Acridine dyes have a common notable characteristic of readily aggregating. Acridine Orange, a typical acridine dye undergoes many interesting phenomena that remain yet to be studied, although a number of investigations have dealt with the concentration dependence of absorption spectra and the equilibrium between monomers and aggregates.[1,2] Schmidt[3] and Chambers *et al.*[4] have studied the behavior of the triplet state as a function of the dye concentration. It was found that dye molecules aggregate to form a complex in which the molecules are orientated in a fixed direction.

It is the purpose of this paper to demonstrate the favorable energy transfer process in a system of dye molecules embedded in a polymer matrix by means of depolarization of the fluorescence and phosphorescence as a function of the dye concentration.

Experimental

The techniques used to prepare poly vinyl alcohol (PVA) films are similar to those employed by Tanizaki *et al.*[5] PVA solutions were prepared by mixing 20 g of PVA powder with 150 ml of redistilled water, followed by vigorous stirring in a boiling water-bath for 2 h. To this solutions was added 50 ml of a hydrochloric acidified ethanol solution of chromatographically purified Acridine Orange. After careful mixing, the solutions were poured over a glass plate (20× 20 cm) and were spread out to a uniform thickness. The solutions were dried in a dust-free box for a few days at room temperature. The hard films obtained have a typical thickness of about 0.2 mm.

Absorption spectra were measured with a Shimadzu MPS-50L spectrophotometer. A 150 W xenon lamp combined with various interference filters was used to excite the samples. A Nikon G-250 grating monochromator was used for the emission spectra. The exciting light beam falls on the film surface at an angle of 60° and the fluorescence was observed in the direction at right angles with the exciting light beam. For the measurement of polarization, two rotatable film polarizers ("Polaroid" HN-22) were used. A quartz depolarizer was inserted in front of the photomultiplior (HTV-R636). The transmittance of the monochromater for the polarized light was independent of the polarization of the incident light for all wavelengths. To obtain phosphorescence spectra, a cylindrical sector was rotated around the cylindrical Dewar flask in which the films were immersed in liquid nitrogen. Absorption spectra were corrected for the transmittance of the neat PVA film without the dye. The degree of polarization P was corrected for the self-polarization of the apparatus.[6] P was determined by $P=(I_{\parallel}-I_{\perp}f)/(I_{\parallel}+I_{\perp}f)$, where f[7] is a correction factor. $I_{\parallel}$ and $I_{\perp}$ are the observed intensities of vertical and horizontal components of the fluorescence with respect to the vertically polarized exciting light.

Results and Discussion

Figure 1 shows the absorption and fluorescence spectra of Acridine Orange cations in PVA films at 77 K. The room temperature absorption spectra in PVA are essentially identical with those in ethanol solutions. At 77 K, however, there is a remarkable difference between the absorption spectra in ethanol solutions and those in PVA films due to the aggregation of dyes in liquid solutions. The first absorption band with the peak at 495 nm is attributed to the $S_1 \leftarrow S_0$ transition of the dye monomers. The second band around 465 nm appears as a shoulder and becomes more prominent relative to the first band, as the concentration of dye cations increases. It is interesting to note that Acridine Orange cations form dimers in PVA films. In studies by Tanizaki *et al.*,[5] the formation of dimers in PVA films was not observed.

To account for the effect of concentration on the absorption spectra in PVA films, the monomer-dimer equilibrium of dye molecules is assumed and an ap-

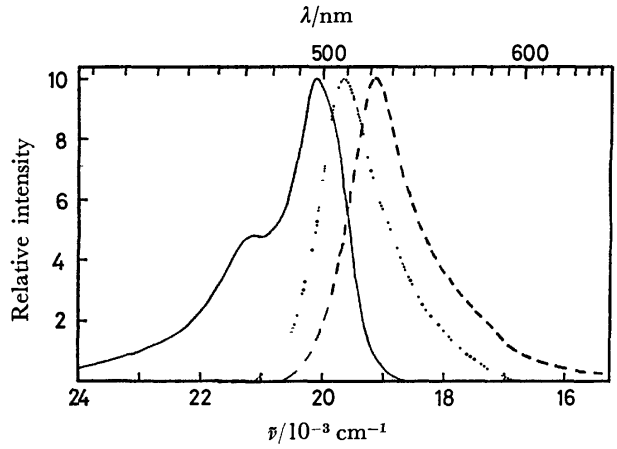

Fig. 1. Absorption and fluorescence spectra of Acridine Orange cations in PVA at 77 K. Absorption; ——: 2.64×10^{-5} M. Fluorescence; ····: 1.32×10^{-6} M. ----: 2.64×10^{-5} M.

propriate K value, 1.3×10^4 M^{-1}, is obtained for concentrations ranging from 10^{-4} to 10^{-6} M. In the case of ethanol solutions at 10^{-4}—10^{-6} M, a value of 1.4×10^4 M^{-1} is obtained for the association constant. The equilibrium constant, 1.3×10^4 M^{-1}, can be attributed to that in the film before it hardens and not to that in the hard film. Spectra derived from this dimerization equilibrium display a shoulder at 470 nm in agreement with the results of Zanker.[1] The 495 nm peak and the 470 nm shoulder have been assigned by Sheppard[8] to the 0–0 and 0–1 vibrational transitions, respectively. The association constant in PVA films is independent of the temperature. Therefore, the dimerization equilibrium is the same as that at room temperature.

The fluorescence spectra show good mirror image relationships with the absorption spectra. In all the experiments, no excitation spectra indicate that the samples contain any free base of the dye. The spectra in PVA are rather diffuse, compared with those of ethanol solutions, as well as the absorption spectra. The change of the fluorescence profile with increasing dye concentration is remarkable on the longer wavelength side of the broad emission band, this change appearing to be due to dimer formation. The peak of the broad emission band at 510 nm shifts toward the red by 490 cm^{-1} for a change in the dye concentration from 10^{-6} to 10^{-3} M. The red shift of the fluorescence peak cannot be interpreted in terms of reabsorption, which is negligible in the present optical system.

In ethanol glasses at 77 K, the fluorescence shows three sharp peaks at 510, 535 and 570 nm. In combination with the concentration change of the fluorescence spectra, these bands are assigned as follows. The first is the monomer band and the second that of the dimer. The third band is attributed to the oligomer band because of the appearance of the same peak for the polycrystalline dye films on a glass plate obtained by solvent evaporation from dye cation solutions. Compared with these complex features of solution fluorescence at 77 K, PVA matrix fluorescence spectra appear to be rather simple. The first sharp band is attributed to the monomer band and the second is a weak, but detectable, broad dimer band mixed with that of the oligomer.

In the highest concentration range, the broad intense phosphorescence at 655 nm is observed with a swift decay rate at room temperature. It is expected that the phosphorescence states are established in PVA films because of the slow quenching reaction of the phosphorescence by oxygen. As shown in Fig. 2, phosphorescence spectra in PVA at 77 K give the main peak at 610 nm and the second peak at 655 nm. The lifetime of the phosphorescence is 2.0 s at 10^{-3} M in PVA films at 77 K. If the dimer band is excited at 465 nm, the intensity of the second phosphorescence band is stronger than the first. In addition to the consistency with the excitation spectra, the intensity of the second phosphorescence band becomes stronger as the dye concentration is increased. On the basis of these spectral changes, the second phosphorescence band is attributed to the triplet state

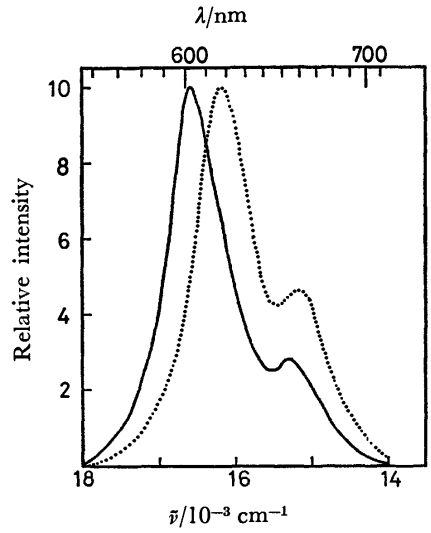

Fig. 2. Phosphorescence spectra of Acridine Orange cations in PVA at 77 K.
——: 7.92×10^{-5} M. ····: 6.12×10^{-4} M.

of the dimer.[4]

However, the energy gap between the triplet states of the monomer and dimer appears to be much larger than the generally accepted values for dimers. The peaks of phosphorescence spectra show a red shift of 600 cm^{-1}, which is larger than that for fluorescence, when the dye concentration increases above 6×10^{-4} M. The energy gap may be interpreted on the basis of the lowering of the triplet state by the formation of complicated aggregates rather than simple dimers.

The second phosphorescence band is shifted makedly toward the red, and is accompanied by an extension of the excitation spectra into the red at concentrations greater than 6×10^{-4} M. Consistent with the present observation, Schmidt[3] and Yamaoka[9] *et al.* have reported the appearance of a broad absorption band with a peak around 570 nm at a high dye concentration above 6×10^{-4} M.

Polarization measurements were made for their fluorescence, phosphorescence and excitation spectra

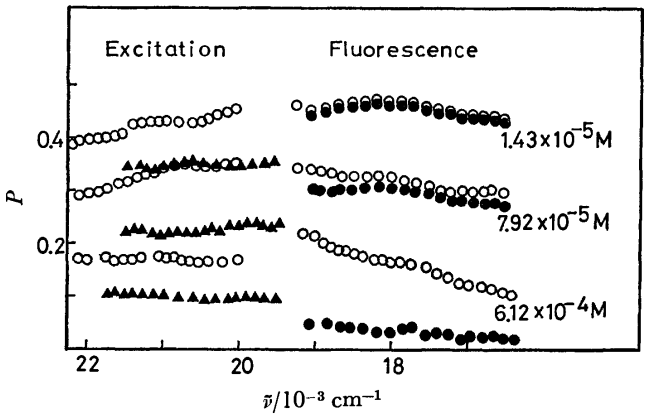

Fig. 3. Polarization degrees of fluorescence and excitation spectra. Fluorescence; ○: excited at 495 nm, ●: excited at 465 nm. Excitation; ○: observed at 525 nm, ▲: observed at 655 nm.

in PVA films. In Fig. 3, the variation of the degree of polarization of excitation as a function of the fluorescence observed at 525 nm is shown. At medium concentrations of 10^{-4}—10^{-6} M, there is a slight, but detectable, difference between the degree of polarization of the monomer at 495 nm and that of the dimer band at 465 nm. The excitation of the dimer band results in a higher depolarization than that of the monomer band. In Fig. 3, fluorescence also exhibits similar differences in the degree of polarization of the monomer, dimer and oligomer bands. Thus, it seems probable that each electronic transition exhibits a certain degree of polarization, but that the separation of each fluorescence band is poor due to the broad emission bands in polymer films. At low concentrations, below 10^{-6} M, it is difficult to obtain a degree of polarization with good reproducibility. At these concentrations, however, the degree of polarization remains constant independent of the fluorescence spectral range. At high concentrations, above 4×10^{-4} M, the structure of the fluorescence spectra disappears in parallel with the fluorescence depolarization.

The fluorescence depolarization indicates energy transfer in PVA films which inhibit molecular diffusion. The plots of $1/P$ *versus* concentration are linear regardless of the exciting or observed wavelengths over the concentration range of 10^{-4}—10^{-6} M, where P is the degree of polarization. Fig. 4 serves to illustrate the linear relation for the case of the monomer-band excitation and observation. For concentrations above 10^{-4} M, $1/P$ at a given concentration is remarkably dependent of the excitation wavelength and the fluorescence wavelength.

The limiting polarization P_0, the degree of polarization in the absence of energy transfer is obtained by extrapolation to zero concentration. Weber[10] derived an equation describing the intermolecular energy transfer as revealed by fluorescence depolarization measurements as follows:

$$\frac{1}{P}-\frac{1}{3}=\left(\frac{1}{P_0}-\frac{1}{3}\right)\left(1+\frac{4\pi NR^6\times 10^{-3}}{15(2a)^3}C\right) \qquad (1)$$

in which N is Avogadro's number, C is the concentration in M, R is the critical distance for two oscillators and a is the effective molecular radius. Assuming a value for $2a$ of 10 Å and utilizing the slope of the straight line in Fig. 4, R was calculated under several conditions and is listed in Table 1.

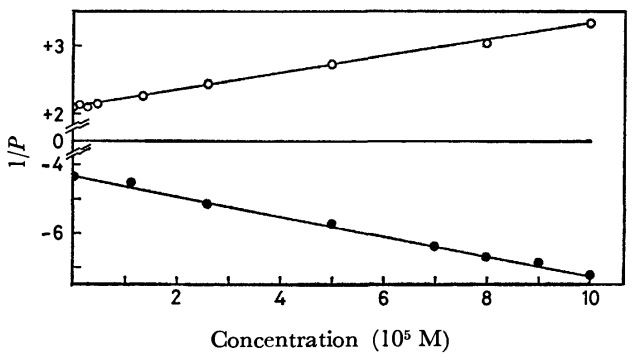

Fig. 4. $1/P$ plots *versus* concentration for fluorescence and phosphorescence spectra. ○; Fluorescence, excited at 495 nm, observed at 525 nm. ●; Phosphorescence, excited at 495 nm, observed at 610 nm.

TABLE 1. CRITICAL DISTANCES OBTAINED FROM FLUORESCENCE DEPOLARIZATION ($10^{-6}-10^{-4}$ M)

Excitation spectra		
Fluorescence	Excitation	
	at 495 nm	465 nm
535 nm	47.5	50.4
570 nm	49.5	52.0
Fluorescence spectra		
Exciting wavelength	Fluorescence	
	at 510—535 nm	570 nm
465	48.3	48.9
500	47.7	48.3

Furthermore, the degree of polarization of the phosphorescence is measured as a function of the concentration at 77 K for two peaks located at 610 and 655 nm. Room temperature phosphorescence is too weak to measure the degree of polarization accurately. The phosphorescence spectra are negatively polarized in contrast with the fluorescence spectra. The degree of polarization around 610 nm is higher than that around 655 nm. The concentration depolarization of phosphorescence is measured for two excitations at 465 and 495 nm while monitoring the phosphorescence peaks. The 465-nm excitation gives a higher depolarization than that at 495 nm.

The results give the relation between the phosphorescence depolarization and the dye concentration as in the case of fluorescence depolarization. A linear relationship between $1/P$ and the concentration is obtained in the concentration range of 10^{-4}—10^{-6} M. Selecting the phosphorescence observed at 610 nm and excited at 495 nm, a linear relation is shown in Fig. 4, for the degree of phosphorescence polarization. Using the slope of Fig. 4, the value of the critical distance R=47.3 Å is obtained from Eq. 1 for the phosphorescence depolarization on the assumption that it is possible to extend the previously mentioned treatment to the case of phosphorescence. This result indicates that the phosphorescence depolarization is also governed by singlet-singlet energy transfer. Above 10^{-4} M, somewhat more complicated features, such as triplet-triplet energy transfer, should be taken into consideration to account for the concentration depolarization of phosphorescence.

The concentration depolarization of phosphorescence has been studied by Chaudhuri and El-Sayed[11] and Iwao *et al.*[12] using the aromatic compounds such as naphthalene and its halogenated or deuterated derivatives. Concerning the primary process of phosphorescence depolarization, the present observations are in agreement with the conclusion obtained by Iwao *et al.*

One of the present authors (T. K.) is greatly indebted to Professor Y. Tanizaki for helpful discussions and suggestions.

Adsorption and Desorption of Molecular Oxygen in Solid State of Polymeric Hemochrome

Kenji HONDA, Seiji HATA, and Eishun TSUCHIDA
Department of Polymer Chemistry, Waseda University, Tokyo 160
(Received July 16, 1975)

The oxygenation of a pyridine-hemochrome bound to a polymer ligand has been studied in solid state. The oxygenation rate and the amount of oxygen adsorbed were determined by volumetry. The rate of adsorption of oxygen depends upon the structure of polymer matrix. Pyridine hemochrome included in a polyion complex takes up oxygen more rapidly than others. The rate of adsorption depends a great deal upon the surface condition of polymer matrix in case of oxygen binding in solid state. The degree of oxygenation was nearly equal in all cases. The difference in the rate of adsorption of oxygen may be due to the difference in gas permeability of the polymer matrix. This was supported by the fact that the hemochrome bound to a porous polymer matrix adsorbs oxygen more rapidly than the hemochrome bound to a non-porous polymer matrix. The surface condition of the polymer matrix greatly affects the reversibility of oxygenation.

An artificial oxygen carrier which can reversibly take up and release molecular oxygen with a relatively small difference in the partial pressure of oxygen in solution or solid state would meet extensive requirements.

Pfeiffer *et al.*[1] found the reversible binding of molecular oxygen of *N,N'*-ethylene bis(salicylideneiminato)-cobalt(II) complex (salcomin) in crystalline state. Calvin *et al.*[2] developed reversible oxygenation systematically for a series of salcomin derivatives in solid state. Studies on a reversible oxygen complex have actively been made in various fields. However, no metal complex which can reversibly take up oxygen in a neutral aqueous solution at room temperature has been synthesized. The failure in synthesizing a stable oxygen complex is due to the rapid irreversible autoxidation of a central metal ion. Wang *et al.*[3] synthesized the imidazole-hemochrome as a hemoglobin model included in polystyrene film and examined the stability and reversibility of the oxygen complex imbedded in the film in the presence of water.

The present authors[4-9] have found that oxygen complex can exist in a stable form even in aqueous dimethylformamide solution at room temperature by modification of a polymer ligand of heme-iron. Recent studies on oxygen complex have been made mainly in organic solvents.[10-15] In contrast, few studies in solid state have been carried out except for the series of Calvin's studies. In this paper, the oxygenation of the polymer-heme complex in solid state will be discussed. The correlation of the oxygenation reactivity to the surface condition of the polymer matrices has been studied.

Experimental

Materials. Poly(4-vinylpyridine) (PVP; $\overline{P}_n=49$) and partially-quaternized poly(4-vinylpyridine) (QPVP: $\overline{P}_n=49$, 24% of quaternization by benzyl chloride) were prepared and purified according to the conventional method.[4,9] Polystyrene sulfonic acid (PSS; $\overline{P}_n=321$, sulfonation=77%), polyglutamic acid (PGA; $\overline{P}_n=331$) and alginic acid (Alg) were purified according to directions reported in previous papers.[16,17] Isolation of chlorohemin from blood was carried out by Willstatter's method.[18] Sodium dithionite ($Na_2S_2O_4$) of a reagent grade was used without purification and α,α'-azobisisobutyronitrile(AIBN)was recrystallized from methanol.

Preparation of Powdery Polymer Matrix Including Hemochrome. A powdery sample of a polymer-bound hemochrome was prepared as follows. Chlorohemin (150 mg) was dissolved in 150 ml of an aqueous solution (pH=12). An aqueous solution (20 ml) containing 4.0 g of $Na_2S_2O_4$ was added, and then 150 ml of an aqueous solution containing 0.6 g of QPVP was added immediately in an atmosphere of nitrogen. The complex formation between heme and QPVP was accompanied by a color change from black brown to reddish brown. Another component of polyion such as PSS, PGA, and Alg was added in order to form a polyion complex; An aqueous solution (80 ml) containing PSS (0.38 g), PGA (0.35 g) or Alg (0.38 g) was slowly added to the above solution. The resulting precipitate was filtered off and dried completely *in vacuo* at 70—80 °C. This type of polymer-heme complex is called "complexed-type hemochrome".

Another type of polymer-heme complex "single-type hemochrome" was also prepared. PVP (1.06 g) and chlorohemin (68 mg) were dissolved in 150 ml of methanol. Methanol (140 ml) containing 0.9 g of L-ascorbic acid was then slowly added with vigorous stirring in an atmosphere of nitrogen. The resulting reddish solution was evaporated and dried at 50 °C *in vacuo*.

The content of heme of the polymer complex was determined by spectrometry to be 5.0×10^{-5} mole per unit gram of the polymer matrix. The powdery sample used for oxygenation analysis was ground to particles under 48 mesh.

Measurement of Magnetic Susceptibility. Metal complexes used were the monomeric and polymeric pyridine hemichromes. The measurement of magnetic susceptibility of powdery samples was carried out by the Faraday method. A magnetic torsion balance was operated at a field strength of 10000 G over the temperature range from liquid nitrogen temperature to room temperature. Gd_2O_3 was used as a standard sample. The magnetic susceptibility was recorded automatically and continuously as a function of temperature on an X-Y recorder. The apparatus used for the measurement is the same as that reported by Kohn.[19] The errors inherent in this method of analysis are of the order of ten per cent.

Manometric Measurement of Oxygen Uptake in Solid State. The time-conversion curves of oxygenation in solid state of polymer-bound hemochrome were obtained by use of a Warburg apparatus. Heme (1.0×10^{-5} mole) imbedded in 0.2 g of the matrix was put into a cuvette in an atmospheric oxygen pressure, the amount of oxygen adsorbed by the powdery sample being checked by use of a manometer. The amount of oxygen adsorbed by the hemochrome was corrected with a small quantity of oxygen adsorbed by the

powdery polymer and an excess of the reductant.

Results and Discussion

Coordination Structure of the Polymer-Heme Complex. The coordination numbers ($\bar{n}$) of the axial ligand and the equilibrium constants (K) of the hemichrome and hemochrome were determined by the method of Miller and Dorough.[20] The parameters $\bar{n}$ and K were calculated on the basis of the analysis of the spectrophotometrical titration for the complexation between hemin or heme and various bases. Application of this method to polymer ligands was reported previously[4,9]

The results given in Table 1 show that the axial 5th site of heme-iron is occupied by the pyridine molecule of PVP or QPVP. Another axial site of heme-iron might be either occupied by water or vacant. However, all the coordination numbers ($\bar{n}$) of the axial ligands were intermediate between 1.0 and 2.0 in both cases of the hemichrome and hemochrome. It is reasonable to consider that the six-coordinate pyridine hemichrome or hemochrome, whose axial sites are both occupied by two pyridine molecules, is mixed with the five-coordinate complex. The result of magnetic susceptibility also suggests that the high spin complex and the low spin complex are in equilibrium, because the molar magnetic susceptibility (X_M) of the pyridine hemichrome was intermediate between the calculated values of the high spin and low spin states (Table 1). From the temperature dependence of the magnetic susceptibility (Fig. 1), it was found that the high spin complex and the low spin complex are in spin equilibrium at the iron(III) state.[21] On the other hand, the equilibrium constant of spin exchange between the high spin state and the low spin state of the heme-ion(II) does not depend upon temperature. The observed value of the magnetic susceptibility was nearly equal to the calculated one of the high spin complex. Thus, in the case of the hemochrome, the six-coordinate complex can hardly be mixed with the five-coordinate complex.

Correlation of the Reactivity of Oxygenation to the Surface Condition of the Polymer Matrix. The oxygen adsorption curves of the complexed-type and the single-type polymeric hemochromes are shown in Fig. 2. Table 2 gives the initial rate, the half-saturation time and the degree of oxygen-saturation for the various types of polymer matrices. We see that the initial rate of the complexed-type system was appreciably larger than that of the single-type system. In general, the rate of adsorption of oxygen in solid state is affected by the diffusion of oxygen in solid matrix.[2b] The difference in the rate of adsorption between the complexed-type and single-type hemochromes may be due to the difference in the rate of diffusion of oxygen in the polymer matrices.

In order to clarify the correlation of the reactivity of oxygenation to gas permeability in the polymer matrix, the rate of adsorption of oxygen was checked for a porous polymer-bound hemochrome prepared by treatment of the matrix with a foaming agent such as

Deoxygenation: 3 mmHg, for 1 h.

azobisisobutyronitrile (AIBN). Figure 3 shows the relationship between the initial rate of oxygen uptake and the amount of AIBN added. The adsorption rate is linearly proportional to the amount of AIBN. This might be due to the increase in porosity of the polymer matrix. The porosity of matrix is of importance for oxygen uptake in solid state.

Table 2 also gives the corresponding parameters of oxygenation of the dispersion system in water. The gas permeability calculated by the Fick's Law becomes very large in the presence of water owing to the formation of water-bridge.[2b] We found that the oxygenation rate of the dispersion system is much larger than that of the solid system. This may also be due to the difference in gas permeability between the solid system and the dispersion system. However, the rate of the dispersion system in water was still much smaller than that of the homogeneous solution system.

Reversible Desorption of the Oxygen Complex Bound to Polymer Matrix. The oxygen complex can reversibly desorb molecular oxygen under reduced pressure, by heating or in a nitrogen stream. When the PVP-heme complex was heated at 90 °C, molecular oxygen bonded to heme-iron(II) was reversibly dissociated from heme-iron(II) with increasing magnetic susceptibility (Fig. 4). The spin state of heme-iron(II) of the pyridine hemochrome changed from the low spin state to the high spin state with deoxygenation.

The reversibility of oxygen binding was affected by the temperature of degassing. Figure 5 shows a plot of the degree of re-oxygenation against the temperature. Deoxygenation is complete in heating above 40 °C for one hour. However, at much higher temperatures, the degree of deoxygenation decreases owing to the irreversible autoxidation. Figure 6 shows the reversibility of oxygenation for the solid system and the dispersion system of the PVP-heme and QPVP/PSS-heme complexes. It is due to the irreversible autoxidation that the degree of oxygenation gradually decreases with the number of cycles of deoxygenation. The autoxidation of the complexed-type hemochrome proceeded more rapidly than that of the single-type hemochrome and the autoxidation of the dispersion system in water proceeded much more rapidly.

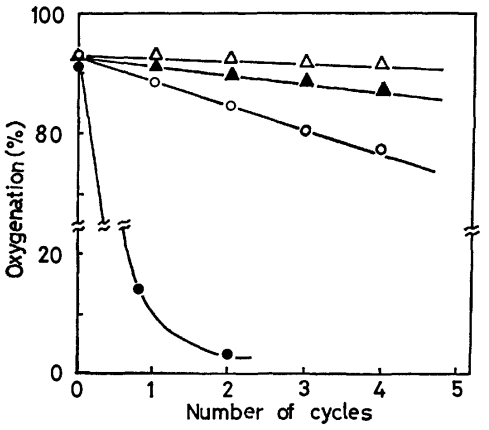

Fig. 6. Reversibility of oxygenation of some types of polymer-bound hemochrome.
PVP: △ solid, ▲ dispersion in H_2O.
QPVP-PSS: ○ solid, ● dispersion in H_2O.

In conclusion, oxygenation in solid state differs from that in solution in the following points: (1) The rate of oxygenation in solid state is smaller than that in solution. (2) Irreversible autoxidation scarcely occurs at room temperature in solid state. (3) The oxygen complex in solid state is much more stable than in solution, especially in comparison with the oxygen complex in an aqueous solution.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Japan (No. 085203). The authors wish to thank Prof. Kay Kohn, Waseda University, for his help in the measurement of magnetic susceptibility.

(Received July 21, 1975)

The crystals of 1-(2-thiazolylazo)-6-bromo-2-naphthol are orthorhombic, with a space group of $P2_12_12_1$, and with unit-cell dimensions of $a=19.044(3)$, $b=31.996(9)$, $c=4.221(1)$ Å, and $z=8$. The crystal structure was solved by the heavy-atom method and refined by the least-squares technique to give an R value of 0.064 for 1608 observed reflections. Both of the two crystallographically independent molecules show a generally similar shape and size. The phenolic oxygen atom is linked to the azo nitrogen atom adjacent to the thiazole ring by intramolecular hydrogen bonding, the O···N distances being 2.54 Å.

1-(2-Thiazolylazo)-2-naphthol(hereafter abbreviated as H-TAN) is a useful analytical reagent for metals. The crystal structures of H-TAN[1] and its metal chelates[2-5] have been determined in order to elucidate the structural change on chelate-ring formation; however, it is possible that the observed conformation for H-TAN is affected by the packing forces. Accordingly, it was desirable to determine the structures of several H-TAN derivatives. The title compound (H-TANBr shown in Fig. 1) was selected. A preliminary communication of this work based on the photographic data has been reported.[6] We will now present a refined structure of H-TANBr based on the newly collected diffractometer data.

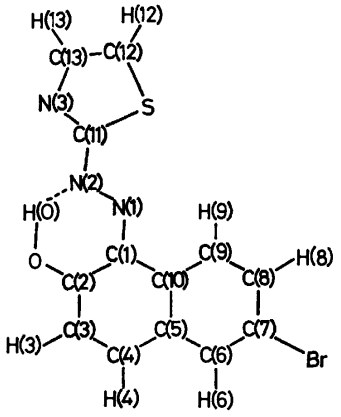

Fig. 1. Numbering of atoms.

Experimental

Red needle crystals of H-TANBr were grown by the sublimation of crude materials. The crystal data are summarized in Table 1. Both the determination of the cell constants and the collection of the intensity data were carried out on a Rigaku automatic four-circle diffractometer, using Cu$K\alpha$ radiation monochromatized with a graphite plate. The density was measured by floatation in an aqueous solution of sodium iodide.

Using the ω-2θ scan technique at a scan rate of 4 °/min, the integrated intensities were measured up to $2\theta=120$ °. The scan ranges were determined according to this formula: $1.5\,°+0.6\,°\times\tan\theta$. The background counts were taken on both sides of each peak for 10 s. The net counts were corrected for Lorentz and polarization effects; no absorption correction was made. The intensities of three standard reflections measured at every 50 reflections showed no significant variations during data collection. From this data set, 1608 reflections with $F\geq 3\sigma(F)$ were used for the subsequent calculations.

Table 1. Crystal data

$C_{13}H_8N_3OSBr$	$V=2572.2$Å^3
F. W.$=334.2$	$Z=8$
Orthorhombic	$D_m=1.72$ g·cm^{-3}
Space group: $P2_12_12_1$	$D_x=1.72$ g·cm^{-3}
$a=19.044(3)$Å	$\mu=61.9$ cm^{-1} (for Cu$K\alpha$)
$b=31.996(9)$Å	
$c=4.221(1)$Å	

Structure Determination and Refinement

The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method on the basis of a set of photographic data ($hk0$~$hk3$ and $0kl$).[6] The R value was 0.12 for 2074 reflections ($R=0.105$ for 1570 non-zero reflections).

Refinement was continued using the data collected on the diffractometer. Anisotropic thermal parameters were employed for the bromine and sulfur atoms, R being reduced to 0.086. A difference synthesis calculated at this stage did not show any significant hydrogen peaks. The hydrogen atoms attached to the ring systems, whose positions were assumed from the suitable geometry and B's to be 5.5 Å^2, were included in the structure-factor calculations in subsequent refinements, but they were not refined. The final R value was 0.064 for the 1608 observed reflections. A unit weight was given to each reflection. The atomic scattering factors were taken from International Tables for X-ray Crystallography.[7] The least-squares calculations were performed using the HBLS-4 program.[8] The final coordinates and thermal parameters are given in Table 2. The observed and calculated structure amplitudes are listed in Table 3.***

Description of the Structures and Discussion

The structure consists of two crystallographically independent H-TANBr molecules (referred to as A and B). Figure 2 shows their conformations projected on the naphthalene plane. As can be seen in the figure, the A and B molecules show generally similar shapes. Each azo group adopts a *trans* conformation,

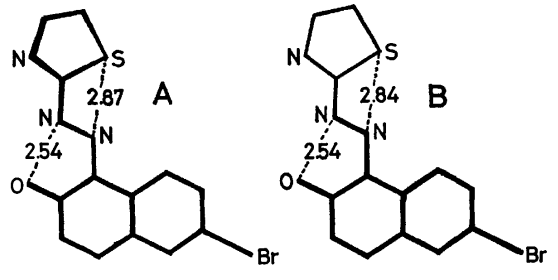

Fig. 2. Conformation of H-TANBr molecules. Views are perpendicular to the naphthalene plane.

and the oxygen atom is linked to the azo nitrogen atom adjacent to the thiazole ring by intramolecular hydrogen bonding, the O···N(2) distances being 2.54 Å.

Molecules A and B are nearly planar, with maximum deviations of 0.15 and 0.07 Å respectively. The A molecule is twisted along the N(1)–C(1) bond, and the naphthol ring makes an angle of 6.7° with the thiazole ring, whereas the B molecule is slightly folded at N(2), and the angle between the thiazole and naphthol rings is 1°. Similar features were observed in the crystals of H-TAN.[1]

It seems that there is no definite reason to restrict the rotation around the C(11)–N(2) bond. In all four crystallographically independent molecules, two in noncentrosymmetric H-TANBr crystals and two in centrosymmetric H-TAN crystals, however, N(1) and N(3) are in the *trans* position. This indicates that the observed conformation is the most stable one. There is no evidence for the strong intermolecular interaction which dominates the molecular conformation. Short intramolecular non-bonded distances of 2.87 Å in A and 2.84 Å in B are found between S and N(1) (Fig. 2).

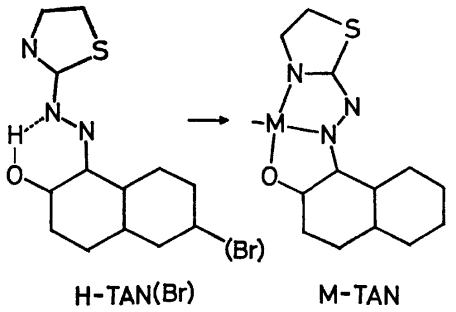

Fig. 3. A comparison of the structures between H-TAN(Br) and M-TAN.

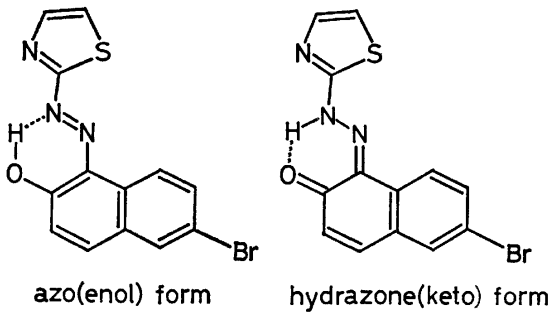

Fig. 4. Two possible tautomers for H-TANBr.

Figure 3 compares the structures of H-TAN(Br) and its metal chelate(M-TAN). If, in solution, the H-TAN(Br) molecules exist in the same conformation as in a solid, it is apparent that both of the two ring systems attached to the central azo group are rotated by 180° upon chelate-ring formation.

The bond lengths and angles are shown in Table 4, along with their estimated standard deviations. All the distances except for that of C(7)-Br agree with the values observed in the crystal of H-TAN, within the range of experimental error. The coexistance of azo and hydrazone tautomers in the crystalline state of H-TAN has been reported[1] previously on the basis of the difference in the electron density map and the examination of the relevant bond lengths. The good agreement in the distances of N(1)-N(2), C(2)-O between H-TANBr and H-TAN may, therefore, indicate that, in the present crystal also, there are the azo and hydrazone tautomers shown in Fig. 4.

The crystal structure projected along the c-axis is shown in Fig. 5. Intermolecular distances less than 3.5 Å are given in Table 5. The molecular planes of both A and B are inclined by about 45° from the (001) plane. This stacking scheme of the molecules along the c-axis is very similar to that of H-TAN. The molecular arrangements in the ab-plane, however, differ considerably from each other as a result of the large effective volume of bromine atoms.

(Received August 11, 1975)

The partial molal volumes of surfactants in the micellar state ($\bar{V}_m$) and in the singly dispersed state ($\bar{V}_s$) have been determined at 25 °C in methanol–water mixtures up to the composition of 25 mol% methanol. The $\bar{V}_m$ of sodium dodecyl sulfate (SDS) increases gradually with the addition of methanol across the plateau region (3—15 mol% methanol). On the other hand, the $\bar{V}_s$ values of SDS and its homologous salts containing the alkyl chain of carbon numbers from 6 to 10 decrease initially with the addition of methanol and then increase up to 25 mol% methanol *via* the minimum at 3 mol% methanol. The value of $\bar{V}_m - \bar{V}_s$ reaches its maximum at 3 mol% methanol and then approaches zero at about 30 mol% methanol. The latter behavior is an indication of the lack of any micelle formation. In order to elucidate the solute-solvent interactions, the split of $\bar{V}_s$ into the contributions of the ionic and the hydrophobic part was attempted. Consequently, the variation in $\bar{V}_s$ with the solvent composition can primarily be attributed to the behavior of the hydrophobic group in solutions. On the basis of these results, the interactions between the hydrophobic part of the solute and the binary solvent were discussed.

The micelle formation of surfactants in solutions has been known to be affected by the temperature, the pressure, and various kinds of additives. Studies of the effect of organic additives on the critical micelle concentration (CMC) have led to an understanding of the part played by the solvent in the micelle formation.[1–6]

The thermodynamic quantity known as the partial molal volume has proved to be a very useful tool in elucidating the interactions occurring in solutions. Studies of the partial molal volume of surfactants have been used to examine the behavior of surfactant solutions.[7–12] They have also proved useful in determining the effect of the pressure on the micelle formation.[7,13,14] With regard to the partial molal volume in a mixed solvent, Lee and Hyne[15] have determined the partial molal volumes of tetraalkylammonium chlorides in ethanol–water mixtures in order to examine ion–solvent interactions in aqueous solvent mixtures. They also discussed the structural changes accompanying the addition of ethanol to water.

In this study, the partial molal volume of sodium dodecyl sulfate (SDS) has been determined above and below the CMC as a function of the cosolvent composition. Methanol was chosen as the cosolvent because it penetrates the micelle only slightly and chiefly changes the solvent property of water. The partial molal volumes of a homologous series of sodium alkyl sulfates have also been determined in the range of concentrations below the CMC in methanol–water mixtures. On the basis of these results, the interactions among water, methanol, and the hydrocarbon chain of a surfactant have been discussed.

Experimental

The SDS and its homologous salts used in this study were synthesized and purified by a method described previously.[16] The water was redistilled from an alkaline permanganate solution. The methanol was distilled before use.

The partial molal volume was determined partly by a density method and also partly by a direct dilatometric method.[7] The values of the partial molal volumes obtained by the two methods were in good agreement with each other. The densities of a series of solutions were simultaneously measured by using seven pycnometers with a capacity of about 20 ml; the errors in measurement was within $\pm 1 \times 10^{-5}$ g/cm^3. The thermostatted bath was controlled to 25($\pm$0.005) °C. The volume of solution per 1000 g of the solvent (water+methanol) was plotted against the molality of the surfactant, resulting in a straight line in the ranges of concentration below and above the CMC, as is shown in Fig. 1. The partial molal volume of the surfactant in aqueous methanol solutions was taken as the slope of the line; it was determined by the least-squares method on the basis of the 7—14 density data. Since the partial molal volume is almost independent of the surfactant concentration over the concentration ranges studied here,[7,8] the experimental values thus obtained have been assumed to be identical with those corresponding to an infinite dilution. The values of the partial molal volume in a pure aqueous solution were 237.5 for SDS below the CMC, 247.0 for SDS above the CMC, and 203.6 for sodium decyl sulfate (SDeS), 172.6 for sodium octyl sulfate (SOS), and 141.3 for sodium

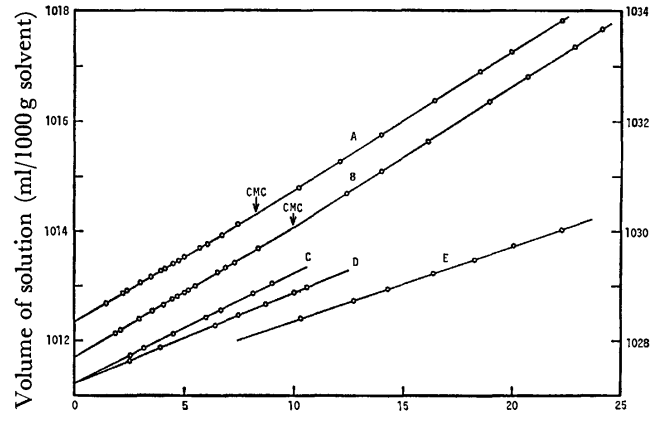

Fig. 1. Representative plots of the volume of solution per 1000 g solvent against the concentration of surfactant. A: SDS(3.31), B: SDS (9.04), C: SDeS (2.94), D: SOS (2.94), and E: SHS (2.87). The numerical values in parentheses indicate mol% of methanol in solvent. (Right scale shown is for B only).

hexyl sulfate (SHS) below the respective CMC's. These values are comparable to those of the literature.[7,8,16]

Results and Discussion

The partial molal volumes of four surfactants in the singly dispersed state and that of SDS in the micellar state are shown in Fig. 2 as functions of the solvent composition. The partial molal volume of the singly dispersed state ($\overline{V}_s$) for any surfactant decreases initially upon the addition of methanol and then increases up to 25 mol% methanol *via* a minimum at about 3 mol% methanol. On the other hand, the partial molal volume of the micellar state ($\overline{V}_m$) increases gradually upon the addition of methanol across the plateau region (3—15 mol% methanol). The $\overline{V}_m$ is slightly affected by the addition of both methanol and urea,[17] whereas the $\overline{V}_s$ is sensitive to such additives as urea[17-19] and alcohols.[15,20] This can reasonably be expected in view of the fact that the solute-solvent interaction, containing structural changes in water around the hydrophobic part of the surfactant, is included in $\overline{V}_s$.

The change in the partial molal volume on micellization, $\Delta\overline{V}_m(=\overline{V}_m-\overline{V}_s)$, was calculated from the results shown in Fig. 2; it is shown in Fig. 3 as a function of the methanol content. The $\Delta\overline{V}_m$ in water is in good agreement with that of the literature.[7,8] As may be seem from Fig. 3, $\Delta\overline{V}_m$ initially increases upon the addition of methanol, and then it decreases *via* the maximum at 3 mol% methanol. The $\Delta\overline{V}_m$ is thermodynamically related to the pressure dependence of the

CMC by the following expression, as has been described previously:[21]

$$\Delta\overline{V}_m = (1+\beta)\,RT\left(\frac{\partial \ln \mathrm{CMC}}{\partial P}\right)_{T,\Delta\overline{G}_m} \quad (1)$$

where β is the constant which indicates the ratio of the number of the counterion to that of the surfactant ion in micelles. The results shown in Fig. 3 suggest that the CMC-increasing effect by compression reaches its maximum at 3 mol% methanol. In practice, the results of CMC measurements under high pressures in methanol–water mixtures have substantiated the above suggestion,[22] although the effect of added methanol on β has still not been elucidated. It can be seen from Fig. 3 that the extrapolation of $\Delta\overline{V}_m$ to a higher methanol content approaches zero at about 30 mol% methanol. This seems to indicate whether $\overline{V}_m$ is merely equal to $\overline{V}_s$ or whether no micelles are formed in about a 30 mol% methanol–water mixture. The latter is more likely from the facts that the CMC increases with the addition of methanol and is ultimately undeterminable at about 30 mol% methanol,[23] that the micellar weight decreases with the increase in the methanol content, and that at about 27 mol% methanol there is no evidence of micelle formation.[2,23]

It is generally known that, in alcohol–water mixtures, compounds containing the hydrophobic chain show a minimal partial molal volume at a water-rich composition and a maximal partial molal volume at a moderate composition of the solvent.[15,20] As may be seen from Fig. 2, the minimum of $\overline{V}_s$ for a homologous series of sodium alkyl sulfates was observed at a definite solvent composition (3 mol% methanol). The value of the minimal $\overline{V}_s$ is smaller by *ca.* 5% than the $\overline{V}_s$ in pure water. This contraction and the following expansion in $\overline{V}_s$ show the solute–solvent interaction characteristic of a system with methanol–water solvent mixtures. Since a surfactant molecule is composed of two parts with opposing properties, a hydrophobic and a hydrophilic group, the interactions between each part of the solute and the solvent should be discussed separately. Therefore, the split of $\overline{V}_s$ into the contributions of the ionic and the hydrophobic part was attempted as follows. By plotting $\overline{V}_s$ against the length of alkyl chain N, straight lines were obtained at various compositions of the solvent, as is shown in

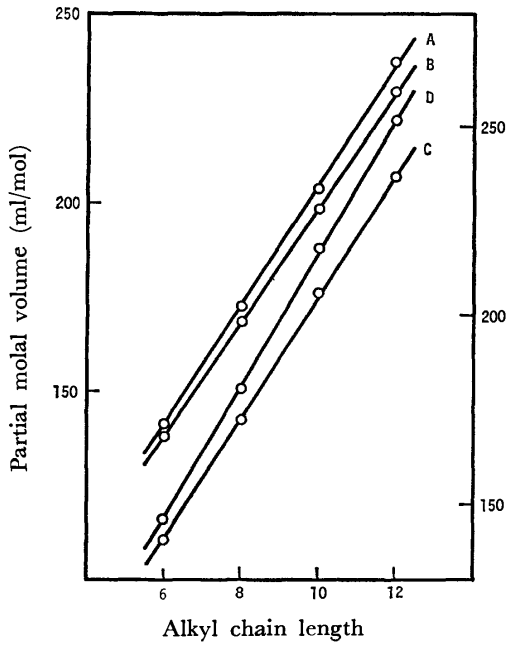

Fig. 4. Partial molal volumes of surfactants as a function of alkyl chain length. A linear relationship between $\overline{V}_s$ and N in mixed solvents of various compositions is typically shown. Methanol composition in mol%; A: 0, B: 5.87, C: 9.05, and D: 19.40. (Left scale shown is for lines A, B, and right scale for C, D.)

Fig. 4. Then the relation between $\overline{V}_s$ and N can be satisfactorily represented by the following expression.

$$\overline{V}_s = \overline{V}_1 + \overline{V}_{me}N \quad (2)$$

where $\overline{V}_{me}$ is the partial molal volume per methylene group and where $\overline{V}_1$ may be assumed to be the contribution of the ionic part, which is obtained by extrapolating N to zero in a linear plot of $\overline{V}_s$ *vs.* N. The value of $\overline{V}_1$ in water (47.0 ml/mol) is in fair agreement with the value estimated by Mukerjee for $NaHSO_4$ (47.5 ml/mol).[24] The value of $\overline{V}_1$ tends to decrease monotonously with an increase in the methanol content. This reduction of $\overline{V}_1$ may be qualitatively explained on the basis of the electrostrictive solvation effect, as was mentioned by Lee and Hyne.[15]

The $\overline{V}_{me}$ has its minimum at 3 mol % methanol, as is shown in Fig. 5. Thus, the variation in $\overline{V}_s$ with the solvent composition can be attributed to the behavior of the hydrophobic group in solutions. It is known that the transfer of hydrocarbons from a nonpolar environment to water results in a negative volume change,[25] which is considered to reflect the ordering of water molecules around the hydrocarbon chains or the "iceberg" formation.[26] Actually, the value of $\overline{V}_{me}$ in water, 15.7 ml/mol CH_2, is smaller than the contribution of the methylene group to the molal volume of normal alkanes at the C_8–C_{12} chain lengths, 16.7 ml/mol CH_2.[27] In an aqueous mixture of 3 mol % methanol, the $\overline{V}_{me}$ is more reduced than in water. This may be explained on the basis of the variation in the structure of the binary solvent with the composition.

Using the multilayer hydration models by Gurney,[28] Frank and Wen,[29] and Eigen and Wicke[30] for ion–water interactions, the partial molal volume of an ion at an infinite dilution, $\overline{V}^0_{ion}$, can be attributed to the following components:[31]

$$\overline{V}^0_{ion} = \overline{V}^0_{int} + \overline{V}^0_{elect} + \overline{V}^0_{disord} + \overline{V}^0_{caged} \quad (3)$$

where $\overline{V}^0_{ion}$ is the intrinsic partial molal volume, $\overline{V}^0_{elect}$ is the electrostriction partial molal volume, $\overline{V}^0_{disord}$ is the disordered partial molal volume, and $\overline{V}^0_{caged}$ is the caged or structured partial molal volume. Here, the $\overline{V}_{me}$ under consideration may be taken to contain only the contributions of $\overline{V}^0_{int}$ and $\overline{V}^0_{caged}$, and can be expressed by the following relation:

$$\overline{V}_{me} = \overline{V}^{int}_{me} + n_h(\overline{V}^h_0 - V_0) \quad (4)$$

where $\overline{V}^{int}_{me}$ is the intrinsic partial molal volume for the methylene group, $\overline{V}^h_0$ is the partial molal volume of structured water around the hydrocarbon chain, V_0 is the molal volume of bulk water, and n_h is the number of hydrated or structured water molecules and is taken as 2 or 3.[26] As has been mentioned above, $\overline{V}^h_0 < V_0$ for structured water around the hydrocarbon chains. We assume that Eq. (4) is applicable to the $\overline{V}_{me}$ values in the aqueous solvent mixtures containing a small amount of methanol. In this case, V_0 should be taken as the mean molal volume of a mixture, and $\overline{V}^h_0$, as the mean partial molal volume of the solvent mixture around the hydrocarbon chain. The value of V_0 increases monotonously with an increase in the methanol content. Of course, $\overline{V}^h_0$ may be affected by the methanol added. The results shown in Fig. 5, however, show that the difference between $\overline{V}^h_0$ and V_0 reaches its maximum at the mixture of about 3 mol % methanol provided that n_h (the number of solvent molecules affected by one methylene group) changes only slightly and monotonously with the methanol content. This means that the initial addition of methanol is likely to be attributable to the structure-promotion of the solvent. By the addition more than 3 mol% of methanol, the difference between $\overline{V}^h_0$ and V_0 decreases gradually; that is, the increase in $\overline{V}^h_0$ with the increase in the methanol content overcomes that of V_0. This indicates that the addition more than 3 mol% of methanol will begin to break down the characteristic water structure.

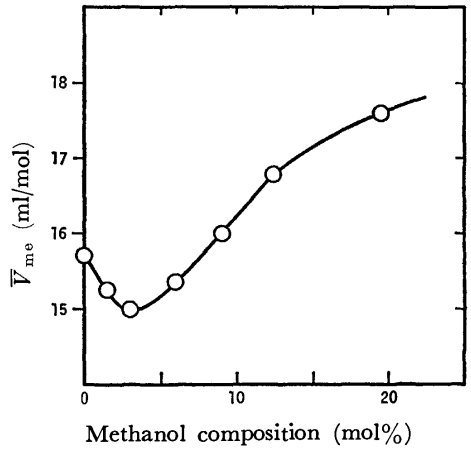

Fig. 5. The partial molal volume per one methylene group as a function of methanol content.

There is an alternative explanation for the minimal $\overline{V}_{me}$ at 3 mol % methanol. We assume that methanol is unaffected by the hydrocarbon chain; *i.e.*, the partial molal volume of methanol around the hydrocarbon chain is the same as that of methanol in the bulk binary solvent. Thus, in Eq. (4), V_0 should be taken as the partial molal volume of water in the binary mixed solvent, and n_h, as the number of water molecules affected by one methylene group, which number probably varies in proportion to the volume fraction of water in the binary solvent. It is well known that, in the methanol–water binary system, the partial molal volume of water increases slightly with the initial addition of methanol and then decreases with an increase in the methanol content *via* a maximum at about 10 mol% methanol; on the other hand, the partial molal volume of methanol has its minimum at the corresponding composition in the binary system.[32] Therefore, it can be seen from Fig. 5 that the methanol composition at which the $\overline{V}_{me}$ has its minimum is not consistent with the composition of the minimal partial molal volume of methanol in the binary system; it is rather low. The results shown in Fig. 5 indicate that the second term of the right-hand side of Eq. (4) reaches its minimum at 3 mol% methanol. This probably means that the decrease in $\overline{V}_0^h$, together with the increase in V_0, is responsible for the initial decrease in $\overline{V}_{me}$ upon the addition of methanol. Thus, it may be concluded that the solvent structure is maximally promoted around the hydrocarbon chain of surfactant ions in the aqueous solvent mixture of 3 mol% methanol.

The Two-step Collapse of Mixed Monolayers of Cholesterol and Its Esters

Masayuki NAKAGAKI and Tetsurou HANDA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received August 28, 1975)

Mixed monolayers of two insoluble components out of cholesterol and its acetate and propionate were spread on a dilute aqueous solution of disodium hexadecyl phosphate. The curves of the surface pressure against the molecular area were found to have two kink points, collapse points, although the curves of each component, and also that of the "concollapse" mixture, had only one collapse point. The diagram showing the relation between these two collapse pressures and the composition was entirely analogous to the phase diagrams of bulk mixtures which have an eutectic point. It has, therefore, been concluded that the mixed monolayer of two mutually immisible substances undergoes a two-step collapse. At the lower collapse point, one of the two components, *i*, starts separating from the monolayer. The lower collapse pressure, F_{Ci}' varies with the mole fraction, X_i, according to $F_{Ci}'=F_{oi}'-(kT/A_{oi})\ln X_i$. At the higher collapse point, the other component starts separating as well. Upon further compression, the surface pressure remains unchanged at the higher collapse pressure, which is equal to the equilibrium-spreading pressure and is independent of the composition.

In studies of insoluble monolayers it has sometimes been noticed that there is a disagreement between the collapse pressure, F_c, and the equilibrium-spreading pressure, F_s. Here, F_c is obtained as the kink point on a curve of the surface pressure, F, against the molecular area, A, when an insoluble monolayer is compressed, while F_s is observed when small particles or droplets of an insoluble substance are placed on a clean aqueous surface. Two reasons can be pointed out for this disagreement: (1) When the insoluble components have large hydrophobic groups, the molecules are oriented completely at the aqueous surface and the cohesion between the hydrophobic groups resists collapse, so that the monolayer is readily supercompressed. (2) For multicomponent monolayers, the disagreement can be explained thermodynamically. It must be emphasized here, however, that the thermodynamic discussion is significant only when the effect of the supercompression has been eliminated completely.

In the case of one-component monolayers, F_c, is greater than or equal to F_s. For example,[1] the monolayers of tristearin, tripalmitin, and trimyristin were supercompressed so that $F_c>F_s$, while the monolayer of trilaurin was in equilibrium with the bulk phase so that $F_c=F_s$.

In the case of a mixed monolayer, however, F_c may be either greater or smaller than F_s. The mixed monolayer of tristealin and trilaurin was supercompressed so that $F_c>F_s$, while that of cholesterol and trilaurin was in thermodynamic equilibrium with the bulk phase so that $F_c<F_s$.[2] For a mixed monolayer of triolein and tricaprylin, which belongs to the latter case with $F_c<F_s$, it has been verified experimentally that at $A\to 0$ agrees with F_s, and that on the phase diagram expressing F against the mole fraction, X, at a fixed temperature, the curve of F_s against X reveals an arc and that of F_s against X reveals another arc, indicating that these two components mix with each other at all proportions.[3]

If the components, on the contrary, do not mix at all in the bulk phase, a phase diagram analogous to that which has an eutectic point would be expected. In this paper, mixed monolayer of two components out of cholesterol(CH) and its acetate (CA) and propionate (CP) will be discussed. For this effect, the following two experimental devices were needed:

1: As the substrate, an aqueous solution of disodium hexadecyl phosphate (SHP) was used at 0.5 mM instead of water because the mixed monolayers studied here were leaky on the water surface; the addition of as much SHP as this concentration made the monolayers stable enough for us to measure the collapse pressures without changing the essential features of the phase diagram. 2: The F—A relation is usually studied by the compression of a monolayer. In order to avoid the supercompression, however, the method of insoluble-component addition to a constant surface area was used, particularly for the monolayers containing CP.

Experimental

Materials. The specimen of CH used was from the Sigma Chemical Co., the CP was from The Aldrich Chemical Co., and the CA, from the Nakarai Chemical Co. was recrystallized from acetone. The specimen of SHP was the same as used in the previous paper,[4] which had been synthesized and dissolved in water as has been reported elsewhere.[5]

Monolayer Spreading. The insoluble components to be spread as a monolayer were dissolved in benzene and supplied from an Agla Micrometer Syringe onto the surface of water or an aqueous SHP solution in a trough ($60\times 20\times 1$ cm) made of methacryl-resin, coated with paraffin, and sectioned by paraffinized glass barriers.[6]

The occupied area per molecule of insoluble components, A(Å^2/molec.), can be calculated by the following equation:

$$A = S/nN_A \qquad (1)$$

where S is the area of the aqueous surface between barriers, where n is the sum of the moles of insoluble components spread in this area, and where N_A is the Avogadro number. Therefore, A can be decreased either by decreasing S (SAD method) or by increasing n (ICA method). In the latter method, n was increased by dropping additional benzene solution without changing the S.

Surface Pressure. The surface pressure, F (dyn/cm), was measured by Wilhelmy's plate method. A ground plate of quartz was used after it had been cleaned by immersion in fuming nitric acid for more than one night and washing well with distilled water. The torsion balance used was Shimadzu T-NR, modified and equipped with mirror in order to magnify the movement of the plate by a lump and scale. The temperature was kept at 25±0.2 °C

by circulating thermostated water through glass tubing immersed in the trough.

The surface pressure-area curve of the cholesterol monolayer thus obtained was in good agreement with that reported in the literature,[7] and the collapse pressure of the monolayer of cholesterol and its ester on the SHP solution were reproducible and stable for a few hours. Therefore, the possiblity of air oxidation[8] will not be considered here, following many papers which have been published without referring to air oxidation.[7]

Equilibrium-spreading Pressure. The equilibrium-spreading pressure, F_s (dyn/cm), was measured by Wilhelmy's plate method, taking the reading at the equilibrium reached when powder of CH, CA, or CP, or of their mixture was sprinkled on the surface of water or a SHP solution contained in a Petri dish 10 cm in diameter. In case of a mixture, its components were dissolved in ethyl ether at a given composition, the solvent was evaporated, and the residue dried in a vacuum was mixed well with a spatula before use.

Results

Monolayer of CA. Prior to the study of mixed monolayers of CH and CA, the monolayers of each component were studied. The results on the CH monolayer have been reported already.[2] On the other hand, the CA monolayer was found to be difficult to study on water, but easier on an aqueous SHP solution.

Figure 1 shows the F—A curves of CA at various values of the SHP concentration, c_2 (mM), the solution of the latter containing $c'=10$ mM of NaOH in order to prevent the binding of the proton to SHP. Figure 1 indicates the following: 1: The CA monolayer is not supercompressed, since the agreement between the data obtained by the SAD method and by the ICA method is good. 2: Each curve has one kink point, to be called the collapse point, with a collapse pressure, F_c, and a collapse area, A_c. 3: The value of F remains constant at F_c when the monolayer is compressed further beyond the collapse point. 4: The F–A curves move toward higher F values when c_2 is larger. Results similar to these have been obtained for CH as well.

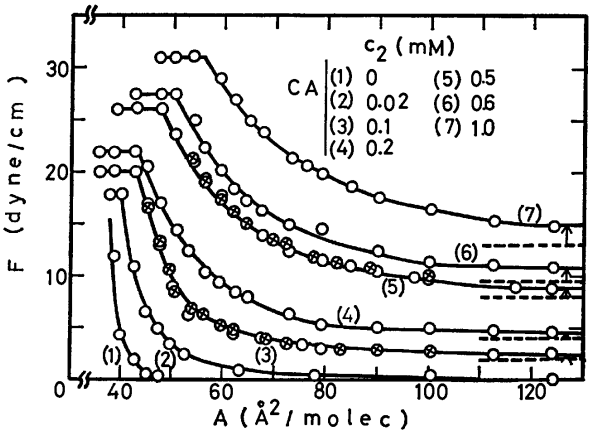

Fig. 1. Relation between the surface pressure, F, and molecular area, A, of CA monolayer at various SHP concentrations, c_2, and at fixed concentration of added NaOH, $c'=10$ mM, at 25 °C, by SAD-method (○) and ICA-method (⊗).

The surface pressure, F, is defined ,as usual, on the basis of the surface tension of pure water, γ_w, by means of the following equation:

$$F = \gamma_w - \gamma \quad (2)$$

where γ is the surface tension of the surface covered with a monolayer. If there is no insoluble monolayer, the surface pressure of the adsorption monolayer of SHP, F_{SHP}, is given by:

$$F_{SHP} = \gamma_w - \gamma_{SHP} \quad (3)$$

where γ_{SHP} is the surface tension of the SHP solution. Each F–A curve on a SHP solution shown in Fig. 1 approaches, when A becomes sufficiently large, a horizontal broken line which represents the F_{SHP}-value. Therefore, the shift of the F–A curves with c_2 toward higher F-values is mainly due to the increase in F_{SHP}. To eliminate this, the practical surface pressure, F', is introduced; it is defined on the basis of the surface tension of the substrate instead of that of pure water:

$$F' = \gamma_{SHP} - \gamma = F - F_{SHP} \quad (4)$$

According to this equation, Fig. 1 is redrawn as Fig. 2, in which the practical collapse pressure, F_c', has turned out to be independent of c_2, at least within the range examined here. On the other hand, the molecular area increases with c_2. This will be discussed in detail in a separate paper.

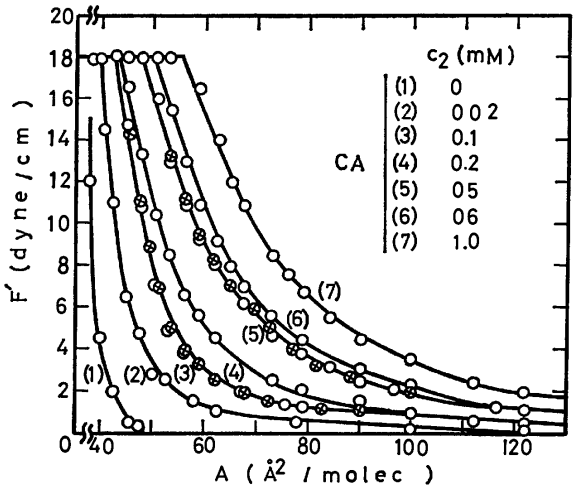

Fig. 2. Relation between the practical surface pressure, F', and molecular area, A, of CA obtained from the data shown in Fig. 1.

Mixed Monolayer of CH and CA. In this case of mixed monolayers, too, the practical surface pressure, F', is adopted: the results obtained for the mixed monolayer of CH and CA on the SHP solution of $c_2=0.5$ mM are shown in Fig. 3. It may be seen in this figure that each F'–A curve of the CH–CA mixed monolayer has, in general, two kind points, in contradistinction to the CH and CA monolayers which had only one kind point. Both of the two kink points of each F'–A curve are collapse points, as will be discussed in detail later on. The mixed monolayer, therefore, undergoes a two-step collapse.

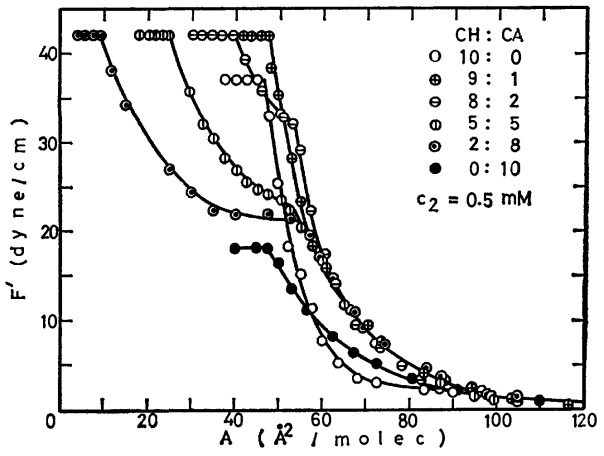

Fig. 3. Variation of F'–A curves of CH–CA monolayers with the composition, at $c_2=0.5$ mM, $c'=10$ mM and at 25 °C.

The collapse pressure and the collapse area at the lower collapse point, which is one located at the lower surface pressure, are designated by F'_{c1} and A'_{c1}, while those at the higher collapse point are designated by F'_{ch} and A_{ch}. Therefore, as may be seen from Fig. 3, F'_{c1} depends on the composition of the mixed monolayer, whereas F'_{ch} is independent of the composition of the mixed monolayer and F' remains unchanged at F'_{ch} when the monolayer is compressed further. Two other points particularly noteworthy in Fig. 3 are that the mixed monolayer at the mole ratio of CH : CA =9 : 1 has only one collapse point, while the F'_c of this monolayer coincides with F'_{ch} at other compositions.

Mixed Monolayer of CA and CP. Before studying the mixed monolayer, the monolayer of CP was examined; it is shown in Fig. 4. The data obtained by the SAD method show that the F'_c of CP increased with c_2 even when the value is expressed as the practical surface pressure, in contradistinction to the cases of CH and CA mentioned above. This is verified to be due to the supercompression on the basis of the observation of the change with time and measurements by the ICA method as follows: 1: The values of F'_c decrease with the time as is shown by the vertical arrows in Fig. 4, and stop decreasing at $F'_c=7.5$ dyn/cm, the value at $c_2=0$ (pure water). 2: The F'—A curves obtained by means of the ICA method showed no change with time, agreed well with the curves obtained by means of the SAD method in the region of low F' values, and gave the value of $F'_c=7.2$ dyn/cm, which is practically equal to the above-mentioned value of the "equilibrium" collapse pressure obtained by means of the SAD method. In Fig. 4, an example obtained by means of the ICA method is shown for $c_2=0.5$ mM.

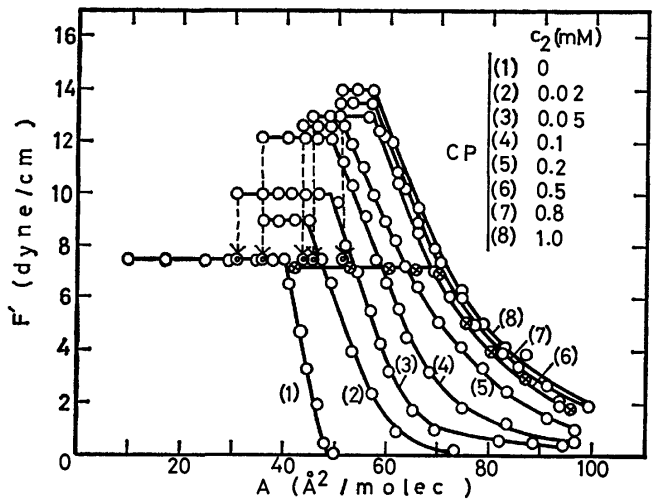

Fig. 4. The F'–A curves of CP monolayer at various c_2 values ($c'=10$ mM) at 25 °C. SAD-method (○), its equilibrium values (◎), and ICA-method (⊗).

The mixed monolayer of CA and CP at $c_2=0.5$ mM gave the F'–A curves shown in Fig. 5, obtained by means of the SAD method. The general features of the CA–CP system are identical with those of the CH–CA system described in the preceding section, since each F'–A curve has, in general, two collapse points except

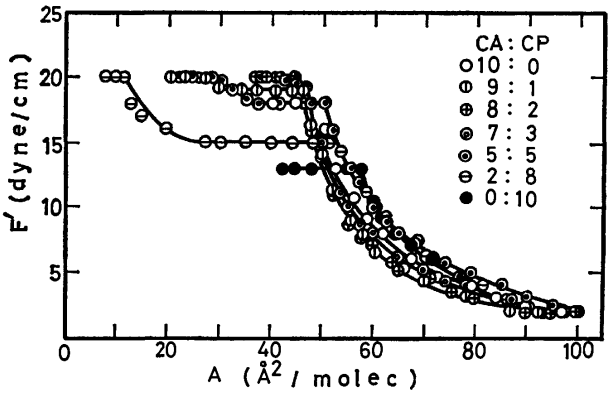

Fig. 5. Variation of F'–A curves of CA–CP monolayers with the composition, at $c_2=0.5$ mM, $c'=10$ mM and at 25 °C.

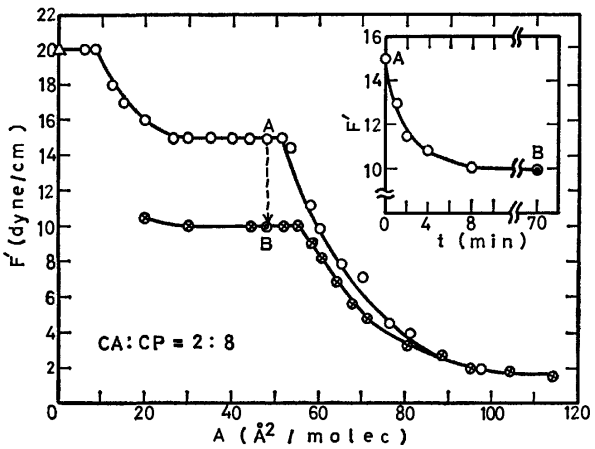

Fig. 6. Comparison of the practical surface pressure, F', obtained by SAD- and ICA-method and the variation with time, t, of the mixed monolayer at the mole ratio of CA : CP=2 : 8, at $c_2=0.5$ mM, $c'=10$ mM and at 25 °C.
SAD-method (○), its equilibrium values (◎), ICA-method (⊗), and the equilibrium spreading pressure, F'_s (△).

for CA : CP=8 : 2, the F'_{ch} is independent of the composition and is in agreement with F'_s, and F'_{cl} depends on the monolayer composition. In contradistinction to the CH–CP system, however, the value of F'_{cl} of this CA–CP system was not steady, but decreased with the time.

As example, the case of a mixed monolayer with the mole ratio of CA : CP=2 : 8 is shown in Fig. 6. The data were obtained by means of the SAD method. Moreover, the vertical arrow in Fig. 6 shows that F' decreased, while the surface area was kept constant, from A to B with the time, t (min), as is shown in the insert; the "equilibrium" collapse pressure at B coincides with the F'_{cl} obtained by means of the ICA method. The same result was also obtained from the experiments at other compositions of the CA–CP system.

Mixed Monolayer of CP and CH. The F'–A curves of CP–CH systems at c_2=0.5 mM are given in Fig. 7. As for the CH monolayer, the agreement between the data obtained by means of the SAD method and ICA method is shown. All the others were obtained by means of the ICA method, becase the time dependence of F' was expected for the monolayers containing CP. The broken lines were drawn according to the calculated value of F'_{ch} and by extrapolation from lower F'-values in order to estimate the A_{ch} values, which will be discussed later on.

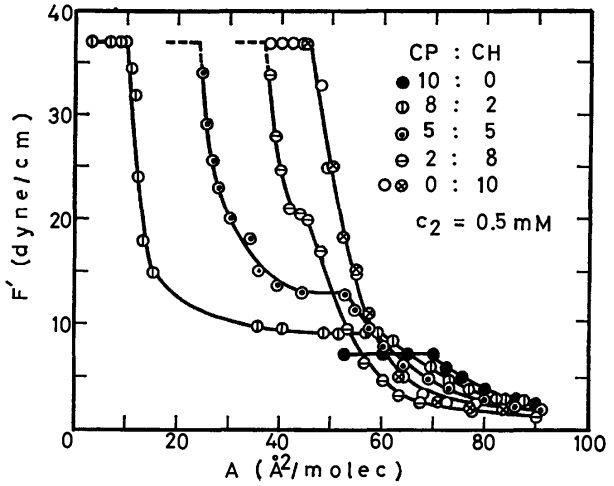

Fig. 7. Variation of F'–A curves of CP–CH monolayers with the composition, at c_2=0.5 mM, c'= 10 mM and at 25 °C, by DAD-method (○) and ICA-method (all others).

Discussion

Two-step Collapse. According to the experimental results shown in Figs. 3, 5, and 7, each F'–A curve of the mixed monolayer consisting of two components out of CH, CA and CP has, in general, two collapse points, indicating that the mixed monolayers undergo a two-step collapse when they are compressed.

The dependence of F_c of the monolayer composition is shown in Fig. 8, taking ,on the abscissa, the mole fraction in the insoluble components, X_4, as defined by:

$$X_4 = n_4/(n_3+n_4) \quad (5)$$

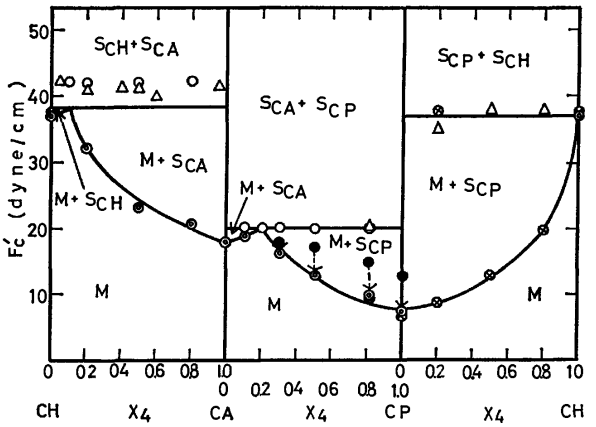

Fig. 8. Relation between the collapse pressure, F'_c, and mole fraction X_4, for CH–CA, CA–CP, and CP–CH systems at c_2=0.5 mM, c'=10 mM and at 25 °C. Solid lines are theoretical by Eq. (15). F'_{ch} (○), F'_{cl} by SAD-method (●), and its equilibrium values (◎), F'_c by ICA-method (⊗), and F'_s (△).

Here, n is the moles and the 3 and 4 suffixes indicate the respective insoluble components, reserving the 1 and 2 suffixes for water and SHP respectively. It has been confirmed here as well as experimentally that the shift of curves with c_2 is mostly cancelled by taking F' instead of F. In Fig. 8, the values of the equilibrium-spreading pressure, which is measured on the same SHP solution and expressed in terms of the practical surface pressure, F'_s, are also plotted to show that the values are independent of X_4 and agree well with F'_{ch}.

Figure 8 shows the dependence of the practical surface pressure at these two collapse points, F_{cl} and F'_{ch}, on the mole fraction in the insoluble components, X_4, indicating that F'_{ch} is independent of X_4 and agrees with F'_s, while F'_{cl} varies with X_4 and its curves merge with F'_{ch} at one point, which can be called a "concollapse point". As a result, the two mixed monolayers of CH : CA=9 : 1 (Fig. 3) and CA : CP= 8 : 2 (Fig. 5) have only one collapse point, whose collapse pressure agrees with the F'_{ch} values of the monolayers at other X_4 values. Thus, Fig. 8 is completely analogous to the ordinary-phase diagram representing the pressure-composition relation, at a given temperature, of a solid-liquid equilibrium of mixtures which have an eutectic point[9] and may be considered to be a phase diagram representing the equilibrium between the monolayer and the bulk phase separated from the monolayer due to the collapse.

Therefore, the following conclusions may be drawn: When a mixed monolayer is compressed, one of the components, which is presented in more than the concollapse composition, starts separating at F'_{cl}. This separation continues during the further compression, accompanying the increase in F' and the approach of the value of X_4 to that of the concollapse monolayer. When the F' reaches F'_{ch}, the other component starts separating simultaneously, but this second deposit does not mix with the first one. Under a given pressure, temperature, and SHP concentration, the freedom of the system become zero when the two

bulk phases have been separated.[2,3,10] Therefore, further compression beyond the higher collapse point does not change F' from $F'_{c\,h}$, the latter being independent of the composition of the starting monolayer, X_4, and being equal to F'_s. Thus, in the regions designated by M, M+S and S_3+S_4 in Fig. 8, there exist the monolayer, the monolayer and a bulk phase, and two bulk phases respectively.

In the CP–CH system, both the $F'_{c\,h}$ and F'_s of the mixed monolayers agree with those of pure CH. This is because the F'_c of CP is much lower than that of CH, that means CP is far easier to collapse than CH, so that the component remaining in the concollapse monolayer is mostly CH.

Collapse Pressure and Composition. The monolayer to be studied here has three components, because the mixed monolayer of two insoluble components, 3 and 4, contains also the soluble component 2 (SHP in our case), which has penetrated from the substrate: The chemical potential of the j component in the monolayer, μ_j^m, is written:[10]

$$d\mu_j^m = kT\,d\ln\xi_j + \omega_j dF \qquad (j=2, 3 \text{ or } 4) \qquad (6)$$

or, if the SHP concentration c_2 is constant so that F_{SHP} is also constant:

$$d\mu_j^m = kT\,d\ln\xi_j + \omega_j dF' \qquad (j=2, 3 \text{ or } 4) \qquad (6a)$$

Here, ξ_j is the mole fraction of the j component in the monolayer:

$$\xi_j = n_j/(n_2+n_3+n_4) \qquad (7)$$

which is different from the mole fraction to X_j, defined by Eq. (5), and ω_j is the partial molecular area of the j component and is related to the (average) molecule area of the insoluble components, A, by:

$$A = \nu_2\omega_2 + X_3\omega_3 + X_4\omega_4 \qquad (8)$$

where ν_2 is the mole of the penetrated component, 2. per mole of insoluble components:

$$\nu_2 = n_2/(_3 + n_4) \qquad (9)$$

The mole fraction which can be assigned experimentally is not ξ_i, but X_i. Therefore, by using the relation:

$$d\ln\xi_i = d\ln X_i - [\xi_i/(1-\xi_i)]\,d\ln\xi_i \qquad (i=3 \text{ or } 4) \qquad (10)$$

Equation (6a) can be rewritten when c_2 is constant and $d\mu_2^m=0$:

$$d\mu_i^m = kT\,d\ln X_i + A_{0i}dF' \qquad (i=3 \text{ or } 4) \qquad (11)$$

where;

$$A_{0i} = \omega_i + \nu_2\omega_2 \qquad (i=3 \text{ or } 4) \qquad (12)$$

This equation may then be used to determine the penetration amount of the 2 component, as will be discussed in a separate paper to be published later. The quantity, A_{0i}, defined by Eq. (12) is a kind of partial molecular area of the i component on the surface of the solution of the 2 component; it is related to the average molecular area of the insoluble components, A, by:

$$A = X_3A_{03} + X_4A_{04} \qquad (13)$$

When a mixed monolayer is in equilibrium with the bulk phase, i, separated from the monolayer at the lower collapse point, the chemical potential of the i component in the monolayer, μ_i^m, is equal to that in the bulk phase, μ_i^b, and the latter is independent of the monolayer composition, X_i, because the other insoluble component is not separated at the lower collapse point. Integrating Eq. (11) with $d\mu_i^m = d\mu_i^b = 0$, the following is obtained for the lower collapse pressure:

$$F'_{c\,i} = F'_{0\,i} - (kT/A_{0i})\ln X_i \qquad (i=3 \text{ or } 4) \qquad (14)$$

Here, $F'_{0\,i}$ is introduced to determine the integration constant on condition that $F'_{c\,i}=F'_{0\,i}$ at $X_i=1$; it is the collapse pressure of the monolayer of the i component on the aqueous SHP solution. To obtain Eq. (14), it has been assumed that A_{0i} is a constant. This is acceptable because the molecular area at the lower collapse point, $A_{c\,l}$, does not change much with the composition, X_i, at a given c_2.

According to Eq. (14), the theoretical values of $F'_{c\,i}$ shown in Fig. 8 by solid curves as a function of X_4 are calculated by using the parameter values, $F'_{0\,i}$ and A_{0i}, obtained experimentally from the collapse point of the one-component monolayer on the aqueous SHP solution; these values are given in Table 1. The agreement between the theoretical curves and the experimental plots in Fig. 8 is good. The intersection of two curves is the concollapse point. For this point, the practical surface pressure, F'_e, and the mole fraction, X_e, are calculated; they are given in Table II. The concollapse pressure, F'_e, is, as has been stated before, equal to the higher collapse pressure, $F'_{c\,h}$, shown by the horizontal solid line in Fig. 8. The agreement between the theoretical value and the experimental plot is, again, fairly good.

TABLE 1. EXPERIMENTAL VALUES OF THE PARACTICAL COLLAPSE PRESSURE, $F'_{0\,i}$, AND COLLAPSE AREA, A_{0i}, AT $c_2=0.5$ mM AND $c'=10$ mM AT 25 °C

Component i	F_{0i} (dyn/cm)	A_{0i} (Å²/molec.)
CH	36.9	46.5
CA	18.0	47.0
CP	7.5	55.0

TABLE 2. CALCULATED VALUES OF CONCOLLAPSE PRESSURE, F'_e, AND CONCOLLAPSE MOLE FRACTION, X_e, AT $c_2=0.5$ mM AND $c'=10$ mM AT 25 °C

Components 3—4	F_c (dyn/cm)	$X_{e,4}$
CH-CA	38.2	0.11
CA-CP	20.0	0.20
CP-CA	37.0	0.98

Collapse Area and Composition. The relation between the collapse area, A_c, and X_4 at $c_2=0.5$ mM is shown in Fig. 9. The molecular area at the higher collapse point, A_{ch}, is, of course, smaller than that at the lower collapse point, A_{cl}. The latter does not depend much on the composition, as has been mentioned before, while the former varies almost linearly with X_4,

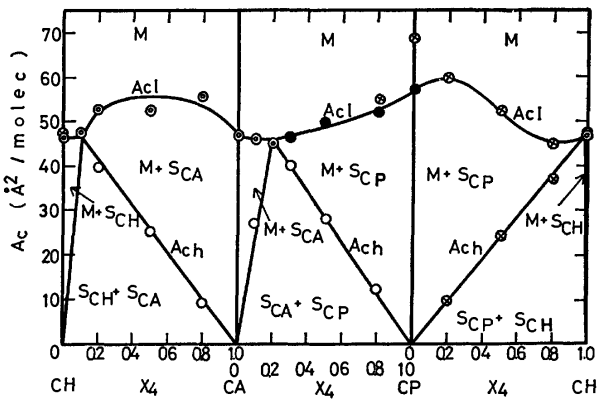

Fig. 9. Relation between the collapse area, A_c, and the mole fraction, X_4, for CH-CA, CA-CP, and CP-CH systems at $c_2=0.5$ mM, $c'=10$ mM and at 25 °C. Symbols are same as in Fig. 8.

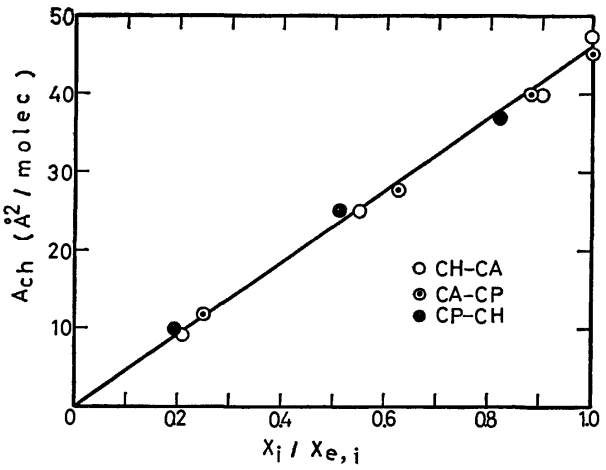

Fig. 10. The proportionality of A_{ch} to $(x_i/X_{e,i})$ expected by Eq. (15), for CH-CA (○), Ca-CP (◎), and CP-CH(●).

describing a triangle, the top of which is the concollapse point with the molecular area of A_e and the mole fraction of X_i.

When a mixed monolayer, consisting of n_3 and n_4 moles of two insoluble components, 3 and 4, respectively, is compressed beyond the lower collapse point, the 4 component (if $X_4>X_{e,4}$) is separated from the monolayer, resulting in a marked decrease in the surface area, S. Therefore, the molecular area, A, calculated on the basis of the initial moles of the insoluble components (n_3+n_4):

$$A = S/[(n_3+n_4)N_A] \quad (1a)$$

decreases remarkably at the lower collapse point.

When the monolayer reachs the higher collapse point upon further compression, the mole fraction in the monolayer becomes equal to that of the concollapse monolayer, X_e, and the total area is expressed as $S=A_e\ (n_3/X_{e,3})N_A$, because n_3 does not change in the process. Therefore, after the introduction of this into Eq. (1a),

$$A_{ch} = A_e X_3/X_{e,3} \quad (X_4>X_{e,4}) \quad (15)$$

or:

$$A_{ch} = A_e X_4/X_{e,4} \quad (X_4<X_{e,4}) \quad (16)$$

These equation are tested in Fig. 10 and proved to be satisfactory, since the experimental A_{ch} value is found to be proportional to $(X_i/X_{e,i})$, the proportionality coefficient being $A_e=46.0$ (Å²/molec.) if the $X_{e,i}$ values given in Table II are used. The straight line in Fig. 9, drawn by using this value of A_e and the values of $X_{e,4}$ given in Table 2, agree well with the experimental plots.

(Received September 5, 1975)

The EPR of TEMPAD single crystals diluted in diamagnetic matrices was studied. The results of the 10% TEMPAD were almost the same as those of the very dilute one studied previously. In the case of the 25% TEMPAD, the spectra are composed of three parts. The central broad line, whose linewidth was analyzed in comparison with the pure TEMPAD case using the three-dimensional Anderson-Weiss formula, is the spectrum of clusters constructed by the free radicals. The side lines with the hyperfine splitting are the spectrum of the isolated TEMPAD molecule, and the outer broad lines are from the molecules coupled in pairs along the a-axis. The EPR spectra of the pure TEMPAD at very low temperature were also measured in order to have information concerning the dipolar interaction in the pure crystal. These spectra are the superposition of the spectra caused by the intra-molecular dipolar interaction and of the spectra due to impurities. All the results were explained with the suitable molecular stack model and the triplet exciton theory.

There have been a number of investigations regarding the magnetic properties of organic stable free radical solids.[2-4)] In these works, the magnetic ordering effects caused by some magnetic interactions between unpaired electrons have been of special interest. When the unpaired electrons couple with each other three-dimensionally, the long-range ordering effect can occur.[2,3)] On the other hand, the low-dimensionally coupled spins or clustering spins induce the short-range ordering effect.[3,4)]

To clarify these magnetic ordering effects, one must study the magnetic interactions, especially the exchange interaction and the dipolar interaction between unpaired electrons. EPR spectroscopy is a powerful technique for the study of these magnetic interactions, because it gives much information about the microscopic magnetic structure and the dynamical behavior of the magnetic system.

Previous magnetic studies of 2,2,6,6-tetramethyl-4-piperidone azine 1,1'-dioxyl (TEMPAD) revealed three kinds of exchange interactions (see Fig. 1):[5-7)] one of them is the stronger inter-molecular exchange interaction along the a-axis (J_1;$J_1/k=-12.8$ K) which produces the broad maximum in the magnetic susceptibility (χ_M) of the pure TEMPAD at the temperature of 16.5 K and the large Weiss constant in the χ_M-T curves of the diluted crystals.[5,7)] The second kind is the weaker inter-molecular exchange interaction (J_1'; $|J_1'|/k\sim 1$ K) in the inter-molecular alternating chain, and the third is the weaker intra-molecular one (J_2; $|J_2|/k\sim 2\times 10^{-2}$ K)which affects the hyperfine structure in the EPR spectrum in solution[6)]; both contribute to the small Weiss constant in the χ_M-T curves of the diluted TEMPAD crystals.[7)]

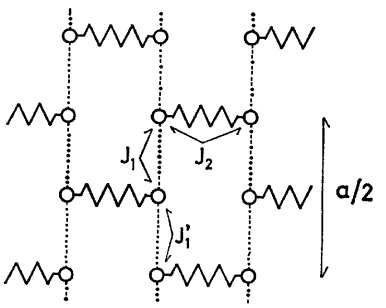

Fig. 1. Exchange interactions in TEMPAD biradical.

The EPR of the diluted TEMPAD in the diamine host was also studied and the principal values and the direction cosines of the inter- and the intra-molecular dipolar interactions were determined.[8)] The angular dependence of the EPR linewidth of the pure TEMPAD could be well explained using the three-dimensional Anderson-Weiss formula, which indicates that the inter-molecular dipolar interaction and the weak exchange interactions (J'_1 and J_2) are very important for the dynamical behavior in our case.[8)] The EPR spectrum of the powdered TEMPAD at room temperature shows one symmetrical line, and new lines appear on both sides of the central line at very low temperatures. They have been explained in terms of the intra-molecular dipolar interaction on the basis of the triplet exciton theory.[1)]

In this paper, the authors will report on their EPR studies of the pure TEMPAD at very low temperature and of the diluted TEMPAD in the diamine host at room temperature. Some discussion is given on the inter- and intra-molecular exchange and dipolar interactions in the biradical crystal by comparison with the data published elsewhere.

Experimental

TEMPAD and 2,2,6,6-tetramethyl-4-piperidone azine (the diamine), whose molecular structures are shown in Figs. 2(a) and 2(b), respectively, were prepared from 2,2,6,6-tetramethyl-4-piperidone supplied by the Aldrich Chemicals Co. in accordance with the method described by Rassat *et al.*[9)] The single crystals of the pure TEMPAD and the 25% and 10% TEMPAD in the diamine host were crystallized from their ethereal solutions.

The EPR spectra were measured using X-band (9.5 GHz) spectrometers, JEOLCO JES-ME-3X equipped with an 80 Hz field modulation at low temperatures and JEOLCO JES-PE-3X equipped with a 100 kHz field modulation at room temperature. In the low temperature measurements, the temperature was determined by measuring the vapor

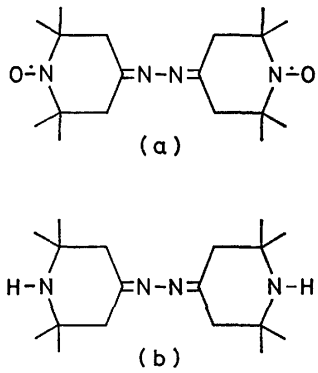

Fig. 2. Molecular structures of the TEMPAD biradical (a) and the corresponding diamine (b).

pressures of liquid helium. The magnetic field was calibrated with 0.1% Mn^{2+} in MgO (the hyperfine coupling constant between central two lines is 86.2×10^{-4} T and $g=2.00641$) and peroxylamine disulfonate, $[\cdot ON(SO_3)_2]^{2-}$ ($A_N=13.0\times10^{-4}$T and $g=2.00550$). The error in the measurements of angles was estimated to be about two degrees.

Results and Discussion

Crystal Structure. The crystal structures of the TEMPAD and the diamine crystals are the monoclinic system with the parameter β of nearly 90° (see Table 1); thus we can adopt the a, b, and c-axes as the rectangular coordinate system for the pure and the diluted single crystals (see Figs. 3(a) and 3(b)). It should be noted here that the molecular stack model presumed from the EPR results[8] indicates that the electron spins form a linear chain along the a-axis. This means that the direction of the largest exchange and dipolar interactions is along the a-axis, as is shown in Fig. 1.

Table 1. The space groups and the lattice constants for the diamine and TEMPAD biradical

	Diamine	TEMPAD
Space group	Monoclinic C_c	Monoclinic C_c or $C_{2/c}$
a	29.0 Å	29.1 Å
b	12.6 Å	12.8 Å
c	10.4 Å	10.5 Å
β	~90°	~90°
z	8	8

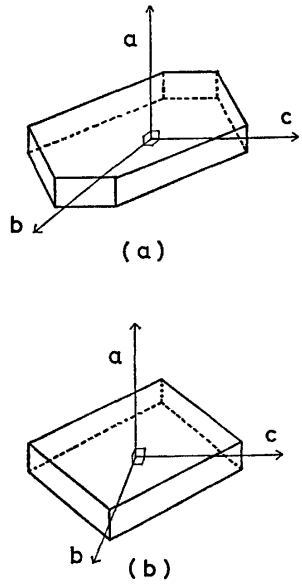

Fig. 3. Coordinate systems of the diamine host (a) and the TEMPAD crystal (b).

Exciton Density. If the electron spins form an alternate linear chain, in which the spins couple with each other through exchange interactions, a short-range ordering will occur at low temperature and then some triplet excitons will be produced. The triplet exciton plays an important role in the dynamic behavior of the unpaired electrons of the TEMPAD biradical at low temperature. The density of the triplet exciton is given by

$$\rho = 1/[1+(1/3)\exp(\delta/kT)] \quad (1)$$

where $\delta=2|J_1|$[10]. From the χ_M-T curve, J_1/k is equal to -12.8 K for the TEMPAD biradial and the density of the triplet exciton at 4.2 K is about 0.5%. Even in a pure TEMPAD crystal, this low density of the triplet exciton makes it possible to observe the EPR spectra modified by the intra-molecular dipolar interaction at low temperature.

Diluted Crystal. The interactions between biradicals in a diamagnetic host crystal may be divided into three types of interaction; that is, an isolated biradical, a dimer, and a cluster which contains three or more interacting biradical molecules. These are shown in Fig. 4. Type I contains only intra-molecular exchange and dipolar interactions; in Type II there are inter-molecular exchange and dipolar interactions in addition to the intra-molecular interactions. "Cluster" has a very complicated interaction mechanism and may exhibit rather exchange-narrowed EPR absorptions.

The EPR results of the 10% TEMPAD single crystal are the same as those of the very diluted case (2% in concentration)[8] except for showing EPR spectra of a low resolution at some orientations. The spectra consist of two parts of the absorption lines, the one due to the intra-molecular interactions (Type I) and

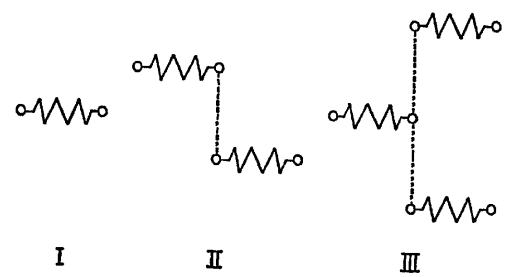

Fig. 4. TEMPAD biradicals in a diamine host crystal. Type I represents an isolated TEMPAD biradical surrounded by diamagnetic host molecules. Type II represents a pair interaction scheme. Type III represents one of the interaction schemes in which three or more TEMPAD molecules interact each other. Type III is called "cluster".

the other due to the inter-molecular interactions (Type II). The former has a doublet splitting due to intra-molecular dipole-dipole interaction and each of the doublet absorptions shows hyperfine splittings attributable to exchange-coupled nitrogen nuclei. It is the exchange interaction, J_2 in Fig. 1, that couples two nitrogen nuclei in the same molecule. The latter spectrum, which is outside of the former spectrum and has an apparently broad linewidth, comes from the inter-molecular dipole-dipole interaction. The angular dependence of these spectra can be obtained and then the principal values of the intra-molecular dipole-dipole interaction tensor and their direction cosines can be determined. These results are quite the same as in the case of the 2% TEMPAD crystal within the accuracy of the experimental error. The results of the direction cosines show that in the 10% TEMPAD crystal the biradical molecules in a unit cell occupy two different sites, the p- and q-sites, as reported in Ref. 8. The principal values and the crystal field parameters are listed in Table 2 and the splitting constants of the spectra at some orientations are summarized in Table 3. The EPR spectra of the 25% and 100% TEMPAD crystals can be analyzed on the basis of these values. The good agreement between the results of 10% and 2% TEMPAD crystals may indicate that the biradical concentration of 10% TEMPAD is not high enough to affect the EPR spectra through the inter-molecular interaction. In other words, there are in the EPR spectra mainly contributions from Types I and II and no appreciable contributions from the cluster in Fig. 4.

The results of the 25% TEMPAD are quite different from those of the 10% or 2% TEMPAD crystals.

TABLE 2. THE PRINCIPAL VALUES OF THE TENSORS OF THE INTRA-MOLECULAR AND INTER-MOLECULAR DIPOLE-DIPOLE INTERACTIONS WITH REGARD TO THE abc-SYSTEM AND THE CRYSTAL FIELD PARAMETERS

Principal values	Crystal field parameters
Intra-molecular dipole-dipole interaction	
D_{xx} $\pm(18.7\pm0.5)\times10^{-4}$T	$\lvert D\rvert/g\mu_B$ $51.0\pm1.5\times10^{-4}$T

D_{zz} $\mp(34.0\pm1.0)$	
Inter-molecular dipole-dipole interaction	
D'_{xx} $\pm13\times10^{-4}$T	$\lvert D'\rvert/g\mu_B$ 130×10^{-4}T
D'_{yy} ±73	$\lvert E'\rvert/g\mu_B$ 30
D'_{zz} ∓86	

TABLE 3. DIPOLAR INTERACTIONS IN TEMPAD BIRADICAL AS THE SPLITTING OF THE SPECTRUM AT EACH ORIENTATION

Axis (//H)	a	b	c
2% D'	264×10^{-4}T	172×10^{-4}T	208×10^{-4}T
10% D	55	40	106
25% D'	263	—	—
25% D	—	—	106
100% D (4.2 K)	—	—	60
100% D (1.7 K)	—	65	73

D': Inter-molecular dipolar coupling
D : Intra-molecular dipolar coupling

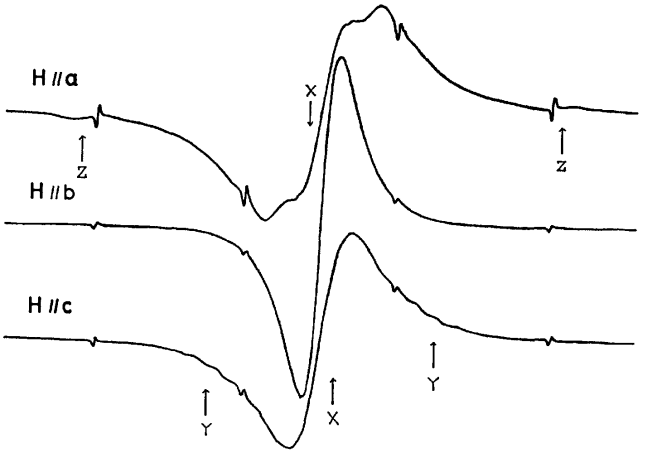

Fig. 5. Typical EPR spectra of the 25% TEMPAD crystal with the static magnetic field parallel to a, b, and c-axes. Small sharp peaks are the spectra of Mn^{2+} in MgO.

This fact indicates that an exchange narrowing effect becomes large in the 25% TEMPAD crystals. The EPR spectra of the 25% TEMPAD single crystal at some orientations are shown in Fig. 5. These spectra are composed of three kinds of spectral lines; one of them is a central broad line (X), the second is the side lines with the hyperfine splitting (Y), and the last is the broad side lines (Z). From comparing these spectra with those of the 10% or 2% TEMPAD case it follows that the contributions from Types I and II are rather decreased and that the contribution from Type III is much more increased. The central broad line can be considered to be the spectrum of the inter-molecular clusters (Type III in Fig. 4). The angular dependence of the linewidth of X is shown in Fig. 6 in comparison with that of the pure TEMPAD. The linewidth of X in the 25% TEMPAD is broader than that of the pure TEMPAD for all orientations of the crystal in the magnetic field H except for the orientation where the linewidth takes a minimum value, and the spectra of X splits into three lines for the case of H//a-axis. For the comparison with the pure TEMPAD

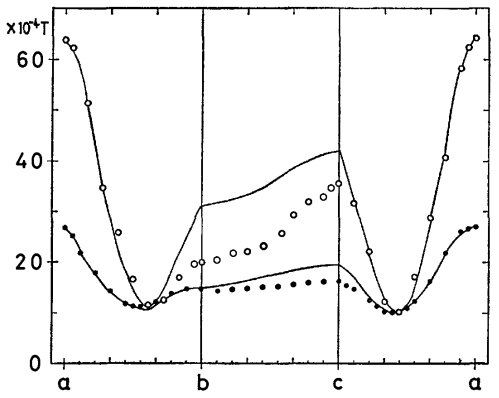

Fig. 6. Peak-to-peak linewidths of the 25% and the pure TEMPAD spectra. The solid curves are the calculated results using the three-dimensional Anderson-Weiss model. ●: Pure TEMPAD, ○: center line X of 25% TEMPAD.

case, we can consider the three-dimensional Anderson-Weiss formula for a Lorenzian line:[11]

$$\Delta H_{pp} = \Delta H_d^2/\sqrt{3}H_{ex} + C \qquad (2)$$

where ΔH_{pp} is the peak-to-peak linewidth, ΔH_d^2 the second moment of the dipolar interaction, H_{ex} an effective exchange field, and C the residual linewidth. The secular part of the second moment ΔH_d^2 was calculated using the term of the inter-molecular dipolar interaction (D') obtained from the 10% or 2% TEMPAD crystal. Thus H_{ex} and C were estimated to be $\sim$0.2 T ($\sim$2000 G or 0.3 K) and $\sim 10^{-3}$ T ($\sim$10 G), respectively. These values reproduce quite well the angular dependence of the linewidth. If we take into account H_{ex}=0.43 T (4300 G) and C=9.5$\times 10^{-4}$ T (9.5 G) in the pure TEMPAD crystal, the averaged inter-molecular exchange interaction in the cluster is weaker than that in the pure TEMPAD and the residual linewidth C is nearly equal to that of the pure TEMPAD. It may be reasonable that the effect of the exchange narrowing in the cluster is reduced by a diamagnetic dilution and that there is no noticeable change in the residual linewidth C because it represents the broadening mechanisms which come mainly from the nuclear hyperfine interaction and the non-secular part of the inter-molecular dipole-dipole interaction.

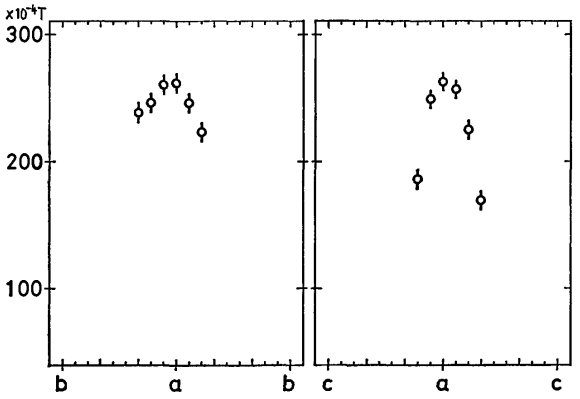

Fig. 7. Dipolar splitting of the line Z of the 25% TEMPAD crystal.

The side doublet line Y with a hyperfine structure can easily be assigned to the line of the isolated TEMPAD biradical (Type I) and corresponds to the intra-molecular dipolar interaction (D), because this spectrum has a hyperfine structure and a maximum separation 106×10^{-4} T at the H//c-axis. The angular dependence of the line separation of the side line Z is shown in Fig. 7. These lines, whose maximum separation is about 264×10^{-4} T at the H//a-axis, are caused by the pair (Type II) and correspond to the inter-molecular dipolar interaction (D') in the 10% or 2% diluted system (see Tables 2 and 3). The angular dependence of Fig. 7 is also in good agreement with that of D'. As the last two groups, Y and Z, are very much weaker than the central line X, the TEMPAD molecules are distributed homogeneously in the diamine host.

Pure Crystal. In the pure crystal, the exchange narrowing effect is so large that we can not obtain much information about any dipolar interactions in the TEMPAD biradical at room temperature. In order to reduce its effect we measured EPR spectra in the liquid helium temperature region, where the triplet exciton density becomes small enough for us to observe the dipolar splitting in EPR spectra. The EPR spectra of the pure TEMPAD single crystal at very low temperature are shown in Fig. 8. These spectra are the superposition of one central line and two side lines. The angular dependence of the two side lines are shown in Fig. 9. These lines have a maximum splitting at an orientation of the H//c-axis with its magnitude of about 60×10^{-4} T. The dipolar splittings of the 2%, 10%, and 25% TEMPAD crystals at room temperature and the pure TEMPAD at low temperature are listed in Table 3. From these results, the two side lines can be determined to be due to the intra-molecular dipolar interaction, which is also consistent with the powder results of 100% TEMPAD.[1] The fact that there is no hyperfine splitting may be caused by the weak inter-molecular exchange inter-

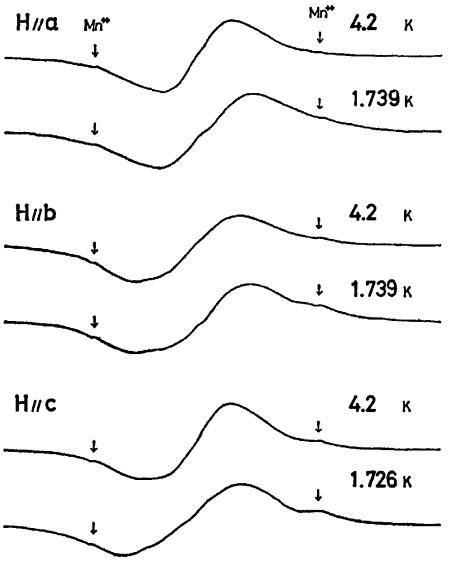

Fig. 8. Low temperature EPR spectra of the pure TEMPAD crystal at some orientations.

action.

For the central line there are four possible interpretations; one of them is that it is attributable to the spectrum of the triplet exciton along the a-axis narrowed by the exciton motion, the second is that it is the spectrum of the isolated cluster, the third is due to that of the non-interacting TEMPAD molecule, and the last is that of the monoradicals derived from the TEMPAD biradical by decomposition. As the density of the triplet exciton at 4.2 K is about 0.5%, the EPR spectrum of the triplet exciton at 4.2 K must be very weak and should have a well-resolved fine structure. The spectrum of the non-interacting TEMPAD molecule shows the hyperfine splitting, as we can see in the 25% TEMPAD spectrum. Zvarykina *et al.* showed the typical spectra of a non-interacting adipate biradical at the temperature of the short-range ordering region,[12] but in our case we cannot observe the hyperfine splitting in all the directions. The *g*-value of the central line is slightly different from that of the two side lines; thus the central line may possibly correspond to the last case. This is also ascertained by the angular dependence of the linewidth of the central line, which is shown in Fig. 10. The dotted line(·····) shows the angular dependence of 100% TEMPAD at room temperature. This angular dependence is well explained on the basis of the three-dimensional Anderson-Weiss model, as was already discussed,

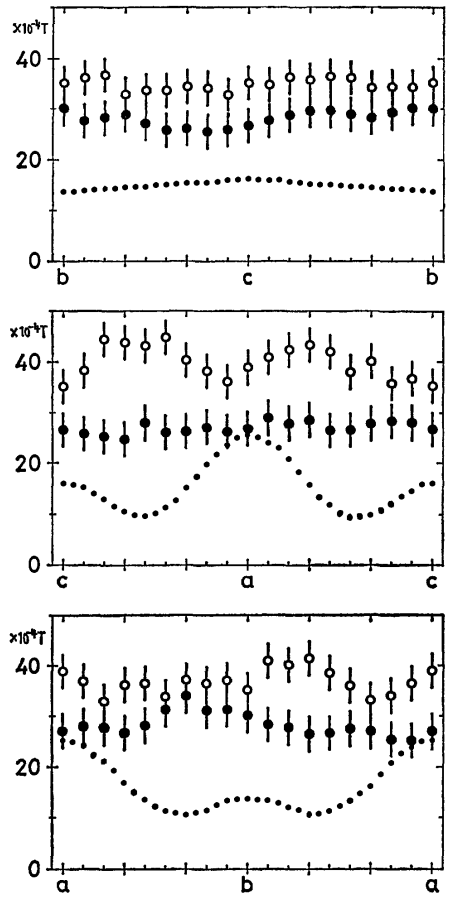

Fig. 10. Peak-to-peak linewidths of the TEMPAD spectra. ●: center line at 4.2 K, ○: center line at 1.74 K, ●: at room temperature.

that is, it depends exclusively on the angular variation of the inter-molecular dipole-dipole interaction parameter, D'. The angular dependence of the linewidth clearly changes as the temperature is lowered, and at 1.73 K it can neither be explained in terms of the inter-molecular dipole-dipole interaction (D') nor the intra-molecular dipole-dipole interaction (D). Thus, we presume that the central line is due to the monoradicals. However, we do not have any reasonable explanation for the broadening mechanism of the linewidth.

As for the dipolar interaction between molecules which have exchange interaction J_1 in Fig. 1, we tried to find some absorptions in a wider magnetic field region, but could not obtain any information, possibly because of the low triplet exciton density.

Microwave Spectrum of *syn*-Acetaldehyde Oxime-*d*

Osamu OHASHI, Ryoji ISHIHARA, Kakuji MURAKAMI, Takeshi SAKAIZUMI, Masao ONDA, and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received September 23, 1975)

The microwave spectrum of *syn*-acetaldehyde oxime-*d* was investigated in the frequency region 7.5~35 GHz. Several a-type R-branch transitions were identified and the following rotational constants in MHz were obtained: $A=45682$, $B=4057.21$, $C=3806.13$. The transitions of *syn*-acetaldehyde oxime-*d* are split into the A and E species by tunneling of the methyl group through the potential barrier hindering the internal rotation. From these separations the height of the barrier was determined to be 1948 cal mol^{-1}. The dipole moment of the molecule was determined to be 0.938 D from the Stark effect.

It has been found that acetaldehyde oxime has α- and β-modifications, which melt at 46.5 °C and 12 °C, respectively.[1] This molecule also has the two geometrical isomers whose conformations are *syn*- and *anti*-forms. The infrared spectrum of acetaldehyde oxime was investigated with attention to the effects of the geometrical isomerism.[2] The nuclear magnetic resonance study has revealed that the conformation change from one isomer to another is made easily.[3] Rogowski and Schwendeman studied the microwave spectrum of acetaldehyde oxime and have shown that the potential barrier hindering the internal rotation of the methyl group is abnormally low in the *anti*-form.[4]

We examined the microwave spectrum of *syn*-acetaldehyde oxime-*d* ($CH_3CH{=}NOD$) and determined the rotational constants, the potential barrier hindering the internal rotation of the methyl group, and the dipole moment. The orientation of the OH bond and the direction of the dipole moment of the molecule have been discussed, in conjunction with Rogowski's results for the normal species ($CH_3CH{=}NOH$).[4]

Experimental

Sample of acetaldehyde oxime obtained commercially (Tokyo Kasei Kogyo Co., Ltd.) was purified by trap-to-trap distillations several times *in vacuo*. No attempt was made to separate the *syn* and *anti* species; all the measurements were, consequently, made with the equilibrium mixture of the isomers. The deuterated species was prepared in the absorption cell as follows. First, the cell was filled with D_2O vapor at room temperature. It was then evacuated by vacuum pump for about half an hour. At the end of this time the sample of acetaldehyde oxime purified beforehand was admitted into the cell.

The spectrometer used was a conventional 100 kHz sinusoidal and square wave Stark modulation type with a phase sensitive detector. Because the sample apparently decomposed slowly at room temperature in the sample cell, the spectrum was observed at 0~−10 °C and the sample was renewed about every half an hour.

Results and Discussion

Observed Spectrum and Assignment. The structure of *syn*-acetaldehyde oxime-*d* was assumed to be the same as that of *syn*-acetaldehyde oxime (normal species) which has been considered to be a planar molecule. This assumption was based on the structural parameters for formaldehyde oxime determined by Levine[5] and the parameters fitted to the rotational constants B and C of the normal species.[4] The bond angles and bond distances assumed are given in Table 1. The projection of the molecule in its plane of symmetry is shown in Fig. 1(a). Although there are two possible orientations of the OH bond in this molecule, as shown in Figs. 1(a) and 1(b), the same orientation as that of formaldehyde oxime was assumed: that is, the OH bond is at the *trans* position relative to the C=N double bond. The assumed orientation of the OH bond will be discussed later. Frequencies of the rotational transitions were predicted from the moments of inertia calculated from the assumed structure. Substitution of a deuterium atom for the hydrogen atom of the hydroxyl group of *syn*-acetaldehyde oxime makes only a small change of the directions of the principal axes of the moment of inertia. Therefore, it was expected that the a-type R-branch transitions would be the most intense, as observed for the normal species.[4] In fact, only the a-type R-branch transitions have been observed and assigned. They were identified by their Stark effects. The b-type transitions were searched for, but there was no absorption line to be assigned as a b-type transition. This may suggest that the b-type transitions are quite weak because of

their small μ_b components, as described later.

The $K_{-1}=1$ absorption lines were split into A and E members by the internal rotation of the methyl group. The absorption lines of the A member showed the second-order Stark effect, while those of the E member showed the first-order Stark effect. Assuming the rigid rotor Hamiltonian, the rotational constants were fitted to the frequencies of the transitions belonging to the A symmetry species. A comparison of the observed and calculated frequencies is given in Table 2. The effective rotational constants obtained from the rigid rotor fit are in Table 3, together with the rotational constants calculated from the assumed structures.

Splittings of the lines due to the nuclear quadrupole moment of the ^{14}N nucleus were observed in the $1_{10} \rightarrow 2_{11}$ and $1_{11} \rightarrow 2_{12}$ transitions of the A member. Only one quadrupole coupling constant, $\chi_{aa}=3.5\pm0.7$ MHz, could be determined.

Barrier to Internal Rotation. The spectra of the A and E species can be treated with the Hamiltonian given by Herschbach.[6] *syn*-Acetaldehyde oxime-*d* is a near prolate symmetric top molecule with the axis of the internal rotation of the methyl group close to the principal a-axis. Therefore, the Hamiltonian for this molecule can be simplified.[4] Using the Hamiltonian including the perturbation terms up to third-order, the A-E splittings of the low J transitions can be fitted to a barrier-dependent parameter from which the barrier height V_3 may be obtained.[4,7]

The A-E splittings of the $K_{-1}=1$ lines were about 1 MHz for $J=2\rightarrow3$ transitions and about 4 MHz for $J=1\rightarrow2$ transitions. A value of the barrier height, 1948±100 cal mol^{-1}, was obtained by averaging the values of V_3 determined from each of the splittings of the $K_{-1}=1$ lines of the $J=1\rightarrow2$ and $J=2\rightarrow3$ transitions given in Table 4. The uncertainty, 100 cal mol^{-1}, was estimated by taking account of the uncertainties of the assumed parameters λ_a and I_α. But, because we took no account of the uncertainty of the moment of inertia I_a, the uncertainty obtained may have been underestimated. The barrier height of the deuterated species obtained in this work is higher by about 100 cal mol^{-1} than that of the normal species.

Principal Axis Coordinates of Hydroxyl Hydrogen Atom. The absolute values of the principal axis coordinates of the hydroxyl hydrogen atom were calculated from the moments of inertia of *syn*-acetaldehyde oxime and its deuterated species, using the expressions given by Kraitchman.[8] The conversion factor used was 505376 MHz·amu·Å^2. The value obtained for the a-coordinate is fairly good, while the value for the b-coordinate has a large error. In particular the c-coordinate could not be determined because of the negative square value of the c-coordinate. This may be attributed to the large uncertainty of the rotational constant A. The uncertainties given in Table 5 were calculated from the standard deviations of the rotational constants fitted to the observed frequencies.

From the results given in Tables 3 and 5, it seems reasonable to be led to the following conclusion: The plausible orientation of the OH bond is as shown in Fig. 1(a). The *trans* form as shown in Fig. 1(a) is consistent with the orientation of the OH bond in formalde-

a) Structure shown in Fig. 1(a). b) Structure shown in Fig. 1(b).

hyde oxime determined by Levine.[5]

Dipole Moment. The dipole moment was determined by measurements of the Stark shifts of the $0_{00}\rightarrow 1_{01}$, $1_{01}\rightarrow 2_{02}$, $2_{02}\rightarrow 3_{03}$, and $3_{03}\rightarrow 4_{04}$ absorption lines. The electric field in the absorption cell was calibrated by measurements of the Stark shifts of the $J=0\rightarrow 1$ and $J=1\rightarrow 2$ absorption lines of OCS. The dipole moment of OCS is 0.71521 D.[9]

The observed and calculated Stark coefficients are given in Table 6. Assuming that the molecule has a plane of symmetry and the component of the dipole moment along the axis perpendicular to the plane of symmetry is zero, we obtained $\mu_a=0.865\pm0.004$ D, $\mu_b=0.363\pm0.015$ D, and $\mu_{total}=0.938\pm0.009$ D. The uncertainties are the standard deviations obtained by the least square fit. The value of μ_{total} obtained in this work is in good agreement with that of *syn*-acetaldehyde oxime.[4]

If it is assumed that the structure of the deuterated species is exactly the same as that of the normal species and its structural parameters are as given in Table 1,

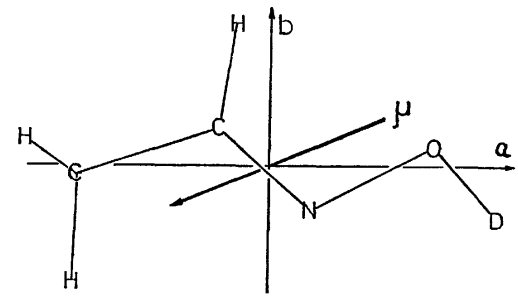

Fig. 2. Orientation of the dipole moment in *syn*-acetaldehyde oxime-*d* molecule.

the orientation of the dipole moment in the molecule can be determined. From the compositions of the dipole moments of normal and deuterated species along the principal axes, the direction of the dipole moment in the molecule was determined as shown with a thick line in Fig. 2. The angle between the dipole moment and the NO bond is 8.09°.

Activity Coefficients of Hydrochloric Acid in Hydrogen Chloride-Metal Perchlorate-Water Systems

Kiichi TERUYA, Kikuo SHIRAOGAWA, and Issei NAKAMORI

Department of Chemical Engineering, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received September 30, 1975)

In the HCl–$LiClO_4$–H_2O, HCl–$NaClO_4$–H_2O, HCl–$Mg(ClO_4)_2$–H_2O, HCl–$Ba(ClO_4)_2$–H_2O, HCl–$LiClO_4$–$NaClO_4$–H_2O, HCl–$NaClO_4$–$Ba(ClO_4)_2$–H_2O, and HCl–$LiClO_4$–$NaClO_4$–$Ba(ClO_4)_2$–H_2O systems, the mean activity coefficients of hydrochloric acid, $\gamma_{\pm HCl}$, have been obtained at 25 °C by emf measuremts of the cell:

$$H_2(Pt)/HCl,\ MClO_4,\ M'(ClO_4)_2,\cdots/AgCl,\ Ag \quad (M=Li,\ Na;\ M'=Mg,\ Ba)$$

Moreover, the following relation has been examined with the experimental results:

$$\log \gamma_{\pm HCl} = \log \gamma^{\circ}_{\pm HCl} + \sum_i a_{i(HCl)} m_i \qquad (i \neq H, Cl)$$

where $\gamma^{\circ}_{\pm HCl}$ is the mean activity coefficient of hydrochloric acid in a solution containing only hydrochloric acid at the same ionic strength as the mixture; m_i is the molality of the i ion, and $a_{i(HCl)}$ is the parameter assigned to the three-ion system of hydrogen, chloride, and i ions, but is independent of the ionic strength. The results of the examination with $a_{M(HCl)}$ determined in our previous paper showed that $a_{ClO_4(HCl)}$ may be about zero regardless of the kind of metal ion coexisting in the solution. The activity coefficients calculated by the above relationship with the determined parameters agree, with deviation of only about 5%, with the experimental results for all the systems.

While a considerable amount of information is available about the activity coefficients in single electrolyte solutions,[1,2] experimental data on the activity coefficients in multicomponent electrolyte solutions are difficult to obtain and relatively few direct measurements have been reported. The activity coefficients in multicomponent electrolyte solutions are, however, important as fundamental data for the treatment of chemical processes, since most electrolyte solutions commonly encountered in chemical industry are multicomponent electrolyte solutions. Most of the direct measurements in the past have been limited to the hydrogen chloride–metal chloride–water systems.[3] Data on hydrogen chloride–metal perchlorate–water systems have been reported only by Bates and Urmston,[4] Prue and Read,[5] Stokes and Stokes,[6] and Weeks,[7] and most of these data are within the limits of low concentrations of hydrochloric acid.

Although many theoretical treatments of the properties of multicomponent electrolyte solutions have been proposed by various authors,[3,8–10] the principal object in these treatments has been the consideration of the interionic forces. As a result, the expressions for the activity and osmotic coefficients in multicomponent electrolyte solutions are complicated in form and contain a number of parameters which are functions of the ionic strength and so are cumbersome for engineering calculations.

In their previous papers, therefore, the present authors proposed a simple and convenient method of estimating the activity coefficients in multicomponent electrolyte solutions for use in engineering calculations[11] and showed that satisfactory results could be obtained when the method was applied to examinations of the activity coefficients of hydrochloric acid in hydrogen chloride–metal chloride–water systems.[12] The object here is to obtain the mean activity coefficients of hydrochloric acid at 25 °C by emf measurements in aqueous solutions containing one or more perchlorates of metal (lithium, sodium, magnesium, or barium) over a wide range of concentrations of hydrochloric acid and to a high total ionic strength, and to examine the method of estimation in these systems containing perchlorate ions on the basis of the experimental results.

Theoretical

The total excess Gibbs energy of an electrolyte solution may be dominated by the effect of the long-range electrostatic forces of the Debye-Hückel type, and the contributions due to the short-range forces resulting from ion–ion and ion–solvent interactions may be added to it with the increase in the concentrations of the solute species. In a previous paper,[11] by assuming that the short-range forces may be independent of the ionic strength, the following method was obtained for the estimation of the activity coefficients of a strong electrolyte 12, $\gamma_{\pm 12}$, in a solution containing 1, 2, ···, i (odd : cation, even : anion) ions:

$$\log \gamma_{\pm 12} = \log \gamma^{\circ}_{\pm 12} + \sum_i a_{i(12)} m_i \qquad (i \neq 1, 2) \qquad (1)$$

where $\gamma^{\circ}_{\pm 12}$ is the mean activity coefficient of the electrolyte 12 in a solution containing only 12 at the same ionic strength as the mixture; m_i is the molality of the i ion and $a_{i(12)}$ is the parameter assigned to the three-ion system of the 1, 2, and i ions. As a result of the assumption used in the derivation of Eq. (1), this parameter may be independent of the ionic strength and the ions coexisting in the solution other than 1, 2 and i. In this treatment, molality scales are used for the concentrations of the ion and the electrolyte and the activity coefficients of the electrolyte.

In the hydrogen chloride (HCl)–metal perchlorate ($M(ClO_4)_n$)–water systems, the activity coefficients of hydrochloric acid, $\gamma_{\pm HCl}$, are given by Eq. (1) as 1=H, 2=Cl, 3=M, and 4=ClO_4 as follows:

$$\log \gamma_{\pm HCl} = \log \gamma^{\circ}_{\pm HCl} + a_{M(HCl)} m_{M^{n+}} + a_{ClO_4(HCl)} m_{ClO_4^-} \qquad (2)$$

or:

$$\log (\gamma_{\pm HCl}/\gamma^{\circ}_{\pm HCl}) = [a_{M(HCl)} + n a_{ClO_4(HCl)}] m_{M(ClO_4)_n} \qquad (3)$$

A considerable amount of information is available about the activity coefficients of hydrochloric acid in the solutions containing only hydrochloric acid, $\gamma^{\circ}_{\pm HCl}$,

required in this treatment.[1,2] If this treatment is appropriate, $\log(\gamma_{\pm HCl}/\gamma^{\circ}_{\pm HCl})$ may be expected to vary linearly with $m_{M(ClO_4)_n}$.

On the other hand, $a_{M(HCl)}$ has been determined for various metal ions in investigations of the hydrogen chloride–metal chloride–water systems at 25 °C. The values are shown in Table 1.[12] It is, therefore, convenient to rewrite Eq. (2) as follows:

$$[\log(\gamma_{\pm HCl}/\gamma^{\circ}_{\pm HCl}) - a_{M(HCl)}m_{M^{n+}}] = a_{ClO_4(HCl)}m_{ClO_4^-} \quad (4)$$

Thus, if the parameter for the perchlorate ion, $a_{ClO_4(HCl)}$, may be independent of the ionic strength and the coexisting metal ion, M^{n+}, a straight line may be obtained by the plots of the left-hand side of Eq. (4) against $m_{ClO_4^-}$ and $a_{ClO_4(HCl)}$ can be determined from the slope of the resultant straight line. Therefore, the activity coefficients of hydrochloric acid in aqueous solutions containing more than one metal perchlorate may be evaluated by means of Eq. (1) using the $a_{M(HCl)}$ and $a_{ClO_4(HCl)}$ values determined in this work and the previous one.[12]

Experimental

The activity coefficients of hydrochloric acid in the hydrogen chloride–metal perchlorate–water systems were obtained by means of emf measurements of the following cell:

$$Pt(H_2)/HCl(m_1), MClO_4(m_2), M'(ClO_4)_2(m_3),\cdots/AgCl, Ag$$
$$(M=Li, Na; M'=Mg, Ba)$$

The techniques and equipment used for the emf measurements were the same as has been described in detail previously.[13] The emf measurements were made at 25.00±0.05 °C. The emf values were reproducible to within about ±0.05 mV. The following systems were investigated: HCl–$LiClO_4$–H_2O, HCl–$NaClO_4$–H_2O, HCl–$Mg(ClO_4)_2$–H_2O, HCl–$Ba(ClO_4)_2$–H_2O, HCl–$LiClO_4$–$NaClO_4$–H_2O, HCl–$NaClO_4$–$Ba(ClO_4)_2$–H_2O, and HCl–$LiClO_4$–$NaClO_4$–$Ba(ClO_4)_2$–H_2O. The reagents used in this work were special-grade and were used without further purification.

In the above-mentioned cell, the emf values corrected to 1.00 atm of hydrogen pressure, E, are expressed by the Nernst equation as follows:

$$E = E^{\circ} - (2RT/F)\ln(m_1\gamma_{\pm HCl}) \quad (5)$$

where E° is the standard potential of the Ag–AgCl electrode and where m_1 is the molality of hydrochloric acid, while T is the absolute temperature; R, the gas constant and F, the Faraday. 0.22234 (V) has been given as the value of E° by Bates and Bower;[14] this value was used in this work. The emf values shown as the results are corrected to a hydrogen pressure of 1.00 atm. Using Eq. (5), the activity coefficients of hydrochloric acid, $\gamma_{\pm HCl}$ (exp), were obtained.

Results and Discussion

The outlines of experimental conditions in the past[4–7] and in this work on the hydrogen chloride–metal perchlorate–water systems at 25 °C are summarized in Table 2. While the data in the past were obtained at low concentrations of hydrochloric acid from 0.01 to 0.1 mol kg^{-1}, these data were used also for the examinations of Eq. (3) or (4).

The experimental data and the calculated results in the three-component systems, HCl–$LiClO_4$–H_2O, HCl–$NaClO_4$–H_2O, HCl–$Mg(ClO_4)_2$–H_2O, and HCl–$Ba(ClO_4)_2$–H_2O, are shown in Table 3. The data in these systems are plotted in Figs. 1 and 2 on the basis of Eq. (3). The literature values are also plotted in these figures. Figures 1 and 2 show that a straight line is obtained by these plots for each system and that the parameters, $a_{M(HCl)}$ and $a_{ClO_4(HCl)}$, may be regarded as approximately independent of the ionic strength; therefore, the treatments on the basis of Eq. (1) may be approximately appropriate.

Plots drawn on the basis of Eq. (4) are shown in Fig. 3. All the data are scattered on the zero axis. It shows that $a_{ClO_4(HCl)}$ seems to be about zero, regardless of the kind of metal ion coexisting in the solution.

The values calculated by Eq. (2) with $a_{M(HCl)}$ in Table 1 and the $a_{ClO_4(HCl)}$ determined above, and the percentage deviations between the experimental and the

calculated values are shown in Table 3 as $\gamma_{\pm HCl}$(calcd) and Dev. %($=100[\gamma_{\pm HCl}(\text{calcd})-\gamma_{\pm HCl}(\text{exptl})]/\gamma_{\pm HCl}$ (exptl)). The Dev.% in these systems are within about 5% over a wide range of ionic strengths, similar results were obtained for the data in the past.[4-7]

The experimental data and calculated results in the four-component systems, $HCl-LiClO_4-NaClO_4-H_2O$, and $HCl-NaClO_4-Ba(ClO_4)_2-H_2O$, are shown in Table 4, while the results in the five-component system, $HCl-LiClO_4-NaClO_4-Ba(ClO_4)_2-H_2O$, are given in Table 5. In the four- and five-component systems, the values calculated by means of Eq. (1)

with the parameters mentioned also agree with the experimental results within about 5%.

In the treatments of the activity coefficients in the three-component systems, *i.e.*, in the solutions containing two electrolytes, the method based on Eq. (1) is similar to the Harned-rule[15] in form. However, the Harned-rule is restricted to the treatments of the three-component systems; furthermore, its parameters are treated as the functions of the ionic strength, while the parameters, $a_{i(12)}$, in Eq. (1) may be treated independently of the ionic strength and the coexisting ions other than 1, 2, and i ions because Eq. (1) has been derived on the assumption that the short-range forces may be independent of the ionic strength. As a result, this method may be expanded to treatments of solutions containing more than two electrolytes.

a) Total ionic strength.

As a matter of course, it seems that the short-range forces may be independent of the ionic strength; the results in a previous[12] and in this one show that indeed the $a_{i(12)}$ values are approximately independent of the ionic strength over a wide range and that the effects on $a_{i(12)}$ of the coexisting ions other than 1, 2, and i ions can generally be ignored. Moreover, the parameters which can be determined easily in the simpler systems containing three or four ions may be applied to the more complicated systems. It should also be noted that this method may be used, with errors in estimation within about 5%, over a wide range of ionic strengths. Although the examinations using this method in this work were made only on the activity coefficients of hydrochloric acid, yet this method may be useful in evaluating that of the other strong electrolytes in multicomponent electrolyte solutions. The method based on Eq. (1) may, therefore, be a convenient one for evaluating the activity coefficients in multicomponent electrolyte solutions for use in engineering calculations.

Properties of Water Solubilized in Reversed Micellar Systems of Dodecylammonium Propionate in Nonpolar Solvents

Manabu SENŌ, Koji ARAKI, and Shinsaku SHIRAISHI

Institute of Industrial Science, University of Tokyo, Roppongi 7-22, Minato-ku, Tokyo 106

(Received October 4, 1975)

The properties of the reversed micelles of dodecylammonium propionate(DAP) and of solubilized water were examined for systems with hexane, chloroform and benzene as a nonpolar component. The aggregation number of DAP, the conductivity, the heat of solution of water, IR and NMR spectra, and near infrared spectra of solubilized water were measured. From the results the properties of the reversed micellar system were analyzed, the following conclusion being obtained. The aggregation state of DAP is scarcely affected by the addition of water. Water is first dispersed in the nonpolar organic phase, and then solubilized in the cores of the reversed micelles. The former is free or weakly bonded water, while the latter is bonded water like that in the bulk phase. The catalytic effect of DAP reversed micellar system is discussed.

Surfactant micelle catalyzes various reactions and serves as a model for the enzyme action. Fendler *et al.* observed that reversed micelles in nonpolar solvents significantly catalyze several reactions, and suggested that this could provide a favorable model for a microenvironment of enzyme active sites.[1] They also suggested that the water solubilized in the polar cavities of reversed micelles is less polar than the water in the bulk phase, which is closely related to the catalytic effect of the reversed micellar systems.[2,3]

We investigated the hydrolysis of adenosine 5'-triphosphate (ATP) in a reversed micellar system where an aqueous ATP phase is solubilized in hexane by dodecylammonium propionate (DAP), and found that the hydrolysis rate in this system is enhanced several times as compared with that in an aqueous system.[4] This reversed micellar system shows an enzyme-like behavior such that the addition of Mg^{2+} or Ca^{2+} enhances markedly the hydrolysis rate, suggesting that the rate enhancement is closely related to the polarity of the water solubilized in the reversed micelles. It is of interest to investigate by more direct methods the properties of the DAP reversed micelles and the solubilized water in relation to the catalytic activities of these systems.

Experimental

Materials. The preparation and purification of dodecylammonium propionate (DAP) were described previously;[4] mp 55—56 °C (Lit, 54—56 °C[5]); Found (Calcd), C, 69.68(69.44); H, 12.38 (12.82); N, 5.32 (5.40)%. Dodecyltrimethylammonium acetate (DTAA) was prepared by the anion exchange reaction of dodecyltrimethylammonium chloride with silver acetate in a 1-propanol-water mixed solvent, and was purified and dried three times by freeze-drying from its benzene solution. The structure and purity were confirmed by IR and NMR spectra and elementary analysis; Found (Calcd): C, 70.24 (71.02); H, 13.10 (12.97), N, 4.75 (4.87)%. Distilled water with conductivity below 10^{-7} mho·cm^{-1}, was used.

Measurements. Conductivity of solutions was measured with a Toa conductmeter model CM-2A equipped with a CG-7001PL cell, the sensitivity being 10^{-7} mho·cm^{-1}. The sample solution was stirred and maintained at 35.0 °C. Vapor pressure osmometric measurements (VPO) were made at 37.0 and 50.0 °C with a Hewlett-Packard vapor pressure osmometer model 302B.

Infrared spectra were recorded with a Jasco IRA-2 spectrometer at room temperature using a pair of cells of 0.05 mm in path length. The reference cell was filled with solvent in order to record spectra of DAP micellar solutions. Near infrared spectra were recorded with a Hitachi spectrophotometer model EPS-3T. The absorption cells were 10 mm in light path and thermostatted at 35.0 °C. A solution containing DAP of the same concentration as that of the sample solution was used as a reference, in order to record the spectra of water solubilized in the reversed micellar system.

The 90 MHz proton nuclear magnetic resonance spectra were taken with a Hitachi R-22 high-resolution spectrometer at 35 °C. The chemical shifts were recorded by using TMS as an internal standard. A coaxial double tube was used for measurements of spectra of water in DTAA reversed micellar system; pure water was contained in the inner tube as an external standard, and the sample solution in the outer tube.

The heat of solution was measured with a Tokyo Riko twin-isothermal calorimeter at 35.0 °C. The water was sealed in a glass ampoule, and after attaining thermal equilibrium the ampoule was crushed into the sample solution. The temperature difference between the sample cell and reference cell was detected by a thermocouple, and calibrated against a standard electric heater.

Results and Discussion

Conductivity of the Systems. Conductivity of DAP reversed micellar systems with hexane, chloroform, and benzene as a nonpolar component was measured at 35.0 °C. The results are shown in Fig. 1 as a function of water concentration. A break point observed in each conductivity curve coincides with

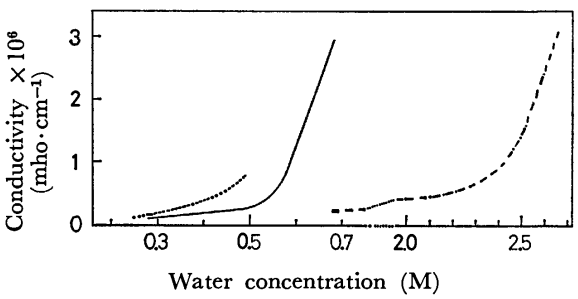

Fig. 1. Conductivities of the DAP (0.2 M) reversed micellar systems at 35.0 °C in hexane (——), chloroform (----), and benzene (-·-·).

the water concentration where a homogeneous solution becomes heterogeneous. At water concentrations below the break point this curve gives the conductivity of homogeneous DAP reversed micellar solution, the values lying within *ca.* 10^{-7}—10^{-6} mho·cm^{-1}. When an aqueous electrolyte solution (0.1 M sodium acetate) was used instead of pure water, the conductivity of the system remained nearly the same. It is thus evident that the conductivity in this concentration range is due to DAP in the system. Increase in water content scarcely affects the association state of DAP. However, the conductivity increases abruptly at water concentrations above the break point. By considering the large values of conductivity, this increase is thought to be caused by the dissociation of DAP salt in water phase which is not solubilized.

The amount of water that could be solubilized in each solution determined from the conductivity measurement is given in Table 1. The value for the benzene solution is almost the same as that reported by Kitahara[5] and Kon-no and Kitahara.[6]

Aggregation Numbers of DAP. Aggregation numbers of DAP in the reversed micellar systems were estimated from the average molecular weights of micelles determined by VPO. In these measurements, it was assumed that the vaporization of water solubilized in DAP reversed micelles is neglected in the range where the amount of water is comparable to that of DAP. The results are shown as a function of water concentration (Fig. 2). The values obtained are nearly the same as those determined by Seoud *et al.* through the NMR method for the systems in benzene, chloroform and carbon tetrachloride in the absence of water.[7] The aggregation number of DAP in the reversed micellar system is much smaller than that in aqueous micelles, the amount of water added scarcely affecting the value. This would mean that the addition of water does not alter significantly the aggregation state of DAP.

Infrared Spectra and Near Infrared Spectra. The effect of water concentration on IR spectra of DAP in the reversed micellar system was examined. It was found that the absorption band of asymmetric stretching of carboxylate anion shifts to a lower wave number side with an increase in water concentration (Table 2). This would indicate that the solubilized water interacts with the carboxylate group of DAP. No further information could be obtained as to the ammonium group of DAP and water, since the absorption bands of these groups are broad.

The near infrared spectra of water in various systems were recorded in the range 1800—2000 nm (5000—5556 cm^{-1}), where water exhibits a strong absorption band due to the $\nu_2+\nu_3$ combination mode. The spectra of the systems with various solvents and various concentrations of water and DAP are shown in Figs. 3, 4, and 5. The water solubilized in the reversed micellar systems in chloroform and benzene has a sharp band at about 1890 nm and a broad band at 1920—1950 nm, while in hexane the former band is observed as a shoulder of the broad band. These bands could be separated into two parts on figures by assuming that the sharp band is of a Gaussian type, and the areas of

Water concentration is kept constant ((A): 0.111 M, (B): 0.167 M), and DAP concentration is varied as follows; (A): 0.05 M (——), and 0.2 M (----); (B): 0.05 M (——), and 0.2 M (----).

these two parts is given in Fig. 6 as a function of water concentration in chloroform. The sharp band at 1890—1900 nm is ascribed to free or extremely weakly bonded water.[8] This assignment suggests that in the present system the sharp band at about 1890 nm is not due to the water solubilized in the polar region of reversed micelles, but to the water dispersed in the nonpolar organic phase. The interpretation is based as follows: 1) This band coincides in position and shape with that of water dissolved in pure solvents in the absence of surfactants (Fig. 3); 2) The increase in DAP concentration does not increase the intensity of this band (Fig. 5); 3) The increasing order of the intensity of this band, chloroform>benzene≫hexane, agrees with that of the solubility of water in these solvents.

The band occurring at wave lengths greater than 1900 nm is thought to be due to the bonded water, usually hydrogen bonded water.[8] The broad band observed at 1920—1950 nm in Fig. 3 is thus ascribed to the water solubilized in the reversed micelles be-

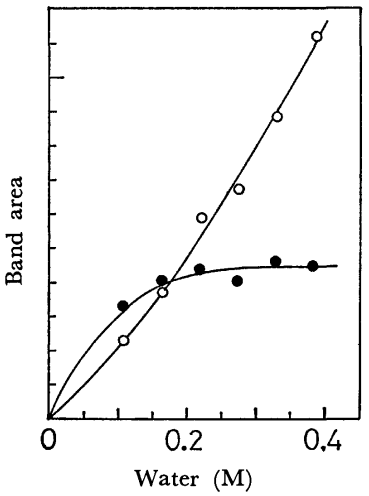

Fig. 6. Band areas of near infrared spectra of water in chloroform at 35.0 °C; one is the sharp band at 1890 nm (●); and the other is the broad band above 1900 nm (○).

cause of the following reasons: 1) The band resembles that of pure water in shape, and water solubilized in micelles could be supposed to form a water phase, while it is hard to suppose that water dispersed in the organic phase forms a water phase; 2) The increase in DAP concentration increases the intensity of this band (Fig. 5); 3) The increase in the amount of water beyond the solubility of water in the organic solvent results exclusively in the increase in intensity of this absorption band. Furthermore, the position of this band (λ_{max}: 1921—1953 nm) shifts a little to a greater wavelength side as compared with that of pure water (λ_{max}: 1919 nm), the increase in water concentration diminishing the extent of this shift. The greater wavelength shift could be caused by the interaction between the water solubilized in the reversed micelles and polar groups of DAP.

These results could be summarized as follows: 1) Two types of water exist in the reversed micellar solution; one is the water dispersed in the organic phase which shows a sharp band at about 1890 nm, and the other is the water solubilized in the reversed micelles which shows a broad band at 1920—1950 nm. 2) In chloroform a considerable amount of water is dispersed in the organic phase, while in hexane almost all the water is solubilized in the reversed micelles. 3) As seen from Fig. 6, water added is at first dispersed in the organic phase and then solubilized in the reversed micelles. 4) The water solubilized in the reversed micelles is bonded to the head groups of DAP or to each other a little more strongly as compared with the case of pure water.

NMR Spectra. The effect of water concentration on chemical shifts of DAP protons in the reversed micellar system in deuterochloroform at 35 °C is shown in Table 3. As the ammonium protons of DAP and water protons gave only a single peak because of the rapid proton exchange between them, we could not observe the dependence of the chemical shift of ammonium protons on water concentration. The dependence of the chemical shift of these protons on solubilizate

DTAA: 0.2 M.

concentration is reported for other solubilizates such as dimethyl sulfoxide or methanol.[9] We have carried out a similar measurement on the reversed micellar system of DTAA which has no ammonium protons exchangeable with water protons. The result is given in Table 4. Both the NMR spectra of DAP and DTAA in the reversed micellar system show a similar feature; the extent of chemical shifts of methylene and methyl protons adjacent to the cationic or anionic group depends somewhat on water concentration, while those of the other protons are not dependent on water content. A similar behavior was observed for other solubilizates.[9] This indicates that the water solubilized in reversed micelles exists near the polar head groups and, in other words, in the cores of reversed micelles.

The water protons give only a sharp single peak, and not a broad one or two peaks as in the case of near infrared spectra. This shows that the lifetime of water of each type is below the NMR time scale. The δ value of water protons in the DTAA reversed micellar system is smaller than that of pure water (δ=4.66) at lower water concentration, but a little greater than that of pure water at higher water concentration. Water dissolved in deuterochloroform without any surfactant gives a peak at δ=1.54. The observed peak position is said to be an average of the two peak positions, one of which is due to the water dispersed in the nonpolar organic phase which gives a high-field shift as compared with that of pure water, and the other to the water solubilized in the core of reversed micelles which gives a small low-field shift.

Calorimetric Measurements. The heat of solution of water in a DAP (0.05 M) reversed micellar system in hexane (100 ml) at 35.0 °C was measured. The results given as an integral heat of solution, ΔH_{soln} (cal/100 ml of hexane), and a differential heat of solution, Δh_{soln} (kcal/mol of water), are shown in Fig. 7. Since the addition of water does not cause a pronounced change in the state of micelles, the values show the enthalpy change between pure water and the water solubilized in the reversed micellar system. The initial step of addition of water is endothermic, while the subsequent steps are exothermic. By the addition of more than 0.03 M water, the differential heat of solution becomes nearly constant, Δh_{soln}= −450 cal/mol of water. When water is dispersed in the nonpolar organic phase, the enthalpy change is thought to be positive because of destruction of water structure in the bulk phase. On the other hand, when water is solubilized in the reversed micelles the enthalpy change is thought to be negative, since water interacts with the polar groups of DAP as elucidated from IR and NMR spectra. Thus the calorimetric measurement provides results which coincide with other results.

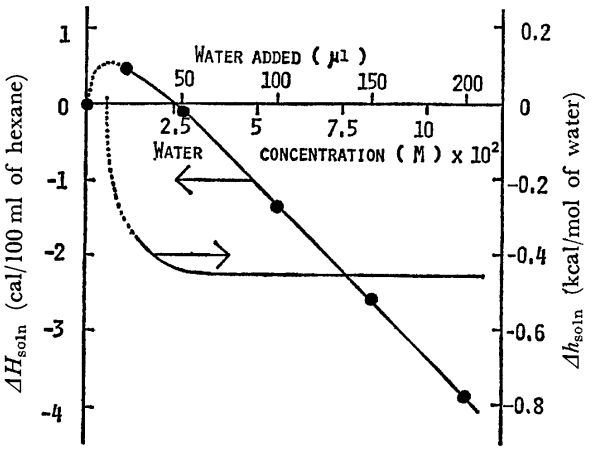

Fig. 7. Integral (ΔH_{soln}) and differential (Δh_{soln}) heats of solution of water in DAP (0.05 M) reversed micellar system in hexane (100 ml) at 35.0 °C.

Catalytic Effect of the DAP Reversed Micellar System. The hydrolysis rate of ATP in the DAP reversed micellar system in hexane is proportional to the DAP concentration and inversely proportional to the concentration of solubilized water.[4] The polarity of the core of DAP micelles in hexane, which was measured by the absorption band shift of pyridine 1-oxide solubilized in the reversed micelles, depends on the [water]/[DAP] ratio, and is less polar than pure water. The catalytic effect of this system would be closely related to this polarity.

The effect of water content on this system could be discussed from the following three related aspects: (a) the effect on the aggregation state of DAP, (b) the effect on the property of solubilized water, and (c) the effect on the substrate in the reversed micelles. In this paper we have discussed the system from (a) and (b), and in the preceding paper from (c).[4] Since the water content scarcely affects the aggregation states of reversed micelles, the micro-environment of the substrate is closely related to the property of water solubilized in the reversed micellar system. As almost all portions of the water added exist in the cores of DAP reversed micelles in hexane, it could be said that the catalytic effect of this system depends greatly on the property of the water solubilized in the reversed micelles,

which is bonded a little more strongly than the water in the bulk phase.

(Received October 6, 1975)

The photoelectron spectra (energy distribution curves, ECDs) of naphthacene, pentacene, perylene, coronene, and *p*-terphenyl by He(I), Ne(I), and Ar(I) resonance lines (photon energies, 11.62—21.22 eV**) and the absorption spectra of naphthacene, pentacene, perylene, and coronene at 4—9.5 eV are measured for evaporated polycrystal films. The absorption spectra are compared with the spectral dependence of the quantum yield (SDQY) of photoemission. A similar comparison is also made for *p*-terphenyl and anthracene. The origin of the structures in SDQY curves is discussed. The analysis reveals that: (1) the MOs of a molecule are preserved even in crystals; (2) the large peak at a low kinetic energy of the photoelectron spectra is due to secondary electrons, and (3) at least for naphthacene, pentacene, and coronene, autoionization takes place with a considerable efficiency.

Photoemission has now become a powerful tool for the study of the electronic properties of solids.[1)]

Polycyclic aromatic hydrocarbons form a major branch of organic semiconductors, and many studies have been made of their electronic properties.[2)] Experiments on photoemission from these compounds in the solid state have also been carried out since the beginning of the 1960s.[2,3)]

Usually two quantities are measured in photoemission experiments: the spectral dependence of its quantum yield (SDQY), and the energy distribution curves of photoelectrons (EDCs, photoelectron spectra) at each photon energy.

SDQY for photoemission from the aromatic hydrocarbons has been studied by many workers.[2,3)] Particular efforts have been made to explain the shape of SDQY around the threshold region in order to make an accurate extrapolation for determining the photoemission thresholds from SDQY.

The photoelectron spectroscopic study of organic solids was first made by Vilesov and his co-workers[4)] in the vacuum-ultraviolet (vacuum-UV) region. They measured the EDCs and discussed the energetics and mechanism of the photoemission. Related studies were also made by Kochi *et al.*,[5)] Hirooka *et al.*[6,7)] and Zagrubskii and Vilesov[8)] in the vacuum-UV region and by Belkind *et al.*[3)] in the region near to and below the threshold. Further, the introduction of the windowless monochromator[8a)] and the use of rare gas resonance lines[9,10)] extended the photon energies, and a high resolution was obtained by the use of a deflector-type analyzer.[10,11)]

These efforts clarified many points about the microscopic mechanism of the photoemission. However, the understanding of the mechanism for aromatic hydrocarbons seems still to be incomplete (for a review, see the article by Belkind *et al.*[3)]). This is partly due to the lack of experimental data. For example, almost all the optical studies of solid aromatics in the vacuum-UV region have been restricted to small molecules.[12)] On the other hand, Schechtman and Spicer[13)] made an extensive study of phthalocyanines and showed that the comparison of the optical spectra with the SDQYs of the photoemission is very useful for the analysis of SDQY. Although several electron energy-loss experiments have been carried out for large aromatics,[12,14)] Kramers-Kronig analysis must be carried out in order to obtain the absorption spectra. This was carried out only by Hinz and Venghaus[14)] for a few compounds. Due to the lack of experimental data on the optical spectra, no comparison between SDQY and the optical spectrum can be made for compounds such as naphthacene, which has been most frequently studied in photoemission work.

Further, almost all the investigations have been restricted to the photon energies of the LiF window cutoff (11.5 eV), with some recent exceptions. The extension of measurements to higher photon energies can be expected to give more useful information. For example, the effect of electron scattering will become clear with the increase in the photon energy. Further, deeper valence levels and upper conduction bands can be investigated by means of higher photon energies.

In this paper, we wish to report: (1) the photoelectron spectra of polycrystals of naphthacene, perylene, pentacene, coronene, and *p*-terphenyl by rare gas resonance lines with photon energies up to 21.22 eV, and (2) a comparison of SDQY with the optical spectra for these compounds and anthracene in the region of 5—11.5 eV. The results will be discussed in order to clarify the energy structures of these compounds and the nature and role of several processes in the photoemission. The results of the photoelectron spectra in the range of 5—11.5 eV have been reported elsewhere.[7)] Particular attention is paid to the characteristic properties of these compounds as molecular crystals; these properties distinguish them from other classes of substances. Information on these points will also be useful in other areas, such as the photoconduction and radiation physics of these substances. Some of the experimental results have already been

reported in other periodicals.[9,15,16]

Experimental

Samples. The materials used in this study were purified by zone refining, recrystallization, and sublimation. X-Ray diffraction measurements revealed that the evaporated samples are oriented polycrystals, with their c-axes perpendicular to the substrates,[15,17] both for the photoemission and for the optical spectra measurements. The crystal structure of perylene is known to be the α-form, in which molecules form dimers.[18]

Photoelectron Spectra. The rare gas discharge lamp was of the π-type. He(I)(21.22 eV), Ne(I)(16.85 and and 16.67 eV), and Ar(I)(11.83 and 11.62 eV) resonance lines were used. For the He(I) discharge, $1—5\times10^{-2}$ Pa of helium was supplied through a liquid nitrogen-cooled charcoal trap. For the Ne(I) and Ar(I) discharges, a small amount of neon and argon was added to the helium gas.[19] An a.c. voltage of 5—8 kV was applied from a neon-sign transformer. The photoelectron energy analyzer was of the retarding-potential type. A gold-plated collector 150 mm in diameter was used, with the emitter located at its center.

The samples were evaportaed onto a polished copper emitter substrate 12—20 mm in diameter in a separate evaporation vessel under a vacuum of $10^{-3}—10^{-4}$ Pa. Measurements were made under a vacuum of $1—3\times10^{-4}$ Pa. The continuous slow sublimation of the organic specimen helped to maintain a clean surface and enabled satisfactory measurements to be made without the use of an ultrahigh vacuum. The sample thickness was monitored with a quartz crystal oscillator (Toyo Tsushinki TVF-1). Considering several factors (the charging of the sample, the effect of the substrate, and the loss of the sample due to sublimation), thin film specimens 30—200 nm thick were employed.

The photoelectron-energy distribution curves were measured by means of an a.c. modulation technique which has been reported previously.[6,7] A Cary-31 vibrating-reed electrometer and a PAR-128 lock-in amplifier were used, with an a.c. modulation of 200 mV_{P-P}, 4 Hz. The total photocurrents were of the order of 10^{-10} to 10^{-11} A. The resolution of the spectrometer was estimated to be about 0.3 eV.

Optical Spectra. The method of the measurement of the absorption spectra of films evaporated onto LiF plates has already been reported.[15]

The measurement of the normal incidence reflection spectra of evaporated films was also attempted; it gave useful preliminary results for perylene and pentacene for $h\nu<7.7$ eV. The experimental details have been reported elsewhere.[20]

Results

Photoelectron Spectra. Figures 1—5 show the EDCs of naphthacene, perylene, pentacene, coronene, and *p*-terphenyl as functions of the retarding potential, *RP*. *RP* is related to the kinetic energy of the electron, *KE*, thus:

$$KE = e(RP+V_S), \quad (1)$$

where V_S is the saturation voltage defined as the negative of the value of *RP* at the right-hand cutoff point of the EDCs. If the electrical contact between the sample and substrate is good enough, the value of V_S is the contact potential difference between the sample and the collector. Further, the ionization

potential, *IP* (binding energy measured from the vacuum level) is derived from the Einstein relation:

$$IP = h\nu - KE. \quad (2)$$

When $h\nu$ is changed, small moving structures in the higher *RP* region and large non-moving structures in the lower *RP* region were observed in all the spectra.

The non-moving structures can be classified into two groups: (1) the shoulders observed near zero *RP* for naphthacene and pentacene (whose spectral shapes and intensities were sensitive to the sample condition) and (2) the peaks observed in all compounds in the *RP*=0.5—1.5 V region (their peak intensities increased rapidly with the photon energy). These two groups of structures were also found by Hirooka[7] at lower photon energies. We shall refer to these structures as "lower energy non-moving structures" (LNMSs) and as "high energy non-moving peaks" (HNMPs) respectively. In Hirooka's work,[7] LNMSs were found for all the compounds, while HNMPs were found only for naphthacene, pentacene, and perylene. A recent report by Hino *et al.*[16] shows that LNMS does not appear in *p*-terphenyl, even at lower photon energies.

A weak charging effect was observed for some samples, due to fairly large photoemission currents. This caused a scatter of the observed values of V_S of 0.2 V. Therefore, the minimum value of V_S obtained was used to calculate the *IP*s. This gave a good agreement with the *IP*s obtained by Hirooka[7] and Hino *et al.*[16] The values of V_S and *KE* for the non-moving structures are listed in Table 1.

Figures 6—10 show the EDCs as functions of *IP*. It may be seen that the *IP*s of the moving structures have nearly constant values, independent of the photon energies. For comparison, the results of molecular photoelectron spectroscopy[21] are also shown in the figures. The *IP*s obtained are listed in Tables 2—6, together with the results of other photoemission studies[5-8,10] and of molecular photoelectron spectroscopy. In the tables, *P* is the polarization energy,[22] defined here as the difference in the *IP* values between the solid and gas phases.

TABLE 1. SATURATION VOLTAGES AND KINETIC ENERGIES OF NON-MOVING STRUCTURES

Compound	V_S/V	*KE*/eV
Naphthacene	0.4	0.5 1.9
Pentacene	0.3$_5$	1.4 0.6
Perylene	0.3	0.8
Coronene	0.4	1.0
p-Terphenyl	0.4	1.1

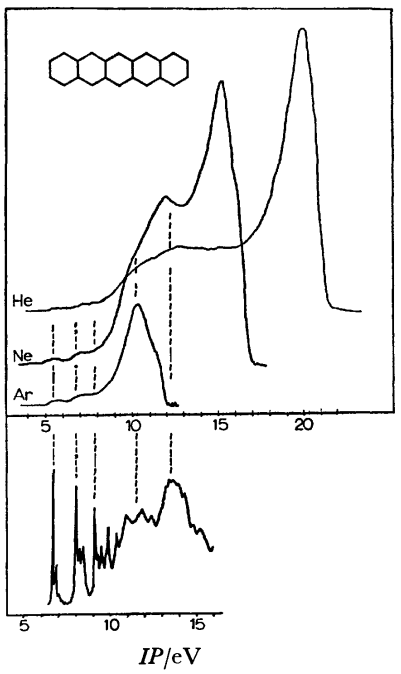

Fig. 8. EDCs of pentacene in ionization potential scale (upper). Photoelectron spectrum of a free molecule is also shown (lower, Ref. 21d).

On the whole, the agreement with the other photoemission studies and the correspondence with the gas-phase data are satisfactory. However, the *IP* values of 15.3 and 16.2 eV for naphthacene, which we reported in the preliminary communication,[9] seem dubious in the light of this work and the recent photoelectron spectrum obtained by Ueno *et al.*[10b] using a He(II) (40.8 eV) resonance line.

Recently, Shibata *et al.*[23] measured the Penning emission from naphthacene by means of rare gas metastable atoms. Their results for the location of valence levels agree with the present results very well.

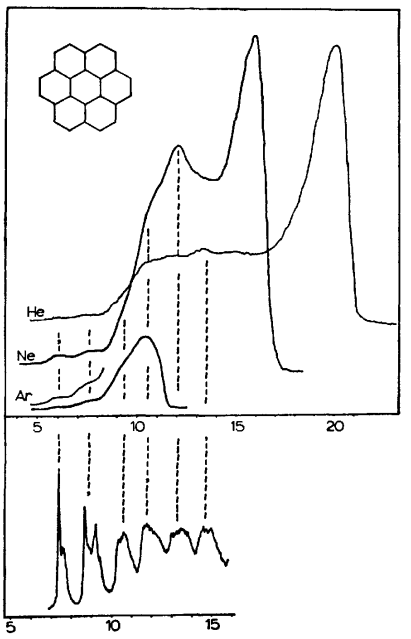

Fig. 9. EDCs of coronene in ionization potential scale (upper). Photoelectron spectrum of a free molecule is also shown (lower, Ref. 21d).

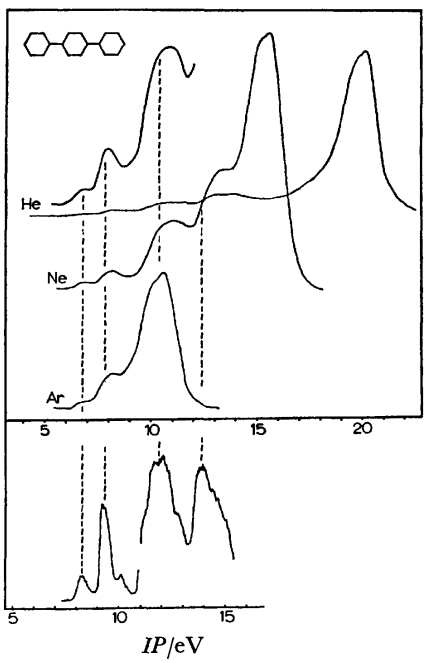

Fig. 10. EDCs of *p*-terphenyl in ionization potential scale (upper). Photoelectron spectrum of a free molecule is also shown (lower, Ref. 16).

The spectra for perylene are much clearer than the preliminary ones reported previously.[9] The sharpness of the structures of coronene depended on the sample preparation. A similar but weaker effect was also found for perylene; its origin is not understood. The structures of the spectra for pentacene are not very

clear. This might be partly due to the fact that the separations between the levels are rather small, as can be seen from the gas-phase photoelectron spectrum.

For *p*-terphenyl, although the molecular structures in the solid and gaseous phases might differ a little, as a result of the rotation of phenyl groups, the correspondence seems to be good. Its details were reported elsewhere.[16]

Optical Spectra. The results of the absorption and reflection spectra for naphthacene, pentacene, perylene, and coronene are shown in Figs. 11—14(c). Further, the absorption spectra of anthracene and *p*-terphenyl obtained from the data by Clark[24] and Venghaus[14] are shown in Figs. 15 and 16(c).

The peaks observed in the absorption spectra are due to molecular excitons. Their interpretation has been discussed in another periodical.[15] The rising baselines may correspond to the direct ionization in solids. Some other workers have also suggested the occurrence of direct ionization.[20,24]

For comparison, the results of SDQY measurements of naphthacene, pentacene, perylene, coronene, and anthracene by Hirooka[7] are shown in Figs. 11—15(b). The result for *p*-terphenyl by Hino *et al.*[16] is also shown in Fig. 16(b). The quantum yield is defined here as

the number of photoelectrons per incident photon, and no correction of reflection is made. However, as will be seen later, the neglect of reflection has no significant effect. The discrepancies in the SDQY curves at 7—8 eV are due to the use of a quartz filter at low photon energies. The small ripples in the SDQYs are due to the experimental uncertainty caused by the use of a many-line hydrogen light source.

For perylene and pentacene, the results for SDQY agree well with those of other works.[5] For anthracene and naphthacene, however, some discrepancies from the findings of other works[5,25] were found. For the time being we shall rely on Hirooka's data,[7] although a more accurate measurement of SDQY should be attempted. For coronene and *p*-terphenyl, no other work is available on the vacuum-UV region.

Further, the EDCs at appropriate photon energies[7,16] are also shown in Figs. 11—16(a) to show the location of the valence-band levels.

Discussion

We adopted the phenomelogical three-step treatment.[1] The three steps are: (1) the formation of a quasi-free electron by photon absorption, (2) transport process to the surface, and (3) transmission through the surface. The characteristic aspects of these processes in molecular crystals are:[3,26] (a) not only direct ionization (DI) but also autoionization through a highly excited molecular exciton (AI) might take place; (b) on ionization, *k*-vector conservation is not an effective selection rule, because of the localization of the hole;[1] (c) quasi-free electrons must escape from geminate recombination in the Coulomb field formed by the hole, and (d) electrons can suffer energy loss due to the excitation of the exciton or the intramolecular vibration of other molecules, in addition to the other processes observed in inorganic solids.

The theory of photoemission for organic solids has already been discussed by several workers.[3,13,27]

I. Moving Structures of EDCs. The moving structures in EDCs are considered to be closely associated with the valence bands of the organic crystals. According to Koopmans' theorem, their *IP*s correspond to the energy of the valence levels. All the results show that the agreement of these levels between the gaseous and crystalline states is fairly good, if the polarization energy is assumed to be constant for a compound. This shows that the MOs of a molecule are preserved even in the solid because of the weak intermolecular interactions.

This result was predicted on the basis of a comparison with MO calculations[4,7] and was verified experimentally for π-levels.[7] Molecular photoelectron spectroscopy studies[21e] report that the onset of the ionization from σ levels is at about 10.6—11.0 eV for aromatic hydrocarbons. Assuming a polarization energy of about 1 eV, the emission from σ levels begins at the solid ionization potential of 9.5—10.0 eV. This should correspond to the observed sharp rise of EDCs at about 9 eV. Therefore, the good correspondence between the gas and solid phases extends into the σ electrons. This confirms the validity of the concept of polarization energy proposed by Lyons.[22]

The origin of the peak width of the photoelectron spectra for a solid was discussed previously.[11] We will not compare the peak intensities of the gaseous and solid phases because of the lack of information about the angular distributions of photoelectrons for gaseous samples. Further, the effect of scattering in the solid state makes comparison difficult for such high photon energies (see II).

II. Non-moving Structures in EDCs. Kochi *et al.*[5c] found the HNMPs for some compounds at $h\nu < 11.5$ eV and ascribed them to secondary electrons. The nature of the secondary electrons for organic crystals has been discussed by them and by Schechtman.[13] Their conclusions are: (1) the EDCs of secondary electrons show a peak at a small kinetic energy, and its position does not move significantly with the change in $h\nu$. (2) Secondary electrons contribute to photoemission only in the higher photon energy region, and their contribution grows rapidly with $h\nu$. Although the assumptions they used to derive these conclusions need some re-examination, these criteria are still valid for distinguishing the effect of secondary electrons (see Appendix).

Zagrubskii and Vilesov[8] also observed HNMP and LNMS for several compounds. However, they argued that they are not due to secondary electrons, for their quantum yields (for naphthacene) remain roughly constant at the photon energy of 12—13 eV before decreasing abruptly. They assigned this phenomenon to autoionization, with a preliminary energy loss (AIPL):

$$\begin{aligned} M &\xrightarrow{h\nu} M_I{}^{**} \\ M_I{}^{**} &\longrightarrow M_J{}^{*} \\ M_J{}^{*} &\longrightarrow M^{+} + e^{-} \\ &\searrow M^{+*} + e^{-}, \end{aligned} \qquad (3)$$

where M is the ground state of a molecule, $M_I{}^{**}$ is a high-energy exciton state, $M_J{}^{*}$ is the autoionizing state, and M^+ and M^{+*} are the ground and excited states of an ion respectively. On the basis of this model, they attributed the structures of naphthacene at $KE=0.4$ and 1.8 eV to autoionization to the M^+ state at 5.68 eV and the M^{+*} state at 7.15 eV. They also atrributed the HNMPs of EDCs for perylene and *p*-terphenyl to this mechanism.

They[8c] further attributed the peaks in the SDQY of naphthacene and perylene to the direct optical excitation of the autoionizing state, M^*_J. The energy values of $M_J{}^{*}$ thus obtained are: 7.56 eV for naphthacene, 6.75 and 8.5 eV for perylene, and 7.13 eV for *p*-terphenyl. Further, they identified these autoionizing levels as plasma oscillations of π electrons on the basis of the coincidence of the reflection spectra of graphite, naphthacene, and *p*-terphenyl.

However, their conclusions are dubious for the following reasons; therefore, we assign HNMP to secondary electrons.

(1) The results obtained here for the high-photon-energy region satisfy the criteria described above. The HNMPs are not observed at lower photon energies. Hirooka[7] examined the ratio of the peak height to

the peak of the maximum *KE* and estimated that these peaks begin to appear at photon energies of 8.5—9.3 eV for naphthacene, pentacene, and perylene. In the present experiment also, this ratio increases monotonically with the photon energy. Further, their peak positions are roughly independent of the photon energy, as is shown in Table 1.

(2) The peak positions of HNMP agree with those of secondary electrons formed by slow electron impact.[10,32]

(3) At least for naphthacene, pentacene, and coronene, the small values of the scattering length, *L*, of the order of 10 nm or less[28b] suggest that scattering does occur in these crystals.

(4) The fact that the peak at $RP \cong 0$ V (LNMS) appears even at lower photon energies, while HNMP appears only at higher photon energies, cannot be explained by the AIPL model.

(5) The peak intervals between the LNMS and HNMP in pentacene do not agree with the interval between M^+ and M^{+*} (see Tables 1 and 4).

(6) At least for naphthacene, pentacene, and coronene, the structures of SDQY can be explained by ordinary autoionization, as will be described in III. Further, no structure is found in the SDQY of *p*-terphenyl at the predicted value, $h\nu = 7.13$ eV.

(7) According to Robin,[12] it is useful for the identification of plasmon to compare the optical absorption and the electron energy-loss spectra. Plasma oscillation is intense in the energy-loss spectra, but it should be much weaker in the absorption spectra. For *p*-terphenyl and naphthacene, the absorption coefficient is fairly large at the predicted photon energies, 7.13 eV and 7.56 eV (Figs. 1 and 6). For perylene, there is a peak in the energy-loss spectrum (calculated from the data by Fuke *et al.*[20]) at about 7 eV, but this can be attributed to the one-electron excitation at 6 eV in optical absorption. Therefore, the possibility of the existence of plasma oscillations at these energies is also dubious.

(8) Further confirmation is afforded by the recent experiment of Penning emission from naphthacene by rare gas metastable atoms.[23] That experiment showed that two nonmoving structures also appear in the Penning-emission spectra at the positions of HNMP and the LNMSs. However, their relative intensities were reversed from those in the photoelectron spectra presented here. Considering the nature of the metastable atom, which cannot penetrate into the solid, the Penning-emitted electrons should be less affected than photoelectrons by bulk properties such as electronic scattering. Therefore, HNMP will become weaker in Penning emission, as was observed in the experiment. It is hard to explain this result by the AIPL model, although the detailed mechanism of Penning emission is not yet clear.

From these considerations, it seems certain that the HNMPs are due to secondary electrons. However, the abrupt decrease in the quantum yield for the HNMP of naphthacene above 13 eV reported by Zagrubskii and Vilesov[8] remains unexplained. Furhter investigations are necessary for this point.

The small shoulders (LMNSs) observed in naphthacene and pentacene at $RP \cong 0$ V probably have a different cause from that of the HNMPs. The other compounds except *p*-terphenyl also show similar structures at lower photon energies, but they seem to be covered by the large peaks for perylene and coronene at the higher photon energies used here. The shapes and intensities of these structures are sensitive to the method of sample preparation. This fact was also found by Hirooka[7] and by Schechtman.[13] Therefore, it could be an effect due to some peculiarity of the transmission probability through the surface or to the effect of surface contamination.[7,13]

III. Spectral Dependence of Quantum Yield (SDQY) and the Absorption spectra. As may be seen from Figs. 11—16(b), three regions can be distinguished in the SDQYs, except for the case of *p*-terphenyl: (a) near the threshold region (up to about 1 eV above the threshold): here a sharp increase in the quantum yield, *Y*, is observed; (b) the intermediate region (from 1 eV above the threshold to about 9.5 eV): here there is a rather gradual increase in *Y*, with several structures, and (c) far beyond the threshold region (above 9.5 eV): here there is a monotonic increase in *Y*.

In the region where the data of reflectance $R(h\nu)$ are available (anthracene,[29] perylene,[20] pentacene, *p*-terphenyl,[8] and naphthacene[8]), $R(h\nu)$ is smaller than 0.15 and the $1-R(h\nu)$ factor does not correspond with SDQY. Therefore, the reflection of the incident light has no significant effect on SDQY.

As has been stated in II, the contributions of secondary electrons are small in the low-energy regions, (a) and (b).

(a) *Near the Threshold Region*: No correspondence is found between *Y* and the total absorption coeffecient, a_t, in this region. This has previously been noted by Lyons and his co-workers.[25,27] Kochi *et al.*[5] assumed that *Y* is determined by the energy distribution of photoelectrons arriving at the surface and by the transmission probability $T(E)$ through the surface. With this assumption, they could derive the cube root law which can explain the experimental results: $Y^{1/3} \sim a(h\nu - E_{th})$, where *a* is a constant and where E_{th} is the threshold of photoemission. This sharp increase in *Y* is sufficient to smear out the effect of the variation in a_t. Therefore, it is not surprising that no correspondence exists in this region.

(b) *Intermediate Region*: Vilesov *et al.*[4] and Kochi *et al.*[5] ascribed the structures of SDQY to the occurrence of the photoemission from deeper levels. As may be seen from the comparison of SDQY and EDC in Figs. 11—16(b) and (a), this theory can be applied to polyacenes. However, the distinct minima in SDQY for perylene and coronene (Figs. 13(b) and 14(b)) cannot be explained in this way. Kochi *et al.*[5c] ascribed the decrease in *Y* in perylene to the abrupt decrease in the escape depth, $L(E)$, casued by the occurrence of pair-production, where *E* is the energy of the quasi-free electron measured from the top of the valence band. However, Zagrubskii and Vilesov[8c] examined the EDC of perylene and concluded that $L(E)$ does not change so much with *E*. Further, it was shown that pair-production is not the main

mechanism of the scattering of electrons (see Appendix).

On the other hand, there is another possible explanation, one based on the change in the absorption coefficient.[13,27] If $L(E)$ is much shorter than the extinction length of the incident light ($a_tL \ll 1$), only light absorbed in a thin layer, L, from the surface can contribute to photoemission. The number of photons absorbed in this layer is determined by the absorption coefficient. Then, if all the photons absorbed in this layer contribute to photoemission, and if the average escape depth does not change significantly with the photon energy, the quantym yield should be proportional to the absorption coefficient, a_t.

Of course, we must note that not all the absorbed photons might contribute to photoemission, unless autoionization occurs with a high probability. Batley[27] analyzed the expected behavior of Y under various conditions (whether scattering is severe and which, AI or DI, dominates ionization) in a way similar to that used by Pope[30a] for photoconduction. His results can be summarized as in Table 7. In Table 7, $a_{DI}(h\nu, E)$ is the effective absorption coefficient to form quasi-free electrons with the E energy, a_{AI} is the absorption coefficient of the autoionizing exciton, $k(h\nu, E)$ is the autoionizing probability to form quasi-free electrons with the E energy, and A_t includes all factors other than the change in a_{DI}, a_{AI}, and a_t. In the last column of Table 7, it is assumed that $\int a_{DI}\,dE$ gradually increases with the photon energy.[13] Note that $a_t \sim a_{AI}$ when autoionization dominates ionization. As may be seen from Table 7, a comparison of the absorption coefficient and SDQY will be useful in determining whether or not autoionization occurs with a high probability.

A comparison of the SDQY and a_t in Figs. 11—15(b) and (c) shows that a good symbatic correspondence exists between them for perylene and coronene and a fairly good one for polyacenes. *p*-Terphenyl seems to be an exception to this. However, as may be seen in Fig. 16(a), the intensity ratio of the first and other peaks of EDC is very large for this compound. Therefore this can be interpreted as ionization from deeper levels overwhelming other changes.

As may be seen from Table 7, the comparison of a_t and Y strongly suggests that $a_tL \ll 1$ and that autoionization takes place with considerable efficience.

Table 7. Expected behavior of quantum yield $Y(h\nu)$

Scattering condition	Dominant mechanism of ionization		Expected behavior of $Y(h\nu)$ when a_t decreases
$a_tL \gg 1$	DI	$Y \sim A_1 \int \frac{a_{DI}}{a_t} dE$	increases
	AI	$Y \sim A_2 \int \frac{a_{AI}k}{a_t} dE$	nearly constant
$a_tL \ll 1$	DI	$Y \sim A_3 \int a_{DI} L\, dE$	gradully increases
	AI	$Y \sim A_4 \cdot a_{AI} kL$ $\sim A_4 \cdot a_t kL$	decreases

The occurence of autoionization has also been suggested by other workers.[30] A similar correspondence between Y and a_t was found for phthalocyanines[13] and several inorganic materials.[31] In the case of polyacenes, the photoemission from deeper levels may also affect the shape of SDQY.

Recently several measurements of L have been made for organic solids.[28] Hino *et al.*[28b,c] showed that $a_tL < 1$ is satisfied for naphthacene, pentacene, and coronene. This confirms the present suggestion. For perylene, however, they reported that $a_tL = 1.3$ ($L = 80$ nm) for electrons injected from CuI by the illumination of light with a photon energy of 7.75 eV. When this is the case, the mechanism described above is not very effective for perylene. On the other hand, the other cases in Table 7 cannot explain the minimum of Y for perylene. One possible explanation involves a combination of the change in a_t and an abrupt decrease in $L(E)$. Such an abrupt decrease in $L(E)$ could occur when the probability of exciton formation increases sharply above a certain energy value, but Zagrubskii and Vilesov[8c] discounted such a possibility. We will not discuss this point in detail because no direct experimental data are available about the E dependence of $L(E)$. Further studies will be necessary for perylene.

Another mechanism to explain the shape of SDQY was proposed by Zagrubskii and Vilesov.[8] Their explanation, however, seems to be dubious, as has been described in II.

(c) *Far-beyond Threshold Region*: The sharp rise in Y in this region corresponds either to the photoemission from a deeper level or to the onset of the large peak in EDC (HNMP). The latter is due to secondary electrons, as has been described in II.

The authors wish to thank Professor Yoshiyo Harada for his constant interest and many helpful discussions. They are also grateful to Mr. Kiyoo Tsuji and Mr. Tatsuo Takeda of their Institute for the preparation of the experimental apparatuses. Thanks are also due to Dr. Kiyokazu Fuke for the measurement of the reflection spectra and his helpful discussions, to Mr. Shojun Hino for his colaboration in the study of *p*-terphenyl, to Dr. J. N. A. Ridyard of Perkin-Elmer Ltd., for the measurement of the molecular photoelectron spectrum of *p*-terphenyl by means of a PS-18 photoelectron spectrometer, and to Professors Satoshi Iwashima and Masahiro Kotani and Dr. Kentaro Murano for the gift of samples. They also wish to thank Professors W. Schmidt and H. Venghaus and Dr. Nobuo Ueno for their communications of experimental results.

PAPENDIX. Remarks on Electron Scattering

In their discussion of the effect of secondary electrons, Schechtman[13] and Kochi *et al.*[5] assumed that pair-production is the main electronic-energy-loss processes of electrons. However, recent results on the energy loss of slow electrons[10,28,33] show that exciton excitation (including triplet excitons) makes a greater contribution to scattering than does pair-production, partic-

ularly at a small energy loss. However, from a comparison of the results of Merkel and Hamill[33] and that of Schechtman, it seems that the conclusion such as that (1) the scattering length $L(E)$ decreases monotonically with E, or that (2) secondary electrons tend to have only a small kinetic energy are also valid for the exciton-excitation process. Therefore, the conclusions described in the discussion should also be valid. The main change in going from pair-production to exciton excitation will be the change in the threshold for scattering: from $2E_g$ for pair-production to E_g+E_x for exciton excitation, where E_g is the band gap and where E_x is the energy of the lowest exciton.

It is somewhat difficult to determine the effective value of E_g for organic crystals. When energy loss occurs, the electron must fall into a lower conduction band. However, the lowest conduction band, at[2,26]

$$E_c' = 2E_{th} - I_g - A_g \quad (4)$$

(where E_{th} is the threshold of photoemission and where I_g and A_g are the ionization potential and the electron affinity of a free molecule), is very narrow, and there may be band gaps between the conduction bands. Therefore, electrons cannot fall into this gap. There seems to be no definite experimental information about the threshold above which an electron with any given energy can undergo inelastic scattering. However, considering the breadth of the exciton bands and the fact that the intermolecular interaction increases with the electron energy, we may use the energy of the bottom of the 'broad conduction band', E_c, evaluated by[2,26]

$$E_c = 2E_{th} - I_g \quad (5)$$

as a guide for the energy of the effective bottom of the continuous band, E_g. The quantities mentioned above are shown in Table 8 for both the lowest triplet and singlet excitons. The results shown in Table 8 demonstrate that almost all the electrons above the threshold can suffer inelastic scattering if triplet excitons are excited. However, no detailed information on the E dependence of $L(E)$ is available at present.

There are other mechanisms of energy loss in organic solids: the excitation and absorption of the phonon and intramolecular vibration, and the excitation of plasmon. The former two do not affect the quantum yield so much, and so we will not discuss them in detail. Plasmon was considered in the discussion of HNMP.

The Microwave Spectrum of Thiirane in Excited Vibrational States

Chiaki HIROSE, Kazuhiro OKIYE, and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received October 13, 1975)

The microwave spectra in the ground and five low-lying vibrational states of $^{12}C_2H_4{}^{32}S$ and in the ground state of $^{12}C^{13}CH_4{}^{32}S$ and $^{12}C_2H_4{}^{34}S$ have been assigned to high-J transitions. The rotational and centrifugal distortion constants were derived. Four of the five vibrational states were found to be in Coriolis interaction in pairs; one of the pairs was identified as the symmetric and antisymmetric ring deformation modes, $\nu_5(A_1)$ and $\nu_{12}(B_1)$, but another pair was unexplicable from any of the previously reported vibrational assignments. The infrared and Raman spectra in the liquid and gas phases were examined, and the latter pair of vibrations was interpreted as $\nu_{14}(B_2)$ at 945 cm^{-1} and $\nu_8(A_2)$ at about 970 cm^{-1}. This novel assignment of ν_8 around 970 cm^{-1} was based on not only the results of microwave spectroscopy, but also on the observation of an unsymmetric band contour in the infrared spectrum of the gaseous sample.

The vibrational spectrum of thiirane has been studied by several authors;[1-7] Thompson and Dupré[1], who reported in 1940 their observation of the infrared spectrum in the gas phase and the Raman spectrum of the liquid state, proposed a molecular symmetry of C_{2v}, along with an assignment of the vibrational modes. The study by Thompson and Cave[2] revised the assignment on the grounds that the band at 711 cm^{-1} which had been assigned to ν_{12} (ring deformation) in the previous paper was due to the impurity hydrogen cyanide, and that the polarization data from the Raman spectrum also reported in the previous paper were questionable because of the background haze introduced by the formation of a solid polymer during the measurement. Guthrie *et al.*[3] reported the observation of the infrared spectra of the liquid thiirane and of the solid polymer which was deposited on the window of the cell, in addition to the calculation of thermodynamic quantities; they proposed an assignment which was different from the previous ones in the ordering of three pairs of modes. Brumant observed the Raman spectrum of liquid thiirane and the infrared spectrum of the solid polymer,[4a] the Raman spectrum of the solid at 85 K,[4b] and the infrared spectrum of the molecule in an argon matrix at 10 K.[4c] The assignment given by Brumant[4a] puts ν_7 and ν_8, which are of an infrared-inactive A_2 symmetry, at 1172 cm^{-1} and 900 cm^{-1} respectively. Venkatesuwarlu and Joseph calculated the force constants and mean-square amplitude of vibrations,[5] and also the Coriolis coupling constants[6] of ethylene oxide and thiirane on the basis of yet another assignment, one differing from those of the previous reports. A recent study by Hirokawa *et al.*[7] of the infrared spectrum and the force field of ethylene oxide and thiirane deduced essentially the same assignment as that given by Thompson and Cave, except for the vibrations of A_2 symmetry. The assignments given thus far are compared in Table 1; it can be easily seen that the assignments are not conclusive for the ν_7 and ν_8 modes, as has been pointed out by Hirokawa *et al.* In most of the above studies, the assignment of ethylene oxide is referred to; one of them also refers to the assignment of aziridine.

The observation of the microwave spectrum in excited vibrational states is known to provide complementary information on the vibrational assignment. A recent study of the microwave spectrum of ethylene oxide,[8] for instance, cast doubt on the previous assignments which place the ν_8 mode (CH_2 twisting of A_2 symmetry) at about 800 cm^{-1}, because it identified but one vibrational state of symmetric (with respect to C_2 operation) species around 800 cm^{-1} which was assigned to the ν_5 mode (ring deformation of A_1 symmetry) on the basis of the analysis of vibration-rotation interaction. The study concluded that the lowest possible state of A_2 symmetry, ν_8, of ethylene oxide is at about 1000 cm^{-1}.

a) 1; Ref. 2, 2; Ref. 3, 3; Ref. 4, 4; Ref. 5, 5; Ref. 7.

This paper will report on the microwave spectrum in the ground and five vibrational states of thiirane. The symmetry properties with respect to the C_2 operation of the respective vibrations were determined from the measurement of the relative intensities, and the effect of Coriolis interaction was observed as a vibrational dependence of the centrifugal distortion. The infrared spectrum of the gas phase and the Raman spectra of the liquid and gas phases were also studied, and the existence of strong interactions among sets of vibrational modes was indicated by the peculiar band shape and/or polarization-depolarization character of the Raman bands. The results of the infrared and Raman spectra will be excerpted to help in the analysis of the microwave spectrum.

Experimental and Results

The sample of thiirane was a distilled fraction of the product of the reaction of ethylene carbonate with potassium thiocyanate;[9] the sample container was wrapped with aluminum foil to inhibit the photochemical decomposition. White particles precipitated slowly during storage, and the presence of ethylene was observed in the infrared spectrum of the gas when sampled without purification. The impurities were removed by evacuating a liquid sample cooled by dry ice and by a subsequent trap-to-trap transfer of the liquid. The NMR spectrum of the distilled liquid showed peaks above 6 ppm with intensities less than 0.1% of the main peak at 3 ppm; the impurities did not show up in the infrared spectrum of a gaseous sample from the outgassed liquid. The infrared spectrum of the gas showed little difference before and after letting the sample container stand for 40 hours and then placing it under sunlight for two hours. No solid deposit was observed on the KBr windows of the cell despite the previous reference to the phenomenon,[3] and all the lines disappeared when the cell was evacuated. It should be mentioned, though, that the intensity of the microwave absorption lines diminished slowly to about half their original height in a couple of hours, without any new line developing; this indicates that the decomposition of the gas is accelerated on a metal (copper and stainless steel in the present case) surfaces, along with a production of a nonpolar gaseous material.

Microwave Spectrum. The microwave spectrum was observed using a conventional Stark modulation spectrometer. The measurement was performed at room temperature of about 293 K. The assignment of the rotational transitions for $^{12}C_2H_4{}^{32}S$, $^{12}C^{13}CH_4{}^{32}S$, and $^{12}C_2H_4{}^{34}S$ from the previous reports[10,11] was extended to transitions with higher J numbers and, for $^{12}C_2H_4{}^{32}S$, to forbidden transitions. The transitions in five excited vibrational states were also assigned on the basis of the Stark effects, the relative intensities, and the spectral pattern. The five states are tentatively designated as ν_a, ν_b, ν_c, ν_d, and ν_e. The results were analyzed by a least-squares method which included centrifugal distortion to the first order. Table 2* lists the observed frequencies of the assigned transitions, along with their differences from the calculated values. The converged values of the parameters are given in Table 3, along with their reliability intervals of 2.5 times the variances. A preliminary analysis indicated that the higher-order effect of centrifugal distortion becomes significant for the transitions with J numbers exceeding 30. Because the transitions with high J numbers are of the Q branch,[12] the inclusion of higher-order effects from centrifugal distortion is not expected to result in any meaningful values to the newly included parameters. Therefore, the higher-order effects in the least-squares fit, which included centrifugal distortion to the first order, were made insignificant by appropriately weighting the larger J transitions; weighting 1 for transitions with the J values less than 20, 0.01 for the J values from 21 to 30, 0.0001 for the J values between 31 and 50, and 0.000001 for the J values of more than 51, with the exception of the forbidden transitions of the ground state of $^{12}C_2H_4{}^{32}S$, for which the intensity of each transition was taken into account.

The measurement of the spectral intensities was only semi-quantitative because of the wide spread of the transition frequencies by vibrational state, and the instrumental instability.** Nonetheless, it was possible to derive the symmetry properties of the vibrations, along with a rough estimate of the vibrational frequencies, from the measured intensities shown in Table 4. A number of lines were left unassigned, but, judging from their intensities, these lines were from vibrational states higher than those for which rotational transitions were identified. The unassigned lines included some of the $J=1\leftarrow0$ and $J=2\leftarrow1$ transitions of ^{33}S species which have been assigned by Shoemaker and Flygare.[13]

The presence of Coriolis interactions between ν_a and ν_b and between ν_c and ν_e is suggested by the large values of the vibration-rotation constants, $\alpha_v^{(c)}$'s, which exceed 1% of the rotational constant, C_0, of the ground state. This becomes evident when one compares the vibrational change in the corrections for the centrifugal distortion (Fig. 1). The assignment of the two lowest vibrational states, ν_a and ν_b, to the symmetric and antisymmetric ring deformations, ν_5 and ν_{12}, is rather straightforward. The calculation by Venkatesuwarlu and Joseph gives $\zeta_{5,12}^{(c)}=-0.882$, indicating that the Coriolis interaction between the two states should indeed be appreciable about the c-axis. The Coriolis terms in the $\alpha_5^{(c)}$ and $\alpha_{12}^{(c)}$ constants through $\zeta_{5,12}^{(c)}$ are calculated to be +279 MHz and −236 MHz respectively by taking the vibrational frequencies of $\nu_5=624\ cm^{-1}$ and $\nu_{12}=660\ cm^{-1}$. The above terms are dominant in the harmonic terms in $\alpha_5^{(c)}$ and $\alpha_{12}^{(c)}$, as the contributions from other Coriolis terms are

* Table 2 is deposited as Document No. 7612 at the office of the Editor of the Bulletin of the Chemical Society of Japan. Available from the authors on request.

** The transitions used for the measurement of the relative intensities were $1_{0,1}\leftarrow0_{0,0}$, $2_{0,2}\leftarrow1_{0,1}$, $5_{2,3}\leftarrow5_{2,4}$, $7_{2,5}\leftarrow7_{2,6}$, $2_{1,1}\leftarrow1_{1,0}$, $2_{1,2}\leftarrow1_{1,1}$, $3_{1,2}\leftarrow3_{1,3}$, $8_{3,5}\leftarrow8_{3,6}$, and $9_{3,6}\leftarrow9_{3,7}$. The spectral lines of the ^{34}S species, which has the abundance ratio of 4.22% were used as the internal standard instead of those of the normal species in order to avoid the possible saturation of lines and instrumental nonlinearity. A variable attenuator was inserted between the preamplifier and the main amplifier; the depth of attenuation was varied until the spectral line was of the same intensity as the corresponding transition of the ^{34}S species. Although the error in each measurement was from 0.5 to 1 dB, the overall error was estimated to be 2 dB because of the instrumental instability and the possible reflection of microwave power inside the cell. The latter may cause serious error with regard to the transitions of the ν_c, ν_d, and ν_e states since the rotational transitions in these states are widely separated from the corresponding lines of the ^{34}S species (see Table 2). Thus, it is quite possible that ν_d and ν_e are at 824 cm^{-1} and 945 cm^{-1} respectively, as will be estimated in the later part of this paper, despite the result derived from the measurement of the relative intensities of the rotational transitions.

Table 3. Derived rotational, vibration-rotation,

Species[b]	A (α_v^A)[c]	B (α_v^B)[c]	C (α_v^C)[c]	τ_{aaaa}

a) τ_{aacc} was assumed to be zero in the least-squares fit. 2.5 times variances are listed as reliability intervals. state, and ν_a to ν_e: vibrational states of $^{12}C_2H_4{}^{32}S$ with their symmetry properties with respect to C_2 being indi- vibrational states.

Table 4. Symmetry and estimated frequencies of vibrations as derived from the relative intensity measurement

State	Symmetry[a]	(cm^{-1})[b]	Proposed assignment[c]
ν_a	A_1 or A_2	680 (580—890)	ν_5(624 cm^{-1})
ν_b	B_1 or B_2	710 (640—810)	ν_{12}(660 cm^{-1})
ν_c	A_1 or A_2	920[c] (850—1050)	ν_7 or ν_8(970 cm^{-1})
ν_d	B_1 or B_2	950 (860—1120)	ν_{15}(824 cm^{-1})
ν_e	B_1 or B_2	800 (700—1020)	ν_{14}(945 cm^{-1})

a) Symmetry properties with respect to the C_{2v} group are indicated. b) Statistical error limits of 2.5 times variances in the relative intensity measurement are transformed and shown in parentheses to indicate the reliability intervals of the derived frequencies. c) Values in parentheses are those reported in Ref. 7 except for that of ν_c which is estimated from the analysis of Coriolis coupling between ν_c and ν_e and the band contour of infrared spectrum of the gas sample in the present study.

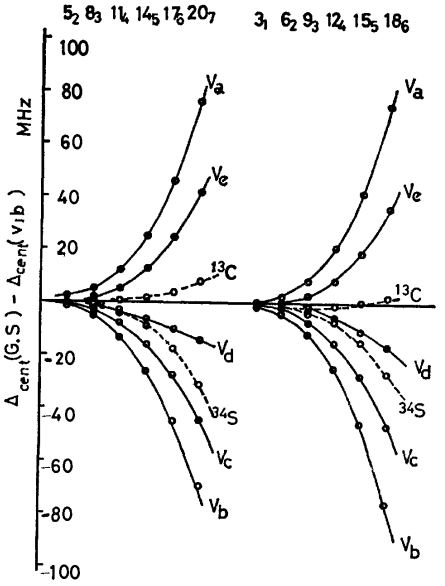

Fig. 1. Vibrational change in the corrections for the centrifugal distortion, $\Delta_{cent}(G.S.)-\Delta_{cent}(v_i)$, and the isotope change are plotted.
Solid and broken lines are drawn to identify the species.

estimated to be within a few megahertz. They are proportional to the inverse of the vibrational difference, $\nu_5-\nu_{12}$, to a good approximation. The observed values are 143.81 MHz and −54.57 MHz for $\alpha_5^{(c)}$ and $\alpha_{12}^{(c)}$ respectively; the rather large difference between the observed and the calculated values indicates that the ν_{12}-ν_5 separation is larger than 26 cm^{-1}, although the value is derived from the most recent assignment.[7] At the same time, the anharmonic terms in the α constants are expected to be of the order of 10 MHz, because when one fits the Coriolis terms in $\alpha_5^{(c)}$ to 140 MHz by putting $\nu_{12}-\nu_5$ to 52 cm^{-1}, there remains a difference of about 60 MHz between the Coriolis term and the observed value of $\alpha_{12}^{(c)}$. A similar situation was encountered in the α constants of ethylene oxide.[8]

The large departure of the centrifugal distortions of the ν_a and ν_b states, each in opposite directions from the ground state seen in Fig. 1, also distinctly shows the presence of the Coriolis interaction. The large uncertainties that accompany the converged values of the centrifugal distortion constants except for those of the ground vibrational state of normal species unfortunately restricted the analysis of the effect and made it semiquantitative.

The almost identical behavior of the pair of ν_c and ν_e to that of ν_b and ν_a in both the $\alpha^{(c)}$ constants and centrifugal-distortion effects strongly suggests another c-type Coriolis interaction between ν_c and ν_e states, with the vibrational frequency ν_c being slightly more than the ν_e. The study of the infrared and Raman spectra which will be outlined in the next section shows that the second lowest antisymmetric vibration is ν_{15} at 824 cm^{-1}; this band is assigned to the CH_2 twisting mode. Other possible candidates for ν_d and ν_c, which are antisymmetric vibrations, are ν_{14} (CH_2 rocking mode) at 945 cm^{-1} and ν_{11} (CH_2 bending mode) at 1050 cm^{-1}. Our results show that ν_c is the second lowest vibration of A symmetry, that is either $\nu_4(A_1)$ or $\nu_8(A_2)$, and we have already mentioned that no conclusive assignment has been given to the ν_7 and ν_8 modes by the study of the vibrational spectra. The values which determine the Coriolis coupling are listed in Table 5, the coupling constants used in the table being excerpted from the paper by Venkatesuwarlu and Joseph.[6] Although the values may change when

a) As for the types of vibrations, see set 4 of Table 1. Contributions of Coriolis terms to $\alpha_v^{(x)}$ and the centrifugal distortion constants are expressed as;

$\Delta\alpha^{(x)}_{v,v'}(\text{Coriolis}) = -8c/\nu_v \cdot \nu_{v'}^2/(\nu_v^2 - \nu_{v'}^2) \cdot (X\zeta^{(x)}_{v,v'})^2$

$\Delta\tau^{v,v'}_{xxxx}(\text{Coriolis}) = c'(\nu_v + \nu_{v'})^4 (X\zeta^{(x)}_{v,v'})^4/(\nu_v - \nu_{v'})^3 \nu_v^2 \nu_{v'}^2$,

where $\Delta\alpha^{(x)}_{v,v'}$ and $\Delta\tau^{v,v'}_{xxxx}$ are the contribution to the vibration-rotation constant $\alpha_v^{(x)}$ and the centrifugal distortion constant τ_{xxxx} in the v-state, respectively, ν_v and $\nu_{v'}$ are the vibrational frequencies of ν_v and $\nu_{v'}$ modes, c and c′ are the constants to give proper units to the quantities, and X is the rotational constant A_0, B_0, or C_0 depending on the principal axis of inertia denoted by x.

other vibrational assignments are used, the changes are expected to be small, as is the case in ethylene oxide. Table 5 indicates that the two pairs, ν_7 and ν_{15}, and ν_8 and ν_{14}, are capable of similar interaction, and thus likely candidates for the ν_c and ν_e pair. The infrared spectrum of the gaseous sample shows a band contour at 945 cm^{-1} (ν_{14}) unsymmetric about the sharp Q-branch peak. The perturbation through Coriolis interaction between ν_{14} and ν_8 modes is a plausible explanation for the peculiar band shape; the assignment of ν_c and ν_e to ν_8 and ν_{14} respectively is then more likely than the other sets. The remaining state, ν_d, can then be assigned to ν_{15} at 825 cm^{-1}. Thus the present study of the microwave spectrum suggests the assignment of ν_8 at 970±5 cm^{-1}.

Infrared and Raman Spectra. The vibrational spectrum of thiirane was reexamined; the infrared spectrum in the gas phase was observed from 400 cm^{-1} to 10000 cm^{-1} using a Perkin-Elmer 125 spectrograph, while the Raman spectrum was recorded on a JEOL model JRS-SI spectrometer in both gas and liquid phases by using a 488-nm line of the Ar$^+$ laser (Coherent Radiation CR-52G) as the exciting source. The sample was outgassed prior to each measurement to get rid of the ethylene impurity produced by decomposition. The cell used for the infrared spectrum was a 10-cm-long Pyrex tube with KBr windows. The liquid sample for the Raman spectrum was distilled and sealed in a conventional cell made of a Pyrex tube of about 8 mm i. d., while the Raman spectrum of the gas was recorded at a pressure of 148 Torr using a multipass configuration of about 30 beams.

A summary of the Raman spectrum is given in Table 6, with the previous observation by Brumant in the liquid phase being given for reference. The infrared spectrum of gaseous thiirane from 800 to 1180 cm^{-1} is shown in Fig. 2. Corresponding to a weak Q-branch peak observed in the infrared spectrum, the Raman spectrum of the liquid sample showed a depolarized band at 825 cm^{-1}, leading us to the assignment of this band to the lowest mode of B_2 symmetry, ν_{15}. The polarized Raman band at 1607 cm^{-1} can then be readily assigned to the overtone, $2\nu_{15}$. A very weak band was observed in the Raman spectrum of the liquid sample; it was also reported by Brumant[4b)] at 895 cm^{-1}. The observation of this band in the infrared spectrum too was reported by Hirokawa *et*

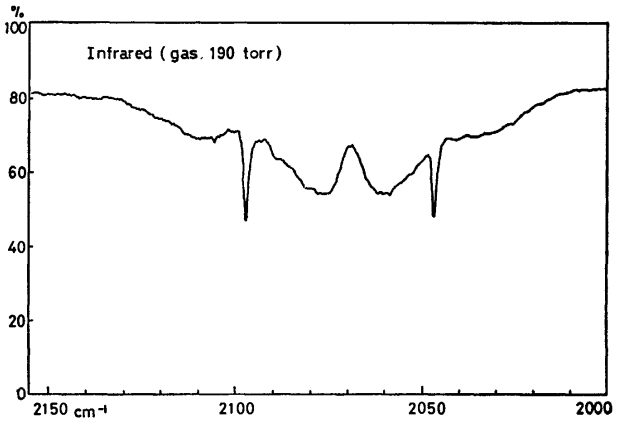

Fig. 3. Infrared spectrum of thiirane in the overtone region of 2000—2150 cm^{-1}.
A B-type band center is situated between the A-type Q-branches of overtones.

al.,[7] who assigned it to the infrared-inactive ν_7 mode, but the present study failed to detect it (see Fig. 2). Since all of the infrared-active fundamentals are found at other frequencies, the band at 895 cm^{-1} has to be interpreted either as an infrared-inactive ν_7 or ν_8 or as due to some impurity. There is no infrared band near 895 cm^{-1} which can give some intensity to an infrared-inactive mode through Coriolis interaction; thus, the assignment of ν_7 or ν_8 at 895 cm^{-1} can be ruled out if the observation by Hirokawa *et al.* is to be retained.

Four vibrational modes have been assigned in the region from 900 to 1200 cm^{-1}; two CH_2 bending modes, $\nu_3(A_1)$ at 1109 cm^{-1} and $\nu_{11}(B_1)$ at 1050 cm^{-1}, a ring breathing, $\nu_4(A_1)$ at 1024 cm^{-1}, and a CH_2 rocking mode, $\nu_{14}(B_2)$ at 945 cm^{-1}.[7] The Raman spectrum of the liquid gave one depolarized band at 947 cm^{-1} and two polarized bands at 1023 and 1113 cm^{-1}. The two polarized bands were also observed in the Raman spectrum of the gas phase. A polarized band was observed at the overtone region of 2230 cm^{-1} in the liquid phase. Although the infrared spectrum of this region is quite complicated, as may be seen from Fig. 2, the assignment of the bands is rather straightforward: $\nu_{14}(B_2)=945$ cm^{-1}, $\nu_4(A_1)=1024$ cm^{-1}, $\nu_{10}(B_1)=1050$ cm^{-1}, and $\nu_3(A_1)=1109$ cm^{-1}, when one takes the Raman results into account. The assignment of lines at 1024 and 1050 cm^{-1} is further confirmed by the appearance of two A-type bands and a B-type band center in between them in the overtone region of the infrared spectrum, as is shown in Fig. 3.

The infrared spectrum shows an anomalous shoulder on the R-branch side of ν_{14} at 945 cm^{-1}. The pressure dependence of the shoulder indicates that it originates from the sample itself. As vibrational modes of A_1, B_1, and B_2 symmetry species are identified at other frequencies, as has been mentioned before, the shoulder can be explained as resulting from the intensity borrowing of an A_2 mode through the Coriolis interaction with ν_{14}. Judging from the values of the Coriolis coupling terms listed in Table 5, the assignment of the symmetric CH_2 twisting at about 970 cm^{-1} is probably the most reasonable. Finally, the weak band observed at 1172 cm^{-1} in the infrared spectrum was explained by Hirokawa *et al.* as due to a polymer,[7] but the pressure dependence of the band (see Fig. 2) seems to indicate that the band is from the sample itself. The explanation is open to speculation at the moment, but it should be remembered that weak and polarized Raman bands were observed at 1230 and 1377 cm^{-1} which can best be explained as the $2\nu_5$ and $2\nu_{12}$ overtones respectively.

Conclusion

Of the five vibrational states for which the rotational spectrum has been identified, the lowest two states, ν_a and ν_b, are in resonance through a Coriolis term; they were assigned to ν_5 and ν_{12} (symmetric and antisymmetric ring deformation modes). Another coupling between the ν_c and ν_e, as observed in the microwave spectrum, indicates the assignment of ν_c to ν_8 (CH_2 twisting) of A_2 symmetry and ν_e to ν_{14} (CH_2 rocking) at about 970 cm^{-1} and 945 cm^{-1} respectively. The fact that ν_c is slightly more than ν_e and that the ν_4 and ν_{11} states are free from Coriolis interactions, as seen by the infrared spectrum in the overtone region (Fig. 3), excludes the assignment of ν_c and ν_e to ν_8 at 970 cm^{-1} and ν_{15} at 824 cm^{-1} or to ν_4 at 1024 cm^{-1} and ν_{11} at 1050 cm^{-1}, respectively. The complicated-looking band contour observed in the infrared spectrum around 950 cm^{-1} supports the present assignment. The remaining state, ν_d, which is antisymmetric to the C_2 operation, is assigned to ν_{15} (CH_2 twising) at 824 cm^{-1}, the lowest vibration of B_2 symmetry and the second lowest of the antisymmetric modes. The very weak Raman band at 895 cm^{-1}, which Hirokawa *et al.* claim to have observed also in the infrared spectrum of the gas phase, may be the remaining mode of A_2 symmetry, although its appearance in the infrared spectrum would present a serious contradiction to this assignment since there is no neighboring band which

can couple with and give away a part of its infrared intensity to the infrared-inactive ν_8 mode. Thus, the band at 895 cm^{-1} may well be due to an impurity. In any event, there is little chance for the ν_8 mode to be around the previously estimated 800 cm^{-1}. This conclusion is in accord with that obtained for ethylene oxide.[8)]

The present study revealed the existence of couplings among several sets of vibrations and suggests the need of further investigations to establish the vibrational assignment of thiirane.

The authors are grateful to Professor Yonezo Morino, Dr. Shuji Saito, and Dr. Charles D. LeCroix for their critical reading of the manuscript.

Electronic Structure and Spectra of Acrylic Acid in the Vapor and Condensed Phases

Hiroshi MORITA, Kiyokazu FUKE, and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received October 27, 1975)

Near and vacuum UV absorption spectra of acrylic acid were measured at room temperature in the vapor phase and at 77 K in the condensed phase. From a comparative study of the observed spectra, a Rydberg excitation band was observed at 7.46 eV in addition to valence-shell transition bands. The estimated value of the quantum defect ($\delta=1.01$) indicates that the Rydberg orbital is 3s. A new modified CNDO-CI method applicable to planar molecules was developed and applied to acrylic acid to investigate the valence-shell transitions, the observed bands at ~5.0 and 6.71 eV being assigned to the transitions to the n-π^* and π-π^*, respectively.

Electronic absorption spectra of carboxylic acids have been studied extensively[1-3] in comparison with those of amides, acyl fluorides, and carbonyls. Concerning acetic acid, Barnes and Simpson[1] assigned the bands at 48000, 58000, 63000, and 68000 cm^{-1} to the transitions to n-π^*, n'-π^*, n-σ^*, and π-π^* states, respectively. On the other hand, from a comparison of the spectrum in the vapor phase with that in the condensed phase and also from the calculation of the electronic structure, Basch, Robin, and Kuebler[3] assigned the bands of trifluoroacetic acid observed near 48000, 62000, 68000, and 77000 cm^{-1} to the transitions to n-π^*, n-3s Rydberg, π-π^*, and n-3p Rydberg states, respectively, emphasizing the existence of Rydberg excitation bands in the vacuum ultraviolet (VUV) region.

Acrylic acid has the vinyl group conjugating with the carboxyl group. The conjugation may be expected to have some effect on both the valence-shell transition bands and the Rydberg excitation bands. According to our knowledge, the absorption spectrum of acrylic acid has scarcely been studied.[4] This is because analysis of the result may be complicated by the existence of the *s-cis-* and *s-trans*-isomers in the vapor phase at room temperature,[5] the formation of the dimer at higher pressure,[6] and the occurrence of thermal and photochemical reactions.[7]

In the present study, we have measured the near and vacuum UV absorption spectra of acrylic acid in the vapor and condensed phases, for the purpose of identifying the Rydberg excitation bands in addition to the valence-shell transition bands. Furthermore, to understand the electronic structure of acrylic acid, we have calculated the electronic structures of the *s-cis-* and *s-trans*-acrylic acids in monomeric form and also of the dimer by a new modified CNDO-CI method suitable for interpretation of electronic structures of planar molecules, σ- and π-orbitals being treated independently in estimating semi-empirical core resonance, Coulomb repulsion, and core potential integrals.

Experimental

Acrylic acid (Wako G. R. grade) was purified by vacuum distillation through a column filled with silica gel and diphosphorus pentaoxide immediately before use. Cyclohexane (Wako Spectro grade) was used without further purification.

Absorption spectra of the cyclohexane solution of acrylic acid were measured at room temperature with a Cary recording spectrophotometer model 14. Vapor-phase absorption spectra of acrylic acid at various pressures were measured at room temperature with a JASCO VUV-3 recording spectrophotometer,[8] a 10 cm cell being used. The vapor pressure of the sample was regulated with a cryogenic bath at various temperatures.

Near and vacuum UV absorption spectra in a condensed phase were measured at 77 K with a spectrophotometer constructed in our laboratory.[9] A thin film of pure acrylic acid was prepared by spraying the vapor onto a refrigerated CaF_2 window on a Dewar flask through a gas-inlet nozzle.

Theoretical

The modified CNDO-CI method (see Appendix) was applied to acrylic acid to investigate the valence-shell transitions. Since the monomeric *s-cis-* and *s-trans*-isomers and dimeric species of acrylic acid co-exist in the vapor phase,[5,6] calculations for all the species were performed by the use of the semi-empirical parameters listed in Table 1.

The geometry and molecular parameters for the monomeric and dimeric species were taken from the electron diffraction study by Ukaji.[10] The O–H bond length was assumed to be 0.96 and 1.00 Å for the monomer and dimer, respectively.

Results and Discussion

The absorption spectra measured with gaseous acrylic acid at various vapor pressures in the 43000—

The concentrations of acrylic acid are a, 8.9×10^{-4} M; b, 1.1×10^{-2} M; c, 2.7×10^{-2} M; d, 2.6×10^{-1} M; e, 2.3×10^{-6} M; f, 4.6×10^{-5} M; g 3.0×10^{-4} M.

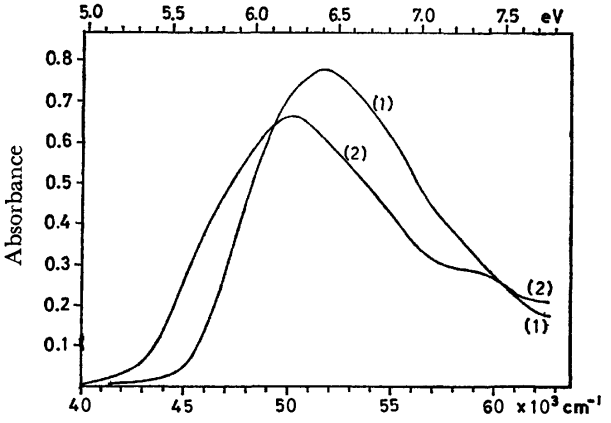

Fig. 2. Near and vacuum UV absorption spectrum observed at 77 K with a thin film of acrylic acid prepared (1) quickly (within one minute) and (2) slowly (for ten minutes).

63000 cm^{-1} region are shown in Fig. 1. This figure also shows the spectra measured for the cyclohexane solution with various concentrations of acrylic acid in the 35000—43000 cm^{-1} region. Spectral curves a and e in Fig. 1 are mainly due to the monomeric species, and curves d and g to the dimeric one. Since the *s-cis*- and *s-trans*-isomers of acrylic acid co-exist comparably,[5] we could only observe the spectrum for the mixture of both isomers. Table 2 gives transition energies and oscillator strengths calculated by the modified CNDO-CI method for the *s-cis*- and *s-trans*-isomers of acrylic acid.

From a comparison of the observed and theoretical values of the band intensity and position, the weak band near 40000 cm^{-1} (~5.0 eV) observed with the cyclohexane solution is safely ascribed to the first n-π^* transition. According to the concentration dependence of acrylic acid on the first n-π^* band (Fig. 1), the band shifts to higher frequencies by about 1000 cm^{-1} (0.12 eV) for the dimer. The result agrees well with the theoretical prediction (higher frequency shift of 0.13—0.14 eV by the dimer formation).

Let us turn to the VUV bands observed with acrylic acid. As is seen in curve e (Fig. 1), two absorption peaks appear at 54100 cm^{-1} (6.71 eV) and at 60200 cm^{-1} (7.46 eV) in the VUV absorption spectrum of gaseous acrylic acid. The band at 7.46 eV is very sensitive to the pressure of acrylic acid and decreases its intensity to a great extent with increasing pressure. This indicates that the upper state of the band is of the "big-orbit" nature. In order to check this point, we measured the VUV absorption spectrum in the condensed phase at 77 K. Actual measurements were made with thin films prepared by spraying gaseous acrylic acid on a cooled CaF_2 plate in a vacuum vessel; the result is shown in Fig. 2. Spectrum 1 was obtained for the sample prepared quickly (within one minute) and may conceivably correspond to that of anomalous solid; spectrum 2 was obtained for the sample prepared slowly (about ten minutes) and may correspond to that of the dimeric species in microcrystal. We can see that the 7.46 eV band observed with gaseous acrylic acid disappears almost completely in the condensed phase. This shows that the band is due to the transition to the upper state of "big-orbit" nature and can safely be assigned to the Rydberg transition.

The Rydberg excitation energy is expected to fit the following formula[3,11]

$$h\nu = I_p - (109737/(n-\delta)^2)$$

where $h\nu$ is the excitation energy (cm^{-1}), I_p is the ionization potential (cm^{-1}), and δ is the quantum defect which results from the penetration of Rydberg orbital into the core. By applying the equation to the observed band at 7.46 eV of acrylic acid, δ was determined to be 1.01, corresponding to $n=3$. This strongly suggests that the band is due to the transition to the 3s Rydberg orbital[11] as the first Rydberg band of CF_3COOH.[3]

The strong band at 6.71 eV in curve e (Fig. 1) is much less sensitive to the pressure of acrylic acid compared with that at 7.46 eV, although it shifts to lower frequencies with increasing pressure (by about 1600 cm^{-1} (0.20 eV)), and appears even in the condensed phase as strongly as in the vapor phase. Therefore, the band is interpreted to be a valence-shell transition band. From a comparison of the observed band position and intensity with the theoretical values given in Table 2, the 6.71 eV band can safely be assigned to the first π-π^* transition.

The spectrum of acrylic acid in the condensed phase (curve 2, Fig. 2) has a peak at 59500 cm^{-1} (7.38 eV). This may correspond to a band at 61800 cm^{-1} (7.66 eV) in the vapor-phase spectrum (curve g, Fig. 1). We interpret that the 7.66 eV band is different from the Rydberg transition band at 7.46 eV; the former is covered by the latter in the spectrum of low vapor pressure (curve e, Fig. 1). From the theoretical results (Table 2), the band at 7.66 eV in the vapor phase may tentatively be assigned to the transition to the second π-π^* state. Curves f and g (Fig. 1) show another weak band appearing as a shoulder at 57500 cm^{-1} (7.13 eV). This band may tentatively be as-

signed to the weak σ-π^* or n-π^* transition.

Next, let us examine the nature of the valence-shell transition bands in detail. Figure 3 shows low-lying electron configurations (with in-plane transition moments) caused by valence-shell excitations and the energy levels of *s-trans*-acrylic acid evaluated by considering the configuration interaction. In this figure, *i-j* represents a singly excited configuration caused by the one-electron excitation from the *i*-th occupied orbital to the *j*-th vacant orbital. The shapes of orbitals 10 to 17 are also shown in Fig. 4. As is shown in Fig. 3, the 13-15 configuration of *s-trans*-acrylic acid contributes predominantly (87.8%) to the first allowed π-π^* state, and the 12-15 and 13-16 configurations contribute mainly (60.0% and 18.1%, respectively) to the second π-π^* state. From the shapes of orbitals 12, 13, 15, and 16 (Fig. 4), it is seen that the 6.71 eV band (*i.e.*, the first π-π^* band) is due to the π-π^* excitation within the vinyl group of acrylic

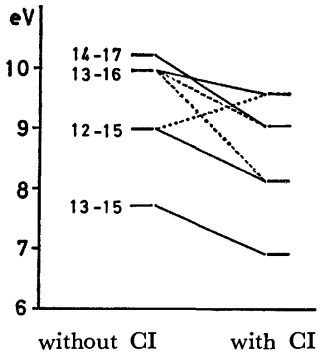

Fig. 3. Energy levels calculated with and without CI treatment for some lower π-π^* and n-σ^* excited states of *s-trans*-acrylic acid.

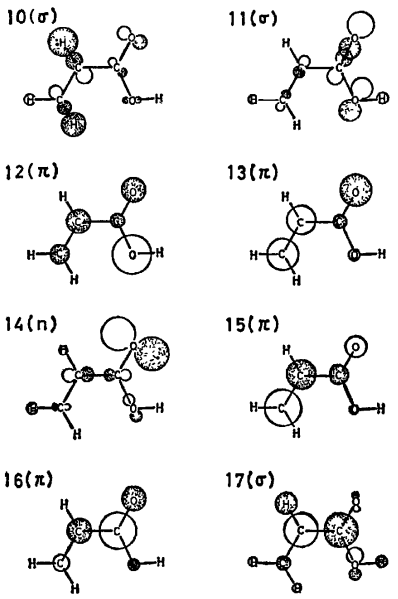

Fig. 4. Schematic shapes of some occupied and vacant MO's of *s-trans*-acrylic acid.

acid, and that the 7.66 eV band (*i.e.*, the second π-π^* band) is due to the intramolecular charge-transfer (from the carboxyl group to the vinyl group) excitation. The nature of the π-π^* transitions is different from that of formic or acetic acid.[2,3] The main configurations of other transitions are also listed in Table 2, and the characters of the transitions can easily be seen from the shapes of orbitals in Fig. 4. Essentially the same conclusion can be derived from the energy levels and wave functions calculated for *s-cis*-acrylic acid and for the dimer.

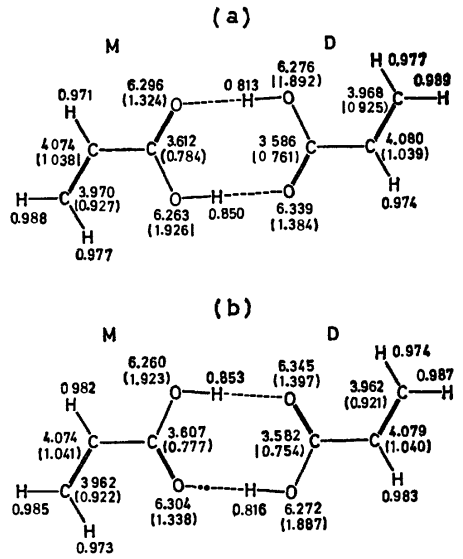

Fig. 5. The total and π- (in parentheses) electron densities calculated for monomeric and dimeric species of (a) *s-trans*-acrylic acid, and (b) *s-cis*-acrylic acid. The electron densities of the monomer and dimer are shown on the left-hand-side and right-hand-side molecules of the dimer, respectively.

Figure 5 shows electron densities for the ground states of monomeric and dimeric species of *s-cis*- and *s-trans*-acrylic acids. The dipole moment in the ground state was calculated to be 1.35 and 0.88 D for *s-trans*- and *s-cis*-acrylic acids, respectively.

The authors are greatly indebted to Dr. Akira Kuboyama, National Chemical Laboratory for Industry, for his kindness in putting a JASCO VUV-3 recording spectrophotometer at their disposal.

Appendix

Modified CNDO-CI Method Applicable to Planar Molecules. The original CNDO method by Pople, Santry, and Segal[12,13] and CNDO/S method by Bene and Jaffé[14] combined with configuration-interaction (CI) were modified to calculate the electronic structures of planar molecules.

a) Conditions for Transformation Invariance: Our guiding principle is to distinguish the σ- and π-electrons from each other in evaluating semi-empirically some kinds of integrals. Our consideration is restricted to only planar molecules. Let us fix the x-y plane as the molecular plane, and define the 2pz atomic orbital (AO) (designated as z_A) as π-orbital on atom A, π_A. Suppose that one of such operations within the molecular (x-y) plane as rotations about local axes and hybridization is designated by an orthogonal transformation matrix, **O**. In order to preserve invariance under these operations based on the assumption of zero differential overlap (ZDO) employed in the present procedure, the CNDO SCF procedure should satisfy the following transformation conditions between original atomic orbital basis functions, $\boldsymbol{\chi}$ and new ones, $\mathbf{t}(=\mathbf{O}\boldsymbol{\chi})$, concerning core Hamiltonian matrix elements (H_{mn}) and Coulomb repulsion integrals ($(mn|ls)$).

$$H_{mn} = \sum_{\mu,\nu} O_{m\mu} O_{n\nu} H_{\mu\nu} \tag{1}$$

$$(mn|ls) = \sum_{\mu}\sum_{\nu}\sum_{\lambda}\sum_{\sigma} O_{m\mu} O_{n\nu} O_{l\lambda} O_{s\sigma} (\mu\nu|\lambda\sigma) \tag{2}$$

where Greek subscripts indicate the original basis functions, and Roman subscripts the new ones. From Eq. 1 the following relations are derived concerning the bonding parameters, $\beta^0_{\sigma_A}$, of the three σ-AO's on atom A and also concerning the core potential integrals, $(\sigma_A\sigma_A|V_B)$, between the σ_A orbitals and the core potential of atom B;

$$\beta^0_{\sigma_A} \equiv \beta^0_{s_A} = \beta^0_{x_A} = \beta^0_{y_A} \tag{3}$$

$$(\sigma_A\sigma_A|V_B) \equiv (s_As_A|V_B) = (x_Ax_A|V_B) = (y_Ay_A|V_B) \tag{4}$$

On the assumption of ZDO, Eq. 2 gives the following relations:
For the one-center Coulomb repulsion integrals;

$$\gamma_{\sigma_A\sigma_A} \equiv \gamma_{s_As_A} = \gamma_{x_Ax_A} = \gamma_{y_Ay_A} = \gamma_{s_Ax_A} = \gamma_{s_Ay_A} = \gamma_{x_Ay_A} \tag{5}$$

$$\gamma_{\sigma_A\pi_A} \equiv \gamma_{s_Az_A} = \gamma_{x_Az_A} = \gamma_{y_Az_A} \tag{6}$$

For the two-center Coulomb repulsion integrals;

$$(\sigma_A\sigma_A|\nu_B\nu_B) \equiv (s_As_A|\nu_B\nu_B) = (x_Ax_A|\nu_B\nu_B) = (y_Ay_A|\nu_B\nu_B) \tag{7}$$

where ν_B is a σ- or π-orbital on atom B. Equations 3—7 are concerned only with the σ-AO's. The corresponding integrals for π-AO, *i.e.*, $\beta^0_{z_A}$, $(z_Az_A|V_B)$, $\gamma_{z_Az_A}$, and $\gamma_{z_Az_B}$ can be determined separately from the values in Eqs. 3—7.

b) Parametrizations: On the basis of the above relationships, the one-center Coulomb repulsion integral, $\gamma_{\sigma_A\sigma_A}$ and $\gamma_{\pi_A\pi_A}$, were taken to be equal to the difference[15] between the ionization potential, I, and electron affinity, A, of an appropriate valence state.[16,17] Their values employed in the present paper are listed in Table 1. The $\gamma_{\sigma_A\pi_A}$ values and two-center Coulomb repulsion integrals between all the σ- and π-AO's were evaluated from the $\gamma_{\sigma_A\sigma_A}$ and $\gamma_{\pi_A\pi_A}$ values by the use of Klopman's equation,[18] Eqs. 6 and 7 being satisfied.

The core potential integral was evaluated for σ-AO by Eq. 8 and for π-AO by Eq. 9.

$$(\sigma_A\sigma_A|V_B) = Z_B \times (\sigma_A\sigma_A|\sigma_B\sigma_B) \tag{8}$$

$$(\pi_A\pi_A|V_B) = Z_B \times (\pi_A\pi_A|\sigma_B\sigma_B) \tag{9}$$

where Z_B is the core charge of atom B. The bonding parameters for σ- and π-AO's were assumed to be proportional to each valence state ionization potential for the carbon and oxygen atoms, whereas the value for the hydrogen atom, β^0_H was fixed to be -12.0 eV. From the best fit between observed and calculated transition energies, a proportionality constant was chosen to be 1.15 in the present calculation; the values are tabulated in Table 1.

Finally, $1/2(I+A)$ values necessary to evaluate one-center core matrix elements, $U_{\mu\mu}$, were adjusted semi-empirically to give a reasonable electron density for the formaldehyde molecule. Consequently, the lower values were found to be preferable for 2s and 2p orbitals of oxygen to the original values;[13] namely, 24.390 eV for the 2s AO, and 8.111 eV for the 2px, 2py, and 2pz AO's.

c) Hartree-Fock and CI Matrix Elements: According

to the present method, the Hartree-Fock matrix elements and the CI matrix elements for the singlet and triplet manifolds are modified from the original equations[13,19] and calculated by the use of the modified semi-empirical values determined above. In the CI treatment on the ZDO approximation, exchange integrals characteristic of the singlet manifold of the CI matrix elements between the n-π^*, σ-π^*, and π-σ^* configurations vanish and the singlet CI element coincides with the corresponding triplet one. Therefore, the calculated transition energies for the singlet and triplet manifolds of n-π^*, σ-π^*, or π-σ^* excited state are equal to each other and should be compared with the observed transition energies to the triplet states.

Results for Some Planar Molecules. The modified CNDO-CI method mentioned above was applied to such planar molecules as ethylene, formaldehyde, formic acid, *s-trans*-butadiene, *s-trans*-glyoxal, and *s-trans*-acrylaldehyde to investigate their electronic structures and to check the applicability of the method. The geometrical structures of these molecules were taken from the analysis of the rotation-vibration spectrum[20,21] and from the electron diffraction studies.[22,23]

a) Orbital Energies: Tables IA and IIA give orbital energies calculated by the present authors, together with experimental values obtained by photoelectron spectroscopy.[24,25] Except for *s-trans*-glyoxal the sequences of molecular orbitals calculated by the present authors are in accordance with those determined experimentally[24,25] and calculated by the other semi-empirical[26-28] and non-empirical[29-31] methods. In the case of *s-trans*-glyoxal, the calculated splitting between the two n-orbitals was nearly twice as large (3.45 eV) as the observed value[24] ($\sim$1.6 eV). Owing to this large calculated splitting, the experimental sequence[24] (n, n, π) was not predicted by the present calculation (n, π, n)

The experimental results[1,25] of formic acid concerning both the sequence of orbitals and transition energies were found to be well reproduced by the theoretical calculation when the β^0 (−27.0 eV) and γ value (17.89 eV) are commonly used for all the 2s and 2p AO's of the two oxygen atoms in the carboxyl group. On the basis of this fact, the calculations of formic acid listed in Tables IA and IIIA and of acrylic acid discussed before were performed by the use of the above β^0 and γ values.

b) Electron Densities: Figure IA shows the electron densities of ethylene, formaldehyde, formic acid, *s-trans*-butadiene, *s-trans*-glyoxal, and *s-trans*-acrylalde-

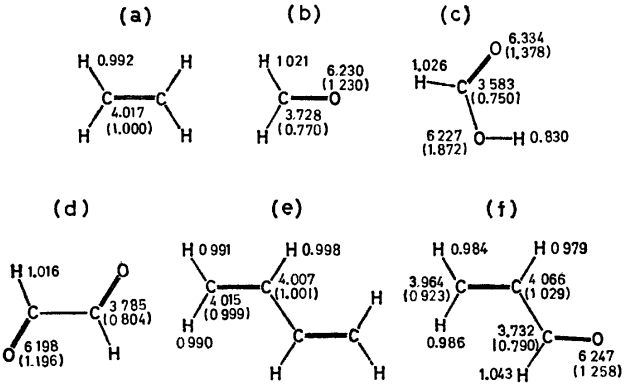

Fig. IA. The total and π- (in parentheses) electron densities of (a) ethylene, (b) formaldehyde, (c) formic acid, (d) *s-trans*-glyoxal, (e) *s-trans*-butadiene, and (f) *s-trans*-acrylaldehyde.

a) Taken from Ref. 24.

hyde. The C=O groups of formaldehyde, formic acid, glyoxal, and acrylaldehyde are fairly polarized. The dipole moments calculated by the present method for formaldehyde (2.25 D), formic acid (1.43 D), and acrylaldehyde (3.02 D) agree better with the experimental values (2.30, 1.4—1.7, 3.11 D, respectively)[32,33] than the theoretical values obtained by other authors.[13,26,34-38]

c) Transition Energies: Tables IIIA and IVA give some lower transition energies calculated for the planar molecules under consideration, together with the observed values. The result shows that the lowest singlet π-π^* transition energy of each molecule agrees satisfactorily with the observed value.[1,39-42]

The transition energies to the n-π^* state calculated for formaldehyde (3.19 eV) and acrylaldehyde (2.88 eV) agree well with the observed values to the triplet state (3.0 eV for both).[43,44] The calculated energy (1.87 eV) for the lowest n-π^* state of glyoxal is slightly lower than the observed triplet energy (2.38 eV).[45]

In the present calculation, the n-σ^* bands of formaldehyde, formic acid, glyoxal, and acrylaldehyde are predicted to appear at 9.46, 8.84, 8.43, and 9.16 eV, respectively, being 1—2 eV higher than the observed values assigned to the Rydberg or n-σ^* excited states.[1,40] Since the n-σ^* state of the molecules under consideration is expected to interact significantly with the Rydberg excited state, it is difficult to expect better agreement between the observed and calculated values of the n-σ^* transition energy in the present calculation in which the Rydberg 3s and 3p orbitals are disregarded.

Table IIIA. Singlet and triplet transition energies ($^1\Delta E$ and $^3\Delta E$ (eV)) and oscillator strength (f) calculated and observed for ethylene, formaldehyde, and formic acid

Modified INDO Calculations of the Electronic Structure of Transition Metal Carbonyl Compounds

Kazuyuki TATSUMI and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received November 4, 1975)

An INDO molecular-orbital method developed for the treatment of systems involving 3d orbitals have been applied to transition metal carbonyl complexes $Ni(CO)_4$, $Cr(CO)_6$, and $Fe(CO)_3$(butadiene). The Koopmans-theorem values of ionization potentials are found to be in excellent agreement with the observed photoelectron-spectroscopic data, except for the cases where a considerable reorganization in electronic distribution accompanies the ionization process. The INDO molecular orbital functions compare well with those reported on the basis of *ab initio* calculations.

There appears to be an increasing necessity of devising reliable theoretical methods for use in the investigation of chemistry of transition metal complexes. Fortunately, recent advances in the He(I) photoelectron spectroscopy provide data useful for testing the validity of theoretical calculations.

We here report the results of INDO calculations for transition metal carbonyl compounds: $Ni(CO)_4$, $Cr(CO)_6$, and $Fe(CO)_3$(butadiene). The primary aim of this work is to examine the vertical ionization potentials of these compounds and thereby to assess the semiempirical procedure here adopted. It will be shown that our method is at least as useful an approximation as *ab initio* calculations hitherto reported.

Computational Method

Since the INDO procedure has already been described in detail elsewhere,[1] we will only give a brief outline here. The basis atomic orbitals consist of 3d, 4s, and 4p functions for central metals and of 2s and 2p functions for first row atoms. Zerner's single-parameter atomic orbitals[2] have been employed for Ni and Fe atoms, Burns' function[3] for Cr atom, and Clementi's functions[4] for ligand atoms. In evaluating one-center integral parameters, we have adopted the same method as described in Ref. 1 using the data compiled by Oleari *et al.*[5-7] and by Hinze and Jaffé.[8] Table 1 summarizes the orbital exponents of the basis set and the valence-orbital ionization potentials (VOIP), together with various two-electron integral values adopted for the transition metals.

The molecular geometries used for calculations were taken from the experimental results. The interatomic distances and coordinate axes chosen are given in Figs. 1 to 3 for $Ni(CO)_4$,[9] $Cr(CO)_6$,[10] and $Fe(CO)_3$(butadiene),[11] respectively.

TABLE 1. ATOMIC PARAMETERS[a] OF THE TRANSITION METALS STUDIED

	Cr	Fe	Ni
Exponents			
3d	2.450	2.722	2.960
4s	1.300	1.370	1.473
4p	0.775	1.370	1.473
VOIP (eV)	(d^4s^2)	(d^6s^2)	(d^{10})
I_d	11.64	12.64	5.02
I_s	6.11	6.73	7.19
I_p	3.23	3.24	3.10
Two-electron integrals (eV)			
J_{sp}	5.955	6.414	6.872
$J_{pp'}$	5.233	5.500	5.768
J_{sd}	8.948	9.509	10.088
$J_{z,zx}$	7.601	8.091	8.583
J_{x,z^2}	7.404	7.867	8.331
$J_{z,xy}$	7.295	7.755	8.215
J_{z,z^2}	7.709	8.203	8.699
$J_{z^2,xy}$	12.590	13.799	15.015
$J_{z^2,xz}$	13.124	14.383	15.644
J_{xy,x^2-y^2}	13.302	14.578	15.854
$J_{xz,yz}$	12.768	13.993	15.225

a) The other parameters, $U_{\mu\mu}$ and $g_{\mu\nu}$, are tabulated in Ref. 7. The exchange integrals $K_{\mu\nu}$ can be obtained from $K_{\mu\nu}=2(J_{\mu\nu}-g_{\mu\nu})$.

Results and Discussion

and by Green *et al.*[13] The first three bands have been assigned to the ionizations from the t_2(Ni-d), e(Ni-d), and t_2(CO) orbital sets.

Table 2 shows the lowest three vertical ionization potentials (IP) obtained by the present calculation. The first two IP's correspond to the removal of an electron from the orbitals which have mainly a metal 3d character with $5t_2$[14] (d_{xz}, d_{yz}, and $d_{x^2-y^2}$) and 2e (d_{xy} and d_{z^2}) symmetries. The third IP, on the other hand, is ascribable to the $4t_2$ orbital which is composed chiefly of the CO σ orbitals. The IP values calculated are in excellent agreement with the experimental data for ionization potential.

Also listed in Table 2 are the results of *ab initio* calculations by Hillier *et al.*[15,16] and by Demuynck and Veillard,[17] together with the IP values calculated by Johnson and Wahlgen[18] using the SCF-X_α scattered-wave method. The *ab initio* calculations predict the same ordering of ionization orbitals as does our INDO treatment. However, the numerical values of IP do not agree well with observation; the Koopmans-theorem values are 2—4 eV higher than the observed IP while the ⊿SCF values too low by *ca.* 2 eV. The SCF-X_α data are apparently more satisfactory than the results of *ab initio* calculations. They are yet no better than the IP values obtained by the present INDO approximation.

The excellent agreement of the INDO results with observation may perhaps be largely fortuitous. However, it appears that the semiempirical method used deserves credit as being a useful working tool.

$Cr(CO)_6$. The He(I) photoelectron spectrum for $Cr(CO)_6$[19] has two peaks at 8.4 and 13.3 eV and a broad band in the range 14—16 eV. The first peak has been assigned to the ionization from the predominantly metal $2t_{2g}$ orbital. The second peak, which is much separated in energy from the first, might be due to the removal of an electron from either the $3e_g$ or (and) $4t_{1u}$ orbital; the assignment has not yet been settled. The order of the highest three occupied orbitals calculated by the self-consistent-charge-and-configuration(SCCC) method[20] is $4t_{1u}<3e_g<2t_{2g}$, while *ab initio*[15] and self-consistent-charge (SCC) molecular-orbital[21] calculations result in the order $3e_g<4t_{1u}<2t_{2g}$.

In Table 3, the first three IP obtained by the INDO and *ab initio* calculations are compared with the experimental values. The assignment of the second and third IP is that predicted by Hillier and Saunders,[15] who ascribe these two ionizations together to the second peak at 13.3 eV. The INDO calculations are successful in reproducing the experimental values for IP, in contrast to the considerable errors of the *ab initio* results. Although there is a disagreement in the ordering of $3e_g$ and $4t_{1u}$ orbitals between the two treatments, they show a common feature that the two orbitals in question are mutually very closely spaced.

For a further comparison between the two theoretical methods, we show in Table 4 the atomic populations in the molecular orbitals of our concern. Strictly speaking, it will be improper to directly compare the

populations derived from the orthogonal (or Löwdin) basis set (INDO) with those reduced from the Mulliken analyses (*ab initio*). Nevertheless, the comparison will still have some significance in a qualitative sense. As Table 4 shows, the populations calculated by the INDO method are uniformly in harmony with the *ab initio* results. Of the highest three levels, the $2t_{2g}$ orbital consists of 60—80% Cr 3d orbitals (d_{xy},d_{yz}, d_{xz}) with an appreciable CO π^* orbitals. The $4t_{1u}$ orbital is predominantly CO π bonds, while $3e_g$ is about 20% Cr 3d ($d_{x^2-y^2}$, d_{z^2}) and 80% CO orbitals.

Fe(CO)$_3$(butadiene). Measurement of photoelectron spectrum for Fe(CO)$_3$(butadiene) was first made by Dewar and Worley[22] using a low-resolution spectrometer. Recently, Connor *et al.*[23] have recorded a preciser spectrum to achieve assignment of the bands with the aid of *ab initio* calculations.

In Fig. 4, we compare the observed spectrum with IP calculated by the INDO and *ab initio* methods. Aside from the 16a' orbital, the sequence of the INDO orbital energies accords well with the *ab initio* results. However, neither set of these Koopmans-theorem values can rationalize the observed spectrum of Fe(CO)$_3$(butadiene). The discrepancy in height between the filled orbitals and the valence ionic states is probably due to greater orbital relaxation on ionization. The ΔSCF results[22] show that the effect of the orbital relaxation is particularly great for the molecular orbitals 17a', 15a', and 11a". For these orbitals, the breakdown of the Koopmans theorem is enormous. In this work, we have not attempted SCF calculations for the resulting ions, since our parametrization was originally aimed at best possible interpretations of the ground-state properties only.

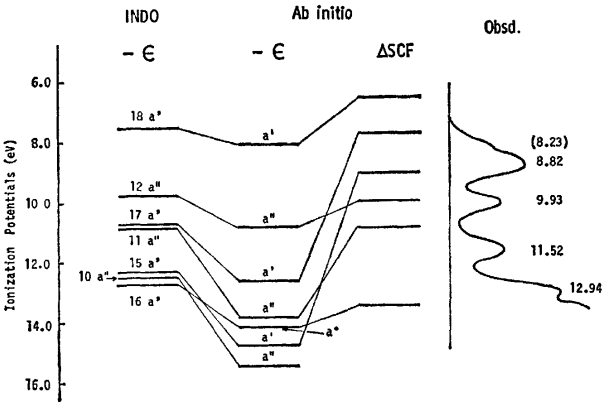

Fig. 4. Computed and experimental ionization potentials of Fe(CO)$_3$(butadiene). Symmetry designations of the molecular orbitals are based on the irreducible representation of the point group C_s.

