Photolyses of I in Cyclic Ethers. A solution of 5.0 g (0.043 mol) of ethyl azidoformate in 0.5 mol of a cyclic ether was irradiated, with stirring and cooling at 0 °C, by a low-pressure mercury lamp (internal-irradiation type) until the evolution of nitrogen was not observed. The nitrogen evolved then gave almost the theoretical amount based on the azide used. The excess substrate was removed by distillation at 25—75 °C under 25—30 mmHg pressure. The residue was analyzed by VPC on Columns A and B. Urethane (VI) had IR and NMR spectra and a VPC retention time identical with those of authentic VI, and a mixed melting point with the authentic sample was undepressed. Ethyl hydrazoformate (VII) was obtained in the yields of 0.02—0.08 g from every experiment; mp 132 °C,[29] IR (Nujol, cm^{-1}): 3240 (NH), 1754 and 1693 (C=O), 1260 (C–O). NMR ($CDCl_3$, τ): 3.24 (NH, 2H, s), 5.80 (CH_2, 4H, q), 8.73 (CH_3, 6H, t). Found: C, 40.96; H, 6.73; N, 15.98%. Calcd for $C_6H_{12}O_4N_2$: C, 40.90; H, 6.87; N, 15.90%. The spectral data of IR and NMR, and elemental analyses of unsaturated *N*-alkoxyurethanes (V) are presented in Table 4.

(a) In Propylene Oxide (IIIa), 1,2-Epoxybutane (IIIb), and 2-Methyloxetane (IIId): *N*-Allyloxyurethane (Va, 1.3 g), *N*-2-

Table 4. NMR and IR data, and analyses of V

V	NMR (τ) in CCl_4	IR (neat, cm^{-1}) NH	IR (neat, cm^{-1}) C=O	IR (neat, cm^{-1}) C–O	Formula		Analyses C%	Analyses H%	Analyses N%

butenyloxyurethane (Vb, 0.9 g), and *N*-3-butenyloxyurethane (Vd, 1.9 g) were isolated.

(b) In Tetrahydrofuran (IIIe): Ethyl 2-tetrahydrofurylcarbamate (IVe, 1.7 g) was isolated. IVe: IR (neat, cm^{-1}): 3300 (NH), 1705 (C=O), 1260 (C–O). NMR (CCl_4, τ): 4.00 (NH, bs), 4.4—4.8 (ring-CH, m), 5.94 (ester-CH_2, q), 6.0—6.5 (ring δ-CH_2, m), 7.7—8.5 (ring β- and γ-CH_2, 4H, m), 8.83 (ester-CH_3, t).[30] Found: C, 52.63; H, 8.45; N, 8.70%. Calcd for $C_7H_{13}O_3N$: C, 52.81; H, 8.23; N, 8.80%.

(c) In 2-Methyltetrahydrofuran (IIIf): Ethyl 2-methyl-2-tetrahydrofurylcarbamate (IVf, 0.29 g) and *N*-4-pentenyloxyurethane (Vf, 0.52 g) were isolated. IVf: IR (neat, cm^{-1}): 3310 (NH), 1760 (C=O), 1258(C–O). NMR (CCl_4, τ): 4.50 (NH, bs), 5.6-6.2 (ring δ-CH_2, m), 5.87 (ester-CH_2, q), 7.5—8.5 (ring β- and γ-CH_2, 4H, m), 8.76 (ester-CH_3, t), 8.80 (α-CH_3, s). Found: C, 55.03; H, 9.04; N, 8.21%. Calcd for $C_8H_{15}O_3N$: C, 55.47; H, 8.73; N, 8.09%.

(d) In Tetrahydropyran (IIIg): Ethyl 2-tetrahydropyranylcarbamate (IVg_1, 1.9 g) and ethyl 3-tetrahydropyranylcarbamate (IVg_2, 0.37 g) were isolated. IVg_1: IR (neat, cm^{-1}): 3300 (NH), 1710 (C=O), 1250 (C–O). NMR (CCl_4, τ): 4.00 (NH, bs), 5.16 (C_2-methine, 1H, bt), 5.86 (ester-CH_2, q), 6.0—6.6 (C_6-methylene, 2H, m), 8.0—8.9 (C_3-, C_4-, and C_5-methylene, 6H, m), 8.76 (ester-CH_3, t).[30] Found: C, 55.01; H, 9.15; N, 8.06%. Calcd for $C_8H_{15}O_3N$: C, 55.47; H, 8.73; N, 8.09%. IVg_2: IR (neat, cm^{-1}): 3300 (NH), 1700 (C=O), 1250 (C–O). NMR (CCl_4, τ): 4.65 (NH, bs), 5.88 (ester-CH_2, q), 6.0—6.6 (C_2- and C_6-methylene, 4H, m), 6.7—6.9 (C_3-methine, m), 8.0—8.9 (C_4- and C_5-methylene, 4H, m), 8.77 (ester-CH_3, t). Found: C, 54.92; H, 9.16; N, 8.19%. Calcd for $C_8H_{15}O_3N$: C, 55.47; H, 8.73; N, 8.09%.

(e) In cis-2,5-Dimethyltetrahydrofuran (IIIh): Ethyl *cis*-2,5-dimethyl-2-tetrahydrofurylcarbamate (IVh_1, 0.64 g) and ethyl *trans*-2,5-dimethyl-2-tetrahydrofurylcarbamate (IVh_2, 1.0 g) were isolated. IVh_1: IR (neat, cm^{-1}): 3300 (NH), 1710 (C=O), 1265 (C–O). NMR (CCl_4, τ): 5.25 (NH, bs), 6.00 (ester-CH_2, q), 5.55—6.25 (ring α-CH, m), 7.22—8.42 (ring β- and γ-CH_2, 4H, m), 8.50 (δ-CH_3, s), 8.75 (α-CH_3, d), 8.85 (ester-CH_3, t). Found: C, 57.50; H, 9.27; N, 7.60%. Calcd for $C_9H_{17}O_3N$: C, 57.73; H, 9.15; N, 7.48%. IVh_2: IR (neat, cm^{-1}): 3290 (NH), 1705 (C=O), 1260 (C–O). NMR (CCl_4, τ): 5.05 (NH, bs), 6.00 (ester-CH_2, q), 5.5—6.2 (ring α-CH, m), 7.22—8.38 (ring β- and γ-CH_2, 4H, m), 8.50 (δ-CH_3, s), 8.85 (α-CH_3, d), 8.77 (ester-CH_3, t). Found: C, 57.57; H, 9.10; N, 7.56%. Calcd for $C_9H_{17}O_3N$: C, 57.73; H, 9.15; N, 7.48%.

(f) In trans-*2,5-Dimethyltetrahydrofuran (IIIi)*: IVh_1 (0.64 g), IVh_2 (0.88 g), and *N*-(1-methyl-4-pentenyloxy)urethane (Vh, 0.96 g) were isolated.

(g) In a Mixture of IIIh and IIIi: IVh_1 (0.88 g), IVh_2 (1.2 g), and Vh (0.64 g) were isolated.

Photolysis of Methyl Azidoformate. A solution of 4.4 g (0.043 mol) of methyl azidoformate in 0.5 mol of *cis*-2,5-dimethyltetrahydrofuran (IIIh) was irradiated in the same manner as in the case of ethyl azidoformate. Methyl *cis*-2,5-dimethyl-2-tetrahydrofurylcarbamate (IVj_1), methyl *trans*-2,5-dimethyl-2-tetrahydrofurylcarbamate (IVj_2), and methyl carbamate were thus isolated in the yields of 0.52 g, 0.90 g, and 1.7 g respectively. IVj_1: IR (neat, cm^{-1}): 3290 (NH), 1710 (C=O), 1265 (C–O). NMR (CCl_4, τ): 4.90 (NH, bs), 5.55—6.12 (ring α-CH, m), 6.42 (ester-CH_3, s), 7.20—8.60 (ring β- and γ-CH_2, 4H, m), 8.51 (δ-CH_3, s), 8.74 (α-CH_3, d). Found: C, 55.52; H, 8.66; N, 8.10%. Calcd for $C_8H_{15}O_3N$: C, 55.47; H, 8.73; N, 8.09%. IVj_2: IR (neat, cm^{-1}): 3300 (NH), 1715 (C=O), 1270 (C–O). NMR (CCl_4, τ): 4.90 (NH, bs), 5.55—6.12 (ring α-CH, m), 6.42 (ester-CH_3, s), 7.20—8.60 (ring β- and γ-CH_2, m), 8.51 (δ-CH_3, s), 8.83 (α-CH_3, d). Found: C, 55.58; H, 8.66; N, 8.18%. Calcd for $C_8H_{15}O_3N$: C, 55.47; H, 8.73; N, 8.09%. Methyl carbamate was identified by comparing its VPC retention time and IR and NMR spectra with those of the authentic sample. No photochemical mutual isomerization between *cis* and *trans* isomers of the insertion products was observed under the conditions of these experiments.

Photolysis of I in a Mixture of a Cyclic Ether and Cyclohexane. A solution of I (5.0 g, 0.043 mol) in III (0.25 mol) and a cyclohexane (21 g, 0.25 mol) mixture was irradiated internally as has been described above. The excess of the substrate was removed by distillation, and the residue was analyzed by VPC. The *N*-cyclohexylurethane was identified by comparison with the authentic sample. The yields of the insertion products and urethane are displayed in Table 2.

The authors are particularly indebted to Dr. Hisao Arakawa for his help in the preparation of this paper and for his many useful suggestion for its improvement.

Dehydroaunulenes. VI. Synthesis and Properties of 1,6,12,17-Tetraphenyl-2,4,13,15-tetrakisdehydro[22]annulene

Shuzo AKIYAMA, Tateo NOMOTO, Masahiko IYODA, and Masazumi NAKAGAWA*

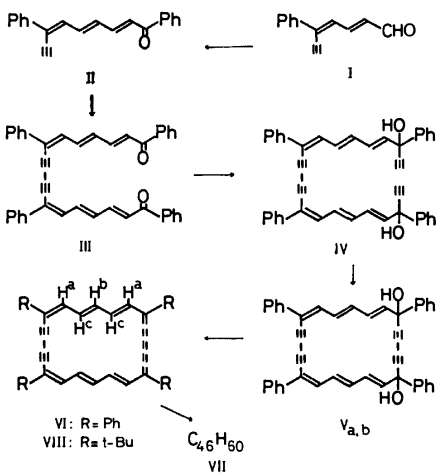
(Received April 23, 1976)

1,6,12,17-Tetraphenyl-2,4,13,15-tetrakisdehydro[22]annulene has been synthesized. The sparlingly soluble tetrakisdehydro[22]annulene was found to be conformationally stable and strongly diatropic.

As reported in previous papers of this series, interesting difference has been observed between the properties of tetra-*t*-butyl-[1] and tetraphenyltetrakisdehydro[18]annulenes.[2] The successful synthesis of tetra-*t*-butyltetrakisdehydro[22]annulene (VIII)[3] prompted us to synthesize tetraphenyltetrakisdehydro[22]annulene (VI) with the purpose to compare their properties.

The aldol condensation of 5-phenyl-2,4-heptadien-6-ynal (I)[4] with acetophenone gave II in a high yield. Oxidative coupling of II with copper(II) acetate in pyridine–methanol yielded diketone (III) as red crystals in an almost quantitative yield. Bis-ethynylation of III could be achieved by lithium acetylide–ethylenediamine complex.[5] Bis-ethynyl alcohol (IV) obtained as yellow fine crystals was oxidatively coupled under high dilution conditions to yield cyclic glycol (V) which could be separated into diastereomers. It was found that V forms containing 1 mol of ethyl acetate as a solvent of crystallization. Formation of similar adducts has been observed in some acyclic[6] and cyclic acetylene glycols.[7]



Scheme 1.

A solution of V in dichloromethane was mixed at −15 °C with a solution of tin(II) chloride dihydrate in concentrated hydrochloric acid. Tetrakisdehydro[22]-annulene (VI) was obtained as unstable and sparlingly soluble black violet crystals. Full hydrogenation of VI over platinum catalyst yielded a mixture of stereoisomers of a saturated hydrocarbon, tetraphenylcyclodocosane (VII). The tetrakisdehydro[22]annulene (VI) forms air sensitive CT-complex with 2,4,7-trinitrofluorenone.

Electronic spectrum of VI consists of three main absorption bands showing characteristic feature of [4*n*+2]annulenes as illustrated in Fig. 1. The spectrum of VI was found to be closely related with that of tetra-*t*-butyltetrakisdehydro[22]annulene (VIII)[3] although VI showed remarkable bathochromic shift.

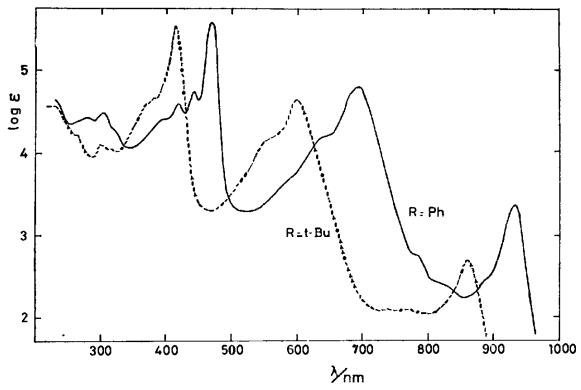


Fig. 1. Electronic spectra of tetra-*t*-butyltetrakisdehydro[22]annulene (VIII) (···) and tetraphenyltetrakisdehydro[22]annulene (VI) (—) in THF.

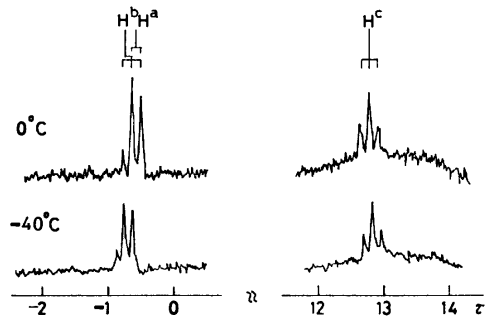

Fig. 2. 100 MH ^{1}H FT-NMR spectra of tetraphenyltetrakisdehydro[22]annulene (VI) in THF-d_8.

The ^{1}H FT-NMR spectra of VI indicate clearly that the tetrakisdehydro[22]annulene (VI) is strongly diatropic showing outer proton signals at a low-field and those of inner protons at fairly high-field (Fig. 2). The NMR parameters of VI are summarized in Table 1 together with those of VIII for comparison. The NMR spectra were essentially temperature independent indicating high conformational stability of the tetrakisdehydro[22]-annulene ring. Appreciable down-field shift for both of the inner and outer proton signals of VI as compared with those of VIII seems to be attributable to deshielding effect of ring current of phenyl groups. Inversely, down-field shift of *ortho*-protons in phenyl groups reflects deshielding effect of diamagnetic ring current induced in the 22-membered ring.

Table 1. 100 MHz H^1 FT-NMR parameters of VI (in THF-d_8) and VIII (in $CDCl_3$) τ-Values, J in Hz.

	VI		VIII
	−40 °C	0 °C	−40 °C
H^b	−0.79 t	−0.62 t	−0.43 t
	J=14	J=14	J=13
H^a	−0.72 d	−0.55 d	0.09 d
	J=14	J=14	J=13
o-H of Ph	0.93 d	1.04 d	
	J=8	J=8	
m,p-H of Ph	2—2.5m	2—2.5m	
H^c	12.80 t	12.76 t	13.71 t
	J=14	J=14	J=13

It was found that VI is less stable and less soluble than the tetra-*t*-butyl analogue (VIII). Remarkable bathochromic shift of electronic spectrum of VI as compared with that of VIII indicates that phenyl groups exert larger electronic perturbation on the dehydroannulene system than *t*-butyl groups. These facts are the further support for the suitable nature of *t*-butyl group as substituent[1] in the study of aromaticity of dehydroannulene system.

Experimental

All melting and boiling points are not corrected. The IR spectra were obtained on a Hitachi EPI-2 or EPI-3G spectrometer. The electronic spectra, measured with a Hitachi-EPS-3T spectrophotometer, were recorded in nm and the ε-values were given in parentheses. Shoulder was denoted by sh. The mass spectra were obtained on a Hitachi RM-50 spectrometer. The ^1H NMR spectra obtained on a Varian XL-100 spectrometer were given in τ-values with respect to TMS as an internal standard, and the coupling constants (J) are recorded in Hz. Silica gel (Merck, Kiesel Gel 60) or alumina (Merck, Act. II—III) was used for column chromatography, unless otherwise stated.

1,7-Diphenyl-2,4,6-nonatrien-8-yn-1-one (II). A solution of sodium hydroxide (0.26 g, 6.6 mmol) in 50% aqueous ethanol (4 ml) was added to a stirred and ice-cooled mixture of I (1.20 g, 6.6 mmol), acetophenone (0.79 g, 6.6 mmol) and ethanol (15 ml). After the mixture had been stirred for 2 h, yellow crystals deposited were collected and washed successively with water, methanol and water to give fairly pure II: mp 92—95 °C; IR (CCl_4): 3300 (C≡CH), 1600 (C=C), 1015, 1000 (*trans* CH=CH) cm^{-1}; NMR (CCl_4): 6.38 (s, 1, C≡CH), 2.52 (m, 15, olefinic and aromatic).

Found: C, 88.49; H, 5.72%. Calcd for $C_{21}H_{16}O$: C, 88.70; H, 5.67%.

1,7,12,18-Tetraphenyl-2,4,6,12,14,16-octadecahexaen-8,10-diyn-1,18-dione (III). A solution of II (7.00 g, 0.025 mol) in pyridine (70 ml) and methanol (70 ml) was added over 30 min period to a solution of copper(II) acetate monohydrate (14.5 g) in pyridine (70 ml) and methanol (70 ml) at room-temperature. After being stirred for 3 h, reddish orange crystals deposited were collected and washed with water and methanol. Slightly crude III (mp 210—214 °C, 6.92 g, 99%) was dissolved in benzene and passed through a short column of alumina. Concentration of the filtrate under reduced pressure yielded pure III: red crystals; mp 213—216 °C; IR (KBr-disk): 1640 (C=O), 1590, 1580, 1565 (C=C and aromatic), 1010, 1000 (*trans* CH=CH) cm^{-1}.

Found: C, 88.98; H, 5.29%. Calcd for $C_{42}H_{30}O_2$: C, 89.05; H, 5.30%.

3,9,14,20-Tetraphenyl-4,6,8,14,16,18-docosahexaen-1,10,12,21-tetrayn-3,30-diol (IV). Lithium acetylide–ethylenediamine complex[5] (6.5 g, 0.07 mol) was added to THF (100 ml) saturated with acetylene. A solution of II (1.00 g, 1.77 mmol) in the same solvent (500 ml) was added to the mixture over 2 h-period under slow bubbling of acetylene, and saturated ammonium chloride solution (30 ml) was added to the reaction mixture under cooling in an ice-salt-bath. The aqueous layer was extracted with ether, and the extract was combined with the organic layer. The combined organic layer was washed successively with saturated ammonium chloride and sodium chloride solutions, and dried ($MgSO_4$). Brown crystalline powder obtained on concentration of the organic layer was dissolved in benzene and chromatographed on alumina (20 g). Elution with ether–benzene (1:9—2:8) yielded acyclic glycol, IV: yellow crystalline solid (attempts to recrystallize this material were failed); mp 84—86 °C; 0.69 g, 63%; NMR (CCl_4): 7.65 (s, 1, OH), 7.28 (s, 1, C≡CH), 4.23—3.03 (m, 5, olefinic), 2.78 (m, 6, *m,p*-H of phenyl), 2.48 (m, 4, *o*-H of phenyl).

Found: C, 88.84; H, 5.78%. Calcd for $C_{46}H_{34}O_2$: C, 89.29; H, 5.54%.

1,6,12,17-Tetraphenyl-8,9,11,17,19,21-cyclodocosahexaen-2,4,13,-15-tetrayn-1,6-diol (V). To a stirred and refluxing solution of copper(II) acetate monohydrate (2.5 g) in pyridine (200 ml), ether (200 ml) and methanol (100 ml) was added a solution of IV (0.95 g, 1.54 mmol) in pyridine (115 ml), ether (115 ml) and methanol (50 ml) over 7.5 h-period using a high dilution apparatus. After being refluxed for further 30 min, the reaction mixture was stirred overnight at a room-temperature. The mixture was concentrated to 1/2 volume under reduced pressure, and the concentrate was extracted with ether (300 ml). The extract was washed successively with chilled water, diluted hydrochloric acid and brine, and dried (Na_2SO_4). Evaporation of the solvent under reduced pressure gave crude cyclic glycol, V (brown crystalline powder). The oxidative coupling was repeated 3 times under the same reaction conditions using the same quantity of materials. Crude (total 2.33 g, 83%), thus obtained, was dissolved in benzene (20 ml). Crystals deposited on standing the benzene solution were collected and washed with benzene–hexane to give one diastereomer of the cyclic glycol, V_a (yellow tiny cubes, 0.52 g, 18%). Recrystallization of the crystals from ethyl acetate yielded V_a containing 1 mol of the solvent: mp *ca.* 200 °C (dec); IR (KBr-disk): 3700—3100 (OH), 2190 (C≡C), 1715 (C=O), 990 (*trans* CH=CH) cm^{-1}; UV (THF): λ_{max} 254.5 (29700), 262 (29800), 280 (17200), 348 (107000), 394 (13500), 416 (17500), 441 (16800) nm; NMR (acetone-d_6): 2.0—4.1 (m, 30, olefinic and aromatic), 4.45 (s, 2, OH), 5.95 (q, 2, CH_2), 8.03 (s, 3, CH_3CO), 8.79 (t, 3, CH_3).

Found: C, 85.29; H, 5.74%. Calcd for $C_{46}H_{32}O_2 \cdot CH_3COOC_2H_5$: C, 85.20; H, 5.72%.

The mother liquor obtained on filtrating the crude V_a was chromatographed on alumina (100 g). The other diastereomer of the cyclic glycol, V_b (light brown crystalline powder, 0.68 g, 24%) was obtained on elution with ether–benzene (4:6), which was recrystallized from benzene–hexane to give pure V_b: yellow needles; mp *ca.* 200 °C (dec); IR (KBr-disk): 3700—3100 (OH), 2190 (C≡C), 990 (*trans* CH=CH) cm^{-1}; UV(THF): λ_{max} 254.5 (27000), 262 (26300), 280 (14900), 348 (98600), 394 (12400), 416 (15900), 441 (15400) nm; NMR (acetone-d_6): 2.0—4.1 (m, 30, olefinic and aromatic), 4.42 (s, 2, OH).

Found: C, 89.57; H, 5.58%. Calcd for $C_{46}H_{32}O_2$: C,

89.34; H, 5.65%.

1,6,12,17-Tetraphenyl-2,4,13,15-tetrakisdehydro[22]annulene (VI). A solution of tin(II) chloride dihydrate (0.1 g, 4 mmol) in concentrated hydrochloric acid (2 ml) was added in one portion to a stirred and chilled (−15 °C) solution of V_b (10 mg, 0.016 mmol) in dichloromethane (80 ml). After 3 min, ice-water was added to the reaction mixture. Resulting dark green organic layer was washed successively with cold water, diluted sodium hydrogen carbonate solution and cold water, and dried (K_2CO_3). The organic layer was passed through a short column of alumina (5 g). Evaporation of the solvent under reduced pressure at low temperature yielded VI: unstable deep violet fine crystals; 8.5 mg, 90%; UV (THF): λ_{max} 290 (25800), 305.5 (29600), 400 (24200), 419 (38200), 442 (54700), 469 (363000), 682 (59500), 942 (2300) nm; NMR: see, Table 1 and Fig. 2.

Owing to unstable nature of VI, elemental analyses gave unsatisfactory results.

V_a containing 1 mol of ethyl acetate also gave VI in a high yield under the same reaction conditions.

CT-Complex of VI with 2,4,7-Trinitrofluorenone. A solution of VI in cold dichloromethane was mixed with a large excess of a solution of 2,4,7-trinitrofluorenone in the same solvent. Dark green fine needles were obtained on standing the mixture at 0 °C for 1 h. Elemental analyses gave no definite results, presumably owing to the sensitivity of the complex to atmospheric oxygen.

Catalytic Hydrogenation of VI. V_b (0.30 g, 0.049 mmol) was converted into VI according to the above procedure. Freshly obtained VI in THF (5 ml) was added to ethyl acetate (100 ml) containing platinum oxide catalyst (0.10 g), and the mixture was vigorously stirred under hydrogen atmosphere at −15 °C for 5 h. Resulting colorless solution was concentrated under reduced pressure to give colorless crystalline material (0.025 g, 84% based on V_b), which was dissolved in hexane and passed through a short column of alumina (Woelm, W200). Crystals obtained on concentration of the filtrate under reduced pressure were recrystallized from pentane–hexane to give VII: colorless rods; mp 108—117 °C; NMR (CD_2Cl_2): 2.6—3.0 (m, 20, aromatic), 7.3—7.6 (m, 4, CH), 8.1—9.0 (m, 36, CH_2).

Found: C, 89.88; H, 9.84%, M^+ 612. Calcd for $C_{46}H_{60}$: C, 90.13; H, 9.87%, Mol. wt, 612.

The Reaction of Arylthallium(III) Compounds with Metal Nitrite. Synthesis of Nitroarenes.[1]

Sakae UEMURA,* Akio TOSHIMITSU, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

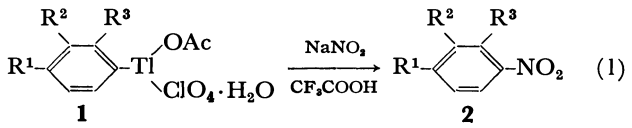
(Received April 23, 1976)

Arylthallium(III) compounds react smoothly with various metal nitrites such as $NaNO_2$, KNO_2, and $AgNO_2$ in trifluoroacetic acid to give nitroarenes in good yields. It has been clarified that the reaction proceeds through substitution of thallium moiety by nitroso group at the (*ipso*) position where thallium was attached previously to aromatic ring to give nitrosoarenes, followed by their oxidation to nitroarenes.

Recently Davies and Thomas reported a facile nitrodethallation of arylthallium(III) compounds by nitrogen dioxide which can be used for selective introduction of a nitro group into aromatic substrates.[2] In the course of our studies on the substitution of thallium moiety in arylthallium(III) compounds by halogen or pseudohalogen[3] we found that a similar nitrodethallation also occurred readily by use of metal nitrite through a different reaction scheme from that by nitrogen dioxide. This reaction may be useful as an alternative method for selective nitration of arenes.

Results and Discussion

When a mixture of *p*-tolylthallium(III) compound (**1**, R^1=Me, R^2=R^3=H) and sodium nitrite was stirred in trifluoroacetic acid at room temperature for 3 h, *p*-nitrotoluene (**2**, R^1=Me, R^2=R^3=H) was obtained almost quantitatively (Scheme 1). No formation of *m*- and *o*-



(1)

nitrotoluene shows that the replacement of thallium moiety by NO_2 occurred at the position where thallium was attached previously to aromatic ring. The reaction also took place in other organic acids such as chloroacetic acid and acetic acid, but it was slower and the yield of *p*-nitrotoluene was lower than that in trifluoroacetic acid, a side-product sometimes being formed. Almost no reaction occurred in organic solvents such as pyridine, dioxane, DMF, and acetonitrile even at refluxing temperature in which halogeno- and pseudohalogenodethallation proceeded smoothly.[3] It was found that the yield of *p*-nitrotoluene is affected by concentrations of both **1** and $NaNO_2$ in trifluoroacetic acid, lower concentration being preferable for higher yield of *p*-nitrotoluene. Other metal nitrites such as $AgNO_2$ and KNO_2 were also effective for this reaction. Typical results are summarized in Table 1.

Application of the reaction to other **1** such as *o*- and *m*-xylyl- and *p*-anisylthallium(III) compounds also afforded readily almost quantitative yield of **2**. In the case of phenyl- and chlorophenylthallium(III) compounds, however, the yield of **2** was low and considerable amounts of nitrosoarene and resinous products were formed. When potassium dichromate was added in

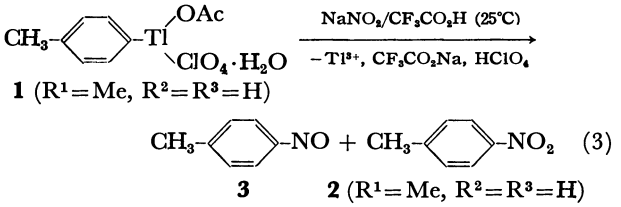
these reaction systems, the yield of **2** increased, no nitrosoarene being detected. The results are given in Table 2. The nitrodethallation procedure is applicable even without the isolation of intermediate arylthallium-(III) compounds. As an example, nitroarenes could be obtained (*in situ* nitrodethallation) when the reaction was carried out at 25 °C for 3 h by adding sodium nitrite to trifluoroacetic acid solution of arylthallium-(III) compound prepared by the method[4] of McKillop *et al.* The yields and isomer ratios of some nitroarenes are as follows ($K_2Cr_2O_7$ was also added in the case of halobenzene): toluene (87%, *o*: *m*: *p*=13: 1: 86), *t*-butylbenzene (92%, *o*: *m*: *p*=2: 6: 92), *o*-xylene (90%, 3-: 4-=7: 93), *m*-xylene (100%, only 4-), mesitylene (27%), biphenyl (mononitro- 47%, dinitro-53%), chlorobenzene (50%, *o*: *p*=19: 81) and bromobenzene (34%, *o*: *p*=19: 81). These isomer ratios should reflect those of intermediate arylthallium(III) compounds.

Metal nitrite reacts with various organic and inorganic acids to give nitrous acid (HNO_2). This gives NO^+ or N_2O_3 in acidic media, the latter being known as a carrier of nitrosyl ion (Scheme 2).[5a,b]

$$\begin{aligned} &NaNO_2 + CF_3COOH \rightleftarrows \\ &\qquad HNO_2 + CF_3CO_2Na \\ &2HNO_2 \rightleftarrows N_2O_3 + H_2O \\ &HNO_2 + H^+ \rightleftarrows NO^+ + H_2O \end{aligned} \quad (2)$$

The presence of nitrosyl ion in trifluoroacetic acid has been shown by cryoscopic experiments and spectral data.[6] From these facts and the reported data for electrophilic nitrosodethallation of arylthallium(III) compounds with nitrosyl chloride (NOCl),[7] nitrosoarenes should be expected as the intermediates in our case. In fact, nitrosoarenes were detected in the reaction products in the cases of phenyl- and chlorophenylthallium(III) compounds. For the sake of clarification we investigated the reaction products and their yields in the nitrodethallation of **1** (R^1=Me, R^2=R^3=H). It was found that when the reaction is stopped in a very short time, *p*-nitrosotoluene (**3**) is mainly formed together with a small amount of *p*-nitrotoluene (Scheme 3). The yield of each product



1 (R^1=Me, R^2=R^3=H)

3 **2** (R^1=Me, R^2=R^3=H) (3)

is plotted against reaction time in Fig. 1. It is seen that the reaction is consecutive involving the conversion of **3** into **2** (R^1=Me, R^2=R^3=H). In order to know how **3** can be converted into **2** (R^1=Me, R^2=R^3=H), the oxidation of **3** prepared separately by the reported method[8] to **2** (R^1=Me, R^2=R^3=H) was examined under various conditions (Table 3). The oxidation of **3** to **2** (R^1=Me, R^2=R^3=H) was rather slow in trifluoroacetic acid containing sodium nitrite, but the addition of thallium(III) salt and perchloric acid, both of which are expected to be formed in the reaction shown in Scheme 3, enhanced the rate remarkably.

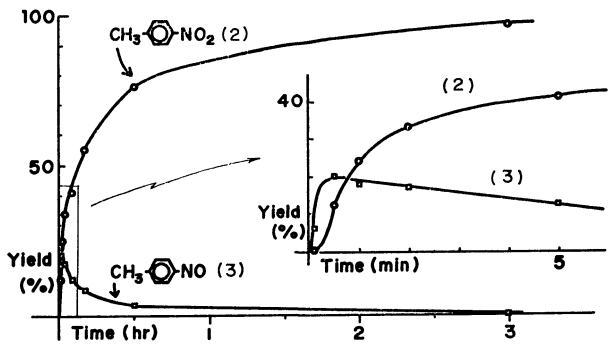


Fig. 1. Effect of reaction time on product and yield in the reaction of Scheme 3. Reaction conditions; **1** 2 mmol, $NaNO_2$ 6 mmol, CF_3CO_2H 15 ml, at 25 °C.

When **1** (R^1=MeO, R^2=R^3=H) was used as an additive, a very good yield of **2** (R^1=MeO, R^2=R^3=H) was obtained, **3** being partly oxidized to **2** (R^1=Me, R^2=R^3=H). This result shows that **1** and/or some species derived from **1** has a strong oxidizing ability and also that the oxidation of *p*-nitrosoanisole to the corresponding nitro compound is faster than that of **3**.

The yield of **2** from **1** (R^1=R^2=R^3=H and R^1 or R^3=Cl or H, R^2=H) was low, while the addition of $K_2Cr_2O_7$ increased it. When the reaction was stopped in a short time in the cases without $K_2Cr_2O_7$, the main product was nitrosoarene. As an example, from **1** (R^1=R^2=R^3=H) nitrosobenzene was obtained in 37% and 51% yield for 2 min and 10 min reaction, respectively, together with a small amount of nitrobenzene (<1.3%), and from **1** (R^1 or R^3=Cl or H, R^2=H) only chloronitrosobenzene was obtained in 14% yield for 2 min reaction (under the conditions shown in Fig. 1). At first glance it seems that the addition of $K_2Cr_2O_7$ helps the oxidation of nitroso compounds. However, it was clarified that the oxidation of nitrosobenzene to nitrobenzene was slow and a lot of nitrosobenzene was lost to unidentified compounds under various conditions (Table 3) or even in the presence of $K_2Cr_2O_7$ (See

Table 3. Results of the oxidation of *p*-nitrosotoluene to *p*-nitrotoluene[a]

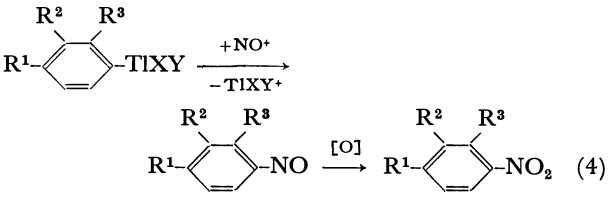
3 (mmol)	$NaNO_2$ (mmol)	Additive (mmol)	Time (min)	**2** (R^1=Me, R^2=R^3=H) Yield (%)
2	6	—	10	0.4
2	6	—	180	90
2	6	$Tl(OAc)_3$ 2	10	25
2	6	70% $HClO_4$ 2	10	50
2	6	$Tl(OAc)_3$ 2, 70% $HClO_4$ 2	10	96
2	6	**1** (R^1=MeO, R^2=R^3=H) 2	10	48[b]

a) CF_3CO_2H 15 ml, at 25 °C. b) *p*-$MeOC_6H_4NO_2$ (89%) was also formed.

Experimental). Therefore the reason for effectiveness of the potassium salt in these cases seems to be attributed to other factors, *i.e.*, oxidation of C–Tl bond by $K_2Cr_2O_7$ followed by NO_2^- attack, a similar scheme having been proposed in the cases of arylpalladium(II) compounds,[9]

In order to confirm the mechanistic difference of nitrodethallation by metal nitrite from that by nitrogen dioxide,[2] nitrodethallation of **1** (R^1=Me, R^2=R^3=H) with nitrogen dioxide was carried out in trifluoroacetic acid at 25 °C, the reaction being stopped after 2 min. Only *p*-nitrotoluene was detected as the product (54% yield), no *p*-nitrosotoluene being formed (Compare with Fig. 1).

From the results it can be concluded that nitrodethallation of **1** with metal nitrite proceeds through electrophilic substitution of thallium moiety by NO^+ to give nitroso compounds followed by facile oxidation to nitro compounds (Scheme 4).



(4)

Experimental

GLC analyses were carried out on a Shimadzu 5APTF apparatus using PEG 6000 (25%)-Chromosorb W (1 m) and Apiezon L (30%)-Celite (1 m) columns (N_2 as a carrier gas).

Materials. Arylthallium(III) acetate perchlorate monohydrate[10] and bistrifluoroacetates[4] were prepared by reported methods. Commercial sodium nitrite was used without further purification. Nitrogen dioxide was prepared by the method of Brook.[11] Commercial organic solvents and substances of guaranteed grade were used. All the nitro compounds and nitrosobenzene were available either commercially or from previous studies in our laboratory. *p*-Nitrosotoluene was synthesized by the reduction of *p*-nitrotoluene to *p*-tolylhydroxylamine followed by oxidation using sodium dichromate.[8]

Reaction of 1 with Sodium Nitrite in Trifluoroacetic Acid (Tables 1 and 2). The following shows a typical experimental procedure. To a white suspension of **1** (R^1=Me, R^2=R^3=H) (0.94 g, 2 mmol) in trifluoroacetic acid (15 ml) was added solid sodium nitrite (0.41 g, 6 mmol) at 25 °C in one portion. The color of the mixture immediately turned dark-brown. The mixture was stirred at 25 °C for 3 h, during which period evolution of a small amount of brown fume was observed. The resulting yellow heterogeneous mixture was poured into water (100 ml) and the products were extracted with benzene. The extract was washed with aq. $NaHCO_3$ and dried over $MgSO_4$. The solvent was removed at atmospheric pressure. GLC analysis of the residue showed the presence of **2** (R^1=Me, R^2=R^3=H) (1.94 mmol, 97%) as the sole product.

When the reaction was stopped in a short time (10 s—0.5 h), variable amount of **3** was detected in GLC together with **2** (R^1=Me, R^2=R^3=H) (See Fig. 1).

Reaction of 1 (R^1=Me, R^2=R^3=H) with Nitrogen Dioxide in Trifluoroacetic Acid. To a solution of nitrogen dioxide[11] (1.5 ml, 50 mmol) in trifluoroacetic acid (15 ml) was added solid **1** (R^1=Me, R^2=R^3=H) (0.94 g, 2 mmol) at 25 °C in one portion and the resulting mixture was stirred for 2 min followed by addition of 100 ml of water to stop the reaction. After the usual work-up procedure, GLC analysis of the organic residue showed the presence of **2** (R^1=Me, R^2=R^3=H) (1.1 mmol, 54%) and none of **3**.

Oxidation of p-*Nitrosotoluene (3) to* p-*Nitrotoluene [2 (R^1=Me, R^2=R^3=H)] (Table 3).* To a stirred solution of $Tl(OAc)_3$ (0.76 g, 2 mmol) and 70% $HClO_4$ (0.29 g, 2 mmol) in trifluoroacetic acid (15 ml) was added solid sodium nitrite (0.41 g, 6 mmol) at 25 °C to give a brown suspension. To this suspension was added **3** (2.39 g, 2 mmol) and the solution was stirred for 10 min. After the usual work-up procedure, GLC analysis of the organic residue showed the presence of **2** (R^1=Me, R^2=R^3=H) (1.94 mmol) and unreacted **3** (0.06 mmol). This indicates that 96% of **3** was oxidized.

Oxidation of Nitrosobenzene to Nitrobenzene [2 R^1=R^2=R^3=H)]. To a green solution of nitrosobenzene (0.10 g, 1 mmol) in trifluoroacetic acid (15 ml) were added solid sodium nitrite (0.14 g, 2 mmol) and $Tl(OAc)_3$ (0.38 g, 1 mmol) in one portion and the resulting dark brown mixture was stirred at 25 °C for 3 h. Water (*ca.* 100 ml) was then added to give a dark brown tarry compound which was filtered. The filtrate was extracted with benzene. GLC analysis of the benzene extract showed the presence of nitrobenzene (0.11 mmol) and nitrosobenzene (0.13 mmol), indicating that 11% of the starting material was oxidized to nitrobenzene, 13% of it was recovered unreacted, and 76% of it was transformed to unidentified compounds. When a similar treatment was carried out with the addition of $K_2Cr_2O_7$ (0.29 g, 1 mmol), 16% of the starting material was oxidized to nitrobenzene and 18% of it was recovered unreacted.

Synthesis of 3,4-Di-*O*-acetyl-6-azido-2,6-dideoxy-2-(2′,4′-dinitroanilino)-α-D-glucopyranosyl Chloride

Seiichiro OGAWA, Hitoshi FUJIMORI, and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received April 28, 1976)

The title compound has been prepared as an intermediate for the chemical synthesis of glycosides of 2,6-diamino sugar.

In the present communication, we should like to report a preparation of the title compound which is a useful intermediate for the chemical synthesis of α-glycosides of 2,6-diamino sugar.

Treatment of 1,3,4-tri-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-6-*O*-tosyl-β-D-glucopyranose (**1**)[1] with sodium azide in *N,N*-dimethylformamide at 80—90 °C for 3 h resulted in displacement of the tosyloxy group with an azide ion to give the 6-azido compound (**2**) in 75% yield. Hydrolysis of **2** with hydrochloric acid gave a crystalline 1,3,4-tri-*O*-acetyl-2-amino-6-azido-2,6-dideoxy-β-D-glucopyranose hydrochloride (**3**) in 73% yield. Treatment of **3** with 2,4-dinitrofluorobenzene in an alkaline solution gave 1,3,4-tri-*O*-acetyl-6-azido-2,6-dideoxy-2-(2′,4′-dinitroanilino)-β-D-glucopyranose (**4**) in 74% yield, whose structure was confirmed by converting it into 1,3,4-tri-*O*-acetyl-2,6-dideoxy-bis(2′,4′-dinitroanilino)-β-D-glucopyranose (**5**).[2] Attempt to prepare α-glycosyl bromide of this azido sugar was not successful, because partial replacement of the azido group by a bromine ion was accompanied when **4** was treated with a common brominating reagent. Thus bromination of **4** with hydrobromic acid in acetic acid resulted in the formation of 3,4-di-*O*-acetyl-6-bromo-2,6-dideoxy-2-(2′,4′-dinitroanilino)-α-D-glucopyranosyl bromide (**9**) in 85% yield. Compound **9** reacted with an excess of methanol in the presence of silver carbonate in dioxane to give methyl 3,4-di-*O*-acetyl-6-bromo-2,6-dideoxy-2-(2′,4′-dinitroanilino)-β-D-glucopyranoside (**10**) in 53% yield.

Chlorination of **4** was effected by treatment with hydrogen chloride in ether at 0 °C and gave 3,4-di-*O*-acetyl-6-azido-2,6-dideoxy-2-(2′,4′-dinitroanilino)-α-D-glucopyranosyl chloride (**6**) in 68% yield as a relatively stable crystalline substance. Methanolysis of **6** in the presence of silver carbonate gave methyl β-glucopyranoside (**7**) in 44% yield, which was further converted into methyl 2,6-diacetamido-3,4-di-*O*-acetyl-2,6-dideoxy-β-D-glucopyranoside (**8**) by the usual method.

Experimental[3]

1,3,4-Tri-O-acetyl-2-deoxy-2-(p-methoxybenzylideneamino)-6-O-tosyl-β-D-glucopyranose (1). This compound was prepared from 2-deoxy-2-*p*-methoxybenzylideneamino-D-glucopyranose by the method of Morel.[1] Mp 203—204 °C, $[\alpha]_D^{20}$ +103° (*c* 2, chloroform) [lit,[1] mp 203—204 °C, $[\alpha]_D^{20}$ +99.3° (*c* 2, chloroform)].

1,3,4-Tri-O-acetyl-6-azido-2,6-dideoxy-2-(p-methoxybenzylideneamino)-β-D-glucopyranose (2). A mixture of **1** (12 g), sodium azide (12 g), and *N,N*-dimethylformamide (300 ml) was heated at 80—90 °C under stirring for 3 h. The reaction mixture was evaporated and the residue was extracted with chloroform (200 ml). The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to give a syrup, which was recrystallized from ethanol to give 7.4 g (75%) of **2**, mp 123.5—124 °C, $[\alpha]_D^{25}$ +127° (*c* 2, chloroform). PMR ($CDCl_3$): δ 1.90 (s, 3), 2.03 (s, 3), 2.06 (s, 3) (OAc), 3.33—3.63 (m, 2, CH_2N_3), 3.87 (s, 3, OMe), 5.15 (t, 1, $J_{3,4}=J_{4,5}=9$ Hz, H-4), 5.50 (t, 1, $J_{2,3}=9$ Hz, H-3), 6.00 (d, 1, $J_{1,2}=9$ Hz, H-1), 6.97 (d, 2), 7.71 (d, 2) (ABq, aromatic ring proton), 8.22 (s, 1, N=CHAr).

Found: C, 53.70; H, 5.33; N, 12.21%. Calcd for $C_{20}H_{24}N_4O_8$: C, 53.59; H, 5.40; N, 12.50%.

1,3,4-Tri-O-acetyl-2-amino-6-azido-2,6-dideoxy-β-D-glucopyranose Hydrochloride (3). To a warm solution of **2** (1.33 g) in acetone (5 ml) was added dropwise 5 M aq. hydrochloric acid (2 ml) under vigorous agitation. The white solid precipitated immediately. After the reaction mixture had been set aside at room temperature for several hours, the product was collected by filtration, washed with ether, and recrystallized from methanol to give 0.69 g (73%) of **3**, mp 147—154 °C (dec), $[\alpha]_D^{25}$ +55.8° (*c* 1, H_2O), $[\alpha]_D^{24}$ +43° (*c* 0.5, methanol).

Found: C, 39.46; H, 5.16; N, 15.10; Cl, 9.46%. Calcd for $C_{12}H_{18}N_4O_7 \cdot HCl$: C, 39.30; H, 5.22; N, 15.28; Cl, 9.67%.

1,3,4-Tri-O-acetyl-6-azido-2,6-dideoxy-2-(2′,4′-dinitroanilino)-β-D-glucopyranose (4). To a stirred mixture of **3** (1.6 g) and sodium hydrogen carbonate (0.9 g) in 50% aq. acetone (12 ml) was added 2,4-dinitrofluorobenzene (0.9 g), and the mixture was allowed to stand at room temperature overnight. Then the mixture was evaporated to dryness and the residue was extracted with ethyl acetate. The extracts were evaporated to give a syrup, which was recrystallized from ethanol to give 1.6 g (74%) of **4**, mp 115.5—116 °C, $[\alpha]_D^{20}$ +108° (*c* 1, chloroform), $[\alpha]_D^{25}$ +102° (*c* 1, acetone). PMR ($CDCl_3$): δ

1.95 (s, 3), 2.03 (s, 3), 2.11 (s, 3) (OAc), 3.45—3.60 (m, 2, C$\underline{H}_2$N$_3$), 5.29 (t, 1, $J_{3,4}=J_{4,5}=9.5$ Hz, H-4), 5.67 (t, 1, $J_{2,3}=9.5$ Hz, H-3), 6.12 (d, 1, $J_{1,2}=8.5$ Hz, H-1).

Found: C, 44.03; H, 4.17; N, 16.89%. Calcd for $C_{18}H_{20}N_6O_{11}$: C, 43.55; H, 4.06; N, 16.93%.

1,3,4-Tri-O-acetyl-2,6-dideoxy-2,6-bis(2′,4′-dinitroanilino)-β-D-glucopyranose (5). A solution of **3** (0.4 g) in methanol containing 6 M hydrochloric acid (0.2 ml) was hydrogenated in the presence of 10% palladium on carbon for 5 h at room temperature (the initial hydrogen pressure of 3.4 kg/cm^2). The catalyst was removed by filtration and the filtrate was evaporated to give a crude diamine dihydrochloride. This was directly treated with 2,4-dinitrofluorobenzene (1 g) in ethanol (4 ml) and acetone (16 ml) in the presence of sodium hydrogen carbonate (1 g) for 2 days at room temperature. The reaction mixture was evaporated and the residue was extracted with chloroform. The crude product was chromatographed on silica gel (16 g) with 3: 1 benzene–ethyl acetate as the eluant to give 0.24 g (35%) of **5**, after recrystallization from chloroform–ethanol, mp 280—281 °C, $[\alpha]_D^{15}$ +111° (*c* 1, acetone). PMR (DMSO-d_6): δ 1.87 (s, 3), 1.94 (s, 3), 2.13 (s, 3) (OAc), 4.74 (td, 1, $J_{1,2}=8.5$ Hz, $J_{2,3}=9$ Hz, $J_{2,NH}=3$ Hz, H-2), 5.17 (t, 1, $J_{3,4}=9$ Hz, H-4), 5.90 (t, 1, H-3), 6.30 (d, 1 H-1).

Found: C, 45.53; H, 4.19; N, 13.06%. Calcd for $C_{24}H_{24}N_6O_{15}$: C, 45.28; H, 3.80; N, 13.21%.

3,4-Di-O-acetyl-6-azido-2,6-dideoxy-2-(2′,4′-dinitroanilino)-α-D-glucopyranosyl Chloride (6). Dry hydrogen chloride was introduced into a solution of **4** (6 g) in dry ether (100 ml) at 0 °C until saturation was completed. The solution was allowed to stand at room temperature for 20 h. The resulting crystals were collected by filtration to give 4 g (68%) of **6**, mp 164—166 °C (dec). Recrystallization from chloroform–ether gave an analytically pure sample, mp 170 °C (dec), $[\alpha]_D^{25}$ +167° (*c* 1, chloroform). PMR (DMSO-d_6): δ 6.90 (d, 1, $J_{1,2}=3$ Hz, H-1).

Found: C, 40.37; H, 3.62; N, 17.37; Cl, 7.64%. Calcd for $C_{16}H_{17}N_6O_9Cl$: C, 40.63; H, 3.62; N, 17.77; Cl, 7.50%.

Methyl 3,4-Di-O-acetyl-6-azido-2,6-dideoxy-2-(2′,4′-dinitroanilino)-β-D-glucopyrauoside (7). A mixture of **6** (1 g), silver carbonate (5 g), and Drierite (14 g) in dioxane (40 ml) and methanol (40 ml) was stirred at room temperature in the dark for a week. An insoluble matter was removed by filtration and the filtrate was evaporated to give a syrup, which was chromatographed on silica gel (40 g) with 40: 3 benzene–ethyl acetate as the eluant. The fractions containing a main component were evaporated and the residue was recrystallized from chloroform–ethanol to give 0.43 g (44%) of **7**, mp 170.5—171 °C, $[\alpha]_D^{25}$ +61.3° (*c* 1, chloroform). PMR (CDCl$_3$): δ 1.96 (s, 3), 2.11 (s, 3) (OAc), 3.58 (s, 3, OMe), 4.71 (d, 1, $J_{1,2}=8$ Hz, H-1), 5.17 (t, 1, $J_{3,4}=J_{4,5}=9$ Hz, H-4), 5.52 (t, 1, $J_{2,3}=9$ Hz, H-3).

Found: C, 43.40; H, 4.30; N, 17.96%. Calcd for $C_{17}H_{20}N_6O_{10}$: C, 43.59; H, 4.30; N, 17.94%.

Methyl 2,6-Diacetamido-3,4-di-O-acetyl-2,6-dideoxy-β-D-glucopyranoside (8). Compound **7** (0.38 g) was treated with methanolic ammonia (16 ml) at room temperature overnight. At this time, the mixture became a clear solution and TLC indicated the formation of a single product. Then Dowex 1×2 (OH$^-$) was added to the solution and the mixture was stirred until all the product was consumed. The resin was removed by filtration and the filtrate was evaporated to give a syrup, which was hydrogenated in water in the presence of platinum oxide (30 mg) at room temperature overnight. The product was then treated with acetic anhydride (5 ml) in pyridine (5 ml) at room temperature overnight. The crude product was recrystallized from ethyl acetate to give 0.12 g (41%) of **8**, mp 208—210 °C, $[\alpha]_D^{25}$ −39° (*c* 1, acetone). PMR (DMSO-d_6): δ 1.80 (s, 3), 1.85 (s, 3), 1.93 (s, 3), 2.00 (s, 3) (Ac), 4.57 (d, 1, $J_{1,2}=9$ Hz, H-1), 4.80 (t, 1, $J_{3,4}=J_{4,5}=10$ Hz, H-4), 5.17 (t, 1, $J_{2,3}=10$ Hz, H-3).

Found: C, 49.72; H, 6.57; N, 7.76%. Calcd for $C_{15}H_{24}N_8O_{12}$: C, 49.99; H, 6.71; N, 7.77%.

Hydrolysis of **8** with 6 M hydrochloric acid at 100 °C for 2 h gave 2,6-diamino-2,6-dideoxy-D-glucopyranose dihydrochloride, which was identified with an authentic specimen derived by hydrolysis of antibiotic neamine.

Methyl 3,4-Di-O-acetyl-6-bromo-2,6-dideoxy-2-(2′,4′-dinitroanilino)-β-D-glucopyranoside (10). To a solution of **4** (2 g) in methylene chloride (10 ml) was added acetic acid (30 ml), saturated with hydrobromic acid under stirring at −20—−15 °C, and the reaction mixture was allowed to stand at the same temperature for 2 h. The mixture was poured into ice–water and extracted with chloroform. The extracts were washed with aq. sodium hydrogen carbonate and water, dried over anhydrous sodium sulfate, and evaporated to give a syrup, which was crystallized from chloroform–petroleum ether to give 1.9 g (85%) of 3,4-di-*O*-acetyl-6-bromo-2,6-dideoxy-2-(2′,4′-dinitroanilino)-α-D-glucopyranosyl bromide (**9**), mp 146—150 °C (dec). This compound did not give satisfactory analytical data (Found: C, 35.36; H, 3.25; N, 8.12%).

Compound **9** (1 g) was treated in the presence of silver carbonate (9 g) in methanol (25 ml) and dioxane (25 ml) under stirring at room temperature overnight. An insoluble matter was removed by filtration and the filtrate was evaporated to give a syrup, which was chromatographed on silica gel (40 g) with 10: 1 benzene–ethyl acetate as the eluant to give 0.41 g (53%) of **10**, mp 183—186 °C, $[\alpha]_D^{20}$ +46.2° (*c* 0.5, chloroform). PMR (DMSO-d_6): δ 1.77 (s, 3), 2.09 (s, 3) (OAc), 3.57 (s, 3, OMe), 4.17 (broad septet, 1, $J_{1,2}=6.5$ Hz, $J_{2,3}=7.5$ Hz, $J_{2,NH}=3$ Hz, H-2), 5.27 (d, 1, H-1), 9.03 (d, 1, N$\underline{H}$).

Found: C, 40.03; H, 3.92; N, 8.18; Br, 15.75%. Calcd for $C_{17}H_{20}N_3O_{10}Br$: C, 40.32; H, 3.98; N, 8.29; Br, 15.79%.

Reaction of Carboxylic Acids with Dioxygen Complexes: A Mechanistic Aspect of the Reaction[1]

Shigeaki MUTO and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received May 1, 1976)

The reaction of carboxylic acids with dioxygen complexes $MO_2(PPh_3)_2$(M=Pt, Pd) at low temperature gives rise to the selective formation of H_2O_2 and the corresponding dicarboxylato complexes characterized by their physical properties. It is suggested that the reaction can be influenced by either the capability of reactant for coordination to metal center or the stability of resulting metal complex. An equimolar addition of $CH_2ClCOOH$ to the dioxygen complexes in the presence of triphenylmethyl bromide at *ca.* −70 °C gives triphenylmethyl hydroperoxide and the corresponding monocarboxylato complexes in good yields, indicating that the reaction of organic acids with $MO_2(PPh_3)_2$ proceeds by stepwise mechanism.

Recently a study on the reaction of metal dioxygen complexes with a variety of organic compounds has received considerable attention. In general, the coordinated molecular oxygen to a metal complex is considered to be peroxidic on the basis of increased O–O bond length.[2] Benzoyl chloride and triphenylmethyl bromide (TPMB) react with $NiO_2(t\text{-BuNC})_2$ to give the corresponding peroxides.[3] Although Vaska[4] and Wilke *et al.*[5] also mentioned the formation of H_2O_2 upon protonation of $IrO_2Cl(CO)(PPh_3)_2$ and $NiO_2(PPh_3)_2$, respectively, the determination of reaction products and the elucidation of protonation mechanism still remain unclarified. In order to elucidate the reaction mechanism, the reaction of some carboxylic acids and phenols with square planar dioxygen complexes $MO_2(PPh_3)_2$ (M=Pt, Pd) was investigated.

In this work, we wish to report that the reaction of organic acids with $MO_2(PPh_3)_2$ results in the selective formation of H_2O_2 and the corresponding dicarboxylato complexes, and that the reaction proceeds by stepwise mechanism. The reaction of *o*- and *p*-substituted phenols was investigated in detail.

Experimental

Melting points were determined on a Yazawa hot-stage apparatus and uncorrected. Chloroacetic acid, triphenylphosphine(PPh_3), and TPMB were purified by recrystallization from ethanol or benzene. All the dioxygen complexes were prepared according to the procedure in literature.[6] The IR spectra were recorded as Nujol mulls on a Nippon Bunko IR-G spectrophotometer(4000—400 cm^{-1}), calibrated with polystyrene film. The NMR spectra were obtained on a JEOL Model JMN-4H-100 spectrometer in $CDCl_3$ solution containing tetramethylsilane as an internal standard. H_2O_2 and triphenylmethyl hydroperoxide obtained by equimolar addition of $CH_2ClCOOH$ to the dioxygen complexes in the presence of TPMB were analyzed by the conventional iodometric method.

General Procedure. The reactions were carried out in CH_2Cl_2 solution in the air or under a nitrogen atmosphere at 0 °C. The total volume was 4 ml for CH_3COOH(4.37 M) and 2 ml for $CH_2ClCOOH$(1.00 M). The concentration of $MO_2(PPh_3)_2$ was in the range $4.23\times10^{-3}-8.83\times10^{-2}$ M. The peroxide formed during the course of reaction was transferred in a vacuum(*ca.* 10^{-2}Torr) and then titrated by iodometry. The transfer efficiency was *ca.* 98 percent. The peroxide transfered could be considered principally to be H_2O_2 since the amount of the peroxide drastically decreased when treated with catalase.

Preparation of Dicarboxylato Complexes. *$Pt(OCOCH_2Cl)_2(PPh_3)_2$*: To a CH_2Cl_2 solution (20 ml) of $PtO_2(PPh_3)_2 1.5C_6H_6$(0.186 g, 0.214 mmol) was added excess $CH_2ClCOOH$(0.189 g, 2.00 mmol) under N_2 at 0 °C. Immediately the yellow solution turned colorless. The solution was stirred for 1 h at room temperature. Removal of the solvent *in vacuo* left a white residue which was recrystallized from ethanol to yield a white solid(0.134 g, 88.2% based on the dioxygen complex used). The solid was identified as $Pt(OCOCH_2Cl)_2(PPh_3)_2$ on the basis of its physical properties(Table 3).

$Pd(OCOCH_2Cl)_2(PPh_3)_2$: A similar treatment of $PdO_2(PPh_3)_2$(0.183 g, 0.235 mmol) with $CH_2ClCOOH$(0.189 g, 2.00 mmol) afforded a yellow solid of $Pd(OCOCH_2Cl)_2(PPh_3)_2$ (0.127 g, 87.7%) which was recrystallized from hexane–ethanol (1: 1 by volume). Physical properties for the yellow solid are also given in Table 3.

Preparation of Monocarboxylato Complexes. *$Pt(OCOCH_2Cl)Br(PPh_3)_2$*: To a CH_2Cl_2 solution(50 ml) of $PtO_2(PPh_3)_2 1.5C_6H_6$(0.869 g, 1.00 mmol) was added equimolar $CH_2ClCOOH$(0.107 g, 1.13 mmol) under N_2 at the temperature of ethanol–Dry Ice. After the resulting orange solution was stirred for 5 min, TPMB(0.329 g, 1.02 mmol) was slowly added. The reaction mixture was stirred another 3 h at the same temperature. The orange solution was allowed to stand overnight in a refrigerator. The reaction mixture containing an appreciable amount of white precipitated was distilled *in vacuo* at room temperature to give 0.841 g(yield 94.2%) of the monocarboxylate, white solid, along with colorless crystals which were chromatographed on alumina(about 300 mesh, deactivated with 1 ml of H_2O/100 g of alumina) and eluted with diethyl ether. The colorless crystals were identified as triphenylmethyl hydroperoxide from the data of its elemental analysis(Found: C, 82.89, H, 5.81%. Calcd for $C_{19}H_{16}O_2$: C, 82.57; H, 5.81%), mp (83—84 °C, lit,[7] 81—82 °C), IR, and chemical reactions. The hydroperoxide exhibited intense IR absorption at 3490 cm^{-1} characteristic of hydroperoxy moiety which shifted at higher frequency (3540 cm^{-1}) when treated with excess PPh_3, indicating that the peroxide was reduced to the corresponding alcohol. The yield of triphenylmethyl hydroperoxide was 0.230 g (83.5% based on the dioxygen complex used).

$Pd(OCOCH_2Cl)Br(PPh_3)_2$: A similar treatment of $PdO_2(PPh_3)_2$(0.789 g, 1.00 mmol) with TPMB(0.291 g, 0.990 mmol) in the presence of $CH_2ClCOOH$(0.107 g, 1.13 mmol) gave a yellow solid of $Pd(OCOCH_2Cl)Br(PPh_3)_2$(0.582 g, 81.4%) and triphenylmethyl hydroperoxide(0.291 g, 50.6% based on TPMB used) which was also purified by the chromatographic method under the same conditions, using benzene–diethyl ether as an eluent. As a by-product, a similar yellow solid was isolated from the residue insoluble in CH_2Cl_2. The solid was

characterized as $PdBr_2(PPh_3)_2$ by analysis (Found: C, 54.46; H, 3.87; Br, 20.18%. Calcd for $C_{36}H_{30}Br_2P_2Pd$: C, 54.46; H, 3.83; Br, 20.21%). The IR spectrum was identical with that of an authentic sample prepared by other routes.

Results and Discussion

Reaction of Carboxylic Acids with $MO_2(PPh_3)_2$. The experimental results on the reaction of CH_3COOH or $CH_2ClCOOH$ with $MO_2(PPh_3)_2$ (M=Pt, Pd) are given in Table 1. $MO_2(PPh_3)_2$ reacted with the organic acids in the air or under a nitrogen atmosphere to give H_2O_2 in 52—77% yield (based on the dioxygen complexes used). The high yields of H_2O_2 under N_2 strongly indicate that H_2O_2 is derived from the coordinated molecular oxygen of $MO_2(PPh_3)_2$. The fact that the yields of H_2O_2 under air are less than those under N_2 suggests that the reaction proceeds stoichiometrically. Formation of H_2O_2 was scarcely recognized in the reaction of $IrO_2Cl(CO)(PPh_3)_2$ and $RuO_2(OH)(NO)(PPh_3)_2$ with $CH_2ClCOOH$.

Table 2. Effect of pK_a on the yields of H_2O_2 at 0 °C[a]

Acid (1.00 M)	pK_a (at 25 °C)	H_2O_2 Yield (%) $PtO_2(PPh_3)_2$	H_2O_2 Yield (%) $PdO_2(PPh_3)_2$[b]
Chloroacetic acid	2.86	66.4	75.3
Benzoic acid	4.21	18.9	32.7
Acetic acid	4.76	76.9[c]	53.5
p-Nitrophenol	7.15		7.1
p-Acetylphenol	≈8	8.6

Catechol[d]	9.45	1.2[f]	trace
3,5-Di-*t*-butyl-catechol[d]	≈9	66.5	32.0
o-Aminophenol[d]		83.2	36.5
Indene	21	—[g]	—[g]

a) All the reactions were carried out under N_2 for 1 h. b) Reaction temperature was 2 °C. c) [CH_3COOH] was 4.73 M. d) Concentration of phenols was 8.25×10^{-2} M. e) pK_a value at 20 °C. f) Treated with catalase prior to iodometry. g) No peroxide was detected by iodometry.

The effect of pK_a(H^+) of the organic acids on the yield of H_2O_2 was also investigated. The yield of H_2O_2 seems to be roughly correlated with the pK_a of substrates (Table 2). Namely the formation of H_2O_2 shows an upward trend with the decreased pK_a value. However, the yield in the presence of bonzoic acid (pK_a= 4.21) was much less than that in CH_3COOH (pK_a= 4.76). *o*-Substituted phenols reacted with **1a** under the same conditions to provide H_2O_2 in 83—85% yield, suggesting that the reaction is fairly influenced by either the capability of substrates for coordination to the metal center or the stability of the resulting metal complex. Namely, the reason why *o*-substituted phenols are more preferred is that their dianions are good ligands. From these results, the following reaction seems to take place.

$$\underset{\textbf{1a}; M=Pt \quad \textbf{1b}; M=Pd}{MO_2(PPh_3)_2} + 2RCOOH \longrightarrow M(OCOR)_2(PPh_3)_2 + H_2O_2 \qquad (1)$$

The analytical data for dicarboxylato complexes **3a** and **3b** obtained in the reaction of $MO_2(PPh_3)_2$ with $CH_2ClCOOH$ and recrystallized from ethanol are given in Table 3. The infrared spectra of **3a** and **3b** are similar to each other. Whereas **1a** and **1b** showed intense absorption due to oxygen-oxygen stretching, respectively, at 821 and 869 cm^{-1}, there were no strong bands in the 900—800 cm^{-1} region for the carboxylates. No band was observed in the region of the spectra near 2200 cm^{-1} which can be attributed to a metal-hydrogen stretching.[8] The complexes exhibited absorptions at 1644—1624 and 1099 cm^{-1} characteristic of a metal-carboxylate and coordinated PPh_3, respectively. The large shift of the ν(C=O) bands of **3a** and **3b** to lower frequency from that of the corresponding free acid

Table 3. Analytical data of the carboxylates

Complex	Mp (°C)	Formula	Analysis (%) Calcd (Found) C	H	Cl	Br	IR(in CH_2Cl_2), cm^{-1}
3a	252—254(dec)	$C_{40}H_{34}O_4Cl_2P_2Pt$	52.48 (52.40)	3.72 (4.02)	7.76 (7.86)		1624m, 1604m, and 1099s
3b	152—157(dec)	$C_{40}H_{34}O_4Cl_2P_2Pd$	58.73 (58.02)	4.16 (4.87)	8.69 (8.65)		1644s, 1608m, and 1099s
4a[a)]	267—269(dec)	$C_{41}H_{38}O_2BrClP_2Pt$	52.81 (52.72)	3.79 (3.83)	3.81 (3.69)	8.57 (8.83)	1662s, 1603w, 1607sh, and 1097s
4b[a)]	145—154(dec)	$C_{41}H_{38}O_2BrClP_2Pd$	58.38 (58.19)	4.19 (4.40)	4.21 (3.92)	9.47 (11.01)	1660sh, 1646w, 1606s, and 1098s

a) Calcd as $M(OCOCH_2Cl)Br(PPh_3)_2 \cdot 0.5C_6H_6$. w; weak, m; medium, s; strong, sh; shoulder.

seems to be due to the interaction between the carbonyl moiety and the central metal. These dicarboxylato complexes gave elemental analyses (Table 3) consistent with the proposed structures, respectively. The NMR spectra also indicates that the complexes could be characterized as $M(OCOCH_2Cl)_2(PPh_3)_2$. Similarly it was confirmed that **3c** and **3d** had characteristic absorptions at 1565 and 1617 cm^{-1}, respectively, attributable to the ν(C=O) of coordinated carboxylates.

Mechanistic Aspect of the Reaction. When **1a** and **1b** were treated with double molar quantity of $CH_2ClCOOH$ at *ca.* −70 °C, characteristic color changes of the solution were observed. The CH_2Cl_2 solution of **1a** gradually turned orange from yellow and then became colorless. In a similar manner, **1b** changed from light blue to wine red, and then to yellow. The IR spectra of **1a** and **1b** treated with exactly equimolar $CH_2ClCOOH$ to the complexes at *ca.* −70 °C were taken in CH_2Cl_2 solution at ambient temperature. Although the spectra were very similar to those of the corresponding dicarboxylates, an other new strong band was observed at *ca.* 3380 cm^{-1} which might be attributed to an oxygen-hydrogen stretching. No band due to the ν(C=O) of free acid was, of course, observed in the region of the spectra near 1700 cm^{-1}. Treatment of **1a** with CH_3COOD under the same conditions also gave an IR spectrum having the characteristic new band at *ca.* 2500 cm^{-1} which might be assigned to the ν(O–D). The results suggest that the reaction of $CH_2ClCOOH$ with $MO_2(PPh_3)_2$ proceeds by stepwise mechanism as shown below:

$$MO_2(PPh_3)_2 \xrightarrow{CH_2ClCOOH} M(OOH)(OCOCH_2Cl)(PPh_3)_2$$
2a; M=Pt
2b; M=Pd

$$\xrightarrow{CH_2ClCOOH} M(OCOCH_2Cl)_2(PPh_3)_2 + H_2O_2 \quad (2)$$
3a; M=Pt
3b; M=Pd

The reaction of a metal hydride with gaseous oxygen gives a metal hydroperoxide as a reactive intermediate.[9] In our complexes, isolation of **2a** and **2b** from the reaction mixtures was unsuccessful because of their thermal labilities. **2b** in particular was unstable in solution and decomposed to give palladium metal when allowed to stand for several minutes at room temperature. In order to elucidate the reaction mechanism, we attempt to prepare triphenylmethyl hydroperoxide by the successive equimolar addition of $CH_2ClCOOH$ and TPMB to $MO_2(PPh_3)_2$ at −70 °C as shown in the following.

$$MO_2(PPh_3)_2 \xrightarrow[\text{in } CH_2Cl_2]{CH_2ClCOOH} M(OOH)(OCOCH_2Cl)(PPh_3)_2$$
$$\xrightarrow{TPMB} M(OCOCH_2Cl)Br(PPh_3)_2 + Ph_3COOH \quad (3)$$

In the reaction of **1a** and **1b**, the hydroperoxide was obtained in 83.5 and 50.7% yields, respectively. In the absence of the complexes no peroxidation of TPMB with gaseous oxygen took place at all. The lower yield in **1b** seems to be due to a smaller stability of **2b**.

Analytical data for the monocarboxylates are given in Table 3. The IR spectra of **4a** and **4b** were close to those of the corresponding dicarboxylates. The NMR spectra of **4a** and **4b**, taken in $CDCl_3$ solution, exhibited singlet peaks at δ 3.31 and 3.39 ppm, respectively, which were easily assignable to their methylene protons. The identification of hydroperoxide was performed by its physical properties and chemical reactions (see Experimental).

The results strongly suggest that the reaction of $MO_2(PPh_3)_2$ with carboxylic acids proceeds by stepwise mechanism (2).

The authors would like to thank Dr. E. Niki, the University of Tokyo, for his valuable discussions.

Syntheses of Some Alkoxy-, Dialkoxy-, and Alkoxyamino-sulfonium Ions and Their *O*-Methylene and *N*-Methylene PMR Chemical Shifts

Hiroshi MINATO,* Kei YAMAGUCHI, Kentaro OKUMA, and Michio KOBAYASHI

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received March 24, 1976)

Alkylation of sulfenates proved to be a good method for synthesis of alkoxysulfonium ion not obtainable by alkylation of sulfoxides. Dialkoxy- and alkoxyamino-sulfonium ions were prepared by alkylation of sulfinates and sulfinamides. Ethoxy- and methoxymorpholinophenylsulfonium tetraphenylborates were obtained as high-melting crystals, which almost quantitatively alkylated amines at room temperature. PMR spectra of $RR'\overset{\oplus}{S}$–OCH_AH_BR'' and $RR'\overset{\oplus}{S}$–$N(R'')CH_AH_BR'''$ were determined, and the relationship between $\delta_A-\delta_B$ and (R,R') were examined.

Sulfonium ions containing hetero atom substituents are interesting compounds, and some of them have been investigated in our laboratoris.[1-3] The two hydrogens of *O*-methylene and *N*-methylene groups in alkoxy- and amino-sulfonium ions are expected to be magnetically non-equivalent if the other two substituents on the sulfonium sulfur atom are different. It seems to be of interest to determine the PMR spectra of $RR'\overset{\oplus}{S}$–OCH_AH_BR'' and $RR'\overset{\oplus}{S}$–$N(R'')CH_AH_BR'''$ and to study the relationship between $\delta_A-\delta_B$ and (R,R'). Some new alkoxy-, dialkoxy-, and alkoxyamino-sulfonium ions were synthesized, and their PMR spectra were examined.

Results and Discussion

Alkoxysulfonium ions were prepared by two different methods. The first method used was alkylation of sulfoxides.[4,5] Ethoxysulfonium trifluoromethanesulfonates (triflates) **1a—c** were prepared by ethylation of the corresponding sulfoxides with ethyl triflate in CD_3NO_2. Alkoxysulfonium salts have been studied by various groups, but few papers described ethoxysulfonium salts.[6-8] In these papers, PMR data were not shown.

$$\underset{\underset{\downarrow}{O}}{R\text{–}S\text{–}R'} + CF_3SO_3Et \longrightarrow \underset{\underset{O\text{–}Et}{|}}{R\text{–}\overset{\oplus}{S}\text{–}R'}\ CF_3SO_3^{\ominus}$$

1 {**a**: R=Me, R'=*p*-Tol; **b**: R=$PhCH_2$, R'=Ph; **c**: R=Et, R'=Bu

Since neopentylation of sulfoxides is not possible, neopentyloxysulfonium ions cannot be prepared from sulfoxides. Although alkylation of sulfenates has not been described in the literature, it is expected to be a possible method for producing alkoxysulfonium salts. Hogg and Robertson[9] treated sodium arenesulfenate with a 10-fold excess of FSO_3Me in 30% aq. dioxane, but a methoxysulfonium ion was not formed. When an equimolar mixture of neopentyl benzenesulfenate and methyl triflate in nitromethane was allowed to stand for 10 min at 34 °C, its PMR spectrum showed that the sulfenate was quantitatively converted to methylphenylneopentyloxysulfonium triflate **1d**. Thus, alkylation of a sulfinate appears to be a good method for producing an alkoxysulfonium ion.

$$Ph\text{–}S\text{–}O\text{–}CH_2CMe_3 + CF_3SO_3Me \longrightarrow Ph\text{–}\overset{\oplus}{S}(Me)\text{–}OCH_2CMe_3\ CF_3SO_3^{\ominus}$$

1d

Compared with **1a—c**, the neopentyloxysulfonium salt **1d** is less stable. When a nitromethane solution of **1d** was allowed to stand at 34 °C, about 10% decomposed in 2 days. When a nitromethane solution of **1d** was evaporated and the residue was treated with an acetone solution of $NaBPh_4$, the corresponding anion-exchanged salt was not obtained, and decomposition products were found. When a CD_3NO_2 solution of **1d** was heated at 75 °C for 18 h, it completely decomposed, and neopentyl alcohol was one of the main product. Apparently a *neopentyloxy*arylalkylsulfonium ion is unstable. Among dialkoxyarylsulfonium ions (**3**) (discussed later), methoxy*neopentyloxy*-*p*-tolylsulfonium triflate (**3a**) and methoxy*benzyloxy*-*p*-tolylsulfonium triflate (**3b**) are found to decompose in solution whereas dimethoxy-*p*-tolylsulfonium triflate (**3c**) is stable in solution.

Dialkoxysulfonium ions were synthesized by alkylation of sulfinates.[1] From alkyl ethanesulfinates and alkyl triflate dialkoxyethylsulfonium triflates **2a—c** were prepared.

$$\underset{\underset{\downarrow}{O}}{Et\text{–}S\text{–}OR} + CF_3SO_3R' \xrightarrow{CD_3NO_2} \underset{\underset{O\text{–}R'}{|}}{Et\text{–}\overset{\oplus}{S}\text{–}OR}\ CF_3SO_3^{\ominus}$$

2 {**a**: R=CH_2CMe_3, R'=Et; **b**: R=CH_2CMe_3, R'=Me; **c**: R=Et, R'=Me

PMR spectra showed that sulfinates were completely converted to dialkoxysulfonium ions.

When benzyl and neopentyl *p*-toluenesulfinates were treated with methyl triflate, the solution became viscous suggesting the occurrence of polymerization, and the corresponding dialkoxysulfonium ions **3a** and **3b** were not obtained. In the case of methyl *p*-toluenesulfinate, the corresponding dimethoxy-*p*-tolylsulfonium salt **3c** was successfully prepared in solution.[1] It is worth

$$\underset{\underset{\downarrow}{O}}{p\text{-Tol–S–OR}} + CF_3SO_3Me \xrightarrow{CD_3NO_2} \underset{\underset{O\text{–}Me}{|}}{p\text{-Tol–}\overset{\oplus}{S}\text{–OR}}\ CF_3SO_3^{\ominus}$$

3 {**a**: R=CH_2Ph; **b**: R=CH_2Me_3; **c**: R=Me

noting that alkoxyneopentyloxyethylsulfonium ions are stable in solution, whereas methoxyneopentyloxy-*p*-tolylsulfonium ion is unstable in solution.

Alkoxyaminosulfonium salts were prepared by alkylation of sulfinamides.[2]

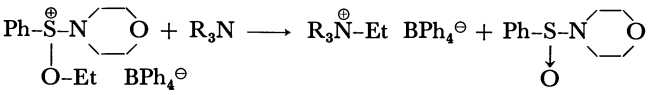
$$\underset{\underset{O}{\downarrow}}{Ar\text{-}S\text{-}NRR'} + CF_3SO_3R'' \xrightarrow{CD_3NO_2} Ar\text{-}\overset{\oplus}{S}(\underset{O\text{-}R''}{\downarrow})\text{-}NRR'\ CF_3SO_3^{\ominus}$$

4 { **a**: Ar=*p*-Tol, R=Ph, R′=Me, R″=Me; **b**: Ar=*p*-Tol, R, R′=$-(CH_2)_4-$, R″=Et; **c**: Ar=Ph, R, R′=$-CH_2CH_2OCH_2CH_2-$, R″=Et; **d**: Ar=Ph, R, R′=$-CH_2CH_2OCH_2CH_2-$, R″=Me

When *N*-phenyl-*N*-methyl-*p*-tolylsulfinamide was treated with methyl triflate in CD_3NO_2 at −20 °C, decomposition took place and the corresponding sulfonium salt **4a** was not found. This apparent instability of a methoxy-*N*-phenylaminosulfonium ion may be related with the low electron density on the nitrogen atom due to the resonance with the phenyl ring. Methoxypyrrolidino-*p*-tolylsulfonium triflate (**4b**) was stable so long as it was kept in solution but decomposed upon evaporation of the solvent. This decomposition may be related with the greater nucleophilicity of the dialkylamino nitrogen atom which attack the alkoxy alkyl group of **4b** itself (pyrrolidinium salts were found to be products of decomposition). The pK_a of morpholine (8.36)[10] is between that of *N*-methylaniline (4.85)[10] and that of pyrrolidine (11.27),[10] and it appeared that alkoxymorpholinosulfonium salts may be stable enough for isolation as solids, since the electron-density on the morpholine nitrogen is not too great nor too small.

When *N*-benzenesulfinylmorpholine was mixed with an equimolar amount of CF_3SO_3R'' (R″=Et or Me) in CD_3NO_2 at room temperature, **4c** or **4d** was formed, which was isolated as stable solids and converted into high-melting crystals by exchanging its anion with $NaBPh_4$.

The reaction of ethoxymorpholinophenylsulfonium tetraphenylborate with pyridine or triethylamine gave ethylated amine (91—95%) and the original sulfinamide (94—98%).



This is in quite a contrast with the reaction of methyl-*p*-tolylmethoxysulfonium ion with nucleophiles which yielded a mixture of various products.[5] If optically-active **4** is prepared (either by resolution of diastereomers with optically-active anions or by alkylation of optically-active sulfinamides derivable from optically-active sulfinates,[11] it can be used as asymmetric alkylating agents, and optically-active sulfinamides can be recovered which can be used again by alkylating it with alkyl triflate. Among various sulfonium salts, **4** is the best alkylating agent.

The PMR spectra of these sulfonium ions were determined, and their *O*-methylene and *N*-methylene chemical shifts are compared in Table 1. Magnetic non-equivalence of methylene protons in sulfinates (RSO_2CH_2R')[12] and sulfinamides ($RSONR'CH_2R''$)[13,14] has been described in the literature, but that in alkoxy-, dialkoxy-, and alkoxyamino-sulfonium ions is described here for the first time.

The relationship between $\delta_A-\delta_B$ and R,R′ in $RR'\overset{\oplus}{S}\text{-}OCH_AH_BR''$ and $RR'\overset{\oplus}{S}\text{-}N(R'')CH_AH_BR''$ are summarized in Table 2. The pairs of R and R′ always giving rise to different δ_A and δ_B are 1) aryl and alkyl, 2) aryl and alkoxy, and 3) aryl and $-O^{\ominus}$, and those giving rise to equal δ_A and δ_B are 1) aryl and alkylamino, and 2) aryl and benzyl.

The non-equivalence of the methylene protons shown in Table 1 is due to the difference in the magnetic environments caused by the chiral sulfur atom.[15] Although N–$\overset{\oplus}{S}$ and O–$\overset{\oplus}{S}$ bonds may have some partial

Table 1. Comparison of O-CH_2 and N-CH_2 ^{1}H-NMR absorptions in $RR''\overset{\oplus}{S}\text{-}OCH_2R''$ and $RR'\overset{\oplus}{S}\text{-}N(R'')CH_2R'''$

(s, 3, $C\underline{H}_3C_6H_4$–), 3.10—3.90 (m, 4, $-C\underline{H}_2N$), 4.57 (q, 2, $-OCH_2$–), 7.32—7.80 (q, 4, $-C_6H_4$–).

Ethoxymorpholinophenylsulfonium Tetraphenylborate. After a mixture of *N*-benzenesulfinylmorpholine (7.6 mmol), ethyl triflate (7.6 mmol) and nitromethane (20 ml) was allowed to stand overnight at room temperature, the solvent was evaporated. The residue was dissolved in a small amount of acetone, and sodium tetraphenylborate (7.6 mmol) was added. Ether was added till the solution became turbid, and in 1 h white crystals were formed; yield, 4.2 g (99%), mp 143 °C. Found: C, 77.57; H, 6.96; N, 2.53%. Calcd for $C_{36}H_{38}O_2$-NB: C, 77.27; H, 6.84; N, 2.50%. PMR (CD_3COCD_3), $\delta=1.49$ (t, 3, CH_3), 3.20—3.50 (m, 4, $-CH_2N$–), 3.50—3.80 (m, 4, $-CH_2C\underline{H}_2O$–), 4.55 (q, 2, $CH_3C\underline{H}_2O$–), 6.60—8.00 (m, 5, Ph–).

Methoxymorpholinophenylsulfonium tetraphenylborate was prepared in a similar manner. Yield, 94%; mp 139 °C. Found: C, 78.68; H, 7.06; N, 2.71%. Calcd for $C_{35}H_{36}O_2$-NB: C, 77.06; H, 6.65; N, 2.57%. PMR(CD_3COCD_3), $\delta=3.38$—3.71 (m, 4, $-CH_2N$), 3.71—4.05 (m, 4, $-CH_2O$), 4.37 (s, 3, CH_3O–), 6.75—8.12 (m, 5, Ph).

Reaction between Ethoxymorpholinophenylsulfonium Tetraphenylborate and Amines. An equimolar mixture of the reactants in CD_3COCD_3 was allowed to stand for 2.5 h at 34 °C, and its PMR spectrum showed the completion of the reaction. Ether was added, and the precipitates formed were filtered. The filtrate was concentrated, and the sulfinamide obtained was dissolved in CCl_4 and its amount was determined by PMR with tetrachloroethane as the internal standard. From triethylamine, $Et_4\overset{\oplus}{N}B\overset{\ominus}{Ph_4}$ (94.8%) and *N*-benzenesulfinylmorpholine (94.3%) were obtained. From pyridine, $C_5H_5\overset{\oplus}{N}$–Et $B\overset{\ominus}{Ph_4}$ (91.0%) and *N*-benzenesulfinylmorpholine (98.2%) were obtained.

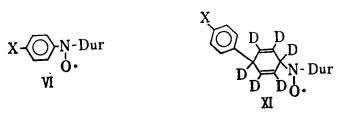
Scheme 3.

Contrary to the case in benzene-d_6, benzoyloxycyclohexadienyl duryl nitroxide (II) was not detected at all in the decomposition of BPO in benzene. Undoubtedly II is oxidized easily by traces of oxygen, while the oxidation of IXa proceeds slowly on account of the deuterium isotope effects.

The decomposition of bis(4-methylbenzoyl) peroxide (Me–BPO) in benzene-d_6 at 45 °C in the presence of nitrosodurene resulted in the formation of one stable paramagnetic species, the deuterated duryl 4-methylbenzoyloxycyclohexadienyl nitroxide (IXb, a_N=13.3 and $a_{\beta-D}$=1.4 gauss), which was then oxidized to a dehydrogenated nitroxide (Xb, a_N=9.8 gauss) on exposure to air. In the decomposition of Me–BPO at 50 °C, however, duryl 4-methylphenyl nitroxide (VIb)[4] was detected in addition to IXb. Bis(4-methoxybenzoyl) peroxide (MeO–BPO) gave a similar nitroxide (IXc, a_N=13.1 and $a_{\beta-D}$=1.5 gauss) at 45 °C and a mixture of IXc and its dehydrogenated nitroxide (Xc, a_N=9.7 gauss) at 50 °C, but none of a spin adduct of 4-methoxyphenyl radicals (VIc) was obtained. The air oxidation of IXc led to the formation of Xc. The alternative assignment of IXb and IXc to arylcyclohexadienyl duryl nitroxides (XIb and XIc, respectively) can be ruled out on the basis of the facts[4] that 4-methyl- and 4-methoxyphenylazotriphenylmethane (Me–PAT and MeO–PAT, respectively) do not yield any amounts of XIb and XIc, but afford the aryl duryl nitroxides, VIb and VIc, respectively. Thus, even if 4-methyl- and 4-methoxyphenyl radicals were generated in the decomposition of Me–BPO and MeO–BPO, respectively, the nitroxides, XIb and XIc, would not be formed at all.

When bis(4-chlorobenzoyl) and bis(4-nitrobenzoyl) peroxide (Cl–BPO and NO_2–BPO, respectively) were decomposed in the presence of nitrosodurene at 45 °C in benzene-d_6, the ESR signals (a_N=13.3 and $a_{\beta-D}$=1.5 gauss from Cl–BPO, and a_N=13.4 and $a_{\beta-D}$=1.6 gauss from NO_2–BPO) similar to those of IXb and IXc were observed and then replaced by other signals (a_N=9.6 gauss from both Cl–BPO and NO_2–BPO) by the air oxidation. The initially observed signals are similar in the shape and the magnitude of a_N to, but different in the magnitude of $a_{\beta-D}$ from, those of the spin adducts, XId (a_N=13.5 and $a_{\beta-D}$=2.1 gauss) and XIe (a_N=13.6 and $a_{\beta-D}$=2.0 gauss), formed from 4-chloro- and 4-nitrophenylazotriphenylmethane in benzene-d_6, respectively.[4] Although Cl–BPO and NO_2–BPO might produce XId and XIe through 4-chloro- and 4-nitrophenyl radicals, respectively, it can be assumed that the nitroxide radicals, IXd, Xd, IXe, and Xe, are also formed in the present cases by analogy with the behavior of the other peroxides.



VI XI

a : X=H b : X=CH_3
c : X=CH_3O d : X=Cl
e : X=NO_2

Finally, it is interesting to note that the spin adduct of 4-methylphenyl radicals (VIb) was detected in the decomposition of Me–BPO at 50 °C, whereas none such was observed in the decomposition of MeO–BPO at the same temperature. This finding might reflect the higher activation energy required for the decarboxylation of 4-methoxybenzoxyl radicals than for that of 4-methylbenzoxyl radicals.[7]

Experimental

Nitrosodurene,[5] substituted dibenzoyl peroxides,[8] and 4-iodophenyl benzoate[9] were prepared according to the methods described in the literatures.

Decomposition of the peroxides was carried out as follows: a solution of nitrosodurene (5 mM) and a peroxide (10 mM) in benzene or benzene-d_6 was purged with argon for 2 min in an ESR tube prior to decomposition in order to remove dissolved oxygen and was heated at the specified temperature for 5 min. The ESR spectra were recorded on a JEOL JES-ME-lX spectrometer. Photolysis of 4-iodophenyl benzoate(VII) was carried out by irradiation of the solution (nitrosodurene, 5 mM and VII, 10 mM in carbon tetrachloride) in a Pyrex tube directly in the cavity by means of a 400 W high pressure mercury arc lamp.

The Photochemical Reaction of 2-Alkoxy-1,4-naphthoquinones with Olefins. III.[1] The Re-examination of the Structures of the Photo-addition Compounds and the Reaction Mechanism

Tetsuo OTSUKI

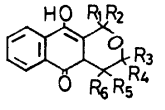
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received February 26, 1976)

In the photochemical reaction of 2-alkoxy-1,4-naphthoquinones with a variety of olefins, two types of photo-addition compounds are found to be produced: the cyclobutane-ring compounds and the oxetanol-ring compounds. Although the present author has assigned the structure of a tetrahydropyran-ring compound to one of the photo-addition compounds primarily on the basis of the analyses of the spectral data, the previously proposed structures should be corrected to an oxetanol-ring compound on the basis of the chemical reactivities. Although some cyclobutane-ring compounds were stable enough to be isolated as final reaction products, the other cyclobutane-ring compounds, though once produced, were too unstable to undergo the subsequent photochemical reaction to give oxetanol-ring compounds on further irradiation. The stability of the cyclobutane-ring compounds was dependent on both the substituents of the olefins and the wavelength of the light. The origin of the stability and the reaction mechanism were investigated.

A variety of compounds characterized by their stimulating physiological activity have been synthesized by means of the photochemistry of quinones.[2] Thus, the photochemical reactions of quinones with olefins have attracted several workers.[3-8] Although 1,4-naphthoquinone has been known to yield photo-addition compounds with olefins, the yields are, in general, low, partly because the photo-reduction of 1,4-naphthoquinone proceeds competitively to form such photo-reduction compounds as 1,4-naphthoquinhydrones or 1,4-naphthalenediol. These complicated features originate partly from the higher oxidation potential of 1,4-naphthoquinone.[9,10]

2-Alkoxy-1,4-naphthoquinones, on the other hand, have lower oxidation potentials than that of 1,4-naphthoquinone;[9,10] hence, the photo-addition products of 2-alkoxy-1,4-naphthoquinones with olefins could be isolated in fairly good yields as a result of a smooth reaction, while there were no photo-reduction products such as quinhydrones or 1,4-diol. The photo-addition compounds obtained in the reaction mentioned above could be classified into two types. Although the present author has assigned the structure of 10-hydroxy-3,4,4a,5-tetrahydro-1*H*-naphtho[2,3-*c*]pyran-5-one derivatives, **1**, to one of the photo-addition compounds[1] primarily on the basis of the analyses of the spectral data, every attempt to derive **1** to 1,4-naphthoquinone derivatives or 1,4-naphthalenediol derivatives *via* keto-enol change, has proven unsuccessful. Thus, in this report the previously proposed structure, **1**, will be revised to the structure, **2**, that of the oxetanol derivatives. The chemical evidences preferring the structure **2** to **1** will be presented. In addition, the course of the reaction was much influenced by both the substituents of the olefins and the wavelength of the light. The mechanism of the reaction, as well as the factors determining these photo-addition products, was investigated.



1

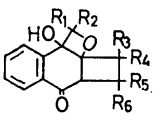
Results and Discussion

The 2-alkoxy-1,4-naphthoquinones examined here are 2-methoxy-, 2-ethoxy-, 2-isopropoxy-, and 2-allyloxy-1,4-naphthoquinones. The olefins selected in this work are 1-hexene, 1-heptene, 1-octene, 1-nonene, 1-decene, cyclohexene, cyclooctene, 1,5-cyclooctadiene, 2-bicyclo[2.2.1]heptene, 2,5-bicyclo[2.2.1]heptadiene, styrene, indene, α-methylstyrene, 1,1-diphenylethylene, and 1,1-di-*p*-tolylethylene.

A benzene solution of a mixture of a 2-alkoxy-1,4-naphthoquinone and an olefin was subjected to irradiation by a high-pressure Hg arc lamp with and/or without the application of a filter, A or B. The transmission characteristics of the filters, A and B, are shown in Table 1. Neither the precipitation of 2-alkoxy-1,4-naphthoquinhydrones nor any coloration was observed during the course of the reaction, even when olefin had active hydrogen atoms, such as 1-hexene; that is, the reaction proceeded smoothly. This is one of the extremely different features of 2-alkoxy-1,4-naphthoquinones compared with 1,4-naphthoquinone itself. The structures of these photo-addition compounds, which were obtained in fairly good yields in every case examined here, proved to be classifiable into two types, **2** and **3**, depending on both the substituents of the olefins and the wavelength of the light.

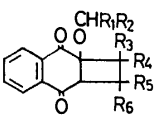
Table 1. Transmission characteristics of the filter

	0% Transmission (nm)	50% Transmission (nm)	90% Transmission (nm)
Filter A	360	390	450
Filter B	390	420	470



2

(or the structure 1)

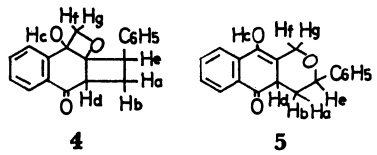


3

When 2-alkoxy-1,4-naphthoquinones and olefins, with the exceptions of 1,1-diphenylethylene and 1,1-di-

p-tolylethylene, were subjected to photochemical reactions under irradiation with no filter, the photo-addition products proved to have, in general, the structure, **2**. On irradiation with use of a filter (A or B), however, these olefins yielded another type of photo-addition compound, **3**. Under the conditions with and/or without a filter, on the other hand, 1,1-diphenylethylene or 1,1-di-*p*-tolylethylene was found to give exclusively the photo-addition compound, **3**. First, the determination of the structures of the photo-addition products will be described.

The Re-examination of the Structure of the Photo-addition Compounds, 2: The re-examination of the structure of the photo-addition compounds, **2**, will be illustrated by referring to the photo-product obtained in the reaction of 2-methoxy-1,4-naphthoquinone with styrene, a typical example. A benzene solution (20 ml) of 2-methoxy-1,4-naphthoquinone (1 mmol) and styrene (2 mmol) was subjected to irradiation by a high-pressure Hg arc lamp (300 W) without a filter until the quinone was completely consumed. The quantum efficiency of the photochemical reaction for the disappearance of 2-methoxy-1,4-naphthoquinone in its reaction with styrene was estimated to be 0.18 (with the filter, A). After the usual work-up of the reaction mixture, white needles were obtained as the main reaction product in a 69% yield. The elemental analysis and the molecular weight determined by mass spectrometry reveal that the photo-addition compound was composed of one molecule of 2-methoxy-1,4-naphthoquinone and one molecule of styrene. The photo-addition compound contained both a hydroxyl group and a carbonyl group, judging from the inspection of the IR and UV spectra. In the ^{1}H-NMR spectrum (Fig. 1), the signal corresponding to H_c disappeared after the treatment of the chloroform solution with D_2O. The nuclear spin-spin interactions among H_a, H_b, H_d, and H_e were confirmed by the spin decoupling technique. When 2-methoxy-d_3-1,4-naphthoquinone was subjected to the same photochemical reaction, the ^{1}H-NMR signals corresponding to H_f and H_g (Fig. 1) disappeared. On the other hand, the ^{1}H-NMR signal corresponding to H_d disappeared completely when 2-methoxy-1,4-naphthoquinone-3-*d* was used in the reaction. These results indicate that the protons, denoted by H_d, H_f, and H_g, of the photo-addition compound originated from the 2-methoxy-1,4-naphthoquinone moiety. Taking into consideration either of the two structures, **4** or **5**, one can reasonably explain the spectral data of the photo-addition compound. Of these, **4** was characterized by an oxetanol ring as well as a cyclobutane ring. A similar structure was once suggested by Anett[11] for the reaction product obtained by the photochemical reaction of 2-methoxy-1,4-naphthoquinone with vinyl acetate and by Ellis and Jones[12] for the photo-dimerization product of 2-methoxy-1,4-naphthoquinone. On the other hand, **5**, characterized by a tetrahydropyran ring and previously proposed by the present author,[1] should be converted to 1,4-naphthoquinone derivatives or 1,4-naphthalenediol derivatives *via* a keto-enol change. Every attempt to do so, how-



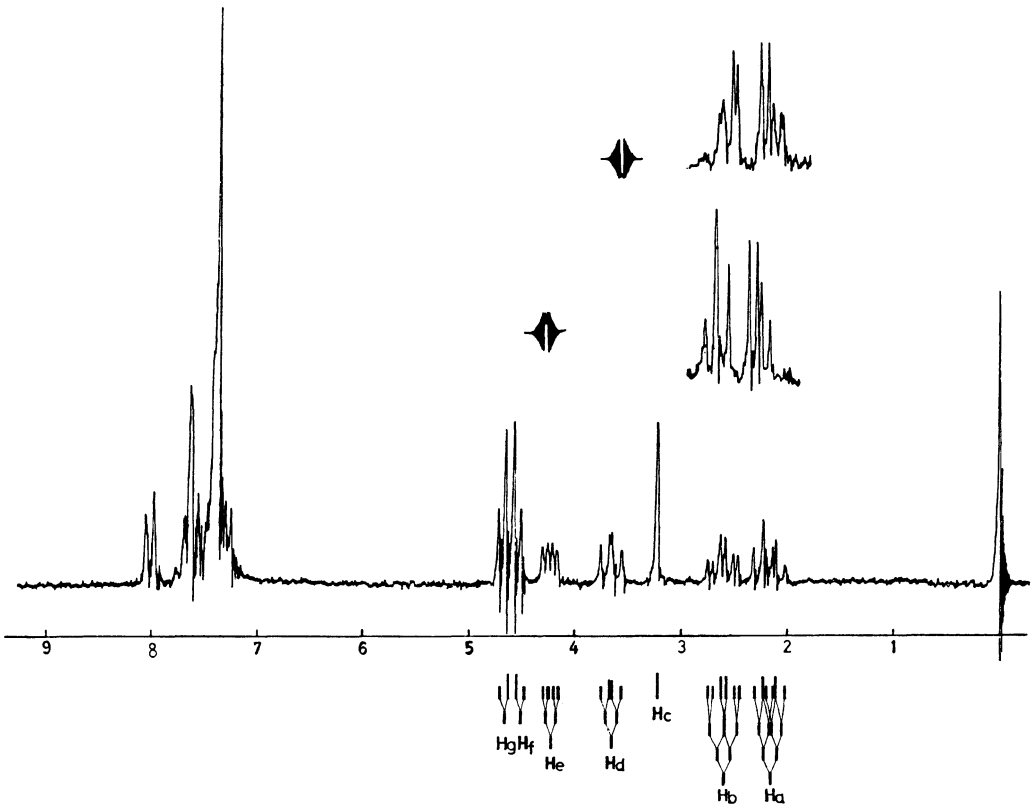


Fig. 1. ^{1}H-NMR spectrum of the photo-addition compound.

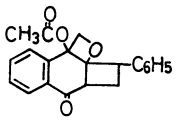
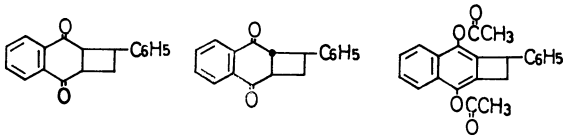
ever, had no success. When the photo-addition compound was acetylated with acetic anhydride for 3 h, a mono-acetylated product, **6**, was obtained (yield: 83%).[13]



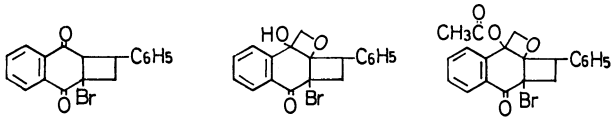
6

The Acid-catalyzed Decomposition of the Photo-addition Compound: After the treatment of the photo-addition compound with hydrochloric acid or sulfuric acid in a chloroform solution at room temperature, a mixture of two products, **7a** and **7b**, was isolated in a 60% yield. **7a** and **7b** have the same molecular weight, suggesting that a formaldehyde unit is released during the treatment. By the photochemical reaction of 1,4-naphthoquinone with styrene we obtained, in actual, the same mixture of **7a** and **7b**, although the relative ratio of the two compounds was not compatible. The 1,4-diacetoxynaphthalene derivative, **8**, was isolated as the sole reaction product when **7a**, as well as **7b**, was treated by sodium acetate–acetic anhydride under reflux conditions. These results confirmed that **7a** and **7b** are isomeric with each other.[14]



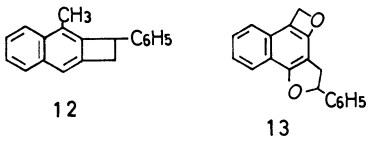
7a **7b** **8**

The Bromination of the Photo-addition Compound: The bromination of the photo-addition compound with bromine in a chloroform solution at room temperature gave a mixture of two compounds, **9** (54%) and **10** (32%). Since **10** was revealed to have a hydroxyl group through the inspection of the IR spectrum, the acetylation of **10** was performed and an acetyl derivative, **11**, was isolated. **9** and **11** were also obtained through the bromination of the acetyl derivative of the photo-addition compound, **6**, in 50 and 36% yields respectively. The structure of **9** was further confirmed by the isolation of **9** as one of the reaction products from the bromination reaction of **7b**.

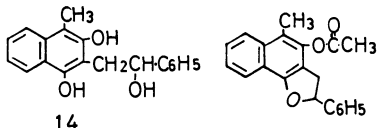


9 **10** **11**

The Clemmensen Reduction of the Photo-addition Compound: Three reaction products, **12**, **13**, and **14**, were isolated from the reaction mixture of the Clemmensen reduction of the photo-addition compound in 17, 7, and 12% yields respectively. **12** was revealed to be the derivative of 1-methylnaphthalene through the isolation of 1-methylnaphthalene as the thermal decomposition product of **12**. The coloration of **14** to deep yellow by ferric sulfate in ethanol suggested the existence of the phenolic hydroxyl group; this is confirmed by the fact that the acetylation of **14** with sodium acetate–acetic anhydride yielded an acetyl derivative, **15**. Moreover, the possibility of 1,4-naphthalenediol derivatives could be excluded since the oxidation of **14** by silver oxide in ether failed to yield 1,4-naphthoquinone derivatives.



12 **13**



14 **15**

The ^{13}C-NMR Spectrum of the Photo-addition Compound: The ^{13}C-NMR spectrum of the photo-addition compound was measured in a solution of chloroform (the chemical shifts were calibrated from TMS as the internal standard): δ; 26.63, 43.44, 49.63, 70.62, 82.33, 90.95, 126.92, 127.05, 127.41, 128.26, 129.17, 130.26, 134.93, 137.60, 143.43, and 197.24 ppm. These data suggest that the photo-addition compound contains six different kinds of sp^3-carbon atoms as its constituents.

From the results described above, it can be deduced that the photo-addition compound should have the structure, **4**, characterized by an oxetanol ring as well as a cyclobutane ring. Here, the present author would like to correct the previously proposed structure, **5**, for the photo-addition compound.

A similar type of photo-addition compound, **2**, obtained in the photochemical reaction of 2-alkoxy-1,4-naphthoquinone with olefins is tabulated in Table 2.

The Structure of the Photo-addition Compounds, **3**: As a typical example, the photochemical reaction of 2-methoxy-1,4-naphthoquinone with 1,1-diphenylethylene will be described. A benzene solution (20 ml) of 2-methoxy-1,4-naphthoquinone (1 mmol) and 1,1-diphenylethylene (2 mmol) was subjected to irradiation by high-pressure Hg arc lamp (300 W) without a filter. After the complete consumption of the quinone, white crystals were isolated as a sole reaction product in a 63% yield. The elemental analysis and the mass data require that the photo-addition compound is composed of one molecule each of 2-methoxy-1,4-naphthoquinone and 1,1-diphenylethylene. The IR and UV spectra show the existence of the carbonyl group, but not the hydroxyl group. The ^1H-NMR spectrum was compatible with the structure, **3a**. The assignment of the ^1H-NMR signals was concreted by the reaction using 2-methoxy-d_3-1,4-naphthoquinone as the starting material. Upon being heated in carbon tetrachloride, the photo-addition compound, **3a**, decomposed again to give 2-methoxy-1,4-naphthoquinone and 1,1-diphenylethylene quantitatively. The half-life of **3a** was estimated to be about 92 min at 75±1 °C.

The Structure of the Photo-addition Compounds and Its Relation to the Substituents of Olefins and the Wavelength of Irradiation: With 1,1-diphenylethylene or 1,1-di-*p*-tolylethylene, 2-alkoxy-1,4-naphthoquinone was found to yield exclusively the photo-addition compound, **3a** or **3b**, characterized by a cyclobutane ring, independent of the wavelength of irradiation. On the other hand, in the photochemical reaction of 2-alkoxy-1,4-naphthoquinone with olefins other than 1,1-diphenylethylene and 1,1-di-*p*-tolylethylene, both of the two different types of photo-addition compounds, **2** and **3**, were obtained, depending on whether the irradiation was with or without a filter (Table 2).

In the photochemical reaction of the quinone with α-methylstyrene, the photo-addition compound, **3c**, was the main reaction product (69% yield); the photo-addition compound, **2m**, was obtained as a minor reaction product (9% yield) on irradiation without a filter. In contrast with the case of α-methylstyrene without a filter, the photo-addition compound, **2l** or **2c**, characterized by an oxetanol ring as well as a cyclobutane ring, could be isolated as a stable product in the reaction of the quinone with another olefin, such as styrene or 1-octene, but none of any cyclobutane-ring compound, such as **3d** or **3e**, could be obtained after the consumption of the quinone had been completed (Fig. 2). By cutting the light of a shorter wavelength with a filter (A or B), one could obtain, however, a cyclobutane-ring compound, **3d** or **3e**, as well as an oxetanol-ring compound, **2l** or **2c**, even in a reaction with styrene or with 1-octene (Fig. 3). The results obtained above indicate that the cyclobutane-ring compounds, once produced, undergo further reaction upon irradiation at a shorter wavelength to the oxetanol-ring compounds, depending on their stabilities. Thus, the tendency of the susceptibility to further reactions is as follows: adduct from 1,1-diphenylethylene or its derivatives < adduct from α-methylstyrene < adduct from the other olefins, such as styrene or 1-octene. The source of the stability of the adduct, **3**, to the light will be discussed in the following sections.

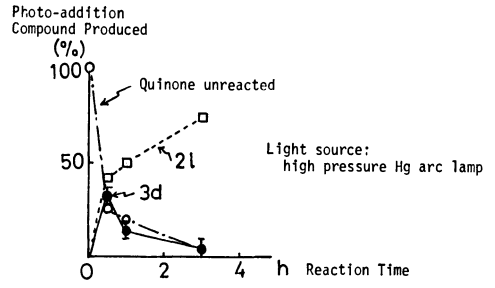

Fig. 2. Photochemical reaction of 2-methoxy-1,4-naphthoquinone with styrene.

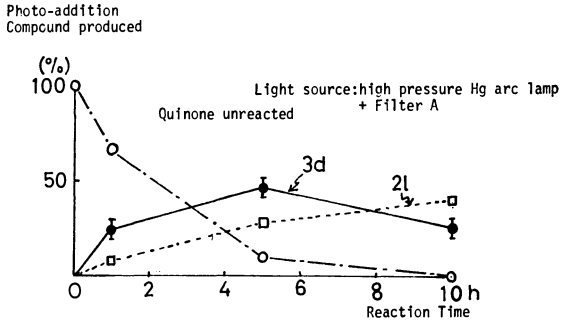

Fig. 3. Photochemical reaction of 2-methoxy-1,4-naphthoquinone with styrene.

The Stability of the Photo-addition Compounds, 3, in Relation to the Substituents of Olefins: The absorption characteristics of the photo-addition compounds, **3**, are summarized in Table 3. In the UV spectrum of **3a** dissolved in carbon tetrachloride or acetonitrile, a new shoulder at a longer wavelength [365 nm(CCl_4), 361 nm(CH_3CN)] appeared which could not be observed in **3d** or **3e**. This absorption can be compared in its wavelength and absorption coefficient [UV_{max} (CH_3CN): 340 nm (ε: 597)] to the charge-transfer band observed in [2,2]paracyclophanequinone.[15] This suggests that the intramolecular interactions exist in the photo-addition compound, **3a**.

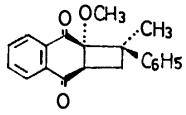
Table 3. The absorption characteristics of the photo-addition compounds **3**

Photo-addition compounds	Solvents	Absorption characteristics nm (ε)
3a	CCl_4	303(2.0×10^3), 312(1.9×10^3), 352(1.7×10^2), 365(1.5×10^2)
	CH_3CN	303(1.9×10^3), 312(1.7×10^3), 349(1.5×10^2), 361(1.4×10^2)
3d	CCl_4	301(2.8×10^3), 310(2.6×10^3), 343(4.5×10^2)
	CH_3CN	301(2.6×10^3), 301(2.4×10^3), 339(4.5×10^2)
3e	CCl_4	300(1.4×10^3), 309(1.3×10^3), 352(1.6×10^2)
	CH_3CN	300(1.5×10^3), 308(1.4×10^3), 349(1.7×10^2)

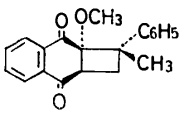
These intramolecular interactions could be understood further by an inspection of the ^{1}H-NMR data. That is, the ring protons of phenyl groups in the compound, **3a**, show complicated ^{1}H-NMR signals which otherwise show broad singlet-like ^{1}H-NMR signals such as those in 1,1-diphenylethylene as a starting olefin. The intramolecular interactions are demonstrated more clearly by the ^{1}H-NMR spectrum of **3b** in carbon tetrachloride, which exhibits the existence of two different kinds of *p*-tolyl groups. That is, two different kinds of methyl protons appeared at δ=2.06 and 2.28 ppm, and two different sets of a multiplet of four protons appeared as an AB-quartet pattern which is characteristic of a para-substituted benzene ring. One of these AB-quartets possessed δ-values of 6.75 and 7.01 ppm (J=10.0 Hz), and the other, those of 7.01 and 7.27 ppm (J=8.0 Hz). The methyl protons of 1,1-di-*p*-tolylethylene as a starting olefin, on the other hand, appeared at δ=2.36 ppm and an AB-quartet of the aromatic protons possesses δ-values of 7.01 and 7.15 ppm (J=8.0 Hz). A comparison of these ^{1}H-NMR data with those of the starting olefins shows that the chemical shifts of the protons belonging to one of the *p*-tolyl groups move to higher field in the photo-addition compound, **3b**. Presumably these shifts to a higher field originate from the anisotropy of the aromatic rings as well as the carbonyl

groups of the quinone moiety in the compound, **3b**. In fact, an inspection of the molecular model reveals that the quinone moiety and one of the *p*-tolyl groups of the olefin moiety are in close proximity.

These results presented above suggest the existence of intramolecular interactions through π-electrons in the cyclobutane type of the photo-addition compounds, **3**, derived from 2-methoxy-1,4-naphthoquinone and 1,1-diphenylethylene or its derivatives.



3c-I



3c-II

In the photochemical reaction of 2-methoxy-1,4-naphthoquinone with α-methylstyrene, the adduct obtained was confirmed to be a mixture of **3c**-I and **3c**-II from an inspection of the ^{1}H-NMR spectra. Because of the non-symmetrical nature of α-methylstyrene, the possible formation of two isomers is explicable; *i.e.*, one is an isomer which has intramolecular interactions between the quinone moiety and the phenyl group of the olefin moiety through π-electrons, **3c**-I, while the other is an isomer which has no interactions, **3c**-II. On irradiation by a high-pressure Hg arc lamp without a filter, the ratio of the isomer contents, **3c**-I/II, was estimated to be 1.0/1.5, as determined by the integration of the ^{1}H-NMR signals. The ratio, **3c**-I/II, was found to be dependent on the wavelength of the light source used (Table 4). The relative ratio of the isomers, **3c**-I/II, is

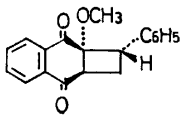
Table 4. The ratio of the isomer contents, **3c**-I/II, in the photochemical reaction of 2-methoxy-1,4-naphthoquinone with α-methylstyrene[a)]

Filter used[b)]	**3c**-I	**3c**-II
None	1.0	1.5
Filter A	1.0	3.9
Filter B	1.0	5.1

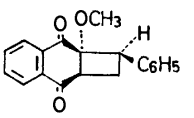
a) The ratio was estimated on the basis of the integration of the ^{1}H-NMR signals of the mixture. b) The light source used was a high-pressure Hg arc lamp.

increased as the relative transmittance at the shorter wavelength is increased by changing the filters. Moreover, on irradiating a benzene solution of a mixture of the two isomers in a Pyrex glass tube by means of a high-pressure Hg arc lamp without a filter, **3c**-II was found to decompose selectively. These results indicate that the isomer, **3c**-I, is more stable than **3c**-II. That is, the cyclobutane ring in the photo-addition compound, **3**, is deduced to be stabilized by intramolecular interactions through π-electrons. The energy relaxation mode *via* the intramolecular interactions might play a considerably important role in the photo-addition compound, **3**, although the sterical requirements exerted by the substitutents of the olefin moiety should also be taken into consideration at the same time for the H-abstraction by excited carbonyl groups in **3**.[16)]

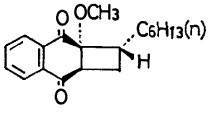
From the results tabulated in Table 4 one can observe that the amount of the isomer, **3c**-II, always surpassed that of **3c**-I. The formation of **3c**-I is less favored, presumably because of the sterical requirements, though the isomer, **3c**-I, once formed, may be more stable than **3c**-II on further irradiation. These sterical requirements might play a more important role in the selective formation of a cyclobutane-ring compound in the case of styrene or 1-octene than in α-methylstyrene. Only one of the possible isomers, **3d** or **3e**, could be obtained, but neither **3d'** nor **3e'**, when styrene or 1-octene and 2-methoxy-1,4-naphthoquinone were submitted to irradiation with a filter. The cyclobutane-ring compound, **3d** or **3e**, was confirmed to have no intramolecular interactions by an inspection of the UV and ^{1}H-NMR spectra.



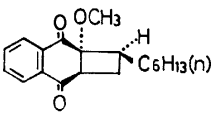
3d



3d'

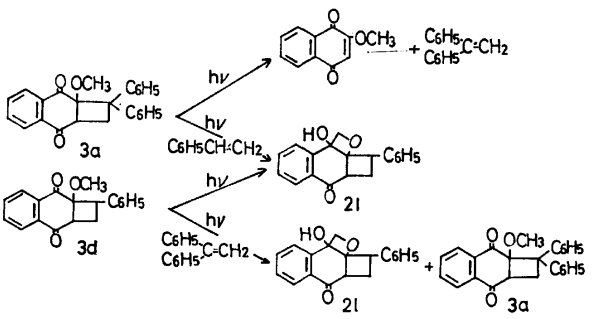


3e



3e'

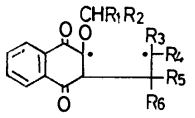
The Reversibility of the Formation of the Cyclobutane-ring Compounds, 3: On further irradiation without a filter, the cyclobutane-ring compound, **3a**, slowly photo-decomposed to give 2-methoxy-1,4-naphthoquinone and 1,1-diphenylethylene. Moreover, when, under the same conditions, the photochemical decomposition of the compound, **3a**, was investigated in the presence of an excess of styrene, the sole reaction product isolated was determined to be **21**; the same product as that derived from the photochemical reaction of 2-methoxy-1,4-naphthoquinone with styrene without a filter. On the other hand, since the cyclobutane-ring compound, **3d**, quantitatively photo-rearranged to the compound, **21**,[17)] a similar photochemical reaction of **3d** was examined in the presence of an excess of 1,1-diphenylethylene; then the compound, **3a**, was isolated as well as **21**. These results are illustrated in Scheme 1. The results presented can all be explained assuming that the formation of a cyclobutane-ring compound is reversible on irradiation.



Scheme 1.

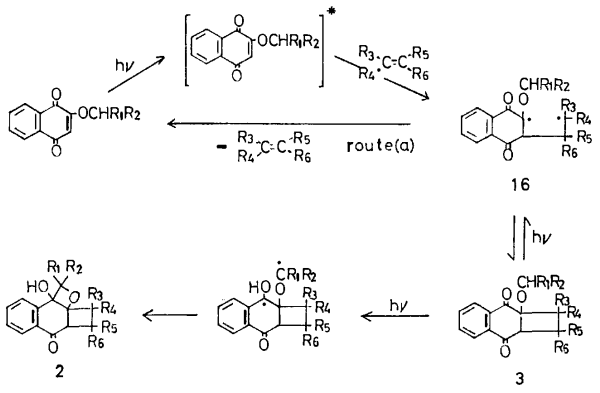
The Reaction Scheme. In the photochemical reaction of 2-alkoxy-1,4-naphthoquinones with olefins, the first stage of the reaction should be the formation of cyclobutane-ring compounds, **3**, from the photo-excited

quinones and olefins. Severals of the cyclobutane-ring compounds derived from such olefins as 1,1-diphenylethylene, 1,1-di-*p*-tolylethylene and α-methylstyrene are stabilized by intramolecular interactions through π-electrons as well as by sterical requirements for the intramolecular H-abstraction by an excited carbonyl group.[16] In another case, the cyclobutane-ring compounds are rather unstable upon further irradiation to undergo the subsequent photochemical reaction *via* intramolecular H-abstraction by a carbonyl group to yield the oxetanol-ring compounds, **2**, which are themselves stable upon further irradiation. The extent of the reversible reaction to the starting quinone and the olefin (Route (a)) is considerable for the diradical, **16**, derived from **3a**, **3b**, **3c**, or **3f**, presumably because of the lower dissociation energy of the bond connecting the quinone with olefin moieties. The bonding between the quinone and olefin moieties of the diradical, **16**,



16

could be weakened by the aryl (or methyl) substitutents of the olefin moiety. Thus, although the cyclobutane-ring compounds, **3a**, **3b**, **3c**, or **3f**, can be relatively stabilized as a result of the intramolecular interactions through π-electrons, the decomposition to the quinone and the olefin might be predominant and no further photochemical reaction to the oxetanol-ring compounds, **2**, could proceed when the cyclobutane-ring compounds, **3**, were irradiated by light of a shorter wavelength.



Scheme 2.

The possible reaction mechanism is summarized in Scheme 2.

Experimental

Starting Materials. *Quinones*: The 2-alkoxy-1,4-naphthoquinones were prepared by the etherification of 2-hydroxy-1,4-naphthoquinone with an appropriate alcohol in the presence of concd sulfuric acid or the boron trifluoride–ether complex, according to the literature; 2-methoxy-1,4-naphthoquinone: mp 178.0—180.5 °C,[18] 2-ethoxy-1,4-naphthoquinone: mp 118.0—119.0 °C,[19] 2-isopropoxy-1,4-naphthoquinone: mp 111.5—112.0 °C,[20] and 2-allyloxy-1,4-naphthoquinone: mp 98.0—100.0 °C.[20]

Olefins: 1,1-Di-*p*-tolylethylene was synthesized by the Grignard reaction of *p*-tolylmagnesium bromide and ethyl acetate; then the 1,1-di-*p*-tolylethanol thus produced was subjected to dehydration with 20% sulfuric acid; mp 61.0 °C.[21] The other olefins examined here were commercially available and were purified by distillation before use.

General Procedures. 2-Alkoxy-1,4-naphthoquinone (1 mmol) and olefin (2 mmol) were dissolved in benzene (20 ml) and irradiated in a glass tube by means of a high-pressure Hg arc lamp (300 W) through a 5-cm-thick water layer. After the 2-alkoxy-1,4-naphthoquinone had been completely consumed, the benzene was distilled off under reduced pressure. The reaction mixture was purified by chromatography on silica gel and then further purified by recrystallization from an appropriate solvent.

Identification of the Photo-addition Compounds. *8-Butyl-2-hydroxy-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one (**2a**)*; colorless oil (yield, 25%). Mass; *m/e*=272 (M^+). IR (liq. film); 3480 (OH), 2920, 2840 (CH), 1680 cm^{-1} (C=O). ^{1}H-NMR (CCl_4): δ; 0.96 (3H, CH_3, br t), 1.40 (6H, aliphatic-H, br m), 1.65-1.90 (2H, C-7 CH_2, m), 2.84 (1H, C-8 CH, m), 3.28 (1H, C-6 CH, t, *J*=10.0 Hz), 3.80 (1H, OH, s), 4.34, 4.56 (2H, C-10 CH_2, AB-q *J*=6.0 Hz), 7.24—7.92 ppm (4H, aromatic-H, m).

*8-Pentyl-2-hydroxy-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one (**2b**)*; white needles from hexane (yield, 50%). Mp 80.0—81.0 °C. Mass; *m/e*=286 (M^+). Found: C, 75.78; H, 8.05%. Calcd for $C_{18}H_{22}O_3$: C, 75.49; H, 7.74%. IR (KBr disk); 3360 (OH), 2920, 2840 (CH), 1670 cm^{-1} (C=O). ^{1}H-NMR (CCl_4); δ: 0.92 (3H, CH_3, br t), 1.36 (8H, aliphatic-H, m), 1.64—1.90 (2H, C-7 CH_2, m), 2.92 (1H, C-8 CH, m,) 3.28 (1H, C-6 CH, t, *J*=10.0 Hz), 3.92 (1H, OH, s), 4.34, 4.56 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 7.22—7.96 ppm (4H, aromatic-H, m).

*8-Hexyl-2-hydroxy-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one (**2c**)*; white needles from hexane(yield, 67%); mp 101.0—101.5 °C. Mass; *m/e*=300(M^+). Found: C, 76.21; H, 8.32%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%. IR (KBr disk); 3320 (OH), 2920, 2840(CH), 1680 cm^{-1} (C=O). ^{1}H-NMR (CCl_4); δ: 0.92 (3H, CH_3, br t), 1.36 (10H, aliphatic-H, m), 1.64—1.90 (2H, C-7 CH_2, m), 2.92 (1H, C-8 CH, m), 3.30 (1H, C-6 CH, t, *J*=10.0 Hz), 3.50 (1H, OH, s), 4.38, 4.58 (2H, C-10 CH_2, AB-q, *J*=6.0 Hz), 7.28—7.96 ppm (4H, aromatic-H, m).

*8-Heptyl-2-hydroxy-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one (**2d**)*; white needles from benzene–hexane (yield, 48%); mp 84.0—85.0 °C. Mass; *m/e*=314 (M^+). IR (KBr disk); 3340 (OH), 2940, 2860 (CH), 1680 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 0.88 (3H, CH_3, br t), 1.10—1.92 (14H, aliphatic-H, m), 2.80 (1H, OH, s), 2.84 (1H, C-8 CH, m), 3.40 (1H, C-6 CH, t, *J*=8.0 Hz), 4.44, 4.62 (2H, C-10 CH_2, AB-q, *J*=8.0 Hz), 7.28—8.00 ppm (4H, aromatic-H, m).

*8-Octyl-2-hydroxy-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one(**2e**)*; white needles from petroleum ether (yield, 45 %); mp 110.0—111.0 °C. Mass; *m/e*=328 (M^+). IR (KBr disk); 3340 (OH), 2940, 2860 (CH), 1680 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 0.90 (3H, CH_3, t), 1.10—2.00 (16H, aliphatic-H, m), 2.80 (1H, OH, s), 2.82 (1H, C-8 CH, m), 3.46 (1H, C-6 CH, t, *J*=8.0 Hz), 4.56, 4.64(2H, C-10 CH_2, AB-q, *J*=8.0 Hz), 7.30—8.04 ppm (4H, aromatic-H, m).

*2-Hydroxy-7,8-tetramethylene-3,4-benzo-1,2-epoxymethanobicyclo-[4.2.0]oct-3-en-5-one(**2f**)*; colorless oil (yield, 39%). Mass; *m/e*=270 (M^+). IR (liq. film); 3350 (OH), 2920, 2840 (CH), 1660 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 0.80—3.25 (10H, aliphatic-H, m), 3.42 (1H, C-6 CH, d, *J*=8.0 Hz), 4.48, 4.64 (2H, C-10 CH_2, AB-q, *J*=6.0 Hz), 4.80 (1H, OH, s), 7.24—8.10 ppm (4H, aromatic-H, m).

*7,8-Hexamethylene-2-hydroxy-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one(**2g**)*; white needles (yield, 74%); mp 191.0—198.0 °C (decomp). Mass; *m/e*=298 (M^+). IR (KBr disk); 3360 (OH), 2920, 2840 (CH), 1660 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 0.90—3.00 (14H, aliphatic-H, m), 3.04 (1H, C-6 CH, d, J=8.0 Hz), 4.52, 4.64 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 4.72 (1H, OH, s), 7.36—8.12 ppm (4H, aromatic-H, m).

*7,8-(3-Hexenylene)-2-hydroxy-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-ene-5-one(**2h**)*; white crystals (yield, 29%); mp 184.0—186.0 °C (decomp). Mass; *m/e*=296 (M^+). IR (KBr disk); 3320(OH), 3000, 2910, 2840 (CH), 1670 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 1.00—2.80 (11H, aliphatic-H and OH, m), 3.16 (1H, C-6 CH, d, J=10.0 Hz), 4.68 (2H, C-10 CH_2, br s), 5.52 (2H, C-3′ and C-4′ CH′ s, br d), 7.28—7.96 ppm (4H, aromatic-H, m).

*2-Hydroxy-7,8[2′,3′]bicyclo[2.2.1]heptano-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one(**2i**)*; white crystals from chloroform (yield, 50%); mp 214.0—217.0 °C. Mass; *m/e*=282 (M^+). Found: C, 76.49; H, 6.63%. Calcd for $C_{18}H_{18}O_3$: C, 75.56; H, 6.44%. IR (KBr disk); 3420 (OH), 2960, 2930, 2880 (CH), 1670 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 1.04—2.16 (7H, aliphatic-H, m), 2.42 (2H, aliphatic-H, m), 2.82 (1H, OH, s), 2.90 (2H, aliphatic-H, m), 4.56, 4.72 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 7.24—7.92 ppm (4H, aromatic-H, m).

*2-Hydroxy-7,8[2′,3′]bicyclo[2.2.1]hept-5′-eno-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one(**2j**)*; white crystals from chloroform (yield, 35%); mp 199.0—201.0 °C. IR (KBr disk); 3380 (OH), 2960, 2880 (CH), 1665 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 1.22 (3H, aliphatic-H, m), 2.76 (2H, aliphatic-H, m), 2.60 (1H, OH, s), 3.06 (2H, aliphatic-H, m), 4.64, 4.78 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 6.04 (2H, C-5′ and C-6′ CH′ s, m), 7.24—7.96 ppm (4H, aromatic-H, m).

*2-Hydroxy-indeno[2′,3′-7,8]-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one(**2k**)*; white needles from benzene–petroleum ether (yield, 73%); mp 225.0—227.0 °C (decomp). Mass; *m/e*=304 (M^+). Found: C, 79.22; H, 5.28%. Calcd for $C_{20}H_{16}O_3$: C, 78.93; H, 5.30%. IR (KBr disk); 3320 (OH), 2920 (CH), 1675 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$); δ: 2.04 (1H, OH, s), 2.64 (1H, C-7 CH, m), 3.04 (2H, C-1′ CH_2, dd, J=6.0, 10.0 Hz), 3.19 (1H, C-6 CH, m), 4.42(1H, C-8 CH, m), 4.48, 4.76 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 7.10—8.00 ppm (8H, aromatic-H, m).

*2-Hydroxy-8-phenyl-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one(**21=4**)*; white needles from benzene (yield, 69%); mp 164.0—164.5 °C. Mass; *m/e* 292 (M^+). Found: C, 78.03; H, 5.45%. Calcd for $C_{19}H_{16}O_3$: C, 78.08; H, 5.52%. IR (KBr disk); 3250 (OH), 2940 (CH), 1675 cm^{-1} (C=O). UV_{max} ($CHCl_3$); 290 nm (ε: 3.0×10^3). ^{1}H-NMR ($CDCl_3$); δ: 2.16 (1H, C-7 CH, m), 2.58 (1H, C-7 CH, m), 3.22 (1H, OH, s), 3.62 (1H, C-6 CH, dd, J=8.0, 12.0 Hz), 4.18 (1H, C-8 CH, dd, J=6.0, 10.0 Hz), 4.56, 4.64 (2H, C-10 CH_2, AB-q, J=6.0 Hz), 7.24—8.10 ppm (9H, aromatic-H, m). ^{13}C-NMR ($CDCl_3$); δ: 26.63 (t, C-7), 43.44 (d, C-8), 49.63(d, C-6), 70.62 (s, C-1), 82.33 (t, C-10), 90.95 (s, C-2), 126.92 (aromatic-C), 127.05 (aromatic-C), 127.41 (aromatic-C), 128.26 (aromatic-C), 128.56 (aromatic-C), 129.17 (aromatic-C), 130.26 (aromatic-C), 134.93 (aromatic-C), 137.60 (aromatic-C), 143.43 (aromatic-C), 197.24 ppm (s, C-5) (chemical shifts were calibrated from TMS as an internal standard).

*2-Hydroxy-8-methyl-8-phenyl-3,4-benzo-1,2-epoxymethanobicyclo[4.2.0]oct-3-en-5-one(**2m**)*; white needles from benzene (yield, 9%); mp 201.0—204.0 °C. Found: C, 78.23; H, 5.88%. Calcd for $C_{20}H_{18}O_3$: C, 78.41; H, 5.92%. Reactions of Aroylhydrazones. II.[1] Oxidative Cyclization of Benzil Bis(aroylhydrazones) to Substituted 1,2,3-Triazoles

Mohammed A. E. SHABAN*† and Mahmoud A. M. NASSR
Chemistry Department, Faculty of Science, Alexandria University, Alexandria, Egypt
(Received September 16, 1975)

Benzil bis(aroylhydrazones) were oxidized with iodine and yellow mercury(II) oxide to 1-(1-α-aroyloxyarylideneamino)-4,5-diphenyl-1,2,3-triazoles. The structure of the prepared compounds was determined by studying their chemical and spectral properties.

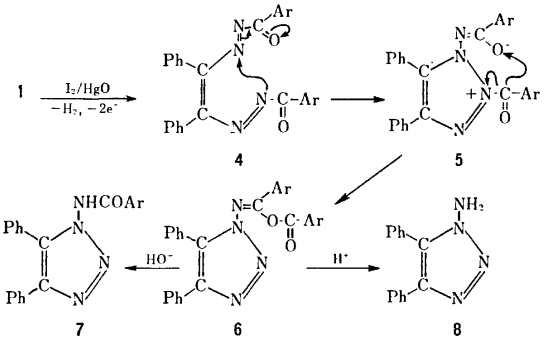
Bis(aroylhydrazones) of 1,2-dicarbonyl compounds have been known to undergo oxidation to give different products[2-5] depending upon the parent 1,2-dicarbonyl compound[2,5] and the oxidizing agent used.[2,6] Oxidation of these compounds with alkaline potassium hexacyanoferrate(III) or iodine and yellow mercuric oxide was first reported by Stolle[6] to give products which ascribed, at that time, 1,2,3,4-dihydrotetrazine structures.[6,8] However, the structure of the oxidation products was reassigned to be substituted 1-amino-1,2,3-triazoles on the basis of their infrared,[2] nuclear magnetic resonance,[2] and X-ray analyses.[9]

Continuing our studies on the reactions of hydrazones,[4,5,10-12] we report now the preparation and oxidative cyclization, with iodine and yellow mercuric oxide, of benzil bis(aroylhydrazones) (**1**) to 1-(α-aroyloxyarylideneamino) - 4,5 - diphenyl - 1,2,3 - triazoles (**6**) with emphasis on their spectral and some of their chemical properties.

Results and Discussion

Benzil bis(aroylhydrazones) **1** were prepared in 70—85% yield by condensing benzil with two equivalents of the required aroylhydrazine in ethanol. The infrared spectra of the bis-hydrazones showed the amide I bands of the aroylhydrazone residues at 1680—1670 cm^{-1} in addition to strong C=N absorption at 1650 cm^{-1} and NH bands at 3250—3200 cm^{-1}. Unlike benzil bis(arylhydrazones) which are orange to brown in color, the bis(aroylhydrazones) are colorless. This is attributed to the different types of tautomerism exhibited by these compounds. Thus, whereas the bis(arylhydrazones) were shown to exhibit arylhydrazono-arylazo tautomerism,[13] benzil bis(aroylhydrazones) exhibit a keto-enol tautomerism (**1**⇌**2**) as evidenced by giving pale yellow colors with sodium methoxide, greenish brown colors with neutral ferric chloride solution, as well as by forming stable cupric complexes.[14] Preliminary studies indicated that the stability of these complexes is due to the formation of tetradentate ligands (**3**) similar to those of osulose bis-(thiosemicarbazones).[15,16] The NMR spectrum of benzil bis(benzoylhydrazone) (**1a**) showed the four phenyl groups as a twenty-proton multiplet at δ 7.53 and the two hydrazono protons as a two-proton singlet at δ 12.85.

Oxidation of the bis-hydrazones **1** with iodine and yellow mercuric oxide in absolute ether afforded crystalline products having two hydrogens less than the parent bis-hydrazone and have no amide or NH absorptions in their infrared spectra. The oxidation products, however, showed strong ester absorption at 1760—1740 cm^{-1} in addition to the C=N absorption at 1640 cm^{-1}. The NMR spectrum of the oxidation product of benzil bis(benzoylhydrazone) revealed the absence of the two hydrazono protons of the parent compound and showed only a twenty-proton multiplet (four phenyl groups) at δ 7.50. The oxidation products were thus assigned the structure of 1-(α-aroyloxyarylideneamino)-4,5-diphenyl-1,2,3-triazoles (**6**). This assignment is in agreement with our[1,4,5] as well as with others[2,3,9] findings. The oxidation products are formed (see Scheme 1) first by abstraction of the two hydrazono hydrogens of **1** to give the bis(aroylazoene) (**4**) which cyclizes to the triazole derivative (**5**) followed by migration of the acylonium ion detached from N-2 of the triazole ring to the nucleophilic oxygen of the polarized acylamino group on N-1 to give **6**.



Scheme 1.

Compatible with the assigned structure **6**, is the splitting of their enol ester groups on alkali hydrolysis with methanolic ammonia at room temperature yielding the expected 1-aroylamino-4,5,-diphenyl-1,2,3-triazoles (**7**) and one equivalent of the corresponding benzoic acid. Infrared spectra of **7** revealed the absence of the ester absorption bands of their precursors with concomitant absorption at 1700—1660 (amide I) and 3250—3200 cm (NH) due to the newly formed amide function. Acid hydrolysis, with aqueous hydrochloric acid, of **6** or **7** split off two or one equivalent respectively of the corresponding benzoic acid and gave one and the same product from the differently substituted **6** and **7** namely: 1-amino-4,5-diphenyl-1,2,3-triazole (**8**).

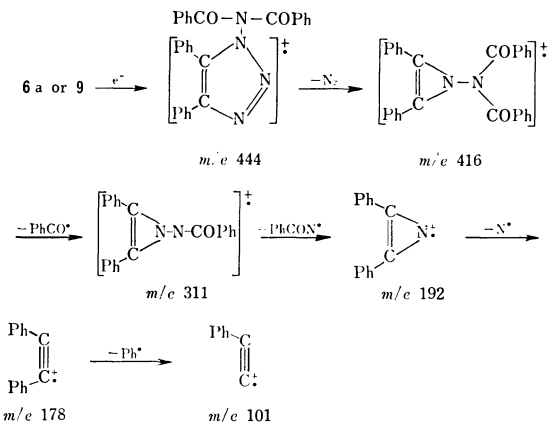
Thermal rearrangement of 1-(α-benzoyloxybenzylideneamino)-4,5-diphenyl-1,2,3-triazole (**6a**), by heating above its melting point, gave 1-dibenzoylamino-4,5-diphenyl-1,2,3-triazole (**9**) through the 1,3-acyl migration of the enol benzoate group. The infrared spectrum of **9** showed only CON absorption band at 1720 cm^{-1} and no ester or NH absorptions. Compound **9** was also obtained when **8** was benzoylated with benzoyl chloride in pyridine. Conversely, **9** was converted to **8** on hydrolysis with aqueous hydrochloric acid. It was interesting to find out that both **6a** and **9** gave exactly the same mass spectrometric fragmentation pattern (see Scheme 2). This is probably due to the thermal isomerization of **6a** to **9** on the probe of the mass spectrometer before it undergoes fragmentation. Thus, both compounds showed the molecular ion peak (M^+) at *m/e* 444 in addition to the fragments at *m/e* 416 (M^+-N_2), *m/e* 311[$M^+-(N_2+PhCO)$]. The latter ion loses an *N*-benzoyl radical to give the diphenylaziridinium ion at *m/e* 192 which successively loses a nitrogen atom to give the diphenylacetylene ion at *m/e* 178 and a phenyl radical to give the phenylacetylene ion at *m/e* 101.



Scheme 2.

Refluxing of either **6a**, **7a**, or **8** with acetic anhydride gave 1-acetamido-4,5-diphenyl-1,2,3-triazole (**10**).

Experimental

Melting points were determined on a Kofler block and are uncorrected. Infrared spectra were recorded, for potassium bromide discs, with a Unicam SP 200 spectrophotometer. Nuclear magnetic resonance spectra were recorded at 60 MHz with a Varian T-60 spectrophotometer and with deuteriodimethylsulfoxide as a solvent containing 1% tetramethylsilane as internal standard. Mass spectral analyses were performed on a Varian M-66 spectrometer. Homogeneity of the prepared compounds were checked by thin layer chromatography on Silica Gel G plates, and the spots were detected by spraying with 20% (v/v) sulfuric acid, followed by heating on a hot plate for a few minutes.

*Benzil Bis(aroylhydrazone) (**1a—1f**; Table 1).* A solution of benzil (1 g) in ethanol (30 ml) was treated with the solution of the required aroylhydrazine (2 equivalents) in ethanol (20 ml) and a few drops of glacial acetic acid, and the mixture was heated on a water bath for 45 min. The mixture was kept at room temperature for an overnight, and the bishydrazone which separated was filtered and crystallized from 1 : 1 mixture of methanol-benzene. The bis-hydrazones are soluble in methanol and ethanol and are insoluble in hexanes.

*1-(α-Aroyloxyarylideneamino)-4,5-diphenyl-1,2,3-triazoles (**6a—6f**; Table 1).* A suspension of benzil bis(aroylhydrazone)

(1 g) in absolute ether (150 ml) was treated with yellow mercuric oxide (2 g), magnesium oxide (0.2 g) and iodine (2 g) for 96 h at room temperature. The suspension was filtered, and the inorganic residue was washed with chloroform (3 × 100 ml), and the filtrate and washings were combined and successively extracted with potassium iodide and sodium thiosulfate solutions and then with water and dried (sodium sulfate). Evaporation of the solvents gave the products which were crystallized from methanol.

*1-Aroylamino-4,5-diphenyl-1,2,3-triazoles (**7a**—**7f**; Table 1).* A solution of 1-(α-aroyloxyarylideneamino)-4,5-diphenyl-1,2,3-triazole (1 g) in methanol (200 ml) was treated with 20% ammonium hydroxide solution (20 ml) for 24 h at room temperature. The mixture was evaporated under reduced pressure, and the residue was triturated with water and filtered. The products were crystallized from methanol (see Table 1). Acidification of the filtrate gave one equivalent of the corresponding substitute benzoic acid.

*1-Amino-4,5-diphenyl-1,2,3-triazole (**8**).* Hydrolysis of compounds **6a**—**6e** or **7a**—**7f** (1 g) was carried out by heating under reflux, with concentrated hydrochloric acid (20 ml) for 24 h after which the reaction mixture was cooled, diluted with ether (200 ml), and the ethereal layer was washed with a saturated solution of sodium hydrogencarbonate and water and then dried (sodium sulfate). Evaporation of the solvent gave **8** (72—81% yield) which crystallized from benzene in plates, mp 136 °C. IR: ν_{max}^{KBr} 3300 cm^{-1} (NH). Found: C, 71.3; H, 5.0; N, 23.5%. Calcd for $C_{14}H_{12}N_4$: C, 71.2; H, 5.1; N, 23.7%. Acidification of the washings gave the corresponding substituted benzoic acid (two equivalents from **6** and one equivalent from **7**).

*1-Dibenzoylamino-4,5-diphenyl-1,2,3-triazole (**9**). (A) From **6a**:* Compound **6a** (0.5 g) was heated at 190 °C in an oil bath for 2 h and then left to cool. The solidified mass was triturated with methanol and filtrered. Crystallization from methanol gave **9** (0.4 g) as plates, mp 155—156 °C. IR: ν_{max}^{KBr} 1720 cm^{-1} (CON). Found: C, 75.5; H, 4.4; N, 12.7%. Calcd for $C_{28}H_{20}N_4O_2$: C, 75.7; H, 4.5; N, 12.6%.

*(B) From **8**:* A solution of **8** (0.5 g) in dry pyridine (5 ml) was treated with benzoyl chloride (2 ml) for 48 h at room temperature. The mixture was poured into ice-water, and the product, which separated, was filtered off and washed with water. Crystallization from methanol gave **9** (0.5 g) as plates, mp 155—157 °C. IR: ν_{max}^{KBr} 1720 cm^{-1} (CON). Found: C, 75.6; H, 4.5; N, 12.8%. Calcd for $C_{28}H_{20}N_4O_2$: C, 75.7; H, 4.5; N, 12.6%.

*1-Acetamido-4,5-diphenyl-1,2,3-triazole (**10**). (A) From **6a**:* Compound **6a** (0.5 g) in acetic anhydride (15 ml) was heated under refluxed for 2 h after which it was poured onto ice and left until the excess acetic anhydride hydrolyzed. The product was filtered, washed with water, and crystallized from methanol to give **10** (0.2 g) as plates, mp 178—180 °C. IR: ν_{max} 3300 (NH), 1670 cm^{-1} (COHN). Found: C, 69.3; H, 5.3; N, 20.0%. Calcd for $C_{16}H_{14}N_4O$: C, 69.1; H, 5.1; N, 20.1%.

*(B) From **7a**:* Compound **7a** (0.5 g) was treated in the same way as described above to give **10** (0.3 g), mp 178—180 °C. Found: C, 68.9; H, 5.1; N, 20.0%.

*(C) From **8**:* Compound **8** was refluxed with acetic anhydride as described above to give **10** in 80% yield having the same properties as mentioned.

Studies in Heterocyclics. VI.[1] Synthesis of Thiazolo-Benzo-Triazepines

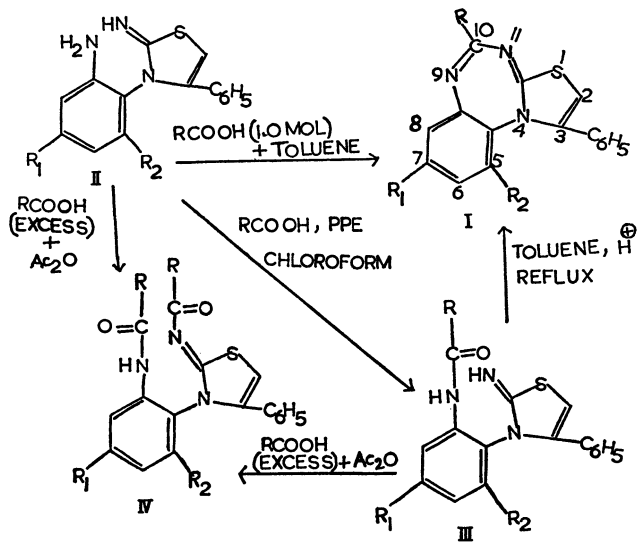
M. P. MAHAJAN,* S. M. SONDHI, and N. K. RALHAN**
Department of Chemistry, Punjabi University, Patiala 147002, India

(Received October 21, 1975)

2-Imino-3-(*o*-aminoaryl)-4-thiazolines (II) gave thiazolo-benzo-triazepines(I) on condensation with various aliphatic carboxylic acids. Both *N*-acyl(III) and *N,N'*-diacyl derivatives(IV) were isolated, and the mono-acyl derivatives(III) were also cyclized to thiazolo-benzo-triazepines.

In continuation of our study on the synthesis of bridgehead seven membered heterocyclic systems, we report herewith the synthesis of a new ring system, *i.e.*, thiazolo[2,3-*d*][1,3,5]benzo-triazepines. Thiazolo-benzo-triazepines (Ia—d; Table 2) have been synthesized according to Scheme 1.

2-Imino-3-(*o*-aminoaryl)-4-thiazolines(II) were synthesized according to the scheme described earlier.[2] The stochiometric quantities of II and requisite carboxylic acid when refluxed in toluene gave thiazolo-benzo-triazepines(I) in one step. In a number of attempts to achieve the synthesis of I by refluxing II and excess carboxylic acids (RCOOH; R=H, CH_3, C_2H_5) in the presence of acetic anhydride, the diacyl derivatives (IV; Table 1) were formed. The characteristic features of IR spectra of these diacyl derivatives are the presence of >NH and >C=O at 3330 and 1635 cm^{-1} in IV ($R_1=R_2=R=H$); at 3270 and 1660 cm^{-1} in IV ($R_1=R_2=H$; $R=CH_3$); at 3350 and 1665 cm^{-1} in IV ($R_1=R_2=H$; $R=C_2H_5$). The structure of IV ($R_1=R_2=H$, $R=CH_3$) was also supported by its NMR spectrum (100 MHz; $CDCl_3$) which shows a singlet at δ 2.14 (3H; CH_3–C(=O)–NH); a singlet at δ 2.30 (3H, CH_3–C(=O)–N=), one H amidic proton at δ 8.60 and aromatic multiplet at δ 6.71—7.96 for C_6H_5–C=CH– and –NH–(C$_6$H$_4$)–N=. These diacyl drivatives did not give I as suggested by Kanaoka *et al.*[3]



(a) $R_1=H$, $R_2=H$, $R=H$, CH_3, C_2H_5
(b) $R_1=CH_3$, $R_2=H$, $R=H$, CH_3, C_2H_5
(c) $R_1=OCH_3$, $R_2=H$, $R=H$, CH_3, C_2H_5
(d) $R_1=H$, $R_2=CH_3$, $R=H$, CH_3, C_2H_5

Scheme 1.

When stoichiometric quantitaties of the carboxylic acid and II along with polyphosphate ester (PPE) in chloroform were refluxed, only mono acyl derivatives (III) were obtained. The IR spectrum of III ($R_1=R_2=H$; $R=CH_3$) showed the characteristics >C=NH; >C=O vibrations at 3260 and 1650 cm^{-1}, respectively. The NMR spectrum (100 MHz; $CDCl_3$) also gave a singlet at δ 2.15 (3H; CH_3CO); a multiplet between δ 6.2—7.92 (10H; C_6H_5–C=CH– and –N–C_6H_4–N–); and a singlet at δ 6.50 (1H; >C=NH). These monoacyl derivatives are cyclized to I on refluxing in toluene. Moreover III are acylated to IV on heating with excess of carboxylic acids and acetic anhydride.

Experimental

The melting points are uncorrected. Microanalysis was carried out by the Microanalytical Service, CSIRO, Australia. IR spectra were run in KBr wafers on a Perkin-Elmer Infracord-137 spectrophotometer, and NMR spectra were recorded on a Varian HA-100 spectrometer.

2-Acylimino-3-(o-acylamino-substituted phenyl)-4-phenyl-4-thiazolines (IV). 3-(*o*-Aminophenyl)-2-imino-4-phenyl-4-thiazoline (2.67 g; 0.01 mol), acetic acid (10 ml) and acetic anhydride (10 ml) were heated under reflux for 3 h. The clear solution thus obtained was evaporated to dryness under reduced pressure and the solid so obtained was recrystallized from ethanol to afford IV ($R_1=R_2=R=CH_3$).

All the other derivatives using formic acid and propionic acid (IVa—d) were prepared following a procedure similar to that described above. Yield, mp, and microanalytical data are reported in Table 1.

3-(o-Acetamidophenyl)-2-imino-4-phenyl-4-thiazoline (III); ($R_1=R_2=H$, $R=CH_3$). 3-(*o*-Aminophenyl)-2-imino-4-phenyl-4-thiazoline (0.534 g; 0.002 mol), acetic acid (0.12 g; 0.002 mol); polyphosphate ester (3.0 g) and chloroform (20 ml) were heated under reflux for 2 h. The solvent was removed under reduced pressure and the residue was treated with aqueous sodium hydrogencarbonate. The solid obtained was filtered, washed with water, air dried and recrystallized from THF/Pet. ether (bp 80—100 °C); yield 0.43 g. (70%), mp 153 °C (Found: C, 65.98; H, 4.64; N, 13.45%. Calcd for $C_{17}H_{15}N_3SO$: C, 66.02; H, 4.85; N, 13.59%).

2-Acetylimino-3-(o-acetamidophenyl)-4-phenyl-4-thiazoline (IVa)

	C_2H_5	H	CH_3	68	172	71.36	5.31	13.21	71.47	5.32	13.16

All the compounds (Ia—d) were crystallized from toluene.

from 3-(o-Acetamidophenyl)-2-imino-4-phenyl-4-thiazoline (IIIa). 3-(*o*-Acetamidophenyl)-2-imino-4-phenyl-4-thiazoline (IIIa) (0.618 g; 0.002 mol), acetic acid (10 ml) and acetic anhydride (10 ml) were heated under reflux for 2 h. The solution obtained was evaporated to dryness under reduced pressure and the solid residue obtained was recrystallized from ethanol, mp 223 °C, yield 0.500 g. (70%) (Found: C, 64.62; H, 5.13; N, 11.66%. Calcd for $C_{19}H_{17}N_3SO_2$: C, 64.95; H, 4.84; N, 11.96%).

The identity of the compound was confirmed by undepressed mixture mp with the authentic sample obtained by the alternative route described above.

3-Phenyl-(10-substituted)-thiazolo[2,3-d][1,5,3]benzotriazepines (**Ia—d**). *(i) III to I*: 3-(*o*-Acetamidophenyl)-2-imino-4-phenyl-4-thiazoline (0.618 g; 0.002 mol) was refluxed in toluene (20 ml) with a drop of acetic acid for 3 h. The solvent was removed under reduced pressure and the solid residue obtained was recrystallized from toluene to afford I ($R_1=R_2=H$, $R=CH_3$). Yield 0.35 g (60%), mp 241 °C (Found C, 70.30; H, 4.52; N, 14.31%. Calcd for $C_{17}H_{13}N_3S$: C, 70.10, H, 4.47; N, 14.43%).

(ii) II to I: 3-(*o*-Aminophenyl)-2-imino-4-phenyl-4-thiazoline (0.543 g; 0.002 mol), acetic acid (0.12 g; 0.002 mol) were refluxed in toluene (20 ml) for 3 h. After removal of the solvent under reduced pressure, the solid obtained was recrystallized from toluene to afford I ($R_1=R_2=H$; $R=CH_3$), yield 0.42 g (74%); mp 241 °C.

I ($R_1=R_2=H$; $R=CH_3$) obtained from routes (i) and (ii) was identical since its mixed mp was underpressed and superimposable IR spectra were obtained.

All the other derivatives of (Ia—d) were prepared by means of method (ii). The yield, mp and microanalytical data are reported in Table 2.

Salient features of IR spectrum of I ($R_1=R_2=H$; $R=CH_3$) are the absence of original bands at 3260 and 1650 cm^{-1} due to >C=NH and >C=O functions and the presence of >C=N vibrations at 1610 cm^{-1}. Other derivatives of Ia ($R_1=R_2=R=H$) and ($R_1=R_2=H$; $R=C_2H_5$) also show the absence of >C=O and >N-H bands. NMR spectra of Ia ($R_1=R_2=H$; $R=H$) and ($R_1=R_2=H$; $R=CH_3$) show the absence of protons due to amino acid >C=NH functions.

Molecular Rearrangements. VII. *N*-Alkylarylamines (III). Thermal Rearrangement of Secondary Arylamines

A. M. Osman, M.Z.A. Badr,* and A. E. Abdel-Rahman

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt, A.R.E.

(Received January 6, 1976)

Heating of *N*-benzyl-*o*- and *p*-toluidines resulted in migration of the benzyl group to the corresponding toluidine nucleus. The pyrolysis of *N*-benzyl-*o*-toluidine produced ammonia, toluene, bibenzyl, *trans*-stilbene, *o*-toluidine together with 4-amino-3-methyldiphenylmethane and 2,3-diphenyl-7-methylindole. *N*-benzyl-*p*-toluidine resulted into the same neutral products together with ammonia, *p*-toluidine, 2,3-diphenyl-5-methylindole together with 2,7-dimethyl-9-phenylacridine. Using phenol or quinoline as solvents, the normal rearranged products were accompanied with 2- and 4-benzylphenols and 2- and 4-benzylquinolines. It was concluded that the pyrolysis of the secondary amines proceeds through their homolytic fission to benzyl and the corresponding toluidino free radicals. Homolysis of some primary products was also observed.

The present paper describes a thermal rearrangement of *N*-benzyl-*o*- and -*p*-toluidines, involding a homolytic fission of the alkyl–*N*-bond. *N*-Benzyl-*o*-toluidine changed on heating in nitrogen atmosphere at about 333 °C to give ammonia, toluene, bibenzyl, *trans*-stilbene, *o*-toluidine, 4-amino-3-methyldiphenylmethane, and 2,3-diphenyl-7-methylindole.

Similarly, *N*-benzyl-*p*-toluidine, under similar conditions at 315 °C, underwent pyrolysis to afford the same neutral products, ammonia, *p*-toluidine, 2,3-diphenyl-5-methylindole and 2,7-dimethyl-9-phenylacridine.

Heating each of *N*-benzyl-*o*- and -*p*-toluidine at its boiling point for several days, gave about the same products but in lower yields, together with some benzaldehyde.

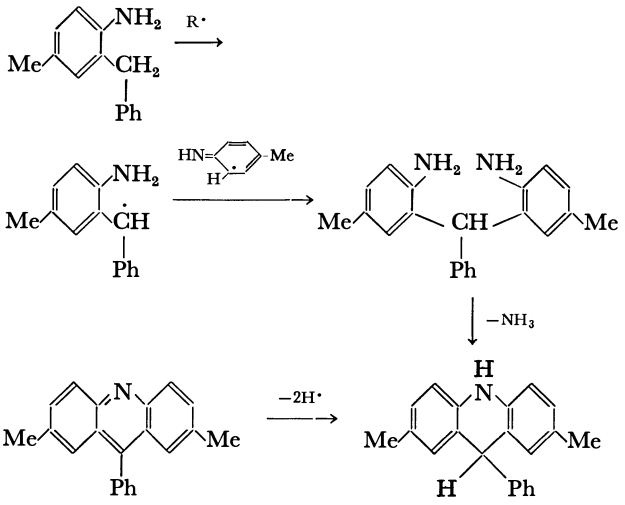
The general feature of this pyrolytic process appears to occur through a mechanism differing in nature from that induced by Lewis acid catalysis.[1]

The formation of toluene, bibenzyl, together with the corresponding toluidines and isomeric diphenylmethylindoles strongly suggests a free radical mechanism.

The homolytic character for the thermal pyrolysis of *N*-alkylarylamines was further confirmed through its study in high boiling solvents and the use of scavengers under nitrogen atmosphere. In phenol, the normal products of the amines rearrangements were obtained together with 2- and 4-benzylphenols. However, in anisole, which underwent preceding pyrolysis, *o*- and *p*-cresols were produced together with phenol, *o*- and *p*-benzylphenols.

The thermal rearrangement of each of *N*-benzyl-*o*- and *p*-toluidines in quinoline gave the normal rearrangement products together with 2- and 4-benzylquinolines, as summarized in Table 1.

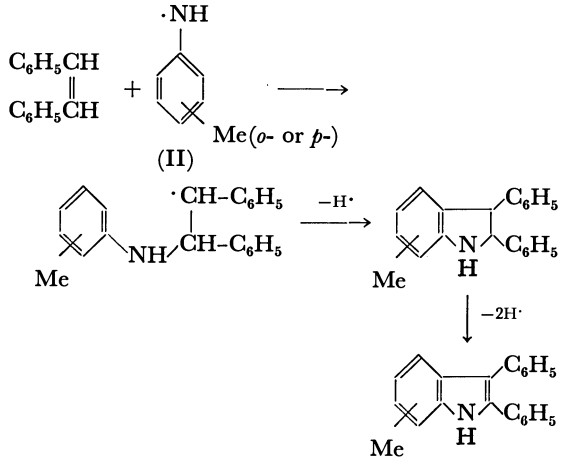
Coupling of benzyl radical (I) and toluidino radicals (II) produced the least stericaly hindered isomer, 3-methyl-4-aminodiphenylmethane, from *N*-benzyl-*o*-toluidine. However, from *N*-benzyl-*p*-toluidine, 2-amino-5-methyldiphenylmethane was not separated but most favorably consumed, after its preliminary production, into the formation of 2,7-dimethyl-9-phenylacridine as final product according to the following scheme.



Heating *o*- or *p*-toluidine alone in a sealed tube at about 315—330 °C for 12 days had resulted in the formation of ammonia.

Consequently, ammonia was assumed to be partially formed through intermediate formation of amino free radical[2] and tolyl radical as observed in isomeric toluidines pyrolysis under the rearrangement conditions.

The formation of both isomeric 2,3-diphenyl-7-methylindole (III) and 2,3-diphenyl-5-methylindole (IV) can be explained according to the following scheme:



III and IV

a) Benzyl derivative of solvent used. b) In nitrogen atmosphere. c) *o*-Toluidine. d) *p*-Toluidine. e) Benzaldehyde was separated and identified. (i) 0.7 g. (ii) 0.5 g. f) 2,3-Dimethyl-7-methylindole. g) 2,3-Diphenyl-5-methylindole. h) 4-Amino-3-methyldiphenylmethane. (i) Identified by paper chromatography as mixture of benzylphenols and by GLC analysis, (i) in ratio of (76.3%) *o*- and (23.7%) *p*-isomers; (ii) in ratio of (89.5%) *o*- and (10.5%) *p*-isomers. (j) Methylamine collected as hydrochloride salt. k) Colorless plates, mp 181—182 °C, IR spectrum showed an absorption at 3450 cm^{-1} (NH), not farther identified. l) Identified as phenols mixture, (i) yield (2.3 g.) in ratio of (67.3%) phenol and (32.7%) cresols, in ratio of *o*-cresol (95.7%) and *p*-cresol (4.3%), (ii) yield (1.1 g.) in ratio of (65.7%) phenol and (34.3%) cresols, in ratio of *o*-cresol (83.1%) and *p*-cresol (16.9%), together with benzylphenols (1.1 g) in ratio of (94.8%) *o*- and (5.2%) *p*-isomers. m) 2,7-Dimethyl-9-phenyl-acridine, collected at bp 230—240 °C/mmHg; M^+ *m/e* 283, (Found: C, 88.9; H, 6.2; N, 4.9%. Calcd for $C_{21}H_{17}N$: C, 89; H, 6; N, 5%) (i) 2.1 g, (ii) 0.7 g, (iii) 0.5 g, (iv) 1 g, (v) 0.2 g. n) Identified by TLC as mixture of 2- and 4-benzylquinolines and by GLC analysis to be (i) in ratio of (44%) 2- and (56%) 4-isomer, (ii) in ratio of (42%) 2- and (58%) 4-isomers.

trans-Stilbene could be resulted by radical abstraction of the methylene hydrogens from bibenzyl.

In anisole separation of *o*- and *p*-benzylphenols instead of benzylanisoles during amines rearrangement insures that anisole had rearranged under such conditions prior to substitution step by benzyl radical.

Migration of the methyl group of anisole was assumed to go through an intramolecular route, which was confirmed by absence of any other methyl derivative, together with the separation of higher yields of *o*-cresol. However, formation of *p*-cresol partially through an intermolecular migration of the methyl group within a solvent cage[3] could not be excluded.

Similarly, methylamine was expected to be formed intermolecularly, from *p*-toluidino radical and the methyl radical from anisole, through *N*-methyl-*p*-toluidine as preliminary product, which undergoes pyrolysis homolytically[4] into *p*-tolyl radical and methylamino radicals, the latter of which gives methylamine. However, methylamine formation was not observed in *N*-benzyl-*o*-toluidine pyrolysis with anisole.

Thermal rearrangement of either of *N*-benzyl-*o*- and -*p*-toluidines in quinoline gave the normal rearrangement products together with 2- and 4-benzylquinolines in a ratio similar to that obtained in the pyrolysis of benzyl naphthyl ethers[5] or *N*-benzyl-*N*-methylaniline[2] with quinoline as solvent, justifying the similarity in nature of all such types of rearrangements.

Experimental

Analysis. IR spectra were measured with a Pye-Unicam IR spectrophotometer, Model SP 200 g. The UV absorptions were carried out by a Pye-Unicam UV spectrophotometer, Model SP 8000. GLC analysis was carried out by a Pye-Unicam gas chromatograph, "series 104" dual flame ionization detector, temperature programed, Model 24. The column used was 20% SE 30 on chromosorb W (35—80 mesh). Thin layer chromatographic analysis of benzylquinolines was carried out on silica gel (25—40 mesh) using hexane–ethyl acetate (3:7 by vol.); paper chromatographic analysis of benzylphenols was carried out using C. Schleicher and Schull paper No. 2816, using 1-butanol–water–ethanol mixture (5:5:1.7 by volume) as eluent. Mass spectral measurements were recorded on both, varian MAT CH-4, and AEI MS-9 mass spectrometers at 70 eV.

Pyrolysis of Each of N-*Benzyl*-o- *and* -p-*toluidines.* Heating each of *N*-benzyl-*o*-toluidine for 10 days at 320 °C and *N*-benzyl-*p*-toluidine for 10 days at 310 °C in sealed tubes, not resulted in their pyrolysis. However, heating each of the secondary amines at elevated temperatures and for the periods as specified in Table 1, either alone or with phenol, anisole or quinoline in nitrogen atmosphere and the reaction products were distilled first under atmospheric pressure where ammonia was evolved and trapped as its hydrochloride, and toluene collected. The higher boiling products were separated into neutral and amine fractions by treatment with

concd HCl and extraction with ether.

Phenolic products were separated by means of Claisen's solution. The results are summarized in Table 1.

Preparation of Reference Compounds.

N-*Benzyl*-o-*toluidine*[6]: Bp 158—160 °C/5 mmHg; mp 56—57 °C.

N-*Benzyl*-p-*toluidine*[7]: Bp 160—162 °C/4 mmHg; n_D^{30}: 1.5985.

2-*Benzylphenol*[8]: Bp 170—180 °C/15 mmHg; phenylurethane derivative, mp 117 °C.

4-*Benzylphenol*[9]: Bp 170—180 °C/14 mmHg; mp 84 °C; benzoate, mp 87 °C.

2-*Benzylquinoline*[10]: Bp 235—240 °C/19 mmHg; picrate, mp 156—157 °C.

4-*Benzylquinoline*[11]. Bp 230 °C/17 mmHg; picrate, mp 178—179 °C.

(Received April 23, 1976)

The alkaline hydrolysis of bis(nitromethyl)prehnitene (**1**) with aqueous sodium hydroxide gave almost quantitatively disodium tetramethylphthalate (**11**). Under milder conditions the sodium salts of tetramethylphthalimide (**8**), *N*-hydroxytetramethylphthalimide (**10**), and 2-hydroxy-3-hydroxyimino-4,5,6,7-tetramethylphthalimide (**9**) were formed, probably as intermediate products of the above reaction. But, pentamethylphenylnitromethane (**14**) and bis(nitromethyl)isodurene (**15**) were not hydrolyzed in an aqueous base. From the above results, it is recognized that the sodium nitronate from **1** is unstable in a different way from general nitronates such as the sodium salt of **14** or **15**. It appears that the instability of **1** arises from the two adjacent nitromethyl groups on the benzene ring.

Phthalic anhydride is used chiefly in the manufacture of alkyd resins, plasticizers, dyes, and pigments. Also, tetrachlorophthalic anhydride is commercially available in heat-stable alkyd resins, dye intermediates, *etc.* Similarly, if polymethylphthalic anhydride could be easily prepared, it would have many uses. But phthalic anhydride is a very unreactive compound with respect to alkylation. Also, tetramethylphthalic anhydride (**13**) or acid is hard to obtain from hexamethylbenzene by the selective oxidation.[2)]

We have previously reported that bis(nitromethyl)-prehnitene (**1**) was obtained by the nitration of hexamethylbenzene with benzoyl nitrate by Willstätter's method.[3,4)] In the present paper, the reaction of **1** with an aqueous base was studied, and a useful procedure for preparing **13** was found.

Hitherto, many studies of the acid hydrolysis of nitroalkanes have been reported. For example, the acid hydrolysis of a salt of a primary or secondary nitroalkane affords an aldehyde or a ketone, respectively, and nitrous oxide (Nef reaction).[5,6)] Closely related to the Nef reaction is the hydrolysis of free primary nitroalkanes with concentrated mineral acid to the corresponding carboxylic acids and hydroxylamine salts.[7)] It is considered that the above reactions of nitroalkanes require an initial acid-catalyzed isomerization to nitronic acid.[8)] But no reports of the alkaline hydrolysis of a salt of a nitroalkane or free nitroalkane seem to have been made.

Results and Discussion

1 was treated with 5% sodium hydroxide at 75 or 100 °C. By addition of silver nitrate solution to the resulting solution, the products were isolated as their silver salts, which were treated with methyl iodide. From the methylated reaction mixture, *N*-methyltetramethylphthalimide (**8'**), 2-methoxy-3-methoxyimino-4,5,6,7-tetramethylphthalimidine (**9'**), *N*-methoxytetramethylphthalimide (**10'**), and dimethyl tetramethylphthalate (**11'**) were isolated by column chromatography. Further, from the reaction mixture in an early stage a trace of methyl 2-cyano-3,4,5,6-tetramethylbenzoate (**12'**) was also isolated.

The reaction was followed by measuring the yields of these products. The results are given in Table 1. Under milder conditions **8'**, **9'**, and **10'** were obtained (Expt. No. 1). But, on continued warming, they rapidly decreased, whereas **11'** increased. Finally, an almost quantitative yield of **11'** was obtained.

TABLE 1. REACTION OF BIS(NITROMETHYL)PREHNITENE WITH AN AQUEOUS SODIUM HYDROXIDE

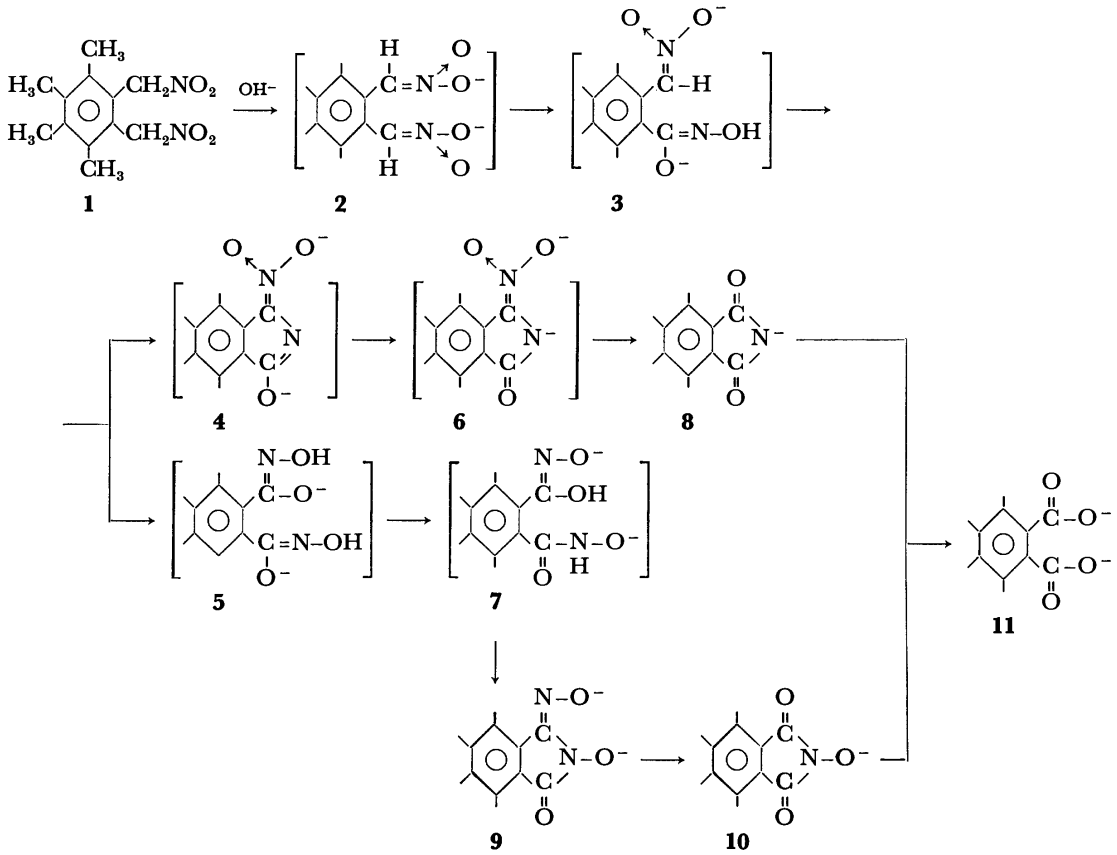
Expt. No.	Conditions		Yields (mol %)[a)]				
	Temp (°C)	Time (min)	**8'**	**9'**	**10'**	**11'**	Unknowns (wt %)
1	75	10	14	2	13	49	8
2	100	15	2	—	15	64	10
3	100	30	—	—	10	77	—
4	100	5 h	—	—	—	97	—

a) The yields were determined by GLC after the products were methylated by warming their silver salts in methyl iodide.

On the other hand, after **1** was treated with 5% sodium hydroxide at 100 °C for 9.5 h, the acidification of the hydrozate with diluted hydrochloric acid gave almost quantitatively tetramethylphthalic anhydride (**13**). The filtrate reduced Fehling's solution. This fact suggested that the hydroxylamine salt was produced, but further investigations were not carried out. Also, when **1** was treated with 10% sodium hydroxide, almost similar results were obtained. But, when pentamethylphenylnitromethane (**14**) or bis(nitromethyl)isodurene (**15**) was treated with 5% sodium hydroxide at 100 °C for 10 h, the acidification of the resulting solution with hydrochloric acid gave unreacted **14** or **15** only. Moreover, upon treatment with 35% hydrochloric acid at 100 °C for 5 h in a sealed tube, **1** was recovered unchanged.

From the above results, it is recognized that the sodium nitronate (**2**) from **1** is unstable in a different way from general nitronates such as the sodium salt of **14** or **15**, and so the conversion of **1** to the phthalate (**11**) does not require the initial isomerization to the free nitronic acid. It appears that the instability of **1** arises from the two adjacent nitromethyl groups on the benzene ring.

A plausible reaction path is shown in the following scheme. But there is no evidence pertaining to the mechanism of conversion of nitronate to hydroxamate.



Scheme 1.

Disodium tetramethylphthalate (**11**) is easily converted to **13** by acidification, probably since the steric repulsion of four methyl groups on the benzene ring facilitates the cyclization between two carboxyl groups. The phthalic acid could not be isolated. Similarly, the hydroxamate **3** or **7** would be easily converted to the cyclized product **4** or **9**, respectively, which is finally hydrolyzed to produce **11**. But it is not clear which is chosen more preferentially as an intermediate, sodium tetramethylphthalimide (**8**) or sodium *N*-hydroxytetramethylphthalimide (**10**).

Experimental

Analyses. All melting points are uncorrected. IR spectra were recorded by means of a Hitachi EPI-S2 spectrometer, while NMR spectra were obtained by a Hitachi R-22 NMR spectrometer at 90 MHz, using tetramethylsilane as an internal standard. The GLC analyses were carried out on a Hitachi 063 apparatus, using Silicone DC 550 (25%)-Celite 545 (4 mm×1 m) columns (Temp: 215 °C; Carrier gas: H_2 40 ml/min).

Materials. **1**, **14**, and **15** were obtained by the nitration of hexamethylbenzene with acetyl nitrate according to the following method.

Fuming nitric acid (30 g, d=1.5) was added over a period of 0.5 h to vigorously stirred acetic anhydride (150 ml), keeping the temperature between 15 and 20 °C by the use of an ice bath. The resulting solution was added to a solution of hexamethylbenzene (14.0 g) in carbon tetrachloride (150 ml), and stirred at about 5 °C for 2 h. The reaction mixture was poured into water (450 ml). The organic layer was separated and washed with dilute sodium carbonate and then with water. Concentration and cooling of the solution yielded a white crystalline solid. Its chromatography (7.2 g) on silica gel gave **14** (0.2 g, mp 85—87 °C; lit,[10] 86—88 °C) from the light petroleum eluates; **1** (6.5 g, mp 139—140 °C; lit,[3] 139 °C) and **15** (0.2 g) from the benzene elutes. **1** and **4** were identified by comparison of these IR and NMR spectra with those of authentic samples. The structure of **15** was deduced from elemental analysis and spectral data.

15: colorless needles, mp 146—147 °C. Found: C, 56.83; H, 6.57; N, 10.96%. Calcd for $C_{12}H_{16}N_2O_4$: C, 57.13; H, 6.39; N, 11.10%. IR (KBr, cm^{-1}): 1542 and 1386 ($-NO_2$). NMR ($CDCl_3$, δ ppm): 2.29 (s, Ar–CH_3, 3H), and 5.75 (s, –C-H_2–, 4H).

General Procedures. **1** (0.100 g) was treated with 5% sodium hydroxide (15 ml) at 75 or 100 °C in a sealed tube. The resulting solution was cooled to room temperature, and treated with a large excess of silver nitrate solution (4.0 g/20 ml). After cooling, the precipitate was collected by filtration, dried, and refluxed with methyl iodide (1 g) in benzene (50 ml) for 6 h. An insoluble material was filtered off, and the filtrate was evaporated to dryness under reduced pressure.

Isolation of the Products. The following example shows a typical experimental procedure (Expt. No. 1, Table 1).

The residue (0.1 g) obtained by the evaporation of the above filtrate was chromatographed on a column (1×12 cm) of alumina (10 g, 200—300 mesh) and eluted successively with petroleum ether (50 ml), petroleum ether–benzene (1: 1, 100 ml), benzene (50 ml), benzene–diethyl ether (1: 1, 100 ml), diethyl ether (50 ml), and diethyl ether–methanol (100 ml). Each fraction was evaporated, and the residue was recrystallized from methanol to afford the following products successively: *N*-methyltetramethylphthalimide (**8'**), dimethyl tetrameth-

ylphthalate (**11′**), 2-methoxy-3-methoxyimino-4,5,6,7-tetramethylphthalimidine (**9′**), and *N*-methoxytetramethylphthalimide (**10′**). **8′**, mp 180—181 °C, was identified by comparison with the IR and NMR spectra of an authentic sample.[9] The structures of **9′**, **10′**, and **11′** were deduced from their elemental analyses and spectral data.

9′: colorless prisms, mp 156—158 °C. Found: C, 64.61; H, 7.06; N, 10.73%. Calcd for $C_{14}H_{18}N_2O_3$: C, 64.10; H, 6.92; N, 10.68%. IR (KBr, cm^{-1}): 1725 (C=N), 1637 (C=N), 1265, 1146, 1121, 1037, 994, and 932 (C–N, C–O or N–O). NMR ($CDCl_3$, δ ppm): 2.15 (d, Ar–CH_3, 6H), 2.50 (d, Ar–CH_3, 6H), and 4.04 (d, O–CH_3, 6H).

10′: colorless needles, mp 203—204 °C. Found: C, 67.15; H, 6.32; N, 6.18%, mol wt (Rast), 236. Calcd for $C_{13}H_{15}NO_3$: C, 66.93; H, 6.48; N, 6.01%; mol wt, 223. IR (KBr, cm^{-1}): 1760, 1719 (C=O), 1254, 1146, 1102, 998, and 905 (C–N, C–O, or N–O). NMR ($CDCl_3$, δ ppm): 2.24 (s, Ar–CH_3, 6H), 2.56 (s, Ar–CH_3, 6H), and 4.00 (s, O–CH_3, 3H).

11′: colorless plates, mp 127.5—128.5 °C. Found: C, 66.95; H, 7.33%. Calcd for $C_{14}H_{18}O_4$: C, 67.10; H, 7.25%. IR (KBr, cm^{-1}): 1724 (C=O), 1233, and 1162 (C–O–C). NMR ($CDCl_3$, δ ppm): 2.25 (Ar–CH_3, 6H), 2.35 (Ar–CH_3, 6H), and 3.85 (–OCH_3, 6H).

Further, from the reaction mixture in an early stage (Expt. No. 1) a trace of **12′**, mp 75—76 °C, was also isolated; it was identified by comparing its retention time in GLC and its IR spectrum with those of an authentic sample.[9]

The progress of the reactions was followed by GLC. The results are shown in Table 1. The yields of products were caculated by assuming that the ratio of the peak areas was identical with the weight ratio of the products. Here, the peak of **8′** overlapped with that of **11′**, and so, if necessary, the ratio of **8′** to **11′** was derived from the result of the column chromatography.

*Preparation of Tetramethylphthalic Anhydride (**13**).* To 5% sodium hydroxide (50 ml), **1** (1.00 g) was added, and the mixture was stirred at 100 °C for 9.5 h. The reaction mixture was cooled to room temperature, and acidified by the addition of 2M hydrochloric acid. The resulting white precipitate was collected by filtration, dried (0.77 g, 95 mol % as **13**), and recrystallized from benzene: colorless needles, mp 238—239 °C. Found: C, 70.70; H, 5.81%; mol wt (Rast), 200. Calcd for $C_{12}H_{12}O_3$: C, 70.61; H, 5.88%; mol wt, 204. IR (KBr, cm^{-1}): 1834, 1767 (C=O), 1200, and 910 (C–O). NMR ($CDCl_3$, δ ppm): 2.3 (Ar–CH_3, 6H) and 2.6 (Ar–CH_3, 6H).

Further, **13** (0.4 g) was dissolved in 2 M sodium hydroxide (30 ml), and the solution was treated with excess silver nitrate solution. The resulting precipitate was collected by filtration, dried, and refluxed with excess methyl iodide (1.5 ml) in benzene (30 ml) for 4 h. After filtration of the insoluble materials, the filtrate was evaporated, and the residue was recrystallized from methanol to afford **11′** (0.3 g) as colorless plates.

The authors would like to express their thanks to Professor Shunroku Kanno of Yamagata University for his advice, and to Professor Tadashi Yamaguchi of Tohoku University and Professor Shigeru Hayama of Yamagata University for the elemental analyses.

Solvation of Metal Acetylacetonate in Organic Solvents

Fumio KAWAIZUMI, Norifumi MATSUMIYA, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 6, 1976)

Synopsis. The velocities of ultrasonic waves in solutions of metal acetylacetonate in organic solvents were measured with an ultrasonic interferometer operating at 4MHz at 5 and 15 °C. The solvation behavior was marked in the [Mg(acac)$_2$]-methanol system. The results are compared with those of such different methods as IR and NMR spectroscopies.

The behavior of metal acetylacetonates in organic solvents has been the subject of considerable interest in various areas. Many of the experimental results of the metal acetylacetonates in solution have been interpreted on the basis of the hydrogen-bonding between the complexes and the solvent, or of the hydration/solvation of the complexes.[1-4] For example, Yamamoto *et al.* have related the heat of solution of cobalt(III) acetylacetonate in alcohols and in water to solvation phenomena of the solute.

