (KBr): 3080—3000, 1595, 1572, 1460, 1442, 1420, 1385, 1335 cm^{-1}. UV (MeOH): 331 (8900), 252 (36000) nm. NMR ($CDCl_3$): δ 8.7—7.1 (m, 6H), 2.55 (s, 6H). MS: *m/e* 208 (M^+), 180 (M^+-N_2), 179.

(Received December 12, 1975)

The reaction of primary and secondary alkyl iodides and bromides with $Hg(OAc)_2$ and $HgCl_2$ in tetrahydrofuran (THF) affords the THF-incorporated compounds (**1**), $RO(CH_2)_4X$ [X=OAc and Cl, respectively], in good yields. When $HgBr_2$ and aqueous or alcoholic $Hg(ClO_4)_2$ were used as mercury(II) salts, the yields of **1**(X=Br, OH, and OR') were low. Similar treatment with HgI_2 gave scarcely any **1**. A reaction scheme which involves *O*-alkyltetrahydrofuranium ion as the intermediate is proposed for the formation of **1**.

Reactions of alkyl halides with mercury(II) salts are of current interest.[1-5] In a previous paper[5] we showed that primary and secondary alkyl halides react with $Hg(SCN)_2$ in THF to give the THF-incorporated compounds, $R[O(CH_2)_4]_nNCS(-SCN)$ ($n=1$, 2), the reaction proceeding through *O*-alkyltetrahydrofuranium ion intermediate. During the course of application of this reaction to various other mercury(II) salts we found that the reaction using mercury(II) acetate and chloride gives $RO(CH_2)_4X$ (X=OAc and Cl) in good yields. Although the direct replacement of the halogen atom in alkyl halides by the carboxyl moiety of mercury(II) salts of carboxylic acids in THF or other organic solvents has been reported,[2] no description is given on the formation of such a THF-incorporated compound. In the present paper we describe the results of the reaction with various mercury(II) salts and discuss its reaction scheme.

Results and Discussion

Reaction with $Hg(OAc)_2$ or $HgCl_2$. The reaction was carried out by stirring alkyl iodides or bromides and mercury(II) salts in THF at refluxing temperature for several hours. The products were the THF-incorporated compounds (**1**) and the expected substitution products (**2**) (Scheme 1). From primary and secondary alkyl iodides or bromides, **1** ($n=1$) was mainly obtained, while alkyl bromides having strong S_N1 characteristics such as *t*-butyl and α-methylbenzyl bromides reacted to give only **2**. Typical results are summarized in Table 1. Predominant formation of **1** ($n=1$) with small amounts of **1** ($n=2$) was characteristic especially in the case of $Hg(OAc)_2$, in contrast to the reaction with $Hg(SCN)_2$ where both **1** ($n=1$) and **1** ($n=2$) were formed as main products.[5] Alkyl chlorides scarcely reacted under the conditions shown in Table 1.

$$RX + HgZ_2 + THF \longrightarrow \underset{\mathbf{1}\ (n=1,\ 2)}{R[O(CH_2)_4]_nZ} + \underset{\mathbf{2}}{RZ} \quad (1)$$

Reaction with $HgBr_2$, HgI_2, or $Hg(ClO_4)_2$. The reaction with $HgBr_2$ or HgI_2 under similar conditions to those described above gave mainly high-boiling substances which seemed to be **1** ($n\geq 2$). As an example, from the reaction of ethyl iodide with $HgBr_2$ for 2 h, **1** ($n=1$) was obtained in 26% yield together with large amounts of high-boiling substances. When the reaction was continued for an additional 4 h, the yield of **1** ($n=1$) decreased to 10%. In the case of HgI_2, **1** ($n=1$) was obtained only in a very low yield, high-boiling substances being mainly formed even under milder reaction conditions. All the starting alkyl halide was consumed in all the cases. On the other hand, the reaction with $Hg(ClO_4)_2$ in THF containing water or an alcohol afforded **1** ($n=1$) and **2** where Z=OH or OR' in good yields, only small amounts of high-boiling substances being formed in this case (see Experimental).

Reaction Scheme. Because of the similarity of the products to those in the reaction with $Hg(SCN)_2$,[5] the reaction seems to proceed through a scheme involving an oxonium ion intermediate as has been proposed in the case of $Hg(SCN)_2$ (Scheme 2). If no considerable competing attacks on this intermediate cation by another THF molecule and by some other nucleophiles

such as water or an alcohol take place, almost exclusive formation of $RO(CH_2)_4Z$ or $RO(CH_2)_4X$ by the S_N2-like attack of $XHgZ_2^-$ where X=I or Br and Z=Cl, OAc, Br, or I should be expected. Here, in the cases of Z=Cl, OAc, and Br a favorable attack by Z can occur to give only $RO(CH_2)_4Z$ because the affinity of I to Hg^{2+} is much greater than that of Cl, OAc, and Br to it by considering HSAB principle[6] (Hg^{2+} is a soft acid; Cl^- and OAc^- are hard bases, Br^- is a borderline base, and I^- is a soft base). In view of the fact that the yields of **1** ($n=1$) were low and considerable amounts of high-boiling substances were formed in the cases of Z=Br and I, the stability of the products, **1** ($n=1$), under the reaction conditions should also be taken into consideration. We have observed in these cases that a longer reaction time resulted in the formation of high-boiling substances which are probably composed of many THF molecule inserted compounds, **1** ($n>2$). It has been found that the reaction of $RO(CH_2)_4Br$ with $Hg(SCN)_2$ proceeds rapidly to give $RO(CH_2)_4NCS$ and $RO(CH_2)_4$-SCN *via* *O*-alkyltetrahydrofuranium ion.[5] This indicates that the reverse reaction from **1** ($n=1$) to the oxonium ion occurs in the presence of a mercury(II) salt, its extent depending a great deal on the kind of Z. The ease of departure of the leaving groups (Z) in S_N1 reaction is known to decrease in this order: I>Br>OAc>OH,OR.[7]

Table 2. Reaction of $EtO(CH_2)_mBr$ with HgZ_2 in n-Bu_2O[a]

m	Z	React temp (°C)	React time (h)	EtO-$(CH_2)_m$Z Yield (%)[b]	EtO-$(CH_2)_m$Br Recovered (%)[b]

4	OAc	70—78	7	81	15
5	Cl	70—78	8	7	61

a) $EtO(CH_2)_m$ Br, 10 mmol. HgZ_2, 10 mmol. n-Bu_2O, 8 ml. b) Determined by GLC.

In order to confirm the above explanation, the reaction of $EtO(CH_2)_mBr$ ($m=2$—5) with $HgCl_2$ or $Hg(OAc)_2$ was carried out with n-Bu_2O as a solvent. The results are given in Table 2. As expected, when $m=4$ thermodynamically more stable $EtO(CH_2)_4Cl$ or $EtO(CH_2)_4OAc$ was obtained in a good yield, while no reaction occurred when $m=2$ and 3 in accordance with a similar result by Winstein *et al.*[8] We also confirmed that the reaction of $EtO(CH_2)_4Cl$ with $HgBr_2$ in n-Bu_2O gave no $EtO(CH_2)_4Br$ under the conditions shown in Table 2 and that of $EtO(CH_2)_4Br$ with HgI_2 in THF gave readily a lot of high-boiling substances.

Experimental

GLC analyses were carried out on a Yanagimoto G800-T and a Shimadzu 5APTF apparatus using DEGS (1m), PEG 6000 (2 and 3m), and EGSS-X (1m) columns (carrier gas, H_2 and N_2 respectively). The NMR spectra were recorded with Varian EM-360 and JEOL MH-100 spectrometers in $CDCl_3$, using TMS as an internal standard. The IR and Mass spectra were taken with Hitachi EPI-S2 and JEOL JMS-01SG spectrometers, respectively.

Materials. All the organic substances, including the solvents, were used after distillation, while commercial inorganic salts were used without further purification. ω-Ethoxyalkyl bromides, $EtO(CH_2)_mBr$, were prepared by the reported method.[9] Authentic samples of **1** ($n=1$, Z=OAc) were prepared by the acetylation of 4-alkoxybutanol synthesized[9] from 1,4-butandiol, sodium, and alkyl bromide. Authentic samples of **1** ($n=1$, Z=Cl) were prepared by the reported method; thus $PhCH_2O(CH_2)_4Cl$ was prepared from benzyl chloride, THF, and $ZnCl_2$,[10] and n-$BuO(CH_2)_4Cl$ from n-$BuO(CH_2)_4OH$ and $SOCl_2$.[11] Commercial authentic samples of **2** were used.

Reaction of Alkyl Halides with $Hg(OAc)_2$ or $HgCl_2$ in THF (Table 1). The following example shows a typical procedure. To a suspension of $Hg(OAc)_2$ (12.8 g, 40 mmol) in THF (30 ml) was added n-PrI (6.8 g, 40 mmol) at 70—75 °C and the resulting homogeneous solution was kept for 7 h under stirring. After being cooled down to room temperature, Et_2O (300 ml) was added and the precipitated inorganic salt was filtered off. The filtrate was washed several times with aqueous KI in order to remove a small amount of dissolved mercury (II) salt and then dried over $MgSO_4$. Distillation gave two fractions, D_1 (propyl acetate, 0.58 g, bp 50—75 °C) and D_2 (4-propoxybutyl acetate, 3.53 g, bp 101—104 °C/20 mmHg), and left 0.2 g of residue.

The boiling points (°C/mmHg) of **1** ($n=1$, Z=OAc) are as follows: R=Et, 90—91/24 (lit,[12] 192—193/756); R=*i*-Pr, 93—95/20; R=*n*-Bu, 118—120/25; R=*s*-Bu, 105—108/24; R=allyl, 104—106/24; R=benzyl, 112—115/2. Those of **1** ($n=1$, Z=Cl) are as follows; R=Et, 56—57/19 (lit,[13] 142/760); R=*i*-Pr, 71—73/25; R=*n*-Bu, 94—95/22 (lit,[11] 84/13); R=allyl, 90—92/35; R=benzyl, 102—104/1 (lit,[10] 137—140/12). **1** ($n=2$ Z=OAc), R=Et, 120—122/2. **1** ($n=2$, Z=Cl), R=Et, 120—125/7; R=*i*-Pr, 88—90/1; R=*n*-Bu, 127—128/4. NMR, IR, and mass spectra of all compounds support the structures. Although some of **1** ($n=2$) could not be isolated in a pure state, the retention time in GLC and NMR spectra supports each structure.

Reaction of n-BuI with Aqueous $Hg(ClO_4)_2$ in THF. Red mercury(II) oxide (4.4 g, 20 mmol) was added to a mixture of THF (15 ml) and 60% $HClO_4$ (6.8 g, 40 mmol), and the mixture was gently heated on a water bath (40—60 °C) under stirring until almost all the mercury(II) salt has dissolved (10—20 min). After being cooled down to room temperature, 4 ml of water and 3.7 g (20 mmol) of n-BuI were added to the mixture which was then stirred at 40 °C for 4 h. The products were then analyzed directly by GLC by use of internal standards: n-BuOH, 0.76 g (10.3 mmol), 51% yield: n-$BuO(CH_2)_4$-OH, 0.90 g (6.2 mmol), 31%; n-$BuO(CH_2)_4O$-n-Bu, 0.36 g (1.8 mmol), 9%. An authentic sample of n-$BuO(CH_2)_4O$-n-Bu was prepared from n-$BuO(CH_2)_4Br$, n-BuOH, and sodium; bp 138—139 °C/40 mmHg (lit,[14] 234—236 °C/760 mm-

Hg). Distillation left only a small amount of residue (<0.05 g).

Reaction of n-*BuI with Alcoholic* $Hg(ClO_4)_2$ *in THF.* To a mercury(II) perchlorate (20 mmol) solution of THF prepared by the same method as described above was added 15 g of *n*-BuOH and 3.7 g (20 mmol) of *n*-BuI. The mixture was then stirred at 40 °C for 4 h. After being cooled down to room temperature, Et_2O (200 ml) was added and the precipitated inogranic salt was filtered off. The filtrate was washed with aq. KI and dried. After evaporation of ether, the products in residue were analyzed by GLC by using some internal standards: *n*-Bu_2O, 1.23 g (9.5 mmol), 47%; *n*-$BuO(CH_2)_4O$-*n*-Bu, 0.96 g (4.8 mmol), 24%; *n*-$BuO(CH_2)_4OH$, 0.23 g (1.6 mmol), 8%. Distillation left only a small amount of residue (<0.05 g).

Reaction of $EtO(CH_2)_mBr$ *with* $HgCl_2$ *or* $Hg(OAc)_2$ *in* n-Bu_2O. *(Table 2).* A typical procedure is given in the following. To a suspension of $HgCl_2$ (2.8 g, 10 mmol) in *n*-Bu_2O (8 ml) was added $EtO(CH_2)_5Br$ (1.95 g, 10 mmol) at 70—75 °C and the resulting mixture was kept for 8 h under stirring. After being cooled down to room temperature, the mixture was filtered from the solid part and the filtrate was analyzed by GLC: recovered $EtO(CH_2)_5Br$, 1.19 g (6.1 mmol), 61%; $EtO(CH_2)_5Cl$, 0.11 g (0.7 mmol), 7%. An authentic sample of $EtO(CH_2)_5Cl$ was prepared by action of $SOCl_2$ on $EtO(CH_2)_5OH$ in pyridine; bp 88 °C/43 mmHg (lit,[13] 72 °C/17 mmHg).

The Photolysis and Thermolysis of 3-(Diphenylhydroxymethyl)-4-(diphenylmethylene)-2-cyclobuten-1-one and Its 2-Bromo Derivative[1)]

Fumio Toda and Eishiro Todo

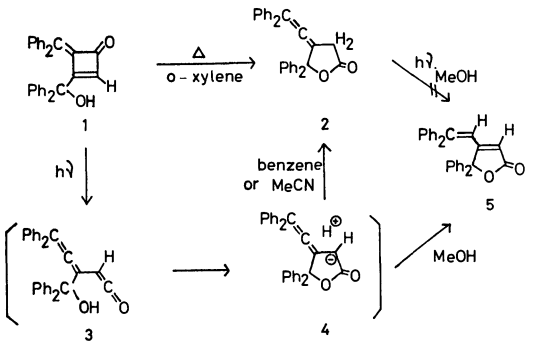
Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received January 20, 1976)

The photolysis of the title methyleneccyclobutenone (**1**) and 2-bromomethylenecyclobutanone (**9**) in MeOH afforded 4,4-diphenyl-3-(2,2-diphenylvinyl)-2-buten-4-olide (**5**) and 3,3,5-triphenyl-1,3-dihydronaphtho[1,2-*c*]-furan-2-one (**11**) respectively. The photolysis of **1** and **9** in benzene, however, afforded 4,4-diphenyl-3-(diphenylvinylidene)-4-butanolide (**2**), and bromo-derivative of **5** (**8**) and **11** respectively. The thermolysis of **1** and **9** in *o*-xylene afforded **2** and 2-bromo derivative of **5**(**10**) respectively. The mechanisms of these reactions were discussed. The solvent effect on the photolysis of **1** and **9** was also discussed.

The photochemical conversion of cyclobutenedione into the bisketene intermediate *via* a Norrish Type I reaction is well established.[2,3)] In order to compare the photolysis of methylenecyclobutenone with that of cyclobutenedione, we studied the photolysis of the title compounds (**1** and **9**) in benzene and MeOH; we found that all the reactions afford products which are probably derived from alleneketene intermediates (**3** and **12**) initially formed by Norrish Type I reactions of **1** and **9** respectively. It was also found that the thermolysis of **1** and **9** probably proceeds *via* the alleneketene intermediates, **3** and **12** respectively.

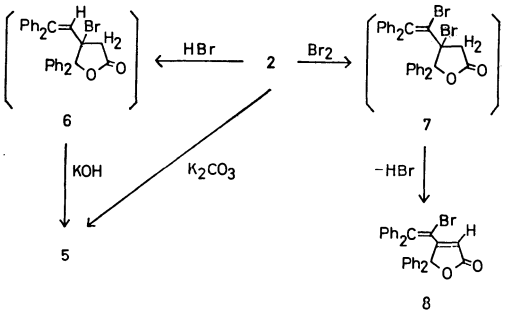
The irradiation of **1** in benzene for 1 h afforded 4,4-diphenyl-3-(diphenylvinylidene)-4-butanolide (**2**) in an 82% yield. The formation of **2** can be explained in terms of intramolecular esterification involving the alleneketene (**3**) as an intermediate produced by the α-cleavage of **1**. Such an easy lactonization has been demonstrated in the photochemical conversion of 3,4-bis (diphenylhydroxymethyl) cyclobut-3-ene-1,2-dione into 4,4,8,8-tetraphenyl-3,7-dioxabicyclo[3.3.0]octane-2,6-dione.[3)]



Scheme 1.

In contrast with the photolysis of **1** in benzene, the photolysis of **1** in MeOH afforded 4,4-diphenyl-3-(2,2-diphenylvinyl)-2-buten-4-olide (**5**) in a 35% yield as the sole isolable product. This reaction would also proceed *via* **3**. It seems that the type of reaction product depends on whether the solvent used is polar or nonpolar. It is clear, however, that **5** was not derived from **2**, because the irradiation of **2** in MeOH did not give **5**, and **2** was recovered unchanged. Nevertheless, a polar solvent is not always sufficient for the formation of **5** in the photolysis of **1**; the photolysis of **1** in MeCN afforded **2**, but not **5**. The formation of **5** can be interpreted by assuming the ion pair (**4**) as an intermediate; it would easily be protonated in MeOH on its allene carbon.

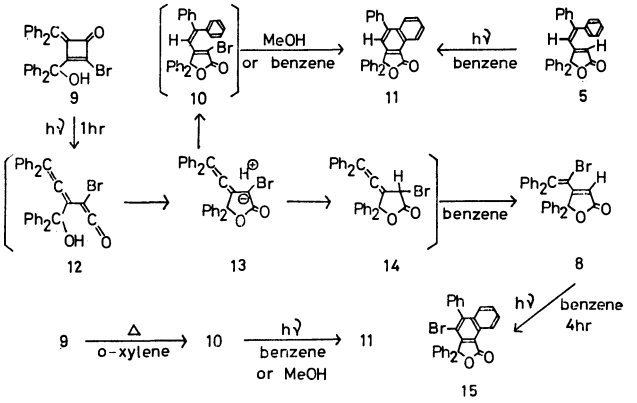
The heating of **1** in *o*-xylene under reflux for 5 h afforded **2** in a 75% yield. This reaction would also proceed *via* the **3** initially formed by the thermal α-cleavage of **1**.



Scheme 2.

The prototropic rearrangement of **2** into **5** occurred easily when **2** was treated with K_2CO_3 in MeOH. The conversion of **2** into **5** was also performed by the treatment of **2** with HBr, followed with KOH. The dehydrobromination of the Br_2-addition product of **2** (**7**) afforded the bromo-derivative of **5** (**8**).

The photolysis and thermolysis of the 2-bromo derivative of **1** (**9**) gave slightly different results from



Scheme 3.

those of **1**. The thermolysis of **9** under the same conditions as those used for **1** afforded the 3-bromo derivative of **5** (**10**) in a 46% yield. The photolysis of **9** in benzene under the same conditions as those used for **1** afforded **8** and 3,3,5-triphenyl-1,3-dihydronaphtho[1,2-*c*]furan-2-one (**11**) in 25 and 27% yields respectively, whereas the photolysis in MeOH afforded **11** in a 20% yield as the sole isolable product. All these reactions can be interpreted by assuming the ion pair (**13**) to be the intermediate which was produced by the intramolecular esterification of the alleneketene intermediate (**12**) initially formed by the α-cleavage of **9** similar to the case of **1**. The ion pair (**13**) would be more stabilized by an inductive effect of Br than would **4**.

In the thermolysis of **9**, **10** would be derived directly from **13**, but not from **14**; the latter probably affords **8**, because the average bond energy of C–H (99) is larger than that of C–Br (68 kcal/mol). The thermal stability of **2** supports this.

The formation of **8** and **11** in the photolysis of **9** in benzene can be interpreted by assuming **14** and **10** as intermediates; *i.e.*, the process involves the rearrangement of Br of **14** and an electrocyclic reaction, followed by the dehydrobromination of **10** to afford **8** and **11** respectively. Evidence for the intermediacy of **10** was obtained by the photolysis of **10** in benzene and MeOH, which affords **11** in 84 and 57% yields respectively. In a similar manner, the prolonged photolysis of **5** and **8** in benzene afforded **11** and its 4-bromo derivative (**15**) respectively. These reactions are similar to the photochemical conversion of stilbene into phenanthrene.[4,5] The exclusive formation of **11** in the photolysis of **9** in MeOH can be interpreted in the way employed for the interpretation of the solvent effect on the photolysis of **1**; *i.e.*, **13** would easily be protonated in MeOH on its allene carbon.

Experimental

All the melting points are uncorrected. The photolysis was carried out at room temperature under a nitrogen atmosphere, using light from a 100-W high-pressure mercury lamp (Riko Kagaku Sangyo Co.), filtered through Pyrex glass. The IR, UV, and NMR spectra were measured in Nujol mull, $CHCl_3$, and $CDCl_3$ respectively, unless otherwise stated. The mass spectra were measured with an ionization energy of 75 eV.

*Photolysis of **1** in Benzene.* A solution of **1**[6] (0.6 g) in benzene (150 ml) was irradiated for 1 h. The crude crystals left after the evaporation of the solvent were recrystallized from MeOH to afford **2** as colorless needles; 0.49 g (82%); mp 112—113 °C. IR: 1790 (C=O), 1400 (CH_2), and 1205 cm^{-1} (lactone); λ_{max}: 270 nm (ε, 14500); NMR: 2.2—3.3 (m, Ph, 20H) and 6.35 τ (s, CH_2, 2H); MS: *m/e* (rel intensity) 414 (M^+, 72), 386 (M^+-CO, 17), and 204 (386−Ph_2CO, 100).

Found: C, 86.77; H, 5.31%. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35%.

*Photolysis of **1** in MeOH.* A solution of **1** (0.4 g) in MeOH (150 ml) was irradiated for 6 h. The oily material left after the evaporation of the solvent was dissolved in CCl_4, after which the solution was chromatographed on Al_2O_3. The crude crystals obtained from the fraction eluted with benzene were recrystallized from MeOH to afford **5** as pale yellow prisms; 0.14 g (35%); mp 148—150 °C. IR: 1755 (C=O), 1625 (C=C), and 1220 and 1180 cm^{-1} (lactone); λ_{max}: 327 nm (ε, 19100); NMR: 2.3—3.2 (m, Ph, 20H), 3.35 (s, =CH, 1H), and 4.85 τ (s, =CH, 1H); MS *m/e* (rel intensity): 414 (M^+, 7), 370 (M^+-CO_2, 84), 232 (M^+-Ph_2CO, 21), and 204 (232−CO, 100).

Found: C, 86.81; H, 5.15%. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35%.

*Thermolysis of **1** in o-Xylene.* A solution of **1** (0.071 g) in *o*-xylene (10 ml) was heated under reflux in a nitrogen atmosphere for 5 h. The crude crystals left after the evaporation of the solvent were recrystallized to afford **2**; 0.053 g (75%).

*Conversion of **2** into **5**.* *a*) When a mixture of **2** (0.056 g), K_2CO_3 (0.1 g) and MeOH (20 ml) was heated under reflux for 1 h, **5** was obtained after recrystallization from MeOH; 0.045 g (81%). *b*) Into a solution of **2** (0.097 g) in $CHCl_3$ (10 ml), HBr was bubbled for 10 min. The oily material left after the evaporation of the solvent was dissolved in 0.5% KOH–MeOH (20 ml), after which the solution was heated under reflux for 1 h. The recrystallization from MeOH of the crude crystals obtained by the dilution of the reaction mixture with water afforded **5**, 0.05 g (52%).

*Preparation of **8**.* To a solution of **2** (0.092 g) in $CHCl_3$ (10 ml), Br_2 (0.05 g) was added. The oily material left after the evaporation of the solvent crystallized when treated with AcOEt (1 ml).

The recrystallization of the crude crystals from AcOEt afforded **8** as pale yellow prisms; 0.054 g (42%); mp 217—218 °C. IR: 1760 (C=O), 1605 (C=C), and 1265 and 1210 cm^{-1} (lactone); λ_{max}^{EtOH}: 248 (31600), 318 (6300), and 332 nm (ε, 5600); NMR: 2.3—3.2 (m, Ph, 18H), 3.6—3.8 (m, Ph, 2H), and 4.18 τ (s, =CH, 1H); MS *m/e* (rel intensity): 494 and 492 (M^+, each 16), 450 and 448 (M^+-CO_2, each 28), 413 (M^+—Br, 20), 369 (413−CO_2, 24), 292 (369—Ph, 28), 231 (413—Ph_2CO, 96), and 203 (231—CO, 100).

Found: C, 72.85; H, 4.16%. Calcd for $C_{30}H_{21}O_2Br$: C, 73.02; H, 4.25%.

*Thermolysis of **9** in o-Xylene.* A solution of **9** (0.318 g) in *o*-xylene (10 ml) was heated under reflux in a nitrogen atmosphere for 5 h. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **10** as pale yellow leaflets; 0.147 g (46%); mp 217—218 °C. IR: 1760 (C=O), 1610 (C=C), and 1230 cm^{-1} (lactone); λ_{max}^{EtOH}: 238 (17700) and 328 nm (ε, 13400); NMR: 2.0—3.0 (m, Ph, 18H), 3.3—3.6 (m, Ph, 2H), and 3.73 τ (s, =CH, 1H).

Found: C, 73.10; H, 4.18%. Calcd for $C_{30}H_{21}O_2Br$; C, 73.02; H, 4.25%.

*Photolysis of **9** in Benzene.* A solution of **9** (0.43 g) in benzene (150 ml) was irradiated for 1 h. The crude product left after the evaporation of the solvent was recrystallized from MeOH–$CHCl_3$ (1: 1) (10 ml) to afford **8**; 0.108 g (25%). The evaporation of the solvent of the mother liquor left after the separation of **8** gave crude crystals, which were then recrystallized from MeOH–acetone to afford **11** as colorless prisms; 0.097 g (27%); mp 157—158 °C. IR 1750 (C=O) and 1180 and 1130 cm^{-1} (lactone); λ_{max}: 250 (31700) and 314 nm (ε, 9900).

NMR: 1.7—2.8 τ (m, Aromatic); MS *m/e* (rel intensity): 412 (M^+, 75), 368 (M^+-CO_2, 27), 335 (M^+—Ph, 73), and 307 (335−CO, 100).

Found: C, 87.31; H, 4.75%. Calcd for $C_{30}H_{20}O_2$: C, 87.35; H, 4.89%.

*Photolysis of **9** in MeOH.* A solution of **9** (0.4 g) in MeOH (150 ml) was irradiated for 1 h. The crude crystals left after the evaporation of the solvent were recrystallized from MeOH–acetone to afford **11**: 0.082 g (25%).

*Photolysis of **10** in Benzene and MeOH.* A solution of **10** (0.102 g) in benzene (150 ml) was irradiated for 2 h. The crude crystals left after the evaporation of the solvent were

recrystallized from MeOH–acetone to afford **11**; 0.072 g (84 %). When a solution of **10** (0.05 g) in MeOH (150 ml) was irradiated for 2 h, and then worked up as above, 0.024 g (57%) of **11** was obtained.

*Photolysis of **5** in Benzene.* A solution of **5** (0.167 g) in benzene (150 ml) was irradiated for 3 h. The recrystallization from MeOH–acetone of the crude crystals left after the evaporation of the solvent afforded **11**; 0.13 g (76%).

*Photolysis of **8** in Benzene.* A solution of **8** (0.1 g) in benzene (150 ml) was irradiated for 4 h. The crude crystals left after the evaporation of the solvent were recrystallized from MeOH–$CHCl_3$ to afford **15** as colorless needles; 0.06 g (60%); mp 276—279 °C. IR: 1765 (C=O) and 1200 and 1140 cm^{-1} (lactone); λ_{max}: 320 (10000) and 332 nm (ε, 8800); NMR: 1.8—2.8 τ (m, Aromatic); MS *m/e* (rel intensity): 492 and 490 (M^+, each 58), 448 and 446 (M^+-CO_2, each 20), 411 (M^+—Br, 14), 367 (411—CO_2, 100), and 290 (367—Ph, 58).

Found: C, 73.42; H, 3.71%. Calcd for $C_{30}H_{19}O_2Br$: C, 73.31; H, 3.87%.

Aminosugars. XXV. Synthesis of Benzyl 2-Acetamido-2-amino-2,3,4-trideoxy-α-D-*arabino*-hexopyranoside[1]

Juji YOSHIMURA, Masaharu IWAKAWA, and Yoshio OGURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received January 24, 1976)

As the attempted substitution of methyl 4-deoxy-2,3-di-*O*-mesyl-6-*O*-trityl-α-D-*xylo*-hexopyranoside with sodium azide gave the unsaturated compound: methyl 2,3,4-trideoxy-6-*O*-trityl-α-D-*glycero*-hex-2-enopyranoside (**4**), benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside was used as the starting material, which was converted into benzyl 2-acetamido-2-deoxy-3-*O*-mesyl-6-*O*-trityl-α-D-mannopyranoside (**10**). For the deoxygenation of C-4 position, chlorination of **10** with sulfuryl chloride gave unexpectedly benzyl 3′-*O*-mesyl-6′-*O*-trityl-α-D-talopyranosid [2′,3′,4′; 4,5,6]-2-methyl-4,5-dihydro-6*H*-oxazine, due to the anchimeric effect of the C_2-axial acetamido group. However, previous change of the conformation of **10** by the substitution of C_3-mesyl group with azido group gave successfully the corresponding chloro derivative (**13**). Reduction of **13** with tributyltin hydride gave the corresponding 3,4-epimino derivative (**14**), due to participation of initially hydrogenated azido group, but, catalytic hydrogenation of **14** gave the title compound as the main product.

L-Tuberactidine: α-(4-hydroxyl-2-imino-hexahydro-6(*R*)-pyrimidinyl)-(*S*)-glycine,[2] was found as the unique component of a peptide antibiotic, tuberactinomycin A.[3] In order to synthesize L-tuberactidine by utilization of sugars for the two asymmetric configurations, the title compound was synthesized as the key intermediate. This paper describes the synthesis and a few anchimeric effects of neighbouring groups in aminosugars found in the course of the study.

Results and Discussion

For the synthesis of a 2,3-diamino-2,3,4-trideoxy-hexose derivative from a neutral sugar, deoxygenation of *C*-4 position and introduction of amino groups into *C*-2 and *C*-3 positions are necessary. Concerning the title compound, Guthrie *et al.*[4] synthesized methyl 3-amino-2-azido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-altropyranoside by ring opening of the corresponding 2,3-epimino derivative with azide anion, which was obtained from D-glucose *via* ten-step conversions. This compound has the same configuration as the title compound, excepting the presence of C_4-hydroxyl group, but the C_4-deoxygenation after introduction of C_3-amino group was considered to be a rather difficult problem. On the other hand, it is known that some reagents such as potassium ethylxanthate,[5] sodium iodide and zinc dust,[6] trimethyl phosphite,[5] and others[7] apt to give unsaturated sugars from the corresponding vicinal disulfonates, while sodium azide gave mainly direct displacement products.[8] Consequently, we have firstly tried a one-step introduction of 2,3-diamino groups into a 4-deoxy sugar.

Partial hydrolysis of methyl 4,6-*O*-benzylidene-2,3-di-*O*-mesyl-α-D-glucopyranoside[5,9] with 70% acetic acid at 90—95 °C gave methyl 2,3-di-*O*-mesyl-α-D-glucopyranoside (**1**) in 98% yield. Tritylation of **1** gave the corresponding 6-*O*-trityl derivative, which was then chlorinated with sulfuryl chloride[10] to give the corresponding 4-chloro-4-deoxy derivative (**2**) in 88% yield. Hydrogenation of **2** with tributyltin hydride gave the desired 4-deoxy derivative (**3**) quantitatively. However, reaction of **3** with sodium azide in *N*,*N*-dimethylformamide for 20 h at refluxing temperature gave the corresponding 2,3-unsaturated compound (**4**) and starting material as main products in 15% and 38% yields, respectively. Although other three minor products were not examined and the reaction mechanism is also ambiguous, this fact indicates that the unsaturation is preferential in this reaction, and that the deoxygenation of *C*-4 position does not make any advantages for the vicinal diazide formation. The structure of **4** was supported by the long range couplings of the allylic system ($J_{1,3}$=2.0, $J_{2,4}$=1.0) in the PMR spectrum (Table 1).

a) NH proton was deuterated.

material in the next experiments. Mesylation of **5** in pyridine gave the corresponding 3-*O*-mesylate (**6**) in a good yield, which was then transformed into 3-azido-3-deoxy derivative (**7**) of D-*altro* type. Hydrogenation of **7** gave the corresponding 3-amino-3-deoxy-derivative (**8**), which was then converted into 3-guanidino-3-deoxy derivative (**9**) by fusion with sodium cyanamide.[12]

For the deoxygenation of *C*-4 position, 4,6-*O*-benzylidene group of **6** was hydrolyzed and then tritylated to give benzyl 2-acetamido-2-deoxy-3-*O*-mesyl-6-*O*-trityl-α-D-mannopyranoside (**10**) in 62% yield. Chlorination of **10** in pyridine with sulfuryl chloride gave a product (**11**) in 80.5% yield, which contains no chlorine atom, and the analytical values consisted with that of monodehydrated product of **10**. Besides, the appearance of H_3 signal as a triplet (J=2.1 Hz) having no long range coupling and the absence of NH proton signal in the PMR spectrum of **11** indicates the normal *C1* conformation and the formation of intramolecular oxazin ring by the participation of axial 2-acetamido group. Consequently, **11** was characterized to be benzyl 3'-*O*-mesyl-6'-*O*-trityl-α-D-talopyranosid[2',3',4';4,5,6]-2-methyl-5,6-dihydro-4H-oxazine. Because the 4-*O*-chlorosulfonyl group formed in the initial step of the chlorination is a good leaving group, the participation of axial acetamido group to the β-carbon observed above will be very reasonable, and a similar participation was recently reported by Meyer zu Reckendorf *et al.*[13] Several attempts to open the oxazine-ring of **11** gave unsuccessful results.

To avoid the participation of the axial acetamido group, conformational change of the lactol ring is

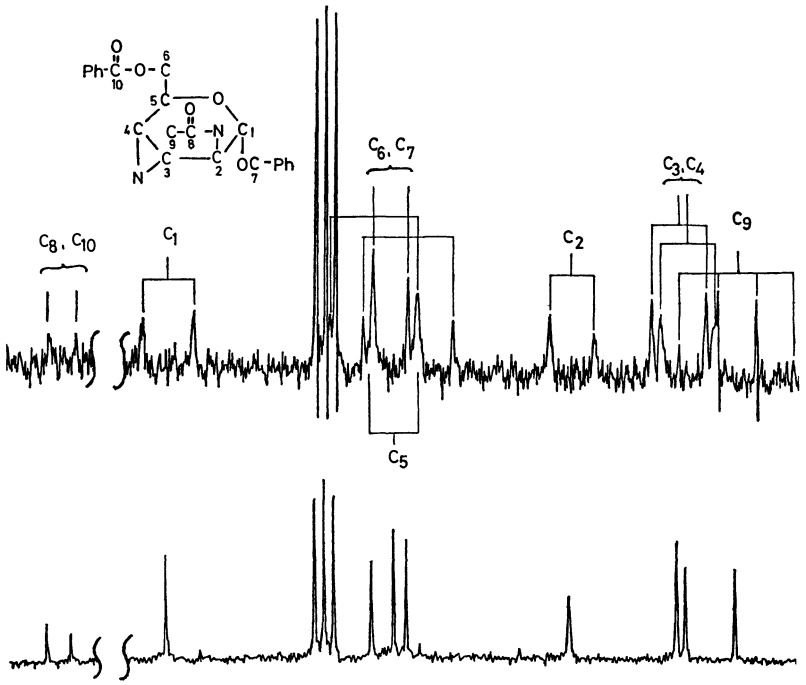

Fig. 1. CMR spectrum of compound **14**.

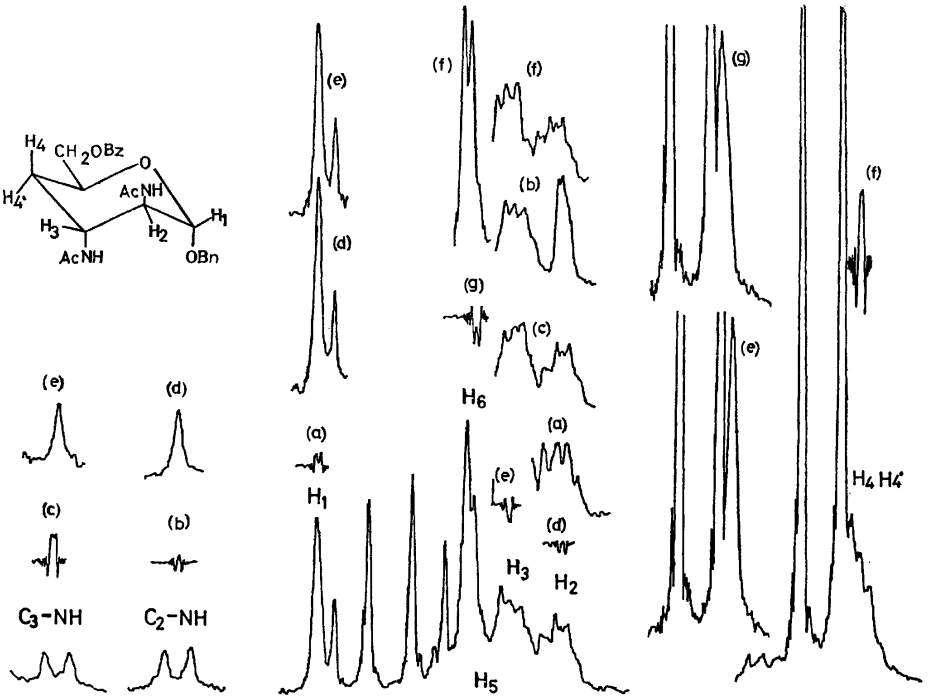

Fig. 2. The proof of the structure of **16** with the decoupling technique.

desirable. So, **7** was partially hydrolyzed, and then partially benzoylated to give benzyl 2-acetamido-3-azido-6-*O*-benzoyl-2-deoxy-α-D-altropyranoside (**12**) in 80% yield. The chlorination of **12** gave the corresponding 4-chloro-4-deoxy derivative (**13**) in 70.5% yield as expected. The coupling constants of ring protons of **12** are very similar to that of **7** (Table 1), indicating the *C1* conformation of **12**. However, it is characteristic that the $J_{1,2}$ values of them are smaller than that of **11** having a typical *C1* conformation, due to the flattening of the pyranose-ring. This tendency of D-*altro*-configuration of **7** and **12** is stronger than that of D-*manno*-configuration of **6** ($J_{1,2}$=1.5) and **10** ($J_{1,2}$=1.0). Consequently, it is deduced that a slight deformation of the conformation in **12** prevented the anchimeric contribution of C_2-acetamido group. It is also noteworthy that **13** has still *C1* conformation, nevertheless, the pyranose-ring has four axial substituents. It seems likely to be due to the dipolar repulsions between four electronegative substituents (Cl, N_3, NHAc, and OBn).

Hydrogenation of chlorine atom of **13** with tributyltin hydride proceeded smoothly together with that of the azido group. The structure of the product (**14**) could not be confirmed to be either the corresponding 3-amino or 3,4-epimino derivative by usual methods, but CMR spectrum (Fig. 1) indicated the presence of only two methylene carbons. Consequently, the structure was determined to be benzyl 2-acetamido-6-*O*-benzoyl-3,4-epimino-2,3,4-trideoxy-α-D-altropyranoside. This conclusion suggests that the hydrogenation of azido group was faster than that of the chlorine atom. Hydrogenation of **14** in the presence of Raney nickel gave fortunately the desired 3-amino-3,4-dideoxy derivative as main product, which was then converted into 3-acetamido derivative (**15**) in 60% yield. The configuration of **15** was completely proved by the double resonance technique in the PMR spectrum (Fig. 2). By irradiation of H_1 and two NH protons (a, b, c), multiplets at *δ ca.* 4.15 and 4.30 were assigned to H_2 and another ring proton (H_3) of the position of the acetamido group, respectively, and the reverse irradiation (d, e) indicated that only the latter is vicinal to the ring methylene protons at *δ ca.* 1.84, showing the sharpening of them. These facts indicate that the deoxygenated position should be *C*-4. Moreover, the conclusion was confirmed by the irradiation of ring-methylene protons (f) and a ring proton (H_5) other than two acetamido positions (g).

Experimental

All melting points were determined with Yanaco micro melting point apparatus and not corrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 50 °C. The IR spectra were measured in KBr discs with a Hitachi EPI-GS spectrometer. The PMR spectra were obtained at 100 MHz with a JEOL 4H-100 spectrometer in deuteriochloroform, using TMS as an internal reference. Specific rotations were measured in a 0.5-dm tube with a Carl Zeiss SEP-AL polarimeter in chloroform unless otherwise stated. Chemical shifts and coupling constants were recorded in *δ* and Hz units, and IR frequencies in cm^{-1}.

Methyl 2,3-Di-O-mesyl-α-D-glucopyranoside (*1*). A suspension of methyl 4,6-*O*-benzylidene-2,3-di-*O*-mesyl-α-D-glucopyranoside (7 g, 16 mmol) in 70% acetic acid (100 ml) was heated at 90—95 °C for 4 h under monitering with TLC until the starting material has disappeared, and then evaporated to give white powder which was crystallized from ethanol. Yield, 5.5 g (98%), mp 148—149 °C; $[\alpha]_D^{22}$+84.2° (*c* 1.0, acetone).

Found: C, 31.07; H, 5.15; S, 17.83%. Calcd for $C_9H_{18}O_{10}S_2$: C, 30.85; H, 5.18; S, 18.30%.

Methyl 4-Chloro-4-deoxy-2,3-di-O-mesyl-6-O-trityl-α-D-galactopyranoside (*2*). A solution of **1** (1 g, 2.9 mmol) and trityl chloride (1 g, 3.6 mmol) in pyridine (30 ml) was kept at room temperature, and then poured into ice-water to give the corresponding 6-*O*-trityl derivative in 86% (1.5 g) yield (mp 155—

156 °C after recrystallization from benzene). To an ice-cooled solution of 6-*O*-trityl derivative (1.5 g, 2.5 mmol) in pyridine was added dropwise sulfuryl chloride (0.27 ml, 3.3 mmol) with stirring, and then poured into ice–water after standing overnight at room temperature. The resulting solution was extracted with chloroform, and the extract was treated in a usual manner to give a sirup (1.36 g, 88%) which was crystallized and recrystallized from methanol. Mp 130—131 °C, $[\alpha]_D^{23}$ +53.0° (*c* 1.0).

Found: C, 55.04; H, 5.11; S, 10.21%. Calcd for $C_{28}H_{31}O_9S_2Cl$; C, 55.02; H, 5.11; S, 10.49%.