Table 5 summarizes the results of population analysis of the molecular orbitals given in Fig. 4. It should be noted that the INDO calculation well reproduces the pattern of the *ab initio* populations. For the aforementioned three orbitals, for which the Koopmans theorem breaks down most seriously, the population on the central metal 3d orbitals is relatively large. Apparently, the orbital relaxation is most closely related with the 3d orbital population. With the orbitals

Table 5. Comparison of population analyses for Fe(CO)$_3$(butadiene) (in percent)

MO	Method	$-\varepsilon$(eV)	Fe(3d)	C_1+C_4	C_2+C_3
18a'	INDO	7.51	15	26	17
	Ab initio	8.1	33	34	9
12a"	INDO	9.75	11	45	20
	Ab initio	10.8	10	62	21
17a'	INDO	10.72	78	1	1
	Ab initio	12.6	51	12	20
11a"	INDO	10.74	84	3	2
	Ab initio	13.8	66	11	8
16a'	INDO	12.69	14	17	51
	Ab initio	14.1	34	12	48
15a'	INDO	12.31	90	2	1
	Ab initio	14.7	65	10	5
10a"	INDO	12.45	2	41	25
	Ab initio	15.4	13	32	18

12a" and 10a", the 3d orbital populations are calculated to be small. Consistently, the INDO Koopmans-theorem values of IP due to these orbitals (9.75 and 12.45 eV) are in reasonable agreement with the observed ionization potentials (9.93 and 12.94 eV).

Finally, we will briefly comment on the bonding character of the various molecular orbitals. The iron (3d)–butadiene (π) bonding is accomplished primarily through the d_{yz}–$1b_1$ and d_{xz}–$1a_2$ mixings in the orbitals 18a' and 12a", respectively. Both the orbitals 17a' and 11a" consist mainly of the iron 3d orbitals with an appreciable CO π orbitals. The orbitals 16a' and 15a' both have a slight iron–butadiene antibonding character. The 10a" orbital is predominantly butadiene σ orbitals.

Concluding Remarks

The INDO calculations combined with Koopmans' theorem are found to be successful in interpreting the photoelectron spectra of transition metal carbonyl compounds, unless the orbital relaxation upon ionization is substantial. However, the results by no means indicate that Koopmans' theorem are indeed applicable to these compounds. In fact, the available results of *ab initio* calculations show that the effects of this relaxation are not negligibly small. It seems that our semiempirical treatment is just in effect allowing favorably for the effects of electron correlation. It follows that the resulting description of the ground states is probably reliable enough to discuss the bonding properties with. One obvious merit of semiempirical theories lies in the computational economy for the quality of the results they provide. One may thus anticipate immediate, though perhaps somewhat limited, usefulness of the present method for the investigation of various chemical problems[1] associated with transition metal complexes.

A Comparison of the Primary Processes of the Radiolyses Induced by α-, β-, and γ-Rays

Shin SATO, Ken-ichi KOWARI, and Kiyoshi OKAZAKI

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 22, 1975)

By using the cross sections derived by the binary encounter collision theory and the assumption of a continuous slowing down, the *G*-values for the ionization and excitation of helium gas irradiated by α-, β-, and γ-rays have been calculated. In the radiolysis by high-energy electrons, the *G*-values started to decrease at an incident electron energy of about 10^3 eV with a decrease in the energy. Calculation showed that, if the radiation energy is extremely high, the *G*-values are independent of the kind of radiation. In the radiolysis induced by α-particles, the ratio of the yield resulting from the direct interaction with α-particles to that due to the secondary electrons was calculated as a function of the energy of the incident α-particles. When the energy was 8 MeV, the ratio for ionization was calculated to be 1.31.

There are several naive questions when we consider the primary process of the radiolyses induced by different ionizing radiations.

1) In radiation chemistry, the radiolysis yield obtained by the irradiation of high-energy electrons is believed to be independent of the energy of the incident electrons if they are high in energy. Then, what eV is the threshold value for calling electrons "high-energy electrons"—10^2, 10^3, or 10^4 eV?

2) It is believed that the chemical reaction induced in such materials as organic compounds by the irradiation of γ-rays from ^{60}Co is exactly the same as the reaction induced by the irradiation of high-energy electrons except for the difference in the penetration of the two ionizing radiations. However, the energy of the secondary electrons produced by the γ-irradiation through the Compton effect distributes down to zero eV. Consequently, the yield obtained by the irradiation of monoenergetic electrons of a high energy, say 100 keV, might not agree quantitatively with the yield obtained by γ-irradiation.

3) According to the experimental data,[1] when the energy of incident radiation is extremely high, the ionization yield in a gas does not depend upon the kind of radiation. However, the interaction of high-energy electrons with a material must be different from the interaction of other particles; for example, an incident electron can replace an electron in a material, but other particles cannot. Such an effect might result in a quantitative difference in the radiolysis yield.

4) When the *W*-value of a certain gas is measured by using α-particles as the radiation source, a question may be raised—what percentage of the ionization is induced by the direct interaction with α-particles, and what percentage by the interaction with the secondary electrons produced?

In this paper, we will attempt to answer these questions by performing numerical calculations on the radiolysis of helium gas. The calculating method is classical and approximate; however, we believe that the result is not far from the truth.

Radiolysis by High-energy Electrons

Throughout this paper, we will use the following equation, derived from the classical binary encounter theory,[2] for the differential cross section of the energy loss:

$$\sigma_{E,\mathrm{dir}} = \frac{\pi e^4}{T+I_i+E_i}\left(\frac{1}{E^2}+\frac{4E_i}{3E^3}\right) \quad (1)$$

for $T \geq I_i+E$. Here, T is the energy of the incident particle; I_i and E_i are, respectively, the binding energy and the average kinetic energy of the target electron, and E is the energy loss of the incident particle. When the incident particle is an electron and when an exchange with the target electron occurs, the differential cross section ($\sigma_{E,\mathrm{exc}}$) is expressed by replacing E in Eq. 1 with $T+I_i-E$.

For the calculation of the yields of ionization and excitation, we use the concept of the degradation spectrum, $y(T)$, and calculate it on the assumption of a continuous slowing down. The details of this procedure have been discussed previously;[3] therefore, we will only briefly outline them here.

According to the assumption of a continuous slowing down, the degradation spectrum of the incident electron, $y_1(T)$, is expressed as a reciprocal of the stopping power of the incident electron in the target gas. While the degradation spectrum of the incident electron is being formed, the secondary electrons are ejected and form their degradation spectrum, $y_2(T)$. The formulation of $y_2(T)$ can easily be carried out by using the differential cross section in Eq. 1. Similarly, the degradation spectrum of the electrons ejected in later steps can be constructed. The total degradation spectrum, $y(T)$, is obviously the sum of these spectra. Once $y(T)$ is obtained, the yield of any process can be calculated by using the total cross section, $Q_s(T)$, for that process:

$$N_s = Nn_i\int_{T_s}^{T_0} y(T)Q_s(T)\mathrm{d}T \quad (2)$$

Here, N_s is the number of species produced in the s process; N is the number of the target atoms in unit volume; n_i is the number of electrons in the i-th shell; T_s is the threshold energy of the incident electron for the s process, and T_0 is the energy of the primary electron. Then, the *G*-value of the product is calculated by this equation:

$$G_s = 100\,N_s/T_0 \quad (3)$$

Figure 1 shows the *G*-values thus calculated for the

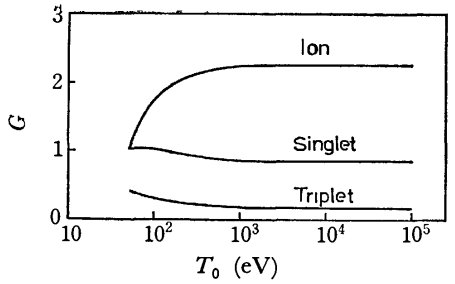

Fig. 1. The G-values for ionization and singlet and triplet excitations as functions of the energy of the primary electron.

TABLE 1. CONSTANTS USED FOR CALCULATION (eV)

Binding energy	$I_i = 24.581$
Singlet excitation energy	$E_s = 21.2$
Triplet excitation energy	$E_t = 19.8$
Average kinetic energy	$E_i = 38.74$

TABLE 2. COMPARISON OF G-VALUES FOR IONIZATION AND EXCITATIONS INDUCED BY DIFFERENT IONIZING RADIATIONS

	G_{ion}	G_{singl}	G_{tripl}
High energy electrons ($>10^3$ eV)	2.27	0.86	0.16
γ-Rays from ^{60}Co	2.30	0.86	0.16
α-Particles (8 MeV)	2.24	0.85	0.15

ionization and singlet and triplet excitations in helium gas as functions of the energy of the primary electrons. The constants used for the calculation are summarized in Table 1.[3] Obviously, the G-value of ionization tends to decrease at 10^3 eV with the decrease in the energy of the primary electrons. Above 10^3 eV, the G-values of any process are independent of the energy of the primary electrons. The values are listed in Table 2.

γ-Radiolysis

Energy Distribution of Compton Electrons. When a material consisting of atoms with low atomic numbers is irradiated by γ-rays from ^{60}Co, the primary interaction occurs mainly through the Compton effect. In order to calculate the energy distribution of the Compton electrons, Davison and Evans[1] derived this equation:

$$\frac{d\sigma(T)}{dT} = \frac{\pi r_0^2}{\alpha h\nu}\left[1+\frac{T^2}{(h\nu-T)h\nu}+\left\{1-\frac{T}{\alpha(h\nu-T)}\right\}^2\right] \quad (4)$$

from the famous Klein-Nishina formula.[5] Here, $\sigma(T)$ is the cross section for the formation of Compton electrons with the energy of T, $h\nu$ is the energy of the incident γ-rays, $\alpha=h\nu/mc^2$, and $r_0=e^2/mc^2$. m is the mass of electron, e is the charge, and c is the velocity of light.

Figure 2 shows the calculated energy distribution of the Compton electrons produced by the irradiation of ^{60}Co γ-rays, which consist of two different photons, 1.17 and 1.33 MeV. This figure is the same as that shown in the literature.[6] It is assumed in this calculation that the interaction of γ-rays with the gas occurs only once; *i.e.*, the interaction of the scattered γ-rays is not taken into account. As Fig. 2 shows, because of the momentum conservation, the maximum energy of the Compton electrons is less than the energy of incident radiation.

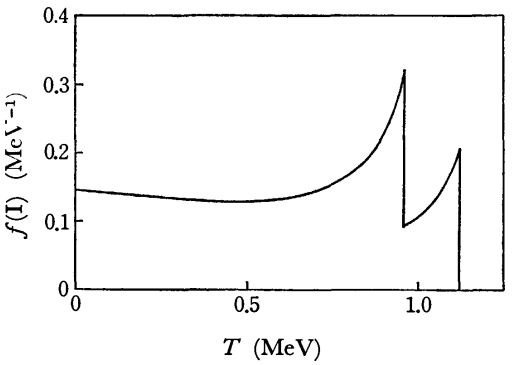

Fig. 2. The energy distribution of Compton electrons produced in helium irradiated by γ-rays from ^{60}Co.

$$T_{max} = \frac{2\alpha}{1+2\alpha}h\nu \quad (5)$$

Comparison with the Radiolysis Induced by High-energy Electrons. Since the energy distribution of the primary electrons produced by the Compton effect has been obtained, the degradation spectrum of electrons in helium irradiated by γ-rays can be calculated in a manner similar to that shown in the previous section. The degradation spectrum of the primary electrons, $y_1(T)$,[7] and the total energy, T_0, absorbed by helium in the present case are expressed as follows:

$$y_1(T) = \int_T^{T_{max}} f(T)dT/S(T) \quad (6)$$

and

$$T_0 = \int_0^{T_{max}} Tf(T)dT \quad (7)$$

Here, $f(T)$ is the fraction of the primary electrons with the energy of T, and $S(T)$ is the stopping power of helium gas for the electrons with the energy of T. $S(T)$ is formulated as follows:[8]

$$S(T) = \sum_i n_i\left\{\int_{E_{si}}^{(T+I_i)/2} E(\sigma_{E,dir}+\sigma_{E,exc})dE + \frac{1}{2}\int_{E_{ti}}^{E_{si}} E\sigma_{E,exc}dE\right\} \quad (8)$$

E_{si} and E_{ti} are the energies of the singlet and triplet excitations for the electron in the i-th shell.

Figure 3 shows the total degradation spectrum, $y(T)$, thus calculated. The calculated G-values for ionization and excitations are summarized in Table 2. Practically no difference can be seen in the G-values calculated for the γ-radiolysis and for the radiolysis by high-energy electrons. The difference of 1% in the G-value of ionization is within the limits of error of the calculation technique.

Radiolysis by α-Particles

According to the binary encounter theory, the differential cross-section for the energy loss of the incident-

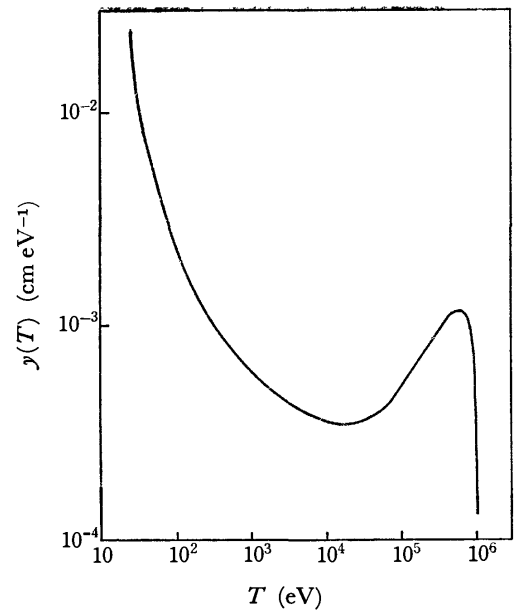

Fig. 3. The degradation spectrum of electrons in helium irradiated by γ-rays from ^{60}Co.

heavy-charged particles can be formulated in a manner similar to that used for electrons. Using the notations of Vriens,[9] the differential cross-sections are expressed as follows:

$$\sigma_1(E) = \frac{\pi Z^2 e^4}{3V_1^2 V_2 E^3}\left\{4V_1^3 - \frac{1}{2}(V_2' - V_2)^3\right\} \quad (9)$$

for $2mV_1(V_1-V_2) \leq E \leq 2mV_1(V_1+V_2)$. Here, $\sigma_1(E)$ is the differential cross section for the energy loss, E; Ze is the charge of the incident particle; V_1 is the incident velocity; V_2 is the velocity of the target electron, and V_2' is that after the collision with the heavy-charged particle. When $E \leq 2mV_1(V_1-V_2)$, the differential cross section has to be modified to this form:

$$\sigma_2(E) = \frac{2\pi Z^2 e^4}{mV_1^2}\left(\frac{1}{E^2} + \frac{2mV_2^2}{E^3}\right) \quad (10)$$

The formulation for these cross-sections has already been reported in detail.[10]

By using Eqs. 9 and 10, we can derive the total cross-sections for ionization and excitation (Q_{ion} and Q_{exc}):

$$Q_{\text{ion}} = \int_{2mV_1(V_1-V_2)}^{2mV_1(V_1+V_2)} \sigma_1(E)\mathrm{d}E + \int_{I_i}^{2mV_1(V_1-V_2)} \sigma_2(E)\mathrm{d}E \quad (11)$$

for $I_i \leq 2mV_1(V_1-V_2)$. Here, I_i is the binding energy of the target electron. When the binding energy is higher than $2mV_1(V_1-V_2)$, the term for σ_2 in Eq. 11 dissappears and Q_{ion} is expressed as follows:

$$Q_{\text{ion}} = \int_{I_i}^{2mV_1(V_1+V_2)} \sigma_1(E)\mathrm{d}E$$

for $2mV_1(V_1+V_2) \geq I_i \geq 2mV_1(V_1-V_2)$. In a similar manner, the total cross-sections for excitations can be formulated:

$$Q_{\text{exc}} = \int_{E_s}^{I_i} \sigma_2(E)\mathrm{d}E$$

for $2mV_1(V_1-V_2) \geq I_i$, and

$$Q_{\text{exc}} = \int_{2mV_1(V_1-V_2)}^{I_i} \sigma_1(E)\mathrm{d}E + \int_{E_s}^{2mV_1(V_1-V_2)} \sigma_2(E)\mathrm{d}E$$

for $2mV_1(V_1+V_2) \geq I_i \geq 2mV_1(V_1-V_2) \geq E_s$, where E_s is the threshold energy for the excitation.

$$Q_{\text{exc}} = \int_{E_s}^{I_i} \sigma_1(E)\mathrm{d}E$$

for $2mV_1(V_1+V_2) \geq I_i \geq E_s \geq 2mV_1(V_1-V_2)$, and

$$Q_{\text{exc}} = \int_{E_s}^{2mV_1(V_1+V_2)} \sigma_1(E)\mathrm{d}E$$

for $I_i \geq 2mV_1(V_1+V_2) \geq E_s \geq 2mV_1(V_1-V_2)$. In the treatment of the binary encounter theory, the excitation into the triplet state results from the exchange between the incident electron and the target electron. Therefore, in the present case, the formation of the triplet state cannot be taken into account.

In a manner similar to that used for electrons, the stopping power for heavy-charged particles is expressed in this form:

$$S(T) = N\sum_i n_i \left\{\int_{2mV_1(V_1-V_{2i})}^{2mV_1(V_1+V_{2i})} E\sigma_1\mathrm{d}E + \int_{E_{si}}^{2mV_1(V_1-V_{2i})} E\sigma_2\mathrm{d}E\right\} \quad (12)$$

Then, the degradation spectrum of the incident-heavy-charged particle may be expressed as follows:

$$y_0(T) = 1/S(T)$$

and the yield of the product formed through the s process in the collision of heavy-charged particles can be calculated by using Eq. 2.

In the radiolysis induced by the irradiation of heavy-charged particles, the secondary electrons ejected play an important role. The treatment on these electrons is similar to that for the Compton electrons produced by the γ-irradiation.

Figure 4 shows the $Ty(T)Q_s(T)$ values as a function of ln T. The incident radiation is 8 MeV α-particles. The solid lines correspond to the direct interaction of α-particles, and the dashed lines, to that of the secondary electrons. The ratio of the G-value for ionization due to the interaction with α-particles to that due to the secondary electrons is 1.31. Similar calculations can also be made for the excitation. The results are summarized in Table 3. Obviously the fraction due to the direct interaction increases with the decrease in the incident energy.

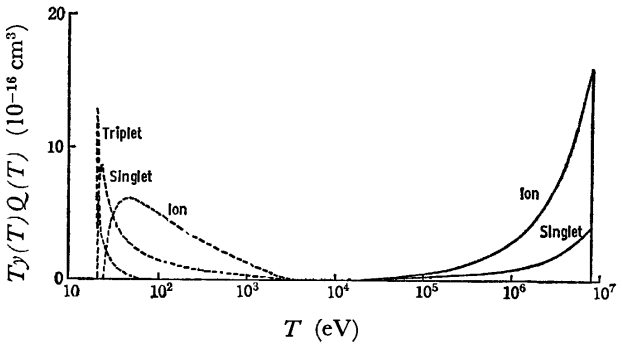

Fig. 4. Contribution of different portions of the degradation spectra of α-particles (solid) and of electrons (dashed) to the ionization and excitations in helium.

Table 3. Ionization and excitations of helium by different energy α-particles

T_0 (MeV)	G_{ion}	f_d (%)	f_s	G_{singl}	f_d (%)	f_s	G_{tripl}

f_d: the fraction due to the direct interaction of α-particles. f_s: the fraction due to secondary electrons.

Conclusion

Let us summarize the answers to four questions proposed in the Introduction. To the first question, the answer is that, from the point of view of the radiation chemist, the lower threshold value for high-energy electrons is about 10^3 eV. The answer to the second question is that the primary process of the γ-radiolysis is certainly the same as that of the radiolysis induced by high-energy electrons. This conclusion has been widely accepted. The present calculation is another support for it. The answer to the third question, regarding the radiation-chemical difference between heavy-charged particles and electrons, is also simple; *i.e.*, if the radiation energies are extremely high, the yield of the primary process is independent of the kind of radiation which induces the reactions. If present, the difference is within a few percent. The answer to the fourth question is shown by the numbers in Table 3. These numbers may be used when discussing the effect of δ-rays on the radiolysis induced by α-particles. Similar calculations can easily be carried out for the radiolysis induced by other heavy-charged particles, such as protons and argon ions. Recently Ohno has made a few such calculations.[11]

The calculating method we have used above is based on two important assumptions, one regarding the cross section for the energy loss, and the other, the assumption of the continuous slowing down. These assumptions probably introduce serious deviations in the numbers. However, the conclusions summarized above may hold nevertheless.

A Photoelectron Spectroscopic Study of Thioformamide

Katsumi KIMURA, Shunji KATSUMATA, Takahiko ISHIGURO,* Akiko Y. HIRAKAWA,* and Masamichi TSUBOI*

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

**Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Tokyo 113*

(Received November 29, 1975)

The He I photoelectron spectrum of thioformamide ($HCSNH_2$) has been measured. On the basis of spectral features, CNDO/2 calculations, and sum rule considerations, the following assignments have been concluded. 1) Six ionization bands appearing below 17 eV correspond to six-p-type MOs and two bands in the region 17—20 eV correspond to s-type MOs. 2) The first ionization band is attributed to the highest occupied (in-plane) MO constructed mainly from the sulfur lone pair which is mixed to some extent with the σ_{CN} orbital. 3) The second and fourth bands are due to the out-of-plane MOs, mainly corresponding to the nitrogen lone pair and the π_{CS} orbital, respectively. 4) The remaining p-type bands may be interpreted in terms of σ_{CS}, σ_{CN}, and π_{NH_2} (pseudo pi) orbitals.

Photoelectron spectroscopy using a He 584 Å source provides valuable information on valence orbital structure as well as vibrational structure in ionized states.[1] The He I photoelectron spectra of simple amides and carboxylic acids were studied by Brundle *et al.*,[2] who payed a special attention to the assignment of the closely overlapped bands due to the n_O (oxygen nonbonding) and π_2 (antisymmetric pi) MOs. Only a few photoelectron works has been published on thiocarbonyl compounds. Kroto *et al.* [3–5] reported the photoelectron spectra of several pyrolytically produced unstable compounds, H_2CS, CH_3CHS, $(CH_3)_2CS$, and F_2CS. No photoelectron studies have so far been published on thioformamide, which is fairly stable in the gaseous phase at room temperature. Debies and Rabalais[6] have recently published the He I and II photoelectron spectra of some amino acids, urea and thiourea. Our primary concern in the present work is to study the valence orbitals of thioformamide by means of He I photoelectron spectroscopy.

Experimental

Measurements of He I photoelectron spectra were carried out with a high-resolution photoelectron spectrometer used previously.[7,8] Calibration of the ionization energy scale was carried out using known ionization energies of Xe as an internal standard. A gaseous sample was introduced through a vacuum glass line with a Teflon needle valve. No metal tube was used to avoid decomposition. The pressure in the spectrometer tank was 1×10^{-6} Torr before the photoelectron measurements and 1 to 5×10^{-5} Torr during the measurements. The ionization chamber of cylindrical type (14 mm in diameter and 27 mm long) was used. The electron analyzer of the spectrometer was operated at ±0.2 V.

The sample of thioformamide used was prepared by a reaction of formamide and phosphorus pentasulfide,[9] and purified by a recrystallization from cold ether and then from cold (>15 °C) ethylacetate. The infrared absorption spectrum of the sample was in a perfect agreement with what Suzuki[10] observed.

Results and Discussion

The He I photoelectron spectrum of thioformamide below 20 eV is shown in Fig. 1, from which the following spectral features may be seen. 1) The first two ionization bands are well resolved with vibrational structure in the region 8.5—10 eV. 2) The third and fourth bands are considerably overlapped with each other in the region 12.5—13.5 eV, the latter being much sharper. 3) The fifth band appearing at about 14.1 eV is much weaker and the sixth band at 15.0—16.5 eV consists of three sub-bands associated with vibrational structure. 4) There are two more additional weak bands in the region 17—20 eV. The individual ionization bands in the photoelectron spectrum in Fig. 1 are indicated by vertical lines with the numbering.

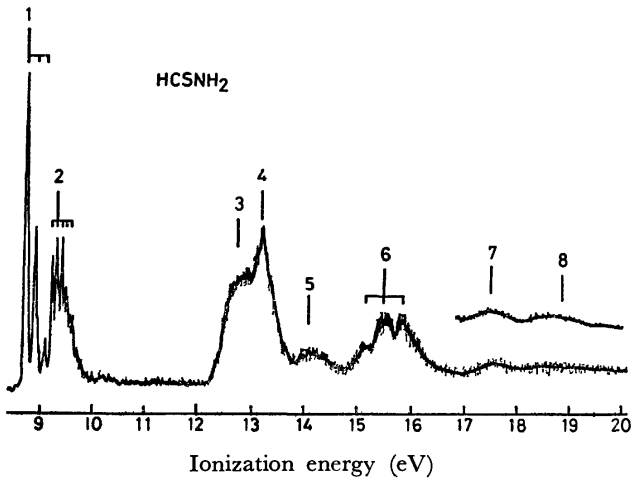

Fig. 1. He I photoelectron spectrum of thioformamide.

All the vertical ionization energies obtained from the thioformamide spectrum are summarized in Table 1.

Table 1. Vertical ionization energies (eV) and orbital assignments of thioformamide

	Vertical ionization energy	Orbital assignment Sym. (Main character)
I_1	8.70	$a'(n_S)$
I_2	9.30	$a''(n_N)-\pi_2$
I_3	12.80	$a'(\sigma_{C=S})$
I_4	13.18	$a''(\pi_{C=S})-\pi_1$
I_5	14.1_5	$a'(\pi_{NH_2})$
I_6	15.52	$a'(\sigma_{CN})$
I_7	17.7_0	$a'(s_S)$
I_8	18.9_0	$a'(s_C)$

As previously done,[7,8,11,12] we use the following p-type localized molecular orbitals (LOs) in order to represent main orbital features of the p-type bands: n_S (sulfur nonbonding), n_N (nitrogen nonbonding), π_{CS} (C=S pi bonding) σ_{CS} (C=S sigma bonding), σ_{CN} (C–N sigma bonding), and π_{NH_2} (amino-group pseudo pi). Since thioformamide has a planar molecular structure (C_s),[13] bonding and antibonding pi MOs (designated as π_1 and π_2, respectively) may be formed from the out-of-plane n_N and π_{CS} LOs. The valence orbitals of thioformamide therefore may be explained in terms of the two out-of-plane p-type LOs (n_N and π_{CS}), four in-plane p-type LOs (n_S, σ_{CS}, π_{NH_2}, and σ_{CN}) and three in-plane s-type LOs (s_C, s_S, and s_N).

In most of the saturated and unsaturated aliphatic compounds so far studied,[7,8,11,12] all p-type photoelectron bands are observed below about 18 eV. From the numbers of p- and s-type LOs, it may be reasonably considered that the six bands appearing below about 17 eV are due to the p-type LOs and the remaining two bands are due to the s-type LOs.

The third, nitrogen s-type band of thioformamide is expected to appear around 27 eV (beyond the He I region), since Potts *et al.*[14] have reported that the nitrogen s-type band of the methylamine is located at 27.5 eV. The carbon s-type bands of the C=O groups in H_2CO and CH_3CHO appear around 18—19 eV.[7] No sulfur s-type bands have so far been reported.

In the present work, we carried out CNDO/2 calculations[15] of orbital energies using a recently available geometry[13] and obtained the following orbital assignments under Koopmans' theorem:[16] $I_1 \rightarrow \varepsilon_1(a', n_S)$, $I_2 \rightarrow \varepsilon_2(a'', \pi_2)$, $I_3 \rightarrow \varepsilon_3(a', \sigma_{CS})$, $I_4 \rightarrow \varepsilon_4(a', \pi_{NH_2})$, $I_5 \rightarrow \varepsilon_5(a'', \pi_1)$, $I_6 \rightarrow \varepsilon_6(a', \sigma_{CN})$, $I_7 \rightarrow \varepsilon_7(a', s_S)$, $I_8 \rightarrow \varepsilon_8(a', s_C)$, and $I_9 \rightarrow \varepsilon_9(a', s_N)$. However, this assignment of I_4 to the π_{NH_2} seems to be incorrect, since the ionization of an electron from the pseudo π orbital always gives rise to a broad band as in methylamine. From the spectral shape, therefore, the fourth, sharp band may be assigned to the out-of-plane π_1 rather than the in-plane π_{NH_2} LO. This may also be supported by the sum rule consideration mentioned later.

The sum rule previously proposed[7,8,11,12] may approximately hold for the vertical ionization energies associated with the out-of-plane LOs of thioformamide, as summarized in Table 2. In the sum rule consideration, we used the empirical ionization energies given in Table 3 which are based on the experimental vertical ionization energies of simple molecules (I^0). The I^0 values given for the n_N and $\pi_{C=S}$ LOs in Table 3 were taken from the available photoelectron data of the first ionization energy of ammonia and the second ionization energy of thioformaldehyde, respectively. As shown in Table 2, good agreement is obtained between the experimental and calculated partial sums for thioformamide. A similar sum rule consideration is also demonstrated for formamide in Table 2, a considerably good agreement being again obtained between experiment and calculation. The orbital assignments finally concluded in the present work (Table 1) therefore differ from those of the CNDO/2 calculations in the order of the fourth and fifth inner orbitals.

TABLE 2. EXPERIMENTAL AND CALCULATED PARTIAL SUMS, $P(a'')$, FOR THE OUT-OF-PLANE LOs

Compound	$(I_s)\rightarrow$(LOs)	$-P(a'')$, eV	
		Expt.	Calcd.
$HCSNH_2$	$(I_2, I_4)\rightarrow a''(n_N, \pi_{C=S})$	22.48	22.66
$HCONH_2$	(I_2, I_4)[a] $\rightarrow a''(n_N, \pi_{C=O})$	25.27	25.38

a) $I_2 = 10.52$ eV, $I_4 = 14.75$ eV, taken from Ref. 2.

TABLE 3. EMPIRICAL ENERGIES (I^0, eV) USED FOR THE LOCALIZED MOLECULAR ORBITALS (LOs) IN THE SUM RULE CONSIDERATIONS

$I^0(n_N)$	$= 10.88$[a]
$I^0(\pi_{C=S})$	$= 11.78$[b]
$I^0(\pi_{C=O})$	$= 14.50$[c]

a) I_1 of NH_3; A. W. Potts and W. C. Price, *Proc. Roy. Soc., Ser. A*, **326**, 181 (1972). b) I_2 of H_2CS; Ref. 4. c) I_2 of H_2CO; C. R. Brundle, M. B. Robin, N. A. Kuebler, and H. Basch, *J. Am. Chem. Soc.*, **94**, 1451 (1972).

The vibrational structures of the first and second bands are shown in an expanded scale in Fig. 2. The vibrational intervals of about 1460 cm^{-1} which appear in the first band of $HCSNH_2$ are probably due to the C–N stretching (about 1450 cm^{-1} in the ground state of neutral liquid thioformamide). The second band of $HCSNH_2$ shows the vibrational intervals of about 730 cm^{-1} which are probably assigned to the C–S stretching (about 840 cm^{-1} in the ground state of neutral liquid thioformamide). These vibrational progressions seem to be closely associated with the facts that the orbital interactions exist between the n_S and σ_{CN} LOs in the highest occupied MO and between the n_N and π_{CS} LOs in the second inner MO.

The experimental orbital levels of thioformamide based on Koopmans' theorem are shown in Fig. 3, compared with those of its some related compounds. The LO levels (n_N, π_{CS}, and π_{CH_3}) are also shown in

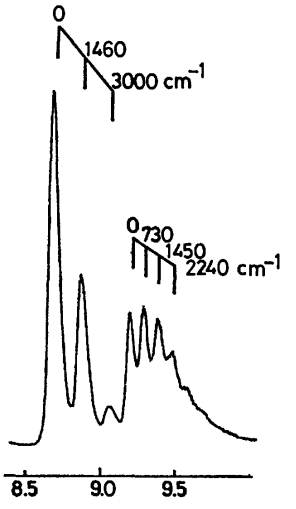

Fig. 2. The vibrational structure of the first two ionization bands of $HCSNH_2$ shown in an expanded scale.

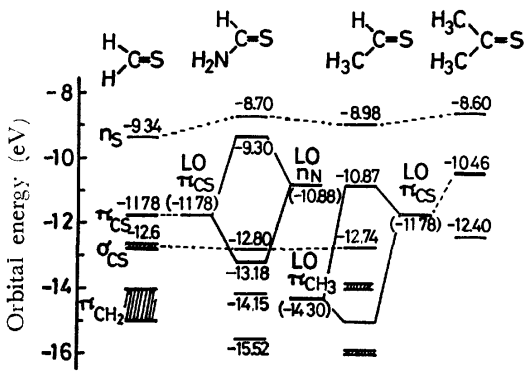

Fig. 3. Experimental (Koopmans' theorem) orbital correlation diagrams for thioformamide and its related compounds. The LO levels are based on the photoelectron data of simple compounds. Orbital energies for H_2CS, CH_3CHS, and $(CH_3)_2CS$ were taken from the literatures.[3,4] (The -12.6 eV level of H_2CS was tentatively assumed from the sharp peak of the available photoelectron spectrum.)

Fig. 3, together with their energy values in parentheses. The interaction schemes of the out-of-plane LOs are indicated by connecting the levels with solid lines. The σ_{CS} level of thioformamide is located at -12.80 eV, close to those of thioformaldehyde and thioacetaldehyde (-12.6 and -12.7 eV, respectively).

The assignment of the first band to the n_S rather than the n_N LO was also confirmed without Koopmans' theorem in the present CNDO/2 calculations by obtaining the difference in total energy between thioformamide and its cation in the ground state, a calculated ionization energy of 9.43 eV being obtained.

According to an electronic absorption study by Hosoya *et al.*,[17] the ultraviolet absorption bands of thioformamide in the regions 260—280 and 220—240 nm may be attributed to electron transitions to the $\pi^*_{C=S}$ orbital from the sulfur and nitrogen lone pair orbitals, respectively. The difference in transition energy between these absorption bands is 0.8 eV. It is interesting to note that this transition-energy difference of thioformamide is considerably close to the separation of the first two photoelectron bands (0.6 eV).

Radiative Triplet Lifetimes in Benzene and Azabenzenes with Particular Reference to Phosphorescence Mechanisms in Benzene

Hirotoshi Ito and Yasumasa J. I'Haya

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182

(Received December 8, 1975)

Calculations of radiative triplet lifetimes of benzene and azabenzenes are carried out by making use of an INDO/S method in which the parametrization of the CNDO/S method is used, retaining the semi-empirical Slater-Condon parameters determined in the INDO/2 method. The calculated excitation energies, oscillator strengths, and radiative lifetimes are in reasonable agreement with experimental values. The possible phosphorescence mechanisms for the $^3B_{1u}$ state of benzene are discussed rather in detail, considering the first-order vibronic as well as the first-order spin-orbit and the second-order spin-vibronic couplings. It is concluded that the strong first-order vibronic coupling between the triplet manifolds, $^3B_{1u}$ and $^3E_{1u}$, is responsible for the almost purely out-of-plane polarized phosphorescence of benzene, borrowing an intensity from the $^3E_{1u}$-$^1A_{1g}$ intercombination, and that the effects of the first-order spin-orbit and the second-order spin-vibronic couplings are small. The conclusion is in accord with the analyses of the Zeeman and MIDP spectra presented by van Egmond and van der Waals.

Theoretical prediction of radiative lifetimes for triplet states of aromatic hydrocarbons not only gives an important information for intersystem crossing mechanisms in luminescence spectroscopy but also serves as a sensitive check for the validity of quantum chemical approximations. The controversy on whether a π-electron model is adequate or states of mixed σ-π electronic character should be included has been almost settled, since the former yields predicted phosphorescence spectra $T_1 \rightarrow S_0$ always to be in-plane polarized whereas observed spectra of many aromatic hydrocarbons are predominantly out-of-plane polarized.[1,2] As for the importance of σ-electrons the earlier paper by Mizushima and Koide[3] was a foresighted one, though the lifetime of the spin-forbidden phosphorescent transition of benzene was only estimated.

As for the phosphorescence mechanisms in benzene, Clementi's scheme[4] for the $^3E_{1u} \rightarrow {}^1A_{1g}$ intercombination and Albrecht's second-order perturbation treatment[5] of the vibronic coupling between the triplet manifolds $^3B_{1u}$ and $^3E_{1u}$ are at present sufficiently convincing. In fact, Veeman and van der Waals[6] calculated the lifetime of the $^3B_{1u} \rightarrow {}^1A_{1g}$ transition to be 23.2 second using those schemes. As for the molecular spin-orbit coupling intergrals, it has been shown by several authors[6-9] that when σ-electron MO's are taken into account together with π-electron MO's the approximation to retain only one-center spin-same orbit coupling integrals is good enough to describe spin-orbit interactions in aromatic hydrocarbons. It is true in general that one-center spin-same-orbit coupling integrals are much larger in their magnitude than two- and three-center ones and also one- and multi-center spin-other-orbit coupling integrals. In the usual π-electron approximation for benzene and other planar aromatic hydrocarbons, all one- and two-center spin-same-orbit integrals vanish and contribution of small three- and four-center integrals to spin-orbit coupling has to be retained to calculate the triplet lifetimes which are therefore too long to compare with the corresponding experimental results.[10]

Though it is clear that the dominant spin-orbit coupling mechanism for radiative $T_1 \rightarrow S_0$ transitions involves $\pi\sigma^*$ and/or $\sigma\pi^*$ rather than $\pi\pi^*$ coupling, what type of approximate method is adequate comes into question. When one uses the CNDO/S method, one meets with a difficulty that energy separations between the singlet and triplet levels of both $\sigma\pi^*$ and $\pi\sigma^*$ states become zero in molecules of high symmetry. It is recognized fairly generally that the original INDO method gives non-zero but too high singlet and triplet states. In order to obtain better wave functions to predict whole lower-lying singlet and triplet levels of molecules, we use in this paper a modified INDO method in which the parametrization of Bene-Jaffé-Ellis-Kuehnlenz's modified CNDO method is adopted without changing the values of the semi-empirical Slater-Condon parameters used in the original INDO/2 method. Another modification is a use of Chojnacki's approximation[13] for two-center electronic repulsion integrals. In this respect, our INDO/S method is somewhat different from those proposed by Chen and Hedges[14] and Ridley and Zerner.[15]

We first check the reliability of the present INDO/S method with regard to singlet and triplet excitation energies and their intensities in benzene and azabenzenes and calculate the radiative lifetimes of lower-lying triplet states. In order to clarify the mechanisms of the phosphorescence in benzene, we investigate the symmetry forbidden lowest triplet radiative lifetime and the phosphorescence polarization in benzene rather in detail.

Theoretical Background

With the first-order perturbation theory, the spin-contaminated wave functions for the ground state, $|S_0^c\rangle$, and ith excited triplet state, $|T_i^c\rangle$, produced by spin-orbit coupling are written down as

$$|S_0^c\rangle = |S_0\rangle + \sum_m \gamma_m |T_m\rangle \text{ with } \gamma_m = \frac{\langle T_m|H_{so}|S_0\rangle}{E(S_0)-E(T_m)} \quad (1)$$

$$|T_i^c\rangle = |T_i\rangle + \sum_n \delta_n |S_n\rangle \text{ with } \delta_n = \frac{\langle S_n|H_{so}|T_i\rangle}{E(T_i)-E(S_n)}. \quad (2)$$

Here the spin-orbit Hamiltonian has the following form in the notation of our previous paper:[16]

$$H_{so} = \alpha^2\{\sum_i \sum_N Z_N(\vec{l}_{Ni}/r_{Ni}^3)\cdot\vec{S}_i + \sum_i \sum_{j\neq i} (2\vec{p}_i - \vec{p}_i) \times (\vec{r}_{ij}/r_{ij}^3)\cdot\vec{S}_i\} \quad (3)$$

The transition moment between the states $|S_0^c\rangle$ and $|T_i^c\rangle$ is then given by

$$\langle S_0^c|\vec{M}|T_i^c\rangle = \sum_n \delta_n\langle S_0|\vec{M}|S_n\rangle + \sum_m \gamma_m^*\langle T_m|\vec{M}|T_i\rangle \quad (4)$$

where $\vec{M}$ is the electric dipole operator. The corresponding oscillator strength and lifetime are derived from

$$f(S_0-T_i) = 1.085\times10^{-5}\,\nu(S_0-T_i)|\langle S_0^c|\vec{M}|T_i^c\rangle|^2 \quad (5)$$

$$\tau(T_i-S_0) = 1.5(g_T/g_S)/[\nu^2(S_0-T_i)f(S_0-T_i)] \quad (6)$$

where $\nu(S_0-T_i)$, the frequency of the emission from the lowest triplet state, is measured in units of cm^{-1} and the transition moment in units of Å. g_S and g_T represent the degeneracies in the ground singlet and excited triplet states, respectively, being put to be $g_S=1$, $g_T=3$ for temperature higher than 4.2 K and $g_T=1$ for temperature lower than 1.34 K according to experimental evidence.[17,18] $g_T/g_S=3$ is used throughout our computation.

The singlet and triplet state functions are expressed in terms of the Slater determinantal wavefunctions ${}^{2S+1}\psi_{i\to j}(SM)$ where S and M denote the total spin angular momentum and its z-projection, as follows:

$$|S(00)\rangle = \sum_i C_{i\to j}^{(i)}\,{}^1\psi_{i\to j}(00) \quad (7)$$

$$|T(1M)\rangle = \sum_i C_{i\to j}^{(i)}\,{}^3\psi_{i\to j}(1M),\quad M=0,\ \pm1 \quad (8)$$

After obtaining CI coefficients, it is convenient for practical applications to transform the triplet state functions $|T(1\,M)\rangle$ into $|T^x\rangle$, $|T^y\rangle$ and $|T^z\rangle$ so as to belong to the same representation of the appropriate point group as the cartesian components of the spin angular momentum.[10] Namely,

$$\begin{aligned}|T^x\rangle &= \frac{1}{\sqrt{2}}\{|T(1-1)\rangle - |T(11)\rangle\} = \sum_i C_{i\to j}^{(i)}\,{}^3\psi_{i\to j}^x\\ |T^y\rangle &= \frac{i}{\sqrt{2}}\{|T(1-1)\rangle + |T(11)\rangle\} = \sum_i C_{i\to j}^{(i)}\,{}^3\psi_{i\to j}^y \quad (9)\\ |T^z\rangle &= |T(10)\rangle = \sum_i C_{i\to j}^{(i)}\,{}^3\psi_{i\to j}^z\end{aligned}$$

where

$$\begin{aligned}{}^3\psi_{i\to j}^x &= \frac{1}{\sqrt{2}}\{{}^3\psi_{i\to j}(1-1) - {}^3\psi_{i\to j}(11)\}\\ {}^3\psi_{i\to j}^y &= \frac{i}{\sqrt{2}}\{{}^3\psi_{i\to j}(1-1) + {}^3\psi_{i\to j}(11)\} \quad (10)\\ {}^3\psi_{i\to j}^z &= {}^3\psi_{i\to j}(10)\end{aligned}$$

The matrix elements over MO's for the one-electron part of H_{so} are given by [19,20]

$$\sum_{\mu=x,y,z}\langle{}^1\psi_0|H_{so}^\mu|{}^3\psi_{i\to j}^\mu\rangle = \frac{1}{\sqrt{2}}\langle i|H_{so}^x - H_{so}^y - H_{so}^z|j\rangle \quad (11)$$

$$\sum_{\mu=x,y,z}\langle{}^1\psi_{i\to j}|H_{so}^\mu|{}^3\psi_{k\to l}^\mu\rangle = \frac{1}{2}\delta_{jl}\langle i|H_{so}^x - H_{so}^y - H_{so}^z|k\rangle - \frac{1}{2}\delta_{ik}\langle j|H_{so}^x - H_{so}^y - H_{so}^z|l\rangle \quad (12)$$

which are reduced to the spin-same-orbit coupling integrals over AO's. The one-center spin-same-orbit integrals over 2p AO's are analytically given as

$$\begin{aligned}&\langle 2p_y|H_{so}^z|2p_x\rangle = -\langle 2p_x|H_{so}^z|2p_y\rangle = -\langle 2p_y|H_{so}^x|2p_z\rangle\\ &= \langle 2p_z|H_{so}^x|2p_y\rangle = \langle 2p_x|H_{so}^y|2p_z\rangle = -\langle 2p_z|H_{so}^y|2p_x\rangle\\ &= i\alpha^2(Z_N^4/24)\ (\text{Rydberg}) = 5.8437\,i\,(Z_N^4/28)\ (cm^{-1}) \quad (13)\end{aligned}$$

where the leading sign is plus when the sequence of the sub- and super-scripts μ=x, y, z on $2p_\mu$ AO's and H_{so}^μ is cyclic and it is minus when the sequence is uncyclic, and Z_N is the effective nuclear charge.

Method of Calculation and Results

We use an INDO-type method based on the parametrization of the CNDO/S method which was first presented by Del Bene and Jaffé[11] and later somewhat reparametrized by Ellis, Kuehnlenz and Jaffé[12], retaining the semi-empirical Slater-Condon parameters determined in the INDO/2 method. The method is therefore called the INDO/S method hereafter. Like the CNDO/S method, the calculation of the off-diagonal matrix elements of the Fock operator $F_{\mu\nu}$, after the notation of Pople and Beveridge,[21] is carried out through the equation

$$F_{\mu\nu} = \beta_{AB}^0 S_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{AB} \quad (\mu\in A,\ \nu\in B) \quad (14)$$

where

$$S_{\mu\nu} = K_\sigma G_\sigma S_{\mu\nu}^\sigma + K_\pi G_\pi S_{\mu\nu}^\pi \quad (15)$$

for a pair of $2p_i$ and $2p_j$ (i, j$\in$x, y, z). G_σ and G_π are geometrical factors needed to project an arbitrary pair of 2p AO's in the cartesian coordinates suitably chosen onto the local bond axis. We adopted $K_\sigma=1$ and $K_\pi=0.585$ which are the values fixed by Del Bene and Jaffé[11] in their CNDO/S method. Other authors use a little different values for parameters K_σ and K_π. We found however that these parametrization does not produce an important effect in the final result, compared with the choice of an approximation for two-center electronic repulsion integrals which will be mentioned below. The zero differential overlap approximation is relaxed by retaining one-center integrals of the type $\langle 2s|\vec{er}|2p_i\rangle$ and $\langle 2p_i|\vec{er}|2p_i\rangle$ in the computation of transition moments.[12]

We have prepared a program for the present INDO/S method by modifying the computer program QCPE 91 for the CNDO/2 method written by Segal.[22] Throughout our computation, we solve 30×30 CI matrices made up of all the excitations which are unconditionally produced from *five* MO's below the highest occupied orbital to *six* MO's above the lowest unoccupied orbital. Reduction of the matrix elements over molecular integrals into those over atomic integrals in the INDO type method is prescribed by Ho *et al.*[23]

and Ridley and Zerner.[15]

With our INDO/S method, we carried out a pilot calculation of the excitation energies and oscillator strengths of benzene using the Nishimoto-Mataga (NM)[24] and the Ohno[25] approximations for two-center electronic repulsion integrals. The NM approximation was found to produce singlet levels tolerably well but lower triplet levels too low. On the other side, when Ohno's approximation is used the low-lying triplet levels are well reproduced but the singlet levels are not, in particular the $^1B_{2u}$ and $^1B_{2u}$ levels turn out to be reversed. These features are not typical of our INDO/S method but are also the cases whenever a Pariser-Parr-Pople type scheme is adopted for a π-electron model benzene (and other aromatic hydrocarbons) with the NM and Ohno approximations.

In order to obtain better wave functions which can predict both excitation energies and oscillator strengths, we tried to find out a parameter θ in the Chojnacki-type approximation[13]

$$\gamma_{AB} = \theta\gamma_{AB}^{NM} + (1-\theta)\gamma_{AB}^{Ohno} \quad (\theta<1) \tag{16}$$

where γ_{AB} is the two-center Coulomb repulsion integral. Chojnacki obtained $\theta=0.4$ in his P-P-P type π-electron calculations,[13] the value producing both first singlet and triplet levels which are in good agreement with experimental values. In our INDO/S calculations, however, a suitable value for θ was not obtained so as to reproduce the singlet and triplet levels of benzene simultaneously well. We adopted the Chojnacki's value $\theta=0.4$ because this was found to give a best compromise in simultaneous singlet and triplet level setting in benzene.

The results of our INDO/S calculation are listed in Table 1 for benzene and in Table 2 for azabenzenes. For comparison, we calculated the lower three $\pi\pi^*$ singlet and triplet state energies with the same procedure as our INDO/S but with the NM and Ohno approximations; these are 4.84, 6.06, 6.98 eV (NM) and 4.62, 4.93, 7.41 eV (Ohno) for the singlets, and 2.41, 3.93, 4.84 eV (NM) and 3.39, 4.45, 4.94 eV (Ohno) for the triplets. In so far as these lower excitation energies are concerned, it can be safely said therefore that the Chojnacki-type approximation produces better overall agreement with observed values than the NM and Ohno approximations. The oscillator strength and the lifetime of the transition $^3E_{1u}\rightarrow{}^1A_{1g}$ in benzene are calculated from Eqs. 5 and 6 and are listed at the bottom of Table 1.

The calculated excitation energies and oscillator strengths of the lower triplet states of some azabenzenes listed in Table 2 are fairly in good agreement with experimental values. As for 1, 3, 5-triazine, though the calculated lowest triplet state $^3E''$ comes rather high, the radiative lifetime from the state is computed to be 0.323 second which compares well with the

observed value 0.4 second and the assignment of the excited triplet states is in reasonable agreement with the experimentally fixed order. We do not list calculated results for lower singlet states of these azabenzenes since the results are quite similar to those obtained by Ridley and Zerner.[15)] These authors used a modified NM approximation in their INDO type calculations of lower excited singlet states of azabenzenes but did not refer to their excited triplet states. The choice of CI's in the present paper is rather different from that of Ridley and Zerner. Nevertheless, this does not yield much discrepancies in the final results for the low-lying singlet states. Chen and Hedges[14)] used a rather different parametrization in their INDO type calculation and obtained fairly good results for both low-lying singlet and triplet levels. Their assignment for higher energy levels is, however, much different from those obtained in the present paper and by Ridley and Zerner.

In the next section, we use the present results as a

theoretical foundation to explain the phosphorescence mechanisms in benzene.

Phosphorescence Mechanisms in Benzene

$^3E_{1u} \rightarrow {}^1A_{1g}$ Intercombination. In the range of our choice of CI's, the $^{1,3}B_{2u}$ and $^{1,3}B_{1u}$ states of benzene are found to be almost pure $\pi\pi^*$ states, so that the matrix element $\langle {}^1B_{2u}|H_{so}^z|{}^3B_{1u}\rangle$ vanishes provided that only the one-center spin-same-orbit coupling integrals are retained. It should be noted therefore that the $^{1,3}E_{1u}$ states having considerable amount of $\sigma\sigma^*$ characters play an important role in the spin-orbit mechanism.

Our starting wave functions for the degenerate E_{1u} states are, for example, of the forms (the state numbers 3A and 3B follow after Table 1)

$$|{}^{1,3}E_{1u}\begin{Bmatrix}3A\\2A\end{Bmatrix}\rangle = \begin{Bmatrix}0.6829\\-0.4011\end{Bmatrix}({}^{1,3}\psi_{14\rightarrow16} - {}^{1,3}\psi_{15\rightarrow17}) - \begin{Bmatrix}0.0983\\0.5824\end{Bmatrix}({}^{1,3}\psi_{14\rightarrow17} + {}^{1,3}\psi_{15\rightarrow16}) + \begin{Bmatrix}0.2193\\0.0021\end{Bmatrix}{}^{1,3}\psi_{12\rightarrow18} - \begin{Bmatrix}0.0026\\0.0043\end{Bmatrix}{}^{1,3}\psi_{13\rightarrow18} \quad (17)$$

$$|{}^{1,3}E_{1u}\begin{Bmatrix}3B\\2B\end{Bmatrix}\rangle = \begin{Bmatrix}0.0983\\0.5824\end{Bmatrix}({}^{1,3}\psi_{14\rightarrow16} - {}^{1,3}\psi_{15\rightarrow17}) + \begin{Bmatrix}0.6829\\-0.4011\end{Bmatrix}({}^{1,3}\psi_{14\rightarrow17} + {}^{1,3}\psi_{15\rightarrow16}) - \begin{Bmatrix}0.0026\\0.0043\end{Bmatrix}{}^{1,3}\psi_{12\rightarrow18} - \begin{Bmatrix}0.2193\\0.0021\end{Bmatrix}{}^{1,3}\psi_{13\rightarrow18} \quad (18)$$

where the upper and lower figures in braces correspond to the singlet and triplet states, respectively, and each configurational wave function is constructed from the ground state configuration as in the following:

$$(1a_{1g})^2(2,3e_{1u})^4(4,5e_{2g})^4(6a_{1g})^2(7b_{1u})^2(8b_{2u})^2(9,10e_{1u})^4\text{-}(11\pi a_{2u})^2(12,13e_{2g})^4(14\pi,15\pi e_{1g})^4(16\pi,17\pi e_{2u})^0(18b_{2u})^0\text{-}(19\pi b_{2g})^0(20,21e_{2g})^0(22a_{1g})^0(23,24e_{1u})^0(25b_{1u})^0(26,27e_{1u})^0(28,29e_{2g})^0(30a_{1g})^0 \quad (19)$$

In the above, each figure before the symmetry designation shows the orbital number in the order of increasing energy (double numbers are used for degenerate levels) and the simbol π after each figure denotes a π-electron MO, a specification for a σ-electron MO being omitted. With this orbital numbers we designate the configurational wave functions appearing in Eqs. 17 and 18 such as $\psi_{14\rightarrow16}$.

We obtained the following spin-contaminated wave functions for the ground state $|G^c\rangle$ and the triplet E_{1u} state $|{}^3E_{1u}^c\rangle$ needed to produce the $^3E_{1u}$-$^1A_{1g}$ intercombination:

$$\begin{aligned}|G^c\rangle &= |{}^1A_{1g}\rangle + \sum_i \lambda_i^{so}|{}^3E_{1g}(\sigma\pi^*,\pi\sigma^*;\ i)\rangle + \sum_i \omega_i^{so}|{}^3A_{2g}(\sigma\pi^*,\pi\sigma^*;\ i)\rangle \\ &= |{}^1A_{1g}\rangle + 0.7059\times10^{-4}|{}^3E_{1g}^x(10A)\rangle - 0.7234\times10^{-5}|{}^3E_{1g}^y(10A)\rangle + 0.7234\times10^{-5}|{}^3E_{1g}^x(10B)\rangle + 0.7059\times10^{-4}|{}^3E_{1g}^y(10B)\rangle \\ &\quad + 0.5152\times10^{-4}|{}^3E_{1g}^x(13A)\rangle + 0.1836\times10^{-3}|{}^3E_{1g}^y(13A)\rangle - 0.1836\times10^{-3}|{}^3E_{1g}^x(13B)\rangle + 0.5152\times10^{-4}|{}^3E_{1g}^y(13B)\rangle - 0.7770\times10^{-4}|{}^3A_{2g}^z(17)\rangle \quad (20)\end{aligned}$$

where λ_i^{so} and ω_i^{so} are the mixing coefficients for the ith perturbing triplets of symmetries $^3E_{1g}$ and $^3A_{2g}$, respectively, and each figure in a parenthesis is the state number in order of increasing energy, a symbol A or B after figure showing either of the degenerate states (see Table 1): and

$$\begin{aligned}|{}^3E_{1u}^c(2A)\rangle &= |{}^3E_{1u}(\pi\pi^*,\sigma\sigma^*;\ 2A)\rangle + \sum_i \nu_i^{so}|{}^1E_{1u}(\pi\pi^*,\sigma\sigma^*;\ i)\rangle + \sum_i \mu_i^{so}|{}^1A_{2u}(\sigma\pi^*,\pi\sigma^*;\ i)\rangle \\ &= |{}^3E_{1u}(2A)\rangle + 0.3689\times10^{-6}|{}^1E_{1u}^z(3A)\rangle + 0.1828\times10^{-6}|{}^1E_{1u}^z(3B)\rangle + 0.9425\times10^{-5}|{}^1A_{2u}^x(4)\rangle - 0.1834\times10^{-4}|{}^1A_{2u}^y(4)\rangle - 0.2521\times10^{-6}|{}^1E_{1u}^z(14A)\rangle - 0.6792\times10^{-6}|{}^1E_{1u}^z(14B)\rangle \quad (21)\\ |{}^3E_{1u}^c(2B)\rangle &= |{}^3E_{1u}(2B)\rangle + 0.1828\times10^{-6}|{}^1E_{1u}^z(3A)\rangle + 0.3689\times10^{-6}|{}^1E_{1u}^z(3B)\rangle - 0.1834\times10^{-4}|{}^1A_{2u}^x(4)\rangle - 0.9424\times10^{-5}|{}^1A_{2u}^y(4)\rangle + 0.6792\times10^{-6}|{}^1E_{1u}^z(14A)\rangle - 0.2510\times10^{-6}|{}^1E_{1u}^z(14B)\rangle. \quad (22)\end{aligned}$$

This computational output is in accord with a group-theoretical consideration given by Clementi,[4] apart from the numerical factors. We have thus a hypothetical transition moment between the $^3E_{1u}$ and the ground $^1A_{1g}$ states (in a.u.):

$$\sum_{i=2A,2B}\langle G^c|\vec{M}|{}^3E_{1u}^c(i)\rangle = 2.2890\times10^{-7}\vec{e}_x - 7.1426\times10^{-7}\vec{e}_y - 9.4013\times10^{-5}\vec{e}_z. \quad (23)$$

If we assume that the main contribution to the phosphorescence polarization comes from the transition $^3E_{1u} \rightarrow {}^1A_{1g}$, the phosphorescence spectrum of benzene is predicted to be almost 100% out-of-plane polarized.

How large is the effect of many-center spin-orbit coupling integrals? Clementi,[4] after the manner of Hameka and Oosterhoff, estimated the contribution of three-center spin-same-orbit coupling integrals and three- and four-center spin-other-orbit coupling integrals to the $|{}^3E_{1u}^c(2A)\rangle$ and $|{}^3E_{1u}^c(2B)\rangle$ states of pure π character. If we use his estimated value of such contribution

$$|{}^3E_{1u}^{cm}(i)\rangle = |{}^3E_{1u}^c(i)\rangle + 2.15\times10^{-5}\sum_{i=3A,3B}|{}^1E_{1u}(i)\rangle \quad (24)$$

we have the following transition moment (in a.u.):

$$\sum_{i=2A,2B}\langle G^c|\vec{M}|{}^3E_{1u}^{cm}(i)\rangle = -5.1001\times10^{-5}\vec{e}_x + 5.0516\times10^{-5}\vec{e}_y$$

$$- 9.4013\times10^{-5}\vec{e}_z. \quad (25)$$

Thus, the ratio of the out-of-plane to the in-plane polarizations of the phosphorescence $^3E_{1u}\rightarrow{}^1A_{1g}$ turns out to be 81 : 51 which is in accord with the observation (*ca.* 3 : 2) of Russel and Albrecht.[1] However, Eq. 25 does not lead to the almost out-of-plane polarized $^3B_{1u}\rightarrow{}^1A_{1g}$ phosphorescence which is the more recent experimental result obtained by van Egmond and van der Waals[2] (*vide infra*). The value 2.15×10^{-5} in Eq. 24 seems to be overestimated, even from the fact that the contribution of the one-center integrals in CH_2[26,27] and H_2CO[16,20] is calculated to be from ten to fifty times larger than that of many-center integrals.

Vibronically Induced $^3B_{1u}\rightarrow{}^1A_{1g}$ *Emission via* $^3E_{1u}$-$^1A_{1g}$ *Intercombination.* If we take account of the vibronic coupling H_{vib} as well as the spin-orbit coupling neglecting spin-vibronic terms, spin- and vibronically-contaminated wave functions for excited triplet states might be given by the second-order perturbation theory, because of relatively large values of vibronic coupling integrals compared with spin-orbit coupling integrals.

$$\begin{aligned}|T_i^c\rangle = |T_i\rangle &+ \sum_{j\neq i}\frac{\langle T_j|H_{vib}|T_i\rangle}{E(T_i)-E(T_j)}|T_j\rangle \\ &+ \sum_j\frac{\langle S_j|H_{so}|T_i\rangle}{E(T_i)-E(S_j)}|S_j\rangle \\ &+ \sum_j\sum_{k\neq i}\frac{\langle S_j|H_{vib}|S_k\rangle\langle S_k|H_{so}|T_i\rangle}{[E(T_i)-E(S_j)][E(T_i)-E(S_k)]}|S_j\rangle \\ &+ \sum_j\sum_{k\neq i}\frac{\langle S_j|H_{so}|T_k\rangle\langle T_k|H_{vib}|T_i\rangle}{[E(T_i)-E(S_j)][E(T_i)-E(T_k)]}|S_j\rangle \quad (26)\end{aligned}$$

or in an abbreviated form

$$\begin{aligned}|T_i^c\rangle = |T_i\rangle &+ \sum_{j\neq i}\delta_j^{vib}|T_j\rangle + \sum_j\gamma_j^{so}|S_j\rangle \\ &+ \sum_j\sum_{k\neq i}\alpha(S_j|S_k|T_i)|S_j\rangle \\ &+ \sum_j\sum_{k\neq i}\beta(S_j|T_k|T_i)|S_j\rangle \quad (27)\end{aligned}$$

where in Albrecht's notation[5] we write

$$H_{vib} = \sum_a (\partial H/\partial Q_a)_0 Q_a. \quad (28)$$

If we adopt the possible phosphorescence routes suggested by Albrecht,[5] we have

$$\begin{aligned}|^3B_{1u}^c(1)\rangle = |^3B_{1u}(1)\rangle &+ \sum_{i=2A,2B}\delta_i^{vib}|^3E_{1u}^c(i)\rangle + \gamma_1^{so}|^1B_{2u}(1)\rangle \\ &+ \sum_{i=3A,3B}[\alpha(^1E_{1u}(i)|^1B_{2u}(1)|^3B_{1u}(1)) \\ &+ \sum_{j=2A,2B}\beta(^1E_{1u}(i)|^3E_{1u}(j)|^3B_{1u}(1))]|^1E_{1u}(i)\rangle \\ &+ [\sum_{i=5A,5B}\alpha(^1A_{2u}(4)|^1E_{2u}(i)|^3B_{1u}(1)) \\ &+ \sum_{i=2A,2B}\beta(^1A_{2u}(4)|^3E_{1u}(i)|^3B_{1u}(1))]|^1A_{2u}(4)\rangle \\ &+ \sum_{i=3A,3B}[\sum_{j=5A,5B}\{\alpha(^1E_{1u}(i)|^1E_{2u}(j)|^3B_{1u}(1)) \\ &+ \beta(^1E_u(i)|^3E_{2u}(j)|^3B_{1u}(1))\} \\ &+ \beta'(^1E_{1u}(i)|^3A_{2u}(7)|^3B_{1u}(1))]|^1E_{1u}(i)\rangle \quad (29)\end{aligned}$$

where

$$\delta_i^{vib} = \frac{\langle ^3E_{1u}^c(i)|H_{vib}|^3B_{1u}(1)\rangle}{E(^3B_{1u}(1))-E(^3E_{1u}^c(i))} \cong \frac{\langle ^3E_{1u}(i)|H_{vib}|^3B_{1u}(1)\rangle}{E(^3B_{1u}(1))-E(^3E_{1u}(i))} \quad (30)$$

and $|^3E_{1u}^c(i)\rangle$ corresponds to Eqs. 21 and 22. These individual contribution are schematically shown in Fig. 1, where (a), (b), (c), (d) and (e) correspond to the second, third, fourth, fifth and the last terms of Eq. 29, respectively. In order to obtain the mixing coefficients of Eq. 29, we adopt experimental values of excitation energies, if available, and otherwise use the corresponding calculated values. For vibronic integrals we use the values determined by Albrecht.[5] The last term of Eq. 29 is cut off, since the values of

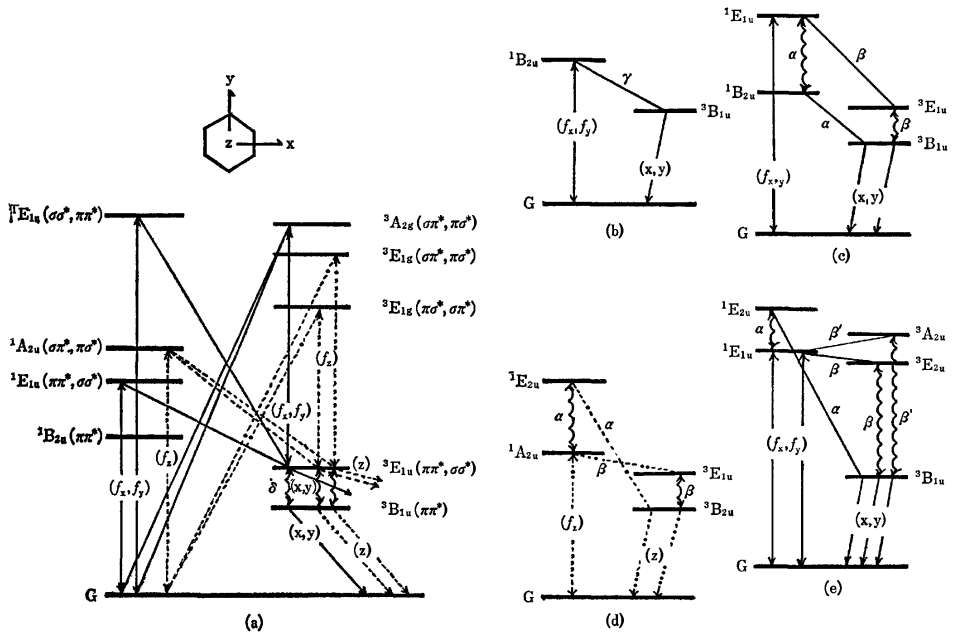

Fig. 1. Possible phosphorescence mechanisms in benzene. (a), (b), (c), (d), and (e) correspond to the 2nd, 3rd, 4th, 5th and 6th terms of Eq. 29 in the text, respectively. Solid arrow: in-plane polarized transition; dashed arrow: out-of-plane polarized transition.

these vibronic integrals are unknown. Matrix elements over many-center integrals are neglected by the reason mentioned before. Only exception is the element $\langle {}^1B_{2u}|H^z_{so}|{}^3B_{1u}\rangle$ which is included in the following in order to estimate the effect of Route (b). The forbidden transition moment $\langle {}^1A_{1g}|M_{x,y}|{}^1B_{2u}\rangle$ is estimated to be $\pm 1.013\times 10^{-2}$ atomic unit from an experimental point of view.

Equation 29 is now calculated to be[28]

$$\begin{aligned}|{}^3B^c_{1u}(1)\rangle &= 0.9025|{}^3B_{1u}(1)\rangle \\ &\quad - 0.3047[|{}^3E^c_{1u}(2A)\rangle + |{}^3E^c_{1u}(2B)\rangle] \\ &\quad + 0.1190\times 10^{-4}|{}^1B_{2u}(1)\rangle \\ &\quad + 0.1473\times 10^{-5}|{}^1E_{1u}(3A)\rangle \\ &\quad + 0.1411\times 10^{-5}|{}^1E_{1u}(3B)\rangle \\ &\quad - 0.3239\times 10^{-5}|{}^1A_{2u}(4)\rangle. \end{aligned} \tag{31}$$

Finally, we have

$$\begin{aligned}\langle G^c|\vec{M}|{}^3B^c_{1u}(1)\rangle &= -0.3047[\langle G^c|\vec{M}|{}^3E^c_{1u}(2A)\rangle \\ &\quad + \langle G^c|\vec{M}|{}^3E^c_{1u}(2B)\rangle] \\ &\quad + 0.1190\times 10^{-4}\langle {}^1A_{1g}|\vec{M}|{}^1B_{2u}(1)\rangle \\ &\quad + 0.1473\times 10^{-5}\langle {}^1A_{1g}|\vec{M}|{}^1E_{1u}(3A)\rangle \\ &\quad + 0.1411\times 10^{-5}\langle {}^1A_{1g}|\vec{M}|{}^1E_{1u}(3B)\rangle \\ &\quad - 0.3239\times 10^{-5}\langle {}^1A_{1g}|\vec{M}|{}^1A_{2u}(4)\rangle \\ &= (-3.411\pm 0.060)\times 10^{-6}\vec{e}_x \\ &\quad + (3.838\pm 0.060)\times 10^{-6}\vec{e}_y \\ &\quad + 2.825\times 10^{-5}\vec{e}_z. \end{aligned} \tag{32}$$

Fractional contributions of the four phosphorescence routes shown in Fig. 1 to the transition moment $\langle G^c|\vec{M}|{}^3B^c_{1u}(1)\rangle$ are listed in Table 3. The final result given in Eq. 32 clearly shows that the phosphorescence from the ${}^3B_{1u}(1)$ state is almost 100% out-of-plane polarized. This is in accord with the results of the Zeeman and MIDP experiments obtained by van Egmond and van der Waals.[2] If we use the observed energy separation 3.95 eV between the ${}^3B_{1u}(1)$ state and the ground state, Eqs. 5 and 6 yield the oscillator strength $f({}^3B_{1u}\rightarrow {}^1A_{1g})=0.7940\times 10^{-10}$ and the lifetime $\tau=55.8$ second.

As evident from Eq. 32, the main contribution to the phosphorescence lifetime comes from the term δ^{v1b} for which we have used Albrecht's value $\langle {}^3E^c_{1u}(i)|H_{v1b}|{}^3B_{1u}(1)\rangle=0.27$ eV, i=2A and 2B. Comparison of the calculated lifetime with the observed value 4.75 second[29,30] suggests that the value of δ^{v1b}, namely the value of $\langle {}^3E^c_{1u}|H_{v1b}|{}^3B_{1u}\rangle$, is underestimated. In fact, van der Waals *et al.*[31] estimated the value of the δ^{v1b} to be -0.4031 which yields $f({}^3B_{1u}\rightarrow {}^1A_{1g})=1.390\times 10^{-10}$ and $\tau=31.9$ second. If one wants to reproduce the observed lifetime 4.75 second by making use of the same computational scheme as above, δ^{v1b} must be taken the value 0.55 and one has

$$\begin{aligned}|{}^3B^c_{1u}(1)\rangle &= 0.63|{}^3B_{1u}(1)\rangle \\ &\quad - 0.78\frac{1}{\sqrt{2}}\{|{}^3E^c_{1u}(2A)\rangle + |{}^3E^c_{1u}(2B)\rangle\} + \cdots. \end{aligned}$$

Thus the mixing coefficients of the triplet B_{1u} and E_{1u} states come out to be absolutely improbable. On the other hand, if the value of δ^{v1b} is fixed to be around -0.4, a value of the z-component of the transition moment between the ${}^3E_{1u}$ and the ground states $-1.3\times 10^{-4}\vec{e}_z$ instead of our calculated value $-9.40\times 10^{-5}\vec{e}_z$ yields the lifetime which is in accord with the observed value. Though further studies are needed to clarify this matter, our conclusion at present is that molecular wave functions to calculate the transition moment due to the ${}^3E_{1u}$-${}^1A_{1g}$ intercombination are very sensitive to the prediction of the triplet lifetime in benzene.

Table 3. Contribution of possible phosphorescence routes to transition moment $\langle G^c|\vec{M}|{}^3B^c_{1u}(1)\rangle$

Route in Fig. 1	M_x	M_y	M_z
a	-0.6978×10^{-7}	2.1756×10^{-7}	2.8646×10^{-5}

Microwave Spectrum of Ethyl Isothiocyanate

Takeshi SAKAIZUMI, Osamu OHASHI, and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received December 16, 1975)

The microwave spectrum of ethyl isothiocyanate, CH_3CH_2NCS, has been obtained in the frequency region from 8.5 to 35 GHz. The spectrum identified is attributed to the *cis* configuration, namely, the methyl group eclipses the isothiocyanato group. The rotational constants for the ground vibrational state obtained are $A=14194\pm10$, $B=1799.27\pm0.02$ and $C=1612.14\pm0.02$ MHz. The dipole moment of this rotamer is $\mu_{total}=3.33\pm0.03$ D ($\mu_a=3.33\pm0.03$ D, $\mu_b=0.07\pm0.02$ D). Two sets of vibrational satellites were observed and assigned to the modes of C–N torsion (58 ± 30 cm^{-1}) and CNC bending (107 ± 30 cm^{-1}).

Recently microwave spectroscopy has been increasingly applied to the study of the rotational isomerism of molecules. Most of these studies have, however, been made on the rotational isomerism about a C–C single bond, and less attention has been paid to that about single carbon-heteroatom bonds. It is interesting, therefore, to study the rotational isomerism of mono-substituted ethanes, having, for example, thiocyanato (–SCN), isothiocyanato (–NCS), selenocyanato (–SeCN), isoselenocyanato (–NCSe) groups, *etc.* Kniseley *et al.*[1] have investigated the structure of ethyl isothiocyanate using infrared spectroscopy and concluded that the molecule existed in two rotameric forms, presumably *trans* and *gauche*. They observed two absorption bands at 2199 and 2154 cm^{-1} at liquid nitrogen temperature and assigned them to the NCS asymmetric stretching vibration in the *gauche* and *trans* configurations. Bjørseth and Marstokk[2] have studied the microwave spectrum of ethyl thiocyanate, CH_3CH_2-SCN, and determined that the molecule exists in a single rotameric form, probably *gauche*, in gas phase, which is more stable than the *trans* form by at least 0.8 kcal·mol^{-1}.

In this paper, the spectrum of ethyl isothiocyanate in a configuration characterized by predominant absorption lines, the *cis* form, is reported and the structure and dipole moment are discussed.

Experimental

The sample of ethyl isothiocyanate was obtained commercially and purified by distillation *in vacuo*. The rotational spectrum was obtained in the frequency region from 8.5 to 35 GHz with a conventional 100-kHz sinusoidal- and square-wave Stark modulation spectrometer. The waveguide cell was cooled with dry ice in order to enhance the intensity of the absorption lines. Transition frequencies were measured with a Hewlett-Packard Model 5245 L frequency counter.

Results and Discussion

Spectrum and Assignment for the Vibrational Ground State. The observed spectrum was considerably dense in appearance, consisting of a large number of absorption lines. This feature may be ascribed to the various rotational isomers and their vibrationally-excited states. Four rotational isomers may be considered for the ethyl isothiocyanate molecule, namely, the *cis*, *gauche*, *skew*, and *trans* forms, as shown in Fig. 1. The moments of inertia calculated from the assumed structure of

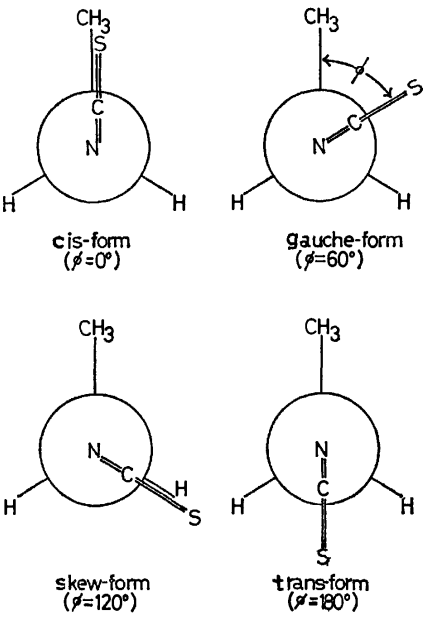

Fig. 1. Model of rotational isomers of ethyl isothiocyanate.
ϕ: dihedral angle.

these isomers indicate that all are nearly prolate symmetric top molecules (the value of the asymmetric parameter of Ray are in the region from −0.998 to −0.974). A large a-component of the dipole moment is expected for these molecules because the –N=C=S group, having a large moment, lies close to the a-axis. Consequently, strong a-type R-branch absorption lines with $K_{-1}=0$ and 1 are expected. In the vicinity of the $K_{-1}=0$ line, absorption lines for K_{-1} equal to or larger than two should appear and a large Stark effect should be observed.

The $J=4\leftarrow3$ transitions with $K_{-1}=0$ and 1 in the ground vibrational state were first observed and identified from their Stark effects. With the preliminary values of the rotational constants fitted to only the low-J transition frequencies, the high-J transition frequencies were predicted from the rigid rotor Hamiltonian. As the values of J and K_{-1} increase, the difference between the observed and calculated transition frequencies was found to become larger, in particular, for lines with values of K_{-1} larger than one as shown in Fig. 2 (obsd and calcd-I). This difference is probably attributable to the centrifugal distortion effect.

The preliminarily determined rotational constants

a) Experimental uncertainty: ±0.20 MHz. b) $\Delta\nu = \nu_{obsd} - \nu_{calcd}$. c) Not included in the least-squares fitting.

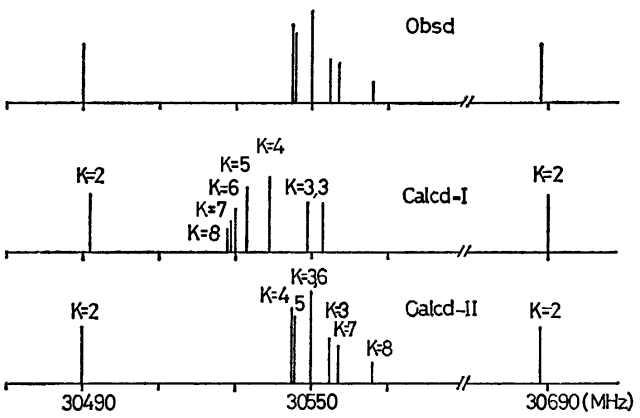

Fig. 2. Observed and calculated $J=9\leftarrow8$ transition of ethyl isothiocyanate (ground vibrational state). Calcd-I: calculated with the rigid rotor model; Calcd-II: calculated using Eq. (1), the centrifugal distortion effect included.

suggest that the molecule studied was a nearly symmetric top. Therefore, the observed transition frequencies given in Table 1 were fitted to the following equations:

$$E = E_r + E_d \quad (1)$$

$$E_d = -D_J J^2(J+1)^2 - D_{JK} J(J+1)K^2 - D_K K^4 \quad (2)$$

where E_r is the energy for a nearly symmetric rigid rotor molecule and E_d the correction for the first-order centrifugal distortion effect.

The rotational and centrifugal distortion constants were obtained by the least-squares method as given in Table 2. The observed and calculated transition frequencies are in good agreement, as is shown in the column of Table 1 with the heading "ground state". As shown in Fig. 2, the transitions with K_{-1} larger than four appear at higher frequencies as their K_{-1} increase, (obsd and calcd-II), in contrast with the rigid rotor spectrum (calcd-I). This is because of the negative value of D_{JK}.

Conformation of the Molecule. For the ground vibrational state, the value of $\Delta(I_a+I_b-I_c)$ is 6.159

Table 2. Rotational constants and moments of inertia[a] for ethyl isothiocyanate

	Ground State	Set-I C-N torsion	Set-II CNC bend
A(MHz)	14194±10	14599±10	15215±15
B(MHz)	1779.27 ±0.02	1748.42 ±0.02	1739.03 ±0.02
C(MHz)	1612.14 ±0.02	1598.18 ±0.02	1590.22 ±0.02
D_J(kHz)	1.58 ±0.02	1.70 ±0.02	2.31 ±0.02
D_{JK}(kHz)	−36.9 ±0.2	−48.6 ±0.2	−61.6 ±0.2
I_a(amu·Å^2)	35.605±0.025	34.617±0.024	33.215±0.033
I_b(amu·Å^2)	284.035±0.003	289.047±0.003	290.608±0.003
I_c(amu·Å^2)	313.481±0.004	316.219±0.004	317.803±0.004
Δ(amu·Å^2)[b]	6.159±0.032	7.445±0.031	6.020±0.040
Δ'(amu·Å^2)[c]	0.084±0.032	−1.202±0.031	0.222±0.040

a) Conversion factor $=5.05376\times10^5$ MHz·amu·Å^2. b) $\Delta=I_a+I_b-I_c$. c) $\Delta'=I_c-I_b-I_a+8m_Hc_H^2$.

amu·Å^2, as calculated from the moments of inertia given in Table 2. If the molecule studied in this work has a plane of symmetry, there are four hydrogen atoms out of this plane. Consequently, the following relation is valid if the molecule is rigid:

$$8m_Hc_H^2 = I_a + I_b - I_c \quad (3)$$

where m_H is the mass of one hydrogen atom and c_H is its distance from the plane of symmetry. There are two possible configurations for the molecule having a plane of symmetry, namely, the *cis* and *trans* forms. Using the assumed structural parameters given in Table 3, the value of $8\,m_Hc_H^2$ for the two forms was calculated to be 6.345 amu·Å^2. This is in good agreement with the value determined experimentally. This result suggests that the configurations of the molecule are the forms having plane symmetry, namely, the *cis* or *trans* form. Moreover, comparing the rotational constants determined experimentally with those calculated from the assumed structures given in Table 4, the preferred configuration is clearly the *cis* form shown in Fig. 3. Ethyl isothiocyanate molecules are in the *cis* conformation in the gas phase as one of the possible rotational isomers. This result is consistent with the fact that propionaldehyde,[3] 1-butene,[4] propionic acid,[5] and propionyl fluoride[6] exist in the *cis* and *skew* forms as rotational isomers, rather than in the *trans* form, with respect to the methyl group and the C=O or C=C double bond.

Three structural parameters, $r_{C_\alpha-N}$, $\angle C_\beta C_\alpha N$ and $\angle C_\alpha NC$, of the ethyl isothiocyanate molecule in the ground vibrational state were obtained from the observed rotational constants, A, B, and C, fixing the remaining structural parameters to the values assumed in Table 3. The results obtained are $r_{C_\alpha-N}=1.454$ Å,

Table 3. Assumed structural parameters[a]

Distances	Angles
C-H : 1.091Å	∠HCH : 108.8°
C_β-C_α : 1.522Å	$\angle HC_\beta C_\alpha$: 109.6°
C_α-N : 1.437Å	$\angle C_\beta C_\alpha H$: 110.6°
N=C : 1.210Å	$\angle C_\beta C_\alpha N$: 109.5°
C=S : 1.550Å	$\angle C_\alpha NC$: 147.5°

a) Carbon atoms at the α- and β-positions are denoted as C_α and C_β, respectively. The structural parameters are taken from mono-substituted ethanes CH_3CH_2X (X=F[9], Cl[10], Br[11], I[12], OH[13], NC[14]) for the ethyl group and from methyl isothiocyanate[15] for the isothiocyanato group.

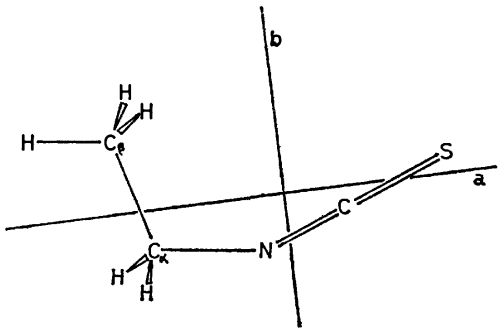

Fig. 3. Configuration of the predominant rotamer, *cis*-ethyl isothiocyanate. The c principal axis is perpendicular to the plane of paper.

Table 4. Observed and predicted rotational constants

	Obsd	Calcd			
		cis	*gauche*	*skew*	*trans*
A(MHz)	14194	14197.29	15558.54	24035.91	33364.61
B(MHz)	1779.27	1778.77	1694.55	1494.95	1427.60
C(MHz)	1612.14	1612.73	1569.60	1451.58	1392.96
κ	−0.973433	−0.973611	−0.982135	−0.996159	−0.997833
Δ(amu·Å^2)[a]	6.159	6.345	8.740	10.925	6.343
ϕ(°)[b]		0	60	120	180

a) $\Delta=I_a+I_b-I_c$. b) ϕ: dihedral angle about the C-N bond, see Fig. 1.

$\angle C_\beta C_\alpha N = 109.6°$ and $\angle C_\alpha NC = 151.0°$.

An attempt was made to assign the microwave spectrum of the other rotamers which would give rather weak absorption lines, but it was unsuccessful. This may be partly because of the overlap of the lines of the vibrationally-excited states of the *cis* form with those of the *skew* or the *trans* form.

Vibrational Satellites. Satellite lines were observed around each rotational transition of the ground vibrational state. They spread from 300 to 500 MHz and have essentially the same Stark effect behavior and K series pattern as the corresponding ground state transitions. Evidently, these satellites are due to molecules in the vibrationally-excited states for which the effective moments of inertia are different from those for the ground states. Figure 4 illustrates the typical satellite pattern of the a-type transitions of $J=4\leftarrow3$. Two sets (set-I and set-II) of vibrationally-excited lines were assigned as shown in Table 1. The

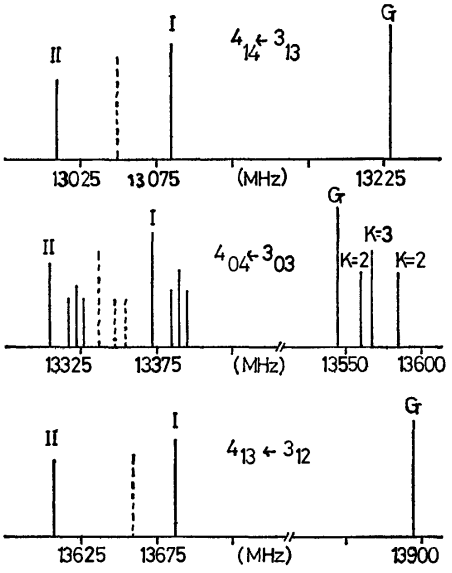

Fig. 4. Observed spectrum of $J=4\leftarrow3$ transitions showing vibrational excited satellite lines, I and II; dotted lines are unassigned lines.

Table 5. Far-infrared spectrum (cm^{-1})

CH_3NCS[a]	CH_3CH_2NCS	Assignment
(100)[b]	70(w)	C–N torsion
180.0	130(s)	CNC bend
	225(w)	C–C torsion
	380(s)	CCN bend (in-plane)[c]
440.0	450(m)	NCS bend (out-of-plane)[c]
569.0	540(s)	NCS bend (in-plane)[c]

Abbreviations: s, strong; m, medium; w, weak.
a) Ref. 15. b) Postulated value. c) Ref. 1.

effective rotational constants obtained for two vibrationally-excited states are given in Table 2.

Measurements of the relative intensities of the satellites with respect to the ground state line yielded vibrational frequencies 58±30 cm^{-1} for set-I and 107±30 cm^{-1} for set-II. Bands were observed at 70, 130 and 225 cm^{-1} in the far-infrared spectrum of ethyl isothiocyanate in the gas phase. Referring to Kniseley's assignment of the infrared spectrum[1] and to the study of methyl isothiocyanate,[15] these bands were assigned to the C–N torsion, CNC bending and C–C torsion modes, respectively, as shown in Table 5. Therefore, the vibrational satellite corresponding to 58 and 107 cm^{-1} can be ascribed to excited states of the C–N torsion and CNC bending modes, respectively. These assignments are supported by the fact that $\Delta'(I_c-I_b-I_a+8m_Hc_H^2)$ for set-I (out-of-plane vibration) has a negative value while the value of Δ' for set-II (in-plane vibration) is larger than that of the ground state[16] as shown in Table 2.

Dipole Moment. From the Stark coefficients of the transitions $4_{04}\leftarrow3_{03}$, $4_{14}\leftarrow3_{13}$, and $4_{13}\leftarrow3_{12}$, the dipole moment of the molecule was determined for both the ground and excited vibrational states. The second-order Stark coefficients determined for the eight Stark component lines and the dipole moment obtained are shown in Table 6. The electric field strength in the absorption cell was calibrated using

Table 6. Stark coefficients ($\Delta\nu/E^2$[MHz/(V/cm)^2]$\times10^{-5}$) and dipole moments

Transition	M	Ground state		Set-I CN torsion		Set-II CNC bend

μ_{total}(D)		3.33±0.03		3.38±0.03		3.50±0.05	

the value of the dipole moment of OCS, 0.71521 D.[7] The dipole moment determined for the ground state was $\mu_{total}=3.33\pm0.03$ D, with $\mu_a=3.33\pm0.03$ D and $\mu_b=0.07\pm0.02$ D. The μ_c component was assumed to be zero because of the plane symmetry as discussed above. The total dipole moment μ_{total} is compared with the value of 3.31 D obtained from dielectric constant measurements in a benzene solution.[8]

The authors wish to express their thanks to Prof. Hiroaki Takahashi and Dr. Norio Kaneko of Waseda University for the use of their Hitachi FIS-3 far-infrared spectrophotometer and for helpful discussions.

(Received December 16, 1975)

The crystal and molecular structure of *N*-carboxy anhydride(NCA) of glycine was determined from three-dimensional X-ray diffraction data. The crystals of glycine-NCA are monoclinic with space group C2/c and $Z=8$; the cell dimensions are $a=9.298(2)$, $b=5.156(2)$, $c=16.900(4)$ Å and $\beta=107.88(2)°$. A pair of molecules forms the dimer structure around a center of symmetry, with two N(1)–H(1)···O(1′) hydrogen bonds in the crystals.

Amino acid-NCA's are very often used for synthesis of polypeptides. The polymerization has been carried out not only in homogeneous system but also in heterogeneous system and crystalline state.[1-3]

Generally, it might be expected that polymers with unique structures may be produced in the crystalline state polymerization, the crystal structure of monomer affecting that of the resulted polymer.[4] There have been several studies about the crystalline state polymerization of amino acid-NCA's. Miller and his co-workers reported that *N*-benzyloxycarbonyl L-lysine-NCA could be polymerized by allowing it to stand in air.[5] Morawetz and his co-workers reported on the polymerization of some amino acid-NCA's by heating.[6] In both cases, however, the complete crystal structures of the NCA's were not determined and therefore, the investigation on the polymerization mechanism could not be done in detail.

We found that high-molecular-weight polypeptides were produced when the crystals of amino acid-NCA's were immersed in hexane (the non-solvent of both the monomer and polymer crystals) and triethylamine or *n*-butylamine was added into the system as the initiator.[7] It becomes necessary to know the crystal structures of the amino acid-NCA's to discuss their polymerizability.

In this paper, we shall report the crystal structure of the simplest amino acid-NCA, glycine-NCA.

Experimental

Powdered glycine (10 g : 0.132 mol) was dispersed in about 700 ml of purified tetrahydrofuran in a round-flask, and 9 ml (0.075 mol) of trichloromethyl chloroformate was added into it. The reaction mixture was allowed to stand at about 50 °C with stirring. After about 6 h the system changed to be clear, and subsequently the sovlent was evaporated up to about 50 ml at reduced pressure and room temperature. Hexane (about 100 ml) was added to the resultant mixture, and then crude crystalline material appeared. The crude crystals were dissovled in ethyl acetate up to saturated state at about 40 °C, and this solution was cooled down to −20 °C to obtain the purified crystals. After several times of this purification process, well-shaped crystals suitable for X-ray work were selected.

Oscillation and Weissenberg photographs taken with nickel-filtered Cu$K\alpha$ radiation indicated the crystals to be monoclinic and the possible space group C2/c or Cc (systematic absences: $h\,k\,l$, $h+k$ odd; $0\,0\,l$, l odd). The former was chosen on the basis of the E(normalized structure factor) statistics and confirmed by the structure analysis.

The density of the crystal was measured by a flotation mothod using the mixture of bromoform and hexane.

Table 1. CRYSTAL DATA OF GLYCINE-NCA

$C_3NO_3H_3$	$U=771.6(4)$ Å^3
M. W. : 101.06	Space group : C2/c
monoclinic	$Z=8$
$a=9.298(2)$ Å	$D_c=1.74$ g·cm^{-3}
$b=5.156(2)$	$D_m=1.74$ g·cm^{-3}
$c=16.900(4)$	μ(Mo$K\alpha$)$=1.940$ cm^{-1}
$\beta=107.88(2)°$	

All diffraction experiments were done within a few days after the crystallization, because the auto-polymerization took place conspicuously in two or three days, which was visible as white turbidity on the crystals.

A colorless prismatic crystal with approximate dimensions $0.4\times0.5\times0.7$ mm was mounted on a Rigaku automated four-circle diffractometer with the b axis nearly parallel to the ϕ-axis of the goniometer. Accurate cell parameters were obtained by the least-squares refinements with 29 high angle reflections. Crystal data are given in Table 1. The intensity data with 2θ less than 55° were collected by usual ω-2θ scans using Zr-filtered Mo$K\alpha$($\lambda=0.7107$ Å) radiation. A total of 887 independent reflections (783 of them were non-zero) were obtained.

Structure Determination

The position of the oxygen atom O(1) was obtained from an analysis of the Harker section (u 0 w) and the interatomic vector resulting from a center of symmetry on a three-dimensional sharpened Patterson function. Subsequently, Buerger's minimum function was calculated using the O–O vectors between four symmetry related atoms, and seven non-hydrogen atoms were located in this map, where the carbon and nitrogen atoms could not be distinguished clearly. Successive Fourier synthesis with the phases based on these seven atoms showed the position of the nitrogen atom.

Refinement by a block-diagonal least-squares method (HBLS V Program[8]) using anisotropic temperature factors was continued until the R-value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) dropped to 0.0683. At this stage, a difference Fourier synthesis map revealed the position of all hydrogen atoms. Finally, all the positional parameters together with the anisotropic temperature factors for the non-hydrogen atoms and the isotropic temperature factors for the hydrogen atoms are refined, and the R-value was reduced to 0.0428. A list of observed and calculated structure factors has

TABLE 2. FINAL ATOMIC COORDINATES AND THERMAL PARAMETERS FOR GLYCINE-NCA WITH THEIR ESTIMATED STANDARD DEVIATIONS

The anisotropic thermal parameters ($\times 10^5$) are expressed in the form:
$\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$
The isotropic thermal parameters of the H atoms are B/Å^2.

Atom	x	y	z	B_{11}(or B)	B_{22}	B_{33}	B_{12}	B_{13}	B_{23}

been deposited with the Chemical Society of Japan (Document No. 7613).

Results and Discussion

The final atomic coordinates and the thermal parameters are shown in Table 2. The perspective view of glycine-NCA molecule is shown in Fig. 1 together with the numbering of the atoms, the bond lengths and angles. The bond length C(1)–O(1) is 1.212(3) Å, slightly longer than the usual value. This might be caused by the hydrogen bond formed between N(1)–H(1) and O(1') as will be discussed later. The bond length C(1)–N(1) (1.326 Å) is shorter than C(3)–N(1) (1.449 Å), probably due to the resonance effect between the double bond of C(1)–O(1) and the lone-pair electrons of the N(1) atom.

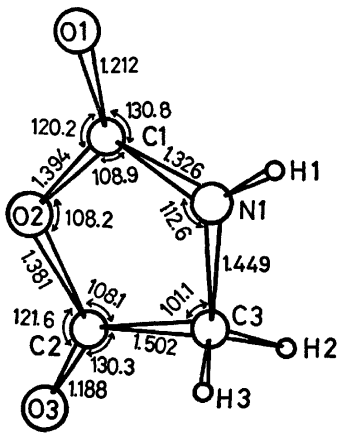

Fig. 1. A perspective view of glycine-NCA seen along the a axis with the numbering of the atoms, the bond lengths (l/Å) and angles (ϕ/°). The estimated standard deviations are 0.002—0.003Å in distances and 0.02° in angles.
The bond lengths involving hydrogen atoms are N(1)–H(1) 0.919(26), C(3)–H(2) 0.996(25) and C(3)–H(3) 0.986(25) Å.
The bond angles involving hydrogen atoms are C(1)–N(1)–H(1) 123.2(16), C(3)–N(1)–H(1) 124.2(16), N(1)–C(3)–H(3) 109.5(15), C(2)–C(3)–H(3) 107.0 (15) and H(2)–C(3)–H(3) 111.7(20)°.

TABLE 3. THE EQUATION OF THE LEAST-SQUARES PLANE THROUGH THE ATOMS IN GLYCINE-NCA

Equation	Atom	Deviation
$-0.8136X+0.5433Y+0.2071Z+3.3117=0$	C(1)	−0.002 Å
	C(2)	0.002
$X=ax+cz\cos\beta$	C(3)	−0.003
$Y=by$	N(1)	0.004
$Z=cz\sin\beta$	*O(1)	0.031
	*O(2)	−0.047
	*O(3)	0.037
	*H(1)	0.037
	*H(2)	0.770
	*H(3)	−0.864

* Atoms not included in the least-squares calculation.

Other bond lengths are normal and well agree with the corresponding values of maleic anhydride and succinic anhydride, respectively.[9,10]

The equation of the best plane through four atoms C(1), C(2), C(3) and N(1) in the five-membered ring of glycine-NCA was calculated and is shown in Table 3, together with the deviations of the atoms from the plane. The atoms C(1), C(2), C(3), and N(1) can be regarded to be coplanar, their maximum deviation from the plane being 0.004 Å. Both the exocyclic atoms O(1) and O(3) are slightly displaced out of the plane on the same side.

The packing of the molecules in the crystal viewed along the b axis are shown in Fig. 2. One can see a dimer joined together in a pair around a center of symmetry, by two N–H···O hydrogen bonds with a distance of 2.915(2) Å and the angle of N(1)–H(1)–O(1') 162(2)°.

Other intermolecular distances can be explained in terms of the packing of van der Waals type.

The authors wish to thank Professor Y. Sasada and his laboratory members at Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology for their help in many facets of this work,

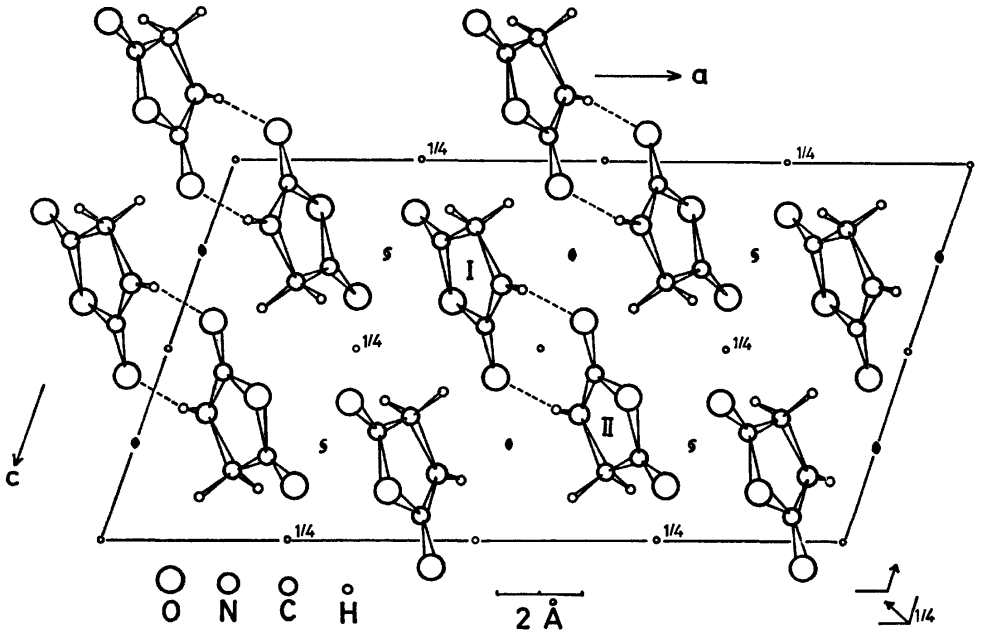

Fig. 2. Projection of the crystal structure of glycine-NCA along the b axis.

ESR Studies of Nitrobenzene Ion-Pair Equilibria in *N,N*-Dimethylformamide

Shinobu Toshima and Kingo Itaya

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received June 17, 1974)

The hyperfine splitting constants of the nitrobenzene radical anion in DMF vary with the type of the counter cations and the concentrations. The tendency of these variations is related to the shift of the half-wave reduction potential of nitrobenzene. The variation of the nitrogen ^{14}N hyperfine splitting constant is attributable to the formation of ion pairs involving the nitrobenzene radical anion and its counter cation. The ion-pair formation constants were evaluated from the changes in the hyperfine splitting and are completely consistent with those obtained from polarographic studies.

In recent years, ESR techniques have been extensively applied to studies of radical ions and ion pairs in the liquid phase, revealing detailed structure and kinetic information of the ion-pair systems.[1-3] In particular, discussions treating the equilibrium between a tight ion pair and a loose ion pair have been reported by a few workers[4,5] and the migrations of the cation in ion-pair systems have also been examined by many workers.[6-8] A large part of these investigations were carried out in solvents such as tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME), in which alkali metal hyperfine splitting (hfs) might arise from ion-pair systems of alkali metal ions and hydrocarbon radical anions. In these solvents, the observed hfs under normal conditions ($\sim 10^{-4}$ M) should be equal to that of the ion-pair system because large numbers of radical ions exist in the form of ion pairs due to the large value of the ion-pair formation constant, thus the existence of a free ion was not confirmed by ESR techniques.

On the other hand, in the solvents having a high dielectric constant, such as *N,N*-dimethylformamide (DMF) and acetonitrile, generally no alkali metal hfs has been observed in the ion-pair systems composed of hydrocarbon radical anions and alkali metal cations. This suggests that the studies on pairing in these solvents based on the hfs due to alkali metal cations are invalid. Furthermore, the observed hfs of the radical ions in these solvents is very close to that for free ions, which may be due to the small value of the ion-pair formation constant. For these reasons, the ion-pairing phenomena in solvents, such as DMF, are very difficult to discuss.

Since the variation in the nitrogen ^{14}N hfs of the nitrobenzene radical anion and its derivatives is very sensitive to the type of alkali metal cation and the concentration,[9-12] many workers have attempted to discuss ion pairing and solvent effects on the basis of the variation of the nitrogen hfs. Kitagawa *et al.* have reported qualitatively on the variation of the hfs of *p*-chloronitrobenzene radical anions with various counter cations and the concentrations of these in DMF.[27] However, the authors were unable to obtain quantitative results concerning the ion-pair equilibrium from their experimental results. Therefore, we discuss more quantitatively the variation of the hfs and obtain interesting quantities such as the ion-pair formation constant, the hfs of the free ion, and that of the ion pair.

The polarographic reduction waves of nitrobenzene are also highly affected by the type of supporting electrolytes as is shown in the paper of Holleck and Becher.[13] The polarographic techniques not only offer some information concerning the ion pair but also allow the present authors to determine the ion-pair formation constant and the coordination number in such solvents.

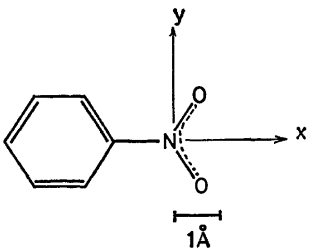

Fig. 1.

In this paper, the influence of alkali metal cations on the ESR spectra is dealt with and the structures of the ion-pair systems and the equilibrium between the free nitrobenzene radical anion and the ion pair composed of alkali metal cations is discussed. Quantitative correlations are drawn between the results obtained from the polarographic studies and those from the ESR studies.

Experimental

Materials. DMF was pre-dried with CaH_2 and was further dried over 4A and 5A molecular sieves in a vacuum. All salts, which were purified by recrystallization from aqueous solutions, were well dried in a vacuum (of less than 5×10^{-5} mmHg) for more than 24 h.

Nitrobenzene was used after additional degassing in a vacuum line and was stored in a graduated 0.5 ml pipet.

Tetrahydrofuran, which was used for the metal reduction of nitrobenzene, was refluxed over potassium metal and then distilled. The distillate was degassed five times in a vacuum and rigorously dried with the addition of sodium anthracenide to absorb trace amounts of moisture and oxygen.

The ESR spectra were measured with a Hitachi X-band ESR spectrometer model 771, employing field modulation at 100 kHz, while maintaining the room temperature at 21—23 °C.

Preparations of the Radical Anion. Electrolytic Reduction: In a solution containing 0.1 M of the supporting electrolytes, nitrobenzene radical anions were prepared by electrolytic reduction in a vacuum electrolytic cell with two Pt electrodes. The concentration of nitrobenzene was about 5×10^{-4} M in the present series of measurements, and a sample solution was electrolyzed carefully for more than 24 h to convert all nitrobenzene to its radical anion in the cavity of the ESR spectrometer. When the electrolyte was

lithium perchlorate, the selective production of the radical anion was so difficult due to the small difference between the first and the second waves in the polarogram that the preparation of the radical anions was carried out by the lithium metal reduction procedure.

Alkali-metal Reduction. Alkali-metal reduction in THF was carried out by the conventional method.[14] Sodium and potassium metals were purified in a vacuum (see Fig. 2) and the surface of the lithium metal was etched by treatment with a THF–nitrobenzene solution. The pieces were stored in a tube with a break-seal.

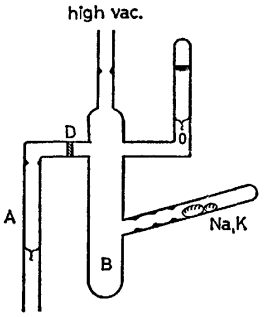

Fig. 2. The apparatus used for preparation of the radical anion.

After the preparation of the radical anion-THF solution, the solution was introduced into A through sintered glass D. The solvent was removed by distillation into a tube B using liquid nitrogen and tube B was sealed off. The solid metal nitrobenzenide was dissolved in DMF containing a given amount of salts. All experiments were carried out in a high vacuum line using break-seals.

Results

Hyperfine Splitting Constants Obtained in a Solution of 0.1 M Salt Concentration. Figure 3 shows the ESR spectra obtained in a solution of 0.1 M salt concentration. The sample solutions were prepared by the electrolytic reduction method excepting the 0.1 M lithium perchlorate solution. Lithium nitrobenzenide was prepared by the metal reduction method and was dissolved in a 0.1 M lithium perchlorate solution. A well-resolved ESR spectrum was obtained in a solution of 0.1 M TEAP, while those obtained in cesium and rubidium salts were extraordinarily broad. Table 1 shows the hfs obtained from an analysis of these spectra, which were confirmed by simulation using a JEOL spectrum computer, model JRA-5. The approximate line-widths ($\Delta H_{1/2}$) are also shown in the table. It was not possible to confirm the spectrum obtained in the solutions of cesium perchlorate and rubidium perchlorate with simulation owing to the broadening of the line-width.

In general, hfs due to the nucleus varies with the kind of salt. The variations of the nitrogen hfs ($\mathbf{a}_N$) and the proton hfs at the *para*-position ($\mathbf{a}_P$) were remarkably large. The values of $\mathbf{a}_N$ and $1/\mathbf{a}_P$ increased with decreasing radius of the cation. Thus, it is possible to compare the nitrogen hfs in the solutions of Li^+, Na^+, K^+, Cs^+ and Rb^+ in descending order (with the value for Cs^+ about the same as that for Rb^+), which is essentially the same as that obtained from the polarographic studies.

Variation of ^{14}N hfs with the Concentration of Counter Cations. Figure 4 shows the variations of the nitrogen hfs as a function of the concentration of the added salt, while maintaining the total ionic strength at 0.1 M with TEAP. The nitrobenzene radical anions were obtained by the metal reduction procedure, and were dissolved in a solution of arbitrary concentration of the added salt. The total concentration of the radical anions was less than 5×10^{-4} M for these experiments.

The variations of the nitrogen hfs show a regular shift in the concentration range of 10^{-3}—10^{-1} M for both sodium perchlorate and potassium nitrate. This behavior is the same as that for the *p*-chloronitrobenzene radical anion in DMF reported by Kitagawa *et al.*[27] However, no reports on the quantitative explanations to the change of the ^{14}N hfs, have apparently been published to date.

The origins of the curves indicate the hfs in a 0.1 M TEAP-solution containing about 5×10^{-4} M of the alkali metal cations. The values of the origins of the two curves are identical and equal to the hfs obtained in a 0.1 M TEAP-solution by the electrolytic reduction method without alkali metal cations. These results show that nitrobenzene radical ion pairs composed of sodium and potassium cations are almost dissociated in a solution of TEAP. We must also mention that the hfs in a 0.1 M TEAP-solution is completely consistent with the hfs obtained in a solution of alkali metal nitrobenzenide ($\sim5\times10^{-4}$ M) in the absence of TEAP. This result seems to indicate that the nitrobenzene radical anions are almost free in a solution of TEAP.

The variation of the nitrogen hfs is shown in Fig. 5 as a function of the concentration of lithium perchlorate.

Table 1. Proton and nitrogen hyperfine splitting constants of nitrobenzene radical anions in a solution with a 0.1 M salt concentration (in gauss)

Position[a]	$LiClO_4$	$NaClO_4$	KNO_3	$RbClO_4$[d]	$CsClO_4$[d]	TEAP
$\mathbf{a}_N$	11.36	11.12	10.50	10.0	≈10.0	9.62
$\mathbf{a}_p$	3.86	3.88	3.95	—	—	4.01
$\mathbf{a}_o$	3.40	3.38	3.35	—	—	3.36
$\mathbf{a}_m$	1.11	1.09_5	1.06	—	—	1.06

r_c[c]	0.60	0.95	1.33	1.48	1.69	—

a) $\mathbf{a}_N$; nitrogen hyperfine splitting constant. $\mathbf{a}_p$, $\mathbf{a}_o$, $\mathbf{a}_m$; *para*-proton hyperfine splitting constant, *etc.* b) Line-width (in gauss). c) Pauling's cationic radius (in Å). d) Still not completely confirmed by simulation.

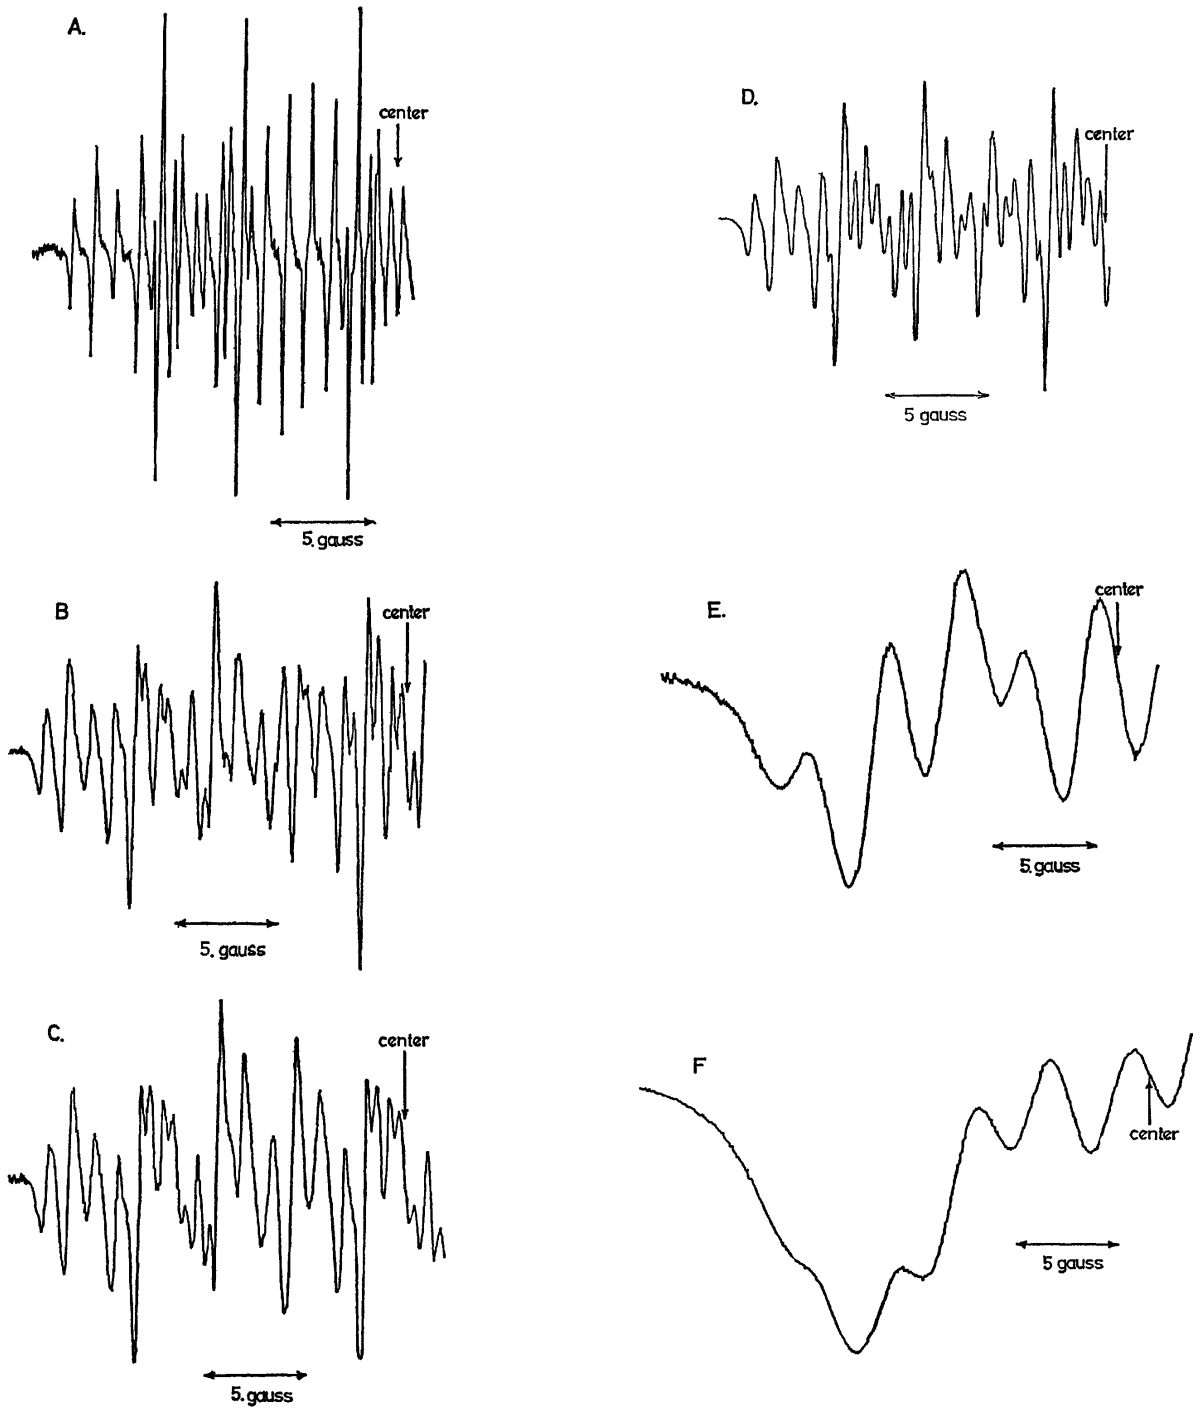

Fig. 3. The ESR spectra obtained in the solution of 0.1 M salt concentration.
A: 0.1 M TEAP, B: 0.1 M $LiClO_4$, C: 0.1 M $NaClO_4$,
D: $\approx$0.1 M (saturation) KNO_3, E: 0.1 M $RbClO_4$, F: 0.1 M $CsClO_4$.

ESR spectra obtained in the region of lower concentration of lithium perchlorate are shown in Fig. 6 and the outlined spectrum simulations are also displayed as stick diagrams. Obviously, the spectra due to two different species are superimposed in these spectra, that is, the two different species are the ion pairs and the free ions, respectively. The relative intensities due to the free ions decrease with increasing concentration of lithium perchlorate. In the region of lower concentration of the salt, the nitrogen hfs due to the ion pair decreases with increasing concentration of the salt. On the other hand, the hfs due to the free ions increases with an increase of the concentration of the salt, as shown in Fig. 5. Thereafter, the hfs increases monotonically with the concentration of sodium and potassium ion pairs, as shown in Fig. 4.

In an infinitely-dilute solution (of less than 5×10^{-4}M), the ESR spectrum consisted of the free ion and the nitrogen hfs coincided with that obtained in a solution of TEAP, as in the studies of the sodium and potassium

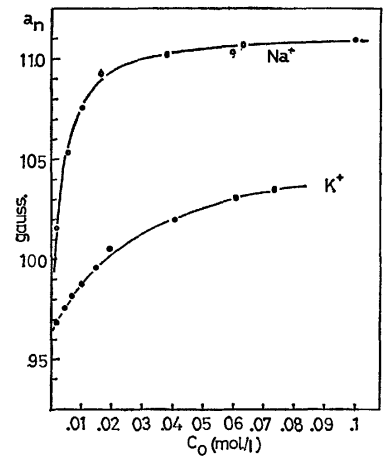

Fig. 4. Variation of the nitrogen hfs with the concentration of the metal cations. Total ionic strength kept formally at 0.1 M.

nitrobenzenide systems.

In the region of high concentration of lithium perchlorate, the ESR spectra also consisted of a single species, the ion pair.

Discussion

Perturbation of the Distribution of Unpaired Spin Densities. As stated above, it is possible to compare the nitrogen hfs in the solutions of Li^+, Na^+, K^+, Cs^+ and Rb^+ in descending order. It seems that the radius of the alkali metal cation may be responsible for this order.

The interactions between the radical anions and the counter cations have been formulated by Huch and Rowland,[15] and McClelland.[16] Since the McClelland theory based on the Hückel approximation is of a simple form, its application to aromatic radical anions and their derivatives has been carried out by many workers.[17–20] Takeshita and Hirota[21] modified the cationic field effects to the following effective Hamiltonian (H'_{eff}):

$$H'_{\mathrm{eff}} = H^0_{\mathrm{eff}} - \frac{Ze^2}{\varepsilon(r)r} \qquad (1)$$

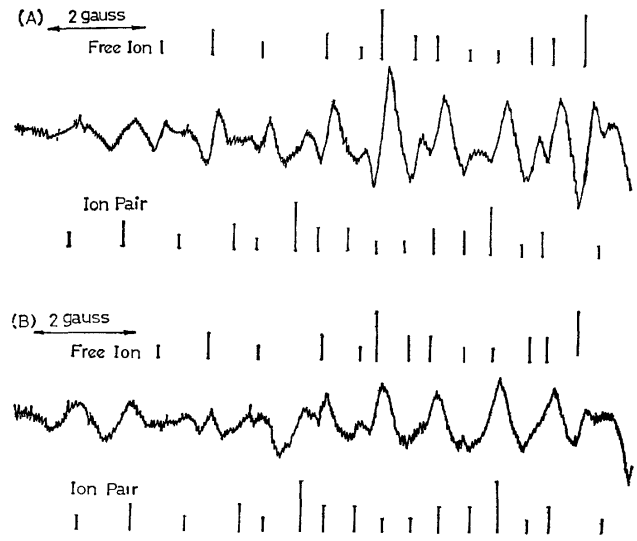

Fig. 6. ESR spectra obtained in the solution of lithium perchlorate.
The stick diagrams indicate the splittings of the ion pair and free ion.
A) In a solution of 5.1 mM lithium perchlorate.
B) In that of 8.8 mM lithium perchlorate.

where $\varepsilon(r)$ is a screening factor which accounts for the screening effects of the solvent in the cationic fields. The solvent effect on the hfs can be taken into account with this screening parameter. In the present calculations of the perturbation energy and the variations of the spin density, some values of the screening parameter have been applied.

The dimensions of the radical anion and the parameters of the Coulomb and exchange integrals were choosen to be as follows:[22]

aromatic C-C=1.39 Å	$\delta\alpha_O = 1.4\beta$
aromatic angle=120°	$\delta\alpha_N = 2.2\beta$
C-N=1.49 Å	$\beta_{NO} = 1.67\beta$

All overlap integrals were neglected in the sense of simple Hückel approximation. From the extensive calculations of the interaction energy, the time averaged position of the cation is determined on the X-axis of the coordination system as shown in Fig. 1. This conclusion agrees with the case of 4-nitropyridine *N*-oxide anion radicals in DME reported by Kawamura *et al.*[23] The interaction energy, when the dielectric constant of DMF is used as the screening factor, is less than that when the factor is equal to 1. However, the minimum points of the potential surfaces are consistent with each other.

The unpaired spin densities of each position were calculated using the method of McClelland with the McLachlan approximate configurational interaction treatment,[24] assuming the cations approach the nitrobenzene radical anions along X-axis.

The calculations of the hfs of ring protons ($\mathbf{a}_H$) were carried out using the following generally applied equation:[25]

$$\mathbf{a}_{II} = -Q \cdot \rho_C^{\pi} \quad (2)$$

where Q is taken to be 27.3

On the other hand, the nitrogen hfs were theoretically calculated using the following equation, which was given by Rieger and Fraenkel:[26]

$$\mathbf{a}_N = 99.0 \cdot \rho_N^{\pi} - 2 \times 35.8 \cdot \rho_O^{\pi} + 17 \cdot \rho_C^{\pi} \quad (3)$$

in which ρ_N^{π}, ρ_O^{π}, and ρ_C^{π} are the π-electron spin densities at the nitrogen, oxygen and adjacent carbon atoms, respectively. In the present calculations of the spin densities, the parameter λ in the procedure of McLachlan was set at 1.2.

Figure 7 shows the calculated hfs of the *para*-proton and nitrogen which are greatly affected by the distance of closest approach of the cations, assuming the screening parameter to be 37.0. The hfs of the *meta*- and *ortho*-protons are apparently not changed by the distance of closest approach of the cations. The nitrogen hfs increases with the decrease in the distance of closest approach of the cations. On the other hand, the *para*-proton hfs shows the opposite tendency. The same observations were made for the cations when the screening parameter was nearly equal to the dielectric constant of DMF. However, when the screening parameter was chosen to be 1, as has often been done by other workers,[3,20] the variations of the nitrogen hfs became extraordinarily large.

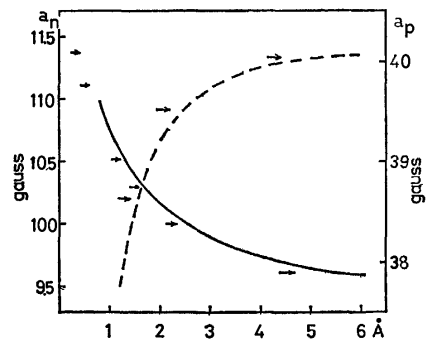

Fig. 7. The calculated hfs of the *para*-proton and nitrogen assuming $\varepsilon(r)=37.0$. The cation is on the X-axis. The arrows indicate the observed value in the solution of 0.1 M salt concentration (Table 1).

Takeshita and Hirota have concluded that the screening parameters in contact ion-pair systems are closer to the macroscopic dielectric constant than to 1.[21] Although detailed information about the ion-pair structures has not been obtained at the present stage of these investigations, it seems to be a reasonable approximation to set the value of the screening parameter in the vicinity of the dielectric constant of DMF. More detailed discussions of the structure of ion pairs will now be presented on the basis of the present research.

It can be semi-quantitatively explained from the above calculations that nitrogen hfs in solutions of Li^+, Na^+, K^+, Cs^+, Rb^+, and Et_4N^+ can be arranged in this descending order. That is, the smaller the radius of the cation, the closer the cation can approach the radical anion of nitrobenzene.

Discussion of Ion-Pair Equilibria. Sodium and Potassium Ion-Pair Equilibria: The above discussion was limited to the observed hfs obtained in solutions with a constant salt concentration (0.1 M). However, the ion-pair formations must be rigorously discussed on the basis of equilibrium considerations.

The regular shifts of the nitrogen hfs as a function of the concentration of the added salts, as shown in Fig. 4, are discussed considering the next equilibrium between the free ions and ion pairs:

$$(A^{\cdot-}, M^+)_{IP} \rightleftharpoons A_f^{\cdot-} + M^+, \quad (4)$$

where $A_f^{\cdot-}$ is the free nitrobenzene radical anion, $(A^{\cdot-}, M^+)_{IP}$ the ion pair and M^+ the counter cation.

The coordination number in the sodium nitrobenzenide ion ion-pair system has been proved to be 1 from polarographic studies. Although the number in the potassium nitrobenzenide ion-pair system was not determined exactly by means of polarography, the discussion of this system is continued assuming the coordination number to be 1.

One can expect that the ion pairs and free ions have different hfs and that the variations of the ring proton hfs are less than those for nitrogen. It is possible to interpret the regular shift of the nitrogen hfs as a function of the concentration of the added salt, based on the rapid equilibrium of reaction (4), assuming that the ring proton hfs does not change for the two different states, *the ion pair* and *the free ion.*

In general, if the forward and backward reaction rates of reaction (4) are slow, the spectrum will consist of two separate signals which are obtained in a solution of lithium perchlorate as described above. If they are rapid, only one signal will appear at an approximately averaged position. In the case of the sodium and potassium nitrobenzenides, the nitrogen hfs showed a regular increase with an increase of the concentration of the counter cation and all ESR spectra could be simulated by one species. These results indicate that the equilibrium of reaction (4) in these cases are in the limit of the rapid exchange region.

According to the two-jump model, the observed nitrogen hfs ($\mathbf{a}_{ob}$) in the limit of rapid exchange between two states is given by:[28,29]

$$\mathbf{a}_{ob} = \frac{\tau_f}{\tau_f + \tau_{IP}} \cdot \mathbf{a}_f + \frac{\tau_{IP}}{\tau_f + \tau_{IP}} \cdot \mathbf{a}_{IP}, \quad (5)$$

where τ_f and τ_{IP} are the lifetimes of the free ions and ion pairs, respectively. Using the rate constants of the forward and backward reactions, the reaction rates are given by the following equations:

for the forward reaction:

$$v_f = \frac{[(A^{\cdot-}, M^+)_{IP}]}{\tau_{IP}} = k_1 \cdot [(A^{\cdot-}, M^+)_{IP}], \quad (6)$$

for the backward reaction:

$$v_b = \frac{[A_f^{\cdot-}]}{\tau_f} = k_{-1} \cdot C_{M^+} \cdot [A_f^{\cdot-}], \quad (7)$$

where $[A_f^{\cdot-}]$, C_{M^+} and $[(A^{\cdot-}, M^+)_{IP}]$ are the concentrations of these species. The ion-pair formation constant for reaction (4) is given by

$$K_f = \frac{k_{-1}}{k_1} = \frac{\tau_{IP}}{\tau_f \cdot C_{M^+}}. \quad (8)$$

When Eq. 8 is substituted into Eq. 5, Eq. 5 can be rewritten as

$$\mathbf{a}_{ob} = \frac{1}{1+K_f \cdot C_{M^+}} \cdot \mathbf{a}_f + \frac{K_f \cdot C_{M^+}}{1+K_f \cdot C_{M^+}} \cdot \mathbf{a}_{IP}. \quad (9)$$

If $\mathbf{a}_{ob}$ is normalized as follows:

$$\mathbf{a}_{ob} = \frac{\mathbf{a}_{ob}-\mathbf{a}_f}{\mathbf{a}_{IP}-\mathbf{a}_f}, \quad (10)$$

Eq. 10 can be expressed in the simple form

$$\bar{\mathbf{a}}_{ob} = \frac{K_f \cdot C_{M^+}}{1+K_f \cdot C_{M^+}}. \quad (11)$$

On the other hand, Eq. 9 can also be transformed into:

$$\frac{1}{\mathbf{a}_{ob}} = \frac{1}{K_f \cdot \mathbf{a}_{IP}} \cdot \frac{1}{C_{M^+}}\left(1-\frac{\mathbf{a}_f}{\mathbf{a}_{ob}}\right) + \frac{1}{\mathbf{a}_{IP}}. \quad (12)$$

For exact arguments concerning the regular increase of the nitrogen hfs from Eq. 12, it is necessary to assume the following approximations.

1. The concentrations of the cation are equal to that of the salt, if the dissociation constant of the salt is large, *i.e.*, $C_{M^+}=C_o$, where C_o is concentration of the salt.

2. Nitrogen hfs of the free nitrobenzene radical anion is equal to that obtained in a 0.1 M solution of TEAP, *i.e.*, $\mathbf{a}_f=9.62$ ($\pm$0.01) gauss.

The second approximation seems to be almost correct as was discussed above.

From a plot of the inverse of the observed nitrogen hfs ($1/\mathbf{a}_{ob}$) *vs.* $1/C_{M^+}\cdot(1-\mathbf{a}_f/\mathbf{a}_{ob})$, the hfs of the ion pairs and the ion-pair formation constants can be obtained by determining the intercept and the slope of the straight-line, respectively.

Figure 8 shows the plot for the solutions of sodium perchlorate. A straight-line is found over the wide concentration range of 1×10^{-3}—10^{-1} M. The hfs of the ion pairs and the formation constant were determined from the intercept and the slope by least-squares calculations, respectively. The nitrogen hfs of the ion pair is equal to $\mathbf{a}_{IP}=11.23$ ($\pm$0.03) gauss, and the formation constant was calculated to be $K_f=220$ ($\pm$5) 1/M from the slope with $\mathbf{a}_{IP}$ obtained from the intercept. It is particularly noteworthy that the

formation constant of the sodium nitrobenzenide system, as determined from the variation of the nitrogen hfs is completely compatible with that obtained from polarographic studies (200 $\pm$20 l/M) to within the experimental error. (Detailed discussions of the polarographic studies will be published elsewhere.) This coincidence seems to be most important argument in this paper. It strongly supports the approximate correctness of the present treatment of the regular increase of the nitrogen hfs. Figure 9 shows the normalized hfs $\mathbf{a}_{ob}$ as a function of the concentration of the counter cation (C_{M^+}) for the various formation constants. The curves in Fig. 9 are in qualitative accordance with the regular shifts of the nitrogen hfs as shown in Fig. 4. The experimental points obtained for the sodium nitrobenzenide system are also plotted in the same figure.

It is also important that the hfs of the ion-pair itself can be evaluated from the above discussion in solvents having a high polarity, such as DMF, because this quantity is useful for discussions of the structure of the ion pairs. The present paper is the first report in which the hfs of the ion-pair itself was determined in a high polar solvent.

Since potassium nitrate does not have a large dissociation constant in DMF, the concentrations of the potassium ions must be calculated. Although there is some question as to the validity of using the dissociation constant ($K_d=0.043$ l/M) reported by Ames and Sears[30] for this purpose, the concentrations of the ion were calculated.

Figure 10 shows the plots of $1/\mathbf{a}_{ob}$ *vs.* $1/C_{M^+}\cdot(1-\mathbf{a}_f/\mathbf{a}_{ob})$ and $1/C_o\cdot(1-\mathbf{a}_f/\mathbf{a}_{ob})$ which give straight lines. The difference in the linearity of the two lines is not significant. But the standard deviations of the slope and intercept of the plot with the potassium nitrate concentration are less than that of the plot as a function of the concentration of potassium ions. The hfs of the ion pair is equal to $\mathbf{a}_{IP}=10.99$ ($\pm$0.05) gauss, and the formation constant was determined to be $K_f=30$ ($\pm$6) 1/M, from the slope and intercept of the line with the concentration of potassium ions. On the other hand, the hfs and the formation constant can also be

determined from the plot as a function of the potassium nitrate concentration, as summarized in Table 2.

Lithium Ion-Pair Equilibrium: As shown in Fig. 6, the ESR spectra obtained in the solutions of lower concentration of lithium ions (of less than 10^{-2} M) are a superposition of the two spectra due to the free ions and ion pairs. In this region, the exchange reaction (4) is a "*slow exchange*" reaction in the sense of magnetic resonance spectroscopy. In general, the spectrum consists of two separate signals when the reaction rates for reaction (4) are small, as stated above.

From the solution of the modified Bloch equation for the two-jump model, the ratio of the separation between the positions of the two maxima (Δ) to that when the exchange between the two states does not exist (Δ_0) is given by:[31]

$$\frac{\Delta}{\Delta_0}=\left[1-\frac{1}{2\cdot\pi^2\cdot\tau^2\cdot(\nu_{IP}-\nu_f)^2}\right]^{1/2}, \qquad (13)$$

assuming that the lifetimes of ion pairs and of the free ions are equal to each other, *i.e.*, that $\tau_{IP}=\tau_f=2\cdot\tau$, and that the inverse of the transverse relaxation times are negligibly small. ν_{IP} and ν_f are the resonance frequencies of the two states, respectively.

Equation 13 means that the greater the difference between the resonance frequencies of the ion pair and the free ion, the greater the decrease in the critical lifetime at which the two signals merge into only one signal. In other words, when the difference of the resonance frequencies is large, the spectrum will consist of two separate signals, even if the exchange reaction rate is relatively large. As shown in Table 1, the nitrogen hfs is highest in the solution of lithium perchlorate. Therefore, the difference between the resonance frequencies of the ion pair composed of lithium cations and the free ions is largest in the present experiments. The exchange rates of reaction (4) are accelerated with increasing concentration of lithium perchlorate, and the resonance lines merge into a single line in the intermediate exchange region.

In the region showing a regular increase of the nitrogen hfs as in Fig. 5, the equilibrium reaction is in the range of the rapid exchange as mentioned above.

Equation 12 was examined in order to determine the ion-pair formation constant and the nitrogen hfs of the ion pair in the rapid exchange region. Figure 11 shows the plot of $1/a_{ob}$ with $1/C_M{}^+\cdot(1-a_f/a_{ob})$. The variations of the nitrogen hfs in the region of rapid exchange are not so large, and the error of the hfs becomes of importance in the accuracy of the formation constant and the hfs of the ion pair. Analyzing the linear relation using the least-squares method, the hfs of the ion pair itself and the formation constant are $a_{IP}=11.36$ (±0.03) gauss and $K_f=340$ (±40) 1/M, respectively. The formation constant determined here is somewhat larger than that determined by polarographic techniques, as shown in Table 2. The accuracy of the formation constant using ESR

techniques is not satisfactory because the change of the nitrogen hfs in the rapid exchange region is not large enough, as shown in Fig. 5. For this reason, the formation constant determined from the variations of the hfs appears to be approximately consistent with that obtained using polarographic techniques, which will be described in detail elsewhere.

The formation constants of the ion pairs between nitrobenzene radical anions and cesium and rubidium cations could not be determined because the line-width of the spectra in the solutions of these salts were extraordinarily large, as is seen in Fig. 3.

We found that the line-widths associated with the nitrogen nuclear spin quantum number $m_z=\pm 1$ were larger than that for $m_z=0$. The line-width broadening effects in the ESR spectra are now under study, a part of the results of which will be reported in the near future.

Summary

The ion pair formation constants, the nitrogen hfs of the ion-pair itself, and the coordination numbers are summarized in Table 2.

In the case of the lithium ion pair, the variations of the nitrogen hfs in the fast exchange region are so small that the formation constant obtained by polarographic techniques seems to be more correct than that obtained using ESR.

The formation constants of the sodium ion pair system obtained from both studies are completely consistent with each other.

The authors wish to thank Professors T. Isobe and M. Matsuda, and Assistant Professors M. Iwaizumi and Y. Ikegami for their kind direction throughout the course of this work.

S_2 Formation during the Pyrolysis of H_2S in Shock Waves

Tetsuo HIGASHIHARA, Ko SAITO, and Hitoshi YAMAMURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received April 28, 1975)

The rate of S_2 formation from shock-heated H_2S was measured by means of the UV absorption technique in the temperature range of 2380—3000 K. At all the temperatures measured, the S_2 absorption during the reaction could be represented by $(S_2)_t=(S_2)_\infty\{1-\exp(-kt)\}$, where:

$$k=10^{9.2}\exp(-72\ \text{kcal}/RT)\ \text{s}^{-1}.$$

The mechanism of the S_2 formation was proposed, and the value of the second-order rate constant, k_1, for the primary reaction, $H_2S+M\rightarrow SH+H+M$, was estimated as follows:

$$k_1 = 10^{13.1}\exp(-92\ \text{kcal}/RT)\ \text{l mol}^{-1}\ \text{s}^{-1}.$$

The effects of the addition of NO and O_2 on the rate of S_2 formation were also investigated. The results showed the validity of the proposed reaction mechanism.

The thermal decomposition of H_2S was studied by a static method by Darwent *et al.*[1] in pure H_2S at pressures between 30 and 300 Torr and in the temperature range of 720—970 K. At the temperatures above 900 K, they found that the reaction was second-order with respect to the concentration of H_2S and that its apparent activation energy was about 50 kcal/mol. The reaction was suggested to be $2H_2S\rightarrow 2H_2+S_2$. In shock waves at temperatures above 1000 K, on the other hand, the primary s.ep of the decomposition of H_2S, which is diluted in an inert gas, may be considered to be as follows:

$$H_2S + M \rightarrow SH + H + M \qquad (1)$$

such as has been reported for the other triatomic molecules. However, no data about the pyrolysis of H_2S in shock waves have been reported, although in the oxidation of H_2S Reaction (1) was recognized to be the primary step.[2] It was then stated that the difficulty in the evaluation of the kinetic data for Reaction (1) was due to the effects of oxygen and other oxidizers which could not be removed from the reactant.[3] In this work, we observe the rate of the S_2 formation from shock-heated H_2S in Ar by using a reactant purified carefully, and discuss the mechanism of the H_2S decomposition.

Experimental

The experiments were conducted in a 5-cm-diameter shock tube with a 4.3-m-long test section. The shocks were generated by high-pressure hydrogen in a 1.7-m-long driver section. The system was pumped by an oil-diffusion pump to less than 1×10^{-4} Torr before each run. All the measurements were made behind the incident shock waves. The light source used for the absorption measurements was a 300W Xe lamp (Ushio Electric Co.). The light was focused with a mirror on the entrance slit of a monochromator (Jarrell-Ash, 0.25 m) which had been placed on the side opposite the light source with respect to the shock tube. The selected light was detected by a photomultiplier (MS9SY), whose output was recorded on a single sweep of an oscilloscope. The rise time of the electronics was 2 μs or less. The concentration of S_2 was followed by observing the absorption intensity at 320 nm ($^3\Sigma_g^-\rightarrow{}^3\Sigma_u^-$ system). Although the SH absorption band lies around 320 nm, the measured absorption at this wavelength was attributed to S_2, since the absorption due to SH was negligibly small compared to the strong absorption of S_2.[4]

Hydrogen sulfide was produced by dropping a saturated NaS aqueous solution into a 10% H_2SO_4 aqueous solution and was dried by passing it through calcium chloride and phosphorus pentoxide. The gas thus obtained was solidified and degassed at −115 °C (mp of EtOH) and then purified by fractional distillations between −115 °C and −196 °C. Mixtures of 5%H_2S–95%Ar, 5%H_2S–1%NO–94%Ar, and 5%H_2S–1%O_2–94% Ar were prepared and kept in 8-l flasks for more than 12 hr before use.

The experimental conditions were as follows: P_1=8—16 Torr, P_2=300—460 Torr, T_2=2380—3000 K and ρ_2(total density)$=(3.2—6.2)\times10^{-6}$ mol/cm^3, where the subscript 2 denotes the condition just behind the shock front (chemically frozen condition).

Results and Discussion

Rate of S_2 Formation. In preliminary experiments, it was found that the rate of the S_2 formation was greatly influenced by trace amounts of oxygen. Therefore, the purification of H_2S was carefully performed in the manner described in the experimental section. For the mixture of 5%H_2S–95%Ar, no induction period of the S_2 formation was observed over the temperature range measured. A typical oscilloscopic trace of S_2 absorption is shown in Fig. 1 (a). The variation in the concentration of S_2 with the time was expressed by the following relation:

$$\ln\{(S_2)_\infty/((S_2)_\infty-(S_2)_t)\} = kt \qquad (I)$$

where $(S_2)_\infty$ denotes the concentration of S_2 at the steady state, which is reached within the observation time. In Fig. 1(b), a plot of the value of the left-hand side of Eq. I is shown as a function of the laboratory time. The experimental conditions and the values of k determined from the above relation are listed in Table 1. The Arrhenius plots of k are shown in Fig. 2, where the data obtained in preliminary experiments are also included for comparison (lines (a) and (b)). In the preliminary experiments, samples were purified by solidifying, degassing, and distilling by using liquid N_2 and were used without further purification. Therefore, it is thought that slight amounts of air were still present in the samples. From this figure, it appears that trace amounts of an impurity accelerate the rate

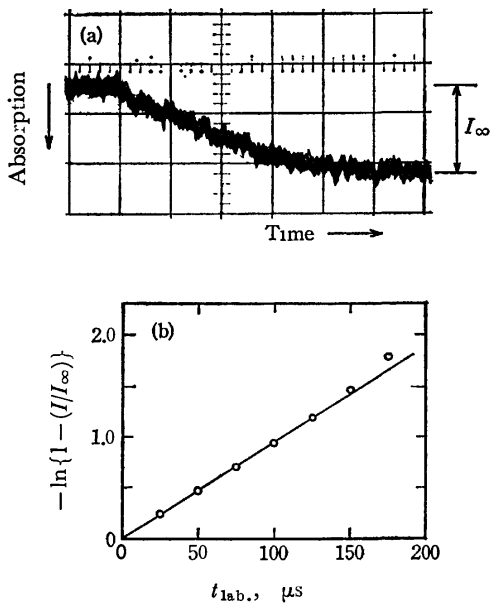

Fig. 1. (a): Sypical oscilloscopic trace of S_2 absorption at 320 nm, 5% H_2S–95% Ar; T_2=2570 K; sweep time=50 μs/cm. (b): Plot of $-\ln\{1-(I/I_\infty)\}$ *vs.* laboratory time.

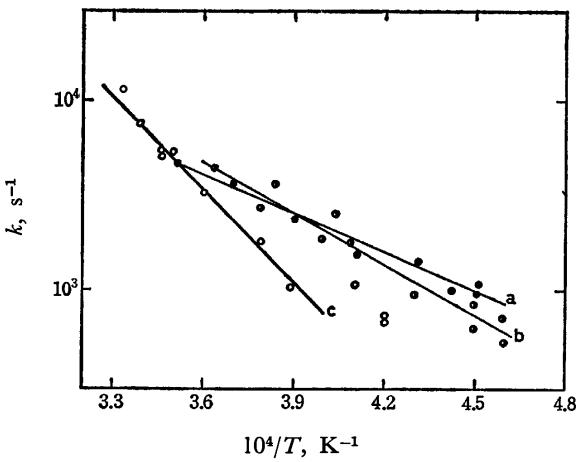

Fig. 2. Arrhenius plots of the rate constant k for S_2 formation. Data around lines (a) and (b) were obtained in preliminary experiments for 5% H_2S–95% Ar mixtures. Data around line (c) were obtained in this experiment for 5% H_2S–95% Ar mixture.

of S_2 production. The data obtained in this experiment, corresponding to the most purified H_2S, show a large temperature dependence compared with the other two sets of data, (a) and (b). The best fitting straight line (c) gives the following expression in the temperature range of 2500—3000 K:

$$k = 10^{9.2}\exp(-72\ \text{kcal}/RT)\ \text{s}^{-1}.$$

In Fig. 3, the values of $\{\ln(I_0/I_e)\}/(H_2S)_0$ are plotted as a function of T, where I_e is the light intensity at the equilibrium and where the subscript o denotes the condition just behind the shock front. Since the extinction coefficient of S_2 does not vary with the temperature,[5] it appears that the quantity of S_2 produced from the unit concentration of H_2S is almost constant over the temperature range measured. This fact means that the recombination of S atoms does not play a dominant role in the S_2 formation because the composition between S_2 and S at the equilibrium, $S_2 \rightleftarrows 2S$, varies largely with the temperature in the range considered.

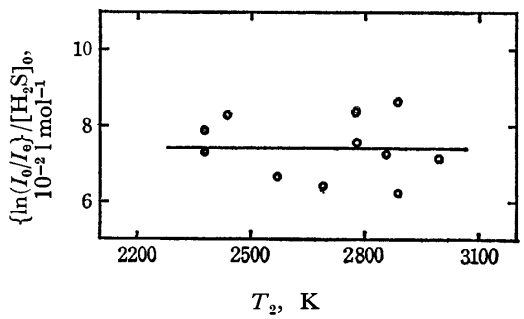

Fig. 3. Plot of $\{\ln(I_0/I_e)\}/(H_2S)_0$ against temperature, where I_0 and I_e are transmitted light intensities at shock front and at equilibrium, respectively.

A possible mechanism of the pyrolysis of H_2S accompanying the S_2 formation is considered to be as follows:

	ΔH°_{298} (kcal/mol)[6]	
$H_2S + M \rightarrow H + SH + M$	90.9	(1)
$H_2S + H \rightarrow H_2 + SH$	−13.3	(2)

$2SH \rightarrow H_2S + S$	− 6.1	(3)
$H_2S + S \rightarrow 2SH$	6.1	(−3)
$2SH \rightarrow H_2 + S_2$	−37.3	(4)
$SH + H \rightarrow H_2 + S$	−19.4	(5)
$SH + S \rightarrow H + S_2$	−17.9	(6)

From the above reaction scheme and the observed result that there existed no induction time for the S_2 formation, it is assumed that the consumption of the intermediates, H, SH, and S, is very rapid compared with their production rate through the primary reaction. Therefore, it is reasonable to use the steady-state method for these radicals. Also, we assume that $(S_2)_\infty = C(H_2S)_0$ and $(S_2)_\infty - (S_2)_t = C(H_2S)_t$, where C is a constant. With these relations, Eq. I is rewritten as:

$$\ln \{(H_2S)_0/(H_2S)_t\} = kt \qquad \text{(II)}$$

It appears that k is the first-order rate constant for the overall reaction of H_2S consumption.

For the S_2 formation in the H_2S pyrolysis, we do not have knowledge about which reaction is dominant under those experimental conditions. Reaction (4) was proposed for the flash photolysis of H_2S by Norrish *et al.*[7] On the other hand, Reaction (6) was proposed by Cullis *et al.*[8] in their review of the combustion of sulfur compounds, on the basis of the reason that the latter is much faster than the former in spite of its lower exothermicity. Also, in the discharge flow system of $H+H_2S$,[9] Reaction (6) was taken as a dominant reaction of S_2 formation. In any event, if the steady-state assumption is used for the intermediates, the following conclusion can be obtained whether Reaction (4) or (6) is taken as the main process of S_2 formation. That is, the overall rate of the H_2S decomposition becomes twice the primary reaction rate, as:

$$-\mathrm{d}(H_2S)/\mathrm{d}t = 2k_1(H_2S)(M) \qquad \text{(III)}$$

Since, in this experiment, the concentration (M) does not vary with the time behind the shock front, the second-order rate constant, k_1, can be determined from Eqs. II and III. The Arrhenius plots of k_1 are shown in Fig. 4, where the preliminary data (corresponding to Lines (a) and (b) in Fig. 2) are also included. It appears that the effects of impurities become apparent at lower temperatures and that, even for the most purified mixture, the data below 2500 K become higher than the (c) line, the one most suitable for the data above 2500 K. It has been shown in the pyrolysis of H_2O and SO_2 that, under the conditions of relatively lower temperatures and higher concentrations of the reactant, the systems involved many bimolecular reactions and that, as a result, the mechanisms were complicated. This seems to hold also for the pyrolysis of H_2S. Thus, the following expression for k_1 was evaluated from the data above 2500 K:

$$k_1 = 10^{13.1} \exp(-92 \text{ kcal}/RT) \text{ l mol}^{-1} \text{ s}^{-1}.$$

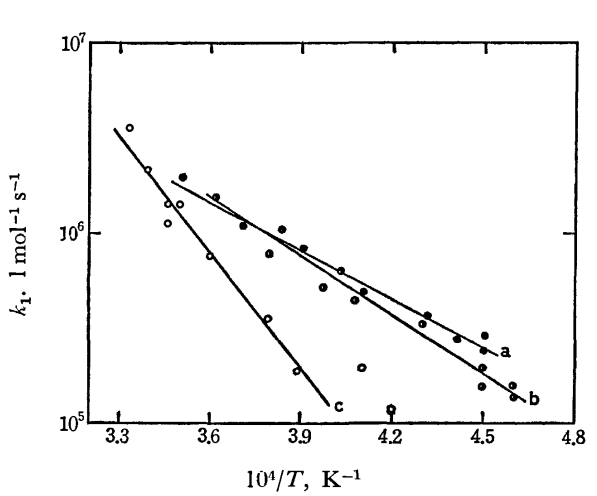

Fig. 4. Arrhenius plots of k_1. Lines (a) and (b) correspond to the preliminary experimental data for 5% H_2S–95% Ar mixtures. Line (c) corresponds to this experiment.

Effects of NO and O_2. When a mixture of 5% H_2S+1% NO+94% Ar was shock-heated, it was found that the rate of S_2 formation slowed down extremely. Because of the large effect of NO, the value of k could not be determined for this mixture. This effect suggests that NO acts as a scavenger of radicals. As has been proposed by Bradley *et al.*[10] in the experiment on the $H+H_2S$ flow system, the following reaction is thought to occur in our system also:

$$SH + NO \rightarrow (SHNO)^* \rightarrow \text{removal of SH} \qquad (7)$$

Furthermore, the following reactions may occur to eliminate H atoms from the system:

$$H + NO + M \rightarrow HNO + M \qquad (8)$$

$$H + HNO \rightarrow H_2 + NO \qquad (9)$$

much like the elimination of S atom observed in the photolysis of CS_2 and COS,[11] but at high temperatures these reactions are thought to be less important than Reaction (7).

As is shown in Figs. 2 and 4, in the presence of trace amounts of impurities the rate of S_2 formation was accelerated in the lower-temperature region. The most effective species is thought to be oxygen, which could not be removed from the sample in the usual manner. In the experiment on the 5% H_2S+1% O_2+94% Ar mixture, it was found that the rate of S_2 formation was further accelerated. This can be explained by adding the following bimolecular reactions to the above reaction Scheme 1—6:

$$H + O_2 \rightarrow OH + O \qquad (10)$$

$$H_2S + O \rightarrow SH + OH \qquad (11)$$

$$H_2S + OH \rightarrow SH + H_2O \qquad (12)$$

These reactions contribute to the formation of the SH radical. Thus, the effects of the addition of both NO and O_2 qualitatively support the above reaction scheme proposed for the decomposition of H_2S, although, from this study, it is not apparent whether the main reaction of S_2 formation is Reaction 4 or 6.

On the Value of k_1. Our experimental result for k_1 can be expressed by the equation of the collision theory: $k_1 = \{pZ(D/RT)^{s-1}/(s-1)!\}\exp(-D/RT)$, where p is the steric factor; Z, the collision frequency; s, the number of effective vibrations in the molecule, and D, the critical energy for HS–H bond dissociation. According to the absorption spectrum of H_2S[12], there

exists a continuum band with a maximum at about 51000 cm^{-1} and extending to 37000 cm^{-1}. This continuum was also observed in the experiment by Watanabe *et al.*[13] and was ascribed to a predissociation. Since, no discrete structure has been observed in the region of further low wave numbers, this continuum is thought to correspond to a nonbonding state which arises from $SH(^2\Pi)+H(^2S)$. Therefore, it may be considered that the dissociation proceeds *via* a crossing point whose potential is higher than the energy state of the products, $SH(^2\Pi)+H(^2S)$. If we take 106 kcal/mol for the critical energy, D,[14] we obtain $s=3.5$. By introducing these values into the empirical equation, $E_a=D-(s-1.5)RT$, the activation energy, E_a, is calculated to be 94 kcal/mol at 2750 K. This value is very close to the experimental value. Assuming the collision diameters for H_2S–H_2S and H_2S–Ar pairs to be 3.5 and 3.0 Å respectively, we obtain $p=0.5$, which is comparable to the value of 0.14 for the analogous molecule, H_2O.[15] The relatively large values of p for these molecules can be feasibly explained by the spin-allowed reactions.

Although, in this study, we did not consider either the temperature change during the course of the reaction behind the shock front or the boundary-layer effects, it may be thought that the results are not essentially changed by these effects.

The Differences in Surface and Catalytic Properties of Two Magnesium Oxides Prepared from the Hydroxide and the Carbonate Hydroxide

Hideshi HATTORI, Katsuaki SHIMAZU, Naoji YOSHII, and Kozo TANABE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 14, 1975)

Two kinds of MgO were prepared; MgO(I) from magnesium hydroxide and MgO(II) from magnesium carbonate hydroxide by evacuating at various temperatures and their surface and structural properties and catalytic actions for alkylation and isomerization reactions were examined. IR spectra of CO_2 retaining or adsorbed showed broad bands on MgO(II), but relatively sharp bands on MgO(I). In the alkylation of phenol with methanol over MgO(I), phenol was selectively alkylated at the *ortho* positions to produce *o*-cresol and 2,6-xylenol. The *ortho*-selectivity of MgO(I) was higher than 96%, while that of MgO(II) was about 75%. A low selectivity of MgO(II) was considered to be caused by a heterogeneity of surface structure of MgO(II), which was suggested by broad IR bands of CO_2 species on MgO(II). For the isomerization of 1-butene, both of MgO became active when evacuated at 450 °C and showed maximum activities when evacuated at 600 °C. The activity and the selectivity (ratio of *cis*-2-butene to *trans*-2-butene) of both catalysts were not much different. However, for the isomerization of *cis*-2-butene, the maximum activity and the selectivity (ratio of *trans*-2-butene to 1-butene) of MgO (I) were about four times higher than those of MgO(II).

The catalytic properties are generally recognized to be dependent on the preparation method. The preparation consists of various factors which determine the property of the final product. These include precipitation method, aging period, washing way, calcining condition *etc.* Among these are kind of starting material and pretreatment condition which give often large effect on catalytic property.

The catalytic properties of alkaline earth oxides are quite dependent on the starting material and the pretreatment temperature. Schächter and Pines[1] observed that CaO prepared from $Ca(OH)_2$ by calcining at 900 °C had little activity for the isomerization of 1-hexene, while CaO prepared from $CaCO_3$ by the same way showed a high activity. MgO was also reported to vary its catalytic property with the pretreatment temperature for the isomerization of 1-butene[2,3] and H_2–D_2 exchange reaction.[4]

In this study, two kinds of MgO were prepared from magnesium hydroxide and magnesium carbonate hydroxide by evacuating at various temperatures, and examined for their surface properties and catalytic actions for the isomerization of butenes and the alkylation of phenol with methanol.

Experimental

MgO(I) was obtained from magnesium hydroxide (guaranteed reagent of Kanto Chemical Co.) and MgO(II) from magnesium carbonate hydroxide (guaranteed reagent of Merck Co.) by evacuating at various temperatures. X-Ray diffraction patterns of the powder samples evacuated at different temperatures were recorded at room temperature by using CuK_α as a radiation source in air. Specific surface area was measured by applying BET equation to the adsorption isotherm of nitrogen at −196 °C.

The amount of CO_2 and H_2O evolved upon heating the starting material were measured as follows. The sample was evacuated at 100 °C, heated up to 200 °C and kept at this temperature for 2 h for MgO(I) (1 h for MgO(II)), the evolved gas being trapped by liq. N_2. The amount of gas evolved when the liq. N_2 was replaced by dry ice was taken as the amount of CO_2 and the amount still trapped by dry ice was taken as the amount of H_2O.

IR spectra of CO_2 retaining on MgO were measured by using an *in situ* cell. The sample was evacuated at a certain temperature for 2 h and a spectrum was measured at room temperature. Then, the sample was evacuated at a temperature higher than the previous evacuation temperature and a spectrum was measured again. The spectrum of CO_2 adsorbed on MgO was also measured. A sample was evacuated at 600 °C and exposed to a certain amount of CO_2 after cooling to room temperature.

The isomerization of butenes was carried out at 30 °C in a closed circulation system with a volume of about 1350 ml. In a quartz reactor, 17—25 mg of $Mg(OH)_2$ or 10—122 mg of $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$ was placed and evacuated at various temperatures. The butenes were purified by passing through molecular sieves 4A kept at −78 °C. For analysis of butenes, a 5 m column packed with 30% propylene carbonate on Uniport C was operated at 0 °C.

The alkylation of phenol with methanol was carried out at 500 °C in a flow reactor. The catalyst used for the reaction was pretreated under a nitrogen stream at 530 °C or 650 °C for 3 h. The equimolar mixture of phenol and methanol was passed over the catalyst at contact time of 1.9 $g \cdot s \cdot ml^{-1}$. The products were trapped at 0 °C and subjected to gas chromatographic analysis. A 2 m column packed with polyethylene glycol 6000 on Celite-545 and thermostated at 100 °C was used.

Results

Upon heating $Mg(OH)_2$ and $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$, the amounts of H_2O and CO_2 evolved are shown in Fig. 1. The evolution of CO_2 from $Mg(OH)_2$ continued over a wide range of the temperature from 200 °C to 700 °C, while the evolution of CO_2 from $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$ occurred sharply around 400 °C. On the other hand, the dehydration of $Mg(OH)_2$ began at 200 °C and almost ended around 400 °C, whereas that of $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$ persisted from 100 to 600 °C. The variations of the specific surface area for MgO(I) and MgO(II) are shown in Fig. 2. Decrease in a surface area was more prominent for MgO(II).

In Fig. 3 are shown the IR spectra of $Mg(OH)_2$ and $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$ evacuated at different temperatures. In the case of MgO(I), the pairs of

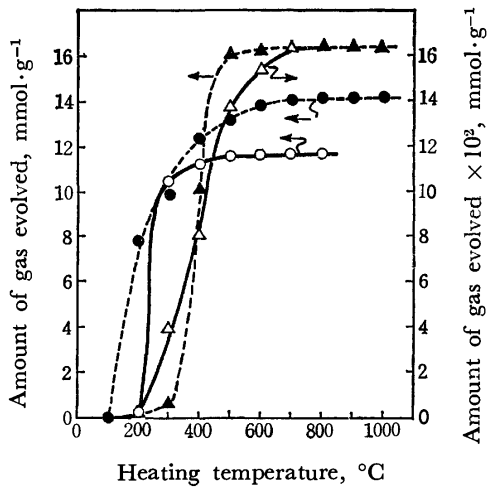

Fig. 1. Evolution of H_2O and CO_2. H_2O (-○-) and CO_2 (-△-) from $Mg(OH)_2$; H_2O (--●--) and CO_2 (--▲--) from $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$.

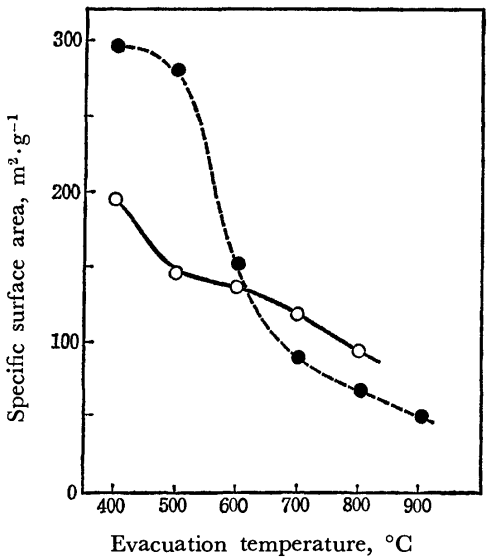

Fig. 2. The variations of specific surface areas of MgO-(I) (-○-) and MgO(II) (--●--) with evacuation temperature.

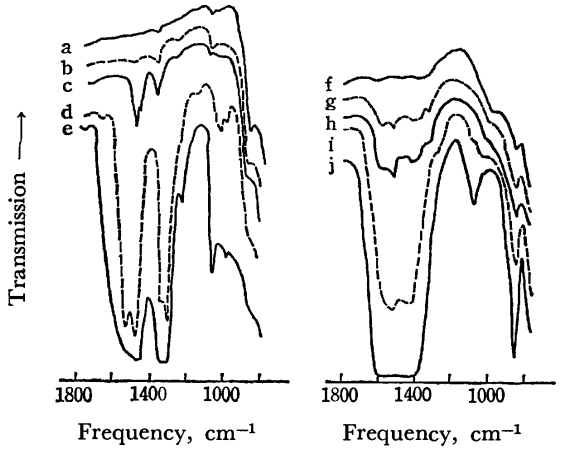

Fig. 3. IR spectra of $Mg(OH)_2$ (left) and $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$ (right) after evacuating at a: 700, b: 600, c: 500, d: 400, e: 300, f: 600, g: 500, h: 480, i: 470, j: 460 °C.

the bands at 1520; 1330 cm^{-1} and 1470; 1340 cm^{-1} indicate that two kinds of CO_2 exist. The absorption bands of MgO(II) are rather broad compared with those of MgO(I). Those bands may be superposed bands of several kinds including unidentate CO_2, bidentate CO_2 and CO_3^{2-}.

Spectra of CO_2 adsorbed on MgO(I) were also different from those on MgO(II) as shown in Fig. 4. Spectrum c shows distinct separations of the bands at 1665 ; 1630 cm^{-1} and 1315 ; 1280 cm^{-1}. However, spectrum e obtained when about the same amount of CO_2 as in spectrum c was adsorbed shows indistinctly separated bands around 1650 cm^{-1} and 1300 cm^{-1}. Besides, it shows very broad shoulders around 1550 cm^{-1} and 1400 cm^{-1}.

X-Ray diffraction patterns of both MgO(I) and MgO-(II) evacuated at 400—900 °C for 2 h showed only a pattern of MgO. Half width of the peak at $2\theta =$ 42 °50' was about 1 °03' and 2 °33' for MgO(I) and MgO(II) evacuated at 400 °C, respectively, while it was about 51' and 30' for MgO(I) and MgO(II) evacuated at 900 °C, respectively.

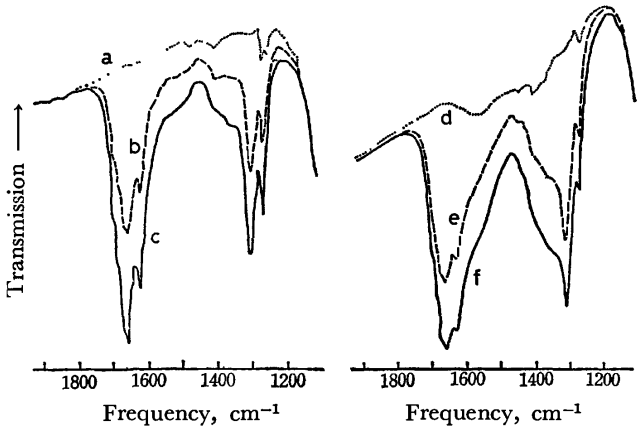

Fig. 4. IR spectra of CO_2 adsorbed on MgO(I) (left) and on MgO(II) (right). a: background of MgO(I), b: 6.5×10^{-5} mol CO_2/g, c: 13.5×10^{-5} mol CO_2/g, d: background of MgO(II), e: 15.0×10^{-5} mol CO_2/g, f: 26.8×10^{-5} mol CO_2/g.

TABLE 1. ALKYLATION OF PHENOL WITH METHANOL OVER MgO

Catalyst		MgO(I)		MgO(II)	
Pretreatment temperature, °C		529	650	533	657
Reaction temperature, °C		498	508	498	505
% Each Product	phenol	88.1	80.5	72.1	77.2
	o-cresol	10.1	16.9	18.7	15.8
	m,p-cresol	0.2	0.4	5.3	4.6
	2,6-xylenol	0.9	1.8	1.2	0.8
	2,4-xylenol	0	0.4	2.0	1.3
	2,4,6-trimethyl-phenol	0	0	0.3	0
	anisole	0	0	0.4	0.3
Activity, %·g⁻¹		11.5	18.9	26.9	22.0
ortho-Selectivity[a]		0.98	0.96	0.73	0.74

a) The ratio of (*o*-cresol+2,6-xylenol)/(*o*-cresol+*m,p*-cresol+2,6-xylenol+2,4-xylenol).

The results of the alkylation of phenol with methanol are listed in Table 1. MgO(I) was less active than MgO(II). However, the *ortho*-selectivity was more than 96% for MgO(I), while it was about 75% for MgO(II).

For the isomerization of 1-butene, the variations of the activity and the selectivity with evacuation temperature were substantially the same for two kinds of MgO as shown in Fig. 5. The maxima of the activity were observed when evacuated at 600 °C for two MgO. The ratio of *cis*-2-butene to *trans*-2-butene decreased to about 1—2 by raising the evacuation temperature to 600 °C and increased again to about 4—6 by evacuating at higher temperature.

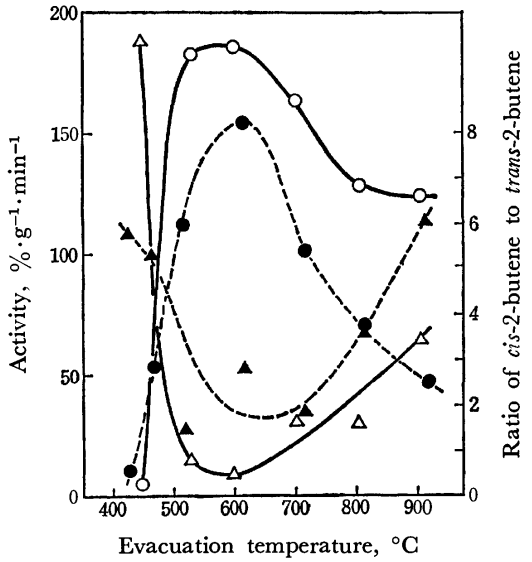

Fig. 5. Activity and selectivity for the isomerization of 1-butene. Activity (-○-) and selectivity (-△-) of MgO(I). Activity (--●--) and selectivity (--▲--) of MgO(II).

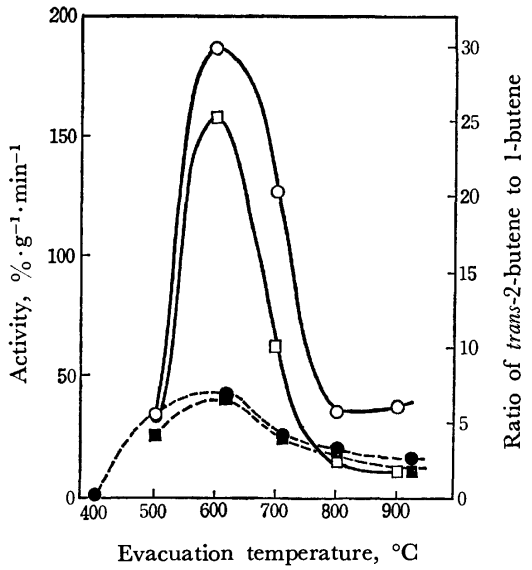

Fig. 6. Activity and selectivity for the isomerization of *cis*-2-butene. Activity (-○-) and selectivity (-□-) of MgO(I). Activity (--●--) and selectivity (--■--) of MgO(II).

Although the shapes of the change in the activity and the selectivity with evacuation temperature were about the same for the isomerization of *cis*-2-butene, the values of the activity and the selectivity were different for two MgO as shown in Fig. 6. Both the activity and the selectivity of MgO(I) at the maximum values were four times as high as those of MgO(II).

Discussion

The surface properties of two kinds of MgO which were prepared from different starting materials were not the same. Broad IR bands of adsorbed CO_2 on MgO(II) suggest that the surface structure of MgO(II) deviates from regularly ordered MgO surface and consists of several different sites for CO_2 adsorption. Rather sharp IR bands of CO_2 on MgO(I) indicates that the surface structure of MgO(I) is ordered much regularly than that of MgO(II). Since spectra of $Mg(OH)_2$ and $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$ evacuated at different temperatures (Fig. 3) shows not only CO_2 on the surface but also CO_2 in the bulk, superposed bands of several kinds of CO_2 observed in MgO(II) indicate that the bulk structure of MgO(II) is also less regularly ordered than that of MgO(I). Since an irregularly ordered structure is not so stable as a regularly ordered structure, a remarkable decrease in the surface area of MgO(II) with a rise of the pretreatment temperature also suggests that MgO(II) is less regularly ordered than MgO(I).

For the alkylation of phenol with methanol, the difference between two MgO was observed in the *ortho*-selectivity. The *ortho*-selectivity was reported to be governed by the adsorption state of phenol.[5] If phenol is adsorbed in such a state that the *para* position is far from the surface, high *ortho*-selectivity is expected. Parallel adsorption of benzene ring to the surface, on the contrary, makes it easy to be alkylated at *meta* or *para* position. Since MgO(II) is considered to have several different kinds of sites, some of them might adsorb phenol in parallel, and produce *m*-, *p*-cresol and 2,4-xylenol.

These differences between MgO(I) and MgO(II), however, did not reflect on the catalytic action for the isomerization of 1-butene. As discussed in the previous paper on MgO(I),[3] the active sites for the formation of *cis*-2-butene appear by removing the carbonate having infrared absorption bands at 1520 and 1330 cm^{-1} and those for the formation of *trans*-2-butene by removing the carbonate having absorption bands at 1470 and 1340 cm^{-1}. Although the pursuit of the kind of CO_2 relevant to activity was not successful because of the existence of several kinds of CO_2 on MgO(II), a coincidence of the variation of the activity and the selectivity with evacuation temperature for two MgO suggests that the active sites of MgO(II) for the isomerization of 1-butene are generated by the same manner as those of MgO(I).

For the isomerization of *cis*-2-butene, the activity and the selectivity changed with evacuation temperature in a similar way for two MgO. The temperature at which the activity increased roughly coincided with

the temperature at which CO_2 evolved. As the variation of the activity is parallel to that of selectivity, the variation of the activity would represent the variation of the rate of the formation of *trans*-2-butene, while the rates of the formation of 1-butene are almost constant. Thus, the active sites for the formation of *trans*-2-butene from *cis*-2-butene are also considered to be generated by the evolution of CO_2. The values of the activity and the selectivity of MgO(I), however, were four times higher than those of MgO(II). The reason for this is still uncertain.

Dielectric Relaxation Mechanism in Some Substituted Phenones

Neera SAHNI, J. P. SHUKLA, and M. C. SAXENA

Microwave and E.P.R. Laboratory, Department of Physics, University of Lucknow, India

(Received October 6, 1975)

Dielectric constants and losses at microwave frequency as well as static dielectric constants and refractive indices have been measured for *o*-methylacetophenone, *m*-methylacetophenone, *o*-hydroxybutyrophenone, 2′,4′-dihydroxyacetophenone and 2′,4′-dihydroxypropiophenone in dilute solutions of 1,4-dioxane. These values are used to calculate the dielectric relaxation times, distribution parameters, dipole moments and activation energies of the molecules. The results have been discussed in terms of the molecular motion of the system in the medium. Comparatively higher relaxation times and their variations irrespective of the molecular size, have been attributed to the intermolecular hydrogen bonding between the solvent and solute molecules.

Fong and Smyth[1] investigated the possibility of rotation of the polar acetyl and hydroxyl groups in molecules and the possible effects of the steric hindrance and resonance energy by determining the dielectric relaxation time of a number of organic molecules. Antony and Smyth[2] determined the dielectric relaxation and intramolecular hydrogen bonding in hydroxy- and methoxyacetophenones. In order to investigate the effect of increasing chain length in the case of hydrogen bonded molecules, Makhija *et al.*[3] have studied the dielectric relaxation of 2′-hydroxy-5′-methyl derivatives of phenones and found that whereas the relaxation time and the distribution parameter increase with increasing chain length, the dipole moment does not change significantly. With a view to study the intramolecular rotation of the polar groups and the intramolecular interaction consisting of hydrogen bonding and steric hindrance, the authors have investigated five phenone molecules of different substitutions and chain lengths.

The most probable relaxation time τ_0 and the distribution parameter α have been determined from the measurements of ε' and ε'' at a single frequency using Higasi's[4] equations. The dipole moment μ and the relaxation time τ have been determined for the same compounds by the single frequency method of Gopala Krishna[5] for dilute solutions. A comparison of the τ values obtained by the above two methods has been made.

The values of the free energy of activation for dielectric relaxation and for the viscous flow have been calculated using Eyring's[6] equations by utilising the values of τ obtained by Gopala Krishna's method at varying temperatures.

Experimental

A dipolemeter based on the principle of heterodyne beat method was used for the measurement of the static permittivity at 300 kHz. Refractive indices of all the solutions were measured by Abbe's refractometer, which in turn determined the optical permittivity ($\varepsilon_\infty = n_D^2$). The dielectric constant ε' and loss ε'' were measured at 3 cm wavelength, at four different temperatures by using the standing wave technique of Roberts and von Hippel[7] and its subsequent simplification by Dakin and Works[8]. The estimated accuracies in the measurements of ε' and ε'' are $\pm 1\%$ and $\pm 5\%$ respectively.

All the substances used were of pure quality obtained from Messers British Drug House. The purest 1,4-dioxane was distilled before use.

Results and Discussion

The values of the relaxation time and the distribution parameter, calculated by Higasi's single frequency method are given in Table 1. The τ value for *o*-methylacetophenone is found to be smaller than that of *m*-methylacetophenone, although the two are of the same molecular size. This could, perhaps, be due to the compact shape of the former molecule in contrast with the greater length of the latter molecule.

The relaxation time for *o*-methylacetophenone is less than that obtained by Antony and Smyth[2] for *o*-hydroxyacetophenone ($\tau = 31.0 \times 10^{-12}$ s) in dioxane, the differences in the molecular sizes of the two molecules being negligibly small. This may be due to the fact that the acetyl group in *o*-methylacetophenone has greater freedom of rotation than the acetyl group in *o*-hydroxyacetophenone which behaves almost as a rigid molecule because of the intramolecular hydrogen bonding between the –OH and acetyl groups.[2] The large value of distribution parameter for *o*-methylacetophenone also indicates the presence of an internal mode of relaxation, apart from the overall rotation of the molecule.

The relaxation time value for 2′,4′-dihydroxypropiophenone is greater than that for 2′,4′-dihydroxyacetophenone. This is expected because of the greater chain length of the former molecule. However, the τ value for *o*-hydroxybutyrophenone is found to be less than that of *o*-hydroxyacetophenone.[2] The nearly zero values of distribution parameters for 2′,4′-dihydroxyacetophenone and *o*-hydroxybutyrophenone indicate that the molecules relax largely due to the overall molecular rotations.

Adgonker and Kher[9] have determined the value of τ to be 38.73×10^{-12} s for 2′-hydroxy-4′-methylacetophenone in solutions of carbon tetrachloride. This value is considerably smaller than that of 2′,4′-dihydroxyacetophenone in dioxane. This may be partly due to the higher viscosity of dioxane than that of carbon tetrachloride and also because of the hydrogen bonding due to the solvent solute interaction at *para* position of the latter molecule. On comparing the τ value for 2′,4′-dihydroxypropiophenone with that obtained by Dhar *et al.*[10] of *p*-hydroxypropiophenone ($\tau = 25.4 \times 10^{-12}$ s in dioxane), it is found that the former value is more than 2½ times greater than the latter value.

Table 1. Slopes of plots of dielectric permittivity against concentration, values of relaxation time and distribution parameter (22 °C)

Compound	a_0	a'	a''	a_∞	τ_0	α

	303	17.0	—	2.82	1.24	−5.22	4.70	3.27	−4.71
	311	15.8	—	2.86	1.24	−5.22	4.75	3.27	−4.75
o-Hydroxy-	295	16.4	2.18	2.71	0.73	−6.70	4.66	3.27	−4.71
butyrophenone	303	15.9	—	2.78	0.73	−6.75	4.70	3.27	−4.71
	311	15.1	—	2.84	0.73	−6.76	4.75	3.27	−4.75
2',4'-Dihydroxy-	287	19.0	—	2.70	1.19	−5.27	4.61	3.27	−4.67
acetophenone	295	18.1	2.19	2.77	1.19	−5.33	4.66	3.27	−4.71
	303	16.6	—	2.80	1.19	−5.32	4.70	3.27	−4.71
	311	15.4	—	2.85	1.19	−5.33	4.75	3.27	−4.75
2',4'-Dihydroxy-	287	21.6	—	2.78	0.87	−6.64	4.61	3.27	−4.67
propiophenone	295	19.1	2.68	2.80	0.87	−6.52	4.66	3.27	−4.71
	303	17.8	—	2.85	0.87	−6.52	4.70	3.27	−4.71
	311	16.7	—	2.90	0.87	−6.52	4.75	3.27	−4.75

Apart from the greater size of the molecule, the unusually high relaxation time of 2',4'-dihydroxypropiophenone can be explained as due to the hydrogen bonding between the solvent and the solute molecules, at various positions of the benzene ring.

It is significant from Table 2 that the values of relaxation times obtained by Gopala Krishna's method are invariably lower than those obtained by Higasi's method (Table 1). This may be due to the fact that unlike Higasi's method, Gopala Krishna's method is based on Debye's model of single relaxation process in which the distribution parameter is zero. Similar results were reported by Krishnaji for esters in solutions.[11]

It is evident from Table 2 that while the relaxation time decreases with increasing temperature, the free energy of activation increases. This is in line with the observation of other workers.[12] The free energy of activation ΔF_η is greater than ΔF_ε, which is quite natural because the viscosity process consists of rotational as well as translational motion of the molecule, while the dielectric relaxation is only due to rotation.

For all the molecules, the free energy of activation is greater than the molar enthalpy of activation, with the result that the entropy of activation is negative. This shows that the activated state is more ordered than the normal state.

The authors are thankful to Dr. B. G. Gokhale, Professor and Head of the Physics department, for his interest in the work. One of us (N.S.) is also grateful to the Council of Scientific and Industrial Research (New Delhi) for giving financial assistance.

The Electronic Spectra of α,ω-Di-1- and α,ω-Di-2-naphthylpolyenes in Solution and in Solid State

Krishnagopal MANDAL and T. N. MISRA

Department of Physics, North Bengal University, Darjeeling, India, Pin 734430

(Received October 24, 1975)

The electronic absorption spectra of α,ω-di-1- and α,ω-di-2-naphthylpolyenes have been studied in solution and in the crystalline state. Both polyenes have four distinct electronic band systems. The spectral properties indicate that the terminal naphthyl group reduces the symmetry of the short-chained polyene molecules whereas long naphthylpolyenes retain the usual conjugated polyene symmetry of C_{2h}. A plot of λ^2_{max}-n gives a straight line and a nearly *all-trans* form seems to be retained by the polyene chain. Unlike that in some conjugated polyenes a good overlap between the first absorption band and the highest energy emission band is observed. This suggests that there is no low-lying forbidden state in these polyenes. Some of the absorption bands of naphthylpolyene crystal could be explained in terms of factor group split components. Two extra bands observed in α,ω-di-2-naphthylpolyenes seem to be related to naphthalene transitions.

Compared to the effort expanded in the spectral study of aromatic molecules little experimental works on the electronic spectrum of conjugated polyenes have been done. A systematic investigation of the electronic spectral properties of polyenes in different states has been undertaken in this laboratory. It has already been established[1-4] that in some linear polyenes with the general structure R_1-$(CH{=}CH)_n$-R_2, R_1 and R_2 being the end groups, there exists a low energy excited state (^1A_g) below the previously observed strongly allowed electronic state (^1B_u) and emission of polyenes originates from this state. The effect of the end groups on the electronic states of polyenes is well known.[5-8] In an earlier[9] paper it has been shown that in anthryl polyenes the lowest excited state is an allowed ^1B_u type. The terminal anthryl group interaction is such that ^1A_g is not lowered relative to ^1B_u in these polyenes. In order to study the effect of other end groups on the electronic excitation of polyacetylene chromophore, it was thought worthwhile to extend the investigation to other polyenes with terminal aromatic groups. Here we report the results of our investigation on the electronic spectra of a series of naphthylpolyenes in solution and also in the solid state.

Experimental

Highly pure, synthetic α,ω-di-1- and di-2-naphthylpolyenes were obtained from Prof. Nakagawa of Osaka University as a gift. They were used without further purification. Solvent tetrahydrofuran (THF) and haxane used were spectrograde. The electronic absorption spectra were measured with Spektromom-202 spectrophotometer of Hungarian optical works at room temperature using a well-matched pair of 1-cm cells. The fluorescence spectra were measured using a high intensity UV mercury source and a Corning C.S 7-54 filter with right angle excitation. The spectra in the solid state were obtained by making a thin crystal on the quartz plate. Five α,ω-di-1-naphthylpolyenes (I_n) and six α,ω-di-2-naphthylpolyenes (I_n') of type R-$(CH{=}CH)_n$-R where R stands for the naphthyl group and n=1—6, have been studied.

Results

Solution Spectra. *α,ω-Di-1-naphthylpolyene(I_n)*: The electronic absorption spectra of a series of I_n are reproduced in Fig. 1. Results are summarized in Table 1. Solvent hexane has been used to get the high energy bands in the region 2000—2400 Å. The spectrum from 2400 Å to the visible region has been measured in solvent THF because of better solubility of the polyenes in this solvent and the THF itself has no absorption in this spectral region.

The solution spectra show four distinct band systems. The transition to the lowest excited singlet state of the polyene is observed in the region 3000—5000 Å and this is very intense. Its intensity increases linearly with the chain length. This band has been identified

a) Values are for THF solution for the A—C bands and for hexane for the D band.
s: strong, w: weak, v: very, m: medium.

as A in the diagram. The band in the region 2600—3200 Å identified as B, is very weak. This band becomes more and more distinct as n is increased in the polyene. An intense band C appears in the region 2400—2700 Å. Its intensity, in general, continues to decrease with the increase in polyene length. The highest energy band D is observed at about 2200 Å. This band is intense. It is observed that in long naphthylpolyenes two bands A, D are strong and B, C weak. The spectra of these polyenes in THF solution are in general agreement with that reported by Yasuhara *et al.*[10]

The fluorescence spectra of I_n have been studied in solvent hexane. The fluorescence bands of I_2 and I_4 are found to have band maxima at 22200 cm^{-1} and 21800 cm^{-1} respectively. The bands of I_2 and I_4 are shown in Fig. 2.

α,ω-Di-2-naphthylpolyene (I_n'): The electronic absorption spectra of I_n are presented in Fig. 3. For clarity the spectra of I'_{1-3} and I'_{4-6} are shown separately in the diagram. Results are given in Table 2. The spectrum, in general, consists of four band systems. One more high energy band is observed in higher members I_4', I_5' and I_6' and an extra low energy weak band is observed only in the lowest member I_1 of the polyene. Here too the high energy bands are measured in hexane and the rest part of the spectrum, in THF.

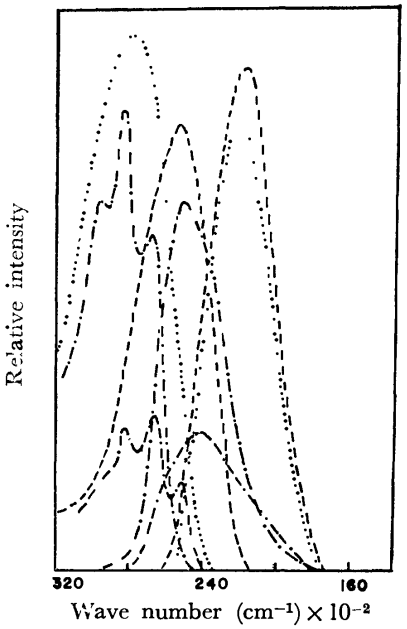

Fig. 2. ·····: First absorption band and fluorescence band of I_2, ----: First absorption band and fluorescence band of I_4, -·-·-: First absorption band and fluorescence band of I_2', --·---·--: First absorption band and fluorescence band of I_3'.

The first allowed singlet–singlet transition appears in the region 3000—5000 Å with sharp vibrational structure. The vibrational spacing is about 1400 cm^{-1}. This band system is very intense. The band in this region has been identified as A in the diagram. In the region 2400—3400 Å, there are two bands B and C in each of I_n'. This is clearly observed in I_2'. Here the band B is in the region 2700—3100 Å and the band C, in the region 2400—2700 Å. The bands B and C become weaker relative to other bands with increasing n. The band D is found to be in the region 2000—2600 Å. The band E in the region 2000—2300 Å appears only in I_4', I_5' and I_6' whereas in I_1' a very weak band is observed at about 3590 Å. The spectra of these polyenes in THF solution are similar to that reported by Yasuhara *et al.*[10]

In THF the second band (B) is much weaker than the first band A. In hexane, however, appreciable intensity enhancement of B band compared to A band is observed in I_1', I_2' and I_4', particularly in the first member.

The fluorescence spectra of I_n' have been studied in solution. The fluorescence band maxima of I_1' in THF is observed at 25000 cm^{-1}. Polyenes I_2' and I_3' (Fig. 2) are found to have fluorescence maxima at 24900 cm^{-1} and 24000 cm^{-1} respectively in hexane.

Solid Film Spectra. The crystal spectra of I_n are broad and the spectral data are summarized in Table 1. The spectra of I_1 and I_2 in the solid state are very broad and retain identity with the spectra in solution. The band B in solution of I_{2-4} is absent in crystals. The crystal spectrum of I_6 is shown in Fig. 4. For brevity crystal spectra of I_3 and I_4 are not presented, the data, however, have been shown in Table 1.

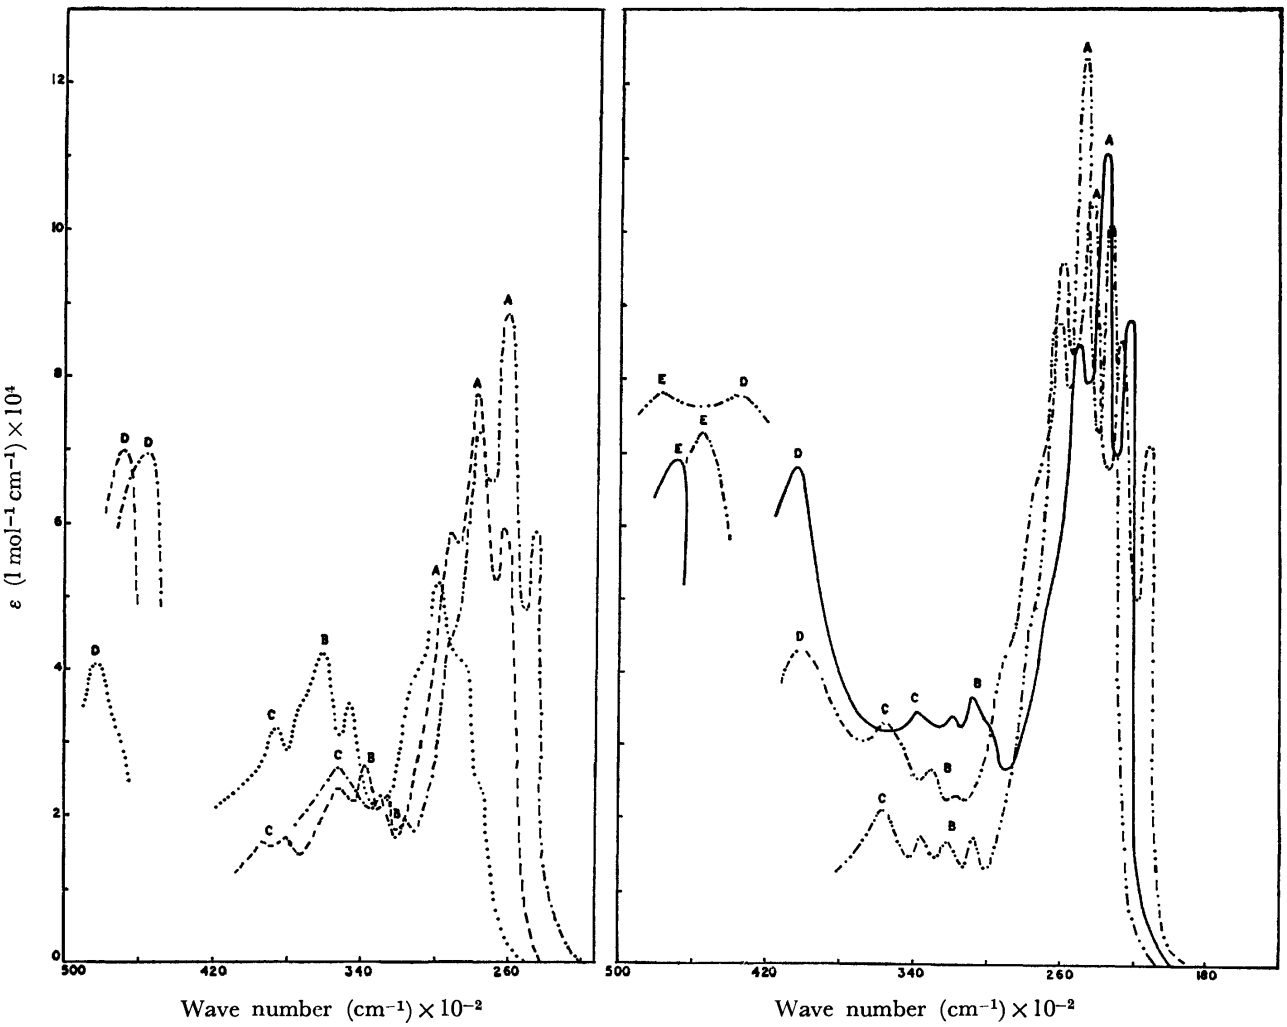

Fig. 3. ·····: Solution spectrum of I_1', ----: Solution spectrum of I_2', -·-·-: Solution spectrum of I_3', -··-··-: Solution spectrum of I_4', ——: Solution spectrum of I_5', --··--; Solution spectrum of I_6'.

The absorption spectra of I_n' in the crystalline state are shown in Fig. 5. The bands in the solid state are broad and shift little towards red or blue from their position in solution. The long wavelength band A appears with subbands. The vibrational spacing is about 1400—1600 cm^{-1}. The spacing between the longest wavelength subband and the next is found to be about 2000 cm^{-1}.

Discussion

Solution Spectra. All-*trans* conjugated polyenes belong to C_{2h} point group. The ground electronic state of these polyenes is ^1A_g and the excited states in increasing energy order are ^1B_u, ^1A_g, ^1A_g, ^1B_u according to the Pariser-Parr-Pople (PPP) method.[11] As

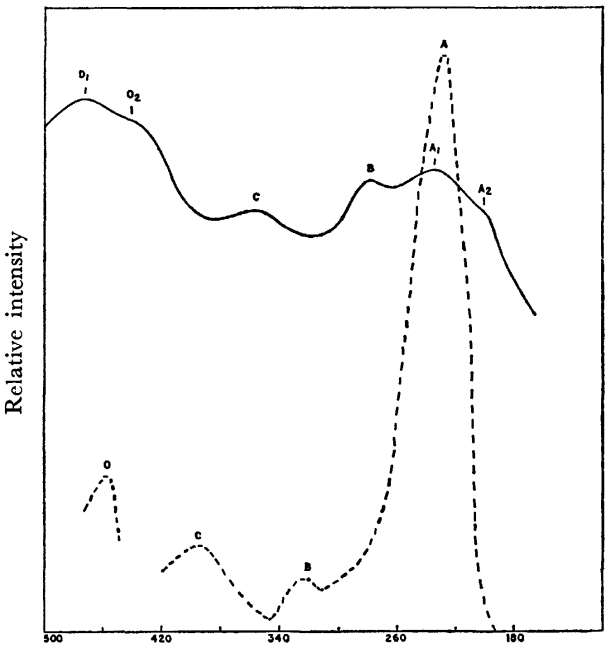

Fig. 4. —— Solid film spectrum of I_6, ----: Solution spectrum of I_6.

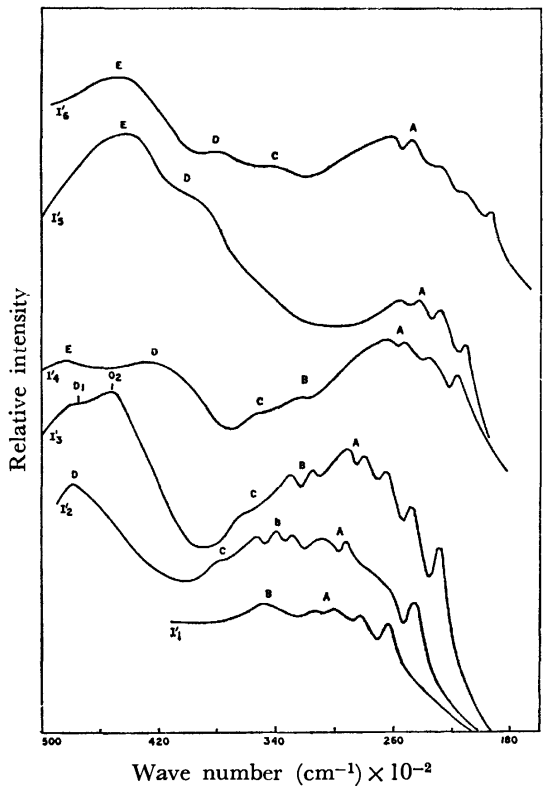

Fig. 5. Solid film spectra of I'_{1-6}.

a result the transitions $^1A_g \rightarrow {}^1B_u$, $^1A_g \rightarrow {}^1B_u$ are generally observed and are strongly allowed. Two $^1A_g \rightarrow {}^1A_g$ transitions are forbidden. From the band-intensity of I_n amd I_n' it is observed that in the higher members two transitions are strongly allowed and the other two transitions, weakly allowed. As the chain length of the polyene decreases the weakly allowed bands become

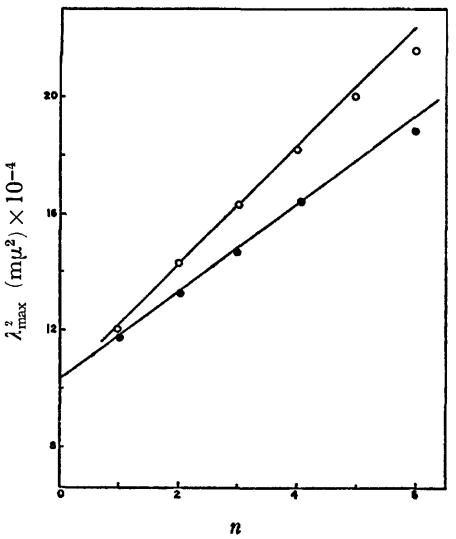

Fig. 6. -●-●-: Plot of $\lambda^2_{max} - n$ of I_n, -○-○-: Plot of $\lambda^2_{max} - n$ of I_n'.

equally intense with the allowed ones. The strong allowedness of the weak bands seems to be due to reduction in symmetry of the molecule by the presence of the terminal naphthyl group. When the polyene chain is short, the naphthyl group possibly destroys the center of symmetry and the lower members of the naphthylpolyene seem to have lower symmetry than C_{2h}. As a result one gets B and C bands as allowed in lower members of both I_n and I_n'.

In our spectra of I_n the bands in the region 3000—5000 Å (A), 2600—3200 Å (B), 2400—2700 Å (C) and 2160—2200 Å (D) possibly belong to the transitions $^1A_g \rightarrow {}^1B_u$, $^1A_g \rightarrow {}^1A_g$, $^1A_g \rightarrow {}^1A_g$ and $^1A_g \rightarrow {}^1B_u$ respectively of C_{2h} symmetry (true for higher members).

In the spectra of I_n', similarly, the bands in the region 3000—5000 Å (A), 2700—3400 Å (B), 2400—2900 Å (C) and 2000—2600 Å (D) seem to belong to transitions $^1A_g \rightarrow {}^1B_u$, $^1A_g \rightarrow {}^1A_g$, $^1A_g \rightarrow {}^1A_g$, and $^1A_g \rightarrow {}^1B_u$ respectively. The band E in the region 2000—2300 Å of I_4', I_5' and I_6' is possibly related to the $^1A_g \rightarrow {}^1B_{3u}$ (^1B_b in Platt's notation) transition of naphthalene and arises from the interaction between the ^1B_u state of the polyene chromophore and the $^1B_{3u}$ state of naphthalene. The long wavelength band at about 3590 Å of I_1' is structurally different from the lowest transition $^1A_g \rightarrow {}^1B_u$ of the polyene chromophore and may be related to the $^1A_g \rightarrow {}^1B_{3u}$ (^1L_b band in Platt's notation) of naphthalene group. In the higher members I'_{2-6} of the naphthylpolyene the band related to the lowest $^1A_g \rightarrow {}^1B_{3u}$ transition of naphthalene molecule may be hidden under the intense $^1A_g \rightarrow {}^1B_u$ band of the polyene chromophore.

As is evident from Figs. 1 and 3 and Tables 1 and 2, the longest wavelength maxima undergo red shift with increasing n. For conjugated polyenes it has generally been accepted[12] and λ^2_{max} is proportional to n, the number of conjugated double bonds. We have made such a plot of λ^2_{max} against n for both I_n and I_n' and the plot as shown in Fig. 6 is a straight line for the four lower members. I_6 and I'_{5-6} are not quite in the straight line. Further weakly allowed

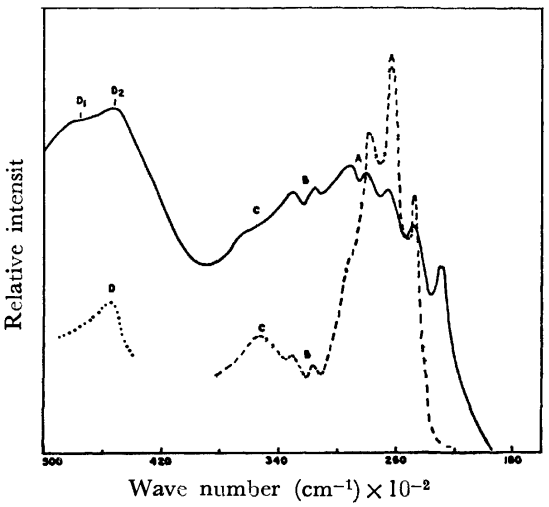

Fig. 7. —— Solid film spectrum of I_3', ----: Solution spectrum of I_3'.

transitions appear in the higher members. This suggests some deviations of the polyene chain from *all-trans* form in higher naphthylpolyenes.

In some conjugated polyenes there exists a low-lying forbidden π-electronic state.[1,4] Fluorescence originates from this state. In naphthylpolyenes four transitions have been observed. No forbidden transition is, therefore, expected. Our fluorescence and absorption spectra of naphthylpolyene I_n and I_n' show that there is a good overlap between the low energy absorption and highest energy emission bands (Fig. 7). We, therefore, conclude that in naphthylpolyenes there is no such low-lying forbidden state as is observed in some other polyenes.[1,4]

Solid Film Spectra. The crystal spectra of I_n differ somewhat from the spectra of free molecules. Identification of solution C and D bands of I_3 and I_4 in the solid state is obvious and no additional band is observed in this region. Both I_3 and I_4 in the solid state have two bands, one intense on the higher energy side and the other broad on the low-energy side of the solution band A. It seems that the band A is split into components A_1 and A_2 in the crystalline state. Free molecular bands B and C of I_6 as shown in Fig. 4 undergo red shift in the solid state. In I_6 in the region of each of the solution bands A and D there are two bands in the spectra of crystal. From these structures of the bands it seems that the band A is split into A_1 and A_2 and D into D_1 and D_2 in the solid state. In solid state the absorption bands of all these polyenes are broad and the assignment of the factor group split components in Table 1 is only tentative and numerical values of splitting are of no significance. Study of single crystal polarized spectra at liquid N_2 or liquid He temperature is required for any unequivocal identification of factor group split components.

The solid film spectra of I_n', in general, are very similar to the solution spectra. The bands D of I_2' and I_3' in solution seem to show some factor group splitting. In I_2' the band D is blue shifted in the solid state and this may be one of the factor group split components, D_1. As is obvious from the spectrum in Fig. 7 the band D of I_3' in the free molecular state has two bands on its high and low energy side in the crystalline state. Two bands are possibly the split components D_1 and D_2 of solution band D. No factor group splitting is observed in other members of I_n'. As has already been pointed out, assignment of these factor group split components is only tentative.

In the intense lowest energy band of each crystal spectrum of I_n' it is observed that the vibrational spacing between the subbands of A is 1400—1600 cm^{-1} in agreement with those observed in solution. The spacing between the longest wavelength maxima and the next, however, is about 2000 cm^{-1}. Thus it seems that this longest wavelength band is a new band system and appears in each of I_n' in the crystalline state. This band is possibly related to the $^1A_g \rightarrow {}^1B_{3u}$ band (^1L_b band in Platt's notation) of naphthalene molecule. In solution this band is found only in I_1'. In the solid state this band is separated out from the intense $^1A_g \rightarrow {}^1B_u$ band of the polyene chromophore in other I_n' polyenes.

The authors thank Prof. Nakagawa for his kind donation of the compounds studied. One of the authors (K. G. M.) expresses his thanks to University Grants Commission, India for a fellowship.

Rotational Isomerism in β-Diketone *cis* and *trans* Enol Ethers. An IR and PMR Study*

Janusz DABROWSKI** and Michal TENCER

Institute of Organic Chemistry, Polish Academy of Sciences, 00-961 Warsaw, Poland

(Received March 31, 1975)

The *cis* (*Z*) isomers of β-alkoxy-α,β-unsaturated ketones, $R^1COCH{=}CR^2OR^3$, have been shown by IR spectra to exist as a mixture of *s-cis* (*ZZ*) and *s-trans* (*ZE*) rotamers, with the equilibrium shifting towards the former upon increasing the steric requirements of the R^1 substituent. The *trans* (*E*) isomers have uniformly the *s-cis* (*EZ*) structure. *O-s-trans* (or non-planar) and *O-s-cis* conformations due to rotation around the C_{sp^2}–O bond have been proposed for the *Z* and *E* isomers, respectively. Based on known structures, a rationalization of the rule governing the chemical shifts of R^1 and R^2 protons, called here the "ene-one cross shielding rule", has been offered.

While the vast majority of β-keto enols obtained to date have a *cis* configuration, obviously due to the stabilizing effect of the chelate hydrogen bond, most β-keto enol ethers have the alkoxy group in the *trans* position with respect to the carbonyl. Such was *e.g.*, the case with ethers of β-keto aldehydes studied in our previous work.[1] The *cis* β-keto enol ethers are kinetic products which spontaneously isomerize into the thermodynamically stable *trans* form. With β-diketone enol ethers, the isomerization is slow enough to enable the isolation and spectral investigation of these two isomers.

The simplest representatives of this class of compounds *viz.*, *cis* and *trans* methyl ethers of the enol of acetylacetone first obtained by Eistert *et al.*[2] have recently been investigated by Awang[3] using NMR spectroscopy. Although his assignments based on indirect data (NOE and ASIS) correctly ascribed the *trans-s-cis* structure to the isomer with a lower boiling point, the *cis* isomer was erroneously assumed to be homogeneous with respect to conformation; as shown below (see Results and Discussion section and Fig. 1) a considerable amount of the *s-cis* rotamer can directly be observed in the infrared spectra together with the *s-trans* one assigned by Awang.[3] Taking advantage of the more favorable time scale of the infrared spectroscopy we have investigated here some of the factors affecting the conformational equilibria, *viz.*, the steric requirements of the alkyl substituents and the solvent effect in a series of β-diketone enol ethers.***

While the *trans*(*E*) β-keto aldehyde enol ethers exhibited up to eight IR bands in the double bond stretching region due to rotation about both the C_{sp^2}–C_{sp^2} and C_{sp^2}–O single bonds,[1] the number of bands never exceeded four in the case of the *cis*(*Z*) and *trans*(*E*) β-diketone enol ethers reported here, which indicates that some of the rotamers are not present. The scrutiny of the IR spectra permitted us to identify the existing rotamers and to estimate their populations.

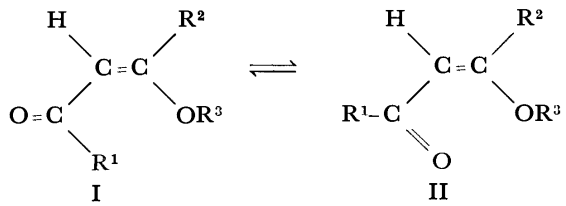
Joint utilization of the IR and NMR data allowed us to investigate the applicability of the rule[3,5–7] governing the shielding of the allylic and acylic protons in the compounds of the type studied here and to propose a rationalization of this rule.

Results and Discussion

IR Spectra. IR spectra data are given in Table 1. In order to illustrate the relationship between band intensities and steric requirements of the alkyl substituents, spectra of selected compounds are shown in Figs. 1 and 3. The dependence of the rotational equilibria upon the polarity of the solvent is illustrated by the spectra presented in Fig. 2.

In the *cis*(*Z*) series of β-diketone enol ethers, four bands are observed in most cases between 1550 and 1700 cm^{-1}. As seen from Fig. 1, one band in the $\nu_{C=O}$ region (band B) and one in the $\nu_{C=C}$ region (band C) decrease in intensity with increasing bulkiness of the substituent R^1 in going from compound **1** *Z* to **2** *Z*, **3** *Z* and **8** *Z*, while the other $\nu_{C=O}$ band (A) and $\nu_{C=C}$ band (D) increase in the same sequence.****

Since the enlargement of the alkyl group R^1 causes a stronger interaction with the alkoxy group in the *s-trans* conformation, these dramatic spectral changes can safely be interpreted as a result of the equilibrium shift towards the *s-cis* form:



I II

ZE (*i.e.*, *cis/s-trans*) *ZZ* (*i.e.*, *cis/s-cis*)

Consequently, as with β-keto aldehyde enol ethers[1] and other α,β-unsaturated ketones,[8,9] the "inner" bands B and C are assigned to the coupled $\nu_{C=O}$ and $\nu_{C=C}$ vibrations of the *s-trans* rotamer and the "outer" ones A and D to the same vibrations of the *s-cis* rotamer.

In view of the strong non-bonded interaction between R^1 and OR^3 it might seem surprising, at first, that the *s-trans* rotamer prevails in the case of the first homologue of the series (**1** *Z*; R^1=Me) and occurs in still

* Paper XX of the series, "Infrared spectra and structure of substituted unsaturated carbonyl compounds."

** Present addres: Max-Plank-Institute for Medical Research, Jahnstrasse 29, D-6900 Heidelberg, Germany.

*** Some of the compounds investigated here have been examined IR-spectroscopically by Giza,[4] but poor resolution of the spectra and some uncertainty (and even incorrectness; see footnote of Table 3) of the configurational assignments render those results unreliable.

**** Although the vibrations of the C=O and C=C groups are undoubtedly strongly coupled, the bands will be denoted, for the sake of simplicity, $\nu_{C=O}$ and $\nu_{C=C}$.

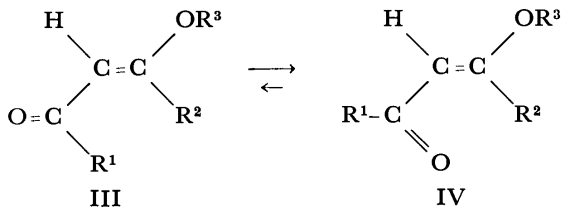
considerable amounts with compound **2** *Z* (R^1=Et). This situation is in contrast with what was found for other *cis* β-substituted unsaturated ketones,[8,9] including the *trans(E)* isomers of the compounds just discussed (*vide infra*) which bear an alkyl *cis* β-substituent and exist entirely as *s-cis* rotamers. This seeming contradiction can reasonably be explained by taking into account the electrostatic repulsion between two oxygen atoms in the alternative *s-cis* conformation. The latter effect, assisted by the greater resonance energy of the *s-trans* structure, seems to account for the preponderance of the *s-trans* rotamer if R^1=Me. Now, both the electrostatic and the resonance factors are practically constant in the whole series under consideration, whereas the non-bonded R^1–OR^3 interactions in the *s-trans* rotamer obviously increase in the sequence, thus satisfactorily explaining the observed equilibrium shift.

The conformational equilibrium is apparently not affected by the size of the substituent R^3: the spectra of compounds **4** *Z*, **5** *Z*, and **6** *Z* with R^3=Et are very similar to those of **1** *Z*, **2** *Z*, and **3** *Z*, respectively, and substitution of R^3=Me by *i*-Bu (compound **7** *Z*) has practically no effect on the relative intensities of the IR bands A—D.

The solvent-induced intensity changes are in agreement with the assignments of the two $\nu_{C=O}$ and two $\nu_{C=C}$ bands: when passing from hexane to tetrachloroethylene and particularly to the considerably more polar tetrahydrofuran solutions, an increase of bands B and C of the more polar *s-trans* form at the expense of the bands A and D is observed (*e.g.*, with R^1=Et a reversal of band intensities occurs; see for **2** *Z* in Fig. 2).

With the *trans(E)* series, only one $\nu_{C=O}$ and one $\nu_{C=C}$ band are observed; their positions clearly indicate that the only observed rotamer is the *s-cis* one (see Fig. 3). This decisive equilibrium shift is obviously due to steric interactions between the R^1 and R^2 alkyl groups in the *s-trans* form:



EE (*i.e.*, *trans/s-trans*) *EZ* (*i.e.*, *trans/s-cis*)

It must be noted, however, that in some of the *trans* compounds weak absorptions near wave numbers characteristic of the *s-trans* rotamer are observed (*e.g.*, see Fig. 3). Since the strain energy in the *s-trans* rotamer is extremely high, it is likely that these absorptions are due to a twisted form. In this connection we should like to mention that, in general, some non-planar deformations may occur in many structures termed here *s-cis* or *s-trans*; in this sense, the terms "*s-cis*" and "*s-trans*" have only an approximate meaning.

Unlike the β-keto aldehyde enol ethers,[1] β-diketone enol ethers exhibit no extra splitting of the $\nu_{C=O}$ or $\nu_{C=C}$ bands caused by rotation around the C_{sp^2}–O bond, obviously because of additional steric hindrance. The conformation of the =C(R^2)–OR^3 fragment, though not directly accessible, can be estimated from model considerations and the comparison of $\Delta\nu_{C=C}^{C=O}$ values obtained here with those previously[1] found for all possible *s-cis*, *s-trans*, *O-s-cis*, *O-s-trans* conformational combinations in β-keto aldehyde enol ethers.

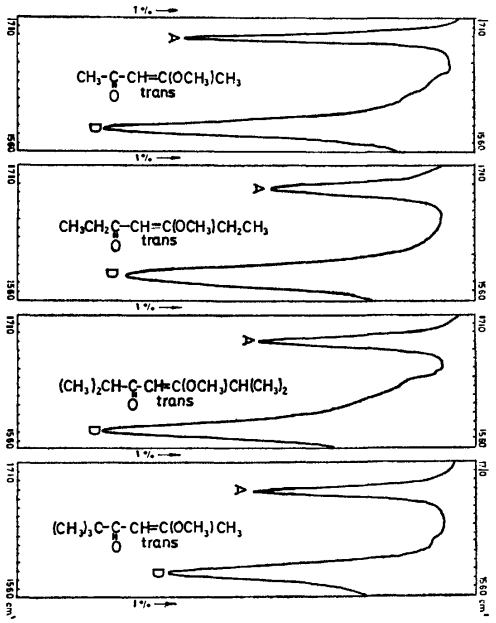


Fig. 3. Infrared spectra of compounds **1** *E*, **2** *E*, **3** *E* and **8** *E* in tetrachloroethylene. Cell thicknesses and concentrations are given in Table 1.

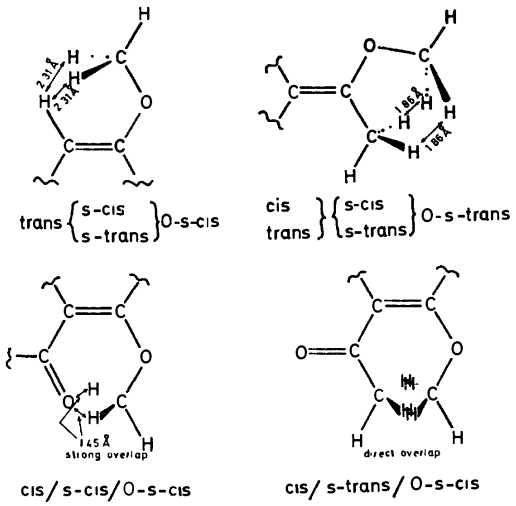

Fig. 4. Interatomic distances in assumed *O-s-cis* and *O-s-trans* conformations of β-methoxy compounds. The orientations of methyl groups were chosen to minimize the Pitzer strain energy.

Thus, there is obviously a much weaker non-bonded interaction in the *trans/s-cis/O-s-cis* isomer than in the *trans/s-cis/O-s-trans* one (see formula IV), with the alternative H–H interatomic distance amounting to 2.31 Å *vs.* 1.86 Å (see Fig. 4).† Besides, the *O-s-cis* rotamer is strongly preferred here for electronic reasons.[1,12] Correspondingly, as can be derived from the data of Table 1, the $\Delta\nu_{C=C}^{C=O}$ values lie within the limits of 90—100 cm^{-1}, in excellent agreement with the previous estimation[1] of 80—100 cm^{-1} while the alternative *O-s-trans* conformation requires 75—85 cm^{-1}.

As for the *cis* structures I and II, steric hindrance is important in both *O-s*-conformations, being particularly pronounced in the *O-s-cis* one where a direct overlap of the nearest non-bonded atoms should occur (see Fig. 4). Hence, the anticipated conformation is *O-s-trans*.†† It was of interest to clear up whether the regularities concerning the wave number differences $\Delta\nu_{C=C}^{C=O}$ in the *trans* series[1] hold also for the *cis* isomers. The agreement is again very good as far as the *s-trans* conformation is concerned: the values now found (26—31 cm^{-1}) lie almost exactly within the limits previously established[1] (20—30 cm^{-1}), whereas 35—50 cm^{-1} was found[1] for the alternative *O-s-cis* conformation. On the other hand, the results for the *s-cis* rotamers are less favorable: although the majority of the *O-s-trans* rotamers II exhibit lower $\Delta\nu_{C=C}^{C=O}$ values as compared with the *O-s-cis* rotamers IV (75—94 cm^{-1} *vs.* 90—100 cm^{-1})—a tendency already noticed for keto aldehyde enol ethers, the upper limit of the range now observed (75—94 cm^{-1}) is moved by 9 cm^{-1} above that found[1] for the latter compounds (75—85 cm^{-1}).

PMR Spectra. With the exception of compounds **8** *Z* and *E*, all the enol ethers studied here contain identical groups $R^1=R^2$, thus the assignment of their signals posed some problems. Anteunis and Schamp[5] examined several unsymmetrically substituted enol ethers ($R^1\neq R^2$) and were able to establish the "ene-one rule", from which it follows that α protons of the R^2 group resonate at lower field than α protons of the R^1 group. While Anteunis and Schamp[5] were not aware of the *trans* configuration of the compounds studied, it was shown subsequently by Gelin and Rouet[6] that the "ene-one rule" holds for the *trans* structures only, whereas an opposite assignment is true for the *cis* configuration. Assignments coinciding with those by Gelin and Rouet were made by Awang[3] for **1** *E* and *Z* and (apparently intuitively) by Elvidge and Stevens[7] for **2** *E* and *Z*.

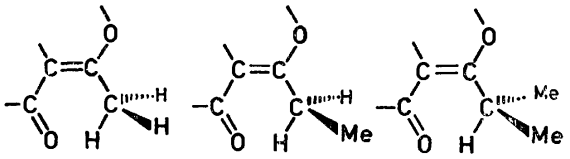
Since the term "ene-one rule" refers to the original incomplete assignments by Anteunis and Schamp[5] and might thus be misleading, it seems appropriate to rename the rule as the "ene-one cross-shielding rule". Terminologic problems aside, it should be emphasized that no rationalization was offered for the rule in either of the papers mentioned. The eight *E*, *Z* pairs of compounds, the conformational equilibria of which were established rather reliably, permit us to propose an explanation of the observed phenomena.

Let us consider first the *trans(E)* isomers of compounds **1**—**7** which, as shown above, all have the *s-cis* conformation (see formula IV on p. 983). Compared with the usual allylic protons, the "ene-side" protons of R^2 are additionally deshielded by both the carbonyl and ether oxygens, whereas the magnetic environment of the "one-side" α-protons is practically the same as in the case of typical acylic groups. The resulting

† For details, see our previous paper;[1] the bond lengths and angles have been taken from the paper by Cahill *et al.*[10] and from the tables.[11] As before, the calculations are for $R^1=R^2=R^3=Me$.

†† It is likely that deviations from planarity may occur not only in the O=C–C=C fragment (*vide supra*) but also in the C=C–OR moiety.

lower-field absorption of R^2 *vs.* R^1 is thus readily explainable. The role of the deshielding of R^2 caused by the carbonyl group is further substantiated by the fact that the δ values increase along with the progressing branching of this substituent:

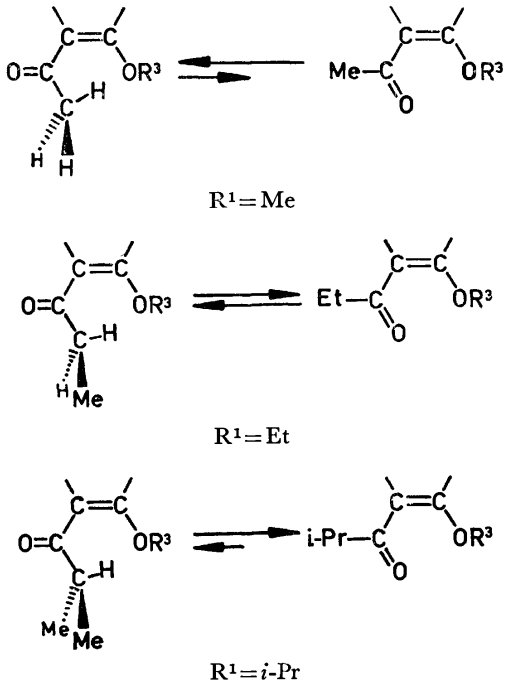


R^2=Me R^2=Et R^2=*i*-Pr

While the deshielding produced by this group, measured as $\Delta\delta_{R^1}^{R^2}$†††, is assumed to be evenly distributed between the three protons of the rotating methyl group, the average effect should be statistically 3/2 and 3 times greater with R^2=Et and R^3=*i*-Pr, respectively, the rotation of these two groups being severely restricted. The observed increase is in fact even greater, $\Delta\delta_{R^1}^{R^2}$ amounting to 0.15, 0.17 and 0.20 ppm for R^2=Me, 0.35, and 0.34 ppm for R^2=Et, and 1.50 and 1.46 ppm for R^2=*i*-Pr†††† (see Table 2). This extra increase of $\Delta\delta_{R^1}^{R^2}$ is explainable in terms of a buttressing effect resulting from the interaction between the ether oxygen and the methyls in R^2=Et and R^2=*i*-Pr.

It seems worth noticing that the deshielding of the methine protons of the isopropyl group in **3** *E* and **6** *E* is so strong as to produce a low-field shift even greater than that observed for the α protons of the R^3 group attached to the ether oxygen.

In the *cis(Z)* isomers R^2 is no longer deshielded by the carbonyl oxygen, so it is natural that the acylic protons absorb, as usual, at lower fields than the allylic ones, *i.e.*, $\Delta\delta_{R^1}^{R^2}$ values are negative. These differential shifts are expected to be more negative in the case of the *s-trans* rotamer, due to additional deshielding of R^1 by the alkoxy and olefinic groups. In this connection it might seem surprising that the branching of R_1, which was shown※ to shift the rotational equilibrium towards the *s-cis* isomer and can thus be anticipated to reduce the additional deshielding just mentioned, leaves the $\Delta\delta_{R^1}^{R^2}$ practically unaffected (see Table 2). It must be taken into account, however, that such branching simultaneously affects the shielding in the opposite direction by a mechanism similar to that discussed above for the *trans* isomer, *i.e.*, by restricting the rotation of the R^1



R^1=Me

R^1=Et

R^1=*i*-Pr

The two effects are apparently compensated in this way.

As for the other NMR signals, only those of the R^3 group seem to be informative. Since the branching of R^1 affects the *s-cis*⇌*s-trans* equilibrium, the constancy of the $\Delta\delta_z^E(R^3)$ values within the two series of compounds containing fixed R^3 and varying R^1 suggest that deshielding of R^3 by the carbonyl group in the *cis*/*s-cis* isomer does not play any marked role. Thus, the *cis*/*O-s-trans* or non-planar conformation proposed in the IR part of the present paper receives additional support.

Experimental

cis(Z) *Isomers*: *4-methoxy-3-penten-2-one* (*1* Z), *5-methoxy-4-hepten-3-one* (*2* Z), *and 5-methoxy-2,6-dimethyl-4-hepten-3-one* (*3* Z) were prepared from acetylacetone, dipropionylmethane[13], or diisobutyrylmethane,[14] by treatment with diazomethane as follows: to an excess of an ethereal solution of diazomethane[15] was added 0.05 M of diketone and 10 ml of methanol. The mixture was allowed to stand in dark for 16 h (with **1** *Z* and **2** *Z*) or 24 h (with **3** *Z*). The ether and the unchanged diazomethane were evaporated. Twofold vacuum distillation afforded fairly pure **1** *Z*, bp 37 °C (0.5 Torr), lit,[2] 84—86 °C (10 Torr), lit,[3] 56—58 °C (3.5 Torr), new compounds; data given in Table 3.

cis(Z) *5-Methoxy-2,2-dimethyl-4-hexen-3-one* (*8* Z): The reaction of pivaloylacetone[13] with diazomethane was carried out analogously for 24 h. The fractionate distillation *in vacuo* gave a mixture of isomers (which was not worked up) and an oil which solidified immediately. The resulting solid was pressed on porous porcelain and sublimed two times at 0.3 Torr to yield pure **8** *Z*.

The analogous reaction of diazoethane[15] with acetylacetone, dipropionylmethane, and diisobutyrylmethane in the presence of methanol (reaction time 16 h) gave after sublima-

††† Since R^1=R^2, the use of the differential shifts $\Delta\delta_{R^1}^{R^2}=\delta_R{}^2-\delta_R{}^1$ allows one to eliminate the difficulty arising from the necessity of comparing the methyl, methylene, and methine protons of R^2.

†††† In order to estimate the deshielding effect of the carbonyl group exerted upon R^2 another differential value concerning the resonance of this group only, *viz.*, $\Delta\delta_z^E$, can be used equally successfully. Indeed, the δ_Z values are good reference points for each of the homologues, as they are influenced by all the deshielding factors, the δ_E values are, except for the contribution of the carbonyl group, just now to be found. Numerically, $\Delta\delta_{R^1}^{R^2}$ and $\Delta\delta_E^Z(R^2)$ are very close.

※ See the part concerning IR spectra.

Table 3. Physical properties and analytical data

Compound	Bp (°C)	Mp (°C)	%C		%H	
			Calcd	Found	Calcd	Found
2*Z*	51 (0.8 Torr)	—	67.57	67.29	9.93	9.91
2*E*	41 (0.8 Torr)	—				
3*Z*	52 (0.8 Torr)	—	70.54	70.60	10.66	10.78
3*E*	45 (0.8 Torr)	—				
4*Z*	—	41	65.59	65.56	9.44	9.38
4*E*[a]	76 (15 Torr)	—				
5*Z*	58 (0.8 Torr)	—	69.19	69.20	10.32	10.26
5*E*	42 (0.4 Torr)	—				
6*Z*	53 (0.7 Torr)	—	71.69	71.33	10.94	10.73

8*E*	41 (1.3 Torr)	—				

Bp and mp were not corrected. a) This *trans*(*E*) compound was described incorrectly by Giza[4] to have a *cis*(*Z*) configuration.

tion *4-ethoxy-3-penten-2-one* (**4** *Z*) and, after distillation, *5-ethoxy-4-hepten-3-one* (**5** *Z*) and *5-ethoxy-2,6-dimethyl-4-hepten-3-one* (**6** *Z*), respectively.

A similar treatment of acetylacetone with 1-diazo-2-methylpropane[15] and methanol yielded *4-isobutoxy-3-penten-2-one* (**7** *Z*).

All the *trans*(*E*) compounds **1**—**8** *E* were prepared by isomerization of their *cis*(*Z*) isomers: the solution of a *cis*(*Z*) isomer in CCl_4 was refluxed for a few hours, then the solvent was removed and the product was distilled *in vacuo*; data given in Table 3.

The physical properties and analytical data of the new compounds and of those whose configuration was not established previously to this paper are given in Table 3.

The structures of all the compounds **1**—**8** *Z* and **1**—**8** *E* were confirmed by NMR spectra (see Table 2). The structures of the unsymmetrical compounds **8** *Z* and *E* were checked additionally by reduction with lithium aluminium hydride:[16] to a suspension of an excess of $LiAlH_4$ in ether was added **8***E* and the mixture was refluxed for 1.5 h. Water and aqueous potassium hydroxide were added and the mixture was filtered off. The ethereal layer was dried over KOH pellets and worked up in the usual manner to yield *5-methoxy-2,2-dimethyl-4-hexen-3-ol* bp 44—45 °C (0.5 Torr). NMR (δ, ppm in $CDCl_3$): 4.53, d, 1H; 3.50, s, 3H; 1.82, s, 3H; 0.90, s, 9H.

Infrared spectra were recorded on a Perkin-Elmer 325 spectrophotometer with a spectral slit width of 0.7—0.9 cm^{-1} and a scanning speed of 0.25 $cm^{-1}\,s^{-1}$. Commercial "for spectroscopy" solvents were used. The substances investigated were freshly distilled or sublimed before the measurements, and the middle fraction was used. The spectra were calibrated with polystyrene.

NMR spectra were recorded on Varian HA-60/IL and JEOL JNM-4H-100 instruments.

This work is a part of the Polish Academy of Sciences Programme for Structural Research (PAN-3).

New Red Pentaamminenitrosylcobalt(III) Complexes Obtained by the Reaction of a Cobalt(II)-ammoniacal Solution with Nitrogen Oxide

Eiichi MIKI* and Tatsujiro ISHIMORI

Department of Chemistry, College of Science, Rikkyo University, 3-Chome, Nishi Ikebukuro, Toshima-ku, Tokyo 171

(Received July 16, 1975)

New Red Pentaamminenitrosylcobalt(III) chloride and nitrate, $[Co_2(N_2O_2)(NH_3)_{10}]Cl_4\cdot 4H_2O$ and $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4\cdot 2H_2O$ were prepared by the reaction of NO at *ca.* 0 °C with a cobalt(II)-ammoniacal solution which had been exposed to air for 20 h at *ca.* 20 °C. Data of the new red salts were compared with those of the red salt $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4\cdot H_2O$ prepared by Sand and Genssler. The new red salt may be considered to be a linkage isomer of the red salt, a binuclear complex in which two of the $Co(NH_3)_5$ groups are bridged through a dimer of nitrosyl group, $N\text{–}O\text{–}O\text{–}N^{2-}$ ion.

Extensively studies have been carried out on the black and red series of compounds with the composition $Co(NH_3)_5(NO)X_2$ (X=Cl, Br, I, and NO_3) since they were first prepared by Sand and Genssler by the reaction of a cobalt(II)-ammoniacal solution with NO gas.[1] Recent X-ray diffraction studies have shown that the black salt $[Co(NO)(NH_3)_5]Cl_2$ is a monomer,[2] and the red one $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4\cdot H_2O$ (Red salt I) is a binuclear complex in which two cobalt atoms are bridged through a *cis*-hyponitrite ion, one cobalt atom being bound to the oxygen atom and the other to the nitrogen atom.[3]

We prepared new red-pentaamminenitrosylcobalt(III) chloride and nitrate (Red salt II), $[Co_2(N_2O_2)(NH_3)_{10}]Cl_4\cdot 4H_2O$ and $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4\cdot 2H_2O$ by the reaction of a ammoniacal cobalt(II)-solution with NO gas.[4] Molar conductivities, UV spectra, ^{15}N-isotopic effects on IR spectra upon ^{15}NO-substitution, and ^{15}N-NMR spectra were measured for Red salt I and II. Red salt II is considered to be a new type of compound containing a dimer of nitrosyl, $N\text{–}O\text{–}O\text{–}N^{2-}$ ion.

Experimental

Preparations. *Red Salt I (Nitrate)*: The compound was prepared according to the method of Moeller and King,[5] and could be recrystallized from a dilute ammoniacal solution and dimethyl sulfoxide (DMSO). Found: Co, 19.2; N, 36.1; H, 4.93; NH_3, 28.4%. Calcd for $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4\cdot H_2O$: Co, 19.19; N, 36.49; H, 5.09; NH_3, 27.73%. The ^{15}NO-complexes (^{15}N atom %=50 and 99) were synthesized in a vacuum line; 4 ml of concentrated ammonia was added to a solution of cobalt (II) salt (2 g of $Co(NO_3)_2\cdot 6H_2O$/9 ml of H_2O) at room temperature. The fresh filtrate was degassed with nitrogen, evacuated, and kept at 20 °C in a reaction vessel. 5 mmol of ^{15}NO was introduced at 20 °C into the ammoniacal solution and allowed to stand for 4 hr. Resulting red precipitates were collected by filtration, washed with concentrated ammonia, methyl alcohol, and ether, succesively, and dried in air. Yield, 50—200 mg.

Red Salt I (Chloride): The compound was prepared from Red salt I (nitrate) by stirring its aqueous solution with anion exchange resins of a chloride-ion form, and then adding a large excess of ammonium chloride to the filtrate. Found: Co, 22.4; N, 31.2; H, 5.71; Cl, 24.3%. Calcd for $[Co_2(N_2O_2)(NH_3)_{10}]Cl_4\cdot 2H_2O$: Co, 22.4; N, 31.9; H, 6.52; Cl, 27.0%.

Red Salt II (Chloride and Nitrate): Red salt II was prepared by the following procedure; 15 ml of ice-cooled concentrated ammonia was added to a cobalt(II) chloride or nitrate solution (5 g of the cobalt(II) salts/20 ml of H_2O) at *ca.* 0 °C. The solution was then exposed to air for 20 h at *ca.* 20 °C. The filtrate thus obtained was poured into a reaction vessel and degassed with nitrogen. Nitrogen oxide was passed into the solution cooled with an ice-water bath to obtain red precipitates. Yield, *ca.* 1 g. Red salt II (chloride) could be recrystallized only from an ice-cooled aqueous solution, and not from an ammoniacal solution. Red salt II (nitrate) could be recrystallized from an ice-cooled aqueous solution and from DMSO. The ^{15}NO-complexes (^{15}N atom %=50 and 99) were synthesized in a vacuum line; by cooling with liquid nitrogen, 5 mmol portion of ^{15}NO was trapped in a reaction vessel containing the ammoniacal cobalt (II) solution (*ca.* 4 g of the chloride or the nitrate/*ca.* 5M ammonia) which had been exposed to air for 20 hr at *ca.* 20 °C. The reaction vessel was shaken under running water until the frozen solution thawed, and was kept at *ca.* 0 °C for 1 hr to obtain the ^{15}NO-complex. Yield, 300—400 mg. The ^{2}H-complex was prepared by use of deuterated ammonia which was obtained by the reaction of magnesium nitride with heavy water. Found: Co, 21.5; N, 30.8; H, 5.4 (± 1.0)[6]; NH_3, 32.0; Cl, 25.2%. Calcd for $[Co_2(N_2O_2)(NH_3)_{10}]Cl_4\cdot 4H_2O$: Co, 20.97; N, 29.90; H, 6.81; NH_3, 30.30; Cl, 25.23%. $\chi_g=-0.170\times 10^{-6}$ (at 117 K), -0.193×10^{-6} (at 157 K), -0.262×10^{-6} (at 244 K), and -0.276×10^{-6} (at 288 K) (c. g. s.). Preparation of the $N^{18}O$-complex of Red salt II (chloride) was attempted by the use of $N^{18}O$ prepared by a reduction of $N^{18}O_2$ (^{18}O atom %=*ca.* 50) using selenium metal. However, the isotopic labeling of the nitrosyl group with ^{18}O was unsuccessful. Found: Co, 18.9; N, 33.63; H, 4.6 (± 1.0)[6]; NH_3, 27.2%. Calcd for $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4\cdot 2H_2O$: Co, 18.64; N, 35.44; H, 5.42; NH_3, 26.94%.

Measurements. The UV spectra in an aqueous solution and in DMSO (Dotite Spectrosol) were measured with a Hitachi 124 spectrometer and the diffuse reflection spectra with a Hitachi EPS-3T spectrometer. The molar conductivities in an aqueous solution (at 2.5 °C) and in DMSO (at 25 °C) were measured with a universal bridge (Model 4225A of Yokogawa-Hewlett-Packard Ltd.). The IR spectra of Red salt I and II were measured in the region 200—4000 cm^{-1} with JASCO DS-402G and JASCO model IR-F spectrometers as Nujol and hexachlorobutadiene mulls. The wave numbers of the observed IR bands were calibrated with polystyrene

* Present address: Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

film, 1,2,4-trichlorobenzene, and water vapor. The differential thermal analyses were performed with a DTA standard-type apparatus of Rigaku Denki Co. Ltd., Gaseous products obtained by the decomposition of Red salt I and II were trapped in a calcium difluoride gas cell with the aid of liquid nitrogen, and were identified from their IR bands.[7] Solid products obtained by dissolving Red salt II in ammonia or water and adding ammonium chloride or acetone to the solution were identified on the basis of their IR spectra[7] and elementary analyses. The Raman spectra for Red salt I (nitrate) and Red salt II (chloride) of the powdered samples and of the rotating potassium bromide disk were measured in the region 650—1700 cm^{-1} on a JASCO R-800 spectrometer equipped with an Ar ion laser, and on a Narumi 750Z-1200 double monochrometer equipped with a He-Ne laser. The magnetic susceptibility was measured by the Gouy method in the temperature range 120—290 K. ^{15}N-NMR spectra of the ^{15}NO-complex (^{15}N atom %=99) or Red salt II (nitrate) in DMSO-d^6 (*ca.* 0.2 g/2 ml) were measured on JEOL JNM-PS-100/PFT-100 FT-NMR system.

Results and Discussion

Red salt II could be prepared at *ca.* 0 °C by the reaction of nitrogen oxide with ammoniacal cobalt(II) solution which had been exposed to the air for 20 h at *ca.* 20 °C. It has been reported that when an ammonical cobalt(II) solution is exposed to the air, some binuclear cobalt(III) ammine complexes containing peroxo, superoxo, or amide groups are likely to be formed,[8] and reactions of these complexes with nitrogen oxide give μ-nitro or μ-nitrato complexes.[9] However, there was no spectroscopic evidence that the μ-nitro or μ-nitrato complexes were formed under the conditions for preparation of Red salt II. A mixture of $[Co(NO)(NH_3)_5]X_2$ and Red salt II was formed but not Red salt I when the time of exposure was less than 20 h and the temperature of the solution was kept below *ca.* 20 °C. No precipitate was obtained nor did the yield of Red salt II decrease when the time of exposure exceeded 20 h and the temperature of the ammoniacal solution was above 20 °C. A mixture of Red salt I and II was obtained when nitrogen oxide, without being fully cooled in an ice-water bath, was passed in the ammoniacal solution which had been exposed to air at 20 °C for 20 h. Red salt I seems to be prepared through the black isomer.[10] It might be possible that the black isomers dimerise to give Red salt II. Another possibility that Red salt II is formed by the reaction of nitrogen oxide with the peroxo complex formed when the cobalt(II)-ammoniacal solution has been exposed to air cannot be excluded. The temperature in the reaction of the ammoniacal cobalt solution with nitrogen oxide might control the formation of Red salt I or Red salt II.

The failure to label the nitrosyl group in Red salt II with ^{18}O is considered to be due to the fact that oxygen of the nitrosyl group is rapidly exchanged with oxygen in the ammoniacal solution.

UV Spectra and Molar Conductivities. The UV spectra for Red salts I and II in an aqueous solution were nearly the same as those in DMSO, and their spectral figures were also similar to those of the diffuse reflection spectra as shown in Table 1.

Table 1. UV spectra of red salts I and II in the solid state and in solution

Complexes	in H_2O		in DMSO		in solid state	
	position of band (in cm^{-1})	log ε	position of band (in cm^{-1})	log ε	position of band (in cm^{-1})	log $f(R)$
Red salt I (nitrate)	20700	1.50	20800	1.28	20700	2.03
	35100	4.05	a)			
	38300	4.15	a)			
Red salt II (chloride)	20300	1.28			20200	1.99
	31000	2.82				
	38000	3.48	insoluble			
	42000	4.08				
Red salt II (nitrate)	20600	1.38	20600	1.18	20500	1.51
	31200	2.91	31000	2.91		
	39000	3.74	a)			
	42000	4.30	a)			

a) These bands could not be measured due to the strong absorption of DMSO.