In relation to our previous study of the hydration of cobalt and iron complexes in aqueous media,[5] metal acetylacetonates attract our attention because of the following facts; they are large complexes without electric charge and the acetylacetones coordinated to the central metal atom sterically hinder the approach of the solvent molecules. The lack of electric charge and the steric hindrance are the unfavorable factors for electrostrictive solvation.

The present study deals with the determination of the degree of solvation of such acetylacetonates as [Be(acac)$_2$], [Mg(acac)$_2$], and [Co(acac)$_3$] in various organic solvents. The same study in aqueous solutions will also be necessary, but is impossible owing to the insufficient solubility of the complexes. The degree of solvation was determined from the adiabatic compressibilities of the solutions. It should be kept in mind that in the present method the term "solvation" means the existence of a certain incompressible region in the solution, while the bulk solvents in solution are assumed to be compressible.

All of the metal acetylacetonates are those commercially available and were used without further purification, except for [Be(acac)$_2$], which was purified once from a solution in acetone. The organic solvents used were acetone, acetylacetone, benzene, methanol, and chloroform. The first three solvents were purified by distillation after suitable treatments. Methanol and chloroform were of guaranteed and spectral grades, respectively.

The adiabatic compressibilities of the solutions were obtained by measurement of the ultrasonic velocities using an ultrasonic interferometer operating at 4 MHz. Details of the experimental apparatus and the method of determination of the solvation number are essentially the same as before.[5,6] Preliminary experiments revealed that as expected, [Co(acac)$_3$] is not solvated in benzene at 30 °C. Measurements were therefore carried out at 15 and 5 °C. But the experiments at 5 °C were very limited by the low solubilities of the metal acetylacetonates at this temperature.

The results are summarized in Table 1, where K_m is the (relative) partial molar compression of the solute and the subscript zero refers to infinite dilution. For $K_m > 0$, K_m becomes the molar solvation volume (cm^3/mol). For $K_m < 0$, it signifies the non-existence of an incompressible region in the solution and in this case, the values of K_m represent the quantities related to the compressibility of the solute in solution.[7] In the present paper, however, the cases of negative values of K_{m0} will be excluded from the discussion below.

TABLE 1. K_{m0} (ml/mol) FOR THE METAL ACETYLACETONATES

		[Be(acac)$_2$]	[Co(acac)$_3$]	[Mg(acac)$_2$]
5 °C	CH_3OH	10	35	102
	CH_3COCH_3	(−66)	—	—
	$CHCl_3$	(−113)	(−199)	—
15 °C	CH_3OH	(−11)	0	53
	CH_3COCH_3	(−17)	0	—
	$CHCl_3$	(−154)	(−160)	—
	$CH_3COCH_2COCH_3$	(−143)	(−96)	—
	C_6H_6	(−122)	−126)	—

Table 1 shows that only methanol can solvate with metal acetylacetonates and that solvation to [Mg(acac)$_2$] is more marked than to [Be(acac)$_2$] and [Co(acac)$_3$]. The solvation numbers calculated from the posivite values of K_{m0} are shown in Table 2.

TABLE 2. SOLVATION NUMBER IN METHANOL (mol/mol)

	[Be(acac)$_2$]	[Co(acac)$_3$]	[Mg(acac)$_2$]
5 °C	0.2	0.8	2.6
15 °C	N.S.	N.S.	1.3

N.S.: non-solvated

The results for the solutions in benzene are reasonable, since benzene can hardly solvate under ordinary conditions.

The present results in methanol and in chloroform are compared with those given by the different methods. The IR spectra obtained by Davis and Fackler,[2] using deuteriochloroform ($CDCl_3$) in carbon tetrachloride and methanol in carbon tetrachloride as the solvents, give an indication that no or very weak hydrogen-bonding occurred with the tetrahedral bis metal ketoenolate complexes, like [Be(acac)$_2$], that stronger hydrogen-

bonding to the planar bis complexes occurred and that for tris complexes the interaction occurred with both deuteriochloroform and methanol. In addition, from NMR techniques, the hydrogen-bonding interaction of $[Co(acac)_3]$ and $[Cr(acac)_3]$ with the solvent in the mixture of chloroform and carbon tetrachloride was observed.[3] The vapor pressure measurement showed that the rareearth acetylacetonates form disolvate with methanol but not with chloroform.[8]

For the solvent methanol, all of these results, together with the present work, agree with one another, whereas some disagreements exist for $[Co(acac)_3]$ and the solvent chloroform. These disagreements arise partially from the fact that the hydrogen-bonding interactions detected by IR and NMR spectroscopies are not always strong enough to correspond to the formation of an incompressible region in the solution or of the solvate in solid form.

The solvation numbers for $[Mg(acac)_2]$ given in Table 2 suggest that the solvated methanol occupies the two vacant sites on the opposite side of the planar structure of the complex. According to the model of Davis and Fackler,[2] chloroform and methanol can form hydrogen-bonding to the oxygen atoms of the chelate in bis metal β-ketoenolate, but the present work does not give any direct information of the position of the solvated methanol.

Hartree-Fock-Slater Calculations of the ESCA Chemical Shifts for Transition Metal Atoms

Kazuyuki TATSUMI and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 26, 1976)

Synopsis. Hartree-Fock-Slater calculations have been carried out for inner-shell orbitals of some transition metal atoms (Ni, Rh, and Pt), and the core ionization energies computed by the transition state approximation. It is found that the ionization energy shifts do not conform to the conventional charge-potential approximation; the electron populations in individual valence d and s orbitals need to be considered separately.

Recent developments in X-ray photoelectron spectroscopy (ESCA) have supplied a great amount of information on core-electron binding energies in atoms and molecules. The changes in the core-electron ionization potentials of an atom in given molecules relative to an appropriate standard are designated as chemical shifts. Siegbahn *et al.*[1] proposed that the shifts in ionization potential ΔE_i^A for core orbital i of atom A are related to the corresponding changes in atomic charge ΔQ_A by

$$\Delta E_i^A = k_i^A \Delta Q_A + \Delta V_A \qquad (1)$$

where k_i^A is an adjustable parameter and the term ΔV_A denotes the change in the Coulomb potential at A due to the other atoms in the molecule. Implicit in Eq. 1 is the assumption that the core binding energy is a function of the initial state of the molecule; the reorganization energy upon ionization is assumed to be independent of the identity of atoms as long as they are in similar bonding environments. The charge-potential formula (1) has been applied extensively to series of compounds comprising first and second row atoms.[2] However, extention of the treatment to transition metal compounds is still lacking because of the great complexity of their bonding properties.

In the present article, we will deal with the core ionization potential shifts of transition metal atoms (Ni, Rh, and Pt) as well as some light atoms (C, N, and F) as the functions of atomic charge. The Hartree-Fock-Slater calculations have been carried out for these isolated atoms using the numerical technique. The transition state model[3] was employed to compute the energy difference between the ground state and an ionized state. The results justify the conventional charge-potential approximation for the case of light atoms but decisively indicate its breakdown for the transition metal atoms.

Method

The radial part of the Hartree-Fock wave equation for electrons in a free atom or ion has been solved numerically by Slater's X_α method.[4] A general procedure for numerical integrations as outlined by Pratt[5] was followed. The "exchange scaling parameter" α was chosen so that the statistical X_α total energy equals the configuration-averaged Hartree-Fock energy.[6]

In obtaining the ionization energies, we have invoked the concept of the "transition state," a hypothetical state of an atom or a molecule in which it is assumed that half an electron has been removed from the orbital in question.[4] The ionization energy E_i associated with the ith orbital is thus the negative of the ith one-electron orbital energy ε_i in the transition state.

Results and Discussion

The core ionization potentials of various atoms were calculated by varying the fractional occupation number of valence orbitals. We here direct our attention to the shifts ΔE_i of ionization potentials, taking the values for neutral atoms as standard ($Q=0$).

Figure 1 shows the shifts ΔE_{2p} of the core 2p orbital for a nickel atom with variations in the "valence-orbital net charges" Q(3d) and Q(4s). The charges were varied in the range between -0.3 and 0.9 of an electron, where the configuration of a neutral nickel atom is assumed to be $(\text{core})^{10}(3s)^2(3p)^6(3d)^8(4s)^2$. We see that ΔE_{2p} increases monotonically with increasing Q(3d)and Q(4s). Both plots appear to be slightly concave upward but may essentially be regarded as linear.

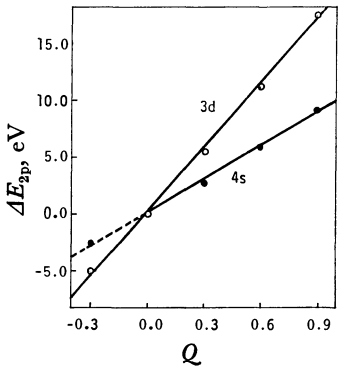

Fig. 1. Plots of the 2p-electron ionization energy shifts ΔE_{2p} of a nickel atom against the 3d as well as 4s orbital net charge.

The slopes for the two linear plots given in Fig. 1 differ clearly from each other. The slopes obtained by the least-squares treatments of the calculated data were $k_{2p}(3d)=18.76$ eV/e and $k_{2p}(4s)=9.84$ eV/e. The results suggest that, for a nickel atom, the effects of the 3d and 4s electron populations on the E_{2p} would have to be considered separately.

Some core-orbital k_i values obtained as above for the C, N, and F atoms as well as the Ni, Rh, and Pt atoms are summarized in Table 1. Two points are noteworthy with these k_i values. First, the shifts of E_{1s} for the light atoms do not depend on the origin of the charge; $k_{1s}(2s)$ is nearly equal to $k_{1s}(2p)$ for each atom. In other words,

Table 1. Exchange scaling parameters α and the calculated k_i values for atoms (eV/e)

Atom(core)[a]	α	Valence orbital	k_i	k_i(CNDO)[b]
C (1s)	0.75928	2s	16.46	21.9
		2p	16.53	
N (1s)	0.75197	2s	18.35	21.5
		2p	18.65	
F (1s)	0.73732	2s	21.96	27.6
		2p	21.81	
Ni (2p)	0.70896	3d	18.76	
		4s	9.84	
Rh (3d)	0.70217	4d	12.52	
		5s	8.21	
Pt (4f)	0.69306	5d	11.90	
		6s	8.10	

a) The orbitals denoted in parentheses show the core orbitals i from which an electron is removed upon ionization. b) Ref. 7.

the binding energy is little influenced by the difference in hybridization of valence orbitals.

Second, the k_i values calculated for the 2p, 3d, and 4s core orbitals of the Ni, Rh, and Pt atoms, respectively, all differ appreciably between the influencing d and s valence orbitals. Thus, the d orbital population exerts an apparently greater influence on the core binding energy of an inner-shell electron than does the valence s orbital population. In discussing the ESCA chemical shifts of transition metal atoms, therefore, we should look into the electron populations in individual d and s valence orbitals separately.

In Table 1 the values of k_{1s}[7] for the C, N, and F atoms in molecules obtained by fitting the observed 1s-electron chemical shifts to the CNDO/2 atomic charges are also listed. The k_{1s} (CNDO) values are uniformly greater than the Hartree-Fock-Slater k_{1s} values calculated. This may be attributed in part to the contraction of valence orbitals in molecules as a result of the accumulation of electronic charge in the bonding region.[8] The contraction should render the core orbitals in molecules more sensitive to the density of a valence electron than in isolated molecules.

Despite these numerical disagreements, the results of the present treatment of atoms lend support to the adequacy of the conventional charge-potential approximation for first-row atoms in molecules. The view that the k_{1s} values are quite different for the influencing 2s and 2p electrons[9] is thus unjustifiable. The better correlation of the two-parameter theory[9] to the shifts as compared with the conventional single-parameter treatment[1,7] is perhaps an artefact arising from the limited accuracy of the CNDO formalism itself. By contrast, it will be essential to resort to a multi-parameter treatment in interpreting the core-electron chemical shifts for transition metal atoms present in metal complexes.

Fouling Mechanism in Liquid Phase Oxidation of Carbon Monoxide Catalyzed by Palladium(II) Salts in Acetic Acid Solvents

Toshinobu IMANAKA, Tetsuo MATSUMOTO, Toshio KIMURA, Katsumi SAKURAI, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 6, 1976)

Synopsis. The fouling mechanism during catalytic activity in the liquid phase oxidation of carbon monoxide has been investigated using catalytic acetic acid solutions containing palladium(II) salts and lithium nitrate as oxidants. The fouling phenomenon becomes understandable upon the recognition that the active palladium catalysts react with the nitrite ion formed during the oxidation reaction to produce inactive-stable complexes.

The liquid phase oxidations of carbon monoxide have been investigated as an extension of the Wacker process[1-4] in water and several reactions catalyzed by palladium salts have also been studied using acetic acid as a solvent.[5-8] Many of these studies were done with respect to the steady state reactions, but only a few have been made on the fouling process during the reaction. The present authors have previously investigated the mechanism of the CO-oxidation reaction using palladium salts in acetic acid solvents[9] and it was shown that the catalytic activity in $Pd(NO_3)_2$ and $Pd(OAc)_2$ systems decrease more rapidly than in the $PdCl_2$ system.

In the present work, the fouling mechanism of the CO-oxidation reaction was studied kinetically using a stirred reactor. It can be considered that the NO_2^- produced by reduction in the catalytic solutions during the reaction reacts with palladium complexes to give inactive-stable complexes.

Experimental

The palladium chloride solutions used were prepared by refluxing palladium chloride(II) and lithium chloride in acetic acid solvents dehydrated by phosphorus pentoxide. These solutions, which were 100 ml in volume, were diluted with 400 ml of dehydrated acetic acid after the addition of lithium nitrate. The catalytic solutions of $Pd(NO_3)_2$ and $Pd(OAc)_2$ were prepared by adding lithium nitrate to the solution of $Pd(NO_3)_2$ or $Pd(OAc)_2$ dissolved in dehydrated acetic acid (100 ml). Carbon monoxide and carbon dioxide were prepared by dehydrating with calcium chloride. Air, oxygen, and nitrogen gases used were dried over silicagel after removing a small amount of carbon dioxide and water with concd sulfuric acid and rod-like sodium hydroxide. The materials used for the preparation of these mixtures were those commercially available. The amount of NO_2^- was determined by measuring the absorbance of light (530 nm) emitted using Griess (G.R.) reagent.

The reactor,[3,4] which was made of glass with a 75 mm inside diameter and a height of 145 mm, was used for bubbling the mixtures of gases with a downward glass filter. The stirrer had a two bladed impeller at a position 40 mm from the bottom of the reactor and the reactions were carried out at 30 °C. The reaction mixtures of the gasses were analyzed by gas chromatography after condensation of acetic acid.

Results and Discussion

In the $Pd(OAc)_2$ system with the highest catalytic activity, the relation between the reaction rate in the steady state and the feed rate or the stirring rate was investigated using the reactor described above. It was shown that the mass transfer rates were unchanged for feed rates of 10—20 cm^3/s and for a stirring rate of 900 rpm., therefore, under these conditions, the rate-determining step is the chemical-reaction processes. Accordingly, all the experiments were carried out under the conditions of $F \geq 10$ cm^3/s and $N=900$ rpm. In the case of $PdCl_2$ or $Pd(NO_3)_2$ systems, it was confirmed that the rate-determining step was the chemical-reaction processes under these conditions.

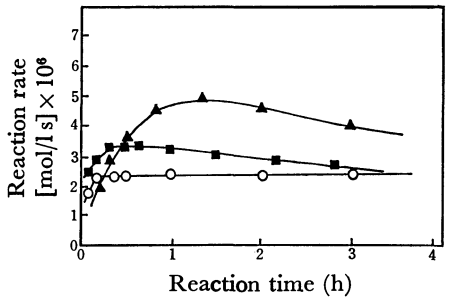

Fig. 1. The dependence of the reaction rate on the reaction time.
○: $PdCl_2$ C_{pd}: 3.59×10^{-4} (mol/l), ■: $Pd(NO_3)_2$ C_{pd}: 2.00×10^{-4} (mol/l), ▲: $Pd(OAc)_2$ C_{pd}: 2.00×10^{-4} (mol/l). C_{co}: 3.30×10^{-4} (mol/l), C_{NO_3} 0.290 (mol/l).

The oxidation rates of carbon monoxide catalyzed by palladium salts are shown in Fig. 1. In the case of palladium chloride, the oxidation rate became linear with time after about 10 min and remained constant for several hours. However, the activity decreased gradually after a long reaction period and the color of the solutions varied from an initial brown to yellow at the end. In the cases of $Pd(NO_3)_2$ and $Pd(OAc)_2$ catalysts, the reaction rate reached a maximum after several minutes and its activity decreased gradually without any precipitate. This reaction rate is of first order with respect to the concentration of the palladium salts, and therefore, the overall rate expression can be represented by

$$r = r_\infty \exp(-k_d t),$$

where r_∞ represents the steady state reaction rate and k_d the rate constant of the fouling reaction. The logarithm of the rates for constant concentration of palladium *versus* reaction time in the $Pd(NO_3)_2$ system for the

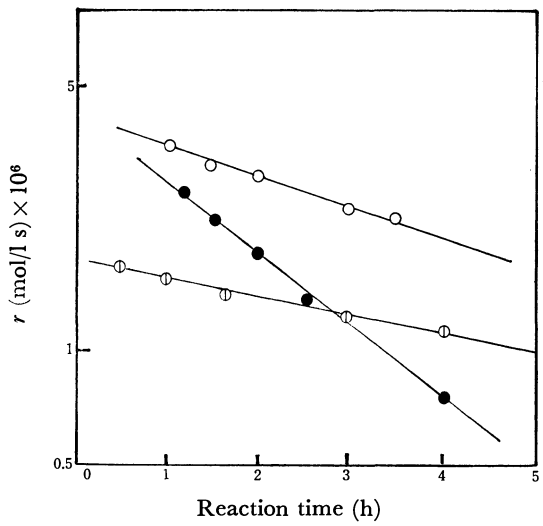

Fig. 2. The dependence of activity of $Pd(NO_3)_2$ catalyst on the reaction time.

	[$LiNO_3$]	CO%	O_2%	N_2%	[NO_2^-]
◫	0.232 [M]	6	18.8	75.2	8800 [μg-N/l]
○	0.928 [M]	15	17.0	68.0	17800 [μg-N/l]
●	1.16 [M]	6	0	94.0	34300 [flg-N/l]

$C_{pd}=0.995—1.02\times10^{-4}$ (mol/l).

various concentrations of lithium nitrate and the various feed streams are linear, as is shown in Fig. 2, and the fouling rate constants were calculated from the slopes. The fouling rate constants increase with decreasing oxygen content in the feed streams and with increasing concentration of NO_2^- formed by the reduction of NO_3^-. In Fig. 3, the logarithm of k_d is plotted against the logarithm of the concentration of NO_2^- formed during the oxidation reaction under the various catalytic solutions and feed streams of carbon monoxide. The values of k_d in the $Pd(NO_3)_2$ system are greater than those in the $Pd(OAc)_2$ system, as is shown in Fig. 3 and were much greater than those ($k_d=0$) in the $PdCl_2$ system under similar conditions. The best fit to the data are seen to be straight lines with slopes of one, which corresponds to a first order reaction in the case of the $Pd(NO_3)_2$ system and of 3.3, in the $Pd(OAc)_2$ system. These results show that the fouling process in the case of the $Pd(NO_3)_2$ catalyst is associated with the concentration of NO_2^- equivalent to $Pd(NO_3)_2$ and in the case of the $Pd(OAc)_2$ catalyst, two moles of NO_2^- to one mole of $Pd(OAc)_2$.

It is well known that NO_2^- in solutions reacts with acetic acid to produce NO_3^- and NO, as is shown by:

$$HOAc + NO_2^- \longrightarrow OAc^- + HNO_2 \quad (2)$$

$$3HNO_2 \longrightarrow H_3O^+ + NO_3^- + 2NO \quad (3)$$

Tamura and Yasui[8] have reported that NO resulting from formula (3) does not form a stable palladium nitrosyl complex. No precipitate is produced with OAc^- formed by in formula (2) and the catalytic activity does not change with the addition of 10% of water in the solution. The fouling rate constants are independent of the concentrations of palladium salts, $LiNO_3$ and

carbon monoxide, but do depend on the concentration of NO_2^- in the solutions.

It can be concluded that the fouling process causes the formation of inactive-stable palladium nitro complexes by the NO_2^- formed during the CO-oxidation reaction, and its fouling reaction rate decreases according to the following sequence:

$$Pd(NO_3)_3 > Pd(OAc)_2 \gg PdCl_2.$$

Photochemistry in the Adsorbed Layer. VII. Steric Hindrance in the Type II Cleavage of Adsorbed Alkyl Ketones

Masakazu ANPO and Yutaka KUBOKAWA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received March 16, 1976)

Synopsis. The type I selectivity in the photolysis of adsorbed alkyl ketones is larger for 3-methyl-2-pentanone than for 2-pentanone. Such behavior can be explained by the concept that the type II cleavage is more hindered for the former owing to a steric hindrance arising from the presence of a solid surface.

Recently we have investigated the spectra and photochemistry of alkyl ketones adsorbed on porous Vycor glass and found the general characteristics of the photochemistry in the adsorbed layer.[1-6] The change in the photochemical reactivity caused by adsorption has been discussed mainly from the electronic aspects. It seems likely that such a change in the photochemical reactivity is attributed in part to the steric effect arising from the presence of a solid surface. An example of this steric effect has been found in the type II cleavage of adsorbed alkyl ketones. The results are described in the present paper.

Experimental

Materials. 3-Methyl-2-pentanone (Tokyo Kasei Kogyo Co., Ltd.) was purified by preparatory chromatography and then vacuum distilled bulb-to-bulb. Analysis by vapor phase chromatography equipped with flame ionization detection showed no impurity. Porous Vycor glass (Corning, No. 7930) was used as an adsorbent.

Apparatus and Procedure. Details of the apparatus and procedures were described previously.[1-6] A conventional vacuum system was used in conjuction with a special quartz cell capable of studying the spectra and photolysis in the adsorbed layer. The specimen of porous Vycor glass which had been heated in oxygen to remove carbonaceous impurities was introduced into the cell and degassed at 500 °C for 7 h. Photolysis was carried out using an ultra high pressure mercury lamp without filter, after ketone molecule had been adsorbed on the specimen. Analysis was carried out by vapor phase chromatography using a 3 m column of porapak Q for hydrocarbons and a 2 m column of molecular sieve 5A for the noncondensable gases.

Results and Discussion

The results of the photolysis of adsorbed 3-methyl-2-pentanone (3-M-2-P) at room temperature are given in Table 1, and those of its photolysis in the gas phase in Table 2. In the gas phase photolysis the rate of ethylene formation is three times higher than that of radical product formation. Such behavior is in agreement with that reported by other workers,[7] who showed that the type II reaction is predominant in the gas phase (below 30 °C) and in solution. Comparison of Tables 1 and 2 show that the rate of radical product formation in the adsorbed layer is much higher than that of ethylene formation. Results of the photolysis of adsorbed 2-pentanone (2-P)[1,6] are given in Table 1. It is seen that the type I selectivity is higher in the adsorbed layer than in the gas phase, its extent being much larger for 3-M-2-P than for 2-P. Furthermore, the marked increase observed in going from 2-P to 3-M-2-P arises mainly from the decrease in the rate of ethylene formation. Such a high type I selectivity in the adsorbed layer was attributed to suppression of the recombination of the radical pairs as well as increased probability of α-cleavage, leading to the increase in the rate of radical product formation.[6] However, it is difficult to explain the marked higher type I selectivity of 3-M-2-P as compared to that of 2-P.

In order to obtain information on the nature of the excited states in the photolysis, the effect of added nitrogen oxide on ethylene formation from adsorbed 3-M-2-P has been investigated in a similar manner to that described previously.[1] The maximum reduction of ethylene formation by added nitrogen oxide, *i.e.*, the formation of ethylene from the triplet excited state, was about 47%, almost the same as the corresponding value observed

TABLE 1. RESULTS OF THE PHOTOLYSIS OF ADSORBED ALKYL KETONES AT 25 °C [a]

	Amount adsorbed[b] 10^{-6} mol/g	Yield of type II 10^{-3} ml/5 min	Yield of[c] type I 10^{-3} ml/5 min	Selectivity (type I/II)
3-Methyl-2-pentanone	5.36	0.21	1.07	5.1
	21.40	0.48	2.21	4.6
	42.80	0.65	2.59	4.0
2-Pentanone[d]	4.28	0.72	0.65	0.89
	22.00	1.92	1.24	0.65

a) The molar extinction coefficient at the wavelength of maximum absorption, ε for 3-methyl-2-pentanone was 1.45 times larger than that for 2-pentanone in the adsorbed layer. This ratio hardly changed with increasing amount of the ketone adsorbed.[2] b) The amount adsorbed of 4.47×10^{-6} mol/g corresponds to $\theta=0.005$ using 25 A^2 as the area that occupied by each molecule. As the amount adsorbed decreases, a marked increase in the type I selectivity as well as in the overall efficiency of the photolysis occurs (Table 2). Such a behavior would be attributed to a heterogeneity of the surface, *i.e.*, the presence of special active sites.[6] c) The amounts of minor products such as methane, propane, butene, and hexane did not exceed 15% of the amount of butane, indicating that the rate of the type I reaction is approximately equal to the rate of butane formation. d) M. Anpo and Y. Kubokawa, *Bull. Chem. Soc. Jpn.*, **48**, 3085 (1975).

Table 2. Results of the photolysis of gaseous 3-methyl-2-pentanone at 30 °C

Relative Yield	CH_4	C_2H_6	C_2H_4	C_3H_8	C_3H_6	C_4H_{10}	C_4H_8	C_5H_{12}	C_6H_{14}
	1.45	1.90	100.0	0.65	4.30	16.6	1.56	5.70	8.20

3-Methyl-2-pentanone pressure, 18.0±0.5 Torr. Irradiation time, 15 min. Selectivity was identified as $(\phi_{C_3}+\phi_{C_4}+\phi_{C_5}+\phi_{C_6})/(\phi_{C_2H_4})$.

with 2-P. There was no marked difference in the lifetimes of the triplet states of 2-P and 3-M-2-P determined from the Stern-Volmer plots for ethylene quenching with nitrogen oxide. This suggests that there is no difference in the nature on the excited states in the adsorbed layer photolysis between both ketones.

The type II reaction proceeds *via* 1,4-biradical intermediate formed by the intramolecular hydrogen abstraction.[8] A favorable conformation would be necessary for such γ-hydrogen abstraction to take place. A six-membered transition state has been proposed for this reaction. On a solid surface the rapid tumbling motion of molecules would be hindered, formation of such a six-membered transition state being disturbed. The steric hindrance would be expected to be more significant for 3-M-2-P than for 2-P owing to the presence of a bulky methyl group instead of a hydrogen. Thus, the marked lower rate of ethylene formation observed with the former as compared to the latter is explicable. Such steric requirements for the type II cleavage have been proposed by Turro and Weiss[9] who found a marked difference in the photochemical behavior of *cis* and *trans*-2-propyl-4-*t*-butylcyclohexanones in cyclohexane solution.

Molar Volume Equations of Several Molten Binary Systems

Junichi MOCHINAGA, Kazuo IGARASHI, Hideo KURODA, and Hironori IWASAKI

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received April 12, 1976)

Synopsis. The molar volumes of YCl_3–KCl, YCl_3–NaCl, YCl_3–$CaCl_2$, $PrCl_3$–KCl, $PrCl_3$–NaCl, $PrCl_3$–$CaCl_2$, $NdCl_3$–KCl, $NdCl_3$–NaCl, and $NdCl_3$–$CaCl_2$ systems in molten state were measured. The results are represented by empirical equations as functions of both temperature and composition. The calculations were carried out by using the methods of least squares and Powell's procedure.

It is important to know the molar volumes of molten salts, since they are used for the calculation of molar values in thermodynamics. The molar volume equation has been customarily expressed as a function of temperature for a fixed mole fraction. If empirical equations for the molar volumes of molten mixture systems are obtained as functions of temperature and mole fraction, they are convinient for the estimation of molar volumes at any temperature and composition over the measured range. Since the molar volume is given as a linear function of temperature, the empirical equation is given as follows.

$$V_m = \sum_0^n a_n x^n + \left(\sum_0^n b_n x^n\right) T$$

where V_m is the averaged molar volume of the molten mixture system in cm^3/mol, a_n and b_n the parameters, x the mole fraction of rare-earth chlorides, and T the temperature in K. The parameters were calculated by the method of least squares, and Powell's method.[1,2] The latter is considered to be effective for finding the minimum value of function containing several variables. The molar volumes calculated from the resulting empirical equations are in agreement with the observed values within 2%.

Experimental

Materials. Rare-earth chlorides were prepared by a procedure similar to that reported.[3] KCl, NaCl, and $CaCl_2$ were dried by heating at a temperature 50 °C below their melting points *in vacuo*.

Measurement. The dilatometer method was used. The volume of the dilatometer, which was made of transparent silica, was determined by use of distilled water at room temperature since the thermal expansion coefficient of quartz is much smaller than that of molten salts. The meniscus of melt in the dilatometer was read with a cathetometer.

Results and Discussion

Comparisons between the observed molar volumes and the values for the molten YCl_3–$CaCl_2$ system obtained by means of empirical equations are given in Figs. 1 and 2 for $n=2$ and $n=3$, respectively. Fitting of the resulting equation for the observed molar volumes is better in the case of $n=3$ than that of $n=2$. The molar volumes of the respective pure component salts in molten state can be obtained from the values at $x=0$ or $x=1$. The parameters for these molten binary systems are given in Table 1. All the excess molar volumes calculated by means of the equations are small. The intersections between experimental curves and additivity lines in the molar volume isotherms were observed except for $PrCl_3$–KCl and $NdCl_3$–KCl systems.

Calculations were carried out with the computers in the University of Tokyo and Chiba University.

(Received April 12, 1976)

Synopsis. CNDO/2 calculations of *i*-PrSMe, *i*-PrSEt, *i*-Pr-S-*n*-Pr, and $(i\text{-Pr})_2S$ gave the stable conformations of these molecules and the optimized angles of ϕ(CSC) of the first three molecules considered.

Conformational analyses of *i*-PrSMe, *i*-PrSEt, *i*-Pr-S-*n*-Pr, and $(i\text{-Pr})_2S$ have been performed extensively on the basis of vibrational spectra and normal coordinate treatment.[2-4] However, for these molecules no theoretical conformational analysis has yet been performed. In the present study in order to test the previous experimental results, the present authors investigated the conformational analyses of these molecules by the CNDO/2 method.[5]

The molecular parameters used for the computations are as follows: r(C–H)=1.09 Å, r(C–S)=1.81 Å, r(C–C)=1.54 Å—ϕ(CSC)=99° or the optimized values for *i*-PrSMe, *i*-PrSEt, *i*-Pr-S-*n*-Pr, and ϕ(CSC)=99, 104, or 109° for $(i\text{-Pr})_2S$—and the other angles were assumed to be tetrahedral. The dihedral angles were 180 and 60° for the *trans* (T) and *gauche* (G) forms, respectively.

With *i*-PrSMe, a local minimum appeared at a rotational angle of *ca.* 60 °. That is, the calculations show that the G (C_1) form is more stable than the T (C_s) form. The present result agrees well with the observed.[2]

For *i*-PrSEt, the stability was assumed to be in the order: GT>GG>TT.[4] In this molecule, conformations are taken into consideration around bonds 1 and 2, H–C(–C)–S–CH_2–CH_3. The CNDO/2 calculations indicate the stability: GT>TT>GG>TG. The most stable form, GT, is well reproduced by the calculations. However, the stabilities for the TT and GG forms are in reverse order of those observed.[4] For the IR study, the most unstable form, TG, is excluded from consideration, since the repulsions between methyl groups in the ethyl and isopropyl groups may be too great.[4] This is explained qualitatively by the present calculations.

For *i*-Pr-S-*n*-Pr, conformations were taken into consideration around bonds 1, 2, and 3, H–C(–C)–S–CH_2–CH_2–CH_3, and from the calculations it was found that the forms which have the T conformation about bond 2 are more stable than those of the G conformation. This agrees well with the experimental result that GTT is the most stable form,[4] although the present calculations show that the energy minimum form is GTG. As has been noted previously,[6] the conformation around the

i-PrSMe: — ϕ(CSC)=99°, ○ ϕ(CSC)=105°.
i-PrSEt: — ϕ(CSC)=99°, -- ϕ(CSC)=105.6°.
i-Pr-S-*n*-Pr: — ϕ(CSC)=99°, -- ϕ(CSC)=105.9°.
$(i\text{-Pr})_2S$: ϕ(CSC)=99°; C_2=−40413, C_1=−40303, C_s=−40295, C_{2v}=−40183 (kcal/mol), — ϕ(CSC)=104°, -- ϕ(CSC)=109°.

* To whom all correspondence should be addressed.

C–S bond is very difficult to determine from only the vibrational spectra and the normal coordinate treatment. Therefore, the CNDO/2 method is available to determine the conformation around the C–S bond for these molecules.

Four conformations can be assumed for $(i\text{-Pr})_2S$: C_2, C_s, C_1, and C_{2v}. It appears that the conformational energy is due mainly to the interactions between methyl groups of the isopropyl groups on both sides. In connection with these interactions, the stability can be predicted to be in the order: $C_2>C_s>C_1>C_{2v}$. The vibrational spectra confirm this order.[4] The CNDO/2 calculations give the result, $C_2>C_1>C_s>C_{2v}$, and the stability between the C_1 and C_s forms is reversed. However, the most stable and unstable forms are well reproduced by the calculations.

The CSC angle was then optimized without changing the other structural parameters assuming the G, GT, and GTT forms for *i*-PrSMe, *i*-PrSEt, and *i*-Pr–S–*n*-Pr, respectively. The angles obtained are 105, 105.6, and 105.9° for *i*-PrSMe, *i*-PrSEt, and *i*-Pr–S–*n*-Pr, respectively. The angles become larger with increasing weight of the normal alkyl group. These angles are rather large in comparison with the 98°52′ of MeSMe[7] and rather close to the 103.9° for MeSEt.[8] Therefore, these angles appear to be reasonably optimized. The results of the calculations using the optimized angles are also considered. The tendency is nearly the same as in the case of $\phi(\text{CSC})=99°$. For $(i\text{-Pr})_2S$, the optimization of angle ϕ(CSC) was not carried out. The total energy decreases with increasing angle from 99° to 109°. Therefore, it is predicted that the angle is larger in this molecule than in other molecules treated.

All of the calculations were also carried out using $K_d=0.492$ instead of 0.75 and others original values,[5] where K_d is the constant of the off-diagonal core matrix elements in relation to third-row elements. As a result, the order of the stability scarcely varied from the case of $K_d=0.75$, but the energy difference between the rotational isomers was slightly refined, *e.g.*, the energy difference between the T and G forms of *i*-PrSMe is postulated to be *ca.* 1—1.5 kcal/mol from the IR study.[2]

Recently, the appropriateness of CNDO/2 studies of molecular conformations has been discussed for some molecules involving third-row elements.[9,10] Generally, the CNDO/2 calculation gives larger energy differences between the rotational isomers than observation. However, this method reproduces energy minimum conformations and some angles fairly well. The CNDO/2 calculation, therefore, is useful as one of the methods of analyzing experimental results, such as the normal coordinate treatment.

The authors wish to thank Dr. Kimihiko Hirao of the Shiga University of Medical Science for his helpful advice. All calculations were performed at the Computing Center of Hiroshima University.

(Received October 7, 1975)

Synopsis. From the distribution ratio of iron(III) between hexane containing trioctylphosphine oxide (TOPO) and a 4 mol dm^{-3} aqueous (H, Na)Cl solution, the extraction constants for the two complexes, $K_{ex_1}=[FeCl_3(TOPO)_2]_{org}[Fe^{3+}]^{-1}[Cl^-]^{-3}[TOPO]_{org}^{-2}$ and $K_{ex_4}=[HFeCl_4(TOPO)_2]_{org}[Fe^{3+}]^{-1}[H^+]^{-1}[Cl^-]^{-4}[TOPO]_{org}^{-2}$, were determined to be $10^{4.5}$ and $10^{4.3}$, respectively. The extractability of tetrachloroferric acid are discussed by comparing the K_{ex} value with that for perchloric acid.

Solvent extraction of iron(III) from hydrochloric acid with oxygen-containing solvents, such as diethyl ether, is one of the oldest applications of this method to metal ions[1,2] and, as reviewed by Diamond and Tuck[3] and Marcus and Kertes,[4] the extracted species is recognized to be tetrachloroferric acid, $HFeCl_4$. In the present work, this extraction was reinvestigated using hexane containing a small amount of trioctylphosphine oxide (TOPO) as the organic phase and the equilibria in the system are discussed.

Experimental and Statistical

The experiments and the analysis of the data were performed in a similar manner to other studies in this series.[5-7] The stock iron(III) solution was prepared by dissolving ferric chloride in hydrochloric acid. All the procedures were performed in a room with the temperature thermostatically controlled at 25±0.3 °C. A portion of hexane containing TOPO and the same volume of an aqueous 4 mol dm^{-3} (H, Na)Cl solution containing 1×10^{-3} mol dm^{-3} iron(III) were placed in a stoppered glass tube, stirred vigorously for 15 min and centrifuged. The iron(III) content in the organic phase was determined from the optical absorption at 425 nm after it was colored by β-isopropyltropolone[8,9] and that in the aqueous phase was determined from the absorption at 480 nm after it was colored by thiocyanate.[10]

All the species in the organic phase are denoted by the subscript "org" and those in the aqueous phase by the lack of any subscript. The stability constants for iron(III) complexes in the aqueous phase are:

$$\beta_n = [FeCl_n^{3-n}][Fe^{3+}]^{-1}[Cl^-]^{-n} \quad (1)$$

As will be seen below, the extraction constants for the trichloride and tetrachloride complexes of iron(III) can be written as:

$$K_{ex_1} = [FeCl_3(TOPO)_2]_{org}[Fe^{3+}]^{-1}[Cl^-]^{-3}[TOPO]_{org}^{-2} \quad (2)$$

and

$$K_{ex_4} = [HFeCl_4(TOPO)_2]_{org}[Fe^{3+}]^{-1}[H^+]^{-1}\times[Cl^-]^{-4}[TOPO]_{org}^{-2} \quad (3)$$

The distribution ratio of iron(III) under the present conditions can be written as:

$$D = [Fe(III)]_{org,total}[Fe(III)]_{total}^{-1}$$
$$= ([FeCl_3(TOPO)_2]_{org}+[HFeCl_4(TOPO)_2]_{org})\times([Fe^{3+}]+[FeCl^{2+}]+[FeCl_2^+])^{-1} \quad (4)$$

By substituting Eqs. 1 through 3 into 4, we can write:

$$D = \{[TOPO]_{org}^2(K_{ex_1}[Cl^-]^3+K_{ex_4}[H^+][Cl^-]^4)\}\times(1+\beta_1[Cl^-]+\beta_2[Cl^-]^2)^{-1} \quad (5)$$

and thus,

$$\log\{D(1+\beta_1[Cl^-]+\beta_2[Cl^-]^2)[Cl^-]^{-3}[TOPO]_{org}^{-2}\} = \log(K_{ex_1}+K_{ex_4}[H^+][Cl^-]) \quad (6)$$

The values of these extraction constants can be obtained by a curve-fitting method using the following standard curve:[12]

$$Y = \log(1+v), \quad X = \log v \quad (7)$$

Results and Discussion

The slope of the log D *vs.* log $[TOPO]_{org}$ plot was +2 for hydrogen-ion concentrations of the 4 mol dm^{-3} chloride solution of either 1×10^{-2} or 1 mol dm^{-3}. The extraction of iron(III) in 4 mol dm^{-3} chloride solutions increased with an increase in the hydrogen-ion concentration. Figure 1 shows the log D *vs.* log [H$^+$] plot.

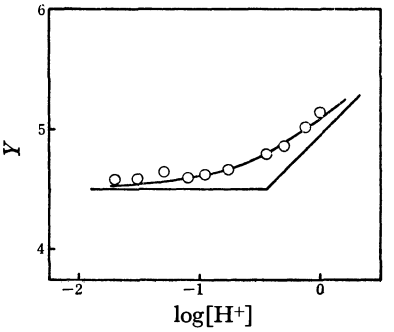

Fig. 1. Increase in the distribution ratio of Fe(III) as a function of the hydrogen-ion concentration. Org. phase: hexane initially containing 3×10^{-3} mol dm^{-3} TOPO. Aq. phase: 4 mol dm^{-3} (H, Na)Cl. The ordinate is $Y=\log\{D(1+\beta_1[Cl^-]+\beta_2[Cl^-]^2)[Cl^-]^{-3}\times[TOPO]_{org}^{-2}\}$. The solid curve is obtained by introducing the extraction constants K_{ex_1} and K_{ex_4} into Eq. 6.

From the dependence of D on the hydrogen-ion and TOPO concentrations described above, the extracted species are assumed to be mainly $FeCl_3(TOPO)_2$ and $HFeCl_4(TOPO)_2$ in the lowest and highest hydrogenion concentration regions, respectively. Using the stability constants previously obtained in 4 mol dm^{-3} aqueous Na(Cl, ClO_4) medium[11] ($\beta=10^{0.88}$ and $\beta_2=10^{0.80}$,

those of the higher complexes being negligibly small) and by correcting for the free TOPO concentration due to the extraction of hydrochloric acid, the data were analyzed by the curve-fitting method. The constants in Eqs. 2 and 3 were determined to be $K_{ex_1}=10^{4.5}$ and $K_{ex_2}=10^{4.3}$, respectively. The solid curve in Fig. 1 was calculated by introducing these constants into Eq. 6.

The extraction of iron(III) chloride with TOPO has been reported previously,[11,13-15] but the equilibria involved have not been discussed in detail.

The dissociation of $HFeCl_4$, a very strong acid which is comparable to perchloric acid,[3,4] should be negligible in hexane containing a small amount of TOPO as in the case of perchloric acid already discussed,[5] and therefore, Eqs. 2—6 can be applied for the present data. On the other hand, the dissociation of this acid should be taken into account in various polar organic solvents saturated in water. This may be one of the reasons why the extraction constant in Eq. 3 has never been reported in previous reports on iron(III) chloride extraction.

The solvation number of $HFeCl_4$ has also been found to be two with respect to tributylphosphate (TBP).[16] The IR absorption of TBP in benzene due to the stretching vibration of the phosphoryl group has been systematically studied.[17] It was found[17] that the shift of the TBP absorption band to lower frequencies upon extracting iron(III) from 6 mol dm^{-3} hydrochloric acid was similar to that which occurred with the TBP solvating nitrates of lanthanoides. Thus it should be reasonable to assume that since the central metal ion should be coordinated to TBP in the extracted iron(III) complex of that report, the TOPO molecules in the present study should be bound to $HFeCl_4$ through a coordination bond, but not to the proton through a hydrogen-bond.

In previous work,[11] neither the $FeCl_3$ nor the $FeCl_4^-$ complex was detected in 4 mol dm^{-3} aqueous chloride solutions to within the limit of experimental error and thus the determination of the following extraction constant was not possible from the present data:

$$K_{ex}(\text{acid}) = [HX(TOPO)_2]_{org}[H^+]^{-1}[X^-]^{-1}[TOPO]_{org}^{-2} \quad (8)$$

However, on assuming that β_4 is smaller than 10^{-1}, the lower limit of the constant in Eq. 8 for the tetrachloroferric acid (X^- is $FeCl_4^-$) was estimated to be $K_{ex}(HFeCl_4)>10^{5.3}$, which is more than ten times the value for perchloric acid (X^- is ClO_4^-) in the 4 mol dm^{-3} ionic medium with TOPO in hexane[9] ($K_{ex}(HClO_4)=10^{4.16}$). Since perchloric acid is known to be one of the most extractable inorganic acids using solvating type extractants,[3-5] one possible explanation for the high extractability of this complex acid may be given as follows: the TOPO molecules are coordinated to the central iron(III) in the complex. However, further information is necessary before a final conclusion can be drawn.

The authors are very grateful to Dr. Akira Yamasaki of the Electrocommunications University, Tokyo, for valuable discussions concerning this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (9), 2631—2632 (1976)

Circular Dichroism of Nickel(II) and Copper(II) Complexes with Optically Active Diamines Containing a Pyrrolidinyl Group

Tasuku MURAKAMI, Sadao KITAGAWA, and Masahiro HATANO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received March 27, 1976)

Synopsis. Nickel(II) and copper(II) complexes of diamines containing a (*S*)-pyrrolidinyl group were prepared and their absorption and CD spectra were measured.

Chelating agents with (*S*)-pyrrolidine ring(s) form stereospecific metal complexes, since the nitrogen atom within the pyrrolidine ring coordinates only with the *S*-configuration.[1,2] As an example, *fac*(*N*)-*Λ*-[Ni(L-prolinate)$_3$]$^-$ was predominantly isolated from an aqueous solution containing nickel(II) carbonate and L-proline.[1] In this note, we wish to report the circular dichroism (CD) of nickel(II) and copper(II) complexes with optically active diamines containing a pyrrolidinyl group.

Experimental

From L-proline, the two optically active diamines, (*S*)-2-(aminomethyl)pyrrolidine (abbreviated to amp) and (*S*)-2-(*N*-methylaminomethyl)pyrrolidine (mamp), were prepared *via* their amides by the usual method.[3] Tris(amp)nickel (II) perchlorate was obtained from 1: 3 mixing of nickel(II) perchlorate

and amp in an aqueous solution. Found: C, 32.43; H, 6.59; N, 14.76%. Calcd for [Ni($C_{15}H_{36}N_6$)] (ClO_4)$_2$: C, 32.28; H, 6.50; N, 15.06%. The absorption and CD spectra of the tris(amp) complex were measured in methanol. For the yellow bis-type complexes of amp and mamp, which have a square planar structure, the spectral measurements were carried out as follows. Difinite amounts of nickel(II) perchlorate and each diamine were mixed in a 1: 2 ratio in an aqueous solution. The blue solution was evaporated and dried in vacuo at 50 °C to give a yellow solid. The solid was dissolved in a difinite amount of nitromethane and the spectra were measured. No absorption band originating from an octahedral species was detected in the spectra obtained in this way.

The copper(II) complex of amp was prepared by 1: 2 mixing of copper(II) nitrate and amp and that of mamp by mixing of copper(II) perchlorate and mamp in an aqueous solution. Found for the bis(amp) complex: C, 30.67; H, 6.35; N, 14.31 %. Calcd for [Cu($C_{10}H_{24}N_4$)] (NO_3)$_2$: C, 30.97; H, 6.24; N, 14.45%. Found for the bis(mamp) complex: C, 38.11; H, 7.62; N, 14.53%. Calcd for [Cu($C_{12}H_{28}O_4$)] (ClO_4)$_2$: C, 38.26; H, 7.49; N, 14.87%.

Results and Discussion

In general, the tris((*S*)-diamine) cobalt(III) complex prefers a *Λ*-configuration of *lel*-form(*Λ*-*δδδ*) to a *Δ*-configuration of *ob*-form.[4] A similar situation was assumed in some tris(diamine)nickel(II) complexes.[5,6] The tris complex of amp, which has an asymmetric carbon atom with an *S*-configuration, is also expected to adopt predominantly a *Λ*-configuration.

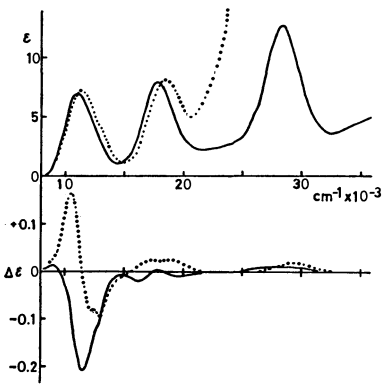

Fig. 1. Absorption and CD spectra of [Ni(amp)$_3$]$^{2+}$ (—) and [Ni((*S*)-3-phenyl-1,2-propanediamine)$_3$]$^{2+}$ (···) in methanol.

Figure 1 shows the absorption and CD spectra of tris(amp)nickel(II) together with those of tris((*S*)-3-phenyl-1,2-propanediamine) complex. The tris(amp) complex exhibits a large negative CD band at the higher wavenumber side and a small positive band at the lower wavenumber side within the region of the first absorption band ($^3A_{2g}\rightarrow{}^3T_{2g}$), which is only one magnetically allowed transition of the three spin-allowed d-d transitions. The CD pattern, a positive component at lower wavenumber and a negative at higher wavenumber, indicates that the complex adopts a *Λ*-configuration as expected.[5,6]

The CD spectra of most of the tris((*S*)-diamine)nickel-(II) complexes have a large positive component and a small negative one at the lower and higher wavenumber sides, respectively, in the region of the first absorption band (Fig. 1; Refs. 5 and 6). In the CD curve of the tris (amp) complex, however, the CD magnitudes of the two components are opposite. This is attributable to

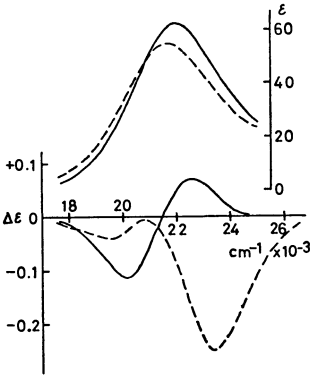

Fig. 2. Absorption and CD spectra of [Ni(amp)$_2$]$^{2+}$ (—) and [Ni(mamp)$_2$] (---) in nitromethane.

the asymmetric nitrogen atom with the *S*-configuration in the pyrrolidine ring. Such a CD curve has also been obtained in the case of tris(L-prolinato)nickel(II).[1]

The absorption and CD spectra of the bis-type yellow complexes of amp and mamp are shown in Fig. 2. The bis(amp) complex exhibits two CD bands, negative at 20200 cm^{-1} and positive at 22500 cm^{-1}. These two bands probably correspond to the two magnetically allowed d-d transitions (d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$, $d_{xy} \rightarrow d_{x^2-y^2}$) of a square planar-type nickel(II) complex. In general, the bis-type yellow complex of *S*-diamine exhibits only one negative CD band at about 22000 cm^{-1} in nitromethane.[7,8] Thus, the appearance of the positive CD band in the bis(amp) complex is due to the asymmetric nitrogen atom in the pyrrolidine ring.

On the other hand, the bis(mamp) complex exhibits only negative CD (Fig. 2). This suggests that another asymmetric nitrogen atom of the methyl-substituted amino group in mamp plays the opposite role in CD sign to the asymmetric nitrogen atom in the pyrrolidine ring. Thus the nitrogen atom of the methylsubstituted amino group in the bis(mamp) complex is expected to have an *R*-configuration.

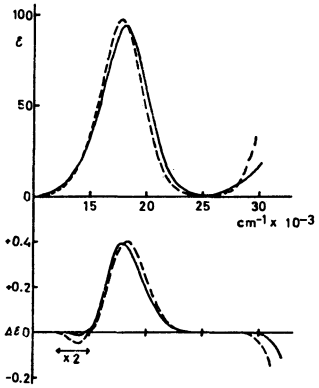

Fig. 3. Absorption and CD spectra of $[Cu(amp)_2]^{2+}$ (—) and $[Cu(mamp)_2]^{2+}$ (---) in water.

Figure 3 shows the absorption and CD spectra of the copper(II) complexes of amp and mamp in aqueous solutions. These two complexes exhibits very similar CD curves which have a main positive CD band at *ca.* 18000 cm^{-1} and a weak negative band at *ca.* 14000 cm^{-1}. Results showing that in some bis(diamine)copper(II) complexes the *N*-substitution of diamine greatly affects the CD spectra have been reported by Morita and Yoshikawa.[9] In the case of mamp, however, the substituted methyl group does not seem to be significant for the CD spectrum of the copper(II) complex. Thus, the *N*-substituted methyl group of mamp may have a different effect on the optical activity of the copper(II) complex from that of the nickel(II) complex.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (9), 2633—2634 (1976)

Reaction Process between Cobalt Tungstate and Chlorine

Hisao NISHIHARA, Ryoko MATSUZAKI, and Yuzo SAEKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 8, 1976)

Synopsis. The reaction between $CoWO_4$ and chlorine proceeds above about 585 °C to form WO_2Cl_2 and $CoCl_2$. In the presence of carbon, the reaction proceeds above about 345 °C to form $CoCl_2$ and WO_3, the WO_3 subsequently reacts with chlorine to form WO_2Cl_2 and $WOCl_4$.

The development of the chlorine process for the recovery of tungsten and cobalt from the sludge generated in the electrochemical grinding of WC-Co cemented carbide is important for the future. The sludge consists of 69% $CoWO_4$, 20% Na_2WO_4, 10% WC, and 1% C. In order to obtain chlorides of tungsten and cobalt from the sludge by selective chlorination, it is necessary to clarify the chlorination processes of the constituents of the sludge.

Concerning the reaction between $CoWO_4$ and chlorine, no information is presently available. In this report, the reaction processes between $CoWO_4$ and chlorine, and between $CoWO_4$ and chlorine in the presence of carbon are examined.

The sample of $CoWO_4$ used was prepared by adding an aqueous $Co(NO_3)_2 \cdot 6H_2O$ solution to an aqueous $Na_2WO_4 \cdot 2H_2O$ solution.[1] Both the salts used were guaranteed reagents. The resulting precipitate was washed with water, air-dried, and dehydrated at 400 °C. The sample obtained was confirmed to be $CoWO_4$[2] by X-ray analysis.

The weight change on the heating of 0.3 g of $CoWO_4$ placed in a quartz crucible in a dry chlorine stream was examined using a thermal balance with a quartz helix. The chlorine flow-rate was maintained at 50 ml/min. and a heating rate of 2.5 °C/min was employed. The sensitivity of the quartz helix was about 0.13 mg/0.01 mm. The results are shown in Fig. 1 (curve (a)).

The TG curve shows that the reaction between $CoWO_4$ and chlorine proceeds above about 585 °C.

The product formed by the chlorination of $CoWO_4$ was examined by heating 6 g of $CoWO_4$ in a quartz boat at a specified temperature and at a chlorine flow-rate of 350 ml/min for 1 h. The products obtained were examined by X-ray analysis[3] using Ni-filtered Cu radiation.

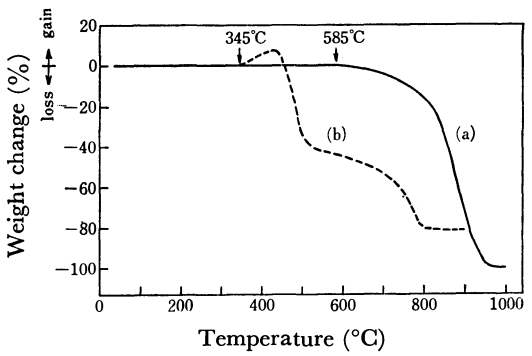

Fig. 1. TG curves of $CoWO_4$ (a), and a mixture of $CoWO_4$ and C(b) in a chlorine stream.

The volatile products obtained by the chlorination of $CoWO_4$ at 600—800 °C were WO_2Cl_2 and $CoCl_2$. No chlorination product was observed in the boat placed in the heating zone. From these experimental results, it was found that the reaction between $CoWO_4$ and chlorine proceeds above about 585 °C to form WO_2Cl_2 and $CoCl_2$.

The chlorination process of metal oxides was affected by the existence of carbon.[4,5] Thus, the effect of the existence of carbon on the reaction between $CoWO_4$ and chlorine was examined. The sample of carbon used was prepared by the pyrolysis of guaranteed reagent grape sugar.

The TG curve of a mixture of $CoWO_4$ and carbon ($CoWO_4$: C=1 : 8 by molar ratio) on heating in a chlorine stream is shown in Fig. 1 (curve (b)).

It is observed that the sample weight increased above about 345 °C, then decreased above about 430 °C, and reached a constant value above about 850 °C. The residue in the crucible, after heating the sample up to 900 °C, was carbon.

The products formed by chlorinating $CoWO_4$ in the presence of carbon at a specified temperature for 0.5 h were examined by X-ray analysis.[2,3,6] The results are shown in Table 1. The weight percentages of the chlorides in the volatile product obtained outside the heating zone were calculated from chemical analysis.[7] The values are shown in parenthesis in Table 1.

Table 1. Chlorination products of a mixture of $CoWO_4$ and C

Temp (°C)	In the boat	Outside the heating zone
380	$CoWO_4$, WO_3, $CoCl_2$	WO_2Cl_2
500	$CoWO_4$, $CoCl_2$	WO_2Cl_2 (>99.9%)
		$WOCl_4$ (<0.1%)
600	$CoWO_4$, $CoCl_2$	$WOCl_2$ (>99.9%)
		$WOCl_4$ (<0.1%)
		$CoCl_2$ (<0.1%)
700	$CoCl_2$	WO_2Cl_2 (95%)
		$WOCl_4$ (2%)
		$CoCl_2$ (3%)
800	$CoCl_2$	WO_2Cl_2 (53%)
		$WOCl_4$ (23%)
		$CoCl_2$ (24%)

At 380 °C, WO_3 and $CoCl_2$ were formed in the boat, and WO_2Cl_2 was obtained outside the heating zone. Above 500 °C, no WO_3 was observed in the boat. Considering the fact that the reaction between WO_3 and chlorine in the presence of carbon begins at about 330 °C and proceeds markedly above about 400 °C to form

volatile WO_2Cl_2 and $WOCl_4$,[4] it appears to be probable that above 500 °C, the WO_3 formed by the chlorination of $CoWO_4$ subsequently reacts with chlorine to form volatile WO_2Cl_2 and $WOCl_4$. Above 600 °C, $CoCl_2$ was obtained outside the heating zone, as well as in the boat. It may be considered that since the vapor pressure of $CoCl_2$ became appreciable above 600 °C,[8] the $CoCl_2$ formed by the chlorination of $CoWO_4$ vaporized and condensed outside the heating zone. Also, the ratio of $WOCl_4$ to WO_2Cl_2 in the volatile product increased with an increase in the reaction temperature. This fact was considered to support the above-mentioned estimate that WO_2Cl_2 and $WOCl_4$ were formed by the chlorination of the WO_3 formed by the chlorination of $CoWO_4$.[4] Furthermore, the weight gain observed at temperatures from 345 to 430 °C in Fig. 1 (curve (b)) was found to be due to the formation of non-volatile WO_3 and $CoCl_2$ by the chlorination of $CoWO_4$.

From these experimental results, the reaction between $CoWO_4$ and chlorine in the presence of carbon proceeds above about 345 °C to form $CoCl_2$ and WO_3, the WO_3 subsequently reacts with chlorine to form WO_2Cl_2 and $WOCl_4$.

In the absence of carbon, the reaction between $CoWO_4$ and chlorine proceeds above about 585 °C to form $CoCl_2$ and WO_2Cl_2, as described above. Considering the fact that the chlorination of WO_3 begins at about 680 °C to form WO_2Cl_2,[4] it appears probable that the WO_2Cl_2 was directly formed by the chlorination of $CoWO_4$ without passing through WO_3.

The authors wish to thank the Ministry of Education for research funds.

Cobalt(II) and Nickel(II) Complexes with Schiff Bases Obtained from Salicylaldehyde Derivatives and *N*-(2-Aminoethyl)-piperazine[1)]

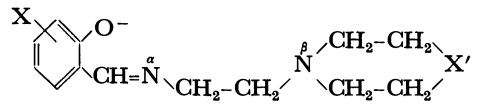
Hiro KUMA and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received June 3, 1976)

Synopsis. Cobalt(II) and nickel(II) complexes have been synthesized with Schiff bases derived from ring-substituted salicylaldehydes and *N*-(2-aminoethyl)-piperazine. Bis-(Schiff base)-metal(II complexes have been isolated. All of them have an octahedral structure, in which the Schiff bases are terdentate. The results are compared with those for complexes of related ligands.

It was reported previously that ligands of the type Ia formed bis(Schiff base)-complexes with cobalt(II) and nickel(II), the structure of which was planar, tetrahedral, octahedral or penta-coordinate, depending upon X as well as upon the metal ion.[2,3)] Ligands of the type Ib, abbreviated as X-salen-pip, contain another nitrogen atom in the heterocyclic ring and might function as a quadridentate ligand. It seems interesting to explore such a possibility, and at the same time to examine if there is any significant electronic effect of the introduced NH group on the donor strength of the β nitrogen atom in the same ligand.



I

(a) X′=CH_2, (b) X′=NH

In the present work, cobalt(II) and nickel(II) complexes with ligands of the type Ib were synthesized and the structure was examined mainly on the basis of spectral and magnetic data. The results were discussed in comparison with those for the corresponding complexes with ligands Ia.

Experimental

Materials. The nickel(II) complexes were prepared by the following method. A solution of nickel(II) chloride hexahydrate (0.01 mol) in ethanol (50 ml) was added to a solution of X-salicylaldehyde (0.022 mol) and *N*-(2-aminoethyl)-piperazine (0.022 mol) at 60 °C. To the resulting solution was added a solution of sodium carbonate in a small amount of water or potassium ethoxide (0.008 mol) in ethanol, and the mixture was stirred at 60 °C for about 3 h. After cooling the precipitate was collected and recrystallized from pyridine or methanol to yield olive-green microcrystals. These nickel(II) complexes are soluble in hot pyridine, slightly soluble in methanol, and insoluble in benzene and chloroform.

The cobalt(II) complexes were prepared in orange microcrystals by a method similar to that for the corresponding nickel (II) complexes. Recrystallization was carried out from pyridine. They are soluble in hot pyridine and almost insoluble in the common organic solvents.

Analytical data of the complexes prepared in the present work are shown in Table 1.

Measurements. Electronic absorption spectra were measured on a Shimadzu MPS-50L spectrophotometer. Magnetic measurements were carried out at room temperature by the Gouy method using $CoHg(SCN)_4$ as a calibrant.

Results and Discussion

Cobalt(II) complexes of the type Co(X-salen-pip)$_2$ were obtained in the present work, X being 5-Cl, 5-Br, and 5-NO_2. These complexes in the solid state show very similar spectra, which have one d-d band at about 10500 cm^{-1} (Table 2). The band maximum is comparatively close to those of the corresponding cobalt(II) complexes of ligands Ia, which were concluded to be octahedral.[3)] The octahedral structure, therefore, is assigned to the present cobalt(II) complexes. In these complexes the ligands are considered to function as a terdentate ligand. In view of the results of the previous studies, it seems most likely that the β nitrogen atom, in addition to the phenolic oxygen and the imine nitrogen atom, is coordinated to the cobalt(II) ion.

These cobalt(II) complexes are of a high-spin type, the values of the magnetic moments at room temperature being 4.6 to 4.8 BM. These values, particularly the lowest value (4.6 BM) for the complex with X=5-NO_2, may appear to be too low for the expected stereochemistry. A similar phenomenon was reported for

octahedral cobalt(II) complexes with ligands of the type Ia and was ascribed to a partial oxidation of the solid.[3]

Nickel(II) complexes of the type $Ni(X\text{-salen-pip})_2$ were obtained in the present work. Since they are only slightly soluble in appropriate solvents, Nujol mull spectra have been measured. The d-d band maxima are shown in Table 2. These complexes exhibit spectra, which are typical of the octahedral nickel(II) complex. The d-d bands at about 10.1—10.4 kK may be assigned to a transition $^3T_{2g} \leftarrow {}^3A_{2g}$ in the scheme of the O_h ligand field symmetry. No absorption bands appear in the lower frequency region, where the five-coordinate and the tetrahedral species are expected to absorb.

They are paramagnetic with magnetic moments of 3.0 to 3.3 BM at room temperature. It is, therefore, presumed that these nickel(II) complexes may have an octahedral structure.

Thus the ligands in these complexes are found to function as a terdentate ligand with the β nitrogen atom bound to the nickel(II) ion. This result differs from that reported previously for ligands of the type Ia. All the nickel(II) complexes of the ligands Ia are diamagnetic and planar in the solid state.[3] The difference in this respect between the ligands Ia and Ib may be ascribed to the electronic factor, since the steric condition is very similar for the ligands of the two types. It is rather surprising that such an apparently slight difference in the ligands gives rise to a remarkable difference in the structure of their nickel(II) complexes.

Gamma-Rays Treatment of Odorous Compound in Water

Setsuko IRIE, Norio KATO, and Shosaku KINOSHITA
Radiation Center of Osaka Prefecture, Sakai, Osaka 593

(Received October 28, 1975)

Synopsis. γ-Rays treatment of earthy odors in public water supplies due to the metabolites in Lake Biwa was studied. The odorous compound was isolated from the metabolites and was identified to be geosmin by the use of gas chromatograph-mass spectrometer. The effect of additives and competition reaction with *p*-nitroso-*N*,*N*-dimethylaniline revealed that geosmin is decomposed effectively by hydroxyl radical produced by the radiolysis of water.

Recently, mustry and earthy odors in public water supplies have become a serious social problem.[1,2] Although attempts have been carried out to remove the odors, no satisfactory method has been developed. Activated carbon can remove some of the odors, but it is expensive and the adoption of this method is restricted to water plants of large municipalities. Chlorine has proved to be useful for removing the odors, but it intensifies some odors, particularly the musty-earthy odor of bluegreens. In comparison with these methods, treatment by ionizing radiation is more promising since the radiolysis product of water is known to effectively decompose trace constituents present in dilute solution[3-8] and chemical application of radiation sources is expected to become advantageous with the increase in the use of atomic energy, through it is expensive at present.

Experimental

Separation and Identification of Odorous Metabolites of Actinomyces Biwako-C Strain. Biwako-C strain was obtained from the Murano purification plant. It was inoculated on Romano agar medium.[9] The medium was incubated with a spore suspension prepared from a slant agar medium of the organism, and the culture flasks were incubated at 28 °C for 8 days with shaking. The shaken cultures (10 liters) thus obtained were distilled and the distillate was extracted with methylene chloride. After being dried, the methylene chloride solution was carefully evaporated, giving a small amount of earthy-smelling oil.

Gas chromatography (GC) was carried out on a 20% SE-30 column (glass tube 2 m×3 mm i.d., on 60—80 mesh chromosorb W) with a Shimadzu gas chromatograph (Model GC-5A). Temperature was raised from 100 to 220 °C at 5 °C/min. Nitrogen (40 ml/min) was used as a carrier gas. Gas-mass spectrum (GC-MS) was measured with a Shimadzu gas chromatograph-mass spectrometer (Model LKB 9000). A column of 3% SE-30 (glass tube 2 m×3 mm i.d., on 60—80 mesh chromosorb W) was used for the measurement. Temperatures of the column and ion source were 150 and 230 °C, respectively.

Irradiation Procedures and Analysis. All chemical reagents were of analytical grade. Aqueous solutions were bubbled with Argon for 40 min. prior to irradiation. Oxygen and nitrous oxide were added to the solution by bubbling for 40 min. Irradiation was carried out with ^{60}Co γ-rays (10000 Ci) at room temperature. The extracts were concentrated in a water bath (30 °C) and then analyzed on a gas chromatograph. After γ-irradiation the odor compound was extracted with methylene chloride from the aqueous solution and was analyzed quantitatively with a gas chromatograph with use of bibenzyl as an internal standard. Threshold odor tests (TO test)[10] following the standard method were carried out in order to confirm the removal of the odors and to compare this treatment with other methods.

Results and Discussion

Identification of the Odor Substances. Biwako-C strain produces a strong earthy odor on liquid cultures with Romano agar medium. The odor metabolite was isolated from the culture as follows. It was distilled at 100°C and the distillate was extracted with dichloromethane. The solution was then evaporated carefully under a slightly reduced pressure. After the evaporation of dichloromethane, a scarcely volatile and oily substance with a strong earthy odor was obtained. In order to identify the isolated odor substance, we measured its gas chromatograph spectra with use of the temperature raising attachment. The spectrum has several peaks except those due to solvent, the peak at the retention time of 17 min. being the main one. The retention time is the same as that of geosmin(I).[11] The spectrum

(I)

of geosmin is measured under the same conditions as for the odor substance. The result suggests that the odor substance is ascribed to geosmin. For the sake of confirmation the mass spectrum of the compound was measured with a gas chromatograph-mass spectrometer and compared with that of geosmin. The parent peak is *m/e* 182 and the highest one *m/e* 112. The mass pattern is similar to that of geosmin. These results unambiguously indicate that the odor substance produced by Biwako-C strain, which is found in the raw water of public water supplies, can be identified as geosmin. Geosmin is thus the origin of the objectionable odor of the public water supplies.

The Effect of γ-Irradiation. In order to examine the effect of γ-irradiation for the removal of the odors we adopted a model system-water solutions containing a given concentration of synthesized geosmin. Table 1 gives the values of threshold odor (TO) treated by γ-irradiation of the odorous water with various doses as well as those treated with activated carbon. It is seen that the initial concentration of odor substances, 100, 200, and 400, decreases. The values were determined by the Standard Method for Water Quality. γ-irradiation to a total dose as low as 8.5×10^2 rads is enough to reduce the TO value of the water to the value obtained by carbon treatment (concentration of 50 ppm) for 30

Table 1. Threshold odor reduction of artificially produced odorous water upon exposure to γ-irradiation

Sample	Threshold Odor[a]					
	Original	Activated Carbon		γ-Irradiation (total dose)[b]		
		10 ppm	50 ppm	8.5×10^2 rads	2.5×10^3 rads	8.3×10^3 rads
A	100[c]	40	10	18	10	5
B	200	61	14	20	10	5
C	400	91	30	22	10	5

a) Threshold odor was determined by the Standard Method for Water Quality. b) Dose rates are 5.1×10^3 rad/h, 1.5×10^4 rad/h, 5.0×10^4 rad/h. c) Concentration of geosmin is 1 ppb.

min. The result suggests that γ-irradiation is effective for the reduction of the odor.

Mechanism of the Reduction of the Odor. Although the real system of water supply is not so simple as the model system we adopted, a study of the decomposition process of the synthesized geosmin in distilled water is indispensable to reveal the fundamental mechanism of the reduction of the odor. Figure 1 shows the destruction of geosmin in water by γ-irradiation with various doses. The concentration of geosmin was determined by gas chromatography with the use of bibenzyl as an internal standard. 1 mg geosmin in 1 liter water undergoes almost completely decomposition giving a value less than the least detectable one by γ-irradiation to a total dose of 5.0×10^4 rads with a dose rate of 3.0×10^4 rad/h. The dependence of the rate of destruction on the dose rate is shown in Fig. 2. The slope is 0.62. The value suggests that destruction is caused by the intermediates, which disappear by second order reaction, probably by radicals. In order to confirm this radical mechanism, the effect of additives is examined. Addition of ethanol (0.02 M), a good hydroxyl radical scavenger, decreases the G-value, though the addition of N_2O, which is a hydrated electron scavenger, increases it. The results indicate that the destruction of geosmin is caused by radicals, especially by hydroxyl radical produced by the radiolysis of water.

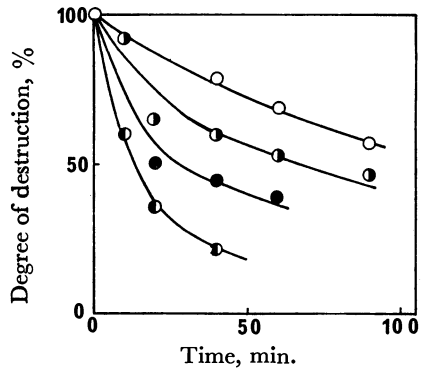

Fig. 1. Destruction of a 1 mg/l geosmin solution. Dose rates are
(○) 2.6×10^3 rad/h, (◑) 5.0×10^3 rad/h, (●) 1.1×10^4 rad/h, (◐) 3.0×10^4 rad/h.

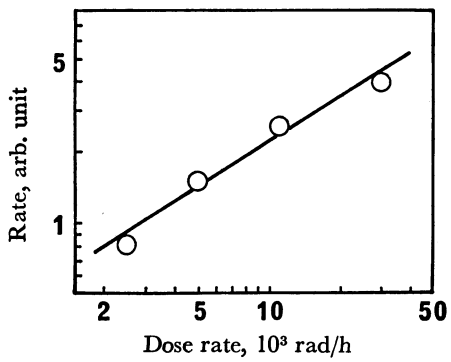

Fig. 2. Dependence of the rate of destruction on the dose rate.

The rate constant of the reaction of OH radicals with geosmin, which is considered to be the primary step for removal of the odors, is determined by competition kinetics using *p*-nitroso-*N*,*N*-dimethylaniline[12] as follows.

$$\mathrm{OH} + \mathrm{PNDA} \xrightarrow{k_1} \text{Product}$$

$$\mathrm{OH} + \text{geosmin} \xrightarrow{k_2} \text{Product}$$

where PNDA is *p*-nitroso-*N*,*N*-dimethylaniline. The decrease of PNDA determined by absorption spectra at 440 nm is expressed by

$$\frac{1}{G(-\mathrm{PNDA})} = \frac{1}{G(\mathrm{OH})}\left\{1+\frac{k_2(\text{geosmin})}{k_1(\mathrm{PNDA})}\right\}$$

The relation between $1/G(-\mathrm{PNDA})$ and (geosmin)/(PNDA) is linear. From the slope the k_2 value of 6.5×10^9 $M^{-1}s^{-1}$ is obtained with use of the k_1 value of 1.1×10^{11} $M^{-1}s^{-1}$.[13] The k value is slightly higher than that of ethanol and phenol. The high k value also confirms the fact that the odor is easily decomposed by γ-irradiation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (9), 2639—2640 (1976)

Preparation of 2,3,4,6-Tetra-*O*-benzyl-D-mannose

Shinkiti KOTO, Naohiko MORISHIMA, Yoko MIYATA, and Shonosuke ZEN

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received February 27, 1976)

Synopsis. 2,3,4,6-Tetra-*O*-benzyl-D-mannopyranose was prepared from methyl α-D-mannopyranoside. Improved preparations of 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose and -galactopyranose are described.

Since Schmidt, *et al.*[1] announced the preparation of a useful synthetic intermediate, 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose, many compounds of this type have been synthesized on various occasions.[2-4] In relation to our search for a systematic synthesis of oligosaccharide,[5,6] this note describes a preparation of 2,3,4,6-tetra-*O*-benzyl-D-mannopyranose (II) from methyl α-D-mannopyranoside. The syrupy compound II is, to the authors' knowledge, a new derivative of D-mannose and was characterized as a crystalline *p*-nitrobenzoate (α-anomer, III).

The following points are worthy of notice. The entire process of preparing the tetra-*O*-benzyl derivative of common hexoses from their corresponding methyl glycosides was significantly improved, in comparison with previous procedures.[1,3,4,7,8]

The use of a large excess of benzyl chloride, the ratio to methyl glycoside being as large as 25: 1 (v/w), in the presence of sodium hydride prevents the reaction from a sudden, violent initiation.[9] Examination of the reaction mixture indicated that the benzylation was essentially finished when the mixture recovered its fluidity with the change of color. The benzylation with use of powdered potassium hydroxide with[2] or without[1] a diluent such as *p*-dioxane was not so practical, because even after much longer heating with occasional additions of fresh potassium hydroxide the reaction was not always complete. It should also be noted that even short unnecessary heating in the hydrolysis step brought about a considerable loss of the desired products.[10]

Experimental

General. Melting points were determined by a Yanagimoto Micro Melting Point apparatus. Optical rotations were measured by a DIP-180 (Japan Spectroscopic) in a jacketed 1-dm cell. PMR was recorded by a Varian S-60-T Spectrometer. TLC was carried out over silica gel No. 7731 (Merck) with coloration by charring with sprayed aqueous sulfuric acid (10%). The column chromatography was done over silica gel (Kanto Kagaku) with irrigation of a mixed solvent system of benzene and 2-butanone.

Methyl α-D-mannopyranoside (Sigma), methyl α-D-glucopyranoside (Tokyo Kasei), and methyl β-D-galactopyranoside (Sigma) were well powdered and stored over phosphorus pentoxide. Sodium hydride (*ca.* 50% in oil, Wako) and benzyl chloride (Koso) were used without any purification.

2,3,4,6-Tetra-O-benzyl-D-mannopyranose (II). A mixture of methyl α-D-mannopyranoside (5 g), sodium hydride (8.5 g, with the oil), and benzyl chloride (125 ml) in a 500-ml round bottomed flask was heated at 125—130 °C (bath temperature) with vigorous stirring (preferably by a magnetic mixer) for 70—90 min under anhydrous conditions. During the course of the reaction, as mentioned earlier,[7] a gray reaction mixture first stiffened with evolution of hydrogen gas and much heat,[11] and then it turned into a yellow thin slurry. After removal of the insoluble material, the solution was concentrated by a water-pump over a boiling water bath to give a yellow syrup (21—25 g), which contained the dispersion oil.

A portion of this syrup (1.0 g) was purified over a column of silica gel to give pure methyl 2,3,4,6-tetra-*O*-benzyl-α-D-mannopyranoside (I), 0.55 g (95%), $bp_{0.01}$ 240—245 °C, $[\alpha]_D^{20}$ +27° (*c* 1, $CHCl_3$), $\delta_H^{CDCl_3}$ (ppm, TMS): 3.31 (3H, singlet, O–C$\underline{H}_3$), 7.30 (15H, singlet, C$_6\underline{H}_5$–), 7.20 (5H, singlet, C$_6\underline{H}_5$–).

Found: C, 75.89; H, 6.92%. Calcd for $C_{35}H_{38}O_6$: C, 75.79; H, 6.91%.

Hydrogenolysis of I (25 mg) over palladium black in methanol at room temperature under 50 psi for 8 h gave crystals (3.7 mg), mp 186—188 °C, which did not depress the melting point of the authentic specimen and showed an IR spectrum (KBr) identical with that of the authentic sample of methyl α-D-mannopyranoside.

The entire syrup mentioned above was immediately heated with a mixture of acetic acid (250 ml) and aqueous sulfuric acid (3M, 30 ml) at 80—85 °C (inside temperature) with good stirring for 30 min. The mixture was diluted with cold water (300 ml) and benzene (300 ml). After washing the organic layer by aqueous sodium hydrogencarbonate and then by water, it was concentrated to give a syrup, which was chromatographed to afford a homogeneous syrup of II, 8.5—10 g (60—72%). Washing this material with cold hexane gave an analytical sample, $[\alpha]_D^{20}$ +11° (*c* 0.9, $CHCl_3$).

Found: C, 75.12; H, 6.67%. Calcd for $C_{34}H_{36}O_6$: C, 75.53; H, 6.71%.

Refluxing II (33 mg) in methanol (0.8 ml) containing methanesulfonic acid (3 μl) for 26 h, followed by chromatography, afforded a homogeneous syrup (21 mg, 61%), which showed an identical PMR spectrum in $CDCl_3$ with that of the above-mentioned I.

2,3,4,6-Tetra-O-benzyl-1-O-p-nitrobenzoyl-α-D-mannopyranose (III). II (0.2 g) was treated with *p*-nitrobenzoyl chloride (0.1 g) in pyridine (1 ml) overnight. The mixture was processed as usual and was chromatographed to give a homogeneous syrup of III as a faster-moving product which was crystallized by diisopropyl ether. Recrystallization from this solvent furnished an analytical sample, 0.12 g (50%), mp 106.5—107 °C, $[\alpha]_D^{20}$ +59° (*c* 0.8, $CHCl_3$), ν_{max}^{KBr} (cm^{-1}): 1730 (carbonyl), 1535, 1355 (nitro), $\delta_H^{CDCl_3}$ (ppm, TMS): 6.46 (1H, a doublet, J=2 Hz), H-1 (equatorial); 7.2—7.4 (20H), C$_6\underline{H}_5$–; a multiplet centered at 8.13 (4H), –C$_6\underline{H}_4$–.

Found: C, 71.58; H, 5.85; N, 1.87%. Calcd for $C_{41}H_{39}NO_9$: C, 71.39; H, 5.70; N, 2.03%.

The β-anomer of III was obtained as a slower-moving syrupy product, which was further washed with cold hexane, $[\alpha]_D^{20}$ −11° (*c* 0.5, $CHCl_3$), $\delta_H^{CDCl_3}$ (ppm TMS): 5.57 (1H, a doublet, J=2 Hz), H-1 (axial); 7.2—7.4 (20 H), C$_6\underline{H}_5$–; a quasi-singlet at 8.15, –C$_6\underline{H}_4$–.

Found: C, 71.07; H, 5.81; N, 1.97%. Calcd for $C_{41}H_{39}NO_9$: C, 71.39; H, 5.70; N, 2.03%.

2,3,4,6-Tetra-O-benzyl-α-D-glucopyranose. The hydrol-

ysis step was carried out at 80—85 °C for 30 min by employing a mixture of acetic acid (250 ml) and aqueous hydrochloric acid (6M, 35 ml) for a syrupy benzylation product (*ca.* 25 g) obtained from 5 g of methyl α-D-glucopyranoside. The hydrolyzate was diluted with cold water (300 ml) and hexane (50 ml) with stirring. Crude crystals (7.5—8 g) were recrystallized from hot ethyl acetate (100 ml) to give a pure material, 4.5—5 g (32—36%), mp 149—149.5 °C, $[\alpha]_D^{20}$ +48° (*c* 1, dioxane). [Lit,[1] mp 148 °C, $[\alpha]_D^{25}$ +48.3° (*c* 3, dioxane)]. (Found: C, 75.59; H, 6.78%).

2,3,4,6-Tetra-O-*benzyl*-α-D-*galactopyranose.* The crude oily benzylation product (*ca.* 25 g) obtained from 5 g of methyl β-D-galactopyranoside gave methyl 2,3,4,6-tetra-*O*-benzyl-β-D-galactopyranoside as crystals, 11.4 g (80%), mp 82—83 °C. [Lit,[4] 80—81 °C].

This galactoside (10 g) was hydrolyzed by heating at 80—85 °C for 20 min with a mixture of acetic acid (100 ml) and aqueous sulfuric acid (3M, 12 ml). The mixture was processed in the same manner as II and chromatographed to give a syrup. This was crystallized from cyclohexane containing little diisopropyl ether to give a practically pure product, 5.4 g (54%), mp 63—66 °C, $[\alpha]_D^{20}$ +74° (*c* 0.8, benzene). [Lit,[5] mp 66—68 °C, $[\alpha]_D^{20}$ +77° (*c* 2.3, benzene)]. (Found: C, 75.02; H, 6.62%).

9) Diminution of the ratio even to 20: 1 often allowed the reaction to run out of control.

10) For example, the yield of tetra-*O*-benzylglucose was less than 7% after heating at 80—85 °C for 50 min.

11) This violent reaction usually continued for about 10 min.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (9), 2641—2642 (1976)

A New Type of Induced Decomposition. IV.[1] Pyrolysis of *t*-Butyl Peroxy-3-butenoate in the Gas Phase

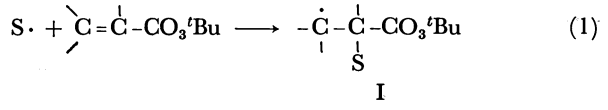
Tameichi OCHIAI, Masayuki YOSHIDA, and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113

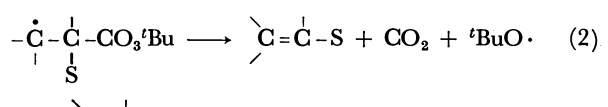
(Received March 8, 1976)

Synopsis. *t*-Butyl peroxy-3-butenoate decomposes in the gas phase at 115 °C to give carbon dioxide, 1-butene, acetone, 1,5-hexadiene, methane, and ethane. Experiments with iodine, an efficient radical scavenger, indicate the operation of induced decomposition. The mechanism of the formation of 1-butene and 1,5-hexadiene is discussed in terms of a new type of induced decomposition.

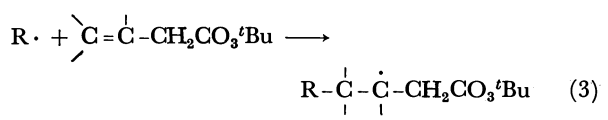
In previous communications[1] we reported that *t*-butyl peroxy-esters derived from α,β-unsaturated carboxylic acids undergo a new type of induced decomposition and proposed a mechanism, in which radicals (S·) derived from solvent (SH) by hydrogen-abstraction add to the unsaturated bond of a peroxide to give an intermediate radical (I) carrying an odd electron on the carbon atom β to the carboxyl group and this radical subsequently undergoes β-scission to afford an olefin, a molecule of carbon dioxide, and a *t*-butoxyl radical (Reactions 1 and 2 in the following scheme).



(1)



(2)



(3)

SH=solvent

Radicals similar to structure I can also be generated by addition of a radical to the γ-position of β,γ-unsaturated peroxy-esters (Reaction 3), which therefore may undergo β-scission in a way similar to Reaction 2. With the view of examining such a possibility the decomposition of *t*-butyl peroxy-3-butenoate was studied.

Results and Discussion

The results of the decomposition of *t*-butyl peroxy-3-butenoate (II) in the gas phase at 115 °C are summarized in Table 1. The major products identified by VPC were carbon dioxide, 1-butene, 1,5-hexadiene, acetone, methane, and ethane, and are readily explained by assuming the following series of reactions.[2] Acetone and ethane result from Reactions 5 and 6. Methane arises from methyl radicals by hydrogen-abstraction from some hydrogen donating species in the system (Reaction 7).

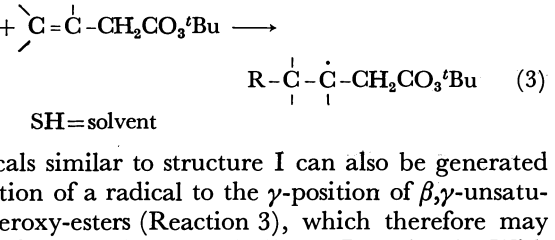
TABLE 1. PRODUCTS FROM PYROLYSIS OF *t*-BUTYL PEROXY-3-BUTENOATE AT 115 °C FOR 3 h

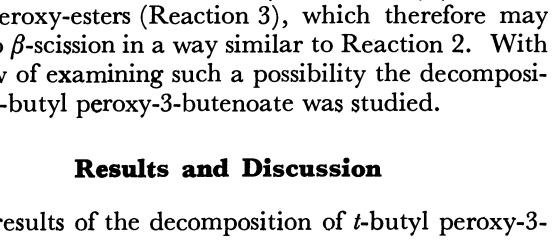
	Run 1	Run 2
Peroxybutenoate, mmol	0.585	0.519
Products, mmol		
Carbon dioxide	0.599 (1.02) [a]	0.512 (0.986)
1-Butene	0.160 (0.274)	0.138 (0.266)
Acetone	0.444 (0.759)	0.389 (0.749)
1,5-Hexadiene	0.136 (0.232)	0.120 (0.231)
Methane	0.054 (0.093)	0.053 (0.101)
Ethane	0.083 (0.144)	0.067 (0.129)

a) Yields in mol per 1 mol of the peroxybutenoate are given in parentheses.

The formation of 1-butene and 1,5-hexadiene is satisfactorily explained, as is anticipated in the introduction, thus:



(8)



(9)

The addition of a methyl radical to the peroxy-3-butenoate gives 1-(*t*-butylperoxycarbonylmethyl)propyl radical, which then decomposes into 1-butene, a molecule of carbon dioxide, and a *t*-butoxyl radical (Reaction 8). 1,5-Hexadiene is given through a similar addition-elimination mechanism (Reaction 9).

An alternative mechanism for the formation of 1-butene and 1,5-hexadiene is the combination of the allyl and methyl radical (Reactions 10 and 11):

(10)

(11)

The exclusive operation of this mechanism, which does not involve any induced path, is ruled out by the experiments summarized in Table 2. The peroxy-3-butenoate was heated in the presence of iodine, an effective radical scavenger, or nitrogen, inert molecules towards radicals, at 115 °C for 1.0 h, and the amount of carbon dioxide evolved was measured. Since the peroxy-3-butenoate affords carbon dioxide quantitatively (Table 1), the amount of carbon dioxide obtained corresponds to that

Table 2. Decomposition of *t*-butyl peroxy-3-butenoate in the presence of iodine or of nitrogen[a)]

Run	Peroxy-butenoate mmol	I_2 mmol	N_2 mmol	CO_2 mmol produced
1	0.281	nil	0.897	0.244 (0.868) [b)]
2	0.286	nil	0.854	0.246 (0.860)

4	0.289	0.168	nil	0.179 (0.620)
5	0.277	0.601	nil	0.034 (0.12)
6	0.294	0.564	nil	0.073 (0.25)
7	0.287	0.618	nil	0.056 (0.20)

a) At 115 °C, for 1.0 h, in the gas phase. b) Yields in mol per 1 mol of peroxide are given in parentheses.

of the peroxy-3-butenoate decomposed. Under the above conditions 87% of the starting peroxy-3-butenoate underwent the decomposition in the presence of 0.9 mmol of nitrogen, while only 62% of the peroxy-3-butenoate was decomposed in the presence of 0.17 mmol of iodine, and the extent decomposition further decreased with increasing iodine concentration. These findings indicate that iodine scavenges efficiently the free radicals which otherwise will cause induced decomposition of the peroxy-3-butenoate and thus support the operation of an induced pathway for the formation of 1-butene and 1,5-hexadiene.

Experimental

t-Butyl Peroxy-3-butenoate. 3-Butenoic acid[3)] (4.7 g), bp 69.0—70.0 °C/12 mmHg, was heated under reflux for 30 min with 1.2 molar equivalents of thionyl chloride, and the resulting 3-butenoyl chloride (3 g) was distilled, bp 95—96 °C. A solution of this chloride (1.68 g) in 8 ml of anhydrous pentane was added to a stirred solution of *t*-butyl hydroperoxide (bp 32 °C/12 mmHg, 1.91 g) and pyridine (1.36 g) in anhydrous pentane (7 ml) at −20——25 °C over a period of 1.3 h. The resulting mixture was allowed to warm to 0 °C, the supernatant solution decanted into a vessel containing ice–water, the remaining pyridinium chloride washed twice with pentane, and the washings added to the ice–water. The organic layer was separated, washed successively with 4 ml of 5% sulfuric acid, 4 ml of 10% aqueous sodium carbonate, and water. and dried with anhydrous sodium sulphate. After removal of pentane under reduced pressure, the oily residue was distilled to give 1.5 g (59%) of *t*-butyl peroxy-3-butenoate, bp 16 °C/2 mmHg (Found: C, 60.60; H, 9.04%. Calcd for $C_8H_{14}O_3$: C, 60.74; H, 8.92%. Purity, 96% by iodometric titration[4)]), IR (neat) 1645 ($\nu_{C=C}$) and 1785 cm^{-1} ($\nu_{C=O}$).

Pyrolysis of t-*Butyl Peroxy-3-butenoate.* A typical run was as follows. *t*-Butyl peroxy-3-butenoate (0.58 mmol) was placed in a glass vessel (730 ml), which was then degassed (three freeze-thaw cycles), sealed and immersed in an oil bath maintained at 115 °C, and the peroxy-ester was allowed to decompose in the gas phase for 3 h. After cooling to room temperature, the vessel was attached to a vacuum system, and the products were transferred to a sampling tube for VPC analysis.

Analyses were carried out with a Perkin Elmer Vapor Fractometer Model 154-D by using helium as carrier gas and the following stainless steel column: 1) A 2m column packed with Silica gel, Type 15 at 51 °C for analysis for methane, ethane, and carbon dioxide; 2) a 2m column packed with dimethylsulfolane at 60 °C for analysis for 1-butene, 1,5-hexadiene and acetone. For authentic materials for comparison commercial products were used except 1,5-hexadiene, which was prepared according to a published procedure.[5)]

Reduction of α,β-Unsaturated Nitrile to Saturated Nitrile with Sodium Borohydride

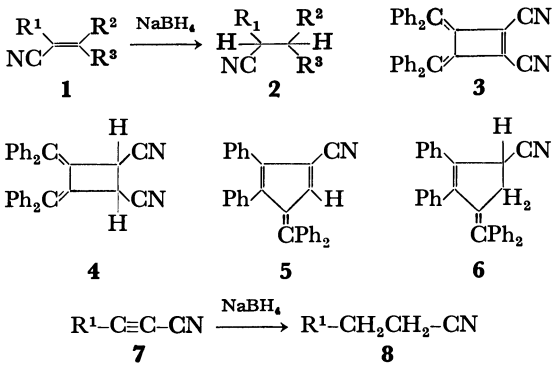
Fumio TODA and Mutsushi KANNO

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received April 1, 1976)

Synopsis. α,β-Unsaturated nitrile (**1**) was easily reduced to saturated nitrile (**2**) with sodium borohydride. Phenyl- (**7a**) and 2-phenanthryl-cyanoacetylene (**7b**) were also reduced with sodium borohydride to the saturated nitriles, **8a** and **8b**, respectively.

The reduction of α,β-unsaturated nitrile (**1**) to saturated nitrile (**2**) can be achieved in poor yield by photochemical,[1] electrochemical,[2] and catalytic hydrogenation.[3] Profitt *et al.*[4] reported that magnesium in methanol is a good reagent for the reduction of **1** to **2**. On the other hand, we have found that sodium borohydride ($NaBH_4$) is effective for the reduction and that $NaBH_4$ is useful for the reduction of conjugated cyanoalkyne (**7**) to cyanoalkane (**8**).



Scheme 1.

Treatment of conjugated cyanoalkanes (**1a—h**) with $NaBH_4$ afforded the reduction products (**2a—c** and **2f**) in the yields summarized in Table 1. In the cases of **1e**, **1g**, and **1h**, however, the reduction of their double bonds was accompanied by the substitution with hydrogen of the nitro and methoxyl groups which had been bound to olefinic carbon. The substitution of nitro group with hydrogen is in contrast with the $NaBH_4$ reduction of nitroolefin to nitroalkane.[6] The cyclic cyanoalkenes, 1,2-dicyano-3,4-bis(diphenylmethylene)-1-cyclobutene (**3**) and 2-cyano-3,4,6,6-tetraphenylfulvene (**5**), were also easily reduced with $NaBH_4$ to their dihydro derivatives, **4** (85) and **6** (90%), respectively. On the contrary, the catalytic reduction of **3** on Raney-Ni afforded **4** only in 20% yield.

Since the $NaBH_4$ reduction product of **3** (**4**) was identical with the catalytic reduction product of **3**, **4** would have a *cis*-form, and the former reduction seems to proceed stereospecifically. Nevertheless, since the *rac*-form[7] of **2b** isomerized into the *meso*-form (**2b**) under the reduction conditions, it is not clear whether the steric course of the $NaBH_4$ reduction is stereospecific or not.

Table 1. Yields, melting points and NMR spectral data of the $NaBH_4$ reduction products (**2**, **4**, **6**, and **8**)

	Reactant R¹	R²	R³	Product	Yield (%)	Mp (°C)	τ_{CH} (ppm)

a) The yield was calculated on the basis of the crude oil.

The $NaBH_4$ reduction was also useful for conjugated cyanoalkyne. The treatment of phenyl- (**7a**) and 2-phenanthrylcyanoacetylene (**7b**) with $NaBH_4$ afforded the tetrahydro derivatives, **8a** and **8b**, respectively (Table 1).

Experimental

All the melting points are uncorrected. The NMR spectra were measured in $CDCl_3$.

General Procedure of the $NaBH_4$ Reduction. To a stirred solution of conjugated cyanoalkene or cyanoalkyne (0.2 g) in 99% EtOH (20 ml) was added $NaBH_4$ by portions until gas evolution ceased (*ca.* 0.1 g) at room temperature. All the reactions were slightly exothermic and ceased within 1 h. The crude crystals formed by the decomposition of the reaction mixture with water were filtered and then recrystallized. When oily material was formed at the decomposition, it was taken up in ether. The ethereal solution was washed with water and dried over anhydrous Na_2SO_4. The crude crystals remaining after the evaporation of the solvent were recrystallized. O fthe reduction products, **2a**—**c** and **8a** were characterized by the comparison of their infrared spectra and/or melting points with those of authentic samples. All the new reduction products (**2f**, **4**, **6**, and **8b**) were characterized on the basis of their NMR spectra (Table 1) and elemental analyses. The analytical data are as follows:

2f) Found: C, 71.28; H, 3.97%. Calcd for $C_{15}H_{12}O_2N_2$: C, 71.41; H, 4.80%.

Synopsis. The photolysis of methylenecyclobutenone in the presence of benzophenone or oxygen affords the one carbon diminished product, methyl 4,4-diphenyl-2-diphenylmethyl-2,3-butadienoate. The reaction pathway is discussed.

Nozaki and his collaborators reported that the photochemical conversion of diphenylketene into benzophenone under nitrogen atmosphere in a higher yield than 50% is puzzling.[1] We found that the photolysis of methylenecyclobutenone (**1**) in the presence of benzophenone or oxygen affords the one carbon diminished product, methyl 4,4-diphenyl-2-diphenylmethyl-2,3-butadienoate (**5**), and that the reaction can well be rationalized by means of the cycloaddition reaction of the methoxyketene intermediate (**2**) initially produced by the α-cleavage of **1**, with benzophenone or oxygen.

The irradiation of a solution of **1** and benzophenone in benzene under nitrogen atmosphere for 5 h afforded **5** in 31% yield. The structure of **5** was elucidated on the basis of its reaction with bromine which affords 3-bromo-4,4-diphenyl-2-diphenylmethyl-2-buten-4-olide (**6**). Base-catalyzed hydrolysis of **5** afforded the corresponding acid (**7**). The formation of **5** can be interpreted by assuming the cycloaddition product (**3**) of **2** and benzophenone as an intermediate. The intermediacy of **2** is undoubted, since the photochemical α-cleavage of methylenecyclobutenone to alleneketene has been established.[2] The ring cleavage of **3** can give **5** and diphenylketene, the latter being converted into benzophenone in the same manner as reported.[1]

The photolysis of **1** in benzene under oxygen atmosphere also afforded **5** in 10% yield. This can be interpreted by assuming **4** as an intermediate, decarboxylation of which affords **5**. Since neither benzophenone nor oxygen is necessary for the photochemical α-cleavage of methylenecyclobutenone,[2] benzophenone and oxygen would only be used for the formation of **3** and **4**, respectively. In their absence, the photolysis of **1** in benzene did not give **5**, **1** being recovered unchanged. This shows that the photochemical α-cleavage of **1** to **2** is reversible.

Experimental

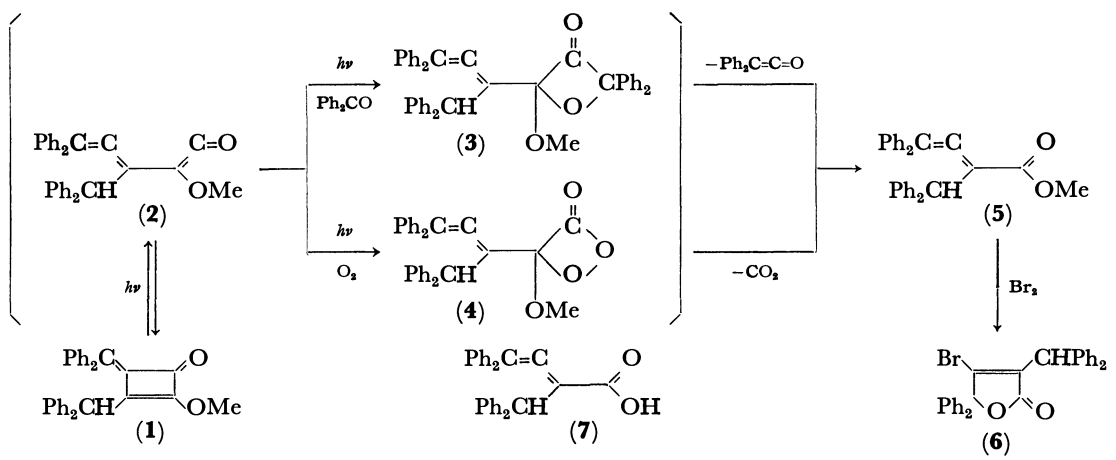
All the melting points are uncorrected. Photolysis was carried out at room temperature, with light from a 400-W high-pressure mercury lamp (Riko Kagaku Sangyo Co.), filtered through Pyrex glass. The IR, UV, and NMR spectra were measured in Nujol mull, $CHCl_3$, and $CDCl_3$, respectively. The mass spetrum was measured with an ionization energy of 75 eV.

*Photolysis of **1** in the Presence of Benzophenone.* A solution of **1** (0.1 g) and benzophenone (0.07 g) in benzene (250 ml) was irradiated under nitrogen atmosphere for 8 h. The crude crystals remaining after evaporation of the solvent were recrystallized from MeOH to afford **5** as colorless prisms; 0.03 g (31%); mp 135—136 °C. IR: 1940 (C=C=C), 1720 (C=O), and 1240 cm^{-1} (ester); λ_{max}: 252 nm (ε, 18800); NMR: 2.5—3.4 (m, Ph, 20H), 4.57 (s, CH, 1H), and 6.34τ (s, Me, 3H); MS *m/e* (rel intensity): 416 (M^+, 25), 385 (M^+—OMe, 56), 357 (385—CO, 66), and 167 ($Ph_2\overset{+}{C}H$, 100).

Found: C, 86.37; H, 5.73%. Calcd for $C_{30}H_{24}O_2$: C, 86.51; H, 5.81%.

*Photolysis of **1** under Oxygen Atmosphere.* A solution of **1** (0.1 g) in benzene (250 ml) was irradiated under oxygen atmosphere for 15 h. The crude crystals remaining after evaporation of the solvent were recrystallized from MeOH to afford **5**; 0.01 g (10%).

*Conversion of **5** into **6**.* Bromine (0.03 g) was added at room temperature to a solution of **5** (0.1 g) in $CHCl_3$ (10 ml). The crude crystals remaining after evaporation of the solvent were recrystallized from AcOEt to afford **6** as colorless prisms; 0.1 g (86%); mp 150 °C. IR: 1760 (C=O), 1630 (C=C), and



1140 cm^{-1} (lactone); λ_{max}: 245 nm (ε, 9600); NMR: 2.4—2.8 (m, Ph, 20H) and 4.38τ (s, CH, 1H).

Found: C, 72.42; H, 4.41%. Calcd for $C_{29}H_{21}O_2Br$: C, 72.35; H, 4.40%.

Hydrolysis of ***5***. A solution of **5** (0.1 g) in 5% KOH–MeOH (20 ml) was heated under reflux for 5 h. The crude crystals formed after the decomposition of the reaction mixture with water were recrystallized from hexane–CH_2Cl_2 to afford **7** as colorless needles; 0.09 g (93%); mp 185—186 °C. IR: 2620 (CO_2H), 1940 (C=C=C), and 1670 cm^{-1} (C=O); λ_{max}: 243 (19200) and 253 nm (ε, 19200); NMR: −1.33 (s, CO_2H, 1H), 2.6—3.1 (m, Ph, 20H), and 4.61 τ (s, CH, 1H).

Found: C, 86.49; H, 5.42%. Calcd for $C_{29}H_{22}O_2$: C, 86.54; H, 5.51%.

Photochemical Reduction of 2,3-Dihydro-2,3-methano-1,4-naphthoquinones with Xanthene

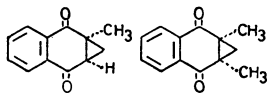
Kazuhiro MARUYAMA and Soji TANIOKA

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received April 14, 1976)

Synopsis. Photochemical reduction of 2,3-dihydro-2-methyl-2,3-methano-1,4-naphthoquinone (**1a**) and 2,3-dihydro-2,3-dimethyl-2,3-methano-1,4-naphthoquinone (**1b**) with xanthene was investigated. 6,7,8,9-Tetrahydrobenzocycloheptene-5,9-dione derivatives and stereochemical isomers of the so-called "1,2-adducts" of xanthene to carbonyl groups were isolated as the reaction products. CIDNP technique was applied for the examination of the course of the reactions.

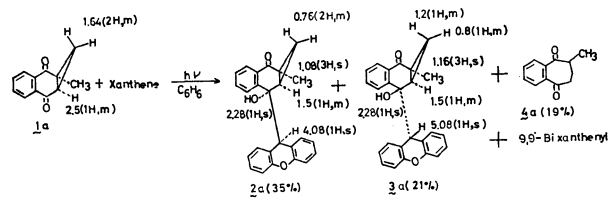
The titled compounds have two vicinal carbonyl groups connected with cyclopropane ring in the molecule, and their photochemical behavior is quite interesting compared with those of 1,4-naphthoquinone and of 1,4-naphthoquinone 2,3-epoxide. Their relative photochemical reactivities for hydrogen abstraction from xanthene are in the following order: 2-methyl-1,4-naphthoquinone > 2,3-dihydro-2-methyl-2,3-methano-1,4-naphthoquinone > 1,4-naphthoquinone 2,3-epoxide.[1] In this work photochemical reaction of **1a** and **1b** with xanthene was investigated in detail.



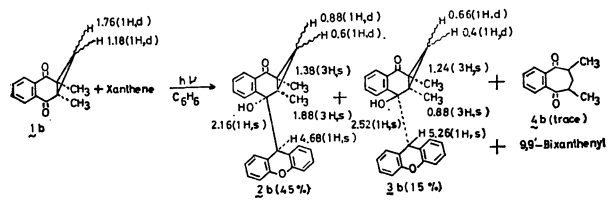
(**1a**) (**1b**)

Experimental

Irradiation of a benzene solution of **1a-b** and xanthene (1:2, M/M) for six hours at a room temperature gave four major products in the respective yields given in the following schemes. The yields of products are mean values of several runs. The products, **2a**; mp 145—146 °C, IR (KBr); $\nu_{C=O}$=1670, ν_{OH}=3400 cm^{-1}, and **3a**; mp 216—218 °C, IR (KBr); $\nu_{C=O}$=1655, ν_{OH}=3400 cm^{-1}, are both 1:1 adduct of **1a** and xanthene[2], and are in the relation of configurational isomers each other, which are confirmed by elemental analysis and spectroscopy along with the chromic acid oxidation of them to give rise to the same products; *i.e.*, **1a** and xanthone. Reduction product (mp 162—164 °C) of **2a** with sodium borohydride revealed that the attaching position of xanthene moiety was at C_4, because the hydrogen atom thus introduced (bonded to C_1) coupled with no other protons. Reduction of **3a** under identical condition afforded the corresponding secondary alcohol (mp 170—172 °C), which led to the same conclusion.



Scheme 1.



Scheme 2.

Assignment of the configuration of **2a** and **3a** rests on their PMR spectra. Outstanding differences of **2a** and **3a** in their PMR spectra are, at first, the chemical shifts of benzene ring protons; in **2a**, ring protons spread into the region of δ: 5.6—7.5 ppm, but in **3a** into δ: 6.8—8.0 ppm (for comparing, in **1a**, in the region of δ: 7.5—8.0 ppm), which is indicative that in **2a**, there are magnetically stronger interactions among three benzene rings than those in **3a**[3]. The other supports for the configutation of **2a** and **3a** are the followings. The methylene protons (*endo*- and *exo*-H) of **2a** give a coincided multiplet, centred at δ: 0.76 (2H) ppm, and the methine proton of xanthenyl moiety appears at δ: 4.08 (1H, s) ppm. On the contrary, in **3a** the methylene protons appear as two separated multiplets, δ: 1.2 (*endo*-H, 1H, m) and δ: 0.80 (*exo*-H, 1H, m) ppm and the methine proton of xanthenyl moiety gives a singlet at δ: 5.08 (1H, s) ppm. The *endo*- and *exo*-H were assigned by referring the works reported[4a,4b], *i.e.*, in **2a**, coupling constants of protons in cyclopropane moiety are J_{trans}: 5.5 Hz, J_{cis}: 7.5 Hz, J_{gem}: 5.5 Hz, and those in **3a** are J_{trans}: 6.3 Hz, J_{cis}: 8.4 Hz J_{gem}: 5.6 Hz.

Such a situation is essentially same for configurational isomers, **2b** and **3b**, but in these cases the methylene protons of **2b** and **3b** appear as two separated doublets (their *endo*- or *exo*-configurations are remained to be decided). Chemical shifts of representative protons are described in Scheme-1 and Scheme 2.

The structure of the third product, **4a** (mp 30 °C), was determined by comparison with the authentic sample prepared by Zn-CH_3COOH reduction of **1a**[5]. The other product in the

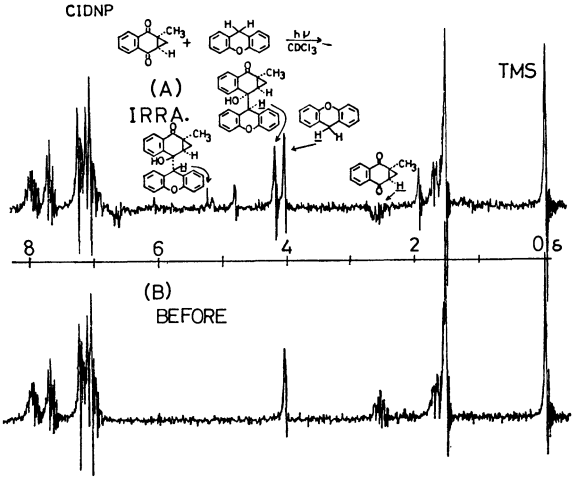


Fig. 1. Examination of the reaction of **1a** with xanthene by means of CIDNP technique.

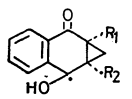
reaction of **1a** and xanthene was 9,9′-bixanthenyl, which was identified by comparison (mixed melting point, chromatographic, spectroscopic, and chemical behaviors) with authentic sample.

The structure of **4b** (mp 97—98 °C), produced in trace, was determined by comparison with the authentic sample, which was prepared by reduction of **1b**.

Examination of the reaction by means of CIDNP revealed some insight of the reaction course. Methine proton of xanthenyl moiety of 1,2-adducts showed absorption polarization (see Fig. 1). The phenomenon leads to the conclusion that 1,2-adduct of **1a** (or **1b**) and xanthene is mostly produced via direct recombination of the original triplet radical pair composed of **5** and xanthenyl radical[6].



5a : $R_1=CH_3$, $R_2=H$
5b : $R_1=CH_3$, $R_2=CH_3$

5

Emission polarization of methine proton of methano-naphthoquinone moiety is another remark indicating the re-production of **1a** from **5a**.

References

1) The relative reactivity was estimated by following the remained amount of xanthene in the reacting mixture after one hour reaction at a room temperature (carbonyl compound: xanthene=0.075/0.15, M/M).

2) Elemental analyses of **2a**, **3a**, **2b**, and **3b** and integrations of their PMR signals reveal that these products are composed of 1 : 1 ratio of **1a** or **1b** with xanthene.

3) From the inspection of the molecular models the assignments of the structures are straightforward.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (9), 2649—2650 (1976)

Syntheses of 4-(4-Hydroxy-2,6-dimethylphenyl)-1,2-butanediol and 4-(4-Hydroxy-2,6-dimethylphenyl)-2-butanol.

Kenji UNEYAMA, Hironori SAKUMOTO, and Sigeru TORII*

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama, 700

(Received May 4, 1976)

Synopsis. 4-(4-Hydroxy-2,6-dimethylphenyl)-1,2-butanediol (**3**) and 4-(4-hydroxy-2,6-dimethylphenyl)-2-butanol (**4**) as precursors for a theaspirone synthesis have been synthesized starting from 3,5-dimethylphenyl methyl ether.

One of the synthetic approach toward theaspirone[1] (**1**) has been focused on how to prepare efficiently the key intermediate, 3,5,5-trimethyl-4-(3-hydroxybutyl)-4-hydroxy-2-cyclohexenone which undergoes acid promoted cyclization leading to **1**. A promising approach would be an electrochemical cyclization of the phenol derivatives **3** and **4** leading to cyclohexadienones **2**, since 3-(4-hydroxyphenyl)propanoic acid,[2] hydroquinone bis(2-hydroxyethyl) ether,[3] and 2,4,6-tri-*t*-butylphenol[4] have been known to suffer anodic oxidation affording 1-oxa-spiro[4,5]deca-6,9-diene-2,8-dione, 8-(2-hydroxyethoxy)-8-methoxy-1,4-dioxaspiro[4,5]deca-6,9-diene, and 2,4,6-tri-*t*-butyl-4-methoxy-2,5-cyclohexadienone, respectively.

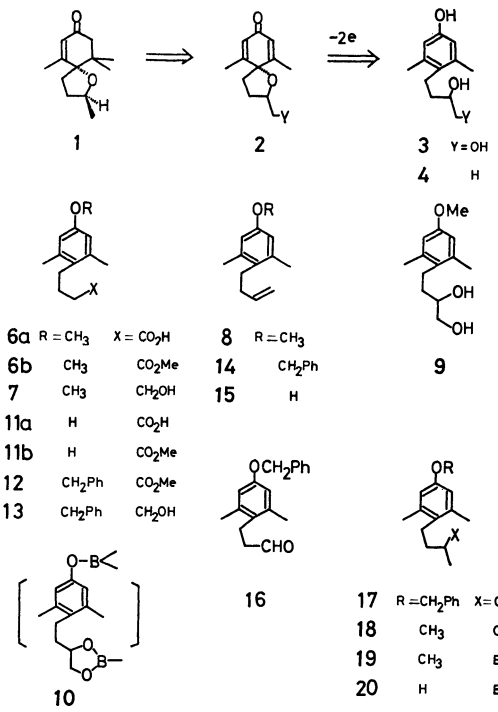
Thus, our attention has been paid to the syntheses of 4-(4-hydroxy-2,6-dimethylphenyl)-1,2-butanediol (**3**) and 4-(4-hydroxy-2,6-dimethylphenyl)-2-butanol (**4**) as starting compounds for the electrolytic cyclization.

The Clemmensen reduction of 3-(2,6-dimethyl-4-methoxybenzoyl)propanoic acid (**5**) and subsequent methylation with diazomethane afforded **6b** in 90% yield. The alcohol **7** obtained by the reduction of **6b** with lithium aluminum hydride was converted into the corresponding xanthate in quantitative yield. The thermal decomposition of the xanthate[5] took place instantaneously at the temperature range between 300—360 °C affording the olefin **8** in 73% yield. Oxidation of **8** with potassium permanganate at −45—−40 °C gave the diol **9** in 57% yield along with 19% of the starting material.

Treatment of **9** with boron tribromide[6] in anhydrous dichloromethane at −70 °C furnished the triol **3** in 69% yield without suffering bromination of aliphatic hydroxy groups on C_1 and C_2. The inertness of the vicinal hydroxyl groups toward the bromination reagent would be due to the formation of the stable chelated complex as illustrated in **10**.[7] In fact, the action of boron tribromide to the alcohol **18** induced the formation of the bromides **19** and **20** preferentially. In order to affect the efficient formation of the phenolic alcohol **4**, lithium metal reduction of the benzyl ether **17** in liquid ammonia was performed.

The cleavage of the methoxyl group of **6a** with boron tribromide followed by methylation with diazomethane provided the phenol ester **11b**. Benzylation of **11b** in DMF was accomplished in 84% yield. The subsequent reduction of **12** to **13** with lithium aluminum hydride and the transformation of **13** to the corresponding xanthate were performed similarly in 88% yield from **12**. The thermolysis of the xanthate took place at 350 °C affording the desired olefin **14** and the phenolic olefin **15** in 40% and 18%, respectively. The higher temperature on the thermolysis and the prolonged heating of the products facilitated the cleavage of the benzyl group.

Ozonolysis of **14** followed by reduction of the ozonide yielded the aldehyde **16** in 74%. Grignard reaction of **16** with methyl magnesium iodide afforded the alcohol **17** in 86%. Finally, reductive scission of the benzyl group of **17** with lithium in liquid ammonia provided the diol **4** in 76%.



Experimental

The NMR and IR spectra were determined with Hitachi R-24 and Hitachi WPI-S2, respectively.

3-(2,6-Dimethyl-4-methoxybenzoyl)propanoic Acid (5). Friedel-Crafts reaction of 1 g of 3,5-dimethylanisole and 0.82 g of succinic anhydride with 2.2 g of aluminum chloride in 6 ml of nitrobenzene and 0.5 ml of CS_2 at −10—−5 °C for 9 h gave 1.58 g (85%) of **5** as colorless crystals, mp 102—102.5 °C: IR (Nujol) 3300—2350 (CO_2H), 1713 (CO_2H), 1696 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 9.35 (br. s, 1H, CO_2H), 6.59 (br. s, 1H, ArH), 6.53 (br. s, 1H, ArH), 3.75 (s, 3H, CH_3O), 3.29—2.53 (m, 4H, CH_2), 2.29 (s, 3H, CH_3), 2.16 (s, 3H, CH_3). Found: C, 66.33; H, 6.99%. Calcd for $C_{13}H_{16}O_4$: C, 66.09; H, 6.83%.

4-(2,6-Dimethyl-4-methoxyphenyl)butanoic Acid (6a). Clemmensen reduction of 3.88 g of **5** gave 3.66 g (90%) of **6** as colorless crystals, mp 96.5—97 °C (benzene–hexane): IR (Nujol) 3350—2350, 1699 (CO_2H) cm^{-1}; NMR ($CDCl_3$) δ

10.05 (br. s, 1H, CO_2H), 6.58 (br. s, 1H, ArH), 6.53 (br. s, 1H, ArH), 3.75 (s, 3H, CH_3O), 2.87—2.11 (m, 4H, CH_2Ar, CH_2CO), 2.27 (br. s, 6H, CH_3) 2.11—1.61 (m, 2H, CH_2). Found: C, 70.14; H, 7.93%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

4-(2,6-Dimethyl-4-methoxyphenyl)-1-butanol (7). Reduction of the methyl ester **6b** was performed with $LiAlH_4$ in ether affording **7** as a colorless oil in 98% yield: IR (neat) 3350 (OH) cm^{-1}; NMR ($CDCl_3$) δ 6.58 (br. s, 1H, ArH), 6.54 (br. s, 1H, ArH), 3.76 (s, 3H, CH_3O), 3.65 (t, J=6.0 Hz, 2H, CH_2O), 2.63 (t, J=7.2 Hz, 2H, CH_2Ar), 2.26 (br. s, 6H, CH_3), 1.75 (br. s, 1H, OH), 1.81—1.16 (m, 4H, CH_2). Found: C, 74.76; H, 9.97%. Calcd for $C_{13}H_{20}O_2$; C, 74.96: H, 9.68%.

4-(2,6-Dimethyl-4-methoxyphenyl)-1-butene (8). The xanthate of **7** was prepared in 98% yield as described previously.[5] The decomposition of 3.496 g of the xanthate took place at 360 °C to form a fumy vapor which was collected in a receiver to give 2.2 g of a yellow oil, whose chromatography over alumina (hexane–CH_2Cl_2 20:1) gave 1.624 g (73%) of **8** as a colorless oil; IR (neat) 1640 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 6.58 (br. s, 1H, ArH), 6.54 (br. s, 1H, ArH), 6.30—4.82 (m, 3H, CH_2=CH), 3.77 (s, 3H, CH_3O), 2.93—2.53 (m, 2H, CH_2Ar), 2.53—1.93 (m, 2H, CH_2), 2.28 (br. s, 6H, CH_3). Found: C, 81.87; H, 9.82%. Calcd for $C_{13}H_{18}O$: C, 82.06; H, 9.53%.

4-(2,6-Dimethyl-4-methoxyphenyl)-1,2-butanediol (9). Into a stirred solution of 0.2 g of **8** in 3 ml of EtOH was added dropwise aq $KMnO_4$ (0.16 g of $KMnO_4$, 0.12 g of $MgSO_4$, 4 ml of H_2O) at −45—−40 °C in 20 min. After stirring at the temperature for additional 2 h and warming to room temperature, the mixture was decantated and the precipitate was rinced with hot water. The combined organic layer was concentrated and extracted with AcOEt to yield 0.135 g of **9** as a colorless oil after chromatographed over silica gel (AcOEt–CH_2Cl_2 1:1): IR (neat) 3367 (OH) cm^{-1}; NMR (CCl_4) δ 6.41 (br. s, 1H, ArH), 6.35 (br. s, 1H, ArH), 4.02 (br. s, 2H, OH), 3.69 (s, 3H, CH_3O), 3.80—3.20 (m, 3H, CH_2O, CHO), 2.64 (t, J=7.8 Hz, 2H, CH_2Ar), 2.18 (br, s, 6H, CH_3) 1.84—1.01 (m, 2H, CH_2). Found: C, 69.34; H, 9.13%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

4-(2,6-Dimethyl-4-hydroxyphenyl)-1,2-butanediol (3). Into a stirred solution of 96 mg of **9** in 2 ml of dry CH_2Cl_2, was added dropwise cautiously 429 mg of BBr_3 at −70 °C under nitrogen. After stirring at −70 °C for 1 h and then at 0 °C for 30 min, the mixture was quenched with 2 ml of saturated $NaHCO_3$ followed by saturated Na_2CO_3. The organic layer was extracted with AcOEt, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed over silica gel (AcOEt–CH_2Cl_2 1:1) to yield 62 mg (69%) of **3** as a white solid, mp 107—108 °C (benzene); IR (Nujol) 3345 (OH) cm^{-1}; NMR ($CDCl_3$) δ 8.18—7.18 (br. s, 1H, OH), 6.62 (br. s, 2H, ArH), 4.91—2.96 (m, 5H, OH, OH, CH_2O, CHO), 2.96—2.54, (m, 2H, CH_2Ar), 2.24 (s, 3H, CH_3), 2.20 (s, 3H, CH_3), 1.94—1.28 (m, 2H, CH_2). Found: C, 68.54; H, 8.91%. Calcd for $C_{12}H_{18}O_3$: C, 68.55; H, 8.63%.

4-(2,6-Dimethyl-4-hydroxyphenyl)butanoic Acid (11a). In a similar manner, reaction of 0.5 g of **6a** with 0.43 ml of BBr_3 gave 0.45 g (97%) of **11a** as colorless crystals, mp 127.5—128.5 °C (benzene–AcOEt); IR (Nujol) 3504 (OH), 3400—2400, 1688 (CO_2H) cm^{-1}; NMR ($CDCl_3$) δ 7.66 (br. s, 2H, OH, CO_2H), 6.53 (br. s, 1H, ArH), 6.45 (br. s, 1H, ArH), 2.95—2.23 (m, 4H, CH_2Ar, CH_2CO), 2.25 (s, 3H, CH_3), 2.22 (s, 3H, CH_3), 2.23—1.62 (m, 2H, CH_2). Found: C, 68.94; H, 7.94%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

Methyl 4-(2,6-dimethyl-4-benzyloxyphenyl)butanoate (12). *O*-Benzylation of **11b** gave **12** as a colorless oil: IR (neat) 1735 (CO_2Me) cm^{-1}; NMR ($CDCl_3$) δ 7.34 (br. s, 5H, Ph), 6.57 (br. s, 2H, ArH), 4.97 (br. s, 2H, CH_2O), 3.55 (s, 3H, CH_3O), 2.89—2.14 (m, 4H, CH_2Ar, CH_2CO), 2.25 (br. s, 6H, CH_3), 2.14—1.59 (m, 2H, CH_2). Found: C, 76.77; H, 8.03%. Calcd for $C_{20}H_{24}O_3$: C, 76.89; H, 7.74%.

4-(2,6-Dimethyl-4-benzyloxyphenyl)butanol (13). Reduction of **12** with $LiAlH_4$ in ether was performed in an usual manner affording **13** as a colorless oil; IR (neat) 3320 (OH) cm^{-1}; NMR ($CDCl_3$) δ 7.24 (br. s, 5H, Ph), 6.51 (br. s, 2H, ArH), 4.83 (s, 2H, CH_2O), 3.46 (t, J=6.0 Hz, 2H, CH_2O), 2.92 (br. s, 1H, OH), 2.64 (t, J=6.6 Hz, 2H, CH_2), 2.19 (s, 6H, CH_3), 1.71—1.28 (m, 4H, CH_2). Found: C, 80.09; H, 8.79%. Calcd for $C_{19}H_{24}O_2$: C, 80.24: H, 8.51%.

4-(2,6-Dimethyl-4-benzyloxyphenyl)-1-butene (14) and 3,5-Dimethyl-4-(3-butenyl)phenol (15). The thermolysis of the xanthate of **13** was performed similarly as described[5] affording **14** (40%) and **15** (18%) as colorless oils: **14** IR (neat) 1636 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 7.30 (br. s, 5H, Ph), 6.54 (br. s, 2H, ArH), 6.32—4.74 (m, 3H, CH_2=CH), 4.95 (s, 2H, CH_2O), 2.98—2.53 (m, 2H, CH_2Ar), 2.53—1.90 (m, 2H, CH_2), 2.24 (s, 6H, CH_3). Found: C, 85.60; H, 8.61%. Calcd for $C_{19}H_{22}O$: C, 85.67; H, 8.32%. **15** IR (neat) 3400 (OH), 1636 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 6.54 (br. s, 1H, ArH), 6.40 (br. s, 1H, ArH), 6.24—4.75 (m, 3H, CH_2=CH), 4.63 (br. s, 1H, OH), 2.96—2.45 (m, 2H, CH_2Ar), 2.45—1.94 (m, 2H, CH_2), 2.25 (s, 3H, CH_3), 2.21 (s, 3H, CH_3). Found: C, 82.01; H, 9.34%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

3-(2,6-Dimethyl-4-benzyloxyphenyl)propanal (16). Ozonolysis of **14** was carried out as usually to give **16** (74%) as a colorless oil: IR (neat) 1721 (CHO) cm^{-1}; NMR ($CDCl_3$) δ 9.66 (t, J=1.8 Hz, 1H, CHO), 7.31 (br. s, 5H, Ph), 6.56 (br. s, 2H, ArH), 4.99 (s, 2H, CH_2O), 3.18—2.79 (m, 2H, CH_2Ar), 2.79—2.15 (m, 2H, CH_2), 2.27 (s, 6H, CH_3). Found: C, 80.41; H, 7.80%. Calcd for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51%.

4-(2,6-Dimethyl-4-benzyloxyphenyl)-2-butanol (17). The alcohol **17** was prepared in 86% yield by Grignard reaction of **16** with MeMgI: IR (neat) 3360 (OH) cm^{-1}; NMR ($CDCl_3$) δ 7.31 (br. s, 5H, Ph), 6.57 (br. s, 2H, ArH), 4.94 (s, 2H, CH_2O), 3.65 (m, 1H, CH), 2.96—2.40 (m, 2H, CH_2Ar), 2.45 (br. s, 1H, OH), 2.26 (s, 6H, CH_3), 2.02—1.30 (m, 2H, CH_2), 1.09 (d, J=6.0 Hz, 3H, CH_3). Found: C, 80.00; H, 8.67%. Calcd for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51%.

4-(2,6-Dimethyl-4-hydroxyphenyl)-2-butanol (4). Treatment of 62 mg of **17** with 13 mg of Li metal in 0.2 ml of dry THF and 5 ml of liquid ammonia at −50 °C for 4 h and an usual work-up provided 32 mg (76%) of **4** as a colorless oil: IR (neat) 3300 (OH) cm^{-1}; NMR (CCl_4) δ 8.24—4.54 (br. m, 2H, OH), 6.42 (br. s, 2H, ArH), 3.66 (m, 1H, CH), 3.08—2.34 (m, 2H, CH_2Ar), 2.19 (s, 3H, CH_3), 2.15 (s, 3H, CH_3), 1.94—1.34 (m, 2H, CH_2), 1.15 (d, J=6.6 Hz, 3H, CH_3) Found: C, 73.90; H, 9.42%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

Studies on Heterocyclics. V.[1] Synthesis of Thiazolotriazepines

M. P. MAHAJAN,* S. M. SONDHI, and N. K. RALHAN**

Department of Chemistry, Punjabi University, Patiala 147002, India

(Received September 23, 1975)

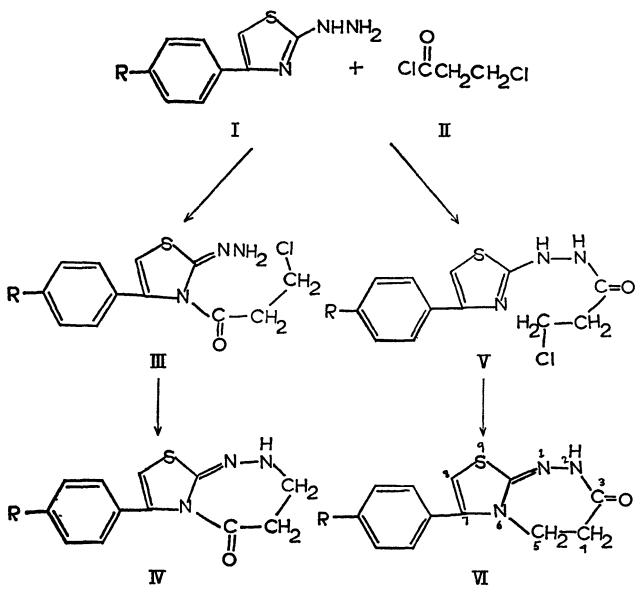
Synopsis. The possible psychosedative, bridgehead thiazolo[2,3-*c*]-1,2,4-triazepines have been synthesized by the condensation of 2-hydrazinothiazoles with β-chloropropionyl chloride.

Recent trends in the synthesis of pharmacologically active compounds, *viz.* thiazolodiazepines[2-4] and oxazolodiazepines,[5] prompted us to carry out the synthesis of thiazolo[2,3-*c*]-1,2,4-triazepines, a new ring system (Scheme 1).

It was anticipated that the most direct route to 2*H*,3*H*,4*H*,5*H*-7-phenylthiazolo[2,3-*c*]-1,2,4-triazepine (VI; R=H) and its derivatives would be from 2-hydrazino-4-arylthiazoles (I)[6] *via* the intermediate V. The method used for the synthesis of thiazolo [2,3-*c*]-1,2,4-triazepines (VI) was analoguos to that used by Fozard and Jones[7] for the synthesis of 2-oxo-2,3,4,5-tetrahydro-1*H*-pyrimido [1,2-*a*] [1,3] diazepinium bromide.

The reaction of I with β-chloro propionyl chloride (II) may give either of the two heterocycles IV[8] and VI. The structure IV can be excluded from the consideration that monoacylation and carbamoylation always occur on the exocyclic amino group[9-14] in α-amino-*N*-heterocyclic compounds. Chloroacyl chloride has been shown to undergo reaction with amines selectively[15,16] with the carbonyl group forming an amide bond leaving V as the only possible intermediate.

Thus $-NH_2$ of hydrazine which is most basic[17] (*i.e.* the strongest nucleophile) will attack at the carbon of the carbonyl which is most electrophilic, resulting in the formation of the intermediate V (Table 1). The IR spectrum of V (R=H) shows characteristic –NH– and >C=O vibrations at 3350 and 1690 cm^{-1}. V is then cyclised in the presence of dry pyridine to VI. The IR spectrum of (VI, R=H) shows bands at 3360 (–NH–); and 1665 (>C=O) cm^{-1}. NMR spectrum (VI: R=Br) taken in $CDCl_3$ (100 MHz) shows a singlet at δ 2.02 (2H) due to $N-CH_2-$ and another singlet at δ 1.8 (2H) due to $-CH_2-\overset{O}{\overset{\|}{C}}-$ and aromatic multiplet at δ 6.8—7.7 (5H) due to $Br-C_6H_4-\overset{|}{C}=CH-$.



Scheme 1.

Experimental

The melting points are uncorrected. Microanalysis was carried out by the Mciroanalytical Service., CSIRO, Australia. IR spectra were obtained in KBr wafers on a Perkin-Elmer Infracord-137 spectrophotometer, and NMR spectra were recorded on a Varian HA-100 spectrometer.

2-Hydrazino-4-(substituted phenyl)thiazoles (I). 2-Chloro-4-phenylthiazole[6] (3.92 g, 0.02 mol), pyridine (2 ml), hydrazine hydrate (5 ml), and ethanol (20 ml) were taken in a flask. The reaction mixture was heated under reflux for 2 h and the solvent was removed under reduced pressure. The residue was poured into cracked ice and the solid thus obtained was crystallized from ethanol or benzene; yield 3.2 g (84%); mp 162 °C. Found: C, 56.64; H, 4.79; N, 22.25%; while: $C_9H_9N_3S$ requires: C, 56.54; H, 4.71; N, 21.99%. NMR spectrum (100 MHz; $CDCl_3$) shows aromatic protons as multiplet at δ 6.8—7.9 and the $-NHNH_2$ protons at δ 2.5—3.5.

The other 2-hydrazino-4-(substituted phenyl)thiazoles were prepared in an analoguos manner.

2-(3-Chloropropionylhydrazino)-4-(p-substituted phenyl)thiazoles (V). 2-Hydrazino-4-phenylthiazole (1.91 g, 0.01 mol) dissolved in tetrahydrofuran (15 ml) was added with stirring over a period of 15 minutes to an ice cooled β-chloropropionyl chloride (10 ml). The solid separated in the reaction mixture and excess of β-chloropropionyl chloride was decomposed with crushed ice, filtered, washed with cold water, and crystallized from ethanol. Yield, mp, solvent of crystallization, and microanalytical data are given in Table 1.

The other 2-(3-Chloropropionylhydrazino)-4-(*p*-substituted phenyl)thiazoles were prepared in a similar way.

2H,3H,4H,5H-7-(p-substituted phenyl)thiazolo[2,3-c]-1,2,4-triazepine-3-ones (VI). 2-(3-Chloropropionylhydrazino)-4-phenylthiazole (1.0 g) was dissolved in dry pyridine (10 ml) and left to stand at room temperature for 30 minutes. The reaction mixture was diluted with water and the solid obtained was crystallized from ethanol.

The other 2*H*,3*H*,4*H*,5*H*-7-(*p*-substituted phenyl)thiazolo [2,3-*c*]-1,2,4-triazepine-3-ones were prepared in a similar way. Yield, mp, solvent of crystallization and microanalytical data are given in Table 2.

The Heat of Solution and Solvation Number of Lithium Salts in Water–Alcohol Mixtures

Michio MASHIMA, Takao TAKASE, Shinroku FUKUDA, and Norio BABA

Faculty of Engineering, Niigata University, Gakko-cho, Nagaoka-shi 940

(Received June 6, 1975)

The solvation numbers of LiCl and LiI, and of KI for comparison, in water–MeOH mixtures and water–*i*-PrOH mixtures were determined at an infinite dilution at 25 °C from the adiabatic compressibility. The heats of solution of these salts were also determined. In general, with an increase in the concentration of alcohol the solvation number increases initially to reach a maximum at 10—30 mol% alcohol, then it decreases to a minimum and increases again from about 75 mol% alcohol. The maximum solvation numbers of the salts determined are as follows: LiCl 11.2 mol/mol at 30 mol% MeOH; LiCl 11.5 mol/mol at 15 mol% *i*-PrOH; LiI 8.2 mol/mol at 12 mol% *i*-PrOH and KI 14.0 mol/mol at 10 mol% *i*-PrOH. The larger the cation, the larger the solvation number. Also, the composition of the solvant where the salt containing larger ions has a maximum solvation number has a lower concentration of alcohol. The maximum solvation number of LiI containing a larger anion is smaller than that of LiCl because an iodide ion has a much larger structure-breaking effect than a chloride ion. By the way, there seems to be difference in the structure of the mixed solvent before and after the maximum solvation number.

The heats of solution and the hydration numbers of the cobalt(III) complexes and simple salts at an infinite dilution at 25 °C have been reported.[1] In this experiment the solvation numbers of lithium chloride, lithium iodide, and potassium iodide for comparison, which are soluble in alcohol, in water–methyl alcohol (subsequently designated MeOH), and water–isopropyl alcohol (subsequently designated *i*-PrOH) mixtures, were determined at an infinite dilution at 25 °C from the adiabatic compressibility. The heats of solution of lithium chloride and lithium iodide at an infinite dilution were also determined. Moreover, the A and B coefficients of the viscosity in the Jones-Dole expression[2] of lithium chloride in water–MeOH mixtures were determined.

Experimental

Determination of Heat of Solution. The heats of solution were determined with a twin-type conduction micro calorimeter with copper-constantan thermocouples, a commercial model (CM-502) of Ōyōdenki Kenkyujo. This apparatus, wrapped in a polyethylene sheet, was put in a thermostat regulated at 25±0.01 °C. This was connected with a d. c. voltage amplifier (a commercial model PM-17A) and a recorder (a commercial model EPR-10A of Tōa Electronics, Ltd.). The heat of solution was calculated from the area drawn by the recorder. The cells for dissolving salts are made of stainless steel. The solid sample was thrown into a cell containing 40 ml of the solvent by means of the attached device. Known amounts of heat occurred in the cell with liquid paraffin when a heater was used; these amounts were then used for obtaining the comparative area, from which the heats of solution of salts were calculated. The quantity of heat which was actually measured is less than, or equals, one figure. Figure 1 shows the heats of solution of lithium chloride in the 12.9 mol% MeOH–water mixture and in the 83.5 mol% *i*-PrOH–water mixture, and that of lithium iodide in water. The heat of solution at an infinite dilution was obtained by the extrapolation of the concentration to zero because the heat of solution per mol of electrolytes decreased linearly with a decrease in the concentration in this case.

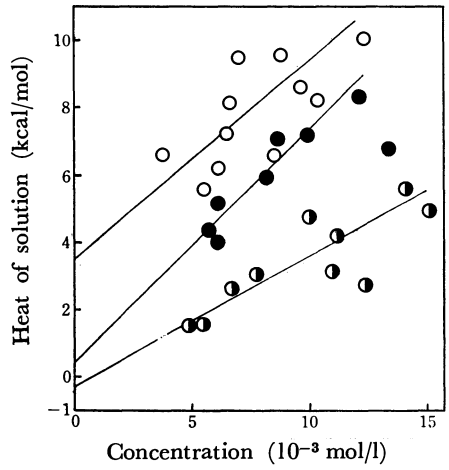

Fig. 1. Relationship between the concentration and the heat of solution (25 °C).
○: LiCl (12.9 mol% MeOH), ●: LiCl (83.5 mol% *i*-PrOH), ◑: LiI (water).

Determination of Solvation Number. The solvation number at an infinite dilution, determined from the adiabatic compressibility[3,4] was obtained by measuring the velocity of sound in the solution by means of an ultrasonic interferometer which had been placed in a thermostat maintained at 25±0.01 °C. The frequency used was 1 MHz. This apparatus was a commercial model (UAC-1-2A) of Chōonpa Kōgyō. Purified water for a solvent was boiled and used immediately after cooling. The solvation number was determined from the (relative) differential specific compressibility; that is,

$$K_{x0} = \lim_{x\to 0}[(d-x)/d_1-(K/K_1)]/x$$

where d and d_1 are the densities of the solution and the solvent, and where x is the concentration of the solution. It was assumed that the composition of the sheath of solvation was the same as that of the solvent.

B-*Coefficient of Viscosity.* The kinematic viscosity of the solution was measured with a kinematic viscosimeter of the Cannon-Fenske type, while the viscosity of the solution was obtained by the multiplication of the kinematic viscosity by its density. The density was measured with a Gay-Lussac-type pycnometer with a capacity of 10 ml. The A and B coefficients of viscosity of the solution in the Jones-Dole expression[2] were calculated from the viscosity of the solution;

$$\eta = \eta_0(1+A\sqrt{c}+Bc)$$

where η_0 is the viscosity of the solvent, c is the molarity, and both A and B are the characteristic constants on the solute.

Table 1. Heats of solution in water and hydration numbers of lithium salts at an infinite dilution (25°C)

Salt	Hydration number		Heat of solution		Hydration number of Li^+	Heat of solution of Li^+
	(mol/mol)	(10^{-4} g/ml)[a]	(kcal/mol)	(10^{-3} mol/l)[a]	(mol/g-ion)[b]	(kcal/g-ion)[b]
LiCl	4.7	3—15	+1.6	6—15	2.7	+2.8
$LiNO_3$	7.0	2—10	+0.3	5—22	2.7	+2.8
LiI	7.1	1—11	−0.3	5—15	4.4	

Hydration number (mol/g-ion)[1] Cl^- 2.0, NO_3^- 4.3, I^- 2.7. Heat of solution (kcal/g-ion)[1] Cl^- −1.2, NO_3^- −2.5. a) The determined range of concentration of the solution. b) Values obtained by subtracting that of an anion from that of a salt.

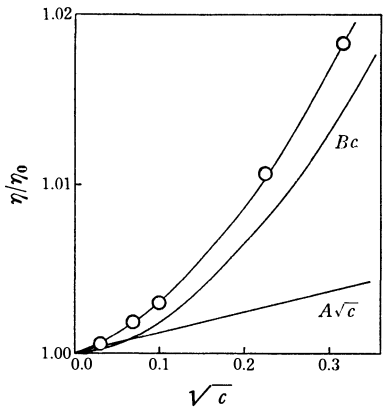

Fig. 2. Relationship between the relative viscosity and the square root of molarity of aqueous solution of lithium chloride (25 °C).

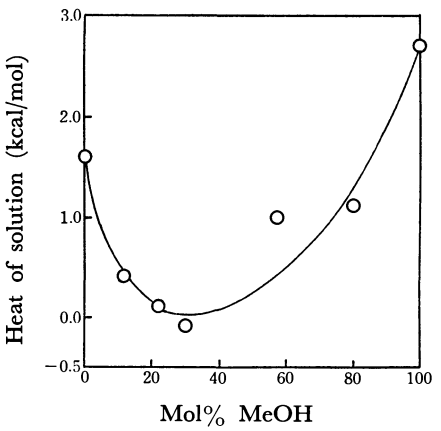

Fig. 3. Heat of solution of lithium chloride in water–MeOH mixture at infinite dilution (25 °C).

Figure 2 shows the relationship between the relative viscosity and the square root of the molarity of an aqueous solution of lithium chloride, drawn to obtain the *A* and *B* coefficients of the viscosity.

Determination of Electric Conductivity. The electric conductivity was measured with an electric conductivity outfit, a commercial model MY-7 of the Yanagimoto Mfg. Co., Ltd. The electrodes were made of platinum gild with platinum black. The equivalent electric conductivity was determined by measuring the resistance of the solution and by extrapolating the concentration to zero because the equivalent electric conductivity of strong electrolytes changed linearly against the square root of the concentration. The cell for measuring the resistance of the solution was put in a thermostat regulated at 25 °C.

Samples. The samples such as lithium salts which are of a guaranteed or extra pure grade were used without further purification. The alcohol was dried with an aluminum amalgam or dehydrated copper sulfate and distilled before use.

Results and Discussion

Table 1 shows the heats of solution in water and the hydration numbers of three kinds of lithium salts at an infinite dilution at 25 °C. The heat of solution in water and the solvation number of a lithium ion were obtained by subtracting those of a negative ion from those of lithium salts, because the additive property held on both the heats of solution in water and the hydration numbers of a nitrate ion and a chloride ion of the simple salts.[1] The hydration number of a lithium ion obtained from that of chloride was, consequently, consistent with that obtained from nitrate, *i.e.*, 2.7 mol/g-ion. Similarly, the heat of solution of a lithium ion was +2.8 kcal/g-ion. However the hydration number of a lithium ion, obtained from the others, did not agree with that obtained from the others, *i.e.*, 4.4 mol/g-ion.

The heats of solution of lithium chloride in water–MeOH mixtures at an infinite dilution at 25 °C are shown in Fig. 3. The heat of solution decreases initially with an increase in the concentration of MeOH to a minimum value at about 30 mol% MeOH, but thereafter it increases. A similar tendency in this system had been reported by Slansky.[5] The heat of mixing per mol of water and MeOH has a maximum value at about 30 mol% MeOH.[6] The viscosity,[7] the velocity of sound,[8] and the refractive index[9] of the mixture have also maxima at almost the same

Table 2. Heats of solution and solvation numbers of lithium chloride and lithium iodide in water, MeOH, and *i*-PrOH respectively (25 °C)

Salt	Solvent	Heat of solution (kcal/mol)	Solvation number (mol/mol)	Heat of solution: Solvation number (kcal/mol)
LiCl	Water	+1.6	4.7	+0.34
	MeOH	+2.7	7.7	+0.35
	i-PrOH	+4.4	10.3	+0.43
LiI	Water	−0.3	7.1	−0.04
	i-PrOH	+3.4	2.5	+1.36

compositions. The heats of solution and solvation numbers of lithium chloride and lithium iodide in water, MeOH, and *i*-PrOH at an infinite dilution at 25 °C are indicated in Table 2. The composition of the sheath of solvation was calculated from the heat of solution per mol of hydrated water or solvated MeOH (Table 2) so that the calculated value of the heat of solution was consistent with the actually determined value (shown in Fig. 3), assuming that the solvation number increases linearly against the concentration of MeOH. Consequently, the composition of the sheath of solvation was little different from that of the solvent, shown by the dotted lines in Fig. 4. Figure 5 shows the Walden products[10] of lithium chloride in water–MeOH mixtures at an infinite dilution at 25 °C. It may be seen in Fig. 5 that the Walden product decreases almost linearly, without having a constant value, in the water-rich region. From these results it seems reasonable to assume that lithium chloride does not solvate selectively water or MeOH in water–MeOH mixtures.[11]

Figure 6 shows the heats of solution of lithium chloride and lithium iodide in water–*i*-PrOH mixtures at an infinite dilution at 25 °C. The heat of solution has a minimum value at 15—20 mol% *i*-PrOH. The heat of mixing[6] and the velocity of sound[8] of the mixture have maxima at almost the same concentration of *i*-PrOH, much like water–MeOH mixtures.

Figure 7 shows the solvation number of lithium chloride in water–MeOH mixtures at an infinite dilution at 25 °C, determined from the adiabatic compressibility. The composition of the sheath of solvation was assumed to be identical with that of the solvent in this case, according to the estimation described above. The solvation number of lithium chloride in water–MeOH mixtures increases with an increase in the MeOH content up to a maximum at about 30 mol% MeOH, thereafter it decreases to a minimum at about 75 mol% MeOH, and then increases again. Thus, the solvation number is probably strongly influenced by the structure of the solvent, that it has a maximum seems to be attributable to a difference in

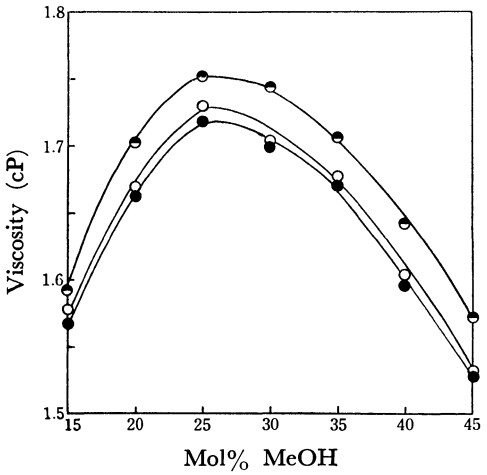

Fig. 8. Viscosity of water–MeOH mixtures containing lithium chloride at 25 °C.
◓: LiCl 0.1 mol/l, ○: LiCl 0.01 mol/l, ●: LiCl 0.001 mol/l.

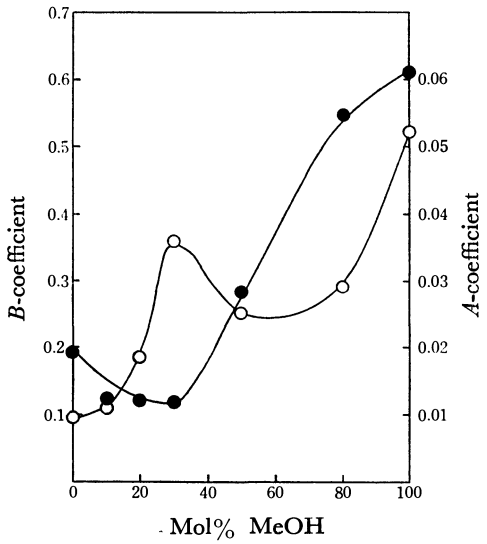

Fig. 9. *A* and *B*-coefficient of viscosity of lithium chloride in water–MeOH mixture (25 °C).
○: *A*-coefficient of viscosity,
●: *B*-coefficient of viscosity.

the structure of the solvent before and after the maximum solvation number, much like water–ethanol systems.[12–15] Many physicochemical properties of water–MeOH mixtures have maxima in a water-rich region. For example, the viscosity of the solution has a maximum at about 25 mol% MeOH, as is shown in Fig. 8. The maximum solvation number of lithium chloride in water–MeOH mixtures is 11.2 mol/mol at about 30 mol% MeOH.

In view of the values of the hydration number previously determined by the present authors,[1] the larger a cation is, the larger the hydration number. Also, the larger the electric charge of the cation, the smaller the hydration number. This result is the reverse of the concept universally believed. The ionic hydration numbers obtained by the authors were $Li^+=2.7$, $K^+=8.4$. The hydration number of the lithium ion was smaller than the literature data, *e.g.*,

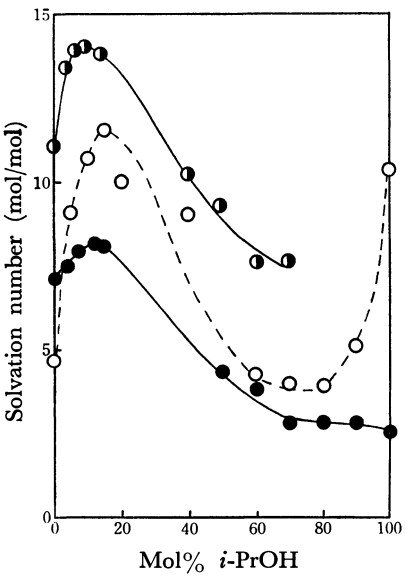

Fig. 10. Solvation numbers of lithium chloride, lithium iodide and potassium iodide in water–*i*-PrOH mixture at infinite dilution (25 °C).
○: LiCl, ●: LiI, ◑: KI.

$Li^+=4.0$,[16] while that of the potassium ion was larger than $K^+=3.5$.[16] Hence, the solvation number determined from the velocity of sound in the solution appears to contain the region in which the molecules around the ion are fixed (A-region) and a part of the outer region (B-region) of the Frank and Wen model for the sheath of solvation.[17,18]

The *A* and *B* coefficients of the viscosity of lithium chloride in water–MeOH mixtures were determined in an effect to investigate the interaction between the solute ion and the solvent in the mixtures at an infinite dilution at 25 °C. These values are plotted against the MeOH content in Fig. 9. The *A* coefficient has a maximum and the *B* coefficient has a minimum at about 30 mol% MeOH, where the solvation number is at its maximum. Consequently, it is considered that the coulombic force between the solute ions is at the maximum, and that the interaction between the solute ion and the solvent is at the minimum, at this composition.[19,20] In a water-rich region, the sheath of solvation determined by this method can be considered to increase with an increment in the MeOH content, because the distance between the solute ion and the solvent increases, as may be seen from the *B* coefficient of viscosity. As a result, the solvation number increases with an increase in the MeOH content when the degree of the increment in the thickness of the sheath of solvation is not very large. Accordingly, when the solvation number determined by this method is at the maximum, the interaction between the ion and the solvent is at the minimum because the distance between them is greatest at that composition, and the heat of solution of the salt is at the minimum, too. The Walden products of lithium chloride in water–MeOH mixtures, as may be seen in Fig. 5, show that the apparent average size of the cation and the anion solvated increases with an increase in the MeOH content in the water-rich region, it has

no constant value in that region. However, the solvation number of *t*-butyl chloride in water–ethanol mixtures has a minimum, determined by Arnett and his co-workers.[12,13] This may be related to the fact that the Walden product of lithium chloride in water–ethanol mixtures has nearly a constant value from 0 to 25 wt% ethanol,[21] despite the effect of the size of the solute.

The solvation numbers of lithium chloride, lithium iodide, and potassium iodide in water–*i*-PrOH mixtures at an infinite dilution at 25 °C are shown in Fig. 10. The experiment on potassium iodide could not be carried out, though, in a solvent more than about 70 mol% *i*-PrOH because the salt was little soluble in the solvent. The maximum solvation numbers of the salts determined are as follows: lithium chloride, 11.5 mol/mol at 15 mol% *i*-PrOH; lithium iodide, 8.2 mol/mol at 12 mol% *i*-PrOH; and potassium iodide, 14.0 mol/mol at 10 mol% *i*-PrOH.

Comparing the solvation number of lithium iodide with that of potassium iodide, both values have roughly the same tendency with regard to the MeOH content, and potassium iodide, which has a larger cation, has a larger solvation number than lithium iodide at all the compositions. Therefore, a potassium ion seems to have an apparent larger sheath of solvation than a lithium ion. On the other hand, the apparent sheath of solvation of a lithium ion appears to be smaller and to be composed of the A region for the most part, because the ion is solvated strongly, much as in pure MeOH.[22,23]

Next, the effect of the solvent on the solvation number will be discussed. As may be seen in Figs. 7 and 10, the maximum solvation number of lithium chloride in a water–*i*-PrOH mixture is larger than that in water–MeOH mixtures, and the composition of the solvent where lithium chloride has the maximum value in water–*i*-PrOH mixtures exists in a lower concentration of alcohol than that in water–MeOH mixtures. This is probably because the apparent sheath of solvation of the salt increases in size for *i*-PrOH molecules which are larger than MeOH molecules.

Comparing the solvation number of lithium chloride with that of lithium iodide, lithium iodide, which has a larger anion, has a larger hydration number than lithium chloride, much as in the case of cations. However, lithium iodide has a smaller solvation number than lithium chloride from about 3 mol% *i*-PrOH, and the maximum solvation number of lithium iodide is smaller than that of lithium chloride. The reason for this is that: the B region of the sheath of solvation of an iodide ion is extremely large because it has a much larger structure-breaking effect than a chloride ion.[24] As a result, the A region and a part of the B region of the ion are determined as the sheath of solvation, resulting in its having a smaller solvation number than a chloride ion.

In the range of high *i*-PrOH concentrations, the solvation number of lithium iodide does not increase, unlike as in the case of lithium chloride. This tendency is presumably due to the same effect of an iodide ion.

Apparatus for Thermal Analytic Microscopy and Its Application to Cholesteryl Nonanoate*

Kazuko Sasaki KUNIHISA and Seiichi HAGIWARA**

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

***Tokyo Rikoh Company, Kitamachi, Hoya-shi, Tokyo 188*

(Received June 30, 1975)

The phase transitions of cholesteryl nonanoate were studied by means of a newly constructed apparatus for thermal analytic microscopy incorporating a thermoelement. It was possible to determine the heat of mesophase transitions more accurately. The transition values of cholesteryl nonanoate on cooling were obtained with the same accuracy as those on heating. The heat of the smectic-solid transition was obtained by slow cooling, which suppressed the supercooling. The vortices caused by cholesteric spherulites, which are similar to those of cholesteryl octanoate, change to circular arrangements of batonnets in the smectic phase. Color changes were observed at the cholesteric-smectic transition in extremely thick specimens. The relations between texture, color, and heat at the cholesteric-smectic transition of cholesteryl nonanoate are discussed.

On the basis of the results of previous works,[1,2] a new apparatus was constructed for thermal analytic microscopy and applied to a study of the phase transitions of cholesteryl nonanoate.

Apparatus

The apparatus is shown in Fig. 1.

Sample Cells. The sample cells are similar to those used previously (Fig. 2)[2] the microscopic cell being equivalent to the thermal ones. The body is made of stainless steel (0.5 mm thick) except for the center part. The cover and the center of the body are made of Pyrex glass. Two kinds of covers have been prepared. One is slightly smaller than the inner diameter of the body easily drops onto the center glass part. It is employed for thin layer (10—20 μ) samples. The other exactly fits the edge inside the top of the body (Fig. 2). It produces an extremely thick layer (300—350 μ) for the study of the characteristic colors at transformation, independent of the retardation color caused by the thin anisotropic layer.

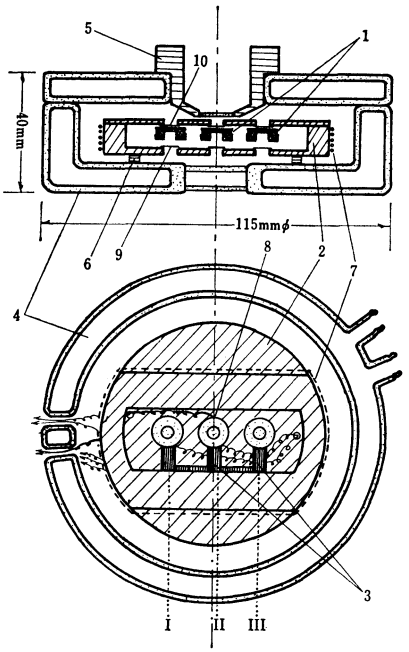

Fig. 1. Apparatus. 1: Sample cell; 2: copper block; 3: thermoelement; 4: jacket; 5: Teflon adapter for microscope; 6: Teflon support; 7: heater; 8: thermocouple for temperature measurement; 9 and 10: glass plates.

Copper Block. A disk-like copper block with a high heat capacity, part of which had been cut off, is used. It has a cover (1.5 mm thick) for maintaining a homogeneous temperature distribution in the interior of the block. A part of the block is cut off to make the thermal conditions as close as possible to those of the three cells.

Connection between Thermoelements. Since a thermoelement is a synthetic material made of several kinds of semiconductor compounds, the thermoelectric power is to some extent dependent on the properties of each thermoelement, and the contact potential differences arisen from the junctions between thermoelements and the block are not identical. Therefore, when the copper block has an inhomogeneous temperature distribution, the differences between each contact potential difference increase. In order to eliminate the potential disturbances, all the thermoelements are connected with the same thermoelement material (Fig. 1).

* Presented at the 32nd National Meeting of the Chemical Society of Japan, Tokyo, April, 1975.

Table 1. Transition values for cholesteryl myristate

		Cryst.-Sm.		Sm.-Ch.		Ch.-Iso.	
		T °C	Q cal/g	T °C	Q cal/g	T °C	Q cal/g
Heating	this work	70.6	18.9	78.4	0.55	83.5	0.37
	previous work[1]	70.6	18.2	78.4	0.5	83.5	0.3
Cooling	this work	50—67	17.4	78.4	0.64	83.6	0.52
	previous work[1]	52—67	16.3	78.5	0.6	83.5	0.5

Jacket. Water is circulated in the glass jacket. Teflon is utilized partly to buffer the heat effect caused by the aproach of the microscope. Three small Teflon pieces are used to place the copper block in the interior of the jacket.

The block heater, the thermocouples for temperature measurement and monitoring, and the sample cell holders are of the same materials as in the previous apparatus.[1]

Results

Calibration by Stearic Acid. By using the heat of the fusion of stearic acid[3] the performance of the apparatus was examined. At the heating or cooling rate of 0.63 °C/min the following items were checked: (1) the sensitivities of the thermoelements, I, II, and III (Fig. 1); (2) the dependence of the heat effect on the sensitivity range of an amplifier, and (3) the dependence of the heat effect on the sample weight.

Comparison of the Apparatus with the Previous One. The peak area for the heat of fusion of stearic acid was found to be 40% greater than that of the previous work.[1] This indicates that the connection of thermoelements is effective in improving the sensitivity of the apparatus. In addition, the base lines of the thermograms were greatly stabilized. The apparatus in the preceding work showed good base lines only with slow heating or cooling.

Calibration by Cholesteryl Myristate. The transition values of cholesteryl myristate were estimated by a comparison with those of the previous work [1] The results on heating or cooling at the rate of 0.63 °C/min are given in Table 1. The apparatus can determine the heat of mesophase transition to one more significant figure than that of the previous results.[1] The heats of two mesophase transitions on cooling were found to be considerably larger than those on heating. The heat of the crystallization of stearic acid is 2% larger than that of fusion. Thus, the thermoelectric effect of the thermoelements shows a hysteresis. A small peak area, such as the mesophase-mesophase transition, depends greatly on the way of drawing a base line under the peak. The difference between the values on cooling and heating, however, amounts to more than 20% of the heat of the mesophase transition. It is much larger than 2% in the case of stearic acid.

Simultaneous Observation in Microscopy and DTA. Figure 3 shows the thermograms and the temperature curves*** of stearic acid with notations of the microscopic changes. Point 'i' indicates the initiation of melting or crystallization, and 'f', the finish of the microscopic change. The temperature 'f' agrees with the starting point of the plateau (69 °C) on the temperature curve. The peak of fusion, 'p', agrees with the end point of the plateau. The temperature for both the complete view change in the microscopy and

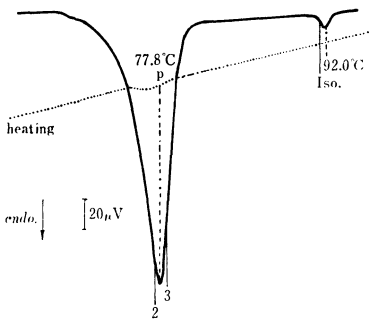

Fig. 5. DTA and temperature curves of cholesteryl nonanoate on heating, with the number of Photos. 2 and 3. Sample weight, 88.53 mg; rate, 0.63 °C/min; samp. range, ±250 μV; chart speed, 240 mm/h.

the peak on the thermogram is equal to 69 °C, the temperature of the fusion of stearic acid.

Figure 4 shows the curves of cholesteryl myristate, with notations denoting the appearance of typical textures. The isotropic-cholesteric transition peak on cooling agrees with the appearance of the homeotropic blue color, but not with that of the cholesteric focal conic texture. According to Gray, both the homeotropic and the focal conic textures belong to the same phase.[4]

The agreement between microscopic and DTA observations has thus been established.

Phase Transitions of Cholesteryl Nonanoate. Thermal Data of Cholesteryl Nonanoate: The sample was purified as in the previous work.[1] Table 2 gives the transition values of cholesteryl nonanoate. The heat of crystallization was measured by slow cooling, which helped to suppress the supercooling.[5] The heat of the isotropic-cholesteric transition on cooling is somewhat

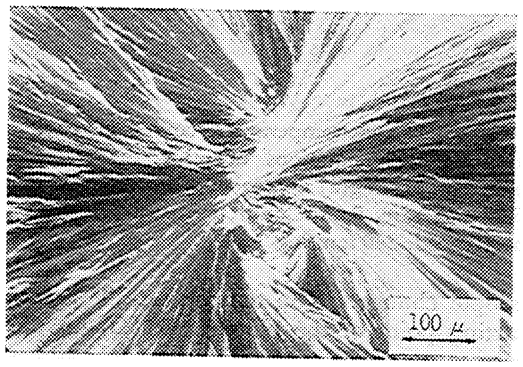

Photo. 1. Spherulitic center of a solid of cholesteryl nonanoate crystallized from the melt.

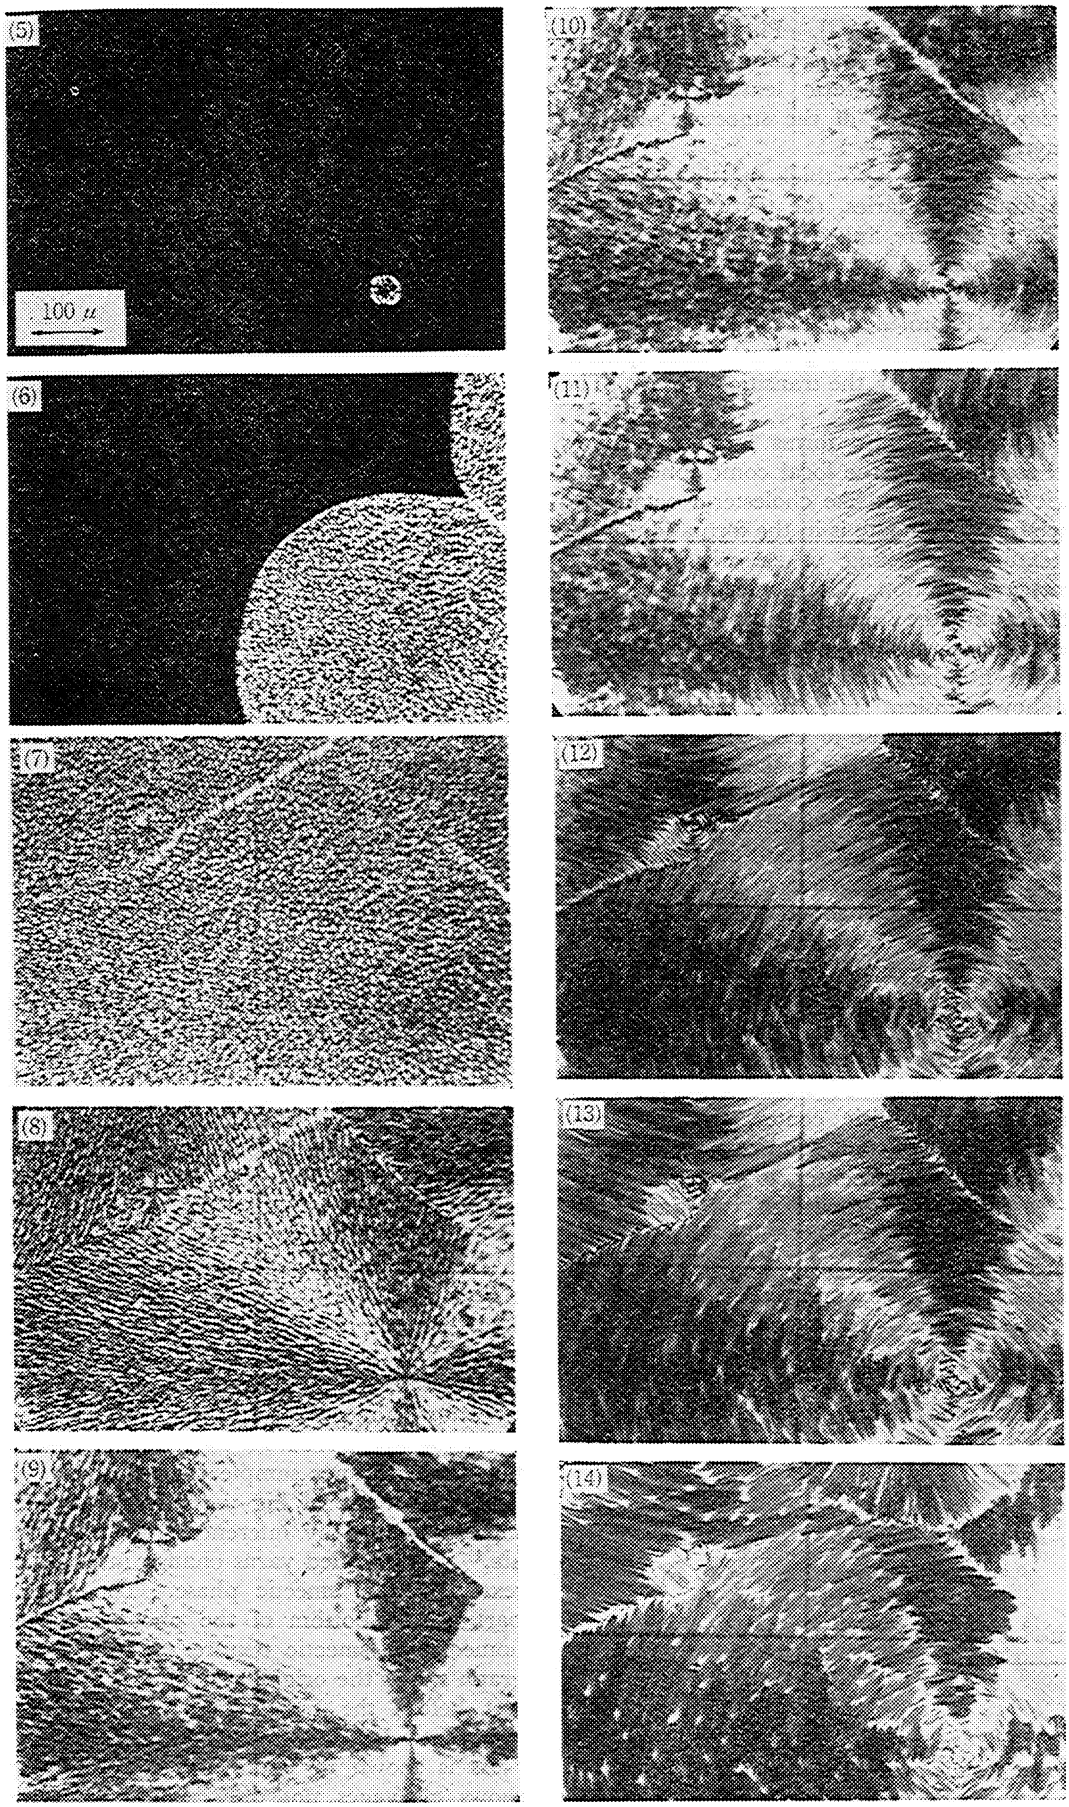
larger than that on heating, as was found for cholesteryl myristate.

Microscopic observation and DTA: Figure 5 shows the curves on heating (0.63 °C/min), along with the numbers of the photographs. Photograph 1 shows the center of a solid phase radially grown from the smectic phase, taken at room temperature. Photo. 2 shows a transient



Photos. 5—14. The microscopic views from the occurrence of the spherulite of cholesteric texture to the appearance of the solid phase in cholesteryl nonanoate on cooling. 5: 84.3 °C; 6: 82.3 °C; 7: 79.5 °C; 8: 73.8 °C; 9: 73.5 °C, 10: 73.2 °C; 11: 72.7 °C; 12: 72.6 °C; 13: 72.2 °C; 14: 43 °C.

state to the mesophase (77.6 °C). Photo. 3 shows the cholesteric phase at 78.3 °C, just after the transition peak (77.8 °C). Th cholesteric texture closely resembles a microscopic view of the smectric phase in cholesteryl myristate.

When the sample layer is so thick that it behaves as a liquid free from boundaries, the texture shows oily streaks.[7] The streaks are linked to each other or are branched and separated by isotropic parts, which become clear as the cholesteric-isotropic transition point approaches (Photo. 4). The streak marked by the light and dark portions changes into small spherulites arranged linearly near the transition point. The spherulite is optically negative.

Cholesteryl nonanoate also forms large spherulites like spherical assemblies of the focal conic spherules in the cholesteric phase, much like cholesteryl octanoate. The difference from octanoate is in the formation of the basket-like texture, consisting of smectic batonnets, after the vortex formation. The smectic texture is extremely stable until the solid phase appears. Figure 6 shows the thermogram on cooling (0.63 °C/min), along with the numbers of Photos. 5—14. These photographs show transient states from the spherulitic growth of the cholesteric phase to the appearance of the solid phase, passing through the basket-like texture of the smectic phase. Photos. 5—7 show the spherulitic growth of the cholesteric focal conic texture, much as in the case of octanoate. No heat evolution accompanies the growth, much as in the case of the cholesteric phase of myristate. Photo. 8 shows the occurrance of a radial ordering at 73.8 °C, which corresponds to the starting point of the peak of the cholesteric-smectic transition. Photo. 9 indicates an ordering in the direction vertical to the radial one. The spherulitic center at the right bottom in the photograph looks like a fylfot or an Airy's spiral. Photo. 10 shows a very speedy vortex around the spherulitic center, which clearly indicates the occurrence of some kind of association on spherical surfaces from the center to the boundary. Photos. 11—13 show the growth of the basket-like texture of the smectic batonnets. The peak of the cholesteric-smectic transition is 72.5 °C ('p' in Fig. 6). The microscopic phenomena are almost finished by 'p'. Photo. 14 shows a fan-like solid phase, which appears in the right top portion in the photograph. The 'f' in Fig. 6 corresponds to the point where the solid covers the smectic texture.

In transmitted light, the visible light intensities increase with the thickness of the sample layer. A thick sample shows, at first, a light blue color with the peak of isotropic-cholesteric transition before the generation of the cloudy cholesteric phase. The color variation during the cholesteric-smectic transition is: first light yellow, then strong yellow, orange, red and finally deep blue. The colors become mixed with the variation Red and other colors remain in the microscopic view when the final blue appears. The arrows in Fig. 6 show the ranges of color appearance. The 'n' in the figure means "no color." The view at 'n' is only a dim light as the result of mixing all the colors. The color variation is similar to that in the case of taking an analyser off. The vortex in Photo. 10 is accompanied by so speedy a color variation that observation cannot follow it.

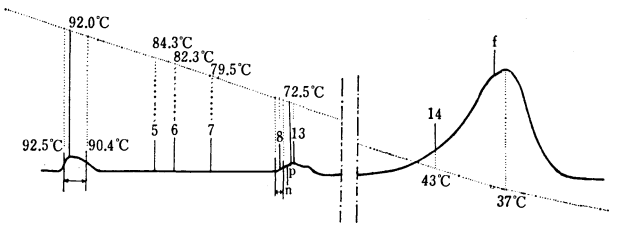


Fig. 6. DTA and temperature curves of cholesteryl nonanoate on cooling, with the number of Photos. 5—14. The experimental conditions are the same as in Fig. 5. The arrows show the ranges of color appearance.

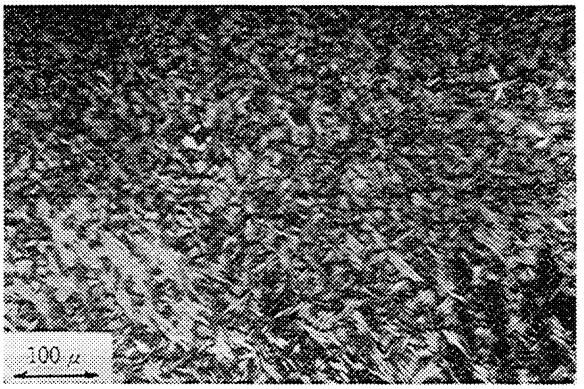

Photo. 15. Cholesteric-smectic transition state of cholesteryl nonanoate in a thin specimen.

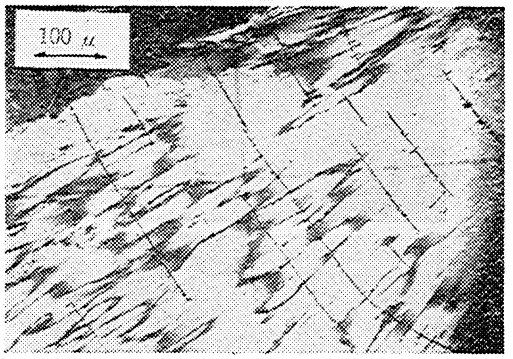

Photo. 16. Cleavages of thin solid film of cholesteryl nonanoate.

Photograph 15 shows the cholesteric-smectic transition for a thinner sample than that of Photo. 5—14. The coils made of big yarns in Photo. 15 suggest a smectic texture by inference from cholesteryl octanoate.[1] The coiled yarns change into the homeotropic texture of the smectic phase. The optically extinct part at the bottom of the photograph indicates the homeotropic smectic texture. The top of the photograph shows the original cholesteric focal conic texture just before the transformation. The selective color light scattering does not appear in this case.

As is shown in Photo. 16, a radially grown solid shows cleavages not only radially but also circumferencially. Solidification on a free surface gives dendritic crystals similar to cholesteryl octanoate.

Discussion

Relation between the Light Scattering in Transmission and in Reflection. A thin, anisotropic specimen generally looks colored under crossed polars because of its own retardation. The thickness most sensitive to retardation is in the range of less than 100 μ. In this work, color observation was carried out for extremely thick samples of more than 300 μ. Therefore, the color observed at the transformation is independent of the thickness. In transmitted light, the visible light intensity increases much more for a thick specimen than for a thin one, making a good contrast to the case of reflected light.[8] In a specimen thicker than 300 μ the molecules in a mesophase may be oriented randomly as a whole, since numbers of molecules restricted by boundary are negligible. Therefore, a theory based on the homeotropical model seems not to be applicable. If the mesophase, however, consists of a crystal structure with a higher order, such as the spherical symmetry of spherulite, the optical axis may naturally be normal to the glass boundary.

The color variation number reflected light was observed using a Mettler fusion-point apparatus. The colors from blue to red were observed in the range of 74—72 °C. Except for the red color, the selective reflection color and the color obtained by our apparatus are complementary. Ennulat[8] studied the selective light reflection of several cholesteryl esters with a monochromator; he found that the wavelengths from 470 nm to 590 nm showed, in the temperature range of 76.78—76.12 °C, the respective intensity maxima with regard to nonanoate. The characteristic colors of this work correspond to the complementary colors of those observed at Ennulat, but the temperature does not agree with his result, although the temperature range 0.7 °C found by us is almost the same as his result (0.66 °C).

Mechanism of the Occurrence of the Vortex. A large spherulite in the cholesteric phase consists of small spherulites with a focal conic texture. In other words, the spherulite has a double structure. An ordinary cholesteric focal conic texture changes into the randomly coiled yarns of the smectic phase, but not into the vortex (Photo. 15). Only an ordered structure of spherical symmetry makes a vortex at the cholesteric-smectic transition. Before being transformed into a vortex, a spherulite seems to be almost solidified by the development of the radial order. In Photo. 9 the isotropic part disappears except for the isogyres of the spherulites. If the same order develops further, the stress force may be accumulated in the system, which will thus be destroyed, and the substance will start to flow as a fluid. In the field of spherical symmetry, the center may be regarded as a singular point similar to a source in hydrodynamics. Consequently, a vortex will come from every spherulite. This inference is just one of many possibilities. A more essential mechanism of vortex formation may be related to the transformation from an optically negative phase to an optically positive phase. A color-light scattering accompanied by a vortex may also be related to some antisymmetric force, such as a twist force caused by the transformation.

Relation between Optical and Thermal Phenomena. It was observed that the microscopic changes in both the fusion and the crystallization of stearic acid agreed with the starting points of the peaks (Fig. 3), suggesting that an optical change precedes the corresponding thermal change. Similar relations were also observed for all the transitions of cholesteryl myristate and nonanoate except for the fusion. The peaks of their fusion show loose curves because of a premelting effect, which makes the starting points of the peaks less clear.

We wish to express our thanks to Dr. Yorihiro Satomi of National Chemical Laboratory for Industry for his guidance regarding the employment of the Mettler fusion-point apparatus.

An Application of $H_{0,max}$ for Estimating the Catalytic Action of Solid Acids and Bases in the Isopropylation of *m*-Cresol

Tohr YAMANAKA

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received January 12, 1976)

A method of estimating the acid-base property of the active sites in terms of the correlation between the catalytic activities of various solids and their $H_{0,max}$ values is presented. The $H_{0,max}$ denotes an H_0 value of the strongest acidic sites and/or conjugate acids of the strongest basic sites. The types of catalytic actions over oxides, hydroxides, a sulfide, sulfates, phosphates, tungstates, and multi-component solid acids in the liquid-phase isopropylation of *m*-cresol without a solvent were classified into three groups: *via* a carbonium ion, *via* a carbanion, and concerted actions. The selectivity for the ortho-isopropylation over every catalyst increased with the increase of $H_{0,max}$, and this effect of $H_{0,max}$ was explained by the orientation of the adsorbed *m*-cresol on the catalyst surface.

It has been well known that a catalytic action changes continuously with the variation in the acid-base property of catalysts.[1,2] A quantitative description of the property with a universal parameter is required for reaction analysis, catalyst design, and developemtnt.[1] In liquid-phase reactions, the p*H* and acidity functions (*e.g.*, H_0 and H_- defined by Hammett *et al.*) have often been used as the parameters of homogeneous catalysts.[2] The electronegativities of metal ions[1] and effective negative charges on combined oxygens[1] have sometimes been used as the parameters of solid catalysts, but they are insensitive to the surface structure.[3]

As a measure of the acidic property of solid acid catalysts, "the highest acid strength" on the H_0 scale has been used in correlations with the catalytic activity and the selectivity for estimating catalytic actions.[4] Recently, the present authors reported a new titration method[5] of the acid-base strength distribution on the common H_0 scale, where the H_0 of the basic sites denotes the ability of proton donation of the conjugate acids. On the acid-base strength distributions of various solids, an H_0 value (termed $H_{0,max}$) which indicates the H_0 value of the strongest acidic sites and/or the strongest basic sites was found. The $H_{0,max}$ of acidic sites has essentially the same value as the highest H_0 value. The acidic sites of $H_0 \geq H_{0,max}$ and the basic sites of $H_0 \leq H_{0,max}$ coexisted on the same solid surface where both sites were measured. Therefore, the role of $H_{0,max}$ as a parameter indicating a basic property as well as an acidic property on a common H_0 scale is noticeable.