*Methyl 4-Deoxy-2,3-di-*O*-mesyl-6-*O*-trityl-α-*D*-*xylo*-hexopyranoside* (**3**). A solution of **2** (200 mg, 0.33 mmol), tributyltin hydride (0.5 ml) and a catalytic amount of 2,2′-azobisisobutyronitrile in toluene (8 ml) was heated at 80—90 °C for 20 h under argon atmosphere, and then evaporated to give crystals quantitatively, which were recrystallized from ethanol. Mp 187—188 °C; $[\alpha]_D^{23}$ +59.5° (*c* 1.0).

Found: C, 58.51; H, 5.90; S, 11.05%. Calcd for $C_{28}H_{32}O_9S_2$: C, 58.31; H, 5.59; S, 11.12%.

*Methyl 2,3,4-Trideoxy-6-*O*-trityl-α-*D*-glycero-hex-2-enopyranoside* (**4**). A suspension of **3** (1.0 g, 1.7 mmol) and sodium azide (680 mg, 10 mmol) in DMF (30 ml) was refluxed for 20 hr, poured into water, and the resulting solution was extracted with ether. The ether layer was washed with saturated sodium chloride, dried with sodium sulfate, and then evaporated to give a sirup which showed five spots on TLC (benzene:ethyl acetate=95:5). The starting material (R_f= 0.20; 380 mg, 38%) and 5 (R_f=0.58; 100 mg, 15%) were isolated as main products on a sillica gel column (benzene). $[\alpha]_D^{22}$ −22.6° (*c* 1.0); IR: 1660 (C=C).

Found: C, 80.14; H, 6.90%. Calcd for $C_{26}H_{26}O_3$: C, 80.80; H, 6.78%.

*Benzyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-mesyl-α-*D*-mannopyranoside* (**6**). To an ice-cooled solution of benzyl 2-acetamido-4,6-*O*-benzylidene-D-deoxy-α-D-mannopyranoside (200 mg, 0.5 mmol) in pyridine (2 ml) was added dropwise methanesulfonyl chloride (150 mg, 1.3 mmol) with stirring. The resulting solution was kept at room temperature for 4 h, Poured into ice–water, and the crystals (230 mg, 96%) deposited were recrystallized from ethanol. Mp 167—168 °C; $[\alpha]_D^{23}$+114.5° (*c* 1.5); IR: 3280 (NH), 1650 and 1535 (amide), 1370 (sulfonate).

Found: C, 57.90; H, 5.74; N, 3.08%. Calcd for $C_{23}H_{27}O_8SN$: C, 57.85; H, 5.70; N, 2.93%.

*Benzyl 2-Acetamido-3-azido-4,6-*O*-benzylidene-2,3-dideoxy-α-D-altropyranoside* (**7**). A solution of **6** (1.0 g, 2.1 mmol) and lithium azide (1.0 g, 143 mmol) in HMPA (50 ml) was heated at 150—157 °C overnight, poured into cold sodium chloride solution, and then extracted with ether. The extracts were washed with 5% sodium chloride, dried, and evaporated to give a sirup (740 mg, 83%) which was crystallized and recrystallized from ethanol. Mp 160 °C; $[\alpha]_D^{23}$ +70.8° (*c* 1.2); IR: 3280 (NH), 2100 (N_3), 1650 and 1535 (amide).

Found: C, 62.39; H, 5.75; N, 13.34%. Calcd for $C_{22}H_{24}N_4O_5$: C, 62.25; H, 5.70; N, 13.20%.

*Benzyl 2-Acetamido-3-amino-4,6-*O*-benzylidene-2,3-dideoxy-α-D-altropyranoside* (**8**). A suspension of **7** (740 mg 1.7 mmol) and Raney nickel (2.3 g) in ethanol (80 ml) was hydrogenated in an autoclave under a hydrogen pressure of 80—100 kg/cm² at room temperature overnight, and then filtered. Evaporation of the filtrate gave crystals (600 mg, 88%) which were recrystallized from ethanol. Mp 236—238 °C; $[\alpha]_D^{19}$ +82.0° (*c* 1.02); IR: 3160—3350 (NH), 1660 and 1560 (amide).

Found: C, 66.25; H, 6.69; N, 6.92%. Calcd for $C_{22}H_{26}N_2O_5$: C, 66.31; H, 6.58; N, 7.03%.

Benzyl 2-Acetamido-2,3-dideoxy-3-guanidino-α-D-altropyranoside (**9**). To a solution of **8** (0.45 g, 1.13 mmol) in aqueous ethanol containing equimolar hydrochloric acid was added cyanamide (72 mg, 1.7 mmol), then the temperature of the mixture was raised to 130 °C in an oil-bath during 1 h, and the mixture was kept at the temperature for 30 min. The glassy reaction mixture was dissolved in aqueous ethanol, treated with IRA-410 (OH form, 5 ml) overnight, and then filtered, The filtrate was heated at 90—100 °C for 6 h together with acetic acid (70%, 40 ml), evaporated, and then absorbed on an Amberlite CG-50 column (20 ml). The column was eluated. in turn with water (200 ml), aqueous ammonia (2.8%, 200 ml), water (200 ml) and then 0.5 M hydrochloric acid. The last effluent of pH 6—8 was evaporated, and the residue was extracted with ethanol. The ethanol extract was treated with IRA-410 (OH^- form, 20 ml) overnight, and the filtrate was evaporated to give a colourless glassy solid (200 mg, 50%) which is positive in the Sakaguchi reaction. $[\alpha]_D^{23}$ +58.7° (*c* 1.07, water).

Found: C, 49.63; H, 6.91; N, 14.85%. Calcd for $C_{16}H_{24}N_4O_5\cdot 2H_2O$; C, 49.47; H, 7.27; N, 14.43%.

*Benzyl 2-Acetamido-2-deoxy-3-*O*-mesyl-6-*O*-trityl-α-*D*-mannopyranoside* (**10**). A suspension of **6** (3.07 g, 6.4 mmol) in 70 % acetic acid (100 ml) was heated at 60—70 °C for 6 h, and after evaporation of the solvent, the residue was washed with petroleum ether. A solution of the dried residue and trityl hloride (2.6 g, 9.3 mmol) in pyridine (50 ml) was kept at room temperature overnight, and evaporated. The residue was purified on a silica gel column (benzene: ethyl acetate=4: 1) to give crystals (2.52 g, 62%). Mp 179—180 °C; $[\alpha]_D^{22}$ +37.4° (*c* 1.0, acetone); IR: 3350 (NH), 1650 and 1520 (amide).

Found: C, 65.92; H, 5.93; N, 2.04; S. 5.12%. Calcd for $C_{35}H_{37}NO_8S$: C, 66.54; H, 5.90; N, 2.22; S, 5.08%.

*Benzyl 3′-*O*-Mesyl-6′-*O*-trityl-α-*D*-talopyranosid[2′,3′,4′; 4,5,6]-2-methyl-5,6-dihydro-4*H*-oxazine* (**11**). To an ice-cooled solution of **10** (1.0 g, 1.6 mmol) in pyridine (50 ml) was added dropwise sulfuryl chloride (0.16 ml, 2.0 mmol), and the mixture was evaporated, after standing overnight in a refrigerator. The residue was dissolved in chloroform, and the solution was washed in turn with cold 2 M hydrochloric acid, saturated sodium hydrogen carbonate and sodium chloride, dried, and then removal of the solvent gave a sirup (1.04 g, 80.5%) which was crystallized from ethanol. Mp 129—130 °C; $[\alpha]_D^{24}$ +18.1° (*c* 1.0); IR: 1660 (C=N), 1360 (sulfonic ester).

Found: C, 68.44; H, 5.72; N, 2.29; S, 5.29%. Calcd for $C_{35}H_{35}O_7S$: C, 68.49; H, 5.74; N, 2.28; S, 5.23%.

*Benzyl 2-Acetamido-3-azido-6-*O*-benzoyl-2,3-dideoxy-α-D-altropyranoside* (**12**). A suspension of **7** (3.5 g, 8.3 mmol) in 70% acetic acid (50 ml) was heated at 60—70 °C for 5 hr, the resulting solution was evaporated, and then the residue was washed with petroleum ether. To a chilled solution of the dried residue in pyridine (50 ml) was added dropwise benzoyl chloride (1.1 ml, 9.5 mmol), the mixture was kept at room temperature overnight, poured into cold saturated sodium hydrogen carbonate, and then extracted with chloroform. Treatment of the extract in a usual manner gave a sirup (3.0 g, 80%) which was purified on a silica gel column (ethyl acetate). $[\alpha]_D^{23}$ +51.7° (*c* 1.0); IR: 3300 (NH, OH), 2100 (N_3), 1720 (ester), 1650 and 1540 (amide).

Found: C, 59.43; H, 5.58; N, 12.30%. Calcd for $C_{22}H_{24}O_6N_4$: C, 59.99; H, 5.49; N, 12.72%.

*Benzyl 2-Acetamido-3-azido-6-*O*-benzoyl-4-chloro-2,3,4-trideoxy-α-D-idopyranoside* (**13**). To an ice-cooled solution of **12** (1.5 g, 3.4 mmol) in pyridine (30 ml) was added dropwise sulfuryl chloride (0.32 ml, 4.0 mmol), the mixture was kept overnight in a refrigerator, and the solvent was evaporated. The residue was dissolved in chloroform, and the solution was washed in turn with cold 2 M hydrochloric acid, saturated

sodium bicarbonate, saturated sodium chloride, dried, and evaporation of the solvent afforded crystals (1.1 g, 70.5%) which was recrystallized from ethanol. Mp 175 °C; $[\alpha]_D^{23}$ +79.8 °C (*c* 1.0); IR: 3250 (NH), 2100 (N_3); 1720 (ester), 1650 and 1550 (amide).

Found: C, 57.39; H, 5.07; N, 12.18%. Calcd for $C_{22}H_{23}O_5N_4Cl$: C, 57.39; H, 5.05; N, 12.21%.

Benzyl 2-Acetamido-6-O-benzoyl-2,3,4-trideoxy-3,4-epimino-α-D-altropyranoside (**14**). A solution of **13** (250 mg, 5.4 mmol) tributyltinhydride (3.0 ml) and catalytic amount of 2,2′-azobisisobutylonitrile in toluene was heated at 80—90 °C for 3 days under argon atmosphere, and crystals deposited at room temperature were filtered and recrystallized from toluene. Mp 142—143 °C; $[\alpha]_D^{22}$ +32.2° (*c* 1.0); IR: 3200—3300 (NH), 1710 (ester); 1660 and 1530 (amide and epimino); CNR (ppm): Ac (22.96), C_3 and C_4 (29.39, 30.53), C_2 (44.70), CH_2 (66.09, 70.71), C_5 (67.78), C_1 (97.78), C=O (165.89, 169.06).

Found: C, 66.09; H, 6.21; N, 6.93%. Calcd for $C_{22}H_{26}O_5N_2$: C, 66.31; H, 6.58; N, 7.03%.

Benzyl 2,3-Diacetamido-6-O-benzoyl-2,3,4-trideoxy-α-D-arabino-hexopyranoside (**15**). A suspension of **14** (200 mg, 0.5 mmol) and Raney nickel (2 g) in ethanol (10 ml) was hydrogenated in an autoclave at room temperature for 2 days, filtered, and the filterate was evaporated to give a sirup. The sirup in pyridine was acetylated with acetic anhydride at room temperature overnight, and the reaction mixture was poured into ice-water to give crystals which were recrystallized from ethanol–hexane. Yield, 130 mg (60%); Mp 214—215 °C; $[\alpha]_D^{22}$ −4.0° (*c* 0.5); IR: 3200—3300 (NH), 1720 (ester), 1660, 1640, 1560, and 1550 (amide).

Found: C, 64.12; H, 6.50; N, 6.09%. Calcd for $C_{23}H_{28}O_6N_2$: C, 64.47; H, 6.59; N, 6.54%.

The authors are indebted to Dr. K. Ajisaka and Mr. H. Matsumoto for NMR measurements, and members of the Laboratory of Organic Analysis for microanalyses.

Aminosugars. XXVI. Synthesis of Amido-bonded Disaccharides Containing Hexosaminuronic Acids[1]

Juji YOSHIMURA, Hiroaki ANDO, Tadahide SATO, Shigeru TSUCHIDA,* and Hironobu HASHIMOTO

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received February 7, 1976)

Synthesis and properties of amido-bonded disaccharides containing hexosaminuronic acids are described. The amino group of D-gluco- and D-mannosamine derivatives was acylated with D-gluco- and D-mannosaminuronic acid derivatives by the dicyclohexylcarbodiimide method, and the protecting groups of a few products were removed. Some of them showed the additive patterns of components in their PMR spectra.

2-Acetamido-2-deoxy-D-glucuronic acid[2-4] and -D-mannuronic acid[5] have been found as a component of several bacterial cell-walls. These hexosaminuronic acids also arouse interest in their polyfunctional character. For examples, several antibiotics such as blasticidine S,[6] gougerotin,[7] and polyoxin C[8] include an amido bond between a certain hexosaminuronic acid and a peptide. Although amido-bonded disaccharides have not been found in nature up to date, we synthesized some of them containing usual aminosugars and uronic acids, and analyzed their PMR spectra as the additive pattern of component sugars in a previous paper.[9]

In this paper, similar disaccharides between hexosaminuronic acids and aminosugars were synthesized, and their properties were examined.

Results and Discussion

In this study, benzyl 2-amino-2-deoxy-α-D-glucopyranoside (**1**),[10] benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**2**)[11] and its de-*O*-benzylidenated derivative (**3**)[9] were used as aminosugars, and benzyl 2-acetamido- (**4**)[12] and 2-benzyloxycarbonylamido-2-deoxy-α-D-glucopyranosiduronic acid (**5**)[13] benzyl 2-acetamido-2-deoxy-α-D-mannopyranosiduronic acid (**6**)[11] as hexosaminuronic acids.

Condensation of **1** and **4** or **5** in pyridine by the dicyclohexylcarbodiimide (DCC) method for five days gave precipitates of a mixture of the product and dicyclohexylurea (DCU), from which benzyl 2-(benzyl 2-acetamido- (**7**) or 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranosiduronyl) amino-2-deoxy-α-D-glucopyranoside (**8**) was obtained by fractional crystallization both in 71% yield. These compounds having the D-*gluco*-type unit are not so soluble even in water and alcohols, and have higher melting points compared with that including the D-*manno*-type unit. The structure of **7** was confirmed by the conversion into the corresponding penta-*O*-acetate (**9**). Similar condensation of **1** and **6**, and separation of the product and DCU by a silica gel column chromatography gave benzyl 2-(benzyl 2-acetamido-2-deoxy-α-D-mannopyranosiduronyl)amino-2-deoxy-α-D-glucopyranoside (**10**) in 64% yield. Acetylation of **10** gave the corresponding penta-*O*-acetate (**11**) in 80% yield.

In the case of **2** and **4**, and also **3** and **6**, the corresponding disaccharides were separated in a pure state only as the tri-*O*-acetate (**13**) and penta-*O*-acetate (**15**), respectively. Treatment of **13** in ethanol with a tiny amount of metallic sodium gave benzyl 2-(benzyl

a) NMR data (chemical shift, splitting and coupling constant) in parentheses and brackets show those of component *O*-acetylated aminosugar and uronic acid moiety, respectively. b) Compound **9** and its component sugars were measured in pyridine-d_5 and others in chloroform-d_1.

2-acetamido-2-deoxy-α-D-glucopyranosiduronyl)amino-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**12**). Partial hydrolysis of **12** with 60% acetic acid gave the corresponding de-*O*-benzylidenated product (**14**).

On the other hand, hydrogenation of **7** and **8** in the presence of palladium–charcoal gave the corresponding free sugars (**16** and **17**) having fairly high melting points in 80 and 66% yields, respectively. Further hydrogenation of **16** with excess sodium borohydride gave quantitatively the corresponding crystalline alditol (**19**). Acetylation of **16** in pyridine with acetic anhydride unexpectedly gave the unchanged materials, but acid-catalyzed acetylation with perchloric acid–acetic anhydride gave successfully the corresponding hepta-*O*-acetate (**18**). The glycosidic configurations of **18** were determined to be α, α from the coupling constants, $J_{1,2}$=3.8 Hz (Fig. 1) and specific rotation ($[\alpha]_D^{23}$ +115°). For the synthesis of amido-bonded trisaccharides, condensation of **17** with **5** by the DCC method was tried several times, but only unsuccessful results were obtained, partly due to the insolubility of **17**.

As was pointed out in the previous paper, PMR spectra of amido-bonded sugars were supposed to show the additive patterns of the component monosaccharides.

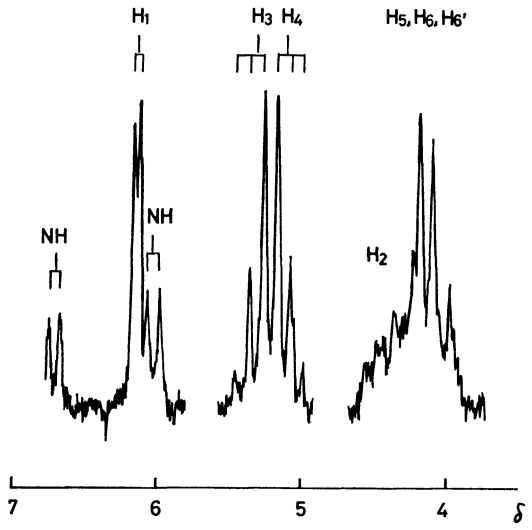

Fig. 1. Ring-proton signals in the NMR spectrum of **18** (in $CDCl_3$ at 100 MHz).

However, the analysis of spectra of pyranose-pyranose type compounds mentioned above were rather difficult due to superimposed signals. The simplest signal pattern in the spectrum of **18** indicated that H_1, H_3, and H_4 protons in both pyranose-rings are almost in the same magnetic circumstance. As was shown in Table 1, the similar additivity was scarcely observed in the spectra of **9** and **15** having the same configuration in both pyranose-rings.

Experimental

The melting points were determined on a sulfuric acid bath and uncorrected. Optical rotations were measured in a 0.5-dm tube with a Carl Zeiss photoelectric polarimeter. NMR spectra were recorded at 100 MHz with a JNM-4H-100 spectrometer. IR spectra were recorded with a Hitachi Model EPI-G2 spectrophotometer. Chemical shifts and coupling constants were recorded in δ and Hz units and IR frequencies in cm^{-1}.

Benzyl 2-(Benzyl 2-acetamido-2-deoxy-α-D-glucopyranosiduronyl)-amino-2-deoxy-α-D-glucopyranoside (**7**). To a solution of benzyl 2-amino-2-deoxy-α-D-glucopyranoside (**1**) hydrochloride(14.0 g, 45.8 mmol) and benzyl 2-acetamido-2-deoxy-α-D-glucopyranosiduronic acid (**4**) (15.0 g, 46.1 mmol) in dry pyridine (140 ml) containing triethylamine (4.6 g, 46 mmol) was added DCC (10 g, 50 mmol), and the resulting solution was stirred at room temperature for 5 days. The gelatinous materials deposited were filtered. The amorphous solid obtained by addition of acetic acid (5%, 10 ml) to the above filtrate was also gathered. Both solids were dissolved in DMF and insoluble DCU was filtered off. The residues obtained by evaporation of the filtrate were crystallized twice from methanol–pyridine. Yield, 18.8 g (71%); mp 283—284 °C (decomp); $[\alpha]_D^{23}$ +156° (*c* 1.0, DMF); IR: 1650 and 1550 (amide) cm^{-1}.

Found: C, 57.96; H, 6.20; N, 4.81%. Calcd for $C_{28}H_{36}N_2O_{11}$: C, 58.32; H, 6.29; N, 4.86%.

Acetylation of **7** by the usual manner, and crystallization of the product from ethanol gave the corresponding penta-*O*-acetate (**9**) in 80% yield. Mp 201—202 °C; $[\alpha]_D^{23}$ +66° (*c* 1.0, pyridine); IR: 1745 (ester), 1685, 1660, 1525 (amide) cm^{-1}.

Found: C, 57.73; H, 5.79; N, 3.52%. Calcd for $C_{38}H_{46}N_2O_{16}$: C, 58.01; H, 5.89; N, 3.56%.

Benzyl 2-(Benzyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranosiduronyl)amino-2-deoxy-α-D-glucopyranoside (**8**). Condensation of hydrochloride of **1** (11 g, 36 mmol) and benzyl 2-

benzyloxycarbonylamino-2-deoxy-α-D-glucopyranosiduronic acid (**5**) (15 g, 36 mmol) in a similar manner as **7**, and recrystallization of the product from pyridine–methanol gave **8** in 71 % (17 g) yield. Mp 272—272.5 °C (decomp); $[\alpha]_D^{23}$ +170° (*c* 1.0, pyridine); IR: 1650, 1525 (amide) cm^{-1}.

Found: C, 60.85; H, 6.02; N, 4.29%. Calcd for $C_{34}H_{40}N_2O_{11}$: C, 61.07; H, 6.03; N, 4.19%.

Benzyl 2-(Benzyl 2-acetamido-2-deoxy-α-D-mannopyranosiduronyl)-amino-2-deoxy-α-D-glucopyranoside (**10**). A solution of hydrochloride of **1** (2.2 g, 7.2 mmol), benzyl 2-acetamido-2-deoxy-α-D-mannopyranosiduronic acid (**6**) (2.4 g, 7.3 mmol) and DCC (1.5 g, 7.3 mmol) in pyridine (6 ml) and triethylamine (1.2 ml) was stirred for 5 days at room temperature, and DCU deposited was filtered off. Evaporation of the filtrate gave a syrup which was fractionally separated on a silica gel column (benzene–methanol=10 : 1) to give the crystalline product which was recrystallized three times from ethanol. Yield, 2.7 g (65%), mp 223—223.5 °C; $[\alpha]_D^{23}$ +142° (*c* 0.57, pyridine), IR: 1655, 1555, 1520 (amide) cm^{-1}.

Found: C, 58.21; H, 6.24; N, 5.07%. Calcd for $C_{28}H_{36}N_2O_{11}$: C, 58.32; H, 6.29; N, 4.86%.

Base-catalyzed acetylation of **10** in a usual manner gave the corresponding penta-*O*-acetate (**11**) in 80% yield, which was purified from ethanol–petroleum ether. Amorphous white solid sintered at 85 °C and melted at 124—125 °C. $[\alpha]_D^{23}$ +54° (*c* 0.92, pyridine); IR: 1740 (ester), 1680, 1510 (amide) cm^{-1}.

Found: C, 57.84; H, 5.95; N, 3.43%. Calcd for $C_{38}H_{46}N_2O_{16}$: C, 58.01; H, 5.89; N, 3.56%.

Benzyl 2-(Benzyl 2-acetamido-3,4-di-O-acetyl-2-deoxy-α-D-glucopyranosiduronyl)amino-3-O-acetyl-4,6-O-benzylidene-2-deoxy-α-D-mannopyranoside (**13**). A solution of benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranoside (**2**) (1.5 g, 4.2 mmol), **4** (1.4 g, 4.3 mmol), and DCC (1.0 g, 4.85 mmol) in pyridine (20 ml) was stirred for 3 days at room temperature, filtered, and then the filtrate was evaporated to give a syrup (2.6 g). To a solution of this syrup in pyridine (4 ml) was added acetic anhydride (1.5 g), and after 2 h, the reaction mixture was poured into ice–water. The solid mass deposited was collected, dried, and then recrystallized from large amount of ethanol to give **13** in 69% yield. Mp 252—253 °C; $[\alpha]_D^{23}$ +90.5° (*c* 1.1, pyridine); IR: 1680, 1560 (amide) cm^{-1}.

Found: C, 62.01; H, 5.65; N, 3.76%. Calcd for $C_{41}H_{46}N_2O_{14}$: C, 62.27; H, 5.86; N, 3.54%.

De-*O*-acetylation of **13** (2.0 g, 2.5 mmol) in absolute ethanol (600 ml) with a trace amount of metallic sodium gave a syrup which was crystallized from methanol to give **12** in 72% (1.2 g) yield. Mp 153—155 °C; $[\alpha]_D^{23}$ +97.8° (*c* 0.64, pyridine); IR: 1650, 1525 (amide) cm^{-1}.

Found: C, 63.01; H, 6.22; N, 4.35%. Calcd for $C_{35}H_{40}N_2O_{11}$: C, 63.24; H, 6.07; N, 4.21%.

Benzyl 2-(Benzyl 2-acetamido-2-deoxy-α-D-glucopyranosiduronyl)-amino-2-deoxy-α-D-mannopyranoside (**14**). A solution of **12** (0.50 g, 0.75 mmol) in 60% acetic acid (20 ml) was heated for 1 h at 80 °C, and then evaporated to give a hard syrup which was crystallized from methanol. Yield, 0.33 g (76%); mp 138—140 °C; $[\alpha]_D^{23}$ +107° (*c* 0.19, DMF); IR: 1680, 1560 (amide) cm^{-1}.

Found: C, 58.01; H, 6.42; N, 4.76%. Calcd for $C_{28}H_{36}N_2O_{11}$: C, 58.32; H, 6.29; N, 4.86%.

Benzyl 2-(benzyl 2-acetamido-3,4-di-O-acetyl-2-deoxy-α-D-mannopyranosiduronyl)amino-3,4,6-tri-O-acetyl-2-deoxy-α-D-mannopyranoside (**15**). Benzyl 2-amino-2-deoxy-α-D-mannopyranoside (**3**) (0.37 g, 1.2 mmol) and **6** (0.40 g, 1.2 mmol) were condensed in a similar manner as above, and the syrupy product was acetylated to give syrupy penta-*O*-acetate (1.0 g) which was purified on a silica gel column (benzene–methanol= 10: 1). Yield, 0.71 g (75%); $[\alpha]_D^{23}$ +72.8° (*c* 0.60, pyridine); IR, 1750 (ester), 1680, 1670, and 1545 (amide) cm^{-1}.

Found: C, 57.72; H, 5.81; N, 3.32%. Calcd for $C_{38}H_{46}N_2O_{16}$: C, 58.01; H, 5.89; N, 3.58%.

2-(2-Acetamido-2-deoxy-D-glucopyranuronyl)amino-2-deoxy-D-glucopyranose (**16**). A suspension of **7** (5.0 g, 8.7 mmol) in methanol (100 ml) adjusted to pH 2 with hydrochloric acid was hydrogenated in the presence of palladium–charcoal (10%, 10 g), and then filtered. Concentration of the filtrate gave no products, but, extraction of the filtered mass several times with hot water gave white solid which was recrystallized from hot water. Yield, 2.8 g (80%); mp 261—262 °C (decomp); IR: 1650, 1620, 1570, and 1540 (amide) cm^{-1}.

Found: C, 42.25; H, 6.31; N, 7.23%. Calcd for $C_{14}H_{24}N_2O_{11}$: C, 42.42; H, 6.10; N, 7.07%.

2-(2-Amino-2-deoxy-D-glucopyranuronyl)amino-2-deoxy-D-glucopyranose Hydrochloride (**17**). A suspension of **8** (12.0 g, 17.9 mmol) in water containing equimolar amount of hydrochloric acid was hydrogenated in the presence of palladium–charcoal (10%, 10 g), filtered, and then evaporated to give a white mass which was recrystallized from water–ethanol. Yield 4.6 g (66 %); mp 230—231 °C (decomp); $[\alpha]_D^{23}$ +80° +62.4° (*c* 1.0, H_2O, 72 h); IR: 1640, 1510 (amide), 1560 ($NH_2 \cdot HCl$) cm^{-1}.

Found C, 36.40; H, 6.01; N, 6.79; Cl, 9.09%. Calcd for $C_{12}H_{22}N_2O_{10} \cdot HCl$: C, 36.88; H, 5.93; N, 7.17; Cl, 9.07%.

2-(2-Acetamido-1,3,4-tri-O-acetyl-2-deoxy-α-D-glucopyranuronyl)amino-1,3,4,6-tetra-O-acetyl-2-deoxy-α-D-glucopyranose (**18**). To an ice-cooled suspension of **16** (0.60 g, 1.5 mmol) in acetic anhydride (15 ml) was added several drops of perchloric acid under stirring, and the resulting solution was kept at room temperature for 30 min, poured into ice–water, and then extracted with chloroform. The extract was washed successively with water, aqueous sodium hydrogencarbonate and water, dried and then evaporated to give crystals which were recrystallized from ethanol. Yield, 0.63 g (60%); mp 190—191 °C $[\alpha]_D^{23}$ +115° (*c* 1.0, $CHCl_3$).

Found: C, 48.92; H, 5.69; N, 4.06%. Calcd for $C_{28}H_{38}N_2O_{18}$: C, 48.70; H, 5.55; N, 4.06%.

2-(5-Acetamido-5-deoxy-L-gulonyl)amino-2-deoxy-D-glucitol (**19**). To an aqueous solution of **16** (0.30 g, 0.76 mmol) was added portionwise sodium borohydride (0.10 g, 3 mmol) with stirring, the resulting solution was stirred at room temperature for 2 h, and then neutralized with Amberlite 120 (H^+ form). The neutral solution was evaporated, and a methanol solution of the residue was evaporated repeatedly to remove boric acid. The product thus obtained was crystallized from methanol–ether. Yield 0.30 g (99%); mp 83—84 °C; $[\alpha]_D^{23}$ −21° (*c* 1.0, H_2O); IR, 1660, 1640, and 1550 (amide).

Found: C, 41.59; H, 7.06; N, 6.87%. Calcd for $C_{14}H_{28}N_2O_{11}$: C, 42.00; H, 7.05; N, 7.00%.

The authors are indebted to the members of the Laboratory of Organic Analysis for microanalysis and to Mr. H. Matsumoto for NMR measurements.

Synthesis of 2,7-Di-*t*-butyl-4,5,9,10-tetraphenyltricyclo[6.2.0.0^{3,6}]deca-1,3(6),4,7,9-pentaene. A Benzo[1,2: 4,5]dicyclobutene[1]

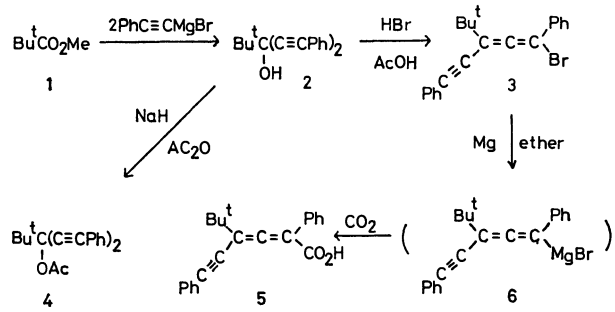
Fumio TODA and Yutaka TAKAHARA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received March 29, 1976)

The title compound (**15**) which has two cyclobutadienes fused to a benzene ring, was synthesized by heating *dl*- (**7**), *meso*-3,8-di-*t*-butyl-1,5,6,10-tetraphenyldeca-3,4,6,7-tetraene-1,9-diyne (**8**), or *E,Z*-3,4-bis(1-*t*-butyl-3-phenyl-2-propynylidene)-1,2-diphenyl-1-cyclobutene (**12**).

Benzocyclobutene has been an interesting subject in relating to antiaromatic cyclobutadiene,[2] and some derivatives of benzocyclobutadiene have been isolated.[3-5] It is, however, much more interesting to fuse an additional cyclobutadiene further to the benzene ring of benzocyclobutadiene, because the resulting carbocycle which has two antiaromatic cyclobutadienes is formally a 10π electrons system. As the first example of this carbocycle, the title compound (**15**) was prepared according to the following routes.



3-*t*-Butyl-1,5-diphenylpenta-1,4-diyn-3-ol (**2**) was prepared by the reaction of methyl pivalate (**1**) with two molar amounts of phenylethynylmagnesium bromide. The treatment of **2** with hydrobromic acid and acetic anhydride afforded 1-bromo-3-*t*-butyl-1,5-diphenylpenta-1,2-dien-4-yne (**3**) and the acetate of **2** (**4**), respectively. The reaction of **3** with magnesium in ether resulted in an ethereal solution of the Grignard reagent (**6**), which on treatment with carbon dioxide afforded 1-carboxy derivative (**5**).

Both the treatments of **3** and **4** with CuCl in *N,N*-dimethylformamide (DMF) according to the previously-reported procedure,[6] afforded *dl*- (**7**)[7] and *meso*-3,8-di-*t*-butyl-1,5,6,10-tetraphenyldeca-3,4,6,7-tetraene-1,9-diyne (**8**), and 3,6-di-*t*-butyl-1,5,8-triphenyl-6-phenylethynylocta-3,4-diene-1,7-diyne (**9**)[7] in the yields summarized in Table 1. The treatment of an ethereal solution of **6** with CuCl also gave **7**, **8**, and **9** in the yields shown in Table 1.

In order to characterize the structure of **9**, the following reactions were carried out. The oxidation of **9** with potassium permanganate afforded 3,6-di-*t*-butyl-1,5,8-triphenyl-6-phenylethynylocta-3,4-diene-7-yne-1,3-dione (**10**). An evidence for the α-diketone structure of **10** was obtained by its sodium borohydride reduction into 3,6-di-*t*-butyl-1,5,8-triphenyl-6-phenylethynylocta-3,4-dien-7-yne-1,2-diol (**11**) which shows NMR signals of two vicinal methine protons. Furthermore, the fact that the stretching frequencies of allene of **10** (1930 cm^{-1}) are lower than those of **11** (1940 cm^{-1}), supported the structure of **10** in which a conjugation between the α-diketone and allene moieties is possible.

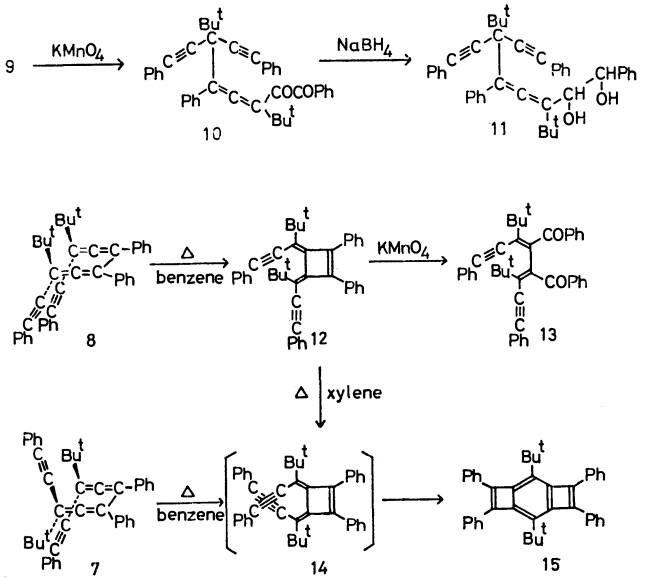
The *meso* structure of **8** was elucidated on the basis of its thermal conversion into *E,Z*-3,4-bis(1-*t*-butyl-3 phenyl-2-propynylidene)-1,2-diphenyl-1-cyclobutene (**12**). The *E,Z*-structure of **12** was determined by means of its NMR spectrum which shows two *t*-butyl signals. The *E,Z*-structure of **12** was further confirmed by its oxidation with potassium permanganate which affords thermally stable *E,Z*-4,5-dibenzoyl-3,6-di-*tert*-butyl-1,8-diphenylocta-3,5-diene-1,7-diyne (**13**).

Because it has been well established that thermal 2+2 cyclization of diallene proceeds by conrotatory manner,[8,9] the diallene (**8**) which affords *E,Z*-dimethylene-cyclobutene (**12**) by heating should be *meso*-form. Finally, the another diallene (**7**) would be *dl*-form.

Table 1. Yields (%) of **7**, **8**, and **9**

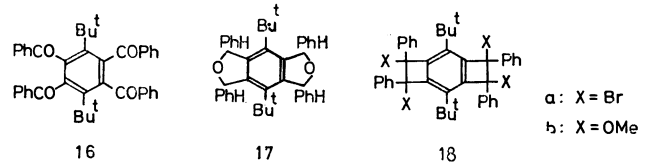
	7	**8**	**9**
3 $\xrightarrow[\text{DMF}]{\text{CuCl}}$	11	11	54
4 $\xrightarrow[\text{DMF}]{\text{CuCl}}$	19	16	41
6 $\xrightarrow[\text{ether}]{\text{CuCl}}$	13	13	69

Heating of **7** in benzene under reflux in nitrogen atmosphere for 30 min gave the title compound (**15**) as greenish blue needles in almost quantitative yield. The UV spectrum of **15** showed the absorption bands at 394 and 643 nm. These bands at longer wavelength region are typical for benzocyclobutene derivatives.[3,4] In the mass spectrum, **15** showed a divalent ion peak at *m/e* 271. The thermal conversion of **7** into **15** presumably proceeds *via* the *E,E*-isomer of **12** (**14**) which was initially formed by a conrotatory cyclization of **7**. In the cyclization of **7**, formation of the *Z,Z*-isomer of **14** would be prohibited because of a steric repulsion between the two *t*-butyl groups. The formation of **15** by a thermal cycloaddition between the two acetylene moieties of **14** is reasonable because such cycloaddition of acetylenes has been reported.[3] Nevertheless, such the cycloaddition reaction which forms two cyclobutadienes and one benzene ring at a time has not been reported, even though this reaction is probably not a



concerted one.

The heating of **8** in *o*-xylene under reflux also afforded **15** in almost quantitative yield. This reaction probably proceeds *via* **12** and **14** successively, because the same treatment of **12** which was prepared from **8** gave **15**. Nevertheless, **12** was inert to the thermal reaction in benzene. This result shows that the conversion of the *E,Z*-geometry of **12** into the *E,E*-one can be performed in boiling *o*-xylene but not in boiling benzene.



In solution, **15** was immediately oxidized but in the crystalline state it was fairly stable and turned gradually into 2,3,5,6-tetrabenzoyl-1,4-di-*t*-butylbenzene (**16**). The treatment of **16** with sodium borohydride followed by hydrogen bromide afforded 1,7-dioxa-4,10-di-*t*-butyl-2,6,8,12-tetraphenyltricyclo[7.3.0.0^{3,11}]dodeca-3,5(9),10-triene (**17**) in almost quantitative yield. The addition of bromine to **15** afforded 4,5,9,10-tetrabromo-2,7-di-*t*-butyl-4,5,9,10-tetraphenyltricyclo[6.3.0.0^{3,6}]deca-1,3(6),7-triene (**18a**), which on treatment with methanol gave the tetramethoxy derivative (**18b**).

Experimental

All the melting points are uncorrected. The IR, UV, and NMR spectra were measured in Nujol mull, $CHCl_3$, and $CDCl_3$, respectively, unless otherwise stated. The mass spectra were measured with an ionization energy of 75 eV.

Synthesis of **2**. To an ethereal solution of ethylmagnesium bromide prepared from Mg (50 g), ethyl bromide (220 g), and ether (1 l), was added a solution of phenylacetylene (208 g) in ether (1 l) under stirring during the period of 1 h. This solution was stirred for further 2 h, and then heated under reflux for 1 h. Into this solution, was added a solution of methyl pivalate (113 g) in ether (500 ml) during the period of 1 h. The reaction mixture was heated under reflux for 2 h, decomposed with dil HCl, and then extracted with ether. The ethereal solution was washed with water and dried over anhydrous Na_2SO_4. The crude crystals left after the evaporation of the solvent were recrystallized from hexane to afford **2** as colorless needles; 196 g (71%); mp 59 °C. IR: 3540 (OH) and 2210 cm^{-1} (C≡C); NMR: 2.3—2.7 (m, Ph, 10H), 7.36 (s, OH, 1H), and 8.72 τ (s, Bu^t, 9H).

Found: C, 87.23; H, 6.75%. Calcd for $C_{21}H_{20}O$: C, 87.46; H, 6.99%.

Synthesis of **3** *and* **5**. To an ice-cooling solution of **2** (144 g) in acetic acid (140 ml), was added concd HBr (72 ml). The reaction mixture was stirred for 1 h under ice-cooling, decomposed with water, and then extracted with petroleum ether. The organic solution was washed with aqueous $NaHCO_3$ and water successively, and dried over anhydrous Na_2SO_4. The evaporation of the solvent afforded **3** as colorless oil; 160 g (91 %), which was used without further purification for all the following synthesis. IR (liquid): 1940 cm^{-1} (C=C=C).

A mixture of **3** (15 g), Mg (1 g), and ether (200 ml) was stirred under N_2 atmosphere for 1 hr, and then heated under reflux for 0.5 h. Into the ethereal solution, CO_2 was bubbled for 2 h. The reaction mixture was decomposed with dil HCl and extracted with ether. The ethereal solution was washed with water and dried over anhydrous Na_2SO_4. The crude crystals left after the evaporation of the solvent were recrystallized from petroleum ether–CCl_4 (10: 1) to afford **5** as colorless needles; 10.1 g (74%); mp 150—152 °C. IR: 1930 (C=C=C) and 1700 cm^{-1} (C=O); λ_{max} 274 nm (ε, 31600); NMR: −1.0 (s, CO_2H, 1H), 2.3—2.8 (m, Ph, 10H), and 8.80 τ (s, Bu^t, 9H).

Found: C, 83.46; H, 6.35%. Calcd for $C_{22}H_{20}O_2$: 83.51; H, 6.37%.

Synthesis of **4**. A mixture of **2** (5 g), NaH (0.44 g), and benzene (25 ml) was kept to stand at room temperature for 1 h. Into this solution, Ac_2O (1.8 g) was added, and the mixture was heated under reflux for 15 min. The crude crystals left after the evaporation of the solvent were recrystallized from hexane to afford **4** as colorless needles; 5.2 g (91%); mp 105 °C. IR: 2210 (C≡C) and 1740 cm^{-1} (C=O); λ_{max}: 254 (35300) and 279 nm (ε, 1440); NMR: 2.2—2.8 (m, Ph, 10H), 7.87 (s, Me, 3H), and 8.70 τ (s, Bu^t, 9H).

Found: C, 83.76; H, 6.57%. Calcd for $C_{23}H_{22}O_2$: C, 83.60; H, 6.71%.

Synthesis of **7**,**8**, *and* **9**. *Procedure A)*. A solution of **2** (253 g) and CuCl (130 g) in DMF (630 ml) was kept to stand at room temperature for 12 h. The crude crystals formed were filtered, washed with MeOH, and dried. The crude crystals were dissolved in acetone (300 ml). The crystals formed after th acetone solution was kept to stand for 5 h were recrystallized from AcOEt to afford **7** as colorless needles; 21.5 g (11%). This compound turned into **15** immediately when melted at 145 °C, and melted again at 296—297 °C. This melting point was measured in N_2 atmosphere[7]. IR ($CHCl_3$): 2200 (C≡C) and 1940 cm^{-1} (C=C=C); λ_{max}: 275 (52900) and 297 nm (ε, 41000); NMR: 2.1—2.8 (m, Ph, 20H) and 8.79 τ (s, Bu^t, 18H); MS *m/e*: 542 (M^+).

Found: C, 92.75; H, 6.78%. Calcd. for $C_{42}H_{38}$: C, 92.94; H, 7.06%.

The crystals formed after the acetone mother liquor was kept to stand for further 5 h were recrystallized from acetone to afford **9** as colorless prisms; 104.4 g (54%); mp 149—151 °C. IR ($CHCl_3$): 2200 (C≡C) and 1940 cm^{-1} (C=C=C); λ_{max}: 280 (30,900) and 297 nm (ε, 26600); NMR: 2.1—2.8 (m, Ph, 20H) and 8.69 and 8.83 τ (each s, Bu^t, 9H); MS *m/e*: 542 (M^+).

Found: C, 92.97; H, 6.81%. Calcd for $C_{42}H_{38}$: C, 92.94; H, 7.06%.