The molar conductivities of Red salts I and II were compared with those of 4: 1-, 3: 1-, and 2: 1-type electrolytes by the method of Feltham and Hayter.[11] In an aqueous solution at 2.5 °C, the molar conductivities at infinite dilution of Red salt I(nitrate), Red salt II(nitrate), and Red salt II(chloride) were 333, 358, and 366 $ohm^{-1}cm^2$, respectively, while those of $K_4[Fe(CN)_6]$, $[Cr(NH_3)_6](ClO_4)_3$, and $K_2[RuBr_5(NO)]$ were 386, 283, and 164 $ohm^{-1}cm^2$, respectively. The result for Red salt I supports that obtained by Feltham.[12] In DMSO at 25 °C, the molar conductivities at infinite dilution of Red salt I(nitrate) and Red salt II(nitrate) were 142 and 169 $ohm^{-1}cm^2$, and those of $[(CH_3)_4N]_4[RuCl(SnCl_3)_5]$, $[Co(phen)_3](ClO_4)_3$, and $[Ru(phen)_3](ClO_4)_2$ were 140, 115, and 77 $ohm^{-1}cm^2$, respectively.

Studies based on the UV spectra and molar conductivities show that Red salt II is a 4: 1-type electrolyte as well as Red salt I, and that the structure of the cationic ions in the solid states of Red salts I and II can be kept in aqueous and DMSO solutions.

Products Obtained by the Decomposition of Red Salts I and II. Gaseous Products Obtained by Thermal and Acid Decompositions of Red Salts I and II: Differential thermal analyses in atmosphere showed that for Red salt I(nitrate) an endothermic peak was observed at 143 °C, a violent exothermic reaction following at 180 °C. For Red salt II (chloride) an endothermic reaction began at 220 °C and a violent exothermic one followed at 260 °C, and for Red salt II(nitrate) an endothermic reaction at 150 °C and a violet exothermic one at 180 °C. These endothermic reactions are considered to correspond to the liberation of water of crystallization. Red salts I and II darkened at *ca.* 180 °C in a vacuum. Red salt II(chloride) was completely decomposed at 210 °C in a vacuum to give a blue powder, $CoCl_2$. Gaseous analyses by the IR spectra showed that NH_3, N_2O, and water vapor were liberated when Red salts I and II were heated in a vacuum up to 350 °C at a rate of *ca.* 10 °C/min in an electric furnace. A small amount of NO was also detected. However, $^{15}NH_3$ could not be identified in the gaseous decomposition

Table 2. Nitrosyl chloride and dinitrogen oxide from acid and thermal decompositions of red salts I and II

Compounds		Acid		Thermal[a]
Red salt I (nitrate)	^{14}NO-complex	6M H_2SO_4	$^{14}N^{14}NO$	$^{14}N^{14}NO$
		6M HCl	$^{14}N^{14}NO$, $^{14}NOCl$

a) The values in parentheses indicate the relative ratio of the amount of dinitrogen oxide.

product of the ^{15}NO-complexes of Red salts I and II. The results obtained are summarized in Table 2. $^{14}N^{14}NO$ and $^{14}N^{15}NO$ were derived from the ^{15}NO-complexes(^{15}N atom%=50 and 99) of Red salt II and from a mixture of the ^{14}NO- and ^{15}NO-complexes-(^{15}N atom%=99)(1:1) of Red salt II. On the other hand, $^{14}N^{14}NO$ and $^{15}N^{15}NO$ were derived from the ^{15}NO-complex(^{15}N atom%=99) of Red salt I and from a mixture of the ^{14}NO- and ^{15}NO-complexes(^{15}N atom%=99)(1:1) of Red salt I. $^{14}N^{14}NO$, $^{15}N^{14}NO$, $^{14}N^{15}NO$, and $^{15}N^{15}NO$ were observed in the ^{15}NO-complex (^{15}N atom%=50) of Red salt I.

Studies on a catalytic reaction of ^{15}NO with a large excess of $^{14}NH_3$ at 200—250 °C on platinum supported on alumina have shown that the reaction products and their relative ratios are $^{15}N^{15}NO$: $^{15}N_2$:$^{14}N^{15}N$:$^{14}N^{15}NO$ =32:6:50:13, and that a considerable amount of $^{14}N^{15}NO$ was obtained but no $^{15}N^{14}NO$ was detected.[13]

The thermal decomposition of ^{15}NO-complex(^{15}N atom%=99) of Red salt I(nitrate) gave $^{14}N^{14}NO$ and $^{15}N^{15}NO$, but not $^{14}N^{15}NO$. The $^{14}N^{14}NO$ from the ^{15}NO-complex of Red salt I(nitrate)(^{15}N atom%=99) probably arise as a by-product in the thermal decomposition; the $^{14}N^{14}NO$ contains two nitrogen atoms which come from the nitrogen of ammines and nitrate ions in this complex. The $^{14}N^{14}NO$ thus obtained occupied *ca.* 40% in all of the N_2O. The relative ratios of $^{14}N^{14}NO$: $^{15}N^{14}NO$: $^{14}N^{15}NO$: ^{15}N-^{15}NO from the hyponitrite ion in the ^{15}NO-complex (^{15}N atom%=50) of Red salt I(nitrate) became 1:1.4:1.2:1, and those of $^{14}N^{14}NO$: $^{15}N^{15}NO$ from the mixture of the ^{14}NO- and ^{15}NO-complexes(^{15}N atom%=99)(1:1) became 1:1.2. If the dinitrogen oxide exclusively comes from the hyponitrite ion in Red salt I without the N–N bond cleavage, the relative ratios of the mixture of $^{14}N^{14}NO$, $^{15}N^{14}NO$, $^{14}N^{15}NO$, and $^{15}N^{15}NO$ derived from the ^{15}NO-complex(^{15}N atom%=50) will be 1:1:1:1, and those of $^{14}N^{14}NO$ and $^{15}N^{15}NO$ from the mixture of ^{14}NO- and ^{15}NO-complexes(^{15}N atom%=99)(1:1) will be 1:1. It is hardly conceivable that the hyponitrite ion in Red salt I(nitrate) is decomposed to give nitrogen oxide, and the nitrogen oxide thus obtained reacts with NH_3.

The $^{14}N^{15}NO$ from the ^{15}NO-complex(^{15}N atom%=99) of Red salt II(chloride and nitrate) suggests the presence of the reaction of ^{15}NO with an excess of coordinated ammonia in these compounds. The ^{14}N-^{14}NO from the ^{15}NO-complex(^{15}N atom%=99) of Red salt II(chloride) seems to arise from oxidation of the $^{14}NH_3$. The $^{14}N^{14}NO$ as a by-product occupied *ca.* 20% of the total N_2O. The relative ratio of $^{14}N^{14}NO$ and $^{14}N^{15}NO$ from the nitrosyl group in the ^{15}NO-complex(^{15}N atom%=50) of Red salt II(chloride) became 1.2:1, and that of $^{14}N^{14}NO$ and $^{14}N^{15}NO$ from

the mixture of the ^{14}NO- and ^{15}NO-complexes(^{15}N atom%=99)(1:1) became 1:1. These isotopic studies suggest that the coordinated nitrosyl groups react with the NH_3 groups to give the dinitrogen oxide. The ratio, the dinitrogen oxide as the by-product to all the dinitrogen oxide derived from Red salt II(nitrate) was about 40%, showing that a considerable amount of the dinitrogen oxide is derived from the reaction of the coordinated NH_3 groups with the nitrate ions.

Table 2 also shows the gaseous products obtained by acid decomposition which is milder than the thermal one. The ^{15}NO-complex (^{15}N atom%=99) of Red salt II(chloride) was decomposed by addition of 6M sulfuric acid to give $^{15}NOCl$ and a very small amount of $^{15}N^{15}NO$, while only $^{15}N^{15}NO$ was derived from the ^{15}NO-complex(^{15}N atom%=99) of Red salt I(nitrate). The result from the addition of 6M sulfuric acid to the ^{14}NO-complex of Red salt I(nitrate) was in agreement with that obtained by Mercer *et al.*[14] The ratio of N_2O to NOCl derived from Red salt II(nitrate) was much smaller than that derived from Red salt I(nitrate) when 6M hydrochloric acid was added.

The thermal and acid decompositions of Red salts I and II suggest the following. If the hyponitrite ion were present in Red salt II, the N–N bond strength of the hyponitrite group would be smaller than that for Red salt I. However, another possibility that a small amount of $^{15}N^{15}NO$ from Red salt II is due to the contamination of Red salt II by Red salt I cannot be excluded (see IR spectra of Red salts I and II). In this case, it may be considered that the hyponitrite group is absent in Red salt II.

Solid Products Obtained by Treating Red Salt II with Ammoniacal Solution and Water: Red salt II(chloride) was completely decomposed in boiling water to give a mixture of cobalt(III) hydroxide and cobalt(III) ammine-complex with coordinated nitro group. The IR spectra of solid products precipitated by the addition of ammonium chloride or acetone to a 3M ammoniacal solution of Red salt II(0.5 g/40 ml) at *ca.* 0°C showed that Red salt II(chloride) was completely decomposed within 4 h to give an orange-yellow compound, the nitro-complex, while, in an aqueous solution of Red salt II at *ca.* 0 °C, Red salt II was stable for 9 days. The pink precipitate obtained by the addition of acetone to the aqueous solution was identified to be Red salt II with a small amount of the nitro-complex. Thus, Red salt II is considered to be stable in water at *ca.* 0 °C.

A yellow product was obtained when the ammoniacal solution of Red salt II was boiled and then cooled at *ca.* −15 °C. The IR spectra of this compound show the characteristic absorption bands of nitro-complex and of nitrate ion[7] and the corresponding bands of the ^{15}N-compound shifted downwards, but no characteristic ones of Red salt II could be observed. The IR spectra of the yellow product obtained from Red salt II(nitrate) was almost equal to that from Red salt II(chloride). Elementary analyses of the yellow salt from Red salt II(chloride) gave a Co: N: H: Cl atom ratio of 1: 7.7: 15.4: 0.2, and those from Red salt II(nitrate) gave a Co: N: H atom ratio of 1: 8.5: 16.9. The results obtained from the IR spectra and the elementary analyses show that a main component of the yellow salts is $[Co(NO_2)(NH_3)_5](NO_3)_2$.

Red salt I(nitrate) is very stable in a boiling 3M ammoniacal solution, and can be recrystallized by cooling the solution to −15 °C, and reprecipitated by addition of a large excess of ammonium nitrate to the ammoniacal solution. In boiling water, however, a part of Red salt I(nitrate) was decomposed to give cobalt(III) hydroxide.

The complex cation of Red salt II might be generally unstable with respect to the nitrosyl groups. No intermediates clearly reflecting structure for the complex cation of Red salt II could be isolated. All of the nitrosyl group in Red salt II might change into the nitro and nitrate ions.

IR Spectra of Red Salts I and II. *Red Salt I(Nitrate)*: No isotopic shifts for the bands in the region 200—700 cm^{-1} could be observed because of the broadness of the bands. Of the bands in the region 700—4000 cm^{-1}, three bands at 1137, 1048, and 930 cm^{-1} shifted to 1112, 1027, and 917 cm^{-1}, respectively, upon ^{15}NO-substitution(^{15}N atom%=99). These bands have been previously assigned to the N–N, the antisymmetric N–O, and the symmetric N–O stretching vibrations, respectively, on the basis of the oxtent of the isotopic shifts upon ^{15}NO-substitution[14] and IR studies on $M_2N_2O_2$ (M=Na and K) containing *cis*-$N_2O_2^{2-}$ ion.[15]

However, our assignments of these three bands differ from those by Mercer *et al.*[14] Five absorption bands for the ^{15}NO-complex(^{15}N atom%=50) were observed at 1137, 1112, 1048, 1027, and 924 cm^{-1}, and six absorption bands for the mixture of the ^{14}NO-complex and the ^{15}NO-complex(^{15}N atom%=99)(1:1) at 1137, 1112, 1048, 1027, 929, and 920 cm^{-1}.

For the ^{15}NO-complex(^{15}N atom%=50), the N–N stretching vibration can be expected to split into three absorption bands, the ^{14}N–^{14}N, the ^{14}N–^{15}N, and the ^{15}N–^{15}N stretching vibrations(their intensity ratio 1:2:1).[16] For the mixture of the ^{14}NO- and the ^{15}NO-complexes(^{15}N atom%=99)(1:1), the ratio of the absorption intensity for the ^{14}N–^{14}N and ^{15}N–^{15}N stretching vibrations can be expected to be 1:1. Both the 1137 cm^{-1} and the 1048 cm^{-1} bands clearly splitted into two bands upon ^{15}NO-substitution(^{15}N atom%=50), so they may not be due to the N–N stretching vibration. On the other hand, the 930 cm^{-1} band shifted to 924 cm^{-1} (this wave number lies midway between 930 cm^{-1} of the ^{14}NO-complex and 917 cm^{-1} of the ^{15}NO-complex) upon ^{15}NO-substitution(^{15}N atom%=50). The 924 cm^{-1} band is seemingly a single band, the half width of this band being larger than that of the 930 cm^{-1} band and of the 917 cm^{-1} one. The 924 cm^{-1} band might therefore consist of three absorption bands, the ^{14}N–^{14}N, the ^{14}N–^{15}N, and the ^{15}N–^{15}N stretching vibrations. The 1137 cm^{-1} and the 1048 cm^{-1} bands could be assigned to the antisymmetric and the symmetric N–O stretching vibrations, respectively, since the wave numbers of antisymmetric stretching vibration are generally larger than those of symmetric one.[7]

If the 930 cm^{-1} band corresponds to the N–N stretching vibration, the bond order of the N–N would be

about one[7] and the bond distance about 1.4 Å.[17] X-Ray diffraction study on Red salt I has shown that the N–N bond distance is 1.25 Å,[3] and the bond order about two,[17] suggesting that the N–N stretching vibration can be observed in the region *ca.* 1300 cm^{-1}. There was a possibility that the N–N stretching vibration could not be observed due to overlapping with very strong broad bands of the nitrate ions at 1360 cm^{-1}. However, this was eliminated by measurement of the IR spectra for the chloride of Red salt I; no absorption band was observed in the 1360 cm^{-1} region except for the band due to the NH_3 symmetric deformation vibration. Three bands at 1154, 1060, and 940 cm^{-1} were observed in the region 900—1200 cm^{-1}. They can be assigned to the antisymmetric N–O stretching vibration, the symmetric N–O one, and the N–N one, respectively.

The N–N stretching vibration for the *cis*-$N_2O_2^{2-}$ ion has been observed in the region 1300—1390 cm^{-1},[15] while the N–N stretching vibration due to the hyponitrite ion bridged with the $Co(NH_3)_5$ groups was observed at 930 cm^{-1}. Lowering of the wave numbers is considered to be due to the coordination of two cobalt atoms to the hyponitrite ion.

Red Salt II(Chloride and Nitrate): The IR spectra and their assignments for Red salt II(chloride) in the region 200—4000 cm^{-1} are shown in Table 3 and Fig. 1.

The absorption bands due to the water of crystallization may be overlapped with the broad bands due to the N–H stretching and the NH_3 degenerate deformation vibrations as observed on Red salt I(nitrate).

IR studies on ammine-complexes show that the NH_3 rocking vibration is sensitive to the oxidation state of the metal atom.[18,19] The wave numbers of these bands of Red salt II seem to support the view that the oxidation state of the cobalt atom for Red salt II is III as for Red salt I. Red salt II was diamagnetic as expected from the oxidation state of the cobalt atom of Red salt II.

Upon ^{15}NO-substitution(^{15}N atom%=99.3), the bands at 1481(vs),[20] 1278(vs), 804(w), and 595(s) cm^{-1} for the chloride shifted, and the bands at 1481, 1278, and 804 cm^{-1} split into two peaks upon ^{15}NO-substitution(^{15}N atom%=50). The band at 1020 cm^{-1}(m) did not shift or split, but shifted downwards by *ca.* 6 cm^{-1} upon ^2H-substitution. The spectral features for the nitrate were similar to those for the chloride except for the absorption band, *ca.* 1360 cm^{-1} due to the nitrate ions. The 1011 cm^{-1}(s) band hardly shifted upon ^{15}NO-substitution as observed on the 1020 cm^{-1} band of the chloride.

From a comparison of the IR spectra of Red salts I and II, II seems to be contaminated with a very small amount of I. I could not be removed from II by crystallization.

If the same N–N bond as in Red salt I and in $K_6[Co_2(CN)_{10}(N_2O_2)]\cdot nH_2O$,[16] is present in Red salt II, the N–N stretching and the N–N–O bending vibrations should be observed on IR and/or Raman spectra and shift and split into three peaks upon ^{15}NO-substitution (^{15}N atom%=50). However no such phenomena were observed. Such a N–N bond might not be present in the complex cation of Red salt II.

IR studies with the use of nitrogen-15 will exclude the possibility that the nitrosyl group terminally coordinates to the cobalt atom, and that two cobalt atoms are bridged through two nitrogen atoms of the two nitrosyl groups; in the former case, the stretching vibration of the terminal NO group is generally observed in the region 1530—1980 cm^{-1},[21] and in the latter case, the coordination number of the cobalt(III) ion

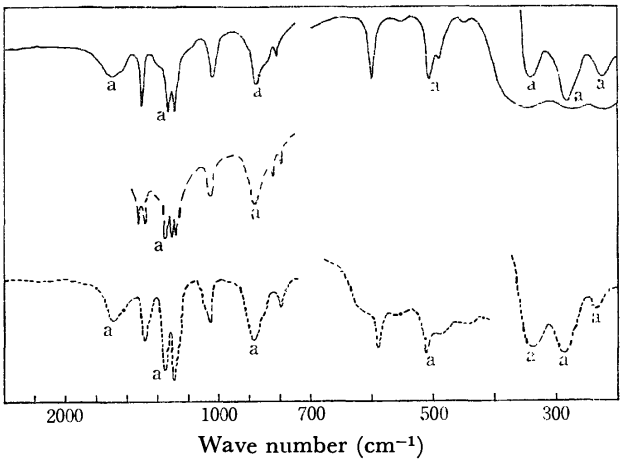

Fig. 1. IR spectra of Red salt II(chloride); —, ^{14}NO-complex; -·-, ^{15}NO-complex (^{15}N atom %=50); ---, ^{15}NO-complex (^{15}N atom %=99.3); a, characteristic bands of cobalt(III)-ammine complex.

Table 3. Wave numbers and assignments of IR bands for red salt II (chloride and nitrate)[a]

Red salt II (chloride)	Red salt II (nitrate)	Assignments
3250 vs, b 3110 vs, b	3280 vs 3200 vs, sh	O–H str and N–H str
1608 m, b	1625 m, b	H_2O bend and NH_3 deg def
1481(31)[b] vs	1491(32) s	N–O str
	1370 vs, b	N–O asym str of NO_3^{1-}
1318 vs	1320 sh	NH_3 sym def
1278(19) vs	1269(20) vs	N–O str
	1050 vw	N–O sym str of NO_3^{1-}
1020(1) m	1011(3) s	O–O str
859 s	852 s	NH_3 rock

501 s 478 m	493 w 475 sh	Co–NH_3 str
334 vs 278 vs 223 vs	325 vs, b 270 m, b	H_3N–Co–NH_3 bend

a) The bands due to Red salt I contained as impurity are excluded. b) The values in parentheses indicate the observed isotopic shift. Abbreviations: str=stretching, bend=bending, deg=degenerate, sym=symmetric, asym=asymmetric, rock=rocking, def=deformation, vs=very strong, s=strong, m=medium, w=weak, vw=very weak, b=broad, sh=shoulder.

becomes seven and the IR bands cannot be explained in terms of this skeleton. Elementary analyses and IR studies show that the number of the nitrogen atoms labeled with nitrogen-15 is two, and two of the nitrosyl groups are present in Red salt II.

The possibility that two of the $Co(NH_3)_5$ groups are bridged through an ion consist of a dimer of nitrosyl, N–O–O–N^{2-} can not be excluded. If the N–O–O–N anion is contained in the complex cation of Red salt II, the five IR bands in the region 580—1490 cm^{-1} could be explained on the basis of this anion; the 1481 and 1278 cm^{-1} bands of the chloride and the 1490 and 1269 cm^{-1} bands of the nitrate can be assigned to the N–O stretching vibrations, the 1020 cm^{-1} band of the chloride and the 1011 cm^{-1} band of the nitrate to the O–O stretching vibrations. The 804 cm^{-1} band of the chloride and the 806 cm^{-1} band of the nitrate may be assigned to the N–O–O bending vibrations. The 595 cm^{-1} band of the chloride and the 586 cm^{-1} band of the nitrate may be assigned to another N–O–O bending or the Co–N–O bending vibrations. The wave numbers of the N–O stretching vibrations for Red salt II are larger than those for the complexes with the hyponitrite ions. This seems to reflect the fact that the bond order of the N–O for Red salt II is larger than that for the complexes with the bridged hyponitrito ion. The O–O stretching vibrations of O_2^{2-} and O_2^{1-} anions are in the region 1050—1090 cm^{-1}, and 1070—1150 cm^{-1} [22] and those of μ-oxo cobalt(III)-ammine complexes and μ-superoxo ones are in the region *ca.* 830 cm^{-1} [23] and 1070—1150 cm^{-1}, respectively.[24] The band in the region 1010—1020 cm^{-1} for Red salt II may be reasonably assigned to the O–O stretching vibration. The N–N–O bending vibration of the hyponitrite ion are also observed in the region 600—860 cm^{-1}.[15,25] Thus, the bridged N–O–O–N^{2-} ion would most likely explain the results obtained.

Raman Spectra of Red Salts I and II. Since the nitrates of Red salts I and II decomposed in DMSO on irradiation with laser, their spectra could not be measured. Satisfactory Raman spectra of the powdered samples and the rotating potassium bromide disk could not be obtained because of a partial decomposition of the compounds. The bands due to nitro group and an unassignable band at 1653 cm^{-1} overlapped with the original bands for Red salt I(nitrate) and Red salt II(chloride). For Red salt II(chloride), the bands due to nitrate ion were also observed. However, all of the bands observed on IR spectra could be observed on Raman spectra for both Red salts I and II.

Nitrogen-15 NMR Spectra of Red Salt II. A preliminary ^{15}N-NMR study of the ^{15}NO-complex(^{15}N atom%=99) of Red salt II(nitrate) in DMSO-d_6 showed one peak, which is considered to support the view that two of the nitrosyl groups are in an equivalent chemical circumstance. The possibility that one cobalt atom is bound to the oxygen atom and the other to the nitrogen one in N–O–O–N^{2-} ion may be excluded.

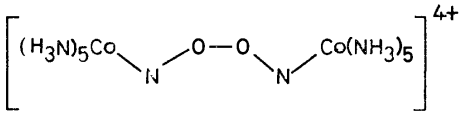

Fig. 2. Probable structure of the complex cation of Red salt II.

From the results, the structure as shown in Fig. 2 can be predicted for the complex cation of Red salt II. The coordination ability of the nitrogen of the N–O–O–N^{2-} ion to the cobalt atom may be stronger than that of the oxygen.

The authors express their appreciation to Mr. Takashi Takakuwa, Japan Spectroscopic Co. Ltd. and to Mr. Hiroshi Saito, Rikkyo University, for measurements of the Raman spectra, and to Mr. Shozo Shimizu of JEOL Ltd. for measurement of the ^{15}N-NMR spectra. The present work was supported in part by a Grant for Scientific Research from the Ministry of Education.

Study of Emulsions in Molten Salts. III. The Concentration, Stability and Particle-Size Distribution of Dispersed Lithium in Molten Lithium Chloride[1)]

Tsuyoshi NAKAJIMA, Koichiro NAKANISHI, and Nobuatsu WATANABE
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received June 21, 1975)

The concentration, stability and particle-size distribution of lithium dispersed in molten lithium chloride were investigated. The maximum content of dispersed lithium obtained by spontaneous emulsification was 4.8×10^{-3} mol/g at 678 °C. The concentration of dispersed lithium somewhat increased with the amounts of lithium oxide and nitride added to the molten salt by the mechanical agitation of the lithium–lithium chloride solution. The concentration was about 1.7 times that obtained by spontaneous emulsification except when a large amount of lithium nitride was added. Dispersed lithium in lithium chloride was shown to be fairly stable in the liquid state, as well as against the solidification of molten lithium chloride. The particle-size distribution of dispersed lithium was obtained by means of a scanning electron microscope. The sizes of the lithium particles dispersed in lithium chloride were shown to be mostly between 0.3 and 0.9 μ.

In previous papers,[1,2)] the authors have reported that, in addition to the true (physical) dissolution, metallic lithium was found to disperse into molten lithium chloride as colloidal particles, when a certain amount of lithium oxide was added to the molten salt or a small amount of oxygen or nitrogen was present in an argon atmosphere. The total concentration of lithium found in the solution thus obtained was considerably larger than the value for physical solubility. These facts may be ascribed to the emulsifying action of lithium oxide (or nitride) which is either simply added to the molten salt or formed by the reaction of lithium with oxygen (or nitrogen) in the atmosphere.[2)] Such metallic lithium–molten salt emulsions have been observed not only in molten lithium chloride but also in LiF–KF and NaCl–$CaCl_2$ systems. Larger amounts of lithium were found to disperse in LiCl and LiCl–KCl eutectic mixture where the solubilities of lithium oxide (or nitride) were almost equal to those in liquid lithium. On the other hand, the amounts of dispersed lithium were smaller in LiF–KF, LiF–LiCl and NaCl–$CaCl_2$ systems where the solubilities of oxide (or nitride) were quite different from those in lithium.[1)] It is interesting to further investigate the various factors governing the concentration and stability of lithium emulsions. In this paper, the concentration, stability and particle-size distribution of dispersed lithium in molten lithium chloride are reported.

Experimental

The concentration of lithium (dispersed as colloidal particles and dissolved to atomic dimensions) in molten lithium chloride was determined in the following manner. Three different instruments were designed and used. A highly-concentrated lithium solution was prepared with the apparatus in Fig. 1 (a), the stability of dispersed lithium was investigated in a stainless steel container (b), and the effect of mechanical agitation on the dispersion of lithium was studied with apparatus (c). For the measurements with (a) and (b), the amount of lithium added was sufficient to completely cover the surface of the molten salt. In the case of apparatus (c), about 1.5 mol (10 g) of lithium was added into 1.5 mol (64 g) of lithium chloride. The rate of agitation of the stirrer was 300 to 1300 rpm.

The methods of chemical analysis of lithium, lithium oxide and nitride, and of the purification of argon which was used as the atmospheric gas were the same as those described previously.[1,2)]

1: Pyrex cap, 2: stainless steel container, 3: silica container, 4: stainless steel container, 5: thermocouple, 6: stainless steel pipe, 7: stirrer, 8: molte lithium, 9: molten lithium chloride.

Furthermore, direct observations of liquid and solid samples were attempted by means of a binocular stereomicroscope and a scanning electron microscope.

Results and Discussion

Concentration of Dispersed Lithium in Emulsion. The amounts of lithium dispersed in molten lithium chloride considerably increased with time using a U-type container (a) with a by-pass in a dried argon atmosphere, as shown in Fig. 2.

Since the true solubility of lithium is about 0.7 mol% at the experimental temperature, it is obvious from the figure that a large amount of lithium was dispersed in lithium chloride. For lithium concentrations higher than 12 mol%, the sampling with a thin silica pipe was difficult owing to the considerable decrease in the surface tension of the lithium–lithium chloride solution. The maximum concentration of dispersed lithium was 17.0 mol% at 678 °C. This value is equal to 4.8×10^{-3} mol/g which is the largest in lithium–lithium chloride emulsions.

Effect of Mechanical Agitation on the Concentration of Dispersed Lithium. The effects of the agitation time, agitation speed and concentration of lithium

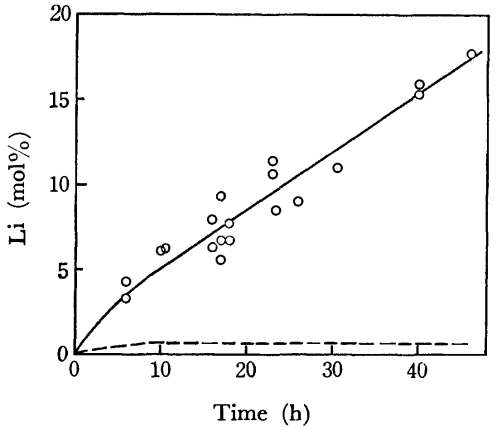

Fig. 2. Concentration of lithium in molten lithium chloride in argon atmosphere *vs.* time plot.

oxide or nitride on the concentration of dispersed lithium were investigated and the results are shown in Figs. 3, 4 and 5, respectively. Figure 6 shows the lithium concentration *vs.* time obtained without mechanical agitation. In this condition, the lithium concentration amounted to about 1.8 to 2 mol% by spontaneous emulsification and true dissolution. As shown in Fig. 5, mechanical agitation did not cause the dispersion of lithium when no lithium oxide or nitride was added to lithium chloride. The addition of oxide and nitride to the molten salt, however, brought about an increase

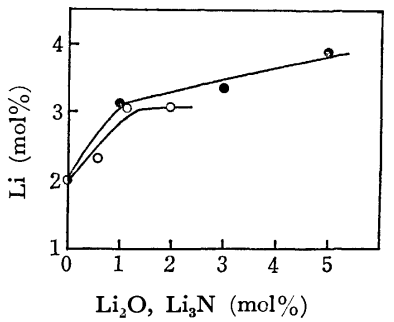

Fig. 5. Effects of lithium oxide and nitride on the lithium concentration.
○: Li_2O, ●: Li_3N.

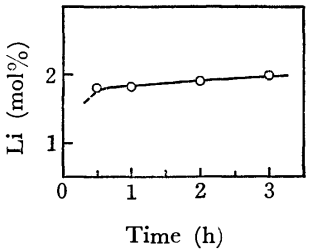

Fig. 6. Concentration of lithium *vs.* time plot in the absence of mechanical agitation.
Temp: 650 °C.

in the concentration of dispersed lithium. The increase in lithium concentration may, therefore, be attributed to the emulsifying action of lithium oxide or nitride. Furthermore, lithium oxide added in excess of its solubility[3] in lithium chloride had little effect on the concentration of dispersed lithium. This result is consistent with that obtained in the absence of mechanical agitation as described in a previous paper.[2] If solid films of lithium oxide are formed on lithium particles, the activity of oxide ions in the molten salt will decrease to some extent. Under the present conditions, the dissolution of lithium oxide to make up for the decrease in the activity of oxide ions should be accelerated by mechanical agitation. Therefore, if the decrease in the activity of oxide ions is not very small, the concentration of dispersed lithium is expected to increase by mechanical agitation in concentrations of lithium oxide higher than about 1 mol%. But this expectation is not supported by the experimental results. This means that lithium oxide acts as the emulsifying agent in an ionized state. On the other hand, the concentration of dispersed lithium increased monotonically with the addition of lithium nitride because its solubility in lithium chloride was 14.6 mol%[1] at 650 °C.

Stability of Lithium–Lithium Chloride Emulsion. The apparatus was sealed when the lithium concentration reached a certain value in a dried, deoxidized argon atmosphere and the change of lithium concentration was monitored. The results are shown in Fig. 7. Since the true solubility of lithium in molten lithium chloride is about 0.6 mol% at the experimental temperature, the amounts of lithium over the solubility

are those of lithium dispersed by spontaneous emulsification. The concentrations of dispersed lithium and lithium compounds[4] were both slightly larger than those obtained at the time when the apparatus was sealed. Somewhat larger increases in the concentrations were, therefore, observed in systems standing for a long time. This is probably because lithium oxide or nitride on the surface of liquid lithium was dissolved or dispersed in the molten salt, or a small amount of air entered into the apparatus. The concentration of lithium in the molten salt depends on the dispersion of lithium due to the emulsifying action of lithium oxide or nitride and the oxidation or nitridation of dispersed lithium on the surface of the molten salt. Figure 7 shows that dispersed lithium may be stable in the molten salt if it is not too oxidized or nitridized with air.

When the emulsion is solidified, it seems possible that dispersed lithium particles in the system are distorted and coalesce with each other, that is, the lithium–lithium chloride emulsion is broken. It is said that the stability of dispersed particles against the solidification of the solvent is a measure of the capability of an emulsifying agent. As shown in Table 1, the lithium concentrations after remelting of the solid samples were slightly lower than those obtained before solidification, but the differences between them are smaller than the true solubility of lithium at the experimental temperature.[5] The emulsion appears to be fairly stable upon solidification. The small decrease in the lithium concentration may be due to the phase separation of lithium physically dissolved to atomic dimensions in the molten salt.

Particle-Size Distribution of Dispersed Lithium. Direct observations of lithium particles in a molten lithium chloride–potassium chloride eutectic mixture at a certain partial pressure of nitrogen were attempted using a binocular stereomicroscope with a long focal distance (maximum magnification : 160 times), because an ordinary optical microscope was difficult to use at the high temperatures of 400 to 650 °C. If the diameter of a lithium particle was larger than 3 μ, the lithium particles could be expected to be observed, but none were found.

Table 1. Stability of dispersed lithium against the solidification of molten lithium chloride

Concentration of lithium before solidification of lithium chloride (mol%)	Concentration of lithium after remelting of lithium chloride (mol%)
2.03	1.59
6.15	5.84

Then, a cross section of a cylindrical solid sample, which was obtained by direct sampling from a salt-rich phase with a thin silica pipe, was observed by means of a scanning electron microscope. Four kinds of samples were prepared at 650 °C:

(a) Lithium chloride containing 5 mol% lithium nitride.

(b) A sample prepared by dissolving lithium physically in lithium chloride with a sealed-type cell.[2]

(c) A sample prepared by dispersing lithium in lithium chloride at a partial pressure of nitrogen of 0.02 atm.

(d) A sample prepared by dispersing lithium in lithium chloride containing 5 mol% lithium nitride by means of mechanical agitation (1000 rpm, 25 min).

No small particles were found in samples (a) and (b). In sample (b), small particles which may have been formed by phase separation of lithium dissolved to atomic dimensions could possibly be observed in solid lithium chloride, but were probably not found because they were too small to be recognized or were covered with solid lithium chloride.

In almost all cases with samples (c) and (d), the recognition of small particles was considerably difficult because granular substances on the cross section were not clearly exposed and were covered with solid salt.

Figures 8, 9 and 10 were obtained with sample (d). A large number of small particles are observed in the figures. It appears that the surface in the figures where many particles exist is not a newly prepared cross section obtained by breaking a solid sample, but is instead a cave hidden inside cylindrical sample. Perhaps for this reason, small particles are clearly observed at the places not thickly covered with solid

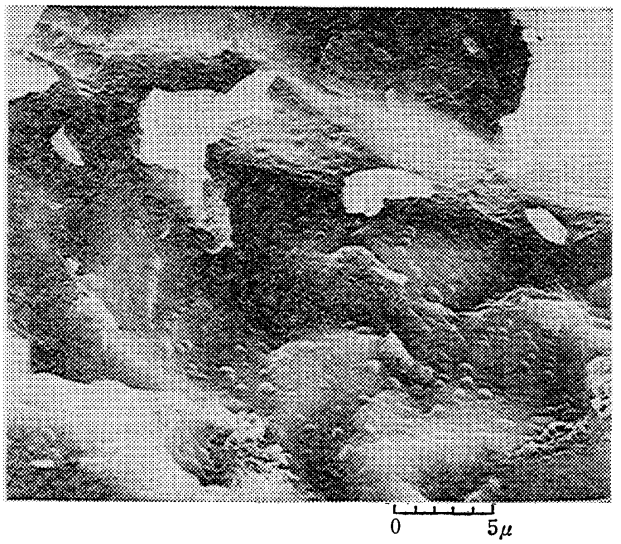

Fig. 8. Scanning electron micrograph of metallic lithium particles in lithium chloride.

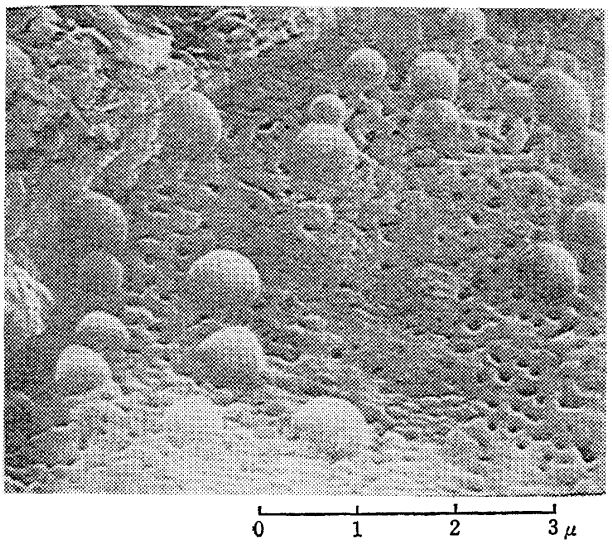

Fig. 9. Scanning electron micrograph of metallic lithium particles in lithium chloride.

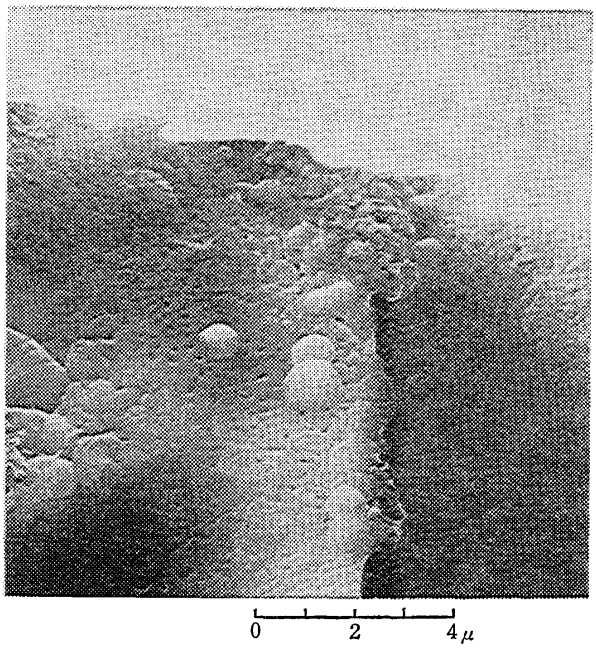

Fig. 10. Scanning electron micrograph of metallic lithium particles in lithium chloride.

salt. Elemental analysis was then carried out by means of an X-ray microanalyser in order to confirm whether these small particles were lithium metal. The distribution of lithium atoms cannot be found directly since the intensity of X-rays emitted by lithium atoms is too weak to be detected efficiently. Therefore, the X-ray intensities emitted from chlorine atoms were compared with each other by applying an electron beam to a small particle and its surroundings on as flat a surface as possible. Both the diameters of an electron beam and its transmission depth are 1 μ. Accordingly, if the diameter of a small particle is less than 1 μ or the small particle is covered with a thin film of solid salt, it is possible that chlorine atoms present around the particle or in the film of the solid salt would be detected and that the difference of both chlorine intensities would not be large. Actually the intensities for chlorine atoms obtained with small particles in the center of Fig. 10 were only slightly smaller than those obtained from their surroundings. If small particles in the figures are not lithium metal but solid salt, the chlorine intensities obtained from the projecting small particles would be considerably larger than those obtained from their surroundings because both concentrations of chlorine atoms are equal. Consequently, the small particles in the figures are regarded as lithium metal.

Now, the following situations should be taken into account when the particle sizes of dispersed lithium metal in the molten salt are evaluated from the small particles in the figures:

(1) Whether or not the coalescence of lithium particles occurred on rapid solidification of the sample.

(2) It is possible that small particles which were formed by the coalescence of lithium dissolved physically to atomic dimensions were mixed in the colloidal lithium.

(3) If lithium particles are covered with solid salt, they may be observed as particles larger than their true sizes.

(4) Since the temperature at which the sample was prepared was different from that at which a scanning electron micrograph was taken, it is necessary to correct for the contraction of the particles.

The particle-size distribution for 100 particles was obtained by taking the above problems into consideration and is given in Fig. 11. Most of the particles are distributed in the range of 0.3 to 0.9 μ and the largest particle has a diameter of 1.2 μ. The sizes of lithium particles in emulsion are then expected to be distributed in this range.

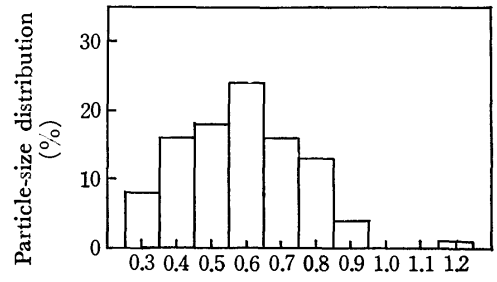

Fig. 11. Particle-size distribution of dispersed lithium in lithium chloride.

Generally, particles formed by spontaneous emulsification are smaller than those formed by mechanical agitation. In other words, it is expected that particles with larger diameters are formed by agitation, and thus the particle-size distribution also becomes slightly broader. For this reason, no lithium particles should be found by direct observation of the liquid state.

Phase Equilibria in $Fe-Fe_2O_3-Ln_2O_3$ (Ln=Sm and Er) Systems at 1200 °C

Kenzo KITAYAMA and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 7, 1975)

Phase equilibria in $Fe-Fe_2O_3-Ln_2O_3$ (Ln=Sm and Er) systems were established at 1200 °C. In the $Fe-Fe_2O_3-Sm_2O_3$ system, perovskite, garnet, magnetite, wustite, and metallic iron were stable, while in the $Fe-Fe_2O_3-Er_2O_3$ system, the $ErFe_2O_4$ phase appeared in addition to the other five phases. On the basis of the phase equilibria, the Gibbs free energy for the reaction of $LnFeO_3$, $Ln_3Fe_5O_{12}$, and $ErFe_2O_4$ from Ln_2O_3, metallic iron, and oxygen was determined to be as follows: $SmFeO_3$ -64.1 ± 0.1 kcal, $Sm_3Fe_5O_{12}$ -298.5 ± 0.5 kcal, $ErFe_2O_4$ -100.8 ± 0.1 kcal, $ErFeO_3$ -59.7 ± 0.3 kcal, and $Er_3Fe_5O_{12}$ -286.2 ± 0.7 kcal.

In previous studies, Kimizuka and Katsura,[1] Sugihara *et al.*,[2] and Kimizuka and Katsura[3,4] have established the phase equilibria in $Fe-Fe_2O_3-Ln_2O_3$ systems (Ln=La, Y, Eu, and Yb) at 1200 °C. They have also determined the standard Gibbs free energy for reaction of each ternary double oxide found in these systems from metallic iron, Ln_2O_3, and oxygen. On the basis of these studies, Kimizuka and Katsura[4] have proposed that $Fe-Fe_2O_3-Ln_2O_3$ systems (Ln=La, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, and Y) can be classified into four groups with respect to the assemblage of ternary compounds which are in stable co-existence at 1200 °C. According to them, the $Fe-Fe_2O_3-Sm_2O_3$ system may belong to the B-type having two ternary compounds, $SmFeO_3$ and $Sm_3Fe_5O_{12}$, while the $Fe-Fe_2O_3-Er_2O_3$ system is of the C-type having the three stable ternary compounds, $ErFeO_3$, $Er_3Fe_5O_{12}$, and $ErFe_2O_4$. Preceding these studies, Schneider *et al.*[5] had studied the subsolidus binary phase equilibria for the $Fe_2O_3-Sm_2O_3$, and the $Fe_2O_3-Er_2O_3$ systems by the X-ray powder diffraction technique at various temperatures, and found the two rare-earth iron oxides of perovskite and garnet at 1200 °C. The discovers of two new compounds, $LnFe_2O_4$ (Ln=Ho, Er, Tm, and Y) and $Ln_2Fe_3O_7$ (Ln=Yb and Lu) have recently been reported by Kimizuka and Katsura,[3,4] Kimizuka *et al.*,[6,7] Kato *et al.*,[8,9] Tannieres *et al.*,[10] and Evrard *et al.*[11,12]

The objectives of the present study are, firstly, to ascertain the validity of the classification for two systems involving Sm_2O_3 and Er_2O_3 at 1200 °C, after establishing the phase equilibria in these systems, and secondly, to determine the standard Gibbs free energy for reaction of $LnFeO_3$, $LnFe_2O_4$, and $Ln_3Fe_5O_{12}$ compounds at 1200 °C from metallic iron, Ln_2O_3, and oxygen.

Experimental

Analytical grade Fe_2O_3, Sm_2O_3(99.9%), and Er_2O_3(99.9%) powder were employed as starting materials. Desired ratios of Ln_2O_3/Fe_2O_3 were obtained by mixing thoroughly in an agate mortar with ethyl alcohol. Mixtures thus obtained were treated by the same procedures as those described previously.[2-4]

Mixed gases of CO_2 and H_2 were used to obtain low oxygen partial pressures in the present experiment. The actual oxygen partial pressures of the gas phase was measured by means of a solid electrolytic cell composed of $(ZrO_2)_{0.85}$-$(CaO)_{0.15}$.[13]

Phases in quenched samples were identified by the powder X-ray diffraction method with Mn-filtered Fe$K\alpha$ radiation.

Details of the apparatus and procedures for maintaining constant temperature, methods of thermogravimetry and quenching, the criterion for equilibrium-establishment, and the method of wet chemical analysis are the same as those described in a previous paper.[2-4,14] Lattice constants were determined by the powder X-ray diffraction method with Mn-filtered Fe$K\alpha_1$ radiation and with a slow scanning speed of 0.5° per minute. Instrumental errors were calibrated by measuring the diffraction angles of a standard specimen of silicon.

Results and Discussion

Phase Equilibria. The $Fe-Fe_2O_3-Sm_2O_3$ System: Six samples with Sm_2O_3/Fe_2O_3 compositions of 0.25, 0.60, 0.724, 1, 1.222, and 1.5 were prepared. The results of the phase equilibria are illustrated in Fig. 1. The following phases were stable under the experimental conditions: samarium sesquioxide (Sm_2O_3),

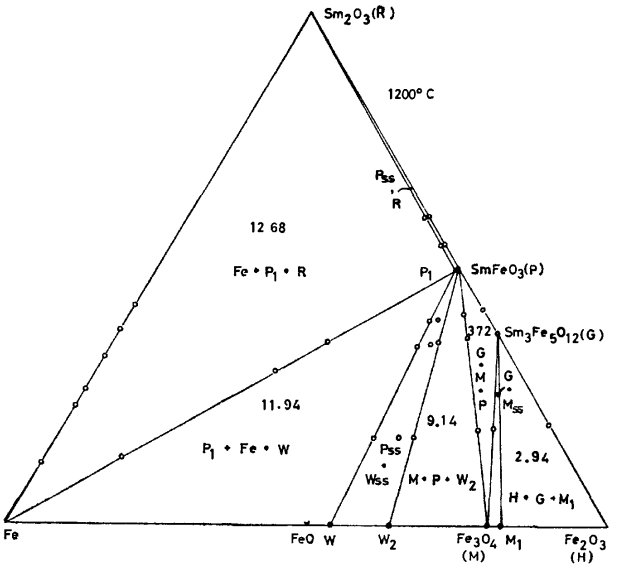

Fig. 1. Phase equilibria in the $Fe-Fe_2O_3-Sm_2O_3$ system at 1200 °C (mol%). Numbers in the figure mean values of $-\log P_{O_2}$ at which three crystalline phases are in equilibrium state. Letters R, P, G, and M represent stoichiometric compositions of Sm_2O_3, $SmFeO_3$, $Sm_3Fe_5O_{12}$, and Fe_3O_4, respectively. M_1 means the endmember of the magnetic solid solution with a chemical composition, $Fe_{2.957}O_4$. P_{ss}, W_{ss}, and M_{ss} mean the solid solution of $SmFeO_3$ from P to P_1, of FeO from W to W_2, and Fe_3O_4 from M to M_1, respectively. The other letters as for in Table 2.

Table 1. Lattice constants of ternary oxides

$ErFe_2O_4$ (hexagonal)				
$ErFe_2O_{3.984}$	3.489±0.001		24.929±0.004	262.8±0.2
$ErFe_2O_{3.957}$	3.494±0.001		24.927±0.004	263.6±0.2
$ErFe_2O_{3.904}$	3.500±0.001		24.948±0.005	264.6±0.3

hematite (Fe_2O_3), magnetite (Fe_3O_4), wustite (FeO), metallic iron (γ-Fe), samarium-iron-perovskite ($SmFeO_3$), and samarium-iron-garnet ($Sm_3Fe_5O_{12}$).

Sm_2O_3 was stable in oxygen partial pressures from one to $10^{-12.8}$ atm at 1200 °C, and appeared to have no significant nonstoichiometry in its composition. The deviation from the stoichiometric composition of $SmFeO_3$ extended up to $SmFeO_{2.982}$ at an oxygen partial pressure of $10^{-12.68}$ atm. The lattice constants of the $SmFeO_3$ solid solution seemed to be constant irrespective of the compositional variation. The data are given in Table 1 together with the data of Geller and Wood.[15] This is the same trend as those found for $EuFeO_3$,[2] $YFeO_3$,[3] and $YbFeO_3$.[4] $Sm_3Fe_5O_{12}$ had no compositional variation and remained stoichiometric under the experimental conditions. The lattice constants of $Sm_3Fe_5O_{12}$ were almost identical with those obtained by Bertaut and Forrat[16] and Espinosa.[17] The data are given in Table 1.

The $Fe-Fe_2O_3-Er_2O_3$ System: Seven samples with Er_2O_3/Fe_2O_3 compositions of 0.25, 0.429, 0.499, 0.6, 0.739, 1 and 1.222 were prepared. Figure 2 shows the experimental results. The following phases were stable under the experimental conditions: erbium sesquioxide (Er_2O_3), hematite (Fe_2O_3), magnetite (Fe_3O_4), wustite (FeO), metallic iron (γ-Fe), erbium-iron-perovskite ($ErFeO_3$), erbium-iron-garnet ($Er_3Fe_5O_{12}$), and $ErFe_2O_4$.

Er_2O_3 was stable in oxygen partial pressures from one to $10^{-12.0}$ atm, and appeared to have no compositional variation. The deviation from the stoichiometric composition of $ErFeO_3$ extended up to $ErFeO_{2.973}$ at an oxygen partial pressure of $10^{-11.19}$ atm. The lattice constants of the $ErFeO_3$ solid solution seemed to be constant irrespective of the compositional variations. The data are given in Table 1. $Er_3Fe_5O_{12}$ had no compositional variation under the experimental conditions, and its lattice constants were almost identical with those obtained by Bertaut and Forrat[16] and Geller *et al.*[18] The data are given in Table 1. The $ErFe_2O_4$ phase had a wide composition range from $ErFe_2O_{3.955}$ at an oxygen partial pressure of $10^{-10.00}$ atm to $ErFe_2O_{3.903}$ at an oxygen partial pressure of $10^{-11.96}$ atm. The lattice constants of the $ErFe_2O_4$ solid solution were determined on the basis of the study of the crystal structure by Kato *et al.*,[8] and these data are also given in Table 1. As shown in Table 1, the lattice constants of this solid solution increase with decreasing oxygen content.

In conclusion, from the studies of the phase equilibria of two systems, it has become clear that the $Fe-Fe_2O_3-Sm_2O_3$ system belongs to the B-type having two ternary compounds as presumed by Kimizuka and Katsura,[4] and that the $Fe-Fe_2O_3-Er_2O_3$ system belongs to the C-type having three ternary compounds, $ErFeO_3$, $Er_3Fe_5O_{12}$, and $ErFe_2O_4$.

Calculations of Standard Gibbs Free Energies of Ternary Compounds. On the basis of the phase equilibria, we can determine the standard free energy of reaction of the respective $ErFe_2O_4$, $SmFeO_3$, $Sm_3Fe_5O_{12}$, $ErFeO_3$, and $Er_3Fe_5O_{12}$ compounds, referring to the following equations:

$$Fe + 1/2Sm_2O_3 + 3/4O_2 = SmFeO_3 \quad (1)$$

$$5Fe + 3/2Sm_2O_3 + 15/4O_2 = Sm_3Fe_5O_{12} \quad (2)$$

$$2Fe + 1/2Er_2O_3 + 5/4O_2 = ErFe_2O_4 \quad (3)$$

$$Fe + 1/2Er_2O_3 + 3/4O_2 = ErFeO_3 \quad (4)$$

$$5Fe + 3/2Er_2O_3 + 15/4O_2 = Er_3Fe_5O_{12} \quad (5)$$

The standard Gibbs free energies of reaction (1) and (3) may be calculated directly by adopting each equilibrium oxygen partial pressure corresponding to the equation. Here, the activity of each component of $SmFeO_3$ and $ErFe_2O_4$ in each solid solution was set equal to one, and where the compositions were $SmFeO_{2.982}$ (P_1 in Fig. 1) and $ErFe_2O_{3.903}$ (A in Fig. 2),

both were in equilibrium with metallic iron and sesquioxide.

In order to calculate the standard Gibbs free energy of reaction (2), it is necessary to calculate the standard Gibbs free energy of the following reaction (6):

$$3SmFeO_3 + 2/3Fe_3O_4 + 1/6O_2 = Sm_3Fe_5O_{12} \quad (6)$$

This may be readily calculated on the basis of the experimental results illustrated in Fig. 1. The activity of the $SmFeO_3$ component in stoichiometric composition which was in equilibrium with both stoichiometric Fe_3O_4 and $Sm_3Fe_5O_{12}$ was calculated by means of the Gibbs-Duhem equation. The relationship between $-1/2 \log P_{O_2}$ and N_O/N_{SmFeO_3}, the fraction ratio of oxygen to $SmFeO_3$, indicating the deviation from stoichiometry, was substantially linear from the present experimental results, and the activity was calculated to be 1.125. A detailed calculation method has been described in the paper of Kimizuka and Katsura.[4] Since the standard Gibbs free energy of formation of Fe_3O_4 referred to the Eq. 7.

$$3Fe + 2O_2 = Fe_3O_4 \quad (7)$$

has been determined by Darken and Gurry,[19] the standard Gibbs free energy of $Sm_3Fe_5O_{12}$ referred to Eq. 2 may be determined by adding together $3\Delta G°(1)$, $\Delta G°(6)$, and $2/3\Delta G°(7)$.

In order to calculate the standard Gibbs free energy referred to Eq. 4, we have to invoke the following reaction (8):

$$1/4Er_2O_3 + 1/2ErFe_2O_4 + 1/8O_2 = ErFeO_3. \quad (8)$$

The standard Gibbs free energy of reaction (8) may be readily calculated on the basis of the experimental results shown in Fig. 2. Here, the activity of the $ErFeO_3$ component with composition $ErFeO_{2.973}$ (P_3 in Fig. 2) was set equal to one. The activity of the $ErFe_2O_4$ component in the $ErFe_2O_4$ solid solution from $ErFe_2O_{3.903}$ to $ErFe_2O_{3.995}$ is calculated by means of the Gibbs-Duhem equation, and the relationship between $-1/2 \log P_{O_2}$ and $N_O/N_{ErFe_2O_4}$ was substantially linear from the experimental results. After determining the activity of $ErFe_2O_4$ with a composition of $ErFe_2O_{3.942}$ (A_1 in Fig. 2), we may determine the standard Gibbs free energy referred to Eq. 4 by adding together $1/2\ \Delta G°(3)$ and $\Delta G°(8)$.

To determine the standard Gibbs free energy referred to Eq. 5, it is necessary to calculate the standard Gibbs free energy of the following reaction (9):

$$3ErFeO_3 + 2/3Fe_3O_4 + 1/6O_2 = Er_3Fe_5O_{12} \quad (9)$$

The procedure for determining the standard Gibbs free energy of reaction (9) is the same as that for reaction (6). Adding together $2/3\ \Delta G°(7)$, $3\Delta G°(4)$, and $\Delta G°(9)$, we obtain the value of $\Delta G°(5)$. The calculated activity data are summarized in Table 2, and the standard Gibbs free energies of reactions (1) to (9) are given in Table 3.

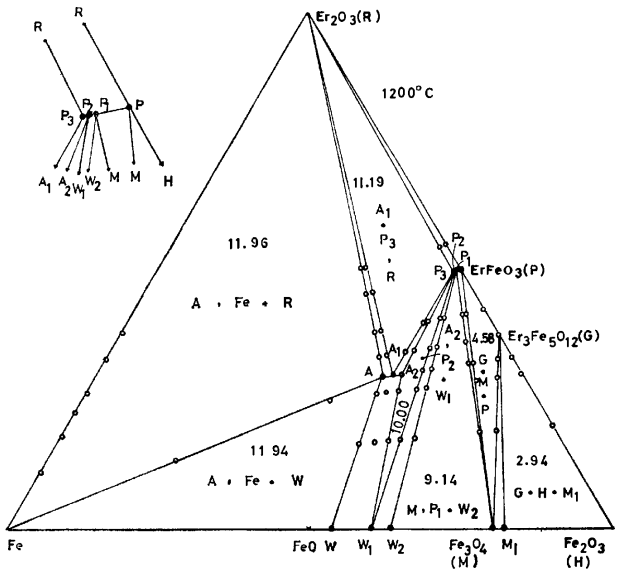

Fig. 2. Phase equilibria in the Fe–Fe_2O_3–Er_2O_3 system at 1200 °C (mol %). Numbers in the figure mean values of $-\log P_{O_2}$ at which three crystalline phases are in equilibrium state. Letters R, P, G, amd M represent stoichiometric compositions of Er_2O_3, $ErFeO_3$, $Er_3Fe_5O_{12}$, and Fe_3O_4, respectively. M_1 means the endmember of the magnetite solid solution with a chemical composition, $Fe_{2.957}O_4$. The other letters as for in Table 2.

Table 2. Composition and activity in solid solutions

Component	Composition	Symbol	$-\log P_{O_2}$	$\log a_i$
FeO	$FeO_{1.049}$	W	11.94	0
	$FeO_{1.125}$	W_1	10.00	−0.0805
	$FeO_{1.166}$	W_2	9.14	−0.150
$SmFeO_3$	$SmFeO_{2.982}$	P_1	12.68	0
	$SmFeO_{3.000}$	P	9.14	0.0512
			0.68	0.0512
$Sm_3Fe_5O_{12}$	$Sm_3Fe_5O_{12.00}$	G	3.72	0
$ErFe_2O_4$[a]	$ErFe_2O_{3.903}$	A	11.96	0
	$ErFe_2O_{3.942}$	A_1	11.19	0.0350
	$ErFe_2O_{3.995}$	A_2	10.00	0.0478
$ErFeO_3$[b]	$ErFeO_{2.973}$	P_3	11.19	0
	$ErFeO_{2.977}$	P_2	10.00	0.0213
	$ErFeO_{2.980}$	P_1	9.14	0.0240
	$ErFeO_{3.000}$	P	3.64	0.0509
$Er_3Fe_5O_{12}$	$Er_3Fe_5O_{12.00}$	G	4.58	0

a) The relationship between the composition and $\log P_{O_2}$ is, $N_O/N_{ErFe_2O_4} = 0.04494 \log P_{O_2} + 0.4447$. b) The relationship between the composition and $\log P_{O_2}$ is, $N_O/N_{ErFeO_3} = 0.03571 \log P_{O_2} + 0.0130$.

Table 3. The summary of the standard Gibbs free energy values

	Reactions	$-\Delta G°$(kcal)
(1)	$Fe + 1/2Sm_2O_3 + 3/4O_2 = SmFeO_3$	64.1±0.1
(2)	$5Fe + 3/2Sm_2O_3 + 15/4O_2 = Sm_3Fe_5O_{12}$	298.5±0.5
(3)	$2Fe + 1/2Er_2O_3 + 5/4O_2 = ErFe_2O_4$	100.8±0.1
(4)	$Fe + 1/2Er_2O_3 + 3/4O_2 = ErFeO_3$	59.7±0.3
(5)	$5Fe + 3/2Er_2O_3 + 15/4O_2 = Er_3Fe_5O_{12}$	286.2±0.7

(7)	$3Fe + 2O_2 = Fe_3O_4$	154.5±0.3
(8)	$1/4Er_2O_3 + 1/2ErFe_2O_4 + 1/8O_2 = Er_2FeO_3$	9.3±0.2
(9)	$3ErFeO_3 + 2/3Fe_3O_4 + 1/6O_2 = Er_3Fe_5O_{12}$	4.1±0.3

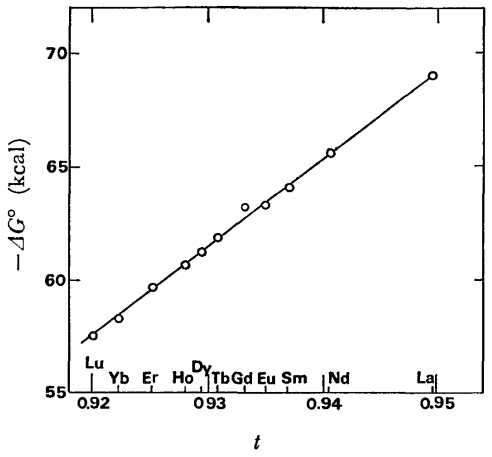

Fig. 3. The relationship between $\Delta G°$ and the tolerance factor t.

The Relationship Between the Value of $\Delta G°$ of Lanthanoid-Iron-Perovskite and the Tolerance Factor. Katsura *et al.*[20] and Kimizuka and Katsura[4] have pointed out that the standard Gibbs free energy of reactions of lanthanoid-iron-perovskite from metallic iron, lanthanoid sesquioxide, and oxygen may change proportionally with the tolerance factor defined by Goldschmidt.[21] The tolerance factor t is defined as $\gamma_A+\gamma_O=t\sqrt{2}(\gamma_B+\gamma_O)$, where γ_A, γ_B, and γ_O are the ionic radii of the A-atom, B-atom, and O-atom of the perovskite, ABO_3, respectively.

The same rule holds also for $ErFeO_3$, $HoFeO_3$,[22] and $LuFeO_3$[23] as seen in Fig. 3. The deviation from the general trend in $GdFeO_3$ is estimated to be about 400—500 cal, and is significant in considering the range of the experimental errors. A more detailed discussion will be published in the near future after the completion of the study of all the lanthanoid-iron-perovskite members.

give 1.196 g (93%) of β-acetyl-γ-butyrolactone (IIIf).

Reaction of 3,4-Dihydro-6-methyl-2H-pyran-2-one with 3-Phenylpropanal. $BF_3 \cdot OEt_2$ (0.142 g, 1 mmol) in 1 ml of methylene chloride was added into a mixture of 3,4-dihydro-6-methyl-2*H*-pyran-2-one (0.244 g, 2 mmol) and 3-phenylpropanal (0.134 g, 1 mmol) in 2 ml of methylene chloride at 0 °C. After the reaction mixture was stirred for 15 h at 0 °C, it was worked up as in the preparation of IIIf, to give 0.206 g (84%) of γ-acetyl-δ-phenethyl-δ-valerolactone (IVa).

IVb—e were obtained by the same procedure. The physical properties and analytical data of IVa—f are shown in Table 2. IR spectra of IVa—f indicated the carbonyl of lactone (1735 cm^{-1}) and acetyl (1710 cm^{-1}). NMR spectra of IVa—f are listed in Table 4.

Reaction of 3,4-Dihydro-6-methyl-2H-pyran-2-one with Formaldehyde. Formaldehyde gas, produced from paraformaldehyde (0.121 g, 4 mmol), was bubbled into a mixture of 3,4-dihydro-6-methyl-2*H*-pyran-2-one (0.224 g, 2 mmol) and $BF_3 \cdot OEt_2$ (0.284 g, 2 mmol) at 0 °C. After the reaction

The Photochemical Cycloaddition of the Enol Acetate of Dimedone to Cyclopentene

Misao UMEHARA, Tomio ODA,* Yoshinori IKEBE,** and Shinzaburo HISHIDA**

Department of Chemistry, Keio University, Hiyoshi-cho, Kohoku-ku, Yokohama 223

(Received July 19, 1975)

The photochemical cycloaddition of the enol acetate of dimedone to cyclopentene yields two stereoisomers I and II of 2-acetoxy-4,4-dimethyltricyclo[6.3.0.0^{2,7}]undecan-6-one. The NMR and IR data suggest a *cis-anti-cis* configuration for I and a *cis-anti-trans* configuration for II. The NMR and IR spectra determined on III, IV and V, the $NaBH_4$ reduction products of I and II, also support these configurations. Both of the photo adducts, I and II, lose acetic acid in the presence of an alkali to give an α,β-unsaturated ketone (VI), while it undergoes retro-aldol cleavage in the presence of an acid to give 4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione (VII). A comparative study was made of the mass spectra of I, II, and VI.

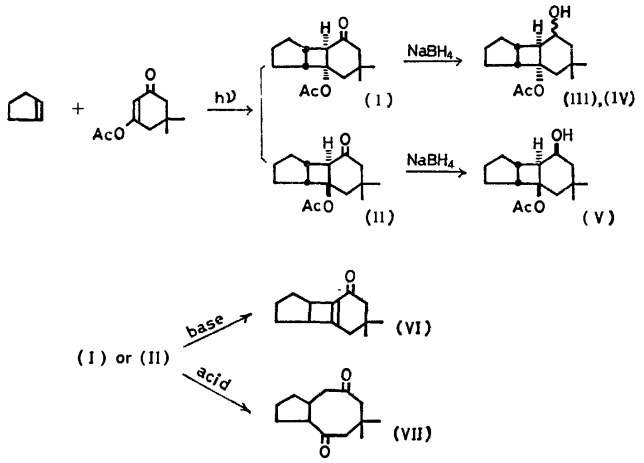
The photochemical cycloaddition of the enol acetates of β-diketones to alkenes has been reported by de Mayo *et al.*[1] These photoadducts undergo retro-aldol cleavage under the basic conditions to give 1,5-diketones. Using this sequence, we undertook the photochemical cycloaddition of cyclopentene to the enolacetate of dimedone as a first step in the synthesis of terpens containing a medium-size ring. However, very few studies have been made of the stereochemistry of such photoannelation adducts. Hence, the purpose of this paper is to determine the configuration of the photo-adducts. The NMR spectral data of the photoadducts thereby obtained are difficult to analyze; hence, the configuration is not easy to determine. In the present study, the configuration was determined with the aid of an NMR-shift reagent—tris(dipivalomethanato)-europium,[2] $Eu(DPM)_3$, which has come into use in recent years.

The product, VII, resulting from the retro-aldol cleavage of the photoadducts, I and II, has a fused ring system consisting of a five-membered ring and an eight-membered ring. Compounds of such a skeleton have rarely been synthesized thus far. They constitute a partial skeleton of some sesterterpenes and are of interest in this respect.

Results and Discussion

The enol acetate of dimedone yields, upon irradiation in cyclopentene, a mixture of two stereoisomeric photoadducts, I and II, in a ratio of roughly 2 : 1. To gain some knowledge of the configuration of such photoadducts, I and II were reduced by $NaBH_4$; I gave two alcohols, III and IV, while II gave one alcohol, V.

I or II readily loses acetic acid at room temperature to yield an α,β-unsaturated ketone (VI) upon treatment with sodium methoxide or sodium hydroxide in methanol,[3] but it does not undergo retro-aldol cleavage to produce a 1,5-diketone.[1] However, I or II undergoes retro-aldol cleavage in methanol containing sulfuric acid to yield a 1,5-diketone (VII).



Scheme 1.

IR Spectra of I and II. As is shown in Table 1, the I photoadduct shows a ketonic carbonyl absorption at 1703 cm^{-1} which is normal for ordinary six-membered ketones. On the other hand, the II photo-adduct shows a ketonic carbonyl absorption at the unusually large wave number of 1730 cm^{-1}, which indicates the presence of a large strain in the six-membered ring of II. This finding suggests that the configuration of the ring junction between the four-membered and six-membered rings is a highly strained *trans* form in II, whereas it is *cis* in I.[4]

NMR Spectra of I and II. The NMR spectra of I and II, as measured in the usual manner, do not allow the assignment of each proton because there are not large differences in chemical shift among the protons. The NMR spectra were, therefore, measured by applying $Eu(DPM)_3$ as a shift reagent.

Figure 1(a) shows the NMR spectrum of I measured in the absence of the shift reagent, while Fig. 1(b) shows the NMR spectrum of I measured in a solution of 20 mg of I in 0.4 ml of carbon tetrachloride to which 60 mg of $Eu(DPM)_3$ had been added. Likewise, Fig. 2(a) shows the NMR spectrum of II, while Fig. 2(b) shows the NMR spectrum measured in a solution of 20 mg of II in 0.4 ml of carbon tetrachloride plus 60 mg of $Eu(DPM)_3$. In both Figs. 1 and 2, the addition of 60 mg of $Eu(DPM)_3$ caused an increase in the chemical shift and a complete separation of proton signals, and the assignment of each proton was done by

m/e=183.

Experimental

The NMR spectra were determined on a Hitachi R-22 spectrometer at 90 MHz, with TMS as the internal standard. The mass spectra measured with a Hitachi RMU-6L and RMU-7M spectrometer. The IR spectra were recorded with a JASCO IR-G spectrophotometer. The UV data were recorded with a Hitachi EPS-3 spectrophotometer. The VPC analyses were carried out on a 063 Hitachi gas chromatograph. The melting points were uncorrected.

2-Acetoxy-4,4-dimethyltricyclo[6.3.0.0^{2,7}]undecan-6-one (I and II). A solution of 16.5 g of dimedone enol acetate in 200 ml of cyclopentene was irradiated for 15 h in a Pyrex tube with a 100-W high-pressure marcury arc at 0—5 °C in a nitrogen atmosphere. The crude crystalline residue remaining after the removal of the solvent was crystallized from ether; 14.4 g were thus yielded as a mixture of I and II (65% yield). Fractional recrystallization from ether afforded 7 g of I and 3.2 g of II.

I: mp 126—127 °C. IR (see Table 1). NMR (see Fig. 1 and Table 2). Found: C, 71.76; H, 8.80%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%. MS (see Fig. 5(a)).

II: mp 117—118 °C. IR (see Table 1). NMR (see Fig. 2 and Table 2). Found: C, 72.04; H, 8.24%. MS (see Fig. 5(b)).

Sodium Borohydride Reduction of I. A solution of 1 g of the I adduct in 20 ml of methanol was stirred, over a 5-min period, into a solution of 0.1 g of sodium borohydride in 10 ml of methanol at 0—5 °C. The mixture was kept in an ice bath for 25 min, diluted with 150 ml of water, and extracted with ether (three times). The evaporation of the extract after drying gave an oily mixture of III and IV (1 g). VPC analysis indicated that the mixture consisted of 66% III and 34% IV. Repeated fractional crystallizations from hexane gave the pure III and IV.

III: mp 49.5—51.5 °C. IR (see Table 1). NMR ($CDCl_3$): δ 0.98 (3H, CH_3), δ 1.02 (3H, CH_3), δ 2.00 (3H, $OCOCH_3$) and δ 3.77 (m, 1H, CHOH). Found: C, 71.22; H, 9.60%. Calcd for $C_{15}H_{24}O_3$: C, 71.43; H, 9.52%

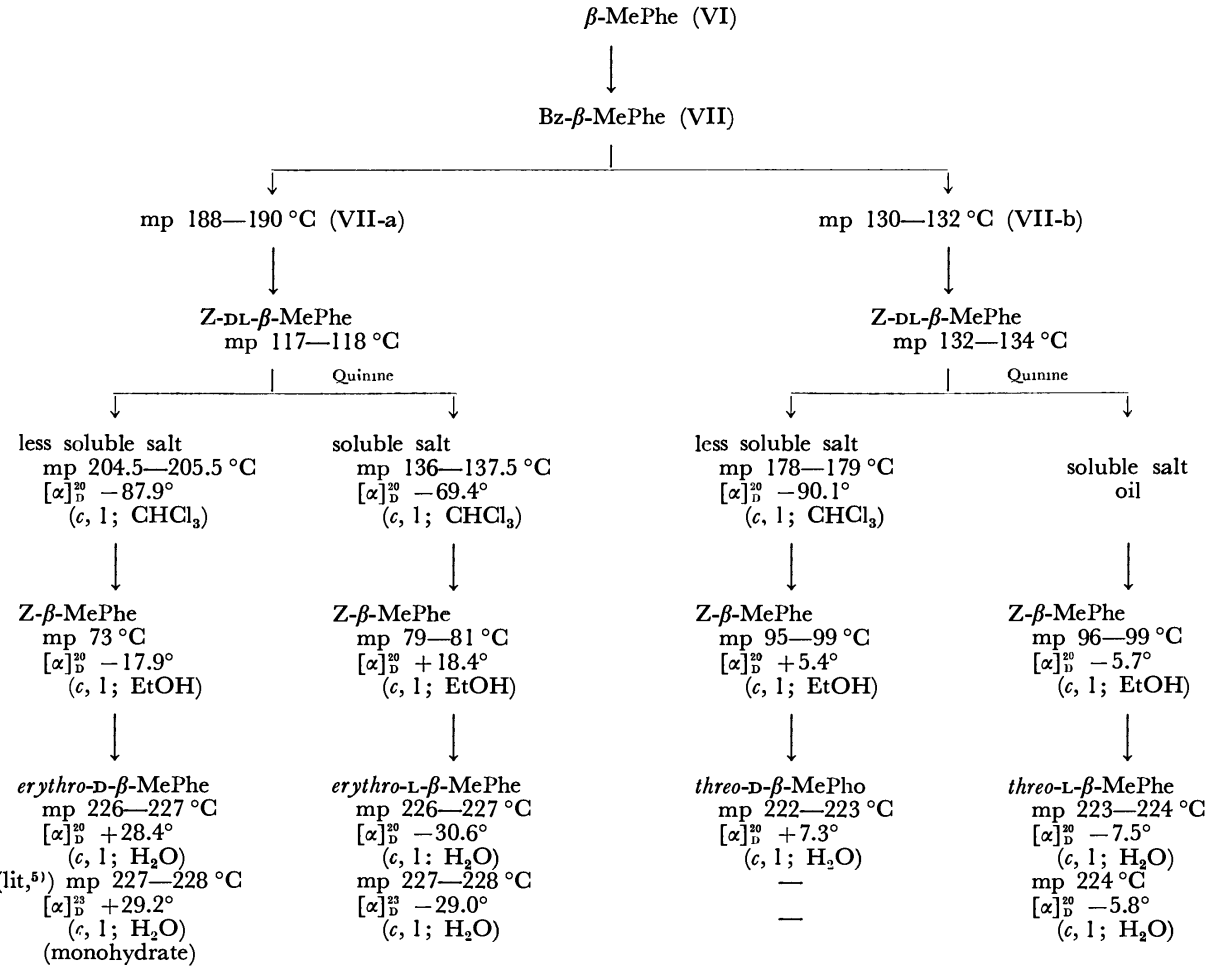
IV: mp 86—88.5 °C. IR (see Table 1). NMR ($CDCl_3$): δ 0.88 (3H, CH_3), δ 0.94 (3H, CH_3), δ 1.98 (3H, $OCOCH_3$) and δ 4.05 (m, 1H, CHOH). Found: C, 71.38; H, 9.27%.

Sodium Borohydride Reduction of II. The II adduct (1 g) was reduced by the method described above. The yielded product showed one peak in VPC and one spot in TLC. The crystallization from hexane gave 0.82 g of V (82% yield). Mp 54.5—55.5 °C (after four recrystallizations). IR (see Table 1). NMR ($CDCl_3$): δ 0.97 (3H, CH_3), δ 1.14 (3H, CH_3), δ 2.07 (3H, $OCOCH_3$) and δ 4.01 (m, 1H, CHOH). Found: C, 71.56; H, 9.34%. Calcd for $C_{15}H_{24}O_3$: C, 71.43; H, 9.52%.

4,4-Dimethyltricyclo[6.3.0.0^{2,7}]-$\Delta^{2,7}$-undecen-6-one, VI (α,β-Unsaturated Ketone). A solution of 5.9 g of photoadducts (mixture of I and II) in 65 ml of absolute methanol was stirred into a solution of sodium methoxide, prepared from 0.6 g of sodium and 50 ml of absolute methanol. The mixture was then allowed to stand at room temperature overnight. The methanol was removed under reduced pressure after neutralization with Dry Ice. The remaining oil was extracted with ether. The ethereal extract was washed with water and dried by sodium sulfate. The subsequent removal of the solvent gave 3.7 g of a pale yellow oil. After distillation. 2 g of a colourless oil was obtained (44% yield). A solution of 1.1 g of I in 50 ml of absolute methanol, in which there was dissolved 0.2 g of sodium, was allowed to stand overnight; 0.61 g of the α,β-unsaturated ketone was thus obtained (76% yield). The 0.2 g of II also produced 0.08 g of VI (53% yield); bp 136—138 °C/14 mmHg; mp 24—25 °C (after three distillations). IR: 1660 cm^{-1}, UV (ethanol): 250 nm (ε, 9250) and 322 nm (ε, 98). Found: C, 82.35; H, 9.12%. Calcd for $C_{13}H_{18}O$: C, 82.11; H, 9.47%. MS (see Fig. 5(c)). 2,4-DNP: mp 173—174 °C.

4,4-Dimethylbicyclo[6.3.0]undecane-2,6-dione, VII. A solution of 1 g of I in 50 ml of methanol containing 1.5 ml of sulfuric acid was left to stand for two weeks at room temperature. The reaction mixture was then concentrated under reduced pressure and extracted with ether. The ethereal extract was neutralized with sodium bicarbonate, washed with water, and then dried over sodium sulfate. The semicrystalline residue remaining after the removal of the ether was sublimed under reduced pressure (13 mm Hg) to give 0.46 g of the dione, VII (56% yield). Also, 1 g of II produced 0.41 g of VII (50% yield). Crystallization from hexane afforded pure crystals; mp 64—65 °C. IR (Nujol) 1695 cm^{-1}. NMR ($CDCl_3$): δ 1.11 (3H, CH_3) and δ 1.13 (3H, CH_3). Found: C, 75.14; H, 9.60%. Calcd for $C_{13}H_{20}O_2$: C, 75.00; H, 9.62%. MS: *m/e* 208 (M^+, $C_{13}H_{20}O_2$, 5%), 193 ($C_{12}H_{17}O_2$, 5), 190 ($C_{13}H_{18}O$, 11), 180 ($C_{12}H_{20}O$, 4), 152 ($C_9H_{12}O_2$, 13), 141 ($C_8H_{13}O_2$, 26), 124 ($C_8H_{12}O$, 41), 112 ($C_7H_{12}O$, 24), 95 (C_6H_7O, 43), 83 (C_5H_7O, base), 81 (C_6H_9, 23), 67 (C_5H_7, 29), 55 (C_4H_7, C_3H_3O, 24) and 41 (C_3H_5, 23).

Determination of the Rate Constants (I and II→VI). The



Scheme 2. Separation of β-methyl-phenylalanine (β-MePhe) into four isomers.

TABLE 1. NMR DATA OF β-METHYL-PHENYLALANINE (60 MHz, DSS)

	Compound	Medium		
		D_2O	D_2O+DCl	D_2O+NaOD
$\delta_{H\alpha}$ (ppm)	VI-a	3.81	4.26	3.34
	VI-b	3.94	4.34	3.41
$\delta_{H\beta}$ (ppm)	VI-a	3.31	3.49	2.98
	VI-b	3.55	3.59	3.19
$J_{CH_3-H\beta}$ (Hz)	VI-a	6.9	7.4	6.8
	VI-b	7.2	7.5	7.2
$J_{H\alpha-H\beta}$ (Hz)	VI-a	7.5	7.2	7.5
	VI-b	4.8	6.0	5.2

It was noted that the difference in $J_{\alpha\beta}$ appeared more remarkable in a neutral medium than in an acidic or a basic condition.

In order to determine the *erythro/threo* ratio, the condensation product (III) was converted into a mixture of free amino acids (VI) by hydrolyzing it with hydrochloric acid. From the NMR spectra of the amino acids, the *erythro/threo* ratios were determined as (1.5—1.7) : 1. The benzyloxycarbonylation of the mixture of the free amino acids afforded the crystalline *threo* isomer and the oily, difficult-to-refine *erythro* derivative; the ratio of the amount of the *erythro* to that of the *threo* compounds was again found to be about 2 : 1. These results apparently indicate that the diastereoselective decarboxylation of the malonic acid derivative occurred quite similarly to Arold's observation.

To resolve each diastereomer, a diastereoselective reaction between *N*-acetyl-β-methyl-phenylalanine and hydrazine in the presence of papain was attempted, but no crystalline hydrazide was obtainable. The benzoyl derivative could not be used in this case because of its low solubility in a buffer solution of pH 5. By using 30% aqueous dioxane, it could be brought into solution, but no desired results were obtained. The resolution of the *N*-acyl derivatives by alkaloid bases was alternatively tried in various combinations; the results are shown in Table 2. The *N*-benzoyl derivative gave no definite alkaloid salt so far as we examined; with a quaternary ammonium hydroxide obtained from quinine by methylation, it gave crystalline salt, but the operations were too troublesome. As to the *erythro* derivative, the best result was obtained by treating the *N*-benzyloxycarbonyl-derivative with quinine in ethanol. *N*-Benzyloxycarbonyl-*erythro*-β-methyl-phenylalanine was mixed with equimolar quinine in ethanol, the less soluble salt was treated with hydrochloric acid to remove the quinine, and then

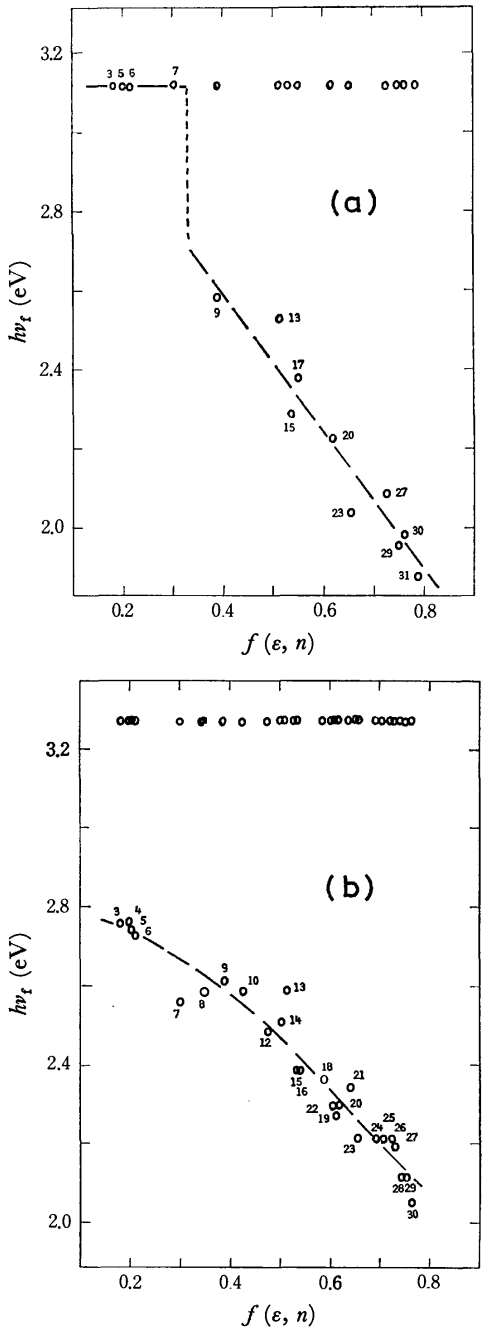


Fig. 5. Observed $h\nu_f$ *vs.* $f(\varepsilon, n)$ relations for A_2 (a) and P_2 (b).

the two moieties. Therefore, the electron transfer state is placed at higher energy than the LE state (S_1) of anthracene or pyrene and there may arise only a very weak interaction between the electron transfer configuration and the LE configuration because of the long distance between the two groups and the unfavorable geometrical configuration for the delocalization interaction. However, because their dipole moments in the CT state are much larger than those of the sandwich type exciplexes, the CT state may be stabilized rather strongly by the interaction with the polar solvent.

The energy of the CT state in solution may be given by Eq. 1, if we neglect the delocalization interaction between the two moieties.

$$\begin{aligned} E_{CT} &= I - A - C - H_s \\ &= I - A - C - (\mu_e^{eq*}/a^3)(\varepsilon - 1/2\varepsilon + 1) \\ &= I - A - C - \frac{1}{2}\mu_e^{eq*} f_\varepsilon \end{aligned} \tag{1}$$

where I and A are the ionization potential of the donor and electron affinity of the acceptor, respectively, C is the coulomb interaction energy between the donor cation and acceptor anion calculated by using the Hückel MO's putting point charges at each AO, and H_S is the solvation energy of the ion-pair. We have approximated here H_S by the interaction energy of a dipole with the surrounding dielectric continuum according to Onsager's reaction field theory. a is the cavity radius in the reaction field theory and μ_e^{eq} is the dipole moment of the excited equilibrium state. For example, the value of (μ_e^{eq*}/a^3) for S_1 was estimated to be 2.1 eV from the slope of the $h\nu_f$—$f(\varepsilon,n)$ linear relation in Fig. 3. Taking I=7.5 eV, A=0.5 eV, C= 3.2 eV, and $(\varepsilon-1/2\varepsilon+1)\approx0.26$ (the CT fluorescence appears above the value of $(\varepsilon-1/2\varepsilon+1)\approx0.26$), E_{CT} was estimated to be 3.25 eV. (For the evaluation of C, it was assumed that the long axis of anthracene is parallel with the short axis of DMA and the angle between the short axis of anthracene and the long axis of DMA is 109°28′.) Since the ground state will have no dipole moment due to CT from DMA to anthracene, the Franck-Condon (FC) ground state may be destabilized with respect to solvation. Again by using the dielectric continuum approximation, the destabilization energy amounts to

$$\begin{aligned} \delta E_g^{FC} &= (\mu_e^{eq*}/a^3)[(\varepsilon - 1/2\varepsilon+1) - (n^2 - 1/2n^2 + 1)] \\ &= (1/2)\mu_e^{eq*}(f_\varepsilon - f_n) \end{aligned} \tag{2}$$

$\delta E_g^{FC}\approx0.12$ eV at $(\varepsilon-1/2\varepsilon+1)\approx0.26$ since $(n^2-1/2n^2+1)\approx0.2$ for almost all solvents used in the present work. Therefore, $h\nu_f=E_{CT}-\delta E_g^{FC}=3.13$ eV. This $h\nu_f$ value is almost equal to that of anthracene LE fluorescence. The circumstance in the case of A_2 and P_1 seems to be quite analogous. Therefore, the solvent-induced change of the electronic structure of these compounds may be regarded as a solvent-induced reversal of two energy levels which do not interact with each other or do interact only very weakly. In other words, the solvent-induced changes of the fluorescence spectra of these compounds can be interpreted satisfactorily on the basis of the solvation of the CT state calculated with the dielectric continuum theory. However, as was pointed out in the introductory part, it may be possible that the solvation of the CT state is accompanied by some change of the geometrical structure. For example, the molecular plane of anthracene or pyrene might be perpendicular to that of DMA in the CT fluorescent state, so that the electronic delocalization interaction between the two moieties would become negligibly small.

The change of the excited electronic structure of these molecules induced by solvation can be observed also by changing the temperature of the solution, as indicated in Fig. 6 for the case of A_1 in dibutyl ether. At high temperatures, one can observe only the anthracene LE fluorescence. When the temperature is lowered,

a) Dry acetic acid. b) Moist acetic acid.

(**6**) with complete inversion. Acetic anhydride–acetic acid (50: 50 by volume) mixture which was prepared without special precaution to remove the trace amount of water gave retention product of **4**. The results with acetic acid were not reproducible. From run to run, the product ratios of **4** (with retention) and **6** (with inversion) changed from 70 :30 to 30: 70. It appears that the difficulty of removing trace amount of water would be responsible for such observations. Since the acetylation of the produced **4**, which proceeds gradually under the conditions, gives **6** with retention, the product analyses after sufficient reaction times give the results as if the steric course of the direct acetolysis is affected by the presence of trace amount of water. The same change of the steric course by the presence of water reported by Winstein and his co-workers[1] may be explained by the same way. It is concluded that the reaction of **1** with water is much faster than those with other reagents and proceeds through the intermediate A or B.

Solvolyses of 4-Acetoxy-2-chloropentane (3) and 4-Acetoxy-2-pentyl tosylate (5). The steric courses of the solvolyses of **3** and **5** which are expected to proceed through AcO-6 cation have been studied by comparing with the results of the reactions of **1** mentioned above. The starting materials of *erythro*- and *threo*-**3** and -**5** were prepared by chlorination and tosylation of the half esters **4**, which were obtained by the hydrolyses of *cis*- and *trans*-**1**, respectively. The results of solvolyses are summarized in Table 2.

The reactions proceeded to give 2,4-diacetoxypentane (**6**) and **4** with no detectable amount of by-product, and were almost complete under the conditions described. By gas-chromatography, the product distributions were determined.

In 98% ethanol containing potassium acetate, *erythro*- and *threo*-**5** gave *threo*- and *erythro*-**4** as the main products with inversion, respectively. Since the solvolyses of these compounds through planar carbonium ion without participation should form the same 50: 50 mixtures of *threo*- and *erythro*-**4**, the mechanism depicted in Fig. 3 appears to be the most probable. Formations of AcO-6 cations with inversion and the subsequent reactions with water, which have been shown to give the retention products, should result in the formation of inversion products. The formations of the retention products in **4** and the inversion products in **6** appear to show the solvolysis without participation proceeded as a minor reaction.

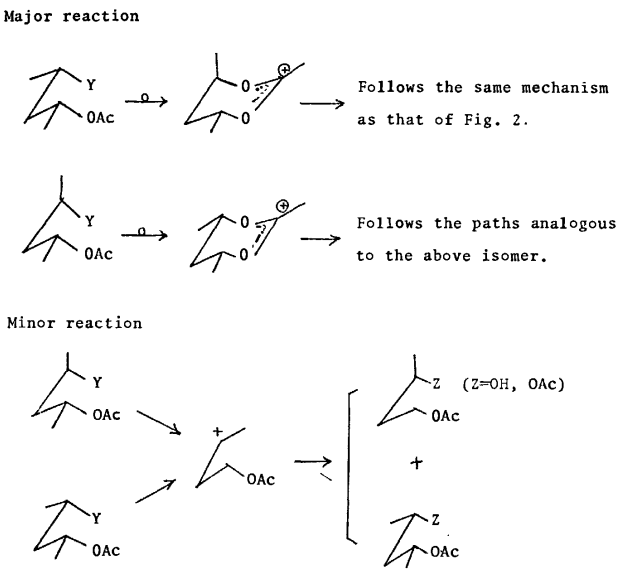

Fig. 3. Mechanism of the solvolysis of 4-acetoxy-2-pentanol derivatives.

The main products of the acetolyses of *erythro*- and *threo*-**5** in dry acetic anhydride and acetic anhydride–acetic acid mixtures containing potassium acetate were *meso*- and *dl*-**6** with retention, respectively. Double inversions in AcO-6 cation formation and the subsequent reaction of the cation with acetate ion explain the

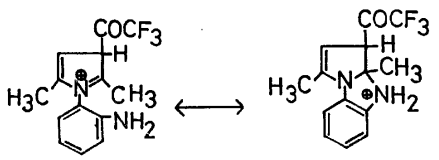
reaction of **1** with trifluoroacetic anhydride gave **3** (mp 42 °C) in 40% yield, together with **2**. **3** was so labile that the sample became deeply colored and melted during storage. However, its NMR spectrum in TFA did not change remarkably at 25 °C for 48 h. Therefore, this possibility can apparently be excluded.



In conclusion, it has been shown that the 1,5-participation of an amino group is possible in the electrophilic substitution of a pyrrole derivative, even TFA acting as an electrophilic reagent in such a case.

Experimental

All the mps and bps are uncorrected. The NMR spectra were taken with a Varian T-60 instrument, and the chemical shift data are reported in ppm (δ) downfield from tetramethylsilane as an internal standard, with a coupling constant (J) in Hz. The mass spectra were run on a Hitachi RMU-7 apparatus with an ionizing potential of 70 eV. The IR spectra were recorded on a Hitachi 215 spectrophotometer, in Nujol, while the absorption maxima are reported in cm^{-1}. The spectral data for the pyrrole derivatives are summarized in Table 2.

The pyrrole derivatives were prepared by the following general method. Into an equimolar mixture of acetonylacetone and the aniline derivative dissolved in benzene, was added a drop of phosphoryl chloride. Then the solution was heated under reflux for 2 to 4 h, taking off the produced water as an azeotropic mixture. After washing, drying, and the evaporation of the solvent, the product was purified either by recrystallization or by distillation; yield, 75—90%.

1-Phenyl-2,5-dimethylpyrrole (4): mp 49—50 °C, lit,[5] 51—52 °C.

1-(2-Hydroxyphenyl)-2,5-dimethylpyrrole (5): mp 95—97 °C, lit,[6] 95 °C.

1-(2-Methylphenyl)-2,5-dimethylpyrrole (6): bp 78 °C (2 Torr), lit,[7] 105 °C (7.5 Torr).

1-(2-Iodophenyl)-2,5-dimethylpyrrole (7): mp 69—72 °C. Found: C, 48.57; H, 4.09; N, 4.70%. Calcd for $C_{12}H_{12}NI$: C, 48.48; H, 4.04; N, 4.52%.

1-(4-Aminophenyl)-2,5-dimethylpyrrole (8): mp 95—97 °C, lit,[7] 97.5—98 °C.

1-(4-Chlorophenyl)-2,5-dimethylpyrrole (9): mp 49—50 °C, lit,[5] 56—57 °C.

These six compounds were stable in TFA at 50 °C for 48 h and could be recovered intact.

1-(2-Aminophenyl)-2,5-dimethylpyrrole (1): mp 50—54 °C, *m/e* (M^+) 186. In addition to the general method, this compound was also prepared by the following procedure. An equimolar mixture of acetonylacetone and *o*-phenylenediamine was dissolved in an aqueous solution of citric acid and sodium hydrogenphosphate adjusted at pH 5.0, the mixture was then stirred at room temperature for 4 h. The precipitates were filtered, washed thoroughly with water, and recrystallized from cyclohexane to give **1** in a 90% yield.

Though the melting points (50—54 °C) of all samples obtained in several runs were different from that (77 °C) reported in the literature,[7] the product was obviously **1**, judging from the data given in Table 2.

1-(2-Aminophenyl)-2,5-dimethyl-3-trifluoroacetylpyrrole (2). A solution of **1** (10 g) dissolved in TFA (65 ml) was kept for 48 h in a thermostat maintained at 25 °C. During this experiment, an aliquot was subjected to NMR measurement at regular intervals in order to observe the relative ratio of the integral intensities between the signals due to the dimethyl groups of the starting **1** and that due to the product (**2**). The half-life of this reaction was 3.5 h, according to such observations. After being poured onto crushed ice, the mixture was neutralized with sodium hydrogencarbonate. The precipitates were filtered and recrystallized from light petroleum; mp 84—86 °C; purified product in a 20% yield. Found: C, 59.27; H, 4.58; N, 9.87%. Calcd for $C_{14}H_{13}N_2OF_3$ C, 59.57; H, 4.61; N, 9.93%.

Reaction of 1 with Trifluoroacetic Anhydride. A mixture of **1** (930 mg, 5 mmol) and trifluoroacetic anhydride (1.12 g, 7 mmol) dissolved in dichloroethane (10 ml) was stirred at room temperature for 1 h. After being poured into ice–water, the mixture was extracted with dichloroethane. The organic layer was washed with aqueous sodium hydrogencarbonate and then with water, after which it was dried over anhydrous sodium sulfate. After the evaporation of the solvent, the residue was separated into components by column chromatography using alumina (10 g). Four compounds were eluted in the following order by a mixture of light petroleum and benzene:

(1) 1-(2-Trifluoroacetylaminophenyl)-2,5-dimethylpyrole (**3**); mp 42 °C, (370 mg). Found: C, 60.51; H, 4.75; N, 10.22%. Calcd for $C_{14}H_{13}N_2OF_3$: C, 59.57; H, 4.61; N, 9.93%. Elementary analysis was unstatisfactory because of its high unstability. IR: 3400, 1740, 1600; NMR: 8.51,

between the anion in the channel and the cation outside the channel. A similar disorder of the "guest" molecule has been found in the 2 : 1 complex of pyromellitic dianhydrate with *trans*-4-methylstilbene.[17]

In the crystal, the hydrogen-bonding contact between primary hydroxyl groups with the *gauche-gauche* conformation is observed between O(6′, G2) and O(6′, G3) ($1/2-x$, $1/2+y$, $-z$). The space outside the channel is filled with water molecules and cations. The water molecules form a hydrogen-bonding network with each other or with hydroxyl groups of α-CDx. O(W1), O(W2), O(W3), and O(W4) are located at positions similar to those in the potassium acetate complex. In Methyl Orange complexes, a relatively small electron density peak was observed at the special position on the electron density map. We considered it that of a water molecule(O(W6)) with an occupancy of 0.25, since it has hydrogen-bonding contacts with water and a hydroxyl group of α-CDx; the distances of O(W6)···O(6′, G1) and O(W6)···O(W4) in the MONa complex are 2.85 and 2.74 Å respectively.

The author wishes to thank Dr. Hisashi Uedaira for supporting this study and for his useful discussions. The author also wishes to acknowledge the helpful discussions and critical comments on the manuscript of Professor Jiro Tanaka of Nagoya University. The computation was carried out on a HITAC 8450 computer in our laboratory.

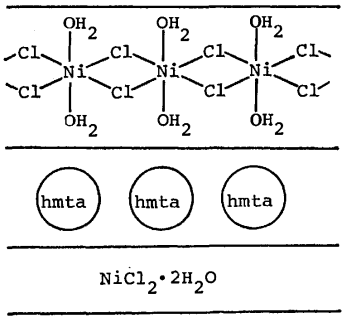

Fig. 4. Postulated structure of $NiCl_2(hmta)_2 \cdot 2H_2O$, in which hmta molecules are captured between chains of the composition of $NiCl_2 \cdot 2H_2O$.

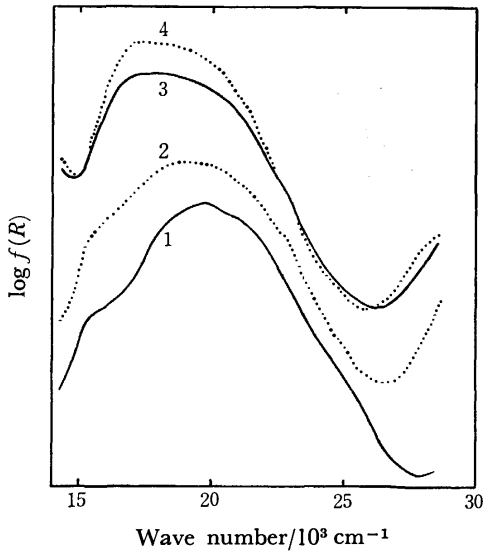

Fig. 5. Visible reflectance spectra of (1) $Co(NO_3)_2(hmta)_2 \cdot 10H_2O$, (2) $Co(NO_3)_2(hmta)_2 \cdot 4H_2O$, (3) $Co(NO_3)_2(hmta)_2 \cdot 2H_2O$ and (4) $Co(NO_3)_2(hmta)_2$.

and four bridging chlorine atoms in a distorted square plane, the dihydrate complex also seems to be composed of similar units (or chains) of $NiCl_2 \cdot 2H_2O$ and of hmta captured between them, probably by hydrogen bondings (Fig. 4).

From the reflectance and infrared spectra, the structure of $NiCl_2(hmta)_2$ and $NiBr_2(hmta)_2$ formed in the next stage was found to be identical with that of the other anhydrous halide complexes. The results of the nickel chloride complex indicate that Cl^- enters into the coordination sphere more easily than hmta.

$Co(NO_3)_2(hmta)_2 \cdot 10H_2O$ loses its water molecules in three steps. The visible reflectance spectra of the cobalt nitrate complexes in each dehydration step are shown in Fig. 5, together with that of the decahydrate. In the first step ($-6H_2O$), the octahedral structure and T_d symmetry of hmta are retained, and the tetrahydrate formed gives strong infrared bands at 1300 and 1440 cm^{-1} (curve 2, Fig. 6), which can be ascribed to the two NO stretching bands of unidentate NO_3^- ligands.[10] The tetrahydrate can thus be described as $[Co(NO_3)_2(H_2O)_4] \cdot 2hmta$.

The dihydrate formed in the second step ($-2H_2O$)

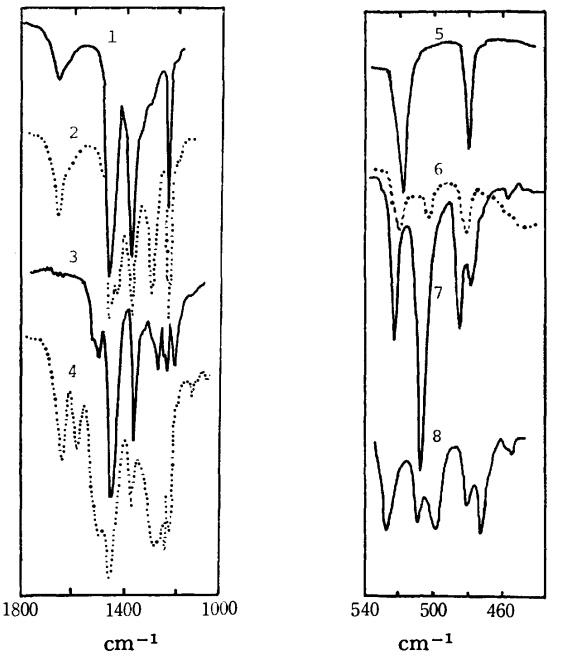

Fig. 6. Infrared spectra of (1) $Co(NO_3)_2(hmta)_2 \cdot 10H_2O$, (2) $Co(NO_3)_2(hmta)_2 \cdot 4H_2O$, (3) $Co(NO_3)_2(hmta)_2$, (4) $Ni(NO_3)_2(hmta)_2$, (5) $Co(NCS)_2(hmta)_2 \cdot 4H_2O$, (6) $Ni(NCS)_2(hmta)_2 \cdot 2.5H_2O$, (7) $Co(NCS)_2(hmta)_2$ and (8) $Ni(NCS)_2(hmta)_2$.

shows an electronic spectrum which is intermediate between the spectrum of a typically octahedral complex and that of a typically tetrahedral one. In this step, the $\bar{\nu}_{max}$ value decreases and $\log f(R)$ increases, but the changes are not so large as those observed in typical octahedral→tetrahedral changes; no definite characteristic splitting of the "*tetrahedral band*" could be observed. This suggests that the dihydrate, and the anhydrous complex which shows a similar electronic spectrum, are deformed octahedral complexes and not simple tetrahedral ones.

On the other hand, the infrared spectra of these two complexes show strong bands at 1290 and 1505 cm^{-1}, which can be ascribed to the NO stretching bands of bidentate NO_3^- ligands.[10] It was also found that the anhydrous complex shows very weak bands at *ca.* 1710 and 1760 cm^{-1}, their positions indicating the presence of bidentate NO_3^-.[11] The symmetry of hmta in the dihydrate is T_d, and that in the anhydrous complex C_{3v}.

All these data lead to the formulation of the dihydrate as $[Co(NO_3)_2(H_2O)_2] \cdot 2hmta$, and that of the anhydrous complex as $[Co(NO_3)_2(hmta)_2]$.

The nickel nitrate complex $Ni(NO_3)_2(hmta)_2 \cdot 10H_2O$ also loses its water molecules in three steps. The visible reflectance spectra indicate that the octahedral structure is retained through all the steps. The ionic NO_3^- of the original complex is transformed into unidentate NO_3^- in the first step, further change into bidentate NO_3^- occurring in the final step (curve 4, Fig. 6). The T_d symmetry of hmta was retained until the second step and changed to C_{3v} in the final step. The nickel in the anhydrous complex thus seems to be surrounded octahedrally by two bidentate

Mechanism for Light Induced Hydrogen Isotope Exchange in Benzonitrile

(Received March 5, 1976)

Light induced tritiation of benzonitrile with diethylamine[N^{3}H] or triethylamine-tritiated water was studied with respect to quenching of benzonitrile fluorescence by the amines and the tritium distribution in the nucleus. A mechanism involving an exciplex possessing charge transfer nature was proposed.

It is well known that photolysis of thiols yields hydrogen atoms, and this method has been used to study the properties of the hydrogen atom in solution.[1,2] Thus, Pryor and his co-workers[2] have reported the aromatic substitution by tritium atoms generated by photolysis of benzenethiol[S^{3}H]. We have also studied[3] the light induced tritiation of aromatic compounds with 1-propanethiol[S^{3}H] in respect of the tritium distribution in the nucleus and the relative rate of tritiation, and found that the nuclear tritium distribution data are different from those reported by Pryor.[2] Kinetic studies[4] have shown that the rate constants for the reaction of hydrogen atoms with aromatic compounds vary only between 2.4×10^8 and 26×10^8 M^{-1} s^{-1}. Electron-donating substituents on the aromatic nucleus enhance the rate and electron-withdrawing groups retard the rate, indicating an electrophilic character of hydrogen atoms for the reaction.[4] On the contrary, our work with 1-propanethiol showed that the rate of nuclear tritiation relative to benzene, obtained in competitive methods, is extremely high in benzonitrile,[3] methyl benzoate,[3] and terephthalonitrile.[5] Furthermore, fluorescence of terephthalonitrile in benzene was quenched by 1-octanethiol with the quenching rate constant near to the diffusion-controlled value.[5] On the basis of these results a mechanism involving a reaction of singlet excited aromatic compounds with thiols was proposed for the tritiation reaction, at least in the case of benzonitrile, methyl benzoate, and terephthalonitrile.

This consideration reminds us the photoreaction of aromatic compounds with amines, in which singlet excited aromatic compounds are demonstrated to interact with amines.[6] Thus, the possibility that such interaction may be followed by hydrogen exchange led us to investigate the positional reactivity of light induced tritiation of benzonitrile with amines as well as quenching of the lowest excited singlet state of aromatic nitriles by amines. The results are interpreted in terms of a mechanism involving formation of an exciplex followed by its decay to a radical pair.

Results and Discussion

Fluorescence Quenching of Aromatic Nitriles. Fluorescence of benzonitrile, α-naphthonitrile, and terephthalonitrile was strongly quenched by diethylamine and triethylamine in benzene. The Stern-Volmer plots of the reciprocal of relative fluorescence intensities against amine concentrations were linear in all compounds investigated, and the slopes of the Stern-Volmer plots ($k_q\tau_s$) are shown in Table 1, where k_q is the rate constant of the bimolecular quenching process, and τ_s is the lifetime of the singlet state in the absence of the amines in aerated benzene. Assuming diffusion-controlled oxygen quenching (1.5×10^{10} M^{-1} s^{-1}),[7] the effect of air saturation on fluorescence intensity affords an estimate of τ_s (air) in benzene; benzonitrile, 25 ns; α-naphthonitrile, 12 ns; terephthalonitrile, 18 ns. The observed $k_q\tau_s$ values for the amines are divided by the τ_s values and the resulting k_q values are listed in Table 1. The quenching rate constants (k_q) of diethylamine are several times larger than those of triethylamine and are close to the diffusion limit. The higher efficiency of the quenching, therefore, indicates the interaction of the singlet excited aromatic compounds with the ground state amine. Furthermore,

containing no builders.

Discussion of the Rolling-up Phenomenon. It is well known that the rolling-up of oily soils occurs at the

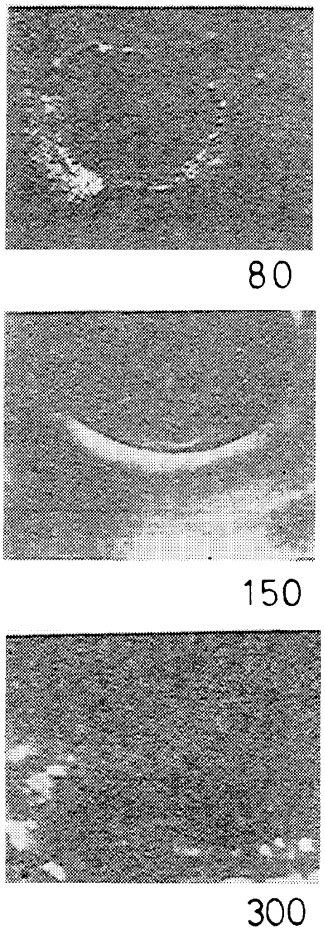

Fig. 11. The microscopic photograph of oily soils in 0.150% NaDBS solution with crossed nicols (number shows the time in minutes after immersion into the solution).
a) oleic acid, b) lauryl alcohol, c) oleyl alcohol.

contact angle (θ) of 180° on the substrates of various kinds of textile fibers.[4,6,9] However, as is shown in Fig. 1, on a low-energy surface such as PP sheet, rolling-up occurs at $0°<\theta<90°$. The process of rolling-up for oleic acid, olive oil, and lauryl alcohol is illustrated schematically in Fig. 8 (a) and (b). In the initial stages [up to Stage 4 in Fig. 8 (a) or up to Stage 3 in Fig. 8(b)], the droplet/substrate contact area (S_{os}) is plotted against the contact angle of the droplet on the substrate in Fig. 9. From these results, the area of S_{os} seems to decrease with an increase in the contact angle of the droplet. The process in Fig. 8 is believed to be caused by the reduction of interfacial tension as a result of the adsorption of surfactant molecules to soil/water and substrate/water interfaces.[3,4,6]

The interfacial tension between oily soils and the NaDBS solution are shown in Fig. 10; the interfacial tension for polar oily soils decreases remarkably with an increase in the surfactant concentration. From the results, the surfactant can be expected to be adsorbed on the surface of polar oily soils.

It seems reasonable to assume that there are three substantial forces by which a liquid oily droplet may be removed by rolling-up in a detergent solution: the

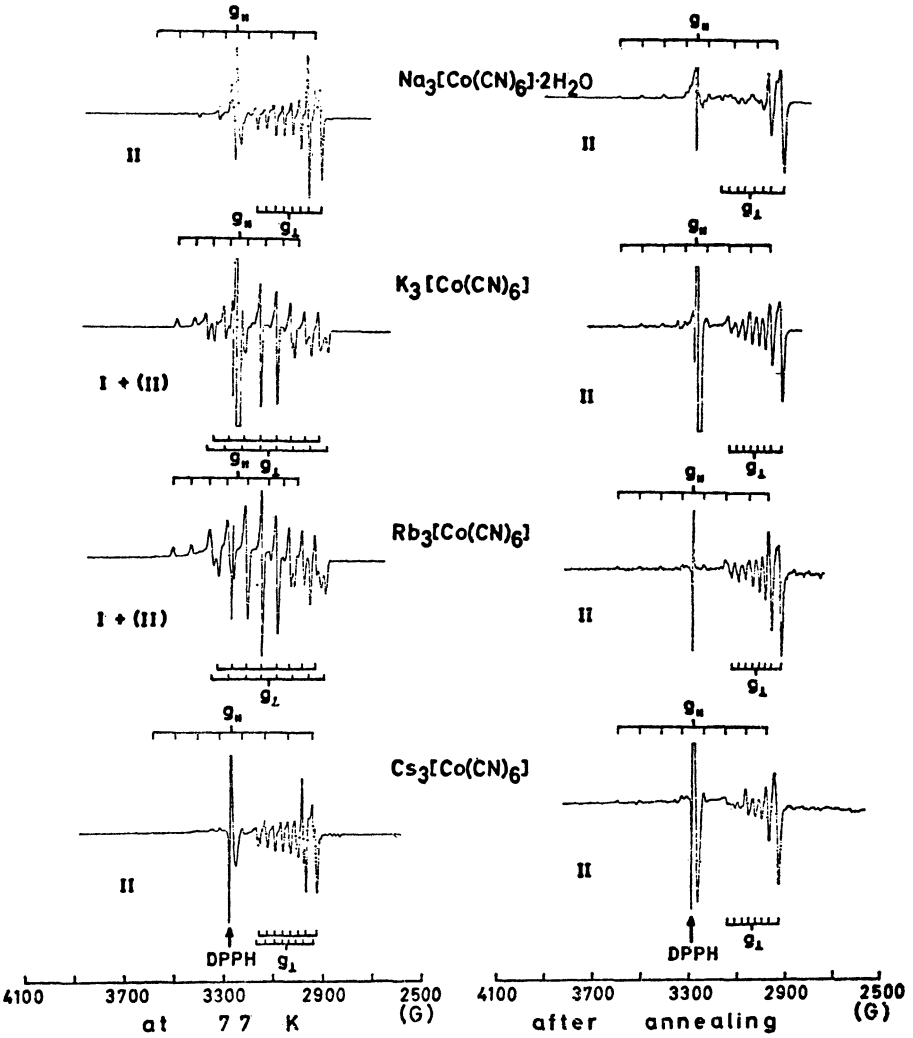

Fig. 9. ESR spectra of γ-irradiated powder of $M_3[Co(CN)_6]$ (M=Na, K, Rb, Cs).

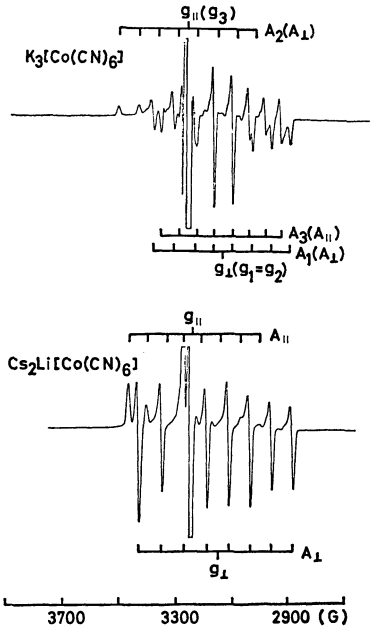

Fig. 10. ESR spectra of γ-irradiated powder of $K_3[Co(CN)_6]$ and $Cs_2Li[Co(CN)_6]$.

When the cation is changed from $3K^+$ to $2Cs^+Li^+$, the crystal system changes from orthorhombic to cubic. ESR parameters of hot ions produced in γ-irradiated $Cs_2Li[Co(CN)_6]$ at 77 K are shown in Table 7 for

TABLE 7. ESR PARAMETERS OF HOT IONS PRODUCED IN γ-IRRADIATED $K_3[Co(CN)_6]$ AND $Cs_2Li[Co(CN)_6]$.

	$g_{//}$	$A_{//}$(G)	$g_\perp$	$A_\perp$(G)
$Cs_2Li[Co(CN)_6]$	2.025	64	2.078	−78.1
$K_3[Co(CN)_6]$	2.011	61.7	2.091	−70.0

comparison with the case of $K_3[Co(CN)_6]$. In the case of $Cs_2Li[Co(CN)_6]$, no superhyperfine structures due to nitrogen atoms were observed. The $A_\perp$ can be seen at the $g_\perp$ part, and the $A_{//}$ can be seen at the $g_{//}$ part (Fig. 10). It can be concluded that the noncollinearity of the g-tensor and the A-tensor is not due to the local nature of the central metal, but to the entire nature of the mother lattice of the compound.

We wish to thank Mr. Shingo Katsura of the γ-ray irradiation center for his experimental assistance. We wish also to thank Dr. Yoji Arata and Dr. Jun-ichi Isoya for their helpful discussion.

alcohols to the imino intermediates **7** and **2**, respectively.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethylsilane as the internal standard.

Materials. Compounds **1** and **3** were prepared by methods previously reported.[10]

Preparation of **6**. Into a solution of **3** (0.0036 mol) in chloroform (10 ml) was added NBS (0.004 mol) portion by portion with stirring at room temperature. After stirring for 20 min, the reaction solution was concentrated to give a yellow syrup containing succinimide. After the addition of carbon tetrachloride (10 ml) to the residue, the succinimide which had thus separated out was filtered off, and the filtrate was evaporated under reduced pressure to give a pale yellow syrup in a quantitative yield. The syrup obtained was purified on a silica gel column using benzene as an eluent. *t*-Butyl 2-acetylimino-3,3-dibromobutanoate, IR (KBr disk): 1720 (-COO), 1655 (>NCO) cm^{-1}, NMR (δ): 2.30 ($COCH_3$). Found: C; 33.80, H; 4.20, N; 3.91%. Calcd for $C_{10}H_{15}NO_3Br_2$: C; 33.64, H; 4.23, N; 3.92%. *t*-Butyl 2-acetylimino-3,3-dibromopentanoate, IR (KBr disk): 1725 (-COO), 1660 (>NCO) cm^{-1}, NMR (δ): 2.29 ($COCH_3$). Found: C, 35.49; H, 4.81; N, 3.61%. Calcd for $C_{11}H_{17}NO_3Br_2$: C, 35.61; H, 4.62; N, 3.77%.

Preparation of **8a**. Into a solution of **6** (R=CH_3, 0.0036 mol) in dry *N,N*-dimethylformamide (10 ml) was added water (3 ml) drop by drop with stirring at room temperature. After stirring for 8 h, the reaction solution was poured into water (30 ml) and then the aqueous solution was extracted twice with benzene (20 ml). The benzene extracts were washed twice with water and then dried over anhydrous sodium sulfate. The benzene layer was evaporated under reduced pressure to give colorless crystals, which were identified as *t*-butyl 2-acetylamino-3,3-dibromo-2-hydroxybutanoate.

Preparation of **8b**. A solution of **6** (R=CH_3, 0.0036 mol) in methanol (10 ml) was stirred for 6 h, and was worked up similarly to give *t*-butyl 2-acetylamino-3,3-dibromo-2-methoxybutanoate.

In a similar manner, *t*-butyl 2-acetylamino-3,3-dibromo-2-methoxypentanoate was obtained from the reaction of **6** (R=C_2H_5) with methanol, after stirring for 24 h.

Preparation of **8c**. *Procedure A*: A solution of **6** (R=CH_3, 0.0036 mol) in ethanol (10 ml) was stirred for 10 h and worked up similarly to give *t*-butyl 2-acetylamino-3,3-dibromo-2-ethoxybutanoate.

In a similar manner, *t*-butyl 2-acetylamino-3,3-dibromo-2-ethoxypentanoate was obtained from the reaction of **6** (R=C_2H_5) with ethanol, after stirring at *ca.* 50 °C for 7 h and purification of the syrup obtained on a silica gel column using benzene–ethyl acetate (20: 1 V/V) as an eluent.

Procedure B: Into a solution of **3** (R=CH_3, 0.0036 mol) in ethanol (10 ml) was added NBS (0.004 mol) portion by portion with stirring at room temperature. After stirring for 6 h, the reaction solution was concentrated under reduced pressure to give a reddish syrup containing succinimide. The residue was dissolved in benzene (30 ml) and then the benzene solution was washed three times with water. The benzene layer was dried over anhydrous sodium sulfate and then evaporated under reduced pressure to give **8c** (R=CH_3). Yield: 69.3%.

Preparation of **8d**. After treating **6** (R=CH_3, 0.0036 mol) with benzyl alcohol (3 ml) with stirring at room temperature for 2 h, a similar work up gave a colorless syrup, which gradually crystallized when allowed to stand at room temperature. The colorless crystals were identified to be *t*-butyl 2-acetylamino-2-benzyloxy-3,3-dibromobutanoate.

In a similar manner, *t*-butyl 2-acetylamino-2-benzyloxy-3,3-dibromopentanoate was obtained from the reaction of **6** (R=C_2H_5) with benzyl alcohol, after stirring for 10 h.

Preparation of **8e**. After treating **6** (R=CH_3, 0.0036 mol) with allyl alcohol (5 ml) with stirring at *ca.* 60 °C for 10 h, a similar work up gave a yellow syrup. The syrup was subsequently purified on a silica gel column using benzene–ethyl acetate (15: 1 V/V) as the eluent to give colorless crystals of *t*-butyl 2-acetylamino-2-allyloxy-3,3-dibromobutanoate.

In a similar manner, *t*-butyl 2-acetylamino-2-allyloxy-3,3-dibromopentanoate was obtained from the reaction of **6** (R=C_2H_5) with allyl alcohol, after stirring for 20 h. The syrup obtained was purified on a silica gel column using benzene–ethyl acetate (20: 1 V/V) as an eluent to give colorless crystals.

Preparation of **8f**. After treating **6** (R=CH_3, 0.0036 mol) with propargyl alcohol (3 ml) with stirring at *ca* 50 °C for 10 h, a similar work up gave a brown syrup. The syrup was subsequently purified on a silica gel column using benzene–acetone (30: 1 V/V) to give colorless crystals of *t*-butyl 2-acetylamino-3,3-dibromo-2-(2-propynyloxy)butanoate.

In a similar manner, *t*-butyl 2-acetylamino-3,3-dibromo-2-(2-propynyloxy)pentanoate was obtained from the reaction of **6** (R=C_2H_5) with propargyl alcohol, after stirring at *ca.* 60 °C for 20 h. The syrup obtained was purified on a silica

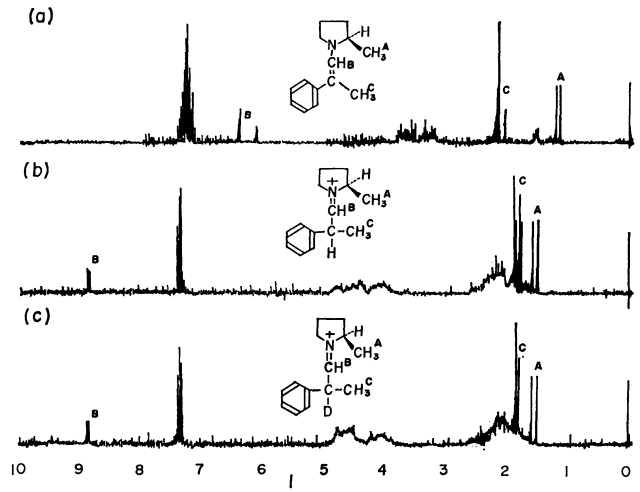

Fig. 2.

active 2-methylpyrrolidine enamine of **1** in $CDCl_3$. The solution has a color varying from initially light yellow to dark-brown at the end. The immonium salt thus prepared was confirmed by NMR spectra. Figure 2 shows NMR spectra of the enamine (a), the immonium salt with HCl (b) and the immonium salt with DCl (c). The existence of two geometrical isomers of the enamine is observed from (a). Their ratio can be obtained by the measurement of peak areas. The spectra of immonium salt, (b) and (c), showed two diastereomeric isomers. Displacement of the balance in favor of one diastereomeric immonium salt can be observed. Possibility of the existence of geometrical isomer (B) can be neglected by consideration of the steric interaction using models (Corey-Pauling-Koltum type and Dreiding type). The mechanism of the optical activation is considered to be an asymmetric, reversible protonation to the enamine and successive hydrolysis of the immonium salt.

Experimental

Illustrative examples of the reactions will be given below.

a) Reaction of 1,1,2,2-Tetrachloroethane (III) with PhONa. In a three-necked flask equipped with a reflux condenser and a mechanical stirrer we placed 200 ml of DMSO, 37.6 g (0.40 mol) of phenol, and 16.0 g (0.40 mol) of NaOH. The mixture was gently warmed up to 70 °C with stirring to dissolve most of the NaOH. To the nearly homogeneous solution we then slowly added 16.8 g (0.10 mol) of III at 70 °C. The stirred mixture was then kept at 70 °C for an additional 5 h, after which the mixture was cooled, diluted with *ca.* 500 ml of water, and saturated with NaCl. The organic layer was extracted with three 100 ml portions of ether. The combined ethereal extracts were washed with water, dried over anhydrous Na_2SO_4, and then distilled to yield 17.0 g of crude *trans*-1,2-dichloro-1-phenoxyethylene; bp 72—74 °C/4 mmHg (yield, 90%).

b) Reaction of Pentachloroethane (IV) with PhSNa. In a similar way, a nearly homogeneous solution of 27.5 g (0.25 mol) of benzenethiol and 10.0 g (0.25 mol) of NaOH in 125 ml of DMF was prepared. Then a 10.1 g portion (0.05 mol) of IV was gradually added at 70 °C, after which the stirring was continued for 5 h at that temperature. All these procedures were carried out under a nitrogen atmosphere to prevent the oxidation of benzenethiol to diphenyl disulfide. The reaction mixture was cooled and diluted with *ca.* 300 ml of water. The resulting precipitate was collected and recrystallized from chloroform to afford 17.0 g of tetrakis(phenylthio)ethylene; mp 154—156 °C (yield, 74%).

The NMR spectra of all the olefinic products are summarized in Table 4.

Nickel-Phosphine Complex-Catalyzed Grignard Coupling. I. Cross-Coupling of Alkyl, Aryl, and Alkenyl Grignard Reagents with Aryl and Alkenyl Halides: General Scope and Limitations

Kohei TAMAO, Koji SUMITANI, Yoshihisa KISO, Michio ZEMBAYASHI, Akira FUJIOKA, Shun-ichi KODAMA, Isao NAKAJIMA, Akio MINATO, and Makoto KUMADA*

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received April 2, 1976)

It has been established that dihalodiphosphinenickel(II) complexes exhibit extremely high catalytic activity for selective cross-coupling of Grignard reagents with aryl and alkenyl halides. This catalytic reaction can be employed in synthetic practice for reasons of simple procedures, mild reaction conditions, high yields and high purity of the coupling products, and the wide applicability to reactions involving primary and secondary alkyl (regardless of the presence or absence of β-hydrogen(s)), aryl, and alkenyl Grignard reagents and nonfused, fused, and substituted aromatic halides and haloolefins. Limitations lie in sluggish reactions between alkyl Grignard reagents and dihaloethylenes. The most effective catalysts are $[Ni\{(C_6H_5)_2P(CH_2)_3P(C_6H_5)_2\}Cl_2]$ for alkyl and simple aryl Grignard reagents, $[Ni\{(CH_3)_2P(CH_2)_2P(CH_3)_2\}Cl_2]$ for alkenyl and allylic Grignard reagents and $[Ni\{P(C_6H_5)_3\}_2Cl_2]$ for sterically hindered aryl Grignard reagents and halides. Great stabilizing effects of phosphine ligands on the catalytic species are demonstrated by no effect observed after aging the catalyst. Organic chlorides are generally the most suitable halide in view of the reasonable reactivities and limited side reactions. Ether is favored over tetrahydrofuran as solvent. About sixty experimental results are presented and several features are discussed.

The metal-promoted coupling reactions of organic halides are one of the most attractive and useful procedures for formation of the carbon-carbon σ bond.[1] In recent years low valent transition metals and organotransition metallics hold an important position as coupling agents for such processes. Representatives include the Ullmann reaction,[2,3] the nickel(0)-promoted coupling reactions,[4-7] and cross-coupling using π-allylnickel complexes,[6] organocuprates,[3,8,9] or organoferrates.[10] Reactions of active organometallic reagents, such as organolithium and Grignard reagents, with transition metal salts also provide a route to the formation of the carbon–carbon bond; salts of Cu(I), Cu(II),[3,9,11] Ag(I), and various Group VIII metals[12,13] have been used successfully. These reactions, however, have the disadvantages that they require at least stoichiometric amounts of transition metals.

It has been known for thirty years that catalytic amounts of transition metal salts induce the coupling reaction of Grignard reagents with organic halides.[12] In spite of a number of mechanistic studies,[14] such catalytic reactions, "Kharasch reaction," have been seldom employed in synthetic practice, because of the formation of a complex mixture of products consisting of homo coupling products and a variety of disproportionation products in substantial amounts. Since 1971, when Tamura and Kochi reported that "soluble catalysts" consisting of silver,[15,16] iron[15,16a] or copper[15] in tetrahydrofuran were extremely effective for selective coupling of Grignard reagents with organic halides, the synthetic applicability of these catalytic reactions has received much attention.[17b,18,19] In 1972, Corriu and Masse[20] and we[21] independently reported that nickel–phosphine complexes catalyze the selective cross-coupling of Grignard reagents with aryl and alkenyl halides:

$$RMgX + R'X' \xrightarrow{[NiL_2Cl_2]} R\text{-}R' + MgXX'$$

More recently, Murahashi *et al.*[22] examined the catalytic activity of a palladium–phosphine complex for the similar Grignard cross-coupling. It was rather surprising that little attention had been paid to the catalytic activity of phosphine–modified transition metals for the Kharasch type reactions, despite extensive studies on a variety of homogeneous catalyses.

The nickel–phosphine complex-catalyzed Grignard coupling has opened up the possibility of preparing a large variety of unsaturated organic compounds from two different organic halides[23,24] and there have been reported several characteristic features of the reaction, including the alkyl group isomerization,[25] stereochemical aspects,[26] asymmetric synthesis,[27] and applications to the cyclophane synthesis[28] and to the heterocycle coupling.[29] In this paper, we report, aside from the mechanistic aspects, the general scope and limitations of the nickel–phosphine complex-catalyzed Grignard cross-coupling.

Results and Discussion

I. Design of a Catalytic Cycle. When undertaking this series of studies, we designed the catalytic process of the cross-coupling reaction as pictured in Scheme 1 by combining two important observations on the chemistry in relation to σ-organonickel complexes bearing "supporting" ligand(s): (1) two organic groups on a nickel complex L_2NiR_2 are released by the action of, for example, a halobenzene R'X' to undergo coupling, along with the formation of $L_2Ni(R')(X')$,[30,31] and (2) such a halogen–nickel bond is readily replaced by a Grignard reagent to form the corresponding organonickel bond, $L_2Ni(R')(R)$.[32]

Thus, a dihalodiphosphinenickel reacts with a Grignard reagent to form the intermediate diorganonickel complex **2** which is subsequently converted to the halo(organo)nickel complex **3** by an organic halide.

2,5-dideoxystreptamine, *viz.* 5-deoxyparomamine.

In the case of a preparation of 6-amino-6-deoxy-D-glucopyranosyl-2,5-dideoxystreptamine, *N*,*N'*-diethoxycarbonyl-2,5-dideoxystreptamine (**1b**) was used instead of **1a** in order to improve solubilities of the products. Condensation of **1b** with 6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl chloride (**10**)[10] was conducted in the presence of mercuric cyanide in a mixture of benzene and dioxane for two weeks at reflux temperature. A mixture of crude products thus obtained could successfully be separated by a silica gel column chromatography to give a crystalline pseudo trisaccharide derivative (**11**)[6] (25%), 6-*O*-(6'-azido-2',3',4'-tri-*O*-benzyl-6'-deoxy-α-D-glucopyranosyl)-*N*,*N'*-diethoxycarbonyl-2,5-dideoxystreptamine (**12b**) (15%), 4- or 6-*O*-β-D-glycoside (**13**) (3%), and an amorphous 4-*O*-α-D-glycoside (**12a**) being contaminated with a trace of **12b** and **13**. Catalytic reduction of the azido group of **12a** by Raney nickel T-4[11] followed by treatment with ethyl chloroformate gave a crystalline 4-*O*-(2',3',4'-tri-*O*-benzyl-6'-deoxy-6'-ethoxycarbonylamino-α-D-glucopyranosyl)-*N*, *N'*-diethoxycarbonyl-2,5-dideoxystreptamine (**14a**) in 5% yield based on **1b** used. The similar treatment of **12b** and **13** gave the corresponding tri-*N*-ethoxycarbonyl derivatives (**14b** and **17**) in 61 and 74% yields, respectively. Hydrogenolysis of **14a** and **14b** in the presence of palladium black and subsequent treatment with aqueous barium hydroxide at 120 °C gave crude free aminoglycosides, which were purified by Amberlite CG-50 (NH_4^+) column chromatography using aqueous ammonia as an eluent to afford 4- and 6-*O*-(6'-amino-6'-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamines (**15a** and **15b**) as a homogeneous glass in 74 and 68% yields, respectively. They were further characterized by converting into the corresponding tri-*N*-acetyl derivatives (**16a** and **16b**). Compound **17** was also converted into the free aminoglycoside (**18**).

In the PMR spectra of **15a** and **15b** in deuterium oxide, signals of the anomeric proton appeared at δ 5.14 and 5.10 as a doublet with 3 and 3.5 Hz spacings, respectively. Empirical rule[12] on difference in the chemical shift of anomeric protons of α-D-glucopyranosyl 2-deoxystreptamine between 4- and 6-glycosides might not be applied to our compounds which lacked the 5-hydroxyl group. But it seems to support the above configurational assignment that the anomeric proton of 4-*O*-α-D-glycoside resonated at relatively lower field than that of 6-*O*-α-D-glycoside. Examination on biological activities of **15a** and **15b** indicated that the

a) Measured in ppm downfield from TMS as an internal standard.

was coupled with ^{31}P (J=2 Hz). Each methine proton, as expected, was readily exchanged by deuterium in the presence of methanol-d_4, and disappeared from NMR spectra. The methyl protons of **4a** and the methylene protons of **4b** and **4d**, at the α-position of alkyl group attached to phosphorous, were coupled with ^{31}P (J= 14.4 Hz). The methyl protons of **4b** and **4d** at the β-position of alkyl group attached to phosphorus were also coupled with ^{31}P. (J=17.5 Hz). These coupling constants are in reasonable accord with literature precedents.

The reaction of acetylene carboxylic acids with ylides of type **2** to give **4** adds to our growing knowledge of acetylene reactions in tetrathiafulvalene (TTF) syntheses.[8] A more detailed knowledge of the mechanism (Scheme 1) is still needed to provide the synthetic chemist insight in developing improved routes to substituted TTF derivatives, compounds of intense current interest.[8]

Experimental

Proton magnetic resonance spectra were recorded on a Hitachi Perkin-Elmer R-20 B with tetramethylsilane as an internal reference. Infrared spectra were obtained with a Beckman IR-33. THF was dried over calcium hydride and distilled prior to use. Melting points are uncorrected. The elemental analyses of sulfur and phosphorus were performed by Schwarzkopf Microanalytical Laboratory, 56—19 37th Avenue, Woodside, New York 11377.

Reaction of Acetylene Carboxylic Acids With Trialkylphosphine–Carbon Disulfide Ylides (2). Trialkylphosphine (0.05 mol) in 50 ml of tetrahydrofuran was added dropwise to a solution of 10 ml of carbon disulfide in 50 ml of tetrahydrofuran at −20——30°C under nitrogen. In the case of trimethylphosphine and triethylphosphine, the ylides, **2**, precipitated. To the deep maroon solution of **2** a solution of acetylene carboxylic acid (0.05 mol) in 50 ml of tetrahydrofuran was added dropwise. The temperature was maintained between −20 and −30 °C during addition. The system was warmed to room temperature and stirred further for 1 h. The zwitterionic products, **4**, were formed as precipitates. The precipitate was filtered and washed with acetone and/or methanol. The crude products, 2-trialkylphosphonio-1,3-dithiole-4-carboxylates, **4a**—**f**, could be recrystallized from solvents shown in Table 1. Table 1 also gives physical characteristics of the compounds prepared. IR absorption bands of **4** and **7** are summarized in Table 2.

2,6(7)-Bis(ethoxycarbonyl)tetrathiafulvalene. The procedure is the same as preparation of **4**. After addition of ethyl propiolate at −20——30 °C, instead of acetylene carboxylic acids, the system was warmed to room temperature and stirred further 3 h. Volatiles were removed under reduced pressure and excess ether was added to the residue which was refrigerated. A precipitate formed and was filtered to give 18% of the title compound. Recrystallization from glyme gave a red-orange crystalline product: mp 176—178 °C (lit,[2] 169—172 °C); NMR ($CDCl_3$) δ 1.35 (t, 3H, methyl H, J=7 Hz), 4.31 (q, 2H, methylene H), and 7.40 (s, 1H, vinyl H).

Hydrolysis of 2-Tributylphosphonio-1,3-dithiole-4-carboxylates (4c and 4e). Zwitterionic salt **4c** (4.00 g: 0.01 mol) was suspended in 40 ml of 1 M sodium hydroxide solution and stirred for 30 min. Crystals dissolved gradually, and an oily material was separated. The oily material was extracted with ether. Removal of ether gave tributylphosphine oxide. The aqueous layer was acidified with 3 M hydrochloric acid, while cooled with ice, to give 1.44 g (69%) of yellow needles of 1,3-dithiole-4,5-dicarboxylic acid hydrate, **7b** H_2O. This crude material was purified by reprecipitation from water solution by acidification with 3 M hydrochloric acid. The filtrate was concentrated under vacuum and the residue was washed with acetone. From the washings another 0.50 g (26%) 1,3-dithiole-4,5-dicarboxylic acid, **7b**, was obtained as orange crystals.

The 1,3-dithiole, **4e**, was also hydrolyzed in the same manner to give 1,3-dithiole-4-carboxylic acid, **7a**, in 90% yield.

Physical properties, elemental analyses, and IR data of 1,3-dithiole carboxylic acids were shown in Tables 1 and 2. The NMR spectrum of **7a** in acetone-d_6 consisted of singlets at δ 7.28 (1H) and 4.68 (2H), assigned to olefinic and methylene hydrogens, respectively. In DMSO-d_6, the NMR spectra of **7a** and **7b** H_2O had a singlet at δ 4.49 and δ 4.02 (methylene

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (7), 2007—2008 (1976)

A Shock-tube Investigation of Ethylene-Oxygen-Argon Mixtures. Chemi-ionization and Apparent Activation Energy

Yoshiaki HIDAKA, Tomofumi NISHI, and Masao SUGA

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received December 25, 1975)

Synopsis. The reaction of ethylene–oxygen mixtures highly diluted with argon was studied over the temperature range of 1400—1800 K behind reflected shock waves by monitoring the total ionization. A kinetic study of the chemi-ionization in the ethylene oxidation was undertaken. It was inferred that the mechanism of CHO^+ formation was dependent on the composition and the temperature, and that the rate-determining step for the chemi-ionization was $C_2H_3+O_2 \rightarrow C_2H_3O+O$.

The oxidation of ethylene has been previously studied by shock-tube techniques.[1-4] Kinetic studies have been mainly done by various optical methods[2-4] and mass spectrometric methods;[1] also, we ourselves have reported our results monitoring the emission from CH*, C_2*, and OH*.[5] The oxidation of ethylene and other hydrocarbons in the shock tube is accompanied by an intense chemi-ionization. In the present paper, we wish to report the results of our simultaneous measurements of CH* emission and chemi-ionization and to discuss the formation mechanism of ions. Another purpose of this paper is to determine the apparent activation energy of the total ionization in the ethylene oxidation.

Experimental

The shock tube and the techniques for measuring the chemiluminescence have already been described.[5] In the present experiment, the time intervals for the shock-speed measurements were determined by the use of a universal counter (Iwatsu US-6141) with a precision of ± 0.1 μs. For the measurement of the ion current, the Langmuir probe was located at the same distance as the quartz window, 1 cm from the reflected plate of the shock tube.

The compositions of the reaction mixtures used were:

(A) 0.5% C_2H_4, 1.0% O_2, 98.5% Ar

(B) 0.5% C_2H_4, 1.5% O_2, 98.0% Ar

(C) 0.5% C_2H_4, 2.0% O_2, 97.5% Ar

The ethylene, oxygen, and argon were commercial gases; then purities were 99.99%, 99.9%, and 99.99% respectively. The initial pressures of the reaction mixtures were about 100 Torr. The ion current (+6.5 V bias on the Langmuir probe) and CH* emission (4315 Å, with a half-width of 25 Å) were simultaneously measured behind reflected shock waves.

Results and Discussion

Some typical oscillograms on the oscilloscope are shown in Fig. 1 (a) and (b). The following characteristics were seen from the profiles of each run:

(1) The onset of the ion signal was earlier than that of the CH* emission signal in the (A) and (B) mixtures below 1700 K. However, in the (A) and (B) mixtures above 1700 K and the (C) mixture over the temperature range of 1400—1800 K, the reverse tendency was true.

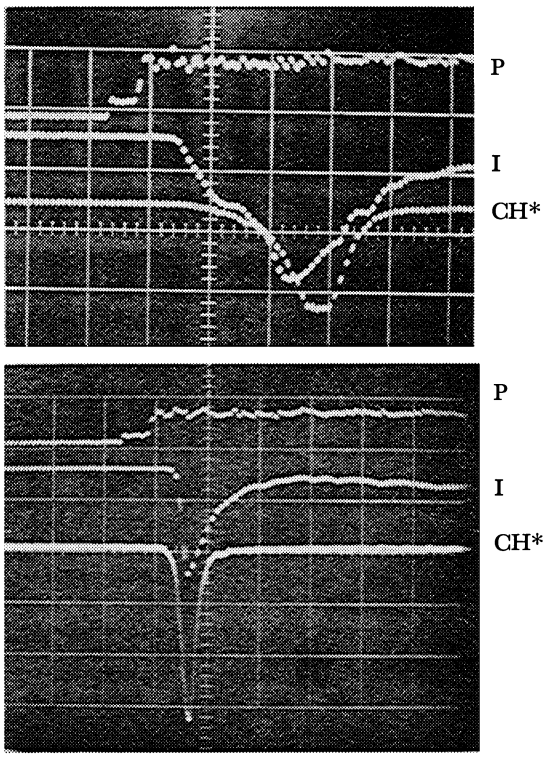

Fig. 1. Time histroy of CH* emission and ion currents.
Upper trace: Pressure signal.
Middle trace: Ion current signal.
Lower trace: CH* emission signal.
(a) $T_5=1593$ K, $P_5=4.04$ atm, Sweep=50 μs/div., 1.0% O_2+0.5% C_2H_4.
(b) $T_5=1610$ K, $P_5=4.48$ atm, Sweep=50 μs/div., 2.0% O_2+0.5% C_2H_4.

(2) In most profiles of the (A) mixture over the temperature range of 1400—1800 K, the arrival time to the peak of the ion signal was earlier than that of the CH* emission signal. In the lower-temperature regions of the (B) mixture (below 1700 K) and the (C) mixture (below 1500 K), the arrival time to the peak of the ion signal was later than that of the CH* emission. In the higher-temperature regions of the (B) and (C) mixture, they were almost identical.

The maximum intensities of the ion signals are plotted against the temperature at the C_2H_4/O_2 ratios of 1/2 (A mixture), 1/3 (B mixture), and 1/4 (C mixture) respectively in Fig. 2. These results indicate that the maximum intensity, I_{max}, increased with the increase in the temperature and the O_2 concentration over the temperature range of 1400—1800 K.

Mass-spectral analysis has shown that, in the oxidation of ethylene in a shock tube, the $C_3H_3^+$ ion is dominant

Table 2. Observed and calculated ^{13}C-NMR chemical shifts[a] for THI and MTI

( ): off-resonance a) In ppm relative to internal TMS.

The selection of a suitable structure for **A** and **B** was governed by the following three factors: (i) by comparison with the ^{13}C-NMR spectra of *endo*- and *exo*-5-vinyl-2-norbornene(VNB),[2] (ii) by matching with the calculated chemical shifts according to parameter of Lindemann[3] for alkane and that of Roberts[4] for alkene and (iii) by referring to the off-resonance decoupling information. From this evidence, **A** and **B** were identified to be the *endo*- and *exo*-5-isopropenyl-2-norbornene (MVN), respectively. The data of the ^{13}C-NMR spectra are listed in Table 1.

Structure of MTI. The following two formulae are presented as possible structures of MTI.

3 **4**

From the results of the ^{13}C-NMR spectra data (in Table 2) and the VPC analysis, it was found that the fraction of MTI consists of only a single component. The determination of the stereochemical structure of MTI contained in the fraction was performed in the following section.

Rearrangement of MVN to MTI. The rearrangement of the fraction of MVN was carried out by a method similar to that reported in a previous paper.[2] In the case of the fraction (*endo*-MVN: *exo*-MVN= 59: 41) obtained from the reaction at 170 °C for 4 h, the *endo*-MVN was rearranged to MTI, while no *exo*-MVN reacted. This fact indicates that MTI was produced along with Cope rearrangement and its structure must be **4**.

Further, the rearrangement kinetics were examined using a fraction having a high content of the *endo*-product(*endo*: *exo*=86: 14), in the temperature range from 145 to 170 °C. The rate constants and the activation parameters are listed in Table 3.

The positive value of $\Delta S^{\ddagger}$ may also support the above mechanism where by the reaction proceeds through Cope rearrangement.[5]

Table 3. Rate constants for the rearrangement of *endo*-MVN to MTI at various temperatures

Reaction temp (°C)	Rate constant ($\times 10^{-4}$ s^{-1})
145	0.22
155	0.38
165	1.13
170	2.25

$\Delta H^{\ddagger}$: 33.8 kcal/mol, $\Delta S^{\ddagger}$: 0.40 e.u. (at 150 °C) calculated from the Eyring equation.

The Diels-Alder reaction of the IP–CP equi-molar mixture gave products **2** and **4**, while neither the **1** nor the **3** compounds were obtained. The reason for the absence of **1** in the products may be illustrated by steric repulsion between the methylene protons of CP(diene) and the methyl group of IP(dienophile).

The reaction scheme is illustrated as follows:

5) The observed $\Delta S^{\ddagger}$ value differs widely in comparison with the value for the reaction of VNB with THI reported in a previous paper.[2] In that work, no explanation of this fact was presented.

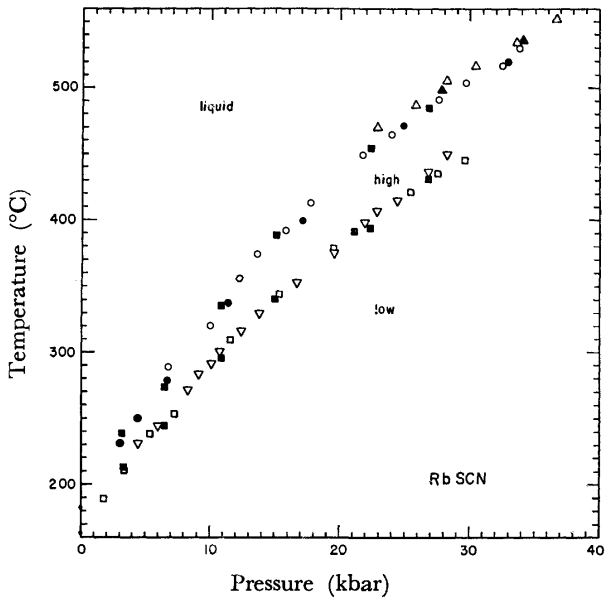

Fig. 2. Solid-solid and melting temperatures for RbSCN. Accepted 1-bar transition temperatures are indicated. Open symbols denote upstroke data; filled symbols denote downstroke data. Circles denote data from first run, triangles second and squares third run, all in aluminium capsules.

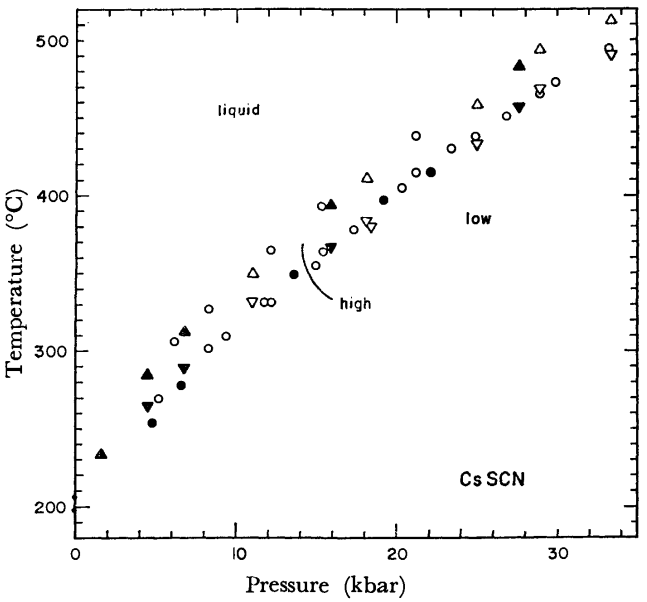

Fig. 3. Solid-solid and melting temperatures for CsSCN. Accepted 1-bar transition temperatures are indicated. Open symbols denote upstroke data; filled symbols denote downstroke data. Circles denote data from first run and triangles those from second run, both in aluminium capsules.

solid transition was observed as before and also data were obtained on decreasing pressure, which were used in the corrections for friction. A single datum was then obtained for the onset of melting, after which decomposition was indicated. The solid-solid transition data (Fig. 1) can be fitted by a straight line of slope 12.6 (±10%) deg kbar^{-1} and intercept 120±4 °C, which agrees with other 1-bar results.[9,10] Taking the 1-bar melting point to be ~146 °C, the tentative slope for the melting curve is ~20 deg kbar^{-1} (Fig. 1).

RbSCN. In all three runs, aluminium capsules were used to contain the RbSCN, which was of unknown origin (and afterwards was shown by X-ray diffraction to contain some RbCl). In the first run, the melting curve was followed on both increasing and decreasing pressure, with the onset of the DTA signal taken for the melting temperature and undercoolings of ~5 to 25 °C, roughly increasing with increasing temperature, observed for the freezing signals. In the second run, the solid-solid transition was detected as a small but distinct break in the DTA signal on heating and as a small peak on cooling, the temperatures corresponding to these features agreeing to within 2—3 °C. Some corroborative melting data were also obtained in this run and the third run provided further corroborative data for both transitions. The data (Fig. 2) for the solid-solid transition can be fitted by a power series with 1-bar intercept 166±3 °C, initial slope (dT/dp) 13.5±1.0 deg kbar^{-1} and initial curvature ($-d^2T/dp^2$) 0.3±0.1 deg kbar^{-2}. The melting data (Fig. 2) can be fitted by a power series with 1-bar intercept 184±2 °C, initial slope 15.7±0.3 deg kbar^{-1} and initial curvature 0.32±0.05 deg kbar^{-2}. Uncertainties are estimated by regression fits of individual sets of data and then of all the data taken together. It cannot be ruled out that the 'melting' curve here is actually the RbSCN-RbCl eutectic but neither the DTA signals nor the DSC results (below) indicated that the transition was spread out over a particularly large temperature range. Since RbCl melts at a much higher temperature than RbSCN and it is unlikely that there is much solid solubility of RbCl in RbSCN, the eutectic is probably 'degenerate', with composition and temperature very close to pure RbSCN and its true melting point, respectively. The present results (Fig. 2) for 'melting' are then a close lower bound to the melting of pure RbSCN.

CsSCN. In both runs, aluminium capsules were used to contain the material, which was obtained from K & K Laboratories. For the solid-solid transition, the onsets of the quite distinct DTA signals on heating and on cooling agreed to within ±1 °C and were taken for the transition temperatures. The onset of the DTA signal on heating was taken as the melting temperature. In the first run, the DTA signals became so indistinct at the higher pressures that the run was abandoned without any data obtained on decrease of pressure. In the second run, however, data were quite reproducibly obtained on both increasing and decreasing pressure. Large undercoolings were observed after melting up to 50 °C or 60 °C— and the melt crystallized directly to the low-temperature phase since only the freezing signal was seen on cooling. The data (Fig. 3) for the solid-solid transition are not fitted well by the usual power series, with intercept ≈197 °C, but there may be estimated an initial slope of $11._8$ ($\pm 1._0$) deg kbar^{-1} and an initial curvature ~0.2 deg kbar^{-2}; similarly, for the melting data (Fig. 3) with intercept ≈206 °C, there may be estimated an initial slope of 14 ($\pm 1._5$) deg kbar^{-2} and an initial curvature ~0.2—0.4 deg kbar^{-2}. The relatively poor fits afforded here by the power series to order p^2 may be due to the difficulties with the friction corrections at the lower pressures.

TlSCN. The first two runs were made with material from Electronic Space Products, in inconel and copper capsules, chronologically. No definite signals could be concluded for the solid-solid transition (see DSC results below) and only signals with rather indistinct onsets for melting; considerable undercooling was noted from the freezing signals. The next two runs were made with material from Ventron, in aluminium and then tantalum capsules. For the solid-solid transition, inflexions in the DTA signals on heating and distinct halts on cooling served to establish

TABLE 1. THE YIELDS AND THE PHYSICAL PROPERTIES OF 3-METHYL-5-(2-OXOALKYL, 2-HYDROXYALKYL, AND 2-HYDROXYALKENYL)ISOXAZOLES AND 4-(3-METHYL-5-ISOXAZOLYL)BUTANOIC ACID DERIVATIVES

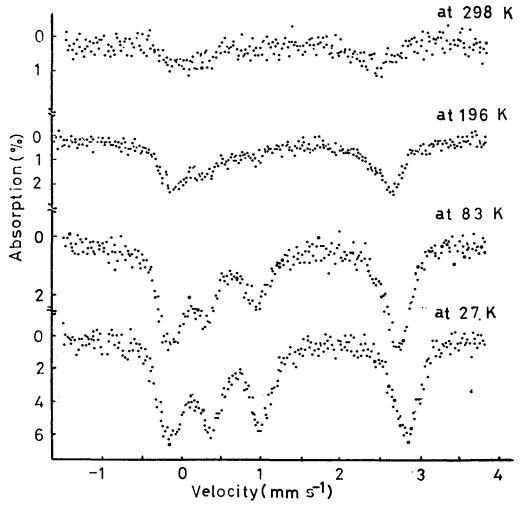

Fig. 3. Mössbauer spectra of $Fe(pot)_2(NCS)_2 \cdot 1/2CHCl_3$ a a variety of temperatures.

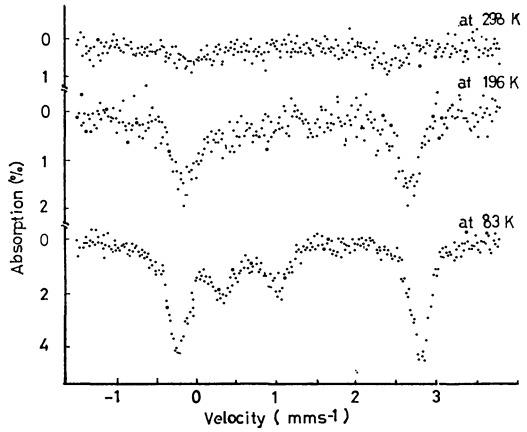

Fig. 4. Mössbauer spectra of $Fe(ppt)_2(NCS)_2$ at a variety of temperatures.

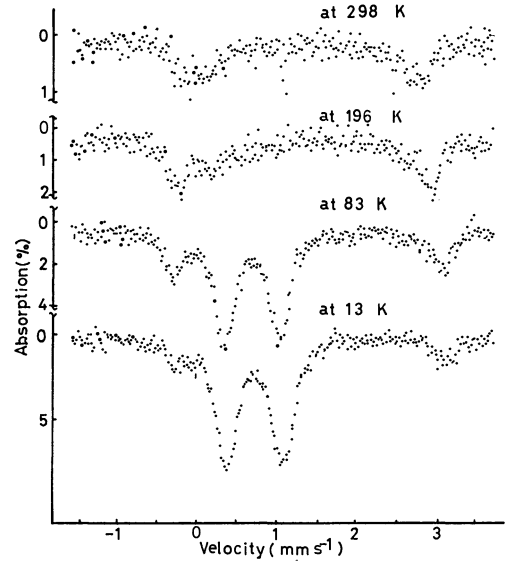

Fig. 5. Mössbauer spectra of $Fe(ppa)_2(NCS)_2$ at a variety of temperatures.

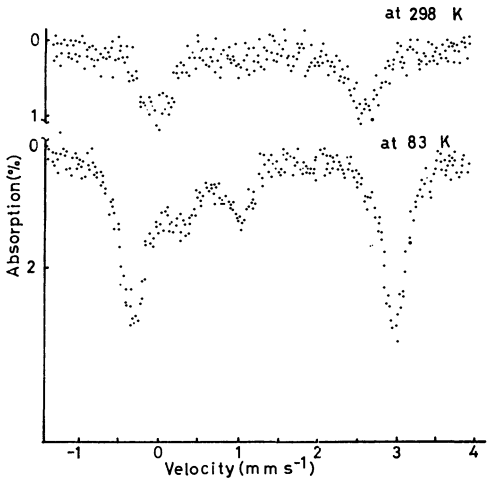

Fig. 6. Mössbauer spectra of $Fe(ppca)_2(NCS)_2$ at a variety of temperatures.

area of iron of the low-spin state to the total absorption area of the Mössbauer spectrum. Based on the general inductive effects of the substituent in the 4-position, it is anticipated that the greater the electronic density of the nitrogen, the greater the ligand-field splitting and the higher the value of Dq. An incomplete transition to the $^1A_1$ state results in a paramagnetic isomer or the existence of a $^5T_2$ excited state having a small energy separation from the $^1A_1$ state. The paramagnetic isomer has still not been observed up to the present time.

The isomer shift of $FeLCl_2$ is smaller than that of FeL_2Cl_2 (L: Schiff bases of quinolinecarbaldehyde or pyridinecarbaldehyde). This fact is interpreted in terms of a tetrahedral structure which is in accordance with the infrared spectral data. The isomer shift of the complexes having a tetrahedral structure is small, in general, because of the smaller s-character or the shielding of the core s-electrons by a larger d-electron contribution.[10]

The spectra of $Fe(qea)_2(NCS)_2$, $Fe(qba)_2(NCS)_2$, $Fe(qea)_2Cl_2 \cdot 1/2H_2O$, and $Fe(qba)_2Cl_2 \cdot 1/2H_2O$ show a pair of lines at 83 K, which is obviously typical for high-spin iron(II) compounds, although the Schiff bases of quinolinecarbaldehyde are more π-electron acceptable and appear to have a stronger field. This ligand field which is weaker than that of the Schiff bases of pyridinecarbaldehyde might be explained by assuming steric interactions, although the quinoline is a better acceptor of π-electrons than the pyridine. A weaker bond has been observed in the cobalt complexes of quinoline *N*-oxide derivatives.[11]

The spectra of the compounds, $Fe(ph)_3(NCS)_2$ and $Fe(pba)_3(NCS)_2 \cdot H_2O$, show the small doublet usually observed for low-spin iron(II) compounds.

Magnetic Properties. The temperature dependences of the magnetic moments, in the range of 77—295 K for the complexes $Fe(pipa)_2(NCS)_2$, $Fe(pa)_2(NCS)_2$, and $Fe(ppa)_2(NCS)_2$ are shown in Fig. 7. The magnetic behaviors of the compounds $Fe(pot)_2(NCS)_2 \cdot 1/2CHCl_3$, $Fe(ppt)_2(NCS)_2$, and $Fe(ppca)_2(NCS)_2$ are similar to that of $Fe(pa)_2(NCS)_2$. At low temperatures, the magnetic moment of $Fe(pipa)_2(NCS)_2$ has values

Table 4. Spectral data of vinyl halides (**4**)—(**7**)

Compd	NMR (CCl_4, δ)	λ_{max} (cyclohexane) nm (ε)	MASS (m/e)
4	3.46 (s, 3H, OCH_3)	285 (13400)	426, 424 (M^+)
	3.65 (s, 3H, OCH_3)	240 (17000)	345 (M^+–Br)
	3.70 (s, 3H, OCH_3)		330 (M^+–CH_3Br)
	6.34—7.25 (m, 12H, arom.)		
5	3.43 (s, 3H, OCH_3)	284 (15500)	382, 380 (M^+)
	3.58 (s, 3H, OCH_3)	240 (16400)	330 (M^+–CH_3Cl)
	6.42—7.23 (m, 12H, arom.)

	6.40—7.30 (m, 12H, arom.)		
7	3.43 (s, 3H, OCH_3)	284 (10500)	396, 394 (M^+)
	3.73 (s, 3H, OCH_3)		315 (M^+–Br)
	6.40—7.25 (m, 13H, arom.)		300 (M^+–CH_3Br)

product other than **8**. Recrystallization (EtOH) gave white plates, mp 125—126 °C. NMR (CCl_4, δ): 3.58 (s, OCH_3), 3.68 (s, OCH_3), 6.58—7.62 (m, 12H, arom.). MS (m/e): 330 (M^+). Found: C, 80.13; H, 5.26%. Calcd for $C_{22}H_{18}O_3$: C, 79.98; H, 5.49%.

Reaction in AcOH: Vinyl bromide (**4**) (70 mg, 0.164 mmol) in AcOH (7 ml) with Na_2CO_3 (85 mg, 0.8 mmol) was refluxed for 27 h. The cooled solution was poured into water, extracted with ether, washed with saturated $NaHCO_3$ solution and water, dried over Na_2SO_4, and then the solvent was evaporated to give the precipitate. Recrystallization (EtOH) gave white needles, mp 124.5—125.5 °C, of **8**. The NMR spectrum of the crude product showed that **8** was probably the only product.

Reaction in 70% Aqueous DMF: Vinyl bromide (**4**) (120 mg, 0.283 mmol) in 70% aqueous DMF (20 ml) was kept in a sealed ampoule at 140 °C for 16 h. The NMR spectrum of the crude product showed the presence of **8** as the sole product.

Reaction in the Presence of Sodium Azide: Vinyl bromide (**4**) (70 mg, 0.165 mmol) in basic (NaOH, 0.4 mmol) 80% EtOH (20 ml) in the presence of sodium azide (650 mg, 10.0 mmol) was kept in a sealed ampould at 120 °C for 6 h. The NMR spectrum of the crude product showed the quantitative formation of **8**.

Reaction in the Presence of Sodium p-*Toluenethiolate*: Vinyl bromide (**4**) (210 mg, 0.49 mmol) and *p*-toluenethiol (87.1 mg, 0.7 mmol) in basic (NaOH, 0.7 mmol) 80% EtOH (7 ml) was sealed in an ampoule and kept at 120 °C for 4 h. After work-up of the solution, the NMR spectrum of the reaction mixture (in CCl_4) showed the presence of **8** (100%) and methyl *p*-tolyl sulfide (47%) (CH_3 at δ 2.02 and SCH_3 at 2.33) which was assigned by comparison with an authentic sample.[22] Since it was hoped that more of the methyl moiety would be trapped by the nucleophile *p*-toluenethiolate ions, the reaction of **4** (200 mg, 0.47 mmol) in basic (NaOH, 1.4 mmol) 80% EtOH (7 ml) in the presence of *p*-toluenthiol (1.4 mmol) was conducted under the same conditions. The NMR spectrum of the reaction mixture this time showed **8** (100%) and methyl *p*-tolyl sulfide (74%).

*Reaction of 2,2-Bis(*o-*methoxyphenyl)-1-(*p-*methoxyphenyl)-vinyl Chloride (5)*. Vinyl chloride (**5**) (60 mg, 0.16 mmol) in basic (NaOH, 0.5 mmol) 80% EtOH (20 ml) was sealed in an ampoule and kept at 160 °C for 25 h. After work-up of the reaction mixture, the NMR spectrum of the crude product showed the dominant formation of **8**.

*Reaction of 2,2-Bis(*o-*methoxyphenyl)-1-*p-*tolylvinyl Bromide (6)*. Vinyl bromide (**6**) (60 mg, 0.15 mmol) in 80% EtOH containing NaOH (0.5 mmol) was kept in a sealed ampoule at 160 °C for 43 h. Work-up of the reaction mixture gave the precipitate of 3-(*o*-methoxyphenyl)-2-*p*-tolylbenzofuran (**9**). The NMR spectrum (in CCl_4) of the crystallized product, mp 89—90 °C, which was identical with that of the crude product, had peaks at δ 2.29 (s, CH_3), 3.56 (s, OCH_3), 6.75—7.44 (m, 12H, arom.). UV: λ_{max} (80% EtOH); 306 nm (ε 26800), 240 (sh, 17200). MS (m/e): 314 (M^+). Found: C, 83.82; H, 5.85%. Calcd for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%.

*Reaction of 2,2-Bis(*o-*methoxyphenyl)-1-phenylvinyl Bromide (7)*. With protection from light, vinyl bromide (**7**) (0.31 g, 0.78 mmol) in AcOH (20 ml) containing silver acetate (0.84 g, 5 mmol) was refluxed for 21 h (100% reaction), followed by filtration, and the solvent was evaporated. Work-up of the reaction mixture gave an oil (0.23 g) which could not be induced to crystallize. An NMR spectrum (in CCl_4) of the crude product showed two different methoxyl proton peaks (singlet at δ 3.58 and 3.31) in addition to aromatic proton peaks (multiplet at δ 6.8—7.7) indicating the possibility of two different products, each one of which would have one methoxyl group. Integration of these methoxyl proton peaks showed two products to be present in the ratio of 91 : 9, respectively. Similarly, the reaction of **7** (63 mg, 0.16 mmol) in basic (NaOH, 0.5 mmol) 80% EtOH (20 ml) in a sealed ampoule at 160 °C for 204 h (95% reaction) and the reaction of **7** (55 mg, 0.136 mmol) in basic (NaOH, 7.0 mmol) 50% EtOH (14 ml) at 160 °C for 26 h (96% reaction) gave the two products in similar product ratios (93 : 7 for both). Twice attempted separation of the two products by thin-layer chromatography (TLC) on silica gel (benzene–hexane 1 : 2 or 1 : 3) gave only poor separations, as judged by the small changes in the relative NMR intensities of the two different methoxyl proton peaks. By treating the reaction mixture (0.103 g) with a hot saturated solution of picric acid in EtOH (3 ml) and allowing the solution to cool, a picrate was separated in orange-red needles (0.122 g), which were then recrystallized (EtOH), mp 108—109 °C. Found: C, 61.02; H, 3.62; N, 7.86%. Calcd for $C_{27}H_{19}O_9N_3$ (1 : 1 π-complex of picric acid and $C_{21}H_{16}O_2$): C, 61.25; H, 3.62; N, 7.94%. The picrate was split by chromatography on alumina and eluted with benzene to give a pale yellow oil. All attempted crystallizations failed. The NMR spectrum of this oil (in CCl_4) showed only one methoxyl singlet at δ 3.45 and an aromatic 13H multiplet at δ 6.9—7.7, indicating the isolated major product. MS (m/e): 330 (M^+). The UV spectrum in cyclohexane showed a characteristic absorption at 305 nm of 2-phenylbenzofuran

double bond character, the rotations around the N–$\overset{\oplus}{S}$ and O–$\overset{\oplus}{S}$ bonds are not restricted, since 2p-3d π overlaps in sulfur compounds are not much affected by S–N rotation.[13,14] Even under conditions of rapid rotation or in the absence of unequal populations of several conformers, methylene hydrogens α or β to a chiral sulfur atom can be non-equivalent.[12–15] Interpretation of the data shown in Tables 1 and 2 is not easy; accumulation of more data is necessary before one can reasonably explain these phenomena.

Experimental

PMR spectra were determined with a Hitachi Perkin-Elmer NMR Spectrometer R-20 (60 MHz) at 34 °C with CH_2Cl_2 (δ 5.30) as an internal standard.[16] The concentrations were about 10 wt %.

Neopentyl benzenesulfenate[17] was prepared by the reaction among benzenesulfenyl chloride (10.4 mmol), neopentyl alcohol (10.4 mmol), and pyridine (10.4 mmol) at −5 °C. Yield, 1.6 g (80%), bp, 80 °C/2 mmHg.

Alkyl triflates were prepared according to the methods described in the literature. CF_3SO_3Me, bp 100 °C (lit,[18] 99 °C). CF_3SO_3Et, bp 119 °C (lit,[19] 115 °C).

Sulfinates (or sulfinamides) were prepared either by the reaction between sulfinyl chlorides and alcohols (or amines) or by the condensation between sulfinic acids and alcohols (or amines) with *N,N′*-dicyclohexylcarbodiimide.[21] *N*-*p*-Toluenesulfinylpyrrolidine was prepared from pyrrolidine and *p*-toluenesulfinyl chloride in ether at 0°, and recrystallized from hexane; yield, 31%; mp 52—53 °C; NMR (CD_3NO_2) δ= 1.55—1.86 (m, 4, N–$CH_2C\underline{H}_2$–), 2.27 (s, 3, $C\underline{H}_3$–C_6H_4), 2.57—3.41 (m, 4, N–$C\underline{H}_2$), 7.10—7.53 (q, 4, –$C_6\underline{H}_4$–); Found: C, 62.77; H, 7.12; N, 6.36%. Calcd for $C_{11}H_{15}ONS$: C, 63.14; H, 7.23; N, 6.69%.

Ethoxysulfonium Triflates ***1a—c.*** They were prepared by mixing equimolar amounts of the corresponding sulfoxides and ethyl triflate in CD_3NO_2. Since they are oils which cannot be distilled, their elemental analyses were not carried out. *p*-$TolMe\overset{\oplus}{S}-OEt\ \overset{\ominus}{BF_4}$ was described in the literature,[6–8] but its PMR data were not shown. PMR: **1a**, δ=1.27 (t, 3, $C\underline{H}_3CH_2$–), 2.39 (s, 3, $C\underline{H}_3C_6H_4$–), 3.60 (s, 3, $C\underline{H}_3$–S), 4.16—4.48 (m, 2, CH_2), 7.40—8.10 (q, 4, –$C_6\underline{H}_4$–); **1b**, δ=1.22 (t, 3, $C\underline{H}_3CH_2$), 4.33 (q, 2, $CH_3C\underline{H}_2$), 5.05 (q, 2, S–CH_AH_B–Ph, $\Delta\delta_{AB}$=0.23 ppm, J_{AB}=12.8 Hz), 6.95—8.00 (m, 10, Ph); **1c**, δ=1.31 (t, 3, $C\underline{H}_3CH_2$–S), 1.39 (t, 3, $C\underline{H}_3CH_2$–O), 0.60—2.20 (m, 7, $C\underline{H}_3C\underline{H}_2C\underline{H}_2$–), 3.26—3.71 (m, 4, $C\underline{H}_2$–S–$C\underline{H}_2$), 4.36 (q, 3, CH_3–S), 3.92 (q, O–CH_AH_B–, J_{AB}=9.1Hz), 7.64—8.20 (m, 5, C_6H_5–).

Neopentyloxymethylphenylsulfonium Triflate ***1d.*** When an equimolar mixture of neopentyl benzenesulfenate and methyl triflate in nitromethane was allowed to stand for 10 min at 34 °C, its PMR spectrum showed that the sulfenate was converted to **1d**. After the solvent was evaporated, the residue was dissolved in a small amount of acetone, and an equimolar amount of $NaBPh_4$ was added. However, the corresponding anion-exchanged salt was not obtained, and only decomposition products were found.

When a CD_3NO_2 solution of **1d** was heated at 75 °C for 18 h, it completely decomposed. Its PMR spectrum showed absorptions at δ=0.85 (s, 9.0H, $(CH_3)_3C$–), 2.35 (s, 0.54H, $PhSC\underline{H}_3$), 2.44 (s, 0.64H, ?), 3.19 (s, 1.29H, ?), 3.63 (s, 1.94H, $Me_3CC\underline{H}_2\overset{\oplus}{O}H_2$), and 7.16—7.83 (m, Ar–H). When an equimolar amount of pentadeuteriopyridine was added, the absorptions of neopentyl alcohol was shifted to δ=0.75 ($(CH_3)_3C$–) and δ=3.12 (CH_2).

PMR of **1d** (CD_3NO_2), δ=0.80 (s, 9, $(CH_3)_3C$–), 3.57 (s, 3, CH_3–S), 4.92 (q, CH_AH_B–CMe_3), 7.64—8.20 (m, 5, Ph).

Alkoxyneopentyloxyethylsulfonium Triflates ***2a,b.*** They were prepared by the reaction of an equimolar mixture of neopentyl ethanesulfinate and ethyl or methyl triflate in CD_3NO_2 at 34 °C for 1 h. They were stable only in solution, and decomposed when the solvent was evaporated. PMR: **2a**, δ=0.92 (s, 9, $(CH_3)_3C$–), 1.41 (t, 3, $C\underline{H}_3CH_2S$–), 1.43 (t, 3, $C\underline{H}_3CH_2O$–), 3.66 (q, 2, $CH_3C\underline{H}_2S$–), 4.26 (q, 2, –OCH_AH_B–CMe_3, J_{AB}=8.8 Hz), 4.68 (q, 2, $OC\underline{H}_2CH_3$); **2b**, δ=0.90 (s, 9, $(CH_3)_3C$–), 1.37 (t, 3, $C\underline{H}_3CH_2S$–), 3.68 (q, 2, $CH_3C\underline{H}_2S$–), 4.29 (s, 3, CH_3O–), 4.29 (q, 2, OCH_AH_B, J=9.0 Hz); **2c**, δ=1.35 (t, 3, $C\underline{H}_3CH_2S$–), 1.42 (t, 3, $C\underline{H}_3CH_2O$–), 3.63 (q, 2, $CH_3C\underline{H}_2S$–), 4.25 (s, 3, CH_3O–), 4.66 (q, 2, $CH_3C\underline{H}_2O$–).

Alkoxyaminosulfonium Triflates ***4b—d.*** They were prepared by the reaction of an equimolar mixture of an arenesulfinamide and alkyl triflate in CD_3NO_2 at 34 °C for 1 h. Upon evaporation of the solvent, **4b** decomposed, whereas **4c** and **4d** could be isolated as oils. PMR(CD_3NO_2) of **4b**; δ= 1.49 (t, 3, $C\underline{H}_3CH_2O$–), 1.85—2.14 (m, 4, $-CH_2CH_2N$), 2.39

Spin Trapping of Benzoyloxycyclohexadienyl Radicals by 2,3,5,6-Tetramethylnitrosobenzene (Nitrosodurene) in the Decomposition of Dibenzoyl Peroxide in Benzene

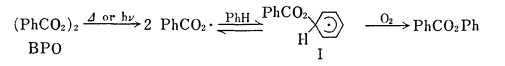
(Received June 7, 1976)

The aroyloxycyclohexadienyl radicals (VIII), the key intermediates in the homolytic aromatic aroyloxylation, were detected and identified in the decomposition of dibenzoyl peroxide, bis(4-methylbenzoyl) peroxide, and bis(4-methoxybenzoyl) peroxide in benzene-d_6 as spin adducts of nitrosodurene.

Irradiation of dibenzoyl peroxide (BPO) in benzene causes a benzoyloxylation of the solvent benzene to give substantial yields of phenyl benzoate at room temperature, if molecular oxygen is present. Such a benzoyloxylation takes place also in the thermal decomposition of BPO in benzene, where the yield of phenyl benzoate increases with lowering of the reaction temperature.[1] The genesis of phenyl benzoate has been accounted for in terms of the reversible addition of benzoxyl radicals to benzene followed by the oxidation of the resulting benzoyloxycyclohexadienyl radicals (I) by molecular oxygen (Scheme 1).[1]

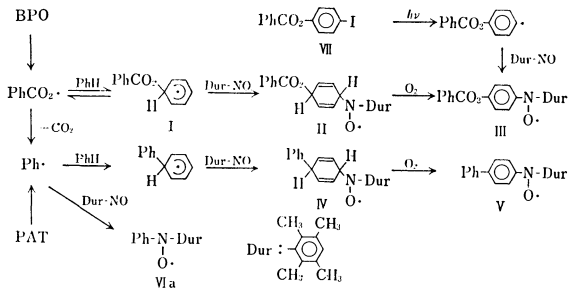


Scheme 1.

In the decomposition of bis(pentafluorobenzoyl) peroxide in the presence of benzene in hexachloro-1,3-butadiene CIDNP effects are detected in the proton NMR spectra of benzene and other products. The observed polarizations have been explained by assuming a singlet radical pair of a pentafluorobenzoyloxycyclohexadienyl radical and a pentafluorobenzoxyl radical.[2] Recently, the direct observation of the radical adduct of benzoxyl radicals to 1,3,5-tris(trimethylsiloxy)benzene was attained by ESR spectroscopy.[3] However, no definitive spectroscopic evidence indicating the formation of I has hitherto been reported in the decomposition of BPO in benzene. We showed previously that the decomposition of arylazotriphenylmethanes in the presence of 2,3,5,6-tetramethylnitrosobenzene (nitrosodurene) in benzene affords arylcyclohexadienyl 2,3,5,6-tetramethylphenyl nitroxides (arylcyclohexadienyl duryl nitroxides). Thus, success has been achieved in trapping arylcyclohexadienyl radicals, produced by the addition of aryl radicals to benzene, by nitrosodurene.[4] We therefore decided to employ this spin trapping technique for the detection of I.

Results and Discussion

Heating dibenzoyl peroxide (BPO) at 80 °C in benzene containing nitrosodurene under an atmosphere of argon gave an ESR spectrum consisting of three complex sets (a_N=9.5 gauss) ascribable to duryl phenyl nitroxides (VIa).[4,5] Apparently these radicals (VIa) are produced by the fast decarboxylation of benzoxyl radicals followed by trapping of the resulting phenyl radicals by nitrosodurene. When the decomposition was carried out at 40 °C in benzene, VIa could not be detected at all; instead an ESR signal (three triplets, a_N=9.7 and $a_{ortho\text{-}H}$=2.7 gauss) consistent with 4-benzoyloxyphenyl duryl nitroxide (III)[6] was observed. The structural assignment is mainly based on the value of the nitrogen hyperfine splitting constant (a_N) and the partially resolved splitting due to the two *ortho*-hydrogens. The possible assignment to 4-biphenylyl duryl nitroxide (V), which might be formed by the oxidation of a spin adduct of phenylcyclohexadienyl radicals (IV), can be eliminated, since no signals due to 4-biphenylyl duryl nitroxide (V) were detected in the decomposition of phenylazotriphenylmethane (PAT) in the presence of nitrosodurene at 40 °C in benzene; the phenyl radicals arising from PAT are trapped by nitrosodurene to yield VIa before they add to benzene. Further verification for the structural assignment of III was obtained in the trapping experiment by the photolysis of 4-iodophenyl benzoate (VII) in carbon tetrachloride (Scheme 2). The ESR spectrum obtained agrees well with that observed above.



Scheme 2.

To gain more insight into the formation of III, BPO was decomposed in benzene-d_6 at 40 °C in the presence of nitrosodurene. The ESR spectrum showed three triplets (a_N=13.4 and $a_{\beta\text{-}D}$=1.5 gauss), which diminished in intensity on exposure to oxygen, while a new signal composed of a broad triplet (a_N=9.6 gauss) increased. The latter signal is attributed to the deuterated 4-benzoyloxyphenyl duryl nitroxide (Xa) by comparison of the a_N value with that of III. The magnitude of the nitrogen and β-hydrogen (deuterium) hyperfine splitting

CH_2, m), 3.20 (3H, OCH_3, s), 3.70 (1H, C-6 CH, dd, J=6.0, 10.0 Hz), 3.92 (1H, C-8 CH, br t, J=8.0 Hz), 6.30 (5H, aromatic-H, br s), 7.76—8.32 ppm (4H, aromatic-H, m). 1-Ethoxy-8,8-diphenyl-3,4-benzobicyclo[4.2.0]oct-3-ene-2,5-dione (3f); white crystals (yield, 60%); mp 112.0—113.0 °C. Mass; m/e=382 (M^+). Found: C, 81.49; H, 5.80%. Calcd for $C_{26}H_{22}O_3$: C, 81.65; H, 5.80%. IR (KBr disk); 1680 cm^{-1} (C=O). ^{1}H-NMR (CCl_4); δ: 1.18 (3H, CH_3, t, J=8.0 Hz), 3.40 (2H, CH_2, q, J=8.0 Hz), 3.38 (3H, C-6 CH and C-7 CH_2, m), 6.72—7.90 ppm (14H, aromatic-H, m).

1-Isopropoxy-8-phenyl-3,4-benzobicyclo[4.2.0]oct-3-ene-2,5-dione (3g); white needles (yield, 41%); mp 91.0—92.0 °C. Mass; m/e=320 (M^+). Found: C, 79.07; H, 5.85%. Calcd for $C_{21}H_{20}O_3$: C, 78.75; H, 6.25%. IR (KBr disk); 2970 (CH), 1690, 1680 cm^{-1} (C=O). ^{1}H-NMR (CCl_4); δ: 0.68 (3H, CH_3, d, J=6.0 Hz), 0.90 (3H, CH_3, d, J=6.0 Hz), 2.14 (1H, C-7 CH, m), 2.83 (1H, C-7 CH, m), 3.60—4.00 (3H, O-CH, C-6 CH, and C-8 CH' s, m), 7.24 (5H, aromatic-H, br s), 7.60—8.24 ppm (4H, aromatic-H, m). UV_{max} ($CHCl_3$); 300 nm (ε: 2.3×10^3), 310 (1.8×10^5), 338 (3.3×10^2).

The Acetylation of the Photo-addition Compound, 4. The acetyl derivative **6** was prepared by standing the photo-addition compound, **4**, (115 mg) in acetic anhydride (5 ml) containing few drops of pyridine for 3 h at room temperature, and by then pouring the mixture into cold water (10 ml). After extraction with ether and subsequent purification using thin-layer chromatography on silica gel, 2-acetoxy-8-phenyl-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one, **6**, was obtained as white plates (110 mg; yield, 83%); mp 92.0—93.0 °C from petroleum ether. Mass; m/e=334 (M^+). IR (KBr disk); 1740, 1682 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 2.13 (3H, $OCOCH_3$, s), 2.60 (2H, C-7 CH_2, dd, J=6.0, 8.0 Hz), 3.56 (1H, C-6 CH, t, J=8.0 Hz), 3.84 (1H, C-8 CH, t, J=6.0 Hz), 4.52, 4.84 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 7.30 (5H, aromatic-H, br s), 7.20—8.05 ppm (4H, aromatic-H, m).

The Acid-catalyzed Decomposition of the Photo-addition Compound, 4. The acid-catalyzed decomposition was completed by treating the photo-addition compound, **4** (200 mg) in chloroform (15 ml) with a few drops of concd hydrochloric acid or concd sulfuric acid at room temperature for 8 h. After the concentration of the reaction mixture and purification using thin-layer chromatography on silica gel, two isomers of 7-phenyl-3,4-benzobicyclo[4.2.0]oct-3-ene-2,5-dione, **7a** (61 mg; yield, 38%) and **7b** (35 mg; yield, 22%), were isolated as white crystals; **7a**; mp 112.0—115.0 °C. Mass; m/e=262 (M^+). IR (KBr disk); 1690 cm^{-1} (C=O). ^{1}H-NMR (CCl_4); δ: 2.70 (2H, C-8 CH_2, m), 3.40—3.70 (3H, C-1, C-6 and C-7 CH' s, m), 7.16 (5H, aromatic-H, br s), 7.92—8.10 ppm (4H, aromatic-H, m). **7b**; mp 147.0—148.0 °C. Mass; m/e=262 (M^+). IR (KBr disk); 1680 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 2.70—3.20 (2H, C-8 CH_2, m), 3.60—4.40 (3H, C-1, C-6, and C-7 CH's, m), 6.90—7.40 (5H, aromatic-H, m), 7.60—8.20 ppm (4H, aromatic-H, m).

The Photochemical Reaction of 1,4-Naphthoquinone with Styrene. A benzene solution (20 ml) of 1,4-naphthoquinone (158 mg) and styrene (210 mg) was submitted to the irradiation of a high-pressure Hg arc lamp. After the complete consumption of the quinone, **7a** (118 mg; yield, 45%) and **7b** (28 mg; yield, 11%) were isolated from the reaction mixture through purification by thin-layer chromatography on silica gel.

The Acetylation of 7a or 7b. 3,8-Diacetoxy-1-phenyl-1,2-dihydrocyclobuta[*b*]naphthalene, **8**, was prepared by refluxing a mixture of **7a** (or **7b**) (70 mg) and sodium acetate (200 mg) dissolved in acetic anhydride (15 ml) for 3 h. **8** was thus obtained in a 57% yield (53 mg) as white needles from benzene–hexane; mp 135.0 °C. Mass; m/e=346 (M^+). Found: C, 76.10; H, 5.38%. Calcd for $C_{22}H_{18}O_4$: C, 76.28; H, 5.25%. IR (KBr disk); 1750 cm^{-1} (C=O). ^{1}H-NMR (CCl_4); δ: 2.16 (3H, $COCH_3$, s), 2.42 (3H, $COCH_3$, s), 3.18 (1H, C-2 CH, dd, J=4.0 14.0 Hz), 3.82 (1H, C-2 CH, dd, J=8.0, 14.0 Hz), 4.78 (1H, C-1 CH, dd, J=4.0, 8.0 Hz), 7.24 (5H, aromatic-H, br s), 7.36—8.04 ppm (4H, aromatic-H,m).

The Bromination of the Photo-addition compound, 4. Bromine (100 mg) was added to a chloform solution (25 ml) of the photo-addition compound, **4** (300 mg), after which the mixture was allowed to stand for 15 h at room temperature. Two products, **9** and **10**, were isolated in 54% (189 mg) and 32% (122 mg) yields respectively after the purification of the reaction mixture using thin-layer chromatography on silica gel. 1-Bromo-7-phenyl-3,4-benzobicyclo[4.2.0]oct-3-ene-2,5-dione (**9**); white crystals from benzene–peroleum ether; mp 136.0—137.0 °C. Mass; m/e=342, 340 (M^+). IR (KBr disk); 1695 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 3.20—3.50 (2H, C-7 CH and C-8 CH, m), 3.78 (1H, C-8 CH, dd, J=8.0, 12.0 Hz), 4.74 (1H, C-6 CH, d, J=8.0 Hz), 7.10-7.50 (5H, aromatic-H,m), 7.70—8.40 ppm (4H, aromatic-H, m). 6-Bromo-2-hydroxy-8-phenyl-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one (**10**); white crystals. Mass; m/e=372, 370 (M^+). IR (KBr disk); 3400 (OH), 1670 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 2.94 (1H, C-7 CH, dd, J=10.0, 12.0 Hz), 3.10 (1H, OH, s), 3.26 (1H, C-7 CH, dd, J=8.0, 12.0 Hz), 3.92 (1H, C-8 CH, dd, J=8.0, 10.0 Hz), 4.64, 4.74 (2H, C-10 CH_2, AB-q, J=8.0 Hz), 7.30—8.00 ppm (9H, aromatic-H, m).

The Bromination of 6. By treating a chloroform solution (10 ml) of **6** (110 mg) with bromine (30 mg) for 15 h at room temperature, **9** (65 mg; yield, 50%) and **11** (49 mg; yield, 36 %) were obtained: 2-acetoxy-6-bromo-8-phenyl-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one (**11**); white needles from benzene–petroleum ether; mp 138.0—138.5 °C. Mass; m/e=414, 412 (M^+). IR (KBr disk); 1740, 1690 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 2.84 (3H, $COCH_3$, s), 2.80 (1H, C-7 CH, dd, J=8.0, 12.0 Hz), 3.42 (1H, C-7 CH, dd, J=8.0, 12.0 Hz), 3.92 (1H, C-8 CH, t, J=8.0 Hz), 4.68, 4.78 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 7.26 (5H, aromatic-H, br s), 7.10—7.90 ppm (4H, aromatic-H, m). **11** was also isolated from the reaction mixture of the acetylation of **10** by acetic anhydride–pyridine.

The Bromination of 7b. **9** was also identified as one of the reaction products of **7b** (115 mg) with bromine (100 mg) in chloroform (10 ml) at room temperature for 20 h.

The Clemmensen Reduction of the Photo-addition Compound, 4. The photo-addition compound, **4** (500 mg), toluene (5 ml), amalgamated zinc (10 g), and concd hydrochloric acid (12 ml) were heated for 8 h. Three reaction products, **12**, **13**, and **14**, were isolated from the reaction mixture using thin-layer chromatography on silica gel in 17% (42 mg), 7% (20 mg), and 12% (37 mg) yields respectively; 8-methyl-1-phenyl-1,2-dihydrocyclobuta[*b*]naphthalene (**12**); colorless oil. Mass; m/e=244 (M^+). IR (liq. film); no OH or C=O. ^{1}H-NMR (CCl_4); δ: 2.56 (3H, CH_3, s), 2.70—3.20 (3H, C-1 CH and C-2 CH_2, m), 7.60 (5H, aromatic-H, br s), 7.10—8.00 ppm

(5H, aromatic-H, m). UV_{max} ($CHCl_3$); 243 nm (ε: 7.9×10^3), 276 (5.0×10^3), 307 (1.7×10^3), 322 (1.4×10^3). 4-Phenyl-3,4-dihydro-1H-oxeto[2′,3′: 3,4]naphtho[1,2-*b*]furan (**13**); white needles from benzene–petroleum ether; mp 137.0—139.0 °C. Mass; $m/e=274$ (M^+). Found: C, 83.06; H, 5.35 %. Calcd for $C_{19}H_{14}O_2$: C, 83.20; H, 5.15%. IR (KBr disk); no OH or C=O. ^{1}H-NMR ($CDCl_3$); δ: 3.14 (2H, C-3 CH_2, m), 4.82 (1H, C-4 CH, dd, $J=4.0$, 10.0 Hz), 5.44 (2H, C-1 CH_2, AB-q, $J=15.0$ Hz), 7.14—7.90 ppm (9H, aromatic-H, m). UV_{max} ($CHCl_3$); 242 nm (ε: 6.9×10^3), 266 (4.9×10^3), 274 (6.1×10^3), 280 (6.3×10^3), 291 (4.8×10^3), 307 (8.8×10^2), 313 (5.7×10^2), 322 (6.6×10^2). 2-(2-Hydroxy-2-phenylethyl)-4-methylnaphthalene-1,3-diol (**14**); colorless oil. Mass; $m/e=276$ (M^+-H_2O). IR (liq. film); 3850, 3400 cm^{-1} (OH). ^{1}H-NMR (CCl_4); δ: 2.56 (3H, CH_3, s), 3.18 (2H, CH, d, $J=6.0$ Hz), 4.82 (1H, CH, t, $J=6.0$ Hz), 7.10—8.00 ppm (9H, aromatic-H, m). UV_{max} ($CHCl_3$); 246 nm (ε: 7.2×10^3), 275 (4.4×10^3), 283 (3.8×10^3), 321 (1.2×10^3).

The Thermal Decomposition of ***12***. The thermal decomposition of **12** at 500 °C for 20 min in a sealed tube gave 1-methylnaphthalene, which was identified by gas-liquid-partition chromatography.

The Acetylation of ***14***. A monoacetylated product, **15**, was identified through the acetylation of **14** with sodium acetate–acetic anhydride: 4-Acetoxy-5-methyl-2-phenyl-2,3-dihydronaphthalene[1,2-b]furan (**15**); Mass; $m/e=328$ (M^+). IR (liq, film); 1730 cm^{-1} (C=O). ^{1}H-NMR (CCl_4); δ: 2.00 (3H, $COCH_3$, s), 2.56 (3H, CH_3, s), 3.18, 3.46 (2H, CH_2, d×AB-q, $J=6.0$, 12.0 Hz), 5.96 (1H, CH, t, $J=8.0$ Hz), 7.00—8.10 ppm (9H, aromatic-H, m).

The Thermal Decomposition of ***3a***. A 0.04 M-CCl_4 solution of **3a** was submitted to thermal decomposition at 75±1 °C; the rate was followed by means of ^{1}H-NMR. The half-life of **3a** was estimated to be about 92 min.

The Determination of the Quantum Efficiency. The light source was a high-pressure Hg arc lamp (300 W) with the filter, A. Irradiation carried out at a constant temperature (16±0.5 °C). The quanta of light absorbed by the reaction mixture was calibrated using an aqueous solution of potassium ferroxalate as a chemical actinometer;[22] it was estimated to be 2.07×10^{-5} mol/10.0 ml/min. The reaction mixture submitted to the measurement was a benzene solution of 2.00×10^{-2} mol/l of 2-methoxy-1,4-naphthoquinone and 4.00×10^{-2} mol/l of styrene. The quantum efficiency was calculated for the disappeaance of 2-methoxy-1,4-naphthoquinone and was estimated to be 0.18.

The author wishes to express his deep gratitude to Professor Kazuhiro Maruyama, Kyoto University, for his fruitful suggestions and invaluable encouragement. He also wishes to thank the Ministry of Education for the financial support for this research.

13) In the following discussion, the structures of the compounds derived from **5** are not illustrated because these structures should be excluded as trivial.
14) The stereochemistry of these isomers was concluded on the basis of an analysis of their ^{1}H-NMR spectra, as is illustrated in **7a** and **7b**. The possibility of the stereoisomers being centered at C-1 can be excluded completely because **4** (or **5**) could be derived from one of the stereoisomers at C-1 (**3d**).

Calcd for $C_{21}H_{25}NO_3$: C, 74.31; H, 7.42; N, 4.13%.

Photo-addition Products of 6-Bromo-1,2-naphthoquinone with Aliphatic Aldehydes. (i) Acetaldehyde: 3-Acetyl-6-bromo-1,2-naphthalenediol [**4**: R=CH_3, R_1=H, R_2=Br]: orange yellow needles (90 mg, 38%), mp 159.5—160.5 °C. IR: ν_{OH} 3440; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 2.78 (s, 3H, CH_3), 5.98 (s, 1H, OH), 7.48—8.05 (m, 4H, aromatic-H), 11.56 (s, 1H, OH). Found: C, 51.17; H, 3.31%. Calcd for $C_{12}H_9BrO_3$: C, 51.27; H, 3.23%. 6-Bromo-1,2-naphthalenediol monoacetate [**5**: R=CH_3, R_1=R_2=H, R_3=Br]: white needles (40 mg, 16.9%), mp 136—137 °C. IR: ν_{OH} 3310; $\nu_{C=O}$ 1742 cm^{-1}. PMR($CDCl_3$), δ: 2.43 (s, CH_3, 70%), 2.52 (s, CH_3, 30%), 7.12—8.18 (m, aromatic-H+OH). Found: C, 51.48; H, 3.17%. Calcd for $C_{12}H_9BrO_3$: C, 51.27; H, 3.23%.

(ii) Propionaldehyde: 3-Propionyl-6-bromo-1,2-naphthalenediol [**4**: R=CH_3CH_2, R_1=H, R_2=Br]: orange prisms (64 mg, 25.7%), mp 143—144.5 °C. IR: ν_{OH} 3375; $\nu_{C=O}$ 1640 cm^{-1}. PMR(CCl_4), δ: 1.30(t, 3H, CH_3), 3.14 (q, 2H, CH_2), 5.92 (s, 1H, OH), 7.37—7.92 (m, 4H, aromatic-H), 11.52 (s, 1H, OH). Found: C, 53.17; H, 3.61%. Calcd for $C_{13}H_{11}BrO_3$: C, 52.91; H, 3.76%. 6-Bromo-1,2-naphthalenediol monopropionate [**5**: R=CH_3CH_2, R_1=R_2=H, R_3=Br]; white crystals (60 mg, 24%), mp 140.5—142 °C. IR: ν_{OH} 3400; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 1.31 (t, CH_3, 70%), 1.38 (t, CH_3, 30%), 2.69 (q, CH_2, 70%), 2.78 (q, CH_2, 30%), 7.00—8.00 (m, aromatic-H+OH). Found: C, 52.81; H, 3.65%. Calcd for $C_{13}H_{11}BrO_3$: C, 52.91; H, 3.76%.

(iii) Butyraldehyde: 3-Butyryl-6-bromo-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_2$, R_1=H, R_2=Br]: orange prisms (67 mg, 25.8%), mp 126.5—128.5 °C. IR: ν_{OH} 3430; ν_{CH} 2960, 2940, 2880; $\nu_{C=O}$ 1655 cm^{-1}. PMR(CCl_4), δ: 1.08 (t, 3H, CH_3), 1.74 (sex, 2H, CH_2), 3.06 (t, 2H, $COCH_2$), 5.95 (s, 1H, OH), 7.38—7.98 (m, 4H, aromatic-H), 11.58 (s, 1H, OH). Found: C, 54.53; H, 4.09%. Calcd for $C_{14}H_{13}BrO_3$: C, 54.39; H, 4.24%. 6-Bromo-1,2-naphthalenediol monobutyrate [**5**: R=$CH_3(CH_2)_2$, R_1=R_2=H, R_3=Br]: white needles (75 mg, 28.8%), mp 131.0—132.5 °C. IR: ν_{OH} 3300; ν_{CH} 2960; $\nu_{C=O}$ 1720 cm^{-1}. PMR($CDCl_3$), δ: 1.08 (t, 3H, CH_3), 1.84 (sex, 2H, CH_2), 2.65 (t, 2H, $COCH_2$), 7.10—8.08 (m, 6H, aromatic-H+OH). Found: C, 54.26; H, 4.37%. Calcd for $C_{14}H_{13}BrO_3$: C, 54.39; H, 4.24%.

(iv) Isobutyraldehyde: 3-Isobutyryl-6-bromo-1,2-naphthalenediol [**4**: R=$(CH_3)_2CH$, R_1=H, R_2=Br]: orange plates (40 mg, 15.4%), mp 116.5—118.0 °C. IR: ν_{OH} 3450; ν_{CH} 2980, 2940; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 1.29 (d, 6H, $(CH_3)_2$), 3.67 (sep, 1H, OH), 5.90 (s, 1H, OH), 7.31—7.96 (m, 4H, aromatic-H), 11.58 (s, 1H, OH). Found: C, 54.72; H, 4.36%. Calcd for $C_{14}H_{13}BrO_3$: C, 54.39; H, 4.24%. 6-Bromo-1,2-naphthalenediol monoisobutyrate [**5**: R=$(CH_3)_2CH$, R_1=R_2=H, R_3=Br]: white prisms (105 mg, 40.4 %), mp 153.0—154.5 °C. IR: ν_{OH} 3440; ν_{CH} 2990, 2950, 2890; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 1.40 (d, 6H, $(CH_3)_2$), 2.91 (sep, 1H, CH), 7.02—8.01 (m, 6H, aromatic-H). Found: C, 54.39; H, 4.19%. Calcd for $C_{14}H_{13}BrO_3$: C, 54.39; H, 4.24%.

(v) Valeraldehyde: 3-Valeryl-6-bromo-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_3$, R_1=H, R_2=Br]: orange needles (49 mg, 18.1%), mp 101—102 °C. IR: ν_{OH} 3450; ν_{CH} 2950, 2880; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 0.98 (t, 3H, CH_3), 1.31—1.88 (m, 4H, $(CH_2)_2$), 3.03 (t, 2H, $COCH_2$), 5.93 (s, 1H, OH), 7.04—7.94 (m, 4H, aromatic-H), 11.65 (s, 1H, OH). Found: C, 55.58; H, 4.52%. Calcd for $C_{15}H_{15}BrO_3$: C, 55.57; H, 4.68%. 6-Bromo-1,2-naphthalenediol monovalerate [**5**: R=$CH_3(CH_2)_3$, R_1=R_2=H, R_3=Br]: white needles (73 mg, 26.9%), mp 121—122 °C. IR: ν_{OH} 3400; ν_{CH} 2960, 2945, 2880; $\nu_{C=O}$ 1722 cm^{-1}. PMR (CCl_4), δ: 0.97 (t, 3H, CH_3), 1.33—1.89 (m, 4H, $(CH_2)_2$), 2.60 (t, 2H, $COCH_2$), 6.10 (s, 1H, OH), 7.00—8.06 (m, 5H, aromatic-H). Found: C, 55.83; H, 4.71%. Calcd for $C_{15}H_{15}BrO_3$: C, 55.75; H, 4.68%.

(vi) Isovaleraldehyde: 3-Isovaleryl-6-bromo-1,2-naphthalenediol [**4**: R=$(CH_3)_2CHCH_2$, R_1=H, R_2=Br]: orange yellow needles (45 mg, 16.6%), mp 117—118 °C. IR: ν_{OH} 3460; ν_{CH} 2960; $\nu_{C=O}$ 1655 cm^{-1}. PMR(CCl_4), δ: 1.04 (d, 6H, $(CH_3)_2$), 2.31 (m, 1H, CH), 2.92 (d, 2H, $COCH_2$), 5.96 (s, 1H, OH), 7.42—7.97 (m, 4H, aromatic-H), 11.69 (s, 1H, OH). Found: C, 55.62; H, 4.61%. Calcd for $C_{15}H_{15}BrO_3$: C, 55.75; H, 4.68%. 6-Bromo-1,2-naphthalenediol monoisovalerate [**5**: R=$(CH_3)_2CHCH_2$, R_1=R_2=H, R_3=Br]: white crystals (75 mg, 27.7%), mp 150—151 °C. IR: ν_{OH} 3420; ν_{CH} 2960; $\nu_{C=O}$ 1720 cm^{-1}. PMR (CCl_4), δ: 1.06 (d, 6H, $(CH_3)_2$), 1.10(d, 6H, $(CH_3)_2$), 2.25(br. m, 2H, CH), 2.45 (t, 2H, $COCH_2$), 2.55 (t, 2H, $COCH_2$), 6.40 (br, 2H, OH), 6.93—8.03 (m, 10H, aromatic-H). Found: C, 55.65; H, 4.75%. Calcd for $C_{15}H_{15}BrO_3$: C, 55.75; H, 4.68.

(vii) Hexanal: 3-Hexanoyl-6-bromo-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_4$, R_1=H, R_2=Br]: orange plates (64 mg, 22.4%), mp 98—99 °C. IR: ν_{OH} 3450; ν_{CH} 2950, 2875; $\nu_{C=O}$ 1655 cm^{-1}. PMR($CDCl_3$), δ: 0.94 (t, 3H, CH_3), 1.27—1.92 (m, 6H, $(CH_2)_3$), 2.99 (t, 2H, $COCH_2$), 6.02 (s, 1H,

OH), 7.25—7.92 (m, 4H, aromatic-H), 11.65 (s, 1H, OH). Found: C, 56.89; H, 5.14%. Calcd for $C_{16}H_{17}BrO_3$: C, 56.99; H, 5.08%. 6-Bromo-1,2-naphthalenediol monohexanoate [**5**: $R=CH_3(CH_2)_4$, $R_1=R_2=H$, $R_3=Br$]: white crystals (95 mg, 33.6%), mp 106—108 °C. IR: ν_{OH} 3410; ν_{CH} 2970, 2948, 2875; $\nu_{C=O}$ 1725 cm^{-1}. PMR (CCl_4), δ: 0.86—1.90 (m, 11H, $CH_3(CH_2)_4$), 6.19 (br. s, 1H, OH), 7.05—8.05 (m, 5H, aromatic-H). Found: C, 56.71; H, 5.10%. Calcd for $C_{16}H_{17}BrO_3$: C, 56.99; H, 5.08%.

(viii) Heptanal: 3-Heptanoyl-6-bromo-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_5$, $R_1=H$, $R_2=Br$]: yellow crystals (59 mg, 20%), mp 72—73 °C. IR: ν_{OH} 3440, ν_{CH} 2945, 2875, $\nu_{C=O}$ 1655 cm^{-1}. PMR (CCl_4), δ: 0.91 (t, 3H, CH_3), 1.25—1.90 (m, 8H, $(CH_2)_4$), 3.06 (t, 2H, $COCH_2$), 5.94 (s, 1H, OH), 7.42—7.96 (m, 4H, aromatic-H), 11.67 (s, 1H, OH). Found: C, 58.31; H, 5.52%. Calcd for $C_{17}H_{19}BrO_3$: C, 58.13; H, 5.45%. 6-Bromo-1,2-naphthalenediol monoheptanoate [**5**: $R=CH_3(CH_2)_5$, $R_1=R_2=H$, $R_3=Br$]: white plates (74 mg, 25%), mp 107—108 °C. IR: ν_{OH} 3440; ν_{CH} 2970, 2970, 2945, 2870; $\nu_{C=O}$ 1722 cm^{-1}. PMR(CCl_4), δ: 0.93 (t, 3H, CH_3), 1.26—1.90 (br. m, 8H, $(CH_2)_4$), 2.57 (t, 2H, $COCH_2$), 6.13 (s, 1H, OH), 7.00—8.05 (m, 5H, aromatic-H). Found: C, 58.06; H, 5.50%. Calcd for $C_{17}H_{19}BrO_3$: C, 58.13; H, 5.45%.

(ix) Octanal: 3-Octanoyl-6-bromo-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_6$, $R_1=H$, $R_2=Br$]: orange plates (71 mg, 23.2%), mp 86—88 °C. IR: ν_{OH} 3440; ν_{CH} 2950, 2925, 2860; $\nu_{C=O}$ 1655 cm^{-1}. PMR(CCl_4), δ: 0.89 (t, 3H, CH_3), 1.20—1.87 (br. m, 10H, $(CH_2)_5$), 3.02 (t, 2H, $COCH_2$), 5.96 (s, 1H, OH), 7.40—7.97 (m, 4H, aromatic-H), 11.67 (s, 1H, OH). Found: C, 59.37; H, 5.63%. Calcd for $C_{18}H_{21}BrO_3$: C, 59.19; H, 5.63%. 6-Bromo-1,2-naphthalenediol monooctanoate [**5**: $R=CH_3(CH_2)_6$, $R_1=R_2=H$, $R_3=Br$]: white crystals (91 mg, 29.7%), mp 99—100 °C. IR: ν_{OH} 3410; ν_{CH} 2960, 2930, 2860; $\nu_{C=O}$ 1738 cm^{-1}. PMR (CCl_4), δ: 0.88 (t, 3H, CH_3), 0.91 (t, 3H, CH_3), 1.81—1.92 (br. m, 20 H, $(CH_2)_{10}$), 2.55 (t, 2H, $COCH_2$), 2.66 (t, 2H, $COCH_2$), 6.14 (2H, OH), 6.88—8.02 (m, 10H, aromatic-H). Found: C, 58.08; H, 5.72%. Calcd for $C_{18}H_{21}BrO_3$: C, 59.19; H, 5.79%.

(x) Nonanal: 3-Nonanoyl-6-bromo-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_7$, $R_1=H$, $R_2=Br$]: yellow crystals (66 mg, 20.8%), mp 77—78 °C. IR: ν_{OH} 3425; ν_{CH} 2930, 2860; $\nu_{C=O}$ 1655 cm^{-1}. PMR (CCl_4), δ: 0.89 (t, 3H, CH_3), 1.15—1.91 (br. m, 12 H, $(CH_2)_6$), 3.04 (t, 2H, $COCH_2$), 5.94 (s, 1H, OH), 7.41—7.96 (m, 4H, aromatic-H), 11.67 (s, 1H, OH). Found: C, 59.93; H, 6.10%. Calcd for $C_{19}H_{23}BrO_3$: C, 60.17; H, 6.11%. 6-Bromo-1,2-naphthalenediol monononanoate [**5**: $R=CH_3(CH_2)_7$, $R_1=R_2=H$, $R_3=Br$]: white crystals (98 mg, 30.3%), mp 97—98 °C. IR: ν_{OH} 3430; ν_{CH} 2940, 2860; $\nu_{C=O}$ 1740 cm^{-1}. PMR (CCl_4), δ: 0.85—1.92 (br. m, 30H, $CH_3(CH_2)_6$), 2.56 (t, 2H, $COCH_2$), 2.68 (t, 2H, $COCH_2$), 6.07 (1H, OH), 6.19 (1H, OH), 6.91—8.03 (m, 10 H, aromatic-H). Found: C, 60.24; H, 6.27%. Calcd for $C_{19}H_{23}BrO_3$: C, 60.17; H, 6.11%.

(xi) Decanal: 3-Decanoyl-6-bromo-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_8$, $R_1=H$, $R_2=Br$]: orange crystals (38 mg, 11.5%), mp 92—93 °C. IR: ν_{OH} 3420; ν_{CH} 2910, 2870; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 0.86 (t, 3H, CH_3), 1.16—1.88 (br. m, 14H, $(CH_2)_7$), 3.02 (t, 2H, $COCH_2$), 5.91 (s, 1H, OH), 7.41—7.94 (m, 4H, aromatic-H), 11.65 (s, 1H, OH). Found: C, 61.08; H, 6.33%. Calcd for $C_{20}H_{25}BrO_3$: C, 61.08; H, 6.41%. 6-Bromo-1,2-naphthalenediol monodecanoate [**5**: $R=CH_3(CH_2)_8$, $R_1=R_2=H$, $R_3=Br$]: white crystals (121 mg, 36.7%), mp 89.0—89.5 °C. IR: ν_{OH} 3425; ν_{CH} 2940, 2860; $\nu_{C=O}$ 1720 cm^{-1}. PMR (CCl_4), δ: 0.88 (t, 3H, CH_3), 1.20—1.87 (br. m. 14H, $(CH_2)_7$), 2.56 (t, 2H, $COCH_2$), 6.14 (1H, OH), 7.02—8.06 (m, 5H, aromatic-H). Found: C, 61.24; H, 6.50%. Calcd for $C_{20}H_{25}BrO_3$: C, 61.08; H, 6.41%.

Photo-addition Products of 6-Methyl-1,2-naphthoquinone with Aliphatic Aldehydes. (i) Acetaldehyde: 3-Acetyl-6-methyl-1,2-naphthalenediol [**4**: $R=CH_3$, $R_1=H$, $R_2=CH_3$]: orange plates (25 mg, 10%), mp 156—157 °C. IR: ν_{OH} 3330 (br); $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 2.26 (s, 3H, CH_3), 2.69 (s, 3H, CH_3), 5.86 (s, 1H, OH), 7.24—8.04 (m, 4H, aromatic-H), 11.47 (s, 1H, OH). Found: C, 72.21; H, 5.63%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%. 6-Methyl-1,2-naphthalenediol monoacetate [**5**: $R=CH_3$, $R_1=R_2=H$, $R_3=CH_3$]: white plates (15 mg, 6%), mp 127—128 °C. IR: ν_{OH} 3360; $\nu_{C=O}$ 1720 cm^{-1}. PMR(CCl_4), δ: 2.29 (s, 3H, $COCH_3$), 2.39 (s, 3H, $COCH_3$), 2.47 (s, 6H, CH_3), 6.10 (2H, OH), 7.08—8.10 (m, 10H, aromatic-H). Found: C, 72.10; H, 5.48%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

(ii) Propionaldehyde: 3-Propionyl-6-methyl-1,2-naphthalenediol [**4**: $R=CH_3CH_2$, $R_1=H$, $R_2=CH_3$]; yellow plates (55 mg, 15.2%), mp 148—149 °C. IR: ν_{OH} 3448; $\nu_{C=O}$ 1647 cm^{-1}. PMR(CCl_4), δ: 1.27 (t, 3H, CH_3), 2.45 (s, 3H, CH_3), 3.14 (q, 2H, CH_2), 5.85 (s, 1H, OH), 7.16—7.95 (m, 4H, aromatic-H), 11.03 (s, 1H, OH). Found: C, 73.22; H, 5.59%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%. 6-Methyl-1,2-naphthalenediol monopropionate [**5**: $R=CH_3CH_2$, $R_1=R_2=H$, $R_3=CH_3$]: white crystals (50 mg, 13.9%), mp 114—116 °C. IR: ν_{OH} 3400 (br); $\nu_{C=O}$ 1722 cm^{-1}. PMR(CCl_4), δ: 1.33 (t, 3H, CH_3), 2.42 (s, 3H, CH_3), 2.72 (q, 2H, CH_2), 5.81 (1H, OH), 6.93—7.53 (m, 5H, aromatic-H). Found: C, 72.89; H, 6.05%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%.

(iii) Butyraldehyde: 3-Butyryl-6-methyl-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_2$, $R_1=H$, $R_2=CH_3$]: yellow orange needles (25 mg, 10.4%), mp 117—118 °C. IR: ν_{OH} 3490; ν_{CH} 2960, 2940, 2880; $\nu_{C=O}$ 1635 cm^{-1}. PMR (CCl_4), δ: 1.05 (t, 3H, CH_3), 1.80 (sex, 2H, CH_2), 2.43 (s, 3H, CH_3), 3.04 (t, 2H, $COCH_2$), 5.87 (s, 1H, OH), 7.18—7.96 (m, 4H, aromatic-H), 11.55 (s, 1H, OH). Found: C, 74.00; H, 6.68%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%. 6-Methyl-1,2-naphthalenediol monobutyrate [**5**: $R=CH_3(CH_2)_2$, $R_1=R_2=H$, $R_3=CH_3$]: white plates (28 mg, 11.5%), mp 99.0—99.5 °C. IR: ν_{OH} 3300(br); ν_{CH} 2980, 2945, 2890; $\nu_{C=O}$ 1725 cm^{-1}. PMR (CCl_4), δ: 1.03 (t, 3H, CH_3), 1.08 (t, 3H, CH_3), 1.65—1.96 (m, 4H, CH_2), 2.45 (s, 3H, CH_3), 2.54 (t, 2H, $COCH_2$), 2.66 (t, 2H, $COCH_2$), 6.00 (2H, OH), 6.91—8.07 (m, 10H, aromatic-H). Found: C, 73.71; H, 6.51%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

(iv) Isobutyraldehyde: 3-Isobutyryl-6-methyl-1,2-naphthalenediol [**4**: $R=(CH_3)_2CH$, $R_1=H$, $R_2=CH_3$]: yellow prisms (31 mg, 7.8%), mp 155—156 °C. IR: ν_{OH} 3450; ν_{CH} 2990, 2940; $\nu_{C=O}$ 1645 cm^{-1}. PMR(CCl_4), δ: 1.29 (d, 6H, $(CH_3)_2$), 2.42(s, 3H, CH_3), 3.75 (sep. 1H, OH), 5.90 (s, 1H, OH), 7.20—8.00 (m, 4H, aromatic-H), 11.65 (s, 1H, OH). Found: C, 73.63; H, 6.47%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%. 6-Methyl-1,2-naphthalenediol monoisobutyrate [**5**: $R=(CH_3)_2CH$, $R_1=R_2=H$, $R_3=CH_3$]: white needles (126 mg, 31.9%), mp 118—119 °C. IR: ν_{OH} 3325; ν_{CH} 2980, 2930, 2890; $\nu_{C=O}$ 1720 cm^{-1}. PMR(CCl_4), δ: 1.34 (d, 6H, $(CH_3)_2$), 2.46 (s, 3H, CH_3), 2.82 (sep, 1H, CH), 5.96 (1H, OH), 6.94—8.08 (m, 5H, aromatic-H). Found: C, 73.49; H, 6.65%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

(v) Valeraldehyde: 3-Valeryl-6-methyl-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_3$, $R_1=H$, $R_2=CH_3$]: yellowish orange needles (58 mg, 13.5%), mp 101—102 °C. IR: ν_{OH} 3410; ν_{CH} 2960, 2930, 2880; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 1.01 (t, 3H, CH_3), 1.30—1.90 (m, 4H, $(CH_2)_2$), 2.48 (s, 3H, CH_3), 3.10 (t, 2H, $COCH_2$), 5.88 (s, 1H, OH), 7.10—8.01 (m, 4H,

aromatic-H), 11.61 (s, 1H, OH). Found: C, 74.43; H, 7.08%. Calcd for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02%. 6-Methyl-1,2-naphthalenediol monovalerate [**5**: R=$CH_3(CH_2)_3$, R_1=R_2=H, R_3=CH_3]: white needles (66 mg, 15.4%), mp 92—94 °C. IR: ν_{OH} 3390; ν_{CH} 2960, 2930, 2880; $\nu_{C=O}$ 1722 cm^{-1}. PMR(CCl_4), δ: 0.96 (t, 3H, CH_3), 1.30—1.86 (m, 4H, $(CH_2)_2$), 2.46 (s, 3H, CH_3), 2.55 (t, 2H, $COCH_2$), 5.98 (s, 1H, OH), 6.29—8.07 (m, 5H, aromatic-H). Found: C, 74.28; H, 6.95%. Calcd for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02%.

(vi) Isovaleraldehyde: 3-Isovaleryl-6-methyl-1,2-naphthalenediol [**4**: R=$(CH_3)_2CHCH_2$, R_1=H, R_2=CH_3]: yellow needles (41 mg, 10%), mp 89—91 °C. IR: ν_{OH} 3400; ν_{CH} 2970, 2890; $\nu_{C=O}$ 1645 cm^{-1}. PMR(CCl_4), δ: 1.05 (d, 6H, $(CH_3)_2$), 2.05 (m, 1H, CH), 2.45 (s, 3H, CH_3), 2.94 (d, 2H, $COCH_2$), 5.87 (s, 1H, OH), 7.25—7.94 (4H, aromatic-H), 11.60 (s, 1H, OH). Found: C, 74.33; H, 6.89%. Calcd for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02%. 6-Methyl-1,2-naphthalenediol monoisovalerate [**5**: R=$(CH_3)_2CHCH_2$, R_1=R_2=H, R_3=CH_3]: white needles (89 mg, 21%), mp 99—100 °C. IR: ν_{OH} 3410 (br); ν_{CH} 2980; $\nu_{C=O}$ 1735 cm^{-1}. PMR(CCl_4), δ: 1.06 (d, 6H, $(CH_3)_2$), 1.10 (d, 6H, $(CH_3)_2$), 2.26 (br. m, 2H, CH), 2.44 (d, 2H, $COCH_2$), 2.46 (s, 6H, CH_3), 2.56 (d, 2H, $COCH_2$), 5.74 (1H, OH), 5.94 (1H, OH), 6.92—8.08 (m, 10H, aromatic-H). Found: C, 74.21; H, 7.01%. Calcd for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02%.

(vii) Hexanal: 3-Hexanoyl-6-methyl-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_4$, R_1=H, R_2=CH_3]: yellowish orange needles (81 mg, 17.4%), mp 88—89 °C. IR: ν_{OH} 3430; ν_{CH} 2960, 2940, 2880; $\nu_{C=O}$ 1643 cm^{-1}. PMR(CCl_4), δ: 0.80—1.90 (br. m, 9H, $CH_3(CH_2)_3$), 2.43 (s, 3H, CH_3), 3.04 (t, 2H, $COCH_2$), 5.85 (s, 1H, OH), 7.20—8.00 (4H, aromatic-H), 11.58 (s, 1H, OH). Found: C, 74.73; H, 7.52%. Calcd for $C_{17}H_{20}O_3$: C, 74.97; H, 7.40%. 6-Methyl-1,2-naphthalenediol monohexanoate [**5**: R=$CH_3(CH_2)_4$, R_1=R_2=H, R_3=CH_3]: white lieves (48 mg, 11%), mp 78—80 °C. IR: ν_{OH} 3390; ν_{CH} 2970, 2930, 2870; $\nu_{C=O}$ 1720 cm^{-1}. PMR (CCl_4), δ: 0.80—2.00 (br. m, 18H, $CH_3(CH_2)_3$), 2.48 (s, 6H, CH_3), 2.54 (t, 2H, $COCH_2$), 2.68 (t, 2H, $COCH_2$), 6.00 (2H, OH), 6.92—8.15 (m, 10H, aromatic-H). Found C, 75.11; H, 7.48%. Calcd for $C_{17}H_{20}O_3$: C, 74.97; H, 7.40%.

(viii) Heptanal: 3-Heptanoyl-6-methyl-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_5$, R_1=H, R_2=CH_3]: orange needles (62 mg, 14%), mp 76—77 °C. IR: ν_{OH} 3370; ν_{CH} 2960, 2930, 2860; $\nu_{C=O}$ 1640 cm^{-1}. PMR(CCl_4), δ: 0.90 (t, 3H, CH_3), 1.23—1.86 (br. m, 8H, $(CH_2)_4$), 2.42 (s, 3H, CH_3), 3.03 (t, 2H, $COCH_2$), 5.85 (s, 1H, OH), 7.18—7.95 (4H, aromatic-H), 11.54 (s, 1H, OH). Found: C, 75.54; H, 7.60%. Calcd for $C_{18}H_{22}O_3$: C, 75.50; H, 7.74%. 6-Methyl-1,2-naphthalenediol monoheptanoate [**5**: R=$CH_3(CH_2)_5$, R_1=R_2=H, R_3=CH_3]: white plates (41 mg, 9.2%), mp 76—77 °C. IR: ν_{OH} 3375 (br); ν_{CH} 2960, 2930, 2860; $\nu_{C=O}$ 1735, 1710 cm^{-1}. PMR(CCl_4), δ: 0.90 (t, 3H, CH_3), 1.25—1.88 (br. m, 8H, $(CH_2)_4$), 2.45 (s, 3H, CH_3), 2.56 (t, 2H, $COCH_2$), 5.95 (s, 1H, OH), 6.95—8.10 (m, 5H, aromatic-H). Found: C, 75.26; H, 7.81%. Calcd for $C_{18}H_{22}O_3$: C, 75.50; H, 7.74%.

(ix) Octanal: 3-Octanoyl-6-methyl-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_6$, R_1=H, R_2=CH_3]: orange plates (21 mg, 4.4%), mp 76—77 °C. IR: ν_{OH} 3440; ν_{CH} 2925, 2860; $\nu_{C=O}$ 1655 cm^{-1}. PMR(CCl_4), δ: 0.90 (t, 3H, CH_3), 1.25—1.88 (br. m, 10H, $(CH_2)_5$), 2.43 (s, 6H, CH_3), 3.05 (t, 2H, $COCH_2$), 5.84 (s, 1H, OH), 7.20—7.97 (4H, aromatic-H), 11.57 (s, 1H, OH). Found: C, 75.63; H, 7.92%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%. 6-Methyl-1,2-naphthalenediol monooctanoate [**5**: R=$CH_3(CH_2)_6$, R_1=R_2=H, R_3=CH_3]: white crystals (22 mg, 4.7%), mp 77—78 °C. IR: ν_{OH} 3425; ν_{CH} 2960, 2930, 2860; $\nu_{C=O}$ 1740 cm^{-1}. PMR(CCl_4), δ: 0.88—1.88 (br. m, 26H, $CH_3(CH_2)_5$), 2.43 (s, 6H, CH_3), 2.53 (t, 2H, $COCH_2$), 2.66 (t, 2H, $COCH_2$), 5.74 (1H, OH), 6.00 (1H, OH), 6.93—8.07 (m, 10H, aromatic-H). Found: C, 75.89; H, 7.86%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%.

(x) Nonanal: 3-Nonanoyl-6-methyl-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_7$, R_1=H, R_2=CH_3]: reddish orange plates (72 mg, 13.8%), mp 74—75 °C. IR: ν_{OH} 3470; ν_{CH} 2940, 2865; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 0.87 (t, 3H, CH_3), 1.18—1.88 (br. m, 12H, $(CH_2)_6$), 2.42 (s, 3H, CH_3), 3.00 (t, 2H, $COCH_2$), 5.86 (s, 1H, OH), 7.16—7.95 (4H, aromatic-H), 11.54 (s, 1H, OH). Found: C, 76.40; H, 8.39%. Calcd for $C_{20}H_{26}O_3$): C, 76.40; H, 8.33%. 6-Methyl-1,2-naphthalenediol mononononanoate [**5**: R=CH_3, R_1=R_2=H, R_3=CH_3]: white crystals (105 mg, 20.2%), mp 76—77 °C. IR: ν_{OH} 3440; ν_{CH} 2940, 2870; $\nu_{C=O}$ 1740 cm^{-1}. PMR(CCl_4), δ: 0.80—1.88 (br. m, 34H, $CH_3(CH_2)_7$), 2.43 (s, 6H, CH_3), 2.53 (t, 2H, $COCH_2$), 2.64 (t, 2H, $COCH_2$), 5.85 (1H, OH), 6.05 (1H, OH), 6.93—8.07 (m, 10H, aromatic-H). Found: C, 76.09; H, 8.39%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.33%.

(xi) Decanal: 3-Decanoyl-6-methyl-1,2-naphthalenediol [**4**: R=$CH_3(CH_2)_8$, R_1=H, R_2=CH_3]: orange plates (53 mg, 9.8%), mp 70—71 °C. IR: ν_{OH} 3450; ν_{CH} 2930, 2855; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 0.87 (t, 3H, CH_3), 1.18—1.90 (br. m, 14H, $(CH_2)_7$), 2.41 (s, 3H, CH_3), 3.02 (t, 2H, $COCH_2$), 5.85 (s, 1H, OH), 7.18—7.95 (4H, aromatic-H), 11.55 (s, 1H, OH). Found: C, 76.75; H, 8.43%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%. 6-Methyl-1,2-naphthalenediol monodecanoate [**5**: R=$CH_3(CH_2)_8$, R_1=R_2=H, R_3=CH_3]: white crystals (41 mg, 7.6%), mp 64—65 °C. IR: ν_{OH} 3420; ν_{CH} 2930, 2860; $\nu_{C=O}$ 1740, 1720 cm^{-1}. PMR(CCl_4), δ: 0.81—1.92 (br. m, 34 H, $CH_3(CH_2)_7$), 2.44 (s, 6H, CH_3), 2.55 (t, 2H, $COCH_2$), 2.67 (t, 2H, $COCH_2$), 5.82 (1H, OH), 6.03 (1H, OH), 6.93—8.07 (m,10H, aromatic-H). Found: C, 77.03, H, 8.49%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

Irradiation of 3-Chloro-1,2-naphthoquinone in the Presence of Acetaldehyde. *(a)* A benzene solution of quinone (200 mg, 1.04 mmol) and acetaldehyde (500 mg) was irradiated for 4 days. Paraldehyde was detected by PMR analysis of the reaction mixture. The solvent and paraldehyde were removed at 60 °C under reduced pressure, and the residue was worked up as usual.

(b) The quinone (300 mg) in acetaldehyde (15 g) was irradiated for 5 days; the metaldehyde which deposited (120 mg) was filtered off and the paraldehyde (13.5 g) was removed at 60 °C under reduced pressure, then the residue was chromatographed over silica gel.

Photo-addition Products of 3-Chloro-1,2-naphthoquinone with Aliphatic Aldehydes. *(i) Acetaldehyde*: 3-Chloro-1,2-naphthalenediol monoacetate [**5**: R=CH_3, R_1=Cl, R_2=R_3=H] white needles (95 mg, 38.7%), mp 149—150 °C. IR: ν_{OH} 3335 (br), $\nu_{C=O}$ 1757 cm^{-1}. PMR ($CDCl_3$), δ: 2.48 (s, 3H, CH_3), 7.33—8.24(m, 6H, aromatic-H+OH). Found: C, 60.85; H, 3.88%. Calcd for $C_{12}H_9ClO_3$: C, 60.90; H, 3.83%. 3-Chloro-4-acetyl-1,2-naphthoquinone: reddish orange needles (12 mg, 4.9%), mp 197—200 °C. IR: $\nu_{C=O}$ 1700, 1685 cm^{-1}. MS, *m/e*: 234 (M^+), 206 (M−CO), 199 (M−Cl), 178 (M−2CO), 171 (M−Cl−CO). PMR($CDCl_3$), δ: 2.30 (s, 3H, CH_3), 7.04—8.16 (m, 4H, aromatic-H). 3-Acetyl-1,2-naphthalenediol(2.1 mg, 1%) was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and acetaldehyde.

(ii) Propionaldehyde: 3-Chloro-1,2-naphthalenediol mono-

a) Decomposition. b) Molecular ion.

The results are shown in Fig. 1. Upon irradiation, the absorption (A) of **1a** at 289 nm rapidly decreased. At the same time, a new absorption (B) appeared at 330 and 505 nm and increased quickly. Then the color of the solution changed from colorless to red. If the irradiation was interrupted at the stage when the peak of (B) was at its maximum and the solution was then kept in the dark, the spectrum of the solution returned to **1a**. This indicates that the change of (A) to (B) is reversible. The first-order rate constant of the change of (A), measured from the decrease in the peak at 289 nm of **1a**, was $3.5\times10^{-3}\ s^{-1}$, while that of the regeneration of (A) from (B), measured from the decrease in the peak at 330 nm of (B), was $2.0\times10^{-4}\ s^{-1}$. Upon further irradiation, another new absorption (C) appeared at about 260 nm and increased with the decrease in (B). The formation of (C) was irreversible, so (C) did not return to (B) or (A) upon remaining in the dark.

In the case of **1a—d**, similar behavior was observed, and the same change occurred in tetrahydrofuran, diethyl ether, and 2-propanol. The peaks of the **1** absorption (A), (B), and (C) in 2-propanol are shown in Table 2. This spectrobehavior was similar to that of phenazine (which has a pyrazine ring in a molecule) upon irradiation.[7] To investigate the relationship between phenazine and pyrazine derivatives, three pyrazine derivatives, **1e**, **1f**, and **1g**, with structures similar to phenazine were synthesized, and the spectral change in them upon irradiation were studied. These results are also shown in Table 2. In the irradiation of

TABLE 2. THE VARIATION IN THE ABSORPTION SPECTRA OF PYRAZINE DERIVATIVES IN 2-PROPANOL

Pyrazine	**1** (A) (nm)	(B) (nm)		(C) (nm)
1a	289	330	505	260
b	288	320	502	256
c	298	384	—	292
d	290	384	—	237
e	317	372	502	290
f	317	366	520	282
g	290	290		290

2g (which does not have an α-carbonyl group), no spectral change similar to that of **1a—f** was shown. In the case of **1e**, the first-order rate constant of the change of (A) to (B), as measured from the decrease in the peak at 318 nm of **1e**, was $4.5\times10^{-2}\ s^{-1}$, while that of the regeneration of (A) from (B), as measured from the decrease in the peak at 374 nm of (B) was $6.7\times10^{-3}\ s^{-1}$.

Colored Compound. The solution of **1c** in diethyl ether gave a violet-colored compound, **5c**, upon irradiation; in the case of **1e** a red-brown-colored compound, **5e**, was precipitated. Both **5c** and **5e** were unstable and turned to **1c** and **1e** respectively after a few weeks in the solid state. They were difficult to dissolve and turned to **1c** and **1e** as soon as they are dissolved. Therefore, the UV spectra were measured in acetic acid under an argon atmosphere, they agreed with the (B) absorption of **1c** and **1e** (**5c**: 384 nm;

a′=Ammine exchange; a″=compound found from metal amine; a‴=en to pn exchange.

valent each of alcoholic solution of salicylaldehyde and 2-OH-1-naphthaldehyde. The mixture was refluxed (75 min) and stirred. The compound obtained was filtered, washed with water and finally with 50% alcohol. The compound was recrystallized from chloroform and analyzed.

Preparation of Methyl and Ethyl Amino Schiff's Base Complexes. Imine Schiff's base complex(I) was treated with methyl or ethylamine solution (0.5 M) and refluxed gently on a water-bath for 3—4 h. Green crystalline solids were obtained. They were washed with water and 50% alcohol, dried and recrystallized from chloroform and analyzed. Ethylamine compound could be obtained in about 3—4 h, whereas refluxing had to be carried out for about 6—7 h in the case of methyl amine reaction.

Preparation of Diamine Schiff's Base Complexes in Case of Cu(II) or Ni(II). {N,N-*Ethylene or Propylene(salicylideneaminato-2-hydroxy-1-naphthylmethyleneaminato}Cu(II) or Ni(II)*: The complexes were obtained by substitution reactions. The preformed mixed imine Schiff's base complexes of Cu(II) or Ni(II) (2 g) were refluxed (3 h) with en (2 ml) or pn (2 ml) in ethanol (25 ml). The reaction mixture was stirred thoroughly to obtain the compounds. It was filtered, washed, dried and recrystallized from chloroform and analyzed.

General Properties of Complexes. All the complexes were found to be crystalline, stable in atmosphere and insoluble in water. All the compounds are soluble in organic solvents.

In order to characterize and determine the structures of complexes the following studies were undertaken.

Analysis. Cu was estimated by complexometric titration against standard EDTA disodium salt solution, using Fast Sulphon Black F as an indicator. Ni was estimated gravimetrically as dimethylglyoximate. The results of metal, carbon, hydrogen, and nitrogen analyses are presented in the table.

TLC Anslysis. TLC analyses of all the complexes were carried out on a silica gel G(Sichen) using a mixture of chloroform–ether (6:4) as a solvent. The solvent was selected after several trials. A mixture of 1:1 bis(salicylaldeneaminato)M-(II) and bis(2-hydroxy-1-naphthylmethyleneaminato)Ni(II) complexes was prepared. On subjecting it to TLC analysis, the mixture was found to give two spots whereas the mixed ligand complex is pure and a single compound rather than the mixture of bis complexes of the two ligands.

Magnetic Measurements. Magnetic measurements were carried out at room temperature (28 °C) using Guoy balance.

Conductance. Conductivity measurements were carried out in chloroform using Toshniwal Conductivity Bridge Type C LO/O1A.

Spectrophotometric Measurements. The visible spectra of all the complexes were a studied in chloroform solution, on a DU2 Beckman Spectrophotometer at room temperature (30 °C) using 1 cm quartz cell in the range 300—1000 nm.

IR Measurements. IR spectra was recorded in Nujol in the range 4000—625 cm^{-1} on a Perkin-Elmer Model 427.

None of the complexes had adequate solubility in the solvents for NMR studies.

Results and Discussion

The molar conductance of all the complexes in chloroform show them to be non electrolytes.

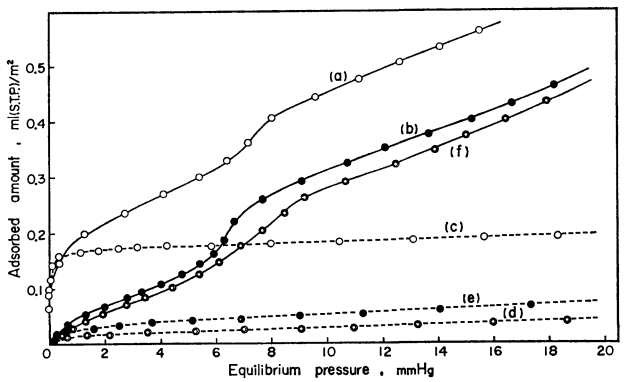

Fig. 1. Adsorption isotherms of H_2O and NH_3 at 25 °C on ZnO surfaces controlled in the amount of chemisorbed H_2O or NH_3. Solid line, H_2O adsorption; broken line, NH_3 adsorption. (a) and (c), on dehydroxylated surface; (b) and (e), on fully hydroxylated surface; (d) and (f), on ammoniated surface.

hydroxylated surfaces, respectively. A large difference is observed between the two curves, because of chemisorption of H_2O on the dehydroxylated surface of ZnO, a distinct discontinuity in the isotherm appearing in the range of relative pressure 0.2—0.3, similar to the case of the ZnO–S sample.[10,13,21-25] Appearance of the discontinuity has been elucidated in terms of the formation of closed hydrogen bonding between the surface hydroxyls on the well-developed $(10\bar{1}0)$ planes of the wurtzite structure.[22]

Curve c is the adsorption isotherm of NH_3 at 25 °C on the dehydroxylated surfaces of ZnO–K, curve d being the second adsorption isotherm of NH_3 on the same sample evacuated at 25 °C after the measurement of the first adsorption isotherm. The two curves are of the Langmuir type and seem to be parallel to each other. It seems that the difference of these two isotherms gives the amount of NH_3 chemisorbed on the surface, as in the case of H_2O adsorption. It should be noted that the amount of NH_3 physisorbed at 25 °C on the NH_3-chemisorbed surfaces, which is represented by the second adsorption isotherm, is much smaller than that of H_2O physisorbed at 25 °C, but the amount of chemisorbed NH_3 seems to be as much as that of chemisorbed H_2O. Curve e is the adsorption isotherm of NH_3 at 25 °C on the fully hydroxylated surfaces of ZnO–K. It is seen that the physisorption of NH_3 on the surface hydroxyls is also as small as that on the ammoniated surface (curve d).

The monolayer capacity calculated on these isotherms is given in Table 1, together with the data on ZnO–S. The V_m and V_p values are the monolayer capacity for the first and second adsorption isotherms, calculated by applying the B-point method to the H_2O adsorption isotherms and the Langmuir equation to the NH_3 adsorption isotherms. Since the difference between V_m and V_p gives the chemisorbed amount, we can obtain the chemisorbed amount V_c by subtracting V_p from V_m. As a small amount of chemisorbed H_2O equal to the H_2O content V_h remains on the 450 °C-treated surface, the total amount of chemisorbed H_2O is calculated by summing the values V_c and V_h. The results (Table 1) indicate that the number of NH_3 molecules chemisorbed on dehydroxylated surfaces of ZnO is almost equal to that of chemisorbed H_2O on the same surfaces. This suggests that a molecule of NH_3 is chemisorbed on the sites formed by dehydroxylation of the two neighboring hydroxyls.