On the other hand, the author and others[6] have been studying the development of solid catalysts in the liquid-phase isopropylation of *m*-cresol (I) with propylene, in order to prepare thymol (II), an important starting material for menthol. The isopropylation involved the multiple formation of the nuclear-substituted products and their ethers. It could not be estimated, on the basis of the literature,[7] whether and how the catalytic activity and the selectivity for the *ortho*-isopropylation of the OH group in I varied with the surface properties of the catalysts. In the vapor phase,[8] a few kinds of solids were investigated, but the results did not provide a guide for the catalyst development.

In this paper, $H_{0,max}$ will be presented as a useful parameter for estimating the acid-base property of the active sites and the catalytic actions over a solid acid, base, and acid-base bifunctional catalysts.

An Approach to Estimate Catalytic Actions

The catalytic activities of solid acid-base catalysts were schematically correlated with their $H_{0,max}$ values as is illustrated in Fig. 1 in the following semiquantitative approach. In the R+R'H→R″ reaction, where the order of the acid strength of the reactants is R'H> R and where the order of base strength is R>R'H, the catalytic action is expected to involve the formation of one or two activated species, *i.e.*, a carbonium ion (RH^+), a carbanion (R'^-), or coordination complexes (R_p and $R'H_p$) which are formed by acidic (A) and/or basic site (B).[9] R_p and $R'H_p$ represent

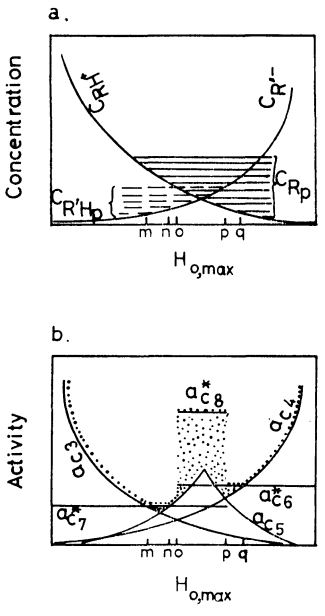

Fig. 1. An illustration for the concentration of activated species (C) and catalytic activities (a_c) *vs.* $H_{0,max}$. a^*_c denotes the maximum value of a_c when $H_{0,A}=H_{0,max}$ and/or $H_{0,B}=H_{0,max}$. The numerical subscribed to an a_c denotes the elementary step *via* which the reaction is catalyzed. The dotted curves and regions represent the overall a_c value to be observed.

a kind of activated complex, $\{B^{+\delta}\rightarrow R^{-\delta}\cdots H^{+}\cdots A'^{-}\}$ and $\{B\cdots H^{+}\cdots R'^{+\delta-1}\rightarrow A^{-\delta}\}$. H'A denotes an acidic site (A) of the Brønsted type.

When the reaction proceeds *via* RH^+ and/or R'^-, the strongest sites on the catalyst surface will be most effective in activating each reactant. At a low coverage of acidic and/or basic sites, the H_0 value of the strongest acidic or basic sites, $H_{0,max}$, will affect the catalytic action more strongly than the site amounts of various strengths.

Then ratios of an activated ionic specie to reactant in an equilibrium may be expressed as:[2c]

$$\log (C_{RH^+}/C_R) = \alpha - H_{0,max};$$
$$\alpha = pK_{RH^+} - \log (f_Z f_{RH^+}/f_{ZH^+} f_R) \quad (1)$$
$$\log (C_{R'^-}/C_{R'H}) = H_{0,max} - \beta;$$
$$\beta = pK_{R'H} - \log (f_Z f_{R'H}/f_{ZH^+} f_{R'^-}) \quad (2)$$

where C, f, and K denote a concentration, an activity coefficient, and an ion dissociation constant defined by the suffix, and where $H_{0,max}$ corresponds to the strongest ability of the proton donation of acidic sites or that of the conjugate acids of basic sites to Z.[5,10] Z represents the indicator base for the titration. C_R and $C_{R'H}$ are regarded as the concentrations of R and R'H in a phase in contact with the surface of physically adsorbed on the surface. The correlation between C_{RH^+} or $C_{R'^-}$ and $H_{0,max}$ in a given reaction medium is illustrated in Fig. 1-a.

In a concerted action, proton or electron transfer between a reactant and active sites will be partial or imperfect. The strength of the individual action of active sites will go in parallel with their acid or base strengths.[3] Therefore, the strongest acidic or basic sites and the basic or acidic sites adjacent to them will be most effective in activating each reactant. It can be postulated as the first approximation that the functions of the strengths of active sites against (C_{R_p}/C_R) or $(C_{R'H_p}/C_{R'H})$ are expressed by $\{(\alpha'-H_{0,max})+(H_{0,B}-\beta')\}$, $\{(\alpha'-H_{0,A})+(H_{0,max}-\beta')\}$, $\{(\alpha''-H_{0,max})+(H_{0,B}-\beta'')\}$, and $\{(\alpha''-H_{0,A})+(H_{0,max}-\beta'')\}$, analogously to Eqs. 1 and 2. Here, $H_{0,A}$ and $H_{0,B}$ denote the H_0 value of the acidic or basic sites which are adjacent to the strongest basic or acidic sites respectively. That is, the arrangement of sites with various H_0 values plays an important role, as does the $H_{0,max}$ value.[9] Provided that α', β', α'', and β'' are independent of $H_{0,max}$, C_{R_p} and $C_{R'H_p}$ are functions of $(H_{0,B}-H_{0,max})$ or $(H_{0,max}-H_{0,A})$. Because of $H_{0,B}\leq H_{0,max}$ and $H_{0,A}\geq H_{0,max}$, C_{R_p} and $C_{R'H_p}$ have their maximum values, independent of $H_{0,max}$, when $H_{0,B}=H_{0,max}$ and $H_{0,A}=H_{0,max}$. This corresponds to the case when the extreme surface where the acidic sites and the basic sites having $H_0=H_{0,max}$ are adjacent to each other. In Fig. 1-a, C_{R_p} and $C_{R'H_p}$ are illustrated as horizontal curves, which vary with the arrangement of sites. Here, the formation of R_p or $R'H_p$ can be expected only when C_{R_p} or $C_{R'H_p}$ is greater than C_{RH^+} or $C_{R'^-}$ respectively.

The activated species over active sites will participate in the following elementary steps:

$$RH^+ + R'H \ (3); \quad R + R'^- \ (4); \quad RH^+ + R'^- \ (5);$$
$$R_p + R'H \ (6); \quad R + R'H_p \ (7); \quad R_p + R'H_p \ (8)$$

In the steps involving a single activated specie (Eqs. 3, 4, 6, and 7), the rates are proportional to the concentration of the corresponding specie. In the steps involving two activated species (Eqs. 5 and 8), the rates are not always proportional to their concentrations, but depend predominantly on the second power of the minor activated specie. The catalytic activities (a_c's) of solids *via* each elementary step involving the formation of activated species in Fig. 1-a are illustrated in Fig. 1-b. Among Steps (3) to (8), the catalytic action of a solid with an $H_{0,max}$ value involves the step which contributes to the highest a_c value. Then, the overall a_c throughout the $H_{0,max}$ values illustrated by the dotted curve and the dotted regions in Fig. 1-b. The overall a_c means the a_c value observed experimentally.

The shape of the overall a_c curve and region depends on the acid-base properties and structures of the reactants concerned; especially, C_{R_p} or $C_{R'H_p}$ will increase if the reactant possesses a functional group which accepts the push-pull action of the active sites.[9] It may be remarked that the bump and fall of the overall a_c curve reflects well the change in the predominant catalytic action at $H_{0,max}=m$, n, or o, and at p or q on the abscissa. Therefore, the acid-base properties of the active sites and their catalytic actions can be estimated in terms of the correlation between a_c and $H_{0,max}$ over various catalysts ranging widely in $H_{0,max}$ values.

The correlations in Fig. 1 are similar to those in a homogeneous catalyst system,[2a] but somewhat different because of the effects of the "surface heterogeneity"[11] and the reduced freedom of an adsorbent, so that it reacts only with another species in its vicinity.

Results and Discussion

The formulae of the products and *m*-cresol (I) are shown in Fig. 2. The H_0 values of the strongest acidic sites ($\{H_{0,max}\}_A$) and the conjugate acids of the strongest basic sites ($\{H_{0,max}\}_B$) of catalysts and the compositions of the reaction mixtures are summarized in Table 1. Here, the catalysts are identified by the numerals used in the Experimental section. The values of $\{H_{0,max}\}_A$ and $\{H_{0,max}\}_B$ were the same when both of them were obtained. The $\{H_{0,max}\}_B$ values of CaO, $Ca(OH)_2$, and MgO were all greater than 6.8, although they could not be determined exactly because of the formation of a precipitate during basicity measurements.[5] Both $\{H_{0,max}\}_A$ and $\{H_{0,max}\}_B$ will be used below as the $H_{0,max}$ value of a catalyst. γ-Al_2O_3 is sometimes regarded as acidic,[8] but no acidity of $H_0\leq 6.8$ was observed on γ-Al_2O_3 in this study. Some of the reaction mixture contained resin, but the resin content was not more than 5 mol% at the conversion of I=90 mol% and so was ignored in this study. CaO gave *ortho*-isopropylated products exclusively.[6]

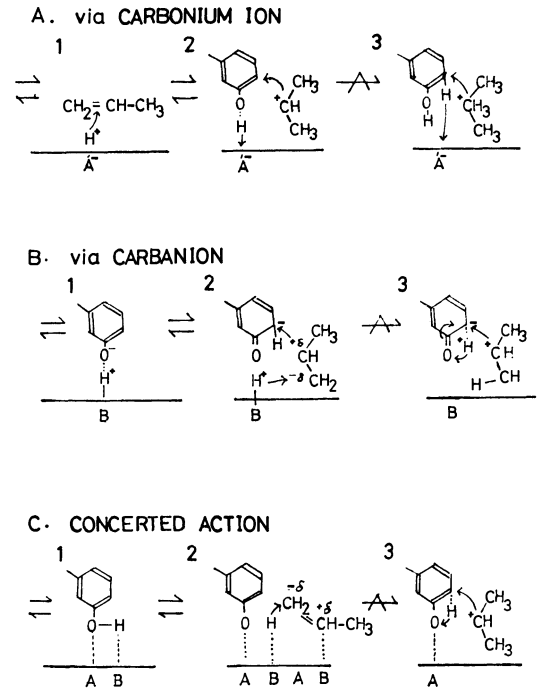
Apparent a_c vs. $H_{0,max}$ Plots and Catalytic Actions. An apparent a_c was obtained as a total conversion of I (mole fraction) at a constant time and temperature. In Fig. 3, the conversions are plotted against the $H_{0,max}$ values in the −5.6—+15 range. *m*-Cresol is a stronger acid ($pK_a \fallingdotseq 10$) than propylene ($pK_a \fallingdotseq 35$[12]). Therefore, catalytic actions *via* the isopropyl cation, the *m*-toluenide anion, or coordinated species of I and/or propylene were expected. The curves through the apparent a_c's in Fig. 3 indicate a bump-and-fall profile similar to the overall a_c curve in Fig. 1. The catalysts may be classified into three groups in terms of the $H_{0,max}$ value: ≤2 (Group 1), 4—8 (Group 2), and ≥10 (Group 3).

In Fig. 3, the a_c in Group 1 increases monotonously with the decrease in $H_{0,max}$ values. The catalytic action corresponds to Eq. 3, and can be explained by Scheme A.[8,13] The isopropyl cation must be formed by the acidic sites of $H_0 \leq 2$. A'^- is more strongly basic than the original basic sites on the surface; the H_0 of the original basic sites is less than $H_{0,max}$. Provided that the reaction occurs on a solid surface, the adsorption of I on A'^- is probable.

The a_c in Group 3 is regarded as increasing monotonously with $H_{0,max}$. This corresponds to Eq. 4. Therefore, the catalytic action must proceed *via* the carbanion, as is shown in Scheme B. Over the basic sites of $H_0 \geq 10$, the abstraction of a proton from the OH group of I occurs easily in Step 1. Hence, *m*-toluenide anions are formed.

In Fig. 3, the plots of Group 2 are raised to various heights above the extension from the conversion-$H_{0,max}$ curves of Groups 1 and 3. The a_c's of Group 2 correspond to a_{c5}, a_{c6}, a_{c7}, or a_{c8}, and the catalytic action of Eq. 5, 6, 7, or 8 is estimated. Provided that *m*-cresol and/or propylene can accept a concerted action, the variations among the a_c's of Group 2 can be explained in terms of their dependence on the arrangement of sites on the surface. This arrangement will be most suitable for concerted actions over γ-Al_2O_3 (No. 13), while it will be most inadequate over the catalysts plotted at the bottom in Group 2 (21, 22, and 15). The most effective catalytic action on the overall a_c of catalysts corresponds to Eq. 8.

On the solid surfaces in Group 2, acidic and basic sites of moderate strength coexist. Compared with Group 1 or 3, the acidic sites in Group 2 are too weak to protonate propylene or to abstract a proton from the OH group of I. Therefore, concerted actions may be postulated as Scheme C. On the surface of a metal oxide, I will be adsorbed by leaving a proton on an oxygen anion (B) and by forming a *m*-tolyloxide with the adjacent metal ion (A). This corresponds to the adsorption model of phenol on MgO[14] and may be comparable to the phenoxide formation on γ-Al_2O_3.[15] It should be noted that the smaller the H_0 of conjugate acidic sites (BH^+), the more easily isopropyl cations are formed. In Scheme C, it is assumed that isopropyl cations are formed by the proton from the OH group of I. As supporting evidence, isopropyl *m*-tolyl ether (I_e) was not isopropylated over CaO under the same conditions as in the isopropylation of I.



Effects of $H_{0,max}$ on the Selectivity. In order to compare it with the *para*-isopropylation, the selectivity for the *ortho*-isopropylation (ϕ) was defined as follows:

$$\phi = \frac{\text{total } \textit{ortho}\text{-isopropylated products}}{\text{total isopropylated products except } I_e}$$

where one-half of the *ortho-para*-isopropylated products (V and V_e) were considered the ortho-isopropylated products.

In Fig. 4, the ϕ's are plotted against the $H_{0,max}$ values by using the data at the conversion of $I \geq 0.2$. At a conversion of less than 0.2, the trace of the para-isopropylated products could not be detected with sufficient accuracy. ϕ increases roughly with the $H_{0,max}$ values. An increase in $H_{0,max}$ means an increase in the strength of the basic sites and a decrease in the strength of the acidic sites. Therefore, it can be interpreted in terms of the orientation of I adsorbed on the surface. The electrostatic repulsion between

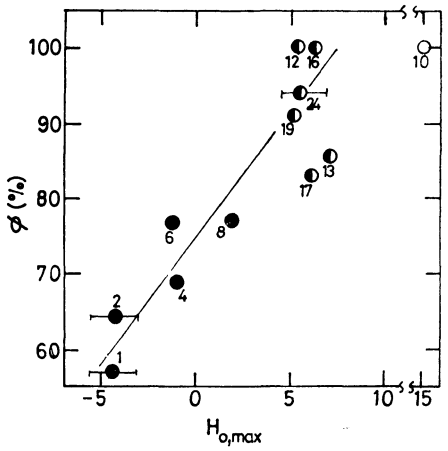

Fig. 4. Correlation between ϕ and $H_{0,max}$ at the same reaction condition to Fig. 3. Catalysts are characterized by the same marks as used in Fig. 3.

π-electrons of the benzene ring of I and the surface will increase with an increase in the base strength (the ability of electron donation) of the surface, that is, with an increase in the $H_{0,max}$ value. The distance of the *para*-position is further from the surface than the *ortho*-position. Consequently, ϕ increases with $H_{0,max}$. The same interpretation has been presented in the methylation of phenol with methanol, for the *ortho*-selectivities over solid acids are lower than those over solid bases,[14,16] even though the interpretation in the literature is merely qualitative.

The $H_{0,max}$ may, therefore, be considered a parameter to represent the surface acid-base property quantitatively. Apart from catalytic actions, $H_{0,max}$ as a surface property of solid will be discussed elsewhere.[17]

Experimental

Catalysts. The following commercial available solids were ground and sieved to prepare a powder of 100—200 mesh. Oxides: WO_3 (6), Sb_2O_3 (7), BaO (10), γ-Al_2O_3 (13, Nikki Chemicals Co., Ltd.), ZnO (16), Bi_2O_3 (17), B_2O_3 (20), TiO_2 (22), ThO_2 (24), CaO (25), and MgO (27). Hydroxides: $Ba(OH)_2$ (15) and $Ca(OH)_2$ (26). A sulfide: ZnS (12). Sulfates: $Al_2(SO_4)_3$ (4) and $NiSO_4 \cdot 7H_2O$ (8). Phosphates: $AlPO_4$ (18) and $Zn_3(PO_4)_2 \cdot 4H_2O$ (19). Tungstates: $Na_2WO_4 \cdot 2H_2O$ (11), $CaWO_4$ (21) and $MgWO_4$ (23). Others: Silica-Alumina-L (1, Nikki Chemicals Co., Ltd.) and Japanese acid clay (2, Wako Pure Chemicals Ind., Ltd.). The numerals in parentheses indicate the corresponding solids. The solids without proviso were of a guaranteed reagent grade. Prior to grinding, $NiSO_4 \cdot 7H_2O$ and CaO were calcined at 300 °C for 4 h in a dry N_2 stream. The solids were stored in glass bottles in the same way as were the commercial reagent used in this study. No particular caution was taken to exclude the adsorption of a trace of moisture in the atmosphere.

Acid-Base Strength Distribution and $H_{0,max}$. A new titration method[5] was used for the determination of acid-base strength distributions of the solids, which expressed in the distribution curves. The values of $\{H_{0,max}\}_A$ and

$\{H_{0,max}\}_B$ were obtained as the H_0 value at the intersection of the acid or base strength distribution curve and the abscissa indicating acidity=0 or basicity=0 respectively.[17] The $\{H_{0,max}\}_A$ value was obtained when it was less than 6.8. The $\{H_{0,max}\}_B$ value was obtained when it was greater than 1.5.

Isopropylation and Analysis of Reaction Products. Desired amounts of I (of a guaranteed reagent grade) and of a catalyst were weighed into an autoclave of a 100-ml capacity equipped with a magnetic stirrer and with gas inlet-outlet pipes. Displacing the air with dry N_2 gas, the apparatus was cooled to −60 °C. The liquid propylene was measured volumetrically as it passed into the autoclave through one of the pipes. The initial mole ratio of propylene to I was 3.0. The amount of the catalyst was 15 wt% against I. The apparatus was heated at 300 °C for 4 h and then cooled to room temperature. After the unreacted propylene had been released, the reaction mixture was dissolved with ether. The ether solution was washed with water, dried over Na_2SO_4, and concentrated. Then the reaction mixture was analyzed by means of a gas chromatograph, using a Kotaki Model GU-21A apparatus on a 2 m×5 mm ϕ column packed with 20 wt% of silicone oil (D.C. 200) on Celite-545 (60—80 mesh). The column temperature was 165 °C, and He gas was used as the carrier at 1.2 kg/cm^2. Isopropyl benzoate was used as the internal standard. Some of the reaction mixture was fractionated into components by means of a modified fractional gas chromatograph, and each of them was identified by means of its infrared absorption spectrum in a Nujol mull.

The measurement of the acid-base strength distribution and that of the isopropylation were done at the same time.

The author wishes to thank Mr. Fumio Nakata for his helpful assistance in the experiments, and also the Takasago Perfumery Co., Ltd., for its permission to publish this article.

Catalytic Properties of Metal Sulfates Supported on γ-Al_2O_3 in the Liquid-Phase Isopropylation of *m*-Cresol with Propylene

Tohr YAMANAKA

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received May 1, 1976)

γ-Al_2O_3 was impregnated with various metal sulfates, calcined, and used as catalysts in the liquid-phase isopropylation of *m*-cresol at 250—300 °C, with the propylene pressure in the range from 15 to 79 kg/cm². The catalytic activities of the sulfates were in the order: $Al_2(SO_4)_3 > ZnSO_4 \approx NiSO_4 > FeSO_4 > CuSO_4 > Li_2SO_4 \approx$ none $\approx CaSO_4 > Na_2SO_4$. The order of the selectivity ϕ for *ortho*-isopropylation over *para*-isopropylation was opposite to that of the catalytic activity. $FeSO_4/Al_2O_3$ catalysts resulted in the best ϕ value and fairly high activity, which were independent of the calcination temperature over the range of 300—500 °C. The formation of Brønsted acidic sites with $1 \leq H_0 \leq 3$ as catalytically-active sites was estimated for the $FeSO_4/Al_2O_3$ and $ZnSO_4/Al_2O_3$ catalysts.

In the past few years,[1] the present authors have studied the use of solid catalysts in the liquid-phase isopropylation of *m*-cresol (I) with propylene (IV) for the preparation of thymol (II), which is an important starting material for menthol. Solid acids, such as silica–alumina and $Al_2(SO_4)_3$, showed high catalytic activity, but the selectivity for *ortho*-isopropylation (ϕ) was not high enough to suppress the formation of 4-isopropyl-5-methylphenol (III) to within the industrial requirements. On the other hand, γ-Al_2O_3 and solid bases such as CaO showed high ϕ values, but were of insufficient catalytic activity.[1b] When some metal sulfates were supported on γ-Al_2O_3, the resultant solids were found to catalyze the reaction with high efficiency and a high ϕ value.[1a] Yet, little has been studied of their catalytic actions. Later, some interesting results were presented on the catalytic activity of supported metal sulfates (on γ-Al_2O_3 and SiO_2) in the vapor phase isopropylation of I with IV.[2a] In this case, the distribution of products other than thymol was different from that in the liquid-phase isopropylation, and therefore, these results are not helpful in the estimation of the catalytic action in the liquid phase.

In this paper, the catalytic properties of various metal sulfates supported on γ-Al_2O_3 are reported for liquid-phase isopropylation, and compared with the recent investigations on the properties of supported sulfates.[2-6]

Experimental

Preparative Procedure of the Catalysts (A). The desired amount of a metal sulfate was dissolved in distilled water, and 75 g of γ-Al_2O_3 (Nikki Chemicals Co., Ltd.; BET surface area: 205 m²/g) of 100—200 mesh was added to the solution. Na_2SO_4, $Li_2SO_4 \cdot H_2O$, $CaSO_4 \cdot 1/2H_2O$, $ZnSO_4 \cdot H_2O$, $CuSO_4$, $Al_2(SO_4)_3$, $FeSO_4 \cdot 7H_2O$, and $NiSO_4 \cdot 7H_2O$ of guaranteed reagent grade were used. The weight of the dissolved sulfate in the anhydrous state was 25 g. After standing for 15—16 h, the impregnated solid was filtered, and washed with 200 ml of distilled water 3 times. The resultant solid was evaporated to dryness on a water bath, and calcined at 500 °C for 4 h. No particular attention was paid to exclude traces of moistures.

Preparative Procedure of the Catalysts (B). Before filtration in the above procedure, the suspension of the impregnated solid in the sulfate solution was concentrated, evaporated to dryness and calcined. In this case, the impregnated amount of the sulfate was expressed in wt% based on the weight of the dissolved sulfate in the anhydrous state against the resultant catalyst.

Surface Acidity of the Catalysts. The acid-base strength distribution of the catalysts were measured by a titration method.[7]

Analysis of $FeSO_4/Al_2O_3$ Catalysts. 0.5 g of the catalyst was dissolved in 25 ml of H_3PO_4 and 10 ml of 33 wt% H_2SO_4 by heating in a CO_2 stream. The iron(II) content was determined by titrating the solution with $KMnO_4$ at room temperature.[8a]

The iron(II) in an extract of the catalyst with dil. HCl was oxidized into iron(III) by HNO_3.[9] The total iron content was determined by titration in the presence of a Variamine Blue B Base which was used as an indicator.[10]

The SO_4^{2-} content in the HCl extract was determined based on the amount of $BaSO_4$ precipitate which had been separated using an ordinary procedure.[8b]

Reaction Procedure (A). The isopropylation of I with IV was carried out in the liquid phase without solvents in an autoclave of 100 ml volume. The IV pressure (P) was maintained constant with the incremental addition of IV. The amount of catalyst (W) was 15 wt% with respect to the initial amount of I.

Reaction Procedure (B). The liquid-phase isopropylation of I was also carried out without the incremental addition of IV. The initial mole ratio IV/I was 3.0. W was 5 or 15 wt% with respect to the initial amount of I.

Products Analysis. After the desired reaction period, the autoclave was cooled rapidly to room temperature in a cold water stream. After the unreacted IV had been released, the reaction mixture was dissolved in ether. The ether solution was washed with water, dried over Na_2SO_4 and concentrated.

Then the reaction mixture was analyzed using gas chromatography, with a Kotaki Model GU-21A on a 2 m × 5 mmϕ column packed with 20 wt% of silicone oil (D.C. 200) on Celite-545 (60—80 mesh). The column temperature was 165 °C, and He was used as the carrier at 1.2 kg/cm². Some of the reaction mixture were fractionated into components by a modified fractional gas chromatograph, and each component was identified by the IR absorption spectrum in a Nujol mull.

Results and Discussion

The products of the isopropylation were thymol (II; main product), 4-isopropyl-5-methylphenol (III), 2,6-diisopropyl-5-methylphenol, 2,4-diisopropyl-5-methyl-

Following Procedure B, $P_{at\ \theta=0}$ was 65 kg/cm² at 250 °C and 79 kg/cm² at 300 °C. d) The S value of $Fe_2(SO_4)_3$ was 4.49.

phenol, a small amount of isopropyl *m*-tolyl ether (I_e), and also a small amount of the isopropyl ethers of the products. No 6-isopropyl-5-methylphenol, 3-isopropyl-5-methylphenol, or isothymol were found as products. The kinds and distributions of the by-products are obviously different from those resulting from vapor-phase isopropylation.[2]

The catalytic properties of the supported catalysts are presented in Tables 1 and 2, where t, P, θ, x, ϕ, and S respectively denote the reaction temperature, pressure of IV, reaction time, conversion of I, selectivity for *ortho*-isopropylation, and electronegativity of the sulfate supported or of Al_2O_3. ϕ was defined as the ratio, $100 \times$ {total *ortho*-isopropylated products}/{total isopropylated products excepting I_e}. The catalytic activities were compared to each other in terms of x, θ, or t. The impregnated amount of a sulfate due to Procedure A was estimated to be less than 10 wt%. The amount of $FeSO_4$ impregnated using Procedure A varied from 3 to 8 wt%, which was determined from the Fe content of the $FeSO_4/Al_2O_3$ catalysts in a series of preparative runs. The values of S were calculated on a relative compactness scale in terms of the Sanderson method.[11]

Catalytic Activity. From Table 1, the activities of catalysts prepared by Procedure B appear to have maximum values for an impregnated amount of *ca.* 20 wt%. It can be deduced from Table 2 that the effect of the sulfate on the activity of the catalysts follows the order: $Al_2(SO_4)_3 > ZnSO_4 \approx NiSO_4 > FeSO_4 > CuSO_4 > Li_2SO_4 \approx$ none $\approx CaSO_4 > Na_2SO_4$.
It is noted that this order holds for both catalysts prepared following Procedure B with 20 wt%-impregnation, as well as those following Procedure A.

Moreover, this is consistent with the order of activities of catalysts supported with various sulfates and calcined at arbitrary temperatures in reaction involving the protonation of olefins, namely, $Al_2(SO_4)_3 > NiSO_4 > BeSO_4 > Li_2SO_4 >$ none over SiO_2 and $Al_2(SO_4)_3 > BeSO_4 > NiSO_4 > MgSO_4 >$ none $> Li_2SO_4 \approx Na_2SO_4$ over γ-Al_2O_3 in the vapor-phase isopropylation of *m*-cresol with propylene,[2a] $MnSO_4 > ZnSO_4 > Cr_2(SO_4)_3 >$

$CuSO_4$>none over silica–alumina in the vapor-phase ethylation of benzene with ethylene,[5] and $Al_2(SO_4)_3$>$ZnSO_4$>$MnSO_4$>K_2SO_4 over silica gel in the vapor-phase hydration of propylene.[4]

Whereas the catalytic activities of unsupported sulfates are sensitive to the preparative conditions such as the calcination temperature,[12] it will be remarked that these orders are almost the same. In these studies, catalytic actions are estimated to involve the protonation of propylene or ethylene,[3-5] and the sulfates are estimated to affect the catalytic activities as a source of acidic sites of the Brønsted type.[2-5] It follows that the relative catalytic activity of the supported catalyst depends on the intrinsic properties of the sulfates.[6] The electronegativity S represents the power of individual atoms in a molecule to attract electrons. Therefore, the acid strength of the molecule can be expressed, to a first approximation, by the value of S: the greater S, the stronger the electron accepting power.[11] Table 2 shows that the order of the activities of supported catalysts or γ-Al_2O_3 is much the same as the order of the S values. The catalytic activity of the supported catalyst appears to depend predominantly on the acid strength of the sulfate.

It will be deduced from Table 2 that only sulfates having the S values greater than that of γ-Al_2O_3 are effective in improving the catalytic activity of γ-Al_2O_3 by the support.

Selectivity. In Table 2, the order of selectivities ϕ is just the opposite to that of the activities, namely, the greater the S of the sulfate, the lower the ϕ of the supported catalyst. The ϕ of a catalyst does not vary with x or θ. This is interpreted as follows.

Phenols have been known to be adsorbed *via* their OH groups, on basic sites of a catalyst.[2,13] No acidic site with $H_0 \leq 6.8$ but basic sites whose conjugate acids had H_0 values less than 7 were observed on γ-Al_2O_3 used as the carrier.[7] Over the supported catalysts, *m*-cresol (I) was adsorbed either on the basic sites of γ-Al_2O_3 when they are exposed, or on the basic sites of the supported sulfate when the sulfate covered the entire surface of γ-Al_2O_3. (Even if the surface possesses strong acidic sites, the coexistence of weak basic sites is reasonable.[14]) Isopropylation occurs between the isopropyl cations formed on the Brønsted acidic sites[5] and the I adsorbed on the basic sites.[2] When the vicinity of the basic sites is strongly acidic, the aromatic ring of I orients itself coplanar to the surface because of the interaction between π-electrons and the surface. On the other hand, when the vicinity of the basic sites is basic, the aromatic ring is tilted upward such that the para position is farther from the surface than the ortho position because of the electrostatic repulsion between the π-electrons and the surface.[13,15] Then, the attack of the isopropyl cation from the surface to the para position is retarded by means of resistance to the transfer of the cation or by means of reduced entropy change. Thus, ϕ increases for a decrease in the acid strength in the vicinity of the basic sites according to a similar scheme as has often been remarked for selectivity in the alkylation of phenols.[15]

Because the acid strength of the surface is predominantly affected by the acid strength of the sulfate,[3] the order of ϕ can be interpreted from the above discussion. In confirmation, the present author found that the apparent activation energy about the rate constant (first order with respect to I) in the formation of 4-isopropyl-5-methylphenol was lower by *ca.* 16 kcal/mol than the formation of thymol. In addition, the higher ϕ value of the catalysts prepared following Procedure A than those prepared by Procedure B in Table 2 are interpreted as being due to the basicity of the exposed γ-Al_2O_3.

It was pointed out by Nitta *et al.*[2a] that the selectivity of thymol formation did not depend on the kind of sulfate supported on γ-Al_2O_3 in the vapor phase isopropylation of I. It should be noted that their definition of the selectivity is quite different from ϕ in the present report and does not indicate the effect of the relative reactivities at the *ortho* and *para* positions.

$FeSO_4/Al_2O_3$ Catalyst. From Table 2, the catalyst impregnated with $FeSO_4$ (labelled the "$FeSO_4$/Al_2O_3 catalyst") will be distinguished from other catalysts in respect of its excellent ϕ value and fairly high catalytic activity, The selectivity of thymol over the catalyst was as high as 74—86 mol% of the total products in the reactions presented in Table 2 and in Fig 3. When heated in the atmosphere, hydrated $FeSO_4$ is known to convert into $Fe_2(SO_4)_3$, $(Fe_2O_3)_n \cdot (SO_3)_m$ (basic iron sulfates), or Fe_2O_3.[15] Most of the Fe was found to be Fe(III) and the ratio, {SO_3 and/or SO_4^{-2}}/Fe(III), was found to be 0.8—1.1 upon analysis of the catalyst prepared by Procedure A. The necessity of SO_3 or SO_4^{2-} for the catalytic action was supported by the fact that a catalyst impregnated with $Fe(OH)_3$ instead of $FeSO_4$ was virtually inactive. Consequently, the $Fe_2O_3 \cdot (SO_3)_2$ or $\{Fe_2(SO_4)_3\}_2 \cdot Fe_2O_3$ was postulated to arise from the $FeSO_4$ participating in the catalytic action.

The catalytic activity and the selectivity ϕ were not affected by the calcination temperature to within 300—500 °C, as is shown in Fig. 1. These insensitivities satisfy the industrial requirements of stable catalytic

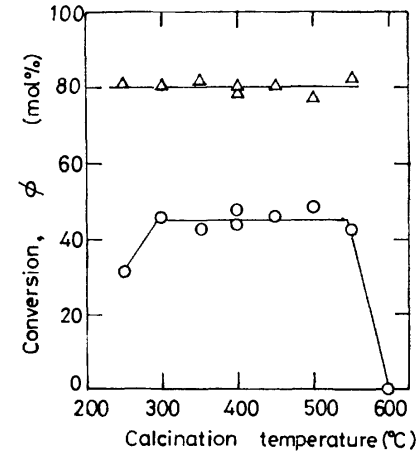

Fig. 1. Effects of calcination temperature on activity and ϕ of $FeSO_4/Al_2O_3$ catalysts prepared by Procedure B. γ-Al_2O_3 were impregnated with $FeSO_4$ by 25 wt% and calcined in air for 4 h. ○: Conversion, △: ϕ. Reaction Procedure B was employed at 260 °C, for 20 min, with W=5 wt%.

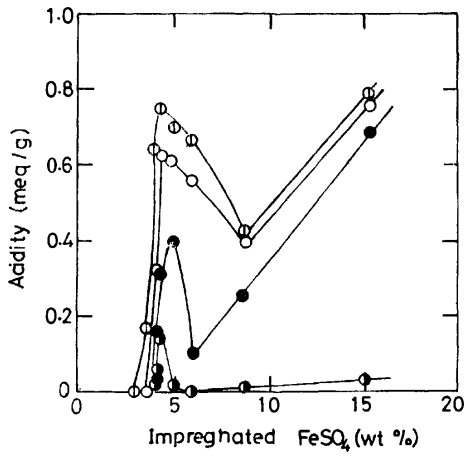

Fig. 2. Acidities of $FeSO_4/Al_2O_3$ catalysts prepared by Procedure A. ⊕, $H_0 \leq 4$; ○, $H_0 \leq 3.3$; ●, $H_0 \leq 1.5$; ◑, $H_0 \leq -3$.

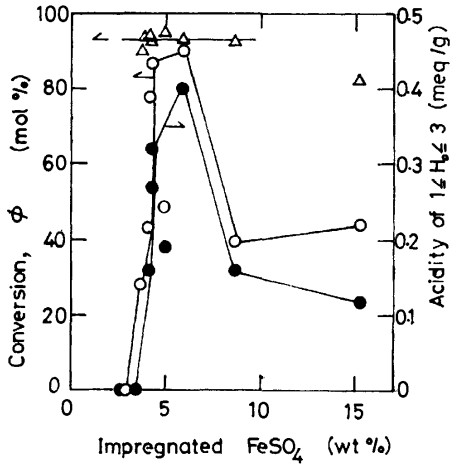

Fig. 3. Effects of impregnated amount on catalytic activity, ϕ, and the acidity of $1 \leq H_0 \leq 3$ over $FeSO_4/Al_2O_3$ catalyst prepared by Procedure A. Reaction Procedure A was employed at 260 °C, for 15 min, with $P = 15$ kg/cm^2. ○: Conversion, △: ϕ, ●: acidity of $1 \leq H_0 \leq 3$.

properties. It has been remarked that the acidic properties of metal sulfates are sensitive to the calcination temperature, and especially the strongest acidic sites on the surface can exist only for a particular calcination temperature with sufficient care being taken to exclude traces of moisture.[2-4,6] Therefore, catalytic activity greatly depends on the calcination temperature when the strongest acidic sites prevail in the catalytic action.[6]

Figure 1 suggests that the active acidic sites on $FeSO_4/Al_2O_3$ are not so strong. The acidities of the catalysts over various H_0 ranges are shown in Fig. 2. The catalyst impregnated with 15 wt% $FeSO_4$, presented in Figs. 2 and 3, was prepared following Procedure A without the washing process. In Fig. 3, the catalytic activity and the acidity for $1 \leq H_0 \leq 3$ indicate correlations exactly in parallel to the impregnated amount and have maximum values for an impregnated amount of about 6 wt%. (The acidities for $1 \leq H_0 \leq 3$ were determined from acid-strength distribution curves correlating the acidities, shown in Fig. 2, the H_0 values.) Then, acidic sites with $1 \leq H_0 \leq 3$ are postulated to be active in the present reaction and to arise most efficiently from $FeSO_4$ at an impregnated amount of about 6 wt%. The strength of the acidic sites will be affected by the interaction between γ-Al_2O_3 and the species arising from $FeSO_4$.

Provided that the acidic sites of a particular H_0 range arise from a particular surface structure, sites on γ-Al_2O_3, where $FeSO_4$ is adsorbed by impregnation and are converted into acidic sites with $1 \leq H_0 \leq 3$, are considered to be filled to an impregnated amount of about 6 wt%. Above this value, the surface of the γ-Al_2O_3 will be occupied by $FeSO_4$ in a scheme different from lower impregnated amounts, which reduces the exposed γ-Al_2O_3 on the surface in the vicinity of the individual adsorbed $FeSO_4$, where efficiency of the $FeSO_4$ for acidic sites, with $1 \leq H_0 \leq 3$ is lowered and instead the efficiency for acidic sites of other types is increased. The catalytic action of acidic sites with $1 \leq H_0 \leq 3$ are interpreted by their arrangement toward the basic sites of γ-Al_2O_3 in the most suitable structure so that isopropyl cations easily attack the adsorbed I. The constant high ϕ value for impregnated amounts less than 9 wt% in Fig. 3 is supported by the basic property of the exposed γ-Al_2O_3 in the vicinity of the acidic sites. While the lower ϕ value at an impregnated amount of about 15 wt% implies a higher coverage of γ-Al_2O_3.

If acidic sites with $1 \leq H_0 \leq 3$ protonate propylene as do the acidic sites over the supported sulfate catalysts,[2-4] they are Brønsted acidic sites.

It is suggested from Table 1 that the active acidic sites on the $ZnSO_4/Al_2O_3$ catalyst are of $1 \leq H_0 \leq 3$. Though, it cannot be deduced that strength of the active sites on the other catalysts in this study are the same, the stronger H_0 range of the sites may not be in contradiction when the sulfate of the stronger acidity, such as $Al_2(SO_4)_3$, is supported.

The author wishes to thank Nikki Chemicals Co., Ltd., for its support in the experimental analysis of the solids. In addition, he thanks Mr. Fumio Nakata for his helpful assistance in the experiments and also the Takasago Perfumery Co., Ltd., for its permission to publish this article.

Conductance of Some High Valence Type Electrolytes in Mixed Solvents. I. Conductance of Tris(1,10-phenanthroline)iron(II) Sulfate and Chloride in Water–Methanol Mixtures at 25 °C*

Eiji KUBOTA and Masatoki YOKOI

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received February 2, 1976)

The conductance of tris(1,10-phenanthroline)iron(II) sulfate, $Fe(phen)_3SO_4$, and chloride, $Fe(phen)_3Cl_2$, has been measured in water–methanol mixed solvent at 25 °C. The data of the sulfate could be explained by means of the Fuoss-Onsager equation (1957) and the Fuoss-Onsager-Skinner equation (1965) on the assumption that the salt is completely dissociated in the entire composition range of the solvent system. Application of the Fuoss-Hsia equation which contains a $c^{3/2}$ term gave association constants increasing from a value of $K_A=40$ in water to $K_A=3900$ in methanol. The $\log K_A$ *vs.* $1/D$ plot is in good agreement with ion association theoreies. The limiting equivalent conductance of $Fe(phen)_3^{2+}$ ion was estimated to be 34.3 in water and 62.3 in methanol.

The behavior of 1 : 1 electrolyte in various solvents has been investigated extensively by conductance measurements.[1] The extended Fuoss-Onsager theory[2] was applied satisfactorily to the analysis of the data, ion association being studied in low dielectric constant media. On the other hand, the investigation of the high valence type electrolyte solutions was often restricted to aqueous solutions because of the limited solubility of the electrolytes in organic solvents. *m*-Benzenedisulfonates of bivalent metals were studied in methanol[3] and some aqueous organic mixture solvents.[4] Tris(1,10-phenanthroline)iron(II) ion is a large bivalent cation, the salts having sufficient solubility in methanol. Thus conductance measurements of the salts in water–methanol mixtures were undertaken for the purpose of studying the change in ion association equilibrium with the variation of the composition of the solvent mixture.

Experimental

Materials. $Fe(phen)_3SO_4$ was prepared by adding a little excess amount of GR 1,10-phenanthroline to the aqueous iron(II) sulfate solution.[5] The solution was concentrated at below 60 °C and the sulfate was precipitated by addition of acetone. The precipitate was dissolved again in water, the procedure being repeated several times. The precipitate was finally crystallized from water and dried at room temperature.

$Fe(phen)_3Cl_2$ was prepared by adding sodium chloride to the aqueous solution of the sulfate and recrystallized from water.[5]

The water content of the sulfate and chloride dried in a dessicator containing silica gel or calcium chloride was not stoichiometric. The number of the water of crystallization was usually less than five. The total cation concentration of each stock solution ($\approx 10^{-2}$ M) was analyzed with Dowex 50-X2 ion exchange resin. The purity of the samples was further checked by spectrophotometry.

Solvents. Methanol was purified by distillation over the activated magnesium and aluminum amalgam.[6] It was then redistilled, the middle fraction being collected. The specific conductivity was less than 8×10^{-8} ohm^{-1} cm^{-1}. Conductivity water was obtained by passing distilled water through a mixed bed ion exchange resin. The specific conductivity was less than 3×10^{-7} ohm^{-1} cm^{-1}.

Apparatus and Measurement. A Jones-type bridge was used for the conductance measurement, alternative current of 3—10 kHz being applied to the bridge. The standard resistors had a precision of ±0.02% and the bridge showed a reproducibility of ±0.005%. Two flask type cells of cell constants of 0.14520 and 0.23322 cm^{-1} were used. The solutions were prepared by adding a certain quantity of the stock solution from a weighing burette to the solvent placed in the cell. Resistance values were obtained by extrapolation to infinite frequency. The temperature of the liquid paraffin bath was controlled to 25.000±0.005 °C. The viscosity B coefficients of $Fe(phen)_3SO_4$ in water and 100% methanol were measured with calibrated Cannon-Fenske type viscometers.

Results and Discussion

The observed conductance values are given in Tables 1 and 2 for the sulfate and the chloride, respectively.

The conductance data of the sulfate were analyzed first by the Fuoss-Onsager (1957)[2] and Fuoss-Onsager-Skinner (1965)[7] equations for symmetrical electrolytes. The form of the former equation for unassociated electrolytes[8] is

$$\Lambda = \Lambda_0 - Sc^{1/2} + Ec\log c + Jc \qquad (1)$$

where Λ_0 is the equivalent conductance at infinite dilution, c is the molar concentration, S is the Onsager slope. Coefficients S, E and J are dependent on temperature, dielectric constant D, viscosity η of the solvent, and Λ_0. J is also a function of ion size parameter $\mathring{a}$.

The conductance equation for associated electrolytes is

$$\Lambda = \Lambda_0 - Sc^{1/2}\gamma^{1/2} + Ec\gamma\log c\gamma + Jc\gamma - K_A c\gamma\Lambda f_\pm^2 \qquad (2)$$

where K_A is the association constant, $f_\pm$ is the mean activity coefficient, and γ is the degree of dissociation. The $f_\pm$'s were calculated by the extended Debye-Hückel theory[9] with the same ion size parameter $\mathring{a}$ as that in J.

In the case of electrolytes containing large ions, the Jc term is replaced by $(J-B\Lambda_0)c$, where B is the viscosity B coefficient of the electrolyte in the solution.

a) c, in M dm^{-3}; Λ, in ohm^{-1} cm^2 equiv.$^{-1}$. b) D, dielectric constant; η, viscosity(poise), Ref. 29.

The form of the equation (1965) for unassociated electrolytes is

$$\Lambda = \Lambda_0 - Sc^{1/2} + E'c\log(6E_1'c) + Lc \quad (3)$$

and for associated electrolytes

$$\Lambda = \Lambda_0 - Sc^{1/2}\gamma^{1/2} + E'c\gamma\log(6E_1'c\gamma) + Lc\gamma - K_Ac\gamma\Lambda f_\pm^2 \quad (4)$$

where L is a parameter depending on $\mathring{a}$.

Analysis was carried out according to the method of Fuoss[8] and Kay[10] applying both 1957 and 1965 theories to the observed $c-\Lambda$ data.

The conductance data of the chloride, 2 : 1 type unsymmetrical electrolyte, were analyzed using the Fuoss-Edelson technique,[11] based on the Onsager limiting theory. The second association to form the nonconducting species as $MA^+ + A^- \rightleftharpoons MA_2$ was assumed to be negligible, only the equilibrium $M^{2+} + A^- \rightleftharpoons MA^+$ being considered. It was also assumed that $\lambda_{MA^+} = 1/2\lambda_{M^{2+}}$. The Debye-Hückel limiting theory[12] was used for the calculation of the activity coefficient f_{2+}. Λ_0 and K_A are the adjustable parameters. They were determined finally by extrapolation.

a) Table 1, a) and b).

All the calculations were performed on FACOM 230-60, HITAC 8800/8700, and HITAC 10-II remote batch system computers[13] using the program in FORTRAN IV.[14]

The data of $Fe(phen)_3SO_4$ were fitted with both Eqs. 1 and 3 of complete dissociation over the entire range of the solvent composition. However, application of Eq. 2 or 4 for an associated electrolyte gave negative K_A values. The values of Λ_0 and $\mathring{a}$ ($\mathring{a}_J$ from Eq. 1 and $\mathring{a}_L$ from Eq. 3) obtained are summarized in Table 3, which also includes the values of $\sigma\Lambda$, the standard deviation, calculated by means of the expression

$$\sigma\Lambda = \left[\frac{\sum(\Lambda_{exp.}-\Lambda_{calcd})^2}{(N-3)}\right]^{1/2} \quad (5)$$

where N is the number of experimental points.

The $\mathring{a}_J$'s and $\mathring{a}_L$'s are about 7.0 Å. There seems to be no systematic change of the value with solvent composition. The viscosity correction was examined for the data of water and 100% methanol. The calculated parameters are also given in Table 3. The correction gave no noticeable change in the parameter values.

The ionic conductance data of $Fe(phen)_3Cl_2$ were analyzed by the Fuoss-Edelson technique and the Λ_0 and K_A values obtained are given in Table 4.

The conductance data of the sulfate could be inter-

preted by means of the conductance equation of complete dissociation in a solvent of a high methanol content. The association constants of *m*-benzenedisulfonates of vibalent metals were reported to be of the order of 10^4 in methanol at 25°C.[3,4] The ion association theories of Bjerrum,[15] Fuoss[16] and Yokoyama-Yamatera[17] predict fairly large values of association constant for 2 : 2 electrolyte in methanol. It seems to be difficult to explain why $Fe(phen)_3SO_4$ is completely dissociated in a low dielectric constant solvent such as aqueous methanol even though it contains a large ion.

The Fuoss-Onsager equation has been frequently used to represent the conductance of a hypothetical completely dissociated electrolyte. Within the last few years use of a more complete conductance equation according to Fuoss and Hsia[18] in the form of Fernandez-Prini,[19]

$$\Lambda = \Lambda_0 - Sc^{1/2} + Ec\log c + J_1c - J_2c^{3/2} \quad (6)$$

has been discussed in a number of publications.[20] Coefficient J_2 is also a function of $\mathring{a}$. The combination of equations,

$$K_A = (1-\gamma)/(c\gamma^2 f_\pm^2)$$

and

$$\Lambda = \gamma(\Lambda_0 - Sc^{1/2}\gamma^{1/2} + Ec\gamma\log c\gamma + J_1c\gamma - J_2c^{3/2}\gamma^{3/2}) \quad (7)$$

yields the following expression for associated electrolytes:

$$\Lambda = \Lambda_0 - Sc^{1/2}\gamma^{1/2} + Ec\gamma\log c\gamma + J_1c\gamma - J_2c^{3/2}\gamma^{3/2} - K_Ac\gamma\Lambda f_\pm^2 \quad (8)$$

where $f_\pm$ is calculated by Eq. 9[9] following the extended Debye-Hückel theory:

$$-\log f_\pm = \frac{Ac^{1/2}\gamma^{1/2}}{(1+B\mathring{a}c^{1/2}\gamma^{1/2})} \quad (9)$$

where A and B depend upon the solvent properties.[21]

The coefficients J_1 and J_2 in Eqs. 6 and 8 are

$$J_1 = \sigma_1\Lambda_0 + \sigma_2;\quad J_2 = \sigma_3\Lambda_0 + \sigma_4 \quad (10)$$

where

$$\sigma_1 = \frac{(\kappa\mathring{a}b)^2}{24c}\left[1.8147 + 2\ln\frac{\kappa\mathring{a}}{c^{1/2}} + \frac{2(2b^2+2b-1)}{b^3}\right] \quad (10a)$$

$$\sigma_2 = \alpha\beta + \frac{\beta\kappa\mathring{a}}{c^{1/2}} - \frac{\beta\kappa\mathring{a}b}{16c^{1/2}}\left[1.5337 + \frac{4}{3b} + 2\ln\frac{\kappa\mathring{a}}{c^{1/2}}\right] \quad (10b)$$

$$\sigma_3 = \frac{b^2(\kappa\mathring{a})^3}{24c^{3/2}}\left[0.6094 + \frac{4.4748}{b} + \frac{3.8284}{b^2}\right] \quad (10c)$$

$$\sigma_4 = \frac{\beta(\kappa\mathring{a}b)^2}{24c}\left[\frac{2(2b^2+2b-1)}{b^3} - 1.9384\right] + \frac{\alpha\beta\kappa\mathring{a}}{c^{1/2}} + \frac{\beta(\kappa\mathring{a})^2}{c} - \frac{\beta b(k\mathring{a})^2}{16c}\left[1.5405 + \frac{2.2761}{b}\right] - \frac{\beta^2\kappa\mathring{a}b}{16c^{1/2}\Lambda_0}\left[\frac{4}{3b} - 2.2194\right] \quad (10d)$$

In Eqs. 10a—10d, α and β are the relaxation and the electrophoretic coefficients, respectively, and b is Bjerrum's parameter given by $b=Z^2e^2/(\mathring{a}DkT)$.[22]

Application of Eq. 8 was examined for the data of sulfate for the entire solvent composition range. Yokoyama and Yamatera applied the Fuoss-Hsia equation to our conductance data[24] of the sulfate in water and reported $K_A=36$.[23]

Starting with preliminary values for Λ_0 and $\mathring{a}$ obtained from the Fuoss-Onsager equation, the corresponding parameters appearing in Eq. 8 were calculated by numerical computations.[14] The program,[13] operating essentially according to the method of Kay,[10] involved successive approximation of γ until $|\gamma_i-\gamma_{i-1}|\leqq 1\times10^{-6}$ and iterative determinations of Λ_0, K_A, and $\mathring{a}$ by solving equations of the form

$$\Delta\Lambda = \frac{\partial\Lambda}{\partial\Lambda_0}\Delta\Lambda_0 + \frac{\partial\Lambda}{\partial K_A}\Delta K_A + \frac{\partial\Lambda}{\partial\mathring{a}}\Delta\mathring{a} \quad (11)$$

for each experimental point. The calculations were discontinued when $\Delta\mathring{a}\leqq 1\times10^{-13}$ and finally the $\sigma\Lambda$ value was calculated by Eq. 5.

TABLE 5. CONDUCTANCE PARAMETERS FOR $Fe(phen)_3SO_4$ IN WATER-METHANOL AT 25 °C, CALCULATED FROM FUOSS-HSIA EQUATION IN THE FORM FERNANDEZ-PRINI[a)]

a) q, Bjerrum's distance (Å). b) With viscosity corrections; $B=1.9_3$ (0%); $B=3.7_8$ (100% Methanol).

Different combinations of the values for Λ_0, K_A, and $\mathring{a}$ may provide almost equally good fits of the conductance equation to the experimental data. In order to investigate the dependence of $\sigma\Lambda$ on $\mathring{a}$ calculations were repeated for a series of ionic separation $\mathring{a}$ between 5 and 30 Å with 0.05 Å increments.

The results are summarized in Table 5. The viscosity correction was examined for the data of water and 100% methanol. The correction made little effect on the parameter values as in the case of analysis by Eq. 1 or 3. The association was observed in the whole range of solvent composition. The $\sigma\Lambda$'s are slightly improved as compared with the values in Table 3. The Λ_0's are very close to those of Table 3 in the solvent of low methanol content, but larger than that obtained from the assumption of complete dissociation in pure methanol. The $\mathring{a}$ values change with the solvent composition, increasing from 12.9 Å in water to 25.5 Å in methanol. The variation of $\mathring{a}$ is parallel to that of the Bjerrum's critical distance q given by $q=Z^2e^2/(2DkT)$,[22)] which varies from 14.3 Å to 34.3 Å (Table 5). The results might be regarded to be in close accordance with the results of Justice[25)] and other authors,[26)] who set $\mathring{a}=q$ in the analysis of 1 : 1 type slightly associated electrolytes.

Log K_A is plotted against reciprocal of dielectric constant in Fig. 1. The ionic crystal radius sum of the complex sulfate is estimated to be about 10 Å. The K_A values are calculated from the ion association theories of Bjerrum, Fuoss and Yokoyama-Yamatera for contact distance of 10 Å and are also plotted in Fig. 1. The observed points start under the line of Yokoyama-Yamatera theory and cross the line, but they are all in the range between the prediction of the Bjerrum and Fuoss theories. The application of Fuoss-Hsia equation[18)] to the analysis of the present data seems to be more satisfactory, the results being consistent with the prediction of the ion association theories.

The limiting ionic conductance of the complex ion in water was estimated from the Λ_0 values by substructing $\lambda_{Cl^-}=76.35$[27)] for the chloride or $\lambda_{SO_4^{2-}}=80.0$[27)] for the sulfate. These values coincide with 34.3. In methanol, the ionic conductance of the complex ion is estimated from the Λ_0 of the chloride as 62.3 ($\lambda_{Cl^-}=52.4$[28)]). The ratio of λ^+ of the complex ion in water to that in methanol is close to the ratio for tetraethylammonium ion whose λ^+ is 32.6 in water[27)] and 60.5 in methanol.[28)] This resemblance would be due to a similar charge to radius ratio of both ions. The limiting ionic conductance of sulfate ion in methanol is about 44 if we use $\lambda^+=62.3$ from the Λ_0 in Table 5. The value should be further checked by the measurements of conductance and transference number for other sulfates in methanol.

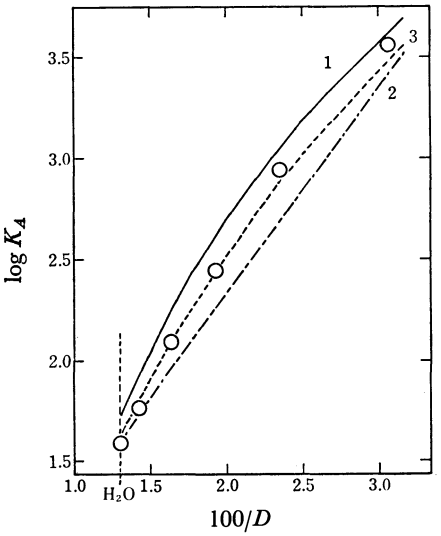

Fig. 1. Plots of log K_A *vs.* $1/D$.
○, Present work at 25 °C. Curves 1, 2, and 3 are theoretical curves due to Bjerrum (——), Fuoss (– – –) and Yokoyama-Yamtera's (– · – · –) theories with $\mathring{a}=10$ Å.

The authors wish to thank the staff of the Nagoya University Computation Center, Tokyo University Computation Center and Shinshu University Remote Batch Computation Center for the use of computers.

The Dual Fluorescence Nature of Some *N*-Monosubstituted Salicylamides

Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received March 10, 1976)

Dual fluorescence from *N*-methylsalicylamide (**1**) in alcoholic solutions was observed under excitation by 280 nm light, and was ascribed to two different molecular species: one with and the other without intramolecular proton transfer in the lowest excited singlet state. Some related compounds having two identical chromophores showed similar dual emission spectra with weak emission bands at shorter wavelengths. This fact was explained as being due to the intramolecular energy transfer between the two chromophores in the excited state. From the temperature dependence of the intensity ratio of the two emission bands for these compounds, the difference between the activation energies for the two emissive states was estimated.

In general, fluorescence of an aromatic molecule occurs only from the lowest excited singlet state and therefore, consists of a single band.[1] However, there are a few exceptional cases in which a molecular system having only one chromophore exhibits dual fluorescence: in the cases of (i) exciplex formation (ii) acid-base equilibrium in the excited state which greatly differs from that in the ground state, and (iii) anomalous dual emission in the case of *p*-dimethylaminobenzonitrile in polar solvents.[2,3]

In this paper, the author reports that *N*-methylsalicylamide (**1**) and some related derivatives show dual fluorescence in alcoholic solvents and single fluorescence in other solvents. The origin of this dual fluorescence and its behavior, especially a possible intramolecular energy transfer for the conversion of the emitting state, are discussed.

Experimental

N-Methylsalicylamide (**1**, mp 88 °C) and *N*-benzylsalicylamide (**2**, mp 134 °C) were prepared by the reaction of methyl salicylate with aqueous methylamine in methanol and with benzylamine, respectively. *N,N'*-disalicyloylethylenediamine (**3**, mp 182 °C), -trimethylenediamine (**4**, mp 180 °C), and -hexamethylenediamine (**5**, mp 141 °C) were prepared from methyl salicylate and appropriate diamines. The products were purified by recrystallization from ethanol.

Absorption and fluorescence spectra were recorded on a Hitachi Model 356 spectrophotometer and a Hitachi Model MPF-2 fluorescence spectrophotometer, respectively.

Temperature-dependent studies of the fluorescence spectra were carried out in a quartz dewar in which the temperature can be controlled to whitin ±0.2 °C around room temperature during the period necessary for recording a fluorescence spectrum.

A slit width corresponding to a wavelength of 8 nm was chosen for both the incident and emitted light.

Results

In Table 1 are shown the peak positions of the absorption and emission bands of **1** in various solvents. The first absorption band lies at about 300 nm and is slightly blue shifted for an increase in the solvent polarity.

The fluorescence emissions of **1** in all solvents examined were very strong. This indicates that the lowest excited singlet state is a π-π^* state. The emission band with a large Stokes' shift can be explained as emission by an intramolecular proton transfer from the phenolic OH to the carbonyl group. This is accomplished through thermal relaxation from the Frank-Condon state, as Weller has proposed for methyl salicylate.[4] This explanation seems to be reasonable because it is well known that phenolic hydroxyl has an increased acidity and the carbonyl group has increased basicity in the excited singlet state.[5]

Another point of interest in Table 1 is that a new emission band with about one half of the intensity of the longer wavelength band, appears at about 338 nm when an ethanol solution of **1** is irradiated by 280 nm light (Fig. 1). (Hereafter, the emission band at about

4	4.2	302	8900	339	85	426	695	0.12
5	4.3	301	8700	339	140	423	860	0.16

a) $\times 10^{-5}$ M. b) Intensity in arbitrary units.

338 nm is referred to as the B-band and that at about 425 nm is the R-band). Weller has observed a weak emission band around 350 nm for methyl salicylate in methylcyclohexane, together with another strong emission band at about 442 nm, but he failed to observe the corresponding emission band at shorter wavelengths for a methanol solution of methyl salicylate. The light source he used, a high-pressure mercury arc, Q-81, together with a filter system UG-11 and aqueous potassium chromate, produced almost zero intensity at wavelengths below 300 nm. This may be the reason why he missed the emission band at shorter wavelengths.

In Table 2 are displayed the relative intensity of the two emission bands of **1** in several alcohols. The intensity of the B-band is independent of the solvent, but that of the R-band distinctly increases upon changing the solvent from methanol to butanol. In ethylene glycol, the intensities of both bands are comparable to those in methanol. The ratio, I_B/I_R, is largest in methanol and ethylene glycol.

In Table 3 are summarized the ratios, I_B/I_R, of several related compounds in methanol solutions subject to 280 nm irradiation. These solutions were of about the same concentration. The molar extinction coefficients for the compounds **3**, **4**, and **5** are about twice those for **1** and **2**, reflecting the presence of the two identical chromophores in each molecule. On the other hand, the values of I_B/I_R are about 0.9 for **1** and **2**, while they are about 0.1—0.2 for **3**, **4**, and **5**. The intensities of the R-band of **3**, **4**, and **5** are clearly much larger than those of **1** and **2**, whereas those of the B-bands are much smaller for **3**, **4**, and **5** than for **1** and **2**. These observations suggest that some intramolecular interactions between the two chromophores are operative in photophysical processes in the excited state.

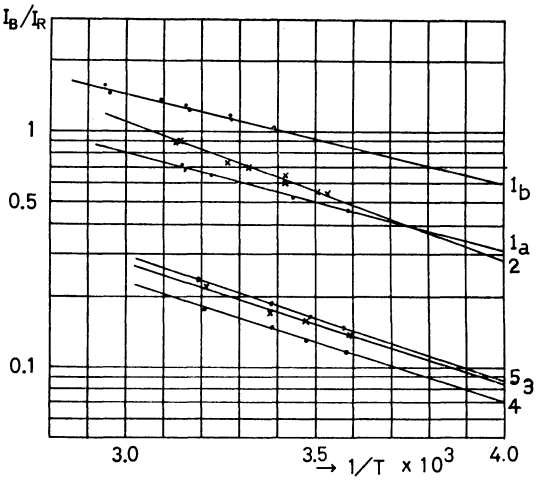

Fig. 2. Temperature variation of the intensity ratio, I_B/I_R.

The ratio, I_B/I_R, shows a temperature dependence. Plotting the quantity log (I_B/I_R) against $1/T$ for several systems resulted in good linear relationships, as is shown in Figure 2. These lines are well expressed by the following equation:

$$\log (I_B/I_R) = A - \frac{\Delta E^*}{2.303RT} \quad (1)$$

In Table 4 are given the ΔE^* values obtained from the slopes of these lines. They are about 2.0 kcal/mol with some divergence.

Table 4. Energy difference (ΔE^*) between two activation energies for the two emissive states

Compound	Solvent	ΔE^*(kcal/mol)
1a	Ethanol	1.76
b	Ethylene glycol	1.67
2	Ethanol	2.72
3	Methanol	2.39
4	Methanol	2.38
5	Methanol	2.41

Discussion

The Origin of the B-band. Irradiation of **1** in alcoholic solutions by 280 nm light yielded two emission bands at about 338 nm (B-band) and 425 nm (R-band). The R-band can be interpreted as emission from the lowest excited singlet state, which is characterized by intramolecular proton transfer.

As mentioned in the introduction, there are some examples showing dual emission bands under special conditions. In the case of **1**, for example, negligible concentration effects may rule out the excimer mechanism as the origin of the B-band. The emission bands from the cation, the neutral molecule, and the anion of salicylamide are located at 383, 435, and 417 nm, respectively.[6] Therefore, the B-band cannot be ascribed to ionic species in the excited state. Recently, Rotkiewicz *et al.*[3] have found new spectroscopic evidence which casts some doubt on the previous interpretation of the anomalous luminescence of *p-N,N*-dimethylaminobenzonitrile and they assigned the two emission bands to two excited species differing in polarity and in the orientation of the $-N(CH_3)_2$ group. This interpretation, however, also does not seem to be applicable to the present case.

Zadorozhnji observed two emission bands for salicylic acid and methyl salicylate but a single luminescent band for salicylamide.[7] He explained the two emission bands as transitions from the two extreme distances in the same vibrational level in the excited state to the same branch of the ground state potential curve, provided that the energy of the intramolecular hydrogen bond in the excited state is considerably higher than that in the ground state. However, this does not seem to explain the excitation-wavelength dependence of the occurrence of the B-band.

The excitation spectrum obtained by monitoring the R-band or the B-band of **1** in ethanol (1.06×10^{-5} M) has a peak at 310 or 299 nm, respectively (no correction was made for, *e.g.*, the energy distribution of the xenon lamp light source). The energy difference between these two wavelengths is 3.38 kcal/mol. The fact that the two excitation spectra were different for the two emission bands, seems to suggest the coexistence of two molecular species in the ground state. With regards to this point it has been reported from parachor measurements that salicylamide exists in an intramolecularly hydrogen bonded form in acetone, ethyl acetate, and dioxane, but this intramolecular hydrogen bond is disrupted in ethanol.[8] However, the peak position and the half width of the first absorption band of **1** in ethanol differ little from those in cyclohexane, indicating that the intramolecular hydrogen bond of **1** survives in ethanol solutions.

The relative intensity of the two emission bands showed a rather marked temperature dependence, while the absorption spectrum of **1** in ethanol, for example, showed a negligible temperature dependence over the range from 10 to 40 °C. Therefore, it is difficult to ascribe the B-band to the molecular species having no intramolecular hydrogen bond in the ground state.

Taking into consideration that the two emission bands were observed only for alcoholic solutions irradiated by 280 nm light, it is assumed that the proton exchanges between alcohol molecules and the solute molecules in the excited state play an important role in the appearance of the B-band. The B-band may originate from a molecular species having no intramolecular hydrogen bonds in the excited state, because the fluorescence band of *N*-methyl-*o*-methoxybenzamide in ethanol, which was measured for comparison, was found to be at about 330 nm, very close to the B-band in question (Fig. 1). The solute molecules excited by 280 nm light reach higher vibrational levels in the excited states. Then some molecules change conformation into species without the intramolecular hydrogen bond through intermolecular interactions with protic solvents, returning to the ground state with the resulting B-band emission. Although water is considered to be more active in proton exchange, the B-band was not observed for aqueous solutions of **1**, although a single broad emission band was observed at about 417 nm, which is ascribed to an anionic species.

Intramolecular Energy Transfer. The ratio, $I_B/I_R=0.14$ for compounds with two identical chromophores in the molecule is in sharp contrast to the values of about 0.9 for **1** and **2**. In the present case, the mean intermolecular distance of about 55 nm estimated from the sample concentration (*ca.* 5×10^{-5} M) is too great for intermolecular energy transfer *via* the exciton mechanism.[9] Furthermore, the fact that the ratios, I_B/I_R, are independent of the number of methylene groups joining the two identical chromophores conflicts with the results of the fluorescence study on a number of diphenylalkanes, where excimer fluorescences were found for diphenylpropane derivatives only.[10] Therefore, it is very likely that some intramolecular interactions are operative between the two chromophores in **3**, **4**, and **5** in the excited state.

Under irradiation by ordinary light sources, it is generally accepted that no chromophoric molecule could be brought to states for which two chromophores in the same molecule are excited by the simultaneous absorption of two photons. In other words, in an excited molecule, one chromophore has to be in the excited state while the other is in the ground state.

Since the B-band of the excited chromophore partially overlaps with the absorption band of the chromophore in the ground state, which is intramolecularly hydrogen bonded, the energy transfer between two chromophores in the same molecule may occur efficiently. The R-band, on the other hand, does not undergo this kind of energy transfer, resulting in relatively weak B-bands for compounds **3**, **4**, and **5**.

Temperature Dependence of the Ratio, I_B/I_R. Considering molecules excited by 280 nm light, some molecules break the intramolecular hydrogen bond resulting in the B-state which can emit B-band fluorescence, while other molecules undergo intramolecular proton transfer yielding the R-state which is responsible for the R-band. For simplicity, it is assumed that back processes may be neglected. Under these conditions, the relative intensity, I_B/I_R, is given by

$$I_B/I_R = \frac{k_f^B/(k_f^B+k_d^B)}{k_f^R/(k_f^R+k_d^R)} \cdot \frac{k^B}{k^R} \quad (2)$$

where the k values are the rate constants for the elementary processes represented in Scheme 1.

$S_0 + h\nu \rightarrow S^*$		absorption	(a)
$S^* \rightarrow S_1$		vibrational relaxation	(b)
$S_1 \rightarrow S_1^R$	k^R	intramolecular proton transfer	(c)
$S_1 \rightarrow S_1^B$	k^B	changing conformation into the B-state	(d)
$S_1^R \rightarrow S_0^R + h\nu^R$	k_f^R	R-band emission	(e)
$S_1^B \rightarrow S_0^B + h\nu^B$	k_f^B	B-band emission	(f)
$S_1^R \rightarrow S_0^R$	k_d^R	internal conversion	(g)
$S_1^B \rightarrow S_0^B$	k_d^B	internal conversion	(h)

Scheme 1.

Assuming the Arrhenius equations for elementary processes (c) and (d), that $k^R=A^R\exp(-E^R/RT)$ and $k^B=A^B\exp(-E^B/RT)$, and that the other processes are temperature independent, can be rewritten as

$$I_B/I_R = K\exp(-\Delta E^*/RT) \quad (3)$$

where $K=\{k_f^B(k_f^R+k_d^R)/k_f^R(k_f^B+k_d^B)\}(A^B/A^R)$ and $\Delta E^*=E^B-E^R$.

Weller has estimated the E^R value to be less than 2.6 kcal/mol for salicylic acid.[4] From this value and the ΔE^* values in Table 4, the E^B value was evaluated to be about 4.5 kcal/mol. This value seems to be reasonable for the activation energy of intramolecular hydrogen bond disruption. Recently, Shizuka *et al.* obtained a similar value for the rapid radiationless decay process of 2,4-bis-(dimethylamino)-6-(2-hydroxy-5-methyphenyl)-*s*-triazine, though the details of the process were not determined.[11]

The Solubilities and Kraft Points of Fatty Acid Soaps of Odd Carbon Numbers

Keizo OGINO and Yukinori ICHIKAWA

Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received March 12, 1976)

The solubilities of sodium soaps of odd carbon-number fatty acids were measured at various temperatures and the Kraft points[1] of the soaps were determined from the phase diagrams showing the temperature dependence of equilibria among monomers, micelles, and hydrated solid. It was found that the Kraft points were related with the carbon numbers of the fatty acids in a zig-zag curve.

The solubility of sodium soaps of fatty acids at room temperature usually decreases with increasing alkyl chain length. The only soaps that do not require elevation of temperature for dissolution are sodium oleate (sodium *cis*-9-octadecanoate) and some soaps of the less saturated fatty acids. The solubilities of most sodium soaps containing long alkyl chains in water at room temperature are lower than those of unsaturated fatty acid soaps. Many reports have been presented on the solubility of sodium soaps, but they are concerned with the fatty acid soaps of even carbon numbers originating from natural fatty oils.[2-6]

Recently, the advance of organic synthesis makes the fatty acids of odd carbon numbers readily available for technical uses. For the current industrial activity, it is necessary to investigate the properties of sodium soaps of odd carbon-number fatty acids. Thus the solubilities in water and the Kraft points have been determined for the sodium soaps of fatty acids of odd carbon numbers in this study.

Experimental

Materials. The sodium soaps of pentanoic (C_5), heptanoic (C_7), nonanoic (C_9), undecanoic (C_{11}), tridecanoic (C_{13}), and pentadecanoic (C_{15}) acids were prepared by neutralizing these acids with ethanolic sodium hydroxide. These soaps were purified by recrystallization and stored in a dessicator at room temperature. The fatty acids were supplied from Ajinomoto Co., Ltd.; their properties have been listed in a previous work.[7]

Determinations of Solubility. The solubility was determined in 200×15 mm Pyrex test-tubes in which 40 ml of water and a sufficient amount of a sodium soap were mixed so as to precipitate the solid phase. The equilibrium was ascertained by the approach in two directions, from the unsaturated and from the supersaturated states. The tubes were stoppered and thermostatted within ±0.02 °C for 24 h. The solution was permitted to stand until the suspended crystals settled. The crystals were filtered by a small glass filter fastened to the inlet of a 25 ml pippet. During the transfer of the solution from the test tube to a weighing bottle through the pippet, the weighing bottle was kept cold in an ice-bath and covered to prevent loss of water vapor. Then the bottle containing the solution was heated to evaporate the water and the residual soap was dried in vacuum at 60 °C for 24 h. The content of the weighing bottle was weighed before and after the evaporation and drying. The dried soap was stored in a dessicator at room temperature before use. The solubility was calculated as the weight of soap (grams) dissolved in 100 g of water.

Determination of CMC. CMC was determined by measuring the specific conductivity of a soap solution at various temperatures. The specific conductivity was measured with a Conduct Meter Model CH-IDB of the Toa Electric Wave Co., Ltd.

Results and Discussion

The solubilities of sodium salts of pentanoic, heptanoic, nonanoic, undecanoic, tridecanoic, and pentadecanoic acids obtained from the experiments are given in Table 1.

The solubilities presented in weight percent have been plotted in Fig. 1. The plots showing the solubilities of sodium pentanoate and heptanoate are presented at the upper right corner in Fig. 1. From the results, it is clear that these two alkyl soaps dissolve appreciably at room temperature. The Kraft points for these soaps were not determined because these soaps freeze at −5 °C. It should be noticed that the melting points of pentanoic and heptanoic acids are −34.5 and −10.5 °C respectively, which are far lower than the freezing points of the corresponding soaps.

On the other hand, the solubilities of all the soaps of the larger carbon numbers are small at room temperature, and increase as a linear function of the temperature until the concentrations reach the critical values. When either the concentration or the temperature goes beyond this critical threshold, the ionic soap species in a monomolecularly dispersed state seem to undergo some kind of aggregation, accompanied by an enormous increase in the solubility. This is a well-defined critical micelle concentration (CMC). That is, the maximum solubility of the monomer ions or molecules appears at CMC; if this saturation point is exceeded, a new phase, the micelles, appears. This point can be clearly detected when the maximum solubility (presented in molarity) is plotted against $1/T$, as shown in Fig. 2.

In Table 2 the critical concentration C_K have been given with the corresponding temperatures.

In order to determine the Kraft point, the critical micelle concentration (CMC) was measured at different temperatures. For the determination of CMC, the electric conductivity method was applied, though many other methods might be applicable.[8-11]

Figure 3 shows the specific conductivity, κ, of aqueous solutions of sodium pentadecanoate at various concentrations at 55 and 65 °C. As shown in Fig. 3, the relations of the specific conductivity with the concentration slightly bend at certain concentrations of the soap solution, that is, at the CMC.

Shinoda *et al.* have mentioned that the Kraft point can be compared to the phase diagram of the ice–water system. In solutions of soaps, the concentration

of monomeric soap molecules plays a role similar to the vapor pressure in the vapor–liquid equilibrium of a one-component system.[12,13] According to Shinoda's analogy, we depicted the phase diagram in the vicinity of the Kraft point of sodium pentadecanoate as shown in Fig. 4.

The Kraft point here can be interpreted as the point at which the solid hydrated soap and the micelles are in equilibrium with the monomers: in terms of the phase rule for three phase systems composed of two components, the equilibrium among the three phase (hydrated solid⇄monomers⇄micelles) is univariant, so that at a given pressure the point is fixed. The concept of the Kraft point as a freezing point of the micelles is also supported by Shinoda.

Hydrolysis is the main source of error in studies of

soap solutions. Therefore, in most of the works performed on the solubilities of soaps, alkaline solutions have been used as the solvent in place of pure water to prevent hydrolysis. In this work, we used distilled water free from carbon dioxide as the solvent, thus minimizing the effect of hydrolysis. From the results, the measurements of the Kraft points seemed to be little influenced by the hydrolysis product, fatty acid.

Similar results were also obtained for the soaps of the other fatty acids, and it was found that the Kraft points agree closely with the melting points of the corresponding fatty acids. When one plots the Kraft points of soaps of saturated fatty acids against the number of carbon atoms, a zig-zag curve (high at even carbon numbers and low at odd) is obtained, as shown in Fig. 5. Here the Kraft points of soaps of even carbon number are cited from McBain's report.[14] Figure 5 shows also the Kraft points of sodium normal alkylsulfates.[15]

In a previous work, we studied the melting behavior of binary and ternary mixtures of odd carbon-number fatty acids. Those results would be useful for the determination of the Kraft points of commercial soaps consisting of mixed soaps of various fatty acids.

Characteristics of Coordination Compounds of Calcein Blue for a Tunable Organic Liquid Laser

Totaro IMASAKA, Teiichiro OGAWA, and Nobuhiko ISHIBASHI
Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812
(Received April 3, 1976)

The lasing and spectroscopic properties of coordination compounds of Calcein Blue with aluminium, calcium, strontium, and barium in water and in a water–ethanol mixture were investigated. The chelate formation improved the lasing properties of Calcein Blue, since the fluorescence quantum yield was increased by the formation of rigid rings in the molecule, and the lasing wavelength could be modified by the metal ion. By using these coordination compounds, tunable laser emissions were observed in the spectral range of 400—478 nm with a low threshold excitation intensity. The threshold excitation intensities excited by the nitrogen laser, the pulse width of which was very short (2.5 ns), were formulated by means of the spectral parameters for such molecules as its Stokes shift was large and its singlet-singlet absorption could be ignored. The calculated values obtained by this formula agreed well with the experimental values in water.

The organic liquid laser has proved itself to be an effective tool for the spectroscopy of atoms and molecules because of its intense power, its narrow bandwidth, and the tunability of its wavelength. Up to this time the organic dyes and scintillators, the fluorescence quantum efficiencies of which are high, have been used as laser materials. The properties of dyes have been improved to obtain a high conversion efficiency, a wide tuning range, a high solubility especially in water, and a high stability. The rigid ring formation of an amide group of coumarin reduces the energy transfer to the vibrational and rotational states and improves the quantum efficiency of the dye.[1] The tuning range is expanded by broadening the fluorescence spectrum in the presence of acidic exciplexes and a neutral form of 4-methylumbelliferone.[2,3] The gain of the organic liquid laser is, however, generally small probably because of its wide fluorescence spectrum. The surfactant increases the solubility of the laser material in water and reduces the thermal fluctuation of the refractive index of the dye solution in the case of a continuous oscillation of the dye laser.[1] The chemical stability of dyes is increased by the trifluoromethylation of the methyl group of 7-diethylamino-4-methylumbelliferone.[4] Nevertheless, there is a need for a laser material with a higher conversion efficiency, a wider tuning range, a higher solubility in water, and a higher chemical stability, especially in the ultraviolet region.

The gain spectroscopy and the threshold analysis provide useful information on the lasing property and the improvement of the laser material. The gain spectroscopy of 4-methylumbelliferone[3] and the threshold analysis of rhodamine B and 6G[5,6] have been carried out previously. However, the threshold analysis under a short-pulse excitation has not been carried out in detail.

The laser action of the coordination compound with a sufficiently high quantum efficiency is expected if there is no particular quenching by the metal ion. Two kinds of organic chelate lasers have hitherto been reported. One of them is europium benzoylacetonate,[7] the first organic laser: its laser emission is due to the emission from a metal ion and its spectral range is very narrow. The other one is the metal phthalocyanine,[8,9] the first organic liquid laser: its spectral property can not be modified reversibly, for example by varying the pH of the solution, and it behaves as an organic dye, as it is usually called.

The laser action of Calcein Blue(4-methylumbelliferone-methyleneiminodiacetic acid) has been reported previously, and the effect of oxygen in the solution has been investigated.[10] On the other hand, Calcein Blue is well-known as a metalfluorechromic indicator in the complexometric determination of zirconium,[11] gallium,[12] and some alkali earth metals.[13]

In the previous letter, we have reported that the coordination compounds of Calcein Blue with aluminium, calcium, strontium, and barium can give laser emission and that the spectral properties of the coordination compound can be modified by changing the metal ions or by varying the pH of the solution.[14] In the present study, a further investigation of the spectral properties and laser characteristics of the coordination compounds of Calcein Blue and the threshold analysis of these lasers has been carried out for the purpose of finding excellent laser materials.

Experimental

Apparatus (Lasers). An experimental arrangement to obtain laser emission is shown in Fig. 1. The exciting source used is a nitrogen laser, which is similar to that described by Basting *et al*,[15] and by Maeda and Miyazoe.[16] It has a 30 cm tube and two 8 nF capacitors made of polyester films and aluminium foils. The output power is 700 kW at 20 kV input, and the pulse width is 2.5 ns (measured by

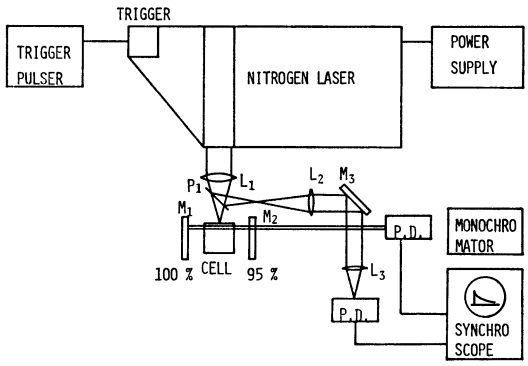

Fig. 1. Experimental arrangement.

a Tektronix 519 oscilloscope). The intense peak power and the short pulse width of the nitrogen laser are suitable for the excitation of an organic liquid laser and for the threshold analysis.

The ultraviolet output of a pulsed nitrogen laser is focused by a spherical lens L_1(f=10 cm) on the surface of the solution of the laser material in a square quartz cell (1×1×5 cm). The cavity of the liquid laser consists of two dielectric coated mirrors with reflectivities of 100 percent (M_1) and 95 percent (M_2), respectively. In the case of tuning the laser oscillation the mirror with 100 percent reflectivity was replaced by a grating (Hitachi Ltd. 3×3 cm, 500 nm blaze, 600 groove/mm) and the square quartz cell was replaced by a quartz cell with nonparallel sides. The laser oscillation of the coordination compound was detected by means of a photocell and was confirmed by observing the coherent radiation. The spectra of the laser emission were photographed by means of an Adam Hilger prism monochromator, and the wavelength was calibrated by a low-pressure mercury lamp. A part of nitrogen laser emission was taken out by a quartz plate (P_1) and was detected by a photodiode (NEC LSD 39A; bandwidth 1 GHz). The signal was integrated by a capacitor (C=3000 pF, R=200 kΩ, and the peak intensity was measured by means of a synchroscope (Iwatsu SS5157).

Apparatus (Fluorescence and Absorption Spectra). The fluorescence spectrum was measured by means of a Hitachi MPF 4 fluorescence spectrophotometer; its spectral response was calibrated by using a rhodamine B cell. The fluorescence spectrum of a concentrated solution was measured in the similar configuration of a quantum counter system using a triangle cell, in which the incident light irradiated the hypotenuse surface of the sample and the fluorescence was measured at a right angle to the incident radiation. The dependence of the fluorescence intensity (peak value) on the concentration of 4-methylumbelliferone was measured by this method. The fluorescence intensity is independent of its concentration above 10^{-4} mol/l. This shows that the excitation light is absorbed completely and that the emission intensity is dependent only on its quantum efficiency, not on its absorbance. The true emission spectrum normalized by the quantum efficiency and the quantum efficiency of the concentrated solution can be measured directly without diluting the solution. It is necessary to use a concentrated solution, since the properties in the concentrated solution may differ from those in the dilute solution because of the difference in the degree of aggregation which may occur in high concentrations. Some deviation from the true fluorescence spectrum due to the self-absorption may occur; however, it is small for 4-methylumbelliferone, Calcein Blue, and its complexes, since the superposition of the fluorescence and absorption spectra is very small (below 1 percent).

The absorption spectra were measured in a split-beam method by using a Hitachi 356 two wavelength/double-beam spectrophotometer.

Reagents. The 4-methylumbelliferone (Tokyo Kasei) was recrystallized twice from water and ethanol to obtain transparent crystals. The Calcein Blue (Dojindo Lab.) was used without purification. The calcium chloride (guaranteed grade; Kishida Chemical Co.), strontium chloride (guaranteed grade; Kishida Chemical Co.), barium chloride (guaranteed grade; Ishizu Pharmaceutical Co.), and aluminium ammonium sulfate (guaranteed grade; Wako Pure Chemical Ind.) were used without purification.

Procedure. A 2.5×10^{-3} mol/l solution of Calcein Blue was prepared by dissolving 0.0803 gram of Calcein Blue and by diluting the solution to 100 ml with freshly distilled water, and adjusted to below pH 4 by adding a buffer solution of sodium acetate. A 10^{-3} mol/l sample solution was prepared by adding the following solutions to a 25 ml volumetric flask in turn; 10 ml of 2.5×10^{-3} mol/l Calcein Blue, a few ml of a 2.5×10^{-3} mol/l metal ion solution (10 ml was used for the formation of the 1 : 1 complex), a solution of sodium acetate, ammonia, or sodium hydroxide to adjust the pH from 4 to 13, and distilled water. The coagulation of aluminium ions or the precipitation of calcium, strontium, and barium hydroxides and carbonates, which disturb the laser action by the scattering of the laser beam, can be reduced by this procedure.

Results

Spectral Properties of Calcein Blue. Calcein Blue has a methyleneiminodiacetic acid group on the 8 position of 4-methylumbelliferone and exhibits three forms(denoted by (1), (2), and (3)) at the respective pH regions, as is shown in Fig. 2. The UV absorption

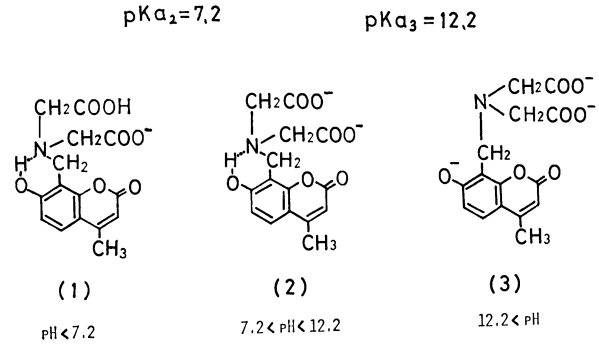

Fig. 2. Structure of Calcein Blue.
The form (1) has two ionizable hydrogen atoms (below pH 7.2). The form (2) has one ionizable hydrogen atom (pH 7.2—12.2). The form (3) has no ionizable hydrogen atom (above pH 12.2).

and fluorescence spectra were measured at various pH values and are shown in Figs. 3 and 4. The existence of three forms of Calcein Blue is confirmed since two isosbestic points are observed at 335 and 354 nm in the UV spectra. As the form of Calcein Blue changes from (1) to (2), the maximum of the absorption band shifts to longer wavelengths: however, the extinction coefficient at 337 nm (the lasing wavelength of the nitrogen laser) does not vary. The wavelength of the maximum emission does not move, and the intensity increases gradually. The small variation in the fluorescence quantum efficiency may be due to the small deformation in the structure by the dissociation of the

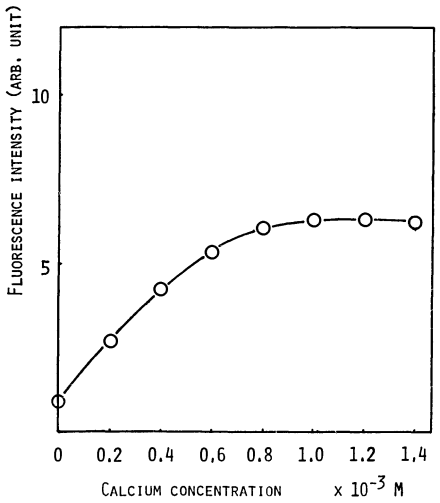

Fig. 6. Composition of calcium Calcein Blue.

hydrogen ion (Fig. 2 (1), (2)). As the form changes from (2) to (3), the extinction coefficient at 337 nm gradually decreases, while the fluorescence intensity decreases steeply. Calcein Blue in the form (3) is non-fluorescent, since the side chain, the methyleneiminodiacetic acid group, becomes flexible by the breakage of the hydrogen bond.[17]

The dependences of the molar extinction coefficient of Calcein Blue at 370 nm and that of the fluorescence intensity at 446 nm on the pH were measured; the acid dissociation constants of pK_a2 and pK_a3 were determined to be about 7.2 and 12.2 respectively.

Composition of Coordination Compound. The color change in the solution of Calcein Blue from blue to violet upon the addition of aluminium ions implies the formation of a coordination compound. The dependence of the fluorescence intensity of the aluminium Calcein Blue on the aluminium concentration was measured in order to determine the composition of the complex; the mole ratio plot is shown in Fig. 5 (1). The figure indicates that a 1 : 1 binary complex of aluminium Calcein Blue is formed at pH 5, since the fluorescence intensity increases as the concentration of the aluminium increases up to an equimolar composition. The gradual decrease in the aluminium excess region may be due to the light scattering by aluminium hydroxide formed in the solution. The absorbance of aluminium Calcein Blue was also measured; the continuous variation plot is shown in Fig. 5 (2). The maximum absorbance was obtained at the equimolar concentration, and the formation of a 1 : 1 binary complex was confirmed.

The dependence of the fluorescence intensity of calcium Calcein Blue on the calcium concentration is shown in Fig. 6. The fluorescence intensity is constant above the equimolar concentration. Accordingly, the metal ion was mixed in a 1 : 1 proportion to the ligand molecule for the preparation of the coordination compound.

Spectral Properties of Aluminium Calcein Blue. The

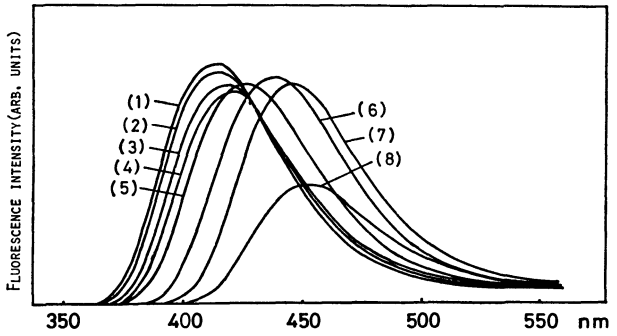

Fig. 8. Fluorescence spectra of aluminium Calcein Blue at various pH. Concentration of aluminium Calcein Blue: 10^{-3} mol/l, pH: (1) 5.0 (2) 6.0 (3) 7.1 (4) 7.9 (5) 9.0 (6) 10.0 (7) 11.0 (8) 12.0, $\lambda_{ex}=$ 337 nm.

fluorescence spectra of the coordination compound of aluminium Calcein Blue at various aluminium concentrations are shown in Fig. 7. The contribution of the coordination compound in the fluorescence spectrum increases as the aluminium concentration increases, as is indicated by the shift of the band to shorter wavelengths. The emission intensity of the coordination compound is stronger than that of the ligand molecule. The iso-emissive point shows that no side reaction takes place.

The effect of the pH on the fluorescence spectrum and the molar extinction coefficient at 370 nm of aluminium Calcein Blue (1 : 1 mixture) are shown in Figs. 8 and 9. The fluorescence spectrum shifts to longer wavelengths as the pH increases, since the complex dissociates to an ion and a ligand in this pH region. The coordination compound of aluminium Calcein Blue is formed predominantly below pH 5, and the equilibrium shifts to the dissociation and the release of a proton occur simultaneously, since the fluorescence spectra show no iso-emissive point.

It is well known that the quantum efficiency of the dyes and the complexes increases in a hydrophobic solvent since the interaction between the solute and the solvent decreases. The laser action is expected to

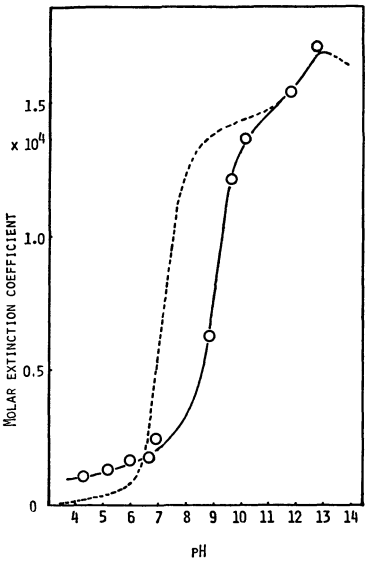

Fig. 9. Molar extinction coefficient at 370 nm at various pH. Solid curve: aluminium Calcein Blue, broken curve: Calcein Blue.

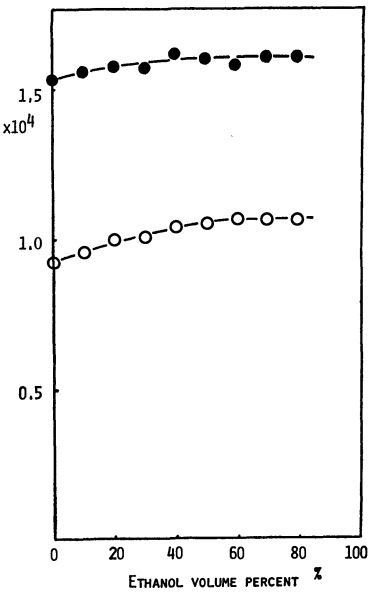

Fig. 10. Fluorescence intensity (○: arbitrary units) and molar extinction coefficient (●) of aluminium Calcein Blue in water-ethanol mixture. $\lambda_{ex}=337$ nm, $\lambda_{em}=446$ nm, $\lambda_{abs}=337$ nm.

be obtained in a ethanol–water mixture under a low excitation intensity. The dependences of the molar extinction coefficient and the fluorescence intensity of aluminium Calcein Blue on the volume percentage of ethanol in water were measured; they are shown in Fig. 10. Although the absorption and the fluorescence spectra do not shift, the extinction coefficient and the fluorescence intensity increase gradually as the ethanol volume percent increases. The quantum efficiency of the aluminium complex does not increase much, since it is already high and near unity in water. The small variation in the spectra indicates that the form and the composition of the coordination compound in

an ethanol–water mixture are identical to those in water.

Spectral Properties of Barium and Calcium Calcein Blue. Barium and calcium Calcein Blue have intense fluorescences at about pH 9 and 13.[13] The dependences of the molar extinction coefficient at 370 nm and the fluorescence intensity at 446 nm of barium Calcein Blue on the pH were measured in detail (*cf.* Fig. 11), in order to clarify the variation in the composition of the coordination compound. The coordination compound of barium Calcein Blue is formed in the region above pH 8, and it has an intense fluorescence even at pH 13. The structure of barium Calcein Blue in the pH 8—13.5 region is proposed to be the form in which a phenolic hydrogen is substituted by an alkali earth metal ion and the free side chain is bound by the metal ion.[13] In this structure the barium ion may not be surrounded by the other oxygen atom, since the barium

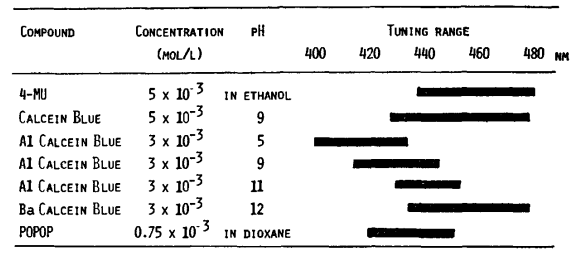

Fig. 13. Tuning ranges of lasers of dyes and coordination compounds.

ion is doubly charged and the quantum yield is not so high as that of aluminium Calcein Blue.

Lasing Wavelength. The laser spectra of Calcein Blue and the coordination compounds are shown in Fig. 12. The laser action of Calcein Blue is observed at around 446 nm at pH 5, but not at pH 12. The coordination compounds of Calcein Blue with calcium, strontium, and barium lase at around 450, 452, and 454 nm respectively at pH 12. It is noteworthy that the coordination compound with an alkali earth metal ion lases at longer wavelengths as the atomic weight of the metal ion increases. The stability constant and the electrostatic force by the metal ion decrease as the atomic weight and the ion radius increase, and the perturbation of the calcium ion to the ligand molecule is expected to be stronger than that of barium. The red shift in the heavier atom complex might be due to the steric effect.

Calcein Blue forms a coordination compound with an aluminium ion at around pH 5, and it lases at around 418 nm; the wavelength is shorter than that of Calcein Blue.

Tuning Range. The tuning ranges (the wavelength ranges in which the narrow-band oscillation is possible) of the coordination compound lasers are shown in Fig. 13, where 4-methylumbelliferone and 1,4-bis(5-phenyloxazol-2-yl)benzene(POPOP) are included for the sake of comparison. Tunable laser emission from 436 nm to 480 nm was observed from the solution of Calcein Blue (pH 9). The tuning range of the aluminium Calcein Blue complex is 400—435 nm at pH 5 and it is longer in the wavelength at a higher pH value. The barium complex lases in the range of 435—478 nm, as in the case of 4-methylumbelliferone. In this way the laser action of the coordination compound of Calcein Blue can be observed in the range from near ultraviolet (400 nm) to blue green (478 nm) with a low threshold excitation intensity by changing the metal ion and by varying the pH. The full width at the half maximum of the laser emission was a few nanometer, which would be due to the short pulse width of the nitrogen laser (2.5 ns) and to the lack of the resolution of the grating. The dioxane solution of the POPOP shows superradiation (amplified spontaneous emission) in a solution more concentrated than 10^{-3} mol/l, and the tunable laser action was not observed at 10^{-3} mol/l.

Discussion

Threshold Analysis. The threshold equation of

the laser action represents a relation between all the parameters affecting lasing; critical inversion, emission wavelength, losses, dye concentration, and extinction coefficient. The gain, α, of the organic liquid laser is written as[3]:

$$\alpha = \sum_i [\sigma_{emi} N_i^* - \sigma_{si} N_i - k_i] - d \quad (1)$$

The summation in the equation shows the sum on such different species as the ligand and the coordination compound. In this equation, σ_{emi} is the emission cross section; σ_{si}, the singlet-singlet absorption cross section at the wavelength of the laser emission, and N_i and N_i^* the population in the ground and the excited states. The first term of this equation is the amplifying term due to the fluorescence; the second term is the loss term due to the singlet-singlet absorption at the lasing wavelength, and the third term, k_i, is the loss term due to the triplet-triplet absorption. The last term, d, represents the loss of the resonating cavity. The third term can be neglected because the pulse width of the excitation source of the nitrogen laser is short (2.5 ns) enough to be able to ignore the absorption from the triplet state.

The gain, α, can be set at zero under the threshold condition, thus,

$$\sum_i [\sigma_{emi} N_i^* - \sigma_{si} N_i] - d = 0. \quad (2)$$

When there are only two species, such as a ligand and a complex, the weight-averages ($\bar{\sigma}_{em}$ and $\bar{\sigma}_s$) are substituted;

$$\bar{\sigma}_{em} N^* - \bar{\sigma}_s N - d = 0. \quad (3)$$

Then, the critical inversion, N^*/N, at the threshold is written as follows;

$$\left[\frac{N^*}{N}\right]_{threshold} = \frac{\bar{\sigma}_s + d/N}{\bar{\sigma}_{em}}. \quad (4)$$

The rate of the formation of N^* by the excitation is represented by:

$$\frac{dN^*}{dt} = \bar{\sigma}' I(t) N - \left(\frac{1}{\tau}\right) N^* \quad (5)$$

where $I(t)$ is the intensity of the excitation source; $\bar{\sigma}'$, the absorption cross section at the wavelength of the nitrogen laser, and τ, the lifetime of fluorescence. This differential equation gives the critical inversion, N^*/N, approximately as follows:

$$\frac{N^*}{N} \simeq \tau \bar{\sigma}' I(t). \quad (6)$$

From Eqs. 4 and 6, we obtain:

$$I_{threshold} \simeq \frac{\bar{\sigma}_s + d/N}{\tau \bar{\sigma}' \bar{\sigma}_{em}}. \quad (7)$$

The absorption cross section, $\bar{\sigma}_s$, at the lasing wavelength is small in the case of a coumarin compound, such as Calcein Blue and its complexes, because the Stokes shifts of these compounds are large and the superposition of the fluorescence and absorption spectra is rather small, and thus $\bar{\sigma}_s$ can be neglected. When $\bar{\sigma}_{em}$ ($=\lambda^4 E/8\pi c\eta^2\tau$) is substituted,[3] Eq. 7 becomes:

$$I_{threshold} \simeq \frac{8\pi c\eta^2 d}{N\bar{\sigma}'\lambda^4 E} \propto \frac{\eta^2 d}{n\bar{\varepsilon}\lambda^4 E}. \quad (8)$$

In this equation, E is the fluorescence intensity normalized by its quantum efficiency; η the refractive index; $\bar{\varepsilon}$, the weight-average of the molar extinction coefficient at the wavelength of the nitrogen laser, and λ the wavelength of the maximum fluorescence intensity. The observed value of the extinction coefficient can be used for $\bar{\varepsilon}$ in the equation. The population in the ground state can be set at the total concentration, n.[18]

The equation can clarify the characteristics of a laser material with a large Stokes shift. The threshold excitation intensity of a given compound can be calculated, and the usefulness of that compound as a laser material can be estimated by the use of spectral parameters. This threshold excitation equation shows the λ^4 term in the denominator requires a higher excitation intensity in the shorter wavelength region; thus, the laser material should be more efficient in this region.

Experimental Evidence for Eq. 8. The dependence of the threshold excitation intensity of the laser emission of 4-methylumbelliferone on the concentration was measured, as it is a typical coumarin compound. The linear relation of n *vs.* $1/I$ was obtained; it proves that the main loss is not the absorption of the laser material, but the loss in the laser cavity. Eq. 8 is thus confirmed.

Laser Emission of Calcein Blue. The threshold excitation intensity of Calcein Blue was calculated from the data of the absorption (Fig. 3) and fluorescence (Fig. 4) spectra; it is represented by the broken line in Fig. 14. The experimental results are also plotted in this figure. The threshold excitation intensity gradually decreases up to pH 11 as the percentage of the form (2) increases. Calcein Blue is non-fluorescent and does not lase above pH 12. The experimental values of the threshold excitation intensity agree well with the calculated ones; Eq. 8 is thus proved to be useful. The wavelength of the laser emission of Calcein Blue is 446 nm and is independent of the pH as in the case of the fluorescence spectrum.

Laser Emission of Aluminium Calcein Blue. The

Concentration of Calcein Blue: 10^{-3} mol/l.

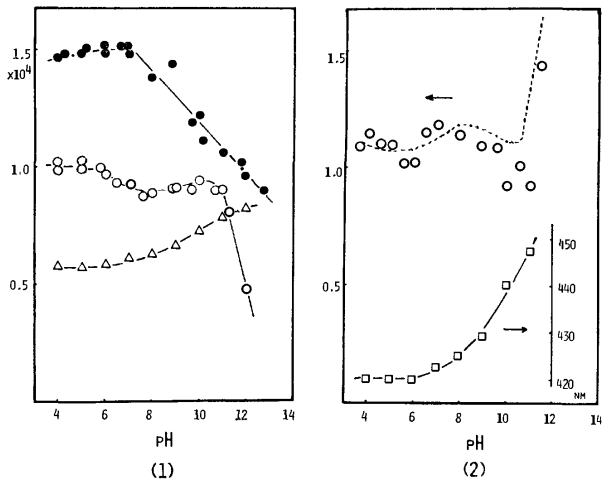

Fig. 16. (1) Dependences of the molar extinction coefficient $\bar{\varepsilon}$(●), the fluorescence intensity E(○: arbitrary units), and λ^4 (△: arbitrary units) of aluminium Calcein Blue on pH. (2) Dependences of the threshold excitation intensity (arbitrary units, ---: calculated value, ○: experimental values) and lasing wavelength (□) of aluminium Calcein Blue on pH. Concentration of aluminium Calcein Blue (1 : 1 mixture): 10^{-3} mol/l.

dependence of the fluorescence intensity, E, the molar extinction coefficient at 337 nm, $\bar{\varepsilon}$, and λ^4 on the aluminium concentration in the Calcein Blue solution are shown in Fig. 15(1). The threshold excitation intensity of the aluminium-Calcein Blue mixture is calculated from the spectroscopic parameters and is shown in Fig. 15(2), along with the experimental values. The increase in $\bar{\varepsilon}$ upon the increase in the aluminium concentration compensates for the decrease in λ^4, and the threshold excitation intensity does not vary much. The calculated value agrees with the experimental value, and it is confirmed that the laser action of the coordination compound is not quenched by the metal ion. However, it is impossible to observe the laser action when a molar excess of aluminium is added in the Calcein Blue solution. This may be due to the scattering effect of aluminium hydroxide; it is known that aluminium hydroxide is formed in the region of pH 4.5—10, then the excess aluminium coagulates and disturbs the laser action more severely than it does the fluorescence.

The lasing wavelength of the aluminium-Calcein Blue mixture gradually shifts to shorter wavelengths as in the case of the fluorescence spectrum, as is shown in Fig. 15(2). In this way the lasing wavelength of this mixture can be modified by varying the aluminium concentration in the Calcein Blue solution.

The data of the fluorescence intensity E, the extinction coefficient $\bar{\varepsilon}$, and λ^4 at various pH values are shown in Fig. 16(1). From these spectroscopic parameters, the threshold excitation intensity of aluminium Calcein Blue was calculated; it is shown in Fig. 16(2). Both the experimental and the calculated values have two minima, and they are consistent. The minimum at pH 11 is due to the dissociation to a ligand and an ion. Above pH 12 the laser action was not observed,

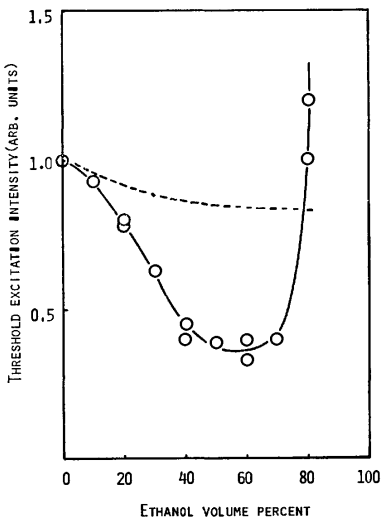

Fig. 17. Dependence of the threshold excitation intensity (arbitrary units) of aluminium Calcein Blue (10^{-3} mol/l) on the ethanol percent in the solvent (water). Solid curve: experimental values, broken curve: calculated value.

as in the case of Calcein Blue itself.

The wavelength of the laser emission of aluminium Calcein Blue is dependent on the pH. In order to modify the wavelength of the laser emission, it will be better to vary the pH than to vary the aluminium concentration, because the pH can be varied easily, for example, by adding a little acid or sodium hydroxide.

The threshold excitation intensity at various volume percentages of ethanol in the solvent was also calculated; the results are shown along with the experimental values in Fig. 17. Both the experimental and the calculated values decrease with an increase in the ethanol per-

Table 1. Characteristics of lasers of coordination compounds

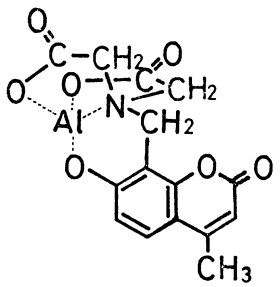

Fig. 18. The suggested structure of aluminium Calcein Blue. The aluminium ion is surrounded by a phenolic oxygen atom, two calboxylic oxygen atoms, and a nitrogen atom of iminodiacetic acid; however, the figure does not specify the number of the hydrogen atom attached to oxygen atoms and the coordination number of the aluminium atom.

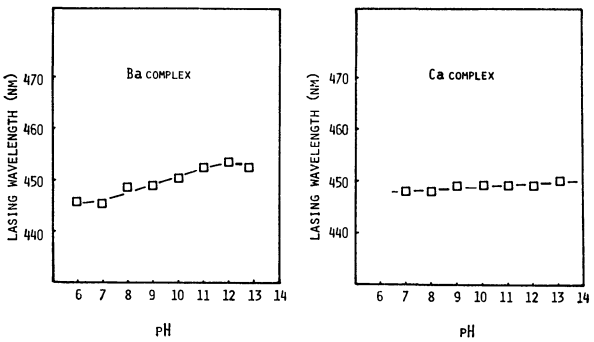

Fig. 19. Dependences of the lasing wavelength of calcium Calcein Blue (10^{-3} mol/l) and barium Calcein Blue (10^{-3} mol/l) on pH.

centage, as had been expected; however, the experimental value decreases more rapidly than does the calculated one. The variation in the refractive index in the mixture is small ($n_{D\ water}=1.3330$, $n_{D\ ethanol}=1.3618$) and can not induce the discrepancy. It may be due to the variation in the refractive index of the solution by heating by the irradiation of the nitrogen laser. However, the effect may not be large enough to induce such a large discrepancy. The steep increase in the threshold excitation intensity above 80 percent is due to the insolubility of the aluminium complex and to the light scattering in an ethanol–water mixture.

It has been reported that the lasing wavelength of 4-methylumbelliferone is modified in a water–ethanol mixture by an exciplex formation. In the case of an aluminium complex, the spectrum and the lasing wavelength in a water–ethanol mixture are close to those in water.

The structure of the aluminium Calcein Blue complex is suggested to be as is indicated in Fig. 18, since (1) the results of the continuous variation and mole ratio plots indicate the formation of a 1 : 1 complex between aluminium and Calcein Blue, (2) aluminium Calcein Blue should have a more rigid structure than Calcein Blue, as its quantum efficiency is larger than that of Calcein Blue, and (3) the phenolic oxygen coordinates with the aluminium ion since the phenolic electron does not take part in the resonance of the π electrons in the molecule, as the fluorescence spectrum does not shift to longer wavelengths. In this structure the aluminium ion is surrounded not only by a nitrogen atom but also by one phenolic and two carboxylic oxygen atoms, and binds the side chains. The structure of aluminium Calcein Blue is more rigid than that of Calcein Blue, in which neither of the side chains (CH_2COO^-) is bound.[17] The formation of such rigid rings in the molecule increases the quantum yield of the material and reduces the threshold excitation intensity.

Laser Emission of Barium and Calcium Calcein Blue. The threshold excitation intensity of the alkali earth complex was calculated. Though the calcium complex lased up to pH 13.5, as had been expected from the calculated value, no quantitative comparison was carried out since the complex decomposed rapidly in high pH solution.

The effects of pH on the lasing wavelengths of barium and calcium Calcein Blue are shown in Fig. 19. The lasing wavelength of the barium complex can be modi-

fied by increasing the pH; however, that of calcium Calcein Blue can be modified only a little.

Laser Emission of Zirconium Calcein Blue. It has been reported that a zirconium ion is able to form a coordination compound with Calcein Blue at pH 5.[11] However, the laser action of this compound was not observed, since the intensity of the fluorescence was not strong and the light scattering by zirconium hydroxide disturbed the laser action at the concentration of 10^{-3} mol/l.

Laser Characteristics of Coordination Compounds. The characteristics of the lasers of the coordination compounds of Calcein Blue and dyes at 10^{-3} mol/l are listed in Table 1. Aluminium Calcein Blue at pH 12 and barium, strontium, and calcium Calcein Blue at pH 5 were identical to Calcein Blue in the threshold, in the wavelength, and in the intensity of the fluorescence band. This may indicate that no coordination compound is formed. The aluminium complex at pH 5 has the most intense fluorescence, and it is an excellent lasing material. The contribution of λ^4, however, does not induce the reduction of the threshold excitation intensity, since the laser emission occurs in the near UV region. Barium, strontium, and calcium complexes at pH 12 have relatively high thresholds compared with Calcein Blue and 4-methylumbelliferone. Though the fluorescence intensity of the POPOP is rather small, the threshold excitation intensity is relatively low, probably because of the large molar extinction coefficient and the solvent effect. The aluminium complex is considered to be superior to POPOP as a laser material, because of (1) the smaller intramolecular loss, since the quantum efficiency is larger (this would be significant for long-pulse excitation), (2) the better tuning capability (the laser action of POPOP is superradiation at 10^{-3} mol/l), (3) the variation in the lasing wavelength by the chelate reaction, and (4) the higher solubility in water. Furthermore, the threshold excitation intensity of an aluminium complex can be reduced by dissolving it in a water–ethanol mixture as low as that of POPOP at the same concentration.

Aluminium Calcein Blue lases in a month from preparation, and it is stable enough for practical use. However, the complex with the alkali earth metal ion in a high pH solution (above pH 13) decomposes in several hours. Calcein Blue can be easily recovered as precipitates from the complex solution by making the solution acidic.

Conclusion

The threshold excitation intensity of the organic liquid laser under a short-pulse excitation can be calculated by means of a simple equation by using its spectral parameters, such as the wavelength of the fluorescence emission at the maximum intensity, the fluorescence intensity, the concentration, and the molar extinction coefficient. The equation has been applied to the coordination compounds of Calcein Blue and found to be useful for the estimation of the lasing capability of a new material.

The coordination compounds of Calcein Blue have interesting characteristics as laser material; the lasing wavelength is easily modified by the complex formation and dissociation reactions, they are soluble in water, and their threshold values are low enough for practical use, since the quantum yield is near unity as a result of the ring formation. The complex with aluminium lases very efficiently at a shorter wavelength than any other efficiently-lasing coumarin derivatives and is stable enough for practical use. Thus, the coordination compound is proved to be a useful laser material.

The authors wish to thank Professors Yasushi Miyazoe and Mitsuo Maeda for their guidance in the construction of the nitrogen laser and for their advice in the measurement of the laser emission. We also wish to thank Mr. Kenyu Kina for his advice in the measurement of the fluorescence and absorption spectra and for his discussions. The authors are also thankful to Dr. Koichi Yamada and Dr. Kazuo Yugi (Toray Industries, Inc.) for supplying a roll of polyester film for the capacitor of the nitrogen laser.

The Crystal and Molecular Structure of an Anti-inflammatory Agent, 1-(Cyclopropylmethyl)-4-phenyl-6-methoxy-2(1*H*)-quinazolinone(SL-573)

Michio KIMURA, Toshiyuki HIROHASHI, and Hisao YAMAMOTO

Institute for Biological Science, Sumitomo Chemical Co., Ltd., Takatsukasa, Takarazuka, Hyogo 665

(Received April 9, 1976)

The crystal structure of the title compound (SL-573), crystallized from an ethyl acetate solution, has been determined by the single-crystal X-ray diffraction method. The crystals are monoclinic, with the space group $P2_1/a$, and these cell constants: $a=17.395(11)$, $b=8.371(5)$, $c=10.871(7)$ Å, $\beta=99°56(4)'$, and $Z=4$. The intensities were measured visually from equi-inclination integrated Weissenberg photographs taken with Cu $K\alpha$ radiation. The structure was solved by the symbolic addition method. The final R factor was 0.119 for 3284 reflections. The molecules are placed in pairs around the centers of symmetry and are linked by van der Waals' distances less than 3.94 Å. The dihedral angle between the quinazoline and phenyl ring planes was found to be 42.8°.

Recently several reports have been published on the syntheses and pharmacology of various quinazolines with marked anti-inflammatory activities.[1-3] Of these, 1-(cyclopropylmethyl)-4-phenyl-6-methoxy-2(1*H*)-quinazolinone(SL-573) has been reported to exhibit not only remarkably anti-inflammatory and analgesic activities in acute inflammation, but also effectiveness in adjuvant-induced chronic inflammation with a low toxicity, especially a minimum gastrointestinal lesion in animal tests.[1] In order to elucidate its pharmacological activities in terms of the molecular conformation, the title compound has now been studied by the X-ray diffraction method.

Experimental

Crystals suitable for X-ray analysis were grown from an ethyl acetate solution. They were rectangular prisms elongated along the b-axis. The unit-cell dimensions were determined from Weissenberg photographs calibrated with NaCl powder patterns superposed on them. The density was measured by flotation in an aqueous solution of KI. The crystal data are listed in Table 1. Crystal specimens with dimensions of $0.527\times0.466\times0.303$ and $0.507\times0.327\times0.547$ mm were selected for data collection around the a and b axes respectively. Weissenberg photographs for the layers of 0kl-12kl and h0l-h6l were taken with nickel-filtered Cu $K\alpha$ radiation. The intensities of 3284 independent reflections were estimated visually. The intensities were corrected for Lorentz and polarization factors, but no corrections were applied for the absorption and the spot shapes. The absolute scale and overall temperature factors ($B=3.81$ Å^2) were determined by Wilson's plot.[4]

Solution and Refinement of the Structure

The symbolic addition procedure[5] was used to solve the structure. Normalized structure factors, $|E_h|$, were calculated, and a set of Σ_2 relationships was tabulated. A starting set of three origin-defining reflections and three reflections assigned symbols are shown in Table 2. Each of these reflections had a high $|E_h|$ value and a large number of Σ_2 interactions. The signs or symbols of 252 reflections out of 473 with $|E_h|\geqslant1.4$

hydrogen atoms. The refinement of the structure was carried out by the block-diagonal least-squares method until the R value reached 0.152. A difference Fourier map using all the reflections indicated the positions of all 18 hydrogen atoms. In further refinement, however, the hydrogen atom coordinates calculated from geometrical considerations were used and were not refined. All the hydrogen atoms were given the same isotropic temperature factors as those of the atoms to which they are attached. The final R value was 0.119 for all the observed reflections. The final atomic parameters are shown in Table 3. The atomic scattering factors were taken from the "Internatioal Tables for X-ray Crystallography".[6] A list of the observed and calculated structure factors is kept by the office of the Chemical Society of Japan, (Document No. 7628).

All the calculations were carried out on the IBM 370 computer at the Computer Center of the Sumitomo Chemical Co., Ltd., using UNICS programs[7] revised for IBM 370 by Michio Kimura, one of the present authors.

Results and Discussion

The bond distances and angles are shown in Fig. 1. The mean estimated standard deviations of the bond distances and angles for the non-hydrogen atoms were 0.011 Å and 0.7° respectively. The averages of the aromatic C–C bond distances and C–C–C angles in the benzene ring C are 1.393 Å and 120.0° respectively. The six-membered ring, A, has a mean C–C bond distance of 1.393 Å and a mean C–C–C angle of 120.0°. These values are quite reasonable. The C(1)–N(1) bond distance of 1.388 Å is similar to those observed in other heterocyclic rings, for instance, dihydrothymidine[8], dihydrouracil[9]; and 5-methyluridine[10].

Table 4. Equations of least-squares planes in the $AX+BY+CZ+D=0$[a] form

The displacements (l/Å) of atoms from the planes are given in square brackets.

Symmetry code	Symmetry operation		
none	x	y	z
i	$1-x$	$1-y$	$1-z$
ii	$1-x$	$2-y$	$2-z$

The O(1)–C(1) bond distance of 1.223 Å are comparable with the value of 1.211 Å for 10-methylisoalloxazine hydrobromide dihydrate[11] and that of 1.213 Å for 3-phenyl-2,4-(1*H*,3*H*)-quinazolinedione.[13] The molecular conformation and thermal ellipsoids are illustrated by a stereoview in Fig. 2. Interest in the conformation of SL-573 is probably centered on the geometry of the linkage [C(2)–C(3) bond] between the phenyl group and the quinazoline ring. The

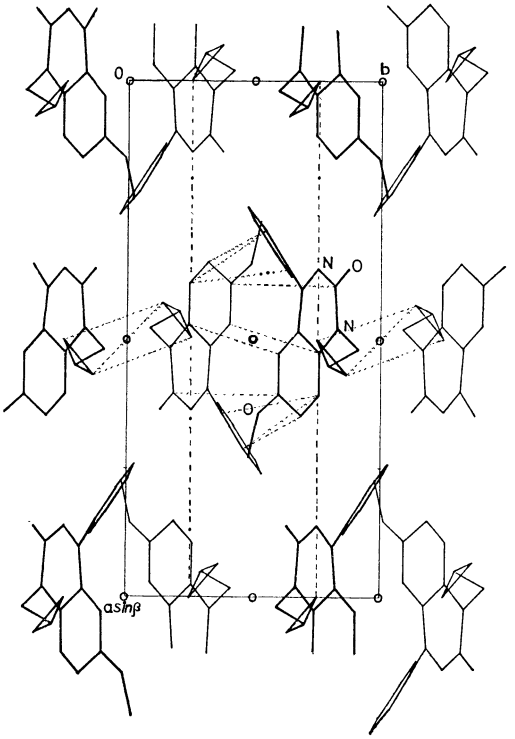

Fig. 5. Projection of the structure along the c axis.

quinazoline ring is very nearly planar, and the phenyl ring is planar within the limits of accuracy. The least-squares planes and the deviations of atoms from these planes are given in Table 4. The O(2) and C(16) atoms are on the quinazoline ring plane, and the O(1) and C(12) atoms deviate from the plane, as is shown in Fig. 3. The C(2)–C(3) bond length is 1.485 Å, close to the value of 1.477 Å proposed by Dewar and Schmeising[12], for the C_{sp^2}–C_{sp^2} single bond. This fact suggests that π-bonding is absent in the C(2)–C(3) bond. The steric repulsion caused by the hydrogens prevents the phenyl plane from being coplanar with the quinazoline ring; the dihedral angle between the phenyl and quinazoline planes is 42.8°. An inspection of the intermolecular distances (Table 5) indicates that the packing of the molecules is very efficient. The molecular arrangement in the crystal viewed along the b and c axes is illustrated in Figs. 4 and 5. The molecules are placed in pairs around the centers of symmetry and form tightly packed columns of molecules in the b axis direction. All the intermolecular contacts correspond to the van der Waals interaction. The shortest intermolecular distance is 3.60 Å, while the others are almost all within 3.94 Å.

Studies of the Removal of Dye Ions by Adsorbing Particle Flotation

Koichi KOBAYASHI, Nobuhiro WATABE, and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received April 19, 1976)

The removal of an anionic dye, Scarlet Red, a zwitterionic dye, Congo Red, and a cationic dye, Crystal Violet, from aqueous solutions was studied by the method of adsorbing particle flotation, using bentonite and benzylhexadecyldimethylammonium chloride as flotation agents. More than 99% of the Crystal Violet and Scarlet Red and 96% of the Congo Red could be floated under optimum conditions. It was found that a larger amount of a cationic surfactant was required for the flotation with an increase in the anionic nature of the dye ions, although the flotation was efficient irrespective of the ionic nature of dyes used. From this fact, the flotations of anionic and cationic dyes were confirmed to differ from each other in that the cationic-dye ions are floated by a direct exchange adsorption on bentonite, while the anionic-dye ions are floated by the adsorption on bentonite through the bimolecular layer of the cationic surfactant. The flotation efficiency of a dye ion, particularly of zwitterionic dye, was confirmed to depend on the pH.

A limited number of studies have been reported of the flotation of dye ions.[1-4] Karger *et al.* examined in detail the solvent sublation process for the removal of two dyes, Methyl Orange and Rhodamine B, using hexadecyltrimethylammonium bromide as the collector and 2-octanol as the immiscible organic liquid layer.[5-7] We ourselves have previously reported that Cu^{2+},Cd^{2+}, and Co^{2+} ions were effectively removed from an aqueous solution by adsorbing particle flotation,[8-10] which is considered to be an effective method of flotation. The process is defined as the removal of the dissolved materials by the flotation of the particle-like bentonite upon which the ions to be removed is adsorbed. So far, however, no application of the adsorbing particle flotation has been made to the removal of dye ions from an aqueous solution. Dye ions are especially suited to the study of flotation since they include various types of ions—namely anions, cations, and zwitterions—and they can be easily detected visually or assayed by colorimetry.

The present paper will describe the applicability of adsorbing particle flotation for the removal of dye ions, such as anionic Scarlet Red, zwitterionic Congo Red, and cationic Crystal Violet, from their aqueous solutions. Here, the effects of the gas-flow time, the pH, the amount of bentonite, the amount of the cationic surfactant, and the nature of the dye ions on the flotation efficiency have been studied.

Experimental

Materials. The benzylhexadecyldimethylammonium chloride (BHDAC) was obtained from the Nippon Oils and Fats Co., Ltd., and was purified by recrystallization from acetone. The bentonite powder(Bt) used as an ion exchanger was obtained from the Wako Pure Chemical Co., Ltd.; the fraction passing through a 350-mesh sieve was collected and dried under reduced pressure. The dyes used included cationic Crystal Violet(CV), anionic Scarlet Red(SR), and zwitterionic Congo Red(CR). These dyes were purified by recrystallization from ethanol and ether. A stock solution of the dye ions of a 1×10^{-4} mol/l concentration was prepared by dissolving these dyes in triply distilled water.

Apparatus and Procedure. The apparatus used for the flotation measurements was the same as has been described in a previous paper.[2] The sample solution of flotation was prepared by introducing 1 ml of a stock solution of the dye ions, and given amounts of Bt and BHDAC into a 10-ml measuring flask, adjusting the pH to a desired value, and diluting the solution to 10 ml with water. Nitrogen gas humidified with water vapor and controlled to a constant rate of gas-flow was bubbled through a glass filter (No. 4) into a flotation cell containing about 10 ml of the sample solution. After the flotation, the underlying liquid was taken out of the flotation cell for the determination of the dye-ion and Bt contents.

For the determination of the dye-ion concentration, the light absorption were measured for the dye ions and the calibration curves were prepared at their maximal absorption wavelengths (500 nm for CR, 580 nm for CV, and 500 nm for SR). The initial concentration of each dye ion of the sample solution was determined by using these calibration curves before the Bt addition. However, the dye-ion concentration after the flotation cannot be determined similarly since the measurement is hindered by the presence of the Bt-particle, which also reduces the light intensity by scattering. The concentration of the dye ions of such a solution was estimated by assuming that the absorbance at the maximal absorption wavelength is the sum of the absorbances of the dye ions and the scattering by Bt, while the absorbance at the minimal absorption wavelength is considered to be mainly due to the scattering by Bt. Then, the calibration curves of Bt without the dyes at the maximal and minimal absorption wavelengths were drawn. The amount of Bt in the sample was determined from the absorbance at the minimal absorption wavelength by applying the calibration curve of Bt at the minimal absorption wavelength; the contribution of the absorbance due to Bt at the maximal wavelength was estimated by applying the calibration curve of Bt at the maximal absorption wavelength. The absorbance due to dye ions alone was obtained by subtracting this contribution from the total absorbance by the sample solution at the maximal absorption wavelength. The concentration of dye ions was determined by using the calibration curve for the dye ions at the maximal absorption wavelength.

The flotation efficiency of the dye ions or Bt is conventionally expressed by:

$$F = \frac{C_i - C_f}{C_i} \times 100\%$$

where C_i and C_f are the initial and final concentrations respectively of the dye ions or Bt.

Results and Discussion

Gas-Flow Time, Amount of Bt, and Flotation Efficiency. First, we studied the effects of the amount of added Bt and the gas-flow time on the flotation efficiency for

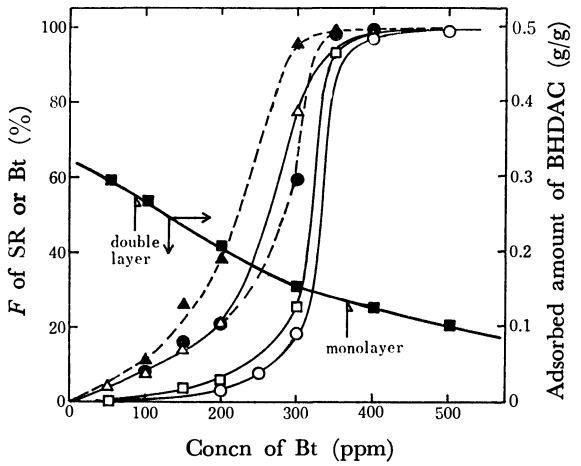

Fig. 1. Effect of gas-flow time on flotation efficiency.
SR: 1×10^{-5} mol/l, BHDAC: 50 ppm, gas-flow rate: 5 ml/min, pH: 5.4—5.9, gas-flow time (○, ●: 2 min, □: 5 min, △, ▲: 15 min), ——: F of SR, ----: F of Bt, ■: adsorbed amount of BHDAC.

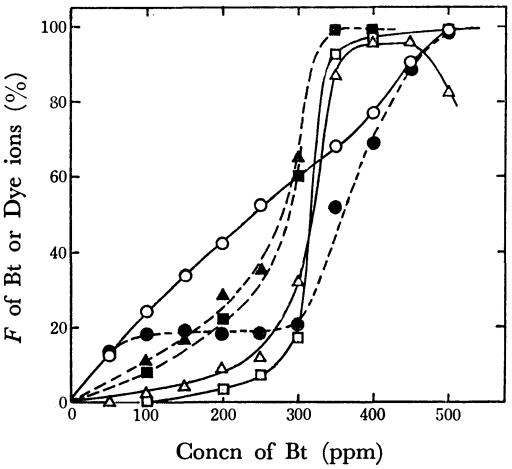

Fig. 2. Effect of ionic nature of dye on flotation efficiency.
Dye ions: 1×10^{-5} mol/l, BHDAC: 50 ppm, gas-flow rate: 5 ml/min, gas-flow time: 2 min, ——: F of dye ions (○: CV, △: CR, □: SR), ----: F of Bt (●: CV, ▲: CR, ■: SR).

the SR–BHDAC–Bt system, keeping the amount of BHDAC and the gas-flow rate constant. The results are shown in Fig. 1. As may be seen in the figure, flotation efficiencies of SR and Bt increase with the increases in the gas-flow time and in the amount of Bt added. The curves sharply rise in the vicinity of 300 ppm Bt, and nearly 100% flotation efficiencies of SR and Bt are obtained at 400 ppm Bt. In the region of Bt content below 400 ppm, the flotation efficiency of SR is lower than that of Bt. This may suggest the presence of free SR being adsorbed neither on Bt nor on an aqueous surface. Since SR alone and the SR–BHDAC complex are not easy to float, as will be shown later (Fig. 8), the coincidence of the SR and Bt curves near 100% flotation at about 400 ppm may indicate the complete adsorption of SR on Bt. Further, the amount of adsorption of BHDAC on Bt, though not directly measured, was presumed from the adsorption isotherm on Bt of hexadecyltrimethylammonium chloride,[11] which has a molecular structure similar to that of BHDAC. The solid squares in Fig. 1 indicate the amount of the adsorption of BHDAC on Bt on such an assumption. Here, the arrows indicate a monolayer and a bimolecular layer adsorption of BHDAC, as estimated from the base-exchange capacity of Bt.[11] As may be seen in the figure, the flotation efficiency of Bt decreases from 100% to a very low value in the concentration region from the monolayer to the bimolecular layer adsorption. This behavior is similar to those reported in a previous paper.[11] Since an F value of 100% was obtained at the gas-flow time of 2 min and above, all the subsequent experiments were carried out under the conditions of 50 ppm BHDAC, 0 to 500 ppm Bt, 1×10^{-5} mol/l dye, pH 5.4 to 5.9, a gas-flow time of 2 min, and a gas-flow rate of 5 ml/min.

Ionic Nature of Dyes and Flotation Efficiency. In order to study the effect of the ionic nature on the flotation efficiency, the flotation experiments were carried out for CR and CV by varying the amount of added Bt under the same conditions as for SR. The results for the flotation efficiency of dye ions and Bt are illustrated by the solid and broken lines respectively in Fig. 2, together with the experimental results for SR shown in Fig. 1. The flotation efficiencies of the dye ions and Bt increase for all the dye–Bt–BHDAC systems with an increase in the amount of added Bt. Here, zwitterionic CR behaves as an anion under experimental condition of a pH value between 5 and 6 since it has an isoelectric point of about 3. Therefore, the F curves for CR–BHDAC–Bt and SR–BHDAC–Bt systems are similar in their behavior: the F curve of the dye ions is lower than that of Bt, and beyond 400 ppm of Bt addition, F increases to 95—97% for both Bt and dye flotation efficiencies. In the case of cationic CV, however, the flotation efficiency of Bt exhibits a low plateau in the region of a small Bt addition: it then increases sharply near the 300 ppm Bt addition, and rise to nearly 100% in the vicinity of 500 ppm Bt. In the case of CV flotation, the flotation efficiency of the dye ions is higher than that of Bt over the whole region of Bt added, while the flotation efficiency of the dye ions is lower than that of Bt in the cases of CR and SR. These discrepancies indicate the existence of free dye ions not adsorbed on Bt; in the case of CV the free ions are adsorbed directly on bubbles and are floated, while CR and SR are not adsorbed and are not floated: this adsorption effect is dominant in the region of smaller amounts of Bt addition and lower F values, where there is not much Bt available for CV adsorption. Further, the possibility that CR and SR combine with BHDAC and float is considered. However, such a possibility can not be practically expected considering the flotation data for various anionic dyes by several cationic surfactants[12] and also the results shown in Fig. 8.

The effects of the anionic and cationic dyes on the flotation efficiency of Bt were further studied in detail in relation to the system without any added dye. The results are shown in Fig. 3. As may be seen in the figure, the flotation curves of Bt for the anionic dye–

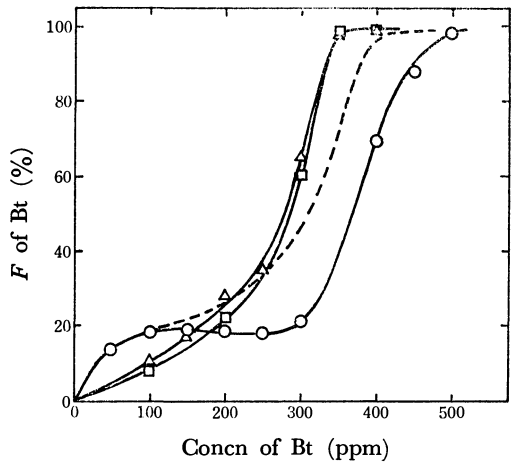

Fig. 3. Effect of dye ions on flotation efficiency of Bt. Dye ions: 1×10^{-5} mol/l, BHDAC: 50 ppm, gas-flow rate: 5 ml/min, gas-flow time: 2 min, ——: F of Bt (○: CV, □: SR, △: CR), ----: F of Bt for system of no added dyes.

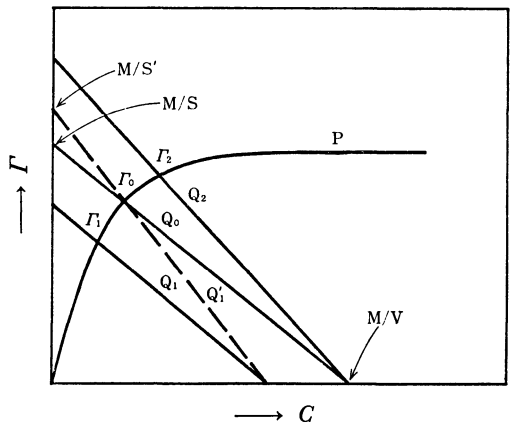

Fig. 4. Relation between amount of adsorption and equilibrium concentration of BHDAC.

BHDAC–Bt and cationic dye–BHDAC–Bt systems shift left and right, respectively, to the curve of the BHDAC–Bt system. These phenomena can be explained from the amount of BHDAC adsorption as follows.

The amount of adsorption of BHDAC on Bt, Γ, can be calculated from the adsorption isotherm;

$$\Gamma = f(C) \tag{1}$$

and

$$S\Gamma + VC = M \tag{2}$$

where V is the volume of solution; C and M, the equilibrium concentration and the total amount of BHDAC respectively, and S, the total amount of Bt added to the system. According to these equations, the value of Γ is graphically obtained to be as is shown in Fig. 4. In this figure, the P and Q lines express Eqs. 1 and 2 respectively, while the point of intersection, Γ, gives the amount of adsorption for a given S, V, and M. Since the intercept of Eq. 2 on the ordinate is M/S, and since that of the abscissa is M/V, Γ is a function of M/S and M/V for a given Eq. 1, that is, for the BHDAC–Bt system. If the straight line, Q_0, expresses

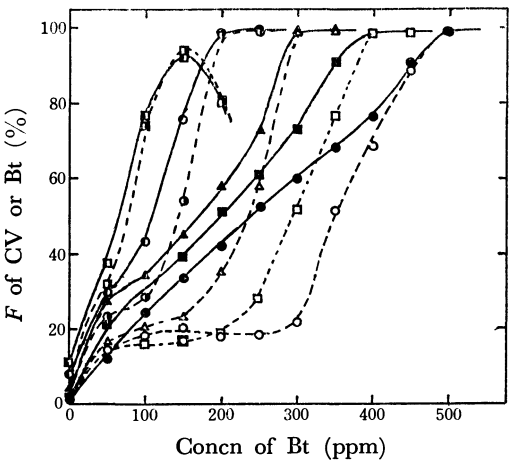

Fig. 5. Effect of BHDAC on flotation efficiency. CV: 1×10^{-5} mol/l, BHDAC (◨, ◧: 10 ppm, ◐, ◑: 20 ppm, △, ▲: 30 ppm, □, ■: 40 ppm, ○, ●: 50 ppm), pH: 5.3—5.9, gas-flow rate: 5 ml/min, gas-flow time: 2 min, ——: F of CV, ----: F of Bt.

Eq. 2 for the system without a dye, the Γ_0 value in Fig. 4 is the amount of adsorption for this system. Now, the amount of effective BHDAC, M, decreases when SR or CR are added because the dye combines with it. Thus, Eq. 2 for the SR system moves from Q_0 to Q_1, and the point of intersection, Γ_1, shifts towards a smaller value. To restore Γ_1 to the original value, Γ_0, for the system without a dye, the value of S should be decreased to S' so as to increase the M/S ,as is shown by the broken line, Q'_1. This means that the same F value can be obtained by a smaller addition of Bt to the SR and CR systems as compared with the system without a dye: this results in a shift of the SR and CR curves in Fig. 3 to the left. In the case of the CV–BHDAC–Bt system, the effective S available for BHDAC adsorption decreases because some of the adsorption sites of Bt are occupied by cationic CV. The decrease in S increases the M/S value, Eq. 2 moves from Q_0 to Q_2 and the Γ_0 value increases to Γ_2. This results in an opposite effect to that in the case of SR and shifts the F curve of CV to the right of that for the system without a dye.

Concentration of BHDAC and Flotation Efficiency. Figure 5 shows the flotation efficiencies of CV and Bt as a function of the amount of Bt for various concentrations of BHDAC. As may be seen in the figure for a given concentration of BHDAC, at a relatively small amount of Bt addition, the F for CV flotation is larger than that for Bt, while both values are close or agree and become 100% at larger amounts of Bt addition, regardless of the concentration of BHDAC. In the case of an BHDAC addition of 10 ppm, however, the flotation efficiency of Bt and CV shows a maximum less than 100% at 150 ppm Bt. This means that the amount of BHDAC adsorbed decreases below the minimum amount of BHDAC adsorption necessary for 100% flotation.

In Fig. 5, the weight ratio of BHDAC/Bt may be observed to be constant to about 1/10 at the shoulder of $F\simeq100\%$, regardless of the amount of BHDAC added. According to the adsorption isotherm of

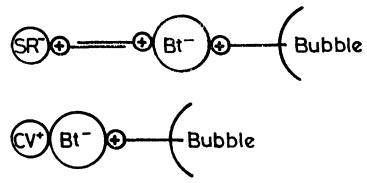

Fig. 6. Comparison of sublate structure of SR–Bt–BHDAC and CV–Bt–BHDAC systems. ⊕——: BHDAC.

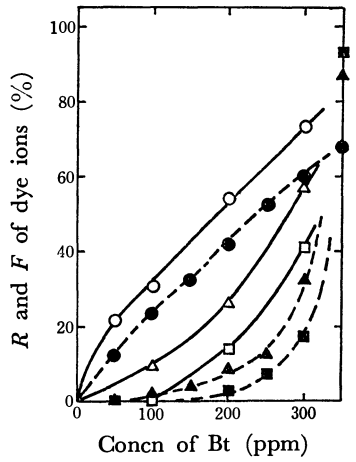

Fig. 7. Effect of dye ions on percent removal of dye ion. Dye ion: 1×10^{-5} mol/l, BHDAC: 50 ppm, gas-flow rate: 5 ml/min, gas-flow time: 2 min, ——: R of dye ions (○: CV, □: CR, △: SR), ----: F of dye ions (●: CV, ■: CR, ▲: SR).

BHDAC on Bt (Fig. 4) this means the constancy of M/S and that Γ is independent of M/V. This can be realized only when the adsorption isotherm (Eq. 1) shows an initial rise very close to the ordinate and exhibits a distinct shoulder, as has previously been reported.[11] Further, since, in this condition, the dyes and Bt nearly completely float, the above BHDAC/Bt ratio is nearly equal to the composition of the BHDAC–Bt sublate. Thus, when we compare the SR system of 50 ppm BHDAC and 400 ppm Bt in Fig. 1 with the CV system of 40 ppm BHDAC and 400 ppm Bt in Fig. 5, both of them showing a nearly 100% flotation efficiency of the Bt and dye ions, a larger amount of surfactant is required for the sublate of SR than for that of CV. Some tentative models for such systems are shown schematically in Fig. 6. The situation is quite similar to the case of Fe^{3+} and MnO_4^- flotation previously reported.[13]

Centrifuging. For systems in which the F values of Bt and dye ions are nearly 100%, as is shown in Figs. 1 and 2, the dye ions are considered to be completely adsorbed on Bt and subsequently floated by BHDAC. However, when the F value is less than 100% and when the curves for dye and Bt do not coincide, some dye ions are considered not to be combined with Bt. To confirm such details, the underlying liquid of the system after flotation carried out under the conditions of Fig. 2 was centrifuged for 20 min at 4000 rpm. In Fig. 7, the total percentage of the removal (R) of dye ions centrifuged and floated, namely,

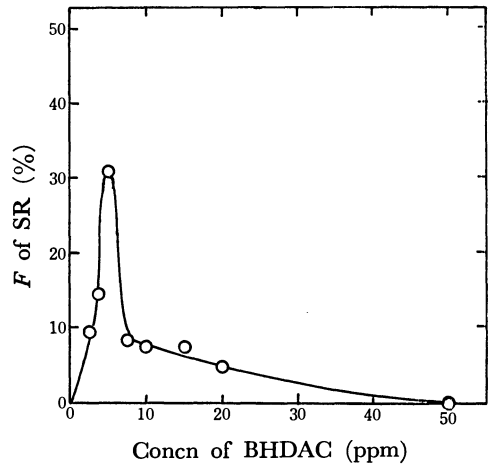

Fig. 8. Flotation efficiency of SR *vs.* BHDAC concentration for SR–BHDAC system. SR: 1×10^{-5} mol/l, gas-flow rate: 5 ml/min, gas-flow time: 2 min.

the percentage obtained by subtracting the percentage of dye ions remaining after centrifugation from 100%, is plotted against the amount of added Bt as solid lines. The dye flotation curves of Fig. 2 are also drawn for comparison. As may be seen, the total removal curves of CV, SR, and CR are located above the flotation curve. The difference in the ordinate between the two curves gives the amount of dyes combined with Bt and retained in the solution. In Fig. 7, the total percentage of the removal of CV is read as 22% for the system of 50 ppm Bt, where the total percentage of the removal of Bt is found to be 100%. From these data, together with the 14% flotation efficiencies of both Bt and CV at 50 ppm Bt addition (Fig. 2), the following equations are obtained:

$$F_0 + F_1 = 14, \quad F_0 + F_1 + S_1 = 22,$$

$$S_1/F_1 = (100-14)/14, \quad S_0 + S_1 + F_0 + F_1 = 100$$

where F_0 is the flotation efficiency of CV ions adsorbed directly on bubbles; F_1, the percentage of CV ions adsorbed on Bt and floated; S_0, the percentage of free CV ions remaining in the solution, and S_1, the percentage of CV ions adsorbed on Bt and remaining in the solution. From the above equations, F_0, F_1, S_0, and S_1 are calculated to be 12.7%, 1.3%, 78.0%, and 8.0%. Thus, we can confirm the amounts of the dye ions in various states in the solution and in the sublate, although this is an instance of rather incomplete flotation, as judged from the position on the curve in Fig. 7.

Flotation of the SR–BHDAC System. Figure 8 shows the flotation efficiency curve for the SR–BHDAC system without Bt. A sharp but small rise in flotation efficiency is seen in the relatively low concentration region. This result shows that the possible formation of the SR–BHDAC complex, if any, does not contribute appreciably to the SR flotation efficiency.[13] Rather, it decreases the free SR ion and hinders the adsorbing flotation, as has been mentioned above. The experiment also confirms that the addition of Bt is essential for a high flotation efficiency, with the possible sublate structure shown in Fig. 6.

Effect of the pH on the Flotation Efficiency. The

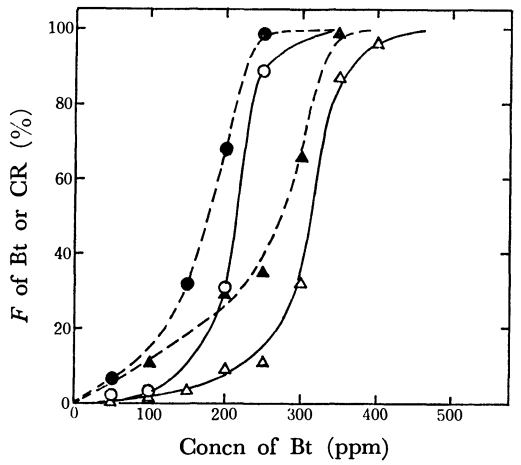

Fig. 9. Effect of pH on flotation efficiencies of CR and Bt. CR: 1×10^{-5} mol/l, BHDAC: 50 ppm, gas-flow rate: 5 ml/min, gas-flow time: 2 min, ——: *F* of CR (○: pH 2, △: pH 5—6), ----: *F* of Bt (●: pH 2, ▲: pH 5—6).

effect of the pH on the ion flotation is usually considered to be important. Figure 9 shows the effect of the pH on the flotation efficiency of the CR and Bt of the CR–BHDAC–Bt system. Here, we used CR as a dye since it is sensitive to the pH because of its zwitterionic nature. The measurements were made at pH 2 and 5, adjusted by the addition of hydrochloric acid. Since the isoelectric point of CR is near 3, CR ions are considered to be in the cationic and anionic forms respectively at the respective pHs. It may be expected, therefore, that the *F* curve of Bt shifts right at pH 2 and left at pH 5 to the *F* curve of Bt without dye addition, as is shown in Fig. 3. The result obtained at pH 5 is in accord with the expectation, while the result at pH 2 is contrary to what is expected: the *F* curve of Bt markedly shifts even left to that of the SR shown in Fig. 2. This can be explained by saying that, since the H^+ ion concentration at pH 2 is markedly higher than that of the BHDAC ion (10^{-5} mol/l), the adsorption of the BHDAC cation on Bt is hindered by hydrogen-ion adsorption; the effect is equal to the reduction of the BHDAC concentration as far as the amount of adsorption is concerned. Thus, the shift of the *F* curve for CR at pH 2 is in the same direction as that for SR, as shown in Fig. 3. Here, as the concentration of the hydrogen ion is much larger than that of the SR ions in Fig. 2, the shift for CR is expected to be far greater than that for SR.

Table 1. The optimum conditions of dye-ion flotation

Dye	CV^+	$CR^\pm$	SR^-
Dye concn. (mol/l)	1×10^{-5}	1×10^{-5}	1×10^{-5}
Surfactant concn. (ppm)	15	50	50
Bt concn. (ppm)	150	400	350
Surfactant/Bt	1/10	1/8	1/7
Gas-flow time (min)	2	2	2
Gas-flow rate (ml/min)	5	5	5
F of dye (%)	98	96	98
Volume of liquid taken (ml)	10	10	10

Optimum Condition of Flotation. The optimum conditions of dye-ion flotation obtained in this study are tabulated in Table 1. In Table 1, the BHDAC/Bt ratio expresses the composition of the solution, which also represents the composition of the sublate for the reasons mentioned already. This table confirms that a larger amount of cationic surfactant is required for the flotation with an increase in the anionic nature of the dye ions; this is in accord with the results obtained for Fe^{3+} and MnO_4^- ion flotation.[12]

Temperature-independent Delayed Fluorescence of Benzo[*f*]quinoline in Biphenyl Host: A New Interpretation of Delayed Fluorescence Behavior around 77 K

Yoshihumi KUSUMOTO,* Yasuhiko GONDO, and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 28, 1976)

The delayed fluorescence observed in the mixed crystals of benzo[*f*]quinoline in biphenyl host has been found to be independent of temperature in the low temperature region from 90 K down to liquid helium temperature, and subtraction of this temperature-independent contribution from the observed total delayed fluorescence intensity above 90 K has given straight-line fits of the log I_{DF}/I_P^2 *vs.* $1/T$ plots, that is, a single activation energy has been obtained over the whole temperature range studied, instead of two different ones as usually assumed. Such a correction has also been given to a new attempt of log I_{DF} *vs.* $1/T$ plots successfully. Moreover, the decay behavior of the delayed luminescence has been studied over the wide temperature and concentration range. It has been concluded that the decay behavior of the temperature-independent delayed fluorescence may mainly be responsible for the nonexponential decay of the delayed fluorescence around 77 K.

Since the delayed fluorescence (DF) was first observed in 1958,[1] a number of studies have been made in a variety of liquid solutions,[2] in rigid glassy solutions,[3] in vapor phases[4] and in so-called "pure" crystals[5] as well as mixed crystals.[6–12] Early investigations in the mixed crystal systems were carried out at temperatures higher than 77 K by many investigators, particularly by Hirota *et al.*[8] and McGlynn and his co-workers,[13] and it has been concluded that the guest triplet excitation migration is a thermally activated process and occurs through the host triplet exciton band. In addition, the kinetic model for the delayed luminescence (phosphorescence and delayed fluorescence) has been proposed and substantiated except for the DF behavior in the vicinity of 77 K, that has been a deadlock encountered in the usual kinetic model and some interpretations have been made thereupon.[8b,13] Under such circumstances, we have investigated the temperature and concentration dependence of DF of benzo[*f*]quinoline in biphenyl host crystals, the temperatures and the concentrations extending over a wide range of 4.2—230 K and 10^{-2}—10^{-4} mol/mol, respectively.

We observed the temperature-independent delayed fluorescence (TIDF) in the low temperature region where the nature of DF had never been satisfactorily understood. Similar TIDF had been noticed by several investigators,[8b,14–16] but the significance of TIDF has never been explored. In this paper, we will discuss the significance of this TIDF for the usual temperature-dependent model. Some of these results have been presented previously as brief reports.[17,18]

Experimental

Chemicals and Samples. The chemicals used were obtained from Tokyo Kasei Kogyo Co., Ltd. Biphenyl was recrystallized twice from ethanol, and was further purified by repeated zone refining over 200 passes. Benzo[*f*]quinoline was subjected to the same chemical treatment as described previously,[19] and was finally zone refined with 250 passes. The polycrystalline samples used were prepared from the melts between two fused-silica plates mounted in a brass or a copper block holder, as will be mentioned later on.

Apparatus. The emission spectra were recorded with a photoelectric recording system which was essentially composed of a Bausch & Lomb 500-mm grating monochromator equipped with an RCA 1P28 photomultiplier, a DC preamplifier incorporating a Teledyne Philbrick operational amplifier model 1009, and a Hitachi recorder model QPD-54. The lifetimes of the delayed luminescence were measured with an Iwasaki SS-5004 synchroscope at appropriate wavelengths. A Becquerel-type rotating-disk phosphoroscope was used to exclude normal fluorescence. Excitation radiation was obtained from a 1-kW high-pressure mercury arc lamp, model Orc-CH-612. The excitation light beam was passed through a selective filter combination.

A Dewar cryostat system has been devised to keep the temperature nearly constant during observation. The brass and copper block holders were used for the regions above and below 77 K, respectively. The equipment was constructed according to Nakamura *et al.*[20] The temperature was raised by natural evaporation of the liquid helium or liquid nitrogen, as the case may be. The rate of evaporation was so slow that we were able to monitor constantly the temperatures of the sample crystals and the intensities of luminescence.

The temperatures higher than 77 K were measured by means of a calibrated copper-constantan thermocouple in contact with a fused-silica plate, and by a Yokogawa microammeter type MPs. The temperatures lower than 77 K were measured with a calibrated 1/8-W, 51-Ω Allen-Bradley carbon resistor which was attached to a portion of the copper block holder close enough to the sample to ensure good thermal contact. The resistance was measured with a hand-made DC Wheatstone bridge incorporating a Yokogawa electronic galvanometer type 2707 and a Yokogawa decade resistance box type RV-61.

Results

Observations at 77 K. Figure 1 shows a comparison of the delayed and normal fluorescence of a polycrystalline sample of biphenyl doped with benzo[*f*]quinoline. The normal and the delayed fluorescence spectrum are in good agreement with each other, confirming that the observed DF is genuine. We have already confirmed that the guest-delayed luminescence is genuine in a previous paper.[21]

We examined the temperature and concentration

dependence in the delayed luminescence in respect of several bands a, b, c and d shown in Figs. 1 and 2.

Temperature Dependence of Intensity. Results in the Temperature Region above 77 K: General features of the temperature dependence of the delayed luminescence intensity were almost identical with those of Hirota and Hutchison,[8a] Hirota,[8] and Misra and McGlynn.[10] The temperature dependences of the delayed luminescence at a guest concentration of 1.2×10^{-2} mol/mol are shown in Fig. 3 as a typical example; results obtained at more dilute concentrations (10^{-3} and 10^{-4} mol/mol) were essentially the same. It can be inferred from Fig. 3 that the DF intensity seems to become constant in the lower temperature region. This was confirmed experimentally as will be described later.

Results in the 4.2—77 K Temperature Range: The temperature dependences of the delayed luminescence intensity at various guest concentrations are shown in

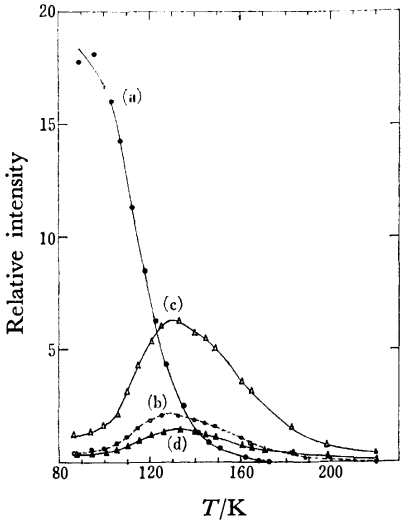

Fig. 3. Temperature dependence of the delayed luminescence of benzo[*f*]quinoline in biphenyl host in the temperature region above 77 K. Concn: 1.2×10^{-2} mol/mol. (a): Phosphorescence intensity observed at 464 nm, *i.e.*, the 0,0-band shown in Fig. 2; (b), (c), and (d): delayed fluorescence intensities observed at the corresponding bands shown in Fig. 1. No correction was made for the spectral response of the apparatus.

Figs. 4a, 4b, and 4c. At a concentration of 1.2×10^{-2} mol/mol (Fig. 4a), the DF intensity was essentially independent of temperature in the range of 25—77 K, while at lower temperatures it was dependent on temperature and reached a sharp maximum around 10 K. Similar behavior was also observed at a guest concentration of 1.25×10^{-3} mol/mol (see Fig. 4b). However, the maxima around 13 K were fairly lower than those in Fig. 4a. At a more dilute concentration of 1.0×10^{-4} mol/mol, the DF intensity remained constant over a wider range (4.2—77 K), without any appreciable maximum around 10 K (see Fig. 4c). This is quite different from the behavior of the other two cases as shown in Figs. 4a and 4b. By application of an empirical relation of Misra and McGlynn,[10] $T_{max}=0.06\,\Delta E/k$, to the maximum around 10 K, an activation energy of the order of 100 cm^{-1} was predicted. This shallow depth and the disappearance of the maximum around 10 K in the concentration as low as 10^{-4} mol/mol lead to a conclusion that the pertinent trap is of the so-called X-trap. In this connection, it may be noted that the mixed crystals studied in the temperature range of 4.2—77 K are sufficiently pure in the sense that this shallow depth is smaller by a factor of 10 than the depth involved in the thermal activation process to be discussed later on, and hence the presence of this shallow trap does not give any influence on the later discussion.

The phosphorescence intensity appeared to be independent of temperature at lower temperatures, while at higher temperatures it fell off with an increase in temperature, in every case shown in Figs. 4a, 4b, and 4c.

Decay Behavior. Results in the Temperature Region above 77 K: The decay behavior of the delayed lumines-

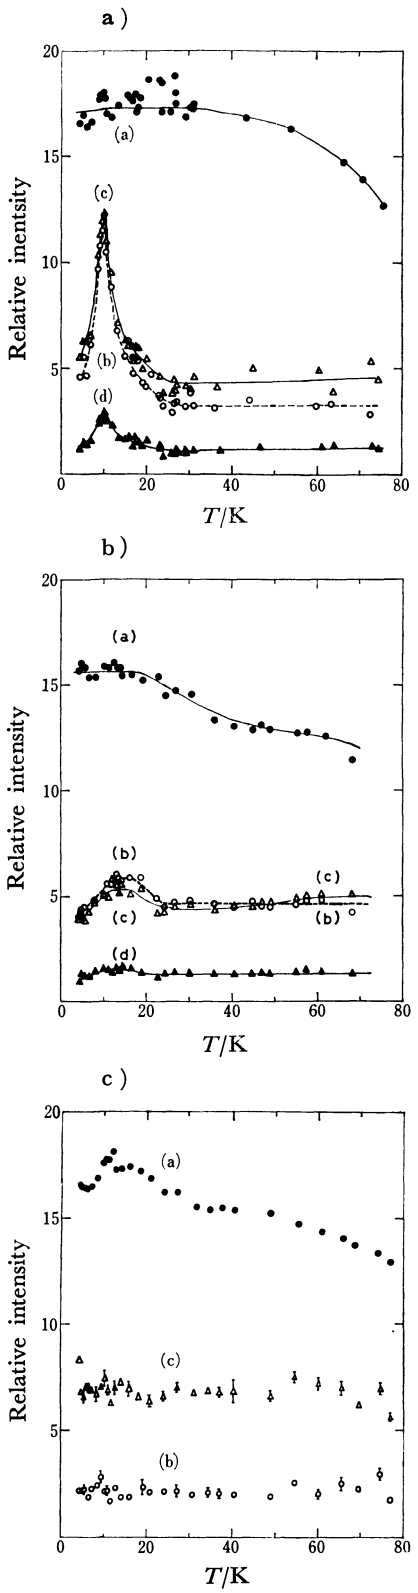

Fig. 4. Temperature dependence of the delayed luminescence of benzo[*f*]quinoline in biphenyl host in the 4.2—77 K temperature range. Magnification of the delayed fluorescence intensity to the phosphorescence intensity: a) × 10, b) × 20, c) × 25. No correction was made for the spectral response of the apparatus.

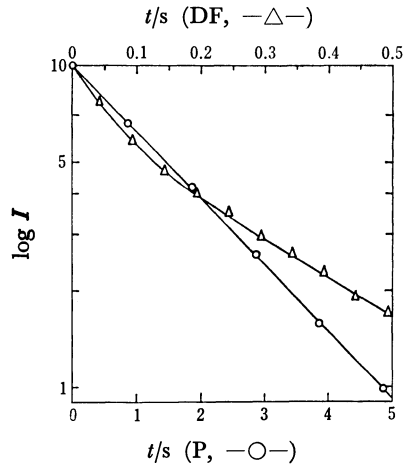

Fig. 5. Phosphorescence (P) and delayed fluorescence (DF) decays of benzo[*f*]quinoline in biphenyl host at 31 K. Concn: 1.2×10^{-2} mol/mol. The upper scale is for the plots of DF decay, and the lower scale for the plots of P decay. The initial intensities are obtained by extrapolation and arbitrarily normalized to 10.

cence at temperatures above 77 K is essentially in agreement with those observed by Hirota and Hutchison[8a] and Hirota.[8] The decay of the phosphorescence was observed to be exponential up to about 100 K and became nonexponential at higher temperatures. The decay of DF was nonexponential in a short time decay region even around 77 K, while it was exponential in a long time decay region. Such an apparently exponential decay behavior only in the long time region was also observed for the overall nonexponential decay of the phosphorescence.

Results in the 4.2—77 K Temperature Range: The decay characteristics of the delayed luminescence observed in the temperature range of 4.2—77 K were investigated for the concentration range of 10^{-2}—10^{-4} mol/mol. The phosphorescence decays were exponential in this temperature range, whereas the DF decays were generally nonexponential in the same temperature range. A typical decay behavior of the delayed luminescence observed for a concentration of 1.2×10^{-2} mol/mol at 31 K is shown in Fig. 5. At long times, however, the DF decay became exponential. As for DF, therefore, we will confine our discussion hereafter to the exponential decay region, that is, the long time decay region. In Fig. 6 is shown the temperature dependence of the delayed luminescence lifetimes measured at the concentration of 1.2×10^{-2} mol/mol. The phosphorescence lifetimes at the temperatures above about 100 K were obtained only in the long time decay region, whereas those below about 100 K were obtained in the whole decay region due to the exponential decay behavior of the phosphorescence. The point observed at the so-called characteristic temperature,[8b,22] where deviation from exponential decay behavior of the phosphorescence begins to appear, is marked with an arrow in Fig. 6. The temperature dependences of the decay behavior observed at the more dilute concentrations of 1.25×10^{-3} and 1.0×10^{-4} mol/mol were similar to that at the higher concentration just mentioned above. As

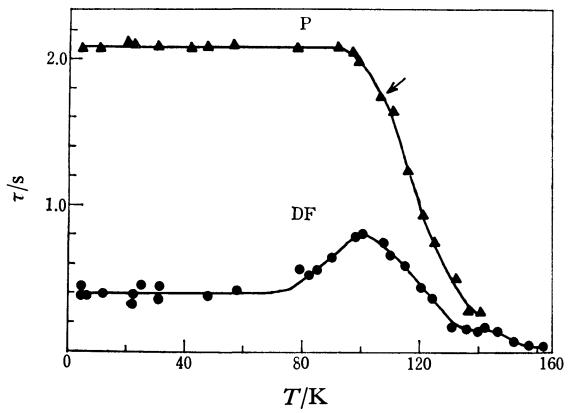

Fig. 6. Temperature dependence of the P and DF lifetimes of benzo[*f*]quinoline in biphenyl host. Concn: 1.2×10^{-2} mol/mol. The arrow refers to the characteristic temperature.

shown in Fig. 6, the decay behavior of the DF and phosphorescence remains constant at least in the temperature range of 4.2—70 K. The mean lifetimes obtained in this temperature range are 2.09 and 0.39 s for the phosphorescence and DF decays, respectively.

Discussion

Kinetics. Since the kinetic model used here has been discussed in detail by many authors,[3a,6a,8,10–12,22] we will briefly summarize the usual temperature-dependent kinetic model for the convenience of discussion. The rate processes with the relevant rate constants are identified in Table 1.[11b] The rate equations for the singlet and triplet guest populations are given by

$$\frac{d[S_{1G}]}{dt} = R_0 - (K_1+k_2)[S_{1G}] + K_4[T_{1G}]^2 \quad (1)$$

$$\frac{d[T_{1G}]}{dt} = \frac{k_2R_0}{K_1+k_2} - K_3[T_{1G}] - k_6[T_{1G}]^2 \quad (2)$$

where

$$k_6 = K_4(2K_1+k_2)/(K_1+k_2) + K_5 \quad (3)$$

From straightforward manipulation of Eqs. 1 and 2, the expressions for the steady-state intensities and the decays of phosphorescence (P) and DF are given by

$$I_P = k_3{*}k_3[(4K+1)^{1/2}-1]/2k_6 \quad (4)$$

$$I_{DF} = k_1{*}K_4K_3^2[(4K+1)^{1/2}-1]^2/[4k_6^2(K_1+k_2)] \quad (5)$$

$$I/I_P = (1-A)/[\exp(K_3t)-A] \quad (6)$$

$$I/I_{DF} = (1-A)^2/[\exp(K_3t)-A]^2 \quad (7)$$

where

$$K = k_2k_6R_0/(K_1+k_2)K_3^2 = A/(1-A)^2 \quad (8)$$

$$A = \frac{k_6[T_{1G}]_0}{K_3+k_6[T_{1G}]_0} = \frac{(1+4K)^{1/2}-1}{(1+4K)^{1/2}+1} \quad (9)$$

From Eqs. 4 and 5, one obtains

$$I_{DF}/I_P^2 = k_1{*}K_4/[(K_1+k_2)k_3{*}^2] \quad (10)$$

The temperature dependences of the quantities K_4, K_5, k_6, and K are given as

$$K_4,\ K_5,\ k_6,\ K \propto \exp(-\Delta E/kT) \quad (11)$$

where ΔE is the energy separation between the host and guest triplet states, and k Boltzmann's constant. With these expressions for the quantities K_4, K_5, k_6, and K, one may predict the temperature dependences of the delayed luminescence intensities and decays, assuming all the other rate constants to be independent of these quantities.[11] In the temperature-dependent triplet-triplet annihilation kinetics described above, it is assumed that there is no significant temperature-independent long range direct interaction between guest triplet states.[11b] It will be shown, however, that such an assumption does not necessarily hold, at least phenomenologically, in the vicinity of 77 K and below.[17,18] Since the kinetic model used here is the temperature-dependent one, the DF intensity (I_{DF}) in Eqs. 4 and 10 should duly be temperature-dependent. Since our experiment revealed the presence of the temperature-independent portion in I_{DF} (I_{TIDF}), the above-described expressions should be applied only for $[(I_{DF})_{total}-I_{TIDF}]$, where $(I_{DF})_{total}$ is the observed total I_{DF}.

Table 1. Definition of the rate processes involved in the triplet-triplet annihilation

	Process[a]	Rate constant	Remarks[b]
(0)	$S_{0H}\rightarrow S_{1G}$	R_0	Over-all rate constant

a) S_0: Ground singlet state; S_1: lowest excited singlet state; T_1: lowest excited triplet state; G: guest; H: host. b) For detail, see text.

Significance of TIDF in Evaluation of Activation Energy. As shown in Figs. 3 and 4, I_P observed in the lower temperature region was dependent on temperature, contrary to the prediction from the kinetic model. The origin of this temperature dependence of I_P in the lower temperature region is not clear at present, although some explanations have been offered.[14,15] From expressions (4), (5), and (10), and relations (11) on the temperature dependence, one can obtain the following three Arrhenius plots:[11]

(1) In the higher temperature region, log I_P *vs.* $1/T$ (plot (1))
(2) in the lower temperature region, log I_{DF} *vs.* $1/T$ (plot (2))
(3) in the whole temperature region, log I_{DF}/I_P^2 *vs.* $1/T$ (plot (3))

Accordingly, we can obtain the activation energy ΔE from the above three plots. Plot (2) has for the first time been attempted by us. Figure 7 shows that the plot of log $[(I_{DF})_{total}-I_{TIDF}]$ *vs.* $1/T$ instead of log $(I_{DF})_{total}$ *vs.* $1/T$ gives a good straight-line fit for plot (2). The straight-line fit of log I_P *vs.* $1/T$ plot in the higher temperature region as predicted from plot

a) See Ref. 23. b) Activation energy calculated from the temperature dependence of the delayed luminescence. See text. c) See Fig. 1. d) T_{max} is the temperature at which maximum intensity of DF occurs. e) Calculated from an empirical relation, $T_{max}=0.06\,\Delta E/k$. See Ref. 10. f) See text. g) Only the corrected plot gives a good fit to a straight line. See text. h) $(I_{DF})_c$ denotes the DF intensity at 85 K, where I_{DF} approximately equals the temperature-independent contribution, *i.e.*, I_{TIDF}. $(I_{DF})_m$ refers to T_{max}.

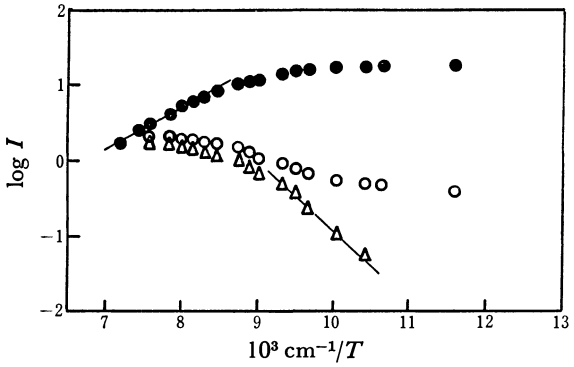

Fig. 7. Plots of $\log (I_{DF})_{total}$ (○), $\log [(I_{DF})_{total}-I_{TIDF}]$ (△), and $\log I_P$ (●) *vs.* $1/T$ with I_{DF} at band b shown in Fig. 1. Concn: 1.2×10^{-2} mol/mol.

(1) is also shown in Fig. 7. The thermal activation energies thus obtained are listed in Table 2. According to Misra and McGlynn,[10] plot (3) gave a good fit to a straight line in the high temperature region, whereas the deviation therefrom was observed in the low temperature region, showing a much smaller slope in the latter temperature region. They have suggested on the basis of the smaller activation energy obtained from this smaller slope that DF observed in the vicinity of 77 K may well be due to the annihilation involving thermal depopulation of defect states. However, DF around 77 K was independent of temperature in our cases as shown in Fig. 4. Moreover, as mentioned above, I_{DF} was independent of temperature in a wide range below 90 K. Therefore, such an analysis as given by Misra and McGlynn should be re-examined taking into account of this TIDF.[17] As Fig. 8 shows, subtraction of the temperature-independent contribution gave straight-line fits of the semilog plots over the whole temperature region studied. The thermal activation energies thus obtained are also listed in Table 2 in the column "corrected," while the corresponding "uncorrected" values

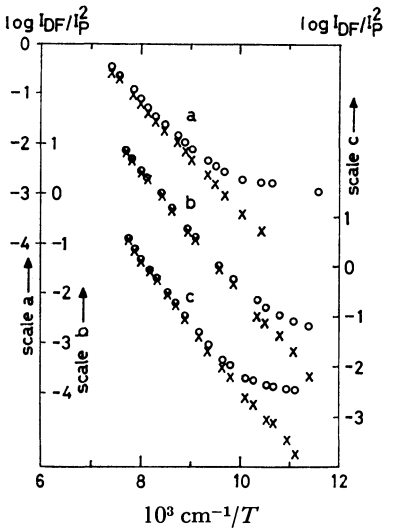

Fig. 8. Plots of $\log (I_{DF})_{total}/I_P^2$ (○) and $\log [(I_{DF})_{total}-I_{TIDF}]/I_P^2$ (×) *vs.* $1/T$ with I_{DF} at band b. Concn: a) 1.2×10^{-2}, b) 1.25×10^{-3}, c) 1.0×10^{-4} mol/mol.

are listed in the neighboring column. The activation energies obtained from the semilog plots, as seen in Table 2, are comparable with the corresponding spectroscopic value[23] of 1465 cm^{-1}, in particular for those obtained from plot (2). The activation energies obtained from plot (3) seem to be dependent on concentration. This may be due to the presence of the trap giving rise to another very weak delayed fluorescence observed at very low concentrations and high temperatures.[24] In order to check the "concentration effect" of the activation energies obtained from plot (3), an exhaustive purification of biphenyl host crystals has been made by repeated zone refining and taking the non-emissive portions of the specimen. The semilog plots for the trap-free benzo[*f*]quinoline–biphenyl mixed crystals are shown in Figs. 9 and 10, and the activation energies evaluated from the corrected plots are listed in Table 3. The validity of the

b) The other values of the ratio are 0.06 and 0.05 for bands b and d at the guest concentration of 1.0×10^{-3} mol/mol respectively, and 0.17 for band b at the guest concentration of 1.0×10^{-2} mol/mol.

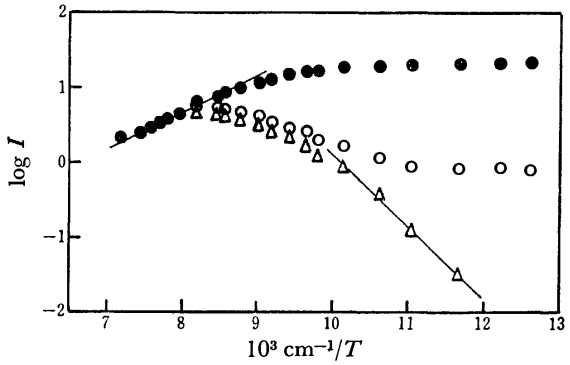

Fig. 9. The same plots as shown in Fig. 7 with I_{DF} at band c, using the trap-free benzo[*f*]quinoline-biphenyl mixed crystals. Concn: 1.0×10^{-2} mol/mol.

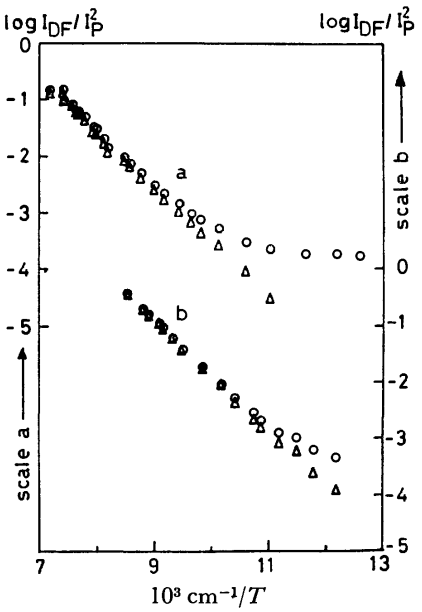

Fig. 10. Plots of $\log(I_{DF})_{total}/I_P^2$ (○) and $\log[(I_{DF})_{total}-I_{TIDF}]/I_P^2$ (△) *vs.* $1/T$ with I_{DF} at band c, using the trap-free benzo[*f*]quinoline-biphenyl mixed crystals. Concn: a) 1.0×10^{-2}, b) 1.0×10^{-3} mol/mol.

correction emphasized above is evident. Moreover, the activation energies obtained from plot (3) at two different concentrations are in accordance with each other within the experimental error. Therefore, it may be concluded that the thermal activation energy is in principle independent of concentration.

For comparison, we have also applied this type of correction to plot (3) of the experimental results on the phenanthrene–biphenyl system published by Misra and McGlynn,[10)] obtaining a straight line that covers the whole temperature range studied. Accordingly, above-described suggestion made by McGlynn *et al.*[10,11b,13)] on DF in the low temperature region, in particular in the vicinity of 77 K, is hardly convincible.

In Table 2 are also collected the values of T_{max}, the temperature at which maximum intensity of DF occurs, and the host-guest triplet separations ΔE deduced from T_{max} through the empirical relation.[10)] The values of T_{max} seem to be in agreement with one another within the experimental error, and hence so seem the corresponding values of ΔE.

A New Interpretation of Decay Behavior around 77 K. The experimental results on the decay behavior are in good agreement with the kinetic model except for the unusual decay behavior of DF around 77 K. The decay deviates considerably from the exponential behavior in the lower temperature region, where the exponential decay would be expected from the usual temperature-dependent model. This peculiarity in the DF decay around 77 K has already been pointed out by Hirota[8b)] and Misra and McGlynn.[10)] Hirota[8b)] reported that the DF decays in the vicinity of 77 K were independent of temperature. On the other hand, Misra and McGlynn[10)] suggested on the nonexponential decays of DF around 77 K that some kinds of traps, probably imperfections in the host-crystal lattice, might be responsible for this decay behavior. Incidentally, Misra[15)] found the temperature-independent decays in the temperature range 6—77 K for the phenanthrene–biphenyl and naphthalene–biphenyl mixed crystal systems. As can be seen in Figs. 5 and 6, the TIDF decay behavior remains constant at temperatures below about 70 K and is still nonexponential in this temperature range. Here, it should be noted that the existence of this temperature-independent delayed-luminescence decay observed over a wide range of temperature is compatible with Hirota's observation of the temperature-independent decay in a smaller range of temperature. Thus, it may be concluded that the unusual decay behavior of DF around 77 K may be due to the presence of TIDF portion. In other words, if no TIDF existed practically, the decay law of DF in the vicinity of 77 K would be exponential, as have been observed experimentally in some mixed crystals.[10,22)] The phosphorescence decay that is exponential even in the vicinity of 77 K, is not affected at all by the nonexponential decay behavior of TIDF, as can be understood through the fact that DF around 77 K is much weaker than the phospho-

rescence.

Nature of TIDF. We evaluated the intensity ratio of DF at 85 K and at T_{max}, I_{DF} (85 K)/$I_{DF}(T_{max})$, since I_{DF} at 85 K equals approximately to its temperature-independent contribution. This ratio gives an approximate value for the fraction of all triplets which decay *via* a second-order mechanism, namely triplet-triplet annihilation, in the temperature-independent range.[14,15] The ratios thus obtained with different guest concentrations are also listed in the last columns of Tables 2 and 3. It may be noted that these ratios seem to depend on the guest concentration. Particularly, the ratios at the concentration of the order of 10^{-2} mol/mol are larger than those at the other lower concentrations. This concentration effect is definitely beyond the experimental error. Since average distances between guests in the biphenyl host crystals are 15.3, 32.9, and 71.2 Å in the concentrations of 10^{-2}, 10^{-3}, and 10^{-4} mol/mol respectively according to Chandrasekhar's expression,[25] the direct triplet-triplet annihilation between guests hardly seems to be operative except for the case of the concentration of 10^{-2} mol/mol. At the high concentration of 10^{-2} mol/mol, the triplet-triplet annihilation due to exchange interaction might be responsible for the existence of TIDF in connection with the relatively higher values of the ratios described above. The fact that we observed TIDF at the low guest concentration of 10^{-4} mol/mol seems to suggest that it may be significant to study the problem of the distribution of guest molecules in mixed crystals.[26]

In the hope to decide whether such an opportune overlap of the T-T absorption and T-S emission as occuring in benzo[*f*]quinoline is responsible for the existence of TIDF,[3b] we have undertaken a similar study with naphthalene as guest in place of benzo[*f*]-quinoline, since this kind of overlap does not take place with this guest. We also observed TIDF and obtained a value of 0.012 for the ratio described above at the concentration of 10^{-2} mol/mol.[27] Thus, the above-mentioned overlap of T-T and T-S transitions is not necessarily required for the occurrence of TIDF.

In conclusion, on the sound basis of the observation of TIDF, we show a new way in which we refrain from invoking traps arbitrarily. The experimental results presented above, however, are not enough to elucidate the nature of TIDF. Further detailed experiments are required to clarify this question fully. Detailed results of this study will be given in Ref. 28.

23) The spectroscopic energy gap of host triplet-guest triplet state is 1465 cm^{-1} for the benzo[*f*]quinoline-biphenyl system, which is obtained by adopting a value of 23010 cm^{-1} for the triplet state of biphenyl.[8] Incidentally, a preliminary study of the X-trap phosphorescence of biphenyl crystal locates the crystal lowest triplet state around 23150 cm^{-1}, a much more favorable value (S. Wada, Y. Gondo, and Y. Kanda, unpublished results).

24) With lower concentrations and higher temperatures, we detected the very weak trap-delayed fluorescence as well as a trap-fluorescence in a shorter wavelength region than that of the guest emission. It should be particularly emphasized that the trap emission became weaker by a more extensive purification of the host biphenyl crystal. For further details, see Ref. 28.