The DMF solution left after the separation of **7** and **9** was decomposed with water and extracted with ether. The ethereal solution was washed with water and dried over anhydrous Na_2SO_4. The crude crystals left after the evaporation of the solvent were recrystallized from acetone to afford **8** as colorless

prisms; 21.1 g (11%); mp 123—124 °C. IR ($CHCl_3$): 2200 (C≡C) and 1940 cm^{-1} (C=C=C); λ_{max}: 276 (59000) and 316 sh nm (ε, 28700); NMR: 2.4—3.7 (m, Ph, 20H) and 8.79 τ (s, Bu^t, 18H); MS *m/e*: 542 (M^+).

Found: C, 92.81; H, 6.84%. Calcd for $C_{42}H_{38}$: C, 92.94; H, 7.06%.

Procedure B). A solution of **4** (50 g) and CuCl (25 g) in DMF (120 ml) was heated at 50 °C for 6 h, and then kept to stand for 12 h. The treatment of the reaction mixture by the same procedure as that used in *Procedure A*, afforded **7** (8.1 g, 19%), **8** (6.8 g, 16%), and **9** (17.5 g, 41%).

Procedure C). To an ethereal solution of **6** prepared from **2** (15 g), Mg (1 g), and ether (200 ml), was added CuCl (7.5 g) under stirring at room temperature during the period of 1 h. The reaction mixture was decomposed with dil HCl and extracted with ether. Fractional recrystallization of the crude crystals left after the evaporation of the solvent by the same procedure as that used in *Procedure A*, afforded **7** (1.5 g, 13%), **8** (1.5 g, 13%), and **9** (8 g, 69%).

*Oxidation of **9** with $KMnO_4$.* A solution of **9** (1 g) and $KMnO_4$ (3 g) in acetone (30 ml) was heated under reflux for 6 h. After excess $KMnO_4$ was decomposed with EtOH, MnO_2 formed was filtered off. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt–MeOH (1: 1) to afford **10** as colorless prisms; 0.74 g (70%); mp 120—121 °C. IR: 1930 (C=C=C) and 1670 cm^{-1} (C=O); λ_{max}: 255 nm (ε, 53400): NMR: 2.1—2.9 (m, Ph, 20H), and 8.75 and 9.10 τ (s, Bu^t, 9H). Ms *m/e*: 578(M^+).

Found: C,87.54; H, 6.38%. Calcd for $C_{42}H_{38}O_2$: C, 87.77; H, 6.66%.

The reduction of **10** (0.5 g) with $NaBH_4$ (0.5 g) in MeOH–THF (1: 1) (20 ml) afforded, **11** as colorless needles after recrystallization from MeOH; 0.41 g (82%); mp 160—161 °C. IR: 3530 (OH), 1940 (C=C=C), and 1020 cm^{-1} (C–O); λ_{max}: 250 (35000) and 257 nm (ε, 35000); NMR: 2.0—2.9 (m, Ph, 20H), 5.10 and 5.80 (d, J=9 Hz, CH, 1H), 6.60 (s, OH, 2H), and 8.80 τ (s, Bu^t, 18H); MS *m/e*: 578 (M^+).

Found: C, 86.88; H, 7.22%. Calcd for $C_{42}H_{42}O_2$: C, 87.16; H, 7.31%.

*Synthesis of **12**.* A solution of **8** (1 g) in benzene (20 ml) was heated under reflux for 2 h. The crude crystals left after the evaporation of the solvent were recrystallized from acetone to afford **12** as pale yellow needles; 0.98 g (98%); mp 161—162 °C. IR: 2200 cm^{-1} (C≡C); λ_{max}: 318 nm (ε, 40600); NMR: 2.3—3.0 (m, Ph, 20H), and 8.47 and 8.90 τ (s, Bu^t, 9H); MS *m/e*: 542 (M^+).

Found: C, 92.72; H, 6.87%. Calcd for $C_{42}H_{38}$: C, 92.94; H, 7.06%.

*Oxidation of **12**.* A solution of **12** (1 g) and $KMnO_4$ (3 g) in acetone (30 ml) was heated under reflux for 2 h. The reaction mixture was treated by the same procedure as that used for the oxidation of **9** afforded **13** as colorless prisms; 0.86 g (81%); mp 129—130 °C. IR: 2160 (C≡C) and 1640 cm^{-1} (C=O); λ_{max} 270 nm (ε, 40900); NMR: 2.4—4.0 (m, Ph, 20H), and 8.50 and 8.80 τ (s, Bu^t, 9H); MS *m/e*: 574 (M^+).

Found: C, 87.54; H, 6.39%. Calcd for $C_{42}H_{38}O_2$: C, 87.77; H, 6.66%.

*Synthesis of **15**.* When a solution of **7** (2 g) in benzene (15 ml) was heated under reflux in N_2 for 1 h, greenish blue needles were formed. Filtration of the crystals under N_2 atmosphere afforded **15**; 1.96 g (98%); mp 296—297 °C. λ_{max}: 394 and 643 nm; NMR: 2.65 (s, Ph, 20H) and 8.88 τ (s, Bu^t, 18H); MS *m/e* (relative intensity): 543 (M^++1, 53), 542 (M^+, 100), 271.5 ($(M+1)^{2+}$, 12), and 271 (M^{2+}, 23). Since **15** was sensitive to oxygen, its melting point, UV, and NMR spectra were measured in N_2 atmosphere, and its correct molecular coefficient in the UV spectrum could not be obtained.

Found: C, 92.85; H, 6.99%. Calcd for $C_{42}H_{38}$: C, 92.94; H, 7.06%.

When **8** and **12** were heated in *o*-xylene under reflux in N_2 for 1 h, **15** was obtained in 97 and 98% yield, respectively.

*Oxidation of **15** into **16**.* When powdered **15** (1 g) was allowed to keep in the air at room temperature for 1 day, **16** was obtained, after recrystallization from acetone, as yellow prisms; 1.06 g (95%); mp 246—247 °C. IR: 1660 and 1640 cm^{-1} (C=O); λ_{max}: 300 (29000), 330 sh (19800), and 350 sh nm (ε, 9400); NMR: 2.5—2.9 (m, Ph, 20H) and 9.20 τ (s, Bu^t, 18H); MS *m/e*: 606 (M^+).

Found: C, 83.06; H, 6.15%. Calcd for $C_{42}H_{38}O_4$: C, 83.14; H, 6.31%.

*Conversion of **16** into **17**.* A mixture of **16** (0.1 g), sodium borohydride (0.6 g), MeOH (15 ml), and tetrahydrofuran (5 ml) was kept to stand at room temperature for 1 h. The reaction mixture was decomposed with water, and then extracted with ether. The ethereal solution was washed with water, and dried over anhydrous Na_2SO_4. The evaporation of the solvent left crude crystals (IR: 3400 and 1070 cm^{-1} (OH)), which were dissolved in $CHCl_3$ (5 ml). Through this solution, HBr was bubbled for 10 min at room temperature. The crude crystals left after the evaporation of the solvent were recrystallized from MeOH to afford **17** as colorless needles; 0.09 g (94%); mp 173—175 °C. IR: 1075 cm^{-1} (ether); λ_{max}: 297 nm (ε, 22600) NMR: 2.5—3.1 (m, Ph, 20H), 7.06 (s, CH, 4H), and 9.32 τ (s, Bu^t, 18H); MS *m/e*: 578 (M^+).

Found: C, 86.88; H, 7.09%. Calcd for $C_{42}H_{42}O_2$: C, 87.16; H, 7.31%.

*Formation of **18a** and **18b**.* To a solution of Br_2 (1.8 g) in $CHCl_3$ (10 ml), was added **15** (2.7 g) under N_2 atmosphere. The colorless prisms formed were filtered, washed with $CHCl_3$ to result in **18a**, 3.87 g (90%); mp>300 °C. λ_{max}: 305 nm (ε, 5800).

Heating of a mixture of **18a** (1.7 g) and MeOH (20 ml) under reflux for 1 h afforded **18b**, after recrystallization from AcOEt, 1.06 g (82%); mp 271—273 °C. IR: 1100 cm^{-1} (ether); λ_{max}: 273 (3700) and 284 nm (ε, 2500); NMR: 2.65 (s, Ph, 20H), 7.20 (s, OMe, 12H), and 8.85 τ (s, Bu^t, 18H); MS *m/e*: 666 (M^+).

Found: C, 82.78; H, 7.48%. Calcd for $C_{46}H_{50}O_4$: C, 82.84; H, 7.56%.

A New Type of Induced Decomposition. II.[1] Decomposition of Phenylpropioloyl Peroxide and *t*-Butyl Phenylperoxypropiolate in Solution

Nobuyuki MURAMOTO, Tameichi OCHIAI, Masayuki YOSHIDA, and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113

(Received March 8, 1976)

Decomposition of phenylpropioloyl peroxide and *t*-butyl phenylperoxypropiolate in cumene, toluene, and cyclohexane was investigated. Product analysis and kinetic study together with the findings that radicals separately generated caused the decomposition of these peroxides demonstrate of a new type of induced decomposition involving radical attack on the triple bond of these peroxides and subsequent β-scission.

Although the chemistry of carbon radicals such as alkyl, vinyl, and phenyl radicals are well documented, much less attention has hitherto been focussed on the ethynyl radical R–C≡C·, in which it is expected the sp hybrid nature of the orbital carrying an odd electron may impart any special characteristics to the behaviour of this type of radicals. One fruitful method for generation of ethynyl radicals is the photolysis of ethynyl iodides.[2,3] An alternative approach to ethynyl radicals should be provided by homolysis of appropriate acetylenic peroxides. Thus we have studied the decomposition in solution of phenylpropioloyl peroxide and *t*-butyl phenylperoxypropiolate with the expectation that it would generate the phenylethynyl radicals. However, there did not appear to be strong indication of the generation of free phenylethynyl radicals, but evidence for a new type of induced decomposition was afforded as preliminarily reported elsewhere.[1] The present paper gives a detailed account of the study of this type of induced decomposition.

Results and Discussion

Phenylpropioloyl peroxide (I) and *t*-butyl phenylperoxypropiolate (II) were allowed to decompose in cumene, toluene, and cyclohexane at 80° and 110°C under a nitrogen atmosphere, and the products were examined (see Tables 1 and 2). Operation of a homolytic mechanism in the decomposition of these compounds is demonstrated by the formation of bicumyl and α-methylstyrene in cumene and of bibenzyl in toluene, all arising from radicals derived from the solvents. Moreover, the formation of acetone and *t*-butyl alcohol in the decomposition of the peroxy-ester (II) is characteristic of the intervention of the *t*-butoxyl radical. The peroxide (I) and the peroxy-ester (II) gave relatively small amounts of carbon dioxide and higher yield of the parent acid compared with common diacyl peroxides and *t*-butyl peroxyacetate. This fact may suggest that the phenylpropioloyloxyl radical if generated by homolysis from these peroxides may tend to abstract a hydrogen atom from a solvent molecule rather than to undergo fission to give carbon dioxide and a phenylethynyl radical. If the carbon dioxide had come solely from the phenylpropioloyloxyl radical, the phenylethynyl radical must have been generated in the corresponding amount, which in turn would have given rise to phenylacetylene by abstraction of a hydrogen atom from a hydrogen donor in the surroundings. Since the phenylethynyl radical is expected to abstract a hydrogen atom readily because of the large heat of formation of an sp C–H bond,[4] the very low yield of phenylacetylene actually found seems to indicate that this radical could have hardly been formed in these decompositions. Thus, the carbon dioxide actually found must have been evolved from some sourses other than the phenylpropioloyloxyl radical. In this connection, the formation of 1,3-diphenylpropyne in toluene and (phenylethynyl)cyclohexane in cyclohexane is of interest, since the combination of a radical derived from a solvent molecule and a

phenylethynyl radical scarcely formed is improbable. These experimental results taken as a whole point to a decomposition pattern different from what is expected from simple homolysis at the peroxidic linkage, and an induced decomposition was suspected. This view is supported by a kinetic study of the decomposition. Kinetic runs were carried out in toluene under a nitrogen atmosphere and followed by iodometric titration. The peroxy-ester (II) disappeared apparently with first order kinetics, but change in the initial concentration of the peroxy-ester from 0.0085 M to 0.12 M resulted in a 1.3-fold increase in the rate of decomposition (Table 3), a fact indicative of the co-operation of an induced pathway. The decomposition of the peroxide (I) in toluene at 70° did not obey a first-order rate law, but approximately a 3/2-order rate law, $-d[p]/dt=k[p]^{3/2}$, where [P] is the concentration of the peroxide (I), the plot of $[P]^{-1/2}$ against time giving a more satisfactory straight line. The observed 3/2-order rate constants, k, are listed in Table 4. They varied with the initial concentration of the peroxide, and their plots against the inverse square root of the initial concentration of the peroxide (I), $[P_0]^{-1/2}$, gave a straight line, which is represented by $k=k_i+k_1[P_0]^{-1/2}$. Thus, the rate of decomposition is approximately expressed by

$$-d[P]/dt = k_1[P] + k_i[P]^{3/2},$$

where k_1 and k_i were found to be 5.9×10^{-5} s^{-1} and 1.6×10^{-3} s^{-1} M$^{-1/2}$, respectively. The presence of a 3/2-order term together with the finding that the rate of decomposition is significantly diminished by traces of oxygen present in the reacting system supports the concurrence of an induced path.[5] Thus the following Reaction sequence 1—5, in which SH stands for a solvent molecule, may represent important pathways for the decomposition of the peroxide (I).

$$2S\cdot \xrightarrow{k_5} S{-}S \quad (5)$$

A similar sequence of reactions will readily be written down for the peroxy-ester (II). Decomposition of the peroxide (I) produces phenylpropioloyloxyl radicals, which abstract a hydrogen from solvents. The newly formed solvent radical S· adds to the triple bond of the peroxide (I) to give vinylic radicals, which would then decompose into an acetylenic compound, a phenylpropioloyloxyl radical, and a molecule of carbon dioxide. Evidently the large heat of formation of carbon dioxide facilitates such a β-scission reaction. The major products of the decomposition are readily explained by reference to this reaction sequence. The absence of 1,3-diphenyl-3,3-dimethylpropyne from the decomposition in cumene is probably due to the circumstances that the α,α-dimethylbenzyl radical is very sluggish in the addition reaction to the triple bond because of its resonance stabilization and bulkiness. The rate law of the decomposition which includes a 3/2 power term[6] is also readily derived by the usual stationary state approximation with the reasonable assumption of Reaction 4 being much more rapid than Reaction 3.

The incursion of an induced path of decomposition is further supported by the following experiments, in which radicals separately generated caused the decomposition of the peroxides at relatively low temperatures, at which they cannot otherwise undergo appreciable decomposition. The peroxide (I) or the peroxy-ester (II) was heated in toluene at 35 °C for 15 h under a nitrogen atmosphere in the presence of di-*t*-butyl diperoxyoxalate, which is known to decompose readily at low temperatures generating *t*-butoxyl radicals.[7] A considerable part of the peroxides decomposed and the characteristic product was 1,3-diphenylpropyne in each case (Table 5). Control experiments showed that these peroxides did not undergo homolytic fission to a measurable extent in the absence of the diperoxyoxalate under otherwise similar conditions. Evidently *t*-butoxyl radicals, generated from the diperoxyoxalate, abstracted

a hydrogen atom from toluene to give a benzyl radical, and this radical immediately attacked the triple bond in the acetylenic peroxides finally to afford 1,3-diphenylpropyne.

N-Nitrosoacetanilide, a generator of phenyl radicals,[8] also brought about the decomposition of the peroxy-ester (II) at room temperature, 1,2-diphenylacetylene being produced (Table 6).

A toluene solution of acetyl peroxide and *di-t*-butyl diperoxyoxalate was kept at 35 °C under a nitrogen atmosphere for 15 h and iodometric titration showed that the acetyl peroxide remained undecomposed, whereas the diperoxyoxalate is believed to have decomposed completely under such reaction conditions.[7] Under similar experimental conditions, benzoyl peroxide did not decompose at all, either (Table 7). Obviously the benzyl radical does not displace the carboxyl group of the peroxides which have no α,β-unsaturated bond.

These results strongly support the addition-elimination mechanism shown in Reactions 3 and 4 for the induced decomposition of the peroxide (I). Similar addition-elimination mechanisms had been postulated in radical induced reaction of methyl propenyl ketone,[9] crotonaldehyde,[10] and phenyl azide[11] at rather high temperatures. Since the discovery of the induced decomposition of benzoyl peroxide by Bartlett and Nozaki,[5] numerous studies[12] have been made, but the present mechanism is unique in that radicals attack the site of unsaturation exclusively.

Experimental

Materials. Toluene, cumene, cyclohexane, and hexane were washed successively with concentrated sulphuric acid and water, dried with calcium chloride, and distilled over sodium, and middle fractions were used. Acetone was purified by distillation after drying with potassium carbonate. Benzoyl peroxide was purified by dissolving in dichloromethane and precipitating with methanol. *t*-Butyl hydroperoxide was purified by distillation, bp 32 °C/12 mmHg.

Product Analysis by Vapour-phase Chromatography. VPC analyses were carried out on a Perkin Elmer Vapor Fractometer Model 154-D using helium as a carrier gas and the following stainless steel columns: 1) a 4 m column packed with polyethylene glycol (15%) at 120° for analysis of acetone, *t*-butyl alcohol, phenylacetylene, and 2-phenylpropene; 2) a 0.4 m column packed with silicone grease SE 30 (15%) at 193°C for analysis of cyclohexylphenylacetylene; 3) a 1 m column packed with silicone grease SE 30 (15%) at 199 °C for analysis of bibenzyl, 1,3-diphenylpropyne, and 2,3-dimethyl-2,3-diphenylbutane. Commercial products were used for comparison of common compounds, but authentic samples of 1,3-diphenylpropyne[13] and cyclohexylphenylacetylene[14] were prepared according to the directions described in the literature.

Phenylpropioloyl Peroxide. Sodium peroxide (2.0 g) was added to a solution of phenylpropioloyl chloride[15] (5.0 g) in ether (50 ml) at −5 °C. The mixture was stirred for 10 min, and then a little water was added dropwise, the temperature being kept at 0—−5 °C. After a vigorous reaction subsided, a further 5 ml of water was added and the mixture was allowed to warm to room temperature. The ether layer was separated and the aqueous layer was extracted with three 10 ml portions of ether. The combined ether solution was washed with 5% sodium carbonate solution and then with water, dried with sodium sulphate and concentrated under reduced pressure. The residue was washed with cold methanol and dissolved in a small amount of dichlomethane. Precipitation by addition of a large quantity of cold methanol gave 3.8 g of crystals, mp 94.1—94.2 °C (Found: C, 73.54; H, 3.32%. Calcd for $C_{18}H_{10}O$: C, 74.48; H, 3.47%. Purity, 99.8% by iodometric titration[16]).

t-Butyl Peroxyphenylpropiolate. Phenylpropioloyl chloride[15] (5.03 g) and 10 ml of water containing 2.09 g of potassium hydroxide were added simultaneously over a period of 40 min to a stirred solution of 2.91 g of *t*-butyl hydroperoxide in 20 ml of water. The temperature was maintained at 8—10 °C during the addition. The reaction mixture was stirred overnight at room temperature. The organic layer was separated and washed successively with 10% aqueous sodium carbonate and saturated sodium chloride solution. The viscous oil obtained (8.3 g, 68%) was dissolved in ether and the solution dried with anhydrous sodium sulphate. Crystallization from ether at −78 °C gave a pure specimen (Found: C, 71.74; H, 6.36%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%. Purity, 99% by iodometric titration[16]).

Decomposition of Phenylpropioloyl Peroxide and t-Butyl Phenylperoxypropiolate in Solutions. A typical run was as follows. A solution of the peroxide (3.20 mmol) in 20 ml of solvent was placed in a two-necked reaction flask equipped with a gas inlet-tube and a reflux condenser which was connected to a trap cooled with solid carbon dioxide–acetone. The other end of the trap was attached to a tube containing Ascarite–magnesium perchlorate. Nitrogen gas was passed through the solution for a while to remove dissolved oxygen. The flask was placed in a bath kept at 80 °C and the peroxide was allowed to decompose completely, a slow stream of nitrogen being passed through the solution. The reaction mixture was diluted to 25.0 ml with the same solvent. A ten millilitre aliquot of the solution was extracted with 5% aqueous sodium carbonate solution. The extract was acidified with hydrochloric acid and the phenylpropiolic acid liberated was extracted with ether and

weighed. The residual solution was washed with 5% aqueous sodium carbonate solution and examined by VPC. The products were identified by comparing their retention times with those of authentic samples. Carbon dioxide was absorbed in an Ascarite–magnesium perchlorate tube and the tube weighed.

Decomposition of Phenylpropioloyl Peroxide and t-*Butyl Phenylperoxypropiolate in the Presence of Di-*t*-butyl Diperoxyoxalate.* A typical run was as follows. A solution of the phenylperoxypropiolate (2.40 mmol) in 8.0 ml of toluene was placed in a two-necked reaction flask equipped with a gas inlet-tube and a reflux condenser which was connected to a trap cooled with acetone and solid carbon dioxide. The other end of the trap was attached to a tube containing Ascarite–magnesium perchlorate. Nitrogen was bubbled through the solution vigorously for a while to remove dissolved oxygen, and di-*t*-butyl diperoxyoxalate[7] (2.43 mmol) was added to the solution. The flask was placed in a constant-temperature bath kept at 35 °C and the peroxy-ester were allowed to decompose, a very slow stream of nitrogen being passed through the reaction mixture. After 15 h (5 half-life period of *t*-butyl diperoxyoxalate), the reaction mixture was diluted to 10.0 ml with toluene in a measuring flask. A 1.0 ml portion of this solution was pipetted out for determination of undecomposed peroxy-ester by iodometry.[16] The remainder of the solution was treated with 10% sodium carbonate solution, and the aqueous layer was separated, acidified with hydrochloric acid and extracted with ether. The ether was removed under reduced pressure and the acidic residue was weighed. The organic layer was treated with 5 ml of acetic acid containing a very small quantity of iron(III) chloride and 1 g of sodium iodide, and the mixture was allowed to stand for 20 min at room temperature in order to decompose the remaining peroxypropiolate; the liberated iodine was reduced with sodium thiosulphate solution, and the organic layer was washed with 10% aqueous sodium carbonate, dried with anhydrous sodium sulphate, and analyzed by VPC. Carbon dioxide was absorbed in an Ascarite–magnesium perchlorate tube and the tube weighed.

*Reaction of Acetyl Peroxide or Benzoyl Peroxide in the Presence of Decomposing Di-*t*-butyl Diperoxyoxalate in Toluene.* A solution of acetyl peroxide (1.92 mmol) and di-*t*-butyl diperoxyoxalate (2.69 mmol) in 8.0 ml of toluene was kept at 35 °C for 15 h under a nitrogen atmosphere. The reaction mixture was diluted to 10.0 ml with toluene. Three 1.0 ml portions of the mixture were taken to determine undecomposed acetyl peroxide by iodometric titration.[16]

Experiments with benzoyl peroxide were carried out similarly.

Decomposition of t-*Butyl Phenylperoxypropiolate in the Presence of* N-*Nitrosoacetanilide.* A typical run was as follows. A solution of the peroxypropiolate (1.75 mmol) and *N*-nitrosoacetanilide (2.44 mmol) prepared according to Grieve and Hey's procedure[8] in 8 ml of hexane was allowed to decompose for 16 h at room temperature under a nitrogen atmosphere. The reaction mixture was diluted to 10 ml with hexane and a 1.0 ml portion of the mixture was withdrawn to determine the undecomposed peroxy-ester by iodometric titration.[16] The remaining solution was treated with sodium iodide (1 g) and 10 ml of acid acetic solution of iron(III) chloride (0.002%). (In the case of acetone solution, the solvent was removed under reduced pressure, and replaced by 10 ml of chloroform. The chloroform solution was then treated with sodium iodide in a way similar to the above.) The mixture was allowed to stand for 15 min, and the liberated iodine was reduced with aqueous thiosulphate solution. The aqueous layer was separated and extracted with benzene. The extracts were combined with the organic layer, washed successively with a 10% sodium carbonate solution and a satruated sodium chloride solution, and dried with anhydrous sodium sulphate. After removal of most of the solvent, the residue was diluted to 2.0 ml with benzene and analyzed by VPC.

Kinetics Measurements. The decomposition of the peroxide (I) or the peroxy-ester (II) was followed by iodometric titration according to Swern's method.[16] In a reaction vessel fitted with a gas inlet-tube and a reflux condenser was placed 50 ml of purified toluene. The vessel was heated in a thermostatted oil bath, and nitrogen was bubbled through the solution for more than two hours. The peroxide (I) of the peroxy-ester (II) was then added to the solution, and allowed to decompose, a slow stream of nitrogen being passed. Aliquots were withdrawn periodically, quenched by chilling to −78 °C, treated with NaI–$CHCl_3$–AcOH (containing 0.002% $FeCl_3$-$6H_2O$), and titrated with a standard sodium thiosulphate solution.

A New Type of Induced Decomposition. III.[1] Induced Decomposition of Cinnamoyl Peroxide, *t*-Butyl Peroxycinnamate and *t*-Butyl 2,3-Diphenylperoxypropionate in Solution

Tameichi Ochiai, Yoshitsugu Usuda, Masayuki Yoshida, and Osamu Simamura
Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113
(Received March 8, 1976)

Phenyl and benzyl radicals were found to induce decomposition of cinnamoyl peroxide or *t*-butylperoxycinnamate to give stilbene and 1,3-diphenylpropene, respectively. Similarly, *t*-butoxyl radicals caused *t*-butyl 2,3-diphenylperoxypropionate to decompose affording stilbene. A mechanism is proposed which involves a radical attack on a substrate peroxide producing a radical carrying an odd electron on the carbon atom β to the carboxyl group and its subsequent collapse to final products by way of β-scission.

In previous papers we showed that phenylpropioloyl peroxide and *t*-butyl phenylperoxypropiolate decompose *via* a new type of induced path involving a radical attack on the triple bond of the peroxides and a subsequent β-scission.[1] We now extended the study to cinnamoyl peroxide[2] and *t*-butyl peroxycinnamate,[3] and *t*-butyl 2,3-diphenylperoxypropionate.

Results and Discussion

trans-Cinnamoyl peroxide or *t*-butyl peroxycinnamate was heated in toluene at 35 °C for 15 h under a nitrogen atmosphere in the presence of di-*t*-butyl diperoxyoxalate, a generator of *t*-butoxyl radicals.[4] Significant part of these peroxides, which are both stable at this temperature in the absence of decomposing di-*t*-butyl diperoxyoxalate, was decomposed, the characteristic product being 1,3-diphenylpropene (see Table 1), which resulted from the reaction with benzyl radicals generated by the action of *t*-butoxyl radicals on toluene.

Similarly phenyl radicals, generated from *N*-nitrosoacetanilide,[5] caused the decomposition of *cis*- and *trans*-cinnamoyl peroxides and *t*-butyl peroxycinnamate to give stilbene (Table 2).

These results are satisfactorily explained by assuming the following reaction sequence (1)—(2) in keeping with the reaction sequence with the acetylenic peroxide set forth in previous papers.[1] Benzyl or phenyl radicals add to the double bond of the peroxides (I and II) to give intermediate radicals (III), which then decompose into 1,3-diphenylpropene or stilbene (Reactions 1 and 2).

a) Yields in moles per mole of peroxides decomposed are given in parentheses.

A possible alternative mechanism may be a direct bimolecular homolytic displacement reaction, in which benzyl or phenyl radicals directly displace the CO_2X group on the α-carbon atom of *t*-butyl peroxycinnamate (II) or cinnamoyl peroxide (I) (Reaction 3). This mechanism, however, can safely be ruled out because both *cis*- and *trans*-cinnamoyl peroxides afforded with phenyl radicals a considerable amount of *trans*-stilbene together with traces of the *cis*-isomer (Table 2). *cis*- and *trans*-Cinnamoyl peroxides would have given stilbene in different isomer rations, if the direct displacement by phenyl radicals had taken place.

In the foregoing scheme, the decomposition of *t*-butyl peroxycinnamate induced by the phenyl radical involves the 2-(*t*-butylperioxycarbonyl)-1,2-diphenylethyl radical (III) (reaction 2), which then decomposes into stilbene, carbon dioxide, and the *t*-butoxyl radical. The same intermediate radical (III) may be generated by abstraction of a β-hydrogen atom from *t*-butyl 2,3-diphenylperoxypropionate (IV), which, accordingly, is expected to undergo a similar type of induced decomposition.

a) The peroxypropionate was decomposed in 3.0 ml of chlorobenzene in degassed ampoules at 35 °C for 12 h. b) Yields in percent based upon the starting peroxypropionate are given in parentheses. Yields given are the averages of results from three in dependent decompositions.

This expectation proved to be true in the following experiments. *t*-Butyl 2,3-diphenylperoxypropionate was heated in chlorobenzene at 35 °C for 12 h in the presence or absence of di-*t*-butyl diperoxyoxalate as radical generator (Table 3). The presence of the diperoxyoxalate increased the decomposition of the peroxypropionate (IV) to 31.3%, while the decomposition took place only to an extent of 20.5% in its absence. The diperoxyoxalate increased the yield of stilbene from 4.0% to 11.6%, but did not affect the yields of bibenzyl 0.6%) and *t*-butyl 1,2-diphenylethyl ether (2%). *t*-Butyl 2,3-diphenylperoxypropionate belongs to a class of peroxy-esters such as *t*-butyl 2-phenylperoxyacetate and 2-methyl-2-phenylperoxypropionate which are rather labile even at relatively low temperature.[3)] It is highly probable, therefore, that the initial homolysis takes place generating a 1,2-diphenylethyl and a *t*-butoxyl radical and a molecule of carbon dioxide in a cage of solvent. Among the products identified, *t*-butyl 1,2-diphenylethyl ether is obviously a cage combination product between a 1,2-diphenylethyl and a *t*-butoxyl radical, since its yield was not changed when more *t*-butoxyl radicals were produced by adding di-*t*-butyl diperoxyoxalate. Bibenzyl was probably formed by disproportionation of 1,2-diphenylethyl radical together with the corresponding amount of stilbene. The stilbene formed in excess of this amount must have been provided by the action of the *t*-butoxyl radical on the starting peroxypropionate, abstraction of a hydrogen atom giving the intermediate radical (III) postulated above and this radical in turn decomposing to give stilbene. In the presence of di-*t*-butyl diperoxyoxalate, the concentration of *t*-butoxyl radicals available in solution will be increased resulting in efficient abstraction of a hydrogen atom, and the amount of stilbene is thus increased.

Experimental

Materials. Chlorobenzene, toluene, and hexane were washed with concentrated sulphuric acid and then with water, dried with calcium chloride, and distilled, and middle fractions were used. *trans*- and *cis*-Cinnamoyl peroxides,[2)] *t*-butyl peroxycinnamate,[3)] di-*t*-butyl diperoxyoxalate,[4)] and *N*-nitrosoacetanilide[5)] were prepared by the published procedures.

t-Butyl 2, 3-Diphenylperoxypropionate. 2, 3-Diphenylpropionic acid, prepared by the published procedure,[6)] mp 87.5—88.0 °C (lit,[6)] mp 88—89 °C), was heated with thionyl chloride under reflux for 7 h and the resulting 2,3-diphenylpropionyl chloride was distilled under reduced pressure, bp 132—134 °C/1.5 mmHg. A solution of this chloride (4.83 g) in 20 ml of anhydrous pentane was added slowly (1.3 h) to a stirred solution of 2.77 g of *t*-butyl hydroperoxide in 2.42 g of pyridine and 60 ml of anhydrous pentane cooled in an ice–water bath. The reaction mixture was allowed to warm to room temperature and stirred for 2 h. A small amount of water was added, followed by pentane until all the precipitate was dissolved. The organic layer was washed with 10% aqueous sodium carbonate, dried over anhydrous sodium sulphate, and cooled in a bath of acetone and solid carbon dioxide, to give a crystaline precipitate, which was filtered off and recrystallized from pentane several times. The yield was 3 g (51%), mp 74.5—76.1 °C (Found: C, 76.48; H, 7.37%. Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%. Purity, 100.8% by iodometric titration[7)]); IR (Nujol) 1775 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) τ 8.95 (s, 9H, *t*-Bu), 6.0—7.2 (m, 3H, CH_2CH), 2.81 (broad s, 5H, phenyl), and 2.70 (broad s, 5H, phenyl).

Decomposition of trans*-Cinnamoyl Peroxide and* t*-Butyl Peroxycinnamate in the Presence of Di-*t*-butyl Diperoxyoxalates.* A typical run was as follows. A solution of the peroxide (1.39 mmol) in 8 ml of toluene was placed in a two-necked reaction flask equipped with a gas inlet tube and a reflux condenser which was connected to a trap cooled with acetone and solid carbon dioxide. The other end of the trap was attached to a tube containing Ascarite–magnesium perchlorate. Nitrogen was bubbled through the solution vigorously for a while to remove dissolved oxygen, and di-*t*-butyl diperoxyoxalate (2.15 mmol) was added to the solution. The flask was placed in a bath kept at 35 °C and the peroxides were allowed to decompose, a very slow stream of nitrogen being passed

through the solution during the course of the reaction. After 15 h (5 half-life periods of di-*t*-butyl diperoxyoxalate[4]), the reaction mixture was diluted to 10.0 ml with toluene. A 1.0 ml portion of this solution was pipetted out to analyze for undecomposed peroxy-ester by iodometric titration.[7] The remainder of the solution was treated with 10% sodium carbonate solution. The aqueous layer was separated, acidified with hydrochloric acid and extracted with ether. The ether was removed under reduced pressure and the acidic residue was weighed. The organic layer was treated with 5 ml of acetic acid containing very small quantity of iron(III) chloride and 1 g of sodium iodide, and the mixture was allowed to stand for 20 min at room temperature in order to decompose the remaining peroxide. The iodine liberated was reduced with sodium thiosulphate solution. The organic layer was washed with 10% aqueous sodium carbonate solution, dried over anhydrous sodium sulphate, and analyzed by VPC (Table I).

Decompositions of cis- *and* trans-*Cinnamoyl Peroxides and* t-*Butyl Peroxycinnamate in the Presence of* N-*Nitrosoacetanilide.* A typical run was as follows. A solution of the peroxy-ester (II, 2.05 mmol) and *N*-nitrosoacetanilide (2.90 mmol) in 8 ml of hexane was allowed to decompose for 16 h at room temperature under a nitrogen atmosphere. The reaction mixture was diluted to 10 ml with hexane and a 1.0 ml portion of the mixture was taken to determine undecomposed peroxy-ester by iodometric titration.[7] The remaining solution was treated and analyzed in the same way as described above (Table 2).

Decomposition of t-*Butyl 2,3-Diphenylperoxypropionate in Chlorobenzene.* A solution (3 ml) of the 2,3-diphenylperoxypropionate in chlorobenzene (0.10 M) was degassed (three freeze-thaw cycles) and allowed to decompose in a bath kept at 35 °C for 12 h. One millilitre aliquot of the reaction mixture was dissolved in 10 ml of chloroform. A small piece of solid carbon dioxide, 0.5 g of sodium iodide, and a little Iron(III) chloride solution in glacial acetic acid (*ca.* 0.002%) were added successively. The resulting mixture was kept at about 60 °C under nitrogen for 15 min and the iodine liberated was titrated with standard sodium thiosulphate solution(0.0316M). The aqueous layer was extracted with chloroform. The extracts were combined with the organic layer, washed with 10% aqueous sodium carbonate, and dried over anhydrous sodium sulphate. The solution was concentrated to 5.0 ml by distillation through a helix-packed column, a weighed amount of diphenylmethane was added as an internal standard, and the whole was subjected to VPC analysis (Table 3).

Decomposition of t-*Butyl 2,3-Diphenylperoxypropionate in the Presence of Di-*t*-butyl Diperoxyoxalate in Chlorobenzene.* A solution (3 ml) of the 2,3-diphenylperoxypropionate (0.1 M) and diperoxyoxalate (0.1 M) in chlorobenzene was degassed and heated at 35 °C for 12 h. The reaction mixture was treated and analyzed in the same way as described above (Table 3).

Product Analysis. Analysis of the products was carried out by vapor phase chromatography on a Hitachi Gas Chromatograph Model K-53 FID or a Perkin Elmer Vapor Fractometer Model 154-D. Most of the products were identified by comparing their VPC retention times on Apiezon grease L (5%) at 190 °C or SE 30 (15%) at 199 °C with those of commercial samples. Stilbene was further identified by comparing its UV spectrum with that of an authentic sample. Carbon dioxide was absorbed on Ascarite–magnesium perchlorate and weighed. *t*-Butyl 1,2-diphenylethyl ether was isolated from the reaction mixture by preparative thin layer chromatography and was identified by elemental analysis and IR and NMR spectra (Found: C, 84.70; H, 8.50%. Calcd for $C_{18}H_{22}O$: C, 84.99; H, 8.72%), IR (neat) 1200 cm^{-1} characteristic of *t*-BuO;[8] NMR (CCl_4) τ 9.12 (s, 9H, *t*-Bu), 7.30 (d, 2H, J=6.1 Hz, CH_2), 2.95 (broad s, 5H, phenyl).

The Decomposition of *t*-Butyl *erythro*- and *threo*-2,3-Diphenylperoxybutyrate in Solution. The Product Analysis and the Cage Effect

Tameichi OCHIAI, Masayuki YOSHIDA, and Osamu SIMAMURA
Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113

(Received March 8, 1976)

Decomposition of *t*-butyl *erythro*- and *threo*-2,3-diphenylperoxybutyrate was examined in solution at 60 °C; there was no indication of induced decomposition taking place as is the case with *t*-butyl 2,3-diphenylperoxypropionate. Various hydrocarbons resulting from the reaction of the 1,2-diphenylpropyl radical in a variety of ways were identified in the product, and *t*-butyl 1,2-diphenylpropyl ether was found to be formed as cage recombination product in the *threo*/*erythro* isomeric ratio which depended on the stereochemistry of the starting peroxybutyrate.

In a previous paper[1] we have demonstrated that *t*-butyl 2,3-diphenylperoxypropionate undergoes decomposition involving a pathway induced by radicals and gives stilbene as product characteristic of this pathway.

$$PhCH_2CHPhCO_3{}^tBu \longrightarrow PhCH_2CHPh\cdot + CO_2 + t\text{-}BuO\cdot \quad (1)$$

$$PhCH_2CHPhCO_3{}^tBu + t\text{-}BuO\cdot \longrightarrow PhC\dot{H}CHPhCO_3{}^tBu + t\text{-}BuOH \quad (2)$$

$$PhC\dot{H}CHPhCO_3{}^tBu \longrightarrow PhCH{=}CHPh + CO_2 + t\text{-}BuO\cdot \quad (3)$$

In order to study the stereochemistry of a β-scission reaction of the type shown in reaction 3, we examined the decomposition of *t*-butyl *erythro*- and *threo*-2,3-diphenylperoxybutyrate (I) in the expectation that they might afford α-methylstilbene (Reaction 6) in different *cis* to *trans* ratios, thus giving some clue to elucidation of the stereochemical course.

$$MePhCHCHPhCO_3{}^tBu \longrightarrow MePhCHCHPh\cdot + CO_2 + t\text{-}BuO\cdot \quad (4)$$

$$MePhCHCHPhCO_3{}^tBu + t\text{-}BuO\cdot \longrightarrow MePhC\dot{C}HPhCO_3{}^tBu + t\text{-}BuOH \quad (5)$$

$$MePhC\dot{C}HPhCO_3{}^tBu \longrightarrow MePhC{=}CHPh + CO_2 + t\text{-}BuO\cdot \quad (6)$$

Results and Discussion

t-Butyl *erythro*-2,3-diphenylperoxybutyrate, mp 96.5—98 °C (dec), and the *threo*-isomer, mp 56.5—57 °C (dec), were prepared from the corresponding acid chloriods and *t*-butyl hydroperoxide according to the usual method and decomposed in chlorobenzene and toluene at 60 °C. The results are summarized in Table 1.

The yield of α-methylstilbene, a product expected from the induced decomposition (Reactions 5 and 6) was relatively low, and the *cis-trans* ratios did not differ appreciably. The decomposition of *t*-butyl *erythro*-2,3-diphenylperoxybutyrate in chlorobenzene was not accelerated in the presence of di-*t*-butyl diperoxyoxalate, a generator of the *t*-butoxyl radical,[2] contrary to the case with *t*-butyl 2,3-diphenylperoxypropionate,[1] and furthermore, kinetic measurements showed that the peroxybutyrate decomposes according to a strict first order rate law without any indication of induced decomposition ($k=6.29\times10^{-5}$ s^{-1} at 60 °C in toluene);[3] accordingly, it may safely be said that with the diphenylperoxybutyrate the hydrogen abstraction of the type shown in Eq. 5 is operative only to a very limited extent, if at all. Thus, the purpose of examining the stereochemistry of Reaction 6 envisaged in the beginning was defeated.

a) The peroxybutyrate (0.30 mmol) in 3.0 ml of solvent was decomposed at 60 °C for 36 h in degassed and sealed ampoules. b) Yields in per cent based upon the starting peroxybutyrate are estimated by VPC and average values from two independent decompositions are given.

The precursor of 1,2-diphenylpropane, one of the major products is obviously the 1,2-diphenylpropyl radical produced in Reaction 4. It either abstracts a hydrogen atom from some hydrogen donors including acetone formed from the *t*-butoxyl radical or disproportionates giving 1,2-diphenylpropane and α-methylstilbene. The fact that the yield of 1,2-diphenylpropane is much lower in toluene than in chlorobenzene is explained by the combination reaction of the 1,2-diphenylpropyl radical with the benzyl radical generated from toluene by hydrogen abstraction by the *t*-butoxyl radical furnished by Reaction 4, giving 1,2,3-triphenylbutane. Thus, Table 1 shows that the 1,2-diphenylpropyl group is better accounted for in the decomposition in toluene than in chlorobenzene. In the absence of the benzyl radical much of the 1,2-diphenylpropyl radical certainly combined with itself to give the dimeric product, which it was not attempted to detect in the present analysis.

2,3-Diphenylbutanes were formed in chlorobenzene solvent in the same *dl*/*meso* ratio of 1.0 from both diastereomeric peroxybutyrates, whereas in toluene none of the butanes was produced at all. Obviously, the butanes are formed by combination of the free 1,2-

diphenylpropyl with the methyl radical generated by decomposition of the *t*-butoxyl radical outside the solvent cage; in toluene the concentration of the methyl radical is too low to give the butanes since the methyl radical or the *t*-butoxyl radical for that matter reacts efficiently with toluene by abstruction of hydrogen.

t-Butyl 1,2-diphenylpropyl ether (II) was isolated by preparative thin-layer chromatography on silica gel, and the structure was established on the basis of the NMR and IR spectra and analytical data. The NMR spectrum showed the ether isolated to be a mixture of the diastereomers. Thus, one set of signals consisting of a sharp singlet at τ 9.15 (9H) and two doublets at τ 8.94 (3H) and 5.56 (1H) corresponding to *t*-butyl, methyl, and methine protons, respectively, is assigned to the *erythro*-diastereomer, and the other set of signals at τ 9.03 (singlet 9H), 8.70 (doublet 3H), and 5.48 (doublet 1H) quite similar in appearance to those of the first set and all shifted to lower field regions is assigned to the *threo*-isomer, because of the fact that *t*-butyl *erythro*-2,3-diphenylperoxybutyrate and *erythro*-2,3-diphenylbutyric acid show the proton signals due to *t*-butyl and methyl groups all at higher field regions than the corresponding peaks shown by the *threo*-peroxybutyrate and *threo*-acid.