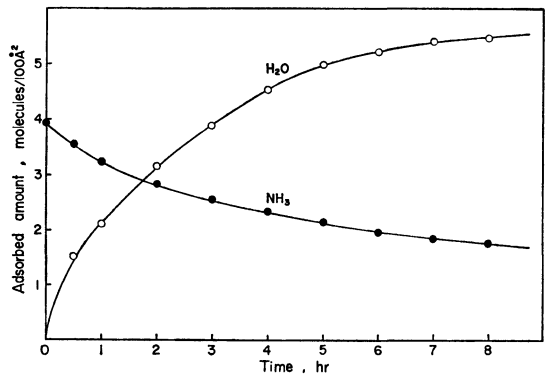

Fig. 2. Exchange reaction of chemisorbed NH_3 on ZnO with H_2O vapor.

Exchange Reaction of Chemisorbed NH_3 on ZnO with H_2O Vapor. Curve f (Fig. 1) is the adsorption isotherm of H_2O at 25 °C on the ammoniated surface of ZnO. The discontinuity in the isotherm reappears in a higher pressure region than in the case of the fully hydroxylated surface of ZnO. Infrared spectroscopic studies have shown qualitatively that NH_3 chemisorbed on ZnO is replaced by H_2O to form hydroxylated surface when exposed to H_2O vapor.[19] Figure 2 shows the change in the amount of chemisorbed H_2O and gaseous NH_3 with time, which was obtained when the ammoniated surface of ZnO was kept in H_2O vapor of the relative pressure 0.7. The equilibrated mixed gas was analyzed by the same procedure as described above. The results (Fig. 2) clearly show that the exchange reaction occurs between the chemisorbed NH_3 and H_2O vapor. The apparently queer phenomenon (curve f, Fig. 1) can thus be interpreted as follows: 1) on account of the exchange reaction the ammoniated surface of ZnO is converted in to the hydroxylated surface, which leads to the appearance of the discontinuity in the adsorption isotherm of H_2O; 2) the shift of the discontinuity to a higher pressure region results from the additional partial pressure of evolved NH_3.

Table 1. H_2O and NH_3 adsorbed on ZnO surface

a) X, Y=F, Cl, Br, or I; Z=CH_2, O, or S; W=O or S.

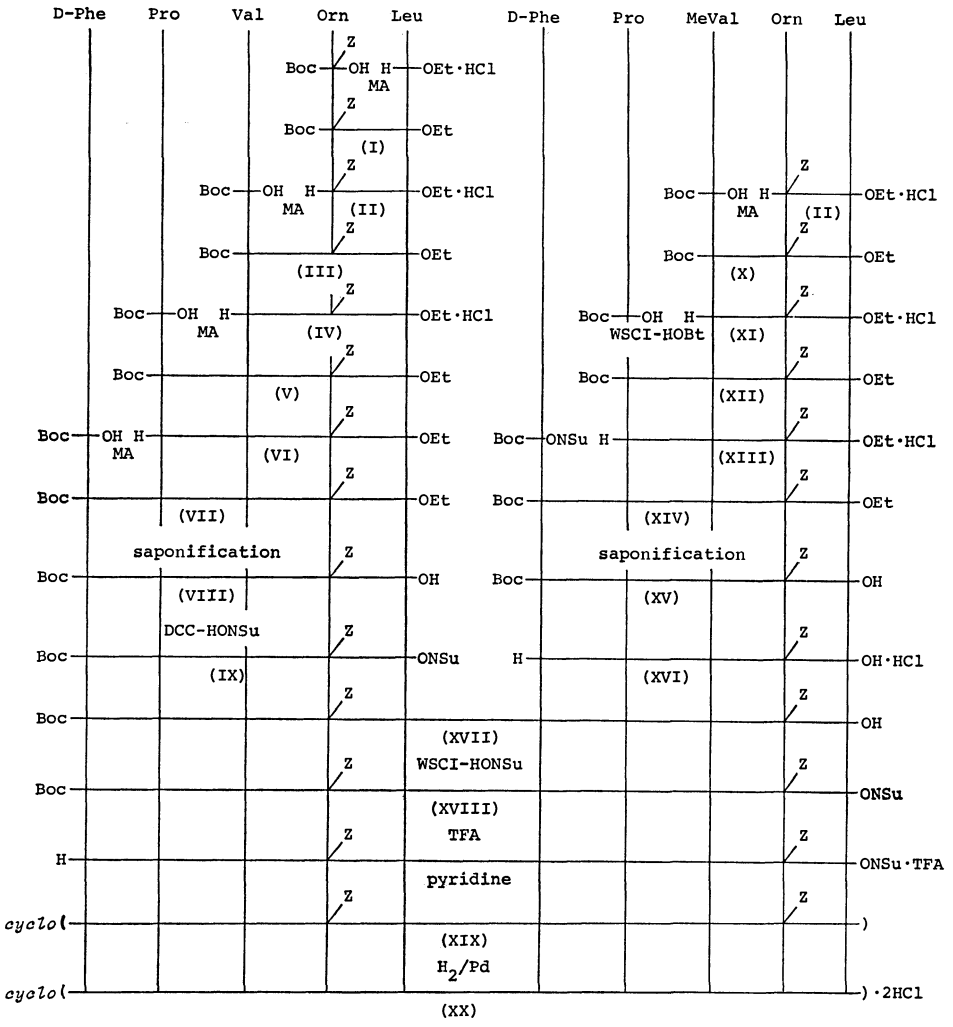
force constants of ethers. Structural parameters and symmetry coordinates used in the calculation and a final set of the force constants are reported in a separate paper.[6)]

The force constants of the ethers were determined in the following way. The force constants associated with a methyl or methylene group which is not bound directly to an oxygen atom were assumed to be the same as those for the paraffin molecules.[18)] The force constants associated with the ether group, including those of neighboring methyl and methylene groups, were refined in the least-squares adjustment with initial values transferred from the results by Shimanouchi *et al.*,[19)] Snyder and Zerbi,[7)] and Matsuura and Miyazawa.[20)] Some of the ether force constants, which were unestimable from the observed frequencies, were assumed to have the same values as those for the corresponding paraffin force constants.

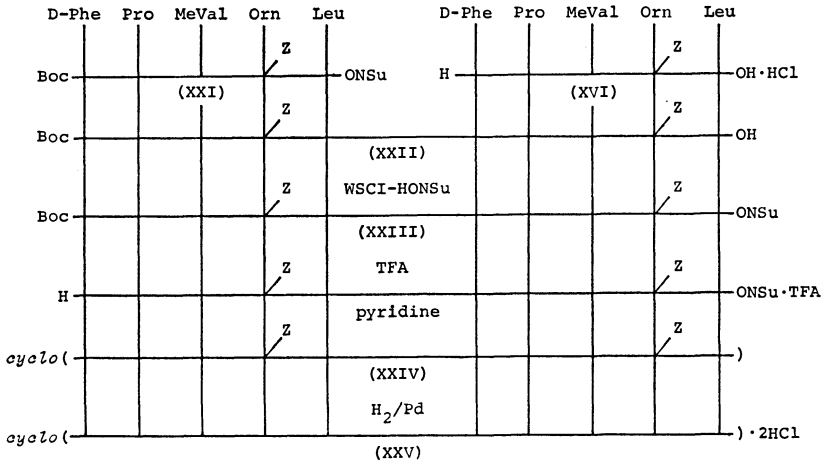
Table 2 shows the procedure of the least-squares calculation. The calculation began with the simplest ethers in the extended form, and then the molecules to be treated were extended to the longer ethers and the non-extended forms. The various deuterated derivatives of ethyl methyl ether and diethyl ether were also included in the force constants refinement. A total of 83 force constants associated with the ether group were determined from 690 Raman and infrared frequencies of 46 forms of 19 molecular species.

Results

Figures 1—9 show the Raman and infrared spectra in the gaseous, liquid, glassy and crystalline states. The observed frequencies and the assignment based on the calculated potential-energy distributions are listed in Tables 3—5. The observed spectra were analyzed with reference to the results of the normal coordinate treatment.



Scheme 1. Synthesis of [MeVal[1]]-GS.



Scheme 2. Synthesis of [MeVal[1,1']]-GS.

tide–ONSu in a satisfactory yield of 66%.

For the syntheses of final [MeVal[1]]-GS and [MeVal[1,1']]-GS, each Z-substituted cyclodecapeptide (XIX and XXIV) was subjected to hydrogenolysis, and the desired analogs were obtained as crystalline dihydrochlorides (XX and XXV). Their homogeneity was confirmed by paper and thin-layer chromatography, paper electrophoresis and elemental analysis.

Antibacterial activity toward several microorganisms was examined, the results being given in Table 1. The two analogs were found to exhibit weak activity for Gram-positive microorganisms, whereas GS showed strong activity. The antibacterial potency of [MeVal[1]]-GS is slightly higher than that of the [MeVal[1,1']]-

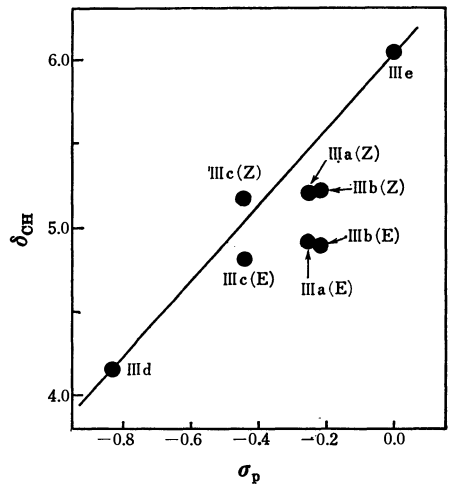


Fig. 1. Hammett's plot of δ_{CH} of ylides III.

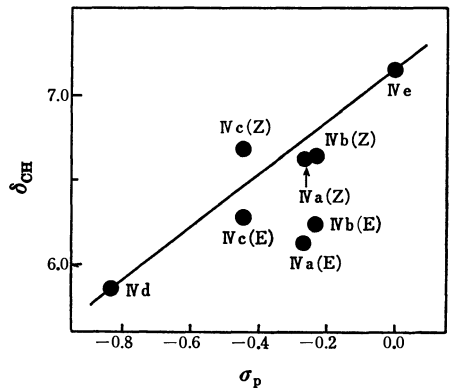

Fig. 2. Hammett's plot of δ_{CH} of oxosulfonium ions IV.

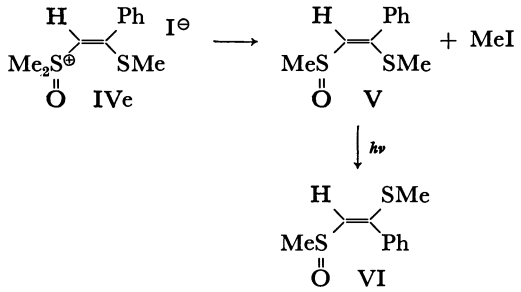
Another result is the decomposition of IVe. Compound IVe was stable in the crystalline state, but it decomposed entirely in a chloroform solution after 24 h at 34.5 °C to give vinyl sulfoxide(V) and methyl iodide in quantitative yields. Compound V(mp 68.5—70 °C) showed one *S*-methyl peak at δ 2.06, SOMe at 2.76, and an olefinic proton at 6.61 in the NMR spectrum. On UV irradiation V gave new peaks at 2.41 (SMe), 2.66 (SOMe), and 6.15 (olefinic proton). Fractional crystallization afforded VI with a mp of 138—140.5 °C, which again gave V on irradiation. The V: VI equilibrium ratio was 1 : 2. Using the values of Pascuel, Meier, and Simon[13] for the chemical shifts of the vinyl protons, the vinyl sulfoxides, V and VI, were confirmed to be the Z and *E* isomers respectively. Thus, we confirmed IIIe to be the *Z* isomer.



Compound IVd decomposed entirely at 40 °C for 3 days in chloroform to give a mixture of unidentifiable compounds (NMR and TLC). IVa, on the other hand, decomposed easily in $CDCl_3$ at 34.5 °C for 20 h to give a new carbonyl-stabilized ylide, I(R=SMe), and methyl iodide in quantitative yields. Although IVb,c also decomposed at 34.5 °C for 3 days to yield a mixture of I (R=SMe) and vinyl sulfoxides (NMR study), no effort was made to isolate them.

Reaction of III with Carbon Disulfide. A number of reactions of sulfur ylides with olefins and carbonyl compounds have been reported.[18] The reactions of IIIb with dimethyl fumarate or maleate failed, since the reagents were recovered after 48 h in THF at reflux. It has been reported that II(R=Ph)[2] reacts with carbon disulfide to give a 1,3-dithiane derivative in chloroform and a 1,2,4-trithiole derivative in ethanol.

The IIIb—e ylides reacted easily with carbon disulfide, even at room temperature, to give 1,2-dithiole-3-thione, VII, in moderate yields (Table 4). The products were confirmed to be VII, by comparison with known samples (VIId,e) and by analyses (VIIb,c) not 1,3-dithiole-2-thione. No crystalline compound was isolated from a reaction mixture of IIIa and carbon disulfide.

The reactivity of III decreased in this order; IIId> IIIb,c>IIIe. This is also the order of the pK_a values of

PMR (CCl_4): δ; 1.16 (s, 3H), 1.38 (s, 3H), 1.50 (s, 5H), 1.52 (s, 3H), 5.44 (s, 1H), 6.9—7.1 (m, 4H), 7.2—7.8 ppm (AB-q, 4H). Found: C, 70.87; H, 6.24; Cl, 9.74%. Calcd for $C_{21}H_{21}O_3Cl$: C, 70.67; H, 5.94; Cl, 9.93%.

Photochemical Reaction of **1** *with Isobutyraldehyde.* The photolysis of **1** (187 mg, 0.9 mmol) and isobutyraldehyde (193 mg, 2.7 mmol) in benzene by the use of the filter solution gave a mixture of 3-hydroxy-3-isobutyryl-1,1,4,4-tetramethyl-2-tetralone, **7h** (49 mg, 17%), 3-isobutyryloxy-1,1,4,4-tetramethyl-2-tetralone, **8h** (127 mg, 47%), 3-hydroxy-3-isopropyl-1,1,4,4-tetramethyl-2-tetralone, **12** (20 mg, 10%), and the reduced product, **3** (22 mg, 11%), accompanied by the evolution of a gas (carbon monoxide) (49—63%), which was identified by means of palladium chloride-test paper; the color changed from yellow to brown. The yield of carbon monoxide was measured volumetrically. **7h**; white needles; mp 84.5—85.5 °C. IR (KBr): 3420 (OH), 1690 cm^{-1} (C=O). PMR (CCl_4): δ; 0.88 (d, 3H), 0.96 (s, 3H), 1.00 (d, 3H), 1.38 (s, 6H), 1.50 (s, 3H), 3.20 (m, 1H), 4.82 (s, 1H; 0H), 7.2—7.3 ppm (m, 4H). Found: C, 74.95; H, 8.54%. Calcd for $C_{18}H_{24}O_3$: C, 74.97; H, 8.39%. **8h**; colorless oil. IR (liq. film): 1740, 1730 cm^{-1} (C=O). PMR (CCl_4): δ; 1.08 (s, 2H), 1.22—1.24 (dd, 6H), 1.40 (s, 3H), 1.49 (s, 3H), 1.54 (s, 3H), 2.66 (m, 1H), 5.40 (s, 1H), 7.1—7.4 ppm (m, 4H). Mass: *m/e*; 288 (M^+). Found: C, 75.25; H, 8.48%. Calcd for $C_{18}H_{24}O_3$: C, 74.97; H, 8.39%. **12**; white crystals; mp 36.0—37.0 °C. IR (KBr); 3470, 3420 (OH), 1695 cm^{-1} (C=O). PMR (CCl_4): δ; 0.56 (d, 3H), 0.89 (d, 3H), 0.98 (s, 3H), 1.48 (s, 3H), 1.53 (s, 3H), 1.56 (s, 3H), 2.00 (m, 1H), 3.84 (s, 1H; OH), 7.1 ppm (m, 4H). Mass: *m/e*; 260 (M^+). Found: C, 78.27; H, 9.38%. Calcd for $C_{17}H_{24}O_2$: C, 78.42; H, 9.29%.

6) The *g*-value of the semidione radical is probably very close to that of the acetoin radical (*cf.* H. Zeldes and R. Livingston, *J. Chem. Phys.*, **47**, 1465 (1967)).

7) The *g*-value of the xanthenyl radical is probably close to that of the diphenylmethyl radical (*cf.* A. L. Lepley and G. L. Closs, "Chemically Induced Magnetic Polarization," John Wiley & Sons, New York (1973), p. 108.

8) The polarized signals observed in the region of methyl protons coincide with those of the product, **2**. So far there are no experimental results on the coupling sign of methyl protons of **5**, but, according to a recent review F. W. King, *Chem. Rev.*, **76**, 157 (1976), the sign of the long-range *hfc* may be positive. Thus, our experimental results may indicate the in-cage combination of **5** and **6**. The absorption polarized signal due to the methine proton on the xanthenyl moiety of the product, **2**, also supports this condideration.

a) NMR spectra were taken as carbon tetrachloride solution with Varian Associates HA-100 and A-60D. b) Isomers were not separated, chemical shift being determined with a mixture. c) Preparation and determination of this material were described in the previous paper.[12] Details will be published later. d) Center of the chemical shift determined by decoupling.

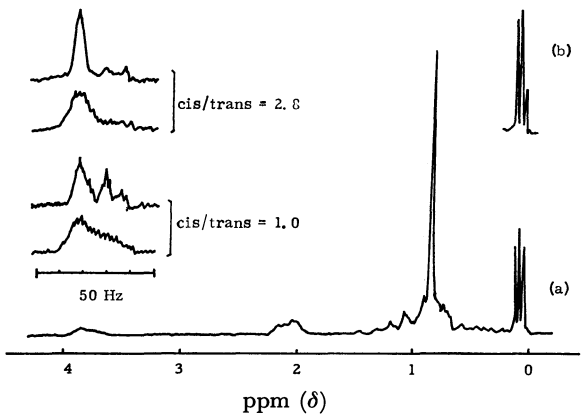

Fig. 1. (a) NMR spectra of **2** (1:1 *cis-trans* mixture) prepared from di-Grignard reagent from **1** and methyldichlorosilane and (b) methyl signals of **2** (2.8:1 *cis-trans* mixture) prepared by reduction of **3** with $LiAlH_4$. Left part of the spectra shows each SiH signals in addition to decoupling signals of **2** irradiated at Si–CH_3.

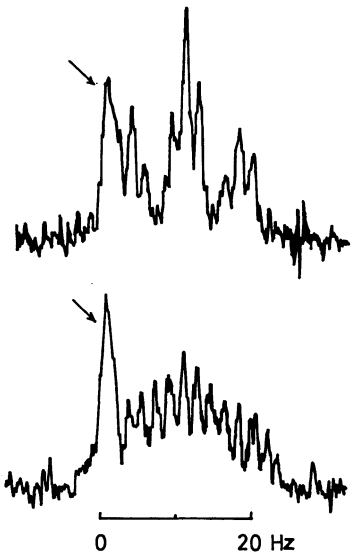

Fig. 2. SiH signal of **2b** (lower) and SiH signal irradiated at the $SiCH_3$ signal of **2b** (upper). The arrows indicate a signal due to unknown impurity.

assign the stereochemistry. The axial Si–Me (*e.g. cis* compounds) gives rise to a resonance at lower field (δ 0.12) than the equatorial SiMe (δ 0.07), whereas the axial hydrogen (δ 3.80) appears at higher field than the equatorial hydrogen (δ 3.91). A similar relationship has been observed for cyclohexane derivatives. Incidentally, West proposed the structure of silacyclohexane ring as a deformed chair form.[15]

Many observations show that the chemical shifts of protons in the functional groups attached to six-membered rings are related to their configuration and that these relations afford a reasonable basis for stereochemical assignments as shown in Table 2.[16] Compounds listed in Table 1 were assigned for their *cis* and *trans* structures on the basis of NMR spectra assuming that the compound with a methyl signal of NMR appearing at lower

Found: C, 91.79; H, 8.17%. Calcd for $C_{28}H_{30}$: 91.73; H, 8.27%. PMR ($CDCl_3$, δ) 1.44 (s, 3H, CH_3), 1.7—3.2 (m, 16H, CH_2), 2.39 (s, 3H, CH_3), 4.90 (s, 1H, ArH), 5.05 (s, 1H, ArH), 5.48 (s, 1H, ArH), 5.63 (d, J=1 Hz, 2H, ArH), 6.79 (s, 1H, ArH), 7.09 (d, J=1 Hz, 2H, ArH). MS m/e 366 (M^+).

The second eluate gave the monosulfur compd **32** (22 mg, 24%), colorless plates from ethanol, mp 187—188 °C.

Found: C, 84.63; H, 7.62; S, 8.17%. Calcd for $C_{28}H_{30}S$: C, 84.37; H, 7.59; S, 8.04%. NMR ($CDCl_3$, δ) 1.71 (s, 3H, CH_3), 2.2—3.6 (m, 16H, CH_2), 2.37 (s, 3H, CH_3), 4.92 (s, 1H, ArH), 5.11 (s, 1H, ArH), 5.49 (s, 1H, ArH), 5.60 (d, J=1 Hz, 2H, ArH), 6.87 (s, 1H, ArH), 7.10 (d, J=1 Hz, 2H, ArH). MS m/e 398 (M^+).

*18,27-Dithia[3.3]paracyclo(4,6)[2.2]metacyclophane (**34**).* A soln of 4,6-bis(bromomethyl)[2.2]metacyclophane **33**[6b] in 35 ml of benzene and a soln of 1,4-bis(mercaptomethyl)-benzene **19** (0.31 g, 1.8 mmol) and sodium hydroxide (0.15 g, 3.8 mmol) in a mixture of water (2 ml) and ethanol (33 ml) were added dropwise and simultaneously over a period of 4 h to boiling ethanol (100 ml) with stirring in a nitrogen atmosphere. The mixture was refluxed for additional 12 h and worked up in the usual way. Chromatography of the product over neutral alumina (30 g, Woelm act. II) using hexane-benzene (1 : 1) gave the desired dithiacyclophane **34** (0.31 g, 34%), colorless needles from benzene-alcohol (1 : 1), mp 238—239 °C.

Found: C, 77.80; H, 6.36; S, 15.78%. Calcd for $C_{26}H_{26}S_2$: C, 77.55; H, 6.52; S, 15.92%. PMR ($CDCl_3$, δ) 1.5—4.0 (m, 17H, CH_2 and one ArH), 4.54 (bs, 1H, ArH), 5.43 (s, 1H, ArH), 7.13 (bs, 4H, ArH), 7.21 (m, 3H, ArH). MS m/e 402 (M^+), 104.

[2.2]Metacyclo(4,6)[2.2]metaparacyclophane (m-m, m-p) *(**9**).* *a) By the Stevens Rearrangement-Raney Nickel Desulfurization.* A mixture of the above dithiacyclophane **34** (0.60 g, 1.5 mmol) and the Borch reagent[11] (1.00 g, 6.2 mmol) in 20 ml of dichloromethane was refluxed with stirring for 15 h. The resulting ppt was filtered and stirred with sodium hydride (0.12 g, 4.8 mmol), washed with dry ether, in dry dimethyl sulfoxide (10 ml) at 20 °C under a nitrogen atmosphere for 1.5 h. The mixture was poured into ice-water to quench the reaction. The resulting ppt was filtered, dried, and then refluxed with 7 ml of Raney nickel (W-II) in benzene (5 ml) and ethanol (50 ml) for 15 h. Raney nickel was filtered and washed with benzene. The filtrate and the washings were combined and concentrated, and then the residue was chromatographed on silica gel (40 g, Merck act. II) using hexane-benzene (9 : 1). The first eluate gave the desired cyclophane **9** (96 mg, 19%), colorless prisms from toluene, mp 209—210 °C.

Found: C, 92.08; H, 7.75%. Calcd for $C_{26}H_{26}$: C, 92.24; H, 7.76%. PMR ($CDCl_3$, δ) 1.5—3.5 (m, 16H, CH_2), 3.66 (s, 1H, ArH), 5.62 (s, 1H, ArH), 5.70 (bs, 1H, ArH), 6.48 (d, J=2 Hz, 2H, ArH), 7.3 (m, 3H, ArH), 7.46 (d, J=2 Hz, 2H, ArH). MS m/e 338 (M^+), 234, 104.

b) By Photodesulfurization. In the same manner as **8** b), irradiation of a soln of **34** (60 mg, 0.15 mmol) in triethyl phosphite (20 ml) for 15 h and purification by column chromatography gave the same compd **9** (19 mg, 35%).

*4,6-Bis(mercaptomethyl)[2.2]metacyclophane (**35**).* A mixture of 4,6-bis(bromomethyl)[2.2]metacyclophane **33** (2.36 g, 6 mmol) and thiourea (1.0 g, 13 mmol) was refluxed in 50 ml of ethanol for 3 h and concd to dryness. The thiouronium salt was hydrolyzed by refluxing with 85% potassium hydroxide (7.30 g) in 50 ml of water for 7.5 h and worked up as usual. The crude product was filtered through a short column of neutral alumina with hexane–benzene (1 : 1) to afford pure dithia compound **35** (1.53 g, 85%), colorless prisms from hexane–benzene, mp 92—93 °C.

Found: C, 71.97; H, 6.71; S, 21.11%. Calcd for $C_{18}H_{20}S_2$: C, 71.94; H, 6.72; S, 21.34%. PMR ($CDCl_3$, δ) 1.80 (t, J=7 Hz, 2H, SH), 3.0—3.5 (m, 8H, CH_2), 3.81 (d, J=7 Hz, 4H, SCH_2), 4.17 (s, 1H, ArH), 4.43 (bs, 1H, ArH), 7.0—7.5 (m, 4H, ArH). MS m/e 300 (M^+).

*21,24-Dimethyl-18,27-dithia[3.3]paracyclo(4,6)[2.2]metacyclophane (**36**).* A soln of 2,5-bis(chloromethyl)-*p*-xylene **10** (1.02 g, 5 mmol) in 40 ml of benzene and a soln of 4,6-bis(mercaptomethyl)[2.2]metacyclophane **35** (1.50 g, 5 mmol) in 40 ml of 80% ethanol were added dropwise and simultaneously over a period of 3.5 h to boiling ethanol (100 ml) under nitrogen and the refluxing was continued for 12 h. The mixture was worked up in the usual way. The crude product was purified by chromatography over alumina (Woelm act. II) with hexane–benzene (4 : 1) to give the pure dithiacyclophane **36** (1.62 g, 74%), colorless fine crystals from ethanol, mp 165—166 °C.

Found: C, 78.23; H, 7.17; S, 14.85%. Calcd for $C_{28}H_{30}S_2$: C, 78.23; H, 6.98; S, 14.90%. PMR ($CDCl_3$, δ) 2.22 (s, 3H, CH_3), 2.32 (s, 3H, CH_3), 2.9—4.0 (m, 16H, CH_2), 4.09 (bs, 1H, ArH), 4.34 (s, 1H, ArH), 5.46 (s, 1H, ArH), 6.9—7.5 (m, 5H, ArH). MS m/e 430 (M^+).

*12,15-Dimethyl[2.2]metacyclo(4,6)[2.2]metaparacyclophane (**37**).* The Stevens rearrangement-Raney nickel desulfurization method was carried out as in the synthesis of **8**. The following conditions were used; methylation of **36** (1.10 g, 2.6 mmol) with the Borch reagent (1.66 g, 10 mmol) in dichloromethane (20 ml) under reflux for 3.5 h, the Stevens rearrangement with potassium *t*-butoxide (3.0 g, 27 mmol) in dry tetrahydrofuran (25 ml) under reflux for 5 h, and desulfurization with Raney nickel (6 ml) in 60 ml of benzene–ethanol (1 : 5) under reflux for 15 h. After chromatography, the desired product **37** was obtained as an oil, which was solidified when treated with a small amount of pentane (141 mg, 15%), colorless fine crystals from toluene, mp 131—132 °C.

Found: C, 91.51; H, 8.06%. Calcd for $C_{28}H_{30}$: C, 91.73; H, 8.27%. PMR ($CDCl_3$, δ) 1.7—3.4 (m, 32H, CH_2), 1.49 (s, 3H, CH_3), 1.98 (s, 3H, CH_3), 2.44 (s, 3H, CH_3), 2.58 (s, 3H, CH_3), 3.71 (s, 2H, ArH), 4.20 (s, 1H, ArH), 5.07 (bs, 1H, ArH), 5.39 (s, 1H, ArH), 5.60 (s, 1H, ArH), 5.80 (bs, 1H, ArH), 6.21 (s, 1H, ArH), 6.87 (s, 1H, ArH), 6.9—7.3 (m, 7H, ArH). MS m/e 366 (M^+).

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, to which the authors' thanks are due.

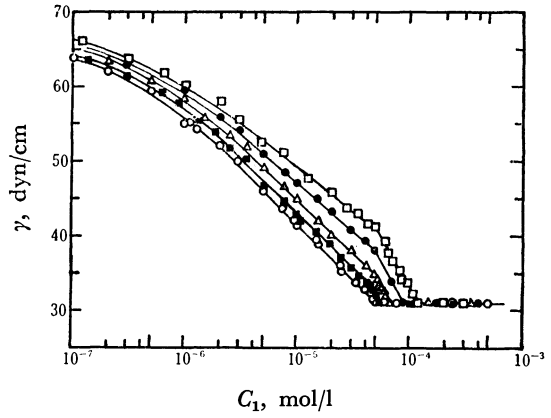

Fig. 1. Surface tension *vs.* concentration curves of $D(EO)_6$ solution at various concentrations of urea. ○: 0 M, ■: 0.04 M, △: 0.40 M, ●: 2.5 M, □: 4.0 M.

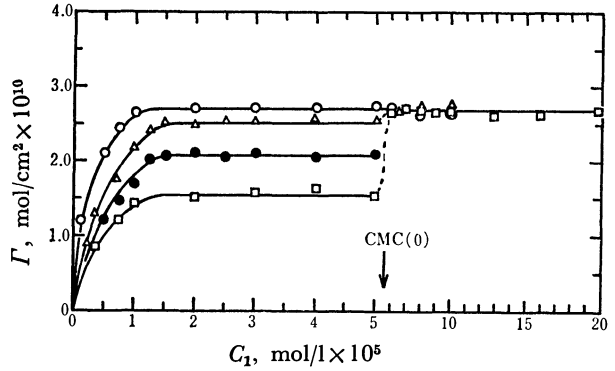

Fig. 2. Adsorption isotherms of $D(EO)_6$ at various concentrations of urea.
○: 0 M, △: 0.04 M, ●: 2.5 M, □: 4.0 M.

characterized by the following two parts above and below about 5.5×10^{-5} mol/l of $D(EO)_6$, which corresponds approximately to the CMC(0) of a $D(EO)_6$ solution without urea. Below the CMC(0) value, adsorption of $D(EO)_6$ obviously decreases with the increasing urea concentration present in the solution as is shown in a previous paper,[1] and reaches saturation. This suggests that urea may directly interact with the poly(oxyethylene) group of $D(EO)_6$ and probably forms some kind of urea–nonionic aggregations. If urea affects the solution by breaking the water structure, the isotherm should not give such a saturated adsorption as that shown in Fig. 2, but should only increase gradually depending on the change in the activity of $D(EO)_6$ in the urea solution. Above the CMC(0) value, the isotherms at varying urea concentrations coincide with the isotherm of the simple $D(EO)_6$ solution. These phenomena will be discussed in later section.

Adsorption of D(EO)$_6$. An attempt was made to apply the Gibbs adsorption isotherm to the calculation of the surface excess of nonionic in the urea–nonionic solution. The Gibbs isotherm is generatlly written as:[7]

$$-d\gamma = RT\sum \Gamma_i \, d\ln a_i \qquad (1)$$

where γ denotes the surface tension, Γ_i and a_i the surface excess and activity of the i-th components of the solution, respectively, and R and T the gas constant and absolute temperature, respectively. The interaction between urea and $D(EO)_6$ in the solution can be expressed implicitly as an activity coefficient (f_i) in Eq. 1. At constant urea concentration, Eq. 1 can be rewritten using the Gibbs-Duhem equation for bulk solutions,

$$-\left(\frac{\partial\gamma}{RT\partial\ln C_1}\right)_{2,3} = \Gamma_1 - \left\{\Gamma_1\frac{C_2}{C_1}-\Gamma_2\right\}\left(\frac{\partial\ln f_2}{\partial\ln C_1}\right)_{2,3} - \Gamma_1\frac{C_3}{C_1}\left(\frac{\partial\ln f_3}{\partial\ln C_1}\right)_{2,3} \qquad (2)$$

where C_i is the concentration of the i-th component in the solution, and the subscripts 1, 2 and 3 refer to $D(EO)_6$, urea and water, respectively. The last term on the right-hand side of Eq. 2 can reasonably be neglected, because the activity coefficient of water in the urea–nonionic solution should be constant at concentrations, C_1, less than 5.5×10^{-5} mol/l. If the cross-differentiation relation of Eq. 3 can be adopted for this system as a good approximation,[13]

$$\left(\frac{\partial\ln f_1}{\partial C_2}\right)_1 = \left(\frac{\partial\ln f_2}{\partial C_1}\right)_2 \qquad (3)$$

Eq. 2 is reduced to:

$$-\left(\frac{\partial\gamma}{RT\partial\ln C_1}\right)_2 = \Gamma_1\left\{1-\left(\frac{\partial\ln f_1}{\partial\ln C_2}\right)_1\right\} \qquad (4)$$

since $C_1/C_2 \ll 1$, *e.g.* $C_1 \leq 5.5\times10^{-5}$ and $C_2 \geq 4.0\times10^{-2}$ mol/l in this study. Tajima *et al.* have reported the following empirical relation from a study on the salting-in effect of urea upon the adsorption of $D(EO)_6$:[1]

$$\Gamma_D = -\frac{4.5\times10^{-11}}{\Delta}C_u^{0.15} \qquad (5)$$

where Γ_D is the surface excess of $D(EO)_6$, C_u ($=C_2$) the concentration of urea and $\Delta=(\partial\ln f_1/\partial\ln C_2)_1$. Substituting Eq. 5 into Eq. 4, we finally obtain

$$\Gamma_1 = -\left(\frac{\partial\gamma}{RT\partial\ln C_1}\right)_2 - 4.5\times10^{-11}C_2^{0.15} \qquad (6)$$

The Γ_1 value in Eq. 6 may be calculated from the data in Fig. 1 at constant concentration, C_2. The calculated and observed values for Γ_1 at various urea concentrations are shown in Table 1, where Γ_1 is compared at 4.0×10^{-5} mol/l for C_1 in the region of saturated adsorption. The values of Γ_1 calculated using Eq. 6 are in good agreement with the observed results. Therefore, it is seen that the adsorption of $D(EO)_6$ in the urea solution takes place according to the relation expressed by Eq. 6, which has a term which is a function of C_2.

Adsorption of Urea. Urea adsorption on the

( ) corresponds to the number of proton(s). (a), peak(s) corresponding to $(+)_{435}$-isomer. (b), peak(s) due to $(-)_{435}$-isomer. (c), not clear due to overlap with other peaks.
a) CH_2-CH_2 protons appear at 3.4—4.6 ppm as broad multiplet, phenyl protons appear between 6.5 and 7.5 ppm as multiplet. b) Center of broad multiplet. c) This complex shows $CHCl_3$ signal at 7.77 ppm.

14—16, and **20** (in the case of L-thr-complex **20**, as shown in Fig. 5 C′, the CH_3–C=N singal splits into three peaks soon after dissolution). These PMR spectral behaviors clearly indicate that the complexes **2—6**, **14—16**, and **20** exist each as an 1 : 1 mixture of the two isomers soon after dissolution, but they exist each as a mixture of the two isomers in which one isomer is over the other at equilibrium conditions. On the other hand, as shown in Figs. 5 B and B′, the L-met-complex **18** shows only one signal for the methyl group of the coordinated L-methionine anion soon after dissolution ,but the signal decreases its intensity and another methyl signal appears at a somewhat lower field at the equilibrium condition. Similar behaviors are seen for the complexes **8** and **17**. Therefore, it is concluded that these three complexes are isolated each as a pure isomer, but they exist each in a mixture of two isomers in solution. By comparison of the time dependences between the optical rotations at 435 nm of the complexes and their PMR spectra, the signals of the alkyl groups of amino acid anions at higher field are assigned to those for $(-)_{435}$-isomers and the lower field signals to $(+)_{435}$-isomers. Thus, the isomer's ratio, $(-)_{435}$-isomer/$(+)_{435}$-isomer, can easily be estimated from the PMR intensity ratio. The ratios for the complexes **2**, **3**, **6**, **8**, **14**, **15**, **18**, and **20** are listed in Table 8.

On the contrary, as shown in Figs. 5 D, D′ and E and E′, the complexes **10—12** and **22—24** in which the amino acid anions have phenyl group show the time dependences not only for the signals of the amino acid anions but for the signals of H–C=N or CH_3–C=N. This is due to the anisotropic effect of the phenyl group. Since the PMR spectral behaviors of these H–C=N and CH_3–C=N signals are similar to those of the alkyl signals of amino acid anions mentioned above, the compositions of $(-)_{435}$- and $(+)_{435}$-isomers both soon after dissolution and at equilibrium conditions are easily estimated; the isomer's ratios in the complexes **10—12** and **22—24** at the equilibrium conditions are listed in Table 8.

In the cases of the L-leu- and L-isoleu-complexes

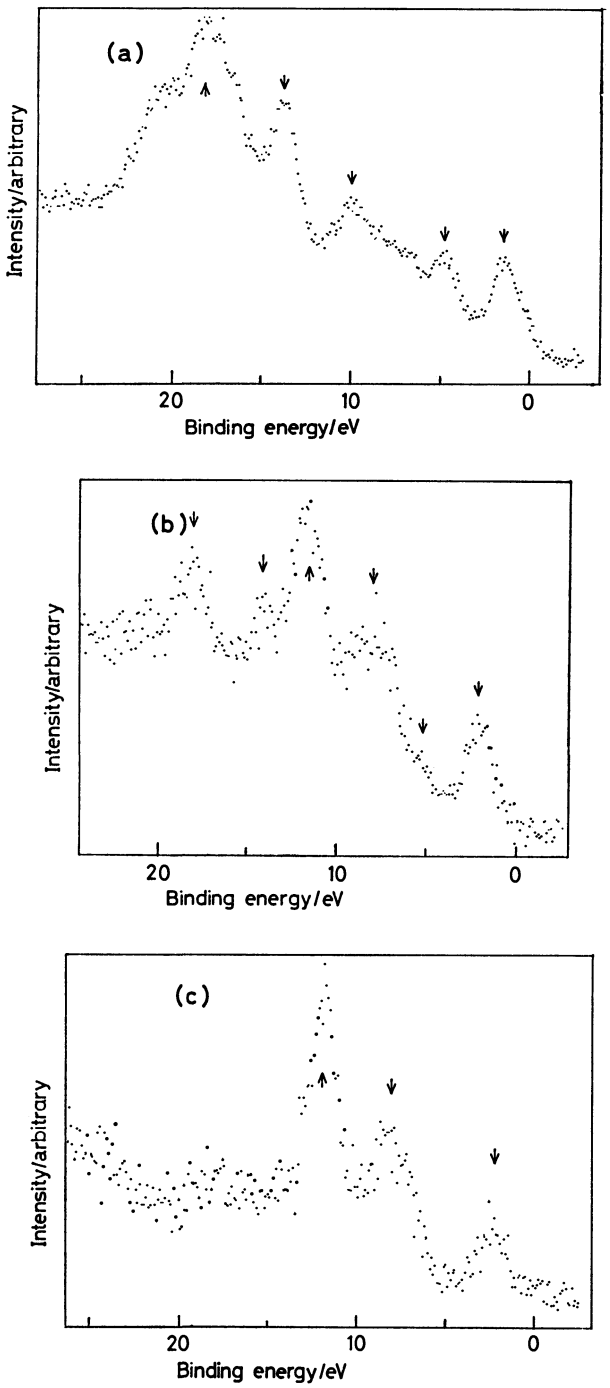

Fig. 1. The valence region of XPS spectra of a) Cr $(C_6H_6)_2$, b) $Cr(C_6H_6)(CO)_3$, and c) $Cr(CO)_6$.

The fact that the binding energies localized on both a central metal atom and ligands give the same shift shows that the magnitude of the matrix effects is constant over a molecule, and that the observed binding energies are little affected by Madelung and polarization energies which may depend upon the lattice points.

The fact must be also true in the case of core electrons, that is, we could obtain the binding energies of core electrons referred to vacuum level as given in Table 1.

The Estimation of the Charge Distribution from XPS Data. It has been shown that the binding energy, BE, of a carbon ls electron can be expressed as follows in terms

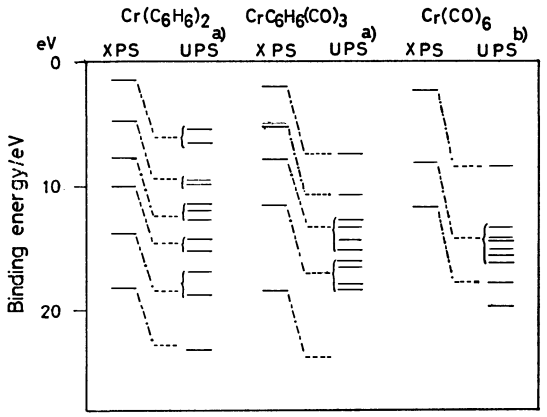

Fig. 2. The comparison of the energy level diagrams observed by XPS method and UPS method. Broken lines denote the corrected binding energies. a) : Ref. 4. b) : Ref. 5.

a) the C 1s binding energy due to carbon atom in benzene.

of the charge density q_C on the carbon atom of the interest:[8]

$$BE = k_C q_C + V + E_R + l_C \quad (1)$$

where V denotes the electrostatic potential at the nuclear caused by surrounding atoms and E_R gives relaxation energy based on the sudden approximation. k_C and l_C are constant to be decided from experiments. Snyder[9] and Gelius[10] suggestes that E_R may also be expressed in terms of q_C. For the group of carefully selected compounds, such a linear relation can be found in Fig. 3 where calculated relaxation energies[11] were plotted against the charge density on the carbon atom obtained by CNDO/2 method. This is expected on the basis of the study of relaxation energies done by H. Siegbahn *et al.*[12] According to their notation, the following equation may be settled for a certain authorized group

$$k^T \cdot \Delta q_A(j) + \Delta V_A(j) + l^T - l = \text{const.}$$

where the constants of k and l for the transition state are denoted by k^T and l^T. In other words, it can be said that the flow of charge onto the ionized atom and potential energy change at the site of the ionized atom as a result of charge reorganization in the rest of the molecule are similar within a certain group.

When the following substitution reaction proceeds

the carge density on the carbon atom may increase by amounts of Δq. It is shown that the chemical shift in

Syntheses of D-Arabinofuranosyl and 2'-Deoxy-D-ribofuranosyl Pyrazolecarboxamides

Osamu MAKABE,* Jutaro YAJIMA, and Sumio UMEZAWA**

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama, Kanagawa 223

(Received December 27, 1975)

Several D-arabino- and 2'-deoxy-D-ribonucleosides of carbamoylpyrazoles were synthesized by an acid-catalyzed fusion reaction of 1-*O*-acetyl derivatives of the corresponding sugars with pyrazole derivatives. Spectral evidences for their *N*-glycosylation sites and anomeric configurations were presented.

In a previous paper we have reported[1] the synthesis of a cytotoxic nucleoside, 1-(β-D-ribofuranosyl)pyrazole-3-carboxamide, which is closely related to the antiviral antibiotic of pyrazomycin[2] [3-(β-D-ribofuranosyl)-4-hydroxypyrazole-5-carboxamide]. Our continued interest in the nucleosides of pyrazolecarboxamide has prompted us to synthesize the corresponding nucleosides, *i.e.*, D-arabino- and 2'-deoxy-D-ribonucleosides of pyrazolecarboxamide and related nucleosides.

Since D-arabinosylation of heterocycles has often been successful in yielding antiviral and cytotoxic activities as exemplified[3] by 1-(β-D-arabinofuranosyl)-cytosine and 9-(β-D-arabinofuranosyl)adenine, we undertook a synthetic investigation of the arabinosylpyrazolenucleoside (**13β**). The β-nucleoside(1',2'-*cis*) was synthesized by use of 1-*O*-acetyl-2,3,5-tri-*O*-benzyl-D-arabinofuranose (**1**) in which the hydroxyl group at *C*-2 is blocked with benzyl group (a nonparticipating group). The 1-*O*-acetyl sugar **1** was prepared by acetylation of 2,3,5-tri-*O*-benzyl-D-arabinofuranose.[4] Fusion of **1** with ethyl pyrazole-3-carboxylate[5] (**2**) in the presence of bis(*p*-nitrophenyl) hydrogenphosphate[6] gave a mixture of ethyl 1-(2,3,5-tri-*O*-benzyl-α-D-arabinofuranosyl)pyrazole-3-carboxylate (**5α**) and its β-anomer (**5β**) in a ratio of *ca.* 3 : 5 together with a small amount of 5-ethoxycarbonyl isomer (**6α**). These products were separated by chromatography and then treated with methanolic ammonia to give 1-(2,3,5-tri-*O*-benzyl-α-D-arabinofuranosyl)pyrazole-3-carboxamide (**9α**), its β-anomer (**9β**), and the α-anomer of 5-carboxamide (**10α**), respectively. Catalytic hydrogenolysis then afforded 1-(α-D-arabinofuranosyl)pyrazole-3-carboxamide (**13α**), its β-anomer (**13β**), and 5-carboxamide (**14α**), respectively.

Chart 1

A similar fusion reaction of diethyl pyrazole-3,5-dicarboxylate[1] (**3**) with **1** afforded an anomeric mixture of (**7**), from which, by treatment with methanolic ammonia followed by chromatographic separation, 1-(2,3,5-tri-*O*-benzyl-α-D-arabinofuranosyl)pyrazole-3,5-dicarboxamide (**11α**) and its β-anomer (**11β**) were obtained in a ratio of 5 : 1. Catalytic hydrogenolysis of the major product **11α** gave 1-(α-D-arabinofuranosyl)-pyrazole-3,5-dicarboxamide (**15α**).

A fusion of diethyl 4-nitropyrazole-3,5-dicarboxylate[1] (**4**) with **1** followed by chromatographic separation afforded diethyl 1-(2,3,5-tri-*O*-benzyl-α-D-arabinofuranosyl)-4-nitropyrazole-3,5-dicarboxylate (**8α**) and its β-anomer (**8β**) in a ratio of 11 : 3. The major product (**8α**) was treated with methanolic ammonia to give the carboxamide (**12α**), which was converted by catalytic hydrogenation into 4-amino-1-(α-D-arabinofuranosyl)-pyrazole-3,5-dicarboxamide (**16α**).

The structures of these nucleosides were assigned on the basis of their PMR and UV spectra. Substitution by the anisotropic carbamoyl group at *C*-5 of the pyrazole portion results in the downfield shift of anomeric proton signal[1,10] and it is observed that the anomeric proton signals of **14α** (δ 6.89), **15α** (δ 6.90), and **16α** (δ 6.41) show downfield shifts as compared with those of **13α** (δ 5.82) and **13β** (δ 6.06). The *H*-5 signals of **13α** (δ 8.17) and **13β** (δ 8.04) were observed in lower field than the *H*-3 signal of **14α** (δ 7.75). The anomeric proton signals of 1',2'-*cis* nucleosides have been shown[7] to occur at lower field than those of the corressponding *trans* anomers. The anomeric proton signals of the nucleoside **13α** and **13β** occurred at δ 5.82 and 6.06, respectively. These data suggested α-configuration(1',2'-*trans*) for **13α** and β-configuration(1',2'-*cis*) for **13β**. Comparison of the PMR spectrum of **8α**(1',2'-*trans*) with that of **8β**(1',2'-*cis*) showed a downfield shift for the anomeric proton of **8β** as expected for a 1',2'-*cis* nucleoside. This suggested α-configuration(1',2'-*trans*) for **16α**. The anomeric configuration of **14α** was suggested as α by the coupling constant ($J_{1',2'}=2.8$ Hz) of its benzyl derivative (**10α**).

Syntheses of the 2'-deoxy-D-ribonucleosides were next performed by use of 1-*O*-acetyl-2-deoxy-3,5-di-*O*-(*p*-nitrobenzoyl)-D-*erythro*-pentofuranose (**17**) which was obtained from methyl 2-deoxy-3,5-di-*O*-(*p*-nitro-

$C_{30}H_{31}O_5N_3$: C, 70.16; H, 6.08; N, 8.18%.

*1-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)pyrazole-5-carboxamide (**10α**).* By a procedure similar to that for **9α**, **6α** (150 mg, 0.28 mmol) gave **10α**, 118 mg (82%), as a colorless syrup; $[\alpha]_D^{25}$+25.0° (*c* 0.50, chloroform). PMR ($CDCl_3$): δ 7.73 (d, 1H, H-3), 7.40 (d, 15H, Ar), 6.95 (d, 1H, H-4), 6.60 (br d, 2H, $CONH_2$), 6.03 (d, 1H, $J_{1',2'}$=2.8 Hz, H-1'), 4.80 (t, 1H, H-2'), 4.60 (s, 6H, CH_2-Ar), 4.80 (m, 2H, H-3', H-4'), 3.71 (d, 2H, H-5',5''). Found: C, 69.94; H, 6.11; N, 8.13%. Calcd for $C_{30}H_{31}O_5N_3$: C, 70.16; H, 6.08; N, 8.18%.

*1-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)pyrazole-3,5-dicarboxamide (**11α**) and Its β-Anomer (**11β**).* A solution of **7** (330 mg, 0.537 mmol) in absolute methanol (30 ml) saturated with ammonia at 0 °C was kept at room temperature for 12 h. After removal of methoanol by evaporation, the resulting syrup was dissolved in acetone and chromatographed on a column of silica gel (15 g, 1×10 cm, packed with 6 : 1 chloroform–acetone) with the same solvent system. The effluent was fractionated into 3 mls.

Fraction Nos. 8—10 gave colorless crystals of **11β**, 46 mg (15.4%); mp 200—202 °C. $[\alpha]_D^{25}$−89.1° (*c* 1.0, dioxane). PMR (CD_3OD): δ 7.50 (m, 16H, Ar, H-4), 7.28 (d, 1H, $J_{1',2'}$=4.9 Hz, H-1'), 4.85—4.20 (m, 9H, CH_2-Ar, H-2', H-3', H-4'), 3.70 (d, 2H, H-5', 5''). Found: C, 66.95; H, 6.01; N, 9.80%. Calcd for $C_{31}H_{32}O_6N_4$: C, 66.89; H, 5.80; N, 10.07%.

Fraction Nos. 13—18 gave a colorless solid of **11α**, 221 mg (74%); $[\alpha]_D^{25}$+72.8° (*c* 1.0, dioxane). PMR (CD_3OD): δ 7.48 (d, 16H, Ar, H-4), 7.22 (d, 1H, $J_{1',2'}$=3.2 Hz, H-1'), 5.03 (dq, 1H, H-2'), 4.75—4.20 (m, 8H, CH_2-Ar, H-3', H-4'), 3.72 (d, 2H, H-5' H-5''). Found: C, 67.02; H, 5.93; N, 10.04%. Calcd for $C_{31}H_{32}O_6N_4$: C, 66.89; H, 5.80; N, 10.07%.

*1-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)-4-nitropyrazole-3,5-dicarboxamide (**12α**).* By a method similar to that described above, **8α** (440 mg 0.668 mmol) gave an oil, which was chromatographed on silica gel column (20 g, 1×15 cm, packed with 3 : 1 benzene–ethyl acetate). Evaporation of the portion containing the product gave a colorless syrup of **12α**, 354 mg (88%); $[\alpha]_D^{25}$+101.3° (*c* 1.0, methanol). PMR (CD_3OD): δ 7.40 (s, 15H, Ar), 6.29 (d, 1H, $J_{1',2'}$=3.2 Hz, H-1'), 5.10 (dt, 1H, H-2'), 4.75—4.00 (m, 8H, CH_2-Ar, H-3', H-4'), 3.69 (d, 2H, H-5',5''). Found: C, 62.06; H, 5.37; N, 11.68%. Calcd for $C_{31}H_{31}O_8N_5$: C, 61.89; H, 5.19; N, 11.64%.

*1-(2,3,5-Tri-O-benzyl-β-D-arabinofuranosyl)-4-nitropyrazole-3,5-dicarboxamide (**12β**).* By a procedure similar to that described above, **8β** (110 mg, 0.167 mmol) gave **12β**. Its recrystallization from methanol afforded its pure sample (79 mg, 78.5%); mp 188—200 °C. $[\alpha]_D^{25}$ −113° (*c* 0.83, dioxane). PMR (CD_3OD): δ 7.40 (s, 15H, Ar), 6.34 (d, 1H, $J_{1',2'}$=5.2 Hz, H-1'), 3.70 (d, 2H, H-5',5''). Found: C, 62.17; H, 5.39; N, 11.42%. Calcd for $C_{31}H_{31}O_8N_5$: C, 61.89; H, 5.19; N, 11.64%.

*1-(α-D-Arabinofuranosyl)pyrazole-3-carboxamide (**13α**).* A solution of **9α** (402 mg, 0.78 mmol) in methanol (40 ml) was hydrogenated in the presence of palladium black at 3.5 atm for 24 h. After removal of the catalyst, the methanol was evaporated and the residue was chromatographed on a silica gel column with 4 : 4: 2 : 3 1-butanol–ethanol–chloroform–17% aqueous ammonia. Evaporation of the portion containing the product gave a colorless glass of **13α** (129 mg, 68%); $[\alpha]_D^{25}$ +30.6° (*c* 0.41, water). PMR (DMSO-d_6): δ 8.17(d, 1H, H-5), 7.50 (br d, 2H, $CONH_2$), 6.84 (d, 1H, H-4), 5.92 (br s, 1H, OH), 5.82 (d, 1H, $J_{1',2'}$=4.7 Hz, H-1'), 5.60 (br s, 1H, OH), 4.85 (br d, 1H, OH), 4.65 (t, 1H, H-2'), 4.30—3.83 (m, H, H-3', H-4'), 3.70 (m, 2H, H-5',5''). UV: λ_{max}^{water} 231 (ε 12800), λ_{max}^{pH1} 198 (ε 13000), λ_{max}^{pH13} 219 nm (ε 11800). Found: C, 42.76; H, 5.51; N, 16.53%. Calcd for $C_9H_{13}O_5N_3$ 1/2H_2O: C, 42.82; H, 5.58; N, 16.65%.

*1-(β-D-Arabinofuranosyl)pyrazole-3-carboxamide (**13β**).* By a procedure similar to that described above, **9β** (560 mg, 1.09 mmol) gave 13β. Its recrystallization from ethanol and benzene afforded its pure sample (198 mg, 74.6%); mp 126—127.5 °C. $[\alpha]_D^{25}$ −22.4° (*c* 0.67, water). PMR (DMSO-d_6): δ 8.04 (d, 1H, H-5), 7.40 (br d, 2H, $CONH_2$), 6.80 (d, 1H, H-4), 6.06 (d, 1H, $J_{1',2'}$=5.2 Hz, H-1'), 5.50 (d, 2H, OH), 5.02 (t, 1H, OH), 4.25 (m, 2H, H-2', H-3'), 3.75 (m, 3H, H-4', H-5',5''). UV: λ_{max}^{water} 213 (ε 11500), λ_{max}^{pH1} 198 (ε 12000), λ_{max}^{pH13} 219 nm (ε 11000). Found: C, 44.16; H, 5.29; N, 17.13%. Calcd for $C_9H_{13}O_5N_3$: C, 44.44; H, 5.39; N, 17.28%.

*1-(α-D-Arabinofuranosyl)pyrazole-5-carboxamide (**14α**).* By a procedure similar to that described above followed by recrystallization from ethanol, **10α** (108 mg, 0.21 mmol) gave crystals of **14α**, 41.2 mg (78%); mp 189—191 °C. $[\alpha]_D^{25}$ +64.0° (*c* 0.88, water). PMR (DMSO-d_6): δ 7.85 (br d, 2H, $CONH_2$), 7.75 (d, 1H, H-3), 7.06 (d, 1H, H-4), 6.89 (d, 1H, $J_{1',2'}$=4.6 Hz, H-1'), 5.58 (q, 2H, OH), 4.80 (m, 2H, OH, H-2'), 4.00 (m, 2H, H-3', H-4'), 3.60 (m, 2H, H-5',5''). UV: λ_{max}^{water} 219 (ε 13700), λ_{max}^{pH1} 221 (ε 10800), 198 (ε 14000), λ_{max}^{pH13} 220 nm (ε 10100). Found: C, 44.42; H, 5.38; N, 17.07%. Calcd for $C_9H_{13}O_5N_3$: C, 44.44; H, 5.39; N, 17.28%.

*1-(α-D-Arabinofuranosyl)pyrazole-3,5-dicarboxamide (**15α**).* A solution of **11α** (210 mg, 0.377 mmol) in 21 ml methanol and dioxane (1 : 1) was hydrogenated with palladium black and hydrogen for 48 h to give a solid, which was recrystallized from methanol and benzene to give crystals of **15α** (63 mg, 58%); mp 237—239 °C. $[\alpha]_D^{25}$ +77.4° (*c* 0.5, water). PMR (DMSO-d_6): δ 7.65 (br d, 2H, $CONH_2$), 7.45 (s, 1H, H-4), 6.90 (d, 1H, $J_{1',2'}$=4.5 Hz, H-1',) 5.70 (d, 1H, OH), 6.40 (d, 1H, OH), 4.85 (m, 2H, OH, H-2'), 4.10 (m, 2H, H-3', H-4'), 3.65 (m, 2H, H-5',5''). UV: λ_{max}^{water} 205 (ε 12000), λ_{max}^{pH1} 207 (ε 10600), λ_{max}^{pH13} 219 nm (ε 8900). Found: C, 42.06; H, 5.00; N, 19.35%. Calcd for $C_{10}H_{14}O_6N_4$: C, 41.96; H, 4.93; N, 19.58%.

*4-Amino-1-(α-D-arabinofuranosyl)pyrazole-3,5-dicarboxamide (**16α**).* A solution of **12α** (300 mg, 0.499 mmol) in methanol (8 ml) was hydrogenated in the same way as described for **13α**. The resulting solid was recrystallized from methanol and benzene to give **16α**, 91.5 mg (61%); mp 208—209 °C. $[\alpha]_D^{25}$ +108.9° (*c* 0.8, water). PMR (DMSO-d_6): δ 7.48 (br s, 4H, $CONH_2$), 6.41 (d, 1H, $J_{1',2'}$= 4.0 Hz, H-1'), 5.65 (d, 1H, OH), 5.31 (br s, 3H, NH_2, OH), 4.85 (m, 2H, OH, H-2'), 3.97 (br d, 2H, H-3', H-4'), 3.60 (m, 2H, H-5',5''). UV: λ_{max}^{water} 204 nm (ε 11000), λ_{max}^{pH1} 207 (ε 98000), 304 (ε 2900), λ_{max}^{pH13} 219 (ε 18000), 302 nm (ε 6800). Found: C, 39.45; H, 4.99; N, 22.98%. Calcd for $C_{10}H_{15}O_6N_5$: C, 39.45; H, 5.02; N, 23.25%.

*1-O-Acetyl-2-deoxy-3,5-di-O-(p-nitrobenzoyl)-D-erythro-pentofuranose (**17**).* Methyl 2-deoxy-3,5-di-*O*-(*p*-nitorobenzoyl)-D-*erythro*-pentoside (4.5 g, 10.1 mmol) was dissolved in a mixture of glacial acetic acid (5 ml) and acetic anhydride (10 ml) under cooling at −15 °C, and concentrated sulfuric acid (0.3 ml) was added with stirring, after which the stirring was further continued for 30 min at −15 °C. The mixture was poured onto ice–water (300 ml) and extracted with chloroform (100 ml). The organic layer was washed successively with water (100 ml×2), saturated aqueous sodium hydrogencarbonate solution, and water, and dried over anhydrous sodium sulfate. Evaporation under reduced

Pressure Effect on the Isomerization Velocities of β-[Co(edda)(tn)]$^+$ and β-[Co(edda)(en)]$^+$ in Solution

Yoichi KITAMURA

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received July 26, 1975)

The rates of the isomerization of β-[Co(edda)(tn)]$^+$ and β-[Co(edda)(en)]$^+$ to the α-isomers in a 0.2 M Na_2CO_3–0.2 M $NaHCO_3$ buffer solution have been measured under pressures of 1, 1000, 2000, and 3000 kg cm^{-2}. The activation volumes have been found to be 14.7 and 20.0 ml mol^{-1} respectively. It may be concluded that these reactions proceed through the SN1 CB mechanism.

The investigation of the pressure effect on a reaction velocity gives the value of the activation volume through the $\Delta V^{\neq} = -RT(\mathrm{d}\ln k/\mathrm{d}P)$ relation and, therefore, some information about the reaction mechanism.[1] Such investigations were carried out for several reactions of complex ions in solution, and the reaction mechanisms were deduced on the basis of the activation volume ($\Delta V^{\neq}$) and the total volume change (ΔV).[2] For an isomerization reaction, since the ligands of the reactant and of the resultant are identical, the total volume change can be assumed to be very small; hence, $\Delta V^{\neq}$ must be directly related to the reaction pathway.

Kuroda found that β-[Co(edda)(tn)]$^+$ and β-[Co(edda)(en)]$^+$ isomerize to the α-isomers in basic solutions, and proposed the Co–N bond rupture as the activation step.[3,4] In this study, the pressure dependence of the reaction rate was involved, and so the mechanism proposed by Kuroda was re-examined from the standpoint of the pressure effect.

Experimental

Materials. The α- and β-ethylenediamine-*N*,*N*′-diacetato(trimethylenediamine)cobalt(III) perchlorate, α- and β-[Co(edda)(tn)]ClO_4 (β-isomer is the monohydrate), were synthesized by the method developed by Kuroda and were identified by the agreement of the absorption spectra with those obtained by him.[3] The β-ethylenediamine-*N*,*N*′-diacetato(ethylenediamine)cobalt(III) perchlorate, β-[Co(edda)(en)]ClO_4, was provided by Kuroda.[5] Commercial reagent-grade chemicals were used. The water was distilled after an ion exchange.

Measurements. On the initiation of a reaction, about 20 mg of the complex salt and 10 ml of a 0.2 M Na_2CO_3–0.2 M $NaHCO_3$ buffer solution (pH=9.47 at 60 °C) at the reaction temperature were mixed in a beaker, and then 4 ml of the mixed solution was immediately poured into a glass syringe. The excess of the solution was quenched by putting the beaker in cold water, and the initial concentration was calculated from the absorption intensity of this quenched solution. The top of the syringe was sealed with a Teflon tape and was then set into liquid paraffin in a special steel cylinder, which had been maintained at the reaction temperature. The cylinder was set between the two plates of a press and pressurized rapidly. After a definite time, the pressure was released and the solution was quenched immediately. The absorption spectrum was measured subsequently.

The temperature of the cylinder block was controlled by circulating water from a thermostat and measured by a copper-constantan thermocouple, inserted in a hole of the cylinder block. It was maintained at 60±0.2 °C for the reaction of β-[Co(edda)(tn)]$^+$ and at 65±0.2 °C for that of the β-[Co(edda)(en)]$^+$.[6] The thermometer and the thermocouple were calibrated within ±0.1 °C by a standard thermometer made by the T. L. M. G. Co., Germany. The pressure value of the press was measured by means of a Bourdon gauge and controlled within ±2 kg cm^{-2}. The gauge was calibrated by a free piston gauge, and the pressure value was reproducible within ±1 kg cm^{-2}. The pressure generated in the cylinder was estimated from the piston-area ratio (22.56).

Results

Figure 1 illustrates the spectra of the initial solution of β-[Co(edda)(tn)]$^+$ and that after a definite reaction time. The three isosbestic points lie within ±4 nm from the positions obtained by Kuroda.[3] The concentration of each isomer was calculated from the absorption intensity at 503 nm, using the absorption coefficients of 153.8 and 64.8 l mol^{-1}cm^{-1} for the β- and the α-isomer respectively. A similar spectral change was observed for the reaction of β-[Co(edda)(en)]$^+$; the three isosbestic points lay within ±5 nm from the positions obtained by Kuroda.[4] The concentration of each isomer was calculated from the absorption intensity at 494 nm, using the absorption coefficient of 150.7 and 56.4 l mol^{-1} cm^{-1} for the β- and the α-isomers respectively.

These reactions have been known to be opposing first-order reversible reactions with respect to the

complex ions at normal pressure.[3,4] This was ascertained to be also true under high pressures, and the rate constants were calculated from the following equations:

$$\beta\text{-[Co(edda)(tn or en)]}^{+} \rightleftharpoons \alpha\text{-[Co(edda)(tn or en)]}^{+}$$

$$k_1 = \frac{1}{(1+1/K)t} \ln \frac{m}{m-x}, \quad K = \frac{k_1}{k_{-1}}, \quad m = \frac{k_1 b - k_{-1} a}{k_1 + k_{-1}}$$

where

k_1, k_{-1}: rate constants of the forward and the backward reactions; K: the equilibrium constant; t: the reaction time at a high pressure; a, b: the concentrations of the α-isomer and of the β-isomer at the biginning of the pressurization, and x: the concentration isomerized during time t

Kuroda has reported, for the β-[Co(edda)(tn)]$^+$ solution, that, at equilibrium, 88.3—89.5% of the initial β-isomer isomerizes to the α-isomer, irrespective of the reaction temperature and the pH value of the solution.[3] For this complex ion in the 0.2 M Na_2CO_3–0.2 M $NaHCO_3$ solution, an 89% isomerization was found after 11 half-lives at 1000 kg cm^{-2} and 68.6 °C. K=7.93, which corresponds to an 88.8% (average value) isomerization, was used throughout the calculations at each pressure. For β-[Co(edda)(en)]$^+$ in the 0.2 M Na_2CO_3–0.2 M $NaHCO_3$ solution at 68.6 °C, a 95.3% isomerization was found after 9 half-lives at normal pressure and a 93.3% isomerization after 8 half-lives at 1000 kg cm^{-2}. The k_1 value is not very much influenced by the small variations in K value, and so K=20.3, which corresponds to a 95.3% isomerization, was used throughout the calculations for this complex. a and b were estimated from the initial concentration and a consideration of the progress of the reaction during the time from the mixing to the attainment of a high pressure. It took about 3 min. Similarly, for the estimation of x, the progress during the time from the release of the pressure to the quenching was taken into account. It took about 2 min.

The rate constants at each pressure are summarized in Table 1. The real reaction temperature in the syringe was slightly lower than the block temperature because of the heat loss through the cylinder bottom and the piston. For the estimation of the temperature difference, the rate constants at a normal pressure in Table 1 were compared with those obtained in a flask in an ordinary thermostat controlled at 60 °C for β-[Co(edda)(tn)]$^+$ (k_1=6.20×10^{-3} m^{-1}) and at 65 °C for β-[Co(edda)(en)]$^+$ (k_1=10.0×10^{-3} m^{-1}). Taking the activation energies into account, the temperature difference was estimated to be 1.4 °C. The rate constants were fitted to the formula: $\ln(k_{1p}/k_{10}) = cP + dP^2$, by the least-mean-square method, where k_{1p} and k_{10} represent the rate constants at a high pressure and at zero pressure respectively.[1] The relationships are shown in Fig. 2. The activation volumes at zero pressure were calculated from the $\Delta V^{\neq} = -RTc$ relation as 19.9 ml mol^{-1} for β-[Co(edda)(tn)]$^+$ and as 25.2 ml mol^{-1} for β-[Co(edda)(en)]$^+$.

Kuroda measured the rate constants at 65 °C at different OH^- ion concentrations. His results show that k_1 is linearly dependent on [OH^-] for β-[Co(edda)-(tn)]$^+$ and that k_1 is expressed as $k_1 = k'_1[OH^-] + k_0$, where k_0 is a parameter.[3] For this complex, k_1 was also measured in the 0.08 M Na_2CO_3–0.32 M $NaHCO_3$ solution (pH=8.90 at 60 °C) at 58.6 °C; it was found to be 2.06×10^{-3}, 1.10×10^{-3}, and 0.46×10^{-3} m^{-1} at 1, 1000, and 2000 kg cm^{-2} respectively. Assuming a linear relationship between k_1 and [OH^-], the k_0 value was obtained to be 1.01×10^{-3}, 0.64×10^{-3}, and 0.15×10^{-3} m^{-1} at 1, 1000, and 2000 kg cm^{-2} respectively. This pressure dependence of k_0 is approximately equal to that of k_1, at least in the lower pressure range ($\leq$1000 kg cm^{-2}); therefore, the pressure dependence of $k'_1[OH^-]$ may be taken as equal to that of k_1. For β-[Co(edda)(en)]$^+$, k_1 is approximately proportional to [OH^-] and may be expressed as $k_1 = k'_1[OH^-]$ for a relatively small range of [OH^-].[4]

The OH^- ion concentration in this buffer solution is given by: $[OH^-] = K_w[CO_3^{2-}]/K_2[HCO_3^-]$, where

K_w is the ionic product of water and where K_2 is the 2nd dissociation constant of carbonic acid.[7] When the buffer concentration is sufficiently high, as in this case, the pressure-induced change in pH does not significantly alter the $[CO_3^{2-}]/[HCO_3^-]$ ratio term.[8] Hence,

$$-RT\frac{d\ln k_1}{dP} = -RT\left[\frac{d\ln k_1'}{dP}+\frac{d\ln[OH^-]}{dP}\right]$$
$$= -RT\left[\frac{d\ln k_1'}{dP}+\frac{d\ln K_w}{dP}-\frac{d\ln K_2}{dP}\right]$$

The pressure dependence of K_w has been measured by Hamann, and that of K_2, by Distèche and Distèche.[9,10] From their measurements, the ΔV value for $H_2O=H^++OH^-$ was calculated to be -20.4 ml mol^{-1} at 25 °C, and that for $HCO_3^-=H^++CO_3^{2-}$, to be -25.6 ml mol^{-1} at 22 °C. Thus, $\Delta V^{\ddagger 1}=-RT\mathrm{d}\ln k_1'/dP$ can be calculated; 14.7 ml mol^{-1} and 20.0 ml mol^{-1} were obtained for β-[Co(edda)(tn)]$^+$ and β-[Co(edda)(en)]$^+$ respectively.

Discussion

Two reaction mechanisms are conceivable in view of the k_1 dependence on [OH$^-$]. One is the associative (SN2) mechanism, and the other is the dissociative (SN1 CB) mechanism. In the associative case, the rate-determining process is the association of the β-isomer with an OH$^-$ ion to form a seven-coordinated intermediate:

$$\beta\text{-[Co(edda)(tn or en)]}^+ + OH^- \rightarrow \beta\text{-[Co(edda)(tn or en)(OH)]}$$

An analogous case would be the substitution reaction of [Pt(dien)X]$^+$ by Y$^-$ (X$^-$=Cl$^-$, Br$^-$, I$^-$, N_3^-; Y$^-$=N_3^-, NO_2^-, I$^-$, SCN$^-$) through the five-coordinated neutral intermediate; activation volumes of -5——-12 ml mol^{-1} were obtained for these reactions.[11] Therefore, negative values of $\Delta V^{\ddagger\prime}$ may be expected in the associative case.

The activation volume would result partly from the intrinsic volume change accompanying the bond formation, and partly from the release of the solvated water molecules owing to the neutralization of the ionic charges of reactant ions, *i.e.*, the electrostrictive volume change. The electrostrictive part for the complex ion may be interpreted by means of Born's equation, which is considered to be valid for a large ion.[12] It amounts to 2 ml mol^{-1}, since the radius of the complex ion may be estimated as 3 Å from the Co–O and Co–N bond distances and the molecular extensions.[13,14] For the OH$^-$ ion, the crystal radius is 1.38 Å, and the absolute partial molal volume, $\overline{V}_{OH^-}$, may be estimated as 1.5 ml mol^{-1} at 60 °C, taking a reasonable average value of $\overline{V}_{H^+}$ (-6.2 ml mol^{-1}) from several reported values.[15] For a singly charged ion of this crystal radius in water, the disordered or the void space volume, $\overline{V}_{disord}$, and the electrostrictive volume, $\overline{V}_{elect}$, have been semiempirically estimated as 9 ± 3 ml mol^{-1} and 7 ± 3 ml mol^{-1} respectively.[15]

The activation process of the substitution reaction of [Pd(Et$_4$dien)X]$^+$ by Y$^-$ (X$^-$=Cl$^-$, Br$^-$, I$^-$; Y$^-$=Br$^-$, I$^-$, N_3^-) is considered to be the incorporation of a water molecule into the complex ion; activation volumes of -14——-10 ml mol^{-1} were obtained.[11] A water molecule has the same crystal radius as the OH$^-$ ion, and the arrangement of the solvent molecules around them must be similar. Therefore, the intrinsic change caused by OH$^-$-ion incorporation would be of a nature analogous to that of a H_2O incorporation, and it may be assumed that

$$\Delta V(H_2O \text{ incorporation})/\Delta V_{int}(OH^- \text{ incorporation}) = \overline{V}_{H_2O}/\overline{V}_{OH^-int}.$$

$\overline{V}_{H_2O}$ may be taken as 18.3 ml mol^{-1} at 60 °C from the water density.

In this situation, the upper limit of the activation volume in the associative case is obtained by assuming the highest value for $\overline{V}_{OH^-elect}$, or the highest value for $\overline{V}_{OH^-disord}$, to give the $\overline{V}_{OH^-}=1.5$ ml mol^{-1};

$\overline{V}_{OH^-int}=\overline{V}_{OH^-cryst}+\overline{V}_{OH^-disord}=6.6+12=18.6$ ml mol^{-1},

$\overline{V}_{OH^-elect}=\overline{V}_{OH^-int}-\overline{V}_{OH^-}=18.6-1.5=17.1$ ml mol^{-1}.

Then the upper limit may be given by $(-10\times18.6/18.3)+2+17.1=8.9$ ml mol^{-1}. This is still considerably smaller than the obtained values of $\Delta V^{\ddagger\prime}$, so the possibility of the associative mechanism can be excluded.

For the SN1 CB mechanism, by analogy with the base hydrolysis of [Co(NH$_3$)$_5$X]$^{2+}$ (X$^-$=Cl$^-$, Br$^-$,NO_3^-), the reaction series may be written as:

$$\beta\text{-[Co(edda)(H}_2\text{N-R-NH}_2\text{)]}^+ + OH^- \rightleftharpoons \beta\text{-[Co(edda)(HN-R-NH}_2\text{)]} + H_2O$$
$$\beta\text{-[Co(edda)(HN-R-NH}_2\text{)]} \rightarrow \alpha\text{-[Co(edda)(HN-R-NH}_2\text{)]}$$
$$\alpha\text{-[Co(edda)(HN-R-NH}_2\text{)]} + H_2O \rightleftharpoons \alpha\text{-[Co(edda)(H}_2\text{N-R-NH}_2\text{)]}^+ + OH^-,$$

where the 1st and 3rd steps are assumed to be rapid and where the 2nd is assumed to be the rate-determining process.[16] Hence, $k'_1=k''_1K_{pre}$, where k''_1 is the rate constant of the 2nd step and where K_{pre} is the equilibrium constant of the 1st step. Thus,

$$-RT\frac{d\ln k_1'}{dP} = -RT\left[\frac{d\ln k_1''}{dP}+\frac{d\ln K_{pre}}{dP}\right],$$
$$\text{or } \Delta V^{\ddagger\prime} = \Delta V^{\ddagger\prime\prime} + \Delta V_{pre}$$

The volume change accompanying the pre-equilibrium (ΔV_{pre}) may be estimated as $\Delta V_{pre}=\overline{V}_{H_2O}-\overline{V}_{OH^-}+\Delta V_{el}$, where ΔV_{el} is the partial molal volume difference between the conjugate base form and the acid form of the β-isomer. ΔV_{el} may be estimated as 2 ml mol^{-1} from Born's equation.[12] Hence, ΔV_{pre} amounts to 18.8 ml mol^{-1} at 60 °C. Then, $\Delta V^{\ddagger\prime\prime}$, which is attributed to the activation of the rate-determining process, is -4.1 mol ml^{-1} and 1.2 ml mol^{-1} for β-[Co(edda)(tn)]$^+$ and for β-[Co(edda)(en)]$^+$ respectively. These magnitudes of $\Delta V^{\ddagger\prime\prime}$ are comparable with that expected from a bond rupture and the resulting solvations, and the SN1 CB mechanism seems reasonable.[17–19]

The activation energy and activation entropy were measured for these reactions by Kuroda; the values of 36.0 kcal mol^{-1} and 29.7 e.u. for β-[Co(edda)(tn)]$^+$ and of 42.1 kcal mol^{-1} and 46.5 e.u. for β-[Co(edda)-(en)]$^+$ were obtained.[3] The large positive values of

the activation entropies are in accordance with the qualitative proportionality relation between the activation volume and the activation entropy.[20] The energy and entropy changes for the pre-equilibrium must be approximately equal for these two complexes, and the differences in the activation energy and in the activation entropy should be attributed to the activation of the rate-determining process.

Following the proposal by Kuroda that the activation of the rate-determining process is the Co–N bond rupture of *tn* or *en*,[3,4] the obtained magnitudes of $\Delta V^{\neq\prime\prime}$ may be interpreted as follows. For β-[Co(edda)-(tn)]$^+$, the long trimethylenediamine chain was rather loosely attached in the complex and could move rather freely in its initial state. Hence, the intrinsic volume change resulting from the bond rupture was rather small, and the negative contribution owing to the solvation to the unoccupied site of the intermediate ion and to the partly liberated polar R–NH_2 group was the dominant factor. In contrast, for β-[Co(edda)-(en)]$^+$, the ethylenediamine chain is rather firmly and compactly attached in the complex; hence, the Co–N bond rupture results in a rather large intrinsic volume change, which compensates for the solvation effects.

The author wishes to thank Professor Jiro Osugi of Kyoto University for the use of the high-pressure apparatus and Professor Kashiro Kuroda of Ehime University for kindly providing the sample and for his valuable suggestions throughout this work.

The Inner-Sphere Mechanism Interpreted by the Hydrogen Ion Effect on the Fe^{2+} Reduction Rate of Oxalato-, Malonato-, Glycolato-, and Chloro-Cobalt(III) Complexes in Aqueous Solution

Kousaburo OHASHI

Department of Chemistry, Ibaraki University, Mito 310

(Received September 1, 1975)

The hydrogen ion effect on the rate of the Fe^{2+} reduction of oxalato-, glycolato-, and chloro-cobalt(III) complexes was investigated kinetically. It was found that the rates of the Fe^{2+} reduction of cobalt(III) complexes such as *trans*(*N*)-Co(ox)(β-ala)$_2^-$, *trans*(*N*)-Co(ox)(gly)$_2^-$, *trans*(*N*)-Co(ox)(gly)(en), Co(ox)$_3^{3-}$, and *trans*-(O,Cl)-Co(Cl)(am)(dien)$^+$ (am=glycinate, α-alaninate or β-alaninate ions) increase with an increase in the hydrogen ion concentration. This result can be explained by accounting for the protonation of the oxygen atom of the carbonyl group of the nonbridging ligand. The inner-sphere mechanism can be deduced for the Fe^{2+} reductions of these complexes due to the hydrogen-ion effect. Moreover, a kinetic study of the Fe^{2+} reduction reaction of Co(Hmalo)$(NH_3)_5^{2+}$ and Co(malo)$(NH_3)_5^+$ was carried out. An inner-sphere mechanism for these reactions is proposed from an analysis of the kinetic data. Discussion of the structure of the precursor complex and of the rate determining step for the Fe^{2+} reduction reactions of cobalt(III) complexes are also made.

One of the major problems of the Fe^{2+} reduction reaction of cobalt(III) complexes is to determine whether electron-transfer reactions proceed through the inner- or outer-sphere mechanisms. It was demonstrated that the reactions of Co(Cl)$(H_2O)_5^{2+}$,[1] and Co(Cl)(Hedta)$^-$ [2] with Fe^{2+} proceed through an inner-sphere mechanism from the kinetic measurements of the formation and decay of the transient species of these reactions. Such a direct evidence of the inner-sphere mechanism for the Fe^{2+} reduction of cobalt (III) complexes has not been so often obtained due mainly to the experimental difficulty caused by the slow rate of formation of transient products of the Fe^{3+} and the possibility of subsequent substitution.

In previous kinetic studies concerning the effect of the nonbridging ligand on the Fe^{2+} reductions of oxalato-,[3] azido,[4] chloro-[5-7] and nitrilopolyaminocarboxylato[8]-cobalt(III) complexes, the present author was inclined to favor the inner-sphere mechanism.

One of the purposes of the present work is to indirectly determine the mechanism of the Fe^{2+} reductions of some oxalato-, malonato-, glycolato-, and chloro-cobalt(III) complexes due to the effect of the hydrogen ion on the electron-transfer rate. Another purpose is the investigation of the structure of the precursor complex for the Fe^{2+} reductions of some oxalato-, malonato-, and chloro-cobalt(III) complexes. The rate-determining step is also discussed.

Experimental

Preparation of Cobalt(III) Complexes. *trans*(*N*)-K[Co(ox)(gly)$_2$],[9,10] *trans*(*N*)-K[Co(ox)(β-ala)$_2$],[11] K$_3$[Co(ox)$_3$],[12] [Co(ox)$(NH_3)_4$](ClO_4),[13] [Co(Hmalo)$(NH_3)_5$]$(ClO_4)_2\cdot 2H_2O$,[14] [Co(glyco)$(en)_2$]Cl$\cdot H_2O$,[15] *trans*(O,Cl)-[Co(Cl)(gly)(dien)](ClO_4),[16] *trans*(O,Cl)-[Co(Cl)(α-ala)(dien)](ClO_4),[16] and *trans*(O,Cl)-[Co(Cl)(β-ala)(dien)](ClO_4),[16] used as oxidants were prepared by the methods described in the references cited. The purities and identities of the complexes were ascertained by microanalysis for carbon, hydrogen, and nitrogen and by comparing the absorption spectra with those reported in the references.

Materials. The preparation of the iron(II) stock solution and the determinations of the concentrations of the iron(II), hydrogen, and perchlorate ions in this solution were carried out by the methods similar to those described in the previous paper.[5] The other reagents were G. R. grade chemicals.

Measurements of the Reaction Rate. The rates for the aquation reactions of the cobalt(III) complexes in strong acid media are negligibly small as compared with those of the Fe^{2+} reduction reactions. The Fe^{2+} reduction rates of the cobalt(III) complexes, except for Co(ox)$_3^{3-}$, were determined by the usual spectrophotometric method. The kinetic runs for Co(ox)$_3^{3-}$ were carried out by a Yanagimoto EPS-1-type stopped flow spectrophotometer under pseudo-first order conditions, the concentration of iron(II) ion being notably in excess of that of the cobalt(III) complex. The decrease in absorption was observed at a wavelength in the vicinity of the first absorption maximum of the complexes.

The concentration of the perchlorate ion in the solution was controlled by the addition of a sodium perchlorate solution. The hydrogen ion concentrations were varied from 0.05 M to 1.3 M by the addition of perchloric acid.

Results and Discussion

Figure 1 shows the dependence of the second-order rate constant on the hydrogen ion concentration for the Fe^{2+} reduction of *trans*(*N*)-Co(ox)(gly)$_2^-$ when the

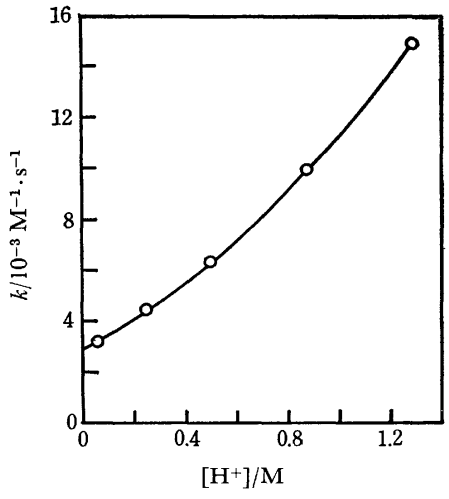

Fig. 1. The relation between the second-order rate constant of *trans*(*N*)-Co(ox)(gly)$_2^-$ and hydrogen ion concentration. $\Sigma[ClO_4^-]=1.30$ M, 25 °C, $NaClO_4$-$HClO_4$ medium.

ionic strength was maintained by the addition of sodium perchlorate. The second-order rate constant increases with the hydrogen-ion concentration. Similar results were obtained in the cases of *trans*-(*N*)-Co(ox)(β-ala)$_2^-$, Co(ox)$_3^{3-}$ (Table 1), *trans*(*N*)-Co(ox)(gly)(en) (Fig. 2),

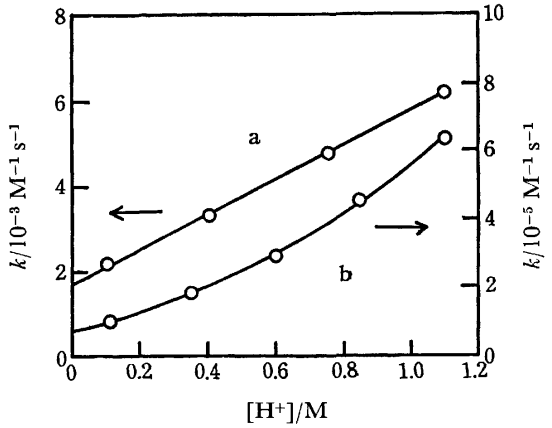

Fig. 3. The relation between the second-order rate constant of *trans* (O,Cl)–Co(Cl)(gly)(dien)$^+$ and *trans*-(O,Cl)–Co(Cl)(β-ala)(dien)$^+$ and hydrogen ion concentration.

trans(O,Cl)-Co(Cl)(gly)(dien)$^+$ (Fig. 3), *trans*(*N*)-Co(Cl)(β-ala)(dien)$^+$ (Fig. 3), and *trans*(O,Cl)-Co(Cl)-(α-ala)(dien)$^+$. In the cases of Co(ox)$(NH_3)_4^+$,[17] Co(ox)$(en)_2^+$, Co(glyco)$(en)_2^+$ (Table 1), and *cis*-Co(Cl)-(A)$(en)_2^{2+}$ (A=alkylamine),[6] however, no evidence of the hydrogen ion dependence was observed. The enhancement of the rate can be explained by the protonation of the carbonyl group of the carboxylate ion of the ligand which cannot be an electron mediator. Protonation would reduce the difficulty of stretching the ligand from the cobalt(III) center before the electron-transfer reaction takes place.

Independent evidence for the protonation of the carbonyl oxygen was obtained in the kinetic study of the acid-catalyzed oxygen exchange reaction between oxalato-cobalt(III) complexes with $H_2{}^{18}O$.[18] Further proof of the protonation of the nonbridging ligand was also indirectly obtained in the Fe^{2+} reduction of *trans*-Co$(N_3)_2(NH_3)_4^+$[19] and *trans*-Co$(N_3)_2(en)_2^+$.[4] For the Fe^{2+} reduction of *trans*-Co$(N_3)_2(NH_3)_4^+$, the kinetic study suggested the inner-sphere mechanism. Therefore, the acid-catalyzed reduction of *trans*(O,Cl)-Co(Cl)-(am)(dien)$^+$ may suggest that the reaction proceeds through the chloride-bridged activated state. As mentioned above, the reduction rates of Co(ox)$(NH_3)_4^+$, Co(ox)$(en)_2^+$, and Co(glyco)$(en)_2^+$ are independent of the hydrogen ion concentration. However, for *trans*-(*N*)-Co(ox)(gly)(en) in which one of the ethylenediamine molecules in the Co(ox)$(en)_2^+$ is replaced with a glycinate ion, an acid-catalyzed enhancement of the rate is observed (Fig. 2). For this complex, the inner-sphere mechanism may be proposed. The hydrogen ion may attack the oxygen atom of the carbonyl group of the glycinate ion of *trans*(*N*)-Co(ox)(gly)(en). The possible structure of the precursor complex for the Fe^{2+} reduction of Co(ox)$(NH_3)_4^+$ may be represented in Fig. 4. The rate of the Fe^{2+} reduction reaction which proceeds by the formation of the precursor complex shown in Fig. 4 should be much larger than that which proceeds by the formation of the iron(II) non-chelated precursor complex.

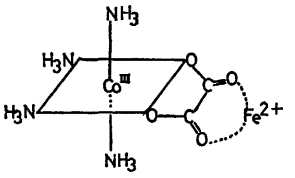

Fig. 4. The structure of the precursor complex for the Fe^{2+} reduction of Co(ox)$(NH_3)_4^+$.

The inner-sphere electron-transfer reaction between cobalt(III) complexes and Fe^{2+} should proceed *via* the following three steps:

$$RCo^{III}L + Fe^{II}(H_2O)_6 \rightleftharpoons RCo^{III}LFe^{II}(H_2O)_{6-n} + nH_2O \quad (1)$$

$$RCo^{III}LFe^{II}(H_2O)_{6-n} \rightleftharpoons RCo^{II}LFe^{III}(H_2O)_{6-n} \quad (2)$$

$$RCo^{II}LFe^{III}(H_2O)_{6-n} + mH_2O \rightleftharpoons RCo^{II}(H_2O)_m + LFe^{III}(H_2O)_{6-n} \text{ (or } RCo^{II}L + Fe^{III}(H_2O)_6) \quad (3)$$

where reactions (1), (2), and (3) indicate the formation of the precursor complex, electron-transfer, and the decomposition of the successor complex, respectively.

The reaction of *trans*-$Co(HCO_2)(en)_2^+$ [20] and *trans*-$Co(N_3)_2(en)_2^+$ [21] with V^{2+} is independent of the hydrogen ion concentration, whereas the reaction of *trans*-$Co(HCO_2)_2(en)_2^+$ with Cr^{2+} [22] involves an important term of first-order with respect to the hydrogen ion concentration. However, the V^{2+} and Cr^{2+} reductions of *cis*-$Co(HCO_2)_2(en)_2^+$ do not exhibit an acid-catalyzed effect. Such a different behavior of the hydrogen ion on the *trans*-$Co(HCO_2)_2(en)_2^+$ has been ascribed to the difference of the rate-determining steps.[22] For the Cr^{2+} reactions, the electron-transfer step is rate determining. This step requires a change in the inner-sphere and the electronic energy levels of the two metal centers. Protonation of the trans ligand on the oxidant appears to have the effect of facilitating such changes and lowering the energy of the acceptor orbital.[22] Therefore, the electron-transfer rate may be accelerated by the addition of a hydrogen ion. With V^{2+} as the reductant, the formation of the precursor complex appears to be rate-determining.[20,21]

The reactivity of the cobalt(III) complex with Fe^{2+}, in general, is strikingly affected by the ligand coordinated to the cobalt(III) center. In a strong acid medium, the successor complex, $Co^{II}LFe^{III}$ should much easily decompose because of the susceptibility of Co(II) and Fe(III) complexes to substitution and of the low stability of Co(II) complexes. The rates of the Fe^{2+} reduction of the oxalato- and chloro-cobalt(III) complexes are notably smaller than that of water exchange between $Fe(H_2O)_6^{2+}$ and $H_2{}^{18}O$.[23] Consequently, water molecule removal from the first-coordination sphere of $Fe(H_2O)_6^{2+}$ in forming a bridged activated state cannot be, in general, a rate-determining step. On the basis of the acid-catalyzed rate enhancement observed in the Fe^{2+} reductions of oxalato- and chlorocobalt(III) complexes, the present author is inclined to favor the electron-transfer step as the rate-determing one. With the rate-determing step being electron-transfer, reorganization of the first coordination sphere of the cobalt(III) complex would be needed before the electron-transfer reaction occurs. The previous investigation showed that the change in the reactivity of $Co(ox)(N_4)^+$ ($N_4=(NH_3)_4$, $(en)_2$, (trien), $(phen)_2$, $(bpy)_2$) with the iron(II) ion was mainly ascribed to the change in the enthalpy of activation.[3] This fact may mean that the rate-determining step is electron-transfer and that the reorganization of the first-coordination sphere of the Co(III) complex is a very important factor in the determination of the electron-transfer rate.

The acid dissociation constant for malonate ions (Hmalo), $Co(Hmalo)(NH_3)_5^{2+}$, which was determined in this work, is $K_a=6.3\times10^{-4}$ M at 25 °C and $I=1.0$. In the $[H^+]$ range from 0.02 M to 0.10 M, the predominant species is $Co(Hmalo)(NH_3)_5^{2+}$, and the concentration of $Co(malo)(NH_3)_5^+$ is very small. Assuming the large reactivity of $Co(malo)(NH_3)_5^+$, the results of the kinetic study on the Fe^{2+} reduction conform to the reaction path shown in reaction (4).

$$\begin{array}{ccc} Co(Hmalo)(NH_3)_5^{2+} & \overset{K_a}{\rightleftharpoons} & Co(malo)(NH_3)_5^+ + H^+ \\ {\scriptstyle Fe^{2+}}\downarrow{\scriptstyle k_{H^+}} & & {\scriptstyle Fe^{2+}}\downarrow{\scriptstyle k_0} \\ Co(II) + Fe(III) & & Co(II) + Fe(III) \end{array} \qquad (4)$$

Then, the observed rate constant k_{obsd} of the form $-d[Co(III)]/dt=k_{obsd}[Co(III)][Fe^{2+}]$ can be expressed as:

$$k_{obsd}=\frac{k_{H^+}[H^+]+k_0K_a}{[H^+]+K_a} \qquad (5)$$

where k_{H^+} and k_0 are the second-order rate constants for $Co(Hmalo)(NH_3)_5^{2+}$ and $Co(malo)(NH_3)_5^+$, respectively. Under the condition that $K_a \ll [H^+]$, k_{H^+} and k_0 can be obtained conveniently by plotting k_{obsd} *vs.* $1/[H^+]$ (Fig. 5). The rate constants obtained are listed along with those for $Co(Hox)(NH_3)_5^{2+}$ and $Co(ox)(NH_3)_5^+$ in Table 2. The reactivities of $Co(ox)(NH_3)_5^+$ and $Co(malo)(NH_3)_5^+$ are about 10^3 times larger than

Table 2. The second-order rate constant for the iron(II) reduction of $Co(L)(NH_3)_5^{n+}$ ($L=Hox^-$, ox^{2-} $Hmalo^-$, $malo^{2-}$) and the pK_a of $Co(Hox)(NH_3)_5^{2+}$ and $Co(Hmalo)(NH_3)_5^{2+}$

Complex ion	Rate constant $M^{-1}s^{-1}$	pK_a

those of the corresponding protonated species (Table 2). The striking variation in the rate between the protonated species and the deprotonated species may be due mainly to the difference in the thermodynamic stability of the precursor complex, although an effect of the difference in charge on the cobalt(III) complex is not completely excluded. In the transition state for the Fe^{2+} reduction of $Co(malo)(NH_3)_5^+$, iron(II) is expected to chelate to a malonate ion(Fig. 6a). The reaction of $Co(Hmalo)(NH_3)_5^{2+}$ should proceed *via* the iron(II) non-chelated precursor complex (Fig. 6b). Moreover, the rate constants of $Co(Hox)(NH_3)_5^{2+}$ and $Co(ox)(NH_3)_5^+$ are larger by a factor of approximately 10^3 than that of the corresponding malonato-cobalt(III) complex. Possibly the difference in reactivity between the oxalato-cobalt(III) complex and the malonato-cobalt(III) complex may be related to the difference in the stabilities of the precursor complex and/or the efficiency of the bridging ligand as the electron mediator.

The author wishes to express his thanks to Professor K. Yamamoto for his helpful discussions.

Some Mixed-Ligand Iron(III) Complexes Produced by Reactions of Tris(acetylacetonato)iron(III) with Hydrogen Halides in Organic Solvents

Kenji TAKEDA*, Kiyoshi ISOBE, Yukio NAKAMURA, and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received September 16, 1975)

Tris(acetylacetonato)iron(III) $Fe(acac)_3$ reacts with an equimolar and double molar amounts of a hydrogen halide in dichloromethane to afford the mixed-ligand iron(III) complexes, $FeX(acac)_2$ and $FeX_2(acac)H_2O$, respectively, where X is Cl or Br. They are all high-spin iron(III) complexes and exist as monomeric five-coordinate molecules in non-coordinating solvents, but behave as uni-univalent electrolytes in methanol. Further reactions of $FeX_2(acac)H_2O$ with an excess of hydrogen halides in dichloromethane followed by the addition of twice as many moles of 1,10-phenanthroline produced $[FeX_2(phen)_2]X$. The reactions of $FeX_2(acac)H_2O$ with excesses of pyridine and 2,2′-bipyridine in tetrahydrofuran gave the six-coordinate complexes $FeX_2(acac)(py)_2$ and $FeX_2(acac)(bipy)$, respectively.

In the present series of studies on the reactions of metal acetylacetonates with bromine and hydrogen bromide in organic solvents, different kinds of products have previously been isolated and characterized.[1] For instance, dibromo(acetylacetone)cobalt(II) $CoBr_2$-(acacH), a novel complex containing an acetylacetone molecule as the bidentate ligand, was produced by the reaction of $Co(acac)_3$ with bromine in dichloromethane. However, an attempt to isolate the intermediary cobalt(III) complex, assumed to be a precursor of the cobalt(II) complex, was unsuccessful.[2] On the other hand, $Mn(acac)_3$ is reduced by hydrogen halides in organic solvents, ultimately resulting in manganese(II) chloride, bromide, or $Mn(acac)_2$, and the intermediary Mn(III) products, $MnX(acac)_2$, where X is Cl, Br, or I, could be isolated from the equimolar reactions.[3]

Collman[4] demonstrated that halogen substitution at the central carbon atom of metal acetylacetonate can be successfully carried out under electrophilic substitution reaction conditions. Thus, $Fe(acac)_3$ was directly brominated with *N*-bromosuccinimide in chloroform[5] or with bromine in buffered acetic acid.[6] On the contrary, one acetylacetonate ring of the acid labile tris-chelate was displaced in the reaction with picric acid in benzene–ethanol, affording the cationic iron(III) complex, $[Fe(acac)_2(H_2O)_2]$picrate.[7] The present paper reports some mixed-ligand iron(III) complexes which were isolated and characterized as intermediary products in the reactions between $Fe(acac)_3$ and hydrogen halides in organic solvents.[8]

Experimental

Materials. Tris(acetylacetonato)iron(III) was prepared and recrystallized according to Ref. 9. Found: Fe, 15.85; C, 51.12; H, 6.12%. Hydrogen chloride was generated by the reaction of hydrochloric acid with sulfuric acid, dried over calcium chloride, and dissolved in dichloromethane (*ca.* 0.2 mol/l). Hydrogen bromide was produced by the reaction between tetralin and bromine, dried over calcium bromide, and dissolved in dichloromethane (*ca.* 0.2 mol/l). Dichloromethane and acetonitrile were distilled twice over phosphorus pentaoxide. Benzene was distilled over metallic sodium. Nitromethane and methanol were also distilled.

The Reactions of Tris(acetylacetonato)iron(III) with Hydrogen Halides. A solution of $Fe(acac)_3$ in dichloromethane was placed in a three-necked flask equipped with a buret, a glass tube containing calcium chloride, and another outlet tube. A solution (*ca.* 0.1 mol/l) of hydrogen chloride or bromide in dichloromethane was added dropwise from the buret to the above solution with magnetic stirring. The usual precautions were taken for preventing moisture during filtration of the reaction product.

Isolation of Chlorobis(acetylacetonato)iron(III): To a solution of $Fe(acac)_3$ in dichloromethane was added a solution of an equimolar amount of hydrogen chloride in dichloromethane from the buret. After the reaction, a dark red precipitate was separated out by the addition of petroleum ether. The precipitate was filtered, washed with petroleum ether and dried *in vacuo*. Found: Fe, 19.88; Cl, 12.40; C, 41.43; H, 4.88%. Calcd for $FeCl(acac)_2=C_{10}H_{14}O_4ClFe$: Fe, 19.29; Cl, 12.25; C, 41.15; H, 4.87%.

Isolation of Bromobis(acetylacetonato)iron(III): A dichloromethane solution of $Fe(acac)_3$ was allowed to react with an equimolar amount of hydrogen bromide in dichloromethane. The initially red-brown solution turned to dark red. The solution was concentrated to a quarter of its original volume, whereupon a red-brown precipitate separated out. The precipitate was filtered, washed with petroleum ether and dried *in vacuo*. Found: Fe, 17.08; Br, 24.37; C, 35.67; H, 4.23%. Calcd for $FeBr(acac)_2=C_{10}H_{14}O_4BrFe$: Fe, 16.72; Br, 23.93; C, 35.96; H, 4.23%.

Isolations of Dichloro(acetylacetonato)aquairon(III) and Dibromo-(acetylacetonato)aquairon(III): When a red-brown solution of $Fe(acac)_3$ in dichloromethane was forced to react with twice as many moles of hydrogen chloride or bromide in dichloromethane, its color turned to dark red. Petroleum ether was added slowly to the reaction mixture producing a dark red precipitate. This was filtered, washed with petroleum ether and dried *in vacuo*. Found for the chloro complex: Fe, 23.09; Cl, 28.86; C, 24.73; H, 3.77%. Calcd for $FeCl_2(acac)H_2O=C_5H_9O_3Cl_2Fe$: Fe, 22.90; Cl, 29.07; C, 24.62; H, 3.72%. Found for the bromo complex: Fe, 16.90; Br, 47.86; C, 18.19; H, 2.80%. Calcd for $FeBr_2$-$(acac)H_2O=C_5H_9O_3Br_2Fe$: Fe, 16.78; Br, 48.02; C, 18.05; H, 2.73%. The same compounds were also produced from the equimolar reactions between $FeX(acac)_2$ and HX (X=Cl or Br) in dichloromethane in a manner similar to that described above.

Further Reactions of $FeCl_2(acac)H_2O$ and $FeBr_2(acac)H_2O$ with Excess Hydrogen Chloride and Bromide. Isolation of FeX_3 as $[FeX_2(phen)_2]X$, where X is Cl or Br: To a suspension of $FeX_2(acac)H_2O$ (X=Cl or Br) in dichloromethane was added an excess of hydrogen chloride or bromide dissolved in the same solvent, whereupon a transparent solution was

* Present address: Toyama Chemical Co., Ltd., Shimookui, Toyama.

produced. Twice as many moles of 1,10-phenanthroline as that of the iron(III) complex used were dissolved in a minimum quantity of dichloromethane and added to the above clean solutions to separate out the precipitates, which were yellow-brown (chloride) and red-brown (bromide), respectively. The precipitates were recrystallized from ethanol and dried *in vacuo*. Found for chloride: C, 51.13; H, 3.08; N, 9.94%. Calcd for $[FeCl_2(phen)_2]Cl=C_{24}H_{16}N_4Cl_3Fe$: C, 51.60; H, 2.89; N, 10.03%. Found for bromide: C, 44.08; H, 3.04; N, 8.21%. Calcd for $[FeBr_2(phen)_2]Br=C_{24}H_{16}N_4Br_3Fe$: C, 43.94; 2.46; N, 8.54%.

Preparation of $FeX_2(acac)(py)_2$ and $FeX_2(acac)(bipy)$, where X is Cl or Br. To tetrahydrofuran solutions of $FeX_2(acac)H_2O$ (X=Cl or Br) was added an excess of pyridine or 2,2′-bipyridine in tetrahydrofuran. The solution was stirred magnetically for about 1 hour, whereupon a precipitate gradually separated out. Found for the dichlorobispyridine complex: Fe, 14.43; Cl, 18.45; C, 46.89; H, 4.52; N. 7.09%. Calcd for $FeCl_2(acac)(py)_2=C_{15}H_{17}O_2N_2Cl_2Fe$: Fe, 14.54; Cl, 18.46; C, 46.91; H, 4.46; N, 7.29%. Found for the dibromobispyridine complex: Fe, 11.29; Br, 33.51; C, 39.07; H, 3.79; N, 5.91%. Calcd for $FeBr_2(acac)(py)_2=C_{15}H_{17}O_2N_2Br_2Fe$: Fe, 11.81; Br, 33.79; C, 38.10; H, 3.62; N, 5.92%. Found for the dichloro(2,2′-bipyridine) complex: Fe, 14.44; Cl, 18.46; C, 47.09; H, 4.25; N, 7.39%. Calcd for $FeCl_2(acac)(bipy)=C_{15}H_{15}O_2N_2Cl_2Fe$: Fe, 14.62; Cl, 18.56; C, 47.16; H, 3.96; N, 7.33%. Found for the dibromo-(2,2′-bipyridine) complex: Fe, 12.09; Br, 34.06; C, 38.42; H, 3.28; N, 6.03%. Calcd for $FeBr_2(acac)(bipy)=C_{15}H_{15}O_2N_2Br_2Fe$: Fe, 11.86; Br, 33.93; C, 38.26; H, 3.21; N, 5.95%.

Analysis. Each compound was subjected to elemental analysis after drying *in vacuo* at room temperature. Iron was determined gravimetrically as iron(III) oxide, and chlorine and bromine as the silver salts. The concentrations of hydrogen chloride and bromide in dichloromethane were measured by the method reported previously.[1]

Measurements. The visible and ultraviolet absorption spectra were measured by means of a Hitachi EPS-3T autorecording spectrophotometer. The infrared spectra were taken in Nujol with JASCO IR-E (4000—700 cm^{-1}), Hitachi EPI-L (700—200 cm^{-1}) and FIS-3 (400—30 cm^{-1}) infrared spectrophotometers.

The magnetic susceptibility was measured at room temperature or at various temperatures down to 80 K by the Faraday method with an automatically recording magnetic balance MB-2 of the Shimadzu Seisakusho Co., Ltd. Mercury(II) tetraisothiocyanatocobaltate(II) (room temperature) and hexaammine chromium(III) chloride (lower temperature) were used as reference compounds.

The molecular weight was determined by vapor-pressure osmometry with an apparatus manufactured by the Knauer Co. of Germany. Benzene, nitromethane, acetonitrile and methanol were used as solvents, and benzil as a reference. The electric conductivity was measured in nitromethane or methanol by means of an MY-7 apparatus of the Yanagimoto Seisakusho, Ltd.

Results

Tris(acetylacetonato)iron(III) reacts in a stepwise manner with an equimolar amount or twice as many moles of hydrogen chloride or bromide to produce halogenobis(acetylacetonato)iron(III) or dihalogeno-(acetylacetonato)aquairon(III), respectively.

Halogenobis(acetylacetonato)iron(III) Complexes. Chloro- and bromo-bis(acetylacetonato)iron(III) complexes were isolated from the equimolar reaction mixtures of $Fe(acac)_3$ and HX, where X is Cl or Br, by the addition of petroleum ether or the evaporation of the solution, respectively, and the composition of $FeX(acac)_2$ was confirmed by elemental analysis. As shown in Table 1, the compounds have magnetic moments typical of high-spin d^5 systems.

The molecular weights determined in benzene are close to the calculated values, indicating that each of the chloro and bromo complexes exists essentially as a discrete molecule in the non-coordinating solvent. The molar conductances in nitromethane at room temperature also indicate that the complexes are essentially non-electrolytes in this solvent.

In methanol, the complexes dissociate almost completely and the observed molecular weights are near to half of the formula weight. The molar conductances (λ_M) in the same solvent reveal that the complexes behave practically as uni-univalent electrolytes, although the values are smaller in comparison with 9.10 Ω^{-1} cm^2mol^{-1} of tetraethylammonium iodide in methanol. It may be presumed that the complexes are solvolyzed in methanol, affording a six-coordinate iron(III) cation and a halide ion:

$$FeX(acac)_2 + 2CH_3OH \rightarrow Fe(acac)_2(CH_3OH)_2^+ + X^-$$

Although the assumed compounds $[Fe(acac)_2(CH_3OH)_2]X$ could not be isolated, similar cationic complexes $[Fe(acac)_2(H_2O)_2]$picrate and $[Fe(acac)_2(TOPO)_2]ClO_4$ (TOPO=trioctylphosphine oxide) have been prepared by Aly[7] and Aggett.[10] The former is weakly dissociated in dichloromethane and the Λ_M value (31.3 $\Omega^{-1}cm^2mol^{-1}$) in the solvent is appreciably smaller

a) The molecular weight was measured at (1.0—5.0)$\times 10^{-2}$ M, and the molar conductance at 1.0×10^{-2} M, both at room temperature.

than that observed for $FeX(acac)_2$ in methanol.

Puri and Mehrotra,[11] and Cox and his coworkers[12] prepared $FeCl(acac)_2$, either by refluxing the appropriate quantities of anhydrous iron(III) chloride and acetylacetone in benzene or by the reaction of stoichiometric amounts of anhydrous $FeCl_3$ and $Fe(acac)_3$ in chloroform. The complex has been shown [13] to possess a slightly distorted square-pyramidal structure, with the iron atom situated 0.51 Å above the basal plane.

Infrared Spectra: In a previous paper,[3] the present authors have discussed the infrared spectra of $FeX(acac)_2$ in comparison with those of $MnX(acac)_2$ in the 1600—700 cm^{-1} region, and therefore, only the far-infrared spectra are discussed here. There are one or two intense bands in the 400—250 cm^{-1} region as shown in Fig. 1. The band at 298 cm^{-1} in the parent complex, $Fe(acac)_3$, is isotopically assigned to the pure ν(Fe–O) vibration.[14] Thus, the peak around 310—300 cm^{-1} is readily attributed to the corresponding vibration in the two $FeX(acac)_2$ complexes.

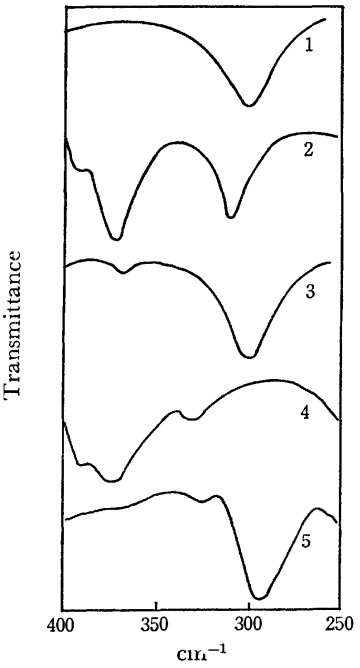

Fig. 1. Infrared spectra in the low-frequency region of $Fe(acac)_3$ (curve 1), $FeX(acac)_2$, where X=Cl (curve 2) or Br (curve 3), and $FeX_2(acac)H_2O$, where X=Cl (curve 4) or Br (curve 5).

The stretching band of the terminal Fe(III)–Cl bond of the five-coordinate iron(III) complexes is usually observed in the 300—400 cm^{-1} region and the exact position is affected by the coexisting ligands: 309 cm^{-1} for $FeCl(S_2CNEt_2)_2$[15], 355 and 375 cm^{-1} for $FeCl_3$-(1,2-dimethoxyethane)[16], 380 cm^{-1} for $FeCl_3$(1,4-dioxane)[17] and 378 cm^{-1} for four-coordinate iron(III) ion $FeCl_4^-$.[18] Thus, the strong band observed at 373 cm^{-1} for $FeCl(acac)_2$ can be reasonably assigned to the ν_t(Fe–Cl) vibration. For the same metal, the ratio ν(M–Br)/ν(M–Cl) is usually 0.77—0.74,[19] and hence the corresponding ν_t(Fe–Br) absorption in the FeBr-(acac)$_2$ complex appears to be incorporated in the ν(Fe–O) band at 300 cm^{-1}.

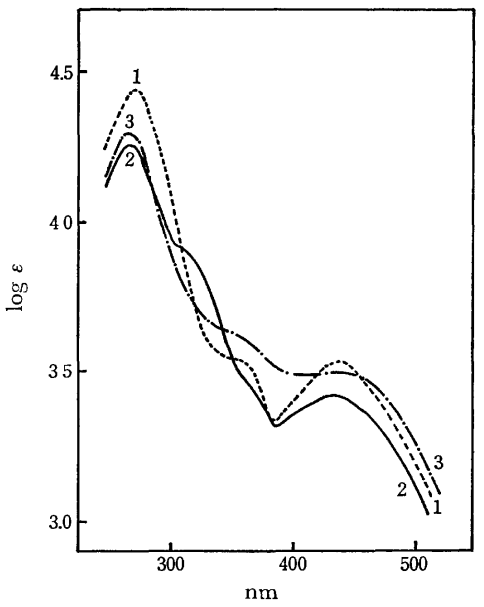

Fig. 2. Absorption spectra of $Fe(acac)_3$ (curve 1) and $FeX(acac)_2$ in CH_2Cl_2, where X=Cl (curve 2) or Br (curve 3).

Electronic Spectra: The electronic spectra of the present $FeX(acac)_2$ complexes in dichloromethane are shown in Fig. 2 together with the curve for the parent complex, $Fe(acac)_3$. The spectrum of $Fe(acac)_3$ has three absorption bands in the 200—600 nm region, and the most intense band at 270 nm is assigned to the intra-ligand π-π^* transition. The other two bands in this region are assigned to a metal-to-ligand($t_{2g}\rightarrow\pi^*$) charge transfer (CT) at 353 nm and a ligand-to-metal ($\pi\rightarrow e_g$) charge transfer (CT) at 436 nm.[20] On the other hand, $FeCl(acac)_2$ exhibits a shoulder on the longer wavelength side (*ca.* 310 nm) of the π-π^* transition band in addition to the original three bands. The new band can be feasibly assigned to a chlorine-to-metal CT transition. For the spectra of $[FeCl_2(bipy)_2][FeCl_4]$

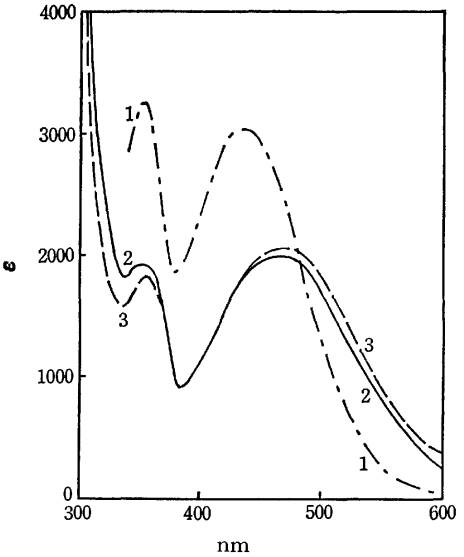

Fig. 3. Absorption spectra of $Fe(acac)_3$ (curve 1) and $FeX(acac)_2$ in methanol, where X=Cl (curve 2) or Br (curve 3).

in dichloromethane, a band at 365 nm is attributed to the same transition.[21] The corresponding bromine-to-metal CT band is not easy to assign in the spectrum of the bromo complex, $FeBr(acac)_2$, but an unusual increase in the absorption intensity is observed around 400 nm, as shown in Fig. 2. This may suggest that the band is obscured by the broad absorption at 435 nm.

The spectra of $FeCl(acac)_2$ and $FeBr(acac)_2$ in methanol are shown in Fig. 3. The measurements were made with 2×10^{-2} M solutions, of which the concentration was almost the same as those used in the molecular weight and molar conductance measurements, by the use of a cell with a 0.1 mm light path. The spectra of both the complexes show a pattern similar to that of the parent complex $Fe(acac)_3$ in methanol, and no absorption due to the halogen-to-metal CT transition was observed. This fact supports the assumed dissociation of a halide ion in methanol.

Dihalogeno(acetylacetonato)aquairon(III) Complexes. The complexes $FeX_2(acac)H_2O$ (X=Cl or Br) were produced by the reaction of $Fe(acac)_3$ with twice as many moles of HX or by the reaction of $FeX(acac)_2$ with an equimolar amount of HX in dichloromethane. The complexes are only slightly soluble in benzene, and hence the molecular weights were measured in nitromethane or in methanol. As shown in Table 1, the values determined in nitromethane are near to the formula weights, suggesting that each of the $FeX_2(acac)H_2O$ complexes also exists in the solvent essentially as a five-coordinate, monomeric complex. The Λ_M values obtained in the same solvent at room temperature also indicate that the complexes are practically non-electrolytes in this solvent, but the slightly large value for $FeCl_2(acac)H_2O$ may suggest some dissociation of a chloride ion.

In methanol, the molecular weights are one-half to one-third of the calculated values, while the Λ_M values imply that the complexes behave substantially as uni-univalent electrolytes in the same solvent. These results suggest that the $FeX_2(acac)H_2O$ complexes liberate only one of their two X^- ligands, and the resulting cations $FeX(acac)(H_2O)(CH_3OH)_2^+$ are partially solvolyzed to replace the aqua ligand with a solvent molecule:

$$FeX_2(acac)H_2O + 2CH_3OH \rightarrow FeX(acac)(H_2O)(CH_3OH)_2^+ + X^-$$

$$-CH_3OH \left\| \right. + CH_3OH$$

$$FeX(acac)(CH_3OH)_3^+ + H_2O$$

The electronic spectra of the complexes in methanol also support this assumption. As shown in Fig. 4, a band due to the halogen-to-metal CT transition reappears at 330 nm in the spectrum of $FeCl_2(acac)H_2O$ and at 410 nm in that of the dibromo analog. Thus, it can be concluded that one halide ligand is still coordinated to the metal in the complex cation produced by the dissociation in methanol.

The magnetic susceptibilities were measured over the temperature range from 300—80 K. As shown in Table 1, the room-temperature moments are close to or slightly less than the 5.92 B.M. predicted by the spin-only formula and these values are independent of temperatures down to 77 K. The plots of χ_A^{-1} against T (Fig. 5) gave straight lines in accordance with the Curie-Weiss law $\chi_A=c/(T+\theta)$. The θ values were obtained from an extrapolation of the straight line and found to be 4 and 8 K for the dichloro and dibromo complexes, respectively. These facts show that each of the $FeX_2(acac)H_2O$ complexes exists as a magnetically dilute molecule in the solid state and that the complexes have no antiferromagnetic interactions with each other.

The infrared spectra of the dihalogeno complexes $FeX_2(acac)H_2O$ in the 4000—700 cm^{-1} region resemble those of the mono-halogeno complexes, except for additional absorption bands due to the coordination of an aqua ligand. As shown in Fig. 1, the strong band at 375 or 294 cm^{-1} in each spectrum of the dihalogeno

$FeBr_2(acac)(py)_2$	385	259	158	473	38.9	150.6	5.82
$FeCl_2(acac)(bipy)$		193	136	382	7.1	66.6	5.85
$FeBr_2(acac)(bipy)$		272	156	471	22.1	84.8	5.77

a) The molecular weight was measured at $(1.0—5.0)\times10^{-2}$ M, and the molar conductance at 1.0×10^{-2} M, with both at room temperature.

complexes can be readily assigned to the stretching vibration of the terminal Fe(III)–X bond in comparison with the corresponding band of the monohalogeno complexes. In contrast to the Fe(III)–X stretching band, it is not easy to specify the band due to the Fe(III)–O(acac) stretching vibration because of its weak intensity. The weak band at 330 cm^{-1} for the dichloro complex and that at 326 cm^{-1} for the dibromo analog were tentatively assigned to the ν(Fe–O(acac)) vibration.

Puri and Mehrotra have also prepared $FeCl_2(acac)$ by the equimolar reaction of anhydrous iron(III) chloride and acetylacetone in benzene, but the compound does not contain an aqua ligand. Unfortunately, its properties and structure have not been reported.[11]

The Six-coordinate Mixed Ligand Fe(III) Complexes. Further reactions of the $FeX_2(acac)H_2O$ complexes with excess hydrogen halides followed by an addition of twice as many moles of phen as that of the complex used gave the precipitate composed of $FeX_3(phen)_2$. A compound of the same composition, $FeCl_3(phen)_2$ was prepared as an acetic acid adduct by Harris and Lockyer[22] and was formulated as a cationic iron(III) complex, $[FeCl_2(phen)_2]Cl\cdot2CH_3CO_2H$. Other similar compounds, $[FeCl_2(phen)_2]X\cdot nCH_3CO_2H$ (X=ClO_4, n=1; X=$FeCl_4$, n=0.5), containing the same cation were also prepared.

The five-coordinate complexes $FeX(acac)_2$ and $FeX_2(acac)H_2O$ have a vacant site to allow for the coordination of another monodentate base B. The former reacted with B to cause a disproportionation reaction, affording exclusively the dihalogeno complexes $FeX_2(acac)B_2$. Thus, the isolation of the six-coordinate complexes of the type $FeX(acac)_2B$ was not successful, whereas the neutral six-coordinate complexes $FeX_2(acac)(py)_2$ and $FeX_2(acac)(bipy)$ (X=Cl or Br) were isolated from the reaction of $FeX_2(acac)H_2O$ with excess pyridine or 2,2′-bipyridine, respectively, in tetrahydrofuran. Molecular weight, conductance and magnetic moment data of these mixed-ligand complexes are shown in Table 2. The magnetic moments at 27 °C lie in the range of 5.77—5.96 B.M., indicating that they are all high-spin Fe(III) complexes.

The molecular weights of the pyridine complexes in acetonitrile are slightly less than the formula weights, while they are close to half of the calculated values in nitromethane. The Λ_M values in nitromethane are not as large as expected for electrolytes. These results might indicate that the $FeX_2(acac)(py)_2$ complexes dissociate a pyridine molecule in this solvent. On the other hand, in methanol the molecular weights of both the pyridine complexes are about one-third of the formula weights, while the Λ_M values of the dichloro and dibromo complexes are comparable to or appreciably larger than that of a uni-univalent electrolyte, respectively. Hence, it may be presumed that both the complexes are solvolyzed in methanol in the following manner:

$$FeCl_2(acac)(py)_2 + 2CH_3OH \rightarrow FeCl(acac)(py)(CH_3OH)_2^+ + Cl^- + py$$

$$FeBr_2(acac)(py)_2 + 2CH_3OH \rightarrow Fe(acac)(py)_2(CH_3OH)_2^{2+} + 2Br^-$$

The affinity of iron(III) for the halide ions is in the order of F>Cl>Br>I. Such a trend might be reflected in the dissociation pattern of the second halide ion.

The electronic spectra of the $FeX_2(acac)(py)_2$ complexes in methanol are shown in Fig. 6. The absorption bands present at *ca.* 350 and *ca.* 450 nm are due to the metal-to-ligand(acac) and the ligand(acac)-to-metal CT transitions, respectively. As can be seen from the figure, in the spectrum of the dichloro complex a chlorine-to-metal CT band appears at *ca.* 330 nm as a

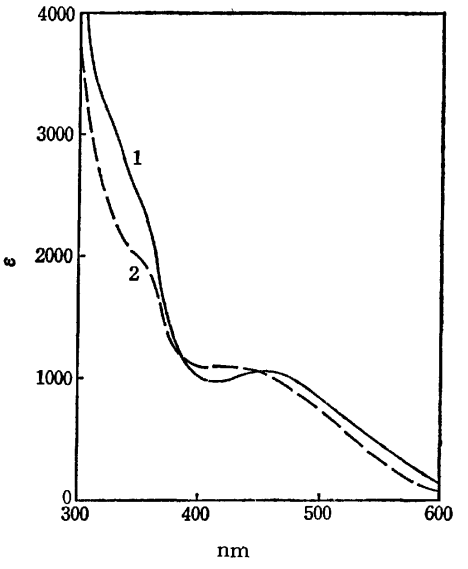

Fig. 6. Absorption spectra of $FeX_2(acac)(py)_2$ in methanol, where X=Cl (curve 1) and Br (curve 2).

discernible shoulder, while a corresponding bromine-to-metal CT band which is expected to appear around 410 nm is not observed for the bromo analog. This seems to reflect the dissociation patterns in methanol described above.

The behaviors of the 2,2′-bipyridine complexes $FeX_2(acac)(bipy)$ in nitromethane and methanol are very similar to those of the $FeCl_2(acac)(py)_2$ complex in the same solvents. Therefore, it can be concluded that they dissolve in nitromethane to dissociate a 2,2′-bipyridine molecule, but are solvolyzed in methanol to give a cation $FeX(acac)(CH_3OH)_3^+$ and a halide ion in addition to a 2,2′-bipyridine molecule:

$$FeX_2(acac)(bipy) + 3CH_3OH \rightarrow FeX(acac)(CH_3OH)_3^+ + X^- + bipy$$

As shown in Fig. 7, the electronic spectra of the $FeX_2(acac)(bipy)$ complexes in methanol show a band due to the halogen-to-metal CT transition at 340 nm for the dichloro complex and at 400 nm for the dibromo analog, respectively, in addition to the two CT metal-to-ligand(acac) and ligand(acac)-to-metal bands. Thus the spectral data are again in accord with the suggested dissociation pattern in methanol.

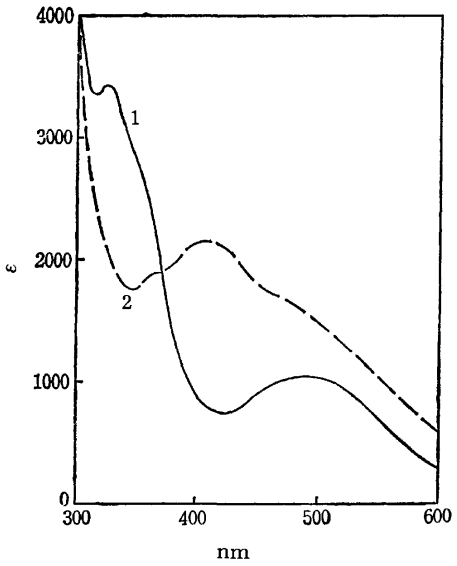

Fig. 7. Absorption spectra of $FeX_2(acac)(bipy)$ in methanol, where X=Cl (curve 1) and Br (curve 2).

Discussion

Despite the biological importance of iron-containing systems, there is a comparative lack of interest in the coordination chemistry of iron, especially in the case of tervalent iron. This can largely be attributed to the properties of the d^5 ion.[23] The present work extends the studies[1-3] of the reactions of metal acetylacetonates with bromine and hydrogen halides in organic solvents to include the iron(III) complex. In some metal acetylacetonates previously studied, the oxidation state of the metal was finally reduced in the reactions with these reagents, but in the present case no reduction to an iron(II) complex occurred throughout the reactions of Fe(acac)$_3$ with HX (X=Cl or Br) in dichloromethane. The detailed mechanism of these reactions could not be established in this investigation, but the reaction steps leading to the dihalogeno complex seem to proceed in the following sequence:

$$Fe(acac)_3 \xrightarrow{+HX} \left[(acac)_2Fe\begin{matrix}X\\ \diagdown\\ acacH\end{matrix}\right] \xrightarrow{-acacH} \begin{matrix}X\\ |\\ (acac)Fe(acac)\end{matrix}$$

Intermediate **1**

$$\begin{matrix}X\\ |\\ (acac)Fe(acac)\end{matrix} \xrightarrow{+HX} \left[\begin{matrix}X\\ |\\ (acac)Fe\\ \diagdown\\ acacH\end{matrix}\begin{matrix}\\ \\ \diagup\\ X\end{matrix}\right]$$

Intermediate **2**

$$\xrightarrow[+H_2O]{-acacH} FeX_2(acac)H_2O$$

Intermediates **1** and **2** have not been identified, but the latter has a composition similar to the chromium (III) complex $CrBr_2(acac)(acacH)$, which has previously been isolated from the reaction of Cr(acac)$_3$ with HBr in dichloromethane containing excess acetylacetone.[24] However, any attempts to isolate intermediate **2** in the present reactions were unsuccessful. This intermediate may be essentially labile, and change irreversibly to the insoluble complex, $FeX_2(acac)H_2O$, upon the addition of petroleum ether to the reaction mixture of Fe(acac)$_3$ and twice as many moles of hydrogen halides in dichloromethane.

In a preceding paper,[3] the present authors have reported that Mn(acac)$_3$ reacted with excess HX to liberate some Mn(II) products, but no reduction occurred in the present case. Such a difference in reactivity could be due to a difference in the reduction potentials of Mn(III) (E=1.51 V) and Fe(III) (E=0.77 V). It was assumed that FeX_3 was produced in the reaction mixture of $FeX_2(acac)H_2O$ with excess HX in dichloromethane:

$$FeX_2(acac)H_2O \xrightarrow[+(n-1)H_2O]{+HX} FeX_3\cdot nH_2O + acacH$$

The existence of FeX_3 in solution has not been confirmed directly, but $[FeX_2(phen)_2]X$ was precipitated from the solution upon the addition of 1,10-phenanthroline:

$$FeX_3\cdot nH_2O + 2phen \rightarrow [FeX_2(phen)_2]X + nH_2O$$

Although the base adducts $FeX_2(acac)B_2$ were readily obtained from $FeX_2(acac)H_2O$, $FeX(acac)_2$ was disproportionated by the reaction with the base B to deposit the dihalogeno complex $FeX_2(acac)B_2$ exclusively:

$$2FeX(acac)_2 + 2B \rightarrow FeX_2(acac)B_2 + Fe(acac)_3$$

Contrary to the Fe(III) complexes, it was noted previously[3] that $MnX(acac)_2B$ (B=dioxane, 4-methylpyridine or pyridine oxide) are stable enough to be isolated in reactions of $MnX(acac)_2$ with B, while $MnCl_2(acac)(O\text{-}py)_2$ is unstable at room temperature and was obtained only at −78 °C.

All the complexes prepared in this work, with the exception of $FeCl_2(acac)H_2O$ and $FeBr_2(acac)(bipy)$, have magnetic moments of 5.82—6.11 B.M. at 27 °C, which are close to the calculated spin-only value of

5.92 B.M. The room-temperature magnetic moments (5.76 and 5.77 B.M.) of the complexes $FeCl_2(acac)H_2O$ and $FeBr_2(acac)(bipy)$ are slightly less than 5.92 B.M. Apparently the former complex retains the possibility of polymeric structure in the solid state, which induces the magnetic interaction between neighboring iron atoms. In practice, however, it obeys the Curie-Weiss law between room temperature and 80 K, and the θ value of 4 K is not so large as to indicate an antiferromagnetic interaction.

Frazer, Qureshi and Taylor[25] studied the reactions of 8-quinolinol or its iron(III) complex with iron(III) halides in organic solvents, and prepared $FeX(oxin)_2$ and $FeX_2(oxin)$(oxin=8-quinolinolate ion and X=Cl or Br). These compounds were concluded to have a polymeric structure in the light of their insolubility and magnetic data. Only a small number of examples of high-spin iron(III) complexes which exist as five-coordinate monomers in solid state have been discovered up to now. They include adducts of $FeCl_3$ with 1,2-dimethoxyethane[16] and 1,4-dioxane,[17] *N*-substituted salicylideneamine complexes, $FeX(sal=NR)_2$ (X=Cl or Br),[26] *N*,*N*′-bis(salicylidene)ethylenediamine complexes, FeX(salen)monomer (X=Cl, Br, Ph or CH_2Ph)[27] and other Schiff-base iron(III) complexes[28] and some iron(III) porphyrins.[29] Both the present complexes, $FeX(acac)_2$ and $FeX_2(acac)$-H_2O, are new examples of this group.

The authors are grateful to Mr. J. Gohda for the elemental analysis. The financial aid of the Ministry of Education is also acknowledged.

Studies on Mixed Chelates. V. Mixed Nickel(II) Chelates with *N,N,N',N'*-Tetraethylethylenediamine and β-Diketones[1]

Yutaka FUKUDA, Reiko MORISHITA (née FUKUSHIMA), and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo 112

(Received September 30, 1975)

Fourteen mixed nickel(II) chelates with the general formula, Ni teen(β-dik)X, were newly obtained. Here teen is *N,N,N',N'*-tetraethylethylenediamine, *i.e.*, a sterically hindered ligand with four bulky ethyl groups on the donor *N* atoms, β-dik is a β-diketonate ion, and X is an anion such as $B(C_6H_5)_4^-$, ClO_4^-, NO_3^- or β-dik. According to the coordination ability of the anion X, the structure of the mixed chelate changes from square planar to octahedral, remarkable solvent effects being observed on the absorption spectra of these chelates. The steric influence of the ligand "teen" was compared with that of the ligand "tmen", *i.e.*, its tetramethyl analog.

Many complexes of nickel(II) with ethylenediamine or its derivatives have been studied.[2-7] The structures of these complexes are sometimes square planar and sometimes octahedral. Although the principal factors which determine the structures are steric and electronic, the former seems to be predominant in a number of cases. Thus *N,N,N',N'*-tetramethylethylenediamine (tmen*) forms a dimeric chelate, $[Ni\ tmen(OH)]_2^{2+}$, instead of the bis-chelate $[Ni\ tmen_2]^{2+}$ in which a strong interligand repulsion occurs.[3] On the other hand, the combination of tmen and the ligand which has no bulky group around the donor atom can form stable mixed complexes, *i.e.*, [Ni tmen(AA)][1,8] or [Ni tmen X_2].[9]

In the present study, a ligand with more bulky groups on the donor *N* atoms, *N,N,N',N'*-tetraethylethylenediamine, which has been studied only little as a chelating agent, was chosen in order to obtain a series of new mixed chelates, Ni teen(β-dik)X, and the properties of the chelates were compared with those of the corresponding chelates of tmen.[1,8]

Experimental

Materials. Commercial "Extra Pure" products were used except for $Ni(ClO_4)_2 \cdot 6H_2O$ prepared from freshly prepared nickel carbonate and perchloric acid and purified by recrystallization.[10] Solvents for spectral measurements were of "Extra Pure" or "Spectro" grade. 1,2-Dichloroethane for electric conductivity measurements was redistilled and dehydrated.

Preparation of the Chelates. *[Ni teen dpm]$B(C_6H_5)_4$*, *[Ni teen aca]$B(C_6H_5)_4$* *and* *[Ni teen dbm]$B(C_6H_5)_4$*: Equimolar amounts of nickel nitrate and an appropriate β-diketone (10 mmol each) were dissolved in 30 ml of acetone. To this solution, 5 mmol of Na_2CO_3 and an excess of teen (slightly above 15 mmol) were added with stirring. After filtration, the resulting mixture was dried up with a rotary evaporator, and the solid obtained was dissolved in 1,2-dichloroethane and filtered in order to separate a white precipitate. When solid $NaB(C_6H_5)_4$ (15 mmol) was added to this solution, the color of the solution turned from green to red, a white powder being precipitated. This was found to be a mixture of $NaNO_3$ and $NaB(C_6H_5)_4$ from the IR spectra. After filtration, the solution was concentrated in a silica-gel desiccator. Brilliant red crystals were obtained from the solution (except in the case of [Ni teen aca]$B(C_6H_5)_4$) and recrystallized from the same solvent. It was difficult to crystallize the aca mixed chelate, but it could be obtained as a crystalline powder from the red solution by addition of ether in excess and cooling with stirring. The same procedure was repeated for purification.

[Ni teen dpm]ClO_4 *and* *[Ni teen bza]ClO_4*: Equimolar amounts of nickel perchlorate and an appropriate β-diketone (10 mmol each) were dissolved in 30 ml of acetone, and 5 mmol of Na_2CO_3 and 15 mmol of teen were added with stirring. After filtration, the solution was dried up with a rotary evaporator and the red solid product was dissolved in 1,2-dichloroethane and concentrated by blowing air stream. A red crystalline powder was finally obtained by addition of ether to the concentrated dichloroethane solution. In the case of dpm, [Ni teen dpm_2] was obtained from the filtrate as a by-product.

[Ni teen aca NO_3], *[Ni teen bza NO_3]* *and* *[Ni teen dbm NO_3]*: Equimolar amounts of nickel nitrate and an appropriate β-diketone(10 mmol each) were dissolved in 30 ml of acetone, and 5 mmol of Na_2CO_3 and an excess of teen (15 mmol) were added with stirring. The solution was concentrated by blowing air stream. The blue or green crystals obtained were recrystallized from 1,2-dichloroethane.

[Ni teen dpm_2], *[Ni teen aca_2]*, *[Ni teen bza_2]*, *[Ni teen dbm_2]*, *[Ni teen tfa_2]* *and* *[Ni teen hfa_2]*: Some of these chelates were obtained as by-products in the preparation of the mixed perchlorate chelates. In the case of tfa and hfa, however, only this type of chelate, [Ni teen $\beta\text{-dik}_2$], could be obtained as crystalline products. The general procedure of preparation of this type of chelate is as follows: 10 mmol of nickel sulfate or nitrate and 20 mmol of an appropriate β-diketone were dissolved in 50 ml of acetone, and 20 mmol of KOH suspended in 20 ml of methanol was added in order to neutralize the β-diketone. To the pale greenish blue solution in which $[Ni\ (\beta\text{-dik})_2(S)_2]$(where S=solvent molecule) was formed, an excess of teen(slightly more than 10 mmol) was added and then filtered. The solution was dried up with a rotary evaporator. After the crude blue or green solid obtained was dissolved in 1,2-dichloroethane, the filtrate was concentrated by blowing air stream until the crystals appeared. The crude product was recrystallized from 1,2-dichloroethane.

Physical Measurements. The electronic spectra of the chelate solutions in the range 340—1500 nm were recorded with a Hitachi EPS-3T spectrophotometer using 10 mm silica cells. The reflection spectra of solid samples in the range 400—750 nm were recorded with a Shimadzu Multi-convertible D-40R spectrophotometer with a reflection

* Other abbreviations used in this article are: teen=*N,N,N',N'*-tetraethylethylenediamine, dpm=dipivaloylmethanate, aca=acetylacetonate, bza=benzoylacetonate, dbm=dibenzoylmethanate, tfa=trifluoroacetylacetonate, hfa=hexafluoroacetylacetonate, diam=diamine, β-dik= a β-diketonate ion, and AA=a bidentate ligand such as β-dik.

attachment and MgO disks for reference. Measurements were performed at room temperature, *ca.* 20 °C. The magnetic susceptibility was measured by the Faraday method with a Shimadzu Tortion Magnetometer MB-100 using $HgCo(NCS)_4$ and Mohr's salt as standard samples for calibration. The IR spectra of the solid chelates in the range 400—4000 cm^{-1} were recorded with a JASCO IR-G spectrophotometer by the Nujol-mull method. The electric conductivity measurements were carried out with a Yanagimoto Conductivity Outfit MY-7 using 1,2-dichloroethane as the solvent.

Results and Discussion

General Properties of the Chelates. The compositions of the chelates obtained as crystals or fine crystalline powders can be expressed with the general formula, Ni teen (β-dik) X, where X is an anion such as $B(C_6H_5)_4^-$, ClO_4^-, NO_3^- or β-dik. The results of chemical analyses and other properties are given in Table 1. As in the case of the tmen chelates,[1,8] these chelates can be classified into two types. Type 1 chelates with $B(C_6H_5)_4^-$ or ClO_4^- are diamagnetic and red,** while type 2 chelates with NO_3^- or one more β-diketone are paramagnetic (*ca.* 3 BM) and green or blue. These facts, together with the spectral features give the formula for each chelate (Table 1).

Table 1 also gives the electric conductivity data of the chelates in 1,2-dichloroethane solution. According to the criterion by Geary[11] who has pointed out that a 1 : 1 electrolyte in 1,2-dichloroethane shows a molar conductivity of *ca.* 23 $ohm^{-1}\,M^{-1}\,cm^2$, all type 1 chelates should be 1 : 1 electrolytes, while all the type 2 chelates are clearly non-charged complexes. This also supports the formulation of these chelates given in Table 1.

Electronic Spectra. Figures 1, 2, and 3 show the absorption spectra of the mixed chelates, Ni teen bza X, in various solvents and in solid state. The other mixed chelates also show similar spectra. Their spectral data are given in Table 2.

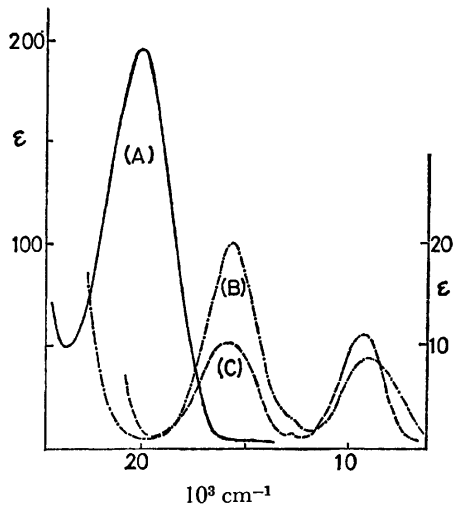

Fig. 1. Absorption spectra of the chelates of the bza series in 1,2-dichloroethane. (A), [Ni teen bza]ClO_4; (B), [Ni teen bza NO_3]; (C), [Ni teen bza_2]. The scale on the left refers to (A), and that on the right to (B) and (C).

The general features of these spectra are similar to those of the corresponding tmen chelates.[1,8] These data indicate that type 1 chelates in 1,2-dichloroethane (a very weakly coordinating solvent) and in solid state are all square planar,[12,13] while type 2 chelates in the same solvent have octahedral structures, in which not only a β-diketonate ion but also a nitrate ion seem to act as a bidentate ligand. They show that, in a strongly coordinating solvent like DMF, the square planar chelate cation [Ni teen β-dik]$^+$ in type 1 chelates are quantitatively converted into the octahedral solvated species [Ni teen β-dik S_2]$^+$ (S= solvent molecule); on the other hand, in a solvent with intermediate coordinating ability like acetone, the spectra indicate that these two species coexist in

** Weak paramagnetism, shown by two of them, might be due to impurities. In fact, type 1 chelates (especially the aca chelate; *cf.* Experimental) were difficult to purify, and even after repeated trials some of them could not be made as pure as most of the type 2 chelates.

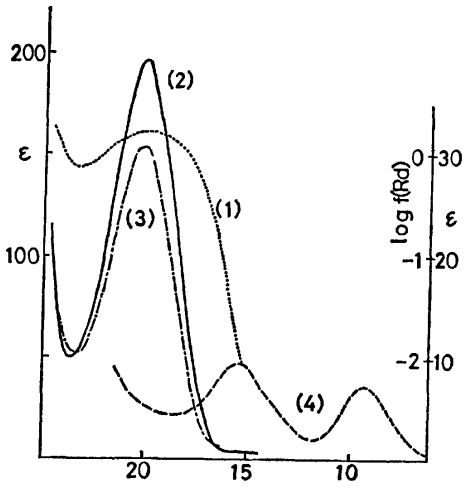

Fig. 2. Absorption spectra of the chelate, [Ni teen bza]ClO_4, in various organic solvents. (1), solid reflectance spectrum; (2), in 1,2-dichloroethane; (3), in acetone; (4), in DMF. The scale on the left refers to (2) and (3), and those on the right to (1) and (4).

equilibrium.***

$$[\text{Ni teen } \beta\text{-dik}]^+ + 2S \rightleftharpoons [\text{Ni teen } \beta\text{-dik } S_2]^+ \quad (1)$$

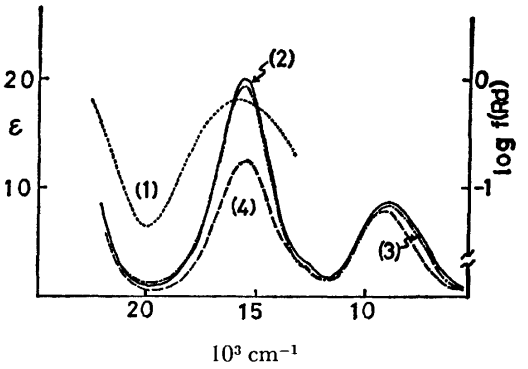

Fig. 3. Absorption spectra of the chelate, [Ni teen bza NO_3], in various organic solvents. Notations are the same as those in Fig. 2. The scale on the right refers to (1), and that on the left to the others.

As can be seen from Fig. 3 and Table 2, there is a small but noticeable difference between the spectrum of a nitrate chelate in 1,2-dichloroethane and that in DMF, and the outlook of the latter spectrum is similar to that of [Ni teen β-dik S_2]$^+$. These facts, together with the information from conductivity data and IR data, lead to the view that a nitrate chelate has the structure [Ni teen β-dik NO_3] both in solid state and in an inert solvent, while in a solvent with stronger

a) Apparent values which are probably somewhat higher than the true ones because of the partial overlap of this band with the strong ligand band (or CT band) in the UV.

*** The coexistence of these two species is more evident in the case of the tmen chelates (*cf.* Table 5), but a comparison of the data shows that the same situation takes place with the teen chelates.

coordinating power the following equilibrium is established:

$$[\text{Ni teen } \beta\text{-dik } NO_3] + 2S \rightleftharpoons [\text{Ni teen } \beta\text{-dik } S_2]^+ + NO_3^- . \quad (2)$$

Finally, the spectra of the bis-β-diketonate chelates show that they retain their octahedral structures in the solid state and also in any solvent. All the structural information correspond very closely to that obtained in the studies of the tmen chelates.[1,8]

Infrared Spectra. The IR spectra of all these chelates are naturally highly complicated. The discussion will be restricted to those of the perchlorate and nitrate anions. As to the perchlorate ion, the spectra show that it merely acts as a counter ion of the square planar cation [Ni teen β-dik]$^+$.[15] In the IR spectra of the nitrate chelates, it was not easy to assign the bands to a coordinated nitrate or the simple counter ion with sufficient accuracy.

Lever *et al.* pointed out the usefulness of the weak band at *ca.* 1750 cm^{-1} (a combination band of ν_1 and ν_4) as a criterion to distinguish whether a nitrate ion in a complex is a coordinating ligand or merely a counter ion.[14] From a large number of data, they concluded that, (1) when this band is not split, the nitrate ion is not bound in the complex, and acts only as a counter ion; (2) when it is split slightly (about 5 to 20 cm^{-1}), the ion acts as a monodentate ligand; and (3) when the splitting is much larger (about 30 to 50 cm^{-1}), the ion acts as a bidentate ligand.

According to this criterion, the nitrate ions in the mixed chelates [Ni teen β-dik NO_3] are apparently bidentate ligands. As an example, the IR data of a nitrate chelate, [Ni teen aca NO_3], are shown in Fig. 4, in which important bands are marked with arrows. They are at 1723 and 1774 cm^{-1}, respectively, and the splitting is 51 cm^{-1}. The corresponding bands of the other nitrate chelates [Ni teen bza NO_3] (B) and [Ni teen dbm NO_3] (C) are also shown.

In previous papers,[1,8] a number of mixed nitrate chelates [Ni tmen β-dik NO_3] were characterized and concluded to be octahedral and to contain a bidentate nitrate ion, by means of the d-d spectra, electric conductivities and IR spectra. Application of the criterion of Lever *et al.* to these tmen chelates confirmed that they contain the bidentate nitrate ion as expected, with a *ca.* 50 cm^{-1} splitting. The values are given in Table 3 together with those of the teen chelates. It seems that the formulation of the nitrate chelates of teen and tmen as [Ni diam β-dik NO_3] with a bidentate nitrate ion is well established.

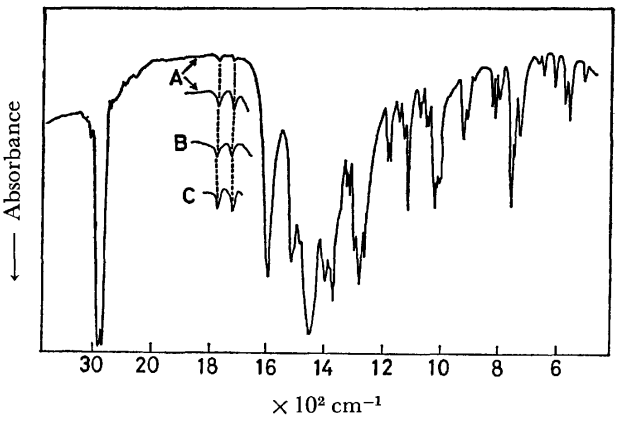

Fig. 4. IR spectra of the chelates; (A), [Ni teen aca NO_3]; (B), [Ni teen bza NO_3]; (c), [Ni teen dbm NO_3]. The data of the latter two are shown only in the range of 1700—1800 cm^{-1}.

[Ni teen dbm NO_3]	1768	1720	48

Comparison of the Mixed Chelates of Teen with Those of Tmen. There are great similarities between the teen chelates obtained in this study and the tmen chelates studied before. The differences between the two groups of chelates will now be considered in some detail.

Ease of Formation and Isolation of the Chelate: Although various mixed chelates containing teen and β-diketonate ions have been obtained, they are not so numerous as those of tmen. The ease of preparation of the mixed chelates is shown in Table 4 for a comparison of teen and tmen. The circle shows that the corresponding chelate can be more or less easily obtained, the triangle that the chelate cannot be isolated as solid crystals, although there is definite spectral evidence that it actually exists in solution, and the cross that the chelate cannot be obtained and that there is no evidence of its formation even in solution. It can be seen that the formation of the teen chelates is, in general, more difficult than that of the tmen chelates.

Ligand Field Strength in the Chelates: Although the coordination ability of the ligand "teen" has not been studied thoroughly, it is easy to see that the steric hindrance caused by the ethyl groups in teen, which increases the interligand repulsion in its chelate, will be much more effective than that of the methyl groups in tmen.

In this connection, it is of interest to compare the apparent ligand field strength(1.f.s.) in the teen chelate with that in the tmen chelate. Spectral data of the square planar species, [Ni teen β-dik]$B(C_6H_5)_4$ in 1,2-dichloroethane are given in Table 2, and those of the corresponding chelates of tmen in Table 5. From a comparison of [Ni teen aca]$B(C_6H_5)_4$ and [Ni tmen aca]$B(C_6H_5)_4$, we see that the 1.f.s. in the former is slightly weaker than that in the latter. This probably reflects the increased steric hindrance of the ethyl

Table 4. Variations in the ease of formation and isolation of the mixed chelates, Ni diam β-dik X (A) is a mixed chelate containing teen as a diamine, (B) the corresponding tmen chelate. As to the remarks, ○ shows that the corresponding chelate could be obtained, △ the chelate could not be obtained but was found to exist in solution, × no chelate formation could be found in this study.

a) sh=shoulder

groups in the diamine, to which the decreased ease of formation of the teen chelates also seems to be related.

Relative Stability of the Square Planar Chelates: Another point of interest is that, in the case of a teen chelate of type 1, the equilibrium (1) established in a solvent of intermediate coordination ability is shifted remarkably to the left hand side, in comparison with that of the corresponding tmen chelate. This can be seen in acetone solutions, but a better comparison can be made with the use of a mixed solvent containing a large amount of an inert solvent and a little of a strongly coordinating solvent. Figure 5 shows the absorption spectra of [Ni teen dpm]$B(C_6H_5)_4$ and [Ni tmen dpm]$B(C_6H_5)_4$ in various mixtures of 1,2-dichloroethane and DMF. In both these cases, the intensity of the band at *ca.* 20000 cm^{-1} decreases with the increase of the DMF content in the solvent, but the decrease in the case of the tmen chelate is far more drastic, showing that the equilibrium in 1,2-dichloroethane,

$$[\text{Ni diam } \beta\text{-dik}]^+ + 2\text{DMF} \rightleftharpoons [\text{Ni diam } \beta\text{-dik } (\text{DMF})_2]^+$$

is shifted more strongly to the right hand side. Approximate calculations with these data and also with the spectral data in acetone solution (Tables 2 and 5), lead to the values in Table 6.†

We see that the apparent value of the equilibrium constant, K, of Eq. 1 in acetone increases *ca.* 20—40 times with the change of [Ni teen β-dik]$^+$ to their

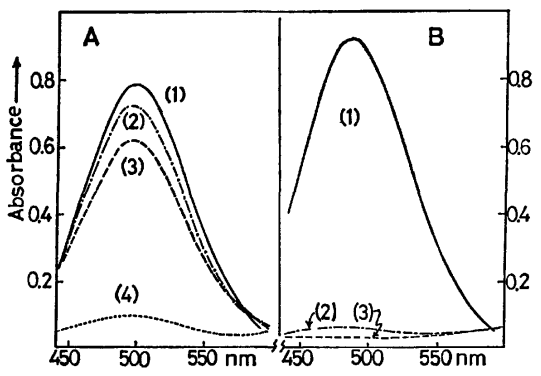

Fig. 5. Absorption spectra of the chelates, [Ni diam dpm]$B(C_6H_5)_4$, dissolved in various $C_2H_4Cl_2$-DMF mixtures. A and B show the case of the teen chelate (conc. 6.1×10^{-3} M) and that of the tmen chelate (conc. 5.9×10^{-3} M), respectively. The content of DMF in the solvent is: 0%; (2), 0.5%; (3), 1%; (4), 5%.

† In these calculations it was assumed that the true molar extinction coefficient of the band at *ca.* 20000 cm^{-1} of a square planar chelate is, in any solvent, practically equal to that in 1,2-dichloroethane.

TABLE 6. PERCENTAGE OF [Ni teen β-dik]$^+$, REMAINING UNSOLVATED IN THE EQUILIBRIUM MIXTURES PRODUCED BY DISSOLVING TYPE 1 CHELATES OF teen IN ACETONE AND IN 1,2-DICHLOROETHANE CONTAINING 1% DMF

The value for [Ni tmen dpm]$B(C_6H_5)_4$ in the mixed solvent ($C_2H_4Cl_2$ + 1% DMF), obtained from Fig. 5, is very low (<4%).

Chelate	Acetone[a)]	$C_2H_4Cl_2$ + 1%DMF
[Ni teen dpm]$B(C_6H_5)_4$	100(49)	82
[Ni teen dpm]ClO_4	100(38)	75
[Ni teen aca]$B(C_6H_5)_4$	82(21)	65
[Ni teen bza]ClO_4	78(9)	46
[Ni teen dbm]$B(C_6H_5)_4$	83(8)	29

a) The values for the corresponding tmen chelates are given in parentheses.

tmen analogs. It can also be seen that the K values among the teen chelates increase in the order dpm→aca→bza→dbm, which is just the same as that observed among the tmen chelates.[1)]

As regards this remarkable difference between the chelates of teen and those of tmen, it is natural to expect that the more bulky ethyl groups on teen hinder the coordination of the solvent molecules at the 5th and 6th coordinating sites of the square planar chelate cation more strongly than the smaller methyl groups on tmen. The fact that the chelates [Ni diam β-dik $(H_2O)_2$]ClO_4, which could be easily obtained with tmen and a number of β-dik, could not be obtained at all with teen (*cf.* Table 4) may also be due to the same kind of steric effect.

All the perceptible differences between the chelates of teen and those of tmen are thus ascribed to the difference in magnitude of the steric effect caused by the *N*-alkyl groups of their ligands. The observed differences are, however, rather small, and the formation of octahedral complexes is by no means made impossible with the use of teen in spite of the great increase in the bulkiness of these groups.

The authors wish to thank Prof. Hiroshi Kakisawa, Tokyo Kyoiku University, for permission to use the Hitachi EPS-3T Spectrophotometer in his laboratory, and also Dr. Ichiro Fujita and Mrs. Etsuko Fujita, Georgia Institute of Technology, for kindly supplying a sample of teen from Aldrich Chem. Co., Milwaukee. This work was financially supported by a grant-in-aid from the Ministry of Education.

Diprotonated Bimetallic Complex between Copper(II) with 3,3′-Bis[*N*,*N*-bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein*

Mutsuo YAMADA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 25, 1975)

The solution chemistry for complexes of copper(II) with 3,3′-bis[*N*,*N*-bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein(XO) is studied by spectrophotometric measurement. Copper(II) is found to form a diprotonated bimetallic complex with XO in weakly acidic medium. Stability constant and molar absorptivity of the complex are evaluated to be log $K_{Cu_2LH_2}=9.86\pm0.05$ and $\varepsilon_{574nm}=3.73\times10^4$ M^{-1} cm^{-1}, respectively, at 25.0 °C and $I=0.1$ M. Thermodynamic parameters are calculated to be $\Delta H=4.3$ kcal·mol^{-1} and $\Delta S=64$ eu at 25.0 °C and $I=0.1$ M.

Xylenol Orange forms mononuclear 1 : 1, 1 : 2 or binuclear 2 : 2 complexes with various metal ions in solution.[1] Nickel(II) and cobalt(II) have been found to form mononuclear monoprotonated 1 : 1 complexes[2] in the presence of an excess of the metal ions to the ligand at pH 3.5—4.4.

However, copper(II) does not form mononuclear 1 : 1 complex but bimetallic 2 : 1 complex in the presence of an excess of the metal ion to the ligand at pH 3.5—5.5. In the present paper the anomalous behavior in copper(II) complex of XO is discussed in terms of the degree of protonation, the stability constant and the thermodynamic parameters of the bimetallic 2 : 1 complex. The structure of the complex is estimated, whose structure would give an important suggestion to the reaction mechanisms of complexation between XO and metal ions.[3,4]

Experimental

Materials. *Reagents*: All the chemicals used were of analytical grade, unless otherwise specified. Water was deionized and distilled.

Xylenol Orange: The acid from of the "*pure*" specimen[5,6] was used. 1.0×10^{-3} M stock solution of XO was prepared by weight. The solution was very stable in a refrigerator.

Copper(II) Perchlorate: Copper(II) perchlorate was prepared from recrystallized copper(II) chloride by heating with a small excess of perchloric acid. Perchlorate was further recrystallized twice from water. The solution was standardized by EDTA titration using PAN as indicator.

Sodium Perchlorate: The purified salt[2] was heated at *ca.* 200 °C to prepare anhydrous salt. The concentration of the solution was determined by weight. The ionic strength of the solution was adjusted to 0.1 M with the sodium perchlorate.

Buffer Solutions: They were prepared from 1.0 M acetic acid and 1.0 M sodium acetate.

Measurements. The equilibria of complexation were measured with a Hitachi 139 spectrophotometer at 574 nm of the maximum absorption for copper(II) complex. Absorption spectra were recorded with a Hitachi recording spectrophotometer Model EPS-3T. A 1-cm glass or quartz cell was used.

The pH values of the solutions were measured with a Radiometer pH Meter 4d (Copenhagen) equipped with a glass electrode Type G 202B and a saturated calomel electrode Type K 401.

Temperature of the solution was maintained constant by circulating thermostated water from a Coolnics Model CTR-1B with a circulator CTE-1A.

Results

Absorption Spectra. Figure 1 shows the absorption spectra for the total concentrations of copper(II) and XO, $T_{Cu}=(0.40—1.20)\times10^{-4}$ M and $T_L=1.60\times10^{-5}$ M, at pH 4.308±0.005, at 25.0 °C and $I=0.1$ M.

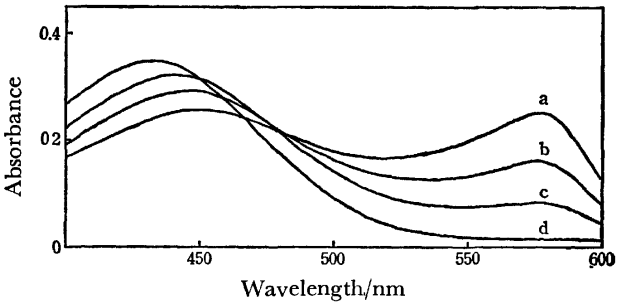

Fig. 1. Absorption spectra of copper(II) complex at various concentrations of copper(II).
T_{Cu}: a) 1.20×10^{-4} M, b) 2.00×10^{-5} M, c) 1.28×10^{-5} M, and d) 0 M. $T_L=1.60\times10^{-5}$ M. pH=4.308±0.005, $I=0.1$ M, 25.0 °C.

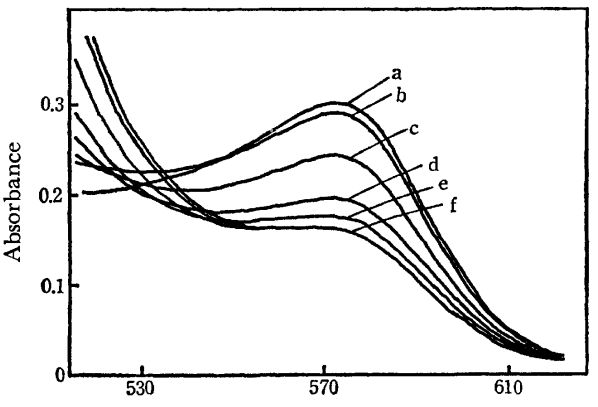

Fig. 2. Absorption spectra of copper(II) complex at various concentrations of XO.
T_L: a) 2.00×10^{-5} M, b) 3.00×10^{-5} M, c) 4.00×10^{-5} M, d) 6.00×10^{-5} M, e) 8.00×10^{-5} M, and f) 1.80×10^{-4} M. $T_{Cu}=4.00\times10^{-5}$ M. pH=4.284±0.024, $I=0.1$ M, 25.0 °C.

* Presented in part at the 25th Annual Meeting on Coordination Chemistry, Tokyo, October 8, 1975, Abstract, p. 161.

The absorption maximum of copper(II) complex is 574 nm, while those of nickel(II) and cobalt(II) are 584 nm.[2] Surprisingly, there is only a little increase in the absorbance at the absorption maximum with the increase of the copper(II) concentration compared with the case of nickel(II) and cobalt(II) complexes with XO.[2] Figure 2 indicates that a successive reaction occurs for $T_{Cu}=8.00\times10^{-5}$ M and $T_L=(0.20—1.80)\times10^{-4}$ M at pH 4.284±0.024 and at 25.0 °C and I=0.1 M.

The Composition of the Complex. The method of molar ratio at 574 nm at pH 4.308±0.005 indicates that the complex species contains 2 copper(II) and 1 XO and that another species of different composition exists as expected in Fig. 2. The curve exhibits an inflection at lower mole fractions of copper(II) (Fig. 3).

Degree of Protonation, Molar Absorptivity and Stability Constant of the Bimetallic Complex. Figure 4 shows pH-dependence of the absorbance of Cu_2XO at 574 nm for $T_{Cu}=2.00\times10^{-4}$ and $T_L=1.60\times10^{-5}$ M at pH 3.458—5.498 at 25.0 °C and I=0.1 M. Under these conditions the ligand and the complex exist predominantly in the form of LH_3^{3-} [7] and Cu_2XO, respectively. So the following equilibrium is postulated for the copper(II) complex. (Charges on the metal and the ligand ions are omitted.)

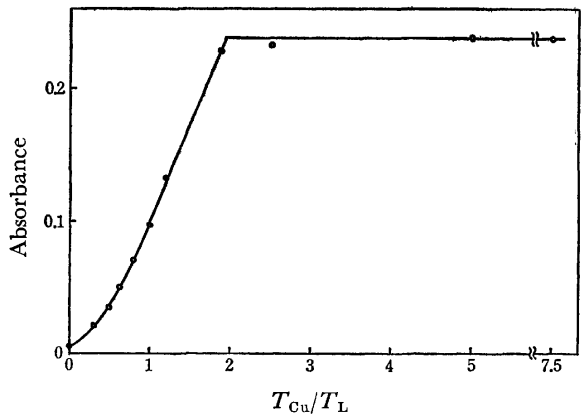

Fig. 3. Curve of molar ratio for copper(II) complex at 574 nm. pH=4.308±0.005, I=0.1 M, 25.0 °C.

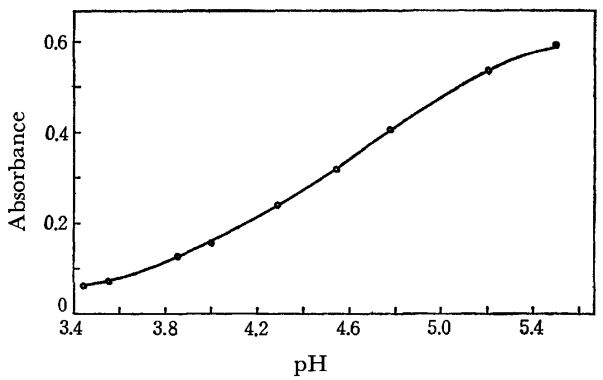

Fig. 4. pH-Dependence of the absorbance for copper(II) complex at 574 nm.
$T_{Cu}=2.00\times10^{-4}$ M and $T_L=1.60\times10^{-5}$ M. I=0.1 M, 25.0 °C.

$$2Cu + LH_3 \rightleftarrows Cu_2LH_i + (3-i)H \quad (1)$$

Applying the law of mass action, we obtain

$$K = [Cu_2LH_i][H]^{3-i}/[Cu]^2[LH_3] \quad (2)$$

and the absorbance of the solution is given by

$$A = \varepsilon_L[LH_3] + \varepsilon_1[Cu_2LH_i], \quad (3)$$

where ε_L and ε_1 are molar absorptivities of LH_3 and Cu_2LH_i, respectively. Analytical concentrations of copper(II) ion and XO are

$$T_{Cu} = [Cu] + 2[Cu_2LH_i] \quad (4)$$

$$T_L = [LH_3] + [Cu_2LH_i]. \quad (5)$$

Combining Eqs. 2—5, and rearranging one leads to

$$\frac{T_L}{A-\varepsilon_L T_L} = \frac{1}{\varepsilon_1-\varepsilon_L} + \frac{[H]^{3-i}}{(\varepsilon_1-\varepsilon_L)K\left\{T_{Cu}-\dfrac{2(A-\varepsilon_L T_L)}{\varepsilon_1-\varepsilon_L}\right\}^2} \quad (6)$$

Under the experimental conditions, Eq. 6 is approximated to Eq. 6′

$$\frac{T_L}{A-\varepsilon_L T_L} = \frac{1}{\varepsilon_1-\varepsilon_L} + \frac{[H]^{3-i}}{\varepsilon_1-\varepsilon_L K T_{Cu}^2} \quad (6')$$

The plot of $T_L/(A-\varepsilon_L T_L)$ against $[H]^{3-i}$ using the data obtained in Fig. 4 gives a straight line for i=2 for copper(II) complex (Fig. 5).

The complex is found to be the diprotonated bimetallic species Cu_2LH_2. The intercept gives 0.313×10^{-4} M cm. From this value and Eq. 6, the exact value 0.270×10^{-4} M^{-1} cm^{-1} is obtained by plotting $T_L/(A-\varepsilon_L T_L)$ against $[H]/\{T_{Cu}-2(A-\varepsilon_L T_L)/(\varepsilon_1-\varepsilon_L)\}^2$. ε_L is evaluated to be 300 M^{-1} cm^{-1} at 574 nm. The molar absorptivity at 574 nm is calculated to be $(3.70+0.03)\times10^4=3.73\times10^4$ M^{-1} cm^{-1} for Cu_2LH_2.

The stability constant of the complex Cu_2LH_2 is determined as follows,

$$2Cu + LH_2 \rightleftarrows Cu_2LH_2 \quad (7)$$

$$K = [Cu_2LH_2]/[Cu]^2[LH_2] \quad (8)$$

$$A = \varepsilon_L' C_L + \varepsilon_1[Cu_2LH_2], \quad (9)$$

where ε_L' and C_L are the apparent molar absorptivity and the total concentration of the free XO, respectively. Total concentrations of copper(II) and XO are

$$T_{Cu} = [Cu] + 2[Cu_2LH_2] \quad (10)$$

$$T_L = C_L + [Cu_2LH_2] \quad (11)$$

and

$$C_L = [LH_2] + [LH_3] + [LH_4]. \quad (12)$$

Combination of Eqs. 7 to 12 and a rearrangement lead to

$$K = \frac{(A-\varepsilon_L' T_L)\alpha}{(\varepsilon_1-\varepsilon_L')\left\{T_{Cu}-\dfrac{2(A-\varepsilon_L' T_L)}{\varepsilon_1-\varepsilon_L'}\right\}^2\left(T_L-\dfrac{A-\varepsilon_L' T_L}{\varepsilon_1-\varepsilon_L'}\right)} \quad (13)$$

and

$$\alpha = 1 + K_1[H] + K_1K_2[H]^2 \quad (14)$$

$$LH_2 + H \rightleftarrows LH_3; \quad K_1 = 10^{6.74}\ [7] \quad (15)$$

$$LH_3 + H \rightleftarrows LH_4; \quad K_2 = 10^{2.85}\ [7] \quad (16)$$

The result is summarized in Table 1. The stability

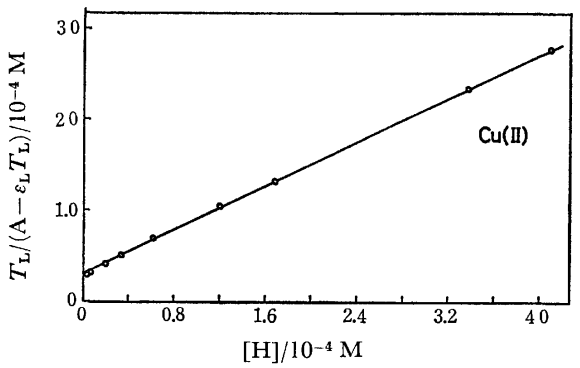

Fig. 5. Plot of $T_L/(A-\varepsilon_L T_L)$ for copper(II) complex against $[H]^{3-i}$ for $i=2$.

Table 1. Stability constant and molar absorptivity for Cu_2LH_2

pH	$-\log[H]$	$\log K$
3.458	3.377	9.91
3.552	3.471	9.89
3.854	3.773	9.86
4.000	3.919	9.83
4.288	4.207	9.81
4.548	4.467	9.81
4.778	4.697	9.84
5.204	5.123	9.91
5.498	5.417	9.85

av. $\log K=9.86\pm0.05$
$\varepsilon_{574\,nm}=3.73\times10^4\ M^{-1}\ cm^{-1}$

constant of the diprotonated bimetallic complex of copper(II) and XO is found to be $\log K=9.86\pm0.05$.

The thermodynamic parameters are spectrophotometrically determined for $T_{Cu}=8.00\times10^{-5}$ M and $T_L=1.60\times10^{-5}$ M and at 15.0, 20.0, 25.0 and 30.0 °C and I=0.1 M. Since the acid-association constants K_1's of XO at 15.0—30.0 °C are spectrophotometrically determined, the calculation of the stability constant $K_{Cu_2LH_2}$ is carried out at higher pH region where it is possible to neglect the concentration of LH^{2-1}. At the higher pH region, $\alpha=1+K_1[H]$.

$K_{Cu_2LH_2}$ is a little larger than 9.86. ΔH is determined to be 4.3 kcal·mol^{-1} by a graphical solution[8] of the following equation

$$\log K = (\Delta S-\Delta H/T)/2.303R$$

and

$$\Delta S_{298} = (\Delta H-\Delta G)/T$$
$$= (4.3+14.7)\times10^3/298$$
$$= 64\ \text{e.u.}$$

Discussion

Xylenol Orange forms mononuclear 1 : 1, 1 : 2 or binuclear 2 : 2 complexes with many metal ions but it is found that XO forms bimetallic 2 : 1 complex with copper(II) ion. Low stability constant of the 2 : 1 copper(II) complex implies the existence of a larger-membered chelate ring than five. Formation of the diprotonated complex species indicates that amine protons of XO do not dissociate but a phenolic proton dissociates on complexation. It is also supported by the fact that a bathochromic shift upon complexation between XO and metal ions is due to the dissociation of a phenolic proton.[9] Furthermore, the endothermicity of the complexation of copper(II) with XO ($\Delta H=4.3$ kcal·mol^{-1}) strongly supports that copper(II) atoms do not coordinate to the nitrogen atoms.[10]

As the amine proton does not dissociate in the experimental pH region, the copper(II) atom in the complex could not be in a plane of three oxygen atoms—a phenolic or a quinoidal and two carboxylic oxygen atoms, but would be a little above or below the plane. Therefore, the copper(II) atom could not take an octahedral or a square-planar structure but a more or less distorted tetrahedral structure.

The structure of Cu_2LH_2 with four nine-membered rings and two eight-membered rings is proposed (Fig. 6). The resonance stabilization due to the bimetallic structure of the complex may contribute to the stability of such structure.

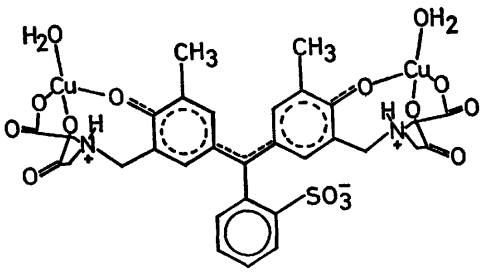

Fig. 6. Proposed structure of Cu_2LH_2 complex.

Despite of large-membered chelate rings, a large positive entropy 64 eu is obtained. It may be due to the reduction of the ordered arrangement of the inner-sphere water molecules around the reactant ions by the formation of the uncharged bimetallic species. The decrease in the coordination number of copper(II), presumably from six to four, also contributes to the positive entropy. The increase in entropy is sufficiently large to overcome the endothermicity of this complexation reaction.

The formation of large chelate rings is also kinetically supported:[4] The overall rate constant of the complex formation of copper(II) with XO is smaller approximately by 3 orders of magnitude than the value expected from the normal substitution reactions of aqua copper(II) ion. Therefore, the complexation reaction of copper(II) ion and XO is a sterically controlled substitution reaction.

The bimetallic diprotonated species Cu_2LH_2 shows reversible thermochromism at pH about 4. The aqueous solution containing $T_{Cu}=2.0\times10^{-4}$ M and $T_L=1.60\times10^{-5}$ M is orange at room temperature and changes reddish purple at about 70 °C and green at 77 K. The phenomena relate to the configurational change around the copper(II), which affects in turn the π-electron system of the coordinated XO. The thermochromism of Cu_2LH_2 would provide a support

for the proposed structure of bimetallic complex Cu_2LH_2. The further details are now in progress.

The author should like to thank to Professor M. Fujimoto for general discussion and reading this manuscript and to Professor T. Ito for the valuable discussion on the configuration of the complex Cu_2LH_2.

Derivatographic Studies on Transition Metal Complexes. XVII.[1] Solid-phase Deaquation-anation of Some Optically Active Aqua-cobalt(III) Complexes[2]

Ryokichi TSUCHIYA, Masakatsu OMOTE, Akira UEHARA, and Eishin KYUNO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received December 17, 1975)

Stereochemical changes involved in the solid-phase deaquation-anation of the following optically active aqua-cobalt(III) complexes were investigated: $(+)_{546}$-*cis*-$[Co(H_2O)_2en_2]X_3\cdot 2H_2O$ (X=Cl or Br), $(+)_{589}$-*cis*-$[CoCl(H_2O)en_2]Cl_2\cdot H_2O$, $(-)_{589}$-*cis*-$[CoCl(H_2O)en_2]Br_2\cdot H_2O$, $(+)_{589}$-α-$[CoCl(H_2O)trien]Cl_2\cdot H_2O$ and $(+)_{589}$-α-$[CoCl(H_2O)trien]Br_2\cdot 2H_2O$, where en and trien denote ethylenediamine and triethylenetetramine, respectively. Thermal deaquation-anation processes for each complex were observed with a derivatograph, polarimeter, and UV and CD spectrophotometers. *cis*-$[Co(H_2O)_2en_2]Cl_3\cdot 2H_2O$ was converted into *cis*-$[CoCl(H_2O)en_2]Cl_2$ at first and then *cis*-$[CoCl_2en_2]Cl$; the stereochemical changes during the first step and the second step were found to be retention and racemization, respectively. In contrast, a predominant stereochemical change involved in the deaquation-anation of *cis*-$[Co(H_2O)_2en_2]Br_3\cdot 2H_2O$ was *cis*-to-*trans* isomerization. The deaquation-anation of *cis*-$[CoCl(H_2O)en_2]Cl_2\cdot H_2O$ and *cis*-$[CoCl(H_2O)en_2]Br_2\cdot H_2O$ was found to be accompanied by racemization and by greater parts of *cis*-to-*trans* isomerization, respectively. However, both α-$[CoCl(H_2O)trien]Cl_2\cdot H_2O$ and α-$[CoCl(H_2O)trien]Br_2\cdot 2H_2O$ undergo deaquation-anation with retention.

Werner found that *cis*- and *trans*-$[Co(H_2O)_2en_2]Cl_3$ evolve waters *in vacuo* or heating at 115 °C to yield the violet product *cis*-$[CoCl_2en_2]Cl$.[3] Chang and Wendlandt studied various *cis*- and *trans*-$[Co(H_2O)_2en_2]X_3$ complexes (X=Cl, Br or NO_3) from the standpoint of thermal deaquation-anation in the solid-phase. They suggested that the variation of the counter anions sometimes causes geometrical isomerization (*cis*↔*trans*) during the course of deaquation-anation.[4]

In addition to the isomerization, other stereochemical changes such as racemization should also be included during the course of deaquation-anation. However, no information has been obtained on such stereochemical changes, except for the report by Mathieu that (+)-*cis*-$[CoCl(H_2O)en_2]Cl_2$ racemizes when heated at 100 °C in the solid-phase.[5]

More detailed information would be obtained if optically active aqua-cobalt(III) complexes were employed for studying deaquation-anation.

We have undertaken to (1) derivatographically investigate the solid-phase deaquation-anation of three types of optically active aqua-cobalt(III) complexes: *cis*-$[Co(H_2O)_2en_2]X_3$, *cis*-$[CoCl(H_2O)en_2]X_2$ and α-$[CoCl(H_2O)trien]X_2$ (X=Cl or Br), and (2) obtain further information on the stereochemical changes during the course of deaquation-anation.

Experimental

Preparation of Complexes. $(+)_{546}$-*cis*-$[Co(H_2O)_2en_2]Cl_3\cdot 2H_2O$ (I) and $(+)_{546}$-*cis*-$[Co(H_2O)_2en_2]Br_3\cdot 2H_2O$(II) were prepared from optically active $[CoCO_3en_2]Cl$.[6]

Complex I, Found: C, 13.58; H, 6.86; N, 14.89%. Calcd for $[Co(H_2O)_2en_2]Cl_3\cdot 2H_2O$: C, 13.42; H, 6.71; N, 15.66%. $[\alpha]_{546}=300°$.

Complex II, Found: C, 10.27; H, 4.90; N, 11.42%. Calcd for $[Co(H_2O)_2en_2]Br_3\cdot 2H_2O$: C, 9.78; H, 4.94; N, 11.42%. $[\alpha]_{546}=200°$.

$(+)_{589}$-*cis*-$[CoCl(H_2O)en_2]Cl_2\cdot H_2O$ (III) and $(-)_{589}$-*cis*-$[CoCl(H_2O)en_2]Br_2\cdot H_2O$ (IV) were obtained through the resolution of racemic *cis*-$[CoCl(H_2O)en_2]Cl_2$ with ammonium (+)-3-bromocamphor-8-sulfonate ((+)-BCS).[7]

Complex III, Found: C, 15.10; H, 6.62; N, 17.43%. Calcd for $[CoCl(H_2O)en_2]Cl_2\cdot H_2O$: C, 14.94; H, 6.28; N, 17.43%. $[\alpha]_{589}=280°$.

Complex IV, Found: C, 11.87; H, 5.15; N, 13.32%. Calcd for $[CoCl(H_2O)en_2]Br_2\cdot H_2O$: C, 11.70; H, 4.88; N, 13.65%. $[\alpha]_{589}=-240°$.

$(+)_{589}$-α-$[CoCl(H_2O)trien]Cl_2\cdot H_2O$ (V) and $(+)_{589}$-α-$[CoCl(H_2O)trien]Br_2\cdot 2H_2O$ (VI) were prepared from α-$[CoCl_2trien]Cl$ and (+)-BCS.[8]

Complex V, Found: C, 20.68; H, 6.68; N, 15.95%. Calcd for $[CoCl(H_2O)trien]Cl_2\cdot H_2O$: C, 20.73; N, 16.12%. $[\alpha]_{589}=610°$.

Complex VI, Found: C, 16.08; H, 5.42; N, 12.68%. Calcd for $[CoCl(H_2O)trien]Br_2\cdot 2H_2O$: C, 15.78; H, 5.34; H, 5.34; N, 12.34%. $[\alpha]_{589}=590°$.

The other complexes, *cis*- and *trans*-$[CoCl_2en_2]Cl$,[9] $(+)_{589}$-*cis*-$[CoCl_2en_2]Cl\cdot H_2O$,[9] *cis*-$[CoBrClen_2]Br\cdot H_2O$,[10] *trans*-$[CoBrClen_2]NO_3$,[10] *cis*-$[CoBr_2en_2]Br\cdot H_2O$[11] and *trans*-$[CoBr_2en_2]NO_3$[11] were prepared in a manner similar to that described in literature, and they were used as the reference complexes.

Derivatographic Measurement. Measurements were carried out with a MOM Derivatograph Typ-OD-102 under constant flow of nitrogen at the heating rate of 1 °C/min. Five tenths grams of the samples was used in each run.

Spectral Measurement. Visible and UV, and CD spectra of the samples were recorded on a Hitachi Recording Spectrophotometer 322, and a JASCO Model DRD/UV-5 Spectrophotometer, respectively.

Polarimetric Measurement. Specific rotatory powers of the samples were measured with a JASCO Model DIP-SL Polarimeter.

Determination of the Ratios of cis- *to* trans-$[CoBr_2en_2]^+$ *and of* cis *to* trans-$[CoBrClen_2]^+$. The ratios of two isomers in the products after heating were determined spectrophotometrically in a manner similar to that reported previously.[12]

Results and Discussion

Diaquabis(ethylenediamine)cobalt(III) Complexes. $(+)_{546}$-cis-$[Co(H_2O)_2en_2]Cl_3\cdot 2H_2O$ *(I).*[13] Figure 1 shows the derivatogram of complex I, together with that of $(+)_{546}$-*cis*-$[Co(H_2O)_2en_2]Br_3\cdot 2H_2O$ (II). We see that the complex evolves three moles of water at first at 46—75 °C and then one mole of water at

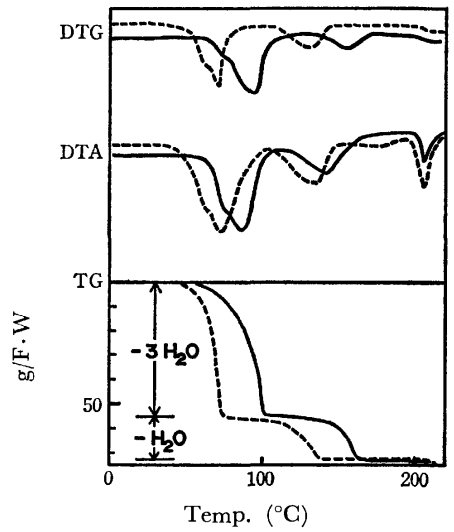

Fig. 1. Derivatograms of complexes I (----) and II (——).

112—138 °C. The initial red color of the complex turned red-violet at first and then violet in each dehydration step. The split DAT and DTG curves for the first water evolution step indicate that three moles of water are evolved in two steps.

Electronic spectra were measured in DMF solution to identify the red-violet and the violet products. Figure 2 shows the electronic spectra of complex I, the red-violet product, the violet product, and the reference complexes *cis*-$[CoCl(H_2O)en_2]Cl_2 \cdot H_2O$ and *cis*-$[CoCl_2en_2]Cl \cdot H_2O$. The numerical values for their absorption bands due to d-d transition are summarized in Table 1, together with those for the other series of complexes. Resemblance in the spectra between the red-violet product and *cis*-$[CoCl(H_2O)en_2]Cl_2 \cdot H_2O$ and between the violet product and *cis*-$[CoCl_2en_2]Cl \cdot H_2O$ proves that the original complex is converted successively into *cis*-$[CoCl(H_2O)en_2]Cl_2$ and then *cis*-$[CoCl_2en_2]Cl$.

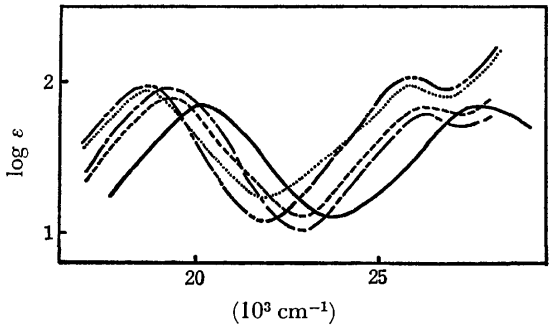

Fig. 2. Electronic spectra of complex I (——), the red-violet product (— — —), the violet product (……), and the reference complexes *cis*-$[CoCl(H_2O)en_2]Cl_2 \cdot H_2O$ (----) and *cis*-$[CoCl_2en_2]Cl \cdot H_2O$ (— — —).

CD spectra were measured to obtain information on the stereochemical changes of the complex during the course of deaquation-anation (Fig. 3). Figure 3(A) shows the CD spectra of complex I, the red-

(A): complex I (——), the red-violet product (----), $(+)_{589}$-*cis*-$[CoCl(H_2O)en_2]Cl_2 \cdot H_2O$ (----) and $(+)_{589}$-*cis*-$[CoCl_2en_2]Cl \cdot H_2O$ (-----); (B): complex II (——) and the first greenish violet product (----); (C): complex V (——) and the violet product (----); (D): complex VI (——) and the violet product (----).

violet product and the reference complexes $(+)_{589}$-*cis*-$[CoCl(H_2O)en_2]Cl_2 \cdot H_2O$ and $(+)_{589}$-*cis*-$[CoCl_2en_2]Cl \cdot H_2O$. All the CD spectra show positive signs in similar patterns, indicating that the red-violet product still remains in an optically active form, the configuration during the process *cis*-$[Co(H_2O)_2en_2]Cl_3 \cdot 2H_2O \rightarrow$ *cis*-$[CoCl(H_2O)en_2]Cl$ being retained. The measurements of CD spectra and specific rotatory powers demonstrate that the violet product is completely optically inactive.

The stereochemical changes during the deaquation-anation of complex I are summarized in Table 2; the first step *cis*-$[Co(H_2O)_2en_2]Cl_3 \cdot 2H_2O \rightarrow$ *cis*-$[CoCl(H_2O)en_2]Cl_2$ involves retention and the second step *cis*-$[CoCl(H_2O)en_2]Cl_2 \rightarrow$ *cis*-$[CoCl_2en_2]Cl$, racemization.

$(+)_{546}$-cis-$[Co(H_2O)_2en_2]Br_3 \cdot 2H_2O$ (II). We see from the TG curve of the bromide (complex II, Fig. 1) that the mass losses of the complex take place in a pattern similar to that of the corresponding chloride (complex I) except that the former decomposes at somewhat higher temperatures than the latter. Complex II evolves three moles of water at 55—100 °C and then one mole of water at 130—162 °C. The complex changes to greenish violet from red, no further change being observed.

From the measurements of the electronic spectra of the greenish violet products obtained at the first and the second steps, it was found that both the products have two absorption bands at 15270 and 18180 cm^{-1}; these bands quite resemble the first bands of *trans*-$[CoBr_2en_2]NO_3$ (15200 cm^{-1}) and *cis*-$[CoBr_2en_2]Br \cdot H_2O$ (18100 cm^{-1}), respectively. Both the greenish violet products seem to consist of a mixture of *cis*- and *trans*-$[CoBr_2en_2]^+$.

The ratios of *cis*- to *trans*-isomers in the product were determined spectrophotometrically in a manner similar to that reported previously.[12] It was found that both the products contain 23% *cis*- and 77% *trans*-isomers. In the case of the bromide, the *cis*-to-*trans* isomerization is a predominant stereochemical change involved in the deaquation-anation.

Such a *cis*-to-*trans* isomerization inevitably causes a considerable reduction in optical activity. However, CD spectral measurements should afford another information on the stereochemical changes. Figure 3(B) shows the CD spectra of complex II and the first and the second greenish violet products (the spectrum of the second product coincides with the base line). A small but clear positive sign is seen in the CD spectrum of the first product, but none was detected in that of the second product. This suggests that optical activities still remain in the first product, but not in the second product.

We see that the stereochemical change during the process *cis*-$[Co(H_2O)_2en_2]Br_3 \cdot 2H_2O \rightarrow$ *cis*- and *trans*-$[CoBr_2en_2]Br \cdot H_2O$ involves most parts of *cis*-to-*trans* isomerization with small portions of retention and the remaining change in the process *cis*- and *trans*-$[CoBr_2en_2]Br \cdot H_2O \rightarrow$ *cis*- and *trans*-$[CoBr_2en_2]Br$ involves racemization (Table 2).

Chloroaquabis(ethylenediamine)cobalt(III) Complexes.
$(+)_{589}$-cis-$[CoCl(H_2O)en_2]Cl_2 \cdot H_2O$ (III).[13]
Figure 4 shows the derivatogram of complex III, together with that of $(-)_{589}$-*cis*-$[CoCl(H_2O)en_2]Br_2 \cdot H_2O$ (IV). Complexes III and IV evolve two moles of water in analogous fashion to each other at 70—130 °C and 45—126 °C, respectively.

The original red-violet chloride (complex III) turned violet at the end of the liberation of two moles of water. Electronic spectral measurements showed that the $\tilde{\nu}_I$ and $\tilde{\nu}_{II}$ of the violet product appear at 18660 and 25570 cm^{-1}, these values being almost the

	Br	α-$[CoCl(H_2O)trien]Br_2\cdot 2H_2O$ (VI) (red-violet) $\xrightarrow[50-85\,^\circ C]{-2\,H_2O}$ α-$[CoCl(H_2O)trien]Br_2$ (red-violet) Step 1	Step 1: evolution of lattice water alone
		$\xrightarrow[85-124\,^\circ C]{-H_2O}$ α-$[CoBrCl trien]Br$ (violet) Step 2	Step 2: retention

same as those (18640 and 25520 cm^{-1}) of *cis*-$[CoCl_2en_2]Cl\cdot H_2O$ (Table 1). From the CD spectra and specific rotatory powers, it was confirmed that the violet product is completely optically inactive.

It can be concluded in the case of complex III that the deaquation-anation proceeds with racemization, the result agreeing with that observed in the second step of the deaquation-anation of complex I.

$(-)_{589}$-cis-$[CoCl(H_2O)en_2]Br_2\cdot H_2O$ (IV). The bromide turned greenish violet from initial red-violet at the final stage of the evolution of two moles of water. As seen from Table 1, the electronic spectrum of the greenish violet product gives two peaks at 18.42 and 15.77 cm^{-1}, each of which satisfactorily agrees with the first bands of *cis*-$[CoBrCl en_2]Br\cdot H_2O$ (18380 cm^{-1}) and *trans*-$[CoBrCl en_2]NO_3$ (15750 cm^{-1}). This indicates that the greenish violet product is in the mixed form of *cis*- and *trans*-isomers. From the spectrophotometrical determination of the ratios of *cis*- to *trans*-isomers, it was found that the product contains 35% *cis*- and 65% *trans*-isomers.

If the configuration of the remaining *cis*-isomer were retained, the product should be, more or less, optically active. However, the measurements of CD spectra and specific rotatory powers revealed that the product is completely optically inactive. It seems that the stereochemical change during the deaquation-anation involves major parts of *cis*-to-*trans* isomerization with small portions of racemization.

Chloroaquatriethylenetetraminecobalt(III) Complexes.[13] Figure 5 shows the derivatograms of complexes V and VI. The chloride (complex V) loses two moles of water at 38—105 °C, turning violet from red-violet. The $\tilde{\nu}_I$ and $\tilde{\nu}_{II}$ for the violet product are respectively 18480 and 26300 cm^{-1}, which coincide with the values (18520 and 26320 cm^{-1}) for α-$[CoCl_2 trien]Cl$. Figure

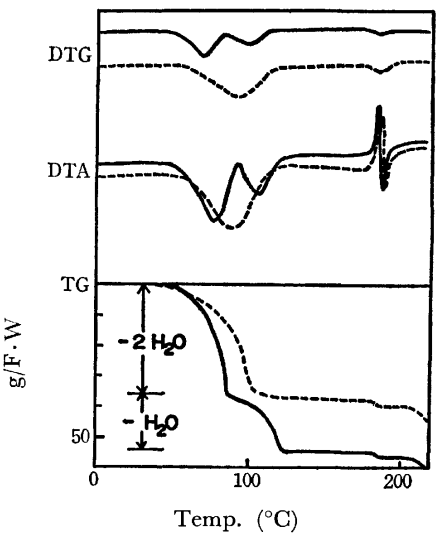

Fig. 5. Derivatograms of complexes V (----) and VI (——).

3(C) shows the CD spectra of the original chloride and the violet product. The CD spectrum of the violet product displays a positive sign similar to that of the original chloride. The measurement of the specific rotatory powers of the violet product indicates that the $[M]_D$ of the product is 2570° (Value of the reference complex α-[$CoCl_2$ trien]Cl: 2770° [8]). It can be concluded from these results that the stereochemical change during the deaquation-anation of complex V is retention.

On the other hand, the bromide (complex VI) evolves two moles of water at first at 50—85 °C and then one mole of water at 85—124 °C. The initial red-violet color of the complex remained unchanged at the first step, but changed to violet at the second step. The first step is probably simple evolution of lattice water and the second step may correspond to deaquation-anation. In the case of complex VI, the absence of the reference complexes such as α-[CoBrCltrien]$^+$ makes it impossible to identify the configuration of the violet product. However, the violet product may be regarded as optically active α-[CoBrCltrien]Br[14] for the following two reasons. Firstly, the spectrum pattern in the first band of the violet product was similar to that of α-[$CoCl_2$trien]Cl_2[8] (not shown) except that the $\tilde{\nu}_I$ of the violet product appears at slightly smaller wave number regions (18280 cm^{-1}) as compared with that (18520 cm^{-1}) of α-[$CoCl_2$trien]Cl. The slight shift may be due to the coordination of a Br^- ion as a consequence of the deaquation-anation. Secondly, the CD spectral changes observed during the deaquation-anation of complex VI are in the same tendency as that found in complex V (Fig. 3(C) and (D)). It might be concluded that the configuration is retained during the course of deaquation-anation.

LeMay and Bailar studied the solid-phase racemization of optically active *cis*-[Cr or $CoCl_2en_2$]Cl·H_2O.[15] They tentatively interpreted the racemization in terms of an aquation-anation mechanism, but obtained no conclusive experimental evidence. Their suggestion may, however, be supported by our present result in which the racemization takes place in the process *cis*-[$CoCl(H_2O)en_2$]Cl_2→*cis*-[$CoCl_2en_2$]Cl.

In the case of the bromides II and IV of the en complexes, the predominant stereochemical changes during the deaquation-anation are *cis*-to-*trans* isomerization, but the case is not the same for the corresponding trien complex.

As for the trien complexes V and VI, the configuration is retained irrespective of the kind of counter anions throughout the deaquation-anation. The trien complexes differ from the corresponding en complexes (the en complexes contain two chelate rings) as regards the inclusion of three fused chelate rings. Owing to the presence of the three fused chelate rings, the configuration of the trien complexes may be more tightly fixed than that of the en complexes.

Copper(II) Chelates with Some Photographic Color Intermediates. Structure-Stability Relationships

Ahmad S. SHAWALI*, Ahmad E. EL-HILALY, and Mohammad S. EL-EZABY

Department of Chemistry, Faculty of Science, University of Kuwait, Kuwait

(Received November 10, 1975)

Acid dissociation constants, pK_1, of a series of benzoylacetanilides (Ia—i) have been determined potentiometrically in 50 vol% ethanol-water media at 30 °C. The stability constants, $\log \beta_1$, of their copper(II) chelates have also been determined. The effects of substituents on the anilide moiety of the ligand on the equilibria are discussed. The data were correlated by the equations: $pK_1 = 9.39 - 0.916\,\sigma$; $\log \beta_1 = 1.34\,pK_1 - 5.42$; and $\log \beta_1 = 7.20 - 1.44\,\sigma$. These results were taken to imply that the stabilization by dative metal-to-ligand π-bonding is not significant in copper(II)-benzoylacetanilide complexes.

Benzoylacetanilides (I) are useful intermediates in the color photographic process.[1] The chelating ability of these compounds to form stable metal chelates has recently elicited interest. Syntheses of iron(III),[2] copper(II),[3] oxo-vanadium(IV),[4] dioxo-molybdenum-(III),[5] dioxo-uranium(VI),[6] titanium(IV),[7] and chromium(III)[8] complexes, and reports concerning the estimation of titanium, vanadium, and mercury[4,7,9] are all that have appeared so far. In continuation of our studies on the relationship between structure and properties of I,[10,11] we have investigated the effects of substituents on the chelating tendency of a series of benzoylacetarylamides (Ia—i) towards copper(II). The acid dissociation constants and stability constants of these ligands and copper(II) cation were determined potentiometrically in 50 vol% ethanol–water solution at 30 °C ±0.1.

a, R=4-MeO	d, R=H	g, R=3-Cl
b, R=4-Me	e, R=3-MeO	h, R=3-Br
c, R=3-Me	f, R=4-Cl	i, R=4-EtOOC-

The object of the present work was, on one hand, to test the applicability of the Hammett equation to correlate the stability constants of copper(II)–benzoylacetanilide complexes, and on the other, to determine the extent of copper(II)-ligand π-bonding in such chelates.

Experimental

Benzoylacetanilides (Ia—i) were prepared by condensation of equimolecular amounts of ethyl benzoylacetate and the appropriate aniline as previously described.[12] The physical constants of the compounds prepared agreed with those in literature.[12,13] The stock solution of each anilide was prepared by dissolving the appropriate weight of the anilide in ethanol.

Absolute ethanol (BDH AnalaR reagent) was used. Carbonate-free sodium hydroxide solution was prepared in 50 vol% ethanol-water. A stock solution (0.1 M) copper nitrate was prepared in doubly distilled water and the copper (II) concentration was determined by standardization with EDTA using Eriochrome Black-T as indicator.[14] A solution of potassium nitrate (0.5 M) was also prepared in 50 vol% ethanol–water.

Titrations were performed using a Radiometer pH meter (type 63) equipped with a combined glass electrode type GK 2311C. The thermostated vessel of 50 ml capacity was tightly covered with a special electrode head through which passed the glass electrode, the nitrogen inlet tube and the delivery tube from the auto-burette. Auto-burette type Metrohm Herisau Multi-Dosimat E 415, accurate to ±0.01 ml was used.

In a typical titration, a 25 ml solution was prepared by mixing the appropriate volume of the ligand solution, 5 ml of potassium nitrate solution, and 0.25 ml of copper(II) solution, and the mixture was diluted to the mark. The concentration of copper(II) was always 1×10^{-3} M and those of ligand were 1×10^{-3} and 2×10^{-3} M. The solution was then transferred to the titration cell. A stream of nitrogen gas, traces of oxygen and carbon dioxide being removed by the method of Albert and Serjeant[15], was bubbled through. A complete titration consisted of successive addition of 0.05 ml or less of the titrant. One minute to two minutes after each addition, the pH meter reading was recorded. The titration was continued up to pH~7.00 in most cases. Visual precipitation occurred at pH~6.50. Each titration was repeated at least twice giving reproducibility of ±0.01 pH units along the titration. The pH readings were caliberated before, and checked after each titration using standard Radiometer buffers of pH's 4.01±0.01 and 7.00±0.01.

Calculated amounts of nitric acid and sodium hydroxide were used to check the pH in 50 vol% ethanol–water. A calibration curve was made and corrections for pH's were recorded.

Results and Discussion

The potentiometric titration curves for some of the ligands studied are illustrated in Fig. 1. No clear inflection was observed at all in the neutralization of these active methylene ligands. The acid dissociation constants of these reagents were calculated from the titration curves as follows. The pH meter readings (B) in 50 vol% ethanol–water solution are converted to hydrogen ion concentration $[H^+]$ by means of the widely used relation,[16] namely:

$$-\log [H^+] = B + \log U$$

where U is the correction factor. The value of $\log U$ in 50 vol% ethanol–water medium at 30 °C was determined and was found to be −0.35. The pK_1 value of the ligand HL was then calculated using the equation:

$$K_1 = \frac{(aT_L + [H^+] - [OH^-])[H^+]}{T_L(1-a) - [H^+] + [OH^-]}$$

* To whom all inquiries should be addressed.

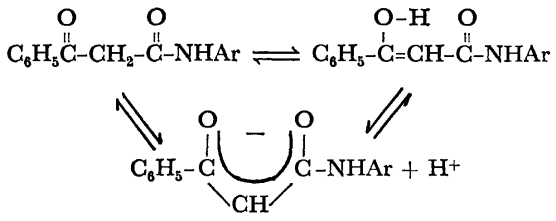
Ii	+0.45	8.98±0.04	6.64±0.05	−1.05

a) s=standard deviation. b) S_f=stabilization factor

where a is the ratio of the mole base added to mole of ligand. The results of the computations are given in Table 1.

The pK_1 values, so obtained, correspond to the overall dissociation constant of the two tautomers of benzoylacetanilide as given by the equation:



The data show that the magnitude of the pK_1 value of I depends on the nature of the substituent on the anilide ring. Electron withdrawing groups increase the acidity whereas electron-donating ones have an opposite effect. The relationship between the acidity constants, pK_1, and the Hammett substituent constant, σ, is shown in Fig. 2. It is obvious that the pK_1 values of the series studied are fairly correlated with σ constant. Using the least squares method, the values of the slope, ρ,

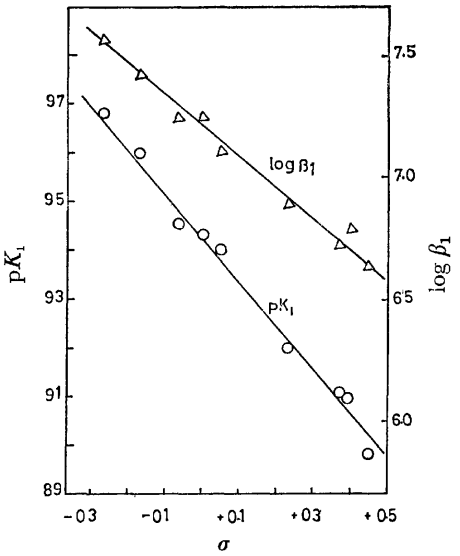


Fig. 2. Correlation of pK_1 and $\log\beta_1$ with Hammett substituent constant, σ.

and the intercept, pK_1, were found to be 0.916 and 9.39 respectively (correlation coefficient, r=0.989). The value of the reaction constant, ρ, so obtained, is somewhat higher than that (ρ=0.741) reported by Pelizzetti *et al.*[17] for related series of anilides. This difference is undoubtedly due to solvent effects.[18] The latter authors have evaluated the value of the reaction constant from measuring the dissociation constants spectrophotometrically at 25 °C in aqueous solutions containing less than 1% organic solvent.

The potentiometric titration curves for copper(II)–benzoylacetanilide systems (1 : 1; 1 : 2) are illustrated in Fig. 1. Similar curves were obtained for other systems investigated. The low solubility of the 1 : 2 Cu(II) chelates caused early precipitation during many of the titrations. Thus the stability constant, β_1, for the 1 : 1 complex species only was calculated and compared. This constant was calculated using the equation:

$$\beta_1 = \bar{n}/(1-\bar{n})L$$

where

$$L = ((1-a)T_L-[H^+])/([H^+]/K_1)$$

and

$$\bar{n} = T_L-(L([H^+]/K_1)+1))/T_M.$$

In these equations T_L and T_M correspond to the total ligand and metal ion concentrations used respectively, and $\bar{n}$ is the average number of ligand bound to the metal ion. The calculated values of $\log\beta_1$ are summarized in Table 1.

As the relation between Cu(II) and these ligands is regarded as a Lewis acid-base reaction, the $\log\beta_1$ value is plotted against the acid dissociation constant, pK_1, in Fig. 3. As shown, the $\log\beta_1$ values are linearly related to the pK_1 values. This implies that the stability of the chelates is mainly dependent upon the basicity, *i.e.*, the pK_1 value, of the ligand. A slope value of 1.34 of the straight line obtained (Fig. 3) was found as calculated by the least squares method. This result suggests that Cu(II) in the complexes studied does

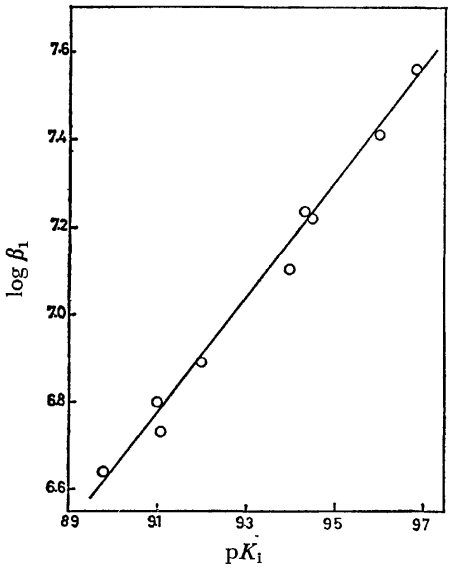

Fig. 3. Relation between acid dissociation constants of benzoylacetanilides, pK_1, and stability constants, log β_1, of their copper(II) chelates.

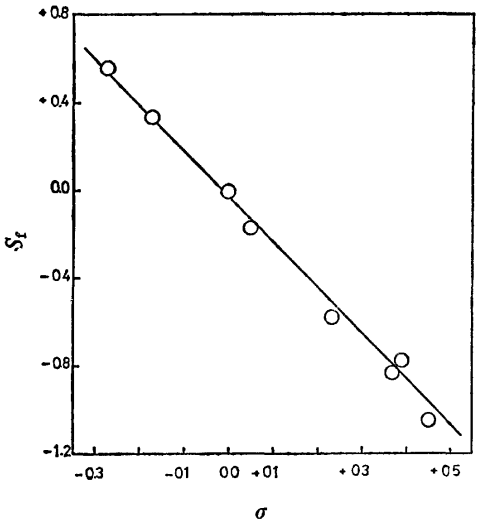

Fig. 4. Correlation of stabilization factor, S_f, with Hammett substituent constant, σ, for 1 : 1 complexes of copper(II) with benzoylacetanilides.

not function as π-electron donor, as it was suggested for copper(II) complexes with substituted benzoic acids.[19] If the 1 : 1 complexes of benzoylacetanilides with Cu(II) were stabilized by back-electron donation from the metal ion to the ligand, the slope of the plot of log β_1 *vs.* pK_1 should be less than unity.[20]

In order to confirm the foregoing conclusion, the stability constants, log β_1 (Table 1), were correlated with the Hammett substituent constant, σ. Figure 2 shows such a correlation. The equation of the straight line obtained is:

$$\log \beta_1 = 7.20 - 1.44\,\sigma.$$

The goodness of this correlation can be judged from the value of the correlation coefficient, r, of 0.955. This observed linear correlation indicates that the mode of chelation between Cu(II) and the ligand does not vary with the substituent; otherwise irregularities would have resulted. Again, the negative value of the reaction constant, *i.e.*, the slope of the plot, can only mean that the reaction studied is favored by electron donation to the metal. This explanation is further supported by plotting the so-called stabilization factor, S_f,[21] defined by the equation:

$$S_f = \log (\beta_1/K_1)_X - \log (\beta_1/K_1) = \rho\sigma$$

versus σ. As shown in Fig. 4, the plot is linear with a nagative slope; $S_f = -2.124\,\sigma$. This result is contrary to what has been reported for Cu(II) complexes of substituted benzoic acids, and for pyridine adducts of Cu(II) acetylacetonates.[21,22] Accordingly, it is not unreasonable to conclude that the explanation of the stabilization of Cu(II) complexes, based on the back donation of electrons from the metal to the ligand, does not seem likely in the Cu(II)–benzoylacetanilide chelates. This conclusion is also in agreement with the recently reported[3] spectral characteristics of the solid benzoylacetanilide complexes of copper(II).

Non-isothermal Studies of Adduct Molecules of Metallic Halides with Oxo Compounds in Solid State. II

N. Ray CHAUDHURI and S. MITRA

Inorganic Chemistry Laboratory, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received April 28, 1975)

Non-isothermal studies of several adduct molecules of metallic halides with oxo-compounds as the type $MX_2(THF)_y$ in solid state were carried out with a Derivatograph, where M is Mn(II), Co(II), Ni(II), Cu(II) or Cd(II), X is Cl^- or Br^-, THF is the abbreviated form of tetrahydrofuran and y is 0.25—2.00. These adduct molecules lost tetrahydrofuran in single or multiple steps upon heating. Thermally stable intermediate products were isolated and characterised by elemental analysis and IR spectral measurement. The activation energy for each step of decomposition of the adducts was evaluated from the analysis of TG, DTG, and DTA curves of the respective derivatograms. Enthalpy change was evaluated from DTA peak area and order of reaction was found to be unity for each step of decomposition. Thermal parameters for the above adducts were compared with those of the adducts of dioxane.

The works on the adduct molecules with tetrahydrofuran had been carried out by several workers.[1-13] They only prepared and characterised some adduct molecules of metallic halides with tetrahydrofuran. Rossmanith and Blaha[8,10] studied the thermal decomposition of the adducts of some rare earth bromides. On the other hand, Barnes and Duncan[12] carried out the thermal decomposition of tetrahydrofuran adducts of $CdCl_2$ and $CdBr_2$ with differential scanning calorimeter. They reported the value of enthalpy changes and decomposition temperatures of the adducts. But they did not evaluate the activation energy and order of reaction for the decomposition of the adducts.

In continuation of our previous work on dioxane,[14] the present paper deals with thermal decomposition of tetrahydrofuran adducts of some metallic halides to evaluate the activation energy for decomposition of the adducts from the results by the simultaneous TG, DTG and DTA measurements as well as the order of reaction (n) from TG curve, ΔH from DTA peak area and thermal stability from the first DTG peak temperature. This paper reveals a comparative picture on the thermal properties of the adducts which are similar in composition and also discusses the thermal properties of the adducts with tetrahydrofuran comparing with those of dioxane[14] studied by us.

Experimental

All the adducts were prepared by using the method described in the earlier work[14] and characterised by elemental analysis and IR spectral measurement. The tetrahydrofuran used was sufficiently purified according to the standard procedure.[15]

The following adducts of the metal halides were prepared

1. $MnCl_2 \cdot 0.50$ THF
2. $MnBr_2 \cdot 2.00$ THF
3. $CoCl_2 \cdot 0.50$ THF
4. $NiCl_2 \cdot 0.25$ THF
5. $NiBr_2 \cdot 0.75$ THF
6. $CuCl_2 \cdot 0.70$ THF
7. $CuBr_2 \cdot 1.00$ THF
8. $CdCl_2 \cdot 1.00$ THF
9. $CdBr_2 \cdot 1.00$ THF

where THF represents tetrahydrofuran.

A Paulik-Paulik-Erdey type MOM Derivatograph was used for thermal analysis. The particle size of the sample was 150—200 mesh. Heating rate was 1.5 °C/min. The volume of the sample in each run was nearly the same. Platinum crucible was used for these studies. All these experiments were conducted in static air.

Results

The adducts of $CuBr_2$, $CdCl_2$ and $CdBr_2$ have the similar composition to each other and lose one molecule of THF in a single step upon heating as indicated by their respective derivatograms in Fig. 1. While the composition of the adduct of $NiBr_2$ is not similar to that of the above adducts, it loses all molecules of THF in a single step as shown in Fig. 2. Derivatogram of $NiCl_2 \cdot 0.25$ THF in Fig. 3 shows a single step decomposition, whereas its DTA and DTG curves are indicative of double step decomposition. The adducts of $MnCl_2$ and $CoCl_2$ are similar in composition and they lose THF molecule in two steps passing through an intermediate as follows: $MCl_2 \cdot 0.50\ THF \rightarrow MCl_2 \cdot 0.25\ THF$ where M=Mn(II) or Co(II). From the comparison of the TG curve of these two adducts, the range giving a plateau in $MnCl_2 \cdot 0.25$ THF is slightly larger than that of $CoCl_2 \cdot 0.15$ THF. The adduct $CuCl_2 \cdot 0.70$ THF loses oxo-compound in three steps upon heating in the following way as seen in Fig. 2: $CuCl_2 \cdot 0.70\ THF \rightarrow CuCl_2 \cdot 0.50\ THF \rightarrow CuCl_2 \cdot 0.50\ THF/CuCl_2$. The TG curve of $CuCl_2 \cdot 0.70$ THF shows that decomposition of $CuCl_2 \cdot 0.50\ THF \rightarrow CuCl_2 \cdot 0.15$ THF is more rapid than the decomposition of $CuCl_2 \cdot 0.15\ THF \rightarrow CuCl_2$ though both the intermediate products *i.e.*, $CuCl_2 \cdot 0.50$ THF and $CuCl_2 \cdot 0.15$ THF are thermally unstable. The adduct $MnBr_2 \cdot 2.00$ THF loses tetrahydrofuran molecules in three steps as observed in Fig. 3 as follows: $MnBr_2 \cdot 2.00\ THF \rightarrow MnBr_2 \cdot 1.00\ THF \rightarrow MnBr_2 \cdot 0.88\ THF \rightarrow MnBr_2$. The intermediate $MnBr_2 \cdot 1.00$ THF is thermally stable, whereas $MnBr_2 \cdot 0.88$ THF is thermally unstable as observed in its thermogram. However, the existence of $MnBr_2 \cdot 0.88$ THF was verified by repeated analysis.

The decomposition of all the adducts gives endotherm in DTA. Temperature ranges of decomposition and DTG peak temperatures for the adducts are listed in the second and third columns in Table 1 respectively. Enthalpy change for each step of decomposition of the adducts was evaluated by the method of Sano[16] using copper sulfate pentahydrate as the standard and the values are also tabulated in the last column in Table 1. When the two DTA curves are too much overlapped with each other, the ΔH

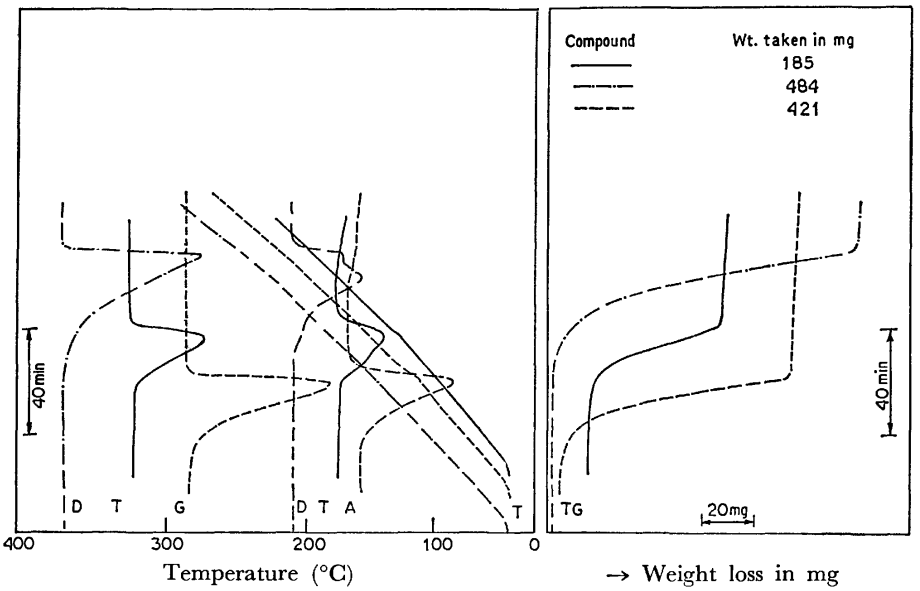

Fig. 1. The derivatograms for $CdCl_2 \cdot 1.00$ THF (——), $CuBr_2 \cdot 1.00$ THF (—·—) and $CdBr_2 \cdot 1.00$ THF (----).

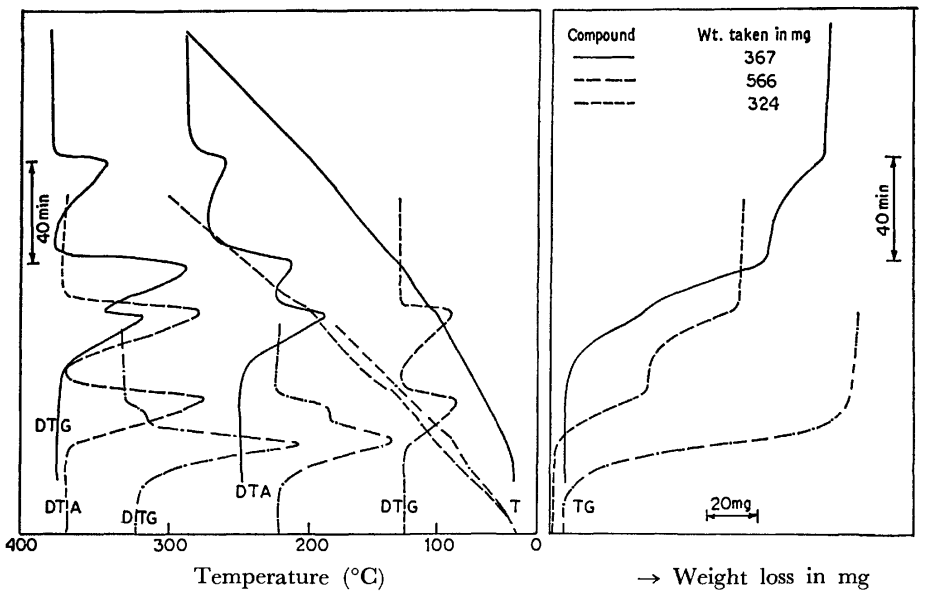

Fig. 2. The derivatograms for $CuCl_2 \cdot 0.70$ THF (——), $NiBr_2 \cdot 0.75$ THF (—·—) and $MnCl_2 \cdot 0.50$ THF (----).

values are evaluated from the overall area of the DTA peaks concerned.

The activation energy for each step of decomposition of the adduct molecules was evaluated from the analysis of the TG curves using Freeman and Carroll's[17] equation. The values are tabulated in the fourth column of Table 1 and the plots of

$$\Delta \log \frac{dw}{dt} \Big/ \Delta \log W_r \text{ vs. } [\Delta T^{-1} / \Delta \log W_r] \times 10^3$$

from TG curves are shown in Fig. 4.

The corresponding values were also evaluated from the analysis of the DTG curve using Dave and Chopra's[18] equation and from the analysis of DTA curve using Brochardt's[19] equation for the first order reaction. These values are tabulated in the fifth and sixth columns in Table 1 respectively. Arrhenius plots of $\log k$ *vs.* $T^{-1} \times 10^3$ from DTG and DTA curves are shown in Figs. 5 and 6 respectively.

IR spectra of the adducts were taken to ensure the presence of tetrahydrofuran molecule in the adduct.

Discussion

The adduct of $MnCl_2$ has been isolated as $MnCl_2 \cdot 1.50$ THF by some workers.[5,12] We have failed to isolate $MnCl_2 \cdot 1.50$ THF. The adduct of this salt with THF we isolated differs in composition from the corresponding adduct with dioxane (D) studied by us. The dioxane adduct of this salt lost oxo compounds in a single step upon heating, whereas $MnCl_2 \cdot 0.50$ THF loses tetrahydrofuran in double step passing

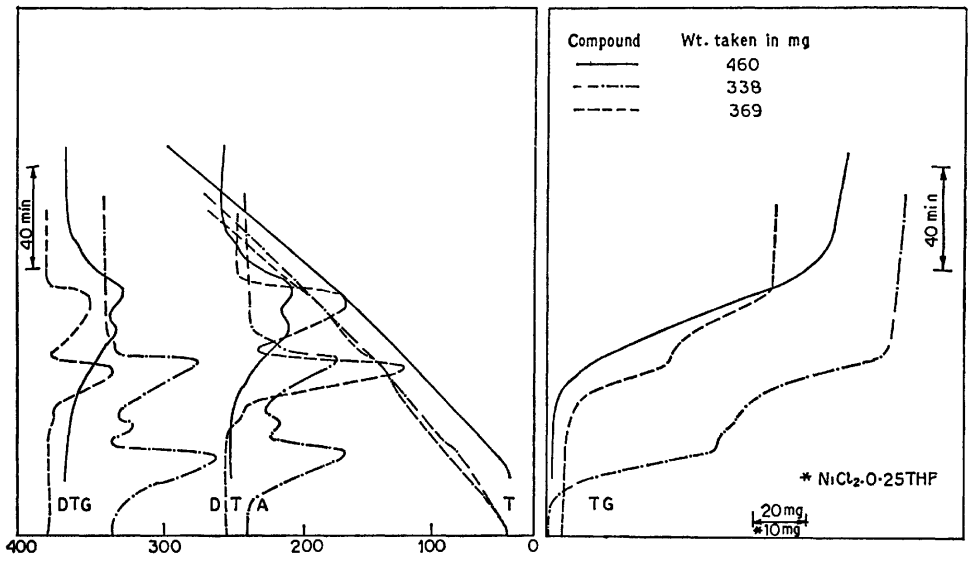

Fig. 3. The derivatograms for $NiCl_2 \cdot 0.25$ THF (——), $MnBr_2 \cdot 2.00$ THF (—·—) and $CoCl_2 \cdot 0.50$ THF (----).

L: Represents tetrahydrofuran. a) Indicates overall enthalpy change. b) Evaluation of activation energy was not possible due to overlapping of the corresponding curves. c) Value in the parentheses evaluated by Barnes and Duncan.

through a thermally stable intermediate $MnCl_2 \cdot 0.25$ THF. The thermal stability of $MnCl_2 \cdot 1.00$ D is greater than that of $MnCl_2 \cdot 0.50$ THF but smaller than that of $MnCl_2 \cdot 0.25$ THF. The value of activation energy and enthalpy change for the decomposition of both the steps of this adduct are high in comparison with that of the adduct with dioxane.

The composition of the adducts $MnBr_2 \cdot 2.00$ THF is similar to the corresponding adduct with dioxane but their nature of decomposition differs from each other. Dioxane adduct of the salt lost oxo compound in two steps passing through a thermally stable intermediate $MnBr_2 \cdot 1.00$ D. Whereas, the corresponding tetrahydrofuran adduct loses oxo compound in three steps passing through a stable intermediate $MnBr_2 \cdot 1.00$ THF like dioxane and then through an unstable intermediate $MnBr_2 \cdot 0.88$ THF. The thermal stability of $MnBr_2 \cdot 2.00$ THF is low in comparison with that of the corresponding adduct with dioxane. The activation energy for the first step of decomposition of the adduct with tetrahydrofuran is also low in comparison with that of the dioxane but the value of enthalpy of this adduct is high in comparison with that of the adduct with dioxane. The thermal stability of the

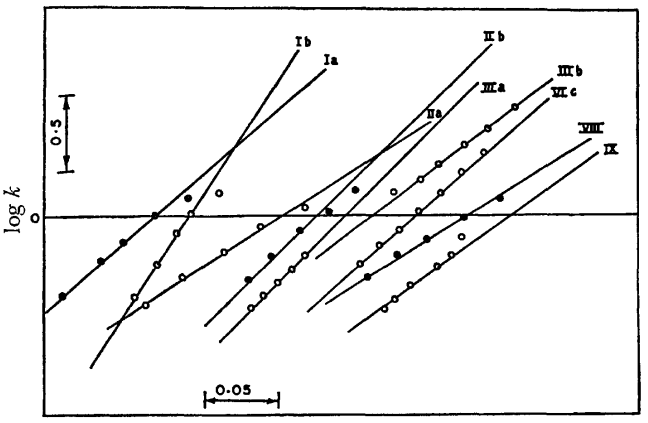

Fig. 6. Arrhenius plots of $\log k$ *vs.* $T^{-1} \times 10^3$, from DTA for the decomposition of $MnCl_2 \cdot 0.50\ THF \rightarrow MnCl_2 \cdot 0.25\ THF$ (Ia), $MnCl_2 \cdot 0.25\ THF \rightarrow MnCl_2$ (Ib), $MnBr_2 \cdot 2.00\ THF \rightarrow MnBr_2 \cdot 1.00\ THF$ (IIa), $MnBr_2 \cdot 0.88\ THF \rightarrow MnBr_2$ (IIb), $CoCl_2 \cdot 0.50\ THF \rightarrow CoCl_2 \cdot 0.25\ THF$ (IIIa), $CoCl_2 \cdot 0.25\ THF \rightarrow CoCl_2$ (IIIb), $CuCl_2 \cdot 0.15\ THF \rightarrow CuCl_2$ (VIc), $CdCl_2 \cdot 1.00\ THF \rightarrow CdCl_2$ (VIII) and $CdBr_2 \cdot 1.00\ THF \rightarrow CdBr_2$ (IX).

intermediate $MnBr_2 \cdot 1.00\ THF$ is also low in comparison with $MnBr_2 \cdot 1.00\ D$.

The adducts of $CoCl_2$ with tetrahydrofuran isolated by Kern[5] and also by Fowles *et al.*[13] were similar in composition *i.e.*, $CoCl_2 \cdot 1.50\ THF$. We isolated the adduct of the same salt with tetrahydrofuran as $CoCl_2 \cdot 0.50\ THF$ which is similar in composition to the adduct with dioxane isolated by us. The composition and the nature of decomposition of $CoCl_2 \cdot 0.50\ THF$ are similar to the adduct of $MnCl_2$ with this oxo compound. Both undergo decomposition through an intermediate $MCl_2 \cdot 0.25\ THF$, where M=Co or Mn. Although the adduct of the same salt with dioxane is similar in composition, it eliminated oxo compound in single step. The values of activation energy and enthalpy change for the decomposition of $CoCl_2 \cdot 0.50\ THF \rightarrow CoCl_2 \cdot 0.25\ THF$ are slightly low in comparison with that of the decomposition $MnCl_2 \cdot 0.50\ THF \rightarrow MnCl_2 \cdot 0.25\ THF$. The activation energy for the decomposition of $CoCl_2 \cdot 0.25\ THF \rightarrow CoCl_2$ is very low in comparison with that for the corresponding step of decomposition of adduct of $MnCl_2$ with THF, whereas the value of enthalpy change for the decomposition of $CoCl_2 \cdot 0.25\ THF$ is slightly higher than the corresponding adduct of $MnCl_2$ with dioxane. It is observed that the activation energy and enthalpy change for the decomposition of $CoCl_2 \cdot 0.50\ D \rightarrow CoCl_2$ is low in comparison with those for the decomposition of the corresponding adduct of $CoCl_2$ with THF though

$CoCl_2 \cdot 0.50$ D decomposes at a temperature higher than that of $CoCl_2 \cdot 0.50$ THF. This may be due to the fact that the adducts differ from each other in the nature of decomposition.

Kern[5] isolated the adduct of $NiCl_2$ as $NiCl_2 \cdot 2.00$ THF by starting from $NiCl_2 \cdot CH_3CN$ complex. Whereas we isolated the adduct as $NiCl_2 \cdot 0.25$ THF alone by starting from anhydrous nickel chloride. The composition of this adduct is similar to that of the intermediate product of the adducts of $MnCl_2$ and $CoCl_2$ with this oxo compound but differs from the adduct of the same salt with dioxane. The thermal stability and the values of activation energy and enthalpy change of decomposition of $NiCl_2 \cdot 0.25$ THF are lower than those of the decomposition of $MnCl_2 \cdot 0.25$ THF$\rightarrow MnCl_2$ and $CoCl_2 \cdot 0.25$ THF$\rightarrow CoCl_2$. Whereas the value of activation energy of decomposition of $NiCl_2 \cdot 1.50$ D$\rightarrow NiCl_2$ is close to the value obtained for the decomposition of $NiCl_2 \cdot 0.25$ THF though the value of enthalpy change for the decomposition of the latter is higher than that of the former.

We isolated the adduct of $NiBr_2$ with this present oxo-compound as $NiBr_2 \cdot 0.75$ THF, but the adduct of dioxane we isolated was simple in composition, though single step of decomposition is observed in both the adducts. This adduct molecule is thermally less stable than the adduct with dioxane. The value of activation energy of this adduct is also lower than that of the adduct with dioxane. Whereas, enthalpy change of $NiBr_2 \cdot 0.70$ THF is higher than that of the adduct with dioxane.

The adduct of $CuCl_2$ with THF was reported earlier by Kern[5] as $CuCl_2 \cdot 0.80$ THF. We isolated the adduct of $CuCl_2$ as $CuCl_2 \cdot 0.70$ THF. The dioxane adduct of $CuCl_2$ was reported earlier by us[14] as $CuCl_2 \cdot 0.75$ D which lost oxo compound in single step, whereas the adduct $CuCl_2 \cdot 0.70$ THF loses oxo compounds in three steps. The thermal stability of the adduct $CuCl_2 \cdot 0.70$ THF is lower than that of the adduct with dioxane we isolated. Whereas, the value of activation energy of this adduct is higher than that of the adduct with dioxane. The intermediate product $CuCl_2 \cdot 0.50$ THF shows similarity in composition with the adduct of $MnCl_2$ and $CoCl_2$ with this oxo compound. The thermally unstable $CuCl_2 \cdot 0.50$ THF decomposes through an intermediate $CuCl_2 \cdot 0.15$ THF which differs in composition from the intermediate product of the adduct of $MnCl_2$ and $CoCl_2$ with THF.

The composition of the adduct of $CuBr_2$ with THF is not similar to that of the adduct of the same salt with dioxane and $CuBr_2 \cdot 1.00$ D as an intermediate product of $CuBr_2 \cdot 2.00$ D corresponds to the adduct with this oxo compound isolated by us. The adduct $CuBr_2 \cdot 1.00$ THF decomposes at higher temperature than that of adduct with dioxane. The activation energy for the decomposition of this adduct is slightly lower than that of the adduct with dioxane but the corresponding enthalpy change is high in comparison with that of the dioxane adduct.

The adduct $CdCl_2 \cdot 1.00$ THF isolated by us is similar in composition to the adduct reported earlier.[12] The composition of dioxane adduct of $CdCl_2$ differs from the adduct of the same salt with tetrahydrofuran but both the adducts lose their oxo compounds in a single step upon heating. The thermal stability, activation energy and enthalpy change for decomposition of this tetrahydrofuran adduct is lower than those of the adduct with dioxane. Barnes and Duncan[12] investigated the thermal decomposition of $CdCl_2 \cdot 1.00$ THF with differential scanning calorimeter, where the heating rate was 8 °C/min. The initial decomposition temperature and peak temperature for this adduct reported by them were 105 and 147 °C respectively. Whereas we observe 80 and 125 °C as the initial decomposition temperature and peak temperature respectively, though the value of enthalpy change evaluated by us is very close to the value reported by them.

The tetrahydrofuran adduct of $CdBr_2$ reported earlier[12] is same in composition to the adduct isolated by us and also similar in composition to the corresponding adduct of dioxane.[14] Both the adducts lose their oxo compounds in a single step. This tetrahydrofuran adduct is thermally less stable than the corresponding dioxane adduct. Whereas, the values of activation energy and enthalpy change for the decomposition of adduct with tetrahydrofuran are very close to that of dioxane. Barnes and Duncan[12] also carried out the thermal decomposition of $CdBr_2 \cdot 1.00$ THF and reported 62 and 177 °C as initial and maximum decomposition temperatures respectively, whereas in our cases these temperatures are 36 and 108 °C respectively. But the value of enthalpy change evaluated by them is very close to the value reported by us.

Thermal stability of the adducts of the composition $MBr_2 \cdot 1.00$ THF where M=Mn(II), Cu(II) and Cd(II) owing to the difference of DTG peak temperature increases in the order Mn<Cd<Cu. The values of activation energy for the decomposition of the adducts of $CuBr_2$ and $CdBr_2$ are close. The values of enthalpy change for these two adducts are also same. Thermal stability of the adduct of $CdCl_2$ is higher than that of the corresponding bromide adduct. Whereas, the value of enthalpy change is higher in the case of bromide adduct than that of chloride, though the values of activation energy of both are close. The general comparative review shows that thermal stability of the adducts of dioxane is higher than the corresponding tetrahydrofuran adducts with a few exception in $CuBr_2 \cdot 1.00$ THF and the corresponding dioxane adduct.

The difference of the values of activation energy for the decomposition of adducts evaluated from TG, DTG and DTA curves is not too much. This shows that all the methods used for the evaluation of activation energy are standard. In general, the value of activation energy for the latter step of decomposition gives larger value than the former. This phenomenon is observed in the decomposition of adducts with tetrahydrofuran like the adducts with dioxane. However, there is exception in the value of activation energies for the first and second step of decompositions of $CuCl_2 \cdot 0.70$ THF like the values obtained for the second and third step of decomposition of $CoBr_2 \cdot 2.00$ D reported by us.

It is noticed that the value of enthalpy change for the decomposition of the adduct is related with the

composition of the adducts; it shows low value where the composition of the adduct is simple, *i.e.*, 12.7 kcal/mol for $CdCl_2 \cdot 1.00$ THF and high value where the composition of the adduct is not so simple, *i.e.*, 63.5 kcal/mol for $CoCl_2 \cdot 0.50$ THF. In general the latter decomposition gives larger ΔH value than the former one. But such tendencies are not observed in the decomposition of all the adducts.

The Participation of Solvents in the Reaction of Alkenes with Manganese(III) Acetate*

Masayoshi OKANO

Faculty of Integrated Arts and Sciences, Hiroshima University, Higashisendamachi, Hiroshima 730

(Received December 4, 1974)

1-Hexene and 2-methyl-2-pentene were heated with manganese(III) acetate at 100 °C in two mixed solvents of glacial acetic acid and acetic anhydride and of propionic acid and propionic anhydride in a nitrogen flow. γ-Acyloxy carboxylic acids, γ-lactones and saturated and unsaturated carboxylic acids were obtained, these oxidative products being considered to be adducts of acetic and propionic acids. Additional investigations were carried out on a mutual reaction of the oxidant and the solvents and on the thermal analysis of manganese(III) acetate. The reaction was explained by a solvent-participating free-radical mechanism.

The present author has reported on the formation of γ-butyrolactones and acetates in the reaction of *d*-limonene, *i.e.*, 1-methyl-4-isopropyl-1-cyclohexene, with manganese(III) acetate in acetic acid.[2] He has subsequently reported on the formation of saturated mono- and diacetates and certain kinds of allylic acetates in the heating of *d*-carvomenthene with a reagent in glacial acetic acid[3] and the formation of carboxymethyl adducts in the heating of *d*-limonene, *d*-carvomenthene, 1-methylcyclohexene, cyclohexene and 1-decene in glacial acetic acid containing catalytic amounts of potassium acetate.[4]

In addition, the formation of γ-lactones has been reported by Bush[5] in refluxing phenyl- and methyl-substituted ethylenes with manganese(III) acetate in a mixed solvent of acetic acid and acetic anhydride, and by Heiba[6] in refluxing certain alkenes, such as *trans*-β-methylstyrene, 1-octene, *trans*-4-octene, cyclooctene, styrene and *trans*-stilbene with manganese(III) acetate in glacial acetic acid containing potassium acetate. Allylic acetate has also been detected by Gilmore and Kasahara[7] in the reaction of cyclohexene, 1-methylcyclohexene, α- and β-methylstyrene. Heiba[6] has described that in these reactions, manganese(III) acetate reacts with olefins *via* a free-radical pathway leading to γ-butyrolactone. Whether or not the solvent participates in the reaction and the detailed mechanism of this reaction, however, have not yet been reported.

Results and Discussion

Characterization of Reaction Products. 1-Hexene and 2-methyl-2-pentene were separately heated with manganese(III) acetate dihydrate at 100 °C in two kinds of mixed solvents of acetic acid and acetic anhydride (solvent A) and of propionic acid and propionic anhydride (solvent P) in flowing nitrogen; the compounds listed in Table 1 were obtained as reaction products. The characterization of the products from the reaction of 1-hexene in solvent A depends upon the establishment of the chemical correlation for structually-known compounds as follows.