Composition and Some Physical Properties of Complex TCNQ Anion Radical Salts Containing Quinolinium, *N*-Methylquinolinium, and their Isomeric Cations

Yoshio MATSUNAGA and Tomio TANAKA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 11, 1976)

Complex TCNQ anion radical salts containing quinolinium, isoquinolinium, and their methyl derivatives were prepared. Quinolinium and cations having molecular envelopes of 2-methylnaphthalene form 1 : 2 salts, whereas isoquinolinium and cations having molecular envelopes of 1-methylnaphthalene give 2 : 3 salts. Only *N*-methylquinolinium forms salts containing the solvent of crystallization. The room temperature resistivities of the polycrystalline compactions are in the range from 0.5 to 3.9 ohm cm, and the Seebeck coefficients are in the range from -41 to -54 μV/deg for the 1 : 2 salts and in the range from -12 to -23 μV/deg for the 2 : 3 salts. The diffuse reflection spectra of all the salts are similar to each other. A splitting of the band in the 10×10^3 cm^{-1} region was observed only for the 1 : 2 salts. In the total reflectance spectra, the salts show Drude-like edges in the region from 6×10^3 to 8×10^3 cm^{-1}.

The complex anion radical salt quinolinium(TCNQ)$_2$ is one of the most highly conducting organic materials.[1,2] The resistivity value at room temperature of the pressed polycrystalline sample has been reported to be 0.25 ohm cm, and that of single crystals along the needle axis 0.01 ohm cm. The minimum resistivity has been observed for single crystals at 223 K by Walatka and Perlstein and at 240 K by Buravov *et al.*[3,4] According to the crystal structure analysis made by Kobayashi *et al.*, the cation adopts either of the alternative orientations with equal probability.[5] The composition appears to depend upon small variations introduced in the cation. The *N*-methylquinolinium cation has been shown to form a 2 : 3 salt and its isomer, the quinaldinium cation, a 1 : 2 salt.[6] Moreover, the former salt has been reported by Flandrois *et al.* to contain approximately one mole of acetonitrile per mole of the salt and by Murakami and Yoshimura two moles of the same solvent per mole of the salt.[7–9] It is of interest to examine more fully complex salts with isomeric cations. Accordingly, the authors set out to study the composition and some physical properties of the isoquinolinium salt and methyl-substituted quinolinium and isoquinolinium salts.

Experimental

Materials. Quinoline, isoquinoline, quinaldine, lepidine, and 6-methyl-, 7-methyl-, and 8-methyl-quinolines were commercially obtained, and used without further purification. The onium iodides were prepared by the usual reactions with hydroiodic acid or methyl iodide. The complex TCNQ salts were crystallized when onium iodide and TCNQ separately dissolved in hot acetonitrile were mixed. They were purified by recrystallization from the same solvent. The compositions were determined by the microanalysis of carbon, hydrogen, and nitrogen, and were checked by the ratio of the optical density at 400 nm to that at 842 nm. This quantity has been reported to be about 1.2 for the 2 : 3 salts and from 1.7 to 2.0 for the 1 : 2 salts.[10]

Measurements. The electrical resistivities and thermoelectric motive force of polycrystalline compactions were measured as a function of the temperature by methods similar to those described elsewhere.[11] The diffuse reflectance of samples diluted with sodium chloride was measured by means of a Beckman DK 2A spectroreflectometer in the range from 325 to 2500 nm. The reference was pure sodium chloride. The spectrum was then plotted using the Kubelka-Munk function. The total reflectance of the compactions was also recorded on the same instrument in the range from 700 to 2700 nm employing a polished copper plate as a reference.

Results and Discussion

Composition. Six new complex TCNQ anion radical salts are listed in Table 1. The results of microanalysis are consistent with their 2 : 3 or 1 : 2 composition, but the ratio of the optical density at 400 nm to that at 842 nm tends to be larger than the above-mentioned figures. For example, Buvet *et al.* obtained 2.00, 1.20, and 1.85 for the quinolinium, *N*-methylquinolinium, and quinaldinium salts respectively.[10] The present values are respectively 2.18, 1.34, and 2.15. Especially, the values found for the 7-methyl- and 8-methylquinolinium salts are much larger than expected. Although the quinolinium cation has been known to form a 1 : 2 salt, the isomer, the isoquinolinium cation, was found to form a 2 : 3 salt. Thus, the distribution of a positive charge in the cationic nucleus appears to be the most important factor determining the composition in this pair of TCNQ salts. The methyl-substituted cations are classified into two groups on the basis of the composition of the resulting TCNQ salts. One group consists of *N*-methylquinolinium, lepidinium, and 8-methylquinolinium, which give 2 : 3 salts. The other includes quinaldinium, *N*-methylisoquinolinium, 6-methylquinolinium, and 7-methylquinolinium. They form 1 : 2 salts. This classification cannot be correlated with the position of the nitrogen atom in the nuclei, but can be correlated with the position of the methyl group. The cations in the first group have molecular envelopes of 1-methylnaphthalene, and those in the second group envelopes of 2-methylnaphthalene. This finding is in sharp contrast with the result found for quinolinium and isoquinolinium cations and also with the report on aminoquinolinium cations by Libera and Bretschneider.[12] All the TCNQ salts containing 2-amino-, 3-amino-,

Table 1. Compositions of TCNQ anion radical salts

Cation		Analysis (%) C	H	N	D_{400}/D_{842}
Isoquinolinium	Found	74.69	3.10	22.34	1.44
	Calcd for 2 : 3	74.47	3.01	22.52	
Lepidinium	Found	74.66	3.49	21.42	1.32
	Calcd for 2 : 3	74.65	3.58	21.77	
8-Methylquinolinium	Found	75.04	3.43	21.75	2.28
	Calcd for 2 : 3	74.65	3.58	21.77	
N-Methylisoquinolinium	Found	73.98	3.17	22.82	2.35
	Calcd for 1 : 2	73.90	3.28	22.81	
6-Methylquinolinium	Found	74.01	3.18	22.86	2.21
	Calcd for 1 : 2	73.90	3.28	22.81	
7-Methylquinolinium	Found	73.40	3.04	23.15	2.85
	Calcd for 1 : 2	73.90	3.28	22.81	

4-amino-, and 5-aminoquinolinium cations were reported to be of 1 : 2 composition. Since the amino group is a little smaller than the methyl group, the latter may be a substituent of such critical size that the molecular envelope dominates the charge distribution in the determination of the composition of complex TCNQ salts.

The *N*-methylquinolinium salt, to which a 1 : 2 composition was originally assigned by Melby *et al.* on the basis of microanalysis,[1] has been shown to be actually of 2 : 3 composition on the basis of the optical density ratio at 400 and 842 nm.[6,10] Differential-scanning calorimetric examinations indicated the presence of an endothermic change above 90 °C assignable to the loss of the solvent of crystallization reported by Flandrois *et al.* and also by Murakami and Yoshimura.[8,9] The enthalpy change observed in this work is in the range from 10 to 15 kcal/mol depending upon the preparations. These values are intermediate between those reported by the above-mentioned two groups: about 5 kcal/mol and 19.1 kcal/mol. Our preparations showed weight losses of about 8.5 percent by heating at 120 °C, indicating the presence of two moles of acetonitrile per mole of the 2 : 3 salt (calculated value: 8.35%). The results of microanalysis before and after the weight loss are in good agreement with the proposed compositions (see Table 2). It may be added that the calculated values for the 2 : 3 salt containing this amount of the solvent are very close to those for the originally assumed 1 : 2 salt, namely, C, 73.90, H, 3.28, and N, 22.81%. This conclusion agrees with that of Murakami and Yoshimura except for the ratio of the cation to the TCNQ, which they suggested to be 1 : 1.6.[9,13] The salt crystallized from acetone showed a weight loss of 9.8 percent by heating. This amount corresponds to 1.7 moles of acetone per mole of the 2 : 3 salt. Employing the less volatile ethyl methyl ketone as the solvent, the salt with a better defined composition could be isolated. The composition is consistent with a 2 : 3 salt containing one mole of the solvent. The observed weight loss by heating, about 7.7%, agrees fairly well with the calculated one, 7.41%. The microanalytical results after heating again agree with a 2 : 3 composition. Contrary to the case of acetonitrile, the loss of these ketones by heating could not be detected by differential-scanning calorimetry. However, the process is well demonstrated by a drastic change of the electrical resistivity as is described in the next section. The last salt in Table 2 was crystallized from boiling ethyl acetate and found to be free from the solvent and to be of 2 : 3 composition. Finally, it must be emphasized that in all the *N*-methylquinolinium salts prepared here the ratio of the cation to the TCNQ is stoichiometric: that is 2 : 3.

Table 2. Composition of *N*-methylquinolinium TCNQ salts

Solvent		Analysis (%) C	H	N
Acetonitrile	Found	73.61	3.79	22.90
	Calcd for 2 : 3 with $2CH_3CN$	73.30	3.90	22.80
Acetonitrile[a]	Found	75.09	3.44	21.98
	Calcd for 2 : 3	74.65	3.58	21.77
Ethyl methyl ketone	Found	73.99	4.13	19.86

a) After the loss of the solvent of crystallization.

Electrical Properties. The electrical resistivities, activation energies for semiconduction, and Seebeck coefficients at 20 °C for polycrystalline compactions are listed in Table 3. The present resistivity values are in the range from 0.5 to 3.9 ohm cm and the activation energies from 0.03 to 0.09 eV. The lowest values for these two quantities were observed with the quinolinium and isoquinolinium salts. As the single crystals of the former salt are known to exhibit a resistivity minimum below room temperature, these values may be considered to arise mostly from contact between the crystals. Therefore, they may be near the limiting values obtainable with compactions of high-conductivity TCNQ salts. The Seebeck coefficients are almost constant or become slightly more negative at the higher temperatures in the measured range (see curve a in Fig. 2). Its

Table 3. Electrical properties of compactions of complex TCNQ salts

Cation	Resistivity at 20 °C (ohm cm)	Activation energy at 20 °C (eV)	Seebeck coeff. at 20 °C (μV/deg)
Quinolinium	0.5	0.03	−41
Isoquinolinium	0.5	0.03	−12
N-Methylquinolinium (with $2CH_3CN$)	3.5	0.24	−23
N-Methylquinolinium (with C_4H_8O)	3.9	0.04	−22
Lepidinium	1.7	0.05	−12
8-Methylquinolinium	1.6	0.06	−21
Quinaldinium	1.2	0.04	−45
N-Methyl-isoquinolinium	0.5	0.09	−47
6-Methylquinolinium	1.9	0.05	−54
7-Methylquinolinium	3.2	0.07	−49

magnitude appears to be largely determined by the composition, namely, the 2 : 3 salts give values from −12 to −23 μV/deg and the 1 : 2 salts values from −41 to −54 μV/deg. Similar behavior has been reported to be characteristic of high conductivity TCNQ salts.[4] Buravov *et al.* have examined the Seebeck coefficient of the quinolinium (1 : 2), acridinium (1 : 2), and 3,3′-diethylthiazolino-2,2′-carbocyaninium (1 : 2) salts and found that the values are nearly independent of temperature above 100 or 150 K and that they are practically the same for all three. The average value they obtained is −60 μV/deg. According to their theory, the coefficient is a function of the composition, however, the relation is so complicated that their equation has been solved only for the 1 : 2 salts. In the high temperature limit, the coefficient S for the 1 : 2 salts can be approximated by $S=-(k/|e|)\ln 2=-59.8$ μV/deg, which is in excellent agreement with their experimental results but not with the present values. Recently, Beni *et al.* have obtained the same theoretical value for the 1 : 2 salts employing an equation derived in connection with the strong coupling Hubbard model.[14] Their equation for the high temperature saturation thermoelectric power is

$$S = -\frac{k}{|e|}\ln 2(1-\rho)/\rho,$$

where ρ is the carrier concentration defined by the ratio of the number of carriers to the number of sites. If we take $\rho=1/2$, the equation yields $S=-59.8$ μV/deg. Conversely, ρ may be estimated to be 0.52—0.55 assuming tentatively the room temperature values as the saturation values and employing the above equation as novel way of determining the amount of charge following a proposal made by Beni *et al.* Similarly, values from 0.60 to 0.62 may be obtained for the 2 : 3 salt. On the other hand, the equation yields $S=0$ for $\rho=2/3$.

The *N*-methylquinolinium salt crystallized from acetonitrile has been reported to show a large irreversible increase in the resistivity by the loss of the solvent of crystallization.[13] In our measurements, the activation energy for semiconduction was temperature-dependent and was about 0.24 eV at 20 °C. The resistivity remained at about 3 ohm cm between 30 and 50 °C, then increased gradually above 50 °C and sharply above 55 °C. The value at 103 °C was about 4300 ohm cm. After this heating process, the room temperature resistivity became about 8000 ohm cm. On the other hand, compaction made after the loss of the solvent of crystallization showed a resistivity of about 2600 ohm cm and an activation energy of 0.25 eV at 20 °C. These values are close to those reported by Murakami and Yoshimura, about 2000 ohm cm and 0.3 eV, and are essentially the same as those given by the solvent-free salt crystallized from ethyl acetate (see curve c in Fig. 1).

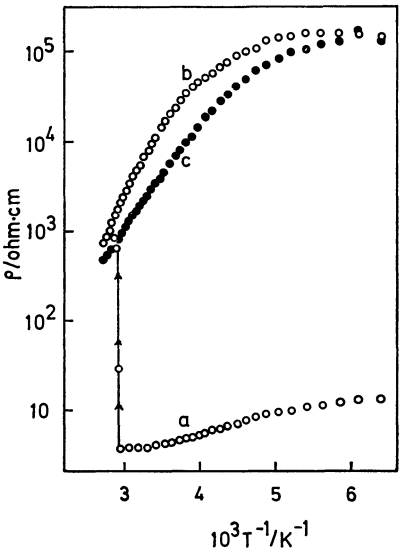

Fig. 1. Electrical resistivities of *N*-methyl quinolinium-TCNQ (2 : 3) salts, (a) with ethyl methyl ketone of crystallization, (b) after the loss of ethyl methyl ketone, and (c) the solvent-free salt crystallized from ethyl acetate.

The results of measurements made on the salt crystallized from ethyl methyl ketone are shown in Fig. 1. The resistivity change occurred over a rather narrow temperature range. The irreversible increase began at 63 °C and ended at 84 °C. The resistivity value at the latter temperature was about 1000 ohm cm and that at room temperature after the loss of the solvent about 10000 ohm cm. Thus, curve b and the corresponding curve observed with the salt crystallized from acetonitrile are in close resemblance with each other. The behavior of the salt crystallized from acetone was very similar to that mentioned above. However, an abrupt increase in the resistivity was observed in a slightly lower temperature range. The increase began at 50 °C and ended at 65 °C, reflecting the volatility of the solvent.

The drastic change in the Seebeck coefficient by the loss of the solvent of crystallization is illustrated in Fig. 2 for the salt crystallized from acetonitrile. The coefficient becomes more negative and markedly temperature dependent by the loss of acetonitrile (see curve b). A minimum value of −0.4 mV/deg is located near 240 K. Above this temperature, the slope defined by $dS/d(1/T)$ is as large as −0.26 V. The same slope

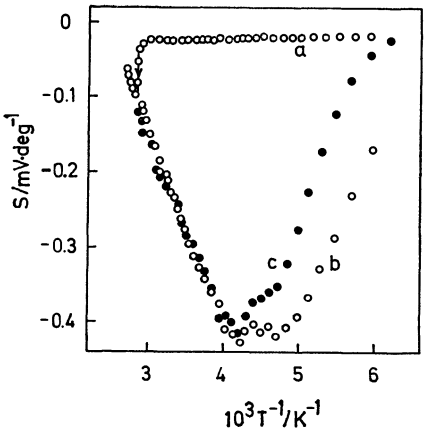

Fig. 2. Seebeck coefficients of *N*-methylquinolinium-TCNQ (2 : 3) salts, (a) with acetonitrile of crystallization, (b) after the loss of acetonitrile, and (c) the solvent-free salt crystallized from ethyl acetate.

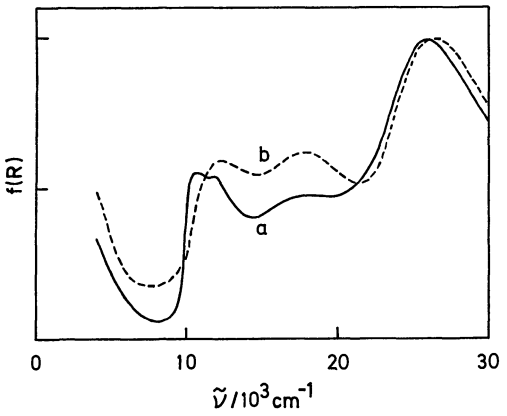

Fig. 3. Diffuse reflection spectra, (a) quinolinium-TCNQ (1 : 2) salt and (b) isoquinolinium-TCNQ (2 : 3) salt.

could be observed with the solvent-free salt crystallized from boiling ethyl acetate (see curve c). However, the agreement between these two below 240 K is merely qualitative.

Optical Properties. The visible and near infrared absorption spectra of complex TCNQ anion radical salts both of intermediate- and high-conductivity are known to resemble each other and to consist of four bands, the maxima of which are approximately located at $<4\times10^3$, 10×10^3, 17×10^3, and 27×10^3 cm^{-1}.[15-17] On the basis of polarized normal-incidence reflection of the methyltriphenylphosphonium salt, the assignment of these bands has been made by Oohashi and Sakata. The band in the near infrared region arises from the charge-transfer interaction between the $TCNQ^-$ anion radical and the neutral molecule and the second one from the charge-transfer interaction between the anions. The latter two bands have been attributed to locally-excited transitions in the anion radical and/or the neutral molecule. Among the TCNQ salts studied here, the following five were examined for diffuse reflection spectra by Iida some years ago: the quinolinium, *N*-methylquinolinium, *N*-methylisoquinolinium, quinaldinium, and lepidinium salts. A splitting of the

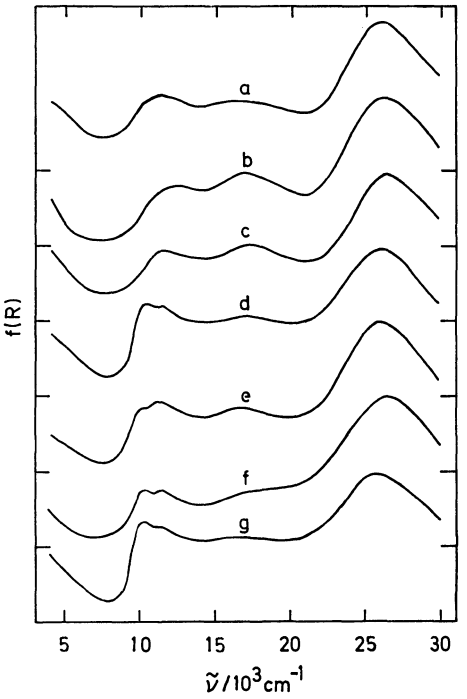

Fig. 4. Diffuse reflection spectra of the complex TCNQ anion radical salts containing (a) *N*-methylquinolinium (solvent-free), (b) lepidinium, (c) 8-methylquinolinium, (d) quinaldinium, (e) 6-methylquinolinium, (f) 7-methylquinolinium, and (g) *N*-methylisoquinolinium.

band around 10×10^3 cm^{-1} was noted in the case of *N*-methylquinolinium and *N*-methylisoquinolinium salts. Assuming a 1 : 2 composition for these five, Iida has noted that the splitting becomes appreciable with an increase of the electrical resistivity. As a matter of fact, such splitting has been commonly observed in the intermediate- and high-conductivity 1 : 2 salts.[15,16] However, the present work clarifies that the five salts studied by Iida are not of the same composition. The measurements on the present five 1 : 2 and four 2 : 3 salts revealed that the spectral pattern is essentially determined by the composition. The difference caused by the composition may be best exemplified by a comparison of the spectrum of the quinolinium salt with that of the isoquinolinium salt exhibiting almost the same electrical resistivity. As is shown in Fig. 3, the quinolinium salt shows a doublet in the 10×10^3 cm^{-1} region. The maxima of the sharp peaks are located at 10.5×10^3 and 11.0×10^3 cm^{-1}. Both previous workers noted only one maximum for this 1 : 2 salt. The location of the former peak agrees well with that recorded by Iida and that of the latter with the value reported by Oohashi and Sakata. On the other hand, a broad single band appears at 12.3×10^3 cm^{-1} in the isoquinolinium salt. The spectra of the complex salts containing methylated cations are presented in Fig. 4. Again, the 1 : 2 salts are generally distinct from the 2 : 3 salts. A splitting of the band in the 10×10^3 cm^{-1} region can be clearly observed in all the 1 : 2 salts but not in the 2 : 3 salts. It must be noted, however, a shoulder around 10×10^3 cm^{-1} is present in the spectrum of the solvent-free *N*-methylquinolinium salt, the only intermediate-conductivity salt examined in the present

work.

Polarized reflectance spectra have been measured on single crystals of $Cs_2(TCNQ)_3$ by Vlasova and Gutman.[18] This complex salt has a resistivity of the order of 10^4 ohm cm at room temperature and has been classified into intermediate-conductivity salts by Siemons *et al.*[2] The reflectance for light polarized parallel to the needle axis rises from a minimum of about 2 percent at 14.5×10^3 cm^{-1} to a value of about 17 percent at 10×10^3 cm^{-1}. They have considered such a rapid decrease of the reflectance to such a low value to be typical of the plasma edge observed with metals and semiconductors and have estimated the plasma frequency for this salt to be 2.8×10^{15} s^{-1}. The spectral behavior of an organic metal, tetrathiofulvalene–tetracyanoquinodimethane (TTF–TCNQ), with a resistivity of the order of 10^{-3} ohm cm along the needle axis has been examined similarly by Bright *et al.* and also by Grant *et al.*[19-21] The change in the reflectance for light polarized parallel to the conducting axis is much more pronounced than that reported for $Cs_2(TCNQ)_3$, less than 1 percent at 7×10^3 cm^{-1} and 34 percent at 5×10^3 cm^{-1} according to the former group. The plasma frequency has been estimated to be 1.80×10^{15} and 2.1×10^{15} s^{-1} and the electronic relaxation time, 2.83×10^{-15} and 2.3×10^{-15} s by Bright *et al.* and by Grant *et al.*, respectively. The conductivity calculated on the basis of these optical data is in good agreement with the measured d.c. conductivity. Bright *et al.* have extended their measurements to 0.8×10^3 cm^{-1} employing a polycrystalline compaction. In this case, the measured reflectance is an average over all crystalline orientations in the solid. Therefore, the component parallel to the conducting axis must be extracted by subtracting the reflectance due to the transverse directions and by correcting the resultant value for $\overline{\cos^2\theta}$. The perpendicular reflectance was assumed constant in the infrared region and equal to the minimum value at the plasma edge. Although, among the salts studied above, only the quinolinium salt is known to show metallic behavior at room temperature, the authors included the measurements of the total reflectance spectra of polycrystalline compactions to find out what kind of optical data one can obtain for these complex TCNQ salts and whether metallic salts can be distinguished from nonmetallic ones by such data.

The spectra for light polarized parallel to the conducting axis were derived from the data on polycrystalline compactions following the procedure proposed by Bright *et al.* In Fig. 5, the Drude-like edges observed with the quinolinium and isoquinolinium salts are presented. The reflectance of the former salt shows a minimum centered at 6.8×10^3 cm^{-1} and rises to a value of 13 percent at 5×10^3 cm^{-1}. There are weak peaks located at 9.9×10^3 and 11.3×10^3 cm^{-1} which may correspond to the absorption bands around 10×10^3 cm^{-1} (see Fig. 3). The curve of the latter salt is shifted slightly to the high-energy side. The minimum is located at 7.5×10^3 cm^{-1} and the value at 5×10^3 cm^{-1} is about 27 percent. In the 10×10^3 cm^{-1} region, a broad band centered at 10.6×10^3 cm^{-1} appears with a shoulder around 9×10^3 cm^{-1}. One assumes that the

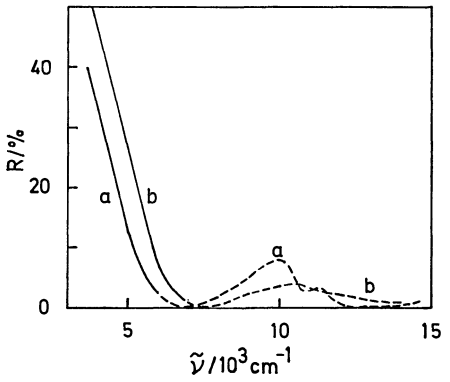

Fig. 5. Reflectance spectra for light polarized parallel to the conducting axis derived from polycrystalline measurements, (a) quinolinium-TCNQ (1 : 2) salt and (b) isoquinolinium-TCNQ (2 : 3) salt.

dielectric constant ε is a function of frequency ω and is given by

$$\varepsilon = \varepsilon_0 - \frac{\omega_p^2}{\omega^2 + i\omega/\tau}$$

where ε_0 is the frequency-independent background dielectric constant, ω_p is the plasma frequency, and τ is the electronic relaxation time. The reflectance R is given in terms of the real and imaginary parts of the dielectric constant $\varepsilon = n^2(1-i\kappa)^2$ by the well-known Drude formula

$$R = \frac{n^2(1+\kappa^2)+1-2n}{n^2(1+\kappa^2)+1+2n}$$

The best fit was obtained with $\varepsilon_0=2.18$, $\omega_p=2.31\times10^{15}$ s^{-1}, and $\tau=1.73\times10^{-15}$ s for the quinolinium salt and with $\varepsilon_0=2.36$, $\omega_p=2.62\times10^{15}$ s^{-1}, and $\tau=1.91\times10^{-15}$ s for the isoquinolinium salt. The solid curves in Fig. 5 are parts of the reflectance fitted to the above expression. In the vicinity of the minimum, the fits cannot be good because of the approximations employed. If the conventional expression relating the plasma frequency and the d.c. conductivity for metals, $\sigma = \omega_p^2\tau/4\pi$, is assumed using the above values for ω_p and τ, one obtains an estimate of 817 ohm^{-1} cm^{-1}, which markedly higher than the experimental value

Table 4. Optical data for TCNQ anion radical salts

Cation (Composition)	ε_0	ω_p (10^{15} s^{-1})	τ (10^{-15} s)	σ (ohm^{-1} cm^{-1})
Quinolinium (1 : 2)	2.18	2.31	1.73	817
Isoquinolinium (2 : 3)	2.36	2.62	1.91	1160
N-Methylquinolinium (2 : 3) with $2CH_3CN$	1.89	2.27	1.68	766
Lepidinium (2 : 3)	2.45	2.66	1.53	958
8-Methylquinolinium (2 : 3)	1.78	1.98	1.39	482
Quinaldinium (1 : 2)	1.75	1.87	1.41	436
N-Methylisoquinolinium (1 : 2)	2.05	2.09	1.69	653
6-Methylquinolinium (1 : 2)	1.77	1.75	1.72	466
7-Methylquinolinium (1 : 2)	1.74	1.79	1.38	391
N-Methylphenazinium (1 : 1)	1.51	1.99	0.96	336
Acridinium (1 : 2)	1.85	1.93	1.55	511

reported by Walatka and Perlstein of 100 ohm^{-1} cm^{-1}.[3]

The change in the spectrum of the *N*-methylquinolinium salt with the loss of the acetonitrile of crystallization is sharp as is shown in Fig. 6. The reflectance at 5×10^3 cm^{-1} decreases from 20 percent to 2.5 percent and the minimum shifts from 7.5×10^3 cm^{-1} to 5.2×10^3 cm^{-1}. The latter change is in the direction opposite to that one might expect from a comparison between $Cs_2(TCNQ)_3$ and TTF–TCNQ. Furthermore, the peaks around 10×10^3 cm^{-1} are intensified by a factor of three, and additional peaks appear in the range from 6×10^3 to 9×10^3 cm^{-1}. Thus, an increase by a factor of one thousand in the electrical resistivity is reflected by a significant change in the spectrum. Therefore, it is rather surprising to see in the other high-conductivity salts that the reflectance in the near-infrared region varies considerably by from 4 percent in the 7-methylquinolinium salt to 22 percent in the lepidinium salt at 5×10^3 cm^{-1}. The minima are scattered in the range from 6×10^3 to 8×10^3 cm^{-1}. The estimates of the background dielectric constant, plasma frequency, relaxation time, and conductivity are listed in Table 4. The *N*-methylphenazinium and acridinium salts included in the table are known to be as conducting as the quinolinium salt and to show resistivity minima below room temperature.[4,22] It may be noted that the estimated d.c. conductivity for the former salt is in good agreement with the value observed by Coleman *et al.*, 380 ohm^{-1} cm^{-1}.[22] Such an agreement is probably fortuitous. The experimental conductivity may depend considerably upon the crystals. The value reported by Coleman *et al.* is more than twice that obtained by Shchegolev *et al.*[23] The latter group has reported a conductivity of about 70 ohm^{-1} cm^{-1} along the direction of the TCNQ column of the acridinium salt.[4] Therefore, it appears to be difficult to judge whether the conductivity estimated from the optical data is in agreement with the experimental value or not. The remarkable feature of the data in Table 4 is the relative insensitivity of the estimated conductivity to the materials. Moreover, there appears to be no correlation with the resistivity observed for polycrystalline compactions. As has been pointed out by Grant *et al.*, the observed Drude-like edge may be of other than simple metallic origin.[20]

The authors wish to express their thanks to Dr. Jun-ichi Aihara for his help in the estimation of the optical data.

Concentration Fluctuation and the Light-scattering Spectrum

Kenji IWASAKI, Masami TANAKA, and Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received April 13, 1976)

Light-scattering spectra were observed for binary solutions of carbon disulfide–chloroform at various concentrations. The relation between the Rayleigh-line intensity and the concentration fluctuation was derived. Using the proposed relation and the observed Rayleigh intensity, the concentration dependence of the concentration fluctuation was then determined. The results suggest that chloroform and carbon disulfide molecules have a tendency to get together in the binary solution.

Local fluctuation in the concentration is considered to afford information which is useful to understand the state of mixing from a molecular point of view. On the basis of this belief, we have planned a series of analyses of the temperature and concentration dependence of the concentration fluctuation in solutions. This, the first report of the series, will concern itself mainly with the determination of the concentration fluctuation through the observation of light-scattering spectra.

A light-scattering spectrum consists of a Rayleigh line, a pair of Brillouin lines, and a Rayleigh wing. Since the concentration fluctuation contributes to only the Rayleigh line, we can determine the concentration fluctuation from the Rayleigh intensity in a binary solution. We will derive an equation which relates the Rayleigh intensity of a light-scattering spectrum with the concentration fluctuation. Then the concentration dependence of the concentration fluctuation will actually be observed for the carbon disulfide–chloroform system through Rayleigh-intensity measurements. We chose the carbon disulfide–chloroform system because the concentration fluctuation of the system has been discussed previously on the basis of a band-width measurement of the infrared absorption spectra.[1]

Experimental

The light-scattering spectrometer used in the present study was designed and constructed in our laboratory.[2] Figure 1 shows the schematic layout of the spectrometer. The instrument is composed of a He-Ne gas laser source (NEC, GLG108, 50 mW), a Fabry-Perot interferometer, a lock-in amplifier (NF, LI573), and an X-Y recorder. The spacer between the interferometer etalons has a thickness of 6 mm, giving a free spectral range of 0.82 cm^{-1} and an overall instrumental half-width of about 0.042 cm^{-1}. The interferometer was pressure-scanned by evacuating the box enclosing the etalons and by allowing air to leak into the box slowly. The samples used in this experiment were commercially available reagents: carbon disulfide without further purification and chloroform purified by a column chromatography on alumina. The binary solutions of carbon disulfide and chloroform were made dust-free by the use of a Millipore-filter FG with a pore size of 0.2 μm. The test of a solution being dust-free can be done in principle by comparing the observed Rayleigh intensity with the true Rayleigh intensity of dust-free samples. As the true Rayleigh intensity is unknown, however, the dust-free test was done by comparing the observed Rayleigh intensity with the best data among the many Rayleigh intensities reported so far. In the case of the light-scattering spectrum, the L–P ratio, defined by $I_C/2I_B$, is the measure of being dust-free, because the Rayleigh intensity, I_C, is strongly influenced by the existence of dust, while the Brillouin intensity, I_B, is hardly influenced at all by the existence of dust. The observed L–P ratios are summarized in Table 1. It may be seen from the table that the present data agree well with those measured by Cummins *et al.*[3] The reason why our values are slightly larger than Cummins' is the difference in the methods by which the spectral components are separated. Because Cummins verified the dust-free state for water, whose L–P ratio is nearly zero, it seems that our optical purification and experimental techniques can realize a nearly dust-free state. Though a dust-free checking method like this is applicable only for pure liquids on which many intensity data are reported, we believe that mixture samples can be purified by the same method as that applied for pure liquids. The preparation (filtration and injection of a sample into a cell) of the sample was repeated five times or more, and the best value was chosen as the measured value. The refractive index of the sample was measured by means of a Shimadzu-Bausch Lomb Abbe refractometer 3L. The composition derivative of the refractive index at the mole fraction, x, was estimated from the difference between refractive indices measured at $x\pm0.05$. All the measurements were performed at the temperature of 20 ± 0.5 °C.

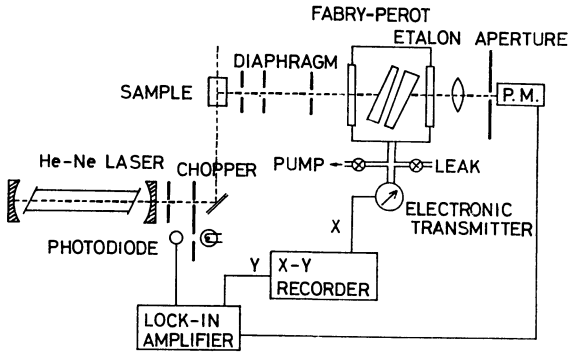

Fig. 1. Schematic layout of light scattering spectrometer.

Results and Discussion

Reduction of Rayleigh Intensity to Concentration Fluctuation. Miller presented an equation which relates the Rayleigh intensity of the light-scattering spectrum with the composition derivative of the chemical potential.[4] Following his theory, we derive an equation which directly relates the Rayleigh intensity of the light-scattering spectrum to the concentration fluctuation. Imagine a small-volume element which contains a constant number of moles, n_1, of one component in a binary solution at a constant temperature and

Table 1. Observed intensities for pure liquids

Liquid	Rayleigh intensity[a]		L-P ratio		Rayleigh wing intensity
	Obsd (24.5 °C)	Calcd	Present (24.5 °C)	Reference[b] (20.0 °C)	
Carbon disulfide	2.00	2.45	0.78	0.71	very strong
Benzene	1.31	1.02	0.93	0.84	medium
Chloroform	1.00	1.00	0.69	—	weak
Diethyl ether	0.82	0.80	0.41	0.35	very weak
Hexane	0.69	0.65	0.36	0.35	very weak
Acetone	0.60	0.57	0.48	0.44	weak
Ethanol	0.43	0.27	0.34	0.23	very weak

pressure. If we consider the dielectric constant, ε, as a function of the entropy, S, the pressure, P, and the number of moles, n_2, of the other component, the mean-square fluctuation in the dielectric constant, $\langle(\Delta\varepsilon)^2\rangle$, is expressed by:

$$\begin{aligned}\langle(\Delta\varepsilon)^2\rangle = {} & (\partial\varepsilon/\partial P)^2_{S,n_2}\langle(\Delta P)^2\rangle + (\partial\varepsilon/\partial S)^2_{P,n_2}\langle(\Delta S)^2\rangle \\ & + 2(\partial\varepsilon/\partial S)_{P,n_2}(\partial\varepsilon/\partial n_2)_{S,P}\langle\Delta S\Delta n_2\rangle \\ & + (\partial\varepsilon/\partial n_2)^2_{S,P}\langle(\Delta n_2)^2\rangle \qquad (1)\end{aligned}$$

because $\langle\Delta S\Delta P\rangle=\langle\Delta P\Delta n_2\rangle=0$. Of the four terms on the right-hand side of Eq. 1, the first term contributes to a Brillouin intensity, while the remaining three terms contribute to a Rayleigh intensity. Thus, we can express Eq. 1 as:

$$\langle(\Delta\varepsilon)^2\rangle = \langle(\Delta\varepsilon_B)^2\rangle + \langle(\Delta\varepsilon_R)^2\rangle \qquad (2)$$

where

$$\langle(\varepsilon_B)^2\rangle = (\partial\varepsilon/\partial P)^2_{S,n_2}\langle(\Delta P)^2\rangle \qquad (3)$$

and

$$\begin{aligned}\langle(\Delta\varepsilon_R)^2\rangle = {} & (\partial\varepsilon/\partial S)^2_{P,n_2}\langle(\Delta S)^2\rangle \\ & + 2(\partial\varepsilon/\partial S)_{P,n_2}(\partial\varepsilon/\partial n_2)_{S,P}\langle\Delta S\Delta n_2\rangle \\ & + (\partial\varepsilon/\partial n_2)^2_{S,P}\langle(\Delta n_2)^2\rangle \qquad (4)\end{aligned}$$

In these expressions, the $\langle\Delta S\Delta n_2\rangle$ term cannot be calculated from any observable quantities. Therefore, we express ε as a function of the temperature, T, the pressure, P, and the number of moles, n_2, of the other component. We thus obtain:

$$\begin{aligned}\langle(\Delta\varepsilon)^2\rangle = {} & (\partial\varepsilon/\partial T)^2_{P,n_2}\langle(\Delta T)^2\rangle + 2(\partial\varepsilon/\partial T)_{P,n_2} \\ & \times (\partial\varepsilon/\partial P)_{T,n_2}\langle\Delta T\Delta P\rangle \\ & + (\partial\varepsilon/\partial P)^2_{T,n_2}\langle(\Delta P)^2\rangle + 2(\partial\varepsilon/\partial P)_{T,n_2} \\ & \times (\partial\varepsilon/\partial n_2)_{T,P}\langle\Delta P\Delta n_2\rangle \\ & + (\partial\varepsilon/\partial n_2)^2_{T,P}\langle(\Delta n_2)^2\rangle + 2(\partial\varepsilon/\partial T)_{P,n_2} \\ & \times (\partial\varepsilon/\partial n_2)_{T,P}\langle\Delta T\Delta n_2\rangle \qquad (5)\end{aligned}$$

instead of Eq. 1. Combining Eqs. 2, 3, and 5, we obtain the expression for $\langle(\Delta\varepsilon_R)^2\rangle$. In this expression, all the necessary terms can be calculated from the observable quantities. The mean square fluctuations[5] of Eqs. 3 and 5 are calculated to be:

$$\left.\begin{aligned}&\langle(\Delta T)^2\rangle = kT^2/C_V, \quad \langle\Delta T\Delta P\rangle = kT^2\alpha/\beta_T C_V \\ &\langle(\Delta P)^2\rangle = kT/V\beta_S, \quad \langle\Delta T\Delta n_2\rangle = \langle\Delta P\Delta n_2\rangle = 0\end{aligned}\right\} \qquad (6)$$

where k is the Boltzmann constant; C_V, the heat capacity at a constant volume; α, the thermal expansivity; β_T, the isothermal compressibility, and β_S, the adiabatic compressibility. Combining Eqs. 2, 3, 5, and 6, we get:

$$\langle(\Delta\varepsilon_R)^2\rangle = \frac{kT^2}{C_P}\left(\frac{\partial\varepsilon}{\partial T}\right)^2_{P,n_2} + \left(\frac{\partial\varepsilon}{\partial n_2}\right)^2_{T,P}\langle(\Delta n_2)^2\rangle \qquad (7)$$

where C_P is the isobar heat capacity. The first term of Eq. 7 is related to entropy fluctuation by:

$$\begin{aligned}\left(\frac{\partial\varepsilon}{\partial S}\right)^2_{P,n_2}\langle(\Delta S)^2\rangle &= \left(\frac{\partial\varepsilon}{\partial T}\right)^2_{P,n_2}\left(\frac{\partial T}{\partial S}\right)^2_{P,n_2}\langle(\Delta S)^2\rangle \\ &= \left(\frac{\partial\varepsilon}{\partial T}\right)^2_{P,n_2}\left(\frac{T}{C_P}\right)^2 kC_P \\ &= \frac{kT^2}{C_P}\left(\frac{\partial\varepsilon}{\partial T}\right)^2_{P,n_2} \qquad (8)\end{aligned}$$

The second term of Eq. 7, on the other hand, is the mean-square fluctuation of n_2 in a small volume containing a constant n_1. Therefore, Eq. 7 can be rewritten symbolically as:

$$\langle(\Delta\varepsilon_R)^2\rangle = \begin{pmatrix}\text{entropy fluctua-}\\\text{tion term}\end{pmatrix} + \begin{pmatrix}\text{concentration fluctua-}\\\text{tion term}\end{pmatrix} \qquad (9)$$

Thus, we could express the concentration fluctuation, $\langle(\Delta n_2)^2\rangle$, in terms of $\langle(\Delta\varepsilon_R)^2\rangle$ and $\langle(\Delta S)^2\rangle$. It is important to emphasize that a small-volume element is chosen because it contains a constant number of moles, n_1. If the incident light, whose electric vector is polarized perpendicular to the scattering plane, passes through the fluctuation volume, V^*, in which mean mole number of one component, n_1, is confined, the intensity of light scattered perpendicularly to the incident light is given in terms of the Rayleigh ratio:

$$R_{90} = (\pi^2/\lambda_i^4)V^*\langle(\Delta\varepsilon)^2\rangle \qquad (10)$$

where λ_i is the wavelength of the incident light. By combining Eqs. 7 and 10, the Rayleigh ratio for a Rayleigh line is expressed as:

$$\begin{aligned}(R_{90})_R = (\pi^2/\lambda_i^4)\Bigg\{ & \frac{kT^2V^*}{C_P}\left(\frac{\partial\varepsilon}{\partial T}\right)^2_{P,n_2} \\ & + \left(\frac{\partial\varepsilon}{\partial n_2}\right)^2_{T,P} V^*\langle(\Delta n_2)^2\rangle\Bigg\} \qquad (11)\end{aligned}$$

Now, we introduce three relations:

$$d\varepsilon = 2\,n\,dn$$

$$dx_2 = dn_2 x_1/(n_1+n_2)$$

$$C_P/V^* = C_{Pg}\cdot M/V^* = C_{Pg}\rho$$

where n is a refractive index; x_1 and x_2, the mole fractions of the 1 and 2 components; C_{Pg}, the isobar heat capacity per gram; ρ, the density, and M, the weight of V^*. Substituting these relations into Eq. 11, we find:

$$(R_{90})_R = (\pi^2/\lambda_1^4)\frac{4kn^2T^2}{C_{Pg}\rho}\left(\frac{\partial n}{\partial T}\right)^2_{P,x_2} + (\pi^2/\lambda_1^4)4n^2\left(\frac{\partial n}{\partial x_2}\right)^2_{T,P} V^*\langle(\Delta x_2)^2\rangle \quad (12)$$

Since the first term of Eq. 12 arises from the entropy fluctuation, the Rayleigh ratio for entropy fluctuation is expressed as:

$$(R_{90})_S = (\pi^2/\lambda_1^4)\frac{4kn^2T^2}{C_{Pg}\rho}\left(\frac{\partial n}{\partial T}\right)^2_{P,x_2} \quad (13)$$

Combine Eqs. 12 and 13, an equation which directly relates the observed Rayleigh intensity with the concentration fluctuation is obtained:

$$V^*\langle(\Delta x_2)\rangle = (\lambda_1^4/\pi^2)\frac{1}{4n^2(\partial n/\partial x_2)^2_{T,P}}\{(R_{90})_R-(R_{90})_S\} \quad (14)$$

From Eq. 14 we can determine $V^*\langle(\Delta x_2)^2\rangle$ experimentally, observing $(R_{90})_R$ and estimating $(R_{90})_S$ by the use of Eq. 13. The concentration fluctuation can be determined in the form of $V^*\langle(\Delta x_2)^2\rangle$ from the observation of the light-scattering spectrum. We cannot, however, determine the concentration fluctuation in the form of $\langle(\Delta x_2)^2\rangle$ from the light-scattering spectrum. We will call this $V^*\langle(\Delta x_2)^2\rangle$ the "fluctuation ability" hereafter.

Light-scattering Spectra. The observed spectra for the chloroform–carbon disulfide system are given in Fig. 2. It may be seen from the figure that the intensity of a Rayleigh line increases remarkably on passing from pure liquids to binary solutions. The intensity change in the Brillouin lines, on the other hand, is small in comparison with that of a Rayleigh line. The background intensity due to a Rayleigh wing is largest for pure carbon disulfide and smallest for pure chloroform.

Determination of the Rayleigh Ratio. The procedure for separating a Rayleigh line from Brillouin lines and from a Rayleigh wing is illustrated in Fig. 3. A Rayleigh wing is assumed to be almost flat along a frequency axis. The outer halves of the Brillouin lines are assumed to be equal to the non-overlapping line shapes. Thus, the intensity of a Rayleigh line was determined by eliminating the areas corresponding to the Rayleigh wing and the Brillouin lines.

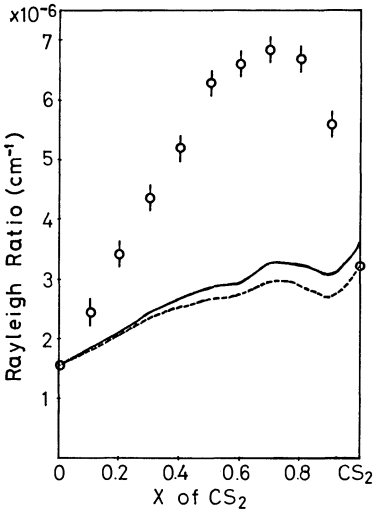

Fig. 4. Concentration dependence of Rayleigh intensity of chloroform–carbon disulfide system. The open circles correspond to $(R_{90})_R$, the solid line $(R_{90})_S$ and the broken line $(R_{90})_S{}^*$. Errors are indicated by the vertical lines.

The reliability of the observed Rayleigh ratios was checked by the use of Eq. 13. The observed Rayleigh ratios and the calculated Rayleigh ratios by Eq. 13 are compared in Table 1.

Since the observed Rayleigh intensities are relative values, we have to express the observed relative intensities, I_R, in terms of the Rayleigh ratios. We first calculate $(R_{90})_S$ for pure chloroform by the use of Eq. 13. We call this $(R_{90})_S{}^{CHCl_3}$. Then, the Rayleigh ratio for binary mixtures, $(R_{90})_R$, is calculated to be:

$$(R_{90})_R = I_R \times \frac{(R_{90})_S^{CHCl_3}}{I_R^{CHCl_3}} \quad (15)$$

where $I_R{}^{CHCl_3}$ is a relative Rayleigh intensity for pure chloroform.[6] The calculated Rayleigh ratios are plotted by open circules in Fig. 4.

Determination of the Concentration Fluctuation. The theoretical values of $(R_{90})_S$ at each mole fraction were

Table 2. Observed rayleigh ratios for a rayleigh line and rayleigh ratios for entropy fluctuation in chloroform–carbon disulfide system

Mole fraction of CS_2	$(R_{90})_R$ (cm^{-1}) (20±0.5 °C)	$(R_{90})_S$ (cm^{-1}) (20 °C)	K	$(R_{90})_S^*$ (cm^{-1})

calculated by substituting the observed values of λ_i, n, T, ρ, $(\partial n/\partial T)_{P,x_2}$, and the C_{Pg} values from the table[7] into Eq. 13 (see Table 2). The observed $(R_{90})_S$ for pure carbon disulfide was slightly different from that calculated from Eq. 13. This disagreement may be ascribed to the separation of a Rayleigh line from the light-scattering spectra. For the observation of the concentration fluctuation, however, the essential quantity is not $(R_{90})_S$ but $\{(R_{90})_R-(R_{90})_S\}$, that is, in intensity increment due to the concentration fluctuation. Therefore, the calculated $(R_{90})_S$ was corrected by means of a suitable parameter to:

$$(R_{90})_S^* = K \times (R_{90})_S$$

where K was chosen so that the calculated $(R_{90})_S$ for pure carbon disulfide was equal to the observed one. The K value for each concentration was thought to change continuously[8] from 1 to 0.876, the latter value of which is the correction factor for pure carbon disulfide (see the 4th column Table 2).

Using the Rayleigh ratios, $(R_{90})_R$, and the Rayleigh ratios for entropy fluctuations, $(R_{90})_S$, the fluctuation ability, $V^*\langle(\Delta x_2)^2\rangle$, was calculated from Eq. 14 at each concentration.

The reliability of the concentration fluctuations observed from Rayleigh intensities in the light-scattering spectra were examined with respect to two main factors:

1) the accuracy of the measured relative Rayleigh intensity, and

2) the observation of $(\partial n/\partial x)_{T,P}$.

The procedure of sampling is most important. As has been described in the previous paragraph, the samples were prepared so as to be almost dust-free. However, there was still a little doubt about the possibility of realizing a dust-free situation for all the samples observed. Therefore, we prepared a sample more than five times for one observation and took the best value as the observed value. We repeated the above procedure four times. The maximum deviation of the observed value from the averaged value was considered to be the error expected for the observed value (see the vertical lines of Fig. 4). The value of $(\partial n/\partial x)_{T,P}$ at the mole fraction x was obtained from the difference between the refractive indices at x±0.05. The precision of the refractive indices observed by means of an Abbe refractometer is about ±0.0001. As the determination of the concentration is precise enough, the precision of $(\partial n/\partial x)_{T,P}$ is about ±0.002. Taking into account the above two factors, the precision for the observed $V^*\langle(\Delta x_2)^2\rangle$ values is estimated to be about $\pm 0.174\times 10^{-23}$ cm^{-1} (see the vertical line of Fig. 5).

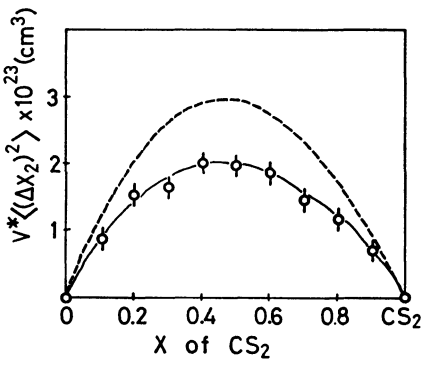

Fig. 5. Concentration dependence of concentration fluctuation for chloroform–carbon disulfide system. The open circules correspond to concentration fluctuation observed for chloroform–carbon disulfide system. The broken line shows concentration fluctuation expected for the ideal binary solution. Errors are indicated by the vertical lines.

Concentration Fluctuation. The concentration dependence of the concentration fluctuation observed for the chloroform–carbon disulfide system is shown in Fig. 5. Consider first the concentration fluctuation expected for the ideal binary solution, whose components are mixed with each other without intermolecular interaction. When a mixture of the 1 and 2 components behaves as a mixture of two simple particles, the chemical potential of the 2 component, μ_2, is given by:

$$\mu_2 = \mu_2^\circ + kT\ln x_2 \qquad (16)$$

where μ_2° is the standard chemical potential. If the chemical potential is known, the fluctuation ability is calculated to be:

$$N\langle(\Delta x_2)^2\rangle = \frac{kTx_1}{(\partial\mu_2/\partial x_2)_{T,P}} \qquad (17)$$

TABLE 3. EVALUATION OF FLUCTUATION ABILITIES FOR CHLOROFORM-CARBON DISULFIDE SYSTEM

1.000	0	1.6280	—	—

where N is the mean number of particles in V^*. Notice that the fluctuation ability is expressed in terms of N and $\langle(\Delta x_2)^2\rangle$ instead of V^* and $\langle(\Delta x_2)^2\rangle$. By combining Eqs. 16 and 17, we get:

$$N\langle(\Delta x_2)^2\rangle = x_2(1-x_2) \tag{18}$$

or

$$V^*\langle(\Delta x_2)^2\rangle = \frac{x_2(1-x_2)}{\rho_n} \tag{19}$$

where ρ_n is the number density and where $N=\rho_n V^*$. The broken line of Fig. 5 shows the fluctuation ability of a binary solution as predicted by Eq. 19. It may be seen from the figure that the observed fluctuation ability of the chloroform–carbon disulfide system is smaller than the prediction of Eq. 19 throughout all the mole fractions. This result suggests that there is a tendency inherent to the chloroform–carbon disulfide system which keeps the macroscopic concentration constant, even in a small volume. If we consider mixing from a microscopic point of view, the concept of concentration fluctuation corresponds to the variation in the concentration due to the thermal motion of molecules within a small volume. When there is no intermolecular interaction, the thermal motion of component molecules can be regarded as completely random. Therefore, the concentration fluctuation can be predicted by means of Eq. 18 or 19. Actually, however, the observed concentration dependence of the concentration fluctuation is different from that of Eq. 18 or 19, which indicates that the thermal motion of the component molecules is not random. This is probably to be ascribed to intermolecular interactions between the molecules of the same and/or different species. Instead of studying the nature of the intermolecular interactions directly, we introduce the concept of the association of molecules. If molecules of the same species have a tendency to get together in a binary solution, the concentration fluctuation takes a larger value than that of an ideal solution. In this case, a few molecules move in close association, therefore, the local concentration change due to thermal motion is much larger than that for the thermal motion of a single molecule. When molecules of different species have a tendency to get together, on the other hand, the concentration fluctuation takes a smaller value than that of an ideal solution. In this case, a complex molecule which is formed from molecules of different species behaves as a single molecule; therefore, the exchange of molecules between the inside and the outside of the small volume in question due to thermal motion brings about a much smaller concentration change inside the volume. The present results obtained for chloroform–carbon disulfide system suggest, therefore, that there is an inherent tendency in chloroform–carbon disulfide system which keeps the macroscopic concentration constant, even in a small volume. A more quantitative analysis of this problem will be made in the next report.

6) Table 1 shows that the ratio of the observed and calculated Rayleigh intensities is quite different from unity in carbon disulfide and in benzene, and almost unity for the other solvents. This singular phenomenon in carbon disulfide is considered to be due to the analytical process of separating the Rayleigh wing and the Rayleigh line. Therefore, chloroform was chosen as the intensity standard in the case of the binary solution of chloroform-carbon disulfide.

7) "International Critical Tables," McGraw-Hill, New York (1926).

8) The parameter, K, was introduced so as to correct the deviation between the observed and calculated intensities originating from the entropy fluctuation in carbon disulfide (see the first and second columns of Table 1). As the deviation is most obvious in carbon disulfide, it can also be expected in binary solutions of carbon disulfide and other solvents. In the case of a binary solution of carbon disulfide and chloroform, the effect is considered to be proportional to the concentration of carbon disulfide.

The Concentration Dependence of the Raman Intensity in Binary Mixtures and the Determination of Polarizability and Hyperpolarizability Derivative Tensors

Jun KOIKE, Tetsuo SUZUKI, and Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received May 1, 1976)

Raman intensities were observed at various concentrations. The observed lines were: the ν_8 line of CH_3CN (in CCl_4 and CH_3I), the ν_3 line of CH_3I (in CCl_4), and the ν_2 line of $CHCl_3$ (in CCl_4). Even after the elimination of the local-field effect, the Raman intensities showed concentration dependencies. The observed solvent effects were explained quantitatively by the use of the dipole interaction model. The polarizability and hyperpolarizability derivatives were determined for the ν_8 fundamental of CH_3CN. The criteria for the internal standard method were discussed quantitatively.

In the preceding report,[1] the solvent effects on the absolute infrared intensities have been discussed quantitatively from the viewpoint of dipole-dipole interaction. It has been shown that the interaction of the dipole-dipole type is a quite reasonable model in explaining the spectroscopic information observed in various binary solutions. It has also been shown in the report that the polarizability derivatives can be determined by observing the solvent effects on the infrared-absorption intensities.

The present report will concern itself with the observation of the Raman intensities of acetonitrile, methyl iodide, chloroform, and carbon tetrachloride in their binary mixtures. Our interest lies in:

1) the possibility of determining the magnitude of polarizability and hyperpolarizability derivatives through the observation of the solvent effects on Raman intensities, and

2) the examination of the criteria for the internal-standard method, which is widely used for the representation of Raman intensities.

Experimental

The spectrometer used for the present work was designed and constructed by the authors. The instrument is composed of a He-Ne gas laser source (NEC, GLG-108, 50 mW), a JSG-125 grating monochromator (JEOL), a HTV R-376 photomultiplier (S-20 response), a handmade lock-in amplifier (375 cps modulation), and a recorder.

The linearity of the whole system with respect to an intensity axis was carefully checked. First the output current of the photomultiplier was plotted against the light energy. The linearity was perfect for the output voltage of 20 V with $R_p=1$ MΩ. Then, the linearity of the amplifier was tested by using attenuators (0.1—120 db for each 0.1 db). Finally, the linearity of the whole system was checked by plotting the final recorder output voltage against the light energy which passes through the entrance slit of the monochromator. The light energy was attenuated by using neutral filters (Kenko, ND). From the standard errors estimated from the linear fitting, the linearity of the whole system was ascertained to be better than 1% of the full scale as long as the output voltage was less than 10 V.

Special attention was paid to the output power of the laser source. The stability of the laser output during the individual spectral measurements was observed by monitoring the light energy which penetrated through the 100-percent reflectance mirror of the laser cavity. When the power of the laser source drifted more than 1 percent during the measurements, the data observed were completely discarded.

All the chemicals were commercial products of a spectroscopic grade. The carbon tetrachloride and methyl iodide were purified by fractional distillation just before the spectral measurement. The chloroform was purified by column chromatography on alumina. The acetonitrile was used without further purification.

The Raman spectra were observed for; the ν_1 band of carbon tetrachloride, the ν_2 band of chloroform, the ν_8 band of acetonitrile, and the ν_3 band of methyl iodide in the binary solutions of $CHCl_3$–CCl_4, CH_3CN–CCl_4, CH_3I–CCl_4, and CH_3CN–CH_3I. All the spectra were recorded at the temperature of 22±1 °C. The band areas were determined by the weight method. The observations were repeated eight times for each concentration. The deviations of the observed band areas from the averaged values were less than 3 percent. The reproducibility of the observed peak frequency was within ±2 cm^{-1}, and no peak frequency shift due to the different concentrations was observed. All the bands observed had intensities strong enough for us to obtain accurate intensity data by the use of our instrument.

Results and Discussion

Concentration Dependence of Relative Intensity. Consider the observation of the relative intensities of two Raman lines arising from two components of a binary solution. The quantities related to the two Raman lines will be distinguished by the suffixes a and b. The observed intensity, I, is proportional to the molar concentration, c_m, the scattering cross section per molecules, Ω, and the corresponding factor for the internal field effect[2]; *i.e.*,

$$I_a = C \cdot c_{ma} \Omega_a \frac{1}{n_s} \left[\frac{n_a^2+2}{(n_a/n_s)^2+2} \right]^4 \quad (1)$$

$$I_b = C \cdot c_{mb} \Omega_b \frac{1}{n_s} \left[\frac{n_b^2+2}{(n_b/n_s)^2} \right]^4 \quad (2)$$

where C is a constant and where n_a, n_b, and n_s are, respectively, the refractive indices of the a component, the b component, and the mixture of the a and b components. It can immediately be concluded from these equations that:

$$\frac{\Omega_a}{\Omega_b} = \frac{I_a}{I_b} \frac{c_{mb}}{c_{ma}} \left[\frac{n_b^2+2}{n_a^2+2} \frac{(n_a/n_s)^2+2}{(n_b/n_s)^2+2} \right]^4 \quad (3)$$

Thus, we can obtain the ratio, Ω_a/Ω_b, of the scattering cross sections from the observed intensity ratio, I_a/I_b,

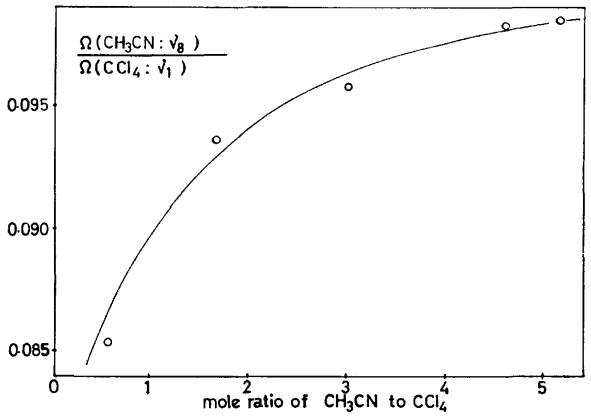

Fig. 1. Concentration dependence of $\Omega(CH_3CN;\ \nu_8)/\Omega(CCl_4;\ \nu_1)$.

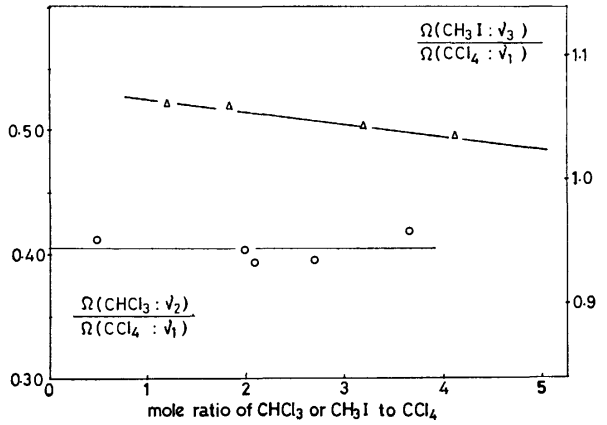

Fig. 2. Concentration dependence of $\Omega(CHCl_3;\ \nu_2)/\Omega(CCl_4;\ \nu_1)$ (circle) and $\Omega(CH_3I;\ \nu_3)/\Omega(CCl_4;\ \nu_1)$ (triangle).

because c_{ma}/c_{mb} is known from the experimental conditions and because the refractive indices can be measured by the use of a refractometer.

Figure 1 shows the ratio of the scattering cross section of the ν_8 band of acetonitrile, $\Omega(CH_3CN;\ \nu_8)$, and that of the ν_1 band of carbon tetrachloride, $\Omega(CCl_4;\ \nu_1)$, observed at several concentrations. It may be seen from the figure that the $\Omega(CH_3CN;\ \nu_8)/\Omega(CCl_4;\ \nu_1)$ ratio decreases as the concentration of acetonitrile decreases. Thus, $\Omega(CH_3CN;\ \nu_8)$ and/or $\Omega(CCl_4;\ \nu_1)$ vary with the change in concentration.

Figure 2 shows the $\Omega(CHCl_3;\ \nu_2)/\Omega(CCl_4;\ \nu_1)$ and $\Omega(CH_3I;\ \nu_3)/\Omega(CCl_4;\ \nu_1)$ ratios observed for the $CHCl_3$–CCl_4 and CH_3I–CCl_4 systems respectively at various concentrations. Obviously, the ratios are not dependent on the concentration. These results probably suggest that $\Omega(CHCl_3;\ \nu_2)$, $\Omega(CH_3I;\ \nu_3)$, and $\Omega(CCl_4;\ \nu_1)$ do not depend on the concentration. Therefore, the concentration dependency of $\Omega(CH_3CN;\ \nu_8)/\Omega(CCl_4;\ \nu_1)$ of Fig. 1 can be ascribed to the concentration dependency of $\Omega(CH_3CN;\ \nu_8)$.

Figure 3 shows the $\Omega(CH_3CN;\ \nu_8)/\Omega(CH_3I;\ \nu_3)$ ratio observed for the CH_3CN–CH_3I system at various concentrations. It may be seen from the figure that the $\Omega(CH_3CN;\ \nu_8)/\Omega(CH_3I;\ \nu_3)$ ratio increases as the concentration of acetonitrile increases. The magnitude of

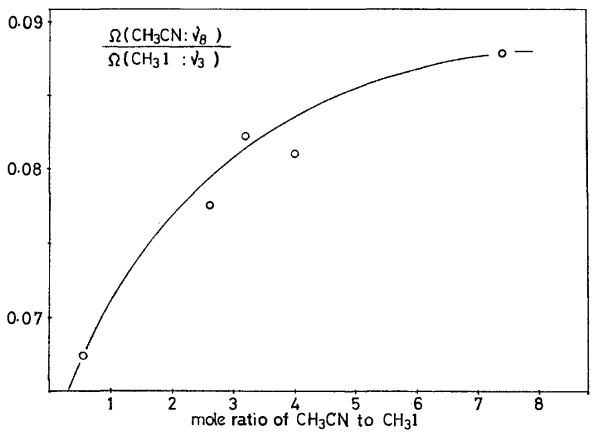

Fig. 3. Concentration dependence of $\Omega(CH_3CN;\ \nu_8)/\Omega(CH_3I;\ \nu_3)$.

the relative cross-section change due to the concentration is as large as that observed for the CH_3CN–CCl_4 system, which may indicate that the concentration dependence is to be ascribed mostly to the physical property of acetonitrile. In the following discussion, therefore, we will focus our attention on the role of a large dipole moment of acetonitrile.

Hyperpolarizability and Dipole Field. It is known that a scattering cross-section is proportional to the square of a transition polarizability, $\boldsymbol{\alpha}_1$,

$$\Omega \propto (\boldsymbol{\alpha}_1)^2 \tag{4}$$

and:

$$(\boldsymbol{\alpha}_1) = (\partial\boldsymbol{\alpha}/\partial Q)\langle I|Q|F\rangle$$

where $\boldsymbol{\alpha}_1$ is a transition polarizability tensor, Q is a normal coordinate, and $\langle I \mid Q \mid F\rangle$ is a matrix element corresponding to the transition between vibrational levels I and F. An i,j-element of a transition polarizability tensor of a molecule changes its magnitide when surrounding molecules produce an electric field, $\langle \boldsymbol{F}_0\rangle_{av}$, on the position of the molecule. As is illustrated in Appendix I, an i,j-element of a transition polarizability under the influence of $\langle \boldsymbol{F}_0\rangle_{av}$ is expressed by the following equation:

$$(\alpha_1)_{ij} = (\alpha_1^0)_{ij} + (\beta_1^0)_{ijk}\langle \boldsymbol{F}_{0k}\rangle_{av} \tag{5}$$

where $(\alpha_1^0)_{ij}$ is an i,j-element of a transition polarizability tensor of an isolated molecule, $(\beta_1^0)_{ijk}$ is an element of a transition hyperpolarizability tensor, and $\langle \boldsymbol{F}_{0k}\rangle_{av}$ is a k-component of $\langle \boldsymbol{F}_0\rangle_{av}$ (see Appendix I).

There are many types of intermolecular interactions which produce electric fields at the position of a given molecule in liquids or solutions. The simplest and most important of these is the interaction of a dipole-dipole type. A molecule with a dipole moment affects the orientational distribution of surrounding molecules through dipole-dipole or dipole-induced dipole interactions. This results in the appearance of a non-zero averaged electric field at the position of the central dipole. For a binary solution, this averaged electric field, $\langle \boldsymbol{F}_{0k}\rangle_{av}$, has been calculated to be[3];

$$\langle \boldsymbol{F}_{0k}\rangle_{av} = \frac{4\pi^2}{27}N_a^2\mu\left[\left(\frac{\mu^2}{kT}+\alpha\right)\frac{\rho}{W_m}c_m + \left(\frac{\mu_s^2}{kT}+\alpha_s\right)\frac{8}{A}c_{ms}\right] \tag{6}$$

with

$$A=\left[\left(\frac{W_m}{\rho}\right)^{1/3}+\left(\frac{W_{ms}}{\rho_s}\right)^{1/3}\right]^3,$$

where μ is a permanent dipole moment, α, the polarizability; c_m, the molar concentration: ρ, the density; W_m, the molecular weight; T, the temperature; k, the Boltzmann constant, and N_a, the Avogadro number. The symbols suffixed by "s" correspond to the solvent molecule.

Symmetry considerations of $(\alpha_1^0)_{ij}$ and $(\beta_1^0)_{ijk}$ are described in Appendix II. Using the results obtained in Appendix II, together with the discussion of Appendix III, we obtain the expression of $\Omega(CH_3CN;\nu_8)/\Omega(CCl_4;\nu_1)$ in temrs of $(\alpha_1^0)_{ij}$, $(\beta_1^0)_{ijk}$, and $\langle F_{0k}\rangle_{av}$ as:

$$\frac{\Omega(CH_3CN;\nu_8)}{\Omega(CCl_4;\nu_1)}=\left(\frac{14}{15}\right)\frac{1}{Q_1(\alpha_1^0)^2}[B+A\langle F_{0z}\rangle_{av}], \quad (7)$$

with

$$A=2[Q_8(\alpha_1^0)_{xy}Q_8(\beta_1^0)_{xyz}+Q_8(\alpha_1^0)_{yz}Q_8(\beta_1^0)_{yzz}]$$

and

$$B=Q_8(\alpha_1^0)_{xy}^2+Q_8(\alpha_1^0)_{yz}^2,$$

where $Q(\alpha_1^0)_{ij}$ is the i,j-element of the transition polarizability tensor which is related with the normal coordinate Q, and where $\langle F_{0z}\rangle_{av}$ is the electric field produced at an acetonitrile molecule in the direction of the molecular axis. No electric field is produced at a carbon tetrachloride molecule, because it has no permanent dipole moment.

Determination of Transition Polarizability and Transition Hyperpolarizability. Equation 7 predicts that a linear relation will hold between $\Omega(CH_3CN;\nu_8)/\Omega(CCl_4;\nu_1)$ and $\langle F_{0z}\rangle_{av}$ if the dipole interaction model is reasonable. Figure 4 shows the relation between the observed $\Omega(CH_3CN;\nu_8)/\Omega(CCl_4;\nu_1)$ and the calculated $\langle F_{0z}\rangle_{av}$ values. In the calculation of $\langle F_{0z}\rangle_{av}$, the permanent dipole moment of acetonitrile was taken to be 3.92 D.[4] Obviously, a linear relation holds between the relative cross-section and the electric dipole field. From the slope, A^*, and the intercept, B^*, of the line, we can determine the corresponding terms of Eq. 7. From the results of Fig. 4, A^* and B^* are given the values of 7.18×10^3 (dyn^{-1} esu) and 0.0776 respectively.

According to the preceding report,[1] the magnitude of $Q_8(\alpha_1^0)_{yz}$ has been observed to be 0.0204 (Å^3) from the measurement of the infrared absorption intensity for the ν_8 fundamental band of acetonitrile in a carbon tetrachloride solution. The $Q_1(\alpha_1^0)$ value of carbon tetrachloride, on the other hand, can be determined by the absolute intensity measurement of the ν_1 fundamental line. Kato *et al.* have reported the $|Q_1(\alpha_1^0)|^2$ value to be 1.99×10^{-50} (cm^6).[7] Thus, we can obtain the following values and relations for the ν_8 line of methyl cyanide:

$$Q_8(\alpha_1^0)_{xy}=0.0352\ (Å^3),$$
$$Q_8(\alpha_1^0)_{yz}=0.0204\ (Å^3),$$

and:

$$|3.52Q_8(\beta_1^0)_{xyz}|+|2.04Q_8(\beta_1^0)|=7.654\times10^{-8}(Å^6\ \text{dyn}^{-1}\ \text{esu}) \quad (8)$$

As is illustrated in Appendix II, all the necessary transition polarizabilities for an e-type fundamental of C_{3v} symmetry are $Q(\alpha_1^0)_{yz}$ and $Q(\alpha_1^0)_{xy}$. That is to say, the scattering polarizability tensor can be completely determined by observing the solvent effects on the infrared absorption and the Raman spectra. In the case of the infrared absorption spectra, only $Q(\alpha_1^0)_{yz}$ is obtained through this relation:

$$\Gamma_c\propto\left(\frac{\partial\mu_y^0}{\partial Q_8}\right)^2+2\left(\frac{\partial\mu_y^0}{\partial Q_8}\right)Q_8(\alpha_1^0)_{yz}\langle F_{0z}\rangle_{av}$$

where Γ_c is an absolute absorption intensity observed in a solution and $(\partial\mu_y^0/\partial Q_8)$ is a dipole moment derivative which can be determined by observing the absolute infrared absorption intensity of the ν_8 fundamental in the gas phase. The sign of the product, $(\partial\mu_y^0/\partial Q_8)Q_8(\alpha_1^0)_{yz}$, can be determined from the solvent effect data; therefore, the sign of $Q_8(\alpha_1^0)_{yz}$ can be definitely determined if the sign of $(\partial\mu_y^0/\partial Q_8)$ is known. In the case of the Raman spectra, on the other hand, the sum, $Q(\alpha_1^0)_{yz}^2+Q(\alpha_1^0)_{xz}^2$, can be obtained. Thus, the signs of $Q(\alpha_1^0)$'s are ambiguous; that is, only an absolute value, $|Q(\alpha_1^0)|$, is obtained by this method.

The ν_3 Line of Methyl Iodide. For an a_1-type line of C_{3v} symmetry, the relation corresponding to Eq. 7 is obtained. As an example, the ν_3 fundamental line of methyl iodide in a carbon tetrachloride solution is expressed as:

$$\frac{\Omega(CH_3I;\nu_3)}{\Omega(CCl_4;\nu_1)}=\left(\frac{1}{15}\right)\frac{1}{Q_1(\alpha_1^0)^2}(B+A\langle F_{0z}\rangle_{av}) \quad (9)$$

with:

$$A=18Q_3(\alpha_1^0)_{xx}Q_3(\beta_1^0)_{xxz}+8Q_3(\alpha_1^0)_{zz}Q_3(\beta_1^0)_{zzz}+2Q_3(\alpha_1^0)_{xx}Q_3(\beta_1^0)_{zzz}+2Q_3(\alpha_1^0)Q_3(\beta_1^0)_{xxz}$$

and:

$$B=9Q_3(\alpha_1^0)_{xx}^2+2Q_3(\alpha_1^0)_{xx}Q_3(\alpha_1^0)_{zz}+4Q_3(\alpha_1^0)_{zz}^2$$

Although the observed data of Fig. 2 for CH_3I–CCl_4 system are not accurate enough, we tried to determine the necessary transition polarizability and transition hyperpolarizability for the ν_3 line of methyl iodide. From the plotting of $\Omega(CH_3I;\nu_3)/\Omega(CCl_4;\nu_1)$ against $\langle F_{0z}\rangle_{av}$, the slope, A^*, and the intercept, B^*, were obtained to be:

$$A^*=-0.0309\times10^{-4}\ \text{dyn}^{-1}\ \text{esu},$$

and:

$$B^*=1.104$$

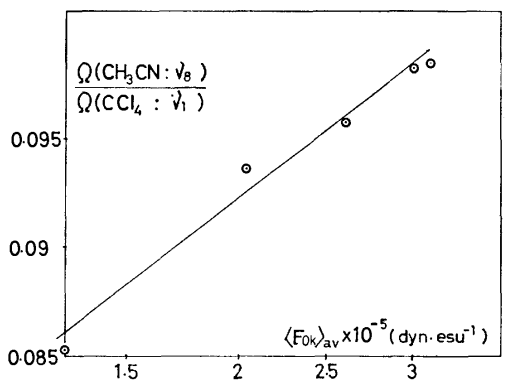

Fig. 4. Plotting of $\Omega(CH_3CN:\nu_8)/\Omega(CCl_4;\nu_1)$ against $\langle F_{oz}\rangle_{av}$.

TABLE 1. $\langle F_{0z}\rangle_{av}$ VALUES CALCULATED FOR $CHCl_3$, CH_3I, AND CH_3CN IN CCl_4 SOLUTIONS

Mole ratio of $CHCl_3$	$\langle F_{0z}\rangle_{av}$ ($\times 10^{-3}$ dyn esu)	Mole ratio of CH_3I	$\langle F_{0z}\rangle_{av}$ ($\times 10^{-4}$ dyn esu)	Mole ratio of CH_3CN	$\langle F_{0z}\rangle_{av}$ ($\times 10^{-5}$ dyn esu)
0.492	1.007	0.550	0.892	0.540	0.741
1.026	1.498	1.214	1.294	1.679	1.474
1.981	1.966	1.840	1.529	2.990	1.889
2.095	2.004	3.202	1.827	4.580	2.013
2.688	2.165	4.124	1.947	5.217	2.231
3.648	2.341				
$\mu_{CHCl_3}=1.05$ D (Ref. 6)		$\mu_{CH_3I}=1.65$ D (Ref. 5)		$\mu_{CH_3CN}=3.92$ D (Ref. 4)	

Using these values and the previous data[1]; ${}^{Q_3}(\alpha_1^0)_{zz}=-1.13\times10^{-25}$ (cm^3), we can obtain the following values and relations;

$${}^{Q_3}(\alpha_1^0)_{xx} = -1.164\times10^{-25} \text{ or } 1.888\times10^{-25}\ cm^3$$

and:

$$18{}^{Q_3}(\alpha_1^0)_{xx}{}^{Q_3}(\beta_1^0)_{xxz} + 8{}^{Q_3}(\alpha_1^0)_{zz}{}^{Q_3}(\beta_1^0)_{zzz} + 2{}^{Q_3}(\alpha_1^0)_{xx}{}^{Q_3}(\beta_1^0)_{zzz} + 2{}^{Q_3}(\alpha_1^0)_{zz}{}^{Q_3}(\beta_1^0)_{xxz} = -9.224\times10^{-51}\ cm^6\ dyn^{-1}\ esu. \quad (10)$$

The A^* and B^* values for the ν_3 line of methyl iodide can be determined in another way. By combining Eqs. 7 and 9, $\Omega(CH_3CN;\nu_8)/\Omega(CH_3I;\nu_3)$ can be expressed as:

$$\frac{\Omega(CH_3CN;\nu_8)}{\Omega(CH_3I;\nu_3)} = \frac{\Omega(CH_3CN;\nu_8)}{\Omega(CCl_4;\nu_1)} \Big/ \frac{\Omega(CH_3I;\nu_3)}{\Omega(CCl_4;\nu_1)} = \frac{(B^*_{CH_3CN}+\langle F_{0z}\rangle_{av}A^*_{CH_3CN})}{(B^*_{CH_3I}+\langle F_{0z}\rangle_{av}A^*_{CH_3I})} \quad (11)$$

As we have the observed $\Omega(CH_3CN;\nu_8)/\Omega(CH_3I;\nu_3)$ values of Fig. 3, and the $B^*_{CH_3CN}$ and $A^*_{CH_3CN}$ values, we can calculate the $A^*_{CH_3I}$ and $B^*_{CH_3I}$ values for the ν_3 line of methyl iodide in the carbon tetrachloride solution as:

$$A^* = -0.0305\times10^{-4}\ dyn^{-1}\ esu$$

and:

$$B^* = 1.528.$$

These values are not very different from those obtained in the previous way.

Criteria for the Internal Standard Method. The present results afford some useful information about the reliability of a so-called internal standard method for the determination of relative Raman intensities which are mutually comparable. The concentration dependency of a relative intensity of a Raman line arises from the existence of the concentration-dependent term, $A^*\langle F_{0z}\rangle_{av}$, of Eq. 7 or 9.

We have very little knowledge about the magnitude of A^*. Therefore, we first compare the magnitudes of $\langle F_{0z}\rangle_{av}$ of chloroform, methyl iodide, and acetonitrile in carbon tetrachloride solutions. Table 1 shows the $\langle F_{0z}\rangle_{av}$ values of chloroform, methyl iodide, and acetonitrile calculated for carbon tetrachloride solutions. It may be seen from the table that the orders of $\langle F_{0z}\rangle_{av}$ are 10^3 for chloroform, 10^4 for methyl iodide, and 10^5 for acetonitrile, in units of dyn esu^{-1}. The difference arises, of course, from the difference in the magnitude of the dipole moments. The dipole moment of acetonitrile is 3.92 D[4], while those of methyl iodide and chloroform are 1.65 D[5] and 1.05 D[6] respectively. These facts are definitely reflected in the observed Raman intensity changes due to the concentration, as is shown in Figs. 1 and 2. Thus, we can conclude that the concentration dependence of a Raman intensity is more distinct for a molecule with a larger dipole moment.

If A^* is large, on the other hand, the concentration dependence of Raman intensity may be large enough to be observed even though $\langle F_{0z}\rangle_{av}$ is small. It has been shown that $A^*\approx0.07\times10^{-5}$ dyn^{-1} esu and $A^*\approx-0.03\times10^{-4}$ dyn^{-1} esu for the ν_8 of acetonitrile and ν_3 of methyl iodide respectively. The corresponding $\langle F_{0z}\rangle_{av}$ values are, respectively, $\approx10^5$ dyn esu^{-1} and $\approx10^4$ dyn esu^{-1}; the result is that the products, $A^*\times\langle F_{0z}\rangle_{av}$, have almost the same magnitudes. In the former case, the main factor which makes the concentration dependence observable is $\langle F_{0z}\rangle_{av}$, while in the latter it is the magnitude of A^*. Detailed discussions of the magnitude of A^* from the viewpoint of the transition polarizability and transition hyperpolarizability are quite difficult at this stage, because A^* is a rather complicated function of the transition polarizability and the transition hyperpolarizability (see Eq. 7 or 9). As there have been reported quite a few number of values for ${}^{Q}(\alpha_1^0)$ and ${}^{Q}(\beta_1^0)$ with their definite signs, except the ${}^{Q}(\alpha_1^0)\approx10^{-26}$ cm^3 and ${}^{Q}(\beta_1^0)\approx10^{-32}$ $cm^3\ dyn^{-1}$ esu, we can only conclude that the concentration dependence might be observed even for a molecule with a much smaller dipole moment. Incidentally, the plus and minus signs of A^* correspond to the increase and decrease in scattering cross sections with the increase in the concentration (see Figs. 1 and 2).

Appendix I. Definition of an Apparent Transition Polarizability Derivative

The energy, U, of a molecule in an electric field, $\boldsymbol{F}$, is expressed as a function of $\boldsymbol{F}$:

$$U = U(\boldsymbol{F}) \quad (A1)$$

The Maclaurin expansion of Eq. A1 yields:

$$U = U(0) - \sum\mu_i^0F_i - \frac{1}{2!}\sum_{ij}\alpha_{ij}^0F_iF_j - \frac{1}{3!}\sum_{ijk}\beta_{ijk}^0F_iF_jF_k - \cdots \quad (A2)$$

and:

$$\mu_i^0 = -(\partial U/\partial F_i)_0$$
$$\alpha_{ij}^0 = -(\partial^2 U/\partial F_i \partial F_j)_0$$
$$\beta_{ijk}^0 = -(\partial^3 U/\partial F_i \partial F_j \partial F_k)_0$$

The coefficients, μ_i^0, α_{ij}^0, and β_{ijk}^0 are independent of $\boldsymbol{F}$. They are called, respectively, a permanent dipole moment, a polarizability, and a hyperpolarizability.

Put a molecule which has a permanent dipole moment, $\boldsymbol{\mu}$, polarizability, $\boldsymbol{\alpha}^0$, and hyperpolarizability, $\boldsymbol{\beta}^0$, in an electric field, $\boldsymbol{F}$. Then the total dipole moment, $\boldsymbol{m}$, of the molecule is:

$$\boldsymbol{m} = \boldsymbol{\mu}^0 + \boldsymbol{p} \tag{A3}$$

where $\boldsymbol{p}$ is an dipole moment induced by the electric field, $\boldsymbol{F}$:

$$\boldsymbol{p} = \boldsymbol{\alpha}^0 \cdot \boldsymbol{F} + \frac{1}{2}\boldsymbol{\beta}^0 : \boldsymbol{FF} \tag{A4}$$

In the present problem, $\boldsymbol{F}$ is composed of two different electric fields. One is an electric field, $\boldsymbol{F}_1$, of radiating light, while the other is an electric field, $\boldsymbol{F}_m$, produced by molecules in a condensed phase. Thus, an induced moment, $\boldsymbol{p}$, is expressed as:

$$\boldsymbol{p} = \boldsymbol{p}_1 + \boldsymbol{p}_m,$$

where $\boldsymbol{p}_1$ is a dipole moment induced by $\boldsymbol{F}_1$ and $\boldsymbol{p}_m$ is that induced by $\boldsymbol{F}_m$. Therefore, the induced moment, $\boldsymbol{p}_1$, is:

$$\begin{aligned}\boldsymbol{p}_1 &= \boldsymbol{p} - \boldsymbol{p}_m \\ &= \left[\boldsymbol{\alpha}^0 \cdot (\boldsymbol{F}_1 + \boldsymbol{F}_m) + \frac{1}{2}\boldsymbol{\beta}^0 : (\boldsymbol{F}_1 + \boldsymbol{F}_m)(\boldsymbol{F}_1 + \boldsymbol{F}_m)\right] \\ &\quad - \left[\boldsymbol{\alpha}^0 \cdot \boldsymbol{F}_m + \frac{1}{2}\boldsymbol{\beta}^0 : \boldsymbol{F}_m \boldsymbol{F}_m\right] \\ &= \boldsymbol{\alpha}^0 \cdot \boldsymbol{F}_1 + \boldsymbol{\beta}^0 : \boldsymbol{F}_m \boldsymbol{F}_1 + \frac{1}{2}\boldsymbol{\beta}^0 : \boldsymbol{F}_1 \boldsymbol{F}_1\end{aligned} \tag{A5}$$

In the present work, the last term of Eq. A5 may be neglected, because $\boldsymbol{F}_1$ is small. Thus,

$$\begin{aligned}\boldsymbol{p}_1 &= \boldsymbol{\alpha}^0 \cdot \boldsymbol{F}_1 + \boldsymbol{\beta}^0 : \boldsymbol{F}_m \boldsymbol{F}_1 \\ &= [\boldsymbol{\alpha}^0 + \boldsymbol{\beta}^0 \cdot \boldsymbol{F}_m] \cdot \boldsymbol{F}_1\end{aligned} \tag{A6}$$

Here, we define "an apparent polarizability" as:

$$\boldsymbol{\alpha} = \boldsymbol{\alpha}^0 + \boldsymbol{\beta}^0 \cdot \boldsymbol{F}_m \tag{A7}$$

Then the induced moment is expressed in this form:

$$\boldsymbol{p}_1 = \boldsymbol{\alpha} \cdot \boldsymbol{F}_1$$

which formally coincides with usual expression for an induced moment. Therefore, an i,j-element of α becomes:

$$\alpha_{ij} = \alpha_{ij}^0 + \sum_k \beta_{ijk}^0 F_{mk} \tag{A8}$$

where F_{mk} is a k-component of $\boldsymbol{F}_m$.

In order to obtain an explicit expression for a Raman scattering cross-section, it is necessary to rewrite Eq. A8 in terms of transition polarizability and transition hyperpolarizability derivatives, which are defined as:

$$^Q(\alpha_1^0)_{ij} = (\alpha_1^0)_{ij}\langle I|Q|F\rangle$$
$$(\alpha_1^0)_{ij} = (\partial \alpha_{ij}^0/\partial Q)_0,$$

and:

$$^Q(\beta_1^0)_{ijk} = (\beta_1^0)_{ijk}\langle I|Q|F\rangle$$
$$(\beta_1^0)_{ijk} = (\partial \beta_{ijk}^0/\partial Q)_0, \tag{A9}$$

where Q is a normal coordinate. Differentiating Eq. A8 with respect to Q, we rewrite Eq. A8 as:

$$^Q(\alpha_1)_{ij} = {}^Q(\alpha_1^0)_{ij} + \sum_k {}^Q(\beta_1^0)_{ijk} F_{mk} + \sum_k \beta_{ijk}^0 (\partial F_{mk}/\partial U)_0 \tag{A10}$$

As $\boldsymbol{F}$ is almost independent of the molecular vibration, we finally obtain:

$$^Q(\alpha_1)_{ij} = {}^Q(\alpha_1^0)_{ij} + \sum_k {}^Q(\beta_1^0)_{ijk} F_{mk} \tag{A11}$$

In the present work, F_{mk} will be replaced by $\langle \boldsymbol{F}_{0k} \rangle_{av}$. It is important to add that the k direction should be parallel to the molecular axis under consideration, because the averaged dipole field has a non-zero value only in the direction of the dipole moment. Thus, Eq. A11 can be rewritten as:

$$^Q(\alpha_1)_{ij} = {}^Q(\alpha_1^0)_{ij} + {}^Q(\beta_1^0)_{ijk}\langle \boldsymbol{F}_{0z} \rangle_{av}$$

where the molecular axis being chosen is the z-axis.

Appendix II. Symmetry Properties of α and β

The molecules studied in the present study belong to the point groups of C_{3v} and T_d. Thus, we will confine our discussion to C_{3v} and T_d symmetries.

a) Polarizability. If a molecule is in an equilibrium position, the polarizability is invariant with respect to the operations, S, of the symmetry group of the molecule:

$$S(\alpha_{ij}^0) = \alpha_{ij}^0 \tag{A12}$$

Eq. A12 requires that some polarizability components, α_{ij}^0, vanish. As an example, let us consider a rotation about the z-axis by an angle of φ. The corresponding symmetry operation, S, is expressed as:

$$S\begin{pmatrix}\alpha_{xx}^0\\ \alpha_{yy}^0\\ \alpha_{xy}^0\\ \alpha_{xz}^0\\ \alpha_{yz}^0\\ \alpha_{zz}^0\end{pmatrix} = \begin{pmatrix} a^2 & b^2 & 2ab & 0 & 0 & 0\\ b^2 & a^2 & -2ab & 0 & 0 & 0\\ -ab & ab & a^2-b^2 & 0 & 0 & 0\\ 0 & 0 & 0 & a & b & 0\\ 0 & 0 & 0 & -b & a & 0\\ 0 & 0 & 0 & 0 & 0 & 1\end{pmatrix}\begin{pmatrix}\alpha_{xx}^0\\ \alpha_{yy}^0\\ \alpha_{xy}^0\\ \alpha_{xz}^0\\ \alpha_{yz}^0\\ \alpha_{zz}^0\end{pmatrix} \tag{A13}$$

where $a=\cos\varphi$ and $b=\sin\varphi$. From Eqs. A12 and A13,

$$a^2\alpha_{xx}^0 + b^2\alpha_{yy}^0 + 2ab\alpha_{xy}^0 = \alpha_{xx}^0$$

and similar relations for other symmetry operation. Thus, for C_{3v} symmetry, these relations;

$$\alpha_{xx}^0 = \alpha_{yy}^0 \neq \alpha_{zz}^0$$

and

$$\alpha_{xy}^0 = \alpha_{xz}^0 = \alpha_{yz}^0 \tag{A14}$$

are obtained. Eq. A14 shows that the polarizability tensor has only the diagonal elements and that the polarizability ellipsoid will become a rotation ellipsoid about the z-axis. These are the results obtained for a molecule in an equilibrium position.

For the displacements of nuclei due to vibration, the symmetry of the molecule is destroyed except when the vibrational mode is totally symmetric. Consider a molecule whose nuclei deviate from their equilibrium position according to a particular normal mode. There are two ways of applying symmetry operations, S, for the molecule. One is to apply the symmetry operations to the polarizability directly, while the other is to apply the symmetry operations to the normal coordinate. The results obtained by these two methods should be the same. Thus,

$$S\alpha_{ij}^0(Q_1, Q_2, \ldots\ldots, Q_n) = \alpha_{ij}^0(S_0Q_1, S_0Q_2, \ldots\ldots, S_0Q_n) \tag{A15}$$

where the symmetry operations are distinguished as S_0 and S, simply because $\boldsymbol{\alpha}$ is a tensor quantity, while Q_i is a vector quantity. In order to calculate the right-hand side of Eq. A15, we have to know the transformation property of a normal coordinate due to the symmetry operation.

Consider a molecule with C_{3v} symmetry like acetonitrile. The normal coordinates, Q_s and $Q_{s'}$, are transformed by the C_3 operation thus:

$$Q_s \xrightarrow{C_3} -\frac{1}{2}Q_s - \frac{\sqrt{3}}{2}Q_{s'}$$

and: (A16)

$$Q_{s'} \xrightarrow{C_3} \frac{\sqrt{3}}{2}Q_s - \frac{1}{2}Q_{s'}$$

The polarizability is expressed in terms of normal coordinates:

$$\alpha^0_{ij} = (\alpha^0_{ij})_0 + \sum_k (\partial\alpha^0_{ij}/\partial Q_k)Q_k \tag{A17}$$

By combining Eqs. A16 and A17, we obtain this relation for α^0_{xx}:

$$\frac{\partial(\alpha^0_{xx})}{\partial(C_3Q_s)} = -\frac{1}{2}\left(\frac{\partial\alpha^0_{xx}}{\partial Q_s}\right)+\frac{\sqrt{3}}{2}\left(\frac{\partial\alpha^0_{xx}}{\partial Q_{s'}}\right)$$
$$= -Q_s(\alpha^0_1)_{xx}/2 + \sqrt{3}Q_{s'}(\alpha^0_1)_{xx}/2 \tag{A18}$$

From Eq. A13, on the other hand,

$$\frac{\partial(C_3\alpha^0_{xx})}{\partial Q_s} = \frac{1}{4}\left(\frac{\partial\alpha^0_{xx}}{\partial Q_s}\right)+\frac{3}{4}\left(\frac{\partial\alpha^0_{yy}}{\partial Q_s}\right)-\frac{\sqrt{3}}{2}\left(\frac{\partial\alpha^0_{xy}}{\partial Q_s}\right)$$
$$= Q_{s'}(\alpha^0_1)_{xx}/4 + 3Q_s(\alpha^0_1)_{yy}/4 - \sqrt{3}Q_s(\alpha^0_1)_{xy}/2 \tag{A19}$$

By equating Eqs. A18 and A19, we obtain this relation:

$$\frac{3}{4}(Q_s(\alpha^0_1)_{xx} + Q_s(\alpha^0_1)_{yy})$$
$$= \frac{\sqrt{3}}{2}(Q_{s'}(\alpha^0_1)_{xx} + Q_s(\alpha^0_1)_{xy}) \tag{A20}$$

Similar but different relations are obtained for other polarizability derivatives and for other normal coordinates by applying the C_3 and σ_v operations. The transformation relations:

$$Q_s \xrightarrow{\sigma_v} -Q_s$$
$$Q_{s'} \xrightarrow{\sigma_v} Q_{s'} \tag{A21}$$

are used for the σ_v operation. From these results, the following relations between the polarizability derivatives or transition polarizability derivatives are obtained:

$$Q_s(\alpha^0_1)_{xx} = Q_s(\alpha^0_1)_{yy} = Q_s(\alpha^0_1)_{zz} = Q_{s'}(\alpha^0_1)_{zz} = 0$$
$$Q_{s'}(\alpha^0_1)_{xy} = Q_{s'}(\alpha^0_1)_{yz} = Q_s(\alpha^0_1)_{xz} = 0$$
$$Q_s(\alpha^0_1)_{xy} = Q_{s'}(\alpha^0_1)_{yy} = -Q_{s'}(\alpha^0_1)_{xx}$$
$$Q_s(\alpha^0_1)_{yz} = Q_{s'}(\alpha^0_1)_{xz} \tag{A22}$$

b) Hyperpolarizability. Generally, a hyperpolarizability tensor has ten independent elements because of its symmetry property. These elements are related to each other in accordance with the molecular symmetry. The procedure of finding the relations between the hyperpolarizability derivatives is exactly the same as that discussed in a). For example, consider a rotation about the z-aixs by an angle of φ. The matrix representation for S corresponding to Eq. A13 is:

$$S\begin{pmatrix}\beta^0_{xxx}\\ \beta^0_{yyy}\\ \beta^0_{xxy}\\ \beta^0_{xyy}\\ \beta^0_{xxz}\\ \beta^0_{yyz}\\ \beta^0_{xyz}\\ \beta^0_{xzz}\\ \beta^0_{yzz}\\ \beta^0_{zzz}\end{pmatrix} = \begin{pmatrix} a^3 & b^3 & 3a^2b & 3ab^2 & 0 & 0 & 0 & 0 & 0 & 0\\ -b^3 & a^3 & 3ab^2 & -3a^2b & 0 & 0 & 0 & 0 & 0 & 0\\ -a^2b & ab^2 & a^3-2ab^2 & 2a^2b-b^3 & 0 & 0 & 0 & 0 & 0 & 0\\ ab^2 & a^2b & b^3-2a^2b & a^3-2ab^2 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & a^2 & b^2 & 2ab & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & b^2 & a^2 & -2ab & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & -ab & ab & a^2-b^2 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & a & b & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -b & a & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1\end{pmatrix} \times \begin{pmatrix}\beta^0_{xxx}\\ \beta^0_{yyy}\\ \beta^0_{xxy}\\ \beta^0_{xyy}\\ \beta^0_{xxz}\\ \beta^0_{yyz}\\ \beta^0_{xyz}\\ \beta^0_{xzz}\\ \beta^0_{yzz}\\ \beta^0_{zzz}\end{pmatrix} \tag{A23}$$

where $a=\cos\varphi$ and $b=\sin\varphi$. As is shown in Appendix I, the elements on which at least one z is subscribed are important in the present work. In other words, only the submatrix of Eq. A23 enclosed in the square of the dotted line is important for the present discussion. It is necessary, therefore, to know the symmetry property of the submatrix. A comparison of Eqs. A13 and A23 shows that the submatrix is exactly the same as that of Eq. A13.

The transformation of β with respect to a normal coordinate is the same as that described in a), as β_{ijk} is expressed as:

$$\beta^0_{ijk} = (\beta^0_{ijk})_0 + \sum_l \left(\frac{\partial\beta^0_{ijk}}{\partial Q}\right)Q_l \tag{A24}$$

Thus, we ascertain the relations between the hyperpolarizability derivatives or transition hyperpolarizabilities by direct analogy with Eq. A22:

$$Q_s(\beta^0_1)_{xxz} = Q_s(\beta^0_1)_{yyz} = Q_s(\beta^0_1)_{zzz} = Q_{s'}(\beta^0_1)_{zzz} = 0$$
$$Q_{s'}(\beta^0_1)_{xyz} = Q_{s'}(\beta^0_1)_{yzz} = Q_s(\beta^0_1)_{xzz} = 0$$
$$Q_s(\beta^0_1)_{xyz} = Q_{s'}(\beta^0_1)_{yyz} = -Q_{s'}(\beta^0_1)_{xxz}$$
$$Q_s(\beta^0_1)_{yzz} = Q_{s'}(\beta^0_1)_{xzz} \tag{A25}$$

Appendix III. Reduction to a Scattering Cross-section

In order to calculate a scattering cross-section, it is necessary to know the actual geometric conditions of the Raman spectral measurement. In the present work, the observed Raman intensities are expressed as:

$$\Omega \propto ((\alpha_1)^2_{YZ} + (\alpha_1)^2_{ZZ}) \tag{A26}$$

where X, Y, and Z are the spece-fixed Cartesian coordinates. The relations between the polarizability tensors expressed in the molecular-fixed Cartesian coordinates and the space-fixed Cartesian coordinates are:

$$\alpha^2_{YZ} = \frac{1}{15}\sum_i \alpha^2_{ii} - \frac{1}{15}\sum_{i<j}\alpha_{ii}\alpha_{jj} + \frac{1}{5}\sum_{i<j}\alpha^2_{ij}$$
$$\alpha^2_{ZZ} = \frac{1}{5}\sum_i \alpha^2_{ii} + \frac{2}{15}\sum_{i<j}\alpha_{ii}\alpha_{jj} + \frac{4}{15}\sum_{i<j}\alpha^2_{ij} \tag{A27}$$

Eqs. A26 and A27, together with Eq. A22, give the cross section, $\Omega(e)$, for the e-type line of a molecule with C_{3v}

symmetry:

$$\Omega(e) \propto \frac{14}{15}({}^{Q}(\alpha_1)^2_{xy} + {}^{Q}(\alpha_1)^2_{yz}) \quad \text{(A28)}$$

In the case of the a_1-type line of C_{3v} symmetry, the relations corresponding to Eq. A22 are:

$$\begin{aligned} &{}^{Q}(\alpha_i^0)_{xx} = {}^{Q}(\alpha_i^0)_{yy},\ {}^{Q}(\alpha_i^0)_{zz}, \\ &{}^{Q}(\alpha_i^0)_{xy} = {}^{Q}(\alpha_i^0)_{yz} = {}^{Q}(\alpha_i^0)_{zx} = 0 \end{aligned} \quad \text{(A29)}$$

Therefore, the cross section, $\Omega(a_1)$, for the a_1-type line of a molecule with C_{3v} symmetry is expressed as:

$$\begin{aligned} \Omega(\alpha_1) \propto 3{}^{Q}(\alpha_1)^2_{xx}/5 + 2{}^{Q}(\alpha_1)_{xx}{}^{Q}(\alpha_1)_{zz}/15 \\ + 4{}^{Q}(\alpha_1)^2_{zz}/15 \end{aligned} \quad \text{(A30)}$$

By inserting Eq. A11 into Eq. A28 or A30, and by neglecting the terms corresponding to $\langle \boldsymbol{F}_{0k} \rangle^2_{av}$, we can express the Raman scattering cross-section in terms of α_1, β_1, and $\langle \boldsymbol{F}_{0k} \rangle_{av}$.

Analysis of the Effect of Added Electrolyte on the Micellar Catalysis

Keishiro SHIRAHAMA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received February 19, 1976)

The effect of added electrolyte on micelle-catalyzed reaction was analyzed. The log [L.S] *vs.* log (total counter ion concentration) plot gives a straight line, where [L.S] is a limiting slope on a rate-surfactant concentration plot at an infinitely dilute micellar concentration. The slope is related to the number and the magnitude of the Coulombic term that may be included in the concentration effect of reactants, and in the intrinsic micellar effect, or the relative stabilization of a transition state in the presence of micelles. The above treatment was applied to (1) the hydrolysis of trimethyl orthobenzoate in sodium dodecyl sulfate solution, (2) the fading reaction of Crystal Violet in hexadecyltrimethylammonium bromide (CTABr) solution, and (3) the nucleophilic substitution reaction of 2,4-dinitrofluorobenzene in CTABr solution. It was found that the concentration effect is predominant in (1), while the relative stabilization of the transition state occurs in (2) and (3) in addition to the concentration effect.

A marked inhibition takes place in many systems on addition of an electrolyte to a micelle-catalyzed reaction. The interpretation of experimental results seems to be qualitative since most experiments were performed at a constant surfactant concentration with varying concentration of added electrolyte.[1-6] The constant surfactant concentration with various amounts of the added electrolyte is not considered to be at a corresponding state. As an example, cmc decreases with an increase in the added electrolyte concentration leading to the increase in micellar concentration.

In a previous paper,[7] a formula was derived for a micelle-catalyzed reaction based upon a microheterogeneous reaction. This was found to be useful for describing the mode of such as rate-surfactant concentration profile, inhibition of a micellar catalysis by an added electrolyte, and an activation energy, taking the hydrolysis of trimethyl orthobenzoate (MOB) in sodium dodecyl sulfate (SDS) solution as a model system.

This communication shows the obtained data to be in line with the derived equations, analysis of the effect of the added electrolyte on the micellar catalysis being made. The selected systems are: (1) MOB–SDS–NaCl system which has been examined by using the published data,[4] (2) Crystal Violet (CV)–Hexadecylammonium bromide (CTABr)–NaBr system,[8,9] and (3) 2,4-dinitrofluorobenzene (DNFB)–CTABr–NaBr system.[5]

Theoretical

The following equation was derived for a chemical reaction of the type, A+B→P, in a micellar solution.[7]

$$k_2 = (\phi_{es}K_AK_Bf+1)k_b/(\phi_mK_A+1) \quad (1)$$

where k_2 is the second-order reaction rate constant in a micellar solution, and k_b that in the bulk, K_A and K_B are the distribution coefficients of reactants A and B between the micellar and bulk phases, respectively, ϕ_m and ϕ_{es} are the volume fractions of the micelles and the effective surface reaction-layer around a micelle, respectively, and $f=\exp(-\Delta G^*/RT)$ represents an intrinsic micellar effect, where $\Delta G^*=G_m^*-G_b^*$, G_m^*, and G_b^*, being the activation free energies in the presence and absence of micelles, respectively. At a very low concentration with respect to micelles, under which assumption Eq. 1 was derived, the volume fractions are represented by $\phi_m=\alpha_m[M]$ and $\phi_{es}=\alpha_{es}[M]$, where α_i is the molar volume of region i, and [M] the micellar concentration, both quantities being on the monomer concentration basis. We get the following equation from Eq. 1.

$$[L.S] = \lim_{[M]\to 0} d(k_2/k_b)/d[M] = \alpha_{es}K_AK_Bf - \alpha_mK_A \fallingdotseq \alpha_{es}K_AK_Bf \quad (2)$$

where [L.S.] denotes the limiting slope of a rate-surfactant concentration profile. The last approximation in Eq. 2 is fairly good for most cases of efficient micellar catalysis. The electrical surface potential of a micelle, ψ_0 is written as a function of the total counter ion concentration, C_t:[10]

$$\psi_0 = -(kT/z_ie)\ln C_t + \text{constant} \quad (3)$$

where k is the Boltzmann constant, T absolute temperature, and z_ie the electric charge of reactant i. If the electrostatic term is included, *e.g.*, in K_B, it should be of the form, $K_B=K_0\exp(-z_Be\psi_0/kT)$, where K_0 is a nonelectrostatic part of the distribution coefficient. The f-factor also may contain a $z_ie\psi_0$ term if the relative stabilization of the transition state is electrostatically caused by the surface potential. In this case, z_i is the number of charge of the transition state taken relative to that of the reactant state, in the rate-determining step. Taking logarithm of Eqs. 2 and 3, and rearranging, we have

$$\ln [L.S] = -\nu \ln C_t + \text{constant} \quad (4)$$

where $\nu=\sum_i[-z_ie\psi_0/|e\psi_0|]$ is the algebraic sum of the number of surface potential terms possibly contained in K_A, K_B and/or in f-terms. If $z_ie\psi_0<0$, K_A and K_B concentrate ionic reactant A and B, respectively, around micelles, and f-term accelerates the reaction, and *vice versa*. The dependence of α_{es} on c_t is neglibigly small. Although Eq. 1 was derived for a reaction system consisting of a buffered reaction partner (H^+ or OH^- for most cases), it is easily extended to a system in which no buffered reactant is included:

$$k_2 = (\phi_{es}K_AK_Bf+1)k_b/(\phi_mK_A+1)(\phi_{es}K_B+1) \quad (5)$$

which is similar to an equation derived by Yatsimirski *et al.*,[6] and leads to the following formula.

$$[L.S] = \lim_{[M]\to 0} d(k_2/k_b)/d[M] = \alpha_{es}K_AK_Bf - \alpha_mK_A - \alpha_{es}K_B \fallingdotseq \alpha_{es}K_AK_Bf \quad (6)$$

The last approximation again holds for efficient micelle-catalyzed reactions. Thus the present treatment does not depend on whether a reaction partner is buffered or not.

Experimental

Most of the experimental techniques were taken from previous works;[4,5,8,9] only the modifications and specifications will be mentioned.

Materials. The synthesis and purification of MOB was the same as in literatures,[4,11] its purity being checked by NMR and UV spectroscopies. DNFB (Tokyo Chemical Ind. Co., Ltd.) was distilled under reduced pressure. CV (C.I. Basic Violet 3) of reagent grade (Wako Pure Chemical Ind. Ltd.) was used. The SDS was the same sample as used previously.[12] CTABr (Tokyo Chemical Ind. Ltd.) was recrystallized once from carbon tetrachloride, and three times from acetone-ethanol mixture (15 : 2 in volume). The cmc's at 25 °C are 8.2 mM for the SDS, and 0.95 mM for the CTABr, which are in good agreement with the authentic values.[13]

Procedures. The reaction was followed with a spectrophotometer (Hitachi model 139) equipped with a pen recorder. The temperature of the cell chamber was kept constant by circulating water from a thermostat. Into 1 ml of a solution containing the surfactant and electrolyte which had been equilibrated in a cuvette, was added 1 ml of a substrate solution with a pipette, and the reaction mixture was quickly stirred with a tiny plastic rod. The substrate solution and the pipette were equilibrated in a thermostat.

Results and Discussion

MOB–SDS System. The second-order rate constants of the MOB hydrolysis at 25 °C with pH 5.40 (0.01 M sodium acetate buffer) are shown in Fig. 1 as a function of SDS concentration, where the multiphasic feature of the profile is partly seen. The initial gradual rise followed by a linear portion would be due to a large substrate-micelle concentration ratio, not assumed explicitly in Eq. 1. Thus the linear portion was taken as a [L.S], since a constant amount of substrate per micelle (probably one substrate molecule per micelle) may be partitioned there. The slope of the linear portion becomes smaller on addition of NaCl. In Fig. 2, log[L.S] is plotted against log C_t in accordance with Eq. 4, where the relation, C_t=cmc+ the buffer concentration + the added electrolyte concentration, is assumed. A slope of $\nu=0.98\fallingdotseq 1$ was obtained. This is identical with the one[7] evaluated by analyzing the data of Dunlap and Cordes.[4] It should be noted that a slope at relatively concentrated region of NaCl (>0.1 M) was used in the previous analysis,[7] because the micellar concentration remains nearly constant at 0.01 M SDS with an increase in NaCl concentration. On the other hand, a slope at relatively low region of the added salt concentration (0—0.03 M) was employed in the present work. The conclusion is naturally the same: $\nu\fallingdotseq 1$ is caused by the concentration effect of proton around micelles, or $K_B=K_0\exp(-z_B e\psi_0/kT)$ with $z_B=1$. The electrostatic stabilization of the transition state is not so important, since the oxonium, a reactant of the rate-determing step, is stabilized to the same degree as the carbonium ion at the transition state, resulting in no relative stabilization, which is contrary to the conclusion of Dunlap and Cordes.[4]

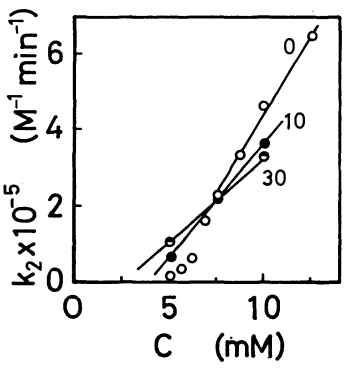

Fig. 1. The second-order rate constant of MOB-SDS system (25 °C, pH 5.40). The numbers in the figure represent the amount of added NaCl in mmol/l. The rate constant at SDS concentration=4 mmol/l in 10 mmol/l NaCl solution coincides with that in 30 m mol/l NaCl solution.

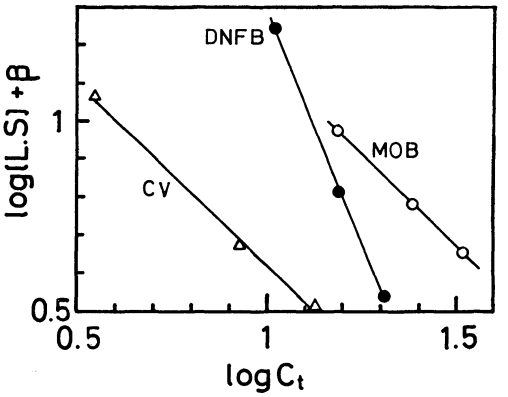

Fig. 2. log[L.S] *vs.* log C_t, C_t in mmol/l.

CV–CTABr System. The fading reaction of Crystal Violet was carried out in 3 mM NaOH solution at 30 °C. The pseudo-first-order rate constants are shown in Fig. 3 as a function of CTABr concentration with various amount of added NaBr. The added electrolyte suppresses the reaction rates at all CTABr concentrations studied. The linear portion was too small to determine the [L.S] directly, because of a strong saturating tendency as compared with those of MOB–SDS and DNFB–CTABr systems. The [L.S] was determined by graphical differentiation. The log[L.S] *vs.* log C_t plot in Fig. 2 gives $\nu=0.94\fallingdotseq 1$, which may be brought about by a little complicated mechanism: the carbonium dye is charged similarly to CTABr micelles, and the same charge yields $\exp(-|e\psi_0|/kT)$ term in K_A, which is, however, cancelled out by $\exp(+|e\psi_0|/kT)$ term contained in K_B, or the OH^- concentration effect. The resultant effect would be zero unless there is a relative stabilization by the micellar charge. It seems that the relative stabilization of the transition state is affected by the fact that the reactant dye is similarly charged to micelles and therefore destabilized, while the transition state is

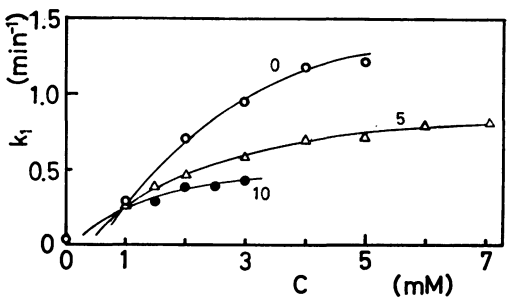

Fig. 3. The pseudo-first-order rate constant of CV–CTABr system (30 °C, 3 mmol/l NaOH). The numbers in the figure refers to the amount of added NaBr in mmol/l.

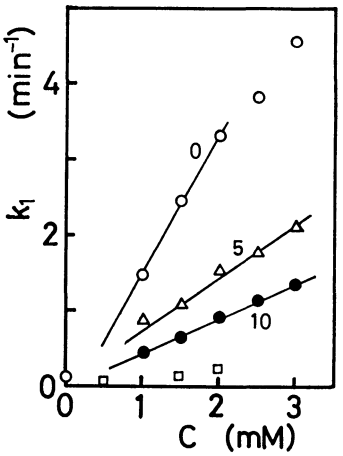

Fig. 4. The pseudo-first-order rate constant of DNFB–CTABr system (25 °C, 10 mmol/l). The numbers in the figure refers to the amount of added NaBr in mmol/l. The squares are the results of Bunton and Robinson.[5]

presumed to be an uncharged alcohol which has little sensitivity to the electrostatic potential. This conclusion is in line with that of Albrizzio *et al.* who stated "one expects less electrostatic destabilization for the zwitterion transition state than for the cation ground state by the cationic micellar surface," stressing the importance of the electrostatic contribution.[8b] The effect of the added electrolyte is offset in the concentration effects between K_A and K_B. The experimentally observed dependence ($\nu \fallingdotseq 1$) should be ascribed to the relative stabilization of the transition state, *viz.*, the f-term contains $\exp(+|z_i e\phi_0|/kT)$ term.

DNFB–CTABr System. The pseudo-first-order rate constants of the nucleophilic substitution reaction of DNFB in the presence of 10 mM NaOH at 25 °C are shown in Fig. 4, as a function of CTABr concentration, where the results under the same conditions as those reported by Bunton and Robinson are also added.[5] The rate they observed remains low even above the cmc (*ca.* 0.6 mM in 10 mM NaOH at 25 °C), while ours increases steeply near the cmc. A similar difference was also reported by Blandamer and Reid.[15] The [L.S] was easily taken owing to the marked efficiency in the micellar catalysis. The slope (Fig. 2)

Table 1. Analysis of the electrostatic contribution to the micellar catalysis

System	$-z_i e\phi_0/\lvert e\phi_0\rvert$			ν_{th}	ν_{ob}
	K_A	K_B	f		
MOB-SDS	0	1	0	1	0.98
CV-CTABr	−1	1	1	1	0.94
DNFB-CTABr	0	1	1	2	2.4

gives $\nu=2.4$, which is unexpectedly large, but can be interpreted as follows. In addition to a term included in K_B, or the OH^- concentration effect, there must be a contribution from the f-term. The Meisenheimer complex[3,14] which is presumably at the transition state may have a negative charge giving rise to the stabilization of the activated anion by the micellar surface potential. Bunton and Robinson ascribed the strong catalysis to the incorporation of DNFB in micelles which give hydroxide ions electrostatically favorable environment to attack the organic substrate,[5] but they did not make any further analysis. It is not clear whether the residual contribution $\nu-2=0.4$ comes from the dipole-field interaction or for some other reason. The reaction between DNFB and aniline in CTABr solution is scarcely sensitive to the added electrolyte.[3] No electrostatic term is included in either K_A, K_B, or in the f-term, since the two reactants as well as the Meisenheimer complex are neutral in this case leading to the result $\nu=0$.

Remarks. The present treatment is useful in clarifying the nature of micellar catalyses, especially as regards the electrostatic effect. The results are summarized in Table 1. A tacit assumption underlying Eqs. 1 and 5 is that the micellar structure does not change much on addition of electrolytes. This assumption might not hold, but the micellar structure would not change so much, since the concentration of added electrolyte is deliberately limited as little as 0.05 M in the present work.

The author thanks Dr. Y. Moroi, Kyushu University, for his interest and discussion.

A Study of *trans* Influence in Methylmercury(II) Compounds by Means of Vibrational Analysis

Noriko IWASAKI

Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received January 10, 1976)

Force constants K(Hg–C) were evaluated for a series of methylmercury compounds: CH_3HgX (X=CH_3, F, Cl, Br, I, CN, SCN, $As(CH_3)_3$, SCH_3, $SHgCH_3$, and $S(HgCH_3)_2$). It was found that K(Hg–C) increases in the following order of X: $S(HgCH_3)_2(1.86) < I(2.27) < SCH_3(2.33) = CH_3(2.330) < As(CH_3)_3(2.37) \leq Br(2.37_7) \leq SHgCH_3(2.38) \leq Cl(2.38_2) < SCN(2.39) < F(2.55) < CN(2.61$ md/Å). This order coincides, except for the cases of CN and $As(CH_3)_3$, with the order of increase in the first ionization potential of X for X=I, SCH_3, CH_3, Br, Cl, and F. Since this effect of X upon K(Hg–C) is regarded as a vibrational *trans* influence, this order was compared with that of the coupling constants in NMR, $J(^{199}Hg-^{13}C)$ and $J(^{199}Hg-^{1}H)$, and with the order of the bond-dissociation energy of CH_3HgX into $\cdot CH_3$ and $\cdot HgX$.

A number of organomercuric compounds with the general formula of R–Hg–X have been reported, where R represents an alkyl or aryl group, and X, an inorganic or organic ligand. It is well known that the Hg–C bonding in those compounds is stable and essentially covalent in nature, but it is considerably affected by the ligand, X. Since the C–Hg–X bonding is linear, this effect may be regarded as the "*trans* influence" of the X upon the C–Hg bond. This has been investigated extensively by various methods. For instance, Hatton *et al.*[1] studied the variation in $^{199}Hg-^{1}H$ geminal coupling constants by varying the ligand, X. Henneike[2] calculated the $^{199}Hg-^{13}C$ and $^{199}Hg-^{1}H$ coupling constants by the extended Hückel MO method. Charnley and Skinner[3] evaluated the Hg–C bond-dissociation energies from thermodynamic measurements in the gas phase. The frequencies of the Hg–C stretching vibration and even some force constants, K(Hg–C), have been reported.[4–19] These values, however, have rather limited significance for the discussion of the *trans* influence of methylmercury compounds because, as is well known, the vibrational frequency is not proportional to the force constant, and the available data on force constants, K(Hg–C), were not calculated by the same principle, *e.g.*, using the same valence field and the same assumption of dynamic units in a molecule. Therefore, in the present study, force constants K(Hg–C) were evaluated for a series of methylmercury compounds (CH_3HgX (X=CH_3, F, Cl, Br, I, CN, SCN, $As(CH_3)_3$, SCH_3, $SHgCH_3$, and $S(HgCH_3)_2$) in order to elucidate the *trans* influence of the X upon the Hg–C bond. The numerical data

on the IR and Raman spectra used for the calculations were taken from the literature[4-19] except for $X=SCH_3$, $SHgCH_3$ and $S(HgCH_3)_2$, the data of which are obtained in this work. Some features of these IR and Raman spectra reduced from the assignments are described.

Experimental

The numerical data of the IR and Raman spectra used for the present calculations were taken from the literature[4-19] except for the following three samples, which were prepared according to the literature[20,21] and well confirmed by measurements of the mp and by elemental analysis of mercury:

CH_3HgSCH_3: mp 25 °C (lit,[20] 25 °C).

$(CH_3Hg)_2S$: mp 145 °C (lit,[20] 145 °C). Found: Hg, 85.6%. Calcd: Hg, 86.6%.

$(CH_3Hg)_3SClO_4$: mp 144 °C (lit,[21] 143 °C). Found: Hg, 77.63%. Calcd: Hg, 77.31%.

The infrared spectra of CH_3HgSCH_3, $(CH_3Hg)_2S$ and $(CH_3Hg)_3SClO_4$ were recorded with KBr disks from 300 to 4000 cm^{-1} and with Nujol mulls on polyethylene sheet from 30 to 600 cm^{-1} at 23 °C. The infrared spectra of $(CH_3Hg)_2S$ and $(CH_3Hg)_3SClO_4$ were recorded from 200 to 600 cm^{-1} with polyethylene matrices at 77 K. The instruments used were a JASCO-403G grating IR spectrometer and a HITACHI FIS-3 grating far-IR spectrometer. The Raman spectra of $(CH_3Hg)_3SClO_4$ were recorded in the powder state and in a saturated aqueous solution (about 15 wt%) with a JEOL JRS-O2AS and a JRS-S1 Raman spectrometer equipped with an Ar^+-ion laser as a source.

Calculations

The vibrational analysis was carried out using the Urey-Bradley field. The methyl group was treated as a dynamic unit. The bond lengths and bond angles used for the calculations are listed in Table 1 along with the references.

Results and Discussion

The IR and Raman spectra of CH_3HgSCH_3 have previously been reported.[18,19] The IR spectrum of $(CH_3Hg)_2S$ has been reported only in the NaCl region,[20] and so the IR spectrum in a region lower than 650 cm^{-1} was measured in this study. Its Raman spectrum could not be recorded, because $(CH_3Hg)_2S$ decomposed into HgS within one minute after exposure to the Ar^+-ion laser beam. The spectra and their assignments will be reported in a separate paper. Here the description will be limited to some tendencies reduced from the assignments of the bands for CH_3HgSCH_3, $(CH_3Hg)_2S$, and $(CH_3Hg)_3SClO_4$: a) the asymmetric deformation, the symmetric deformation, and the rocking vibrations of the methyl group appear at 1404, 1177, and 768 cm^{-1} respectively, when the methyl group is attached to the mercury atom, and at 1431, 1310—1284, and 955 cm^{-1} when it is attached to the sulfur atom; b) the Hg–C stretching vibration of CH_3–Hg is found at 515—565 cm^{-1}; c) the Hg–S stretching bands of $(CH_3Hg)_2S$ split into four under the influence of the lattice field, though there should be two; therefore the values of (354+334)/2 and (310+291)/2 cm^{-1} are used for the calculations as the antisymmetric and symmetric Hg–S stretching frequencies respectively.

As may be seen in Table 2, a satisfactory agreement between the calculated and experimentally observed frequencies is obtained. The force constants are summarized in Table 3. Arranging the X of CH_3HgX in an increasing order of K(Hg–C), a vibrational *trans* influence series is obtained, where the numerical values of K(Hg–C) are written in parentheses in md/Å units: $S(HgCH_3)_2(1.86) < I(2.27) < SCH_3(2.33) = CH_3(2.330) < As(CH_3)_3(2.37) < Br(2.37_7) \leq SHgCH_3(2.38) \leq Cl(2.38_2) < SCN(2.39) < F(2.55) < CN(2.61)$.

On the other hand, the K(Hg–C) of CH_3HgX in the generalized valence field increase in the following order of X: I(2.290 md/Å)[12] < Cl(2.42)[9] < Br(2.48)[10] according to Meić[9,10,12] and Randić,[9,10] or I(2.50 md/Å) < Br(2.60) < CN(2.78) according to Goggin and Woodward.[13] Since not only the values of K(Hg–C) but also the order of X thus depend upon the types of the potential function, the recalculation in this work is regarded as significant for the investigation of

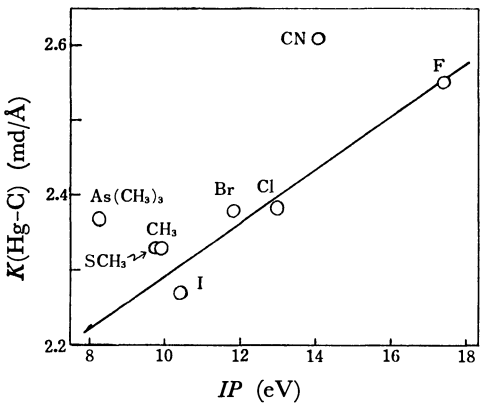

Fig. 1. Relation between K(Hg–C) and the ionization potentials of X.

the *trans* influence.

Let us now discuss the factor which will determine the K(Hg–C). As may be seen in Fig. 1, a linear relationship is found between K(Hg–C) and the first ionization potential, *IP*, of X for this series, except in the cases of X=CN and $As(CH_3)_3$, whose K(Hg–C) values are considerably larger than those to be expected from the linearity. The increase in K(Hg–C) with the increase in the first ionization potential of X can be explained in terms of the inductive effect of X through the σ path. On the other hand, the deviation in the linearity may be ascribed to the π-back donation from the mercury to the arsine group.

Some previously reported data may be referred to in order compare them with the presented vibrational *trans*-influence order (Table 4). The order of K(Hg–C) is considerably different from that of $J(^{199}Hg\text{–}CH_3)$[1,2]: $CH_3 < SHgCH_3 < CN < As(CH_3)_3 < I < SCN < Br < Cl$. Particularly, cyanide changes its position extremely between K(Hg–C) and $J(^{199}Hg\text{–}CH_3)$. The K(Hg–C) increases parallel to the increase in the bond-dissociation energy.[3] It is worthwhile to refer the present results to the well-known *trans*-effect series established in Pt(II) complexes, where CN<I<Br<Cl.[33] Thus, the presently obtained *trans*-influence series for methylmercury compounds is unique in the position of CN.

The author is gratefull to Professor Sigeo Kida of Kyushu University for his valuable discussions. The numerical calculations were carried out with the FACOM 230-25 computer system of Kumamoto University and with the FACOM 230-60 computer system of Kyushu University.

Preparation and Geometrical Isomers of Cobalt(III) Complexes with Tridentate O–S–O Ligand Thiodiacetate or 3,3′-Thiodipropionate

Kan KANAMORI, Tokiko SUDANI, and Kiyoyasu KAWAI

Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received March 31, 1976)

cis(S)-fac- and *trans(S)-fac-*Isomers of bis(thiodiacetato)cobaltate(III), *trans(O)-mer-*, *s-cis(O)-fac-*, and *u-cis(O)-fac-*isomers of (thiodiacetato)(diethylenetriamine)cobalt(III) and *trans(O)-mer-*isomer of (3,3′-thiodipropionato)(diethylenetriamine)cobalt(III) were prepared. Their geometrical configurations were assigned on the basis of their absorption and PMR spectra. The stereochemistry of the Co(III) complex with a tridentate ligand thiodiacetate is similar to that of the Co(III) complex with iminodiacetate.

Metal complexes with amino carboxylates containing the sulfide group have been recognized as regards their biochemical importance.[1] However, only a few studies have been carried out on stereochemistry of cobalt(III) complexes with sulfide ligands.[2] Thiodiacetic acid we chose is a simple ligand of typical linear type which contains one sulfide group. The framework of the coordinated ligand around Co(III) ion is similar to that of iminodiacetate ligand O–N–O.

In this paper,[3] the preparation and separation of isomers of bis(thiodiacetato)cobaltate(III), (thiodiacetato)(diethylenetriamine)cobalt(III) and (3,3′-thiodipropionato)(diethylenetriamine)cobalt(III) are reported. The stereochemistry of the complexes is discussed in relation to that of the ida Co(III) complexes.[4,5]

Experimental

Preparation of cis(S)- *and* trans(S)-*Hydrogen Bis(thiodiacetato)-cobaltate(III)* : $H[Co(tda)_2]\cdot nH_2O$

(1) cis(S)-$H[Co(tda)_2]\cdot 3H_2O$ *(Green Isomer)*: To a suspension containing 3.0 g (0.02 mol) of thiodiacetic acid in 30 dm³ of water was added 1.1 g (0.01 mol) of freshly prepared $Co(OH)_3$.[6] The mixture was stirred at room temperature for about an hour. The reaction mixture was filtered in order to remove a small amount of insoluble material. 20 dm³ of ethanol was added to the filtrate. The green complex deposited was filtered and washed with ethanol and ether. The crude complex was recrystallized from as little water as possible by adding a small amount of ethanol. Found: C, 23.00; H, 3.22; S, 15.08%. Calcd for $H[CoC_8H_8O_8S_2]\cdot 3H_2O$: C, 23.42; H, 3.69; S, 15.63%.

(2) trans(S)-$H[Co(tda)_2]\cdot 6H_2O$ *(Violet Isomer)*: The reaction mixture obtained by the same method as in (1) was stirred at about 80 °C for half an hour. The resulting mixture was filtered in order to remove a fairly large amount of insoluble material. The violet filtrate was cooled to room temperature. A small amount of violet precipitate appeared. Recrystallization of the complex was unsuccessful because of its instability in water. Found: C, 20.48; H, 4.31; S, 14.11%. Calcd for $H[CoC_8H_8O_8S_2]\cdot 6H_2O$: C, 20.69; H, 4.57; S, 13.81%.

(3) Preparation and Separation of the Isomers of $[Co(tda)(dien)]^+$: A mixture containing 5.0 g (0.019 mol) of $[CoCl_3(dien)]$,[7] 4.2 g (0.028 mol) of thiodiacetic acid and 1.6 g (0.028 mol) of potassium hydroide in 50 dm³ of water was heated at *ca.* 50 °C and stirred for about an hour. The resulting mixture was filtered in order to remove a small amount of insoluble material. The red filtrate was poured into a column (30 mm × 450 mm) containing strong-acid cation exchange resin (Dowex 50 W × 8 200—400 mesh, hydrogen form). After the column had been swept with water, the adsorbed band was eluted with 0.15 M sodium perchlorate at a rate of *ca.* 2.5 dm³/min. Three colored bands, red (I), pinkish red (II), and pink (III) were eluted one after the other. Each eluate was concentrated to dryness in a vacuum evaporator. The resulting isomers contaminated with a large amount of sodium perchlorate were washed with ethanol. Each isomer obtained was dissolved in as little water as possible to recrystallize. The pure complex was obtained by adding ethanol to the solution. The yield of isomer (I) was less than those of other two. Found for isomer (I): C, 22.88; H, 4.31; N, 10.52%. Found for isomer (II): C, 22.93; H, 4.33; N, 10.21%. Found for isomer (III): C, 22.89; H, 4.55; N, 10.38%. Calcd for $[CoC_8H_{17}N_3O_4S]ClO_4\cdot 0.5H_2O$: C, 22.95; H, 4.34; N, 10.04%.

(4) Preparation of $[Co(tdp)(dien)]ClO_4\cdot H_2O$: The complex was prepared by the same method as in (3) except for the use of 3,3′-thiodipropionic acid instead of thiodiacetic acid. Only one violet band was eluted. Found: C, 26.13; H, 5.21; N, 9.38%. Calcd for $[CoC_{10}H_{21}N_3O_4S]ClO_4\cdot H_2O$: C, 26.35; H, 5.10; N, 9.22%.

Measurement. Electronic absorption spectra were measured with a Hitachi 124 spectrophotometer. PMR spectra were recorded on a JEOL MH-60 spectrometer. Deuterium oxide was used as a solvent with *t*-butyl alcohol (TBA) as an internal standard.

Results and Discussion

Three geometrical isomers, one meridional(*mer*) and two facial(*fac*) with respect to the coordination of O–S–O ligand thiodiacetate, are expected for bis(thiodiacetato)cobaltate(III) complex (Fig. 1). However, only two isomers were isolated. The electronic absorption spectra of the isomers obtained are shown in Fig. 2 and their data are given in Table 1. The charge transfer band due to the coordinated sulfide of bis(L-methioninato)Co(III) complex is situated at the lower energy side for *trans(S)*-isomer in comparison with *cis(S)*-isomer.[2] We see from Fig. 2 and Table 1 that the sulfide charge transfer band of the green isomer is situated at the energy side (*ca.* 32×10^3 cm^{-1}) higher

than that of the violet one (*ca.* $30 \times 10^3\ cm^{-1}$). This indicates that the former has *cis(S)* configuration and the latter *trans(S)* one. This assignment is supported by the semiempirical consideration for the pattern of the first absorption band.[8] Namely, *cis(S)*-isomer might be expected to show a sharp band in the lower energy side and *trans(S)*-isomer a broad one in the higher energy side. This is realized as shown in Fig. 2. Considering the framework of the coordinated ligands, iminodiacetate (ida) and tda, $[Co(tda)_2]^-$ is similar to $[Co(ida)_2]^-$ though the ligand field strength due to tda is slightly less than that of ida. In the case of ida Co-(III) complex, the *mer*-isomer has not been obtained except for the mixed complex $[Co(ida)(dien)]^+$.[5] This suggests that the *trans(S)*-isomer isolated in the present work is a *fac* coordinated one rather than a *mer* one.

The *trans(S)*-isomer shows an interesting shoulder at *ca.* $21 \times 10^3\ cm^{-1}$ (Fig. 2), which is independent of the degradation product or the isomerization of the complex, since its absorption intensity diminishes regularly with that of the main absorption peak at *ca.* $18 \times 10^3\ cm^{-1}$ (Fig. 3).

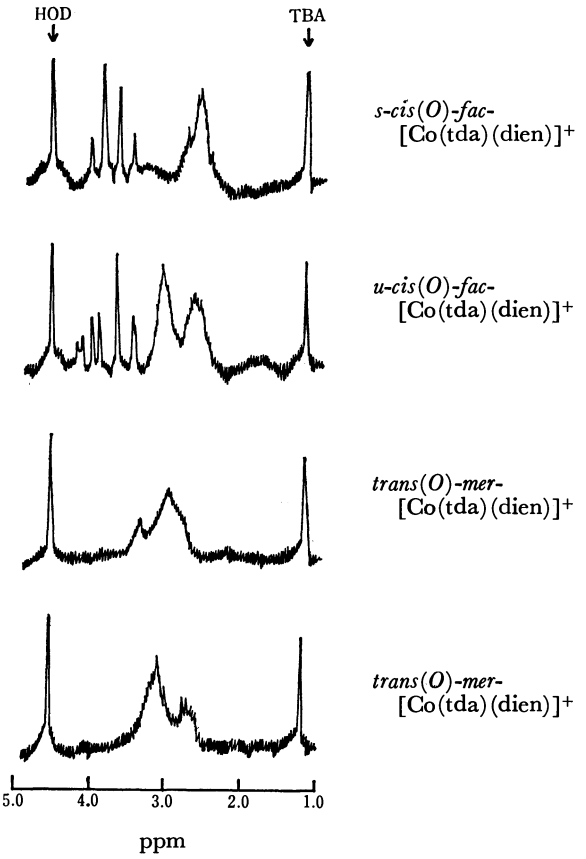

Fig. 7. Proton magnetic resonance spectra (60 MHz) of the three isomers of $[Co(tda)(dien)]^+$ and the one isomer of $[Co(tdp)(dien)]^+$.

The PMR spectra of *cis(S)*- and *trans(S)*-$[Co(tda)_2]^-$ are shown in Fig. 4 and their data in Table 2. Since the *trans(S)*-isomer has a plane of symmetry (Fig. 1), two pairs of methylene protons in the coordinated tda are fixed in the same chemical environment. The *trans(S)*-isomer is thus expected to exhibit one AB quartet due to two spin-coupled protons. On the other hand, the *cis(S)*-isomer is C_1 symmetry and two AB quartets are expected. As seen in Fig. 4, the *trans-(S)*-isomer assigned from the absorption spectral consideration exhibits one AB quartet, whereas the *cis(S)*-isomer shows two AB quartets.

In order to confirm the assignment of geometrical isomers of $[Co(tda)_2]^-$, the mixed type complex $[Co(tda)-(dien)]^+$ was synthesized. Three geometrcial isomers *trans(O)-mer*, *s-cis(O)-fac*, and *u-cis(O)-fac** are expected (Fig. 5). Three isomers were isolated by ion-exchange column chromatographic method (see Experimental). The electronic absorption spectra of the three isomers of $[Co(tda)(dien)]^+$ are shown in Fig. 6. From the splitting pattern of the first absorption band,[8] the isomer first eluted is assigned to *trans(O)*-type which only *mer* coordination is possible. Thus, it is considered that the remaining two isomers are *cis(O)-fac*-type. This designation coincides with that on the basis of the column chromatographic elution order,[9] *viz.*,

* The prefix *s* denotes symmetrical arrangement and prefix *u* unsymmetrical arrangement.

the *trans(O)-mer*-isomer which has low dipole moment is eluted earlier than the two *cis(O)*-isomers.

In order to assign the remaining two *cis(O)*-isomers, their PMR spectra were recorded (Fig. 7 and Table 2). The plane of symmetry in *s-cis(O)-fac*-[Co(tda)(dien)]$^+$ gives rise to only one AB pattern as in the case of *trans-(S)-fac*-[Co(tda)$_2$]$^-$. On the other hand, *u-cis(O)-fac*-[Co(tda)(dien)]$^+$ has no plane of symmetry. The two pairs of methylene protons of the tda ligand should differ in the chemical environment (Fig. 5). In Fig. 7, the PMR spectrum of isomer II shows only one AB quartet and that of isomer III exhibits the split at the lower field component of the corresponding AB quartet. It is unknown in the present that the high field component does not split. This consideration leads isomer II to *s-cis(O)-fac*-[Co(tda)(dien)]$^+$ and isomer III to *u-cis(O)-fac*-[Co(tda)(dien)]$^+$. On the basis of this assignment, the column chromatographic elution order for the three isomers becomes *trans(O)-mer*, *s-cis(O)-fac* and *u-cis(O)-fac*. The order is similar to that for the isomers of analogous complex, [Co(ida)-(dien)]$^+$.[5] The PMR spectrum of *trans(O)-mer*-[Co-(tda)(dien)]$^+$ provided little information on the structure of the isomer because of its low solubility in D_2O.

The coordination mode of ida is regulated in [Co-(ida)(dien)]$^+$ by the dominant coordination of dien.[5] The present results are similar to the case of ida Co(III) complex. Of the three isomers of [Co(tda)$_2$]$^-$ complex, *viz.*, the two *fac*-isomers except for *mer*-type were obtained and the three isomers containing *mer*(tda)-type were obtained for [Co(tda)(dien)]$^+$ complex.

The above conclusion can be confirmed by the attempt to isolate the isomers of [Co(tdp)(dien)]$^+$. Molecular model examination suggests that in expansion from the five-membered chelate ring to the six-membered ring, the *fac* coordination of O–S–O ligand strains more than the *mer* one. Only one isomer was obtained for [Co(tdp)(dien)]$^+$ complex. The absorption spectral measurement indicates that the isomer obtained is *mer*(tdp)-form (Fig. 6). The broad splitting of the first absorption band is more remarkable for *trans(O)-mer*-[Co(tdp)(dien)]$^+$ than for *trans(O)-mer*-[Co(tda)(dien)]$^+$. This may arise from the weakness of the ligand field strength due to the change from the five-membered chelate ring to the six-membered ring.

The PMR spectrum of *trans(O)-mer*-[Co(tdp)(dien)]$^+$ where ABCD or AA'BB' pattern can be expected is apparently similar in chemical shifts to that of *trans(O)-mer*-[Co(tda)(dien)]$^+$, but the assignment in detail is difficult. The results indicate that the only one isomer for [Co(tdp)(dien)]$^+$ is *trans(O)-mer*-form and that the molecular model consideration is reasonable.

In conclusion, the stereochemistry of Co(III) complex with tda is similar to that of ida Co(III) complex in both case of the bis type[4] and the mixed one.[5] The tda ligands in *trans(S)*-[Co(tda)$_2$]$^-$ is facially coordinated as in the case of *trans(N)*-[Co(ida)$_2$]$^-$.

A Kinetic Study of the Chromium(II) Reduction of Several (Amino acid)pentaamminecobalt(III) Complexes

Hiroshi OGINO, Keiichi TSUKAHARA, and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received April 30, 1976)

A kinetic study of the chromium(II) reduction of (O-bonded amino acid)pentaamminecobalt(III) complexes has been carried out in acid solutions. The second-order rate constants in $M^{-1}\,s^{-1}$ (1 M = 1 mol dm^{-3}) at 25 °C and I = 1.0 M ($NaClO_4$) for α-alanine, phenylalanine, α-aminoisobutyric acid, β-alanine, β-aminobutyric acid, γ-aminobutyric acid, and ε-aminohexanoic acid complexes are 1.8×10^{-2}, 1.5×10^{-2}, 2.4×10^{-3}, 7.5×10^{-2}, 5.0×10^{-2}, 1.22×10^{-1}, and 1.49×10^{-1} respectively. The values of ΔH^{*} lie in the range of 6.4—7.7 kcal mol^{-1} (1 cal = 4.184 J), and those of ΔS^{*}, in the range of −42—−37 cal $K^{-1}\,mol^{-1}$, except for the α-aminoisobutyric acid complex, the ΔH^{*} and ΔS^{*} values of which are 11.4 kcal mol^{-1} and −32 cal $K^{-1}\,mol^{-1}$ respectively. The role of the amino acid ligands in the inner-sphere electron-transfer reactions is discussed.

The chromium(II) reduction of a number of carboxylatopentaamminecobalt(III) complexes has been known to proceed predominantly through an inner-sphere mechanism.[1,2] In these reactions, the steric crowding of the alkyl groups influences the electron-transfer rate significantly. The chromium(II) reduction of the pentaammineglycinecobalt(III) complex has also been investigated by several researchers[3-5] and found to proceed predominantly through an inner-sphere mechanism. The reduction rate of this complex was found to be smaller than that of the acetatopentaamminecobalt(III) complex. This fact was interpreted in terms of the difference in the positive charge on the complexes.

In this work, the rate of the chromium(II) redution of a number of (O-bonded amino acid)pentaamminecobalt(III) complexes was measured in acid solutions in order to reveal the factors which control the electron-transfer reaction rate. The abbreviations used in this work are as follows: amino acid=amH, $^{-}O_2CCH_2NH_3^{+}$ (glycine)=glyH, $^{-}O_2CCH(CH_3)NH_3^{+}$ (α-alanine)=alaH, $^{-}O_2C(CH_2)_2NH_3^{+}$ (β-alanine)=balaH, $^{-}O_2CCH(CH_2C_6H_5)NH_3^{+}$ (phenylalanine)=pheH, $^{-}O_2CCH_2CH(CH_3)NH_3^{+}$ (β-aminobutyric acid)=babH, $^{-}O_2CC(CH_3)_2NH_3^{+}$ (α-aminoisobutyric acid)=aibH, $^{-}O_2C(CH_2)_3NH_3^{+}$ (γ-aminobutyric acid)=gabH, and $^{-}O_2C(CH_2)_5NH_3^{+}$ (ε-aminohexanoic acid)=ahH.

Experimental

Reagents. (O-bonded amino acid)pentaamminecobalt(III) complexes were prepared as perchlorates by the method reported previously.[6,7] The $[Co(babH)(NH_3)_5](ClO_4)_3$ and $[Co(ahH)(NH_3)_5](ClO_4)_3$ complexes were purified by the use of an SP-Sephadex C-25 column. Each amino acid complex adsorbed on the column moved faster than aquapentaamminecobalt(III) ions with an 0.3 M $NaClO_4$ solution at pH 3 (1 M = 1 mol dm^{-3}). Table 1 gives the analytical data of the complexes used in this work.

All the solutions used for the measurements were prepared from redistilled water. A solution of hexaaquachromium(III) perchlorate was prepared from sodium dichromate as has been reported previously.[8] A chromium(II) perchlorate solution was prepared by the reduction of the hexaaquachromium(III) perchlorate with a zinc amalgam in a nitrogen atmosphere. The hydrogen-ion concentration of the chromium(II) solution was determined by a method reported previously.[9,10] A sodium perchlorate solution was prepared by neutralizing a primary standard sodium carbonate solution with perchloric acid.

Product Analyses. The products of the reactions of Cr^{2+} ions with $Co(alaH)(NH_3)_5^{3+}$ and $Co(aibH)(NH_3)_5^{3+}$ ions were examined. After the reaction had been quenched by the introduction of air into the system, the solution was cooled and passed through an SP-Sephadex C-25 column chilled below 5 °C with a water-jacket. The colored species were adsorbed on the column in four bands: pink, bluish violet, red, and green from the bottom to the top of the column. The pink species was eluted with an 0.1 M $HClO_4$–0.1 M $NaClO_4$ solution and was identified as Co^{2+} ions. The bluish violet species was eluted with an 0.1 M $HClO_4$–0.3 M $NaClO_4$ solution and was found to be chromium(III) species. The visible spectrum of the species was similar to $Cr(H_2O)_6^{3+}$, but not identical. Therefore, the species was considered to be $Cr(amH)(H_2O)_5^{3+}$ or a mixture of $Cr(amH)(H_2O)_5^{3+}$ and $Cr(H_2O)_6^{3+}$. The red species was eluted with an 0.1 M $HClO_4$–0.3 M $NaClO_4$ solution and identified as

$Co(amH)(NH_3)_5^{3+}$. The green species was eluted with an 0.1 M $HClO_4$–0.9 M $NaClO_4$ solution and identified as $(H_2O)_4Cr(OH)_2Cr(H_2O)_4^{4+}$, which was considered to have been derived by the air oxidation of Cr^{2+} ions.[11,12]

The chromium content was determined spectrophotometrically in the form of CrO_4^{2-} after oxidation with an alkaline hydrogen peroxide solution. The cobalt(II) content was determined spectrophotometrically as $Co(NCS)_4^{2-}$ in 50% acetone. The cobalt(III) complexes were reduced to cobalt(II) with a zinc amalgam and then subjected to the determination of the cobalt(II) as $Co(NCS)_4^{2-}$. From the results of the product analyses, it was confirmed that 1 mol of Cr^{2+} is consumed per mole of the $Co(alaH)(NH_3)_5^{3+}$ or $Co(balaH)(NH_3)_5^{3+}$ complex.

The amounts of amH and Co^{2+} released by the Cr^{2+} reduction were determined for the reactions of $Co(alaH)(NH_3)_5^{3+}$ and $Co(aibH)(NH_3)_5^{3+}$. The following procedures were employed: the reaction mixture was poured into an SP-Sephadex column. The solution which was passed through the column was reserved. The effluent was collected until the Co^{2+} band almost reached the bottom of the column by eluting with a cold 0.1 M $HClO_4$–0.1 M $NaClO_4$ solution. The solution reserved and the effluent were then combined and alkalified with NaOH. The solution was heated on a boiling-water bath for half an hour to expel the ammonia and then acidified with $HClO_4$. The alaH content of the solution was determined spectrophotometrically with ninhydrin, as has been reported by Yemm and Cocking.[13] The aibH content was determined by pH titration under nitrogen with a standard NaOH solution. The pH values were measured with a Hitachi-Horiba F-5 pH meter.

Kinetic Measurments. Solutions containing a cobalt(III) complex, $NaClO_4$ and $HClO_4$ were added to an optical cell, which was then sealed with a serum cap. After the solution has been purged with nitrogen gas for 15 min, the reaction was initiated by the addition of a Cr^{2+} solution with a syringe. The change in the absorbance with the time was followed at 500 nm with a Hitachi EPS-3 spectrophotometer. The ionic strength of the solution was adjusted to 1.0 M throughout the work, unless otherwise stated. The temperature was controlled by circulating water through the cell holder. The temperature was kept constant within 0.1 °C at each desired temperature.

Results

Determination of the Rate Constants of the Electron-transfer Reactions. The spectral changes observed during the reaction of Cr^{2+} with the pentaamminecobalt(III) complex of balaH, gabH, ahH, or babH gave three isosbestic points within the range of 340—600 nm. The electron-transfer reactions of Cr^{2+} with the $Co(amH)(NH_3)_5^{3+}$ complexes are considered to proceed predominantly through an inner-sphere mechanism; this is on the basis of the earlier observation of the reaction of $Co(glyH)(NH_3)_5^{3+}$:[5]

$$Cr^{2+} + Co(amH)(NH_3)_5^{3+} + 5H^+ \rightarrow Cr(amH)(H_2O)_5^{3+} + Co^{2+} + 5NH_4^+ \quad (1)$$

The rate of the reaction of Cr^{2+} with the pentaamminecobalt(III) complex ligating alaH, pheH, or aibH was smaller than that of the complex ligating balaH, gabH, ahH, or babH, and in the cases of the former complexes the isosbestic points collapsed with the time, as is shown in Fig. 1. This may be attributed to the occurrence of the Cr^{2+}-catalyzed aquation of $Cr(amH)(H_2O)_5^{3+}$:

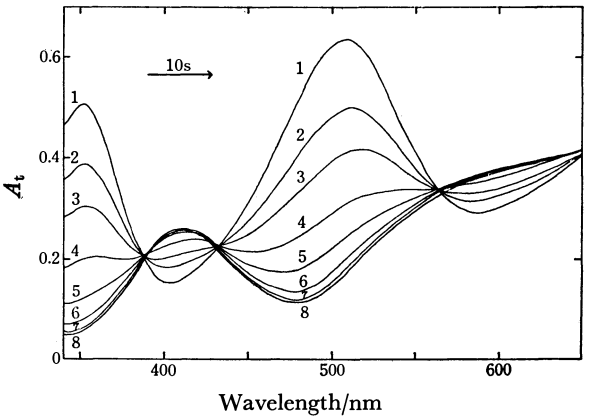

Fig. 1. The spectral changes during the reaction of Cr^{2+} with $Co(alaH)(NH_3)_5^{3+}$ at $[Cr^{2+}]_0=0.100$ M, $[Co(III)]_0=9.59\times10^{-3}$ M, $[H^+]=0.100$ M, 35 °C, and $I=1.0$ M ($NaClO_4$): 1, 20 s; 2, 2 min 20 s; 3, 4 min 20 s; 4, 8 min 20 s; 5, 13 min 20 s; 6, 20 min 20 s; 7, 29 min 20 s; 8, 39 min 20 s after the reaction. Times given are for start of scan at 340 nm.

$$Cr(amH)(H_2O)_5^{3+} + Cr^{2+} \rightarrow Cr^{2+} + amH + Cr(H_2O)_6^{3+} \quad (2)$$

If Reaction 1 obeys this rate equation:

$$-\frac{d[Co(III)]}{dt} = k[Co(III)][Cr^{2+}] \quad (3)$$

Equation 4 can be derived thus:

$$\log\frac{\varepsilon_{Co(III)}l([Cr^{2+}]_0-[Co(III)]_0)-\varepsilon_{Cr(III)}l[Cr^{2+}]_0+A_t}{A_t-A_\infty} = \frac{[Cr^{2+}]_0-[Co(III)]_0}{2.303}kt + \log\frac{[Cr^{2+}]_0}{[Co(III)]_0} \quad (4)$$

where $[Cr^{2+}]_0$ and $[Co(III)]_0$ indicate the initial concentrations of Cr^{2+} and $Co(amH)(NH_3)_5^{3+}$ respectively. A_t and A_∞ denote the absorbances at time t and infinity respectively. The symbols, $\varepsilon_{Co(III)}$ and $\varepsilon_{Cr(III)}$, are the molar absorption coefficients of $Co(amH)(NH_3)_5^{3+}$ and $Cr(amH)(H_2O)_5^{3+}$ at 500 nm respectively, and l denotes the optical path length. The plots of the left-hand side of Eq. 4 *vs.* t for each system expect that of the aibH complex gave a linear relation for at least three half-lives. The second-order rate constant, k, was determined from the slope of this straight line. In these calculations, the values of $\varepsilon_{Cr(III)}$ were estimated from the values of A_∞. Equation 4 held even in the reactions for the alaH and pheH complexes. This may be because of the following reasons: (a) Reaction 2 is much slower than 1. (b) The ε value of $Cr(amH)(H_2O)_5^{3+}$ is quite similar to that of $Cr(H_2O)_6^{3+}$ at the wavelegth used for the measurements (500 nm). (c) The $\varepsilon_{Cr(III)}$ value is much smaller than the $\varepsilon_{Co(III)}$ value at 500 nm. In the reaction of Cr^{2+} with $Co(aibH)(NH_3)_5^{3+}$, however, the accurate determination of the values of A_∞ was difficult due to the considerable contribution of Reaction 2 to Reaction 1. Therefore, the method of Guggenheim[14] was employed.

Kinetic measurements were carried out under various concentrations of Cr^{2+} (0.05—0.1 M), $Co(amH)$-

a) Each value is the average of two to eleven determinations. The uncertainty is the average deviation.

$(NH_3)_5^{3+}$ (5×10^{-3}—1×10^{-2} M), and hydrogen ions (0.1—0.5 M). The second-order rate constants (k) were found to be independent of the concentration of the hydrogen ions. The rate constants at various temperatures are given in Table 2, and the kinetic parameters, in Table 3, along with the data obtained by other researchers.

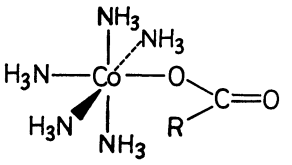
Cr^{2+}-catalyzed Aquation of $Cr(amH)(H_2O)_5^{3+}$. The analytical results for Co^{2+} and amH released by the Cr^{2+} reduction are summarized in Table 4, which shows that the amount of amH is always smaller than that of Co^{2+} and that it increases with the reaction time. These findings support the consideration that the mechanism of the electron-transfer reactions is predominantly of the inner-sphere type[16] and indicate that the prolonged contact of $Cr(amH)(H_2O)_5^{3+}$ with Cr^{2+} causes Reaction 2 to a considerable extent. If the reaction between Cr^{2+} and $Co(aibH)(NH_3)_5^{3+}$ proceeds exclusively through an inner-sphere mechanism, the rate constant of the Cr^{2+}-catalyzed aquation of $Cr(aibH)(H_2O)_5^{3+}$ is estimated from the data given in Table 4 to be approximately $7\times10^{-5}\ M^{-1}\,s^{-1}$.

Discussion

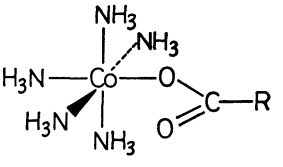
The data given in Table 3 show the following facts: (a) The substitution of methyl groups or a benzyl group for α hydrogens of glyH causes a decrease in the rate of the electron-transfer reaction (compare the k values of glyH, alaH, aibH, and pheH complexes). (b) The rate of the electron-transfer reaction increases with the increase in the number of methylene groups between carboxylate and ammonium groups in amH (compare the k values of glyH, balaH, gabH, and ahH complexes). (c) The ΔH^* values as well as the ΔS^* values of all the complexes except the aibH complex are quite similar to each other.

It has been shown that cobalt(III) ammine complexes ligating alkyl carboxylate ligands were reduced by Cr^{2+} at carbonyl oxygen atoms.[17-19] Fact (a) indicates that the substitution of bulky groups for α hydrogens of glyH hinders the C=O attacking by Cr^{2+}. It is known that the rates of the reduction of *N*-methyl-substituted glycinepentaamminecobalt(III) ions by Cr^{2+} decrease with the increase in the number of the *N*-methyl groups.[5] The data given in Table 3 indicate that the alkyl substitution on the methylene group in glyH hinders the C=O attack more seriously than that on the ammonium nitrogen does. This result can be understood when the steric crowding around the C=O group is considered.

The steric crowding around the C=O group in $Co(O_2C(CH_2)_nNH_3)(NH_3)_5^{3+}$ may increase as the number of methylene groups between carboxyl and ammonium groups increases; hence, the rate of the electron-transfer reactions would decrease with the increase in the number of methylene groups. However, Fact (b) is opposed to this expectation. The discrepancy may be understood by considering electrostatic repulsions between the ammonium group, the cobalt(III) center, and the attacking Cr^{2+} ion. The positively charged ammonium group will tend to be separated from the positively charged cobalt(III) center due to the electrostatic repulsion. Therfore, the charge separation between the ammonium group and the cobalt(III) center becomes larger as the methylenic chain of the amH becomes longer. The approach of the positively charged Cr^{2+} ion to the C=O moiety becomes easier as the number of methylene groups of the amH increases. Balahura and Jordan made it clear that the conformation of the coordinated formate ion in $Co(O_2CH)(NH_3)_5^{2+}$ is of Form I (R=H).[19]



I



II

For other cases such as with the acetato complex, they claimed that Form II would be greatly favored by steric consideration. For the conformation of the amH in $Co(amH)(NH_3)_5^{3+}$, Form II would be favored over Form I. When this conformational situation and the electrostatic repulsion between the ammonium group and the cobalt(III) center are considered, molecular models indicate that the $-(CH_2)_nNH_3^+$ group takes a severely restricted orientation and that the steric crowding around the C=O group is slightly altered

a) At 25 °C, I=0.7 M ($NaClO_4$), and $[H^+]$=0.090 M. b) At 35 °C, I=1.0 M ($NaClO_4$), and $[H^+]$=0.10 M.

by the increase in the methylenic chain length. It should also be noted that the variation in the pK_a values of amH may influence the rate constants. The pK_a values of the amH are given in Table 3. The rate constants of the pentaamminecobalt(III) complexes ligating sarcosine, balaH, gabH, and ahH increase with the increase in the pK_a values. Molecular models indicate that the steric crowding around the C=O groups of these complexes is comparable with respect to the attack on the C=O groups by Cr^{2+}. The increase in pK_a values may cause the increase in the electron density of the carboxylate group, which, in turn, may make the attack of the carboxylate position by Cr^{2+} easier.

The similarity in the activation parameters among all the complexes studied except the aibH complex indicates that the reactions take place by the same mechanism. Although the $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values of the aibH complex are larger than those of the other complexes by 4—5 kcal mol^{-1} and 5—10 cal K^{-1} mol^{-1} respectively, the product analyses indicated that the mechanism for the aibH complex was predominantly

of an inner-sphere type.

The second-order rate constant of the reactions of Cr^{2+} with some pentaamminecobalt(III) complexes ligating $^-O_2C(CH_2)_nCH_3$ and $^-O_2C(CH_2)_nNH_3^+$ ligands are compared in Scheme 1. The rate of the carboxylato complexes decreases with the increase in the methylenic chain length. This trend is in contrast with that observed for the amH complexes. Although the positive charge of the butyrato complex is less than those of the amH complexes, the rate of the former complex is smaller than those of $Co(gabH)(NH_3)_5^{3+}$ and $Co(ahH)(NH_3)_5^{3+}$. As has been mentioned above, the $-(CH_2)_nNH_3^+$ group takes a severely restricted orientation and the ammonium group is located apart from the C=O moiety. On the other hand, the alkyl group, which is electrically neutral, is able to wander about in the vicinity of the C=O moiety in the same complex ion. Therefore, the alkyl group may hinder increasingly the attack on the C=O group by Cr^{2+} with the increase in the methylenic chain length.

Crystal Structure and Magnetic Properties of Hydrothermally Synthesized Barium Ferrite, $Ba_4Fe_9O_{20}H_6$*

Katsuki KITAHAMA and Ryôiti KIRIYAMA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 4, 1976)

A new barium ferrite, $Ba_4Fe_9O_{20}H_6$, has been synthesized by a hydrothermal technique. This crystallizes in a monoclinic system with $a=10.263(5)$, $b=5.986(3)$, $c=14.559(6)$ Å, $\beta=95.20(3)°$, $Z=2$, space group C2/m. The structure was determined by Patterson and Fourier methods from three-dimensional X-ray counter data and refined by block-diagonal least-squares calculations to $R=0.098$ for 1128 reflections. The structure consists of condensed layers of ferrite anions, $Fe(OH)_6^{3-}$ clusters, and Ba^{2+} cations; it has the character of a crystal growth from aqueous solutions. The presence of Fe^{2+} was confirmed; such ions are located in the condensed ferrite layer. Consequently, the true formula should be written as $Ba_4[Fe^{III}(OH)_6][Fe^{II}Fe_7^{III}O_{14}]$. This crystal is ferrimagnetic below the Nèel point of 515 K. The magnetic moment was estimated to be about 10 μ_B per formula unit at 0 K.

The BaO–Fe_2O_3 and BaO–Fe_2O_3–MeO systems have been studied by many workers because of their great importance as useful magnetic materials. Most of them have been synthesized by firing or flux methods at temperatures higher than 700 °C.[1,2] Hydrothermal syntheses of these substances seem worthwhile, not only for the manufacture of magnetic materials but for the reaction chemistry with respect to the amphoteric behavior of Fe^{3+} ions in aqueous solutions. Of these, barium monoferrite, $BaFe_2O_4$, has an interesting structure characterized by wide-open cavities.[3] In the early stage of hydrothermal studies, our aim was to ascertain whether Ba^{2+} cations leach through the channels of this structure, as is often observed in zeolites, or not. Such hydrothermal treatments and growth of new barium ferrites, however, revealed that the reaction proceeds through dissolution of the starting material. By processing $Ba(OH)_2$ and Fe_2O_3 under hydrothermal conditions, four kinds of barium ferrite were obtained: these are $Ba_4Fe_9O_{20}H_6$, $Ba_8Fe_{13}O_{30}H_6$,[4] and two modifications of $BaFe_4O_7$.[5,6] Successive X-ray studies showed that their crystal structures certainly reflect some characteristics of the crystal growth from aqueous solutions. This paper is concerned with the crystal structure and magnetic properties of $Ba_4Fe_9O_{20}H_6$. This substance was designated Phase II among the hydrothermal products and was considered to have the structure of a modified Y ferrite in a previous paper.[7]

Experimental

Preparation. Barium hydroxide octahydrate (0.63 g), and α-Fe_2O_3 (0.32 g), both of which were commercial guaranteed reagent grade, and 5 ml of distilled water were charged in a platinum capsule with a lid. The capsule was inserted into a Morey bomb sealed with a copper gasket. The contents were heated at a rate of 4 °C min^{-1} up to 300 °C, kept at this temperature for 5 days, and then quenched into ice water. The pressure inside the bomb during the reaction was roughly estimated as 150 bar from a filling ratio-temperature diagram given by Kennedy.[8] Partial reduction of Fe^{3+} to Fe^{2+} may be caused by hydrogen, probably resulting from corrosion of the stainless steel vessel by water. In fact, for a shorter reaction period of one or two days, where the reduction was not enough, the product was contaminated with a hexagonal phase ($P6_3/m$) of $BaFe_4O_7$. The crystalline product was filtered and then washed with distilled water. The obtained crystals were platy hexagons in shape and were strongly magnetic, so they could be easily separated by use of a hand magnet.

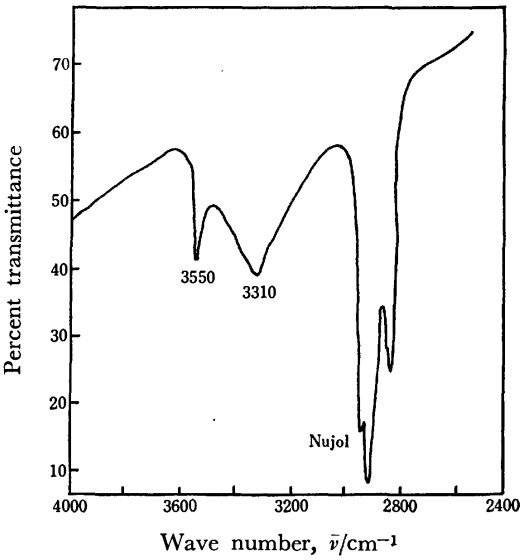

Fig. 1. Infrared spectra of $Ba_4Fe_9O_{20}H_6$.

Chemical Composition. The molar ratio of Ba/Fe was determined as 4 : 8.89 from an ordinary gravimetry measurement and as 4 : 8.80 by a fluorescent X-ray analysis; these values agree within their experimental errors. The presence of OH groups was evidenced by IR spectroscopy. As shown in Fig. 1, the two OH stretching bands occurred at about 3550 and 3310 cm^{-1}, whereas no peak were observed in the region 1500—1800 cm^{-1}. The weight loss corresponding to $3H_2O$ was found at about 695 K by means of TG analysis; from this the amount of H could be determined. The presence of ferrous ions was detected from the color test of $K_3Fe(CN)_6$ in an aqueous solution. Although its amount was roughly estimated from iodometry, the exact content was successfully determined by referring to the number of peaks assigned to oxygen atoms in the electron density maps described below.

X-Ray Data Collections. The crystals synthesized hydrothermally were dark red transparent hexagonal plates; almost all crystals were twins or aggregates grown epitaxially. A

* Thesis submitted by one of the authors(K.K.) to Osaka University in partial fulfillment of the requirements for the degree of Doctor of Science.

Table 1. Crystal data for $Ba_4Fe_9O_{20}H_6$

Space group C2/m	$\rho_{obsd}=5.06$ g cm^{-3}
$a=10.263(5)$ Å	$\rho_{calcd}=5.137$
$b=5.986(3)$	$F(000)=1248$ e cell^{-1}
$c=14.559(6)$	F. W. $=1377.98$ g mol^{-1}
$\beta=95.20(3)°$	$V=890.72$ Å^3
$Z=2$	$\mu_{MoK\alpha}=158.9$ cm^{-1}

single crystal happened to be found with the shape of an irregular hexagonal plate with dimensions of $0.08\times0.04\times0.015$ mm^3; this crystal was used for the present X-ray study. Weissenberg and precession photographs indicated the crystal to be monoclinic, with a space group either C2, Cm, or C2/m; the last group was confirmed by solution of the structure (the systematic absences: hkl, $h+k$ odd). The same crystal was mounted on a Rigaku four-circle diffractometer with its c-axis along the ϕ-axis of the goniostat. The lattice parameters were determined from the setting angles of the same diffractometer, using Mo$K\alpha_1$ radiation. The results are listed in Table 1 together with other crystal data. Intensity data were collected by use of zirconium-filtered Mo$K\alpha$ radiation, with a 2θ-ω scan mode. The scan speed was 1°min^{-1} in 2θ and background intensities were measured for 10 s at both ends of the scan. In total, 1128 independent reflections with $\sin\theta/\lambda$ less than 0.65 Å^{-1} were measured. The reference reflections that were monitored periodically showed no significant intensity fluctuations during the collection of intensity data. For reflections having scan counts below the background levels, the intensity values were taken as 0.0. No corrections were made for absorption or extinction.

Magnetization. Magnetic properties were measured by means of a Faraday method on a Naruse electro-mechanical balance equipped with an automated recording device. The values of magnetization were calibrated by using powdered nickel (99.999%).

Mössbauer Spectroscopy. The measurement was made on a Hitachi AA40 Mössbauer spectrometer with a ^{57}Co(Pd) source moving against a specimen in a constant acceleration mode. An iron foil was used for the calibration of velocity.

Structure Determination and Refinement

Three-dimensional Patterson maps showed peaks only on the planes at $y=0$, 1/2, and at about $y=1/4$, and suggested the presence of mirror planes perpendicular to the b-axis. Because these peaks were comparable in height, owing to the periodical stacking of oxygens, Patterson maps were calculated again with reflections of $\sin\theta/\lambda>0.4$ Å^{-1} and with a sharpening factor of $B=2.0$ Å^2. (Of the 1128 reflections, 280 were eliminated from this calculation; the sum of $|F_0|$ of these 280 reflections amounts to 50% of the $\Sigma|F_0|$ of the total reflections.) Such a modification of the Patterson function resolved the diffuse peaks and was helpful in solving the structure. Thus the positions of Ba and Fe were easily determined. All positions of oxygen atoms were found on successive three-dimensional electron density maps phased with Ba and Fe atoms. Although a full-matrix least-squares refinement was started from these atomic positions in the isotropic mode, the structure did not converge below $R=0.15$. Therefore, the block-diagonal least-squares refinement was performed, varing the individual isotropic thermal parameters, an overall temperature factor, and a scale factor. At the stage of $R=0.118$, anisotropic thermal parameters were introduced for Ba an Fe atoms. Difference Fourier maps computed at this stage showed no ripple higher than 2.0 e Å^{-1}. After four further cycles of refinement, R dropped to 0.098. No atomic parameters shifted by more than one fourth of their associated standard deviations in the final cycle. The scattering factors for Ba^{2+}, Fe^{3+} (applied for all Fe), and O^- were taken from *International Tables for X-Ray Crystallography, Vol. IV.*[9] The quantity minimized during the least-squares procedure was $\Sigma w(|F_o|-|F_c|)^2$, all weights being unity. All computations were performed on the NEAC 2200/700 computer of this university, using local modifications of RSSFR-5, RSFLS, HBLS V, and RSDA-4 in the UNICS program system,[10] and the stereoscopic drawing program ORTEP written by Johnson.[11] The observed and calculated structure factors are compared in Table 2. The final positional thermal parameters are given in Table 3.

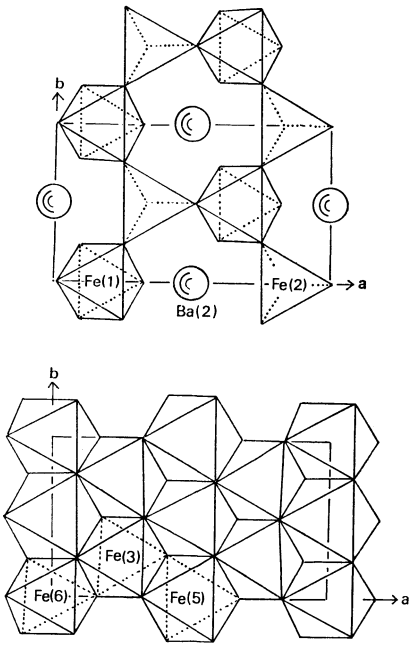

Fig. 2. Two kinds of slices in the condensed ferrite layer viewed along the c* direction. Above: one of the outer slices of the triple layer ($z\approx0.19$). Below: a middle sheet of the triple layer.

Results and Discussion

Crystal Structure. The structure consists of eminent triple layers of oxygen coordination polyhedra around Fe atoms parallel to the (001) plane, and Fe$(OH)_6^{3-}$ anion clusters and Ba^{2+} cations both intervening between triple layers. Of the nine Fe atoms in the chemical formula, seven atoms are coordinated octahedrally by oxygen atoms while the other two are surrounded tetrahedrally. The triple layer is composed of two kinds of slices: that is, one type is sandwiched between the others. As shown in Fig. 2, each

O(7)	8447(20)	0	743(20)	70(31)					

a) Estimated standard deviations are given in parentheses. The anisotropic thermal factors are of the form $T=\exp\left[-\frac{1}{4}(h^2a^{*2}B_{11}+\cdots+2klb^*c^*B_{23})\right]$.

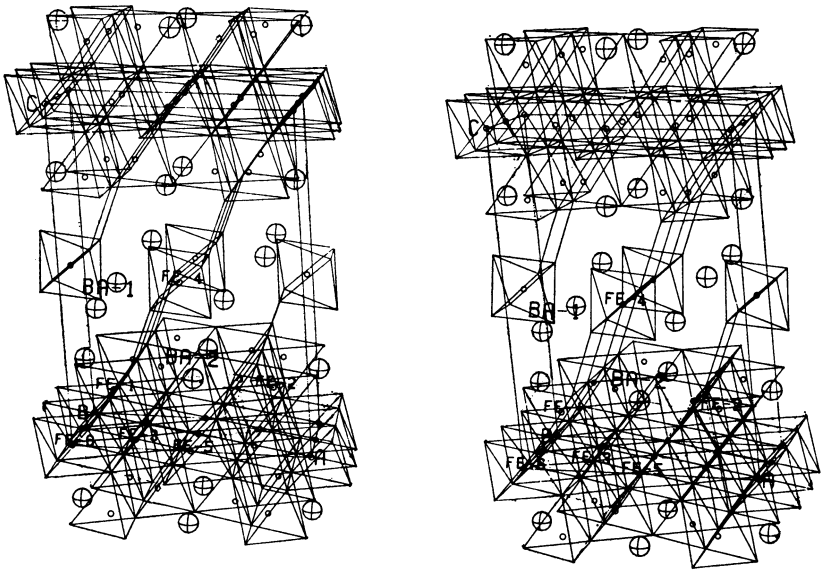

Fig. 3. Stereoscopic drawing of the crystal structure of $Ba_4Fe_9O_{20}H_6$.

$Fe(OH)_6^{3-}$ cluster between these layers. Interatomic distances are summarized in Table 4.

Ba(1) and Ba(2) are surrounded respectively by nine and ten oxygen atoms at distances ranging from 2.61 to 3.02 Å. It is noticeable that each Ba is close to one oxygen atom, with a separation of less than 2.70 Å. Similar situations occur in $BaFe_2O_4$ obtained by firing,[3] in $Ba_2[Al_2(OH)_{10}]$[12], and $Ba_3[Al_2(OH)_{12}]$,[13] both grown from aqueous solutions, and in $Ba(OH)_2 \cdot 8H_2O$.[14] On the other hand, in hexagonal barium ferrites,[15] such a close contact of Ba to O is not found, but their structures are close-packed build-ups of O and Ba: for example, in $Ba_2Zn_2Fe_{12}O_{22}$ (ofen referred to as Y ferrite), Ba is surrounded by twelve oxygens at distances between 2.95 and 3.26 Å.[16]

The coordination octahedron around Fe(4) consists of four equivalent oxygen atoms [O(3)] in equatorial positions and two O(6) atoms in axial positions. This octahedron is much more regular than the other Fe octahedra and does not share any vertices, edges, or faces with the adjacent polyhedra. These findings strongly suggest that all vertices of the octahedron around Fe(4) are occupied by OH groups. The equatorial oxygen O(3) in the cluster is close to O(2) in the triple layer, at a distance of 2.872 Å, and forms a weak hydrogen bond, while the axial oxygen O(6) does not participate in any hydrogen bond. This hydrogen-bonding scheme is quite consistent with the IR spectrum described above. Each of the four equivalent hydrogen bonds is shown in the stereoscopic drawings of Fig. 3, together with the $Fe(OH)_6^{3-}$ clusters, Ba^{2+} ions, and triple layers of condensed ferrite anions.

One would expect the Fe–O distances to provide a powerful assistance for establishing the position of Fe

TABLE 4. INTERATOMIC DISTANCES (l/Å)

with oxidation number two. All Fe–O distances in the tetrahedron (mean 1.88 Å) and octahedra (mean 2.01 Å) other than those concerning Fe(1) and Fe(5) are nearly equal to those of Fe with oxidation number three, as reported in the literature.[17] On the other hand, distances of Fe–O concerning Fe(5) are significantly larger (2.12—2.13 Å), in fair agreement with typical values for Fe with oxidation number two. Hence, the position of Fe with oxidation number two could be confirmed to be in the middle slice of the triple layer. As a consequence, the formula should be written $Ba_4[Fe^{III}(OH)_6][Fe^{II}Fe_7^{III}O_{14}]$. This finding suggests that Ba^{2+} ions, $[Fe(OH)_6]^{3-}$ ions, and some condensed ferrite anions with sheet-like structures exist generally in the hydrothermal medium.

The Fe–O distances around Fe(1) vary from 1.941 to 2.183 Å. In this octahedron, O–O distances of the shared edges in the basal plane are shorter than those of the unshared edges in the top plane which faces toward the outside of the triple layer. The Fe(1) is displaced toward the outside of the triple layer, so that Fe(1) is closer to the three oxygens of the shared vertices (1.942 and twice 1.941 Å) than to those of the shared edges (2.134 and twice 2.183 Å). Such a variety of Fe–O distances was also found in α-Fe_2O_3[18] and in two modifications of $BaFe_4O_7$.[5] In the former case, where two FeO_6 octahedra are stacked by sharing their faces, the distortion was explained in terms of a

large electronic interaction between two Fe across the shared plane. The repulsion between Fe^{3+} and Ba^{2+} might cause an additional distortion in the structure of both modifications of $BaFe_4O_7$. In the present case, however, the distances of Fe(1)–O can not be understood only by such local interactions. This suggests that the three Fe(1)–O bonds concerning the oxygen atoms shared by FeO_4 tetrahedra are more covalent than the other three.

Polymerization of ferrite anions has been discussed by many workers.[19–21] On the basis of the structure of $Ba_4[Fe(OH)_6][Fe_8O_{14}]$ determined just above, we suppose three stages of condensation of ferrite anions, such as the following: (1) The free hydroxo-complex anion, $[Fe(OH)_6]^{3-}$, found in solution is enclosed into nuclei of the lattice together with Ba^{2+} cations. (2) The condensation of the hydroxo-complex anions proceeds with accompanying dehydration, and the FeO_6 octahedra necessarily share their vertices or edges with each other. (3) During such a condensation process, a part of the FeO_6 octahedra are allowed to convert into FeO_4 tetrahedra, as evidenced by the Fe(2) tetrahedra kept back in the crystal lattice. If all FeO_6 octahedra transform to FeO_4 tetrahedra sharing their vertices, then the resulting framework of condensed ferrites would become tetrahedral chains or a two- or three-dimensional network analogous to silicates, aluminosilicates, and aluminates. Such a situation is encountered in barium monoferrite, $BaFe_2O_4$, obtained by firing. We have recently found another example of a three-dimensional framework of FeO_4 tetrahedra in $Ba_8Fe_{13}O_{30}H_6$[5] synthesized by a hydrothermal reaction.

Magnetic Properties. The easy axis of magnetization was examined by a combined use of an optical microscope and a hand permanent magnet. Batches of samples were classified into two groups because of their quite remarkably different magnetizations; the easy magnetization axes of one batch of samples lay on the basal plane of the hexagonal plates, while those of the other batch were directed toward the outside of the plane. The single crystal used for this X-ray study was obtained from the former; its easy magnetization axis pointed in the a-direction. The latter batch of crystals emerged less frequently. These distinct groups of samples showed somewhat different Mössbauer spectra; these are compared in Fig. 4. Such a difference can not be explained in terms of a preferred orientation of the sample grains. It is therefore probable that two modifications would occur, owing to only slight differences in either the contents or the locations of Fe atoms with oxidation number two. Although the Mössbauer spectra are quite complicated, a tentative assignment was made for three Fe species by assuming that the oxidation numbers of all Fe are three and that their isomer shifts are in the range of $0.0<\delta<0.7$ mm s^{-1} (referred to Fe foil). Considering the numbers of equivalent positions and the coordination number of oxygens, we assigned the three Fe species to Fe(2), Fe(1), and Fe(3) in the increasing order of δ. The Mössbauer parameters thus obtained are given in Table 5.

The magnetic measurement was made only for crystals

a) with respect to the centroid of the spectrum of iron foil at 293 K. b) $1G=10^{-4}$ T.

with easy axes parallel to the (001) plane. The variation of magnetization against field strength was measured from 900 to 12000 G at room temperature. The value stayed constant at 13.80 ± 0.05 emu g^{-1} above 2000 G and saturation was considered to be reached. Figure 5 shows the temperature dependence of magnetization from 77 to 573 K measured at 4000 G, together with the Néel point, $T_N=515$ K. This plot is far from a Langevin curve, indicating complicated mechanisms of magnetic interaction. An extrapolation of this curve gives a magnetic moment of about $10\,\mu_B$ per formula corresponding to just two Fe^{3+} ions. If the magnetic moments are simply ordered parallel and antiparallel below T_N, then a space group of P2/m with the same cell dimensions or doubling of the unit sell in volume would be required for the magnetic unit cell.

Twining. Twinning of this crystal would be expected to occur in various ways, owing to the pseudo-hexagonal symmetry possessed by the triple layer of the condensed ferrite anion in the structure (the axial

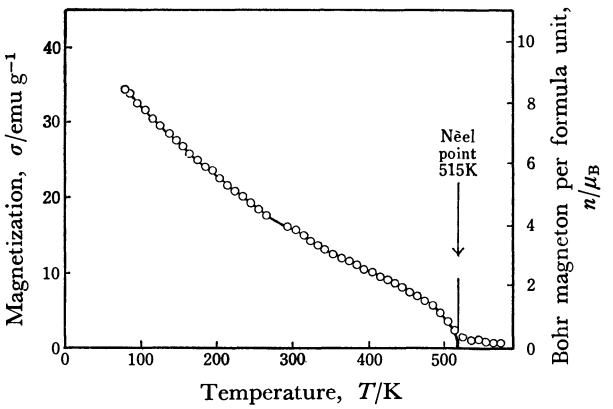

Fig. 5. Variation of magnetization at 4000 G with temperature.