A similar ether, namely *t*-butyl 1,2-diphenylethyl ether, is formed in the thermolysis of *t*-butyl 2,3-diphenylperoxypropionate in chlorobenzene, and this has been shown to be the cage recombination product between the *t*-butoxyl and the 1,2-diphenylethyl radical.[1] *t*-Butyl 1,2-diphenylpropyl ether was therefore thought, by analogy, also to be a cage product, and experiments with scavenger confirmed this view. Thus, the amount and isomer ratio of the ether produced did not change appreciably (Table 2) in the presence of 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl,[4] which is known to capture radicals generated in the autoxidation of diphenylmethane very efficiently, that is, almost at the same rate as molecular oxygen does.[5]

Table 2. *t*-Butyl 1,2-diphenylpropyl ether from decomposition of *t*-butyl *erythro*-2,3-diphenylperoxybutyrate in toluene in the presence of 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl[a]

Nitroxyl, M	*t*-Butyl Ether	
	erythro + *threo*[b]	*threo*/*erythro*
0.00	9.2	0.96
0.14	8.8	0.92
0.40	8.7	0.89
0.80	8.3	0.89

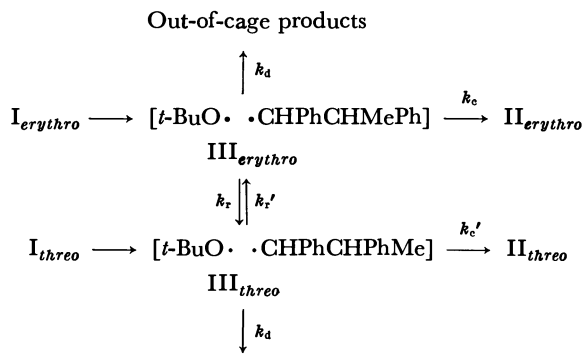
a) The peroxybutyrate (0.10 M) was decomposed at 60 °C for 36 h in degassed and sealed ampoules. b) Yields in per cent based upon the starting peroxybutyrate.

The formation of 1,2,3-triphenylbutane (25—39%) in the decomposition in toluene shows that 1,2-diphenylpropyl radicals from the peroxybutyrate combined outside the solvent cage with free benzyl radicals generated from toluene by hydrogen abstraction by the *t*-butoxyl radical, while absence of even traces of benzyl *t*-butyl ether from the product indicates that all *t*-butoxyl radicals have been consumed before they combine with benzyl radicals; accordingly, the *t*-butoxyl radical does not have any chance to react with free 1,2-diphenylpropyl radicals to yield *t*-butyl 1,2-diphenylpropyl ether outside the cage.

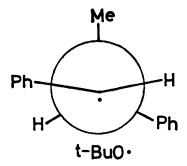
A change in solvent from toluene to chlorobenzene caused a slight increase in the yield of the *t*-butyl ether (II); this effect may be attributed to solvent viscosity effect (chlorobenzene, 0.51 cP; toluene, 0.39 cP at 60 °C).[6]

All these observations considered above support that almost all of the *t*-butyl ether (II) is formed in the solvent cage.

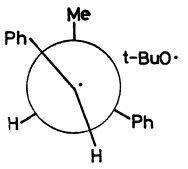
Obviously, the *threo* to *erythro* ratio in which *t*-butyl 1,2-diphenylpropyl ether (II) was produced depends on the stereochemistry of the starting peroxybutyrate (I). The decomposition of the isomeric peroxybutyrates, with special regard to the cage effect, may be formulated as shown in the annexed scheme, in which the solvent cage is denoted by brackets. These peroxybutyrates undergo most likely a two-bond scission[7] giving rise to a 1,2-diphenylpropyl and a *t*-butoxyl radical and carbon dioxide, the last of which is omitted from the scheme for the sake of simplicity. It is assumed that, at the moment of generation, a radical pair (III) of 1,2-diphenylpropyl and *t*-butoxyl as a whole retains the stereochemistry of the parent peroxybutyrate and that the stereoisomeric radical pairs interconvert in the cage with rate constants k_r and k_r'. Thus, the diffusion of radicals from the cage with rate constant k_d results in the formation of out-of-cage products and the recombination of radicals give isomeric *t*-butyl 1,2-diphenylpropyl ethers $II_{erythro}$ and II_{threo} with rate constants k_c and k_c', respectively. The usual steady state treatment of this reaction scheme using the yields of the respective ethers in toluene gives the relative values of the reaction constants as follows: $k_c=1$, as standard; $k_c'=1.1$; $k_d=10$; $k_r=21$; $k_r'=12$.



Although it is natural to suppose that the radical pair in the cage (III) consisting of a 1,2-diphenylpropyl and a *t*-butoxyl radical resembles the parent peroxybutyrate in stereochemistry and, therefore, that such structures as shown below are probable for the diastereomeric radical pairs in the cage, further discussion in terms of steric effects of substituents would seem



$III_{erythro}$



III_{threo}

meaningless, because, in the first place, such steric effects are not known accurately enough and secondly, the difference between the interconversion rates $k_r=21$ and $k_r'=12$ corresponds to an energy difference between the two conformations of only 370 cal/mol at 60 °C.

Greene and his coworkers studied the cage effect in the thermolysis of *S*-(+)-*t*-butyl 2-phenylperoxypropionate using butanethiol as a scavenger and determined the relative rates of the processes occurring in the cage.[8]

We attempted experiments with 1-propanethiol as possible scavenger in the decomposition of *t*-butyl *erythro*-2,3-diphenylperoxybutyrate in toluene at 60 °C, but copious precipitation of 2,3-diphenylbutyric acid took place, which was not observed in the absence of the thiol. The acid was evidently produced by the direct bimolecular reaction of the thiol and the peroxybutyrate, since the normal mode of the decomposition of the peroxybutyrate is thought to be a two-bond scission expelling a molecule of carbon dioxide.[7] In view of this finding the use of thiols seems to be inadequate for scavenging experiments.

Experimental

Materials. Di-*t*-butyl diperoxyoxalate,[2] 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl,[4] 2,3-diphenylbutane,[9] benzyl *t*-butyl ether,[10] and *trans*-[11] and *cis*-α-methylstilbene[12] were prepared by published procedures.

The following compounds were also prepared for comparison with reaction products in VPC analysis.

erythro-*1,2,3-Triphenylbutane.* *erythro*-1,2,3-Triphenyl-1-butanone[13] (2.0 g) was hydrogenated in 60 ml of ethanol containing 10 drops of concentrated hydrochloric acid over 290 mg of 10% palladium on carbon catalyst at room temperature under atmospheric pressure. The catalyst and the solvent were removed, and the product was chromatographed on silica gel using benzene as eluent and recrystallized from ethanol to give 0.6 g (31%) of *erythro*-1,2,3-triphenylbutane (Found: C, 92.60; H, 7.72%. Calcd for $C_{22}H_{22}$: C, 92.26; H, 7.74%), mp 88.0—88.5 °C; *m/e* 286 (M^+); NMR ($CDCl_3$) τ 9.0 (d, 3H, J= 6.0 Hz, CH_3), 7.7—6.8 (m, 4H, $-CH\dot{C}H\dot{C}H_2-$), and 3.5—2.6 (m, 15H, phenyls).

1,2-Diphenylpropane. *trans*-α-Methylstilbene (1.7 g) in 50 ml of ethanol was hydrogenated over 10% palladium on carbon (91 mg) under atmospheric pressure at room temperature. Hydrogenation was stopped when the hydrogen uptake corresponded to one mole of hydrogen per mole of the compound. Removal of the catalyst and solvent left a colourless liquid, which was gas-chromatographically pure, yield 1.5 g (88%).

t-*Butyl* erythro-*2,3-Diphenylperoxybutyrate.* *erythro*-2,3-Diphenylbutyric acid[14] was allowed to react with thionyl chloride at room temperature for 7 h. The resulting *erythro*-2,3-diphenylbutyryl chloride (1.77 g), without further purification, was added to a stirred solution of 1.0 g of *t*-butyl hydroperoxide in 0.9 g of pyridine and 60 ml of pentane cooled in an ice–water bath. The addition required 15 min and stirring was continued for four more hours. Cold 10% aqueous sulphuric acid was added, and the product was extracted with ether. The ethereal layer was washed with cold 10% aqueous sodium carbonate solution and then with water, and dried with anhydrous sodium sulphate at 0 °C. After removal of the solvent under reduced pressure, the residue was recrystallized from ether to give 1.4 g (67%) of *t*-butyl *erythro*-2,3-diphenylperoxybutyrate (Found: C, 77.04; H, 7.90%. Calcd for $C_{20}H_{24}O_3$: C, 76.89; H, 7.94 %. Purity, 99% by iodometric titration[15]), mp 96.5—98.0 °C (dec); IR (Nujol) 1760 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) τ 9.08 (s, 9H, *t*-Bu), 8.99 (d, J=5.9 Hz, 3H, CH_3), 6.8—6.1 (m, 2H, $-C\dot{H}C\dot{H}-$), and 3.0—2.4 (m, 10H, phenyls).

t-*Butyl* threo-*2,3-Diphenylperoxybutyrate.* *threo-2,3*-Diphenylbutyronitrile (mp 31.5—32.5 °C; lit,[14] mp 35—36 °C), prepared from benzyl cyanide and α-chloroethylbenzene according to the procedure of Hauser and Brasen[14] with the modification that the anion derived from benzyl cyanide and sodium amide was added to α-chloroethylbenzene, was hydrolyzed by heating in a mixture of 50% aqueous sulfuric acid and glacial acetic acid under reflux for 80 h. The resulting crude *threo*-acid was dissolved in acetone and the solution allowed to evaporate slowly to dryness at room temperature until a mixture of crystalline *threo*- and *erythro*-2,3-diphenylbutyric acids formed. Well developed larger crystals of the *threo*-acid were sorted out manually, mp 135.3—136.0 °C (lit,[14] mp 130—133 °C). The *threo*-acid (3.0 g) was treated with thionyl chloride at room temperature for 20 h. The resulting acid chloride, without purification, was dissolved in 25 ml of anhydrous pentane, and the solution added very slowly (40 min) to a solution of *t*-butyl hydroperoxide (1.56 g) and pyridine (1.17 g) in 25 ml of anhydrous pentane cooled in an ice–water bath. The reaction mixture was stirred for 2 h at 2 °C, while a pasty mass formed. Ice–water (20 ml) was added to the reaction mixture and the organic layer was washed successively with 10% sulphuric acid, water, 10% sodium carbonate, and water, and dried with anhydrous sodium sulphate at 0 °C overnight. The dried solution was chilled in a Dry Ice bath, and the crystals which separated were filtered off and recrystallized from pentane–dichloromethane (1: 1) to give 1.5 g (37%) of *t*-butyl *threo*-2,3-diphenylperoxybutyrate (Found: C, 77.01; H, 7.53%. Calcd for $C_{20}H_{24}O_3$: C, 76.89; H, 7.74%. Purity, 98% by iodometric titration[15]), mp 56.5—57.0 °C (dec); IR (Nujol) 1760 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) τ 8.80 (s, 9H, *t*-Bu), 8.59 (d, 3H, J=5.9 Hz, CH_3), 6.8—6.1 (m, 2H, $-C\dot{H}C\dot{H}-$), and 3.2—2.7 (m, 10H, phenyls).

Decomposition of t-*Butyl* erythro- *or* threo-2,3-*Diphenylperoxybutyrate in Solution.* A solution of either peroxybutyrate in chlorobenzene (3.0 ml, 0.100 M) was placed in an ampoule, degassed (three freeze-thaw cycles), and, the ampoule having been sealed, allowed to decompose in a constant-temperature bath at 60 °C for 36 h. A weighed amount of diphenylmethane was then added as an internal standard to the reaction mixture and it was subjected to VPC (Hitachi Gas Chromatograph Model K-53 FID). The following three columns were used: a 2 m column packed with Apiezon L grease (5%) to analyze for *meso*- and *dl*-2,3-diphenylbutanes, *t*-butyl 1,2-diphenylpropyl ether, and *trans*-α-methylstilbene at 190 °C; a 2 m column packed with Ucon oil LB-550-X (5%) plus a 1 m column packed with Silicone grease (5%) to analyze for *cis*-α-methylstilbene and 1,2-diphenylpropane at 175 °C; and a 300 ft. capillary column coated with Apiezone L grease to separate *erythro*- and *threo*-*t*-butyl 1,2-diphenylpropyl ethers.

The decomposition in toluene was carried out in a similar manner as described above.

Decomposition of the *erythro*-peroxybutyrate in the presence of 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl was similarly

carried out in toluene (Table 2).

Decomposition of t-*Butyl* erythro-*2,3-Diphenylperoxybutyrate in Chlorobenzene in the Presence of Di-*t*-butyl Diperoxyoxalate.* A solution of *t*-butyl *erythro*-2,3-diphenylperoxybutyrate (1.02 mmol) and di-*t*-butyl diperoxyoxalate (1.45 mmol) in chlorobenzene (3.0 ml) was heated at 35 °C for 14.5 h under a nitrogen atmosphere, and the remaining peroxybutyrate was determined by iodometric titration[15] (0.75 mmol, 74% of the peroxybutyrate used). A control experiment without di-*t*-butyl diperoxyoxalate showed the same result, demonstrating that the peroxyoxalate caused no induced decomposition.

Separation and Purification of t-*Butyl 1,2-Diphenylpropyl Ether and 1,2,3-Triphenylbutane.* *t*-Butyl *erythro*-2,3-diphenylperoxybutyrate (1.2 g) in 50 ml of toluene was heated at 61 °C for 70 h under nitrogen. After removal of most of the solvent by distillation under atmospheric pressure, the mixture was distilled under reduced pressure (0.1—0.5 mmHg), while the temperature of the heating bath was maintained below 160 °C. The distillate was subjected to purification by thin-layer chromatography on silica gel using chloroform–petroleum ether (1: 1) as eluent. A band of R_f 0.6 was extracted with diethyl ether, the extract condensed, and the residue purified by trap-to-trap distillation to give *t*-butyl 1,2-diphenylpropyl ether (Found: C, 85.11; H, 8.91%. Calcd for $C_{19}H_{24}O$: C, 85.02; H, 9.01 %), IR (neat) 1195 cm^{-1} characteristic of *t*-BuO.[16]

The residue from the vacuum distillation was chromatographed on silica gel. The faster-moving component was purified by molecular distillation to give an oil, which was gas chromatographically pure, *m/e* 286 (M^+) (Found: C, 92.56; H, 8.01%. Calcd for $C_{22}H_{22}$: C, 92.26; H, 7.74%). Comparison of its IR and NMR spectra with those of authentic *erythro*-1,2,3-triphenylbutane led to the conclusion that the oil was a mixture of *erythro*- and *threo*-1,2,3-triphenylbutanes in equal amounts.

Kinetics of Decomposition of t-*Butyl erythro-2,3-Diphenylperoxybutyrate.* A solution of the peroxybutyrate (*ca.* 0.1 M) in toluene was decomposed in sealed tubes at 60 °C. The tubes were removed from the bath at intervals and chilled at −78 °C to quench the reaction. The peroxybutyrate was determined by titration according to Swern's method,[15] and plots of the logarithms of the concentration of the peroxybutyrate *vs.* time gave a straight line up to 85% decomposition.

Synthesis and Properties of Organocobalt(III)octaethylporphyrins

Hisanobu OGOSHI, Ei-ichi WATANABE, Norihisa KOKETSU, and Zen-ichi YOSHIDA
Department of Synthetic Chemitry, Kyoto University, Kyoto 606
(Received March 15, 1976)

The syntheses of alkylcobalt(III)octaethylporphyrins(OEP) *via* nucleophilic attack of the Co(I) complex to unsaturated compounds are reported. Olefins with an electron-withdrawing group and acetylenes react with Co(I)(OEP), whereas olefins with an electron-donating group such as propylene and cyclohexene are unreactive. A novel ring cleavage of cyclopropyl methy ketone initiated by Co(I)(OEP) affords alkylCo(III)(OEP). The reduction of cobalt(II) *N*-methyloctaethylporphyrin acetate results in intramolecular methyl migration from nitrogen to the central cobalt atom. Five-coordination has been established for the organocobalt(III)(OEP) complexes on the basis of their analytical, infrared and NMR data. Some anomalous behavior of the proton signals of the α-carbon atom in their NMR spectra has been discussed in terms of quadrupolar relaxation and electronegativity of the cobalt ion.

The potential nucleophilicity of the d^8 metal ion in a macrocyclic square planar ligand is of particular interest because of its chemical relevance to vitamin B_{12s}[1] and homogeneous catalysts.[2] For example, cobalt(I)[1a,c,f,g] and rhodium(I)[3] ions, bound to a wide variety of square planar ligands, undergo nucleophilic substitution with alkyl halides and addition to olefins and acetylenes, to generate trivalent metal complexes, accompanied by the formation of metal–carbon bonds.

In earlier studies[4] on the rhodium(I)octaethylporphyrin[Rh(I)(OEP)] as a model system of vitamin B_{12}, we have noted novel carbon–carbon cleavage reactions of a number of substituted cyclopropanes and strained polycyclics such as quadricyclene, bicyclobutane, and their derivatives, yielding stable organorhodium(III) complexes. Clarke and his co-workers[5] first reported the synthesis of alkylcobalt(III)etioporphyrin-II by the reaction of Co(I)porphyrin with alkyl halides. The reaction with unsaturated compounds, however, has not been reported previously. We have now examined the generality of these reactions for cobalt(I)octaethylporphyrin. The present work describes the addition to olefins and acetylenes, the ring cleavages of three membered ring compounds, and ring cleavage reaction of cyclopropyl methyl ketone. The novel methyl migration in cobalt(II) *N*-methyloctaethylporphyrin is also reported.[6]

Results and Discussion

Nucleophilic Substitution. A variety of methods to generate cobalt(I) complex as precursor for higher valent cobalt complexes with unsaturated equatorial ligand have been exploited.[1f,g] In this study, the reduction of Co(II)porphyrin was performed by the method used for the generation of Co(I)tetraphenylporphyrin[Co(I)(TPP)][7] and Co(I)etioporphyrin-II [Co(I)(etio)].[5] The NMR spectrum of pyridine-d_5 solution of Co(I)(OEP) thus obtained showed signals at τ 1.03 (s, =CH–), 6.90 (q, $-CH_2-$), and 8.40 (t, $-CH_3$). The chemical shifts are shifted to higher field than those observed for the Co(III)(OEP) complexes, apparently indicating the existence of the low-spin diamagnetic cobalt(I) complex. Attempts to reduce bromopyridinecobalt(III)octaethylporphyrin with sodium borohydride in ethanol to Co(I)(OEP) failed, and only resulted in quantitative formation of Co(II)(OEP). Reduction of Co(II)(OEP) with borohydride in THF was also unsuccessful.

The reaction of Co(I)(OEP) with alkyl halides gave alkyl Co(III)(OEP) in moderate yields. Treatment of Co(I)(OEP) with methyl iodide, ethyl iodide, ethyl 2-bromopropionate, and 2-bromoethylamine yielded the corresponding organocobalt(III)porphyrins (**1**, **2**, **3**, and **4**). The products from benzyl bromide and tertiary alkyl halides were not isolable because of their thermal instability and/or susceptibility to light. Clarks and co-workers[5] have previously assigned a hexacoordinate structure for the alkyl Co(III)(ethio) complex. They proposed a water molecule as the sixth ligand based on the single sharp hydroxy stretching band at 3670 cm^{-1}. No IR absorption due to coordinated water, however, was observed for the OEP complexes, **1**—**4**. In the NMR no signal associated with water protons was detected in $CDCl_3$. These facts together with analytical data led us to conclude that all the alkyl-Co(III)(OEP) complexes are pentacoordinate. Diamagnetic character of these complexes is evidently shown by the positions of chemical shifts and sharp signals of the peripheral ethyl and methene protons. In general, a pentacoordinate structure is a most unusual geometry for the trivalent state of cobalt.[8,9] However a few examples of the isolation of stable pentacoordinate complexes are known for the cobalt(III) complexes of bae.*[10] Furthermore, it has been argued that a strongly electron-donating ligand would be expected to more easily form a pentacoordinate alkylcobalt(III) complexes in the order bae*>salen*>$(dmg)_2$*>[(do)(doH)pn].*[11]

trans-β-Bromostyrene reacted readily with Co(I)-(OEP), with complete retention of configuration, to yield exclusively the *trans*-styrylcobalt(III)complex, (**5**). Similarly complete retention of configuration has been reported in the reaction of cobaloxime(I) with *trans*-β-bromostyrene.[12]

Reaction with Olefins and Acetylenes. Addition of the olefins substituted with an electron-withdrawing group to a tetrahydrofuran solution of Co(I)(OEP),

followed by treatment with a portion of aqueous alkali (0.1 N) gave exclusively β-substituted alkylcobalt(III)-porphyrins, (**6**) and **3**, in moderate yield (Eq. 1). It was clearly proved by the NMR signals due to the

$$[Co(I)(OEP)]^- \xrightarrow[2.\ H_2O\text{-}NaOH]{1.\ CH_2{=}CHX} Co(III)(OEP)\cdot CH_2CH_2X \quad (1)$$

X: CN, (**6**); CO_2Et, (**3**)

axially coordinated alkyl protons that the bond formation had taken place at the β carbon atom (*vide infra*). This is also supported by the fact that the product obtained from ethyl acrylate was identical with an authentic sample of 2-(ethoxycarbonyl)ethylcobalt(III)(OEP) (**3**). In marked contrast to the olefins with an electron-withdrawing substituent, the reaction with propylene and cyclohexene resulted in spontaneous formation of divalent cobalt complex before addition of aqueous alkaline solution. As has been proposed in the reaction of cobaloxime(I) and other Co(I) complexes with olefins,[1f,g] it seems that the reaction species is not a hydrido complex (**13**) but rather a complex anion (**12**). However, the presence of **13** cannot be completely excluded under the present conditions since a small amount of the α-styryl complex (**9**) was formed in the reaction with phenylacetylene as described below.

of Co(I)(OEP) gave vinylcobalt(III)(OEP) (**7**) isolated in 19% yield. Phenylacetylene readily reacted with the Co(I)(OEP) and the product (29% yield based on the NMR spectrum) was found to be a mixture of *cis*-β-styryl (**8**) and α-styrylCo(III)(OEP) (**9**). They were not separable by chromatography.

The ratio of isomers **8** and **9** was determined as 3: 1 by intensity ratio of the *meso*-proton chemical shifts at τ 0.17 and −0.05. As demonstrated in Table 3, full assignments of the NMR signals were accomplished by comparing the spectra of complexes **8** and **9**, with that of the *trans*-conformer **5** and that for mixture of partially deuterated styryl complexes (**10**) and (**11**) prepared from deuteration experiments. Assignments were also confirmed with the aid of the spectra for the corresponding *cis*- and *trans*-β-styryl rhodium(III)(OEP) complexes.[4] The relatively small vicinal coupling constant (4.0 Hz) compared to that observed for **5** (J_{trans}=12.0 Hz) rationalizes the stereochemistry of *cis*-conformer **8**. The α-styryl complex **9** has been also confirmed by the β-carbon proton signals at τ 10.85 and 12.76 with the coupling constant of 1.5 Hz due to geminal protons. Furthermore, inspection of molecular models suggests that anisotropic shielding of a phenyl group in the *cis*-conformer **8** causes high field shifts of the *meso*-positions and in turn the phenyl group would experience the ring current of the porphyrin ring. Thus the higher field peak at τ 0.17 is assigned to the *meso*-protons of **8**. The chemical shifts of the phenyl protons appear at a higher magnetic field than those of the *trans*-conformer **5**.

For cobaloxime(I), it has been reported that a mixture of α-styryl and *cis*-β-styryl complexes is formed in a mildly alkaline solution.[12,13] The formation of an α-styryl complex may arise from a hydridocobalt(III) complex (**13**) as has been discussed for the cobaloximes.[12-15] The reaction yields for the acetylenic compounds are considerably lower due to the generation of Co(II)(OEP) during chromatography. In contrast, the reactions of cobaloxime and Rh(OEP) with acetylenic compounds give quantitative formation of the vinylmetal complexes.[4,12-15] It is of interest to note that the Co(I) complex of the water soluble porphyrin catalyzes only the reduction of acetylene[16] whereas we have obtained the vinylcobalt(III) complex **7**. Thus, low yields may be in part ascribed to the homolytic decomposition of the carbon–cobalt(III) bond to Co(II)(OEP) and a radical species.

Reaction with Three Membered Ring Compounds. Co(I)(OEP) reacted readily with ethylene oxide and ethyleneimine to yield 2-hydroxyethyl- and 2-aminoethylcobalt(III)(OEP), **14** and **4**, respectively. The cleavage of the C–X bond was confirmed by the IR and NMR spectra. For example, **14** shows a sharp hydroxy stretching vibration at 3570 cm^{-1} and NMR

$$[Co(I)(OEP)]^- + \triangle^{X} \xrightarrow{H_2O} Co(III)(OEP)\cdot CH_2CH_2XH \quad (4)$$

X: O, (**14**); NH, **4**

signals at τ 14.36 and 13.08, assigned to α-and β-carbon protons of the axially coordinated alkyl group respectively. Likewise reaction of ethyleneimine gave the 2-aminoethyl analogue, identical with the product obtained from β-bromoethyl amine. The analytical values of the product are somewhat poor, presumably due to its low stability in the crystalline state. However, the infrared spectrum shows clear bands at 3250, 3305 cm^{-1}, characteristic of the N–H stretching vibration of the primary amino group.[17] In the NMR spectrum two signals assignable to the α- and β-methylene protons are observed at τ 16.17 and 12.75, respectively. These spectral data support the proposed structure **4**.

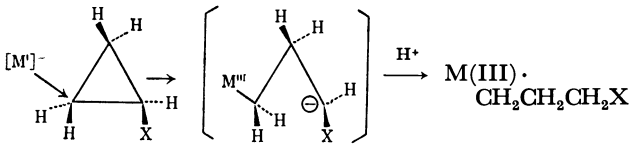
As described in the introduction, Rh(I)(OEP) cleaves cyclopropanes with an electron-withdrawing substituent to form the Rh–C bond at the γ-position with respect to form the Rh–C bond at the γ-position with respect to the substituent.[4] This fact is surprising since the cyclo-

$$[M(I)(OEP)]^- + X\text{-}\overset{2}{\underset{1}{\triangle}}\overset{}{\underset{3}{}} \xrightarrow{H_2O} M(III)(OEP)\cdot {}^{\alpha}CH_2{}^{\beta}CH_2{}^{\gamma}CH_2X \quad (5)$$

M=Rh: X=CH_3CO, CO_2Et
M=Co: X=CH_3CO, (**15**)

propane ring is considered to be stable towards the nucleophilic attack, and in general cleavage of cyclopropane ring by nucleophiles proceeds under severe conditions.[18] At room temperature, treatment of $[Co(I)(OEP)]^-$ with cyclopropyl methyl ketone gave readily 4-oxopentyl-cobalt(III)(OEP) (**15**). The ring fission along the 1, 2 bond was verified by the NMR spectrum which showed a broad signal at τ 14.37, a multiplet at 15.00 and a triplet at 10.90, assignable to α-, β-, and γ-carbon protons, respectively. A sharp singlet due to the terminal methyl group was observed at τ 9.38. However, no product was obtained for cyanocyclopropane but reaction with ethyl cyclopropanecarboxylate gave a small amount of product which showed a sharp carbonyl stretching absorption at 1720 cm^{-1}. In both cases, chloromethylcobalt(III)(OEP) (**16**) was isolated as a major product by the competitive substitution with the solvent methylene chloride. This result indicates that the reaction with cyclopropyl derivatives to form a σ bond is relatively slow and the unreacted Co(I) complex anion still remained in the reaction mixture.

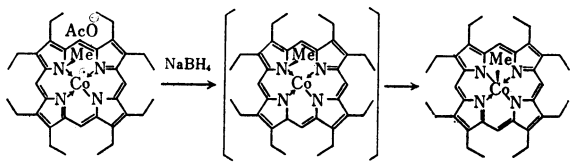
In rhodium octaethylporphyrin the *endo*-configuration has been established for the product obtained from nortricyclanone.[19] It has thus been suggested that cleavage of the cyclopropyl ring by a rhodium(I) anion follows a S_N2 mechanism, *e.g.*, the reaction does not proceed *via* a π-type complex formed between the cyclopropane and the complex anion but rather *via* an intermediate carbanion stabilized by an electron-withdrawing substituent (Scheme 1). The observed activation by an acyl group may imply a similar mechanism.



Scheme 1.

Weber and Schrauzer have reported that rhodoxime(I) is less nucleophilic than cobaloxime(I) in the substitution with alkyl halides.[20] Marked difference in the reactivity between Co(I)(OEP) and Rh(I)(OEP), however, may arise from the difference in stability of the various oxidation states. For metalloporphyrins, the cobalt ion is able to exist in the various oxidation states such as Co(I), Co(II) and Co(III).

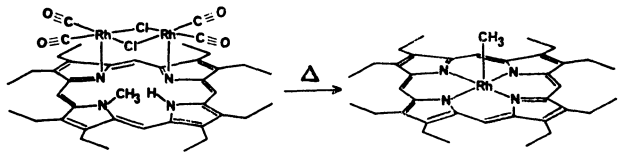
Intramolecular Methyl Migration to Cobalt Atom. Reduction of Co(II) *N*-methyloctaethylporphyrin acetate $[Co(II)(N\text{-MeOEP})]^+OAc^-$ (**17**) with sodium borohydride proceeded to completion in thirty minutes at room temperature. The expected monovalent complex (**18**) was not obtained, but the trivalent cobalt-methyl derivative **1**, generated in 58% yield.



17 **18** **1**

In contrast with the complicated visible spectra of *N*-alkyl metalloporphyrin,[21] the generated complex showed a characteristic spectrum of metalloporphyrins.[22] Conclusive evidence for the cobalt–methyl bond was provided by the NMR spectrum which is identical with that observed for **1**. The complex is also identical with the protuct obtained by the substitution of pyridinebromocobalt(III)(OEP)[21] with methyl lithium. Grigg and co-workers[23] have reported that alkyl groups in Ni(II) and Pd(II) *N*-alkyl corroles migrate thermally from the pyrrolic nitrogen to the β-carbon atom of the pyrrolic ring. Perhaps the methyl migration proceeds through nucleophilic attack of the Co(I) ion, which may be assisted by the release of strain in the porphyrin ring coordination.

Previously we observed the migration of an alkyl group from nitrogen to the central metal atom for the dirhodium(I) complex of *N*-alkyl OEP (**19**) concomitant with the oxidation of the monovalent state of the metal, yielding alkylmetal(III) σ-complexes.[4] The present study suggests that the alkyl migration in the complex **19** proceeds *via* an intermediate analogous to



19 1

the postulated monovalent metal complex **18**. The present alkyl migration can be considered to be an intramolecular oxidative addition through the C–N bond to the Co(I) ion.

^1H NMR Spectra. Table 3 lists the NMR spectra of the alkylcobalt(III) complexes. Structures are proposed on the basis of the proton chemical shifts of the axially coordinating alkyl groups. These protons experience the influence of the ring current of the porphyrin macrocycle. The chemical shifts for the methyl and ethyl complexes **1** and **2** are quite similar to those observed for the corresponding aquoalkylcobalt(III) complexes of etioporphyrin II.[6] The hydrogens of the carbon directly attached to the cobalt atom (denoted as H_a in Table 3) appear at lower field as compared with those for other corresponding alkyl metalloporphyrins. For example, methyl hydrogens in the complex **1** resonate at τ 15.20, whereas the chemical shifts of the methyl hydrogens in Rh(OEP)·CH_3·H_2O[4] and Ge(porphin)$(CH_3)_2$[24] appear at 16.47 and 17.98, respectively. The hydrogens in the alkyl group for Rh(OEP)·R·H_2O, and Ge(porphin)(R_2) appear in the expected order C_α–H_2>C_β–H_2>C_γ–H_2……. In contrast, the methyl protons in the ethyl complex **2** resonate at lower magnetic field than those of the methylene protons. This lower field shift of the C_α-hydrogen can be explained if we assume that the cobalt(III) ion in the organocobalt porphyrin is more electronegative than those of other metals. This explanation seems to be reasonable since the geminal coupling constant in the vinyl complex **7** is relatively large (J_{gem}=4.0 Hz) as compared with those (<1 Hz) for other vinyl metal complexes.[4,12,13] In general, a large geminal coupling constant is associated with a high electronegativity of the substituent of the vinyl derivatives.[25]

Figure 1 shows representative spectra of Co(III)(OEP)R in the high field region in $CDCl_3$. Anomalous line broadening has been observed for the proton signals of α-carbon atom. The broadening is common to all the complexes. The rest of the signals of the axial alkyl group are all normal, indicating the absence of dimer-formation in solution as reported for cobaloximes.[26] Clarke and his co-workers have ascribed similar line broadenings for the C_α-hydrogens in etioporphyrin II to the poorly resolved nuclear spin-spin coupling between ^{59}Co–^{1}H.[6] If this is true, it seems rather surprising since the naturally occurring cobalt (100%, ^{59}Co) has a large electric quadrupole moment, Q= 0.5×10^{-24} cm^2 [27] and hence spin-spin coupling between protons and a nucleus is normally not observed in solution due to rapid spin-relaxation of the quadrupolar nucleus.[28] Accordingly, spin coupling between protons and cobalt has never been observed for either the pentacoordinate[29] or hexacoordinate alkyl cobalt σ

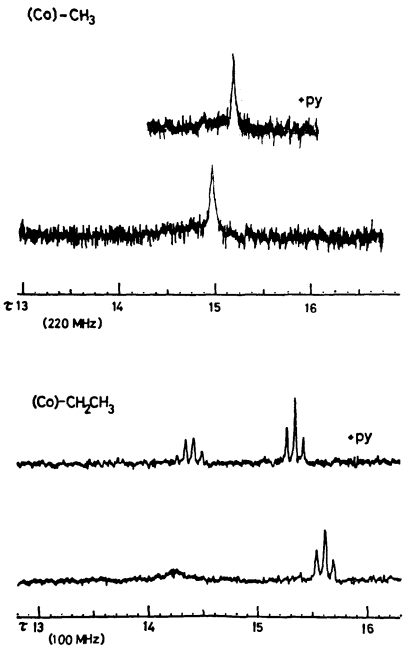


Fig. 1. NMR spectra of **1** and **2** in the high field region (measured in $CDCl_3$).

complexes hitherto reported. As is shown in Fig. 1, the signal shape was appreciably sharpened to give well resolved hyperfine structure when an excess amount of pyridine was added. Consequently, the expected quartet of the methylene group at τ 14.38 could definitely be identified for the ethyl cobalt(III)(OEP) **2**. Concomitantly, signal due to C_α-hydrogens was shifted to higher field by 0.4—0.5 ppm while slight shift to lower field was observed for the signal due to C_β-hydrogens. These observations lead us to postulate that the broadened line shape of the C_α-hydrogens is due to partially relaxed cobalt–proton coupling caused by quadrupolar relaxation. Similar phenomena have been observed for tricarbonyl(η-cycloheptatrienyl)vanadium(I)[30] and the mechanism is well understood.[28] The rate of relaxation depends on the strength of the coupling between the quadrupole moment and fluctuating electric field gradients at quadrupolar nucleus.[28] The electric field gradient at the cobalt atom in the pentacoordinate porphyrin complex might be weak; in consequence, despite a relatively large value of Q, the quadrupole coupling constant might be small enough to observe ^{1}H–^{59}Co spin-spin coupling. Coordination of pyridine would cause an increase in the covalency of the cobalt(III)–carbon bond and in turn the field gradient becomes so strong as to yield complete decoupling in the present system. It would be of great use to elucidate the mechanism of the line broadening in respect of the controversial problems related to the nature of Co–carbon bonds in vitamin B_{12}.[31–33]

Figure 2 shows the spectra of Co(OEP)·$CH_2CH_2CO_2Et$ **3** and Co(OEP)·$CH_2CH_2CH_2COCH_3$ **15** in the high field region. Again signals due to the C_α-hydrogens are broad and overlapped by a less resolved peak due to C_β-hydrogens. In the presence of pyridine, **3** shows a sharp multiplet at τ 14.34, typical of AA'BB' pattern,[34] for the protons (C_α–H and C_β–H) while **15** showed a

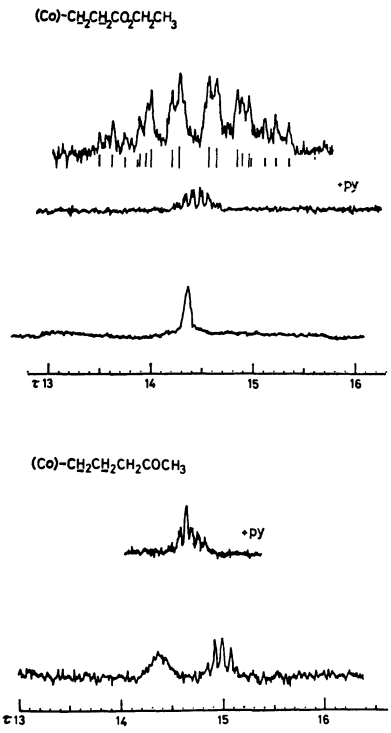

Fig. 2. 100 MHz NMR spectra of **3** and **15** in the high field region (measured in $CDCl_3$).

multiplet at ≈14.70 associated with C_α- and C_β-protons. The AA'BB' type splitting may arise from the exclusive presence of a rotational conformer as reported in 1,2-disubstituted ethane.[34,35]

Of the organocobalt(III)(OEP) complexes some, **3,5—9**, show double quartets due to the methylene protons of the peripheral ethyl groups of porphyrin, even though the difference in chemical shifts between the two quartets is quite small. Axial ligation of some unsaturated organic group forms a different magnetic anisotropic effect above and below the macrocyclic plane (diastereotopism).[36] The ratio of intensity for the two quartets is almost unity. Therefore, four of the methylene groups and the rest of four methylenes experience the different magnetic anisotropy due to the five coordinated metalloporphyrin. Free rotation of peripheral ethyl groups around the bond between the CH_2 and porphyrin carbon atom seems to be restricted to some extent due to the crowding of the ethyl groups.

Experimental

Spectral Measurements. Visible spectra (340—700 nm) were obtained in chloroform using a Hitachi EPS-3T spectrophotometer, and infrared spectra (4000—400 cm^{-1}) were determined in a KBr disk with a Hitachi-G3 spectrophotometer. NMR spectra were taken on Varian HA-100 and HR-220 spectrophotometers. All NMR spectra except for Co(I)(OEP) were recorded with deuteriochloroform as solvent and tetramethylsilane as internal standard. Pyridine was dried and distilled prior to use.

Reaction of Co(I)(OEP) with Organic Halides. A General Procedure: Co(II)(OEP) (100 mg) and sodium amalgam (2%, 3.0 g) were placed in a two necked flask (50 ml). The center neck was connected to a high vaccum tap and another neck was connected *via* a high vaccum tap to a 25 ml flask. Dry tetrahydrofuran (30 ml) was introduced to the flask and the solution was deareated by a repeated freeze-thaw method, and then stirred magnetically overnight. The color of the solution changed from reddish purple to lustrous orange-red. After the solution was transfered through a glass filter to the 25 ml flask, an excess of degassed alkyl halide (methyl iodide, ethyl iodide, ethyl 2-bromopropionate, *trans*-β-bromostyrene, or 2-bromoethylamine) was added, and then the solution was stirred for 10 min in the absence of light. The color of the solution changed to dark red. Methylene chloride (15 ml) was added to the reaction mixture and the solution was then

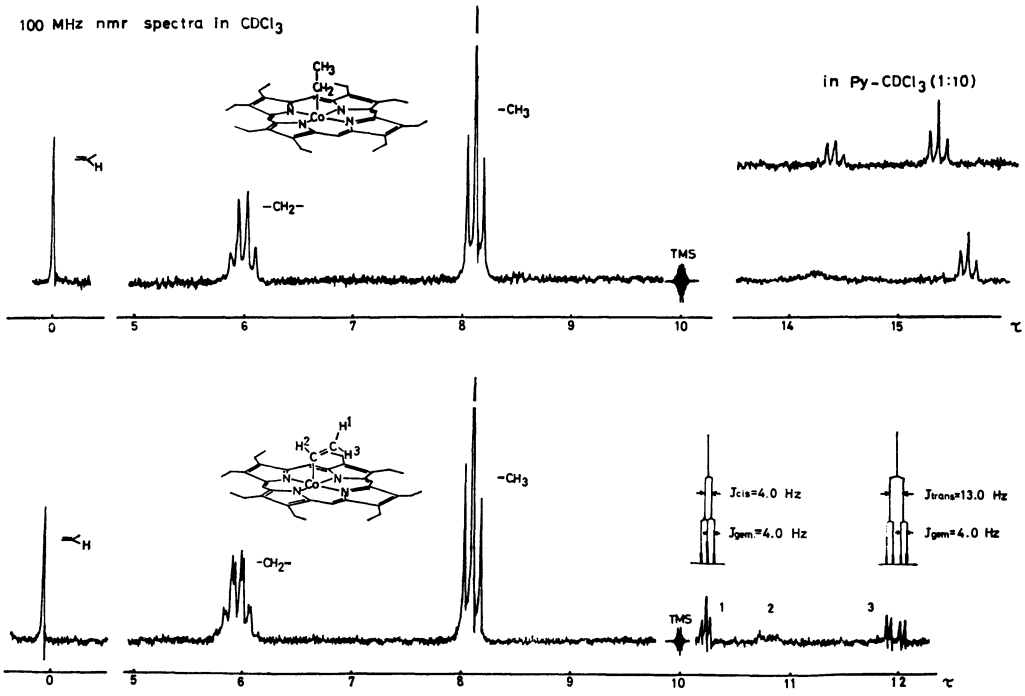

Fig. 3. 100 MHz NMR spectra of **2** and **7** measured in $CDCl_3$.

poured into 200 ml of cold water. The organic layer was separated, successively washed with water (200 ml × 3), and dried over Na_2SO_4. The solvent was removed at room temperature under reduced pressure and the residue was chromatographed on thin layer silica gel with benzene–methylene chloride (Merck, 60 PF_{254}, 20×20×0.1 cm^{-1}). The reddish orange zone was separated and extracted with methylene chloride. The solvent was removed and recrystallization of the residue afforded alkylcobalt(III)(OEP).

Co(OEP)·CH_3: This was eluted with methylene chloride–petroleum ether (1:3). Recrystallization from methylene chloride–petroleum ether afforded purple prisms (67 mg, 65%).

Co(OEP)·CH_2CH_5: This was eluted with methylene chloride–petroleum ether (1:5). Recrystallization from methylene chloride–petroleum ether afforded purple crystals (63 mg, 60%).

Co(OEP)·$CH_2CH_2CO_2Et$: Elution was carried out with methylene chloride–hexane (1:3). Recrystallization from methylene chloride–acetone gave purple crystals (50 mg, (42.7%).

trans-*Co(OEP)·CH=CHPh*: Eluent: methylene chloride–petroleum ether (1:3). Recrystallization from methylene chloride–petroleum ether afforded purple crystals (67 mg, 57%).