*γ-Lactone of 4-Hydroxyoctanoic Acid (**2**)*: The product with the lowest boiling point, $C_8H_{14}O_2$, from the reaction of 1-hexene in solvent A exhibited an IR absorption band characteristic of γ-lactone at 1775 cm^{-1}. Its reduction with lithium aluminum hydride furnished viscous 1,4-octanediol, which was converted into a methyl ester of a keto acid in a good yield by potassium permanganate oxidation followed by the treatment with diazomethane together with a small amount of the returned original γ-lactone. The keto ester was then subjected to Clemmensen reduction to give methyl octanoate. The structure of this compound is thus certain.

*3-Octenoic and 4-Octenoic Acids (**3**,**4**)*: An acidic substance isolated from the middle fraction of the reaction products, after being methylated, was separated into two unsaturated methyl esters by means of preparative gas chromatography, the quickly eluted one being identified as methyl 3-octenoate and the other as an unsaturated methyl ester containing a *trans*-disubstituted double bond, which gave methyl octanoate after catalytic hydrogenation. On the other hand, potassium permanganate oxidation of the mixed acidic substance furnished butyric and valeric acids. This evidence indicates the presence of 3-octenoic and 4-octenoic acids.

*4-Acetoxyoctanoic Acid (**1**)*: The product with the highest boiling point, $C_{10}H_{20}O_4$, was found to possess a carboxyl group (2670, 1710 cm^{-1}, 10.02 ppm) and an acetoxy group in its IR and NMR spectra. The compound was reduced *via* methylation with $LiAlH_4$ into 1,4-octanediol obtained in a similar treatment of **2**, and it was heated at 250 °C and converted into **2** and acetic acid in good yields together with a small amount of 3-octenoic and 4-octenoic acids.

The structures of the reaction products obtained in the other runs were determined based on spectral evidence and the structural analogy of the above-mentioned products.

Participation of the Solvent in the Reaction. Several kinds of products obtained from 1-hexene and 2-methyl-2-pentene in the manganese(III) acetate oxidation in two solvents are classified into acyloxy carboxylic acids, γ-lactones and unsaturated and saturated carboxylic acids; all the classes of these compounds were uniformly isolated in each run with the exception of acyloxy carboxylic acid which was not formed in the reaction of 2-methyl-2-pentene with solvent P. In these classes acyloxy carboxylic acids were a new class in the oxidation of alkenes with manganese(III) acetate. On the other hand, the reaction products from solvent A are considered as adducts of acetic acid, while those

* A part of the result has been preliminarily reported.[1]

Table 1. Products of the reaction of 1-hexene and 2-methyl-2-pentene with manganese(III) acetate

Solvent A (acetic acid and acetic anhydride)		Solvent P (propionic acid and propionic anhydride)	
	1-Hexene		
	Yield		Yield
(1) $CH_3(CH_2)_3CH(OAc)(CH_2)_2COOH$	61%	(6) $CH_3(CH_2)_3CH(OPr)CH_2CH(CH_3)COOH$	44%
(2) 	19%	(7) 	15%
(3) $CH_3(CH_2)_3CH{=}CHCH_2COOH$	5%	(8) unsaturated carboxylic acid	trace
(4) $CH_3(CH_2)_2CH{=}CH(CH_2)_2COOH$	8%		
(5) $CH_3(CH_2)_6COOH$	7%	(9) $CH_3(CH_2)_5CH(CH_3)COOH$	41%
	2-Methyl-2-pentene		
(10) 	14%		
(11) 	55%	(14) 	35%[a]
(12) 	22%	(15) 	38%
(13) 	9%	(16) 	27%[b]

a) This compound was separated into two diastereoisomers in relative amounts of 13 to 1. b) This compound was separated into two diastereoisomers in relative amounts of 5 to 1.

from solvent P are recognized to be adducts of propionic acid.

Furthermore, when the reaction of 1-methylcyclohexene with manganese(III) acetate was carried out in acetic acid containing acetic acid-^{14}C, radioactive γ-lactone[8,9] and acetates[9] were obtained. This indicates that the solvent participates in the reaction of alkenes with manganese(III) acetate.

Thermal Decomposition of Manganese(III) Acetate Dihydrate. The thermal analysis of manganese(III) acetate dihydrate was performed to determine the weight loss and differential thermal analysis curves, shown in Fig. 1 for a standard of silicone dioxide. In the weight loss curves about 50 to 100 °C corresponds to the loss of the two hydrated waters of manganese acetate molecule and about 100 to 130 °C to the loss of one acetic acid residue from the molecule. When manganese(III) acetate dihydrate itself was also heated in a flask by gradually raising the temperature in flowing nitrogen gas, violent evolution of carbon dioxide was observed at about 110 °C. Both results indicate that at the reaction temperature used in the present investigation manganese(III) acetate dihydrate decomposes into manganese(II) acetate *via* two steps: the first step is the release of the two hydrated waters, which may be promoted by the acetic anhydride, and the second is the rupture of one acetic acid residue.

Thermal Reaction of Manganese(III) Acetate Dihydrate in the Solvent. Manganese(III) acetate dihydrate was heated at 100 °C in solvent A and P without the

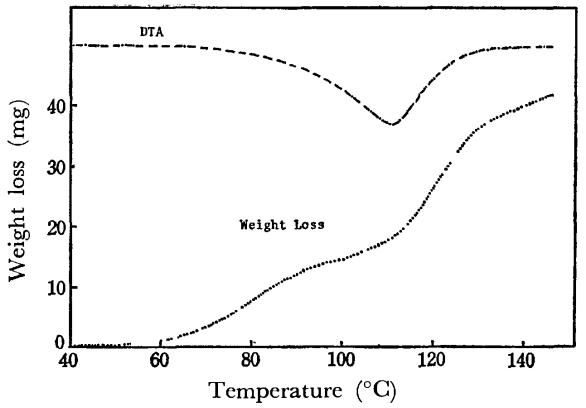

Fig. 1. Thermal analysis of $Mn(OAc)_3 \cdot 2H_2O$.*

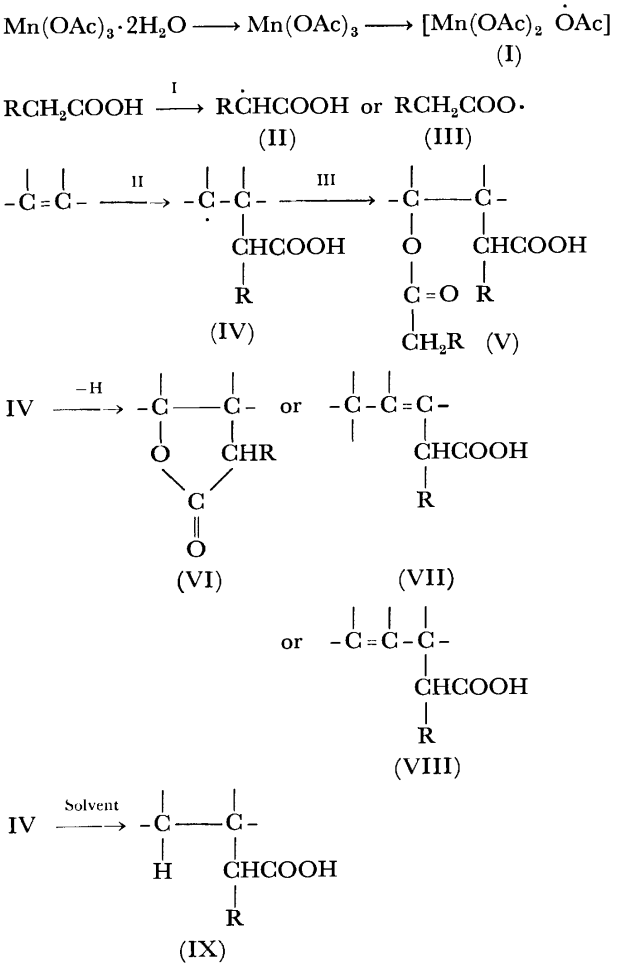
reactant, an appreciable amount of succinic acid and a trace of acetoxyacetic acid being isolated in the heating with solvent A, and *dl*-2-propionyloxypropionic acid and 2,3-dimethylsuccinic acids which consisted of *dl*- and *meso*-isomers in a ratio of 3 : 1 being obtained in the heating with solvent P. Together with the fact that, in the above reaction of alkene in solvent P, only propionic acid adducts were isolated, this result demonstrates that $\cdot CH_2COOH$, $CH_3COO\cdot$, $\cdot\dot{C}HCOOH$



Sceme 1. Reaction mechanism.

* 104.8 mg of $Mn(OAc)_3 \cdot 2H_2O$ was used.

and $CH_3CH_2COO\cdot$ radicals were formed with the participation of the solvents in the manganese (III) acetate reaction.

Reaction Mechanism. On the basis of this evidence, the reaction of alkenes with manganese(III) acetate in the solvent may be explained by the reaction mechanism presented in Scheme 1.

For the first time, hydrated water of manganese(III) acetate is abstracted by acid anhydride. The anhydrous molecule of manganese(III) acetate thus produced is thermally decomposed releasing an acetoxy radical, which should be stabilized within the coordination sphere of the manganous ion. This radical does not react directly with the substrate, but with a surrounding molecule of the solvent to furnish an alkyl carboxymethyl(II) or an acyloxy(III) radical.

The addition of II to a double bond of alkene gives a radical intermediate (IV), which may be immediately stabilized by the following reactions: 1) the addition of an acyloxy radical(III) to give γ-acyloxy carboxylic acid (V), 2) the release of a hydrogen atom to give γ-lactone (VI) and unsaturated carboxylic acid (VII or VIII), and 3) the abstraction of a hydrogen atom from the solvent to give saturated carboxylic acid (IX).

Experimental

Analytical and preparative GLC were carried out on a Hitachi 023 gas chromatograph equipped with a thermocouple detector in connection with a stainless steel column (3 mm in diameter) which was packed with Celite 545 (40—60 mesh) impregnated with 20% PEG-20M or 25% DEGS. The NMR spectra were determined on a JEOL model JNM-MH-60 spectrometer in CCl_4, $CDCl_3$ or C_6D_6 with an internal reference of tetramethylsilane. The mass spectra were taken on a Hitachi RMS-4 instrument with a 70-eV ionization voltage and a 200 °C ionization chamber temperature. The molecular weight was determined on a Hitachi Perkin-Elmer 115 MW apparatus in benzene. Thermal analysis was carried out on a Shimadzu model DTB-2B DTA-TG apparatus.

Reagents. A Tokyo Kasei guaranteed reagent of 1-hexene and extra-pure reagent of 2-methyl-2-pentene were used. These materials each showed one peak in the GLC and the IR and NMR spectra were coincident with authentic samples.

Preparation of Manganese(III) Acetate Dihydrate. $Mn(OAc)_2 \cdot 4H_2O$ was oxidized with potassium permanganate according to a modification of the procedure of Heiba.[10] Crystallized $Mn(OAc)_3 \cdot 2H_2O$ filtering up from the reacted mixture was washed with ether, and preserved over sodium hydroxide *in vacuo* for a week. The purity was 99% according to iodometric titration.

Reaction of 1-Hexene and 2-Methyl-2-pentene with Manganese(III) Acetate. 1-Hexene and 2-methyl-2-pentene (8.4 g, 100 mmol of each) were added to a solution of manganese(III) acetate (53.6 g, 200 mmol) in a mixed solvent (400 ml) of acetic acid and acetic anhydride (v/v, 1 : 1, solvent A) or of propionic acid and propionic anhydride (v/v, 1 : 1, solvent P) drop by drop at 70 °C in flowing nitrogen, the mixture being stirred with a gradual increase of the reaction temperature up to 100 °C. When the brown color of the Mn(III) ions disappeared, the stirring was stopped, and the reaction mixture was cooled, diluted with water (*ca.* 300 ml)

and extracted with ether. Brown oily substances were obtained (from 1-hexene, 12 g in solvent A and 16 g in solvent P; from 2-methyl-2-pentene, 7 g in solvent A and 9 g in solvent P). The oily substances were then separated by a combination of fractionation and preparative gas chromatography into individual compounds whose characterizations were carried out as follows.

*Reaction of 1-Hexene in Solvent A. 4-Acetoxyoctanoic Acid (**1**)*: The highest boiling product was isolated as a colorless viscous substance which showed a blue-violet spot after the spraying of a vanillin-sulfuric acid reagent and a yellow spot with a solution of BCG indicator in TLC using silica gel and a mixed solvent of hexane and ethyl acetate (v/v 1 : 4) at R_f: 0.0—0.3 (tailing). ν_{max}^{neat} 2670 and 1710 (COOH), 1240 cm^{-1}(acetate); $\delta_{ppm}^{CCl_4}$ 0.91t(3H, J=5 Hz), 1.1—1.7 m(6H), 1.97s(4H), 1.8—2.1m(6H), 4.84t(1H, J=6 Hz), 10.02s(1H, exchangeable with D_2O)

It was treated with diazomethane to give a colorless liquid methyl ester. $C_{10}H_{20}O_4$(MS and elementaly analysis). *m/e* 173(7%, $M^+-C_2H_3O$), 142(4%, $M^+-C_3H_6O_2$), 117 (81%, $M^+-C_2H_3O-C_4H_7$), 85(42%, $M^+-C_3H_6O_2-C_4H_9$), 74 (17%, $C_3H_6O_2$), 55(35%, C_4H_7), 43(100%, C_2H_3O); ν_{max}^{neat} 1740(ester), 1240 cm^{-1}(acetate); $\delta_{ppm}^{CCl_4}$ 0.92t(3H, J=5 Hz), 1.1—1.6 m(6H), 1.96 m(6H), 1.7—2.5 m(4H), 3.60s(3H), 4.80t(1H, J=6 Hz). Found: C, 61.30; H, 9.11%; mol wt, 216±2. Calcd for $C_{10}H_{20}O_4$: C, 61.11; H, 9.26%; mol wt, 216.

In the reduction of the methyl ester (0.4 g) with $LiAlH_4$ (LAH, 0.4 g), 1,4-octanediol (0.3 g) was obtained. $C_8H_{18}O_2$ (MS). *m/e* 89(18%, $M^+-C_4H_9$), 87(12%, $M^+-C_3H_7O$), 71(100%, $M^+-C_4H_9-H_2O$), 69(40%, $M^+-C_3H_7O-H_2O$) 59(5%, C_3H_7O), 57(15%, C_4H_9); ν_{max}^{neat} 3330 cm^{-1} (OH); $\delta_{ppm}^{CCl_4}$ 0.91t(3H, J=5 Hz), 1.34bs(6H), 1.51bs(4H), 3.50bs(2H, exchangeable with D_2O).

In heating at 100 °C with solvent A, the compound showed no decomposition, but it (0.5 g) decomposed at 250 °C to give acetic acid (*ca.* 0.1 g) and the γ-lactone of 4-hydroxyoctanoic acid (*ca.* 0.30 g) described below. On the other hand, **1** was not obtained by refluxing **2** in solvent A.

*γ-Lactone of 4-Hydroxyoctanoic Acid (**2**)*: The compound was isolated as the oily product with lowest boiling point. The IR and NMR spectra were coincident with those of authentic samples. $C_8H_{14}O_2$(MS). *m/e* 142(2%, M^+), 85(100%, $M^+-C_4H_9$); ν_{max}^{neat} 1775 cm^{-1} (γ-lactone); $\delta_{ppm}^{CCl_4}$ 0.93t(3H, J=5 Hz), 1.1—1.8 m(6H), 1.8—2.6 m (4H), 4.31 m(1H).

In reduction with LAH (0.4 g), it (0.4 g) gave 1,4-octanediol (0.38 g), which was also obtained by LAH reduction of **1**. The oxidation of 1,4-octanediol (0.20 g) with potassium permanganate (0.5 g) followed by treatment with diazomethane gave, together with a minor amount of returned **2**, methyl 4-oxooctanoate as a main product. $C_9H_{16}O_3$(MS). *m/e* 141(8%, M^+-CH_3O), 130(13%, $M^+-C_3H_6$), 98 (24%, $M^+-C_3H_6-CH_4O$), 115(22%, $M^+-C_4H_9$), 87(19%, $M^+-C_4H_9-CO$), 59(65%, $M^+-C_7H_{13}O$), 57(100%, C_4H_9); ν_{max}^{neat} 1740(ester), 1720 cm^{-1} (ketone); $\delta_{ppm}^{CCl_4}$ 0.93t (3H, J=5 Hz), 2.3bs(2H), 2.51bs(2H), 3.59s(3H).

Methyl 4-oxooctanoate (0.10 g) was reduced to methyl octanoate in the Clemmensen reaction, which was indicated by admixing with the authentic sample in GLC and analysis of the MS, IR and NMR spectra.

*3-Octenoic Acid (**3**), 4-Octenoic Acid (**4**) and Octanoic Acid (**5**)*: The treatment of the middle fractions with diazomethane gave a mixture of three methyl esters which furnished common methyl octanoate by hydrogenation over a Raney nickel catalyst (W-2) in hexane in an autoclave. After three methyl esters were separated by preparative GLC, two were identified as methyl esters of **3** and **5** by gas chromatographic and spectrometric comparisons with authentic samples. The remaining methyl ester eluted in the middle position of the GLC exhibited and IR spectrum closely resembling that of methyl 3-octanoate, but the NMR spectrum was somewhat different. ν_{max}^{neat} 1740(ester), 970 cm^{-1} (*trans*); $\delta_{ppm}^{CCl_4}$ 0.87t(3H, J=6 Hz), 1.1—2.1m(4H), 2.24s(4H), 3.54s(3H), 5.33t(2H, J=3 Hz).

The potassium permanganate oxidation of the fraction (0.20 g) followed by a treatment with diazomethane gave methyl esters (*ca.* 0.15 g) of butyric acid, valeric acid and unchanged octanoic acid, which were identified by admixing the authentic samples and analysis by GLC.

*Reaction of 1-Hexene in Solvent P. 2-Methyl-4-propionyloxyoctanoic Acid (**6**)*: The product with the highest boiling in the reaction. $C_{12}H_{22}O_4$(MS). *m/e* 156(2%, $M^+-C_3H_6O_2$), 74(100%, $C_3H_6O_2$); ν_{max}^{neat} 2650 and 1705(COOH), 1735(ester), 1180 cm^{-1} (propionate); $\delta_{ppm}^{CCl_4}$ 0.87t(3H, J=5 Hz), 1.0—2.0(14H), 1.06t(J=7 Hz), 1.15d(J=7 Hz), 2.23q (2H, J=7 Hz), 4.86 m(1H), 11.18 s(1H).

In heating at 260 °C, the acid (0.5 g) decomposed into propionic acid and the lactone (**7**) described in the following section.

After methylation, the substance was separated into equivalent amounts of diastereoisomers by means of preparative GLC. The quickly eluted isomer: $C_{13}H_{24}O_4$ (MS). *m/e* 187(19%, $M^+-C_3H_5O$), 88(78%, $C_4H_8O_2$), 57(100%, C_3H_5O); ν_{max}^{neat} 1735(ester), 1190 cm^{-1} (propionate); $\delta_{ppm}^{CCl_4}$ 0.90t (3H, J=5 Hz), 1.10t(3H, J=7 Hz), 1.12d(3H, J=7 Hz), 2.19q (3H, J=7 Hz), 3.56s(3H), 4.72m(1H). Found: C, 64.04; H, 9.91%. Calcd for $C_{13}H_{24}O_4$: C, 63.88; H, 9.91%. The slowly eluted isomer: $C_{13}H_{24}O_4$(MS). *m/e* 187(16%, $M^+-C_3H_5O$), 88(100%, $C_4H_8O_2$), 57(100%, C_3H_5O); ν_{max}^{neat} 1735(ester), 1185 cm^{-1} (propionate); $\delta_{ppm}^{CCl_4}$ 0.90t(3H, J=5 Hz), 1.10t(3H, J=7 Hz), 1.12q(3H, J=7 Hz), 2.21q (3H, J=7 Hz), 3.54s(3H), 4.78s(1H).

*γ-Lactone of 4-Hydroxy-2-methyloctanoic Acid (**7**)*: The oily product with the lowest boiling in the reaction. $C_9H_{16}O_2$ (MS). *m/e* 156(1%, M^+), 99(100%, $M^+-C_4H_9$); ν_{max}^{neat} 1770 (γ-lactone); $\delta_{ppm}^{CCl_4}$ 0.92t (3H, J=5 Hz), 1.0—2.0 (11H), 1.20d(J=6 Hz), 2.45m(1H), 4.24m(1H); $\delta_{ppm}^{C_6D_6}$ 0.82t (3H, J=5 Hz), 0.95d(1.5 H, J=6 Hz), 1.00d(1.5 H, J=6Hz), 1.0—1.5 m(4H), 2.08m(2H), 3.80m(1H). These spectral data suggest the γ-lactone to be a mixture of two diastereoisomers.

*2-Methyloctanoic Acid (**9**)*: Colorless oil. $C_9H_{18}O_2$ (MS). *m/e* 158(1%, M^+), 74(100%, $C_3H_6O_2$); ν_{max}^{neat} 2650 and 1705 (COOH); $\delta_{ppm}^{CCl_4}$ 0.88t(3H, J=5 Hz), 1.0—1.6(13H), 1.15d (J=7 Hz), 1.28bs(10H), 2.30m(1H), 11.96s(1H); amide mp 80—81 °C (lit,[11] 80—81 °C).

*Reaction of 2-Methyl-2-pentene in Solvent A. 4-Acetoxy-3-ethyl-4-methylpentanoic Acid (**10**)*: Upon treatment with diazomethane, the acid was converted into a colorless liquid methyl ester. $C_{11}H_{20}O_4$ (MS and elementaly analysis). *m/e* 157(5%, $M^+-C_2H_4O_2$), 127(15%, $M^+-C_2H_4O_2-CH_3O$), 97(21%, $M^+-C_2H_4O_2-C_2H_3O_2$), 96(41%, $M^+-2C_2H_4O_2$), 59(38%, $C_2H_3O_2$), 55(91%, $M^+-2C_2H_4O_2-C_3H_5$), 43 (100%, $C_2H_3O_2$), 41(62%, C_3H_5); ν_{max}^{neat} 1735(ester), 1250 cm^{-1} (acetate); $\delta_{ppm}^{CDCl_3}$ 0.97t(3H, J=5 Hz), 1.0—2.1 (5H), 1.92s (3H), 1.40s (3H), 1.48s (3H), 3.66s (3H).

The methyl ester (0.1 g) was reduced with LAH (0.1 g) to give a diol which was identical with that obtained in the LAH reduction of **11**.

*γ-Lactone of 3-Ethyl-4-hydroxy-4-methylpentanoic Acid (**11**)*: Colorless oil. $C_8H_{14}O_2$ (MS). *m/e* 142(5%, M^+), 127(44%, M^+-CH_3), 69(40%, C_5H_9), 59(100%, C_3H_7O); ν_{max}^{neat} 1775 (γ-lactone), 1390 and 1375 cm^{-1}(*gem*-dimethyl); $\delta_{ppm}^{CCl_4}$ 0.96t(3H,

J=5 Hz), 1.20s(3H), 1.39s(3H), 2.25d(2H, J=7 Hz).

Upon reduction with LAH (1.0 g), the compound (0.1 g) gave 3-ethyl-4-methyl-1,4-pentanediol, mp 44—45 °C, (*ca.* 0.9 g). $C_8H_{18}O_2$(MS). *m/e* 131(2%, M^+-CH_3), 113(14%, $M^+-CH_3-H_2O$), 84(6%, $M^+-CH_3-H_2O-C_2H_5$), 57 (100%, C_3H_7O); ν_{max}^{neat} 3330(OH), 1150(*tert.* OH), 1050 (*prim.* OH), 1380 and 1355 cm^{-1} (*gem*-dimethyl); $\delta_{ppm}^{CCl_4}$ 0.98t (3H, J=6 Hz), 1.05s(3H), 1.20s(3H), 1.56m(3H), 3.52m (2H), 5.02bs(2H, exchangeable with D_2O).

The diol (0.2 g) was oxidized with potassium permanganate (0.5 g) and returned to the original γ-lactone. It (0.6 g) was also treated with a mixture (5 ml) of acetic anhydride and pyridine (1 : 3, v/v) to give 3-ethyl-4-hydroxy-4-methylpentyl acetate as a colorless oily substance (*ca.* 0.6g). $C_{10}H_{20}O_3$ (MS). *m/e* 113 (21%, $M^+-C_2H_4O_2-CH_3$), 110 (17%, $M^+-C_2H_4O_2-H_2O$), 59(92%, $C_2H_3O_2$), 43(100%, C_2H_3O); ν_{max}^{neat} 3450(OH), 1740(ester), 1250(acetate), 1150 cm^{-1} (*tert.* OH); $\delta_{ppm}^{CCl_4}$ 0.93t(3H, J=5 Hz), 1.03s(3H), 1.13s (3H), 1.80s(1H, exchangeable with D_2O), 1.93s(3H), 4.03t (2H, J=7 Hz). Dehydration of this acetate (0.5 g) with acetic anhydride (1 ml) at 250 °C gave 3-isopropenyl-1-pentyl acetate as a colorless liquid (*ca.* 0.4 g). $C_{10}H_{18}O_2$ (MS). *m/e* 110(35%, $M^+-C_2H_4O_2$), 69(37%, $M^+-C_2H_4O_2-C_3H_5$), 43(100%, C_2H_3O), 41(80%, C_3H_5); ν_{max}^{neat} 3070, 1640 and 890 (C=C), 1740(ester), 1245 cm^{-1} (acetate); $\delta_{ppm}^{CCl_4}$ 0.83t(3H, J=7 Hz), 1.60s(3H), 1.92s(3H), 3.90t(2H, J=7 Hz), 4.72m(2H).

Upon treatment with LAH (0.3 g), the above acetate (0.3 g) was reduced to 3-isopropenyl-1-pentanol (0.2 g). Colorless oil. $C_8H_{16}O$ (MS). *m/e* 128(3%, M^+), 113(2% M^+-CH_3), 110(3%, M^+-H_2O), 84(64%, $M^+-CH_3-C_2H_5$) 81(23%, $M^+-H_2O-C_2H_5$), 69(80%, $M^+-H_2O-C_3H_5$), 41(100%, C_3H_5); ν_{max}^{neat} 3340 and 1055 (*prim.* OH), 3080, 1640 and 890 cm^{-1} (C=C). The unsaturated primary alcohol (0.1 g) was hydrogenated over a Raney nickel catalyst in ethanol to give 3-isopropyl-1-pentanol which was identified by means of gas chromatographic and IR and NMR spectrometric comparisons with an authentic sample synthesized as the final description.

*3-Isopropenylpentanoic Acid (**12**)*: After methylation, the acid was isolated as a colorless liquid in a highly homologous state from the highest fraction of the reaction product together with a dimethyl ester of the following dibasic acid (**13**). $C_9H_{16}O_2$ (MS). *m/e* 156 (7%, M^+), 141(6%, M^+-CH_3), 125(9%, M^+-CH_3O), 124(13%, M^+-CH_4O), 97 (20%, $M^+-C_2H_3O_2$), 96(48%, $M^+-C_2H_4O_2$), 59(27%, $C_2H_3O_2$), 55(100%, $M^+-C_2H_4O_2-C_3H_5$), 41(59%, C_3H_5); ν_{max}^{neat} 3070, 1645 and 890 (C=C), 1740 cm^{-1} (ester); $\delta_{ppm}^{CCl_4}$ 0.82t (3H, J=6 Hz), 1.65s(3H), 2.40s(2H), 3.64s(3H), 4.74bs(2H).

Upon reduction with LAH (0.1 g), the methyl ester (0.1 g) gave 3-isopropenyl-1-pentanol as a colorless oil, which was also derived from **11**.

*3-Ethyl-4-methyleneheptanedioic Acid (**13**)*: The compound was isolated from the highest fraction after methylation. $C_{12}H_{20}O_4$(MS and elementaly analysis). *m/e* 196(9%, M^+-CH_3O), 168(9%, $M^+-C_2H_3O_2$), 166(5%, M^+-2CH_3O), 116(8%, $M^+-2C_2H_3O_2$), 59(100%, $C_2H_3O_2$); ν_{max}^{neat} 3075, 1640 and 890 (C=C), 1735 cm^{-1} (ester); $\delta_{ppm}^{CCl_4}$ 0.84t(3H, J=6 Hz), 1.0—1.9 m(3H), 2.41bs(6H), 3.64s(3H), 3.66s(3H), 4.81bs (2H). Found: C, 62.94; H, 9.16%. Calcd for $C_{12}H_{20}O_4$: C, 63.11; H, 8.84%. Reduction of the methyl ester (0.1 g) with LAH (0.1 g) gave 3-ethyl-4-methylene-1,7-heptanediol as a colorless oily substance. ν_{max}^{neat} 3330 and 1055 (*prim.* OH).

*Reaction of 2-Methyl-2-pentene in Solvent P. γ-Lactone of 2,4-Dimethyl-3-ethyl-4-hydroxypentanoic Acid (**14**)*: From the lowest boiling fraction of the reaction products two colorless liquids determined to be diastereoisomers were separated in the relative amounts of 13 : 1 by preparative GLC. Quickly eluted isomer: $C_9H_{16}O_2$ (MS). *m/e* 141 (25%, M^+-CH_3), 112(18%, M^+-CO_2), 97(12%, $M^+-CO_2-CH_3$), 55(100%); ν_{max}^{neat} 1770 (γ-lactone), 1390 and 1375 cm^{-1} (*gem*-dimethyl); $\delta_{ppm}^{CCl_4}$ 0.8—1.8(15H), 1.02t(3H, J=5 Hz), 1.20d(3H, J=7 Hz), 1.21s(3H), 1.41s(3H), 2.17m(1H); $\delta_{ppm}^{C_6D_6}$ 0.60t(3H, J=5 Hz), 0.81s(3H), 1.10s(3H), 1.05d(3H, J=6 Hz), 0.5—1.5 m(3H), 1.87m(1H). Slowly eluted isomer:$C_9H_{16}O_2$ (MS). *m/e* 141(25%, M^+-CH_3), 112(16%, M^+-CO_2), 97(12%, $M^+-CO_2-CH_3$), 55(100%); ν_{max}^{neat} 1765 (γ-lactone), 1390 and 1375(*gem*-dimethyl); $\delta_{ppm}^{CCl_4}$ 0.81—1.7 m(2H), 0.97t(3H, J=6 Hz), 1.20d(3H, J=7 Hz), 1.26s(3H), 1.39s(3H), 2.11m (1H), 2.57m(1H); $\delta_{ppm}^{C_6D_6}$ 0.55t(3H, J=6 Hz), 0.91s(3H), 1.02s(3H), 0.97d(3H, J=6 Hz), 1.58q(2H), 2.31q(1H, J=8 Hz).

*3-Ethyl-2,4-dimethyl-4-pentenoic Acid (**15**)*: Colorless oily substance. $C_9H_{16}O_2$ (MS). *m/e* 156 (9%, M^+), 83(75%, $M^+-C_3H_5O_2$), 55(100%); ν_{max}^{neat} 2650 and 1710(COOH), 1650 and 895 (C=C); $\delta_{ppm}^{CCl_4}$ 0.7—1.6 (11H), 0.77t(3H, J=6 Hz), 1.14d(3H, J=6 Hz), 1.53s(3H), 2.31m(2H), 4.78s (1H), 4.87s(1H), 11.3s(1H). Upon treatment with diazomethane, it gave a colorless oily methyl ester: ν_{max}^{neat} 3080, 1640 and 895 (C=C), 1735 cm^{-1} (ester); $\delta_{ppm}^{CCl_4}$ 0.75t(3H, J=6 Hz), 0.96d(3H, J=6 Hz), 1.0—1.4m(2H), 1.50s(3H), 2.10m (2H), 3.48s(3H), 4.61s(1H), 4.67s(1H).

*3-Ethyl-2,6-dimethyl-4-propionyloxymethyl-1,7-heptanedioic Acid (**16**)*: By preparative GLC of the fraction with the highest boiling point (0.5 g) of the reaction products, two colorless isomeric esters were separated in a ratio of 5 : 1 after treatment with diazomethane. Quickly eluted ester: $C_{17}H_{30}O_6$ (MS). *m/e* 154 (7%, $M^+-2C_4H_8O_2$), 139(13%, $M^+-2C_2H_3O_2-C_3H_5O_2$), 95(18%, $M^+-2C_4H_8O_2-C_2H_3O_2$), 88 (18%, $C_4H_8O_2$), 59 (8%, $C_2H_3O_2$), 57(100%, $C_3H_5O_2$); ν_{max}^{neat} 1735(ester), 1195 cm^{-1} (propionate); $\delta_{ppm}^{CCl_4}$ 1.05t(3H, J=6 Hz), 1.14d(6H, J=7 Hz), 1.68 m(7H), 2.20q(4H, J=7 Hz), 3.56s(6H), 4.80m(2H). Slowly eluted ester: $C_{17}H_{30}O_6$ (MS) *m/e* 154 (3%, $M^+-2C_4H_8O_2$), 139(11%, $M^+-2C_2H_3O_2$), 95(63%, $M^+-2C_4H_8O_2-C_2H_3O_2$), 88(48%, $C_4H_8O_2$), 59 (19%, $C_2H_3O_2$), 57(100%, $C_3H_5O_2$); ν_{max}^{neat} 1735(ester), 1195 cm^{-1} (propionate); $\delta_{ppm}^{CCl_4}$ 1.07t(3H, J=6 Hz), 1.14d(6H, J=7 Hz), 1.70m(7H), 2.18q(4H, J=7 Hz), 3.56s(6H), 5.02m (2H). Since sixteen isomers are possible for 3-ethyl-2,6-dimethyl-4-propionyloxymethyl-1,7-heptanedioic acid, these substances should still be mixed esters.

Reactions of $Mn(OAc)_3\cdot 2H_2O$ in Solvents A and P. $Mn(OAc)_3\cdot 2H_2O$ (26.8 g, 100 mmol) was heated with solvent A (200 ml) without a reactant for 6 h in a manner similar to the above reaction in flowing nitrogen. The reacted mixture was concentrated as a viscous liquid, which produced a small amount of white crystals when allowed to stand. The crystals, mp 184—186 °C, 1.3 g, showed no depression during a mixed mp determination with an authentic sample of succinic acid and the IR spectrum was coincident with that of an authentic sample. The liquior remaining after filtration of the crystals was methylated and then the reacted mixture was separated by preparative gas chromatography. Together with succinic acid, acetoxyacetic acid was isolated and it was identified based on gas chromatographic and spectrometric comparisons with an authentic sample prepared from hydroxyacetic acid. During heating, the nitrogen gas passing through the reaction flask passed into a saturated aqueous solution of calcium hydroxide (200 ml); although the solution became slightly cloudy, no precipitate was formed.

$Mn(OAc)_3\cdot 2H_2O$ (53.6 g, 200 mmol) was also heated with solvent P (400 ml). A similar treatment of the reacted mixture gave a mixture (1.7 g) of *meso-* (2 mmol, mp 196—

198 °C, lit,[11] 198 °C) and *dl*-2,3-dimethylsuccinic acid (6 mmol) and *dl*-2-propionyloxypropionic acid (2 mmol). They were separated by preparative GLC after methylation. *dl*-2-Propionyloxypropionic acid was identified by IR and NMR spectral comparisons with an authentic sample synthesized from *dl*-lactic acid. Similarly *dl*-2,3-dimethylsuccinic acid was identified by its MS, IR and NMR spectra. $C_8H_{14}O_4$ (MS). *m/e* 143 (28%, M^+-CH_3O), 115(30%, $M^+-C_2H_3O_2$), 59(100%, $C_2H_3O_2$); ν_{max}^{neat} 1740 cm^{-1} (ester); $\delta_{ppm}^{CCl_4}$ 1.11d(6H, J=6Hz), 2.71m(2H), 3.65s(6H).

Thermal Analysis of $Mn(OAc)_3 \cdot 2H_2O$. The thermal analysis of $Mn(OAc)_3 \cdot 2H_2O$(104.8 mg) was carried out with a Shimadzu DTA-TG apparatus with temperature programming of 2°C/min in flowing nitrogen, and the weight loss (mg) and differential thermal analysis were recorded using a standard of fused SiO_2 (Fig. 1). On the other hand, $Mn(OAc)_3 \cdot 2H_2O$ (26.8 g, 100 mmol) was gradually heated up to 130 °C in flowing nitrogen, and the emerging gas from a reaction flask was bubbled into a saturated solution (200 ml) of calcium hydroxide. When the temperature reached 110 °C, the formation of a white precipitate was observed.

Synthesis of 3-Isopropyl-1-pentanol. 2-Methyl-3-pentanol (9.0 g, 88 mmol) which was prepared from propionaldehyde and isopropylmagnesium bromide[12] was oxidized with Jones reagent at room temperature for 6 h to give 2-methyl-3-pentanone, bp 113—118 °C (lit,[11] 115—116 °C), as a colorless liquid (7.5 g, yield 85%). The Reformatsky reaction[13] of 2-methyl-3-pentanone (7.5 g, 75 mmol) thus obtained with methyl bromoacetate(12.2 g, 80 mmol) gave methyl 3-hydroxy-3-isopropylpentanoate (8.5 g, 48.8 mmol); ν_{max}^{neat} 3530(OH), 1730 and 1715 (ester), 1385 and 1370 cm^{-1} (isopropyl); $\delta_{ppm}^{CCl_4}$ 0.87t(3H, J=7 Hz), 1.50q(2H, J=6 Hz), 1.90 d(6H, J=7 Hz), 2.40bs(2H), 3.69s(3H), 3.15bs(1H, exchangeable with D_2O). The alcohol, after dehydration with acetic anhydride, was subjected to catalytic hydrogenation to give methyl 3-isopropylpentanoate as a colorless liquid (bp 163—164 °C, 2.4 g, yield 59%). $C_9H_{18}O_2$ (MS). *m/e* 127(11%, M^+-CH_3O), 84(17%, $M^+-C_3H_6O_2$), 74 (100%, $C_3H_6O_2$), 59(31%, $C_2H_3O_2$); ν_{max}^{neat} 1745 (ester), 1390 and 1370 cm^{-1} (isopropyl); $\delta_{ppm}^{CCl_4}$ 0.91t(3H, J=4 Hz), 0.86 t (3H, J=6 Hz), 0.89d(3H, J=6Hz), 2.15 m(2H), 3.59s(3H).

Reduction of this methyl 3-isopropylpentanoate (1.0 g) with LAH(1.0 g) gave 3-isopropyl-1-pentanol (*ca.* 0.9 g). $C_8H_{18}O$ (MS). *m/e* 112 (2%, M^+-H_2O), 84(23%, $M^+-H_2O-C_2H_4$), 44(100%, C_3H_8), 40(96%, C_3H_4); ν_{max}^{neat} 3340 and 1055 (*prim.* OH), 1385 and 1367 cm^{-1} (isopropyl); $\delta_{ppm}^{CCl_4}$ 0.84d(6H, J=6 Hz), 3.46t(2H, J=7 Hz), 3.18s(1H, exchangeable with D_2O).

Thanks are expressed to Professor Shūichi Hayashi of Hiroshima University, for his guidance and encouragement throughout this work and to Dr. Kōzō Akabori of the same institution for the measurements of the thermal analysis of manganese(III) acetate dihydrate.

The Hydrogen-Deuterium Exchange of 3,5-Dimethylisoxazoles

Choji KASHIMA, Yasuhiro YAMAMOTO, Yoshihiko TSUDA, and Yoshimori OMOTE
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31
(Received December 27, 1974)

By the hydrogen-deuterium exchange reaction in methanol-d_4, 3,5-dimethylisoxazole (**1**) was found to react regioselectively at the C-5 methyl group. This methyl group was, however, less reactive than the methyl groups of 2-picoline or quinaldine. This reaction was shown to be retarded by the electron-donating substituents, and to be accelerated by the electron-withdrawing substituents, at the C-4 position of **1**.

The isoxazole derivatives frequently show some pharmaceutical activities, and they are also employed as intermediates for the syntheses of peptides[1] and natural products.[2] Previously, we reported that 3,5-dimethylisoxazole (**1**) reacted with various kinds of electrophiles in the presence of bases to give 5-substituted 3-methylisoxazoles.[3-5] For example, 3-methyl-5-ethylisoxazole was obtained by the treatment of **1** with methyl iodide in the presence of sodium amide in liquid ammonia.[3] For the development of these reactions, it is necessary to investigate the application and the limitation of these reactions. However, no quantitative study has yet been reported.

The reaction of active methyl and methylene groups on the heteroaromatic compounds, such as 2-picoline[6] and quinaldine,[7] has been extensively investigated. White and Anderson[8] reported that the hydrogen on the methyl group of 5-methylisothiazole was exchanged with the activation energy of 5.61×10^4 J/mol in deuterium oxide. Also, Zatspina *et al.*[9] reported that the activation energies of the hydrogen exchange of 2-picoline and quinaldine are 1.03×10^5 and 8.70×10^4 J/mol respectively in deuterium oxide. In these papers, the rate-determining step of these reactions is supposed to be the formation of the corresponding carbanions by proton abstraction from active methyl and methylene groups.

The rate-determining step of the reaction of **1** with the electrophiles should be the formation of the carbanion of **1**. Therefore, the stability of an intermediate carbanion was calculated by means of the MINDO/2 method. Also, the present study will report the results of the sodium methoxide-d_3 catalyzed isotopic exchange of **1** in methanol-d_4 in order to compare the reactivity of **1** with those of the heteroaromatic compounds with a methyl group. Furthermore, the substituent effect of 4-substituted 3,5-dimethylisoxazoles is discussed in terms of the hydrogen-deuterium-exchange reaction rates.

Results and Discussion

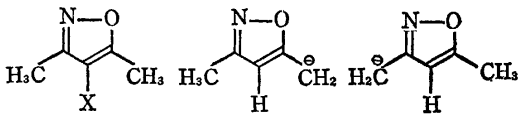
Regioselectivity. Two methyl groups of 3,5-dimethylisoxazole (**1**) are expected to be activated by the isoxazole ring. When the proton abstraction from the active methyl group is considered to be the rate-determining step, the stability of the carbanion should reflect the reactivity of the corresponding methyl groups. The total energies of the (3-methyl-5-isoxazolyl)methyl carbanion (**2**) and the (5-methyl-3-isoxazolyl)methyl carbanion (**3**) were calculated by means of the MINDO/2 calculation method. The calculation showed that **2** is more stable than **3** by 3×10^3 J/mol. These results were roughly supported by the following data. The carbanions introduced from **1** were prepared by the treatment of **1** with butyllithium in ether. After equilibration for 3 h at room temperature, the resulting carbanions were quenched by deuterium oxide. The deuterated products were then analyzed by mass spectrometry; the results are summarized in Table 1. In this table, the relative intensity of *m/e* 98 showed that the monodeutero derivative was formed in a yield of 37%. The peak of *m/e* 82 was assigned to the **4** ion, while the peak of *m/e* 54 was assigned to the **5** ion.[10] In both ions, **4** and **5**, the C-5 methyl group was expelled from the molecule. When the mass spectrum of **1** was compared with that of the deuterated products, the isotopic peaks of **4** and **5**, *m/e* 83 and 55, were observed to have a difference in relative intensity.

Table 1. Mass Spectral data of **1** and the deuterated derivative

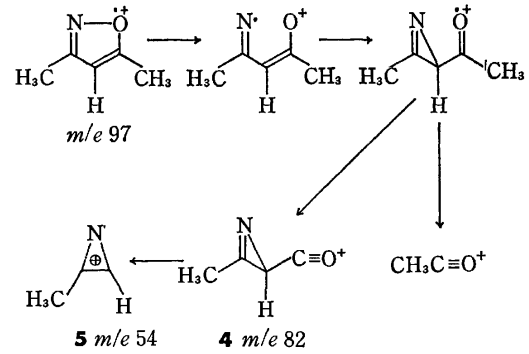
m/e	Relative intensity	
	1	Deuterated derivative
99	0.9	6.1
98	11.9	36.2
97	78.6	49.0
83	5.1	7.1
82	100.0	100.0
56	2.0	5.0
55	30.4	31.7
54	70.3	67.5

The hydrogen-deuterium exchange rates of very weak acids often parallel the acidities of this type of heteroaromatic compound.[11] This parallelism can be expected from the Brønsted catalysis law.[12] The relative reactivity of the methyl group of **1** was studied kinetically by means of a hydrogen-deuterium exchange reaction at 110.6 °C in the presence of sodium methoxide-d_3 in methanol-d_4 (16.5 mg/282 mg). Actually, the hydrogen-deuterium exchange was monitored by the decreases in the NMR peaks of **1** at δ 2.13 and 2.30 ppm, which were identified as C-3 methyl and C-5 methyl groups respectively. The pseudo-first-order rate constants of this reaction were found to be $k=3.3\times10^{-4}$ s^{-1} at the C-5 methyl group and $k=1.2\times10^{-6}$ s^{-1} at the C-3 methyl group. That is, the C-5 methyl group was activated 280 times as much as the C-3 methyl group.

Reactivity. The reaction rates of the hydrogen-deuterium exchange on the C-5 methyl group of **1**



1 X=H **2** **3**
6 X=OCH_3
7 X=CH_3
8 X=Cl
9 X=I
10 X=$COOCH_3$
11 X=NO_2



m/e 97

5 *m/e* 54 **4** *m/e* 82

were also measured at 80.1, 89.0, 100.0, and 121.2 °C in methanol-d_4. The activation parameters for the C-5 methyl group of **1** were calculated to be $E_{act}=(1.200\pm0.008)\times10^5$ J/mol and log $A=12.76$, while those for the methyl groups of 2-picoline and quinaldine were $E_{act}=1.03\times10^5$ J/mol; log $A=9.86$ and $E_{act}=8.70\times10^4$ J/mol; log $A=9.77$, respectively.[9] Apparently the C-5 methyl group of **1** is less reactive than those of 2-picoline and quinaldine.

Effect of Substituents. The hydrogen-deuterium exchange reaction rates for the C-5 methyl group of 4-substituted 3,5-dimethylisoxazoles were measured in order to clarify the effects of the substituents. The 4-methoxy- (**6**), 4-methyl- (**7**), 4-chloro- (**8**), 4-iodo- (**9**), 4-carbomethoxy- (**10**), and 4-nitro- 3,5-dimethylisoxazoles (**11**) were prepared and the exchange rates were measured in methanol-d_4 in the presence of sodium methoxide-d_3 at 34.2, 80.1, and/or 110.6 °C. The results are presented in Table 2. Unfortunately, the reaction of **10** was too fast for us to determine the exchange rate accurately at 34.2 °C. The NMR peak of the C-5 methyl group of **11** could not be observed even 1 min after the **11** and methoxide-d_3 were dissolved in methanol-d_4 at room temperature. Table 2 shows that the hydrogen-deuterium exchange was retarded by the electron-donating groups at the C-4 position of the isoxazole ring.

TABLE 2. HYDROGEN-DEUTERIUM EXCHANGE REACTION RATES OF 4-SUBSTITUTED 3,5-DIMETHYLISOXAZOLES

4-Substituents	Temp (°C)	Reaction rate (s^{-1})	
		C-3 CH_3	C-5 CH_3
OCH_3	110.6	6.4×10^{-7}	1.3×10^{-5}
CH_3	110.6	4.1×10^{-7}	7.8×10^{-5}
H	110.6	1.2×10^{-6}	3.3×10^{-4}
	80.1	—	9.5×10^{-6}
Cl	80.1	—	5.5×10^{-4}
I	110.6	7.7×10^{-5}	8.0×10^{-3}
	80.1	—	9.4×10^{-4}
$COOCH_3$	34.2	—	$>2\times10^{-3}$

Experimental

MINDO/2 Calculations. Using the coordinates shown in Table 3, the total energies of the **2** and **3** carbanions were calculated as −1252.483 and −1252.149 eV respectively by means of the MINDO/2 method.

TABLE 3. THE COORDINATES OF **2** AND **3**

Isoxazole ring			
Bond length		Bond angle	
O-N	1.39 Å	C-5-O-N	107°

Materials. *3,5-Dimethylisoxazole (**1**)* was prepared by the method of Lampe[13] from acetylacetone and hydroxylamine hydrochloride. Yield, 59%; bp 139—141 °C (lit, 140—142 °C[13]).

*3,5-Dimethyl-4-methoxyisoxazole (**6**).* According to the method of Katritzky,[14] **6** was prepared from diazomethane and 3,5-dimethyl-4-hydroxyisoxazole [NMR: δ^{CDCl_3} 2.17 (s, 3H), 2.27 (s, 3H), and 5.5 ppm (broad s, 1H)]; yield (from 4-acetoxy-2,4-pentanedione), 8%; bp 106—115 °C/2 mmHg. NMR: δ^{CD_3CD} 2.19 (s, 3H), 2.53 (s, 3H) and 3.78 ppm (s, 3H).

*3,4,5-Trimethylisoxazole (**7**).* According to the method of Sokolov,[15] **7** was prepared from 3-methyl-2,4-pentanedione, hydroxylamine hydrochloride, and anhydrous potassium carbonate. Yield, 26%; bp 98—99 °C/69 mmHg. NMR: δ^{CD_3OD} 1.89 (s, 3H), 2.16 (s, 3H), and 2.28 ppm (s, 3H).

*3,5-Dimethyl-4-chloroisoxazole (**8**).* According to the method of Sokolov,[15] **8** was prepared from 3-chloro-2,4-pentanedione and hydroxylamine hydrochloride. Yield, 63%; bp 82 °C/25 mmHg. NMR: δ^{CD_3OD} 2.22 (s, 3H), and 2.37 ppm (s, 3H).

*3,5-Dimethyl-4-iodoisoxazole (**9**).* According to the method of Kochetkov,[16] **9** was prepared from **1**, iodine, and a catalytic amount of nitric acid. Yield, 59%; mp 51—53.5 °C (lit, 51.5—53 °C[16]). NMR: δ^{CD_3OD} 2.21 (s, 3H), and 2.42 ppm (s, 3H).

*3,5-Dimethyl-4-carbomethoxyisoxazole (**10**).* According to the method of Stork,[17] **10** was prepared from nitroethane and methyl acetoacetate. Yield, 30%; bp 95—98 °C/3 mmHg. NMR: δ^{CD_3OD} 2.34 (s, 3H), 2.59 (s, 3H), and 3.83 ppm (s, 3H).

*3,5-Dimethyl-4-nitroisoxazole (**11**).* By the method of Morgan,[18] **1** was nitrated by nitric acid and concentrated sulfuric acid. Yield, 60%, mp 62—64 °C (lit, 63.5 °C[18]). NMR: δ^{CD_3OD} 2.50 (s, 3H), and 2.75 ppm (s, 3H).

Hydrogen-Deuterium Exchange Reaction Rate. Isoxazole (0.45 mmol) was treated with sodium methoxide-d_3 (16.5 mg) in methanol-d_4 (282 mg) in sealed tubes at the refluxing temperature of tetrachloroethylene (bp 121.2 °C), toluene (bp 110.6 °C), water (bp 100.0 °C), aqueous *p*-dioxane (bp 89.0 °C), or benzene (bp 80.1 °C), and at appropriate time intervals the NMR spectra were measured at 34.2 °C, using cyclohexane as the internal standard, by means of a JEOL H-100 NMR spectrometer. From the NMR data, the reaction rates were calculated; they are summarized in Table 2.

Mass Spectral Analysis of Deuterated Derivative. To a solution of **1** (1.01 g) in anhydrous ether, a 15% hexane solution of butyllithium (6 ml) was added at −70 °C. The mixture was then stirred for 3 h at room temperature under a nitrogen atmosphere. After the addition of deuterium oxide (1.97 g), the stirring was continued for another 0.5 h at room temperature. The reaction mixture was separated. The organic layer was washed with dilute hydrochloric acid, water, and aqueous sodium chloride, and dried over anhydrous sodium sulfate. After the solvent had been removed, the residue was distilled. Yield, 0.21 g; bp 135—142 °C. NMR: δ^{CDCl_3} 2.21 (s), 2.33 (s), and 5.78 ppm (s); the intensity ratio is 30 : 26 : 11.

The authors are indebted to Dr. Osamu Kikuchi, Department of Chemistry, University of Tsukuba, for doing the MINDO/2 calculations.

Studies of Tritylated Pentoses and Methyl Pentoses. I. The *O*-Tritylation of Methyl α-D-Fucopyranoside

Toshiki OTAKE and Toru SONOBE*

Nippon Electric Varian, Ltd., Yotsuya, Fuchu-shi Tokyo 183

**Tobishi Pharmaceutical Co., Ltd., Omori-Nishi, Ota-ku, Tokyo 143*

(Received March 17, 1975)

Two trityl derivatives of fucose, methyl 2-*O*- (II) and 3-*O*-trityl α-D-fucopyranoside (III), were obtained in good yields by the reaction of methyl α-D-fucopyranoside (I) and trityl chloride in pyridine. The ratio of II and III in the reaction mixture was about 3 : 2. The structures were mainly established by NMR with appropriate derivatives. The gas chromatography-mass spectrometry of the partial methyl ethers of I was also discussed.

O-Tritylation[1] usually proceeds much more rapidly on primary hydroxyl groups. It has been used to determine quantitatively the number of primary hydroxyl groups in a molecule, or to protect the group for further synthetic procedures. However, in some cases, equatorial secondary hydroxyl groups are also tritylated rapidly. Hocket and Hudson[2] reported that methyl α-L-fucopyranoside, which contains only secondary hydroxyl groups, reacted readily with trityl chloride to form a mono-*O*-trityl ether. However, they did not describe its structure.

This paper will deal with the *O*-tritylation of I and with the etherified positions of the trityl derivatives. The *O*-tritylation of various pentoses and methyl pentoses can give information about the reactivity of secondary hydroxyl groups in different environments and can be used to protect a certain hydroxyl group for further synthetic procedures. This paper will also deal with the mass spectra of the partially methylated methyl fucosides prepared from the trityl derivatives.

Results and Discussion

The reaction of I with trityl chloride in a 1 : 2 mole ratio readily formed substituted derivatives under the conditions described by Helferich.[1] The tritylated product gave two adjacent spots on a thin-layer chromatogram and two peaks on a high-speed liquid chromatogram, as is shown in Fig. 1. The compound corresponding to the first peak(II) was isolated as a pyridine complex and was then recrystallized as monoethyl alcoholate. The second peak(III) was separated by liquid chromatography, and crystallized as monohydrate. The analyses and PMR spectra of the appropriate derivatives of II and III indicated that they both consisted of mono-*O*-trityl ether of I.

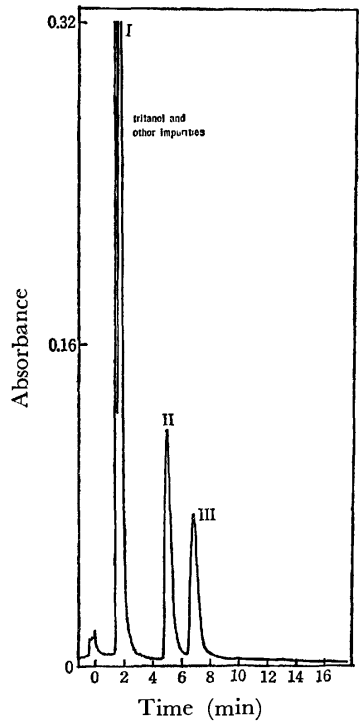

Fig. 1. Liquid chromatogram of the reaction mixture column: MicroPak si-10 2 mm×20 cm; solvent: 20% hexane/methylene chloride; flow rate: 50 ml/h; detector: UV (254 nm).

IV	$R_2=Tr, R_3=R_4=Ac$	XI	$R_3=Ac, R_2=R_4=CH_3$
V	$R_2=Tr, R_3=R_4=CH_3$	XII	$R_4=H, R_2=R_3=CH_3$
VI	$R_2=H, R_3=R_4=CH_3$	XIII	$R_4=Ac, R_2=R_3=CH_3$
VII	$R_2=Ac, R_3=R_4=CH_3$		

All the methine-proton signals in a PMR spectrum of the peracetyl derivative of II (IV) were assigned with the aid of the decoupling technique shown in Fig. 2. The signals of H-3 and H-4 lay in the *O*-acetylmethine-proton area, while the H-2 resonated at a higher field than would be expected for an *O*-tritylmethine-proton. Most of the methine protons attached to alkoxylated or hydroxylated carbon resonate at δ4.0—2.5. However, trityl groups may sometimes cause anomalous chemical shifts of the adjacent protons by means of their strong anisotropic effect.[3,4] To confirm the structure, the PMR of a methyl di-*O*-methyl mono-*O*-acetylfucoside (VII) which had been derived from permethyl ether of II (V) was analyzed by the aid of the homodouble-resonance technique,[5]

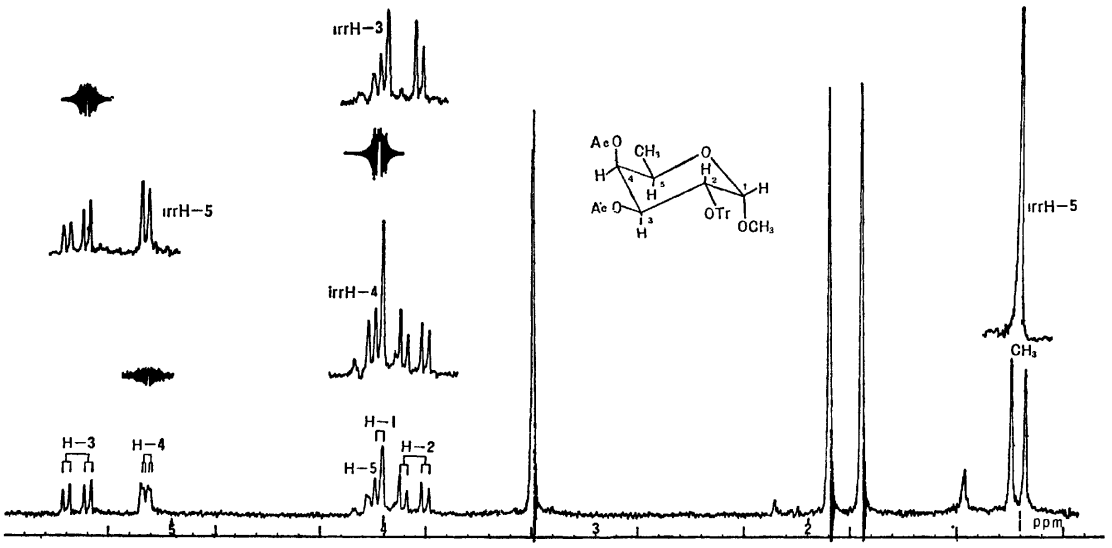

Fig. 2. Parts of the NMR spectrum at 100 MHz of IV.

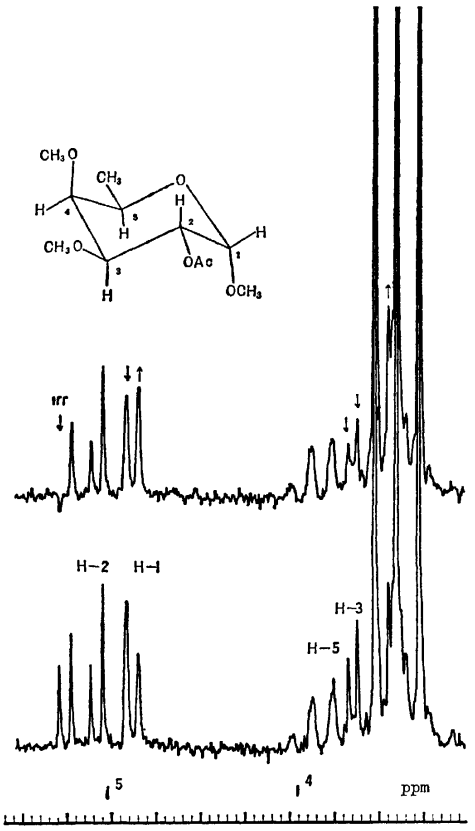

Fig. 3. A part of the NMR spectrum at 60 MHz (FT-mode) of VII. No. of scans: 10. Arrows show increasing or decreasing of signal intensities compared with those on the normal spectrum.

irradiating with a selective π-pulse at a resonance line of δ5.25, and observing the signal intensities using the Fourier transform mode, as is shown in Fig. 3. The spectrum showed that the H-2 was an *O*-acetylmethine proton, judging from the chemical shift. Accordingly, Compound II was confirmed to be 2-*O*-trityl α-D-fucopyranoside.

A PMR spectrum of the acetylation product of III (VIII) indicated that the hydroxyl group at C-2 alone was replaced by an acetyl group. Since protons of hydroxylmethine and alkoxylmethine resonate in a common area, however, the complete identification of VIII is difficult. In the PMR spectrum of di-*O*-methyl mono-*O*-acetylfucoside (XI) derived from the permethyl ether of III (IX) through its detritylation product (X), all the methine-proton signals were

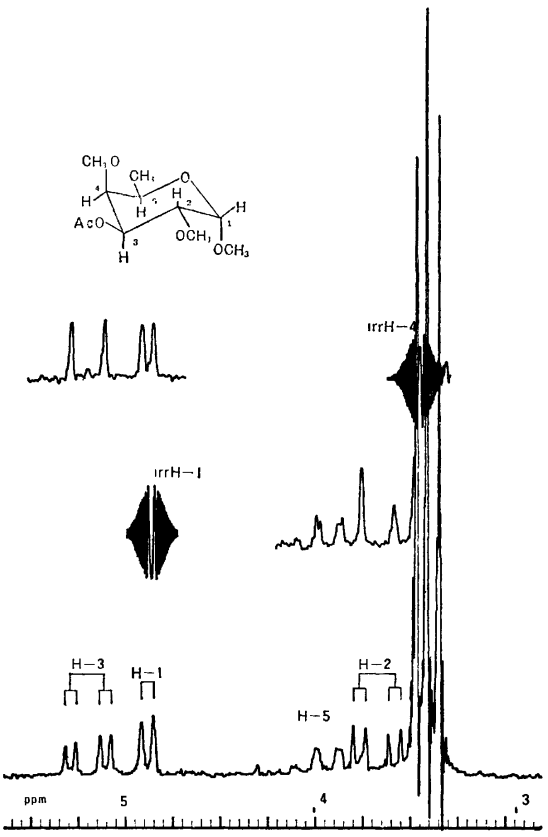

Fig. 4. A part of the NMR spectrum at 60 MHz of XI.

assigned with the aid of the decoupling technique, as is shown in Fig. 4. The H-3 was regarded as an acetylmethine proton from its chemical shift, and Compound III was identified as methyl 3-*O*-trityl α-D-fucopyranoside.

During these studies, the mass spectra of methyl di-*O*-methylfucoside (VI and X) were also analyzed. The mass spectra of methyl ethers of methyl glycosides have previously been studied in detail. For example, Kochetkov *et al.*[6-9] and Heyns *et al.*[10-11] have assigned the peaks on the mass spectra of permethylated methyl glycosides and calculated the contributions of isomeric ions to the total peak intensities. Later, Heyns *et al.*[12] analyzed the peaks of partially methylated methyl glucoside.

Some of the structures of ions and their contributions to the total peak intensities are presented below.

m/e	Structure[a]	Designation[9,12]	Contribution[b]
58 72	$[CH_3\text{-}CH{=}CH\text{-}OR(4)]^+$	K_1	100
74 88	$[R(2)O\text{-}CH{=}CH\text{-}OR(3)]^+$	H_1^2	78
75	$[CH_3(3)O{=}CH{=}OCH_3(1)]^+$	J_1^1	60
87 101	$R(4)O\text{-}CH{=}CH\text{-}CH{=}O^+R(2)$	F_1^2	62
87 101		G_1^4	15
119		D_1	100
115 129		C_2	48
161		J_4	
		J_3	

a) R's are CH_3 or OH, and the numbers in parentheses agree with the attached positions of the OR-groups in the original ethers.

b) The contributions were calculated with methyl 2,3,4-tri-*O*-methyl β-D-fucoside.

c) The peaks at *m/e* 119 and 75 are mainly formed by the migration of the methoxyl (3). Therefore, their hydroxyl analogues are scarcely afforded at all.

The relative intensities of the characteristic peaks of VI, X, and those of methyl 2,3-di-*O*-methyl α-D-fucopyranoside (XII) are presented in Table 1, while the mass spectra of these compounds are in Fig. 5.

The mass spectra of these ethers are well elucidated by the structures of ions and their contributions to the total peak intensities. For example, the comparatively low intensities of the peaks at *m/e* 75, 88, and 119 in the spectrum of X indicate the absence of methoxyl (3). The major ions which contribute to these peak intensities all include this methoxyl group.

TABLE 1. THE RELATIVE INTENSITIES ON MASS SPECTRA OF PARTIALLY METHYLATED METHYL α-D-FUCOPYRANOSIDES

m/e	VI	X	XII	Permethyl α-D-fucose[14]
72	50	42	2	20
74	91	100	15	1
75	54	18	30	38
85	14	8	42	2
87	19	8	10	2
88	100	43	100	100
101	6	23	18	20
102	2	15	3	1.5
115	6	5	2	1
119	5.2	0.4	2.2	1.7
129	1.5	3.9	0	1.6
130	4.5	0.6	6.5	0
143	1.8	2.4	2.4	0
157	0.2	0.6	0.1	0.4
161	2.0	0.2	1.3	0

189	0	0	0	1.4

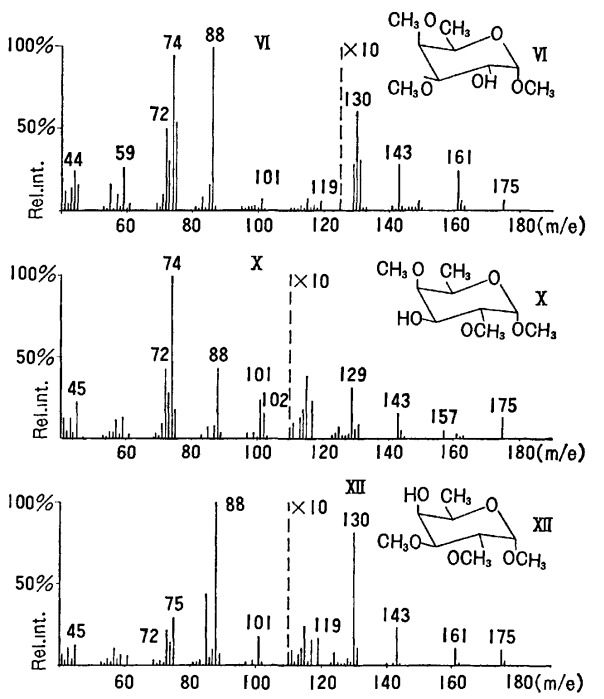

Fig. 5. Gas chromatography-mass spectra of VI, X and XII.

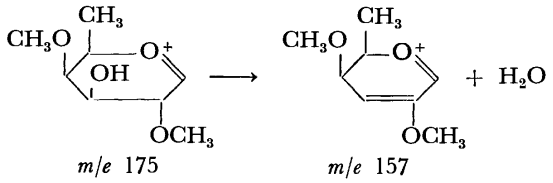
Similarly, the low intensity of the peak at *m/e* 101 in the spectrum of VI, and that of the peak at *m/e* 72 in the spectrum of XII, are elucidated by the absence of methoxyl (2) and methoxyl (4) respectively. The pathway of fragmentation should also be taken into consideration. The comparatively low intensity of the peak at *m/e* 101 in the spectrum of X may be explained by the lack of methoxyl (3). Because the F_1^2 ion is formed by the migration of methoxyl (3) from C-3 to C-1, in the case of permethylated methyl fucopyranoside, the absence of this group would reduce

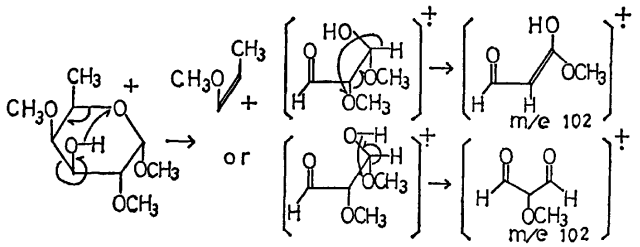
the contribution of F_1[2] to the peak intensity.

The formation of *m/e* 161 (J_3,J_4) accompanies proton-transfers from OH (2) or OH (4) to the ring oxygens of VI or XII, indicating the presence of hydroxyl gorups at C-2 or C-4 in molecular ions.

There were other peaks, like *m/e* 157, 130, and 102, which were characteristic of each isomeric ether. The peak at *m/e* 157 appeared only in the spectrum of X and was considered as a dehydrated fragment of an ion of *m/e* 175:



The peak at *m/e* 130 appeared in the spectra of VI and XII. The peak at *m/e* 102 appeared in the spectrum of X. The pathway of the fragmentation was assumed to be as follows:



Experimental

General Methods. For high-performance liquid chromatography, a Varian Model 8520 Liquid Chromatograph, equipped with a Micro Pak Si-10 column, was used. The solvent for elution was 20% hexane/methylene chloride. Thin-layer chromatography was effected using Merck silica gel G as an adsorbent in a thickness of 0.25 mm, with a solvent system of acetone-benzene. Preparative column chromatography was carried out using silica gel, 60—80 mesh (Kanto Chemical Co.). The PMR spectra were recorded on a Varian HA-100D (100 MHz) apparatus and an NV-14 (60 MHz) spectrometer equipped with Adapts, a computor system (Varian Data Machins), using chloroform-*d* with tetramethylsilane as the internal lock, the signal positions being expressed in δ values. Gas chromatography-mass spectrometry was carried out using a Varian MAT 111 GC/MS system.

Tritylation of I. A mixture of 0.593 g of I ($[\alpha]_D^{25}$+ 189°) and 1.853 g of recrystallized trityl chloride was dissolved in 20 ml of dry pyridine, and was then allowed to stand for 120 h at room temperature. At the end of the reaction period, 1 ml of water was added to the solution. The solution was then concentrated *in vacuo* at 40 °C until it became hard syrup. A thin-layer chromatogram with a solvent system of 20% acetone/benzene showed spots corresponding to II and III, with R_f values of 0.69 and 0.63 respectively. On a high-performance liquid chromatogram, two peaks corresponding to II and III had retention times of 5°00′ and 6°48′ respectively, with a flow rate of 50 ml/h. The reaction concentrate was chromatographed on 15 g of silica gel. After the column had been washed with benzene (300 ml), trityl ethers were eluted with 4% acetone/benzene (300 ml). The evaporation of the last solvent left 1061 mg of a glass which consisted of II and III. The combined yield of the ethers was about 71%.

Methyl 2-O-Trityl α-D-Fucopyranoside (II). The derivative, II, was crystallized as a pyridine complex from the pyridine solution of the glass. Then it was recrystallized several times from the ethanol solution as monoethyl alcoholate, which melted at 68—70 °C and which had an $[\alpha]_D^{20}$ of +55.5 °(*c* 1, chloroform).

Found: C, 72.07; H, 7.00%. Calcd for $C_{26}H_{28}O_5 \cdot C_2H_5OH$: C, 72.08; H, 7.35%.

The monoethyl alcoholate was dried over phosphorous pentoxide at 60 °C for 24 h.

PMR data for unhydrous II (100 MHz): δ 1.15 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ 3.25 (s, 3H, OCH_3).

Found: C, 73.96; H, 6.74%. Calcd for $C_{26}H_{28}O_5$: C, 74.26; H, 6.71%.

Methyl 3-O-Trityl α-D-Fucopyranoside (III). The mother liquid of the recrystallization of II from the pyridine solution was dried *in vacuo* and chromatographed on 10 g of silica gel. The column was washed with 2% acetone/benzene (200 ml) and with 2.5% acetone/benzene (200 ml). The eluent was divided into eight 50-ml fractions. Each of them was dried *in vacuo*, and each residue was chromatographed on a thin-layer plate. The combined solid from the fractions which consisted of III weighed 417 mg. The crude III was recrystallized as monohydrate from a 60% methanol solution. The crystalline III had an $[\alpha]_D^{20}$ of +81.4° (*c* 1, chloroform) and melted at 71—74 °C.

PMR data for III (60 MHz): δ 0.98 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ2.03 (dd, 1H, $J_{4,5}$ 1.5 Hz, $J_{3,4}$ 2.8 Hz, H-4), δ3.27 (s, 3H, OCH_3), δ3.41 (qd, 1H, H-5), δ 4.66 (d, 1H, $J_{1,2}$ 3.2 Hz, H-1).

Found: C, 71.04; H, 6.62%. Calcd for $C_{26}H_{28}O_5 \cdot H_2O$: C, 71.23; H, 6.85%.

Acetylation of II and III. About 0.1 g of each sample was dissolved in 2 ml of dry pyridine and then acetylated with 0.2 ml of acetic anhydride and allowed to stand for 24 h. Each residue of the evaporation *in vacuo* was chromatographed on 10 g of silica gel. The peracetyl product of II (IV) was eluted with 1% acetone/benzene (200 ml) after the column had been washed with benzene (200 ml). The acetylation of III only gave a monoacetyl product (VIII). It was eluted with 2% acetone/benzene (200 ml) from the column. The yields were almost theoretical. The repeated crystallization of IV from 80% aqueous acetone gave needles; mp 172—174 °C, $[\alpha]_D^{20}$ +38.02° (*c* 1, chloroform).

Found: C, 71.00; H, 6.68%. Calcd for $C_{30}H_{32}O_7$: C, 71.41; H, 6.40%.

PMR data for IV (100 MHz): δ 1.01 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ 1.75 (s, 3H, OAc), δ 1.90 (s, 3H, OAc), δ 3.30 (s, 3H, OCH_3), δ 3.80 (dd, 1H, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 10 Hz, H-2), δ 4.04 (qd, 1H, $J_{4,5}$ 1.5 Hz, H-5), δ 4.02 (d, 1H, H-1), δ 5.12 (dd, 1H, $J_{3,4}$ 3.5 Hz, H-4), δ 5.45 (dd, 1H, H-3).

PMR data for VIII (60 MHz): δ 1.00 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ 2.02 (s, 3H, OAc), δ 2.25 (dd, 1H, $J_{4,5}$ 1.5 Hz, $J_{3,4}$ 3.5 Hz, H-4), δ 3.22 (s, 3H, OCH_3), δ 3.47 (qd, 1H, H-5), δ4.07 (dd, 1H, $J_{2,3}$ 10 Hz, $J_{3,4}$ 3.5 Hz, H-3), δ4.75 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), δ 5.31 (dd, 1H, H-2).

Methylation of II and III. Each of the trityl ethers (0.1 g) was methylated in dry *N,N′*-dimethylformamide (5 ml) with methyl iodide (0.4 ml) and 0.8 g of a 1 : 1 mixture of silver oxide and barium oxide for 24 h. After filtration, each filtrate was concentrated *in vacuo*, and the residue was resolved in an admixture of methyl ethyl ketone and benzene (1 : 1 v/v) (20 ml), after which the solution was filtered to remove any insoluble matter. Each residue of the evaporation was chromatographed on 10 g of silica gel. The per-

methylated products, V and IX, were eluted with 1% acetone/benzene (200 ml). The yields were about 60% in both cases. The preparation of V and IX showed spots of R_f-values of 0.67 and 0.45 respectively on a thin-layer chromatogram with 6% acetone/benzene. Both derivatives were crystallized from 80% ethanol solutions as prisms; mp for V: 124 °C and mp for IX: 131—133 °C. The $[\alpha]_D^{20}$ of V was +24.5 ° (*c* 1.6, chloroform), and the $[\alpha]_D^{20}$ of IX was +131.1° (*c* 1.5, chloroform).

PMR data for V (60 MHz): δ 1.09 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ 2.96 (s, 3H, OCH_3), δ 3.17 (d, 1H, $J_{1,2}$ 3.4 Hz, H-1), δ 3.47 (s, 3H, OCH_3), δ 3.57 (s, 3H, OCH_3), δ 4.13 (dd, 1H, $J_{2,3}$ 10.0 Hz, H-2).

PMR data for IX (60 MHz-FT): δ 0.89 (d, 3H, $J_{5,6}$ 6.7 Hz, CH_3), δ 1.72 (s broad, 1H, H-4), δ 3.23 (s, 3H, OCH_3), δ 3.27 (s, 3H, OCH_3), δ^{ca} 3.33 (H-5), δ 3.63 (s, 3H, OCH_3), δ^{ca} 3.85 (dd, 1H, $J_{1,2}$ 3.3 Hz, $J_{2,3}$ 10.0 Hz, H-2), δ^{ca} 4.13 (dd, 1H, $J_{3,4}$ 2.2 Hz, H-3), δ 4.77 (d, 1H, H-1).

Found for V: C, 74.96; H, 7.25%. Calcd for $C_{28}H_{32}O_5$: C, 74.97; H, 7.19%.

Found for IX: C, 74.91; H, 7.20%. Calcd for $C_{28}H_{32}O_5$: C, 74.97; H, 7.19%.

Detritylation of V and IX. Each 50-mg portion of V and IX was dissolved with 80% acetic acid (0.5 ml) and heated at 90 °C in a sealed tube for 30 min. The solutions were then concentrated with toluene (3 ml) *in vacuo*. The residue of evaporation were chromatographed on 5 g of silica gel. The detritylation products, VI and X, were eluted with chloroform (100 ml). The subsequent evaporation of the eluting solvent left VI and X in almost theoretical yields. Retention index (I_R)[13] on GLC (He: 22 ml/min, column: 5′×1/8″, glass, column temperature: 140 °C) for VI: 2026 (5% NPGS/Chromosorb W) and 1526 (2% OV 17/Chromosorb W), for X: 2035 (5% NPGS) and 1584 (2% OV 17). Both ethers were crystallized from hexane solutions as needles; mp for VI: 82—85 °C, and mp for X: 74—78 °C, $[\alpha]_D^{20}$ for VI: +201.1 ° (*c* 0.9, chloroform) and $[\alpha]_D^{20}$ for X: +175.4° (*c* 1.2, chloroform).

Found for VI: C, 52.25; H, 8.57%. Calcd for $C_9H_{18}O_5$: C, 52.41; H, 8.80%.

Found for X: C, 52.23; H, 8.53%. Calcd for $C_9H_{18}O_5$: C, 52.41; H, 8.80%.

Methyl 2,3-Di-O-methyl α-D-Fucopyranoside (XII). Methyl 2-*O*-methyl α-D-fucopyranoside (0.5 g) was methylated in almost the same manner as is described above with methyl iodide (0.25 ml). After the removal of the catalyzer and the silver iodide, the residue of evaporation was chromatographed on 10 g of silica gel. The partially methylated products, X and XII, were eluted with 9% acetone/benzene (200 ml). The eluent was divided into five 40-ml fractions. Then it was re-chromatographed four times, while the fractions were gradually returned to the column with additional eluting solvent to get thirteen fractions. Each residue of evaporation was chromatographed on a thin-layer plate. The combined fractions, which contained only XII, were dried *in vacuo*. The residue weighed about 60 mg and had an $[\alpha]_D^{20}$ of +145.0 ° (*c* 1.0, chloroform). The structure of XII was confirmed by PMR as its acetylated derivative (XIII). I_R for XII: 2000 (5% NPGS) and 1584 (2% OV 17).

Found: C, 52.10; H, 8.60%. Calcd for $C_9H_{18}O_5$: C, 52.41; H, 8.80%.

Acetylation of VI, X and XII. The acetylation procedure used for these ethers was almost the same as that used for II and III. The acetylation products, VII, XI, and XIII, were purified by chromatography, after having been eluted with 1% acetone/benzene (200 ml) from silica gel column (10 g). The evaporation of the eluting solvent left the acetylation products in an almost theoretical yield as glass: $[\alpha]_D^{20}$ for VII; +156.4° (*c* 0.3, chloroform), for XI; +156.0° *c* 1.3, chloroform), and for XIII; +138.7° (*c* 0.6, chloroform). I_R for VII; 2095 (5% NPGS) and 1700 (2% OV 17), for XI; 2112 (5% NPGS) and 1770 (2% OV 17) and for XIII; 1981 (5% NPGS) and 1667 (2% OV 17).

PMR data for VII (60 MHz): δ 1.25 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ 2.08 (s, 3H, OAc), δ 3.34 (s, 3H, OCH_3), δ 3.45 (s, 3H, OCH_3), δ 3.57 (s, 3H, OCH_3), δ 3.87 (qd, 1H, H-5), δ 4.85 (d, 1H, $J_{1,2}$ 3.7 Hz, H-1), δ 5.12 (dd, 1H, $J_{2,3}$ 10.0 Hz, H-2), for XI (60 MHz): δ 1.22 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ 2.10 (s, 3H, OAc), δ 3.37 (s, 3H, OCH_3), δ 3.43 (s, 3H, OCH_3), δ 3.48 (s, 3H, OCH_3) δ^{ca} 3.48 (H-4), δ 3.70 (dd, 1H, $J_{1,2}$ 3.7 Hz, $J_{2,3}$ 10.3 Hz, H-2), δ 3.93 (qd, 1H, H-5), δ4.82 (d, 1H, H-1), δ 5.10 (dd, 1H, $J_{3,4}$ 3.2 Hz, H-3), and for XIII (100 MHz): δ 1.17 (d, 3H, $J_{5,6}$ 6.5 Hz, CH_3), δ2.20 (s, 3H, OAc), δ 3.44 (s, 3H, OCH_3), δ 3.46 (s, 3H, OCH_3), δ 3.55 (s, 3H, OCH_3), δ 4.03 (qd, 1H, H-5), δ 4.89 (d, 1H, $J_{1,2}$ 3.2 Hz, H-1), δ 5.36 (dd, 1H, $J_{4,5}$ 1.2 Hz, $J_{3,4}$ 3.0 Hz, H-4).

Relative peak intensities on MS for VII: *m/e* 72; 77, *m/e* 74; 82, *m/e* 75; 86, *m/e* 88; 100, *m/e* 97; 5.0, *m/e* 101; 18, *m/e* 116; 23, *m/e* 129; 14, *m/e* 157; 0.5, *m/e* 185; 4.0, *m/e* 204 ($M-CH_3CHO$); 0.8, *m/e* 217 ($M-CH_3O$); 0.3, for XI; *m/e* 72; 51, *m/e* 74; 100, *m/e* 75; 38, *m/e* 88; 36, *m/e* 97; 20, *m/e* 101; 30, *m/e* 116; 40, *m/e* 129; 24, *m/e* 157; 6.0, *m/e* 185, 1.2, *m/e* 204 ($M-CH_3CHO$); 0, *m/e* 217 ($M-CH_3O$); 1.0, and for XIII: *m/e* 72; 2.0, *m/e* 73; 18, *m/e* 74; 10, *m/e* 75; 44, *m/e* 85; 24, *m/e* 88; 100, *m/e* 97; 4.5, *m/e* 101; 8.5, *m/e* 116; 3.0, *m/e* 125; 5.4, *m/e* 129; 5.5, *m/e* 157; 0.8, *m/e* 185; 1.2, *m/e* 204 ($M-CH_3CHO$); 1.0, *m/e* 217 ($M-CH_3O$); 1.4.

The authors wish to thank Mr. Katsuhiko Kushida for determining the NMR spectra.

A Convenient Synthesis of β-Acetyl-γ-substituted-γ-butyrolactones and γ-Acetyl-δ-substituted-δ-valerolactones

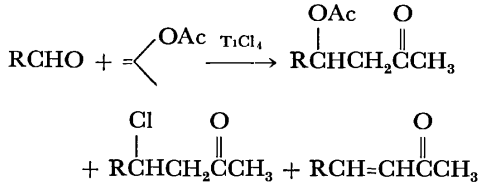
Toshio SATO, Junichi HANNA, Hideo NAKAMURA, and Teruaki MUKAIYAMA*

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 16, 1975)

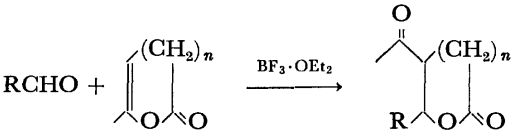
A convenient method for the preparation of β-acetyl-γ-substituted-γ-butyrolactones (III) and γ-acetyl-δ-substituted-δ-valerolactones (IV) is described. It was established that α-angelicalactone (I) and 3,4-dihydro-6-methyl-2*H*-pyran-2-one(II) react with various aldehydes in the presence of boron trifluoride etherate ($BF_3 \cdot OEt_2$) to afford the corresponding γ and δ-lactones, respectively, in good yields.

In the course of our continuing studies of useful synthetic reactions promoted by $TiCl_4$, it was found recently that trimethylsilyl enol ethers or isopropenyl acetate react with various aldehydes, ketones, or acetals to give the aldol type addition products in good yields.[1] For example, isopropenyl acetate reacts with aldehydes to afford β-acetoxy methylketones along with β-chloroketones and α,β-unsaturated ketones. The latter two products are formed by the subsequent displacement or elimination reaction



of the β-acetoxy methylketones initially formed.

In the present experiment, it was found that β-acetyl-γ-substituted-γ-butyrolactones (III)[2] and γ-acetyl-δ-substituted-δ-valerolactones (IV) are synthesized in good yields by the reactions of α-angelicalactone (I) or 3,4-dihydro-6-methyl-2*H*-pyran-2-one (II), chosen as cyclic enol esters in place of isopropenyl acetate in the above experiment, with various aldehydes activated by $BF_3 \cdot OEt_2$.



I, II I, III ($n=1$) III, IV

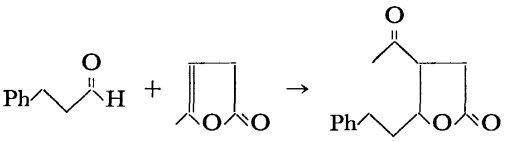
II, IV ($n=2$)

Rothe *et al.*[3] reported that β-acetyl-γ-butyrolactones are produced by treating levulinic acid and aldehydes with potassium carbonate; however, this is not suited to the preparative method since the reaction was carried out under rather severe conditions and the yields were very low.

Results and Discussion

In the present experiment, it was found that, when the mixture of α-angelicalactone (I) and 3-phenylpropanal in methylene chloride was stirred in the presence of $TiCl_4$ or $SnCl_4$ at room temperature over night, β-acetyl-γ-phenethyl-γ-butyrolactone (IIIa) was obtained in 54% or 44% yield, respectively, along with a considerable amount of levulinic acid produced by hydrolysis of α-angelicalactone. In the above experiment, the reaction was carried out in a heterogeneous system, since $TiCl_4$ or $SnCl_4$ formed solid complexes between the aldehydes, α-angelicalactone, and the products in methylene chloride. On the other hand, when $BF_3 \cdot OEt_2$ is used in place of $TiCl_4$ or $SnCl_4$ in the above experiment, the reaction was carried out in a homogeneous system and the corresponding lactone was obtained in 94% yield after 8 h at 0 °C. This result showed that $BF_3 \cdot OEt_2$ was more suitable for this reaction than $TiCl_4$ and $SnCl_4$. It was also found that the lactone was produced in 94 or 87% yield, respectively, when a half molar or a catalytic amount of $BF_3 \cdot OEt_2$ was used.

Table 1. The effect of solvent on the yield of the γ-butyrolactone (IIIa)



Solvent	Temp	Time (h)	Yield of IIIa (%)
CH_2Cl_2	0 °C	1	85
C_6H_5	r. t.	1	84
CCl_4	0 °C	6	71
Et_2O	0 °C	12	83
	r. t.	20	

Concerning the effect of solvents, it was shown that benzene and methylene chloride are more suitable solvents than diethyl ether and carbon tetrachloride with respect to yield and reaction velocity, as shown in Table 1.

In a similar manner, the reaction of α-angelicalactone with various aldehydes, such as benzaldehyde, cinnamaldehyde, chloroacetaldehyde, dichloroacetaldehyde, and formaldehyde, were carried out in the presence of an equimolar amount of $BF_3 \cdot OEt_2$ in methylene chloride, and the corresponding β-acetyl-γ-butyrolactones were obtained in good yields, as shown in Table 2.

Next, it was established that γ-acetyl-δ-phenethyl-δ-valerolactone (IVa) was obtained in 69% yield by treating 3,4-dihydro-6-methyl-2*H*-pyran-2-one (II) with 3-phenylpropanal in the presence of $BF_3 \cdot OEt_2$ in methylene chloride at 0 °C over night. The yield of the lactone was increased to 84% by employing two molar amounts of II against one molar amount

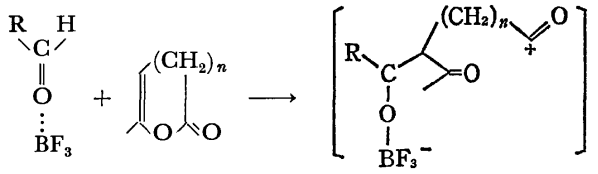
a) Two isomers (*trans* (higher melting point) : *cis*(lower melting point)=8 : 1) were isolated by silica gel chromatography (solvent: benzene–ethyl acetate). These were isomerized by $BF_3 \cdot OEt_2$ in methylene chloride and the ratio of *trans* and *cis* was 8 : 1 at equilibrium. b) Lit, 118—125/5.[3] c) Decomposed during the course of vacuum distillation.

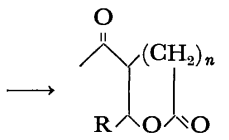
of 3-phenylpropanal, based on the observation that II reacted with aldehydes more slowly than α-angelicalactone and that II was gradually decomposed by $BF_3 \cdot OEt_2$.

Similarly, various γ-acetyl-δ-valerolactones were obtained by the reaction of II with various aldehydes, such as propionaldehyde, chloroacetaldehyde, phenylacetaldehyde, benzaldehyde, and formaldehyde, as shown in Table 2.

This reaction may be explained by assuming an initial formation of aldehyde–$BF_3 \cdot OEt_2$ complex, which in turn reacts with α-angelicalactone (I) or 3,4-dihydro-6-methyl-2*H*-pyran-2-one (II) to give an addition product of V or VI. The intermediate



I, II V, VI



III, IV

I, III, V (n=1)
II, IV, VI (n=2)

adduct (V or VI) immediately cyclizes to form γ or δ-lactone (III or IV).

It is expected that the present reaction provides a simple and useful method for the syntheses of naturally occurring γ or δ-lactone derivatives. Actually, we recently reported the stereospecific synthesis of antibiotic botriodiplodin from β-acetyl-α-methyl-γ-butyrolactone produced by the reaction of α-methyl-α-angelicalactone with formaldehyde.[4]

Experimental

All boiling points and melting points were uncorrected. The IR spectra were recorded with a Hitachi Model EPI G3 spectrometer. The proton NMR spectra were obtained in carbon tetrachloride or deuterio chloroform solutions on a Varian T-60 spectrometer with TMS as an internal standard.

α-Angelicalactone (I) was prepared from levulinic acid. Bp 56—58 °C/12 Torr.[5] 3,4-Dihydro-6-methyl-2*H*-pyran-2-one (II) was prepared according to Shiroyan *et al.*[6] Bp 82—83 °C/23 Torr.

Reaction of α-Angelicalactone with 3-Phenylpropanal. $BF_3 \cdot OEt_2$ (0.142 g, 1 mmol) in 4 ml of methylene chloride was added slowly at 0 °C into a mixture of α-angelicalactone (0.098 g, 1 mmol) and 3-phenylpropanal (0.134 g, 1 mmol) in 6 ml of methylene chloride. The reaction mixture was stirred for 8 h at 0 °C. After being quenched with saturated NaCl solution, it was extracted with benzene. The extract was dried over anhydrous sodium sulfate. After removal of the solvent, 0.201 g (94%) of β-acetyl-γ-phenetyl-γ-butyrolactone (IIIa) was isolated by silica gel chromatography (solvent: benzene–ethyl acetate).

Similarly, IIIb—d were obtained under the reaction conditions shown in Table 2. The NMR and IR spectra of IIIa—f are shown in Table 3.

Reaction of α-Angelicalactone with Formaldehyde. Formaldehyde gas, prepared by thermal cracking of paraformaldehyde (0.604 g, 20 mmol) at 200 °C, was introduced into α-angelicalactone (0.982 g, 10 mmol) in 25 ml of methylene chloride at 0 °C. After stirring for 15 min, $BF_3 \cdot OEt_2$ (1.42 g, 10 mmol) in 5 ml of methylene chloride was added slowly into the reaction mixture at 0 °C and the reaction mixture was stirred for 1 h. After being quenched with saturated sodium hydrogen carbonate solution, it was extracted with methylene chloride. The extract was dried over anhydrous sodium sulfate, concentrated, and the residue was chromatographed on silica gel (solvent: benzene–ethyl acetate) to

mixture was stirred for 30 min at 0 °C, it was worked up as in the preparation of IIIf, to afford 0.255 g, (90%) of γ-acetyl-δ-valerolactone (IVf).

Hydrolysis of Carbohydrates in the Presence of a Reversed Micelle. I. Hydrolysis of Sucrose in a Dioxane-Water Mixed Solvent

Kenichiro ARAI, Yoshitaka OGIWARA, and Kazuyoshi EBE

Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received April 18, 1975)

Formation of a reversed micelle by dodecybenzenesulfonic acid (DBSH) in a dioxane-water mixed solvent was discussed in terms of the behavior of critical micelle concentration and NMR study. Hydrolysis of sucrose in the presence of the reversed micelle was then investigated. The pseudo-first-order rate constant of the reaction showed a tendency to increase with decreasing substrate concentration and increasing dioxane composition, and the maximum rate acceleration obtained in the present experiment was 21-fold on the basis of the reaction in aqueous solution. The rate acceleration may result from the solvent effect of dioxane relating to the structuredness of water and the substrate binding effect due to the formation of the reversed micelle.

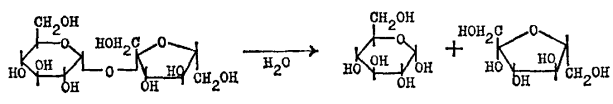
The hydrolysis of carbohydrates in the presence of catalysts has been studied.[1-3] Numerous studies have been made on catalysis in the presence of a micelle[4] and also in the presence of a reveresed micelle.[5-9] In the present work the hydrolysis of sucrose as a model substance of carbohydrates in the presence of a reversed micelle was investigated. First the formation of the reversed micelle in the dioxane–water mixed solvent was examined, since carbohydrates are not sufficiently soluble in a polar solvents such as benzene and cyclohexane for the reaction rate to be followed accurately. If dodecylbenzenesulfonic acid (DBSH) can form a reversed micelle in the mixed solvent and the carbohydrates are bound into the micelle, it can be expected that the hydrolysis rates of sucrose are affected; the carbohydrates bound into the micelle are hydrolyzed in the presence of locally concentrated protons in the interior of the micelle.

There is little information on the reversed micelle in a mixed solvent, and its behavior was predicted to be very complicated.[10] The analyses were therefore carricd out with emphasis on the rate enhancement.

Experimental

Materials. Reagent grade sucrose, dioxane and hydrochloric acid (Wako Chemical Co., Tokyo) were used. Deionized and distilled water was used. Commercial sodium dodecybenzenesulfonate (Tokyo Chemical Co., Tokyo) was passed through a cation-exchange resin column in order to obtain free acidic surfactant.

Measurement of the Reaction Rate. DBSH was dissolved in a dioxane–water mixture and added to a sucrose aqueous solution, and the resulting mixture was kept at 40 °C. Aliquots of the mixture were taken out at intervals and the optical rotatory powers were measured by an automatic digital polarimeter (Nippon Bunko Co., Tokyo, DIP-180; accuracy ±0.002°). The logarithm of the difference between the optical rotatory powers, m_t at a reaction time t and m_∞ at infinite time (practically at ten times half life), was plotted against the reaction time, and the pseudo-first-order rate constant, k_1, was estimated from the slope (Fig. 1).



$[\alpha]_D^{20} = 66.45$ $[\alpha]_D^{20} = -19.7 + 0.36C$

A fairly good straight line was obtained for each plot. The changes in optical rotatory powers in water are as above.

Critical Micelle Concentration (CMC). Electric conductances of DBSH–dioxane–water mixed solutions were measured with an electric conductance titrator (Mitamura Riken Co., Tokyo) at various concentrations of DBSH, specific electric conductances being plotted against the concentration of DBSH. The maximum experimental error of specific conductance was ±0.001 S. The CMC was estimated from the break in the plots.

NMR Study. NMR spectra were obtained with an analytical NMR spectrometer (Nichiden-Varian Co., Varian A-60D, 60 MHz) at various concentrations of DBSH and hydrochloric acid, the chemical shifts of water-proton being measured. Sodium 3-trimethylsilylpropanesulfonate was used as a reference.

Results and Discussion

Formation of Reversed Micelle. First we examined whether reversed micelle could be formed by DBSH. Figure 2 shows the plots of the electric conductance of DBSH–dioxane–water mixtures against the con-

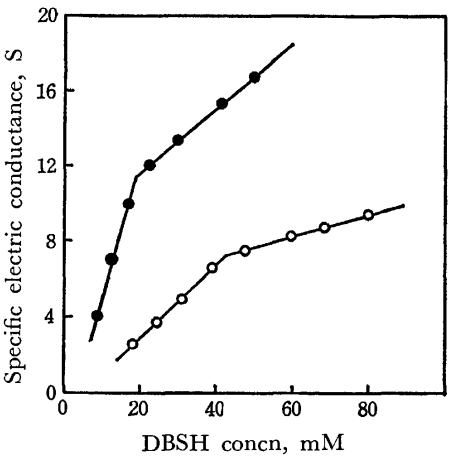

Fig. 2. The plots of the specific electric conductance of DBSH in dioxane-water mixtures against the concentration of DBSH at 40 °C.
Solvent: ○; dioxane 70 vol%, ●; dioxane-free.

centration of DBSH at compositions of dioxane 0 and 70 vol%. The concentration of surfactant corresponding to the break point of the straight lines obtained is considered to be CMC. The break point of the straight line can be clearly seen for the mixture with dioxane composition of 70 vol% as well as in the dioxane-free medium (Fig. 2), although it has been reported that the CMC of a reversed micelle is not clear.[11] This suggests the formation of a micelle even at higher dioxane composition.

Figure 3 shows the temperature dependence of the CMC estimated by the electric conductance method. It was found that the CMC is scarcely influenced by temperature. This behavior is in approximate agreement with the general characteristics of the micelle of ordinary alkylbenzenesulfonates.

Figure 4 shows the changes in CMC with the concentration of added sucrose. The CMC in the mixed solvent of dioxane 70 vol% decreases with addition of sucrose up to about 50 mM, and then levels off, but hardly changes in the dioxane-free solvent. The decrease in CMC with the addition of polar substrate was also found by Fendler *et al.*[6] in the reversed micelle system, and might indicate substrate binding into the micelle. The leveling off of the CMC with increasing sucrose concentration at higher dioxane compositions might be due to the fact that the amount of sucrose bound into the micelle does not increase any more with increasing concentration of sucrose under the conditions.

Figure 5 shows the relationship between the CMC and dioxane composition in the mixed solvents. DBSH was found to be insoluble in the range 20—50 vol% of dioxane. This suggests that the micelle formed at above 60 vol% of dioxane is the reversed micelle. The CMC is scarcely influenced by the dioxane composition in the lower range. In the higher range of dioxane composition, however, the CMC increases with increasing dioxane composition, and then shows a maximum at 80 vol% of dioxane. In the higher range of dioxane composition than those shown in Fig. 5, measurement of CMC was impossible because of the phase separation. The increase in CMC with increasing dioxane composition does not necessarily rule out the possibility of the reversed micelle formation, since the size of the micelle in the mixed solvent probably changes remarkably with changing solvent composition.[10]

The proton magnetic resonance shifts of water-proton in the presence of DBSH and hydrochloric acid in the dioxane–water mixed solvent at various concentrations were measured in order to investigate the reversed micelle formation. It has been established that the chemical shift of the proton magnetic resonance is concentration-dependent in the solutions of electrolytes which yield hydrogen-containing ions. The chemical exchange averages the chemical shifts in the proton resonance position over the different chemical species, and the averaged shifts observed are correlated with the dissociation of the solute.[12–15] Figure 6 shows the plots of averaged chemical shift *vs.* acid concentrations in the aqueous solution and in the dioxane–water mixed solvent with 70 vol% of dioxane. In the aqueous solution, the changes in the chemical shift with addition of acids were relatively small and

the difference in the chemical shifts of DBSH and hydrochloric acid appeared to be within the error limit. In the mixed solvent the chemical shift shifted to higher magnetic field with addition of dioxane, the changes in the chemical shift with addition of acids being greater than those in aqueous solution. The shifts may be related to the changes in structuredness of water. The changes in chemical shift were found to become smaller with addition of DBSH than with that of hydrochloric acid with an increase in acid concentration above 30 mM. The difference may result from the decrease in dissociation of DBSH due to "concentration" of sulfonic acid groups in the interior of the reversed micelle.

It seems that DBSH could form a reversed micelle in a dioxane–water mixed solvent with dioxane above 60 vol%, although the micelle might be less stable than the typical reversed micelle formed in neat apolar solvents.

Hydrolysis of Sucrose in the Presence of the Reversed Micelle. Hydrolysis of sucrose in dioxane–water mixed solvents in the presence of the reversed micelle mentioned above was investigated. Figure 7 shows the plots of the pseudo-first-order rate constant, k_1, estimated from the changes in the optical rotatory power of the reaction mixture (see Fig. 1) *vs.* the concentration of DBSH. Above 60 vol% of dioxane each plot gives two half lines, whereas below 10 vol% it gives only one straight line. In the hydrolysis of sucrose in the presence of hydrochloric acid, each similar plot of k_1 gives only one straight line independent of dioxane composition in the mixed solvent. Since k_1 was defined as the pseudo-first-order rate constant at a constant concentration of DBSH, the slope of the straight lines gives the apparent second-order rate constant, k_2, when the changes in the amount of water in the mixed solvent are not considered. Above 60 vol% of dioxane, k_2's in the lower and higher concentration ranges of DBSH are denoted by k_{2L} and k_{2H}, respectively. k_2 for the hydrolysis of sucrose in the presence of hydrochloric acid is denoted by k_{2HCl}. Although the concentration of DBSH corresponding to the break point on the straight line was slightly higher than the CMC estimated by the electric conductance method under the same conditions, the concentration may be considered as CMC, since CMC is known to be slightly affected by the measuring method and also the changes in concentration corresponding to the break point with change in concentration of DBSH and sucrose qualitatively agree with those of the CMC estimated by the electric conductance method (Table 1). Fendler *et al.*[7] also found a change in rate constant at a certain concentration by changing the concentration of surfactant. The hydrolysis of sucrose seems to be accelerated with formation of reversed micelle.

k_2's estimated at various concentrations of sucrose and dioxane are summarized in Table 2. It was found that k_2's increased with increasing dioxane composition in the mixed solvents for all of the k_{2H}, the k_{2L} and the k_{2HCl}. The increase may arise from the increase in activities of proton and water molecules due to the decrease in structuredness of water with addition of dioxane.[16] At the same composition of dioxane, k_{2L}'s were always smaller than k_{2HCl}. These differences may be due to the differences in the degree of dissociation. Above 60 vol% of dioxane and higher concentration range of DBSH, however, k_{2H}'s were greater than k_{2L}'s and even greater than k_{2HCl}. This rate enhancement might result from the substrate binding into the reversed micelle in which protons

were concentrated. The ratio k_{2H}/k_{2L} could be regarded as a measure of rate enhancement produced by the formation of reversed micelle. The ratios were found to increase with increasing dioxane composition. It is presumed that the stability of reversed micelle increases with lowering polarity of the mixed solvent or increasing dioxane composition, the effect leading to rate enhancement. The ratio k_{2H}/k_{2L} was also found to decrease with increasing sucrose concentration. The decrease could be explained as the result of averaging of reaction rates in and out of the reversed micelle, since the amount of sucrose bound into the micelle was presumed not to change, at least remarkably, with increasing total amount of sucrose, while the amount of sucrose existing out of the micelle increased, and the averaged reaction rate or the rate enhancement decreased with increasing total amount of sucrose. This explanation is supported by some investigations published so far. For example, Konno and Kitahara[17] reported that a small amount of water solubilized in reversed micelle is firmly bound into the micelle, but the binding become more loose, even less than that of free water, with the increase in amount of water solubilized. Kitahara[18] found that the change in the amount of water solubilized in the anionic surfactant reversed micelle scarcely influences the amount of micelle. The value of k_{2H}/k_{2L} corresponding to the sucrose concentration 41.6 mM and dioxane 85 vol% was found to deviate from the tendency mentioned above (Table 2). A similar deviation of the value of CMC estimated by the electric conductance method under the same conditions is shown in Fig. 5.

It may be concluded that DBSH forms a reversed micelle in dioxane–water mixture with above 60 vol% of dioxane and the micelle accelerates the hydrolysis of sucrose by binding the substrate inside. The maximum rate enhancement obtained in the present investigation was *ca.* 21-fold, and it was predicted to increase with decreasing sucrose concentration. The rate enhancement may result from the solvent effect of dioxane relating to the structuredness of water and the substrate binding effect due to the formation of reversed micelle.

We are very grateful to Professor Norio Ise, Kyoto University, Kyoto, for his helpful discussion.

Solvent Effects on Stereo and Regioselectivities of Ring-opening Reaction of Epoxide with Aluminum Chloride

Masashi INOUE, Toshio SUGITA,* Yoshiaki KISO, and Katsuhiko ICHIKAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received May 31, 1975)

The ring-opening of 2,3-epoxybutane with aluminum chloride yielding 3-chloro-2-butanol was carried out in several different solvents. The reaction proceeds with 94% retention of configuration in a nitromethane solvent. The retentive ring-opening was observed to variable extents when nitro compounds, ethers, and aromatics were utilized as the solvents, but a complete inversion resulted in the other solvents. The regioselectivity was examined using 1,2-epoxypropane. The composition of the 1-chloro-2-propanol and 2-chloro-1-propanol thus produced was also strongly affected by the solvent. The latter was exclusively produced in nitromethane, though the former predominated in several other solvents. The structure of aluminum chloride in various solvents is discussed, and aluminum chloride–solvent 1 : 1 addition compounds in solution are concluded to be important for retentive and abnormal ring-opening.

Much has been written regarding the ring-opening reaction of epoxides. Nevertheless, the stereo and regioselectivities of the reaction are still somewhat confused subjects.[1] Ring-openings of epoxides with a nucleophile are generally accompanied with inversion of configuration at the point of attack, and can be explained by S_N2 mechanism. Reactions which proceed with retention of configuration have been reported in some cases of phenyl and acyl substituted epoxides. A double inversion mechanism with neighboring groups and a four-centered mechanism with an ion-pair have been proposed for these reactions.[2-5] Parker and Isaacs proposed that the reactions which proceed with racemization take place not by S_N1, but by concurrent S_N2 and S_Ni mechanisms.[1a]

When unsymmetrically substituted epoxides are involved, ring-opening can occur in either of two different directions:

$$\text{R-CH(O)CH}_2 \xrightarrow{\text{HA}} \text{R-CH(OH)-CH}_2\text{A} + \text{R-CH(A)-CH}_2\text{OH}$$

Normal product Abnormal product

In general, a reaction to cleave the bond between less substituted carbon and oxygen is termed "normal ring-opening," while the other direction is termed "abnormal." In the case of base-induced reactions of epoxides, normal ring-opening is predominant, but acid-catalyzed substitution reactions usually give considerable amounts of abnormal products.

Yielding chlorohydrins by the reaction of epoxides with aluminum chloride is well known not only as a side reaction of the Friedel-Crafts reaction, but also as a modification of catalyst in cationic polymerizations of epoxides. We reported in a previous paper that an alkyl-substituted epoxide, propylene oxide, afforded a chlorohydrin with a retained configuration in a reaction with aluminum chloride in a nitromethane solution.[6] In the present paper, we wish to report the solvent effect on the stereo and regioselectivities of the ring-opening reaction of epoxide with aluminum chloride.

Results and Discussion

Stereoselectivity. The ring-opening reaction of *cis*- and *trans*-2,3-epoxybutane (**1**) with aluminum chloride (**2**), yielding *erythro*- and *threo*-3-chloro-2-butanols (**3**), was examined in several different kinds of solvents. The stereochemical results are summarized in Table 1. It was also confirmed that the stereochemistry of the product was not affected in the course of hydrolysis of the produced aluminum alkoxide, since no ^{36}Cl was introduced into the product when the reaction mixture was hydrolyzed with aqueous $H^{36}Cl$.

$$\underset{\textbf{(1)}}{\text{CH}_3\text{-CH(O)CH-CH}_3} \xrightarrow[\text{ii) } H_3O^+]{\text{i) } AlCl_3\ (2)} \underset{\textbf{(3)}}{\text{CH}_3\text{-CH(OH)-CH(Cl)-CH}_3} \quad (1)$$

The solvents in which the reaction proceeds with retention of configuration are limited to aromatics, ethers, and nitro compounds. The product corresponding to the retention of configuration predominated only in the solvents of nitro compounds.

The ring-opening of **1** with **2** was carried out in carbon disulfide containing variable amounts of nitro-

a) Reactions were run in 8 ml of the solvent unless specified otherwise on 4 mmol scale of **1** with 1.5 equiv. of **2** for 2 h. b) Cooling bath temperature. c) **1** (4.88 mmol), **2** (5.59 mmol), **4** (4 ml), $CHCl_3$ (4 ml). d) **1** (2.80 mmol), **2** (5.60 mmol), sulfolane (39.4 mmol), $(CH_2Cl)_2$ (4 ml). e) **1** (5.30 mmol), **2** (5.48 mmol), $(CH_3)_2SO_2$ (100 mmol), $(CH_2Cl)_2$ (20 ml). f) **1** (4.35 mmol), **2** (5.07 mmol), C_5H_5NO (17.0 mmol), $CHCl_3$ (10 ml). g) Nakajima reported that the ring-opening reaction of 1,2-epoxypropane with **2** proceeds with 12% retention of configuration in a mixed solvent of sulfolane and 1,2-dichloroethane.[7]

methane (**4**). In Fig. 1, the percentages of retention are plotted against the amounts of **4** added. Nearly linear correlations between the amounts of **4** added and the percentage of retention are observed in the regions of **4**/**2**<0.5 and **4**/**2**>4. From the intersection to these two straight lines, values of **4**/**2**=1.4 and 1.8 are obtained for *cis*- and *trans*-**1** respectively. This fact seems to indicate that the ring-opening is connected with the 1 : 1 addition compound of **2** and **4**, although the possibility of the participation of the 1 : 1.5 or 1 : 2 addition compound cannot be completely excluded. On the other hand, it has been reported that nitroalkanes and many aromatic nitro compounds react with **2** to form crystalline solids, generally with the formula of $AlCl_3 \cdot RNO_2$, but also, in a few cases, that of $AlCl_3 \cdot 2RNO_2$.[8a]

Table 2. Stereochemistry of ring-opening of 2,3-epoxybutane with $AlCl_3$ in the presence of nitrobenzene derivatives (p-X-C_6H_4-NO_2)[a]

OH[c]	2.4	−0.82

a) Reactions were carried out using *cis*-**1** in 1,2-dichloroethane containing nitrobenzene derivatives (1.0 M) at 0 °C, **2**/**1**=1.0−1.4, nitrobenzene derivatives/**2**=8.6−8.9. b) Reaction is homogeneous. c) Reaction is heterogeneous.

The substituent effects of p-substituted nitrobenzenes were investigated in order to account for the specificity of nitro compounds; the results are shown in Table 2. Within the nitro compounds which are soluble in 1,2-dichloroethane, a good correlation is obtained between the percentages of retention and the $\sigma_p - \sigma_m$ values of the substituents, which have been suggested as measures of the resonance effect of the given substituents. This fact indicates that the resonance between π-electrons of an aromatic ring and a nitro group is very significant in the retention process. On the other hand, the $\sigma_p - \sigma_m$ values should reflect the stabilities of the 1 : 1 addition compounds, of which structural information has been reported by Gagnaux.[9] Thus, the more stable 1 : 1 addition compounds, $AlCl_3 \cdot Sv$ (**5**, Sv=solvent), increases the retentive ring-opening reaction.

p-Cyano-, p-hydroxy- and p-amino-nitrobenzenes are insoluble in 1,2-dichloroethane, and the reaction systems are heterogeneous. A nonpolar solvent capable of undergoing a homogeneous reaction was searched for in vain. The reaction is accompanied with an almost complete steric inversion when these nitrobenzenes were added. In these cases, the group coordinating to aluminum may be not nitro, but cyano, hydroxyl or amino group, even if these compounds form complexes with **2**.

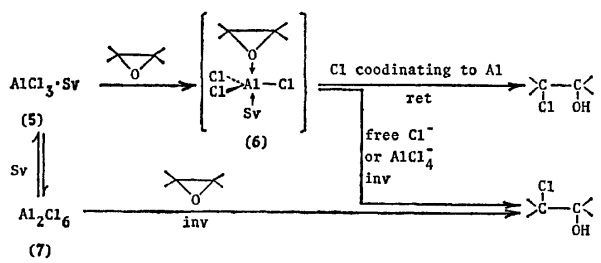
The proportions of the retention slightly increase in the order of: benzene<toluene<mesitylene, although the Friedel-Crafts reactions occur predominantly in these solvents. It is still less certain that **2** interacts with aromatic hydrocarbon, but these has been evidence of weak complex formation from solubility measurements.[8b] Roberts[10] reported that the susceptibility toward a **2**-induced rearrangement of n-propyl side chains decreased in the series of n-propylbenzene, n-propyltoluene, and n-propylxylene. He attributed

this to the postulate that the catalyst is progressively less active due to complex formation with aromatics with increasing Lewis basicities. In the present case, the percentage of retention is also proportional to the stability order of the aluminum chloride complexes to be formed.

The same conclusion can also be drawn from a series of aliphatic nitro compounds. It is well-known that the steric effects have an important influence on the stability of the 1 : 1 complexes of Lewis acids and bases.[11] Brown[12] reported that the stabilities of the 1 : 1 complexes of boron trifluoride and ethers decreased in the order of: $Me_2O \cdot BF_3 > Et_2O \cdot BF_3 > i\text{-}Pr_2O \cdot BF_3$. The stabilities of the complexes of **2** and nitro compounds are expected as: $MeNO_2 \cdot AlCl_3 > n\text{-}PrNO_2 \cdot AlCl_3 > i\text{-}PrNO_2 \cdot AlCl_3$. The sequence is actually consistent with the observed order of the percentages of retention.

In the earlier reports on the ring-opening reactions of epoxides which proceeded with retention of configuration, the mechanism was discussed in the following terms: 1) a double inversion with the participation of neighboring groups, and 2) a four-centered or an ion-pair mechanism. Although the mechanism 1 was proposed for the case of phenyl- and carbonyl-substituted epoxides,[2,3,5] it is improbable for an alkyl-substituted epoxide in the present case. The mechanism 2 was proposed by Wasserman and Aubrey[5] as a possible explanation of the results of the reaction of dypnone oxide with hydrogen chloride. Brewster[4] also supposed an ion-pair in a solvent cage to explain the *cis* ring-opening of *trans*-α-methylstilbene oxide with acetic acid. An analogous mechanism, shown in Scheme 1, seems to be applicable to the present case.

Solvates of different compositions are known for **2** containing from one to six donor molecules per molecule of **2**. Solvents of a weak coordinating affinity give 1 : 1 addition compounds, and those of better coordinating properties give 1 : 1, 1 : 1.5, and 1 : 2 compounds, while 1 : 4 and 1 : 6 compounds are limited only to some powerful coordinating solvents. A solvate of the $AlCl_3 \cdot Sv$ type was regarded as an acceptor solvate,[13] since it is capable of accepting further solvent or other donor molecules.



Scheme 1.

On the addition of epoxide, the solvated aluminum chloride (**5**) may accept lone-pair electrons of epoxide and is transformed into the complex **6**. The collapse of **6** gives chlorohydrin of a retained configuration whose chlorine comes from the coordinating site to aluminum. On the contrary, the inverted product can be derived by the attack of the free chloride ion in the solution on the solvated complex **6**. An analogous mechanism involving a common intermediate leading to both *cis* and *trans* oxymercurials was recently proposed by Bach and Richter.[14] Furthermore, in the present case, the solvated complex **5** may be equilibrated with the aluminum chloride dimer (**7**). **2** is well-known to exist as a dimer in carbon disulfide or in chloroform. Since a chlorohydrin with an inverted configuration is obtained in these solvents, the reaction of epoxide and **7** is considered to proceed with inversion. In the system involving a stable addition compounds, the equilibrium should lie towards the complex **5** rather than **7**; that is, the more stable addition compounds afford an increased amount of the chlorohydrin with a retained configuration.

If the ring-opening of epoxide with **2** is assumed to follow Scheme 1, free ion species and also **7** should not exist in the system which produces a chlorohydrin with a retained configuration. However, an inconsistency inheres in this condition. To satisfy the condition, the solvent must be moderately basic; free chloride ion may be formed by the cleavage of Al–Cl bonds if the solvent basicity is too strong.

Table 3. Stereochemistry of ring-opening of 2,3-epoxybutane with $AlCl_3$ in nitromethane. Effects of the additional lithium halide

Lewis acid (mole ratio)	Stereochemistry Retention %
2	85
2+LiCl (1 : 1)	6
2+HCl (1 : 1)	3
2+HCl (1 : 0.03)	72
2+LiBr (1 : 1)	2[a]
$AlBr_3$+LiCl (1 : 1)	1[a]
(LiCl)	No reaction
(LiBr)	No reaction

a) The product is 3-bromo-2-butanol containing trace of **3**.

In order to discuss the effect of a free ion, the ring-opening reaction of **1** was pursued in **4** by the addition of lithium salts as a source of free ions. The results are tabulated in Table 3. The reaction process alters from retention to inversion by the addition of an equivalent amount of lithium chloride. In the experiments using $Li^{36}Cl$, the produced **3** contained 22.6% of the activity. This result indicates that all the chlorines of lithium chloride and **2** are equivalent within the limits of experimental error. The addition of lithium chloride creates an equilibrium:

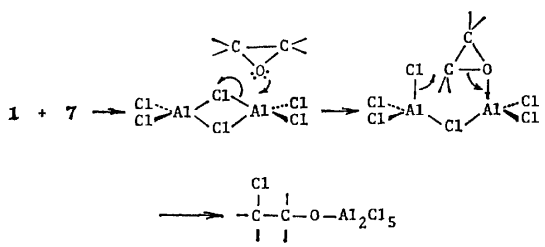
$$AlCl_3 \cdot Sv + LiX \overset{Sv}{\rightleftharpoons} LiSv_n^+ + AlCl_3X^- \qquad (2)$$

The anion, $AlCl_4^-$, formed in this equilibrium attacks epoxide, and the reaction proceeds with inversion of configuration.

A mechanism involving the back-side shielding by a solvent may be expected, but it is inadequate for the present system by the facts that a high retention of configuration is observed only in nitro compound

solvents, and that the reaction proceeds with complete inversion in acetonitrile, which exhibits a good back-side shielding effect in solvolysis.[15] The substitution reaction of epoxides under acidic conditions was claimed not to proceed by the *A*1 mechanism, but by the borderline *A*2 mechanism even in a system stabilizing the carbonium ion such as styrene oxide.[16] It was also reported that the rearrangement of oxirane to carbonyl compounds does not occur through a planar carbonium ion, but occurs in a more concerted manner.[17] The temperature effect on the stereoselectivity shown in Table 1 seems to constitute evidence for the arguments on the intermediacy of the fully developed carbonium ion. If the ring-opening in **4** proceeds by means of the carbonium ion–back-side shielding mechanism, the ratio of racemization would increase at higher temperatures. At 27 °C, the result is 25% retention and 75% inversion, which means 50% inversion and 50% racemization. As inversion and racemization at 18 °C are 28 and 72% respectively, an inversion process prevails at higher temperatures. The observed temperature effects cannot be explained by assuming the formation of a carbonium ion. These results suggest a larger activation entropy and enthalpy for the reaction accompanied with steric inversion than for the reaction with retention. Taking the cyclic transition state, the S_Ni reaction can be expected to have a smaller activation enthalpy and a larger negative value of activation entropy than the S_N2 reaction. The observed temperature effect is explainable by assuming the S_N2 mechanism for the ring-opening reaction with inversion and the S_Ni mechanism for the reaction with retention. However, the differences in the relative rates due to the reaction temperature are too large to be accounted for by only the competition of S_N2 and S_Ni reactions. These differences may also be due to an equilibrium between **5** and **7**, as is indicated in Scheme 1.

The ring-opening reaction proceeds with inversion of configuration in nonpolar solvents, such as carbon disulfide and chloroform, in which **2** is dimeric. In these solvents, however, it is difficult to assume a free ionic species which attacks the coordinated epoxide from the back-side. Therefore, it seems to be difficult to explain an inversion mechanism by a model for the transition state at a single metal atom center. A mechanism which involves two separate metal sites has been proposed by Price for the triethylaluminum–water catalyzed epoxide polymerization, which proceeds with inversion of configuration at the carbon atom undergoing ring-opening attack.[18] We propose, on these bases, a most plausible mechanism for the ring-opening of epoxide with **7** in a nonpolar solvent (Scheme 2), although we expected a mechanism including two molecules of **2** for the reaction in a previous paper.[6]



Scheme 2.

Many studies have been made concerning the structure of **2** in solutions; among them, the investigation by means of NMR appears to be most reliable. The solution structures of **2** can be classified into the following four groups on the basis of the experimental results obtained by NMR techniques:

Type 1. Solutions in which **2** is completely dissociated into ions.

Solutions of **2** in protic and aprotic polar solvents belong to this group. In dimethyl sulfoxide (DMSO)[19] and ethanol,[20] the Al–Cl bonds are completely dissociated into ions, and the aluminum cation is coordinated by six molecules of the solvents.

$$AlCl_3 + 6Sv \longrightarrow AlSv_6^{3+} + 3Cl^- \quad (3)$$

Type 2. Solutions in which disproportionation occurs.

The apparent solvation number of **2** in acetonitrile is 1.5,[21] and the Al–Cl bonds dissociate partially into ions.[20,22]

$$4AlCl_3 + 6Sv \longrightarrow AlSv_6^{3+} + 3AlCl_4^- \quad (4)$$

Type 3. Solutions in which **2** forms 1 : 1 addition compounds with the solvents.

$$AlCl_3 + Sv \longrightarrow AlCl_3 \cdot Sv \quad (5)$$

Although many compounds are reported to form 1 : 1 addition compounds in the crystalline state with **2**, the existence of the 1 : 1 compounds in solution has been confirmed in a few cases. Nitro compounds are considered to form the 1 : 1 adduct in solution.[23] Ether and benzene may also form 1 : 1 adducts in the equilibrium state.[20,24] The 1 : 1 adducts are acceptor solvates, as has been mentioned before.

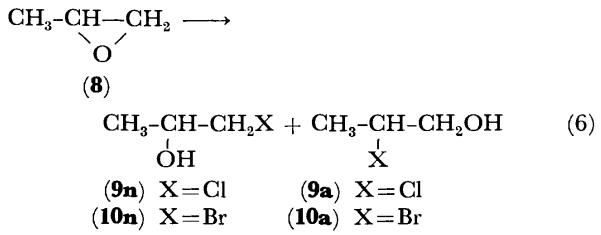
Type 4. Solutions in which **2** exists as a dimer.

2 exists as a dimeric form (**7**) in nonpolar solvents, such as carbon disulfide and chloroform.[25] Ether and benzene are considered to contain **7** under equilibrium with the 1 : 1 adducts.[20,24]

The ring-opening of epoxide with **2** proceeds with retention of configuration only in the solvents of Type 3. In mixed solvents, the one with the stronger ability to coordinate to aluminum determines the nature of the solution; *e.g.*, the solution structures of the mixed solvents of Types 1 and 2, and of Types 2 and 3 are dominated by the solvent natures of Types 1 and 2 respectively. When an equivalent amount of **4** to **2** is added to an acetonitrile solvent, the structure of the solution is Type 2, and the epoxide is ring-opened with 100% inversion. This result is in good contrast with that of the reaction carried out in a carbon disulfide solution containing **4**.

Haraguchi reported the order of coordination affinity against aluminum as $H_2O > EtOH \gg I > Br > Cl > PhCN > CH_3CN$.[20,24] If lithium halide is added to the solutions of Types 2 and 3, aluminum in the solution will mostly be in the state of $AlCl_3X^-$, since the halogen has a stronger affinity than the solvent does. In these systems, the reaction proceeds with inversion.

Regioselectivity. The reaction was carried out in a way similar to that mentioned in the stereochemical section, using 1,2-epoxypropane (**8**) instead of **1**. The isomer distributions of the produced chloropropanols (**9**) are summarized in Table 4.



(**8**)

$$CH_3\text{-}CH(OH)\text{-}CH_2X \quad (\mathbf{9n})\ X=Cl \quad (\mathbf{10n})\ X=Br$$
$$+\ CH_3\text{-}CH(X)\text{-}CH_2OH \quad (\mathbf{9a})\ X=Cl \quad (\mathbf{10a})\ X=Br \qquad (6)$$

Table 4. Ring-opening reaction of 1,2-epoxypropane with $AlCl_3$ in various solvents[a]

Solvent	Yield **9** (%)	Product ratio (%)	
		9n	**9a**
CS_2	54.0	47	53
$ClCH_2CH_2Cl$	71.0	17	83[b]
Et_2O	26.3	57	43
CH_3NO_2	51.6	2	98
CH_3CN	97.5	87	13
EtOH	96.4	91	9
DMSO	18.7	81	19

a) Experimental conditions are **8** : **2** : solvent = 1 : 1 : 50. b) The proportion of **9a** depends upon the rate of addition of **8**, and it decreases until a minimum 18% when **8** is added rapidly.

In contrast with the fact that normal ring-opening is predominant in acetonitrile, ethanol, and DMSO, the proportion of the abnormal ring-opening product (**9a**) is increased in ether, carbon disulfide, and 1,2-dichloroethane. Furthermore, an extensive abnormal ring-opening as much as 98% is observed in nitromethane. A few reactions are known which proceed with more than 90% abnormal ring-opening. In these cases, nucleophiles preferably attack the hindered carbon atom.

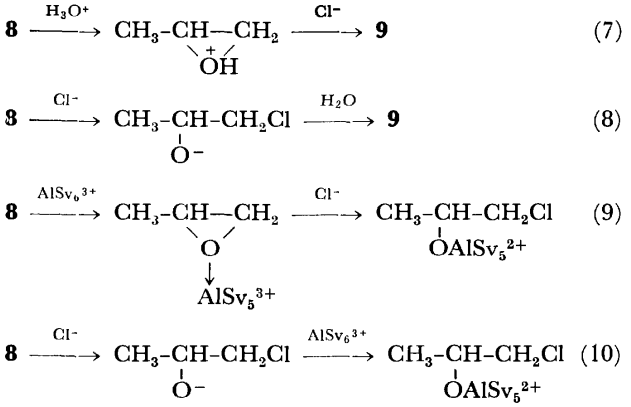
Although several different mechanisms have been called into play to explain the divergent results of ring-opening reactions of epoxides, a consistent explanation can be given in terms of a "push-pull" mechanism.[26] Because of the strain in the three-membered ring of epoxide, the cleavage of the C–O bond will be important, especially in acid-catalyzed reactions, in which proton or Lewis acid coordinates to the epoxide oxygen. The coordination of these acids provides a strong pull in the displacement. As a result, steric factors are less influential than usual.

The ring-opening of aliphatic epoxide with **2** in **4** cannot be considered to involve a fully developed carbonium ion, but the 1 : 1 adduct of **2** and **4** is an acceptor solvate and can coordinate on the epoxide oxygen. Thus, favorable bond-breaking may occur between secondary carbon and oxygen giving the abnormal product (**9a**).

Such mode of reaction is often observed in the substitution reactions of heterocyclic compounds.[27] For example, the Friedel-Crafts reaction of **8** proceeds with inversion of configuration, accompanied with a complete abnormal ring-opening.[6] The ring cleavage of cyclic sulfate has been considered to proceed by S_N1 mechanism under acidic conditions, because the reaction of unsymmetrical cyclic sulfate from 1,3-butanediol with hydrochloric acid takes place on the secondary carbon.[28] However, the ring-opening of the cyclic sulfate of 2,4-pentanediol with hydrochloric acid proceeds with complete inversion of configuration, yielding 4-chloro-2-pentanol.[29]

As has been postulated in the foregoing stereochemical section, $AlCl_3 \cdot Sv$ (**5**) is the reacting species in **4** and ether solutions, and the chlorine atom of the products comes from the coordination sphere of aluminum. In DMSO, ethanol, and acetonitrile, on the contrary, chloride and $AlCl_4^-$ ions play an important role in the nucleophilic substitution of epoxide. The dissociated aluminum cation is completely solvated, fulfilling its coordination number, and it seems no longer to provide a strong pull by the coordination of the epoxide oxygen.

It has also been reported that the ring-opening reaction of **8** with hydrochloric acid proceeds concurrently by the two paths shown in Eqs. 7 and 8.[16] Analogous courses can be considered for the reaction of **8** with **2** in polar solvents (Eqs. 9 and 10):



$$\mathbf{8} \xrightarrow{H_3O^+} CH_3\text{-}CH(\overset{+}{O}H)\text{-}CH_2 \xrightarrow{Cl^-} \mathbf{9} \qquad (7)$$

$$\mathbf{8} \xrightarrow{Cl^-} CH_3\text{-}CH(O^-)\text{-}CH_2Cl \xrightarrow{H_2O} \mathbf{9} \qquad (8)$$

$$\mathbf{8} \xrightarrow{AlSv_6^{3+}} CH_3\text{-}CH(O\rightarrow AlSv_5^{3+})\text{-}CH_2 \xrightarrow{Cl^-} CH_3\text{-}CH(OAlSv_5^{2+})\text{-}CH_2Cl \qquad (9)$$

$$\mathbf{8} \xrightarrow{Cl^-} CH_3\text{-}CH(O^-)\text{-}CH_2Cl \xrightarrow{AlSv_6^{3+}} CH_3\text{-}CH(OAlSv_5^{2+})\text{-}CH_2Cl \qquad (10)$$

The nucleophiles produced in DMSO and ethanol are free and solvated chloride ions respectively, but $AlCl_4^-$ ion is the nucleophile in acetonitrile.[19,20,22] Equation 9 may be considered as a usual acid-catalyzed reaction *via* an onium ion, and Eq. 10, as a reaction with a base. It is well known that the base-induced reaction of epoxide exclusively results in the normal ring-opening. As the normal product (**9n**) is favored in DMSO, ethanol, and acetonitrile, the respectable part of the ring-opening in these solvents is expected to proceed by means of Eq. 10.

The regioselectivity of the ring-opening reaction appears to depend upon the counterbalance of the pull by Lewis acids and the push by nucleophiles. The result that the normal product predominates in the polar solvents may reflect the weak pull by the $AlSv_6^{3+}$ cation and the strong push by the chloride and $AlCl_4^-$ ions. This is in good contrast with the results of the Friedel-Crafts reaction, in which a bulky and weak nucleophile, benzene, provides only a weak push, while **2** pulls very strongly; thus, the result is a complete abnormal ring-opening, as has been mentioned before.

Table 5. Ring-opening reaction of 1,2-epoxypropane in the presence of salts[a)]

DMSO	13.8	69	13	17	1
EtOH	80.4	69	8	21	2
EtOH	100	49	6	43	2

a) Experimental condition; **8** : **2** : LiBr : solvent = 1 : 1 : 1 : 20.

To confirm these considerations we examined the effect of added alkali metal halide on the regioselectivity of the ring-opening of **8** with **2**. Quite a different regioselectivity was observed when the salts are added to **4** and ether solvents.

The results shown in Table 5 can be summarized as follows: 1) the normal ring-opening becomes predominant when the salts are added, and bromides are more effective than chlorides; 2) the bromopropanols (**10**) predominate when bromides are added, except in the cases of sodium and potassium bromides in ether; 3) the difference of cation has little influence on the product compositions.

As is shown in Table 6, the product distribution in acetonitrile is similar to those obtained in **4** and ether; in these solvents $AlCl_3Br^-$ is a reacting species, but it distinctly differs from those in DMSO and ethanol, in which the added salts completely dissociate into ions. This fact indicates that the regioselectivity is related intimately to the anionic species. It has been reported that AlX_4^- has nucleophilicity to some extent, though it is a weaker nucleophile than halide ion.[30)]

If the equilibrium 2 is taken into account, lithium cation should be the acid providing the pull in Eq. (9) when the solvents of the second and third types are used. Although it has been reported that lithium salts have catalytic activities in the ring-opening and rearrangement reactions of epoxides,[31)] only a weak participation of lithium cation may be displayed by the electrostatic interaction in the present case, since not only lithium but potassium salt is effective and the reaction is not so much affected by the change of cations. As the pull provided by the lithium cation may be much weaker compared with that by **5**, the more normal ring-opening results when the lithium halides are added to **4**. When sodium and potassium bromides are added, the equilibrium 2 stays far to the left in ether, because these salts are insoluble in this solvent. Thus, these salts seem to have no influence on the regioselectivity in an ether solvent.

As affinity of bromide ion to aluminum is stronger than that of chloride,[24)] the formation of AlX_4^- species in the equilibrium is more satisfactory when lithium bromide instead of chloride is added. As a result, the more normal ring-opening product is obtained by the addition of lithium bromide.

The results shown in Table 6 can be explained appropriately by taking the before-mentioned types of the solution structure into account. The first class of solvent, consisting of polar solvents such as DMSO, DMF, and ethanol, can completely dissociate **2** and lithium salts into ions. In these solvents, metal cations are strongly coordinated by the solvent molecules. The distribution of the halohydrins produced depends upon the nucleophilicities of the halide ions. In aprotic polar solvents, halide ions are not solvated and their nucleophilicities depend upon their basicities, $Cl^- > Br^-$.[32)] On the contrary, halide ions are solvated in protic solvents, their nucleophilicities do not depend upon the basicities, and the order of nucleophilicities has been well established as $Br^- > Cl^-$.[33)] Accordingly, the predominant product is **9** in aprotic polar solvents, and the extended proportion of **10** results in protic solvents.

In the moderately basic solvents of the second type (acetonitrile, acetone, *etc.*), and in **4** and ether of the third type, a larger amount of **10** was yielded than was to be expected from the nucleophilicities of halide ions in aprotic solvents. The reaction without the addendum in **4** and ether proceeds *via* the complex **6**, where no ionic species are present. An $AlCl_3Br^-$ ion is formed according to Eq. 2 when the lithium bromide is added to solvents of the second and the third classes. It is most reliable that the ring-opening is caused by the attack of $AlCl_3Br^-$ instead of free chloride or bromide ions in these systems. However, insufficient evidence is available to us at this time to interpret the predominant formation of **10** with the use of $AlCl_3Br^-$. One of the most reasonable elucidations for this subject may be offered by Pearson's HSAB principle. Bromine is a softer base within four halogens in $AlCl_3Br^-$, and the carbon atom of epoxide is a soft acid. As a soft acid is favorable to react with a soft base, **10** should be the predominant product of the reaction with $AlCl_3Br^-$.

If the reaction conditions of LiBr/**8**$\geqq$1 are satisfied

Table 7. Effects of mole ratio of the reagents on the ring-opening reaction[a)]

Mole ratio			Product ratio (%)			
8	**2**	LiBr	**9n**	**9a**	**10n**	**10a**
1	1	1	7	1	85	7
1	1	0.5	37	9	50	4
1	1	2	2	trace	89	9
1	0.5	1	4	1	87	8
1	2	1	4	2	86	8
0.5	1	1	5	1	84	10
2	1	1	36	8	51	5

a) Solvent: Et_2O (100 mol eq.)

as is shown in Table 7, **10** is the principal product and no difference is observed in the product distributions. The exhaustive formation of **10** in the system of **8** : **2** : LiBr=1 : 2 : 1 may be indicative that the reaction rate of $AlCl_3Br^-$ and **8** is faster than that of **5** and **8**, for the same amount of **5** as $AlCl_3Br^-$ should exist in the system even if Eq. 2 is completely shifted to the right under these conditions.

In the nonpolar solvents which are classified as the fourth type (carbon disulfide, dichloroethane, *etc.*), the abnormal ring-opening product indicates a tendency to predominate over the normal product. The addition of lithium bromide shows little effects, as is shown in Tables 4 and 6. The composition of the normal ring-opening product, **9n**, was increased in the order of 17, 27 and 37% with an increase in the mole ratio of **8**/**2**=1.0, 2.0, and 3.0 in 1,2-dichloroethane. These results indicate that the alkoxyaluminum chloride, which is given by the reaction of **8** and **2**, reacts with additional **8** to give more **9n** than in the reaction of **2**. The proportion of normal ring-opening seems to increase in the order of **2**<$AlCl_2OR$<$AlCl(OR)_2$; these reacting species may be present as dimers in such solvents. As the Lewis acidities generally increase with an increase in the electronegativities of X in metal salts, MX_n, the Lewis acidities decrease in the order of **2**>$AlCl_2OR$>$AlCl(OR)_2$. Thus, the abnormal ring-opening should be favored in the cases of stronger Lewis acids. The product distribution was strongly affected by the rate of addition of **8** to **2**, and the proportion of **9n** was varied from 17 to 82% by rapid addition. As **2** is less soluble in these solvents, the reaction was initially heterogeneous, but **2** was completely dissolved when an equivalent amount of **8** had been carefully added. When **8** is added rapidly, the ring-opening reaction with $AlCl_2$-OR and $AlCl(OR)_2$ may not be neglected. The reactions in these nonpolar solvents are insufficiently reproducible. Since the dissolving rate of **2** should be significantly influenced by the nature of the crystal of **2** and with the mechanical stirring efficiency, the insufficiency of reproducibility appears to be due to these facts.

The results of the present paper are summarized in Table 8.

Experimental

Materials. *cis*-2,3-Epoxybutane (*cis*-**1**) and *trans*-2,3-epoxybutane (*trans*-**1**) were prepared by the method of Pasto and Cumbo.[34] VPC analysis (a 45 m polypropylene glycol Ucon oil LB-550X capillary column was employed) indicated the *trans*-**1** to be free of any *cis*-isomer, whereas *cis*-**1** was accompanied with 1.4% of the *trans*-isomer. Commercial 1,2-epoxypropane (**8**, special grade) was distilled before use. Commercial special grade aluminum chloride (**2**) was purified by sublimation three times under a reduced pressure before each use. Lithium chloride and bromide were dried over P_2O_5 at 140 °C in vacuum. All the solvents were dried by the most efficient ways appeared in the literature[35] and were distilled before use.

A Typical Procedure of Ring-opening Reaction. Into a solution of **2** (0.877 g, 6.58 mmol) in 4 ml of acetonitrile,[36] **1** (0.318 g, 4.69 mmol) in 4 ml of acetonitrile was slowly added under well-stirring in an ice bath. It took 2 h for the addition at a constant temperature, and stirring was continued for an additional 30 min. After the duration, the reaction mixture was poured into a mixture of 10 ml of concd HCl and 50 g of ice. The organic layer was separat-

a) Those indicated in italics are the active species of each reaction.

ed and washed with 20 ml of water. The combined aqueous layer was saturated with NaCl and extracted twice with 30 ml and then with 20 ml of ether. The combined organic layer was dried over Na_2SO_4 after the addition of mesitylene as an internal standard. The solvent was evaporated off, and the residual product was submitted to VPC analysis. *erythro*-3-Chloro-2-butanol (**3**) was obtained in 38% yield based on **1**, and neither *threo*-**3** nor the unreacted **1** was detected. The product was identified by a comparison of the VPC retention time with those of the authentic samples.[37] The product was converted into *trans*-**1** with dil. NaOH.

When 1,2-epoxypropane (**8**) was treated with **2** in ether, 1-ethoxy-2-propanol (yield 8.1%) was obtained, accompanied with chloropropanols (**9**, yield 26.3%). The former was identified after the product mixture had been treated with dil. NaOH, converting **9** to **8**, by comparisons of the VPC retention time and the NMR spectrum with those of an authentic sample prepared from **8** and sodium ethoxide.

A Typical Reaction Procedure in the Presence of Lithium Bromide. In a cold nitromethane (30.5 g, 500 mmol), 1.4 g (10 mmol) of **2** was dissolved, then 0.87 g (10 mmol) of lithium bromide was added, the mixture turned to a brown homogeneous solution. To the well-stirred solution, 0.61 g (10.5 mmol) of **8** was added dropwise during a period of 20 min in an ice bath. After a duration of 40 min, the reaction mixture was worked up as mentioned above. The yields of **9** and **10** were 8.6 and 37.8% respectively by VPC analysis, the product ratio was 14.0 (**9n**), 4.5 (**9a**), 68.6 (**10n**), and 12.9% (**10a**).

It was confirmed that the products compositions did not change after they were treated again under the reaction conditions.

Vapor-phase Chromatographic (VPC) Analyses. The VPC analyses were carried out on Hitachi K-53 and Shimadzu 3AH gas chromatographs. The retention times of *threo*- and *erythro*-**3**, *threo*- and *erythro*-3-bromo-2-butanols, and mesitylene were 7.4, 8.9, 13.7, 15.7, and 10.4 min respectively on a 2 m column packed with 25% tricresyl phosphate and 1.5% H_3PO_3 on Chamelite CK at a column temperature of 100 °C. The retention times of **9n**, **9a**, **10n**, **10a**, and tetraline (an internal standard) were 3.2, 3.9, 4.8, 6.1, and 9.1 min respectively on a 3 m column of 10% PEG-20M on Celite 545 at 120 °C.

TABLE 9. RESULTS OF ^{36}Cl TRACER EXPERIMENTS OF RING-OPENING REACTION OF 2,3-EPOXYBUTANE WITH $AlCl_3$ IN NITROMETHANE SOLVENTS

Entry	Sample (mmol)	Automatic external standard ratio	dpm	dpm/mmol
1	Blank	0.8777	47.0	
2	**3** (0.292)[a]	0.8817	63.9	
3	$H^{36}Cl$ (1.94×10^{-3})	0.6604	2839.9	1473.7×10^3

a) An authentic non-active sample. b) The product obtained by hydrolyzing the non-active reaction mixture with $H^{36}Cl$ specified in entry 3. **2**: 15.58 mmol, $H^{36}Cl$: 4.85 mmol, ^{36}Cl/total Cl: 9.40%. c) The product obtained by the reaction with **2** (15.25 mmol) and $Li^{36}Cl$ (entry 6; 15.29 mmol), ^{36}Cl/total Cl: 25.2%, ^{36}Cl taken into **3**/total Cl: 22.6% (111920/495404).

^{36}Cl Tracer Experiments. The radioactivity measurements were performed by means of a Packard Tri-Carb liquid scintillation spectrometer model 3380. VPC preparation was made on an Aerograph Auto-prep A-700 chromatograph. Radioactive lithium chloride was prepared from lithium carbonate and 1 N $H^{36}Cl$; it was dried at 140 °C in vacuum until the weight was constant.

The crude **3** obtained by the reaction was purified by means of preparative VPC (Carbowax-20 M 20%, 20 ft column) and then submitted to measurements of the radioactivity. A solution of PPO (4 g) and dimethyl-POPOP (0.1 g) diluted with toluene to 1.0 l was used as the scintillator. The radioactivities of $H^{36}Cl$ and $Li^{36}Cl$ were measured in homogeneous solutions prepared by the addition of small amounts of ethanol or ethanol and water. Quenching corrections were carried out with the use of an external standard channel ratio method. The results of the experiments are summarized in Table 9.

We wish to express our thanks to Professors S. Suga and T. Nakajima, Kanazawa University, for their many helpful discussions. We are especially indebted to Drs. M. Hamada and R. Kiritani, Radiation Center of Osaka Prefecture, where the radioactive tracer experiments were carried out. This work was supported in part by a Scientific Research Grant from the Ministry of Education, Japan (No, 911511).

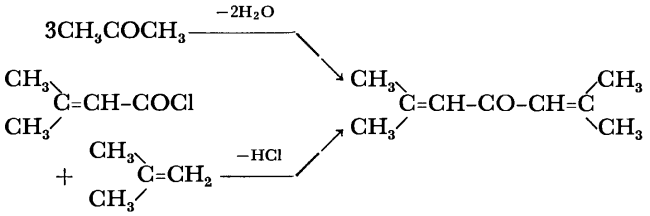
Preparation of Phorone

Yasuo NAKADA, Yasuo YURA, and Keisuke MURAYAMA
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received June 5, 1975)

A new method for preparation of 2,6-dimethylhepta-2,5-dien-4-one (**4**; phorone) from isobutene and carbon tetrachloride is described. A redox addition of carbon tetrachloride to isobutene in the presence of ferric chloride, benzoin, and diethylamine hydrochloride yielded 3-methyl-1,1,1,3-tetrachlorobutane (**1**). 2,6-Dimethyl-2,4,4,6-tetrachloroheptane (**2**) was obtained by the addition of **1** to isobutene or the twofold addition of carbon tetrachloride to isobutene. Treating **2** with ethanolic potassium hydroxide gave 2,6-dimethylhepta-1,5-dien-3-yne (**3**). Hydration of **3** by treating with methanolic boron trifluoride in the presence of mercuric oxide and with aqueous sulfuric acid gave **4**.

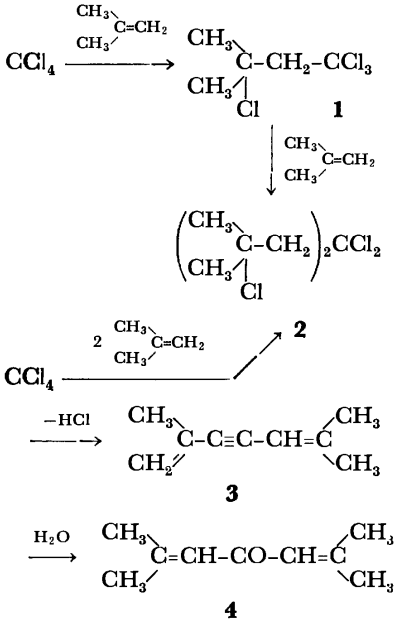
Phorone has been chiefly prepared by dehydrative trimolecular condensation of acetone (method A) under various catalysts such as beryllium chloride[1], ferric oxide[2], and bromomagnesium alcoholate[3], but with less satisfactory results on yield and selectivity. Colonge and Dumont[4] reported another method (method B) treating β,β-dimethylacrylyl chloride with isobutene in the presence of stannic chloride to yield phorone selectively.



The redox addition of haloalkanes to olefins using copper or iron salts as catalysts have been known[5]. Recently, Moore[6] reported the twofold redox addition of carbon tetrachloride to olefins.

$$CCl_4 + 2CH_2{=}CHR \longrightarrow (RCHClCH_2)_2CCl_2$$

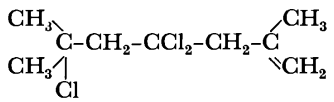
We now wish to report a new preparation method of phorone from isobutene and carbon tetrachloride *via* the twofold addition product as shown in Scheme I.



Scheme I.

The method has the following advantages over the methods described above in spite of having three steps. The yield and selectivity of each steps are better than those of the method A, and starting materials, isobutene and carbon tetrachloride are easily available by comparison with the method B.

According to the procedure of Asscher and Vofsi,[5] the redox addition of carbon tetrachloride to isobutene in the presence of ferric chloride, benzoin, and diethylamine hydrochloride afforded 3-methyl-1,1,1,3-tetrachlorobutane (**1**)[7] in a high yield. The compound **1** was treated with an additional mol of isobutene to yield 2,6-dimethyl-2,4,4,6-tetrachloroheptane (**2**) in 46% yield. Also, the compound **2** was directly obtained from 1 mol of carbon tetrachloride and 2 mol of isobutene under the same conditions in 47% yield. The mass spectrum of **2** showed peaks at *m/e* (relative intensity): 235 (1), 233 (8), 231 (20), and 229 (20, M−35) suggesting 1 : 2 adduct of carbon tetrachloride and isobutene. The NMR spectrum of **2** showed two singlet peaks at τ 8.15 (12H) and τ 6.96 (4H) corresponding to four equivalent methyl groups and two equivalent methylene groups respectively. Since 2,6-dimethyl-2,4,4,6-tetrachloroheptane (**2**) is a key compound for the preparation of phorone (**4**), we sought the optimum conditions for these redox addition. The results are summarized in Table 1. Thus an optimum result was obtained in Run No. 2. At a temperature above 60 °C the yield of **2** decreased and a dehydrochlorinated product of **2** (**5**; 2,6-dimethyl-4,4,6-trichlorohept-1-ene) and a large amount of distillation residue were formed.



5

At a lower temperature the yield of **2** also decreased.

Dehydrochlorination of **2** with excess ethanolic potassium hydroxide gave 2,6-dimethylhepta-1,5-dien-3-yne (**3**) and 4-chloro-2,6-dimethyl-6-ethoxyhepta-2,4-diene (**6**) in 62 and 23% yields respectively by GLC analysis (silicone DC 550, 125 °C). The IR spectrum of **3** showed characteristic absorptions at 2200 (−C≡C−) and 895 cm^{-1} (>C=CH_2).

According to the procedure of Islam and Raphael,[8] **3** was hydrated by treating with methanolic boron trifluoride in the presence of mercuric oxide and with

Table 1. Preparation of 2,6-dimethyl-2,4,4,6-tetrachloroheptane (2)

Run number	Reactants: Haloalkane	Reactants: Mole ratio Haloalkane/Isobutene[a]	Reaction condition: Temperature (°C)	Reaction condition: Time (h)	Products (%): 2	Products (%): 1

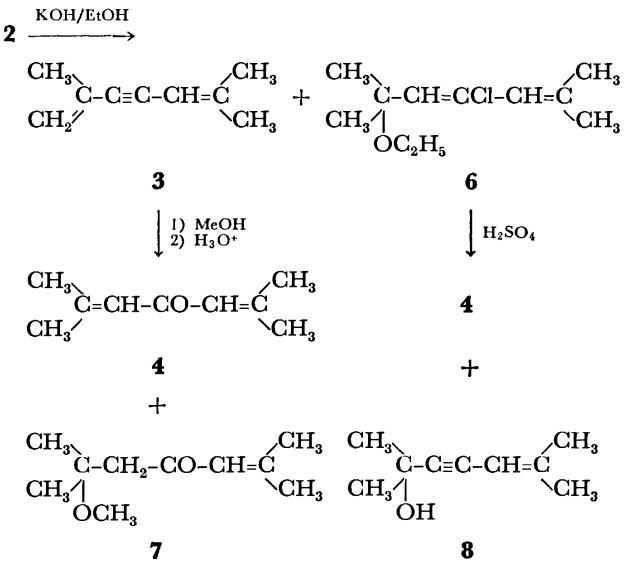
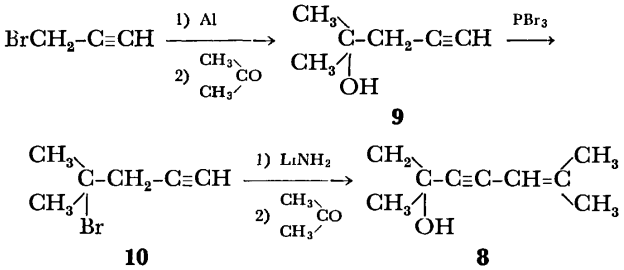
a) Isobutene; 0.30 mol, 2-propanol; 0.45 mol, ferric chloride hexahydrate; 0.0022 mol, benzoin; 0.0022 mol, and diethylamine hydrochloride; 0.0033 mol were used. b) Based on haloalkane. c) A dehydrochlorinated product (**5**; 3%) and a distillation residue(14.3 g) were obtained. d) Based on isobutene.

aqueous sulfuric acid to give 2,6-dimethylhepta-2,5-dien-4-one (**4**, phorone) and 2,6-dimethyl-6-methoxyhept-2-en-4-one (**7**) in 57 and 13% yields respectively by GLC analysis (silicone DC 550, 140 °C). The compound **4** was treated in the same manner as **3** to afford **7** in 62% yield. The structure of **4** was identified by comparing its IR, UV, and NMR spectra with those of an authentic sample.

The treatment of **6** with aqueous sulfuric acid in the presence of mercuric sulfate in water–dioxane (1 : 1) afforded **4** in 27% yield. When **6** was treated with aqueous sulfuric acid in the absence of the mercuric salt, **4** and 2,6-dimethylhept-5-en-3-yn-2-ol (**8**) were obtained in 17 and 72% yields respectively.



The mechanism of formation of **8** is not clear. An IR spectrum of **8** showed characteristic absorptions at 3400 (–OH) and 2220 cm^{-1} (–C≡C–). The structure of **8** was identified by comparing its IR, UV, and NMR spectra with those of an authentic sample which was synthesized independently by the route shown in Scheme II. Thus treating acetone with propargyl aluminium bromide[9] gave 2-methylpent-4-yn-2-ol (**9**). The compound **9** was brominated by phosphorus tribromide to afford 4-bromo-4-methylpent-1-yne (**10**), which was treated with excess lithium amide in liquid ammonia, followed by addition of acetone to give **8**.



Scheme II.

Experimental

3-Methyl-1,1,1,3-tetrachlorobutane (1). According to the procedure of Asscher and Vofsi,[5] a mixture of carbon tetrachloride (92.4 g, 0.60 mol), liquid isobutene (28.5 ml, 0.30 mol), isopropanol (27.0 g, 0.45 mol), ferric chloride hexahydrate (0.60 g, 0.0022 mol), benzoin (0.45 g, 0.0022 mol), and diethylamine hydrochloride (0.36 g, 0.0033 mol) was heated at 80 °C for 6 h to afford 3-methyl-1,1,1,3-tetrachlorobutane (**1**) in 80% yield (Table 1, Run 7): bp 75—77 °C (18 Torr), lit,[7] bp 43—45 °C (3 Torr); IR, ν_{max} cm^{-1}: 710 (C–Cl): NMR (CCl_4): τ 8.13 (s, 6H) and 6.61 (s, 2H); MS, *m/e* (relative intensity): 179(1), 177(7), 175 (17), and 173 (20, M−35).

2,6-Dimethyl-2,4,4,6-tetrachloroheptane (2). A 1 : 1 mixture of **1** and isobutene (Run 9) or 1 : 2 mixture of carbon tetrachloride and isobutene was treated in the similar procedure to the above giving 2,6-dimethyl-2,4,4,6-tetrachloroheptane (**2**) in yields as shown in Table 1: bp 73—75 °C (0.28 Torr); IR, ν_{max} cm^{-1}: 690 (C–Cl); NMR (CCl_4): τ 8.15 (s, 12H) and 6.96 (s, 4H); MS, *m/e* (relative intensity): 235 (1), 233 (8), 231 (20), 229 (20, M−35), 197 (12), 195 (57), and 193 (78, M−71). The reaction was carried out at 70 °C to give 2,6-dimethyl-4,4,6-trichlorohept-1-ene (**5**), which was separated by preparative GLC (carbowax 20 M, 130 °C): IR, ν_{max} cm^{-1}: 1642 and 680; NMR (CCl_4): τ 8.18 (s, 6H), 8.04 (d, 3H; J=1.0 Hz), 7.14 (s, 2H), 6.93 (s, 2H), and 4.8—5.1 (m, 2H); MS, *m/e* (relative intensity): 234 (1), 232 (6), 230 (13), 228 (13, M^+), 197 (20), 195 (98), and 193 (147, M−35).

Dehydrochlorination of **2**. A solution of **2** (5.3 g, 0.020 mol) and potassium hydroxide (9.0 g, 0.16 mol) in ethanol (20 ml) was heated under reflux for 6 h and cooled. After addition of saturated aqueous sodium chloride, the reaction mixture was extracted with ethyl acetate. The extracts were dried over anhydrous magnesium sulfate and evaporated to give 2,6-dimethylhepta-1,5-dien-3-yne (**3**) and 4-chloro-2,6-dimethyl-6-ethoxyhepta-2,4-diene (**6**) in 62 and 23% yields respectively by GLC analysis (silicone DC 550, 125 °C).

Compound **3** and **6** were separated by preparative GLC and their spectral data were obtained as follows: compound **3**[10]; IR, ν_{max} cm^{-1}: 2200, 1610, and 895; UV, λ_{max}^{EtOH} mμ: 241, 252, and 265; NMR (CCl_4): τ 8.24 (d, 3H; J=1.0 Hz), 8.20 (d, 6H; J=1.0 Hz), 4.8—5.0 (m, 2H), and 4.7—4.8 (m, 1H); MS, *m/e* (relative intensity): 120 (14, M$^+$) and 105 (10, M−15) and compound **6**; IR, ν_{max} cm^{-1}: 1635 and 855; UV, λ_{max}^{EtOH} mμ: 234; NMR (CCl_4): τ 8.88 (t, 3H; J=6.8 Hz), 8.62 (s, 6H), 8.05—8.25 (m, 6H), 6.64 (q, 2H; J=6.8 Hz), and 4.3—4.5 (m, 2H); MS, *m/e* (relative intensity): 204 (10), 202 (24, M$^+$), 189 (15), 187 (39, M−15), 167 (44, M−35), 158 (65), and 156 (169, M−46).

Phorone (**4**). Products were separated by preparative GLC and their yields were determined by analytical GLC (silicone DC 550, 140 °C).

Hydration of **3**. A mixture of methanol (1.5 ml), mercuric oxide (0.10 g, 0.00046 mol), ethereal boron trifluoride (0.05 ml), and trichloroacetic acid (trace) was heated under reflux for 10 min and cooled. A solution of **3** (0.12 g, 0.001 mol) in methanol (1.5 ml) was added to the mixture in an ice water bath and stirred at room temperature for 20 min. After pouring into cooled 10% aqueous sulfuric acid (20 ml) the mixture was extracted with ether. The extracts were dried over anhydrous sodium carbonate and evaporated to yield phorone (**4**) and 2,6-dimethyl-6-methoxyhept-2-en-4-one (**7**) in 57 and 13% yields respectively. Also **7** was given in 62% yield by stirring phorone and methanol under the same catalyst for 2 h at room temperature. Following spectral data of **7** were obtained: IR, ν_{max} cm^{-1}: 1680, 1619, and 850; UV, λ_{max}^{EtOH} mμ: 240; NMR (CCl_4): τ 8.83 (s, 6H), 8.15 (d, 3H; J=1.0 Hz), 7.91 (d, 3H; J=1.0 Hz), 7.55 (s, 2H), 6.88 (s, 3H), and 3.9—4.1 (m, 1H); MS, *m/e* (relative intensity): 170 (10, M$^+$) and 138 (16, M−32).

Hydrolysis of **6**. A solution of **6** (0.13 g, 0.00064 mol) in dioxane (1 ml) was added to a solution of mercuric oxide (0.10 g, 0.00046 mol) in 20% aqueous sulfuric acid (1.2 ml) and stirred at room temperature for 3 h. After addition of water the mixture was extracted with ether. The extracts were dried over anhydrous sodium sulfate and evaporated to give phorone in 27% yield. In the absence of mercuric oxide in this system phorone and 2,6-dimethylhept-5-en-3-yn-2-ol (**8**) were obtained in 17 and 72% yields respectively. Following spectral data of **8**[10] were obtained; IR, ν_{max} cm^{-1}: 3400, 2220, and 1630; UV, λ_{max}^{EtOH} mμ: 232; NMR (CCl_4): τ 8.60 (s, 6H), 8.2—8.4 (m, 6H), 7.95 (s, 1H), and 4.7—4.9 (m, 1H); MS, *m/e* (relative intensity): 138 (18, M$^+$), 123 (111, M−15), and 121 (10, M−17).

2-Methylpent-4-yn-2-ol (**9**). According to the procedure of Eiter and Oediger[9], a mixture of propargyl aluminium bromide, prepared from aluminium strips (2.4 g, 0.089 atom), propargyl bromide (1.42 g, 0.12 mol), and mercuric chloride (two spoons), and acetone (7.5 g, 0.13 mol) in tetrahydrofuran (35 ml) was stirred at 0 °C for 1 h to obtain 2-methylpent-4-yn-2-ol (**9**) in 69% yield: bp 68—71 °C (115 Torr); IR, ν_{max} cm^{-1}: 3400, 3310, and 2140; UV, λ_{max}^{EtOH} mμ: 238; NMR[11] (CCl_4): τ 8.74 (s, 6H), 8.05 (t, 1H; J=2.4 Hz), 7.17 (d, 2H; J=2.4 Hz), and 7.44 (s, 1H); MS, *m/e* (relative intensity): 83 (25, M−15) and 81 (10, M−17).

4-Bromo-4-methylpent-1-yne (**10**). A solution of phosphorus tribromide (3.3 g, 0.012 mol) in ether (10 ml) was dropwise added to a solution of **9** (3.0 g, 0.030 mol) and pyridine (1.2 g, 0.015 mol) in ether (20 ml) below 0 °C and stirred for 30 min at 0 °C. After pouring into ice, the mixture was extracted with ether. The extracts were washed with 5% hydrochloric acid and 5% aqueous sodium carbonate and dried over anhydrous sodium carbonate. Evaporation of ether gave crude **10** in 28% yield, which was not purified further because of its unstability. The IR spectra showed characteristic peaks at 3300, 2210, and 650 cm^{-1}.

2,6-Dimethylhept-5-en-3-yn-2-ol (**8**). A solution of **10** (1.0 g, 0.0062 mol) in ether (20 ml) was dropwise added at −60 °C to a solution of lithium amide in liquid ammonia (100 ml) and stirred at −65 °C for 3 h. A solution of acetone (1.3 g, 0.020 mol) in ether (15 ml) was dropwise added to the mixture and stirred at −60 °C for 3 h. After addition of ammonium chloride the mixture was allowed to stand overnight to evaporate ammonia. After addition of water the mixture was extracted with ether. The extracts were washed with 5% hydrochloric acid, 5% aqueous sodium hydrogen carbonate, and saturated aqueous sodium chloride successively, and dried over anhydrous sodium sulfate. Evaporation, followed by distillation gave 0.36 g (42%) of **8**, bp 63—67 °C (6 Torr).

shift of each proton varies with the amount of $Eu(DPM)_3$ added in the manner shown in Figs. 3 and 4. It is hence possible to determine by interpolation the chemical shift of each proton in the absence of $Eu(DPM)_3$. The values thus obtained are shown in Table 2. The coupling constants of protons are given in Table 3.

The difference in chemical shift for each proton before and after the addition of 60 mg of $Eu(DPM)_3$, designated as $\Delta\delta$, is shown in Table 2. In the case of the addition of 60 mg of $Eu(DPM)_3$, the values of $\Delta\delta$ suggest that $Eu(DPM)_3$ forms complexes with both ketone and ester groups. A comparison of the $\Delta\delta$

values reveals information on the configurations of I and II. As is shown in Table 2, the H_a of I has a considerably larger $\Delta\delta$ value than the H_a of II. It is likely that the proximity of H_a and –OAc in I, or a *cis* configuration as suggested by the IR data, results in a larger shift for H_a, while a *trans* configuration for H_a and –OAc in II is affected less by the shift reagent. On the other hand, the spatial relationship between H_a and the ketone carbonyl group seems not to differ from I to II. Now, the $\Delta\delta$ for the H_d of II is larger than that for the H_d of I, although the difference here is not so pronounced as in the $\Delta\delta$ for H_a. In considering the configuration of H_d and –OAc, it is likewise assumed that the shift appears larger in II because of the *cis* configuration for H_d and –OAc, while the shift is smaller in I on account of the *trans* configuration for H_d and –OAc. Moreover, H_h is little affected by the shift reagent, as it is located in the β-position relative to both carbonyl and ester groups; only a small difference in chemical shift is found between I and II.

In the NMR spectra measured in the absence of the shift reagent, I shows the chemical shift of H_h at a normal value of $\delta=2.5$, while II shows it in an unusually low magnetic field of $\delta=3.2$. The configuration for H_h and –OAc is *cis* in II; that is, H_h is nearer to the ester carbonyl group. The anisotropy[5] of this ester carbonyl group seems to account for the appearance of the chemical shift of H_h in the lower magnetic field. On the contrary, the lack of such a phenomenon in I suggests that H_h and the ester group in I are not *cis* to each other.

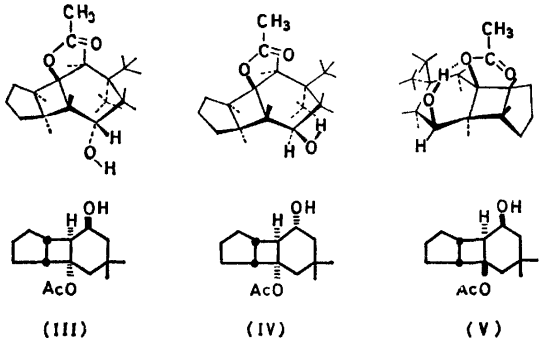
In summary, the above-mentioned results indicate that I assumes a *cis-anti-cis* configuration, while II assumes a *cis-anti-trans* configuration. The fusion of the five-membered and four-membered rings is *cis* in both I and II.

IR Spectra of III, IV, and V. The infrared spectra were measured on the III, IV, and V alcohols which had been obtained from I and II by reduction with $NaBH_4$ in order to determine whether or not there was an intramolecular hydrogen bond between the alcoholic OH and the carbonyl oxygen or ether oxygen of the ester group. The measurements were made in carbon tetrachloride at concentrations of 0.1, 0.01, and 0.001 mol/l. The absorptions due to OH stretching look alike in III and IV. As is shown in Table 1, the alcohol, III or IV, arising from the reduction of I produces an absorption peak due to free hydroxyl at 3620 cm^{-1} and a broad absorption peak due to the hydrogen-bonded hydroxyl group near 3500 cm^{-1}; the relative intensity of these peaks varies with the concentration. The absorption near 3500 cm^{-1} becomes exceptionally strong at high concentrations (0.1 mol/l), but it weakens as the concentration diminishes. This indicates that the absoption near 3500 cm^{-1} is due to an intermolecular hydrogen bond. On the other hand, the compound, V, which has been obtained by the reduction of II shows a strong and sharp absorption peak at 3580 cm^{-1} and a weak but sharp absorption peak at 3460 cm^{-1}, and the relative intensity of these two peaks is not affected at all by the concentration in the range from 0.1 to 0.001 mol/l. It is, therefore, likely that these two absorptions are due to intramolecular hydrogen bonding.

Corresponding to these OH absorptions, V shows an absorption of ester carbonyl at 1744 cm^{-1}, as is shown in Table 1. This peak is shifted towards the larger-wave-number side from 1740 cm^{-1}, where the ester carbonyl absorption of II appeared before reduction. It is known that hydrogen bonding between OH and ester carbonyl shifts the infrared absorption of the carbonyl towards the smaller-wave-number side, while hydrogen bonding between OH and ether oxygen of

the ester group shifts it towards the larger-wave-number side.[6] It is, therefore, assumed that the principal hydrogen bond of V (OH absorption at 3580 cm^{-1}) gives rise to a six-membered ring involving the OH and ether oxygen of the ester group. The carbonyl absorption of V has a shoulder at 1700 cm^{-1} which seems to be due to some contribution from a hydrogen bond between OH and ester carbonyl (the formation of an eight-membered ring); the weak but sharp OH absorption at 3460 cm^{-1} is likely to correspond to such a hydrogen bond.

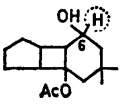
Let us suppose that II assumes a *cis-anti-trans* configuration as has been mentioned above. The six-membered ring would then be in the chair form and hydride would attack a less hindered site in the $NaBH_4$ reduction to produce only an alcohol with a configuration such as V. The construction of a molecular model shows that the OH group is axial and comes very close to the ether oxygen of the -OAc group to facilitate formation of an intramolecular hydrogen bond. On the other hand, if one assumes a *cis-anti-cis* configuration for I, the six-membered ring would not be in the chair form, but rather, in the boat form or labile form, and hydride would attack the carbonyl group from both sides in the $NaBH_4$ reduction to yield two alcohols, III and IV. Molecular models of III and IV show that the OH group and the ester group are sufficiently separated to make the formation of an intramolecular hydrogen bond impossible.



Scheme 2.

NMR Spectra of III, IV, and V. The NMR spectra of III, IV, and V, like those of I and II, do not show much differences in chemical shift, and the definite assignment of each proton is not possible. However, the proton linked to the carbon carrying the OH group can be distinguished because its signal appears in lower magnetic fields than the other protons. Table 4 shows the chemical shift and the half-width ($W_{1/2}$) of this signal. When three or more protons are present on neighboring carbon atoms, as in $-CH_2-CH(OH)-CH<$, the proton on the carbon atom carrying the OH group has a larger coupling constant and, hence, ordinarily a larger half-width of the signal in the axial conformation than in the equatorial conformation —in general, 16 Hz or more in the axial conformation and 12 Hz or less in the equatorial conformation.[7] If this is applied to III, IV, and V, the proton in question is equatorial in III and V and axial in IV, as is shown in Table 4. These results agree with those obtained from the IR data on V mentioned above and support the configuration of V.

Table 4. The NMR signals for 6-hydrogen of III, IV, and V



Compd	δ	$W_{1/2}$ (Hz)	Conformation of 6-hydrogen
III	3.77	9	equatorial
IV	4.05	18	axial
V	4.01	10	equatorial

Table 5. The rate constants of I and II→VI at 25 °C

Comp.	Initial concentration a=[NaOH] (mol/l)	k (s^{-1})
I	8.40×10^{-5}	8.87×10^{-5}
II	8.34×10^{-5}	2.25×10^{-4}

Rate of Formation of α,β-Unsaturated Ketone (VI) from I or II. I or II loses acetic acid in an alkaline solution to yield an α,β-unsaturated keton (VI). The rate of this reaction was determined in ethanol at 25 °C. An ethanol solution of sodium hydroxide was used as an alkali. The reaction is first-order, and a plot of $\log(a-x)$ against t gave a linear relationship wherein a is the initial concentration of I or II, x is the amount of VI formed, and t is the reaction time. The rate constant, k, obtained from the slope of this straight line is given in Table 5.

The rate constant, k, in this case varies with the concentration of alkali. Since the alkaline concentration is the same for I and II, equal to the initial concentration of I or II, the k for II is about 2.7 times as large as that for I. In general, the ionic elimination reaction proceeds more readily in a *trans* configuration than in a *cis* configuration; this also supports the idea that the ring fusion of the four-membered and six-membered rings is *trans* in II and *cis* in I.

Any of the above-mentioned results indicates that I has a *cis-anti-cis* configuration, while II has a *cis-anti-trans* configuration.

Mass Spectra of I, II, and VI. The mass spectra of I and II are shown in Figs. 5(a) and 5(b) respectively. Neither shows any molecular peak corresponding to m/e=250 indicating a cleavage of the cyclobutane ring. On the other hand, the elimination of acetic acid also takes place. In particular, II shows a mass spectral pattern similar to that of the α, β-unsaturated ketone (VI) shown in Fig. 5(c), signifying a ready occurrence of the elimination of acetic acid. I undergoes the elimination of acetic acid only slightly, about 1/20 as much as II; it primarily suffers a cleavage of the cyclobutane ring.

The principal fragment ions and estimated fragmentations are shown below. A metastable peak is observed at m/e=108.8; this indicates the formation of a fragment ion of m/e=141 from a fragment ion of

rate of the elimination reaction of acetic acid (I or II→VI) was followed spectrophotometrically at the absorption maximum of 250 nm.

The solutions of I (2.80×10^{-3} mol/l), II (2.78×10^{-3} mol/l), and sodium hydroxide (8.01×10^{-3} mol/l) in ethanol were each thermally equilibrated at 25 °C. To a 100-ml volumetric flask, 3 ml of a solution of I or II was added, after which the solution was diluted with ethanol (equilibrated at 25 °C) to a volume of nearly 89 ml. Then an equimolar portion of sodium hydroxide solution was added to the flask (1.05 ml for I and 1.04 ml for II), and finally the mixture was diluted to 100 ml with ethanol. The flask was placed in a thermostatic bath at 25 °C. Suitable aliquots of the sample solution were withdrawn at 10—30 min intervals, and immediately the absorbance was measured against an ethanol blank at 250 nm. The concentration of VI (x) was calculated from its extinction coefficient (ε, 9250). In these experiments, the initial concentration of I was 8.40×10^{-5} mol/l, and that of II was 8.34×10^{-5} mol/l. The results are shown in Table 5.

Studies of Unusual Amino Acids and Their Peptides. VI. The Syntheses and the Optical Resolutions of β-Methylphenylalanine and Its Dipeptide Present in Bottromycin

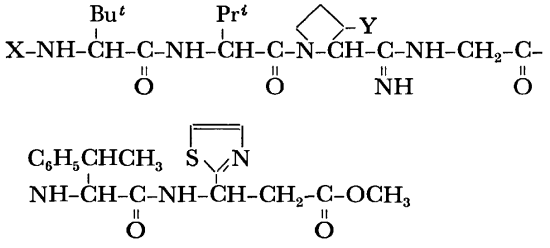
Yoshiharu KATAOKA,* Yasuhiko SETO,** Masaaki YAMAMOTO,*** Takashi YAMADA, Shigeru KUWATA, and Hiroshi WATANABE

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada, Kobe 658

(Received July 25, 1975)

β-Methyl-phenylalanine was prepared by the condensation of α-methylbenzyl bromide with acetaminomalonate, followed by the hydrolysis and decarboxylation of the condensate. The decarboxylation occurred diastereoselectively to some extent. The *erythro* and the *threo* isomers could be separated by the fractional crystallization of their benzoyl derivatives, and differentiated by means of their NMR spectra. The optical resolution of the respective isomers was attained by treating the benzyloxycarbonyl derivatives with qunine or quinidine; thus, the four isomers could be obtained in a pure state. A dipeptide present in the C-terminal of bottromycin was synthesized by coupling N-protected *erythro*-L-β-methyl-phenylalanine with either L-β-(2-thiazolyl)-β-alanine ester or, more conveniently, with the DL-compound, and by separating thereafter.

Bottromycin, a peptidic antibiotic discovered in the fermentation broths of *Streptomyces bottropensis* by Waisvisz and his co-workers,[1] contains many unusual amino acids. Structural studies of this antibiotic were carried out by Waisvisz[1,2] and by Umezawa *et al.*;[3] the formula shown in Fig. 1 has been proposed by the latter.

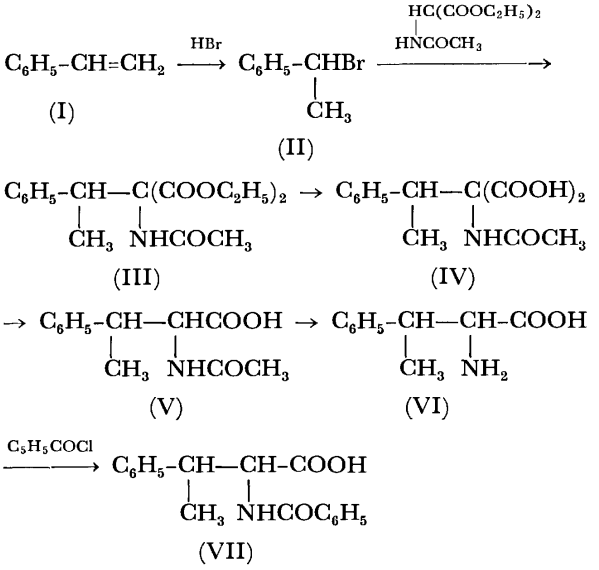


X=Pivaloyl or Δ^1-isocaproyl
Y=H or CH_3

Fig. 1. Structure of bottromycin.

In a previous paper[4] we have made clear the absolute configuration of β-(2-thiazolyl)-β-alanine, situated at the carboxyl terminal in this peptide oligomer, by resolving the synthesized racemate into antipodes and by then investigating their ORD curves.

This paper will treat β-methyl-phenylalanine, the amino acid just neighboring β-(2-thiazolyl)-β-alanine. Umezawa and his co-workers[3] attributed this amino acid to the L-series from the facts that its dithioethoxycarbonyl derivative shows a positive Cotton effect in methanol and that the amino acid is not decomposed by D-amino acid oxidase. Arold and his co-warkers[5] have shown that the amino acid present in bottromycin belongs to the *erythro*-L series by preparing *ethythro*-β-methyl-phenylalanine and by then resolving it into antipodes. We, too, prepared this amino acid by another route and succeeded in obtaining the four possible isomers by resolving both *erythro*- and *threo*-



Scheme 1. Synthetic route of β-Methyl-phenylananine.

compounds into antipodes; the scheme is illustrated in Schemes 1 and 2. α-Methylbenzyl bromide, prepared by the addition of hydrogen bromide to styrene according to Walling,[6] was condensed with acetaminomalonate. The condensate, α-methylbenzylacetaminomalonate (III), was then hydrolyzed with aqueous sodium hydroxide and decarboxylated without isolation of the intermediate hydrolysate (IV). In order to separate the product mixture into *erythro*- and *threo*-compounds, it was first converted into the easily crystallizable benzoyl derivative, which was then separated, by crystallization from aqueous ethanol, into two : A high-melting substance (mp 188—190 °C)(VII-a) and a low-melting one (mp 130—132 °C) (VII-b).

It has been reported that *erythro* and *threo* isomers can easily be differentiated by means of a comparison of their NMR spectra; *i.e.*, in β-alkylsubstituted α-amino acids, the coupling constant ($J_{\alpha\beta}$) between C_α–H and C_β–H is larger in the *erythro* form than in the *threo* form.[7] In our case, the β-methyl-phenylalanines obtained from VII-a always gave larger values than those obtained from VII-b, as may be seen in Table 1. This suggests that the former belongs to an *erythro* type.

Methanol	−			−					
Ethanol		−	+		−	−	−	−	−
1-Propanol	−	−	±	−	−	−		−	−
Ethyl acetate		−		±		−			
Benzene						−			
Chloroform			−			−		−	−

Bz=Benzoyl derivative; Ac=Acetyl derivative; Z=Benzyloxycarbonyl derivative. +, crystal; ±, trace; −, no precipitate.

with hydrogen bromide in acetic acid to remove the benzyloxycarbonyl group. We thus obtained a free amino acid of $[\alpha]_D$+28.4°. From the soluble quinine salt, its antipode of $[\alpha]_D$−30.6° was isolated. The latter is identical with the β-methyl-phenylalanine ($[\alpha]_D$−31°) obtained from bottromycin by Umezawa and his co-workers[3] as well as with the one belonging to the *erythro*-L form reported by Arold.[5] Another way to isolate the *erythro*-L isomer was to treat the benzyloxy-carbonyl compound with quinidine and to regenerate the free amino acid from the less soluble alkaloid salt. In this case, it was not the D-isomer but the L-isomer that made the less soluble salt, so it was more convenient to obtain the L-isomer present in bottromycin, though the yield was somewhat inferior to that of the preceding method. In a similar way, the *threo*-compound was also resolved into its antipodes. Thus, all four theoretically possible isomers were successfully prepared.

Now both the optically-active amino acids present in the carboxyl terminal of bottromycin, *i.e.*, L-β-(2-thiazolyl)-β-alanine and L-β-methyl-phenylalanine, could be prepared, so we tried to build up the dipeptide which constitutes the most important part of bottromycin.[8] *N*-Benzyloxycarbonyl-*erythro*-L-β-methyl-phenylalanine was coupled with L-β-(2-thiazolyl)-β-alanine methyl ester by the carbodiimide method; the desired protected dipeptide was thus obtained in a 70% yield. As the standard sample was prepared in this way, we attempted a more convenient method of synthesizing this dipeptide by coupling the optically-active β-methyl-phenylalanine with the racemic β-(2-thiazolyl)-β-alanine, and by then separating the product mixture into its respective diastereomers. After coupling the components by the carbodiimide method, the product was fractionally recrystallized from ethanol; we thus obtained a diastereomer with a mp of 159—161 °C, and one with a mp of 182—182.5 °C in *ca.* a yield 60% of the theoretical amount respectively. The ORD curve and IR spectrum of the former were completely identical with those of the standard sample described above. The other compound must be a diasteromer composed of L-β-methyl-phenylalanine and D-β-(2-thiazolyl)-β-alanine, because it has a different melting point and a different value of $[\alpha]_{300}$ from those of the L-L-compound, though the IR spectra of the two compounds in chloroform coincided completely. In order to ascertain the configuration of the β-(2-thiazolyl)-β-alanine contained in this dipeptide, it was hydrolyzed by refluxing with 6 M hydrochloric acid for a short time (1.5 h); the desired amino acid was then isolated by silica-gel dry-column chromatography. Its ORD curve apparently showed that it belongs to the D-series, though the values of α are very small because of its easily racemizable property under acid-hydrolytic conditions.[4] The phenomenon that the curve shifts to the positive side when 2 drops of 6 M hydrochloric acid or a concentrated sodium hydroxide solution (more remarkably) are added supports this conclusion.[9]

Experimental[10]

α-Methylbenzyl Bromide (II). This compound was prepared according to the method of Walling[6] by passing dry hydrogen bromide gas to freshly distilled styrene under ice-cooling; bp 79—80 °C/8 mmHg, n_D^{22} 1.564. lit,[11]: bp 78—82 °C/10 mmHg, n_D^{20} 1.5612.

Diethyl α-Methylbenzylacetaminomalonate (III). Diethyl acetaminomalonate (9.1 g) was dissolved in a sodium ethoxide solution in ethanol (sodium, 0.97 g; absolute ethanol, 50 ml); II (9.3 g) was then added, and the mixture was kept at 30 °C for 20 h. After the sodium bromide had then been filtered off and washed with hot ethanol, the combined ethanolic solution was concentrated *in vacuo*. The residual solid was recrystallized from 50% aqueous ethanol. The yield was 9.9 g (73%); mp 122—122.5 °C. Found: C, 63.31; H, 7.41; N, 4.40%. Calcd for $C_{17}H_{23}NO_5$: C, 63.54; H, 7.21; N, 4.36%.

N-*Acetyl*-DL-*β-methyl-phenylalanine (V).* III (6.43 g) was hydrolyzed by refluxing with a 10% sodium hydroxide solution (30 ml) for 30 min; then to this boiling solution 3 M hydrochloric acid (*ca.* 23 ml) was carefully added, drop by drop, until no more evolution of carbon dioxide was observed. The resulting mixture was allowed to stand in a refrigerator overnight, after which the separated acetylamino acid (V) was collected. The yield was 3.91 g (88%). The crude product was used for the next reaction without further purification, though it showed a broad melting point.

Diastereomeric Mixture of erythro- *and* threo-DL-*β-Methyl-phenylalanine Hydrochloride (VI).* V was refluxed with 6 M hydrochloric acid for 8 h, after which the solution was concentrated to dryness *in vacuo*. The residue was diluted with some water and concentrated again; the repetition of this operation gave a crude diastereomeric mixture (VI) in an almost quantitative yield. TLC and a paper chromatogram showed only one spot. For analysis it was recrystallized from water; mp 181—190 °C. Found: C, 55.56; H, 6.48; N, 6.68%. Calcd for $C_{10}H_{13}NO_2 \cdot HCl$; C, 55.69; H, 6.49; N, 6.49.%

N-*Benzoyl*-DL-*β-methyl-phenylalanine and Its Separation into* erythro- *and* threo-*Forms.* VI was benzoylated in a usual manner in a 93% yield. When the crude product was fractionally crystallized from aqueous ethanol, compounds melting at 188—190 °C (VII-a) and 130—132 °C (VII-b) were obtained.

Determination of the Structures of the erythro- *and the* threo-*Compounds (VII-a and VII-b) by Means of the NMR Data.* Both the *N*-benzoylated derivatives (VII-a and VII-b) were hydrolyzed with 6 M hydrochloric acid, and the resulting hydrochlorides were converted into free amino acids by treating them with an ion-exchange resin (Amberite IR 120). The

NMR data of both the amino acids are shown in Table 1. In order to estimate the *erthro/threo* ratio of the decarboxylation product (V), the crude sample of V was hydrolyzed to a free amino acid mixture and its NMR spectrum was measured. From the intensity of the peaks corresponding to the two α-H signals (100 MHz), the *erythro/threo* ratio was calculated as 1.7 : 1. The free amino acids derived from the acetaminomalonate in one step by treating it with 6 M hydrochloric acid also gave a similar *erythro/threo* ratio (1.5 : 1), as estimated from their NMR spectra.

N-Benzyloxycarbonyl erythro- *and* threo-DL-*β-Methyl-phenylalanine (IX-a and IX-b).* VII-a and VII-b were hydrolyzed with 6 M hydrochloric acid and benzyloxycarbonylated by the usual method (yields, >90%).

VIII-a derived from VII-a (mp 117—118 °C). Found: C, 68.95; H, 6.20; N, 4.48%. Calcd for $C_{18}H_{19}NO_4$: C, 69.00; H, 6.11; N, 4.47%.

VIII-b derived from VII-b (mp 132—134 °C). Found: C, 69.09; H, 6.16; N, 4.63%.

Separation of the N-*Benzyloxycarbonylated β-Methyl-phenylalanine into the* erythro- *and the* threo-*Derivatives.* The amino acid mixture obtained by the hydrolysis of V was benzyloxycarbonylated as usual. Part of the crude reaction product crystallized easily and could be isolated by filtration, though the rest remained oily (the ratio of the oil to the crystal was about 2 : 1). The crystalline compound was found to be identical with the *threo*-compound (VIII-b) derived from VII-b, and the residual oil was concluded to be composed of the *erythro*-derivative contaminated with some *threo*-compound, judging from the NMR spectrum of the free amino acid reproduced from it.

NMR data of VIII-a and VIII-b (60 MHz, DMSO-d_6):

VIII-a (*erythro*): δ 1.27 (3H, CH_3, d, J=7.2 Hz), 3.15 (1H, H_β, d-q, J=9.1 Hz and 7.1 Hz), 4.29 (1H, H_α, t, J=9.0 Hz), 4.99 (2H, benzyl-CH_2, s).

VIII-b (*threo*): δ 1.25 (3H, CH_3, d, J=7.5 Hz), 3.26 (1H, H_β, qi, J=7.0 Hz), 4.27 (1H, H_α, d-d, J=6.9 Hz and 9.0 Hz), 5.01 (2H, benzyl-CH_2, s), 7.66 (1H, NH, d, J=9.0 Hz).

Optical Resolutions of N-*Benzyloxycarbonyl*-erythro- *and* threo-DL-*β-Methyl-phenylalanine.* Equimolar amounts of VIII-a and quinine were dissolved in hot ethanol, and the solution was allowed to stand overnight. A white crystalline salt which separated as needles was collected. From the salt, the quinine was removed by treatment with 2 M hydrochloric acid in ether; thus *N*-benzyloxycarbonyl-*erythro*-D-*β*-methylphenylalanine was obtained. From the mother liquor, the *erythro*-L-derivative was obtained by a similar treatment. By the same proceddre, the *threo*-D-compound was obtained from VIII-b through easily crytallizable quinine salt, and the *threo*-L-compound, from the mother liquor. The results are summarized in Scheme 2.

Similarly, VIII-a was treated with quinidine, and from the less soluble salt (mp 171—171.5 °C (from chloroform–ethanol) $[\alpha]_D^{20}$ +122.1° (*c* 1, $CHCl_3$)), the L-compound ($[\alpha]_D^{20}$ +17.6° (*c* 1, C_2H_5OH)) was obtained in a 62% yield.

Four Isomers of Optically Active β-Methyl-phenylalanine. Four isomers of the optically-active benzyloxycarbonyl derivative of the amino acid obtained above were debenzyloxycarbonylated by hydrogen bromide in acetic acid and converted into free amino acids by treatment with an ion-exchange resin (Amberlite IR 120). Their optical properties are shown in Scheme 2.

Methyl β-(2-Thiazolyl)-β-alaninate Dihydrochloride. Thionyl chloride (1.31 g) was gradually stirred into methanol (30 ml) at about −10 °C, and to the resulting solution DL-*β*-(2-thiazolyl)-*β*-alanine[4] (1.72 g) was added. After stirring for 1 h at that temperature and for 6 h at room temperature, the reaction mixture was concentrated to dryness *in vacuo*, and after which anhydrous ether was added. The colorless crystals (1.72 g; 73%) precipitated were collected and recrystallized from methanol–ether. The yield was 1.16 g (48%); mp 153—155 °C. Found: C, 32.29; H, 4.79; N, 10.76%. Calcd for $C_7H_{10}N_2O_2S \cdot 2HCl$: C, 32.44; H. 4.67; N, 10.81%.

Similarly, the L-compound was prepared; mp 152—153 °C, $[\alpha]_{270}^{19}$ −8.8° (*c* 1, CH_3OH).

N-Benzyloxycarbonyl-erythro-L-*β*-*methyl-phenylalanyl*-L- *and* DL-*β*-(2-*thiazolyl*)-*β*-*alanine Methyl Ester and Its Resolution into Diastereomers.* Into a solution of *N*-benzyloxycarbonyl-*erythro*-L-*β*-methyl-phenylalanine (175 mg) in dichloromethane (4 ml), dicyclohexylcarbodiimide (115 mg) in the same solvent (2 ml) was stirred under ice-cooling. After 5 min, a solution of methyl L-*β*-(2-thiazolyl)-*β*-alanine dihydrochloride (145 mg) and *N*-methylmorpholine (113 mg) in dichloromethane (4 ml) was added, and the mixture was stirred overnight at room temperature. After treatment as usual, the crude dipeptide was obtained; 256 mg (95%); mp 152—155 °C. Recrystallization from aqueous ethanol gave a sample with a mp of 159.5—162 °C, $[\alpha]_{300}^{19}$ +89.3° (*c* 0.268, $CHCl_3$). Found: C, 62.34; H, 5.70; N, 8.62%. Calcd for $C_{25}H_{27}N_3O_5S$: C, 62.35; H, 5.65; N, 8.73%.

The coupling of the *erythro*-L-acid (1.38 g) and the DL-ester (1.08 g) was quite similarly carried out by using triethylamine in place of *N*-methylmorpholine. The crude dipeptide (1.89 g; 89%) was fractionally crystallized from 70% ethanol and could be separated into two components:

L-D-Compound, mp 182—182.5 °C, $[\alpha]_{300}^{27}$ +103.7° (*c* 0.27, $CHCl_3$). Found: C, 62.65; H, 5.69; N, 8.60%.

L-L-Compound, mp 159—161 °C, $[\alpha]_{300}^{19}$ +90.0° (c, 0.242, $CHCl_3$). Found: C, 62.33; H, 5.68; N, 8.56%.

Reactions of Perfluoro-2-methyl-2-pentene and Octafluoroisobutylene with Arylamines

Nobuo Ishikawa and Akira Nagashima

Tokyo Institute of Technology, Department of Chemical Engineering, Ookayama, Meguro-ku, Tokyo 152

(Received August 4, 1975)

Treatment of perfluoro-2-methyl-2-pentene with four moles of arylamine provided 1-aryl-2,4-bis(arylimino)-3-(1-arylimino-2,2,3,3,3-pentafluoropropyl)azetidine, 3-(*N*,*N*′-diarylamidino)-4-arylamino-2-(pentafluoroethyl)-quinoline and 2,4-bis(arylamino)-3-(1-arylimino-2,2,3,3,3-pentafluoropropyl)quinoline, depending on the basicity of the arylamine and on the solvent used. Octafluoroisobutylene also yielded similar azetidine and quinoline derivatives.

As has been previously reported,[1] perfluoro-2-methyl-2-pentene (**1**) is much more reactive with *O*-nucleophiles than another isomer of hexafluoropropene dimer, perfluoro-4-methyl-2-pentene. Reactions of **1** with alcohols and phenol very easily produced addition and substitution products. Now we wish to report on reactions of **1** with primary arylamines, which proceeded with similar facility, but with much more complexity.

Results and Discussion

Reaction of Perfluoro-2-methyl-2-pentene with Arylamines. Haszeldine and his co-workers[2] very recently reported that two moles of arylamine react with **1** affording a quinoline derivative, **3**. They presumed that the reaction occurs with the formation of a ketenimine, **2**, followed by intramolecular cyclization. We had independently found this quinoline ring formation using about two moles of aniline, toluidines and chloroanilines in *N*,*N*-dimethylformamide.[3] The results of this quinoline formation are summarized in Table 1.

However, we further found that as much as four moles of arylamine react with **1** to give azetidine and quinoline derivatives, **5**—**7**, depending on the basicity of the arylamine and on the solvent used.

For example, when a large excess of aniline was allowed to react with **1** in the presence of triethylamine in diethyl ether, yellow crystals of 1-phenyl-2,4-bis(phenylimino)-3-(1-phenylimino-2,2,3,3,3-pentafluoropropyl)azetidine, **5** (Ar=Ph), was obtained in a fair yield (52%). The structure of this compound was established on the basis of the spectral data. In the IR spectrum, a strong, wide absorption band at 1660 cm^{-1} was observed, which should be due to the C=N groups adjacent to the azetidine ring. A sharp band at 1765 cm^{-1} was ascribed to a similar group apart from the ring. In the PMR, one singlet signal at τ 4.90 and several signals in the region of τ 1.7—4.6 were assigned to one >CH proton and fifteen aromatic protons, respectively. In the MS, the parent peak and the fragment peaks appeared appropriately (Experimental section). These spectral data, in contrast with those of the quinoline derivatives, strongly supported the azetidine structure.

Naturally, this compound was susceptible to reactions with acids and alkalies, *e.g.*, acetic and hydrochloric acids, and aqueous alkali hydroxide solutions, and these reactions produce several decomposition products.

Interestingly, when this azetidine compound was treated with ethanolic hydrochloric acid at room temperature, it isomerized into a quinoline derivative, **6** (Ar=Ph; X=H) in a 34% yield.

The structure of **6** was evident also from its spectral analysis. The IR spectrum revealed the presence of N–H groups by the two absorption bands at 3400 and 3350 cm^{-1}. In the mass spectrum, a peak at *m/e* 440 (M^+—NHPh) was observed, which confirmed the structure of **6**, but not that of another isomeric quinoline derivative, **7**.

When *p*-toluidine was used instead of aniline under the same conditions, the quinoline derivative **3** (Ar=*p*-MeC_6H_4; X=6-Me) was obtained as a main product (38%).

Table 1. Physical data of quinoline and azetidine derivatives

Compound No	Ar	X	Yield %	Mp °C	F-Anal % (Calcd)	IR (KBr) cm^{-1}	^{19}F NMR ($CHCl_3$) δ[a]	^{1}H NMR ($CDCl_3$) τ

a) Given in δ ppm from ext. CF_3CO_2H. b) Yield obtained by isomerization of **3** (Ar=Ph).

When *p*-fluoro- and *p*-chloroaniline were used, the azetidine derivatives (**5**) were obtained as in the case of aniline (Table 1).

m-Chloroaniline, however, gave two quinoline derivatives, **6** and **7** (Ar=*m*-ClC_6H_4; X=Cl), in yields of 16 and 18%, respectively. In this case, these isomeric quinoline derivatives were separated from each other by means of a column chromatography. A fraction which was assumed to contain azetidine derivative was obtained, but no confirmation of compound **5** (Ar=*m*-ClC_6H_4) could be made.

Assignments for the two quinoline derivatives, **6** and **7**, were rather easy. In their IR spectra, both compounds showed absorption at about 1650 cm^{-1}, characteristic of a C=N group. However, the C=N absorption of **6** was situated in that of the amidino group, so it was much stronger than that of **7**. The mass spectra gave more unambiguous evidence. Besides the parent peak at M^+ 668, the amidinoquinoline **6** showed a strong peak at *m/e* 542 ($M^+-NHC_6H_4Cl$), whereas arylaminopentafluoropropylquinoline **7** gave a peak at *m/e* 549 ($M^+-C_2F_5$). The former peak of *m/e* 542 was absent in the spectrum of **7**, and *vice versa*.

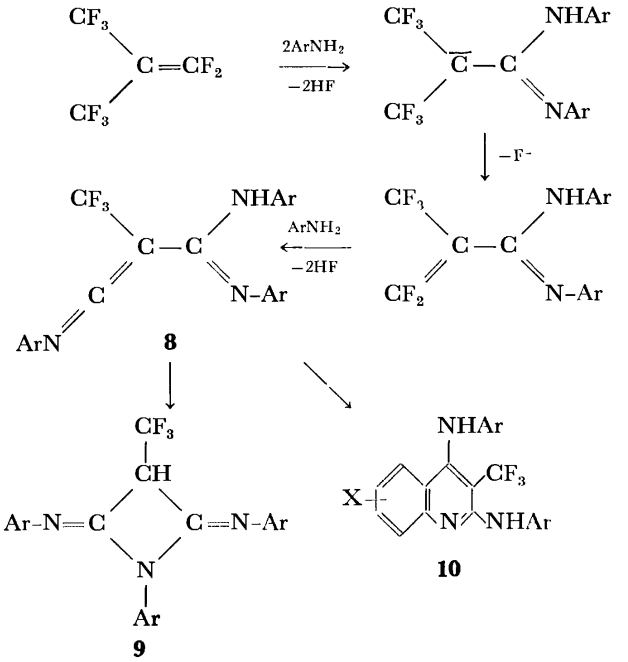
The reaction mechanisms assumed for the formation of the azetidine and quinoline derivatives are shown in the scheme. Four moles of aniline nucleophilically attacked **1**, replacing fluorine atoms successively to give the ketenimine intermediate **4**. When the positive carbon atom of the ketenimine attacked the nitrogen atom of ArNH, the azetidine ring was formed to give **5**. On the other hand, when the positive carbon atom attacked the *ortho* position of the aromatic ring of arylimino group, either Ar* or Ar**, a quinoline ring was formed to give **6** or **7**.

In general, the amino group should be kinetically more readily attacked by the ketenimine group to give azetidine, **5**. The azetidine derivatives thus formed are thermodynamically less stable than the quinoline derivative, so that **5** will isomerize into **6** by means of an acid or a base. This was confirmed experimentally as mentioned above. Presumably, the electron donative methyl group of toluidine prompted the intramolecular attack of the ketenimine group of **2** on the toluidino ring, and further retarded the reaction of **2** with other toluidino molecules.

When *p*-halogenoanilines were used, the *ortho* position to the amino group, *i.e.*, the *meta* position to the halogen, should be electron deficient, which means they are rarely attacked by the ketenimine group. Thus no quinoline derivatives, neither **6** nor **7**, could be obtained from *p*-chloro or *p*-fluoroaniline.

On the other hand, the amino group of *m*-halogenoaniline is less basic than that of the *p*-isomer, so that it will retard the formation of the azetidine ring. Conversely, the *ortho* position to the amino group, *i.e.*, *para* position to the halogen, may be attacked more easily by the ketenimine group than that of *p*-halogenoaniline. Thus, only quinoline derivatives **6** and **7** from *m*-chloroaniline could be obtained, though in poor yields.

Reaction of Octafluoroisobutylene with Arylamine. As has been mentioned previously, perfluoro-2-methyl-2-pentene (**1**) reacts easily with primary aromatic amines



to give azetidine and quinoline derivatives. This high reactivity and the mode of the reaction should have resulted from the existence of a *gem*-bis(trifluoromethyl) methylene group, $=C(CF_3)_2$. This prompted us to examine the similar reaction with octafluoroisobutylene, the simplest olefin of this type. We carried out the reaction of octafluoroisobutylene with an excess of *p*-toluidine in diethyl ether in the presence of triethylamine, and in *N,N*-dimethylformamide.

In diethyl ether in the presence of triethylamine, three moles of *p*-toluidine reacted, giving the azetidine derivative **9** (Ar=*p*-MeC_6H_4) in a 18% yield.

In *N,N*-dimethylformamide, also three moles of toluidine reacted, and as expected, a quinoline derivative **10** (Ar=*p*-MeC_6H_4; X=6-Me) was obtained in a 12% yield. In each case, large quantities of by-products were formed. The by-products could not be identified, but they were assumed to be other imidoyl fluoride derivatives.[4]

The structures of these azetidine and quinoline derivatives were evident from the spectral data. In particular, in the ^{19}F and ^1H NMR spectra of **9**, there appeared a doublet due to C**F**$_3$ and a quartet due to C**H**. This means that a $CH(CF_3)$ group is present in the molecule, and this fact strongly supports the azetidine structure.

The reaction mechanism is understood in a similar way, as in the case of **1**. Arylamine should have attacked the terminal difluoromethylene groups successively, thereby forming an amidinoketenimine intermediate, **8**. When the positive carbon of the ketenimine attacked the nitrogen atom in the arylamino group, the azetidine derivative was formed. On the other hand, if the *ortho* position of the arylimino group was attacked, the quinoline derivative was produced.

Experimental

*2-Pentafluoroethyl-3-trifluoromethyl-4-anilinoquinoline (**3**(Ar=Ph; X=H)).* A solution of aniline (2.23 g, 0.022 mol)

in *N,N*-dimethylformamide (5 ml) was added into an ice-cooled mixture of perfluoro-2-methyl-2-pentene (**1**) (3.0 g, 0.01 mol) and *N,N*-dimethylformamide (15 ml) in a pressure vessel. After sealing, the mixture was heated with stirring at 70 °C for 2.5 h, and the reaction mixture was poured into water (100 ml). The resulting precipitate was separated by filtration to give a crude product (3.3 g, mp 84—89 °C). Recrystallization from hexane yielded a pure quinoline derivative **3** (2.2 g), mp 99—100 °C, in a 53% yield.

Found: C, 53.51; H, 2.48; N, 7.03; F, 37.8%. Calcd for $C_{18}H_{10}N_2F_8$: C, 53.20; H, 2.48; N, 6.90; F, 37.4%. MS: 406 (M^+), 337 (M^+-CF_3), 218 ($M^+-CF_3-C_2F_5$).

In the above procedure, toluidines and chloroanilines were used instead of aniline. The formed quinoline derivatives (**3**) are tabulated in Table 1.

*1-Phenyl-2,4-bis(phenylimino)-3-(1-phenylimino-2,2,3,3,3-pentafluoropropyl)azetidine (**5** (Ar=Ph)).* Into a solution of aniline (8.2 g, 0.088 mol) and triethylamine (14.2 g, 0.154 mol) in diethyl ether (30 ml), a solution of perfluoro-2-methyl-2-pentene (6.0 g, 0.02 mol) in diethyl ether (15 ml) was added dropwise, while keeping the temperature at 35—40 °C. After the addition, the mixture was stirred at room temperature for 1 h. The reaction mixture was washed with dilute hydrochloric acid to remove excess triethylamine, and with water, and then dried over magnesium sulfate. On removing the ether, yellow crystals were produced, which were collected to give the crude product (7.1 g, 67%), mp 102—118 °C. Recrystallization from hexane yielded pure **5** (Ar=Ph), mp 128—129.5 °C (5.5 g, 52%).

Found: C, 67.62; H, 3.87; N, 10.55; F, 17.7%. Calcd for $C_{30}H_{21}N_4F_5$: C, 67.66; H, 3.97; N, 10.52; F, 17.8%. MS: *m/e* 532 (M^+), 338 (M^+–Ph–N=C=N–Ph), 219 (PhN=C–CH=C=NPh), 194 (PhN=C=NPh).

p-Fluoro- and *p*-chloroanilines were used instead of aniline in the above reaction and similar azetidine derivatives were obtained (Table 1).

*2-Pentafluoroethyl-3-(N,N'-diphenylamidino)-4-anilinoquinoline (**6** (Ar=Ph; X=H)).* The azetidine compound **5** (Ar=Ph) (0.5 g) was dissolved in ethanol (15 ml), and a small amount of conc. hydrochloric acid (5 drops) was added. The mixture was stirred at room temperature for 3 h and poured into water (200 ml). The resulting oily material containing crystals was taken into diethyl ether, and the ethereal solution was washed with water, and dried over magnesium sulfate. The ether was removed and the residue (0.7 g) was crystallized from petroleum ether, giving **6** (Ar=Ph; X=H) (0.17 g, 34%), mp 132—132.5 °C.

Found: C, 67.71; H, 3.76; N, 10.59; F, 17.7%. Calcd for $C_{30}H_{21}N_4F_5$: C, 67.66; H, 3.97; N, 10.52; F, 17.8%.

*2-Pentafluoroethyl-3-[N,N'-bis(m-chlorophenyl)amidino]-4-(m-chloroanilino)-7-chloroquinoline (**6** (Ar=m-ClC_6H_4; X=7-Cl)) and 2,4-bis(m-chloroanilino)-3-(1-m-chlorophenylimino-2,2,3,3,3-pentafluoropropyl)-7-chloroquinoline (**7** (Ar=m-C_6H_4; X=7-Cl)).* Into a solution of *m*-chloroaniline (5.6 g) and triethylamine (7.1 g) in diethyl ether (15 ml), a solution of perfluoro-2-methyl-2-pentene (3.0 g) in diethyl ether (15 ml) was added dropwise at ~40 °C. After 1 h of stirring at room temperature, the reaction mixture was washed with dilute hydrochloric acid and water, then dried over magnesium sulfate. The ether was removed, leaving a semi-solid mass (7.0 g). This crude product was subjected to silica-gel column chromatography, using a mixture of benzene and hexane as the eluent. Of the two main yellow bands observed, the first band was eluted. Evaporation of the eluate provided crystals (1.21 g, 18%), which were recrystallized from hexane yielding pure **7** (Ar=*m*-ClC_6H_4, H=7-Cl), mp 129.5—130 °C.

Found: C, 54.09; H, 2.50; N, 9.08; F, 14.0%. Calcd for $C_{30}H_{17}N_4Cl_4F_5$: C, 53.76; H, 2.56; N, 8.36; F, 14.2%. MS: 668 (M^+), 549 ($M^+-C_2F_5$), 111 (ClC_6H_4).

Elution of the second main band, followed by evaporation of the solvent, provided more of the product (1.07 g, 16%). Recrystallization from hexane gave pure **6** (Ar=*m*-ClC_6H_4; X=7-Cl), mp 169.5—170 °C.

Found: C, 54.25; H, 2.58; N, 8.65; F, 14.5%. Calcd for $C_{30}H_{17}N_4Cl_4F_5$: C, 53.76; H, 2.56; N, 8.36; F, 14.2%. MS: *m/e* 668 (M^+), 542 ($M^+-NHC_6H_4Cl$), 126 (NHC_6H_4Cl).

*1-(p-Tolyl)-2,4-bis(p-tolylimino)-3-(trifluoromethyl)azetidine (**9** (Ar=p-MeC_6H_4)).* *p*-Toluidine (7.07 g, 0.066 mol), triethylamine (11.1 g, 0.11 mol) and diethyl ether (25 ml) were placed in a glass pressure tube equipped with a mechanical stirrer. This reaction vessel was cooled to *ca.* −50 °C into which liquefied octafluoroisobutylene (4.0 g, 0.02 mol) was introduced. The mixture was stirred for 1 h at −20 to −5 °C, for 30 min at 0 °C, then for 1 h at room temperature. After the unreacted octafluoroisobutylene was driven off by an aspirator, the reaction mixture was washed with dilute hydrochloric acid and water, and was dried over magnesium sulfate. Diethyl ether was evaporated and the remaining oily material (7.1 g) was recrystallized from petroleum ether. The azetidine derivative **9** (1.5 g, 18%), mp 122—123 °C, was thus obtained, and was recrystallized further to give the pure product, mp 124.5—125 °C.

Found: C, 71.74; H, 5.44; N, 10.27; F, 13.6%. Calcd for $C_{25}H_{22}N_3F_3$: C, 71.24; H, 5.26; N, 9.97; F, 13.5%. MS: *m/e* 421 (M^+), 352 (M^+-CF_3), 222 (Ar–N=C=N–Ar), 199 (M^+—Ar–N=C=N–Ar).

*6-Methyl-2,4-bis(p-toluidino)-3-(trifluoromethyl)quinoline (**10** (Ar=p-MeC_6H_4; X=6-Me)).* *p*-Toluidine (3.54 g, 0.033 mol), *N,N*-dimethylformamide (15 ml) and octafluoroisobutylene (2.0 g, 0.01 mol) were placed in a reaction vessel as described above. The mixture was stirred for 30 min at room temperature, then for 2.5 h at 65—70 °C. A considerable amount of unidentified yellow crystals (2.33 g, mp 205—211 °C) were produced. This solid was removed by filtration and the filtrate was poured into water. The solid material thus obtained (0.50 g, 12%) was recrystallized from hexane to give pure **10**, mp 131—131.5 °C.

Found: C, 71.28; H, 5.49; N, 10.15; F, 13.6%. Calcd for $C_{25}H_{22}N_3F_3$: C, 71.24; H, 5.26; N, 9.97; F, 13.5%. MS: *m/e* 421 (M^+), 380 ($M^+-2HF-H$), 91 ($C_6H_5CH_2^+$).

(Received September 23, 1975)

1α-Phenyl-5α-cholestan-3-one was prepared from 5α-cholestan-1-en-3-one by treatment with the Grignard reagent in the presence of copper (I) chloride. In the mono- and dibromination of 1α-methyl-3-keto steroids, it was found that the position and configuration of bromine were the same as in the case of the 1-nonsubstituted 3-keto steroid. The A-ring conformations of these bromoketones were studied by means of NMR and ORD.

Synthetic and conformational studies of physiologically active 1-methyl-3-keto steroids have been made by several groups.[1] Kirk and Hartshorn[2a] stated that 3-keto-1-en-5α-steroids undergo the conjugate addition of methyl Grignard reagents to give 1β-methyl derivatives. This fact was explained by assuming that the β attack is sterically favored by the convexity of the β face of the molecule. However, other workers contend that this statement is wrong since 1α-methyl derivatives are formed. Recently, Pelc *et al.*[3] reported that the A ring of 1α-methyl-5α-androstan-3-one is in a chair conformation with the α-oriented C_1 methyl group. The α-attack of Grignard reagents is explained by the steric hindrance of the C_{10} methyl group.[4] From the fact that 1α-methyl-5β-cholestan-3-one (Va), which is derived from 1α-methyl-5α-cholestan-3-one (IIa), showed an unusual rotatory dispersion curve, Mori[5] suggested that the A ring of Va has a boat conformation. However, only very little information can be found on 1-alkyl-3-keto steroids concerning the synthesis of their derivatives and their reactivity.

In the present paper, we will describe the bromination of 1-methyl-3-keto steroids and will discuss the conformations of 1-methyl bromoketones.

Results and Discussion

The bromination of 5α- and 5β-cholestan-3-one occurred at the $C_{2\alpha}$ and $C_{4\beta}$ positions respectively.[6] The direction of bromination is dependent on that of enolization. The strong preference for a C_2-enolization in the 5α-series can be accounted for by both the 6β/19 interactions and the "hyperconjugation" of the C_1-methylene group.[2b] In the case of the 5β-series, the preference for C_4-enolization can be explained in terms of the relief of the nonbonded interactions between the 4α-hydrogen and the 7α- and 9α-hydrogens when a trigonal center is formed at C_4.[2b] Accordingly, 1-substituted 3-keto steroids are particularly interesting in the point of whether or not they show the same results as 1-unsubstituted 3-keto steroids on enolization and subsequent bromination.

Mori[5] reported that the bromination of IIa gave a C_4 brominated product, which was not purified. The bromination at the C_4-position was determined by the formation of 1α-methyl-cholest-4-en-3-one (IV) when the crude bromoketone was treated with LiCl/DMF. In our case, pure bromoketone (IIIa) was isolated; its configuration was determined by means of ORD and NMR (Tables 1 and 2).

The rotatory dispersion of this pure bromoketone

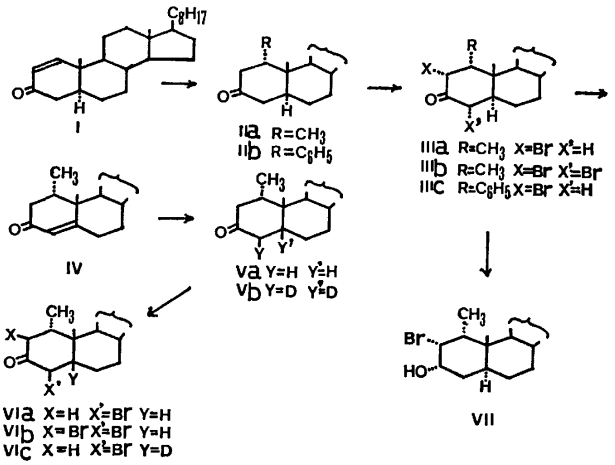

TABLE 1. ORD AND CD DATA OF 1-SUBSTITUTED 2- AND 4-BROMO-3-KETO STEROIDS

	$[\phi]_1$(nm)	$[\phi]_2$(nm)	a	$[\theta]$(nm)
IIa	2320(317)	−2132(273)	45	3416(296)
IIIa	1779(313)	−3319(272)	51	3531(298)
IIIb	402(310)			2112(288)
Va	848(314)	161(272)	7	848(290)
VIa	2532(313)	1204(268)	37	3029(292)
VIb	−369(367)	1285(300)	−17	−1143(337)
IIb	2897(311)	2014(285)	9	1667(297)
IIIc	3528(317)	925(277)	26	3976(294)

(IIIa) does not change the nature of the Cotton effect, and the wavelength shifts are negligible or tend toward shorter wavelength region, compared with the case of the parent ketone (IIa). The NMR spectrum showed peaks at 5.00 ppm (doublet, J=4.8 Hz) due to -CHBr-. Accordingly, the bromination product of (IIa) is concluded to be a 2α-bromo compound (IIIa) in a normal chair conformation. The dihedral angle, which was calculated using the Karplus equation from the coupling constant, also supported the results (Table 2). The dehydrobromination of IIIa with $CaCO_3$/DMF gave IV. This reaction was accompanied by a rearrangement of the bromine atom in the elimination reaction from C_2 to C_4 to give IV. If the 1,2-*trans* diaxial elimination of IIIa occurs, the A-ring requires a boat conformation in the process of elimination. In this reaction, the A-ring can not adopt a boat form by the nonbonded interaction of the 1α-methyl/11-methylene group. Therefore, the rearrangement of the substituent must have occurred.

Table 2. Chemical shifts, coupling constants, and dihedral angles of 2- and 4-bromo-3-keto steroids

Compound	CHBr (ppm)	J (Hz)	$\phi_{H_1\beta H_2}$ [c]	$\phi_{H_4H_5}$ [c]
5α-Cholestan-3-one derivative				
2α-Bromo-[a]	4.83(dd)	6.5	44°	
2α,4α-Dibromo-[a]	4.80(d)	12.7		161°
	4.45(dd)	6.2	45°	
IIIa	5.00(d)	4.8	52°	
IIIb	4.46(d)	12.0		156°
	5.11(d)	4.5	53°	
IIIc	5·14(d)	6.0	46°	
5β-Cholestan-3-one derivative				
4β-Bromo-[b]	4.98(d)	12.5		159°
2β,4β-Dibromo-[b]	4.82(dd)	14.6	180°	
	5.08(d)	11.4		153°

The reduction of IIIa with $NaBH_4$ gave a bromohydrine as the only product. The NMR spectrum of the bromohydrine showed peaks at 4.66 ppm (d,d, J= 3.0 and 4.8 Hz) attributable to –CHBr–. Moreover, the bromohydrine was identified as 1α-methyl-2α-bromo-5α-cholestan-3α-ol (VII) on the basis of the small coupling constants (*i.e.*, not diaxial vicinal coupling constants). Because of shielding for the reducing reagent by the 1α-methyl group, the reduction of the 3-keto group occurred only on the β-side. The bromination product of IIa was also determined to be a 2α-bromo compound (IIIa) from the above fact that IIIa had no diaxial vicinal coupling constants.

The 1α-phenyl derivative, with its bulky substituent at the C_1 position, is interesting in the point of the direction of bromination. Therefore, the introduction of a phenyl group at the C_1 position was tried for the 1,4-addition with PhMgI in a manner similar to that used with CH_3MgI. The NMR spectrum of this reaction product (IIb) showed peaks at 7.10 ppm (m, 5H) and 3.25 ppm (bd, J=6.0 Hz, 1H) due to the aromatic protons and –CHPh– respectively. From the relatively small coupling constant of the C_1 proton, its configuration was equatorial. Therefore, it appears that the phenyl group was also introduced at the $C_{1\alpha}$-position, in a manner similar to that in the case of the methyl group.

The NMR spectrum of the monobromination product of IIb had peaks at 3.58 ppm (d, J=6.0 Hz, $C_{1\beta}$–H) and 5.14 ppm (d, J=6.0 Hz, C_2–H). Its ORD curve did not change the nature of the Cotton effect, and the wavelength shifts were negligible compared with those of the parent ketone (IIb) (Table 1). From this spectral evidence, the bromination product was determined to be 1α-phenyl-2α-bromo-5α-cholestan-3-one (IIIc), with an equatorial bromine atom. From the coupling constants of IIIc, the dihedral angle of C_1H_e–C_2H_a was calculated using the Karplus equation. This calculation resulted in 46°(44° in 2α-bromo-5α-cholestan-3-one[7]) (Table 2); hence, the A-ring conformation of phenyl bromoketone (IIIc) seemed to be of approximately a normal chair form.

The above results do not show any differences in the 1α-substituent with respect to the direction of bromination and A-ring conformation.

The NMR spectrum of the dibromination product of IIa revealed peaks at 4.46 ppm (d, $J_{4\beta,5\alpha}$=12.0 Hz) and 5.11 ppm (d, $J_{1\beta,2\beta}$=4.5 Hz) due to vicinal diaxial coupling and equatorial-axial coupling respectively. Accordingly, the dibromination product was determined to be 1α-methyl-2α,4α-dibromo-5α-cholestan-3-one (IIIb). The dihedral angles ($\phi_{4\beta,5\alpha}$ and $\phi_{1\beta,2\beta}$) were calculated using the Karplus equation. It was found that the A-ring conformation of IIIb is a nearly normal chair form. These values are also listed in Table 2.

1α-Methyl-5β-cholestan-3-one (Va), which has been synthesized by following the procedure of Mori,[5] was brominated. The monobrominated product (VIa) of Va showed a peak at 4.64 ppm (d, J=10.5 Hz) attributed to –CHBr– in the NMR spectrum. It can not be determined from the above NMR data whether the bromine atom is attached to the C_2 or C_4 position. In order to determine the brominated position, IV was reduced with deuterium in cyclohexane. From the fact that the mass spectrum showed a peak at *m/e* 402 [M^+], this reduced product was found to be 1α-methyl-4β,5-dideuterio-5β-cholestan-3-one (Vb). The reaction of Vb with bromine in acetic acid gave a monobromoketone, melting at 136—139 °C. This product was determined to be 1α-methyl-4-bromo-5-deuterio-5β-cholestan-3-one (VIc) from the fact that the NMR spectrum showed a singlet at 4.64 ppm due to –CHBr–. From the above facts, it was found that the bromination of Va occurs at the C_4 position. The configuration of the C_4 bromine atom was determined to be equatorial (β-linkage) in the A-ring with the boat conformation from the fact that the rotatory dispersion of 1α-methyl-4β-bromo-5β-cholestan-3-one (VIa) does not change the nature of the Cotton effect; the wavelength shifts are negligible compared with those of the parent ketone, Va. If the A-ring takes a normal chair conformation, the ORD curve can be expected to show a negative Cotton effect. The dibromination of Va produced 2,4-dibromoketone (VIb); it showed a negative Cotton curve with a small amplitude (−17) and a red shift of 53 nm from that of the parent keton (Va). From these results, we may conclude that the two bromine atoms are attached to an axial-like bond. Because of the counteraction of the opposite contribution due to 2- and 4-bromine for the Cotton effect, it seems that the amplitude is small. From the coupling constants, $J_{1,2}$=8.3 Hz and $J_{4,5}$=13.5 Hz, of the dibromoketone, the dihedral angles were calculated using the Karplus equation; we obtained 35° and 166° respectively. These values differ from those for the angles of 2β,4β-dibromo-5β-cholestan-3-one (Table 2). From these data, it was concluded that the dibromoketone was 1α-methyl-2β,4β-dibromo-5β-cholestan-3-one

(VIb), with a twist boat conformation.

All of the facts observed in these experiments with respect to the direction and orientation proved to be the same as those in the case of 1-unsubstituted 3-keto steroids; thus, these seems to be no drastic 1α-substituent effect.

Experimental

All the melting points are uncorrected. The IR spectra were measured (KBr) with a Hitachi model 215 grating infrared spectrophotometer. The ORD spectra were obtained in dioxane with a JASCO model J-20 instrument. The NMR spectra were recorded in carbon tetrachloride, with tetramethylsilane as the internal standard, using a Hitachi-Perkin Elmer R-20A apparatus. The mass spectra were obtained with a Hitachi RMU-6M spectrometer at 20 eV.

1α-Phenyl-5α-cholestan-3-one (IIb). To Mg (0.9 g) in absolute ether (24 ml), under a nitrogen atomosphere was added dropwise iodobenzene (9.6 g) with stirring. After 30 min, absolute tetrahydrofuran (40 ml) was slowly added. The solvent was distilled until the boiling point was 62 °C; the mixture was then cooled to room temperature, and CuCl (0.2 g) and 5α-cholestan-1-en-3-one (2.0 g) in tetrahydrofuran (21 ml) were added. To facilitate stirring, tetrahydrofuran (40 ml) was added. After 30 min, the mixture was cooled to 0 °C, a saturated ammonium chloride solution was added, the mixture was extracted with ether, the aqueous solution was discarded, and the organic phase was washed successively with a sodium thiosulfate solution, the saturated ammonium chloride solution, and water. After a usual work-up, the resulting oil was distilled under reduced pressure at 180 °C to remove the non-keto substance. The residue was chromatographed on silica gel. Elution with benzene afforded 1α-phenyl-5α-cholestan-3-one (IIb) (1.2 g), which crystallized from ethanol as needles; mp 140—141 °C; IR cm^{-1}: ν_{max} 1707, 1600, and 703; NMR: 3.25 ppm (bd, J=6.0 Hz, 1H) and 7.10 ppm (m, 5H); Found: C, 85.60; H, 11.00, $C_{33}H_{50}O$ requires C, 85.65; H, 10.89%.

1α-Methyl-2α-bromo-5α-cholestan-3-one (IIIa). 1α-Methyl-5α-cholestan-3-one (2 g) in acetic acid (62 ml) was treated with bromine (0.811 g) in acetic acid (19 ml) containing a few drops of 48% hydrobromic acid at room temperature for 25 min. The reaction mixture was then treated in the usual manner. The crystallization of the resulting oil from ethanol gave IIIa (1.54 g); mp 177—180 °C; IR cm^{-1}: ν_{max} 1726 and 890; NMR: 5.00 ppm (d, J= 4.8 Hz, 1H); Found: C, 70.18; H, 9.80, $C_{28}H_{47}OBr$ requires C, 70.12; H, 9.88%.

1α-Methyl-2α, 4α-dibromo-5α-cholestan-3-one (IIIb). To a solution of IIa (0.300 g) in acetic acid (18 ml) and one drop of 48% hydrobromic acid was added bromine (0.231 g) in acetic acid (15 ml) with stirring for 30 min at room temperature. The reaction mixture was then taken up in ether, and the ether extracts were washed, dried, and evaporated. On the chromatography of the residue with silica gel, elution with benzene-petroleum ether (1 : 1) gave an oily product. The crystallization of the resulting oil from ethanol afforded needles (0.125 g) of IIIb; mp 145—148 °C, IR cm^{-1}: ν_{max} 1740 and 613; NMR: 4.46 ppm (d, J=12.0 Hz, 1H) and 5.11 ppm (d, J=4.5 Hz, 1H); Found: C, 59.92; H, 8.07%, $C_{28}H_{46}OBr_2$ requires C, 60.22; H, 8.30%.

1α-Phenyl-2α-bromo-5α-cholestan-3-one (IIIc). The bromination of IIb (0.5 g) was carried out using the technique for the synthesis of IIIa. After the usual work-up, the resulting oil was chromatographed on silica gel. Elution with benzene-petroleum ether (1 : 1) afforded IIIc (0.400 g), which crystallized from ethanol-methanol as needles; mp 74—76 °C, IR cm^{-1}: ν_{max} 1723 and 789; NMR: 3.58 ppm (d, J=6.0 Hz, 1H), 5.14 ppm (d, J=6.0 Hz, 1H), and 7.20 ppm (m, 5H); Found: C, 73.35; H, 9.30%, $C_{33}H_{49}OBr$ requires C, 73.17; H, 9.12%.

1α-Methyl-4β,5-dideuterio-5β-cholestan-5-one (Vb). The synthesis was carried out following the procedure of Shapiro and Djerassi.[8] A mixture of IV (0.168 g), palladium black (0.100 g), and cyclohexane (30 ml) was shaken in a deuterium atmosphere. The deuterium uptake was completed within 7 h. The catalyst was then removed by filtration, and the filtrate was evaporated. The residue was recrystallized from methanol to give Vb (0.079 g); mp 84—85 °C, IR cm^{-1}: ν_{max} 1718 (1718, CCl_4); MS: m/e 402 (M^+).

1α-Methyl-4β-bromo-5β-cholestan-3-one (VIa). The bromination of Va (0.100 g) was carried out using the technique used for the synthesis of IIIa. The crystallization of the resulting oil from ethanol gave VIa (0.094 g); mp 136—139 °C; IR cm^{-1}: ν_{max} 1718 (1730, CCl_4) and 572; NMR: 4.64 ppm (d, J=10.5 Hz, 1H), Found: C, 70.30; H, 9.62%, $C_{28}H_{47}OBr$ requires C, 70.12; H, 9.88%.

1α-Methyl-2β, 4β-dibromo-5β-cholestan-3-one (VIb). The dibromination of Va (0.300 g) was carried out using the technique used for the synthesis of IIIb. The crystallization of the resulting oil from ethanol gave VIb (0.180 g); mp 139—144 °C; IR cm^{-1}: ν_{max} 1733 (1720, CCl_4) and 624; NMR: 4.37 ppm (d, J=13.5 Hz, 1H) and 4.55 ppm (d, J=8.3 Hz, 1H), Found: C, 60.12; H, 8.00%, $C_{28}H_{46}OBr_2$ requires C, 60.22; H, 8.30%.

1α-Methyl-4β-bromo-5-deuterio-5β-cholestan-3-one (VIc). The bromination of Vb (0.060 g) was carried out using the technique used for the synthesis of IIIa. The crystallization of the resulting oil from ethanol gave VIc (0.045 g); mp 136—139 °C, IR cm^{-1}: ν_{max} 1718 (1730, CCl_4) and 572; NMR: 4.64 ppm (s, 1H); MS: m/e 480 and 482 (M^+).

1α-Methyl-2α-bromo-3α-hydroxy-5α-cholestane (VII). The synthesis used was virtually identical with the method of Fieser.[9] A solution of IIIa (0.400 g) and sodium borohydride (0.050 g) in methanol (60 ml) was stirred at room temperature for 30 min. After the usual work-up, the crystallization of the resulting oil from ethanol gave VII (0.315 g); mp 148—152 °C; IR cm^{-1}: ν_{max} 3499 and 1030; NMR: 3.96 ppm (m, 1H) and 4.66 ppm (dd, J= 3.0 and 4.8 Hz, 1H); Found: C, 70.01; H, 10.40%, $C_{28}H_{49}OBr$ requires C, 69.83; H, 10.26%.

The authors wish to thank Professors Jisaku Kuroda, Machiko Tozawa, and Tsunetaka Kushimoto of the Jikei University School of Medicine for their great support during this work.

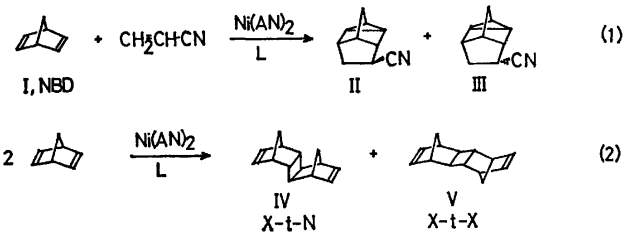
The Effects of Phosphorus Ligands on the Stereoselectivity of the Nickel-catalyzed Dimerization of Norbornadiene

Susumu YOSHIKAWA,* Jitsuo KIJI,** and Junji FURUKAWA
Department of Synthetic Chemistry, Kyoto University, Kyoto 606
(Received September 25, 1975)

The effects of phosphorus ligands on the stereoselectivity of the nickel-catalyzed 2+2 cyclodimerization of norbornadiene have been studied. The electronic factor, $\nu_{CO}(A_1)$, of $Ni(CO)_3L$ (where L is the ligand) is correlated with the ratio of the *exo-trans-exo* (X-t-X) to the *exo-trans-endo* (X-t-N) isomers of the product, but no simple correlation is apparent between the steric parameter and the selectivity. A three-coordinated Ni(0) species is proposed as the intermediate. The values of $\Delta H^{\neq}_{X\text{-}t\text{-}X}-\Delta H^{\neq}_{X\text{-}t\text{-}N}$ and $\Delta S^{\neq}_{X\text{-}t\text{-}X}-\Delta S^{\neq}_{X\text{-}t\text{-}N}$ are large and negative.

Ligand effects in homogeneous catalytic reactions are generally divided into electronic and steric factors. Contrary to the electronic factor, the estimation of the steric factor is rather complicated, and little appears to be known about the steric effect on the selectivity of a reaction. Stereoselective organic syntheses have been attracted increasing interest in recent years. Our work in this series was initiated in order to clarify the factors which control the steric course of some homogeneous catalytic reactions. In the previous paper we described that the steric effect of trivalent phosphorus ligands dominates the steric course of the 4+2 cycloaddition of norbornadiene (NBD) with acrylonitrile (AN) catalyzed by bis(acrylonitrile)nickel $Ni(AN)_2$ (Eq. 1).[1]



A steric parameter, the cone angle,[2] was correlated with the ratio of the stereo-isomers (II and III). It seems to us that the reaction of norbornadiene is simple enough for the evaluation of the effect of the added ligands, because both isomerization and retro-reaction can be minimized by temperature control under these conditions. The dimerization (Eq. 2) is catalyzed by various transition metal complexes.[3] In the nickel carbonyl-catalyzed dimerization,[4] ir-radiated $Ni(CO)_4$ with ultraviolet gives a different selectivity from that of the dark reaction.[5] If a ligand added to this system, instead of irradiating, alters the stereoselectivity, the effects of the ligand can be evaluated from the product distribution.

This paper will deal with the dominant role of the electronic effect in the 2+2 cyclodimerization of norbornadiene (Eq. 2).

Results

The present study employed bis(acrylonitrile)nickel $Ni(AN)_2$ combined with phosphorus ligands as the catalyst. Early in the reaction, $Ni(AN)_2$ was insoluble, but it was gradually dissolved by complexing with the phosphorus ligands. With a strong donor ligand, $Ni(AN)_2$ was rapidly dissolved and the system turned reddish-yellow. During the reaction, the acrylonitrile, which was coordinated to the nickel, reacted with norbornadiene to give II and III as the by-products. The radio of II and III was controlled by the cone angle of the phosphorus ligands used, as has been described in the previous paper.

The dimers, *exo-trans-endo* (IV, abbreviated as X-t-N) and *exo-trans-exo* (V, X-t-X), were the major products.[6] The ratio of IV to V is considered to reflect the stereoselectivity of the reaction under these conditions (65.8—130 °C), because neither isomerization nor retro-reaction occurred. In fact, the purified product, IV or V was heated with the catalyst. In this case, however, the isomer was recovered unchanged. Figure 1 shows the effects of the added triphenylphosphine on the yield and on the ratio of IV to V. An inspection of Fig. 1 reveals that the selectivity is independent of the amount of triphenylphosphine (P/Ni>2). This observation shows that the active species is specified not by the amount but by the kind of the phosphorus ligand added. This is consistent with the previous observation.[1] A correlation for the temperature indicated that the IV isomer was preferably formed as the temperature rises.

As has been reported earlier,[1] the electronic and steric factors of the ligands were estimated by means of the $\nu_{CO}(A_1)$ of $Ni(CO)_3L$ and the cone angle, θ,

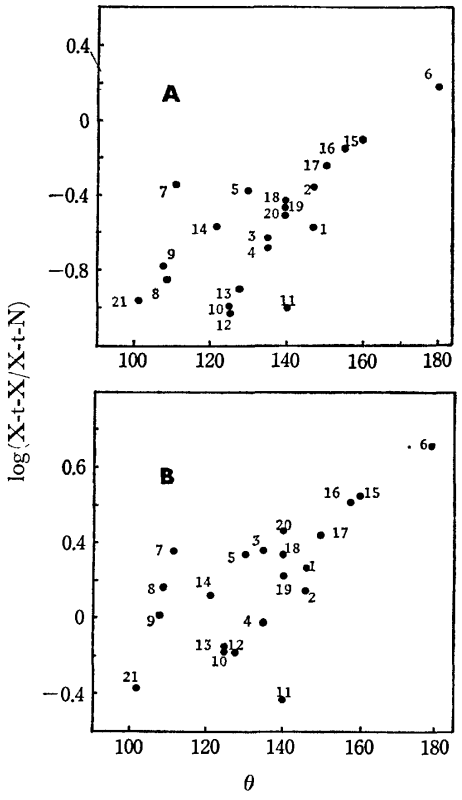

Fig. 2. Selectivity *vs.* cone angle. A, 110°; B, 7.15 °C. Ligands numbers refer to Experimental section.

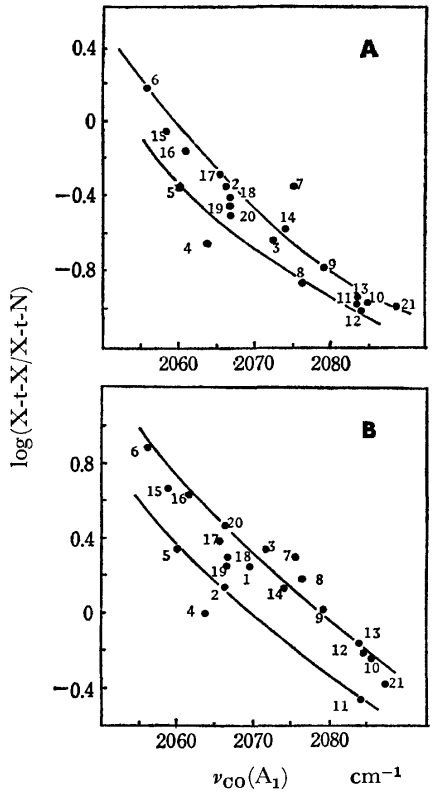

Fig. 3. Selectivity *vs.* ν_{CO}. A 110°; B, 71.5 °C.

respectively. The ratio of IV to V was correlated with ν_{CO} rather than with θ, as is shown in Figs. 2 and 3. No simple correlation is apparent between the cone angle and the selectivity. For example, ligands of different bulkiness, $(O\text{-}o\text{-}C_6H_4CH_3)_3P$ (**11**), $(O\text{-}m\text{-}C_6H_4CH_3)_3P$ (**12**), $(C_6H_5O)_3P$ (**10**), and $CH_3C(CH_2O)_3P$ (**21**), gave a similar ratio. This is in marked contrast to the 4+2 cycloaddition of norbornadiene with acrylonitrile, where a clear-cut correlation of the bulkiness of the ligands with the selectivity was found.

On the other hand, the importance of the electronic effect is indicated by the rather good correlation between $\nu_{CO}(A_1)$ and log V/IV. No appreciable difference in the effects was observed between phosphines and phosphites, except that the former gave higher yields than the latter.