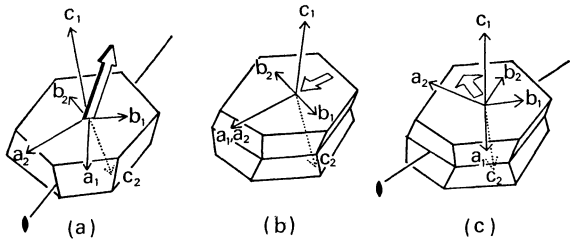

Fig. 6. Three twin laws of $Ba_4Fe_9O_{20}H_6$.
(a) [110] axial twinning. (b) Twin and composition plane (001). (c) [130] axial twinning. Directions of easy magnetization axes are shown by open arrows. Twin axes are shown by diad axes in (a) and (c).

ratio of a/b is 1.714). In fact three kinds of twin laws were confirmed by X-ray techniques, and the direction of the easy magnetization axis for each twinned specimen was determined by use of a permanent magnet. Relative orientations of individual crystals, which were determined by Weissenberg and precession photographs, are shown in Fig. 6 together with the direction of easy magnetization. The first kind is the [110] axial twinning; here the easy direction is perpendicular to the twin axis, but it leans at an angle of about 30° from the normal of the (001) plane (Fig. 6a). The second is not axial, and the (001) plane corresponds to the twin and composition plane (Fig. 6b). In this case, the a-axes of both individuals are coincident and the easy magnetization axis is parallel to this direction. The third twinning is [130] axial twinning, in which the easy magnetization axis is perpendicular to the twin axis and lies on the (001) plane (Fig. 6c). It is plausible that twinning repeats during the crystal growth according to these laws. Many sorts of polysynthetic twins were found very often under an optical microscope. In addition, the latter two kinds of twins appeared as a mixture in a batch, while the first appeared in a different batch. The direction of easy magnetization can not be explained solely on the basis of a vector sum of individual contributions. This finding also suggests the occurrence of two or more modifications in this compound.

The authors thank Dr. Masayasu Tokonami of this Institute for his assistance in the X-ray intensity data collection. The authors also thank Dr. Hideko Kiriyama of this Institute for her helpful criticisms of the manuscript.

A Mössbauer Study of Graphite Intercalated with Iron(III) Chloride and Aluminum Chloride

Takeshi TOMINAGA, Takuhiko SAKAI, and Tomohiko KIMURA

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 2, 1976)

The Mössbauer spectra of graphite–$FeCl_3$ and graphite-$FeCl_3$–$AlCl_3$ compounds with varying $FeCl_3/AlCl_3$ ratios were measured. At 298 K, the isomer shift of the Fe^{3+} peak of $FeCl_3$ intercalated in the graphite–$FeCl_3$ compounds was larger than that of pure anhydrous $FeCl_3$, and two sets of Fe^{2+} quadrupole doublets appeared in the spectra of the graphite-$FeCl_3$–$AlCl_3$ compounds with $FeCl_3/AlCl_3$ ratios of approximately one or less. These results may be accounted for in terms of the transfer of graphite π-electrons to intercalated $FeCl_3$.

In 1967 one of the present authors (T.T.) investigated the Mössbauer spectra of the graphite–$FeCl_3$ intercalation compounds with a view to obtaining a clue as to the nature of the bonding in such systems.[1] The isomer shift of the intercalated iron(III) chloride was found to be larger than that of pure anhydrous iron(III) chloride, indicating the possibility of the transfer of graphite π-electrons to the intercalated molecules. Similar results have been reported thereafter from several groups of workers for the Mössbauer spectra of graphite intercalated with iron chloride, or iron chloride and aluminum chloride.[2-9] In contrast to the previous report[3] that the spectra of the graphite–$FeCl_3$–$AlCl_3$ compounds were essentially the same as those of the graphite–$FeCl_3$ compound, we have recently observed the presence of quadrupole doublets of Fe^{2+} in the Mössbauer spectra of the graphite–$FeCl_3$–$AlCl_3$ compounds with $FeCl_3/AlCl_3$ ratios of about one or less.[9]

The object of the present article is to report the detailed results of the Mössbauer spectroscopic study on the graphite–$FeCl_3$–$AlCl_3$ compounds with varying $FeCl_3/AlCl_3$ ratio so as to elucidate the chemical states of iron chloride intercalated in such systems.

Experimental

Materials. A pulverized natural graphite (Spectroscopic Powder) purchased from Union Carbide Corp. was used for preparation of the intercalation compounds. The graphite–$FeCl_3$ compounds were obtained by procedures similar to those described in the literature.[10] Mixtures of weighed quantities of graphite and anhydrous iron(III) chloride were heated in sealed glass tubes between 230 and 350 °C. The products were freed from unreacted iron chloride by washing with hot 2 M HCl and then dried at 110 °C. The products were analyzed for their metal content by decomposition to oxides. The chlorine content was determined by neutron activation analysis. The analytical results of the intercalation compounds obtained under various heating conditions are summarized in Table 1.

The graphite–$FeCl_3$–$AlCl_3$ compounds were prepared by methods essentially similar to those reported in the literature.[11,12] Mixtures of graphite with anhydrous iron(III) chloride and aluminum chloride were heated in sealed glass tubes at temperatures between 210 and 300 °C, and excess metal chlorides were removed by washing with hot 2 M HCl. The analytical results of the products prepared under various conditions are also summarized in Table 1.

Mössbauer Spectroscopy. The Mössbauer spectra of the intercalation compounds were measured at 298 and 80 K by using a Hitachi AA-40 or a Shimadzu MEG-1A Mössbauer spectrometer with a ^{57}Co source diffused into copper foil. The isomer shifts are given as related to the centroid of the spectrum of iron foil at 298 K. The errors in isomer shifts and quadrupole splittings are generally of the order of 0.02—0.03 mm/s, except for the spectra subjected to larger uncertainties because of weak absorption intensities or the complexity of overlapping peaks.

Results and Discussion

Graphite–$FeCl_3$ Compounds. As a typical example of the graphite–$FeCl_3$ compounds, Mössbauer spectra of $C_{10}FeCl_3$ (compound II with 55.8 % $FeCl_3$) at 298 and 80 K are illustrated in Figs. 1a and 2a respectively. The spectrum at 298 K consists of a single absorption peak of Fe^{3+} with an isomer shift of 0.50 mm/s, which is obviously larger than that of pure anhydrous iron(III) chloride, $FeCl_3$ (δ=0.42 mm/s). This observation is in agreement with the results obtained previously,[1-8] and may indicate that the graphite π-electrons are transferred to the d-orbitals of iron in all iron(III) chloride molecules rather than in one quarter of the intercalated molecules as postulated by Dzurus and Hennig.[12,13] Such an electron transfer mechanism may be further confirmed by the reverse effect observed in boron nitride–$FeCl_3$ compounds:[14] the isomer shift of $FeCl_3$ intercalated in boron nitride was lower than that of pure anhydrous $FeCl_3$, revealing that an electron transfer from $FeCl_3$ to boron nitride layers probably takes place in the system. However, the isomer shift of $C_{10}FeCl_3$ at 80 K (0.54 mm/s) is very close to that of pure anhydrous $FeCl_3$ (0.52 mm/s). Hence, it is probable that the electron transfer from graphite to $FeCl_3$ is considerably attenuated at low temperatures.

The Mössbauer spectra of all the graphite–$FeCl_3$ preparations appear to be essentially similar; the isomer shift does not change significantly with the $FeCl_3$ content or with the heating temperature (Table 2). It is worth mentioning that only a very weak component of an Fe^{2+} doublet was observed in the spectrum of C_9FeCl_3 prepared by heating at 350 °C (compound III), whereas no iron(II) state was detected in the spectrum of $C_{10}FeCl_3$ reheated at 300 °C *in vacuo* (compound IV). On heating $C_{10}FeCl_3$ at 400 °C in vacuum or air, two sets of Fe^{2+} doublets arose in the spectrum, indicating the formation of $FeCl_2$ by decomposition.

Graphite–$FeCl_3$–$AlCl_3$ Compounds. The Mössbauer spectra of typical graphite–$FeCl_3$–$AlCl_3$ compounds at 298 and 80 K are represented in Figs. 1 and 2 respective-

a) Parameters given in parentheses involve rather large uncertainties (±0.05 mm/s) due to the weak absorption intensities of overlapping peaks.

ly. The Mössbauer spectra at 298 K of the graphite–$FeCl_3$–$AlCl_3$ compounds with $FeCl_3/AlCl_3$ ratios of 4—1.2 (compounds V to VII) were essentially similar to those of the graphite–$FeCl_3$ compounds composed of an Fe^{3+} singlet alone (Figs. 1b and 1c.) As the $FeCl_3/AlCl_3$ ratio was decreased to one, however, a weak Fe^{2+} quadrupole doublet appeared in addition to the Fe^{3+} peak (compound VIII, Fig. 1d). In the spectra of the compounds with $FeCl_3/AlCl_3$ ratios of 0.5 and 0.3 (compounds IX and X), a second Fe^{2+} doublet arose outside of the initial doublet, and the intensities of both doublets exceeded that of the Fe^{3+} peak (Figs. 1e and 1f). Hence we may presume that iron chloride molecules intercalated in the graphite–$FeCl_3$–$AlCl_3$ compounds with $FeCl_3/AlCl_3$ ratios of 0.3—0.5 exist predominantly in high-spin iron(II) states.

The Mössbauer spectra at 80 K of the intercalation compounds with $FeCl_3/AlCl_3$ ratios of 1—0.3 (compounds VIII to XI) similarly show the presence of the Fe^{2+} doublets. However, the Fe^{2+}/Fe^{3+} area ratio at 80 K becomes considerably smaller than that at 298 K; thus the percentage of the Fe^{2+} fraction tends to decrease with the decrease in temperature. Although the origin of such temperature dependence of the Fe^{2+}/Fe^{3+} area ratio cannot yet be explained without ambiguities, it is likely that the transfer of graphite π-electrons to

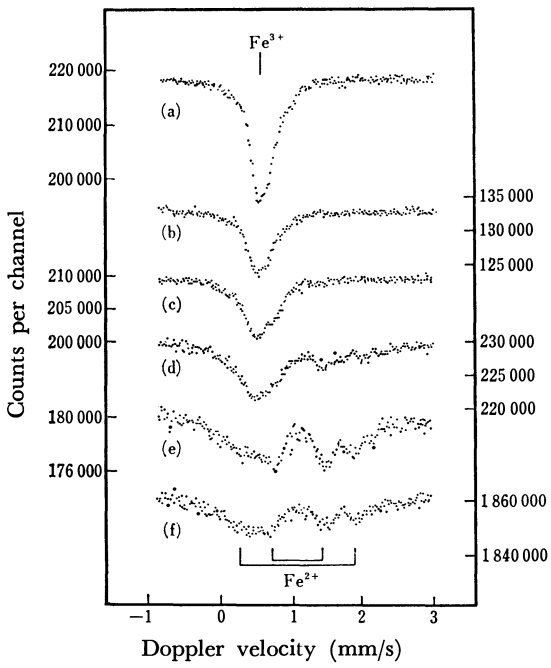

Fig. 1. Mössbauer spectra at 298 K of (a) graphite–$FeCl_3$ intercalation compound, and (b)—(f) graphite–$FeCl_3$–$AlCl_3$ intercalation compounds: (a) compound II, (b) compound V, (c) compound VI, (d) compound VIII, (e) compound IX, (f) compound X.

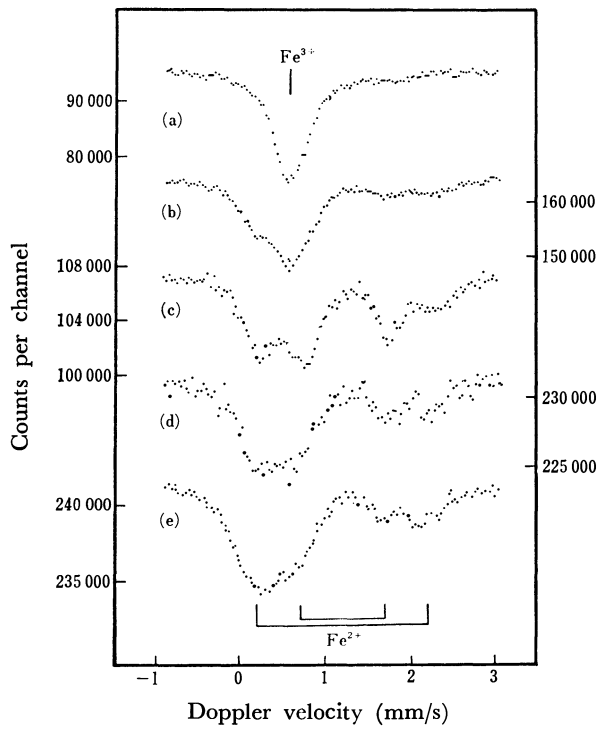

Fig. 2. Mössbauer spectra at 80 K of (a) graphite–$FeCl_3$ intercalation compound, and (b)—(e) graphite–$FeCl_3$–$AlCl_3$ intercalation compounds: (a) compound II, (b) compound VIII, (c) compound IX, (d) compound X, (e) compound XI.

$FeCl_3$ may be attenuated at low temperatures, as has been observed with the graphite–$FeCl_3$ compounds; the other possibilities, such as an effect due to the difference in temperature dependence of the recoilless fractions of Fe^{2+} and Fe^{3+} species,[15] or any irreversible change in structure over the above temperature range,[16] may be ruled out.

As shown in Table 2, two sets of quadrupole doublets with nearly equal isomer shifts arise in the Mössbauer spectra of the graphite–$FeCl_3$–$AlCl_3$ compounds with $FeCl_3/AlCl_3$ ratios of 1—0.3. This is indicative of the presence of two kinds of Fe^{2+} ion sites, one of which (corresponding to the inner doublet) may not differ appreciably from the Fe^{2+} site in pure anhydrous $FeCl_2$ because their Mössbauer parameters are alike. Moreover, it is worthwhile mentioning that the Mössbauer parameters of the Fe^{2+} doublets of the graphite–$FeCl_3$–$AlCl_3$ compounds are generally similar to those of the Fe^{2+} peaks of the graphite–$FeCl_2$ compounds obtainable by reduction of the graphite–$FeCl_3$ compounds.[4,6-8] The origin of the two Fe^{2+} sites in the graphite–$FeCl_2$ compounds has been ascribed to dissimilar distortions from a regular octahedron of chlorine in the $FeCl_2$ structure.[8]

The appearance of the Fe^{2+} doublets in the graphite–$FeCl_3$–$AlCl_3$ compounds with small $FeCl_3/AlCl_3$ ratios may be tentatively accounted for as follows.[17] If the $AlCl_3$ concentration in the metal halide layer is small, a graphite π-electron donated to an Fe^{3+} ion may be shared among several neighboring Fe^{3+} ions through a rapid exchange process, and eventually will increase the isomer shift of the Fe^{3+} single peak. As the $AlCl_3$ concentration exceeds the $FeCl_3$ concentration ($FeCl_3/AlCl_3 \leq 1$), the donated electron may be localized on one Fe^{3+} ion to produce Fe^{2+}, since the iron ion is surrounded with Al^{3+} ions which are not electron acceptors, and no direct exchange of an electron between Fe^{3+} ions is probable. Accordingly, this may give evidence that a species of the type $C_n^+Cl^-$-$FeCl_2 \cdot 3AlCl_3$ is formed by the transfer of graphite π-electrons in the compounds with $FeCl_3/AlCl_3$ ratios of about 0.3, as postulated by Dzurus and Hennig.[12]

The present authors wish to express their thanks to Professor Nobufusa Saito, of the University of Tokyo, for his encouragement and support.

15) The Fe^{2+}/Fe^{3+} area ratios measured at 298 and 80 K for a mixture of pure anhydrous $FeCl_2$ and $FeCl_3$ were nearly equal, within about 10% uncertainty. The layer structures of pure anhydrous iron chlorides may be essentially retained in the intercalation compounds where they are sandwiched between graphite layers.

16) The spectrum at 298 K was reproducible even after the compound had been cooled to 80 K and then warmed up to room temperature again.

17) We may exclude the possibility of the formation of $FeCl_2$ by decomposition under the conditions employed in this work. In fact, the observed Cl/(Fe+Al) ratios (Table 1) were close to 3, while the ratio should be as low as 2.76 if $FeCl_3$ was completely decomposed to $FeCl_2$ in the compounds with $FeCl_3/AlCl_3$ ratio of about 0.3.

Solvent Effects on the ESR Spectra of Copper(II) Complexes. A Consideration of the Donicity of Water and Methanol

(Received June 7, 1976)

Solvent effects on the ESR spectra of bis(2,6-dimethyl-3,5-heptanedionato)copper(II) ([Cu(dibm)$_2$]) and a similar copper(II) complex were investigated in some detail. A clear relationship between the ESR parameters and the donicity of the solvents was confirmed, and this is discussed with the intention of investigating the donicities of water and methanol. The donor number for water in an aqueous solution was estimated to be about 30 from a precise analysis of the ESR spectra of [Cu(dibm)$_2$] in water-methanol mixtures.

The concept of donicity has become increasingly important in the chemistry of non-aqueous solvents, but the donicities of some protic solvents such as water and alcohol still remain open to investigation.[1,2] Solvent effects on various properties of metal complexes have been studied widely for the purpose of determining the donicity of the solvents. Gutmann has found a relationship between the donicity or donor number (DN) of a solvent and the visible absorption band of bis(acetylacetonato)oxovanadium(IV) dissolved in the solvent.[2] Adato and Eliezer[3] have investigated solvent effects on the ESR spectra of bis(acetylacetonato)-copper(II) in connection with the DN of the solvents, but there seems to be some uncertainty in their data, as is described below. In addition, they did not refer at all to the DN of water or methanol.

The purpose of the work reported here is to re-investigate the relationship between the ESR parameters and the DN of solvents, using some stable planar copper(II) complexes which are soluble in many solvents, and to attempt to estimate the DN of water and methanol.

Experimental

Bis(2,6-dimethyl-3,5-heptanedionato)copper(II) (hereafter abbreviated to [Cu(dibm)$_2$]) and bis(*N*-salicylidenepropylaminato)copper(II)([Cu(*N*-Pr-sal)$_2$]) were prepared and purified by the usual method.[4,5] For the ligand of the former complex, 2,6-dimethyl-3,5-heptanedione, which was purchased from the Eastman Kodak Company, was used.

Acetonitrile, propylene carbonate, *N*,*N*-dimethylformamide, and dimethyl sulfoxide were purified according to the methods in the literature.[6-8] The other solvents were purified by the usual method.[9]

ESR spectra of the complexes in solutions (about 10 mM) were measured with a Hitachi 771 X-band ESR spectrometer at 77 K. Mixtures of toluene and the other solvents at various molar fractions were used as solvents.

Results and Discussion

The Relationship between the ESR Parameters and the DN of Solvents. As the first step in this study, it is absolutely necessary to obtain well-defined ESR spectra, and this could be achieved by using mixtures of toluene and the other solvents. Several typical ESR spectra of [Cu(dibm)$_2$] in various solvents at 77 K are shown in Fig. 1. All the spectral line shapes observed in this work were of axial or nearly axial symmetry,[10] and, in addition, the line-widths were rather narrow. Hence, the $g_{//}$ and $|A_{//}|$ values can be accurately determined from these spectra.

The $g_{//}$ and $|A_{//}|$ values of planar copper(II) complexes respectively increase and decrease to a significant extent as the axial ligand field is strengthened by apical coordination of the solvent molecules. Therefore, these values, as well as $g_{\perp}$, are good parameters for use in the investigation of the donicity of the solvents. The data obtained from the work reported here are given in Table 1, together with the DN and dipole moments (μ) of the solvents, where the DN of toluene was assumed to be approximately zero. Table 1 clearly indicates that $g_{//}$ and $|A_{//}|$ do not correlate with μ, but with DN. A correlation between $g_{//}$ and DN is shown in Fig. 2; the $g_{//}$ value increases with DN, and the order of the solvents is the same as that previously reported with regard to DN.[1] This result, therefore, suggests that the $g_{//}$ value can be used to estimate the DN. Similar results were obtained for [Cu(*N*-Pr-sal)$_2$]; for example, its $g_{//}$ values were 2.225 in pure toluene(T), 2.245 in T–DMF and 2.260 in

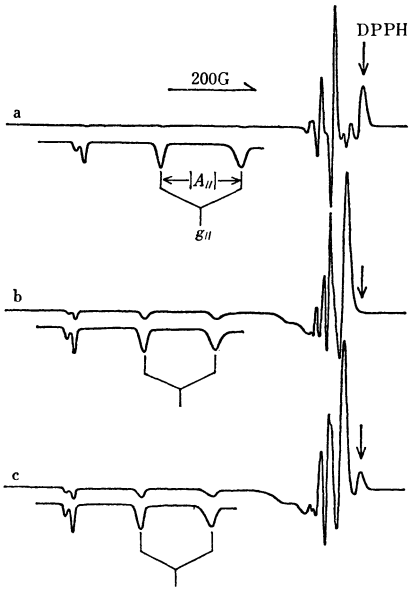

Fig. 1. ESR spectra of [Cu(dibm)$_2$] in pure T (a), T-MeOH (b) and T-DMSO (c).

TABLE 1. ESR DATA IN VARIOUS SOLVENTS

Solvent	$g_{//}$[a]	$\frac{\lvert A_{//}\rvert^{a)}}{10^{-4}\ cm^{-1}}$	DN	$\frac{\mu}{10^{-18}\ cm\ esu}$
Toluene (T)	2.251	193	0	0.37
Nitromethane (NM)	2.254	198	2.7	3.54
Nitroethane (NE)	2.259	195	—	3.60
1-Nitropropane (NP)	2.265	190	—	3.59
Acetonitrile (AN)	2.282	181	14.1	3.37
Propylene carbonate (PC)	2.277	185	15.1	5.2
Acetone (AC)	2.284	179	17.0	2.27
Water (W)	2.297[b]	178[b]	18.0	1.8
Methanol (MeOH)	2.290 2.289[c] 2.288[d] 2.291[e]	175 176[c] 175[d] 177[e]	19.1	1.66
Tetrahydrofuran (THF)	2.284	181	20.0	1.68
N,*N*-Dimethylformamide (DMF)	2.293	174	26.6	3.86
Dimethyl sulfoxide (DMSO)	2.294	175	29.8	3.9
Pyridine (Py)	2.297	168	33.1	2.20

a) These values were obtained in solvents of various toluene molar fractions at 77 K. No dependency of the data on the molar fraction was found. b) Obtained in an MeOH-water mixture. c) Obtained in an MeOH-NP mixture. d) Obtained in an MeOH-PC mixture. e) Obtained in a pure MeOH.

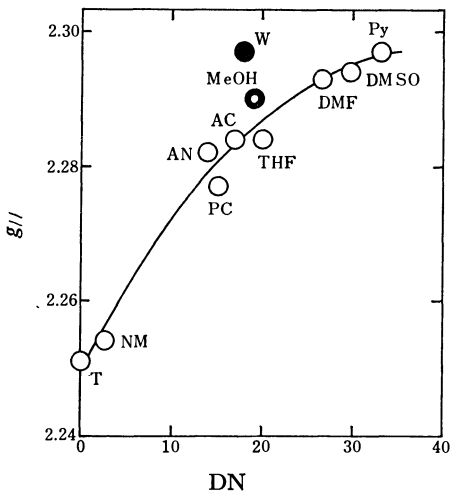

Fig. 2. The relationship between $g_{//}$ value and DN.

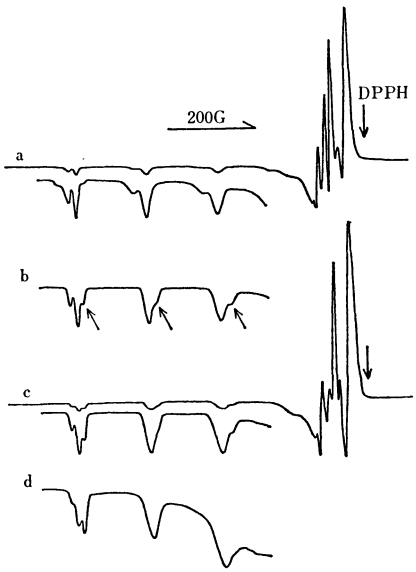

Fig. 3. ESR sepctra of [Cu(dibm)$_2$] in MeOH-water mixture at MeOH molar fractions of 0.31 (a), 0.57 (b), 0.80 (c), and 1.00 (d). The arrows are the absorption line due to MeOH adduct.

T-DMSO. Its $|A_{//}|$ values also decreased for an increase in DN.

Hence, the authors comment on the data of Adato and Eliezer.[3] First, when DMSO, DMF and other solvents were used, the resulting ESR spectra were all broad and not well-defined, and from these spectra it was not possible to obtain data similar to those in Ref. 3. Some of the data in Ref. 3 could be reproduced using solvents without purification. Accordingly, a great deal of this data is considered to be due to bis(acetylacetonato)copper(II) which interacts with impurities in the solvents. Second, it is theoretically reasonable to discuss the $g_\perp$ value of a planar copper(II) complex from the point of view of solvent effects as has been done in the case of the visible absorption spectra of bis(acetylacetonato)oxovanadium(IV).[11] Generally speaking, however, it is not easy to determine accurately the $g_\perp$ values of copper(II) complexes in solution.[12] Adato and Eliezer applied an approximate method to estimate $g_\perp$ from the equation, $g_0 = (1/3)(g_{//}+2g_\perp)$, using the experimentally-determined g values in two different states (g_0 for a fluid solution and $g_{//}$ for a rigid or glassy solution). It must be noted, however, that this method is likely to introduce some uncertainty into the results, because the solvent effects are not always the same for the two different states,[13] and because some complexes exist in solution as two or more configurationally different species in equilibrium.[14] In order to discuss solvent effects as rigorously as possible, therefore, the authors use only the $g_{//}$ and $|A_{//}|$ values determined in solutions at 77 K throughout this report.

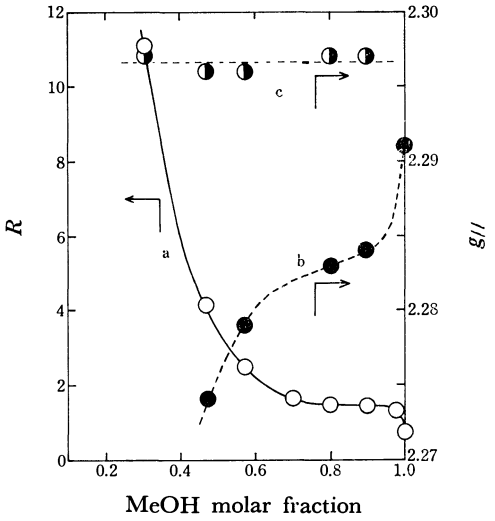

Fig. 4. Plots of R (a) and the $g_{//}$ values of MeOH (b) and water (c) adducts against the molar fraction of MeOH in MeOH–water mixtures.

Donicity of Water and Methanol. As shown in Table 1, the $g_{//}$ values were almost the same in the solvent systems T–MeOH, NP–MeOH and pure MeOH. Furthermore, the $g_{//}$ value in the T–MeOH system did not change with the MeOH molar fraction. This fact indicates that the stereochemical and electronic structures of the MeOH adduct do not depend on environmental changes. Using this $g_{//}$ value and the relationship between DN and $g_{//}$ shown as a solid line in Fig. 2, the DN of MeOH can be estimated to be larger than 19.1 (the generally accepted value[15]), but smaller than 33.8 (the value estimated by Gutmann from the data of Selbin[2]).

On the other hand, the ESR behavior in the water–MeOH system was entirely different. Several ESR spectra in water–MeOH mixtures at different MeOH molar fractions are shown in Fig. 3. The ratios (R) of the water adduct to the MeOH adduct in the ESR absorption intensity, which are nearly proportional to the ratios of their concentrations,[16] were plotted against the MeOH molar fraction, as shown in Fig. 4. Although Fig. 4 indicates that there is a correlation between R and the MeOH molar fraction, its implications appear to be complicated; they should be considered from the standpoint of the preferential solvation of water in this solvent system.

The fact that the $g_{//}$ value of the MeOH adduct in the water–MeOH system varies remarkably with the MeOH molar fraction means that the effects of water in the methanolic solution are significant even at low concentrations. The tendency of the $g_{//}$ value to decrease with an increase in water concentration indicates that the bonding between the complex and the MeOH molecules in the adduct becomes weak, although no definite explanation for this can be offered at the present time. On the other hand, the $g_{//}$ value of the water adduct is constant, as is seen in Fig. 4. This means that water and methanol as solvents have almost the same structural and electronic effects on this water adduct. Using this $g_{//}$ value and the relationship given by a solid line in Fig. 2, the DN of water could be estimated to be about 30, which coincides with the value previously reported by Gutman.[1]

The authors wish to thank Professor Taro Isobe for his encouragement and discussion during the course of this study.

Preparation of Some Alkylthallium(III) Dichlorides and Their Reactions with Potassium and Copper Halides

Sakae UEMURA,* Akio TOSHIMITSU, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received July 24, 1975)

A simple synthesis is given for the stable monoalkylthallium(III) dichloride, $C_6H_5CH(OR)CH_2TlCl_2$ (**1**) from the corresponding diacetate (**2**) and potassium chloride in methanol or acetonitrile. **1**(R=Me) reacts slowly with potassium and copper(I) halides to give mainly α-methoxystyrene and $C_6H_5CH(OMe)CH_2X$ (X=Cl, Br, I), respectively. It is concluded that **1**(R=Me) is less susceptible than **2**(R=Me) to S_N1, S_N2, and S_Ni reactions.

In contrast to the readily prepared monoarylthallium(III) dihalides, monoalkylthallium(III) dihalides are unstable[1,2] and their successful isolation has so far been limited to pyridiomethylthallium(III) dichloride[3] and neopentylthallium(III) dihalide.[4] We report herewith on the preparation of 2-alkoxy-2-phenylethylthallium(III) dichlorides and their behavior towards metal halides in various solvents.

Results and Discussion

Preparation of 2-Alkoxy-2-phenylethylthallium(III) Dichloride (1). It was found that the reaction shown below proceeds at the refluxing temperature of the solvent (Table 1).

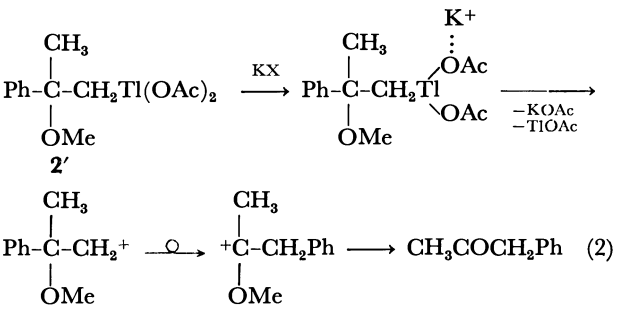
$$\underset{\text{OR}}{\overset{|}{\text{PhCHCH}_2\text{Tl(OAc)}_2}} \xrightarrow[\text{MeOH or MeCN}]{\text{KCl}} \underset{\text{OR}}{\overset{|}{\text{PhCHCH}_2\text{TlCl}_2}} \quad (1)$$

2 **1**

(R=Me, Et, *n*-Pr, *i*-Pr)

Isolation of **1** was carried out by evaporating the filtrate under reduced pressure and also by adding water to the filtrate. The former procedure gave a colorless tarry residue soluble in organic solvents such as methanol, DMSO and pyridine. The NMR spectrum of the residue showed the presence of monoalkylthallium(III) species other than **2** and dialkylthallium(III) species from several coupling constants J_{Tl-H} (Table 2). The latter procedure gave a white amorphous solid, sparingly soluble in almost all solvents, together with 10—15% of phenylacetaldehyde. Recrystallization of the solid from a large volume of acetonitrile gave **1** (Table 1). The difference in solubility of the tarry residue and **1** may be due to the difference in the mode of association.

It has been reported that the reaction of methyl thallium(III) diacetate with aqueous sodium chloride gives methyl chloride instead of the corresponding dichloride. The difference in behavior of methylthallium(III) diacetate and **2** to chloride ion can be ascribed to their difference in susceptibility to S_N2 reaction. Since **2** has a bulky $C_6H_5CH(OR)$-group on the carbon which bears Tl moiety, it seems that the attack of chloride anion from the rear to expel $Tl(OAc)_2$ is hindered profoundly. We therefore attempted to isolate a similar compound by the reaction of KCl with 2-methoxy-2-methyl-2-phenylethylthallium(III) diacetate (**2'**)[5] which has more bulky substituent than **2**. However, even in the reaction in MeCN at room temperature for 1 h, neither the corresponding alkylthallium(III) dichloride nor alkyl chloride was obtained, benzyl methyl ketone being produced instead in 83% yield. The ketone was also obtained in 85—95% yield with use of KBr, KI, or even KOAc in place of KCl, while almost all of **2'** was recovered (only 6% yield of ketone) under similar conditions without potassium salt. The results suggest that potassium cation prompts the decomposition of **2'** to a thallium(I) salt and an alkyl cation, the latter giving the ketone after phenyl migration (Scheme 2). The reason why phenyl migration is more prominent in the reaction of **2'** than in that of **2** might be explained by the difference in the steric crowding in **2'** and **2**. The thermal instability of **2'** as compared to **2** has been observed in many cases.[6]



Comparison of Reactivities of 1(R=Me) and 2(R=Me) under Various Conditions (Table 3). First, the stability of **1**(R=Me) was checked by heating **1**(R=Me) in acetonitrile, 1,4-dioxane, and methanol for 5 h for comparison with that of **2**(R=Me). In acetonitrile and methanol almost no decomposition occurred. In 1,4-dioxane the total yields of the decomposition products were only 20% as shown in Scheme 3, while **2**(R=Me) gave 40—80% yield of the decomposition products under the same conditions. The fact that **3**(X=Cl) and **5** were scarcely obtained suggests both S_Ni and S_N1 type reactions of **1** to be very slow. Second, in the reaction with potassium halide only a low yield of **3** was obtained, showing that S_N2 displacement of thallium moiety in **1** by halide anions is very slow. A considerable amount of α-methoxystyrene(**4**) was obtained in methanol especially in the reaction with KI or KBr, while **4** was not produced from **2** under the same conditions.[5] We confirmed that **3**(X=I or Br) is not the precursor of **4** under the reaction conditions. Although the details of this dehydrothallation reaction giving **4** are not yet

(3)

clear, such reaction is not common in organothallium compounds. So far it has been proposed only in the allylic oxidation of cyclohexene by $Tl(OAc)_3$ to explain the formation of 2-cyclohexenyl acetate.[7] The reaction of **1**(R=Me) with copper(I) salt was carried out. The yield of **3** was low except in the case of copper(I) bromide. Almost no reaction occurred with copper(I) cyanide and thiocyanate in contrast to the case of **2**(R=Me) from which **3** was obtained in a good yield by use of many kinds of copper(I) salts.[5] This also shows that **1**(R=Me) is less reactive than **2**(R=Me).

From all results on reactivities of **1** described above it can be concluded that **1** is less susceptible to S_N1, S_N2, and S_Ni reactions than **2**.

Experimental

The IR spectra were taken with Hitachi EPI-S2 and Perkin-Elmer 521 spectrometers in paraffin mull and KBr disks. The far-infrared spectra (400—30 cm^{-1}) were taken with a Hitachi FIS-3 spectrometer in paraffin mull or liquid film. The NMR spectra were recorded with Varian A-60 and EM-360 and JEOL MH-100 spectrometers in suitable solvents, using TMS as an internal standard. GLC analyses were carried out on a Shimadzu 5APTF apparatus, using Apiezon L(30%)-Celite(1 m) and PEG 6000(25%)-Chromosorb W (3 m) columns (N_2 as the carrier gas).

Materials. All the organic materials except **2**[5] and **2'**[5] were purified by distillation before use, while commercial inorganic materials were used without further purification.

	CD_3OD	755 (2.86)	932 (2.93)	671 (4.74)
OEt Ph-$CH_ACH_BH_CTl(OAc)_2$[c] **2**(R=Et)	d_6-DMSO	780 (2.67)	934 (2.88)	701 (4.52)
	CD_3OD	780 (2.93)	937 (3.06)	741 (4.69)
	$CDCl_3$[d]	768 (3.08)	921 (3.11)	737 (4.82)
OMe $(Ph-CH_ACH_BH_C)_2TlCl$[c]	$CDCl_3$	274 (2.50)	486 (2.69)	325—345 (4.85—4.95)

a) In the form of a colorless tarry residue. b) Similar J values were obtained in the cases of **1**(R=Me, *n*-Pr, and *i*-Pr). c) White amorphous solid, prepared by the method given in Ref. 5. d) Reported in Ref. 5.

Table 3. Reaction[a] of 1(R=Me) (1 mmol) with KX and CuX

KX or CuX (2 mmol)	Solvent (10 ml)	Products (yield,[b] %)		
		3	4	5
—	MeOH	1	1	2
—	MeCN	4	0	—
KCl	MeOH	1[c]	1	2
KCl	MeCN	4[c]	0	—
KBr	MeOH	7[d]	24	2
KBr	MeCN	6[d]	0	—
KI	MeOH	8[e]	44	0
KI	MeCN	11[e]	9	—
CuCl	MeCN	19[c]	0	—
CuBr	MeCN	51[f]	0	—
CuI	MeCN	20[g]	0	—

a) At reflux for 5 h. b) Based on the amount of **1**. c) X=Cl. d) X=Br. e) X=I. f) X=Br (43%) and X=Cl (8%). g) X=I (19%) and X=Cl (1%).

*Preparation of 2-Methoxy-2-phenylethylthallium(III) Dichloride (**1**, R=Me).* A white heterogeneous mixture of **2**(R=Me) (2.29 g, 5 mmol) and potassium chloride (2.38 g, 20 mmol) in acetonitrile (25 ml) was stirred under reflux** for 1 h (Table 1). The white precipitate (1.8 g) composed of a mixture of TlCl and KCl was filtered off. The filtrate was evaporated at 20 Torr leaving a colorless tarry residue (*ca.* 2.5 g), a part of which being used for NMR measurement. For isolation, 150 ml of ice-water was added to the filtrate, and a white voluminous solid formed was filtered and washed three times with small portions of ether (0.67 g, 33% yield). Recrystallization from 300 ml of acetonitrile afforded 0.43 g of a white amorphous solid (21% yield) of **1**(R=Me); mp 146—147 °C (dec.). IR; 1454 (m), 1100 (s), 765 (s), 700 (s), 640 (m), 420 (s), and 405 (sh) cm^{-1} (weak absorptions are not shown). The spectrum clearly shows the absence of absorptions due to ν_{CO_2} characteristic of **2**(R=Me)[5] and also that of strong absorptions at 162 and 100 cm^{-1} which bis(2-methoxy-2-phenylethyl)thallium(III) chloride has. The IR spectrum of the latter compound is as follows: 1450 (s), 1093 (s), 761 (s), 698 (s), 640 (m), 569 (m), 274 (m), 233 (m), 162 (s), and 100 (s) cm^{-1}.

** At room temperature the reaction was incomplete even after 5 h, the separation of **1**(R=Me) from the unreacted **2**(R=Me) being difficult.

GLC analysis of the organic layer after the usual work-up of the filtrate revealed the presence of 1.17 mmol of phenylacetaldehyde (23% yield), 0.09 mmol of methyl α-methylbenzyl ether (1.6%), and trace amounts of unidentified compounds.

*Preparation of **1**(R=Et, n-Pr, i-Pr, n-Bu, and i-Bu).* In the case of **1**(R=Et, *n*-Pr, and *i*-Pr), the white solid (*ca.* 1—1.5 g) obtained by the method described above was washed three times with methanol (10 ml×3) to remove water and some organic products, leaving crude **1**. Each compound (Table 1) was obtained by washing the crude product with 20 ml of MeOH and by evaporating the methanol washing. We could also isolate crude **1**(R=*n*-Bu and *i*-Bu) as a white solid by a similar treatment in 30—50% yield, but the analysis was unsatisfactory.

*Reaction of **1**(R=Me) with KI.* To a white suspension of **1**(R=Me) (0.82 g, 2 mmol) in methanol was added 0.67 g (4 mmol) of KI and the resulting yellow heterogeneous mixture was stirred under reflux for 5 h. After being cooled down to room temperature the mixture was filtered from the yellow precipitate(0.55 g; a mixture of **1**, KI, and thallous salts) and water(100 ml) was added to the filtrate which was extracted with benzene. GLC analysis of a part of the extract revealed the presence of α-methoxystyrene (**4**) (44%), **3**(X=I) (8%), styrene (5%), and methyl α-methylbenzyl ether (5%) (butyrophenone as an internal standard). Distillation gave 30 mg of almost pure **4**(bp 58—60 °C/22 Torr). The NMR and IR spectra and retention time in GLC of **4** was identical with those of an authentic sample prepared by the reported method.[8]

Oxidation of Acetaldehyde Catalyzed by Cobalt(II) Tetraphenylporphyrin

Meguru TEZUKA, Osamu SEKIGUCHI, Yasukazu OHKATSU, and Tetuo OSA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 7, 1975)

Cobalt(II) tetraphenylporphyrins catalyzed the autoxidation of acetaldehyde giving peracetic acid quantitatively. The *p*-substituents of phenyl groups of tetraphenylporphyrin influenced the catalytic activity, cobalt(II) tetra(*p*-methylphenyl)porphyrin being remarkably active. The effect of the base added into the reaction system was such that an appropriate quantity of the base gave rise to a maximum rate of oxidation. The rate equation was determined experimentally. From the results of kinetics and ESR study, it was concluded that an oxygen molecule activated through the electron transfer from a cobalt(II) ion abstracted the hydrogen of acetaldehyde to initiate the autoxidation.

So far, a number of studies have been made with regard to various porphyrins, especially from the viewpoint of a model compound of oxygen carrier in living system such as hemoglobin.[1]

On the other hand, as the model of heterogeneous catalysts, the thermostable and easily accessible tetraphenylporphyrins of phthalocyanines have been investigated,[2] since the compounds, where every metal ion is surrounded by the same ligand, are convenient for catalytic research of the metal ion. Cobalt(II) tetraphenylporphyryin (CoTPP) is well known to take up an oxygen molecule reversibly.[3] However, the reactivity of coordinated oxygen has been scarcely investigated. In the case of metal phthalocyanine or polyphthalocyanine, the low-valent metal ion activates oxygen molecule to catalyzed the autoxidation of cumene, acetaldehyde, and so on.[4] Therefore, it is expected that metal porphyrin behaves similarly because of the analogy of the structure of both compounds.

We have confirmed that an oxygen molecule activated to the superoxide through the electron transfer from CoTPP abstracts the hydrogen of acetaldehyde to initiate the auoxidation. The effect of the *p*-substituents of phenyl rings (Fig. 1) was examined and cobalt(II) tetra(*p*-methylphenyl)porphyrin [Co-(*p*-CH_3)-TPP] was found to be remarkably active. The effect of the base added into the reaction system was explained in terms of porphyrin-base complex from the ESR study.

Experimental

Synthesis of Catalysts. Tetraphenylporphyrin (H_2TPP) was prepared according to the method by Falk.[5] Pyrrole (0.8 mol) and benzaldehyde(0.8 mol) were refluxed in 3 l of propionic acid for one-half hour under nitrogen atmosphere. On being left to stand, H_2TPP was precipitated. The crystals were filtered, washed several times with methanol and then with hot water, and dried; yield, approximately 20%.

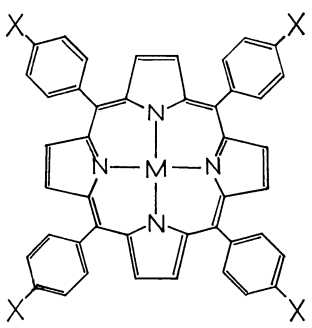

Fig. 1. Metal tetra(*p*-substituted phenyl)porphyrin.

Cobalt(II) tetraphenylporphyrin (CoTPP) was prepared according to the method by Rothemund and Menotti.[6] Five hundred mg of H_2TPP was refluxed in 50 ml of chloroform and 50 ml of glacial acetic acid saturated with cobalt(II) acetate for two hours, then 100 ml of methanol being added. The crude CoTPP precipitated on cooling was filtered, washed several times with methanol, and dried; yield, approximately 80%. The crude CoTPP prepared above was repeatedly treated with cobalt(II) acetate by a similar method except for the use of the CoTPP in place of H_2TPP to complete the complexation. The product was then subjected to the Soxhlet extraction with methanol, the unreacted materials being removed. Cobalt(II) tetra(*p*-methylphenyl)porphyrin [Co(*p*-CH_3)TPP], tetra(*p*-methoxyphenyl)prophyrin [Co(*p*-OCH_3)TPP], and tetra(*p*-chlorophenyl)porphyrin [Co(*p*-Cl)TPP] were also synthesized by the method described above from *p*-tolualdehyde, *p*-anisaldehyde, and *p*-chlorobenzaldehyde, respectively, in place of benzaldehyde as the starting material. The reagents used in the synthesis of catalysts had been purified by the ordinary methods.

Oxidation of Acetaldehyde. The oxidation of acetaldehyde was carried out in ethyl acetate at 10 °C using a closed oxygen-circulating system, similar to that described previously.[7] The reaction was started by the addition of a certain amount of acetaldehyde to the solution. The amount of oxygen absorbed during the course of the reaction was pursued by means of a gas burrete. Acetaldehyde was distilled under nitrogen atmosphere just before use. Ethyl acetate was purified by distillation. Pyridine and *N,N*-dimethylformamide as additive were also distilled under reduced pressure.

Analysis. All the peroxides in the liquid phase were estimated by an iodometric titration designed to determine the separate concentrations of hydrogen peroxide, peracetic acid and other peroxides.[8] Hydrogen peroxide was first estimated by charging 1 to 2 ml of an accurately weighed sample into an Erlenmeyer flask containing 150 ml of 5% sulfuric acid and sufficient cracked ice; the temperature of the mixed solution was maintained at 0 to 5 °C; titration was carried out with 0.1 N ceric sulfate until the salmon color of the ferroin indicator disappeared. The concentration of hydroperoxide in the feedstock of the solution obtained after oxidation was below 3×10^{-3} wt% in every experiment. To the resulting mixture was added 10 ml of a 10% potassium iodide solution, and the iodine liberated was titrated with 0.1 N sodium thiosulfate. Peracetic acid was thus estimated. The solution was then for 5 to 10 min, and the liberated iodine was titrated with sodium thiosulfate. The active oxygen in various peroxides other than hydrogen peroxide and peracetic

acid was thus estimated. From preliminary experiments, the titration was confirmed to be suitable. Peracetic acid could be completely analyzed at 0 to 5 °C, and any other peroxides which might be formed during the reaction were titrated in the last titration step. Neither separate quantification of acetaldehyde monoperacetate (AMP nor analysis of acids which might be formed) was made.

ESR Study. The ESR spectra of a solution of Co(*p*-CH_3)TPP in ethyl acetate were recorded at −196 °C with a JEOL Model JES-PE-IX spectrometer. The solution was prepared by the complete removal of dissolved oxygen according to the usual freeze-pump-thaw method. Oxygen or air was subsequently introduced little by little, when necessary, to get signals of the activated oxygen. The spectra were also measured in the presence of pyridine as an additive. The *g*-factors and coupling constants of the spectra were determined in comparison with those of Mn^{2+} marker.

Results and Discussion

In the absence of a catalyst, acetaldehyde was not oxidized within three hours at 10 °C. However, as shown in Fig. 2, the presence of CoTPP caused the absorption fairly soon, indicating the occurrence of the autoxidation of acetaldehyde. The *p*-substituents attached to the phenyl groups of porphyrin ring influenced the catalytic activity, the *p*-methyl group in particular making the corresponding porphyrin remarkably active. The activity of Co(*p*-CH_3)TPP was ten times as much as that of the other porphyrins. The order of activity was $-CH_3 \gg -CHO_3 > -Cl > -H$. This does not correspond to that of oxidation potentials of *p*-substituted porphyrins obtained by a cyclic voltammetric method.[9] This shows that the effect of the *p*-substituent cannot be explained only from the viewpoint of the electron-donating or attracting property of the substituent.

In the autoxidation, peracetic acid was obtained selectively and accumulated as the reaction proceeded. Hydrogen peroxide or any other peroxides could not be detected by titration (see Experimental). The mole ratio of peracetic acid formed to oxygen molecule absorbed remained constant *ca.* 0.8 in the course of the oxidation (Fig. 3). This suggests that Co(*p*-CH_3)-TPP has no ability to decompose peracetic acid sub-

stantially under the reaction conditions, in contrast to the fact that general transition metal salts and complexes can decompose peroxides heterolytically:

$$ROOH + M^{(n+1)+} \longrightarrow ROO\cdot + M^{n+} + H^{+} \quad (1)$$

$$ROOH + M^{n+} \longrightarrow RO\cdot + M^{(n+1)+} + OH^{-} \quad (2)$$

This also indicates that the initiation of autoxidation does not involve the formation of free radicals by the decomposition of peracetic acid.

The catalytic effect of Co(p-CH_3)TPP is deduced by kinetic consideration. The rate equation was (Table 1):

$$-d[O_2]/dt = k[CH_3CHO]^{1.5}[O_2]^{0.5}[Co(p\text{-}CH_3)TPP]^{0.5} \quad (3)$$

in which k was obtained as 2.8×10^{-2} $l^{3/2}$ $mol^{-3/2}$ s^{-1} over the range of concentration of acetaldehyde (0.5 to 1.25 M) and Co(p-CH_3)TPP (0.8 to 10 mM) and the partial pressure of oxygen (0.4 to 1.0atm) in the oxidation system.

For autoxidation under the conditions of fairly long chain-length and sufficient partial pressure of oxygen,

$$RH \longrightarrow R\cdot \qquad R_i \quad (4)$$

$$R\cdot + O_2 \longrightarrow RO_2\cdot \quad (5)$$

$$RO_2\cdot + RH \xrightarrow{k_p} ROOH + R\cdot \quad (6)$$

$$2RO_2 \xrightarrow{k_t} \text{non-radicals} \quad (7)$$

the rate equation is

$$-d[O_2]/dt = k_p k_t^{-1/2}[RH]R_i^{1/2} \quad (8)$$

in which RH, R_i, k_p, and k_t, represent acetaldehyde, the initiation rate, the propagation rate constant and the termination rate constant, respectively.[10]

Comparison of Eq. 3 with Eq. 8 leads to Eq. 9 as the expression of the initiation rate:

$$R_i = k_i[CH_3CHO][O_2][Co(p\text{-}CH_3)TPP] \quad (9)$$

where k_i denotes $k^2k_p^{-2}k_t$. As regards acetaldehyde, the constant k_p at 10 °C is approximately calculated to 3.6×10^3 l mol^{-1} s^{-1} from k_p at 0 °C (2.7×10^3 l mol^{-1} s^{-1})[11] and the activation energy of k_p (4.2 kcal/mol), which is assumed to be equal to that of n-decanal.[12] The constant k_t may be 1.04×10^8 l mol^{-1} s^{-1} which is reported for the value of k_t at 0 °C of acetaldehyde,[11] since the value can be considered to be almost independent on the temperature. Therefore, $k_pk_t^{-1/2}$ for acetaldehyde can be calculated to be 0.36 $l^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$ at 0 °C. As the concentration of oxygen dissolved in ethyl acetate at 10 °C and at atmospheric pressure is 1.15×10^{-2} mol l^{-1},[13] the constant k_i is calculated to be approximately 0.6×10^{-2} l^2 mol^{-2} s^{-1}. This value is slightly smaller than that of Fe or Fe, Co polyphthalocyanine catalyst but much smaller than that of Fe, Cu polyphthalocyanine catalyst.[14] We see from Table 1 that the chain of the autoxidation is long enough to satisfy Eq. 8.

Equation 9 suggests that the initiation mechanism can be described as follows:

$$Co^{2+}(p\text{-}CH_3)TPP + O_2 \rightleftharpoons [Co^{3+}(p\text{-}CH_3)TPP]\cdots O_2^{-} \quad (10)$$

$$[Co^{3+}(p\text{-}CH_3)TPP]\cdots O_2^{-} + CH_3CHO \longrightarrow [Co^{3+}(p\text{-}CH_3)TPP]\cdots O_2H^{-} + CH_2\dot{C}O \quad (11)$$

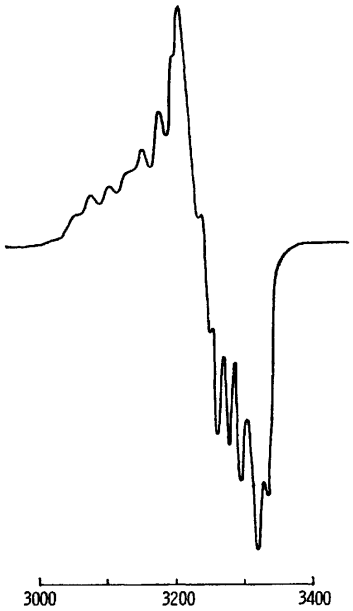

Fig. 4. ESR spectrum of Co(p-CH_3)TTP in ethyl acetate containing oxygen (*ca.* 0.02 atm.) at −196 °C. ν=9.262 GHz, field in gauss.

An evidence of the activation of oxygen molecule, namely, the formation of superoxide through the electron transfer, might be given by ESR study. In the absence of oxygen, Co(p-CH_3)TPP in ethyl acetate gave a complex pattern of lines at −196 °C. This could be attributed to the overlapping spectra of Co(p-CH_3)-TPP in ethyl acetate glass and the polycrystals due to the segregation of Co(p-CH_3)TPP.[15] After the contact with oxygen, a new type of singal appeared in addition to the original spectrum (Fig. 4). The new signal of the hyperfine splittings due to cobalt(II) was attributed to the superoxide formed through the electron transfer from the d_{z^2} orbital of cobalt to $2p\pi^*$ orbital of oxgen molecule according to the investigations relating to porphyrin–oxygen complex.[15-19] The electro-generated superoxide ion gave a similar spectrum except that it did not display the hyperfine lines.[20-22] These results seem to support firmly the step expressed in Eq. 10.

After the completion of the oxidation, the catalyst was recovered almost quantitatively and could be used with the same activity in the subsequent experiment as in the previous run. This suggests the regeneration of the catalyst as follows.

$$[Co^{3+}(p\text{-}CH_3)TPP]\cdots O_2H^{-} \longrightarrow Co^{2+}(p\text{-}CH_3)TPP + HO_2\cdot \quad (12)$$

The hydroperoxy radical can also abstract the hydrogen atom from acetaldehyde to initiate the oxidation forming hydrogen peroxide.

$$HO_2\cdot + CH_3CHO \longrightarrow CH_3\dot{C}O + H_2O_2 \quad (13)$$

Although no hydrogen peroxide could be detected by titration throughout this study, the step 13 may be another initiation reaction step in the autoxidation. In either case, it is concluded that an oxygen molecule activated by Co(p-CH_3)TPP can abstract the hydrogen of acetaldehyde. The hydroperoxy radical, in addition

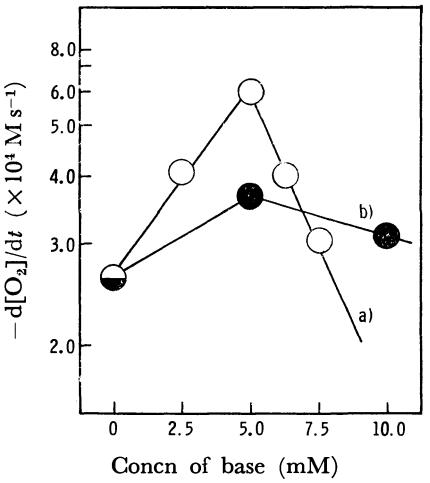

Fig. 5. Effect of base on oxidation of acetaldehyde by Co(*p*-CH_3)TPP catalyst in ethyl acetate at 10 °C. Acetaldehyde (1.0 M). Catalyst (5 mM). Base: a) pyridine, b) *N*,*N*-dimethylformamide.

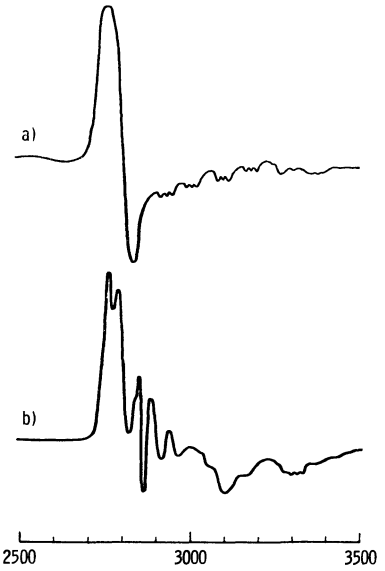

Fig. 6. ESR spectrum of Co(*p*-CH_3)TPP in ethyl acetate containing pyridine [a) 0.1, b) 5.0 vol %] at −196 °C. *ν*: a) 9.250, b) 9.238 GHz, field in gauss.

to reaction 13, may react with other free radicals to become inert compounds.

$$HO_2\cdot + R\dot{C}O \longrightarrow RCOO_2H \quad (14)$$

$$HO_2\cdot + RCOO_2\cdot \longrightarrow RCOO_2H + O_2 \quad (15)$$

Addition of a base such as pyridine or *N*,*N*-dimethylformamide into the reaction system influenced the rate of oxidation (Fig. 5). The rate increased with the addition of pyridine, becoming maximum at 5×10^{-3}M concentration. The maximum rate was about 2.5 times of that in the absence of the base. In contrast, further addition caused a decrease in the rate. A similar phenomenon was observed also with regard to *N*,*N*-dimethylformamide, although it was not so prominent as in the case of pyridine. A similar effect of the base was found in the study of polyphthalocyanine catalyst.

The effect of the base was also examined by ESR study. Figure 6 shows the spectra of Co(*p*-CH_3)TPP in ethyl acetate containing pyridine. At low concentration of pyridine (0.1 vol%), a spectrum was obtained which displayed superhyperfine splittings due to the interaction with one nitrogen (Fig. 6a). This indicates that the species present at this concentration of pyridine is a 1 : 1 complex, where pyridine coordinates to the cobalt(II) ion as a fifth ligand. The result given in Fig. 6b was obtained for higher concentration of pyridine (5 vol%). Although the spectrum lacks superhyperfine lines, it would be reasonably ascribed to a 2 : 1 pyridine–Co(*p*-CH_3)TPP complex, where pyridine occupies both the fifth and sixth coordination sites, as discussed in detail by Walker[15,17,19] in his study on Co(*p*-OCH_3)TPP–amine complex on toluene glass. After contact with oxygen, a spectrum similar to that in Fig. 4 was also obtained in the presence of pyridine, the amount of which was approximately such an amount as to produce the 1:1 complex. This may be attributed to the complex of Co(*p*-CH_3)TPP with one pyridine and one oxygen molecule as the fifth and sixth ligands, respectively. Therefore, from the result of ESR study, the effect of the base on the rate of oxidation (Fig. 5) could be explained by the concept that an appropriate amount of base would coordinate to the central cobalt(II) ion of the planar porphyrin molecule as a fifth ligand, facilitating the electron transfer from the cobalt(II) ion to the oxygen molecule as the sixth ligand. However, the excess base prevents the oxygen molecule from the coordination sites. The effect of the excess base, especially pyridine, is partly ascribed to the deactivation of the peroxy radical, namely the chain-carrier of autoxidation by the complex formation,[23] resulting in a decrease in the rate of oxidation.

From the results described above it would be most accepted that the catalyst activates an oxygen molecule to superoxide, which abstracts the labile hydrogen from acetaldehyde to initiate autoxidation.

We would like to express our thanks to Prof. Taiseki Kunugi for his valuable advice and discussion.

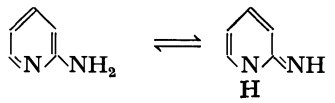
(Received September 19, 1975)

2-(*N*-Methylanilino) and 1-methyl-2-phenylimino derivatives of pyridine and quinoline were prepared as models for the amino and the imino tautomers of 2-anilino-pyridine and -quinoline. The ultraviolet, infrared and NMR spectra of these compounds were compared with those of the model compounds. The spectral data show that the amino tautomers are by far preferred in various solvents. The pK_a measurement on 1-methyl-2-phenylimino-1,2-dihydropyridine allows the assumption of the tautomeric equilibrium constant.

Tautomerism of aminopyridines has long been studied by several investigators, and earlier researches, mostly by chemical means, was summarized by Angyal *et al.*[1] 2-Aminopyridine is proved to exist as amino- (**1a**) by comparing its ultraviolet spectrum with those of 1-methyl-2-pyridoneimine and 2-dimethylaminopyridine,[2] and M. J. Cook *et al.*[3] have determined the tautomeric equilibrium constant between **1a** and **1b**.



(**1a**) (**1b**)

The infrared spectroscopic studies affirmed the above conclusion,[4,5] and the dipole moment[6] and mass spectrometric[7,8] investigations were also carried out. Molecular orbital calculations[9] have predicted that the amino tautomer is more stable than the imino one.

As to anilinopyrines Cook *et al.* have recently discussed their tautomeric behavior on the basis of the ultraviolet spectra.[10] On the other hand, Bell[11] and Rud'ko[12] measured the infrared spectra of a series of substituted 2-anilinopyridines and assumed the existence of the imino tautomers. The present authors have investigated on the splittings of the N–H stretching absorptions of 2-anilino-pyridines and -lepidines, and assigned them to the rotational isomers.[13] The possibility of the tautomeric equilibrium is rejected on the basis of the fact that 3-carboline, which can exist as tautomers but not as rotational isomers, show only a single symmetric N–H stretching band. The present report deals with the tautomerism of 2-anilinopyridine and related heterocycles by means of ultraviolet, proton magnetic resonance and molecular orbital theoretical approaches, and excludes the presence of the considerable amounts of the imino tautomers.

Experimental

Preparation of Materials. 2-Anilinopyridine and Its Methyl Derivatives: 2-Anilinopyridine (**2**) and 2-(*N*-methylanilino)-pyridine (**3**) are known substances, and prepared by the condensation of 2-chloropyridine with aniline or *N*-methylaniline according to the procedures reported previously.

1-Methyl-2-phenylimino-1,2-dihydropyridine (1-methylpyridone phenylimine) (**4**), the model of the imino tautomer, was prepared by the following procedure. In a sealed tube, 11.4 g of 2-chloropyridine and 28.4 g of methyl iodide were heated for 3 h at 130 °C to produce 2-iodo-1-methylpyridinium iodide. The product of this methylation procedure depends on the reaction temperature, and 2-chloro-1-methylpyridinium iodide is obtained when the reaction is run at room temperature for 24 h. The 2-chloro and 2-iodo methiodides were identified by the different chemical shifts (δ: 4.40 and 4.48, respectively) of *N*-methyl protons. The iodo-methiodide thus obtained was condensed with aniline by heating it with an excess of aniline for 1 h at 100 °C. The crude 1-methyl-2-anilinopyridinium iodide was recrystallized from chloroform. Brownish yellow needles with mp 175—178 °C (decomp.). Yield: 55%. The same iodide was obtained by reacting 2-anilinopyridine with methyl iodide.

The elimination of hydrogen iodide to produce the anhydrobase (**4**) was accomplished by reacting freshly prepared silver oxide. The crude anhydrobase was obtained almost quantitatively and then it was extracted with cyclohexane and recrystallized from hexane. Yellow prisms with mp 70.5 °C. Found: C, 78.50; H, 6.61; N, 15.31%. Calcd for $C_{12}H_{12}N_2$: C, 78.23; N, 6.57; N, 15.20%. MS, *m/e* 184 (parent peak).

2-Anilino-4-methylquinoline[16] *and Its Methyl Derivatives*: 2-(*N*-methylanilino)-4-methylquinoline (**6**) is a hitherto unknown substance and prepared by a similar procedure with 2-anilino-4-methylquinoline. A mixture containing 5.3 g of 2-chloro-4-methyl-quinoline, 3.9 g of *N*-methylaniline, 4.3 g of anhydrous potassium carbonate and a few drops of pyridine was heated for 4 h at 140 °C. The reaction mixture was digested with 50 ml of 30% aqueous K_2CO_3 solution. Then, the product was extracted with chloroform and distilled under reduced pressure. Recrystallization from hexane gave yellow prisms. Yield; 58% mp, 81 °C. Found: C, 81.95; H, 6.51; N, 11.52%. Calcd for $C_{17}H_{16}N_2$: C, 82.22;, H, 6.49; N, 11.28%. 1,4-Dimethyl-2-phenylimino-1,2-dihydroquinoline (1-methyl-2-lepidone phenylimine) (**7**) was prepared similarly to 1-methyl-2-phenylimino-1,2-dihydropyridine. The final product was recrystallized from hexane to give yellow prisms. Overall yield from 2-chloro-4-methylquinoline is 9.2%. Mp, 112 °C. Found: C, 82.43; H, 6.63; N, 11.35%. Calcd for $C_{17}H_{16}N_2$: C, 82.22; H, 6.49; N, 11.28%. MS, *m/e* 248 (parent peak).

Measurements of the Spectra. Ultraviolet spectra were measured with a Hitachi EPS-3T recording spectrophotometer in various solvents. The solvents were purified in the following way. Chloroform and carbon tetrachloride were carefully distilled immediately before use, and water was distilled at least twice. The others were commercially available spectrograde ones. NMR spectra were measured with a JEOL JNM C60-H high resolution spectrometer and,

when necessary, $Eu(fod)_3$ was used to separate the overlapping signals. Infrared spectra were obtained by employing a Hitachi Model 225 grating infrared spectrometer. Besides the usual 4000—400 cm^{-1} region spectra in potassium bromide pellets, the 1700—1600 cm^{-1} region ($\nu_{C=N}$ region) spectra were measured in various solvents of a wide range of polarity, including both protic and aprotic ones. Mass spectra were determined with a Hitachi RMU-6L mass spectrometer.

Results and Discussion

Ultraviolet Spectra and MO Calculations. The ultraviolet absorption maxima of 2-anilinopyridine, 2-anilino-4-methylquinone and their *N*-methyl derivatives are given in Table 1 and some typical spectra of them are illustrated in Fig. 1. As recognized at a glance of Fig. 1, the spectra of 2-anilinopyridine and

a) The lowest π-π^* transitions are given. b) Bonds in the carbocyclic ring of quinoline nucleus.

2-anilino-4-methylquinoline are similar to those of the corresponding 2-(*N*-methylanilino) derivatives and different considerably from those of the 1-methyl derivatives. This tendency is quite general when the spectra in aprotic solvents (given in Table 1) are compared. This suggests that 2-anilinopyridines (**2**) exist as amino tautomers at least in these solvents. Results of MO calculations on these tautomers are in accordance with the observations. In all cases, the amino structure is estimated to be more stable than the imino structure irrespective of the calculation methods.

The imino model compounds **4** and **7** possess intense bands at longer wavelengths. They are located at 372 and 383 nm, respectively in inert nonpolar solvents, and assigned to the π-π^* electronic transitions of the iminodiene chromophores from their intensities and locations. The imino tautomers are predicted to possess iminodiene characters judging from the bond alternation in the heterocyclic rings (as shown in the bond order values in Table 2). Considerable destablization of the imino tautomer might arise from

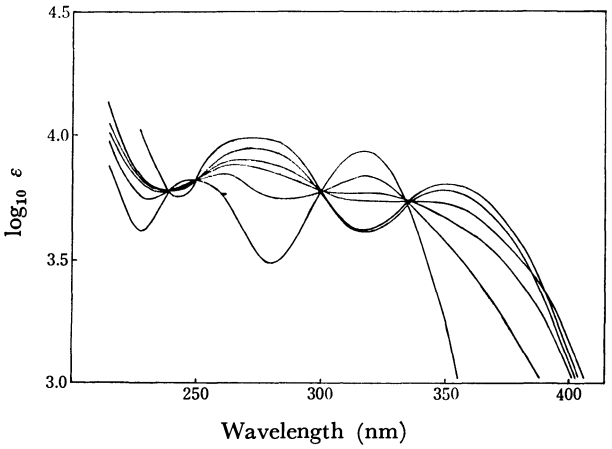

Fig. 2. The ultraviolet spectra of 1-methyl-2-phenyl-imino-1,2-dihydropyridine at various pH's.

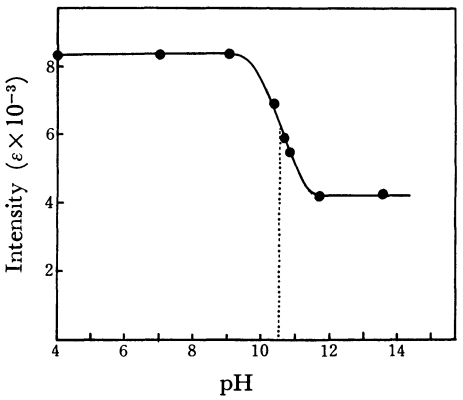

Fig. 3. The pH dependence of the intensity of the 318 nm-band of the anhydrobase (**4**).

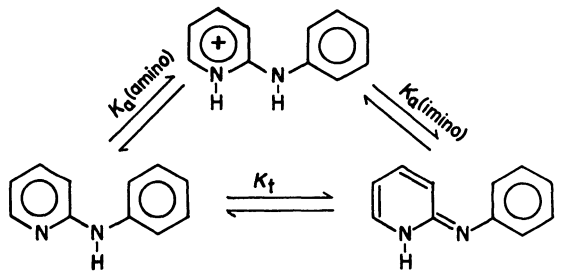
the loss of aromaticity in the heterocyclic ring. The lowest π-π^* transition from the destablized ground state to the "aromatic" excited state should shift to the longer wavelength, and this actually occurs in the spectra of the imino model compounds **4** and **7**.

The absorption patterns of 2-anilinopyridine and 2-anilino-4-methylquinoline are similar to those of the corresponding amino model compounds **3**, **6**, and rather insensitive to the nature of the solvent. However, the lowest π-π^* bands of the 1-methyl derivatives **4** and **7** shift towards longer wavelengths with increase in the polarity of the solvents. By far larger hypsochromic shifts are observed when protic solvents are used for the measurement of the former imino compound, and this is assumed to arise from its protonation in this solvents. The anhydrobase (**4**) is expected to be enough basic to capture the hydroxylic protons from the protic solvents (alcohols and water). Existence of the acid-baseq euilibrium is assertained by observing the isosbestic points at 335, 300, and 249 nm in its ultraviolet spectra measured at different pH's (shown in Fig. 2).

Then, the ionization constant, pK_a, of the anhydrobase (**4**) is determined from the pH dependence of the ultraviolet spectra. Thus, the intensity of the its 318 nm peak is plotted against pH, and pK_a of **4** is estimated to be 10.5 from the curve shown in Fig. 3. The tauto-

meric equilibrium constant between the amino and the imino forms of 2-anilinopyridine is estimated according to the scheme proposed by Angyal *et al.*[1] for the estimation of the pK_a of 2-aminopyridine.



(**2a**) (**2b**)

If the pK_a's of the both forms (**2a** and **2b**) are known, the tautomeric equilibrium constant K_t is easily obtained by the following equation.

$$K_t = \frac{[\mathbf{2a}]}{[\mathbf{2b}]} = \frac{K_a(\text{amino})}{K_a(\text{imino})}$$ [17]

Since the K_a values of the amino and the imino tautomers could not be determined separately by any means, those of the model compounds are used instead for the calculation of the tautomeric equilibrium constant. The K_a values of **3** (6.0×10^{-6}) is comparable to that of 2-anilinopyridine (1.4×10^{-6}) itself. Moreover, the effect of *N*-methyl substitution is not serious upon the pK_a values of pyridone and its thio analogs,[18-20] the above assumption might be permissible. The K_t is then calculated to be 2×10^5. As expected, the predominance of the amino form is again proved.

NMR Spectra. The NMR spectra of the heterocyclic ring protons of 2-anilinopyridine, 2-anilino-4-methylquinoline and their *N*-methyl derivatives are given in Table 3. The assignments of the signals are based on the comparison with those of analogous heterocycles and on their lanthanide induced shifts.

As described in the preceding part of this report, a considerable decrease in aromaticity is predicted to the heterocyclic part of the imino tautomer. Jackman *et al.*[21] have assumed the low field shift by the "ring current" of aromatic ring structure to be 1.55 ppm, and have estimated the aromaticity of pyridones. The ring current theory has been criticized by several authors.[22] However, the chemical shift serves doubtlessly as an index for aromaticity, since there exists a close relationship between aromaticity and diamagnetic susceptibility. The heterocyclic protons of the imino compounds **4** and **7** resonate at remarkably higher fields. The high field shift of 0.95 ppm (in average) in the 2-anilinopyridine series corresponds to 41% of aromaticity if evaluated by Jackman's method, and loss of aromaticity is again significant. In 2-anilino-4-methylquinoline series, the high field shift is about half of that in the 2-anilinopyridine series. The loss of aromaticity is considerably less. This is in accordance with the fact that the anhydrobase (**7**) of the anilinoquinoline series is a weaker base with lesser extent of bond alternation.

Table 3. The NMR spectra (δ ppm in $CDCl_3$)

Compound	H(3)	H(4) or CH_3	H(5)	H(6)	N-CH_3
(**2**)	7.25	7.44	6.65	8.14	—

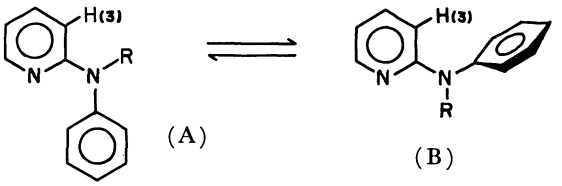
(**6**)	6.49	2.38	—	—	3.54
(**7**)	6.31	2.21	—	—	3.70

a) The H(4) signals of these compounds cannot be separated from the phenyl signals even when the shift reagent was added.

When compared with those of the parent anilino derivatives, the 3-H of the heterocyclic part resonates at a higher field in 2-(*N*-methylanilino) derivatives. As described in a previous paper of the present authors,[13] 2-anilinopyridines can exist either of the rotational isomers (A) or (B).



(A) (B)

In 2-anilino-pyridine and -4-methylquinoline, the rotamer (A) is somewhat more stable than the rotamer (B) probably because of the steric hindrance between the hydrogen atom at 3-position (3-H) and the phenyl. When the substituent R is methyl, the CH_3–H(3) interaction in conformer (A) prevent the planar arrangement of the heterocyclic ring and exocyclic nitrogen.[23] This enforces to take a twisted conformation about the exocyclic C_2–N bond which have larger double bond charactor than the N–Ph bond. On the other hand, the conformer (B) can still be coplanar by the sacrifice of the N–Ph coplanarity. Thus, the conformer (B) might become more favorable when the substituent on the anilino nitrogen is changed from hydrogen to methyl. In this conformation, the 3-H lies just above the phenyl ring and is subject to its diamagnetic effect which produce a high field shift.

Infrared Spectra. The tautomerism will affect profoundly the N–H stretching and the C=N stretching modes of vibration in the infrared region. The ν_{NH} spectra were discussed in the previous paper of the present authors.[13]

1-Methyl-2-pyridoneimine absorbs intensely at 1652 cm^{-1} and this band is assigned to the C=N stretching mode of vibration. 2-Anilinopyridine also has a weak absorption at 1650 cm^{-1} in the solid state, and Rud'ko *et al.* have concluded the existence of the imino tautomer. Thus, the spectra in the $\nu_{C=N}$ region are measured for a series of compounds investigated, and tabulated in Table 4. The absorption which appears at 1645 cm^{-1} is tentatively assigned to the C=N stretching mode; since it is very intense in the spectra of the imino model compound (**4**). As the solution spectra of 2-anilinopyridine shows no absorption in this region, this compound is supposed to take solely the amino form. However, since 2-anilinopyridinium salts have also the 1645 cm^{-1} bands (as shown in Table 4), the weak 1645 cm^{-1} band of 2-anilinopyridine in the solid state cannot necessarily related to the presence of

Table 4. The infrared spectra in the 1700 to 1600 cm^{-1} region

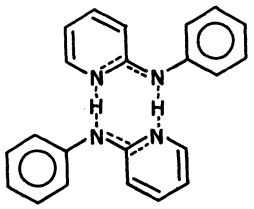
a small amount of the imino tautomer. At present, the participation of a strongly hydrogen bonded dimeric structure (**2d**) also explains the infrared spectra, rather more adequately, since a remarkably lower NH stretching frequency is observed in the solid spectra of (**2**).



(**2d**)

In conclusion, 2-anilinopyridine (**2**) and 2-anilino-4-methylquinoline (**5**) exist as the amino tautomers. In solutions, the tautomeric equilibria are so preferable to the amino tautomers that no indications to the coexistence of the imino tautomer is obtained. Tautomeric equilibria in solids are not thoroughly studied; however, it is evident that the amino tautomer is by far more predominant than the imino tautomer.

The authors are grateful to Professor Hiroshi Kakiuchi, Yokohama National University, for his valuable advice and encouragement throughout this work. They also wish to express their hearty thanks to Mrs. Shigeko Yoshida for NMR measurement and to Miss Hiroko Endo for measurement of mass spectra.

Carboxylation of Phenol Derivatives. XXII.[1] Formation of Alkali Alkyl Carbonate by the *O*-Carboxylation of Alcohol in the Presence of an Alkali Salt of a Weak Acid

Ichiro HIRAO, Taketoshi KITO, Takatomo FUNAMOTO, Taketoshi MURAKAMI, and Katsuyuki USAMI

Laboratory of Industrial Chemistry, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kitakyushu-shi 804

(Received October 30, 1975)

O-Carboxylation of the alcohol (ROH) occurred to give alkali alkyl carbonate in a good yield when carbon dioxide was introduced into the mixture of an alkali salt of a weak acid, alcohol, and acetone (or THF) at room temperature under atmospheric pressure. Such alkali salts as PhOM, *p*-R'C_6H_4OM (R'=CH_3, CH_3O, or Br), Et_2NCSSM, NaCN, and $C_6H_4(CO)_2NK$ (M=K or Na) were effective. The mixture of HOC_6H_4COOM and ROCOOM was obtained from the reaction using MOC_6H_4COOM as an alkali salt. However, the mixture was composed of equimolar amounts of *p*-HOC_6H_4COOM and ROCOOM when *p*-MOC_6H_4COOM was used. In this reaction, two mechanisms have been examined.

Alkali alkyl carbonates, which are known as carboxylating agents of alkali phenoxide, are usually prepared by the introduction of carbon dioxide into the alcohol solutions of alkoxides which are obtained from a metallic alkali and alcohol or by the removal of the formed water from alkali hydroxide and alcohol at an azeotrope with alcohol.[2]

It has been well known that hydroxybenzoic acids are formed when alkali phenoxide is heated under carbon dioxide pressure at a high temperature and, on the other hand, the complex is formed when alkali phenoxide is brought into contact with carbon dioxide at a low temperature. The latter reaction has been studied by many authors.[3]

During the investigation of the complex, we discovered a new reaction that forms alkali alkyl carbonates from alcohol and carbon dioxide in the presence of an alkali salt of a weak acid.

Results and Discussion

When carbon dioxide was introduced into the methanol solution of alkali phenoxide, precipitates of alkali methyl carbonate were formed in good yields. This reaction was further examined and generalized as Eq. 1: where, AM represents an alkali salt of a weak acid.

$$AM + ROH + CO_2 \rightarrow AH + ROCOOM \quad (1)$$

The results with many alklali salts of weak acids are summarized in Tables 1 and 2.

Potassium and sodium hydroxides cannot be used as alkali sources because the water formed in the reaction decomposes the alkali alkyl carbonates according to Eq. 2:

$$ROCOOM + H_2O \rightarrow ROH + MHCO_3 \quad (2)$$

Alkali salts of weak acids, such as the sodium salt of phenol, *p*-cersol, *p*-methoxyphenol, *p*-bromophenol, diethyldithiocarbamic acid, or hydrogen cyanide and the potassium salt of phenol, diethyldithiocarbamic acid, or phthalimide, are effective, while alkali salts such as the sodium salt of nitrous acid, thiocyanic acid, sulfurous acid (mono salt), or hydrogen sulfide (di- and mono-salts), and potassium thiocyanate are not. The pK_a's of most of the parent acids of the uneffective alkali salts are lower than 7.2. For example, the pK_a's of some parent acids (in water at 25 °C) are as follows:[4] thiocyanic acid, 0.85; sulfurous acid, pK_1=1.90, pK_2=7.20; nitrous acid, 3.29; hydrogen sulfide, pK_1=6.88, pK_2=14.15. Among the parent acids of effective alkali salts, the strongest acid, is *p*-bromophenol, whose pK_a at 25 °C is 9.24 (*cf.* hydrogen cyanide, 9.32; phthalimide, 9.90, phenol, 9.99. Although there is no data for the pK_a of diethyl dithiocarbamic acid, it may be a weaker acid than *p*-bromophenol). Therefore, it can be concluded that an alkali salt whose parent acid has a pK_a of more than about 9 will be effective.

In most reactions, acetone or tetrahydrofuran (THF) was used as a solvent. Alkali phenoxides dissolve considerably in methanol and ethanol, but these salts and other alkali salts are practically insoluble in other higher alcohols. In addition, potassium methyl carbonate dissolves to some extent in methanol at room temperature (see Table 4). Acetone and THF were good solvents for the sodium and potassium salts of phenol and *p*-substituted phenols.

The products prepared according to Eq. 1 were confirmed to be alkali alkyl carbonates by the elementary analyses and by the comparison of each IR spectrum with that of an authentic sample. However, the elementary analyses of the carbon and hydrogen atoms of the potassium alkyl carbonates, in most cases, did not accord with the calculated values within ± 1%, and are not listed in Table 2.

Introduction of carbon dioxide into a mixture of sodium phenoxide, isobutyl alcohol, and acetone, followed by the addition of an excess of methanol, gave fine crystallines. The main component of the crystallines was found to be sodium methyl carbonate. The reaction of Eq. 3 might occur after the reaction of Eq. 1, where

$$i\text{-}C_4H_9OCOONa + CH_3OH \rightarrow CH_3OCOONa + i\text{-}C_4H_9OH \quad (3)$$

AM, R, and AH are PhONa, i-C_4H_9, and PhOH, respectively. In addition, sodium benzyl carbonate and sodium dodecyl carbonate, which are prepared only with difficulty by the previous method, were

a) At least 0.06 mol of alcohol was used. b) The calcd values are shown in parentheses. The K% was evaluated by the titration of the $KHCO_3$ in the product with 1 M HCl ($ROCOOK + H_2O \rightarrow ROH + KHCO_3$). c) The IR spectra of these products were in good agreement with those of authentic ones. d) Potassium phthalimide. e) Although the K% deviated 2.24% from the calcd value, the IR spectrum was nearly identical with that of potassium methyl carbonate.

easily obtained by the present reaction.

Kwan and his co-workers reported that a carbon atom with an active hydrogen is carboxylated by carbon dioxide in *N,N*-dimethylformamide in the presence of potassium phenoxide.[5] However, the yields were less than 50%. In the present reaction an oxygen atom of alcohol is carboxylated to give alkali alkyl carbonate in good yield. As was mentioned already, not only alkali phenoxide but also many alkali salts of weak acids were available as alkali sources.

Two mechanisms for the present reaction, Eq. 1, can be considered. It is well known that alkali phenoxide forms a stable complex with carbon dioxide. We also reported that the complex is formed in good yield (about 80%) when the mixture of potassium phenoxide and light oil is stirred vigorously under a carbon dioxide atmosphere at room temperature for 30 min.[1] It will be reasonable to assume that the first product formed in the present reaction of Eq. 1, where AM is alkali phenoxide, is a complex, because alcohol does not react with carbon dioxide at room temperature. Two complexes ($PhOK \cdot CO_2$ and $PhONa \cdot CO_2$) were prepared from potassium phenoxide and sodium phenoxide plus carbon dioxide, and then methanol was added to each complex. Potassium methyl carbonate and sodium methyl carbonate were obtained in good yields (see the last columns of Tables 1 and 2). Therefore, the complexes may be considered as intermediates in the present reaction and this reaction process can be expressed by two equations, (4) and (5). In Eq. 5 the oxygen atom of the alcohol would attack the

$$AM + CO_2 \rightarrow AM \cdot CO_2 \quad (4)$$

$$AM \cdot CO_2 + ROH \rightarrow ROCOOM + AH \quad (5)$$

carbon atom of the carbon dioxide of the complex, and as a result, phenol and alkali alkyl carbonate would be formed.

The second mechanism can be formulated as Eqs. 6 and 7:

$$AM + ROH \rightleftharpoons AH + ROM \quad (6)$$

$$ROM + CO_2 \longrightarrow ROCOOM \quad (7)$$

Equation 6 is equlibrium state, while Eq. 7 is substantially irreversible at room temperature.

It was reported that methyl ω-methoxyalkanoate was formed at high temperatures from the reaction shown in Eq. 8.[6] Also when a mixture of sodium phenoxide (0.1 mol), benzyl chloride (0.1 mol), and

$$p\text{-}CH_3OOCC_6H_4ONa + Cl(CH_2)_nCOOCH_3 \xrightarrow{\text{in MeOH}} p\text{-}CH_3OOCC_6H_4O(CH_2)_nCOOCH_3 + NaCl \quad (8)$$

methanol (100 ml) was refluxed for 2 h, benzyl methyl ether was obtained in 12% yield. These two facts support the assertion that at high temperature a considerable amount of sodium methoxide is formed by the equilibrium shown in Eq. 9, although both methyl

$$p\text{-}RC_6H_4ONa + CH_3OH \rightleftarrows p\text{-}RC_6H_4OH + CH_3ONa \quad (R=H \text{ or } CH_3OOC\text{-}) \quad (9)$$

p-hydroxybenzoic acid ($pK_a=8.47$ at 25 °C) and phenol ($pK_a=10.0$ at 25 °C) are considerably stronger acids than methanol ($pK_a=15.5$ at 25 °C).[7] However, at room temperature, where the present reactions were carried out, the equilibrium will lie further to the left if we consider the pK_a values. Therefore, the second mechanism may be less important than the first one. Alkali alkyl carbonate will be formed mainly by the first mechanism.

The mixture of sodium cyanide or sodium diethyldithiocarbamate and cyclohexane was stirred under a carbon dioxide atmosphere; the insoluble product was filtered. After the carbon dioxide had been replaced by nitrogen, methanol and acetone (solvent) were added into the product, but sodium methyl carbonate was not obtained. However, we noticed that these alkali salts absorbed carbon dioxide under atmospheric pressure. The difference between alkali phenoxides and other alkali salts may be as follows: although alkali phenoxide can form a stable complex with carbon dioxide,[1] the other salts can not form such stable complexes. However, when an alcohol exists, the oxygen atom of the alcohol would attack the positively charged carbon atom of the carbonyl group of the complex and give alkali alkyl carbonate.

The difference of the reactivity toward sodium phenoxide in acetone between butyl alcohol and isobutyl alcohol was examined. The butyl alcohol reacted about 30 times faster than the isobutyl alcohol and 40 times faster than *s*-butyl alcohol. The oxygen atom of the branched alcohol must have difficulty in approaching the carbon atom of the carbonyl group of the complex. Therefore, the large differences of the reactivity between butyl alcohol and the branched alcohols (*i*-C_4H_9OH and *s*-C_4H_9OH), and between isobutyl alcohol and *s*-butyl alcohol are attributed to the steric hindrance of the branched alcohol. The electronic effect of the alkyl group of alcohol would scarcely influence its reactivity because the difference of the electronic effect between the three alkyl groups, especially between the butyl and isobutyl groups, will be small.

Both di-alkali salts of salicylic acid and *p*-hydroxybenzoic acid may be employed as an alkali source. These results are summarized in Table 3. It was found that the content of *p*-hydroxybenzoic acid in each precipitate was in good agreement with the value calculated on the assumption that the precipitate is composed of equimolar amounts of mono-potassium salt or mono-sodium salt of *p*-hydroxybenzoic acid and potassium methyl carbonate or sodium methyl carbonate respectively, when the di-potassium salt or the di-sodium salt of *p*-hydroxybenzoic acid is used as an alkali source. However, the content of salicylic acid in each precipitate deviated significantly from the calculated value and, moreover, differed in every run when *p*-hydroxybenzoic acid was replaced with salicylic acid.

Alkali salts of *p*-hydroxybenzoic acid and salicylic acid can be well dissolved in methanol, but the solubility of sodium methyl carbonate is poor, only 1.0 g in 50 ml of methanol (see Table 4).

The results summarized in Table 3 can be explained as follows: when carbon dioxide is introduced into the methanol solution of the di-potassium salt of *p*-hydroxybenzoic acid, potassium methyl carbonate and potassium *p*-hydroxybenzoate are formed. Further introduction

Table 3. Reactions using di-alkali salts of POB or SA[a]

Alkali salt[b] (g)		ppt (g)	POB or SA (wt%)[c] in product	pptd	Analyses (%)[d] C	H
POB di-K	4.94	2.75	51.9	(47.6)	—	—
POB di-K	5.07	2.78	52.0	(47.6)	—	—
POB di-Na	5.00	4.44	54.2	(53.5)	40.67	3.61
POB di-Na	2.89	3.27	55.8	(53.5)	40.74	3.37
SA di-K	6.50	0.37	76.1	(47.6)	—	—
SA di-Na	6.12	2.12	38.5	(53.5)	41.34	3.02

a) POB=*p*-Hydroxybenzoic acid, SA=Salicylic acid; di-K=di-potassium salt, di-Na=di-sodium salt. b) These salts are dissolved in 50 ml of methanol. c) The values in parentheses were calculated on the assumption that the precipitates were composed of equal molar amounts of mono-alkali salt of POB or SA and alkali methyl carbonate. For example, [POB(Mw. 138.1)]×100/[POB mono-K(Mw. 176.2)+CH_3OCOOK (Mw. 114.1)]=47.6(%). The determination of POB or SA was carried out by the UV technique. d) Calcd for (POB or SA mono-Na+$CH_3OCOONa$): C, 41.88%; H, 3.12%.

Table 4. Solubilities of alkali salts in methanol

Alkali salt[a]	Solubility[b] (g)	Alkali salt	Solubility (g)
POB di-K	12.0	POB di-Na	9.7
POB mono-K	10.0	POB mono-Na	5.0
SA di-K	6.5	SA di-Na	4.7
SA mono-K	7.0	SA mono-Na	10.5
CH_3OCOOK	9.5	$CH_3OCOONa$	1.0

a) See Table 3. b) Solubilities are defined as the amounts which dissolved easily in 50 ml of methanol at room temperature.

of carbon dioxide gives the complex composed of potassium *p*-hydroxybenzoate, carbon dioxide, and potassium methyl carbonate and the complex precipitates. However, carbon dioxide may escape from the complex during drying *in vacuo* after filtration. A similar explanation can be applied to the reaction using the di-sodium salt of *p*-hydroxybenzoic acid as an alkali source. There are other facts which support the above idea. When the methanol solutions of potassium *p*-hydroxybenzoate and of potassium methyl carbonate or the same solutions of sodium *p*-hydroxybenzoate and of sodium methyl carbonate were mixed, no precipitates were formed in either case. However, when carbon dioxide was introduced into each solution, precipitates were formed immediately from both.

The difference of the reactivity between the di-alkali salts of salicylic acid and of *p*-hydroxybenzoic acid was also observed in the Williamson ether syntheses. In the Williamson ether syntheses of the di-alkali salt of salicylic acid or *p*-hydroxybenzoic acid and benzylchloride in methanol at reflux temperature for 2 h, methyl benzyl ether was formed. Although di-alkali salts of *p*-hydroxybenzoic acid gave methyl benzyl ether only in about 4% yield, di-potassium and di-sodium salts of salicylic acid gave the same product in 67 and 47% yields, respectively. In addition, when the di-potassium salt of salicylic acid was recrystalized from methanol, the precipitate was the mono-potassium salt of salicylic acid (potassium salicylate). On the basis of these data, it was speculated that the di-potassium salt of salicylic acid easily changes into potassium salicylate. The reason may be due to the chelating structure of the salicylate; that is, the alkali atom of mono-alkali salicylate will be considerably neutralized and therefore the bonding force between the alkali atom of mono-alkali salicylate and the oxygen atom of carbon dioxide must be extremely weak.

Experimental

Authentic Alkali Alkyl Carbonate. Metallic potassium or sodium was dissolved in anhydrous alcohol and then carbon dioxide was introduced with vigorous stirring. From this mixture, excess alcohol was evaporated off at about 100 °C *in vacuo*.

Syntheses of Alkali Alkyl Carbonates by the Present Reaction. A typical example is as follows. Into a 200 ml four-necked flask, provided with a mechanical stirrer, a thermometer, and a gas-inlet tube whose top was connected to a calcium chloride tube, were placed sodium phenoxide (3.48 g, 0.03 mol), anhydrous methanol (3 ml), and anhydrous acetone (50 ml, as a solvent of sodium phenoxide). A sufficient volume of dry carbon dioxide was slowly introduced into the stirred acetone solution and white precipitates soon formed. These precipitates were collected on a glass filter, washed with dry ether, and then dried in *vacuo* at room temperature: yield, 98.0%.

In the preparations of the branched alkyl alkali carbonates, the mixture became a slurry when carbon dioxide was introduced into the mixture of sodium phenoxide, alcohol, and solvent (acetone or THF). Therefore, these carbonates might partially decompose into alcohol and sodium hydrogen carbonate by contact with the moisture in the air, since rapid filtration was very difficult. Another possibility is that these carbonates contain some amounts of solvent, because of the difficulty of the complete evaporation of the solvent from these carbonates in a slurry-state. Owing to the above reasons, the values of the elementary analyses of the branched alkyl alkali carbonates would deviate more than 1% from the calculated values.

Competitive Reactions. Carbon dioxide was introduced into a mixture of isobutyl alcohol (0.10 mol), butyl alcohol (0.10 mol) and sodium phenoxide (0.021 mol) in acetone (100 ml); the precipitates were filtered, washed with ether, and then decomposed with water into alcohols and sodium hydrogen carbonate. The resulting alcohol were extracted with ether, and butyl alcohol and isobutyl alcohol were determined by gas chromatography (internal standard compound, cyclohexane; instrument, Yanagimoto G80; column, PEG 20 M, 2.25 m; temp, 98 °C). The ratio of butyl alcohol/isobutyl alcohol was 33.

Similarly, the reaction was carried out using the mixture of *s*-butyl alcohol (0.10 mol), butyl alcohol (0.10 mol), sodium phenoxide (0.021 mol), and acetone (100 ml); the alcohols derived from sodium butyl carbonates were determined by gas chromatography (column temp, 90 °C). The ratio of butyl alcohol/*s*-butyl alcohol was 41.

Reactions using Di-alkali Salts of Hydroxybenzoic Acids as Alkali Sources. An example is as follows. Five grams of di-sodium salt of *p*-hydroxybenzoic acid were dissolved in 50 ml

of anhydrous methanol; into this mixture dry carbon dioxide was introduced. Within several minutes, white precipitates formed. After 30 min, the precipitates were filtered and dried *in vacuo* at room temperature: yield was 4.44 g. When di-potassium salt of salicylic acid was used, the formation of the precipitates was slower. Generally speaking, the readiness of the formation of the precipitates decreased in the following order: di-sodium salt of *p*-hydroxybenzoic acid>di-sodium salt of salicylic acid>di-potassium salt of *p*-hydroxybenzoic acid>di-potassium salt of salicylic acid.

The Formation of the Complex from Mono-alkali Salt of p-*Hydroxybenzoic Acid, Potassium Methyl Carbonate, and Carbon Dioxide.* Into a four-necked flask with a mechanical stirrer, 10.27 g of monopotassium salt of *p*-hydroxybenzoic acid and 50 ml of methanol were placed, and into this mixture carbon dioxide was introduced. The precipitates (perhaps mono-potassium salt of *p*-hydroxybenzoic acid) were filtered off. To the filtrate, a solution of 7.55 g of potassium methyl carbonate in 60 ml of methanol was added and then carbon dioxide was introduced. The precipitates were filtered and dried *in vacuo*: yield was 5.61 g. The content of *p*-hydroxybenzoic acid was 50.9% (determined by UV technique[2]). This value was in good agreement with the calculated one (47.6%, see Table 3), within experimental error. Therefore, this product must be composed of nearly equimolar amounts of mono-potassium salt of *p*-hydroxybenzoic acid and potassium methyl carbonate.

A similar reaction was carried out using sodium *p*-hydroxybenzoate and sodium methyl carbonate. The resulting content of *p*-hydroxybenzoic acid was 50.3%. This value is also in good agreement with the calculated one (53.5%, see Table 3), within experimental error.

Reactions of Alkali Salts with Benzyl Chloride. Into a 200 ml three-necked flask, with a mechanical stirrer and a reflux condenser whose top was connected to a calcium chloride tube, were placed 9.10 g of di-sodium salt of salicylic acid (0.05 mol), 6.35 g of benzyl chloride (0.05 mol), and 100 ml of methanol. The mixture was refluxed with vigorous stirring for 2 h. The volume of the solution was reduced to about half by evaporation of the methanol. The insoluble product was filtered off and then methyl benzyl ether was determined by gas chromatography (internal standard compound, dimethylaniline; column, PEG 20 M, 2.25 m; temp, 200 °C).

Thanks are due to Mr. Kazumi Hirakawa and Mr. Junji Anai for their assistance in the experimental work.

The Reactions of Sodium Diethyldithiocarbamate and Tetraethylthiuram Disulfide with Mercury(II) Chloride[1)]

Norio KOBAYASHI and Tamotsu FUJISAWA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received December 17, 1975)

Sodium diethyldithiocarbamate (**1**) and tetraethylthiuram disulfide (**2**) have been found to react with excess mercury(II) chloride ($HgCl_2$) in water to give complexes with the general formula $Et_2NCS_2HgS_2CNEt_2 \cdot (HgCl_2)_{m-1}$, where the m value can be as high as five. The complex with $m=2$ was isolated and characterized. The reaction pathway was discussed in some detail. Also studied were the reactions of **2** with $HgCl_2$ in organic solvents.

While the strong metal-binding properties of dithiocarbamates, notably sodium diethyldithiocarbamate (**1**), are well recognized,[2)] the previous investigations of the interaction of dithiocarbamates with mercury compounds have been made almost exclusively from the viewpoints of analytical chemistry. The simple question of what amount of mercury salt can react with dithiocarbamates has been left unanswered. During the course of an investigation on the sulfur-containing polymers, it became highly desirable to determine the complex-forming ability of dithiocarbamates and their derivatives with mercury. Accordingly, we have studied the reaction of **1** with mercury(II) chloride ($HgCl_2$). It was found that the reaction proceeds according to Eq. 1, and that the m value

$$2Et_2NC(=S)SNa + mHgCl_2 \xrightarrow{-2NaCl} \underset{\mathbf{1}}{} Et_2NC(=S)SHgSC(=S)NEt_2 \cdot (HgCl_2)_{m-1} \quad (1)$$

in Eq. 1 can be as high as five. Tetraethylthiuram disulfide (**2**), an oxidation product of **1**, has also been found to react with $HgCl_2$ in a smilar manner.

Results and Discussion

Reaction of 1 with $HgCl_2$ The reaction of **1** with $HgCl_2$ was carried out in water for 22 h at room temperature. The solid product was filtered, washed with water, and then dried. The results are summarized in Table 1. As can be seen, the yields and the mercury contents of the products increased with an increase in the amount of $HgCl_2$ used. The IR spectra of the products varied depending on the mercury content, especially in the C–N partial double bond region (around 1500 cm^{-1}) (Fig. 1). In the case of the products with high mercury content, new bands appeared at 460, 1610, 3500, and 3560 cm^{-1} (Fig. 1c and 1d). The first band is characteristic of $HgCl_2$, thus indicating the presence of weakly bonded $HgCl_2$. No reasonable explanation could be given for the second band. The last two bands seem to be similar in nature to those observed for some tertiary amide–$HgCl_2$ complexes.[3)] The FIR spectra of these products showed two strong band at 300 and 345 cm^{-1}.

The product of the 1 : 0.5 reaction was a light yellow crystalline solid; its IR spectrum (Fig. 1a) was very close to that of bis(diethyldithiocarbamato)mercury (**3**). Recrystallization of the product from acetonitrile gave **3** in 85% yield.

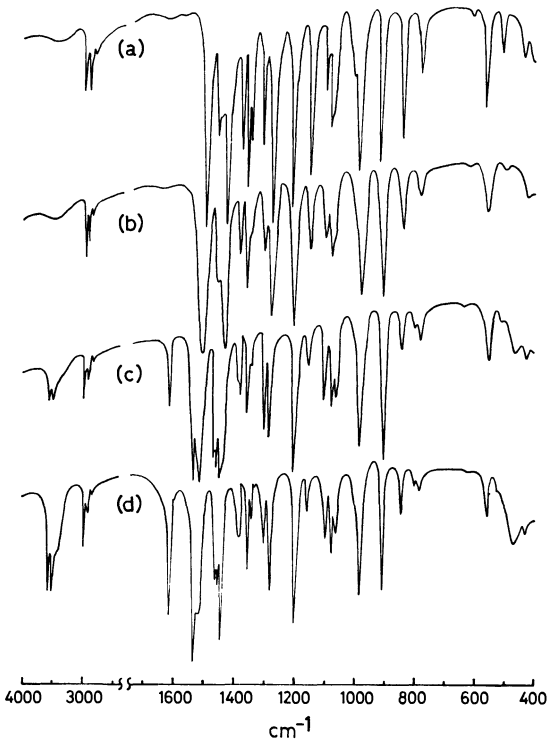

Fig. 1. The IR spectra of the mercury complexes formed in the reaction of **1** with $HgCl_2$ in water (KBr disks). **1**/$HgCl_2$; (a) 1: 0.5, (b) 1 : 1, (c) 1 : 2, and (d) 1 : 3.

The product of the 1 : 1 reaction was a faintly yellow solid and gave dichlorobis(diethyldithiocarbamato)-dimercury(II) (**4**) in 85% yield as colorless rod-like crystals on recrystallization from acetonitrile–acetone (4 : 1) below 60 °C. The confirmation of the structural formula of **4** was obtained by elemental analysis, IR, FIR, and NMR spectra, and independent synthesis; **4** was synthesized in high yields by the reaction of **3** with a stoichiometric quantity of $HgCl_2$ in acetone. It should be noted that **4** is a new type of stable mercury complex. The IR spectrum resembles that of dichlorotetrakis(diethyldithiocarbamato)trimercury(II), $Hg_3Cl_2(S_2CNEt_2)_4$.[4)] However, there are distinct differences in elemental composition and thermal properties between these two complexes.[5)]

All the other reaction products were white solids. Attempts to purify them were unsuccessful, because they were relatively unstable toward organic solvents;[6)]

recrystallization from acetone lowered the mercury content, and repeated recrystallization resulted in the formation of **4**. The products of the 1 : 2.5 and 1 : 3 reaction had essentially the elemental analyses for $Et_2NCS_2HgS_2CNEt_2\cdot(HgCl_2)_3$ and $Et_2NCS_2HgS_2CNEt_2\cdot(HgCl_2)_4$, respectively.

From these findings, the following pathway for the reaction of **1** with $HgCl_2$ may be assumed. The initial step involves the condensation reaction giving rise

$$\underset{\mathbf{1}}{2Et_2NCSNa_2} + HgCl_2 \xrightarrow{-2NaCl} \underset{\mathbf{3}}{Et_2NCSHgSCNEt_2} \quad (2)$$

$$\mathbf{3} + HgCl_2 \longrightarrow \underset{\mathbf{4}}{Et_2NCSHgSCNEt_2\cdot HgCl_2} \quad (3)$$

$$\mathbf{4} + nHgCl_2 \longrightarrow Et_2NCSHgSCNEt_2\cdot(HgCl_2)_{n+1} \quad (4)$$

to **3**. Addition of another molecule of $HgCl_2$ to **3** gives a stable complex **4**. Further addition of $HgCl_2$ to **4** yields relatively unstable complexes with higher mercury contents. The net reaction is represented by Eq. 1. On the basis of the above assumptions the number of mercury atoms per diethyldithiocarbamate residue (DEDC), Hg/DEDC, in the product complex was calculated from the yield. The Hg/DEDC values were also calculated from the analytical values of carbon and mercury. In Fig. 2, Hg/DEDC in the product is plotted against the reactant ratio, $HgCl_2$/**1**. The Hg/DEDC values obtained from the yield are in

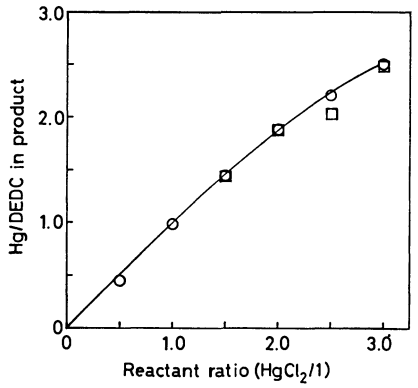

Fig. 2. Influence of reactant ratio on Hg/DEDC in product: ○ based on yield, □ based on analysis.

TABLE 4. REACTION OF 2 WITH $HgCl_2$ IN BENZENE–ETHANOL[a)]

$HgCl_2$ (g)	2/$HgCl_2$	Benzene (ml)	Ethanol (ml)	Yield (g)	Mp (°C)
2.71	1 : 1	50	70	2.64	133—138
5.42	1 : 2	50	70	7.94	134—137
8.13	1 : 3	50	70	8.26	132—135
10.80	1 : 4	70	100	8.30	134—137
13.55	1 : 5	70	100	8.28	131—133

a) Reaction conditions: **2** 2.96 g, stirring for 30 min at room temperature.

fair agreement with those obtained from the results of elemental analysis. Figure 2 also shows that the reaction proceeds almost quantitatively in the region $HgCl_2/\mathbf{1} < 1.5$, and that **1** can react with more than 2.5-mol of $HgCl_2$, that is, the *m* value in Eq. 1 can be as high as five.

Further support for these assumptions is the fact that the reaction of $HgCl_2$ with **3**, in place of **1**, proceeds in a similar manner to give the same mercury complexes as above (Table 2).

Reaction of 2 with $HgCl_2$ Since tetraethylthiuram disulfide (**2**) is practically insoluble in water, the reaction of **2** with $HgCl_2$ in water requires more than 50 h for completion.[7)] Thus the reaction was conducted by stirring a mixture of $HgCl_2$ and **2** in water for 90 h at room temperature. The results are summarized in Table 3. The yields and the mercury contents of the products increased with an increase in the amount of $HgCl_2$ used. It is clear that **2** can react with more than 4 mol of $HgCl_2$.[8)] The $\nu_{C=N}$ band shifted to a higher wavelength with mercury content. In addition, the products with higher mercury contents gave new bands at 1610, 3500, and 3560 cm^{-1}. This tendency is the same as that observed in the reaction of **1** with $HgCl_2$. It therefore seems reasonable to conclude that the reaction of $HgCl_2$ with **2** proceeds like the reaction with **1**, except that the first step is the insertion reaction of mercury into the S–S bond of **2**, as evidenced by the isolation of **3** from the 1 : 1 reaction product.

$$\underset{\mathbf{2}}{Et_2NC(=S)SSC(=S)NEt_2} + HgCl_2 \xrightarrow{-Cl_2} \underset{\mathbf{3}}{Et_2NC(=S)SHgSC(=S)NEt_2} \quad (5)$$

This type of reaction has been reported for several heavy metals, including mercury.[9–13)]

The literature contains some reports on the mercury complexes of thiuram disulfides, which were prepared in organic media and have elemental compositions that can not be explained by the reaction pathway described above.[14,15)] So the reaction of $HgCl_2$ with **2** was studied in several organic solvents.

A solution of **2** in benzene was added to a stirred solution of $HgCl_2$ in ethanol,[16)] and the mixture was stirred for 30 min. The precipitate was filtered, washed with ethanol, and dried. Table 4 lists the results of the reaction. Interestingly, all the products were essentially identical in physical appearance, thermal properties, and IR spectra. The IR spectra were characterized by a prominent band of $\nu_{C=N}$ at 1530 cm^{-1}. The results of the elemental analysis indicated the incorporation of about 2 atoms of mercury per molecule of **2**.

Table 5 summarizes the results of the reaction in acetone and ethanol. The 1 : 1 reaction in acetone gave the same product as that obtained in benzene–ethanol. On the other hand, an undertemined oily material was formed in ethanol. In both solvents, the use of excess $HgCl_2$ afforded products which resembled those obtained in water judging from IR spectra.

Conclusion. The reaction of **1** with $HgCl_2$ in water proceeds according to Eq. 1. The first step of the reaction is the formation of **3**, which can react with other molecules of $HgCl_2$ to give **4** and complexes with higher mercury content. The **4** complex is stable and it can be purified by recrystallization. The reaction of **2** with $HgCl_2$ proceeds in a similar manner. It is, however, to be emphasized that this is true only in water; the reaction is greatly affected by the solvent or solvent system used. These findings may be helpful in the design of heavy-metal adsorbing resins.

Experimental

Instrumentation. The following instruments were used in this study: a Hitachi EPI-G3 grating infrared spectrophotometer, a Hitachi FIS-3 far-infrared spectrophotometer, a Varian T-60 NMR spectrometer, a Perkin-Elmer DSC-2 differential scanning calorimeter, and a Yanaco micro melting point apparatus.

Materials. Sodium diethyldithiocarbamate (**1**) was prepared as trihydrate by the reaction of diethylamine with carbon disulfide in the presence of sodium hydroxide. Commercial tetraethylthiuram disulfide (**2**) was recrystallized from ethanol. $HgCl_2$ (Kanto Kagaku guaranteed reagent) was used as received.

Reaction of 1 with $HgCl_2$. The reaction of **1** with $HgCl_2$ was carried out in water. The results are summarized in Table 1. The following is an example of the general procedure. A mixture of 2.25 g of **1** (as trihydrate), a prescribed amount of $HgCl_2$, and 80 ml of water was stirred

a) For solid product precipitated during the reaction. b) Mp 128—132 °C. c) A distinct mp was not observed. d) An oily yellow material was formed.

magnetically for 22 h at room temperature. The solid was filtered off, washed thoroughly with water, and then dried at room temperature under a vacuum.

The 1 : 0.5 reaction product was recrystallized from acetonitrile to give **3** as a yellow crystal in 85% yield; mp 139—141 °C (lit,[13] mp 138—139 °C).

IR (KBr disk): 1500 cm^{-1} ($\nu_{C=N}$).

NMR ($CDCl_3$): δ 1.33 (t, J=7 Hz, 12H), 3.84 (q, J=7 Hz, 8H).

Found: C, 24.32; H, 4.19; Hg, 39.98%. Calcd for $C_{10}H_{20}N_2S_4Hg$: C, 24.16; H, 4.06; Hg, 40.35%.

The 1 : 1 reaction product was recrystallized from acetonitrile–acetone (4 : 1) below 60 °C to give **4** as a colorless rod in 85% yield: mp 105—107 °C.

IR (KBr disk): 1510 cm^{-1} ($\nu_{C=N}$).

FIR (Nujol mull): 334 cm^{-1} (ν_{Hg-Cl}).

NMR (d_6-acetone): δ 1.34 (t, J=7 Hz, 12H), 3.85 (q, J=7 Hz, 8H).

Found: C, 15.66; H, 2.68; S, 16.70; Hg, 52.27%. Calcd for $C_{10}H_{20}N_2S_4Hg_2Cl_2$: C, 15.63; H, 2.62; S, 16.69; Hg, 52.19%.

Recrystallization of 2.00 g of the 1 : 3 reaction product from 150 ml of acetone gave 0.99 g of white crystals. The IR spectrum showed a single band due to $\nu_{C=N}$ at 1510 cm^{-1}, but the bands at 460, 1530, 1610, 3500, and 3560 cm^{-1} characteristic of the original product (Fig. 1d) were completely absent.

Found: C, 12.59; H, 1.51; Hg, 56.34%.

*Reaction of **3** with $HgCl_2$ in Acetone.* A mixture of 4.96 g of **3** and 120 ml of acetone was heated at about 60 °C until it became homogeneous. To this solution was added 2.71 g of $HgCl_2$, and the mixture was stirred for 1 h under reflux. After cooling, the white crystals of **4** were collected and dried. From the filtrate a small amount of **4** was obtained by concentration, followed by crystallization. The total yield of **4** was 7.35 g (95%). Recrystallization of the raw product from acetonitrile–acetone gave 6.02 g (78%) of **4** in a pure form.

*Reaction of **3** with $HgCl_2$ in Water.* A mixture of 0.99 g of **3**, a prescribed amount of $HgCl_2$, and 40 ml of water was stirred for 90 h at room temperature. The work-up procedure was the same as that followed with **1**. The results are summarized in Table 2. The IR spectra were very close to those of the corresponding products obtained in the reaction of **1** with $HgCl_2$.

*Reaction of **2** with $HgCl_2$ in Water.* The results of the reaction are summarized in Table 3. The following is a typical example. A mixture of 0.59 g of **2**, 2.17 g of $HgCl_2$, and 40 ml of water was stirred for 90 h at room temperature. The solid product was filtered, washed thoroughly with water, and then dried at room temperature under a vacuum. The yield was 2.32 g. The IR spectrum revealed characteristic bands at 460, 1515, 1530, 1610, 3500, and 3560 cm^{-1}.

Found: C, 9.33; H, 1.22; Hg, 58.77%.

*Reaction of **2** with $HgCl_2$ in Benzene–Ethanol.* The results of the reaction are summarized in Table 4. The following is a typical example. To a stirred solution of 8.13 g of $HgCl_2$ in 70 ml of ethanol was added dropwise a solution of 2.96 g of **2** in 50 ml of benzene. A white crystalline precipitate started to separate almost immediately. The mixture was stirred for 30 min at room temperature and filtered. The filtered solid was washed with ethanol and then dried at room temperature under a vacuum. The yield was 8.26 g; mp 132—135 °C (dec.).

IR (KBr disk): 1530 cm^{-1} ($\nu_{C=N}$).

Found: C, 15.64; H, 2.67; S, 16.30; Cl, 11.14; Hg, 48.08%.

Repeated recrystallization of the product from acetonitrile gave a small amount of **4**: mp 105—107 °C.

Found: C, 15.35; H, 2.36; S, 16.63%. Calcd for $C_{10}H_{20}N_2S_4Hg_2Cl_2$: C, 15.63;, H, 2.62; S, 16.69%.

*Reaction of **2** with $HgCl_2$ (1 : 5) in Acetone.* To a stirred solution of 6.78 g of $HgCl_2$ in 150 ml of acetone was added a solution of 1.48 g of **2** in 50 ml of acetone. The mixture was stirred for 20 h at room temperature. The white precipitate was filtered and dried. The yield was 1.11 g. The IR spectrum showed characteristic bands at 460, 1510, 1530, 1610, 3500, and 3560 cm^{-1}. Essentially the same product was obtained from the filtrate by concentration, followed by treatment of the residue with acetone–ether. The yield was 2.44 g.

Found: C, 7.69; H, 1.23; S, 8.23%.

*Reaction of **2** with $HgCl_2$ (1 : 3) in Ethanol.* A solution of 8.13 g of $HgCl_2$ in 80 ml of ethanol was added to a stirred solution of 2.96 g of **2** in 120 ml of ethanol. In time, the system became cloudy, and then a viscous yellow material began to separate. The stirring was continued for 20 h. During this period the yellow material turned to a white crystalline solid. The solid was filtered, washed with ethanol, and dried. The yield was 6.71 g. The IR spectrum showed characteristic bands at 460, 1515 (sh), 1530, 1610, 3500, and 3560 cm^{-1}.

Found: C, 13.11; H, 2.16; S, 13.35; Hg, 50.50%.

The authors are indebted to Dr. Hitoshi Iwasaki of the Institute of Physical and Chemical Research for supplying a sample of $Hg_3Cl_2(S_2CNEt_2)_4$.

The Association Constants of Hexaamminechromium(III) and Tris-(ethylenediamine)chromium(III) Ions with Several Univalent Anions in Aqueous Solutions

Tatsuo TAKAHASHI and Takefumi KOISO

Department of Chemistry, Fukushima Technical College, Iwaki 970

(Received December 22, 1975)

The thermodynamic ion-association constants of hexaamminechromium(III) and tris(ethylenediamine)-chromium(III) with several univalent anions were determined in aqueous solutions at 25.0 °C. The log K_{con} values obtained by the conductometric method are 1.3_7 for $[Cr(NH_3)_6]^{3+}$–Cl^-, 1.5_8 for $[Cr(en)_3]^{3+}$–Cl^-, 1.5_7 for $[Cr(NH_3)_6]^{3+}$–Br^-, 1.5_0 for $[Cr(en)_3]^{3+}$–Br^-, 1.5_3 for $[Cr(NH_3)_6]^{3+}$–NO_3^-, and 1.4_9 for $[Cr(en)_3]^{3+}$–NO_3^-. The log K_{sp} values obtained by the spectrophotometric method are 1.6_5 for $[Cr(en)_3]^{3+}$–Cl^-, 1.4_6 for $[Cr(en)_3]^{3+}$–Br^-, and 0.9_0 for $[Cr(en)_3]^{3+}$–ClO_4^-; the value for $[Cr(en)_3]^{3+}$–ClO_4^- could be indirectly calculated from the apparent ion-association constant of $[Cr(en)_3]^{3+}$–Br^- determined in the solutions containing both bromide and perchlorate ions. Though the detailed comparison of the ion-association constants obtained in this study was limited, it could be concluded that the K_{con} values were in relatively good agreement with the K_{sp} values obtained on the given ion-pairs and that the ion-association constants of chromium(III) complex cations with several univalent anions are slightly less than those of the corresponding cobalt(III) complex cations with their anions.

In view of the fact that the theories for ion association proposed by Bjerrum,[1] Fuoss,[2] and other authors were not fully related to the Debye-Hückel[3] theory of electrolyte solutions, Yokoyama and Yamatera[4] showed that the ion-association constant could be derived in direct relation to the Debye-Hückel theory, reexamined to explain the ion-association. Meanwhile, the determination of the standard enthalpies and entropies for the ion-pair formation,[5] and the comparison of the ion-association constants obtained by the various types of measurements[6–9] were considered to provide some significant information concerning the interaction between the ions.

In this paper, a conductometric investigation of the ion-pairs, $[Cr(NH_3)_6]^{3+}$–X^-, $[Cr(en)_3]^{3+}$–X^- (X=Cl, Br, NO_3) and a spectrophotometric investigation of $[Cr(en)_3]^{3+}$–Br^-, $[Cr(en)_3]^{3+}$–Cl^-, $[Cr(en)_3]^{3+}$–ClO_4^- will be presented. The ion-association constants which were determined in this study and the previous study[10] (X=I, ClO_4) will be compared with the values reported for the corresponding cobalt(III) complex cations with several univalent anions, and will be briefly discussed in terms of Bjerrum's theory of ion-association.

Experimental

The compounds, $[Cr(NH_3)_6]Cl_3$, $[Cr(NH_3)_6]Br_3$, $[Cr(en)_3]Cl_3 \cdot 3.5H_2O$, $[Cr(NH_3)_6](NO_3)_3$, $[Cr(en)_3](NO_3)_3$, and $[Cr(en)_3]Br_3 \cdot 4H_2O$, were prepared according to the procedures described in the literature. Each compound was carefully recrystallized three times from redistilled water. The purity was examined by the method described in a previous paper;[10] the results were in very good agreement with the theoretical values. All the chemicals used were of an analytical reagent grade and were highly purified by recrystallization from redistilled water.

Solutions of various concentrations were carefully prepared by using conductivity water of a low specific conductance ($<4\times10^{-7}$ $\mho$ cm^{-1}). The electric conductivities were measured with a Yanagimoto conductivity outfit, Model MY-7, in an atmosphere of purified nitrogen over the surface of the solution, after the dissolved carbon dioxide in the solution had been removed by bubbling nitrogen gas through the solution. All the measurements were carried out within 30 min after the preparation of the solution, in a water-thermostat of 25.00±0.02 °C. The absorbancy measurements of solutions were made with a 124-type Hitachi spectrophotometer with a thermostated cell compartment (25.0±0.1 °C), using a 10-mm quartz cell, within 30 min after the preparation of the solution. Increasing quantities of sodium chloride or potassium bromide were added to each solution containing a small, constant concentration of the complex. The reference solutions used for the measurement had exactly the same concentration of Cl^- or Br^- as in the corresponding sample solutions.

Results and Discussion

The equivalent conductivities, Λ, of the complexes at various concentrations are summarized in Tables 1 and 2. The relations between the equivalent conductivities obtained and the ionic strength (I) are shown in Figs. 1—3. Table 3 presents the limiting equivalent conductivities, Λ°, of each complex, as determined by Onsager's method of extrapolation,[11] and also the limiting ionic equivalent conductivities, λ°, of each complex cation calculated from the Λ° values. Table 4 summarizes the so-called Stokes' radii, r_s, of $[Cr(NH_3)_6]^{3+}$ and $[Cr(en)_3]^{3+}$, as determined from the conductivity data in this study and those of the corresponding cobalt(III) complex cations.

Figures 1—3 show the plots of Λ against $I^{1/2}$; the broken lines indicate the theoretical Onsager lines[11] calculated. The slight deviation between the experimental conductivity lines and the theoretical lines was assumed to be due to the ion-pair formation between the cations and the anions:

$$M^{3+} + X^- \rightleftharpoons M^{3+}X^- \qquad (1)$$

$M = Cr(NH_3)_6$, $Cr(en)_3$

X = Cl, Br, NO_3

The degrees of dissociation, α, of the possible ion pairs were determined according to the successive approximation method described by Jenkins and Monk.[12] The thermodynamic ion-association constants, K, for Eq. 1 were calculated from both the

degree of dissociation thus obtained and the activity coefficient, f, of ions as estimated from the Debye-Hückel limiting equation. The results are summarized in Tables 1 and 2. In the present calculation, the λ° values of ion-pairs were assumed to be equal to two-thirds of those of complex cations, and the actual ionic strength, I, is $(1+\alpha)C$, where C is the equivalent concentration of the complex. If the distance of the closest approach of the two ions of an ion-pair is assumed to be equal to the sum of their Stokes' radii, the ion-association constant of the ion-pair can be estimated by Bjerrum's theory.[1] Table 5 presents the log K values calculated theoretically.

It has generally been observed that, in the ultraviolet region, the ion-association is usually accompanied either by the appearance of a new absorption band or by a shift of an existing band. The present authors also found an increase in the optical densities of the charge-transfer band in the ultraviolet region of $[Cr(en)_3]Cl_3 \cdot 3.5H_2O$ and $[Cr(en)_3]Br_3 \cdot 4H_2O$ upon

$[Cr(en)_3]^{3+}$-Cl^-	1.6_7

the addition of Cl^- or Br^- as a result of the ion-association. When the Reaction 1 of ion-pair formation was in equilibrium, the spectrophotometric data could be approximately treated according to the following equation:

$$\frac{[X^-]_T}{\varepsilon_{obsd}-\varepsilon_M}\cdot\frac{f_M f_X}{f_{MX}} = \frac{1}{K(\varepsilon_{MX}-\varepsilon_M)} + \frac{[X^-]_T}{\varepsilon_{MX}-\varepsilon_M}\cdot\frac{f_M f_X}{f_{MX}} \quad (2)$$

where ε_{obsd} is the observed molar extinction coefficient;

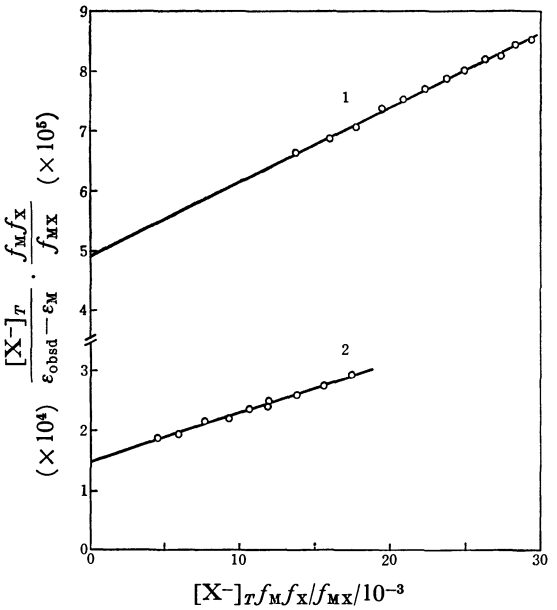

Fig. 4. Plots of the left-hand side of Eq. 2 against the $[X^-]_T f_M f_X/f_{MX}$ at 230 nm
(1): $[Cr(en)_3]^{3+}$–Br^-, (2): $[Cr(en)_3]^{3+}$–Cl^-.

ε_M and ε_{MX}, the molar extinction coefficients of M^{3+} and $M^{3+}X^-$, and f_M, f_X, and f_{MX}, the activity coefficients of M^{3+}, X^- and an ion-pair, $M^{3+}X^-$, respectively. The plot of the left-hand side of Eq. 2 *vs.* $[X^-]_T \cdot f_M f_X/f_{MX}$ gives a straight line, and the thermodynamic ion-association constant, K, can be determined from the ratio of its slope to the intercept. The activity coefficient was calculated from the following equation:

$$\log f_i = \frac{-0.5115\, Z_i^2\sqrt{I}}{1+0.329a\sqrt{I}} \qquad (3)$$

The ion-size parameters, a,[13] used in the calculation are 3.0 Å for Cl^- and Br^-, 3.5 Å for ClO_4^-, and 6.0 Å for $[Cr(en)_3]^{3+}$, $[Cr(en)_3]^{3+}$–Cl^-, and $[Cr(en)_3]^{3+}$–Br^-. The results of the experiments are shown in Fig. 4. The linear relationship in Fig. 4 suggests that no appreciable contribution of the ion-pair formations, such as $[Cr(en)_3]^{3+}$–$2Cl^-$, as $[Cr(en)_3]^{3+}$–$2Br^-$, were to be expected in these systems. The $\log K$ values thus obtained were 1.6_5 for $[Cr(en)_3]^{3+}$–Cl^- and 1.4_6 for $[Cr(en)_3]^{3+}$–Br^-. No change was found in the ultraviolet spectra of the $[Cr(en)_3](ClO_4)_3$ solution at higher concentrations of ClO_4^-. These results do not always indicate the lack of the $[Cr(en)_3]^{3+}$–ClO_4^-, ion-pair. On the basis of the conclusion from the conductometric investigation that the $[Cr(en)_3]^{3+}$ did also associate with the ClO_4^- added to adjust the ionic strength, the determination of the ion-association constant of $[Cr(en)_3]^{3+}$–ClO_4^- was carried out by the spectrophotometric method on a system containing both Br^- and ClO_4^-.[14]

Under such experimental conditions, the Eq. 2 is rewritten as:

$$\frac{[Br^-]_T}{\varepsilon_{obsd}-\varepsilon_M} = \frac{1}{K'_{c,MBr}(\varepsilon_{MBr}-\varepsilon_M)} + \frac{[Br^-]_T}{\varepsilon_{MBr}-\varepsilon_M} \qquad (4)$$

The apparent ion-association constant of $[Cr(en)_3]^{3+}$–Br^- determined at the given ionic strength, $K'_{c,MBr}$, is

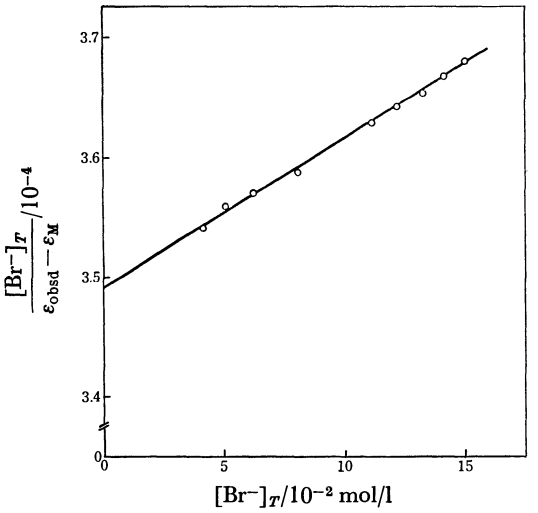

Fig. 5. Plot of the left-hand side of Eq. 4 against the total concentration of bromide ions at I=0.1530 at 230 nm.

given by:

$$K'_{c,MBr} = \frac{K_{c,MBr}}{1+K_{c,MClO_4}\cdot A}\left(1-\frac{K_{c,MClO_4}}{K_{c,MBr}}\right) \qquad (5)$$

where $K_{c,MBr}$ and $K_{c,MClO_4}$ are the concentration ion-association constants of $[Cr(en)_3]^{3+}$–Br^- and $[Cr(en)_3]^{3+}$–ClO_4^-, and where A indicates the values of $[Br^-]_T$ plus $[ClO_4^-]_T$, which was kept constant in this study. The value of $K'_{c,MBr}$ was found to be 3.6 from the analysis of the plot of Eq. 4 shown in Fig. 5. In this case, the activity coefficients of these ions are not a unit; therefore, the thermodynamic ion-association constant, K_{MBr}, determined by the spectrophotometric method was reduced to 6.0 ($K_{c,MBr}$) at the ionic strength of 0.1530. With the $K'_{c,MBr}$, $K_{c,MBr}$ and A values, $K_{c,MClO_4}$ was evaluated to be 1.6 with the aid of Eq. 5. The ion-association constant of $[Cr(en)_3]^{3+}$–ClO_4^- at an infinite dilution was calculated to be 8.0 after correction for the activity coefficients of the ions.

The K value for $[Cr(en)_3]^{3+}$–ClO_4^-, estimated indirectly by the spectrophotometric method, was in relatively good agreement with that of the conductometric method, showing that ClO_4^- acts as a counter anion for the ion-association. From these results, it might be considered that the ion-association constants determined by the conductometric method and the spectrophotometric method are not very different from each other. Similar conclusions were drawn in the case of the previous studies of the $[Cr(en)_3]^{3+}$–I^-, $[Cr(en)_3]^{3+}$–ClO_4^-, $[Cr(NH_3)_6]^{3+}$–I^-, and $[Cr(NH_3)_6]^{3+}$–ClO_4^- ion-pairs. On the basis of the assumption that most cations do not associate with ClO_4^- in aqueous solutions, spectrophotometric studies have been made by many investigators of solutions containing large amounts of sodium perchlorate. However, we found that there was a difference between the values obtained previously by the conductometric and spectrophotometric methods. The difference did not occur when a different method was used. However, it might be caused by the fact that the above assumption is in-

correct, not by the different working principles of the various methods. The thermodynamic ion-association constants for the corresponding cobalt(III) complex cations with some anions have been determined by various methods and/or by various researchers; they are given in Table 6, together with the results obtained in this study and the previous study. It seems certain that the ion-pairs of the chromium(III) complex cations with some anions are slightly less stable than those of the corresponding cobalt(III) complex cations, even if the inaccuracy in the determination of the ion-association constants is taken into consideration. Table 6 also indicates that the ion-pairs formed between $[Cr(NH_3)_6]^{3+}$ and such a Br^-, ClO_4^-, or NO_3^- are much more stable than those of $[Cr(en)_3]^{3+}$ with their anions, whereas the ion-pairs, $[Cr(NH_3)_6]^{3+}$ with I^- or Cl^- are less stable than those of $[Cr(en)_3]^{3+}$ with their anions.

Since the Stokes' radii of $[Cr(en)_3]^{3+}$ are larger than that of $[Cr(NH_3)_6]^{3+}$, the lower tendency of $[Cr(NH_3)_6]^{3+}$ to associate with I^- or Cl^-, shown by the present and previous studies, seems rather unexpected, in so far as the ion-association is assumed to depend on only a pure electrostatic. The ion-association constants of the corresponding cobalt(III) complex cations with Cl^- or SO_4^{2-} were determined by various methods. Similar results were obtained regardless of the method used. That is, the value of $[Co(en)_3]^{3+}$–Cl^- is somewhat greater than that of $[Co(NH_3)_6]^{3+}$–Cl^-, whereas the value of $[Co(NH_3)_6]^{3+}$–SO_4^{2-} is greater than that of $[Co(en)_3]^{3+}$–SO_4^{2-}. Therefore, it seems appropriate to state that the electrostatic interaction between ions exerts a dominant influence, but also the internal conjugate base (ICB) effect[18] proposed in the complex formation mechanism should be considered in the ion-pair formation.

The authors wish to express their sincere thanks to Professor Nobuyuki Tanaka (Department of Chemistry, Faculty of Science, Tohoku University) for his kind guidance in the course of this work. The authors also wish to thank Mr. Eichi Ôsawa and Mr. Yasuaki Kobayashi for the computer calculations, all of which were performed on an OKITAC-4500 computer using a FORTRAN program.

The Photochemical Reaction of 1,2-Naphthoquinones with Aldehydes. II.[1] The Photo-addition Reactions of Aliphatic Aldehydes to 1,2-Naphthoquinones

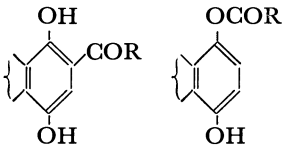
Akio TAKUWA

Department of Chemistry, Faculty of Literature and Science, Shimane University, Matsue 690

(Received January 12, 1976)

3-Acyl-1,2-naphthalenediols and 1,2-naphthalenediol monoacyl esters were obtained from the photochemical reactions of 1,2-naphthoquinones with aliphatic aldehydes. 3-Halogeno-1,2-naphthoquinones gave the corresponding 1,2-naphthalenediol monoacyl esters, 3-acyl-1,2-naphthalenediols, which are the same products as those from the photochemical reactions of 1,2-naphthoquinone with those aldehydes and 3-halogeno-4-acyl-1,2-naphthoquinone when they were irradiated in aldehydes. 3-Methyl-1,2-naphthoquinone, however, gave the corresponding 1,2-naphthalenediol monoacetate and 3-methyl-4-acetyl-1,2-naphthoquinone when it was irradiated in acetaldehyde. These photochemical reactions were applicable for syntheses of 3-acyl-1,2-naphthalenediols and 1,2-naphthalenediol monoacyl esters.

The wide variety of photo-induced reactions among quinones and aldehydes has been examined by several workers.[2] The photochemical reactions of *p*-benzoquinones and 1,4-naphthoquinones with aliphatic or aromatic aldehydes give acyl or aroylquinols (**1**) and quinol monoesters (**2**).

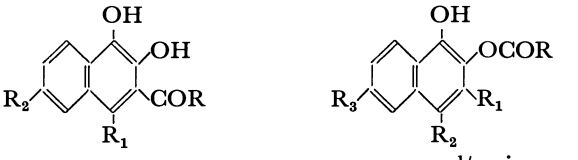


1 **2** **3** R=Alkyl or Aryl

On the other hand, *o*-quinones usually give the corresponding enediol monoesters (**3**) exclusively. For example, tetrachloro-1,2-benzoquinone yields tetrachlorocatechol monoacetate and monobenzoate when it is irradiated in the presence of acetaldehyde and benzaldehyde.[3] 9,10-Phenanthrenequinone reacts in a similar fashion with both aliphatic or aromatic aldehydes.[4] 4-Cyano-1,2-naphthoquinone, however, behaves differently, since with aromatic aldehydes it gives naphthalenediol monoesters, but the products from the reaction with acetaldehyde and propionaldehyde are reported to be the corresponding 1,2-dihydroxy-3-acyl-4-naphthalenecarbonitriles.[5] But no factor leading to monoesters of 1,2-naphthalenediol or to ring-acylated 1,2-naphthalenediols has been discovered yet. Therefore, it is necessary to scrutinize the photochemical reactions of 1,2-naphthoquinones with aliphatic aldehydes. In this work, the photochemical reactions of 1,2-naphthoquinone and its derivatives with a variety of aliphatic aldehydes were examined. It was found that 3-acyl-1,2-naphthalenediols and 1,2-naphthalenediol monoacyl esters were usually obtained with the exception of the cases in which the 3-position of a quinone ring was substituted.

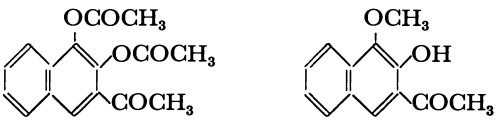
Results and Discussion

The 1,2-naphthoquinones examined in this work are 1,2-naphthoquinone and its 3-chloro-, 3-bromo-, 3-methyl-, 4-cyano-, 6-bromo-, and 6-methyl-derivatives. The aldehydes used are acetaldehyde, propionaldehyde, butyraldehyde, isobutyraldehyde, valeraldehyde, isovaleraldehyde, hexanal, heptanal, octanal nonanal, and decanal.



4 R=$CH_3(CH_2)_n$ **5** (n=0—8) and/or isomer

A benzene solution of 1,2-naphthoquinones and an aldehyde was irradiated by means of a 300-W high pressure Hg arc lamp through a 5 cm thick layer of flowing water. The structures of the photo-addition compounds were determined by the following procedures. As a typical example, the photochemical reaction of 1,2-naphthoquinone with acetaldehyde will be illustrated. After the usual work-up of the reaction mixture, orange colored prisms (**4a**: R=CH_3, R_1=R_2=H; 24%) and white crystals (**5a**: R=CH_3, R_1=R_2=R_3=H; 39%) were obtained. The compound, **4a**, has carbonyl (1652 cm^{-1}) and hydroxyl (3400 cm^{-1}) groups, judging from its infrared spectrum. The PMR of **4a** showed signals at δ: 2.76 (s, 3H, $COCH_3$), 5.91 (s, 1H), 7.18—8.08 (m, 5H, aromatic protons), and 11.48 (s, 1H). The signal at δ: 5.91 and 11.48 disappeared after shaking with deuterium oxide, so these two signals could be assigned to the hydroxyl groups. The signal which appears at δ: 11.48 should be assigned to the 2-hydroxyl group, which is intramolecularly hydrogen-bonded to the adjacent carbonyl of the neighboring acetyl group.



6 **7**

The acetylated or methylated derivatives were confirmed to be **6** and **7** by their IR and PMR analyses. From these results the orange-colored photo-addition compound should have structure **4a**. Such photo-addition compounds are colored yellow to orange. The IR of another white photo-adduct (**5a**) showed absorption bands at 3400 and 1743 cm^{-1}, corresponding to hydroxyl and carbonyl groups respectively. The white crystal was the nearly 1 : 1 mixture of two isomeric esters, since two sorts of methyl proton signals of acetoxyl

groups were observed at δ: 2.42 and 2.52 by PMR analysis.

3-Acyl-1,2-naphthalenediols and 1,2-naphthalenediol monoacyl esters were also obtained from the photochemical reactions of nonsubstituted 1,2-naphthoquinone, 4-cyano-, 6-bromo-, and 6-methyl-derivatives of 1,2-naphthoquinone with aliphatic aldehydes. Awad and Hafez have reported that when a strong electron attracting group such as the cyano group was introduced at position 4 of 1,2-naphthoquinone, 3-acylated 1,2-naphthalenediols were the products in the photochemical reactions with acetaldehyde or propionaldehyde.[6] Since 3-acylated 1,2-naphthalenediols were also obtained from the photochemical reactions of 1,2-naphthoquinone with aliphatic aldehydes, it is of interest to investigate the role of the cyano group in the reaction.

Photochemical reactions of 3-substituted 1,2-naphthoquinones, such as 3-chloro-, 3-bromo-, and 3-methyl-1,2-naphthoquinone, with aliphatic aldehydes were chosen for this purpose. Irradiation of 3-halogeno-1,2-naphthoquinone in acetaldehyde afforded, however, 3-halogeno-1,2-naphthalenediol monoacetates (**5**: R=CH_3, R_1=Cl or Br, R_2=R_3=H, 26%) as the main products, plus paraldehyde (*ca.* 90%) along with a little metaldehyde. The use of benzene as a solvent did not interfere with these photochemical reactions. Polymerization of acetaldehyde suggested that a hydrogen halide had been formed in the reaction system.

In view of these results, a detailed analysis of the minor products in these reactions was required. In fact, 3-acetyl-1,2-naphthalenediol (1—3%), which is the same product as in the photochemical reaction of 1,2-naphthoquinone with acetaldehyde, and 3-halogeno-4-acetyl-1,2-naphthoquinone (2—5%) were isolated. 3-Chloro-4-acetyl-1,2-naphthoquinone was identified by comparison with the authentic sample prepared by the chlorination of 4-acetyl-1,2-naphthoquinone. Analogous products were also obtained from the photochemical reactions of 3-halogeno-1,2-naphthoquinone with other aliphatic aldehydes. Irradiation of a benzene solution of 3-methyl-1,2-naphthoquinone and acetaldehyde gave 3-methyl-1,2-naphthalenediol monoacetate (17.7%) and 3-methyl-4-acetyl-1,2-naphthoquinone (6.6%). It is thought that 3-halogeno-4-acetyl-1,2-naphthalenediols and 3-methyl-4-acetyl-1,2-naphthalenediol converted into the corresponding quinones by oxidation with the original quinone in the reaction system or with air during the separation procedure, since 3-chloro-4-acetyl-1,2-naphthalenediol was easily auto-oxidized into 3-chloro-4-acetyl-1,2-naphthoquinone in silica gel or in benzene solution.

Even after a benzene solution of 1,2-naphthalenediol monoacetate [**5a**; λ_{max} (ε): 329 nm (2310)] was irradiated for 1—3 days, no 3-acetyl-1,2-naphthalenediol (**4a**) was detected by PMR analysis. However, the rearrangement of **5a** to **4a** might be sensitized by 1,2-naphthoquinone. This possibility was checked by irradiating a mixture of 1,2-naphthoquinone and **5a** in benzene, but no **4a** was detected. Therefore, under these conditions the photo-induced Fries rearrangement of **5a** to **4a** is unlikely. The detailed mechanism of the formation of these photo-adducts remains still unestablished, but the results examined so far have been described in this paper as a preliminary report.

Experimental

All melting points were determined on a Yanagimoto Micro-melting Point apparatus and are uncorrected. Yields were based on the amount of quinones used. PMR spectra were taken with a JEOL MH-100 spectrometer in CCl_4 or $CDCl_3$ solution using TMS as the internal standard. The coupling constants were 7.0—8.0 Hz in all compounds. Infrared spectra were obtained on a Hitachi 215 spectrometer, using a KBr disc. Ultraviolet spectra were recorded by means of a Hitachi 124 spectrophotometer.

Materials. 1,2-naphthoquinone (mp 121—122 °C) was prepared by the oxidation of 1-amino-2-naphthol hydrochloride with iron(III) chloride.[7] 3-Chloro (mp 171 °C)[8] and 3-bromo-1,2-naphthoquinone (mp 164 °C)[9] were prepared by chlorination or bromination of 1,2-naphthoquinone. 3-Methyl-1,2-naphthoquinone (mp 120 °C) was prepared by the oxidation of 3-methyl-α-tetralone with selenium dioxide.[10] 4-Cyano-1,2-naphthoquinone (mp 175—176 °C) was prepared by the oxidation of 1-amino-2-hydroxy-4-cyanonaphthalene with chromium trioxide.[11] 6-Bromo-1,2-naphthoquinone (mp 156 °C) was prepared by the oxidation of 6-bromo-2-naphthol with Fremy's salt.[12] 6-Methyl-1,2-naphthoquinone (mp 126—127 °C) was prepared by the oxidation of 6-methyl-2-naphthol with Fremy's salt at 15 °C.[14] All commercially available aldehydes were further purified by distillation under nitrogen.

General Procedures. A typical photochemical reaction was performed as follows: 1,2-naphthoquinone derivatives (200 mg, 0.84—1.27 mmol) and aldehydes (500 mg, 3—11 mmol) were dissolved in 25 ml of benzene, and the solution was irradiated from outside in an ordinary tube by a 300 W high-pressure mercury arc lamp through a 5 cm thick layer of flowing water at 15—20 °C. After 2—10 days, the characteristic color of 1,2-naphthoquinones faded to yellow. Benzene was removed under reduced pressure, and then the residue was chromatographed on silica gel, using benzene as the eluting solvent. Appropriate fractions were collected and concentrated and then light petroleum was added; these gave photo-adducts. The photo-adducts were further purified by recrystallization from benzene or benzene-light petroleum or by a florisil column.

Photo-addition Products of 1,2-Naphthoquinone with Aliphatic Aldehyde. (i) Acetaldehyde: 3-Acetyl-1,2-naphthalenediol [**4a**: R=CH_3, R_1=R_2=H]: orange prisms (60 mg, 24%), mp 135—136 °C. IR: ν_{OH} 3440; $\nu_{C=O}$ 1652 cm^{-1}. PMR (CCl_4), δ: 2.76 (s, 3H, CH_3), 5.91 (s, 1H, OH, removed by D_2O), 7.17—8.08 (m, 5H, aromatic-H), 11.48 (s, 1H, OH, removed by D_2O). UV($CHCl_3$): λ_{max} (ε), 409 (7330), 300(21500), 263(38500). Found: C, 71.07; H, 4.49%. Calcd for $C_{13}H_{10}O_3$: C, 71.28; H, 4.98%. Treatment with acetic anhydride afforded 3-acetyl-1,2-naphthalenediol diacetate (**6**): pale yellow crystals from ethanol, mp 155–157 °C. IR: $\nu_{C=O}$ 1770, 1687 cm^{-1}. PMR($CDCl_3$), δ: 2.37(s, 3H, $OCOCH_3$), 2.46 (s, 3H, $OCOCH_3$), 2.67(s, 3H, $COCH_3$), 7.28—8.18 (m, 5H, aromatic-H). Treatment with dimethylsulfate in aqueous sodium hydroxide afforded 1-methoxy-2-hydroxy-3-acetylnaphthalene (**7**): yellow crystals, mp 80—81 °C. IR: ν_{OH} 3420; $\nu_{C=O}$ 1655 cm^{-1}. PMR(CCl_4), δ: 2.78(s, 3H, $COCH_3$), 4.06(s, 3H, OCH_3), 7.16—8.05 (m, 5H, aromatic-H), 11.42(s, 1H, OH, removed by D_2O). 1,2-Naphthalenediol monoacetate [**5a**: R=CH_3, R_1=R_2=R_3=H]: white crystals (100 mg, 39%), mp 136—138 °C. IR: ν_{OH} 3400; $\nu_{C=O}$ 1740 cm^{-1}. PMR($CDCl_3$), δ: 2.40(s, 3H, CH_3),

2.52(s, 3H, CH_3), 7.13—7.88(m, 14H, aromatic-H+OH). UV($CHCl_3$): $\lambda_{max}(\varepsilon)$, 329(2310), 288(4960), 278 nm (6090). Found: C, 70.98; H, 4.76%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.98%. Treatment with acetic anhydride afforded 1,2-naphthalenediol diacetate: white crystals, mp 108—111 °C. It was identified (mixed melting point, IR and PMR spectra) by comparison with an authentic sample.

(ii) Propionaldehyde: 3-Propionyl-1,2-naphthalenediol [**4**: $R=CH_3CH_2$, $R_1=R_2=H$]: orange yellow prisms (51mg,19%), mp 129—130.5 °C. IR: ν_{OH} 3455; $\nu_{C=O}$ 1660 cm^{-1}. PMR (CCl_4), δ: 1.32 (t, 3H, CH_3), 3.20 (q, 2H, CH_2), 5.93 (s, 1H, OH, removed by D_2O), 7.16—8.11 (m, 5H, aromatic-H), 11.57 (s, 1H, OH, removed by D_2O). Found: C, 72.36; H, 5.62%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%. 1,2-Naphthalenediol monopropionate [**5**: $R=CH_3CH_2$, $R_1=R_2=R_3=H$]: white crystals (38 mg, 14%), mp 105—106 °C. IR: ν_{OH} 3440; $\nu_{C=O}$ 1750 cm^{-1}. PMR($CDCl_3$), δ: 1.32 (t, 3H, CH_3), 1.42 (t, 3H, CH_3), 2.72(q, 2H, CH_2), 2.84 (q, 2H, CH_2), 7.10—7.83(m, 14H, aromatic-H+OH). Found: C, 72.15; H, 5.80%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

(iii) Butyraldehyde: 3-Butyryl-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_2$, $R_1=R_2=H$]: orange prisms (59 mg, 20%), mp 98.0—99.5 °C. IR: ν_{OH} 3455; ν_{CH} 2980; $\nu_{C=O}$ 1655 cm^{-1}. PMR(CCl_4), δ: 1.06(t, 3H, CH_3), 1.82(sex, 2H, CH_2), 3.06 (t, 2H, $COCH_2$), 5.84 (s, 1H, OH), 7.06—7.98(m, 5H, aromatic-H), 11.45(s, 1H, OH). Found: C, 72.94; H, 6.02%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%. 1,2-Naphthalenediol monobutyrate [**5**: $R=CH_3(CH_2)_2$, $R_1=R_2=R_3=H$]: white crystals (21 mg, 7%), mp 77—78 °C. IR: ν_{OH} 3320; ν_{CH} 2980; $\nu_{C=O}$ 1725 cm^{-1}. PMR($CDCl_3$), δ: 1.08 (t, 3H, CH_3), 1.88 (sex, 2H, CH_2), 2.64 (t, 2H, $COCH_2$), 7.08—8.10 (m, 7H, aromatic-H+OH). Found: C, 73.58; H, 6.35%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%.

(iv) Isobutyraldehyde: 3-Isobutyryl-1,2-naphthalenediol [**4**: $R=(CH_3)_2CH$, $R_1=R_2=H$]: yellow crystals (15 mg, 5%), mp 105—107 °C. IR: ν_{OH} 3500; ν_{CH} 2985, 2950; $\nu_{C=O}$ 1655 cm^{-1}. PMR (CCl_4), δ: 1.30 (d, 6H, $(CH_3)_2$), 3.77 (sep, 1H, CH), 5.97(s, 1H, OH), 7.12—8.12 (m, 5H, aromatic-H), 11.80 (s, 1H, OH). Found: C, 72.81; H, 6.21%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%. 1,2-Naphthalenediol monoisobutyrate [**5**: $R=(CH_3)_2CH$, $R_1=R_2=R_3=H$]: white crystals (80 mg, 27.5%), mp 73—74 °C. IR: ν_{OH} 3350 (br), ν_{CH} 2955; $\nu_{C=O}$ 1742, 1725 cm^{-1}. PMR($CDCl_3$), δ: 1.37(d, 6H, $(CH_3)_2$), 1.46(d, 6H, $(CH_3)_2$), 2.78 (sep, 1H, CH), 3.00(sep, 1H, CH), 7.13—8.30 (m, 14H, aromatic-H+OH). Found: C, 72.83; H, 5.96%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%.

(v) Valeraldehyde: 3-Valeryl-1,2-naphthalenediol (**4**: $R=CH_3(CH_2)_3$, $R_1=R_2=H$]: orange yellow prisms (25 mg, 8.1%), mp 131—132 °C. IR: ν_{OH} 3455; ν_{CH} 2970; $\nu_{C=O}$ 1645 cm^{-1}. PMR(CCl_4), δ: 0.98 (t, 3H, CH_3), 1.24—1.88(m, 4H, $(CH_2)_2$), 3.05 (t, 2H, $COCH_2$), 5.92 (s, 1H, OH), 7.13—8.05 (m, 5H, aromatic-H), 11.44(s, 1H, OH). Found: C, 73.53; H, 6.71%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%. 1,2-Naphthalenediol monovalerate [**5**: $R=CH_3(CH_2)_3$, $R_1=R_2=R_3=H$]: white crystals (48 mg, 15.5%), mp 68.5—71.0 °C. IR: ν_{OH} 3410; ν_{CH} 2960, 2940; $\nu_{C=O}$ 1735 cm^{-1}. PMR (CCl_4), δ: 0.98 (t, 3H, CH_3), 1.29—1.94 (m, 4H, $(CH_2)_2$), 2.47 (t, 2H, $COCH_2$), 6.17(1H, OH, broad), 6.87—7.67 (m, 6H, aromatic-H). Found: C, 74.00; H, 6.48%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

(vi) Isovaleraldehyde: 3-Isovaleryl-1,2-naphthalenediol [**4**: $R=(CH_3)_2CHCH_2$, $R_1=R_2=H$]: orange yellow oil (23 mg, 8%). PMR(CCl_4), δ: 1.00(d, 6H, $(CH_3)_2$), 2.30(m, 1H, CH), 2.89(d, 2H, $COCH_2$), 5.85 (s, 1H, OH), 7.08—8.05 (m, 5H, aromatic-H), 11.67 (s, 1H, OH). 1,2-Naphthalenediol monoisovalerate [**5**: $R=(CH_3)_2CHCH_2$, $R_1=R_2=R_3=H$]:white crystals (50 mg, 16%), mp 79.0—81.5 °C. IR: ν_{OH} 3420; ν_{CH} 2960, 2940, 2875; $\nu_{C=O}$ 1735, 1725 cm^{-1}. PMR (CCl_4), δ: 1.05 (d, 6H, $(CH_3)_2$), 1.09 (d, 6H, $(CH_3)_2$), 2.10—2.45(m, 2H, CH), 2.42(d, 2H, $COCH_2$), 2.56(d, 2H, $COCH_2$), 6.06(OH, 2H, broad), 6.90—8.18(m, 10H, aromatic-H). Found: C, 73.28; H, 6.81%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

(vii) Hexanal: 3-Hexanoyl-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_4$, $R_1=R_2=H$]: orange yellow prisms (40 mg, 12.3%), mp 119—120 °C. IR: ν_{OH} 3450; ν_{CH} 2935, 2870; $\nu_{C=O}$ 1645 cm^{-1}. PMR ($CDCl_3$), δ: 0.80—1.95 (m, 9H, CH_3-$(CH_2)_3$), 3.07 (t, 2H, $COCH_2$), 5.97 (s, 1H, OH), 7.20—8.02 (m, 5H, aromatic-H), 11.60 (s, 1H, OH). Found: C, 74.31; H, 6.95%. Calcd for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02%. 1,2-Naphthalenediol monohexanoate [**5**: $R=CH_3(CH_2)_4$, $R_1=R_2=R_3=H$]: white crystals (40 mg, 12.3%), mp 79.0—81.5 °C. IR: ν_{OH} 3410; ν_{CH} 2960, 2935, 2870; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 0.83—1.90 (m, 18H, $CH_3(CH_2)_3$), 2.57 (t, 2H, $COCH_2$), 2.70(t, 2H, $COCH_2$), 6.90—7.70 (m, 12H, aromatic-H+OH). Found; C, 74.56; H, 7.20%. Calcd for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02%.

(viii) Heptanal: 3-Heptanoyl-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_5$, $R_1=R_2=H$]: yellow plates (35 mg, 10.2%), mp 105—106 °C. IR: ν_{OH} 3470; ν_{CH} 2975, 2945, 2855; $\nu_{C=O}$ 1645 cm^{-1}. PMR(CCl_4), δ: 0.92 (t, 3H, CH_3), 1.23—1.90 (m, 8H, $(CH_2)_4$), 3.04(t, 2H, $COCH_2$), 5.95 (s, 1H, OH), 7.13—8.07 (m, 5H, aromatic-H), 11.65 (s, 1H, OH). Found: C, 74.77; H, 7.30%. Calcd for $C_{17}H_{20}O_3$: C, 74.97; H, 7.40%. 1,2-Naphthalenediol monoheptanoate [**5**: $R=CH_3$-$(CH_2)_5$, $R_1=R_2=R_3=H$]: white needles (65 mg, 19%), mp 59 °C. IR: ν_{OH} 3460; ν_{CH} 2950, 2870; $\nu_{C=O}$ 1760, 1740 cm^{-1}. PMR(CCl_4), δ: 0.80—1.96 (m, 22H, $CH_3(CH_2)_4$), 2.64 (t, 2H, $COCH_2$), 2.76 (t, 2H, $COCH_2$), 7.12—8.32 (m, 14H, aromatic-H+OH). Found: C, 75.15; H, 7.47%. Calcd for $C_{17}H_{20}O_3$: C, 74.97; H, 7.40%.

(ix) Octanal: 3-Octanoyl-1,2-naphthalenediol [**4**: $R=CH_3$-$(CH_2)_6$, $R_1=R_2=H$]: orange prisms (40 mg, 14%), mp 98—99 °C. IR: ν_{OH} 3460; ν_{CH} 2945, 2872; $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4), δ: 0.90 (t, 3H, CH_3), 1.22—1.89 (m, 10H, $(CH_2)_5$), 3.05(t, 2H, $COCH_2$), 5.98 (s, 1H, OH), 7.11—8.04 (m, 5H, aromatic-H), 11.72(s, 1H, OH). Found: C, 75.32; H, 7.64%. Calcd for $C_{18}H_{22}O_3$: C, 75.50; H, 7.74%. 1,2-Naphthalenediol monooctanoate [**5**: $R=CH_3(CH_2)_6$, $R_1=R_2=R_3=H$]: white plates (75 mg, 26.2%), mp 53—54 °C. IR: ν_{OH} 3340; ν_{CH} 2920, 2855; $\nu_{C=O}$ 1755, 1735 cm^{-1}. PMR (CCl_4), δ: 0.82—1.82 (m, 26H, $CH_3(CH_2)_5$), 2.50 (t, 2H, $COCH_2$), 2.62 (t, 2H, $COCH_2$), 6.12 (2H, OH), 6.98—8.16 (m, 12H, aromatic-H). Found: C, 75.66; H, 7.70%. Calcd for $C_{18}H_{22}O_3$: C, 75.50; H, 7.74%.

(x) Nonanal: 3-Nonanoyl-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_7$, $R_1=R_2=H$]: yellowish orange prisms (38 mg, 10%), mp 99—100 °C. IR: ν_{OH} 3475; ν_{CH} 2975, 2945, 2855; $\nu_{C=O}$ 1647 cm^{-1}. PMR(CCl_4), δ: 0.87 (t, 3H, CH_3), 1.18—1.90 (m, 12H, $(CH_2)_6$), 3.06 (t, 2H, $COCH_2$), 5.91 (s, 1H, OH), 7.14—8.07 (m, 5H, aromatic-H), 11.64 (s, 1H, OH). Found: C, 75.63; H, 7.81%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%. 1,2-Naphthalenediol monononanoate [**5**: $R=CH_3(CH_2)_7$, $R_1=R_2=R_3=H$]: white needles (62 mg, 16.4 %), mp 62.5—63.5 °C. IR: ν_{OH} 3400, ν_{CH} 2935, 2863; $\nu_{C=O}$ 1730 cm^{-1}. PMR (CCl_4), δ: 0.80—1.90 (m, 15H, CH_3-$(CH_2)_6$), 2.77 (t, 2H, $COCH_2$), 7.12—7.84 (m, 7H, aromatic-H +OH). Found: C, 76.08; H, 7.94%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%.

(xi) Decanal: 3-Decanoyl-1,2-naphthalenediol [**4**: $R=CH_3(CH_2)_8$, $R_1=R_2=H$]: orange prisms (34 mg, 8.6 %), mp 88—89 °C. IR: ν_{OH} 3465; ν_{CH} 2945, 2857; $\nu_{C=O}$ 1648 cm^{-1}.

PMR(CCl_4), δ: 0.87 (t, 3H, CH_3), 1.15—1.89 (m, 14H, $(CH_2)_7$), 5.90 (s, 1H, OH), 7.14—8.06 (m, 5H, aromatic-H), 11.64 (s, 1H, OH). Found: C, 76.37; H, 8.27%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.33%. 1,2-Naphthalenediol monodecanoate [**5**: $R=CH_3(CH_2)_8$, $R_1=R_2=R_3=H$]: white needles (61 mg, 15.4%), mp 67—68 °C. IR: ν_{OH} 3385; ν_{CH} 2935, 2860; $\nu_{C=O}$ 1729 cm^{-1}. PMR (CCl_4), δ: 0.86—1.82 (m, 17H, $CH_3(CH_2)_7$), 2.85 (t, 2H, $COCH_2$), 7.08—7.80 (m, 7H, aromatic-H+OH). Found: C, 76.67; H, 8.42%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H. 8.33%.

Photo-addition Compounds of 4-Cyano-1,2-naphthoquinone with Aliphatic Aldehyde. *(i) Acetaldehyde*: 1,2-Dihydroxy-3-acetyl-4-naphthalenecarbonitrile [**4**: $R=CH_3$, $R_1=CN$, $R_2=H$]: orange yellow needles (56 mg, 22.5%), mp 213—217 °C. IR: ν_{OH} 3435; ν_{CN} 2225; $\nu_{C=O}$ 1640 cm^{-1}. PMR ($CDCl_3$), δ: 3.17 (s, 3H, CH_3), 6.73 (s, 1H, OH, removed by D_2O), 7.52—7.77, 8.10—8.52 (m, 4H, aromatic-H), 12.03 (s, 1H, OH, removed by D_2O). Found: C, 69.04; H, 3.99; N, 5.98%. Calcd for $C_{13}H_9NO_3$: C, 68.72; H, 3.99; N, 6.16%. Treatment with acetic anhydride afforded 1,2-diacetoxy-3-acetyl-4-naphthalenecarbonitrile; white needles from alcohol, mp 159—160 °C. IR: ν_{CN} 2240; $\nu_{C=O}$ 1780, 1700 cm^{-1}. PMR($CDCl_3$), δ: 2.33 (s, 3H, $OCOCH_3$), 2.50 (s, 3H, $OCOCH_3$), 2.78 (s, 3H, $COCH_3$), 7.66—8.00, 8.25—8.39 (m, 4H, aromatic-H). 1,2-Dihydroxy-4-naphthalenecarbonitrile monoacetate [**5**: $R=CH_3$, $R_1=R_3=H$, $R_2=CN$]: white needles (29 mg, 11.6 %), mp 172—174 °C. IR: ν_{OH} 3375; ν_{CN} 2235; $\nu_{C=O}$ 1745 cm^{-1}. PMR($CDCl_3$), δ: 2.46 (s, 3H, CH_3), 7.56—7.87, 8.08—8.50 (m, 5H, aromatic-H+OH). Found: C, 68.86; H, 3.89; N, 6.20%. Calcd for $C_{13}H_9NO_3$: C, 68.72; H, 3.99; N, 6.16%. The acetylate compound was identical with authentic 1,2-diacetoxy-4-naphthalenecarbonitrile (mixed melting point, IR and PMR).

(ii) Propionaldehyde: 1,2-Dihydroxy-3-propionyl-4-naphthalenecarbonitrile [**4**: $R=CH_3CH_2$, $R_1=CN$, $R_2=H$]: orange plates (131 mg, 49.5%), mp 171—174 °C. IR: ν_{OH} 3310; ν_{CN} 2220; $\nu_{C=O}$ 1640 cm^{-1}. PMR ($CDCl_3$), δ: 1.34 (t, 3H, CH_3), 3.57 (q, 2H, CH_2), 6.68 (s, 1H, OH), 7.46—7.60, 8.02—8.28 (m, 4H, aromatic-H), 11.90 (s, 1H, OH). Found: C, 69.64; H, 4.52; N, 5.86%. Calcd for $C_{14}H_{11}NO_3$: C, 69.70; H, 4.60; N, 5.81%. 1,2-Dihydroxy-4-naphthalenecarbonitrile monopropionate [**5**: $R=CH_3CH_2$, $R_1=R_3=H$, $R_2=CN$]: white needles (29 mg, 11%), mp 135—136 °C. IR ν_{OH} 3455; ν_{CN} 2230; $\nu_{C=O}$ 1740 cm^{-1}. PMR ($CDCl_3$), δ: 1.34 (t, 3H, CH_3), 2.75 (q, 2H, CH_2), 7.46—7.68, 8.00—8.30 (m, 6H, aromatic-H+OH). Found: C, 69.53; H, 4.67; N, 5.74%. Calcd for $C_{14}H_{11}NO_3$: C, 69.70; H, 4.60; N, 5.81%.

(iii) Butyraldehyde: 1,2-Dihydroxy-3-butyryl-4-naphthalenecarbonitrile [**4**: $R=CH_3(CH_2)_2$, $R_1=CN$, $R_2=H$]: orange plates (81 mg, 29%), mp 138.5—140 °C. IR: ν_{OH} 3300; ν_{CH} 2965, 2840; ν_{CN} 2230; $\nu_{C=O}$ 1640 cm^{-1}. PMR($CDCl_3$), δ: 1.07 (t, 3H, CH_3), 1.87(sex, 2H, CH_2), 3.50 (t, 2H, $COCH_2$), 6.74 (s, 1H, OH), 7.47—7.68, 8.12—8.34 (m, 4H, aromatic-H), 12.05(s, 1H, OH). Found: C, 70.50; H, 5.21; N, 5.44%. Calcd for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13; N, 5.49%. 1,2-Dihydroxy-4-naphthalenecarbonitrile monobutyrate [**5**: $R=CH_3(CH_2)_2$, $R_1=R_3=H$, $R_2=CN$]: colorless needles (8 mg, 3%), mp 110—111 °C. IR: ν_{OH} 3320; ν_{CN} 2220; $\nu_{C=O}$ 1738 cm^{-1}. PMR($CDCl_3$), δ: 1.07 (t, 3H, CH_3), 1.83 (sex, 2H, CH_2), 2.66 (t, 2H, $COCH_2$), 7.56—7.84, 8.06—8.44 (m, 6H, aromatic-H+OH). Found: C, 70.49; H, 5.06; N, 5.37%. Calcd for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13; N, 5.49%.

(iv) Isobutyraldehyde: 1,2-Dihydroxy-3-isobutyryl-4-naphthalenecarbonitrile [**4**: $R=(CH_3)_2CH$, $R_1=CN$, $R_2=H$]: orange plates (90 mg, 32%), mp 147—149 °C. IR: ν_{OH} 3330; ν_{CH} 2980, 2940; ν_{CN} 2220; $\nu_{C=O}$ 1640 cm^{-1}. PMR($CDCl_3$), δ: 1.34(d, 6H, $(CH_3)_2$), 4.42(sep, 1H, CH), 6.77(s, 1H, OH), 7.50—7.73, 8.15—8.40(m, 4H, aromatic-H), 11.45(s, 1H, OH). Found: C, 70.65; H, 5.10; N, 5.45%. Calcd for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13; N, 5.49%. 1,2-Dihydroxy-4-naphthalenecarbonitrile monoisobutyrate [**5**: $R=(CH_3)_2CH$, $R_1=R_3=H$, $R_2=CN$]: colorless crystals (15 mg, 5.4%), mp 126.5—127 °C. IR: ν_{OH} 3245; ν_{CH} 2990, 2950; ν_{CN} 2235; $\nu_{C=O}$ 1765 cm^{-1}. PMR($CDCl_3$), δ: 1.30 (d, 6H, $(CH_3)_2$), 2.97(sep, 1H, CH), 7.55—7.80, 8.09—8.40(m, 6H, aromatic-H+OH). Found: C, 70.44; H, 5.19; N, 5.53%. Calcd for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13; N, 5.49%.

(v) Valeraldehyde: 1,2-Dihydroxy-3-valeryl-4-naphthalenecarbonitrile [**4**: $R=CH_3(CH_2)_3$, $R_1=CN$, $R_2=H$]: orange plates (91 mg, 31%), mp 112.5—113.0 °C. IR: ν_{OH} 3340; ν_{CH} 2964, 2940, 2880; ν_{CN} 2220; $\nu_{C=O}$ 1638 cm^{-1}. PMR($CDCl_3$), δ: 0.98 (t, 3H, CH_3), 1.30—1.95 (m, 4H, $(CH_2)_2$), 3.50 (t, 2H, $COCH_2$), 6.80 (s, 1H, OH), 7.46—7.65, 8.04—8.20 (m, 4H, aromatic-H), 11.97(s, 1H, OH). Found: C, 71.24; H, 5.69; N, 5.13%. Calcd for $C_{16}H_{15}NO_3$: C, 71.36; H, 5.61; N, 5.20%. 1,2-Dihydroxy-4-naphthalenecarbonitrile monovalerate [**5**: $R=CH_3(CH_2)_3$, $R_1=R_3=H$, $R_2=CN$]: white needles (22 mg, 7.4%), mp 118—119 °C. IR: ν_{OH} 3275; ν_{CH} 2960, 2940, 2880; ν_{CN} 2235; $\nu_{C=O}$ 1753 cm^{-1}. PMR(CCl_4), δ: 0.98(t, 3H, CH_3), 1.27—1.90 (m, 4H, $(CH_2)_2$), 2.63 (t, 2H, $COCH_2$), 6.81 (s, 1H, OH), 7.40—8.25 (m, 5H, aromatic-H). Found: C, 71.40; H, 5.55; N, 5.26%. Calcd for $C_{16}H_{15}NO_3$: C, 71.36; H, 5.61; N, 5.20%.

(vi) Hexanal: 1,2-Dihydroxy-3-hexanoyl-4-naphthalenecarbonitrile [**4**: $R=CH_3(CH_2)_4$, $R_1=CN$, $R_2=H$]: orange plates (87 mg, 28%), mp 129.5—130.0 °C. IR: ν_{OH} 3300; ν_{CH} 2960, 2940, 2865; ν_{CN} 2220; $\nu_{C=O}$ 1640 cm^{-1}. PMR ($CDCl_3$), δ: 0.92 (t, 3H, CH_3), 1.35—1.88 (m, 6H, $(CH_2)_3$), 3.47 (t, 2H, $COCH_2$), 6.65 (s, 1H, OH), 7.13—8.18 (m, 4H, aromatic-H), 11.83 (s, 1H, OH). Found: C, 71.88; H, 6.10; N, 4.97%. Calcd for $C_{17}H_{17}NO_3$: C, 72.07; H, 6.05; N, 4.94%. 1,2-Dihydroxy-4-naphthalenecarbonitrile monohexanoate [**5**: $R=CH_3(CH_2)_4$, $R_1=R_3=H$, $R_2=CN$]: white needles (15 mg, 5.3%), mp 105.5—106.5 °C. IR: ν_{OH} 3275; ν_{CH} 2960, 2930, 2860; ν_{CN} 2220; $\nu_{C=O}$ 1760 cm^{-1}. PMR(CCl_4), δ: 0.94 (t, 3H, CH_3), 1.31—1.85 (m, 6H, $(CH_2)_3$), 2.61 (t, 2H, $COCH_2$), 6.85 (s, 1H, OH), 7.46—8.25 (m, 5H, aromatic-H). Found: C, 72.33; H, 6.18; N, 4.79%. Calcd for $C_{17}H_{17}NO_3$: C, 72.07; H, 6.05; N, 4.94%.

(vii) Heptanal: 1,2-Dihydroxy-3-heptanoyl-4-naphthalenecarbonitrile [**4**: $R=CH_3(CH_2)_5$, $R_1=CN$, $R_2=H$]: orange plates (94 mg, 28.8%), mp 108—109 °C. IR: ν_{OH} 3300; ν_{CH} 2960, 2930, 2860; ν_{CN} 2220; $\nu_{C=O}$ 1640 cm^{-1}. PMR ($CDCl_3$), δ: 0.90 (t, 3H, CH_3), 1.24—1.94 (m, 8H, $(CH_2)_4$), 3.45 (t, 2H, $COCH_2$), 6.60(s, 1H, OH), 7.17—8.12 (m, 4H, aromatic-H), 11.71(s, 1H, OH). Found: C, 72.65; H, 6.56; N, 4.67%. Calcd for $C_{18}H_{19}NO_3$: C, 72.71; H, 6.44; N, 4.71%. 1,2-Dihydroxy-4-naphthalenecarbonitrile monoheptanoate [**5**: $R=CH_3(CH_2)_5$, $R_1=R_3=H$, $R_2=CN$]: white needles (15 mg, 4.6%), mp 91—92 °C. IR: ν_{OH} 3290; ν_{CH} 2960, 2935, 2867; ν_{CN} 2235; $\nu_{C=O}$ 1765 cm^{-1}. PMR (CCl_4), δ: 0.90—1.90 (m, 11H, $CH_3(CH_2)_4$), 2.61 (t, 2H, $COCH_2$), 6.82(1H, OH), 7.46—8.25 (m, 5H, aromatic-H). Found: C, 72.29; H, 6.33; N. 4.72%. Calcd for $C_{18}H_{19}NO_3$: C, 72.71; H, 6.44; N, 4.71%.

(viii) Octanal: 1,2-Dihydroxy-3-octanoyl-4-naphthalenecarbonitrile [**4**: $R=CH_3(CH_2)_6$, $R_1=CN$, $R_2=H$]: orange plates (98 mg, 28.7%), mp 112.0—112.5 °C. IR: ν_{OH} 3315; ν_{CH} 2955, 2940, 2860; ν_{CN} 2215; $\nu_{C=O}$ 1640 cm^{-1}. PMR(CCl_4), δ: 0.86 (t, 3H, CH_3), 1.25—1.90 (m, 10H, $(CH_2)_5$), 3.42 (t, 2H, $COCH_2$), 6.46 (s, 1H, OH), 7.30—

propionate [**5**: R=CH_3CH_2, R_1=Cl, R_2=R_3=H]: white needles (75 mg, 28.9 %), mp 107—108 °C. IR: ν_{OH} 3300; $\nu_{C=O}$ 1740 cm^{-1}. PMR($CDCl_3$), δ: 1.36 (t, 3H, CH_3), 2.77 (q, 2H, CH_2), 7.33—8.22 (m, 6H, aromatic-H). Found: C, 62.37; H, 4.46%. Calcd for $C_{13}H_{11}ClO_3$: C, 62.29; H, 4.42%. 3-Propionyl-1,2-naphthalenediol (8 mg, 3.6%) was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and propionaldehyde.

(iii) Butyraldehyde: 3-Chloro-1,2-naphthalenediol monobutyrate [**5**: R=$CH_3(CH_2)_2$, R_1=Cl R_2=R_3=H): white needles (70 mg, 24.4%), mp 116.5—118 °C. IR: ν_{OH} 3360; ν_{CH} 2960, 2930, 2880; $\nu_{C=O}$ 1735 cm^{-1}. PMR ($CDCl_3$), δ: 1.10 (t, 3H, CH_3), 1.14 (t, 3H, CH_3), 1.88 (sex, 2H, CH_2), 1.92 (sex, 2H, CH_2), 2.75 (t, 2H, $COCH_2$), 2.79 (t, 2H, $COCH_2$), 7.29—8.15 (m, 12H, aromatic-H). Found: C, 63.54; H, 4.88%. Calcd for $C_{14}H_{13}ClO_3$: C, 63.52; H, 4.95%. 3-Butyryl-1,2-naphthalenediol (11.5 mg, 4.6%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and butyraldehyde.

(iv) Isobutyraldehyde: 3-Chloro-1,2-naphthalenediol monoisobutyrate [**5**: R=$(CH_3)_2CH$, R_1=Cl, R_2=R_3=H]: white needles (92 mg, 33.5%), mp 116.0—117.5 °C. IR: ν_{OH} 3405; ν_{CH} 2990, 2940; $\nu_{C=O}$ 1735 cm^{-1}. PMR ($CDCl_3$), δ: 1.42 (d, 6H, $(CH_3)_2$), 1.46 (d, 6H, $(CH_3)_2$), 3.02 (sep, 1H, CH), 3.06 (sep, 1H, CH), 5.72 (1H, OH), 5.84 (1H, OH), 7.01—8.23 (m, 10H, aromatic-H). Found: C, 63.33; H, 4.99%. Calcd for $C_{14}H_{13}ClO_3$: C, 63.52; H, 4.95%. 3-Isobutyryl-1,2-naphthalenediol (15 mg, 5.9%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and isobutyraldehyde.

(v) Valeraldehyde: 3-Chloro-1,2-naphthalenediol monovalerate [**5**: R=$CH_3(CH_2)_3$, R_1=Cl, R_2=R_3=H]: white needles (80 mg, 27.7%), mp 89—90 °C. IR: ν_{OH} 3275; ν_{CH} 2960, 2940; $\nu_{C=O}$ 1735 cm^{-1}. PMR (CCl_4), δ: 0.92 (t, 3H, CH_3), 1.30—1.88 (m, 4H, $(CH_2)_2$), 2.60 (t, 2H, $COCH_2$), 6.10 (1H, OH), 7.30—8.12 (m, 5H, aromatic-H). Found: C, 64.57; H, 5.46%. Calcd for $C_{15}H_{15}ClO_3$: C, 64.64; H, 5.42%. 3-Chloro-4-valeryl-1,2-naphthoquinone: orange plates (9 mg, 3.1%), mp 144.5—145.5 °C. IR: ν_{OH} 2969, 2940, 2883; $\nu_{C=O}$ 1704, 1688 cm^{-1}. PMR(CCl_4), δ: 0.97 (t, 3H, CH_3), 1.33—1.82 (m, 4H, $(CH_2)_2$), 6.91—8.08 (m, 4H, aromatic-H). MS, *m/e*: 276 (M^+), 241 (M−Cl), 213 (M−CO−Cl), 191 (M−COR). Found: C, 65.02; H, 4.81%. Calcd for $C_{15}H_{13}ClO_3$: C, 65.11; H, 4.74%. 3-Valeryl-1,2-naphthalenediol (15 mg, 5.9%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and valeraldehyde.

(vi) Isovaleraldehyde: 3-Chloro-1,2-naphthalenediol monoisovalerate [**5**: R=$(CH_3)_2CHCH_2$, R_1=Cl, R_2=R_3=H]: white needles (93 mg, 32.2%), mp 125—125.5 °C. IR: ν_{OH} 3315, ν_{CH} 2972, 2922, 2880; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 1.08 (d, 6H, $(CH_3)_2$), 2.30 (m, 1H, CH), 2.60 (d, 2H, $COCH_2$), 7.40—8.20 (m, 6H, aromatic-H+OH). Found: C, 64.66; H, 5.38%. Calcd for $C_{15}H_{15}ClO_3$: C, 64.66; H, 5.42%. 3-Chloro-4-isovaleryl-1,2-naphthoquinone: reddish orange plates (12 mg, 4.2 %), mp 138—140 °C. IR: ν_{CH} 2970, 2942, 2885; $\nu_{C=O}$ 1704, 1687 cm^{-1}. PMR(CCl_4), δ: 1.07 (d, 6H, $(CH_3)_2$), 2.35 (m, 1H, CH), 2.70 (d, 2H, $COCH_2$), 6.94—8.10 (m, 4H, aromatic-H). Found: C, 65.00; H, 4.61%. Calcd for $C_{15}H_{13}ClO_3$: C, 65.11; H, 4.74%. 3-Isovaleryl-1,2-naphthalenediol(3.8 mg, 1.5%) was identical (PMR spectrum) with the photo-adduct of 1,2-naphthoquinone and isovaleraldehyde.

(vii) Hexanal: 3-Chloro-1,2-naphthalenediol monohexanoate [**5**: R=$CH_3(CH_2)_4$, R_1=Cl, R_2=R_3=H]: white needles (89 mg, 29.3%), mp 95.5—96.5 °C. IR: ν_{OH} 3200; ν_{CH} 2960, 2940; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 0.92 (t, 3H, CH_3), 1.30—1.90 (m, 6H, $(CH_2)_3$), 2.69 (t, 2H, $COCH_2$), 7.40—8.20 (m, 6H, aromatic-H+OH). Found: C, 65.73; H, 5.83%. Calcd for $C_{16}H_{17}ClO_3$: C, 65.64; H, 5.85%. 3-Chloro-4-hexanoyl-1,2-naphthoquinone: orange plates, mp 111—112 °C. IR: ν_{CH} 2960, 2935, 2870; $\nu_{C=O}$ 1705, 1680 cm^{-1}. 3-Hexanoyl-1,2-naphthalenediol was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and hexanal.