Co(OEP)·$CH_2CH_2NH_2$: β-Bromoethyl amine was prepared prior to use by treating its hydrogen chloride salt with an equimolar amount of triethylamine. The purification procedure is the same as that described above except that the organic layer was washed with diluted hydrobromic acid (200 ml×5). Elution was carried out with methylene chloride–methanol (10:1). Recrystallization from methylene chroride–petroleum ether afforded dark purple crystals (43 mg, 40%).

Reaction of Co(I)(OEP) with Olefins, Acetylenes and Three Membered Ring Compounds. A General Procedure: An excess molar amount of the substrate was added to (acrylonitrile, ethyl acrylate, phenylacetylene, ethylene imine or cyclopropyl methyl ketone) or bubbled into (acetylene and ethylene oxide) the THF solution of Co(I)(OEP) prepared from 100 mg of Co(II)(OEP) as described above. The reaction mixture was stirred for 15 min and then a portion of 0.5 M NaOH was poured into the reaction vessel. Stirring was continued until the solution turned dark red (10—30 min). The succeeding procedures for separation and purification of the products are identical with those described in the reaction with alkyl halides.

Co(OEP)·CH_2CH_2CN: Eluted with methylene chloride–petroleum ether (1:3). Recrystallization from methylene chloride–petroleum ether affords purple crystals (50 mg, 44%).

Co(OEP)·$CH_2CH_2CO_2Et$: The products are identical with those prepared from ethyl 2-bromopropionate as described above (35 mg, 30%).

Co(OEP)·$CH=CH_2$: Thin layer chromatography of the reaction mixture on silica gel indicated that Co(II)(OEP) was formed together with alkyl cobalt complexes. Highly insoluble Co(II)(OEP) was removed by filtration before the separation by TLC was carried out. Recrystallization from methylene chloride–petroleum ether yielded vinyl cobalt(III)(OEP) (18 mg, 19%).

cis-*Co(OEP)·CH=CHPh and Co(OEP)·PhC=CH_2*: Monitoring reaction procedure by means of TLC showed that Co(II)(OEP) had generated during the reaction together with vinyl complexes. Elution was carried out with methylene chloride–hexane (1:5). Recrystallization from methylene chloride–acetone gave a mixture of *cis*-Co(OEP)·CH=CHPh and Co(OEP)·PhC=CH_2 (3:1) (34 mg, 29%). The deuteration experiment was carried out according to the general procedures described above except an addition of deuterium oxide solution of NaOD in place of aqueous NaOH solution.

Co(OEP)·CH_2CH_2OH: Eluent chloroform–hexane (1:2). Recrystallization from chloroform–hexane gave purple crystals (72 mg, 67%).

Co(OEP)·$CH_2CH_2NH_2$: The products are identical with those obtained in the reaction of Co(I)(OEP) with 2-bromoethylamine (35 mg, 33%).

Co(OEP)·$CH_2CH_2CH_2COCH_3$: Elution was carried out with methylene chloride–petroleum ether (1:3). Recrystallization from methylene chloride–petroleum ether gave 50 mg of deep purple crystals (44%).

Reaction with Carboethoxycyclopropane. The method used is entirely analogous to that described in the reaction with cyclopropyl methyl ketone. The main zone separated from TLC gave chloromethyl derivative, Co(OEP)·CH_2Cl. Recrystallization from methylene chloride–acetone gave 87 mg of deep purple crystals (79.8%). A minor zone gave an alkyl derivative (2 mg) with carbonyl stretching band at 1720 cm^{-1}.

Reaction with Cyanocyclopropane. The reaction mixture was stirred for 30 min. Co(OEP)CH_2Cl was obtained (31 mg, 37.5%).

Analytical data for the alkylcobalt(III)(OEP) complexes are given in Table 1. Visible and characteristic infrared data are listed in Table 2 and NMR data in Table 3. All reactions and manipulations involving cobalt(I) complexes were performed entirely under an atmosphere of purified argon. A 2% sodium amalgam was prepared by addition of mercury to the melted sodium metal in toluene. All procedures involving alkylcobalt(III) complexes were carried out in the dark whenever possible.

Intramolecular Methyl Migration. *N*-methyloctaethylporphyrinatocobalt(II) acetate [Co(*N*-MeOEP)]$^+OAc^-$ was prepared by a usual method[22] from Co(II) acetate and *N*-methyloctaethylporphyrin.[37] 80 mg of *N*-methyloctaethylporphyrinatocobalt(II) acetate was dissolved in THF and air was purged by argon. 10 mg of $NaBH_4$ in aqueous sodium hydroxide solution (0.5 M 0.5 ml) was added to the solution and the reaction mixture was stirred for 35 min. The color of the solution changed from dark green to dark red. Ten ml of methylene chloride was added to the solution and washed with water, and dried over Na_2SO_4 and evaporated. The resulting residue was chromatographed on silica gel (TLC 20×20×0.1 cm) with methylene chloride–petroleum ether (1:3). Recrystallization from methylene chloride–petroleum ether afforded deep purple crystals (42 mg, 57.6%).

Reaction of Co(III)(OEP)Br·py with Methyllithium. To 100 mg of pyridinobromocobalt(III)octaethylporphyrin[21] dissolved in anhydrous dimethoxyethane was added an equimolar amount of methyllithium prepared from methyl iodide and lithium metal under nitrogen. The reaction was monitored by TLC (silica gel). After the reaction was completed, the reaction mixture was poured into 200 ml of water, washed with water several times and dried over Na_2SO_4. The succeeding procedures are identical with those described above. Recrystallization from methylene chloride–petroleum ether afforded Co(OEP)–CH_3 (72 mg, 55%).

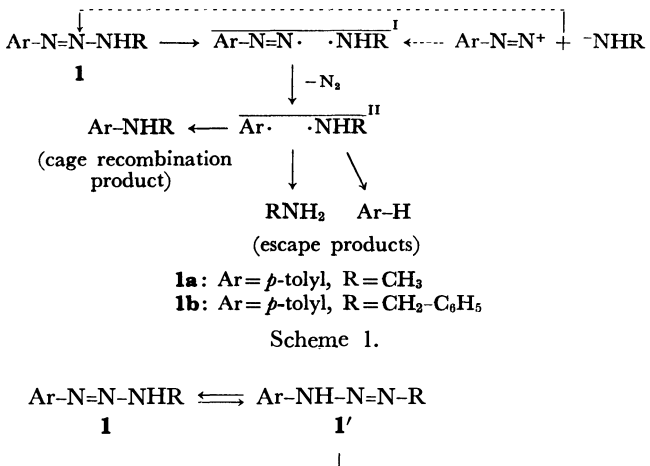
CIDNP Investigation of Aminyl Radicals Formed by Thermolysis of Triazenes[1)]

Klaus ALBERT, Karl-Michael DANGEL, and Anton RIEKER*
Department of Organic Chemistry, University of Tübingen, D-74 Tübingen, Auf der Morgenstelle, G.F.R.
Hiizu IWAMURA,* and Yuzo IMAHASHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received March 19, 1976)

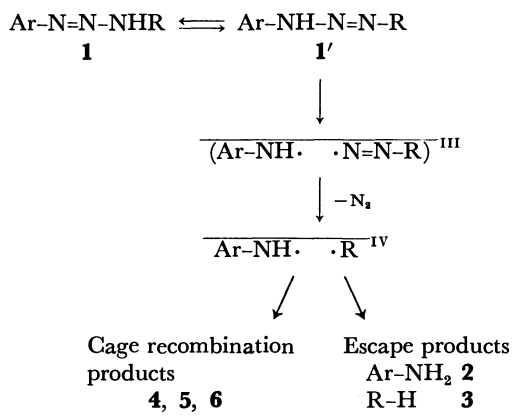
Thermolysis of asymmetric triazenes Ar–N=N–NH–R **1** produces anilines Ar–NH_2 **2**, hydrocarbons R–H **3**, and *N*-alkylated anilines Ar–NH–R **4** as the main reaction products. ^{1}H-and ^{13}C-CIDNP experiments show polarization of nuclei in Ar–NH_2, Ar–NH–R, R–H and some additional products (especially ring alkylated anilines). These observations are in agreement with the formation of an intermediate radical pair [Ar–NH··R] which must have been formed *via* homolysis of the tautomeric form ArNH–N=N–R **1′**. Temperature-dependent ^{13}C-NMR spectra show a rapid equilibrium between **1** and **1′** at room temperature and above, the tautomeric form **1** being predominant. From the CIDNP spectra the signs of the ^{1}H and ^{13}C hyperfine couplings of aminyl radicals Ar–NH· and alkyl radicals R· have been determined.

Recently an important role of free radicals in the reactions of onium compounds with nucleophiles was pointed out.[1,2)] Electron transfer from nucleophiles to onium ions should initially lead to the primary radical pair I, Scheme 1, from which cage and escape products and/or secondary cages II might be formed. Alternatively, a direct ionic recombination of both components could occur to form a homopolar bond which consecutively would homolyse into the same radical pairs.

As a mechanistic model of one of these reactions, namely, the reaction of aryldiazonium salts with strongly nucleophilic amines or amide anions,[3)] we have examined the thermolysis of 1-aryl-3-alkyltriazenes **1** in various solvents at 125—135 °C.



Scheme 1.



Scheme 2.

Contrary to the expectation (derived from the structure of triazenes **1**) that arenes ArH and amines R–NH_2 as escape products and *N*-alkylaniline derivatives as the cage recombination products would be formed predominantly in hydrogen-donating solvents as shown in Scheme 1, anilines Ar–NH_2 **2** have been found as the main products indicating the preferential formation of arylaminyl (anilino) radicals in these reactions. Therefore we wish to propose Scheme 2 as revealed by the ^{1}H- and ^{13}C-CIDNP investigations and by the product analysis of the thermal decomposition of the triazenes.

Experimental

The triazenes **1** were synthesized in analogy with the preparation of 1-phenyl-3-methyltriazene[4)] or purchased from Willow Brook Labs. Inc., Waukesha, Wisc., USA. The samples were crystallized from petroleum ether before use. The authentic sampeles for the reaction products are commercially available except *N*-methyl-*p*-toluidine **4a**, *N*-benzyl-*p*-toluidine **4b** and 2-benzyl-4-methylaniline **5b**. These were prepared according to the literature.[5,6)]

The ^{1}H-NMR spectra were obtained on a Hitachi R-20 B (60 MHz) spectrometer and a Bruker HFX-90 (90 MHz) spectrometer (δ ppm from TMS). In typical CIDNP experiments, solutions of 38 mg of triazene in 0.4 ml of solvent (Hitachi) or 70 mg in 1 ml of solvent (Bruker) were heated in the spectrometer probe. CIDNP spectra were registered at 130 °C by a continuous wave scan of 600 Hz/200 s on both instruments. For the Bruker instrument an internal deuterium lock made of DMSO-d_6 was sealed in a 2 mm capillary and placed concentrically in a sample tube of 5 mm o.d., using a perforated vortex plug to allow for gas escape.

The ^{13}C-NMR spectra were obtained at 25.15 MHz on a JEOL PS 100 PFT spectrometer and at 22.628 MHz on the Bruker HFX-90 instrument. The internal deuterium lock described above was used with both instruments. The diameter of the capillary was raised to 4 mm and to 5 mm as a consequence of the 8 mm o.d. (JEOL) and 10 mm o.d. (Bruker) sample tubes. Further conditions for the JEOL instrument: a radiofrequency 45° pulse of 11 μs was applied with a repetition time of 1.0 s over the spectrum width of 6.25 KHz. Accumulation of the FID signals was started at 30 s after insertion of a sample solution (185 mg of **1b** in 1 ml of a solvent, for

a) No additional weak emission signals at δ 0.88 and 1.00 in TCE can be assigned. b) Due to the overlap of shift values of **4a** and **5a**, discrimination is not possible. c) Shifts of authentic sample taken at 37 °C with Varian A 60: 6.24, 6.38 ppm. d) No CIDNP observed in TCE. e) Shifts of authentic sample taken at 37 °C with Varian A 60: 6.23, 6.37 ppm.

example) into the preheated NMR probe and was continued until the sum of 300 was obtained. Further condition for the Bruker instrument: *ca.* 300 mg of triazene **1a** in 2 ml of solvent was decomposed. The probe was preheated at 80 °C and accumulation started 40 s after the temperature had reached 130 °C. A 10 μs pulse was applied 1024 times with a repetition time of 0.4 s over the spectrum width of 5.0 KHz. In each case the sample temperature was controlled as usual by preheated nitrogen flow and thermostatted by a heat-sensor in an effluent gas stream.

Unless otherwise stated, the assignment of both the ^{1}H- and ^{13}C-CIDNP signals was made by careful comparison of chemical shifts with those of the authentic samples under the same experimental conditions. This was effectively done by adding small amounts of the authentic sample to the reacion mixture-right before and after recording the CIDNP spectra and observing the corresponding increase in absorption intensity of the signals in question. Product analyses were performed by vapor phase chromatography on Shimadzu GC-4A and on Perkin Elmer F-7 instruments in the usual manner using authentic samples for comparison. The amount of nitrogen-plus methane evolved was determined volumetrically by means of a thermostatted azotometer.

Results and Discussion

a) ^{1}H-CIDNP Results. All the results are summarized in Tables 1 and 2. The aliphatic region

Table 2. ^{1}H-CIDNP (δ ppm from internal TMS) in the thermolysis of **1b** in 1,1,2,2-tetrachloroethane (TCE), *trans*-decalin (DC) and 1,2-dichlorobenzene (DCB)

a) Assignment tentative. b) Due to overlap, assignment of the anilino part CIDNP signals to **4b** or **5b** is impossible.

of a typical ^{1}H-CIDNP spectrum of the thermolysis of **1a** in *o-dichlorobenzene* at 130 °C is reproduced in Fig. 1. At this temperature the intensity of the *N*-methyl and aromatic methyl singlets at δ 3.14 and 2.24, respectively, due to **1a** decreases with a half-life of 2—3 min. A strongly polarized absorption due to methane is noted at δ 0.13 throughout a 10—12 min period of the reaction. There are several emission singlets in the methyl region of the spectrum. The one at δ 1.01 is tentatively assigned to the methyl protons of 4,4-dimethyl-cyclohexa-2,5-dien-1-imine **6a**.[7,8] The strongest emission at δ 1.98 corresponds to the *ortho*-methyl group of 2,4-dimethylaniline **5a**. Both the aromatic methyl and *N*-methyl protons of *N*-methyl-*p*-toluidine **4a** cause weak emission signals at δ 2.15 and 2.64, respectively. The signal of the aromatic *p*-methyl protons of **5a**, also for which emission is predicted, coincides with that of **4a**. At δ 2.13 the methyl signal of *p*-toluidine **2** itself is observed in weakly enhanced absorption. Some toluene has also been formed as can be seen from the signal at δ 2.22.

The thermal decomposition of the triazene **1a** in 1,1,2,2-tetrachloroethane and in *trans*-decalin supplements the above CIDNP experiments. In *1,1,2,2-tetrachloroethane* a short-lived emission at δ 2.98 is considered to be due to methyl chloride **7** formed in 12% yield (vapor phase chromatography) specifically in this solvent. In the aromatic region, the high-field part of the AA'BB' pattern is emissive while the low-field half is slightly enhanced during the first 5 min period of the reaction. Although the AA'BB' multiplet due to the aromatic ring protons of *p*-toluidine and its *N*-methyl derivative **4a** is quite similar under these conditions and also the doublet of H-6 of 2,4-dimethylaniline **5a** is found at the same shift values as H-2,6 of **4a**, we might conclude that the CIDNP effect is derived from the main reaction product *p*-toluidine. At a later stage of the reaction (8—15 min) we note a new emission singlet at the chemical shift corresponding to the aromatic protons of toluene. At the end of the reaction (30 min after the start) in 1,1,2,2-tetrachloroethane, the signals at δ 1.18, 2.12, and 7.18 are barely detected as absorptions, suggesting the formation of only a small amount of imine **6a**, aniline **5a**, and toluene, respectively (*vide infra*).

In *trans-decalin* the high-field half of the AA'BB' pattern shows emission for *p*-toluidine and enhanced absorption for **4a**/**5a**. The latter two, of course, cannot be distinguished.

The ^{1}H-CIDNP experiments with 1-*p*-tolyl-3-benzyltriazene **1b** (Ar=*p*-$CH_3C_6H_4$, R=CH_2Ph; Table 2) in principle support our results obtained from thermolysis of **1a**. Therefore, they are not discussed in detail. It should be mentioned, however, that toluene **3b** is formed mainly *via* the benzyl radical and that bibenzyl **8** also shows CIDNP.

b) ^{13}C-CIDNP Results. A nearly full interpretation of the polarized signals during thermolysis of **1a** has been successfully achieved and is given in Table 3. As shown in Fig. 2 (decalin solution), the aliphatic region is not very informative since most of the aromatic *C*-methyl signals coincide and are compensated due to alternating polarizations. Thus it depends on small changes of the reaction conditions, whether the signal at δ 20.6—20.7 ppm is in weak absorption or emission.

The CIDNP pattern of the aliphatic region of **1a** in *o*-dichlorobenzene is shown in Fig. 3 with a clear-cut emission mode of the 20.6 ppm line. The low CIDNP intensity of the aromatic *C*-methyl signals might be due to short spin-lattice relaxation times of these carbon atoms as a result of spin rotation mechanisms available for the methyl groups. On the other hand, those methyl groups originating from the methyl radical of the radical pair III (Scheme 2) show reasonable enhancement factors. This is true for the *N*-methyl carbon of **4a** and for the 2-methyl group of **5a**, which are clearly detected as being in enhanced absorption in or close to the region of the solvent signals. Consequently, lower ^{13}C-hyperfine coupling constants a_i of the aromatic methyl carbon atoms in arylaminyl radicals with

a) Shifts are given in δ ppm from internal TMS; TCE=1,1,2,2-tetrachloroethane, DC=*trans*-decalin, DCB=1,2-dichlorobenzene; w=weak, vw=very weak, s=strong. b) *A*: 25.15 MHz spectra; *B*: 22.628 MHz spectra. c) The signal at 20.6—20.7 ppm is due to the overlap of the 4-methyl signals of **2** and **4a**. Thus it depends on small variations of the reaction conditions (solvent, temperature, concentration) whether it appears in weak emission or weak enhanced absorption.

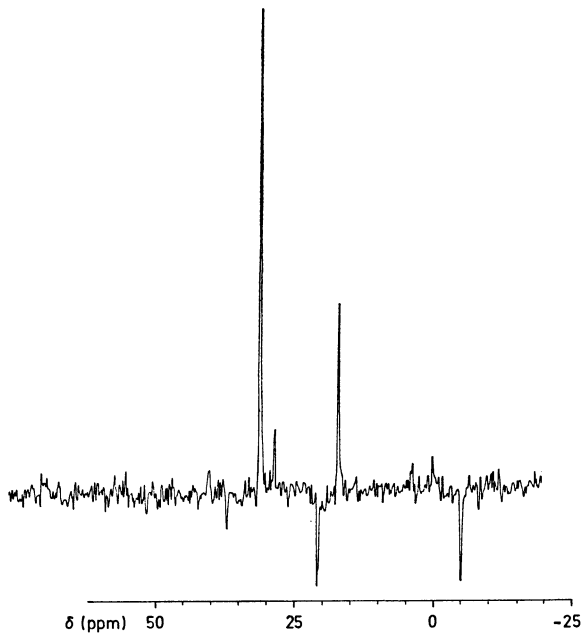

Fig. 3. The ^{13}C PFT CIDNP pattern of the aliphatic region of a reacting solution of **1a** in *o*-dichlorobenzene.

respect to a_{CH_3} seem to be mostly responsible for the low intensity.

The methane resonance at δ—5 is found in emission. In the case of ^{1}H–^{13}C coupled spectra the methane signal appears as a quintet (J_{H-C}=125 Hz) showing a relatively large Δg effect (superimposed multiplet and net effect) which seems to be reasonable (*vide infra*).

In the aromatic region the spectrum is more complicated. All the observed resonances can, however, be assigned to compounds **2**, **4a**, and **5a**, already determined by ^{1}H-CIDNP as recombination and escape products. The signs of polarization at C-1, C-2, C-3, and C-4 for *p*-toluidine **2** are E, A, E, and A, respectively. The positionally alternating signs are inversed in *N*-methyl-*p*-toluidine **4a**. In striking contrast to the methyl carbons, we note that, while the aromatic C-1 and C-4 are the weakest in the thermally equilibrated spectra because of the lack of the nuclear Overhauser effect under wide-band proton decoupling, these carbons show strongest polarization (see Table 3). The greater T_1 values for these quaternary carbons are considered mainly to be responsible for the apparent increase in enhancement. The enhancement factors of the ^{13}C-signals of toluene **3b** are small; the effect cannot always be reproduced. ^{13}C-signals of **6a** could not be

a) Shifts are given in δ_{ppm} from internal TMS; resonance frequency 25.15 MHz; TCE=1,1,2,2-tetrachloroethane, DC=*trans*-decalin; w=weak, vw=very weak, s=strong. b) Numbering of the *N*-benzyl ring: N-CH_2- 
detected, which is not unreasonable due to the small amount of **6a** present and to the unknown line positions.

The ^{13}C-CIDNP results obtained on **1b** (Table 4, Fig. 4) support our findings with **1a**, although the spectrum is more complicated, since R in Scheme 2 is now $CH_2C_6H_5$. The signals of **6b** could not be assigned so far.

c) Product Analyses. A typical thermolysis of a 0.33—0.39 M solution of **1a** in decalin at 130 °C gives the following products as revealed by VPC analyses: *p*-toluidine (**2**), 38%; *N*-methyl-*p*-toluidine (**4a**), 11%; toluene (**3b**), 4%; 2,4-dimethylaniline (**5a**), 5%. The intensities of further peaks in VPC are not greater than 0.9%. Therefore, the cyclohexadienimine **6a** is formed in yields <1%. An experiment performed in 1,2-dichlorobenzene as solvent (0.33 M) showed the following product analysis: **2**, 40%; **4a**, 13%; **3b**, 2%; **5a**, 7%. Ditolylamine and bitolyl derivatives were difficult to determine by VPC; bibenzyl was not detected.

p-Azotoluene could be isolated by preparative thin-layer chromatography in 3—4% yield (thermolysis in 1,2-dichlorobenzene). Methane was determined volumetrically together with nitrogen evolved. Provided that 96—97% of the theoretical amount[9a] of nitrogen is formed, the yield of methane can be calculated to be about 44—45% (in decalin) and 11—12% (in 1,2-dichlorobenzene).

d) Mechanistic Implications. Chemical Aspects: While the thermal decomposition of 1,3-diaryltriazenes has been thoroughly reported,[10] little is known on the mechanism of similar reactions of 3-alkyl-1-aryltriazenes,[11] aside from kinetic measurements and a study of gaseous products.[9b] All the results of our present work appear to be well interpreted in terms of Scheme 2; the tautomeric form **1′** decomposes to give *p*-tolylaminyl-methyldiazenyl radical pair. Elimination of nitrogen molecule from the latter component of the pair should be very facile ($\geq 10^7$—10^9 s^{-1}) and leads to *p*-tolylaminyl-alkyl radical pair IV $\overline{p\text{-}CH_3\text{-}C_6H_4\text{-}NH\cdot}$ $\cdot\overline{R}$. There are three positions available for the *p*-tolylaminyl radical to cage-recombine with the alkyl radical as shown in Scheme 3 by the canonical structure of the former. The first one should lead direct to *N*-alkyl-*p*-toluidine **4**. The other two are expected to

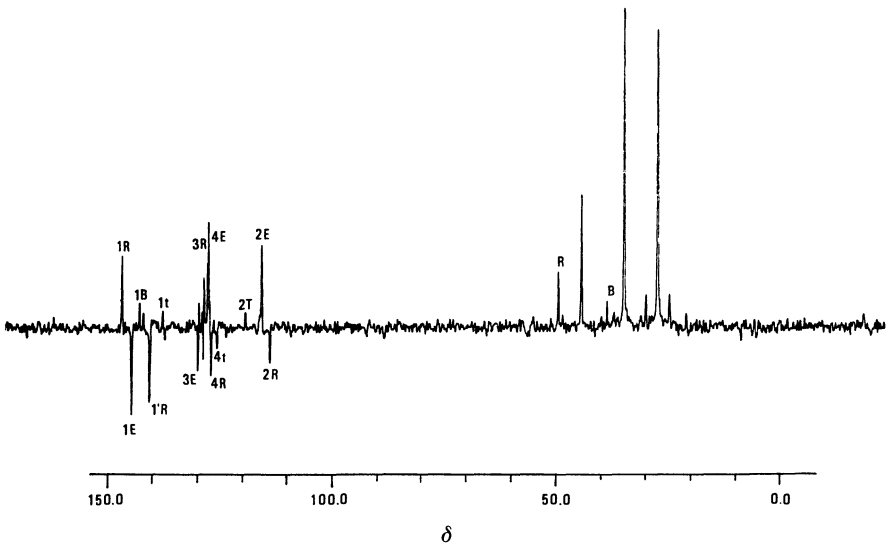

Fig. 4. ^{13}C-CIDNP spectrum (25.15 MHz PFT) of a decomposing solution of 3-benzyl-1-*p*-tolyltriazene **1b** in decalin at 125 °C.

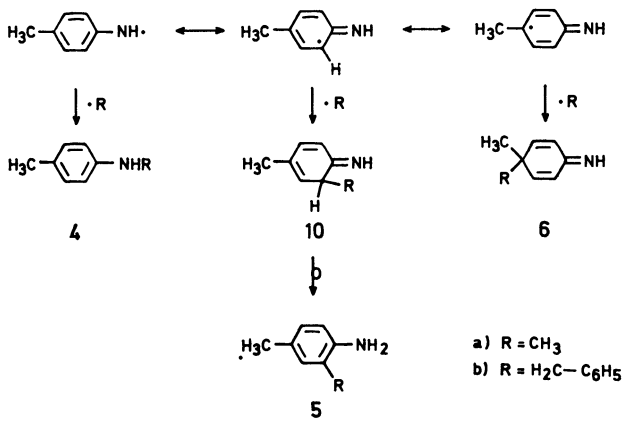
give the corresponding cyclohexadienimines **6** and **10**. The 2-alkyl-4-methyl derivative out of these two appears to be susceptible to 1,3-prototropy under the experimental conditions to form 2-alkyl-4-methylaniline **5** as the final product. This 1,3-prototropy must be much faster than the relaxation time (spin-lattice) of the protons.[12] Thus the memory of polarization in pair IV is transferred to the rearranged **5**, while the steady-state concentration of **10** is considered too low to be detected by NMR even if intensities of their signals might be enhanced by CIDNP.

p-Tolyl-alkylaminyl radical pair II $\overline{p\text{-}CH_3\text{-}C_6H_4\cdot \cdot NHR}$ in Scheme 1 cannot explain the formation of



Scheme 3.

these two recombination products (**5** and **10**). The predominant formation of *p*-toluidine **2** instead of toluene in thermolysis of **1a** as one of the escape products is also consistent with Scheme 2. Our mechanistic interpretation that **1** decomposes *via* its tautomeric 1-alkyl-3-aryltriazene form **1'** is further supported by the thermal stability of 1-*p*-tolyl-3,3-dimethyltriazene which decomposes only at 245—250 °C[3] in contrast to 120—130 °C of **1**. The formation of a more stable arylaminyl radical as compared to methylaminyl radical is considered to be a driving force of the reaction going by way of **1'**. The thermochemically calculated N–H bond dissociation energies of aniline and methylamine are 92.3 and 97.8 (105.0 observed) kcal/mol,[13] respectively, supporting the above explanation.

The formation of toluene in 2—5% yield (as compared to 36—38% of *p*-toluidine **2** in thermolysis of **1a**) might indicate the small contribution of Scheme 1 to these reactions; toluene could then be formed by escape of *p*-tolyl radicals from the cage II $\overline{p\text{-}CH_3\text{-}C_6H_4\cdot \cdot NHCH_3}$ followed by abstraction of the hydrogen atom from solvents. On the other hand, we have precedents for the formation of arenes either by the following induced decomposition reaction of triazenes[14a]

$$Ar\text{-}N{=}N\text{-}NRR' + Et_3Sn\cdot \longrightarrow Ar\cdot + N_2 + Et_3Sn\text{-}NRR'$$

$$Ar\cdot + Et_3SnH \longrightarrow Ar\text{-}H + Et_3Sn\cdot$$

or by the thermolysis[14] of a pentaza-1,4-diene[Ar–N=N–N(CH_3)–N=N–Ar] which could be formed under the reaction conditions.

Discussion on CIDNP: According to the theory of S-T_0 transitions in the radical pair models of CIDNP,[15] the sign of polarization is given by $\mu\cdot a_i\cdot \Delta g\cdot \varepsilon$, where Δg is the difference in the *g* factors in the radical pair, a_i is the hyperfine coupling constant of ^1H and ^{13}C of interest, μ is minus for singlet precursors and plus for triplet and random phase reactions, and ε is taken as

Table 5. Isotropic hyperfine coupling constants; signs as determined by CIDNP

a) Calculated values taken from Ref. 18, signs taken from Ref. 15. b) Average of H-2, H-3, H-4, the signals of which coincide. c) CIDNP signals coincide with those of other C-atoms. d) The values of the unsubstituted phenylaminyl radical taken from Ref. 17. e) Estimated from $\rho^{\pi}_{C-4}=0.179$ in Ref. 17.

plus for cage recombination and minus for escape products. In $\overline{p\text{-}CH_3C_6H_4NH\cdot\cdot R}$ the arylaminyl radical has a larger g value (*ca.* 2.0030[16,17]) than the alkyl counterpart $R\cdot$ ($g_{CH_3}=2.0026$,[18] $g_{CH_2-H_5C_6}=2.0025$[17]). The pertaining hyperfine coupling constants available from literature ESR data and/or estimated from calculations are summarized in Table 5.

The sings for $\cdot CH_3$, and $H_3CC_6H_4NH\cdot$ (thermolysis of **1a**) derived from CIDNP correspond nicely to the calculated ones (Table 5), thus providing an experimental proof for the sign of hfs which can otherwise be difficult to determine experimentally.[19] To the best of our knowledge, the sings and values of a_i for *p*-tolylaminyl itself do not appear to have been determined by other methods.[20]

The observed proton enhanced absorption and carbon emission for *methane* are due to opposite a_i sign (negative for hydrogen and positive for carbon) in the methyl radical. When CIDNP signal is emission in *p*-toluidine **2**, the corresponding nucleus in *N*-methyl-*p*-toluidine **4a** shows a signal of enhanced absorption. The contrasting sign inversion of polarization is interpreted in terms of recombination *vs.* escape products: different sign in ε. The positional sign alternation clearly demonstrated in C-1 through C-4 of **2** and **4a** corresponds to sign alternation in the hyperfine coupling as shown in Table 5.

While *N*-methyl-*p*-toluidine **4a**, 2,4-dimethylaniline **5a** and 4,4-dimethylcyclohexa-2,5-dien-1-imine **6a** which are considered to be derived from the same cage are formed in a ratio of about 1 : 0.5 : 0.08, the observed relative intensities of their proton emission signals due to the entering methyl group are 1 : 9.3 : 2.6. This means that the enhancement factor for the *N*-methyl group of *N*-methyl-*p*-toluidine should be unduly small. The trend may be ascribed to smaller T_1 value of these protons due to quadrupole relaxation by the nitrogen atom.

The toluene formed from **1a** shows clear-cut CIDNP (emission) only of C-4. This would be compatible with Scheme 1, since only C-1 (this position is C-4 in toluene) of *p*-tolyl has a large (positive) a_i value.[24] A weak enhanced absorption, sometimes observed for the methyl protons, may be also explained by a *p*-tolyl σ-radical ($a_{CH_3}=2.4$ G[25]). The *delayed emission* for the aromatic protons of toluene in 1,1,2,2-tetrachloroethane (TCE) may be considered as being derived from a secondary decomposition reaction of the intermediately formed azo compounds, *e.g.* $p\text{-}CH_3C_6H_4\text{–}N{=}N\text{–}X$ in which X will be a fragment or some combination of TCE employed as a solvent. The polarized methyl chloride observed in TCE must also emanate from a secondary pair, since simple chlorine abstraction by polarized methyl radicals escaped from pair IV should result in the opposite CIDNP sign.

The hyperfine signs derived from the CIDNP observed in the thermolysis of **1b** again support Scheme 2 with respect to *p*-tolylaminyl and benzyl radicals (Table 5). Only an effective sign of averaged hyperfine coupling can be obtained on the ring protons of the benzyl radical since these protons show singlets in the products, **4b**, **5b**, and **8**. There is a deviation, however, for the aromatic protons of the later-appearing toluene. Applying the Kaptein rules, one would expect from the observed emission an average plus sign for the a_i values of H-2, H-3, H-4 of benzyl. However, according to the MO calculations (Table 5) and the observations on **4b**, **5b**, and **8**, the overall sign should be negative. A

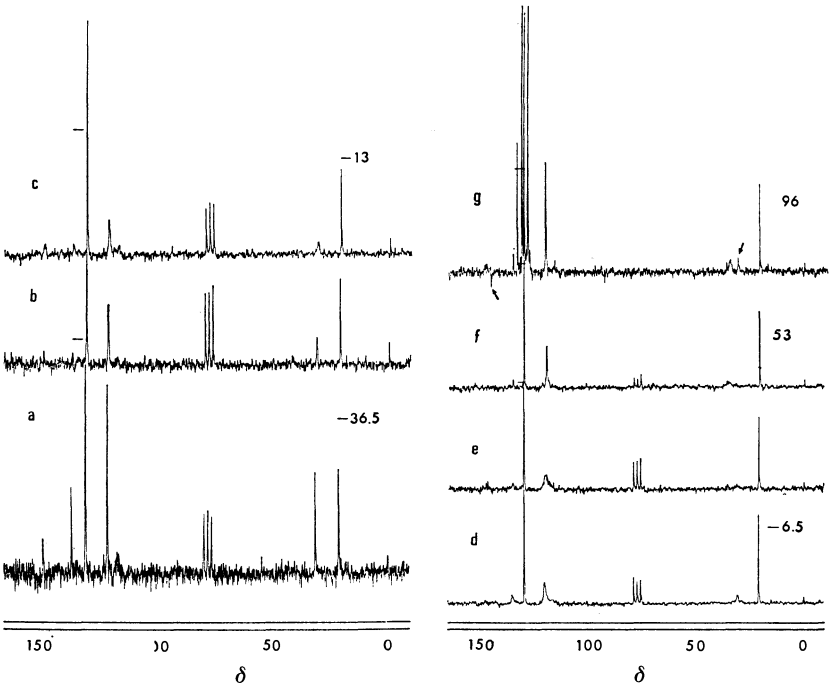

Fig. 5. ^{13}C-NMR spectra (20.1 MHz) of 3-methyl-1-*p*-tolyltriazene **1a** in $CDCl_3$ at various temperatures: (a)—(f) in $CDCl_3$ and (g) in *o*-dichlorobenzene.
The arrows in (g) show CIDNP signals already coming out.

reasonable explanation stems from the fact that the above mentioned effect can be observed only in TCE. Obviously in this solvent some of the reaction products (*e.g.* **3b**) can be formed *via* different pathways (see also discussion of methyl chloride formation in thermolysis of **1a** in TCE). In the reaction path *via* pair IV (R= CH_2Ph) especially the nuclei in the recombination products **4b** and **5b** and in bibenzyl **8** are polarized, whereas in some other reaction (not involving the benzyl radical) the ring protons of the later-formed toluene are polarized preferentially. One candidate for a radical component in such a pair would be the *p*-tolyl radical (ring proton hfs signs expected to be >0; ring carbon hfs signs the same as in the benzyl radical).[24]

e) Tautomerism in ***1a*** The occurrence of tautomerism in **1a** assumed to account for the chemical product formation and CIDNP in the thermolysis of this compound has been independently confirmed by IR-[26] and ^{1}H-NMR[27] spectroscopy. An additional support has been obtained in this work by the temperature dependent ^{13}C-NMR spectra. As shown in Fig. 5, all the ^{13}C signals (due to **1a**) are sharp at −36.5 °C in $CDCl_3$ and consistent with structure **1a**, namely, 1-*p*-tolyl-3-methyltriazene. The singlets due to *N*-CH_3, C-1, C-2, and C-4 start to broaden at about −25 °C. This broadening is so effective that *N*-methyl and C-1 carbons cannot be seen at 2—53 °C. Only the singlet at δ 129.4 due to C-3 remains constant in its peak height. The *N*-methyl signal becomes again observable at temperatures only higher than 60 °C. The position is, however, shifted to the lower field by 3.9 ppm, indicating the enhanced rate of prototropy and increase in the population of tautomeric 1-methyl-3-*p*-tolyltriazene structure **1a'** at higher temperatures. Closer inspection of the spectrum at −36.5° (Fig. 5) reveals that there is an additional weak singlet at δ 54.0 which could be due to *N*-methyl carbon of **1a'**. In the case of the signal of C-2 (120.0 ppm) we note at −36.5 °C a "satellite" of very low intensity on the highfield side (115.6 ppm) which might be attributed to C-2 of **1a'**. At about 2 °C the two signals coalesce and at 53 °C we observe the fast exchange singlet at 119.1 ppm.

f) CIDNP, its Advantages and Limitation in Mechanistic Studies. ^{1}H- and ^{13}C-CIDNP investigations have shown that triazenes **1** may thermolyse *via* the tautomeric form **1'** and that radical pairs like IV can be intermediates, thus qualitatively proving the conclusions drawn from chemical product analysis. It is even possible to give the hfs signs of carbon and hydrogen atoms of *p*-tolyl-aminyl unambiguously, although no ESR spectrum of this radical has been measured.

New reaction paths, hitherto not taken into account,[9] *e.g.* formation of **5** and **6**, were discovered. One of these compounds, **6**, still resists chemical isolation and separate preparation untill the present day. On the other hand, the CIDNP technique of a level employed in this study does not necessarily give quantitative account of the decomposition of all the triazene molecules. The chemical product analyses of the thermolysis of **1a** show a large excess of "escape" products, **2** and **3a**, over the "recombination" products **4a**, **5a**, **6a**. The formation of methane **3a** (0.33 M solution of **1a**) depends a great deal on the solvent used: 46% (in decalin) and 12% (in tetrachloroethane). This effect has also been found for other 3-alkyl-1-aryltriazenes in solvents of the corresponding hydrogen donating ability.[9b] The amount of *p*-toluidine **2** does not differ much in decalin and tetrachloroethane. This indicates that a part of the reaction might proceed *via* ionic pathways induced by traces of water or acid present in the system.[27,28]

We would like to add that, whereas it is difficult to interpret our CIDNP data in terms of pair III only, we were not able to disclose the positive role of the methyldiazenyl radical in Scheme 2. If there is an internal return to **1'** by recombination, it is usually the case in which CIDNP is detected in the starting material as exemplified by the photolysis of phenylazocumene.[29] Our failure to detect CIDNP in the starting material may be due to a shorter life-time of the methyldiazenyl as opposed to the phenyldiazenyl radicals. Either prototropic tautomerism in the starting materials (*vide supra*) or quadrupole relaxation due to the nitrogen atoms could also be responsible for making the possible CIDNP effect in **1** obscure.[30]

We wish to thank the Japan Society for the Promotion of Science and Deutscher Akademischer Austauschdienst for the awards of visiting professorship to A. R. (1973 in Tokyo) and to H. I. (1974 in Tübingen), respectively. The cooperative research reported here was made possible through grants from the Ministry of Education, Science and Culture of Japan and from Founds der Chemischen Industrie.

Multifunctional Hydrolytic Catalyses. V. The Reaction of *o*-Substituted Benzohydroxamic Acids and *p*-Nitrophenyl Acetate[1]

Toyoki KUNITAKE, Yoshio OKAHATA, Reiko ANDO, and Sumio HIROTSU

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received March 22, 1976)

Salicylohydroxamic acid(SHA), *N*-methylsalicylohydroxamic acid(MSHA), and *N*-methylphthalohydroxamic acid(MPHA) were prepared and their acylation reactions with *p*-nitrophenyl acetate were studied in aqueous ethanol at 30 °C. Both the acidity and nucleophilicity of the hydroxamic acid group were affected by the functional *ortho*-substituents(–OH, –COOH). In particular, the undissociated hydroxamic acid group in the MPHA monoanion possessed nucleophilic reactivity. This was brought forth by the general base assistance of the adjacent carboxylate group, as confirmed by the presence of the solvent isotope effect of $k^H/k^D=2.5$. Only the hydroxamate anion acted as the nucleophile in all other cases.

At the active site of serine proteases, the nucleophilic reactivity of the seryl hydroxyl group is enhanced by hydrogen bonding with the aspartic carboxylate *via* the histidyl imidazolyl group.[2] We prepared several catalytic compounds which possess the hydroxamate and imidazole functions as model serine proteases, and employed them for the hydrolysis of phenyl esters.[3-5] In these systems, acylation by phenyl esters occurs at the hydroxamate site without assistance of the neighboring imidazolyl groups. The latter function is involved only in the deacylation process.

The juxtaposition of two functional groups at the hydrogen-bonding distance would be advantageous for realization of the simultaneous involvement of these functional groups in a single reaction step. The two functional groups at the *ortho* position of the benzene ring can form intramolecular hydrogen bonding as in salicylic acid and phthalic acid. It should be interesting to prepare benzohydroxamic acid derivatives with *ortho*-substituents having hydrogen-bonding capacity and to investigate their catalytic behavior, in connection with the multifunctional character of the acylation process of serine proteases.

The *o*-substituted benzohydroxamic acids employed in this study are salicylohydroxamic acid (SHA), *N*-methylsalicylohydroxamic acid (MSHA), and *N*-methylphthalohydroxamic acid (MPHA). The nucleophilic reactivity of these compounds was compared with those of unsubstituted counterparts, benzohydroxamic acid (BHA) and *N*-methylbenzohydroxamic acid (MBHA).

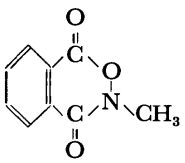
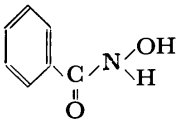
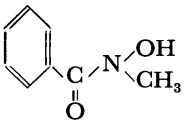
MPHA



MPHA anhydride



BHA



MBHA

Experimental

Materials. *p*-Nitrophenyl acetate was prepared by acylation of *p*-nitrophenol with acetic anhydride and recrystallized from cyclohexane, mp 78 °C (lit,[6] mp 81—82°C).

Salicylohydroxamic acid was prepared from salicyloyl chloride (bp 62 °C/12 mmHg) and hydroxylamine. The crude product was purified in the form of the copper chelate and then recrystallized from water, mp 161—162 °C (lit,[7] mp 169 °C).

N-Methylsalicylohydroxamic acid was similarly prepared in chloroform in the presence of triethylamine from salicyloyl chloride and *N*-methylhydroxylamine. The crude product was purified in the form of the copper chelate, and then recrystallized from water, mp 133—135 °C(lit,[7] mp 136 °C).

N-Methylphthalohydroxamic acid anhydride was synthesized as follows: 14 g (0.1 mol) of phthalic anhydride, 18 g (0.21 mol) of *N*-methylhydroxylamine hydrochloride and 23 g (0.25 mol) of triethylamine were dissolved in 300 ml of dry DMF and heated for 30 min at 100 °C. Then solvent was removed *in vacuo* and the residual oil was extracted with hot cyclohexane. Colorless flakes separated upon cooling, mp 120 °C. Yield, 40—60%. Found: C, 61.10; H, 3.98; N, 8.01%. Calcd for $C_9H_7NO_3$: C, 61.02, H, 3.98; N, 7.91%.