The solvent effect was investigated by using PPh_3 as the auxiliary ligand at 92 and 110 °C. Solvents similar in their volume to norbornadiene were used. Figure 4 shows the relation between their molar polarizability and the selectivity. Acetonitrile behaved

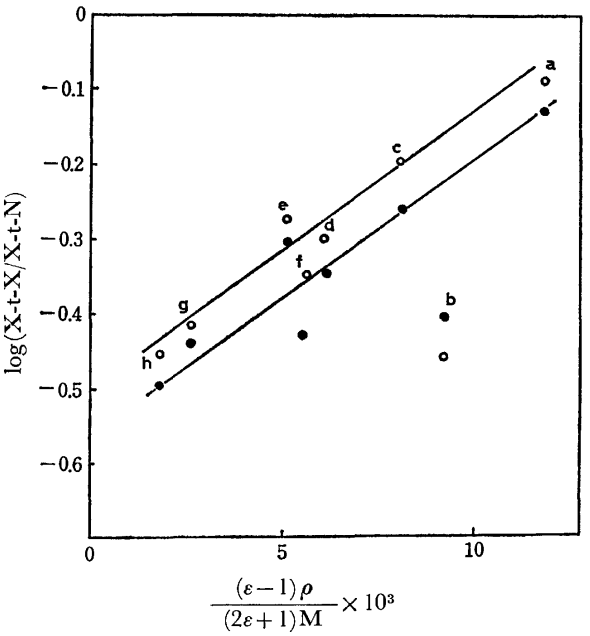

Fig. 4. Solvent effect. a, methanol; b, acetonitrile: c, ethanol; d, 2-propanol; e, tetrahydrofuran; f, pyridine; g, benzene; h, triethylamine. ●, 110 °C; ○, 92 °C. Conditions: NBD, 6 mmol; $Ni(AN)_2$, 0.04 mmol; PPh_3, 0.12 mmol; solvent, 1 ml; 3 h.

differently from the other solvents. This is attributable to the coordination of the CN group to the nickel. The increase in the polarity of the solvent preferred the formation of the X-t-X isomer. However, the solvent effect was smaller than that of the ligand.

It is noteworthy that the 4+2 cycloaddition of norbornadiene to acrylonitrile is strongly influenced by the cone angle of the ligands coordinated to the nickel, while the 2+2 cyclodimerization of norbornadiene is influenced by their electronic factor. This difference is attributable to the limited coordination number of the central metal. Due to a steric inter-

action of reactants in the coordination sphere, the reaction follows an unexpected course. The reaction of acetylenes with norbornadiene is an example.[7] Bulky diphenylacetylene undergoes 2+2 cycloaddition with norbornadiene on nickel, while dicarbomethoxyacetylene undergoes 4+2 cycloaddition. The failure of the 4+2 cycloaddition of diphenylacetylene may be ascribed to the steric interaction of the bulky phenyl group. In the reaction (Eq. 1) the tetrahedral configuration around the nickel was assumed. Zerovalent nickel (d^{10}) has the maximum coordination number 4, and the stabilization energy of its ligand field is highest. However, the steric interaction caused by adding the fourth bulky ligand may cost more energy than would be gained by completing the coordination number, 4. In fact, Seidel and Tolman[8] have reported that, in the homolog of NiL_4, coordinatively unsaturated NiL_3 is obtained with bulky $P(O\text{-}o\text{-}C_6H_4CH_3)_3$.

A supposed intermediate of the dimerization is shown in Fig. 5, where one molecule of norbornadiene is bidentately coordinated, and the other, unidentately, by assuming that the C–Ni bond is 2.1 Å. In this configuration the cone angle of the ligand coordinated to the fourth site must be smaller than 95°. None of the phosphorus ligands used in the present study can occupy the site, because they are too bulky to be coordinated to the nickel. Therefore, a three-coordinated Ni(0) species is here proposed as the intermediate.[9] This assumption is in striking contrast to that used for the reaction of norbornadiene with acrylonitrile.[1]

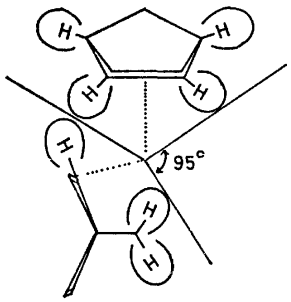

Fig. 5. Proposed coordination of bidentate and unidentate norbornadiene.

Plots of V/IV (the ratio of X-t-X to X-t-N formed) against $1/T$ were used to determine the values of $\Delta H^{\ddagger}_{X\text{-t-}X}-\Delta H^{\ddagger}_{X\text{-t-}N}$ ($\Delta\Delta H^{\ddagger}$) and $\Delta S^{\ddagger}_{X\text{-t-}X}-\Delta S^{\ddagger}_{X\text{-t-}N}$ ($\Delta\Delta S^{\ddagger}$), by assuming that the ratio of the products formed reflects that of the rate constants. The values of $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ are large and negative, in general (Fig. 6). The isokinetic temperature is derived as 79 °C.

The thermally "forbidden" dimerization of norbornadiene is here considered to proceed *via* a metal-carbon bonded intermediate.[10] In fact, an analogous iridocycle has been prepared and can be regarded as a stabilized intermediate.[11] The stercochemistry of the carbon–carbon bond formation on the iridium metal is not altered during the reductive elimination, which gives the 2+2 cycloaddition products. That is, no isomerization is involved in these steps. Before

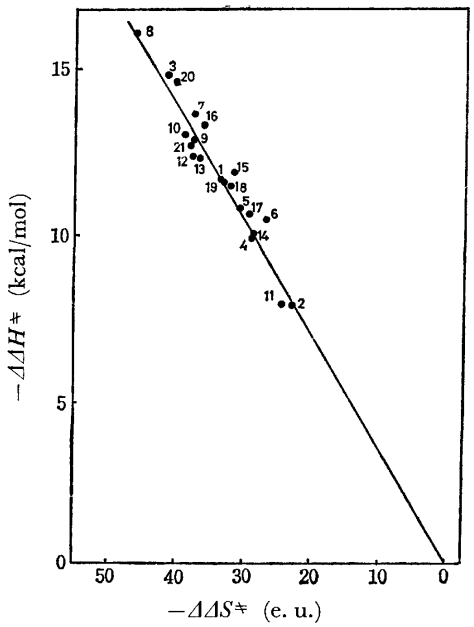

Fig. 6. Isokinetic relation. Ligands numbers refer to Experimental section.

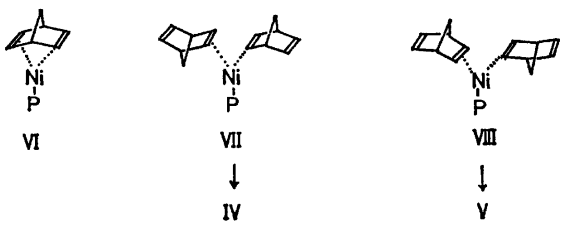
the coupling of two double bonds, the coordination of both reactants to the central metal is required. In the nickel-catalyzed 2+2 cycloaddition of norbornadiene with a strained olefinic double bond, the transient bidentate (*endo*) coordination of norbornadiene is assumed, because this catalytic system gives exclusively an adduct having *endo* stereochemistry.[12] The mode of the coordination before the coupling is considerd to determine the stereochemistry of the products.

In general, due to its strain each double bond of norbornadiene can participate in the coordination;[9] thus, the *endo* coordination through chelation is inherent in the present reaction. Consequently, prior to the coupling of norbornadiene, the corresponding *exo-endo* (VII) and *exo-exo* (VIII) coordinations can be assumed with likelihood; they afford *exo-trans-endo* (IV) and *exo-trans-exo* (V) isomers respectively.



No sufficient explanation of the electronic effect of the phosphorus ligands on the reaction can be made on the basis of the present study. However, the following explanation is possible. The donor ligand increases the electron density of the nickel. The coordination of norbornadiene on the less-hindered *exo* side gives a greater overlap of the orbitals between the nickel and the double bond.[13] The terms of enthalpy dominates the formation of VIII. On the other hand, the formation of VII is favorable in terms of its smaller entropy loss on the basis of the assumption that both VII and VIII are derived from VI by substituting one and two

double bonds of the originally *endo*-coordinated norbornadiene with the incoming norbornadiene. A higher temperature also favors the formation of IV (Fig. 3). Therefore, the entropy term is considered to be dominant in the formation of VII. If the intermediates (VII and VIII) participate in the product-determining step, the selectivity is determined by the ease of their formation.

Experimental

Commercially available phosphorus compounds were used without further purification. All the reactions were carried out in glass tubes (8 mm in diameter) without stirring. The reaction conditions are indicated in the figures. The separation of the isomers was performed by gas chromatography on a Silicon DC 550 column (3 m) at 180 °C. They were identified by comparing the NMR spectra of the gas chromatographically collected samples with those of the reported ones.[4d] The yields were determined by gas chromatography, using tetralin as the internal standard. The total yields (X-t-X and X-t-N formed) of a typical reaction (NBD, 8 mmol) in the presence of $Ni(AN)_2$ (0.04 mmol) and the ligand (0.12 mmol) in benzene (1 ml) are as follows (% at 71.5 °C for 15 h, 110 °C for 3 h): $(C_6H_5)_3P$ (**1**), (65.2, 49.0); $(p\text{-}CH_3C_6H_4)_3P$ (**2**), (70.2, 59.2); $(C_6H_5)_3As$ (**3**), (46.4, 4.8); $(C_2H_5)_2(C_6H_5)P$ (**4**), (55.0, 3.7); $(n\text{-}C_4H_9)_3P$ (**5**), (43.9, 35.7); $(C_6H_{11})_3P$ (**6**), (36.6, 24.5); $(C_4H_9O)_3P$ (**7**), (47.1, 15.3); $(C_2H_5O)_3P$ (**8**), (27.4, 3.6); $(CH_3O)_3P$ (**9**), (20.8, 1.9); $(C_6H_5O)_3P$ (**10**), (32.2, 1.4); $(O\text{-}o\text{-}C_6H_4CH_3)_3P$ (**11**), (31.6, 0.9); $(O\text{-}m\text{-}C_6H_4CH_3)_3P$ (**12**), (27.6, 0.5); $(O\text{-}p\text{-}C_6H_4CH_3)_3P$ (**13**), (36.7, 0.9); $(C_2H_5O)_2(C_6H_5)P$ (**14**), (35.4, 6.9); $(o\text{-}C_6H_4CH_3)_3P$ (**15**), (42.3, 31.6); $(o\text{-}C_6H_4OCH_3)_2(C_6H_5)P$ (**16**), (59.8, 23.1); $(o\text{-}C_6H_4OCH_3)(C_6H_5)_2P$ (**17**), (55.0, 20.1); $(C_6H_5)_2PCH_2P(C_6H_5)_2$ (**18**), (47.6, 10.4); $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$ (**19**), (36.2, 15.9); $(C_6H_5)_2P(CH_2)_3P(C_6H_5)_3$ (**20**), (41.6, 7.3); $CH_3C(CH_2O)_3P$ (**21**), (25.8, 3.6).

Bromination and Mercuration of Bis-dimethlglyoximato(1-octenyl)-pyridinecobalt(III), 1-Octenyl Cobaloxime

Masaru TADA, Minoru KUBOTA, and Hiraku SHINOZAKI

Department of Chemistry, School of Science and Engineering, Waseda Univerity, Shinjuku, Tokyo 160

(Received October 2, 1975)

cis-1-Octenyl(pyridine)cobaloxime (I) and *trans*-1-octenyl(pyridine)cobaloxime (II) were prepared by the reaction of cobaloxime anion with *cis*- and *trans*-1-halooctene, respectively. Bromination of I and II in polar solvents gave preferentially *trans*-1-bromooctene. Bromination of I in carbon disulfide also gave preferentially *trans*-1-bromooctene, but bromination of II gave more *cis*-1-bromooctene. Mercuration of I and II with mercuric acetate in DMF gave preferentially 1-octenylmercury(II) compound with retention of configuration, but the mercuration in acetic acid gave *ca.* 1 : 2 mixture of *cis* and *trans*-1-octenylmercury(II) compound. Two mechanisms are proposed for these electrophilic displacement reactions; one involves the addition of electrophile as a first step, followed by the elimination of cobaloxime moiety, and the other involves the addition of bromonium or mercury(II) ion, followed by the elimination of cobaloxime moiety.

In recent years much attention has been paid to the electrophilic displacement of alkyl metal-complexes,[1] especially bis-dimethylglyoximato(alkyl)pyridinecobalt-(III).[2-5] Kinetic studies[6,7] and the stereochemical consequences of these reactions suggest that the nature of these reactions is a concerted S_E2 reaction with inversion of the configuration at the reaction center. Little is known about the electrophilic displacement of alkenyl cobalt-complex. Johnson and Meeks[8] recorded in a preliminary report that the halogenation of bis-dimethylglyoximato(styryl)pyridinecobalt(III) in acetic acid proceeded with retention of configuration to give β-halostyrene.

In this paper we wish to report the steric course of the electrophilic displacement, bromination, and mercuration of bis-dimethylglyoximato(*cis*-1-octenyl)pyridinecobalt(III) (I) and bis-dimethylglyoximato(*trans*-1-octenyl)pyridinecobalt(III) (II), for which the conventional name octenyl(pyridine)cobaloxime is used hereafter, and to discuss the reaction mechanism.

Experimental

Preparation of cis *and* trans-*1-Octenyl(pyridine)cobaloxime (I and II).* To the stirred mixture of *cis*-1-bromooctene (382 mg, 2 mmol) and dimeric pyridinecobaloxime,[9] $(Co(dmgH)_2py)_2$ (368 mg, 0.5 mmol) in 20 ml of ethanol containing sodium hydroxide (0.01 mol/l) was added under nitrogen 1.3 g of zinc powder in portions over the period of 3 days. The reaction mixture was filtered and the filtrate was condensed under reduced pressure. The condensate was passed through a column of Florisil (10 g) with dichloromethane to remove impurities. Evaporation of the solvent from the eluate gave essentially pure *cis*-1-octenyl(pyridine)-cobaloxime (I) in 35% yield. Recrystallization of I from acetonitrile gave pure cobaloxime.

The same procedure starting with *trans*-1-chlorooctene gave *trans*-1-octenyl(pyridine)cobaloxime (II) in the yield of 33%. I, mp 149—151 °C. Found: C, 52.47; H, 7.31; N, 14.87%. Calcd for $C_{21}H_{34}N_5O_4Co$: C, 52.61; H, 7.15; N, 14.61%. IR (KBr): 2940, 2855, 1598, 1439, 1230, 1080, and 725 cm^{-1}. NMR($CDCl_3$):[10] 8.75 (d, J=6.5, 2H), 7.80 (t, J=6.5, 1H), 7.40 (t, J=6.5, 2H), 5.80 (d, J=7, 1H), 4.96 (q, J=7, 1H), 2.08 (s, 12H), 1.0—1.4 (m, 10H), and 0.88 ppm (δ) (t, J=6, 3H).

II, mp 171—173 °C. Found: C, 52.32; H, 7.35; N, 14.90%. Calcd for $C_{21}H_{34}N_5O_4Co$: C, 52.61, H, 7.15; N, 14.61%. IR(KBr): 2940, 2860, 1600, 1560, 1442, 1225, 1082, and 945 cm^{-1}. NMR($CDCl_3$): 8.74 (d, J=6.5, 2H), 7.81 (t, J=6.6, 1H), 7.40 (t, J=6.6, 2H), 5.71 (d, J=14, 1H), 5.08 (quintet, J=14 and 7, 1H), 2.08 (s, 12H), 1.0—1.4 (m, 10H), and 0.82 ppm (δ) (t, J=6.5, 3H).

Bromination of 1-Octenyl(pyridine)cobaloximes (I and II). The solution of I or II (120 mg, 0.25 mmol) in one of the solvents (10 ml) was treated with one equivalent of bromine or NBS dissolved in 10 ml of the same solvent, and the mixture was stirred for 30 min at ambient temperature. After evaporation of most of the solvent, the products were dissolved in hexane. When DMF was used as the solvent, the reaction mixture was added to water and extracted with hexane. Passing of the hexane solution through the column of alumina (Merck activity II-III, 500 mg) gave the eluate containing 1-bromooctene. This eluate was subjected to GLC analysis (N_2, 5% Carbowax 20 M on Chromosorb W, 90 °C) for the determination of the product composition. Evaporation of the solvent of the eluate gave 1-bromooctenes in the yields listed in the tables. Assignment of the bromides to *cis* and *trans*-1-bromooctene was made by the comparison of GLC, IR, and NMR spectra of the products with those of the authentic samples. The reaction in carbon disulfide at a controlled temperature was carried out using a cooling bath (−50 °C) or by boiling the reaction mixture (46 °C). The effect of bromide ion on the product composition was determined by using a mixture of DMF and water (9 : 1) containing a certain amount of tetraethylammonium bromide.

Mercuration of 1-Octenyl(pyridine)cobaloximes (I and II). The solution of I or II (120 mg, 0.25 mmol) in DMF or acetic acid (5 ml) was treated with 1.2 equivalents of mercuric acetate and the mixture was stirred for 30 min at ambient temperature. The mixture was further stirred for 10 min after addition of 4 ml of saturated aqueous solution of sodium chloride and extracted with dichloromethane after further addition of water (20 ml). The extract was washed with water and then condensed at reduced pressure to remove any residual DMF. The crude product thus obtained was passed through a column of Florisil (1.2×15 cm) using dichloromethane, and evaporation of the solvent gave 1-octenylmercury(II) chloride (IVa and IVb) in the yields listed in Table 3. The product composition was determined by the relative intensities of the NMR signals of olefinic hydrogen of this product mixture in $CDCl_3$. Recrystallization of the product from hexane gave pure *cis* and *trans*-1-octenylmercury(II) chloride (IVa and IVb). The structures of IVa and IVb were deduced by transforming these organomercury(II) compounds into *cis* and *trans*-1-bromooctene with bromine in pyridine.

IVa, low melting solid. IR(KBr): 3005, 1598, 1460,

965, 950, and 690 cm^{-1}. NMR($CDCl_3$): 6.74 (double t, J=10 and 7, 1H), 6.03 (d, J=10, 1H), 2.28 (m, 2H), 1.2—1.6 (8H), and 0.91 ppm (δ) (t, J=6.5, 3H). IVb, mp 103—104 °C.[11] IR(KBr): 3005, 1600, 1462, 969, 952, and 717 cm^{-1}. NMR($CDCl_3$): 5.81 (m, 2H), 2.20 (m, 2H), 1.1—1.6 (8H), and 0.90 ppm (δ) (t, J=6.5, 3H).

Results and Discussion

cis-1-Octenyl(pyridine)cobaloxime and *trans*-1-octenyl (pyridine)cobaloxime (I and II) were prepared by the action of the cobaloxime anion on *cis*-1-bromooctene and *trans*-1-chlorooctene, respectively (Eqs. 1 and 2). The cobaloxime anion was usually prepared *in situ* from dimethylglyoxime, pyridine, cobalt(II) chloride, and sodium tetrahydroborate in methanol, but the yield (*ca.* 15%) of 1-octenyl(pyridine)cobaloxime was moderate by this method. We prepared the cobaloxime anion conveniently by the reduction of dimeric pyridinecobaloxime $(Co(dmgH)_2py)_2$[9] with zinc powder in ethanol containing sodium hydroxide (0.01 mol/l). The yields of 1-octenyl(pyridine)cobaloximes were always over 30%, though we did not maximize the yields.

The stereochemistry of 1-octenyl(pyridine)cobaloximes (I and II) can be easily assigned by examination of the coupling constants of the olefinic hydrogens, J=7 Hz for I and 14 Hz for II. The stereochemistry of 1-octenyl(pyridine)cobaloxime is the same as that of the starting halooctenes; this is in sharp contrast to the inversion of the configuration at the reaction center when the displacement of alkyl halide is carried out

$$n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagup X + [Co(dmgH)_2py]_2 \xrightarrow[NaOH/EtOH]{Zn} \underset{(I)}{n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagup Co(dmgH)_2py} \quad (1)$$

$$n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagdown X + [Co(dmgH)_2py]_2 \xrightarrow[NaOH/EtOH]{Zn} \underset{(II)}{n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagdown Co(dmgH)_2py} \quad (2)$$

with cobaloxime anion.[1] These facts suggest that the formation of alkenyl cobaloxime results from the addition of cobaloxime anion to 1-haloalkene and the elimination of halide anion. This process usually proceeds with retention of configuration,[12,13] whereas the reaction of alkyl halide with cobaloxime anion takes S_N2 process with inversion of configuration.[14]

The reaction of bromine with *cis*- and *trans*-1-octenyl-(pyridine)cobaloxime (I and II) was carried out in polar solvents such as acetic acid, pyridine, DMF, and methanol; the bromine was consumed smoothly at ambient temperature (*ca.* 20 °C). The reaction gave only *cis* and *trans*-1-bromooctene (IIIa and IIIb); the results are shown in Table 1. The yields listed in the table were obtained from the isolated bromides; the yields analyzed by GLC gave much better figures. The relative ratio of the two isomeric bromides of the isolated products was essentially the same as the ratio of the crude products, and we did not maximize the isolated yields. The results summarized in Table 1 show that the bromination of *cis*-cobaloxime I in polar solvents proceeds almost completely with inversion of the configuration, whereas *trans*-cobaloxime II takes a different steric course, retention.

$$\left.\begin{array}{l} n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagup Co(dmgH)_2py \\ \quad (I) \\ n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagdown Co(dmgH)_2py \\ \quad (II) \end{array}\right\} \xrightarrow{Br_2} \left.\begin{array}{l} n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagup Br \\ \quad (IIIa) \\ + \\ n\text{-}C_6H_{13}\!\!\diagdown\!\!=\!\!\diagdown Br \\ \quad (IIIb) \end{array}\right. \quad (3)$$

The bromination of *cis* and *trans*-1-octenyl(pyridine)-cobaloxime (I and II) in carbon disulfide gave the results shown in Table 2. *cis*-Cobaloxime I gave preferentially *trans*-1-bromooctene (IIIb) with inversion, and *trans*-1-octenyl(pyridine)cobaloxime (II) gave more *cis*-1-bromooctene IIIa again with predominant inversion. The temperature effect on the product composition is opposite for I and II; a lowering of temperature induces more retention with I and more inversion with II. The stereoselectivity of the reaction in carbon disulfide is worse than in polar solvents, even at the lower temperatures. The low stereoselectivity in the bromination of 1-octenyl(pyridine)cobaloximes in carbon disulfide suggests the possibility of the intrusion of a radical mechanism. Bromination of the cobaloximes in the presence of 2,4,6-tri-*t*-butylphenol (2 equivalents), however, changed the isomeric ratio of the products by less than 5%. In the case of *trans*-cobaloxime II, addition of 2,4,6-tri-*t*-butylphenol gave products with more *cis*-bromide IIIa (64%) than its *trans*-isomer IIIb (36%). The preferential formation of thermo-

Table 1. Stereochemical compositions of 1-bromooctene

Starting material	Solvent	Yield[a] (%)	IIIa[b] (%)	IIIb[b] (%)
I	Methanol	67	2	98

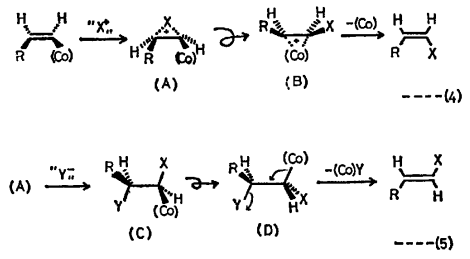
I	46 °C	80	11	89
	20 °C	72	13	87
	−50 °C	80	17	83
	20 °C[c]		14	86
II	46 °C	80	56	44
	20 °C	67	59	41
	−50 °C	65	72	28
	20 °C[c]		64	36

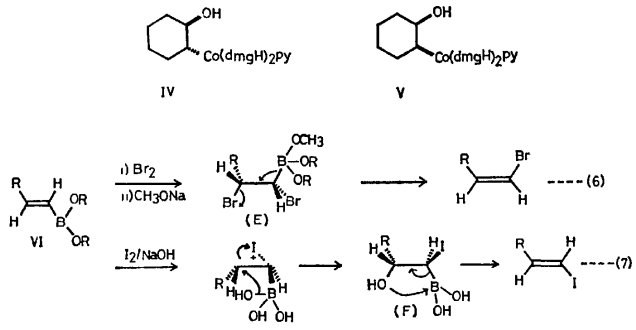
a) Isolated yield; some part of the products was lost on evaporation of the solvent. b) Calculated from the ratio of the peak area in GLC analysis. c) Carried out in the presence of 2 equivalents of 2,4,6-tri-*t*-butylphenol.

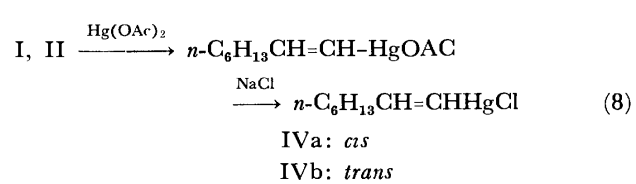


dynamically unstable *cis*-bromide IIIa from *trans*-cobaloxime II and the slight effect on the product composition from the radical inhibitor, 2,4,6-tri-*t*-butylphenol, exclude the possibility that the bromination of I and IIb is a radical process. The minor temperature effect on the product composition can be understood by considering a slight thermal isomerization of IIIa to IIIb under reaction conditions. Vinyl-type organocobaloxime is more stable than the corresponding alkyl cobaloxime; inparticular the former resists photodecomposition and photo-oxygenation under the conditions in which the latter decomposes with extreme easiness, giving alkyl radical as an intermediate. This feature is one of the reasons for eliminating a radical process for the bromination of cobaloxime I and II. A concerted S_E2 reaction also does not seem reasonable since the S_E2 reaction of alkyl cobaloxime has been settled to proceed with inversion of configuration due to the steric hindrance of the front side by dimethylglyoximato-ligand.[1] Bromination in the present study, nevertheless, proceeds with preferential retention under some conditions. These discussions imply a π-participated mechanism, as is generally believed to be responsible for the halogenation of vinyl-type organometallic compounds vinyl borane,[15] vinyl silicone,[16] and vinyl mercury(II) compound.[17] We prefer, therefore, the π-participated mechanisms depicted in Eq. 4 for the bromination with retention and in Eq. 5 for the bromination with inversion. There is large steric repulsion between the alkyl group and dimethylglyoximato-ligand in the intermediate (A) and also between alkyl and bromide in the intermediate (B). The bromination of *cis*-1-octenyl(pyridine)cobaloxime (I) *via* the route depicted in Eq. 4 must be disadvantageous for this reason. In the case of *trans*-1-octenyl(pyridine)-cobaloxime (II), the lack of severe steric repulsion in the intermediates of the types of (A) and (B) drives the reaction, as in Eq. 4, almost completely in non-polar solvents and appreciably in carbon disulfide. The reaction of *trans*-cobaloxime II in carbon disulfide, however, proceeds still preferentially with inversion, especially at the lower temperature. This means that the bridged carbonium ions (A) and (B) from *trans*-cobaloxime II are not sufficiently stabilized in polar solvents and an addition-elimination mechanism (Eq. 5) is still the favorable one. This concept is supported by the effect of temperature on the product composition—the lowering of temperature induces more inversion. In the latter mechanism (Eq. 5), we preclude the *cis*-elimination of halo-cobaloxime (CoY) from the intermediate (C) by the following reasons. Organo-(pyridine)cobaloxime has a central cobalt(III) ion whose coordination number is saturated by six ligand sites to take the nominal electronic structure of an inert gas. In support of this concept, notice that *trans*-2-hydroxycyclohexyl(pyridine)cobaloxime (IV) enters the elimination reaction with extreme easiness, giving cyclohexene, whereas its *cis* isomer V does not eliminate the cobaloxime residue easily.[1] These features are nicely illustrated by the halogen displacement of vinyl boronate (VI), in which *trans*-elimination takes place from the intermediate (E) in the presence of sodium methoxide (Eq. 6)[18] and *cis*-elimination takes place from the intermediate (F) in the presence of a weaker base (Eq. 7).[19] In these examples the intermediate (E) has the boron with saturated coordination number, whereas the intermediate (F) has the boron with unsaturated coordination number.

Next we examined the effect of the anion on the steric course of the reaction. Succinimide anion is considered to be a poor nucleophile, as exemplified in the oxybromination of olefin by *N*-bromosuccinimide in water or alcohol.[20] The use of *N*-bromosuccinimide as a bromonium ion source forces the reaction to take the route shown in Eq. 4, and the reaction proceeded more stereospecifically with retention of configuration, I : 72% retention and II : 71% retention in carbon disulfide. It is of special interest that the stereoselectivity was reversed, more retention, when *N*-bromosuccinimide was used. On the same ground, the existence of more bromide ions in the reaction system may induce more inversion as a result of the enhanced probability of giving the intermediate (C). Actually addition of tetraethylammonium bromide upon bromination of II with bromine in DMF caused more inversion—IIIa(*cis*)/IIIb(*trans*)=8/92, 14/86, and 29/71 when 0, 1.9, and 7.7 equivalents, respectively, of tetraethylammonium bromide was added.

The reaction of *cis*- and *trans*-1-octenyl(pyridine)-cobaloxime (I and II) with mercuric acetate followed by the treatment with sodium chloride was less stereospecific and gave *cis* and *trans*-1-octenylmercury(II) chloride (Eq. 8), as summarized in Table 3.





1-Octenylmercury(II) chloride thus formed was identified by transformation of these mercury-compounds

TABLE 3. ISOMERIC COMPOSITION OF 1-OCTENYLMERCURY(II) CHLORIDE FROM 1-OCTENYL(PYRIDINE)COBALOXIME

Starting material	Solvent	Yield[a] (%)	IVa[b] (%)	IVb[b] (%)
I	DMF	80	74	24
	Acetic acid	93	35	65
II	DMF	50	37	63
	Acetic acid	70	31	69

a) Isolated yield. b) Determined by the relative intensity of the NMR signals of olefinic hydrogen.

into *cis* and *trans*-1-bromooctene (IIIa and IIIb) by treatment with bromine in pyridine. In DMF, mercuration of I and II gave more products with retention. The low stereospecificity is not due to the isomerization of the starting *cis* and *trans*-cobaloxime (I and II), since mercuration of the cobaloxime with less than one equivalent of mercuric acetate recovered the starting cobaloxime in intact form. The reaction of *cis*-cobaloxime I in acetic acid, however, gave predominantly *trans*-1-octenylmercury(II) chloride (IVb). One of the possible courses is an addition-elimination mechanism due to the nucleophilic nature of acetic acid to give the intermediate of type (C) (Y=OAc) in Eq. 5, since the intermediate (A) and (B) are rather unstable due to the steric repulsion between alkyl and mercury (II) ion. A radical mechanism resulting from the initial electron transfer from the cobaloxime to mercury (II) ion (Eq. 9)[21] may be a mechanistic candidate, but the preferential formation of thermodynamically unstable *cis*-1-octenylmercury(II) chloride (IVa) from *cis* cobaloxime in DMF can be a justification for precluding the radical mechanism. Thus the mercuration of 1-octenyl(pyridine)cobaloxime (I and II) in polar solvents such as acetic acid and DMF can be considered to take both paths depicted in Eq. 4 and 5 competitively.

$$C_6H_{13}CH{=}CH{-}Co(dmgH)_2py + Hg^{2+} \longrightarrow [C_6H_{13}CH{=}CH{-}Co(dmgH)_2py]^+ + Hg^+ \xrightarrow{-Co(dmgH)_2py^+} C_6H_{13}CH{=}CH\cdot + Hg^+ \longrightarrow C_6H_{13}CH{=}CHHg^+ \quad (9)$$

In conclusion, the electrophilic substitution of 1-octenyl(pyridine)cobaloxime takes two competitive reaction paths—a stepwise mechanism involving bridged carbonium ions (Eq. 4) and a mechanism involving addition-elimination (Eq. 5). The relative importance of the two mechanisms depends on the stereochemistry of the starting 1-octenyl(pyridine)cobaloxime, the nature of the electrophilic reagent, and the solvent system of the reaction.

A Convenient Synthesis of Indolotropones and 6-Substituted 5-Azabenz[*b*]azulenes*

Kameji YAMANE and Kunihide FUJIMORI

Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto 390

(Received October 6, 1975)

Several substituted indolo[2,3-*b*]tropones were prepared by the dehydrobromination of 7,7-dibromo-7,8,9,10-tetrahydrocyclohept[*b*]indole-6(5*H*)-ones (**2a—h**), which had been obtained by the bromination of 7,8,9,10-tetrahydrocyclohept[*b*]indol-6(5*H*)-ones (**1a—h**) with phenyltrimethylammonium tribromide (PTAB). 6,7,8,9-Tetrahydrocyclohept[*b*]indole-10(5*H*)-one (**5a**) and 6,7,8,9-tetrahydro-5-methylcyclohept[*b*]indol-10(5*H*)-one (**5b**) were obtained by the oxidation of hexahydrocyclohept[*b*]indole (**4a**) and the 5-methyl derivative (**4b**) with dichlorodicyanobenzoquinone (DDQ). Indolo[3,2-*b*]tropones (**6a** and **6b**) were derived from **5a** and **5b** respectively. The reactions of 6-chloro-5-azabenz[*b*]azulene (**8**) with nucleophilic reagents gave the corresponding substituted products (**9a—j**).

In a previous paper,[1] it has been reported that cyclohept[*b*]indol-6(5*H*)-ones (indolo[2,3-*b*]tropones) were obtained by using 2-hydrazinotropones as the starting material.

We will outline here a convenient method for the synthesis of cyclohept[*b*]indol-6(5*H*)-ones and cyclohept[*b*]indol-10(5*H*)-ones (indolo[3,2-*b*]tropones) by a modification of the synthetic method of G. Jones and his co-workers for heterocyclic tropones.[2] It will also be described for substitution reactions of 6-chloro-5-azabenz[*b*]azulene, obtained from **3a**, with several nucleophilic reagents.

Results and Discussion

Cyclohept[b]*indol-6(5*H*)-ones.* 7,8,9,10-Tetrahydrocyclohept[*b*]indol-6(5*H*)-one (**1a**) was brominated with phenyltrimethylammonium tribromide (PTAB) in dry tetrahydrofuran to give 7,7-dibromo-7,8,9,10-tetrahydrocyclohept[*b*]indol-6(5*H*)-one (**2a**). The dehydrobromination of the dibromo compound (**2a**) with lithium chloride in boiling *N*,*N*-dimethylformamide (DMF) gave yellow micro needles (mp 245—246 °C).

The IR spectrum was identical with that of the cyclohept[*b*]indol-6(5*H*)-one prepared by the dehydrogenation of 1,2,3,4-tetrahydrocyclohept[*b*]indol-6(5*H*)-one with chloranil or 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ).[1]

Further, several substituted cyclohept[*b*]indol-6(5*H*)-ones (**3b—h**) were obtained from the corresponding 7,8,9,10-tetrahydrocyclohept[*b*]indol-6(5*H*)-ones (**1b—h**) in the same way. The results are shown in Tables 1, 2, and 3.

* Presented at the 32nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1975.

Cyclohept[b]*indol-10(5*H*)-ones.* 5,6,7,8,9,10-Hexahydrocyclohept[*b*]indole (**4a**) reacts rapidly with DDQ at room temperature in wet dioxane to give colorless micro prisms (mp 224—225 °C).

The analytical data revealed a composition with the formula of $C_{13}N_{13}ON$. The IR spectrum does not agree with that of **1a**.

The structure of this product was confirmed by a direct comparison with an authentic sample of 6,7,8,9-tetrahydrocyclohept[*b*]indol-10(5*H*)-one (**5a**) prepared[4] from the phenylhydrazone of 5-acetylvaleric acid.

Compound **5a** has also been prepared[4] by the hydrolysis of 5,6,7,8,9,10-hexahydro-10-*p*-tolylsulphonyliminocyclohept[*b*]indole or by the irradiation of acridine *N*-oxide, followed by hydrogenation.

6,7,8,9-Tetrahydro-5-methylcyclohept[*b*]indol-10-(5*H*)-one (**5b**) was also obtained by the reaction of hexahydro-5-methylcyclohept[*b*]indole (**4b**) with DDQ by a similar method. It was identical with the material obtained by the methylation of **5a** with dimethyl sulfate.

The bromination of **5a** and **5b** with PTAB afforded α,α-dibromo ketones **6a** and **6b**, which were then converted to cyclohept[*b*]indol-10(5*H*)-ones **7a**[4b] and **7b** respectively by dehydrobromination with lithium chloride.

Nucleophilic Substitution Reactions of 6-Chloro-5-azabenz[b]*azulene.* In the previous paper,[1] we have reported that 6-chloro-5-azabenz[*b*]azulene (8-chlorobenz[*b*]-1-azaazulene) (**8**) was obtained when cyclohept[*b*]indol-6(5*H*)-one (**3a**) was heated with phosphoryl chloride or thionyl chloride.

The treatment of Compound **8** with sodium methoxide, sodium hydrosulfide, dimethylamine, aniline, *etc.* in ethanol or dimethyl sulfoxide gave the corresponding substituted products (**9a—j**). The results are shown

Compound **9d** can exist in two tautomeric forms, such as **A** and **B**:

A **B**

The IR spectrum contained a band at 3226 cm^{-1} due to NH, but no band due to SH between 2600—2550 cm^{-1}. On the UV and visible absorption spectra, the absorption maxima of the visible portion was shifted to shorter wavelengths than those of **8**, **9e**, and **9i**, which could take only the type-B tautomeric form. Therefore, it is assumed that Compound **9d** takes the type-A tautomeric form.

Also, we can consider a similar tautomerism on Compounds **9a**, **9f**, **9g**, **9h**, and **9j**. However, it is difficult to decide on the basis of only the UV and IR spectra toward which form the equilibria of these compounds tend.

Experimental**

All the melting points are uncorrected.

Bromination of 7,8,9,10-Tetrahydrocyclohept[b]*indole-6(5*H*)-ones (**1a—h**) with PTAB.* *7,7-Dibromo-7,8,9,10-tetra-*

** The authors are grateful to the Sankyo Co., Ltd., for doing some of the elemental analyses.

hydrocyclohept[b]*indol-6(5H)-one (2a)*: To a solution of **1a** (0.3 g) in dry tetrahydrofuran (15 ml), we added phenyltrimethylammonium tribromide (PTAB) (1.1 g) at room temperature. The mixture was stirred for 15 h. The precipitate was filtered and washed with tetrahydrofuran. The combined tetrahydrofuran solutions were evaporated, and the residue was recrystallized from methanol to give **2a** as yellow micro needles (0.49 g, 91%); mp 154—155 °C.

Dibromo compounds (**2b—h**) were also prepared from the corresponding cyclic ketones (**1b—h**) by a method similar to that described above. The results are given in Table 1.

Dehydrobromination of 7,7-Dibromo-7,8,9,10-tetrahydrocyclohept[b]*indol-6(5H)-ones (2a—h). Cyclohept*[b]*indol-6(5H)-one (3a)*: A mixture of **2a** (0.6 g) and lithium chloride (0.2 g) in DMF (20 ml) was refluxed under nitrogen for 3 h. The solvent was then removed under reduced pressure, after which the residue was diluted with water to give a precipitate. The separated material was collected and dried. Recrystallization from benzene gave **3a** as yellow micro needles, (0.27 g, 82%); mp 245—246 °C.

Cyclohept[*b*]indol-6(5*H*)-ones (**3b—h**) were also prepared from the dibromo compounds (**2b—h**) by a method similar to that described above. The results are given in Table 2.

6,7,8,9-Tetrahydrocyclohept[b]*indol-10(5H)-one (5a)*. Into a solution of 5,6,7,8,9,10-hexahydrocyclohept[*b*]indole (**4a**) (1.0 g) in dioxane (100 ml) and water (10 ml), we stirred DDQ (2.4 g) at 5 °C. After 10 min, the precipitate was filtered off, and the filtrate was evaporated. The residue was extracted with chloroform. The chloroform layer was washed with a dilute sodium hydrogencarbonate solution, dried over anhydrous sodium sulfate, and evaporated to leave a residue. It recrystallized from benzene–ethanol to give **5a** as colorless micro prisms (0.73 g, 68%); mp 224—225 °C.

9,9-Dibromo-6,7,8,9-tetrahydrocyclohept[b]*indol-10(5H)-one (6a)*. To a solution of **5a** (0.3 g) in dry tetrahydrofuran (30 ml) we added PTAB (1.1 g). The mixture was then treated by a method similar to that used for the preparation of **2a—h**. Yellow prisms (0.48 g, 89%); mp 182—184 °C (dec). IR(KBr): 3238, 2925, 1610, 1595, and 1445 cm^{-1}. Found: C, 43.92; H, 3.15; N, 3.79; Br, 44.68%. Calcd for $C_{13}H_{11}ONBr_2$: C, 43.73; H, 3.11, N, 3.92; Br, 44.76%.

Cyclohept[b]*indole-10(5H)-one (7a)*. A mixture of **6a** (0.3 g) and lithium chloride (0.11 g) in DMF (10 ml) was refluxed under nitrogen for 3 h. The reaction mixture was treated by a method similar to that used for the preparation of **3a—h**. Yellow micro prisms (0.27 g, *ca.* 100%); mp 285—286 °C.

6,7,8,9-Tetrahydro-5-methylcyclohept[b]*indol-10(5H)-one (5b)*. (*a*): To a solution of hexahydro-5-methylcyclohept[*b*]indole (**4b**) (1.0 g) in dioxane (50 ml) and water (5 ml), we added DDQ (2.28 g). The mixture was treated by a method similar to that used for the preparation of **5a**. Colorless scales (0.47 g, 44%), were recrystallized from cyclohexane; mp 136—137 °C.

(*b*): A mixture of **5a** (0.2 g) and dimethyl sulfate (0.24 g) in acetone (10 ml) and 1 M sodium hydroxide (3 ml) was heated at 90 °C for 30 min. The reaction mixture was then diluted with water and extracted with chloroform. The chloroform layer was dried over anhydrous sodium sulfate and evaporated to leave a oily residue. It was recrystallized from cyclohexane to give colorless scales (0.08 g, 38%); mp 135—136 °C.

The IR spectrum was identical with that of a sample prepared by Method (a), and the mixed melting point was not depressed.

9,9-Dibromo-6,7,8,9-tetrahydro-5-methylcyclohept[b]*indol-10(5H)-one (6b)*. To a solution of **5b** (0.3 g) in dry tetrahydrofuran (30 ml), we added PTAB (1.1 g). The mixture was then treated by a method similar to that used for the preparation of **2a—h**. Pale yellow prisms (0.41 g, 79%); mp 173 °C (dec). IR(KBr): 2962, 2939, 1624, 1511, 1471, 1406, and 1414 cm^{-1}. Found: C, 45.00; H, 3.47; N, 3.72; Br, 42.83%. Calcd for $C_{14}H_{11}ONBr_2$: C, 45.31; H, 3.53; N, 3.78; Br, 43.07%.

5-Methylcyclohept[b]*indol-10(5H)-one (7b)*. A mixture of **6b** (0.1 g) and lithium chloride (0.04 g) in DMF (5 ml) was refluxed under nitrogen for 3 h. The reaction mixture was then treated by a method similar to that used for the preparation of **3a—h**. Yellow micro needles (0.05 g, 89%); mp 169—170 °C. IR(KBr): 1628, 1556, and 1478 cm^{-1}. Found: C, 79.84; H, 5.28; N, 6.64%. Calcd for $C_{14}H_{11}ON$: C, 80.36, H, 5.30; N, 6.69%.

The Reaction of 6-Chloro-5-azabenz[b]*azulene with Nucleophilic Reagents. General Procedure*: (*a*); A solution of **8** (0.0005 mol) and a nucleophilic reagent (0.0007 mol) in ethanol (6 ml) was refluxed for 30 min on a water bath. The solvent was then removed. The resdiue was diluted with water, made slightly alkaline by adding aqueous sodium hydrogencarbonate, and extracted with benzene. The benzene layer was concentrated and passed through a silica gel column. The product obtained from the main effluent was recrystallized from cyclohexane, hexane, or cyclohexane–benzene.

(*b*); A mixture of **8** (0.0005 mol) and a nucleophilic reagent (0.0007 mol) in dimethyl sulfoxide (5 ml) was stirred for 15 min at room temperature. The reaction mixture was then diluted with water to separate the precipitate. The solid was collected, dried under reduced pressure, and recrystallized from cyclohexane. The results are given in Tables 4 and 5.

The authors wish to express their gratitude to Professor Gurnos Jones of the University of Keele for his kind discussion.

The Reaction of Anhydrochloralurethanes with Ketene Acetals

Tetsuo AKIYAMA, Nobuaki URASATO, Takeshi IMAGAWA, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received October 6, 1975)

The reaction of anhydrochloralurethanes (I) with ketene acetals (II) has been found to give novel carbamate derivatives (III) in quantitative yield. The intermediacy of a cyclic intermediate, an oxazine derivative (IV), was confirmed by spectroscopic methods, although several attempts to isolate IV have been unsuccessful. The mechanism for formation of IV is discussed.

In 1968 Ulrich and coworkers[1] established the structure and the synthetic method of *N*-(2,2,2-trichloroethylidene)alkoxycarbonylamine (I), commonly called anhydrochloralurethane. They also reported that the C=N double bond of I was highly reactive and easily attacked by several nucleophiles, such as water, alcohols, and amines.[1]

In a previous report from this laboratory, we have demonstrated the potentiality of I as a dienophile in a Diels-Alder reaction.[2]

A literature survey reveals that investigations about the reactivity of I have mainly noted the C=N double bond.[1-3]

Since the CCl_3 group is equivalent to the CO_2H group, I might be valuable for constructing the α-amino acid skelton. However, the synthetic application of I is rather limited.[4]

As judged from the structure of I, we have been intrigued with the supposition that I, as a heterodiene (C=N–C=O),[5] might formally undergo a [4+2] Diels-Alder type reaction with inverse electron demand against an electron-abundant nucleophilic olefin to give an adduct.

In this report, we should like to present the results obtained in the reaction of I with ketene acetal (II) to give novel acyclic carbamates (III), and also convincing evidence for the intermediacy of cyclic oxazine derivatives (IV) which could arise from the above-mentioned reaction.

Results and Discussion

When I ($R=C_2H_5$) and excess II ($R'=C_2H_5$) in benzene were heated under reflux for 15 h, a single product was obtained in a quantitative yield. Elementary analysis as well as spectral investigations established the structure as IIIa. Although its parent peak was missing, the mass spectrum had a peak corresponding to M^+-CCl_3 fragment ion as the base peak originating from the fragmentation β at the nitrogen atom. The NMR spectrum showed a typical ABX pattern corresponding to $-CH_2CH(CCl_3)-$, accompanied by the signals of NH and two $-OCH_2CH_3$.

A plausible mechanism for the formation of III is shown in Scheme 1:

A Diels-Alder type reaction between I and II in a sense of inverse electron demand affords a dihydro-1,3-oxazine (IV),[6] hydrolysis (by atomospheric moisture or work-up) of which will give III.

Although the adduct (IV) was not obtained in a pure state, its existence was confirmed as follows. The crude product-mixture just after the reaction gave an additional peak in GLC along with that of III. Taking as an example the case of the reaction between Ia and IIa, in the mass spectrum [Fig. 1(a)], the parent peak

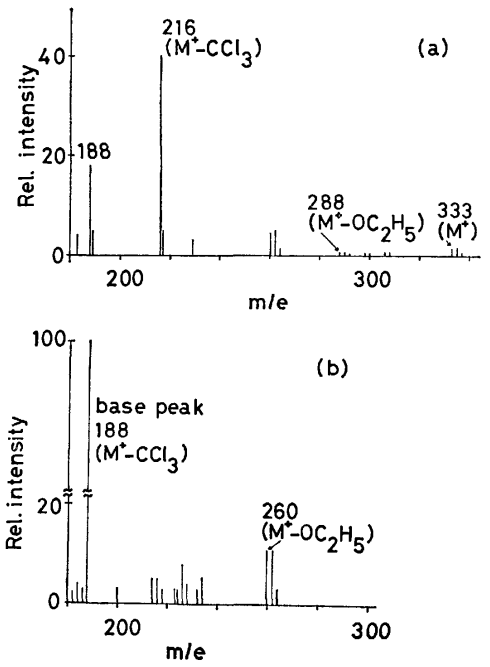

Fig. 1. Mass spectra of the reaction products between Ia and IIa.

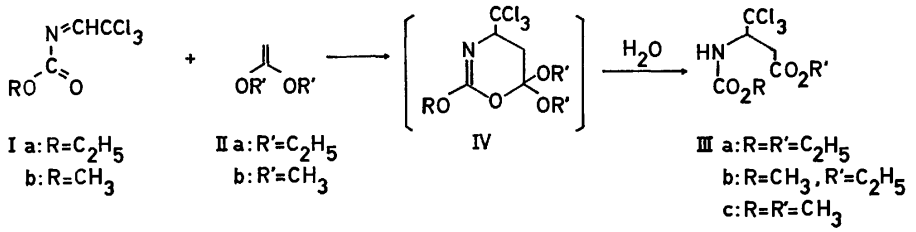
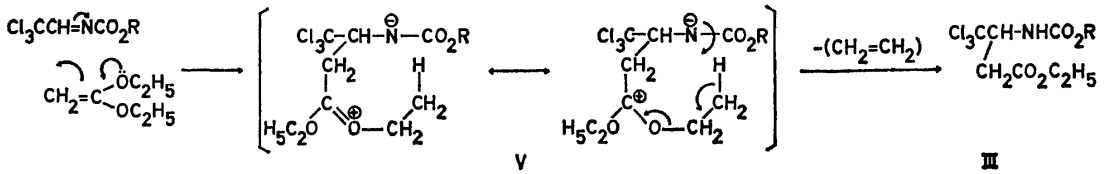


Scheme 1.



Scheme 2.

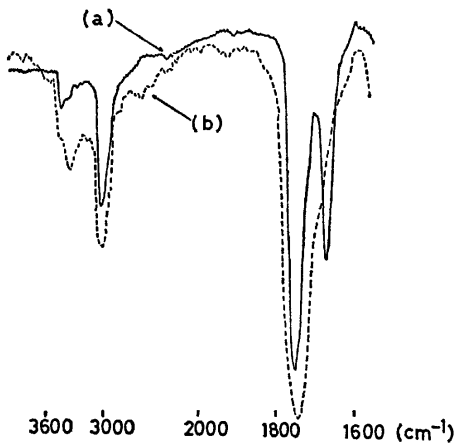


Fig. 2. IR spectra of the reaction products between Ia and IIa.
(a) For the crude products in the reaction of Ia and IIa. (b) For the analytically pure IIIa.

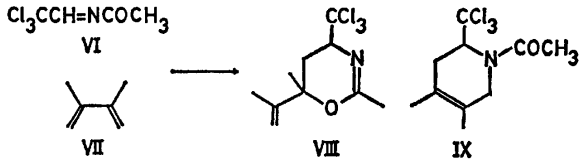
of IV (R=R'=C_2H_5), *m/e* 333, and the peak due to $M^+ - CCl_3$ of IV, *m/e* 216, which were absent in the spectrum of IIIa [Fig. 1(b)], were clearly observed. The IR spectrum in CCl_4 solution [Fig. 2(a)] had only a small NH absorption band, which grew gradually significant after several hours in air, when the absorption band at 1680 cm^{-1} due to the C=N bond became disappeared. The crude reaction mixture was gradually hydrolyzed by atmospheric moisture. The intentional treatment of the reaction mixture with dil hydrochloric acid rapidly afforded III. It should be noted that the addition reaction giving IV is highly regioselective as far as the product is concerned.

An alternative path giving III from I and II may be the one shown in Scheme 2, in which a zwitterionic intermediate (V) would expel the neutral ethylene molecule as the leaving group. This mechanism could also explain the regioselectivity of the reaction.

However, this scheme cannot be compatible with the spectral data mentioned above, and the fact that the reaction Ib with IIb gave a similar product IIIc cannot be adequately explained by this scheme (In this case a neutral molecule as a good leaving group cannot exist).

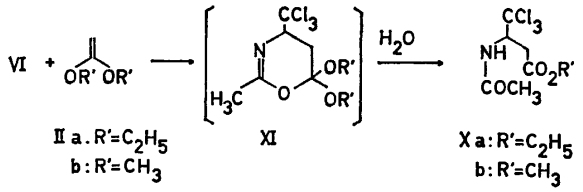
More recently, Arbuzov *et al.* reported[7] that the reaction between *N*-(2,2,2-trichloroethylidene)acetamide (VI) and 2,3-dimethylbutadiene (VII) gave an oxazine derivative (VIII) together with the normal Diels-Alder adduct (IX). The oxazine derivative (VIII) and its crystalline salt, on reaction with strong acids, were obtained in pure form (Scheme 3).

We expected similar oxazine derivatives to be isolable



Scheme 3.

in the reaction between VI, instead of anhydrochloralurethane (I), with ketene acetal. However, also in this case the adduct (XI) was not stable toward any conventional methods of purification, and the hydrolyzed product X was again produced in quantitative yield (Scheme 4).



Scheme 4.

Based on these facts, we can safely conclude that the mechanism depicted in Scheme 1 is highly plausible.

In summary, a Diels-Alder type reaction with inverse electron demand between anhydrochloralurethane and ketene acetal takes place, giving novel carbamate derivatives. This reaction might emerge as a powerful synthetic route to α-amino acids. The investigation aiming at this point is currently under way in this laboratory.

Experimental

All the temperatures are uncorrected. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The mass spectra were taken by Hitachi RMS-4 Mass Spectrometer. The NMR spectra were obtained on a Varian EM-360 spectrometer, TMS being chosen as the internal standard.

Reaction of N-*(2,2,2-Trichloroethylidene)ethoxycarbonylamine (Ia) with Ketene Diethyl Acetal (IIa).* Refluxing a benzene (26 ml) solution of $CCl_3CH{=}NCO_2C_2H_5$ (Ia) (260 mg, 1.19 mmol) and ketene diethyl acetal (360 mg, 3.10 mmol) for 15 h gave a yellow oily mixture after evaporation of benzene and ketene diethyl acetal. After hydrolysis with dil hydrochloric acid, this mixture was distilled under vacuum to afford a quantitative yield (365 mg, 1.19 mmol) of IIIa, bp 100—104 °C/0.15 mmHg. IR (CCl_4): 3320, 1740 (broad) cm^{-1}. MS: *m/e* 260 (11%, $M^+-OC_2H_5$), 262 (11), 264 (3), 188 (100, M^+-CCl_3), 142 (33), 116 (41), 70 (36), 59 (81), 56 (37). NMR (CCl_4): δ 1.28 ppm (t, 6H, $-OCOCH_2-$

CH_3), 2.68 [dd, 1H, J=15.2, 3.6 Hz, $-CH_2CH(CCl_3)-$], 3.18 [dd, 1H, J=15.2, 9.0 Hz, $-CH_2CH(CCl_3)-$], 4.16 (q, 4H, $-OCOCH_2CH_3-$), 4.91 (m, 1H, $-CHCCl_3-$), 5.48 (d, 1H, J=10.0 Hz, NH). Found: C, 34.82; H, 4.74; N, 4.60%. Calcd for $C_9H_{14}Cl_3NO_4$: C, 35.26; H, 4.60; N, 4.57%.

Reaction of Ib with IIa. Refluxing a benzene (32 ml) solution of Ib (320 mg, 1.56 mmol) and an excess of IIa for 15 h gave an oily mixture. After being left at room temperature for several days, the reaction mixture turned into a white solid of IIIb (458 mg) quantitatively, mp 71.5—73.5 °C after recrystallization from hexane. IR (Nujol): 3300, 1750, 1710 cm^{-1}. MS: *m/e* 260 (3%, M^+-OCH_3), 262 (3), 264 (1), 246 (11, $M^+-OC_2H_5$), 248 (11), 250 (3), 174 (100, M^+-CCl_3), 132 (30), 128 (52). NMR (CCl_4): δ 1.27 ppm (t, 3H, $-OCH_2CH_3$), 2.69 (dd, 1H, $-CH_2CH(CCl_3)-$], 3.07 [dd, 1H, $-CH_2CH(CCl_3)-$], 3.71 (s, 3H, $-OCOCH_3$), 4.18 (q, 2H, $-OCOCH_2CH_3$), 4.92 (m, 1H, $-CHCCl_3-$), 5.50 (d, 1H, NH). Found: C, 32.74; H, 4.18; N, 4.80%. Calcd for $C_8H_{12}Cl_3NO_4$: C, 32.85; H. 4.13; N, 4.79%.

IIIc was similarly obtained from Ib and IIb (15 h; 100%), mp 96—99 °C (hexane). IR (Nujol): 3350, 1760, 1730 cm^{-1}. MS: *m/e* 246 (8%, M^+-OCH_3), 248 (7.5), 250 (2), 160 (100, M^+-CCl_3), 138 (80). NMR (CCl_4): δ 2.69 ppm [dd, 1H, $-CH_2CH(CCl_3)-$], 3.08 [dd, 1H, $-CH_2CH(CCl_3)-$], 3.70 (s, 6H, $-OCOCH_3$), 4.88 (m, 1H, $-CHCCl_3-$), 5.50 (d, 1H, NH). Found: C, 30.24; H, 3.64; N, 5.04%. Calcd for $C_7H_{10}Cl_3NO_4$: C, 30.19; H, 3.62; N, 5.03%.

Reaction of N-(2,2,2-Trichloroethylidene)acetamide (VI) with Ketene Acetals (II). In a manner similar to the above, Xa was obtained from VI and IIa (15 h at 80 °C, 100%), mp 61.5—63.0 °C (hexane). IR (Nujol): 3300, 1740, 1680 cm^{-1}. MS: *m/e* 230 (9%, $M^+-OC_2H_5$), 232 (9), (9), 234 (3), 158 (44, M^+-CCl_3), 116 (100). NMR (CCl_4+$CDCl_3$): δ 1.27 ppm (t, 3H, $-OCH_2CH_3$), 2.08 (s, 3H, $-COCH_3$), 2.72 [dd, 1H, $-CH_2CH(CCl_3)-$], 3.13 [dd, 1H, $-CH_2CH(CCl_3)-$], 4.17 (q, 2H, $-OCH_2CH_3$), 5.32 (m, 1H, $-CHCCl_3-$), 6.43 (d, 1H, NH). Found: C, 34.49; H, 4.44; N, 5.28%. Calcd for $C_8H_{12}Cl_3NO_3$: C, 34.75; H, 4.37; N, 5.06%.

Similarly, Xb was obtained from VI and IIb (15 h at 80 °C, 100%), mp 132.0—132.5 °C from hexane and benzene (1 : 1). IR (Nujol): 3300, 1760, 1680 cm^{-1}. MS: *m/e* 230 (4%, M^+-OCH_3), 232 (4), 234 (1), 144 (33, M^+-CCl_3), 102 (100). NMR (CCl_4+$CDCl_3$): δ 2.09 ppm (s, 3H, $-COCH_3$), 2.73 [dd, 1H, $-CH_2CH(CCl_3)-$], 3.10 [dd, 1H, $-CH_2CH(CCl_3)-$], 3.73 (s, 3H, $-OCOCH_3$), 5.27 (m, 1H, $-CHCCl_3-$), 6.27 (d, 1H, NH). Found: C, 32.13; H, 3.85; N, 5.36%. Calcd for $C_7H_{10}Cl_3NO_3$: C, 32.03; H, 3.84; N, 5.34%.

Aminocyclitols. 33. Synthesis of Diaminocyclopentanetriols[1]

Kinnichi TADANO, Yasufumi EMORI, Mitsukuni AYABE, and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received October 2, 1975)

Three hitherto unknown 2,5-diamino-1,3,4-cyclopentanetriols have been prepared. Their structures were established by chemical evidence.

We have been studying a synthesis of carbocyclic nucleoside analogs[2] and during the course of this study, we needed 2,5-diamino-1,3,4-cyclopentanetriols with analogous configurations as those of the pentose moiety of naturally occurring nucleoside antibiotics, such as puromycin[3] and 3'-amino-3'-deoxyadenosine.[4]

In the first attempt for this aim, 5-acetamido-1-*O*-benzoyl-1,2,3,4-cyclopentanetetrol (**2**) seemed to be an adequate starting material, which was obtained by mono-*O*-benzoylation of 2,3-*O*-cyclohexylidene-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**1**),[5] followed by mild acid hydrolysis. Sodium metaperiodate oxidation of **2** afforded the corresponding dialdehyde (**3**) and then **3** was cyclized with nitromethane in the presence of sodium ethoxide. The product was catalytically hydrogenated and subsequently acetylated. The product was purified on a silica gel column to give penta-*N*,*O*-acetyl-2,5-diamino-1,3,4-cyclopentanetriol (**4**) as a main product in 11% yield. A few minor products were detectable on TLC, but they were not isolated in a crystalline state.

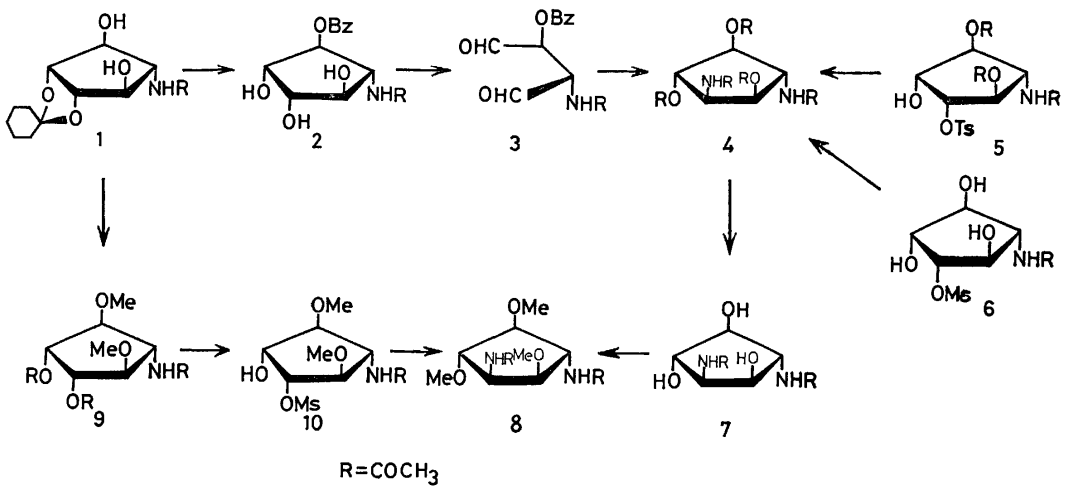
There are ten theoretically possible stereoisomers (A—J) in 2,5-diamino-1,3,4-cyclopentanetriols. In the present reaction, three new chiral centers are introduced in the product and therefore, seven stereoisomers are possible for **4**. Since the PMR spectrum of **4** indicated a lack of a molecular symmetry, five stereoisomers: E, F, G, H and J are possible. On the other hand, when 2-*O*-tosyl- (**5**)[8] or 2-*O*-mesyl-DL-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**6**)[8] was heated with sodium azide in *N*,*N*-dimethylformamide (DMF), an azido derivative was obtained. The product was hydrogenated and subsequently acetylated to give the same compound **4**.

Considering from the reaction employed, the configurations on C-3, 4 and 5 are not changed. Therefore, three stereoisomers: F, G and H are possible for **4**. To distinguish these three, following reactions have been attempted.

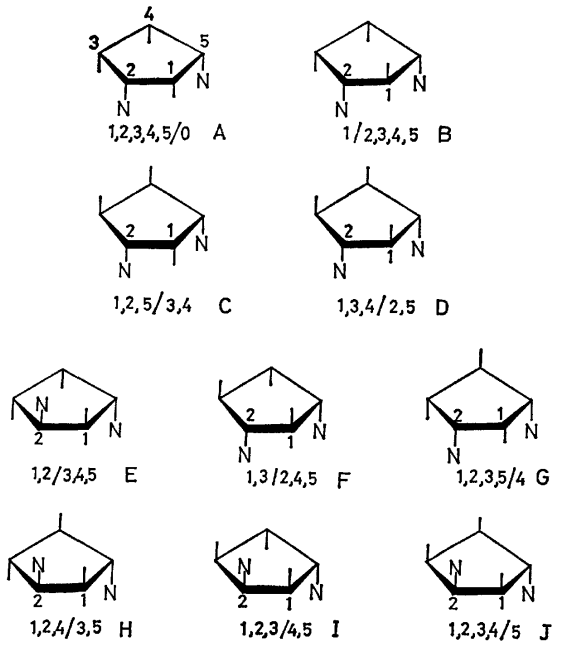
Since a possibility of neighboring group participation on the azidolysis of **6** is avoided by methylating the hydroxyl groups on C-1 and 4, 1,4-di-*O*-methyl derivative of **6** (**10**) has been submitted to the azidolysis. The azide derivative thus obtained was hydrogenated and *N*-acetylated to give 2,5-diacetamido-1,4-di-*O*-methyl-1,3,4-cyclopentanetriol. The product was further *O*-methylated to give 2,5-diacetamido-1,3,4-tri-*O*-methyl-1,3,4-cyclopentanetriol (**8**), which was identified with the compound derived from **4** *via* **7**. This fact indicated that the displacement of the mesyloxy group by a highly nucleophilic azide ion occurred in a direct S_N2 mechanism with a Walden inversion of the configuration on C-2.[6,7] Therefore, the configuration of **4** was established to be H.

In the second attempt, two other stereoisomers of 2,5-diamino-1,3,4-cyclopentanetriols (**14** and **15**) were prepared by azidolysis of 2,3-di-*O*-mesyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol[8] (**11**). Azidolysis of **11**, followed by acetylation afforded two diastereomers of 1,3,4-tri-*O*-acetyl-5-acetamido-2-azido-1,3,4-cyclopentanetriols (**12** and **13**) in 32 and 7% yield respectively. The corresponding penta-*N*,*O*-acetyl-2,5-diamino-1,3,4-cyclopentanetriols (**14** and **15**) were prepared from **12** and **13**.

The configurations of **14** and **15** were established to be those of I and F respectively by the following evidence. (1) Both diacetamido-cyclopentanetriols (**16** and **17**) which were prepared from **14** and **15** respectively,



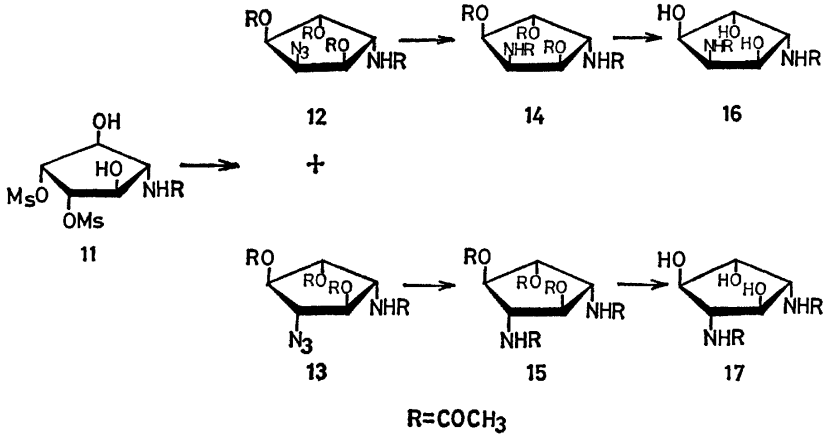
Scheme 1.



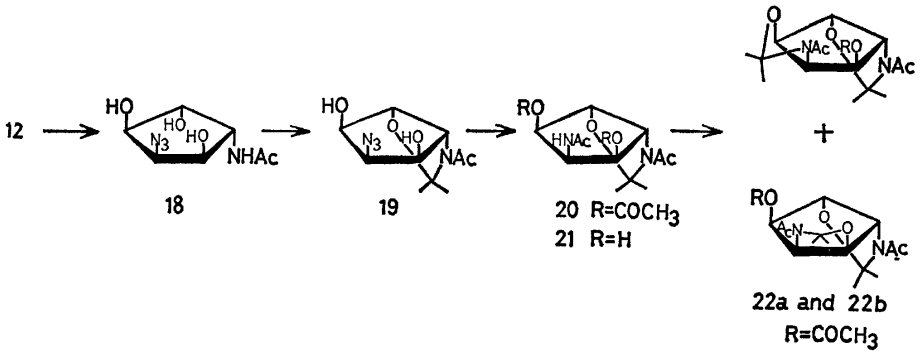
Scheme 2. 2,5-Diaminocyclopentanetriols.

consumed one molar equivalent of periodate respectively, and this fact indicated that they had two acetamido groups on C-2 and 5 (not on C-1 and 5). (2) Displacement of the mesyloxy group on C-3 of **11** proceeded *via* an intermediary epoxide with a participation of the hydroxyl group on C-4 and the epoxide was attacked by a hydroxide ion to give *trans*-3,4-diol.[8] Therefore, four stereoisomers: F, G, H and I are likely for **14** and **15**, but none of them is identical with **4** (H-configuration). Also a formation of a compound with G-configuration is hardly explained without a big contradiction of *cis*-opening of an intermediary epoxide between C-1 and C-2 by an azide ion. (3) When the azido-acetates (**12** and **13**) were catalytically hydrogenated, **12** gave a ninhydrin negative product and **13** gave a ninhydrin positive product. This fact suggested that the former had an acetyl group migration from O to N between a vicinal *cis*-located amino-acetate and I-configuration was given to **12**. Accordingly, F-configuration was given to **13**. (4) This was further confirmed by a formation of di-*N*,*O*-isopropylidene derivatives in the case of **16** and a formation of mono-*N*,*O*-isopropylidene derivative in the case of **17**.[10]

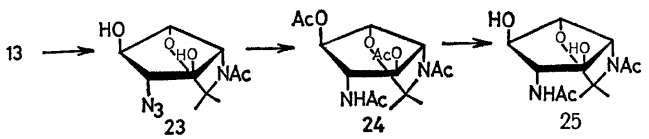
A direct S_N2 mechanism is proposed to the displace-



Scheme 3.



Scheme 4.



Scheme 5.

ment of the mesyloxy group on C-2 of **11** by an azide ion in a formation of **12**, and an anchimeric reaction mechanism is proposed in a formation of **13**.

Experimental

Mps were measured in capillary tubes and are uncorrected. Acetylation was carried out in the usual manner with acetic anhydride in pyridine. De-*O*-acetylation was performed in methanolic ammonia. Hydrogenation was carried out with Raney nickel in a hydrogen atmosphere (3.4 kg/cm^2) in Parr shaker apparatus. Silica gel (Wakogel C-200, Wako Pure Chemical Ind. Ltd.) was used for column chromatography and TLC was performed on a Wakogel B-10 plate in benzene–ethanol (5 : 1, v/v) solvent system. PMR spectrum was measured at 60 MHz on a Varian A-60D spectrometer in $CDCl_3$ with reference to tetramethylsilane as an internal standard and the peak positions are given in τ values. Elemental analyses were performed by Mr. Saburo Nakada, to whom our thanks are due.

*2,3-O-Cyclohexylidene-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**1**).* The compound was prepared by the method described in the previous paper.[5]

*1-O-Benzoyl-*DL*-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**2**).* Compound **1** (5.0 g) was dissolved in dry pyridine (50 ml), and benzoyl chloride (3.5 ml) was added to the solution drop by drop under ice cooling with mechanical agitation. After settled overnight at room temperature, the reaction solution was poured into ice cold water to give crystalline precipitates (7.97 g) which consisted of two components of R_f 0.7 and 0.5 on TLC. The precipitate was heated in 50% aqueous acetic acid for 2 h under reflux and then evaporated. The residue was dissolved in cold water (150 ml) and the solution was extracted with chloroform repeatedly. From the combined chloroform layers, 1,4-di-*O*-benzoyl derivative[9] was obtained in 31% yield.

The aqueous layer was evaporated and the residue was recrystallized from ethanol to give 1.84 g (34%) of **2**, mp 163—165 °C.

Found: C, 56.66; H, 5.88; N, 4.58%. Calcd for $C_{14}H_{17}NO_6$: C, 56.94; H, 5.80; N, 4.74%.

*Periodate Oxidation of **2**.* Sodium metaperiodate (675 mg) was dissolved in ice cold water (35 ml) and **2** (775 mg) was added to the solution under ice cooling with agitation. After 1 h another crop of sodium metaperiodate (576 mg) was added to the solution and the reaction solution was settled overnight in a refrigerator. Crystalline products which appeared in the solution were collected by filtration to give 546 mg (79%) of the dialdehyde (**3**), mp 138—142 °C. The product was used for the successive reaction without any purification.

*Nitromethane Cyclization of **3**.* Compound **3** (546 mg) was dissolved in methanol (10 ml) and nitromethane (0.7 ml) was added to the solution in the presence of 0.9 M methanolic sodium methoxide (7 ml) under ice cooling with agitation. After settled overnight in a refrigerator, the solution was adjusted to pH 5 with glacial acetic acid and then catalytically hydrogenated for 18 hr. After the catalyst was filtered off, the solution was evaporated and the residue was acetylated. The product was fractionated on a silica gel column. Fractions which showed a single spot at R_f 0.4 on TLC were combined and evaporated to give a crystalline residue (100 mg). Recrystallization from ether afforded 80 mg (11%) of 1,3,4-tri-*O*-acetyl-DL-(1,2,4/3,5)-2,5-diacetamido-1,3,4-cyclopentanetriol (**4**), mp 191—193 °C; PMR: τ 8.04 (s, 6, 2NAc), 7.95 (s, 3, OAc), 7.93 (s, 3, OAc), 7.90 (s, 3, OAc), 3.48 (d, 1, J=8 Hz, NH), 2.67 (d, 1, J=8 Hz, NH).

Found: C, 50.58; H, 6.13; N, 7.54%. Calcd for $C_{15}H_{22}N_2O_8$: C, 50.28; H, 6.19; N, 7.82%.

*Azidolysis of 1,4-Di-O-acetyl-2-O-tosyl-*DL*-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**5**).* Compound **5**[8] (0.50 g) was heated with sodium azide (0.76 g) in DMF (10 ml) at 120 °C for 10 h with agitation. The reaction mixture was filtered and the filtrate was evaporated. The residue was extracted with warm ethyl acetate and the ethyl acetate solution was catalytically hydrogenated for 40 h. After the catalyst was removed by filtration, the filtrate was settled in a refrigerator to give 28 mg (9%) of crystalline product, mp 226—228 °C. The product was acetylated and then recrystallized from ether to give 30 mg (7%) of **4**, which was identified with an authentic sample.

The ethyl acetate mother liquor was evaporated and the residue was acetylated. The product was fractionated on a silica gel column to give 109 mg (26%) of 1,2,3,4-tetra-*O*-acetyl-DL-(1,2,4/3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol, mp 110—111 °C, which was identified with an authentic sample.[8]

*Azidolysis of 2-O-Mesyl-*DL*-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetraol (**6**).* Compound **6**[8] (0.65 g) was heated in DMF (20 ml) at 115 °C with sodium azide (1.57 g) for 10 h with agitation. The mixture was filtered and the filtrate was evaporated. The residue was acetylated overnight and the reaction solution was poured into ice cold water. The mixture was extracted with chloroform repeatedly and the combined chloroform layer was evaporated. The residue was hydrogenated in ethanol (12 ml) and the product was acetylated to give 0.59 g (68%) of **4**, 189—191 °C, which was identified with an authentic sample.

*DL-(1,2,4/3,5)-2,5-Diacetamido-1,3,4-cyclopentanetriol (**7**).* Compound **4** (188 mg) was de-*O*-acetylated and the product was recrystallized from ethanol to give 84 mg (69%) of **7** as hygroscopic crystals, mp 171—172 °C.

*1,3,4-Tri-O-methyl-*DL*-(1,2,4/3,5)-2,5-diacetamido-1,3,4-cyclopentanetriol (**8**).* Compound **7** (99 mg) was treated with methyl iodide (0.17 ml) in DMF (2 ml) in the presence of silver oxide (0.44 g) for 70 h with agitation. The reaction mixture was filtered and the filtrate was evaporated. The residue was extracted with warm ethanol and the alcoholic solution was evaporated. The residue was recrystallized from ethyl acetate–petroleum ether to give 40 mg (34%) of **8**, mp 193—194 °C; PMR: τ 8.00 (s, 3, NAc), 7.97 (s, 3, NAc), 6.60 (s, 3, OCH_3), 6.58 (s, 6, $2OCH_3$), 3.73 (d, 1, J=8 Hz, NH), 2.92 (d, 1, J=9 Hz, NH).

Found: C, 52.43; H, 7.83; N, 10.27%. Calcd for $C_{12}H_{22}N_2O_5$: C, 52.54; H, 8.09; N, 10.21%.

*2,3-Di-O-acetyl-1,4-di-O-methyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**9**).* Compound **1** (2.81 g) was methylated analogously as described in the preparation of **8**. The product was hydrolyzed in 0.1 M hydrochloric acid for 2 h under reflux, and then the solution was evaporated. The residue was acetylated and the product was purified on a silica gel column. The product was recrystallized from benzene to give 1.72 g (55%) of **9**, mp 98—99 °C; PMR τ 7.99 (s, 3, NAc), 7.95 (s, 6, 2OAc), 6.62 (s, 6, $2OCH_3$), 3.74 (d, 1, J=9 Hz, NH).

Found: C, 51.76; H, 7.13; N, 4.51%. Calcd for $C_{13}H_{21}NO_7$: C, 51.48; H, 6.98; N, 4.62%.

*2-O-Mesyl-1,4-di-O-methyl-*DL*-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**10**).* Compound **9** (2.63 g) was de-*O*-acetylated to give 2.36 g of syrup. The syrup was *O*-mesylated with mesyl chloride (1.5 ml) in pyridine (8 ml) overnight with agitation. After an excess of mesyl chloride was decomposed by adding cold water (4 ml), the reaction solution was evaporated. The residue was extracted with

chloroform, and the extract was purified on a silica gel column. Fractions which showed a single spot at R_f 0.37 on TLC were combined and evaporated to give crystals. Recrystallization from ethyl acetate afforded 1.37 g (53%) of **10**, mp 115—116 °C; PMR ($CDCl_3$–pyridine-d_5 3 : 1, v/v): τ 7.95 (s, 3, NAc), 6.82 (s, 3, OSO_2CH_3), 6.51 (s, 3, OCH_3), 6.47 (s, 3, OCH_3), 2.00 (d, 1, J=8 Hz, NH).

Found: C, 40.58; H, 6.32; N, 4.56; S, 10.67%. Calcd for $C_{10}H_{19}NO_7S$: C, 40.40; H, 6.44; N, 4.71; S, 10.78%.

Acetylation of **10** (30 mg) yielded 29 mg (85%) of the corresponding mono-*O*-acetyl derivative, mp 79—80 °C; PMR τ 7.98 (s, 3, NAc), 7.87 (s, 3, OAc), 6.95 (s, 3, OSO_2CH_3), 6.57 (s, 3, OCH_3), 6.53 (s, 3, OCH_3), 3.84 (d, 1, J= 9 Hz, NH).

Found: C, 42.71; H, 6.11; N, 4.01; S, 9.27%. Calcd for $C_{12}H_{21}NO_8S$: C, 42.47; H, 6.24; N, 4.13; S, 9.45%.

From the fractions (R_f 0.57), 0.29 g (9%) of 2,3-di-*O*-mesyl derivative, mp 132—133 °C, was obtained. PMR ($CDCl_3$–pyridine-d_5 1 : 1, v/v): τ 7.96 (s, 3, NAc), 6.80 (s, 6, $2OSO_2CH_3$), 6.48 (s, 6, $2OCH_3$), 2.15 (d, 1, J=12 Hz, NH).

Found: C, 35.21; H, 5.49; N, 3.65; S, 16.88%. Calcd for $C_{11}H_{21}NO_9S_2$: C, 35.19; H, 5.64; N, 3.73; S, 17.08%.

Azidolysis of ***10***. Compound **10** (1.00 g) was heated with sodium azide (2.2 g) in DMF (10 ml) at 95 °C for 42 h, and the product was treated analogously as described in the azidolysis of **6**. The product was purified on a silica gel column to give 123 mg (14%) of 1,4-di-*O*-methyl-DL-(1,2,4/3,5)-2,5-diacetamido-1,3,4-cyclopentanetriol, mp 179—180 °C.

Found: C, 50.69; H, 7.60; N, 10.60%. Calcd for $C_{11}H_{20}N_2O_5$: C, 50.76; H, 7.75; N, 10.76%. A 376 mg portion of the starting material **10** was recovered from the column.

The above mentioned diacetamido derivative (120 mg) was further *O*-methylated and then purified on a silica gel column to give 58 mg (46%) of **8**, 191—192 °C, which was identified with an authentic sample.

*Azidolysis of 2,3-Di-*O*-mesyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**11**).* Compound **11**[8] (3.00 g) was heated with sodium azide (5.67 g) in DMF (25 ml) at 125 °C for 3 hr, and the product was acetylated. The acetylated product was recrystallized from ethyl acetate to give 692 mg (23%) of 1,3,4-tri-*O*-acetyl-DL-(1,2,3/4,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol (**12**), mp 163—164 °C; PMR τ 8.04 (s, 3, NAc), 7.92 (s, 3, OAc), 7.88 (s, 6, 2OAc), 3.71 (d, 1, J=8 Hz, NH).

Found: C, 45.49; H, 5.19; N, 16.55%. Calcd for $C_{13}H_{18}N_4O_7$: C, 45.61; H, 5.30; N, 16.37%. The mother liquor was evaporated and the residue was fractionated on a silica gel column to give 240 mg (8%) of **12** (Rf 0.3 on TLC) and 216 mg (7%) of 1,3,4-tri-*O*-acetyl-DL-(1,3/2,4,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol (**13**), mp 110—112 °C (recrystallized from ether); R_f 0.4 on TLC; PMR: τ 8.06 (s, 3, NAc), 7.90 (s, 9, 3OAc), 3.84 (d, 1, J=8 Hz, NH).

Found: C, 45.51; H, 5.23; N, 16.54%. Calcd for $C_{13}H_{18}N_4O_7$: C, 45.61; H, 5.30; N, 16.37%.

*1,3,4-Tri-*O*-acetyl-DL-(1,2,3/4,5)-2,5-diacetamido-1,3,4-cyclopentanetriol (**14**).* Compound **12** (921 mg) was catalytically hydrogenated in ethanol (15 ml) for 5 hr, and subsequently acetylated. The product was recrystallized from ethanol to give 651 mg (68%) of **14**, mp 205—206 °C; PMR (pyridine-d_5) τ 8.19 (s, 3, NAc), 8.06 (s, 3, NAc), 8.04 (s, 3, OAc), 8.01 (s, 3, OAc), 7.98 (s, 3, OAc), 1.93 (d, 1, J=9 Hz, NH), 0.61 (d, 1, J=9 Hz, NH).

Found: C, 50.48; H, 6.31; N, 7.65%. Calcd for $C_{15}H_{22}N_2O_8$: C, 50.28; H, 6.19; N, 7.82%.

*1,3,4-Tri-*O*-acetyl-DL-(1,3/2,4,5)-2,5-diacetamido-1,3,4-cyclopentanetriol (**15**)* Compound **13** (534 mg) was hydrogenated analogously as described in the preparation of **14** to give 232 mg (41%) of **15**, mp 206—207 °C; PMR (pyridine-d_5): τ 8.14 (s, 3, NAc), 8.07 (s, 3, NAc), 8.04 (s, 3, OAc), 7.95 (s, 3, OAc), 7.89 (s, 3, OAc), 1.26 (d, 1, J=8 Hz, NH), 0.85 (d, 1, J=8 Hz, NH).

Found: C, 50.17; H, 6.27; N, 7.58%. Calcd for $C_{15}H_{22}N_2O_8$: C, 50.28; H, 6.19; N, 7.82%.

*DL-(1,2,3/4,5)-2,5-Diacetamido-1,3,4-cyclopentanetriol (**16**).* Compound **14** (0.70 g) was de-*O*-acetylated and the product was recrystallized from ethanol to give 395 mg (87%) of **16**, mp 193—194 °C.

Found: C, 46.46; H, 7.05; N, 12.08%. Calcd for $C_9H_{16}N_2O_5$: C, 46.54; H, 6.96; N, 12.06%. Compound **16** consumed 0.9 molar equivalent of periodate in 0.05 M sodium metaperiodate solution for 2 h at room temperature.

*DL-(1,3/2,4,5)-2,5-Diacetamido-1,3,4-cyclopentanetriol (**17**).* Compound **15** (216 mg) was de-*O*-acetylated and the product was recrystallized from ethanol to give 93 mg (66%) of **17**, mp 180—181 °C.

Found: C, 46.86; H, 6.96; N, 11.73%. Calcd for $C_9H_{16}N_2O_5$: C, 46.54; H, 6.96; N, 12.06%. Compound **17** consumed 0.9 molar equivalent of periodate in the same conditions as described above.

*Structural Determinations of **12** and **13** by Acetyl Migration.* Compound **12** (33 mg) was hydrogenated in the presence of platinum oxide in ethanol (5 ml) overnight to give a practically ninhydrin negative product (28 mg). The product was de-*O*-acetylated and subsequently treated with Amberlite IR-120 (H^+) to give 19 mg (85%) of a ninhydrin negative product, mp 193—194 °C, which was identified as **16** by a comparison with an authentic sample.

Compound **13** (22 mg) was hydrogenated analogously as described above to give 15 mg (74%) of a ninhydrin positive product as a syrup.

*DL-(1,2,3/4,5)-5-Acetamido-2-azido-1,3,4-cyclopentanetriol (**18**).* Compound **12** (707 mg) was de-*O*-acetylated to give 340 mg (76%) of **18**, mp 168—169 °C.

Found: C, 38.77; H, 5.74; N, 25.60%. Calcd for $C_7H_{12}N_4O_4$: C, 38.89; H, 5.60; N, 25.92%.

*4,5-*N,O*-Isopropylidene-DL-(1,2,3/4,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol (**19**).* Compound **18** (280 mg) was treated with 2,2-dimethoxypropane (0.7 ml) in DMF (12 ml) at room temperature in the presence of *p*-toluenesulfonic acid (3 mg) for 46 h. After neutralized with Amberlite IRA-400 (OH^-), the reaction solution was evaporated and the residue was recrystallized from ethyl acetate to give 228 mg (69%) of **19**, mp 131—133 °C.

Found: C, 46.70; H, 6.23; N, 22.06%. Calcd for $C_{10}H_{16}N_4O_4$: C, 46.87; H, 6.29; N, 21.86%.

*1,3-Di-*O*-acetyl-4,5-*N,O*-isopropylidene-DL-(1,2,3/4,5)-2,5-diacetamido-1,3,4-cyclopentanetriol (**20**).* Compound **19** (396 mg) was hydrogenated in hydrogen atomosphere (3.4 kg/cm^2) in the presence of Raney nickel in ethanol (24 ml) overnight. The hydrogenation product was acetylated and the product was recrystallized from ethyl acetate to give 363 mg (66%) of **20**, mp 167—168 °C; PMR: τ 8.49 and 8.31 (each 3, CMe_2), 8.01 (s, 3, NAc), 7.93 (s, 3, NAc), 7.85 (s, 6, 2OAc), 4.21 (d, 1, J=9 Hz, NH).

Found: C, 53.76; H, 6.76; N, 7.94%. Calcd for $C_{16}H_{24}N_2O_7$: C, 53.93; H, 6.79; N, 7.86%.

*4,5-*N,O*-Isopropylidene-DL-(1,2,3/4,5)-2,5-diacetamido-1,3,4-cyclopentanetriol (**21**).* Compound **20** (323 mg) was de-*O*-acetylated and the product was recrystallized from ethyl acetate to give 229 mg (93%) of **21**, mp 163—164 °C.

Found: C, 52.65; H, 7.27; N, 10.29%. Calcd for $C_{12}H_{20}N_2O_5$: C, 52.93; H, 7.40; N, 10.29%.

O-*Acetyl-di*-N,O-*isopropylidene*-DL-*(1,2,3/4,5)-2,5-diacetamido-1,3,4-cyclopentanetriols (**22a** and **b**).* Compound **21** (149 mg) was treated with 2,2-dimethoxypropane (0.3 ml) in DMF (10 ml) in the presence of *p*-toluenesulfonic acid (3 mg) at room temperature for 21 h. After neutralized with Amberlite IRA-400 (OH^-), the reaction solution was evaporated to give 168 mg of a crystalline residue. The residue was fractionated on a silica gel column with benzene–ethanol as an eluate to give 119 mg of a main product and 30 mg of a minor product. The main product showed a single spot of R_f 0.5 and the minor one showed a single spot of R_f 0.4 on TLC in benzene–ethanol (5 : 1, v/v).

A 50 mg portion of the main product was acetylated to give 40 mg (70%) of **22a**, mp 197—198 °C (recryst. from ether); PMR: τ 8.50, 8.47, 8.38 and 8.32 (each 3, $2CMe_2$), 7.90 (s, 3, 2NAc), 7.85 (s, 3, OAc).

Found: C, 57.79; H, 7.33; N, 7.85%. Calcd for $C_{17}H_{26}N_2O_6$: C, 57.61; H, 7.40; N, 7.90%.

A 30 mg portion of the minor product was acetylated to give 20 mg (57%) of **22b**, mp 135—136 °C (recryst. from ether); PMR: τ 8.46, 8.43, 8.34 and 8.30 (each 3, $2CMe_2$), 8.00 (s, 6, 2NAc), 7.88 (s, 3, OAc).

Found: C, 57.39; H, 7.28; N, 7.72%. Calcd for $C_{17}H_{26}N_2O_6$: C, 57.61; H, 7.40; N, 7.90%.

4,5-N,O-*Isopropylidene*-DL-*(1,3/2,4,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol (**23**).* Compound **13** (293 mg) was de-*O*-acetylated to give 243 mg of colorless syrup. The syrup was treated with 2,2-dimethoxypropane (0.6 ml) in DMF (8 ml) in the presence of a catalytic amount of *p*-toluenesulfonic acid (3 mg) for 49 h at room temperature. After neutralized with Amberlite IRA-400 (OH^-), the solution was evaporated. The residue was recrystallized from ethyl acetate–petroleum ether to give 55 mg (25%) of **23**, mp 111—112 °C.

Found: C, 46.83; H, 6.33; N, 21.91%. Calcd for $C_{10}H_{16}N_4O_4$: C, 46.87; H, 6.29; N, 21.86%.

1,3-Di-O-*acetyl-4,5*-N,O-*isopropylidene*-DL-*(1,3/2,4,5)-2,5-diacetamido-1,3,4-cyclopentanetriol (**24**).* Compound **23** (36 mg) was acetylated and subsequently hydrogenated in the presence of Raney nickel in ethanol (2 ml) in hydrogen atmosphere (3.4 kg/cm²) for 5 h. The product was acetylated to give 27 mg (54%) of **24** as a syrup; PMR: τ 8.45 and 8.25 (each 3, CMe_2), 8.03 (s, 3, NAc), 7.88 (s, 9, NAc and 2OAc), 3.63 (d, 1, J=9 Hz, NH).

Found: C, 53.71; H, 6.70; N, 7.93%. Calcd for $C_{16}H_{24}N_2O_7$: C, 53.93; H, 6.79; N, 7.86%.

A 72 mg portion of **24** was de-*O*-acetylated give to 58 mg of 4,5-*N,O*-isopropylidene-DL-(1,3/2,4,5)-2,5-diacetamido-1,3,-4-cyclopentanetriol (**25**) as a syrup.

Compound **25** (58 mg) was treated with 2,2-dimethoxypropane as described in the preparation of **22a** and **b**, but only **24** was recovered in 88% yield (67 mg).

The Electrochemical Fluorination of Trifluoromethyl-substituted Benzenes

Michimasa YONEKURA,* Shunji NAGASE, Hajime BABA, Kazuo KODAIRA, and Takashi ABE

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received October 13, 1975)

The electrochemical fluorination of benzenes containing one or two trifluoromethyl groups has been carried out. They afforded perfluorocyclohexane derivatives with the trifluoromethyl group in good yields. Chlorobenzenes containing a trifluoromethyl group yielded chlorine-containing perfluorocyclohexane derivatives carrying the trifluoromethyl group. Trifluoromethylbenzonitriles gave perfluoro(dimethylcyclohexane)s, whereupon the nitrile group was converted into a trifluoromethyl group, thus releasing nitrogen trifluoride. The electrochemical fluorination of a trifluoromethylnaphthalene gave perfluoro(methyldecahydronaphthalene) only in a small yield.

Alicyclic fluorocarbons for practical use have received much attention, for example, in the electrical field,[1] because of their unique chemical inertness and physical properties. The preparation of these compounds by the electrochemical fluorination of aromatic hydrocarbons had been known to be unsatisfactory because of the conversion of the starting materials into tar in an electrolytic cell and the formation of polymeric substances on the surface of electrodes which impede the further smooth passage of the current. Sander and Blöch[2] obtained perfluoro compounds in good yields by the electrochemical fluorination of partially fluorinated cyclic alkanes.

In continuing our work on the electrochemical fluorination of aromatic compounds,[3] we have now found that the alicyclic fluorocarbons can be obtained in a reasonable yield by the fluorination of benzenes containing a trifluoromethyl group. However, in the case of the fluorination of trifluoromethyl-substituted naphthalene, the amount of the perfluorinated product was limited.

This report will further deal with the results of the electrochemical fluorination of (trifluoromethyl)benzenes carrying a nitrile group, which was found to be converted into a trifluoromethyl group by releasing nitrogen as nitrogen trifluoride during the fluorination. Thus, trifluoromethylbenzonitriles gave perfluoro-(dimethylcyclohexane)s. These perfluorocyclohexane derivatives have often been prepared by the exhaustive fluorination of cyclic hydrocarbons with high-valency metallic fluorides.[4]

Results and Discussion

The trifluoromethyl group attached to the benzene nucleus had a good effect in increasing the yields of polyfluorinated products in the electrochemical fluorination. For example, benzylidyne trifluoride afforded perfluoro(methylcyclohexane) (I) in a 47.6% yield, together with a small amount of perfluoro(1,2-dimethylcyclopentane) (II). The results are shown in Table 1. The fragmented fluorocarbons, such as carbon tetrafluoride and hexafluoroethane, were among the by-products. No unsaturated fluorocarbons were isolated. The electrochemical fluorination of benzylidyne trifluoride could be carried out even without using a conductivity additive, such as sodium fluoride (Run 2).

Benzenes containing two trifluoromethyl groups gave the expected products, perfluoro(dimethylcyclohexane)s (Runs 3 and 4). As has been shown in the electrochemical fluorination of chlorobenzenes,[3] the chlorine atom attached to the benzene ring was retained during the fluorination, giving chlorine-containing perfluorocyclohexane derivatives. Thus, trifluoromethyl-substituted chlorobenzenes yielded chlorotrifluoromethyldecafluorocyclohexanes (Runs 5, 6, and 7). However, I was obtained as the main product. This indicates that the carbon–carbon bond between the trifluoromethyl group and the benzene ring of the chlorotrifluoromethylbenzenes is much more stable to the electrochemical fluorination than the carbon–chlorine bond.

The fluorination of these aromatic compounds may proceed by the successive addition of fluorine radicals to the benzene nucleus to produce partially fluorinated cyclohexane derivatives; the replacement of the hydrogens by fluorines is expected to follow, yielding perfluoro compounds. The cleavage of the carbon–carbon bond may occur in this replacement stage by means of the energy liberated by the formation of the hydrogen-fluorine and carbon-fluorine bonds. II is probably produced by the rearrangement of the carbon skeleton of the partially fluorinated cyclohexanes. Rearrangements like this have often been observed in the electrochemical fluorination of such cyclic compounds, for example, perfluoro(methylcyclopentane) from benzene.[3] The isomerization of the cyclohexane ring to methylcyclopentane has also been known.[5]

The fact that the benzenes stabilized by the trifluoromethyl group give perfluorocyclohexane derivatives in good yields in the electrochemical fluorination may be explained as follows. First, these compounds do not generate such radicals as fluorocyclohexylmethyl or benzyl, which, among others, seem to be responsible for tar formation. For example, toluene, which has been known to yield only a very small amount of C_7 fluorocarbons, but a considerable amount of tarry materials, in the electrochemical fluorination,[2,6] can be expected to produce radicals of this type. Second, the introduction of trifluoromethyl group to the benzene nucleus could give higher solubilities in anhydrous hydrogen fluoride than those of the corresponding aromatic hydrocarbons[7] because of the increased polarity of the molecule.

The trifluoromethyl group attached to the naphtha-

TABLE 1. FLUORINATION OF TRIFLUOROMETHYL-SUBSTITUTED BENZENES

Run No.	Starting material (mol)	Electricity passed (A·h)	Total amount of fluorocarbons obtained[b] (g)	Principal product	
				Yield[c,d] (%)	Amount[f] (g)
1	Benzylidyne trifluoride(0.197)	129	43.1	I[e] 47.6, II 6.1	37.2
2	Benzylidyne trifluoride(0.197)	123[a]	35.1	I 34.8, II 11.9	32.2
3	1,3-Bis(trifluoromethyl)-benzene(0.197)	148	25.2	I 1.7, III 23.9	20.0
4	1,4-Bis(trifluoromethyl)-benzene(0.200)	143	24.6	I 1.8, perfluoro(1,4-dimethylcyclohexane)[e] 23.5	20.1
5	1-Chloro-2-trifluoromethyl-benzene(0.202)	151	36.9	I 27.7, II 2.2, 1-chloro-2-trifluoromethyl-decafluorocyclohexane 14.5	31.8
6	1-Chloro-3-trifluoromethyl-benzene(0.204)	151	29.3	I 19.1, II 1.1, 1-chloro-3-trifluoromethyl-decafluorocyclohexane 10.1	22.0
7	1-Chloro-4-trifluoromethyl-benzene(0.203)	159	22.6	I 16.8, II 1.0, 1-chloro-4-trifluoromethyl-decafluorocyclohexane 9.4, perfluorocyclohexane 0.6	20.0
8	1-Trifluoromethylnaphthalene (0.102)	127	4.2	perfluoro(1-methyldeca-hydronaphthalene) 4.4	2.3
9	2-Trifluoromethylbenzonitrile (0.204)	150	10.8	I 1.1, perfluoro(1,2-dimethylcyclohexane)[e] 9.7	8.7
10	3-Trifluoromethylbenzonitrile (0.188)	150	27.8	I 5.3, III 20.5	18.9
11	3,5-Bis(trifloromethyl)benzonitrile (0.199)	150[a]	4.2	III 1.3, perfluoro(1,3,5-trimethylcyclohexane)[e] 2.6	3.4

a) Carried out without using the conductivity additive. b) Includes fragmented products such as CF_4 and C_2F_6. c) Yields were calculated as follows; (moles of respective product/moles of starting material) × 100. d) I=perfluoro(methylcyclohexane), II=perfluoro(1,2-dimethylcyclopentane), III=perfluoro(1,3-dimethylcyclohexane). e) IR spectra of these compounds agree with those listed in Ref. 13. f) Total amount of the principal products.

lene ring was not obviously effective. The electrochemical fluorination of 1-trifluoromethylnaphthalene afforded perfluoro(1-methyldecahydronaphthalene) only in a poor yield, 4.4% (Run 8). A considerable amount of tarry materials was found in the cell.

Trifluoromethylbenzonitriles are soluble in anhydrous hydrogen fluoride. In the fluorination, the carbon–nitrogen bond of the nitrile group was extensively cleaved, but the carbon–carbon bond between the benzene ring and the nitrile group remained intact; consequently, the nitrile group was converted into the trifluoromethyl group. The adsorption of the hetero-atom compounds at the active sites on the nickel anode may produce the proper conditions for the preferential attack of fluorine on the nitrogen atom.[8] Thus, perfluoro(dimethylcyclohexane)s (Runs 9 and 10) and perfluoro(1,3,5-trimethylcyclohexane) (Run 11) were obtained, but the yields of the products were depressed by the formation of a polymeric material. The presence of the nitrile group of the starting materials may assist the polymerization reaction.

Experimental

Materials and Apparatus. 1-Trifluoromethylnaphthalene,[9] 3-trifluoromethylbenzonitrile, and 4-trifluoromethylbenzonitrile[10] were prepared according to the methods described in the literature. The other reagents were commercial products and were used as received. The anhydrous hydrogen fluoride was more than 99.5% pure.

The electrolytic cell used was similar to that described previously.[11] Analytical gas chromatography was carried out with a Shimadzu GC-2C chromatograph using Col. A [1.5 m (3 mm diam.), silica gel (60—80 mesh), 80—100 °C], and Col. B [6 m (3 mm diam), 15% Silicone DC QF-1 on Chromosorp P-AW (60—80 mesh), 25—50 °C]. For the semi-preparative work, a Shimadzu GC-1C chromatograph [10 m (6 mm diam), 25% Silicone DC QF-1 on Chromosorp P-AW (60—80 mech)], was used. The IR spectra were recorded on a Hitachi EPI-S2 spectrometer, and the mass spectra, on a Hitachi RMU-7 instrument at 70 eV, as before.[3]

Fluorination of Trifluoromethyl-substituted Benzenes (Run 1). To electrically purified anhydrous hydrogen fluoride (1.28 l) in the cell, sodium fluoride (10 g) was added, and, then benzylidyne trifluoride (28.8 g, 0.197 mol) was introduced into the cell continuously over a period of 2 h by means of a micro-pump in the early period of the reaction. This process was accompanied by the continuous passage of an electric current with an anodic current density of 0.9—1.4 A/dm^2 (the effective surface areas of the anodes and cathodes were each 20 dm^2), a cell voltage of 5.5—5.8 V, and a cell temperature of 5—7 °C. During the reaction, helium (150 ml/min) was blown into the cell through a bubbler, made of poly(tetrafluoroethylene) fiber, fitted in the bottom of the cell.

The gases evolving from the cell were passed through a reflux condenser kept at −15 °C and then consecutively through an iron tube packed with sodium fluoride pellets, polyethylene- and glass-made gas washing bottles filled with an aqueous solution of potassium sulfite containing a small amount of potassium iodide, and finally a series of cold traps immersed in ice and in liquid nitrogen respectively.

The products formed were sufficiently volatile under these conditions so that the major portion of them moved with the stream of hydrogen and the carrier gas of helium from the cell into these traps. The total quantity of electricity passed through was 129 A·h over a period of 5 h. After the electrolysis was over, the blowing of helium was continued for 1.5 h to forward the portion of the products still remaining in the reaction system.

The products (43.1 g) collected in the cold traps were separated into two fractions by trap-to-trap distillation. Each fraction was further subjected to gas-chromatographic analysis (the compositions were calculated on the basis of the chromatographic peak areas, assuming, as usual, equal weight sensitivities for all components),[12] using Col. A for the lower-boiling portion (1.4 g) and Col. B for the higher-boiling portion (41.6 g). The following compounds were thus obtained: CF_4 (0.6 g), C_2F_6 (0.1 g), CHF_3 (0.1 g), CH_2F_2 (0.1 g), *n*-C_4F_{10} (trace), *n*-C_5F_{12} (trace), $CF_3\overline{CF(CF_2)_3}CFCF_3$ (4.2 g), $\overline{CF_2(CF_2)_4}CFCF_3$ (33.0 g), and others (4.9 g, an unidentified complex mixture). These compounds were identified on the basis of their known IR spectra[13] or by a spectral comparison with authentic samples, as before.[3] The authentic sample of perfluoro(1,2-dimethylcyclopentane) was prepared by the electrochemical fluorination of *cis*-1,2-dimethylcyclopentane. Bp 72 °C (lit,[14] bp 71.5—71.8 °C). (All the boiling points are uncorrected). MS: *m/e* 331 [M−F], 281 [M−CF_3], 243 [C_6F_9), 231 [C_5F_9], and 219 [C_4F_9].

The procedures for the other runs (Runs 2, 3, and 4) were essentially the same as those described above; the results obtained for the principal products are shown in Table 1. (Run 2 was carried out without using sodium fluoride).

Fluorination of Trifluoromethyl-substituted Chlorobenzenes (Run 5). 1-Chloro-2-trifluoromethylbenzene (36.5 g, 0.202 mol) was fluorinated, in the presence of sodium fluoride (10 g), with an anodic current density of 1.1—1.5 A/dm², a cell voltage of 5.1—6.0 V, and a cell temperature of 7—8 °C. A total quantity of electricity of 151 A. hr was supplied for a period of 6 hr. The flow rate of helium was 150 ml/min. After the electrolysis was over, the blowing of helium was continued for 1.5 hr.

The products (33.8 g) in the cold traps were separated into lower- (1.7 g) and higher-boiling portions (32.2 g) by trap-to-trap distillation, and each was subjected to gas-chromatographic (Col. A, and Col. B) and spectral analyses. In addition to these products, a small amount of a clear, heavy liquid was drained from the cell through the drain-cock by breaking the bubbler; this liquid was washed with water and with an alkaline solution, dried over anhydrous sodium sulfate, and subjected to gas chromatography (Col. B). This portion (3.1 g) was found to consist of mostly 1-chloro-2-trifluoromethyldecafluorocyclohexane,[15,16] which was also obtained in the cold traps. Bp 103 °C (lit,[15] bp 103 °C). MS: *m/e* 366 [M], 347 [M−F], 331 [M−Cl], 312 [C_7F_{12}], and 297 [C_6ClF_{10}]. The summarized results of the analyses for these three portions of the products are as follows: CF_4 (0.5 g), C_2F_6 (0.6 g), $CClF_3$ (0.5 g), $CF_3\overline{CF(CF_2)_3}CFCF_3$ (1.6 g), $\overline{CF_2(CF_2)_4}CFCF_3$ (19.6 g), $\overline{CFCl(CF_2)_4}CFCF_3$ (10.7 g) and others (3.5 g). For the other runs (Runs 6 and 7), the results obtained for the principal products are shown in Table 1. The 1-chloro-3-trifluoromethyldecafluorocyclohexane obtained in Run 6 had a bp of 103 °C (lit,[16] bp 102—103 °C). MS: *m/e* 366 [M], 347 [M−F], 331 [M−Cl], 312 [C_7F_{12}], and 297 [C_6ClF_{10}]. The 1-chloro-4-trifluoromethyldecafluorocyclohexane obtained in Run 7 had a bp of 103 °C (lit,[16] bp 102—103 °C). MS: *m/e* 366 [M], 347 [M−F], 331 [M−Cl], 312 [C_7F_{12}], and 297 [C_6ClF_{10}].

Fluorination of 1-Trifluoromethylnaphthalene. By following procedures similar to those used for Run 1, 1-trifluoromethylnaphthalene (20.0 g, 0.102 mol) was fluorinated in the presence of sodium fluoride (10 g), with an anodic current density of 1.2—1.4 A/dm², a cell voltage of 5.0—6.8 V, and a cell temperature of 10—11 °C. A total quantity of electricity of 127 A·h was supplied for a period of 5 hr. The flow rate of helium was 50 ml/min.

After the electrolysis was over, most of the anhydrous hydrogen fluoride was distilled off from the cell; the remaining vaporizable residue was driven out with the helium carrier gas from the cell, which had been heated to 70 °C, into a polyethylene bottle containing water. A small amount of fluorocarbons was condensed at the bottom of the bottle. It was separated from water, washed with an alkaline solution, and dried over anhydrous sodium sulfate. This product (2.3 g) was found to consist of mostly perfluoro(1-methyldecahydronaphthalene) (Col. B, 100 °C), bp 159 °C (lit,[17] bp 161 °C). MS: *m/e* 512 [M], 493 [M−F], 443 [M−CF_3], 424 [$C_{10}F_{16}$], and 405 [$C_{10}F_{15}$]. The formation of possible isomers such as perfluoro(perhydroindan)s[2] could not be confirmed under the present conditions. From the tarry residue in the bottom of the cell, 1-trifluoromethylnaphthalene (9.5 g) was recovered unchanged by acetone extraction. No other isolable product was found. The products (1.9 g) obtained in the cold traps consisted of the following compounds: CF_4 (1.1 g), C_2F_6 (0.1 g), CHF_3 (0.2 g), CH_2F_2 (0.2 g), and others (0.3 g).

Fluorination of Trifluoromethyl-substituted Benzonitriles (Run 9). An initial portion of 3-trifluoromethylbenzonitrile was added into the cell, drop by drop, through a sampling valve; electrolysis was then carried out in the presence of sodium fluoride (10 g) with an anodic current density of 1.1—1.6 A/dm², a cell voltage of 5.3—7.2 V, and a cell temperature of 5—7 °C. After a 50 A·h electrolysis, a second portion of 3-trifluoromethylbenzonitrile was added to the cell to bring the total of the two portions to 32.2 g (0.188 mol), after which the electrolysis was continued. A total quantity of electricity of 150 A·h was supplied for a total period of 5.5 h. The flow rate of helium was 150 ml/min. After the electrolysis was over, the blowing of helium was continued for 1.5 h.

The products (27.8 g) obtained in the cold traps were separated into lower- (6.1 g) and higher-boiling portions (21.6 g) by trap-to-trap distillation, and each was subjected to gas chromatography (Col. A and Col. B). The following compounds were obtained: CF_4 (1.9 g), NF_3 (2.4 g), C_2F_6 (0.3 g), CHF_3 (0.8 g), C_3F_8 (0.5 g), *n*-C_5F_{12} (trace), $\overline{CF_2(CF_2)_4}CFCF_3$ (3.5 g), $CF_3\overline{CFCF_2CF(CF_3)(CF_2)_2}CF_2$ (15.4 g), and others (2.9 g). Perfluoro(1,3-dimethylcyclohexane) had a bp of 101 °C (lit,[14] bp 101.7—101.9 °C). MS: *m/e* 381 [M−F], 331 [M−CF_3], 312 [C_7F_{12}], 293 [C_7F_{11}], and 281 [C_6F_{11}]. The results obtained for the principal products of this series of fluorinations (Runs 10 and 11) are shown in Table 1. (Run 11 was carried out without using sodium fluoride.)

The authors wish to thank the Daikin Industries Corporation for supplying the anhydrous hydrogen fluoride.

Catalytic Reduction of Sulfoxide by Bromine–Hydrogen Bromide System

Tetsuo AIDA, Takeshi AKASAKA, Naomichi FURUKAWA, and Shigeru OAE

Department of Chemistry, The University of Tsukuba Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received October 15, 1975)

A small amount of hydrogen halides or halogens was found to catalyze the decomposition of dimethyl sulfoxide (DMSO), affording dimethyl sulfide (DMS) and other oxidized products. Of the halides or halogens, either bromine or hydrogen bromide is the most effective. DMSO decomposes until it is completely consumed. This catalytic decomposition takes place with other sulfoxides such as diethyl or tetramethylene sulfoxide but sluggishly with alkyl aryl or diaryl sulfoxides. The reaction with bromine apparently proceeds *via* the initial α-bromination of DMSO to afford α-bromomethyl methyl sulfoxide which is oxidized by (Kornblum Reaction) to afford such products as formaldehyde, methanesulfonic acid, and hydrogen bromide. These consecutive reactions form a process of "Oxidation-Reduction Cycle" between bromine–hydrogen bromide and DMSO–DMS. The effects of salts and DMS on the rate of decomposition are discussed.

Recently, halide ions were found to catalyze the Stevens-type rearrangement of *S*-alkyl *S*-phenyl *N*-*p*-tosylsulfilimine in DMSO or *N*,*N*-dimethylformamide.[1] However, when DMSO was used as a solvent, an unexpected reduction of DMSO was observed besides the above rearrangement. The rate and amount of reduction vary with the halide ion. The catalyzed reduction of DMSO was attained most effectively with bromide ion, while the yield of dimethyl sulfide did not depend upon the amount of sulfilimide and bromide ion used. Reduction did not proceed in the absence of either the sulfilimine or bromide ion. These observations seem to indicate that the reduction is "triggered" by some species which is formed as a transient intermediate in the initial reaction of the sulfilimine and bromide ion (SB-System). A trapping experiment with a nucleophilic olefin confirmed that molecular bromine is formed during the course of reaction of the sulfilimine with bromide ion. Thus, the reduction is considered to be catalyzed by the molecular bromine formed during the course of reaction. This is supported by the fact that a drop of bromine or aqueous hydrobromic acid solution is enough to reduce DMSO to DMS completely upon heating. This catalytic reduction also takes place with other sulfoxides such as diethyl and tetramethylene sulfoxides. Although the reduction of sulfoxides with other acids has been reported,[2] this is the most facile and convenient catalytic reduction of sulfoxides.

This paper describes detailed observations on this new catalytic reduction of the sulfoxide triggered by the reaction of the sulfilimine with bromide ion and the implication of the reaction.

Results and Discussion

Reaction of N-p-*Tosylsulfilimines with Halide Ion in DMSO.* The reactions of *S*-methyl *S*-phenyl *N*-*p*-tosylsulfilimine with lithium halides were carried out in DMSO at 110 °C for 5 h. The products and yields obtained are summarized in Table 1.

In the case of bromide ion (SB-System) the reaction was apparently quite different from others (chloride ion or iodide ion), a large amount of dimethyl sulfide being obtained. The reaction with iodide ion gave a small amount of molecular iodine. In order to clarify the nature of this abnormal reaction with bromide ion, the yield of dimethyl sulfide was examined by changing the concentration of the bromide ion in DMSO. The results are given in Table 2.

Even though the total yield of dimethyl sulfide calculated from the amount of the SB-System markedly depends upon the initial concentration of the SB-System, the net yields of dimethyl sulfide calculated from the amount of DMSO used always remain at *ca.* 55%. During the course of reaction, about a half molar amount of DMSO used was reduced to the sulfide until DMSO was consumed. This suggests that the SB-System acts only as a "trigger" in the reduction of DMSO, and apparently a certain active species is generated from the SB-System during the course of reduction.

In order to understand the mechanism of the reaction with SB-System and the active species involved, the effect of structure of the sulfilimine on this reaction

a) Calculated from the yield of DMS obtained after a certain reaction time. b) Sulfilimine.

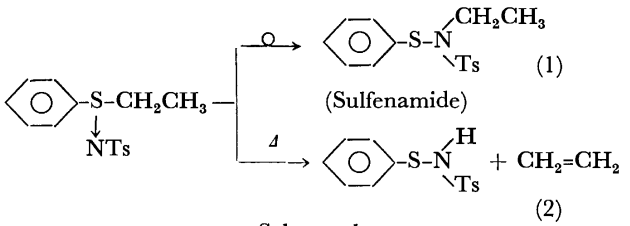
was investigated. The reactivity was determined by comparing the amount of dimethyl sulfide formed after a certain reaction time. The results are summarized in Tables 3 and 4.

The ability of the triggered system (sulfilimine–lithium bromide system) toward the reduction of DMSO appears to depend considerably on the structure of the sulfilimine (Table 3), the reduction proceeding favorably in the order $PhCH_2$>*i*-Pr>Me>Et>Ph. This trend of order does not seem to fit any single conceivable factor. In addition, β-elimination apparently takes place with the sulfilimines having β-hydrogen,[3] *i.e.*, Et- and *i*-Pr- derivatives, playing an important role in the catalytic reduction. The sulfenamides (1 or 2) which are formed in both reactions (rearrangement and β-elimination) seem to be the key compounds (Scheme 1).



(Sulfenamide) (1) (2)

Scheme 1.

A study on the effect of substituent in the sulfilimine on this reaction reveals that the reduction is accelerated by the electron-withdrawing substituent. This trend is in line with the Stevens rearrangement reaction of the sulfilimine with halide ion.

In order to clarify the nature of the active species formed in the reaction of the SB-System and acting as a catalyst for the reduction of DMSO, the controlled experiments were carried out with various substances. The results are summarized in Table 5. All the compounds seem to have a similar triggering ability for the reduction of DMSO, and the common active species is considered to be either bromine or hydrogen bromide since both benzyl bromide and ethyl bromide generate bromine or hydrogen bromide in the reactions with DMSO, (Kornblum reaction[3] and reduction[2]), as shown in Scheme 2.

(Kornblum reaction)

(Reduction)

Scheme 2.

The effect of additional third components on the reduction of DMSO with the SB-System was examined. The results are given in Table 6. The active species is very likely to be molecular bromine, since the reduction was retarded remarkably when styrene was added in the reaction system, while a small amount of (1,2-dibromoethyl)benzene was detected by GLC. Although no bromo-derivative could be detected in the case of phenol, phenol is known to react readily with molecular bromine affording the corresponding *o*- or *p*-substituted derivative, thus trapping molecular bromine.

Thus, the generation of active species (bromine or hydrogen bromide) is suggested as shown in Scheme 3.

Product Analysis of the Catalytic Reduction of DMSO by Molecular Bromine. In order to simplify the catalytic system for the reduction of DMSO, molecular bromine was used as a catalyst and both the products and yields

$(CH_2O)_n$	600	18

a) Calculated from a molar amount of Br_2. b) Conversion percentage for DMSO.

were examined. The results are given in Table 7. The reduced product is dimethyl sulfide, while the oxidized products are both methanesulfonic acid derivatives and formaldehyde, the yields of which are nearly equal.

A similar product distribution was also observed in the reduction of DMSO by a catalytic amount of hydrogen bromide or benzyl bromide (Table 4). In order to confirm the applicability of this catalytic reduction, the same experiments were carried out with various sulfoxides. The results are summarized in Table 8. Apparently the reduction depends on the structure of the sulfoxide (R or R'). Diphenyl sulfoxide is non-reactive and was recovered quantitatively even under drastic reaction conditions. This suggests that the presence of acidic hydrogen is essential. The sequence of reactivities of these sulfoxides, Me>Et>$-(CH_2)_4-$>*n*-Bu, seems to suggest that both steric and inductive effects of alkyl substituent are important in the rate determining step of the reduction.

The yield of DMS in the reduction of DMSO by bromine was followed by means of GLC (Fig. 1.). The formation of DMS increases gradually at the initial stage of the reduction, and then the increase becomes remarkably when the reduction reaches near to completion. The formation of DMS was apparently accelerated by the initial addition of DMS. This suggests that there are at least two routes for the catalytic formation of DMS whose relative rates differ and DMS itself may accelerate the reduction. Since the reduction is not affected by radical initiating reagents such as 2,2'-azobisisobutyronitrile and oxygen atmosphere, it is undoubtedly an ionic reaction.

Table 8. Catalytic reduction of various sulfoxides R-S-R' by molecular bromine
(Sulfoxide/Br_2=100/1; molar ratio)

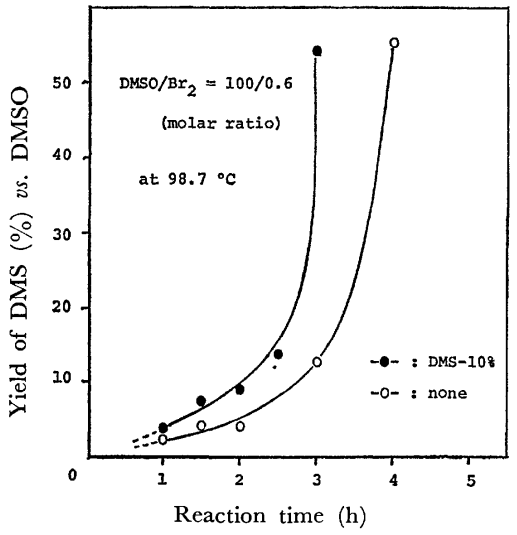

Fig. 1. The effect of DMS for the reduction of DMSO.

The effects of various salts on the reduction were also investigated (Fig. 2). Lithium chloride apparently accelerates, while both lithium bromide and lithium perchlorate retard the reduction.

These and other observations such as product analyses and the rate of formation of DMS, suggest that the reduction can be explained in terms of two main catalytic cycles (Scheme 4). The reaction is obviously initiated by the facile bromination of DMSO or DMS by bromine. The α-bromo-sulfoxide or sulfide reacts with DMSO (Kornblum reaction) affording the sulfide and oxidation products, accompanied by hydrogen bromide which is known to reduce the sulfoxide to the sulfide, forming bromine and water.[2]

If these catalytic cycles work competitively in this reaction while the cycle (2) proceeds faster than the cycle (1), an explanation can be given for the char-

Scheme 4.

acteristic phenomenon of the formation of DMS, namely the gradual increase of DMS at an early stage, followed by a remarkable increase during the reaction. At the initial stage of the reaction, cycle (1) would work predominantly since the amount of DMS in the reaction mixture is too small for cycle (2) to operate; however, the accumulation of DMS during the course of reduction would gradually change the main reaction from cycle (1) to cycle (2). Since cycle (2) proceeds faster than cycle (1), the formation of DMS would increase remarkably near the completion of the reaction.

The Kornblum reaction is probably the slowest one in cycle (1), while the rate-determining step of the reaction is the proton abstraction from the oxo-sulfonium salt (3) by the counter anion (Scheme 5), in view of the interesting salt effects. Since bromide ion acts as a common salt which prevents the formation of the oxo-sulfonium salt(3), and perchlorate ion is a

weaker base than bromide ion to abstract the proton of the oxo-sulfonium salt(3), the reduction would be retarded by perchlorate ion. Chloride ion is a stronger counter anion than bromide or perchlorate ion. Thus, the whole scheme of the catalytic reduction DMSO to DMS may be illustrated as shown in Fig. 3. The formation of trimethylsulfonium methanesulfonate ($(CH_3)_3S^+CH_3SO_3^-$) is shown in Scheme 6.

Experimental

Materials. N-p-*Tosylsulfilimine*: All the *N-p*-tosylsulfilimines were prepared from the corresponding sulfides and chloramine-T by the modified Mann-Pope reaction.[5] These sulfilimines were identified by comparison of their mp, IR, and NMR spectra with those reported.[5]

Lithium Halide and Perchlorate: Commercial anhydrous products were used without purification.

Sulfoxide: Commercial DMSO was dried over calcium hydride and distilled before use. Diethyl, tetramethylene, dibutyl, methyl phenyl and diphenyl sulfoxides were prepared by oxidation of the corresponding sulfides with bromine in acetic acid.[6]

Other Reagents: Commercial dimethyl sulfide, benzyl bromide, ethyl bromide and cyclohexene were used after distillation. Commercial styrene and phenol were distilled in order to remove the stabilizer. Commercial bromine and aqueous hydrobromic acid solution were used without purification.

Reaction of S-*Methyl* S-*Phenyl*-N-p-*Tosylsulfilimine with Halide Ion in DMSO.* A typical run is as follows; a mixture of *S*-methyl *S*-phenyl *N-p*-tosylsulfilimine (3 mmol) and lithium bromide (12 mmol) was dissolved in DMSO (5 g) containing 0.5 g of benzene as an internal standard for GLC. The solution was heated in a sealed tube at 110 °C for 12 h. The reaction mixture was then cooled to ice-water temperature. In order to determine the yield of dimethyl sulfide formed in the reaction, it was injected into the GLC-column and then poured into 30 ml of cold water. The products were extracted from the solution with chloroform and separated by column chromatography (silica gel; benzene); $TsNHCH_3$ 43%, CH_3SCH_3 1400%, $(CH_2O)_n$ 10% and  34%, respectively. The yields were calculated from the molar amount of the sulfilimine used. The structure of  was determined by the following data; IR ν_{SO_2} 1340, 1160 cm^{-1} ν_{COC} 1160 cm^{-1}; NMR is shown in Fig. 4.

Found: C, 50.2; H, 5.35; N, 5.93%. Calcd for $C_{10}H_{13}NO_4S$: C, 49.4; H, 5.35; N, 5.77%.

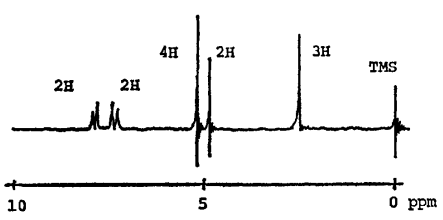

Fig. 4. NMR spectrum of Ts-  (in $CDCl_3$).

Reactions of Various N-p-*Tosylsulfilimines with Lithium Bromide in DMSO.* A mixture of the *N-p*-tosylsulfilimine (3 mmol) and lithium bromide (12 mmol) was dissolved in DMSO (5 g) containing benzene (0.5 g) as an internal standard for GLC. The solution was heated in a sealed tube at 110 °C. for 5 h, and then cooled to ice-water temperature. The isolation and determination of the products formed in the reaction were carried out as described above.

Catalytic Reduction of DMSO by Various Bromides. As a typical example, a solution of ethyl bromide (0.33 g; 3 mmol) and DMSO (8.0 g; 100 mmol) was placed into a sealed tube, and heated at 100 °C for 24 h. The yield of dimethyl sulfide was determined by GLC.

Product Analysis in the Reduction of DMSO by Bromine. The reaction was carried out by heating an ampouled mixture of bromine (1 mmol) and DMSO (8.0 g; 100 mmol) at 100 °C for 5 h. After the reaction, the reaction mixture was separated into two layers. From the upper layer dimethyl sulfide was detected by GLC as the sole product (56%). The under layer was poured into 100 ml of acetone, and then the crystalline precipitates were filtrated off and recrystallized from acetone–ethanol. The compound was identified as trimethylsulfonium methanesulfonate ($(CH_3)_3S^+CH_3SO_3^-$) by comparison of its IR and NMR spectra with those of an authentic sample prepared from trimethylsulfonium iodide ($(CH_3)_3S^+I^-$) and methanesulfonic acid. The yield of the sulfonium salt was 12%. Methanesulfonic acid was separated from the filtrate by means of the anion exchange resine (7%). Paraformaldehyde condensed in the cold part of the sealed tube (18%).

Catalytic Reductions of Various Sulfoxides by Bromine. A typical run is as follows; a mixture of bromine (0.1 mmol) and dibutyl sulfoxide (0.62 g; 10 mmol) was put into a sealed tube and heated at 100 °C for 10 days. The yield of the corresponding sulfide was determined by GLC.

Measurement of the Rate of Formation of Dimethyl Sulfide. A typical run is as follows; a mixture of bromine (0.35 mmol) and DMSO (8.0 g; 100 mmol) containing benzene (0.5 g) as an internal standard for GLC was divided into six portions which were put into separate ampoules. The ampoules were heated in a constant temperature oil bath (100 °C) at the same time, and then removed at set intervals. The yield of dimethyl sulfide was determined by GLC. The effect of the initial addition of dimethyl sulfide (5%) was observed by the same procedure as described above. Addition of various lithium salts to the reaction mixture was also carried out, the molar ratio of DMSO, bromine and lithium salt being 100 : 0.35 : 0.35.

Synthetic Studies on Phosphorylating Reagent. V. A Convenient Synthesis of 2′,3′-Cyclic Coenzyme A

Yoshihiko TAGUCHI, Noriyuki NISHIMURA, Toshio KAKIMOTO, and Yoshitaka MUSHIKA

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

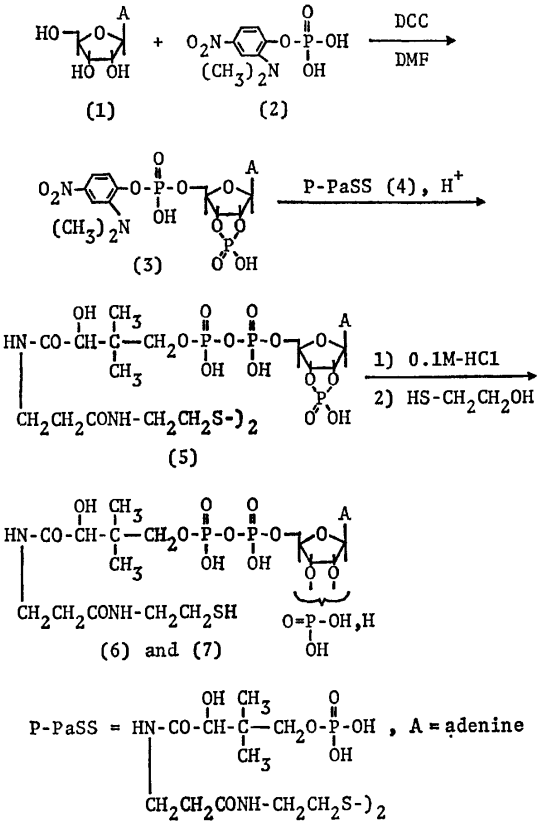
(Received October 17, 1975)

A convenient method has been developed for the preparation of 2′,3′-cyclic Coenzyme A (**5**). It was readily prepared in a good yield from the reaction of adenosine-5′ 2-dimethylamino-4-nitrophenyl phosphate (**3**) with D-pantethine-4′,4″-diphosphate (**4**) in the presence of acetic acid in pyridine. Compound **3** and the diphosphate **4** were prepared in a good yield from the condensation of adenosine (**1**) with 2-dimethylamino-4-nitrophenyl phosphate (**2**) in the presence of dicyclohexylcarbodiimide (DCC) and the phosphorylation of D-pantethine with **2**, respectively.

Phosphate **5** was hydrolyzed with 0.1 M-hydrochloric acid and subsequently reduced with 2-mercaptoethanol to confirm its structure of **5**. One of the products, Coenzyme A (reduced form) (**6**) showed 102% activity with phosphotransacetylase.

It was reported in the previous papers[1–4] that the selective phosphorylation of the hydroxyl group of polyalcohols and amino alcohols including nucleosides, such as adenosine and cytidine *etc.*, was achieved by employing 2-dimethylamino-4-nitrophenyl phosphate (**2**), a new phosphorylating reagent having "an activatable protecting group" to afford the corresponding phosphate esters such as glycerol-1-phosphate, 2-aminoethyl phosphate, adenosine-5′-phosphate and adenosine-3′,5′-cyclic phosphate.

In the present paper, we will describe a convenient preparation of 2′,3′-cyclic Coenzyme A (**5**) using the phosphorylating reagent **2**. There are several papers[5–9] concerning the total synthesis of Coenzyme A (**6**). All methods comprised the synthesis of 2′,3′-cyclic Coenzyme A (**5**) as a precursor of Coenzyme A. However, these methods seem to be impractical because of the difficulties of isolation and purification. Phosphate **5** has not been isolated yet from the reaction mixture and the exact character of **5** has remained unknown. We have attempted the synthesis[10] of **5** using the new phosphorylating reagent **2**. The synthesis of **5** was carried out according to the route shown in Scheme 1.



Scheme 1.

Adenosine-2′,3′-cyclic phosphate-5′ 2-dimethylamino-4-nitrophenyl phosphate (**3**), which acts as a phosphorylating reagent, was prepared by the condensation of the unprotected adenosine (**1**) and the reagent **2** with DCC. Formation of the phosphate **3** was observed in the reaction of **1** and **2** with DCC.[1] Phosphate **3** was obtained as a by-product, the yield being very low. The coupling reaction was reinvestigated in order to find optimum conditions. As a result, phosphate **3** was obtained in quantitative yield when 3 equiv. of the monotriethylammonium salt of **2**, 1 equiv. of adenosine (**1**) and 10 equiv. of DCC were used in the reaction carried out at room temperature in *N,N*-dimethylformamide (DMF). Isolation and purification of product **3** were easily achieved by column chromatography on DEAE-Sephadex according to the usual procedure. Phosphate **3** was obtained in 93% yield as its dilithium salt.

The other component of Coenzyme A (**6**), D-pantetheine-4′-phosphate or D-pantethine-4′,4″-diphosphate (**4**) was necessary for the preparation of **6**. We chose D-pantethine-4′,4″-diphosphate (**4**) as a starting material since the thiol group of D-pantetheine-4′-phosphate would be unfavorable for making the pyrophosphate linkage of **6**. Diphosphate **4** was prepared by Michelson.[6] His method consists of three steps, phosphorylation of D-pantetheine with dibenzyl phosphorochloridate, debenzylation of dibenzyl D-pantetheine-4′-phosphate and oxidation of the thiol group. The procedure seemed to be somewhat intricate. Consequently, a one step synthesis of diphosphate **4** was undertaken with the use of **2**. Thus, the desired diphosphate **4** was readily obtained in 62% yield as its barium salt when a mixture of 1 equiv. of D-pentethine and 2 equiv. of monotriethylammonium salt of **2**

in pyridine was heated under reflux in the presence of 3 equiv. of acetic acid. All the materials including D-pantethine should be thoroughly dried to obtain good results, since this reaction is especially sensitive to the presence of water. The complete drying of D-pantethine was very difficult.

The final step in the preparation of **5** was carried out as follows. The desired pyrophosphate **5** was obtained in 65% yield when 1 equiv. of the triethylammonium salt of **3** was reacted with 3 equiv. of the pyridinium salt of **4** at 50—60 °C for 5 days in pyridine without acid. On the other hand, the yield of **5** increased to 93% when 3 equiv. of glacial acetic acid was added. DMF used in place of pyridine gave the poorest results. The effects of the other acidic media on the yield of **5** are listed in Table 1. The separation of **5** was successfully achieved by eluting a column of DEAE-Sephadex with a linear gradient (0.005—0.30 M) of triethylammonium hydrogencarbonate after applying the reaction mixture to the column and washing with a sufficient amount of water. Analytically pure **5** was obtained as its trilithium salt, a white powder melting at 247—249 °C. The data concerning paper partition chromatography (PPC) and paper electrophoresis (PEP) of compound **5** and the related ones are summarized in Table 2. The structure of **5** was also comfirmed, biologically and chemically, by converting **5** into Coenzyme A (**6**) and *iso*-Coenzyme A (**7**) according to the method of Moffatt and Khorana.[5] Compound **5** (disulfide form) was treated with 0.1 M-hydrochloric acid at room temperature for 1 hr to cleave the cyclic phosphate ring and to reduce subsequently the disulfide linkage with 2-mercaptoethanol at pH 6.0. The products, **6** and **7**, which were isolated as their lithium salts, were chromatographically and electrophoretically identical to a commercially available sample of **6**. The enzymatic assay of the mixture of **6** and **7** by the phosphotransacetylase method[11] showed 102% activity on the basis of **6**.

Table 1. 2′,3′-Cyclic Coenzyme A

Solvent	Acid	Yield (%)
Pyridine	no acid	65
Pyridine	CH_3COOH	93
Pyridine	H_2SO_4	89
Pyridine	CF_3COOH	80
Pyridine	p-$CH_3C_6H_4SO_3H$	78
Pyridine	BF_3-$(C_2H_5)_2O$	65
DMF	BF_3-$(C_2H_5)_2O$	74
DMF	H_2SO_4	48

In conclusion, the key intermediate for the synthesis of Coenzyme A, adenosine-2′,3′-cyclic phosphate-5′ 2-dimethylamino-4-nitrophenyl phosphate (**3**), was easily prepared in one step by the DCC coupling reaction of adenosine (**1**) and the phosphorylating reagent (**2**) in a high yield. A simpler preparation of D-pantethine-4′,4″-diphosphate (**4**) was achieved by using **2**. It was clear that the mild reactivity of phosphate **3** was due to protonation on the nitrogen atom, and **3** reacted with **4** to afford the oxidized form of 2′,3′-cycle Coenzyme A in a good yield.

This method should be useful for the syntheses of other nucleotides having pyrophosphate linkages.

Experimental

Paper chromatography (PPC) was carried out by descending technique using Toyo Roshi No. 51A paper. Solvent systems used were: A, EtOH–0.5 M ammonium acetate buffer (pH 3.8) (5 : 2); B, EtOH–1 M ammonium acetate buffer (pH 7.5) (5 : 2); C, 1-butanol–acetic acid–water (5 : 2 : 3).

Paper electrophoresis (PEP) was performed at pH 7.5 (0.05 M triethylammonium hydrogencarbonate, 900 V/40 cm). The spots of adenosine derivatives on chromatograms were detected with UV lamp (2540 Å). The phsphorus-containing compounds were detected with the Hanes and Isherwood reagent.[12] Chromatographic and electrophoretic mobilities are given in Table 2.

Table 2. Paper chromatography and paper electrophoresis

Compound	R_f in solvent A	B	C	Electrophoretic mobility[a]
Adenosine-2′,3-cyclic phosphate-5′ 2-dimethylamino-4-nitrophenyl phosphate	0.60			0.83
2′,3′-Cyclic Coenzyme A (SS)	0.10	0.08	0.11	1.17
Coenzyme A (SS)	0.07	0.06	0.08	1.20
Coenzyme A (SH)	0.23	0.24	0.23	1.15
Pantethine-4′,4″-diphosphate			0.55	0.50

a) Mobility relative to adenosine-5′-phosphate.

Melting points were determined on a Yamato apparatus, MP-21. The NMR spectra were determined on a Hitachi Perkin-Elmer R-20A instrument (DSS as internal standard). IR spectra were determined on a Shimadzu IR-27G spectrophotometer.

*Adenosine-2′,3′-cyclic Phosphate-5′ 2-Dimethylamino-4-nitrophenyl Phosphate (**3**).* A DMF solution (20 ml) of adenosine (**1**) (0.27 g, 1 mmol), DCC (2.06 g, 10 mmol) and pyridinium 2-dimethylamino-4-nitrophenylphosphate (**2**), prepared from ammonium salt of **2** (0.84 g, 3 mmol) by the cation exchange method on Dowex 50W×8 resin (pyridinium form), was allowed to stand at room temperature for 2 days. After removal of the precipitate by filtration, the filtrate was applied to a column (1.8×60 cm) of DEAE-Sephadex (HCO_3^- form) and eluted with a linear gradient of 0.0005 M and 0.1 M of triethylammonium hydrogencarbonate solution (2 l each). The eluates were continuously followed by the UV-monitor (260 nm). The desired compound, adenosine-2′,3′-cyclic phosphate-5′ 2-dimethylamino-4-nitrophenyl phosphate (**3**), was eluted at roughly 0.07 M salt concentration. The combined fractions containing **3** were evaporated to dryness after complete removal of the volatile compounds by co-evaporation of two 10-ml portions of methanol. The residue was dissolved in methanol (5 ml) and a stoichiometric amount of lithium chloride was added. Acetone (20 ml) was added to the methanolic solution to give the crude dilithium salt

of **3** as a yellow precipitate. The recrystallization of the crude product from a mixture of ethanol and acetone gave 0.63 g (93%) of pentahydrate of dilithium salt of **3**. It was confirmed by PPC, PEP and NMR spectroscopy that phosphate **3** was identical to an authentic sample prepared previously.[1]

D-Pantethine-4′,4″-diphosphate (4). To a pyridine solution (30 ml) of D-pantethine (2.77 g, 5 mmol), which was well dried by co-evaporation with three 30-ml portions of pyridine, were added monotriethylammonium 2-dimethylamino-4-nitrophenyl phosphate (**2**) (3.62 g, 10 mmol), acetic acid (1.80 g, 30 mmol) and triethylamine (1.01 g, 10 mmol) and the solution was refluxed for 3 hr. After evaporating the reaction mixture, the residue was dissolved in water (50 ml) and subsequently applied to a column (1.3×75 cm) of Dowex 50W×8 resin (H^+ form). Th column was washed with water (3000 ml) and the aqueous washings were adjusted to pH 7.5 with barium hydroxide. After removal of the precipitate by filtration, the filtrate was evaporated to dryness at a temperature below 40 °C. The residue was treated with ethanol (100 ml) to give 3.05 g (62%) of dibarium D-pantethine-4′,4″-diphosphate (**4**) as white precipitate; NMR (D_2O, ppm): 0.81 (s, 6H, $CH_3\times2$), 0.97 (s, 6H, $CH_3\times2$), 2.50 (t, 4H, $CH_2\times2$), 2.85 (s, 4H, $CH_2\times2$), 3.40—3.63 (m, 12H, $CH_2\times6$), 4.09 (s, 2H, $CH\times2$). IR (Nujol, cm^{-1}): 3280 (OH), 1655, 1563, 1545 (CONH), 1240 (P=O), 1120, 1080 (P–O–C). These data were identical with those of an authentic sample prepared according to Michelson's method.[6]

2′,3′-Cyclic Coenzyme A (5). Typical Procedure: An aqueous solution of dibarium D-pantethine-4′,4″-diphosphate (1.48 g, 3 mmol) was passed through a column of Dowex 50W×8 resin (pyridinium form) and the column was washed with water. The combined eluate and washings were evaporated to dryness. The residue was well dried by co-evaporation with three 10-ml portions of pyridine. After adding the triethylammonium salt of adenosine-2′,3′-cyclic phosphate-5′ 2-dimethylamino-4-nitrophenyl phosphate (**3**) (0.72 g, 1 mmol) to the above residue, the mixture was again dried by co-evaporation with two 25-ml. portions of pyridine. To a solution of the residue in pyridine (25 ml) was added acetic acid (0.18 g, 3 mmol) and the solution was allowed to stand at 50—60 °C for 5 days. After evaporating the solvent, an aqueous solution (500 ml) of the residue was applied to a column (2.4×50 cm) of DEAE Sephadex (HCO_3^-) and the column was washed with water until the optical density of the washings became negligible. The column was then eluted with a linear gradient of 0.005 M and 0.3 M of triethylammonium hydrogencarbonate solution (4 l each) and four hundred 20-ml portions of the fractions were collected. The desired compound, 2′,3′-cyclic Coenzyme A (**5**), was eluted with *ca.* 0.13 M salt solution. The combined fractions, which contained the product **5**, were evaporated to dryness at a temperature below 40 °C. After adding a stoichiometric amount of lithium chloride to a solution of the residue in methanol, the solution was diluted with acetone (40 ml) to give the crude lithium salt of **5**. Repeated reprecipitation of the crude product **5** from methanol and acetone gave 0.77 g (93%) of the pure lithium salt of **5** as white powder; mp 247—249 °C (dec.); NMR (D_2O, ppm): 1.27 (s, 6H, $CH_3\times2$), 1.39 (s, 6H, $CH_3\times2$), 2.75—3.58 (m, 8H, $CH_2\times4$), 3.87—4.29 (m, 18H, $C_5'H_2\times2+C_4'H\times2+CH_2\times6$), 4.37—5.14 (m, 6H, $C_2'H\times2+C_3'H\times2+CH\times2$), 6.11 (d, 2H, $C_1'H\times2$), 8.17 (s, 2H, $C_2H\times2$), 8.52 (s, 2H, $C_8H\times2$). IR (Nujol, cm^{-1}): 3320 (OH), 1655, 1610, 1545 (CONH), 1240 (P=O), 1120, 1080 (P–O–C), 945 (P–O–P). Found: C, 30.07; H, 4.14; N, 11.60%. Calcd for $C_{42}H_{60}N_{14}O_{30}S_2P_6Li_6\cdot8H_2O$: C, 30.08; H, 4.57; N, 11.70%.

Hydrolysis of 2′,3′-Cyclic Coenzyme A (5) with 0.1 M-HCl. An aqueous solution (5 ml) of 2′,3′-cyclic Coenzyme A (disulfide form) (6510 OD units) was allowed to stant at room temperature for 1 hr after its pH had been adjusted to 1.0 with 0.1 M-HCl. The solution was then readjusted to pH 6.0 with ammonium hydroxide. To the neutral solution was added 2-mercaptoethanol (20 ml) and the solution was left overnight. After diluting with water (500 ml), the reaction mixture was applied to a column (3.5×30 cm) of DEAE Sephadex (Cl^- form) and the column was washed with water until the optical densities of the washings became negligible. The column was than eluted with a linear gradient of 2 l of 0.003 M-hydrochloric acid (mixing vessel) and 2 l of 0.003 M-hydrochloric acid containing of 12.72 g (0.3 mol) of lithium chloride (reservoir). Twenty-ml portions of fractions were collected and the elution curve is shown in Fig. 1.

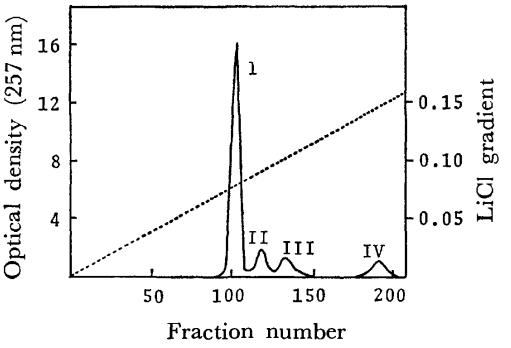


Fig. 1. Chromatography on a DEAE-Sephadex column. Products of the acidic hydrolysis and reduction with 2-mercaptoethanol of 2′,3′-cyclic Coenzyme A (disulfide form).
Peak I, Coenzyme A + *iso*-Coenzyme A; Peak II and III, unidentified; Peak IV, Coenzyme A + *iso*-Coenzyme A (disulfide form).

Peak I (3460 OD units, 49.4%) was a mixture of Coenzyme A and *iso*-Coenzyme A. Peak II (5.8 %) and Peak III (5.5%) could not be identified. Peak IV (320 OD units, 4.6%) was a mixture of oxidized Coenzyme A and *iso*-Coenzyme A. Assay of the mixture of Coenzyme A and *iso*-Coenzyme A, which was obtained from Peak I, by the phosphotransacetylase method[11] using purified commercially available Coenzyme A as the standard proved to be 102% activity on the basis of Coenzyme A, as the ratio of Coenzyme A and *iso*-Coenzyme A was presumed to be 1 : 1.[5]

We wish to express our thanks to Professor Yasumitsu Tamura, Drs. Takashi Takayanagi, Ichiro Chibata, Muneji Miyoshi, Naoto Yoneda, and Ichizo Inoue for their valuable discussions and suggestions.

Effects of Alkali Metal Cation, Solvent, and Alkylating Agent on the Alkylation of Alkali Metal Enolates of Ethyl Acetoacetate

Yoshinori HARA and Minoru MATSUDA

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira 2-Chome, Sendai 980

(Received October 20, 1975)

Alkylation of Li^+, Na^+, and K^+ enolates of ethyl acetoacetate by dimethyl sulfite in dimethyl sulfoxide, hexamethylphosphoric triamide, and *N,N*-dimethylformamide at 50 °C has been studied. The ratio of O/(C+C,C)-alkylation is considerably dependent on the size of the counter cation and the solvent. The tightness of the ion pair is responsible for determining the ratio. The structure of alkylating agents has also influence upon the alkylation ratio. Dimethyl sulfite gives a higher O/(C+C,C)-alkylation ratio than methyl halides which may be ascribed to the hard methyl sulfite anion as leaving group.

It seems to be of interest to determine the factors affecting the alkylation site of ambident anions such as alkali metal enolates of ethyl acetoacetate. Several studies of this area have revealed that the ratio of O/(C+C,C) in alkylation reactions is remarkably dependent on the structure of the alkylating agents, the size of the metal cations, the solvent, and the temperature.[1-6] In connection with our previous studies concerned with the syntheses of organic compounds having sulfite linkages,[7,8] our attention has been focused on the use of dimethyl sulfite in organic reactions in order to understand the chemical properties of the relatively less known alkyl sulfite as alkylating agent.[9] We will report here the alkylation reaction of the alkali metal enolates of ethyl acetoacetate by dimethyl sulfite and the results are discussed in terms of the effects of the size of alkali metal cations, the solvent, and the alkylating agent.

Results

Solvent Effects on the Isomer Ratio in Alkylation Reaction. Results obtained from alkylation of sodium enolate of ethyl acetoacetate by dimethyl sulfite in several solvents at 50 °C are listed in Table 1. The O/(C+C,C)-alkylation ratio increases in the order of diglyme< *N,N*-dimethylformamide (DMF)<dimethyl sulfoxide (DMSO)<hexamethylphosphoric triamide (HMPA)< liquid SO_2. Reaction in liquid SO_2 proceeds in a heterogeneous system. The yield of C,O-isomers is negligibly small.

Counter Cation Effects. Results obtained in DMSO at 50 °C are listed in Table 2. The O/(C+C,C)-alkylation ratio increases in the order of $Li^+<Na^+<K^+$

depending on the size of the counter cation radius (r_c^+).

Leaving Group Effects. Results are listed in Table 2 together with the results reported for other methylating agents. Although it is difficult to compare rigorously among the data which have been obtained under the different reaction conditions,[6] the O/(C+C,C)-alkylation ratio increases roughly in the order $I^- < Br^- < CH_3OS(O_2)O^- < CH_3OS(O)O^- < TsO^-$ (as listed in Table 2 data of Br^- and TsO^- cited from Ref. 6 and these have been obtained in HMPA with potassium salts). Methyl iodide in DMSO yields the C,C-isomer in higher yield compared with dimethyl sulfite.

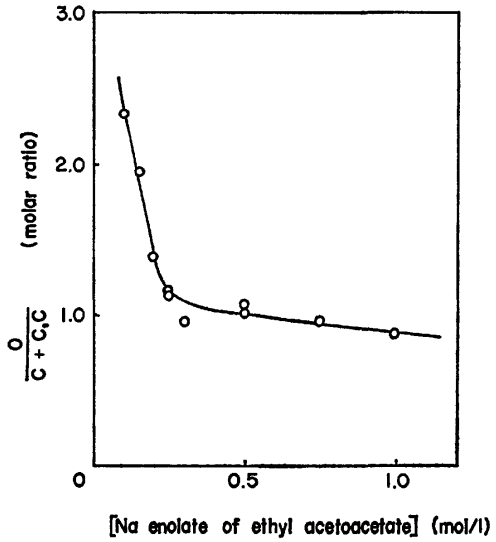

Fig. 1. Dilution effects on the O/(C+C,C)-alkylation ratio obtained with the sodium enolate of ethyl acetoacetate in DMSO at 50 °C.

Dilution Effects. As depicted in Fig. 1 the O/(C+C,C)-alkylation ratio tends to increase with increasing dilution, especially in a region of low enolate concentrations less than 0.3 mol/l pronounced dilution effects in DMSO was clearly appreciable.

Discussion

As shown in the preceding section the O/(C+C,C)-alkylation ratio of the alkali metal enolates of ethyl acetoacetate is affected by the size of the counter cation, solvent, leaving group, and dilution. The alkylation scheme is represented in Fig. 2 and according to this scheme an enhanced O/(C+C,C)-alkylation ratio of ambident anions is expected from the free ions. Kurts *et al.* measured the conductances of solutions containing alkali metal enolates and explained the enhanced ratios by the increased fraction of free ions.[4-6] Dilution effects observed in a region of the low enolate concentrations less than about 0.3 mol/l also reflect the formation of the free ions (see Fig. 1).

On the other hand, solvent effects (Table 1) and counter cation effects in DMSO (Fig. 3) observed in the higher enolate concentration region more than 0.3 mol/l can be explained by the relative amounts of the two species, the contact and solvent-separated ion pairs, which were found to depend on the counter cation and the nature of the solvent. The solvent-separated ion pairs play an important role in the O/(C+C,C)-alkylation ratio when the fraction of the dissociated species, the free ions, is small, which is the similar situation to that proposed by Winstein *et al.* to account for the observed salt effects in the solvolysis of certain arene sulfonates.[10]

The observed order of the solvent effects may be correlated to the solvating power to alkali metal ca-

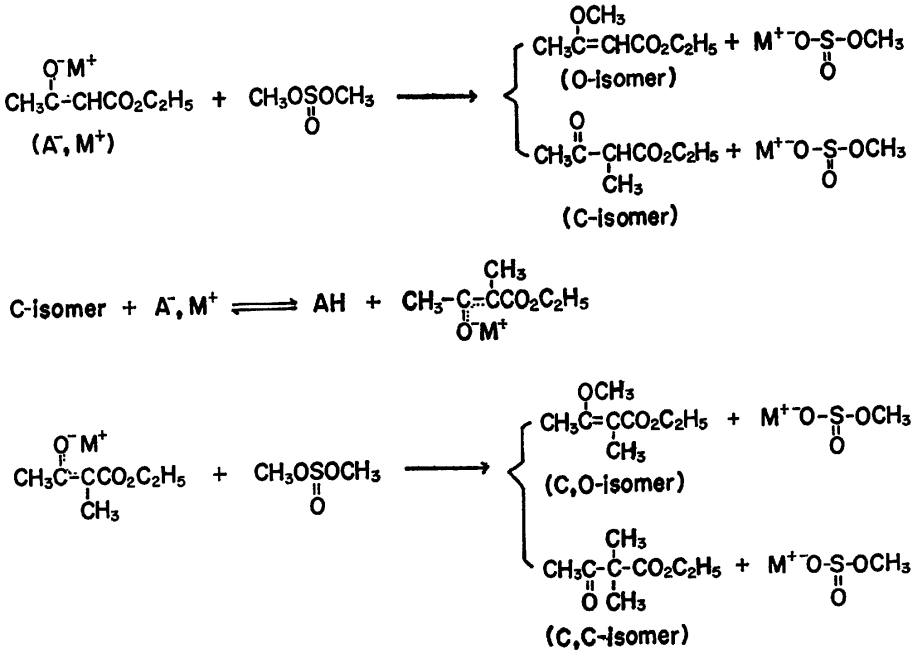

Fig. 2. Reaction scheme.

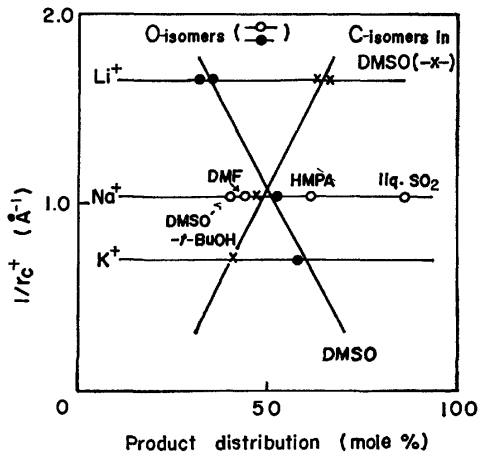

Fig. 3. Relationship between the inverse of the alkali metal cation radius ($1/r_c^+$) and the product distribution at 50 °C. ●, O-isomers in DMSO. ○, O-isomers in other solvents. ×, C-isomers in DMSO. Concentration of enolate was being kept constant at 0.5 mol/l.

tions. The solvating power does not depend on their dielectric constants, but on their ability to donate the negative charge to the cations.[11] The donor property is measured, for example, by solvent's "donicity"[12] and our O/(C+C,C)-alkylation ratio would be correlated with the donicity numbers rather than dielectric constants (see Table 1). DMSO and DMF are polarizable powerful bases like HMPA and the negative charge in their solvents is localized on a bare oxygen atom (nucleophilicity is centered on this oxygen[13]). The external solvation of HMPA, DMSO, or DMF to alkali metal cation tends to disperse the cationic charge and may contribute to weakening the coulombic interaction between the oxygen atom of the ambident anions and alkali metal cations. Thus in the DMSO, DMF, and HMPA, most of the fluorenyl salts (carbanions)[14] and thiolate salts (sulfur anions)[15] form solvent-separated ion pairs, even at room temperature. The polyethyleneglycol dimethyl ethers with the general formula, $CH_3O(CH_2CH_2O)_nCH_3$, referred to as glymes are effective alkali metal-solvating reagents[11] and have often been used to enhance the reactivity of organo-alkali metal compounds. Diglyme, $x=2$ in the general formula, can coordinate alkali metal cations using three coordinate sites. Our observed O/(C+C,C)-alkylation ratio in digylme is small than those in DMF, DMSO, and HMPA. Similar has been reported by Kornblum *et al.* that the O/C-alkylation ratio of sodium β-naphthoxide with benzyl bromide increased in the order tetrahydrofuran≃diglyme<DMF<DMSO[16] which is in accord with order observed in this study. Zook and Miller also found that the O/C-alkylation ratios of sodium enolate in DMSO are substantially larger than in diglyme and rates of enolate alkylation in DMSO are 10^3-fold greater than in glyme solvents.[17] These results may probably be due to the use of the sodium counter cation, and reactivity of diglyme is the most extensive for lithium salts.[18] The addition of *t*-butyl alcohol to DMSO lowered the O/(C+C,C)-alkylation ratio, since the protic solvent prevents the alkylating agent from approaching the oxygen atom of the ambident anion due to the formation of hydrogen bonding.

The size of the alkali metal cations strongly affects the fraction of tight ion pairs formed under otherwise identical conditions. Zaugg and Schaefer[18] found for the anions of phenols and enols that the fraction of the tight ion pairs decreases with increasing cation radius and that the absence of appreciable covalency interactions with alkali metals. The relationship between the inverse of the alkali metal cation radius ($1/r_c^+$) and the product distribution is depicted in Fig. 3. The larger the cation yields the higher the O-isomer; the fraction of O-isomer is proportional to the cation radius in DMSO. The oxygen atom of the alkali metal enolates of ethyl acetoacetate would be associated neither with solvent used nor with cations in these media except for liquid SO_2 (Reaction in liquid SO_2 is discussed below).

The structure of alkylating agents has also influence upon the alkylation. Although the results listed in Table 2 have been obtained under the different reaction conditions, the formation of enol ethers by methylating agents obviously depends on the nature of the leaving groups. In accordance with the hard soft acid base principle[20] the leaving group effects have been explained in terms of the symbiotic stabilization of the transition state; the more essential stabilization must be expected when both the leaving group and nucleophile are soft (or hard) Lewis bases.[21] Our results obtained by dimethyl sulfite, relatively high O/(C+C,C)-alkylation ratio, may be ascribed to that methyl sulfite anion as leaving group displays a fairly hard base, since the oxygen atom of enolate anions is a hard center.

The methylation in liquid SO_2 proceeds in a heterogeneous system which is rather assist to obtain the C-isomers. The observed O/(C+C,C)-alkylation ratio in liquid SO_2 is rather strangeness on the basis of the results obtained in aprotic and electron donating solvents, HMPA, DMSO, and DMF. Liquid SO_2 is also dipolar aprotic solvent, but behaves as an electron acceptor toward most of olefins and a large number of organic compounds having lone pair electrons.[22] Solvation of liquid SO_2 to alkali metal cations is not conceivable. Effects of liquid SO_2 is probably due to the stabilization for leaving groups, *i.e.*, methyl sulfite anion may be stabilized by the presence of electron accepting liquid SO_2.

Experimental

Solvents, HMPA, DMSO, DMF, diglyme, and liquid SO_2, were purified by usual methods. The alkali metal enolates of ethyl acetoacetate were prepared by addition of ethyl acetoacetate to the corresponding ethoxide salts, followed by the careful removal of ethanol and the dissolution of the remaining solid in solvent. Dimethyl sulfite was enclosed in the glass ampoule which was broken in a closed reaction vessel containing the alkali metal enolate of ethyl acetoacetate solution. Quantitative analysis of the four products was carried out by means of VPC.

The Enzyme-like Reaction Catalyzed by Flavin-Reduced Keratin Systems

Fujio Takahashi, Tatsuo Ogasa, Morio Hirano, and Shuichi Suzuki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received October 24, 1975)

The reduced keratin (RK), which was obtained by the reductive cleavage of human hair, was found to act as an apoenzyme and to furnish the reaction field for flavin adenine dinucleotide (FAD): the absorbance of the succinic acid–FAD–RK system in solution increased in the region of 200—250 nm with the lapse of time. From this system fumaric acid was isolated. FAD was found to form a complex with RK and the FAD–RK complex exhibited a catalytic activity for the dehydrogenation reaction of succinic acid to fumaric acid. FAD was reduced in this reaction and the reduced FAD was oxidized by oxygen. It was found that the process of the dehydrogenation reaction obeyed the Michaelis-Menten kinetics; the equilibrium constants of the complex formation between FAD and RK were determined by measuring the initial velocities of the dehydrogenation reaction. The binding site of FAD and RK in the complex was discussed.

It has been known that a coenzyme locates in the active center of an enzyme and exhibits a catalytic activity which can not be realized without an apoenzyme.[1,2] As a plausible speculation, we would assume that an apoenzyme might furnish a coenzyme with a reaction field, in which the coenzyme could exhibit the catalytic activity. If this assumption is true, we can expect that a catalytic reaction may occur in a solution containing the coenzyme combined with a compound which could produce the reaction field, like apoenzyme.

Keratin is known to be one of the albuminoids and contains 10—15% cystine residues, which can be reduced to form thiol groups.[3] The physico-chemical properties of RK obtained by the reductive cleavage of human hair have already been reported.[4] It was expected in the viewpoint of practical use that RK might be utilized as a catalyst. Alcohol dehydrogenase and succinate dehydrogenase are known to be thiol enzymes.[3] The former contains nicotinamide adenine dinucleotide (NAD) and the latter FAD as the coenzyme, respectively. Supposing a thiol group can stimulate NAD and FAD to exhibit the catalytic activity, RK may furnish the reaction field for NAD and FAD.

Aiming at the preparation of an artificial enzyme and the practical use of keratin in our study, preliminary experiments were made for an ethanol–NAD–RK system and a succinic acid–FAD–RK system. No reaction was found to occur in the former case. On the other hand it was found that the dehydrogenation of succinic acid to fumaric acid occurred in the latter case as follows:

$$\mathrm{FAD} + \mathrm{RK} \rightleftharpoons \mathrm{FAD{\cdot}RK} \tag{1}$$

$$\mathrm{FAD{\cdot}RK} + \text{Succinic acid} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{FAD{\cdot}RK{\cdot}Succinic\ acid\ complex} \xrightarrow{k_2} \mathrm{FADH_2RK} + \text{Fumaric acid} \tag{2}$$

$$\mathrm{FADH_2RK} + 1/2\mathrm{O_2} \longrightarrow \mathrm{FAD{\cdot}RK} + \mathrm{H_2O} \tag{3}$$

The dehydrogenation of succinic acid catalyzed by a FAD and FAD-protein system has not been known so far. Takemoto *et al.* have reported the redox reaction of isoalloxazine residues which are introduced in the vinyl polymer, but they did not discuss the reaction field in the polymer.[5]

This paper will present the results of spectrophotometric studies for the verification of Eqs. 1—3 and the isolation of the reaction product.

Calculation

The association constant, K, in Eq. 1 is expressed as

$$K = \frac{[\mathrm{FAD{\cdot}RK}]}{[\mathrm{FAD}][\mathrm{RK}]} \tag{4}$$

where [FAD], [RK], and [FAD·RK] are the concentrations of free FAD, free RK, and the FAD–RK complex. The value of K can be determined by Eq. 10, which is obtained by the following derivation. If the reaction in Eq. 2 obeys the Michaelis-Menten kinetics and makes the rate-determining step, then the initial velocity, v_0, of the succinate dehydrogenation could be expressed as:

$$v_0 = k_2[\mathrm{FAD{\cdot}RK{\cdot}S}] \tag{5}$$

where [FAD·RK·S] is the concentration of the three component complex of FAD, RK, succinic acid.

When the condition of the reactions of Eqs. 2 and 3 reach the steady state, the following equation is given:

$$\frac{\mathrm{d}[\mathrm{FAD{\cdot}RK{\cdot}S}]}{\mathrm{d}t} = k_1[\mathrm{FAD{\cdot}RK}][\mathrm{S}] - (k_{-1}+k_2)[\mathrm{FAD{\cdot}RK{\cdot}S}] = 0 \tag{6}$$

The Michaelis constant, K_m, is expressed as:

$$K_\mathrm{m} = \frac{k_{-1}+k_2}{k_1} \tag{7}$$

Therefore from Eqs. 6 and 7 we obtain,

$$K_\mathrm{m} = \frac{[\mathrm{FAD{\cdot}RK}][\mathrm{S}]}{[\mathrm{FAD{\cdot}RK{\cdot}S}]} \tag{8}$$

where [S] is the concentration of succinic acid. Let F, R, and S be the concentration of total FAD, total RK, and total succinic acid. And let R and S be greater then F, and S be constant; then

$$\left.\begin{aligned} \mathrm{F} &= [\mathrm{FAD}] + [\mathrm{FAD{\cdot}RK}] + [\mathrm{FAD{\cdot}RK{\cdot}S}] \\ &\ll \mathrm{R} \fallingdotseq [\mathrm{RK}] \\ \mathrm{F} &\ll \mathrm{S} \fallingdotseq [\mathrm{S}] \end{aligned}\right\} \tag{9}$$

From Eqs. 4, 5, 8, and 9, the following equation is obtained:

$$\frac{1}{v_0} = \left(\frac{K_\mathrm{m}}{k_2\mathrm{FSK}}\right)\left(\frac{1}{\mathrm{R}}\right) + \frac{1}{k_2\mathrm{F}}\left(1+\frac{K_\mathrm{m}}{\mathrm{S}}\right) \tag{10}$$

From Eq. 10, a plot of $1/v_0$ *vs.* 1/R yields a straight line, from which the value of K can be determined.

Experimental

Materials. The RK was prepared in the same way as was described in the previous paper.[4] The molecular weight of RK was 4500 (by viscometry). Thiol group: 0.21 mg-eq/g and S content: 2.7%. All the other chemicals were of reagent grade or the best commercially available.

The Measurements of Initial Velocities. Stock solutions of 2.5×10^{-5} M FAD, 2.5×10^{-4} M RK, and various concentrations of succinic acid in 1/30 M phosphate buffer were prepared. The requisite amounts of FAD and RK stock solutions were poured into 10-ml volumetric flasks and enough 1/30 M phosphate buffer were added to reach the 10-ml mark. The sample solution was prepared by pipetting 4 ml of FAD-RK solution out of the volumetric flask and adding it into 1 ml of succinic acid solution. The reference solution contains the same concentration of FAD and RK as the sample solution, except that succinic acid is omitted. The initial velocities were determined from the slopes of absorbance-time curves which were obtained by measuring the absorbance change at 225 nm ($\varepsilon=5.7\times10^3$) and 240 nm ($\varepsilon=2.1\times10^3$) for fumaric acid with the lapse of time. Measurements of absorption spectra were made with a Shimadzu spectrophotometer UV-200 at controlled temperatures.

Results and Discussion

Absorbance-Time Relation for the Flavin–RK–Succinic Acid Systems. Various flavins and/or RK were dissolved into 1/30 M phosphate buffer (pH 7.5) and then succinic acid was added. With these solutions differential absorption spectra were measured. The absorbance of each solution was found to increase in the region of 200—250 nm and the absorption maximum at 206 nm appeared in the case of the FAD-solution (inserted figure in Fig. 1). The results for the absorbance (at 225 nm) *vs.* time relation are shown in Fig. 1. The initial velocity was calculated from the slope of each line at zero time in Fig. 1. No reaction occurred without flavin. The initial velocities in the solution containing riboflavin (RF), flavin mononucleotide (FMN), and FAD were obtained to be 4×10^{-8}, 2×10^{-8}, and 5×10^{-7} M/min, respectively.

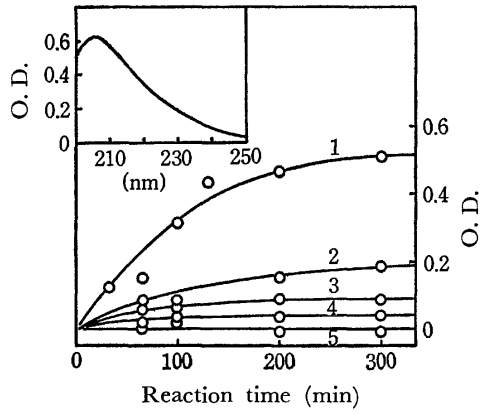

Fig. 1. The absorbance change during reaction. 1/30 M Phosphate buffer (pH 7.5), 35 °C. FAD, FMN, RF: 1.0×10^{-5} M, RK: 1.3×10^{-4} M, Succinic acid (S): 1.0×10^{-4} M. 1: S-FAD-RK, 2: S-RF-RK, 3: S-FMN-RK, 4: S-FAD, 5. S-RK.

ly. It could be thought that the adenine moiety of FAD might combine with RK to form a complex. A little activity (2×10^{-8} M/min) was observed in the case of FAD-succinic acid solution without RK. From this fact, it could be speculated that RK might furnish FAD with the reaction field, as was expected. Paper chromatogram (1-butanol : formic acid : water=10 : 2 : 15)[6] of the succinic acid–FAD–RK system showed one spot (R_f=0.73), assigned to be succinic acid, before reaction. Another spot (R_f=0.84), assigned to be fumaric acid, appeared with the lapse of time. Maleic acid (R_f=0.46) was not found. From the results of absorption spectra and paper chromatography it was suggested that succinic acid was dehydrogenated to form fumaric acid in this reaction.

The absorbance (at 450 nm) of the succinic acid–FAD–RK system, through which nitrogen gas was passed, was found to decrease with the lapse of time and increase again by the aeration. It can be thought that FAD may be reduced to form reduced FAD ($FADH_2$) during the reaction and $FADH_2$ may be reoxidized by oxygen. These results suggested that Eq. 2 might be the rate-determining step in the reaction of Eqs. 2 and 3.

Isolation of Fumaric Acid. Fumaric acid was isolated from the solution of the succinic acid–FAD–RK system as follows: Into distilled water, 5 mmol (590 mg) succinic acid, 1 mmol FAD, and 1.3 mmol RK were dissolved, and sodium hydroxide solution was added to adjust to pH 7.0. Finally, the total volume of the mixture was set to 1000 ml by adding distilled water. The solution was allowed to stand at 25 °C with occasional aeration. The reaction was broken off after 4 days because of the coagulation of RK. The conversion of succinic acid to fumaric acid was estimated to be nearly 20% by the determination of absorption spectra. The solution of the succinic acid–FAD–RK system was concentrated by evaporation and adjusted to pH below 1 by adding hydrochloric acid. Precipitation occurred. Precipitates were separated by centrifugation and then suspended in methanol. The methanol solution separated from insoluble matter was evaporated. The extraction with ethyl ether was carried out and ether was removed from the extract. A white crystal from the residual matter was obtained by recrystallization from water. Yield: 23 mg. The yield can be raised if the separation processes are repeated. The elemental analysis: Found: C, 41.0; H, 3.8%. Calcd for fumaric acid ($C_4H_4O_4$), C, 41.4; H, 3.5%. NMR: 6.84 ppm, singlet in CD_3OD (succinic acid: 2.57, maleic acid; 6.40 ppm).

It was found that a higher yield of fumaric acid could not be obtained because of the activity change of the FAD–RK system during the reaction or the preservation in solution. A stock solution of 1/30 M phosphate buffer (pH 7.5) containing 1.1×10^{-5} M FAD and 1.4×10^{-4} M RK was prepared and divided into two parts. One was bubbled by air, and nitrogen gas was passed through the other. Both were preserved at 25 °C. After the requisite time each was mixed with 1/30 M phosphate buffer (pH 7.5) containing succinic acid and the mixture was aerated. After

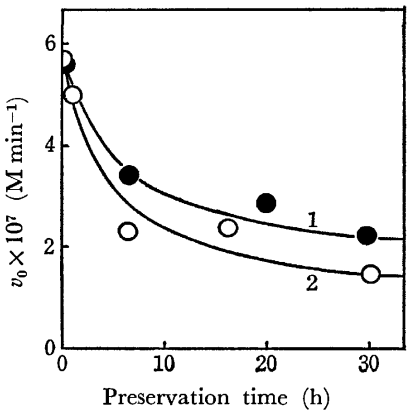

Fig. 2. Activity changes of FAD-RK systems during preservation. 1: Nitrogen gas passed. 2: Aerated.

that the initial velocity of the reaction was calculated by measuring the absorbance change at 225 nm. The mixture contained 1.0×10^{-5} M FAD, 1.3×10^{-4} M RK, and 1.0×10^{-4} M succinic acid. The activities were found to decrease during the preservation, as showin in Fig. 2. The activity change in the solution containing oxygen was larger. Oxidation of RK by oxygen might be the cause of the activity change.

pH Profile. The initial velocities at different pH were determined at 35 °C to obtain the optimum pH for the dehydrogenation of succinic acid. The sample solutions were composed of 1.0×10^{-5} M FAD, 1.0×10^{-4} M RK, and 2.0×10^{-4} M succinic acid in 1/30 M phosphate buffer (pH 6.6—8.4). The optimum pH was found to be in the region of pH 7.5—7.7 (Fig. 3).

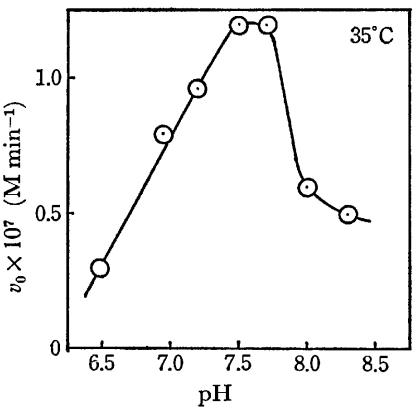

Fig. 3. pH profile.

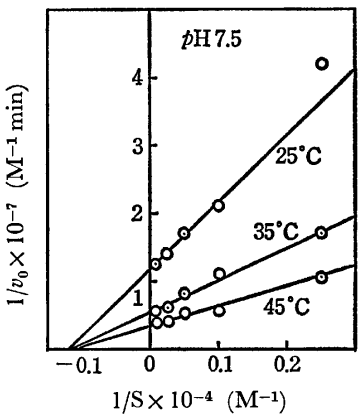

Fig. 4. Lineweaver-Burk plots.

Michaelis-Menten Kinetics. The final concentrations of FAD, RK, and succinic acid in 1/30 M phosphate buffer (pH 7.5) were 1.0×10^{-5}, 1.0×10^{-4}, and 0—10×10^{-4} M, respectively. The initial velocities were measured at different temperatures. The Lineweaver-Burk plots fell on straight lines (Fig. 4), which means that the reaction obeys Michaelis-Menten kinetics. From the straight lines the values of K_m and V_{max} were calculated. The results are summarized in Table 1. The reaction velocity at 60 °C decreased lower than that at 45 °C.

Table 1 Maximum velocities, michaelis constants, and equilibrium constants

	25 °C	35 °C	45 °C
V_{max} (M min^{-1})	8.7×10^{-8}	2.0×10^{-7}	3.3×10^{-7}
K_m (M)	8.7×10^{-5}	9.4×10^{-5}	1.0×10^{-4}
K (M^{-1})	3.8×10^{3}	3.7×10^{3}	3.5×10^{3}

The K_m values of the succinic acid–FAD–RK complex are about half as big as that of the succinate dehydrogenase.[7]

Equilibrium Constant of FAD–RK Complex. The final concentrations of FAD, succinic acid, and RK in 1/30 M phosphate buffer (pH 7.5) were 1.0×10^{-5}, 2.0×10^{-4}, and 0—2.0×10^{-4} M, respectively. Plots of $1/v_0$ *vs.* 1/R gave straight lines, as shown in Fig. 5, from which the assumptions for the derivation of Eq. 10 seemed to be verified. The values of K were calculated (Table 1) by using Eq. 10 with the K_m values and slopes and intercepts obtained from the straight lines. In the solution containing 1.0×10^{-5} M FAD, 1.0×10^{-4} M RK, and 1.0×10^{-3} M succinic acid, 80% (25 °C), 79% (35 °C), and 77% (45 °C) of FAD forms the succinic acid–FAD–RK complex, whose concentration can be calculated from K_m and K values. In turn, the values of k_2 can be obtained to be 1.1×10^{-2} (25 °C), 2.6×10^{-2} (35 °C), and 4.4×10^{-2} (45 °C) min^{-1} from Eq. 5 with the values of V_{max}. These values are 10^5 time smaller than that of succinate dehydrogenase.[7] The activation energy was determined to be 13 kcal/mol from an Arrhenius plot, using the values of k_2 (Fig. 6). The values of enthalpy change and entropy change of the formation

Table 2. The thermodynamic parameters

	ΔH kcal/mol	ΔS e. u.
FAD-RK complex formation	−0.8	+14
Succinic acid-FAD-RK complex formation	−1.3	+15

of the FAD–RK complex and the succinic acid–FAD–RK complex calculated by the van't Hoff's plots (Fig. 6) are summarized in Table 2.

It is known that the overall entropy changes for the formation of an ES complex in many enzymatic reactions give positive values caused by the elimination process of water molecules. It is plausible that a similar process may occur in the formation of the FAD-RK complex and the succinic acid–FAD–RK complex.

The Amino Acid Residues' Part in Catalytic Activity. Various chemical modification reagents were added to the RK solution in order to modify the specific functional groups in RK, and the amino acid residues which play a part in the catalytic activity were assigned from the changes of the reaction velocity caused by the modification of the amino acid residues.

p-Chloromercuribenzoic acid, *N*-acetylimidazole, and glyoxal were used for the chemical modification reagents of cysteine, tyrosine, and arginine residues, respectively.[8–10] The results are summarized in Fig. 7.

The modification of thiol groups made the FAD–RK system inactive. It is very possible that the thiol group participates in the catalysis. However a question still remains: A bulky group of *p*-mercuribenzoate may hinder sterically the complex formation for the dehydrogenation. The initial velocity in the FAD solution containing RK modified by glyoxal is comparable to that in the FMN–RK system. It seems that the adenine moiety of FAD may not interact with modified RK. The arginine residue in RK may made a binding site for the adenine moiety of FAD. Tyrosine residues may not play any part in the catalytic activity.

As a conclusion we suggest that the FAD–RK complex can be formed by the interaction between an arginine residue of RK and an adenine moiety and pyrophosphate linkage of FAD, and that the catalytic activity can be exhibited by the interaction between an isoalloxazine moiety of FAD and a thiol group of RK.

The FAD–RK complex cannot be a model of succinate dehydrogenase, because succinate dehydrogenase is an iron-sulfur flavoprotein and the product of reduced flavin and oxygen is hydrogen peroxide, not water. However, it is significant that the FAD–RK complex exhibits the catalytic activity of an artificial enzyme.

(Received November 26, 1975)

Upon treatment with boron trifluoride etherate, 3α,4α-epoxyshionane (**7**) rearranged into bacchar-12-en-3α-ol (**9**) and D : B-friedo-bacchar-5(10)-en-3α-ol (**10**), and their structures have been determined. Revision of the structure for the latter product from previously reported D : C-friedo-bacchar-8-en-3α-ol (**20**) to **10** was described.

A structure of baccharis oxide,[2] obtained from dried roots of *Baccharis halimifolia* L., has been proposed as **1b**[2,3] and then revised to **1a** by X-ray study.[4] Dihydrobaccharis oxide was shown to rearrange into bacchar-12-en-3β-ol (**2**) by treatment with boron trifluoride etherate.[2]

Being interested in close biogenetic relationship between baccharis oxide (**1a**) and shionone (**3**)[5,6] and in their acid-catalyzed backbone rearrangements, we examined a backbone rearrangement reaction of 3α,4α-epoxyshionane (**7**) catalyzed by boron trifluoride etherate.

Shion-3-ene (**6**),[7] prepared from shionone (**3**) *via* shionan-3-one (**4**) and shionan-3β-ol (**5**), was subjected to epoxidation with *m*-chloroperbenzoic acid in benzene at room temperature. The reaction mixture was separated by silica gel chromatography to give two epoxides in a ratio of *ca.* 7 : 3. Assignment of the epoxide group was easily accomplished by PMR measurement using Eu(fod)$_3$-d_{27} as a shift reagent.

The signals due to all methyl groups of the minor epoxide suffered downfield shifts (Fig. 1), while in the case of the major epoxide the signals due to four methyl groups suffered downfield shifts and the signals due to other four methyl groups caused upfield shifts (Fig. 2). Assuming that the shift reagent is associated with the epoxide oxygen atom as shown in Figs. 1 and 2, the fact that the signals due to the four methyl groups caused upfield shifts would be explicable only in the case of 3α,4α-epoxyshionane (**7**) and these four methyl groups could be assigned to 13α-, 20β-, and the side chain two methyl groups which would be placed outside of a cone area suffered an upfield shift (Fig. 2). The epoxide ring of the major epoxide (**7**) was thus shown to be in an α-configuration. The 3β,4β-epoxide structure (**8**) follows for the minor isomer.

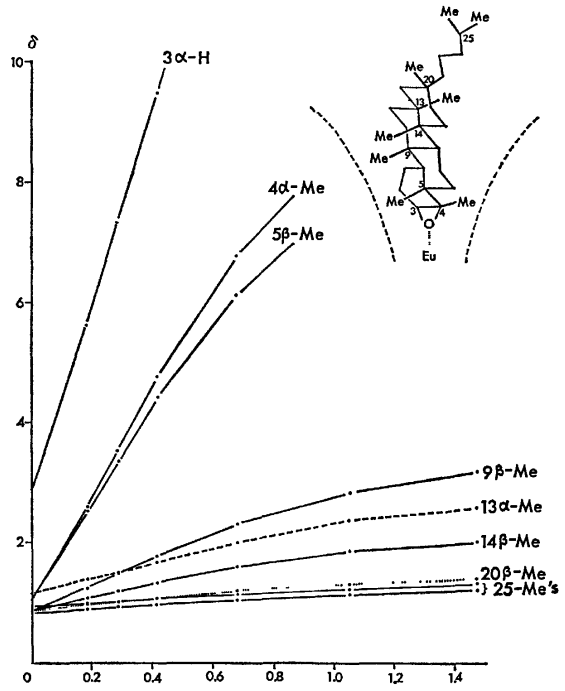

Fig. 1. Induced paramagnetic shifts for the 3β,4β-epoxide (**8**). [Eu(fod)$_3$-d_{27} was added to a 4% (w/v) solution of **8** in $CDCl_3$].

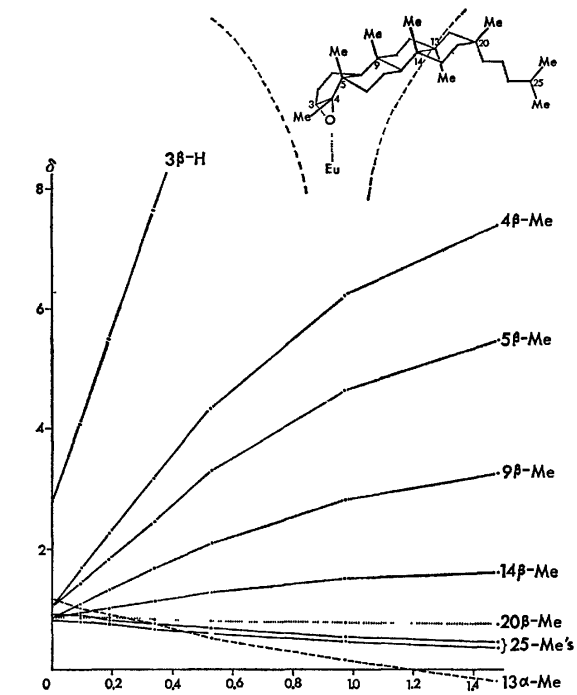

Fig. 2. Induced paramagnetic shifts for the 3α,4α-epoxide (**7**). [Eu(fod)$_3$-d_{27} was added to a 4% (w/v) solution of **7** in $CDCl_3$].

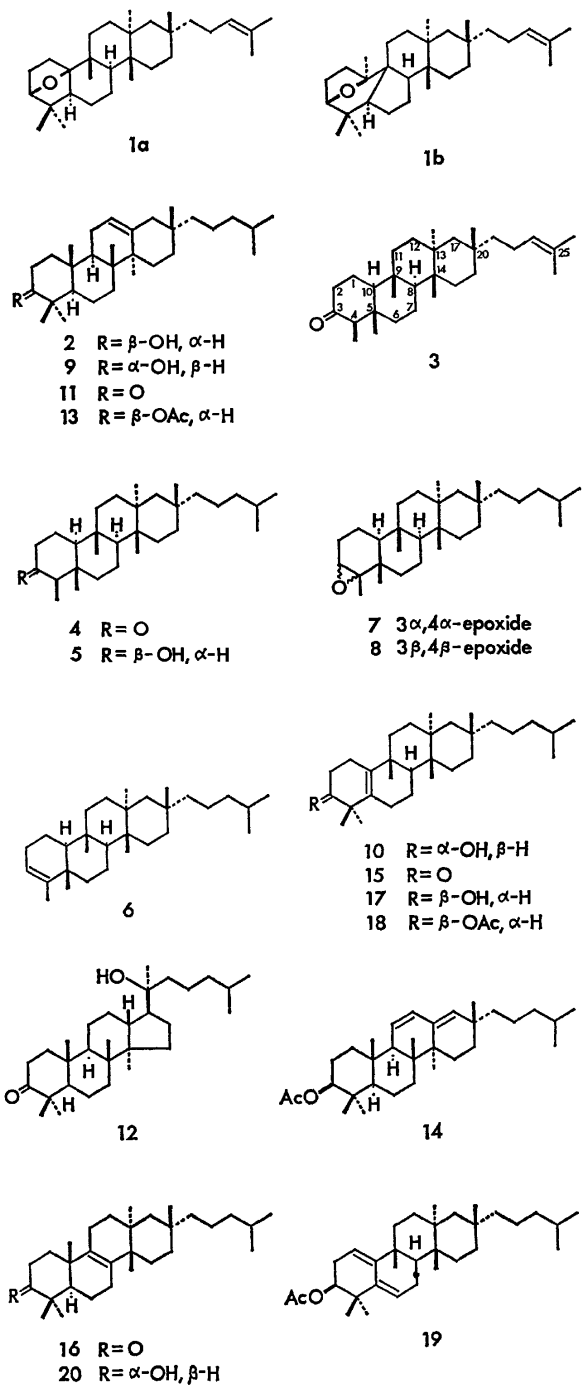
3α,4α-Epoxyshionane (**7**) in dry benzene was treated with boron trifluoride etherate at room temperature. Examination by thin layer chromatography (TLC) showed that the starting material was consumed within 10 min and that a complex mixture was formed. The resulting mixture was separated by column chro-



matography to give a mixture, which was later shown to be a mixture of bacchar-12-en-3α-ol (**9**) and D : B-friedo-bacchar-5(10)-en-3α-ol (**10**).

The mixture (**9** and **10**) without further separation was then subjected to the Collins oxidation to give after column chromatographic separation two unsaturated ketones (**11** and **15**).

A more polar ketone, crystallized from methanol, showed mp 111—112 °C (previously reported 102—102.5 °C[1]); IR (Nujol) 1710 and 815 cm^{-1}, and was shown to be bacchar-12-en-3-one (**11**) by the following evidence and derivation. The enone (**11**) showed PMR signals at δ 2.43 (2H, m) and 5.27 (1H, t-like, J=*ca.* 2 Hz). The former signal due to α-methylene protons to the carbonyl group is similar to those of triterpenes bearing 3-oxo-4,4,10-trimethyl moiety such as β-amyrone and lupenone. The latter signal is due to an olefinic proton. The CD data of **11** ($[\theta]_{290}$+2600, $[\theta]_{325}$−90 in methanol) was almost the same as those of dipterocarpol (**12**).[8] The A/B/C ring junctures were therefore suggested to be the same as those of **12**.

Reduction of bacchar-12-en-3-one (**11**) with sodium borohydride gave an alcohol. On column chromatographic separation followed by crystallization from methanol, there obtained pure bacchar-12-en-3β-ol [**2**; mp 143.5—144 °C (lit,[2] 147—148 °C); M^+ at *m/e* 428 (lit,[2] 428.403); $[\alpha]_D$ +55° (lit,[2] +39°)]. The PMR signals due to an axial proton at C-3 bearing an equatorial hydroxyl group were observed at δ 3.23 as double doublets (J=5 and 8 Hz) and an olefinic proton at C-12 resonated at δ 5.11 as a multiplet. On acetylation with acetic anhydride and pyridine, bacchar-12-en-3β-ol (**2**) afforded an acetate (**13**; mp 177—178 °C. lit,[2] 181—182 °C).

The acetate (**13**) was treated with selenium dioxide in acetic acid at 85 °C for 4 h to give bacchara-11,13-(17)-dien-3β-yl acetate[6] [(**14**; UV λ_{max}^{EtOH} 250 nm (ε 12500), 241 (19400), and 234 (17000); M^+ at *m/e* 468]. The PMR, UV, and mass spectral data were completely identical with those of the authentic sample[2] which was kindly donated from Dr. T. Bruun.

A less polar ketone (**15**) was previously reported as D : C-friedo-bacchar-8-en-3-one (**16**) on the basis of the following evidence. The ketone showed no signals due to olefinic proton and the molecular formula was shown to be $C_{30}H_{50}O$ by the elemental analysis and the mass spectrometry. These findings suggested that the ketone must contain a tetrasubstituted double bond and could be formulated as either D : C-friedo-bacchar-8-en-3-one (**16**) or D : B-friedo-bacchar-5(10)-en-3-one (**15**). The previously reported melting point, 174.5—177.5 °C[1] was not coincident with that of D : B-friedo-bacchar-5(10)-en-3-one (mp 78—80 °C[9]), which was prepared from shionan-3-one (**4**). These facts led to the conclusion that the ketone was not D : B-friedo-bacchar-5(10)-en-3-one (**15**), but was, instead, D : C-friedo-bacchar-8-en-3-one (**16**).

However, on reinvestigation of the less polar ketone, it was found that the melting point was 84—84.5 °C and the previously reported melting point (174.5—177.5 °C) was that of the decomposition product. The misinterpretation seemed to be mainly due to a fragility of the ketone. Thus, it is shown that the previous assignment (**16**) must be withdrawn and the ketone should be represented by D : B-friedo-bacchar-5(10)-en-3-one (**15**). The conclusion was supported by a direct comparison (mp, mixed mp (84—84.5 °C), TLC, IR and PMR spectra) with D : B-friedo-bacchar-5(10)-en-3-one (**15**; 84—84.5 °C), prepared from shionan-3-one (**4**) *via* D : B-friedo-bacchara-1,5(10)-dien-3-one.[10]

The ketone (**15**) was reduced with sodium borohydride to give D : B-friedo-bacchar-5(10)-en-3β-ol (**17**), mp 140.5—141 °C (lit, mp 135—136 °C[1]; 140.5—141 °C[9]; 141.5—142 °C[10]). The PMR signals due to 3α-(axial) proton were observed at δ 3.42 as double doublets (J=5 and 10 Hz).

The alcohol (**17**) was converted by a usual procedure into an acetate (**18**), mp 147—148 °C. Oxidation of the acetate (**18**) with selenium dioxide in acetic acid under reflux gave D : B-friedo-bacchara-1(10),5-dien-3β-yl acetate (**19**), mp 123—123.5 °C, which showed characteristic ultraviolet absorption bands due to heteroannular transoid dienone at 248 (sh. ε 12100), 238 (20900), and 231 nm (19400).[11]

The formation of the alcohols (**9** and **10**) from the α-epoxide (**7**) by boron trifluoride etherate-catalyzed rearrangement was thus shown. The structure of D : C-friedo-bacchar-8-en-3α-ol (**20**)[1] previously given for the latter product (**10**) should be revised to **10**.

Experimental

IR and UV spectra were measured on a Hitachi EPI-G2 and EPS-2 spectrometers, respectively. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer operating at 70 eV with a direct inlet system. PMR spectra were measured using a JEOL JNM PS-100 (100 MHz), a Hitachi R-20 (60 MHz) or a Hitachi R-24 (60 MHz) spectrometer. Chemical shifts were expressed in ppm downfield from TMS as an internal standard (δ value) and coupling constants in Hz. ORD and CD measurements were carried out on a JASCO ORD/UV-5 spectrometer. Measurements of optical rotation were carried out using a JASCO polarimeter DIP-SL. Thin layer chromatography (TLC) was carried out on Kieselgel G or PF_{254} (E. Merck) in 0.25 mm thickness. Wakogel C-200 (Wako Pure Chemical Ind.) was used for column chromatography. All melting points were determined on a hot block and reported uncorrected.

*3α,4α-Epoxyshionane (**7**).* A solution of *m*-chloroperbenzoic acid (516 mg) in benzene (12 ml) was added to shion-3-ene[7] (**6**; 1.00 g) in benzene (10 ml) at room temperature. The reaction mixture was allowed to stand for 1.5 h, and washed with a saturated sodium hydrogencarbonate solution and then with brine. After usual work-up, a residue (1.04 g), which gave two spots on TLC, was subjected to silica gel chromatographic separation quickly. 3α,4α-Epoxyshionane (**7**; 0.70 g) was eluted with benzene and crystallized from acetone to give colorless needles, mp 147—148 °C; PMR (100 MHz, $CDCl_3$) δ 0.86 (s; 3×*t*-CH_3), 0.87 (d, J=5.5 Hz; 2×*s*-CH_3), 1.04 (s; 2×*t*-CH_3), 1.17 (s; *t*-CH_3), and 2.83 (t, J=3 Hz; $C_{(3)}$–H); mass spectrum *m/e* 428 (M^+); Found: C, 84.12; H, 12.37%. Calcd for $C_{30}H_{52}O$: C, 84.04; H, 12.21%.

Further elution with the same eluent afforded 3β,4β-epoxyshionane (**8**; 0.28 g) mp 154—155 °C; PMR (100 MHz, $CDCl_3$) δ 0.86 (s: 3×*t*-CH_3), 0.88 (d, J=5 Hz; 2×*s*-CH_3), 1.05, 1.06, 1.16 (each s; *t*-CH_3), and 2.89 (t, J=*ca.* 1 Hz; $C_{(3)}$–H); mass spectrum *m/e* 428 (M^+); Found: C, 84.00; H, 12.14%. Calcd for $C_{30}H_{52}O$: C, 84.04; H, 12.21%.

The PMR spectral data using Eu(fod)$_3$-d_{27} as a shift reagent were given in Figs. 1 and 2.

*Reaction of 3α,4α-Epoxyshionane (**7**) with Boron Trifluoride Etherate.* To a solution of 3α,4α-epoxyshionane (**7**; 1.00 g) in benzene (40 ml, dried over sodium), freshly distilled boron trifluoride etherate (1.0 ml) was added with swirling. The reaction was monitored by TLC examination. After 10 min, the starting material completely disappeared and two new major spots were observed on TLC. The reaction was stopped by addition of a saturated sodium hydrogencarbonate solution, and the organic layer was washed with brine, dried over sodium sulfate, and evaporated to give a colorless oil (1.13 g).

The resulting oil was dissolved in benzene, passed through a column of silica gel (200 g), and eluted with the following solvents (each fraction 100 ml): frs 1—15, benzene; frs 16—19, benzene–ether (97 : 3). From fractions 6—9, a mixture of alcohols (**9** and **10**; 598 mg) was obtained.

*Collins Oxidation of the Alcohol Mixture (**9** and **10**).* The alcohol mixture (**9** and **10**; 596 mg), without further separation, was dissolved in dichloromethane (11 ml) and added to the Collins reagent (prepared from chromium trioxide (0.844 g), dry pyridine (1.4 ml), and dichloromethane (10 ml, dried over Zeolite)). After the solution was kept at room temperature for 2 h, the reaction mixture was passed through a short column of silica gel and eluted with ether. The eluates were combined and evaporated to yield a yellow oil (437 mg), which was dissolved in benzene, passed through a dry column of silica gel (300 g), and eluted with benzene (each fraction 100 ml). Fractions 5—8 gave D : B-friedo-bacchar-5(10)-en-3-one (**15**; 289 mg), fraction 9 gave a mixture (45 mg) of **15** and **11**, and fractions 10—16 gave bacchar-12-en-3-one (**11**; 69 mg).

D : B-Friedo-bacchar-5(10)-en-3-one (**15**) was crystallized from methanol to give colorless fine needles, mp 84—84.5 °C; IR (Nujol) 1715 cm^{-1}; PMR: no signal due to olefinic proton; mass spectrum *m/e* 426 (M^+); $[\alpha]_D$ −103° (*c* 0.10, methanol); ORD *a*=−66 (*c* 0.10, methanol); Found; C, 84.51; H, 11.51%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

Bacchar-12-en-3-one (**11**) was crystallized from methanol and gave mp 111—112 °C; IR (neat) 1710 and 815 cm^{-1}; PMR (100 MHz, $CDCl_3$) δ 2.43 (m; 2×$C_{(2)}$–H) and 5.27 (t-like, J=2 Hz; $C_{(12)}$–H); ORD *a*=+33 (*c* 0.10, methanol); CD $[\theta]_{290}$+2600, $[\theta]_{325}$−90 (*c* 0.10, methanol); Found: C, 84.57; H, 11.97%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

*Reduction of Bacchar-12-en-3-one (**11**) with Sodium Borohydride.* To a solution of bacchar-12-en-3-one (**11**; 47 mg) in methanol (10 ml), sodium borohydride (52 mg) was added and the reaction mixture was allowed to stand overnight at room temperature. After addition of dilute hydrochloric acid and removal of the solvent under reduced pressure, the reaction products were extracted with ether three times. On usual work-up, a residue (45 mg) was obtained, which was subjected to separation by silica gel (25 g) dry column chromatography. Elution with benzene (270 ml) afforded an oily product (4 mg) and successive elution with the same solvent (410 ml) gave bacchar-12-en-3β-ol (**2**; 36 mg), mp 143.5—144 °C (crystallized from methanol); IR (neat) 3400, 1045, and 820 cm^{-1}; PMR (100 MHz, $CDCl_3$) δ 3.23 (dd, J=5 and 6 Hz; $C_{(3)}$–H) and 5.11 (m; $C_{(12)}$–H); $[\alpha]_D$+55° (*c* 0.49, methanol); mass spectrum *m/e* 428 (M^+). (lit,[2] mp 147—148 °C; $[\alpha]_D$+39° (*c* 1.82); mass spectrum *m/e* 428.403).

*Acetylation of Bacchar-12-en-3β-ol (**2**).* A solution of bacchar-12-en-3β-ol (**2**; 17 mg) in pyridine (0.3 ml) was treated with acetic anhydride (0.2 ml) and was allowed to stand overnight at room temperature. Methanol was added and the reaction mixture was poured into water and extracted with ether twice. On usual work-up, a pale yellow crystal (18 mg) was obtained, which was recrystallized from methanol to give bacchar-12-en-3β-yl acetate (**13**; 8 mg) as colorless crystals, mp 177—178 °C; IR (neat) 1735, 1280, 1030, and 815 cm^{-1} (lit,[2] mp 181—182 °C; $[\alpha]_D$+21° (*c* 1.58); mass spectrum *m/e* 470.411).

*Bacchara-11,13(17)-dien-3β-yl Acetate (**14**).*[6] A mixture of bacchar-12-en-3β-yl acetate (**13**; 14 mg) in acetic acid (1 ml) and selenium dioxide (15 mg) in 96% aqueous

acetic acid solution (0.2 ml) was heated at 85 °C for 4 h. Extraction with ether and usual work-up gave a yellow solid (14 mg), which was subjected to separation by silica gel chromatography to afford bacchara-11,13(17)-dien-3β-yl acetate (**14**; 6.5 mg) as a pale red solid; IR (Nujol) 1735, 1280, 1245, and 875 cm^{-1}; UV λ_{max}^{EtOH} 250 nm (ε 12500), 241 (19400), and 234 (17000); PMR (100 MHz, $CDCl_3$) δ 2.03 (s; $-OCOCH_3$), 4.53 (dd, J=7 and 9 Hz; $C_{(3)}$–H), 5.23 (br. s; $C_{(17)}$–H), 5.55 (dd, $J_{11,12}$=10 Hz, $J_{9,12}$=1 Hz; $C_{(12)}$–H), and 5.92 (dd, $J_{11,12}$=10 Hz, $J_{9,11}$=3 Hz; $C_{(11)}$–H); mass spectrum *m/e* 468 (M^+) [lit,[2] mp 152—153 °C; PMR (60 MHz, $CDCl_3$) δ 5.16 (br. s; $C_{(17)}$–H), 5.40 (dd, $J_{11,12}$=10.5 Hz, $J_{9,12}$=1 Hz; $C_{(12)}$–H), and 5.82 (dd, $J_{11,12}$=10.5 Hz, $J_{9,11}$=3 Hz; $C_{(11)}$–H); mass spectrum *m/e* 468.397 (M^+)].

The PMR, UV, and mass spectra of Bruun's authentic sample were measured under the same conditions as mentioned above. These spectral data were shown to be completely superimposable with ours.

*Reduction of D : B-Friedo-bacchar-5(10)-en-3-one (**15**) with Sodium Borohydride.* D : B-Friedo-bacchar-5(10)-en-3-one (**15**; 246 mg) in methanol (50 ml) was treated with sodium borohydride (200 mg) as the same procedure as described for bacchar-12-en-3-one (**11**) to afford a residue (239 mg), which gave two spots on TLC (a more polar spot was predominant). This was dissolved in benzene and passed through a dry column of silica gel (100 g). A minor component was eluted first with 600 ml of benzene, and successive elution with the same solvent (750 ml) afforded D : B-friedo-bacchar-5(10)-en-3β-ol (**17**; 176 mg), which was crystallized from methanol to give fine needles, mp 140.5—141 °C; IR (Nujol) 3350, 1175, 1120, 1070, 1040, 1030, and 980 cm^{-1}; PMR (100 MHz, $CDCl_3$) δ 3.42 (dd, J=10 and 5 Hz; $C_{(3)}$–H); Found: C, 83.90; H, 12.53%. Calcd for $C_{30}H_{52}O$: C, 84.04; H, 12.21%.

*Acetylation of D : B-Friedo-bacchar-5(10)-en-3β-ol (**17**).* Acetic anhydride (2 ml) was added to a solution of D : B-friedo-bacchar-5(10)-en-3β-ol (**17**: 123 mg) in pyridine (3 ml), and the solution was kept at room temperature for 2 h and then at 70 °C for 2 h. After addition of methanol to decompose excess of the reagent, the solution was poured into water and extracted with ether twice. Usual treatment gave a residue (162 mg), which was crystallized from methanol to give D : B-friedo-bacchar-5(10)-en-3β-yl acetate (**18**), mp 147—148 °C; IR (Nujol) 1725, 1250, 1025, and 970 cm^{-1}; PMR (100 MHz, $CDCl_3$) δ 2.03 (s; $-OCOCH_3$) and 4.64 (dd, J=10 and 5 Hz; $C_{(3)}$–H).

*D : B-Friedo-bacchara-1(10),5-dien-3β-yl Acetate (**19**).* A mixture of D : B-friedo-bacchar-5(10)-en-3β-yl acetate (**18**; 90 mg) in acetic acid (10 ml) and selenium dioxide (158 mg) in water (2 ml) was heated under reflux (bath temperature 100—130 °C) for 4.5 h. After addition of a cold aqueous potassium hydroxide solution, the mixture was extracted with ether twice, washed with a potassium hydroxide solution and then with brine. The ethereal layer was dried over sodium sulfate and evaporated. On standing for 2 days, the residue crystallized. The product was subjected to separation by silica gel (20 g) dry column chromatography using benzene as an eluent (each fraction 30 ml). Fractions 1 and 2, showing two spots on TLC, were combined and further separated by preparative TLC (2 plates (20×20 cm), SiO_2 0.5 mm in thickness; detection: I_2) to give D : B-friedo-bacchara-1(10),5-dien-3β-yl acetate (**19**; 43 mg), mp 123—123.5 °C; UV λ_{max}^{EtOH} 248 nm (sh. ε 12100), 238 (20900), and 231 (19400); PMR (100 MHz, $CDCl_3$) δ 2.04 (s; $-OCOCH_3$), 4.72 (dd, J=6 and 10 Hz; $C_{(3)}$–H), 5.28, and 5.68 (each m; $C_{(1)}$–H and $C_{(6)}$–H); mass spectrum *m/e* 468 (M^+).

The authors wish to thank Dr. T. Bruun for the generous gifts of the authentic bacchara-11,13(17)-dien-3β-yl acetate and of the IR and PMR spectra of bacchar-12-en-3β-ol and its acetate.

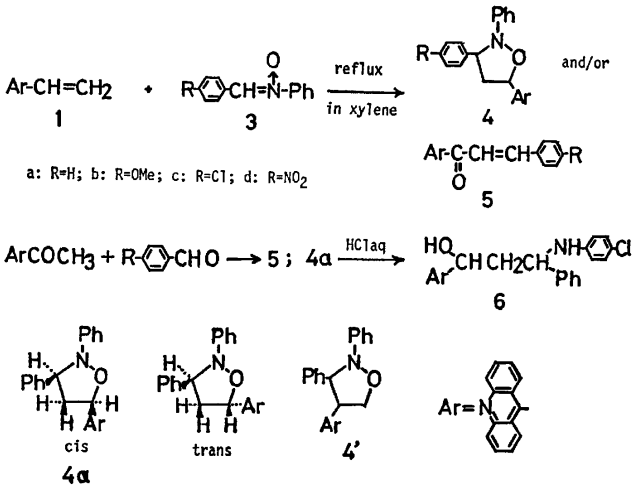
(Received December 19, 1975)

The reaction of 9-vinylacridine (**1**) with *C,N*-diarylnitrones (**3**) in xylene under reflux afforded 5-(9-acridinyl)-2,3-diarylisoxazolidines (**4**) and/or 9-acridinyl styryl ketones (**5**). On heating isoxazolidines **4** were readily converted into the styryl ketones **5** with the elimination of anilines: this is a new type of thermal decomposition of isoxazolidine ring. However, thermal decomposition of 3-(9-acridinyl)-2,5-diarylisoxazolidines (**9**) which were prepared from *N*-(9-acridinylmethylene)aniline *N*-oxide (**7**) and styrene (**8**), did not observed. On the other hand, the reaction of 9-ethynylacridine (**2**) with nitrones **3** in ethanol under the influence of hydrochloric acid proceeded smoothly to give the reversed 4-(9-acridinyl)-4-isoxazolines (**11**), which on heating were converted into the corresponding 4-oxazolines **12.**

It is known that the reactions of *C*-aryl-*N*-alkyl(or aryl)nitrones with mono-substituted alkenes proceed regioselectively to give only the 5-substituted isoxazolidines.[2-6] However, Huisgen, *et al.*[7,8] observed diminished regioselectivity in the cycloaddition reaction of *C*-phenyl-*N*-methylnitrone with methyl propiolate. Recently, it has been reported that *C*-phenyl-*N*-methylnitrone added to electron-deficient monosubstituted dipolarophiles such as nitroethylene and cyanoacetylene to yield only the reversed 4-substituted cycloadducts.[9]

Thus, it seemed of interest to investigate the reactions of 9-vinyl- (**1**) and 9-ethynylacridine (**2**) with nitrones, because the 9-acridinyl group is rather bulky and electron-withdrawing. In this paper we wish to report the reactions of **1** and **2** with *C,N*-diarylnitrones which revealed some unusual phenomena.



Scheme 1.

Results and Discussion

The reaction of 9-vinylacridine (**1**) with *C,N*-diphenylnitrone (**3a**) in boiling benzene did not take place. When a solution of equimolar quantities of **1** and **3a** in xylene was refluxed for 1.5 h, an 1 : 1 adduct **4a**, mp 188—189 °C, and 9-acridinyl styryl ketone (**5a**)[1] were obtained in 11 and 1% yields respectively, together with tarry materials.

On the basis of the chemical conversion and spectral data, **4a** was assigned to be 5-(9-acridinyl)-2,3-diphenylisoxazolidine (normal cycloadduct). Hydrolysis of **4a** with 20% aqueous hydrochloric acid at room temperature for 1.5 h afforded 1-(9-acridinyl)-3-(*p*-chloroanilino)-3-phenyl-1-propanol (**6**), mp 216—217 °C, in 60% yield. However, the configuration of **6** could not be determined, because the measurement of NMR spectrum of **6** was unsuccessful owing to its insolubility in solvents. Previously,[10] we have reported that hydrolysis of *cis*-2,3,5-triphenylisoxazolidine gave 1,3-diphenyl-3-(*p*-chloroanilino)-1-propanol. Thus, the reversed 4-(9-acridinyl) isomer **4'** can be excluded form the possibility for the structure of **4a**.

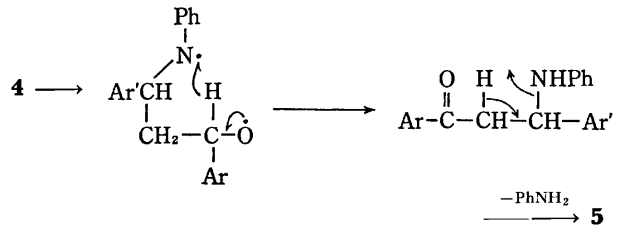
An inspection of Dreiding models indicates that there is a significant steric interaction between the acridinyl and *N*-phenyl groups in *trans*-isoxazolidine, but not in *cis*-isoxazolidine. Therefore, *cis*-configuration seems to be favorable to **4a**.

Under similar conditions, **1** reacted with *C*-*p*-anisyl-*N*-phenylnitrone (**3b**) to afford a normal cycloadduct **4b**, mp 202—203 °C, in 11% yield. However, the reaction of **1** with *C*-*p*-chlorophenyl- (**3c**) and *C*-*p*-nitrophenyl-*N*-phenylnitrone (**3d**) did not give the cycloadducts, but only acridinyl styryl ketones **5c**, mp 241—242 °C, and **5d**, mp 284 °C, were obtained in 27 and 13% yields respectively. The structures of **5c** and **5d** were confirmed by comparison with the authentic samples prepared from 9-acetylacridine and the corresponding benzaldehydes.

When heated in boiling xylene, isoxazolidines **4a** and **4b** were quantitatively converted into the corresponding acridinyl styryl ketones **5a** and **5b**, mp 200—201 °C. Thus, the formation of styryl ketones **5** in the reaction of **1** with **3** may be explained as arising from the corresponding isoxazolidines **4**. Little attention has been paid to the thermal decomposition of isoxazolidines. To our knowledge, the only one example has been reported on thermal isomerization of a bicyclic isoxazolidine.[11]

The transformation of isoxazolidines **4** into α,β-unsaturated ketones **5** is noteworthy as a new type of thermal decomposition of isoxazolidine ring. Although the exact pathway for the formation of **5** from **4** is not clear, we tentatively proposed the potential one as

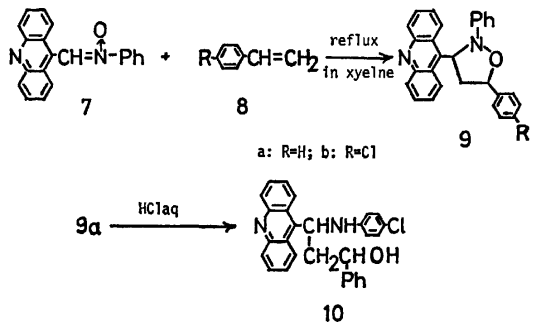
* To whom all correspondence should be addressed.



Ar=9-acridinyl: Ar'=*p*-substituted phenyl

depicted below. The cleavage of N–O bond of **4**, followed by the hydrogen shift gives 1-(9-acridinyl)-3-anilino-3-(*p*-substituted phenyl)propanone. Subsequent elimination of aniline from the propanone yields the final acridinyl styryl ketone **5**.

In this context, it appeared of interest to know whether a positional isomer of **4** is thermally decomposed or not. The reaction of *N*-(9-acridinylmethylene)-aniline *N*-oxide (**7**) with styrene (**8a**) in xylene under reflux afforded the expected 3-(9-acridinyl)-2,5-diphenylisoxazolidine (**9a**), mp 202—203 °C, in 37% yield. The structure of **9a** was confirmed by the spectral data as well as by the result of hydrolysis.



Scheme 2.

Hydrolysis of **9a** with 20% aqueous hydrochloric acid gave 3-(9-acridinyl)-3-(*p*-chloroanilino)-1-phenyl-1-propanol (**10**), mp 112—113 °C, in 68% yield. Similarly, *p*-chlorostyrene (**8b**) reacted with nitrone **7** to give 3-(9-acridinyl)-5-(*p*-chlorophenyl)-2-phenylisoxazolidine (**9b**), mp 205—206 °C, in 41% yield. Even when heated in boiling xylene for a long while, isoxazolidines **9a** and **9b** were recovered quantitatively.

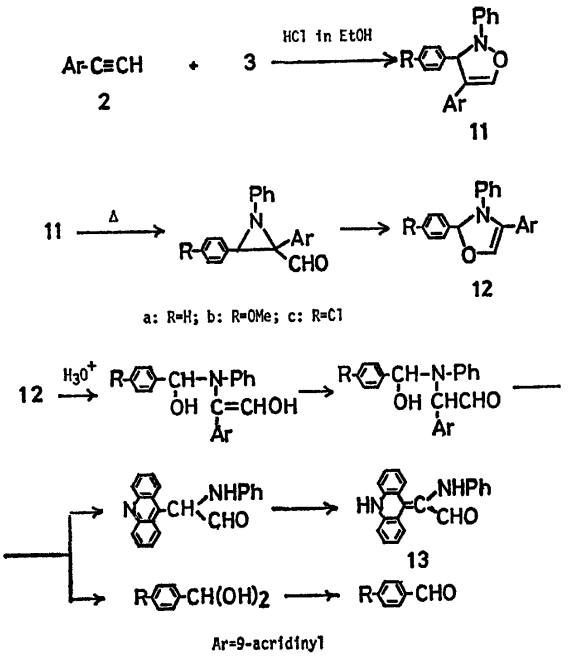
On the other hand, the reaction of 9-ethynylacridine (**2**) with nitrones **3** in xylene under reflux yielded only tarry materials. However, we found that **2** reacted with *C*,*N*-diphenylnitrone (**3a**) in ethanol under the influence of hydrochloric acid at room temperature to afford a 1 : 1 cycloadduct **11a**, mp 115—115 °C (dec); whose yield depended on the amounts of hydrochloric acid used as shown in Table 1.

Table 1. Reaction of **2** with **3a**[a]

HCl, ml	**11a**, Yield (%)	HCl, ml	**11a**, Yield (%)
0.01	37	0.1	33
0.02	59	0.3	30
0.05	45	0.5	21

a) A mixture of **2** (1.0 g), **3a** (1.0 g), and the specified amount of hydrochloric acid (d^{27} 1.1748) in ethanol 20 ml) was stirred at room temperature for 10 min.

On the basis of the spectral data and chemical conversion, the structure of **11a** was deduced to be a reversed cycloadduct, 4-(9-acridinyl)-2,3-diphenyl-4-isoxazoline. The NMR spectrum (CS_2) of **11a** exhibited two doublets (each 1H, J=2 Hz) at δ 5.83 (3-H) and 6.83 ppm (5-H), besides aromatic protons (18H). As will be described below, **11a** was readily converted into the corresponding 4-oxazoline. These observations agreed with the assigned structure **11a**, but not with a normal cycloadduct, 5-(9-acridinyl) isomer **11'** (Scheme 3).



Scheme 3.

Similarly, the reaction of **2** with nitrones, **3b** and **3c** afforded the corresponding 4-(9-acridinyl)-4-isoxazoline compounds **11b**, mp 119 °C (dec), and **11c**, mp 85—86 °C (dec), in fairly good yields.

Previously, we have found that hydrochloric acid is an extremely effective catalyst for the reactions of 9-alkyl-,[12–14] 9-vinyl-,[15] and 9-ethynylacridine[16] with nitrosobenzenes. Although the reaction of **1** with *C*,*N*-diarylnitrones in the presence of hydrochloric acid afforded only tarry materials, hydrochloric acid was also very effective for the reaction of **2** with **3**. Catalytic behaviour of hydrochloric acid in the above reactions is not clear at the present stage.

Baldwin, *et al.*[17] demonstrated the existence of the facil thermal valence rearrangement of 4-isoxazolines to 2-acylaziridines, and subsequently to 4-oxazolines. Although attempts to isolate an acylaziridine intermediate were unsuccessful, heating of 4-isoxazoline **11a** in boiling benzene afforded 4-(9-acridinyl)-2,3-diphenyl-4-oxazoline (**12a**), mp 142—143 °C (dec), in 70% yield. Under similar conditions, 4-isoxazolines **11b** and **11c** were converted into the corresponding 4-oxazolines **12b**, mp 168 °C (dec), and **12c**, mp 114—115 °C (dec), in 85 and 50% yields respectively.

The structures of 4-oxazolines **12** were deduced on the basis of the spectral data and chemical conversion. Hydrolysis of **12a** with 20% aqueous hydrochloric acid at room temperature afforded violet prisms **13** ($C_{21}H_{16}N_2O$), mp 192—193 °C, in a good yield, and from the reaction mixture benzaldehyde was identified as its 2,4-dinitrophenylhydrazone. Similarly, **12b** and **12c** yielded **13** and *p*-methoxy- or *p*-chlorobenzaldehyde.

The IR spectrum of **13** displayed the absorption bands at 3360, 3280 (NH) and 1620 cm^{-1} (conjugated C=O), and a strong absorption band appeared at 523 nm in the UV spectrum. The NMR spectrum (DMSO-d_6) exhibited signals at δ 6.7—8.3 (14H, N**H** and aromatic protons), 9.1 (1H, s, C**H**O) and 11.95 ppm (1H, s, N**H**). The above observations indicated that **13** was (9,10-dihydro-9-acridinylidene)anilinoacetaldehyde.

The pathway for the formation of **13** from **12** is shown in Scheme 3. Previously,[18] we have reported that 9-methyleneacridine compounds were easily transformed into 9,10-dihydro-9-acridinylidene compounds. Thus, hydrolysis of **12** gives 9-acridinylanilinoacetaldehyde with the elimination of benzaldehyde, and then isomerization yields the stable 9,10-dihydro-9-acridinylidene compound **13**. The formation of **13** from **12** strongly supported the assigned structure **12**.

Although hydrolysis of 4-isoxazoline **11a** under similar conditions afforded **13** and benzaldehyde, this result may be understood in terms of an initial isomerization of **11a** to **12a**, followed by hydrolysis of **12a**.

Experimental

All the melting points are uncorrected. The NMR spectra were determined with a Hitachi R-20 Model spectrometer, with TMS as the internal standard. The IR spectra were measured as KBr disks, and the mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV.

*Reaction of 9-Vinylacridine (**1**) with* C,N-*Diphenylnitrone (**3a**).* A solution of **1**[19] (1.0 g) and **3a** (1.0 g) in xylene (10 ml) was refluxed under a stream of nitrogen for 1.5 h. Then, the reaction mixture was evaporated *in vacuo*, and the residue was chromatogaphed on alumina using benzene as the eluent, giving 0.32 g (11%) of 5-(9-acridinyl)-2,3-diphenylisoxazolidine (**4a**), mp 188—189 °C, as pale yellow needles, and 20 mg (1%) of 9-acridinyl styryl ketone (**5a**), mp 258 °C (lit,[1] mp 258 °C), as pale yellow prisms. The NMR spectrum ($CDCl_3$) of **4a**: δ ppm 2.93 (1H, ddd, 4-**H** (*cis*), J=9, 12, and 13 Hz), 3.3 (1H, ddd, 4-**H** (*trans*), J=7, 9, and 13 Hz), 5.15 (1H, t, 3-**H**, J=9 Hz), 6.55 (1H, dd, 5-**H**, J=7 and 12 Hz), 7.0—8.7 (18H, m, aromatic protons). Mass spectrum: *m/e* 402 (M^+). Found: C, 84.81; H, 5.61; N, 6.01%. Calcd for $C_{28}H_{22}N_2O \cdot C_6H_6$: C, 84.97; H, 5.87; N, 5.83%.

Similarly, the reaction of **1** with C-*p*-anisyl-N-phenylnitrone (**3b**) afforded 5-(9-acridinyl)-3-(*p*-anisyl)-2-phenylisoxazolidine (**4b**), mp 202—203 °C, as pale yellow prisms in 11% yield. NMR spectrum ($CDCl_3$): δ ppm 2.9, 3.3 (each 1H, m, 4-**H**), 3.85 (3H, s, OC**H**$_3$), 4.92 (1H, dd, 3-**H**, J=6 and 9 Hz), 6.8—8.8 (18H, m, >C**H** and aromatic protons). Mass spectrum: *m/e* 416 (M^+). Found: C, 83.64; H, 5.80; N, 6.93%. Calcd for $C_{29}H_{24}N_2O$: C, 83.47; H, 5.94; N, 7.15%.

On the other hand, the reaction of **1** with *C-p*-chlorophenyl-(**3c**) or *C-p*-nitrophenyl-*N*-phenylnitrone (**3d**) for 0.5 h under similar conditions afforded only the corresponding styryl ketone **5c** or **5d** in 27 or 13% yield respectively. The styryl ketones **5c** and **5d** were identical with the authentic samples prepared from the reaction of 9-acetylacridine with *p*-chloro- and *p*-nitrobenzaldehyde in the presence of sodium hydroxide in ethanol.

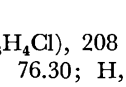
9-Acridinyl *p*-chlorostyryl ketone (**5c**): mp 241—241 °C, yellow prisms. IR spectrum: 1680 cm^{-1} (C=O). Mass spectrum: *m/e* 345, 343 (M^+). Found: C, 77.17; H, 4.04; N, 4.17%. Calcd for $C_{22}H_{14}NOCl$: C, 76.86; H, 4.08; N, 4.08%.

9-Acridinyl *p*-nitrostyryl ketone (**5d**): mp 284 °C, yellow prisms. IR spectrum: 1680 cm^{-1} (C=O). Mass spectrum: *m/e* 354 (M^+). Found: C, 74.80; H, 3.80; N, 7.91%. Calcd for $C_{22}H_{14}N_2O_3$: C, 74.56; H, 3.98; N, 7.91%.

*Thermal Decomposition of Isoxazolidine **4b**.* A solution of **4b** (0.1 g) in xylene (10 ml) was refluxed under a stream of nitrogen for 2 h. Then, the mixture was evaporated *in vacuo* to leave yellow crystals, which on recrystallization from benzene gave 80 mg (*ca.* 100%) of 9-acridinyl *p*-methoxystyryl ketone (**5b**), mp 200—201 °C, as pale yellow prisms. This compound was identical with the authentic sample prepared from 9-acetylacridine and *p*-anisaldehyde. Found: C, 82.55; H, 5.02; N, 3.94%. Calcd for $C_{23}H_{17}NO_2$: C, 82.39; H, 5.05; N, 4.13%.

Similarly, thermal decomposition of isoxazolidine **4a** afforded **5a** quantitatively.

*Hydrolysis of Isoxazolidine **4a**.* A suspension of **4a** (50 mg) in 20% aqueous hydrochloric acid (2 ml) was stirred at room temperature for 1.5 h. Then, the mixture was neutralized with aqueous ammonia to give yellow prisms, which on recrystallization from benzene afforded 30 mg (60%) of 1-(9-acridinyl)-3-(*p*-chloroanilino)-3-phenyl-1-propanol (**6**), mp 216—217 °C, as yellow prisms. IR spectrum: 3200—3400 (OH and NH), 830 cm^{-1}. Mass spectrum: *m/e* 440, 438 (M^+), 422, 420 (M^+-H_2O), 311 ($M^+-H_2NC_6H_4Cl$), 222 (acridinyl–CH–CH_2), 218, 216 (Ph$\overset{+}{C}$HNH–C_6H_4Cl), 208 (9-acridinyl–$\overset{+}{C}$HOH), 205, 193, 178. Found: C, 76.30; H, 5.42; N, 6.06%. Calcd for $C_{28}H_{23}N_2OCl$: C, 76.27; H, 5.67; N, 6.35%.



Reaction of N-*(9-Acridinylmethylene)aniline* N-*oxide (**7**) with Styrene (**8a**).* A solution of nitrone **7**[12] (0.2 g) and **8a** (0.1 g) in xylene (3 ml) was refluxed under a stream of nitrogen for 1.5 h. Then, the mixture was evaporated *in vacuo* to leave yellow crystals, which on recrystallization from benzene afforded 50 mg (37%) of 3-(9-acridinyl)-2,5-diphenylisoxazolidine (**9a**), mp 202—203 °C, as pale yellow prisms. NMR spectrum ($CDCl_3$): δ ppm 2.9—3.5 (2H, m, >C**H**), 5.45 (1H, dd, >C**H**, J=6 and 12 Hz), 6.3 (1H, dd, >C**H**, J=10 and 12 Hz), 6.9—8.5 (18H, m, aromatic protons). Mass spectrum: *m/e* 402 (M^+). Found: C, 83.26; H, 5.33; N, 6.67%. Calcd for $C_{28}H_{22}N_2O$: C, 83.55; H, 5.51; N, 6.92%.

Similarly, the reaction of **7** with *p*-chlorostyrene (**8b**) afforded a 41% yield of 3-(9-acridinyl)-5-(*p*-chlorophenyl)-2-phenylisoxazolidine (**9b**), mp 205—206 °C, as pale yellow needles. NMR spectrum ($CDCl_3$): δ ppm 2.6—3.4 (2H, m, >C**H**), 5.4 (1H, dd, >C**H**, J=5 and 13 Hz), 6.1—6.4 (1H, m, >C**H**), 6.7—8.5 (17H, m, aromatic protons). Mass spectrum: *m/e* 438, 436 (M^+). Found: C, 76.89; H, 4.61; N, 6.65%. Calcd for $C_{28}H_{21}N_2OCl$: C, 76.97; H, 4.81; N, 6.14%.

*Hydrolysis of Isoxazolidine **9a**.* A suspension of **9a** (0.25 g) in 20% aqueous hydrochloric acid (10 ml) was

stirred at 90 °C for 1 h. The mixture was neutralized with aqueous ammonia to give yellow crystals, which on recrystallization from a mixture of benzene and petroleum ether (bp 60—85 °C) afforded 0.17 g (68%) of 3-(9-acridinyl)-3-(*p*-chloroanilino)-1-phenyl-1-propanol (**10**), mp 112—113 °C, as yellow prisms. IR spectrum: 3200—3400 (OH and NH), 830 cm^{-1}. Mass spectrum: *m/e* 440, 438 (M^+), 422, 420 (M^+-H_2O), 319, 317 ($M^+-PhCH(OH)CH_2$), 206, 204, 193, 178. Found: C, 78.80; H, 5.58; N, 5.58%. Calcd for $C_{28}H_{23}N_2OCl\cdot C_6H_6$: C, 78.99; H, 5.61; N, 5.42%.

*Reaction of 9-Ethynylacridine (**2**) with* C,N-*Diphenylnitrone (**3a**).* A solution of **2**[16] (1.0 g) and **3a** (1.0 g) in ethanol (20 ml) containing concd hydrochloric acid (0.02 ml) was stirred at room temperature for 10 min. Filtration gave yellow crystals, which were washed with ethanol (20 ml×3) to leave 4-(9-acridinyl)-2,3-diphenyl-4-isoxazoline (**11a**), mp 115—116 °C (dec), as pale yellow prisms. Isoxazoline **11a** was subjected to microanalysis without further purification. NMR spectrum (CS_2): δ ppm 5.83 (1H, d, >C**H**, J= 2 Hz), 6.83 (1H, d, >C**H**, J=2 Hz), 7.0—8.1 (18H, m, aromatic protons). Mass spectrum: *m/e* 400 (M^+). Found: C, 83.77; H, 5.24; N, 6.71%. Calcd for $C_{28}H_{20}N_2O$: C, 83.97; H, 5.03; N, 7.00%.

The results of other reactions under varying amounts of hydrochloric acid are shown in Table 1.

Similarly, the reaction of **2** with *C-p*-anisyl- (**3b**) and *C-p*-chlorophenyl-*N*-phenylnitrone (**3c**) gave the corresponding 4-isoxazolines **11b**, mp 119 °C (dec), **11c**, mp 85—86 °C (dec), in 73 and 41% yields respectively.

4-(9-Acridinyl)-3-(*p*-anisyl)-2-phenyl-4-isoxazoline (**11b**). NMR spectrum (CS_2): δ ppm 3.51 (3H, s, OCH_3), 5.8 (1H, d, >C**H**, J=2 Hz), 6.8 (1H, d, =C**H**, J=2 Hz), 6.4—8.1 (17H, m, aromatic protons). Mass spectrum: *m/e* (M^+). Found: C, 81.09; H, 5.09; N, 6.30%. Calcd for $C_{29}H_{22}N_2O$: C, 80.90; H, 5.15; N, 6.51%.

4-(9-Acridinyl)-3-(*p*-chlorophenyl)-2-phenyl-4-isoxazoline (**11c**). NMR spectrum (CS_2): δ ppm 5.82 (1H, d, >C**H**, J=2 Hz), 6.84 (1H, d, =C**H**, J=2 Hz), 6.6—8.1 (17H, m, aromatic protons). Mass spectrum: *m/e* 436, 434 (M^+). Found: C, 77.16; H, 4.37; N, 6.34%. Calcd for $C_{28}H_{19}N_2OCl$: C, 77.16; H, 4.16; N, 6.05%.

*Thermal Isomerization of 4-Isoxazoline **11a**.* A solution of **11a** (0.2 g) in benzene (5 ml) was refluxed for 5 min. Then, the mixture was evaporated *in vacuo* to leave orange crystals, which on recrystallization from petroleum ether (bp 60—85 °C) afforded 0.14 g (70%) of 4-(9-acridinyl)-2,3-diphenyl-4-oxazoline (**12a**), mp 142—143 °C (dec), as orange prisms. NMR spectrum (CS_2): δ ppm 6.6—8.1 (18H, m, aromatic protons), 8.6, 8.73 (each 1H, d, J= 2 Hz). Mass spectrum: *m/e* 400 (M^+), 371 (M^+-CHO), 323 (M^+-Ph), 294 ($M^+-PhCHO$), 281 (9-acridinyl-$C\equiv\overset{+}{N}$-Ph, base peak). Found: C, 84.26; H, 4.93; N, 6.83%. Calcd for $C_{28}H_{20}N_2O$: C, 83.97; H, 5.03; N, 7.00%.

Similarly, other 4-isoxazolines **11b** and **11c** were easily isomerized into the corresponding 4-oxazolines. 4-(9-Acridinyl)-2-(*p*-anisyl)-3-phenyl-4-oxazoline (**12b**), mp 168 °C (dec), as orange prisms (from petroleum ether). Yield, 85%. NMR spectrum (CS_2): δ ppm 3.81 (3H, s, OCH_3), 6.6—8.2 (17H, m, aromatic protons), 8.64, 8.75 (each 1H, d, J=2 Hz). Mass spectrum: *m/e* 430 (M^+), 401 (M^+-CHO), 323 ($M^+-MeOC_6H_4$), 294 ($M^+-MeOC_6H_4CHO$), 281 (base peak). Found: C, 80.90; H, 4.99; N, 6.36%. Calcd for $C_{29}H_{20}N_2O_2$: C, 80.90; H, 5.15; N, 6.51%.

4-(9-Acridinyl)-2-(*p*-chlorophenyl)-3-phenyl-4-oxazoline (**12c**), mp 114—115 °C (dec), as orange prisms (from benzene). Yield, 50%. NMR spectrum (CS_2): δ ppm 6.6—8.2 (17H, m, aromatic protons), 8.55, 8.68 (each 1H, d, J= 2 Hz). Mass spectrum: *m/e* 436, 434 (M^+), 407, 405 (M^+-CHO), 323 ($M^+-ClC_6H_4$), 294 ($M^+-ClC_6H_4CHO$), 281 (base peak). Found: C, 78.25; H, 4.81; N, 5.75%. Calcd for $C_{28}H_{19}N_2OCl\cdot 1/2C_6H_6$: C, 78.48; H, 4.62; N, 5.91%.

*Hydrolysis of 4-Oxazoline **12b**.* A solution of **12b** (0.3 g) in ethanol (5 ml) was stirred with 20% hydrochloric acid (5 ml) at room temperature for 2 h, and then the mixture was neutralized with aqueous ammonia. Filtration gave violet crystals, which on recrystallization from chloroform afforded 0.21 g (96.7%) of (9,10-dihydro-9-acridinylidene)-anilinoacetaldehyde (**13**), mp 192—193 °C, as violet prisms. UV spectrum (EtOH): λ_{max} nm (log ε) 252 (4.9), 362 (3.8), 380 (3.9), 399 (3.8), 523 (3.1). Found: C, 80.50; H, 5.04; N, 8.98%. Calcd for $C_{21}H_{16}N_2O$: C, 80.75; H, 5.16; N, 8.97%.

From the filtrate *p*-anisaldehyde was identified as its 2,4-dinitrophenylhydrazone.

Similarly, hydrolysis of 4-oxazolines **12a** and **12c** gave **13** and the corresponding benzaldehydes.

Oxidation of 4-Alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes: Formation of 4-Alkyl-2,6-di-*t*-butylnitrobenzenes *via* Iminoxyl Radical

Yoshio INAGAKI, Renji OKAZAKI, and Naoki INAMOTO

(Received December 19, 1975)

Reactions of 4-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**1**) with silver(I) oxide afforded 4-alkyl-2,6-di-*t*-butylnitrobenzenes (**2**) mainly, which were found to be formed *via* an iminoxyl radical on the base of the ESR spectra and by-products, 4-alkyl-1-*t*-butoxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**3**). This reaction is a novel oxidative decomposition of iminoxyl radical and provides a practical preparative method for the nitrobenzenes (**2**). Oxidation of **1** with other reagents (nickel peroxide and *m*-chloroperbenzoic acid) and oxidation of 6-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadienes (**5**) have also been described.

Although many iminoxyl radicals have been studied by means of ESR, there have been only two examples of iminoxyl radicals which were so stable as to be isolated.[1,2] We attempted to prepare and isolate another type of stable iminoxyl radicals by hydrogen abstraction from highly sterically hindered oximes, 4-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**1**) which were prepared from 2,4,6-tri-*t*-butylnitroso-[3a] and -nitrobenzenes.[3b] Intermediary iminoxyl radical was observed by ESR, but could not be isolated because of further reaction. We describe here the novel oxidative decomposition of the iminoxyl radical found during this attempt and the usefulness of this reaction as a preparative method for 4-alkyl-2,6-di-*t*-butylnitrobenzenes (**2**).[4]

Oxidation with Silver(I) Oxide or Nickel Peroxide. The reaction of the oxime (**1**) with excess silver(I) oxide or nickel peroxide[5] in benzene at room temperature gave 4-alkyl-2,6-di-*t*-butylnitrobenzene (**2**) mainly, along with 4-alkyl-1-*t*-butoxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**3**) and 2,4,6-tri-*t*-butylnitrobenzene (**4**) as minor products. The yields of the products and reaction conditions are summarized in Table. The products were isolated by means of thin layer chromatography (TLC) and characterized by their spectral and analytical data except for **2d** where the pure specimen free from **4** has not been obtained owing to the similar R_f value of **2d** and **4**, and the yield was determined by means of high speed liquid chromatography with a UV detector assuming that both **2d** and **4** have the same molar extinction coefficient at 254 nm.

There has been no practical method for the synthesis of 1-substituted 4-alkyl-2,6-di-*t*-butylbenzenes except for phenols and their derivatives:[6] the preparation of nitrobenzenes (**2**) by nitration of the corresponding hydrocarbons is very difficult owing to the bulky *t*-butyl groups, and for example, Mhyre *et al.* reported that nitration of 3,5-di-*t*-butyltoluene affords the corresponding 2- and 4-nitro derivatives in 98.5 and 1.5% yields respectively.[7] Therefore, the present reaction provides a convenient method for the synthesis of **2**. Furthermore, in view of a key role of a nitro group in synthetic chemistry, this reaction might also give an access to other various derivatives.

Similar oxidation of 1-hydroxyimino-6-methyl-2,4,6-tri-*t*-butyl-2,4-cyclohexadiene (**5**) with silver(I) oxide afforded 2,4-di-*t*-butyl-6-methylnitrobenzene (**6**), the corresponding nitrosobenzene (**7**), and 1-*t*-butoxyimino-2,4,6-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**8**) (see Table).

9	**5**		Ag_2O	0.5		**6**(14), **7**(14), **8**(16)

a) Reaction in a degassed system. b) *m*-Chloroperbenzoic acid. c) 1-Adamantyl group.

ESR Study of the Reaction. During the reactions of **1** with a defficient amount of nickel peroxide (Ni-PO), lead(IV) dioxide (PbO_2), or silver(I) oxide (Ag_2O), a strong ESR signal (Type A; a_N=32 G, a_H=4 G, g=2.006) was recorded irrespective of the 4-substituent (Fig. 1). This signal was identical with that observed in the reaction of **1** with photo-excited benzophenone,[8] which has been reported to be an excellent reagent for the formation of an iminoxyl radical from an oxime.[9] Therefore, Type A signal is assignable to the corresponding iminoxyl radical (**9**). The signal was so stable that the intensity was not reduced even after a day at room temperature under air. The line shape varied reversibly with temperature (Fig. 2), and this may be ascribed to a conformational change. The line shape was also changed by the solvent (Fig. 2).