(viii) Heptanal: 3-Chloro-1,2-naphthalenediol monoheptanoate [**5**: R=$CH_3(CH_2)_5$, R_1=Cl, R_2=R_3=H]: white needles (103 mg, 32.4%), mp 80.5—82.0 °C. IR: ν_{OH} 3422; ν_{CH} 2958, 2935, 2870; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 0.92 (t, 3H, CH_3), 1.20—1.90 (m, 8H, $(CH_2)_4$), 2.70 (t, 2H, $COCH_2$), 5.80 (1H, OH), 7.40—8.20 (m, 5H, aromatic-H). Found: C, 66.71; H, 6.20%. Calcd for $C_{17}H_{19}ClO_3$: C, 66.56; H, 6.24%. 3-Chloro-4-heptanoyl-1,2-naphthoquinone: yellow crystals (12 mg, 3.8%), mp 105—106 °C. IR: ν_{CH} 2967, 2940, 2874; $\nu_{C=O}$ 1708, 1685 cm^{-1}. PMR (CCl_4), δ: 0.90 (t, 3H, CH_3), 1.23—1.84 (m, 8H, $(CH_2)_4$), 2.77 (t, 2H, $COCH_2$), 6.95—8.14 (m, 4H, aromatic-H). Found: C, 66.89; H, 5.57%. Calcd for $C_{17}H_{17}ClO_3$: C, 67.00; H, 5.62%. 3-Heptanoyl-1,2-naphthalenediol (23 mg, 8.2%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and heptanal.

(ix) Octanal: 3-Chloro-1,2-naphthalenediol monooctanoate [**5**: R=$CH_3(CH_2)_6$, R_1=Cl, R_2=R_3=H]: white needles (47 mg, 14.1%), mp 79.5—80.5 °C. IR: ν_{OH} 3290, ν_{CH} 2960, 2935, 2860; $\nu_{C=O}$ 1737 cm^{-1}. PMR($CDCl_3$), δ: 0.88—1.90 (br. m, 13H, $CH_3(CH_2)_5$), 2.72 (t, 2H, $COCH_2$), 5.80 (1H, OH), 7.40—8.20 (m, 5H, aromatic-H). Found: C, 67.50; H, 6.30%. Calcd for $C_{18}H_{21}ClO_3$: C, 67.39; H, 6.60%. 3-Octanoyl-1,2-naphthalenediol (15 mg, 5.1%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and octanal.

(x) Nonanal: 3-Chloro-1,2-naphthalenediol mononononanoate [**5**: R=$CH_3(CH_2)_7$, R_1=Cl, R_2=R_3=H]: white needles (72 mg, 20.7%), mp 76—77 °C. IR: ν_{OH} 3280; ν_{CH} 2970, 2945, 2870; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 0.88—1.90 (br. m, 15H, $CH_3(CH_2)_6$), 2.72 (t, 2H, $COCH_2$), 7.40—8.20 (m, 6H, aromatic-H+OH). Found: C, 68.15; H, 6.83%. Calcd for $C_{19}H_{23}ClO_3$: C, 68.15; H, 6.92%. 3-Chloro-4-nonanoyl-1,2-naphthoquinone: orange crystals (18 mg, 5.2%), mp 108—109 °C. IR: ν_{CH} 2967, 2938, 2870; $\nu_{C=O}$ 1720, 1680 cm^{-1}. PMR(CCl_4), δ: 0.88 (t, 3H, CH_3), 1.17—1.86 (br. m, 12H, $(CH_2)_6$), 2.78 (t, 2H, $COCH_2$), 6.92—8.07 (m, 4H, aromatic-H). Found: C, 68.64; H, 6.31%. Calcd for $C_{19}H_{21}ClO_3$: C, 68.57; H, 6.36%. 3-Nonanoyl-1,2-naphthalenediol (27 mg, 9.4%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and nonanal.

(xi) Decanal: 3-Chloro-1,2-naphthalenediol monodecanoate [**5**: R=$CH_3(CH_2)_8$, R_1=Cl, R_2=R_3=H]: white needles (79 mg, 21.8%), mp 67—68 °C. IR: ν_{OH} 3290; ν_{CH} 2960, 2930, 2860; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 0.84 (t, 3H, CH_3), 1.10—1.90 (br. m, 14H, $(CH_2)_7$), 2.68 (t, 2H, $COCH_2$), 7.40—8.20 (m, 6H, aromatic-H+OH). Found: C, 69.10; H, 7.37%. Calcd for $C_{20}H_{25}ClO_4$: C, 68.86; H, 7.22%. 3-Chloro-4-decanoyl-1,2-naphthoquinone: orange plates (19 mg, 5.3%), mp 103—104 °C. IR: ν_{CH} 2986, 2935, 2865; $\nu_{C=O}$ 1718, 1678 cm^{-1}. PMR ($CDCl_3$), δ: 0.87 (t, 3H, CH_3), 1.17—1.85 (br. m, 14H, $(CH_2)_7$), 2.85 (t, 2H, $COCH_2$), 6.98—8.14 (m, 4H, aromatic-H). MS; *m/e* 346 (M^+), 311 (M−Cl), 283 (M−CO−Cl). Found: C, 69.33; H, 6.54%. Calcd for $C_{20}H_{23}ClO_3$: C, 69.26; H, 6.68%. 3-Decanoyl-1,2-naphthalenediol (18 mg, 5.5%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and decanal.

Synthesis of 3-Chloro-4-acetyl-1,2-naphthoquinone. 4-Acetyl-1-naphthol (930 mg, 5 mmol) was dissolved in acetone (100 ml) and added to a solution of Fremy's salt (3 g) dissolved in water (200 ml) and M/6 KH_2PO_4 solution (50 ml). The solution became red after 30 min and an oily substance was separated. The solution was extracted with chloroform (70 ml×3), then the extract was washed with water and dried (Na_2SO_4). After the solvent was removed, the quinone was solidified. 4-Acetyl-1,2-naphthoquinone: red crystals from alcohol, mp 92—93 °C. Yield was theoretical. Dry chlorine was passed into the mixture of 4-acetyl-1,2-naphthoquinone (193 mg) and acetic acid (1.6 g) until the quinone was dissolved. Hot water (80—90 °C) was added into the reaction mixture, then the 3-chloro-4-acetyl-1,2-naphthoquinone which separated was collected and washed with water: reddish orange needles from chloroform, mp 194—197 °C. Its IR and PMR spectra were identical with the data of the corresponding quinone obtained from the photo-induced reaction of 3-chloro-1,2-naphthoquinone with acetaldehyde.

Auto-oxidation of 3-Chloro-4-acetyl-1,2-naphthalenediol The reduction of 3-chloro-4-acetyl-1,2-naphthoquinone with sodium hydrosulfite gave 3-chloro-4-acetyl-1,2-naphthalenediol. This was oxidized into the original quinone in benzene or through a silica gel column.

Photo-addition Products of 3-Bromo-1,2-naphthoquinone with Aliphatic Aldehydes. (i) Acetaldehyde: 3-Bromo-1,2-naphthalenediol monoacetate [**5**: R=CH_3, R_1=Br, R_2=R_3=H]: white needles (44 mg, 18.6%), mp 159.5—160.5 °C. IR: ν_{OH} 3310; $\nu_{C=O}$ 1745 cm^{-1}. PMR ($CDCl_3$), δ: 2.47 (s, 3H, CH_3) 7.32—8.23 (m, 6H, aromatic-H+OH). Found: C, 51.11; H, 3.28%. Calcd for $C_{12}H_9BrO_3$: C, 51.27; H, 3.23 %. 3-Bromo-4-acetyl-1,2-naphthoquinone (trace); IR: $\nu_{C=O}$ 1700, 1690 cm^{-1}. 3-Acetyl-1,2-naphthalenediol (4 mg, 2.4%) was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and acetaldehyde.

(ii) Propionaldehyde: 3-Bromo-1,2-naphthalenediol monopropionate [**5**: R=CH_3CH_2, R_1=Br, R_2=R_3=H]: white needles (20 mg, 8.1%), mp 112—114 °C. IR: ν_{OH} 3320 (br); ν_{CH} 2980; $\nu_{C=O}$ 1740 cm^{-1}. PMR($CDCl_3$), δ: 1.37 (t, 3H, CH_3), 2.78 (q, 2H, CH_2), 7.40—8.22 (m, 6H, aromatic-H). Found: C, 53.08; H, 3.87%. Calcd for $C_{13}H_{11}BrO_3$: C, 52.91; H, 3.76%. 3-Propionyl-1,2-naphthalenediol (15 mg, 8.3%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and propionaldehyde.

(iii) Butyraldehyde: 3-Bromo-1,2-naphthalenediol monobutyrate [**5**: R=$CH_3(CH_2)_3$, R_1=Br, R_2=R_3=H]: white crystals (28 mg, 10.8%), mp 126—128 °C. IR: ν_{OH} 3360; ν_{CH} 2970, 2940, 2880; $\nu_{C=O}$ 1740 cm^{-1}. PMR($CDCl_3$), δ: 1.12 (t, 3H, CH_3), 1.90 (sex, 2H, CH_2), 2.72 (t, 2H, $COCH_2$), 7.32—8.00 (m, 6H, aromatic-H+OH). Found: C, 54.22; H, 4.21%. Calcd for $C_{14}H_{13}BrO_3$: C, 54.39; H, 4.24%. 3-Butyryl-1,2-naphthalenediol (8 mg, 4.2%) was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and butyraldehyde.

(iv) Isobutyraldehyde: 3-Bromo-1,2-naphthalenediol monoisobutyrate [**5**: R=$(CH_3)_2CH$, R_1=Br, R_2=R_3=H]: white needles (38 mg, 14.7%), mp 106—107 °C. IR: ν_{OH} 3380 (br); ν_{CH} 2980, 2940, 2880; $\nu_{C=O}$ 1730 cm^{-1}. PMR($CDCl_3$), δ: 1.41 (d, 6H, $(CH_3)_2$), 1.44 (d, 6H, $(CH_3)_2$), 2.95 (sep, 1H, CH), 2.98 (sep, 1H, CH), 7.24—8.20 (m, 12H, aromatic-H +OH). Found: C, 54.15; H, 4.12%. Calcd for $C_{14}H_{13}BrO_3$: C, 54.39; H, 4.24%. 3-Butyryl-1,2-naphthalenediol (10 mg, 5.2%) was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and isobutyraldehyde.

(v) Valeraldehyde: 3-Bromo-1,2-naphthalenediol monovalerate [**5**: R=$CH_3(CH_2)_3$, R_1=Br, R_2=R_3=H]: white needles (69 mg, 25.5%), mp 96—97 °C. IR: ν_{OH} 3250 (br); ν_{CH} 2965, 2935, 2870; $\nu_{C=O}$ 1728 cm^{-1}. PMR(CCl_4), δ: 0.88 —1.90 (m, 7H, $CH_3(CH_2)_2$), 2.60 (t, 2H, $COCH_2$), 6.61 (1H, OH), 7.30—8.10 (m, 5H, aromatic-H). Found: C, 55.55; H, 4.49%. Calcd for $C_{15}H_{15}BrO_3$: C, 55.75; H, 4.68%. 3-Bromo-4-valeryl-1,2-naphthoquinone: orange needles (8 mg, 3%), mp 141—142 °C. IR: ν_{CH} 2965, 2935, 2880; $\nu_{C=O}$ 1700, 1685 cm^{-1}. PMR(CCl_4), δ: 0.96 (t, 3H, CH_3), 1.30—1.80 (m, 4H, $(CH_2)_2$), 2.78 (t, 2H, $COCH_2$), 6.94—8.08 (m, 4H, aromatic-H). Found: C, 56.13; H, 4.21%. Calcd for $C_{15}H_{13}BrO_3$: C, 56.10; H, 4.08%. 3-Valeryl-1,2-naphthalenediol (18 mg, 8.8%) was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and valeraldehyde.

(v) Isovaleraldehyde: 3-Bromo-1,2-naphthalenediol monoisovalerate [**5**: R=$(CH_3)_2CHCH_2$, R_1=Br, R_2=R_3=H]: white needles (59 mg, 21.8%), mp 124.5—125.5 °C. IR: ν_{OH} 3335; ν_{CH} 2960, 2877; $\nu_{C=O}$ 1735 cm^{-1}. PMR($CDCl_3$), δ: 1.10 (d, 6H, $(CH_3)_2$), 1.13 (d, 6H, $(CH_3)_2$), 2.30 (m, 2H, CH), 2.54 (d, 2H, $COCH_2$), 2.57 (d, 2H, $COCH_2$), 5.60 (1H, OH), 5.90 (1H, OH), 7.23—8.20 (m, 10H, aromatic-H). Found: C, 55.68; H, 4.62%. Calcd for $C_{15}H_{15}BrO_3$: C, 55.75; H, 4.68%. 3-Bromo-4-isovaleryl-1,2-naphthoquinone: orange crystals (6 mg, 2.2%), mp 151—153 °C. IR: ν_{CH} 2975, 2885; $\nu_{C=O}$ 1700, 1685 cm^{-1}. PMR(CCl_4), δ: 1.14 (d, 6H, $(CH_3)_2$), 2.35 (m, 1H, CH), 2.65 (d, 2H, $COCH_2$), 6.95—8.09 (m, 4H, aromatic-H). 3-Isovaleryl-1,2-naphthalenediol (14 mg, 6.8%) was identical (IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and isovaleraldehyde.

(vii) Hexanal: 3-Bromo-1,2-naphthalenediol monohexanoate [**5**: R=$CH_3(CH_2)_4$, R_1=Br, R_2=R_3=H]: white needles (57 mg, 20.1%), mp 89.5—90.5 °C. IR: ν_{OH} 3250; ν_{CH} 2950, 2875; $\nu_{C=O}$ 1730 cm^{-1}. PMR(CCl_4), δ: 0.92 (t, 3H, CH_3), 1.20—1.90(m, 6H, $(CH_2)_3$), 2.60(t, 2H, $COCH_2$), 6.10(1H, OH), 7.32—8.16(m, 5H, aromatic-H). Found: C, 56.83; H, 5.19%. Calcd for $C_{16}H_{17}BrO_3$: C, 56.99; H, 5.08%. 3-Bromo-4-hexanoyl-1,2-naphthoquinone: orange plates (7 mg, 2.5%), mp 100—101 °C. IR: ν_{CH} 2970, 2946, 2878; $\nu_{C=O}$ 1703, 1683 cm^{-1}. PMR(CCl_4), δ: 0.93(t, 3H, CH_3), 1.27—1.88(m, 6H, $(CH_2)_3$), 2.81(t, 2H, $COCH_2$), 6.87—8.04(m, 4H, aromatic-H). 3-Hexanoyl-1,2-naphthalenediol (15 mg, 6.9%) was identical(IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and hexanal.

(viii) Heptanal: 3-Bromo-1,2-naphthalenediol monohexanoate[**5**: R=$CH_3(CH_2)_5$, R_1=Br, R_2=R_3=H]: white needles (30 mg, 10.2%), mp 78.5—79.5 °C. IR: ν_{OH} 3375; ν_{CH} 2958, 2940, 2860; $\nu_{C=O}$ 1725 cm^{-1}. PMR(CCl_4), δ : 0.94—1.88(br. m, 11H, $CH_3(CH_2)_4$), 2.62(t, 2H, $COCH_2$), 6.06 (1H, OH), 7.30—8.20(m, 5H, aromatic-H). Found: C, 58.24; H,5.44%. Calcd for $C_{17}H_{19}BrO_3$: C,58.13; H, 5.45%. 3-Heptanoyl-1,2-naphthalenediol(17 mg, 7.5%) was identical(IR and PMR spectra) with the photo-adduct of 1,2-naphthoquinone and heptanal.

(ix) Octanal: 3-Bromo-1,2-naphthalenediol monooctanoate[**5**: R=$CH_3(CH_2)_6$, R_1=Br, R_2=R_3=H]: white needles (20 mg, 6.5%), mp 65—66 °C. IR: ν_{OH} 3350(br); ν_{CH} 2930, 2860; $\nu_{C=O}$ 1735 cm^{-1}. PMR(CCl_4), δ: 0.82—1.90(br.m, 26H, $CH_3(CH_2)_5$), 2.64(t, 2H, $COCH_2$), 2.67(t, 2H, $COCH_2$), 5.96(2H, OH), 7.30—8.20(m, 10H, aromatic-H). Found: C,59.16; H,5.85%. Calcd for $C_{18}H_{21}BrO_3$: C, 59.19; H, 5.79%. 3-Octanoyl-1,2-naphthalenediol (5 mg, 2.1%) was identical(IR spectrum) with the photo-adduct of 1,2-naphthoquinone and octanal.

(x) Nonanal: 3-Bromo-1,2-naphthalenediol mononononanoate[**5**: R=$CH_3(CH_2)_7$, R_1=Br, R_2=R_3=H]: white needles (27 mg, 8.5%), mp 82—83 °C. IR: ν_{OH} 3275(br); ν_{CH} 2925, 2860; $\nu_{C=O}$ 1735 cm^{-1}. PMR(CCl_4), δ: 0.82—1.95

(br. m, 15H, $CH_3(CH_2)_6$), 2.66(t, 2H, $COCH_2$), 5.99(s, 1H, OH), 7.33—8.23 (m, 5H, aromatic-H). Found: C, 60.33; H, 6.10%. Calcd for $C_{19}H_{23}BrO_3$: C,60.17; H, 6.11%. 3-Bromo-4-nonanoyl-1,2-naphthoquinone: orange crystals (8 mg 2.5%), mp 87—88 °C. IR: ν_{CH} 2945,2870; $\nu_{C=O}$ 1715, 1675 cm^{-1}. PMR(CCl_4), δ: 0.86(t, 3H, CH_3), 1.29—1.90(br. m, 12H, $(CH_2)_6$), 2.76(t, 2H, $COCH_2$), 6.93—8.08(m, 4H, aromatic-H). Found: C,60.25; H,5.50%. Calcd for $C_{19}H_{21}BrO_3$: C, 60.49; H, 5.61%. 3-Nonanoyl-1,2-naphthalenediol(9 mg, 3.6%) was identical (IR spectrum) with the photo-adduct of 1,2-naphthoquinone and nonanal.

(xi) Decanal: 3-Bromo-1,2-naphthalenediol monodecanoate [**5**: $R=CH_3(CH_2)_8$, $R_1=Br$, $R_2=R_3=H$]: white needles (28 mg, 8.5%), mp 79—80 °C. IR: ν_{OH} 3250(br); ν_{CH} 2960, 2920, 2858; $\nu_{C=O}$ 1728 cm^{-1}. PMR(CCl_4), δ: 0.80—1.95(br. m, 17H, $CH_3(CH_2)_7$), 2.62 (t, 2H, $COCH_2$), 6.19(1H, OH), 7.30—8.10(m, 5H, aromatic-H). Found: C, 60.94; H, 6.44%. Calcd for $C_{20}H_{25}BrO_3$: C,61.08; H,6.41%. 3-Bromo-4-decanoyl-1,2-naphthoquinone: orange plates (10 mg, 3%), mp 89—90 °C. IR: ν_{CH} 2945, 2870; $\nu_{C=O}$ 1715, 1675 cm^{-1}. PMR(CCl_4), δ: 0.88(t, 3H, CH_3), 1.17—1.84 (br. m, 14H, $(CH_2)_7$), 2.84(t, 2H, $COCH_2$), 6.96—8.13 (m, 4H, aromatic-H). Found: C,61.35; H,5.82%. Calcd for $C_{20}H_{23}BrO_3$: C,61.39; H,5.92%. 3-Decanoyl-1,2-naphthalenediol (8 mg, 3%) was identical(IR spectrum) with the photo-adduct of 1,2-naphthoquinone and decanal.

Photo-addition Products of 3-Methyl-1,2-naphthoquinone with Acetaldehyde: 3-Methyl-1,2-naphthalenediol monoacetate [**5**: $R=CH_3$, $R_1=CH_3$, $R_2=R_3=H$]: white crystals (37 mg, 17%), mp 127—128 °C. IR: ν_{OH} 3340(br); $\nu_{C=O}$ 1739 cm^{-1}. PMR($CDCl_3$), δ: 2.28(s, 3H, CH_3), 2.37(s, 3H, CH_3), 2.40(s, 3H, $COCH_3$), 2.46(s, 3H, $COCH_3$), 5.47(1H, OH), 5.60(1H, OH), 7.29—8.15(m, 10H, aromatic-H). Found: C, 72.08; H, 5.59%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%. 3-Methyl-4-acetyl-1,2-naphthoquinone: orange crystals (14 mg, 6.5%), mp 180—182 °C. IR: $\nu_{C=O}$ 1700, 1675 cm^{-1}. PMR(CCl_4), δ: 1.90(s, 3H, CH_3), 2.44(s, 3H, $COCH_3$), 6.88—8.05 (m, 4H, aromatic-H). Found: C, 73.03; H, 4.83%. Calcd for $C_{13}H_{10}O_3$: C, 72.89; H, 4.71%.

The author wishes to express his gratitude to Professor Kazuhiro Maruyama of Kyoto University and Professor Osamu Soga of Shimane University for their invaluable suggestions and encouragement. Financial support from the Ministry of Education is acknowledged with pleasure.

**Department of Chemistry, Aichi Kyoiku University, Kariya, Aichi 448*

(Received January 13, 1976)

The 2E doubly charged ion mass spectra of twelve simple monosubstituted aromatic compounds were recorded. The spectral pattern of these compounds can be classified into three types. When the substituent is strongly electron-donating such as the amino or dimethylamino group, a very intense molecular ion peak appears, no fragment ion peak being observed. Phenol, anisole, toluene, and chlorobenzene show both molecular and fragment ion peaks in varying intensities. The parent benzene itself behaves similarly. Only fragment ion peaks were observed for nitrobenzene and aromatic carbonyl compounds such as benzaldehyde, acetophenone, methyl benzoate, or benzoic acid. The major fragmentation reactions are discussed.

In the 2E doubly charged ion mass spectrum[1,2] we can observe singly charged ions arising from the charge exchange reaction between doubly charged ions and any neutral species in the first field-free region of a mass spectrometer. Under these spectral conditions, aromatic hydrocarbons[3,4] exhibit several peculiar fragmentations including drastic skeletal changes, the spectra showing strong similarity irrespective of hydrocarbon structure. On the other hand, the spectra of aromatic amines[5] and substituted aromatic carbonyl compounds[6] afford certain characteristic fragmentation patterns with structures. The purpose of the present work is to investigate the structure-spectrum correlation in more detail by using simple monosubstituted aromatic compounds.[7]

General Appearance of the Spectrum

The 2E spectra of twelve simple aromatic compounds are given in Table 1 and Fig. 1. The spectral pattern of these compounds can be classified into three types. When the substituent is strongly electron-donating such as the amino or dimethylamino group, a very intense molecular ion peak appears, no fragment ion peak being observed. This indicates that the substituent can accomodate two positive charges within the benzene ring and the molecular ion is stable enough to be detected.

The compounds with other electron-donating substituents, *e.g.*, phenol, anisole, or toluene, show both molecular and fragment ion peaks in varying intensities. The parent benzene itself behaves similarly. Chlorobenzene, in which the substituent is electron-withdrawing, also exhibits a strong molecular ion peak as well as several fragment ion peaks of comparable intensity. In this case, the presence of lone-pair

a) Spectra of aniline, phenol, and benzoic acid are shown in Fig. 1. b) No molecular ion peak was observed.

electrons on the chlorine atom seems to be a dominant factor for stabilization of two positive charges.

On the other hand, only fragment ion peaks were observed for nitrobenzene and aromatic carbonyl compounds such as benzaldehyde, acetophenone, methyl benzoate, or benzoic acid. Since the substituents of these compounds are electron-withdrawing, two positive charges are not stable in the molecular framework. This might be responsible for the exclusive occurrence of fragmentations.

Major Fragmentation Patterns

Two peaks which might be due to the ions of $[M-H_2]$ and $[M-2H_2]$ appear in the spectra of aniline and *N,N*-dimethylaniline. These ions were also observed in the substituted aniline derivatives.[6] The [M−H] peak in *N,N*-dimethylaniline is also significant. On the other hand, phenol and anisole gave fragment ions at 62, 63, 64, and 65 mass units with expulsion of oxygen-containing fragments. In contrast to the case of aromatic amines,[5] elimination of hydrocarbon fragments does not seem to be very favorable for these compounds. Thus, the behavior of phenol and anisole seems to be similar to that in the ordinary singly charged ion spectrum.

The fragmentation of benzene and toluene has been discussed in detail in a previous paper.[4] Thus, the ions at 74 for benzene and 86 for toluene correspond to the allene-type dication of $H-\overset{+}{C}(=C=)_x\overset{+}{C}-H$ with x being 4 and 5, respectively. This series of hydrocarbon ions may appear at 62, 74, 86, 98, *etc.* The peak at 86 is usually observed if the compound has a side chain containing at least one carbon atom directly bound to an aromatic ring. The [M−H] and $[M-H_2]$ peaks were also prominent in benzene and toluene spectra.

Chlorobenzene showed a group of peaks at 74, 75, and 76 mass units as in benzene. These peaks are also characteristic of nitrobenzene and carbonyl compounds. Besides the usual ions of [M−NO] and $[M-NO_2]$, a moderately intense peak at 62 mass units appeared in the nitrobenzene spectrum. The origin of this peak would be the same as in phenol and anisole.

For aromatic carbonyl compounds, C_6H_5–CO–R, two successive fragmentations, [M−R] and [M−R−CO], which eventually give rise to a phenyl ion at 77, were commonly observed as in the ordinary mass spectrum.

On the other hand, the [M−CO] peak was also noticeable in the spectrum of benzaldehyde or benzoic acid (peaks at 78 and 94 mass units, respectively). This is ascribable to the novel fragmentation that involves a rearrangement reaction of the side chain, the peak being encountered in most of the *para*- and some of the *meta*-substituted aromatic carbonyl compounds.[6,8] Acetophenone and methyl benzoate exhibited a weak $[M-H_2O]$ peak. The mechanism of this fragmentation is obscure.

From these results, it is apparent that the fragmentation patterns of simple aromatic compounds clearly reflect the nature of the substituent. However, we have no evidence for the mechanism of these fragmentations. Due to the unusually drastic skeletal changes, the mechanistic interpretation in the 2E mass spectra may not be straightforward as in the ordinary mass spectra. Another difficulty in analyzing the fragmentation in the 2E spectrum is the involvement of collisional charge exchange process during the course of formation of each fragment ion. The relative intensities of individual peak should be examined with care, as Ast and Beynon have pointed out.[5] Empirically, however, the 2E doubly charged ion mass spectrum may prove useful in obtaining information on the structure of unknown compounds, or in discriminating the isomer pairs of certain molecules.[6]

Experimental

Materials. Commercial compounds were used. All the samples were characterized and checked for purity by conventional mass spectrometry prior to the determination of doubly charged ion mass spectra.

Doubly Charged Ion Mass Spectra. The spectra were recorded with an Hitachi RMU-7 double focusing mass spectrometer by the method previously described.[4] Standard operating conditions were as follows: ionizing energy 70 eV, ionizing current 80 μA, source temperature 250 °C, sample pressure $1—5\times10^{-6}$ Torr, and accelerating voltage 1.8 kV.

Catalytic Dehydration of Ethers on Nickel Oxide–Silica–Alumina

Hisao IMAI

Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 21, 1976)

The dehydration of diethyl ether was studied on synthetic nickel oxide–silica–alumina catalysts in the temperature range of 340—400 °C and at pressures less than 50 Torr. It was found that ethylene, butenes, water, and small amounts of carbon monoxide and methane were formed on the catalysts of lower nickel content. The rate constant for the formation of butenes showd a maximum on the catalyst of 10 atom% nickel. The mechanism of the formation of the butenes was discussed by studying the catalytic dehydration of various ethers.

The dehydration of alcohols or ethers on solid acid catalysts has been studied for many years.[1,2] However, the dehydration of alcohols or ethers on supported nickel oxide has been reported only rarely. In a series of papers, Pines *et al.*[3] studied the dehydration of alcohols in the presence of hydrogen over supported and unsupported nickel oxide catalysts, and found the following facts: In most of these dehydration reactions, ether is the main product, while the other dehydration products are the paraffins formed by hydrogenation of the olefins produced from the alcohol. Paraffins with one carbon less than the original alcohols are also formed in competition with the dehydration reaction.

In the present research, the reaction of diethyl ether on nickel oxide–silica–alumina catalysts was investigated. It was found that in addition to ethylene, which was a normal dehydration product of the ether, butenes were formed on the catalysts of lower nickel content. The mechanism of the formation of the butenes is studied by investigating the reaction products of various ethers and alcohol.

Experimental

Materials. Nickel oxide–silica–alumina catalysts were prepared by a co-precipitation method with sodium silicate and nickel nitrate solutions in the same way as described elsewhere[4]. The catalysts were sized (1—2 mm) and stored for use after the treatment in a stream of dried air for 16 h at 350°C. Some properties of the catalysts are summarized in Table 1. The specific surface area was obtained by applying the standard B. E. T. method to the adsorption isotherm of nitrogen at −196 °C.

Ethers and ethanol were of guaranteed grade. All of these reagents were distilled in a vacuum and stored in glass reservoirs for use in the reactions.

Apparatus and Procedures. The activities of the catalysts were measured by an all-glass circulatory flow system, 713 ml in total volume. Prior to the reaction, the catalyst was treated *in situ* in a stream of dried air for 16h at 400°C, and then evacuated for 3 h ($\approx 10^{-5}$ Torr) at the same temperature. After admitting 50 Torr of ether vapor to the gas circulation system, a small portion (*ca.* 2 ml) of the circulating gas was withdrawn at intervals from the system for the analysis. The analysis was made by gas chromatographs (6 m benzyl cyanide–$AgNO_3$, 5 m Carbowax 1500 and 1.5 m activated carbon columns) and by a Hitachi RMU-6E mass spectrometer.

20	20	337
40	40	425
50	50	442
80	80	265

Results and Discussion

Figure 1 is an example of the reactions of diethyl ether on the catalysts of lower nickel content. Ethylene, butenes, water, and small amounts of carbon monoxide and methane were formed on the NS-20 catalyst at 360 °C; the initial pressure of the ether was 50.0 Torr. The composition of the reacting mixture, expressed as atom% of the carbon in each molecule, changed linearly with an increase in the reaction time. This fact indicates that all these reactions are zero order with respect to ether pressure. The butenes were produced as an almost equilibrium mixture of 1-butene, *cis*-2-butene, and *trans*-2-butene (1-butene: *cis*-2-butene : *trans*-2-butene=1.0 : 1.6 : 2.2). While carbon monoxide and methane were produced at small rates on the catalysts of lower nickel content, they were produced at much higher rates on the catalyst of NS-80, as shown in Fig. 2. Ethylene was formed only at the beginning of the reaction on this catalyst. No butene was found, but small amounts of ethane and carbon dioxide were found in the products. The ratio of carbon monoxide to methane was found to be almost unity on all the catalysts studied. A material

balance of the products obtained at the reaction time of 10 min revealed that about 50% of the oxygen atoms in the products originated from the catalyst.

The effect of catalyst composition on the catalytic activity is shown in Fig. 3. In this figure, the zero order rate constant per unit surface area of the catalyst (k_s) is plotted against the catalyst composition (atom% of nickel). The rate constant for the consumption of the ether decreases with an increase in the nickel content and then increases with a further increase in the nickel content. This increase observed in the catalysts of higher nickel content (>50%) can be ascribed to the increase in the rates of formation of carbon monoxide and methane. The rate constant for the formation of ethylene decreases with increasing nickel content. On the other hand, the rate constant for the formation of butenes shows a maximum at a nickel content of about 10%.

The effect of temperature was studied by using the catalyst of NS-20, as shown in Fig. 4. The Arrhenius plots of the rate constants are linear and the apparent activation energies obtained are also shown in the figure. The fact that the activation energies of these reactions are different suggests that these reactions take place at different active sites or by different mechanisms. The value of the activation energy for the formation of ethylene falls within the range of the literature values (14—24 kcal/mol)[1)] obtained in the catalytic dehydration on silica and alumina surfaces. As shown in Fig. 3, the rate constant for the formation of ethylene decreases with increasing nickel content until its value becomes zero at the catalyst of NS-80. These facts may suggest that the formation of ethylene takes place on the surface of silica. The formation of carbon monoxide and methane, on the other hand, may take place on the surface of nickel oxide, because carbon monoxide and methane are produced as the main products on the catalyst of high nickel content (NS-80). As to the formation of butenes, it can be presumed that

the reaction takes place on the active sites of the dimerization of olefins, because the nickel oxide–silica–alumina is known to be active for the dimerization of olefins.[5-8]

The following three mechanisms can be considered for the formation of the butenes: (1) Ethylene is produced from the ether and desorbed to the gas phase. The desorbed ethylene is again adsorbed on the active sites for the dimerization to form butenes. (2) Ethylene is produced from the ether. The chemisorbed ethylene reacts, before desorption to the gas phase, on the active sites to form butenes. (3) Butenes are formed by the intramolecular dehydration condensation of diethyl ether.

The reactions of various ethers were studied on NS-20 catalyst at 360 °C in order to get an insight into the mechanism of the reaction. The results are summarized in Table 2. In all cases, the rate of formation of olefins could be expressed by a zero-order rate equation, as in the case of diethyl ether. The reaction products of diethyl ether were ethylene and butenes, as described before. Carbon monoxide and methane are not listed in the table, although small amounts of these molecules were produced in every case. When a mixture of diethyl ether (50.1 Torr) and propene (26.1 Torr) was in contact with the catalyst, ethylene and butenes were formed, but neither pentenes nor hexenes were formed. Moreover, the rate constant for the formation of butenes was almost the same as that obtained when only diethyl ether was the reactant. If the reaction takes place according to the first mechanism, it is expected that pentenes and hexenes will also be produced when the reactant is the mixture of diethyl ether and propene. Thus, it is concluded that the first mechanism, *i.e.*, the desorbed ethylene is adsorbed again to form butenes, does not hold in the present case. If the reaction takes place according to the third mechanism, *i.e.*, the intramolecular dehydration condensation, it is expected that only pentenes will be produced in the reaction of ethyl propyl ether. The experimental result obtained with ethyl propyl ether showed that butenes, pentenes, and small amount of hexenes were produced in the molar ratio of 1.0 : 0.46 : 0.11, respectively, in addition to ethylene and propene. This fact indicates that the third mechanism also does not hold in the present case. The result of the reaction with dipropyl ether was almost the same as that obtained for diethyl ether, except that the ratio of the formation of olefin dimer was smaller in the former case. When ethanol was used as the reactant, ethylene and butenes were produced, and the rate constant for the formation of butenes was comparable to that obtained in the reaction of diethyl ether—the former was 1.36 times of the latter. These facts suggest that the second mechanism, *i.e.*, the chemisorbed ethylene which was produced by the dehydration of ether reacts, before desorption, to form butenes, may hold in the present case.

The Photoreaction of Pyrazine Derivatives

Kazutoshi YAMADA, Kiyoshi KATSUURA, Hideaki KASIMURA, and Hirotada IIDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received February 27, 1976)

The irradiation of the pyrazine derivative with an α-carbonyl substituent (**1**) under a nitrogen atmosphere gave hydroxypyrazine (**2**) and two solvent adducts (**3** and **4**). In the case of **1e**, the charge-transfer complex of pyrazine and dihydropyrazine, produced by the reduction of the pyrazine, was isolated. The mechanism of this photoreaction was similar to that of flavine. The attack of oxygen on dihydropyrazine produced **2**. Furthermore, the photoreduction with DTT occurred through the intermediate, which was similar to the case of flavine. The reaction rates of various pyrazines were measured. The quenching studies indicate that the photoreaction proceeds *via* the n-π^* triplet state.

We have previously investigated the reactions of enaminoketone and have reported the relation between the conformation of the enaminoketone and its photoreaction. At that time, we planned also to study the photoreaction of the pyrazine derivative (**1**) as a model of enaminoketone with a fixed conformation.[1]

Several photoreactions of pyrazines have been studied, but the photoreaction of pyrazine with an α-carbonyl substituent is not known. Padwa and his co-workers prepared pyrazine by the photodimerization and the photoisomerization of azirine.[2] Chambers and his co-workers showed the rearrangement of pyridazine to pyrazine by irradiation.[3] Lahmani and Ivanoff irradiated pyrazine derivative and thus obtained the pyrimidine derivative.[4] Furthermore, in the case of phenazine, which had a pyrazine ring in a molecule, the photoreaction occurred in either an acidic or reducible condition, and 1-alkoxyphenazines were produced as photoproducts.[5]

We wish now to report the results on the photobehavior of the pyrazine derivative (**1**), which produced hydroxypyrazine (**2**) and two solvent adducts (**3** and **4**), and discuss the mechanism, which might be similar to that in the behavior of flavin. It was found that pyrazine exhibited photochromism and could be considered a model of the photoreaction of flavin.

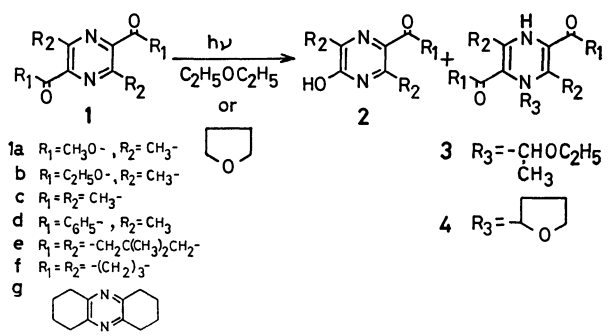
Results and Discussion

Photolysis of Pyrazine Derivatives. The irradiation of the pyrazine derivative **1a** in diethyl ether with a 450-W high pressure mercury lamp (>330 nm) gave two significant photoproducts (**2a** and **3a**) (Scheme 1).

The structures of **2a** and **3a** were identified as methyl 3,6-dimethyl-5-hydroxypyrazine-2-carboxylate and a solvent adduct respectively on the basis of their physical data. The mass spectrum of **2a** gave a molecular ion at *m/e* 182 ($C_8H_{10}N_2O_3$). The UV spectrum showed absorptions at 236 (ε 13900) and 307 nm (ε 6650). The IR spectrum had a hydroxyl absorption at 3430 cm^{-1}. The NMR spectrum of **2a** in $CDCl_3$ showed three sharp singlets for the C(2), C(3), and C(6) methyl groups, and a broad singlet for the hydroxyl group. Moreover, the structure of **2a** was identified by the fact that the hydrolysis and further thermal degradation of **2a** gave 3,6-dimethyl-2-pyrazinol, identical with the independently prepared sample.[6] The mass spectrum of **3a** showed peaks at *m/e* 298 ($M^{+\cdot}$; $C_{14}H_{22}N_2O_5$) and 225 ($M^{+\cdot}-C_4H_9O$). The UV spectrum showed absorptions at 266 (ε 14000) and 322 nm (ε 5300). The NMR spectrum of **3a** in $CDCl_3$ showed three sharp singlets for the C(2), C(3), C(5), and C(6) methyl groups, and nine protons for the 1-ethoxyethyl group. The presence of a NH group was confirmed by the IR band at 3270 cm^{-1}. Thus, **3a** was identified as dimethyl 1,4-dihydro-3,6-dimethyl-1-(1-ethoxyethyl)-2,5-pyrazinedicarboxylate.

Using tetrahydrofuran as a solvent, **2a** and a solvent adduct (**4a**) were obtained. In each case of **1b**, **1c**, and **1d**, the corresponding hydroxyl compound (**2**) and a solvent adduct (**3** or **4**) were given. However, the physical data and yields of **3b**, **3d**, **4b**, and **4d** were hard to obtain, because the isolation of these compounds was difficult. The yields and physical data of **2**, **3**, and **4** are given in Table 1.

Spectrobehavior of Pyrazine Derivatives. The change in the absorption spectrum of **1a** during the photoreaction under an argon atomosphere was examined.



Scheme 1.

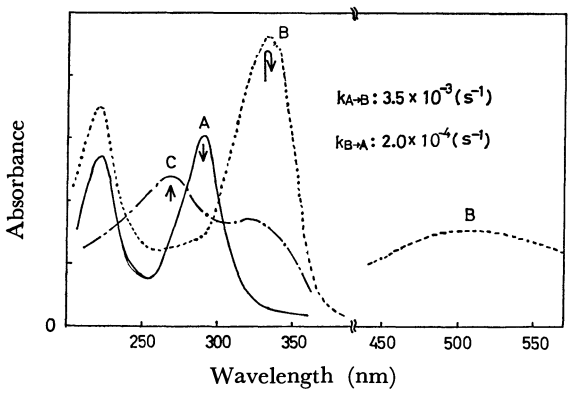


Fig. 1. Spectral change of **1a** in 2-propanol with irradiation.

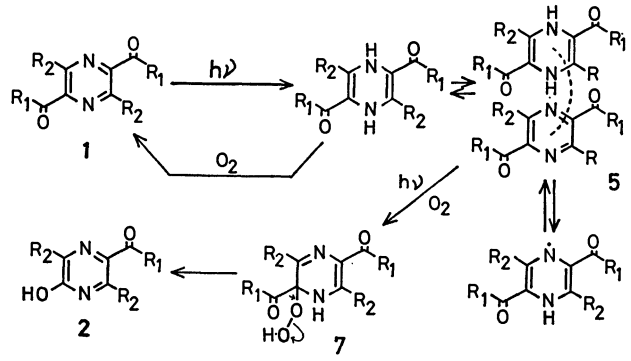
5e: 372 and 504 nm). The mass spectra of **5c** and **5e** showed peaks more than that of **1c** and **1e** by two (**5c**: *m/e* 194 ($M^{+\cdot}+2$) and 192 ($M^{+\cdot}$); **5e**: *m/e* 274 ($M^{+\cdot}+2$) and 272 ($M^{+\cdot}$)). The NMR spectrum of **5e** in CD_3COOD showed a signal of the NH proton at δ 2.15. By D–H exchange, the signal of the hydroxyl proton of acetic acid at δ 11.30 soon appeared and increased with a decrease in the signal at δ 2.15. The above facts indicate that these colored compounds surely have the structure of dihydropyrazine. Also, in the photoreaction of phenazine, a similar colored compound obtained; it was reported to be a dimer of phenazine and dihydrophenazine.[8]

Mechanism. We may conclude from the experiments described above that this reaction includes both a reduction process and an oxidation process. Therefore we investigated the oxidations and reductions of several compounds with heteroenone structures such as **1**. Beinert reported that the spectral behavior of reduced flavine upon oxidation was similar to that of **1** upon irradiation.[9] The redox mechanism of flavine can also well explain the initial process of this reaction. It appears that **1** is reduced by irradiation to produce dihydropyrazine because, first, the molecular complex **5** of pyrazine and dihydropyrazine is obtained as a colored precipitate, and second, a solution of dihydropyrazine hydrochloride, **6**, dissociated to show a (B) absorption identical with that of the molecular complex **5**. The peak near 500 nm of (B) of **1** is characteristic of the charge-transfer complex, and the peaks in the wavelength region of about 320 to 400 nm are due to the semiquinone radical produced by the dissociation of the complex. The complex and radical coexist at equilibrium to form the (B) absorption. In fact, the ESR spectrum of **5e** in acetic acid was obtained, but the hyperfine structure was not clear. The reversibility between the (A) and (B) absorptions may be based on the instability of the radical to the oxidation with oxygen.

The continuous irradiation of the solution showing the (B) absorption gave a mixture containing the solvent adduct and came to show the (C) absorption. The nature of the mixture is not clear, but the precursor of **2** is surely present in this mixture because the mixture reacted with oxygen upon irradiation to give **2**. The hydroxyl compound **2** was not detected in the solution showing the (C) absorption, nor was it obtained by the bubbling of oxygen into the solution showing the (C) absorption. The formation of **2** from the solution required both oxygen and light. Furthermore, the irradiation of the solvent adduct (**3** and **4**) did not yield **2**. These results indicate that the formation of **2** is different from the reaction which gave **3** or **4**.

From the above results and the mechanism of the photo-oxidation of tetrahydropteridine reported by Mager,[10] we presumed that **2** was formed through the intermediate, **7**, which was produced by the attack of oxygen on the dihydropyrazine derivative. Therefore the mechanism for this reaction may be illustrated as is shown in Scheme 2.

Photobehavior of Pyrazine Derivatives with 1,4-Dimercapto-2,3-butanediol. Flavin derivatives, *e.g.*, flavin adenine dinucleotide (FAD) and lipoic acid, are included in the cycle of the decarboxylation of α-ketoacid in a living organism.[11] In this cycle, FAD oxidizes dihydrolipoic acid to lipoic acid and is then itself reduced to dihydroflavin ($FADH_2$). This reaction of flavin presumably passes through the 4-adduct of flavin, with dihydrolipoic acid as an intermediate.[12] In order to confirm the mechanism of the photoreaction of **1**, we presumed **1** to be a model of flavin and 1,4-dimercapto-2,3-butanediol (DTT; **8**) to be a model of dihydrolipoic acid, and we studied reaction of **1** and DTT.



Scheme 2.

The change in the absorption spectrum during the photoreaction was examined. A solution of **1e** and DTT in 50% acetic acid in a quartz cell was irradiated under an argon atmosphere. All the original peaks diminished rapidly and were replaced by new peaks centered at 357 (ε 20900) and 500 nm (ε 1630), and the solution changed from colorless to red. The curves of the change in the absorption clearly defined two isosbestic points at 232 and 333 nm. The spectrum remained unchanged for at least several days in the dark. This suggests that there is no substantial dark side reaction and that the photoproduct is stable under these reaction conditions. After a four-hour irradiation the change in the spectrum almost entirely ceased. The resulting spectrum was identical in shape with that of the charge-transfer complex (**5e**). When the solution was then kept in the dark, the spectrum returned to the **1e** state upon air oxidation. The pseudo first-order rate constant of this reaction was measured from the decrease in the peak at 318 nm of **1e** and the increase in the peak at 357 nm (Table 3).

These results indicate that the photoreduction of **1** occurs in this system. We neglected the equilibrium between reactant and product and considered that **1** reacted with DTT to give a complex **9**, as is shown in Scheme 3. K_d was the dissociation constant of the equilibrium of the complex formation; k_1 and k_2 were

the rate constants for the reactions designated, and k_{obsd} was the observed rate constant. [DTT] was the concentration of DTT. When DTT existed in a larger quantity than **1e**, we obtained Eq. 1 (Lineweaver-Burk plots[13]):

$$(k_1-k_{obsd})^{-1} = (k_1-k_2)^{-1} + K_d(k_1-k_2)^{-1}[DTT]^{-1} \quad (1)$$

A series of measurements of the reaction rate with varying concentrations of DTT were carried out. A typical run was zero-order in the DTT and first-order in **1e**. The results, given in Fig. 2, were obtained by plotting 1/[DTT] *vs.* $1/(k_1-k_{obsd})$. From the good linearity of Fig. 2, we may conclude that the pyrazine derivatives, **1**, form the **9** complex with DTT such as do the flavin derivatives. From the intercept and slope of plotting, $K_d=5.1\times10^{-5}$ mol/l and $k_2=5.3\times10^{-5}$ s^{-1} were obtained. The DTT had a quenching effect, because k_2 was smaller than k_1 ($k_2/k_1\simeq10^{-3}$).

As the photoreaction of **1** was quenched by DTT, the quenching experiment was examined. The quantum yields were determined by using potassium tris(oxalato)ferrate(III) actinometry.[14] A Stern-Volmer plot of Φ against the concentration of DTT is given in Fig. 3, it shows good lineality, even in a large excess of DTT to **1** (DTT/**1**$>10^2$). Such examples are very few, but an instance has been shown in the photoreaction of pyridine; the quenching effect might be attributed to the reaction of pyridine and the quencher.[15] These data further indicate that the quenching effect of DTT occurs by the formation of a complex of pyrazine and DTT. The photoreaction of disulfide derivatives has been reported to produce dithiol derivatives ($\Phi=1$).[16] The low reactivity of the **9** complex on irradiation may be attributed to a difficulty on the

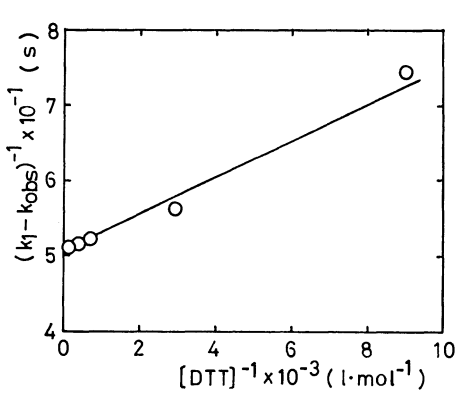

Fig. 2. Dependence of $1/(k_1-k_{obs})$ on the reciprocal of DTT. [**1e**]$=5\times10^{-5}$ mol/l.

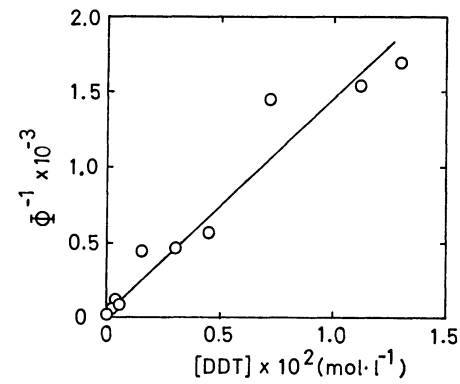

Fig. 3. Inverse quantum yields for photoreaction of **1e** (5×10^{-5} mol/l) against 1/[DTT].

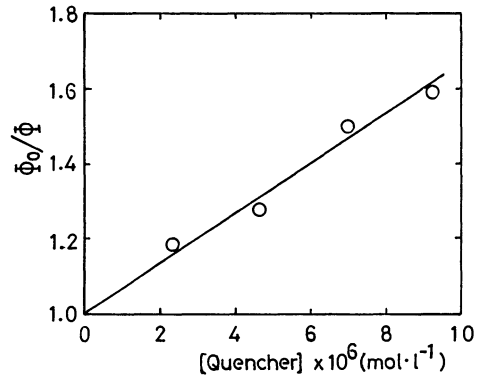

Fig. 4. Stern-Volmer plots of photoreduction of **1e** in 2-propanol solution (5×10^{-5} mol/l). The reaction was quanched by 9-fluorenone.

TABLE 4. SUBSTITUENT EFFECT ON THE PHOTOREACTION OF PYRAZINE DERIVATIVES WITH DTT IN 50% ACETIC ACID

Pyrazine	$k_1\times10^4$ s^{-1}	k_1/k_0
1a	5.22	1.0[a]
b	13.0	2.5
d	23.8	4.6
e	26.3	5.1
f	11.9	3.2

a) k_0.

formation of the disulfide derivative on irradiation.

The substituent effect of this reaction was studied, but no substituent effect was obtained, as is summarized in Table 4. This result indicates that the adduct of pyrazine with DTT as a **9** complex may have been formed.

Quenching Effects with 9-Fluorenone and Anthracene. In order to confirm the excited species, the quenching experiments were examined. The Stern-Volmer plots, which indicated a good linearity in the low-concentration areas of 9-fluorenone, are shown in Fig. 4. From the slope of Fig. 4, $k_q\tau=6.6\times10^4$ l/mol was obtained. Furthermore, from the quenching effect with anthracene, $k_q\tau=3.1\times10^4$ l/mol was obtained. As a result, a triplet state is proposed for this reaction, probably as a single excited species.

Experimental

All melting points were measured with a Yanagimoto micro melting point apparatus. The UV spectra were taken on a Hitachi ERS-3T or a Shimadzu UV-200 spectrometer. The IR spectra were measured using a Jasco IR-G spectrometer. The NMR spectra were measured with a Hitachi R-24 spectrometer using tetramethysilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6E mass spectrometer. The elementary analyses were performed at the Faculty of Pharmaceutical Sciences, Chiba University.

Materials. All materials, obtained from the Wako Pure Chemical Industries Ltd. and the Tokyo Kasei Co., were used without further purification. Dimethyl 3,6-dimethyl-2,5-pyrazinedicarboxylate (**1a**) and diethyl 3,6-dimethyl-2,5-pyrazinedicaboxylate (**1b**) were prepared by the method of Iida and his co-workers.[6]

*2,5-Diacetyl-3,6-dimethylpyrazine (**1c**).* To a solution of 200 g 2,4-pentanedione in 224 ml of acetic acid, a solution of 152 g of sodium nitrite in 270 ml of water was slowly added for 1 h below 7° C in ice bath. The solution was stirred for an hour at 30 °C and furthermore for two hours with 200 ml of water. The aqueous mixture was extracted with 200 ml of ether. The extracted liquor was neutralized, washed and dried with soldium sulfate. Romoval of the solvent gave 197 g (76 %) of white flaky crystals of 3-nitroso-2,4-pentanedione. A solution of 37.6 g of 3-nitroso-2,4-pentanedione in 120 ml of ethanol and 36 ml of acetic acid was reduced at room temperature using 4.0 g of 10% palladium charcoal as catalyst in 500 ml autoclave. The solution containing catalyst was filtered. The solvent of filtrate was removed and the residue was chromatographed on silica gel to give 14.2 g (16 %) of pale yellow needles of of **1c**, mp 99 °C, ν_{max} (KBr) 1699 cm^{-1}, λ_{max} (EtOH) 234 (ε 5200) and 298 nm (ε 8600), δ ($CDCl_3$) 2.67 (6H, s) and 2.79 (6H, s); *m/e* 192 ($M^{+\cdot}$). Found: C, 62.46; H, 6.63; N, 14.46%. Calcd for $C_{10}H_{12}N_2O_2$: C, 62.48; H, 6.63; N, 14.58%.

*2,5-Dibenzoyl-3,6-dimethylpyrazine (**1d**).* To a solution of 50 g of 1-phenyl-1,3-butanedione in 49 ml of acetic acid, a solution of 24 g of soldium nitrite in 47 ml of water was slowly added for about an hour below 25 °C in water bath. The solution was stirred for half an hour at 30 °C and was cooled to give white crystals of 1-phenyl-2-nitroso-1,3-butanedione. The solution containing the crystals was filtered and the filtrate was extracted with ether. The extracted liquor was concentrated and poured into a large quantity of water to give crystals of 57.5 g (97%) of 1-phenyl-2-nitroso-1,3-butanedione. The crystals were washed well. A solution of 17 g of 1-phenyl-2-nitroso-1,3-butanedione of 60 ml of ethanol and 20 ml of acetic acid was reduced at room temperature using 3.6 g of 10% palladium charcoal as catalyst in 500 ml autoclave. The solution containing catalyst was filtered. The solvent of filtrate was removed and the residue was dissolved in chloroform. The solution was neutralized, washed and dried with sodium sulfate. The chloroform was removed and the residue was dissolved in ethanol. Aeration of the solution for three hours gave 728 mg (2.6%) of white crystals of **1d**, mp 167—169 °C; λ_{max} (EtOH) 256 (ε 23300) and 290 nm (ε 21000); δ ($CDCl_3$) 2.59 (6H, s), 7.25—8.95 (10H, m); *m/e* 316 ($M^{+\cdot}$). Found: C, 75.97; H, 5.15; N, 8.79%. Calcd for $C_{20}H_{16}N_2O_2$: C, 75.93; H, 5.10; N, 8.86%.

*1,2,3,4,6,7,8,9-Octahydro-3,3,8,8-tetramethyl-1,6-phenazinedion (**1e**).* 5,5-Dimethyl-2-(hydroxyimino)-1,3-cyclohexanedione was prepared by the method of Hass.[17] A solution of 2 g of 5,5-dimethyl-2-(hydroxymino)-1,3-cyclohexanedione in 50 ml of ethanol was reduced using 0.2 g of 10% palladium charcoal as catalyst in 100 ml autoclave. The solution containing catalyst was filtered and the filtrate was aerated for three hours at 40—60 °C. After removal of the solvent, the separation of the reaction mixture by column chromatography gave 0.35 g (18%) of **1e**, mp 214—219 °C; λ_{max} (EtOH) 233 (ε 9400) and 317 nm (ε 9300); δ ($CDCl_3$) 1.17 (12H, s), 2.72 (4H, s), and 3.27 (4H, s); *m/e* 272 ($M^{+\cdot}$). Found: C, 70.17; H, 7.43; N, 10.11%. Calcd for $C_{16}H_{20}N_2O_2$: C, 70.17; H, 7.40; N, 10.29%.

Furthermore, **1e** was prepared by the following manner. Decahydro-3,3,8,8-tetramethyl-1,6-phenazinedione dihydrochloride (**6e**) in methanol was neutralized. The methanol was removed. The purification of the residue gave pale yellow crystals of **1e**.

*1,2,3,4,6,7,8,9-Octahydro-1,6-phenazinedione (**1f**).* Decahydro-1,6-phenazine dihydrochloride (**6f**) in methanol was neutralized. After the solvent was removed, the residue was chromatographed on silica gel to give **1f** (45%), mp 250—260 °C; λ_{max} (EtOH) 230 (ε 13700) and 317 nm (ε 15600); δ($CDCl_3$) 2.30 (4H, dt), 2.88 (4H, t), and 3.30 (4H, t); *m/e* 216 ($M^{+\cdot}$). Found: C, 66.38; H, 5.60; N, 12.75%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%

*1,2,3,4,6,7,8,9-Octahydrophenazine (**1g**).* 2-Chlorocyclohexanone was synthesized by the method of Organic Synthesis.[18] Ammonia was bubbled into a solution of 24 g of 2-chlorocyclohexanone in 350 ml of ethanol for about three hours below 7 °C in ice bath. The solution, which was added 40 ml of 3M-HCl, was extracted with four 80 ml portions of ether. Adjustment of the extracted liquor to pH 2 with sodium hydroxide gave white crystals in good yield. Upon recrystalization from acetone, **1g** was obtained as white plates, mp 108 °C; λ_{max} (EtOH) 290 nm (ε 10800), δ($CDCl_3$) 1.84 (8H, m) and 2.79 (8H, m); *m/e* 188 ($M^{+\cdot}$).

*Decahydro-3,3,8,8-tetramethyl-1,6-phenazinedione Dihydrochloride (**6e**).* 2-Amino-5,5-dimethyl-1,3-cyclohexanedion was prepared by the method of Regitz and Stadler.[19] A 10 g of 2-amino-5,5-dimethyl-1,3-cyclohexanedione was refluxed in 150 ml 15% HCl for few hours to obtain yellow crystals of **6f**. After filtration, same operation were repeated. **6f**, mp 177 °C; *m/e* 218 ($M^{+\cdot}-2HCl$). Found: C, 49.02; H, 5.48; N, 9.62; Cl, 23.94%. Calcd for $C_{12}H_{12}N_2O_2 \cdot 2HCl$: C, 49.50; H, 5.54; N, 9.62; Cl, 24.35%.

Irradiation of Pyrazine Derivatives. A solution of 2.0 g of **1a**—**d** in 2 l of diethyl ether was irradiated with a Ushio UM-425 450-W high pressure mercury lamp for six hours. After irradiation, the solvent was removed *in vacuo* at room temperature and the oily residue was chromatographed on silica gel to give **2a**—**d** and the viscous liquid of solvent adducts **3a** and **3c**. **3a** was crystalized very slowly from hexane–benzene. Using tetrahydrofuran as a solvent, **4a** and **4c** were obtained. The yields and physical data of **2**, **3**, and **4** were shown in Table 1.

*Determination of the Structure of **2**.* A solution of 200 mg of methyl 3,6-dimethyl-5-hydroxypyrazine-2-carboxylate (**2a**) in 5 ml of water containing 0.09 g of potassium hydroxide was stirred for an hour at room temperature and further for an hour at 40 °C. From the solution adjusted to pH 4—5 by dil. HCl, **2a** which had not reacted was removed by the extraction with ether. The residue was dried by repetition of azeotropy with benzene and extracted with ethanol in a Soxhlet extracter. Removal of the solvent gave 40 mg of residue. By thermolysis and sublimation of the mixture of this residue, a solid and

a liquid were obtained. Solid, mp 202 °C; λ_{max} (EtOH) 267 nm. The solid compound was identical with 3,6-dimethyl-2-pyrazinol from its melting point (lit,[7] 207 °C).

Measurement of the Reaction Rate of Pyrazine Derivatives with DTT. Equivolume of distilled water and dried acetic acid were mixed as the solvent. **1e** (3.19 mg, 1.15×10^{-5} mol) was dissolved in 50 ml of the solvent using a volumetric flask DTT (20 mg, 1.3×10^{-4} mol) was transferred to a volumetric flask and diluted to 20 ml with the solvent. From solution of DTT, an appropriate aliquot was further dilute to yield 10^{-4}—10^{-2} mol/l solution for spectral analysis. One ml of a solution of **1e** and 0—3 ml of solution of DTT were mixed in a 1 ml quartz cell and diluted to 4 ml with the solvent.

After bubbling of argon gas for an hour, a quartz cell was sealed. Consecutive irradiations of short duration were carried out with a Ushio UM-103B 100-W high pressure mercury lamp in a sealed quartz cell which was transferred periodically to the UV spectrometer for spectral recording.

The reaction rate calculated from the decrease of the peak at 318 nm (ε 12000) of **1e** or the increase of the peak at 357 nm (ε 21800) of **5e**.

Substituent Effects on the Reaction of Pyrazines. Equivolume of distilled water and dried acetic acid were mixed as the solvent. Pyrazine derivatives **1** (1.1×10^{-5} mol) was dissolved in 50 ml of the solvent. DTT (1.37 mg, 8.88×10^{-6} mol) was dissolved in 20 ml of the solvent. 1 ml of each solutions were mixed and diluted to 4 ml of the solvent in a quartz cell.

After bubbling of argon gas for an hour, irradiations were carried out with a 100-W high pressure mercury lamp. Periodically UV spectra were recorded. And the reaction rates were calculated from the decrease of the peak of the pyrazine.

Quenching of the Photoreaction of Pyrazine Derivatives. Pyrazine **1e** (3.67 mg, 1.35×10^{-5} mol) was dissolved in 50 ml of dried 2-propanol. 9-Fluorenone (3.33 mg, 1.85×10^{-5} mol) was dissolved in 100 ml of dried 2-propanol. From a solution of 9-fluorenone, an appropriate aliquot was further diluted for spectral analysis. One ml of a solution of **1e** and 0—3 ml of a diluted solution of 9-fluorenone were mixed in a 1 ml quartz cell and diluted to 4 ml with dried 2-propanol. In analogy with measurement of substituent effects, the reaction rates were measured: a linear Stern-Volmer plots of $\Phi_0/\Phi(=k_0/k)$ *vs.* concentration of quencher was obtained with $k_q\tau=6.6\times10^4$ l/mol.

From the quenching effect of **1e** (5.5×10^{-5} mol/l) with anthracene in dried acetic acid, $k_q\tau=3.1\times10^4$ l/mol was obtained.

The Reaction of Monoketones with Manganese(III) Acetate

Masayoshi OKANO and Takaaki ARATANI

Faculty of Integrated Arts and Sciences, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received March 19, 1976)

When acetone, ethyl methyl ketone (EMK), and cyclohexanone were heated with manganese(III) acetate dihydrate in a mixed solvent of glacial acetic acid and acetic anhydride at 100 °C, acetoxy ketones were obtained as common products. Furthermore, ketone dimers (1,4-diketones) were obtained from acetone and cyclohexanone, which also gave 1,2,3,4-tetrahydrodibenzofuran. When mixtures of these ketones and 1-hexene were heated with the oxidant, saturated and unsaturated ketones and γ-acetoxy ketones were obtained as common products, and 2-propylchromene was obtained as a new product from the cyclohexanone–1-hexene mixture. The formation courses of these reaction products are discussed.

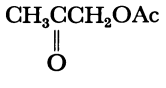
In the previous paper,[1] it was established that the reaction of alkenes with manganese(III) acetate in carboxylic acid solvents containing acid anhydride proceeds through a solvent-participating free radical reaction mechanism. α-Carboxyalkyl or acyloxy radicals are formed in the first step by abstraction of a hydrogen atom on the α-carbon or that in the carboxyl group of the carboxylic acid by an acetoxyl radical produced directly from the oxidant; then these redicals may add to the alkenes. Furthermore, acid anhydride accelerates the reaction rate by abstraction of hydrated water from the oxidant.

The reaction of ketones–alkenes mixtures[2,3] and ketones–enol esters mixtures[4] with manganese(III) acetate have been studied in considerable detail. Heiba *et al.*[3] reported that 2-undecanone, unstaurated ketone, and keto acetate were obtained from an acetone–1-octene mixture (27 : 1) at 85 °C in glacial acetic acid containing potassium acetate; they proposed an electron transfer mechanism (formation of carbonium ion) through a radical addition.

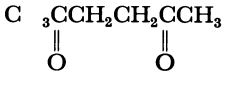
In the present investigation, the formation of the characteristic products, such as ketone dimers (**2** and **6**) and the acetoxy ketones (**2**, **3**, **4**, and **5**), requires the generation of the ketonyl radical and the manganese acetate radical(I)[1] which are not easily further oxidized. To account for these facts the reaction course in Scheme 1 is proposed as reasonable.

Results and Discussion

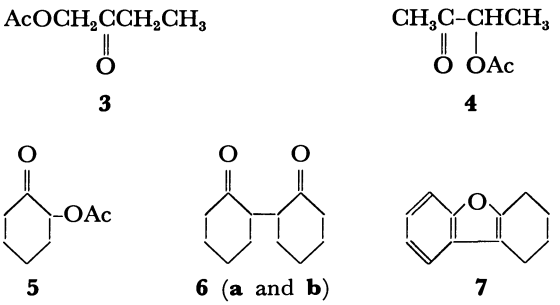
The Reaction of Monoketones with Manganese(III) Acetate. When acetone was heated with manganese(III) acetate in a mixture of glacial acetic acid and acetic anhydride (1 : 1, v/v, solvent A), acetonyl acetate (**1**, 30%) and acetonylacetone (**2**, 9%) were obtained. In the case of EMK, 1-acetoxy-2-butanone (**3**, 15%) and 3-acetoxy-2-butanone (**4**, 6%) were obtained, while in the case of cyclohexanone, 2-acetoxycyclohexanone (**5**, 18%), bicyclohexane-2,2′-dione (*meso*(**6a**): 3%, *dl*(**6b**): 5%), and 1,2,3,4-tetrahydrodibezofuran (**7**, 4%) were obtained. Thus, α-acetoxy ketones (**1**, **2**, **3**, **4**, **5**) and dimers (**2**, **6a**, **6b**) were obtained as the major products.



1



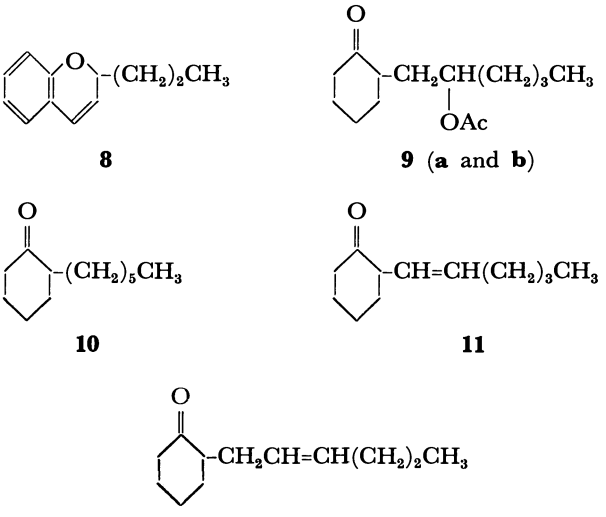
2



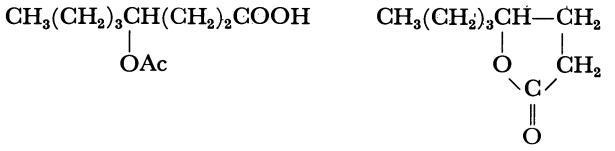
3 **4** **5** **6** (**a** and **b**) **7**

These results suggest the formation of α-keto radicals and an acetoxyl radical, which should be stabilized within the coordination sphere of the manganese(II) ion.[1] The α-acetoxy ketones may be formed by the addition of the acetoxyl radical to each α-keto radical, because the α-keto radical is not easily oxidized due to the electron-withdrawing character of the carbonyl group.[5]

The Reaction of Cyclohexanone–1-hexene Mixture with Manganese(III) Acetate. When the cyclohexanone–1-hexene mixture was heated with manganese(III) acetate in solvent A, a new type of 2-propylchromene (**8**, 13%) was obtained as a major product, in addition to the known types[2,3] of 2-(2-acetoxyhexyl)cyclohexanone (**9**, this is a mixture of the two diastereoisomeric **9a** and **9b** types, in the ratio 8% : 8%), 2-hexylcylohexanone (**10**, 6%), 2-(1-hexenyl)cyclohexanone (**11**, 8%), 2-(2-hexenyl)cyclohexanone (**12**, 4%), 4-acetoxyoctanoic acid (**13**, 4%), and 4-octanolide (**14**, 12%).



8 **9** (**a** and **b**) **10** **11** **12**



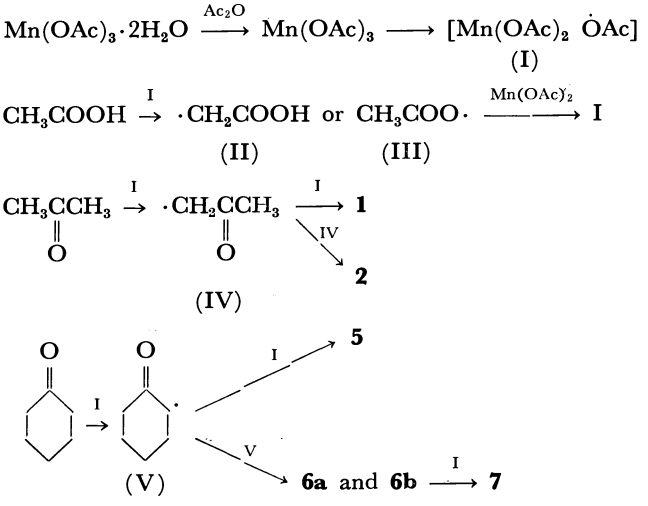
13 14

Of these products, **8**, **9a**, **9b**, **10**, **11**, and **12** may be obtained by the oxidative coupling of cyclohexanone and 1-hexene, and **13** and **14** by the reaction of solvent acetic acid and 1-hexene. Thus, the reaction might proceed through two pathways; the former would be predominant, because the total yield of the former is 47% and of the latter is 24%. The latter reaction may proceed through the radical course explained previously[1] and the former by a similar course.

When 1-decene was used instead of 1-hexene, 2-heptylchromene (**15**) and the known types of compounds were obtained. The formation of these chromene derivatives is very interesting because it is a novel tocopherol synthesis.

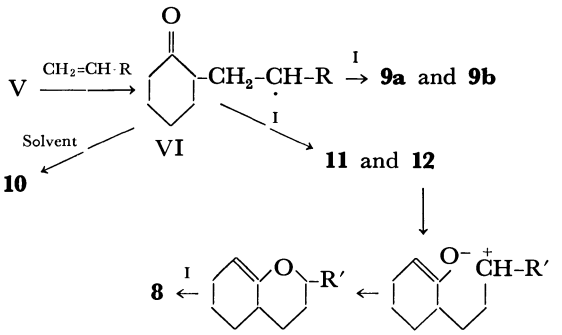
The products obtained by using 1-octene and 1-nonene instead of 1-hexene were identified as the same types of compounds as those obtained in the case of 1-hexene by their relative retention times in GLC.

The Reaction Course of Ketone–Alkene Mixtures. On the basis of the formation of α-acetoxyketones and ketone dimers, the reaction of ketones may proceed as shown in Scheme 1. First, manganese(III) acetate dihydrate is dehydrated by acetic anhydride or heating to give anhydrous manganese(III) acetate. By heating, the anhydrous manganese(III) acetate changes to a manganese acetate radical(I)[1] in which the acetoxyl radical is prevented from decomposing. The radical (I) then abstracts a hydrogen atom on the α-position or the caboxyl group in acetic acid to give carboxymethyl radical(II) or acetoxyl radical(III), which is somewhat stabilized by the formation of I. A hydrogen atom on the α-position of ketone also abstracted by the radical(I) to give an α-keto radical(IV or V). The keto radical may react with I to form α-acetoxy ketones (**1** or **5**) or react with each keto radical to form dimers (**2** or **6a** and **6b**). Furthermore, **6a** and **6b** may be enolized, dehydrated, and dehydrogenated in the allylic positions to give 1,2,3,4-tetrahydrodibenzofuran (**7**).



Scheme 1.

On the basis of the above results, the reaction of the ketone–alkene mixture may proceed as shown in Scheme 2. The α-keto radical(V) adds to the alkenes in the first step to form the radical intermediate(VI), which may be converted to γ-acetoxy ketones (**9a** and **9b**) by the reaction between VI and I. The intermediate(VI) may also be converted to unsaturated ketones (**11** and **12**) or to a saturated one (**10**) by abstraction or addition of a hydrogen atom. Furthermore, **12** may be converted to chromene derivatives (**8**) by cyclization of enol and abstraction of allylic hydrogens.



Scheme 2.

The formation of 4-acetoxyoctanoic acid (**13**) and the corresponding γ-lactone (**14**) suggests that the reaction of ketone-alkene mixtures proceeds through a pathway similar to that in the reaction of alkenes with manganese(III) acetate in solvent A,[1] in addition to the pathway in Scheme 2.

Experimental

The analytical and preparative GLC were carried out on a Hitachi 023 gas chromatograph equipped with a thermocouple detector in connection with a stainless steel column (3 mm in diameter) which was packed with Celite 545 (40—60 mesh) impregnated with 20% PEG-20 M or 25% DEGS. The NMR spectra were determined on a JEOL model JNM-MH-60 spectrometer in CCl_4 or $CDCl_3$ with an internal reference of tetramethylsilane. The mass spectra were taken on a Hitachi RMS-4 instrument at 70 eV ionization voltage and 200 °C ionization chamber temperature.

Preparation of Manganese(III) Acetate Dihydrate. $Mn(OAc)_2 \cdot 4H_2O$ was oxidized with potassium permanganate according to a modification of the procedure of Heiba.[3] The crystallized $Mn(OAc)_3 \cdot 2H_2O$ which filtered up from the reacted mixture was washed with ether and preserved over sodium hydroxide *in vacuo* for a week. The purity was 99%, according to iodometric titration.

Reaction of Acetone, EMK, and Cyclohexanone with Manganese(III) Acetate. Acetone(5.8 g, 100 mmol), EMK(7.2 g, 100 mmol), and cyclohexanone(9.8 g, 100 mmol) were each added to a solution of manganese(III) acetate (53.6 g, 200 mmol) in a mixed solvent of acetic acid and acetic anhydride(v/v, 1 : 1, solvent A, 400 ml) drop by drop at 70 °C in flowing nitrogen. The mixture was then heated up to 100 °C with stirring. When the brown color of the Mn(III) ions disappeared, the stirring was stopped and the reaction mixture was cooled, diluted with ether (*ca.* 300 ml), and neutralized with sodium carbonate. The precipitate was filtered off and washed with ether, and the mother liquor was evaporated away, leaving brown oily substances. The

oily substances were then separated by a combination of column chromatography (100—200 mesh silica gel, hexane-ethyl acetate(4:1, v/v)), and preparative gas chromatography into individual compounds. Their characterizations were carried out as follows:

*Reaction Products of Acetone. Acetonyl Acetate (**1**)*: This compound was isolated as a colorless liquid by preparative GLC(DEGS, 2m, 160 °C, t_R 1.8 min) from the reaction mixture. $C_5H_{18}O_3$(MS). *m/e* 116(42%, M^+), 73 (22%, $C_3H_5O_2$), 43(100%, C_2H_3O); $\delta^{CCl_4}_{ppm}$ 2.10 s (6H), 4.45 s (2H). The IR spectrum coincided with that of authentic acetonyl acetate.[6]

*Acetonylacetone (**2**)*: This compound was isolated as a colorless liquid. $C_6H_{10}O_2$(MS). *m/e* 114(40%, M^+), 99 (48%, M^+-CH_3), 71 (48%, $M^+-C_2H_3O$), 43 (100%, C_2H_3O); $\delta^{CCl_4}_{ppm}$ 2.10 s (6H), 4.45 s (4H). The IR spectrum coincided with that of authentic acetonylacetone.[6]

*Reaction Products of EMK. 1-Acetoxy-2-butanone (**3**)*: A colorless liquid. n_D^{25} 1.4189. $C_6H_{10}O_3$(MS). *m/e* 130 (4%, M^+), 73(8%, $M^+-C_3H_5O$), 57(63%, C_3H_5O), 43 (100%, C_2H_3O); $\delta^{CCl_4}_{ppm}$ 1.08 t (3H, J=7 Hz), 2.15 s (3H), 2.45 q (2H, J=7 Hz), 4.65 s (2H); ν^{neat}_{max} 1750(ester), 1735 (ketone), 1230(acetate).

*3-Acetoxy-2-butanone (**4**)*: A colorless liquid. $\delta^{CCl_4}_{ppm}$ 1.39 d (2H, J=7 Hz), 2.15 s (6H), 5.06 q (1H, J=7 Hz); ν^{neat}_{max} 1740(ester), 1235(acetate).

*Reaction Products of Cyclohexanone. 2-Acetoxycyclohexanone (**5**)*: A colorless liquid. n_D^{25} 1.4571. $C_8H_{12}O_3$(MS). *m/e* 156(12%, M^+), 113(56%, $M^+-C_2H_3O$), 96(14%, $M^+-C_2H_4O_2$), 43(100%, C_2H_3O); $\delta^{CCl_4}_{ppm}$ 2.05 s (3H), 4.95 t (1H, J=6 Hz); ν^{neat}_{max} 1750(ester), 1720(ketone), 1240(acetate).

meso-*Bicyclohexane-2,2'-dione (**6a**)*: A colorless crystal. mp 60—61 °C. $C_{12}H_{18}O_2$(MS). *m/e* 194(39%, M^+), 98 (100%, $M^+-C_6H_8O$), 97(73%, $M^+-C_6H_9O$); $\delta^{CCl_4}_{ppm}$ 1.85 m (12H), 2.21 t (4H, J=6 Hz), 2.74 d (2H, J=14 Hz); ν^{KBr}_{max} 1710(ketone).

dl-*Bicyclohexane-2,2'-dione (**6b**)*: A colorless liquid. $C_{12}H_{18}O_2$(MS). *m/e* 194 (3%, M^+), 98 (100%, $M^+-C_6H_8O$), 97(42%, $M^+-C_6H_9O$); $\delta^{CCl_4}_{ppm}$ 1.85 m (12H), 2.23 m (6H); ν^{neat}_{max} 1710(ketone). A mixture (0.1 g) of **6a** and **6b** was allowed to undergo a pyrrole reaction which gave 1,2,3,4,5,6,7,8-octahydrocarbazole(dark green crystal, mp 88—90 °C). $C_{12}H_{17}N$(MS). *m/e* 175 (100%, M^+); $\delta^{CCl_4}_{ppm}$ 1.63 bs (8H), 2.24 m (8H), 6.64 m (1H); ν^{Nujol}_{max} 3350(NH).

*1,2,3,4-Tetrahydrodibenzofuran (**7**)*: A colorless liquid. n_D^{25} 1.5732. $C_{12}H_{12}O$ (MS). *m/e* 172 (76%, M^+); λ^{EtOH}_{max} 252 (ε=12200), 279(ε=4700), 286(ε=4300) nm. This compound was refluxed in xylene with chloranil to give dibenzofuran, which was identified by comparing its t_R with that of the authentic one.

Reaction of Cyclohexanone-1-hexene Mixture with Manganese(III) Acetate. Cyclohexanone–1-hexene mixture (100 mmol : 100 mmol) was added to a solution of manganese(III) acetate(53.6 g, 200 mmol) in the solvent A (400 ml) drop by drop at 100 °C in flowing nitrogen; the mixture was carried out as in the reaction of ketone. The reaction products were identified as follows:

*2-Propylchromene (**8**)*: A colorless liquid. n_D^{25} 1.5199. $C_{12}H_{14}O$ (MS and elementary analysis). *m/e* 174.1045(62%, M^+, calcd *m/e*: 174.1045), 131(100%, $M^+-C_3H_7$); Found: C, 83.07; H, 8.16%. Calcd for $C_{12}H_{14}O$: C, 82.70; H, 8.11%. $\delta^{CCl_4}_{ppm}$ 0.95 t (3H, J=6 Hz), 1.23—1.70 m (4H), 2.16—2.83 m (2H), 6.27 bs (1H), 7.00—7.37 m (4H); ν^{neat}_{max} 3050 and 1600(aromatic), 1250(phenyl ether).

*2-(2-Acetoxyhexyl)cyclohexanone (**9a** and **9b**)*: **9a** and **9b**, diastereoisomers, were separated by a preparative GLC as colorless liquids. **9a**: $C_{14}H_{24}O_3$(MS). *m/e* 240(1%, M^+), 197 (3%, $M^+-C_2H_3O$), 180(25%, $M^+-C_2H_4O_2$), 98(100%, $C_6H_{10}O$), 43 (71%, C_2H_3O); $\delta^{CCl_4}_{ppm}$ 0.93 t (3H, J=5 Hz), 1.39 s (3H), 2.15 m (5H); ν^{neat}_{max} 1735(ester), 1710(ketone), 1250 (acetate). **9b**: $C_{14}H_{24}O_3$(MS). *m/e* 240 (1%, M^+), 197 (1%, $M^+-C_2H_3O$), 180(23%, $M^+-C_2H_4O_2$), 98(100%, $C_6H_{10}O$), 43 (71%, C_2H_3O); $\delta^{CCl_4}_{ppm}$ 0.93 t (3H, J=5 Hz), 1.37 m (12H), 1.96 s (3H), 2.24 m(5H), 4.80 m (1H); ν^{neat}_{max} 1735(ester), 1710(ketone), 1250(acetate).

A mixture of **9a** and **9b** (0.4 g) was treated with LAH (0.4 g) in dried ether to give two diols (0.35 g), which were separated by a preparative GLC. The easily moving diol (colorless oil): $C_{12}H_{24}O_2$(MS). *m/e* 182(6%, M^+-H_2O), 164(16%, M^+-2H_2O), 143(17%, C_4H_9), 125(64%, M^+-H_2O C_4H_9), 107(33%, $M^+-2H_2O-C_4H_9$), 98(100%, $C_6H_{10}O$), 57(26%, C_4H_9); $\delta^{CCl_4}_{ppm}$ 0.90 t (3H, J=5 Hz), 1.34 m (17H), 3.05—3.80 m (2H), 4.44 bs (2H, exchangeable for D_2O); ν^{neat}_{max} 3320 (associated OH). The slowly moving diol (colorless oil): $C_{12}H_{24}O_2$(MS). *m/e* 182(9%, M^+-H_2O), 164(11%, M^+-2H_2O), 143(17%, $M^+-C_4H_9$), 125(88%, $M^+-H_2O-C_4H_9$), 98(100%, $C_6H_{10}O$), 57(53%, C_4H_9); $\delta^{CCl_4}_{ppm}$ 0.90 t (3H, J=5 Hz), 1.33 m (17H), 3.00—3.83 m (2H), 4.65 m (2H, exchangeable for D_2O); ν^{neat}_{max} 3300(associated OH). A mixture of these diols(0.20 g) was treated with Jones reagent(0.6 ml) to give diketone (0.15 g): $C_{12}H_{20}O_2$ (MS). *m/e* 196 (24%, M^+), 139 (90%, $M^+-C_4H_9$), 111 (100%, $M^+-C_5H_9O$), 85(54%, C_5H_9O), 57(60%, C_4H_9); ν^{neat}_{max} 1710(ketone). Another mixture of **9a** and **9b** (0.4 g) was heated at 250 °C for 1 h to give acetic acid, **11**, and **12** which were identified by an admixing GLC of the autherntic samples.

*2-Hexylcyclohexanone (**10**)*: A colorless liquid. $C_{12}H_{22}O$(MS). *m/e* 182(10%, M^+), 98(100%, $C_6H_{10}O$); $\delta^{CCl_4}_{ppm}$ 0.93 t (3H, J=5 Hz), 1.25 bs(10H), 1.92 m (6H), 2.15 m (3H); ν^{neat}_{max} 1710(ketone).

*2-(1-Hexenyl)cyclohexanone (**11**)*: A colorless liquid. $C_{12}H_{20}O$(MS). *m/e* 180(39%, M^+), 98(100%, $C_6H_{10}O$); $\delta^{CCl_4}_{ppm}$ 0.89 t (3H, J=6 Hz), 1.3—1.9 m (12H), 2.22 m (3H), 5.35 m (2H); ν^{neat}_{max} 1710(ketone), 970(C=C).

*2-(2-Hexenyl)cyclohexanone (**12**)*: A colorless liquid. $C_{12}H_{20}O$(MS). *m/e* 180(33%, M^+), 98(100%, $C_6H_{10}O$); $\delta^{CCl_4}_{ppm}$ 0.91 t (3H, J=6 Hz), 1.3—1.9 m (12H), 2.20 m(3H), 5.34 m (2H); ν^{neat}_{max} 1710 (ketone), 970 (C=C). A mixture of **11** and **12** (0.30 g) was hydrogenated in ethanol (70 ml) at 45 °C for 2 h using Raney nickel (W-2, 0.5 g) under a hydrogen pressure of 55 kg/cm² to give **10** (*ca.* 0.2 g). Another mixture of **11** and **12** (0.1 g) was oxidized with potassium permanganate in water (50 ml) at 50 °C for 2 h. The reacted mixture was acidified with 10% sulfuric acid, extracted with ether, then methylated with diazomethane to give methyl esters of butanoic and pentanoic acids, which were identified by an admixing GLC of the authentic samples.

*4-Acetoxyoctanoic Acid (**13**)*: A colorless liquid. n_D^{25} 1.4563. The spectral data coincided with those of the authentic sample obtained by the reaction of 1-hexene with mangnese(III) acetate in the solvent A.[1] **13** (0.18 g) was treated with LAH (0.18 g) to give 1,4-octanediol (0.15 g): $C_8H_{18}O_2$(MS). *m/e* 115(26%, M^+-CH_3O), 71(71%, $M^+-C_4H_9$), 69(55%, $M^+-C_3H_7O$), 59(18%, C_3H_7O), 57(34%, C_4H_9); $\delta^{CCl_4}_{ppm}$ 0.91 t (3H, J=5 Hz), 1.36—1.53 m (12H), 3.55 m (3H), 4.54 bs (2H, exchangeable for D_2O); ν^{neat}_{max} 3325 (associated OH), 1055 (prim. OH). This diol (0.13 g) was oxidized with Jones reagent (0.5 ml) to give 4-octanolide (0.10 g), which was identified by an admixing GLC and by comparing the IR and mass spectra with those of the authentic sample.

*4-Octanolide (**14**)*: A colorless liquid. This compound was identified by an admixing GLC and by comparing

the IR spectrum with that of the authentic sample.

2-Heptylchromene(**15**, colorless liquid) was obtained by the reaction of cyclohexanone-1-decene mixture with the oxidant. $C_{16}H_{22}O$ (MS and elementary analysis). *m/e* 230.1692(29%, M^+, calcd for $C_{16}H_{22}O$: 230.1671), 131 (100%, $M^+-C_7H_{15}$); Found: C, 83.60; H, 9.67%. Calcd for $C_{16}H_{22}O$: C, 83.41%; H, 9.64%. $\delta_{ppm}^{CCl_4}$ 0.89 t (3H, $J=5$ Hz), 1.30 bs (12H), 2.47 t (2H, $J=7$ Hz), 6.29 s (1H), 7.0—7.5 m (4H); ν_{max}^{neat} 3050 and 1600(aromatic), 1255(phenyl ether).

Synthesis of 4-Amino-2-hydroxybutanoic Acid and Its 3-Methyl Derivative

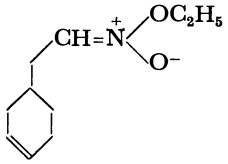
Hiroko SATO, Takenori KUSUMI, Kyoto IMAYE, and Hiroshi KAKISAWA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

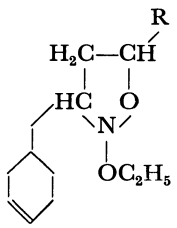
(Received December 4, 1975)

1,3-Dipolar addition of the nitronic ester (**3**) to methyl acrylate afforded regiospecifically the isoxzolidine (**4**), which produced the oxime ether (**7**) on heating. Reduction of **7** followed by hydrolysis gave the hydroxy amino acid (**6**), which is known to improve anitibiotic activities. The nitronic ester (**3**) also reacted regio- and stereospecifically with methyl crotonate to produce the adduct (**8**). Pyrolysis of (**8**) followed by reduction and hydrolysis gave the *erythro* hydroxy amino acid (**11**).

Recent investigation of the modification of antibiotics disclosed that acylation of kanamycin with L-4-amino-2-hydroxybutanoic acid (**6**) at the C-1 amino group of deoxystreptamine moiety improved the antibiotic activities;[1] the acylated kanamycin inhibited some kanamycin resistant microorganisms including *Psudomonas* species. This amino acid, 4-amino-2-hydroxybutanoic acid (**6**), was discovered as a constituent of an antibiotic butyrosin,[2] and had been synthesized[2] from 2-hydroxybutyrolactone in conjunction with the synthesis of deoxyeritadenine. In the course of studies on the new annelation reaction we have found that, whereas the nitronic ester (**1**) was not cyclized by intramolecular 1,3-dipolar cycloaddition of the nitronic ester group to the isolated double bond,[4] **1** was regiospecifically condensed to an acrylate or acrylonitrile to give isoxazolidines (**2a** and **2b**). The fuctionalities in the adduct (**2a**), an oxygen atom at α-position and a nitrogen atom at γ-position to the carboxy ester group indicate a new synthetic route to the 4-amino-2-hydroxybutanoic acid (**6**).



(**1**)

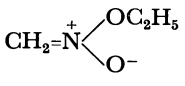


(**2a**; R=$COOCH_3$)
(**2b**; R=CN)

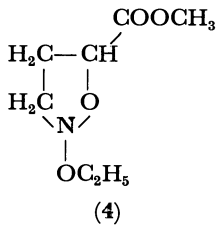
This paper deals with a new synthesis of 4-amino-2-hydroxybutanoic acid (**6**) and its 3-methyl derivative (**11**) from the adducts of the nitronic ester (**3**) with methyl acrylate and metyl crotonate.

Many methods are known for the preparation of nitronic esters. The *O*-alkylation of sodium, potassium, or silver salts of nitroalkanes with alkyl halides has been examined extensively. The initial product is found to be nitronic esters, but they decompose easily to form oximes and carbonyl compounds. The ester (**3**) was thus prepared by the ethylation of sodium salt of nitromethane with triethyloxonium fluoroborate at 0 °C,[6] the ester being used for the reaction with methyl acrylate without purification. The cycloaddition reaction proceeded smoothly at −10 °C to yield a 1 : 1-adduct. Although two structures, (**4**) and (**5**), were considered feasible for the adduct, the NMR spectrum and TLC showed the exclusive formation of **4**. The spectrum showed a double-doublet at 4,66 assignable to the proton at C-5 besides other signals consistent with structure (**4**).

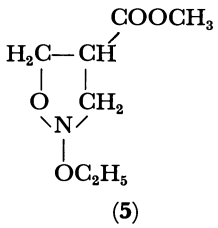
The isoxazolidine (**4**) was quantitatively converted into a mixture of *syn*- and *anti*-oxime ethers (**7**) on heating at 100 °C. The NMR spectrum of the mixture showed two signals with almost equal intensities at 7.40 and 6.75, which are assignable to protons attached to imino carbon atoms of *syn*- and *anti*-oxime ethers, respectively. Catalytic hydrogenation of the oxime ethers over platinum oxide afforded methyl 4-amino-2-hydroxybutanoate in a good yield. Acid catalyzed hydrolysis and purification by ion exchange chromatography afforded the hydroxy amino acid (**6**) in 37% overall yield from adduct (**4**). The NMR spectrum and R_f value in paper chromatography of the synthetic hydroxy amino acid (**6**) were identical with those of natural 4-amino-2-hydroxybutanoic acid.



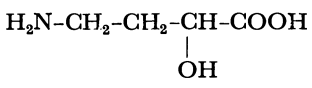
(**3**)



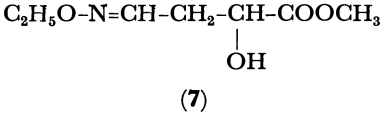
(**4**)



(**5**)



(**6**)



(**7**)

Regiospecificity of the 1,3-dipolar addition of the nitoronic ester (**3**) was also observed when **3** reacted with methyl crotonate. The structure of the cycloaddition product (**8**) was determined from the spectra, and the stereochemistry was assigned from the reaction mechanism. Huisgen *et al.*[7] reported that intermolecular cycloaddition of the nitrone (**9**) to methyl crotonate proceeds regiospecifically to give the isoxazolidine (**10**). The discrepancy in the regiospecificity of the two reactions would be explained in terms[8] o diffference of electron distribution in the nitronic ester and the nitrone.

The isoxazolidine (**8**) was converted into the *erythro* hydroxy amino acid (**11**) in the same manner as described above. Isomerization of **8** to the corresponding oxime ether at 200 °C, followed by catalytic hydrogenation and hydrolysis yielded 4-amino-*erythro*-2-hydroxy-3-methylbutanoic acid (**11**).

Experimental

NMR spectra were obtained with a Hitachi H-60 instrument using TMS as an internal standard. All the infrared spectra were taken on a Hitachi EPI-S2 spectrophotometer. Melting points and boiling points are uncorrected.

*Methyl 2-Ethoxy-5-isoxazolidinecarboxylate (**4**) and Methyl 4-Ethoxyimino-2-hydroxybutanoate (**7**).* A 1.8 M solution of sodium ethoxide in ethanol (300 ml; 0.54 mol) was added to nitromethane (30 g ; 0.50 mol) with stirring at room temperature. The mixture was stirred for 20 min, and the solvent was removed with a suction pump at 40°. The resulting sodium salt of nitromethane was dried *in vacuo* for 3 h. To this was added dry dichloromethane (400 ml), and the suspension was cooled at −5 °C. A solution of triethyloxonium fluoroborate (100 g ; 0.53 mol) in dichloromethane (80 ml) was added to the suspension under nitrogen atmosphere during 5 min, and the mixture was stirred for 15 min at −5 °C. Freshly distilled methyl acrylate (46.8 g ; 0.55 mol) was added to the ethyl nitronate solution, and the reaction mixrure was allowed to stand at −15 °C overnight. The precipitates were filtered away, and the filtrate was evaporated. Distillation yielded **4** (8.1 g) ; bp 95—99 °C/10 Torr; ν_{max} (CCl_4) : 1735 cm^{-1} ; δ(CCl_4) : 1.20 (3H, t, J=6 Hz), 2.2—3.3 (2H, m), 3.60 (2H, t, J=5.5 Hz), 3.78 (3H, s), 3.90 (2H, q, J=6 Hz), and 4.66 (1H, dd, J=5 and 9 Hz ; *m/e* 175 (M^+), 146 (M^+-OCH_3), 130 ($M^+-OC_2H_5$), and 129 ($M^+-HOC_2H_5$). Found: *m/e* 175.083. Calcd for $C_7H_{13}NO_4$: 175.084. Another fraction with higher boiling point, 78.5 °C/4 Torr, was found to be the oxime ether (**7**) (19.5 g); δ(CCl_4) : 1.25 (3H, t, J=6 Hz), 2.5—3.4 (1H, m), 3.80 (3H, s), 4.05 (1H, q, J=6 Hz), 4.10 (1H, q, J=6 Hz), 4.40 (1H, t, J=6.5 Hz), 6.75 (1/2H, t, J=5 Hz), and 7.40 (1/2H, t, J=6 Hz). Found : C, 48.04 ; H, 7.19 ; N, 8.32%. Calcd for $C_7H_{13}NO_4$: C, 47.99 ; H, 7.19 ; N, 8.00%. The adduct (4) was quantitatively converted to the oxime ether (**7**) on heating at 100 ° for 1 h.

*4-Amino-2-hydroxybutanoic Acid (**6**).* The oxime ether (**7**) (2.0 g ; 11.4 mmol) was hydrogenated over platinum oxide (400 mg) in methanol (8 ml) in the presence of concentrated hydrochloric acid (1.3 ml). Crude methyl 4-amino-2-hydroxybutanoate (1.8 g) was heated with 6M hydrochloric acid (20 ml) for 6 h. The product was adsorbed on a cation exchanger (Amberlite Type I CG 120) (13 g). Elution with water afforded the recovered methyl ester, and with 0.5% aqueous ammonia 4-amino-2-hydroxybutanoic acid (**6**) (469 mg ; 37% from **7**) ; mp 189—190 °C (lit,[1] 191—192 °C) ; δ(D_2O) : 2.08 (2H, m), 3.12 (2H, t), and 4.12 (1H, dd).

*Methyl 2-Ethoxy-4-methyl-5-isoxazolinecarboxylate (**8**).* The procedure was essentially the same as that for the preparation of **4**. Nitromethane (15 g) was converted to sodium salt, and treated with triethyloxonium fluoroborate (31 g) and methyl crotonate (17 ml). The mixture was allowed to stand at −15 °C overnight. Distillation afforded **8** (950 mg) ; bp 65—66 °C/0.9 Torr. The NMR spectrum of this material showed peaks at δ : 1.16 (3H, t), 1.33 (3H, d), 2.5—3.5 (3H, m), 3.7 (3H, s), and 4.3 (1H, d), and no others. Its TLC showed only one spot. Found : 189.098. Calcd for $C_8H_{15}NO_4$: 189.100.

*4-Amino-*erythro*-2-hydroxy-3-methylbutanonic Acid (**11**).* The isoxazolidine (**8**) was heated at 200 °C in a sealed tube for 10 min producing methyl 4-ethoxyimino-2-hydroxy-3-methylbutanoate in a quantitative yield ; ν_{max}(CCl_4) : 3500, 1735, and 1610 cm^{-1} ; δ(CCl_4) : 1.20 (3H, d), 1.20 (3H, t), 6.60 (1/3H, d), and 7.20 (2/3H, d). The oxime ether (317 mg ; 1.67 mmol) was hydrogenated over platinum oxide (60 mg) in methanol (5 ml) containing three drops of concentrated hydrochloric acid. The crude product was heated in 6M hydrochloric acid (20 ml), and the resulting mixture was chromatographed on a cation exchanger (Amberlite Type I CG 120) (13 g). Elution with 0.5% aqueous ammonia afforded **11** (176 mg) as a thick oil ; ν_{max} (KBr) : 3500 (br.), 1580 (br.), 1460, 1400, 1130, and 1060 cm^{-1}. Paper chromatography of this amino acid showed a single spot (water–butanol–acetic acid), and its NMR spectrum showed peaks at δ (D_2O) : 1.05 (3H, d, J=7Hz), 2.2 (1H, br.), 3.05 (2H, d, J=6 Hz), and 4.0 (1H, d, J=4 Hz). No other signals showing the presence of impurities were found in the spectrum. The amino acid was characterized as a *N*-phthaloyl derivative, which was prepared according to Nefken's method[9], and purified by chromatography on Sephadex LH 20. This phthaloyl derivative was an oil, showing one spot in its TLC. Its NMR spectrum exhibited peaks at δ : 1.15 (3H, d), 2.5 (1H, m), 4.15 (1H, d), 3.8 (2H, ABX), and 7.85 (5H, br.s), and no others. Found : 263.079. Calcd for $C_{13}H_{13}NO_5$: 263.081.

The authors thank Dr. T. Naito, Bristol-Banyu Research Laboratories, for providing the authentic sample of 4-amino-2-hydroxybutanoic acid.

Retrograde Aldol Reaction of 3-(1-Hydroxy-2,2,2-trichloroethyl)-2,4-pentanedione Catalyzed by the Bivalent Metal Complexes of 2,4-Pentanedione[1]

Kaku UEHARA, Yoshiyuki OHASHI, and Makoto TANAKA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

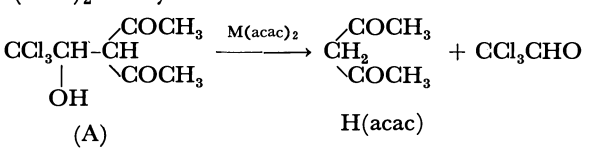
(Received March 29, 1976)

The bivalent metal complexes of 2,4-pentanedione($M(acac)_2$) catalyzes the conversion of 3-(1-hydroxy-2,2,2-trichloroethyl)-2,4-pentanedione(A) into chloral and acetylacetone(Hacac) in a chloroform solution. The order of activity of $M(acac)_2$ as the catalyst is: Mg(II), Mn(II)>Co(II)>Ni(II)>Cu(II)<Zn(II). It was found that the catalyzed reaction proceeds through saturation-type kinetics. The Lineweaver-Burk-type plots show linear relationships and are consistent with a mechanism in which a preequilibrium complex formation between $M(acac)_2$ and a substrate is followed by the rate-determining decomposition to give the products. Acetylacetone acts as a competitive inhibitor for the $Cu(acac)_2$-catalyzed reaction. The third stability constant for the Cu–Hacac chelate system can be evaluated from the inhibitor constant as $\log K_3=4.3$. The retrograde aldol reactions of 3-(1-hydroxy-2,2,2-trichloroethyl)-5-methyl-2,4-hexanedione and 3-(1-hydroxy-2,2,2-trichloroethyl)-4-phenyl-2,4-butanedione were studied in the same manner as 3-(1-hydroxy-2,2,2-trichloroethyl)-2,4-pentanedione. A possible mechanism for the catalysis is proposed.

A number of studies have been carried out on the catalysis of metal ions or chelates for the clarification of the role of metal ions in metalloenzymes. Sigman and Jorgensen[2] reported the zinc(II)-catalyzed transesterification of *N*-(2-hydroxyethyl)ethylenediamine by *p*-nitrophenyl picolinate which involved a reactive ternary complex analogous to metalloenzyme–substrate complexes. Breslow *et al.*[3] found that the mechanism of metal-catalyzed hydration of 2-cyano-1,10-phenanthroline is related to the "rack mechanism" proposed for some enzymatic processes.

These metal-catalyzed processes represent models for the catalytic role of metals in the active site and not for overall enzymatic processes, since catalysis of metal ions or chelates differs essentially from that of enzymes. However, the rate of the metal-catalyzed reaction can be described by saturation-type kinetics if the substrate(S) coordinates to a vacant site of metal ion or chelate(M) to give the complex(SM) which is decomposed to products(P) and M; $S+M \rightleftarrows SM \rightarrow P+M$. Tsuchida *et al.*[4] found that the oxidative polymerization of 2,6-xylenol with a copper–amine complex proceeds *via* a mechanism similar to that of a Michaelis-Menten-type reaction.

In the present paper it is shown that the rates of $M(acac)_2$-catalyzed retrograde aldol reaction (1) can be explained in terms of saturation-type kinetics, and that the third stability constant for the Cu–Hacac chelate system can be obtained from the kinetic parameters of the inhibitory action of acetylacetone on the $Cu(acac)_2$-catalyzed reaction as shown below.



(A) H(acac) (1)

Experimental

Materials. 3-(1-Hydroxy-2,2,2-trichloroethyl)-2,4-pentanedione(A) was prepared according to the method described in the preceding paper.[5] Similarly, 3-(1-hydroxy-2,2,2-trichloroethyl)-5-methyl-2,4-hexanedione(B) was prepared from a mixture of 5.9 g (0.046 mol) of isobutyrylacetone,[6] 6.8 g (0.046 mol) of chloral and a few drops of piperidine in a yield of 20% (2.54 g). Mp 59 °C. Found: C, 39.19; H, 4.70%. Calcd for $C_9H_{13}O_3Cl_3$: C, 39.23; H, 4.76%. IR(KBr disk): 3380(s), 2920(m), 1720(s), 1690(s), 1460(s), 1350(s), 1290(m), 1150(m), 1100(m), 990(w), 810(s), and 710 cm^{-1} (s). UV($CHCl_3$): λ_{max} 290 nm(ε_{max} 137). 3-(1-Hydroxy-2,2,2-trichloroethyl)-4-phenyl-2,4-butanedione (C) was synthesized from 3.1 g (0.019 mol) of benzoylacetone and 2.8 g (0.019 mol) of chloral in the presence of piperidine (yield, 3.4 g(59%)). Mp 91 °C. Found: C, 46.14; H, 3.52%. Calcd for $C_{12}H_{12}O_3Cl_3$: C, 46.41; H, 3.89%. IR(KBr disk): 3370(s), 1705(s), 1680(s), 1450(m), 1360(s), 1290(s), 1180(s), 1100(s), 1050(w), 980(m), 840(m), 805(m), 790(s), 760(s), and 700 cm^{-1}(m). UV($CHCl_3$): λ_{max} 252 nm(ε_{max} 317). $M(acac)_n$ of GR grade reagents(Dojindo Co. Ltd., Research Laboratories, Kumamoto) were used without further purification. Copper(II) chelates of isobutyrylacetone and benzoylacetone were prepared by the method of Adams *et al.*[6] Commercial acetylacetone and chloroform were distilled before use.

Spectral Measurements. The IR spectra were measured with a Hitachi Model 215 grating spectrophotometer, the UV spectra with a Shimadzu UV-200 spectrophotometer, and the NMR spectra with a Hitachi Model R-20 spectrometer. Tetramethylsilane was used as an internal standard, deuteriochloroform being used as the solvent. Elemental analyses were carried out with a Yanagimoto Model MT-2 CHN analyzer.

Kinetic Measurements. Kinetic measurements were carried out spectrophotometrically by monitoring the spectral changes in the 250—350 nm region. The absorbance of a mixed solution of A(or either B or C) and $M(acac)_2$ increased with time, the spectrum being similar to that of acetylacetone (or the corresponding β-diketones) even at a very low conversion(below 2%) since absorbance of A and chloral is regarded as negligible as compared with that of acetylacetone. The chloroform solution containing only $M(acac)_2$ showed no observable spectral change during the course of measurement. An example of the time-dependent UV spectra of a reaction mixture is shown in Fig. 1. The initial rate of the retrograde aldol reaction can be followed conveniently by the measurement of UV absorption. The amount of produced acetylacetone, or consumed A, can be calculated as follows: where Abs(t) and $c_{Hacac}(t)$ denote absorbance and concentration, respectively, of acetylacetone at time t, c_A^0 and c_M^0 the initial concentrations of A and $M(acac)_2$, respectively, and ε_A, ε_M, ε_{Hacac}, and $\varepsilon_{chloral}$ the molar extinction coefficients of A, $M(acac)_2$, Hacac, and chloral,

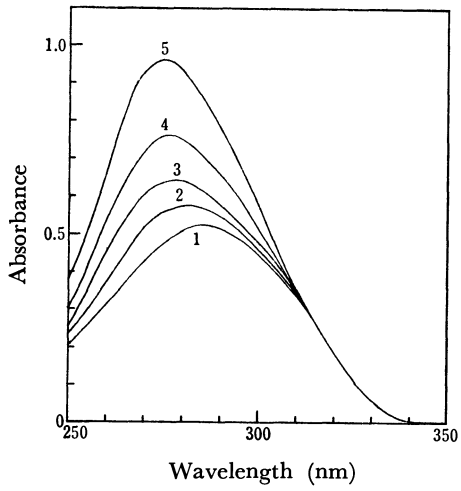


Fig. 1. Time-dependent UV spectra of a mixture of A and $Cu(acac)_2$ at 26 °C in chloroform after mixing. $[A]=3.53\times10^{-3}$ M, $[Cu(acac)_2]=5.83\times10^{-6}$ M, 1 : t=2 min, 2 : t=11 min, 3 : t=21 min, 4 : t=37 min, 5 : t=63 min (conversion=1.77%).

$$A + M(acac)_2 \rightarrow Hacac + chloral + M(acac)_2 \quad (2)$$

$$Abs(t) = \varepsilon_A c_A^0(1-x) + \varepsilon_M c_M^0 + \varepsilon_{Hacac} x c_A^0 + \varepsilon_{chloral} x c_A^0 \quad (3)$$

$$c_{Hacac}(t) = x c_A^0 = \frac{Abs(t) - \varepsilon_A c_A^0 - \varepsilon_M c_M^0}{\varepsilon_{Hacac} + \varepsilon_{chloral} - \varepsilon_A} \quad (4)$$

respectively. The initial rate of reaction can be calculated from the initial slope obtained from a time-conversion curve. For example, at 280 nm,

$$Rate = \frac{Abs(\Delta t) - Abs(0)}{\Delta t \times 2.598 \times 10^7} \quad (M\,s^{-1}) \quad (5)$$

At low conversions below 2%, time-conversion curves gave straight lines passing through the origin, suggesting that the ligand exchange reaction beween A and $M(acac)_2$ can be neglected.

Spectrometric Determination of Equilibrium Constant. The reaction (1) is reversible.[7] The formation of A was followed by means of NMR in a deuteriochloroform solution of chloral, acetylacetone, and $M(acac)_2$. 0.0013 g of $M(acac)_2$ was added to a 2 ml deuteriochloroform solution of chloral and acetylacetone($[CCl_3CHO]=[Hacac]=1.02$ M). The NMR spectrum of this solution was measured after it had been left to stand at room temperature for a few hours. Similarly, the NMR spectrum of a deuteriochloroform solution containing A ($[A]=1.02$ M) and 0.0013 g of $Mg(acac)_2$ was also measured after being left to stand for several hours. The two spectra agreed with each other. The equilibrium constant K of Eq. 6 was obtained to be 1.22 M^{-1} from the NMR data.

$$Chloral + Hacac \overset{K}{\rightleftharpoons} A \quad (6)$$

Results and Discussion

Rate Equation of Retrograde Aldol Reaction. Though the reaction took place without catalyst, the reaction rate in chloroform solution was low at room temperature. The rate of catalyzed reaction was found to be of pseudo-first order with respect to $M(acac)_2$ at constant initial concentration of A. Thus, the rate of disappearance of A is described as

$$Rate = k_{cat}[M(acac)_2] + E \quad (7)$$

Table 1. Pseudo-first-order rate constants catalyzed by $M(acac)_n$, second stability constants for metal complexes with acetylacetone, and force constants of $M(acac)_2$
$[A]=3.35\times10^{-3}$ M, at 26 °C in chloroform

$M(acac)_n$	$k_{cat}\times10^2$ s^{-1}	log K_2[8]	K(M-O)[12] N cm^{-1}
$Mg(acac)_2$	14.0	6.27	
$Mn(acac)_2$	14.0	7.35	
$Co(acac)_2$	6.5	9.54	1.50

$Zn(acac)_2$	1.2	8.81	1.50
$Cu(acac)_2$	0.08	16.34	2.20
$Co(acac)_3$	0		2.40
$Cr(acac)_3$	0		2.30

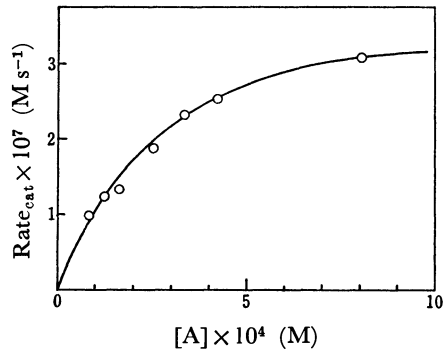

Fig. 2. Plot of initial rate of retrograde aldol reaction, catalyzed by $Co(acac)_2$ *vs.* concentration of A at 26 °C in chloroform. $[Co(acac)_2]=5.66\times10^{-6}$ M.

where E is the rate for the spontaneous reaction in the absence of $M(acac)_2$. The values of k_{cat} for various $M(acac)_2$ are given in Table 1. The trivalent metal complexes of 2,4-pentanedione such as $Co(acac)_3$ and $Cr(acac)_3$ were inactive as a catalyst. It was found that the order of activity of $M(acac)_2$ as the catalyst is: Mg(II), Mn(II) > Co(II) > Ni(II) > Cu(II) < Zn(II). $M(acac)_2$ having a stable O–M bond is unfavorable for a high catalytic activity. Thus, it is suggested that the present catalysis also proceeds *via* the dissociation of the O–M bond as shown for the metal-ion-catalyzed alcoholysis of β-diketones.[9]

Figure 2 shows a typical example of the plots of observed initial rates *vs.* concentrations of A. The observed saturation phenomenon can be analyzed in terms of saturation-type kinetics. The kinetics is based on the assumption that substrate A coordinates reversibly to a vacant site of $M(acac)_2$ to form a complex which is then decomposed, giving back the free $M(acac)_2$ and products(acetylacetone and chloral). The kinetic expression for the present reaction can be written as

$$A + M \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} AM \xrightarrow{k_2} M + P \quad (8)$$

where M stands for $M(acac)_2$, A is 3-(1-hydroxy-2,2,2-trichloroethyl)-2,4-pentanedione, and P is acetylacetone and chloral.

If the aldol reaction ($P \overset{M}{\rightarrow} A$) is neglected when

the concentration of P is sufficiently small, the catalyzed reaction rate ($Rate_{cat}$) is expressed as follows from the steady state of the intermediate AM.

$$Rate_{cat} = \frac{V[A]}{K_m + [A]} \tag{9}$$

where $V=k_2[M]^0$, $K_m=(k_{-1}+k_2)/k_{+1}$. This is of the same form as the Michaelis-Menten mechanism and explains the fact that the rate of the catalyzed reaction is proportional to the initial concentration of $M(acac)_2$ at a given concentration of A and that the initial rate *vs.* [A] curve shows a pronounced saturation. Equation 9 can be rearranged to give Eq. 10. If $1/Rate_{cat}$ is plotted against 1/[A] (Lineweaver-Burk plot),[10] the values of the maximum rate V and the constant K_m can be obtained from the intercepts of vertical and horizontal axis, respectively.

$$\frac{1}{Rate_{cat}} = \frac{1}{V} + \frac{K_m}{V}\frac{1}{[A]} \tag{10}$$

As shown in Fig. 3, the Lineweaver-Burk plot (Fig. 2) gives a straight line with intercepts of vertical axis of $1/V$ and of horizontal axis of $-1/K_m$, supporting the above hypothesis that the present reaction can be written by Eq. 8 and the aldol reaction is neglected presumably because of very low concentration of P in the initial stage of the reaction. The rate constant k_2 is evaluated from the maximum rate V, which is defined as $k_2[M]^0$. The values of K_m, k_2 and k_2/K_m obtained from Lineweaver-Burk plots for the various $M(acac)_2$-catalyzed reactions are given in Table 2. If $k_{-1} \gg k_2$, K_m can be defined as k_{-1}/k_{+1} (dissociation constant of complex AM), and if $k_{-1} \ll k_2$, $K_m=k_2/k_{+1}$. An approximate parallelism is observed between K_m and k_2 within a series of $M(acac)_2$-catalyzed retrograde aldol reactions of A(Table 2).

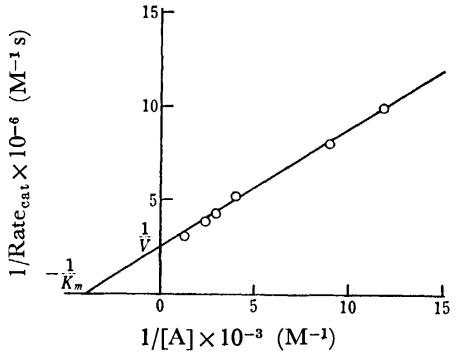

Fig. 3. Lineweaver-Burk-type plot of the data of Fig. 2.

Table 2. Kinetic parameters for the retrograde aldol reaction of A catalyzed by various $M(acac)_2$ at 26 °C in chloroform

$M(acac)_2$	$K_m \times 10^4$ M	$k_2 \times 10^2$ s^{-1}	k_2/K_m M^{-1} s^{-1}
$Mg(acac)_2$	37.0	14.0	38
$Co(acac)_2$	2.6	7.1	270
$Ni(acac)_2$	7.2	2.2	30
$Zn(acac)_2$	9.1	1.4	15
$Cu(acac)_2$	0.34	0.076	22

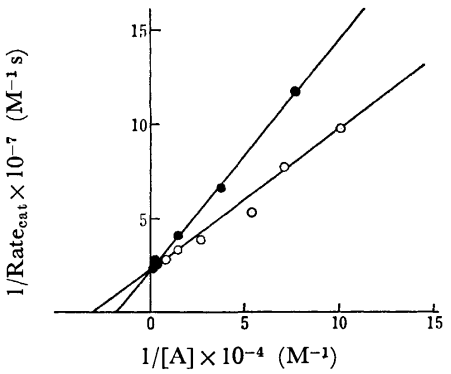

Fig. 4. Inhibitory action of acetylacetone on the $Cu(acac)_2$-catalyzed retrograde aldol reaction of A at 26 °C in chloroform. $[Cu(acac)_2]=5.92\times10^{-5}$ M.
—○—: In the absence of Hacac,
—●—: in the presence of Hacac ([Hacac]$=3.11\times10^{-5}$ M).

Inhibitory Action of Acetylacetone on the $Cu(acac)_2$-Catalyzed Reaction. It is highly probable that the catalytic action of $M(acac)_2$ will be suppressed in the presence of a compound which can coordinate to $M(acac)_2$. Conversely, observation of the inhibitory action should emphasize the validity of the proposed mechanism. Acetylacetone which is one of the reaction products is an effective ligand for the metal ions and should act as a competitive inhibitor. In the presence of acetylacetone, the initial rate of the $Cu(acac)_2$-catalyzed retrograde aldol reaction of A in chloroform was measured as a function of the concentration of A. Figure 4 shows the relationship between initial rate and substrate concentration [A] in the absence and presence of acetylacetone. Compared with the initial rate in the absence of the inhibitor, the initial rate in the presence of acetylacetone was somewhat reduced without alteration of the maximum rate. This suggests that acetylacetone behaves as a typical competitive inhibitor, *i.e.*, acetylacetone competes with A for occupation of the coordination site of $Cu(acac)_2$ to form a five-coordinated copper(II) complex. The whole reaction containing the inhibition of acetylacetone can be represented as follows.

$$A + M \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} AM \xrightarrow{k_2} Hacac + CCl_3CHO + M \tag{11}$$

$$Hacac + M \underset{k_{-1}}{\overset{k_{+1}}{\longrightarrow}} Hacac\cdot M \tag{12}$$

By applying the steady-state treatment to AM, we obtain the rate equation

$$Rate_{cat} = \frac{V[A]}{K_m(1+i/K_i)+[A]} = \frac{V[A]}{K_p+[A]} \tag{13}$$

where i is concentration of acetylacetone, and K_i is dissociation constant of Hacac·M, *viz.*, $K_i=k_{-1}/k_{+1}$. K_i is also called the inhibitor constant. The value of $K_p(=K_m(1+i/K_i))$ was found to be 5.6×10^{-5} M at $i=3.11\times10^{-5}$ M from Fig. 4, and the K_i value to be 4.8×10^{-5} M from K_p and K_m values.

Since the reciplocal of K_i should be the stability constant of Hacac·M, the value of log $(1/K_i)$, 4.3, corresponds to the third stability constant for the Cu–

Hacac chelate system. The first and second stability constants have been reported to be 8.22 and 6.73, respectively.[11]

Kinetics for Compounds B and C. The kinetics was studied for the retrograde aldol reactions of 3-(1-hydroxy-2,2,2-trichloroethyl)-5-methyl-2,4-hexanedione(B) and 3-(1-hydroxy-2,2,2-trichloroethyl)-4-phenyl-2,4-butanedione(C) in the same manner as for compound A. Copper(II) chelate of isobutyrylacetone and benzoylacetone were employed as catalyst for the reaction of B and C, respectively. The initial rate of the copper(II)-catalyzed reaction was found to be proportional to the initial concentration of copper(II) chelate at a given concentration of B or C. The saturation-type kinetics was again observed in the plots of initial rates *vs.* concentrations of B or C. The corresponding Lineweaver-Burk-type plots were found to be linear. Kinetic parameters for the reaction of A, B, and C are summarized in Table 3.

Table 3. Kinetic parameters for the reaction of A, B, and C at 26 °C in chloroform

Substrate	$K_m \times 10^4$ M	$k_2 \times 10^3$ s^{-1}	k_2/K_m M^{-1} s^{-1}
A	0.34	0.76	22
B	0.46	6.2	135
C	13	34	26

The k_2 values increase in the order A<B<C. This arises from replacement of the methyl group of acetylacetone by the isopropyl or phenyl group. The substituent effect can be attributed to an increased steric hindrance of intermediate. There is a tendency for the value of K_m to increase with increase in k_2. When the metal ion of $M(acac)_2$ changes as Cu→Ni→Mg, a similar variation in K_m and k_2 values (Cu<Ni<Mg) was observed. This parallelism in K_m and k_2 may be characteristic of the present retrograde aldol reaction, but it is impossible to understand its meaning.

Reaction Mechanism. On the basis of the results, a possible mechanism for the $M(acac)_2$-catalyzed retrograde aldol reaction of A may be proposed as follows. Compound A coordinates to a vacant site of $M(acac)_2$ to give the intermediate AM. The hydroxyl group of the complex is then deprotonated to give acetylacetone with the concomitant rearrangement of electrons in the intermediate leading to chloral elimination and regeneration of $M(acac)_2$.

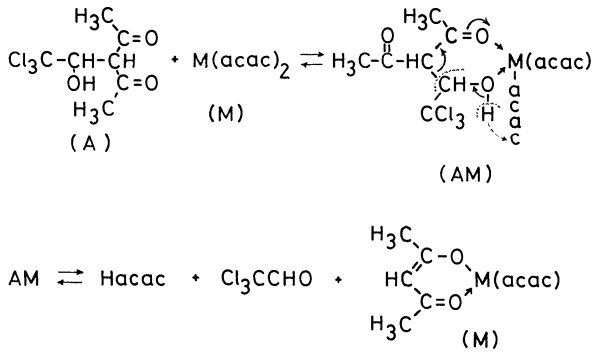

Fig. 5. Reaction scheme.

The present reaction is reversible, the equilibrium constant for the overall reaction being 1.22 M^{-1}. Reaction of acetylacetone with chloral by $M(acac)_2$ will occur with the opposite route of the retrograde aldol reaction to give an equilibrium mixture.

Preparation of Polyvinylamine by the Hofmann Degradation of Polyacrylamide[1)]

Hiroo TANAKA and Ryoichi SENJU

Department of Forest Products, Faculty of Agriculture, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 29, 1976)

Polyvinylamine which contained 95.6 mol% amine units was obtained when the Hofmann degradation was applied to polyacrylamide by use of a very slight excess of sodium hypochlorite and a large excess of sodium hydroxide at 0 to −15 °C for about 15 h. Polyvinylamine hydrochloride (PVAm·HCl) was isolated almost quantitatively as a white powder. PVAm·HCl was freely soluble in water, but insoluble in organic solvents such as methanol, acetone, dioxane, *N,N*-dimethylformamide (DMF), and dimethyl sulfoxide (DMSO). The desalting of PVAm·HCl was performed by passing its aqueous solution through columns of ion exchange resins. The product containing 30.5% nitrogen was obtained in reasonable yield. Polyvinylamine was freely soluble in water, acetic acid, or lower alcohols, but insoluble in solvents such as acetone, dioxane, DMF, and DMSO.

It is well known that *N*-haloamides are highly stable at a temperature as low as 0 °C and activation energy of the Hofmann degradation is about 30 kcal/mol. Therefore, the Hofmann degradation is generally carried out by dissolving the amide in a very slight excess of cold aqueous hypohalite solution, followed by rapid warming.[2)]

However, the Hofmann degradation of polyacrylamide (PAM) is exceptional. It has been previously shown in this laboratory that the Hofmann degradation of PAM is accelerated very much by the neighboring-group participation and the *N*-haloamide groups of PAM are easily converted to amino groups even at a temperature below 0 °C.[3)] According to this procedure, the partial amination of PAM was easily accomplished while limiting the formation of carboxyl groups to a very small percentage.[4)]

The present investigation was undertaken in order to find some suitable methods for increasing further the contents of amine units, and for the separation and the purification of polyvinylamine (PVAm). PVAm containing as much as 95.6 mol% amine units could be purely isolated almost quantitatively.

Experimental

Materials. Acrylamide and $K_2S_2O_8$ were recrystallized twice from benzene and water solution respectively. All of the other chemicals used were reagent grade.

Polymerization of acrylamide was carried out in 10% aqueous solution with the use of $K_2S_2O_8$-2-propanol redox initiator under nitrogen atmosphere at 60 °C for 60 min. The resulting polymer was purified by reprecipitating twice from water-methanol. The nitrogen content of PAM was 18.9% and the content of carboxyl groups was negligible small. The intrinsic viscosity of PAM was 2.1 dl/g at 30 °C.

Sodium hypochlorite solution was prepared by passing chlorine gas through a 7 M NaOH solution cooled with an ice bath. The concentration of NaOCl measured by the iodometry was 2.0 mol/l and that of NaOH by the acidmetry after removal of NaOCl with a small excess of H_2O_2 was 2.5 mol/l.

The ion exchange resins used were Amberlite IR-120B and IRA-400.

Reaction Procedure. Twenty-four grams of 10.3% PAM (1.4 mol/l per amide group) cooled to 0 °C were added into 10 ml of alkaline NaOCl cooled to about −5 °C with vigorous stirring. The resulting solution was cooled rapidly by dipping in a bath of −15 °C. When the temperature of the solution reached about −10 °C, a desirable amount (1—40 ml) of 10 mol/l NaOH cooled to −15 °C was added with stirring and maintained at −10 to −15 °C for 1—2 h. Then the reaction mixture was warmed to 0 °C and allowed to stand for 10—15 h.

Isolation and Purification. The polymer was isolated by pouring the mixture into about a 4-fold amount of methanol. The resulting precipitate was dissolved in about 25 ml of water and 6 M HCl was added dropwise to this solution with stirring. Although CO_2 gas evolved and the polymer precipitated once, it was soon dissolved completely by the continuous stirring, keeping the pH about 2. The resultant solution was poured into about a 4-fold amount of methanol again. The supernatant solution was decanted and the residual precipitate was filtered through the weighed sintered glass disk, then washed with methanol and ethanol successively and dried *in vacuo* over P_2O_5. The ash content of polyvinylamine hydrochloride (PVAm·HCl) obtained in this manner was less than 0.3%.

The repetition of the reprecipitations was undesirable because the purified PVAm·HCl was precipitated with great difficulty. Since PVAm·HCl is very hygroscopic, care had to be taken in handling it.

The aqueous solution (2—3%) of PVAm·HCl was passed through the columns of cation and anion exchange resins successively and the columns were washed with water about double in volume. The collected effluent from the columns was concentrated to about 5% under reduced pressure and the resultant solution was poured into a large amount of acetone. The precipitate obtained was filtered and dried *in vacuo*.

Analytical Method. Contents of both amino and carboxyl groups were measured by the colloid titration method.[5)] For details of the analyses the previous paper[3)] should be referred to.

The chlorine content of PVAm·HCl was determined as follows: Dilute sulfuric acid was added to 100 ml of the aqueous solution containing about 0.1 g PVAm·HCl to adjust the pH to about 2. A proper amount (50—100 ml) of 0.01 M potassium poly(vinyl sulfate)[5)] was added to this solution until the supernatant solution became clear, and the resulting precipitate was filtered off and washed several times with a small amount of water. The combined filtrate was neutralized and titrated by 0.05 M $AgNO_3$ (Mohr method). If the PVAm was not removed, the end point of the titration became imprecise and the content of chlorine was overestimated.

Table 1. Reaction conditions of the Hofmann degradation of PAM and the analytical results

No.	Reaction conditions			Analytical results			Analytical results of PVAm·HCl				
	PAM (mol/kg)	NaOCl (mol/kg)	NaOH (mol/kg)	Amino group (mol/kg)	Degree of amination (%)	Carboxyl group (mol%)	Yield (g)	Ash (%)	Chlorine (%)	Nitrogen (%)	Carboxyl group
1	0.740	0.751	1.16	0.395	53.4	5	1.49	0.3	25.9	17.2	neg. small
2	0.500	0.507	2.99	0.435	87.0	4	1.52	0.2	40.3	16.0	neg. small

						PVAm·HCl (calcd)	1.61	0	44.6	17.6	0

In the case of Nos. 6—8, 3 ml of dioxane (No. 6), 3 ml of methanol (No. 7) or 10 ml of water saturated with NaCl (No. 8) were added to 14 g of 10.3% PAM solution before mixing it with the alkaline NaOCl.

Nitrogen contents were determined by the Kjeldahl method.

Results and Discussion

Effect of NaOH Concentration on Yields of Amine Units. During the progress of the Hofmann degradation, the isocyanato groups which are formed as transient intermediates react with water to yield the objective amino groups on the polymer chain in the presence of excess alkali[2] On the other hand, a part of these resulting amino groups give the urea derivatives due to the reaction between the amino and isocyanato groups. These two reactions can be illustrated as follows:

$$R\text{-}CONH_2 \xrightarrow{OCl^-} R\text{-}CON^-Cl \longrightarrow [R\text{-}N{=}C{=}O] \xrightarrow{OH^-} R\text{-}NH_2 \quad (1)$$

$$R\text{-}N{=}C{=}O + R\text{-}NH_2 \longrightarrow R\text{-}NHCONH\text{-}R \quad (2)$$

Therefore the yields of amine increase with an increase in concentration of NaOH. When PAM was subjected to the Hofmann degradation in the presence of 4.2 mol/l NaOH, 88% of the amide units converted to amine, as described earlier[3]. Although the yields of amine units could be expected to increase further if an additional amount of NaOH was applied, the salting-out of the polymer, which took place on the occasion of mixing the PAM solution with alkaline aqueous NaOCl, precluded an experiment with a high concentration of NaOH.

After various attempts were made, it was found that the concentrations of NaOH could be increased still more, without any salting-out of the polymer, by adding the large amount of 10—20 mol/l NaOH to the mixrure of PAM and NaOCl prepared in the presence of a small amount of NaOH. This may be responsible for the fact that the *N*-chlorinated PAM salt outed with more difficulty than the PAM.

Results are shown in Table 1. The degrees of amination based on amide groups were 53.4 and 87.0% in the presence of 1.16 and 2.99 mol/kg NaOH respectively. Since these experimental data are similar to the results of the paper reported previously,[3] the degree of amination has been found to be little influenced by the addition procedures of NaOH.

The degree of amination increased further with increase of the concentration of NaOH and amounted to 95.6 mol% in the presence of 5.28 mol/kg NaOH. However, when an excess concentration of NaOH such as 8.15 mol/kg (No. 5) was applied, the degree of amination was limited to 94.8 mol% because the polymer salt outed as a pasty cake. The higher limit of NaOH concentration in the homogeneous reaction seemed to be 6—7 mol/kg.

In the cases shown above (No. 1—5), 2—5 mol% of carboxyl groups were formed, even though PAM cooled to 0 °C was used. It may be preferable to mix alkaline NaOCl with PAM at a lower temperature to reduce the formation of carboxyl groups[3]. Further, it has already been found that the degree of amination increases with decrease of the reaction temperature[3]. No. 6—8 were the cases in which PAM cooled to −5 to −10 °C after the addition of dioxane, methanol, or water saturated with NaCl was mixed with an alkaline NaOCl to −15 °C. As can be seen from Table 1, the formation of carboxyl groups was less than 1%. However, the degree of amination was reduced also, contrary to our expectation. That the degree of amination is particularly low in the presence of methanol may be due to the formation of some urethane linkages.

Isolation of PVAm·HCl and Analytical Results. Results are shown in Table 1. The products of 1.49—1.55 g were obtained from 1.44 g PAM. Since the molecular weight of monomer units of PAM and PVAm·HCl are 71.1 and 79.5 respectively, the theoretical yield of PVAm·HCl is 1.61 g. In the case of No. 4 in which 95.6% of the amide units converted to amine, 1.55 g of PVAm·HCl was obtained.

The ash contents of the products were very small (0.1—0.3%). The chlorine contents of the products increased with increase of amine units. The chlorine content (43.3%) of No.4 is 97.1% of the theoretical

Table 2. Analytical results of PVAm desalted from PVAm·HCl by ion exchange

No.	Yield (%) found	Yield (%) calcd	Nitrogen (%)	Molecular weight per nitrogen	Molecular weight per amino group	Carboxyl group
1	72.5	73.1	22.0	63.7	104.9	neg. small
2	57.3	58.4	25.0	56.0	59.1	neg. small
3	54.0	55.5	28.5	49.2	49.9	neg. small
4	53.7	55.4	30.5	45.9	46.5	neg. small
PVAm (calcd)		54.2	32.5	43.1	43.1	0

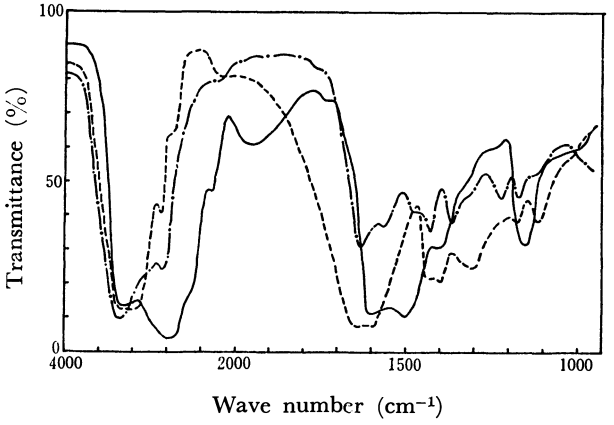

Fig. 1. IR spectra of PAM, PVAm·HCl(No. 4) and PVAm(No. 4).
----: PAM, ——: PVAm·HCl, ——: PVAm.

value (44.6%). This value agreed closely with the degree of amination (95.6%) determined by colloid titration.

The carboxyl contents were negligible small. The disappearance of carboxyl groups appeared to be due to the formation of methyl ester which occured during the isolations and purifications, because methanol was detected in the hydrolysis solutions of purified products by the gas chromatography.

PVAm·HCl was highly hygroscopic and freely soluble in water. However, it was insoluble in pure organic solvents such as methanol, acetone, dioxane, *N*,*N*-dimethylformamide (DMF), and dimethyl sulfoxide (DMSO), though soluble in methanol, DMF, or DMSO containing 10—20% water.

The infrared absorption spectrum of PVAm·HCl (No.4) in a KBr disk is shown in Fig. 1 and compared with that of PAM. The absorption band at 1640 cm^{-1} in PAM, which was assigned to $CONH_2$, diminished and new bands due to NH_3^+ appeared at 2800, 1950, and 1500 cm^{-1}. A very weak absorption band due to the ester was observed at 1700 cm^{-1}. The absorption bands due to NH_2 exist at 3335 and 1610 cm^{-1}.

Preparation of PVAm from PVAm·HCl. Attempts to obtain the pure PVAm by pouring the PVAm·HCl solution with a small excess of NaOH into various organic solvents were unsuccessful. Even if the above solution was added into a large amount of methanol the solids did not appear. Although some milky precipitates were obtained by pouring such a solution into ethanol or 2-propanol, the filtration was actually impossible. By using the acetone–ethanol (4 : 1) or dioxane–ethanol (2 : 1) mixture as precipitant, precipitates which could be filtered easily were obtained, but these contained as much as 30—60% ash.

The ion exchange resins were also applied to desalt PVAm·HCl. Results are shown in Table 2. The yields of products were satisfactory, as can be seen from comparison of found and calculated values, and accordingly the amount of PVAm bound to cation exchange resins was extremely small.

The nitrogen contents of the products were 22.0—30.5%. The latter value (30.5%) approximates adequately to the theoretical nitrogen content of PVAm (32.5%). Then the equivalent molecular weights per nitrogen (EW-N) were compared with those per amino group (EW-A) determined by colloid titration. In the case of No. 1, EW-N was 63.7 and EW-A 104.9. This serious difference shows that No. 1 contains a large amount of non-amine-type nitrogens. EW-N and EW-A are brought close together with increase of the degree of amination. In the case of No. 4 (degree of amination: 95.6%), the nitrogen was found to be virtually an amine-type one since EW-N was 45.9 and EW-A 46.5.

The contents of carboxyl groups were small enough to neglect. The ester seems not to be hydrolyzed by passing it through the ion exchange resins.

PVAm was hygroscopic and freely soluble in water, acetic acid, or lower alcohols such as methanol, ethanol, and 2-propanol. However, it was insoluble in organic solvents such as acetone, dioxane, tertahydrofuran, DMF, DMSO, benzene, and choroform.

The infrared absorption spectrum of PVAm in a KBr disk is shown in Fig. 1, in comparison with that of PVAm·HCl. The absorption bands due to NH_2 existed at 3340 and 1635 cm^{-1}, although the bands at 2800, 1950, and 1500 cm^{-1} in PVAm·HCl, which were assigned to NH_3^+, diminished.

The intrinsic viscosity of PVAm (No.4) measured at 30 °C in 0.1 M NaCl solution was 0.70 dl/g.

The Reaction of Disodium Tetracarbonylferrate(−II) with Carboxylic Esters and Carbothioic Esters[1)]

Yoshihisa WATANABE, Masakazu YAMASHITA, Mineo IGAMI,
Take-aki MITSUDO, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received April 5, 1976)

The reaction of carboxylic and carbothioic esters with disodium tetracarbonylferrate has been studied. Aryl and thiolic esters reacted with the ferrate under mild conditions to give aldehydes after the reaction mixture had been quenched with acetic acid, but alkyl esters did not. 3-Benzylidenephthalide and phthalide gave 2-phenyl-1,3-indanedione and a dimeric product respectively.

Recently, several works have demonstrated that alkali metal tetracarbonylferrate, $[Fe(CO)_4]^{2-}$ (**1**), is useful for the syntheses of aldehydes,[2-5)] carboxylic acid derivatives,[6)] and ketones[7,8)] from alkyl halides, acid chlorides, carboxylic anhydrides, and carboxylic carbonic anhydrides. Though these carboxylic acid derivatives have great reactivities to **1**, little attention has been paid to other carboxylic acid derivatives. In this paper, we wish to report that the ferrate (**1**) also has some reactivities as a nucleophile to carboxylic esters and carbothioic esters, which can be transformed into the corresponding acyl tetracarbonylferrate (**2**). This is the first example of an anionic metal carbonyl reacting with an ester linkage.

Results and Discussion

Reactions of Carboxylic Esters with 1. Aryl esters, such as phenyl benzoate and phenyl propionate, reacted with a tetrahydrofuran(THF) solution of **1** at room temperature, and the corresponding aldehydes and phenols were formed after the treatment of the reaction mixture with glacial acetic acid.

$$\mathrm{RCOOPh} \xrightarrow[\text{ii) } H^+]{\text{i) } Na_2Fe(CO)_4} \mathrm{RCHO} + \mathrm{PhOH}$$

Alkyl esters, such as ethyl propionate and benzyl benzoate, scarcely reacted at all with **1** even at rather higher temperatures. The results are summarized in Table 1.

In the case of the aryl esters, the infrared spectra of the reaction mixture show bands at 1890 and 1550—1600 cm^{-1} which are not detectable before the addition of the esters. This indicates that the corresponding acylcarbonylferrates (**2**) are formed as intermediates.[9)]

$$\mathrm{RCOOPh} + [Fe(CO)_4]^{2-} \rightarrow [\mathrm{R\text{-}C(=O)\text{-}Fe(CO)_4}]^- + \mathrm{PhO}^-$$

(**1**) (**2**)

2 is assumed to be formed by the uncleophilic attack of **1** on the carbonyl carbon of the ester. The remarkable difference in reactivity between the aryl esters and the alkyl ones appears to arise partly from the electronic effects of the phenoxyl and alkoxyl group. The electron-withdrawing property of the phenoxyl group is larger than that of the alkoxyl group. Therefore, the electron density on the carbonyl carbon of the aryl esters may be lower than that of alkyl carboxylates. This slight difference may make the aryl esters active in the nucleophilic attack of **1**. Such an influence of the electron density of the carbonyl carbon on the attack of **1** has also been observed in the reaction of mixed carboxylic anhydrides.[4)]

Reaction of Carbothioic Esters with 1. Carbothioic esters such as *S*-*p*-chlorophenyl benzenecarbothioate reacted readily with **1** to give the corresponding

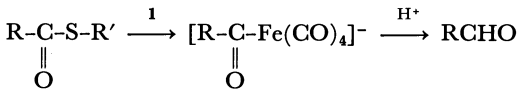
aldehydes in high yields after the treatment of the reaction mixture with glacial acetic acid. The results are shown in Table 2. In these reactions, the infrared spectra of the reaction mixture had bands at 1890 and 1550—1600 cm^{-1}. Therefore, the formation of the acyl tetracarbonylferrate (**2**) as an intermediate in this reaction is also strongly suggested.

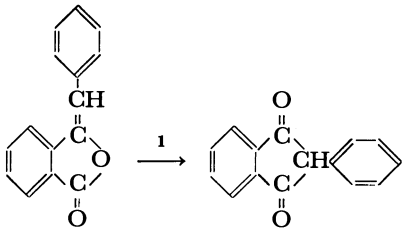


(**2**)

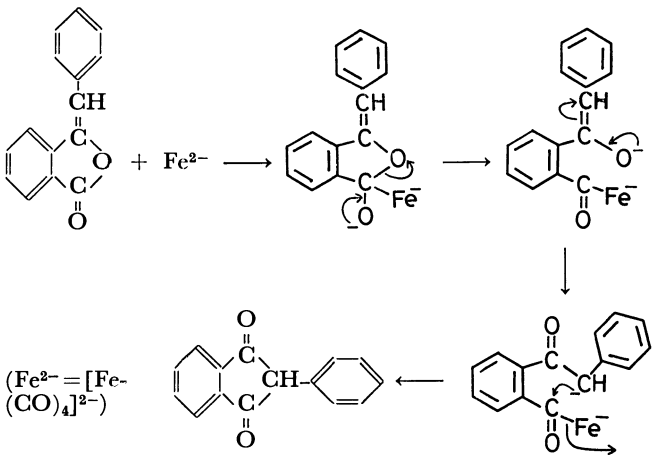
A comparison of the reaction conditions and the yields of the products in Tables 1 and 2 show that carbothioic esters have a greater reactivity to a nucleophilic attack of **1** than usual carboxylic esters. This agrees with the order of susceptibility of carboxylic acid derivatives to a nucleophilic attack.

Reaction of Cyclic Carboxylic Esters with ***1****.* The reaction of **1** with carboxylic esters was applied to cyclic esters. As the esters, phthalide, coumarin, 3,4-dihydrocoumarin, 3-benzylidenephthalide, and γ-butyrolactone were employed. If the reaction proceeds as expected, the corresponding aldehydes with a hydroxyl group will be produced, but the aldehydes were not obtained in these reactions. When coumarin, 3,4-dihydrocoumarin, and γ-butyrolactone were treated with **1**, some reaction took place, with a color change in the reaction mixture from pale-yellow to reddish-black. However, the formation of acyl carbonylferrate as an intermediate is not clear; the infrared absorption bands characteristic of the acyl carbonylferrate (**2**) were not detectable. In these reactions, only a black, tarry material was obtained even after treatment with acetic acid or methyl iodide.

3-Benzylidenephthalide gave 2-phenyl-1,3-indanedione in *ca.* a 50% yield by a reaction with **1**.



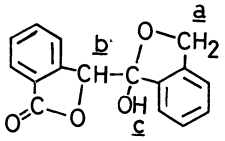
The reaction mechanism is not completely clear at the present time, but a plausible reaction scheme is that described in Scheme 1.



Scheme 1.

In this scheme, an acyl carbonylferrate is also considered to be an intermediate. Such a transformation of 3-benzylidenphthalide takes place in the presence of sodium alkoxide as the catalyst.[10)]

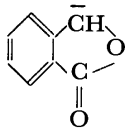
Phthalide also reacted with **1** to give white crystals in a 71% yield (based on the amount of phthalide); these crystals are soluble only in acetone and dimethyl sulfoxide. The infrared spectra of this compound had absorption bands at 3400 and 1740 cm^{-1}, characteristic of the hydroxyl group and of a carbonyl in a strained ring respectively. Thermolysis under reduced pressure (180 °C 1 Torr) and hydrolysis in a hot 3.5 M NaOH alcoholic solution gave phthalide in 85 and 70% yields respectively. From these results and elemental analysis, the structure of this compound is considered to be **3**.



(**3**)

The mass spectrum did not exhibit a peak corresponding to the parent molecular ion, but the following peak

assignments were made: *m/e* 251[M−OH]$^+$, 135[M−$\overline{C_6H_4COOCH}$]$^+$, 134[$\overline{C_6H_4CH_2OCO}$]$^+$, 133[M−135]$^+$, 118[135−OH]$^+$. **3** may be a mixture of two diastereomers. In the NMR spectra, there are three types of signals besides that of the benzene ring: i) τ 5.04 and 4.90, both the AB type, assigned to a in **3**, ii) τ 4.09 and 4.25, both signlets, assigned to b, and iii) τ 3.75 and 3.70, both singlets, assigned to c, which disappeared upon the addition of D_2O. The fractional recrystallization of **3** from an acetone–water solution gave white needles (**4**), which have a similar infrared spectrum to, and the same composition as **3**. The NMR spectrum of **4** showed signals at τ 4.90 (AB type, 2H), 4.25 (singlet, 1H), and 3.70 (singlet, 1H). These results show that **4** is the one of the diastereomers of **3**, although its steric configuration is unknown at the present time.



(**5**)

The mechanism of the formation of **3** is not clear at present, but the phthalide anion (**5**) is assumed to be formed by the reaction of phthalide with **1**; the anion will attack a carbonyl carbon of the second phthalide to give **3** after protonation. The phthalide anion (**5**) is also suggested to be formed by the treatment of phthalide with a basic reagent and to react with carbonyl compounds to give cross-adducts.[11] However, in the reaction of phthalide with **1** in the presence of such carbonyl compounds as benzyl benzoate, the cross-adducts were not obtained.

Experimental

The NMR spectra were obtained on a JEOL JNM-PMX 60 NMR spectrometer and a Varian Model HR-220 NMR spectrometer. The infrared spectra were measured on a Hitachi model 215 grating infrared spectrometer. The mass spectra were recorded on a JMS=OISG mass spectrometer. The melting points are uncorrected.

Materials. *p*-Chlorophenyl benzoate, *p*-chlorophenyl propionate, phenyl *p*-chlorobenzoate, phenyl *p*-toluate, *S*-*p*-chlorophenyl benzenecarbothioate, *S*-*p*-chlorophenyl *p*-toluenecarbothioate, *S*-*p*-chlorophenyl decanethioate, and *S*-*p*-chlorophenyl *p*-chlorobenzenecarbothioate were prepared according to the usual manner from acid chlorides and phenol, *p*-chlorophenol, or *p*-chlorothiophenol. The pentacarbonyliron, acetic acid, and other compounds employed in this study were all commercial products; their purities were checked by GLPC and found to be satisfactory for the reaction. Tetrahydrofuran was dried over lithium aluminium hydride and distilled before use.

*Preparation of Disodium Tetracarbonylferrate (**1**).* All the reactions were carried out in a 200-ml, three-necked flask equipped with a gas buret and a magnetic stirrer under an argon atmosphere. $Na_2[Fe(CO)_4]$ (**1**) was prepared according to the method described in a previous paper.[3] Six mmol of **1** in 30 ml of tetrahydrofuran were used in each run.

General Reaction Procedures and Analyses. To a solution of 6 mmol of **1** in tetrahydrofuran, an equimolar amount of an ester compound was added, and the reaction mixture was agitated at a desired temperature. After a certain reaction time, 0.6 ml of glacial acetic acid was poured in by means of a syringe and the mixture was stirred for an additional five minutes. A 0.2-ml sample of the solution was taken off and then submitted to GLPC analyses; column (3 mmϕ, 1.5 m) packed with Diethylene Glycol Adipate Polyester on chromosorb. The aldehydes were identified by a comparison of their retention times in GLPC with those of authentic samples, and the yields of the aldehydes were determined using internal standards.

*Reaction of 3-Benzylidenephthalide with **1**.* 3-Benzylidenephthalide (11 mmol) was added to a tetrahydrofuran solution of **1** (11 mmol) under an argon atmosphere, and the mixture was stirred for about 5 h at 40 °C. The mixture was acidified with 30 ml of 25% sulfuric acid, the tetrahydrofuran was removed *in vacuo*, and the residue was shaken with 100 ml of diethyl ether. The clean aqueous layer was discarded, and the green-black ether layer was shaken with two 70-ml portions of a 20% sodium cabonate solution. The acidification of the sodium carbonate solution with hydrochloric acid furnished white solids. The solid was terated with about 200 ml of diethyl ether, and the yellow-brown ether solution was left overnight at room temperature over sodium sulfate and then dried. After the removal of the solvent, 2-phenyl-1,3-indanedione (1.2 g, yield *ca.* 50%) was obtained and recrystallized from ethanol; mp 148 °C (literature mp 147—148 °C).[12] Found: C, 81.23; H, 4.34%. Calcd for $C_{15}H_{11}O_2$: C, 81.06; H, 4.54%. The IR and NMR spectra are identical with those of an authentic sample.

*The Reaction of Phthalide with **1**.* Into a tetrahydrofuran solution of **1** (11 mmol), we stirred 1.34 g (10 mmol) of phthalide in tetrahydrofuran at room temperature under argon. After 24 h, to the reaction mixture we added 3 ml of glacial acetic acid and the solvent was distilled off under reduced pressure. A 100-ml portion of a mixture of acetone and water, (5 : 1 v/v) was poured into the residue, and then 100 more ml of water were added. Diethyl ether (50 ml) was poured into the solution, and the organic layer was separated after vigorous shaking with the spearatory funnel. The organic solution was dried over sodium sulfate overnight, and the solvent was evaporated under reduced pressure. The white solids (**3**) thus obtained were recrystallized from acetone (0.95 g; yield 71% based on phthalide); mp 149.5—150.5 °C. Found: C, 71.52; H, 4.40%. Calcd for $C_{16}H_{12}O_4$: C, 71.63; H, 4.51%. Mass; *m/e* 251, 135, 134, 133, 118, 105. The fractional recrystallization of **3** was conducted as follows. 105 mg of **3** were dissolved in 15 ml of an acetone-water mixed solution (5 : 1 v/v), and the solution was permitted to stand in the open air. After about one week, the precipitated white crystals (**4**) were collected(28 mg). Found: C, 71.59; H, 4.61%.

Studies of Enamines. VIII.[1] Reactions of Enamino Ketones with Benzoyl and Thiobenzoyl Isocyanates

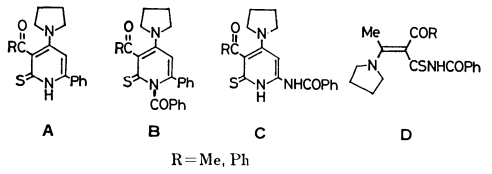
Otohiko Tsuge* and Akitaka Inaba

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 16, 1976)

The reaction of enamino ketone **1**, derived from acetylacetone, with benzoyl isocyanate (**4**) gave the isomeric benzoylcarbamoyl derivatives **6** and **9**, and/or 2-pyridone **7**, depending upon the reaction conditions. Similarly, enamino ketone **2**, derived from benzoylacetone, reacted with **4** to afford the isomeric benzoylcarbamoyl compounds **12**, **13**, and/or 2-pyrone **14**. It has been found that the carbamoyl compound **12** was thermally converted into **13** and **14**. Enamino ketones **1** and **2** reacted with thiobenzoyl isocyanate (**5**) at room temperature to yield the 2-pyridones **7** and **15**, respectively. On the other hand, enamino ketones **3**, derived from benzoylacetaldehyde and secondary amines, reacted with **4** to give the corresponding 2-benzoylcarbamoyl-2-penten-2-one compound **18**, while in the reaction with **5**, **3** gave the 1,3-thiazin-4-one **19** and/or (4+2) cycloaddut **20**.

In a previous paper,[1] we reported that enamino ketones, 4-(1-pyrrolidinyl)-3-penten-2-one (**1**) and 1-phenyl-3-(1-pyrrolidinyl)-2-buten-1-one (**2**), react with benzoyl isothiocyanate to yield 2-thiopyridone derivatives, **A**—**C**, and/or 3-benzoylthiocarbamoyl-3-penten-2-one compound **D** (R=Me), depending upon the nature of enamino ketones and the reaction conditions. Although a few reports are available on the reaction of simple enamines with acyl and thioacyl isocyanates,[2-4] the reaction of enamino ketones with these isocyanates has not been investigated.

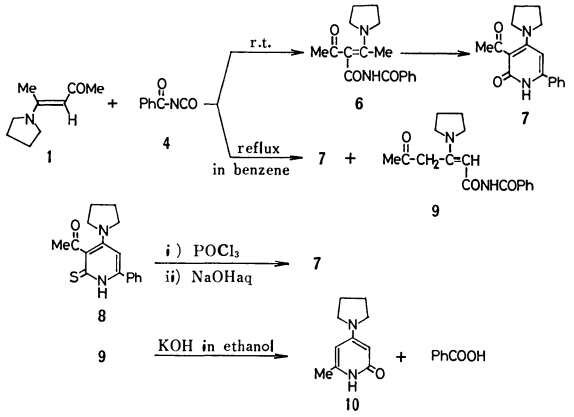


For a comparison with the reactions of enamino ketones with aryl isocyanates,[5] and with benzoyl isothiocyanate,[1] it seemed of interest to investigate the reaction of enamino ketones, **1** and **2**, with acyl and thioacyl isocyanates. It might be expected that enamino ketones, **3**, derived from benzoylacetaldehyde which were inactive toward phenyl isocyanate, would be able to react with acyl isocyanates, since acyl isocyanates are one of the most reactive systems among isocyanates. This paper deals with the reactions of enamino ketones, **1**—**3**, with benzoyl (**4**) and thiobenzoyl isocyanates (**5**).

Results and Discussion

Reaction of Enamino Ketone 1. When a solution of equimolar quantities of **1** and benzoyl isocyanate (**4**) in benzene was stirred at room temperature for 6 h, a product **7**, mp 264—266 °C (decomp), was obtained as colorless prisms in a 35% yield, together with 1,2-dibenzoylurea and benzamide.

On the basis of the following evidence, compound **7** was assigned to be 3-acetyl-6-phenyl-4-(1-pyrrolidinyl)-2-pyridone whose structure corresponds to that of a compound arising from 3-benzoylcarbamoyl-4-(1-pyrrolidinyl)-3-penten-2-one (**6**) by dehydration. The molecular formula of **7** agrees with that of the assigned structure, the IR spectrum showing bands at 2800—3000 (NH) and 1645 cm^{-1} (C=O), respectively. The NMR spectrum in $CDCl_3$ displays signals at δ 2.62 (3H, s, C**H**$_3$), 6.10 (1H, s, =C**H**), and 12.27 ppm (1H, br, N**H**), besides pyrrolidinyl and aromatic protons. **7** is identical with a sample prepared by the reaction of 3-acetyl-6-phenyl-4-(1-pyrrolidinyl)-2-thiopyridone (**8**)[1] with phosphoryl chloride, and the subsequent hydrolysis (Scheme 1).



Scheme 1.

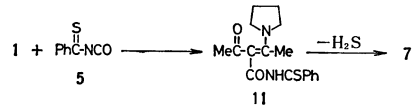
Although attempts to isolate the 1 : 1 adduct **6** were unsuccessful, it was confirmed by NMR spectroscopic study that the 1 : 1 adduct **6** is initially formed in the reaction of **1** with **4**. The NMR of a solution of equimolar quantities of **1** and **4** in $CDCl_3$ was measured at room temperature. The spectrum changed with time, and after about 30 min it showed only signals ascribable to the protons of **6**. That is, signals appeared at δ 1.95, 3.79 (each 4H, m, C**H**$_2$), 2.01, 2.51 (each 3H, s, C**H**$_3$), 7.2—8.2 (5H, m, aromatic protons), and 13.9 ppm (1H, br, N**H**). After 2 h, a singlet ascribable to a ring proton of **7** showed up at δ 6.10 ppm.

On the other hand, **1** reacted with **4** in refluxing benzene to afford **7** and 5-benzoylcarbamoyl-4-(1-pyrrolidinyl)-4-penten-2-one (**9**), mp 152—153 °C, in 12 and 15% yields respectively, together with 1,2-dibenzoylurea. The structure of **9** was assigned from the result of microanalysis and of spectral data. The

* To whom all correspondence shoud be addressed.

IR spectrum exhibited bands at 3240 (NH), 1690, 1720 (C=O), and 1635 cm^{-1} (C=C), and the NMR spectrum in $CDCl_3$ showed signals at δ 2.12 (3H, s, CH_3), 4.02 (2H, s, CH_2), 5.01 (1H, s, =CH), and 12.7 ppm (1H, br, NH), besides pyrrolidinyl and aromatic protons. Treatment of **9** with an ethanolic potassium hydroxide solution at room temperature for 5 h gave benzoic acid and 6-methyl-4-(1-pyrrolidinyl)-2-pyridone (**10**), mp 273—275 °C (decomp), in 37 and 76% yields, respectively (Scheme 1). In contrast to the 1 : 1 adduct **6**, however, the 1 : 1 adduct **9** remarkably resisted dehydration.

The reaction of **1** with thiobenzoyl isocyanate (**5**) at room temperature proceeded in the same manner as that with isocyanate **4**. After **1** was allowed to react with **5** at room temperature for 1 h, the reaction mixture was chromatographed on alumina to give pyridone **7** in only 3% yield, together with **1**. However, an initial product in the reaction was found to be 3-thiobenzoylcarbamoyl-4-(1-pyrrolidinyl)-3-penten-2-one (**11**), which was partially converted into **7** with time, by NMR spectroscopic study in nitrobenzene-d_5 (see Experimental).

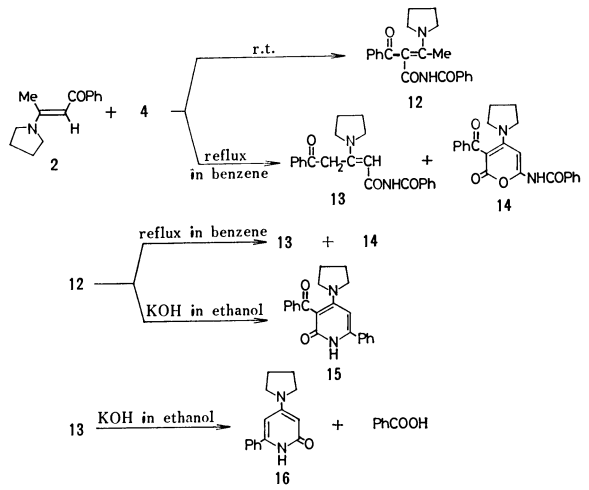


Reaction of Enamino Ketone **2**. Enamino ketone **2** reacted with an equimolar quantity of the isocyanate **4** in benzene at room temperature for 5 h to give 2-benzoylcarbamoyl-1-phenyl-3-(1-pyrrolidinyl)-2-buten-1-one (**12**), mp 133—134 °C (decomp), in a good yield. Since the 1 : 1 adduct **12** is liable to thermally decompose, **12** was recrystallized from a mixture of ethanol and petroleum ether (bp 40—60 °C) below 50 °C, and its structure was deduced from the spectral data.

On the other hand, the reaction of **2** with **4** in refluxing benzene afforded two compounds, **13** (mp 141—142 °C), and **14** (mp 187—188 °C), in 15 and 17.5% yields respectively, together with 1,2-dibenzoylurea. From the spectral data, compound **13** was assigned to 4-benzoylcarbamoyl-1-phenyl-3-(1-pyrrolidinyl)-3-buten-1-one.

The molecular formula of **14** agreed with that of a compound derived from an 1 : 2 adduct of **2** and **4** with the elimination of benzamide. The IR spectrum of **14** showed bands at 3240 (NH), 1650, 1670, and 1725 cm^{-1} (C=O), and the NMR spectrum in $CDCl_3$ displayed signals at δ 6.65 (1H, s, =CH) and 12.33 ppm (1H, br, NH), besides pyrrolidinyl and aromatic protons. Thus, compound **14** was deduced to be 3-benzoyl-6-benzamido-4-(1-pyrrolidinyl)-2-pyrone. Further support for this assignment of **14** was provided by its chemical conversions.

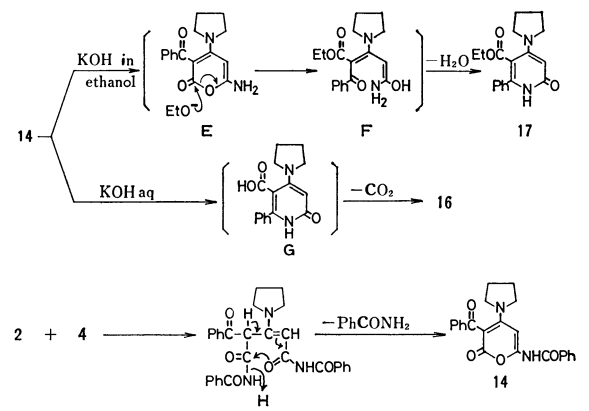
When a benzene solution of the 1 : 1 adduct **12** was refluxed for 1 h, the 1 : 1 adduct **13** and pyrone **14** were obtained in 17 and 15% yields, respectively, together with 1,2-dibenzoylurea and benzamide. This indicates that the 1 : 1 adduct **12** thermally dissociates into the starting materials **2** and **4**, giving **13** and **14**. On treatment with an ethanolic potassium hydroxide



Scheme 2.

solution, the 1 : 1 adduct **12** was converted into 3-benzoyl-6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**15**) in a 42% yield. On the other hand, the same treatment of the 1 : 1 adduct **13** gave a 56% yield of 6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**16**) (Scheme 2).

In order to obtain further information on the structure of the pyrone **14**, its chemical conversions were attempted. On treatment with an ethanolic potassium hydroxide solution at room temperature, **14** was converted into 5-ethoxycarbonyl-6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**17**), mp 236—238 °C, in an 87% yield. The structure of **17** was assigned on the basis of the following evidence. The IR spectrum of **17** showed bands at 2800—3080 (NH), 1730 (C=O), and 1600—1630 cm^{-1} (C=O and C=C). The NMR spectrum in $CDCl_3$ displayed signals at δ 1.33 (3H, t, CH_2CH_3), 4.33 (2H, q, CH_2Me), 6.02 (1H, s, =CH), and 11.8—12.4 ppm (1H, br, NH), besides pyrrolidinyl and aromatic protons. The mass spectrum showed the parent peak (M^+) at *m/e* 312, together with major peaks at *m/e* (M^+-Et), 267 (M^+-OEt), and 239 (267^+-CO, base peak). The pathway for the formation of **17** from **14** could be interpreted as depicted in Scheme 3. 6-Amino-3-benzoyl-4-(1-pyrrolidinyl)-2-pyrone (**E**) would be initially formed by hydrolytic cleavage of benzamido group of **14**. This would be

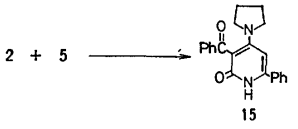


Scheme 3.

followed by attack of ethoxide ion to yield an open chain intermediate **F**, and the concurrent dehydration would give the final product **17**. On the other hand, **14** afforded the pyridone **16** in an 85% yield when treated with an aqueous potassium hydroxide solution. The formation of **16** from **14** could be reasonably interpreted by decarboxylation of 2-pyridone-5-carboxylic acid derivative **G** produced in a similar way to that for **17**.

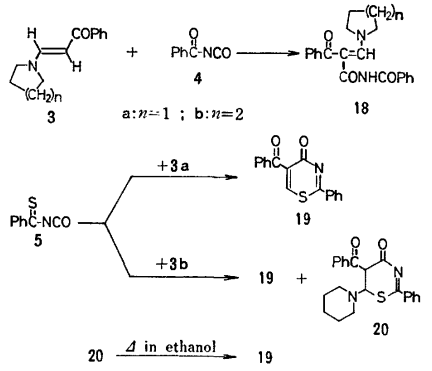
Enamino ketone **1** reacts with aryl isocyanates to yield 1 : 2 adducts, 3,5-bis(arylcarbamoyl)-4-(1-pyrrolidinyl)-3-penten-2-ones.[5] Thus, the pathway for the formation of **14** can be viewed as depicted in Scheme 3. That is, enamino ketone **2** would react with two moles of **4** to form 1-phenyl-2,4-bis(phenylcarbamoyl)-3-(1-pyrrolidinyl)-3-buten-1-one(**H**).[6] A nucleophilic attack of the oxygen atom of 4-benzoylcarbamoyl group to the carbon atom of 2-benzoylcarbamoyl group, and the concurrent elimination of benzamide from **H** would give the pyrone **14**.

On the other hand, **2** reacted with thiobenzoyl isocyanate (**5**) in xylene at room temperature for 2 h gave 3-benzoyl-6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**15**) in a 12% yield, accompanied by the recovery of **2**.



Reaction of Enamino Ketone ***3***. The reaction of 1-benzoyl-2-(1-pyrrolidinyl)ethylene (**3a**) with an equimolar quantity of benzoyl isocyanate (**4**) in benzene at room temperature for 2 h afforded 1-benzoyl-1-benzoylcarbamoyl-2-(1-pyrrolidinyl)ethylene (**18a**), mp 171—172 °C (decomp), almost quantitatively. Similarly, 1-benzoyl-2-(1-piperidyl)ethylene (**3b**) reacted with **4** to give the corresponding benzoylcarbamoyl compound **18b**, mp 140—141 °C, in a 75% yield. The structures of **18a** and **18b** were confirmed by the results of microanalyses and their spectral data.

The reaction of **3a** with thiobenzoyl isocyanate (**5**) at room temperature for 2 h afforded a 58% yield of 5-benzoyl-2-phenyl-1,3-thiazin-4-one (**19**), mp 180—181 °C, whose structure corresponded to that of a compound derived from a (4+2) cycloadduct with the elimination of pyrrolidine. **3b** reacted with **5** to give **19** and an 1 : 1 adduct **20**, mp 108—110 °C (decomp),



Scheme 4.

in 9 and 35.5% yields, respectively. The IR spectrum of the 1 : 1 adduct **20** showed no NH absorption bands, and the NMR spectrum in $CDCl_3$ displayed signals at δ 7.2—8.2 (11H, m, aromatic protons and $\rangle$**CH**) and 8.17 ppm (1H, d, $\rangle$**CH**, J=7 Hz), besides piperidyl protons. On heating in ethanol **20** was easily converted into the 1,3-thiazine **19**. Thus, **20** is concluded to be the (4+2) cycloadduct, 5,6-dihydro-5-benzoyl-2-phenyl-6-(1-piperidyl)-4*H*-1,4-thiazin-4-one.

Experimental

All the melting points are uncorrected. The NMR spectra were determined with a Hitachi R-20 Model spectrometer, with TMS as an internal standard. The IR spectra were measured as KBr disks, the mass spectra being obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV.

Materials. 4-(1-Pyrrolidinyl)-3-penten-2-one (**1**) was prepared from acetylacetone and pyrrolidine.[5]

1-Phenyl-3-(1-pyrrolidinyl)-2-buten-1-one (**2**): A solution of 18.0 g of sodium salt of benzoylacetone, prepared from sodium salt of acetophenone and ethyl acetate, and 10.0 g of hydrochloride of pyrrolidine in 100 ml of water was stirred at room temperature for 5 h, during which time crystals precipitated. Filtration gave crystals, which on recrystallization from a mixture of benzene and petroleum ether (bp 60—80 °C) afforded 18.7 g (87%) of enemino ketone **2**, mp 157—158 °C, as yellow prisms. IR spectrum: 1595 (C=O), 1520 cm^{-1} (C=C). NMR spectrum ($CDCl_3$): δ ppm 1.97, 3.43 (each 4H, m, CH_2), 2.68 (3H, s, CH_3), 5.62 (1H, s, =**CH**), 7.3—8.0 (5H, m, aromatic protons). Mass spectrum: *m/e* 215 (M^+). Found: C, 78.39; H, 7.87; N, 6.42%. Calcd for $C_{14}H_{17}NO$: C, 78.10; H, 7.96; N, 6.51%.

1-Benzoyl-2-(1-pyrrolidinyl)ethylene (**3a**) and 1-benzoyl-2-(1-piperidyl)ethylene (**3b**) were prepared from sodium salt of benzoylacetaldehyde prepared from sodium salt of acetophenone and ethyl formate, and the corrseponding hydrochlorides of amines. **3a**: Mp 118—119 °C, pale yellow prisms. IR spectrum: 1630 (C=O), 1540 cm^{-1} (C=C). NMR spectrum ($CDCl_3$): δ ppm 1.93, 3.90 (each 4H, m, CH_2), 6.10, 8.66 (each 1H, d, =**CH**, J=12Hz), 7.3—8.2 (5H, m, aromatic protons). Mass spectrum: *m/e* 201 (M^+). Found: C, 77.29; H, 7.36; N, 7.04%. Calcd for $C_{13}H_{15}NO$: C, 77.58; H, 7.51; N, 6.96%. **3b**: Mp 89—90 °C (lit,[7] mp 80—81 °C).

Benzolyl isocyanate (**4**) was prepared by the reported method.[8] In order to prepare thiobenzoyl isocyanate (**5**), a solution of 2-phenylthiazoline-4,5-dione in xylene was heated at 120 °C, giving a reddish-violet solution of **5** which was used *in situ*.[9]

Reaction of Enamino Ketone ***1*** *with Benzoyl Isocyanate (****4****).* *i*) A solution of 1.53 g (0.01 mol) of enamino ketone **1** and 1.47 g (0.01 mol) of the isocyanate **4** in 30 ml of benzene was stirred at room temperature for 6 h. Filtration gave 0.35 g of 1,2-dibenzoylurea. The filtrate was chromatographed on alumina using benzene as the eluent to give 0.98 g (35%) of 3-acetyl-6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**7**), mp 264—266 °C (decomp), as colorless prisms, 0.2 g of benzamide, and 0.25 g of unreacted **1** respectively.

The pyridone **7**: NMR spectrum ($CDCl_3$) δ ppm 1.92, 3.22 (each 4H, m, CH_2), 2.62 (3H, s, CH_3), 6.10 (1H, s, =**CH**), 7.3—8.0 (5H, m, aromatic protons), 12.27 (1H, br, **NH**). Mass spectrum: *m/e* 282 (M^+), 267 (M^+—NH, base peak), 254 (M^+—CO), 239 (M^+—HNCO). Found: C, 72.07; H, 6.41; N, 9.72%. Calcd for $C_{17}H_{18}N_2O_2$: C, 72.32;

H, 6.43; N, 9.92%.

Compound **7** was identical with a sample prepared from 3-acetyl-6-phenyl-4-(1-pyrrolidinyl)-2-thiopyridone (**8**).[1] After a solution of 30 mg of **8** in 2ml of phosphoryl chloride was refluxed for 1 h, the reaction mixture was poured into ice-water. The resulting solution was alkalized with aqueous potassium hydroxide solution, and then neutralized with hydrochloric acid to give 10 mg of **7**.

ii) After a solution of 1.53 g of **1** and 1.47 g of **4** in 30 ml of benzene was refluxed for 1 h, filtration gave 0.19 g of 1,2-dibenzolylurea. The filtrate was evaporated *in vacuo* and the residue was chromatographed on alumina using chloroform as the eluent to give 0.28 g (12%) of **7** and 0.45 g (15%) of 5-benzoylcarbamyl-4-(1-pyrrolidinyl)-4-penten-2-one (**9**), mp 152—153 °C, as colorless needles. Found: C, 67.88; H, 6.69; N, 9.34%. Calcd for $C_{17}H_{20}N_2O_3$: C, 67.98; H, 6.71; N, 9.33%.

Hydrolysis of the 1:1 Adduct ***9***. A solution of 0.1 g of **9** in 10 ml of 4% ethanolic potassium hydroxide solution was stirred at room temperature for 5 h. The reaction mixture was poured into water, giving crystals. Filtration gave crystals, which on recrystallization from ethanol afforded 45 mg (76%) of 6-methyl-4-(1-pyrrolidinyl)-2-pyridone (**10**), mp 273—275 °C (decomp), as colorless prisms. IR spectrum: 2800—3000 (NH), 1630 cm^{-1} (C=O). NMR spectrum ($CDCl_3$): δ ppm 1.95, 3.27 (each 4H, m, CH_2), 2.28 (3H, s, CH_3), 5.28, 5.51 (each 1H, d, =CH, J=2.5 Hz), 12.9 (1H, br, NH). Mass spectrum: *m/e* 178 (M^+, base peak), 177, 150 (M^+-CO), 135 (M^+-HNCO). Found: C, 67.09; H, 7.90; N, 15.60%. Calcd for $C_{10}H_{14}N_2O$: C, 67.38; H, 7.92; N, 15.72%.

The filtrate was acidified with hydrochloric acid to give 15 mg (37%) of benzoic acid.

Reaction of Enamino Ketone ***1*** *with Thiobenzoyl Isocyanate (****5****).* *i*) A solution of 3.06 g (0.02 mol) of **1** was added to the isocyante **5**, generated from 3.82 g (0.02 mol) of 2-phenylthiazoline-4,5-dione in 50 ml of xylene, and the solution was stirred at room tempreature for 1 h. The reaction mixture was concentrated *in vacuo* to leave a residue, which on chromatography on alumina using chloroform as the eluent gave 0.17 g (3%) of the 2-pyridone **7** and 1.90 g (62%) of unreacted **1**.

ii) The same reaction was followed by NMR spectroscopy. A solution of equimolar quantities of **1** and **5** in nitrobenzene-d_5 was prepared, and its NMR spectrum was measured at room temperature. After *ca.* 30 min, the spectrum showed only signals ascribable to the protons of 3-thiobenzoylcarbamoyl-4-(1-pyrrolidinyl)-3-penten-2-one (**11**) as follows: δ ppm 1.93, 3.0—4.0 (each 4H, m, CH_2), 2.45, 2.63 (each 3H, s, CH_3), 7.2—8.3 (5H, m, aromatic protons), 12.0 (1H, br, NH). After 1 h the formation of **7** was observed, crystals separating out within 5 h.

Reaction of Enamino Ketone ***2*** *with Benzoyl Isocyanate (****4****).* *i*) A solution of 1.0 g (4.65 mmol) of **2** and 0.75 g (5.1 mmol) of **4** in 30 ml of benzene was stirred at room temperature for 5 h, during which time crystals precipitated. Filtration gave crystals, which on recrystallization from a mixture of ethanol and petroleum ether (bp 40—60 °C) below 50 °C afforded 1.45 g (86%) of 2-benzoylcarbamoyl-1-phenyl-3-(1-pyrrolidinyl)-2-buten-1-one (**12**), mp 133—134 °C (decomp.), as colorless needles. IR spectrum: 2800—3000 (NH), 1705, 1655 cm^{-1} (C=O). NMR spectrum ($CDCl_3$): δ ppm 1.95, 3,66 (each 4H, m, CH_2), 2.12 (3H, s, CH_3), 7.2—8.3 (10H, m, aromatic protons), 13.74 (1H, br, NH). Found: C, 73.04; H, 6.06; N, 7.64%. Calcd for $C_{22}H_{22}N_2O_3$: C, 72.91; H, 6.12; N, 7.73%.

ii) A solution of 1.07 g (5 mmol) of **2** and 0.75 g (5.1 mmol) of **4** in 30 ml of benzene was refluxed for 1 h, during which time 0.25 g of 1,2-dibenzoylurea precipitated. The filtrate was concentrated *in vacuo* to leave a residue, which was dissolved in 10 ml of ethanol. The ethanol solution was allowed to stand overnight to give crystals. Filtration gave crystals, which on recrystallization from a mixture of chloroform and petroleum ether (bp 50—60 °C) afforded 0.33 g (17.5%) of 3-benzoyl-6-benzamido-4-(1-pyrrolidinyl)-2-pyrone (**14**), mp 187—188 °C, as colorless needles. NMR spectrum ($CDCl_3$): δ ppm 2.0, 3.65 (each 4H, m, CH_2), 6.65 (1H, s, =CH), 7.3—8.2 (10H, m, aromatic protons), 12.33 (1H, br, NH). Mass spectrum: *m/e* 388 (M^+), 283 (M^+-PhCO), 266 (283^+-OH), 241 ($M^+-PhCONCO$), 213 (241^+-CO), 184, 147 ($PhCONCO^+$), 105 ($PhCO^+$, base peak). Found: C, 70.92; H, 5.20; N, 7.25%. Calcd for $C_{23}H_{20}N_2O_4$: C, 71.12; H, 5.19; N, 7.21%.

The ethanol filtrate was concentrated *in vacuo*, and the reside was recrystallized from a mixture of ethanol and petroleum ether (bp 60—80 °C) to give 0.27 g (15%) of 4-benzoylcarbamoyl-1-phenyl-3-(1-pyrrolidinyl)-3-buten-1-one **13**), mp 141—142 °C, as pale yellow prisms. IR spectrum: 2800—3000 (NH), 1750 cm^{-1} (C=O). NMR spectrum ($CDCl_3$): δ ppm 2.02 4H, m, CH_2), 3.42, 4.0 (each 2H, m, CH_2), 4.22 (2H, s, CH_2), 5.79 1H, s, =CH), 7.3—8.3 (10H, m, aromatic protons), 12.66 (1H, br, NH). Mass spectrum: *m/e* 362 (M^+). Found: C, 72.71; H, 6.06; N, 7.67%. Calcd for $C_{22}H_{22}N_2O_3$: C, 72.91; H, 6.12; 7.73%.

Thermolysis of the 1:1 Adduct ***12***. A solution of 1.0 g of **12** in 20 ml of benzene was refluxed for 1 h. The reaction mixture was then allowed to stand overnight, giving 0.11 g (30%) of 1,2-dibenzoylurea. The filtrate was concentrated *in vacuo*, and the residue was chromatographed on alumina using chloroform as the eluent to give 0.17 g (17%) of **13** and 0.16 g (15%) of **14**. Further elution with ethanol afforded 60 mg (18%) of benzamide.

Hydrolysis of ***12***. A solution of 0.45 g of **12** in 10 ml of 13% ethanolic potassium hydroxide solution was stirred at room temperature for 1 h, during which time crystals precipitated. Filtration gave 0.11 g (33%) of 1,2-dibenzoylurea. The filtrate was neutralized with hydrochloric acid to give crystals, which on recrystallization from ethanol afforded 0.18 g (42%) of 3-benzoyl-6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**15**), mp 305—307 °C (decomp.), as pale orange needles. IR spectrum: 2800—3000 (NH), 1660 cm^{-1} (C=O). NMR spectrum (DMSO-d_6): δ ppm 1.9, 3.6 (each 4H, m, CH_2), 5.87 (1H, s, =CH), 7.2—8.7 (10H, m, aromatic protons), 11.7—12.0 (1H, br, NH). Mass spectrum: *m/e* 344 (M^+), 327 (M^+-OH), 315 (M^+-COH, base peak). Found: C, 76.95; H, 5.88; N, 7.98%. Calcd for $C_{22}H_{20}N_2O_2$: C, 76.72; H, 5.85; N, 8.13%.

Hydrolysis of the 1:1 Adduct ***13***. A solution of 0.23 g of **13** in 10 ml of 4% ethanolic potassium hydroxide solution was stirred at room temperature for 5 h, and then the reaction mixture was poured into water. The resulting solution was acidified with hydrochloric acid and filtration gave 20 mg (26%) of benzoic acid. The filtrate was neutralized with aqueous sodium hydroxide solution to give crystals, which on recrystallization from ethanol afforded 86 mg (56%) of 6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**16**), mp 267—269 °C (decomp.), as colorless prisms. IR spectrum: 2800—3000 (NH), 1600—1640 cm^{-1} (C=O and C=C). NMR spectrum ($CDCl_3$): δ ppm 2.0, 3.34 (each 4H, m, CH_2), 5.39, 5.99 (each 1H, d, =CH, J=2.5 Hz), 7.3—8.0 (5H, m, aromatic protons), 9.5—10.5 (1H, br, NH). Mass spectrum: *m/e* 240 (M^+). Found: C, 74.78; H, 6.83; N, 11.55%. Calcd for $C_{15}H_{16}N_2O$: C, 75.00 H, 6.67; N, 11.67%.