Determination of pK_a. The pK_a values for the hydroxyl and hydroxamic acid groups were determined by the potentiometric titration and the UV spectrophotometric titration at 0.1 M KCl, 30 °C in 28.9 v/v% EtOH–H_2O.

The pK_a value of the hydroxamic acid group of SHA was determined by the potentiometric titration of 0.01 M SHA with 0.1 M NaOH, using Eq. 1.

$$pK_a = pH + \log\frac{1-\alpha}{\alpha} \quad (1)$$

where α is the degree of dissociation. The pK_a value of the hydroxyl group in SHA was determined by UV spectrophotometric titration at 330 nm, using Eq. 2.

$$pK_a = pH + \log\frac{OD_I - OD}{OD - OD_M} \quad (2)$$

where OD_M and OD_I are absorbances at 330 nm of the undissociated and dissociated phenolic hydroxyl groups, respectively, and OD is the absorbance (330 nm) at a given pH. OD_I was obtained by extrapolation of OD values at pH 10—12[5,8] and OD_M was obtained at pH 9: $OD_I=0.516$ and $OD_M=0.290$.

The two pK_a values for MSHA were similarly determined using OD_I (330 nm)=0.506 and OD_M (330 nm)=0.480.

The pK_a of the hydroxamic acid group of MPHA was determined by the potentiometric titration (Eq. 1). The

pK_a of the carboxylic acid group could not be determined by the conventional procedure, because MPHA was readily hydrolyzed to phthalic acid at pH<6. The $pK_{a,HA}$ of MPHA in the deuterated solvent was determined by potentiometric titration in 28.9 v/v% EtOD-D_2O at 30 °C, μ=0.1 with 0.1 M KOH in D_2O: $pK^D_{a,HA}$=9.80±0.15. The pD values were taken as the pH meter readings plus 0.40 at 30 °C.[9]

Rate Measurements. The reaction of PNPA with hydroxamic acids was carried out in the presence of large excesses of the latter, and the formation of *p*-nitrophenolate anion was followed at 401 nm. The reactions obeyed the pseudo-first-order kinetics. The rate constant k_{total} was determined from absorbances of *p*-nitrophenolate at time *t*, OD_t, and at the infinite time, OD_∞. When the reaction was slower, k_{total} was obtained from Guggenheim plots[10] of up to 2—3 half-lives. The apparent second-order rate constant of acylation, $k_{a,obsd}$ was calculated from the rate constants of total and spontaneous hydrolyses.

$$k_{a,obsd} = \frac{k_{total} - k_{spont}}{[HA]_T} \quad (3)$$

where $[HA]_T$ is the total concentration of hydroxamic acids. The hydrolysis condition is 28.9 v/v% EtOH-H_2O, 30 °C, μ=0.1 (KCl) and pH 6.5—9.5. Phosphate, Tris, and Barbital buffers were used.

The reaction of MPHA and PNPA in the deuterated medium was studied at 30 °C, μ=0.1 (KCl), pD 7.1—9.2 in 28.9 v/v% EtOD-D_2O. The buffer solution was prepared from sufficiently dried Tris and commercial 30% DCl in D_2O.

Instruments. Electronic spectra were obtained with a Hitachi 124 UV-visible spectrophotometer equipped with a thermostated cell compartment. A Toa digital pH meter (Model HM-15A) was employed for the pH measurement, and a Toa pH stat system was used for the potentiometric titration. The reaction rates were calculated using a programmable desk calculator Compet 364P. The least-squares method was used wherever possible. The correlation coefficient was better than 0.99 unless stated otherwise.

Results

pK_a Values. The pK_a value of the hydroxamic acid group is considerably influenced by the *ortho*-substituent, as summarized in Table 1. The $pK_{a,HA}$ value of SHA, 7.90, is lower than that of benzohydroxamic acid by 1.45 pK_a units. This is attributable to the stabilization of the monoanionic species SHA^- by the intramolecular hydrogen bonding, as already considered in order to explain the pK_a difference between the carboxyl groups of salicylic acid and benzoic acid ($pK_{a,COOH}$=2.98 and 4.21 respectively, in water, 25 °C)[11] The $pK_{a,OH}$ value of SHA, 10.3, is close to those of phenol and *m*-hydroxybenzoic acid (9.95 and 9.74, respectively, in water, 25 °C),[12] in spite of electrostatic repulsion of the neighboring hydroxamate anion. This may be explained by the stabilization of the dianionic species due to hydrogen bonding. In accord with this view, $pK_{a,OH}$(=12.7) for MSHA which cannot form hydrogen bonding is much higher and is close to that of salicylic acid ($pK_{a,OH}$=13.0[13] in

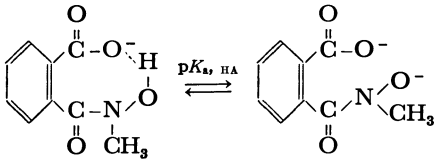
water, 25 °C). The lower $pK_{a,HA}$ value of MSHA relative to that of MBHA (6.70 and 8.59,[14] respectively) again suggest the hydrogen-bonding stabilization of the monoanionic species.

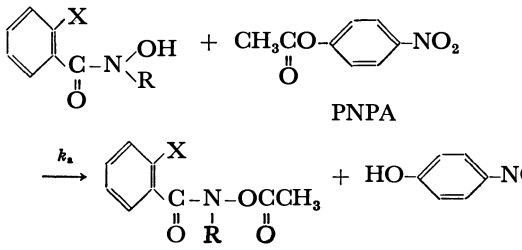
The higher $pK_{a,HA}$ value of MPHA relative to that of MBHA (9.50 and 8.60, respectively) may be caused by stabilization of the monoanionic species by the intramolecular hydrogen bonding or by the electrostatic repulsion in the dianionic species.



(6)

Hydrolysis of MPHA Anhydride. MPHA anhydride is readily converted to the ring-opened derivative, MPHA, in acidic and alkaline solutions. Furthermore, MPHA is easily hydrolyzed to phthalic acid at pH<*ca.* 6 due to the general acid catalysis of the neighboring carboxyl group. This hydrolysis is complete in less than 3 h at pH 4.5, 30 °C. The MPHA anhydride shows an absorption maximum at 294 nm (ε=2520) in CH_3CN. The ring-opened product gives ε=230 at 294 nm, pH 8.57. The absorbance difference at 294 nm was used to follow the ring opening reaction, and the apparent first-order rate constant was calculated from the ordinary first-order plot. The experiments carried out at four concentrations of MPHA anhydride (1.0, 2.0, 3.0, and 4.0×10^{-4} M) gave the following rate constant: $k_{obsd}=(1.89\pm0.04)\times10^{-2}$ s^{-1} in 1.4 v/v% CH_3CN–H_2O, 30 °C, μ=0.1 (KCl), pH 8.57, 0.1 M Tris buffer.

Reaction of PNPA with o-Substituted Benzohydroxamic Acids. The reactions of PNPA (10^{-4} M) with *o*-substituted benzohydroxamic acids (10^{-2}—5×10^{-4} M) were carried out in 28.9 v/v% EtOH–H_2O in the pH range of 6.5 to 9.5.



(7)

The apparent second-order rate constant $k_{a,obsd}$ was calculated according to Eq. 3. The pH-rate profiles are given in Fig. 1. If the hydroxamate anion is the only nucleophile, the profile is composed of an ascending limb (slope=1) and a plateau. However, this is not the case for most of the *o*-substituted benzohydroxamic acids. These anormal behavior is more clearly seen in the plot of $k_{a,obsd}$ against α_{HA} (degree of dissociation of hydroxamic acid) given in Figs. 2 and 3.

In Fig. 2, the plots for BHA give a straight line which passes the origin. This indicates that the hydroxamate anion acts as the nucleophile, as have been shown for a variety of simple hydroxamic acids.[15–18] On the other hand, the plots for SHA give a linear relation up to

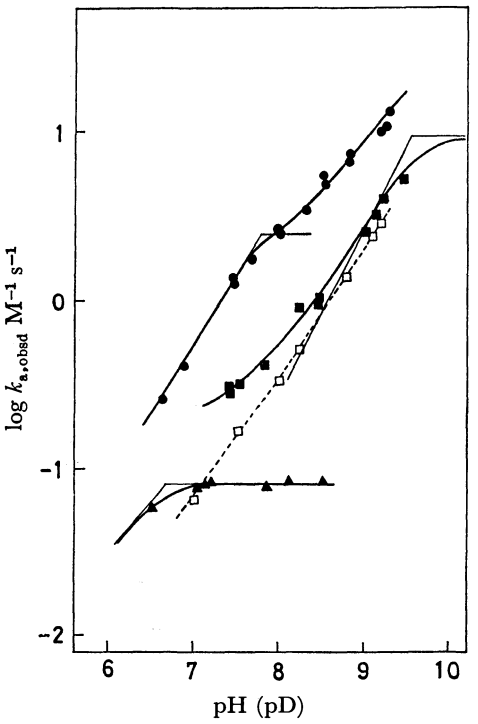


Fig. 1. pH-rate profile of the reaction of PNPA with *o*-substituted benzohydroxamic acids. Reaction Condition; 30 °C, μ=0.1 (KCl) in 28.9 v/v% EtOH–H_2O ●; SHA, ■; MPHA, ▲; MSHA in 28.9 v/v% EtOD–D_2O □; MPHA.

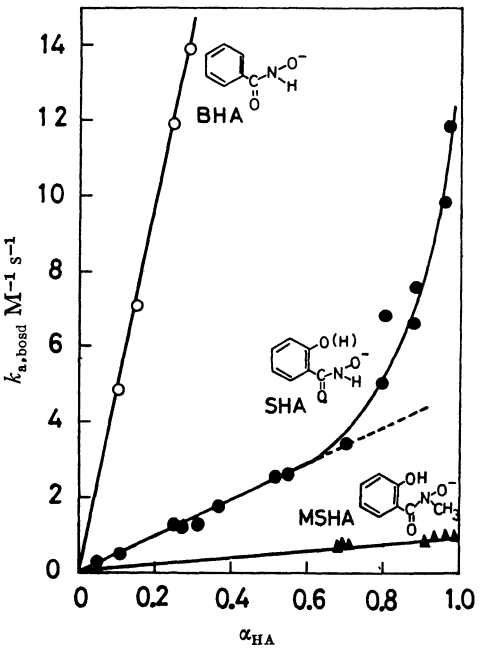

Fig. 2. Reaction of PNPA with some hydroxamic acids. Reaction condition: 28.9 v/v% EtOH–H_2O, 30 °C, μ=0.1 (KCl), 0.15 M Barbital buffer.

$\alpha_{HA}\approx0.5$, and then show a steep rise. The slope of the steeper portion is close to that of BHA.

SHA can exist in three forms: neutral, monoanionic and dianionic species (Eq. 4). Since the linear portion of the $k_{a,obsd}$–α_{HA} relation passes the origin, the neutral species cannot be reactive, and the apparent

rate constant will be composed of the monoanionic and dianionic terms as follows:

$$k_{a,obsd} = k_{A^-}\left[\frac{\alpha_{HA}(1-\alpha_{OH})}{1-\alpha_{OH}(1-\alpha_{HA})}\right] + k_{A^{2-}}\left[\frac{\alpha_{HA}\cdot\alpha_{OH}}{1-\alpha_{OH}(1-\alpha_{HA})}\right] \quad (8)$$

where k_{A^-} and $k_{A^{2-}}$ are second-order rate constants for the monoanionic and dianionic species, respectively. α_{HA} and α_{OH} are degrees of dissociation of the hydroxamic acid and phenol groups, respectively.

The solid curve for SHA was calculated from Eq. 8 using pK_a values of Table 1 and by assuming appropriate k_{A^-} and $k_{A^{2-}}$ values. The best fit with the experimental data was obtained for $k_{A^-}=4.85\ M^{-1}\ s^{-1}$ and $k_{A^{2-}}=60\ M^{-1}\ s^{-1}$.

A similar situation may as well exist for MSHA. However, the $k_{a,obsd}-\alpha_{HA}$ relation for this hydroxamic acid is simple as shown in Fig. 1. This is explained by the fact that $pK_{a,OH}$ of MSHA is rather high (12.7) and that the dianionic form is virtually nonexistent in the pH range employed (pH 6.5—8.5). The k_{A^-} value calculated from the slope is $0.080\ M^{-1}\ s^{-1}$.

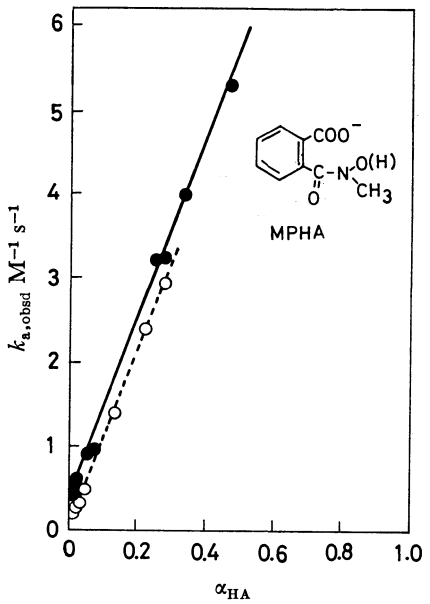

Fig. 3. Reaction of PNPA with MPHA. Reaction condition; 30 °C, μ=0.1 (KCl)
●; 28.9 v/v% EtOH–H_2O, 0.15 M Tris
○; 28.9 v/v% EtOD–D_2O, 0.1 M Tris

Figure 3 gives $k_{a,obsd}-\alpha_{HA}$ relations for MPHA in undeuterated and deuterated media. Two linear relations are obtained with different intercepts. The fact that positive intercepts were observed suggests that the undissociated hydroxamic acid possesses nucleophilic reactivity. Since the concentration of the neutral MPHA species is negligible based on the estimated $pK_{a,COOH}$ value (see Table 1), the apparent rate constant is given by

$$k_{a,obsd} = k_{A^-}\cdot\alpha_{HA} + k_{HA}(1-\alpha_{HA}) \quad (9)$$

where k_{A^-} and k_{HA} are second-order rate constants for $MPHA^{2-}$ and $MPHA^-$ species, respectively (Eq. 6).

The k_{A^-} and k_{HA} values were calculated using the slopes and intercepts of the linear relations, and the deuterium solvent kinetic isotope effects were calculated as listed in Table 2.

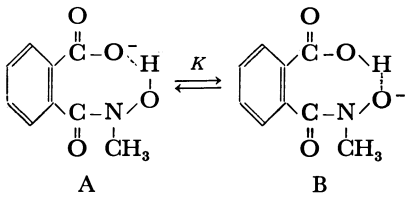
Table 2. Deuterium solvent isotope effects in the reaction of PNPA with MPHA[a]

	Solvent: 28.9 v/v% EtOH–H_2O	Solvent: 28.9 v/v% EtOD–D_2O	k^H/k^D
k_{A^-}[b]	$10.8\ M^{-1}\ s^{-1}$	$10.6\ M^{-1}\ s^{-1}$	1.0
k_{HA}[b]	$0.22\ M^{-1}\ s^{-1}$	$0.088\ M^{-1}\ s^{-1}$	2.5

a) 30 °C, μ=0.1 (KCl), 0.1 M Tris buffer b) Calculated from Eq. 9.

Discussion

Acyl Transfer to Undissociated Hydroxamic Acid. The kinetic data summarized in Table 2 indicate that the monoanionic species of phthalohydroxamic acid, $MPHA^-$, possess nucleophilic reactivity toward PNPA. The following monoanionic species cannot be kinetically distinguished.



(10)

The reaction rates for species A and B are given, respectively, by

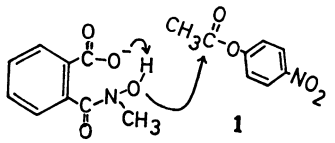
$$v_A = k_A[A][PNPA] \quad (11)$$

$$v_B = k_B[B][PNPA] = k_BK[A][PNPA] \quad (12)$$

where k_A and k_B are second-order rate constants for the respective species and K is the equilibrium constant.

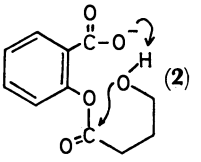
pK_a of *N*-methylbenzohydroxamic acid is 4—5 pK_a units higher than that of benzoic acid,[12] and a similar pK_a difference may be expected for the first ionizations of the two functional groups of MPHA. Then, K is estimated to be 10^{-4}—10^{-5}. If species B is solely responsible for the observed rate constant ($k_{HA}=0.22\ M^{-1}\ s^{-1}$), k_B must be as large as 2000—20000 $M^{-1}\ s^{-1}$. This value is too large for a nonmicellar hydroxamate anion.[19] Furthermore, if species B is the effective nucleophile, the observed isotope effect must arise from the general acid catalysis of the neighboring carboxylic acid. This is unlikely for a substrate with good leaving group (PNPA).

These arguments now establish species A as the effective nucleophile. The carboxylate-catalyzed cleavage of PNPA in unlikely, since its second-order rate constant is estimated to be *ca.* $10^{-6}\ M^{-1}\ s^{-1}$.[21] Therefore, the observed reactivity is explained as the nucleophilic attack of the undissociated hydroxamic acid assisted by the general base catalysis of the *ortho*-carboxylate group (**1**).



1

The solvent isotope effect observed ($k^{H}_{HA}/k^{D}_{HA}=2.5$, Table 2) is consistent with this mechanism. Although the observed isotope effect is by itself consistent with the direct general base catalysis of the carboxylate anion and buffer bases, this mechanism cannot explain the observed rate constant. The magnitude of this isotope effect is similar to that ($k^{H}/k^{D}=2.28$) found by Kirby and Lloyd for the general base catalysis of the neighboring carboxylate group in the hydrolysis of 2-carboxyphenyl 4-hydroxybutyrate (**2**).[22]



(2)

The solvent isotope effect was not observed for the reaction of the dianionic species, $MPHA^{2-}$, in agreement with the simple nucleophilic mechanism for the hydroxamate anion.

To our knowledge, the above mechanism (**1**) is the first example of the *intermolecular*, concerted nucleophilic attack on the ester carbonyl group. The reaction of simple hydroxamate anions with phenyl esters have been investigated extensively.[15-18] In all these cases, it was confirmed that only the anionic species were effective nucleophiles. This was also the case with bifunctional catalysts which contain hydroxamic acid and imidazole group[3,4,5,23,24] Apparently, the presence of the intramolecular hydrogen bonding as inferred from the pK_a data must render the concerted action more feasible.

Acyl Transfer to Hydroxamate Anion. It should be interesting to see how the *ortho*-substituent affects the reactivity of the hydroxamate anion. This question may be discussed in terms of the Brønsted relation. The Brønsted relation has been shown to hold true for several classes of hydroxamic acids.[15,17,26]

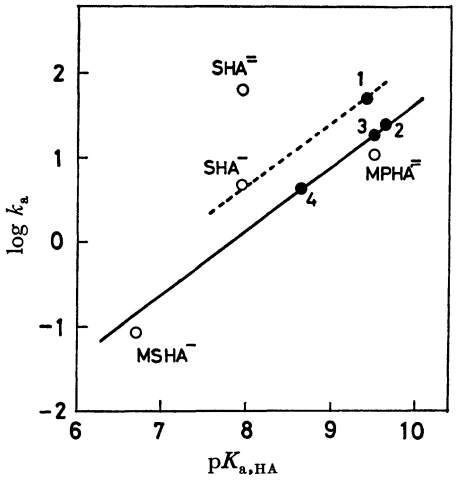


Fig. 4. Brønsted plots for the reaction of hydroxamic acids with PNPA.
Reaction condition; 30 °C, 28.9 v/v% EtOH–H_2O, μ=0.1 (KCl).
1; BHA, 2; *N*-phenylisobutyrohydroxamic acid, 3; *N*-benzylbenzohydroxamic acid, 4; *N*-methyl-α-naphthohydroxamic acid.

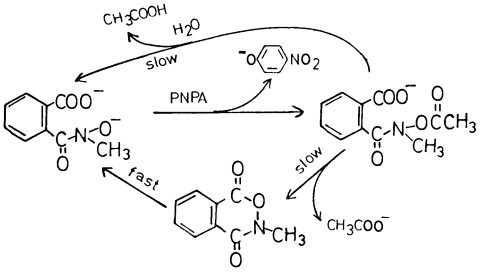
The solid line in Fig. 4 is obtained for several *N*-substituted hydroxamic acids with no additional functional groups and is given by

$$\log k_a = 0.68pK_a - 4.8 \quad (13)$$

The slope is the same as that reported by Hershfield and Bender[26] for some other *N*-substituted hydroxamic acids under a somewhat different condition. The plots for two *N*-methylhydroxamate anions, $MPHA^{2-}$ and $MSHA^{-}$, are located very close to this relation. The broken line is a tentative Brønsted relation for *N*-unsubstituted hydroxamic acids obtained by using the plot for BHA and the slope (0.72) found by Dessolin *et al.* for a series of *N*-unsubstituted hydroxamic acids under a different condition.[17] The plot for SHA^{-} agrees with this relation. This indicates that lowering of the nucleophilicity of SHA^{-} ($k_{A^-}=4.85\ M^{-1}\ s^{-1}$) relative to that of BHA ($k_{A^-}=50\ M^{-1}\ s^{-1}$) is accompained by the corresponding decrease in pK_a. Thus, the hydrogen bonding of the hydroxamate anion with the *ortho* hydroxyl group brought forth decreases of both of nucleophilicity and basicity.

In contrast, the plot for the dianionic form SHA^{2-} is considerably deviated: $k_{A^{2-}}$ is larger than expected from $pK_{a,HA}$. This may be explained as follows: (1) the nucleophilicity of the hydroxamate anion in SHA^{2-} is intrinsically greater than that of SHA^{-} or (2) the phenolate anion in SHA^{2-} is directly involved in the reaction besides the hydroxamate anion. The second-order rate constant of the reaction of PNPA and a phenoxide anion of $pK_a \approx 10$ has been estimated to be $0.97\ M^{-1}\ s^{-1}$ under a comparable condition.[21] This value is too small compared with the $k_{A^{2-}}$ value observed, and, consequently, the phenoxide anion cannot act as a nucleophile to any significant extent. Therefore, the increased reactivity is attributed to the increased nucleophilicity of the hydroxamate anion, which was probably caused by activation due to hydrogen bonding with the neighboring phenoxide anion (see Eq. 4).

Turnover of MPHA. MPHA is readily obtained as the cyclic anhydride. If the acyl hydroxamate intermediate is quickly converted to the cyclic compound with expulsion of the acetate ion, the catalytic cycle would be completed as below.



The first-order rate constant of the ring-opening step is $1.89\times10^{-2}\ s^{-1}$ at pH 8.57, and the apparent rate of acylation of MPHA is $(0.86—1.8)\times10^{-4}\ s^{-1}$ with PNPA of $(0.9—1.9)\times10^{-4}$ M under similar conditions. Therefore, the cyclic intermediate, if formed, would be readily converted to the reactive catalyst, and the ring opening process could not be rate-determining in the catalytic cycle.

However, the turnover of MPHA was not clearly observed when it was reacted with excess PNPA. This means that the deacylation step was negligibly slow. It was expected that the deacetylation rate would be enhanced by facile cyclization or by the general base catalysis of the *ortho*-carboxylate group. Unfortunately, both of these processes were proved to be insignificant. Attempted preparation of the acetyl derivative was not successful, and the separate determination of the rate of deacylation was impossible.

Reactions of Dihydridotetrakis(triphenylphosphine)ruthenium(II) with Olefins and Isolation of New Ruthenium-Olefin Complexes

Sanshiro KOMIYA and Akio YAMAMOTO

Contribution from Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 24, 1976)

Dihydridotetrakis(triphenylphosphine)ruthenium(II), $RuH_2(PPh_3)_4$, reacts with olefins (ethylene, propylene, styrene and butadiene) to give olefin-coordinated complexes of the type, $Ru(olefin)(PPh_3)_3$ and equimolar amounts of their hydrogenation products per mol of the dihydride complex. The olefin coordinated with ruthenium can be exchanged with other olefins. Olefin-coordinated complexes easily react with molecular hydrogen to afford tetrahydridotris(triphenylphosphine)ruthenium, $RuH_4(PPh_3)_3$, releasing alkane at room temperature. Under hydrogen atmosphere, catalytic hydrogenation of the olefins smoothly takes place with $RuH_2(PPh_3)_4$. (Ethylene)tris(triphenylphosphine)ruthenium(0) reacts with methyl iodide to give propylene and a trace of bu a-dien.e along with methane, ethylene, and small amounts of ethane and butenes. The formation of propylene suggests that oxidative addition involving cleavage of the C–H bond of ethylene to ruthenium giving a hydrido-vinyl complex may be taking place. Reactions of $Ru(C_2H_4)(PPh_3)_3$ with methyl-d_3 iodide and ethyl iodide, and of $Ru(C_3H_6)(PPh_3)_3$ with methyl iodide were examined to test the generality of this type of reaction. The reaction of $Ru(C_2H_4)(PPh_3)_3$ with CD_3I released CD_4 and CD_2H_2 together with CD_3H suggesting the involvement of α-hydrogen abstraction.

Recent progress in organo-transition metal chemistry has contributed to better understanding of the reaction mechanisms in various olefin catalysis with transition metals and their compounds. Study of properties of transition metal dihydride complexes[1] or transition metal complexes, which form dihydride complexes on reaction with molecular hydrogen,[2] has shed light on the detailed mechanism how an olefin coordinates to the transition metal hydride and is inserted between the metal-to-hydrogen bond. Dihydridotetrakis(triphenylphosphine)ruthenium(II),[3] **1**, has been found to serve as a particularly illustrative model compound of olefin catalyses, since it is itself catalytically active in hydrogenation, isomerization,[4] polymerization[5] and isotopic hydrogen exchange[6] of olefins, and on the other hand it gives many olefin-coordinated complexes on reactions with various olefins. We describe here characterization and properties of these olefin-coordinated complexes (ethylene, propylene, styrene and butadiene complexes) and the mechanism of formation of the olefin complexes from **1**. We have previously found that a seemingly simple olefin-coordinated complex with an apparent composition of Ru(alkyl methacrylate)$(PPh_3)_3$ was in fact a hydrido–propenyl type complex $RuH\{CH=C(CH_3)C(O)OR\}(PPh_3)_3$ which was formed by oxidative addition involving cleavage of C–H bond adjacent to the double bond.[7] Examination of the properties of the present olefin-complexes also revealed some features which may be best accounted for by assuming the contribution of a hydrido-vinyl type structure.

Results and Discussion

*Reactions of $RuH_2(PPh_3)_4$ **1** with Olefins.* The dihydridoruthenium complex **1** reacts with very electronegative olefins such as tetracyanoethylene and maleic anhydride to give stable olefin complexes[3] and initiates the polymerization of less electronegative vinyl compounds such as acrylonitrile, methacrylonitrile, acrylaldehyde and methyl acrylate.[5] Olefins such as ethylene, propylene, styrene and butadiene, on the other hand, react with **1** to give their hydrogenated products and ruthenium complexes containing these olefins.

$$\underset{\mathbf{1}}{RuH_2(PPh_3)_4} + \diagdown C{=}C \diagup \longrightarrow$$

$$Ru(olefin)(PPh_3)_3 + PPh_3 + \diagdown C{-}C \diagup \quad (H \text{ on } \diagup,\ H \text{ on } \diagdown)$$

2, olefin = ethylene
3, olefin = propylene
4, olefin = styrene
5, olefin = butadiene

These olefin-complexes **2**—**5** are thermally labile than complexes containing very electronegative olefins but can be isolated under appropriate conditions. Table 1 summarizes the analytical data, yields, NMR data and physical properties of the isolated complexes.

The reactions of ethylene, propylene and styrene with **1** proceed smoothly at room temperature to form quantitatively 1 equiv. of ethane, propane and ethylbenzene, respectively. The hydrogenation product of butadiene with **1** consisted of 1-butene and small amounts of *cis*- and *trans*-2-butene, the latters may be formed by isomerization of 1-butene catalyzed by **1**.[4] The molar ratio of the sum of the *cis*- and *trans*-2-butene to 1-butene decreased with increase in the amount of butadiene used in the reaction. The result also suggests that the isomerization of 1-butene was catalyzed by the remaining dihydride complex **1** and not by the butadiene-complex.

In the presence of a large excess of butadiene, **1** afforded an extremely soluble complex which could not be completely characterized but appears to contain two butadiene molecules coordinated with ruthenium.

Characterization of the Olefin-coordinated Complexes. The isolated complexes were characterized by means of elemental analysis, IR and NMR spectroscopy and chemical reactions.

None of the isolated olefin-complexes showed an IR

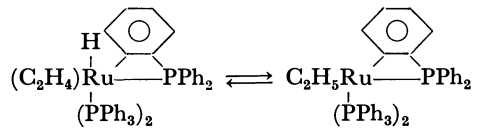
band ascribable to ν(Ru–H). Unambiguous assignment of the ν(C=C) band of the coordinated olefin was not feasible because the shift of the weak ν(C=C) band to lower frequency on coordination of the olefin to ruthenium makes it overlap with other strong bands due to triphenylphosphine.

a) Ethylene- and Propylene-coordinated Complexes: On iodolysis in benzene solution at room temperature complex **2** released one equiv. of ethylene, whereas thermolysis and acidolysis of **2** liberated ethane in addition to ethylene. The reaction product of **2** with acetic acid gave the known hydrido acetate complex $RuH(OAc)(PPh_3)_3$.[8] The formation of ethane in the acidolysis and thermolysis may be caused by intervention of an ethylruthenium complex formed by *ortho*-metallation of one of the triphenylphosphine ligands in **2** by presence of equilibria such as:

$$(C_2H_4)Ru(PPh_3)_3 \rightleftharpoons \mathbf{2}$$



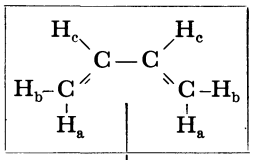
A low activity of the ethylene complex **2** in comparison to the high activity of the dihydride complex **1** for polymerization of vinyl compounds may be also due to the presence of the above equilibria. In contrast with **2**, the propylene-coordinated complex **3** released only small amounts of propylene on iodolysis, thermolysis and acidolysis.

The NMR spectrum of **2** in benzene showed a broad band at δ 1.5—2.5 which may be due to the coordinated ethylene. In the presence of added ethylene both peaks of the coordinated and uncoordinated ethylene were observed and they showed broadening on raising the temperature suggesting an exchange reaction taking place between the coordinated and uncoordinated ethylene. Further support for the exchange was obtained by studying the exchange reaction of C_2D_4 with **2**.[4,6]

b) Styrene-coordinated Complex 4: The styrene-coordinated complex **4** can be obtained as a purple solid which can be crystallized from toluene containing styrene. In the absence of free styrene, complex **4** is unstable and readily decomposed in many solvents. Addition of a large excess of toluene to **4** caused the separation of a yellow precipitate which was identified as $RuH_2(PPh_3)_4$ on the basis of its elemental analysis and IR spectrum showing a ν(Ru–H) band at 2080 cm^{-1}. The decomposition of **4** in toluene released ethylbenzene and strene in a molar ratio of *ca.* 3: 1. The combined molar amount of ethylbenzene and styrene was equivalent to **4**. When **4** was decomposed in tetrachloroethylene, which carries no hydrogen to be abstracted, the molar ratio of ethylbenzene to styrene sharply decreased to 1: 9. The fact indicates that the solvent was the major hydrogen source in decomposition of **4** in toluene. The generation of the small amount of ethylbenzene in the decomposition of **4** in tetrachloroethylene may be ascribed to hydrogen abstraction from the triphenylphosphine ligands. The decomposition product in tetrachloroethylene had a composition close to $Ru(C_2Cl_4)(PPh_3)_3$. The molar ratio of ethylbenzene to styrene generated in the decomposition of **4** in various solvents depended on the solvents used; *e,g.*, in pyridine the ratio was 1:3. No gas was released on iodolysis of **4**.

Because of the instability of **4** in solvents other than styrene itself, the NMR spectrum of **1** was observed in styrene. In addition to the signals of ethylbenzene, two broad peaks at δ 7.51 and 5.79 were observed in a ratio of 1: 2. By comparison of the peak intensities of these peaks with the resonances of ethylbenzene, 1 equiv. of which was confirmed to be formed by an independent method using gas chromatography, these broad peaks are assigned to vinyl protons of styrene coordinated to ruthenium in a 1: 1 molar ratio.

c) Butadiene-coordinated Complex 5: The ^{1}H-NMR spectrum of **5** in benzene shows three peaks of an equal intensity at δ −0.05, 1.49, and 4.91 ppm. These signals may be due to protons H_a, H_b, and H_c of butadiene coordinated with ruthenium as illustrated by a model below to represent one of the possible structures for this complex:



P_2—Ru—P_2

P_1

5 $P_1=P_2=PPh_3$

Keim reported the preparation of a butadiene-coordinated rhodium complex having a composition of $Rh(C_4H_6)(PPh_3)(Ph_2PC_6H_4)$ which shows three peaks of equal intensity at δ 0.4, 2.3, and 4.9 ppm and assigned these peaks in a similar manner to the present case.[9]

The proton decoupled ^{31}P-NMR spectrum of **5** shows an AX_2 type spectrum at 58.7 (triplet) and 50.5 ppm (doublet) downfield from reference PPh_3 in a ratio of 1 : 2. The spectrum is consistent with the above structure having two equivalent and one non-equivalent triphenylphosphine ligands.

Reactions of the Olefin-complexes with Hydrogen. Contact of a benzene solution of $Ru(olefin)(PPh_3)_3$ with molecular hydrogen at room temperature converts the coordinated olefin into its hydrogenated product and gives the known tetrahydridotris(triphenylphosphine)-ruthenium.[10] The reaction probably proceeds through an unstable intermediate $RuH_2(olefin)(PPh_3)_3$ from which alkane may be produced.

$$Ru(olefin)(PPh_3)_3 + H_2 \longrightarrow RuH_2(olefin)(PPh_3)_3$$
$$\downarrow$$
$$Ru(PPh_3)_3 + \text{alkane}$$
$$\downarrow +2H_2$$
$$RuH_4(PPh_3)_3$$

Olefin Exchange Reactions. The olefin coordinated with ruthenium in the isolated complexes **2**—**5** can be readily displaced by another olefin. Scheme 1 summarizes the typical exchange reactions. Ethylene in **2** may be readily displaced by styrene with liberation of ethylene and ethane, and styrene in **4** by ethylene with release of styrene and ethylbenzene. Methacrylonitrile displaces ethylene in **2** and styrene in **4** to give a methacrylonitrile-coordinated complex with a ν(C≡N) band at 2180 cm^{-1} which is shifted to lower frequency by *ca.* 40 cm^{-1} from the ν(C≡N) band of free methacrylonitrile, the shift indicating a coordination through the olefinic double bond to ruthenium.[11] The ^{1}H-NMR spectrum of the methacrylonitrile-complex having broad peaks of the vinylic protons of the coordinated methacrylonitrile at δ 5.3 and 4.9 ppm, which are shifted to higher field than the resonances of free methacrylonitrile, also suggests the π-type coordination. Purification of the complex by recrystallization has failed.

In contrast to the reaction of vinyl acetate with **1** which causes the C–O bond cleavage of vinyl acetate to give ethylene and $RuH(OAc)(PPh_3)_3$[12] the reaction of vinyl acetate with **2** gave a vinyl acetate–ruthenium complex with a ν(C=O) band at 1736 cm^{-1}. The structure of the complex has not been fully characterized.

As reported separately, the reaction of ethyl methacrylate with **2** or **4** gave a new oxidative addition product **6**, which has a five-membered ring as shown in Scheme 1.[7] Reaction of ethylene with **6** partially converted **6** to **2**.

Evidence for Oxidative Addition of Olefins to Ruthenium Affording Hydrido-vinylic Complexes. The bonding between an olefin and a transition metal in an olefin-coordinated complex is generally elucidated in terms of Dewar-Chatt-Duncanson model[13] and there are ample examples[14] in which the side-on type π-coordination of the olefin to the metal has been established by X-ray structural determination.[15] However, we recently encountered a case that a seemingly simple olefin complex between between alkyl methacrylate and ruthenium turned out to have a σ-vinylic-hydrido structure, $RuH(CH{=}C(CH_3)COOR)(PPh_3)_3$, **6**. This complex appeared first as a simple olefin complex on the basis of characterization technique we routinely employ. For example, thermolysis, iodolysis and acidolysis of the complex liberated the alkyl methacrylate. However the treatment with methyl iodide released the methyl substituted product of the alkyl methacrylate at the β-position, *i.e.*, $CH_3CH{=}C(CH_3)(COOR)$. This result

$Ru(C_3H_6)(PPh_3)_3$ **3**	MeI	65		t	t	58	6	11	21	1	3	0

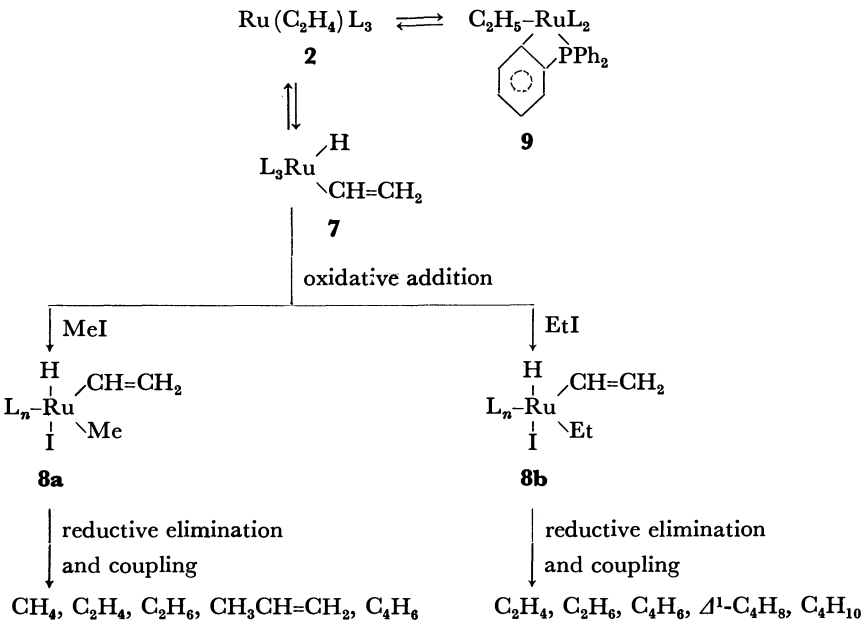
a) Percentage of gas evolved per mol of olefin complex. b) Compositions of the gases other than methane in percentage. The symbols t and tt mean that very small amounts of the gases were detected; t, <0.5%; tt, 0.05%.

together with the IR and NMR spectral analysis led us to the conclusion that the methacrylate-coordinated complex has the hydrido-vinylic structure, which has prompted us to reexamine the olefin-coordinated complexes reported here to see if the seemingly olefin-coordinated complexes actually have hydrido-σ-vinyl structures or if a tautomeric equilibrium such as shown below may exist:

$$(PPh_3)_3Ru\cdots\overset{CH_2}{\underset{CH_2}{\|}} \rightleftharpoons (PPh_3)_3Ru\begin{matrix}\diagup CH{=}CH_2\\ \diagdown H\end{matrix}$$

Neither NMR nor IR spectra of **2** showed any sign of the hydridovinyl structure and chemical reactions of **2**, such as thermolysis, iodolysis, and acidolysis provide no information to support the presence of the hydrido-vinyl species. However, experimental results in favor of the involvement of the hydrido-vinylic species were obtained from the analysis of the reaction products of **2** and **3** with alkyl halides. Table 2 shows the compositions of gases evolved on reactions of **2** and **3** with methyl and ethyl iodides. The composition of the evolved gas on treatment of **2** with methyl iodide varied depending on the reaction temperature. At −30° the gas evolved consisted predominantly of ethylene and traces of propylene and 1-butene. Upon raising the reaction temperature the content of propylene in the evolved gas significantly increased. The similar reaction of **2** with ethyl iodide produced a considerable amount of 1-butene. Noteworthy here is the formation of butadiene although in a minute amount. Scheme 2 shows the reaction paths and olefins expected to be produced, provided that the oxidative addition of methyl iodide to the suspected vinyl-hydrido species should take place.

Formation of methane and ethane in the reaction of methyl iodide with **2** may be accounted for by assuming reductive elimination of the methyl and hydrido ligands and intermolecular coupling of the methyl ligands in the assumed reaction intermediate **8a** which may be formed by oxidative addition of methyl iodide to the hydrido-vinylic intermediate **7** in Scheme 2. Ethylene may arise directly by liberation of the coordinated ethylene from **2** and/or by reductive elimination of the ethyl and hydrido ligands in **8a**. The formation of propylene may be accounted for by reductive elimination of the methyl and vinyl ligands in **8a**. Butadiene may also arise by intermolecular coupling of the two vinyl groups in **8a**. If the assumption of the presence of the vinyl-hydrido species **7** should be valid, the fact that the amount of propylene increases at the

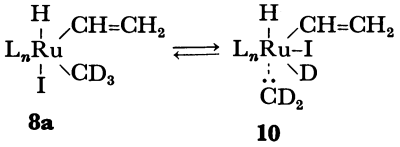


Scheme 2.

expense of ethylene as temperature rises may indicate the shift of the equilibrium between **2** and **7** to the side of **7**. The reaction path **2**→**7**→**8a**, on the other hand, does not account for the formation of butenes in the reaction of **2** with methyl iodide, and it seems necessary to invoke the intervention of the previously discussed ethylruthenium species *(vide supra)* which might produce butene by cross-coupling with the vinyl complex **8a**. The presence of the ethylruthenium species such as **9** in Scheme 2 has previously been suggested on the basis of experiments using deuterated compounds.[6,16]

Similar arguments may be advanced to account for the reaction products of **2** with ethyl bromide by assuming an intermediate **8b** in Scheme 2. 1-Butene formed in the reaction of **2** with ethyl iodide may be produced by reductive elimination of the ethyl and vinyl groups and butane by an intermolecular coupling of the ethyl groups in **8b**.

In order to obtain further information on the reaction of the olefin complex with alkyl halide, the reaction products of **2** with methyl-d_3 iodide were examined. The gas evolved on reaction of **2** with CD_3I at 65 °C was fractionated by GLC and analyzed by mass spectrometry. The result of the product analysis revealed another unexpected aspect of the reaction as shown in experimental section. The formation of CD_4 may be explained by deuterium abstraction from CD_3I or by α-elimination process. The former possibility does not reconcile with the formation of polydeuterated butenes C_4D_8, C_4D_7H and others. Therefore we propose that α-elimination is involved here as shown below.

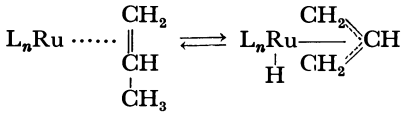


8a **10**

We have previously presented evidence for such α-elimination reaction in the decomposition of a methyl–iron complex.[17] Formation of CD_3H, C_2H_4, C_2H_3D, C_2D_6, and $C_3H_3D_3$ can be elucidated by assuming the species **8a** and **10** shown above. The formation of polydeuterated butenes may be accounted for by H–D exchange in the ethyl group in species **9** and in the vinyl group in species **10** and cross-coupling of the ethyl and vinyl groups.