When an excess amount of Ni-PO, PbO_2, or Ag_2O, was used, Type A signal was recorded at first, but the signal rapidly decreased in its intensity and changed into a signal due to another iminoxyl radical (Type B; a_N=32 G, g=2.006) (Fig. 3), whose structure remains unknown.

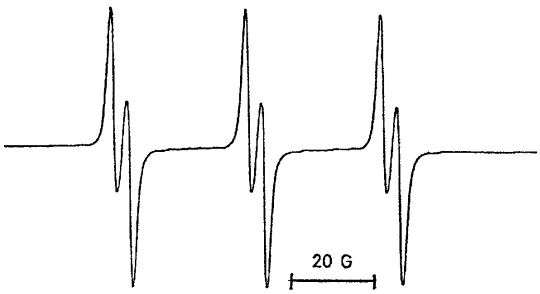

Fig. 1. Type A signal obtained by the reaction of **1b** with Ni-PO in benzene at room temperature.

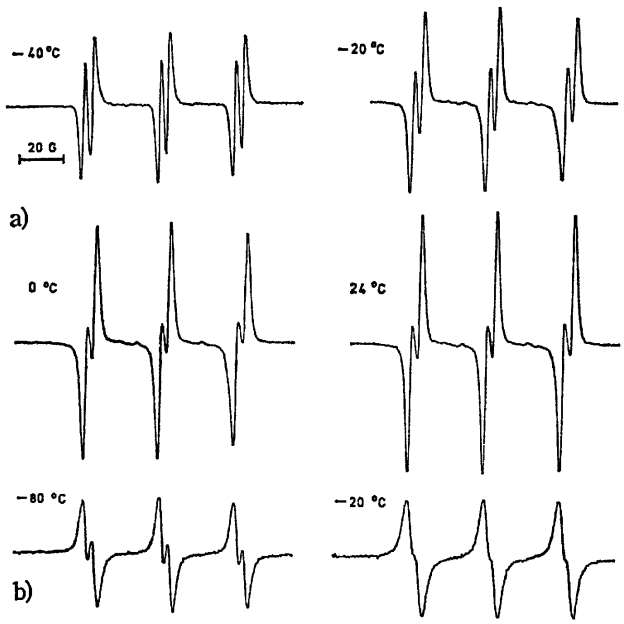

Fig. 2. Temperature and solvent dependence of the line shape of Type A signal: a) **1b**+photoexcited benzophenone in CH_2Cl_2, b) **1b**+photoexcited benzophenone in hexane.

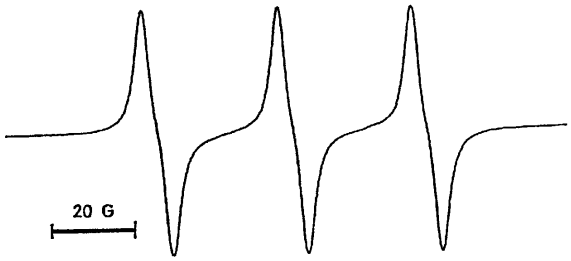

Fig. 3. Type B signal obtained by the reaction of **1c** with an excess amount of Ni-PO in hexane at room temperature.

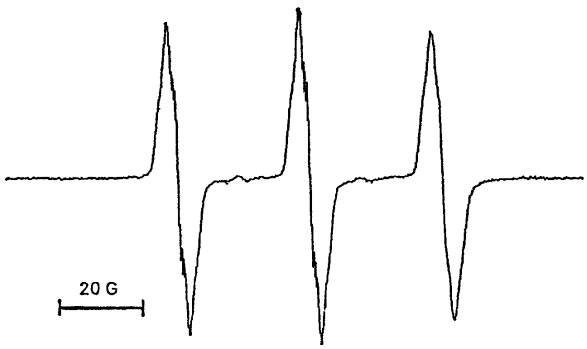

Fig. 4. Type C signal obtained by the reaction of **5** with photoexcited benzophenone in CH_2Cl_2 at −84 °C.

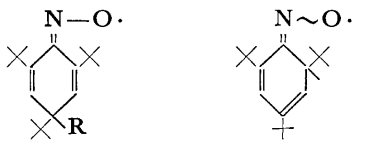
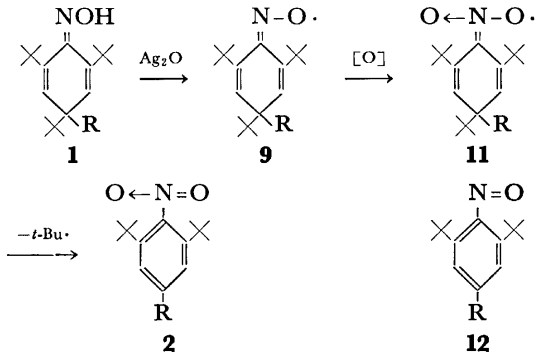
On the other hand, Type C signal (a_N=32 G, g=2.006) (Fig. 4) was observed during the oxidation of oxime (**5**) with photo-excited benzophenone and this may be assigned to the iminoxyl radical (**10**). Reaction of oxime (**5**) with excess Ni-PO, PbO_2, or Ag_2O gave a signal similar to Type B signal (a_N=32 G, g=2.006).

The iminoxyl radical (**9**) showed a splitting due to one of the protons on the 3- or 5-position; such a long range coupling is characteristic of iminoxyl radicals[10] and often observed in σ-radicals.[11] It is interesting that the iminoxyl radical (**10**) did not show any such splitting due to the ring proton.



9 **10**

Reaction Mechanism. The nitrobenzenes (**2**) are considered to be formed *via* the initially produced iminoxyl radicals (**9**) in the following manner.



This pathway is supported by the observation of a strong ESR signal due to **9**, which was destroyed by excess oxidizing agents, and the formation of the oxime ether (**3**) by the combination between **9** and *t*-butyl radical.

An alternative route *via* 4-alkyl-2,6-di-*t*-butylnitrosobenzene (**12**), which might be formed by the elimination of a *t*-butyl radical from **9** can be ruled out, because 2,4,6-tri-*t*-butylnitrosobenzene was never oxidized into **4** by Ni-PO or Ag_2O at room temperature even after a day.

We consider a similar mechanism can also be applied to the oxidation of **5**. In this case, however, elimination of *t*-butyl radical from the initially formed iminoxyl radical (**10**) also took place as suggested by the formation of a considerable amount of 2,4-di-*t*-butyl-6-methylnitrosobenzene (**7**).

The source of the oxygen which is responsible for the oxidation of **1** into **2** remains obscure: although involvement of stubbornly adsorbed oxygen may be possible, the oxygen seems to stem from the silver(I) oxide, because **9** is fairly stable even under air as suggested by before-mentioned ESR spectroscopy, also because the formation of **2** was still observed even in the degassed solvent and with degassed silver(I) oxide. The reaction of **1b** in a degassed system (No. 3 in Table) afforded also **3b** besides **2b** in contrast to the reaction under air. This formation of **3b** is probably ascribed to the prolonged life times of **9b** and the eliminated *t*-butyl radicals in the absence of oxygen. Therefore, it seems preferable to carry out the reaction in the presence of atmospheric oxygen in order to obtain **2** in a high yield.

This reaction is a novel type of fragmentation of iminoxyl radicals and the first example of the formation of nitro compound in silver(I) oxide oxidation of oximes. This unusual reaction is ascribable to the following two reasons: first, the bulky *t*-butyl groups on **9** make a barrier against intermolecular coupling which is a main decomposition pathway in usual iminoxyl radicals; secondly, an inclination of the cyclohexadienone oxime system to aromatize by an elimination of the bulky *t*-butyl group favours the reaction energetically.

In the cases of **1a** and **1b**, the selective elimination of the *t*-butyl group took place, while in the cases of **1c** and **1d**, a considerable amount of **4** which represents the elimination of benzyl or 1-adamantyl group, respectively, was obtained. These facts imply that the elimination of 1-adamantyl radical which is less stable than *t*-butyl radical[12] competed with that of *t*-butyl radical, and that the elimination of *t*-butyl radical was favorable over that of benzyl radical although the latter is more stable than the former. Therefore, it is concluded that the more bulky group is selectively eliminated, although elimination of a small group can competitively occur if it is more stable as a free radical than a bulky group.

Oxidation with m-*Chloroperbenzoic Acid.* The reaction of **1** with *m*-chloroperbenzoic acid is interesting, because it is expected that the reaction is initiated by heterolytic oxidation of the nitrogen of the oxime, suggesting elimination of *t*-butyl group as a cation. Thus there must be some differences in the reaction products compared with the silver(I) oxide oxidation. The reaction afforded similar products to those obtained in the silver(I) oxide oxidation (Table), but the product ratio **2d**/**4** was inversed. Although the yields of the nitro compounds were relatively low, this inversion seems to imply the mechanistic difference between the two reactions.

Experimental

All melting points were not corrected. The IR and UV spectra were recorded with Hitachi EPI-G2 and EPS-3 spectrophotometers respectively. The NMR spectra were measured with a Hitachi R-24 (60 MHz) spectrometer using tetramethylsilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6L mass spectrometer. The ESR spectra were recorded with a JEOL JES-ME spectrometer and *g* values were determined on the basis of Mn^{2+} marker. Solvents were not degassed unless otherwise noted.

Materials. 4-Alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**1**),[3] 1-hydroxyimino-2,4,6-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**5**),[3] 2,4,6-tri-*t*-butylnitrosobenzene,[13] 2,4-di-*t*-butyl-6-methylnitrosobenzene (**7**),[13] 2,4,6-tri-*t*-butylnitrobenzene (**4**),[14] and 2,4-di-*t*-butyl-6-methylnitrobenzene (**6**)[14] were prepared by the reported methods.

*Oxidation of 1-Hydroxyimino-2,4,6-tri-t-butyl-4-ethyl-2,5-cyclohexadiene (**1a**) with Silver(I) Oxide.* To a suspension of a few hundred miligrams of silver(I) oxide in 2 ml of benzene was added a benzene solution (2 ml) of 40.4 mg (0.132 mmol) of **1a**. After the mixture was stirred for 24.5 h at room temperature, the insoluble part was filtered off. After removal of the solvent from the filtrate, the residue was treated with TLC (silica gel, hexane–benzene (4 : 1)), and each fraction was eluted with ether. The first fraction (R_f=0.83) gave 8.0 mg (17%) of 1-*t*-butoxyimino-2,4,6-tri-*t*-butyl-4-ethyl-2,5-cyclohexadiene (**3a**) as a tarry material, which was purified by TLC (silica gel, hexane) followed by molecular distillation. IR (neat): 965 cm^{-1} (NO); NMR (CCl_4): δ 0.65 (t, J=7 Hz, 3H), 0.82 (s, 9H), 1.22 (s, 9H), 1.28 (s, 9H), 1.32 (s, 9H), 1.65 (q, J=7 Hz, 2H), and 5.75 (ABq, $\Delta\delta$=0.13, J=2 Hz, 2H); λ_{max} (hexane): 258 nm (ε 5940); MS: *m/e* 304 (M−57, 32%) and 57 (100%).

The second fraction (R_f=0.67) gave 19.3 mg (56%) of **2a** which was recrystallized four times from aqueous methanol, mp 100.5—101.5 °C; IR (KBr): 1525 and 1375 cm^{-1} (NO_2); NMR (CCl_4): δ 1.31 (t, J=7 Hz, 3H), 1.42 (s, 18H), 2.70 (q, J=7 Hz, 2H), and 7.23 (s, 2H); λ_{max} (hexane): 247 (ε 960) and 348.5 nm (180); MS: *m/e* 263 (M^+, 19%) and 248 (100).

Found: C, 72.84; H, 9.43; N, 5.51%. Calcd for $C_{16}H_{25}NO_2$: C, 73.00; H, 9.51; N, 5.32%.

Another reaction under similar conditions afforded 64% of **2a**.

*Oxidation of 1-Hydroxyimino-2,4,6-tri-t-butyl-4-isopropyl-2,5-cyclohexadiene (**1b**) with Silver(I) Oxide.* Reaction of 50.0 mg (0.156 mmol) of **1b** and a large excess of silver(I) oxide in 4.5 ml of benzene for 24 h followed by treatment with TLC (silica gel, hexane–benzene (4 : 1)), afforded 41.6 mg (96%) of 2,6-di-*t*-butyl-4-isopropylnitrobenzene (**2b**) as white crystals (R_f=0.78—0.61), which were recrystallized twice from aqueous methanol, mp 101—103 °C; IR (KBr): 1525 and 1370 cm^{-1} (NO_2); NMR (CCl_4): δ 1.25 (d, J=7 Hz, 6H), 1.35 (s, 18H), 2.88 (sep, J=7 Hz, 1H),

and 7.21 (s, 2H); λ_{max} (hexane): 246 sh (ε 1740) and 340 nm (350); MS: *m/e* 277 (M^+, 17%) and 262 (100). Crude material showed a peak at *m/e* 291 (trace) which indicates the contamination of trace of 2,4,6-tri-*t*-butylnitrobenzene (**4**).

Found: C, 73.68; H, 9.68; N, 4.98%. Calcd for $C_{17}H_{27}NO_2$: C, 73.65; H, 9.75; N, 5.05%.

*Reaction of **1b** with Silver(I) Oxide in Degassed System.* A few hundred miligrams of silver(I) oxide in 3.5 ml of dry benzene was degassed four times, and a solution of 44.3 mg (0.139 mmol) of **1b** in 0.5 ml of dry benzene was added under argon atmosphere. After the mixture was stirred for 24.5 h at room temperature, the insoluble part was filtered off. The filtrate was evaporated *in vacuo* and treated with TLC (silica gel, hexane–benzene (4 : 1)). A fraction with R_f of 0.78 gave 6.8 mg (13%) of 1-*t*-butoxyimino-2,4,6-tri-*t*-butyl-4-isopropyl-2,5-cyclohexadiene (**3b**) as colorless oil, IR (neat): 975 cm^{-1} (NO); NMR (CCl_4): δ 0.90 (s, 9H), 1.22 (s, 9H), 1.29 (s, 9H), 1.32 (s, 9H), 5.89 (ABq, $\Delta\delta$=0.15, J=2 Hz, 2H), and the signals due to the isopropyl group were obscure; λ_{max} (hexane): 259 nm (ε 7590); MS: *m/e* 318 (M−57, 23%) and 57 (100),

Found: C, 80.00; H, 12.36; N, 3.69%. Calcd for $C_{25}H_{45}NO$: C, 79.93; H, 12.08; N, 3.92%.

A fraction with R_f of 0.5 gave 21.6 mg (56%) of **2b**, which was identified by the IR and NMR spectra.

*Reaction of **1b** with Nickel Peroxide.* Reaction of **2b** (60.7 mg, 0.190 mmol) with a large excess of nickel peroxide in 5 ml of benzene for 22.3 h at room temperature followed by treatment with TLC (silica gel, hexane–benzene (4 : 1)) gave 18.6 mg (37%) of **2b**.

*Reaction of 1-Hydroxyimino-4-benzyl-2,4,6-tri-t-butyl-2,5-cyclohexadiene (**1c**) with Silver(I) Oxide.* Reaction of **1c** (46.2 mg, 0.126 mmol) and a large excess of silver(I) oxide in 4 ml of benzene for 24.5 h at room temperature followed by TLC (silica gel, hexane–benzene (4 : 1)) afforded the following compounds. The first fraction (R_f=0.89) gave 5.0 mg (9%) of 1-*t*-butoxyimino-4-benzyl-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (**3c**) as white crystals, which were recrystallized from aqueous methanol, mp 107—109 °C; IR (KBr): 750 cm^{-1} (NO); NMR (CCl_4): δ 0.91 (s, 9H), 0.98 (s, 9H), 1.19 (s, 9H), 1.27 (s, 9H), 2.93 (s, 2H), 5.89 (s, 2H), and 7.12 (s, 5H); λ_{max} (hexane): 259 nm (ε 9540); MS: *m/e* 366 (M−57, 21%) and 57 (100).

Found: C, 82.34; H, 11.09; N, 3.34%. Calcd for $C_{29}H_{45}NO$: C, 82.21; H, 10.71; N, 3.30%.

A fraction with R_f of 0.72 gave 3.9 mg (10%) of **4**. A fraction with R_f of 0.56 afforded 22.7 mg (55%) of 4-benzyl-2,6-di-*t*-butylnitrobenzene (**2c**) as white crystals, mp 110—112 °C (from aqueous methanol); IR (KBr): 1525 and 1375 cm^{-1} (NO_2); NMR (CCl_4): δ 1.32 (s, 18H), 3.95 (s, 2H), and 7.1—7.3 (m, 7H); λ_{max} (hexane): 249 (ε 1380), 254.5 (1380), 259 (1330), 262 sh (1250), 265 sh (1140), 269.5 (1202), and 345 nm (200); MS: *m/e* 325 (M^+, 29%) and 310 (100).

Found: C, 77.40; H, 8.58; N, 4.41%. Calcd for $C_{21}H_{27}NO_2$: C, 77.50; H, 8.37; N, 4.31%.

Another reaction under similar condition afforded **2c** (68) and **3c** (16%).

*Reaction of 1-Hydroxyimino-4-(1-adamantyl)-2,4,6-tri-t-butyl-2,5-cyclohexadiene (**1d**) with Silver(I) Oxide.* Reaction of **1d** (21.9 mg, 0.053 mmol) with a large excess of silver(I) oxide in benzene (2 ml) for 21 h at room temperature followed by treatment with TLC (silica gel, hexane–benzene (4 : 1)) gave 13.5 mg of white crystalline material, which was a mixture of **4** and 4-(1-adamantyl)-2,6-di-*t*-butylnitrobenzene (**2d**). The molar ratio was determined to be 1 : 2.3 (**4**; 26%, **2d**; 48%) by means of high speed liquid chromatography (styrene–divinylbenzene copolymer, methanol–aqueous ammonia (1%)) with a UV detector assuming that both **4** and **2d** have the same molar extinction coefficient at 254 nm. The spectral data of the mixture were as follows, IR (KBr): 1525 and 1380 cm^{-1} (NO_2); NMR (CCl_4): δ 1.37 (s, 18H), 1.78 (m, 15H), 7.32 (s, 2H), and signals due to **4**; MS: *m/e* 369 (M^+ of **2d**, 13%), 354 (53), 291 (M^+ of **4**, 8), 276 (55), 135 (Ad^+, 32), and 57 (100).

*Reaction of 1-Hydroxyimino-4-benzyl-2,4,6-tri-t-butyl-2,5-cyclohexadiene (**1c**) with m-Chloroperbenzoic Acid.* A dichloromethane solution (4 ml) of **1c** (50.0 mg, 0.14 mmol) and 98.1 mg (0.74 mmol) of *m*-chloroperbenzoic acid was stirred for 24 h at room temperature. Subsequently, the reaction mixture was shaken with an aqueous sodium hydrogen carbonate and extracted with dichloromethane. The extract was washed with water and dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was treated with TLC (silica gel, hexane–benzene (4 : 1)). A fraction with R_f of 0.63—0.51 gave 14.8 mg (37%) of consumed **1c** of **2c**. From a fraction with R_f of 0.26—0.17, 5.8 mg (11.6%) of **1c** was recovered.

*Reaction of 1-Hydroxyimino-4-(1-adamantyl)-2,4,6-tri-t-butyl-2,5-cyclohexadiene (**1d**) with m-Chloroperbenzoic Acid.* A dichloromethane solution (4 ml) of *m*-chloroperbenzoic acid (132 mg, 0.765 mmol) and **1d** (48.2 mg, 0.117 mmol) was stirred for 22.5 h at room temperature. Usual work-up afforded 13.5 mg of white crystals, which were a mixture of **4** and **2d** according to the NMR and IR spectra, and the yields were calculated to be 28 and 10% respectively.

*Reaction of 1-Hydroxyimino-2,4,6-tri-t-butyl-6-methyl-2,4-cyclohexadiene (**5**) with Silver(I) Oxide.* A mixture of **5** (134.4 mg, 0.46 mmol) and a large excess of silver(I) oxide in 8 ml of benzene was stirred for 35 min at room temperature. The mixture was worked up as usual and treated with TLC (silica gel, hexane–benzene (4 : 1)). A fraction with R_f of 0.86–0.72 afforded 26.1 mg (16%) of 1-*t*-butoxyimino-2,4,6-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**8**) as white crystals, mp 76—79 °C (from aqueous methanol); IR (KBr): 970 cm^{-1} (NO); NMR (CCl_4): δ 0.86 (s, 9H), 1.09 (s, 9H), 1.31 (s, 18H), 1.55 (s, 3H), 5.20 (d, J=2 Hz, 1H), and 6.13 (d, J=2 Hz, 1H); λ_{max} (hexane): 314 nm (ε 6400); MS: *m/e* 290 (M^+−*t*-Bu, trace), 204 (75%), 57 (94), and 41 (100). Fraction (R_f=0.50—0.56) and a fraction (R_f=0.39—0.47) afforded 14.8 mg (14%) of 2,4-di-*t*-butyl-6-methylnitrosobenzene (**7**) and 15.9 mg (14%) of 2,4-di-*t*-butyl-6-methylnitrobenzene (**6**) respectively, which were identified by comparing the spectral data with those of the authentic samples.

ESR Measurements. An oxime and an oxidizing agent were mixed in a solvent and transferred into a sample tube directly or in a pyrex capillary just before a measurement. A procedure for a reaction between an oxime and photo-excited benzophenone was as follows: a mixed solution of an oxime and a carbonyl compound whose concentration was controlled to be *ca.* 0.1 mol/l for the oxime and *ca.* 0.05 mol/l for benzophenone, was placed in a pyrex capillary, which was transferred into a sample tube and irradiated with a high pressure mercury lamp in a cavity of ESR spectrometer.

Vapor-Phase Photolysis of *cis*-Cyclononene

Yoshihisa INOUE,* Setsuo TAKAMUKU, and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received September 12, 1975)

Synopsis. Direct and sensitized photolyses of *cis*-cyclononene (**1c**) vapor were investigated. The direct irradiation of **1c** gave 1,8-nonadiene(**2**) and vinylcycloheptane *via* the thermally-activated ground state produced by rapid internal conversion from the excited singlet state initially generated. On the other hand, the sensitized photolysis of **1c** gave **2** and five bicyclononanes, which are interpreted in terms of intramolecular hydrogen transfer reactions.

We have investigated the direct and sensitized photolyses of alkenes.[1] On direct irradiation in the vapor phase, the excited singlet alkene generated was reported to suffer rapid internal conversion to thermally-activated ground state molecule.[1e,2] On the other hand, the vibrationally-excited triplet alkene produced in vapor-phase photosensitization has been demonstrated to undergo intramolecular hydrogen transfer reactions[1a,d,f] along with the well-known *cis-trans* isomerization and allylic bond cleavage.[3] As for the photochemistry of cycloalkenes, little is known of the photochemical behavior of medium-ring alkenes, although considerable study has been made of the sensitized photolysis of common-ring alkenes.[4] We wish now to report the results of the direct and sensitized photolyses of cyclononene vapor.

Experimental

All the experiments were carried out at room temperature and under static conditions. The apparatus and basic procedures employed were the same as described previously.[1d,e] The light source of the direct photolysis at 1849 Å was a 30 W low-pressure mercury lamp fitted with a Suprasil envelope. In the sensitized photolyses, radiation from the lamp was filtered by a Toshiba UV-25 filter. The products were analyzed by GLC on a 6 m column of 15% polyethylene glycol-6000 and a 3 m column of 15% tritolyl phosphate. All the products had retention times on GLC identical to those of the authentic specimens or, in the case of *cis*- and *trans*-bicyclo-[5.2.0]nonanes, to those reported in the literature.[5] Attempts for the separation on GLC of *trans*-cyclononene from the *cis*-form were unsuccessful.

Preparation of cis-*Cyclononene (**1c**).* Cyclononanone, prepared from dimethyl azerate according to procedures similar to those described in "Organic Syntheses,"[6,7] was reduced with $LiAlH_4$ to cyclononanol. The alcohol was heated with phosphoric acid to yield *cis*-cyclononene(**1c**), which was purified to 99.5% by preparative GLC.

Preparative Photolysis. The mercury photosensitization of *cis*-cyclononene(**1c**) with 10% nitric oxide was carried out at the pressure of 1.5 Torr for 12 h using the 30 W mercury lamp and a preparative irradiation apparatus which was made up of a 5 l Pyrex vessel, two quartz cells for irradiation, and a thermosiphone for circulation of the gas. Isolation of the products, **2**, **5c** and **6c**, was performed by preparative GLC. The NMR and mass spectra of the products separated above made the identification certain.

*Independent Syntheses of the Authentic Specimens. 1,8-Nonadiene(**2**)* was synthesized by pyrolysis of nonamethylene glycol diacetate at 500 °C according to the method of Marvel and Stile.[8]

*Vinylcycloheptane(**3**)* was synthesized by pyrolysis of **1c** at 800 °C.[9]

cis-*Bicyclo[4.3.0]nonane(**4c**)* was prepared by hydrogenation of indene on Raney nickel W-2 at 180°C for 3 h at the hydrogen pressure of 200 atm in an autoclave.

trans-*Bicyclo[4.3.0]nonane(**4t**)* was prepared by acetone-sensitized photoepimerization of **4c**.[10]

cis-*Bicyclo[6.1.0]nonane(**6c**)* was synthesized by a Simmons-Smith reaction of cyclooctene with diiodomethane in the presence of zinc-copper(II) chloride mixture, according to the procedure described by Rawson and Harrison.[11]

Results and Discussion

The products resulting from the direct and sensitized photolyses of *cis*-cyclononene(**1c**) vapor are shown in Table 1.

On direct photolysis of **1c** at 1849 Å, 1,8-nonadiene (**2**) and vinylcycloheptane(**3**) were obtained as the major products. The formation of **2** and **3** was also observed in the pyrolysis of **1c** at 520—720 °C.[9] The electronically-excited singlet state of simple alkenes has been shown in other systems to undergo rapid internal conversion.[1e,2] Thus, it may be inferred that the electronically-excited singlet of **1c** generated by the direct irradiation suffers rapid internal conversion to a thermally-activated ground state, which gives the products similar to those from the pyrolysis of **1c**. The absence of the bicyclic products, **4**, **5**, and **6**, indicates the low efficiency of the S→T intersystem crossing process, since the photoisomerization to the bicyclic products is characteristic of the triplet species, as shown below in the photosensitization of **1c**.

In sensitized photolysis, mercury and benzene vapor were used as the sensitizers. The products of the photosensitization of **1c** were 1,8-nonadiene(**2**), *cis*- and *trans*-bicyclo[4.3.0]nonanes (**4c** and **4t**), *cis*- and *trans*-bicyclo[5.2.0]nonanes(**5c** and **5t**), and *cis*-bicyclo-[6.1.0]nonane(**6c**), as shown in Table 1. The marked difference in the product distribution between the mercury and benzene sensitizations is attributable to the different triplet energies of the sensitizers; the triplet energies of mercury and benzene are 113 and 84 kcal/mol, respectively. Since the benzene sensitization of **1c** in the liquid phase did not afford any of these products, it is considered that the intermediate

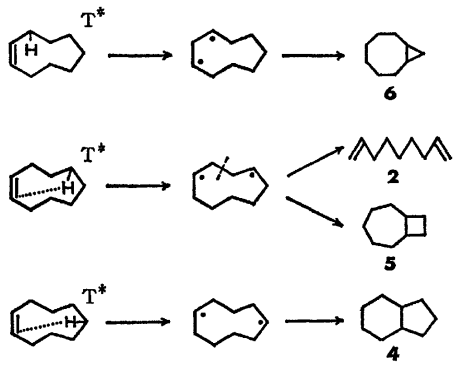
Mercury-sensitization	1.0	2.0	0.07	c)	0.11	0.12	0.54	1.18	0.04
Benzene-sensitization[b]	1.0	30	0.05	c)	0.23	0.08	0.02	0.02	c)

a) A small amount (0.04μmol) of unidentified C_9H_{16} product was also obtained. b) One Torr of benzene vapor was added as the sensitizer. c) Not detected (<0.01μmol). d) Not determined.

involved in the vapor-phase photosensitization is a vibrationally-excited triplet of **1c** and that the vibrational activation in the triplet state enhances the photorearrangement. Similarly to the mechanism shown in the norcarane formation in the mercury photosensitization of cycloheptene,[1b] the formation of **6c** is interpreted in terms of a 1,2-shift of allylic hydrogen followed by ring closure of the resulting 1,3-biradical (Scheme). The intramolecular hydrogen abstractions by the excited C=C double bond *via* two possible six-membered transition states give cyclic 1,4- and 1,6-biradicals, and the subsequent β-cleavage or recombination of the resulting biradicals leads to the products **2**, **5**, and **4**.



Scheme.

It is thus confirmed in this system that the 1,2-shift of allylic hydrogen and the intramolecular hydrogen abstractions *via* six-membered transition states are the main course of the photo-sensitization of simple alkenes in the vapor phase.

Comments on the Energy Calibration in X-Ray Photoelectron Spectroscopy

Shuichi KINOSHITA, Toshiaki OHTA, and Haruo KURODA

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo 113

(Received November 14, 1975)

Synopsis. The change of the contact potential difference between the sample and spectrometer was examined on the adsorbed carbon/Au system by observing the low kinetic energy limit of the X-ray photoelectron spectrum. Discussions are given on the use of the contamination carbon for energy calibration.

In X-ray photoelectron spectroscopy (XPS) of solid materials, the observed kinetic energies of photoelectron peaks are affected not only by the contact potential difference between the sample and spectrometer, but also by the charge-up of sample caused by X-ray irradiation. The latter, called "charging effect", is known to be particularly significant in the case of insulating samples. There are two methods most widely used to calibrate the energies of photoelectron peaks; the one is to use the C 1s peak of "contamination carbon" as the reference, and the other to use the Au $4f_{7/2}$ peak of a very thin gold film deposited on the sample surface.

It has been pointed out by Ascarelli and Missoni[1] that the contact potential difference between the spectrometer and sample under the condition of the measurement of XPS spectrum can be directly known by observing the low kinetic-energy limit of the photoelectron spectrum. This low energy limit can be observed if an appropriate potential difference is externally applied between the sample and spectrometer. When a voltage $V_{ext.}$ is externally applied on the sample against the spectrometer, the following relation is expected,

$$E_k^0 = (\Phi - \Phi_{sp}) - eV_{ext.} \quad (1)$$

where E_k^0 is the observed kinetic energy of the low-energy limit of the photoelectron spectrum, and Φ and Φ_{sp} are the work functions of the sample and spectrometer, respectively. This method provides another way to calibrate the energies of photoelectron peaks.[2]

In the present study, we have examined if the above three calibration methods do provide results consistent with each other. We carried out experiments with McPherson ESCA 36 electron spectrometer employing Al$K\alpha_{1,2}$ (1486.6 eV). We prepared a gold film by evaporating gold onto an aluminum plate within the sample chamber of the spectrometer, and observed the changes in the Au $4f_{7/2}$ peak of the film and the C 1s peak of "contamination carbon".[3] At the same time, we observed the low kinetic energy limit of photoelectron spectrum by applying −50 volt on the sample against the spectrometer. The low kinetic energy limit appeared as a sharp edge, of which position was able to be determined with an accuracy of ±0.03 eV. Throughout the experiment the vacuum of the sample chamber was kept at about 10^{-8} Torr by means of the combined action of a turbomolecular pump and a cryopump.

As shown in Fig. 1, the intensity of C 1s peak of contamination carbon gradually increased with time, which being accompanied by a decrease of the intensity of Au $4f_{7/2}$ peak. These changes ceased after about two hours, and thereafter, the intensities of both peaks remained constant. On the other hand, no trace of C 1s peak was observed during the measurement. Accordingly, the saturation of the growth of C 1s peak is likely to correspond to the complete coverage of the sample surface with adsorbed hydrocarbon. Thus we took the ratio of the C 1s intensity observed at a given time to the intensity at the saturated state as a measure of surface coverage.

From the low kinetic energy limit of photoelectron spectrum, we estimated the contact potential difference $\Delta\Phi$ according to Eq. 1. The change of $\Delta\Phi$ from the initial value is plotted in Fig. 2 against the surface coverage by adsorbed carbon. We note that the

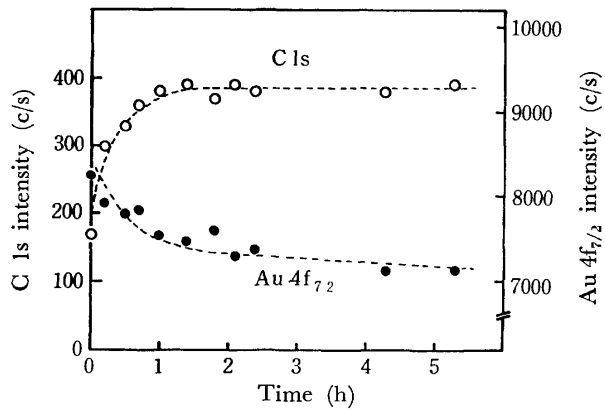

Fig. 1. The variations of the intensities of C 1s and Au $4f_{7/2}$ peaks with time.

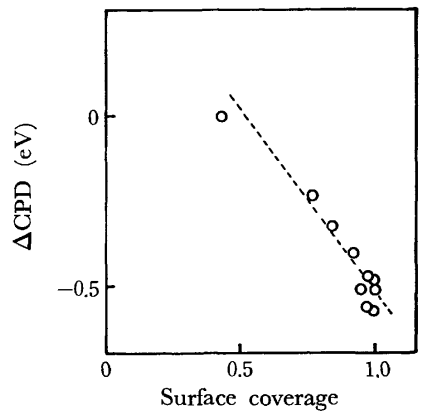

Fig. 2. The relation between the contact-potential-difference change (ΔCPD) and the amount of adsorbed carbon.

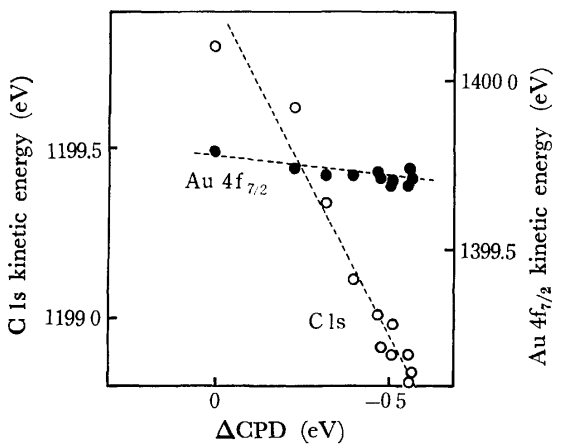

Fig. 3. The dependences of the energies of Au $4f_{7/2}$ and C 1s peaks on the contact-potential-difference.

contact potential difference decreases on increasing the surface coverage. This is consistent with the reported effect of hydrocarbon adsorption on the surface potentials of metals.[4]

In Fig. 3, we have plotted the observed kinetic energies of the C 1s and Au $4f_{7/2}$ peaks against the change of the contact potential difference (CPD). We found that the C 1s peak was shifted to lower kinetic energy linearly depending on the decrease of contact potential difference, whereas the $Au4f_{7/2}$ peak remained almost at the same position.

The above result seems quite reasonable since the Fermi level of the gold film must be little affected by the adsorption of hydrocarbons on its surface while the carbon atoms of the adsorbed layer are under the strong influence of the electrical double layer formed on the surface by the adsorption.

Several conclusion may be derived from the present result. First, the energy of the C 1s peak of "contamination carbon" adsorbed on metal surface can vary depending on the amount of adsorption, consequently its use as the reference of energy calibration seems to be dubious in some cases, especially for metallic samples. Second, the contact potential difference determined from the low kinetic energy limit of photoelectron spectrum, sensitively reflects only the very surface properties, and not necessarily useful to calibrate the energies of the photoelectron peaks associated with the bulk material. One could expect that it might be useful at least for the calibration of the energies of the peaks associated with the adsorbed layer. In this respect, however, it should be noted that, although the observed energy of the C 1s peak of adsorbed carbon was found to be linearly dependent on the change of contact potential difference, its shift was about two times of the value expected from the latter change. This indicates the difficulty in employing the average contact potential difference determined from the low energy limit of photoelectron spectrum even for the purpose of energy calibration of the photoelectron peaks of adsorbed layer. Finally, we wish to point out the possibility that the photoelectron peaks of the bulk material can be distinguished from those of the surface by examining their dependence on the change of contact potential difference as demonstrated by the results shown in the present paper.

Primary Photochemical Process of Sulfur in Solution

Chiho NISHIJIMA,* Nobuaki KANAMARU,** and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received December 27, 1975)

Synopsis. A photochemical intermediate possibly attributed to linear S_8 has been found with a flash-photolysis technique and a rigid-glass technique. The decay behavior of transient in ethanol at room temperature between 10 and 100 ms may be interpreted in terms of the dimerization and polymerization of the linear S_8.

Since a very early work by Lallemand,[1] several groups[2] have studied the phenomenon of photopolymerization of sulfur in solution. Previously, the photoproduct has been explained in terms of allotropes and called "photosulfur". However, no studies on its reaction mechanism and intermediate species have been published so far. In the present work we considered it interesting to study the primary process of the formation of photosulfur in solution by means of a flash photolysis technique as well as a low-temperature UV-irradiation technique.

Experimental

Sulfur (Wako Chemical 99.999%) was recrystallized from carbon disulfide. Low temperature photolysis experiments of sulfur were carried out in EPA glass (2 : 2 : 5) by UV light in the region 250—350 nm using a high-pressure mercury lamp combined with a filter system which consists of an aqueous $NiSO_4$ solution and a Toshiba UV-D25 glass filter. In the low-temperature experiments, absorption spectrum measurements were carried out with a Cary Model 15 spectrophotometer, a quartz cell of 1-cm path length being used. Flash photolysis experiments were carried out with degassed solutions of sulfur in ethanol at room temperature using a flash photolysis apparatus described previously[3] and using a quartz cell of 15 cm long.

Results and Discussion

Sulfur in EPA glass at 77 K shows absorption peaks at 262 and 278 nm ($\varepsilon \approx 6 \times 10^3$ l/mol cm), as shown by Curve 1 in Fig. 1. When an EPA glass containing sulfur (4×10^{-4} M) at 77 K was irradiated by the 250—350 nm light for about 2—3 min, the absorption spectrum shown by Curve 2 was obtained, indicating a new absorption band peaking at 420 nm with an optical density of 0.15 which disappears by warming.[7] Meyer *et al.*[4-6] have recently published the visible absorption bands of S_2, S_3, and S_4 photolytically produced from S_2Cl_2, S_3Cl_2, and S_4Cl_2, respectively, in rigid matrices. The photo-induced 420 nm band in Fig. 1 more or less differs from those of S_2, S_3, and S_4. As far as each S_8 molecule is trapped in EPA glass at 77 K, it may be difficult to consider that a further

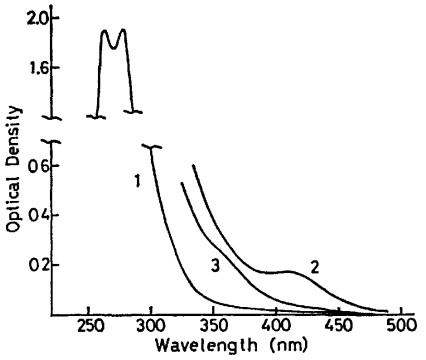

Fig. 1. Electronic absorption spectra before and after the Hg-lamp irradiation of sulfur in EPA glass at 77 K, shown by Curves 1 and 2, respectively. Curve 3 is the spectrum obtained when the irradiated glass was warmed up to room temperature.

dissociation forming $S+S_7$, S_2+S_6, S_3+S_5, or $2S_4$ takes place in the 77-K matrix. Therefore, the photo-induced spectrum (Curve 2, Fig. 1) may be assigned to the linear S_8 biradical formed by ring opening.

$$S_8 \xrightarrow{h\nu} \cdot S_8 \cdot \text{ (linear)} \qquad (1)$$

The flash UV-irradiation of a degassed ethanol solution of sulfur (1×10^{-5} M) at room temperature gave rise to the transient spectra shown in Fig. 2 in which the upper spectra (Curves 1—3) were obtained within about 30 μs after flash, while the lower spectrum was obtained at 10 ms that resembles the low-temperature spectrum (Curve 2, Fig. 1). However, transient spectra taken within about 30 μs are somewhat complicated, suggesting several short-lived transients. Under non-degassed conditions, no transients were detected (possibly because of quenching by oxygen).

The second- and first-order plots of the absorbances of the transients against the time (t) at various wave-

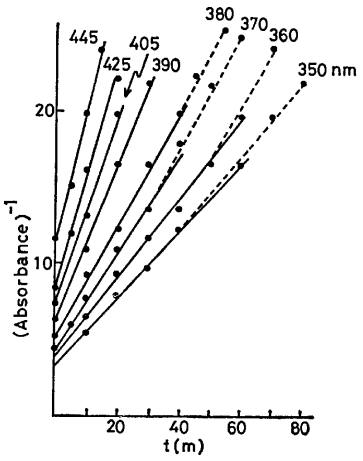

Fig. 3. Second-order decay plots of the transient absorbances obtained at various wavelengths at room temperature under degassed conditions. (An ethanol solution of 2×10^{-5} M sulfur was used.)

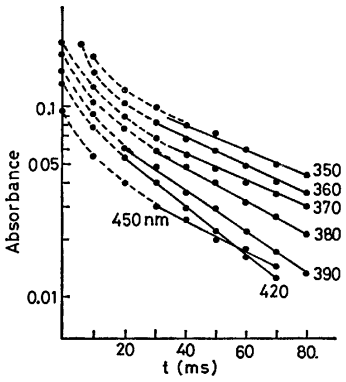

Fig. 4. First-order decay plots of the transient absorbances obtained at various wavelengths at room temperature under degassed conditions. (An ethanol solution of 2×10^{-5} M sulfur was used.)

lengths are shown in Figs. 3 and 4, respectively, suggesting that the 350—450 nm absorption may be ascribed to a single species in the time scale 10—100 ms with a minor contribution from other species. The rate of second-order decay obtained from the plots of the 350—380 nm and 440—450 nm absorptions in Fig. 3 is $C_0k_2=75\pm10$ s^{-1}, where C_0 is the initial concentration of the transient species. (There is some anomaly in the region 390—430 nm) Similarly, we obtained the rate of first-order decay $k_1=16$ s^{-1}, using the plots of the 350—380 nm and 440—450 nm absorptions in Fig. 4.

From the present experimental results, it may be suggested that the intense flash irradiation of sulfur in ethanol solution gives rise to the linear S_8 as well as its some decomposed species (such as S and S_7) which decay much faster than the linear S_8. The observed second- and first-order decays in the range 10—100 msec may be interpreted in terms of the dimerization and polymerization of the linear S_8,

$$2S_8 \longrightarrow S_{16} \quad (2)$$

$$S_8 + S_{8n} \longrightarrow S_{8(n+1)} \quad (3)$$

where $n\geq2$. Such mechanisms seem to be consistent with the formation of photosulfur which has been understood as a polymeric substance of sulfur for a long time.[2)]

The main conclusion obtained here is that the decay of transient species around 10—40 ms may be interpreted mainly in terms of the dimerization of the linear S_8 biradical, whereas the decay observed after about 40 ms may be explained mainly with the polymerization of the linear S_8.

7) It should also be mentioned that a further UV-irradiation at 77 K for a much longer time, *e.g.*, about 30 min, gives rise to another spectrum (with absorption maxima at about 370 and 420 nm) which disappears at higher temperature. The 370-nm band may be possibly due to some photo-decomposed species such as S and S_7.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49(4), 1153—1154 (1976)

The Crystal Structures of Sterigmatocystin and *O*-Methylsterigmatocystin, Metabolites of the Genus *Aspergillus*

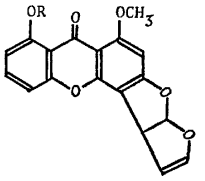
(Received December 27, 1975)

Synopsis. The crystal and molecular structures of sterigmatocystin and *O*-methylsterigmatocystin have been studied by the X-ray diffraction method. Both compounds crystallized in the space group $P2_1$ with $Z=2$. The cell dimensions are $a=16.068$, $b=4.293$, $c=11.243$ Å, and $\beta=113.23°$ for sterigmatocystin, and $a=8.835$, $b=16.769$, $c=5.403$ Å, and $\beta=109.21°$ for *O*-methylsterigmatocystin.

Sterigmatocystin (I) was isolated as a metabolite of *Aspergillus versicolor* (Vuillemin) Tiraboschi.[1] The structure and absolute configuration have been determined by chemical and X-ray methods.[2,3] *O*-Methylsterigmatocystin (II) was isolated by Burkhardt *et al.* from *Aspergillus flavus* Link ex Fries, and was synthesized by the methylation of sterigmatocystin.[4] In the series of studies of the structures of the metabolites of the genus *Aspergillus*,[5] X-ray structure analyses of the title compounds have been undertaken.



(I) R:H
(II) R:CH_3

Sterigmatocystin crystallized from aqueous acetone solution in the form of pale yellow needles elongated along the b axis. *O*-Methylsterigmatocystin crystallized from acetone solution in the form of colorless prisms elongated along the c axis. The crystal data for each compound are listed in Table 1. The intensities of each compound were measured up to $\sin\theta/\lambda=0.53$ on a Toshiba four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The approximate size of specimen used in the intensity measurement was $0.10\times0.35\times0.12$ mm for sterigmatocystin and $0.11\times0.14\times0.31$ mm for *O*-methylsterigmatocystin. The stationary-crystal stationary-counter method was used, with a counting time of 30 s. The background for each reflection was taken from plots of background as a function of 2θ. The intensities were corrected only for Lorentz and polarization factors.

TABLE 1. CRYSTAL DATA

	Sterigmatocystin	*O*-Methylsterigmatocystin
Molecular formula	$C_{18}H_{12}O_6$	$C_{19}H_{14}O_6$
Molecular weight	324.3	338.3
Crystal system	Monoclinic	Monoclinic
Space group	$P2_1$	$P2_1$
a	16.068(5) Å	8.835(4) Å
b	4.293(2)	16.769(6)
c	11.243(3)	5.403(3)
β	113.23(8)°	109.21(8)°
Z	2	2
D_x	1.51 g/cm³	1.49 g/cm³
D_o	1.50	1.50
μ(for Cu$K\alpha$)	9.7 cm^{-1}	9.6 cm^{-1}

* Faculty of Agriculture, Tottori University, Koyama, Tottori 680.

Sterigmatocystin. The structure was solved by interpretation of Patterson function followed by successive Fourier syntheses. The structure was refined to $R=0.08$ by a block-diagonal least-squares method with anisotropic temperature factors for non-hydrogen atoms. The positions of all the hydrogen atoms were determined from difference synthesis. Including positional parameters and isotropic temperature factors of hydrogen atoms, the refinement reduced the R value to 0.074 for 1018 independent reflections ($R=0.060$ for non-zero reflections). The weighting scheme adopted in the final calculations was; $w=0.3$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq20$, and $w=1.0/(1.0+0.75(F_o-20))$ for $20<F_o$. The final atomic parameters are given in Tables 2(a) and 3(a).

O-Methylsterigmatocystin. The structure was solved by application of the convolution molecule method[6] followed by Fourier syntheses. The refinement was carried out in the same way as that of sterigmatocystin. The final R value is 0.060 for 973 independent reflections ($R=0.055$ for non-zero reflections). The weighting scheme adopted in the final calculations was; $w=0.2$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq15$, and $w=1.0/(1.0+0.83(F_o-15))$ for $15<F_o$. The final atomic parameters are given in Tables 2(b) and 3(b). The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[7]

The bond lengths and angles with their estimated standard deviations are shown in Fig. 1. The difference Fourier synthesis indicates that sterigmatocystin molecule has a intramolecular hydrogen bond, O(3)–H(O3)···O(2). The methoxy groups of both compounds are nearly coplanar with xanthone skeleton; the torsion angle of C(1)–C(2)–O(1)–C(18) in sterigmatocystin is −8.0°, and the angles of C(1)–C(2)–O(1)–C(18) and C(7)–C(6)–O(3)–C(19) in *O*-methylsterigmatocystin are 0.3° and 1.2° respectively. The dihedral angle between the xanthone skeleton and the terminal five-membered ring in sterigmatocystin is 64.9°, and that in *O*-methylsterigmatocystin is 61.0°.

The crystal structure for each compound is shown in Fig. 2. The molecules of sterigmatocystin are stacked with the interplanar distance of xanthone skeleton of 3.4 Å along the b axis to form a column. In *O*-

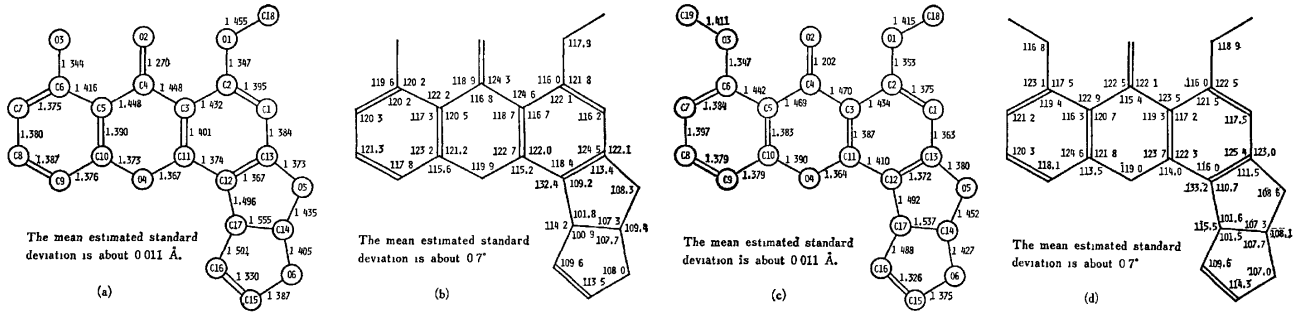


Fig. 1. Bond lengths and angles. (a) and (b) are those in sterigmatocystin, and (c) and (d) are in *O*-methylsterigmatocysten.

Table 2. Final atomic parameters and e.s.d.'s ($\times 10^4$) for non-hydrogen atoms

The anisotropic temperature factors are of the form; $\exp(-\beta_{11}h^2-\beta_{22}k^2-\beta_{33}l^2-\beta_{12}hk-\beta_{13}hl-\beta_{23}kl)$.

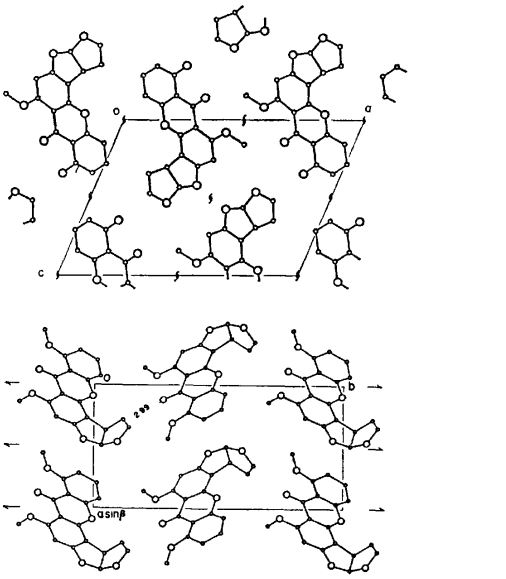

Fig. 2. Projections of the crystal structures of (a) sterigmatocystin and (b) *O*-methylsterigmatocystin.

methylsterigmatocystin the interplanar distance of the xanthone skeletons related by unit translation along the c axis is 3.5Å. The xanthone planes related by screw axis make an angle of 76° in sterigmatocystin, while the angle is 48° in *O*-methylsterigmatocystin. The closest intermolecular contact in the crystal of *O*-methylsterigmatocystin is observed between the terminal of the dihydrofuranofuran moiety and carbonyl oxygen atom. The distances between the C(15) and O(2) atoms and between the H(C15) and O(2) atoms are 2.99 Å and 2.3Å respectively. No intermolecular hydrogen bond is observed in both crystals.

The authors wish to thank Mr. Isao Tanaka and Professor Tamaichi Ashida of Nagoya University for computer programs. They are also indebted to Mr. Fumiyoshi Nishimura for the assistance in this work.

The Infrared Frequency Shift and Half Width of the Hydrogen-Bonded Band in Some Phenol–Nitrile Systems

Inam JAWED

Department of Physical Chemistry, Peshawar University, Peshawar, Pakistan

(Received March 18, 1975)

Synopsis. The relationship between the infrared frequency shift and half width of the hydrogen bonded band for a number of phenol–nitrile systems has been studied. A linear relationship, $(\Delta\nu_{1/2})_{\text{bonded}}=0.31\,\Delta\nu+21.7\ \text{cm}^{-1}$, has been obtained. It seems that in such plots the intercept is about the magnitude of the half width of the free or unbonded ν(XH) band; *i.e.*, at zero value of the frequency shift, the half width of the bonded band equals that of the free band.

Huggins and Pimental[1] were first to report a linear relationship between half width and frequency shift of the hydrogen bonded ν(XH) vibrational band and further noted that the same plot was applicable to a wide variety of intermolecular hydrogen bonded systems. Their equation was:

$$(\Delta\nu_{1/2})_b = 0.72\,\Delta\nu + 2.5\ \text{cm}^{-1}$$

Since then, many workers have found similar relationships for different hydrogen bonded systems.[2-6] Recently, Lopes and Thompson[7] reported the following correlation for some phenol–nitrile systems:

$$(\Delta\nu_{1/2})_b = 0.58\,\Delta\nu + 2.0\ \text{cm}^{-1}$$

The present study was undertaken to investigate this relationship further for a number of phenol–nitrile systems. However, this investigation differs from the previous one[7] in that here the dependence of the spectroscopic parameters on the concentration of proton acceptors has also been taken into account. This concentration dependence is now more or less established.[8-10]

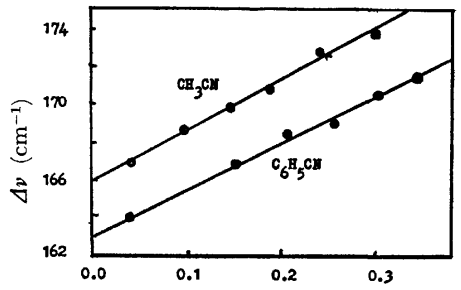

Fig. 1. Frequency shift *vs.* nitrile concentration.
Proton donor: *p*-chlorophenol.

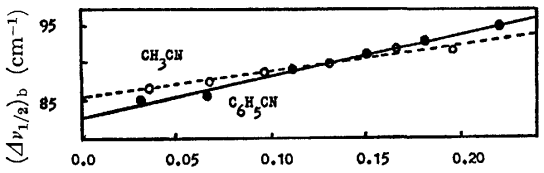

Fig. 2. Half width of the bonded band *vs.* nitrile concentration.
Proton donor: *p*-nitrophenol.

Experimental

The spectra were recorded on a Perkin-Elmer model 125 infrared grating spectrophotometer using an expanded scale(1 cm=5 wave nos.). Tetrachloroethylene was used as the solvent which was dried and fractionally distilled. Quartz cells, 20 mm long, were used. All measurements were made at 25 °C.

The concentration of proton donors is found to have no effect on the spectroscopic parameters whereas that of acceptor has a marked effect. Hence the values of half width and frequency shift are those obtained by extrapolation to infinite dilution of the proton acceptors as shown in Figs. 1 and 2. The concentrations of the proton donors and acceptors used were as follows:

p-Methoxyphenol, phenol and *p*-chlorophenol	5.0×10^{-5} M.
p-Cyanophenol and *p*-nitrophenol	2.5×10^{-5} M.
Trichloroacetonitrile	0.2 M to 1.5 M.
Benzonitrile and acetonitrile	0.03 M to 0.35 M.
t-Butyl cyanide	0.015 to 0.2 M.

Results and Discussion

Tables 1 and 2 give the values of frequency shift and half width respectively of the bonded bands for the systems investigated. Using this data, the following straight-line correlation was obtained by the method of least squares (Fig. 3):

$$(\Delta\nu_{1/2})_b = 0.31\,\Delta\nu + 21.7\ \text{cm}^{-1}$$

The slope and intercept of this straight line are widely different from those obtained by Lopes and Thompson.[7]

TABLE 1. INFRARED FREQUENCY SHIFTS (at 25 °C)

Phenol	Frequency shifts (cm^{-1}) for nitriles			
	Cl_3CCN	C_6H_5CN	CH_3CN	$(CH_3)_3CCN$
p-Methoxyphenol	60.5	142.0	145.0	155.0
Phenol	63.5	148.0	152.5	162.5
p-Chlorophenol	71.0	163.0	166.0	179.0
p-Cyanophenol	91.0	194.0	197.5	215.5
p-Nitrophenol	95.5	207.0	209.5	226.0

TABLE 2. HALF WIDTH OF THE BONDED BANDS (at 25 °C)

Phenol	Half width of the bonded band (cm^{-1})			
	Cl_3CCN	C_6H_5CN	CH_3CN	$(CH_3)_3CCN$
p-Methoxyphenol	37.0	64.0	68.5	75.0
Phenol	40.0	70.5	75.5	74.0
p-Chlorophenol	39.5	75.0	80.0	78.0
p-Cyanophenol	49.0	80.0	82.5	84.5
p-Nitrophenol	55.0	83.5	85.5	86.5

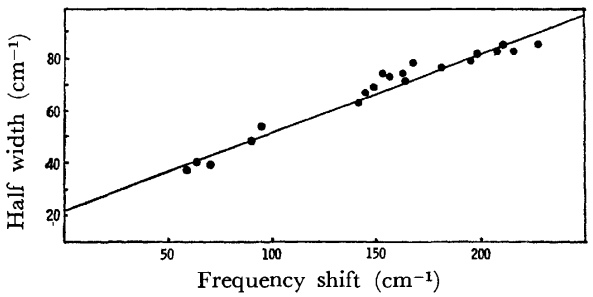

Fig. 3. Plot of frequency shift against half width of the hydrogen bonded band for phenol-nitrile systems.

However, there is an interesting point about our relationship. We note that the intercept of the $(\Delta\nu_{1/2})_b$-axis is just about the average of the half widths of the free ν(OH) bands of the phenols under study. This finding is quite reasonable if we consider both the frequency shift and half width of the bonded band to be related to the strength of the hydrogen bond. Then smaller frequency shift and half width would mean weaker hydrogen bond and hence a stronger X–H link. In the case of no hydrogen bonding at all, the X–H bond should return to its original strength, *i.e.*, it should show the frequency and half width of the free ν(XH) band. Present results should be more reliable since the values of frequency shift and half width used here are those obtained by extrapolation to infinite dilution of the proton acceptors. This concentration dependence of the spectroscopic parameters has been frequently overlooked in previous works.

The author is grateful to Professor Sir Harold Thompson, Physical Chemistry Laboratory, Oxford, for help with this work and to the Government of Pakistan for a fellowship.

Syntheses of 3,4-Dimethylpyrrole

Kunihiro ICHIMURA, Susumu ICHIKAWA,* and Kazuo IMAMURA*

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received August 25, 1975)

Synopsis. Treatment of *N*-sulfinyl compound with 2,3-dimethylbutadiene gives a cycloadduct which affords 3,4-dimethylpyrrole in satisfactory yields by heating in a strongly alkaline methanolic solution.

From an interest in synthesizing porpyrins, we have attempted to prepare a large amount of 3,4-dimethylpyrrole (I). Although various pyrrole syntheses have been worked out,[1] 3,4-disubstituted pyrroles have been available only *via* several steps. The Knorr synthesis affords in *ca.* 50% yield ethyl 2,3,4-trimethylpyrrole-5-carboxylate which we converted into I in 20–40% yield based on Fischer's procedure.[2] The unsatisfactory results prompted us to find a new synthetic route to I.

Alkaline hydrolysis of 2-aryl-3,6-dihydro-4,5-dimethyl-1,2-thiazine 1-oxide gives 1-aryl-3,4-dimethylpyrrole in high yields[3] whereas various 2-substituted 3,6-dihydrothiazine 1-oxide exclusively yield γ,δ-unsaturated amine by acidic, neutral or even alkaline hydrolysis.[4] We have carefully investigated the alkaline hydrolysis of some derivatives of dihydrothiazine 1-oxide (III), the 2-position of which is substituted by ester groups.

The *N*-sulfinylamides (IIa R=CO_2Et,[5] IIb R=CO_2Ph, IIc R=$PO(OEt)_2$[6]) were obtained in excellent yields by the action of thionyl chloride and dry pyridine upon the corresponding carbamate or phosphoramidate. In order to attain a good yield, thionyl chloride and pyridine should be added dropwise to a benzene solution of carbamate or phosphoramidate at the same rate. A poor yield was attained when thionyl chloride was added to a solution of urethane and pyridine.[5b] The *N*-sulfinyl compounds were not purified on account of the high sensitivity toward heat and moisture, as characterized by means of IR spectra. IIb crystallized on cooling. The IR spectrum exhibits bands at 1260 and 1100 cm^{-1} characteristic of the N=S→O group [4a] and at 1750 cm^{-1} due to the carbonyl group. After pyridine hydrochloride had been removed under protection from moisture, 2,3-dimethylbutadiene was added to the solution of crude *N*-sulfinylamide followed by refluxing to give the cycloadduct (III). 2-Ethoxycarbonyl (IIIa)[5a] and diethoxyphosphonyl (IIIc) derivatives have a high boiling point and were not purified because of reduction in yield caused by distillation. They were characterized by IR spectra. 2-Phenoxycarbonyl derivative (IIIb) was purified by recrystallization from cyclohexane to give 79.5% yield of hydroscopic crystals, mp 84—86 °C, which decompose with the evolution of sulfur dioxide on being left to stand at room temperature.

When cycloadducts (III) were heated in strongly alkaline methanol, 3,4-dimethylpyrrole was formed (Table 1) although Levchenko and coworkers described the exclusive formation of γ,δ-unsaturated amine by the action of 2.5 mol sodium hydroxide on IIIa in ethanol.[5a] The pyrrole was isolated by steam-distillation. A dark resinous substance remained. Evolution of hydrogen sulfide and sulfur dioxide was observed on acidification of the aqueous residue. The strength of alkali played a key role for the formation of the pyrrole; when the cycloadduct were heated in aqueous alkali, the yield of the pyrrole was always smaller than in methanol (run 5, Table 1).

Table 1. Syntheses of 3,4-dimethylpyrrole

Exp. run	R in III	Alkali[a]	Mol of alkali	Solv.	Yield (%)[b]
1	CO_2Et	NaOMe	4	MeOH	5—10
2	CO_2Et	KOH	8	MeOH	34—48
3	CO_2Et	NaOMe	7	MeOH	62
4	CO_2Ph	NaOH	5	MeOH	40
5	CO_2Ph	NaOH	5	H_2O	trace[c]
6	CO_2Ph	NaOMe	7	MeOH	59
7	$PO(OEt)_2$	KOH	8	EtOH-H_2O	22
8	$PO(OEt)_2$	NaOMe	6	MeOH	27

a) Alkali hydroxide; 20—30 w/w% in methanol or water. Sodium methoxide: *ca.* 10 w/w% in methanol. b) Based on the crude cycloadduct (III) except runs 4—6 where the purified cycloadduct was used. c) Ehrlich's test was positive.

Similarly, 3-methylpyrrole was obtained in 13% overall yield when isoprene was used instead of dimethylbutadiene. The poor yield of the pyrrole in this case should results from less sufficient cycloaddition.

Attempts to isolate 2-unsubstituted 3,6-dihydrothiazine 1-oxide (III; R=H) by the reaction of IIb with such weaker bases as ammonia and aniline were unsuccessful.

Experimental

Materials. Benzene was dried over sodium wire, and pyridine over potassium hydroxide. Thionyl chloride

* Department of Chemistry, Faculty of Technology, Kanagawa University, Kanagawa, Yokohama.

was distilled just before use.

3,4-Dimethylpyrrole (Starting From Ethyl Carbomate). In a 1 l round-bottomed flask, equipped with a mechanical stirrer, a reflux condenser attached with a calcium chloride tube, and two 100 ml dropping funnels, were placed 27.1 g ethyl carbamate and 150 ml dry benzene. Pyridine and thionyl chloride were added dropwise at the same rate with efficient stirring and cooling with cold water. After the mixture was further stirred for one hour at room temperature, 25.0 g 2,3-dimethylbutadiene was added in one portion. The mixture was heated under mild refluxing and stirring and then allowed to stand overnight. After voluminous pyridine hydrochloride was filtered and washed with benzene, the filtrates were evaporated under reduced pressure to afford an oily residue of crude 2-ethoxycarbonyl-3,6-dihydro-4,5-dimethyl-1,2-thiazine 1-oxide, ν_{max} (neat); 1725, 1317, 1250, 1100 cm^{-1}. To the residue was added 135 g potassium hydroxide dissolved in 300 ml methanol, and the dark colored mixture was refluxed 2 h. The solvent was distilled under ordinary pressure, and the reaction mixture was steam-distilled to give an oily substance which was extracted repeatedly with ether. The extracts were dried over anhydrous potassium carbonate, and the solvent was removed. Vacuum distillation of the oily residue gave 13.77 g 3,4-dimethylpyrrole of bp_{25} 67—70 °C (lit, bp_{14} 65.5–66 °C).[7] The yield was 47.7% based on ethyl carbamate.

2-Phenoxycarbonyl-3,6-dihydro-4,5-dimethyl-1,2-thiazine 1-Oxide. After 30.0 g phenyl carbamate was treated with 35.1 ml pyridine and 15.1 ml thionyl chloride in 250 ml benzene in the same manner as above, pyridine hydrochloride was filtered off and washed with dry benzene. To the combined benzene solutions was added 19.8 g 2,3-dimethylbutadiene, and the mixture was refluxed for 1 h after being left standing overnight. The solvent was removed by vacuum distillation to afford crystalline residue which was recrystallized from cyclohexane. The 1,2-thiazine 1-oxide weighed 46.1 g (79.6% based on phenyl carbamate) and melted at 84—86 °C. ν_{max}(KBr); 1745, 1342, 1211, 1080 cm^{-1}. Found: C, 58.84; H, 6.14; N, 5.26%. Calcd for $C_{13}H_{15}NO_3S$: C, 58.84; H, 5.69; N, 5.28%. The crystals decomposed gradually with evolution of sulfur dioxide. Treatment of this compound with alkali yielded 3,4-dimethylpyrrole as shown in Table 1.

Phenyl *N*-sulfinylcarbamate was isolated when the benzene solution was removed *in vacuo* under protection from moisture, after the reaction of phenyl carbamate with thionyl chloride in the presence of pyridine. The new *N*-sulfinyl derivative crystallized on cooling in a refrigerator, showing characteristic IR bands at 1260 and 1100 cm^{-1} due to N=S→O groups.[4a]

3-Methylpyrrole. In the same way as mentioned above, crude ethyl *N*-sulfinylcarbamate, obtained by the reaction of 30.0 g ethyl carbamate with 40.0 g thionyl chloride and 26.5 g pyridine, was treated with 28.0 g isoprene. The mixture was refluxed for 3 h. After pyridine hydrochloride had been removed by filtration, the salt was washed with benzene. The benzene was distilled *in vacuo* to afford an oily residue which was heated with 130 g potassium hydroxide in 300 ml methanol for 3 h. The solvent was distilled off, and the residue was steam-distilled. The distillate was extracted with ether, and the solvent was distilled off after the ether had been dried with potassium carbonate. Distillation of the residue gave 6.60 g crude 3-methylpyrrole which was purified by redistillation: 3.93 g (13% based on ethyl carbamate), bp 140—145 °C (lit,[2a] bp 142—143 °C).

A Synthesis of Methyl 2-Dimethylphosphoenolpyruvate by Dephosphorylation

Kugako WATANABE, Michiko (KATO) ISHIMATSU, and Koa TASAKA

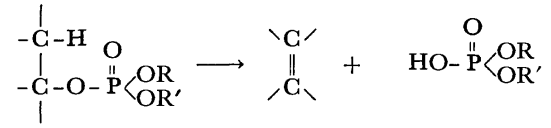
Division of National Science, International Christian University, Osawa, Mitaka-Shi, Tokyo 181

(Received September 25, 1975)

Synopsis. Methyl 2-dimethylphosphoenolpyruvate was obtained by base-catalyzed dephosphorylation of methyl 2,3-bis(dimethylphospho)glycerate.

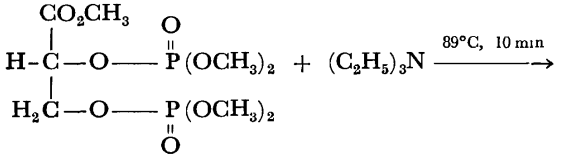
Phosphoenolpyruvate(PEP) has a very large free energy of hydrolysis among the so called "energy-rich" phosphates in biological systems.[1] In glycolysis, it is considered that 3-phosphoglycerate is transformed into 2-phosphoglycerate by phosphoglycerate mutase with the help of 2,3-diphosphoglycerate, and the PEP is formed by dehydration of 2-phosphoglycerate[2]. Organic syntheses of PEP have been performed by various methods.[3]

In the present work, a synthesis of methyl 2-dimethylphosphoenolpyruvate by dephosphorylation was investigated. The term "dephosphorylation" is used here for the reaction in which a phosphoric acid or ester is eliminated from a mono-, di- or tri-ester of phosphoric acid to form an alkene;

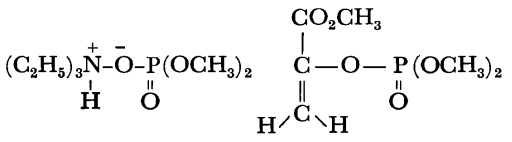


Dephosphorylation of bis-phosphate should lead to the formation of enolphosphate.

No decomposition took place when 1,2-bis(dimethylphospho)propanediol was subjected to pyrolysis at 250 °C. Methyl 2,3-bis(dimethylphospho)glycerate was prepared by the phosphorylation of methyl glycerate, decomposition taking place at 250 °C. The reaction mixture turned dark brown. It was difficult to isolate the products. On the other hand, when the reaction was carried out in the presence of triethylamine, the dephosphorylation occurred at a much lower temperature. The amine acts not only as a catalyst but it is consumed by forming a salt. Pyridine could be also used as a base, but was found less effective.



(1)



(2)

When a mixture of diphosphoglycerate(**1**) and two mole equivalent of triethylamine was kept in a oil-bath of 89 °C for 10 min and the ammonium salt was removed, the methyl ester of phosphoenolpyruvate was obtained in 50% yield by use of a short-path distillation apparatus *in vacuo*. The distillate showed identical H^1-NMR and IR spectra with those of phosphoenolpyruvate methyl ester (**2**) prepared by the Perkow reaction from methyl β-bromopyruvate and trimethyl phosphite.[4] 2,3-Diphosphoglycerate is known to be extremely stable toward hydrolysis among the biologically important phosphoric esters[5]. However, the lability of its esters toward elimination is not known. We are investigating the dephosphorylation of 2,3-diphosphoglycerate and its other esters under various conditions.

Experimental

The IR spectra were taken with a JASCO IRA-2 spectrophotometer, and NMR spectra with a Hitachi-Perkin Elmer R-20 spectrometer. The chemical shifts in NMR measurement were recorded in δ values relative to tetramethylsilane (TMS) as an internal standard.

*Preparation of Methyl 2,3-Bis(dimethylphospho)glycerate(**1**)* Glyceric acid was converted into methyl ester by the usual way,[6] and the methyl glycerate was phosphorylated with dimethylphosphorochloridate in the following way. To an ethereal solution of methyl glycerate(1.2 g, 0.01 mol) and pyridine(1.6 ml, 0.02 mol) was added dimethylphosphorochloridate(3.0 g, 0.02 mol) dropwise under cooling and stirring. The mixture was left to stand overnight at room temperature and the pyridinium salt was removed by decantation and extraction with water from chloroform solution. After removal of the solvent, methyl 2,3-bis(dimethylphospho)-glycerate(**1**) (1.5 g, 45%, bp 80 °C/0.1 mmHg) was obtained by distillation. NMR δ ppm (in $CDCl_3$); 2.92(12H, doublet, $POCH_3$, J=11.3 Hz), 3.00(2H, multiplet, CH_2), 3.17(3H, singlet, $COCH_3$), 3.90(1H, multiplet, CH). IR νcm^{-1} (in $CHCl_3$); 1270(s) νP=O, 1185(m), νC–O–P, 1035(s) νC–O–P.

*Dephosphorylation of Methyl 2,3-Bis(dimethylphospho)glycerate (**1**).* A mixture of methyl 2,3-bis(dimethylphospho)-glycerate (0.42 g, 12 mmol) and triethylamine (0.20 g, 24 mmol) was kept in an oil-bath of 89 °C for 10 min and extracted with CCl_4 at room temperature. The extract was concentrated under reduced pressure and distilled *in vacuo*. Methyl 2-dimethylphosphoenolpyruvate(**2**), 0.13 g (50.0%, bp 60—64 °C/0.02 mmHg), was obtained as a colorless liquid. NMR δ ppm(in CCl_4); 3.79(3H, singlet, CO_2CH_3), 3.80(6H, doublet, P–OCH_3, J=11.3 Hz), 5.56 and 5.86 (2H, two triplets, $=CH_2$). IR ν cm^{-1} (in CCl_4); 3020(w) νH–C=, 1750(vs) νC=O, 1650(s) νC=C, 1290(vs) νP=O, 1160(vs) νC–O–(C), 1050(vs) νP–O–(C). The IR and NMR spectra of the compound were identical with those of **2** prepared by the Perkow reaction.

*Preparation of Methyl 2-Dimethylphosphoenolpyruvate(**2**) by Perkow Reaction.* Compound **2** was synthesized from α-bromopyruvate (0.83 g., 5 mmol) and trimethyl phosphite (0.57 g, 5 mmol) in benzene according to the procedure of Cramer and Garther[4]. The product was distilled at 65—67 °C/0.03 mmHg, and **2** was obtained in 68.5% yield.

NMR Spectroscopic Studies on the Tautomerism in Schiff Bases of Tenuazonic Acid Analogs

Tatsuaki YAMAGUCHI, Kimitoshi SAITO, Toshio TSUJIMOTO,* and Hidetaka YUKI*

Laboratory of Organic Chemistry, Chiba Institute of Technology, Narashino, Chiba 275

**Faculty of Pharmaceutical Sciences, Osaka University, Yamadakami, Suita, Osaka 565*

(Received October 13, 1975)

Synopsis. A NMR spectroscopic study of ^{15}N-enriched Schiff bases of such tenuazonic acid analogs as 3-acetyltetramic acid, 3-acetyltetronic acid, and 3-acetylthiotetronic acid showed the predominance of ketamine forms in their tautomeric equilibria in $CDCl_3$. The ratios of "external tautomers" between two different ketamine forms, as calculated from the ^{15}N–H signal intensities, were compared favorably with the ratios obtained from the ring methylene signals.

In connection with the study[1] of the antitumor activities of Schiff bases of tenuazonic acid analogs,[2] their tautomeric structures were examined by means of NMR spectroscopy. These Schiff bases[3] may exist in a solution in any form of "external tautomers" (B_N, $B_O \rightleftharpoons C_N$, C_O), besides "internal tautomers" ($B_N \rightleftharpoons B_O$, $C_N \rightleftharpoons C_O$), as Forsén and coworkers have suggested for unsymmetrical β,β'-triketones.[4] They have also estimated the ratios of the "external tautomers" of unsymmetrical cyclic β,β'-triketones from the intensities of the split NMR signals of the ring methylene.

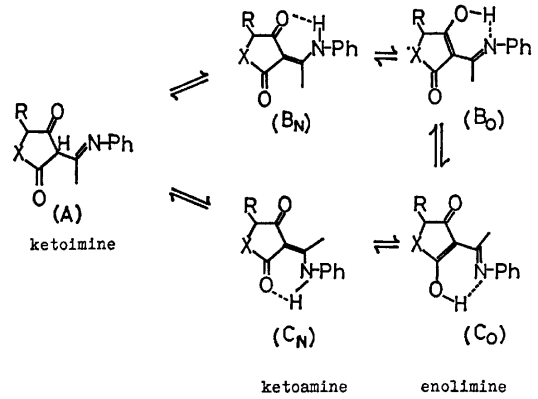

Chart 1.

Results and Discussion

The presence of "external tautomers" in the Schiff bases of these tenuazoinc acid analogs was detected from the splitting of the ring methylene (5-position) signals (3.70—4.53 ppm) in their NMR spectra. The counterpart in the higher field of the split methylene signals can be assigned to the tautomeric pair of B_N and B_O, and the lower one, to the pair of C_N and C_O, since the anisotropic effect[5] of the neighboring carbonyl group (4-position) can be expected to be more pronounced in the forms of C_N and C_O than in B_N and B_O, in which the carbonyl groups are hydrogen-bonded (B_N) or enolized (B_O). The ratios of the "external tautomers", B_N+B_O to C_N+C_O, for these Schiff bases were calculated from intensities of the corresponding signals (Table 1).

The observed NMR spectra of these Schiff bases showed a broad doublet arising from the active hydrogen in the region of 11.66—13.67 ppm (Table 2). In order to elucidate the exact assignment of these signals to the tautomeric structures, the Schiff bases of tenuazonic acid analogs were synthesized using commercially available aniline-^{15}N, since sharp signals can be expected for protons bonded to the ^{15}N-nucleus ($I=1/2$), and the ^{15}N–H spin coupling constant of *ca.* 90 Hz makes possible a ready detection of any "internal" tautomerization between N–H and O–H.[6]

The spectrum of the ^{15}N-substituted Schiff base (IA) from 3-acetyltetramic acid contained two pair of sharp doublets at nearly the same position relative to the corresponding ^{14}N-compound (Fig. 1). The observed ^{15}N–H spin coupling constant was 90.0 Hz for each doublet at 34 °C in $CDCl_3$. Upon raising the sample temperature to +60 °C or lowering it to −70 °C, no changes were observed in the chemical shifts, signal intensities, or coupling constants of this compound. Therefore, it can be concluded that IA primarily exists in the ketoamine forms, B_N and C_N. The intensity ratio of the higher-field doublet to the lower one showed a good coincidence with the ratio of "external tautomers" calculated from the intensities of the ring methylene signals (Table 1). Accordingly, the higher-field doublet can be ascribed

Table 1. Ratios of "external tautomers" calculated from the intensity ratios of ring methylene signals and ^{15}NH signals

No.	Compounds X	Compounds R	B_N+B_O/C_N+C_O (from CH_2)	B_N/C_N (from ^{15}NH)
IA	NH	H	1.13	1.17
IB	NH	$CH_2C_6H_5$	1.39	1.41
II	O	H	0.37	0.36
III	S	H	0.34	0.32

Table 2. Chemical shifts of active hydrogens

No.	δ^{14}_{NH} (ppm)		δ^{15}_{NH} (ppm) B_N form	(J^{15}_{N-H}) (Hz) C_N form
IA	12.09	12.44	12.17 (90.0)	12.52 (90.0)
IB	12.08	12.40	12.11 (90.0)	12.48 (90.0)
II	11.66	12.44	11.61 (90.0)	12.57 (91.8)
III	12.89	13.67	12.86 (90.9)	13.66 (86.4)

to the B_N form, and the lower one to the C_N form.

The observed spectra of the other compounds showed patterns similar to that of IA and indicated the same conclusion in the assignment of the signals. However, the observed ^{15}N–H coupling constant (86.4 Hz) of the C_N form in the Schiff base (III) of 3-acetylthiotetronic acid is found to be markedly smaller than the values for the others. This suggests that *ca.* 5% of the C_O form is present at 34 °C in the $CDCl_3$ solution of this compound. The presence of the C_O form in III is also supported by the results for the ^{13}C-NMR spectrum of III, which showed an additional small signal of enolic carbon at 193.88 ppm (from TMS) besides two signals at 195.18 and 198.81 ppm arising from free carbonyl carbon and hydrogen-bonded carbonyl carbon respectively. The exceptional feature of III could be explained by the geometry of the molecule. Simple molecular orbital calculation are in progress to obtain further insights in this field.

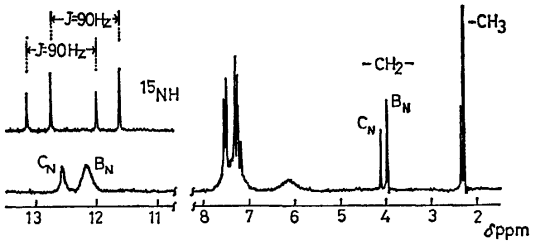

Fig. 1. NMR spectrum of 3-(1'-anilinoethylidene)-pyrrolidine-2,4-dione (IA) in $CDCl_3$ at 90 MHz.

Experimental

Materials. The IA,[7] IB,[7] II,[8] and III[9] were prepared according to the procedures described in the literature cited. Aniline-^{15}N (95% isotopic purity) was obtained from Prochem BOC, Ltd.

Measurements. The NMR spectra were measured with a Hitachi Perkin-Elmer R-22 spectrometer at 90 MHz at 34 °C, using TMS as the internal standard. Solutions were made so as to contain 1.5×10^{-4} mol of compounds in 0.4 ml of $CDCl_3$.

The ^{13}C-NMR spectra measured on a JNM-FX60 spectrometer equipped with a PFT-100 Fourier transform accessory at 25.1 MHz, using TMS as the internal reference and a 10-mm-diameter NMR tube. The spectra were obtained by 5000-times accumlations measured on a broad-band proton decoupler. The solution contained 200 mg of the sample in 2 ml of $CDCl_3$.

The authors are grateful to Mr. Muneki Ohuchi of the Japan Electron Optics Laboratory for the ^{13}C-NMR measurement.

Pyridoxal Model Compounds. II. The Diels-Alder Reaction of 9-Substituted 2-Methoxyanthracenes

Masaaki IWATA and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received November 10, 1975)

Synopsis. The Diels-Alder reactions of several 2-methoxyanthracenes with tetracyanoethylene (TCNE), dimethyl acetylenedicarboxylate (DMAD), and maleic anhydride (MA) were examined. TCNE gave charge-transfer complexes, but not an addition product in every case. MA gave one-to-one adducts with anthracenes, while DMAD afforded no adduct.

Following the regioselective formylation of 2-methoxyanthracenes,[1] the Diels-Alder reactions of maleic anhydride (MA), tetracyanoethylene (TCNE), and dimethyl acetylenedicarboxylate (DMAD) with 9-substituted 2-methoxyanthracenes were examined in an attempt to synthesize a possible precursor of asymmetric inversion catalysts. The anthracene derivatives used are shown in Fig. 1.

The qualitative results obtained are shown in Table 1. These results clearly show that only MA was effective

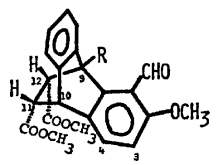
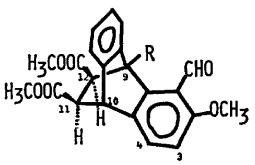
in the Diels-Alder addition to 9-substituted 2-methoxyanthracenes; this is consistent with the fact that, in early reports concerning the Diels-Alder addition to 9-arylanthracenes, MA was frequently used as a dienophile.[2] Contrary to our expectation, however, TCNE resulted in only the formation of the corresponding charge-transfer complex, and DMAD gave no addition product. The lack of reactivity in these dienophiles may be explained by the steric interaction in the transition state between the aryl group at C_9 and the bulky functional group of the dienophiles.[3]

In relation to our interest in the construction of asymmetric inversion catalysts, the confirmation of the structure of adducts between MA and **3** was important. Thus, the reaction mixture was treated with aqueous 5% trimethylamine and then with diazomethane to convert the products to esters. Mainly, four products were detected on a thin-layer chromatogram; their R_f values were 0.5, 0.35, 0.25, and 0.18. The R_f=0.35 and 0.18 compounds were separated by elution chromatography with silica gel and shown to be one-to-one adducts of **3** with dimethyl maleate; the structures were unequivocally assigned to **9** and **10** respectively on the basis of their NMR spectra and lanthanide-induced NMR spectra. A comparison of the NMR spectra of **9** with that of **10** showed that two methoxycarbonyl groups, at C_{11} and C_{12}, were parallelly disposed to the nearer direction to the formyl-substituted benzeno-ring in **9** and to the more remote direction in **10**, because the two ester methyl groups in **10** showed the same chemical shifts at 3.58 ppm.



9

R=4-isopropyl-*o*-tolyl



10

R=4-isopropyl-*o*-tolyl

The ratio of the yield of **9** to that of **10** was 47 : 53; it was probably caused by the dipole interaction of the groups between the formyl group at C_1 of **3** and maleic anhydride.

Experimental

The IR spectra were obtained using a Shimadzu IR-27 apparatus. The ^{1}H-NMR spectra were recorded on a Varian HA-100D apparatus, with tetramethylsilane as the internal standard. The chemical shifts and the coupling constant were represented in δ and Hz units respectively. The UV spectra were measured by means of a Hitachi 124

spectrophotometer. Merck Art. 7734 and Wakogel B-5 FM were used for the preparative separation of the products on a silica gel column by elution chromatography and for thin-layer chromatography (TLC) respectively. The melting points are uncorrected.

Materials. All the dienophiles used, TCNE, DMAD, and MA, are commercially available. Compounds **1** through **8** were prepared by the previously reported method.[1b]

Reaction of Anthracenes with MA. In general, MA equivalent in weight to the anthracene derivative used was treated in a suitable amount of *m*-dichlorobenzene at 125—165 °C, and the reaction was monitored by TLC.

9-(4-Isopropyl-*o*-tolyl)-2-methoxyanthracene (**2**) gave a one-to-one adduct in a 14% yield after a reaction for 6 days; mp 210—211 °C. Found: C, 79.15; H, 6.04%. Calcd for $C_{29}H_{26}O_4$: C, 79.43; H, 5.98%.

A mixture of 9-(4-isopropyl-*o*-tolyl)-2-methoxy-1-anthracenecarbaldehyde (**3**) (1.5 g) and 1.5 g of MA in 10 ml of *m*-dichlorobenzene was heated without stirring at 135—145 °C for 40 h. In order to obtain the products as esters, the reaction was then treated with 20 ml of aqueous 5% trimethylamine at room temperature for 2 h, followed by treatment with an ether solution of diazomethane after a usual work-up. Mainly four products were detected on TLC (benzene–ethyl acetate=9 : 1 v/v); their R_f values were 0.5, 0.35, 0.25, and 0.18. On the basis of the color reaction of the products when sprayed with a $FeCl_3$(2 g)–concd HCl (5 ml)–H_2O(95 ml) solution,[4] the products, R_f=0.35 and 0.18, were the compounds bridged between the C_9 and C_{10} of the anthracene ring.

The compound showing R_f=0.35 was obtained in a 19.6% yield and found to be a racemic mixture of dimethyl (9R,10R,11R,12R)-1-formyl-9-(4-isopropyl-*o*-tolyl)-2-methoxy-9,10-dihydro-9,10-ethano-11,12-anthracenedicarboxylate (**9**) and its enantiomer on the basis of the following properties: colorless fine needles from ethanol, mp 189—190 °C. Found: C, 75.04; H, 6.19%. Calcd for $C_{32}H_{32}O_6$: C, 74.98; H, 6.29%. IR (KBr disk): 1740 (–$COOCH_3$), 1705(–CHO), and 1215(=C–O–C) cm^{-1}. UV(ethanol): λ_{max} (log ε) 212 (4.60), 272(3.49), 280(3.53), and 290(3.53)nm. NMR(CCl_4): 1.32(6H, d, J=7.0, –CH($\underline{CH_3}$)$_2$), 1.65(3H, s, Ar–$\underline{CH_3}$), 2.94(1H, quin, J=7.0, –$\underline{CH}$(CH_3)$_2$), 3.66(3H, s, –OCH_3), 3.33 (3H, s, C_{11}– or C_{12}–COO$\underline{CH_3}$), 3.48(3H, s, C_{12}– or C_{11}–COO$\underline{CH_3}$), 3.08 (1H, quar, J=1.75 and 10.75, C_{11}–$\underline{H}$), 3.94 (1H, d, J=10.75, C_{12}–$\underline{H}$), 4.61(1H, d, J=1.75, C_{10}–$\underline{H}$), 6.66 (1H, d, J=8.5, C_3–$\underline{H}$), 7.23(1H, d, J=8.5, C_4–$\underline{H}$), and 9.06 (1H, s, –CHO). MS: (M^+)*m/e* 512.

The compound showing R_f=0.18 was obtained in a 22.5% yield and found to be a racemic mixture of dimethyl (9*R*,10R,11S,12S)-1-formyl-9-(4-isopropyl-*o*-tolyl)-2-methoxy-9,10-dihydro-9,10-ethano-11,12-anthracenedicarboxylate (**10**) and its enantiomer on the basis of the following data: colorless crystals from ethanol, mp 195—196 °C. Found: C, 75.08; H, 6.00%. Calcd for $C_{32}H_{32}O_6$: C, 74.98; H, 6.29%. IR (KBr disk): 1760(–$COOCH_3$), 1690(–CHO), and 1260 (=C–O–C) cm^{-1}. UV(ethanol): 212(4.60), 261(3.79), 270 (sh)(3.68), 281(sh)(3.51), and 318(3.56) nm. NMR($CDCl_3$–CCl_4 1 : 1 v/v): 1.31(6H, d, J=7.0, –CH($\underline{CH_3}$)$_2$), 3.75(3H, s, –OCH_3), 3.58(6H, s, C_{11}– and C_{12}–COO$\underline{CH_3}$), 3.17(1H, quar, J=1.75 and 11.0, C_{11}–$\underline{H}$), 3.80(1H, d, J=11.0, C_{12}–$\underline{H}$), 4.69(1H, d, J=1.75, C_{10}–$\underline{H}$), 6.86(1H, d, J=8.25, C_3–$\underline{H}$), 7.47(1H, d, J=8.25, C_4–$\underline{H}$), and 9.30(1H, s, –CHO). MS: (M^+) *m/e* 512.

9-Phenyl-2-methoxyanthracene (**6**) gave a one-to-one adduct in a 87% yield after a reaction for 14.5 h; colorless crystals, mp 224—226 °C. Found: C, 78.25; H, 4.66%. Calcd for $C_{25}H_{18}O_4$: C, 78.52; H, 4.74%.

9-(*m*-Tolyl)-2-methoxyanthracene (**4**), 9-(4-isopropyl-*o*-tolyl)-2-methoxy-3-anthracenecarbaldehyde (**5**), 9-(2,6-xylyl)-2-methoxyanthracene (**7**), and 9-(2-methoxyphenyl)-2-methoxyanthracene (**8**) were found to react with MA to give yields of 20% (after 18 h) for **4**, 40% (6 days) for **5**, (2 days) for **7**, and 75% (14 h) for **8** on the basis of the TLC spots.

The author wishes to thank Mr. Jun Uzawa and Mrs. Tamiko Chijimatsu for their NMR spectral measurements, and the staff of the Organic Microanalysis Lab. in this Institute for their elemental analyses. This study was supported in part by a Grant for Life Science from this Institute.

The Structure and Reactivity of $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$

Michihiro ISHIMORI, Tokio HAGIWARA, Teiji TSURUTA, Yasushi KAI*, Noritake YASUOKA*, and Nobutami KASAI*

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

**Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565*

(Received December 8, 1975)

Synopsis. The molecular structure of $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$, an enantiomorphic catalyst for the polymerisation of methyloxirane, has been determined.

It has been reported that zinc dialkoxide exhibits an excellent stereoselective behaviour as a catalyst for the polymerisation of methyloxirane. In the systematic studies of organozinc compounds as polymerisation catalysts, a complex, $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$ has been isolated in colourless crystalline form.[1] All the stereochemical results so far obtained led to the conclusion that polymerisation of methyloxirane with a catalyst involving zinc dialkoxide proceeds by an enantiomorphic catalyst site control mechanism,[2] similar to the polymerisation of α-olefin to an isotactic polymer with Ziegler-Natta catalyst.[3] The structure of such catalyst sites, however, has not been studied in detail. Thus, elucidation of the structure of zinc dialkoxide complex, $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$, is of particular interest.

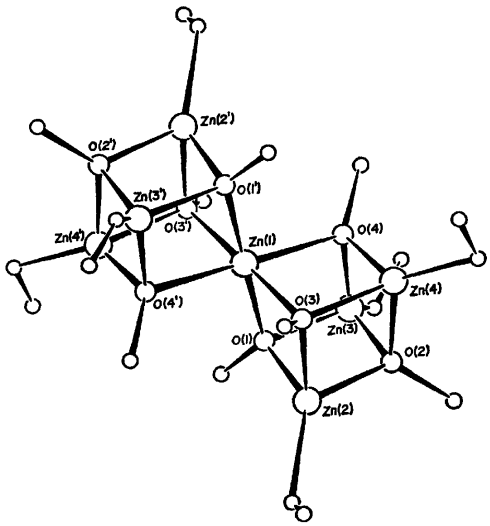
The complex was prepared by addition of 16 mmol of methanol to 14 mmol of diethylzinc in 10 ml of heptane under an argon atmosphere (a typical example). The complex has been formulated as $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$, based on the cryoscopic measurement in benzene as well as analyses by EDTA titration for Zn^{2+}, by VPC for CH_3OH and by ethane evolution after hydrolysis. The 100 MHz NMR spectra of the complex in benzene were recorded at 5 to 10 w/v %. The chemical shifts (δ) of CH_2 at 0.54 (relative intensity, 2), CH_3 at 1.46 (3) and CH_3O at 3.51 (4) were observed at room temperature (23 °C). In contrast, the resonance of CH_3O group was split into a doublet having the intensity ratio of 1 : 3 at 80 °C; 0.53 (2) for CH_2, 1.43 (3) for CH_3 and 3.56 (1) and 3.58 (3) for CH_3O. Coupling constants, $J_{CH_2-CH_3}$, were 8.0 Hz in both cases. There was no sign of dissociation for this complex by an equilibrium involving $ZnEt_2$, $(EtZnOMe)_4$, $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$, *etc.* (*cf.* $Me_6Zn_7(OMe)_8$[4]).

In accord with the line split of methoxy groups, the complex showed catalytic activity for methyloxirane at 80 °C, whereas no catalytic activity was observed at room temperature; methyloxirane/complex=2.1(mol/mol), methyloxirane/benzene(solvent)$=5.8\times10^{-2}$(v/v), 3 days : methyloxirane converted=97% at 80 °C and 0% at 30 °C, CH_3O group reacted per mol of the complex=0.58 mol at 80 °C and 0 mol at 30 °C. Under the conditions of methyloxirane/complex=150 (mol/mol) at 80 °C for 4 days, high molecular weight poly(methyloxirane) was obtained in 56% yield.

The molecular structure of $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$ was determined by maens of X-ray diffraction. In spite of very careful sealing in glass-capillary tubes in argon, most of the crystals decomposed after a few days, only one crystal being found useful to some extent for the X-ray analysis.

Crystal Data: $C_{20}H_{54}O_8Zn_7$, M 880.24, monoclinic, $P2_1/c$, $a=11.276(3)$, $b=15.741(3)$, $c=10.715(2)$ Å, $\beta=106.68(2)°$, $U=1821.9(7)$ Å^3, $1.59/D_m/1.63$ g·cm^{-3}. (floatation in cyclohexyl iodide and *n*-butyl iodide), $Z=2$, $D_c=1.604$ g·cm^{-3}.

The determination of unit-cell dimensions and collection of intensity data were carried out on a Rigaku automated, single crystal diffractometer using Nickel-filtered Cu$K\alpha$ radiation. A total of 1884 integrated intensities was measured by θ-2θ scan technique up to $(\sin\theta)/\lambda=0.50$, of which only 942 reflexions were above the background because of rapid decrease of diffraction intensity in high angle region. The structure was solved by the heavy-atom method and refined by the block-diagonal least squares procedure. Applying isotropic temperature factors for non-hydrogen atoms except zinc the R index converged to 0.142 for observed reflexions. The temperature factors were relatively large especially for the terminal methyl carbon atoms of ethyl groups.



The molecular structure is shown in the Figure. The centrosymmetric complex consists of two enantiomorphic distorted cubes which share a corner, the center of symmetry. Each distorted cube is similar to that of $(MeZnOMe)_4$; the zinc atoms occupy the corners of a tetrahedron and oxygen atoms the corners of an interpenetrating but smaller tetrahedron. The average bond distances and bond angles are : Zn–O 2.06, O–C 1.48, Zn–C 2.07 Å, O–Zn–O 82.5°, and Zn–O–Zn 97.0°. The largest distortions are observed

in the geometry of the central zinc atom, Zn(1), Zn(1)–O(4) (2.18(3) Å) and Zn(1)–O(3) (2.12(3) Å) being longer and O–Zn(1)–O angles (average 80.2°) smaller than the average values of other zinc atoms.

The X-ray results suggest the cleavage of two zinc(1)–oxygen bonds involving Zn(1)–O(4) and/or Zn(1)–O(4') at elevated temperatures. This reasonably explains the results of NMR and reactivity of [Zn-$(OMe)_2$·$(EtZnOMe)_6$]. Namely, the zinc dialkoxide part has vacant seats for coordination of methyloxirane under the influence of chiral circumstance at 80 °C, by a process of dissociation of two methoxy groups.

An Improved Synthesis of Dibenzoxanthene

Koki OTA and Taketoshi KITO

Department of Chemistry, Kyushu Institute of Technology, Tobata-ku, Kitakyushu-shi 804

(Received October 2, 1975)

Synopsis 14*H*-Dibenzo[*a*,*j*]xanthene was easily synthesized by heating alkali (K or Na) 2-naphthyloxide under CO and CO_2 pressure.

14*H*-Dibenzo[*a*,*j*]xanthene (DBX) and its derivatives have been synthesized by several methods. A mixture of DBX, dibenz[*a*,*j*]acridine, *N*-formyl-2-naphthylamine, 1-methyl-2-naphthol, and bis(2-hydroxy-1-naphthyl)methane (HNM) was formed by heating a mixture of 2-naphthol and formamide.[1] In this reaction, however, DBX was always not the main product, in addition, it was hard to separate from the other products. 3,11-Dimethyl-14*H*-dibenzo[*a*,*j*]-xanthene was obtained in a good yield from the reaction of 2-naphthol and formaldehyde, followed by internal cyclization using phosphoryl chloride.[2,3] Now, we wish to report a one-step synthesis of DBX in a higher state of purity.

Results and Discussion

DBX was obtained by heating alkali (K or Na) 2-naphthyloxide in a nonpolar solvent under an atmosphere of CO and CO_2. Such solvents as *N*,*N*-dimethylformamide and dioxane, in which alkali 2-naphthyloxide dissolves, prevent the reaction. The yield of DBX increases slightly in a reaction of more than 2 h, but the temperature affects the yield considerably. The presence of both CO and CO_2 is essential for the present reaction, and the pressure of CO appreciably affects the yield of DBX. The CO_2 may act as a neutralization agent of alkali salt, in which case the alkali metal would be consumed as alkali carbonate. Thus, the yield of 35% was attained in the reaction at 250 °C for 2 h under a pressure of CO (50 kg/cm^2) and CO_2 (8 kg/cm^2).

Pure DBX was formed as needles when the reaction was carried out in the presence of an alcohol, such as 1-butanol, 1-pentanol, 1-octanol, and 6-methyl-1-heptanol, although the yield of DBX fell slightly upon the alkylation of 2-naphthol by alcohol.[4] For example, the maximum yield of 26.0% was obtained from a reaction at 240 °C for 8 h under pressure of CO (56 kg/cm^2) and CO_2 (10 kg/cm^2) in the presence of octanol; the molar ratio of $C_8H_{17}OH$/2-$C_{10}H_7OK$ was 3.5.

Sodium 2-naphthyloxide gave DBX in a poorer yield than the potassium salt.

The thermal stability of DBX was also examined. A mixture of DBX, 1-butanol-*d*, potassium carbonate, and cyclohexane was heated under CO and CO_2 pressure at 240 °C for 1 h; 93.6% of the DBX was recovered and in it no deuterium was found. As a result, it was concluded that DBX is a thermally stable product; in other words, the two methylene hydrogens were thermally inactive under these conditions. On the other hand, at least four deuteriums were found in DBX when a mixture of potassium 2-naphthyloxide, 1-butanol-*d*, and cyclohexane was heated under CO and CO_2 pressure at 240 °C for 2.5 h (this was examined by means of a high-resolution mass spectrometer). Moreover, it was confirmed by NMR analyses that the two methylene protons of this DBX were almost entirely replaced by deuteriums. This fact suggests that the aromatic nucleus is also activated in the transition state and that the two hydrogen atoms in the methylene group of DBX come from both the aromatic nucleus and alcohol.

Experimental

The NMR spectra were obtained on a Japan Electron Optics Laboratory spectrometer (JNM, C-60 HL), with TMS used as the internal standard. The mass spectra were obtained on a Hitachi mass spectrometer (RMU-6L), using an electron-accelerating voltage of 70 eV. The IR spectrum was measured with a Japan Spectroscopic spectrometer (IRA-2).

DBX. One example will be described in detail. In a 300 ml autoclave, with an electromagnetic stirrer, we placed potassium 2-naphthyloxide (4.01 g), and cyclohexane (40 ml). After the air had been replaced by N_2, CO (50 kg/cm^2) and CO_2 (7 kg/cm^2) were introduced into the autoclave. The autoclave was then heated at 250 °C for 2 h. After cooling, aq. 2% NaOH was added to the reaction mixture, and the insoluble product (crude DBX) was filtered on a glass filter. The crude DBX was washed with small amounts of MeOH and then excess water, and the DBX was dissolved with trichloroethylene. The DBX was then obtained as a residue by the evaporation of the trichloroethylene. Yield, 1.09 g (35%, based on potassium 2-naphthyloxide). The melting point, MS, NMR, and IR of this product were consistent with those of authentic DBX.

Analyses of DBX. (i) Elementary analysis, Found: C, 88.91%; H, 4.96%. Calcd for $C_{21}H_{14}O$: C, 89.33%; H, 5.00%. (ii) MS: M^+=282 ($C_{21}H_{14}O$), 65%. (iii) NMR (δ value in CS_2 at 24 °C): 4.50, s(2H): 7.1—8.1, m(12H). (iv) IR(cm^{-1}): no absorptions in the range of 1800—1600; 1585, m; 1390, m; 1230, s; 950, m~w; 800, m; 760, m~w; 740, m. (v) Mp. 194 °C (from CS_2) determined by DTA.

Thermal Stability of DBX. A mixture of DBX (1.00 g), 1-butanol-*d* (0.58 g), potassium carbonate (0.57 g), and cyclohexane (35 ml) was heated under pressure of CO (34 kg/cm^2) and CO_2 (8 kg/cm^2) at 240 °C for 1 h (the pressure at 240 °C was 82 kg/cm^2). The recovery of the DBX was 93.6%.

*Reaction in the Presence of 1-Butanol-*d. A mixture of potassium 2-naphthyloxide (2.05 g), 1-butanol-*d* (5.20 g), and cyclohexane (40 ml) was heated under pressure of CO (65 kg/cm^2) and CO_2 (10 kg/cm^2) at 240 °C for 2.5 hr. The yield of DBX was 0.35 g. The results of the high resolution mass spectra of the DBX were as follows; *m*/*e*=282 (62%), 283 (71%), 284 (77%), 285 (45%), and 286 (19%). In

the NMR spectrum of this DBX, the ratio of aromatic protons/methylene protons was 0.042. The calculated ratio is 0.167.

Authentic DBX. HNM was prepared according to the directions;[2] DBX was thus obtained, with reference to the synthesis of 3,11-dimethyl-14*H*-dibenzo[*a*,*j*]xanthene,[3] by treating phosphoryl chloride on HNM.

Branched-chain Sugars. VI. Reaction of Methylene Dimagnesium Bromide with Uloses[1]

Juji YOSHIMURA, Ken-ichi SATO, Hiroo WAKAI, and Masuo FUNABASHI

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo, 152

(Received December 5, 1975)

Synopsis Application of methylene dimagnesium bromide, instead of the Wittig reagent, to several uloses gave the corresponding methylene derivatives in nearly equal yields, when the hydroxyl groups vicinal to the carbonyl function are protected with alkaline-stable groups.

The Wittig reaction with uloses is widely used for synthesis of the corresponding substituted and unsubstituted methylene derivatives, which are useful intermediates for preparation of branched-chain sugars as well as for elongation of carbon-chain of monosaccharides.[2]

Bertini *et al.*[3] reported that methylene dimagnesium bromide prepared from dibromomethane and magnesium amalgam in ether–benzene (1 : 1), instead of magnesium turnings in ether only, easily reacts with aldehydes and ketones to afford the corresponding methylene derivatives in good yields. If this method is applicable to uloses, it might be rather easier than the Wittig reaction to handle a large amount of compounds. The present paper describes the results obtained by the reaction of methylene dimagnessium bromide with uloses in comparison with the Wittig reaction.

Results and Discussion

Examination of the conditions for preparation of methylene dimagnesium bromide disclosed that the addition of catalytic amount of iodine and mercuric chloride, instead of magnesium amalgam, easily activates magnesium turnings. (Method A). Moreover, preparation and concurrent reaction of methylene dimagnesium bromide with uloses, by the final addition of dibromomethane to a suspension of an ulose and activated magnesium turnings in tetrahydrofuran gave the best results both in the yield and in handling. (Method B). Such a concurrent preparation-reaction system may prevent the formation of unreactive species of methylene dimagnesium bromide[4], even though tetrahydrofuran was used as a solvent.[3]

As uloses, 1,2 : 5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**)[5], 1,2-*O*-isopropylidene-3-*O*-methyl-6-*O*-trityl- (**2**)[6] and -6-*O*-benzyl-α-D-*xylo*-hexofuranos-5-ulose[6] (**3**), and methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-*ribo*-hexopyranos-3-ulose[7] (**4**) were used. The yields of methylene derivatives are summarized in Table 1, together with that of the Wittig reaction reported in literatures. The structure of products were confirmed by elemental and spectrometric analyses and also by the melting point of admixture. In the case of **4**, only an intractable sirup was obtained both in the Grignard and Wittig reactions. These results indicate that methylene dimagnesium bromide is almost as useful as the corresponding Wittig reagent for preparation of methylene derivatives of uloses.

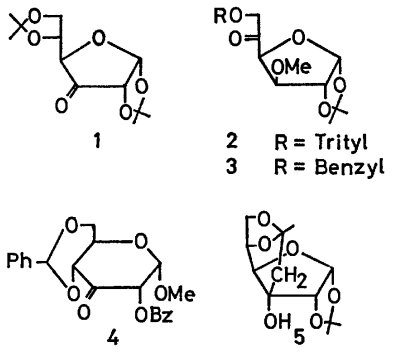

TABLE 1. COMPARISON OF YIELDS OF THE METHYLENE DERIVATIVES (**1**, **2** AND **3**)

Uloses	Yields (%)	
	Wittig reaction	Grignard reaction
1	55[9b], 60[1,9a]	60[a], 72[b]
2	50[6] c)	70[a]
3	85[6]	50[a], 60[b]

a) Method A, b) Method B, c) The yield was 80% in the case of the corresponding 3-*O*-benzyl derivative.[1]

Although the lack of reproducibility remained unexplained, a peculiar compound (**5**) was obtained in 86% yield, in the case of **1** in the method A without ether.

NMR spectrum of **5** showed the appearance of a quartet of isolated methylene group and a very broad signal of a hydroxyl proton, and the disappearance of one methyl signal of isopropylidene group.

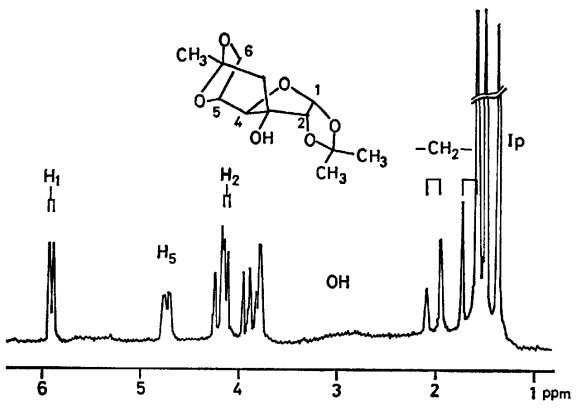

Fig. 1. NMR spectrum of **5**.

From this fact, in addition to the disappearance of the absorption of carbonyl group in IR spectrum, and elemental analysis, the structure **5** was tentatively determined to be 1,2-*O*-isopropylidene-3-*C*-(2'-oxopropyl)-α-D-allofuranose-(2'-*C*, 5-*O*, 6-*O*)-ketal. Examination of the structure with Dreiding model indicates no steric hindrance in this fused-ring system, and a similar structure is known in 1,2-*O*-isopropylidene-[3-*C*, 5-*O*, 6-*O*-(methylmethylidyne)]-α-D-allofuranose.[8]

Experimental

Optical rotations were measured in a 0.5 dm tube with a Carl Zeiss LEP-Al polarimeter. IR spectra were measured with a Hitachi Model EPI-G2 spectrometer. NMR spectra were taken with JEOL 4H-100 spectrometer in deuteriochloroform containing TMS as an internal refernce. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR in cm^{-1}.

Reaction of Uloses with Methylene Dimagnesium Bromide. *Method A.* A suspension of magnesium turning (1.46 g, 60 m atom), catalytic amount of iodine and mercuric chloride in benzene (40 ml) and ether (40 ml) was refluxed for the activation of magnesium, and then the addition of dibromomethane (4.35 g, 25 mmol) to the above suspension with stirring, under cooling if necessary, to form methylene dimagnesium bromide. A solution of uloses (5 mmol) in benzene was added dropwise into the Grignard solution with stirring at room temperature, and the mixture was poured into saturated ammonium chloride after stirring for 1 h. The resulting solution was filtered, and the filtrate was concentrated into a half volume, extracted with chloroform. Concentration of the extracts gave the corresponding methylene derivatives, which were purified by the methods reported in the literatures and identified with authentic specimens.

Method B. To a suspension of magnesium activated as mentioned in method A in tetrahydrofuran, was added, in turn, a solution of uloses in THF and dibromomethane with stirring, under cooling if necessary. The reaction mixture was treated in the same way as above.

1,2-O-Isopropylidene-3-C-(2'-oxopropyl)-α-D-allofuranose-(2'-C, 5-O,6-O)-ketal (5). As an example, methylene dimagnesium bromide (the same scale as method A) was prepared in benzene only. 1,2 : 5,6-Di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose was then added to the Grignard solution. The work-up of the reaction mixture gave crude crystals which were recrystallized from benzene to give needles having mp 139—140° and $[\alpha]_D^{23}$ −2.8° (*c* 1.1, $CHCl_3$). IR: 3500 (OH), NMR: 5.91 (H_1; d, $J_{1,2}$=3.75), 4.74 (H_5; q), 4.13 (H_2; d), 4.3—3.7 (H_3, H_4, H_6, H_6'; m), 2.02 and 1.66 (CH_2; q, J_{gem}=17.5), 1.60, 1.50 and 1.38 ($3\times CH_3$).

Found: C, 55.66; H, 7.14%. Calcd for $C_{12}H_{18}O_6$: C, 55.80; H, 7.03%.

The Inclusion Effects of Cyclodextrins on the Photolysis of *p*-Benzoquinone in Aqueous Solution

Kazutoshi YAMADA, Shigeo KOHMOTO, and Hirotada IIDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

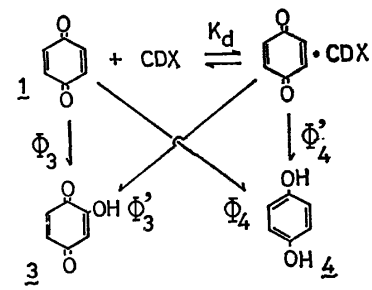
(Received December 20, 1975)

Synopsis. The additive effects of cyclodextrins on the photolysis of *p*-benzoquinone in water were investigated spectrophotometrically. By applying Michaelis-Menten keinetics, the dissociation constant of the inclusion complex was determined. The quantum yield for the formation of hydroquinone from the complex increased, while that of 2-hydroxy-1,4-benzoquinone decreased.

The cyclodextrin inclusion effects are known as a good enzymatic action model and many reports on their catalytic activities have been published.[1] Cyclodextrins associate with a variety of organic substances in aqueous solution. This complexation leads to their catalytic selectivity. In the previous papers, we reported the photochemical reaction control by cyclodextrins.[2] In this note, we wish to report the effects of cyclodextrins on the photolysis of *p*-benzoquinone in aqueous solution and to show that the addition of water to *p*-benzoquinone must be inhibited.

Recently several investigations of the photolysis of quinones in an aqueous solution have been reported. In the photolysis of *p*-benzoquinone (**1**) in aqueous solution, hydroquinone (**4**) has been isolated as the sole stable product in addition to the transient formation of 1,2,4-benzenetriol (**2**) and 2-hydroxy-1,4-benzoquinone (**3**)[3]. Kurein and Robins[4] suggested in their spectrophotometric study that the primary photochemical process of this photolysis was the conversion of **1** into **2**. According to their report, **3** and **4** are formed by dark reaction between **1** and **2**, and the result is the approximately equal quantity of **3** and **4**. Kano and Matsuo[5] tried this photolysis of **1** in the presence of the surfactants. The quantum yield for the disappearance of **1** was accelerated by the addition of the anionic surfactant, but was suppressed by the cationic one. Shirai and Tanaka[6] suggested an electrophilic attack of the excited **1** on water.

α-Cyclodextrin (α-CDX) and β-cyclodextrin (β-CDX) were used in this work. CDX was dissolved in an aqueous solution of **1**. CDX has little absorption above 230 nm and no spectral change was observed within experimental errors after the addition of CDX. After irradiation with 254 nm light, the reacted solution was quickly converted to acidic (because **3** is not stable in the neutral pH range), and the curve resolution was carried out to determine the yield conversions of **3** and **4**. In the absence of CDX, oxidation of the reacted solution by $Ce(SO_4)_2$, the same method used by Robins, showed that products were about equal quantity of **3** and **4**, and also the curve resolution showed the same value. Scheme 1 shows the processes of the CDX catalyzed photolysis of **1**. Here, we assumed that **1** and CDX would make a 1 : 1 complex. In this scheme, K_d represents the dissociation



Scheme 1. The mechanism of CDX catalyzed photolysis of **1**.

constant of the inclusion complex, Φ_3 and Φ_4, the quantum yield for the formation of **3** and **4** from **1**, respectively, and Φ'_3 and Φ'_4, the quantum yield for the formation of **3** and **4** from the inclusion complex, respectively. The modified form of Michaelis-Menten's equation[7] was applied to this system. The equation was modified by using the quantum yield instead of the first order rate constant[8]. This equation was used separately for the formation of **3** and **4**. The following equations were used in our calculations.

$$(1-\Phi_{obs}/\Phi_3)^{-1} = (1-\Phi_3'/\Phi_3)^{-1} + K_d(1-\Phi_3'/\Phi_3)^{-1}[CDX]^{-1} \quad (1)$$

$$(\Phi_{obs}/\Phi_4-1)^{-1} = (\Phi_4'/\Phi_4-1)^{-1} + K_d(\Phi_4'/\Phi_4-1)^{-1}[CDX]^{-1} \quad (2)$$

In these equations, Φ_{obs} represents the observed quantum yields for the formation of **3** and **4** when CDX was added. Figure 1 shows the plots of the modified form of Michalis-Menten's equation in the case where α-CDX was added. The plots obtained from Eqs. 1 and 2 were strictly linear and these two lines were coincident. This means that the quantum yield for the formation of **3** from the inclusion complex decreases,

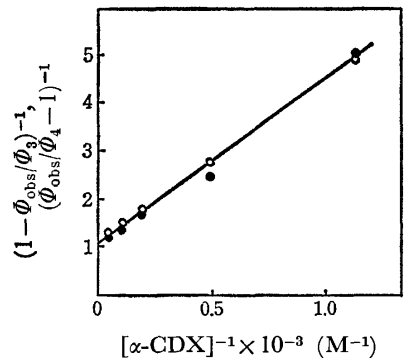


Fig. 1. The plots of Michaelis-Menten's equation.
—○—: Plots for **3** calculated from Eq. 1.
—●—: Plots for **4** calculated from Eq. 2.

Table 1. Values of the quantum yield ratios and the dissociation constants obtained from the modified form of Michaelis-Menten's equation

	α-CDX	β-CDX
Φ_3'/Φ_3	0.2±0.1	0.1±0.1
Φ_4'/Φ_4	1.9±0.2	2.1±0.4
$K_d \times 10^3$ (M)	2.1±0.1[a)] / 1.9±0.2[b)]	2.0±0.1[a)] / 2.3±0.6[b)]

a) Obtained from Eq. 1. b) Obtained from Eq. 2.

but on the other hand that of **4** increases. This was also true when β-CDX was added and the same linear relationship was obtained. Obtained values of Φ and K_d by Eqs. 1 and 2 are showed in Table 1. In Table 1 Φ'_3/Φ_3 is nearly zero while Φ'_4/Φ_4 is nearly two and K_d obtained from Eqs. 1 and 2 quite agree with each other, in both complexes.

Next, we examined the additive effects of α-methyl D(+)-glucoside (α-MG) and poly(vinyl alcohol) (PVA, $n=500$). α-MG has only one glucopyranose unit which is contained in CDX. PVA has a helix structure and was reported to make an inclusion complex with iodine[9]. Both α-MG and PVA showed the same tendency as CDX. But this tendency is very weak for α-MG. From the above results, we conclude that CDX makes the 1 : 1 inclusion complex with **1** in aqueous solution and conformationally inhibits the addition of water to **1**, and probably the excited **1** will abstract hydrogen from CDX.

Experimental

The light source used in this work is USHIO ULO-6DQ 6 watt low pressure mercury lamp. For the counting of the photons irradiated, potassium ferrioxalate actinometry was used. Irradiations were carried out in the spectrophotometric cell (width 1 cm) according to the method proposed by Parker[10]. The light intensity at 254 nm measured in our irradiation system is $(3.54+0.57)\times 10^{17}$ quanta/s·l. three ml of arerobic solution of **1** was pipeted in the spectrophotometric cell (4.4×10^{-5} M), and after the irradiation for constant time 1 ml of 2M-H_2SO_4 solution was added to the reacted solution, and UV spectrum was measured. The curve resolution was carried out at 246 nm and 256 nm to determine the yield conversions of **3** (λ_{max} 256 nm, ε 13700, ε at 246 nm is 11100) and **4** (λ_{max} 289 nm, ε at 246 nm is 180, and ε at 256 nm is 190). To ensure this curve resolution, parrallel experiment, oxidation of the reacted solution by $Ce(SO_4)_2$ was carried out. **2** is converted into **3**, and **4** is converted into **1** quantitatively by $Ce(SO_4)_2$. This oxidation gave nearly same values of conversion which obtained by the curve resolution. CDX did not disturb this oxidation. After the complete photolysis (40 min irradiation), both the curve resolution and oxidation of the reacted solution suggested that the products were about equal quantity of **3** and **4**. The quantum yield for dissaperance of **1** is 0.44± 0.09, and for appearance of **3** and **4** is *ca.* 0.22 without CDX.

8) The modified form of Michaelis-Mentens equation.

$$S + C \underset{K_d}{\rightleftharpoons} S\cdot C \xrightarrow[k_2]{} \text{Products}$$

$k_1 \downarrow$

Products

S, substrate C, CDX

The modified form of Michaelis-Mentens' equation was showed by the following form. See Refs. 1 and 7.

$$(k_{obs}-k_1)^{-1} = (k_2-k_1)^{-1} + K_d(k_2-k_1)^{-1}\,C^{-1} \quad (3)$$

k_1, the uncatalyzed first order rate constants
k_2, the catalyzed first order rate constants

We can show the quantum yield by the next equation. Here, we assume that the products effect little on the absorption of photons by substrate at the irradiating wavelength.

$$\Phi = \frac{C_0\cdot V\cdot \Delta x\cdot N_A}{\int_t^{t+\Delta t} N_{pabs}\cdot V\cdot(1-x)\,dt} \quad (4)$$

C_0, the initial concentration of the substrate
V, the volume of the solution
x, the conversion of the substrate at the reaction time "t"
$x+\Delta x$, the conversion of the substrate at the reaction time "$t+\Delta t$"
N_A, Avogadro number
N_{pabs}, the number of photons absorbed at the initial concentration

Next, we assume that this photochemical reaction proceeds according to the first order rate law, following equation will be applied.

$$\ln\frac{1}{1-x} = kt \quad (5)$$

k, the first order rate constant

From Eqs. 4 and 5 we get the very simple relation between the quantum yield and the first order rate constant.

$$\Phi = \frac{C_0\cdot N_A\cdot k}{N_{pabs}} \quad (6)$$

From Eqs. 3 and 6, we obtain the Eqs. 1 and 2.

Phosphinidenes and Related Intermediates. V.[1] Reactions of Phosphinylidenes with *cis*- and *trans*-Stilbene Oxides

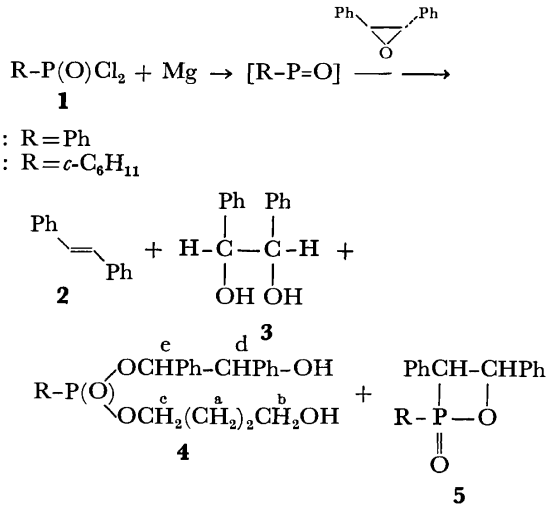
Shigenobu NAKAYAMA, Masaaki YOSHIFUJI, Renji OKAZAKI, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received January 16, 1976)

Synopsis. Reactions of phenyl- and cyclohexylphosphinylidenes with *trans*-stilbene oxide gave *trans*-stilbene and 4-hydroxybutyl 2-hydroxy-1,2-diphenylethyl phosphonate derivatives. In the case of cyclohexylphosphinylidene, 2-cyclohexyl-3,4-diphenyl-1,2-oxaphosphetane 2-oxide was also formed. Reactions with *cis*-stilbene oxide gave *cis*- and *trans*-stilbenes.

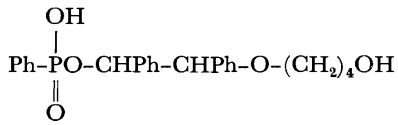
In the previous paper,[1] we reported that phosphinothioylidenes reacted with *cis*- and *trans*-stilbene oxides to give 1,3,2-oxathiaphospholane derivatives stereospecifically in most cases and *cis*- and/or *trans*-stilbenes. On the other hand, the reaction of phosphinylidenes gave different products except the formation of stilbenes.

Phenylphosphonic dichloride (**1a**) was allowed to react with magnesium in the presence of *trans*-stilbene oxide in tetrahydrofuran (THF) under nitrogen. *trans*-Stilbene (**2**), *meso*-1,2-diphenylethane-1,2-diol (**3**), and 4-hydroxybutyl 2-hydroxy-1,2-diphenylethyl phenylphosphonate (**4a**) were obtained in 10, 36, and 12% yields, respectively. A similar reaction using cyclohexylphosphonic dichloride (**1b**) gave 2,3,4-hydroxybutyl 2-hydroxy-1,2-diphenylethyl cyclohexylphosphonate (**4b**), and 2-cyclohexyl-3,4-diphenyl-1,2-oxaphosphetan 2-oxide (**5b**) in 11, 9, 12, and 8% yields, respectively.



The structures of **4** and **5** were determined by the elemental analyses and spectral data.

In the NMR spectrum of **4a**, the presence of the multiplet at δ 3.5—4.0 ppm would rule out another possible structure **4a'**.

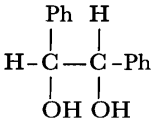


4a'

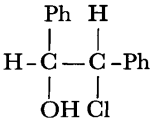
Comparison of the NMR spectrum of **4b** with that of **4a** suggests that **4b** is a mixture of isomers concerning with two methine parts (see Experimental). The IR spectrum of **5b** showed a strong broad band at 3150 cm^{-1} which is probably assignable to water of crystallization.

The fact that the reaction of *trans*-stilbene oxide with magnesium-magnesium(II) chloride did not give **3**[1] suggests a participation of phosphinylidene in the formation of **3**.

Reaction of phenylphosphinylidene with *cis*-stilbene oxide gave *cis*- and *trans*-stilbenes, *dl*-1,2-diphenylethane-1,2-diol (**6**), and *threo*-2-chloro-1,2-diphenylethanol (**7**), but the corresponding product of **4** could not be isolated in a pure state. A similar reaction of cyclohexylphosphinylidene gave *cis*- and *trans*-stilbenes and **7**.



6



7

Experimental

All reactions were carried out under nitrogen.

Reaction of ***1a*** *with Magnesium and* trans-*Stilbene Oxide.* A solution of **1a**[2] (3.90 g, 20 mmol) in THF (5 ml) was added dropwise to a stirred mixture of magnesium (0.53 g, 21.8 mmol) and *trans*-stilbene oxide[3] (2.00 g, 10.3 mmol) in THF (40 ml) at room temperature, and the mixture was stirred until exothermic reaction had ceased (*ca.* 1 h). Unchanged magnesium (10 mg) was filtered off and the solvent was evaporated *in vacuo* from the filtrate. The residue was extracted with $CHCl_3$. The extract was washed with aq. NH_4Cl and dried over $MgSO_4$. After evaporation, the residue was chromatographed on a silica gel dry column to give 0.13 g (0.7 mmol) of unchanged oxide, 0.18 g (1 mmol) of *trans*-stilbene (**2**), 0.74 g (3.5 mmol) of **3**, mp 136—138 °C (from CCl_4) (lit,[4] 137 °C), and 0.47 g (1.1 mmol) of **4a**. The yields of **2**, **3**, and **4a** were 10, 36, and 12%, respectively, based on *trans*-stilbene oxide consumed.

4a: mp 116—119 °C (from CCl_4); IR (KBr): 3345 (OH), 1218 (P=O), 1138 (P-Ph), 1000, and 988 cm^{-1} (P-O-C); NMR ($CDCl_3$): δ 1.4—1.8(m, 4H, $2CH_2$), 2.95(s, 2H, 2 OH), 3.2—3.5(m, 2H, $C\underline{H}_2OH$), 3.5—4.0(m, 2H, $POCH_2$), 4.95 (d, J_{HCCH} 5 Hz, 1H, $C\underline{H}PhOH$), 5.8(dd, J_{HCCH} 5, J_{POCH} 9 Hz, 1H, $POC\underline{H}Ph$), and 6.9—7.9(m,15H, 3Ph); MS: *m/e* 338 ($PhP(OH)_2OCHPhCHPh^+$ or $PhP(OH)OCHPhCHPhOH^+$, 19%), 230 ($PhP(O)OCHPh^+$, 24), 178($PhC{\equiv}CPh^+$, 86), 167($PhP(O)OC_2H_3^+$, 72), 159 ($PhPO_3H_3^+$, 34), 141 ($PhPO_2H^+$, 61), 124 ($PhPO^+$, 31), and 77 (Ph^+, 100).

Found: C, 65.86; H, 6.46; P. 6.52%. Calcd for $C_{24}H_{27}O_5P \cdot 3/5H_2O$: C, 65.93; H, 6.50; P, 7.08%.

Reaction of ***1b*** *with Magnesium and* trans-*Stilbene Oxide.* A solution of **1b**[5] (4.02 g, 20 mmol) in THF (5 ml) was added

dropwise to a stirred mixture of magnesium (0.53 g, 21.8 mmol) and *trans*-stilbene oxide (2.00 g, 10.3 mmol) in THF (40 ml) at room temperature, and the mixture was stirred overnight. After a usual treatment, dry column chromatography on silica gel gave unchanged oxide (0.52 g, 2.7 mmol), **2**(0.14 g, 0.8 mmol), **3**(0.14 g, 0.7 mmol), **4b**(0.40 g, 0.9 mmol), and **5b**(0.20 g, 0.6 mmol) in 11, 9, 12, and 8% yields, respectively, based on *trans*-stilbene oxide consumed.

4b: mp 113.5—116.5 °C (from hexane); IR (KBr): 3390 (OH), 1228, 1200 (P=O), 995, and 985 cm^{-1} (P–O–C); NMR ($CDCl_3$): δ 0.8—2.0(m, 15H, *c*-C_6H_{11} and $2CH_2$), 2.8(bs, 2H, 2 OH), 3.25—4.0(m, 4H, $2CH_2O$), 4.93 (d+d, $J_{H^dH^e}$ 6 and 4 Hz, 1H, H^d), 5.56(dd+t, $J_{H^dH^e}$ 6 and 4 Hz, J_{POCH^e} 14 and 4 Hz, 1H, H^e), and 6.9—7.6 (m, 10H, 2Ph); MS: *m/e* 344 (*c*-$C_6H_{11}P(OH)_2OCHPhCHPh^+$ or *c*-C_6H_{11}-$P(OH)OCHPhCHPhOH^+$, 10%), 178($PhC{\equiv}CPh^+$, 63), 163(*c*-$C_6H_{11}PO_3H^+$, 16), 91($C_7H_7^+$, 70), and 55($C_4H_7^+$, 100).

Found: C, 64.00; H, 7.44; P, 7.13%. Calcd for $C_{24}H_{33}$-$O_5P\cdot H_2O$: C, 63.99; H, 7.83; P, 6.88%.

5b: mp 172—173 °C (from aq. EtOH); IR (KBr): 3150(br) (H_2O), 1213 (P=O), 1180, 1168, 1159, 1140, and 1090 cm^{-1} (P–O–C); NMR ($CDCl_3$): δ 0.8—2.4 (m, 11H, *c*-C_6H_{11}), 4.5—4.8 (m, 2H, 2CH), and 7.1—7.6 (m, 10H, 2Ph); MS: *m/e* 196 ($CHPhCHPhO^+$, 3%) and 167 ($PhC_2H_3O_2P^+$, 100).

Found: C, 72.35; H, 7.63; P, 8.86%. Calcd for $C_{20}H_{23}$-$O_2P\cdot 2/5H_2O$: C, 72.01; H, 7.19; P, 9.29%.

Reaction of ***1a*** *with Magnesium and* cis-*Stilbene Oxide.* Dichloride **1a** (6.01 g, 30.8 mmol) in THF (5 ml) was added dropwise to a mixture of *cis*-stilbene oxide[6] (3.00 g, 15.3 mmol) and magnesium (0.81 g, 33.3 mmol) in THF (45 ml) with stirring at room temperature over 1 h and the mixture was refluxed for 3 h. After a similar treatment, the residue was chromatographed on a silica gel dry column to afford unchanged oxide (0.21 g, 1.1 mmol), *cis*-(0.24 g, 1.3 mmol, 4.4%), and *trans*-stilbenes (1.9 g, 1.1 mmol, 3.7%), and **6** (0.10 g, 0.5 mmol, 1.7%), mp 121.5—122.5 °C (from CCl_4) (lit,[4] 120 °C). An oily fraction analogous to **4** (0.7 g) was obtained, but could not be purified. In addition, **7** (0.6 g, mp 43—45 °C (from hexane) (lit,[7] 47 °C) was obtained. The yields were calculated based on *cis*-stilbene oxide consumed.

Reaction of ***1b*** *with Magnesium and* cis-*Stilbene Oxide.* The reaction was carried out in the same scale as that of **1a**, and *cis*-(0.68 g, 3.7 mmol, 11%) and *trans*-stilbenes (1.22 g, 6.8 mmol, 22%), and **7** (0.15 g, 1.1 mmol, 3.7%) were obtained.

This work was supported by a grant-in-aid from the Ministry of Education.

Metal Phosphinylides and Phosphinothioylides. VI.[1] Some Observations in Reactions of Diphenylphosphinic Chloride with Tetrahydrofuran in the Presence of Metal Chlorides

Koshiro GODA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received January 16, 1976)

Synopsis. ^{31}P-NMR data showed a formation of a stable 1 : 1 complex between diphenylphosphinic chloride (**1**) and aluminum chloride. The effect of common chloride ion on the reaction of **1** with tetrahydrofuran in the presence of zinc or cuprous chloride supported a cationic mechanism in the former case, and no free radical but homolytic mechanism in the latter.

We reported in a previous paper[2] that diphenylphosphinic chloride (**1**) reacted with tetrahydrofuran (THF) in the presence of cuprous, cupric, zinc, aluminum or ferric chloride to give *O*-4-chlorobutyl diphenylphosphinate (**2**) in all cases, and it was suggested that **2** was formed through no free radical but homolytic mechanism in the case of cuprous chloride. This note describes on further observation in the above reactions.

Though zinc, aluminum, and ferric chlorides are typical Lewis acids, the latter two chlorides give **2** in a moderate yield.[2]

^{31}P-NMR data showed that **1** formed a stable 1 : 1 complex (**3**) with aluminum chloride (see Table 1) as reported in analogous systems,[3] but that, in the case of zinc chloride, ^{31}P chemical shift of **1** did not change within the experimental error. Therefore, it is considered that the reactivity of **1** becomes very low in the presence of aluminum chloride, because of the formation of the stable complex (**3**). Thus, zinc chloride becomes more effective as a catalyst than aluminum chloride.

$$\underset{\underset{\mathbf{1}}{\|}}{\underset{O}{Ph_2P\text{-}Cl}} + AlCl_3 \longrightarrow \underset{\underset{\mathbf{3}}{\|}}{\underset{O\rightarrow AlCl_3}{Ph_2P\text{-}Cl}}$$

Table 1. Changes in ^{31}P chemical shift of **1** in the presence of aluminum chloride in nitrobenzene

$AlCl_3$/**1** (mol/mol)	0	0.28	0.56	0.62	0.83	1.05	1.38	2.06
$-\delta^{31}$P (ppm)	42.8	44.1	46.5	49.6	55.9	60.6	60.5	60.6

Similarly, ^{31}P-NMR data also showed that **1** did not form a complex with cuprous chloride in acetonitrile.

These tendency were also similar in the case of diphenylphosphinothioic chloride.

In order to make clear a difference in mechanisms in the presence of zinc or cuprous chloride, effects of addition of lithium chloride on the yields of **2** were scrutinized. The results are shown in Table 2.

$$\underset{\mathbf{1}}{Ph_2P(O)Cl} + THF \xrightarrow[\text{or CuCl}]{ZnCl_2} \underset{\mathbf{2}}{Ph_2P(O)O(CH_2)_4Cl}$$

Table 2. Effect of addition of lithium chloride on yields of **2** (at 120 °C for 6 h)

a) In the case of zinc chloride

[LiCl]/**1** (mol/mol)	[LiCl]/[$ZnCl_2$]	Yield of **2** (%)
0	0	36
2.4×10^{-2}	1.3	62
9.2×10^{-2}	5.2	61
16×10^{-2}	10.1	58
34×10^{-2}	18.6	55

b) In the case of cuprous chloride

[LiCl]/**1** (mol/mol)	[LiCl]/[CuCl]	Yield of **2** (%)
0	0	38
1.9×10^{-2}	1.1	7
8.1×10^{-2}	4.6	9
17×10^{-2}	9.0	12
31×10^{-2}	17.0	12
98×10^{-2}	∞[a]	13

a) In the absence of cuprous chloride.

The effect of the common chloride ion showed an extreme contrast in both cases as shown in Table 2, suggesting a different mechanism in each case. Increase in yield of **2** in the case of zinc chloride is in agreement with the following ionic mechanism.

$$Ph_2P(O)Cl + ZnCl_2 \rightarrow Ph_2\overset{\delta+}{P}(O)\cdots\overset{\delta-}{Z}nCl_3 \xrightarrow{THF} \left[\overset{+}{O}\text{-}P(O)Ph_2 + ZnCl_3^- \text{ (or } Cl^-)\right] \rightarrow \mathbf{2} + ZnCl_2$$

Furthermore, in the case of cuprous chloride, ten times molar amounts (based on cuprous chloride) of cupric acetate w re added in place of lithium chloride under the same condition, but 4-acetoxybutyl diphenylphosphinate could not be detected. The product was only **2** (45%). This result ruled out a cationic mechanism.

The **1**-CuCl system did not result in isomerization of *cis*-stilbene in acetonitrile at 120 °C for 24 h, indicating the absence of free $Ph_2\dot{P}O$ radical. Therefore, a mechanism containing an inner-sphere electron transfer as shown in the following scheme might be more reasonable.

$$\underset{\underset{O}{\|}}{Ph_2P\text{-}Cl} + CuCl \rightleftarrows \underset{\underset{O}{\|}}{Ph_2\dot{P}\text{-}Cu^{II}Cl_2} \xrightarrow{THF} \left[\underset{\underset{O}{\|}}{Ph_2\bar{P}\text{-}\overset{+}{O}}\right] CuCl_2 \rightarrow \mathbf{2} + CuCl$$

The remarkable decrease in the yield of **2** in the presence of chloride ion is understandable, assuming that chloride ion coordinates with cuprous chloride and the electron transfer becomes difficult. A similar effect of lithium chloride has been reported in a carbon tetrachloride–cuprous chloride–olefin system.[4]

The yield of **2** is expected to decrease by addition of acetonitrile which can coordinate to cuprous chloride. In fact, addition of 3.5 times amounts of acetonitrile decreased the yield of **2** from 38% to 29%.

Moreover, the yield of **2** was better in the presence of cupric chloride than in the presence of cuprous chloride.[2] In order to make this point clear, cupric chloride was heated in THF at 120 °C for 24 h, and 12% of cuprous chloride was formed. Thus, the previous result is explained by the formation of more reactive cuprous chloride *in situ*.

Experimental

The ^{31}P-NMR spectra were measured with a Hitachi R-20 B-R-204-PB spectrometer using 85% phosphoric acid as an external standard. All reactions were carried out under nitrogen in a sealed tube.

*Reaction of Diphenylphosphinic Chloride (**1**) with THF in the Presence of Metal Chloride.* *1) Zinc Chloride*: A mixture of **1**[5] (6.2—6.8 mmol) and zinc chloride (0.11—0.12 mmol) in 8 ml of THF was heated in the presence of an appropriate amount of lithium chloride for 6 h at 120 °C. The reaction mixture was treated with methanol, concentrated, and determined by gas chromatography (column: H 523 on Diasolid at 210 °C) with methyl diphenylphosphinodithioate as an internal reference.

2) *Cuprous Chloride*: A mixture of **1** (5.6—5.8 mmol) and cuprous chloride (0.10—0.11 mmol/mmol of Cu atom) in 9 ml of THF was heated in the presence of an appropriate amount of lithium chloride for 6 h at 120 °C. The reaction mixture was treated similarly.

We are grateful to Dr. M. Yoshifuji and Dr. T. Kawashima of our laboratory for ^{31}P-NMR measurements. This work was supported by a grant-in-aid from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49(4), 1177 (1976)

Olefination of Aldehydes by Methylenedicalcium Diiodide

Nariyoshi KAWABATA,* Michiharu NAKA, Takao KOMAZAWA, and Shinzo YAMASHITA

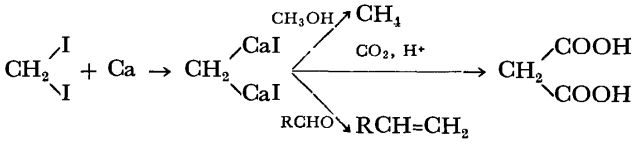
Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received December 15, 1975)

Synopsis. Reaction of diiodomethane with calcium in tetrahydrofuran gave methylenedicalcium diiodide in 17% yield. Reaction of the calcium compound with aldehydes was shown to give the corresponding olefins in estimated yields of 53—94%.

Only a few works are available in the literature on the reaction of organocalcium compounds. We have demonstrated that methylcalcium iodide is a useful organometallic reagent in several organic reactions.[1,2] This paper describes the reaction of methylenedicalcium diiodide with carbonyl compounds. *gem*-Dimetallic compounds of lithium,[3] magnesium,[4] and zinc[5] are known to olefinate carbonyl compounds, but no information is available in the literature on the reaction of methylenedicalcium dihalides with carbonyl compounds.

Reaction of diiodomethane with calcium in tetrahydrofuran at −30 °C gave methylenedicalcium diiodide in 17% yield. Gas chromatographic analysis showed that diiodomethane was not remained in the reaction mixture. The yield was determined based on the amount of methane evolved by the addition of methanol. The geminal dimetallic nature of the organocalcium compound was confirmed by carboxylation, which gave malonic acid in 12% yield based on diiodomethane (71% based on methylenedicalcium diiodide).



Reaction of diiodomethane with calcium in the presence of aldehydes at room temperature in tetrahydrofuran was found to give the corresponding olefins in 9–16% yields based on diiodomethane as is shown in Table 1. Since the yield of methylenedicalcium diiodide was 17% based on diiodomethane, the yields of olefins based on the organocalcium compound was estimated to be 53—94%. The reaction of bromoiodomethane with calcium in the presence of *p*-tolualdehyde gave *p*-methylstyrene though in a lower yield, but dibromomethane and dichloromethane did not react with calcium under the conditions. The reaction of diiodomethane with calcium in the presence of ketones did not give the corresponding olefins.

Experimental

Diiodomethane and aldehydes were purified by distillation. Bromoiodomethane was prepared by a conventional method.[6] Tetrahydrofuran and nitrogen were purified, and metallic calcium was rasped as described in our previous papers.[7,8] Methylenedicalcium diiodide was prepared from 0.26 g (6.50 mmol) of calcium and 0.74 g (2.76 mmol) of diiodomethane in 5.0 ml of tetrahydrofuran at −30 °C according to our previous procedure[8] with minor modifications. Carboxylation of methylenedicalcium diiodide was carried out at −70 °C according to our previous procedure[2] with minor modifications. Olefination of aldehydes was carried out by the addition of dihalomethane to a mixture of metallic calcium and aldehyde in tetrahydrofuran at room temperature under a nitrogen atmosphere. The reaction mixture was allowed to remain at room temperature for an additional 1 h, and worked up in the usual manner. Yields were determined by gas chromatographic analyses of the reaction mixture.

Electronic Structure of Porphyrins. I. SCF-MO-CI Calculation Based on π-Electron Approximation

Kotaro TOMONO and Kichisuke NISHIMOTO

Department of Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 6, 1975)

The electronic structure and electronic spectra of metal free and metal porphyrins have been investigated by the MO method. In order to elucidate the effect of electron correlation on the electronic transitions, a new approximation for electron repulsion integral has been examined. For metal free porphyrin, the effect of hydrogen bondings on the electronic transitions has also been investigated. In metal porphyrin, the present calculation showed that almost two units of charges are transferred from the ligand porphyrin to the central metal ion through σ-type co-ordination bond. A satisfactory agreement between the calculated results and the experimental data was obtained when a new expression for electron repulsion integral, in which the effect of electron correlation is considered, was used. It was found that the Soret band of metal free porphyrin consists of almost degenerated B_x and B_y species.

Metal porphyrins are very important molecules in the field of biochemistry and biology. From this reason, a number of studies of the physico-chemical properties of these molecules have been carried out.[1] It is well known that hemoglobin, myoglobin, and cytochrome contain iron porphyrins. Vitamin B_{12} and chlorophyll also contain porphyrins. The porphyrin parts play most important roles in the chemical behavior of these molecules. Howver, their electronic spectra have not been clarified. Kobayashi,[2] Weiss *et al.*[3] and others[4-6] have calculated two strong allowed transitions for metal free porphyrin in the region of 400 nm. However, the observed spectra show only one strong absorption band in this region, so-called the Soret band. The excited energy levels of the molecule should be important, for understanding its photo-chemical behavior. One of the main purposes of this paper is to elucidate the nature of the Soret band, so that we have carried out SCF-MO-CI calculations. The effect of electron correlation on the electronic transitions is an interesting theoretical subject. So that, we used two kinds of approximations for electron repulsion integrals, one of them is older one[7] and another[8] is newly derived from a quantum field theory.

Calculation

SCF-MO-CI calculation based on π-electron approximation was carried out. Parameters were evaluated as following manner.

(*A*) *The Framework and Core Charges.* Webb and Fleischer[9] studied the crystal structure of metal free porphyrin by X-ray analysis. They treated the two hydrogen atoms attached to the nitrogens as four half-atoms. The two hydrogen can be considered to be statistically disordered or involved in the rapid interconversion of N–H tautomers. From the infrared spectroscopy,[10] it has been confirmed that inner hydrogens form hydrogen bonds with neighboring non-bonded nitrogens (Fig. 1). In order to elucidate the effect of hydrogen bond on the electronic structure of the porphyrin, we carried out MO calculations in which the core charges of nitrogens are assumed to change with the hydrogen bond formation. For the sake of simplicity, we assumed the D_{4h} symmetry for the porphyrin molecular frame-work. The bond distances and the bond angles were taken to be the same as those for the metal porphyrins. However, this causes no serious effect on the calculated results of electronic structure, since we used the variable β approximation.[11] Fleischer,[12] and Fleischer *et al.*[13] measured molecular dimensions of various metal porphyrins by X-ray analysis. The average interatomic distances associated with C–N, β–β, α–β, α–meso, and metal–N bonds are 1.38 Å, 1.35 Å, 1.44 Å, 1.40 Å, and 2.00 Å, respectively. In this paper we assumed the following interatomic distances: C–C 1.40 Å, C–N 1.38 Å, N:N (opposite to each other) 4.00 Å. When the value of CNC angle is assumed to be 108°, the other bond angles can be evaluated as shown in Fig. 2, because of the D_{4h} symmetry.

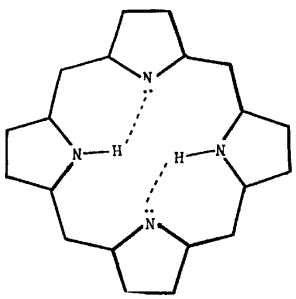

Fig. 1. Hydrogen bonds in metal free porphin.

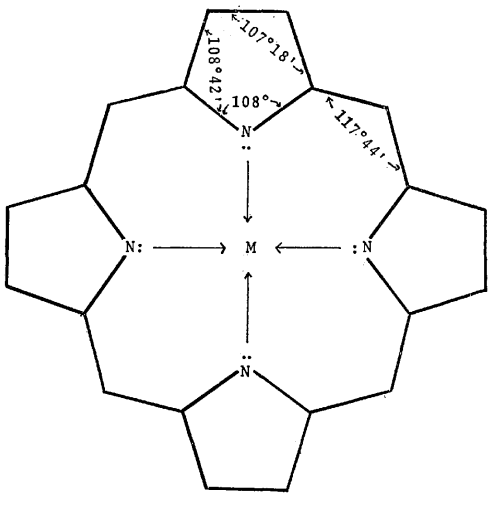

Fig. 2. Assumed porphin frame-work.

The number of π electrons is assumed to be 26 which is the same as that of free porphyrin. In the metal porphyrin, the lone pair electrons of a nitrogen should be largely transferred to the central metal ion by the formation of σ-type co-ordination bond. The net charge of central divalent metal ion is, therefore, expected to be considerably decreased. We have assumed the following various core charges for a nitrogen, +1.0, +1.3 and +1.5, which correspond to the net charges of the central metal ion, +2.0, +0.8, and 0.0, respectively.

(B) One-center Core Integral. When we neglect the penetration integrals, the core integral $\alpha_{\mu\mu}$ can be written as

$$\alpha_{\mu\mu} = \int \phi_\mu(1) H_{\text{core}}(1) \phi_\mu(1) d\tau = -I_\mu - \sum_{\nu \neq \mu} Q_\nu \gamma_{\mu\nu} \quad (1)$$

where ϕ_μ: 2pπ AO of atom μ

I_μ: valence state ionization potential of atom μ

Q_ν: core charge of atom ν

$\gamma_{\mu\nu}$: two-center electron repulsion integral.

I_μ can be represented by the following quadratic equation of core charge Q:[14]

$$I_\mu(Q) = (1/2)\{I(2) - 2I(1) + EA\}Q^2 - (1/2)\{I(2) - 4I(1) + 3EA\}Q + EA \quad (2)$$

where $I(2)$: second ionization potential

$I(1)$: first ionization potential

EA: electron affinity.

(C) Two-center Core Integral. The two-center core integral $\beta_{\mu\nu}$ associated with μ–ν bond,

$$\beta_{\mu\nu} = \int \phi_\mu(1) H_{\text{core}}(1) \phi_\nu(1) d\tau$$

has been evaluated by the variable β approximation.[11]

They are expressed as,

$$\beta_{\mu\nu}(\text{C–C}) = -0.51 P_{\mu\nu} + \beta^0(\text{C–C}) \text{ eV}$$
$$\beta_{\mu\nu}(\text{C–N}) = -0.53 P_{\mu\nu} + \beta^0(\text{C–N}) \text{ eV} \quad (3)$$

where $P_{\mu\nu}$ is the bond order associated with μ–ν bond. For non-neighbors, the $\beta_{\mu\nu}$'s are neglected. The values of β^0's are estimated to reproduce the lowest transition energy of the molecule.

(D) One-center Electron Repulsion Integral. This integral can be evaluated by the Pariser-Parr approximation:

$$\gamma_{\mu\mu} = \int \phi_\mu^2(1)(e^2/r_{12}) \phi_\mu^2(2) d\tau = I_\mu - EA_\mu \quad (4)$$

where EA_μ represents the electron affinity associated with ϕ_μ. When we consider a core charge dependence on the valence state energy, $\gamma_{\mu\mu}$ will be given by the following linear equation of core change Q.[14]

$$\gamma_{\mu\mu}(Q) = \{\gamma_{\mu\mu}(2) - \gamma_{\mu\mu}(1)\}Q + 2\gamma_{\mu\mu}(1) - \gamma_{\mu\mu}(2) \quad (5)$$

where

$$\gamma_{\mu\mu}(2) = I_\mu(2) - I_\mu(1)$$
$$\gamma_{\mu\mu}(1) = I_\mu(1) - EA_\mu$$

The values of parameters are summarized in Table 1.

(E) Two-center Electron Repulsion Integral. Two-center repulsion integral,

$$\gamma_{\mu\nu} = \int \phi_\mu^2(1)(e^2/r_{12}) \phi_\nu^2(2) d\tau$$

are calculated by two kinds of approximation, NM[7] and KHN[8]. In NM approximation, $\gamma_{\mu\nu}$ is given by

Table 1. The values of parameters

Atom	Q	I (eV)	EA (eV)	$\gamma_{\mu\mu}$ (eV)
C	+1.0	11.16	0.03	11.13
N	+1.0	14.12	1.78	12.34
N	+1.1	15.37	2.52	12.85
N	+1.2	16.62	3.26	13.36
N	+1.5	20.38	5.49	14.89
N	+1.8	24.17	7.75	16.42
N	+1.9	25.43	8.50	16.93
N	+2.0	26.70	9.26	17.44

$$\gamma_{\mu\nu} = e^2/(R + a)$$

where R is the interatomic distance between μ and ν atoms. Recently, we[8] have derived the following expression for $\gamma_{\mu\nu}$ from Brueckner equation,[15] by assuming ZDO and point charge interaction.

$$\gamma_{\mu\nu} = e^2/(R + (\Delta E_B/\Delta E)A_B) = e^2/(R + kA_B) \quad (6)$$

where A_B: parameter for benzene

ΔE_B: average transition energy of benzene

ΔE: average transition energy of the molecule

k: correlation parameter $(\Delta E_B/\Delta E)$.

NM expression can be obtained, when we put $k=1$. For the porphyrin molecule, $\Delta E_B/\Delta E$ is estimated to be 2.0 from the Soret band. In order to examine the effect of k on the electronic transition energies, the value is varied from 1 to 2.5.

Results and Discussion

Electronic Spectra. In order to elucidate the effect of σ-donation from the ligand porphyrin to the central metal ion, SCF-MO-CI calculations based on various models for the σ-framework have been carried out. First of all, we used NM approximation for two-center repulsion integrals and various β^0's. Models and the values of β^0 are shown in Table 2. In the calculation of metal porphyrin, we neglected the dπ-pπ interaction. The calculated results are summarized in Tables 3 and 4, together with the experimental data. It was found that better results are obtained by Model

II for free porphyrin and Model IX for metal porphyrin. These results suggest that the appropriate values of β^0's are β^0 (C–C) $=-2.04$ eV and β^0 (C–N) $=-2.24$ eV, respectively. The values fit benzene and its derivatives. According to our previous work,[11] the best value of β^0 is usually reduced with an increase in the size of the cata-condensed hydrocarbon system. Since porphyrin is a much larger conjugated system than benzene, the present estimation seems to be unusual. However, there are some exceptions. For an example, in polyenes, it is not necessary to decrease the value of β^0 with increase in the length of conjugated system.[16] An improvement was obtained in the present study as compared with the previous investigation.[3] However, the calculated interval between Q and B bands is still too large.

In order to examine the effect of electron correlation on the electronic transitions, we have carried out SCF-MO-CI calculation based on KHN approximation. In the calculation, correlation parameter k in Eq. 6 is used as an adjusting parameter. We have varied the value of k from 1.0 to 2.5. The calculated results are given in Tables 5 and 6. The interval between Q and B bands decreases considerably with the increase in the value of k. A satisfactory agreement between the experimental and calculated results is obtained for $k=2.0$. In KHN approximation, the value of k is given by the ratio of the transition energy associated with p-band of benzene to that of a given molecule. In porphyrin, the value is to be 2.0, which agrees with the above mentioned best value. It is of interest to

note that the results are not affected by the number of excited configurations taken into the calculation of configuration interaction. Namely, a satisfactory result is also obtained by a so-called four orbital model. This fact suggests us that KHN approximation takes fairly well the effect of electron correlation into account. In the case of free porphyrin, Rimington *et al.*[17] pointed out that the B_y band should lie very close to the strongest B_x band. Their suggestion seems to be of significance in porphyrin chemistry. This has been justified by the present study. Recently, Hatano[19] showed from MCD experiment that the Soret band consists of very closed B_x and B_y species. The calculated oscillator strengths of free porphyrin based on KHN approximation are considerably influenced by σ-framework. The second band (Q_y) seems to be too weak theoretically. However, there is a possibility of acquiring an intensity from the neighboring very intense Soret band, similar to the case of benzene's p-band.

It has been suggested by infrared spectroscopy[10] that there are hydrogen bonds between inner hydrogens and pyridine type nitrogens in free porphyrin. The wave function of a hydrogen bonded system can be, to a first approximation, expressed by the linear combinations of a non-dative and a proton transferred dative structure. Thus, in a simple treatment, the effect of hydrogen bond formation on the electronic structure of porphyrin can be considered by the variation of

Table 7. Calculated orbital energies (in eV) of highest occupied (HOMO) and lowest unoccupied (LUMO) orbitals (NM approximation)

Model	I	II	V	VI	VII	VIII	IX
HOMO	−8.06	−8.10	−5.38	−7.99	−1.36	−5.40	−8.03

core charges of nitrogens. Models III and IV were used for this purpose (Table 2). The calculated results are given in Table 5. It is expected that when the degree of proton transfer from N–H bond to pyridine type nitrogen increases, the interval between Q_x and Q_y and also that of B_x and B_y decrease.

Orbital Energy. According to Koopmans' theory,[20] the ionization potential and the electron affinity of a molecule can be calculated by the orbital energies associated with the highest occupied and the lowest unoccupied molecular orbitals. The calculated results are given in Table 7. As seen from this Table, Model IX for metal porphyrin gives almost the same ionization potential and electron affinity with those of free porphyrin. The experimental values of the half-wave potentials of metal porphyrins for oxidation[21] and reduction[22] are very close to those of free porphyrin.[21] This experimental result can be explained fairly well by means of Model IX. This provides another evidence that the Model IX in which the core charge of nitrogen is assumed to be 1.5 should be most appropriate for metal porphyrin. The model suggests that the net charge of the central metal ion varies from +2.0 to 0 by the formation of σ-type co-ordination bond.

The calculated MO energies of free porphyrin and the metal porphyrin are summarized in Tables 8 and 9, respectively. When k increases, the orbital spacings become narrow. The reason for this is as follows. Larger k corresponds to an increase in the effect of electron correlation. As a result, the two-center electron repulsion integral is reduced, so that the magnitude of off-diagonal Hartree-Fock element becomes small.

Electron Density and Bond Order. The effect of correlation parameter k on the electron distribution in the ground state of free porphyrin is shown in Fig. 3. When k increases, the electron density of α-carbon decreases slightly and that of nitrogen increases, for the pyrrole type ring. Reverse changes are found in another ring which has no N–H bond. Referring to the bond orders associated with aromatic hydrocarbons, we might say that mobile π-electrons move along bonds,

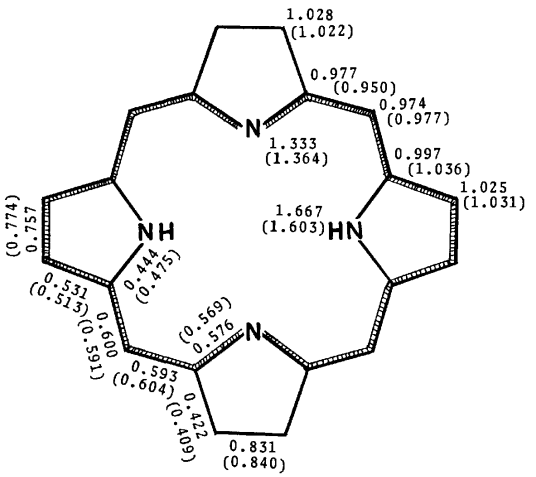

Fig. 3. Charge densities and bond orders of free porphin in the ground state, calculated by k=2.0. The results calculated by k=1.0 are shown in the parentheses.

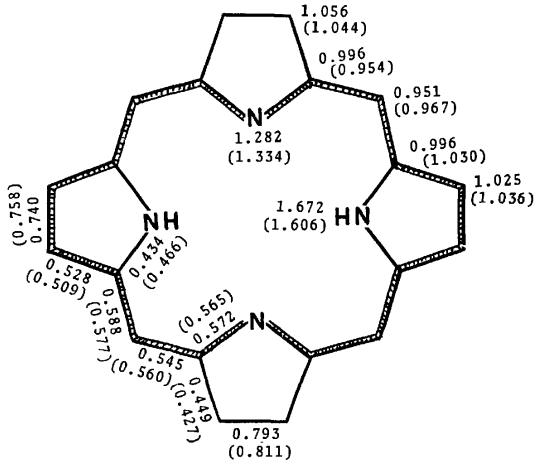

Fig. 4. Charge densities and bond orders of free porphin in the lowest excited singlet state, calculated by $k=2.0$. The results calculated by $k=1.0$ are shown in the parentheses.

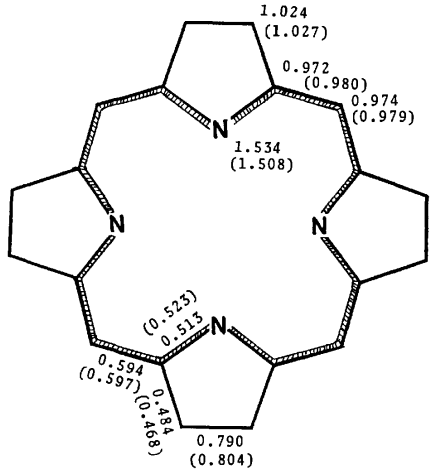

Fig. 5. Charge densities and bond orders of metal porphin in the ground state, calculated by $k=2.0$. The results calculated by $k=1.0$ are shown in the parentheses.

where bond orders are in the range 0.5—0.75. Thus, the path of mobile electrons in metal free porphyrin can be described by a shaded line in Fig. 3. The electron correlation might cause a slight increase in the mobility of π-electrons. The molecular diagram of free porphyrin in the lowest excited singlet state calculated by Model II is shown in Fig. 4. The effect of excitation causes a very small decrease in the electron densities of meso carbon and pyridine type nitrogen. The effect of k value on the electron distribution in metal porphyrin calculated by Model IX is shown in Fig. 5. It is seen from this figure that the mobility of π-electron along the outer ring increases slightly with increase in the value of k. The shaded framework includes 17.75 π-electrons; namely Huckel's $4n+2$ rule is approximately satisfied.

The 0–0 transitions of the Soret bands of both free and metal porphyrins are extremely intense. This fact suggests that the change of molecular framework by an excitation is very small. The molecular diagram of metal porphyrin in the lowest excited singlet state is shown in Fig. 6. The present calculation predicts that the changes of bond orders by an electronic transition are very small.

X-Ray Photoelectron Spectra of Aryl-nickel Complexes

Manabu SENŌ, Shinji TSUCHIYA, Masanobu HIDAI,* and Yasuzo UCHIDA*

Institute of Industrial Science, The University of Tokyo, 7-22, Roppongi, Minato-ku, Tokyo 106

**Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, 7-3, Hongo, Bunkyo-ku, Tokyo 113*

(Received July 3, 1975)

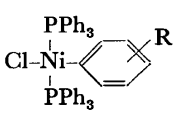
The nature of bondings in aryl–nickel complexes has been clarified by means of X-ray photoelectron spectroscopy (XPS). Pi bonding between nickel and aryl ligand seem to be of little importance. Ni–Cl bondings are of partially ionic character. A correlation between stereochemical structure and satellites has been discussed. It is suggested that the aryl-nickel complexes examined have diamagnetic square-planar structures. Measurements of solid-state susceptibilities support this view.

The stability of the aryl-nickel complexes is extremely high in contrast to the instability of transition metal-alkyl complexes. The increasing stability is probably ascribed to either or both of the following two factors; the substitution of β hydrogen atoms to the metal atom, and the stabilization by π acceptor ligands. Pi bonding between the transition metal and the aryl-ligand has been discussed in various aspects since the work by Chatt and Shaw.[1] It could be said that the stability of the complex is related with the energy difference (ΔE) between the highest occupied d orbital and the lowest unoccupied orbital. Since π bonding between the metal d orbital and the aryl-ligand reduces the energy of the d orbital and increases ΔE, the stability of the complex increases. Experimental evidence for this interaction is still ambiguous.

Recent studies on coordination complexes by X-ray photoelectron spectroscopy (XPS) revealed its usefulness, and we have applied this method to examination of a series of aryl-organometallic complexes.[2] Through measurements of the binding energies, we obtained some information on the nature of metal-ligand bondings. We also found the satellites associated with the 2p photoelectron lines of the nickel compounds. These satellites seem to originate from the shake-up process related to the paramagnetism.[2,3] A detailed discussion is given on the stereochemical structure on which the magnetic state depends.

Results and Discussion

The Nature of Nickel-Ligand Bondings. The observed values of Ni 2p, Cl 2p, and P 2s binding energies are summarized in Table 1. The structures of aryl-nickel complexes are shown in I.



I

Ni 2p binding energies of aryl-nickel compounds are lower than those of $NiCl_2$ (**1**) and $Ni(PPh_3)_2Cl_2$ (**2**). It could be pointed out from these results that the positive charge less than that of (**1**) or (**2**) is assigned to Ni atom in aryl-nickel complexes, and the coordinated aryl group donates considerably more electron density to nickel atom than the chlorine ligand. Hence, the nickel-aryl π bonding or back-donation seems to be of little importance in the aryl-nickel complexes. If metal-aryl π bonding does exist, it would be the most important in square-planar *ortho*-substituted aryl-nickel complexes where the ligands locate to form a conformation ensuring a maximum $p\pi$-$d\pi$ overlap by steric constraints. However, for even *ortho*-substituted aryl-nickel complexes $Ni(PPh_3)_2Cl$-  (**9**) and $Ni(PPh_3)_2Cl$-  (**10**), a high binding energy could not be observed. Similar results have been obtained by Fahey and Baldwin.[4]

TABLE 1. Ni $2p_{3/2}$, Cl 2p, AND P 2s BINDING ENERGIES ON NICKEL COMPLEXES

		Ni $2p_{3/2}$	Cl 2p	P 2s
1	$NiCl_2$	857.3	199.5	—
2	$Ni(PPh_3)_2Cl_2$	856.2	198.4	189.0
3	$Ni[P(n\text{-}C_4H_9)_3]_2Cl_2$	854.3	198.3	189.5
4	$Ni(PPh_3)_2Cl$-	854.6	198.4	188.4
5	$Ni(PPh_3)_2Cl$- -Cl	855.0	200.4 198.5	189.3
6	$Ni(PPh_3)_2Cl$- -OMe	854.4	198.9	189.5
7	$Ni(PPh_3)_2Cl$- -CH_3	854.4	198.3	188.9
8	$Ni(PPh_3)_2Cl$-	855.3	199.0	189.5
9	$Ni(PPh_3)_2Cl$-	854.8	198.5	189.4
10	$Ni(PPh_3)_2Cl$-	854.7	198.8	188.7
11	$Ni(PPh_3)_2Cl$-	854.1	199.0	188.9

P 2s binding energies of nickel complexes remain constant for all the series of compounds. A small or no change is expected in P 2s binding energies on coordination of phosphine to a metal atom. From a comparison of Ni 2p binding energy of $NiCl_2$ (857.3 eV) with that of $Ni(PPh_3)_2Cl_2$ (856.2 eV), it is suggested that a net electron transfer from phosphines to a nickel atom might occur.

Cl 2p binding energies of some compounds containing

chlorine are summarized in Table 2. Cl 2p binding energies vary considerably in the series of related compounds. We see that Cl 2p binding energy takes a maximum value in chlorine combining to aryl group and a minimum in NH_4Cl (Tables 1 and 2). Cl 2p binding energies in aryl-nickel complexes (198.3—199.0 eV) are lower than that of $NiCl_2$ (199.5 eV), but higher than that of NH_4Cl (196.9 eV). This shows that, although Cl 2p binding energies are highly affected through a Madelung contribution in these ionic structures, the electron density on Cl in aryl-nickel complexes increases by coordination of PPh_3 or aryl group and nickel-chlorine bond has partially ionic character. On the other hand, it is revealed from measurements of a series of chloroacetamides that, when the chlorine combines to the atom with higher electron density, the electron density on chlorine should increase and the Cl 2p binding energies in aryl-nickel complexes have about the same value of Cl 2p binding energy in α-chloroacetamide. This suggests that the chlorine in aryl-nickel complexes withdraws the electron on nickel atom to which the electron is supplied from the ligand.

As for complex Cl-  -$Ni(PPh_3)_2Cl$ (**5**), the Cl peak corresponding to binding energy of 198.5 eV is assigned to Cl coordinated directly to central Ni atom and the peak of binding energy of 200.4 eV to Cl bonded to aryl group. The large difference in energy shows that the two bonds differ largely from each other in nature. Cl 2p binding energies do not change among chlorine atoms bonded to aryl group in the compounds such as chloranil, 2,3-dichloro-1,4-naphthoquinone, and Cl- -$Ni(PPh_3)_2Cl$. The results indicate that the electron withdrawing from Ni to the aryl substituent in the complex (5) is not probable and, therefore, back-donation is of minor importance.

Stereochemical Structure and Satellites. We have observed photoelectron satellites accompanied by the Ni 2p line. Generally, the satellites associated with the 2p photoelectron lines of Ni compounds are interpreted to be due to promotion of a nickel 3d electron into an unoccupied level, this being called a shake-up phenomenon.[3] Matienzo *et al.* reported the selection rule ($\Delta L_v=0$, $\Delta S_v=0$) for the monopole shake-up transitions and discussed the correlation between

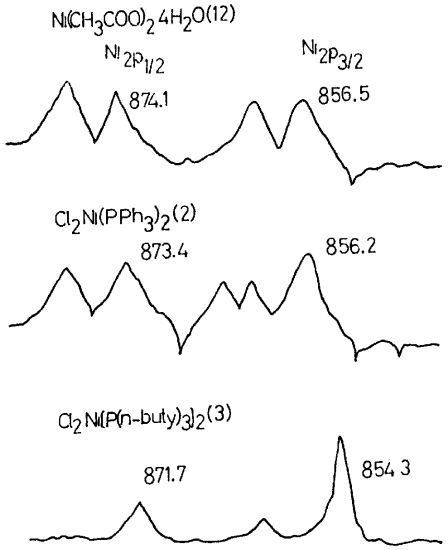

Fig. 1. Ni 2p XPS spectra of octahedral (**12**), tetrahedral (**2**), and square-planar (**3**) compounds of nickel.

paramagnetism and shake-up satellites. They suggested that, for the same ligand under different stereochemical geometries, the 2p binding energies of the nickel ion increase in the order, planar<tetrahedral<octahedral.[5] However, experimental evidence is insufficient for confirming the suggestion. For the sake of clarification, we have measured Ni 2p binding energies of $Ni(AcO)_2 4H_2O$ (**12**) (octahedral), $Ni(PPh_3)_2Cl_2$ (**2**) (tetrahedral), and $Ni[P(n\text{-}C_4H_9)_3]_2Cl_2$ (**3**) (square-planar). The results are shown in Fig. 1. It was found for paramagnetic nickel compounds **2** and **12** that parent lines are broad and large shake-up satellites appear, whereas for diamagnetic nickel compound(**3**) narrow parent lines and a small satellite only for $3p_{3/2}$ peak appear. The result for paramagnetic nickel compounds is consistent with that of previous studies, but not for diamagnetic compounds; no satellites were observed in the XPS spectra of diamagnetic nickel compounds reported previously.[2,5] Thus, the cause of the appearance of the small satellite for **3** is uncertain in the present state. A possibility is as follows; A paramagnetic substance is partially formed in the surface region of complex **3** on X-ray irradiation. Two satellites for Ni $2p_{3/2}$ of complex **2** would be assigned

Table 3. Ni 2p binding energies of nickel complexes

Compound	Ni $2p_{3/2}$	Sat.	Ni $2p_{1/2}$	Sat.
1	857.3	862.6	874.5	878.8
2	856.2	862.1, 865.3	873.4	879.8
3	854.3	861.8	871.7	—
4	854.6	861.3	871.8	880.7
5	855.0	861.8	871.8	880.3
6	854.4	861.8	871.0	881.8
7	854.4	861.3	871.7	881.1
8	855.3	861.8	871.7	880.3
9	854.8	862.3	872.0	—
10	854.7	862.8	872.2	—
11	854.1	861.6	871.6	—

to two type transitions, probably 3d→4s and 3d→ligand transitions. The possibility of development of a satellite due to the 3d→ligand transition is discussed by Frost *et al.*[3] Figure 1 also indicates that a definite correlation exists between the binding energy and stereochemistry of complexes. Hence, it is confirmed that information on the stereochemistry can be obtained through the measurements of the binding energy and satellites.

Table 4. Molar magnetic susceptibilities of nickel complexes

	Compound	Molar magnetic susceptibilities (emu/mol)
2	$Ni(PPh_3)_2Cl_2$	$+4.86\times10^{-3}$
4	$Ni(PPh_3)_2Cl$–	-2.70×10^{-4}
6	$Ni(PPh_3)_2Cl$– –OMe	-1.16×10^{-4}
11	$Ni(PPh_3)_2Cl$– 	-2.97×10^{-4}

The main peak (Ni 2p) and satellites in the aryl-nickel complexes are summarized in Table 3. For all the aryl-nickel complexes, small satellites are observed on core level of nickel. In the case of aryl-nickel complexes **4**, **5**, **6**, **7** and **8**, there is a satellite for each parent peak, while in the case of aryl-nickel complexes **9**, **10** and **11**, there is a satellite only for $2p_{3/2}$. We have no good explanation for these satellites, but it is to be noted that the satellites observed in the complexes **9**, **10** and **11** are as sharp and weak as those in the diamagnetic complex **3** as shown in Fig 2. It is not clear whether the weak satellites associated with Ni $2p_{1/2}$ peak in the complexes **4**—**8** are of intrinsic origin or are due to the partial decomposition by X-ray irradiation. However, these satellites are very weak and the parent lines are narrow and sharp as compared with those observed for typical paramagnetic complexes like **12** and **2**. The binding energies of the Ni 2p peaks in these complexes are lower than those observed for complexes **12** and **2**. The difference between complexes

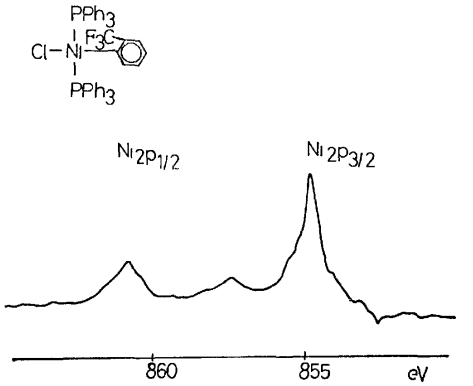

Fig. 2. Ni 2p XPS spectra of aryl-nickel complex (**10**).

4—**8** and complexes **9**—**11** is considered to be due to the stabilization of the latter complexes by the *ortho*-substitution of ligand.[1] It could be deduced from these considerations that all the aryl-nickel complexes examined have the diamagnetic square-planar nickel.

For the sake of confirmation, we have measured solid-state magnetic susceptibilities. The result shows that the aryl-nickel complexes are diamagnetic (Table 4). The conclusion from XPS measurements is thus supported.

Experimental

Aryl-nickel complexes were prepared as described in a previous report.[6]

Photoelectron spectra were taken with a JASCO ESCA-1 electron spectrometer. The Mg*K*α X-ray line (1253.6 eV) was used as a photoelectron excitation source. The samples were used as fine powder dusted onto aluminum foil or Scotch tape which was mounted on a copper sample holder. The recorded binding energies were recorded in triplicate, accuracy being within ±0.25 eV in most cases. All raw binding energies were corrected to C ls value of 284 eV. The procedure appeared very reasonable in the case where the compound contained many carbons. The binding energy of $NiCl_2$ were calibrated by using ls line of the impurity carbon. An attempt was made to refer the spectra to the Au($4f_{7/2}$) photoelectron line. The photoelectron line of Au($4f_{7/2}$) deposited *in vacuo* onto the samples were defined as 83 eV. The results from the two methods agreed with each other.

Solid-state magnetic susceptibilities were measured with a Faraday balance at room temperature.**

Studies of Spontaneous Emulsification. II. The Effect of Nonionic Surfactants

Keizo OGINO and Motoki OTA

Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received August 26, 1975)

At the oil/water interface, spontaneous emulsification occurs when oil containing certain oil-soluble substances such as cholesterol is allowed to stand in contact with aqueous nonionic surfactant solutions. In this study, the interfacial tension between oil and water phases was measured in the presence of various oil-soluble substances, such as cholesterol, 1-dodecanol, and *cis*-9-octadecene-1-ol, added as ingredients in oil and various nonionic and anionic surfactants added in water, this study ascertained their effects on the emulsification.

When oil and water phases are brought quietly into contact, spontaneous emulsification sometimes occurs on one or both sides of the interface without any external mechanical work. The spontaneous emulsification is considered to be a result of one or more of the following three reasons[1,2]: i) The instability of the interface due to a non-uniform diffusion of the components of the phases across the interface, which causes a kicking of the interface violent enough to break off droplets of the adjacent bulk phases. ii) An accompanying diffusion of oil and an additive into the water, which results in a dilution of the additive with the water, leaving oil droplets stranded and thus forming the emulsion. iii) The temporary appearance of a negative interfacial tension, which causes an enlargement of the interfacial area.

Schulman and Cockbain[3] have shown that, when a complex is formed between an oil-soluble substance and a water-soluble surfactant at the oil/water interface, spontaneous emulsification occurs, and that the molecular interaction at the interface is sensitively influenced by the stereochemical configuration and the kinds of the polar groups of the two interacting molecules. Davies and Haydon[4] have reported that hexadecanol in toluene and sodium decyl sulfate in water are spontaneously brought into emulsion in the presence of surfactant or alcohol at concentrations higher than certain levels. In this system, interfacial tension was measured at low concentrations of solutes, this tension was proved to be negative when extrapolated to the higher concentration range of the solutes. From this result, they have estimated that a negative interfacial tension is the cause of the spontaneous emulsification. In such a system, emulsification does not occur spontaneously below a certain concentration of the solutes. To clarify the cause of this emulsification, therefore, the detailed measurement of interfacial tension with various concentrations of solutes is essential.

The present investigation was undertaken to reveal the mechanism of the spontaneous emulsification by measuring the interfacial tension in a system including oil-soluble substances and nonionic surfactants at various concentrations; also, the molecular interaction at the Nujol/water interface was studied in relation to the kinds of additives and to the tendency of spontaneous emulsification.

Experimental

Materials. *Surfactants*: The anionic surfactant, sodium dodecyl sulfate (SDS), and various nonionic surfactants were obtained from the Nikko Chemical Co. The characteristic properties of the nonionic surfactants are shown in Table 1. The surface tension *vs.* concentration curves of these nonionic surfactants are shown in Fig. 1.

Oil-soluble Substances: Cholesterol, 1-dodecanol, and *cis*-9-octadecene-1-ol (oleyl alcohol) of an extra pure grade (Tokyo

Kasei Co.) were adopted.

Water and Oil: Deionized and distilled water and liquid paraffin (commercial grade "Nujol") were used.

Apparatus. The interfacial tension and its time-course were measured by a Wilhelmy-type surface-tension meter (Shimadzu Surface Tensiometer ST-1).

Procedure. The oil-soluble substances and surfactants were dissolved in oil and water respectively, and the interfacial tension was measured at various concentrations of the solutes in each of the systems at 25 °C. These measurements were started 6 min (in the case of the anionic surfactants) 12 min (in the case of the nonionic surfactants) after the beginning of contact between the two phases, because the equilibria at these interfaces were reached after 5 min and 10 min respectively.

Results and Discussion

The Effects of Oil-soluble Substances. Figure 2 shows the effects of the oil-soluble substances on the interfacial tension in the Nujol/PCA-20 solution. In the figure, the dotted line shows the interfacial tension at which spontaneous emulsification occurs, while the arrow indicates the limit concentration of the component corresponding to the beginning of the emulsification, where the phases show a milky turbidity.

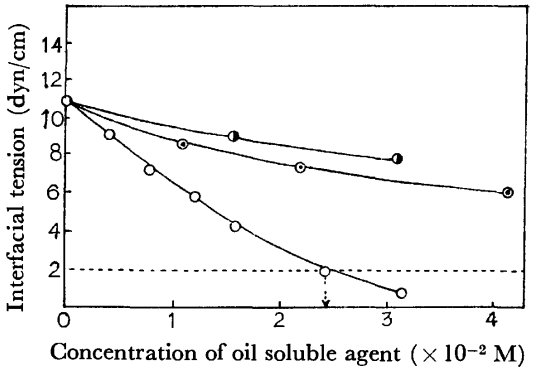

Fig. 2. Effect of oil soluble agents on the interfacial tension at Nujol/PCA-20 soln. interface.
Water phase; 2.7×10^{-3} M. PCA-20 soln.
○ Cholesterol; ◑ 1-dodecanol; ⊙ *cis*-9-octadecene-1-ol.

As shown in Fig. 2, it is clear that the interfacial tension is greatly lowered by the addition of oil-soluble substances; the degree of lowering is in the following order; cholesterol>*cis*-9-octadecene-1-ol>1-dodecanol. It is also clear that the most strongly effecting substance is cholesterol, suggesting that the interaction between cholesterol and a nonionic surfactant should be the strongest in these systems. In the system of cholesterol, spontaneous emulsification takes place at the level of 2.5×10^{-2} M; therefore, the interfacial tension is estimated to be about 2 dyn/cm. Unlike systems including SDS,[5] *cis*-9-octadecene-1-ol has more effects than 1-dodecanol in the systems including nonionic surfactants.

The Effects of Surfactants. The Influence of the Structures of Surfactants: In systems in which cholesterol is included in the oil phase, surfactant molecules with various bond structures and nearly the same HLB were examined for their effects on the interfacial tension

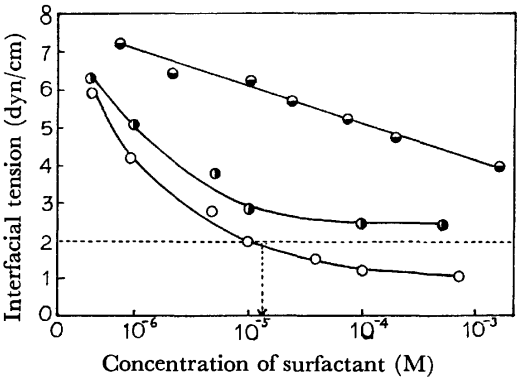

Fig. 3. Effect of surfactants on the interfacial tension at Nujol containing cholesterol/water interface.
Oil phase; 3 M/100 cholesterol soln.
○ PCA-40; ◑ PS-40; ◒ POPA-30.

(Fig. 3). As is shown in Fig. 3, the interfacial tension between water containing the surfactants and Nujol including cholesterol is effected in this order; ether type>ester type>phenyl ether type. In these systems, spontaneous emulsification was observed for the ether-type at an interfacial tension of about 2 dyn/cm.

The Influence of the Hydrophobic Group in Surfactants: Since ether-type nonionic surfactants are most effective in causing spontaneous emulsification, the influence of the hydrophobic group in the surfactants on the interfacial tension between Nujol containing cholesterol

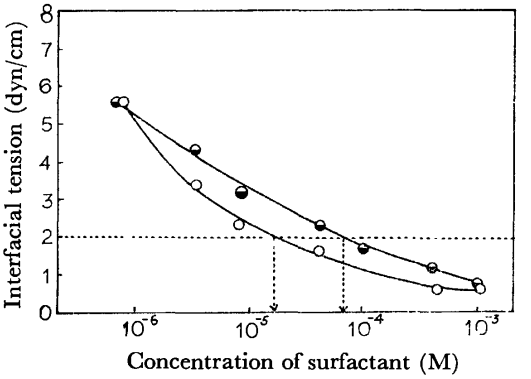

Fig. 4. Effect of surfactants on the interfacial tension at Nujol containing cholesterol/water interface.
Oil phase; 3M/100 cholesterol.

○ PCA-20; ◒ POA-20.

and water was studied; the results are plotted in Fig. 4. The surfactants consited of 20 units of ethylene oxide and had nearly equal HLB values. Figure 5 shows the equal intensity of the influence on the interfacial tension of the system in which the oil phase contains no oil-soluble substances. As can be seen in Fig. 5, cis-9-octadecene-1-ol ether-type nonionic surfactants lower the interfacial tension more intensively than do hexadecyl ether-type ones, in agreement with the results of Wrigley *et al.*[6] However, when the oil phase contains cholesterol, hexadecyl ether-type surfactants lower, the interfacial tension more than do *cis*-9-octadecene-1-ol ether-type ones, as is shown in Fig. 4. Therefore, it may be presumed that hexadecyl ether-type nonionic surfactants interact with cholesterol more strongly than do *cis*-9-octadecene-1-ol ether-type ones.

The Influence of Hydrophilic Chain Length in Surfactants, The relation between the hydrophilic chain length in surfactants and the effect on the interfacial tension at a Nujol-containing cholesterol/water interface was studied; the results are in Figs. 6 and 7. The hydrophobic group was the same in all kinds of surfactants. The interfacial tension was reduced to a larger extent by the surfactants with longer hydrophilic chains in the lower concentration range, but the degree of reduction is reversed in the higher concentration range of the surfactants, and in the case of *cis*-9-octadecene-1-ol ether-type nonionics, spontaneous emulsification was not observed with the surfactant containing 50 units of ethylene oxide groups. Therefore, it may be presumed that the interaction between the surfactants and cholesterol decreases with an increase in the hydrophilic chain length above 20 units of ethylene oxide groups.

○ POA-20; ◒ POA-50.

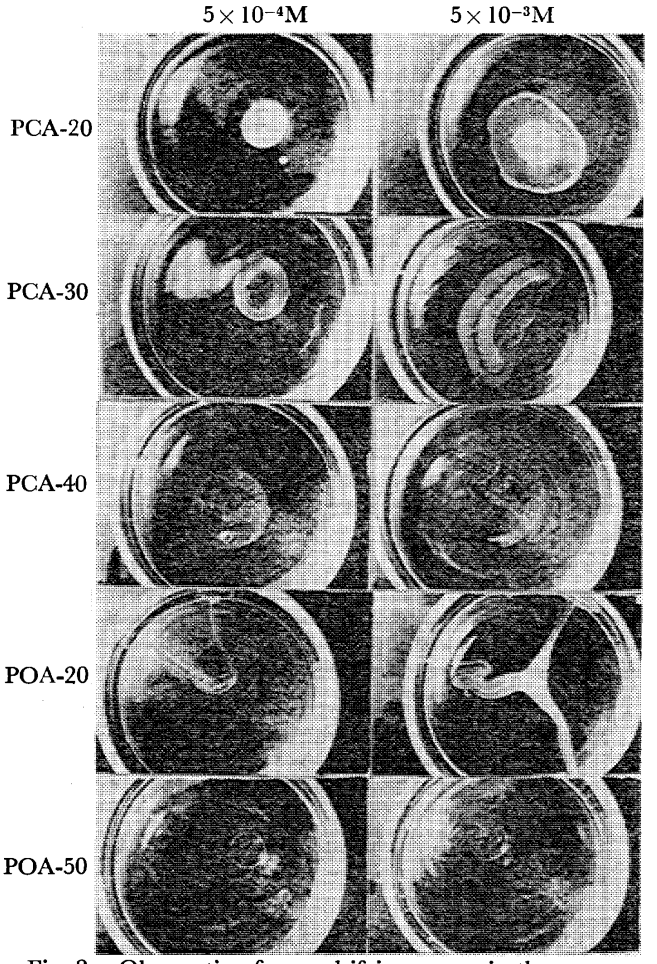

Fig. 8. Observation for emulsifying power in the system of Nujol with 3×10^{-2}M cholesterol/surfactant aqueous soln.

Figure 8 shows the appearance of spontaneous emulsification on the addition of a drop of oil containing 3×10^{-2} M cholesterol to aqueous solutions containing ether-type surfactants at 5×10^{-4} M and 5×10^{-3} M concentrations. The photograph shows the greater deformation of an oil drop and the higher turbidity, *i.e.*, the easier spontaneous emulsification. The emulsifying power of a surfactant decreases with an increase in the ethylene oxide chain length; that is, the interaction of nonionic surfactants with cholesterol decreases with the increase in the effect of hydrophilic groups in the surfactant. This agrees with the results shown in Figs. 6 and 7.

Further, the above results and the results for anionic surfactant systems, such as the cholesterol-sodium-dodecyl sulfate system, in which spontaneous emulsification occurs in the oil phase by means of the formation of a complex drawn up into the oil phase,[5] lead us to presume that a shorter length of the polyoxyethylene chain exhibits a greater likelihood of forming a complex

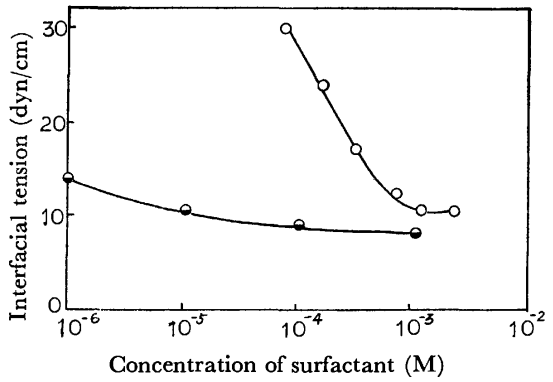

Fig. 9. Effect of surfactants on the interfacial tension at Nujol/water interface.
○ SDS; ◒ PCA-20.

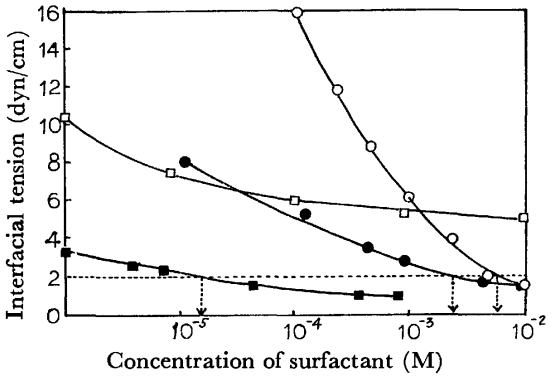

Fig. 10. Comparison between anionic and nonionic surfactants on the interfacial tension at Nujol containing cholesterol/water interface.

and causing spontaneous emulsification.

Comparison between Anionic and Nonionic Surfactants, Figures 9 and 10 show the effects of anionic and nonionic surfactants comparatively. When an oil phase contains no substances, the interfacial tension in the SDS system is 30 dyn/cm at the concentration of 5×10^{-4} M, as is shown in Fig. 9. That is, the interfacial tension of the PCA-20 system is lower than that of the SDS system at lower concentrations. On the other hand, as is shown in Fig. 10, when an oil phase contains 1×10^{-2} M cholesterol, the interfacial tension of the SDS system is lowered to a greater extent than that of the PCA-20 system above the surfactant concentration of 1.5×10^{-3} M, and spontaneous emulsification occurs above the concentration of 4.6×10^{-3} M. Therefore, it may be presumed that SDS interacts with cholesterol stronger than PCA-20.

Nevertheless, when an oil phase contains 3×10^{-2} M cholesterol, three times the above concentration, the interfacial tension *vs.* concentration curve shifts down turned and emulsification occurs at the level of 1.8×10^{-5} M in the case of PCA-20, while in the system of SDS emulsification occurs at 2.2×10^{-3} M. The case of SDS is not very different. That is, in the SDS system spontaneous emulsification occurs at a level about 100 times that in the PCA-20 system.

In a previous work[5] we found, with anionic surfactants containing different polar groups, that the oil-soluble cholesterol interacted in the following order: sodium dodecyl sulfate>sodium dodecanoate>sodium dodecylbenzene sulfonate.

From the above results, the molecular interaction between oil-soluble cholesterol and water-soluble surfactants may be thought to vary with the concentration of cholesterol in the oil phase, and its interaction with nonionic surfactants may be thought to be larger than that with anionic ones above a certain concentration of cholesterol in the oil phase.

Summary

In a Nujol/water system the oil phase of which contains both oil-soluble additives and water and the water phase contains oil and a surfactant, spontaneous emulsification scarcely occurs at all, while in systems composed of an oil phase containing a substance and of a water phase containing a surfactant, spontaneous emulsification is apt to take place, whereupon molecular interaction is presumed to occur to form a complex at the oil/water interface. This interaction is sensitive to the stereochemical configuration and polar groups of anionic surfactants molecules in the case of anionic surfactants and sensitive to bond structures, hydrophobic groups, and the polyoxyethylene chain length of nonionic surfactants.

Comparing anionic surfactants with nonionic ones, the former cause emulsification at lower concentrations than the latter in the presence of polar substances at low concentrations in the oil phase, but in the higher concentration range of the polar substances, on the contrary, nonionic surfactants interact with polar substances more strongly than do anionic ones, and spontaneous emulsification occurs at lower concentrations.

An X-Ray Study of Non-stoichiometric $Pr_{0.6}Gd_{0.4}O_{1.5+\delta}$

Kazuhiro ENDO*, Shigeru YAMAUCHI*, Kazuo FUEKI**, and Takashi MUKAIBO*

*Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

**Department of Synthetic Chemistry, Faculty of Engineering, The Uniuerity of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 27, 1975)

Non-stoichiometric $Pr_{0.6}Gd_{0.4}O_{1.5+\delta}$ (δ=0.000, 0.075, 0.120, and 0.157), with a bixbyite structure, was investigated by X-ray diffraction. The intensities of the superlattice lines were found to decrease with an increase in δ. The structure analysis has revealed that metal ions gradually move to the ideal positions of the fluorite structure with an increase in δ and that excess oxygen ions preferentially occupy the Z-sites.

The bixbyite structure common in rare-earth sesquioxides is closely related to the fluorite structure. For example, the X-ray powder pattern of the bixbyite structure can be interpreted as the superposition of the superlattice lines on the pattern of the fluorite structure. The unit cell of the bixbyite structure[1] (space group Ia3) is composed of eight unit cells with the fluorite structure, in which one-fourth of the oxygen-ion sites are vacant. These vacant sites, named Z-sites by Anderson,[2] can be regarded as interstitial positions for the bixbyite structure. Oxygen ions, O(1), occupy the general positions (48e) of Ia3. One-fourth of the metal ions, M(1), occupy the (8b) special positions, with the remaining three-fourths, M(2), occupy the (24d) special positions. As is shown in Fig. 1, the coordination polyhedron around M(2) is a cube consisting of six oxygen ions and two Z-sites. The Z-sites occupy the face diagonal corners, and the position of the M(2) ion is displaced from the centre of this cube.

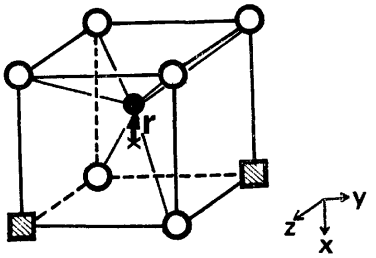

Fig. 1. Schematic drawing of the coordination polyhedron surrounding M (2) ion.
○: oxygen ion, ▨: Z-site, ●: M(2) ion, ×: the centre of the cube, $\boldsymbol{r}$: the displacement vector.

Rare-earth sesquioxides, such as $CeO_{1.5+\delta}$, $PrO_{1.5+\delta}$, and $TbO_{1.5+\delta}$, change their non-stoichiometry, δ, with the change in the oxygen partial pressure and the temperature. On the basis of the ordered intermediate phases of Pr_nO_{2n-2} (n=7, 9, 10, 11, 12), Hyde and his co-investigators[3] suggested that the excess oxygen ions in the non-stoichiometric σ-phase of $PrO_{1.5+\delta}$ occupy the Z-sites. Bratton[4] measured the density and lattice constants of yttria doped with zirconia and concluded that the predominant point defects are not cation vacancies but interstitial anions. Subbarao and his co-workers[5] obtained a similar result on yttria doped with thoria and inferred that such interstitial positions were Z-sites.

The present authors have carried out an X-ray diffraction study of non-stoichiometric $Pr_{0.6}Gd_{0.4}O_{1.5+\delta}$ and have found that the intensities of the superlattice lines decrease with the increase in δ. The purpose of the present study is to elucidate the relationship between the intensities of the superlattice lines and the non-stoichiometry of $Pr_{0.6}Gd_{0.4}O_{1.5+\delta}$, which has a wide non-stoichiometric range.

Experimental

Praseodymium oxide and gadolinium oxide supplied by the Shin-etsu Chemical Co. were used as the starting materials. The purity of the oxides was 99.99%. Each oxide was dissolved in G. R. -grade nitric acid, and the two solutions were mixed in such a ratio that a composition of Pr: Gd= 3: 2 was obtained. Then an excess amount of a G. R. -grade oxalic acid solution was added, and the resulting oxalate precipitate was separated by filtration, oven-dried, and decomposed into oxide in air at 900 °C. Then the oxide sample was ground in an agate mortar, cold-pressed at 7 ton/cm^2, and sintered at 1550 °C for 20 h to homogenize the solid solution. The samples thus treated were placed in a quartz basket, suspended from a beam of a Cahn RG electrobalance,[6] and equilibrated with gas mixtures of argon and oxygen at 900 °C so that δ-values of 0.000, 0.075, 0.120, and 0.157 could be obtained. Then the samples were quenched to room temperature as soon as possible. The X-ray diffraction study was carried out using Rigaku Rotaflex PV 100 with Ni-filtered Cu$K\alpha$ radiation. The intensity calculation was done by means of a HITAC-8700/8800 computer. The atomic scattering factors were taken from the International Table for X-ray Crystallography.[7] The program used for the computation was the full matrix least-squares program for X-ray powder diffraction.[8] In the least-squares calculations, the quantity of $\sum(I_o-I_c)^2$ was minimized. The reliability factor, R, was defined as $\sum|I_o-I_c|/\sum I_o$. Twenty-nine reflection lines observed in each sample were used in the calculation.

Results and Discussion

Table 1 shows the relative intensities of typical superlattice lines of $Pr_{0.6}Gd_{0.4}O_{1.5+\delta}$ as a function of the non-stoichiometry, δ. The strongest line, (222), is

a) M(1) atoms are at (1/4 1/4 1/4) and its equivalents, and M(2) at (u 0 1/4) and the equivalents. O(1) atoms are at (x y z) and the equivalents, and Z-sites are (x x x) and the equivalents.

taken as the standard for the calculation of the relative intensities. As may be seen in the table, the intensities of the superlattice lines decrease with increase in δ. In the structure analysis, it was assumed that gadolinium and praseodymium ions are randomly distributed between M(1) and M(2) cation sites and that the atomic scattering factors for the ions equal those for neutral atoms. Two distribution parameters, A_1 and A_z, were introduced for the analysis. A_1 and A_z are the average numbers of oxygen ions on O(1) sites and on Z-sites respectively per metal ion. The numbers of total oxygen ions (*i.e.*, A_1+A_z), O(1) sites, and Z-sites per metal ion are $1.5+\delta$, 1.5, and 0.5 respectively. The intensities were calculated by the least-squares method by changing the A_1, A_z, and positional parameters. In a preliminary calculation, minimum R-value was obtained for the over-all temperature factor, B, of 1 Å^2. Therefore, the least-squares calculations were carried out on the assumption of $B=1$ Å^2. The smallest values of the reliability factor, R, were obtained when the distribution and positional parameters had the values given in Table 2. The standard deviations and lattice parameters are also given in the same table. The R-values ranging from 2.7 to 4.7% are satisfactorily small from the point of view of X-ray powder diffraction analysis. The atomic parameters of the oxygen ions have much larger standard deviations than those for the M(2) ions.

In order to examine the dependence of the observed u-values (the positional parameters of the M(2) ions) upon the atomic parameters of the oxygen ions, a calculation was made on the assumption that excess oxygen ions occupy the ideal positions of the Z-sites. The results are shown in Table 3, where the standard deviations are also given in parentheses. The values of u and R are similar to those in Table 2. This means that the u-values estimated by the least-squares method are reliable and are nearly independent of the atomic parameters of the oxygen ions.

Table 3. Atomic parameters obtained on the assumption that excess oxygen ions occupy the ideal position of the Z-sites

δ	O(1)			M(2)	R
	x	y	z	u	
0.000	0.400	0.128	0.413	−0.0296	0.057
	(0.006)	(0.007)	(0.005)	(0.0017)	
0.075	0.389	0.164	0.367	−0.0273	0.045
	(0.010)	(0.005)	(0.008)	(0.0017)	
0.120	0.404	0.133	0.405	−0.0232	0.031
	(0.004)	(0.005)	(0.004)	(0.0013)	
0.157	0.399	0.153	0.364	−0.0167	0.044
	(0.013)	(0.007)	(0.011)	(0.0019)	

As has been mentioned above, the Pr and Gd ions are assumed to be randomly distributed between M(1) and M(2) sites. In order to verify the validity of this assumption in the present discussion, the intensities of the superlattice lines were calculated in such extreme cases that M (1) sites were occupied by only Pr or Gd ions. The intensities were found to agree with those shown in Table 1, within the range of experimental error. This result indicates that the intensities of the superlattice lines are nearly independent of the distribution of Pr and Gd ions. This is probably caused by the small difference in scattering factors between the two kinds of cations.

The relationship between u and δ is plotted in Fig. 2. The u-value expresses the degree of displacement of M(2) ions from the centre of the coordination polyhedron. The displacement vector, $\boldsymbol{r}$, in Fig. 1 has a component of $(-u, 0, 0)$. Clearly, the displacement

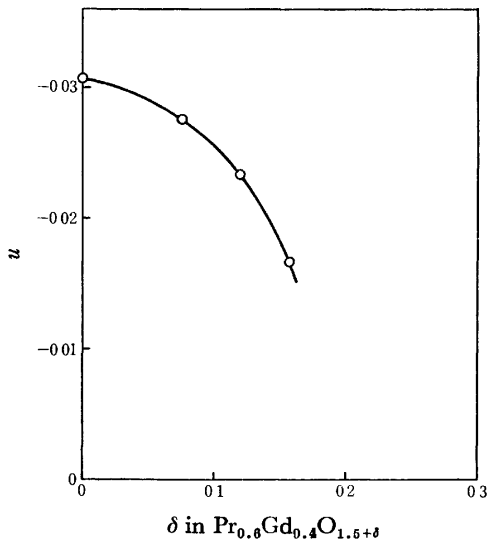

Fig. 2. Dependence of u on δ.

of the M(2) ions from the ideal positions in the fluorite structure decreases as δ increases. The negative value of u indicates that the M(2) ions shift from the ideal positions in the fluorite to the opposite direction against the plane including Z-sites. Such a tendency is generally observed in α-Mn_2O_3[9,10], In_2O_3[11], and rare-earth sesquioxides,[9-12] such as Y_2O_3, Dy_2O_3, and Tm_2O_3. Mertens and Zemann[13] have calculated the Madelung constant of yttria as a function of u and found that the Madelung energy increases with the increase in u and reaches a maximum at the observed u-value. Probably the displacement of yttrium ions is caused by the anisotropic arrangement of the oxygen ions surrounding the yttrium ions. Accordingly, the u-value can be regarded as a measure of the Coulombic anisotropy around the M(2) ions. Excess oxygen ions occupying the Z-sites would decrease the anisotropy; consequently, the M(2) ions would return to the ideal positions in the fluorite structure when the non-stoichiometry becomes large.

At δ=0.157, more than 30% of the Z-sites are occupied by excess oxygen ions, while the u-value is about 50% of that at δ=0.000. This means that a considerable degree of anisotropy still remains even at δ=0.157. From the above discussion, it may be concluded that excess oxygen ions preferentially occpy the Z-sites.

The authors wish to express their gratitude to professor Goro Yamaguchi, the University of Tokyo, for his valuable discussions and also for allowing them to use his computer program.

ENDOR Studies of the Hindered Internal Rotation of Alkyl Groups in the 1,4-Dialkyl Naphthalene Radical Anions

Fujito NEMOTO

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received September 16, 1975)

The ENDOR spectra were measured for the anion radicals of 1,4-dimethylnaphthalene, 1,4-diethylnaphthalene, and 1,4-dipropylnaphthalene. The β-proton splittings of the alkyl groups were 3.30, 2.85, and 2.44 G at -80 °C for 1,4-dimethyl-, 1,4-diethyl-, and 1,4-dipropylnaphthalene respectively, and the positive temperature dependence of the β-proton splitting was demonstrated. Based on the Heller-McConnell relationship, $a^{\beta}_{1,4}=(B_0+B_2\cos^2\theta)\rho^{\pi}_{1,4}$ the β-proton splittings and their temperature dependence were interpreted in terms of a modified model of the restricted internal rotation of ethyl and propyl groups over two kinds of potential barriers. The rotational potential barriers thus estimated were 3.0 and 0.7 kcal/mol for the 1,4-diethylnaphthalene anion and 6.0 and 1.2 kcal/mol for the 1,4-dipropylnaphthalene anion. In the ENDOR spectra of potassium 1,4-diethylnaphthalene observed in THF solutions, two ENDOR lines attributed to the non-equivalent alkyl β-protons were observed at -110 °C, these lines collapsed to a single line when the temperature was raised to -70 °C. This phenomenon can be understood on the assumption that the steric effect of the solvated cation alters the rotational potential curve from a symmetric to an asymmetric one.

Based on the ESR observation, the evidence of an internal restricted rotation on the alkyl groups has now been widely established, and the temperature dependence of the alkyl β-proton splitting has been well understood in terms of the $\cos^2\theta$ rule, as has been discussed by Stone and Maki.[1] In particular, for the *para*-substituted alkylbenzene and 9-alkylanthracene, the hindered internal rotation of the ethyl group was investigated in detail. According to the ESR studies of the 4,4'-diethylbiphenyl anion radical,[2] the ethyl group may undergo a restricted rotation in the twofold-potential well, which has a barrier height of 1 kcal/mol. On the other hand, the ethyl group in 9-ethylxanthyl[3] is thought to be strongly restrained, and the ethyl β-proton is almost fixed at the most stable conformation ($\theta_0=\pi/3$).

In this context, studies of the hindered internal rotation of the alkyl groups in 1,4-dialkylnaphthalene become very intersting, because the motion of the alkyl group in 1,4-dialkylnaphthalene is thought to be restricted by two different steric repulsions, due to the neighboring α-CH and β-CH groups of the naphthalene moiety. The former steric repulsion is similar to that restricting the motion of the alkyl group in 9-alkylxanthyl, while the other is analogous to the case in 4,4'-dialkylbiphenyl.

From the investigation of the hindered internal rotation of the alkyl group in the 1,4-dialkylnaphthalene, one can expect to obtain a revised view of the rotational potentials of the alkyl groups in the alkylated aromatic radicals previously reported. Nevertheless, the ESR spectra of 1,4-dialkylnaphthalene anion radicals have never been reported, except for the case of the 1,4-dimethylnaphthalene anion.[4]

The ESR spectra observed for the 1,4-diethyl- and 1,4-dipropylnaphthalene anion radicals revealed a poor resolution because of the superposition of the hyperfine components due to the ring 2- and ring 6-proton hyperfine couplings. Furthermore, the extra alkyl γ-proton splittings bring additional complexities to the ESR hyperfine structures. In order to determine the hyperfine coupling constants, it seemed desirable to apply the ENDOR technique.[5,6]

Experimental

The 1,4-dimethylnaphthalene was synthesized from *p*-xylene by the method previously reported by Barnet *et al.*[8] The other 1,4-dialkylnaphthalenes were prepared by the Friedel-Crafts reaction of the appropriate acylhalide and α-alkylnaphthalene, and by subsequent reduction.[9,10] The materials were purified by means of preparative fractional gas chromatography. The materials thus obtained were all recrystallized from ethanol at *ca.* -20——-30 °C.

The anion radicals were prepared by reduction with lithium, sodium, or potassium metal in several different solvents, such as tetrahydrofuran (THF), 1,2-dimethoxyethan (DME), and *N*,*N*-dimethylformamide (DMF).

The ESR and ENDOR spectra were recorded in the temperature ranges from $+20$ °C to -120 °C, and from -60 °C to -120 °C, respectively. The ESR and ENDOR spectrometers employed here and their operating conditions have been described in previous papers.[11,12]

Results and Discussion

ESR Spectra. The ESR spectra of the 1,4-dimethylnaphthalene anion, the reference compound of the 1,4-dialkyl derivatives, have already been reported by Gerson *et al.*[4] The spectra of the 1,4-diethylnaphthalene anion observed in DME, DMF, and THF solutions are shown in Fig. 1. The analysis of the spectra of DME and DMF solutions was hindered by the complicated overlapping of the hyperfine structures due to the alkyl γ-proton splitting (70 mG), which was detected in the temperature range between -20 °C and -50 °C. On the other hand, the ESR spectrum of the THF solution could be roughly analyzed; the results are listed in Table 1. However, the temperature dependence of the hyperfine coupling constants was not precisely determined due to line broadening. For the 1,4-dipropylnaphthalene anion, only a poorly resolved spectrum was observed everywhere, as is shown in Fig. 2; the hyperfine coupling constants could not be determined.

ENDOR Observation. The ENDOR spectra of the 1,4-dimethyl-, 1,4-diethyl-, and 1,4-dipropylnaphtha-

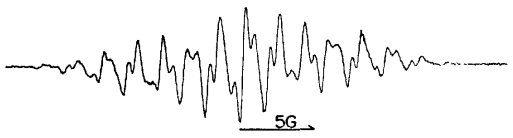

Fig. 2. The ESR spectrum of the 1,4-dipropylnaphthalene anion by reduction with potassium observed with the THF solution at +20 °C.

lene anion radicals observed in DME are shown in Fig. 3.

The spectra can be easily analyzed with reference to the ESR spectra of 1,4-dimethylnaphthalene anions. For example, 1,4-diethylnaphthalene reveals absorptions at 14.0, 16.2, 16.4, 17.9, and 21.4 MHz, which are assigned to the splitting due to the alkyl γ-, the 2,3-ring, the 6,7-ring, the alkyl β-, and the 5,8-ring protons respectively.

Of particular interest is the fact that γ-protons of the propyl group give rise to two different hyperfine coupling constants (0.17 G and 0.05 G), although the ethyl γ-protons reveal only one hyperfine coupling constant. The results are summarized in Table 1. The experimental results indicate that the coupling constants due to ring protons remain almost unchanged on the substitution of alkyl groups.

When the 1,4-dialkylnaphthalene anion radicals were prepared in THF by reduction with potassium, the alkyl β-protons exhibited anomalous hyperfine interactions. The methyl β-proton splitting of 1,4-dimethylnaphthalene showed the minimum value (3.11 G); furthermore, the methylene protons of the ethyl group

exhibited non-equivalent splittings at 17.4 and 17.9 MHz below −110 °C. When the temperature was gradually elevated, the two lines of alkyl β-protons were merged into a single line (17.6 MHz), as is shown in Fig. 4. The propyl β-protons also exhibited two different signals (at 17.3 and 18.3 MHz) at −110 °C, as is

shown in Fig. 5, but the β-proton splittings could not be detected clearly above −110 °C.

Measurements of the β-proton splittings were extensively performed in other systems, such as DME–Na, DME–Li, THF–Na, THF–Li, and DMF–K, but the alkyl β-protons exhibited the equivalent splitting everywhere.

Temperature Dependence of the Alkyl β-Proton Splittings. The ENDOR spectra in solution can be observed in only a limited temperature range because of the complicated relaxation mechanism which determines the ENDOR intensity.[17] The temperature dependences of the alkyl β-proton splittings of the 1,4-dialkylnaphthalene anions, therefore, have been examined in different solvents with various alkali metal cations.

As is shown in Fig. 6, the ethyl β- and the propyl β-proton hyperfine coupling constants show a positive temperature dependence. The slope of the temperature dependence for the propyl β-proton splitting is slightly larger than that for the ethyl β-proton splitting.

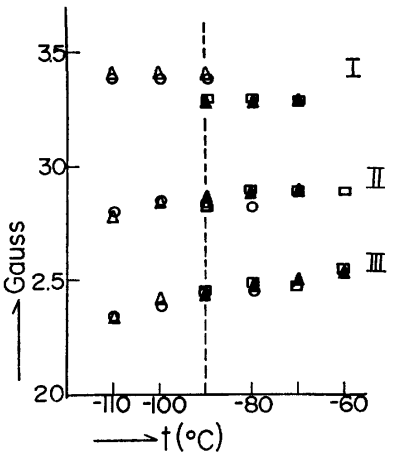

Fig. 6. Temperature dependence of the β-proton splittings observed with the 1,4-dialkylnaphthalene anions. I) 1,4-dimethylnaphthalene, II) 1,4-diethylnaphthalene, III) 1,4-dipropylnaphthalene.
□; K-DME, ▲; Li-DME, ○; Na-THF, △; Li-THF.

The reduction in the alkyl β-proton splitting from the methyl proton splitting has been successfully explained in terms of the hindered internal rotation of the alkyl group.[1,2,3,6]

To calculate the β-proton splitting as a function of the temperature, the following equations were used:[2,3,6,7]

$$Q(\theta) = B_0 + B_2 \cos^2\theta \tag{1}$$

$$a_{1,4}^\beta = \langle Q(\theta)\rangle \rho_{1,4}^\pi = B\rho_{1,4}^\pi \langle \cos^2\theta\rangle,\ \theta = \alpha + \theta_0 \tag{2}$$

$$\langle \cos^2\theta\rangle = \frac{\sum_{i=0}^{\infty}\langle \Phi_i(\alpha)|\cos^2(\alpha+\theta_0)|\Phi_i(\alpha)\rangle e^{-E_i/kT}}{\sum_{i=0}^{\infty} e^{-E_i/kT}} \tag{3}$$

Where B_0 and B_2 are the empirical parameters, $\rho_{1,4}^\pi$ is the spin density on the ring carbon atom adjacent to the alkyl group, and θ is the dihedral angle between the aliphatic C–H bond and the symmetry axis of the 2 p_z orbital on the aromatic carbon atom.[1,2] In Eq. 2, the contribution from B_0 was neglected and the value of $B\rho_{1,4}^\pi$ was estimated to be 2×3.35 G from the methyl proton splitting of the 1,4-dimethylnaphthalene anions by assuming the free rotation of the methyl group.[13] In Eq. 3, the wave function, $\Phi_i(\alpha)$, and the eigenvalue, E_i, were obtained by solving this equation:

$$-\left(\frac{\hbar^2}{2I}\right)\left(\frac{d^2\Phi_i}{d\alpha^2}\right) + [V(\alpha) - E_i]\Phi_i = 0 \tag{4}$$

where the moment of inertia, I, of the molecule fragment, Φ-R, was calculated to be 0.55×10^{-38} g·cm² for 1,4-diethylnaphthalene and 2.65×10^{-38} g·cm² for 1,4-dipropylnaphthalene, assuming that a preferred rotation of the residual group occurs about the C_1–C_4 axis of the molecule of 1,4-dialkylnaphthalenes.

In order to determine the rotational potentials, $V(\alpha)$, in Eq. 4, we assumed that the potential barrier arises from

an intermolecular interaction between the alkyl group and the aromatic ring. The external barrier sources, such as a solvation of anions, were neglected, because the dependence of the β-proton splittings on the solvents and counter cations is very small, as is shown in Fig. 6.

For 1,4-diethyl- and 1,4-dipropylnaphthalene, there are two distinct steric repulsions. The major steric repulsions are those between the γ-methyl and the γ-ethyl groups, respectivery, and the 5-CH or 8-CH group of the naphthalene moiety. The other is between the γ-alkyl group and the 2-CH or 4-CH group of the naphthalene moiety. Thus, the appropriate potential function of the ethyl and propyl groups has two maxima with different heights, as is illustrated in Fig. 7. The equilibrium conformation corresponds to the (B) state given in Fig. 7. The calculation of the Lennard-Jones repulsion energy between the non-bonded ethyl and the neighboring aromatic protons supported this result. According to the above consideration, the rotational potential can be approximated as:

$$V(\alpha) = \sum_{i=0}^{3} a_i \cos i\alpha$$

$$a_0 = \frac{1}{4}(V_a + V_c), \quad a_1 = \frac{3}{8}(V_a - V_c),$$

$$a_2 = \frac{1}{4}(V_a + V_c), \quad a_3 = \frac{1}{8}(V_a - V_c) \qquad (5)$$

where V_a and V_c are the potential energies corresponding to the (A) state and the (C) state respectively, as is given in Fig. 7.

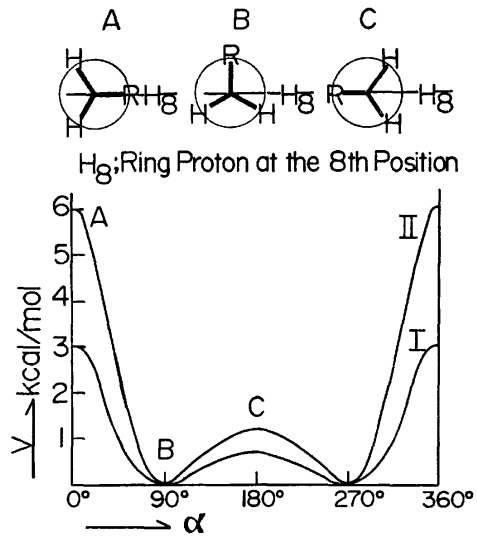

Fig. 7. Possible equilibrium conformations of the 1,4-dialkylnaphthalene anion and the rotational potential curve of the alkyl groups as a function of α. I) 1,4-diethylnaphthalene, II) 1,4-dipropylnaphthalene.

At the (A) conformation, the dihedral angle, θ_0, of the β-proton in Eq. 2 is equal to $\pi/6$. The matrix, $|\langle i|H|j\rangle|$, was diagonalized by expanding the function into a Fourier series:

$$\Phi_i(\alpha) = \sum_{j=0}^{\infty}(C_{ij}\sin j\alpha + D_{ij}\cos j\alpha) \qquad (6)$$

The $\langle\cos^2\theta\rangle$ values calculated for 1,4-diethyl- and 1,4-dipropylnaphthalene in the temperature range

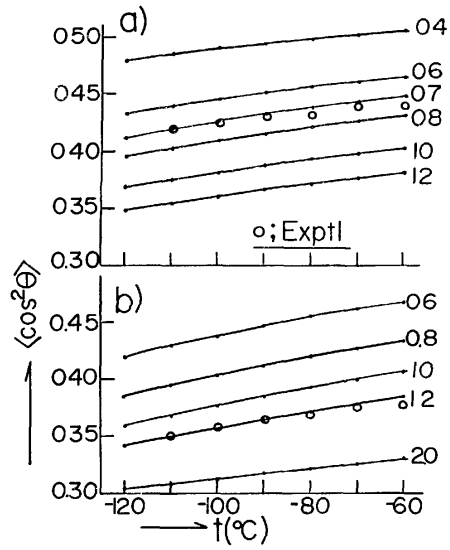

Fig. 8. Theoretical temperature dependence of $\langle\cos^2\theta\rangle$ for rotating alkyl groups. Numerical calculations were carried out by taking the potential barrier, V_c, as a variable parameter, where the barrier height, V_a, was fixed to 3 and 6 kcal/mol for 1,4-diethyl- and 1,4-dipropylnaphthalene, respectively. a) 1,4-diethylnaphthalene, b) 1,4-dipropylnaphthalene.

from -120 °C to -60 °C for various values of V_a and V_c are shown in Fig. 8.

The best agreement between the calculated and experimental temperature dependence of $\langle\cos^2\theta\rangle$ was obtained with V_a=3.0, V_c=0.7, and V_a=6.0, V_c=1.2 kcal/mol for 1,4-diethyl- and 1,4-dipropylnaphthalene respectively.

Based on the theoretical calculation and the experimental result, it can be said that, at room temperature, the ethyl group in the 1,4-diethylnaphthalene rotates in the rotational potential in Fig. 7. On the other hand, the motion of the propyl group is thought to be a torsional oscillation around the equilibrium conformation (B) rather than a restricted rotation.

Non-equivalent Alkyl β-Proton Splittings. In the ENDOR spectra for the 1,4-diethylnaphthalene-THF-K system, two signals attributed to the non-equivalent splittings of the β-methylene protons were recorded at -110 °C. They collapsed into a single line as the temperature was raised to -70 °C (see Fig. 4.). Previous ESR and ENDOR studies[14,15] of non-equivalent alkyl β-proton splittings have established a tightly locking model of an alkyl group. The Heller-McConnell relationship gives nearly $2\pi/3$ for the sum of the two dihedral angles of the non-equivalent β-protons.[16] On the contrary, for the 1,4-diethyl- and 1,4-dipropylnaphthalene anions, the sum of the dihedral angles does not coincide with $2\pi/3$, but is much smaller. It would appear that the splitting of the methylene lines for the 1,4-diethylnaphthalene anion arises neither from rotational isomers nor from the tightly locked ethyl group.

In order to explain the anomalous non-equivalene splitting detected for the two β-methylene ENDOR lines at -110 °C, it is postulated that the steric repulsion between the solvated cation and the rotating alkyl

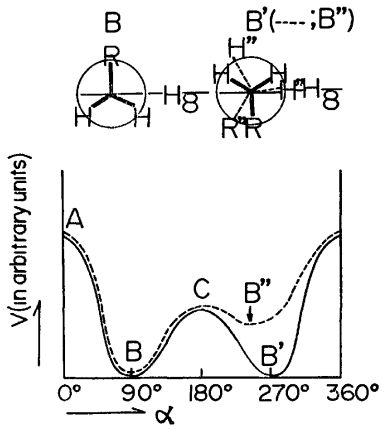

Fig. 9. Schematic diagram of the change in the potential curve due to the steric effect of the solvated-cation. (B"); Probable equilibrium conformation.

groups alters the rotational potential curve from a symmetric to an asymmetric one, where the motion of the alkyl groups take the fast rotational limit. In consequence, the averaged $\cos^2\theta$ in Eq. 3 for each alkyl β-proton may have a different value.

Based on the conductivity and ESR measurements,[18-20] it is well established that the naphthalene anions form solvent-separated ion pairs in THF solutions at low temperatures (<-70 °C) and that a potassium ion, which becomes fully coordinated with THF molecules, is located on the plane of the aromatic ring. The separation between the two opposite charges has been estimated to be 6.5—7 Å for the naphthalene anion,[21] and it has been considered to be insensitive to the aromatic moiety, as has been discussed by Chang *et al.*[19] The radius of the THF-coordinated potassium ion, which is larger than those of lithium and sodium, may be more than 4 Å[21] In 1,4-diethylnaphthalene, the ethyl substitution increases the averaged halfthickness of the aromatic moiety by about 4 Å. At the equilibrium configuration, B', shown in Fig. 9, the γ-methyl group, which is perpendicular to the aromatic plane, gives rise to a strong steric repulsion between the alkyl group and solvated cation. If the steric repulsion due to the solvated cation is negligible, the populations at the (B) and (B') states will be equal in a symmetric rotational potential. The steric effect of the solvated cation, however, destabilizes the (B') state more than the (B) state and, at the same time, the (B') state is converted into a new equilibrium conformation (B"), as is shown in Fig. 9. The rotational potential, therefore, is altered from a symmetric to an asymmetric one, and the averaged $\cos^2\theta$ for each alkyl β-proton in an asymmetric potential may take a different value. The nonequivalent alkyl β-proton splittings observed for the 1,4-dipropylnaphthalene anion may be understood on the basis of the same assumption.

At -75 °C, two signals attributed to the β-methylene protons collapsed into a single line. This means that the thermal activation energy accelerated the motion of the alkyl group; thus, the averaged thickness of the anion were increased. The distance between the paired ions becomes greater, and the asymmetry potential again approaches the original symmetric one.

The numerical calculations were carried out on the FACOM 230-75 at the Data Processing Center, Kyoto University.

The author wishes to thank Professor Kazuhiko Ishizu and Dr. Kazuo Mukai for their helpfull advice and discussion.

The Tribosorption of Hydrogen to Silicon Carbide

Koji Ichioka, Tomoyasu Ito,* Toshiaki Shirakawa, Keio Toi, and Taneki Tokuda
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received September 26, 1975)

The tribosorption of hydrogen into granular silicon carbide was studied under shaking in the pressure range of 0.04—1 Torr at room temperature. The sorption was observed when the frequencies of the vibration were 10.0 and 13.3 Hz, but was not observed when they were 0 and 6.7 Hz. The rate of tribosorption evaluated from the change in the pressure of gas had its maximum value when the sample was shaken for 20—40 h. It was found that this tribosorption could be attributed to an absorption to the solid and could be treated as a diffusion process. The time dependence of the diffusion coefficient showed a behavior similar to that of the lattice defect. It is suggested that the chemical properties of hydrogen and the activation of the solid play important roles in the tribosorption process.

Chemical reactions generally take place by the absorption of heat, radiation, *etc.* On the other hand, reactions have been known to be similarly induced by mechanical treatments of a solid, *e.g.*, by friction, compression, or impact.[1,2] That is to say, such mechanical workings gradually produce various disturbances in the crystal lattice, such as bond rupture, irregular atomic displacement, strain, and lattice defect, and chemical reactions or phase transitions proceed in and on the solid. In the last one and a half decades Heinicke and his co-workers[3-5] have made an extensive study of tribochemical reactions, especially in the presence of gases, through phenomenological observations of the reaction and measurements of lattice disorders induced in the solid, and so on. In addition, the relations between the so-called tribosorption and the tribochemical reactions have been discussed by them.

In tribochemistry many parameters participate in a reaction, so that it is necessary to select the most simple reaction system in order to obtain reproducible experimental results and to clarify the reaction mechanism. In this sense, a homomolecular isotopic exchange reaction is considered to be one of the most probable. Therefore, a study of a hydrogen–deuterium gas system, $H_2+D_2=2HD$, was made under the mechanical treatment of granular silicon carbide,[6] and an increase in the reaction rate with the shaking time was found. For a further discussion of the experimental results, and investigation of tribosorption is necessary.

Recently Heinicke *et al.*[7] investigated the tribosorption of the system consisting of powdered silicon carbide and hydrogen. They dealt mainly with the primary and secondary changes in the structure produced in the silicon carbide powder during mechanical working in the presence of hydrogen; they found a close correlation between the disturbances in the lattice and the amount of tribosorption. However, an analysis of the sorption process itself has been scarcely done.

In the present paper, the tribosorption of hydrogen into granular silicon carbide was carried out with the intention of analysing the sorption process kinetically, and some discussion is given of the mechanism of the tribosorption.

Experimental

The silicon carbide (Showa Denko K. K.) employed was black, *ca.* 1.2 mm in granular size, 98.5% pure; it was α-SiC in the hexagonal crystal system. One to twenty grams of SiC, which had been evacuated at 850 °C for a period of more than 10 h, was shaken in a 100 ml quartz vessel by a Irie Model TS-3 shaker in 0.04—1 Torr H_2 at room temperature; its amplitude was 10 mm, and the vibrational frequencies were 6.7, 10.0, and 13.3 Hz. The sorption rate was measured through the continuous measurement of the pressure change of H_2 in the system (total volume: 1.3 l) by a Pirani gauge. The existence of the reaction products was checked by means of a Hitachi Model RM-50 mass spectrometer.

In order to observe the changes of the SiC granules with the shaking, their surface area was measured by the BET adsorption method using krypton at the boiling point of liquid nitrogen, and the changes in their surface state were photographed with the aid of a JEOL Model JSM-15 scanning electron microscope.

Results and Discussion

Tribosorption Rate. When the granular SiC was left at room temperature in H_2 without shaking, no sorption was observed. On the other hand, when the mechanical treatment was used, the pressure of H_2 decreased, and tribosorption was observed. This sorption rate showed a steep increase in the initial stage of the shaking time; it reached its maximum value near 20 to 40 h, after which there was a monotonous decrease (Fig. 1). In a usual sorption which takes place ther-

* To whom correspondence should be addressed.

mally, no such maximum of the sorption rate is observed generally. Consequently, the appearance of this maximum may be considered to be one of the most important features of the tribosorption.

Prior to the investigation of the tribosorption mechanism, the contributions of the inner wall of the quartz vessel and the quartz powder which might be produced by abrasion to the observed tribosorption were examined. First, in order to see the effect of the inner wall of the vessel, the effect of the amount of SiC on the sorption rate was investigated. The sorption rate was found to be proportional to the amount of SiC (Fig. 2).

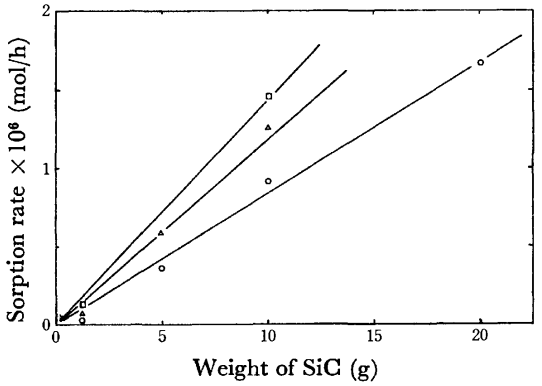

Fig. 2. The effect of SiC amount on the sorption rate: $f=10$ Hz; hydrogen pressure $P=0.04$—1 Torr. Shaking time: ○, 3 h; △, 10 h; □, 30 h.

Then, tribosorption was carried out by adding the quartz glass powder to SiC. The sorption in this case showed no increase but, rather, a little decrease compared with that in the case free from additives (Fig. 3). From the results of these experiments, it can be seen that the sorption occurred exclusively on SiC.

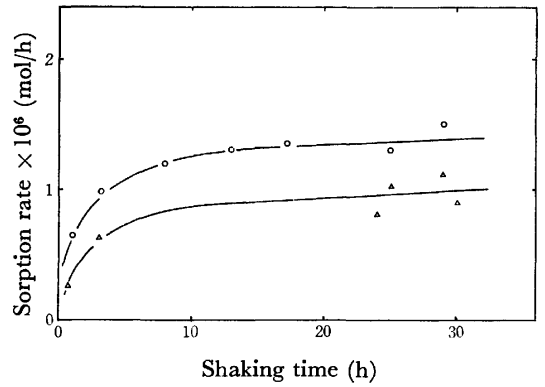

Fig. 3. The effect of quartz glass powder on the sorption rate: $f=10$ Hz; $P=0.04$—1 Torr. ○, SiC 10 g; △, SiC 10 g+glass powder 10 mg.

Next, it is necessary to distinguish whether the sorption is due to adsorption or absorption. For this purpose, the sorption rate was measured in two regions of H_2 pressure, namely, 0.02—0.2 and 5—15 Torr. In spite of the pressure difference of a factor of about 100, the ratio of the two sorption rates was merely about 2:1. This result indicates that the pressure dependence of the sorption rate is effectively nil; hence, the surface of SiC is always saturated with hydrogen. Heinicke *et al.*[4] also showed that the adsorption was very fast and immediately attained equilibrium when CO_2 was tribosorbed into metals. If the observed sorption was due chiefly to adsorption, the shaking time dependence of the sorption amount should, therefore, correspond to that of the surface area of SiC. The measurement of the surface area resulted in an initial rapid increase and a subsequent slower one, while the sorption amount had an induction time at the same initial stage (Fig. 4). Consequently, there is no simple correspondence between the two.

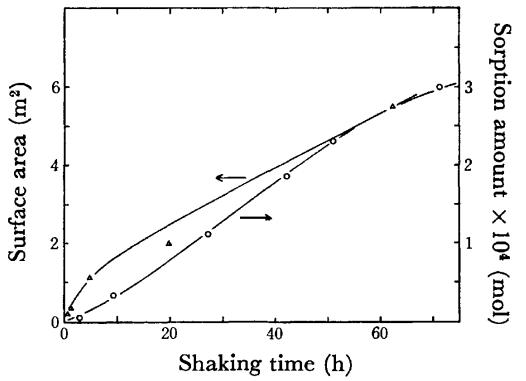

Fig. 4. The variations of the sorption amount and the surface area of SiC with shaking time: $f=13.3$ Hz; $P=0.04$—1 Torr; $W=10$ g. ○, sorption amount; △, surface area of SiC.

If this sorption is mainly absorption, the rate of resorption on SiC which, after the sorption experiment for a long period, has been evacuated under shaking to make the concentration near the surface vanishingly small, can be expected to be at its maximum at the beginning, to decrease slowly, and finally to attain the value extrapolated from the first run. Our measurement of the re-sorption after the 160 h tribosorption gave the result just anticipated, and the sorption rate attained the extrapolated value after 20 h (Fig. 5). In addition, Henning[8] showed that SiC absorbed about 10 times of the monolayerly adsorbed amount of H_2; Heinicke *et al.*[4] also reported that absorption occurred in many tribochemical processes. On the basis of these

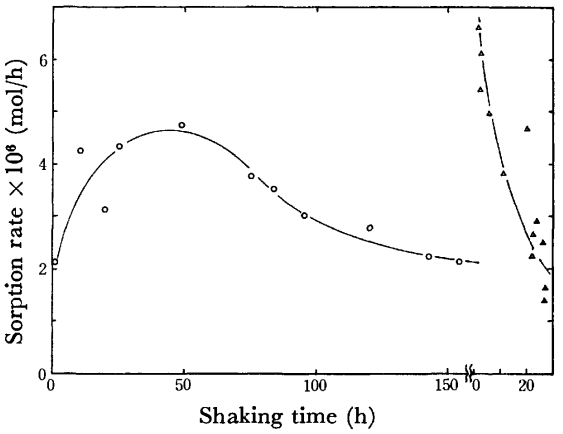

Fig. 5. The resorption rate of triboevacuated SiC after long time sorption: $f=10$ Hz; $P=5$—15 Torr; $W=20$ g. ○, sorption rate; △, resorption rate.

facts, it can be seen that the observed tribosorption results mainly from the absorption phenomenon.

Analysis of the Tribosorption Curves. Considering that the adsorption rate on the SiC surface was very rapid and that the re-sorption rate attained the extrapolated original value after a considerably long time, about 20 h, as is shown in Fig. 5, the tribosorption attributed to an absorption may be treated as a diffusion process. However, the diffusion coefficient obtained from the sorption rate may include the effects of the quartz glass powder and the tribo-desorption. As has previously been mentioned, the quartz glass powder caused a slight decrease in the sorption rate (Fig. 3). However, the amount of powder produced, which was estimated from the weight change in the vessel in each sorption experiment, was considerably less than the quantity added in the run shown in Fig. 3. Therefore, the effect of the quartz powder can be virtually neglected. If it is clearly seen that the already absorbed hydrogen and the tribochemical reaction products are desorbed from the SiC surface during the tribosorption, the sorption rate evaluated from the pressure change in the gas phase does not give a true value. However, SiC which had just been subjected to a tribosorption experiment exhibited a very small tribo-desorption rate (Fig. 1), and the results of a mass-spectrometric analysis of the gas which remained in the vessel after the sorption experiment under conditions favorable for the formation of the reaction products indicated the presence of only small amounts of methane and ethane, with a large amount of hydrogen. In addition, all the gas in the system was evacuated and H_2 was refreshed within 15 h in the sorption experiments. Therefore, the tribo-desorption may be thought to influence the sorption rate scarcely at all.

Absorption rate decreases monotonously in a usual simple diffusion system. However, a maximum in the rate can be expected in the case of a varying surface concentration or in the case of a varying diffusion coefficient with the time.[9] The former is inapplicable to the present case because of the rapid adsorption rate and because of the quick attainment to the saturated surface concentration. The following discussion will be concerned with the latter case.

In the tribosorption, the structures and properties of the solid will change during the shaking. Thus, the diffusion coefficient changes with the time. A more quantitative analysis is performed through the application of Fick's diffusion equation to the observed sorption rate by regarding the SiC granule as a sphere. Two assumptions are adopted here; one is that the radius of the granule does not vary during the shaking, and the other is that H_2 is absorbed mainly by the granular SiC and not by the powdery SiC produced during the shaking. Actually, neither the variation in the granular size nor the presence of large broken pieces was much observed after the tribosorption. Furthermore, granular SiC (10 g) was shaken with powdery SiC (0.44 g), but the sorption rate was scarcely influenced at all. Consequently, the above two assumptions seem reasonable. Then, in case of radial diffusion in a sphere of radius a, the equation takes this form:[10]

$$\frac{\partial U}{\partial t} = D\frac{\partial^2 U}{\partial r^2}, \tag{1}$$

where t is the diffusion time; D, the diffusion coefficient; r, the distance from the center of the sphere, and $U=Cr$, where C is the surface concentration. When the diffusion coefficient depends on t, T is defined as follows:

$$\mathrm{d}T = D\mathrm{d}t. \tag{2}$$

Under the following conditions:

$$\begin{aligned} U &= 0 \quad & r &= 0 \quad & t &> 0, \\ U &= aC \quad & r &= a \quad & t &> 0, \\ U &= 0 \quad & 0 &< r < a \quad & t &= 0, \end{aligned} \tag{3}$$

the solution of Eq. (1) is given by:

$$\frac{M_t}{M_\infty} = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-n^2\pi^2 T/a^2\right), \tag{4}$$

where M_t and M_∞ are the sorption amounts at the times of t and infinity respectively.