Hydrolysis of the Pyrone ***14***. *i*) A solution of 0.2 g of

14 in 10 ml of 13% ethanolic potassium hydroxide solution was stirred at room temperature for 2 h, and then the reaction mixture was poured into 20 ml of water. Filtration gave crystals, which on recrystallization from ethanol afforded 0.14 g (87%) of 5-ethoxycarbonyl-6-phenyl-4-(1-pyrrolidinyl)-2-pyridone (**17**), mp 236—238 °C, as colorless prisms. NMR spectrum ($CDCl_3$): δ ppm 1.33 (3H, t, CH_2CH_3, J=7.2 Hz), 1.96, 3.45 (each 4H, m, CH_2), 4.33 (2H, q, CH_2-Me), 6.02 (1H, s, =CH), 7.2—7.9 (5H, m, aromatic protons), 11.8—12.4 (1H, br, NH). Found: C, 69.01; H, 6.23; N, 9.18%. Calcd for $C_{18}H_{20}N_2O_3$: C, 69.23; H, 6.41; N, 8.97%.

ii) After a suspension of 0.2 g of **14** in 20 ml of 20% aqueous potassium hydroxide solution had been heated under reflux for 1 h, the reaction mixture was poured into water. The resulting solution was neutralized with hydrochloric acid to give crystals, which on recrystallization from ethanol afforded 105 mg (85%) of **16**.

Reaction of Enamino Ketone 2 with Thiobenzoyl Isocyanate (5). A solution of 2.15 g (0.01 mol) of **2** and **5**, generated from 1.91 g (0.01 mol) of 2-phenylthiazoline-4,5-dione, in 30 ml of xylene was stirred at room temperature for 2 h. The reaction mixture was concentrated *in vacuo* to leave a residue, which on fractional recrystallization from ethanol afforded 0.42 g (12%) of **15** and 0.85 g (40%) of **2**.

Reaction of Enamino Ketone 3 with Benzoyl Isocyanate (4). A solution of 0.4 g (2 mmol) of the enamino ketone **3a** and 0.3 g (2 mmol) of **4** in 10 ml of benzene was stirred at room temperature for 2 h, during which time crystals precipitated. Filtration gave crystals, which were recrystallized from a mixture of chloroform and petroleum ether (bp 40—60 °C) to give 0.68 g (98%) of 1-benzoyl-1-benzoylcarbamoyl-2-(1-pyrrolidinyl)ethylene (**18a**), mp 171—172 °C (decomp.), as colorless prisms. IR spectrum: 2800—3000 (NH), 1730, 1670 cm^{-1} (C=O). NMR spectrum ($CDCl_3$): δ ppm 1.87 (4H, m, CH_2), 3.21, 3.55 (each 2H, m, CH_2), 7.3—8.3 (11H, m, =CH and aromatic protons), 12.77 (1H, br, NH). Found: C, 72.47; H, 5.78; N, 8.01%. Calcd for $C_{21}H_{20}N_2O_3$: C, 72.39; H, 5.79; N, 8.04%.

Similaly, the reaction of 0.53 g (2.5 mmol) of the enamino keton **3b** with 0.37 g (2.5 mmol) of **4** in 10 ml of benzene afforded 0.68 g (75%) of 1-benzoyl-1-benzoylcarbamoyl-2-(1-piperidyl)ethylene (**18b**), mp 140—141 °C, as colorless prisms. IR spectrum: 2800—3000 (NH), 1720, 1660 cm^{-1} (C=O). NMR spectrum ($CDCl_3$): δ ppm 1.58 (6H, m, CH_2), 3.30 (4H, m, CH_2), 7.3—8.3 (11H, m, =CH and aromatic protons), 12.9 (1H, br, NH). Found: C, 73.11; H, 6.25; N, 7.58%. Calcd for $C_{22}H_{22}N_2O_3$: C, 72.91; H, 6.12; N, 7.73%.

Reaction of Enamino Ketone 3 with Thiobenzoyl Isocyanate (5). A solution of 1.01 g (5 mmol) of **3a** and **5**, generated from 0.95 g (5 mmol) of 2-phenylthiazoline-4,5-dione, in 30 ml of xylene was stirred at room temperature for 2 h. The reaction mixture was evaporated *in vacuo* to leave a residue, which was triturated with petroleum ether to give crystals. Recrystallization from ethanol afforded 0.85 g (58%) of 5-benzolyl-2-phenyl-1,3-thiazin-4-one (**19**), mp 180—181 °C, as colorless prisms. IR spectrum: 1670, 1630 cm^{-1} (C=O). NMR spectrum ($CDCl_3$): δ ppm 7.2—8.3 (10H, m, aromatic protons), 8.21 (1H, s, =CH). Found: C, 69.69; H, 3.72; N, 4.90%. Calcd for $C_{17}H_{11}NO_2S$: C, 69.62; H, 3.78; N, 4.72%.

Similarly, the reaction of 1.07 g (5 mmol) of **3b** with **5**, generated from 0.95 g (5 mmol) of 2-phenylthiazoline-4,5-dione, in 30 ml of xylene afforded 0.13 g (9%) of **19** and 0.67 g (35.5%) of 5,6-dihydro-5-benzoyl-2-phenyl-6-(1-piperidyl)-4*H*-1,3-thiazin-4-one (**20**), mp 108—110 °C (decomp.), as pale pink crystals. IR spectrum: 1670 cm^{-1} (C=O). NMR spectrum ($CDCl_3$): δ ppm 1.55 (6H, m, CH_2), 3.25 (4H, m, CH_2), 7.2—8.2 (11H, m, $\geqslant$CH and aromatic protons), 8.17 (1H, d, $\geqslant$CH, J=7 Hz). Found: C, 69.75; H, 5.83: N, 7.69%. Calcd for $C_{22}H_{22}N_2O_2S$: C, 69.82; H, 5.86; N, 7.40%.

Kinetics and Mechanism of the Reactions of Butenenitrile with Imidazoles

Fukiko YAMADA, Osamu KITANO, Soichi SHINDO, and Harunori UEDA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received April 19, 1976)

The reaction kinetics of 3- and 2-butenenitriles with 2-alkylimidazoles were studied by using NMR, and a mechanism consistent with the results is proposed. The imidazoles were active in isomerizing 3-butenenitrile to 2-butenenitrile, and then reacted only with the 2-butenenitrile to give the corresponding 1-(2-cyano-1-methylethyl)imidazoles. These consecutive reactions, isomerization and cyanoethylation, are second-order over all. For example, in the reaction of 3-butenenitrile with imidazole, the rate measurements of the isomerization at various temperatures, ranging from 30 to 90 °C, afforded the activation parameters of E_a= 14.6 kcal/mol and ΔS^*= −35.3 cal/degree. On the other hand, in the case of 2-butenenitrile with imidazole, the measurements of the cyanoethylation at 60—100 °C gave these parameters; E_a= 15.3 kcal/mol and ΔS^*= −45.7 cal/degree. In this case, the rates of the isomerization ($k_1 = 6.0 \times 10^{-6}$ l/mol s at 60 °C) are approximately ten times larger than those of the cyanoethylation ($k_2 = 0.53 \times 10^{-6}$). A mechanism is discussed on the basis of their NMR spectral and kinetic data.

Recently, in our previous paper, the kinetic data on the reaction of acrylonitrile with imidazole have been reported.[1] By means of the NMR method, factors governing the points of the cyanoethylation and the polymerization of acrylonitrile are well understood. The studies have now been extended to unsaturated nitriles with a view to obtaining a clear picture of the reaction.

In this paper, we wish to describe the kinetics of the reactions of 3- and 2-butenenitriles (3-BN and 2-BN) with imidazole (Im), 2-ethylimidazole (EtIm), and 2-isopropylimidazole (*i*-PrIm) respectively, and their possible mechanism.

Experimental

Measurements. All the boiling and melting points are uncorrected. The NMR spectra were obtained at 60 MHz with a Japan Electron Optics Model JNM-3H-60 spectrometer at room temperature. The chemical shifts were reported in ppm downfield from the internal TMS (δ). The IR spectra were recorded on a Shimadzu Model 27-G grating spectrophotometer on a KBr disk for the solid materials or on a NaCl plate for the liquid ones. The GLC analysis was carried out on a Shimadzu gas chromatograph, Model GC-5AP$_3$T, using a 3.00-m column packed with silicone HV grease (20-wt%). The percentage composition of the product was estimated by means of the relative peak areas (uncorrected).

A constant-temperature bath with a temperature control of ±0.1 °C was employed.

Materials. Im, EtIm, and *i*-PrIm were recrystallized from benzene several times; mps, 88—89, 83—84, and 133—134.5 °C respectively. Imidazole-1-*d*[2] and 3-BN (bp 118—121 °C)[3] were prepared by the reported methods. 2-BN (bp 115—118 °C) was of a reagent quality and was used without further purification. In all the materials, the purities were determined by means of NMR and GLC analyses.

Kinetic Measurements. The reactions of the imidazoles with 3- or 2-BN were carried out in sealed tubes. The rate of the appearance of the product was followed by using NMR.[1] In a typical preparation, about 1.5 g of Im was placed in a 10-ml volumetric flask and weighed. Then the volume was quickly made up to 10 ml with the nitrile. This solution was transferred into ten separate tubes and sealed. The first NMR analysis was performed as soon as feasible after the sample preparation. The sealed tubes were shaken at a constant temperature for a given time. The rate measurements were then performed by means of the NMR method.[1] Each experiment was repeated in order to check the reproducibility.

Reaction Products. After the reaction had been completed, the reaction mixture collected from each run was treated and purified by the method reported previously.[1] The physical properties of the corresponding 1-(2-cyano-1-methylethyl)imidazoles thus obtained may be shown as follows:

Product 1. 1-(2-Cyano-1-methylethyl)imidazole (**1**); bp 128 °C/0.9 Torr. Picrate; mp 125.0—126.0 °C, Found: C, 42.73; H, 3.23; N, 23.25%. Calcd for $C_{13}H_{12}N_6O_7$: C, 42.84; H, 3.32; N, 23.08%. IR (C≡N) : 2254 cm^{-1}. NMR (CH_2Cl_2) : δ 1.53 (d, 3H, CH_3), 2.82 (d, 2H, $-CH_2CN$), 4.53 (sextet, 1H, N⩾CH), 6.97—7.05 (2H, ring-proton), 7.53 (s, 1H, ring).

Product 2. 1-(2-Cyano-1-methylethyl)-2-ethylimidazole (**2**); bp 105 °C/0.4 Torr. Picrate; mp 152.0—153.0 °C, Found: C, 46.16; H, 3.90; N, 22.03%. Calcd for $C_{15}H_{16}N_6O_7$: C, 45.92; H, 4.11; N, 21.42%. IR (C≡N): 2257 cm^{-1}. NMR (CH_2Cl_2) : δ 1.51 (d, 3H, CH_3), 2.81 (d, 2H, $-CH_2CN$), 4.54 (sextet, 1H, N⩾CH), 1.29 and 2.70 (t, 3H ; q, 2H, 2-C_2H_5), 6.90 and 7.02 (2H, ring).

Product 3. 1-(2-Cyano-1-methylethyl)-2-isopropylimidazole (**3**); mp 51.0—53.0 °C. Picrate ; mp 151.5—152.5 °C. Found: C, 47.41; H, 4.35; N, 20.95%. Calcd for $C_{16}H_{18}N_6O_7$: C, 47.27; H, 4.46; N, 20.68%. IR (C≡N) : 2248 cm^{-1}. NMR (CH_2Cl_2) : δ 1.54 (d, 3H, CH_3), 2.77 (d, 2H, $-CH_2CN$), 4.56 (sextet, 1H, N⩾CH), 1.24 and 1.32 (d, d, 3H, 3H, 2CH_3 of *i*-Pr), 3.01 (septet, 1H, ⩾CH of *i*-Pr), 6.88—6.95 (2H, ring).

Results and Discussion

Reactions. In the reaction between Im and 3-BN, the changes in the NMR spectra with the time are shown in Fig. 1. One-proton and two-proton singlets due to the ring protons of Im appear at 7.3 and 8.0 ppm respectively. In the earlier period of the reaction, the new singals of the methyl and olefinic protons due to 2-BN, the product of the isomerization, began to appear in the regions of 2.0—2.2 and 6.5—6.9 ppm respectively (after 60 min, in Fig. 1). Their intensities increased with the reaction time. After a considerable amount of 2-BN had been produced (900 min), the signals of Compound **1** appeared at 1.8 (CH_3), 3.1 ($-CH_2CN$), and 4.9 ppm (N⩾CH) respectively. Therefore, the progress of the reaction

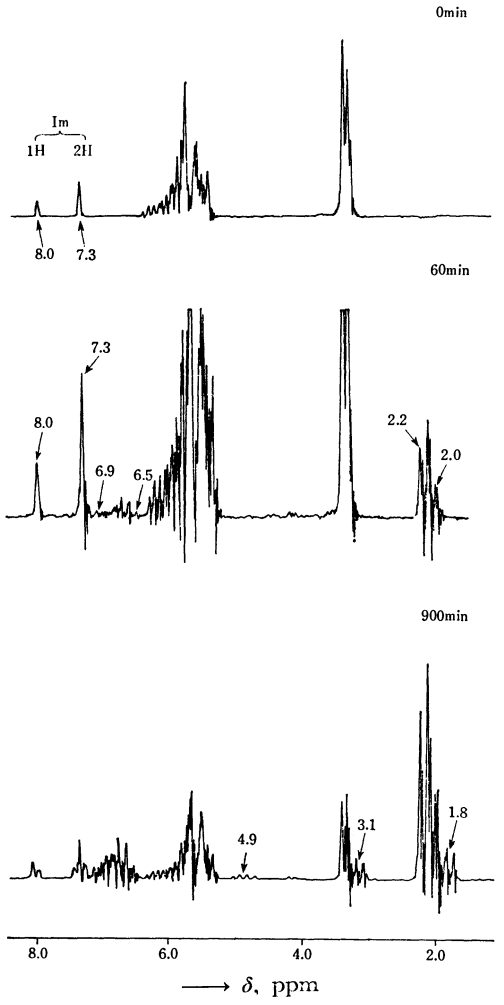

Fig. 1. Changes of the NMR spectra with reaction time, in the reaction of Im (1.325 mol/l) with 3-BN (11.396 mol/l) at 77 °C. After 900 min, the conversion of 3-BN to 2-BN was 67.4%.
3-BN, NMR (CCl_4): δ 3.23—3.38 (2H, CH_2) and 5.27—6.28 (3H, H_2C=CH–).
2-BN, NMR (CCl_4): δ 1.98—2.23 (3H, CH_3), and 5.44—5.74 and 6.47—7.18 ppm (2H, –CH=CH–).

was followed by observing the rates of the appearances of the signals of 2-BN and Compound **1**.

In this reaction at 90 °C, the time-conversion curves of the above two products and the plots of the NH shift and its content at the reaction time are shown in Fig. 2.

From these observations, it is clear that 3-BN is first converted to 2-BN in the presence of Im, and that then 2-BN reacts with Im to give Compound **1**. That is, Im is active in isomerizing 3-BN to 2-BN. It is also easily observable in Fig. 2 that the isomerization proceeds much faster than the cyanoethylation and that, during the proceeding of the isomerization, the NH signal moves downfield.

On the other hand, it was observed by means of the NMR method that, in the reaction of Im with 2-BN, Compound **1** was the sole product. Figure 3 shows both the conversion and NH shift curves in this reaction. The two curves show a similar tendency. The NH signal moves upfield with an increase in the yield of

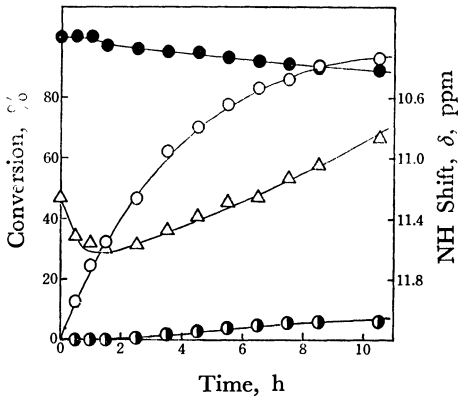

Fig. 2. Time-conversions and NH shift curves in the reaction of Im (1.679 mol/l) with 3-BN (11.110 mol/l) at 90 °C.
○: Conversion of isomerization, 3-BN to 2-BN;
◑: conversion for compound **1**;
△: NH shift; ●: NH content, %.

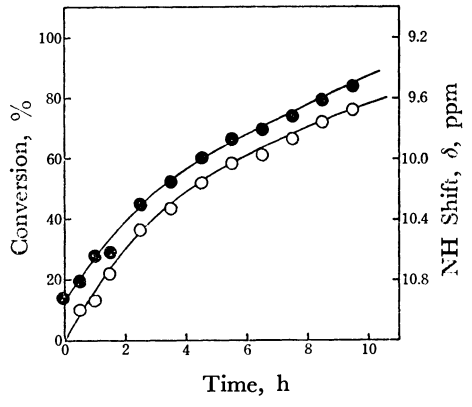

Fig. 3. Time-conversion and NH shift curves in the reaction of Im (1.736 mol/l) with 2-BN (10.800 mol/l) at 90 °C.
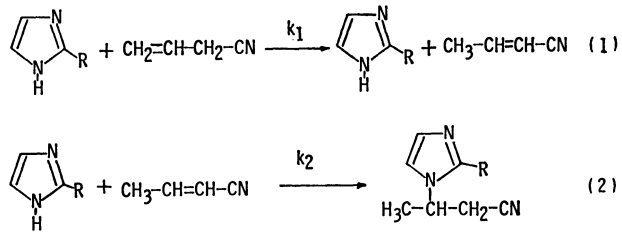
○: Conversion; ●: NH shift.

Compound **1**. On the contrary, in the isomerization (Fig. 2) the NH signal moves downfield. Thus, the reactions of the imidazoles with 2-BN yielded the corresponding 1-(2-cyano-1-methylethyl) imidazoles (**1**, **2**, and **3**).

Rates. From the above observations, this consecutive reaction can be represented as follows:



The isomerizaation (Eq. 1) was monitored by the NMR method to trace a time-conversion curve and may be expressed as:

$$d(2\text{-BN})/dt = k_1(3\text{-BN})^m(\text{Im})^n \quad (3)$$

When this process is carried out with an excess of 3-BN, the changes in the concentration of Im are

Table 1. Reaction rates[a] and activation parameters for the isomerization of 3-BN to 2-BN

Temp, °C	30	35	40	45	50	60	70	77	80	90	E_a[b]	ΔS^*[c]
Im	0.8	1.1	1.7	2.3	3.0	6.0	11.8	15.8	28.2	45.2	14.6	−35.3
EtIm					16.2	34.7	68.8		134.0		16.2	−35.1
i-PrIm						39.8		103.0		273.0	15.5	−37.1

a) Calculated by the least-squares method, $k_1 \times 10^6$ l/mol s. b) Activation energy, kcal/mol. c) Calculated at 70 °C, cal/degree.

Table 2. Reaction rates and activation parameters for the cyanoethylation of 2-BN with imidazoles

Imidazoles	$K_2 \times 10^6$ l/mol s (Temperature, °C)						kcal/mol E_a	ΔS^* cal/degree
Im	0.53 (60)	1.3 (70)	1.9 (80)	4.0 (90)	6.5 (100)		15.3	−45.7
EtIm	4.3 (110)	5.4 (120)	7.5 (130)	10.0 (140)			9.2	−63.6
i-PrIm	0.61 (100)	1.2 (120)	2.1 (140)	2.3 (150)	2.7 (160)	2.8 (170)	7.8	−70.1

negligible. Therefore, the apparent rate of the isomerization depends only on the concentration of 3-BN. Consequently, Eq. 3 can be written as:

$$d(2\text{-BN})/dt = k_{obsd}(3\text{-BN})^m \quad (4)$$

The orders, m and n, are determined by the initial-rates (V_0) method.[4] In fact, when the (3-BN) or (Im) concentrations are kept constant and the (Im) or (3-BN) concentrations (C_0) are varied, the plots of log V_0 against log C_0 are linear and their slopes are $m = 1.01$ and $n = 0.96$. That is, the orders are assumed to be 1.0. Consequently, we can rearrange Eqs. 3 and 4 by substituting the above values and can rewrite the equations as follows:

$$d(2\text{-BN})/dt = k_1(3\text{-BN})(\text{Im}) \quad (5)$$

$$= k_{obsd}(3\text{-BN}) \quad (6)$$

All the runs, carried out with an excess of 3-BN, gave excellent pseudo first-order kinetics to at least 70% completion. The rates were measured at various temperatures between 30 and 90 °C. The rate constants, k_1, derived for the isomerization and their activation parameters in the reactions of the imidazoles with 3-BN are listed in Table 1. In the case of 2-methylimidazole, it was difficult to get an accurate value because of its low solubility in the reaction mixture. As is obvious from the table, the rate constants increase with the change in R in the order of ethyl and isopropyl, while the values of E_a and ΔS^* are almost constant.

On the other hand, the reactions of the imidazoles with 2-BN were found to follow second-order rate equations[1]:

$$d(\text{product})/dt = k_2(2\text{-BN})(\text{Im}) \quad (7)$$

The values of the second-order rate constants, k_2, were obtained by a method reported previously.[1] Table 2 shows the rate constants at various temperatures, along with the values of the activation parameters. Small E_a values and large negative ΔS^* values are observed. In general, such facts indicate that the reaction involves a strongly polarized and/or crowded transition state. In this case, the above fact implies that not only a polar effect, but also a steric effect of R, is a controlling factor. Furthermore, the plot of E_a *vs.* ΔS^* for R of H, C_2H_5, and *i*-Pr shows a good compensation effect.

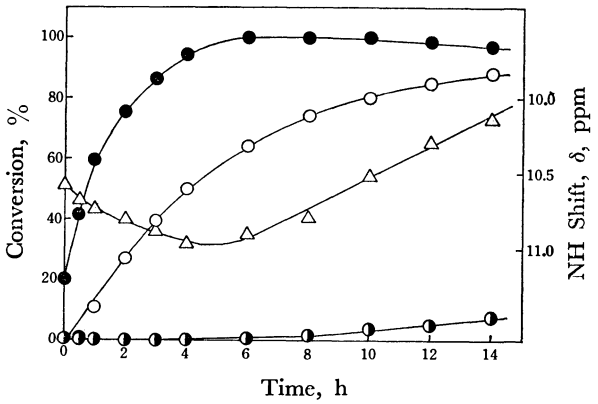


Fig. 4. Time-conversions and NH shift curves in the reaction of imidazole-1-d_1 (1.702 mol/l) with 3-BN (11.090 mol/l) at 70 °C.
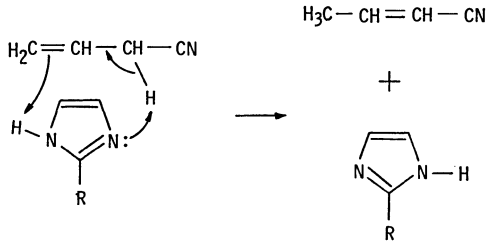
○: Conversion of isomerization, 3-BN to 2-BN;
◑: conversion for compound **1**;
△: NH shift; ●: NH content, %.

Possible Reaction Mechanism. *(A) Isomerization.* To elucidate the mechanism, the reaction of imidazole-1-*d*, containing up to 19.2% NH, with 3-BN was performed by monitoring the NMR method. Plots of NH shift, its content, and the conversions against the reaction time are shown in Fig. 4. In the beginning of the reaction, the NH content of imidazole-*d* was 20%; it then increased with an increase in the reaction time. When its content approached 100%, the NH signal began to move upfield and the formation of Compound **1** was observed. The curves of the NH shifts and the conversions in Fig. 4, are identical with those illustrated in Fig. 2. As can be seen in both Figs. 2 and 4, the NH shift in each lowest field appeared at approximately 11 ppm. These phenomena support the idea that either the hydrogen of NH in the Im molecule is bonded to another mole-

cule, probably the 3-BN molecule, by a very weak bond such as a hydrogen bond, or, since the bonding energy of NH falls, the distance is sufficiently stretched. On the other hand, a hydrogen atom of the methylene group in the 3-BN molecule is activated by the −I-effect of the CN group.

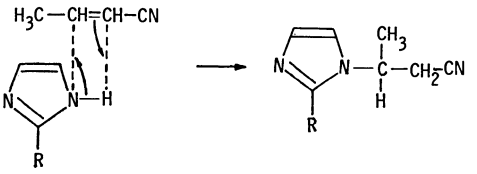
We also attempted the reactions of pyrrole, pyrazole, and imidazole nitrate with 3-BN under the same conditions. However, no products could thus be obtained.

These considerations lead us to believe that the following reaction mechanism holds:



A. Isomerization mechanism

(B) Cyanoethylation. In the reaction of Im with acrylonitrile, we have already reported the value for the activation energy, $E_a = 12.0$ kcal/mol. In this work, the activation energy of the reaction of Im with 2-BN was 15.3 kcal/mol. This result suggests that the reaction of 2-BN with Im is somewhat more difficult than that of acrylonitrile. This may be due to the +I-effect of the metyl group in 2-BN. As can be seen in Fig. 3, the NH signal appears at around 11 ppm in the beginning of the reaction. On the basis of the results mentioned above and other considerations,[1] a possible mechanism for the cyanoethylation can be described as follows:



B. Cyanoethylation mechanism

We wish to thank the Shikoku Fine Chemicals Co., Ltd., for the supply of the imidazoles.

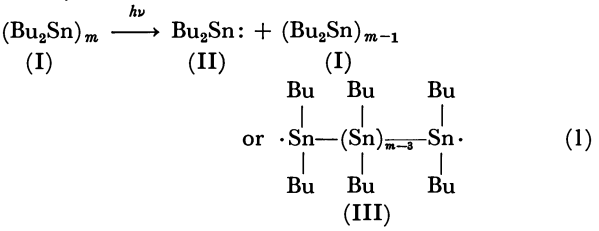
(Received April 22, 1976)

The photochemical reactions of dibutyltin, $(Bu_2Sn)_m$, with alkyl monohalides, R'X, give $Bu_2R'SnX$-type compounds by the insertion of the intermediately formed dibutylstannylene to the C–X bond of alkyl halides. This provides a facile method for preparing $Bu_2R'SnX$ compounds, since the reaction proceeds quickly under mild conditions giving the products in good yields, the only by-product Bu_3SnX which can be distilled being obtained only in a low yield. The reactions with dihalomethanes were also successful. The reaction pathway is discussed in connection with the reactivities of the substrates.

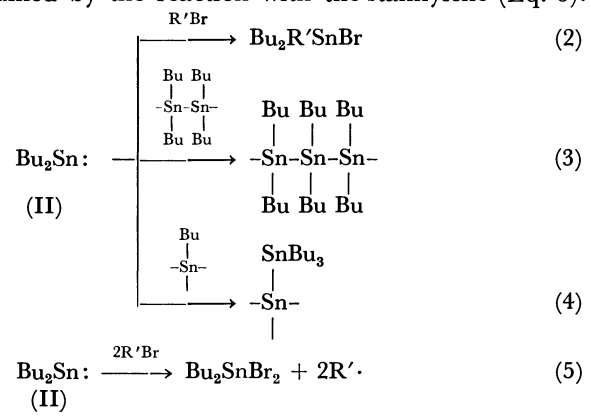
In previous papers,[1,2] thermal reactions of polymeric diorganotins, $(R_2Sn)_m$, with alkyl halides, R'X, were reported to yield the insertion products, $R_2R'SnX$, together with a variety of disproportionation products, R_4Sn, R_3SnX, and $RR_2'SnX$. Kumada and his collabolators reported on the formation of silylenes, R_2Si:, by the photolysis of organopolysilanes.[3] Schroer and Neumann,[4] and Neumann and Schwarz[5] reported on the transient formation of dialkylstannylenes, R_2Sn:, by the thermal decomposition of 1,2-dichlorotetraalkylditin, and by the photolysis of dialkyltins, respectively. These reports have promped us to disclose our recent results of the photochemical reactions of dibutyltin with organic halides. This paper deals mainly with the reactions of dibutyltin with organic bromides and chlorides, giving a discussion on the reaction pathway comparing the results of the photolytic reactions with those of the thermal reactions.

A solution of dibutyltin, $(Bu_2Sn)_m$, in a large excess of alkyl bromides, R'Br, was irradiated with a high pressure mercury lamp through a Pyrex filter at 0 °C for 30 min to give $Bu_2R'SnBr$ in about 60% yield, together with a small amount of Bu_3SnBr (1—3%). From the distillation residue, bis(dibutylbromotin) oxide, $(Bu_2BrSn)_2O$, was isolated in about 30% yield. Yellow coloration of dibutyltin still remained when the solution was kept in the dark at room temperature for 10 days. Irradiation, therefore, apparently induced the reaction. The major product, $Bu_2R'SnBr$, could be formed by the insertion of transiently formed dibutylstannylene, Bu_2Sn:, into the C–Br bond of alkyl bromide. Since polymeric diorganotins are yellowish liquid or solids,[6] they have absorptions in the ultraviolet and visible regions (Fig. 1). The absorptions could be attributed to the polymeric Sn–Sn bonds. Thus, irradiation with UV light could cleave the Sn–Sn bonds of diorganotins. Photolysis of cyclic dibutyltin, $(Bu_2Sn)_m$, could produce dibutylstannylene, Bu_2Sn:, accompanied by the formation of cyclic dibutyltin, $(Bu_2Sn)_{m-1}$, and/or acyclic polydibutyltin biracdical (III) (Eq. 1). The spin state



(1)

of the stannylene, singlet or triplet can not be discussed from our present results. A part of the stannylene thus formed undergoes insertion into the C–Br bond of the alkyl bromide (Eq. 2), and the rest of the stannylene could be inserted into the Sn–Sn bonds and/or C–Sn bonds of dibutyltin (Eqs. 3 and 4).[7] It is also probable that the stannylene abstracts two bromine atoms from alkyl bromide successively to form dibutyltin dibromide. No dibutyltin dibromide was found in the distillation product, however, a small amount of the dibromide (*ca.* 4%) was detected in the reaction mixture (Eq. 5). A part of the dibromide could be consumed by the reaction with the stannylene (Eq. 6).



It has been confirmed that dibutyltin dibromide readily reacts with dibutyltin under the same irradiation

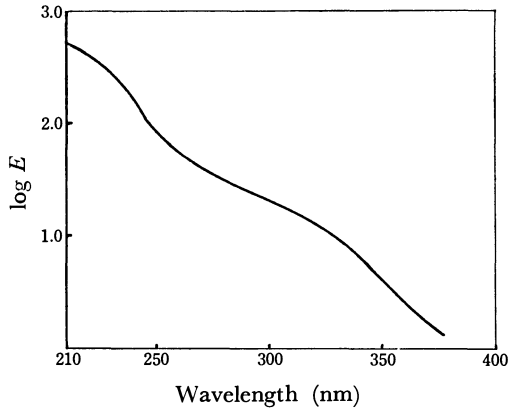


Fig. 1. Ultraviolet spectrum of dibutyltin in cyclohexane.

conditions to yield 1,2-dibromotetrabutylditin (IV) in 80% yield together with tributyltin bromide in 20% yield (Eq. 6). After the photolysis, the reaction mixture was exposed to air to oxidize the residual Sn–Sn bonds.[8] Thus, bis(dibutylbromotin) oxide (V) in the distillation residue should be formed by the air oxidation of 1,2-dibromotetrabutylditin (IV) (Eq. 7). Ditin compounds (IV) could be formed by the successive abstraction of two bromine atoms from alkyl bromide by tetrabutylditin biradical (Eq. 8), or by the reaction of dibutyltin dibromide with the stannylene (Eq. 6).

$$Bu_2SnBr_2 + (Bu_2Sn)_m \xrightarrow{h\nu} \underset{\text{(IV)}}{Br\text{-}Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}Br} + Bu_3SnBr \quad (6)$$

(I)

$$\underset{\text{(IV)}}{Br\text{-}Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}Br} \xrightarrow{O_2} \underset{\text{(V)}}{Br\text{-}Sn(Bu)_2\text{-}O\text{-}Sn(Bu)_2\text{-}Br} \quad (7)$$

$$\underset{\text{(IV)}}{\cdot Sn(Bu)_2\text{-}Sn(Bu)_2\cdot} \xrightarrow{2R'Br} \underset{\text{(IV)}}{Br\text{-}Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}Br} + 2R'\cdot \quad (8)$$

The minor by-product, Bu_3SnBr, can be produced by the reaction of tributyltin radical with alkyl bromide. This reaction was found to occur in the dehalogenation of organic halides by organotin hydrides.[9] There might be several possible pathways for the formation of tributyltin radical. One of them is the insertion of dibutylstannylene into the Bu–Sn bond of dibutyltin to give tributyltin group (Eq. 4), which could be cleaved by the irradiation (Eq. 9). This insertion

$$-Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}Sn(Bu)(SnBu_3)\text{-} \xrightarrow{h\nu} -Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}\dot{S}n(Bu)\text{-} + Bu_3Sn\cdot \quad (9)$$

pathway, however, could be a minor one since the yield of Bu_3SnBr was independent of the concentration of $(Bu_2Sn)_m$.

Another one is the intramolecular transposition of butyl group to give the tributyltin group at the terminal position together with the monobutyltin group (Eq. 10). The possibility of this pathway has been con-

$$-Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}\dot{S}n(Bu)_2 \xrightarrow{h\nu} -Sn(Bu)_2\text{-}Sn(Bu)\cdot\text{-}Sn(Bu)_2\text{-}Bu \quad (10)$$

firmed by the irradiation of polymeric dibutyltin in the absence of alkyl halide. By the photolysis of dibutyltin in benzene (0.503 g/8 ml) for 80 min, 9% of dibutyltin fragments were converted into tributyltin and monobutyltin fragments. In the case of the more dilute benzene solution (0.158 g/24 ml), the conversion proceeded more efficiently (23%). The disproportionation, therefore, would take place *via* the intramolecular process. This intramolecular transposition of butyl group might be a major pathway for the formation of tributyltin group. The tributyltin group thus formed is photochemically cleaved to afford tributyltin radical (Eq. 11).

$$-Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}Sn(Bu)_2\text{-}Bu \xrightarrow{h\nu} -Sn(Bu)_2\text{-}\dot{S}n(Bu)\cdot + Bu_3Sn\cdot \quad (11)$$

The reaction of dibutylstannylene with the free butyl radical cleaved photochemically from dibutyltin might be also possible. A similar photochemical disproportionation was reported in the photolysis of bis[bis(trimethylsilyl)methyl]stannylene to give the trisubstituted stannyl radical.[10] The probability of this pathway can not be eliminated by our present results.

In the reaction with propyl chloride, a longer reaction time was required to achieve a good conversion than in the cases of alkyl bromides. The insertion product, $Bu_2PrSnCl$, and the disproportionation product, Bu_3SnCl, were obtained in 57 and 7.3% yield, respectively. It is to be noted that the photochemical reaction occurred at lower temperature (0 °C), in shorter reaction time (80 min), in contrast to the thermal reaction,[1] where the insertion product, $Bu_2PrSnCl$, was produced under drastic conditions in the presence of catalysts (160 °C, 15 h) accompanied by many thermally scrambled alkyltin products. No bis(dibutylchlorotin) oxide was detected in the distillation residue exposed to air, but organopolystannoxane containing more than two tin atoms, presumably a trimer or a tetramer, was found. Since the C–Cl bond of alkyl chloride is less reactive than the C–Br bond, the rate of the insertion of dibutylstannylene toward the C–Cl bond could be much lower. In the reaction with alkyl chloride, accordingly, the reformation of Sn–Sn bonds from the stannylene (Eq. 3) could be enhanced. Therefore, the chance for the formation of tributyltin fragments increases, and the relatively longer chains of Sn–Sn bonds remain in the reaction mixture.

Dibutylstannylene also undergoes the insertion reaction into C–X bonds of dichloro- and dibromomethane to afford analytically pure dibutyl(chloromethyl)tin chloride (58%)[11] and dibutyl(bromomethyl)-tin bromide (70%), respectively. No disproportionation products, Bu_3SnCl and Bu_3SnBr were detected in the reaction products. Since the stannylene was captured effectively by the dihalomethanes, the reformation reaction of polydibutyltin from the stannylene (Eq. 3) could be restricted, and the disproportionation to produce tributyltin fragment, therefore, might be extremely suppressed.

$$(Bu_2Sn)_m + XCH_2X \xrightarrow{h\nu} Bu_2SnCH_2X \quad (12)$$

(X)

Experimental

Reactions with Alkyl Monohalides. Dibutyltin was prepared from dibutyltin dihydride and dibutyltin dimethoxide by the method of Neumann, Pedain, and Sommer.[12] In all

the experiments, freshly prepared yellow liquid of dibutyltin was used. The ^{13}C-NMR spectra were recorded in the pulse Fourier transform mode with a JEOL-FX 60 spectrometer operating at a resonance frequency of 15.03 MHz. The parameters used were: pulse width 8 μs, spectral width 2500 Hz for 8 K data points.

In a typical procedure, a mixture of 1.106 g of dibutyltin and 8 ml of ethyl bromide in a sealed Pyrex glass ampoule was irradiated with a high pressure mercury lamp (450 W) externally at 0 °C under nitrogen atmosphere for 30 min. The reaction mixture was then exposed to air, and the excess of ethyl bromide was removed by distillation *in vacuo*. The product was distilled under reduced pressure to give 0.946 g of distillate (bp 96—98 °C/3 mmHg), containing 57% yield of dibutylethyltin bromide and 1.1% of tributyltin bromide. Dibutylethyltin bromide was identified by comparing the retention time on gas chromatography and the IR and ^{13}C-NMR spectra with those of the authentic samples.[1] ^{13}C-NMR($CDCl_3$): δ 9.6(Sn-**C**H_2CH_3 $J_{C-^{119}Sn}$=334 Hz), 10.3 (Sn-CH_2**C**H_3). The colorless crystals in the distillation residue (0.527 g, 35%) were recrystallized from acetone and identified as bis(dibutylbromotin) oxide, $(Bu_2BrSn)_2O$.[13]

In a similar procedure, the reaction of dibutyltin with propyl bromide gave dibutylpropyltin bromide (66%),[1] tributyltin bromide (2.5%) and bis(dibutylbromotin) oxide (26%). Dibutylpropyltin bromide: ^{13}C-NMR($CDCl_3$): δ 20.5 (Sn-**C**$H_2CH_2CH_3$ $J_{C-^{119}Sn}$=338 Hz), 19.4 (Sn-CH_2-**C**H_2CH_3), 18.3 (Sn-CH_2CH_2**C**H_3).

In the reaction with alkyl chlorides, the irradiation time was extended to 80 min. Thin-layer chromatography of the residual stannoxane developed with CH_2Cl_2 showed no detectable spot of bis(dibutylchlorotin) oxide, but those of longer chain stannoxanes in the lower R_f-values.

The reaction of 1.194 g of dibutyltin with 8 ml of propyl chloride gave dibutylpropyltin chloride (0.913 g, 57%),[1] tributyltin chloride (0.121 g, 7.3%) and residual stannoxane (0.412 g). Dibutylpropyltin chloride: ^{13}C-NMR($CDCl_3$): δ 20.3 (Sn-**C**$H_2CH_2CH_3$ $J_{C-^{119}Sn}$=338 Hz), 19.4 (Sn-CH_2**C**H_2CH_3), 18.3 (Sn-CH_2CH_2**C**H_3).

Tributyltin chloride (1.063 g, 69%) was obtained in pure form, together with the residual stannoxane (0.326 g), from 1.107 g of dibutyltin and 8 ml of butyl chloride.

Reactions with Dihalomethanes. Under similar conditions, a solution of 3.24 g of dibutyltin in 10 ml of dichloromethane was irradiated for 30 min. Excess dichloromethane was evaporated off. Distillation of the residue gave analytically pure dibutyl(chloromethyl)tin chloride (bp 80—82 °C/0.01 Torr) in 58% yield (n_D^{25} : 1.5087, lit[11]). The compound was identified by elemental analysis, IR, PMR and ^{13}C-NMR spectra. PMR($CDCl_3$) : δ 3.40 (s, 2H, CH_2Cl). ^{13}C-NMR($CDCl_3$) : δ 29.3 (CH_2Cl, $J_{C-^{119}Sn}$= 325 Hz). The reaction of dibutyltin and dibromomethane was carried out in a similar manner to give 70% yield of the new compound, dibutyl(bromomethyl)tin bromide, $Bu_2BrSnCH_2Br$, (bp 87—88 °C/0.009 Torr, n_D^{25} : 1.5395). PMR ($CDCl_3$) : δ 3.00 (s, 2H, CH_2Br). ^{13}C-NMR($CDCl_3$) : δ 11.8 (CH_2Br, $J_{C-^{119}Sn}$=293 Hz). Found: C, 26.30; H, 4.89%. Calcd for $C_9H_{20}Br_2Sn$: C, 26.56; H, 4.92%.

Reaction with Dibutyltin Dibromide. Dibutyltin dibromide (0.689 g) was added to the cyclohexane solution of dibutyltin (0.408 g) in a sealed Pyrex glass ampoule, and the mixture was irradiated under the same conditions. After the photolysis, the reaction mixture was exposed to air. A trace of organopolystannoxanes insoluble in $CDCl_3$ was removed by filtration. The gas chromatographic analysis and ^{13}C-NMR spectra showed that the reaction mixture consisted of bis(dibutylbromotin) oxide (80%) and tributyltin bromide (20%). The ratio of these compounds was determined by the integral values of their peaks assigned to the α-carbons of butyl groups in the ^{13}C-NMR spectra measured by gated decoupling technique without NOE. ^{13}C-NMR ($CDCl_3$) : δ 36.1, 36.3 (C(1) of $(Bu_2BrSn)_2O$), 17.3 (C(1) of Bu_3SnBr).

Photolysis of Dibutyltin in the Absence of Alkyl Halide. The benzene solution of dibutyltin (0.503 g/8 ml) was irradiated for 80 min under the same conditions as above. To the irradiation product was added a benzene solution of iodine at 0 °C to cleave the Sn–Sn bond completely. The mixture was stirred for 5 min at 0 °C, and was treated with a large excess of methylmagnesium iodide. The distribution of the three products, $BuMe_3Sn$, Bu_2Me_2Sn, Bu_3MeSn, was determined by gas chromatographic analysis to be 4.6, 91, and 4.2%, respectively. When the diluted solution (0.158 g/24 ml) was irradiated, the distribution of the methylated products were found to be 11, 77, and 12%, respectively.

The Synthesis of Benzannelated Annulenes. Dibenzo-tetrakisdehydro-[18]annulene, and Tribenzo-bisdehydro[14]annulene

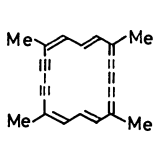
Jūro Ojima,* Tadayoshi Yokomachi, and Akihiko Kimura
Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received April 26, 1976)

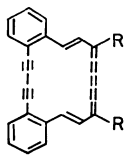
In order to establish the effect of the annelation of benzene rings on [4*n*+2]annulenes, the syntheses of benzannelated dehydroannulenes were attempted. Dibenzo-tetrakisdehydro[18]annulenes (IIa and IIb) were prepared according to the reaction sequence developed in the synthesis of tetramethyltetrakisdehydro-[18]annulene (I) from *o*-ethynylbenzaldehyde (VIII); both of them proved to be unstable. Tribenzo-bisdehydro[14]annulene (XVII) was also prepared from VIII by a double Wittig reaction, followed by oxidative coupling. An examination of the NMR spectrum indicated that XVII is atropic.

The effect on the ring current of diatropic macrocyclic $(4n+2)\pi$-electron systems produced by the annelation of one or more benzenoid rings seems to be of considerable interest.[1]

In 1968, one of the present authors (J. O.) reported the synthesis of 1,5,10,14-tetramethyl-6,8,15,17-tetrakisdehydro[18]annulene (I).[2] The strong diatropicity observed in I prompted us to synthesize the corresponding dibenzo analogue, 11,16-dimethyldibenzo-[*a*,*g*]-3,5,12,14-tetrakisdehydro[18]annulene (IIa), in



I

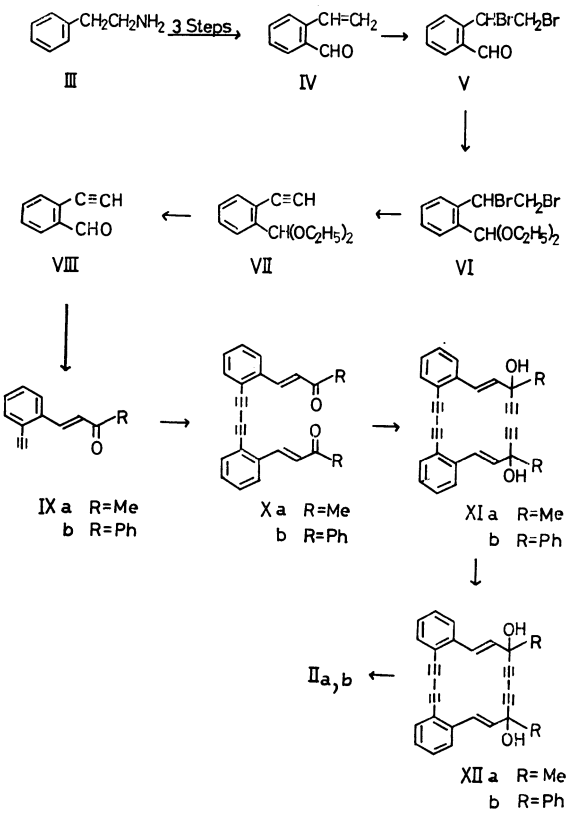


IIa R=Me
b R=Ph

order to examine the effect of the annelation of the benzene nuclei on the conjugated eighteen-membered ring system containing formal diacetylene and hexapentaene linkages.[3] To this end, a synthesis of *o*-ethynylbenzaldehyde (VIII) was required. VIII appeared to be a valuable intermediate for the synthesis of other conjugated macrocycles with fused benzene nuclei. Related experiments designed along similar lines have been reported in preliminary form by several workers after the completion of this work.[4]

Recently, Weavers and Sondheimer have reported the synthesis of benzo-1,3-bisdehydro[14]annulene (XIX) and showed that the fusion of one benzene ring reduces the diatropicity of the 1,3-bisdehydro[14]-annulene series.[4i] By the use of *o*-ethynylbenzaldehyde (VIII), we have prepared the corresponding tribenzo analogue, XVII, in order to examine the relative magnitude of the ring current in the "1,3-bisdehydro[14]annulene" system. In this paper, we wish to report the syntheses and properties of 11, 16-dimethyldibenzo[*a*,*g*]-3,5,12,14-tetrakisdehydro[18]annulene (IIa), the diphenyl derivative (IIb), and tribenzo[*a*,*e*,*i*,]-11,13-bisdehydro[14]annulene (XVII).

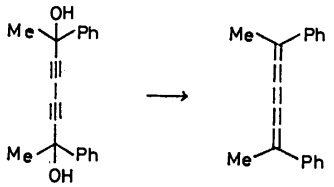
The key compound, *o*-vinylbenzaldehyde (IV), was prepared from phenethylamine (III) as has been described by Dale *et al.*[5] The reaction of *o*-vinylbenzaldehyde (IV) with a 1 molar equivalent of bromine in carbon tetrachloride gave *o*-(1,2-dibromoethyl)-benzaldehyde (V) in a 74% yield; this substance was converted with triethyl orthoformate into diethyl acetal (VI) in an 88% yield. The dehydrobromination of VI was effected by means of potassium hydroxide in boiling methanol to give *o*-ethynylbenzaldehyde diethyl acetal (VII). VIII was obtained in a good yield after the hydrolysis of the VII with dilute hydrochloric acid. The over all yield of VIII in the seven-step synthesis from I was *ca.* 20%.



The conversion of VIII to IIa and IIb was performed according to the reaction sequence developed for the synthesis of tetramethyltetrakisdehydro-[18]annulene (I). The condensation of VIII with acetone gave the ketone (IXa) in a 52% yield; the ketone was oxidatively coupled to afford the diketone (Xa) in an 82% yield by the use of copper(II) acetate in a mixture of pyridine and methanol.[6] The reaction of IXa with the lithium acetylide–ethylenediamine complex[7] in tetrahydrofuran gave the glycol (XIa) as a yellow, viscous liquid in a 63% yield. The intramolecular oxidative coupling of XIa was per-

*To whom correspondence should be addressed.

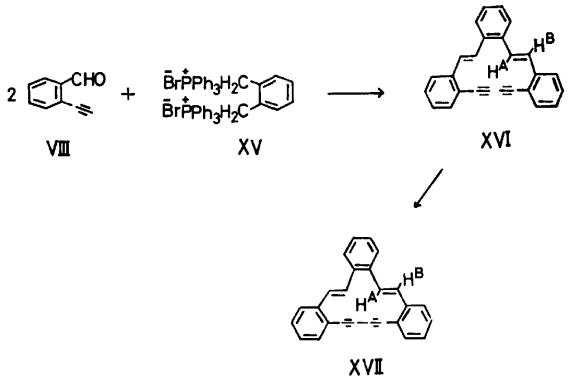
formed under high-dilution conditions, using ether as the entraining agent, by Eglinton's method.[6] The dehydroxylation of cyclic glycol XIIa could be effected by tin(II) chloride in concentrated hydrochloric acid. The rapid color change of the resulting oil seemed to suggest the unstable nature of the dibenzannelated annulene (IIa). The substance could be kept at room temperature in a relatively dilute solution for less than half an hour. As all attempts to obtain IIa in the neat state or in a concentrated solution resulted in decomposition, we were unable to determine the well-defined IR, UV, NMR and mass spectra. The UV spectrum [$\lambda_{max}^{benzene}$ (>300 nm) 350, 418, 437, 510 sh nm] was similar to that of 1,6-dimethyl-1, 6-diphenylhexapentaene (XIV) [$\lambda_{max}^{benzene}$ 352, 419, 443 nm]. Consequently, it seemed that the product obtained was IIa. XIV was prepared from 2,7-diphenyl-3,5-octadiyne-2,7-diol (XIII) on treatment with tin(II) chloride in concentrated hydrochloric acid.[8] Since it was expected that the unstability of IIa might be reduced by the introduction of a substituent group bulkier than a methyl group, the synthesis of the diphenyl derivative was attempted by the same route. The oxidative coupling of IXb gave the diketone, Xb, in a 65% yield. However, as Xb was poorly soluble in usual solvents, XIb could be obtained only in a low yield by the bisethynylation of Xb. Therefore, the conversion of XIb to IIb was performed by using crude products. The IIb thus obtained proved to be as unstable as IIa.



XIII XIV

Recently, Weavers and Sondheimer have reported the synthesis of benzobisdehydro[14]annulene (XIX) by the oxidative coupling of the acyclic compound (XVIII), which has been synthesized by a double Wittig reaction between *cis*-3-methyl-2-penten-4-ynal and the salt XV.[41] In order to examine the relative magnitude of the ring current in 1,3-bisdehydro[14]-annulene system, we decided to prepare the corresponding tribenzo analogue of this type, tribenzo[*a*,*e*,*i*]-11,13-bisdehydro[14]annulene (XVII), by using *o*-ethynylbenzaldehyde (VIII) according to the route developed for the synthesis of XIX. The Wittig reaction of 2 molar equivalents of *o*-ethynylbenzaldehyde (VIII) and 1 molar equivalent of α,α'-bis-(triphenylphosphonio)-*o*-xylene dibromide[9] (XV) in *N*,*N*-dimethylformamide with ethanolic lithium ethoxide led to a mixture of geometrical isomers which, upon chromatography on alumina, gave the di-*trans* isomer (XVI) in a 16% yield. The oxidative coupling of XVI with copper(II) acetate monohydrate in pyridine afforded the desired XVII in a 33% yield.

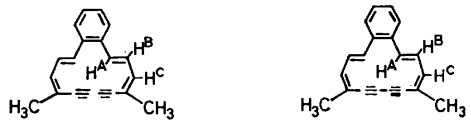
The chemical shifts of the protons of the XVI and XVII thus obtained are summarized in Table 1, along



VIII XV XVI XVII

with those of XVIII and XIX reported by Weavers and Sondheimer.[41] As is shown in Table 1, there is not much difference in the NMR spectra between XVI and XVII, particularly on the chemical shift of the inner proton, H^A. That is, the observed chemical shift of H^A of XVII is in the normal region of the olefinic proton. Therefore, it is apparent that XVII is not diatropic, but atropic.

On the other hand, a comparison of the NMR spectra of XVIII and XIX suggests that compound XIX is diatropic, because the H^A resonance has moved to a higher field, and the H^B, H^C, and CH_3 resonances, to a lower field, as compared with the resonances of XVIII.



XVIII XIX

From these results, it may be concluded that the diatropic nature, which is revealed in the monobenzo-fused compound, XIX, is completely suppressed in the tribenzo-fused compound, XVII.

Table 1. ^{1}H-NMR parameters of XVI, XVII, XVIII, and XIX in $CDCl_3$
(τ-values; TMS as the internal standard)

Proton	XVI[a,c]	XVII[a,d]	XVIII[b]	XIX[b]
H^A	3.42[e]	3.33[e]	3.12	5.01
H^B	f)	f)	2.85	2.56
benzenoid	2.45—3.15	2.37—2.70		
H^C			3.51	2.92
CH_3			8.10	7.64

a) At 60 MHz. b) At 100 MHz. c) In addition, a singlet at 6.70 (-C≡CH). d) The ^{1}H-NMR spectrum of XVII was essentially temperature-independent in the range from −60 °C to 25 °C. e) We assigned the high-field signal to the H^A proton by referring to the chemical shifts of the related compound.[4e,f,h] However, some ambiguity remains because we do not have data definitely supporting this assignment. f) This proton signal is submerged by those of the benzenoid protons.

Experimental

All the melting and boiling points are uncorrected. Brockmann alumina (Act. II—III) was used for column

chromatography. The IR and UV spectra were taken on Hitachi EPI-S2 and Hitachi 124 spectrophotometers respectively. The shoulders in the UV spectra are indicated by sh. The NMR and mass spectra were taken on JEOL-C-60A and JEOL-JMS-OI-SG-2 spectrometers respectively. The chemical shifts are given in τ-values with respect to TMS as the internal standard, while the coupling constants are given in Hz.

o-Vinylbenzaldehyde (IV). *o*-Vinylbenzaldehyde was prepared by the reported method,[5] with slight modifications.

o-[1,2-Dibromoethyl]benzaldehyde (V). Bromine (43.2 g, 0.27 mol) was added, in one portion, to a solution of the aldehyde (IV, 34.1 g, 0.26 mol) in chloroform (280 ml) over a period of 1 h at 0 °C, after which the solution was stirred for a further 3 h at room temperature. After the addition of an aqueous sodium carbonate solution (150 ml) to the cooled mixture, the organic and benzene extracts of the aqueous layer were combined and worked up in the usual way. The dark red liquid thus obtained gave a solid mass of crystals (V, 70.4 g, 74%) on cooling. Recrystallization from light petroleum-benzene afforded pure V as colorless cubes; mp 74.5—75.1°C. IR (KBr disk): 1700 cm^{-1} (CHO), NMR (CCl_4): −0.18 (s, 1H, -CHO), 2.1—2.5 (m, 4H, phenyl H), 3.36 (t, J=8, 1H, -CHBr), 5.97 (d, J=8, 2H, $-CH_2Br$).

Found: C, 37.17; H, 2.69%. Calcd for $C_9H_8OBr_2$: C, 37.02; H, 2.76%.

o-Ethynylbenzaldehyde (VIII). A solution of dibromide (V, 82.6 g, 0.28 mol), triethyl orthoformate (55 g, 0.37 mol), and *p*-toluenesulfonic acid (1.6 g) in absolute ethanol (126 ml) was refluxed for 5 h. After pouring into 3M-aqueous ammonia, the mixture was extracted with ether. The extracts were then washed successively with 3M-aqueous ammonia (2 times) and a saturated sodium chloride solution (3 times), dried over potassium carbonate, and evaporated to give a dark red liquid (VI, 91 g). The liquid shows no IR absorption due to an aldehyde group, but it does show that due to an acetal group, IR (neat): 1100, 1070, 1050 cm^{-1} (C-O-C).

The crude product (VI, 91 g, 0.25 mol) in methanol (35 ml) was stirred into a solution of potassium hydroxide (159 g, 2.83 mol) in boiling methanol (247 ml) for 1 h. Crystals of potassium bromide deposited soon. The mixture was then heated under reflux for an additional 3 h, poured into water (1500 ml), and extracted with ether. The extracts were washed with a saturated sodium chloride solution and dried over potassium carbonate. The dark red liquid after the evaporation of the solvent was distilled under reduced pressure to give ethynyl acetal as a colorless liquid (VII, bp 85—97°C/2 Torr, 26.5 g, 52%); IR (neat): 3350 (-C≡CH), 2150 (-C≡C-), 1100, 1040 cm^{-1} (C-O-C).

The ethynyl acetal (VII, 26.5 g, 0.13 mol) in ether (82 ml) was stirred with 3M-hydrochloric acid (165 ml) at room temperature for 2 h. The organic and ethereal extracts from the aqueous layer were combined and worked up in the usual way. A partly crystallized liquid thus obtained was dissolved in benzene and absorbed on alumina (200 g).

Elution with light petroleum gave VIII (9.3 g, 55%).

Recrystallization from hexane afforded pure VIII as colorless needles; mp 62.5—63.5 °C, IR (KBr disk): 3250(-C≡CH), 2100 (-C≡C-), 1695 cm^{-1} (CHO), UV: λ_{max}^{EtOH} 250 (8800), 255 (9210), 305 (2370), 314 (2410), NMR ($CDCl_3$): −0.43 (s, 1H, -CHO), 2.0—2.7 (m, 4H, phenyl H), 6.54 (s, 1H, -C≡CH).

Found: C, 82.80; H, 4.58%. Calcd for C_9H_6O: C, 83.06; H, 4.65%.

4-(o-Ethynylphenyl)-1-buten-2-one (IXa). An ice-cooled mixture of 12% aqueous sodium hydroxide (16 ml) and ethanol (8 ml) was added to a stirred and ice-cooled solution of the aldehyde (VIII, 5.2 g, 0.04 mol) in acetone (5 ml). After being stirred for 90 min at the same temperature, the reaction was quenched with 1M-sulfuric acid (8 ml). A dark red liquid obtained from the ethereal extracts was chromatographed on alumina (200 g) with light petroleum-ether (8:2) to afford a pale yellow liquid (IXa, 3.5 g, 52%). Crystallization from hexane gave pure IXa as yellow plates; mp 64—65°C,[10] Mass: *m/e* 170 (M^+, 35%), 120 (base); mol. wt, 170.20, IR (KBr disk): 3250 (-C≡CH), 2100 (-C≡C-), 1700, 1615, 1595 (C=O, C=C), 990, 970 cm^{-1} (*trans* C=C), UV: λ_{max}^{EtOH} 230 sh (14400), 242 (17700), 247 (16200), 291 (13800), NMR ($CDCl_3$): 2.02 (d, J=16, 1H, olefinic H), 2.3—2.8 (m, 4H, phenyl H), 3.33 (d, J=16, 1H, olefinic H), 6.57 (s, 1H, -C≡CH), 7.59 (s, 3H, Me).

Found: C, 84.77; H, 6.21%. Calcd for $C_{21}H_{10}O$: C, 84.68; H, 5.92%.

1,4-Bis[o-(3-oxo-1-butenyl)phenyl]-1,3-butadiyne (Xa). A solution of the ketone (IXa, 8.4 g, 0.049 mol) in methanol (126 ml) and pyridine (210 ml) was stirred, drop by drop over a 2 h period at room temperature, into a solution of copper(II) acetate monohydrate (19 g, 0.095 mol) in methanol (660 ml) and pyridine (660 ml). The mixture was then stirred for an additional 3 h at the same temperature, concentrated under reduced pressure to a quarter volume, poured into 2M-sulfuric acid (1800 ml), and extracted with ether. The ethereal extracts were washed successively with water, aqueous sodium hydrogencarbonate, and saturated sodium chloride solutions, and dried over sodium sulfate. The dark red liquid obtained by evaporating the solvent was chromatographed on alumina (100 g) with benzene to give Xa (6.82 g, 82%). Recrystallization from methanol gave pure Xa as yellow needles; mp 144.0—145.5°C, IR (KBr disk): 2200 (-C≡C-), 1670—1630 (triplet, C=O), 995, 975 cm^{-1} (*trans* C=C), NMR ($CDCl_3$): 1.92 (d, J=16, 2H, olefinic H), 2.15—2.65 (m, 8H, phenyl H), 3.16 (d, J=16, 2H, olefinic H), 7.56 (s, 6H, Me).

Found: C, 84.93; H, 5.21%. Calcd for $C_{24}H_{18}O_2$: C, 85.18; H, 5.36%.

1,4-Bis[o-(3-hydroxy-3-methyl-1-penten-4-ynyl)phenyl]-1,3-butadiyne (XIa). To a mixture of the lithium acetylide-ethylenediamine complex (14.1 g, 0.153 mol) and tetrahydrofuran (500 ml) saturated with acetylene we added a solution of the diketone (IXa, 24.1 g, 0.14 mol) in the same solvent (150 ml) for 5 hr at 35°C under stirring and bubbling with acetylene. After the reaction mixture had been stirred vigorously for an additional 2 h under the slow introduction of acetylene, a cold saturated sodium chloride solution (200 ml) was added to the cooled reaction mixture. The organic layer, combined with ethereal extracts, was washed successively with 2M-hydrochloric acid, aqueous sodium hydrogencarbonate, and saturated sodium chloride solutions, and dried over sodium sulfate. After the solvents had been removed under reduced pressure, a dark red liquid thus obtained was chromatographed on alumina (500 g) with benzene-ether to give XIa (17.4 g, 63%) as a yellow liquid. All attempts to crystallize the liquid failed; the IR (neat) (3300 (-OH), 3250 (-C≡CH), 2200, 2100 (-C≡C-), 965 cm^{-1} (*trans* C=C)) and the NMR ($CDCl_3$) (2.5—3.0 (m, 8H, phenyl H), 3.04 (d, J=16, 2H, olefinic H), 3.87 (d, J=16, 2H, olefinic H), 6.8 (broad s, 2H, -OH), 7.42 (s, 2H, -C≡CH), 8.37 (s, 6H, Me)) were found to be in accord with the structure of XIa.

1,6-Dimethyl-9,10 : 15,16-dibenzocyclooctadeca-7,17-diene-2,4,11,

13-tetrayne-1,6-diol (XIIa). A high-dilution apparatus was used in this experiment. A solution of the acyclic glycol (XIa, 4.66 g, 0.012 mol) in ether (60 ml), methanol (72 ml), and pyridine (290 ml) was stirred, over a 15-h period, into a refluxing mixture of copper(II) acetate monohydrate (13.1 g, 0.066 mol) in ether (300 ml), methanol (360 ml) and pyridine (1400 ml). The reaction mixture was refluxed for an additional 1 h, concentrated to 300 ml under reduced pressure, and then poured into 2M-hydrochloric acid (1800 ml). The ethereal extracts from the aqueous layer were worked up in the usual way. The dark red liquid thus obtained was chromatographed on alumina (700 g) with ether–ethyl acetate to give XIIa (1.54 g, 33%). Recrystallization from acetone yielded pure XIIa as pale yellow plates; mp 160°C (dec). Although a satisfactory elemental analysis is not obtained, the IR (KBr disk) (3350 (-OH), 2200, 2140 (-C≡C-), 1595 (C=C), 965 cm^{-1} (*trans* C=C)), the NMR (DMSO-d_6) (2.65 (d, J=16.5, 2H, olefinic H), 2.05—2.75 (m, 8H, phenyl H), 3.48 (d, J=16.5, 2H, olefinic H), 6.40 (broad s, 2H, -OH), 8.40 (s, 6H, Me), and the mass (*m/e* 388 (M^+); mol. wt., 388.4) were found to be consistent with the assigned structure.

11,16-Dimethyldibenzo[a,g]*-3,5,12,14-tetrakisdehydro[18]annulene (IIa).* Into a suspension of cyclic glycol (XIIa, 550 mg, 1.4×10^{-3} mol) in pentane (20 ml) benzene (10 ml), we stirred at room temperatuer a solution of tin(II) chloride dihydrate (730 mg, 3.2×10^{-3} mol) in concentrated hydrochloric acid (8 ml). After 10 min, benzene (30 ml) was added in 5-ml portions for 15 min. The reddish reaction mixture was then poured into water (100 ml), and the layers were separated. The organic layer and ethereal extracts were combined, washed successively with water, aqueous sodium hydrogencarbonate and saturated sodium chloride solutions, dried over sodium sulfate, and evaporated under reduced pressure. The residue was chromatographed on alumina with light petroleum–benzene to give a reddish fraction which was concentrated to one-third its original volume. After the addition of benzene, this fraction was subjected to UV measurement. UV: $\lambda_{max}^{benzene}$ (>300 nm) 350 (relative optical density, 0.50), 418 (0.93), 437 (1.00), 510 sh nm. The further concentration of this eluent gave yellow substances which were insoluble in benzene.

3-(o-Ethynylphenyl)-1-phenyl-2-propen-1-one (IXb). To a stirred and ice-cooled solution of the aldehyde (VIII, 2.5 g, 0.019 mol) in ethanol (13 ml), we added, drop by drop, a 40% aqueous potassium hydroxide solution (10 ml) and acetophenone (2.3 g, 0.019 mol) simultaneously over a 15-min period; then the mixture was stirred for a further 3 h at room temperature. The reaction mixture was then poured into 3M-hydrochloric acid (100 ml) and extracted with ether. The ethereal extracts were worked up in the usual way. The dark red liquid thus obtained was chromatographed on alumina (200 g) with light petroleum–ether (8:2) to give Xb (1.1 g, 25%). Recrystallization from cyclohexane gave pure Xb as pale yellow cubes; mp 55.0—55.5°C, IR (KBr disk): 3300 (-C≡CH), 2100 (-C≡C-), 1660 (C=O), 1605, 1600 (C=C), 1020, 985 cm^{-1} (*trans* C=C), UV: λ_{max}^{EtOH} 249 (16300), 254 (16800), 308 (18200), NMR ($CDCl_3$): 1.57 (d, J=17, 1H, olefinic H), 1.8—2.6 (m, 10H, phenyl and olefinic H), 6.33 (s, 1H, -C≡CH), Mass: *m/e* 232 (M^+, 45%), 203 (base); mol. wt., 232.27.

Found: C, 87.72; H, 5.28%. Calcd for $C_{17}H_{12}O$:C, 87.90; H, 5.21%.

1,4-Bis[o-(*2-benzoylvinyl*)*phenyl*]*-1,3-butadiyne (Xb).* A solution of the ketone (IXb, 4.7 g, 0.021 mol) in methanol (19 ml) and pyridine (19 ml) was stirred, over a period of 30 min at room temperature, into a solution of copper(II) acetate monohydrate (12.2 g, 0.06 mol) in methanol (77 ml) and pyridine (77 ml), and then the mixture was stirred for a further 3 h at the same temperature. The reaction mixture was then poured into 3M-hydrochloric acid (600 ml). The resulting solids (Xb, 3.0 g, 65%) were collected on a filter and washed with water (300 ml). Recrystallization from benzene gave an analytical specimen; mp 192—194°C, IR (KBr disk): 1660 (C=O), 1600—1580 (triplet, C=C), 1010, 990 cm^{-1} (*trans* C=C), UV: λ_{max}^{THF} 267 (28700), 290 (21600), NMR ($AsCl_3$): 1.62 (d, J=16, 2H, olefinic H), 1.8—2.8 (m, 20H, phenyl and olefinic H), Mass: *m/e* 463 (M^+, 75%), 357 (base); mol. wt., 462.52.

Found: C, 88.26; H, 4.80%. Calcd for $C_{34}H_{22}O_2$: C, 88.29; H, 4.79%.

11,16-Diphenyldibenzo[a,g]*-3,5,12,14-tetrakisdehydro*[*18*]*annulene (IIb).* This experiment was carried out by almost the same procedure as that used in the preparation of IIa. However, as the Xb diketone was poorly soluble in usual solvents and was, hence, converted to XIb in only a very low yield, the crude products were used for the preparation of IIb as well as XIIb. The UV spectrum of IIb is as follows: $\lambda_{max}^{benzene}$ 417 (relative optical density, 1.00), 498 (0.46), 530 (0.48), 550 nm (0.45).

2,7-Diphenyl-3,5-octadiyne-2,7-diol (XIII). XIII was prepared by the ethynylation of acetophenone, followed by oxidative coupling; mp 194—195°C (lit, 194°C)[11] NMR ($CDCl_3$): 2.3—2.8 (m, 10H, phenyl H), 6.69 (broad s, 2H, -OH), 8.15 (s, 6H, Me).

Found: C, 82.61; H, 6.27%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

1,6-Dimethyl-1,6-diphenylhexapentaene (XIV). XIV was prepared like IIa. The UV spectrum of XIV is as follows: $\lambda_{max}^{benzene}$ 352 (relative optical density, 0.27), 419 (0.60), 443 nm (1.00).

o-*Bis*[trans-*2-(o-ethynylphenyl)vinyl*]*benzene (XVI).* Lithium ethoxide prepared from lithium (323 mg, 0.046 gatm) in ethanol (120 ml) was stirred, drop by drop under a nitrogen atmosphere at 80—85 °C for 1 h, into *o*-ethynylbenzaldehyde (VIII, 6.0 g, 0.046 mol) and α,α′-bis(triphenylphosphonio)-*o*-xylene dibromide[9] (XV, 18.6 g, 0.023 mol) in dry *N,N*-dimethylformamide (460 ml). After the completion of the addition, the reaction mixture was stirred under a nitrogen atmosphere at 80—85°C for further a 2 h; then it was poured into water (1500 ml) and extracted with ether (500 ml×3). The ethereal extracts were worked up in the usual way to give a dark red liquid. The liquid was passed through a column of alumina (200 g) with light petroleum to give a mixture of XVI and other geometrical isomers (4.5 g, 59%) as a dark red liquid. Repeated chromatography on alumina (100 g) with light petroleum afforded the *trans-trans* isomer, XVI (1.2 g, 16%). Recrystallization from hexane gave pure XVI as white needles; mp 107—108°C, IR (KBr disk): 3300 (-C≡CH), 2120 (-C≡C-), 1615, 1600 (C=C), 945 cm^{-1} (*trans* C=C), UV: λ_{max}^{THF} 259 (26500), 315 (20500), mass: *m/e* 330 (M^+, 100%); mol. wt., 330.40, NMR ($CDCl_3$): 3.42 (d, J=14.5, 2H, H_A) 2.45—3.15 (m, 14H, phenyl and H), and see Table 1.

The elementary analyses of XVI always afforded low values of carbon, but the spectral properties clearly support the structure of XVI.

Tribenzo[a,e,i]*-11,13-bisdehydro*[*14*]*annulene (XVII).* A solution of XVI (2.0 g, 0.006 mol) in pyridine (45 ml) was stirred, drop by drop over a 20 min period, into a solution of copper(II) acetate monohydrate (18 g) in pyridine (60 ml) kept at 50 °C; the mixture was then stirred for a further 2 h at 60—65 °C. Then the mixture was chilled, diluted with benzene (200 ml), and poured into 6% hydro-

chloric acid (1000 ml). The layers were separated, and the aqueous layer was extracted with ether (150 ml×2). The organic and ethereal extracts were combined, washed successively with aqueous sodium hydrogencarbonate and saturated sodium chloride solutions, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on alumina (200 g) with light petroleum–ether (8:2) to give XVII (650 mg, 33%). Recrystallization from hexaene–benzene gave pure XVII as colorless cubes; mp 202—203°C, IR (KBr disk): 2200 (-C≡C-), 950 cm^{-1} (*trans* C=C), UV: λ_{max}^{THF} 237 (24800), 256 (21400), 291 (34700), 330 (22800), 356 (11300), mass: *m/e* 328 (M^+, 100%); mol wt, 328.39, NMR ($CDCl_3$): 3.33 (d, J=14.5, 2H, H^A), 2.3—2.7 (m, 14H, phenyl and H^A), and see Table 1.

Found: C, 95.25; H, 5.01%. Calcd for $C_{26}H_{16}$: C, 95.09; H, 4.91%.

The authors wish to thank Professor Masazumi Nakagawa, Osaka University, for the mass spectral measurement, and Mr. Michiaki Takagi and Misses Michiko Enkaku and Miyako Ishiyama for their experimental help. This work was supported by a Grant-in-Aid (4089, 1970) for Scientific Research from the Ministry of Education, which is gratefully acknowledged.

Nitration of Binary and Ternary Schiff Base Complexes of Cu(II)

B. T. THAKER and P. K. BHATTACHARYA

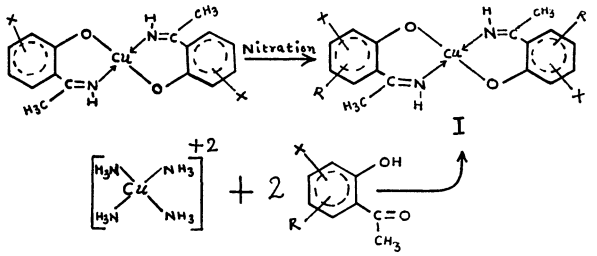
Chemistry Department, Faculty of Science, M.S. University of Baroda, Baroda 390002, India

(Received November 18, 1975)

Nitration of the coordinated ligands in the complexes bis[1-(2-hydroxyphenyl)ethylideneamine or its methyl derivative]Cu(II) and *N,N'*-ethylene or propylene bis[1-(2-hydroxyphenyl)ethylideneaminato]Cu(II) have been carried out. Similar nitration reactions of mixed diamine Schiff base complexes of Cu(II) have also been carried out. The substitution products have been characterized by elemental analyses, comparison with authentic samples in case of binary complexes and by means of magnetic moments, electronic and IR spectral studies. The orientation of incoming substituents in the chelates is found to be the same as that in uncomplexed 2-hydroxyacetophenone or methyl substituted 2-hydroxyacetophenone. Nitration reactions in case of mixed ligand complexes confirm the structure.

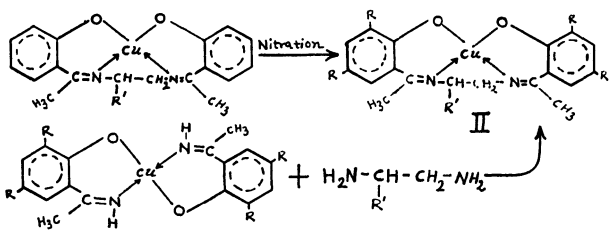
Nitration of metal salicylaldehyde and metal acetylacetonates using different nitrating agents such as N_2O_4, a mixture of copper nitrate, beryllium nitrate in acetic anhydride[1-3] or $N_2O_4 \cdot BF_3$[4] has been reported earlier. This paper describes the substitution of nitro groups in Schiff base present in binary and ternary Cu(II) complexes. The mild nitrating agent, acetyl nitrate used in the present reactions is formed *in situ* by the reaction of copper nitrate with acetic anhydride. This mild reagent has been used for many nitration reactions and in the case of coordinated ligands the reagent seems to have many advantages over other strong nitrating agents such as N_2O_4, HNO_3, and H_2SO_4 which cause decomposition of the Schiff base complexes. The mechanism of electrophilic substitution over a benzene ring in a coordinated ligand has been reported by Singh *et al.*[2]

In the present investigation nitrated compounds have been prepared by direct substitution of nitro groups, into the appropriate unsubstituted Schiff base complexes. These derivatives were characterized by comparison with authentic samples obtained by complexing appropriate nitrated 2-hydroxyacetophenone or methyl substituted 2-hydroxyacetophenone.



I

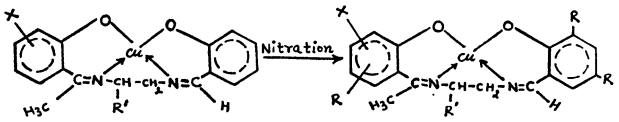
X=H or 4-CH_3, R=3-NO_2 and 5-NO_2
X=3-CH_3 or 5-CH_3, R=5-NO_2 or 3-NO_2



II

R=3-NO_2 and 5-NO_2
R'=H or -CH_3

The nitration reactions were further extended to the mixed Schiff base complexes reported by us earlier.[5] The reaction can be shown as follows:



III

X=H or 4-CH_3, R=3-NO_2 and 5-NO_2
X=3-CH_3 or 5-CH_3, R=5-NO_2 or 3-NO_2
R'=H or -CH_3

Experimental

Material Used. Bis[1-(2-hydroxyphenyl)ethylideneamine or its methyl derivative]Cu(II), *N,N'*-ethylene or propylene bis[1-(2-hydroxyphenyl)ethylideneaminato]Cu(II) and mixed ligand *N,N'*-ethylene or propylene [salicylideneaminato, 1-(2-hydroxyphenyl)ethylideneaminato or its methyl derivative]Cu(II) were prepared as reported earlier.[5,6] Acetic anhydride (BDH), cupric nitrate trihydrate (Riedell, pure, Germany), and sodium acetate crystal (Pfiezer) were used. Ethanol was of analytical grade.

Method and Apparatus. The magnetic susceptibilities of the Cu(II) complexes were determined at room temperature by the Gouy method using $Hg[Co(NCS)_4]$ as a calibrant. TLC was carried out for most of the complexes. Infrared spectra in KBr disc were recorded on a Perkin Elmer model 427 infrared grating spectrophotometer in the range 4000—625 cm^{-1}. The reflectance spectra of the complexes have been taken on a DU2 Beckman Spectrophotometer.

Synthesis of bis[1-(2-hydroxy-3,5-dinitrophenyl)ethylideneamine]Cu(II), bis[1-(2-hydroxy-3,5-dinitro-*p*-tolyl)ethylideneamine]Cu(II), bis[1-(6-hydroxy-5-nitro-*m*-tolyl)ethylideneamine]Cu(II), bis[1-(2-hydroxy-5-nitro-*m*-tolyl)ethylideneamine]Cu(II), *N,N'*-ethylene or propylene bis[1-(2-hydroxy-3,5-dinitrophenyl)ethylideneaminato]Cu(II), *i.e.*, I and II R=3-NO_2 and 5-NO_2, R'=H or $-CH_3$, X=H, 3-CH_3, 4-CH_3, or 5-CH_3. 0.5 g of bis[1-(2-hydroxyphenyl)ethylideneamine or its methyl derivative]Cu(II) or *N,N'*-ethylene or propylene bis[1-(2-hydroxyphenyl)ethyleneaminato]Cu(II) Schiff base and acetic anhydride (14 ml) were taken in a 250 ml conical flask fitted with a calcium chloride drying tube and stirred magnetically over an ice bath for half an hour. Powedred $Cu(NO_3) \cdot 3H_2O$ (0.82 g) was added in small portions over a period of 30 min. The ice bath was removed after 4 h but the stirring was continued for additional 4 h. The resulting green substance was decomposed by pouring into 150 ml of ice-cold water containing sufficient amount of sodium acetate and stirring for 2 h. The precipi-

tate thus obtained was filtered, washed with water, then with ethanol.

The above bis complexes were also prepared by direct treatment of tetra ammine Cu(II) salt with nitrated 2-hydroxyacetophenone or its methyl derivatives. 2-Hydroxy-3,5-dinitroacetophenone, 2 - hydroxy - 5 - methyl - 3 - nitroacetophenone, 2-hydroxy-3-methyl-5-nitroacetophenone were prepared as described in the literature.[7] These nitrated 2-hydroxyacetophenone were converted into above shown Cu(II) Schiff base complexes by treating Cu–ammine solutions with 2 moles of appropriate ethanolic solutions of nitrated 2-hydroxyacetophenone or its methyl derivatives. The mixture was refluxed for half an hour. The precipitate thus obtained was filtered, washed with water, then with ethanol.

The above nitrated ethylideneamine and propylenediamine complexes were also prepared by direct treatment of nitrated imine Schiff base complex with ethylenediamine or propylenediamine.

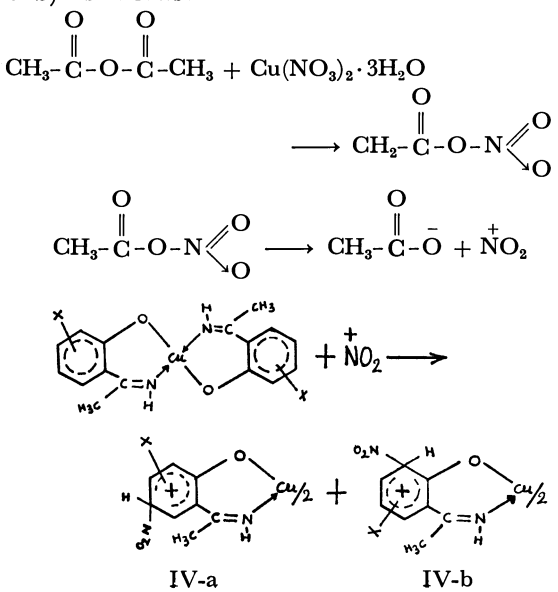
Synthesis of mixed *N,N'*-ethylene or propylene[3,5-dinitrosalicylideneaminato, 1-(2-hydroxy-3,5-dinitro-*p*-tolyl) or (2-hydroxy-3,5-dinitrophenyl)ethylideneaminato]Cu(II), *N,N'*-ethylene or propylene[3,5-dinitro salicylideneaminato, 1-(2-hydroxy-5-nitro-*m*-tolyl)ethyleneaminato]Cu(II) and *N,N'*-ethylene or propylene[3,5-dinitro salicylideneaminato, 1-(6-hydroxy-5-nitro-*m*-tolyl)ethyleneaminato]Cu(II), *i.e.*, III R= 3-NO_2 and 5-NO_2, R'=H or $-CH_3$ and X=H, 3-CH_3, 4-CH_3 or 5-CH_3. The procedure is the same as that for binary Schiff base complexes.

Analysis. Cu(II) in the complexes was analyzed iodometrically, after the complexes had been decomposed in nitric acid. Carbon, hydrogen, and nitrogen were determined by the micro analytical method. The analytical data are given in Table 1.

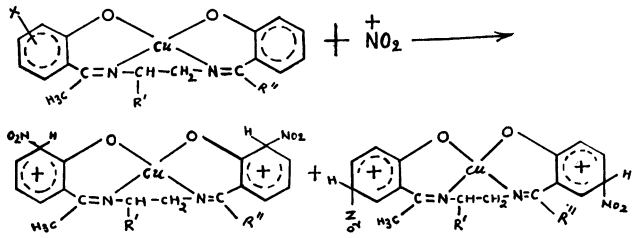
The solubilities of nitrated binary and mixed Schiff base complexes of Cu(II) in organic solvents are very low. TLC of all the compounds have been carried out on silica gel G(Sichem) using chloroform: acetone (6 : 4) mixture as the solvent. Only one dot is obtained for dinitro and mononitro complexes indicating that the complex formed is a single compound.

Results and Discussion

In these reactions the nitronium ions produced from the acetyl nitrate act as electrophile to form two stable σ-complex intermediates (IV-a and b) (V-a and b) as follows:



IV-a IV-b



V-a V-b

X=H, 3-CH_3, 4-CH_3 or 5-CH_3 R'=R''=H or -CH_3

The proton is removed from each of these intermediates and the dinitro chelates further react with the NO^+_2 ion in the same manner resulting in the formation of the di-, tri, or tetranitro compounds I, II, or III. In the case of 3-methyl and 5-methyl substituted binary imine complexes, however, only mononitro complexes were formed, one of the positions 3 or 5 being already occupied by the methyl group. This shows that the nitration reaction takes place over benzene ring at positions 3 and 5 rather than positions 4 and 6. This is due to *ortho*, *para* orienting effect of phenolic O and *meta* directing effect of –C=N–. Thus the orientation of incoming substitutions in the binary Schiff base complexes is found to be the same as that for the uncomplexed 2-hydroxyacetophenone or methyl substituted 2-hydroxyacetophenone. The nitration reaction, however, requires a long time of refluxing. This shows that the electrophilic substitution reaction is retarded on the coordination of the ligand with the metal.

The analysis, magnetic moments and spectral properties of the above binary nitrated complexes and the corresponding binary complexes obtained by the reaction of metal with nitrated Schiff base are found to be similar.

In the case of complexes of ethylenediamine Schiff base coordinated at two ends with 2-hydroxy-4-methyl- or 2-hydroxyacetophenone and salicylaldehyde, tetranitro complexes were formed. Both salicylaldehyde and 2-hydroxy-4-methyl or 2-hydroxyacetophenone get nitrated at positions 3 and 5. In the case of diamine Schiff base, complexes of 2-hydroxy-3-methyl or 5-methyl acetophenone and salicylaldehyde trinitrated complexes were formed, since salicylaldehyde gets nitrated at positions 3 and 5 while 2-hydroxy-3-methyl and 5-methyl acetophenone gets nitrated only at positions 5 and 3, respectively, the other position being already occupied by the methyl group.

TLC shows only one dot indicating that nitro compounds are single compounds. This confirms the proposed structure[5] for these new Schiff base complexes with ethylenediamine condensed at two ends with aldehyde and ketone.

All nitrated Cu(II) Schiff base complexes are paramagnetic (μ=1.8 to 2.0 B.M.) indicating the presence of one unpaired electron. There is no change in the paramagnetic value of nitrated compounds of Cu(II) Schiff base complexes from those without nitro substitution. The reflectance spectra of nitrated compounds exhibit one broad band at ≈550 nm as expected for a square planar structure. This shows that the

square planar structure of the complex is retained even after the substitution of the nitro groups.

The IR spectra of the nitrated compounds show bands similar to those of unsubstituted Schiff base complexes.[5,6] However, there is a broadening in the bands showing the presence of nitro groups. The IR spectra of the nitro compounds obtained by the two methods are also almost superimposable indicating that the complexes are identical. Nitration of the coordinated ketone and aldehyde is thus confirmed.

Thanks are due to Prof. S. M. Sethna, Head, Department of Chemistry, M. S. University, Baroda, for providing necessary laboratory facilities.

Sound Velocity in Aqueous Solutions of Ammonium Halides

Harumi Endo* and Otohiko Nomoto**

Department of Applied Physics, National Defense Academy, Yokosuka 239

(Received June 25, 1975)

The sound velocity in water aqueous solutions increases with increasing temperature and reaches the maximum velocity (V_p) at a peak temperature (T_p). In the present paper, the concentration dependence of T_p and V_p in ammonium halides are reported. It was found empirically that the relationship between the hydration number and the slope ($\Delta T_p/\mu$) of T_p at infinite dilution for many electrolytes is linear, but that for ammonium halides this is not the case.

The sound velocity in water increases with increasing temperatures and reaches a maximum velocity (V_p) at 74 °C, while the adiabatic compressibility of water has a minimum at 64 °C. This temperature for V_p is termed the peak temperature (T_p) of water. This behavior is characteristic of water and aqueous solutions. It is known that water is an associated liquid exhibiting structural equilibrium. The origin of the maximum velocity in water can be explained on the basis of a decrease in the structural compressibility and an increase in the instantaneous compressibility with increase in temperature.

When substances are dissolved in water, the values of T_p and V_p for the solutions shift from those of pure water, since the structural equilibrium of water is also affected by the solutes. Therefore, it is possible to study the effects of solutes on the water structure on the basis of the shifts of T_p and V_p from the values for pure water.

For aqueous solutions of electrolytes, the concentration dependences of T_p have been reported by many investigators.[1-6] In the case of solutions of NH_4I,[6] a unique behavior of the concentration dependence of T_p was observed, in which the temperature remained nearly constant up to about 4.5 mol %, and then decreased more and more sharply with increase in concentration. While the V_p in aqueous solutions usually increases as compared with that in pure water, it decreases in some cases, such as in solutions of $Pb(NO_3)_2$ and NH_4I.

In the present paper, measurements on NH_4Br and NH_4Cl solutions are extended.

Experimental

Apparatus. A crystal-controlled ultrasonic interferometer operating at a frequency of 5 MHz is used to measure the wavelength of standing waves. The measuring cell containing a solution is immersed in an oil bath controlled to within ±0.1 °C at moderate temperatures and to within ±0.4 °C at higher temperatures. To determine the wavelength one hundred standing waves are used. While the accuracy of the wavelength measurement is ±0.006%, the dominant cause of error in the sound velocity measurements is the temerature fluctuation. So the overall accuracy of the velocity measurements is about ±0.02%.

Materials. NH_4Cl, NH_4Br, and $(NH_4)_2SO_4$ were purified by recrystallization of reagent grade products from water.

Results and Discussion

In Figs. 1 and 2, the sound velocities (V) for NH_4Cl and NH_4Br are respectively plotted against the concentration (μ: mol %) over the temperature (T) range from 20—100 °C at 5 °C intervals. In order to compare

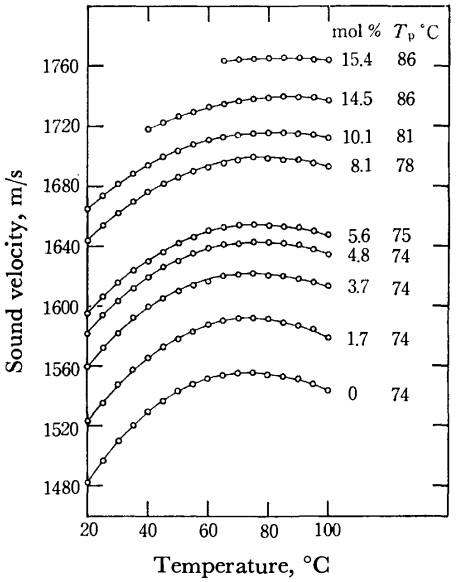

Fig. 1. Sound velocity *vs.* temperature in ammonium chloride aqueous solutions at various concentrations.

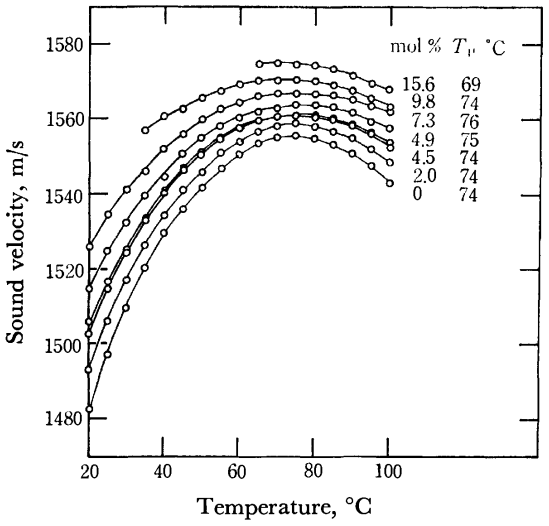

Fig. 2. Sound velocity *vs.* temperature in ammonium bromide aqueous solutions at various concentrations.

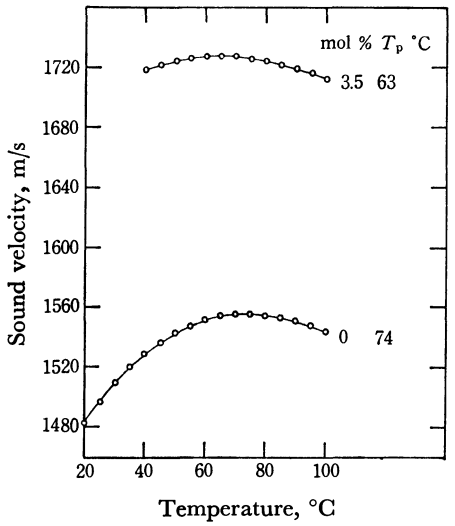

Fig. 3. Sound velocity *vs.* temperature in ammonium sulfate aqueous solutions at various concentrations.

with ammonium halides (NH_4X), the sound velocity in an $(NH_4)_2SO_4$ aqueous solution at 3.5 mol % was measured. These results are shown in Fig. 3.

In all cases of ionic or nonionic aqueous solutions, the $V(T)$-curves are of parabolic type like that of pure water. Except for solutions at high concentrations, the $V(T)$-curves are, within the limits of experimental error, the same as a displaced curve for water. Therefore, the template of curve for water was used to fix the T_p of the solutions, while the V_p in the solutions were also determined at the same time from the smoothed curve of the template. The accuracies of the T_p and V_p values at lower concentrations were within ± 1.5 °C and ± 1 m/s, respectively. For solutions at high concentrations, the T_p of solutions was successively determined from the smoothed curve for a lower concentration which was previously determined, starting from the template of the curve for water. The accuracies of the T_p and V_p values at high concentrations were within ± 2.0 °C and ± 1 m/s, respectively. Figures 4 and 5 show, respectively, the V_p and T_p values as functions of concentration for aqueous solutions of NH_4X together with other electrolytes.[6] The values of V_p in electrolytes usually increase with increasing concentration, but there are some exceptions such as NH_4I, $Pb(NO_3)_2$, *etc.*[7] These electrolytes have a heavy ion in the molecule. On the other hand, the values of T_p usually decrease, although there are some rare exceptional cases, with increasing concentration. The results obtained from Figs. 4 and 5 indicate that the slopes ($\Delta V_p/\mu$ and $\Delta T_p/\mu$) at infinite dilution are nearly constant.

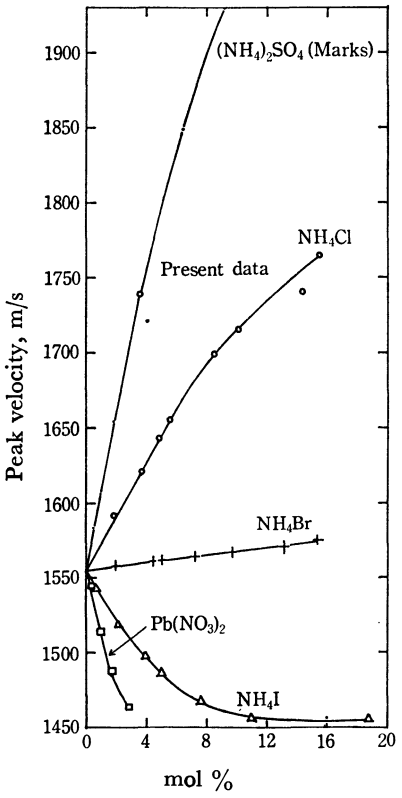

Fig. 4. Peak velocity *vs.* concentration for various solutes.

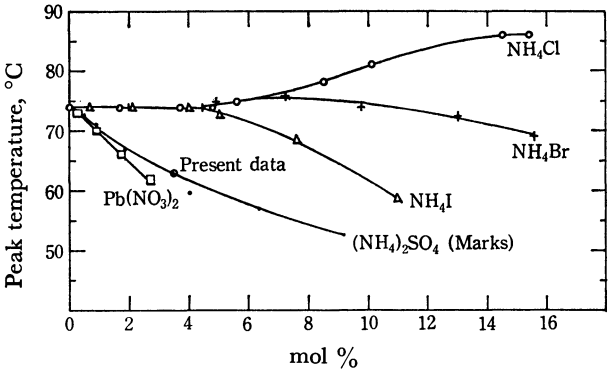

Fig. 5. Peak temperature *vs.* concentration for various solutes.

As can be seen in Fig. 5, the discrepancy between NH_4X and the other electrolytes is evident. First the T_p of NH_4X aqueous solutions are approximately constant to *ca.* 4.5 mol % regardless of the kind of anion,

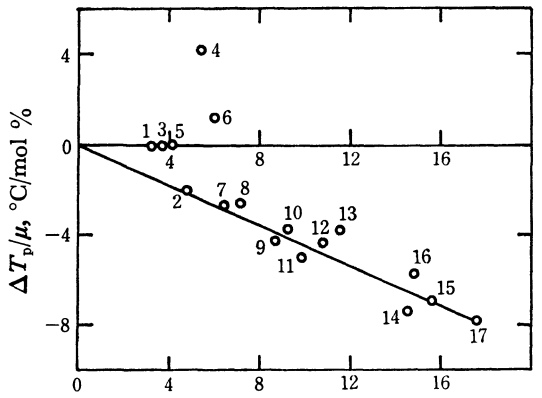

Fig. 6. $\Delta T_p/\mu$ *vs.* h for various electrolytes.
1: NH_4I, 2: LiI, 3: NH_4Br, 4: LiBr, 5: NH_4Cl, 6: LiCl, 7: KCl, 8: NaCl, 9: LiOH, 10: KOH, 11: NaOH, 12: $Pb(NO_3)_2$, 13: $(NH_4)_2SO_4$, 14: Li_2SO_4, 15: K_2SO_4, 16: $MgSO_4$, 17: Na_2SO_4.

and secondary, the behaviors of T_p (μ)-curves at higher concentrations beyond *ca.* 4.5 mol % are quite different depending on the anions. On the other hand, the T_p of $(NH_4)_2SO_4$ solutions monotonical decreases with increasing concentration as in many other electrolytes.

The values of $\Delta V_p/\mu$ and $\Delta T_p/\mu$ for various electrolytes[3-6] are summarized in Table 1 together with the hydration number[8] (h) of the solutes at 25 °C. Although there are many methods[9] for determining the hydration number, the values of the hydration numbers used here are the results of acoustical measurements obtained on the basis of Passynski's assumption.[10] Since it is necessary to investigate the relationship between h and $\Delta T_p/\mu$, in Fig. 6 $\Delta T_p/\mu$ is plotted against h for various electrolytes. A large part of them, except for NH_4X, are gathered about the straight line: $\Delta T_p/\mu = -0.44\,h$.

Kinetics of Oxidation of α-Hydroxy Acids by Ceric Sulfate

K. C. TEWARI, H. N. SINGH, and V. S. SINGH
Department of Chemistry, Aligarh Muslim University, Aligarh, India
(Received November 7, 1975)

The mechanism of the oxidation of α-hydroxy acids by ceric sulfate in sulfuric acid medium has been re-examined in the temperature range 15—30 °C and the thermodynamic parameters have been calculated. The role of HSO_4^- ion as an active inhibitor has been discussed quantitatively.

Kinetics of the oxidation of α-hydroxy acids with ceric sulfate as oxidant has been the subject of several recent studies.[1-8] The mechanism of oxidation in presence of moderate sulfuric acid concentration, in general, involves a rapid formation of an activated complex between the hydroxy acid and the metal species which then decomposes slowly to yield organic radical and reduced metal ion. However, the present work on the oxidation of lactic, DL-malic, and mandelic acid by ceric sulfate was undertaken to re-examine the conflicting claims on the assumption of reactive species of cerium by different authors,[1,4,5] the effect of sulfuric acid on the reaction rate, particularly the role of HSO_4^- ion as an active inhibitor and to furnish further information on the little known temperature dependence of ceric oxidation.

Experimental

The materials used were of the highest purity available (AnalaR or E. Merck's Guaranteed Reagents).

A solution[9] of ceric sulfate in 1: 1 v/v sulfuric acid was diluted and standardized by titration against ferrous ammonium sulfate, *N*-phenylanthranilic acid being used as an indicator. The sulfuric acid contents were determined by the method reported by McAuley.[5] The solutions of organic acids were standardized by titration against sodium hydroxide. The progress of the reaction was followed as for the reaction between ceric ion and thallous ion.[10] The stoichiometry of the reaction was determined by allowing the reaction mixtures containing large excess of Ce(IV) to stand for several days in a thermostat-bath at 25 °C. The excess of Ce(IV) was then estimated by titration against ferrous ammonium sulfate. An average of five determinations in each case showed that one mol of mandelic, DL-malic, and lactic acid requires 2.0, 8.5, and 5.75 mol, respectively, of ceric ion.

Results

Our kinetic result on the oxidation of α-hydroxy acids by ceric sulfate, in presence of sulfuric acid of moderate concentration, are in agreement with that reported by Krishna and Tewari.[1] The concentration range 0.5—3.0 N of sulfuric acid is referred to as moderate concentration. The reaction is of simple kinetic order if the molar concentration of ceric sulfate is not greater than that of the hydroxy acid. The rate studies were made at temperatures 15—30 °C, in moderate sulfuric acid medium and found to be of first order with respect to each reactant. The second order rate constant, k_2, was derived from the plot of log $[(a-x)/(b-x/y)]$ against time t, where a and b are the initial concentrations of the reactants, x is the amount of ceric sulfate consumed after time t and y is the moles of ceric sulfate required for complete oxidation of one mole of the hydroxy acid.

The reaction rate depends inversely on the square of concentration of sulfuric acid present. Sulfuric acid was varied in the concentration range 0.5—3.0 N.

TABLE 1. VARIATION OF REACTION RATE WITH TEMPERATURE
$[Ce(SO_4)_2] = 1 \times 10^{-2}$ M
[Hydroxy acid] $= 1 \times 10^{-2}$ M

Hydroxy acid	$[H_2SO_4]$ M	Temperature °C	$k_2 \times 10^3$ 1 mol^{-1} s^{-1}
Lactic	0.6	20.0	3.23
		23.0	4.53
		25.0	5.69
		27.5	8.15

		20.0	56.46
		25.0	96.26
		30.0	166.02

TABLE 2. THERMODYNAMIC PARAMETERS FOR CERIC OXIDATION AT 25 °C

Hydroxy acid	$[H_2SO_4]$ M	Frequency factor $\times 10^{-14}$ 1 mol^{-1} s^{-1}	Activation energy kcal mol^{-1}	ΔH^* kcal mol^{-1}	ΔF^* kcal mol^{-1}	ΔS^* e.u.	Ref.
Lactic	0.6	0.62	21.8	21.21	20.52	2.0	
	1.0	1.19	22.7	22.11	21.43	2.3	
DL-Malic	1.0	1.03	21.6	21.00	20.98	0.1	
Mandelic	2.0	0.11	19.1	18.51	18.31	0.7	
	1.0	0.18	18.9	18.30	18.40	−0.3	6
Glycollic	1.0	0.36	23.2	22.61	22.18	1.4	5

Addition of nitric or hydrochloric acid in small amounts produces only insignificant retardation. However, hydrogen sulfate and sulfate ions produce a marked retardation. Addition of potassium chloride or nitrate produces negative salt effect while thorium nitrate increases the reaction rate.

The dependence of the rate with temperature for lactic, DL-malic and mandelic acid is shown in Table 1. The values of the activation energy were calculated from the slope of the straight line obtained by plotting log k_2 against $1/T$. The calculated thermodynamic parameters are given in Table 2.

Discussion

Ceric sulfate in aqueous sulfuric acid medium is known to exist[11-14] in variety of complex ions. The composition of these solutions, in general, is governed by the following equilibria:

$$Ce(SO_4)_2 \rightleftharpoons Ce(SO_4)^{2+} + SO_4^{2-}$$
$$Ce(SO_4)_2 + SO_4^{2-} \rightleftharpoons Ce(SO_4)_3^{2-}$$
$$Ce(SO_4)_2 + HSO_4^- \rightleftharpoons HCe(SO_4)_3^-$$
$$\rightleftharpoons Ce(SO_4)_3^{2-} + H^+$$
$$HCe(SO_4)_3^- + HSO_4^- \rightleftharpoons H_2Ce(SO_4)_4^{2-}$$
$$\rightleftharpoons Ce(SO_4)_4^{4-} + 2H^+$$

$Ce(SO_4)_2$, $HCe(SO_4)_3^-$, and $Ce(SO_4)^{2+}$ have been postulated as the reactive species by different authors[1,4,5] in the oxidation of α-hydroxy acids by ceric sulfate in a moderate sulfuric acid medium. From the equilibrium constants of Hardwick and Robertson,[14] for the formation of various ceric sulfate species, the concentration of various species at different $[HSO_4^-]$ and at constant acidity can be estimated. The results along with the observed dependence of the reaction rate on sulfuric acid concentration indicate $Ce(SO_4)_2$ and $Ce(SO_4)^{2+}$ are the possible reactive species. In the presence of moderate sulfuric acid, the experimental results could best be explained by assuming $Ce(SO_4)_2$ as the dominant reactive species as postulated by Krishna and Tewari.[1] At high acid concentration the reaction rate depends inversely on the square of concentration of sulfuric acid present. McAuley[5] has discussed the influence of $[HSO_4^-]$ on the reaction velocity over a smaller concentration range and found that the linear relationship deviates markedly at higher pH values. Possible existence of the reactive ions of the type $Ce(SO_4)^{2+}$ could not be ruled out[14] in a narrower concentration range.

In a solution containing a moderate amount of sulfuric acid and small amount of ceric sulfate, the concentration of HSO_4^- ion would be practically equal to the concentration of sulfuric acid taken. Sulfuric acid dissociates in the following stages

$$(a)\ H_2SO_4 \rightleftharpoons H^+ + HSO_4^-$$
$$(b)\ HSO_4^- \overset{K}{\rightleftharpoons} H^+ + SO_4^{2-}$$

In the first stage the dissociation is cent percent while in the second stage the dissociation is determined by the magnitude of K which is equal to 0.01 at zero ionic strength and 0.075 at an ionic strength of one unit.[15] At higher ionic strengths the equilibrium constant will be the same but the equilibrium quotient of the second stage, *i.e.*$(C_{H^+}C_{SO_4^{2-}}/C_{HSO_4^-})$ will be slightly greater. In any case the dissociation in the second stage will be limited and the concentration of HSO_4^- ion will be equal to the initial concentration of sulfuric acid taken. The active ceric complex species which reacts in the rate determining step is $Ce(SO_4)_2$ formed from the following reaction steps which occur rapidly in succession.

$$(c)\ H_2Ce(SO_4)_4^{2-} \rightleftharpoons HCe(SO_4)_3^- + HSO_4^-$$
$$(d)\ HCe(SO_4)_3^- \rightleftharpoons Ce(SO_4)_2 + HSO_4^-$$

The scheme completely explains the inhibitory action of sulfuric acid and also the proportionality of the reaction rate to the ceric salt concentration. The assumption that most of the ceric salt in the presence of moderate concentration of sulfuric acid exists in the form $H_2Ce(SO_4)_4^{2-}$ in which hydrogen is tightly bound also explains why hydrogen ions from an external source, *i.e.* other than sulfuric acid, do not perceptibly affect the velocity of the reaction. This leads to the conclusion that HSO_4^- ion is the effective retarding agent. In the presence of a moderate sulfuric acid concentration the hydrogen ions added in small quantities, equilibrium (b) will shift very little from right to left and addition of hydrogen ion upto 0.1 M will be hardly perceptible. On the other hand, even a small quantity of SO_4^{2-} ion as will be available from K_2SO_4 up to 0.1 M due to the second dissociation of K_2SO_4 will produce a perceptible change in equilibrium from right to left with the consequent formation of HSO_4^- ions resulting in an appreciable inhibition of the reaction velocity. The observed lowering of reaction rate due to the addition of potassium sulfate could therefore be attributed partly to the increase in the ionic strength and partly to the dissociation in the following two stages.[16]

$$(e)\ K_2SO_4 \longrightarrow K^+ + KSO_4^-$$
$$(f)\ KSO_4^- \rightleftharpoons K^+ + SO_4^{2-}$$

The dissociation constant for the second stage is 0.151. Addition of K_2SO_4 to a solution of sulfuric acid will produce more of HSO_4^- ion due to the reaction

$$SO_4^{2-} + H^+ \rightleftharpoons HSO_4^-$$

causing the observed retardation in the reaction velocity. Another reason for retardation in velocity could be that only a small part of KSO_4^- formed gives rise to SO_4^{2-} ions and the rest remains undissociated and very likely forms a complex with $Ce(SO_4)_2$ according to the following reaction

$$(g)\ Ce(SO_4)_2 + 2KSO_4^- \rightleftharpoons K_2Ce(SO_4)_4^{2-}$$

thus reducing the active species. A similar reasoning could be given for the inhibitory action of $(NH_4)_2SO_4$.

The main inhibitory role of HSO_4^- ion can be examined quantitatively on the following consideration. In a solution containing sulfuric acid the increment in HSO_4^- will be equal to the concentration of $KHSO_4$ added. Since the velocity constant is inversely proportional to the square of the concentration of sulfuric acid, we may write

$$k_2 \propto \frac{1}{[H_2SO_4]^2}$$

or

$$k_2 \propto \frac{1}{[HSO_4^-]^2} = \frac{b}{[HSO_4^-]^2} \quad (1)$$

where b is the proportionality constant. Differentiating with respect to $[HSO_4^-]$ and rearranging, we obtain

$$-[HSO_4^-]^3 \frac{dk_2}{d[HSO_4^-]} = 2b = \text{constant} \quad (2)$$

Since the amount of $KHSO_4$ added is small in comparison to the total concentration of H_2SO_4 already present, we can make the approximations

$$d[HSO_4^-] \approx \Delta[HSO_4^-] = \Delta[KHSO_4]$$

$$dk_2 \approx \Delta k_2$$

therefore,

$$-[HSO_4^-]^3 \frac{\Delta k_2}{\Delta[HSO_4^-]} = \text{constant}$$

or

$$-[H_2SO_4]^3 \frac{\Delta k_2}{\Delta[KHSO_4]} = \text{constant} \quad (3)$$

where $[H_2SO_4]^3$ is the cube of the average concentration of H_2SO_4 initially taken, plus the concentration of $KHSO_4$ added, *i.e.* the average of the concentration of HSO_4^- ion between which Δk_2 is measured. The validity of Eq. 3 is shown in Table 3. The data both for mandelic and DL-malic acid have been taken from the oxidation studies reported by Krishna and Tewari.[1]

Table 3. Inhibitory effect of HSO_4^- ion[a]

Hydroxy acid	$[H_2SO_4]$ M	$[KHSO_4]$ M	Δk_2	$-[H_2SO_4]^3 \cdot \Delta k_2/\Delta[KHSO_4]$
Mandelic	1.01	0.02	−0.245	12.61
	1.02	0.04	−0.426	11.30
	1.04	0.08	−0.920	12.93
	1.05	0.10	−1.091	12.63
DL-Malic	0.400	0.05	−0.379	0.486
	0.425	0.10	−0.588	0.456
	0.450	0.15	−0.800	0.486

a) Data taken from Ref. 1.

We see from Table 3 that the values in the last column are practically constant. This justifies the assumption that the main inhibitory ion is HSO_4^-.

The small negative salt effect observed by the addition of potassium chloride or nitrate follows no mathematical regularity and is hard to visualize in the presence of high ionic strength. The observed increase in the reaction velocity due to the addition of thorium nitrate may be due to some kind of complex formation between thorium and any one of the reactants.

A comparison of the values of different thermodynamic parameters (Table 2) for the oxidation of different hydroxy acids by ceric sulfate in presence of moderate sulfuric acid medium suggests a common mechanism,[17] *viz.*, a rapid formation of an activated complex between Ce(IV) and organic acid and subsequent slow decomposition into organic radical.

A Comparative Study of Electrochemical Kinetic Parameters by the Potential Step Method. Electrode Reactions of CyDTA and EDTA Complexes of Cu(II) at DME

G. A. BHAT*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

(Received November 11, 1975)

By using the same current-time (*I-t*) curves, electrochemical kinetic parameters are determined by two methods, (a) using the ratio of current at a given potential to the diffusion-controlled limiting current and (b) curve fitting method, for the reduction of Cu(II)–CyDTA complex. The analysis by the method (a) shows that the rate determining step involves only one electron although the overall reduction of the complex involves two electrons suggesting thereby the stepwise reduction of the complex. The nature of *I-t* curves suggests the adsorption of intermediate species at the electrode surface. Under these circumstances more reliable kinetic parameters can be obtained by the method (a) compared to that of (b). Similar observations are found in the case of reduction of Cu(II)–EDTA complex.

The determination of electrochemical kinetic parameters of metal complexes by comparative methods is not found common. Particularly, such studies are lacking for the systems involving more than one electron in the reduction process. A comparative study of kinetic parameters of such systems by different methods of analysis could verify the reliability of the results obtained by each method and also throw some light on the mechanism of reduction of the complexes at the electrode interface. With this in view, kinetic parameters of two complexes, Cu(II)–*trans*-1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetic acid (Cu–CyDTA) and Cu–EDTA, were determined by the potential step method. Current-time (*I-t*) curves were analyzed by the two different methods: method (a) using the ratio of current at a given potential to the diffusion-controlled limiting current, and method (b) using the curve fitting procedure. The details of the methods employed were reported elsewhere.[1-3]

The basic equations relating the conditional rate constant, $k_c^{\ominus}$, with the rate constants for the oxidizing (k_{ox}) and reducing (k_{red}) reactions, $O+ne \rightleftharpoons R$, can be written as follows:

$$k_{red} = k_c^{\ominus} \exp\left[-\frac{\alpha_c nF}{RT}(E-E^{\circ\prime})\right] \quad (1)$$

$$k_{ox} = k_c^{\ominus} \exp\left[\frac{\alpha_a nF}{RT}(E-E^{\circ\prime})\right] \quad (2)$$

where α_c and α_a are cathodic and anodic transfer coefficients respectively, $E^{\circ\prime}$ is the conditional potential, and R, T, n, F have their usual meaning. These equations can be used to determine the kinetic parameters from the current-time relationship at each potential.

Experimental

Apparatus and Chemicals. The electronic potential step generator along with a timer for dislodging the mercury drop was constructed by using operational amplifiers. The cell was of conventional type. The working electrode was a slowly dropping mercury electrode the drop time and the rate flow of mercury being 18.0 s and 0.624 mg s^{-1} respectively, measured at the height of the mercury column of 42 cm. A spiral of bright platinum was used as the counter electrode. The solution was deaerated with pure nitrogen and was kept under nitrogen atmosphere throughout the experiment. The temperature of the solution was kept constant at 25±0.2 °C. All solutions were prepared in double distilled water and all chemicals used were of analytical grade.

Cu(II)–CyDTA complex was prepared by mixing equimolar solutions of $CuCl_2$ and disodium salt of CyDTA.[4] Cu(II)–EDTA complex was prepared by mixing equimolar solutions of $CuCl_2$ and disodium salt of EDTA.[5]

Method of Measurement. The initial potential for the Cu(II)–CyDTA system was fixed at −0.200 V *vs.* SCE. The potential was stepped up at 14 s after the mercury drop starts growing. The current-time curves were photographed on a Tektronix oscilloscope, Type 564, with a Type 2A63 differential amplifier and Type 2B67 time-base unit. The difference between each potential step-up in subsequent steps was of the order of 5 mV along the rising portion of the reduction wave and 25 mV on the limiting current plateau. Enlarged prints were used for calculating the current. The calculation was programmed on a SOBAX ICC-2700 calculator.

For the Cu(II)–EDTA system the initial potential was fixed at −0.130 V *vs.* SCE and the rest of the measurement was the same as in the case of the Cu(II)–CyDTA system.

The ohmic resistance of the system was about 50Ω, and the effect of the ohmic drop was neglected in the present analysis. The uncertainty of the electrode potential due to the ohmic drop was estimated to be of the order of several millivolts at potentials near $E^{\circ\prime}$. However, this uncertainty will not affect the following discussion on the kinetic parameters of the systems or on the mechanism of reduction of the complexes.

Results and Discussion

Electrode Reaction of Cu(II)–CyDTA System. Analysis by the Method (a)[1,3]: Under the conditions where the current corresponds to a large value of t ($t=t_\infty$), and the potential is sufficiently negative so as to satisfy the conditions, $Q\sqrt{t}>5$ and $k_{red} \gg k_{ox}$, the following relationships can be obtained**

* Research Fellow of the Japan Society for the Promotion of Science in the Inorganic Chemistry Laboratory, The Institute of Physical and Chemical Research, Wako-shi, Saitama 351, Japan.

** The symbols and terminology are according to IUPAC recommendations.[6]

$$\frac{I(t)I_d(t_\infty)}{I(t_\infty)I_d(t)} = \sqrt{\pi}Q\sqrt{t}\ \exp(Q^2t)\ \mathrm{erfc}\ (Q\sqrt{t}) \quad (3)$$

$$k_{red} = Q\frac{I(t_\infty)}{I_d(t_\infty)}\sqrt{D_0} \quad (4)$$

$$k_{ox} = Q\left[1-\frac{I(t_\infty)}{I_d(t_\infty)}\right]\sqrt{D_R} \quad (5)$$

where $I_d(t)$ and $I_d(t_\infty)$ are the currents at far negative potentials and Q is the parameter at a given electrode potential E at which $I(t)$ and $I(t_\infty)$ were measured. For this system, t=400 μs and t_∞=1.0 s were used. The currents $I(t)$ and $I(t_\infty)$ were measured at several potentials in the neighbourhood of $E^{o\prime}$. Also, the diffusion-controlled currents, $I_d(t)$ and $I_d(t_\infty)$, were measured at several potentials on the diffusion current plateau. These values were substituted into Eq. 3 to get Q. By using these Q-values k_{red} and k_{ox} were obtained from Eqs. 4 and 5 assuming $D_0=D_R=6.8\times10^{-6}$ cm^2 s^{-1}, estimated from the polarographic diffusion current by the Ilkovic equation.

Figure 1 gives the typical plots of log k_{red} and log k_{ox} *vs.* potential for one value of I_d measured at a potential on the diffusion current plateau. The conditional rate constant $k_c^\ominus$ was obtained from the intersection of two straight lines and α_c and α_a were obtained from the slopes. In a similar way, by using other values of I_d's several $k_c^\ominus$-values were obtained and were plotted

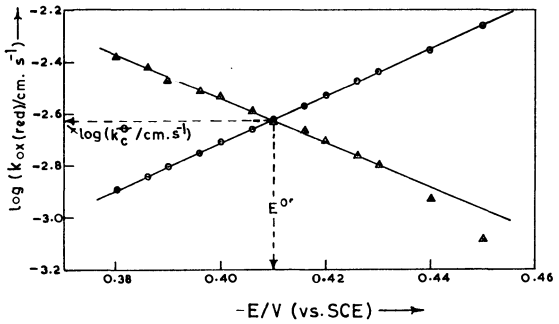

Fig. 1. Plots of log (k_{red}/cm s^{-1}) and log (k_{ox}/cm s^{-1}) *vs.* E; the rate constant obtained by the method (a) using diffusion-controlled limiting current. System: 6.0 mM Cu(II)–CyDTA complex in a 0.4 M KNO_3 solution containing 0.1 M acetate buffer and 3 μM polyoxyethylene lauryl ether (LEO).

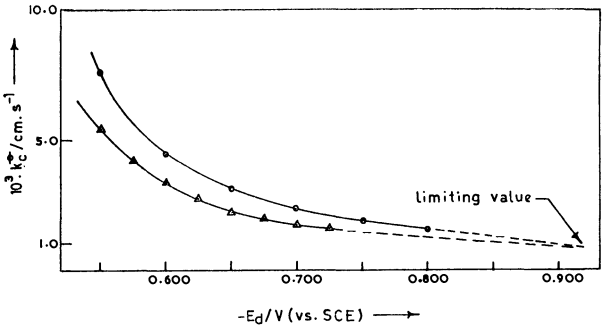

Fig. 2. Variation of $k_c^\ominus$ with potentials, E_d, at which I_d's are measured; analysis by the method (a). System: 4 mM (△) and 6 mM (○) Cu(II)–CyDTA in 0.4 M KNO_3 solutions containing 0.1 M acetate buffer and 3 μM LEO.

against the electrode potential, E_d, where the I_d-values were measured (Fig. 2).

It is obvious from Fig. 2 that the rate constant decreases as the potential becomes more and more negative and finally comes to a limiting value. However, at far negative potentials the distortion of *I-t* curves was noticed (broken lines in Fig. 2 correspond to the potentials where the distortion was observed). The curve, $k_c^\ominus$ *vs.* E_d, was extrapolated in this region to obtain the limiting value of $k_c^\ominus$ which is in reasonably good agreement with that obtained by other methods[7] (see, Table 1).

Table 1. Kinetic parameters obtained by different methods of analysis for Cu(II)–CyDTA and Cu(II)–EDTA complexes

System	Method	$n\alpha_c$	$n\alpha_a$	$k_c^\ominus\times10^3$ / cm s^{-1}
Cu(II)–CyDTA	Potential-step; method (a)	0.52	0.48	0.8
	Potential-step; method (b)	0.5	—	1.4
	Faradaic impedance method	—	—	0.63[a]
Cu(II)–EDTA	Potential-step; method (a)	0.53	0.48	1.7
	Potential-step; method[10]	0.54	0.46	4.0
	Faradaic impedance method	—	—	0.85[a]

a) To be published.

At all potentials of the I_d-measurement $n\alpha_c$ and $n\alpha_a$ obtained as slopes add up to one unlike in the case of Zn(II) system.[1] This suggests that the number of electrons involved in the rate determining step is only one although the overall reduction of the complex involves two electrons.[8] Therefore, the mechanism of reduction of the complex at DME can be written as follows.

$$\text{Cu(II)–CyDTA} + e \xrightarrow{\text{slow}} \text{Cu(I)–CyDTA}$$

$$\text{Cu(I)–CyDTA} + e \overset{\text{fast}}{\rightleftharpoons} \text{Cu}^o\text{(Hg)} + \text{CyDTA}$$

Analysis by the Curve Fitting Method (b)[1,2]: At any given potential the best values of $I(t=0)$ and Q were calculated by the trial-and-error method using Eq. 6:

$$I(t)/I(t=0) = \exp(Q^2t)\ \mathrm{erfc}\ (Q\sqrt{t}) \quad (6)$$

where

$$I(t=0) = -nFAk_{red}c_0 \quad (7)$$

$$Q = k_{red}/\sqrt{D_0} + k_{ox}/\sqrt{D_R} \quad (8)$$

By knowing the concentration c_o, of the complex, and surface area, A, of the mercury drop and by using Eq. 7, the values of k_{red} were calculated at several potentials in the neighborhood of $E^{o\prime}$ from the best values of $I(t=0)$, and were plotted against E. From the resulting straight line graph $k_c^\ominus$ was read at $E^{o\prime}$ obtained by the method (a). From the slope α_c was calculated. These values agree well with the values obtained by the method (a) (see Table 1). However, the values of k_{ox} obtained by using appropriate Q values employing expression (8) were found to be much higher than expected (of the order of 10^{-2} cm s^{-1}).

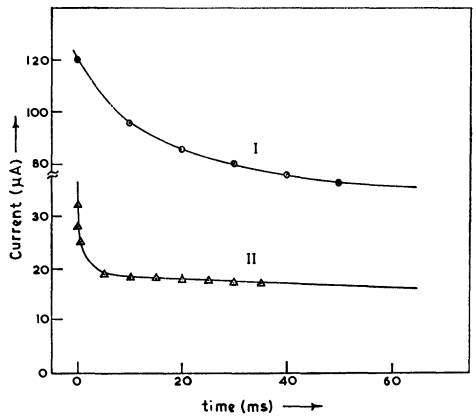

Fig. 3. (I) *I-t* curve for the reduction of zinc(II) at −0.994 V *vs.* SCE. 8.0 mM $Zn(NO_3)_2$ in a 0.5 M KNO_3 solution containing 0.2 mM HNO_3.
(II) *I-t* curve for the reduction of Cu(II)–CyDTA at −0.410 V *vs.* SCE. 6.0 mM Cu(II)–CyDTA in a 0.4 M KNO_3 solution containing 0.1 M acetate buffer and 3.0 μM LEO.

Figure 3 gives the *I-t* curves for the Cu(II)–CyDTA system and for the Zn(II) system near to their respective $E^{\circ\prime}$. A comparison of the *I-t* curves for these two systems shows that the decay of current with time is much faster in the case of the Cu–CyDTA complex than in the case of the Zn(II) system. According to Eqs. 6 and 7 the decay of current with time should be comparable for two systems if their conditional rate constants, α's and D's are comparable. However, in the above two cases their *I-t* curves are found to be quite different though their kinetic parameters are comparable. Because of this the curve fitting in the case of the Cu(II)–CyDTA system had to be carried out between 600 μs and 900 μs where exists a perceptible difference in the current with time. Such a behavior of the system is probably due to the adsorption of the short-lived intermediate species during reduction. This adsorption of intermediate species could act as a capacitance in parallel to the faradaic impedance and thereby shunts the latter to make the current decay more rapidly.[9]

Electrode Reaction of Cu(II)–EDTA System. Analysis by the Method (a): The procedure adopted in this case is the same as in the previous case. The two time limits chosen were, $t=350$ μs and $t_\infty=1.0$ s. The limiting value, $k_c^\ominus$, obtained by extrapolating $k_c^\ominus$ *vs.* E_d curve is given in Table 1. In this case also, the distortion of *I-t* curve was found at far negative potentials. The values of $n\alpha_c$ and $n\alpha_a$ add up to make one suggesting that the number of electrons involved in the rate determining step is one only. Therefore, the mechanism of the reduction process can be written as follows:

$$\text{Cu(II)-EDTA} + e \xrightarrow{\text{slow}} \text{Cu(I)-EDTA}$$

$$\text{Cu(I)-EDTA} + e \overset{\text{fast}}{\rightleftharpoons} \text{Cu}^{\circ}\text{(Hg)} + \text{EDTA}$$

The nature of *I-t* curves in this case, *i.e.*, the decay of current with time is similar to that of the Cu(II)–CyDTA system indicating the adsorption of intermediate species.

Conclusion. The reduction of Cu(II)–CyDTA and Cu(II)–EDTA complexes occurs at DME in two steps and each step involves one electron in the reduction process. When the reduction is further complicated by the adsorption of intermediate species the analysis of *I-t* curves by the curve fitting method introduces some uncertainty in the results. On the other hand, the analysis by the method (a) can be adopted to obtain more reliable kinetic parameters.

Studies with Parchment Supported Membranes. VII. Application of Fick's Diffusion Law and Nernst-Planck Formulae for Electrical Potential—Consideration of Membrane Field Strength and Energetics of Permeation of Cations

Fasih A. SIDDIQI, M. Nasim BEG, Abdul HAQUE, and Surendra P. SINGH

Division of Physical Chemistry, Department of Chemistry, Aligarh Muslim University, Aligarh, India

(Received December 8, 1975)

Electrolytic transport processes occurring across parchment supported membranes have been described by Nernst-Planck flux equation taking into account the membrane resistance R_m, membrane potential E_m *etc.* E_m values for various electrolytes display very interesting phenomena. In the case of 1:1 electrolyte the E_m values are all positive, while in the case of (2:1) and (3:1) electrolytes surface charge reversal takes place. The diffusion rate sequence and selectivity of the membrane for different uni-, bi-, and tri-valent cations was found to be primarily dependent on the difference in the hydration energies of counter ions in the external solution. On the basis of Eisenman-Sherry theory the diffusion rate sequence of alkali metal cations point towards the weak field strength of the fixed charge groups. Various thermodynamic parameters, $\Delta H^{\neq}$, $\Delta F^{\neq}$, and $\Delta S^{\neq}$ were evaluated by applying the theory of absolute reaction rates to the diffusion process through parchment supported membranes. The values of $\Delta S^{\neq}$ were found to be negative, indicating that diffusion takes place with partial immobilization in the membrane phase. The relative partial immobility was found to increase with increase in the valence of the ions constituting the electrolyte. A formal relation between $\Delta H_{hydration}$, $\Delta F_{hydration}$, and $\Delta S_{hydration}$ of cations with the corresponding values of $\Delta H^{\neq}$, $\Delta F^{\neq}$, and $\Delta S^{\neq}$ for diffusion, was also found to exist for these membranes.

Transport processes occuring across membranes are of great interest for biologists, who use them as simple models for physiological membranes in order to understand the behavior of complex cell membranes in terms of established physico-chemical principles. It was demonstrated by Teorell[1] that the gastric mucosal membrane, in some formal aspects at least, behaved exactly like parchment membrane. His findings, that electrolytic transport processes in stomach could be handled by something similar to Fick's diffusion law and that Nernst-Planck formulae for electrical potential were applicable, has encouraged us to proceed further with the studies of (a) the parchment supported membranes[2-9] and (b) the asymmetric polymeric membranes[10-14] which mimic some of the properties of nerve cells[15,16] as models for biological system.

This paper deals with the studies of diffusion rate of biologically important electrolytes through parchment supported membranes. The results are discussed in the light of Eisenman-Sherry field strength model[17-20] and the theory of absolute reaction rates.[21-23]

Experimental

The parchment supported membranes of (i) silver (ii) cadmium hexacyanoferrate(II) and (iii) barium phosphate were prepared by the method of interaction described by Siddiqi *et al.*[2-9] In order to precipitate these substances in the interstices of the parchment paper, 0.2 M solution of potassium hexacyanoferrate(II) was kept inside a glass tube to one end of which was tied the parchment paper. This was suspended for 72 h in a 0.2 M solution of silver nitrate or cadmium chloride (for hexacyanoferrate(II) membranes). The two solutions were interchanged later and kept for another 72 h. A similar procedure was adopted for the preparation of barium phosphate membrane by taking 0.5 M solutions of barium chloride and potassium di-hydrogen orthophosphate. The membranes thus prepared were washed with deionized water for removal of free electrolytes.

The apparatus and procedures used to measure membrane potential E_m, membrane resistance R_m, and electrolyte concentrations were described by siddiqi *et al.*[2] The membrane was held between two half cells, each containing 125 ml of the electrolyte solution. Initially the concentrations C_1 and C_2 were 0.001 and 0.1 M, respectively. Each of the half cell was fitted with two platinized platinum electrodes firmly fixed to follow concentration changes and two anion reversible Ag–AgCl electrodes-one a disc type to pass a small d. c. current and the other a J-shaped wire electrode placed 1.7 cm apart from the membrane surface to measure membrane potential (Pye precision potentiometer No. 7568) and changes in membrane potential following current flow. The solutions in both the half cells were kept well stirred by magnetic stirrers. The whole cell assembly was immersed in a water thermostat maintained at 10, 15, 20, 25, and 30 °C (±0.1 °C).

Conductance changes on the dilute solution side was followed by means of the conductivity bridge (Cambridge Instrument Co. England No L-350140). The exact concentration of the solution at any given time was estimated from a calibration curve. The membrane resistance was determined by applying an external emf to the disc-type Ag–AgCl electrodes and measuring the change in potential across the membrane using J-type wire electrodes. The current passed through the membrane system was determined by measuring IR drop across a precision kilo-ohm resistor. The current was kept very low in order to minimize the ion transfer during the period (2—3 min) required for each resistance measurement. The direction of current flow was reversed in each successive measurement. The resistance measurements gave a value for the system electrolyte solution (R_e')-Membrane (R_m)-electrolyte solution (R_e''). In order to measure R_m directly, the wire electrodes should be placed strictly on the membrane surfaces. When this was done, resistance values were not reproducible This procedure was therefore abondoned in favor of the former and corrections for the electrolyte resistances R_e' and R_e'' were applied to derive a value for R_m. Since the geometry of the system (area=24.6 cm^2 and the distance at which wire electrode was placed from the membrane face=1.7 cm) and the specific conductance of the electrolyte solutions were known accurately (better than 0.5%), the sum ($R_e'+R_e''$) can be computed easily. Thus R_m, the membrane resistance only, can be derived as the difference between the measured total resistance and the sum of the

calculated electrolyte resistances ($R_e'+R_e''$). Although the membrane potential could be measured to a better accuracy than $\pm 1\%$, the estimation of membrane resistance was accurate to $\pm 3\%$.

Results and Discussion

The transport phenomena are often described by some extended form of the Nernst-Planck flux equation.[24] Evaluation of flows requires integration of these flux equations under suitable boundary conditions governing the behavior of the membrane system. Some time ago, Kittelberger[25] from the simple laws of electrolysis, developed the equation

$$\frac{dQ_+}{dt} = \frac{1}{Z_+FR_m}\left[\frac{RT}{Z_+F}\ln\frac{a_2}{a_1} - E_m\right] \times\left[\left(\frac{Z_+Z_-}{Z_++Z_-}\right)\left(\frac{E_m}{\frac{RT}{F}\ln\frac{a_2}{a_1}}\right)+\frac{Z_+}{Z_++Z_-}\right] \quad (1)$$

where Q_+ is the milli-equivalents of cations diffusing in time t s, Z_+, Z_- are the valencies of cation and anion, respectively, R_m is the resistance in ohm of the membrane, E_m is the membrane potential in millivolts, a_1 and a_2 are the activities of the two electrolyte solutions on either side of the membrane, R, T, and F have their usual meanings to describe the rate of flow of a charged species or electrolyte through a membrane.

$$\frac{Z_+Z_-}{Z_++Z_-}\frac{E_m}{\frac{RT}{F}\ln\frac{a_2}{a_1}}+\frac{Z_+}{Z_++Z_-} \quad (2)$$

is the cation transport number expressed in terms of observed membrane potential E_m. The term

$$\frac{RT}{Z_+F}\ln\frac{a_2}{a_1} - E_m \quad (3)$$

is the effective potential acting on the ion.

The emf measured across the membrane using the J-type Ag–AgCl electrodes is made up of two components, the electrode potential difference E_e due to the Ag–AgCl electrodes existing in the two chloride solutions of different activity a_1 and a_2, and the membrane potential E_m arising across the membrane due to flow of electrolyte through it. E_e is given by the equation

$$E_e = \frac{RT}{Z-F}\ln\frac{C_2\nu_2}{C_1\nu_1} \quad (4)$$

where ν's are the activity coefficients of the electrolyte solutions. Since (E_e+E_m) is measured directly, E_m can be evaluated by substraction.

Changes in E_m and R_m with time are shown in Figs. 1 and 2 for various electrolytes diffusing through a cadmium hexacyanoferrate(II) membrane. At any given time, the membrane resistance R_m increases in the order; KCl, NaCl, LiCl, for electrolytes (1: 1), $CaCl_2$, $MgCl_2$, $BaCl_2$ for electrolytes (2: 1), and electrolyte (3: 1) $AlCl_3$ produces the highest value for R_m.

E_m values for the various electrolytes display a very interesting phenomenon. In the case of (1: 1) electrolytes, the values are all positive (dilute solution side C_1 taken as positive) indicating thereby that the membrane is cation selective. In the case of (2: 1) and (3: 1) electrolytes, E_m changes sign. This indicates that the

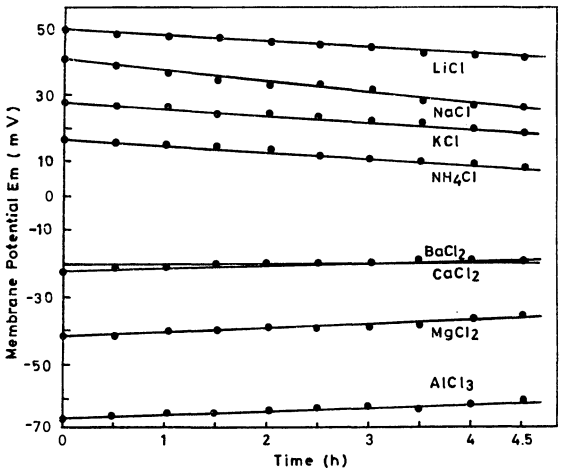

Fig. 1. Plots of membrane potential E_m against time for various electrolytes with cadmium hexacyanoferrate(II).

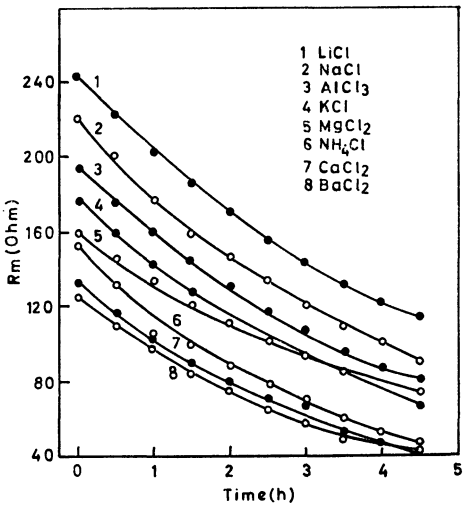

Fig. 2. Plots of R_m against time for various electrolytes with cadmium hexacyanoferrate(II).

membrane has become anion selective. The change in the selectivity character of the membrane is evidently due to adsorption of multivalent ions leading to a state where a net positive charge is left on the membrane surface taking it anion selective. Adsorption of Al^{3+} makes the membrane more anion selective than it is with the adsorption of other divalent cations. Such behavior seems to be observed with a number of other systems.[26–28]

The surface charge reversal occurred in every one of the membranes and electrolytes (2: 1) and (3: 1) and can be seen in the results given in Table 1 (a, b). E_m and R_m values are recorded.

With the help of Eq. 1, the rate at which various electrolytes diffuse through the membranes can be calculated. For electrolyte (1: 1), ($Z_+=Z_-=1$), Eq. 1 becomes

$$\frac{dQ_+}{dt} = \frac{dQ_-}{dt} = \frac{dQ}{dt} = \frac{1}{2FR_m}\left[59.16\log\frac{C_2\nu_2}{C_1\nu_1} - E_m\right] \times\left[\frac{E_m}{59.16\log\frac{C_2\nu_2}{C_1\nu_1}}+1\right] \quad (5)$$

For electrolyte (2: 1), ($Z_+=2$ and $Z_-=1$), it becomes

Table 1(a). Values of membrane potential E_m, membrane resistance R_m, and diffusion rate D_r at the end of 1/2 and 4 h periods at 25 °C[a)]

a) Area of membrane=24.6 cm^2.

$$\frac{dQ_+}{dt} = \frac{1}{2}\frac{dQ_-}{dt} = \frac{dQ}{dt} = \frac{1}{3FR_m}\left[29.58 \log \frac{C_2\nu_2}{C_1\nu_1} - E_m\right] \times \left[\frac{E_m}{59.16 \log \frac{C_2\nu_2}{C_1\nu_1}} + 1\right] \quad (6)$$

For electrolyte (3: 1), ($Z_+=3$ and $Z_-=1$), it becomes

$$\frac{dQ_+}{dt} = \frac{1}{3}\frac{dQ_-}{dt} = \frac{dQ}{dt} = \frac{1}{4FR_m}\left[19.72 \log \frac{C_2\nu_2}{C_1\nu_1} - E_m\right] \times \left[\frac{E_m}{59.16 \log \frac{C_2\nu_2}{C_1\nu_1}} + 1\right] \quad (7)$$

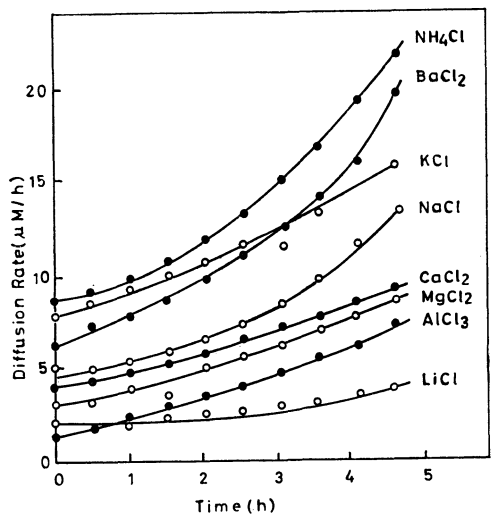

Fig. 3. Plots of diffusion rate *vs.* time through cadmium hexacyanoferrate(II).

The electrolyte fluxes dQ/dt *i.e.* D_r calculated from Eqs. 5—7 for various electrolytes at 25 °C are given in Table 1 for all the three membranes. The reproducibility of the results were within ±3% at a certain temperature. The changes in R_m, E_m, and D_r with time for cadmium hexacyanoferrate(II) membrane are shown in Figs. 1—3, while comparative values for various cations are given in Fig. 3a.

The diffusion rate derived from the electrometrically or conductometrically determined changes in the salt concentration of the test solution C_1 is called "observed diffusion rate," while the values computed from the measured concentration potential and electrolytic resistance of the membrane *i.e.* from Eqs. 5—7 is designated the "computed" diffusion rate. The "computed" and "observed" diffusion rates of KCl, NaCl, LiCl for barium phosphate membrane are shown in Fig. 4a. For

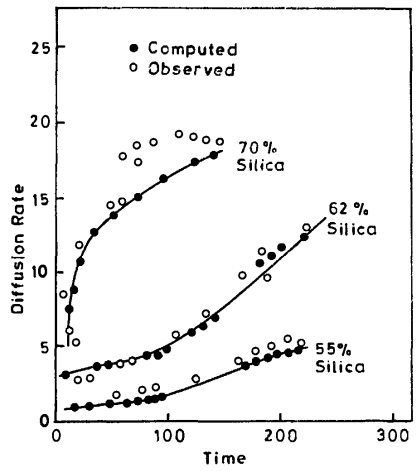

Fig. 4b. Plots of observed and computed diffusion rate against time for hydrochloric acid through polyvinyl butyral membrane.

the sake of comparison the rates of diffusion of hydrochloric acid through poly (vinyl butyral) membranes obtained by Kittelberger[25] are also given in Fig. 4b. Agreement is fair in both cases.

The diffusion of the electrolyte through the membrane is slower than in free solution. The order does not remain the same due to various reasons; (a) only a part of the frame work is available for free diffusion, (b) the diffusion paths in the membrane phase are more tortuous and therefore longer (*i.e.* the tortuousity factor), (c) the large hydrated ions in the narrow mesh region of the membrane might be impeded in their mobility by the frame work and (d) the interaction of the diffusing species with the fixed groups on the membrane matrix. Parchment paper, except for the presence of some stray and end carboxyl groups, contains very few fixed groups. Deposition of inorganic precipitate gives rise to a net negative charge on the membrane surface in the case of electrolyte (1: 1) leading to the type of ionic distribution associated with the electrical double layer. However, use of electrolyte (2: 1) or (3: 1) leaves a net positive charge on the membrane and results in the formation of the electrical double layer. The system is considered as having charged capillary structures or gels which can be judged in the light of classical fixed charge theory of Teorell,[29] Meyer and Sievers,[30] Sollner,[31] Gregor,[32] and Schmid.[33,34] Flow of electrolyte by diffusion because of the presence of a net charge ($-ve$ or $+ve$) on the membrane gives rise to the membrane potential as opposed to the liquid junction potential ordinarily observed under similar conditions in the absence of the membrane, which regulates the flow of electrolyte by increasing the speed of slow moving ion and by decreasing the speed of the faster moving ion. The regulated rate of flow (*i.e.* diffusion) measured for different electrolytes through the investigated membranes follow the sequence: $NH_4^+ > K^+ > Na^+ > Li^+$ and $Ba^{2+} > Ca^{2+} > Mg^{2+} > Al^{3+}$.

Depending on the size and electrical charge pattern of a pore, it may either admit or repel a solute particle. This is the basis of ion selectivity. Mullins[35] proposed that the hydration of the materials of the pores themselves may provide a favorable water environment for particular ions or molecules, so that they slip into the pores away from their previous water molecules. This could result in selection of a particular size with discrimination against both smaller and larger hydrated ions. In order to obtain a quantitative relation between the ease of penetration and the ion size, it is necessary to know the electrostatic force which acts between the ions and the material of the membranes, since this force provides energy to displace water of hydration. Eisenman *et al.*[17-19] pointed out that the order of the ease of penetration of cations depends on the energy available from the ion-fixed charge interaction. From a simplified model, in which field strength was taken as a controlling variable, the Coulomb energies of interaction of alkali cations with the charged sites were compared with the free energy of hydration of cations. A simplified theory of selectivity for four alkaline earths (Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+}) in a cation exchange membrane has been worked out by Sherry.[20] Specificity is determined by the difference between the free energy of hydration of

alkaline earth cations and their Coulomb energies of interaction with the negatively charged sites. On the basis of Eisenman-Sherry theory,[17–20] the diffusion rate sequence obtained with the investigated membranes point towards the weak field strength of charged groups.

The theory of absolute reaction rates[21–23] has been applied to diffusion processes in membranes by several investigators.[36–39] According to Laidler *et al.*[22–23] the integral diffusion coefficient $\bar{D}$ is given by the expression

$$\bar{D} = Ae^{-E_a/RT} \tag{8}$$

where E_a is the observed activation energy for diffusion and A is the frequency factor. Thus, if log D is plotted against $1/T$, the slope gives (Fig. 5) the value of energy of activation for the diffusion process. These values of E_a were determined for a number of electrolytes and with all the three membranes, and are given in Tables 2 (a, b).

According to Zwolinski *et al.*,[21] we have

$$\bar{D} = \lambda^2\left(\frac{KT}{h}\right)\exp(\Delta S^*/R)\exp\left(\frac{-\Delta H^*}{RT}\right) \tag{9}$$

where λ is the distance between successive equilibrium positions of diffusing species, ΔS^* the entropy of activation, ΔH^* the enthalpy of activation, k, h, R, and T having their usual meanings.

The Eyring enthalpy of activation ΔH^* is calculated from the activation energy E_a (previously determined) by means of the relation

$$\Delta H^* = E_a - RT \tag{10}$$

Assuming λ to be equal to 3 Å for different electrolytes (values 1—5 Å for λ have been used by different investigators) and substituting the value of diffusion coefficient $\bar{D}$, the value of ΔS^* has been calculated. The free energy of activation ΔF^* is then calculated by the Gibbs-Helmholtz equation

$$\Delta F^* = \Delta H^* - T\Delta S^* \tag{11}$$

The values so derived for the different thermodynamic parameters are given in Tables 2 (a, b).

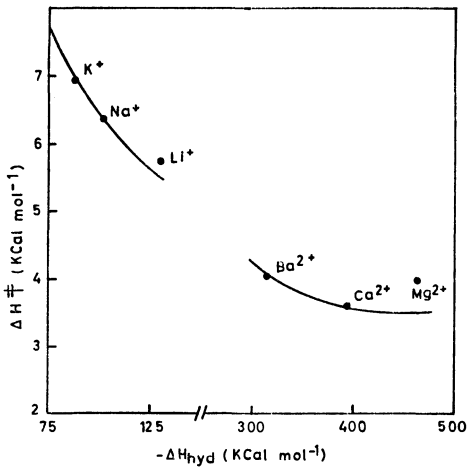

Fig. 6a. Plots of ΔH^* for the diffusion of various electrolytes (at 25 °C) against $-\Delta H_{hyd}$ for the respective cations through cadmium hexacyanoferrate(II).

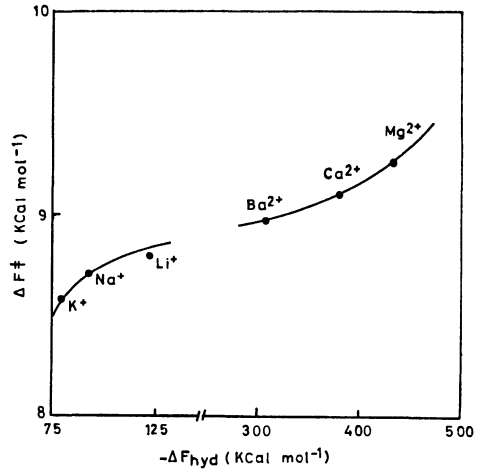

Fig. 6b. Plots of ΔF^* for the diffusion of various electrolytes (at 25 °C) against $-\Delta F_{hyd}$ for the respective cations through cadmium hexacyanoferrate(II).

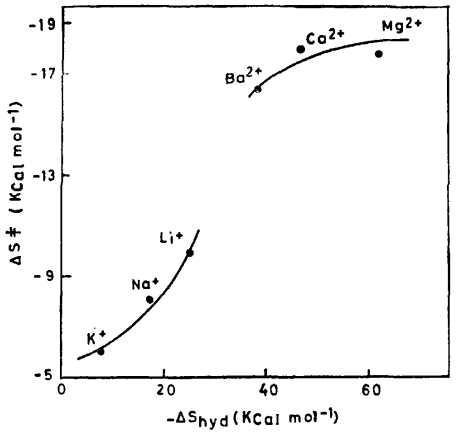

Fig. 6c. Plots of ΔS^* for the diffusion of various electrolytes (at 25 °C) against $-\Delta S_{hyd}$ for the respective cations through cadmium hexacyanoferrate(II).

The results indicate that electrolyte permeation gives rise to negative values of ΔS^*. The values of ΔS^* for all the three membranes show a similar behavior for different electrolytes. With increase in valence of the individual ion, the decrease in the values of ΔS^* is enhanced. It is believed that the membrane and not the solution-membrane interface controls the electrolyte diffusion process. The negative values of ΔS^* as suggested by Schular *et al.*[23] indicate electrolyte diffusion with partial immobilization in the membrane, the relative partial immobility increasing with increase in the valence of ions constituting the electrolyte. In Fig. 6 (a, b, c) the individual ionic contribution to the properties of aqueous ions given by Noyes[40] namely $\Delta H_{hydration}$, $\Delta F_{hydration}$, and $\Delta S_{hydration}$, of Li^+, Na^+, K^+, as well as those of Ba^{2+}, Ca^{2+}, and Mg^{2+} are plotted against the corresponding ΔH^*, ΔF^*, and ΔS^* values for diffusion through the membrane. It is found that at least some formal relationship exists between these thermodynamic parameters.

Studies with Parchment Supported Membranes. VIII. Determination of the Thermodynamic Effective Fixed Charge Density of Barium Phosphate Membrane by Various Methods and Evaluation of Permselectivity

Fasih A. SIDDIQI, M. Nasim BEG, Surendra P. SINGH, and Abdul HAQUE
Physical Chemistry Division, Department of Chemistry, Aligarh Muslim University, Aligarh, India
(Received December 8, 1975)

The thermodynamic effective fixed charge density, the most important parameter governing transport phenomena in membranes, was estimated by methods of TMS, Altug and Hair and the most recent one of Kobatake based on the thermodynamics of irreversible processes. Kobatake's equation has also been utilized for the evaluation of permselectivity of membranes. The two limiting forms of his equation for dilute and concentrated ranges gave identical values of θ (charge density) for barium phosphate membrane. The theoretical predictions for membrane potential by the equation were borne out quite satisfactorily by experimental results obtained with the investigated membranes.

The theories of transport of charged or uncharged particles through membranes have been treated on the basis of the following: (a) the idealized theory of TMS[1-2] and its refinements,[3] (b) the pseudo thermodynamic approach due to Scatchard[4] and treatment based on the thermodynamics of irreversible processes,[5-8] and (c) a kinetic approach based on the theory of absolute reaction rates.[9-10] In the preceeding paper[11] we showed that the parchment supported membranes can generate potentials when they are used to separate electrolyte solutions of different concentrations. This is attributed to the presence of a net charge (negative in the case of 1:1 electrolyte and positive in the case of 2:1 or 3:1 electrolyte) on the membrane probably due to the adsorption of anions or cations.[12-19] This communication deals with the evaluation of membrane fixed charge density on the basis of various approaches of TMS,[1-2] Altug and Hair[20] and Kobatake *et al.*[21-26] based on the thermodynamics of irreversible processes.

Experimental

The barium phosphate parchment supported membrane was prepared as described in part VII of this series.[11] The potential developed across the cell was measured by using a Pye Precision Vernier Potentiometer (No. 7568) at 25 °C (±0.1 °C).

Results and Discussion

The membrane potential data obtained with the barium phosphate parchment supported membrane in various 1:1 electrolyte solutions are plotted as a function of log $(C_1+C_2)/2$ with the ratio r of concentration C_2/C_1 fixed at 10 and are shown in Fig. 1.

The total membrane potential according to the Teorell[1] and Meyer-Sievers theories[2] consists of two Donnan potential at the two solution-membrane interfaces (π_1 and π_2) and a diffusion potential ($\phi_2-\phi_1$)

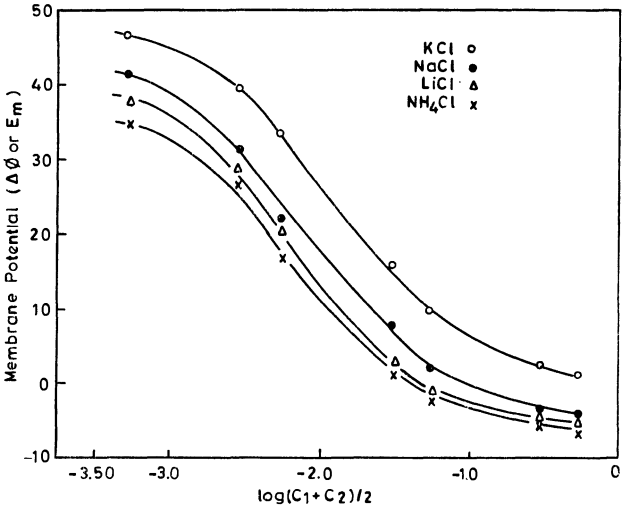

Fig. 1. Plots of observed potentials against log $(C_1+C_2)/2$ for various electrolytes with barium phosphate membrane.

arising from the unequal concentrations of the mobile ions at the two membrane surfaces. The membrane potential E_m or $\Delta\phi$ in millivolts according to TMS theory applicable to a highly idealized system is given by

$$E_m = 59.16\left[\log\frac{C_1(\sqrt{4C_2^2+\bar{X}^2}+\bar{X})}{C_2(\sqrt{4C_1^2+\bar{X}^2}+\bar{X})} + \bar{U}\log\frac{\sqrt{4C_1^2+\bar{X}^2}+\bar{X}\bar{U}}{\sqrt{4C_2^2+\bar{X}^2}+\bar{X}\bar{U}}\right] \quad (1)$$

where $$\bar{U} = \frac{\bar{u}-\bar{v}}{\bar{u}+\bar{v}}$$

$\bar{u}$ and $\bar{v}$ are the mobilities of cation and anion, respectively, in the membrane phase (the bars refer to the parameters in the membrane phase), $\bar{X}$ is the effective charge on the membrane expressed in equivalents/litre of the imbibed solution. In order to evaluate this parameter for the simple case of 1:1 electrolyte and membrane carrying a net negative charge of unity (*i.e.* $\bar{X}=1$) theoretical values for E_m were calculated as a function of C_2, the ratio r of C_2/C_1 being kept at 10 for the different values of the mobility ratio $\bar{u}/\bar{v}$ and plotted as shown in Fig. 2.

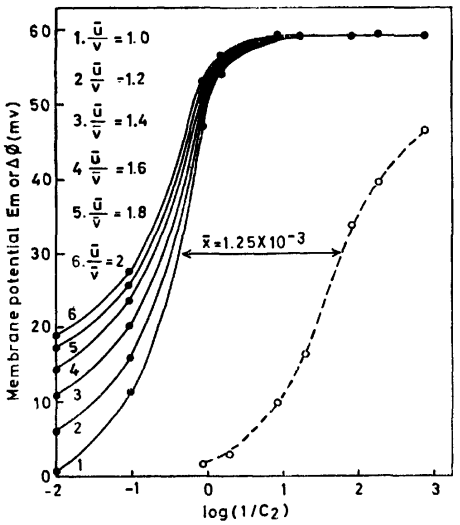

Fig. 2. Evaluation of membrane charge density x and the mobility ratio $\bar{u}/\bar{v}$ in the membrane phase. The different curves for different mobility ratio; O. The observed value E_m for barium phosphate membrane for KCl are plotted against log $(1/C_2)$.

The observed membrane potential values for barium phosphate membrane and KCl electrolyte are plotted in the same graph as a function of log $(1/C_2)$. The experimental curve shifts horizontally and runs parallel to one of the theoretical curves. The extent of this shift gives log $\bar{X}$ and the parallel theoretical curve the value $\bar{u}/\bar{v}$. The values of $\bar{X}$ and $\bar{u}/\bar{v}$ so derived for the barium phosphate membrane and various 1 : 1 electrolytes are given in Table 1.

Table 1. Values derived for the membrane parameters $\bar{X}$ and $(\bar{u}/\bar{v})$

Membrane	Parameter	KCl	NaCl	LiCl	NH_4Cl
Barium phosphate	$(\bar{X})\times 10^3$ eq/l	1.259	3.162	1.995	1.995
	$(\bar{u}/\bar{v})$	1.0	1.0	1.0	1.0

In a modification of this type of plotting, Altug and Hair[20] evaluated $\bar{X}$ on the glass membrane chosing the aqueous electrolyte solution values for $\bar{u}$ and $\bar{v}$ and calculating the values for E_m assigning different values for $\bar{X}$. The total membrane potential E_{calcd} is given by

$$E_{calcd} = (\pi_1+\pi_2) + (\phi_2-\phi_1) \tag{2}$$

where

$$\pi_1 = -\frac{RT}{F}\ln r_1 \tag{3a}$$

$$\pi_2 = \frac{RT}{F}\ln r_2 \tag{3b}$$

r_1 and r_2 are the Donnan distribution ratios, which are determined by means of the equation

$$r = \left\{1+\left(\frac{w\bar{X}}{2a}\right)^2\right\}^{1/2} - \left(\frac{w\bar{X}}{2a}\right) \tag{4}$$

where a is the external solution concentration. The diffusion potential $(\phi_2-\phi_1)$ for 1 : 1 electrolyte is given by

$$(\phi_2-\phi_1) = \frac{u-v}{u+v}\frac{RT}{F}\ln\left\{\frac{a_1(r_1u+v/r_1)}{a_2(r_2u+v/r_2)}\right\} \tag{5}$$

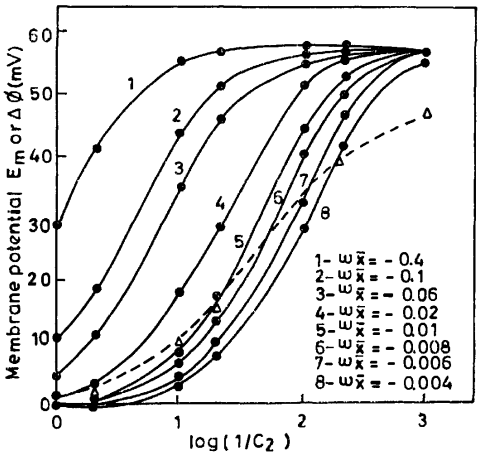

Fig. 3. Plots of membrane potential across barium phosphate membrane for KCl electrolyte of varying concentrations at fixed charge density against log $(1/C_2)$ (observed value are shown by brokenline).

where u and v are the cationic and anionic mobilities respectively, subscripts 1 and 2 referring to the solution on each side of membrane. Substitution in Eq. 2 gives

$$E_m = \frac{u-v}{u+v}\frac{RT}{F}\ln\frac{a_1\left(r_1u+\frac{v}{r_1}\right)}{a_2\left(r_2u+\frac{v}{r_2}\right)} + \frac{RT}{F}\ln\frac{r_2}{r_1} \tag{6}$$

Thus the membrane potentials are calculated by Eq. 6 for different values of fixed charge density $\bar{X}$. They are plotted in Fig. 3 as a function of the external solution concentration. The experimental values of membrane potential observed in the case of KCl for barium phosphate membrane are plotted against solution concentration. The theoretical curve which most nearly coincides with the experimental one gives the value of fixed charge density $\bar{X}$. The value of $\bar{X}$ thus calculated for KCl is given in Table 4.

Starting with the basic flow equations provided by the thermodynamics of irreversible processes Kobatake *et al.*[21] derived the following expression for the membrane potential $\Delta\phi$:

$$\Delta\phi = -\left(\frac{RT}{F}\right)\left[\frac{1}{\beta}\ln\frac{C_2}{C_1} - \left(1+\frac{1}{\beta}-2\alpha\right) \times \ln\left(\frac{C_2+\alpha\beta\theta}{C_1+\alpha\beta\theta}\right)\right] + \cdots \tag{7}$$

where

$$\alpha = \frac{l_+}{l_++l_-} \tag{8a}$$

and

$$\beta = 1 + (KF\theta/l_+). \tag{8b}$$

l_+ and l_- are the molar mobilities of $+ve$ and $-ve$ ions, respectively, defined in terms of the mass fixed frame of reference, K is a constant which is considered to depend on the viscosity of the solution and the structural details of the polymer net work of which the membrane is composed, θ is the charge density (in mol/cm^3) and F is the Faraday constant. These parameters have been assumed to be independent of salt concentration C_2 and C_1.

For the analysis of data, Eq. 7 can be used under two sets of conditions, two limiting forms thus being

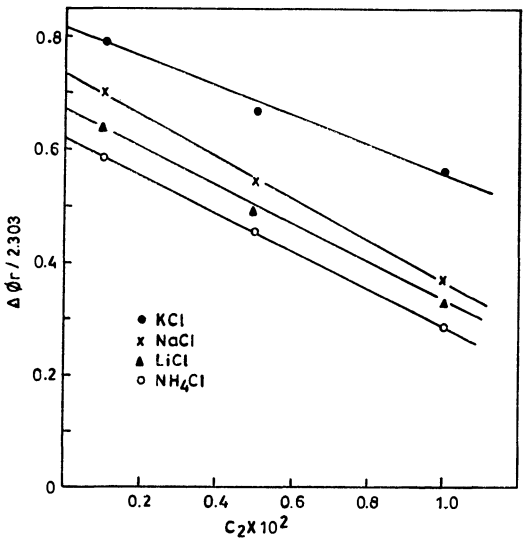

Fig. 4. $|\Delta\phi_r/2.303|$ *vs.* $C_2\times 10^2$ plots for various electrolytes with barium phosphate membrane.

obtained: (a) when concentration C_2 becomes sufficiently small, (extreme dilute range) Eq. 7 can be expanded to give

$$|\Delta\phi_r| = \frac{1}{\beta}\ln\nu - \frac{\nu-1}{\alpha\beta\nu}\left(1+\frac{1}{\beta}-2\alpha\right)\frac{C_2}{\theta} + \cdots \qquad (9)$$

where $|\Delta\phi_r|$ is the absolute value of reduced potential defined by

$$|\Delta\phi_r| = \frac{F\Delta\phi}{RT}. \qquad (10)$$

Equation 9 indicates that the value of β and a relation between α and θ can be obtained by evaluating the intercept and initial slope of a plot for $|\Delta\phi_r|$ against C_2. Figure 4 shows plots for $|\Delta\phi_r|$ *versus* C_2 in the region of very low concentration determined for four electrolytes with barium phosphate membrane. The values of the intercepts for all electrolytes were equal to $(1/\beta)\ln\nu$ from which the values of β were evaluated (Table 2).

Table 2. Values of parameters α, β, and θ for various electrolyte with barium phosphate membrane at $\nu=10$

Electrolyte	α	β	θ
KCl	0.51	1.23	0.008
NaCl	0.46	1.33	0.0071
LiCl	0.44	1.53	0.0020
NH_4Cl	0.44	1.69	0.0070

(b) It is well-known experimentally that at fixed ν the inverse of an apparent transference number, *i.e.* $t_{\bar{a}pp}$, for the co-ion species in a negatively charged membrane is proportional to the inverse of concentration C_2 in the region of high salt concentration. Here $t_{\bar{a}pp}$ is defined by the relation

$$|\Delta\phi_r| = (1-2t_{\bar{a}pp})\ln\nu \qquad (11)$$

Substituting for $\Delta\phi_r$ from Eq. 7 and expanding the resulting expression for $1/t_{\bar{a}pp}$ in powers of $1/C_2$ gives

$$\frac{1}{t_{\bar{a}pp}} = \frac{1}{(1-\alpha)} + \frac{(1+\beta-2\alpha\beta)(\nu-1)}{2(1-\alpha)^2\ln\nu}\left(\frac{\theta}{C_2}\right). \qquad (12)$$

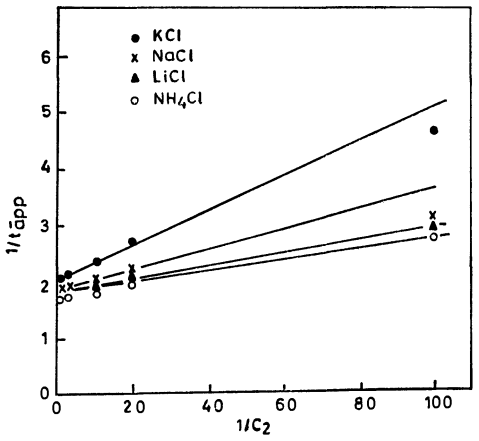

Fig. 5. $1/t_{\bar{a}pp}$ *vs.* $1/C_2$ plots for various electrolytes with barium phosphate membrane.

This indicates that intercept for a plot of $1/t_{\bar{a}pp}$ against $1/C_2$ at fixed ν allows the value of α to be determined. Plots of $1/t_{\bar{a}pp}$ against $1/C_2$ for various 1 : 1 electrolytes are shown in Fig. 5. The values of α are given in Table 2. There are two limiting cases for the evaluation of θ; (i) In the dilute range (1×10^{-3}M) using Eq. 9, the slope is given by

$$\frac{\nu-1}{\alpha\beta\nu}\left(1+\frac{1}{\beta}-2\alpha\right)\times\frac{1}{\theta}.$$

The graphical value of the slope determined from Fig. 4 is equated to the above equation, and the values of α and β are substituted. θ is thus evaluated, the value being designated as θ_d. (ii) In the concentration range (1.0 M) using Eq. 12, the slope is given by

$$\frac{(1+\beta-2\alpha\beta)(\nu-1)}{2(1-\alpha)^2\ln\nu}\times\theta.$$

The graphical value of slope determined from Fig. 5 is equated with the above expression and the values of α and β are substituted. θ is thus evaluated, the value being designated as θ_c.

In the present investigation with barium phosphate membrane, the two values of θ, *viz.* θ_c and θ_d, obtained from the opposite limits agree well with each other (Table 2) confirming the applicability of Kobatake's equation to this system. Also the value of α in Kobatake's treatment is defined by $u_+^0/(u_+^0+u_-^0)$ where u_+^0 and u_-^0 stand for the mobilities of cation and anion respectively in free solution. Thus, the value of α should be 0.5· KCl. The value of α obtained for KCl with barium phosphate membrane (Table 2) is 0.5. This implies that the assumption in the equation of Kobatake holds good for the barium phosphate membrane. It is evident that the constancy of the stoichiometric fixed charge density of the barium phosphate membrane is maintained, which is the basic assumption of the TMS theory[1-2] and its revised form given by Schlögl[3] and Kobatake *et al.*[21-26]

Comparison can be made between theoretical and experimental data and the applicability of Kobatake *et al.* equation to barium phosphate membrane can be tested by the following analytical technique suggested by Kobatake.

Equation 7 can be rewritten as

$$\frac{\nu-e^q}{e^q-1}=X \tag{13}$$

with q and X defined by

$$q=\frac{[|\Delta\phi_r|+(1-2\alpha)\ln\nu]}{1/\beta+(1-2\alpha)} \tag{14a}$$

$$X=\frac{C_2}{\alpha\beta\theta}. \tag{14b}$$

(The X is not the same as the one used in TMS or Altug and Hair method for the evaluation of charge density). Thus if Eq. 7 is valid, the values of log $(\nu-e^q)/(e^q-1)$ calculated from measured $\Delta\phi$ and the given value of ν must fall on a straight line, which has a unit slope and passes the coordinate origin when plotted against log X as shown in Fig. 6, the theoretical predictions from the Kobatake *et al.* membrane potential equation are borne out quite satisfactorily by our experimental results with barium phosphate membrane.

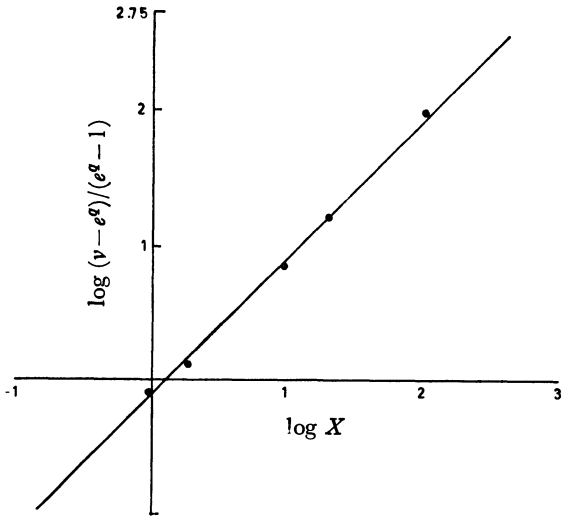

Fig. 6. Plot of log $(\nu-e^q)/(e^q-1)$ *vs.* log X for KCl with barium phosphate membrane.

A method of characterization of the membrane electrolyte system has been developed by Siddiqi and Pratap[12] for parchment supported membranes. Recently a general method of characterization applicable to any system irrespective of ion species has been developed by Kobatake.[26] Consider the present system of negatively charged membrane immersed in an electrolyte solution of average concentration C (*i.e.* $(C_1+C_2)/2$) for which Donnan equilibrium for small ions holds. The mass transference number τ_- of anions in the membrane is given by

$$\tau_-=1-\alpha\frac{(4\xi^2+1)^{1/2}+1}{(4\xi^2+1)^{1/2}+(2\alpha-1)} \tag{15}$$

where ξ and α stand for the relative concentration defined by $C/\phi X$ and $u_+^0/(u_+^0+u_-^0)$ respectively.

On the other hand the apparent transference number of anions in the membrane, *i.e.* t_{app}^-, is defined from the derived membrane potential by the Nernst equation

$$\Delta\phi=-\frac{RT}{F}(1-2t_{app}^-)\ln\frac{C_2}{C_1}. \tag{16}$$

The difference between τ_- (in Eq. 15) and t_{app}^- (in Eq. 16) was less than 2% within a wide range of salt concentration.[26] If τ_- is replaced by t_{app}^-, and C by $(C_1+C_2)/2$, Eq. 15 is applicable even when the concentration of the two sides of the membrane differs. Rearrangement of Eq. 15 leads to the following expression

$$\frac{1}{(4\xi^2+1)^{1/2}}=\frac{1-t_{app}^--\alpha}{\alpha-(2\alpha-1)(1-t_{app}^-)}\equiv P_s \tag{17}$$

where P_s is a measure of permselectivity of the membrane electrolyte system. The value of P_s takes a value between zero and unity depending on the external salt concentration for a given system of a membrane and an electrolyte pair. P_s can be calculated from the data of the membrane potential, while the left hand side of Eq. 17 is a function of the relative concentration $\xi=C/\phi X$ or $(C_1+C_2)/2\phi X$. Thus the values of the right hand side should be independent of the mobilities of ion species involved. Equation 17 implies that the plot of P_s against $(1+4\xi^2)^{-1/2}$ should give a straight line of unit slope.

For the evaluation of the effective fixed charge density, another procedure suggested by Kobatake[26] was also adopted for barium phosphate membrane. The various values of P_s were calculated by substituting the value of α (bulk) and t_{app}^- in Eq. 17 (*vide* Table 3) and then plotted against by log $(C_1+C_2)/2$. A curve was obtained as shown in Fig. 7 when the average concentration C, *i.e.* $(C_1+C_2)/2$, becomes equal to the effective fixed charge density ϕX, the value of ξ becomes equal

Table 3. Values of permselectivity P_s for various electrolytes of barium phosphate membrane at different concentrations

Table 4. Comparison of charge density (ϕX or $W\bar{X}$ or $\bar{X}$) by different methods for KCl

Membrane	TMS $\bar{X}$	Altug and Hair $W\bar{X}$	Kobatake's Eq. 12 θ^*	Kobatake's Eq. 9 θ^*	Kobatake's P_s *vs.* log $(C_1+C_2)/2$ $\phi\bar{X}$
Barium phosphate	0.1259×10^{-2}	0.800×10^{-2}	0.8×10^{-2}	2.0×10^{-2}	1.14×10^{-2}

$$\theta^* = \text{slope}\frac{2(1-\alpha)^2 \ln \nu}{(1+\beta-2\alpha\beta)(\nu-1)\alpha} \qquad \theta^* = \frac{\nu-1(1+1/\beta-2\alpha)}{\text{slope }(\alpha\beta\nu)}$$

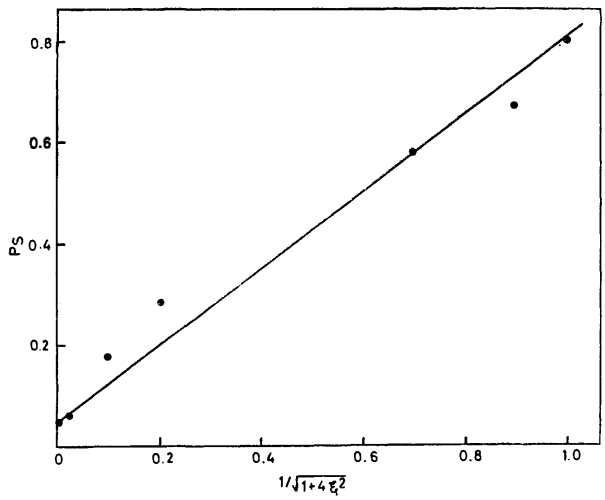

Fig. 8. Plots of P_s against $1/\sqrt{1+4\xi^2}$ for KCl electrolyte with barium phosphate membrane.

to unity, *i.e.* $C/\phi X=1$. Substituting this value of $\xi=1$ into $P_s=1/(4\xi^2+1)^{1/2}$, the value of P_s 0.448 is obtained. At this particular value of 0.448, the corresponding concentration is obtained from the curve P_s *versus* log C (Fig. 7). This value of concentration is equal to the fixed charge density (Table 4). The plot of P_s *versus* $(1+4\xi^2)^{-1/2}$ is drawn for barium phosphate membrane with KCl electrolyte is (Fig. 8). It is evident that the line passes through the origin with unit slope confirming the applicability of Kobatake's equation.

All the theories derived for the fixed charge membrane and used in these investigations give the effective fixed charge density θ or ϕX instead of X itself, when the charge density is evaluated from the data of membrane phenomena such as the membrane potential, ion permeability, electric resistance *etc.* Thus, the values of X do not differ from ϕX ($0<\phi<1$). For the evaluation of true X the titration and isotopic methods were tried. The titration method proved very inconvenient and inaccurate. The isotopic method was discarded in view of strong ionic adsorption phenomenon exhibited by these systems. Consequently the potentiometric method was used.

The authors are grateful to Professor W. Rahman, Head, Department of Chemistry for providing necessary facilities and also to Dr. N. Lakshminarayanaiah of the University of Pennsylvania U.S.A. for valuable discussions. The financial assistance from C.S.I.R. (New Delhi) India to two of us (S.P.S. and A.H.) is gratefully acknowledged.

Dielectric Relaxation in Some Substituted Benzaldehydes in Benzene at Different Temperatures

Buta SINGH and J. K. VIJ

Department of Physics, Punjabi University, Patiala 147002, Punjab, India

(Received February 20, 1976)

Measurements of the relative permittivity at 1 MHz and 9.27 GHz, and of the refractive index for the sodium-D line have been made for (A) *o*-nitrobenzaldehyde, (B) *m*-nitrobenzaldehyde, (C) *m*-chlorobenzaldehyde, and (D) *p*-chlorobenzaldehyde, at 15, 25, 35, and 45 °C in dilute solutions of benzene. The dielectric relaxation times $\tau_{(1)}$ and $\tau_{(2)}$ have been calculated using the Higasi, Koga, and Nakamura method. The results suggest that the relaxation time for the overall rotation decreases at a greater rate than the one for the internal rotation. The thermodynamic energy parameters have been calculated. The results show that the freedom of rotation of the –CHO group increases around the C_{alip}–C_{arom} bond as an electronegative substituent moves from the *o*- to *m*- to *p*- positions.

The present work is an extension of the study previously undertaken on the dielectric relaxation mechanism in some substituted benzaldehydes[1] to include temperature as another variable. Since our previous communication, we have come across the results reported by Mountain and Walker[2] on benzaldehyde, *p*-fluoro-, *p*-chloro-, *p*-bromo-, and *p*-nitro-benzaldehydes in dilute solutions of *p*-xylene at a single temperature and *p*-chlorobenzaldehyde at five temperatures. On the whole, our results and some of the inferences drawn agree with them, though we studied the materials only at a single frequency in the dispersion region. This provides a good test for the Higasi, Koga, and Nakamura method[3,4] of analysing the relative permittivity data. Our results[1] showed that benzaldehydes interact with the benzene molecule through the π-electrons from the benzene molecule. Mountain and Walker's results[2] of benzaldehydes in *p*-xylene show a similar interaction. They have postulated it to be a weak hyderogen bonding of the type $-\overset{\overset{O}{\|}}{C}-H\cdots\pi$. On the other hand, our results,[1] on the study of the benzaldehyde–dioxane systems, indicated that the hyderogen bonding of the type $-\overset{\overset{O}{\|}}{C}-H\cdots O$, if at all, there is fairly weak. There is no confirmation to this fact as yet.

The temperature is introduced as another variable in making a comparative study of the benzaldehydes and their interactions with benzene.

Experimental and Results

The materials are of the same purity standard as previously discussed.[1] The relative permittivity and the refractive index measurements have been made by the same techniques. However, the dielectric cell used for the measurements at 1 MHz was a two terminal one with an air capacitance of 17.9 pF. The cell was calibrated

Literature values of ΔF_ε for *p*-chlorobenzaldehyde are calculated from the values of the relaxation time for overall rotation (τ_1) reported by Mountain and Walker.[2]

for each temperature. The values of the slopes are calculated from the experimental plots of the data *versus* weight fraction. The dielectric relaxation times are calculated using the same techniques.[1]

Values of the parameters a_0, a', a'', $a_{\infty 1}$, $a_{\infty 2}$, $\tau_{(1)}$, and $\tau_{(2)}$ (defined already[1]), for all the four materials at each temperature, are given in Table 1. The table also includes the literatures values[2] of τ_1 and τ_2 for *p*-chlorobenzaldehyde in *p*-xylene as well as value of the dipole moment for internal rotation ($\mu_{\text{int., rot.}}$) which was calculated in the same way as described earlier[1] (Table 1).

The thermodynamic energy parameters are calculated using Eyring's equation[5,6] for the relaxation time $\tau_{(2)}$ since it has been shown[4] to be nearly equal to the relaxation time for overall rotation (τ_1). These values are given in Table 2.

Discussion

Comparing the present values of the dielectric realaxtion times $\tau_{(2)}$ with those of τ_1 given by Mountain and Walker,[2] for *p*-chlorobenzaldehyde in *p*-xylene, and also, keeping in view the accuracy of determination and a slight viscosity difference betweem the two solvents, we find that the agree is reasonably good. This establishes at least the fact that benzene and *p*-xylene have similar characteristics in so far as the interactions with benzaldehydes are concerned. Values of $\tau_{(1)}$ and $\tau_{(2)}$ for each material at a particular temperature are quite distinct from each other. This shows that these molecules possess more than one dielectric relaxation time.

A comparison of the enthalpy of activation (ΔH_ε) for the isomers shows an interesting aspect. The energy barrier for the dielectric relaxation mechanism decreases from *o*- to *m*- and from *m*- to *p*- isomers both for the chloro- and nitro-benzaldehydes.

Since the relaxation time involved is $\tau_{(2)}$, the energy barrier is a combination of barrier to the molecular and to the internal rotations. However, if one assumes, at the worst, that the barrier to the molecular rotation remains the same for the different isomers of a substituted benzaldehyde, the barrier to the internal rotation decreases in the order, *o*- to *m*- and from *m*- to *p*- substituents. This shows indirectly that the freedom of the –CHO group along the C_{alip}–C_{arom} bond increases when these substituents move from the *o*- to *p*- position through *m*- position. Mountain and Walker[2] have explained it in terms of inductive and mesomeric effects of the substituents on the electron density of the C_{alip}–C_{arom} bond. This concept successfully explain why the aldehyde group, when present alone, dose not rotate around the C_{alip}–C_{arom} bond.