In order to examine the generality of this type of reaction the reaction products of other ethylene-complexes, $Fe(C_2H_4)(diphos)_2$[18] and $Pd(C_2H_4)(PPh_3)_2$,[19] with methyl iodide were examined. Ethylene and methane were the main products and only traces of propylene and butenes were detected.

Table 2 also includes the reaction products of $Ru(C_3H_6)(PPh_3)_3$ **3** with methyl iodide at 65 °C. In addition to propylene and propane considerable amounts of butadiene and butenes accompanied by traces of ethylene and ethane were produced. The pattern of the product distribution is noticeably different from that of the reaction of **2** and alkyl halide, and it is required to invoke another type of a reaction intermediate as shown below.



The predominant formation of 1-butene and its isomerization products may be accounted for by postulating the involvement of the π-allyl-hydrido species. The formation of butadiene requests α-elimination of the methyl group to produce a hydrido-carbene species, which may combine with the π-allyl group. The formation of π-allyl-hydrido species from a π-propylene complex has a precedent in a nickel complex prepared by Bönneman *et al.*,[20] and we have also observed hydrogen abstraction from the methyl group in the alkyl methacrylate complex **6**.[7]

The formation of propylene and butenes from **2** and methyl and ethyl iodides may be alternatively explained by postulating the insertion of ethylene into the Ru–CH_3 or Ru–C_2H_5 bond formed by oxidative addition of the alkyl halides to **2**, followed by β-elimination to produce propylene and butenes leaving a ruthenium hydride. However, the bulk of evidence presented here is difficult to explain without assuming the hydrogen abstraction from the coordinated olefins.

The results we reported here indicates the quite complicated nature of the olefin complexes when they are subjected to various reactions. The behavior of the olefin complexes has implications in the mechanisms of ethylene polymerization by Phillips process using chromium oxide,[21] and palladium-promoted substitution reactions of olefins.[22]

Experimental

General. All the reactions were carried out under nitrogen atmosphere or in a vacuum. Solvents and olefins were purified by usual methods and stored under nitrogen before use. Liquid olefins were introduced by trap-to-trap distillation in a vacuum into the reaction vessel containing the dihydrido-ruthenium complex, **1**. Gaseous olefins were bubbled into or brought in contact with the solution of the dihydrido complex.

Analysis of gases was carried out by mass spectrometry and gas chromatography. Non-condensable gas at liquid nitrogen temperature was collected using a Toepler pump, by which the volume of the gas was measured. Analysis of the hydrogenated products in the reaction of olefins with the ruthenium complexes were carried out by gas chromatography using Shimadzu-3BT Gas Chromatograph after collecting the liquid by trap-to-trap method. IR and NMR spectra were measured with a Hitachi-EPI-G3 spectrometer and a JEOL-100 MHz spectrometer. Complex **1** was prepared by the method reported previously.[3]

(Ethylene)tris(triphenylphosphine)ruthenium, **2**. Complex **1** (798 mg, 0.693 mmol) in benzene was brought in contact with ethylene (3.73 mmol) for a day at room temperature. The color of the solution changed from yellow to red brown accompanied by evolution of ethane which was 110% per mol of complex **1**. By concentration of or on addition of hexane to the solution, white crystals were obtained which were washed several times with hexane and dried in a vacuum. Bubbling ethylene into the 20 ml toluene suspension of complex **1** (4.0 g, 3.5 mmol) at room temperature turned the color of the solution to red in an hour and off-white crystals precipi-

tated in a few hours. (Yield: 49%).

Reaction of 2 with Iodine. Complex **2** (0.1569 g, 0.171 mmol) in benzene readily reacted with excess iodine liberating only ethylene (3.96 ml, 0.177 mmol) which was 103% of the calculated value, at room temperature.

Thermal Decomposition, Acidolysis and Oxidation of Complex 2. By thermal decomposition of complex **2** up to 200 °C ethylene and ethane (the molar ratio was 1: 0.6 and total amount was 56% for complex **2**) were evolved. By the reaction of complex **2** (0.16 mmol) with sulfuric acid (10 ml), ethylene and ethane (the molar ratio was 1: 1 and total amount was 0.058 mmol, 36%) were evolved. Oxidation of **2** by dry oxygen liberated ethylene.

Reaction of 2 with Methyl Iodide. Methyl iodide (1 ml) was introduced to complex **2** (245 mg, 0.267 mmol) by trap-to-trap distillation. The colorless mixture turned rapidly to black accompanied by evolution of a gas mixture at room temperature. The contents of C_1, C_2, C_3, C_4 olefins and alkanes evolved at −30 °C, room temperature and 65 °C are listed in Table 2.

Reaction of 2 with Methyl-d_3 Iodide. Methyl-d_3 iodide (0.5 ml) reacted with complex **2** to liberate various gases at 65 °C. The content of the isotopic mixture of the gaseous hydrocarbons formed was analyzed by mass spectrometry after separating the components by gas chromatography. The product consisted of the following compositions.

Methane: CD_4, 65%; CD_3H, 35%, the other, trace. Ethylene: C_2H_4, 79%, C_2H_3D, 21%; the other, trace. Ethane: C_2D_6, main; the other, trace. Propylene: $C_3H_3D_3$, main; the other, trace. Butene: the whole range of butenes from C_4D_8 to C_4H_8 were detected.

Reaction of Complex 2 with Ethyl Iodide. Excess ethyl iodide was introduced to complex **2** to release ethylene, butane and 1-butene, and small amounts of ethane, and *cis*- and *trans*-2-butene at room temperature. (see Table 2).

Reaction of Complex 2 with Ethyl Methacrylate. Ethyl methacrylate (2 ml) was introduced to complex **2** (106 mg, 0.108 mmol) by trap-to-trap distillation. Ethylene (20 ml) was evolved and yellow crystals were obtained after the reaction mixture was stirred for a day at room temperature. The yellow complex was identified as $RuH(CH{=}C(CH_3)COOEt)(PPh_3)_3$ on the basis of its IR spectrum; ν(Ru–H), 1960 cm^{-1}; ν(C=O), 1580 cm^{-1}. In the case of the reaction of **2** with *cis*-β-ethyl methacrylate-d_1 (isotopic purity, 72%), deuterated ethylene (C_2H_4, 52%; C_2H_3D, 39%; $C_2H_2D_2$, 9%) was evolved but the resulted complex was scarcely deuterated. Deuteriums in ethyl methacrylate recovered after the reaction were found to be distributed in vinyl and methyl positions (isotopic purity, 9%).

Reaction of Complex 2 with Styrene. Styrene (2 ml) was introduced to complex **2** (155 mg, 0.192 mmol) by trap-to-trap distillation. The initial partly heterogeneous solution gradually changed to a reddish purple homogeneous solution liberating ethylene (4.23 ml, 0.189 mmol) in a day at room temperature. Although the resultant complex was not purified sufficiently because of its instability toward solvents, it is considered to be a styrene-coordinated complex $Ru(St)(PPh_3)_3$ by comparison of its color and stability with the styrene complex prepared from **1** and styrene.

Reaction of 2 with Acetic Acid. Acetic acid (0.5 ml) in benzene (2.5 ml) was introduced to complex **2** (191 mg, 0.209 mmol) by trap-to-trap distillation. The colorless heterogeneous mixture thus formed changed to a yellow homogeneous solution liberating ethylene and ethane in a molar ratio of 2: 1 (total amount of the gas was 0.167 mmol) at room temperature in a few hours. The yellow precipitate was obtained by concentrating the homogeneous solution and was identified as $RuH(OAc)(PPh_3)_3$ by comparison of its IR spectrum with that of an authentic sample. ($\nu(OCO)_{asym}$, 1530 cm^{-1}; $\nu(OCO)_{sym}$, 1450 cm^{-1}).

Reaction of 2 with Methacrylonitrile. Methacrylonitrile (2.0 ml) was introduced to complex **2** (482 mg, 0.527 mmol) by trap-to-trap distillation. A yellow homogeneous solution was obtained accompanied by evolution of ethylene (0.392 mmol) in a day at room temperature. Excess methacrylonitrile was evaporated completely to give a yellow oily product. From its extract with hexane a yellow solid was obtained. The IR spectrum of the yellow solid showed a $\nu(C{\equiv}N)$ band at 2180 cm^{-1} and its NMR spectrum in C_6D_6 showed signals attributable to coordinated methacrylonitrile through the double bond. (δ $C{=}CH_2$, 5.3 and 4.9 ppm; CH_3, 1.3 ppm) and some other unidentified small peaks in a range 1—3 ppm. The resultant complex is tentatively assigned as Ru(methacrylonitrile)-$(PPh_3)_3$.

(Propylene)tris(triphenylphosphine)ruthenium, 3. Propylene (147 ml) was brought in contact with complex **1** (533 mg, 0.463 mmol) in toluene (15 ml) in a sealed system for 2 days at room temperature. Propane (11.4 ml, 110% per complex **1**) was liberated. By adding hexane to the toluene solution a pale brown precipitate was obtained which was washed with hexane and dried in a vacuum. Thermolysis at *ca.* 170 °C and acidolysis by sulfuric acid liberated a small amount of propylene. (5%).

Reaction of 3 with Methyl Iodide. Excess methyl iodide (2 ml) was introduced to complex **3** (*ca.* 100 mg) by trap-to-trap distillation at room temperature and methane, propylene and 1-butene were liberated. Small amounts of *cis*- and *trans*-2-butene, butadiene and propane were also detected.

(Styrene)tris(triphenylphosphine)ruthenium, 4. Styrene (3.12 g) was introduced to complex **1** (1.20 mmol) to give a homogeneous purple solution at room temperature in a day. No polymer was obtained from the solution. The solution was evaporated in a vacuum line and ethylbenzene (1.13 mmol) which corresponds to 94% equivalent of complex **1** was detected in the volatile matter. Red crystals were obtained on crystallization from the mixture of styrene and toluene. When complex **4** was dissolved in excess toluene, styrene and ethylbenzene in a molar ratio of 67: 33 were released. From the solution yellow crystals of $RuH_2(PPh_3)_4$ were recovered. (Found: C, 74.9; H, 5.2%. Calcd for $C_{72}H_{62}P_4Ru$: C, 75.1; H, 5.4%.) ν(Ru–H), 2080 cm^{-1} (KBr disk). Complex **4** decomposed also in pyridine to produce a yellow precipitate, apparently $RuH_2(PPh_3)_4$. In pyridine, styrene and ethylbenzene in a molar ratio of 26: 74 were evolved. Complex **4** reacted with tetrachloroethylene to afford a brown complex $Ru(C_2Cl_4)(PPh_3)_3$ releasing styrene and ethylbenzene in a molar ratio of 89: 11. The brown complex was washed several times with hexane and dried in a vacuum. (Found: C, 63.8; H, 4.5%. Calcd for $C_{56}H_{45}Cl_4Ru$: C, 63.7; H, 4.3%.)

Reaction of Complex 4 with Ethylene. Ethylene (300 ml) was brought in contact with complex **4** (*ca.* 300 mg) which was frozen in benzene (5 ml) at −196 °C. Temperature of the reaction mixture was raised up to room temperature immediately. A brown homogeneous solution was obtained in 1 h. In the solution styrene and ethylbenzene were detected in a molar ratio of 1: 1. The benzene solution was evaporated to dryness by freeze-drying method to give a pale yellow solid which was tentatively assigned to $Ru(C_2H_4)(PPh_3)_3$ based on the result of thermolysis giving ethylene and ethane in a molar ratio of 2: 1 and no styrene.

Reaction of Complex 4 with Ethyl Methacrylate. Ethyl methacrylate (2 ml) was introduced to complex **4** (*ca.* 300 mg) by trap-to-trap distillation. The color of the solution changed to yellow in an hour and yellow crystals were obtained with

release of styrene. The yellow crystals were identified as $RuH(CH{=}C(CH_3)COOEt)(PPh_3)_3$ by IR spectroscopy. ν(Ru–H), 1960 cm^{-1}; ν(C=O) 1580 cm^{-1}.

Reaction of Complex 4 with Dry Deuterium Chloride. Dry deuterium chloride was introduced to complex **4** (*ca.* 300 mg) in C_6D_6 by trap-to-trap distillation. After 1 day a red purple precipitate was obtained. All the volatile matter was collected and examined by NMR spectroscopy. Deuterated styrene in which vinyl protons were deuterated by 20% were detected.

Reaction of Complex 4 with Methacrylonitrile. Excess methacrylonitrile reacted with complex **4** at room temperature giving the same compound as the complex obtained from the reaction of complex **2** with methacrylonitrile.

Reaction of Complex 4 with Acrylonitrile. Acrylonitrile (5.0 ml) was introduced to complex **4** (*ca.* 100 mg) by trap-to-trap distillation. Slow polymerization of acrylonitrile took place at room temperature. Yield 1.26 g (31%).

Reaction of Complex 4 with Carbon Dioxide. Carbon dioxide was bubbled into a mixture of toluene and styrene containing the styrene complex for a day at room temperature to give a brown solution. By adding hexane to the brown solution, a brown precipitate was obtained and was washed several times with hexane and dried in a vacuum. The IR spectrum of the brown precipitate shows new bands at 1932 (w), 1660 (m), 1635 (s), 1505 (m), and 600 (s) cm^{-1}. Thermolysis of the brown precipitate (82 mg) liberated carbon dioxide (1.47 ml, 0.0656 mmol). dec 120 °C.

Reaction of Complex 4 with Hydrogen. Hydrogen was bubbled into the styrene solution of complex **4** for a week at room temperature to give a yellow precipitate. Styrene was found to be completely converted to ethylbenzene and $RuH_2(PPh_3)_4$ was obtained. ν(Ru–H), 2080 cm^{-1}.

(Butadiene)tris(triphenylphosphine)ruthenium, ***5***. Butadiene (2.22 mmol) was brought in contact with complex **1** (1.30 g, 1.13 mmol) in benzene (10 ml) in a sealed system for a day at room temperature to give greenish yellow crystals releasing butenes. In the gas phase 1-butene, *trans*-2-butene and *cis*-2-butene (the molar ratio of 75: 18: 7) were formed and no butadiene was detected. Greenish yellow crystals were recrystallized from benzene or toluene as yellowish green needles which were washed several times with hexane and dried in a vacuum. Thermolysis of the resulted crystals gave *ca.* 5% of 1-butene and acidolysis gave no gas.

A large excess of butadiene (9.59 mmol) reacted with complex **1** (1.86 g, 1.62 mmol) to give an oily product and 1-butene with a small amount of *trans*- and *cis*-2-butene. The oily product could not be characterized because of the difficulty of purification, but the NMR spectrum of the oily product showed signals attributable to the coordinated butadiene (−0.75, 2.00, and 4.54 ppm down field from TMS) and triphenylphosphine. As the amount of butadiene absorbed in the reaction was *ca.* 2.7—3.8 mmol, two butadiene molecules appear to be coordinated to ruthenium.

Reaction of Complex 2 and 5 with Hydrogen. Hydrogen (300 ml) was brought in contact with a benzene suspension (*ca.* 5 ml) of **2** (*ca.* 200 mg) giving a yellow brown homogeneous solution at room temperature. Only ethane was detected in the gas phase. After 1 day white needles were formed, which were identified as $RuH_4(PPh_3)_3$ on the basis of IR analysis and its reaction with PPh_3 affording hydrogen and $RuH_2(PPh_3)_4$. Complex **5** in benzene also reacted with hydrogen at room temperature similarly giving $RuH_4(PPh_3)_3$ and butane. ν(Ru–H), 1940 cm^{-1}.

Studies of Carbenium Ion on Unsaturated Carbon. II.[1] Exclusive Formation of Benzofurans *via* Vinyl Cations in the Solvolytic Reactions of 1-Aryl-2,2-bis(*o*-methoxyphenyl)vinyl Halides

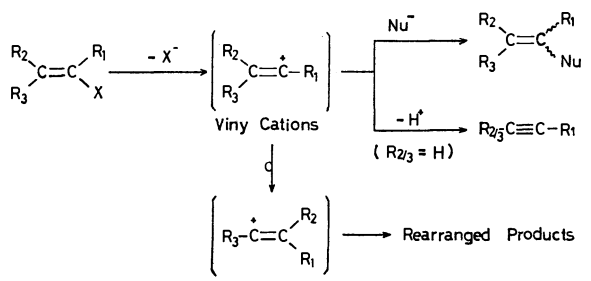
Takaaki SONODA, Shinjiro KOBAYASHI, and Hiroshi TANIGUCHI

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received March 27, 1976)

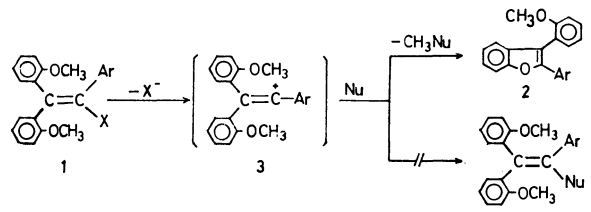
The reactions of 1-aryl-2,2-bis(*o*-methoxyphenyl)vinyl halides (**4**)—(**7**) in 80% aqueous ethanol (80% EtOH), acetic acid (AcOH), or 70% aqueous *N*,*N*-dimethylformamide gave benzofurans (**8**)—(**10**), respectively. The kinetic results *i.e.*, 1) first-order reaction rates, 2) large α-substituent effect ($\rho = -4.12$ against σ^+), 3) large leaving group effect ($k_{Br}/k_{Cl} = 85$ in 80% EtOH and 28 in AcOH) and 4) the solvent effect ($m = 0.53$), are consistent with the formation of the intermediate vinyl cations (**3**) which are captured exclusively by the β-*o*-methoxyl group. In the reaction of vinyl bromide (**7**), the formation of 7—9% of benzofuran (**11**) results from the β-*o*-methoxyphenyl migration in the vinyl cation (**17**) followed by cyclization. The exclusive intramolecular cyclization of the vinyl cations is discussed in terms of the proximity effect of the β-*o*-methoxyl group.

Extensive studies on solvolysis of vinyl derivatives in the last decade have definitely substantiated the vinyl cations as the reactive intermediates.[2] In these reactions, the products are generally those compounds derived from the nucleophilic attack of solvents or nucleophiles on the intermediate vinyl cations. Acetylenic compounds are obtained if β-hydrogens are present in the vinyl substrates. The same kinds of compounds are also formed by the rearrangement of vinyl cations.[3] Moreover, there are several examples



of the participation of neighboring groups, such as β-sulfur atom,[4] ω-double bond,[5] or ω-triple bond,[6] which resulted in the formation of cyclized compounds. However, the selectivity of the cyclization is not high since the external nucleophilic attack to vinyl cations competes with the cyclization.

We found that in solvolytic conditions 1-aryl-2,2-bis(*o*-methoxyphenyl)vinyl halides (**1**) underwent a new type of internal cyclization to benzofurans (**2**) *via* vinyl cation intermediates (**3**). The most remarkable feature

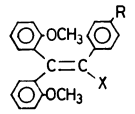


of these reactions is that the formation of benzofurans occurs exclusively and that no other product is obtained by an external nucleophilic attack to the vinyl cations even in the presence of strong nucleophiles.

This paper describes the results of kinetics in relation to α-substituent group, solvent, and leaving group effects aimed at confirming the intermediacy of the vinyl cations (**3**) in the reaction of **1**.

Results

Products. Vinyl halides (**4**)—(**7**) were prepared by bromination or chlorination of the corresponding ethylenes, which is similar to the method used for the preparation of the 2-*p*-methoxyphenylvinyl derivatives.[7]



4 R=OCH_3, X=Br
5 R=OCH_3, X=Cl
6 R=CH_3, X=Br

The reaction of 2,2-bis(*o*-methoxyphenyl)-1-(*p*-methoxyphenyl)vinyl bromide (**4**) in 80% EtOH at 120 °C for 4 h in the presence of excess sodium hydroxide (NaOH) gave 2-(*p*-methoxyphenyl)-3-(*o*-methoxyphenyl)benzofuran (**8**); this was isolated and its structure was determined by microanalysis and by comparing its characteristic UV spectrum with other benzofuran derivatives. The NMR spectrum of the crude product was identical with that of the isolated **8**, which indicates the exclusive formation of **8**. The reactions of **4** in other solvent systems *i.e.*, AcOH and 70% aqueous *N*,*N*-dimethylformamide, always gave **8** in essentially quantitative yields. The selective formation of **8** was not affected by strong nucleophiles. In the presence of sodium azide, the reaction of **4** in 80% EtOH at 120 °C for 6 h also gave **8** as a sole product. The reaction of **4** in 80% EtOH at 120 °C for 4 h in the presence of 1.5 and 3 equivalents of sodium *p*-toluenethiolate afforded **8** exclusively, with 47 and 74% yields of methyl *p*-tolyl sulfide, respectively, which were derived from the capture of methyl moieties by the nucleophile *p*-toluenethiolate ions. A similar result, leading to a quantitative formation of **8**, was obtained in the reaction of the corresponding vinyl chloride (**5**) in basic 80% EtOH at 160 °C for 25 h.

The reaction of 2,2-bis(*o*-methoxyphenyl)-1-*p*-tolylvinyl bromide (**6**) in basic 80% EtOH at 160 °C for 43 h

gave 3-(*o*-methoxyphenyl)-2-*p*-tolylbenzofuran (**9**) as the sole product.

In contrast to 1-(*p*-methoxyphenyl)- and 1-*p*-tolylvinyl derivatives (**4**) and (**6**), the reaction of 1-phenylvinyl derivative (**7**) was much more sluggish; two different products were obtained. The NMR spectrum of the reaction of 2,2-bis(*o*-methoxyphenyl)-1-phenylvinyl bromide (**7**) in basic 80% EtOH at 160 °C for 204 h (95% reaction) showed two kinds of methoxyl singlets (at δ 3.45 and 3.34 in CCl_4) which were different from the methoxyl signals of the starting vinyl bromide (**7**). Integration of the two different methoxyl signals showed two products to be present in the ratio of 93: 7. The major one of these products was isolated as the picrate (mp 108—109 °C). Microanalysis of the picrate and the UV spectrum of the major product regenerated by alumina chromatography (see Table 1) showed the major one as a benzofuran derivative of $C_{21}H_{16}O_2$ (**10**). Attempts to isolate the minor product from the filtrate of the picrate (the major/minor ratio of 74/26) by formation of the picrate, by crystallization, and by thin-layer chromatography (silica gel) failed. However the high-pressure liquid chromatogram (alumina, hexane) of the filtrate showed two peaks and their UV spectra were measured by the stop-flow scanning method. As shown in Table 1, the UV spectrum of the major peak of the chromatogram showed λ_{max} at 306 nm, which was identical with that of the isolated major product (**10**). The minor peak, whose UV spectrum showed λ_{max} at 320 nm, was then assigned to the minor product (**11**). By consideration of the NMR and IR spectra of the reaction mixture and the UV spectrum of the minor product, the minor one has only one methoxyl group and can not be a product such as a ketone or ethyl vinyl ether which may be derived from external nucleophilic attack,[7] it was assigned as the isomeric benzofuran of the major one. The structures of isomeric **10** and **11** were determined as follows.

As shown in Table 1 benzofurans with 2-methoxyphenyl groups (**8**, **12**, and **13**) have higher λ_{max} than the benzofurans with 2-phenyl groups (**14** and **15**), or the benzofuran with 2-tolyl group (**9**). On the basis of this trend of chromophores, the major product (**10**) whose UV spectrum shows a lower λ_{max} (306 nm) than the minor one (320 nm) is assigned to a 2-phenyl-substituted benzofuran entity and then the minor one to a 2-methoxyphenyl-substituted benzofuran. Consequently, it is concluded that the major product (**10**) in the reaction of **7** is 3-(*o*-methoxyphenyl)-2-phenylbenzofuran and the minor one (**11**) is 2-(*o*-methoxyphenyl)-3-phenylbenzofuran.

The reactions of **7** in basic 50% EtOH at 160 °C for

a) t, titration method, u, UV method, n, NMR method. b) Extrapolated from data at lower temperature. c) Rates are averages of duplicate determinations.

26 h (96% reaction), and in AcOH with excess silver acetate at 118 °C for 21 h (100% reaction) also gave these isomeric benzofurans in similar product ratios (the **10**/**11** ratios of 93/7 and 91/9, respectively).

Kinetics. Reaction rates of vinyl halides (**4**)—(**7**) in aqueous EtOH with NaOH and in AcOH with NaOAc were measured by titration of the formed bromide ions (titration method), and by measuring the UV spectra of the reaction mixtures (UV method). Since the results from the titration method were identical with those from the UV method within experimental errors, most of the measurements were made by the UV method. The reaction rates of **7** in 80% EtOH and of **5** in AcOH were followed by NMR spectroscopy (NMR method) as the reaction rates of these reactions were very sluggish.

The kinetic results in aqueous EtOH are summarized in Table 2. All the runs followed accurately the first-order kinetic law. The rate constants were not affected by the concentrations of the substrates and the added base(NaOH). Solvent polar effects were studied with **4** in 70, 80, and 90% EtOH. A plot of log k for **4** *vs.* Grunwald-Winstein's Y value[8] is linear and the m value is 0.53 at 120 °C. The reactivity ratio of (**4**) 1650: (**6**) 24: (**7**) 1 suggests a large α-substituent effect. The Hammett plot of log k against σ^+ [9] gave $\rho=-4.12$ (correlation coefficient $r=0.999$) in 80% EtOH at 160 °C. The bromide (**4**)/chloride (**5**) reactivity ratio in 80% EtOH at 140 °C is 85. Activation parameters for solvolysis of **4** in 80% EtOH are $\Delta H^{\neq}=26.8\pm0.4$ kcal/mol and $\Delta S^{\neq}=-7\pm1$ e.u. (120 °C).

Solvolysis rates of **4** and **5** in AcOH are shown in Table 3. The reactions obeyed good first-order kinetics up to 80% conversion. The bromide (**4**)/chloride (**5**) reactivity ratio in AcOH at 140 °C is 27.8.

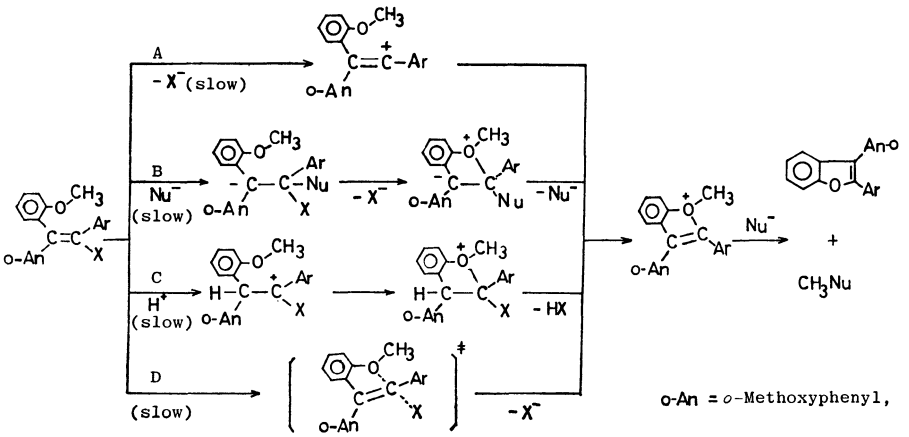
Discussion

Evidence for the Vinyl Cation Intermediates. Several possible mechanisms for the exclusive intramolecular cyclization of 1-aryl-2,2-bis(*o*-methoxyphenyl)vinyl halides are shown in Scheme 1.

Path A *via* vinyl cation intermediates can be supported by the following criteria. The solvolysis rates fit first-order rate plots and do not depend on the base concentrations. The large α-substituent effect ($\rho=-4.12$ against σ^+) suggests the formation of a cation center on the α-carbon in the transition state. The solvent polar effect ($m=0.53$ at 120 °C) also indicates the cationic intermediate. Moreover, in addition to the electrophilic catalysis by the silver ions, the large leaving group effect ($k_{Br}/k_{Cl}=85$ in 80% EtOH and 27.8 in AcOH) suggests a heterolytic C–X bond fission in the rate-determining step. These reactivity ratios which depend on solvent,[7,10] α-substituent,[10,11] and leaving group[7,12,13] effects are similar to those of the solvolysis of vinyl halides for which the intermediacy of vinyl cations has been established.

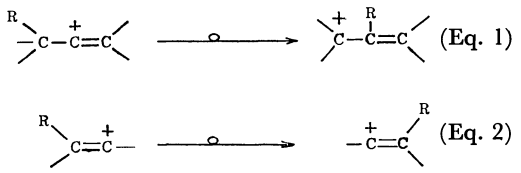
On the other hand, the possibilities of paths B–D, which may compete with the S_N1 mechanism in the solvolysis of vinyl derivatives,[2] can be ruled out as follows. Path B involves an external nucleophilic attack on the double bond followed by displacement of the halogen by the β-*o*-methoxyl oxygen with elimination of the nucleophile. This pathway is unlikely in 80% EtOH or AcOH since the rate constants do not depend on the base concentrations. The nucleophilic addition-elimination mechanism was observed in the solvolysis of 9-(α-haloarylidene)fluorenes in 80% EtOH with strong nucleophiles,[14] but the kinetic behavior of the fluorenyl systems are very different from those of our systems. Path C is a rate-determining electrophilic addition (protonation) followed by a methoxyl oxygen attack with elimination of the hydrogen halide.[15,16] If path C could operate in our systems, the electrophilic addition should be faster in AcOH than in 80% EtOH. However, the solvolysis rates of **4** and **7** in 80% EtOH were faster than in AcOH ($k_{80\%\ EtOH}/k_{AcOH}$ of 4.4 for **4** at 120 °C and of 1.4 for **5** at 140 °C). Moreover, the



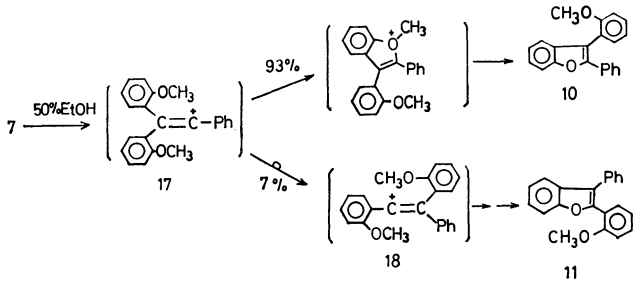
Scheme 1. Possible reaction paths for cyclization reaction.

effect of the leaving groups for the electrophilic addition-elimination route suggests the reactivity order: $k_{Cl} > k_{Br}$,[13] which is contrary to our systems. The exclusive cyclization to benzofurans and the lack of incorporation of the external nucleophiles suggest path D, which involves a one-step direct intramolecular S_N2-type attack of the β-*o*-methoxyl oxygen on the α-carbon with synchronous elimination of the halogen. However, such direct displacements at vinyl carbons are energetically unfavorable,[17] and have so far not been observed in vinyl systems. In path D, it could be expected that the solvolysis of 2-*o*-methoxyphenyl-substituted vinyl halides should be faster than that of the corresponding 2-*p*-methoxyphenyl-substituted vinyl derivatives in which the anchimeric acceleration by the β-methoxyl group is inherently impossible to operate. In practice, however, the solvolysis of 1,2,2-tris(*p*-methoxyphenyl)vinyl bromide (**16**)[7] is faster than that of **4** (k(**16**)/k(**4**) ratio of 1.7 in 80% EtOH at 120 °C and of 1.1 in AcOH at 120 °C). This result argues against the possibility of the anchimeric acceleration by the neighboring β-*o*-methoxyl group.

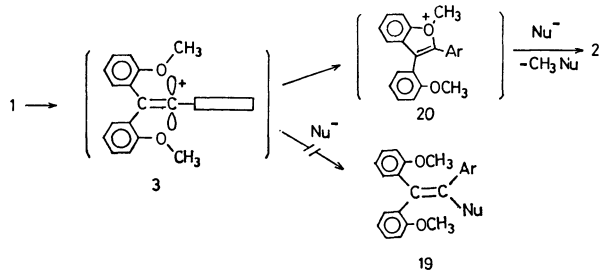
Cyclization vs. *2-o-Methoxyphenyl Migration.* As in the case of saturated carbenium ions, the rearrangement of the reactive vinyl cations to more stable cations is a characteristic feature of vinyl cation intermediates. In vinyl cations two types of rearrangements are known: to the double bond[18] (Eq. 1) and across the double bond[3,19] (Eq. 2).



Solvolysis of **7** gave small amounts of **11** (7, 7, and 9% in 50% EtOH, 80% EtOH, and AcOH with AgOAc, respectively) in addition to the normal cyclization product (**10**). Benzofuran (**11**) resulted from the 2-*o*-methoxyphenyl migration in the vinyl cation (**17**) to the more stable vinyl cation (**18**). The rearranged vinyl cation (**18**) is also exclusively attacked by the β-*o*-methoxyl oxygen. These results indicate that the nucleophilic attacks to the vinyl cation (**17**) are in the following ordering: internal nucleophilic attack (cyclization)>2-*o*-methoxyphenyl group participation (migration)≫external nucleophilic attack.



In conclusion, it is a remarkable feature of the solvolytic reactions of 1-aryl-2,2-bis(*o*-methoxyphenyl)-vinyl halides (**1**) that exclusive cyclization to benzofurans (**2**) occurs in preference to the external nucleophilic attack to the vinyl cations (**3**) even in the presence of the strong nucleophiles. The origin of this exclusive cyclization can be discussed as follows. There exists a large steric hindrance between the aryl groups in **1**, because the substituents attached to the unsaturated carbons are held in the plane of the molecule. Vinyl cations (**3**) have the sp-hybridized structure and the α-aryl rings of the vinyl cations come to be perpendicular to the molecular plane in order to allow the π-orbital of the α-aryl groups to overlap well with the vacant *p*-orbital of the vinyl cations.[2] While some of the *cis* α-aryl and β-*o*-methoxyphenyl steric interaction is relieved in the sp-hybridized vinyl cations, the approach of the external nucleophiles to the cation center is still retarded because of the steric and electronic repulsions between the β-substituents and the approaching nucleophiles.[13,20] Moreover, even if such an external nucleophilic attack had occurred, the resulted vinyl derivatives (**19**) should be still sterically hindered. On the other hand, the intramolecular attack of the β-*o*-methoxy oxygen atoms upon the vinyl cations is entropically favorable since the β-*o*-methoxyl groups are located in suitable positions to attack the vacant *p*-orbital of the vinyl cations (**3**) and the resulted oxonium ions (**20**) are stabilized by the relief of the steric repulsion presented in the starting materials.[21] It seems likely that the proximity effect of the β-*o*-methoxyl group, in addition to the stability of the resulting product, is the driving force of the exclusive cyclization.



Experimental

All melting points are uncorrected. NMR spectra were taken on a JEOL JNM-MH-60 spectrometer. All mass spectra were obtained with a JEOL JMS-07 spectrometer. UV spectra were recorded with HITACHI 124, Shimadzu UV-200S, and UV-202S spectrometers. All IR spectra were obtained with a Shimadzu IR-400 spectrometer. Aqueous ethanolic mixtures were prepared according to Grob.[10] Acetic acid was prepared by refluxing glacial acetic acid with 1% acetic anhydride and then fractionally distilling. Sodium acetate solutions were prepared by disolving analytical sodium carbonate in acetic acid. *N,N*-Dimethylformamide (DMF) was dried over phosphorus pentoxide overnight and the fraction boiling at 78—79.5 °C (28—30 mm) was collected and stored over molecular sieves. 70% aqueous DMF was obtained according to Kaufman.[11]

Preparation of Vinyl Halides. Vinyl halides were prepared by appropriate modifications of the methods used for the preparation of 2-*p*-methoxyphenyl-substituted vinyl halides.[7] Spectral data of the vinyl halides are given in Table 4.

2,2-Bis(o-methoxyphenyl)-1-(p-methoxyphenyl)vinyl Bromide (4). *1,1-Bis(o-methoxyphenyl)-2-(p-methoxyphenyl)ethanol*: A solution of *o*-methoxyphenylmagnesium bromide was prepared in the usual manner from magnesium (2.43 g, 0.1

mol), *o*-bromoanisole (18.71 g, 0.1 mol), and ether (80 ml). As soon as the metal reacted, ethyl *p*-methoxyphenylacetate (9.71 g, 0.05 mol) in ether (40 ml) was added and the reaction mixture was heated under reflux for 20 min and allowed to stand overnight. The aqueous solution was extracted twice with CH_2Cl_2 and the combined extracts and the ether layer were washed with water, dried over Na_2SO_4, and evaporated to dryness. The solid obtained (10.75 g, 59%) was recrystallized three times (CH_2Cl_2–EtOH) and gave white needles, mp 164—169 °C, of 1,1-bis(*o*-methoxyphenyl)-2-(*p*-methoxyphenyl)ethanol. IR(Nujol): 3500 cm^{-1} (OH). NMR ($CDCl_3$, δ): 3.44 (d-s, 6H, OCH_3), 3.66 (d-s, 5H, OCH_3 and CH_2), 4.83 (s, OH), 6.45—7.45 (m, 12H, arom.). Found: C, 75.54; H, 6.73%. Calcd for $C_{23}H_{24}O_4$: C, 75.80; H, 6.69%.

2,2-Bis(o-methoxyphenyl)-1-(p-methoxyphenyl)ethylene: Phosphoric acid (85%, 8 ml) was added to 1,1-bis(*o*-methoxyphenyl)-2-(*p*-methoxyphenyl)ethanol (7.3 g, 20.1 mmol) and the mixture was kept at 100 °C for 3 h with stirring. The cooled mixture was washed four times with water by decantation and the residual oil was dissolved in CH_2Cl_2 and dried over Na_2SO_4. After solvent removal, recrystallization from CH_2Cl_2–EtOH (1:4) gave 2,2-bis(*o*-methoxyphenyl)-1-(*p*-methoxyphenyl)ethylene, mp 99.5—100.5 °C (6.57 g, 95%). NMR ($CDCl_3$, δ): 3.50 (s, OCH_3), 3.61 (s, OCH_3), 3.70 (s, OCH_3), 6.52—7.25 (m, 13H, =CH– and arom.). UV: λ_{max} (cyclohexane); 285 nm (ε 19200) and 208 (37000).

2,2-Bis(o-methoxyphenyl)-1-(p-methoxyphenyl)vinyl Bromide (4): 1. To 1,1-bis(*o*-methoxyphenyl)-2-(*p*-methoxyphenyl)-ethanol (6.06 g, 0.017 mol) in AcOH (24 ml), bromine (2.75 g, 0.017 mol) was added and the mixture was kept for 30 min with stirring. The mixture was poured into water and extracted with ether. The ether extract was washed with saturated $NaHCO_3$ solution and water, and dried over Na_2SO_4. After solvent removal, the residual oil was chromatographed over neutral alumina. The solvent removal from the benzene fraction gave the solid (2.33 g, 33%). Recrystallization (benzene–EtOH 1:1) afforded white needles, mp 126.5—128 °C, of 2,2-bis(*o*-methoxyphenyl)-1-(*p*-methoxyphenyl)vinyl-bromide (**4**). Found: C, 65.20; H, 5.05%. Calcd for $C_{23}H_{21}O_3Br$: C, 64.95; H, 4.98%.

2. *N*-Bromosuccinimide (1.8 g, 10 mmol) and benzoyl peroxide (50 mg) were added to 2,2-bis(*o*-methoxyphenyl)-1-(*p*-methoxyphenyl)ethylene (3.5 g, 10 mmol) in CCl_4 (50 ml). The mixture was refluxed for 1 h with irradiation with a photographic reflector spot lamp. After cooling to 0 °C, the succinimide was filtered and the filtrate washed with water, dilute NaOH solution, and water again. After solvent removal, recrystallization (CH_2Cl_2–EtOH 1:1) gave **4** (4.52 g, 71%), mp 128—130 °C.

2,2-Bis(o-methoxyphenyl)-1-(p-methoxyphenyl)vinyl Chloride (5). To 2,2-bis(*o*-methoxyphenyl)-1-(*p*-methoxyphenyl)-ethylene (2.79 g, 8.05 mmol) in CCl_4 (20 ml), chlorine (0.6 g, 8.475 mmol) was added over the period of 120 min. After the solution was stirred for an additional 90 min, the solvent was evaporated and a white solid (2.68 g, 87%) precipitated. Recrystallization (CH_2Cl_2–EtOH) gave 2,2-bis(*o*-methoxyphenyl)-1-(*p*-methoxyphenyl)vinyl chloride (**5**), mp 112—113 °C. Found: C, 72.38; H, 5.63%. Calcd for $C_{23}H_{21}O_3Cl$: C, 72.53; H, 5.56%.

2,2-Bis(o-methoxyphenyl)-1-p-tolylvinyl Bromide (6). *1,1-Bis(o-methoxyphenyl)-2-p-tolylethanol*: To *o*-methoxyphenylmagnesium bromide (23.8 g, 0.112 mol) in ether (100 ml), dry benzene (40 ml) and then ethyl *p*-tolylacetate (10.0 g, 0.056 mol) in dry benzene (44 ml) were added, and the solution was allowed to stand overnight. After the solution was refluxed for 20 min, 2M-HCl (90 ml) was added and the reaction mixture was extracted with CH_2Cl_2. Work-up of the reaction mixture gave the solid. Recrystallization (CH_2Cl_2–EtOH 1:2) gave 1,1-bis(*o*-methoxyphenyl)-2-*p*-tolylethanol (15.11 g, 77.5%), mp 168—169 °C. NMR($CDCl_3$, δ): 2.20 (s, CH_3), 3.42 (d-s, 6H, OCH_3), 3.68 (s, CH_2), 4.84 (s, OH), 6.65—7.50 (m, 12H, arom.). IR(Nujol): 3570 cm^{-1} (OH). Found: C, 79.03; H, 6.98%. Calcd for $C_{23}H_{24}O_3$: C, 79.28; H, 6.94%.

2,2-Bis(o-methoxyphenyl)-1-p-tolylethylene: 1,1-bis(*o*-methoxyphenyl)-2-*p*-tolylethanol (10.0 g, 0.028 mol) was treated with phosphoric acid (85%, 15 ml) at 100 °C for 3 h. Work-up of the reaction mixture gave 2,2-bis(*o*-methoxyphenyl)-1-*p*-tolylethylene (8.69 g, 92%), mp 87.2—88.8 °C (EtOH). NMR (CCl_4, δ): 2.20 (s, CH_3), 3.43 (s, OCH_3), 3.56 (s, OCH_3), 6.55—7.20 (m, 13H, =CH– and arom.). UV: λ_{max} (cyclohexane); 283 nm (ε 17800), 220 (26900). Found: C, 83.58; H, 6.82%. Calcd for $C_{23}H_{22}O_2$: C, 83.60; H, 6.71%.

2,2-Bis(o-methoxyphenyl-1-p-tolylvinyl Bromide (6): Bromine (0.97 g, 6.05 mmol) in CCl_4 (10 ml) was added slowly to 2,2-bis(*o*-methoxyphenyl)-1-*p*-tolylethylene (2.0 g, 6.09 mmol) in CCl_4 (15 ml) while cooling, with stirring which continued for an additional 30 min. Solvent removal gave the solid and recrystallization (CH_2Cl_2–EtOH 1:5) gave white needles, mp 123—124 °C, of 2,2-bis(*o*-methoxyphenyl)-1-*p*-tolylvinyl bromide (**6**) (3.25 g, 87.5%). Found: C, 67.17; H, 5.33%. Calcd for $C_{23}H_{21}O_2Br$: C, 67.49; H, 5.17%.