Here let us deal with the case shown in Fig. 1. It is assumed that each unit cell of SiC can finally absorb one hydrogen atom (M_∞=30 mmol as H_2) and that, from the granular size, a^2 is equal to 3.6×10^{-7} m^2. When M_t observed at t is substituted into Eq. (4), the time dependence of the diffusion coefficient is obtained by Eqs. (2) and (4) (Fig. 6). In the above treatment,

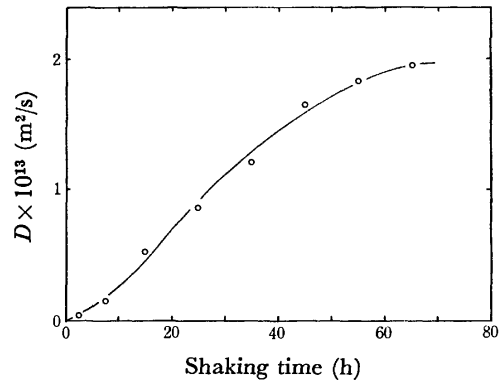

Fig. 6. The shaking time dependence of the diffusion coefficient calculated from Eqs. (2) and (4).

if the surface area effective for diffusion increases with the time, the apparent value of D should vary. The surface area observed by the BET method increased by a factor of about 10 during 60 h (Fig. 4). On the other hand, as has previously been described, the sorption rate in the case of adding powdery SiC was approximately equal to that without the powder. Accordingly, we may consider that the enlargement of the surface area observed is mainly attributable to the production of powdery SiC and powdery quartz glass, and that this increase scarcely contributes to the enlargement of the surface area effective for diffusion. It can, therefore, be understood that the time dependence of D results exclusively from that of the activity of the solid for diffusion. In fact, a scanning electron microscope showed that, at least on the surface, roughness grew during the tribosorption (Fig. 7).

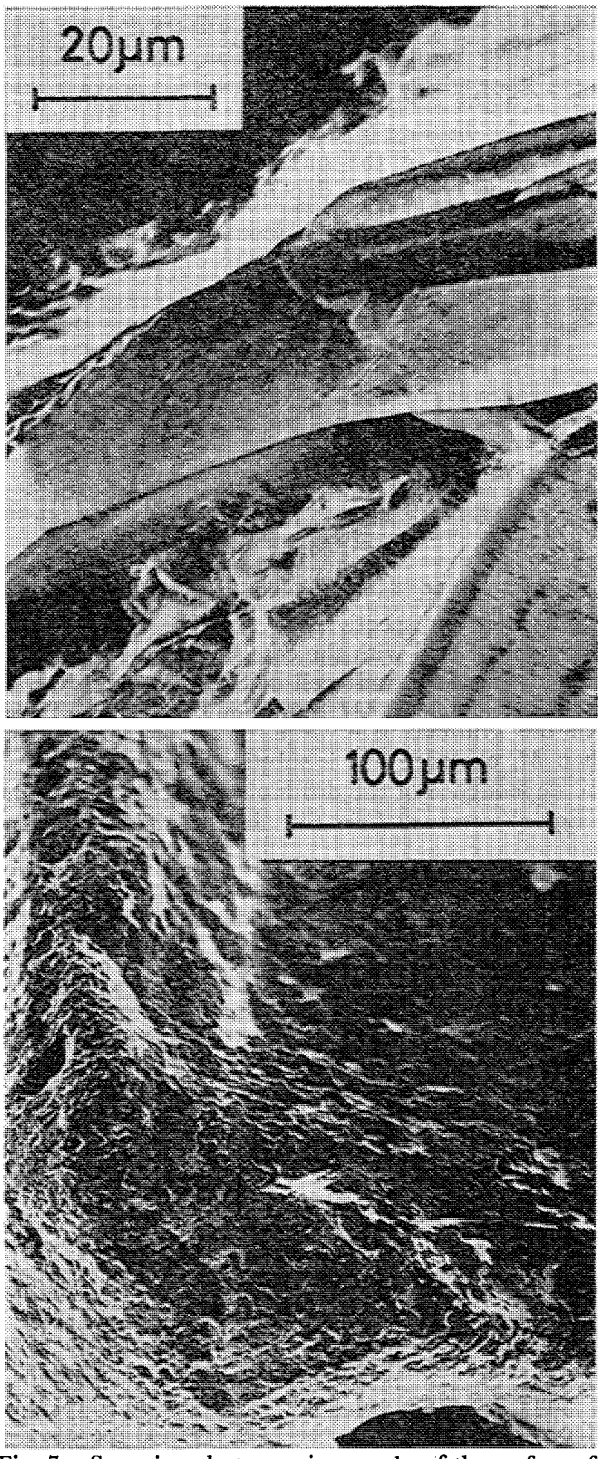

Fig. 7. Scanning electron micrographs of the surface of SiC: (a), before shaking; (b), after shaking.

Heinicke *et al.*[7] carried out the experiments of X-ray diffraction and ESR, together with the tribosorption of H_2 on SiC powders, and measured quantitatively the changes in the disturbances of the solid, such as the size of the primary grain, the disorder of the lattice, and the concentration of the free radical, *etc.* of SiC. In thier experiments all these disturbances exhibited similar time dependence, and their patterns were analogous to that of D obtained in our experiment. In particular, the disorder of the lattice is regarded as an activity which indicates the ease of hydrogen diffusion in the solid. From this point of view, too, it may be reasonable that the diffusion coefficient exhibited the variation shown in Fig. 6.

The powder system used by Heinicke *et al.*[7] had no maximum in its tribosorption rate, but only a monotonous decrease. In this regard, our experimental results differ from theirs. This probably comes from the difference in experimental condition; the granular system in the shaker and the powder system in the ball mill. In terms of the amounts of hydrogen absorbed at the same shaking time, the value obtained by Heinicke *et al.* was greater than ours by a factor of about 100. There may also be a maximum in the sorption rate at the very initial stage in their powder system.

Mechanism of the Diffusion. Then the sorption experiments of inert gases were carried out in a similar manner to ascertain whether the sorption process of SiC–H_2 system is a physical or chemical one. Helium, with a smaller molecular radius than hydrogen, and krypton, with a larger, were used, and neither of them was tribosorbed at all. Therefore, it may be seen that the sorption process of hydrogen proceeds not as a merely physical one but as a process with chemical interaction between SiC and hydrogen. Further, when deuterium was subjected to the sorption experiment, the isotope effect was not found. This information suggests that the activation step of diffusion needs an extremely high energy. Thus, as the mechanism of the tribodiffusion of hydrogen in SiC, it may be assumed that H_2 is dissociated into atomic hydrogen at high-energy points, *e.g.*, the lattice distortion and the so-called magma plasma which are produced by the collision of solids, and that the atomic hydrogen diffuses into the distorted lattice with chemical bonding processes.

As has previously been mentioned, the sorption rate was independent of the H_2 pressure and proportional to the SiC weight (Fig. 2). The surface area effective for the diffusion and activity of SiC are usually functions of the time. Therefore, D may be expressed as follows:

$$D = kP^0WA(t)S(t), \qquad (5)$$

where k is the constant; P, the gaseous pressure; W, the weight of SiC; A, the activity of the solid for diffusion, and S, the effective specific surface area. In addition, considering the vibrational frequency, no sorption was observed at 6.7 Hz, and the sorption rate at 10 Hz was one-third of the sorption rate at 13.3 Hz. The variation in the vibrational frequency seems to influence in a complicated manner the diffusion coefficient through A, S, and the activation of hydrogen.

There may be much problems in the application of Fick's equation to such a complex process as tribosorption. In the present case, all the factors due to rough approximation must be included in the activity, A, of Eq. (5). However, A and the distortion of the solid showed similar patterns in their time dependences. Hence, this treatment is correct, at least qualitatively.

In conclusion, the tribosorption of H_2 into SiC can be interpreted as a diffusion process which is essentially chemical in its nature. The diffusion coefficient in this case varies during the shaking; its variation may be caused by the activity change in the solid under mechanical treatment in the presence of H_2.

The authors wish to thank Assistant Professor Y. Tanabe of this university for his valuable suggestions. They are also grateful to Mr. Y. Shimizu for his assistance in the electron-microscopic observations.

Study of Cholesteryl Formate and Cholesteryl Octanoate by Means of Thermal Analytic Microscopy with a Thermoelement

Kazuko SASAKI KUNIHISA and Seiichi HAGIWARA*

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

**Tokyo Riko Company, Kitamachi, Hoya-shi, Tokyo 188*

(Received June 6, 1975)

A simple apparatus using a thermoelement was constructed for thermal analytic microscopy and the phase transitions of cholesteryl formate and cholesteryl octanoate were studied. The isotropic–cholesteric transition of cholesteryl formate and the cholesteric–smectic transition of cholesteryl octanoate were observed microscopically but not thermally. Upon slow cooling cholesteryl octanoate gives large spherulites with a cholesteric focal conic texture. The spherulites are optically negative. They give rise to the vortices which turn to smectic reeled yarns in specimens with appropriate thickness. The solar spectrum which appears at the cholesteric-smectic transition of cholesteryl octanoate was observed repeatedly, namely, blue, yellow, red, blue, *etc.* A melt recrystallized sample of cholesteryl formate forms a block similar to a sphere in the thermal cell. Both solid phases of cholesteryl formate and octanoate grow radially in the microscopic cell plates.

One of the authors (K.S.K.) developed thermal analytic microscopy, simultaneous observation by polarizing microscopy and by DTA.[1] This was applied to cholesteryl myristate using an improved apparatus with a modified sample holder.[2] The present work was carried out in order to systematically study (1) the aliphatic esters of cholesterol and (2) the operation of the apparatus using a thermoelement in place of the thermocouple for DTA. The temperature sensitivity of the thermoelement is 180 μV/°C based on the contact potential difference between copper and the thermoelement,[3] three or four times EMF of thermocouple. Cholesteryl formate (Ch. F.) and cholesteryl octanoate (Ch.O.) were studied. The interior of a hot stage for a microscope was reconstructed.

Apparatus

Only the reconstructed part will be described. Three thermoelements protrude like arms from the copper block wall as shown in Fig. 1. This protrusion is necessary to make the thermoelement sensitive to the temperature gradient between the specimen and the heat wall. The center arm has a copper ring at the terminal to hold a microscopic sample which is sandwiched between two quartz plates (1 mm thick). The sample thickness usually is 10—15 μ. Both side arms have their copper cell holders attached to DTA cells which are also made of copper (inside volume, 130 μl). The leads to the amplifier extend from the bases of the holders for the purpose of detecting the potential proportional to the temperature difference between the sample and the reference substance (Al_2O_3).

The copper block is surrounded by a manganin heater and has no cover. It is assumed that the temperature distribution near the specimen is approximately homogeneous due to nearly equivalent conduction of heat through the thermoelements. The temperature of the sample was measured by setting a copper–constantan thermocouple (0.1 mm ϕ) at the center ring for microscopy. The thermocouple for temperature monitoring, also copper–constantan (0.3 mm ϕ), is placed between the block wall and the manganin wire. The central part of the bottom of the block is made of glass for the sake of light transmission. The light source is an ordinary tungsten lamp of 30 W. The surroundings of the hot stage are covered with moltprene and teflon sheets.

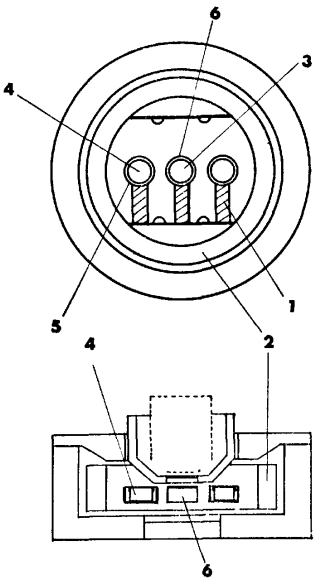

Fig. 1. Hot stage devised for thermal analytic microscopy.
1: Thermoelement, 2: copper block, 3: quartz cell, 4: copper DTA cell, 5: copper cell holder, 6: copper ring.

Sample

Commercial Ch. F. and Ch. O. were successively recrystallized from 1-pentanol[4] and ethanol, washed with acetone and dried at 60 °C for one day, as in the case of cholesteryl myristate (Ch.M.).[2]

Performance of the Apparatus

Stearic acid recrystallized from benzene was used to calibrate the heats of transition. The heats of transition were determined by taking three copies for the respective peaks and weighing the copied peak areas.

Table 1. Transition values for cholesteryl myristate

		Cryst.-Sm.		Sm.-Ch.		Ch.-Iso.	
		T °C	Q cal/g	T °C	Q cal/g	T °C	Q cal/g
Heating	This work	70.6	18.2	78.4	0.5	83.5	0.3
	Barrall II *et al.*[5]	73.6	18.7	79.7	0.41	85.6	0.41
	Davis *et al.*[6]	70.5	18.6	77.8	0.56	83.2	0.41
Cooling	This work	52—67	16.3	78.5	0.6	83.5	0.5
	Barrall II *et al.*[5]	36.7	16.8	70.0	0.56	76.5	0.44

This was done for the purpose of averaging the fluctuations (about 2%) of the density of the paper and of the mode of trimming the peak area.

Table 1 gives the transition values for Ch.M., which was further purified from the compound previously studied.[2] Thermal data are available for Ch.M.[9] since it is a typical sample giving rise to both liquid crystalline states, cholesteric and smectic, which are enantiotropic. The result of Davis *et al.*[6] is the most recent. The work of Barrall II *et al.*[5] refers to the cooling data besides heating ones. Our values of the heat of transition do not exceed the reference ones in accuracy mainly due to the fluctuations in the copy paper density. However, the transition temperatures show a better agreement between heating and cooling than the reference ones regarding every transition. The precision of the transition temperatures on heating is ± 1 °C, which is independent of the scanning rate (0.25, 0.5, 1, 2, and 4 °C/min).

Results and Discussion

The transition points of both esters on heating (mp) were reproducible and independent of the heating rate (0.25, 0.5, 1, 2, and 4 °C/min), but not those on cooling. The transition temperatures on cooling change with cooling rate and sample. Both Ch.F. and Ch.O. sometimes crystallize leaping over the mesophases, as pointed out by Friedel.[10] Discrepancy was found between the temperature determined by the DTA peak and that determined by the microscopic change. Table 2 gives the results of Ch. F. The mesophase transition was not detectable by DTA curves,** while the cholesteric texture appears microscopically a few degrees above the solidification temperature. In most cases, solidification temperature determined by DTA was higher than that by microscopy.

Table 2. Transition temperatures of cholesteryl formate, depending on DTA or microscopic samples and the cooling rates

Cooling rate	Transition temperatures (°C)		
	DTA	Microscopy	
°C/min	Crystn. point	Ch. focal conic	Crystn.
0.25	61.2	58.5	56.4
1	60.3	58.0	55.0
4[a]	57.6	57.7	52.4

a) The practical rate was 1.2 °C/min around 60 °C, due to no water circulation.

In order to clarify the discrepancies, the temperatures of thermal and microscopic samples were measured simultaneously by setting another thermocouple on the DTA cell holder of sample side. The temperature difference between the microscopic sample and the DTA sample diminishes with the decrease in the scanning rate. Both temperatures coincided within ± 1 °C below 100 °C. It seems that the difference in shape of the two sample cells causes the discrepancy rather than the inhomogeneity of the temperature distribution in the block, even taking into account the instability of the

a) *cf.* Ref. 6.

** The mesophase transition of Ch. F. in DTA appeared only once. The heat evolution was estimated to be 0.1 cal/g (shown in parentheses in Table 3).

mesophase of Ch.F. Translational or rotational motions start easily in the DTA sample in liquid state in the free space inside the cylindrical cell, solidifying directly without taking the mesophase. On the other hand, a microscopic sample in the thin space between the quartz plates is not free since it receives adhesive forces at the boundaries, being forced to take the course to the mesophase.

Multiplicate runs on a microscopic sample give rise to some depression of the transition temperature of Ch.F. It seems that the space in the plates becomes thinner due to flowing out of the sample by repetition of melting. The sample can hardly undergo transformation against the boundary forces. This is supported by the fact that a thick sample of Ch.F. for microscopy shows no cholesteric texture, solidifying at 59.6 °C under 1 °C/min cooling. No quantitative relations between the mesophase appearance and the sample thickness were studied.

The transition temperatures become lower with the increase of the cooling rate also in DTA samples as shown in Table 2. This indicates that the transformation can not follow the cooling rate above a certain rate. The lowest cooling rate 0.25 °C/min gave the highest crystallization temperature 61.2 °C.

Disagreement of the transition temperatures determined by DTA with those by microscopy also occurred in the case of Ch.O. However, the isotropic–cholesteric transition was observed by DTA and microscopy. The cholesteric–smectic transition was observed by microscopy but not by DTA. The transition temperatures of Ch.O. on cooling (Table 3) are the most probable values, their fluctuations being ± 5 °C. The reported values of both substances also markedly differ (Table 3).[5-9] The results of Ch.F. and Ch.O. may be due to the unstable properties of the mesophases as well as to the apparatus conditions. Davis *et al.*[6] concluded from their DSC studies that the lowest molecular weight saturated aliphatic ester of cholesterol to show mesophase behavior is the propionate.

Microscopy. Optical studies on aliphatic esters of cholesterol were carried out by Fridel[10] and others.[7] The studies dealt with the characteristic color reflections of the cholesteric phases and the results were restricted to liquid crystalline states. Our results might give some new information on the morphological mechanism of the transformation. The observations for the solid states may be useful to elucidate their liquid crystalline states.

Cholesteryl Formate. Ch.F. shows a mesophase similar to the cholesteric focal conic texture of Ch.M. a few degrees above the solidification temperature. When the cholesteric texture appears slowly, the phase front makes spherulitic balls and then takes them in the texture (Photo. 1). The view field is faintly light (turns faintly orange by taking off analyser) until the texture appears. Indigo blue appears near the boundary of the texture in a specimen of proper thickness. Photograph taken with a color sensitive plate gives an ordered cholesteric phase somewhat like woolen texture (Photo. 2).

The solidification speed is considerably great as compared with that of the cholesteric phase growth. The solid phase develops radially like a film which seems to retain the liquid property. The cholesteric texture is once destroyed and transformed into isotropic (dark in view) before solidification. In a properly thick specimen, the flow caused by the texture destruction appears in dark vermilion and dark green under crossed polars. The two color directions appear to make a right angle.

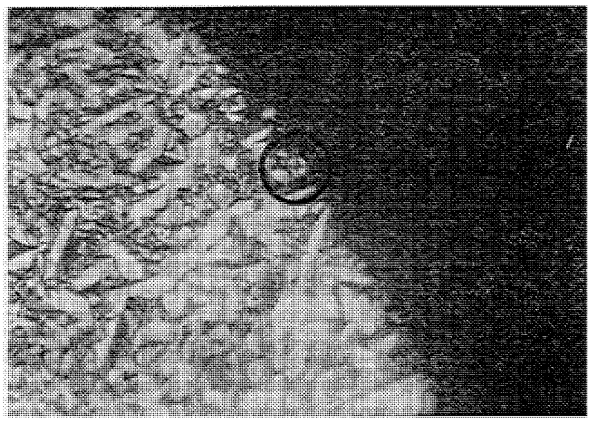

Photo. 1. Cholesteric texture appearance of cholesteryl formate. 0.25 °C/min cooling at 58.5 °C, The circle in the photograph indicates the spherulitic ball.

Radial cleavages occur after solidification. Photograph 3 shows the center of a radially grown solid phase which indicates a spherulitic growth. A sample recrystallized after melting in the DTA cell forms a block similar to a sphere and to an illustration, drawn by G. W. Gray, for an explanation of a smectic phase.[11]

Cholesteryl Octanoate. In this work, the homeotropic texture gave colors from blue to yellow. The most retainable color was sapgreen. Both the brilliance and hue are dependent on the thickness of sample. The color increases in luminosity and approaches the longer wavelength with the thickness, similar to the case of Ch.M.

Ch.O. lies in the series of aliphatic esters of cholesterol whether the smectic phase appears or not. The focal conic texture is sometimes similar to the cholesteric focal conic of Ch.M. and at others to the smectic focal conic of Ch.M. With a very thin specimen ($<10\,\mu$) the cholesteric focal conic texture disappears and turns isotropic, a smectic texture like the smectic strings of Ch.M. appearing at the transformation into solid phase. The strings turn many small spherulites before a solidification wave front appears discontinuously.

Photographs 4—9 show the course of spherulitic growth of the cholesteric focal conic texture from occurrence to destruction by invasion of the solidification wave front. It is evident by means of a color sensitive plate that the large spherulite is also optically negative.***

The spherulite causes a rapid rotation around the center somewhat like a spinning wheel or a vortex just

*** The colors, yellow and blue, of the quadrants of the spherulite interchange their positions by photography.

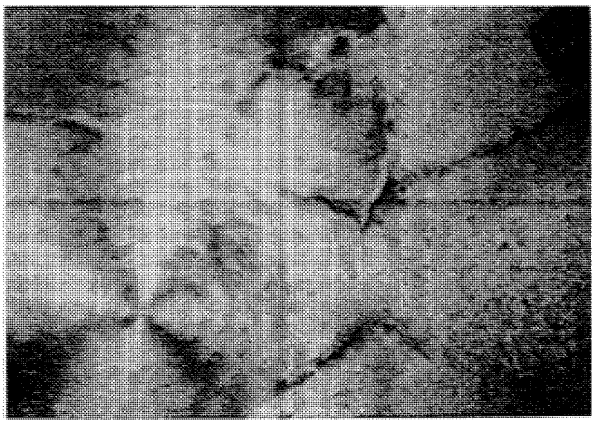

Photo. 10. Generation of the spherulites in the cholesteric phase.

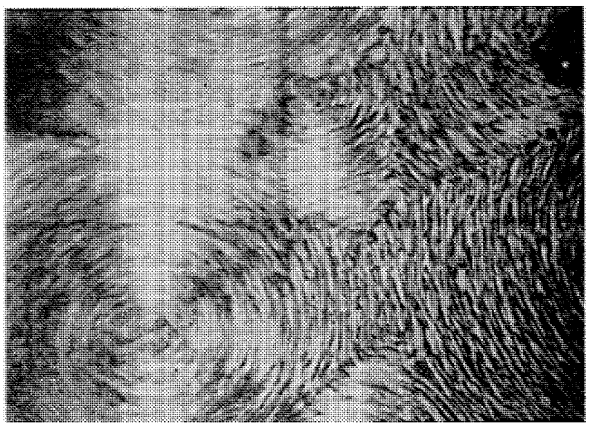

Photo. 11. Vortices around the spherulitic centers, just before the solidification.

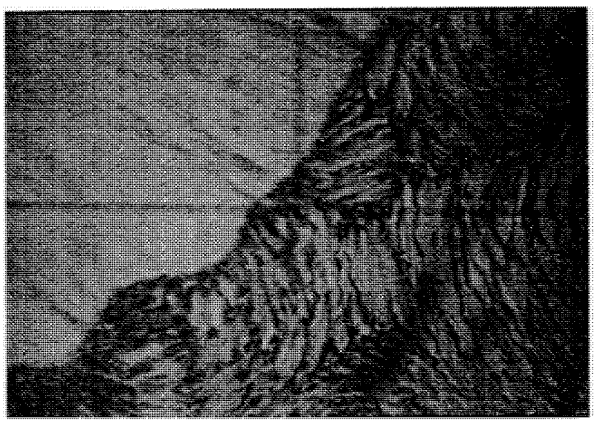

Photo. 12. The solid wave front and the smectic phase as the finish of the vortices.

Photos. 10—12. Vortices caused by the spherulites in cholesteryl octanoate.
All the photographs show observation under crossed nicols. (×100)
A color sensitive plate was used for Photos. 2, 3, 5, 7, 8, and 9.

before solidification (Photos. 10—12). The vortex is accompanied by iridescent colors, blue, yellow, red, blue and so on. The colors do not end at red but blue appears successively. It seems that the visible spectrum does not reflect the characteristic wavelength at a certain temperature but repeats from short wavelength to long one at the transformation. The color intensity decreases with the lowering of the rotational speed. We cannot observe the repetition of the solar spectrum completely. In many cases, blue does not appear a second time. The vortex turns a state similar to big reels of yarn, which suggest a smectic texture when the speed is lowered. The yarns are suddenly invaded by the solid phase. The domains formed by the growths of the cholesteric spherulites hold their regions when the smectic phase appears. The boundaries are clarified by the formation of the smectic yarns (Photo. 12).

The solid phase of Ch.O. also grows radially but the center of the growth is entirely independent of the center of the mesophase spherulite. Photograph 13 shows a dendritic growth of the solid phase with a free surface. A radially grown solid sample is gradually transformed into regular ordered state similar to Photo. 13.

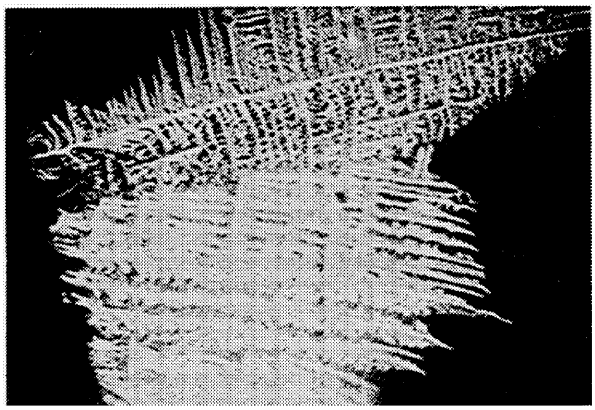

Photo. 13. Dendritic crystal growth of cholesteryl octanoate with the free surface.

The above results can be classified as follows.

Spherulitic Growths at the Phase Transitions. We observed spherulitic growths in both mesophases of Ch.F. and Ch.O. "Focal conic texture" as called by Friedel might be interpreted as the resultant texture of the spherulitic growth. According to Friedel's study, a cholesteric phase is optically negative while the smectic phase is optically positive. The cholesteric spherulites of both Ch.F. and Ch.O. are also optically negative. It is not clear whether the smectic spherulites of Ch.O. are optically positive because they appear only for an instant. Ch.M. makes small but very stable smectic spherulites which show themselves to be optically positive. It seems to be of significance that the optical sense of the spherulites coincides with that of the mesophase.

We also observed the radial growths, that is the spherulitic growths of the solid phases in the large scales. The texture has an almost spherical symmetry even in the large scale (Photo. 3). Many kinds of spherulites seem to have been studied in the field of polymer. Fischer[12] and Kobayashi[13] found that a spherulite in polymer is constructed by the layers which have essentially the same structure as the single crystals deposited from the solutions. Studies of spherulites in polymer field may be useful for elucidating the spherulitic

growths of the liquid crystals.

Color Appearance and Phase Transition. Coloration appears twice, in Ch.O., before the appearance of the cholesteric focal conic texture and the smectic phase. The former color covers the range from blue to yellow and the latter from blue to red repeatedly.

Ch.F. which is colorless, still scatters iridescent colors just before solidification, when it is rapidly quenched.

Vortices Caused by the Cholesteric Spherulites. The vortices seem to be of interest. It is not clear whether they are a characteristic of Ch.O. or not. The formation of the smectic reeled yarns was observed with a sample of proper thickness. The aggregation force of the strings may be strong enough for them to reel themselves up in a large quantity, but not in a small amount, due to hindrance by quartz boundaries.

DTA Peaks and Their Textures. Ch.F. shows the mesophase thermally only once but displays the cholesteric texture microscopically. Since the smectic phase of Ch.O. appears microscopically for an instant just before solidification it can not be detected thermally.

Both isotropic–cholesteric transition points of Ch.F. and Ch.O. are a few degrees above their solidification temperatures.

We wish to express out sincere gratitude to Dr. S. Tanaka and Dr. M. Goto of the National Chemical Laboratory for Industry for their help and encouragement.

Magnetic Properties of $[(H_2O)_2M\{(OH)_2Coen_2\}_2](X)_2\cdot nH_2O$ (M=Ni or Co, X=SO_4 or S_2O_6 and n=5 or 7)

Hanako KOBAYASHI, Kazuo OHKI, Ikuji TSUJIKAWA, Keiji OSAKI,* and Norikiyo URYÛ*

Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 8, 1975)

The magnetic properties of $[(H_2O)_2Ni\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$, $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$, $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$, and $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2\cdot 5H_2O$ were investigated on powder samples. The paramagnetism of these compounds was considered to be that of the central Ni^{2+} or Co^{2+} ion. From the fits of the experimental data with the calculated magnetic susceptibilities and the simulations of the ESR derivative curves, the ligand field parameters and g-values were determined. The ligand field around the Co^{2+} ion in $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$ was concluded to be tetragonal and in the other samples the ligand fields at the central divalent ions were found to be rhombic.

Werner[1] obtained a series of tri-nuclear $[(H_2O)_2Co\{(OH)_2Coen_2\}_2]$ salts from the partly oxidized mixtures of cobalt(II) salts and ethylendiamine. Cambi[2] later observed the magnetic susceptibility of the sulfate at room temperature. The main structure of the complex ion is considered to be a Co^{2+} ion linked to two Co^{3+} ions on wings through double OH bridges. Two other ligand sites for the central Co^{2+} ion are occupied by two H_2O molecules and four other ligand sites of each Co^{3+} ion by two ethylendiamines, as shown in Fig. 1. The magnetic properties of such complex compounds with mixed valencies are of interest because the magnetic properties of the mixed valency compounds[3,4] are not well known, except for the double exchange interaction in mixed compounds of $LaMnO_3$ and $BaMnO_3$.[3] In the course of this investigation, a new method of synthesis of this kind of complex compound was discovered by Mori *et al.*[5] in which $[(H_2O)_2M\{(OH)_2Coen_2\}_2]X_2\cdot nH_2O$, where M=$Ni^{2+}$, Co^{2+}, Mg^{2+}, Zn^{2+} or Cd^{2+}, X=SO_4^{2-}, $S_2O_3^{2-}$ or $S_2O_6^{2-}$ and n=5 or 7, were synthesized. Samples synthesized by the new method were offered by Mori *et al.* for the present investigation.

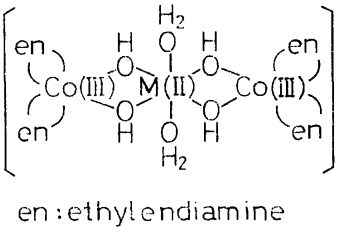

Fig. 1. The schema of $[(H_2O)_2M\{(OH)_2Coen_2\}_2]^{4+}$ complex ion.

In the present paper, the magnetic properties of $[(H_2O)_2Ni\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$, $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$, $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$ and $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2\cdot 5H_2O$ are examined. Mori *et al.*[5] observed the reflection spectra of these salts on powder. The d-d bands of the magnetic central Ni^{2+} or Co^{2+} ions were not discernible because of the much smaller absorptivity in comparison with those of the d-d bands of the trivalent cobalt chromophores. It was, therefore, impossible to determine the orbital energy levels by optical measurements.

Experimental

Preparation of Samples. $[(H_2O)_2M(II)\{(OH)_2Coen_2\}_2](SO_4)_2\cdot nH_2O$ with M=Mg, Co, Ni(n=7) and Zn, Cd (n=5) were prepared according to the method of Mori *et al.*[5] The new procedure gave only this product with seven molecules of water of crystallization for the salt of M=Co, so that $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$ was prepared according to the original method of Werner *et al.* with a slight modification. One hundred and forty-five grams of cobalt(II)sulfate heptahydrate were dissolved in 180 ml of water, and 300 ml of a 10% ethylenediamine aqueous solution was added to it. After about four hours, a green precipitate, with a pink precipitate, was filtered off. From the filtrate a massive amount of pink silky crystals soon began to precipitate. The silky precipitate was filtered through a glass filter and washed with water. Then the precipitate was placed between unglazed plates (Ton platten).

The results of the chemical analysis are as follows. For $[(H_2O)_2M(II)\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$, Found: M=Mg(II), 3.07; Co(III), 14.13%. Calcd for: Mg(II), 3.02; Co(III), 14.13%. Found: M=Co(II), 7.01; Co(III), 13.65%. Calcd for: Co(II), 7.02; Co(III), 14.04%. Found: M=Ni(II), 6.69; Co(III), 13.38%. Calcd for: Ni(II), 7.00; Co(III), 13.38%. Found: M=Zn(II), 7.79; Co(III), 13.49%. Calcd for: Zn(II), 8.07; Co(III), 14.55%. Found: M=Cd(II), 13.25; Co(III), 13.82%. Calcd for: Cd(II), 13.12; Co(III), 13.75%. For $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$, Found: H, 6.21; C, 11.17; Co, 21.33; N, 13.37%. Calcd for: H, 6.28; C, 11.98; Co, 22.02; N, 13.95%, and for $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2\cdot 5H_2O$, Found: H, 4.96; Co, 23.06; N, 12.31%. Calcd for: H, 5.41; Co, 22.96; N, 12.03%.

The hepta hydrate of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2$ prepared from the penta hydrate by the Werner method did not give good analytical values.

Magnetic Susceptibilities. Magnetic susceptibilities at liquid helium and liquid hydrogen temperatures were measured with a Hartshorn alternating current bridge. A Faraday magnetic balance with a field strength of *ca.* 9000 Oe was also employed for magnetic susceptibilities between 4.2 K and room temperature. The magnetic susceptibility of anhydrous hexaamminechromium(III) chloride powder was used as a "thermometer" which was calibrated at each run to an atmospheric liquid helium temperature with corrections for the Hg-barometer and gravitational constant following procedure of Linder.[6] The accuracy for all the measure-

Table 1. Diamagnetic part of the magnetic susceptibility per mole (cgs emu)

Compound	Estimated from expt	Calcd by Pascal's rule
$[(H_2O)_2Zn\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$	−0.00041	−0.00036
$[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$	−0.00042	−0.00037
$[(H_2O)_2Mg\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$	−0.00031	−0.00038
$[(H_2O)_2Ni\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$	−0.00032	−0.00040
$[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$	−0.00033	−0.00040

ments was not less than 5% in the case of the AC bridge method and 10% in the case of the Faraday method.

Taking into account the isomorphism[5] of the sulfates with the same number of water molecules of crystallization, the corrections for the diamagnetic part of the susceptibilities were performed as follows: for the estimation of the diamagnetic part of the susceptibility of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$, e.g., the diamagnetic susceptibility of a free Zn^{2+} ion in the literature[7] was subtracted from the observed susceptibility at room temperature for $[(H_2O)_2Zn\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$, then the diamagnetic susceptibility of a free Co^{2+} ion was added. A similar correction for the heptahydrate salts was made using the observed susceptibility of $[(H_2O)_2Mg\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$. Table 1 shows these corrections together with the diamagnetic susceptibilities calculated from Pascal's rule.

Electron Spin Resonance. The electron spin resonance of a powder sample was measured using a Japan Electron Optics Laboratory Co., Ltd., JES-3 ESR spectrometer at liquid helium temperatures. X-Band spectra were observed with an 80 Hz modulation of 15 V. The external magnetic field was swept to about 23 kOe. Sixty minutes/3000 Oe scans were usually made.

Results and Discussion

Molar magnetic susceptibilities of $[(H_2O)_2Ni\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$ are shown as a function of temperature in Fig. 2 and Table 2. The compound was paramagnetic down to 1.3 K, *i.e.*, magnetic interactions between magnetic ions in this complex compound are negligibly small compared to the thermal energy except at very low temperatures. The effective Bohr magneton number of 3.17 in the higher temperature region shown in Fig. 3 indicates that the paramagnetism is due to a Ni^{2+} ion, and that the two Co^{3+} ions may be in low spin states of the complex ion. The Ni^{2+} ion is surrounded by six oxygen atoms, of which four oxygen atoms are part of –OH– bridges and two oxygen atoms are part of co-ordinated water molecules, provided we accept the idea of Werner. No preliminary calculations of the temperature dependence of the susceptibility, ignoring the rhombic terms, show any agreement with the observed susceptibility, and therefore, a rhombic symmetry of the ligand field formed by six co-ordinated oxygen atoms was assumed for the components of the magnetic susceptibility. A temperature-independent paramagnetic susceptibility, that is, a high-frequency term, was graphically obtained from extrapolation of the plots of the observed molar mag-

The experimental χ_M values are corrected for the diamagnetic susceptibility and the temperature-independent paramagnetic susceptibility.

The χ_M values calculated from Eq. 2, with $D=-3.0$ cm^{-1}, $E=-1.0$ cm^{-1}, $g=2.25$, and $\theta=-0.1$ K, are shown in parentheses.

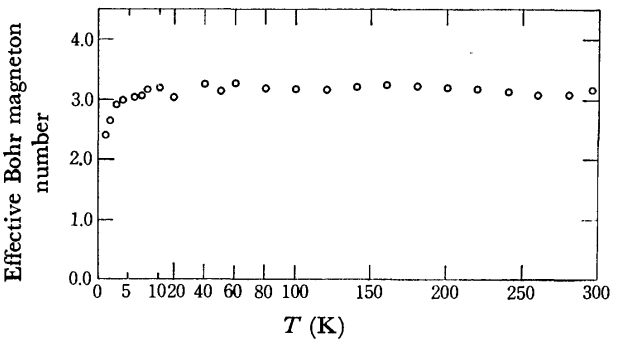

Fig. 3. The effective Bohr magneton numbers of $[(H_2O)_2Ni\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$ *versus* temperatures.

netic susceptibilities *versus* reciprocal temperatures for $1/T \to 0$. The temperature-independent paramagnetic susceptibility per mole was 0.0001 cgs emu., from which the energy difference between the ground orbital state and the first-excited orbital state was estimated to be about 10^4 cm^{-1}.[8] A nickel ion in the nickel Tutton salts is also co-ordinated by six oxygen atoms. In this case, the F state of the nickel ion is split into two triplet and one singlet substates by the cubic ligand field, and the energy splitting between the lowest singlet and the lower triplet is estimated to be about 8000 cm^{-1}. Though it is not known how the lower triplet is further split by the non-cubic ligand field, the temperature-independent paramagnetic susceptibility mentioned above is considered to show a cubic-field splitting similar to that of the nickel Tutton salt. The magnetic susceptibility was calculated, therefore, following the spin Hamiltonian

$$H = DS_z^2 + E(S_x^2 - S_y^2) + g\beta HS, \qquad (1)$$

where D and E are axial and rhombic ligand field parameters, respectively, β is the Bohr magneton and H the applied magnetic field. In order to obtain a molar magnetic susceptibility corrected for the diamagnetic susceptibility and the temperature-independent paramagnetic susceptibility, a fit with a calculated magnetic susceptibility was made assuming fairly small magnetic interactions. The formula[9] used for the calculation, in which the magnetic interaction is considered to be corrected for temperature, is:

$$\chi_{\text{powder}} = \frac{1}{3}(\chi_x + \chi_y + \chi_z), \qquad (2)$$

where

$$\chi_x = \frac{2Ng^2\beta^2}{\frac{D+E}{2}} \frac{\sinh \frac{D+E}{2k(T-\theta)}}{\exp\left(\frac{-3E-D}{2k(T-\theta)}\right) + 2\cosh \frac{D+E}{2k(T-\theta)}},$$

$$\chi_y = \frac{2Ng^2\beta^2}{\frac{D-E}{2}} \frac{\sinh \frac{D-E}{2k(T-\theta)}}{\exp\left(\frac{-3E-D}{2k(T-\theta)}\right) + 2\cosh \frac{D-E}{2k(T-\theta)}},$$

and

$$\chi_z = \frac{2Ng^2\beta^2}{E} \frac{\sinh \frac{E}{k(T-\theta)}}{\exp\left(\frac{D}{k(T-\theta)}\right) + 2\cosh \frac{E}{k(T-\theta)}}.$$

Assuming isotropic g values, a fairly good fit was obtained for $D = -2.9 \sim -3.0$ cm^{-1}, $E = -1.0$ cm^{-1}, $g = 2.25$ and $\theta = -0.1$ K, as is seen in Fig. 2 and Table 2. In conformity with the above values of D and E, the X-band ESR of this sample at 4.2 K gave no signal up to 23 kOe of the applied magnetic field.

The effective Bohr magneton number was 3.17 in the temperature region above 8 K and at lower temperatures it decreased showing the effect of the rhombic ligand field and antiferromagnetic interactions among magnetic complex ions.

The molar magnetic susceptibilities of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2 \cdot 5H_2O$, corrected for diamagnetic susceptibility, are shown in Figs. 4a and 4b and Table 3. The compound is paramagnetic down to 1.3 K, *i.e.*, the magnetic interactions among the magnetic ions are very weak, but the temperature dependence of the susceptibility is not simply that of the Curie-

Weiss law. In the case of a Co^{2+} ion co-ordinated by oxygen atoms in the form of an octahedron, it is known that the Co^{2+} ion has an effective spin of 1/2 at very low temperatures, where the spins are populated only in the lowest energy level. The Weiss constant of from −0.4 to −0.6 K, which was determined at liquid helium temperatures, was considered to be mainly due to the magnetic interaction. The high-frequency term was graphically obtained from data between 150 K and room temperature, that is, the extrapolation of the molar magnetic susceptibility as a function of the reciprocal temperature for $1/T\rightarrow 0$ was about 0.0007 cgs emu per mole. A similar extrapolation of the molar magnetic susceptibilities for $1/T\rightarrow 0$ from data between 14 and 20 K did not result in the same value, but it appears that the high-frequency term is not temperature independent suggesting that there are some excited levels of low excitation energy. The high-frequency term cannot be uniquely determined in these cases. On the other hand, the effective Bohr magneton number was also temperature dependent as

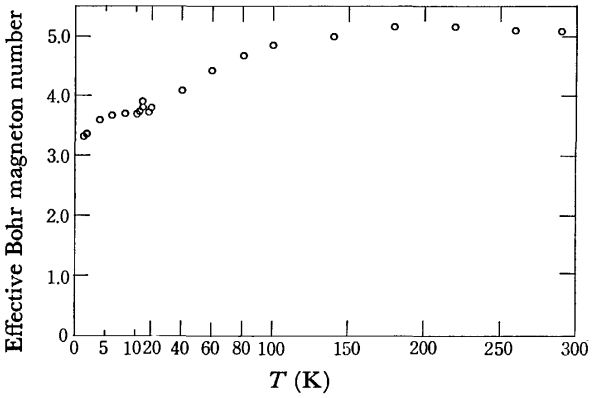

Fig. 5. The effective Bohr magneton numbers of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$ *versus* temperatures.

shown in Fig. 5. The value was about 5.1 at room temperature and gradually decreased to about 3.3 at 1.4 K. This decrease is more than that due to the antiferromagnetic interactions, indicating that the ground orbital level splits due to the ligand field of low symmetry.

The ESR derivative curve of this sample in powder form at 4.2 K is shown in Fig. 6. The signal intensity was weaker than that for $Co(NH_4)_2(SO_4)_2\cdot 6H_2O$ powder at 4.2 K, as shown in Fig. 7, but shapes of these two signals are quite similar. In $Co(NH_4)_2(SO_4)_2\cdot 6H_2O$, each Co^{2+} ion is surrounded by six oxygen atoms of coordinated water molecules with tetragonal symmetry and its g-values have been measured for single crystals by Bleaney and Ingram[10] to be $g_{\perp}=3.06\pm 0.06$ and $g_{//}=6.45\pm 0.13$. Simulations of the

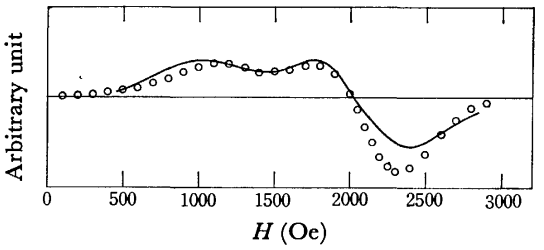

Fig. 6. ESR derivative curve of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$ on powder at 4.2 K. —: Experimental curve. ○: Simulation with parameters of $g_1=2.900$, $g_2=2.901$, $g_3=5.80$, $I=7/2$, $A_1=21.0$ Oe, $A_2=22.0$ Oe, $A_3=260.0$ Oe and line width=350 Oe.

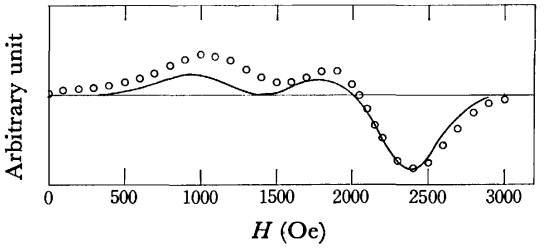

Fig. 7. ESR derivative curve of $Co(NH_4)_2(SO_4)_2\cdot 6H_2O$ on powder at 4.2 K. —: Experimental curve. ○: Simulation with parameters of $g_1=3.000$, $g_2=3.002$, $g_3=6.60$, $I=7/2$, $A_1=21.0$ Oe, $A_2=22.0$ Oe, $A_3=260.0$ Oe and line width=350 Oe.

ESR spectrum of $Co(NH_4)_2(SO_4)_2\cdot 6H_2O$ powder with g-value, hyperfine constant and line width parameters according to the Kneübuhl method[11] were attempted to see if simulation is applicable to this sort of compound. Computations were performed with a FACOM 230—75 computer at Kyoto University using a program of Kuwada.[12] The best fit simulation for $Co(NH_4)_2(SO_4)_2\cdot 6H_2O$ was obtained with the parameters: g-values, $g_1=3.000$, $g_2=3.002$, and $g_3=6.60$, hyperfine constants, $A_1=21.0$, $A_2=22.0$, and $A_3=260.0$ Oe and a line width of 350 Oe. The results are plotted in Fig. 7. The fair agreement between these g-values and those for single-crystal ESR proves that simulation can be used to estimate g-values. The hyperfine constants used are equal to those determined by Bleaney and Ingram[10] in single-crystal experiments. These constants were also used in simulations of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$, $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$ and $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2\cdot 5H_2O$. The line shapes of cobalt ammonium Tutton salt and $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$ are quite similar, and the best fit for the latter was obtained with $g_1=2.900$, $g_2=2.901$ and $g_3=5.80$ and line width of 350 Oe, as is shown in Fig. 6. Thus, the symmetry of a Co^{2+} ion in $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$ was concluded to be tetragonal as for the cobalt ammonium Tutton salt, though a difference of 0.001 between the values of g_1 and g_2 was necessary for a satisfactory fit. In Fig. 8, an example of simulations of ESR derivative curves is shown. All the curves were calculated for the same g_1 and g_3 values, that is, $g_1=3.060000$ and $g_3=6.450000$, but with the g_2 value varying from 3.060000 to 5.060000. It is worthwhile to note that when the anisotropy of the g values are almost tetragonal, the shapes of the ESR derivative curves are very sensitive to the anisotropy between the g_1 and g_2 values.

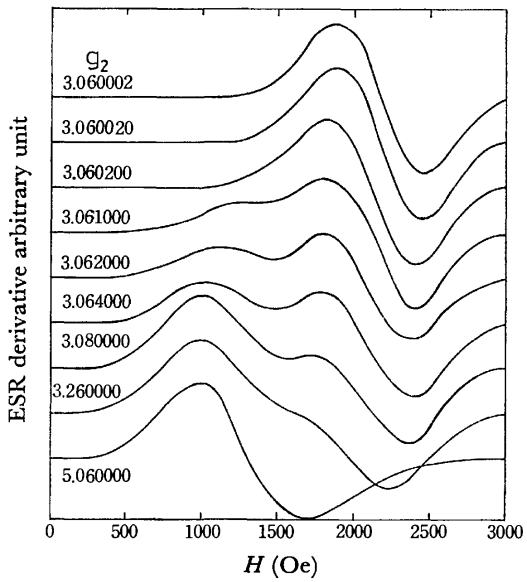

Fig. 8. Simulations of ESR derivative curves, where $g_1=3.060000$ and $g_3=6.450000$ are kept through all the cruves, but g_2 is varied from 3.060000 to 5.060000, which are written in the graph. The hyper-fine interaction is not considered.

The magnetic susceptibilities of Co^{2+} ions in the Tutton salts have been calculated by several authors[13] on the basis of the theory of Abragam and Pryce.[14] Calculations of the magnetic susceptibilities of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 5H_2O$ were attempted assuming tetragonal symmetry and considering spin-orbit interaction in order to obtain a fit with the experimental values. The calculation was performed using the equations proposed by Bose *et al.*,[13] but with orbital levels up to the third level taken into consideration. Some good fits were obtained though the g-values were not completely equal to those from the ESR simulation. The best fit to the results are given in Table 3 in parentheses and are shown in Figs. 4a and 4b. The parameters of the best fit are $g_{//}=5.915$ and $g_{\perp}=3.566$ and $\alpha=1.450$ and $\alpha'=1.950$, where $-\alpha$ and $-\alpha'$ are the effective axial and perpendicular Landé factors,[14] respectively, in the spin-orbit coupling terms expressed by the fictitious orbital angular momentum. The energy

difference between the ground level and the first-excited level is about 280 k, which is comparable to that of the Tutton salt.[13] If we follow the idea of the hexa coordination proposed by Werner,[1] it is reasonable to assume tetragonal symmetry.

The molar magnetic susceptibility of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2 \cdot 7H_2O$ was close to that of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2 \cdot 5H_2O$, as is seen in Figs. 9a and 9b and 10, and Table 3, but the ESR of the former is much more difficult to observe than that of the latter. The derivative curves of ESR were quite different, as is shown in Figs. 6 and 11. Because of the very broad line width, which seems to be more than 400 Oe, simulations would include numerous ambiguities. A calculated ESR derivative curve with g-values of 2.00, 3.00, and 4.50 and a line width of 400 Oe is shown in Fig. 11, this curve being one of the best fits though the g-values are unexpectedly small. This anisotropy of the g-values of a Co^{2+} ion in $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2 \cdot 7H_2O$ suggests that the ligandation of water molecules is different from that of penta hydrate. The Weiss constant of −0.6 to −0.7 K, which was obtained in the lowest temperature region, of the hepta hydrate is a little larger in absolute value than that of the penta hydrate. However, the hepta hydrate is, on the whole, considered to be more dilute for magnetic ions than the penta hydrate, suggesting some changes of the superexchange interaction paths. It was thought that the symmetry of the ligand field in the hepta hydrate is lower than that of the

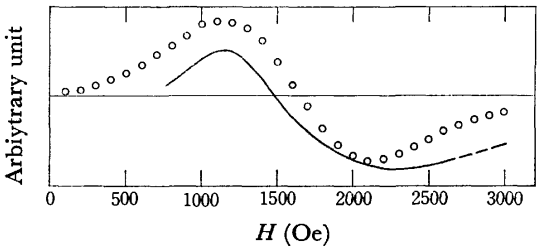

Fig. 12. ESR derivative curve of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2 \cdot 5H_2O$ on powder at 4.2 K. —: Experimental curve. ○: Simulation with parameters of $g_1=2.30$, $g_2=5.20$, $g_3=5.80$, $I=7/2$, $A_1=21.0$ Oe, $A_2=22.0$ Oe $A_3=260.0$ Oe, and line width=600 Oe.

tetragonal from the symmetry of the g-values. On the other hand, the ESR derivative curve of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2 \cdot 5H_2O$ was different from both the sulfate penta hydrate and the sulfate hepta hydrate, as is shown in Fig. 12. The simulation of this dithionate penta hydrate gave g-values of $g_1=2.30$, $g_2=5.20$, and $g_3=5.80$ with a width of 600 Oe. This anisotropy of the g-values is of the type $g_1<g_2\approx g_3$. A dithionate ion is larger in size than a sulfate ion, so it was supposed that $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2 \cdot 5H_2O$ would be magnetically more dilute than $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2 \cdot 5H_2O$. However, the observed magnetic susceptibility resulted in a negative Weiss constant having an absolute value larger than that of the penta hydrate and with a maximum near 2 K. The magnetic interactions may be operating *via* anions and some water molecules, and the dithionate ion does not result in a weaker linkage among the complex ions than does the sulfate ion in this case.

An attempt was made to calculate the magnetic susceptibilities of the dithionate penta hydrate and the sulfate hepta hydrate under the assumption of a rhombic ligand field symmetry. The method of calculation using the operator equivalents,[15] for which octahedral ligandation of oxygen atoms was assumed, is described in the appendix. The parameters for the best fit were as follows: for the dithionate penta hydrate, $\Delta r=8800$ cm^{-1}, $B_4^0=2.00$ cm^{-1}, $B_2^2=30.00$ cm^{-1}, $B_2^0=100.0$ cm^{-1}, $\alpha_x=1.81$, $\alpha_y=1.74$, $\alpha_z=0.90$, $g_x=5.044$, $g_y=5.768$ and $g_z=2.286$ and for the sulfate hepta hydrate, $\Delta r=8800$ cm^{-1}, $B_4^0=-2.00$ cm^{-1}, $B_2^2=75.00$ cm^{-1}, $B_2^0=40.0$ cm^{-1}, $\alpha_x=1.62$, $\alpha_y=1.52$, $\alpha_z=1.35$, $g_x=4.126$, $g_y=5.961$, and $g_z=2.690$. The calculated magnetic susceptibilities of the best fits are shown in Table 3 in parentheses and Figs. 9a and 9b, and 13a and 13b. As mentioned above, the dithionate penta hydrate showed that it has antiferromagnetic interactions, and therefore, in the lowest temperature region, the observed susceptibilities deviate from the calculated susceptibilities, for which magnetic interactions between magnetic ions are not taken into consideration. The discrepancy between the g-values from the ESR simulation and those from the magnetic susceptibility calculation is small in the case of $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2 \cdot 5H_2O$, however, the case of the sulfate hepta hydrate cannot be explained. If it is recalled that $[(H_2O)_2Ni\{(OH)_2Coen_2\}_2](SO_4)_2 \cdot 7H_2O$ has a rhombic ligand field for Ni^{2+} ion, a fairly good fit of the calculated magnetic

Fig. 13a. susceptibility for $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$ under the assumption of rhombic anisotropy appears reasonable.

In conclusion, the magnetic properties of the $[(H_2O)_2M\{(OH)_2Coen_2\}_2]^{4+}$ ion, where M=Ni^{2+} or Co^{2+}, can be explained by those of the central divalent ion, that is, roughly speaking, the Co^{3+} ions in the wings are diamagnetic. In the solid state, the magnetic properties of the $[(H_2O)_2M\{(OH)_2Coen_2\}_2]^{4+}$ ion are not independent of the anion and crystalline water molecules, that is, the ligand field of sulfate penta hydrate was concluded to be tetragonal while those of sulfate hepta hydrate and dithionate penta hydrate were found to be rhombic, and the superexchange interactions were also to some extent dependent on the anions and crystalline water molecules.

This work was completed with the cooperation of Professor Masayasu Mori, Dr. Takashi Shibahara and Mr. Moriyoshi Hatta of Osaka City University, to whom the authors wish to express their deep gratitude for having provided the new compounds used in these experiments.

The authors wish to thank Professor Keiji Kuwada of Osaka University and Professor Shunichi Ohnishi of Kyoto University for valuable discussions on ESR simulation.

Appendix

Orbital energy levels, g-values of the lowest orbital level and molar magnetic susceptibilities for a ^4F state ion with a rhombic ligand field were calculated using the method of operator equivalents.[15] The operator equivalent method is based on the fact that, within a multiplet, the matrix elements of the potential function of the ion are proportional to the matrix elements of the appropriate polynomials of the orbital angular momentum operator.

The ligand field potential V that has been considered is

$$\begin{aligned} V &= V_K + V_{T2} + V_{T4} + V_{R2} \\ &= 20A_4(x^4+y^4+z^4-\frac{3}{5}r^4) + A_2^0(3z^2-r^2) \\ &\quad + A_4^0(35z^4-30z^2r^2+3r^4) + A_2^2(x^2-y^2), \end{aligned} \tag{3}$$

where V_K is the cubic potential function, V_{T2} and V_{T4} are the second- and fourth-order tetragonal potential functions, respectively, and V_{R2} is the second-order rhombic potential function. A_4, A_2^0, A_4^0, and A_2^2 are the coefficients of these potential functions, V_K, V_{T2}, V_{T4}, and V_{R2}, respectively. V_K is assumed to be much larger than V_{T2}, V_{T4}, and V_{R2}, so that the contributions from the latter terms can be treated as a perturbation. The matrix[16] of the cubic potential V_K for the orbital states $|M_L\rangle$ ($M_L=\pm 3, \pm 2, \pm 1, 0$) is

$$60B_4 \times \begin{pmatrix} 3 & 0 & 0 & 0 & \sqrt{15} & 0 & 0 \\ 0 & -7 & 0 & 0 & 0 & 5 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & \sqrt{15} \\ 0 & 0 & 0 & 6 & 0 & 0 & 0 \\ \sqrt{15} & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 5 & 0 & 0 & 0 & -7 & 0 \\ 0 & 0 & \sqrt{15} & 0 & 0 & 0 & 3 \end{pmatrix}, \tag{4}$$

where $B_4=-2A_4\langle r^4\rangle/315$. The eigenstates of this secular matrix are the singlet Γ_2 and the triplets Γ_5 and Γ_4, for which the wave functions are

$$\varphi_1 = \sqrt{\frac{3}{8}}|-1\rangle+\sqrt{\frac{5}{8}}|+3\rangle = |\Gamma_4, 1\rangle,$$

$$\varphi_2 = -|0\rangle = |\Gamma_4, 0\rangle,$$

$$\varphi_3 = \sqrt{\frac{5}{8}}|-3\rangle+\sqrt{\frac{3}{8}}|+1\rangle = |\Gamma_4, -1\rangle,$$

$$\phi_1 = \sqrt{\frac{5}{8}}|-1\rangle-\sqrt{\frac{3}{8}}|3\rangle = |\Gamma_5, 1\rangle,$$

$$\phi_2 = \frac{1}{\sqrt{2}}(|2\rangle+|-2\rangle) = |\Gamma_5, 0\rangle,$$

$$\phi_3 = \sqrt{\frac{5}{8}}|1\rangle-\sqrt{\frac{3}{8}}|-3\rangle = |\Gamma_5, -1\rangle,$$

and

$$\chi = \frac{1}{\sqrt{2}}(|2\rangle-|-2\rangle) = |\Gamma_2, 0\rangle.$$

$$\begin{pmatrix} 6B_2^0+135B_4^0 & 0 & 6B_2^2 & -3\sqrt{15}(B_2^0+5B_4^0) & 0 & \sqrt{15}B_2^2 \\ 0 & -12B_2^0+360B_4^0 & 0 & 0 & 2\sqrt{15}B_2^2 & 0 \\ 6B_2^2 & 0 & 6B_2^0+135B_4^0 & \sqrt{15}B_2^2 & 0 & -3\sqrt{15}(B_2^0+5B_4^0) \\ -3\sqrt{15}(B_2^0+5B_4^0) & 0 & \sqrt{15}B_2^2 & 105B_4^0+\Delta_\Gamma & 0 & 0 \\ 0 & 2\sqrt{15}B_2^2 & 0 & 0 & -420B_4^0+\Delta_\Gamma & 0 \\ \sqrt{15}B_2^2 & 0 & -3\sqrt{15}(B_2^0+5B_4^0) & 0 & 0 & 105B_4^0+\Delta_\Gamma \end{pmatrix}, \quad (5)$$

Following the process introduced by Abragam and Pryce[14] for the case of ligand fields of low symmetry, we take into account the orbitals Γ_4 and Γ_5, but neglect the contribution from the Γ_2 orbital.

The matrix elements of V_{T2}, V_{T4}, and V_{R2} based on $\{\varphi_i\}$ and $\{\varphi_i\}$ $(i=1, 2, 3)$ are, if we set $B_2^0=-2A_2^0\langle r^2\rangle/105$, $B_2^2=-2A_2^2\langle r^2\rangle/105$, and $B_4^0=-2A_4^0\langle r^4\rangle/315$,
where Δ_Γ is the separation between the Γ_4 and Γ_5 levels and is equal to $480|B_4|$. The orbital levels obtained by the diagonalization of (5) are shown in Fig. 14.

The components of the orbital angular momentum L based on $\{\varphi_i\}$ and $\{\varphi_i\}$ $(i=1, 2, 3)$ are represented as follows,

$$L_x=\frac{1}{2}\begin{pmatrix} 0 & \frac{-3}{2}\sqrt{2} & 0 & 0 & \sqrt{\frac{15}{2}} & 0 \\ \frac{-3}{2}\sqrt{2} & 0 & \frac{-3}{2}\sqrt{2} & -\sqrt{\frac{15}{2}} & 0 & -\sqrt{\frac{15}{2}} \\ 0 & \frac{-3}{2}\sqrt{2} & 0 & 0 & \sqrt{\frac{15}{2}} & 0 \\ 0 & -\sqrt{\frac{15}{2}} & 0 & 0 & \frac{\sqrt{2}}{2} & 0 \\ \sqrt{\frac{15}{2}} & 0 & \sqrt{\frac{15}{2}} & \frac{\sqrt{2}}{2} & 0 & \frac{\sqrt{2}}{2} \\ 0 & -\sqrt{\frac{15}{2}} & 0 & 0 & \frac{\sqrt{2}}{2} & 0 \end{pmatrix},$$

$$L_y=\frac{-i}{2}\begin{pmatrix} 0 & \frac{-3}{2}\sqrt{2} & 0 & 0 & -\sqrt{\frac{15}{2}} & 0 \\ \frac{3}{2}\sqrt{2} & 0 & \frac{-3}{2}\sqrt{2} & \sqrt{\frac{15}{2}} & 0 & -\sqrt{\frac{15}{2}} \\ 0 & \frac{3}{2}\sqrt{2} & 0 & 0 & \sqrt{\frac{15}{2}} & 0 \\ 0 & -\sqrt{\frac{15}{2}} & 0 & 0 & \frac{-\sqrt{2}}{2} & 0 \\ \sqrt{\frac{15}{2}} & 0 & -\sqrt{\frac{15}{2}} & \frac{\sqrt{2}}{2} & 0 & \frac{-\sqrt{2}}{2} \\ 0 & \sqrt{\frac{15}{2}} & 0 & 0 & \frac{\sqrt{2}}{2} & 0 \end{pmatrix},$$

and

$$L_z=\begin{pmatrix} \frac{-3}{2} & 0 & 0 & \frac{\sqrt{15}}{2} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{3}{2} & 0 & 0 & \frac{-\sqrt{15}}{2} \\ \frac{\sqrt{15}}{2} & 0 & 0 & \frac{-1}{2} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{-\sqrt{15}}{2} & 0 & 0 & \frac{1}{2} \end{pmatrix}. \quad (6)$$

The lowest three orbital states ξ_1, ξ_2, and ξ_3 in matrix (5) are given by

$$\xi_1=\mu_1\varphi_1+\mu_1'\varphi_3+\nu_1\phi_1+\nu_1'\phi_3,\ \xi_2=\mu_2\varphi_2+\nu_2\phi_2,$$
$$\text{and } \xi_3=\mu_3\varphi_1+\mu_3'\varphi_3+\nu_3\phi_1+\nu_3'\phi_3. \quad (7)$$

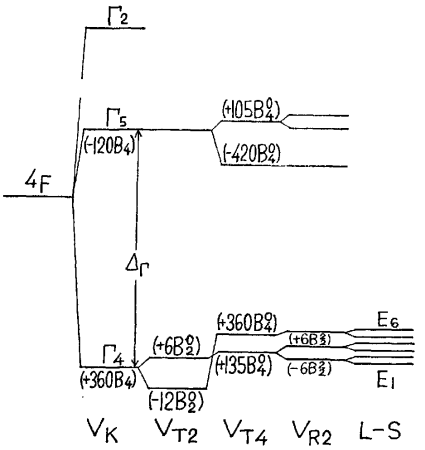

Fig. 14. Orbital energy level splittings of a ^4F state in a field of rhombic symmetry.

The components of the angular momentum based on $\{\xi_i\}$ $(i=1, 2, 3)$ are

$$L_x=\frac{1}{2}\begin{pmatrix} 0 & \rho_x & 0 \\ \rho_x & 0 & \rho_x' \\ 0 & \rho_x' & 0 \end{pmatrix},$$

$$L_y=\frac{-i}{2}\begin{pmatrix} 0 & \rho_y' & 0 \\ -\rho_y' & 0 & \rho_y \\ 0 & -\rho_y & 0 \end{pmatrix},$$

and

$$L_z=\begin{pmatrix} \rho_z' & 0 & \rho_z \\ 0 & 0 & 0 \\ \rho_z & 0 & \rho_z'' \end{pmatrix}, \quad (8)$$

where ρ_v, ρ_v', and ρ_v'' $(v=x, y, z)$ are, using (7),

$$\rho_x=\frac{-3\sqrt{2}}{2}\mu_2(\mu_1+\mu_1')+\sqrt{\frac{15}{2}}\{\nu_2(\mu_1+\mu_1')-\mu_2(\nu_1+\nu_1')\}+\frac{\sqrt{2}}{2}\nu_2(\nu_1+\nu_1'),$$

$$\rho_x'=\frac{-3\sqrt{2}}{2}\mu_2(\mu_3+\mu_3')+\sqrt{\frac{15}{2}}\{\nu_2(\mu_3+\mu_3')-\mu_2(\nu_3+\nu_3')\}+\frac{\sqrt{2}}{2}\nu_2(\nu_3+\nu_3'),$$

$$\rho_y=\frac{3\sqrt{2}}{2}\mu_2(\mu_3-\mu_3')+\sqrt{\frac{15}{2}}\{\nu_2(\mu_3-\mu_3')+\mu_2(\nu_3-\nu_3')\}+\frac{\sqrt{2}}{2}\nu_2(\nu_3-\nu_3'),$$

$$\rho_y'=\frac{3\sqrt{2}}{2}\mu_2(-\mu_1+\mu_1')+\sqrt{\frac{15}{2}}\{\nu_2(-\mu_1+\mu_1')+\mu_2(-\nu_1+\nu_1')\}+\frac{\sqrt{2}}{2}\nu_2(-\nu_1+\nu_1'),$$

$$\rho_z = \frac{-3}{2}(\mu_1\mu_3-\mu_1'\mu_3')+\sqrt{\frac{15}{2}}(\mu_1\nu_3+\nu_1\mu_3-\mu_1'\nu_3'-\nu_1'\mu_3') -\frac{1}{2}(\nu_1\nu_3-\nu_1'\nu_3'),$$

$$\rho_z' = \frac{-3}{2}(\mu_1^2-\mu_1'^2)+\sqrt{15}(\mu_1\nu_1-\mu_1'\nu_1')-\frac{1}{2}(\nu_1^2-\nu_1'^2),$$

and $$\rho_z'' = \frac{-3}{2}(\mu_3^2-\mu_3'^2)+\sqrt{15}(\mu_3\nu_3-\mu_3'\nu_3')-\frac{1}{2}(\nu_3^2-\nu_3'^2).$$

The solution of the secular equation shows that $\mu_1'=\mu_1, \nu_1'=\nu_1$, $\mu_3'=-\mu_3$, and $\nu_3'=-\nu_3$ in the case of orthorhombic ligand fields, and therefore,

$$\begin{aligned}\xi_1 &= \mu_1(\varphi_1+\varphi_3)+\nu_1(\phi_1+\phi_3),\\ \xi_2 &= \mu_2\varphi_2+\nu_2\phi_2,\\ \text{and}\quad \xi_3 &= \mu_3(\varphi_1-\varphi_3)+\nu_3(\phi_1-\phi_3).\end{aligned} \tag{9}$$

If we define the α_v ($v=x, y, z$) as follows

$$\alpha_x = \frac{-\rho_x}{2} = \frac{3\sqrt{2}}{2}\mu_1\mu_2-\sqrt{\frac{15}{2}}\{\mu_1\nu_2-\mu_2\nu_1\}-\frac{\sqrt{2}}{2}\nu_1\nu_2,$$

$$\alpha_y = \frac{\rho_y}{2} = \frac{3\sqrt{2}}{2}\mu_2\mu_3+\sqrt{\frac{15}{2}}\{\nu_2\mu_3+\nu_3\mu_2\}+\frac{\sqrt{2}}{2}\nu_2\nu_3,$$

and $$\alpha_z = -\rho_z = 3\mu_1\mu_3-\sqrt{15}(\mu_1\nu_3+\nu_1\mu_3)+\nu_1\nu_3, \tag{10}$$

and it is known that

$$\rho_x' = \rho_y' = \rho_z' = \rho_z'' = 0,$$

then the components of the angular momentum can be written as follows,

$$L_x = -\alpha_x\begin{bmatrix}0&1&0\\1&0&0\\0&0&0\end{bmatrix} = -\alpha_x l_x',$$

$$L_y = -\alpha_y\begin{bmatrix}0&0&0\\0&0&i\\0&-i&0\end{bmatrix} = -\alpha_y l_y',$$

and $$L_z = -\alpha_z\begin{bmatrix}0&0&1\\0&0&0\\1&0&0\end{bmatrix} = -\alpha_z l_z', \tag{11}$$

where $l_x'^2+l_y'^2+l_z'^2 = l(l+1) = 2,\ (l=1).$

The α_x, α_y, and α_z indicate the contributions from the Γ_5 orbital level. When there is no contribution from the Γ_5 level, that is, when the lowest triplet Γ_4 state consists of only the wave functions $\{\varphi_1\}$, α_x, α_y, and α_z are

$$\alpha_x = \alpha_y = \alpha_z = 1.5.$$

The potential function (3) is replaced by the equivalent angular momentum operators[15] as follows,

$$\begin{aligned}\hat{V} &= \hat{V}_K+\hat{V}_{T2}+\hat{V}_{T4}+\hat{V}_{R2}\\ &= B_4(O_4^0+5O_4^4)+B_2^0O_2^0+B_4^0O_4^0+B_2^2O_2^2,\end{aligned} \tag{12}$$

where $B_4 = \langle L\|\beta\|L\rangle A_4\langle r^4\rangle$,
$B_2^0 = \langle L\|\alpha\|L\rangle A_2^0\langle r^2\rangle$,
$B_4^0 = \langle L\|\beta\|L\rangle A_4^0\langle r^4\rangle$,
and $B_2^2 = \langle L\|\alpha\|L\rangle A_2^2\langle r^2\rangle$.

$\langle L\|\alpha\|L\rangle$ and $\langle L\|\beta\|L\rangle$ are the proportional coefficients,[16] $-2/105$ and $-2/315$, respectively, and $\langle r_j\rangle$ is the average of r_j over the radial part of the wave function. O_3^0, O_2^2, O_4^0, and O_4^4 can be written using the orbital angular momentum operator L, thus

$$\begin{aligned}O_2^0 &= 3L_z^2-L(L+1),\\ O_2^2 &= \frac{1}{2}(L_+^2+L_-^2),\\ O_4^0 &= 35L_z^4-30L(L+1)L_z^2+25L_z^2\\ &\quad -6L(L+1)+3L^2(L+1)^2,\\ \text{and}\quad O_4^4 &= \frac{1}{2}(L_+^4+L_-^4).\end{aligned} \tag{13}$$

Using the α_x, α_y, and α_z mentioned above and $l=1$, the V_{T2}, V_{T4}, and V_{R2} (in Eq. 12) can be written as follows,

$$\begin{aligned}\hat{V}_{T2} &= \frac{1}{4}B_2^0Q_2^0,\\ \hat{V}_{T4} &= B_4^0Q_4^0,\\ \hat{V}_{R2} &= \frac{1}{4}B_2^2Q_2^2,\end{aligned} \tag{14}$$

where $Q_2^0 = (8\alpha_z^2+2p)l_z^2-4p-q(l_+^2+l_-^2)$,
$Q_4^0 = u_1l_z^2+u_2(l_+^2+l_-^2)+u_3$,
$Q_2^2 = p(l_+^2+l_-^2)-2ql_z^2+4q$,
$p = \alpha_x^2+\alpha_y^2$,
$q = \alpha_x^2-\alpha_y^2$,
$u_1 = 8\alpha_z^4-12p\alpha_z^2+19\alpha_z^2+3p-\frac{9}{4}p^2+\frac{3}{4}q^2$,
$u_2 = \frac{3}{2}q\left(\frac{p}{2}-4\alpha_z^2-1\right)$,
and $u_3 = 3p(p-2)$.

The first-order perturbation Hamiltonian containing the spin-orbit interaction is

$$\begin{aligned}\mathcal{H} &= \frac{1}{4}B_2^0Q_2^0+B_4^0Q_4^0+\frac{1}{4}B_2^2Q_2^2\\ &\quad -\lambda(\alpha_xl_xS_x+\alpha_yl_yS_y+\alpha_zl_zS_z).\end{aligned} \tag{15}$$

When the rhombic symmetry is taken into account, $m(=l_z+S_z)$ is not a good quantum number. The secular matrix of Eq. 15 represented in the basis set of $|l_z, S_z\rangle$ is

$$\begin{array}{cccccc}|-1,\tfrac{3}{2}\rangle & |-1,\tfrac{-1}{2}\rangle & |1,\tfrac{3}{2}\rangle & |1,\tfrac{-1}{2}\rangle & |0,\tfrac{1}{2}\rangle & |0,\tfrac{-3}{2}\rangle\\ |1,\tfrac{-3}{2}\rangle & |1,\tfrac{1}{2}\rangle & |-1,\tfrac{-3}{2}\rangle & |-1,\tfrac{1}{2}\rangle & |0,\tfrac{-1}{2}\rangle & |0,\tfrac{3}{2}\rangle\end{array}$$

$$\begin{pmatrix}
T_f+R_f+\frac{3}{2}\alpha_z\lambda & 0 & \frac{1}{2}(pB_2^2-qB_2^0)+2u_2B_4^0 & 0 & \frac{-\sqrt{6}}{4}r\lambda & 0\\
0 & T_f+R_f-\frac{1}{2}\alpha_z\lambda & 0 & \frac{1}{2}(pB_2^2-qB_2^0)+2u_2B_4^0 & \frac{-\sqrt{2}}{2}s\lambda & \frac{-\sqrt{6}}{4}r\lambda\\
\frac{1}{2}(pB_2^2-qB_2^0)+2u_2B_4^0 & 0 & T_f+R_f-\frac{3}{2}\alpha_z\lambda & 0 & \frac{-\sqrt{6}}{4}s\lambda & 0\\
0 & \frac{1}{2}(pB_2^2-qB_2^0)+2u_2B_4^0 & 0 & T_f+R_f+\frac{1}{2}\alpha_z\lambda & \frac{-\sqrt{2}}{2}r\lambda & \frac{-\sqrt{6}}{4}s\lambda\\
\frac{-\sqrt{6}}{4}r\lambda & \frac{-\sqrt{2}}{2}s\lambda & \frac{-\sqrt{6}}{4}s\lambda & \frac{-\sqrt{2}}{2}r\lambda & 0 & 0\\
0 & \frac{-\sqrt{6}}{4}r\lambda & 0 & \frac{-\sqrt{6}}{4}s\lambda & 0 & 0
\end{pmatrix}, \tag{16}$$

where
$$T_f = \left(2\alpha_z^2 + \frac{1}{2}p\right)B_2^0 + u_1 B_4^0,$$
$$R_f = -\frac{1}{2}qB_2^2,$$
$$r = \alpha_x + \alpha_y,$$
and
$$s = \alpha_x - \alpha_y.$$

The six Kramers doublets, which are deduced from the lowest orbital triplet, are obtained through the diagonalization of (16). The energy levels of the six Kramers doublets are expressed as E_i ($i=1, 2, ..., 6$) and their wave functions as $\Phi_{\pm i}$ ($i=1, 2, ..., 6$). Then

$$\Phi_{+i} = \sum_{j=1}^{6} C_{ij}\zeta_j,$$
and
$$\Phi_{-i} = \sum_{j=1}^{6} C_{ij}\zeta_j^*, \qquad (17)$$

where $\{\zeta_j\}$ is the base of the secular matrix (16) and its coefficient of linear combination, C_{ij}, can be determined from the solution of the secular equation. The g factors of the lowest Kramers doublet are given as follows:

$$\begin{aligned}
g_x &= 2\langle\Phi_{+1}|-\alpha_x l_x + 2S_x|\Phi_{-1}\rangle \\
&= -2\sqrt{2}\,\alpha_x(C_{11}C_{16}+C_{12}C_{15}+C_{13}C_{16}+C_{14}C_{15}) \\
&\quad +4\sqrt{3}\,(C_{11}C_{14}+C_{12}C_{13}+C_{15}C_{16})+8C_{12}C_{14}+4C_{15}^2, \\
g_y &= 2\langle\Phi_{+1}|-\alpha_y l_y + 2S_y|\Phi_{-1}\rangle \\
&= -2\sqrt{2}\,\alpha_y(-C_{11}C_{16}-C_{12}C_{15}+C_{13}C_{16}+C_{14}C_{15}) \\
&\quad +4\sqrt{3}\,(C_{11}C_{14}+C_{12}C_{13}-C_{15}C_{16})-8C_{12}C_{14}+4C_{15}^2, \\
g_z &= 2\langle\Phi_{+1}|-\alpha_z l_z + 2S_z|\Phi_{+1}\rangle \\
&= 2[(C_{11}^2+C_{12}^2-C_{13}^2-C_{14}^2)\alpha_z+3(C_{11}^2+C_{13}^2-C_{16}^2) \\
&\quad -C_{12}^2-C_{14}^2+C_{15}^2]. \qquad (18)
\end{aligned}$$

The magnetic susceptibility per mole is given by

$$\chi_v = \frac{N\beta^2}{Z}\left(\frac{G^v}{kT}+2G'^v\right), \quad (v=x, y, z)$$

where
$$G^v = \sum_{i=1}^{6} G_i^v \exp\frac{-(E_i-E_1)}{kT},$$
$$G_i^v = \sum_{\pm}|\langle\Phi_{\pm i}|-\alpha_v l_v+2S_v|\Phi_{\pm i}\rangle|^2,$$
$$G'^v = \sum_{i=1}^{6} G'^v_i \exp\frac{-(E_i-E_1)}{kT},$$
$$G'^v_i = \sum_{j(\neq i)}^{6} G'^v_{ij},$$
$$G'^v_{ij} = \sum_{\pm}\frac{|\langle\Phi_{\pm i}|-\alpha_v l_v+2S_v|\Phi_{\pm j}\rangle|^2}{E_j-E_i},$$
and
$$Z = 2\sum_{i=1}^{6}\exp\frac{-(E_i-E_1)}{kT}.$$

The G_i^v and G'^v_{ij} are

$$\begin{aligned}
G_i^x &= 2[-\sqrt{2}\,\alpha_x(C_{i1}C_{i6}+C_{i2}C_{i5}+C_{i3}C_{i6}+C_{i4}C_{i5}) \\
&\quad +2\sqrt{3}\,(C_{i1}C_{i4}+C_{i2}C_{i3}+C_{i5}C_{i6})+4C_{i2}C_{i4}+2C_{i5}^2]^2, \\
G_i^y &= 2[\sqrt{2}\,\alpha_y(C_{i1}C_{i6}+C_{i2}C_{i5}-C_{i3}C_{i6}-C_{i4}C_{i5}) \\
&\quad +2\sqrt{3}\,(C_{i1}C_{i4}+C_{i2}C_{i3}-C_{i5}C_{i6})-4C_{i2}C_{i4}+2C_{i5}^2]^2, \\
G_i^z &= 2[\alpha_z(C_{i1}^2+C_{i2}^2-C_{i3}^2-C_{i4}^2)+3(C_{i1}^2+C_{i3}^2-C_{i6}^2) \\
&\quad -C_{i1}^2-C_{i4}^2+C_{i5}^2]^2,
\end{aligned}$$

$$\begin{aligned}
G'^x_{ij} &= \frac{2}{E_j-E_i}[\sqrt{3}\,(C_{i1}C_{j4}+C_{i4}C_{j1}+C_{i2}C_{j3}+C_{i3}C_{j2} \\
&\quad +C_{i5}C_{j6}+C_{i6}C_{j5})-\frac{\sqrt{2}}{2}\alpha_x(C_{i1}C_{j6}+C_{i6}C_{j1}+C_{i2}C_{j5} \\
&\quad +C_{i5}C_{j2}+C_{i3}C_{j6}+C_{i6}C_{j3}+C_{i4}C_{j5}+C_{i5}C_{j4}) \\
&\quad +2(C_{i2}C_{j4}+C_{i4}C_{j2}+C_{i5}C_{j5})]^2,
\end{aligned}$$

$$\begin{aligned}
G'^y_{ij} &= \frac{2}{E_j-E_i}[\sqrt{3}\,(C_{i1}C_{j4}+C_{i4}C_{j1}+C_{i2}C_{j3}+C_{i3}C_{j2} \\
&\quad -C_{i5}C_{j6}-C_{i6}C_{j5})+\frac{\sqrt{2}}{2}\alpha_y(C_{i1}C_{j6}+C_{i6}C_{j1}+C_{i2}C_{j5} \\
&\quad +C_{i5}C_{j2}-C_{i3}C_{j6}-C_{i6}C_{j3}-C_{i4}C_{j5}-C_{i5}C_{j4}) \\
&\quad -2(C_{i2}C_{j4}+C_{i4}C_{j2}-C_{i5}C_{j5})]^2,
\end{aligned}$$

$$\begin{aligned}
G'^z_{ij} &= \frac{2}{E_j-E_i}[\alpha_z(C_{i1}C_{j1}+C_{i2}C_{j2}-C_{i3}C_{j3}-C_{i4}C_{j1}) \\
&\quad +3(C_{i1}C_{j1}+C_{i3}C_{j3}-C_{i6}C_{j6})-C_{i2}C_{j2}-C_{i4}C_{j4} \\
&\quad +C_{i5}C_{j5}]^2.
\end{aligned}$$

We must estimate the error in the operator equivalent method used in the above calculation. The method is valid for the lowest multiplet ^4F. The effect of mixing with the upper state of a different multiplet, *e.g.*, the Γ'_4 state arising from ^4P, can be estimated from the matrix element of $\hat{V}_{T2}+\hat{V}_{T4}+\hat{V}_{R2}$ between the lowest and the excited multiplets. Roughly, the contribution of the mixing with the upper mul-

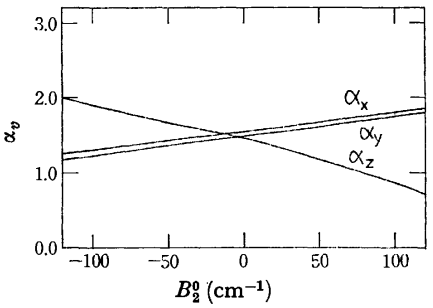

Fig. 15. α_v as a function of B_2^0. The graph is calculated for $\Delta\Gamma=8800$ cm^{-1}, $B_4^0=2.00$ cm^{-1}, and $B_2^2=30.0$ cm^{-1}.

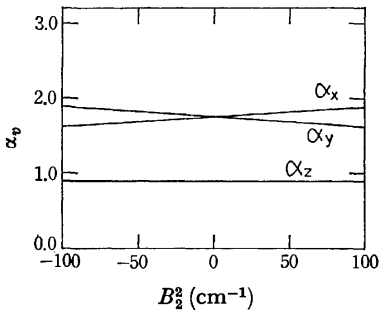

Fig. 16. α_v as a function of B_2^2, where $\Delta\Gamma=8800$ cm^{-1}, $B_2^0=100$ cm^{-1} and $B_4^0=2.00$ cm^{-1} were used.

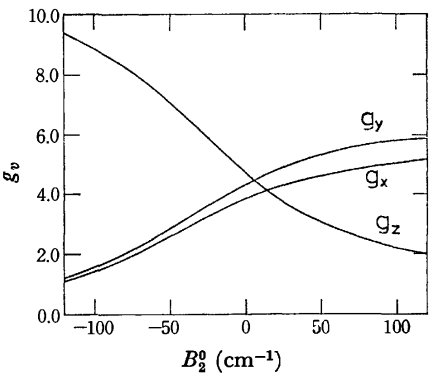

Fig. 17. g_v as a function of B_2^0 where $\Delta\Gamma=8800$ cm^{-1}, $B_4^0=2.00$ cm^{-1}, and $B_2^2=30.0$ cm^{-1} were used.

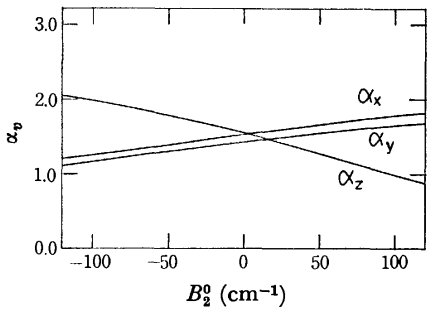

Fig. 18. α_v as a function of B_2^0, where $\Delta_\Gamma=8800$ cm^{-1}, $B_4^0=-2.00$ cm^{-1}, and $B_4^0=75.0$ cm^{-1} were used.

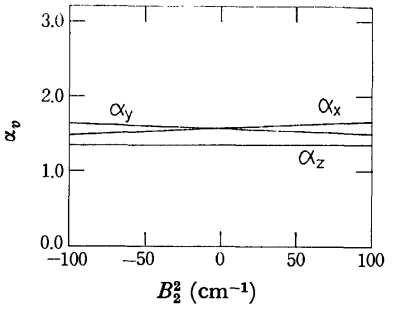

Fig. 19. α_v as a function of B_2^2, where $\Delta_\Gamma=8800$ cm^{-1}, $B_2^0=40.0$ cm^{-1}, and $B_4^0=-2.00$ cm^{-1} were used.

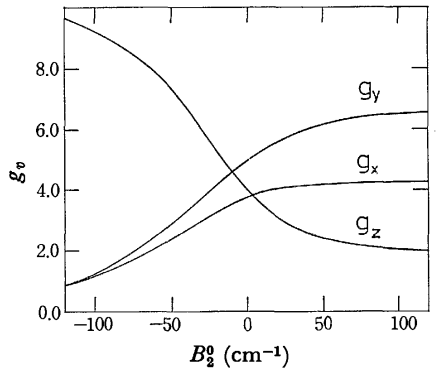

Fig. 20. g_v as a function of B_2^0, where $\Delta_\Gamma=8800$ cm^{-1}, $B_4^0=-2.00$ cm^{-1} and $B_2^2=75.0$ cm^{-1} were used.

tiplet to $\Delta\alpha$, the difference between α_v and 1.5, will be of the order of the ratio of the matrix element $\langle L=3|\hat{V}_{T2}+\hat{V}_{T4}+\hat{V}_{R2}|L\neq 3\rangle$ to the energy difference between the multiplets. Within the lowest multiplet, the more the Γ_5 level is separated from the Γ_4 level, the less the deviation of α_v from 1.5. The case of $\alpha_v=1.5$ has been analyzed by Uryû *et al.*[17] who dealt with $CoCl_2\cdot 6H_2O$. The same g-values as those of the Co Tutton salt[9] are found with the following parameters: $\alpha_x=\alpha_y=\alpha_v=1.5$, $B_4^0=2.00$ cm^{-1}, $B_2^0=-70.0$ cm^{-1}, and $B_2^2=0.00$ cm^{-1}.

In Figs. 15 and 16, α_v, $(v=x, y, z)$, is plotted as a function of B_2^0 and B_2^2, respectively. In Fig. 17, g_v, $(v=x, y, z)$, is shown as a function of B_2^0. In Figs. 15—17, the functions are calculated using the parameters, $\Delta_\Gamma=8800$ cm^{-1}, $B_4^0=2.00$ cm^{-1} and $B_2^0=100$ cm^{-1} or $B_2^2=30.0$ cm^{-1}, that is, those which showed the best fit for $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](S_2O_6)_2\cdot 5H_2O$. In Figs. 18—20, similar calculations are shown using the parameters, $\Delta_\Gamma=8800$ cm^{-1}, $B_4^0=-2.00$ cm^{-1}, and $B_2^0=40.0$ cm^{-1} or $B_2^2=75.0$ cm^{-1}, that is, those which showed the best fit for $[(H_2O)_2Co\{(OH)_2Coen_2\}_2](SO_4)_2\cdot 7H_2O$.

Numerical computations in the appendix and those of the magnetic susceptibilities were performed with a FACOM 230—45 computer at the Computer Center of Kyushu University.

An Investigation of the Triplet State Dynamics of *p*-Chloroaniline by Microwave Induced Changes in the Phosphorescence Intensity and by Triplet ← Singlet Absorption

Nobuyuki NISHI and Minoru KINOSHITA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received October 18, 1975)

The phosphorescent triplet state T_1 of *p*-chloroaniline (PCA) in a *p*-xylene host, in a neat crystal (n-trap), and in a PCA crystal doped with *p*-dichlorobenzene (x-trap) has been studied with the aid of phosphorescence spectra, optically detected zero-field magnetic resonance, and $T_1 \leftarrow S_0$ absorption spectra at temperatures below 4.2 K. The dynamic properties, particularly the radiative properties, of the individual spin states of T_1 are discussed in detail using the emission spectra for each spin state obtained with microwave techniques. For the x-trap system, the emissions from the T_y and T_z sublevels are found to be coincident in contrast to the other two systems. From this observation, it is suggested that the characters of the T_y and T_z states of normal PCA are mixed together in the x-trap.

The populating rates for the individual spin states were examined for the PCA crystal systems as a function of the excitation energy, when the excitation was induced by light having wavelengths in the $T_1 \leftarrow S_0$ absorption region. The relative populating rates thus obtained are dependent on the excitation energy. Therefore, it is concluded that the spin alignment produced by direct optical pumping from the ground state to the triplet manifold of the crystal is conserved during the vibrational relaxation and energy transfer processes. By using this unique wavelength dependence of the populating rates, the nature of the n- and x-traps is discussed and the vibrational structure of the $T_1 \leftarrow S_0$ spectrum is analyzed.

Detailed information on the static and dynamic properties of the phosphorescent triplet state of aromatic molecules has been successfully obtained in the past few years by using microwave techniques in combination with the conventional optical methods. In a previous paper,[1] it was shown that the emissions from the individual spin states in the lowest triplet state of *p*-chloroaniline (PCA) in *p*-xylene can be well separated at 1.3 K by applying the technique of microwave induced delayed phosphorescence (MIDP). This MIDP spectroscopy has proved to be useful in determining the mechanism of the $T_1 \rightarrow S_0$ radiative processes and in analyzing the vibrational structure of the phosphorescence. This work has been extended to two more PCA systems: a neat crystal and a PCA crystal doped with a small amount of *p*-dichlorobenzene. In these crystals, the phosphorescence is found to arise from the trap PCA molecules. It will be shown in this paper that the sublevel emissions of these traps are quite different from one system to another, although the phosphorescence spectra look much the same. From this observation the nature of the emitting centers will be deduced.

The $T_1 \leftarrow S_0$ absorption spectrum of a PCA crystal has also been observed and an attempt was made to analyze its vibrational structure using populating rates obtained by microwave techniques. Under the condition that spin-lattice relaxation is well suppressed, the spin directions produced by direct optical pumping into the triplet manifold are expected to be conserved during the vibrational relaxation, energy transfer, and phosphorescence decay processes. Therefore, the relative populating rates, if determined when the excitation is made by light of wavelengths corresponding to those of each vibronic band of the $T_1 \leftarrow S_0$ spectrum, are considered to be selective, and therefore, to be useful in the vibrational analysis of the spectrum.

Experimental

p-Chloroaniline, *p*-dichlorobenzene, and *p*-xylene were purchased from Tokyo Kasei Co. The former two materials were zone-refined (about 60 passes) and the purified portions were further sublimed in a vacuum. *p*-Xylene was purified by multiple distillation.

The light sources for the emission measurements were an Ork CH-612 1-kW mercury arc lamp and an Ushio UXL-1000D-O 1-kW DC xenon lamp. The exciting light was passed through a Corning 7-54 glass filter and a saturated $NiSO_4$ aqueous solution filter, and chopped with an Uniblitz L12 type electromagnetic shutter. The exciting light for photo-excitation experiments or the emission light from the sample was isolated by a Spex 1700-III 3/4-m spectrometer. The observing time was controlled by using an Uniblitz 26 type shutter in front of an EMI 6256-SA photomultiplier. The signal was fed into a low-pass filter and measured through a signal averager system (Nomura Electric Co. NP-800 or Ortec Model 4620/4623) or a PAR Model 128 lock-in amplifier. Hewlett-Packard Model 8620A and Weinschel Model 221 sweep oscillators were used as the microwave source with an appropriate microwave filter. The MIDP spectra were measured in a manner similar to that described in detail in a previous paper.[1] The repetition rate for the excitation and observation cycles was controlled to be 0.1—1 Hz by an Ortec 4653/4654 pulse generator system.

The light source for the absorption measurements was an Ushio UXL-500 500 W DC xenon lamp. The light transmitted through a 6 mm thick crystal was observed in the second order diffraction of the 3/4-m spectrometer.

The populating rate ratios for the triplet sublevels for each excitation energy were obtained by the fast passage PMDR method, first used by Winscom and Maki,[2] or a modified MIDP method. In the analysis of the signals, the values of the total decay and the relative radiative decay rate constants obtained by the ordinary MIDP techniques[3,4] were used.

Factor Group States

The crystal structure of PCA has been studied by

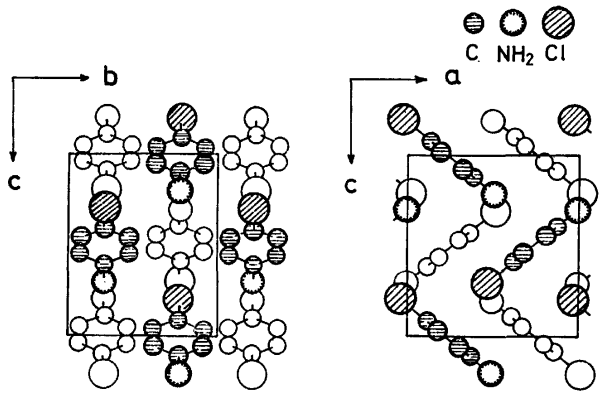

Fig. 1. The crystal structure of *p*-chloroaniline projected along the a and b axes.

Palm and was found to belong to the orthorhombic space group P_{nma} (D_{2h}^{16}),[5] as is shown in Fig. 1. The unit cell contains four PCA molecules. The long molecular axis (z: N–Cl direction) makes a larger projection on the a axis than on the c axis, and the medium in-plane axis (y: perpendicular to the long axis) is exactly parallel to the b axis. The molecular plane makes an angle of 39°40′ with the ab plane and the angle between the planes of two molecules is 79°20′. The coincidence of the molecular y axis with the crystal b axis offers many advantages in studying the optical properties of a PCA crystal.

TABLE 1. THE TOTAL SYMMETRIES OF THE THREE SPIN STATES IN THE FOUR ELECTRONIC FACTOR GROUP STATES

	T_a	T_b	T_c
^3A_g	B_{1g}	B_{2g}	B_{3g}
$^3B_{1u}$	A_u	$B_{3u}(c)$	$B_{2u}(b)$
$^3B_{2g}$	B_{3g}	A_g	B_{1g}
$^3B_{3u}$	$B_{2u}(b)$	$B_{1u}(a)$	A_u

The excited triplet A_1 (π,π^*) state of the free PCA molecule splits into the four factor group states of B_{1u}, B_{3u}, A_g and B_{2g} in the crystal. The three spin substates of the exciton level are designated by T_a, T_b and T_c, and their total symmetries are summarized in Table 1 with the polarization characteristics of the transition between the ground state and each substate. The crystal vectors a, b and c are designated as B_{1u}, B_{2u} and B_{3u}, respectively. Four of the twelve substates in Table 1 have the possibility of carrying dipole activity. If we assume that the one-center spin-orbit interaction between the (π,π^*) and (σ,π^*) states is predominant in acquiring the dipole activity, only two substates remain as strongly active substates: the $T_b(B_{3u})$ substate in the B_{1u} factor group state and the $T_b(B_{1u})$ substate in the B_{3u} factor group state. The transition involving the former state is polarized parallel to the c axis and the one involving the latter parallel to the a axis. By following the theoretical treatment of Hochstrasser and using the crystal geometry, the intensity ratio of the (0,0) transition of $^3B_{1u}\leftarrow{}^1A_g$ to that of $^3B_{3u}\leftarrow{}^1A_g$ is estimated to be about 1.5. In the high-resolution $T_1\leftarrow S_0$ absorption spectrum of a PCA crystal, the (0,0) band is found to split into two lines, the lower-energy component being 3–4 times stronger than the higher-energy one. Although this observed intensity ratio is larger than the ratio calculated on the basis of the crystal structure, we can safely conclude that the lowest dipole-allowed component has the strongest intensity and is assigned to the $^3B_{1u}$ state.

It has been found by Marchetti[6] that the ordering of the crystal zero-field levels of this state is $T_b>T_a>T_c$ and the top sublevel has the strongest dipole activity. This ordering in the crystal system leads to the following ordering of the molecular zero-field levels: $T_y>T_z>T_x$. These facts eliminate the possibility of the $^3B_2(\pi,\pi^*)$ state as the phosphorescent state of the free PCA molecule. The assignments of the $^3A_1(\pi,\pi^*)$ state to T_1 of isolated PCA and the $^3B_{1u}$ state to the lowest exciton state coincide well with the results presented below.

Results and Discussion

Phosphorescence Spectra, Zero-field Splittings and Kinetic Constants. The phosphorescence spectra of PCA were observed in three different systems: (1) in PCA molecules doped in a *p*-xylene crystal in which the PCA molecules are considered to be not too distorted by the host lattice, (2) in a neat PCA crystal the phosphorescence of which arises mainly from a trap 283 cm^{-1} below the $T_1\leftarrow S_0$ absorption origin, and (3) in a PCA crystal which has been doped with a small amount of *p*-dichlorobenzene. The phosphorescence origin of this latter crystal is lower by 67 cm^{-1} than the absorption origin of the crystal. The trap thus induced by *p*-dichlorobenzene is hereafter referred to in this text as an x-trap, because the appearnce of this trap resembles that of the so-called x-trap produced by doping quinoxaline in a naphthalene crystal[7]. The trap of the neat crystal is referred to as an n-trap for convenience. The phosphorescence spectra of these n- and x-traps are similar in shape to the spectrum reported previously for the PCA-doped xylene system[1].

The MIDP signals were observed at 4.559, 2.495 and 2.064 GHz for PCA isolated in *p*-xylene. The first two signals were strong but the latter was very weak. For the other systems, very strong PMDR and MIDP signals were observed. The x-trap phosphorescence produced signals at 4.539, 2.308 and 2.23 GHz and the n-trap at 4.063, 2.533 and 1.53 GHz.

The kinetic constants were obtained from an analysis of the MIDP signals by means of the method described by Schmidt *et al.*[3,4] with some modifications. The total decay rate constants of the sublevel emissions and

TABLE 2. ZERO-FIELD SPLITTINGS AND DECAY RATE CONSTANTS OF *p*-CHLOROANILINE

	PCA in *p*-xylene	n-trap	x-trap
D cm^{-1}	0.1176	0.1099	0.1128
E cm^{-1}	0.0344	0.0255	0.0385
k_y s^{-1}	9.5	42	16
k_z s^{-1}	6.8	20	12
k_x s^{-1}	0.1	1.1	0.5

the zero-field splitting constants in each system are summarized in Table 2. The zero-field microwave transitions were assigned according to the results stated in the previous section and the spin-orbit selection rule.

The D and E values are both positive for every system. Decreases in the D and E values of the n-trap system are noticeable. The latter value is reduced to about 66% of that observed in the x-trap system. While the total decay rate constant k_y for the n-trap is about four times larger than that for PCA in xylene, k_x increases by about 10 times in the n-trap. As will be seen, this increase in k_x for the PCA-crystal systems is attributed to the external heavy-atom effect. On the other hand, the changes in k_y and k_z in the n-trap may be correlated to the decrease in the E value.

Spin-Lattice Relaxation Rates. It has been shown that the spin-lattice relaxation rates in the phosphorescent triplet state in a zero magnetic field can be obtained from steady-state microwave induced phosphorescence experiments, if one knows the three total decay rates obtained in isolation.[8] Following the treatment of Antheunis,[8] one can derive the following equation for the spin-lattice relaxation rates, W_{xy} and W_{xz}* between the T_x and T_y sublevels and the T_x and T_z sublevels, respectively, as:

$$(k_x/k_y+1)W_{xy} + W_{xz} = \left(\frac{h_{x-y}(0;\ \mathrm{ISOL.})}{h_{x-y}(0;\ T;\ \mathrm{y=z})} - 1\right)k_x$$

where h_{x-y} (0;ISOL.) is the height of the microwave induced change in the steady-state phosphorescence intensity on sweeping through the T_x—T_y resonance in isolation and h_{x-y} (0;T; y=z) is the height under continuous microwave contact between T_y and T_z at temperature T. If $k_y \gg k_x'$ the left-hand side of the equation becomes the sum of the spin-lattice relaxation rates, *i.e.*, $W_{xy}+W_{xz}$.

In the n-trap system of the PCA crystal, $k_x/k_y=0.026$ and the approximation of $1+k_x/k_y \cong 1$ can be applied to within the error of the k_x value. The sum of the relaxation rates for the n-trap triplet state is plotted against the temperature in Fig. 2, which indicates that the isolation condition is well fulfilled below 1.8 K.

Vibrational Analysis of the $T_1 \rightarrow S_0$ Spectrum. The phosphorescence spectrum of each system was decomposed into the three sublevel emission spectra using MIDP techniques. The MIDP spectra for the three systems at 1.3 K are shown in Figs. 3–5.

For the PCA-doped xylene system, the vibrational

a) Relative intensity: s > m > w > vw, bend: bending mode, str: stretching mode, o.p.: out-of-plane, i.p.: in-plane.

analysis indicated in Table 3 has been reported previously.[1)] First, the band at 0—323 cm^{-1} was assigned to the out-of-plane b_1 vibration and that at 0—1581 cm^{-1} to the in-plane vibration of b_2 symmetry. Then the other bands were analyzed using the following characteristics of the MIDP spectra of Fig. 3:

1) The bands involving totally symmetric vibrations are active in the emission from the T_y spin state.

2) The bands involving the vibrations of b_1 symmetry are active in the emissions from T_y, T_z and T_x.

3) The bands involving the vibrations of b_2 symmetry are active in the emissions from T_z and T_x.

The mechanisms whereby each sublevel of the isolated PCA molecule acquires its dipole activity are summarized in Table 4 along with the observed intensities of the individual vibronic species in the sublevel spectra.

For the other two systems, the analysis was also performed in a similar manner. For the n-trap, the characteristics of the MIDP spectra are almost identical to those described for isolated PCA with the exception of the fact that the b_1 vibrations are less active than the a_1 vibrations in the T_x spectrum. The same statement holds for the T_x spectrum of the x-trap. However, the T_y and T_z spectra of the x-trap are quite different from those of the n-trap. They are considered to be a mixture of the T_y and T_z spectra of the n-trap. Using these features and the results in Table 3, a vibrational analysis of the phosphorescences of the n- and x-traps was completed as shown in Tables 5 and 6.

Radiative Properties of the Triplet Sublevels. The relative radiative decay rates for the main vibronic bands were examined by the method of Schmidt *et al.*[4)] and the results obtained for the (0,0), (0,0—320 cm^{-1}) and (0,0—1580 cm^{-1}) bands are tabulated in Table 7. Since the height of each vibronic band in the sublevel spectra of Figs. 3—5 is nearly proportional to the radiative decay rate k_u^r for that band (u=x, y and z), the relative values of k_u^r for the other bands may be estimated from Figs. 3—5 and Table 7.

Although the phosphorescence spectra are not shown here, the T_y spectrum of each system is almost identical to the phosphorescence spectrum of the respective system except for the intensity of the (0,0—1580 cm^{-1}) band. The intensity of this band in the phosphorescence spectra of the isolated PCA and of the n-trap results from the T_z emission, as can be seen from Table

Table 4. Main perturbing mechanisms for the $^3A_1 \rightarrow {}^1A_1$ radiative transition for *p*-chloroaniline in *p*-xylene

7 and Figs. 3 and 4. For the x-trap system, on the other hand, the spectra of the T_y and T_z emissions resemble each other as is seen in Fig. 5 and the emissions contribute nearly equally to the phosphorescence, as is shown in Table 7. For the T_x spectra, the non-totally symmetric vibrations appear relatively strongly in the isolated PCA system, while the totally symmetric vibrations are dominant in the n- and x-trap systems.

For the isolated PCA system, the characteristic appearance of the (0,0−323 cm^{-1}) b_1 band in each sublevel spectrum can be understood in terms of the internal heavy-atom effect which enhances the spin-orbit coupling between the $^{3,1}A_1$ (π,π^*) and $^{1,3}B_1$ (σ,π^*) states. The b_2 band at 0−1581 cm^{-1} which has a notable intensity in the T_z spectrum was assigned to the ν_{8b} type C=C stretching vibration. The ν_{8b} vibration was also observed in the phosphorescence spectra of benzene[9)] and toluene[10)]. The notable appearance of this vibration has been discussed in relation to the pseudo-Jahn-Teller interaction between the phosphorescent $^3(\pi,\pi^*)$ state and nearby $^3(\pi,\pi^*)$ state. The fact that this in-plane non-totally symmetric vibration bands has a considerable intensity in the phosphorescence spectrum indicates that the second order spin-orbit vibronic process plays a role comparable to the first order process producing the (0,0) band intensity. However, the oscillator strength of the $^1B_1$ (σ,π^*)←$^1A_1$ transition is considered to be smaller by a factor of 10^{-2}–10^{-4} than that of the $^1B_2$ (π,π^*)←$^1A_1$ transition. It is therefore concluded that a strong vibronic interaction exists between the $^3A_1$ (π,π^*) and $^3B_2$ (π,π^*) states *via* the ν_{8b} type vibration, which leads to the pseudo-Jahn-Teller distortion.

The sublevel spectra for the x-trap have structures quite different from those for isolated PCA. The T_y

The maximum experimental error is estimated to be 25%.

and T_z spectra resemble each other except for the small intensity difference in the individual vibronic bands. These are considered to be a mixture of the T_y and T_z characters of isolated PCA. Each spectrum contains the strong (0,0), (0,0−325 cm^{-1}) and (0,0−1577 cm^{-1}) bands which belong to the a_1, b_1 and b_2 symmetries, respectively. On the other hand, the T_y and T_z spectra of the n-trap system seem to show a feature similar to those of isolated PCA. The (0,0) band in the T_z spectrum is weaker than the (0,0−322 cm^{-1}) band, but the relative intensity of the (0,0−1578 cm^{-1}) band is extremely strong compared with that in the T_y spectrum. This anomalous behavior of the two types of traps in the PCA crystals is considered to originate from a distortion of the electronic structure induced by impurity molecules (*p*-dichlorobenzene for the x-trap) or by defects in the crystal.

The lifetime of the T_x sublevel emission of isolated PCA in *p*-xylene is about 10 s or about 100 times longer than that of the T_y emission. Although the presence of the out-of-plane vibrations is well understood by the mechanisms given in Table 4, the strong appearance of the ν_{8b} type vibration and the (0,0) band in the T_x spectrum cannot be explained by the selection rule for the C_{2v} symmetry, because the spin-orbit coupling between the $^3A_1$ (π,π^*) and $^1B_2$ (π,π^*) states is small. The emission from the weakly radiative T_x sublevel seems to be sensitively affected by the crystal field.

The T_x spectra of the n- and x-traps contain strong (0,0) and (0,0−1577 cm^{-1}) bands and have similar stuctures except for the quasi-continuum background intensity. The intensities of the totally symmetric vibration bands apparently exceed those of the out-of-plane vibronic bands. This phenomenon can be attributed to the external heavy-atom effect due to the chlorine atoms of the nearby PCA molecules.

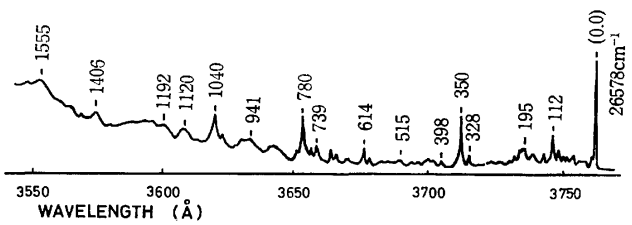

Fig. 6. The $T_1 \leftarrow S_0$ absorption spectrum of the *p*-chloroaniline crystal.

Direct Pumping of Each Triplet Vibronic Level, Energy-Transfer and Nature of the Traps. The $T_1 \leftarrow S_0$ absorption spectrum of a PCA crystal is shown in Fig. 6. The spectrum exhibits a relatively strong (0,0) band at 26578 cm^{-1} and resembles that of a symmetry allowed transition. On the shorter wavelength side of 3650 Å, it becomes much broader. The excitation spectrum was also observed with a high-pressure mercury arc lamp and nearly the same band widths as those in the absorption spectrum were obtained. Under the same conditions as those for the observation of the excitation spectrum, the dependence of the relative populating rates for the three sublevels on the excitation energy was examined by means of the MIDP and fast passage PMDR techniques. Typical fast passage

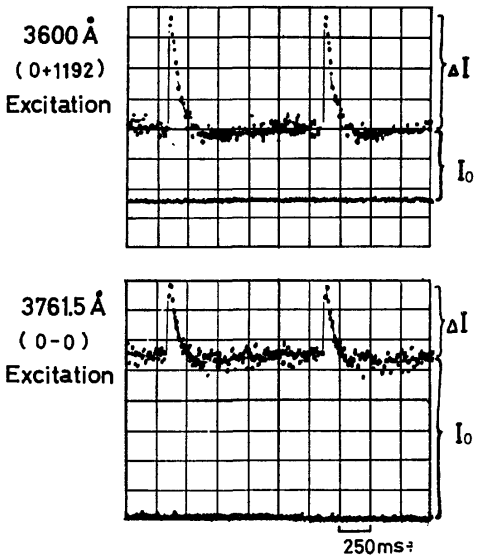

Fig. 7. Typical examples of the fast passage PMDR signals obtained by observing the total phosphorescence of the x-trap when the sample was excited at the (0,0) band (bottom) and at the (0,0+1192 cm^{-1}) band (top) of the $T_1 \leftarrow S_0$ spectrum.

PMDR signals for the two different excitation energies are shown in Fig. 7. The quantity, $\Delta I/I_0$, in Fig. 7 is a measure of the population difference between the sublevels connected by the resonant microwave pulse. After some manipulation, it yields the relative populating rate.

The transition probability for excitation to each sublevel in the triplet manifold is expected to change with the electronic and geometrical stucture of the excited vibronic state. In other words, the populating rate obtained by pumping one of the vibronic levels in the lowest triplet state of the crystal and by monitoring the trap emission is expected to reflect the transition probability for excitation to one of the individual spin states in that vibronic level, if spin alignment is conserved during the processes of vibrational relaxation, energy transfer and phosphorescence decay.

The vibrational relaxation to the lowest exciton level is believed to be fast enough to preserve the selective pumping probabilities. For the triplet-triplet energy transfer process, El-Sayed *et al.* have shown that the spin directions are conserved in the case of the x-trap emission of a naphthalene crystal doped with quinoxaline.[11,12] These authors have concluded that the triplet-triplet energy transfer takes place by the electron exchange mechanism and the probability of transfer between one spin direction in the molecular framework of a donor and the three spin directions in the molecular framework of an acceptor is proportional to the squares of the projection of the spin direction of the donor onto the spin directions of the acceptor.

The dependence of the relative populating rates on the excitation energy for both the n- and x-traps are shown in Fig. 8. As can be seen from the figure, the populating rate ratios change dynamically from one vibronic band to another. Figure 8 shows the following important facts:

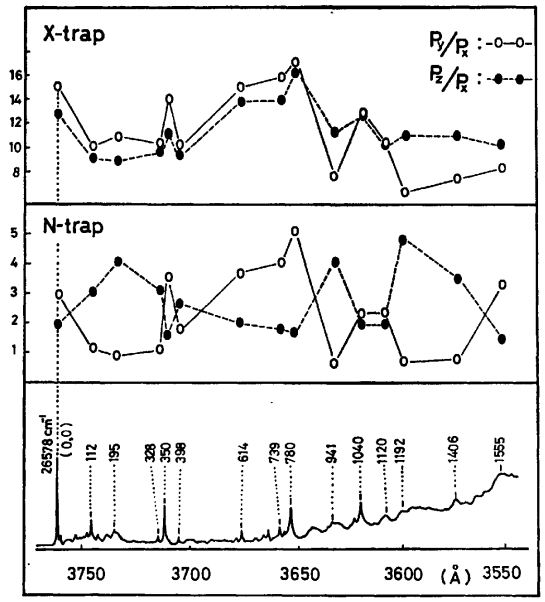

Fig. 8. The populating rate ratios obtained at 1.3 K by pumping each of the vibronic levels in the triplet manifold of the neat crystal (middle) and the *p*-chloroaniline crystal doped with *p*-dichlorobenzene (top) are plotted against the excitation energy. At the bottom, the $T_1 \leftarrow S_0$ absorption spectrum is shown for convenience.

1) The ratios P_u/P_x (u=y and z) change in a similar way with the excitation energy in the x-trap system, while they change in a different manner in the n-trap system.

2) The P_u/P_x ratios for (0,0) band excitation are in good agreement with the (0,0) band k_u^r/k_x^r ratios for the x-trap, while for the n-trap they are much smaller than the k_u^r/k_x^r ratios.

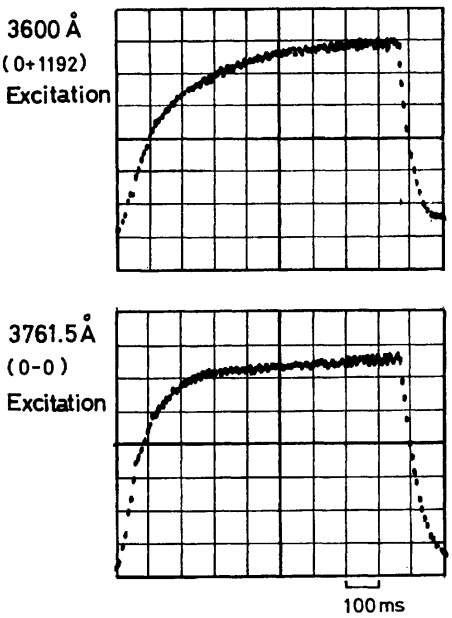

Fig. 9. The phosphorescence rise curves for the x-trap obtained by exciting at the (0,0) band (bottom) and at the (0,0+1192 cm^{-1}) band (top) of the $T_1 \leftarrow S_0$ absorption. After the excitation for about 860 ms, the exciting light was removed to observe the initial part of the decay.

In order to check the growing process of the sublevel population, the phosphorescence rise curves for the respective exciting energies were examined under the same conditions as those for the observation of the excitation spectrum. Typical examples are shown in Fig. 9, where the initial part of the phosphorescence decay is also recorded after the observation of the growth curve for about 860 ms. The two curves in Fig. 9 apparently indicate that the growing rate of the longer lifetime component is considerably faster than the decay rate and that the optical pumping of the crystal spin state from which the relaxation occurs mainly to the T_x sublevel is fairly enhanced on the excitation in the (0,0+1192 cm^{-1}) band compared with that in the (0,0) band.

The marked changes in the rise curves and the populating rates for trap molecule systems suggest that the spin-lattice relaxation in the exciton spin states scarcely affects the deactivation processes to the sublevels of the emitting trap molecules. The fact that the x- and n-traps in the PCA crystals have different populating rate ratios for the same exciting energy is considered to give support to the conclusion obtained by El-Sayed *et al.*[11,12]

In the x-trap system, the characters of the T_y and T_z sublevels are different from those in isolated PCA. The sublevel spectra and the ratios of the radiative decay rates of the x-trap can be explained by the mixing of the T_y and T_z states of isolated PCA. If *p*-dichlorobenzene molecules are substituted into the PCA crystal, one of the two chlorine atoms of the *p*-dichlorobenzene is found at a position otherwise occupied by an amino group, and is expected to interact with the two neighboring chlorine atoms of the nearby PCA molecules, because these three chlorine atoms are located closely together on a plane nearly paralled to the bc plane of the crytal, as is shown in Fig. 10. Therefore, repulsive forces act between the chlorine atoms, and the chlorine

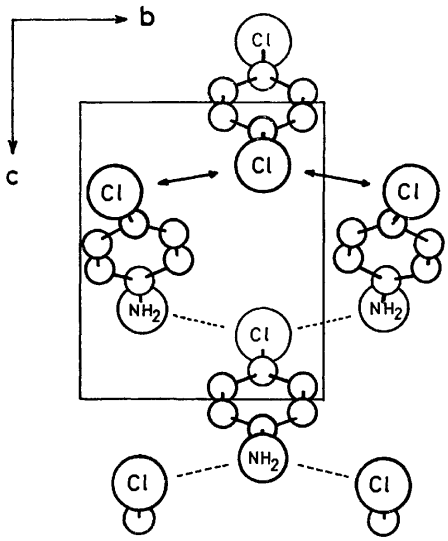

Fig. 10. Illustration of a possible structure of the x-trap induced in the *p*-chloroaniline crystal by doping *p*-dichlorobenzene. The solid arrow indicates the repulsive force and the dotted line shows attractive force.

atoms of these PCA molecules approach the neighboring amino groups. The y axes of the PCA molecules are thus expected to be distorted so as to be bent from the crystal b axis, which otherwise coincides with the y axis. Electronic distortion of these molecules is also expected to occur mainly in the molecular yz plane. This model seems to explain well the observed results for the x-trap system, where the z spin axis is considered to change its direction from the molecular long (N–Cl) axis toward the crystal b axis.

By using the conclusion of El-Sayed *et al.*, the spin directions or, equivalently, the populating rates for the trap sublevels under (0,0) band excitation are explained by the squares of the direction cosines between the crystal spin axes and those in the trap molecules. The (0,0) band pumping is expected to excite the crystal selectively to the T_b spin state, and also to a small extent to the T_a and T_c states by means of the external heavy-atom effect. Spin-orbit coupling which gives the transition intensity for the (0,0) band excitation of the $T_a \leftarrow S_0$ and $T_c \leftarrow S_0$ transitions comes from three-center integrals and is weaker than the external heavy-atom perturbation in the PCA crystal as mentioned above. However, the transition probability to the T_a or T_c spin state is not considered to exceed 10% of that to the T_b state, because the k_y^r/k_x^r values in the n- and x-trap systems are large enough for the (0,0) band emission. Since excitation at the (0,0) origin of the $^3B_{1u}$ or $^3B_{3u}$ factor group state results mostly in the population of the T_b spin state, the observed ratio of $P_y/P_z \cong 1.2$ is then expected to represent the ratio $\cos^2\theta_{by}/\cos^2\theta_{bz}$, where $\cos\theta_{by}$ and $\cos\theta_{bz}$ are the projections of the crystal b axis onto the y- and z-spin axes of the x-trap molecule, respectively. By assuming that the angle between the y- and z-spin axes is 90° and the yz plane includes the b axis, θ_{by} and θ_{bz} are estimated to be about 42° and 48°, respectively. Spin axis rotation of 45° has been recently reported for the case of tetramethylpyrazine in durene.[13]

The populating rate ratios P_u/P_x are small in the n-trap or, equivalently, the populating rate P_x is relatively large. This cannot be explained by the external heavy-atom effect alone, as mentioned previously. The large P_x is considered to be caused by the trapping process from the crystal T_b state to the trap T_x state. Considering the experimental errors in the populating rate ratios obtained, one may roughly estimate the range of the angles of the n-trap molecule to be $35° \lesssim \theta_{by} \lesssim 45°$, $53° \lesssim \theta_{bz} \lesssim 63°$ and $60° \lesssim \theta_{bx} \lesssim 70°$. We already know that the radiative decay rate ratios for the n-trap molecules are not so different from those of the isolated PCA molecules in *p*-xylene. Therefore, we can conclude that the deviation in orientation of the n-trap molecules does not affect its electronic structure as much as in the case of the x-trap, where the intermolecular interaction between the trap PCA and the neighboring *p*-dichlorobenzene is considered to play an important role in determining its electronic structure. Probably, the n-trap is not induced by a chemical impurity, but is produced by a crystal defect characteristic of the PCA crystal, because the n-trap is produced quite generally and no strong emissions from other traps can be found in the same spectral region.

Vibrational Analysis of the $T_1 \leftarrow S_0$ Spectrum. The variations of the P_u/P_x ratios with the excitation energy reflect the characteristics of the vibronic levels in the triplet manifold, and are thus utilized for the vibrational analysis of the $T_1 \leftarrow S_0$ absorption spectrum of the PCA crystal. Although the vibronic selection rule for the $T_1 \leftarrow S_0$ transition of the crystal depends on the representations of the factor group states, it is expected that the selection rule is correlated with the vibronic characteristics of the emission spectrum.

From the feature described for the n-trap system in the section on the vibrational analysis of the phosphorescence spectrum and the results shown in Fig. 8, it can be said that the transitions involving totally symmetric vibrations give a relatively large P_y/P_x ratio and a small P_z/P_x ratio, while the transitions involving the vibrations of b_2 symmetry give a relatively small P_y/P_x ratio and a large P_z/P_x ratio for the populating processes in the n-trap. On the other hand, it seems rather difficult to predict the P_u/P_x ratios for transitions involving the out-of-plane a_2 and b_1 vibrations.

The out-of-plane vibrations are expected to have low frequencies in the T_1 state. The bands at $0+112$, $0+195$, $0+328$ and $0+398\ cm^{-1}$ show small P_y/P_x ratios and large P_z/P_x ratios, and all of these low-frequency vibrations appear to have little possibility of belonging to the b_2 in-plane mode. If we attach considerable importance to the facts that they have relatively large P_u/P_x values and low-vibrational frequencies, these bands could be assigned to transitions to the out-of-plane vibronic levels.

The transitions corresponding to the band at $0+350\ cm^{-1}$ is active in the processes to T_y and T_x and this vibration can possibly be assigned to the a_1 or b_1 vibration in the crystal system. By assuming a mirror-image relation of the spectral features for emission and absorption, this strong band might be assigned to the transition to the b_1 vibrational level. The corresponding emission band appears at $0-323\ cm^{-1}$ in the PCA-doped xylene system. However, it should be noted that this ν_{10} type out-of-plane mode in *p*-dichlorobenzene shows no frequency change in the triplet and ground states and the frequencies of other vibrations also change very little[14]. If the band at $0+350\ cm^{-1}$ is due to the ν_{10} type vibration, which involves an out-of-plane C–Cl bending, the increment in frequency becomes about 8% upon transfer to the excited state. This seems to be too large. The line at $0+350\ cm^{-1}$ is more reasonably assigned as being due to a totally symmetric C–Cl bending vibration that is at $379\ cm^{-1}$ in the ground state in the *p*-xylene solution, since the populating rate ratios for excitation to this level are close to those obtained for the (0,0) band excitation, and the strong totally symmetric vibration band has been observed at $0+356\ cm^{-1}$ in the $^1B_2\ (\pi,\pi^*) \leftarrow {}^1A_1$ spectrum by Marchetti.[15]

In the wavelength region shorter than 3650 Å, the spectrum becomes broader and the bands, which can be assigned to b_2 vibrations, appear. The intensities of these b_2 bands, however, are not too strong. Burland, Castro and Robinson have studied the $^3B_{1u} \leftarrow {}^1A_{1g}$ absorption spectrum of benzene using the phosphores-

cence photo-excitation method.[16] They concluded that the ν_8 type vibration, the direction of which is related to the direction of the molecular distortion, is shifted by the pseudo-Jahn-Teller interaction from 1600 cm^{-1} in the ground state to 250 cm^{-1} in the excited triplet state.[16] In PCA, this normal mode splits into the ν_{8a} (a_1) and ν_{8b} (b_2) vibrations. The frequencies of these normal modes in the ground state are 1600 and 1581 cm^{-1}, respectively, in the *p*-xylene solution.[1] The absorption band at $0+1555$ cm^{-1} is reasonably assigned as being due to the a_1 fundamental corresponding to the ν_{8a} type vibration. The frequency change is about -3%, but larger than those found in *p*-dichloro- and *p*-dibromo-benzenes, where the frequency changes are $+0.3$ and $+0.2\%$, respectively.[14]

This ν_{8a} assignment leads to the conclusion that the force constants for the C=C stretching vibration in the excited state is much the same as in the ground state and does not produce such a low frequency for the antisymmetric ν_{8b} type vibration as in the case of benzene. The geometrical change caused by the pseudo-Jahn-Teller interaction is not expected to be large. This conclusion seems to be consistent with the fact that the (0,0) band in the T_z sublevel spectrum of PCA in *p*-xylene is extremely weak. The most probable band due to the ν_{8b} type mode is the one at $0+1406$ cm^{-1}.

The final results of the analysis of the main bands observed in the absorption spectrum of the PCA crystal are summarized in Table 8, where the frequencies of each state are compared. The frequency changes in the observed normal modes in the ground state, in the first excited singlet and triplet states are relatively small and the structural difference of the molecule between the first excited singlet and triplet states is also regarded as being very small.

Degradation Spectra and the *G*-values for Ionization and Excitation of the Mixtures of Noble Gases

Kiyoshi OKAZAKI, Eizo OKU, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 31, 1975)

Degradation spectra of electrons and the *W*-values in the mixtures of He–Ne, He–Ar, Ne–Ar, and Ne–Kr irradiated by 100 keV electrons have been calculated by using the binary-encounter theory and the theory of the degradation spectrum. On the basis of these calculations, the Jesse effect, the negative Jesse effect, and the non-metastable Penning effect have been reconsidered. It was shown that at least a part of the negative Jesse effect and the non-metastable Penning effect are explicable as due to the degradation spectra of electrons.

The yield of electrons in a binary mixture of noble gases irradiated by charged particles has been measured by several investigators. In some cases, a drastic change in the yield with the change of mixing ratio has been found. In 1952 Jesse and Sadauskis found that the yield of electrons, G_e, in helium is increased remarkably by the addition of a very small amount (~0.01%) of argon (the Jesse effect).[1] They attributed this increase to the well-known metastable Penning ionization. Hurst and his co-workers also found that the yield of electrons in argon is increased after the addition of foreign gases.[2] In order to explain this increase, they considered not only the metastable Penning ionization but also the resonance state Penning ionization which occurs through photon imprisonment. Kubota measured the yield of electrons in a helium–neon mixture, in which the metastable Penning ionization cannot energetically occur; however, he obtained a positive deviation as if the Penning ionization were occurring.[3] He attributed this deviation to the non-metastable Penning ionization. Klots observed an extraordinary behavior of the yield of electrons in the mixtures of Ne–Ar, Ne–Kr, and He–CH_4.[4] For example, when krypton is added to neon, the yield of electrons rapidly increases to a high value symptomatic of the Jesse effect, but then plummets to a minimum before finally climbing up again to the value characteristic of pure krypton (the negative Jesse effect). He interpreted this phenomenon in terms of the Hornbeck-Molnar process and some process competing with it. In this manner, the variation of the yield of electrons with the change of components in binary mixtures has been interpreted in terms of the metastable, resonance state, and non-metastable Penning ionizations and also of the Hornbeck-Molnar process. There is definite evidence for the metastable Penning ionization,[5,6] but no explicit evidence exists for the non-metastable Penning ionization and for the quenching of the Hornbeck-Molnar process.

Previously, we estimated the *G*-values for ionizations and excitations of pure noble gases irradiated by 100 keV electrons by a combination of the binary encounter collision theory and the theory of degradation spectrum.[7–11] The calculated *G*-values of electrons in pure noble gases are in fair accordance with the experimental values obtained by considering the double collision and the inner shell excitation. In that paper, we predicted that the yields for ionizations and excitations in the mixture greatly depend on the components, because the degradation spectra of electrons are quite dependent upon the type of noble gas.

In this paper, we apply the calculating method to estimate the *G*-values for ionizations in the mixtures of noble gases irradiated by 100 keV electrons and investigate the effect of the degradation spectra on the change of the yields of ionizations and excitations. We choose the mixtures of He–Ne, He–Ar, Ne–Ar, and Ne–Kr, because in these mixtures drastic changes of the *G*-values of electrons have been reported.

Method of Calculation

We consider a mixture of A and B gases. The basic procedure for the calculation on the mixture is analogous to that of a pure gas. The equations of the differential cross section, $\sigma_E(T)$, and of the cross section for ionization and excitation, $Q_s(T)$, are the same as those shown in the previous papers.[7,8] The cross sections for the double collisions and the inner shell excitations are also the same as those shown previously.[8]

Stopping Power. First we calculate the stopping power of the pure A gas, $S_A(T)$, and that of the pure B gas, $S_B(T)$, by use of the equation described previously.[7] Then, the stopping power of A–B mixture, $S_m(T)$, may be described as the combination of $S_A(T)$ and $S_B(T)$:

$$S_m(T) = \frac{p_A}{p_A+p_B}S_A(T) + \frac{p_B}{p_A+p_B}S_B(T) \qquad \text{(I)}$$

for $T \geq E_{t,A}$. Here, $E_{t,A}$ is the energy of the lowest excited triplet state of the A gas and $E_{t,A} > E_{t,B}$ is assumed. $E_{t,B}$ is the energy of the lowest excited triplet state of the B gas. p_A and p_B are the partial pressures of each component. Equation (I) holds only in the energy range where both A- and B-components can contribute to the energy loss of the incident electron.

When the energy of the incident electrons is lower than $E_{t,A}$, the A-component cannot contribute to the energy loss and only the B-component participates in the energy loss of the electrons. That is, when $E_{t,B} \leq T < E_{t,A}$, the first term of the right-hand side of Eq. (I) disappears; when $T < E_{t,B}$, both terms disappear.

Degradation Spectrum. On the assumption of a continuous slowing down, the degradation spectrum of the incident electron in the mixture may be expressed in a manner similar to that described previously:[7]

$$y_1(T) = 1/S_m(T) \qquad \text{(II)}$$

The degradation spectrum of the secondary electrons

consists of two terms, which correspond respectively to the ionizations of the A- and B-components.

$$y_2(T) = \frac{p_A}{p_A+p_B}\frac{N}{S_m(T)}\sum_i n_{i,A}\int_T^{(T_0-I_{i,A})/2}\int_{2T_2+I_{i,A}}^{T_0} \times y_1(T_1)\sigma_A(T_1, T_2)\mathrm{d}T_1\mathrm{d}T_2 + \frac{p_B}{p_A+p_B}\frac{N}{S_m(T)}\sum_i n_{i,B}\int_T^{(T_0-I_{i,B})/2}\int_{2T_2+I_{i,B}}^{T_0} \times y_1(T_1)\sigma_B(T_1, T_2)\mathrm{d}T_1\mathrm{d}T_2 \quad \text{(III)}$$

Here, N is the number of atoms in a unit volume, n_i is the number of electrons in the i-th shell, T_0 is the energy of the incident electrons, I_i is the binding energy of the electron in the i-th shell, and $\sigma(T_1, T_2)$ is the differential cross section for the production of a secondary electron with the energy of T_2 in a collision between the atomic electron in the i-th shell and the incident electron with the energy of T_1. The suffixes A and B correspond to A- and B-components. Similar equations may be constructed for the electrons ejected in the later steps.

The total degradation spectrum, $y(T)$, is the sum of the above spectra:

$$y(T) = \sum_k y_k(T) \quad \text{(IV)}$$

The $y(T)$ thus obtained contains the electrons produced in the ionization of the B-component in the collision with the electrons ejected from the A-component and *vice versa*.

Once $y(T)$ is obtained, the yields of ionizations and excitations can be calculated by using the following equation:

$$N_s = \int_{T_s}^{T_0} Ty(T)Q_s(T)\mathrm{d}\ln T \quad \text{(V)}$$

$$G_s = 100N_s/T_0 \quad \text{(VI)}$$

Here, N_s is the number of species produced in the s-process, T_s is the threshold energy for the s-process and G_s is the G-value of s-process.

The constants used for the calculation are the same as those reported in the previous paper.[7,8]

Results

He–Ne Mixture. Figure 1 shows the component dependence of $y(T)$ in the helium–neon mixture under a constant total pressure (1 atm). The $y(T)$ in pure helium is completely separated from those calculated for the mixtures in the whole energy range.

In order to investigate the effect of the change of $y(T)$ on the yield of ionization, the $Ty(T)\,Q_s(T)$'s for the ionization of helium and for that of neon are plotted as a function of ln T in Figs. 2A and 2B, respectively. The $Ty(T)\,Q_s(T)$ for helium in the 1:1 mixture is about 0.13 times that in pure helium, while that for neon is about 0.91 times that in pure neon; *i.e.*, the changes in the ionization yield do not compensate with each other.

Figures 3A and 3B show the G-values for the ionizations and excitations of helium and neon as a function of the parameter Z. This parameter was used by Kubota and equals the ratio of $p_{Ne}/(p_{Ne}+0.316\,p_{He})$.[3] p_{Ne} and p_{He} are the partial pressures of neon and helium, and 0.316 is the ratio of the stopping powers of the two gases. As Fig. 3A shows, the decreasing curve of the G-value for the ionization of helium is concave, while the increasing curve for neon is convex, and the total G-values of ionization do not lie on a straight line. In this figure, the energy exchange between Ne and He is not taken into account.

a, $p_{Ne}/(p_{He}+p_{Ne})=0$; b, 0.038; c, 0.096; d, 0.162; e, 0.473; f, 1.0.

He–Ar Mixture. Figure 4 shows $y(T)$'s for the helium–argon mixtures. The curves are similar to those for the helium–neon mixtures shown in Fig. 1. Figures 5A and 5B show the component dependence of the $Ty(T)\,Q_s(T)$'s for the ionization of helium and for that of argon from the 3p shell. The $Ty(T)\,Q_s(T)$ for helium decreases smoothly with a decrease in the partial pressure of helium, while the $Ty(T)\,Q_s(T)$ for argon behaves strangely in the electron energy range below

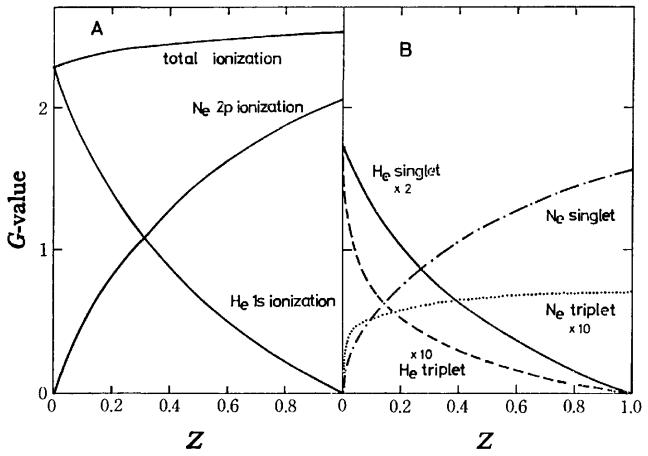

Fig. 3. The G-values for the ionizations and excitations of He and Ne in the He–Ne mixture as a function of Z.
A, Ionization; B, excitation.

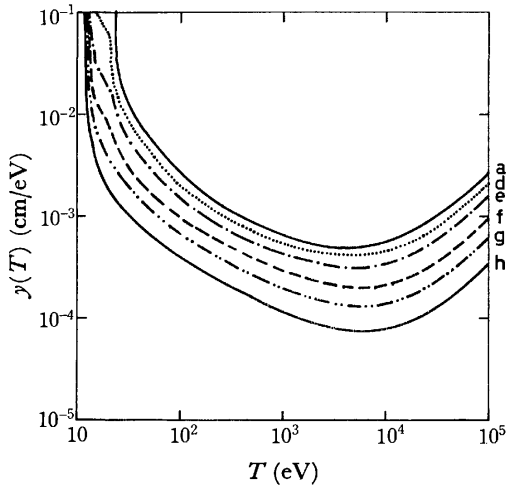

Fig. 4. The component dependence of $y(T)$ in the He–Ar mixture as a function of ln T.
a, $p_{Ar}/(p_{He}+p_{Ar})=0$; d, 0.040; e, 0.112; f, 0.274; g, 0.5; h, 1.0.

20 eV. This part of $T\,y(T)\,Q_s(T)$ does not decrease with a decrease in the partial pressure of argon. The reason is obviously that, since the lowest triplet state of helium is 19.8 eV, the electrons whose kinetic energies are lower than 19.8 eV cannot lose their energies in the collision with helium, but lose their energies only in the collision with argon.

Figures 6A and 6B show the G-values for ionizations and excitations of each component as a function of the parameter Z. This parameter equals $2.79\,p_{Ar}/(2.79\,p_{Ar}+p_{He})$. Here, 2.79 is the ratio of the stopping powers of two gases in the treatment of Klots.[4] It is characteristic in Fig. 6B that the G-value for the triplet excitation of Ar in the mixture with helium is larger than that in pure argon. In this mixture, we must also consider the Penning ionization, which will be discussed later.

Ne–Ar Mixture. Figure 7 shows the component dependence of $y(T)$ in the neon–argon mixture. It is noticeable that the curves for $y(T)$ intersect at two points, where the energies of electrons are 56 and 10^4 eV.

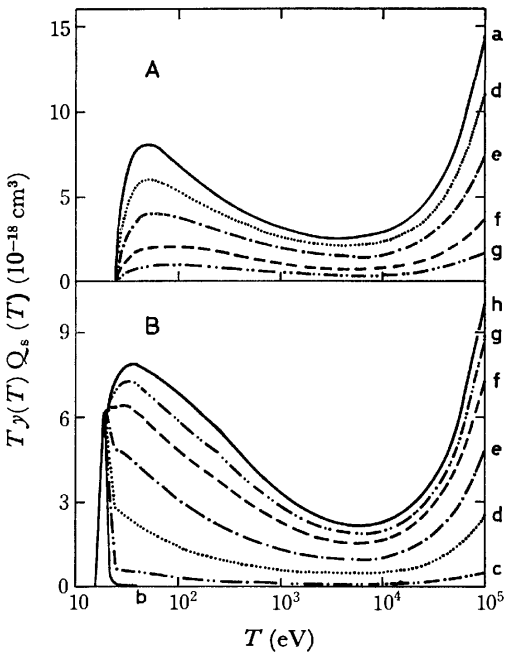

Fig. 5. The component dependence of $T\,y(T)\,Q_s(T)$ in the He–Ar mixture as a function of ln T.
A, Ionization of He; B, ionization of Ar from the 3p shell.
a, $p_{Ar}/(p_{He}+p_{Ar})=0$; b, 0.001; c, 0.007; d, 0.040; e, 0.112; f, 0.274; g, 0.5; h, 1.0.

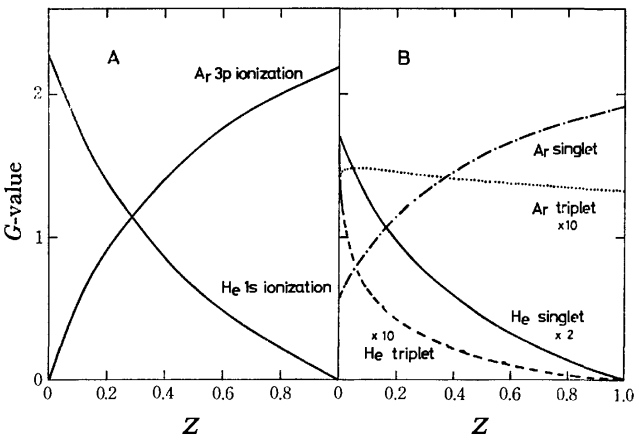

Fig. 6. The G-values for the ionizations and excitations of He and Ar in the He–Ar mixture as a function of Z.
A, Ionization; B, excitation.

Such crossings were not obtained in the mixtures of helium–neon and helium–argon.

Figure 8 shows the component dependence of the $T\,y(T)\,Q_s(T)$ for the ionization of argon from the 3p shell. There is a non-decreasing part at about 20 eV with the decrease in the partial pressure of argon. This is similar to the $T\,y(T)\,Q_s(T)$ for the ionization of argon in the He–Ar mixture.

Figures 9A and 9B show the G-values for the ionizations and excitations of each component. Here the parameter $Z=p_{Ar}/(p_{Ar}+0.75\,p_{Ne})$ is used as the abscissa, according to the treatment of Klots.[4] It is noticeable in Fig. 9A that the tendency of the change of the G-values for the ionizations in the Ne–Ar mixture is oppo-

site to that in the He–Ar mixture: *i.e.*, the curve of the G-value for the ionization of neon, whose ionization potential is higher than that of argon, is convex, while the curve for the ionization of argon is concave. The situation of the excitations in the Ne–Ar mixture is also quite different from that in the He–Ne and He–Ar mix-

tures. For example, the change of the G-values for singlet excitation of neon shows an S-shaped curve.

Ne–Kr Mixture. The $y(T)$'s and $Ty(T)\ Q_s(T)$'s for the Ne–Kr mixture are similar to those for the Ne–Ar mixture. These are shown in Figs. 10 and 11. Figures 12A and 12B show the G-values for the ionizations and excitations of each component. The abscissa is the parameter Z, which is equal to $p_{Kr}/(p_{Kr}+0.465\ p_{Ne})$ according to the treatment of Klots.[4] The general tendency of each curve is similar to that for the Ne–Ar mixture.

Discussion

He–Ne Mixture. Since the lowest excited states of helium are located at 19.8 (^{3}S) and 21.2 eV (^{1}P) and the ionization potential of neon is known to be 21.56 eV, the so-called Penning ionization cannot energetically occur in this mixture. Consequently, Haeberli *et al.* expected that the W-values in this mixture should satisfy this equation:[12]

$$1/W_m = (1/W_A - 1/W_B)Z + 1/W_B \qquad (1)$$

Here, $Z=[p_A+(S_B/S_A)\ p_B]^{-1}\ p_A$. A and B stand for He and Ne in the present case, and S_A and S_B for the stopping powers of the two gases. However, Kubota observed that the experimental results do not satisfy Eq. 1: *i.e.*, the total G-value of ionization deviates positively from the straight line expected from Eq. 1.[3] He explained this positive deviation as due to the non-metastable Penning ionization. According to the present calculation, however, a similar positive deviation can be obtained as the result of the change of $y(T)$. This is shown in Fig. 3.

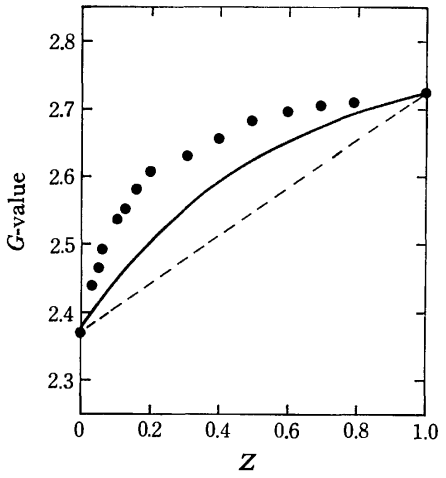

Fig. 13. The total G-value of electrons in the He–Ne mixture as a function of Z.
—, Calculated; ●, Kubota's experimental.

In order to check the deviation quantitatively, Kubota's experimental results are reproduced in Fig. 13 together with the calculated curve. The absolute G-values for ionizations in pure states calculated and experimentally obtained do not coincide with each other. Therefore, the following correction has been made for the calculated G-values:

$$G_{ion}' = G(A^+)f_A + G(B^+)f_B \qquad (2)$$

Here, $G(A^+)$ and $G(B^+)$ are the calculated G-values of A^+ ion and B^+ ion in a mixture and f_A and f_B are the ratios of the experimentally obtained G-values to the calculated G-values in the pure states of A and B.

As Fig. 13 shows, about a half of positive deviation can be explained as the result of the change of $y(T)$. It may be obvious from this figure that the non-metastable Penning ionization is not a unique explanation for the deviation from the straight line expected from Eq. 1.

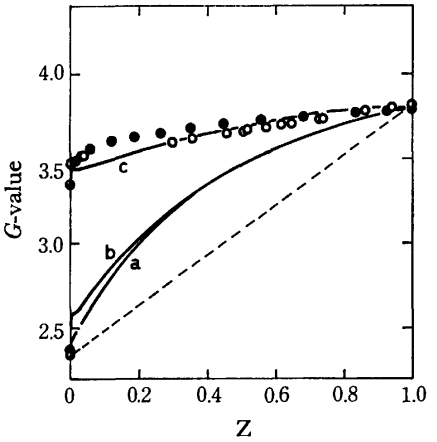

Fig. 14. The total G-value of electrons in the He–Ar mixture as a function of Z.
—, Calculated; ●, Kubota's experimental; ○, Klots' experimental.

He–Ar Mixture. There are two sets of experimental data for this mixture: one is that of Klots,[4] the other of Kubota.[3] They are reproduced in Fig. 14, together with the calculated curve. The curve a was obtained in a manner similar to that used in the case of the He–Ne mixture. In this mixture, we have to consider the Penning ionization, because the ionization potential of argon (15.7 eV) is much lower than the energy of the lowest triplet state of helium (19.8 eV).

If the metastable Penning ionization is taken into account:

$$He(^3S)^* + Ar \longrightarrow He + Ar^+ + e^- \qquad (3)$$

the calculated G-values increase to the curve b. The curve c was drawn by taking into account the so-called resonance state-Penning ionization.

$$He(^1P)^{**} + Ar \longrightarrow He + Ar^+ + e^- \qquad (4)$$

The radiative lifetime of the $He(^1P)^{**}$ is very short; however, the photon imprisonment will prolong its apparent lifetime.[13] The agreement between experimental plots and the calculated curve is very good.

Ne–Ar Mixture. In the case of this mixture, Klots did not show the experimental data in his paper, but did report the parameters obtained by his interpretation.[4] Using his parameters, the curve for the ionization has been reproduced in Fig. 15. The curves a,b, and c have been drawn by using the calculated values in a manner similar to that in curves a,b, and c in Fig. 14. The calculated curve does not agree at all with the curve obtained experimentally. However, there is another

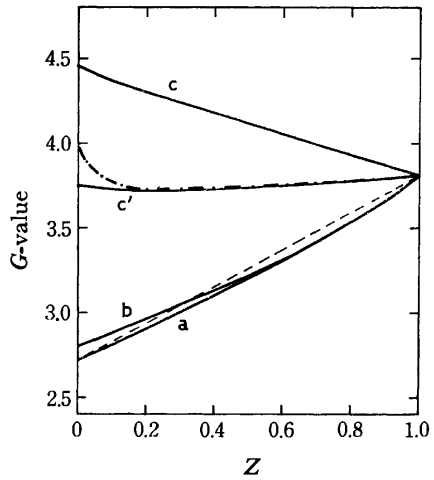

Fig. 15. The total G-value of electrons in the Ne–Ar mixture as a function of Z.
—, Calculated; —·—, Klots' experimental.

problem we have to consider here: *i.e.*, the ratio between the calculated G-value and the experimentally obtained G-value for the excitation is not necessarily equal to the ratio for the ionization, f_A or f_B. If the ratio between the calculated G-value and the experimental one for the singlet excitation of the A gas, Ne in the present case, is assumed to be 0.58, then the curve c′ in Fig. 15 can be obtained. In spite of this modification, the agreement between experiment and calculation could not be attained, especially in the range of small partial pressure of Ne. This disagreement might reflect some invalidity in the present explanation; however, a detailed inspection of the following mixture suggests that our explanation is one of the possibilities.

Ne–Kr Mixture. Klots' experimental data is reproduced in Fig. 16. The curves a, b, and c were drawn in a manner similar to that used in the case of the Ne–Ar mixture. Although the curve c does not agree at all with the experimental data, a small bump observed at a very small concentration of Kr is reproduced in the curve c. In the interpretation by Klots, this bump comes from the incomplete quenching of the excited state of Ne by Kr atoms. However, the small bump in the curve c is the result of a calculation in which the incomplete quenching was not taken into account.

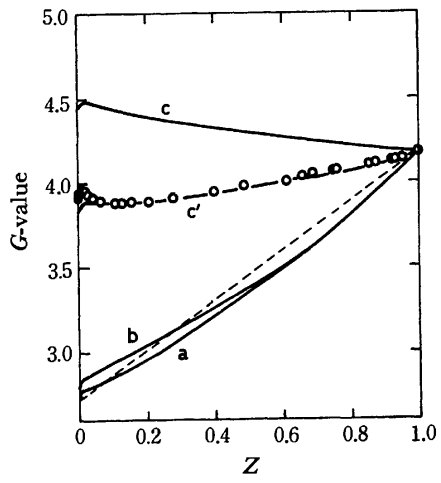

Fig. 16. The total G-value of electrons in the Ne–Kr mixture as a function of Z.
—, Calculated; ○, Klots' experimental.

As was done in the case of the Ne–Ar mixture, if the ratio between the experimentally obtained G-value and the calculated one for the singlet excitation of Ne is assumed to be 0.63, the curve c′ can be obtained. The experimental plots lie close to the curve c′.

Conclusion

In order to explain the change of the W-values in binary rare gas mixtures with the change of the mixing ratio, unestablished processes such as the non-metastable Penning ionization and the quenching of the Hornbeck-Molnar process have so far been proposed. As has been shown above, we can explain some of the change of the W-values which accompanies the change of the mixing ratio in terms of the change of the degradation spectra. Consequently, it may be conclude that, when we discuss the W-value of a binary mixture, we have to consider the degradation spectrum in detail.

An Analytical Study of pre-Inca Pigments, Dyes, and Fibers

K. Maresuke KASHIWAGI

Department of Textiles and Clothing, Kyoritsu Women's University, Hitotsubashi, Chiyoda-ku, Tokyo 101

(Received November 12, 1975)

The total analysis of 800-year-old Peruvian pigments with regard to the inorganic elements was carried out; some typical pigments, like mercury sulfide and iron oxide, are shown. Some characteristic pre-Inca (6—7 th century Tiahaunaco and 13—14 th century Chancay) dyes including cochineal, indigo, and probably logwood were identified from old fabrics by means of absorption spectroscopy and also chromatographic analysis. Two kinds of fiber constituting those fabrics were also investigated, and a few chemical analyses, including that of the amino-acid composition of protein fiber and that of the extent of the degradation of old cellulose fiber, were made.

Aside from the marvellous weaving technology of the pre-Inca period, which was developed at a very early date (2000 B.C.) and which remains in use today, the colors developed by those people present very interesting scientific problems today. Our present knowledge of those ancient dyestuffs is limited because the Incas did not leave any written documents and because those Indios who are their descendants have not yet been completely assimulated into Western culture.

Two kinds of dyed fabrics and five kinds of pigments were obtained by the courtesy of Mr. Yoshitaro Amano of the Museo Amano, Lima, Peru. One kind of fabrics was identified at the museum as from Chancay in the 13—14 th century, and the other, as from Tiahaunaco in the 6—7 th century. The pigments, all in powdered state, were found at Lauri, 87 km north of Lima, some time ago and were identified as of pre-Inca times (about 800 years ago).

Experimental

In addition to our previous methods–namely, paper chromatography[1,2] and the modern knowledge of organic chemistry,[3,4] all of which were successfully applied to the identification of certain dyestuffs in the old textiles, the present author adopted mass spectroscopy and high-frequency plasma spectroscopy of old inorganic pigments and absorption spectroscopy with regard to the extracted dyes.

Analysis of Pigments. About 10^{-2} g of each substance was dissolved by heating in a mixture of 0.5 ml of sulfuric acid and 2 ml of nitric acid, the mixture was then diluted to make a 20 ml solution. A Hitachi high-frequency plasma torch instrument, Model 300, was used to measure the characteristic spectra of each element at temperatures higher than 6000 °C. The mass spectroscopic measurements were carried out by the use of a Hitachi Mass Spectrometer, RNU6MG.

Analysis of Dyes. Dye extraction from the fabrics was made mostly according to Saltzman's method[5] using sulfuric acid, which destroyed the substrate fiber. However, we sometimes used our previous method for extraction employing ethanol and a small amount of hydrochloric acid.[2] Paper chromatography experiments were carried out at 30 °C with a developing solvent composed of butanol–acetic acid–water (4–1–1 by volume) except for the blue dyes of the indigo type. The developing solvent for the blue dye was composed of the supernatant solution from a mixture methyl acetate–2-propanol–25% aq. NaOH (45–35–20). The absorption spectra of those extracted dyes were measured by means of a Shimadzu Spectrophotometer, MPS-50L.

Analysis of Fibers. The fabrics were composed of Peruvian cotton and animal fiber of a Llama or Alpaca type, both of which could easily be recognized under a microscope.[6] The two kinds of fiber were further examined under a scanning electron microscope, Shimadzu EMX-SM. To estimate the extent of deterioration of the cellulose fiber, a small amount of white cellulose was removed from one of the Chancay fabrics and nitrated to measure the degree of polymerization by way of viscometry.[7] The amino acid composition of the protein fiber was determined by the use of the JLC-5AH analyzer at the Kanagawa Industrial Research Institute.

Results and Discussion

The analytical results for those pigments are shown in Table 1, together with some additional data from mass-spectroscopic measurements. According to Table 1, showing information which is here disclosed for the first time, we may suppose that the pre-Inca people did have a good knowledge of iron, contrary to a common belief that they did not know how to use iron.

Among the possible red dyes used in those days, cochineal was very widely known in this area.[8,9] Other possible dyes were kermes, lac-dye, and a mixture of those with cochineal.[9] Those dyes are known to contain compounds structurally related to one another, all being derivatives of anthraquinone, as is shown in Fig. 1.[10,11] Beside those, a shell fish dye called purpula could supply red color depending on the kind of mordant used.[9]

The dyes extracted from the red parts of the Chancay and Tiahaunaco fabrics gave a single red spot at values between 0.51 and 0.54 of R_f on a paper chromatogram, while cochineal itself showed a single red spot at 0.54. The absorption spectra of those red dyes in dilute sul-

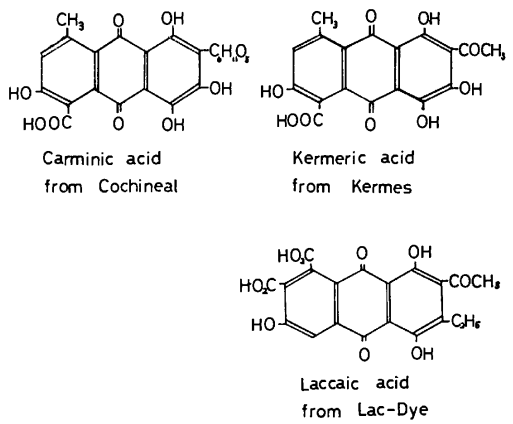

Fig. 1. Some anthraquinone dyes.

TABLE 1. ANALYSIS OF PIGMENTS USED 800 YEARS AGO IN CHANCAY AREA

Specimen	Color	Elements found (principal constituent and other minor ingradients)	Main constituent
1	red	Hg≫Sr, Na, Zn, Fe, Mg, Cu, Ni, Cr, Ca, Al, K	HgS
2	brown red	Fe≫Na, Zn, Mn, Mg, Cu, Ca, Al, K, Sr, Pb	Fe_2O_3
3	green	Cu≫P, Zn, Fe, B, Si, Mn, Mg, Ni, Cr, Ti, Mo, Ca, Al, K, Sr, Na	$CuCO_3Cu(OH)_2$ Marachite
4	dark yellow	mainly organic, metals found are Cu, Zn, Fe, Mg, Ca, Al, K, Na	lake with absorp. max. at 230 and 270 nm in acidic media
5	yellow	Fe≫Zn, Mg, Cu, Ca, Al, K, Sr, Na	$Fe_2O_3 \cdot H_2O$ or FeOOH

Other evidences found by Mass Spectra are:

1. Isotope conposition of Hg are the following.

Atomic wt.	Ratio%
198	10
199	16
200	23
201	13
202	30
203	0
204	7

4. Important constituent is organic.

furic acid were quite similar to that of cochineal, as is shown in Fig. 2. Moreover, the pH shifts of the absorption maxima of the dyes were quite identical to that of conhineal; they all exhibited maxima at 490 nm in acidic, 520—530 nm in neutral, and 550—560 nm in alkaline media.

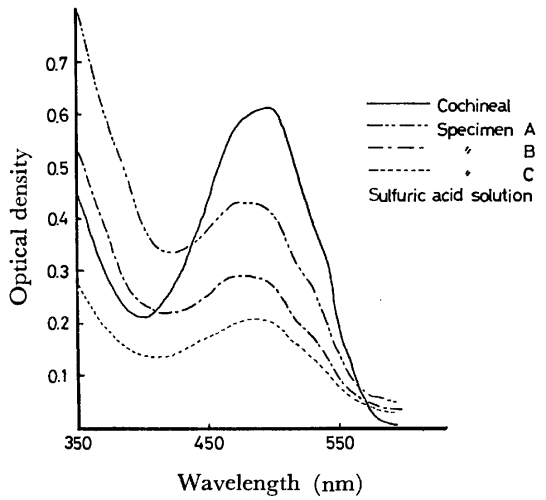

Fig. 2. Absorption spectra of the pre-Inca dyes and cochineal.

The blue dyes were extracted from the blue part of the old fabrics with sulfuric acid and chloroform. The extracts showed one blue spot at values from 0.68 to 0.72 of R_f in a paper chromatograph, while synthetic indigo showed one at 0.69.

The absorption spectra of those solution containing the blue dye extracted from fabrics and that of synthetic indigo are compared in Fig. 3. There seems to be little doubt that the blue dyes from the old fabrics were indigo; therefore, we can conclude that those blue colors must have been from a certain indigo-producing plant.

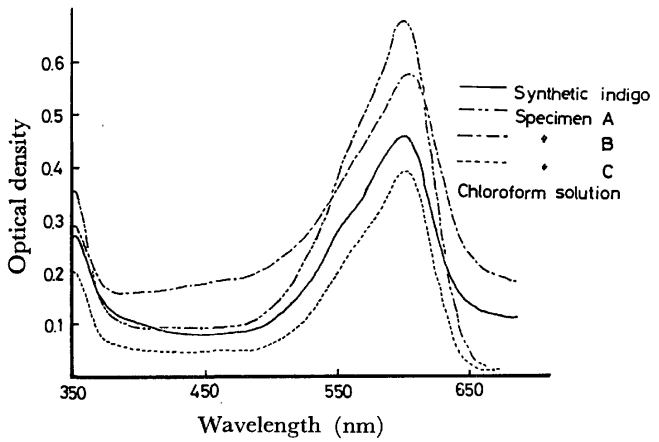

Fig. 3. Absorption spectra of the pre-Inca blue dyes and synthetic indigo.

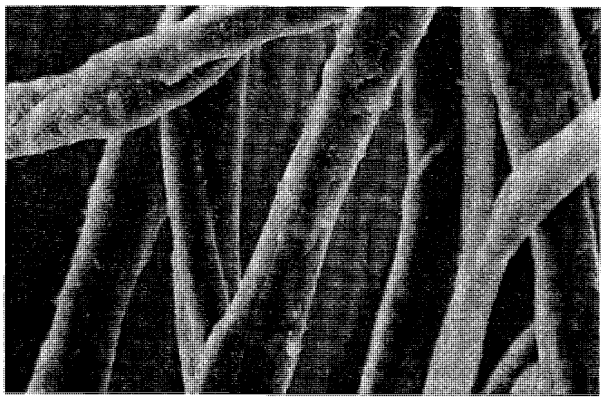
Beside this indigo spot, another red spot with an R_f value of 0.84 appeared on the paper chromatogram. We tried to assign this red dye to some flavonoid compound by means of absorption spectra[12] and also by a few spot tests,[13] but we have not succeeded thus for. The pre-Inca people might, as in some other parts of the world, have attempted to produce a purple color from red and blue (mostly indigo),[9,14] as well as the famous purpula.

Black and golden yellow colors were often found in those fabrics. The dye extracted from the black parts of the fabrics exhibited two spots paper-chromatographically, one at 0.54 and the other at 0.34 of R_f, both of a dark yellow color. Moreover, the extracted golden yellow dye showed exactly the same spots as the black. This is taken to show that both colors originate from the same material, probably only the difference being the kind of mordant used. We further found that those two spots agreed with those from logwood extracts (R_f: 0.35 and 0.53). Logwood is well known to contain haematoxylin, which, on exposure to air, becomes

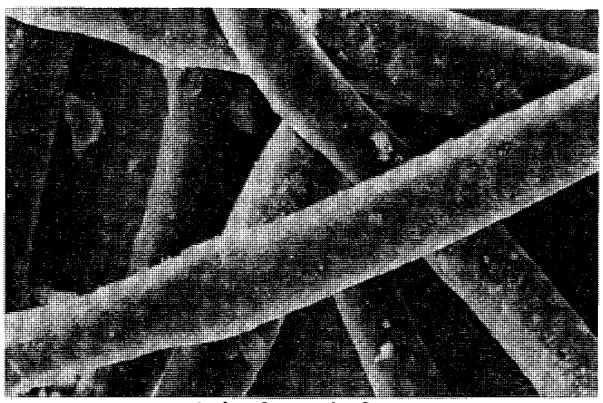
oxidized to haematein.

In addition, a series of dyeing experiments were undertaken, in them, among other items of interest, only logwood (Haematoxylon capechianum L.) exhibited both black as a result of the mordanting of $CuSO_4$ with a small amount of Fe and golden yellow color as a result of the use of acetic acid on silk cloth. We have not yet been successful in obtaining dependable absorption spectra and there is even a possibility that this dye polymerizes,[15] but it appears that both the black and golden yellow colors in those fabrics are probably from logwood.

Many pre-Inca fabrics were composed of cotton and animal protein fiber, one as warp and the other as weft, but sometimes the fabrics were interwoven in a more complicated manner. Those two kinds of fibers from one of the Chancay fabrics are shown in Fig. 4.



Cotten fiber.



Animal protein fiber.

Fig. 4. Two kinds of old Peruvian textile fibers.

Many soil particles were often found everywhere along the fiber surfaces, and surface scratches were found under close examination. This evidence probably indicates that the fabrics had deteriorated over the long period of aging. To investigate the deterioration more quantitatively, both the degree of polymerization of cellulose (*DP*) and the total amino acid composition of the protein fiber were determined. The average *DP* for the old cellulose fiber thus calculated was 585, which was obviously lower than for natural cotton fiber. The following relation may approximately hold for cellulose deterioration under limited conditions.[16]

$1/DP - 1/DP_0 = kt$, where *DP* is the degree of polymerization at a certain time, DP_0 is the initial *DP* of cellulose, k is a constant, and t is the number of years elapsed. If k is assumed to be 1.86×10^{-6} and if DP_0 be 3500,[16] then we get $t=766$ years which corresponds to the early 13 th century. Table 2 shows the amino acid composition of pre-Inca protein fiber from fabrics which are known to be of the Llama type.

TABLE 2. AMINO ACID COMPOSITION OF PROTEIN FIBER (mol/10^5 g)

Amino acid	pre-Inca fiber	Llama	Camel	Merino wool
Lys.	14.7	19.3	20.9	20.6
His.	2.4	4.0	3.8	5.9
Arg.	50.6	55.8	56.0	52.0

Val.	35.5	35.9	35.4	43.0
Met.	4.0	3.7	4.7	3.6
iso Leu.	19.9	20.8	20.0	21.5
Leu.	51.6	56.9	55.9	62.0
Tyr.	14.2	20.9	19.0	31.3
Phe.	15.1	24.1	16.4	23.9
Pro.	86.0	80.0	83.0	56.4

For comparison, the amino acid analyses of three other fresh protein fibers—llama, camel, and merino wool—was carried out; the results are shown in Table 2. From Table 2 it appears that the pre-Inca protein fiber was more similar to that of camel rather than that of llama, except for the difference in cystine content (10.9/44.3). Whether this and other minor differences in amino acid content are attributable to selective degradation due to long aging, or, to the pre-Incan people's use of other kinds of animal fiber, like vicuna or alpaca, is not clear at this stage.

The author wishes to thank especially Mr. Yoshitaro Amano of the Museo Amano, Lima, Peru for his courtesy and Prof. T. Yamanobe for his encouragement. He also appreciates the cooperation of Hitachi Ltd. and other organizations, including the Shimadzu Seisakusho Ltd. and the Kanagawa Industrial Research Institute. The expences were jointly taken care of by Kyoritsu Women's University and the Foundation Foreign Service for Private Universities, Japan.

The Conformations of Oligosaccharides. III. The Crystal and Molecular Structure of Melibiose Monohydrate*

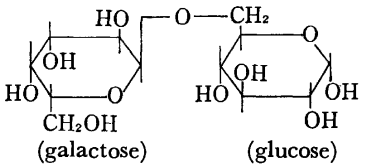
Ken HIROTSU and Taiichi HIGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received November 12, 1975)

The crystal structure of α-melibiose monohydrate ($C_{12}H_{22}O_{11}\cdot H_2O$) was determined by direct methods using two-dimensional cosine invariants. The space group is $P2_12_12_1$, with $Z=4$ and unit cell dimensions of $a=15.814$ (5), $b=10.924$ (5), $c=8.903$ (4) Å. The structure was refined to $R=0.044$ for 1439 reflections measured with Mo$K\alpha$ radiation. Difference synthesis indicated the partial (15%) random substitution of α-melibiose molecules by the β-anomer. The molecular conformation of α-melibiose is almost the same as that previously found in the melibiose moiety of raffinose, although some of the bond lengths and angles are significantly different. The molecules are linked by complex hydrogen-bond systems which consist of six-link finite chains and five-membered closed loops.

The crystal structure of α-melibiose monohydrate has been determined as a part of a series of reports on the X-ray diffraction of carbohydrates.[1,2] α-Melibiose (*O*-α-D-galactopyranosyl-(1→6)-α-D-glucopyranoside) is the principal disaccharide of the melibiose group. It contains a galactose and a glucose moiety as shown in (I). The first purpose of this investigation was to compare the conformation of the melibiose unit in different intermolecular environments, *i.e.*, in this molecule and in the melibiose moiety of raffinose (Berman 1970).[3] The second purpose was to compare the bond lengths and bond angles common to melibiose and raffinose. The hydrogen bond scheme in the crystal is also of interest.



(I)

Experimental

Crystal Data. $C_{12}H_{22}O_{11}\cdot H_2O$, mol wt=360.3, orthorhombic, $a=15.814$ (5), $b=10.924$ (5), $c=8.903$ (4) Å, $U=1538.0$ Å^3. $D_m=1.54$ g·cm^{-3} (by flotation), $Z=4$, $D_c=1.556$ g·cm^{-3}. Mo$K\alpha$ radiation, $\lambda=0.7107$ Å, μ (Mo$K\alpha$) $=1.32$ cm^{-1}. Space group $P2_12_12_1$ (D_2^4, No. 19).

The crystal was grown by slow evaporation from a saturated aqueous solution of commercially available α-melibiose monohydrate. Unit cell parameters were determined using a standard Philips PW1100 X-ray diffractometer computer program, which investigates rows in the reciprocal lattice through the origin and scans the four highest weighted reflections and their anti-reflections (weighted by intensity and sin θ). The centers of gravity of these eight profiles are then used in a least-squares refinement of the spacing for that row.

Intensity Measurement. A crystal with the dimensions $0.22\times0.30\times0.18$ mm was used to measure the cell parameters and intensities with a Philips PW 1100 four-circle automatic diffractometer. The $\omega/2\theta$ scan method was employed (scan speed 0.03° s^{-1}, scan width $1°+0.3°\times\tan\theta$). The background was measured for 15 s on either side of the peak. Data were collected to a maximum θ of 27.5° with graphite-monochromated Mo$K\alpha$ radiation ($\lambda=0.7107$ Å). Of the 2062 independently measured reflections, 1439 were considered to be observed with $I>2.5\,\sigma(I)$, where $\sigma(I)=[(0.04I)^2+S+TAU^2\times B]^{1/2}$ S=scan count, B=total background count, and TAU=ratio of scan time to total background time. The intensities were corrected for Lorentz and polarization factors but not for absorption.

Structure Determination and Refinement. The structure was determined by a phasing procedure, based on the two-dimensional structure invariants $\cos(\phi_1+\phi_2+\phi_3)$ whose values were calculated with the following modified triple product formula[4] at an E threshold level of 1.85:

$$\cos(\phi_1+\phi_2+\phi_3) \simeq \frac{K\Psi}{|E_1E_2E_3|} + \frac{R_3}{|E_1E_2E_3|} \qquad (1)$$

where

$$\Psi = \langle(|E_{\vec{k}}|^{1/2}-\overline{|E|^{1/2}})(|E_{\vec{h}_1+\vec{k}}|^{1/2}-\overline{|E|^{1/2}})\times (|E_{-\vec{h}_1+\vec{k}}|^{1/2}-\overline{|E|^{1/2}})\,\big|\,|E_{\vec{k}}|>t\rangle_{\vec{k}},$$

$$\overline{|E|^{1/2}} = \langle|E_{\vec{k}}|^{1/2}\rangle_{\vec{k}},$$

$$\phi_i = \phi_{\vec{h}_i},\ |E_i| = |E_{\vec{h}_i}|,\quad i=1,2,3$$

$$R_3 = \frac{\sigma_3}{4\sigma_2^{3/2}}\left[\frac{3}{2}(|E_1E_2|^2+|E_2E_3|^2+|E_3E_1|^2) + |E_1|^2+|E_2|^2+|E_3|^2-\frac{7}{2}\right],$$

$h_1+h_2+h_3=0$, and the parameter K is the sliding scale factor. The phasing process was similar to that described by Duax, Weeks and Hauptman (1972).[5] The positions of 24 non-hydrogen atoms were easily located from the E-map and further confirmed by a least-squares refinement. Six cycles of isotropic block-diagonal least-squares refinement followed by two cycles of anisotropic refinement resulted in an R $(=\sum||F_o|-|F_c||/\sum|F_o|)$ value of 0.082. A difference map revealed hydrogen atoms attached to all carbon atoms and some of the hydroxyl hydrogen atoms. The electron density (1.22 e·Å^{-3}) of the peak at the position for the hydrogen atom attached to C(1) was about three times that of the other peaks (0.31—0.52 e·Å^{-3}). The second difference map after three cycles of anisotropic refinements, in which hydrogen atoms were included with an isotropic temperature factor, revealed the remaining hydrogen atoms. This map additionally showed a residual electron density of 0.95 e·Å^{-3} near the position assigned to H(Cl), which probably indicates the presence of a small amount of the β-anomer. The β-oxygen atom was located at about 1.38 Å from C(1). A similar example was found in the structure of α-lactose monohydrate (Fries, Rao and Sundaralingam, 1971).[6] Refinement of the carbon, oxygen and hydrogen parameters and of the occupancy factors for αO(1) and βO(1) was completed

* The papers in *Chem. Lett.*, **1973**, 83 and *Bull. Chem. Soc. Jpn.*, **47**, 1872 (1974) are designated as parts I and II, respectively, of this series.

a) Isotropic temperature parameter. The occupancy parameters of O(1) and βO(1) are 0.848 and 0.152, respectively.

by the full matrix least-squares program. The total of the occupancy parameters was constrained to unity through the refinement. The function minimized was $\sum w(|F_o|-k\times|F_c|)^2$, where $w=1/\sigma(F)^2$. The final cycle gave an R value of 0.044 for all reflections. The occupancy parameter of αO(1) was 0.848 and that of βO(1) was 0.152. The atomic scattering factors used were those of the International Tables for X-ray Crystallography[7] and for the hydrogen atoms, those of Stewart, Davidson, and Simpson (1965).[8] The final positional and thermal parameters are given in Table 1; corresponding structure factors are listed in Table 2.**

** Table 2 has been submitted to, and is kept by the office of the Chemical Society of Japan, 5, 1-Chome, Kanda-Surugadai, Chiyoda-ku, Tokyo 101. (Document No. 7614).

Discussion

The molecular conformation of melibiose monohydrate is shown in Fig. 1, where the atomic numbering of the galactose moiety is primed.

Bond Lengths and Angles. The bond lengths and angles involving carbon and oxygen atoms are shown in Fig. 2, excluding those involving the βO (1) atom. The standard deviations are 0.004—0.005 Å for C–C and C–O bonds and 0.3° for the valence bond angles. E.s.d's for the C–H and O–H distances are 0.03—0.04 Å. The C(1)–βO(1) length is 1.32 Å. The C(2)–C(1)–βO(1) and O(5)–C(1)–βO(1) angles are 110.0° and 116.2°, respectively. The C(5)–C(6) bond length of the (1→6) linkage is 1.496 Å, which is rather short for a

	O(5)–C(1)	−61.0	O(5′)–C(1′)	−61.3
Extracyclic torsion angles	O(1)–C(1)–C(2)–O(2)	51.6°	O(6)–C(1′)–C(2′)–O(2′)	59.7°
	O(2)–C(2)–C(3)–O(3)	64.9	O(2′)–C(2′)–C(3′)–O(3′)	57.3
	O(3)–C(3)–C(4)–O(4)	−64.5	O(3′)–C(3′)–C(4′)–O(4′)	57.4
	O(4)–C(4)–C(5)–C(6)	56.3	O(4′)–C(4′)–C(5′)–C(6′)	−56.8
			O(5′)–C(5′)–C(6′)–O(6′)	65.6
			C(4′)–C(5′)–C(6′)–O(6′)	−173.5

C–C single bond. In planteose[9] also, the C(5)–C(6) bond of the (1→6) linkage is 1.494 Å. However, the corresponding bond in raffinose[3] is not markedly short (1.520 Å). A slight shortening of the exocyclic C(5)–C(6) bond has been observed in many carbohydrate structures.[2,6,10–12]

The C(1)–O(1) and C(1′)–O(6) bond lengths of melibiose are rather short. This shortening effect in the anomeric positions has been generally observed in oligosaccharides[13] and investigated theoretically.[14,15] The C–O bonds in both pyranoside rings show the same type of systematic disproportion. The C(1′)–O(5′) and C(5′)–O(5′) bond lengths in the galactose moiety are 1.409 and 1.447 Å, respectively, the latter bond being longer than the former by about 9σ. The same trend is observed in glucose moiety. The ring C–O and anomeric C–O bond lengths for the hemi-acetal group in di- and trisaccharides which contain glucose or galactose moiety are listed in Table 3. When R (the substituent at O(1)) is H or CH_3, the C(1)–O(1) lengths are markedly short. Systematic disproportion is not observed in ring C–O distances. When R is a pyranosyl group and O(1) is in an equatorial position, the mean distance of the C(1)–O(1) bonds is 1.391 Å. When O(1) is in an axial position, the corresponding mean distance is 1.416 Å, which is slightly longer than that of the axial C(1)–O(1) bond. The systematic disproportion, C(5)–O(5)>O(5)–C(1), is distinctly observed in both α- and β-pyranosides, excluding methyl β-cellobioside and isomultulose. The mean distances of C(5)–O(5) and O(5)–C(1) are 1.438 and 1.415 Å, respectively. There is a correlation between C(1)–O(1) and the ring C–O lengths of di- and trisaccharides given in Table 3. The difference between the C(5)–O(5) and O(5)–C(1) bond lengths becomes small with a shortening of the C(1)–O(1) bond. The difference becomes large with a lengthening of the C(1)–O(1) bond to the normal C–O single bond length.

The valence angles shown in Fig. 2 are not remarkable. The C(5)–C(6)–O(6) angle is 112.2°, which is larger by 4.2° than the corresponding angle in raffinose. The C(1′)–O(6)–C(6) angle is 111.8°

Molecular Conformation. The conformational angles in the pyranose rings are listed in Table 4. The torsion angles of the galactose moiety range from 53.8° to 61.6° with an average value of 57.6°. Those of the glucose moiety range more widely from 46.3° to 65.6° with an average value of 55.0°. The corresponding angles in the melibiose moiety of raffinose range from 52.7° to 59.5° and from 53.8° to 62.2° for the glucose and galactose moieties, respectively. The torsion angles around the ring C–O bonds are the largest, while those around C(2)–C(3), C(3)–C(4), C(2′)–C(3′), and C(3′)–C(4′), which are at the positions opposite to the ring C–O bonds, are the smallest. In the glucose moiety of melibiose, this trend is distinct. The difference between the torsion angles C(1)–C(2)–C(3)–C(4) and C(2)–C(3)–C(4)–C(5) is −95.4°, while the difference between the torsion angles C(4)–C(5)–O(5)–C(1) and C(5)–O(5)–C(1)–C(2) is 126.6°. This indicates smaller puckering in the region of C(3) and larger puckering in the region of O(5). Also, in the exocyclic torsion angles, those of the glucose moiety range more widely than those of the galactose moiety.

The conformation of the C(5′)–C(6′) bond of the galactose moiety is *plus synclinal*, while that of the corresponding bond of raffinose is *antiperiplanar*. From intramolecular interactions, these two conformations seem to be equally preferable, while *minus synclinal* conformation should be unfavorable because this conformation would have short O(6′)···O(4′) intramolecular contact.

TABLE 5. A COMPARISON OF THE TORSION ANGLES OF THE (1→6) LINKAGE IN MELIBIOSE AND RAFFINOSE

	Melibiose	Raffinose
O(5)–C(5)–C(6)–O(6)	−63.3°	−64.8°
C(4)–C(5)–C(6)–O(6)	59.6	58.4
C(5)–C(6)–O(6)–C(1′)	−173.9	−169.5
C(6)–O(6)–C(1′)–C(2′)	−160.5	−167.6
C(6)–O(6)–C(1′)–O(5′)	76.1	71.9

The conformation around the (1→6) linkage is of interest in that it determines the overall molecular form, and gives basic data which can be used to construct a model of macromolecular polysaccharides with a (1→6) linkage. The torsion angles around the (1→6) linkage in melibiose and raffinose are listed in Table 5. The conformations around the bridge bond of these two compounds are almost the same. The C(1′)–O(6) conformation is *plus synclinal*, the C(6)–O(6) conforma-

Symmetry code

The letters refer to the symmetry operations to be applied to the coordinates listed in Table 1.

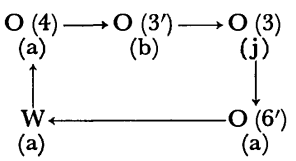
(a)	x,	y,	z	(g)	$-1/2+x$, $1/2-y$, $-z$
(b)	x,	y,	$1+z$	(h)	$-1/2+x$, $1/2-y$, $1-z$
(c)	x,	y,	$-1+z$	(i)	$1-x$, $1/2+y$, $1/2-z$
(d)	$1/2-x$,	$-y$,	$1/2+z$	(j)	$1-x$, $1/2+y$, $3/2-z$
(e)	$3/2-x$,	$-y$,	$-1/2+z$	(k)	$1-x$, $-1/2+y$, $1/2-z$
(f)	$1/2-x$,	$-y$,	$-1/2+z$	(l)	$1-x$, $-1/2+y$, $3/2-z$

tion is *antiperiplanar*, and the C(5)–C(6) conformation is *minus synclinal*. C(5), C(6), O(6), and C(1′) in melibiose are coplanar to within 0.04 Å. The same conformation of the (1→6) linkage is maintained in these two compounds in different intermolecular environments.

Hydrogen Bonding. The arrangement of the molecules in the structure is shown in Fig. 3. The molecules are linked by the complex system of hydrogen bonds given in Table 6. There are two major hydrogen bond sequences. One comprises a six-link finite chain:

O (1) (c) → O (4′) (g) → W (i) → O (2′) (a) → O (2) (f) → O (5) (a)

where → indicates the donor direction and the small letters refer to the symmetry codes given in Table 6. The other system consists of a five-membered closed loop:



As shown in Table 6, the separation between βO(1) and O(5′) (2.683 Å) corresponds to the hydrogen bond distances. When the α-anomer in the crystalline melibiose is replaced by a β-anomer, the hydrogen bond, O(1)···O(4′), is missing, but there appears to be one compensating hydrogen bond between βO(1) and O(5′). Thus, the β-anomer can easily be accomodated in the crystal.

Each hydroxyl group except O(1)–H participates in two hydrogen bonds, in one as a donor and in the other as an acceptor. O(1)–H serves only as a donor. A

water molecule serves as a donor for two hydrogen bonds and an acceptor for two others. The ring oxygen O(5) takes part in hydrogen bonds as an acceptor. About 15% of the O(5′) atoms should be hydrogen bond acceptors. The glycosidic linkage oxygen atom is not involved in hydrogen bonds, just as in all crystal structures of di- and trisaccharides. There are no intramolecular hydrogen bonds.

Computer Programs

All calculations were performed on a FACOM 270/30 computer at the Computer Center of Osaka City University using the following programs: RSSFR-3,[20] HBLS-IV,[20] RSFLS-4,[20] MTPF (calculation of cosine invariants),[21] PHASE III (tangent refinement),[22] BOND (molecular dimensions),[23] and TECS (stereoscopic drawing of crystal and molecular structures).[24]

Formation Constants of Dibenzo-18-crown-6 Complexes with Alkali Metal Ions in DMSO, DMF, and PC at 25 °C

Niro MATSUURA, Kisaburo UMEMOTO, Yasuyuki TAKEDA, and Atsuko SASAKI

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received November 12, 1975)

The formation constants (K_f) for the 1:1 complexes of dibenzo-18-crown-6 (DBC) with alkali metal ions in DMSO (dimethyl sulfoxide), DMF (*N,N*-dimethyl formamide), and PC (propylene carbonate) have been determined conductometrically. The formation constant sequences of the alkali metal ions with DBC in DMSO, DMF, and PC are $K^+ > Rb^+ > Cs^+ \cong Na^+ \gg Li^+$, $K^+ > Rb^+ > Cs^+ > Na^+ > Li^+$, and $K^+ \gg Na^+ > Rb^+ > Cs^+ > Li^+$ respectively. The K_f value series about the same alkali metal ion among these nonaqueous solvents are given in the order of DMSO<DMF<PC. These results show that the selectivity of DBC toward the alkali metal ions is dependent on the ionic diameter and the ring-hole size of DBC, and that the donor number of the organic solvent as a component factor is important in determining the process of the formation of the DBC complexes constant.

In a number of recent papers Pedersen[1] has described many macrocyclic polyethers synthesized by him; these compounds form complexes with various salts. The complexing of alkali cations by neutral molecules is an uncommon and only recently observed phenomenon. The formation of the complexes between cyclic polyethers and alkali metal salts has been determined by several methods, for example, by a calorimetric titration technique by Izatt *et al.*,[2] by potential and conductance measurements by McLaughlin *et al.*,[3] by spectroscopic methods by Wong *et al.*,[4] by UV spectra and solvent extraction by Pedersen,[1b] and by potentiometry with cation-selective electrodes by Frensdorff.[5] They have reported the formation constants for complexing of these polyethers with several cations, and suggested that the specificity of the complexation is due to the surrounding solvent for the free cation and the required fit between the ionic radius and the hole size of the cyclic polyether ring. The present study was undertaken in order to quantify the strength of complexing in a solution as a function of the ionic radius, the hole size of the cyclic polyether ring, and the physical properties of the solvent. In this paper the formation constants for 1:1 complexes of dibenzo-18-crown-6 (DBC) with alkali metal ions (Li^+, Na^+, K^+, Rb^+, Cs^+) in DMSO (dimethyl sulfoxide), DMF (*N,N*-dimethyl formamide) and PC (propylene carbonate) have been determined conductometrically.

Experimental

Conductance Cell. The conductance cell was similar to those reported previously.[6]

Apparatus and Procedure. The measurements were carried out by means of a Yokogawa-Hewlette-Packard Universal Bridge. Cell solutions were thermostated to 25± 0.02 °C in a double water bath. The solution in the cell was stirred by means of a magnetic stirrer so that we might quickly obtain a temperature equilibrium. The cell temperature change was readily detected by the shift of resistance readings exceeding 0.01%. For the first run, DBC and alkali metal perchlorate were dissolved in the solvent in order to make the concentration of DBC equal that of alkali metal perchlorate. After a constant value of resistance had been attained, a 30-ml portion of the solution was siphoned out and equal volume of the solvent was added to the cell. This procedure was continued. The concentration range was from 7.6×10^{-4} to 3.1×10^{-3} M. For the second run, DBC of about 7.5×10^{-3} M was added to the solvent in the cell and the resistance of the solution was measured. Then a step-by-step increase in the alkali metal perchlorate concentration was effected by a quick transfer from the weighing bottle to the conductance cell. The concentration range was from 1.0×10^{-4} to 1.5×10^{-2} M. The Λ *vs.* $\sqrt{C}$ curve for this series is given by (3) in Figs. 1—5.

Materials. The method of the purification of solvents and electrolytes was as has previously been described.[7] Dibenzo-18-crown-6 was obtained from the Aldrich Chemical Company, Inc. DBC was dissolved in chloroform and filtered.

1: Λ *vs.* $\sqrt{C}$ curve for alkali metal perchlorate in PC at 25 °C —phoreogram-1.

2: Λ *vs.* $\sqrt{C}$ curve for the same concentration of alkali metal perchlorate as that of DBC in PC at 25 °C —phoreogram-2.

3: Λ *vs.* $\sqrt{C}$ curve for the stepwise increase of the alkali metal perchlorate concentration against the constant DBC concentration in PC at 25 °C — phoreogram-3.

Then it was recrystallized from benzene five times and, before use, dried at 50 °C in a vacuum oven.

Results

The Λ *vs.* $\sqrt{C}$ curves for alkali metal perchlorates and their complexes with DBC in PC at 25 °C are given in Figs. 1—5. Figures 1,2,3,4, and 5 correspond to the cases of lithium, sodium, potassium, rubidium, and cesium perchlorate respectively. The experimental curves in DMSO and DMF are similar and hence have been omitted. The phoreogram-3 consists of either one linear line or two different ones. The former is found only in the case of $NaClO_4$ in DMSO, and the slope of the Λ *vs.* $\sqrt{C}$ curve is negative. The latter has three types. In the case of the first type, the slope changes from positive to negative with an increase in the concentration, as can be seen in Fig. 1. This type can also be seen in the case of the $NaClO_4$ in DMF. In the case of the second type, the slope changes from negative to positive, as can be seen in Figs. 2—4. In the case of the last type, both slopes are negative, the absolute values of these two slopes are different from each other, and the absolute value of the slope changes from large to small with an increase in the concentration, as can be seen in Fig. 5. This type can also be seen in the cases of $LiClO_4$, $KClO_4$, $RbClO_4$, and $CsClO_4$ in DMSO and DMF. Accordingly, the phoreogram-3 obtained can be classified into the four types. In every case, however, the phoreogram-2 always lies between the phoreogram-1 and the phoreogram-3. That is, the phoreogram-1 is at the top, the phoreogram-2 is in the middle, and the phoreogram-3 is at the bottom. It may be noted from Figs. 1—5 that the distance from the phoreogram-2 to the phoreogram-1 differs from that from the phoreogram-2 to the phoreogram-3 in the concentration range of the phoreogram-2. These tendencies in DMSO and DMF are similar. It seems that the 1:1 complex of DBC with the alkali metal ion is larger than the alkali metal ion itself. Therefore, it can be supposed that the former is more mobile than the latter in these solutions. Judging from the above, it is assumed that, in the case of the phoreogram-3, most of the alkali metal ions form complexes with DBC and that these complexes are of the 1:1 type when the concentration of DBC exceeds that of alkali metal ions. As the phoreogram-2 lies between the phoreogram-1 and the phoreogram-3, it is considered that the uncomplexed cation and the complexed cation attain to a chemical equilibrium in the case of the phoreogram-2. The equilibrium equation is given by;

$$\underset{C(1-\alpha)}{M^+} + \underset{C(1-\alpha)}{DBC} \overset{K_f}{\rightleftharpoons} \underset{C\alpha}{M(DBC)^+} \qquad (1)$$

where C is the initial molar concentration of the alkali metal ion and DBC, while α is the fraction of the cation in the 1:1 complex. Accordingly, the complex formation constant, K_f, is given by;

$$K_f = \frac{[M(DBC)^+]}{[M^+][DBC]} = \frac{\alpha}{C(1-\alpha)^2} \qquad (2)$$

where $[M^+]$, $[M(DBC)^+]$, and [DBC] are the molarities of the uncomplexed cation, the complexed cation, and uncomplexed DBC respectively. The observed specific conductance, κ_{ob}, is given by;

$$\kappa_{ob} = \kappa_{M^+} + \kappa_{M(DBC)^+} + \kappa_{ClO_4^-} \qquad (3)$$

where κ_{M^+}, $\kappa_{M(DBC)^+}$, and $\kappa_{ClO_4^-}$ are the specific conductances of the uncomplexed cation, the complexed cation, and the perchlorate ion respectively. The ionic equivalent conductances are given by;

$$\lambda_{M^+} = \frac{\kappa_{M^+}}{[M^+]} = \frac{\kappa_{M^+}}{C(1-\alpha)} \quad (4)$$

$$\lambda_{M(DBC)^+} = \frac{\kappa_{M(DBC)^+}}{[M(DBC)^+]} = \frac{\kappa_{M(DBC)^+}}{C\alpha} \quad (5)$$

$$\lambda_{ClO_4^-} = \frac{\kappa_{ClO_4^-}}{[ClO_4^-]} = \frac{\kappa_{ClO_4^-}}{C} \quad (6)$$

where λ_{M^+}, $\lambda_{M(DBC)^+}$, and $\lambda_{ClO_4^-}$ are the ionic equivalent conductances of the uncomplexed cation, the complexed cation, and the perchlorate ion respectively. As a consequence of Eqs. 4, 5, and 6, Eq. 3 would be transformed into;

$$\Lambda_{ob} = \frac{\kappa_{ob}}{C} = (1-\alpha)\Lambda_{MClO_4} + \alpha\Lambda_{M(DBC)ClO_4} \quad (7)$$

where Λ_{ob} is the observed equivalent conductance and where Λ_{MClO_4} and $\Lambda_{M(DBC)ClO_4}$ are the equivalent conductances of alkali metal perchlorate and alkali metal DBC perchlorate respectively. If the α value is obtained, the value of K_f at each concentration can be calculated. The procedure for obtaining the α value is as follows. First, the α value is estimated arbitrarily. Using this α value, the concentrations of alkali metal perchlorate and alkali metal DBC perchlorate are found to be $C(1-\alpha)$M and $C\alpha$M respectively. As the values of Λ_{MClO_4} and $\Lambda_{M(DBC)ClO_4}$ at these concentrations can be obtained from the phoreogram-1 and the phoreogram-3 respectively, the right side of Eq. 7 can be calculated. As the value of the left side of Eq. 7 is the observed one, these calculations are continued until the value of the right side of Eq. 7 becomes equal to that of the left side of Eq. 7. When the value of α is finally obtained, K_f can be calculated from Eq. 2. As a result, the formation constants of the 1:1 complexes of DBC with alkali metal ions for each concentration are as shown in Table 1. It may be noted from Figs. 1—5 and Table 1 that the closer the phoreogram-2 approaches the phoreogram-3, and the more the phoreogram-2 departs from the phoreogram-1, the larger the value of the K_f of each concentration becomes. These phenomena in DMSO and DMF are similar. The formation constant sequences of the alkali metal ions with DBC in PC at 25 °C are $K^+ \gg Na^+ > Rb^+ > Cs^+ > Li^+$. In the cases of DMSO and DMF, however, they are $K^+ > Rb^+ > Cs^+ \cong Na^+ \gg Li^+$ and $K^+ > Rb^+ > Cs^+ > Na^+ > Li^+$ respectively.

Discussion

The K_f value series about the same alkali metal ion among these nonaqueous solvents are given in the order of DMSO<DMF<PC from Table 1. The formation constant sequences of the complex in PC differ from those in DMSO and DMF. Of all the alkali metal ions, the K_f value of K^+ is the largest, and that of Li^+ is the smallest, in each solvent. These results show that the ability of the alkali metal ion to form complexes with DBC in these solvents is dependent on the ionic diameter, as can be seen in Table 2, and that the solvent used is important in determining the formation constant in these systems. This can be considered to reflect the competition between complex formation and solvation. This is supported by the K_f values in Table 1, which show, that for alkali metal cations of approximately the same ionic diameters, *i.e.*, K^+ (2.66 Å), the K_f value of K^+ is the largest. Pedersen[1] has observed that the complexing power can be expected to be weak when the hole of the polyether is too small or too large for the cation, because the salt-polyether complexes are formed by ion-dipole interaction between the cation and the negatively charged oxygen atoms symmetrically arranged in the polyether ring. In addition, the poor selectivity for Li^+ is probably due to its small size (ionic diameter, 1.20 Å) as compared to the size of the hole of DBC (hole size, 2.6—3.2 Å). The solvation is very important in determining cation selectivity, and in this respect it will be more difficult to strip the solvent molecules from Li^+ than from all the other alkali metal ions. Of course, this will depend very greatly on the nature of the solvent. The potential series on the

Table 2. Ionic diameters and hole size (Å)[a]

normalized potential scale were given in the order of DMSO<DMF<PC, indicating that the metal ion-solvent interaction increases with an increase in the electron-donor property of the solvent.[8] The K_f value sequences were given in the order of DMSO (ε=46.7[9])<DMF (ε=36.7[9])<PC (ε=64.4[9]). Accordingly, it seems that the donor number of the solvent is a very influential factor in the alkali metal ion-DBC complexing. Pedersen[1b] has reported that the selectivity of polyethers with respect to the complexation of alkali metal ions increases as the dielectric constant of the organic solvent is lowered. However, it seems that the donor number is a main factor in determining the selectivity of DBC for the alkali metal ion in the organic solvent.

Pulse Radiolysis of $HgBr_2$ in Aqueous Solutions

Shin-ichi FUJITA, Hideo HORII, Toshiaki MORI, and Setsuo TANIGUCHI
Radiation Center of Osaka Prefecture Shinke-cho, Sakai, Osaka 593

(Received November 20, 1975)

Pulse radiolysis of aqueous $HgBr_2$ solutions was investigated in the range from visible to 260 nm. $HgBr_2$ is reduced by e_{aq}^-, H, CO_2^-, and some alcohol radicals except *t*-butyl alcohol radical to yield a transient species, HgBr, having an absorption spectrum with a maximum at 350 nm ($\varepsilon^{350}=(4.3\pm0.2)\times10^3$ M^{-1} cm^{-1}). $k(e_{aq}^-+HgBr_2)$ was determined by the pseud-first order decay of e_{aq}^- observed at 500 nm as $(4.0\pm0.3)\times10^{10}$ M^{-1} s^{-1}. The reactivities of the other reducing species toward $HgBr_2$ were estimated to be in the order $e_{aq}^->CO_2^-\gtrsim$ĖtOH≈*i*-ṖrOH>MeOH by comparing the absorption yields of HgBr in equimolar $HgBr_2$ solutions containing the parent substances of the respective species. HgBr was found to decay following a second order rate law ($2k=(1.0\pm0.1)\times10^{10}$ M^{-1} s^{-1}), producing Hg_2Br_2. $HgBr_2$ reacts also with the OH radical to give a transient species which shows a similar spectrum to that of Br_2^-. It is considered that the transient may be $HgBr_3$ instead of Br_2^-.

Pulse radiolysis of aqueous solutions of various mercuric salts has recently been investigated in order to find unstable mercurous species[1,2] and to clarify their behavior before they fall into the stable state.[3,4] It was found that the mercurous species behave in different ways depending on the pair anions attached. The results obtained for aqueous of mercuric bromide are described in the present report.

Experimental

Details of pulse radiolysis measurements have been described previously.[2,3] The dose per pulse was controlled by changing the pulse duration ($\lesssim1$ μs) and the thickness of aluminum plate situated between the reaction cell and the outlet of the beam. With a thickness of 1—3 mm the delivered doses to the cell depended linearly on the coulomb values monitored by the system.[2] The light source used was a 500 W xenon lamp. All the solutions were prepared with guaranteed reagents and triply distilled water.

Results and Discussion

The spectra were obtained in a deaerated aqueous solution of 500 μM $HgBr_2$ containing 10 mM *t*-BuOH on irradiation with about 1 μs electron pulses (Fig. 1). The immediate absorption after the pulse has a peak at 350 nm. It decays rapidly following a second order rate law. Concurrently with the decay of the transient a residual intense absorption appears at shorter wavelengths within about 100 μs. Most of these absorptions were reduced by saturation of N_2O.

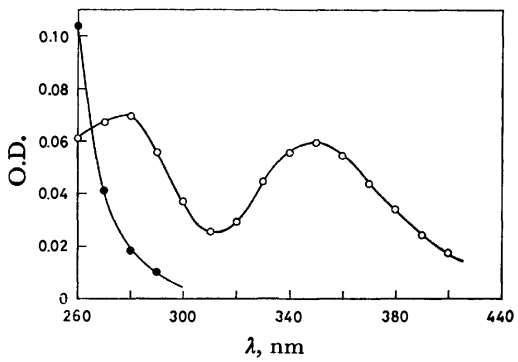

Fig. 1. Absorption spectra obtained in an deaerated aqueous solution of 500 μM $HgBr_2$ and 10 mM *t*-BuOH, immediately (○) and 100 μs (●) after the pulse; average dose, 2500 rad.

Irradiation of water with electron pulses produces the e_{aq}^-, H and OH radicals as reactive species. The OH radical is, however, scavenged by *t*-BuOH.[5] Since N_2O is known to react rapidly with the e_{aq}^-,[6] it is expected that the initial absorption is due to Hg(I) resulting from reduction of $HgBr_2$ by e_{aq}^-, the residual one being due to its dimer, $Hg_2(I)$.

$$e_{aq}^- + HgBr_2 \longrightarrow Hg(I) \quad (1)$$

$$Hg(I) + Hg(I) \longrightarrow Hg_2(I) \quad (2)$$

By observing the life time of e_{aq}^- at 500 nm in the range 10—30 μM $HgBr_2$, the rate constant, $k(e_{aq}^-+HgBr_2)$, was determined to be $(4.0\pm0.3)\times10^{10}$ M^{-1} s^{-1}.

Entirely similar spectra were found in a deaerated 500 μM $HgBr_2$ solution with 10 mM *t*-BuOH at pH 2 where e_{aq}^- was converted into the H radical by the reaction with H^+.[7] It is accepted, therefore, that the H radical also reduces $HgBr_2$ rapidly.

$$H + HgBr_2 \longrightarrow Hg(I) \quad (3)$$

In the presence of other OH scavengers, such as formate ion, methanol, ethanol, and 2-propanol, additional growth curves appeared. Consequently the total absorption yields at 350 nm increased up to nearly twice as much as that in Fig. 1 in the case of formate ion as a scavenger. The resultant absorption spectra in these systems were also similar to those shown in Fig. 1. These results were not influenced essentially by saturation of N_2O in solutions.

Thus, it seems that the OH radical contributes to the reduction of $HgBr_2$ through its reaction products with scavengers.

$$OH + HCO_2^- \longrightarrow CO_2^- + H_2O \quad (4)$$

$$CO_2^- + HgBr_2 \longrightarrow Hg(I) + CO_2 \quad (5)$$

$$OH + ROH \longrightarrow \dot{R}OH + H_2O \quad (6)$$

$$\dot{R}OH + HgBr_2 \longrightarrow Hg(I) + \text{aldehyde or ketone} \quad (7)$$

where Reactions 4 and 6 are known to be very fast.[8,9] $k(CO_2^-+HgBr_2)$ was found to be 9×10^9 M^{-1} s^{-1} from the formation curve of the Hg(I) absorption at 350 nm. This value should, however, be accepted as an upper limit because, owing to its fast decay, Hg(I) could not attain the full equivalent for the CO_2^- yield. Thus,

Table 1. Transient absorption yields in deaerated aqueous solutions of 0.87 mM $HgBr_2$ containing various OH-scavengers at a dose of 2700 rad

Scavengers	O. D.$_{max}$	O. D.$_{relative}$ [a)]
HCO_2Na	0.103	1.0
i-PrOH	0.092	0.89
EtOH	0.090	0.87
MeOH	0.065	0.63

a) Normalized to the value for HCO_2Na.

as to similar reactivities of some alcohol radicals, the order among each other was determined on the basis of the observed Hg(I) yield. Table 1 gives the maximum optical densities of the absorptions obtained in solutions of 0.87 mM $HgBr_2$ containing 10 mM respective alcohols or the formate ion at a dose of 2700 rad. Each maximum optical density should depend on the formation rate constant, k_5 or k_7, since the Hg(I) absorption decays rapidly at almost a uniform rate under these conditions. The values relative to the one for the formate ion are listed in the third column of Table 1. The results and the kinetic data show that the reactivities toward $HgBr_2$ are in the order $e_{aq}^- > CO_2^- > \dot{E}tOH \approx i\text{-}\dot{P}rOH > \dot{M}eOH$.

In a *t*-BuOH contained solution of 0.87 mM $HgBr_2$, a linearity of the absorption quantities *vs.* dose per pulse was obtained up to *ca.* 3000 rad. From the slope of the line the absorption coefficient of Hg(I) was calculated to be $\varepsilon^{350}=(4.3\pm0.2)\times10^3\ M^{-1}\ cm^{-1}$ on the basis of $G(Hg\ (I))=G_H+G_{e_{aq}^-}=3.3$.

The results of the tests of a second order rate law for the decay of the transient at 350 nm at different doses in $HgBr_2$ solutions containing various OH-scavengers are given in Fig. 2. All the plots are linear, their slopes ($=2k_2/\varepsilon l$), giving the same value of $(1.6\pm0.1)\times10^6\ s^{-1}$ for all the scavengers except *t*-BuOH. Thus, $2k_2=(1.0\pm0.1)\times10^{10}\ M^{-1}\ s^{-1}$ ($l=1.5$ cm). The rate constant was not affected by ionic strength of the solutions. The transient might be assigned to HgBr with no charge.

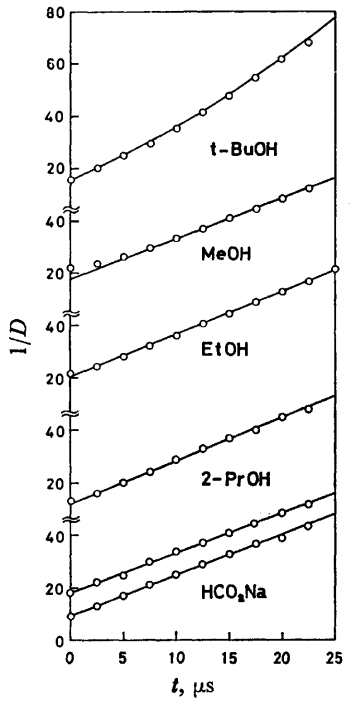

Fig. 2. Test of second order kinetics for the decay of Hg(I) at 350 nm in the presence of various OH-scavengers: $[HgBr_2]=500\ \mu M$, [scavenger]$=10$ mM; dose, ranging between 1300—2700 rad. In the case of HCO_2Na the dose giving the lower result is as nearly twice as that giving the higher one.

The corresponding plots for solutions containing *t*-BuOH deviate slightly from the straight line (Fig. 2), indicating that *t*-butyl alcohol radical interacts with HgBr. In reference to the results for HgCN,[4] it is expected that the other alcohol radicals also react with HgBr. In the present system, however, the deviation from linearity in the decay kinetics may be negligible, because the attainable radical concentration is kept low owing to Reaction 7.

The residual absorbing species at shorter wavelengths may be ascribed to be Hg_2Br_2 in view of the similarity with the $HgCl_2$ system (Fig. 1).[1] It may be supported by the fact that the slow increase of the absorption at 260 nm occurs simultaneously with the second order decay of HgBr (Fig. 3).

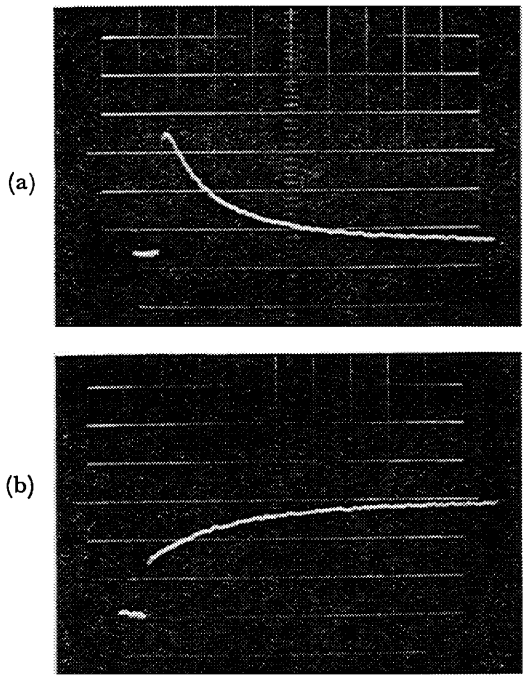

Fig. 3. Oscillographic traces obtained in a deaerated aqueous solution of 500 μM $HgBr_2$ and 10 mM *i*-PrOH: (a) 350 nm, (b) 260 nm; average dose, 2100 rad; ordinates, 4.5%/div., abscissa, 10 μs/div.

Figure 4 shows the absorption spectra obtained in a N_2O-saturated solution of $HgBr_2$. Two kinds of species are recognized: one absorbing at shorter wavelengths appears just after the pulse and disappears rapidly, while the other with an absorption maximum at 355 nm builds up slowly and decays according to a second order kinetics. The formation rate of the latter becomes greater with increasing $HgBr_2$ concentration. No residual absorption was found in this system.

In N_2O-saturated aqueous solutions the OH radical should work mainly as reactive species to solutes with

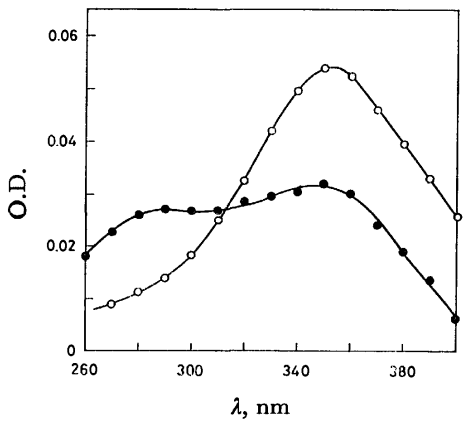

Fig. 4. Absorption spectra obtained in a N_2O-saturated aqueous solution of 500 μM $HgBr_2$, immediately (●) and 7 μs (○) after the pulse; average dose, 1600 rad.

$G(OH)=G_{e_{aq}^-}+G_{OH}=5.5$.[10] Most of the former absorption, however, may be due to HgCl reduced by the H radical and some part of the e_{aq}^- in view of the results obtained in deaerated solutions. Though the absorption quantity at 280 nm seemed somewhat larger (initially about twice as much) than that in the solution containing *t*-BuOH as an OH scavenger, no evidence was obtained suggesting a species other than HgCl. The latter absorption would be interpreted by the occurrence of the oxidation of Br^-, since no evidence that mercury(II) ions in some other complexes are further oxidized by the OH radical.[2-4]

Radiolysis of aqueous solutions of KBr gives rise to transient Br_2^- ions having an absorption spectrum with a maximum at 360 nm ($\varepsilon^{360}=8200$ M^{-1} cm^{-1}),[12] which is similar to the one at 7 μs after the pulse (Fig. 4).

$$Br^- + OH \longrightarrow Br + OH^- \quad (8)$$

$$Br + Br^- \longrightarrow Br_2^- \quad (9)$$

Contribution of the free Br^- to Br_2^- formation, however, should be ruled out, because $HgBr_2$ is little dissociable and little hydrolyzed in aqueous solutions.[13] Thus, the following processes might take place.

$$HgBr_2 + OH \longrightarrow HgBrOH + Br \quad (10)$$

$$Br + HgBr_2 \xrightarrow{H_2O} HgBrOH + Br_2^- + H^+ \quad (11)$$

If these processes actually occur, Br_2^- should recombine to produce the stable Br_3^- having an intense absorption with a peak at 267 nm ($\varepsilon\approx40000$ M^{-1} cm^{-1})[14]

$$2Br_2^- \longrightarrow Br_3^- + Br^- \quad (12)$$

It was found, however, that even in the case of a N_2O–KBr system such an intense absorption was observed only in the acidic solutions (pH 2). No residual absorption was observed in N_2O-saturated $HgBr_2$ solutions at the same pH. The results suggest that the 355 nm-transient species is not Br_2^- (Fig. 4). This may be supported by some characteristic differences between the transient and Br_2^-:

(i) ε^{360} of the transient obtained in N_2O-saturated $HgBr_2$ solutions (100—500 μM) is *ca.* 75% of that of Br_2^- appearing in a N_2O-saturated 1 mM KBr solution. Both values were compared with each other at very low doses (30—150 rad), to avoid the effect of decay (Fig. 5).

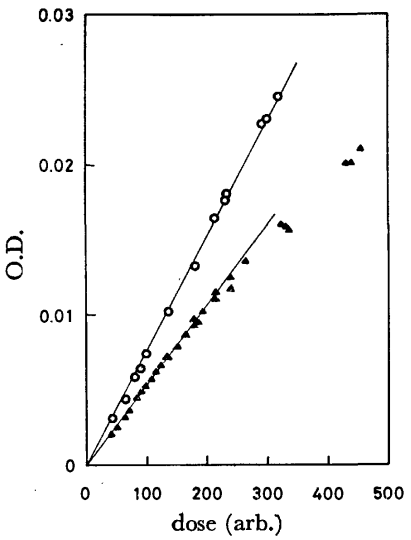

Fig. 5. Comparison between the 355 nm-absorption yields from Br_2^- in a N_2O-saturated KBr solution and the transient in a N_2O-saturated $HgBr_2$ solution: ○: N_2O+1 mM KBr, ▲: N_2O+500 μM $HgBr_2$. The dose unit is roughly in agreement with "rad", though not calibrated.

(ii) $2k/\varepsilon^{360}$ of the transient calculated from the slope of the plots of $1/D$ *vs.* t is about twice as much as that of Br_2^- (6.0 and 3.4×10^5 $cm\ s^{-1}$, respectively, where the latter value is consistent with the reported one[15]).

Čerček pointed out the existence of the Br_3^{2-} ion in aqueous solutions of highly concentrated KBr.[16] It can be assumed that the transient can be a complex molecule such as $HgBr_3$ in view of the charge equivalency.

$$Br + HgBr_2 \longrightarrow HgBr_3 \quad (13)$$

If the assumption is correct, Hg(II) seems to increase the stability of Br_3^{2-} structure since there exist few free Cl^- ions in the solution. Since the transient gives rise to no Br_3^- absorption after the second order decay, the bimolecular reaction of $HgBr_3$ would produce Br_2, though the determination of Br_2 was not carried out.

$$2HgBr_3 \longrightarrow 2HgBr_2 + Br_2 \quad (14)$$

The second order rate constant of the transient formation was determined to be 9×10^8 M^{-1} s^{-1} from the analysis of the formation curve in N_2O-saturated solutions of 100—200 μM $HgBr_2$.

Hydrates of Organic Compounds. II. The Effect of Alkyl Groups on the Formation of Quaternary Ammonium Fluoride Hydrates

Haruo NAKAYAMA and Kazuichi WATANABE

Department of Chemistry, Faculty of Engineering, Yokohama National University, Ooka-machi, Minami-ku, Yokohama 233

(Received December 25, 1975)

The solid–liquid phase diagrams for the binary mixtures of water with various quaternary ammonium fluorides, $(n\text{-}C_4H_9)_3RNF$ (R=H, CH_3, C_2H_5, $n\text{-}C_3H_7$, $i\text{-}C_3H_7$, $n\text{-}C_4H_9$, $i\text{-}C_4H_9$, $n\text{-}C_5H_{11}$, $i\text{-}C_5H_{11}$, $n\text{-}C_6H_{13}$, $n\text{-}C_7H_{15}$, and $C_6H_5CH_2$), have been determined in order to see the effect of alkyl groups on the formation of clathrate hydrates. It has been found that, among these compounds, not only $(n\text{-}C_4H_9)_4NF$, which has been known as a clathrate hydrate-forming salt, but also several other compounds with R=C_2H_5, $n\text{-}C_3H_7$, $i\text{-}C_3H_7$, $i\text{-}C_4H_9$, $n\text{-}C_5H_{11}$, and $i\text{-}C_5H_{11}$ can form hydrate type. These hydrates are believed to be of the clathrate hydrates since they have almost the same hydration numbers as that of $(n\text{-}C_4H_9)_4NF$ hydrate. From the melting points of these hydrates, it has been concluded that the most suitable alkyl chain length of quaternary ammonium salts for their clathrate-hydrate formation is C_4-chain (butyl or isopentyl). In the cases of R=CH_3 and $C_6H_5CH_2$, hydrates having lower melting points and smaller hydration numbers than those of the above group of hydrates have been detected. No hydrates have been observed for the salts with R=H, $n\text{-}C_6H_{13}$ and $n\text{-}C_7H_{15}$.

In 1940 the formation of a variety of crystalline hydrates of tetra butyl and tetra isopentyl quaternary ammonium salts was reported by Kraus and his coworkers.[1] Later McMullan and Jeffrey[2-4] carried out a detailed X-ray structural analysis of the hydrates formed by a large number of these salts and have found that they were the clathrate type, similar to the gas hydrates.[5] In these hydrates, the central N^+ atom lies at a common vertex of four large polyhedra formed by the association of water molecules through hydrogen bondings, and each of the four alkyl chains extends into one of the polyhedral cages. Up to the present it has been known that these hydrates have various characteristic features: 1) an unusually high proportion of water of crystallization; 2) high melting points as compared with ordinary gas hydrates; 3) the capability of forming hydrates with various kinds of anions. However, so far as we know, no systematic investigation of these properties, particularly of their thermodynamic properties, such as heats of fusion of the hydrates and vapor pressure of water molecules which form polyhedral cages, has been extensively done. There is no doubt that such information would be very helpful for the studies of aqueous solutions of these compounds, particularly in connection with the structural modification of water molecules in the vicinity of hydrophobic solutes.[6]

First of all, we are here concerned mainly with the effect of alkyl chain length and/or shape on the stability of the clathrate hydrates of quaternary ammonium salts. It has been reported that quaternary ammonium salts having either a butyl or an isopentyl group can make fairly stable crystalline hydrates. On the other hand an attempt to make the hydrates of tetra propyl ammonium salts was unsuccessful.[7] We have examined as well the solid–liquid phase diagram of the system $(n\text{-}C_3H_7)_4NF$+water and concluded that $(n\text{-}C_3H_7)_4NF$ certainly does not form a clathrate hydrate; the phase diagram of this system is shown in Fig. 1. These facts indicate that the stability of the clathrate hydrate of a quaternary ammonium salt depends significantly on the type of its alkyl group.

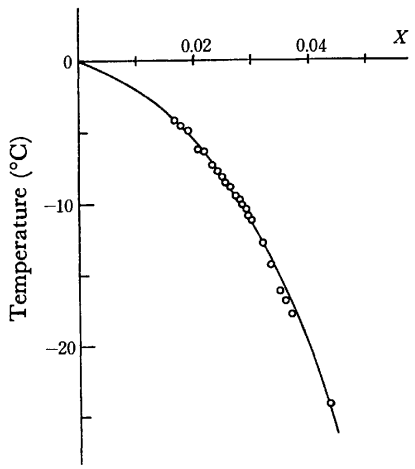

Fig. 1. The solid–liquid phase diagram for the $(n\text{-}C_3H_7)_4NF$+water system; X is the mole fraction of $(n\text{-}C_3H_7)_4NF$.

In order to make this point clearer and, at the same time, to determine what conditions are required for this type of hydrate to be formed (with respect to the length and/or shape of alkyl groups of quaternary ammonium cations), we have examined the formation of hydrates of quaternary ammonium fluorides in which one of the four butyl chains of tetra butylammonium fluoride is substituted for by various kinds of alkyl chains R, *i.e.*, $(n\text{-}C_4H_9)_3RNF$.

Experimental

Alkyltributylammonium iodides (or bromides), $(n\text{-}C_4H_9)_3RNI$ (or Br), were prepared by the quaterization of tributylamine with the appropriate alkyl iodide (or bromide): HI; CH_3I; C_2H_5I; $n\text{-}C_3H_7I$; $i\text{-}C_3H_7I$; $n\text{-}C_4H_9I$; $i\text{-}C_4H_9I$; $n\text{-}C_5H_{11}I$; $i\text{-}C_5H_{11}I$; $n\text{-}C_6H_{13}Br$; $n\text{-}C_7H_{15}Br$; $C_6H_5CH_2Br$. The obtained solid products were recrystallized from ethyl acetate+acetone mixtures and confirmed by the NMR spectra. The aqueous solutions of their fluorides were prepared by the triple decomposition of a mixture of BaF_2, Ag_2SO_4, and the corresponding iodide (or bromide) by using

stoichiometric amounts of the latter two components and an excess of the former.[8] The mixture of the silver salts was removed by filtration.

Each solution (about 5 ml) of a known concentration was sealed in a glass ampoule and was cooled until the solid phase appeared. After being annealed at low temperature for several hours, each ampoule was warmed very slowly in a constant temperature bath with vigorous shaking. By measuring the temperatures, for each ampoule, at which the solid phase disappeared completely, the solid-liquid phase diagram was determined. The differential scanning calorimeter[6] was also employed when the determination of the dissolution temperature was somewhat ambiguous. The water content of each solution was determined by the Karl Fischer titration method.

Results and Discussion

The solid-liquid phase diagrams for the systems water+$(n\text{-}C_4H_9)_3RNF$ with R=H—$n\text{-}C_4H_9$ are shown in Fig. 2, those for the systems water+$(n\text{-}C_4H_9)_3RNF$ with R=$n\text{-}C_5H_{11}$—$n\text{-}C_7H_{15}$, and $C_6H_5CH_2$ are shown in Fig. 3, and those for the systems water+$(n\text{-}C_4H_9)_3$-RNF, with R a branched alkyl group ranging from isopropyl to isopentyl, are shown in Fig. 4. For comparison, the curve for the system water+$(n\text{-}C_4H_9)_4NF$ is also included in Figs. 3 and 4.

As is obvious from these figures, among this series of compounds, the salt $(n\text{-}C_4H_9)_4NF$ forms a hydrate which has the highest melting point, *i.e.*, the most stable hydrate. The melting point and hydration number of this hydrate have been determined to be 28.3 °C and 28.0 (34.1 wt %) respectively. These values are somewhat different from those reported by McMullan and Jeffrey, who reported 24.9±0.1 °C[8] for the melting point and for hydration number 34.0[8] by chemical analysis and 32.8[4] by crystallographic analysis. It is

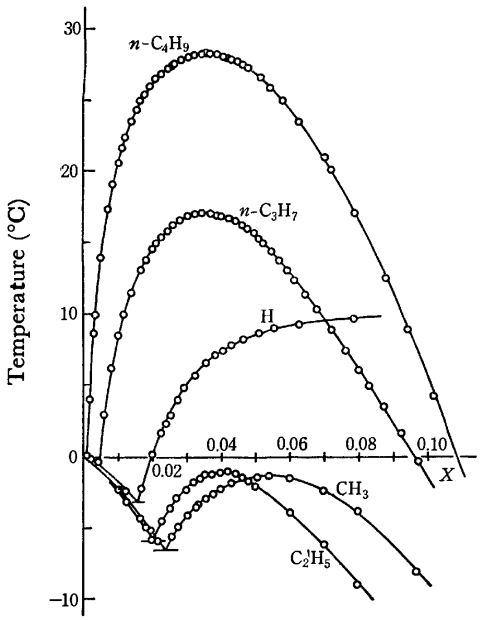

Fig. 2. The solid-liquid phase diagrams for the $(n\text{-}C_4N_9)_3RNF$+water systems; R=H, CH_3, C_2H_5, $n\text{-}C_3H_7$, and $n\text{-}C_4H_9$. X is the mole fraction of the salts.

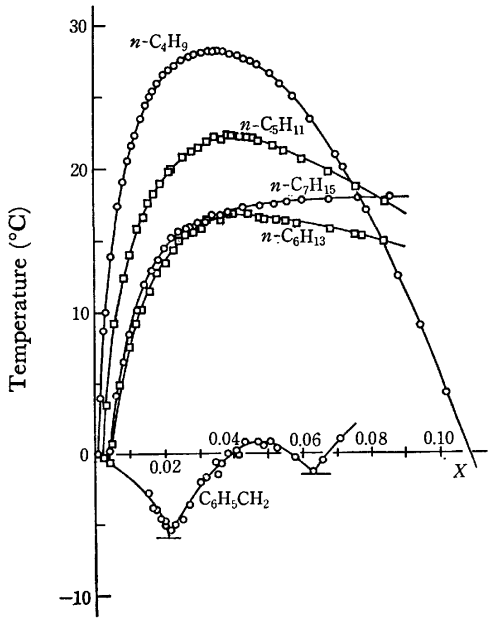

Fig. 3. The solid-liquid phase diagrams for the $(n\text{-}C_4H_9)_3RNF$+water systems; R=$n\text{-}C_4H_9$, $n\text{-}C_5H_{11}$, $n\text{-}C_6H_{13}$, $n\text{-}C_7H_{15}$ and $C_6H_5CH_2$. X is the mole fraction of the salts.

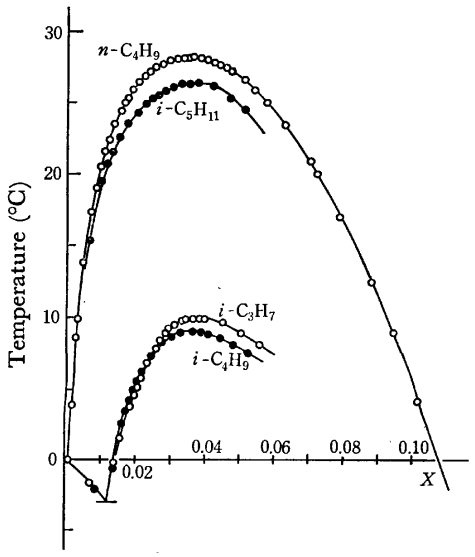

Fig. 4. The solid-liquid phase diagrams for the $(n\text{-}C_4H_9)_3RNF$+water systems; R=$i\text{-}C_3H_7$, $i\text{-}C_4H_9$, $i\text{-}C_5H_{11}$, and $n\text{-}C_4H_9$. X is the mole fraction of the salts.

conceivable that these discrepancies can be attributed to the fact that our values are for the hydrate which is in equilibrium with an aqueous solution of the same composition as that of the hydrate itself. It has been noticed that the composition of the hydrate which is separated from its solution phase and is exposed to the atmosphere varies considerably with time and as a result of this its apparent melting point decreases. Such a property and some other thermodynamic properties of the $(n\text{-}C_4H_9)_4NF$ hydrate are now in under investigation and the results will be published in the near future.

TABLE 1. MELTING POINTS AND HYDRATION NUMBERS OF THE HYDRATES OF TRIBUTYL MONOALKYL AMMONIUM FLUORIDES, $(n\text{-}C_4H_9)_3RNF$

R	Melting point (°C)	Hydration number
CH_3	−1.5	17.5[a)]
C_2H_5	−1.1	26.0
$n\text{-}C_3H_7$	17.1	27.1
$i\text{-}C_3H_7$	10.0	27.6
$n\text{-}C_4H_9$	28.3(24.9[6)])	28.0(32.8[4)]; 34.0[6)])
$i\text{-}C_4H_9$	9.1	28.0
$n\text{-}C_5H_{11}$	22.1	25.4
$i\text{-}C_5H_{11}$	26.4	27.8(32.8[7)])
$C_6H_5CH_2$	1.0	21.5[a)]

a) See text.

Figures 2—4 indicate that $(n\text{-}C_4H_9)_3(C_2H_5)NF$, $(n\text{-}C_4H_9)_3(n\text{-}C_3H_7)NF$, $(n\text{-}C_4H_9)_3(i\text{-}C_3H_7)NF$, $(n\text{-}C_4H_9)_3(i\text{-}C_4H_9)NF$, $(n\text{-}C_4H_9)_3(n\text{-}C_5H_{11})NF$, and $(n\text{-}C_4H_9)_3(i\text{-}C_5H_{11})NF$ can also make hydrates. The melting points and hydration numbers of these hydrates are summarized in Table 1, together with the values reported before. These hydrates are considered to be of the clathrate type since they have hydration numbers similar to that of the $(n\text{-}C_4H_9)_4NF$ hydrate. This indicates the fact that a formation of a clathrate hydrate of quaternary ammonium salts is not limited only to salts containing either butyl or isopentyl chains, though the melting point is very much affected by a change in length and/or shape of the alkyl chain. The formation of the clathrate hydrate of $(n\text{-}C_4H_9)_3(i\text{-}C_5H_{11})NF$ has been known.[7)] However, as in the case of $(n\text{-}C_4H_9)_4NF$ hydrate, there is some difference in hydration number between our value (27.8) and the reported one (32.8 ± 1).[7)] This discrepancy may also be explained, at least partly, by the same reason as given above in connection with the $(n\text{-}C_4H_9)_4NF$ hydrate.

From Table 1, it can be seen that, for the salts whose R is either a propyl or butyl chain, the hydrate of salt having a normal alkyl chain has a higher melting point than that having a branched alkyl chain; on the contrary, in the hydrates of the salts containing a pentyl group, the isopentyl chain can stabilize the hydrate more effectively than the pentyl chain. These results undoubtedly indicate that the most suitable length of an alkyl chain of quaternary ammonium salt for the formation of a clathrate hydrate is C_4-chain (butyl or isopentyl chain).

The solid-liquid equilibrium curves for the systems of water+$(n\text{-}C_4H_9)_3(CH_3)NF$ and water+$(n\text{-}C_4H_9)_3(C_6H_5CH_2)NF$ (Figs. 2 and 3) suggest a formation of hydrates. However, these hydrates do not seem to belong to the same group as the $(n\text{-}C_4H_9)_4NF$ hydrate since the hydration numbers (Table 1) are rather low as compared with that of the $(n\text{-}C_4H_9)_4NF$ hydrate. For the systems $(n\text{-}C_4H_9)_3HNF$+water, $(n\text{-}C_4H_9)_3(n\text{-}C_6H_{13})NF$+water, and $(n\text{-}C_4H_9)_3(n\text{-}C_7H_{15})NF$+water, the formation of hydrates was not recognized. Although the solid-liquid phase equilibrium curve exhibits a slight maximum in the system of $(n\text{-}C_4H_9)_3(n\text{-}C_6H_{13})NF$+water (Fig. 3), it is dubious whether this is due to the formation of a hydrate, since in the solutions whose concentrations are higher than $X=0.04$ (X is the mole fraction of the salt) the appearance of droplets of an oily substance has been observed. This oily substance was identified as tributylamine by means of its NMR spectrum. The same phenomena was also noted in the $(n\text{-}C_4H_9)_3(n\text{-}C_7H_{15})NF$+water system.

In conclusion, it has been found that there is some permitted limit for the length and/or shape of alkyl groups of quaternary ammonium salts if their clathrate hydrates are to be formed. That is, though it seems clear that the most suitable alkyl-chain length for their clathrate-hydrate formation is C_4-chain (butyl or isopentyl chain), other alkyl groups such as propyl, isopropyl, pentyl, and even ethyl, have some ability to make clathrate hydrates.

(Received December 26, 1975)

Properties of aqueous solutions of surfactants, $C_{n-1}H_{2n-1}OCH_2COONa$ ($n-1=12$—18), which may be non-toxic, non-allergic and bio-degradable, have been studied. The Krafft points in aqueous solutions of these surfactants are close (+8.5——1.5 °C) to those of the corresponding fatty acid soaps R_nCOONa. The critical micelle concentrations are also close to those of corresponding fatty acid soaps in spite of the introduction of an oxygen atom in the hydrocarbon chain. A study of the effect of water hardness on the solubility revealed that this type of surfactant is, unlike soap, soluble in town water (hardness 4°) in the presence of equal weight of tripolyphosphate.

The majority of ionic surfactants used nowadays are sodium alkyl or alkylaryl sulfonates or sulfates. Great consumption of such substances is undesirable from the viewpoint of environmental preservation and biological recycling. It is expected that compounds composed solely of carbon, hydrogen and oxygen atoms and whose structures resemble fatty acids or their analogues may be easily bio-degradable, non-toxic and non-allergic. However, fatty acid soaps are insoluble in hard water and scum forms in washing process. Thus, surfactants whose ionic groups are carboxyl and are more soluble in hard water could be of some advantage. The present investigation was undertaken to prepare such compounds and study their physico-chemical properties in aqueous solutions.

Experimental

Materials. $R_{n-1}OCH_2COONa$($R_{n-1}=C_{n-1}H_{2n-1}$; $n-1=12$—18) were synthesized from respective alcohols, $C_{n-1}H_{2n-1}OH$, and sodium chloroacetate. These acids were purified by vacuum distillation and then neutralized. Their melting points and boiling points and purity determined by gas chromatography are summarized in Table 1.

TABLE 1.

Molecular formula	Mp °C	Bp °C	Purity
$R_{12}OCH_2COOH$	46.0	147(0.06 mmHg)	99.8
$R_{14}OCH_2COOH$	56.2	150(0.025 mmHg)	99.4
$R_{16}OCH_2COOH$	64.3	176(0.025 mmHg)	99.8
$R_{18}OCH_2COOH$	70.8	208.5(0.023 mmHg)	99.2

Procedure. The critical micelle concentration (CMC) was determined by electrical conductivity measurements. The Krafft point was determined from the change in solubility with temperature.[1] It was also confirmed from the color change of pinacyanol chloride since the solubility and the cmc agree at the Krafft point.

Results and Discussion

Critical Micelle Concentration (CMC). The CMC values determined from electrical conductivity *vs.* concentration curves are summarized in Table 2.

TABLE 2.

Molecular formula	CMC mmol/l	Krafft point (°C)
$R_{12}OCH_2COONa$	7.5(55.0 °C)	42
$R_{14}OCH_2COONa$	2.2(64.9 °C)	49
$R_{16}OCH_2COONa$	0.73(75.1 °C)	56
$R_{18}OCH_2COONa$	0.40(75.5 °C)	62

The CMC values of the corresponding fatty acid soaps, R_nCOONa, are close to those of $R_{n-1}OCH_2COONa$. Insertion of oxygen atom in the hydrocarbon chain has little effect on the CMC. Klevens empirically found that the logarithms of the CMC values and the fatal lengths of surfactant molecules from the terminal carbon atom to the atom carrying the charge change linearly.[2] The relation fortuitously holds in several ordinary ionic surfactants. It is evident, however, that the relation will not hold in the case of $C_nH_{2n+1}O(CH_2CH_2O)_mSO_3Me$,[3-5] since the CMC is determined by the free energy change of respective groups at micellization.[6] The ether oxgen atom in R_nOCH_2COONa might increase the hydrophilic property of this surfactant on one hand, but the water and gegenions distributed around polar groups might depress the electrical repulsion on the

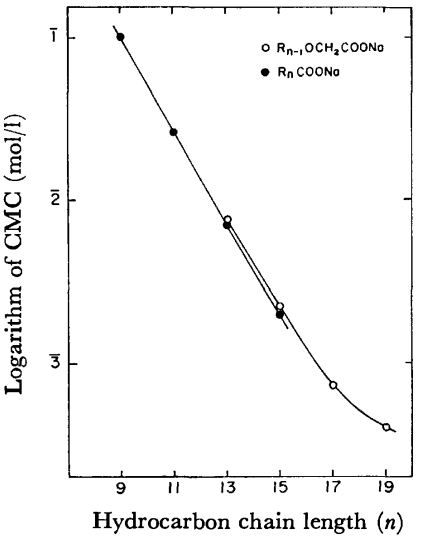

Fig. 1. The CMC values of $R_{n-1}OCH_2COONa$ and R_nCOONa as a function of hydrocarbon chain length of respective surfactants. The CMC values have been determined slightly above respective Krafft points.

other hand. A comparison of the CMC values of these surfactants with those of fatty acid soaps as a function of hydrocarbon chain length is shown in Fig. 1.[2] Since the change in CMC value with temperature is relatively small over 20—70 °C,[7,8] the CMC values slightly above the Krafft points were plotted.

The logarithms of the CMC values decrease linearly up to 15 carbon atoms, but the slope *vs.* hydrocarbon chain length gradually decreases above 17 carbon atoms. The CMC values as a function of hydrocarbon chain length are expressed as follows:

$$\ln \mathrm{CMC} = -\frac{1}{1+K_g}\frac{m\omega}{kT} - K_0 \qquad (1)$$

where ω is the free energy increase transferring one methylene group from the interior of micelle to aqueous environment, K_g a constant obtained from the change of CMC with the concentration of gegenions, m the number of carbon atoms in hydrocarbon chain and K_0 the experimental constant.[9]

Krafft Point. The Krafft point was determined from the change of solubility of $R_{n-1}OCH_2COONa$ with temperature and the CMC value (Fig. 2).

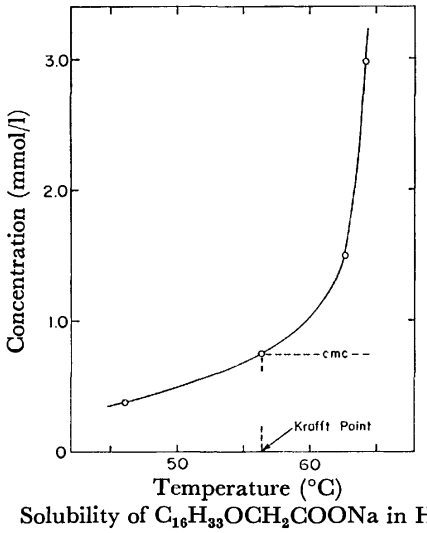

Fig. 2. The change of solubility of $C_{16}H_{33}OCH_2COONa$ in water with temperature and the Krafft point.

The results are summarized in Table 2. The Krafft point is a temperature at which hydrated solid surfactant melts.[1] Thus the Krafft points and melting points of corresponding acids are closely related. The relation is plotted in Fig. 3.

Krafft points of fatty acid soaps are about 20 °C lower than those of the corresponding fatty acids, whereas the Krafft point of $R_{n-1}OCH_2COONa$ is not so low compared with the melting points of $R_{n-1}OCH_2COOH$. The melting points of $R_{n-1}OCH_2COOH$ are merely 3—8 °C lower than those of $R_{n-1}CH_2COOH$. It is evident that the insertion of oxygen atom in the hydrocarbon chain neither depresses the Krafft points nor increases the CMC values. However, the Krafft point of $R_{12}(OCH_2CH_2)OCH_2COONa$ is below 0 °C.

The Change of Krafft Point of $R_{n-1}OCH_2COONa$ as a Function of Water Hardness. Ordinary soaps are salted out by the addition of a very small amount of

multi-valent cations. In the case of $R_{n-1}OCH_2COONa$, however, the Krafft point is gradually enhanced with added calcium chloride, particularly in the presence of the chelating agent, tripolyphosphate. The results are plotted in Fig. 4 as a function of the water hardness.

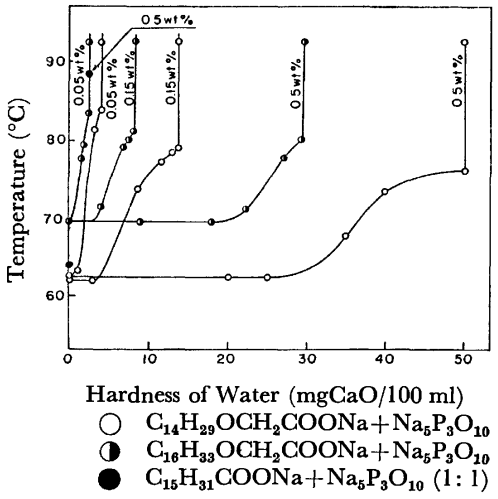

Fig. 4. The change of Krafft point as a function of the concentration of calcium chloride (water hardness).

The solubility gradually decreases with time, because the tripolyphosphate slowly becoming degraded. Since the solutions contained the same weight of tripolyphosphate and surfactants, concentrated solutions were less sensitive to the calcium ions added. Surfactants are usually used at about 0.05 wt % and contain roughly the same weight of tripolyphosphate. It is clear from Fig. 4 that 0.05 wt % solutions of $R_{14}OCH_2COONa$ and $R_{16}OCH_2COONa$ are durable up to about 4° and 2.5°, respectively. Whereas 0.05 wt % $R_{15}COONa$ in the presence of equal weight of tripolyphosphate was salted out at the hardness of 0.3°.

The authors express their sincere thanks to Dr. K. Nagase of Kao-Soap Co. for the synthesis and purification of $R_{n-1}OCH_2COOH$, and to Mr. M. Tahara for the experiments on added salts.