2,2-Bis(p-methoxyphenyl)-1-phenylvinyl Bromide (7). *1,1-Bis(o-methoxyphenyl)-2-phenylethanol*: To *o*-methoxyphenylmagnesium bromide(*o*-bromoanisole, 22.47 g, 0.12 mol, magnesium, 2.67 g, 0.11 mol) in ether (100 ml), ethyl phenylacetate (8.2 g, 0.05 mol) in dry benzene (70 ml) was added slowly and heated under reflux for 4 h. On cooling, 2M-HCl (70 ml) was added and a work-up of the reaction mixture similar to that of 1,1-bis(*o*-methoxyphenyl)-2-(*p*-methoxyphenyl)-ethanol gave the precipitate (10.23 g, 61%). Recrystallization (CH_2Cl_2–EtOH) gave 1,1-bis(*o*-methoxyphenyl)-2-phenylethanol, mp 154 °C. NMR ($CDCl_3$, δ): 3.43 (d-s, 6H, OCH_3), 3.72 (s, CH_2), 4.83 (broad s, OH), 6.64—7.46 (m, 13H, arom.). IR (Nujol): 3560 cm^{-1} (OH). Found: C, 78.92; H, 6.63%. Calcd for $C_{22}H_{22}O_3$: C, 79.01; H, 6.63%.

2,2-Bis(o-methoxyphenyl)-1-phenylethylene: 1,1-Bis(*o*-methoxyphenyl)-2-phenylethanol (5.0 g, 0.015 mol) was treated with phosphoric acid (11 ml) at 100 °C for 3 h. Work-up of the reaction mixture gave 2,2-bis(*o*-methoxyphenyl)-1-phenylethylene (4.59 g, 97%), mp 91—92 °C. NMR (CCl_4, δ): 3.41 (s, OCH_3), 3.57 (s, OCH_3), 6.55—7.15 (m, 14H, =CH– and arom.). UV: λ_{max} (cyclohexane) 284 nm (ε 16000), 250 (12500). Found: C, 83.24; H, 6.40%. Calcd for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37%.

2,2-Bis(o-methoxyphenyl)-1-phenylvinyl Bromide (7): 2,2-bis(*o*-methoxyphenyl)-1-phenylethylene (3.50 g, 0.01 mol) was treated with *N*-bromosuccinimide (2.00 g, 0.012 mol) and benzoyl peroxide (50 mg) in CCl_4 (70 ml) in a manner similar to that used preparation of **4**. The solid obtained (3.87 g, 89%) was recrystallized (CH_2Cl_2–EtOH 2:5) to give white needles, mp 142—143 °C, of 2,2-bis(*o*-methoxyphenyl)-1-phenylvinyl bromide (**7**). Found: C, 66.85; H, 4.85%. Calcd for $C_{22}H_{19}O_2Br$: C, 66.84; H, 4.84%.

Reaction of 2,2-Bis(o-methoxyphenyl)-1-(p-methoxyphenyl)vinyl Bromide (4). Reaction in 80% EtOH: Vinyl bromide (**4**) (70 mg, 0.164 mmol) in 80% EtOH (20 ml) containing NaOH (0.5 mmol) was kept in a sealed ampoule at 120 °C for 8 h. The solvent was removed and ether was added, then the inorganic salt was removed, dried over Na_2SO_4, and the ether was evaporated to give 3-(*o*-methoxyphenyl)-2-(*p*-methoxyphenyl)benzofuran (**8**) exclusively. The NMR spectrum and the thin-layer chromatogram of the crude product showed no

chromophor; its structure was assigned to 3-(*o*-methoxyphenyl)-2-phenylbenzofuran (**10**), as discussed in Table 1. Attempts to isolate the minor product from the filtrate of the picrate by TLC or by formation of the picrate failed. The high-pressure liquid chromatogram of the filtrate (by Shimadzu 840 instrument; column, Varian-Aerograph Micro Pack AL-10 2.2$\phi \times$0.25 m; eluent, hexane; flow rate, 0.4 ml/min) showed two separated peaks and their UV spectra were recorded by the stop-flow method, as shown in Table 1. The assignment of these peaks was previously discussed.

Kinetics. *Titration Method*: Kinetic runs were achieved according to a method similar to Rappoport's.[7] Titration of the bromide ions against standard silver nitrate using Eosin or Uranin indicators (Fajans method) showed ambiguous end-points of titration, so this method was abandoned. Titrimetri-rate constants were determined by the Volhald method as follows. The reaction mixtures in ten to fifteen sealed ampoules, each of which was quenched at appropriate times, were diluted with water ten times. A weighted quantity of the standard silver nitrate was added to each solution. After addition of concd nitric acid (2 ml), nitrobenzene (3—5 ml), and iron alum solution (2 ml), back-titration by the standard 0.01 M potassium thiocyanate gave a sharp end-point.

UV Method: The reaction mixtures of UV concentration in ten to fifteen ampoules were quenched at appropriate intervals and the change in the absorbance (at 300—310 nm) of the reaction mixture was followed by an UV spectrometer. In some runs, concd reaction mixtures were diluted to UV concentration and their UV spectra were measured.

NMR Method: Five to six sealed ampoules, each of which contained vinyl halides (50 mg) in 80% EtOH or AcOH with buffers, were quenched at appropriate times. After work-up of the reaction mixtures, rate constants were obtained by following the relative NMR intensities of the different methoxyl peaks of vinyl halides and benzofurans.

All rate constants are calculated by the least-squares method.

(Received March 29, 1976)

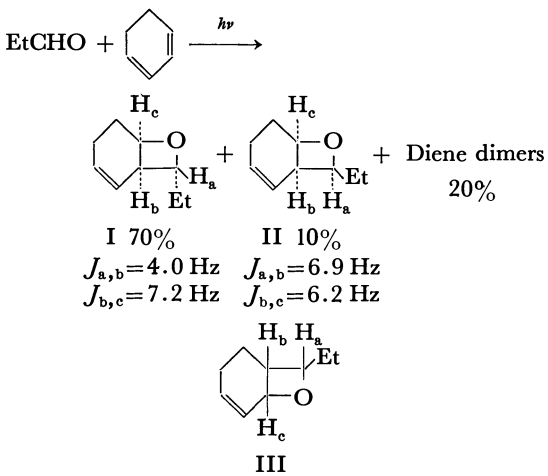
The photocycloaddition of propanal to 1,3-cyclohexadiene leads to oxetanes, as well as to the dimers of 1,3-cyclohexadiene. A mechanism of oxetane formation is proposed in which singlet excited propanal attacks a ground-state 1,3-cyclohexadiene to give a singlet complex with a charge-transfer character. The complex either decays to the ground-state reactants or reacts to give oxetanes. Quantum yield measurements and kinetic analysis show a rate constant of 4×10^9 $M^{-1}s^{-1}$ for singlet complex formation from propanal and 1,3-cyclohexadiene in benzene. The quenching data of propanal fluorescence support such a mechanism.

The photocycloaddition of carbonyl compounds with olefins to form oxetanes is a topic of recent preparative and mechanistic interest.[3,4] Although a few cases are now known for which ketone singlets attack the olefins,[4c,4d,4e,4f] ketone triplets are generally thought to be the chemically active species in oxetane formation.[3] For electron-rich olefins the reaction is usually believed to involve an electrophilic attack[5] by the oxygen atom of the n,π^* state of the ketone on the olefin. For electron-deficient olefins, the reaction is considered to involve a nucleophilic attack by the electron-rich π^* orbital of the n,π^* singlet state of the ketone.[4d,4e,5] Recently, it has been suggested that an exciplex which leads to oxetane formation is formed between excited carbonyl compounds and olefins.[5,6] However, the reaction of excited carbonyl compounds with conjugated dienes has been little studied.[7] Conjugated dienes have frequently been used as quenchers of the triplet excited state of ketones because of their relatively low triplet energies.[8] However, in the case of benzophenone, the n,π^* triplet state can still undergo photoaddition to conjugated dienes to form oxetanes, in inefficient competition with triplet energy transfer.[7e]

Recently there has been interest in the interaction of acetone with conjugated dienes, studied both by the observation of the fluorescence quenching of singlet acetone[9] and by the isolation of oxetane products.[7b,7d,7f,7h,10] However, few attempts have been made to analyze the products[3g] and mechanism of photoaddition of alkanals such as propanal whose intersystem crossing rate constant seems to be as small as that of acetone.[11] In view of these facts, the photoreaction of propanal with 1,3-cyclohexadiene was investigated. We wish to report our results on the products and mechanism of the interaction of propanal with conjugated dienes;[12] it is interesting to compare our results with those of acetone.[7h]

Results and Discussion

Reaction Products. Irradiation of propanal in the presence of 1,3-cyclohexadiene resulted in the formation of oxetane I and II in good yield. Dimers of 1,3-cyclohexadiene were also formed as minor products. The products assigned the oxetane structures were 1:1 adducts of propanal with the diene, and the IR spectra showed the absence of any carbonyl or hydroxyl group. Instead, each compound showed a strong band in the region 1000—900 cm^{-1}, which is the reported absorption region of the oxetane ring.[13] Oxetanes exhibited two signals near δ 4.7 and one signal near δ 3.0. The former absorptions were assigned to the ring protons α to the ring oxygen, while the higher field absorption was assigned to the ring hydrogen β to the ring oxygen. These are consistent with the reported absorption ranges.[3e,14] The stereochemical assignments for I and II were made on the basis of their vicinal H–H coupling constants in oxetanes. $J_{a,b}$ in the *cis*-isomer II is larger than that in the *trans*-isomer I and as large as $J_{b,c}$ in I and II. These are consistent with the reported observations.[15] The alternative orientation III of cycloaddition was ruled out by the fact that decoupling experiments showed the presence of the coupling between olefinic protons and H_b.



III

Mechanism. In these investigations, the irradiation of propanal with 1,3-cyclohexadiene was conducted in a Pyrex apparatus. Under these conditions, only propanal is excited to its n,π^* singlet state. The UV spectra showed no evidence for a ground-state complex of propanal with the diene. Formation of the diene dimers is thought to proceed *via* the attack of a triplet diene on another ground-state diene molecule.[16] Alkanals and alkanones are believed to have triplet energies of $\approx$80 kcal/mol,[17–19] and after efficient diffusion-controlled transfer[20] of triplet energy (E_T) to the diene (E_T=54 kcal/mol),[21] efficient formation of diene dimers is expected; therefore, the formation of

oxetanes in good yield is mechanistically interesting.

The following routes are possible for oxetane formation: (i) triplet propanal attacks the diene directly to produce the oxetane; (ii) the triplet diene which is produced by energy transfer from triplet propanal attacks ground-state propanal;[7c] or (iii) excited singlet propanal attacks the diene.

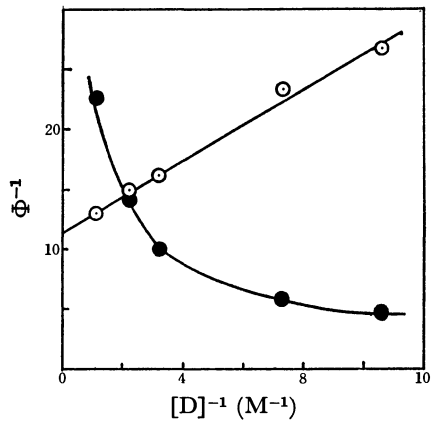


Fig. 1. Dependence of the reciprocal of the quantum yield for products formation on the reciprocal of 1,3-cyclohexadiene concentration; ○, oxetanes; ●, dimers. Slope=1.6 M, Intercept=11.6.

Figure 1 shows plots of the quantum yields for the formation of oxetanes and the diene dimers as a function of 1,3-cyclohexadiene concentration. The dimers decrease as the concentration of 1,3-cyclohexadiene increases. On the other hand, plots for oxetanes are linear up to high concentrations of 1,3-cyclohexadiene. This indicates that different precursors exist for the formation of oxetanes and dimers. It is well known that dimers are formed *via* diene triplets.[16] Therefore, if oxetanes were formed by route (i) or (ii), dimers would have to increase with the concentration of 1,3-cyclohexadiene. This is incompatible with the results. Route (ii) is also ruled out by the fact that oxetanes are hardly obtained under conditions such as those under which triplet dienes are exclusively formed (phenanthrene-sensitized experiments). Therefore, route (iii) is thought to be the mechanism of this reaction. Furthermore, the following evidence indicates that oxetane formation results from the attack of singlet propanal on the diene: (a) the fluorescence of propanal is quenched by addition of 1,3-cyclohexadiene (Fig. 2); and (b) the yield of diene dimers decreases by *ca.* 20% in the presence of air, while that of oxetanes is unchanged. The quantum yield for oxetane formation is much lower than unity even at very high diene concentrations, implying that the reaction of propanal singlet with 1,3-cyclohexadiene is inefficient. The mechanism suggested in the following Scheme is conceivable. The observed inefficiency in formation of oxetanes can be accounted for by formation of an intermediate, C, which can collapse to oxetanes or to propanal and 1,3-cyclohexadiene.

$$C \xrightarrow{k_5} P + D$$
$$C \xrightarrow{k_6} \text{Oxetanes}$$
$$^3P + D \xrightarrow{k_7} {}^3D + P$$
$$^3D + D \xrightarrow{k_8} \text{Diene dimers}$$
$$^3D \xrightarrow{k_9} D$$
$$^3P \xrightarrow{k_{10}} P$$

^1P: singlet propanal ^3P: triplet propanal
^3D: triplet 1,3-cyclohexadiene C: singlet complex

Steady-state treatment of the species ^1P, ^3P, ^3D, and C leads to the expressions

$$\frac{1}{\Phi_{ox}} = \frac{k_5+k_6}{k_6} + \frac{(k_1+k_2+k_3)(k_5+k_6)}{k_4k_6}[D]^{-1} \quad (1)$$

$$\Phi_d = \frac{k_3k_7k_8[D]^2}{(k_1+k_2+k_3+k_4[D])(k_7[D]+k_{10})(k_8[D]+k_9)} \quad (2)$$

where Φ_{ox} and Φ_d are the quantum yields for the formation of oxetanes and dimers, respectively. The behavior predicted by Eq. 1 is observed experimentally, as shown in Fig. 1.

The rate of quenching of triplet propanal by 1,3-cyclohexadiene, k_7, is thought to be diffusion-controlled (in benzene, 5×10^9 M^{-1} s^{-1}).[20] Therefore, if the rate of radiationless decay of the propanal triplet, k_{10}, is assumed to be $\approx 10^6$ s^{-1},[22] at concentrations of diene greater than 0.1 M, $k_{10} \ll k_7[D]$ and Eq. 2 becomes Eq. 3.

$$\Phi_d = \frac{k_3k_8[D]}{(k_1+k_2+k_3+k_4[D])(k_8[D]+k_9)} \quad (3)$$

Rearranging Eq. 3 gives Eq. 4.

$$\frac{1}{\left(1+\frac{k_9}{k_8}[D]^{-1}\right)\Phi_d} = \frac{k_1+k_2+k_3}{k_3}\left(1+\frac{k_4}{k_1+k_2+k_3}[D]\right) \quad (4)$$

Figure 3 is a plot of $\Phi_d^{-1}(1+k_9/k_8[D])^{-1}$ against [D], where k_9/k_8 is calculated from the data of Hammond and coworkers[23] to be 0.03. Equation 4 explains the

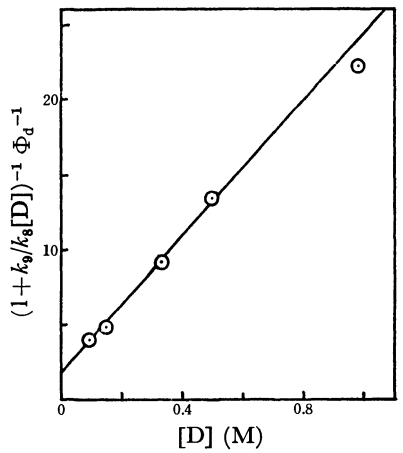

Fig. 3. Plot of $(1+k_9/k_8[D])^{-1}\,\Phi_d^{-1}$ against [D].

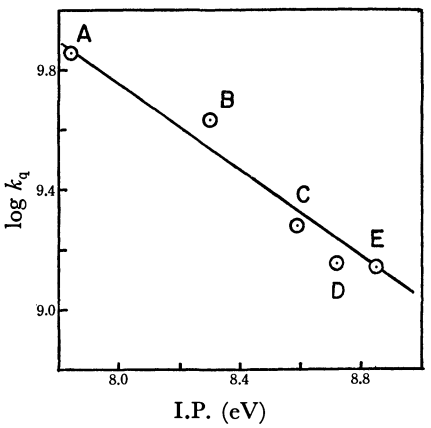

Fig. 4. Correlation of quenching rate constants for propanal with diene ionization potentials.

behavior of the dimerization of 1,3-cyclohexadiene qualitatively.

A Stern-Volmer treatment of the fluorescence quenching (Fig. 2) using Eq. 5 yields a slope of 7.8 M^{-1}.

$$\frac{F_0}{F} = 1 + \frac{k_4[D]}{k_1+k_2+k_3} \qquad (5)$$

F_0: propanal fluorescence intensity in the absence of 1,3-cyclohexadiene

F: propanal fluorescence intensity in the presence of 1,3-cyclohexadiene

The slope and intercept of the Stern-Volmer analysis for oxetane formation with the diene (Fig. 1) show the following:

$$\frac{\text{intercept}}{\text{slope}} = \frac{k_4}{k_1+k_2+k_3} = 7.3M^{-1}$$

This is in good agreement with the value of $k_4/(k_1+k_2+k_3)$ obtained from the quenching of fluorescence of propanal by 1,3-cyclohexadiene, 7.8 M^{-1} (Eq. 5). These results indicate that the fluorescence quenching and oxetane formation by the diene proceed *via* the same intermediate and offer some experimental support to the kinetic Scheme proposed above.

The fluorescence of propanal was also quenched by other conjugated dienes (Table 1). The singlet excitation energy of 1,3-butadiene has been suggested to lie at 112 kcal/mol or somewhat higher[24] and that of 1,3-cyclohexadiene is unlikely to be very different. The lowest excited singlet level of propanal is expected to be a few kilocalories per mole below that of acetone (84 kcal/mol), since the absorption spectrum of propanal is red-shifted by ≈10 nm from that of acetone.[25] Therefore, such quenching is unlikely to proceed by physical energy transfer. It is noteworthy that the rate constants for quenching by 2,5-dimethyl-2,4-hexadiene and 1,3-cyclohexadiene are essentially equal to that for diffusion in the solvent, benzene. In Fig. 4 the function log k_q is plotted against ionization potentials of several 1,3-dienes. The linear behavior indicates that charge transfer interaction contributes to stabilization of this quenching process.[26] The efficient endothermic quenching and linear relationship between log k_q and ionization potentials suggest that the complex mentioned previously is an exciplex involving the interaction between the highest filled orbital of the conjugated diene and the half-vacant n-orbital of propanal.[5a] The simple Hückel MO calculations[27] suggest that the wave-function coefficient of the highest filled orbital of the conjugated diene is largest at the p-orbital of either end. Therefore, an attack by the non-bonding oxygen electron on either end of the diene generates a more stable exciplex. The stability of this exciplex seems to determine the regioselectivity of oxetane formation.

Table 1 shows that rate constants for quenching of propanal n,π^* singlet state by dienes are 5—20 times greater than rate constants for quenching of acetone n,π^* singlet state. These results are consistent with the data suggested by Dalton *et al.*[28] The greater reactivity of propanal n,π^* singlet state toward dienes will probably be a steric effect, *i.e.*, that interaction of the highest filled orbital of conjugated dienes with the electrophilic oxygen *n* orbital in the plane of the carbonyl is less sterically hindered in aldehydes than in ketones, as

Table 1. Diene ionization potentials and rate constants for fluorescence quenching of propanal by conjugated dienes

Diene	$k_q\tau$,M^{-1} a)	k_q,$M^{-1}\,s^{-1}$ b)	I.P.,c) eV
2,5-Dimethyl-2,4-hexadiene (A)	13 (2.07)	7.2×10^9	7.84

Isoprene (E)	2.5(0.13)	1.4×10^9	8.85

a) $k_q=k_4$: quenching rate constants. The values in parentheses are those for acetone.[7h,9b] b) Calculated from the data of Turro *et al.*, Ref. 9c. τ (the lifetime of singlet propanal) is estimated to be 1.8 ns. c) See Ref. 26.

suggested by Dalton *et al.*[11b]

Experimental

General. IR spectra were obtained on a Hitachi EPI-S2 spectrophotometer. UV spectra were obtained on a Hitachi 124 spectrophotometer. Fluorescence spectra were obtained on a Hitachi MPF-2A spectrofluorometer. NMR spectra were taken on a Hitachi Perkin-Elmer R-20 spectrometer. VPC were performed on a Shimadzu GC-3AF. A 2 m 25% PEG 6000 on a Chromosorb W column was used for analysis of the products.

Materials. Benzene was treated with concentrated sulfuric acid, washed with water, and finally purified by distillation over sodium. 1,3-Cyclohexadiene was prepared as described by Marvel and Hartzell.[29] 2,3-Dimethyl-1,3-butadiene was prepared by the method of Allen and Bell.[30] Propanal, 1,3-pentadiene, isoprene, and 2,5-dimethyl-2,4-hexadiene were obtained commercially, and were purified by distillation before use.

Irradiation of Propanal and 1,3-Cyclohexadiene. In a Pyrex vessel, a mixture of propanal (14.5 g, 0.25 mol) and 1,3-cyclohexadiene (20 g, 0.25 mol) was irradiated for 55 h with a 350 W high-pressure mercury lamp. After removal of the reactants, the remaining liquid was distilled under reduced pressure to give a liquid (5.9 g, bp 73—105 °C/18 mmHg), leaving a viscous liquid (1 g). VPC (PEG 6000, 130 °C) of the distillate showed oxetane I (70%), II (10%), and 1,3-cyclohexadiene dimers (20%). 1,3-Cyclohexadiene dimers were identified by a comparison of their VPC retention times (PEG 6000 and DNP) with those of authentic samples.[16] Oxetane I and II were isolated by preparative VPC on a 2 m 25% PEG 6000 column at 125 °C.

Oxetane I was collected as a colorless oil: bp 70—71 °C/18 mmHg; IR 1650 (C=C) and 982 cm^{-1} (oxetane ring); NMR (CCl_4) δ 0.90 (t, J=6.5 Hz, 3H, methyl), 1,1—2.5 (m, 6H, methylene), 2.76 (*ca.* q, 1H, H_b), 3.89 (td, J=4.0 and 6.0 Hz, 1H, H_a), 4.88 (dt, J=3.0 and 7.2 Hz, 1H, H_c), and 5.83 (m, 2H, olefinic). Found: C, 78.23; H, 10.40%; mol wt, (cryoscopic in benzene), 144. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%; mol wt, 138.

Oxetane II was collected as a colorless oil: IR 1650 (C=C) and 983 cm^{-1} (oxetane ring); NMR (CCl_4) δ 0.73 (t, J=7.1 Hz, 3H, methyl), 1.0—2.5 (m, 6H, methylene), 3.10 (q, J=6 Hz, 1H, H_b), 4.63 (q, J=6.9 Hz, 1H, H_a), 4.90 (dt, J=2.5 and 6.3 Hz, 1H, H_c), and 5.83 (m, 2H, olefinic). Found: C, 78.00; H, 10.29%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

Quantum Yields. Benzene solutions (4 ml) containing 0.11 M propanal and 0.1—1 M 1,3-cyclohexadiene were degassed and sealed in 10 ml o.d. quartz tubes which had been attached to Pyrex tubes *via* graded seals. The sample tubes were then irradiated on a merry-go-round apparatus at room temperature, using a 350 W high pressure mercury lamp and a filter solution with a path length of about 1 cm containing 5 g potassium hydrogen phthalate made up to 1 l with distilled water (>310 nm). Photolysis was carried out to 10% or less conversion (irradiation time, 30 min); the conversion was linear out to 80 min. Actinometers (propanal–2-methyl-2-butene system)[4b] were photolyzed simultaneously. The solutions were analyzed on VPC (PEG 6000, 125 °C), using tetralin as the internal standard.

Sensitization with Phenanthrene. A benzene solution containing 0.12 M propanal, 0.13 M 1,3-cyclohexadiene, and 0.02 M phenanthrene was degassed, sealed, and irradiated for 20 min through a filter solution containing 15 g naphthalene made up to 1 l with hexane (>320 nm). The formation of oxetanes was only <1% of diene dimers, according to VPC, though it was expected to be 20% of diene dimers at such a diene concentration. The formation of a small amount of oxetanes was considered to be due to the directly excited propanal.

Fluorescence Quenching. A propanal solution, 0.2 M, was prepared in benzene. A known volume of the propanal solution was pipetted into a quartz fluorescence cell and the fluorescence was observed using an excitation wavelength of 320 nm. Aliquots of dienes were added to the solution by means of a micro syringe while monitoring the decrease in fluorescence intensity at 420 nm.

Quenching with Oxygen. Two samples were prepared. Each contained 4.0 ml of a benzene solution of 0.13 M propanal and 0.052 M 1,3-cyclohexadiene. One was degassed and sealed. Both samples were irradiated for 45 min with a 350 W high pressure mercury lamp through a potassium hydrogen phthalate cut-off filter (>310 nm). The yield of diene dimers in the non-degassed sample was less than that in the degassed sample by *ca.* 20%, but that of oxetanes was unchanged in both samples, according to VPC (PEG 6000, 125 °C).

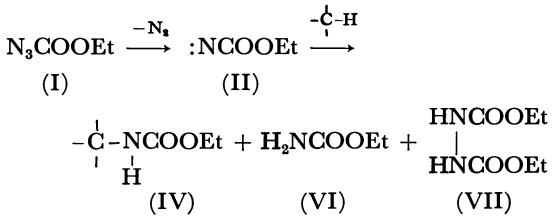
(Received April 2, 1976)

Ethoxycarbonyl nitrene, generated by the photolysis of ethyl azidoformate (I), were inserted preferentially into the α C–H bonds of cyclic ethers. The α C–H bonds of cyclic ethers were much more reactive than the corresponding C–H bonds of hydrocarbons for the insertion of the nitrene. In addition, the reactions in cyclic ethers with an alkyl group at the α-position gave unsaturated alkoxyurethanes *via* a cleavage of the ring C–O bond. It was found that the nitrene insertion into the α C–H bonds of *cis*- and *trans*-2,5-dimethyltetrahydrofurans proceeded non-stereospecifically, while the insertion into the C–H bonds of hydrocarbons proceeded stereospecifically. The formation of the alkoxyurethanes can be explained by a mechanism in which an O–N ylide is included as an intermediate of the nitrene reaction; the non-stereospecific insertion of the nitrene give support to this mechanism.

The relative reactivities for the insertion of nitrenes toward C–H bonds have been reported for primary: secondary:tertiary,[1,2] exo:endo, bridge:bridgehead,[3,4] and axial: equatorial[5] C–H bonds, and in those earlier experiments hydrocarbons have been employed as the substrates. In the reaction of ethoxycarbonyl nitrene, which was generated by the photolysis of ethyl azidoformate, with cyclic ethers, was found that the α C–H bonds showed unusually large reactivities compared with the corresponding C–H bonds of hydrocarbons in the insertion of the nitrene, and observed that cyclic ethers with an α-methyl (or ethyl) group gave unsaturated alkoxyurethanes as a result of the ring C–O bond cleavage. According to Nozaki's report, ethoxycarbonyl nitrene is inserted into the α C–H bonds of five- and six-membered cyclic ethers[6] and into the α-methylene C–H bonds of cyclohexanone ethylene acetal; this is, in a radical sense, a hydrogen abstraction-recombination process.[7] On the other hand, the nitrene insertion into the cyclohexane ring C–H bonds of the acetal was explained in terms of the intermediacy of the oxygen-imine or the direct attack of the singlet nitrene on the C–H bonds. In the present paper, we wish to report that the reaction of the nitrene with cyclic ethers includes an O–N ylide (oxygen-imine) as an intermediate and that the nitrene insertion into the α C–H bonds of the ethers proceeds by means of a mechanism different from that advanced in the insertion into the hydrocarbon C–H bonds.[8]

Results and Discussion

Photolyses of Ethyl Azidoformate in Cyclic Ethers. Ethyl azidoformate (I) in cyclic ether (III) was irradiated by the light (mainly 2537 Å) of a low-pressure mercury arc at 0 °C with stirring under an atmosphere of nitrogen. The insertion products (IV) of ethoxycarbonyl nitrene (II) into the C–H bonds of the cyclic ethers, except for the three- and four-membered cyclic ethers, were obtained accompanied by the hydrogen abstraction product, urethane (VI), and small amounts (0.5—2%) of diethyl hydrazoformate (VII). In addition, the reactions of I with α-alkyl cyclic ethers gave unsaturated alkoxyurethanes (V). No insertion products into the ring C–H bonds were recognized in the reactions with the three- and four-membered cyclic



ethers. In the reactions with the five- and six-membered cyclic ethers, the insertion took place preferentially at the ring C–H bonds of the α-position. The yields of the products mentioned above are listed in Table 1.

The reaction in 2-methyltetrahydrofuran, which bears a tertiary hydrogen atom, gave an increased yield of urethanes (VI) compared with the reactions in tetrahydrofuran and in tetrahydropyran. This can be understood in terms of hydrogen abstraction by the triplet nitrene.[9] The reactions with the small ring ethers gave comparatively low yields of VI. It seems that some of the triplet nitrene and/or some of the amido radical, HNCOOEt, has been consumed in the ring-opening polymerization of the small-ring ethers employed.

Relative Reactivities. As has been mentioned above, the α C–H bonds of the cyclic ethers are more reactive than the others for the nitrene insertion; the reactivities of the α C–H bonds are greatly enhanced. Therefore, in order to compare the insertion reactivities of the C–H bonds of the cyclic ethers with those of cyclohexane, the photolysis of I was carried out in a mixture of equimolar amounts of a cyclic ether and cyclohexane. The product distributions and the relative reactivities are summarized in Table 2. These relative reactivities are displayed in Fig. 1, where they are compared with

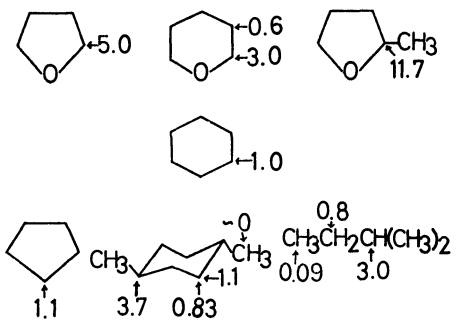


Fig. 1. Relative reactivit.es of various C–H bonds.

TABLE 1. PHOTOLYSES OF I IN CYCLIC ETHERS

TABLE 2. PHOTOLYSIS OF I IN A MIXTURE OF A CYCLIC ETHER AND CYCLOHEXANE

Product (%)[a]				
Insertion (IV)		Cyclohexyl-urethane	Type of C–H bond	Relative reactivity[b]
(e)	18.1	10.8	2° (Ring-α)	5.0(±0.1)[c]
(f)	6.9	7.0	3° (Ring-α)	11.7(±1.1)
(g_1)	13.3	13.5	2° (Ring-α)	3.0(±0.2)
(g_2)	2.6		2° (Ring-β)	0.6(±0.1)

a) Calculated on the basis of the azide used. b) Relative reactivities: per C–H bond of cyclohexane. c) The relative errors appear in parentheses.

those of some hydrocarbons,[10] obtained in experiments carried out under the same conditions as the present work.

The relative reactivities of primary, secondary, and tertiary C–H bonds of the cyclic hydrocarbons toward ethoxycarbonyl nitrene are as follows: $1° \ll 2° < 3°$; these values are about the same as those of the corresponding C–H bonds of the acylic hydrocarbons. On the other hand, it was found that the α C–H bonds of the cyclic ethers were much more reactive than the corresponding C–H bonds of hydrocarbons in the nitrene insertion. Such unusual reactivities suggest that the insertion in question must proceed by a mechanism other than that proposed in the reaction with hydrocarbons.[3,8,11] Therefore, the reaction of I with cyclic ethers was studied from the stereochemical point of view as one approach to the problem.

Stereochemistry of the Insertion Reaction. Ethyl azidoformate (I) was irradiated in *cis*- and *trans*-2,5-dimethyltetrahydrofurans (IIIh and IIIi). Two insertion products (stereoisomers) into the α C–H bonds and the abstraction product were well separated from the reaction mixture by the use of gas chromatography. The IR and NMR spectral data of neither of these stereoisomers, however, led to a decision between the two alternative conformations because of the extreme similarity of their IR and NMR spectra. Methyl azidoformate (VII) was then employed instead of I, since the structures of the insertion product into IIIh were more simple than those formed in the reaction of I. The reaction of VII gave two insertion products (stereoisomers, XI and XII) and an abstraction product (methyl carbamate) in yields of 19% and 53% respectively. A comparison between the reactions of VII and I showed that the interrelationships of the yields, the VPC retention times, and the IR and NMR spectra between XI and XII were very similar to those between IVh_1 and IVh_2. Such information may lead to the consideration that the conformations of XI and XII correspond to those of IVh_1 and IVh_2 respectively. The NMR spectrum of a mixture of the insertion products, XI and XII, is shown in Fig. 2-i. Each of the peaks in Fig. 2 was due to XI or XII, judging from a comparison of the peak areas. After a shift reagent, $Eu(fod)_3$, had been added to the solution, the NMR spectrum was measured (Fig. 2-ii). The singlet peak (XIIb) of the 2-methyl protons of XII was shifted to a field lower than that (XIb) of XI. Their peaks were far separated by the further addition of the shift reagent (Fig. 2-iii), while the induced downfield shift for the NH proton

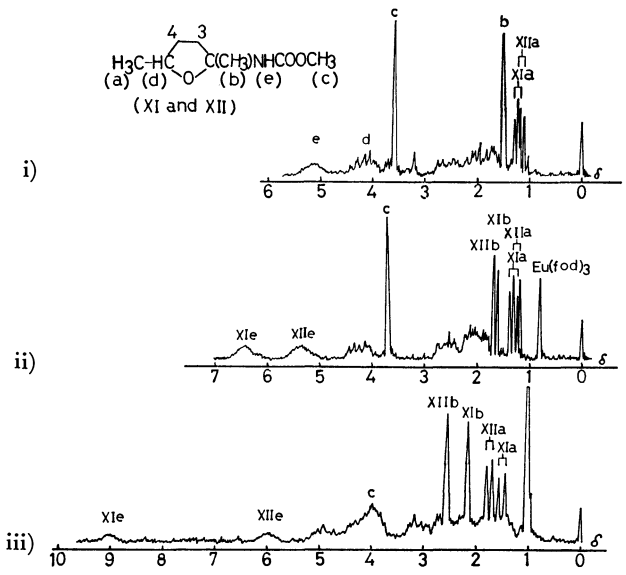

Fig. 2. NMR spectra of a mixture of XI and XII in ratio of 45: 55.
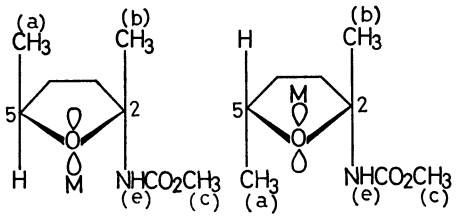
i) A 0.2 ml of CCl_4 contains 20 mg of a mixture of XI and XII.
ii) The solution contains 3 mg of $Eu(fod)_3$.
iii) The solution contains 9 mg of $Eu(fod)_3$.

(XIIe) of XII was smaller than that (XIe) of XI. The addition of the shift reagent caused a downfield shift of XII larger than that of XI also with regard to the two doublet peaks (XIIa and XIa) of the 5-methyl protons. These findings can be explained as follows: the bulky shift reagent approaches the ethereal oxygen atom through an opening in the crowded environment of two methyl and one NHR groups. The *cis*-isomer (with regard to two methyl groups), one of the stereoisomers, coordinates to the shift reagent at the side on which the NHR group in the isomer is located, thus giving XIII. The other, the *trans*-isomer, coordinates to the shift reagent at the opposite side of the NH group, thus giving XIV.



The singlet peak of the 2-methyl protons of XIV should then be shifted to a field lower than that of XIII. The peaks of XI and XII in Fig. 2 were thus assigned to the protons of XIII and XIV respectively. The difference between the induced shifts of the XIa and XIIa peaks, in spite of the relationship between the 5-methyl group and the shift reagent being the same at both XIII and XIV, shows that XIV might be formed more rapidly than XIII. That is, a coordination equilibrium in the *trans*-isomer lies further toward XIV compared with an equilibrium in the *cis*-isomer. The great downfield shift of the XIe peak compared with that of the XIIe peak means that the difference in the distances between the shift reagent and the NH proton affects the shift more strongly than that in the concentrations of the adducts (XIII and XIV).

In the case of I, one insertion product, IVh_1, has the same conformation as XI, while the other, IVh_2, has the same conformation as XII since XI and XII correspond to IVh_1 and IVh_2 respectively, as has been described above. Table 3 shows the product yields in the reactions of I.

The coordination compound between the shift reagent and the NH or the $COOCH_3$ group is not formed. If the coordination compound between the shift reagent and the NH group were formed, the peak (XIIe) of the NH proton must be shifted downfield as well as the XIe peak. If the coordination compound between the shift reagent and the $COOCH_3$ group were formed, the induced downfield shifts for the ester methyl protons (Peak c) must have larger magnitudes than those for the 2-methyl protons(Peak b)(Fig. 2-i—ii).

It may be concluded that the insertion reactions of the nitrene (II) into α C–H bonds of the cyclic ethers proceed non-stereospecifically, in contrast to the stereospecific insertion of II into the C–H bonds of hydrocarbons.[3,8,11]

The nitrene (II) is able to coordinate, by means of its nitrogen atom, to an ethereal oxygen atom as the nitrene does to the sulfur atoms of thioethers[12,13] and sulfoxides[13,14] to give the nitrogen-sulfur ylides. Therefore, the reaction of the nitrene with ethers is initiated by an electrophilic attack of the nitrene on the ethereal

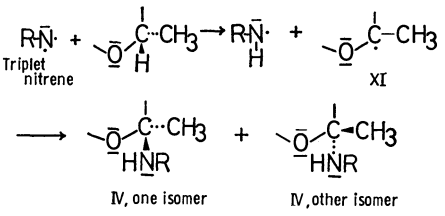
Path B Cleavage of ring C–O bond

oxygen atom to give an O–N ylide (oxygen-imine intermediate, Scheme 1).

The ylide (VIII) abstracts a proton from the α C–H bond to give IX, followed by the homolytic cleavage of the O–N bond to give a radical species (X). The radical, ṄHR, combines with the α-carbon radical to give IV (Path A). On the other hand, VIII leads to V *via* hydrogen abstraction from the α-methyl or α-methylene group and the cleavage of the C–O bond in a concerted pericyclic manner (Path B).

The non-stereospecific insertion by ethoxycarbonyl nitrene into C–H bonds of cyclic ethers does not exclude a hydrogen abstraction-recombination mechanism.

The triplet nitrene is able to abstract a hydrogen atom from the α-position of ethers, giving an amido radical and XI, whose recombination leads to the insertion products (IV isomers).



Scheme 2.

The mechanism of Scheme 2 has been ruled out for the nitrene insertion into C–H bonds of hydrocarbons.[8,11] The XI radical, however, is stabilized by the adjacent oxygen atom in comparison with a hydrocarbon radical. Consequently, IV may be formed by the radical recombination.

In the isomerization from the O–N ylide (VIII) to the insertion product (IV), the distance between the nitrogen atom and one C–H bond, to which the nitrene would be inserted, seems to be an important factor. In the case of tetrahydropyran, the insertion product (IVg_1) into the α C–H bond, which is located nearly at the nitrogen atom of the ylide, is derived from the ylide intermediate. On the other hand, the insertion product (IVg_2) into the β C–H bond is formed by the one-step mechanism[8] proposed in the reaction of nitrene with hydrocarbons, since the β C–H bond is too far from the ylide nitrogen atom. These two distinct mechanisms can explain the difference between the reactivities of the α and β C–H bonds shown in Table 2.

Experimental

The IR spectra were recorded on a Hitachi EP-S photometer and a Nippon Bunko (JASCO) Model IR-E photometer, while the NMR spectra were taken on Hitachi R-20 and Hitachi R-24 instruments, using tetramethylsilane as the internal standard. Gas chromatography (VPC) was done on Shimadzu GC-2C and Nippon Denshi (JEOL) JGC 20K units, employing as absorbents: A, 20% Ucon Oil 5 HB 2000 on Celite (60—80 mesh); B, 10% polyethylene glycol succinate on Neopak 1A (60—80 mesh). The products were separated by VPC, and the structures of the products were determined by means of elemental analyses and by measurements of the IR and NMR spectra. The quantitative analyses of the products by VPC and test for the stability of each product during VPC analysis have been described in a previous paper.[15]

Materials. The ethyl azidoformate (I) was prepared by the method of Lwowski and Mattingly.[16] The methyl azidoformate (VII) was prepared from methyl chloroformate and sodium azide in the manner used for the preparation of ethyl azidoformate; bp 24 °C/40 mmHg; yield, 83%. All the cyclic ethers, except for oxetanes (IIIc and IIId), dichloromethane, and cyclohexane were used after the commercial reagents had been purified according to the published directions.[17] The oxetane was prepared by the ring closure of 3-chloropropyl acetate,[18] which had been obtained by the chlorination of 1,3-propanediol[19] followed by the acetylation.[20] The 2-methyloxetane was prepared in a way similar to the synthesis of oxetane. The introduction of dry hydrogen chloride into 500 g (5.6 mol) of 1,3-butanediol gave 314 g (3 mol) of the chlorohydrin;[21] bp 63—65 °C/11 mmHg; yield, 54%. A reaction of the chlorohydrin (314 g) and acetic acid (240 g, 4 mol) gave 260 g (1.7 mol) of the ester;[22] bp 70—74 °C/13 mmHg; yield, 57%. The ester (260 g) was cyclized by potassium hydroxide into 42 g (0.6 mol) of 2-methyloxetane; bp 60 °C,[23-25] yield; 35%. NMR (CCl_4, τ): 4.8—5.4 (CH, m), 5.5 (ring γ-CH_2, m), 7.0—8.0 (ring β-CH_2, m), 8.65 (CH_3, d). The cyclohexylurethane was prepared from cyclohexylamine and ethyl chloroformate.[16] The data of mp, IR, and NMR were in good agreement with those reported in the literature. The *cis*-2,5-dimethyltetrahydrofuran (IIIh) (bp 90 °C (lit, 90—91 °C)) was prepared by the ring closure of *dl*-2,5-hexanediol[26] (*dl*-diol), which had itself been obtained by the separation of a mixture of *dl*- and *meso*-diols.[27] The *trans*-2,5-dimethyltetrahydrofuran (IIIi), bp 93 °C (lit, 92—

94 °C) was also prepared from *meso*-diol separated from the mixture. Their IR and NMR spectra were in good agreement with those reported in the literature.[28] In the same manner, a mixture of *cis*- and *trans*-2,5-dimethyltetrahydrofurans was prepared by the ring closure of a mixture of *dl*- and *meso*-diols; bp 92—94 °C; yield, 86%. No photochemical isomerization between *cis*- and *trans*-2,5-dimethyltetrahydrofurans was observed under the conditions of these experiments.