Another interesting aspect of the results is that $\Delta H_\varepsilon < \Delta H_\eta$. The ratio $\Delta H_\varepsilon/\Delta H_\eta(=x)$ for the different materials is listed in Table 2. The values of this factor is 0.59 for *o*-nitrobenzaldehyde whereas it is $\approx$0.50 for the other materials. According to the classification of polar liquids, given by Krishnaji and Mansingh,[7] substances for which $x>0.55$ do not show solid rotator phase and those for which $x<0.45$ show such a phase. Since the values of x for the three materials B, C, and D are between the two limits, there is some possibility that these materials, particularly *p*-chlorobenzaldehyde, may show a solid rotator phase.

Values of $\mu_{int.,\,rot.}$ for a particular material remain constant with temperature within experimental error. This indicates that the internal rotations of the –CHO group and the nature of its interactions with the benzene molecule are independent of temperature.

The authors are thankful to Prof. B. S. Sood, Head of the Physics Department, for his valueable suggestions and interest in this work. They are also grateful to Dr. K. K. Srivastava of the Physics Department, Panjab University Chandigarh, for the fruitful discussions during the course of research.

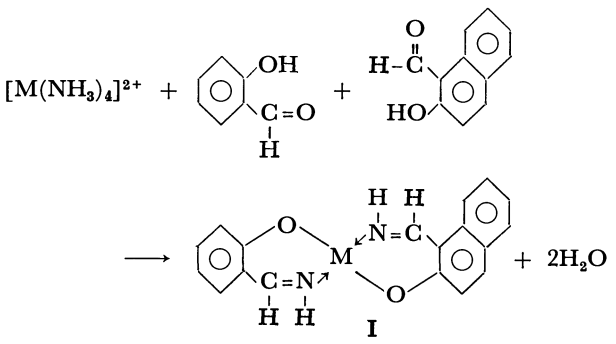
Studies on Some Mixed Schiff's Base Complexes. V.

Rakesh Kumar KOHLI and P. K. BHATTACHARYA
Department of Chemistry, M. S. University, Baroda, 390002, India
(Received November 18, 1975)

As regards the preparation and characterization of some new mixed complexes of the type MLL′ where M= Cu(II), Ni(II); L=salicylaldimine and L′=(*o*-hydroxybenzyl)(ethylideneamine) or *o*-hydroxydiphenylenethyleneamine or their derivatives, we have carried out the preparation of a few similar types of complexes where L′=2-hydroxy-1-naphthylmethyleneamine. The mixed imine Schiff's base complexes have been prepared by treating the metal ammine complex with an equivalent amount of salicylaldehyde and 2-hydroxy-1-naphthaldehyde. Amine exchange reactions were also been carried out by treatment of mixed imine Schiff's base complex with ethylenediamine(en) or propylenediamine(pn). The complexes of new Schiff's base were formed where diamine have salicylaldehyde condensed at one end and 2-hydroxy-1-naphthaldehyde at the other end. The complexes have been characterized by elemental analysis, TLC analysis, conductance measurements, magnetic measurements, and spectral analysis.

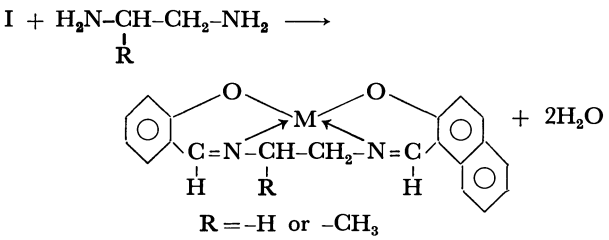
The preparation of the compound of the type ML_2 where L=salicylaldehyde and their reactions with ammonia leading to the formation of the Schiff's base complexes have been reported.[1-5] Reactions of bis-salicylaldehyde complexes with ethylenediamine[6] and aniline[7] have also been reported. Transamination and transamidation reactions have been performed on the Schiff's base complexes.[3-8] The study of reactions of amines with bis 2-hydroxy-acetophenone or bis-2-hydroxy benzophenone complexes of Cu(II) and Ni(II) have also been prepared.[9-10] The possibility of the formation of Mixed-Schiff's base complexes has been indicated by Chakravorty and Holm,[11] on the basis of NMR studies. However, such complexes were not been isolated in solid state. Schiff's base formation reaction of mixed ligand complexes of the type MLL′, where L= salicylaldineamine and 1(*o*-hydroxyphenyl)ethylideneamine[12] or *o*-hydroxydiphenylmethyleneamine and their derivatives have been reported. The present paper deals with the preparation and reactions of a series of mixed ligand complexes of general formula MLL′ where M=Cu(II) or Ni(II), L=salicylideneamine, L′=2-hydroxy-1-naphthyleneamine.

The mixed Schiff's base complex was prepared by treating the metal ammine complex with one equivalent of salicylaldehyde and another of 2-hydroxy-1-naphthaldehyde.



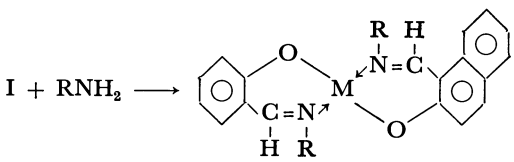
M=Cu(II) or Ni(II)

Complex(I) was treated with ethylenediamine(en) or propylenediamine(pn), leading to the formation of new Schiff's base complexes with the diamine condensed to one end with salicylaldehyde and at the other end with 2-hydroxy-1-naphthaldehyde.



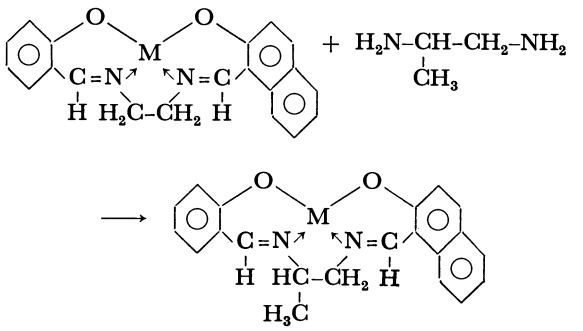
R=–H or –CH_3
M=Cu(II) or Ni(II)

Similar reactions were also carried out with methyl and ethyl amine and the following type of mixed complexes were obtained.



R=–CH_3 or –C_2H_5
M=Cu(II) or Ni(II)

When the en Schiff's base is treated with pn, en is slowly replaced by pn, as shown in the following equn.



M=Cu(II) or Ni(II)

Experimental

Material. Ligand of AR quality and nickel nitrate and cupric chloride of Analar grade were used.

Preparation of Amine Schiff's Base Complex. (Salicylaldeneaminato)(2-hydroxy-1-naphthylmethyleneaminato)Cu(II) or Ni(II): To the metal chloride solution was added an excess of ammonia till the hydroxide formed dissolved resulting in the formation of metal ammine complex. To this was added one equi-

Structure of Cu(II) Complexes. All the Cu(II) complexes are paramagnetic showing the presence of one unpaired electron. The values of μ expected for one unpaired electron is 1.73 B.M., the slightly higher value obtained for the present complexes can be attributed to spin-orbit coupling.[13] The visible spectra show a broad band at ≈590 or ≈520 nm; and agree with the square planar geometry. The Cu(II) imine Schiff's base complex shows a band around ≈550 nm (ε=123) and the en and pn Schiff's base complexes exhibit at ≈560 (ε=410) and at ≈550 (ε=478), respectively. The spectrum of complex {*N*,*N*'-ethylene(salicylideneaminato-2-hydroxy-1-naphthylmethyleneaminato)}Cu(II) (No. 7) was compared with that of (bis-ethylene salicylideneaminato)Cu(II) and (bis-ethylene 2-hydroxy-1-naphthylmethylenediaminato)Cu(II) complexes. The complex (No. 7) shows one peak falling between the two bis compounds. This indicates the mixed nature of these complexes.

Structure of Ni(II) Complexes. All the complexes were recrystallized until constant magnetic susceptibility was obtained. They exhibit some paramagnetism. Anomalous magnetic behavior of Ni(II) Schiff's base complexes were studied and interpreted in detail.[14,15] The visible spectra of the imine Schiff's base complex in chloroform solution shows a shoulder at ≈550 nm with (ε=274). A similar spectrum was obtained in the case of en and pn Schiff's base complexes, the shoulder shifting to ≈530 nm and ≈550 nm with (ε=418) and (ε=343), respectively. The absence of bands beyond 600 nm confirms square geometry for the complexes.

In the IR spectra of all the compounds bands in the range ≈3400 cm^{-1} are absent indicating that O–H hydrogen of the aldehyde or the Schiff's base get dissociated after complexation. In the spectra of Cu(II) and Ni(II) complexes(I) a band at 1600 cm^{-1} corresponding to C=N stretch appears. There is a strong band at ≈3200 cm^{-1} corresponding to N=H stretching frequency. This is absent in the en and pn diamine Schiff's base and also in methyl and ethyl amines compounds showing the absence of free =NH group.

The authors wish to express their sincere thanks to Prof. S. M. Sethna, Head, Department of Chemistry, M. S. University of Baroda, for providing all the laboratory facilities. Thanks are also due to Malti-Chem Research Centre, Nandesari, Baroda, for the recording of the IR spectra of the complexes. One of the authors (R.K.K.) is grateful to U.G.C., New Delhi for awarding the Junior Research Fellowship.

A Study of Self Oscillatory Chemical Reaction of Gallic Acid and Potassium Bromate System

J. Sreekantha Babu, M. M. Bokadia, and K. Srinivasulu
School of Studies in Chemistry, Vikram University, Ujjain 456010, India

(Received September 5, 1975)

Synopsis. The oscillatory phenomenon during oxidation of gallic acid with potassium bromate, catalyzed by cerium ion in acid medium with stirring was investigated. The cross section of a three dimensional graph for the regions where the oscillatory behavior can be observed is given. Effect of Ag^+ and Br^- on the oscillatory behavior was studied.

Oscillation in the concentrations of Br^- and Ce^{4+}/Ce^{3+} during the oxidation of malonic acid by bromate ion with cerium ion as a catalyst was studied by different workers.[1-7] Similar oscillatory phenomenon was observed in gallic acid-bromate system catalyzed by cerium ions.

Experimental

A freshly recrystallized gallic acid (GA)(Riedel), 1,10-phenanthroline ferrous sulphate complex (ferroin) solution (0.025 M)(BDH) and other BDH AR grade chemicals were used.

A requisite quantity of gallic acid was dissolved in distilled water, to which a ceric solution with sulphuric acid was added. The reaction was studied at constant temperature and with constant moderate stirring on addition of a requisite volume of bromate solution and a drop of ferroin indicator, the total volume being kept 10 ml. The color change from red to green, *i.e.*, Ce(III) to Ce(IV), takes place abruptly. The oscillations visually observed are reporducible within the limits of experimental error.

Results and Discussion

Important parameters for the occurrence of oscillations in the system are bromate, gallic acid and cerium ion concentrations. A minimum concentration of acid which depends upon the concentration of other reactants, is required to start the reaction. When the reactant concentrations are kept constant, the frequency of oscillations (n) increases, and the total time of oscillation (T) decreases with increasing acid concentration. A large number of oscillations were observed at an acid concentration of 2.57 N.

Effect of Individual Reactant. (Other Variables Being Kept Constant).

(a) Gallic Acid Variation.

($[BrO_3^-]=0.1$ M, $[Ce(IV)]=0.003$ M, [acid]=2.57 N). The total number of oscillations (N) is high at concentration of 0.03 M, and decreases when the concentration becomes greater or smaller than this value. The value of n decreases and T increases with a decrease in gallic acid concentration.

(b) Bromate Variation.

($[GA]=0.04$ M, $[Ce(IV)]=0.001$ M, [acid]=2.57 N). The value of N is maximum for $[BrO_3^-]=0.1$ M. Values of n and I (induction period) decrease while T increases when $[BrO_3^-]$ increases.

(c) Cerium Ion Variation.

($[GA]=0.04$ M, $[BrO_3^-]=0.1$ M, [acid]=2.57 N). In the concentration range 3.0×10^{-4}—1.0×10^{-4} M, a great number of oscillations were observed and outside the range the value of N decreased. With increase and decrease in concentrations of total cerium ion beyond the mentioned range, the n value increased and decreased respectively. The system showed 80 oscillations in 150 min before the oscillation ceased, when $[GA]=0.045$ M, $[BrO_3^-]=0.1$ M, $[Ce(IV)]=3.0\times10^{-4}$ M and [acid]=2.57 N.

The oscillatory cycle can be divided into two processes, the former is a trigger process and the latter is a recovery.

$$Ce^{3+} \xrightarrow[H^+]{BrO_3^-} Ce^{4+} \quad (1)$$

$$Ce^{4+} \xrightarrow{GA} Ce^{3+} \quad (2)$$

The products of bromate reduction in the trigger process (1) may brominate gallic acid. Bromide ion is formed as a result of decomposition of gallic acid-bromine derivatives induced by ceric ion oxidation (2). It was verified experimentally that bromide ion is a strong inhibitor of trigger process. Addition of Br^- inhibits the trigger process, resulting in the dampening of oscillation. At 0.005 M of $[Br^-]$, inhibition of oscillatory behavior was observed. Addition of Ag^+ which removes Br^- also dampens down and at 0.1M concentration inhibits the oscillation. This indicates that $[Br^-]$ plays an important role in the oscillatory behavior[7] (Fig. 1).

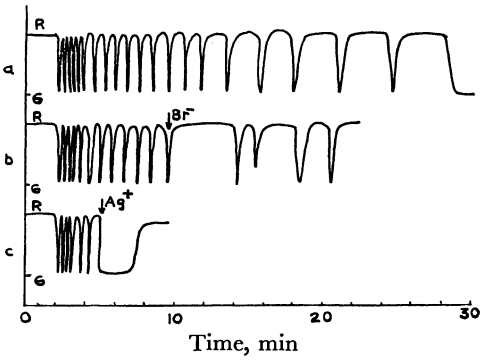

Fig. 1. Oscillatory curve with respect to time. (As indicated by ferroin.) R- Red and G- Green representing Ce(III) and Ce(IV) respectively.
(a) $[GA]=0.0425$ M, $[BrO_3^-]=0.1$ M, $[Ce(IV)]=0.0005$ M and [acid]=2.57 N.
(b) Effect of bromide ion. Concentrations similar as in (a) and [KBr]=0.05 M.
(c) Effect of silver ion. Concentrations similar as in (a) and $[AgNO_3]=0.05$ M.
Arrow indicates the point of addtion.

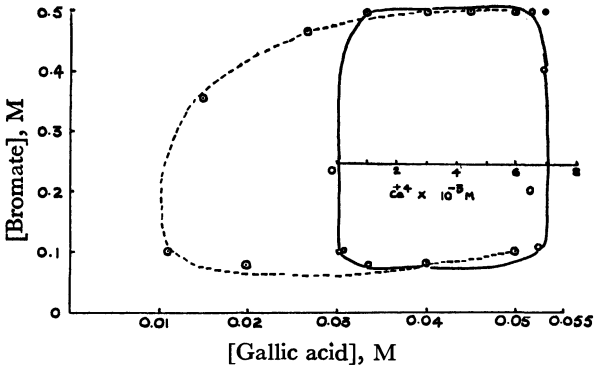

Fig. 2. Cross sections of three dimensional plot for the boundary region where oscillations are observed. Temperature 35 °C. [Sulfuric acid] 2.57 N. [GA]—X axis, $[BrO_3^-]$—Y axis and [Ce(IV)]—Z axis.
------ represents the curve of [GA] *vs.* $[BrO_3^-]$.
—— represents the curve of [Ce(IV)] *vs.* $[BrO_3^-]$ when [GA]=0.04 M.

Oscillations could be observed in the concentration range of reactants studied (Fig. 2). The boundary conditions of gallic acid, bromate and cerium ion concentrations were determined keeping temperature, acidity and stirring constant. The upper limit of [GA] could not be fixed due to its solubility limitation. As the concentrations of reactants approach the boundary conditions, the oscillations tend to cease and beyond it, they are not significant.

The authors are thankful to the Council of Scientific and Industrial Research, India, for the financial assistance.

Some New β-Diketone Complexes of Ruthenium(III) with Triphenylphosphine and Triphenylarsine

K. NATARAJAN and Umesh AGARWALA

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, U.P., India

(Received April 7, 1976)

Synopsis. The syntheses of some new β-diketone complexes of Ru(III) with triphenylphosphine and triphenylarsine have been described. Their spectral (IR and visible) and magnetic properties have been reported. Some of them show unusual magnetic moment.

Mixed complexes of ruthenium(II) with triphenylphosphine and β-diketones have been reported in the literature,[1] but no work has so far been done on similar complexes of ruthenium(III).

In this communication, we report the preparations of the ruthenium(III) complexes of the type $[RuX_2L_2(bdk)]$ (X=Cl, Br; L=PPh_3, $AsPh_3$; bdk=acetylacetonate, dibenzoylmethanate, benzoylacetonate) starting from $[RuCl_3(AsPh_3)_3]$,[2] $[RuBr_3(AsPh_3)_3]$,[3] $[RuCl_3(PPh_3)_3]$,[4] and $[RuBr_3(PPh_3)_2(MeOH)]$.[5] Their spectral and magnetic properties have also been studied.

The general procedure to prepare these complexes is as follows:

A solution of 0.4 g of $[RuX_3L_3]$ or $[RuX_3L_2(MeOH)]$ in 20 ml of benzene or dichloromethane was mixed with another solution of β-diketone (0.2 g) in 5 ml of ethyl alcohol. It was heated under reflux for 3—5 h whereby the desired complex was separated out on concentrating the refluxing solution. The colour in the case of chloro complexes was green while that of bromo ones, brown. All the compounds were recrystallized from dichloromethane–methanol mixture.

Magnetic susceptibilities of the complexes were determined with a Gouy balance. The electronic spectra of the complexes were recorded in chloroform solution with a Cary-14 recording spectrophotometer in the range of 1000—300 nm. The infrared spectra of the complexes were taken with the help of a Perkin-Elmer 521 grating infrared spectrophotometer in the range of 4000—300 cm^{-1} using KBr pellets of the samples. The major IR bands are given in Table 1.

TABLE 1.

Sl. No.	Complex	Mp °C	Magnetic moment B.M.	IR bands cm^{-1}
1	$RuCl_2(acac)(AsPh_3)_2$	267	2.54	1530, 1565
2	$RuCl_2(dbm)(AsPh_3)_2$	281	2.53	1540, 1610
3	$RuCl_2(ba)(AsPh_3)_2$	255	2.10	1530, 1570, 1610
4	$RuCl_2(acac)(PPh_3)_2$	215	2.00	1530, 1570
5	$RuCl_2(dbm)(PPh_3)_2$	230	2.71	1525, 1540, 1600
6	$RuCl_2(ba)(PPh_3)_2$	214	2.31	1540, 1560
7	$RuBr_2(acac)(AsPh_3)_2$	290	2.03	1530, 1570
8	$RuBr_2(dbm)(AsPh_3)_2$	267	2.07	1530, 1570
9	$RuBr_2(ba)(AsPh_3)_2$	231—233	2.02	1530, 1570, 1605
10	$RuBr_2(acac)(PPh_3)_2$	224	1.80	1545, 1575
11	$RuBr_2(dbm)(PPh_3)_2$	222	2.00	1535, 1550, 1610
12	$RuBr_2(ba)(PPh_3)_2$	206	1.91	1535, 1560, 1600

acac=acetylacetonate; dbm=dibenzoylmethanate; ba=benzoylacetonate.

The analytical data of carbon, hydrogen, ruthenium and halide ion of the complexes confirm the general formula $[RuX_2L_2(bdk)]$.

The IR spectra of the complexes showed all the bands due to triphenylphosphine or triphenylarsine. Besides these, two or three bands were also present in the region 1525—1610 cm^{-1}. These may be assigned to the characteristic bands of the coordinated β-diketones arising due to the normal coordinates having contributions from ν(C=O) and ν(C=C).[6,7] The molecular weight determination in bromoform solution of the complexes confirm monomeric structure for all the compounds.

The electronic spectra of all the complexes in chloroform solution showed two to three bands in the region 600—350 nm. The bands are very much characteristic of the octahedral surrounding of the ligand molecules around ruthenium(III) ions.[8-10] Generally in the visible region ruthenium(III) ion show charge transfer bands around 400 nm.[11,12] It is also clear by the shift in the positions of both the bands in the bromo complexes towards lower wavelength side because of the greater reducing power of Br than Cl.[12]

The values of the magnetic moments were a little abnormal (see Table 1). Since ruthenium(III) belongs to d^5 system, having one unpaired electron, it should normally show a value of the magnetic moment around 2.00 B. M. In some of the cases of β-diketone derivatives of ruthenium(III), the values of magnetic moment are found to be in the range of 2.3—2.7 B. M. This high value can not be explained by the presence of one unpaired electron and hence a spin-free system must be invoked.[13] In order to explain this, further studies on low temperature magnetic measurements and ESR are under progress. Preliminary ESR studies showed the presence of two lines, indicating distorted octahedral nature of the complexes.[14]

Thermogravimetric Analysis of Tetraalkylammonium Haloborates. I.

S. U. SHEIKH

Department of Chemistry, University of Islamabad, Islamabad, Pakistan

(Received April 28, 1976)

Synopsis. Thermogravimetric analysis of tetraalkylammonium haloborates lead to the formation of trialkylamine trihaloborane and dialkylamino dihaloborane followed by ill-predictable intermediates leading to the formation of boron-nitrogen polymers.

Pyrolysis and thermoanalytical techniques applied to tetraalkylammonium haloborates is a part of an extensive research investigation into the factors to develop chemically and thermally stable boron-nitrogen polymers.[1-2] Considerable interest is attached to prepare polymers in which main chain is composed of elements other than carbon, in the hope that the thermal stability would be greater than that of the known organic polymers. Although a number of useful thermally stable polymers have in fact been developed by organic chemists but the interest given to the development of some areas of organometallic chemistry has been inadequate. Our work which is being presented in this and succeeding papers is directed towards the preparation of boron-nitrogen polymers.

Polyborazynes $[XBNR]_n$ exist as cyclic dimers, trimers and linear polymers.[3-5] The great difficulty in the preparation of linear polyborazynes is the overwhelming propensity of polyborazynes to exist as small rings.[6] It was thought that one method to prevent the formation of small rings and constraining polymerization to only linear polymers was to introduce some measure of steric inhibition to ring formation. In our efforts to prepare linear polymers two approaches were devised. The first was to discover whether by a suitable choice of reactants or experimental conditions the formation of ring compounds might be suppressed in favor of linear polymers. The second approach was to devise means whereby ring compounds might be linked in linear chains either directly or through suitable bridging groups. This paper describes part of our work on the first approach namely the study of dealkylhalogenation of the 1:1 adducts tetraalkylammonium haloborates[7] selected as suitable models for the study of the possible inhibition of ring compound formation and for the preparation of linear polymers.

Experimental

Appropriate tetraalkylammonium haloborates were prepared by interaction of equimolar quantities of tetraalkylammonium halides and trihaloborane in dichloromethane. Tetraalkylammonium tetraphenylborates were prepared in aqueous medium.

$$R_4N^+X^- + BX_3 \longrightarrow R_4N^+BX_4^-$$

$$R_4N^+Cl^- + Na^+BPh_4^- \longrightarrow R_4N^+BPh_4^- + NaCl$$

R = Et, *n*-Pr and *n*-Bu

X = Cl, Br and $PhBCl_2$

Thermogravimetric analyses were carried out by using Stanton HT-SM Thermobalance. All samples of haloborates and haloboranes were subjected to heat in an atmosphere of nitrogen with a flow rate of 5 l/h. Nitrogen gas provided a blanket of an inert atmosphere by preventing ingress of air. Samples varied in weights from 0.1 g to 0.2 g were used. Platinum crucible with or without platinum lid was used and its capacity varied between 10 to 15 mm. To achieve better resolution heating rates from 0.5 to 6 °C per minute were employed depending on the relative rates of decomposition of each reaction intermediate.

Results and Discussion

Tetraalkylammonium haloborates $[R_4N^+BX_4^-]$ undergo interesting transformations. When in the above complex R was ethyl and X was chloride and phenylboron dichloride inflection corresponding to the ejection of one molecule of ethyl chloride was observed with the formation of 1:1 complex $[R_3NBX_3]$. When R was butyl and X was chloride and bromide in the complex $[R_4N^+BX_4^-]$, the complex ejected two molecules of butyl halide in one step with the formation of dibutylamino dihaloborane. When R was butyl and X was

$$Et_3NBPhCl_2 \longrightarrow Et_2NBPhCl + EtCl \quad (3)$$

$$Bu_4N^+BX_4^- \longrightarrow Bu_2NBX_2 + 2BuX \quad (4)$$

$$Bu_4N^+BPhCl_3^- \longrightarrow Bu_3NBPhCl_2 + BuCl$$

$$Bu_3NBPhCl_2 \longrightarrow Bu_2NBPhCl + BuCl. \quad (5)$$

Thermogravimetric analysis of tetrabutylammonium tetraphenylborate did not give any indication for the formation of any resolvable intermediate. However, in the case of tetraethylammonium tetraphenylborate system an intermediate, equivalent to $[Et_3NBPh_3]$ was indicated with possible loss of one molecule of ethylbenzene.

All the thermogravimetric analysis results were further supported by the differential thermal analysis. The latter technique afforded no identification of the thermal decomposition sequence beyond the point of formation of 1:1 complex except in the case of triethylamine and tributylamine trichloroboranes, where, there are some indications of the possible formation of diethylamino and dibutylamino dichloroborane respectively. These indications are obtained by comparison of relevant differential thermal analysis curves.

Helpful guidance of Dr. B. R. Currell during the course of this work is acknowledged.

Oxidation of Flavanone Hydrazones with Manganese Dioxide

T. C. SHARMA, Amba LAL, and (Mrs) Vinita SAKSENA
School of Studies in Chemistry, Vikram University, Ujjain 456010, India

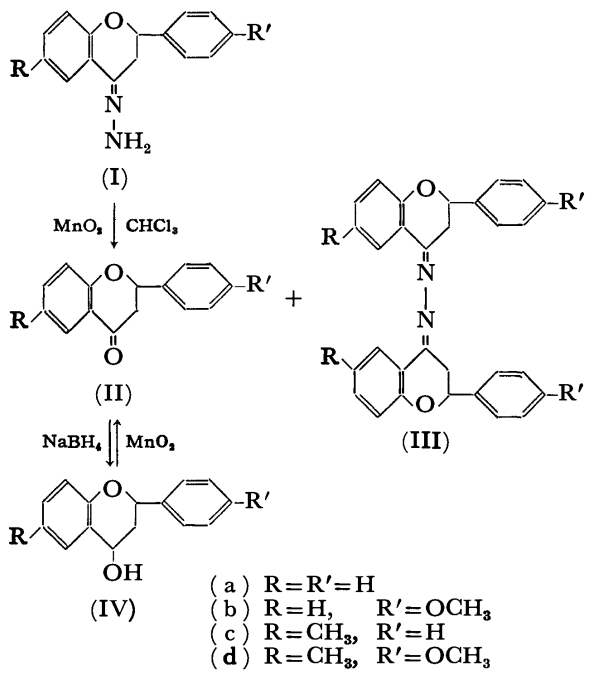
(Received January 27, 1976)

Synopsis. Oxidation of flavanone hydrazones(I) with active manganese dioxide gave a mixture of flavanones(II) and the azines(III).

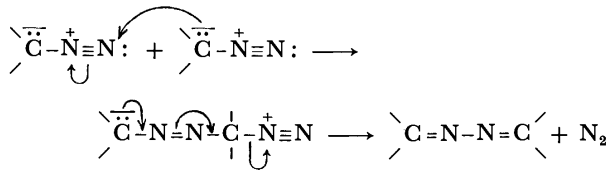
The oxidation of hydrazones with manganese dioxide has been studied by many workers.[1-8] Scrutiny of literature shows that manganese dioxide oxidation of hydrazones gives different types of products depending upon the reaction conditions and the structure of the parent carbonyl compound. In the present investigations, we have examined the oxidation of flavanone hydrazones with manganese dioxide.

We found that when flavanone hydrazones(I) are shaken with manganese dioxide in chloroform at room temperature, a mixture of the parent ketone(II) and the corresponding azine(III) results in each case.

The identity of the ketones was confirmed by means of melting point and the mixture melting point with authentic samples. Azines were characterized from their elemental analysis and infrared spectra; azines show a strong absorption peak in the region 1605—1610 cm^{-1} due to the conjugated C=N stretching frequency.



Maier and Heep[8] oxidized some hydrazones with manganese dioxide to the carbonyl compounds and suggested that diazoalkanes are the intermediates in these reactions. Thus, the formation of flavanone azines can be explained if it is assumed that the intermediate diazo compounds dimerize followed by the loss of nitrogen (Scheme 1).



Scheme 1.

However, the conversion of the hydrazones into flavanones can also be explained by a free radical mechanism* (Scheme 2).

Experimental

All mps are uncorrected.

Flavanone Hydrazones (I). These compounds were synthesized following the reported procedure.[10]

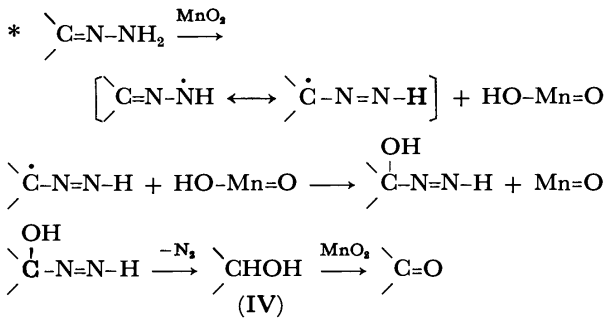
Oxidation of Flavanone Hydrazone (Ia). A mixture of flavanone hydrazone (2 g) and manganese dioxide (10 g) in chloroform (160 ml) was shaken at room temperature for 6 h. The residue, obtained after removal of solvent and manganese dioxide, on fractional crystallization from a mixture of benzene and chloroform gave azine (IIIa) as yellow needles (0.45 g), mp 256—257 °C (lit[10] 254—260 °C). Found: C, 80.4; H, 5.8; N, 6.7%. Calcd for $C_{30}H_{24}N_2O_2$: C, 81.0; H, 5.4; N, 6.3%.

The IR spectrum (KBr) of this azine has absorption bands at 1617, 1607, 1523, 1460, 1380, 1320, 1238, 1220, 1150, 1115, 1070, 1027, 990, 907, 752, and 700 cm^{-1}.

From the mother liquor, flavanone (0.2 g) was also isolated which melted at 76 °C. Mixture melting point with an authentic sample gave no depression.

The oxidation of other flavanone hydrazones was similarly studied. Data for the new compounds are given in Table 1.

Oxidation of Flavan-4-ol (IVa). A mixture of flavan-4-ol



Scheme 2.

We propose this scheme since compounds containing C–N=N–H are usually unstable and decompose to C–H+N_2, possibly *via* a free radical mechanism. The proposed intermediates flavan-4-ols (IV), however, could not be isolated from the reaction mixture but we found that flavan-4-ols undergo oxidation to the corresponding flavanones under similar reaction conditions. The free radical mechanism was also suggested earlier[9] for the oxidation reactions of diamines, hydrazines and phenylhydrazones with manganese dioxide.

Table 1. Data for the new compounds

					80.0	6.6	—

(2 g) and manganese dioxide (10 g) in chloroform was shaken for 6 h. The reaction mixture was worked up as usual to afford flavanone (1.2g), mp and mmp 76 °C.

The other flavan-4-ols[11,12] when oxidized similarly gave the corresponding flavanones in 50—55% yield.

The authors thank Professor M. M. Bokadia for providing laboratory facilities and to the authorities of Chemistry Department I. I. T. Kanpur for providing analytical and spectral data. One of us (V. S.) is grateful to U. G. C., New Delhi for the award of a research fellowship.

An Application of Current-pulse Electrolysis to an Electro-initiated Polymerization of Acrylamide*

Zempachi OGUMI, Zenichiro TAKEHARA, and Shiro YOSHIZAWA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received August 13, 1975)

A unidirectional current pulse was applied to the electro-initiated polymerization of acrylamide in a Kolbe system, and the behavior of intermediate was investigated. The formation rate of the oligomer during the current-on pulse was not affected by the pulse length, and it was almost the same as that under steady conditions. An oligomer was also formed during current-off pulse. The formation rate of the oligomer during the current-off pulse was calculated on the base of the mechanism presented in previous papers; the calculated results agreed well with the experimental results. The half-life time of intermediate radical, [RM·], was about 10 ms.

In previous papers[1,2] it was clarified that the concentration of an intermediate at an electrode interface had an important influence on the current efficiency of the oligomer formation and that the current density was more important than the electrode potential. Current-pulse electrolysis was applied to an electro-initiated polymerization of acrylamide in the system of Kolbe electrolysis based on the prediction that the intermediates had a finite lifetime.

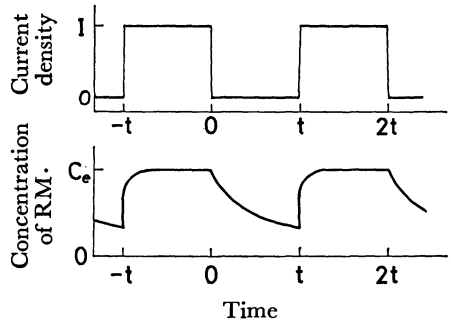

Fig. 1. The concentration change under unidirectional pulse conditions.

The concentration of an intermediate will be changed by electrolysis under unidirectional pulse conditions (Fig. 1). The concentration of the intermediate increases rapidly at the current-on pulse up to a steady value, C_e, depending on the current density and decreases at the current-off pulse depending on the rate of the following chemical reaction. If the pulse electrolysis is applied to the system in which a rise-up time is negligibly short compared with the length of the current-on pulse, the electrode reaction during the current-on pulse may be considered to be the same as that under steady conditions. In this case the formation rate of a product during the current-off pulse can be calculated. If the reaction mechanism is known, the concentration change of intermediate may be calculated using the formation rate obtained above. In the present paper, a unidirectional current pulse was applied to an electro-initiated polymerization of acrylamide in the Kolbe system.

* Studies of Electro-Initiated Polymerization. Part V.

Experimental

An H-shaped glass cell fitted with an anion-exchange membrane as a diaphragm was used as the electrolysis cell. A smooth platinum plate (3×1.5 cm^2) and a smooth platinum cylinder electrode (1.3 cm diameter, 3 cm height, 10 cm^2 area) were used as working electrodes. As a cathode, a smooth platinum electrode (3×3 cm^2) was used. The working electrodes were pretreated prior to use, as has been described before.[1] A solution prepared by dissolving 1 mol of acetic acid and 1 mol of potassium acetate in distilled water to 1 liter was used and will be designated as the 2 M acetate solution from now on. The electrolyte was prepared by dissolving a given amount of acrylamide in this solution. The acrylamide was refined by recrystallization. A current interrupter (Hokuto Denko CI253) was used as the current source. The details of the experimental procedure were described in a previous paper.[1]

The amount of the polymerized product, an oligomer, was measured as follows. When the anolyte was poured into 1 liter of methanol after electrolysis, a white precipitate of an insoluble polymerized product came out. This was filtered through a #4 glass filter, dried at 60—80 °C under reduced pressure, and weighed. The yield of the oligomer thus produced was also calculated as follows. The yield during electrolysis time, T_t, is Y_t. The real time of current flowing, T_{on}, is the sum of the current-on time. The yield per unit of time by electrolysis under steady conditions at the current density equal to it in the current-pulse electrolysis is Y_s. It is assumed that the rate of oligomer formation during the current-on pulse under pulse conditions is the same as under steady conditions. The yield for the total current in time Y_{on} is calculated from Y_s and T_{on}. The yield, Y_{off}, for the total current-off time, T_{off}, can also be calculated by means of Y_{on} and Y_t:

$$Y_{off} = Y_t - Y_{on} \quad (1)$$

$$Y_{on} = Y_s \times T_{on} \quad (2)$$

The yield per current-off pulse, y, is calculated as follows:

$$y = Y_{off}/(T_t/t_t) \quad (3)$$

t_t is the pulse length (on time+off time). The quantity of electricity passed through was measured by means of a hydrogen/oxygen coulometer and a transistorized coulometer manufactured by Hokuto Denko Co., Ltd.

Results and Discussion

Kolbe Reaction under Galvanostatic Pulse Conditions. Constant current pulse electrolysis was first of all applied

a) Steady-current electrolysis.

to the Kolbe electrochemical reaction, and the effect of current pulse on the charge-transfer reaction in the system of the electro-initiated polymerization of acrylamide was investigated. The current efficiency of carbon dioxide was examined on a smooth platinum plate electrode in a 2 M acetate solution. The carbon dioxide was measured by using 0.1 M $Ba(OH)_2$. The current efficiency does not depend on the pulse length and is almost the same as that in steady-current electrolysis (Table 1). Wood[3] has reported that acetate is completely oxidized to carbon dioxide and water in an acidic aqueous solution on a platinum electrode at a potential less positive than that where the electrode surface is completely covered with oxide. Fleischmann *et al.*[4] have investigated the Kolbe electrolysis under pulse conditions where they have used the potential pulse between E_h (2.2 V *vs.* NHE) and E_l (−0.15 V *vs.* NHE). Under these conditions, the surface oxide formed on the electrode at E_h is reduced at E_l. The state of the electrode surface just after setting the potential at E_h is considered to be different from the state which is normally attained as the Kolbe reaction proceeds. Accordingly, the Kolbe reaction does not proceed at the beginning of the setting at E_h. Complete oxidation, as in Eq. 4, and surface-oxide formation proceed simultaneously until the surface state necessary for the Kolbe reaction is attained:

$$CH_3COO^- + 2H_2O \longrightarrow 2CO_2 + 7H^+ + 8e \quad (4)$$

Moreover, these reactions result in lowering the current efficiency of the Kolbe reaction and in decreasing the formation of carbon dioxide.** Hickling and Wilkins[5] and Wilson and Lippincott[6] have investigated the application of the alternating current pulse to the Brown-Walker and Kolbe reactions. They examined the effect of the pulse length on the current efficiency of the dimerized product and ascertained that the current efficiency was independent of the pulse length and was equal to that obtained by steady-state electrolysis when the reverse (cathodic) current was zero, that is, when the pulse current was applied instead of the alternating current. On the other hand, when the alternating pulse current with a small reverse current was applied, the current efficiency decreased and depended on the coulombic amount of reverse electricity. When the reverse electricity exceeded a critical value, the current efficiency again became high. However, in the present system, the current efficiency of carbon dioxide did not depend on the pulse length and almost coincided with the value obtained by steady-current electrolysis (Table 1). This fact indicates that the formation of surface oxide and the complete oxidation described by Eq. 4 do not occur, differing from the result of the potential pulse electrolysis of Fleischmann *et al.*[4] and also from results reported by Hickling and Wilkins,[5] and Wilson and Lippincott.[6] It is a possible to conclude that, under the present pulse conditions, a usual Kolbe reaction proceeds during the current-on pulse.

An Oligomer Production and the Effects of Some Electrolysis Conditions. The above investigation made it clear that, by electrolysis using a unidirectional pulse current, carbon dioxide was produced at the same current efficiency as with steady-current electrolysis. The change in the surface state under the pulse conditions was examined by measuring the electrode potential. The electrode potential is considered to change with the change in the electrode surface state and not to attain the steady-state value until the electrode surface reaches the steady state. The measurement was carried out by using a cathode-ray oscilloscope. The measuring circuit is shown diagramatically in Fig. 2. The potential was referred to SCE. The potential change is shown representatively in Fig. 3. The time, τ, which was required for attaining the steady potential and the potential difference, ΔE, were measured and tabulated in Table 2 in the system with and without the addition of acrylamide. The potential change, ΔE, increased with the pulse length; the time, τ, also increased in the

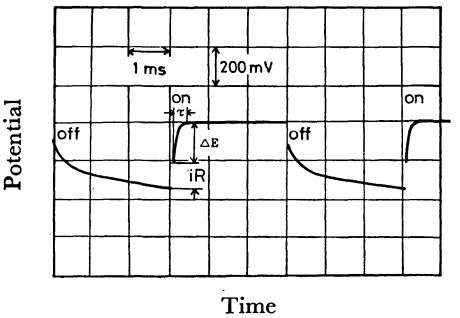

Fig. 3. Typical potential change in current pulse electrolysis at 200 mA/10 cm² on a rotating cylinder electrode (2000 rpm). *iR* means an ohmic drop.

** In Reaction 4, only 1 mol of CO_2 is produced by the electrolysis of 4 Faraday, but in the Kolbe reaction ($2CH_3COO^- \rightarrow CH_3-CH_3 + 2CO_2 + 2e$), 4 mol of CO_2 are produced by this electrolysis.

Table 2. Dependence of the rise-up time, τ, on the pulse length on a rotating cylinder electrode (2000 rpm) at 250 mA/10 cm² 2 M acetate solution, 100 ml.

Pulse length (ms)	Without acrylamide		With acrylamide (20 g)	
	ΔE (mV)	τ (ms)	ΔE (mV)	τ (ms)
0.4	160	0.08		
1	200	0.10	280	0.08

6	320	0.14	400	0.10
10	355	0.16	410	0.11
14	400	0.18	420	0.12
20	440	0.20	480	0.14
30	480	0.23	510	0.15
40	530	0.25	580	0.15
60	580	0.25	590	0.16
100	610	0.26		
	760	0.24		

same manner. The ratio of τ to the pulse length is easily calculated; its value is small and decreases as the pulse length becomes longer. The ratio is especially very small in the system with acrylamide added. Furthermore, the steady potential after the rise-up was independent of the pulse length and was 2.4 and 3.2 V in the systems with and without acrylamide respectively. As has been described above, the surface state required for the occurrence of the Kolbe reaction might be destroyed during the current-off pulse. This would lower the current efficiency of the Kolbe reaction. However, the potential drop during the current-off time, which is equal to ΔE, is so small, and the steady potential attained during the current-on time is so high (2.4 or 3.2 V), that the destruction of the surface state does not occur (Table 2). This consideration might allow us to conclude that the Kolbe reaction proceeds during the rise-up time, τ, except for a small current for the charging of the double layer. In addition to this, it has already been established that, in the electro-initiated polymerization of acrylamide in the Kolbe system, the formation rate of the polymerized product hardly depended on the current density at the potentials large enough for the Kolbe reaction.[1,2] Accordingly, it can reasonably be presumed that the formation rate of the oligomer during the rise-up time is almost the same as in the steady state. In order to confirm this assumption, the dependence of the oligomer-formation rate on the current-on pulse length was examined at a constant current-off pulse length. The measurement was carried out in a 2 M acetate solution containing 20 g of acrylamide by utilizing a rotating cylinder electrode (1450 rpm) at 200 mA/cm². The length of the current-on pulse had little effect on the yield (Fig. 4). This fact shows that the oligomer production during the rise-up time proceeds almost at the same rate as the steady state. From now on the ratio of the current-on time to the current-off time will be set at 1 unless specifically stated.

An effect of the rotation rate was next examined on a cylinder electrode and compared with the results

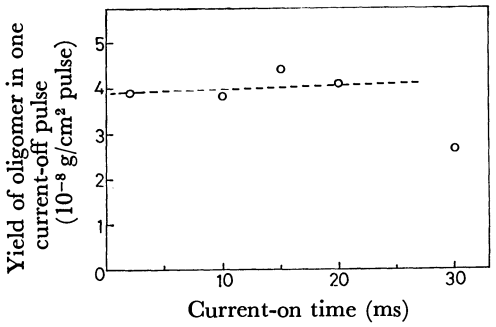

Fig. 4. The effect of current-on pulse length on the oligomer yield at 200 mA/10 cm² on a rotating cylinder electrode (1450 rpm) in the solution 2 M acetate solution 100 ml+acrylamide 20 g. Current-off pulse= 10 ms.

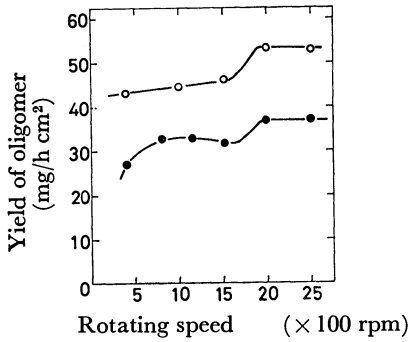

Fig. 5. Dependence of the yield on rotation rate on a rotating cylinder electrode at 200 mA/10 cm² in the solution 2 M acetate solution 100 ml+acrylamide 20 g. a —●—: With pulse current of 20 ms, b —○—: with steady current.

obtained by steady-current electrolysis (Fig. 5). Curve a in this figure represents the yield per hour, including the current-off time under pulse conditions of a 20 ms pulse length at 200 mA/10 cm². Curve b represents the yield under steady conditions at the same current density. On both curves an abrupt change is observed between 1500 and 2000 rpm; above and below this range, the change is not remarkable. The yield during the current-off pulse can be calculated from Fig. 5 (Fig. 6). The rotation rate has no effect on the yield except for a point at 400 rpm, and no abrupt change is observed in

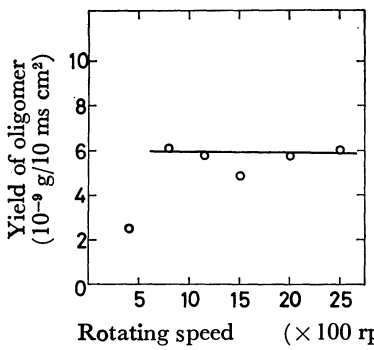

Fig. 6. The effect of rotation rate on the yield during current-off pulse in the solution 2 M acetate solution 100 ml+acrylamide 20 g on a rotating cylinder electrode at 200 mA/10 cm².

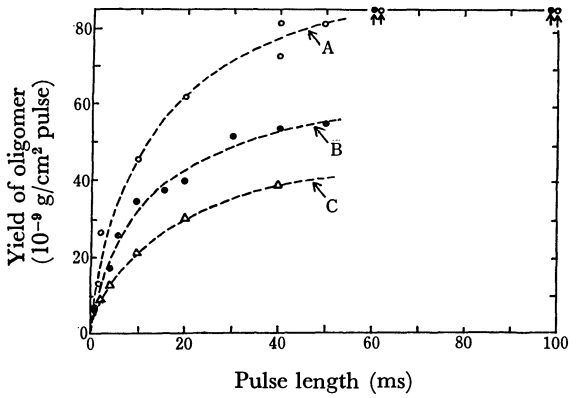

Fig. 7. Relationship between pulse length and the oligomer yield during one current-off pulse on a rotating cylinder electrode in the solution 2 M acetate solution 100 ml+acrylamide 20 g.
A: 250 mA/10 cm^2, 2000 rpm.
B: 200 mA/10 cm^2, 2000 rpm.
C: 200 mA/10 cm^2, 400 rpm.

Fig. 6. Thus, the formation of the oligomer during the current-off pulse is not remarkably affected by the mass-transfer rate to the electrode.

The relationship between the current-pulse length and the yield of the oligomer during the current-off pulse was also examined (Fig. 7). The yield increased with the pulse length in the region of short pulse lengths. However, the yield suddenly reached a high value at pulse lengths longer than 60 ms. In this case, a high polymer was observed besides an oligomer. The high polymer is considered to be formed through a different process, which is still ambiguous, from that of oligomer formation.

Behavior of Intermediate Radicals and a Theoretical Treatment of It. In the Kolbe system two intermediate radicals, $CH_3\cdot$ and $CH_3COO\cdot$, are considered to exist on or near an electrode surface. In spite of vigorous investigations by many workers, however these intermediates have never been directly detected. The electrode surface is covered with oxide and intermediates. Bruno and Dobois[7] reported that a hydrophobic polymer film like polyethylene covered the surface, and authors also found that, in an electro-initiated polymerization of acrylamide in an aqueous solution of trifluoroacetate, an electrode surface was covered with a hydrophobic film which was not easily removed.[9] Kolbe intermediates are considered to exist at the interface under interaction with the above species adsorbed on the surface. As has been reported in the previous papers,[1,2] the polymerized product in the Kolbe system is formed by the reactions of intermediates. A low current efficiency of polymerization was ascribed to that polymerization was initiated on or just near the electrode surface, where the radical concentration was high. The fact that an oligomer was formed during current-off pulse explicitly shows that some intermediate species which have the ability to initiate the polymerization have a finite lifetime. Taking this into consideration the mechanism of oligomer formation under pulse conditions was examined. The reaction proceeds as follows:[1]

$$CH_3COO^- \longrightarrow R\cdot + e \quad (5)$$

R· represents two Kolbe intermediate radicals, $CH_3\cdot$ and $CH_3COO\cdot$.

$$R\cdot + R\cdot \xrightarrow{k_1} R\text{-}R \quad (6)$$

$$R\cdot + M \xrightarrow{k_2} RM\cdot \quad (7)$$

$$R\cdot + RM\cdot \xrightarrow{k_3} RMR \quad (8)$$

M represents an acrylamide monomer. The RM· thus formed reacts further into polymerized products as follows:***

$$RM\cdot + M \xrightarrow{k_4} RMM\cdot \quad (9)$$

$$RMM\cdot + nM \xrightarrow{k_p} RM_{n+2}\cdot \dashrightarrow \text{Oligomer} \quad (10)$$

$$RM\cdot + RM\cdot \xrightarrow{k_5} RMMR \quad (11)$$

$$RM\cdot + B \xrightarrow{k_6} RMX + B' \quad (12)$$

B represents some impurity *etc.*, RMX includes a stable radical which can not initiate polymerization. B′ can not initiate polymerization, either. The formation rate of R·, v, is expressed as follows:

$$v = g\cdot I/F \quad (13)$$

I and g represent the current density and the current efficiency respectively. F is the Faraday constant. The change in the R· concentration is:

$$d[R\cdot]/dt = v - 2k_1[R\cdot]^2 - k_2[R\cdot][M] - k_3[RM\cdot][R\cdot] \quad (14)$$

The change in the RM· concentration is:

$$d[RM\cdot]/dt = k_2[R\cdot][M] - k_3[RM\cdot][R\cdot] - k_4[RM\cdot][M] - 2k_5[RM\cdot]^2 - k_6[RM\cdot][B] \quad (15)$$

In the above expressions, it was assumed that mass-transfer did not cause any probelms in any reaction. The rate of oligomer formation is:

$$v_p = k_4[RM\cdot][M] \quad (16)$$

It is considered for the sake of simplification, that all the R· formed in Eq. 5 proceeds Reaction 7 into RM·, because it was clarified in a previous paper[2] that no dimerized Kolbe product, R–R, was produced in this system, and the contributions of Reactions 8 and 12 are considered to be small when acrylamide is used at concentrations higher than 2.5 mol/l (see another previous paper).[2] In this experiment, the concentration of acrylamide was about 2.8 mol/l. Therefore, $k_3[RM\cdot]\times[R\cdot]$ and $k_6[RM\cdot][B]$ in Eqs. 14 and 15 can be neglected.

Then,

$$k_2[R\cdot][M] = v \quad (17)$$

By replacing [RM·] and [M] with C and m respectively, Eq. 15 is written as follows:

*** As lower-molecular-weight products are formed in our system, RMR, RMMR, and RMX were mainly detected.[2] The other reactions besides Eqs. 8, 11, and 12 (*e.g.*, $RM\cdot + RM_2\cdot \rightarrow RM_3R$) were thus not considered as terminating reactions.

$$dC/dt = v - (k_4'C + 2K_5C^2) \quad (18)$$

Here, $k'_4 = k_4 m$. The concentration at the interface should be taken as m. Under steady conditions at constant-current electrolysis,

$$dC/dt = 0. \quad (19)$$

Then C_e, the steady value of C, is

$$C_e = (-k_4' + \sqrt{k_4'^2 + 8k_5 v})/(4k_5). \quad (20)$$

At the current-off time under pulse conditions, $v=0$. Then, from Eq. 18 under the condition that $C=C_e$ at $t=0$,

$$C = k_4'/(2k_5 \times [\exp\{k_4'(K+t)\} - 1]). \quad (21)$$

$$K = \ln\{k_4'/(2k_5C_e) + 1\}/k_4' \quad (22)$$

Using the average molecular weight, M_0, the yield of the oligomer is:

$$y = M_0 \int_0^t v_p dt. \quad (23)$$

The yield at the current-off time is calculated from Eq. 23 using Eqs. 16 and 21 as follows:

$$y = M_0 \frac{k_4'}{2k_5} \ln \frac{1 - \exp\{-k_4'(K+t)\}}{1 - \exp(-k_4'K)} \quad (24)$$

When the pulse is very long,

$$y|_{t\to\infty} = M_0 \frac{k_4'}{2k_5} \ln\left(1 + \frac{2k_5C_e}{k_4'}\right). \quad (25)$$

On the other hand,

$$\left.\frac{dy}{dt}\right|_{t=0} = M_0 k_4' C_e = v_{p0} M_0. \quad (26)$$

Here v_{p0} represents the rate of oligomer formation at a steady current which is equal to the value at the current-on pulse. If the values of M_0, v_{p0}, v, $y|_{t\to\infty}$ are experimentally known, k'_4, k_5, and C_e can be calculated from Eqs. 20, 25, and 26. This calculation was carried out for Curve B (Fig. 7) as one example. Also, the relationship between the pulse length and the yield during the current-off pulse was obtained.

The molecular weight of the oligomer obtained under pulse conditions was almost the same as that obtained under steady conditions. Hence, M_0 was assumed to be 1000 based on the result by Yoshizawa *et al.*[8] v_{p0} was obtained from $dy/dt|_{t=0}$ or the observed rate of oligomer formation under steady conditions. v was calculated form the current density, assuming a 100% current efficiency. $dy/dt|_{t=0}$, can be obtained from Fig. 7. On the other hand, the yield suddenly became a high value beyond a pulse length at 60 ms (Fig. 7). It is impossible to obtain $y|_{t\to\infty}$ from the experimental results. Therefore, it is necessary to calculate the values of k'_4, k_5, and C_e based on the supposed $y|_{t\to\infty}$ (Table 3). In this calculation v_{p0} was obtained from Fig. 7 as 1.3×10^{-8} mol

Table 3. C_e, k_5, and k'_4 parameters at different $Y|_{t\to\infty}$ values

$Y\|_{t\to\infty}$ (10^{-8} g/cm^2)	C_e (10^{-10} mol/cm^2)	k_5 (10^{12} cm^2/mol/s)	k'_4 (10 s^{-4})	Fig. 8
3.4	1.6	0.35	12.5	a
5.4	2.9	1.2	4.5	b
9.5	5.4	3.3	2.4	c

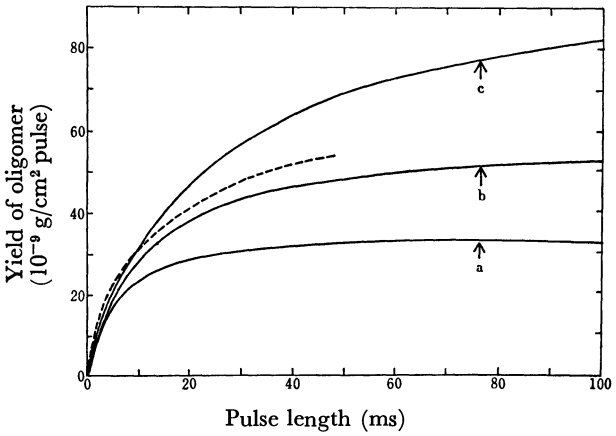

Fig. 8. Relationship between pulse length and the oligomer yield during one current-off pulse calculated by using Eq. 24. a, b, and c represent those in Table 3 respectively. A dotted line represents curve B in Fig. 7.

cm^{-2} s^{-1}, which agreed well with the value, 1.5×10^{-8} mol cm^{-2} s^{-1}, obtained from a steady-state electrolysis at 200 mA/10 cm^2. Using these values, the relationship between the yield, y, and the pulse length, t, was calculated (Fig. 8). The dotted line in this figure shows the experimental result. The calculated curves does not agree perfectly with the experimental results, but the agreement is fairly good. From these calculated results, the half-lifetime of the intermediate, RM·, can be calculated; it becomes about 10 ms. This value is much larger than the half-lifetime of $CH_3\cdot$ (10^{-10} s). An experiment to detect this intermediate was attempted by utilizing the cyclic voltammetry technique at a high scanning rate. However, the reduction current due to intermediates was never observed. Accordingly, the intermediates are considered to be electrochemically inactive.

Conclusion

The following results were obtained from an application of current-pulse electrolysis to an electro-initated polymerization of acrylamide by the Kolbe electrochemical reaction in an aqueous acetate solution.

(1) Under unidirectional current-pulse conditions, the current efficiency of the Kolbe reaction is independent of the pulse length and equal to that under steady conditions.

(2) In the electro-initiated polymerization under pulse conditions, polymerized products are formed not only during the current-on pulse, but also the current-off pulse.

(3) The behavior of intermediates, namely, the production path of polymerized products during the current-off pulse, can be explained well by assuming the rate-determining step to be a simple chemical reaction on or near an electrode.

(4) Intermediate species are electrochemically inactive and have a half-life of about 10 ms.

(5) The application of pulse electrolysis to electrode reactions, in which successive chemical reactions have a decisive influence on the current efficiency of the

intended reaction, allows us to improve the reaction selectivity and the current efficiency and, moreover, to analyze the following chemical reactions in more detail.

(6) In a current-pulse electrolysis the current loss for nonfaradaic processes, such as double-layer charging, *etc.*, has only an insignificant effect.

Cathodic Reduction of Nitrobenzene on the Packed-bed Copper Electrode

Shiro YOSHIZAWA, Zenichiro TAKEHARA, Zempachi OGUMI, and Toshio TSUJI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received January 29, 1976)

An application of a packed-bed copper electrode to the formation of aniline by the cathodic reduction of nitrobenzene was investigated. As the particles for the packed-bed, spherical particles of an anion exchange resin chemically plated with copper were successfully used. Though the current efficiency for the aniline formation on the packed-bed electrode in a batch cell decreased with continuing electrolysis, the efficiency was improved by the electrolysis under a flowing electrolyte and became very high, *i.e.*, near 100%. This is due to the removal of the accumulated products on the electrode surface by the flowing electrolyte. The effective depth of the bed electrode on which the nitrobenzene reacted cathodically was also determined from the measurement of the potential profile in a packed-bed electrode: the result was about 3 mm. This low value of the effective depth is ascribed to the low conductivity of the electrolyte and to the high electronic conductivity of the packed-bed. This may be improved by using bed particles of lower electronic conductivity and a higher cell capacity may be expected.

The electrochemical production of organic compounds at a high rate is generally difficult due to the low exchange current density of the electrode reaction and the disturbance of the electrode reaction by the accumulation of the reaction products on the electrode surface, in the case of the formation of low solubility products. Thus, an application of a packed-bed electrode, which is a three-dimensional electrode may be considered. By its operation under a flowing electrolyte the accumulation of the reaction products on the electrode surface may be avoided. Such a packed-bed electrode was applied to the cathodic reduction of nitrobenzene in acidic solution, which is an electrode process which has a well-known reaction mechanism,[1] and the probability of scaling up the cell capacity was examined.

Experimental

Electrolytic Cell. The anode compartment of the electrolytic cell (Fig. 1) was separated from the cathode one by a diaphragm of an ion exchange membrane. A platinum plate was utilized as the counter electrode (anode), and the working electrode (cathode) was made from a packed-bed. The diameter of the working surface was 25 mm and the distance between the diaphragm and the current feeder was 40 mm. A copper net was used as the current feeder. A 2% (volume) aqueous sulfuric acid solution was used as an anolyte. A catholyte was prepared from an EWS solution, which consisted of 35 parts of ethanol, 10 parts of water, and two parts of sulfuric acid and nitrobenzene. The catholyte flowed through the bed from top to bottom and the anolyte was circulated. The electrolysis was operated at room temperature. The particles for the packed-bed electrode were prepared from an anion exchange resin, Amberlite IR-410 as follows:[2] Pretreatment: 1. Stir in ethanol. 2. Keep in a 15% aqueous solution of potassium carbonate for 15 min below 70 °C under stirring. 3. Wash with distilled water. 4. Keep in a solution composed of 1 part of 1% aqueous silver nitrate solution and 1 part of ethanol at room temperature for 5 min under stirring (surface activation). 5. Vacuum dry below 40 °C. Each particle thus pretreated was chemically plated. A plating bath was prepared by dissolving 180 g of glycerine and 180 g of copper carbonate in 1 liter of 20% NaOH solution. The solution was kept for a day before use. A 28% formaldehyde solution was used as a reducting reagent. One gram of particles was put in 10 ml of plating bath and a reducing reagent was added 1 ml at a time until the color of the copper ions disappeared. Particles plated with copper were dried under a reduced pressure after being washed with distilled water, and were kept in a desiccator.

E: Plastics net.

Analysis. Each fraction of the effluent electrolyte was analyzed as follows: It was first neutralized by a NH_3 solution and then it was extracted by ether. The extract was analyzed by utilizing a liquid chromatography technique.

Potential Measurement. A probe was devised to measure the particle potential in a bed electrode. A copper wire of 0.5 mm diameter was covered with polyethylene. One end of it was bare only at an edge and the other was bare for the contact to the measuring circuit. This probe was supported by a glass pipe. A fine Luggin capillary was attached, with a porous porcelain tip on its edge to prevent bed particles from coming into the capillary. If that occurred, the solution potential measured by the capillary would be disturbed by the dissolution of copper.

Results and Discussion

Current-Potential Relationship. The potential on the copper-plate electrode where the nitrobenzene reacted in a mixed solution (EWS) was examined by cyclic voltammetry (Fig. 2). The reduction of nitrobenzene begins at about −0.2 V (*vs.* SCE) and hydrogen evolution begins at about −0.5 V. Accordingly, only the reduction of nitrobenzene occurs between −0.2 and −0.5 V.

Electrolysis in a Batch-Cell. The current efficiency for aniline formation was examined at a copper-plate

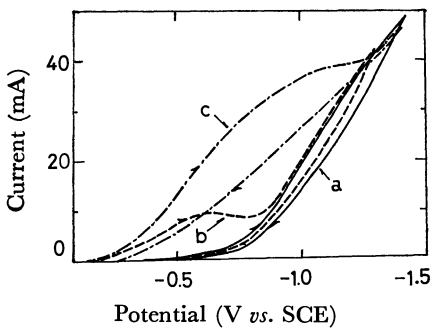

Fig. 2. Current-potential curves on the copper-plate electrode in EWS solution by a cyclic voltammetry with sweep rate of 0.1 V/s.
a: Without nitrobenzene, b: with 1% nitrobenzene, c: with 5% nitrobenzene.

electrode in an H-shaped batch-cell which was equipped with an ion exchange membrane as a diaphragm. At the early stage of electrolysis under a constant current, of 10 mA/cm^2, for example, the current efficiency of aniline formation was very high, about 70—80%. However, the electrode surface was covered by a colloidal product with continuing electrolysis and the current efficiency decreased with electrolysis time. After a few hours electrolysis the current efficiency decreased to 30—40% and hydrogen evolution occurred as a side reaction. Besides the copper plate, a copper-particle bed was used as the electrode in a batch-cell. As the latter electrode, 1 g of particles was inserted in a glass vessel (10 mm diameter, 10 mm height). A copper wire which was set at the bottom of the vessel was utilized as a current feeder. The rate of aniline formation on this electrode was examined under a constant current electrolysis (Fig. 3). A solid product accumulated on the bed electrode; it was identified as anilinium sulfate by its IR spectrum. No other compound was observed. A straight line in this figure represents the calculated rate of aniline formation by supposing that the current efficiency of aniline formation is 100%. The experimentally obtained rate was lower than the calculated one. This may be due to the hydrogen evolution as a

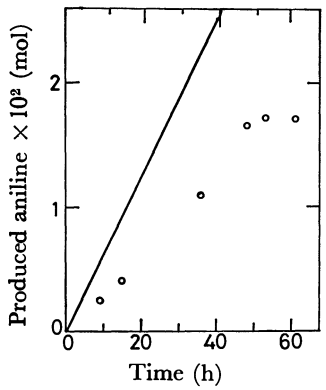

Fig. 3. Current efficiency for aniline formation at constant current (100 mA) electrolysis by using packed-bed copper electrode in a batch cell.
—: Calculated rate as 100% current efficiency,
○: observed value.

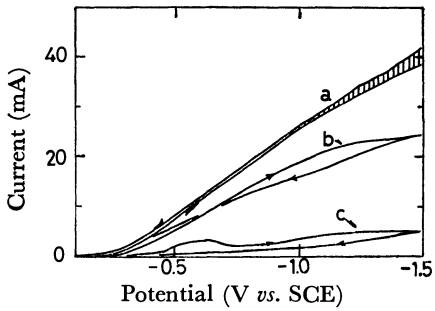

Fig. 4. Current-potential curves on the copper-plate electrode in EWS solution containing 5% nitrobenzene by a cyclic voltammetry with sweep rate 0.1 V/s.
a: By using copper electrode not covered by a colloidal product,
b: by the use of the solution added with 0.3% aniline after the measurement of "a",
c: by using copper electrode after 3 h electrolysis at 10 mA covered by a colloidal product.

side reaction. The rate of aniline formation hardly decreased after about 48 h electrolysis.

The potential-current curve by cyclic voltammetry on the copper-plate electrode covered by the colloidal product was measured (Fig. 4). The current in the potential region in which the reduction of nitrobenzene occurred decreased exceedingly after being covered by the colloidal product. By adding aniline, which is the reaction product, the decrease of current was also observed, but it was very slight. This may show that a colloidal product retards the cathodic reduction of nitrobenzene very much and accelerates the hydrogen evolution, due to the shift of the potential to a more negative value during the constant current electrolysis. Thus, the current efficiency for aniline formation may be decreased with continuing constant current electrolysis in a batch-cell.

Electrolysis at a Packed-Bed Electrode. By using a packed-bed electrode (Fig. 1), an EWS solution containing 5% nitrobenzene was electrolyzed at a constant current (100 mA) under flow. The effluent electrolyte was collected by 10 ml at a time. Each fraction was analyzed for the aniline content, and the rate of aniline

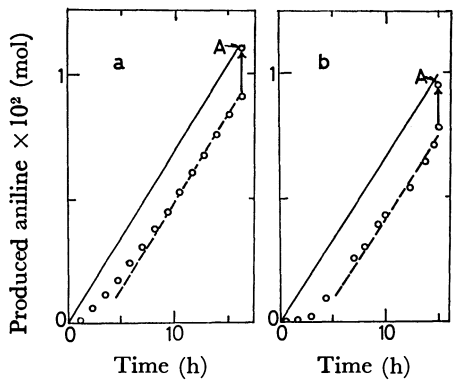

Fig. 5. Current efficiency for aniline formation at constant current (about 100 mA) electrolysis by using packed-bed copper electrode under flowing electrolyte.
a: bed depth, 30 mm, b: bed depth, 10 mm.
—: Calculated rate as 100% current efficiency,
○: observed value.

formation was calculated (Fig. 5). a and b in this figure represent results obtained by the cells of 30 and 10 mm heights, respectively. Straight lines represent results which were calculated by assuming that the current efficiency of aniline formation was 100%. At the early stage of electrolysis, the rate is apparently slow. This is due to the induction period before the flowing out of the solution under the bed electrode. The experimental results fell almost on the dotted lines which represent the current efficiency of 100%. It becomes clear from this fact that the current efficiency is very high. The electrolyte contained in the cell flowed out after electrolysis and was analyzed for the aniline content. Then the amount of aniline became point A in Fig. 5. These results also show that the current efficiency is very high, approximately 100%.

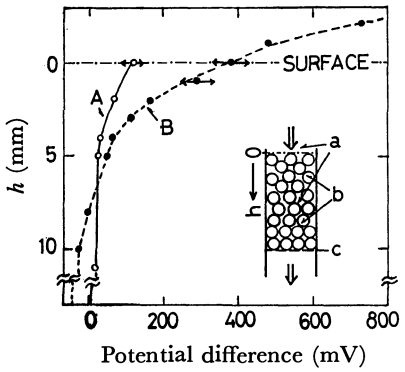

Fig. 6. Potential profile in a packed-bed copper electrode at 75 mA/cm² electrolysis under flowing electrolyte.
A: Potential difference between particles and feeder at various positions (b—c),
B: potential difference between solution and feeder at various positions (a—c).

Potential Profile in a Packed-Bed Electrode. The potential profile in a packed-bed electrode was examined under the conditions of constant current electrolysis (Fig. 6). The change of solution potential was measured along the bed depth by using a fine Luggin capillary. The change of particle potential was measured also along the bed depth by the probe described in the experimental section. Both potentials were referred to a current feeder which was at the furthest position from a counter electrode. In this experiment the total current was 100 mA and the apparent current density per cross sectional area of packed-bed electrode became 75 mA/cm². Potential changes became very small at the current densities lower than 10 mA/cm² and, on the other hand, the convection occurred in the bed at the current densities higher than 400 mA/cm². This convection is ascribed to the large Joule heat. Accordingly, the same profile as in Fig. 6 was observed between 10 mA/cm² and 400 mA/cm². The effective depth of the bed electrode on which nitrobenzene reacts is considered from Fig. 6 to be less than 3 mm, because the particle potential must be more negative by 200 mV than the solution potential for the reduction of nitrobenzene, as shown in Fig. 2. The low value of the effective depth is ascribed to the low conductivity of the electrolyte and to the high electronic conductivity of the packed-bed. At deeper positions in the packed-bed electrode, the potential of the particle electrode became more positive than the solution potential at the same position. This may cause the dissolution of copper. In order to increase the effective depth of the packed-bed electrode, bed particles of lower electronic conductivity must be used.

The authors wish to thank the staff of the Asahi Glass Foundation for the Contribution to Industrial Technology for their support of this work.

Absorption Spectra of Four Naphthalenediols with C_{2v} Symmetry. Interpretation by Means of Configuration Analysis

Tsuneo FUJII and Satoshi SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received January 12, 1976)

The electronic absorption spectra of four substituted naphthalenes with two electron-donating groups, 1,4-, 1,8-, 2,3-, and 2,7-naphthalenediols, have been investigated by means of configuration analysis, with particular attention paid to the dependence of the spectra on the positions of substitutions and on the molecular symmetry. The wave functions calculated by the Pariser-Parr-Pople method are analyzed in terms of locally-excited states and intramolecular charge-transfer states. The excited electronic wave functions of naphthalenediols have been expanded not only in terms of the electronic states of naphthalene, but also in terms of those of naphthol. The present configuration analysis shows that the electronic states of all these four naphthalenediols may reasonably interpreted in terms of locally-excited states of the parent compounds and charge-transfer states from the substituents to the parent compounds. The characteristic spectral changes in the L_b, L_a, and B_b bands caused by substitution are adequately explained in relation to the positions and to the molecular symmetry. The intensification of the L_b band caused by the introduction of the hydroxyl groups is interpreted as due to the mixing between the L_b and B_b bands. The B_b reference state interacts with the L_b and A_g^- reference states in 1,4- and 2,3-naphthalenediols, whereas it interacts with the L_b, B_{1g}^+, and B_{1g}^- reference states in 1,8- and 2,7-naphthalenediols.

The electronic absorption spectra of naphthalene derivatives show characteristic behavior depending on the position and the properties of the substituents. The electronic spectra of monosubstituted naphthalenes are now well understood both theoretically and experimentally.[1-8]

However, little attention has been directed to the electronic spectra of disubstituted naphthalenes, although some studies have been made from both theoretical and experimental points of view.[4,9-12]

The present paper will report on the results of configuration analysis (hereafter abbreviated to CA) for four naphthalenediols, 1,4-, 1,8-, 2,3-, and 2,7-naphthalenediols (hereafter abbreviated to 1,4-, 1,8-, 2,3-, and 2,7-diol respectively), based on two different types of reference compounds, naphthalene and naphthols. The 1,4- and 2,3-diols have a symmetry axis along the long(b) axis of the naphthalene ring while the 1,8- and 2,7-diols have a symmetry axis along the short(a) axis. The interaction scheme of the naphthalenediols is expected to be more simple than that of monosubstituted naphthalenes.

Calculation

The method of a semi-empirical LCAO-SCF-CI calculation and the procedure of the CA are the same as has been described previously.[6,7] It is assumed that the molecules studied have a planar structure and that the naphthalene ring consists of regular hexagons with every C–C bond length equal to 1.40 Å. The parameters, the bond lengths, r, the valence-state ionization potentials, I, the electron affinities, A, and the resonance integrals, β, are the same in a previous paper.[6] The C–C–O bond angle is assumed to be equal to 120°.

The SCF MO's are numbered in the order of increasing energy. In the CI calculation of 1,4-diol, the following eleven singly excited configurations are included: 7→8, 9, 10, 11; 6→8, 9, 10; 5→8, 9; 4→8, 9. One more configuration is added for the other diols. The added configuration is as follows: for 1,8-diol, 5→10; for the 2,3- and 2,7-diols, 6→11.

Experimental

The 1,4-, 2,3-, and 2,7-diols were purified by treating them with decolorizing carbon and by repeated crystallizations and subsequent sublimation *in vacuo* prior to use. Isooctane (2,2,4-trimethylpentane) was fractionally distilled and then passed through a column of silica gel. The absorption spectra were recorded on a Hitachi EPS-3 recording spectrophotometer.

Results

The calculated energies, the oscillator strengths(f), and the directions of the transition moments for the lower singlet states of naphthalenediols are presented in Table 1, together with the observed data. The data of naphthalene and naphthols used in the present study were given in a previous paper.[6] The symbols used in the present paper for denoting the electronic states and absorption bands have the same meaning as the corresponding symbols in that previous paper,[6] unless otherwise noted. The X-axis and Y-axis are taken along the long and short axes of the naphthalene ring respectively. The newly observed absorption spectra of three naphthalenediols are shown in Figs. 1, 2, and 3. The calculated energies are indicated in the figures by vertical lines, the lengths of which represent the relative values of the oscillator strength.

The results of the CA of naphthalenediols on the basis of the state functions of naphthalene are presented in Tables 2, 4, 6, and 8. The reference MO's employed in the present study are the SCF MO's of naphthalene ϕ_1°, ϕ_2°,……, ϕ_{10}°, and two MO's of the substituents, ϕ_{0+}° and ϕ_{0-}°, which are linear combinations of the two AO's, χ_{01} and χ_{02}, of the substituents:

$$\phi_{0+}^\circ = \frac{1}{\sqrt{2}}(\chi_{01}+\chi_{02}),$$

$$\phi_{0-}^\circ = \frac{1}{\sqrt{2}}(\chi_{01}-\chi_{02}).$$

a) Estimated for an isooctane solution. See Text.

The reference states which were taken into account in this analysis are as follows: the ground reference state and thirteen excited reference states of naphthalene, Ψ_G°, Ψ_1°,……, Ψ_{13}°; six intramolecular charge-transfer reference states, and $\Psi_{CTO\to k+}^\circ$ and $\Psi_{CTO\to k-}^\circ$, which correspond to a one-electron excitation from ϕ_{0+}° and ϕ_{0-}° to ϕ_k° with $k=6$, 7, and 8. Of these nineteen excited reference states, the seven locally excited reference states and six intramolecular charge-transfer reference states are listed in Tables 2, 4, 6, and 8. The total weight means the sum of the weights of all the twenty reference states described above.

The CA of naphthalenediols calculated on the basis of the state functions of 1- or 2-naphthol can also be made in an analogous manner. These results are presented in Tables 3, 5, 7, and 9. In these cases, the reference MO's are the SCF MO's of naphthols ϕ_1°, ϕ_2°,……, ϕ_{11}°, and the π-AO of the substituent, ϕ_0°. In these calculations the reference states are as follows: the ground reference state, Ψ_G°, and the locally excited reference states of naphthol (13 states for 1-naphthol or 14 states for 2-naphthol), and the three intramolecular charge-transfer states, $\Psi_{CTO\to k}^\circ$, which correspond to a one-electron excitation from ϕ_0° to ϕ_k° with $k=7$, 8, and 9. The total weight means the sum of the weights of all the seventeen (or eighteen) reference states for 1,4- and 1,8- (or 2,3- and 2,7-) diols.

The band assignments are given in Tables 2—9. When a single reference state has a weight higher than 50%, the state notation of the state is indicated in the columns of the band assignments. The notations given in the columns of the reference absorption bands of Tables 3, 5, 7, and 9 are the same as the band assignments of 1- and 2-naphthols given in a previous paper.[6]

Discussion

It may be seen in Table 1 that the calculated energies for the naphthalenediols are in good agreement with the observed values.

Naphthalenediols, like monosubstituted naphthalene,[6,7] show absorption spectra characteristic of the positions of substituents. The first and second absorption bands (L_b and L_a in naphthalene) overlap strongly in 1,8-diol, and coalesce into one band in 1,4-diol. Two absorption bands appear in the region of the B_b band of naphthalene in 1,4-diol, while only one absorption band appears in the B_b band region in 1,8-diol. In contrast to this, the spectra of 2,3- and 2,7-diols resemble the naphthalene spectrum in the first and second absorption bands, although a weak absorption band appears on the lower side of the strong absorption band in the region of the B_b band of naphthalene.

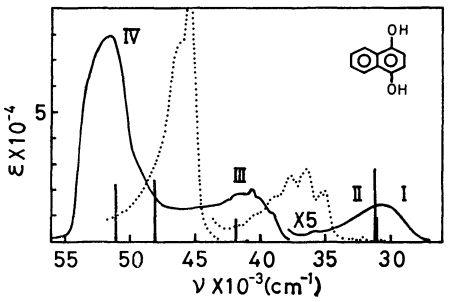

Fig. 1. Absorption spectrum in isooctane solution of 1,4-naphthalenediol. The dotted curve is the spectrum of naphthalene. Vertical lines represent theoretical spectra, with the lengths of lines indicating relative values of oscillator strengths.

1,4-Naphthalenediol. Figure 1 shows the absorption spectrum of 1,4-diol in isooctane, including the calculated data. With reference to the results shown in Tables 1 and 2, Bands I, II, and III may be assigned to the transitions to the Ψ_1, Ψ_2, and Ψ_4 while Band IV is actually composed of two absorption bands related to Ψ_6 and Ψ_7.

Table 2 shows that Bands I and II can reasonably be assigned to the L_b and L_a states respectively. The $\Psi_{CTO\to 7+}^\circ$ state makes an important weight contribution to the Ψ_1 state (11.4%). The $\Psi_{CTO\to 6+}^\circ$ state similarly

makes a large weight contribution to the Ψ_2 state (18.1 %). This large contribution is responsible for the large red shift of Band II. The 1,4-diol has C_{2v} symmetry, so that the L_b state does not interact with the L_a state but interacts with the B_b state, from which the intensity of Band I is derived.

The B_b state interacts with the A_g^- state and splits into two bands, Bands III and IV. The B_{2u}^+ state (Ψ_7) overlaps with the B_b (Ψ_6), yielding Band IV. This interaction is characteristic of the naphthalene derivatives with a substituent at the 1-position.[8] The $\Psi_{CTO\to 7+}^\circ$ state has a weight of 10.0% in the Ψ_4 state. There are no substantial contributions of charge-transfer states to the Ψ_6 and Ψ_7 states.

It may be seen from Table 3 that Bands I, II, III, and IV can also reasonably be assigned to Bands i, ii, iii, and iv of 1-naphthol. The $\Psi_{CTO\to 7}^\circ$ and $\Psi_{CTO\to 8}^\circ$ states make a important weight contributions to the Ψ_2 and Ψ_1 states (9.7 and 7.0% respectively). The results show that the hydroxyl group still has an electron-donating character with respect to 1-naphthol. The total weights of the individual excited states are about 90%; therefore, the electronic states of 1,4-diol can be well reproduced from the ground and the excited reference states of 1-naphthol and the intramolecular charge-transfer reference states.

1,8-Naphthalenediol. The observed values obtained by other authors between 220 and 350 nm in ethanol are used in the present study.[18] There are three bands, I, II, and III; their energies are 3.7, 4.1, and 5.5 eV respectively. The band shifts of Bands i, ii, and iii of 1-naphthol on going from an isooctane to an ethanol solution are 150, 750, and 700 cm^{-1} respectively. Provided that the band shifts of 1,8-diol are the same as those of 1-naphthol, the state energies of 1,8-diol in isooctane may be estimated to be 3.7, 4.2, and 5.6 eV

respectively.

According to Table 4, Bands I, II, and III can reasonably be assigned to the L_b, L_a, and B_b states respectively. As in the case of 1,4-diol, the L_b state interacts not with the L_a state, but with the B_b state, because of symmetry. The intensity of Band I is derived from the mixing with the B_b. The $\Psi_{CTO\to7+}^\circ$ and $\Psi_{CTO\to6+}^\circ$ states make weight contributions to the Ψ_1 and Ψ_2 states of 7.6 and 8.4% respectively.

The B_b state interacts not with the A_g^- state, but with the B_{1g}^+ and B_{1g}^- states. Hence, there is no interaction characteristic of naphthalene derivatives with a substituent at the 1-position. It is noteworthy that the interactions of the B_b state with the B_{1g}^+, A_g^-, and B_{1g}^- states are extremely small in extent in 1,8-diol compared with the other diols studied in this paper (see below).

Table 5 shows the results of the CA for 1,8-diol using the state functions composed of 1-naphthol and the OH substituent as the reference state functions. Band i of 1-naphthol contributes to the Ψ_1 state by a weight of 51.5%. Bands II and III have no reference states which singly exceed 50.0%. The total weights of 1,8-diol are smaller than those of 1,4-diol by about 20—30%.

calculated data.

From Table 6, the mixing between the B_b and A_g^- states is responsible for the Ψ_3 (Band III) and Ψ_6 (Band IV) states, and Band IV is composed of the two states which correspond to the transitions to the Ψ_5 and Ψ_6 states. Bands I and II are assigned to the L_b and L_a respectively. The $\Psi_{CTO\to6-}^\circ$ state makes contributions of 10.1 and 8.2% to the Ψ_1 and Ψ_3 states. The $\Psi_{CTO\to7-}^\circ$ state makes an important weight contribution to the Ψ_5 state of 21.5%.

Table 7 shows the results of the CA for 2,3-diol using the state functions composed of 2-naphthol and the OH substituent as the reference state functions. Bands I and II are assigned to Bands i and ii of 2-naphthol respectively. There is large mixing among the Ψ_3°, Ψ_4°, and Ψ_5° states and among the Ψ_5°, Ψ_6°, and Ψ_7° states. These mixings are responsible for Bands III and IV. The $\Psi_{CTO\to7}^\circ$ state makes contributions of 5.6, 2.8, and 5.0% to the Ψ_1, Ψ_2, and Ψ_3 states respectively. The $\Psi_{CTO\to8}^\circ$ state makes a contribution of 11.6% to the Ψ_5 state.

The total weights are about 90%, so that the electronic states of 2,3-diol are well expanded in terms of the electronic states of 2-naphthol and the charge-transfer states from the substituent to 2-naphthol, as in the case of 1,4-diol.

2,7-Naphthalenediol. The absorption spectrum of 2,7-diol in isooctane is shown in Fig. 3, together with the calculated data. Table 1 shows that Band IV is composed of the transitions of the Ψ_5, Ψ_6, and Ψ_7 states. From Table 8, Bands I and II may be assigned to the L_b and L_a states respectively. The Ψ_5 state is made from the interaction among the B_{1g}^+, B_b, and B_{1g}^- states. The $\Psi_{CTO\to6-}^\circ$ state contributes to the Ψ_1 state by a weight of 10.5% and to the Ψ_4 state by a weight of 6.4%.

Table 9 shows the results of the CA of the 2,7-diol

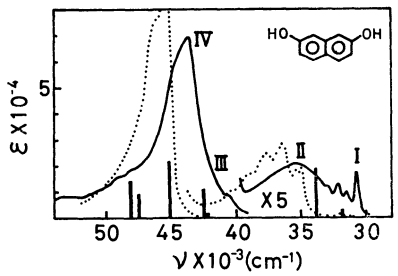

Fig. 3. Absorption spectrum in isooctane solution of 2,7-naphthalenediol. The dotted curve and the lengths of lines have the same meaning as in Fig. 1.

based on 2-naphthol. The results of the CA indicate that Bands I, II, and IV are closely connected with Bands i, ii, and iii of 2-naphthol respectively. The total weights of 2,7-diol are smaller than those of 2,3-diol by about 20—30%. This is analogous to the situation between 1,4- and 1,8-diol.

Remarks and Conclusions. When one chooses 1- or 2-naphthol as the parent compound in the CA, there is a marked difference in the total weight depending on the type of naphthalenediol. The total weights for the 1,4- and 2,3-diols, which have two substituents in the same benzene ring, are slightly larger on the naphthol basis than those on the naphthalene basis, whereas the total weights for 1,8- and 2,7-diols, which have one substituent in every benzene ring, are considerably smaller on the naphthol basis than those on the naphthalene basis. Such a marked difference indicates that the state functions of naphthols are a good basis for the expansion of the state functions of 1,4- and 2,3-diols; however, they are a poor basis for 1,8- and 2,7-diols. This suggests that the interaction between two substituents in diols differs depending on whether or not the two substituents lie on the same benzene ring.

The Surface Tension of Aqueous Solutions Saturated with Triacetin-Tributyrin Mixtures

Noriaki FUNASAKI and Sakae HADA

Kyoto College of Pharmacy, Yamashina, Kyoto 607

(Received March 12, 1976)

The surface tension of aqueous solutions saturated with triacetin–tributyrin mixtures was measured in order to study the phase equilibria among an adsorbed monolayer (m), an aqueous solution (w), and an oily mixture (l). The variation in the surface tension, γ, of saturated aqueous solutions with an increase in the number of moles, m_t, of the added mixtures depended on the mole fractions, x_2, of tributyrin in the mixtures; the γ value remained unchanged in the case of $x_2=0.0027$, decreased in the case of $x_2>0.0027$, and increased in the case of $x_2<0.0027$. The results of the theoretical analysis of the γ *vs.* m_t curves gave the mole fractions, x_2^l, of tributyrin in the oily mixtures. The x_2^l values thus evaluated agreed with those determined gas-chromatographically. It was found that all of the γ *vs.* x_2^m, γ *vs.* x_2^l, and γ *vs.* x_2^w curves have a minimum, at which the γ values are identical and at which $x_2^m=x_2^l>x_2^w$. The characteristics of these curves were explained thermodynamically on the basis of the assumption that triacetin and tributyrin form a regular mixture in a monolayer as well as in a liquid.

The overcompression and the dissolution of a spread monolayer often make it impossible to study the equilibrium state between the spread monolayer and the bulk of the film-forming substance on an aqueous surface.[1-4] When a film-forming substance is soluble in the underlying water, the equilibria among the adsorbed monolayer, the bulk, and the saturated aqueous solution are easily established.

Hence, the present authors measured the surface tension of aqueous solutions saturated with triacetin–tributyrin mixtures and discussed thermodynamically the results of the adsorbed monolayer-bulk equilibrium in comparison with those of the spread monolayer-bulk equilibrium.[2-6]

Theoretical

We consider a system composed of a liquid mixture of Component 1 and 2 (oily phase) and an aqueous solution (aqueous phase) in equilibrium with each other. The notations used hereafter are summarized in Table 1. The superscripts, w, l, and m mean the aqueous phase, the oily phase, and an adsorbed monolayer at the air-water interface. The superscript o means the pure substance or the standard state. The subscripts 1 and 2 mean triacetin and tributyrin, and the subscript t means the sum of the parts of triacetin and tributyrin.

Table 1. List of notations

γ: surface tension of an aqueous solution
F: surface pressure on an aqueous surface
V: total volume of water in the system
C: concentration of an aqueous solution
C_i^{ow}: solubility of a pure liquid, i, in water
Γ: adsorption amount at the air-water interface
$\bar{A}_i$: partial molecular area of Component i
μ_i: chemical potential of Component i
B: constant representing the intermolecular interaction
m: moles of triglyceride
R: gas constant
k: Boltzmann constant
T: absolute temperature
N: Avogadro number
$C_t=(m_1+m_2)/V$
$x_2^l=m_2^l/(m_1^l+m_2^l)$
$x_2^m=\Gamma_2/(\Gamma_1+\Gamma_2)$
$x_2^w=C_2^w/(C_1^w+C_2^w)$

Surface Tension of Saturated Aqueous Solutions. Although the following consideration is entirely general, we illustrate the γ *vs.* log C_t curves for triacetin–tributyrin mixtures in Fig. 1a. We consider the interrelation between the curves of γ *vs.* log C_t and γ *vs.* x_2^l in the presence of both aqueous and oily phases.

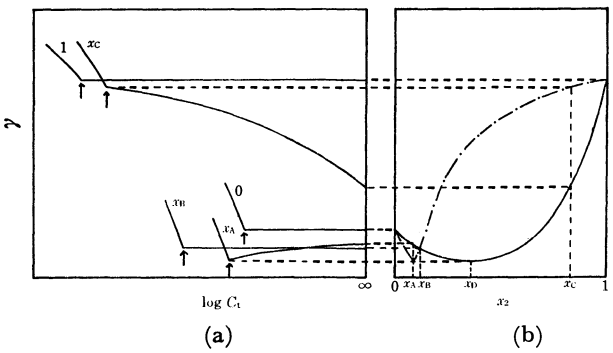

Fig. 1. Schematic interrelationship between curves of (a) γ *vs.* log C_t, and (b) γ *vs.* x_2^l (solid line) and x_2^w (chained line). Arrows indicate saturation.

When we drop a liquid mixture with the composition of x_2 into water of a given volume, V, we have a kinkpoint on the γ *vs.* log C_t curve, as is shown in Fig. 1a. The concentration at the kinkpoint, C_t^w (shown by an arrow), indicates the solubility. The relation between the surface tension and the mole fraction of Component 2 in the aqueous solution, x_2^w (equal to the value of the dropped-in liquid mixture, x_2) at the kinkpoint is shown by a chained line in Fig. 1b. When we drop in an infinite amount of a liquid mixture, though, we can neglect the amount dissolved into the water. Thus, we can obtain the relation between the surface tension at $C_t\to\infty$ and the mole fraction of Component 2 in the oily phase, x_2^l (equal to the value of the dropped-in liquid mixture, x_2), as is shown by a solid line in Fig. 1b. This relation can also be obtained through the simultaneous determination of the surface tension of the aqueous solution and the composition of the oily mixture

in equilibrium with the former.

As is shown in Fig. 1a, the surface tension of the aqueous solution saturated with the pure substance, 1 (Curve 0) or 2 (Curve 1), remains unchanged regardless of the presence of an excess of the substance. In particular, the liquid mixture with the composition, x_B, at which the solid and chained lines in Fig. 1b intersect each other, behaves as if it were a pure substance in this respect (Curve x_B). On the other hand, as the dropped-in amount of a liquid mixture at $x_2<x_B$ increases, the surface tension passes through a minimum (*e.g.*, Curve x_A). When a liquid mixture at $x_2>x_B$ is dropped in, the surface tension gradually decreases with an increase in the C_t (*e.g.*, Curve x_C). In the case of mixtures, a variation in the surface tension of aqueous solutions with an increase in C_t results from the simultaneous variation of the compositions in the aqueous and oily phases.

We can obtain the relation between x_2^w and x_2^l at an equilibrium state from Fig. 1b. If a horizontal line is drawn at a given surface tension in Fig. 1b, the points of the intersection of this line with a solid and a chained line give the mole fractions of Component 2 in the oily and aqueous phases respectively. For example, it is found that the aqueous solution with the composition of x_A is in equilibrium with the oily mixture with the composition of x_D.

When we drop a mixture with the composition of x_2 into water above its solubility, we can calculate the γ *vs.* log C_t relation, using the experimental values of γ, C_1^w, and C_2^w of the aqueous solution in equilibrium with the oily mixture with the composition of x_2^l. The total moles of Components 1 and 2 can be given by the following equations:

$$C_t x_1 V = C_1^w V + m^l x_1^l \quad (1)$$

$$C_t x_2 V = C_2^w V + m^l x_2^l \quad (2)$$

Eliminating m^l, the total moles of the oily mixtures, from Eqs. 1 and 2, we obtain Eq. 3:

$$C_t = \frac{C_1^w x_2^l - C_2^w x_1^l}{x_1 x_2^l - x_2 x_1^l} \quad (3)$$

Using Eq. 3, we can calculate a C_t value at a given surface tension for the saturated aqueous solution.

Conversely, we can also obtain the expression for x_2^l from Eq. 3:

$$x_2^l = \frac{C_t x_2 - C_2^w}{C_t - C_1^w - C_2^w} \quad (4)$$

Hence, we can calculate an x_2^l value (the composition of the oily mixture) at a given surface tension from Eq. 4, using the γ *vs.* log C_t relation.

Equilibria among Aqueous, Oily, and Surface Phases. Assuming that triacetin and tributyrin form a regular solution in an oily mixture as well as in an adsorbed monolayer, and that they behave as a dilute solution in an aqueous solution, we can express the chemical potentials, μ_i, of Component i (i=1 or 2) in the oily mixture, the adsorbed monolayer, and the aqueous solution as follows:

$$\mu_i^l = \mu_i^{ol} + RT \ln x_i^l + B^l(1-x_i^l)^2 \quad (5)$$

$$\mu_i^m = \mu_i^{om} + RT \ln x_i^m + B^m(1-x_i^m)^2 + N\bar{F}\bar{A}_i \quad (6)$$

$$\mu_i^w = \mu_i^{ow} + RT \ln C_i^w \quad (7)$$

where μ_i^{ol} is the chemical potential of the pure liquid, i; μ_i^{om} and μ_i^{ow} are the standard chemical potentials, and $\bar{A}_i$ is the partial molecular area of Component i. Equation 6 has also been used for a spread monolayer.[3-6]

Equilibrium between Aqueous and Oily Phases. From the equality of the chemical potential in the phase equilibria, we can obtain:

$$\mu_1^{ow} + RT \ln C_1^w = \mu_1^{ol} + RT \ln x_1^l + B^l(x_2^l)^2 \quad (8)$$

$$\mu_2^{ow} + RT \ln C_2^w = \mu_2^{ol} + RT \ln x_2^l + B^l(x_1^l)^2 \quad (9)$$

using Eqs. 5 and 7. When x_i^l is equal to 1, we obtain from Eqs. 8 and 9:

$$\mu_1^{ow} + RT \ln C_1^{ow} = \mu_1^{ol} \quad (10)$$

$$\mu_2^{ow} + RT \ln C_2^{ow} = \mu_2^{ol} \quad (11)$$

where C_i^{ow} represents the solubility of the pure liquid, i, in water. Using Eqs. 8—11, we obtain Eqs. 12—14:

$$C_1^w = C_1^{ow} x_1^l \exp\left[\frac{B^l}{RT}(x_2^l)^2\right] \quad (12)$$

$$C_2^w = C_2^{ow} x_2^l \exp\left[\frac{B^l}{RT}(x_1^l)^2\right] \quad (13)$$

$$C_t^w = C_1^{ow} x_1^l \exp\left[\frac{B^l}{RT}(x_2^l)^2\right] + C_2^{ow} x_2^l \exp\left[\frac{B^l}{RT}(x_1^l)^2\right] \quad (14)$$

If the B^l value is assumed appropriately, we can calculate the C_t^w *vs.* x_2^l curve from Eq. 14, and also the C_t^w *vs.* x_2^w curve from Eqs. 12 and 13.

Equilibrium between Oily and Surface Phases. In the equilibrium state of the two phases, we can obtain from Eqs. 5 and 6 the following equations:

$$\mu_1^{ol} + RT \ln x_1^l + B^l(x_2^l)^2 = \mu_1^{om} + RT \ln x_1^m + B^m(x_2^m)^2 + N\bar{F}\bar{A}_1 \quad (15)$$

$$\mu_2^{ol} + RT \ln x_2^l + B^l(x_1^l)^2 = \mu_2^{om} + RT \ln x_2^m + B^m(x_1^m)^2 + N\bar{F}\bar{A}_2 \quad (16)$$

Using Eqs. 15 and 16, as has been shown previously,[5] we can obtain the following equations:

$$x_1^l \exp\left[B^l (x_2^l)^2\right] = x_1^m \exp\left[\frac{B^m}{RT}(x_2^m)^2 + \frac{F\bar{A}_1 - F_{1e}A_{1e}}{kT}\right] \quad (17)$$

$$x_2^l \exp\left[\frac{B^l}{RT}(x_1^l)^2\right] = x_2^m \exp\left[\frac{B^m}{RT}(x_1^m)^2 + \frac{F\bar{A}_2 - F_{2e}A_{2e}}{kT}\right] \quad (18)$$

where F_{ie} and A_{ie} are the surface pressure and the molecular area at the interface between the air and an aqueous solution saturated with a pure substance, i. We can obtain the F *vs.* x_i^l and F *vs.* x_i^m relations by solving Eqs. 17 and 18 simultaneously if the $\bar{A}$ value is found and if the B^l and B^m values are assumed appropriately.

Equilibrium between Aqueous and Surface Phases. We can calculate the F *vs.* x_i^w curve using Eqs. 12, 13, 17, and 18 if the B^l and B^m values are assumed appropriately.

Experimental

Materials. The triacetin and tributyrin used were

obtained from Nakarai Chemicals.[7] The ion-exchanged water was twice distilled before use.

Measurement. A triacetin–tributyrin mixture was dropped into water of a given volume with a weight-pippete and the surface tension of the aqueous solution was measured at 37±0.2 °C by means of the Wilhelmy method.[7] The concentration, C, was expressed on a solute mole/water volume basis. When the amount of the oily mixture was relatively great, we measured the surface tension of the aqueous solution separated from the oily mixture.

The composition of the oily mixture separated from the aqueous solution was determined with a Shimadzu gas chromatograph, GC-3BT. The water content in the oily mixtures was found to be negligibly small.

Results

Figure 2 shows the plots of the surface tension of aqueous solutions, γ, against the logarithm of the total concentration, C_t, when a triacetin–tributyrin mixture with the composition of x_2 was dropped into the water. The kinkpoints (indicated by arrows) on the γ *vs.* log C_t curves indicate saturation.

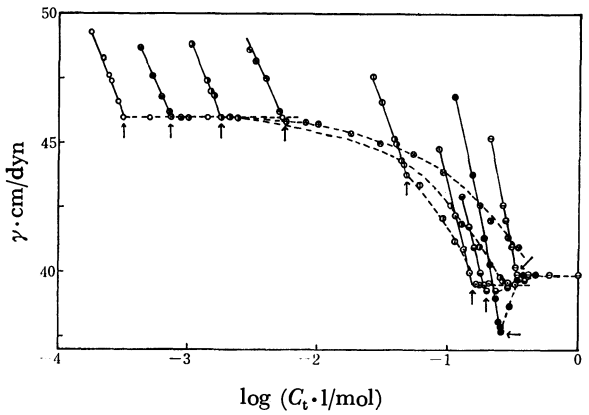

Fig. 2. The γ *vs.* log C_t relations at different compositions x_2: ○; 1, ⊗; 0.500, ◑; 0.234, ⊕; 0.0863, ⓘ; 0.010, ⊙; 0.0027, ◒; 0.0020, ●; 0.00059, ⊖; 0. Dotted lines are calculated from Eq. 3.

The surface tension above the concentration of the saturation points remained unchanged when the liquid dropped in was either a pure substance (triacetin or tributyrin) or a mixture at x_2=0.0027, which is nearly equal to the composition of the intersection of the solid lines in Fig. 4 to be described below. On the other hand, the γ value increased in the case of mixtures at $x_2<0.0027$, but decreased in the case of mixtures at $x_2>0.0027$, with an increase in the C_t.

Figure 3 shows the relation between the surface tension and the logarithm of the total concentration of triacetin, C_1, when triacetin was dropped into tributyrin solutions with the concentration of C_2. The kinkpoints (shown by arrows) indicate the saturation.

The open circles in Fig. 4 show the relation between the surface tension and the mole fraction of tributyrin in an aqueous solution, x_2^w. Furthermore, the closed circles in Fig. 4 show the relation between the surface tension of the aqueous solutions and the mole fraction of tributyrin in the oily phase (in equilibrium with the former), x_2^l, which was determined gas-chromatographically.

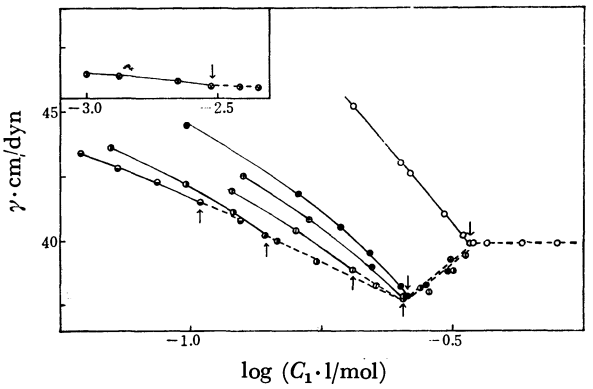

Fig. 3. The γ *vs.* log C_1 relations at different concentrations of tributyrin C_2 (mol/l)×10⁴: ⊗; 3.94, ◒; 3.31, ◑; 3.02, ⓘ; 1.89, ⊕; 1.46, ●; 1.13, ○; 0. Dotted lines are calculated from Eq. 22.

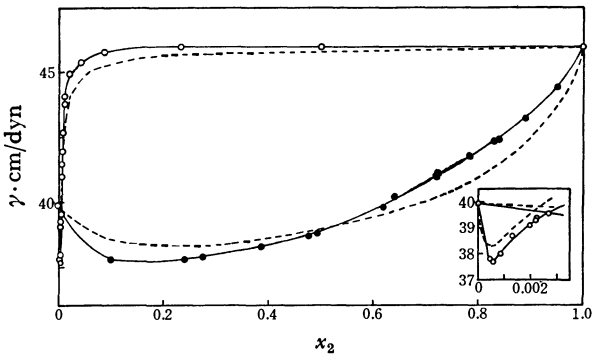

Fig. 4. The curves of γ *vs.* x_2^l (closed circles) and γ *vs.* x_2^w (open circles) with partial expansion of tributyrin-poor region as an insert. Dotted lines are calculated from Eqs. 12, 13, 17, and 18 with $B^l=0.5RT$ and $B^m=-1.9RT$.

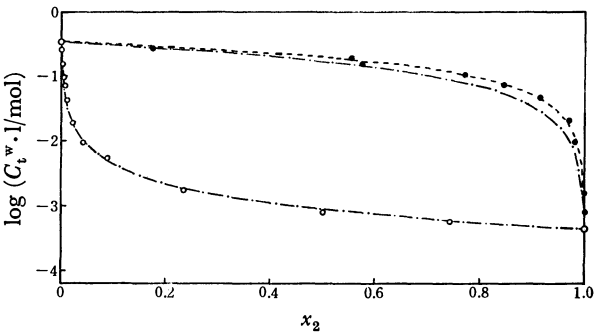

Fig. 5. The plots of log C_t^w *vs.* x_2^w (open circles) and *vs.* x_2^l (closed circles). Chained and dotted lines are calculated from Eqs. 12—14 with $B^l=0$ and $B^l=0.5RT$.

The open circles in Fig. 5 show the log C_t^w *vs.* x_2^w relation obtained from the kinkpoints (indicated by arrows) in Figs. 2 and 3. In addition, the closed circles in Fig. 5 show the log C_t^w *vs.* x_2^l curve determined from the x_2^l *vs.* x_2^w relation, which was obtained from the intersections of the horizontal line with the γ *vs.* x_2^w and γ *vs.* x_2^l curves in Fig. 4.

We can write the Gibbs adsorption equation in aqueous solutions of Components 1 and 2 as:[8]

$$-d\gamma = \Gamma_1 RT\, d\ln C_1^w + \Gamma_2 RT\, d\ln C_2^w \quad (19)$$

In the case of a constant C_1^w/C_2^w ratio, Eq. 19 is reduced to:

$$-d\gamma = (\Gamma_1+\Gamma_2)RT\, d\ln C_t^w \quad (20)$$

Hence, we can obtain the γ *vs.* $(\Gamma_1+\Gamma_2)$ relation for the adsorbed monolayers in equilibrium with oily mixtures; the respective values of γ and $(\Gamma_1+\Gamma_2)$ are evaluated at the kinkpoints in Fig. 2.

On the other hand, in the case of a constant C_2^w, Eq. 19 is reduced to:

$$-d\gamma = \Gamma_1 RT\, d\ln C_1^w \quad (21)$$

Hence, we can obtain the γ *vs.* Γ_1 relation for the adsorbed monolayers in equilibrium with oily mixtures; the respective values of γ and Γ_1 are evaluated at the kinkpoints in Fig. 3.

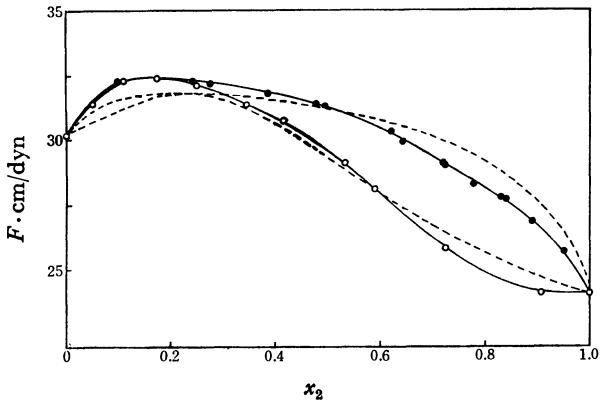

Fig. 6. The plots of F *vs.* x_2^1 (closed circles) and *vs.* x_2^m (open circles). Dotted lines are calculated from Eqs. 17 and 18 with $B^1=0.5RT$ and $B^m=-1.9RT$.

Thus, we can obtain the relation between the surface pressure, F, and the mole fraction, x_2^m, of tributyrin in an adsorbed monolayer from the combination of the γ *vs.* $(\Gamma_1+\Gamma_2)$ and γ *vs.* Γ_1 relations. This result, shown by open circles in Fig. 6, is found to be similar to that for the spread mixed monolayers of 1-hexadecanol and 1-octadecanol.[4] The upper and lower curves in Fig. 6 correspond to the curves of the equilibrium-spreading pressure and the collapse pressure respectively.

Discussion

Surface Tensions of Saturated Aqueous Solutions. We can calculate a C_t value by substituting into Eq. 3 the values of C_1^w and C_2^w (determined from the kinkpoints in Figs. 2 and 3) and x_2^1 (obtained from the upper solid curve in Fig. 6) at a given surface tension when a liquid mixture with the composition of x_2 is dropped in and when the aqueous and oily phases coexist in equilibrium. The γ *vs.* log C_t curves thus obtained are shown by dotted lines in Fig. 2. Similarly, when we drop triacetin into a tributyrin solution with the concentration of C_2, we can calculate the C_1 value by means of the following equation:

$$C_1 = C_1^w + \frac{(C_2-C_2^w)}{x_2^1} \times x_1^1 \quad (22)$$

Here, the experimental values of C_1^w, C_2^w, and x_2^1 at a given surface tension are substituted into Eq. 22. The γ *vs.* log C_1 curves thus obtained are shown by dotted lines in Fig. 3. The dotted lines in Figs. 2 and 3 were found to be in good agreement with the experimental results.

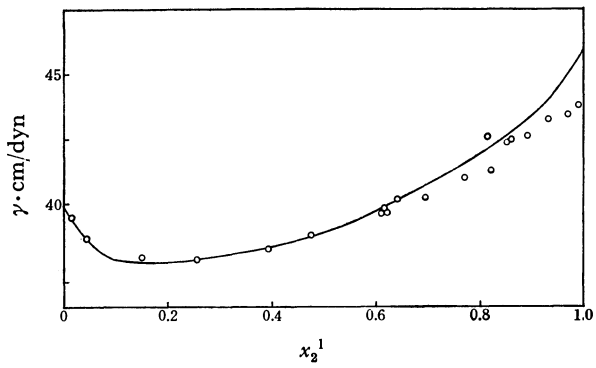

Fig. 7. The γ *vs.* x_2^1 relation in which a solid line is etermined gas-chromatographically and open circles are calculated from Eq. 4.

Conversely, we can calculate an x_2^1 value at a given surface tension by using Eq. 4 and the experimental results of the γ *vs.* log C_t curves in Fig. 2. The results thus calculated are plotted by open circles in Fig. 7. The solid line is drawn through the x_2^1 values determined gas-chromatographically. Thus, it was found that we can evaluate the composition of oily mixtures from the concentration dependence of the surface tension of aqueous solutions saturated with oily mixtures.

Equilibria among Aqueous, Oily, and Surface Phases. Assuming that $B^1=0.5RT$, we can calculate the log C_t^w *vs.* x_2^w (lower curve) and log C_t^w *vs.* x_2^1 (upper curve) relations from Eqs. 12—14. These relations, shown by dotted lines in Fig. 5, agree well with the experimental results. The chained lines in Fig. 5 show the relations calculated from Eqs. 12—14 with $B^1=0$, *viz.*, as an ideal solution in the oily mixture. It should be noted that the B^1 value has little effect on the log C_t^w *vs.* x_2^w relation.

Furthermore, assuming that $B^1=0.5RT$ and $B^m=-1.9RT$, we can calculate the F *vs.* x_2^m (lower curve) and F *vs.* x_2^1 (upper curve) relations from Eqs. 17 and 18. These relations are shown by dotted lines in Fig. 6. In the above calculation, we used the values of $F_{1e}=30.19$ dyn/cm, $F_{2e}=24.12$ dyn/cm, $A_{1e}=41.6$ Å^2/molec, $A_{2e}=81.3$ Å^2/molec, $C_1^{ow}=0.343$ mol/l, and $C_2^{ow}=4.41\times10^{-4}$ mol/l and assumed that the $\bar{A}$ value is equal to the molecular area in an adsorbed monolayer of the pure substance.

The dotted lines in Fig. 4 are reproduced from the dotted lines in Figs. 5 and 6.

The dotted lines in Figs. 4, 5, and 6 represent fairly well the trend of the experimental results; this means that the above thermodynamic treatment is approximately valid.

The Partial Molar Volumes of Normal Alkanols in Aqueous Sodium Dodecyl Sulfate Solutions

Masahiro MANABE, Keishiro SHIRAHAMA,* and Masaharu KODA

Department of Industrial Chemistry, Niihama Technical College, Niihama, Ehime 792
**Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840*

(Received May 1, 1976)

The partial molar volumes of normal alkanols ($C_mH_{2m+1}OH$, $m=1$—10) in aqueous sodium dodecyl sulfate solutions were measured by a dilatometric method at 25 °C. For the alkanols ($m=4$—8), different constant partial molar volumes appeared below and above the CMC value, whereas no such difference was observed for lower alkanols ($m=1$—3), and for higher alkanols ($m=8$—10) the partial molar volumes above the CMC value are nearly identical with their own molar volumes. The partition coefficient of the alkanols between the bulk and micellar phases is estimated on the basis of the volumetric results.

It is known that the addition of small amounts of alkanol depresses the critical micelle concentration (CMC) of surfactants,[1-4] and some factors have been considered in order to explain the phenomenon from the viewpoint that the added alkanol is partitioned between the bulk and micellar phases. Few determinations, excepting a single work,[5] have ever been made of the amount of alkanol solubilized in micelles, in spite of the necessity of the quantity for estimating the factors contributing to solubilization phenomena. It is known that the partial molar volumes of alkyl derivatives[6-9] including surfactants[10-14] increase on passing from an aqueous environment to a nonpolar one. There have been, however, restricted investigations[15,16] of the volumetric behavior of solubilizates.

In the present study, the partial molar volumes of a series of normal alkanols were determined in sodium dodecyl sulfate solutions below and above CMC. On the basis of these results, a partition coefficient of alkanol between the bulk and micellar phases is estimated.

Experimental

The sodium dodecyl sulfate (SDS) were prepared as follows. Esterized dodecyl alcohol with sulfuric acid in absolute acetone was neutralized with a concentrated aqueous sodium hydroxide solution. The crude SDS crystal obtained from the acetone phase of the reaction mixture was recrystallized five times from acetone containing a small amount of water and then refluxed with petroleum ether. The CMC of the SDS in water was 8.30 mmol/kg[17] as determined by the conductivity method at 25 °C.

The methods of purification of water and normal alkanols used were the same as those described in an earlier paper.[9] Among the alkanols, nonyl alcohol was a commercially purified material (Tokyo Kasei Kogyo Co., Ltd., G. R. grade) and was used without further purification.

Partial molar volumes of alkanols in SDS solutions were measured using the same dilatometric method as shown in a previous paper,[9] in the alkanol-concentration range up to about 1 g/l. For higher alkanols, the solution in the dilatometer was stirred with each addition of alkanol for about one hour in order to insure sufficient dissolution. The dilatometer used in the measurements of the molar volumes of pure alkanols consits of only a glass capillary and injection parts.

Results and Discussion

Partial Molar Volumes of Normal Alkanols. The partial molar volume, V_a, of normal alkanols ($m=1$—10) was determined at different specific SDS concentrations, where m refers to the number of carbon atoms in the alkanol molecule. The results are plotted in Fig. 1 against the SDS concentration. It was found for alkanols with $m=4$—8 that a pair of almost constant V_a values appears: one below the CMC of SDS, expressed as V_a^D, and the other above CMC, V_a^M, where the CMC values are the ones in the presence of the added alkanols. This figure is coincident with the volumetric results of surfactants in water,[10] that is, in line with a pseudo-phase separation model of micelle formation.[18] Accordingly, the V_a^D value can be regarded as a partial molar volume of alkanol dissolved in a singly dispersed state, since the V_a in water cannot be distinguished from V_a^D, and V_a^M is probably contributed form the alkanol molecule dissolved in both the singly dispersed and solubilized states.

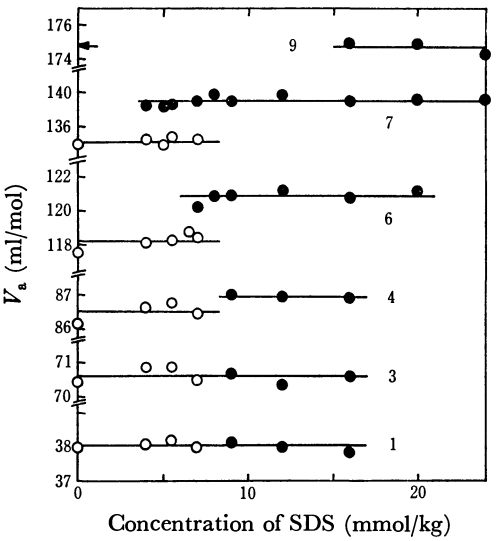

Fig. 1. Dependence of V_a on SDS concentration; ○: V_a below CMC, ●: V_a above CMC, and —: averaged V_a (V_a^D or V_a^M). The number indicates chain length of alcohol, and the arrow molar volume of nonyl alcohol.

For lower alkanols ($m=1$—3), however, all V_a values obtained here do not correspond to V_a^M but only to V_a^D even at SDS concentrations above the CMC value. During some determinations of the V_a^M of higher alkanols ($m=8$—10), the concentration of alkanol eventually

attained a maximum additive concentration (MAC),[19] at which turbidity appeared. The V_a^M in the absence of turbidity is little different from the partial molar volume determined in the presence of turbidity, and also from the molar volume of alkanol in the normal liquid state. The V_a^D value of alkanols (m=9, 10) could not be determined because of their very slight miscibility in water[20] and in SDS solutions below the CMC value. The almost constant V_a^D values as well as V_a^M values were averaged, respectively, and the mean values are shown in Table 1.

Table 1. The molar volumes and partial molar volumes of normal alkanols in SDS solutions, and the values of j and $j/(1-j)$

m	V_a^D (ml/mol)	V_a^M (ml/mol)	molar volume (ml/mol)	j	$j/(1-j)$
1	38.05		40.72[a]		
2	55.05		58.68[a]		
3	70.61		75.13		
4	86.48	86.90	91.85	0.077	0.084

10		191.6_8	191.1_2		

a) Taken from Ref. 29.

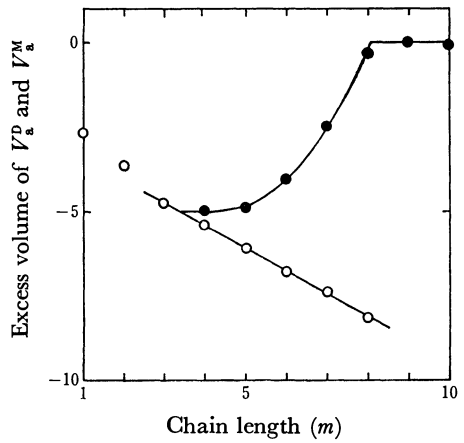

Fig. 2. Correlation of excess volumes with chain length of alcohol; ○: excess volume of V_a^D, ●: excess volume of V_a^M.

Figure 2 shows the dependence of both V_a^D and V_a^M on the chain length, m, in terms of the excess partial molar volume, the increment in the partial molar volume with respect to the molar volume, $V_a°$, which is calculated from the equation:

$$V_a° = 16.55m + 25.71 \quad (m=3—10). \qquad (1)$$

This equation is obtained by the least-squares method from the measured molar volumes given in Table 1. The excess volume of V_a^D is negative and decreases linearly with an increase in the chain length (m=3—8) except for lower alkanols (m=1, 2). Such a finding has also been made on the partial molar volumes of normal alkanols in water.[9] Hence the relation between V_a^D and the chain length is expressed by the least-squares method as

$$V_a^D = 15.87m + 23.02 \quad (m=3—8). \qquad (2)$$

The excess volume of V_a^M is negative and increases with an increase in the chain length for m=4—7 and then becomes zero at about m=8 or above. From the viewpoint of a pseudo-phase separation model of micelle formation, it is supposed that the added alkanol in the micellar solution is partitionally dissolved between the bulk and micellar phases. The solubilized fraction of added alkanol probably increases with the chain length of the alkanol molecule, and almost the entire amounts of these higher alkanols would be solubilized; the partial molar volume of the alkanol in the solubilized state should be identical with the molar volume in their normal liquid states.[16]

The curve for V_a^M, in Fig. 2, can be extrapolated to intersect with the one for V_a^D at about m=3.5. This critical chain length is comparable with that (C_3—C_5) estimated from the partial molar volume change of the surfactants on micellization as the shortest one needed for micellization according to Corkill *et al.*[12] It is likely that a solubilizate as well as surfactant with a normal alkyl chain shorter than four carbon atoms can hardly participate in the solubilization or micellization.

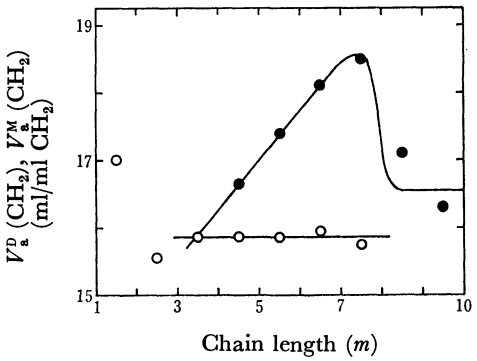

Fig. 3. Dependence of volume increment per methylene group on chain length of alcohol; ○: V_a^D (CH_2), ●: V_a^M (CH_2).

Volume Increment per Methylene Group. It is interesting and useful to discuss the increment in the partial molar volume per methylene group for normal alkanols with successive numbers of carbon atoms since the increment gives information about the environment of the group. As is shown in Fig. 3, the increment for V_a^D, denoted by $V_a^D(CH_2)$, except for lower alkanols (m=1, 2), has an almost constant value (15.87 ml/mol CH_2, *cf.* Eq. 2) which is in good agreement with the corresponding values of various normal alkyl chain derivatives in water (≈16 ml/mol CH_2).[21,22] The increment for V_a^M, $V_a^M(CH_2)$, indicates a nearly linear increase with an increase in the chain length (m=4—7) and then sharply decreases passing through a maximum to a probably constant value (16.55 ml/mol CH_2, *cf.* Eq. 1) above m=8, taking into account the identity of V_a^M and the molar volume. The $V_a^M(CH_2)$ attains the

constant $V_a^D(CH_2)$ at about $m=3.5$. These results for $V_a^M(CH_2)$ may be consistent with the interpretation on Fig. 2. The linear increase in the increment means that the V_a^M value is a quadratic function of the chain length:

$$V_a^M = 0.3675m^2 + 13.34m + 27.66 \quad (m=4—7), \quad (3)$$

where the coefficients were determined by the method of least squares.

Corkill *et al.*[12] supposed that the interior of the micelles is in a more expanded state than that in the normal liquid form of normal alkanes because the volume increment per methylene group of some homologous series of surfactants above CMC was 17.3 ml/mol CH_2, where the corresponding value of normal alkanes[12] and normal alkanols in their liquid states is identically 16.6 ml/mol CH_2 (*cf.* Eq. 1). However, the present results indicate that the $V_a^M(CH_2)$ of the higher alkanols ($m=8—10$) is rather comparable to the latter value. The apparent expansion of micelles formed with surfactant molecules alone may be caused, in addition to the volume increment per methylene group itself, by some other additional factors characteristic of micellization, which also depend linearly on the chain length of the surfactant. Because the volume increment per methylene group appears to be variable, as in the present case, $V_a^M(CH_2)$ increases even up to about 18.5 ml/mol CH_2, as is seen in Fig. 3.

Estimation of the Partition Coefficient. It is possible to estimate a partition coefficient for the alkanol in a solution with any composition, between the bulk and micellar phases, from the difference between V_a^D and V_a^M. The fraction of alkanol solubilized in one mol of added alkanol, j, may be related with the volumetric values, as follows:

$$V_a^M = \bar{V}_a^D(1-j) + \bar{V}_a^M j \quad (4)$$

where $\bar{V}_a^D$ and $\bar{V}_a^M$ are the partial molar volumes of alkanol in the singly dispersed and solubilized states, respectively, and the former is regarded as same as the V_a^D shown in Table 1. If the $\bar{V}_a^M$ value is identical with the molar volume for all alkanols, as in the case of higher alkanols ($m=8—10$), the equation can be calculated for j. The values obtained of j and $j/(1-j)$ which is the ratio of the fraction of alkanol solubilized to that dissolved monomerically are shown in Table 1.

The logarithmic values of j, $1-j$, and $j/(1-j)$ are plotted against chain length in Fig. 4. The curve of $\log j$ increases with an increase of m and attains zero at about $m=8$, whereas $\log(1-j)$ increases with decreasing m and attains zero at about $m=3.5$. These results are also consistent with the explanation given above. The $\log\{j/(1-j)\}$ *vs.* m plot is a straight line with a positive slope given by

$$\log\{j/(1-j)\} = 0.453m - 2.89 \quad (m=4—7), \quad (5)$$

which was obtained from a least-squares fit of the plots. If the decrease in the CMC value for the addition of alkanol is negligible, a partition coefficient, K, for alkanol between the bulk and micellar phases is defined in molar fraction units as

$$K = \{j/(C_s - C_s^\circ)\}/\{(1-j)/n_w\}, \quad (6)$$

where C_s is the total SDS concentration, C_s° is the CMC value in water, 8.30 mmol/kg, and n_w is molar number of water, 55.5 mole. It is noted that the K of a given alkanol depends on C_s although $j/(1-j)$ does not. Hayano and Hayase[5] have determined the partition coefficients of alkanols ($m=4—6$) by vapor pressure measurements in a 30 mmol/l SDS solution at 25 °C. The present calculated values of K for the respective alkanols at the same SDS concentrations are in fairly good agreement with their values, *e.g.*, for amyl alcohol, 6.24×10^2 was obtained here in comparison with their value of 7.29×10^2.

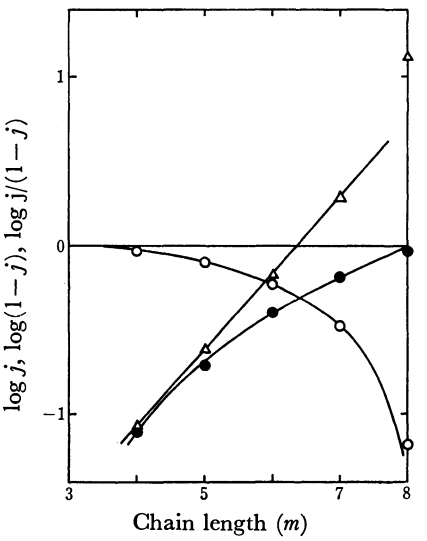

Fig. 4. Dependence of $\log j$, $\log(1-j)$, and $\log\{j/(1-j)\}$ on chain length of alcohol; ●: $\log j$, ○: $\log(1-j)$, △: $\log\{j/(1-j)\}$.

The standard free energy change of transfer for the methylene group of an alkanol molecule from the bulk to micellar phases can be calculated from the K values and was found to be −619 cal/mol CH_2. This value is independent of the SDS concentration, and is in good agreement with the corresponding values of various surfactants on their micellizations.[23-25]

The authors would like to acknowledge the continuing guidance and encouragement of Professor Ryohei Matuura and Assistant Professor Shoji Kaneshina of Kyushu University.

The Microwave Spectrum of Ethyl Isocyanate

Takeshi SAKAIZUMI, Osamu YAMADA, Kyoichi USHIDA, Osamu OHASHI, and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received May 6, 1976)

The microwave spectrum of ethyl isocyanate, CH_3CH_2NCO, has been obtained in the frequency region from 8.5 to 35.5 GHz. The spectrum identified is attributed to the *cis* conformation, in which the methyl group eclipses the isocyanato group. The rotational constants in the ground vibrational state obtained are $A=14110\pm3$, $B=3067.91\pm0.02$, and $C=2605.01\pm0.02$ MHz. The dipole moment (μ_a) for this rotamer is 2.81 ± 0.02 D. Four sets of vibrational satellites were observed and assigned to the transitions in the first, second, third, and fourth excited states of the C–N torsional vibration.

We have previously reported the microwave spectrum of the *cis*-rotational isomer of ethyl isothiocyanate,[1] CH_3CH_2NCS, as an example of the rotational isomerism about single carbon-heteroatom bonds in mono-substituted ethanes. Kniseley *et al.* have studied the structure of ethyl isocyanate using infrared spectroscopy. They reported that the rotational isomerism about the C–N bond for alkyl isocyanate was not possible on the basis of these observation that, in the solid-state spectrum, the absorption band assigned to the NCO asymmetric stretching vibration decreased sharply in intensity and usually exhibited a poorly defined band envelope.

It is interesting to determine the conformation of the ethyl isocyanate molecule and compare the result with that for ethyl isothiocyanate.[1] In this paper, the microwave spectrum of ethyl isocyanate in the *cis*-conformation will be reported and the structure and the dipole moment will be discussed.

Experimental

The sample of ethyl isocyanate was obtained commercially (from the Tokyo Kasei Co.) and was purified by distillation *in vacuo*. The rotational spectrum was measured over the frequency range from 8.5 to 35.5 GHz with a conventional 100-kHz sinusoidal- and square-wave Stark modulation spectrometer. The wave-guide cell was cooled with Dry Ice in order to enhance the intensity of the absorption lines. The transition frequencies were measured with a Hewlett-Packard Model 5245 L frequency counter.

Results and Discussion

Microwave Spectrum and Assignment of the Vibrational Ground State. The observed spectrum was quite dense in appearance, consisting of a large number of absorption lines. This feature may be ascribed to the various rotational isomers and their vibrationally-excited states. Four rotational isomers may be considered for ethyl isocyanate, as for ethyl isothiocyanate, namely, the *cis*, *gauche*, *skew*, and *trans* forms, as is shown in Fig. 1. The moments of inertia calculated from the assumed structure, indicated that all the isomers are nearly prolate symmetric tops (the value of Ray's asymmetric parameter lie in the range from −0.995 to −0.920). A large a-component of the dipole moment can be expected for these isomers because the –N=C=O bond, with a large moment, lies close to the a-axis. Consequently, strong

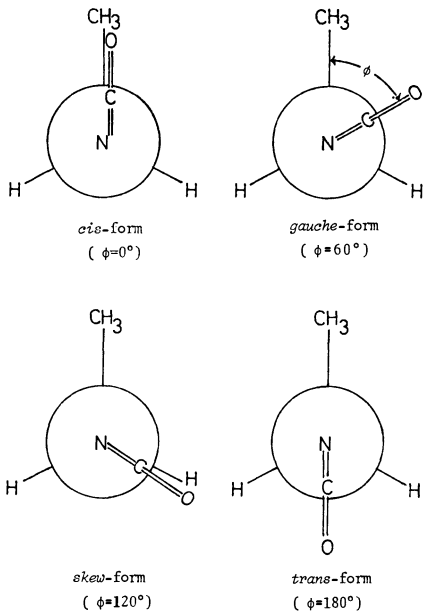

Fig. 1. Model of rotational isomers of ethyl isocyanate. ϕ: dihedral angle.

a-type R-branch transitions with $K_{-1}=0$ and 1 are to be expected. In the vicinity of the $K_{-1}=0$ line, absorption lines for K_{-1} equal to or larger than two should appear, and a large Stark effect should be observed.

The $J=3\leftarrow2$ transitions with $K_{-1}=2$ were first observed with a low Stark voltage, and next a $K_{-1}=0$ line in the vicinity of the $K_{-1}=2$ line was observed with a high Stark voltage. The transitions of $3_{13}\leftarrow2_{12}$, $3_{03}\leftarrow2_{02}$, and $3_{12}\leftarrow2_{11}$ were identified from their characteristic Stark behavior. The frequencies of the observed transitions in the ground vibrational state are listed in Table 1.

With the preliminary values of the rotational constants fitted to the low-J transition frequencies, the high-J transition frequencies were predicted by the rigid-rotor approximation. As the values of J and K_{-1} increased, the difference between the observed and calculated transition frequencies was found to become larger, in particular for the lines with K_{-1} values larger than one, as in the case of ethyl isothiocyanate. This deviation is probably attributable to the centrifugal distortion effect. Therefore, the observed transition frequencies given in Table 1 were fitted to the equation of the rotational energy, with correction for the first-order centrifugal

distortion effect.

The rotational and centrifugal distortion constants, as obtained by the least-squares method, are given in Table 2. The observed and calculated transition frequencies are in good agreement, as is shown in Table 1. The centrifugal distortion effect of ethyl isocyanate was similar in magnitude to that of ethyl isothiocyanate.[1)]

Conformation of the Molecule. If the molecule studied in this work has a plane of symmetry, *viz.*, a *cis* or *trans* conformation, four hydrogen atoms are located out of this plane. For this instance, the following relation is valid if the molecule is a rigid rotor:

$$8m_Hc_H^2 = I_a + I_b - I_c$$

where m_H is the mass of one hydrogen atom and c_H is its distance from the plane of symmetry. Using the assumed structural parameters given in Table 3, the value of

Table 3. Structural parameters[a)]

Distances	Angles
C–H: 1.091 Å[b)]	∠HCH: 108.8°[b)]
C_α–C_β: 1.520 Å[b)]	$\angle HC_\beta C_\alpha$: 109.6°[b)]

	∠N=C=O: 180°[b)]

a) The carbon atoms at the α- and β-positions are denoted as C_α and C_β respectively. The structural parameters are taken from the mono-substituted ethanes, CH_3CH_2X,[1)] for the ethyl group and from the methyl isocyanate for the isocyanato group.
b) Assumed parameters fixed for structural analysis. Three other were also determined.

$8m_Hc_H^2$ for the two forms, *cis* and *trans*, was calculated to be 6.344 amu Å^2. This is in good agreement with the value determined experimentally. This result suggests that the conformation of the molecule for which the transitions are assigned is a form having a plane of symmetry, namely, the *cis* or *trans* form. Moreover, comparing the rotational constants determined experimentally with those calculated from the assumed structures, as are shown in Table 4, the preferred conformation is clearly the *cis* form shown in Fig. 2.

Ethyl isocyanate, as one of the rotational isomers, is in the *cis* conformation in the gas phase. This result is consistent with the case of ethyl isothiocyanate,[1] for which the spectrum identified is attributed to the *cis* conformation.

Three structural parameters, ($r_{C_\alpha-N}$, $\angle C_\beta C_\alpha N$, and $\angle C_\alpha NC$), of the ethyl isocyanate were obtained from the observed rotational constants, fixing the remaining parameters to the values assumed. The results thus obtained are given in Table 3.

Comparing the CNC angle obtained (142°) here for CH_3CH_2NCO with that (151°) obtained for CH_3CH_2NCS[1] in the previous work, a large increase in the angle (about 9°) is seen on the replacement of O by S. Similar trends are evident for the cases of the HNC angle of HNCO[3] (128°) and HNCS[4] (135°), and the CNC angle of CH_3NCO[5] (140°) and CH_3NCS[5] (147.5°).

The dense spectrum suggests the presence of other rotamers in appreciable concentrations. An attempt

a) $\Delta=\nu_{obsd}-\nu_{calcd}$. b) Not included in the least-squares fitting.

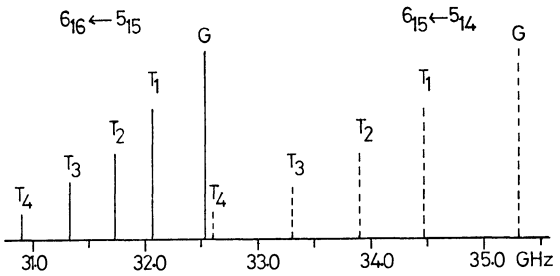

Fig. 3. Typical satellite pattern of $J=6\leftarrow5$ transitions of *cis*-ethyl isocyanate: dotted lines are $6_{15}\leftarrow5_{14}$ transition.

was made to find the transitions due to *skew* or *trans* forms. Measurements were carefully made near the transition frequencies predicted by the rotational constants of the models of the *skew* and *trans* forms calculated with the structural parameters in Table 3. However, no transition could be assigned which might be ascribed to the *skew* or *trans* form.

Vibrationally-excited State. Four sets of the spectrum due to the vibrationally-excited states were found. The satellite lines have essentially the same Stark effect behavior and the same K_{-1} series pattern as those of the ground state. Figure 3 illustrates same typical satellite patterns of $6_{16}\leftarrow5_{15}$ and $6_{15}\leftarrow5_{14}$ transitions. The vibrationally-excited states lines were assigned as is shown in Table 5. The effective rotational constants of the four excited vibrational states were obtained in a manner similar to that used for the ground state. These results are also given in Table 2.

From the relative intensities of the satellite lines with respect to the ground-state line, the vibrational frequency of 150 ± 50 cm^{-1} for $v_t=1$ was obtained. Referring to Kniseley's assignment of this molecule and to the study of ethyl isothiocyanate, the observed vibrational frequencies (100, 144, and 224 cm^{-1}) were assigned to the C–N torsion, CNC bending, and C–C torsion modes respectively, as is shown in Table 6. Because the value of $\Delta'I(I_c-I_b-I_a+8m_Hc_H^2)$ obtained for $v_t=1$ has a negative value,[6] the vibrational satellite corresponding to 150 cm^{-1} can be ascribed to the excited state of the C–N torsion mode.

number of the C–N torsion is non-linear, as is shown in Fig. 4. Therefore, this torsional vibration is rather anharmonic.

Dipole Moment. From the Stark coefficients of the $3_{03}\leftarrow 2_{02}$, and $3_{12}\leftarrow 2_{11}$ transitions for the ground state and the excited states, $v_t=1$, 2, and 3, and the $4_{04}\leftarrow 3_{03}$ and $4_{13}\leftarrow 3_{12}$ for $v_t=4$, the dipole moment of ethyl isocyanate was determined for both the ground and excited vibrational states. From the second-order Stark coefficients determined for the five Stark component lines, the dipole moments shown in Table 7 were obtained. The c-component of the dipole moment was assumed to be zero because of the symmetry, as has been discussed above. The b-component was not determined exactly, since no b-type transitions were observed. The electric-field strength in the absorption cell was calibrated using the $J=1\leftarrow 0$ transition of OCS.[7] The dipole moment (μ_a) for the ground state was determined to be 2.81 ± 0.02 D.

The authors wish to express their thanks to Professor Hiroaki Takahashi and Dr. Norio Kaneko of Waseda University for the use of Hitachi FIS-3 far-infrared spectrophotometer and for their helpful discussions.

The Dissociative Excitation and Dissociative Ionization of Simple Aliphatic Hydrocarbons by Controlled Electron Impact

Masaharu Tsuji,* Teiichiro Ogawa, Yukio Nishimura,* and Nobuhiko Ishibashi

Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received May 12, 1976)

Photoemissions from the following excited species were observed from simple aliphatic hydrocarbons (CH_4, C_2H_2, C_2H_4, 1,3-C_4H_6) under controlled electron-impact excitation (0—400 eV) at wavelengths from 300 to 600 nm: H(Balmer), CH(A–X, B–X, C–X), CH^+(A–X, B–A, b–a), C_2(C–A, d–a; not from CH_4), and $C_4H_2^+$(A–X; not from CH_4). All the excited species except for $C_4H_2^+$ from C_2H_2 and C_2H_4 were confirmed to be primarily produced. The excitation function (0—400 eV) and the appearance potential of H, CH, and CH^+ produced from CH_4 and C_2H_2 were measured, and the corresponding processes of the fragmentation near the threshold were determined. The $CH_4+e\rightarrow CH^+(B)+H_2(X)+H(n=1)$ and $C_2H_2+e\rightarrow CH^+(B)+CH(X)$ processes were concluded to be responsible for the formation of CH^+(B). The formation of ionic species, H^+ and CH^+, can be considered as the limiting case of the dissociative excitation for producing H and CH. A triplet excitation process may contribute to the formation of CH(A) from C_2H_2. The observed threshold energies indicated that superexcited states were involved in the formation of excited neutral fragment species.

Spectroscopic investigations of the dissociative excitation of simple aliphatic hydrocarbons (CH_4, C_2H_2, C_2H_4, C_2H_6) have been extensively carried out by the irradiation of vacuum ultraviolet photons,[1,2] by the impact of an ion beam,[3,4] and by the impact of an electron beam,[5–11] and photoemissions from the excited atoms (H, CI, CII) and molecular fragments (C_2, CH, CH^+, CH_2) have been observed.

The electron-impact method is a very effective method, partly because the excitation energy is variable over a wider range and partly because a relatively intense photoemission can be obtained even at a low excitation energy near the threshold. Thus, the emission cross section, the excitation function, and the appearance potential of some fragment species of various molecules have been measured under the electron-impact excitation. Sroka[5] and Morgan and Mentall[10] have reported the excited atomic lines, H(Lyman), CI, and CII, from CH_4 in the VUV region. De Heer *et al.*[11] determined the emission cross sections of some excited fragments from simple aliphatic hydrocarbons (CH_4, C_2H_2, C_2H_4, C_2H_6) as a function of the electron-impact energy and clarified the dissociative-excitation processes. Recently, Finn *et al.*,[12] using time-of-flight techniques, investigated the production of hydrogen and carbon atoms in metastable and high-lying Rydberg states by electron impact on CH_4 and CD_4.

The CH^+ ion is an important species in astrophysics, mass spectroscopy, and radiation chemistry; three systems ($A^1\Pi$–$X^1\Sigma^+$, $B^1\Delta$–$A^1\Pi$, $b^3\Sigma^-$–$a^3\Pi$) have been known in the emission spectrum. The latter two systems were first observed and analyzed by Carré[4] under proton bombardment on CH_4 and C_2H_2; they were also identified by Beenakker and de Heer[11] under electron impact on CH_4, C_2H_2, C_2H_4, and C_2H_6. However, no studies have been carried out on the mechanism for the formation of CH^+ in the excited electronic state because of the weakness of the emission intensity. We have previously communicated the emission spectra of CH^+ produced from CH_4 and C_2H_2 by controlled electron impact.[13] The present paper will describe the emission spectra of simple aliphatic hydrocarbons (CH_4, C_2H_2, C_2H_4, 1,3-C_4H_6) and the mechanism for the fragmentation of H($n=4$), CH(A), and CH^+(B) from CH_4 and C_2H_2 under the electron-impact excitation.

Experimental

The apparatus and the experimental techniques used in this investigation were similar to those described previously.[14] The electrons emitted from a tungsten filament were accelerated and focused into the collision chamber, where they collided perpendicularly with a molecular jet introduced from a nozzle 0.1 mm in diameter. The electron-beam current in the collision chamber ranged between 0.1 and 3000 μA for electron energies from 0 to 400 eV. The pressure in the collision region was estimated to be of the order of 10^{-3} Torr when the sample gas was introduced.

The emission spectra in the 300—600 nm region were measured by use of a JASCO CT-50 monochromator equipped with an EMI 9558QB photomultiplier, which was connected to a DC amplifier. The spectral bandpass used in this experiment was in the 4—5 Å range.

For the measurements of the excitation function and the appearance potential, a cell whose inside wall was made of brass was employed to reduce the space-charge effect on the wall. In this case, photons modulated by a mechanical chopper were detected by the same monochromator equipped with a HTV R585 photomultiplier, which was connected to an NF PC545A photon counter. The excitation functions and the appearance potentials of N_2 (3371 Å; the (0, 0) band of the second positive system) and N_2^+ (3914 Å; the (0, 0) band of the first negative system) produced from N_2 were measured in order to check the efficiency of this apparatus and to calibrate the electron energy. The satisfactory agreement with the results by Stanton and John[15] indicated that our apparatus could be used for the measurements of the excitation function and the appearance potential.

The gas samples were of a Research Grade obtained from the Takachiho Trading Co.; their purities were specified as 99.95% for CH_4, 99.6% for C_2H_2, 99.8% for C_2H_4, and 99.5% for 1,3-C_4H_6. They were subjected to several freeze-pump-thaw cycles before use.

Results and Discussion

The Spectra of Methane and Acetylene. Photoemissions from excited fragments and a dimeric ion were found in the 300—600 nm region, as is shown in Figs. 1 and 2. In the longer wavelength region (above 390 nm) of both spectra, the Balmer series of the hydrogen atom ($H_{\beta,\gamma,\delta,\varepsilon,\zeta}$), and the 4300 Å system ($A^2\Delta$–$X^2\Pi$) and the 3900 Å system ($B^2\Sigma^-$–$X^2\Pi$) of CH are identified. In addition, the line at 423 nm, which is superimposed upon the intense band of CH(A–X), is assigned to the (0, 0) band of $CH^+(A^1\Pi$–$X^1\Sigma^+)$.[16] In the spectrum of C_2H_2, the $\Delta v=1$, 0, and -1 sequences of the Swan system of $C_2(d^3\Pi_g$–$a^3\Pi_u)$, and the (0, 0) sequence of the Schüler's T spectrum of $C_4H_2^+(A^2\Pi_g$–$X^2\Pi_u)$, designated as A,[16] are also identified.

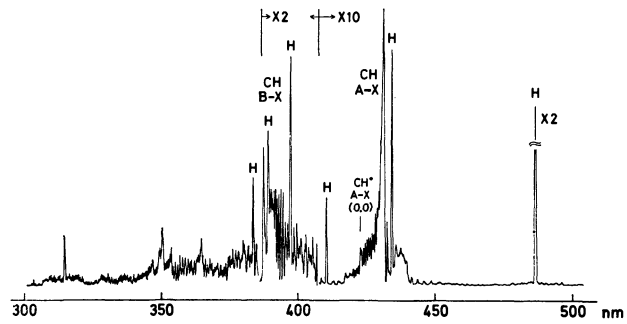

Fig. 1. Emission spectrum of CH_4 by controlled electron impact. Electron energy 200 eV, electron-beam current 800 μA.

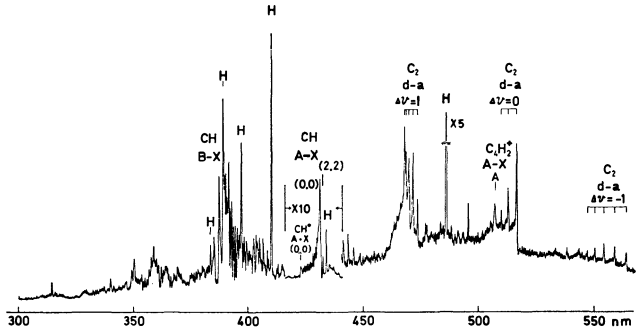

Fig. 2. Emission spectrum of C_2H_2 by controlled electron impact. Electron energy 200 eV, electron-beam current 500 μA.

In the shorter-wavelength region of both spectra, some weak features come out, as is shown in detail in Fig. 3. The $H_{\gamma,\delta}$ lines of the Balmer series of the hydrogen atom, the (1, 0) band of the CH(B–X), and the 3100 Å system ($C^2\Sigma^+$–$X^2\Pi$) of CH are identified in both spectra. In addition, the features at 347—362 nm, which are more clearly observed in the spectrum of CH_4, are assigned to the $B^1\Delta$–$A^1\Pi$ and $b^3\Sigma^-$–$a^3\Pi$ transitions of CH^+ by reference to Carré's results on CH_4 and C_2H_2 by proton bombardment.[4] The (0, 0) and (1, 1) bands of the B–A transition are observed at 350 and 347 nm. The (0, 0) band of the b—a transition is observed at 349—362 nm, superimposed upon the (0, 0) band of the B–A transition; the band head

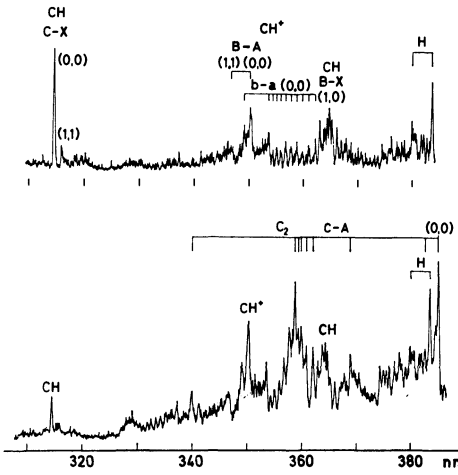

Fig. 3. Emission spectra of CH_4 and C_2H_2 in the 310—385 nm region by controlled electron impact (expanded for the detailed analysis). Top; CH_4, electron energy 300 eV, electron-beam current 800 μA. Bottom; C_2H_2, electron energy 200 eV, electron-beam current 600 μA.

is located at 349 nm, and its rotational structure extends towards the longer wavelengths (up to 362 nm). Some weak features at 327—347 nm are probably related to these two systems, as was observed by Carré.

Other numerous bands, which complicate the spectrum of C_2H_2, are ascribed to the Delandres-D'Azambuja system of $C_2(C^1\Pi_g$–$A^1\Pi_u)$; the (0, 0) band is found at 385 nm. Principal bands of this system, described in the Pearse and Gaydon table,[16] are indicated by the straight lines; most of the other features observed in C_2H_2 may be assigned to this system.

Mass-spectrometric studies have shown that the CH^+ ion is an important primary ion produced by electron impact on CH_4 and C_2H_2 and that it constitutes 2—3% of the total ions at a 50—500 eV electron impact on CH_4[17] and 2—4% of the total ions at a 50—500 eV electron impact on C_2H_2.[18] The calculated potential energy curves of the CH^+ ion show that the repulsive $c^3\Sigma^+$ state crosses with the $B^1\Delta$ and $b^3\Sigma^-$ states.[19] The weakness of the emission intensity of CH^+ compared with that of H and CH may be partly due to the competition of the predissociation with photoemission.

Current and Pressure Dependence of the Emission Intensity. The number of the electron and the molecule which participate in the formation of excited species can be determined by the dependence of the photoemission intensity on the electron-beam current and the gas pressure. The intensity of the CH^+ emission was measured on the band at 350 nm under the assumption that the band overlapping with the b–a transition is negligible. This assumption is supported by the finding that the triplet system did not affect the lifetime measurement of the (0, 0) band of the B–A system.[6]

Figures 4 and 5 show that the band intensities of H, CH, C_2, and CH^+ from C_2H_2 are proportional both to the electron-beam current and to the gas pressure at the constant electron energy. Similar linear relationships have been obtained for other fragment species (H, CH, CH^+) from CH_4, as was reported for H and CH by one of the present authors.[7] These results suggest

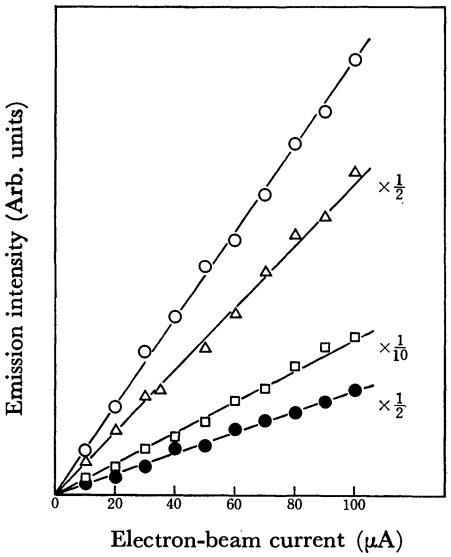

Fig. 4. Dependence of photoemission intensities of C_2H_2 on the electron-beam current. Electron energy 200 eV. ○: CH(431 nm), △: H_γ, □: CH^+ (350 nm), ●: C_2 (468 nm).

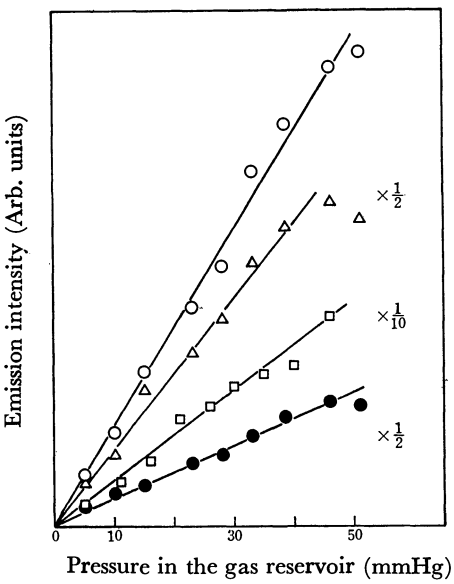

Fig. 5. Dependence of photoemission intensities of C_2H_2 on the pressure in the gas reservoir. Electron energy 200 eV, electron-beam current 50 μA. ○: CH(431 nm), △: H_γ, □: CH^+ (350 nm), ●: C_2 (468 nm).

that emitting excited species are produced through a primary collision of an incident electron with a molecule and that they are not collisionally deactivated within their radiative lifetimes. However, the behavior of the intensity of $C_4H_2^+$ from C_2H_2 to the electron-beam current is exceptional; it is probably produced in a dimerization-excitation process.[20]

Dissociation Processes from Methane. The dependence of the photoemission intensities of H_γ, CH(A–X), and CH^+(B–A) from CH_4 on the electron-impact energy up to 400 eV is shown in Figs. 6 and 7. The energy dependence of H_β was similar to that of H_γ. No discrete structure can be observed on these excitation functions,

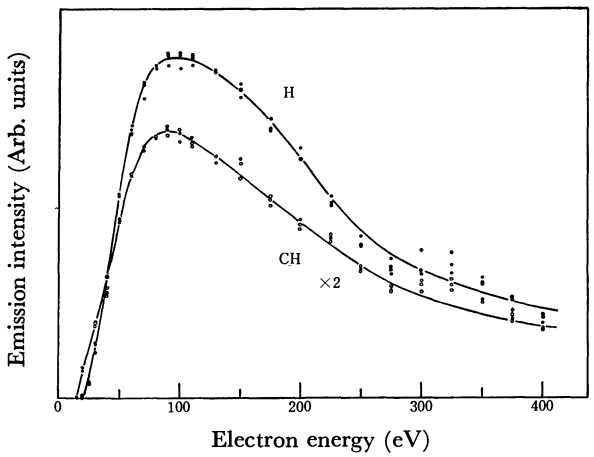

Fig. 6. Excitation functions of H and CH produced by electron impact on CH_4. ●: H_γ electron-beam current 3 μA, ○: CH(431 nm) electron-beam current 3 μA.

and the maximum emission cross section is located at about 100 eV for H_γ, at about 90 eV for CH(A–X), and at about 130 eV for CH^+(B–A). The maximum positions of H_β and H_γ in the present study nearly agree with those of the previous investigations of the Balmer and Lyman series[5,8,10,11] and of the metastable and high Rydberg hydrogen fragments.[12] On the other hand, the maximum position of CH(A–X) is higher than the values reported by Aarts *et al.*[11] (about 60 eV) and by Fujita[8] (about 80 eV), while that of CH^+(B–A) is also higher than the maximum ionization cross section of CH^+ as measured by means of a mass spectrometer[17] (about 80 eV).

The appearance potentials of H_β, CH(A–X), and CH^+(B–A) were measured through the careful determination of the excitation function at a low energy; the results obtained are given in Table 1. Table 1 also enumerates the possible dissociative-excitation and dissociative-ionization processes for the formation of H(n=4), H(high Rydberg states), H^+, CH(A), CH^+(X), and CH^+(B); their minimum excitation energies were calculated by making use of the following dissociation

Table 1. Threshold energies for dissociative excitation and dissociative ionization of CH_4 by electron impact

a) Ref. 11. b) Ref. 5. c) Ref. 12. d) Ref. 1. e) Ref. 23. f) Ref. 24. g) Ref. 25.

(D) and ionization (I) energies: D(H–H)=4.48 eV,[21] D(CH_3–H)=4.41 eV,[22] D(CH_2–H)=4.90 eV,[22] D(CH–H)=4.46 eV,[11] and I(CH)=11.1 eV.[21] In the right column of Table 1, the threshold energies of $H_\beta(n=4-2)$ and CH(A–X) obtained by Aarts *et al.*,[11] of $Ly_\gamma(n=4-1)$ obtained by Sroka,[5] and of high Rydberg hydrogen fragments obtained by Finn *et al.*[12] under electron-impact excitation, and those of H_β and CH(A–X) obtained by Welch and Judge[1] under photo-excitation, are given, in addition to the appearance potentials of H^+[23,24] and CH^+.[23,25]

The observed threshold energy of H_β is slightly lower than those of H_β and Ly_γ reported by the other investigators, while it is higher by approximately 1 eV than that of H_β obtained by photo-excitation. By comparing the experimental value with the calculated energies, the most significant process for the formation of $H(n=4)$ near the threshold is concluded to be the process (1). The excess energy of 3.8±1.0 eV, which is close to the translational energy of high Rydberg hydrogen fragments (4.0±0.5 eV),[12] is imparted to the fragments as the rotational, vibrational, and translational energies. The coincidence of the excess energy may indicate that $H(n=4)$ and H(R) are produced by a similar process.

By photo-excitation Welch and Judge[1] observed the threshold energy of CH(A–X) near 12.0 eV. The present result, which agrees well with the finding of Aarts *et al.*, is higher by 2.5 eV than that obtained under photo-excitation. From the energy consideration, near the threshold it is believed that the process (10) is responsible for the formation of CH(A) and that about 2.3 eV is released as internal and kinetic energies.

The appearance potential of the CH^+(B–A) emission was observed at 30.2±1.0 eV. As to the dissociative-ionization process for CH^+(B), the three following mechanisms through highly excited states of methane designated as CH_4** and/or through the highly excited methane ion are possible:

$$CH_4 + e \longrightarrow (CH_4^{**}, CH_4^{+*}) \longrightarrow \begin{cases} CH^+(B^1\Delta) + H_2(X^1\Sigma_g^+) + H\ (n=1) \\ CH^+(B^1\Delta) + 3H\ (n=1) \\ CH^+(B^1\Delta) + H_2(X^1\Sigma_g^+) + H\ (n=2). \end{cases}$$

The most likely mechanism is the process (16), and the excess energy of about 3.3 eV is released to the fragments as internal and kinetic energies at the threshold.

The appearance potential of the ion upon mass spectroscopy gives information on the formation of ionic species in the ground state. Smith[23] and McDowell and Warren[25] found the appearance potential of CH^+ from CH_4 at 23.3±0.6 eV and 22.4±0.1 eV respectively. From Table 1, the energetically possible process at the threshold is the process (13) and the excess energy of 2—3 eV is imparted to the fragments. The most likely process for the formation of CH^+(B) in the present study is similar to that of CH^+(X).

Since the production of ionic species can be considered as a limiting case of the formation of the corresponding neutral excited species, a similar mechanism can be expected to be involved in the dissociative-excitation and related dissociative-ionization processes. The facts that the process for the formation of CH(A) is similar to that of CH^+(X) and that the excess energy of the former (2.3±0.5 eV) is close to that of the latter (2.0±0.1 eV,[25] 2.9±0.6 eV[23]) support the above expectation.

Four reactions can account for the formation of H^+ near the threshold, as is shown in Table 1. Smith[23] found the appearance potential of H^+ at 22.7 ± 0.5 eV, and recently Appell and Kubach[24] observed H^+ ions with kinetic energies between 1.4 and 3.4 eV at an appearance potential of 24.0 ± 0.5 eV. Both values indicate that the energetically possible process is the process (6), which is similar to the process (1).

Platzman pointed out that neutral primary products are formed in a radiation-induced reaction through a highly excited neutral state just above the first ionization potential (IP_1) of the molecule named the superexcited state, where dissociation and preionization are competitive.[26] The isotope effect of the Balmer emission from CH_4 under electron-impact excitation has been interpreted as support that excited hydrogen atoms originate from such a superexcited state.[8,11] Since the observed threshold energies of H_β and CH(A–X) are larger than the IP_1 of CH_4 (12.99 eV[22]) and the ionic fragment is not involved in the resulting species, it is concluded that they are produced through the superexcited states.

The superexcited state of CH_4 has been investigated on the basis of the difference between the absorption (energy loss) and ionization spectrum,[26–28] and recently Backx *et al.*[28] have found two regions of superexcited states by means of electron-electron and electron-ion coincidence measurements at keV electron impact. The first state ranged between the IP_1 and 17 eV, which was attributed to high vibrationally-excited Rydberg states converging to the ground state of CH_4^+, $(1t_2)^{-1}$, with reference to the interpretation of Nishikawa and Watanabe.[29] The second state occurred in the region of 22—24 eV, which was connected with the second ionic state, $(2a_1)^{-1}$. The observed threshold energy of CH(A–X) emission indicates that the formation of CH(A) near the threshold proceeds through the first superexcited states. The threshold energy of H_β in the present study and that of the Balmer and Lyman series,[1,5,10–12] and high Rydberg hydrogen fragments[12] are all in the range between 20 and 22 eV. Therefore, superexcited states can be expected to exist in this energy region, although the possibility of excitation to these superexcited states may be small because excited hydrogen atoms are formed by optically forbidden processes.[11] However, Backx *et al.*[28] found no superexcited states in the region of 17—22 eV, which is consistent with the works of Platzman[26] and Nishikawa and Watanabe.[29] Meanwhile, the results by Metzger and Cook,[30] and Rebbert and Ausloos (the ionization efficiency $\eta_i=0.96$ at 21.2 eV)[31] under photo-excitation, and by Ehrhards and Linder[27] under 70 eV electron-impact excitation, support the existence of superexcited states in the same energy range.

Dissociation Processes from Acetylene. The excitation functions of H_β, CH(A–X), and CH^+(B–A) from C_2H_2 are shown in Figs. 8 and 9. The excitation function of H_γ was nearly identical with that of H_β when it was normalized at the maximum. The excitation functions of H_β and CH^+(B–A) have no structure; the former has a maximum at about 100 eV, and the latter, at about 130 eV. The excitation function of CH(A–X) rapidly increases near the threshold; the second threshold can

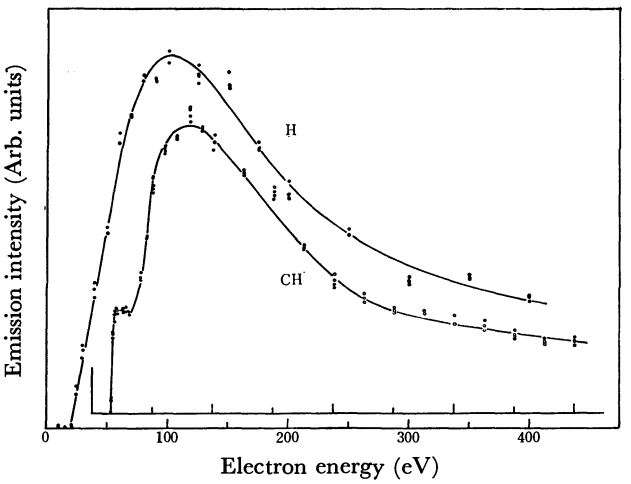

Fig. 8. Excitation functions of H and CH produced by electron impact on C_2H_2. ●: H_β electron-beam current 1.5 μA, ○: CH(431 nm) electron-beam current 1 μA.

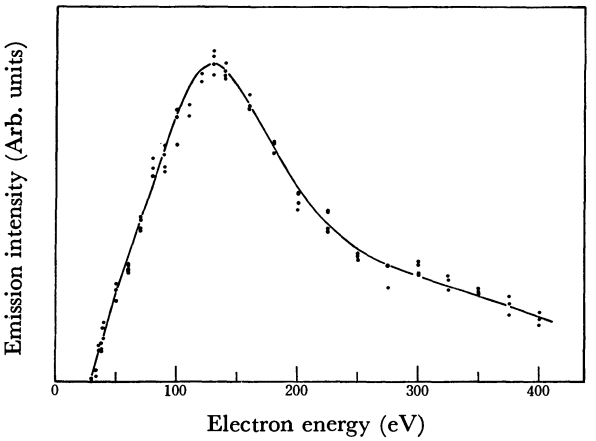

Fig. 9. Excitation function of CH^+ (350 nm) produced by electron impact on C_2H_2. Electron-beam current 5 μA.

be observed at about 30 eV, as was found by Beenakker and de Heer[11] at 28 ± 2 eV. The maximum position of the emission cross section of H_β agrees with the Beenakker and de Heer's result, while that of CH(A–X) is higher than theirs (about 60 eV). The maximum position of CH^+(B–A) is also higher than that of the ionization cross section of CH^+ as measured by a mass spectrometer (about 90 eV).[18] At present no explanation can be given for the discrepancy in the maximum positions of CH and CH^+ from CH_4 and C_2H_2 between the present work and the others; the excitation functions were measured with as low an electron-beam current as possible to avoid the space-charge effect, although higher currents are required for CH^+(B–A) because of the weakness of the intensity.

The appearance potentials and the predominant dissociation channels for the formation of H(n=4), CH(A), and CH^+(B) are enumerated in Table 2. Table 2 also shows the possible dissociative-ionization processes for H^+ and CH^+, and their appearance potentials as obtained in mass-spectrometric studies.[18,32] The threshold energies were calculated using data

a) Ref. 11. b) Ref. 18. c) Ref. 32.

identical with those employed by Beenakker and de Heer.[11] The observed appearance potentials of H_β and CH(A–X), which agree well with the work of Beenakker and de Heer,[11] indicate that the significant dissociative-excitation processes for $H(n=4)$ and CH(A) near the threshold are both the lowest-energy processes, (1) and (7). The excess energies of about 2.5 eV for $H(n=4)$ and about 0.7 eV for CH(A) are imparted to the resulting fragment species as the internal and kinetic energies. Meanwhile, mass-spectrometric studies show that the dissociative-ionization processes (4) and (13), which are similar to the dissociative-excitation processes for $H(n=4)$ and CH(A), contribute to the formation of H^+ and CH^+. It should be noticed that the excess energies of H^+ (2.7±1.0 eV) and CH^+ (0.9 eV) are in good agreement with those of $H(n=4)$ and CH(A) described above. Thus, the formation of H^+ and CH^+ from C_2H_2 can be considered as the limiting case of the excitation of H and CH.

The excitation function of CH(A–X) differs from that of the other fragments in the inclination near the threshold; it increases steeply and has the second threshold. The excitation function for a spin-forbidden transition is known to exhibit a sharp maximum at a slightly higher energy than the threshold and to drop rapidly at a still greater electron energy; meanwhile, the maximum cross section for an optically allowed transition is located at a fairly higher energy than the threshold, and the peak is not very sharp.[11] These features in the excitation functions for the excitation and the ionization of the parent molecule are also manifest in those for the dissociative excitation. The dissociative-excitation process (7) can proceed both through the singlet and the triplet states of the excited parent molecule, according to the spin-conservation rule. Thus, the steep increase and the first threshold of the excitation function of CH(A) from C_2H_2 can probably be interpreted as the contribution of the spin-forbidden process, and the further increase up to 80 eV, as that of one or a few optically allowed processes. The second threshold may be due to the superposition of the two excitation processes. The shape of the excitation function of CH(A) from CH_4 indicates that the contribution of the triplet excitation process is unimportant in the dissociative excitation of CH_4 into CH(A).

The threshold energy of the CH^+(B–A) emission was found at 29.3±1.0 eV. Above this threshold, CH^+(B) is probably formed in the process (16), which is the lowest-energy process, as in the case of CH^+(X), and the fragment species carry off an excess energy of about 1.8 eV.

Since the threshold energies of H_β and CH(A–X) emissions exceed the IP_1 of C_2H_2 (11.41 eV[22]) and no ions are produced in the reactions, they are produced through superexcited states of C_2H_2. It is noteworthy that all the dissociation processes of CH_4 in Table 1 need more excess energy than that required in the corresponding dissociation processes of C_2H_2 in Table 2, assuming that the calculated threshold energies are accurate. This can be interpreted by means of the fact that energy between the cross point of a repulsive potential with the primarily prepared highly-excited

states and the dissociation limit is larger in all cases of CH_4, where the energy of the cross point determines the observed appearance potential.

Ethylene and 1,3-Butadiene. The emission spectra of C_2H_4 and C_4H_6 in the 300—600 nm region were measured. The resulting spectra consist of H(Balmer), CH(A–X, B–X, C–X), CH^+(A–X, B–A, b–a), C_2(C–A, d–a), and $C_4H_2^+$(A–X), which are qualitatively identical with the spectrum of C_2H_2. However, the intensity of the CH^+ emission relative to the H and CH emissions is much weaker than that in the cases of CH_4 and C_2H_2. This is consistent with the lower fraction of the CH^+ ions relative to the total ions observed in the mass-spectrometric studies.[33]

The formation of excited H, CH, CH^+, and $C_4H_2^+$ except for $C_4H_2^+$ from C_2H_4[20] are confirmed to be primarily produced by the linear dependence of the intensities on both the electron-beam current and the gas pressure. A more sensitive device will make it possible to measure the excitation function and the threshold energy of the CH^+ emission.

The authors wish to thank Professor Fumiyuki Nakashio and Dr. Minoru Toyoda for their discussions. They are also indebted to Professor Tomoo Oyama for the use of his CT-50 monochromator.

Localized Molecular Orbital Studies of Chemical Reaction. II. Abstraction and Addition Reactions of Triplet Methylene

Shigeru NAGASE and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received May 13, 1976)

Energy-localized molecular orbitals (LMO) generated from UHF–INDO wave functions have been used for the studies of the mechanistic details of the abstraction and addition reactions of triplet methylene. The UHF LMO mapping procedure which we have previously developed permits a clear understanding of the nature of the chemical bonds to be formed or broken on reaction. Significance of the three-stage mechanism, which should involve the successive β- and α-spin electron delocalizations between reactants and the concomitant spin polarization of the reacting bond, is emphasized. The whole aspects of the reactions are well in accord with the customarily accepted mechanistic schemes.

In the preceding paper of this series,[1] we dealt with mechanistic details of radical reactions in terms of the localized molecular orbitals (LMO). The results were found to be chemically meaningful in many respects. The success has encouraged us to take up the abstraction and addition reactions of triplet methylene, $CH_2(^3B_1)$. Specifically, we wish to elucidate the nature of the deformation of bonds due to the intermolecular interactions. To this end, we have carried out the LMO mapping analysis of the unrestricted Hartree-Fock (UHF) wave functions for the entire reacting systems on one hand and the schematic description of the movement of the LMO charge centroids with reaction on the other. Further, the UHF wave functions of the interacting systems were expanded as a superposition of various electronic configurations of reactant molecules, and their relative importances to the reaction were assessed. The results are found to be useful for the understanding of mechanistic features of the reactions in question.

Calculation Method

The canonical molecular orbitals (CMO) for isolated molecules as well as the reacting systems were calculated by the UHF method[2] in the INDO approximation.[3] The UHF LMO's were generated by the successive two-by-two rotation method[4] for α- and β-spin electrons separately. All possible two-orbital transformations were repeated until further increase in the sum of intraorbital Coulomb energies did not exceed 10^{-6} eV. Virtual CMO's were also localized by the same method.

The UHF LMO's $\boldsymbol{\phi}^\gamma$ for the entire reacting systems obtained at various reaction path points are mapped over the LMO's $\boldsymbol{\phi}^\gamma$ for the isolated reactant molecules:

$$\boldsymbol{\phi}^\gamma = \boldsymbol{\phi}^\gamma \boldsymbol{T}^\gamma \tag{1}$$

where $\boldsymbol{T}^\gamma$ is a unitary matrix pertinent to the mapping, the superscript γ denoting the α- or β-spin. The LMO mapping matrix $\boldsymbol{T}^\gamma$ was obtained by the same procedure as described in a previous paper.[1]

The UHF ground-state wave functions at given path points can be expanded into various electronic configurations:

$$\begin{aligned}\Psi_{\mathrm{UHF}} &= |\psi_1^\alpha \psi_1^\beta \cdots\cdots \psi_p^\alpha \psi_p^\beta \psi_{p+1}^\alpha| \\ &= C_{\mathrm{G}}\Phi_{\mathrm{G}} + \sum_{\mathrm{K}}\sum_i C_{\mathrm{K}i}\Phi_{\mathrm{K}i}\end{aligned} \tag{2}$$

where Φ_{G} is the ground configuration and where $\Phi_{\mathrm{K}i}$ is the i-th configuration of type K—local excitation (LE) of reactant molecule, charge transfer (CT) from reactant to $^3CH_2$, back charge transfer (BCT) from $^3CH_2$ to reactant, and so on.[1] The configurational coefficients, C_{G} and $C_{\mathrm{K}i}$'s, were calculated by the technique similar to the one used by Baba *et al.*[5] All computations were carried out on a FACOM 230-60 at the Kyoto University Computation Center.

Results and Discussion

A. Characteristics of the UHF–LMO's of Methylene. It is recognized that methylene (CH_2) can exist in both singlet ($^1A_1$) and triplet ($^3B_1$) states. The bond angles calculated by the INDO method for a fixed bond length (R_{CH}=1.094 A) are 107 and 132°, respectively,[3] which are both in good agreement with observations (102.4 and 136°, respectively[6-8]). The LMO's which we obtained at these calculated equilibrium angles are shown in Table 1, where $CH_2(^3B_1)$ is assumed to have two more α-spin electrons than β-spin ones. It can be seen that each LMO is certainly little delocalized (less than 1%).

The total energy E of methylene can be expressed as the sum of contributions from individual occupied LMO's, provided the nuclear charge of each atom is assumed to be expressible in the form[9-11]

$$Z_{\mathrm{A}} = \sum_i Z_{i,\mathrm{A}} \tag{3}$$

where $Z_{i,\mathrm{A}}$ is the part of the nuclear charge on atom A partitioned to the i-th LMO. The value of $Z_{i,\mathrm{A}}$ is taken to be equal to 1 for an unpaired LMO as well as an LMO localized mainly around two atoms, whereas $Z_{i,\mathrm{A}}$=2 for a lone-pair LMO. The component energies ε_i^γ thus derived are given by

$$\varepsilon_i^\gamma = \frac{1}{2}\langle\phi_i^\gamma|\boldsymbol{F}^\gamma + \boldsymbol{H}^c|\phi_i^\gamma\rangle + c_i\sum_j\sum_{\mathrm{A}}\sum_{\mathrm{B}} e^2 Z_{i,\mathrm{A}} Z_{j,\mathrm{B}}/R_{\mathrm{AB}} \tag{4}$$

where $\boldsymbol{F}^\gamma$ and $\boldsymbol{H}^c$ are the Hartree-Fock and core Hamiltonian operators, respectively; R_{AB} is the internuclear distance between atoms A and B; and c_i is a constant which is 1/2 for the i-th α-spin counterpart of a β-spin LMO and 1 for an unpaired radical-center LMO.

Figures 1 and 2 show the variations in ε_i^γ of various filled LMO's of the singlet and triplet methylenes, respectively, with the bond angle ∠HCH. The numbers

appended indicate the values of x for hybridization (sp^x)of the carbon orbitals involved.

Comparison of Fig. 1 with Fig. 2 shows that the energies ε_i^{γ} have a roughly similar pattern of angular variations for both spin states. The lone-pair (L) and unpaired (N) orbital energies have the greatest angular variations and are decreased as the bond angle decreases. On the contrary, the C–H bond energies for both spin states increase with the decreasing bond angle. In other words, the nonbonding orbitals tend to make the methylene molecule bent, while the C–H bond orbitals are energetically in favor of the linear geometry. The equilibrium bond angles would be a compromise between these two opposing contributions. The results are in accord with those obtained by the electrostatic force theory,[12] in which the former contribution is ascribed to the "atomic dipole" force and the latter, to the "exchange" force.

Here, considerations of the spatial arrangement of the C–H bond orbitals themselves seem to be in order. In the triplet methylene, the LMO's for the α-spin electrons can be described roughly as tetrahedral (sp^3) in type while those for the β-spin electrons as linear (sp). Pauling[13] pointed out qualitatively that the two $(C\text{-}H)^{\alpha}$ bond orbitals would tend to bring the HCH bond angle to 90° while the two $(C\text{-}H)^{\beta}$ bond orbitals, to 180°. The directions of the C–H bond orbitals obtained by the present treatment for varying bond angle are as illustrated in Fig. 3. Deviations of the direction of bond orbitals from that of the C–H bonds may be taken as reflecting the force with which the orbitals attract the H nucleus. It would then appear as though the bond angle were determined by the balance between the attractive forces from the $(C\text{-}H)^{\alpha}$ and $(C\text{-}H)^{\beta}$ bond orbitals. Thus, at the equilibrium bond angle, the hydrogen atom is situated nearly on the bisector of the angle between the bond orbitals. For the singlet state, things are much simpler; only when the equilibrium

bond angle is reached, can the hydrogen atom locate itself in the direction of the (C–H) bond orbital. These results may serve as a useful guide for the prediction of the changes in nuclear motions during chemical reactions.

B. Abstraction Reaction. We wish to examine the reaction of triplet methylene with methane as a prototype of abstraction reactions. The reaction is considered to proceed *via* a linear transition state[14] as shown in Fig. 4. This was indeed confirmed by the calculations[15] of the intermolecular interaction energy based on our intermolecular perturbation method.[16] A similar transition state geometry has been assumed for the hydrogen abstraction reaction of triplet methylene from molecular hydrogen.[17]

The main purpose of this study is to analyze the alteration in electronic structure of molecules during

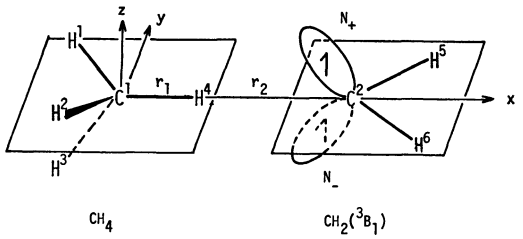

Fig. 4. Coordinate system for the abstraction reaction of methane by triplet methylene.

reaction rather than the change in the total energy, and to interpret it in an orderly manner in terms of the LMO mappings. We specify the reaction path with the notation (r_1, r_2), where r_1 is the distance in units of Å between carbon C^1 and hydrogen H^4, while r_2 is that between carbon C^2 and hydrogen H^4 (Fig. 4). Calculations were carried out at model path points A(1.09, 2.5), B(1.09, 2.0), C(1.09, 1.5), and D(1.29, 1.3),[18] where 1.09 Å is the equilibrium C–H distance of methane.[19]

Variations in hybridization during the reaction are shown in Table 2. It is seen that the bond orbitals C^1–H^1 and C^1–H^4 of methane suffer variations in hybridization in different manners. The α-spin C^1–H^4 bond destined to be cleaved diminishes in p character as the reaction proceeds. In the meantime, the remaining three α-spin C–H bonds gain p character to make up the decrease in p character of the α-spin C^1–H^4 bond. On the other hand, the β-spin C^1–H^4 bond gains p character, being accompanied by the decrease in p character of the remaining three β-spin C–H bonds. As for the methylene molecule, the p character of both the α- and β-spin C–H bonds tends to be increased while that for the unpaired α-spin orbitals is decreased. It is only the C^1–H^4 bond that suffers drastic change in form during the reaction.

a) The entries are the values of x for the hybridization sp^x. b) See Fig. 4. c) Isolated reactants.

Shown in Fig. 5 are the movements of the centroids of the LMO charge distributions with the progress of reaction. The approach of two unpaired electrons of the methylene carbon decouples the electron pairing in the C^1–H^4 bond. The β-spin electron moves toward the H^4 atom while the α-spin electron, in the opposite direction. This separation of the α- and β-spin electrons will effectively weaken (and eventually break) the bond. Meanwhile, the β-spin electron begins to be coupled with one of the α-spin electrons of CH_2. The situation is closely related to the conventional representation as follows:

A better insight into the mechanism of bond rearrangement can be obtained from the results of LMO mapping analysis (Table 3). The bonds other than the C^1—H^4 bond of methane and the $N_\pm$ orbitals of methylene suffer little deformation during the reaction. The α-spin electrons in $N_\pm$ orbitals are delocalized mainly into the antibonding orbital $(C^1$–$H^4)^*$, which will weaken the C^1–H^4 bond. On the other hand, the β-spin orbital

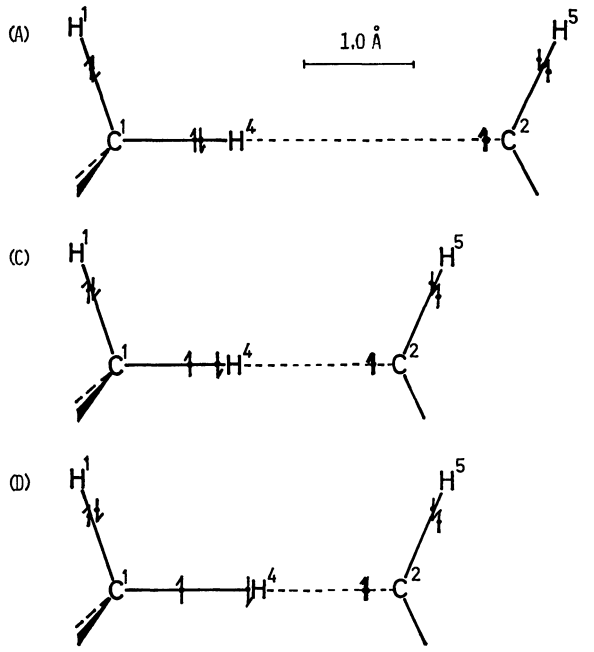

Fig. 5. Top view of the centroids of localized molecular orbitals in the CH_4–$CH_2(^3B_1)$ system at the path points (A), (C), and (D).

(C^1–H^4) mixes first with the vacant unpaired orbital N* of methylene in a strongly bonding way and then with the antibonding orbital (C^1–H^4)* with a negative sign. The corresponding α-spin orbital allows the orbital (C^1–H^4)* to mix into it with a positive sign. The mixing of the antibonding orbital (C^1–H^4)* into the corresponding α- and β-spin bonding orbitals (C^1–H^4) in different signs is what is usually called "spin polarization." The spin polarization induces an excess α-spin density around the carbon C^1 and an excess β-spin density around the hydrogen H^4.

All the above arguments converge into a concept of three-stage mechanism as follows: The main bond deformation caused at the initial stage of reaction is due to the mixing of the β-spin C^1–H^4 orbital into the vacant unpaired orbital $N_\pm$*. At the middle stage, the mixing of the α-spin $N_\pm$ orbital into the antibonding orbital (C^1–H^4)* develops, to form a three-center bond. As the reaction approaches the final stage, the mixing of the α-spin orbital (C^1–H^4) into the antibonding orbital (C^1–H^4)* becomes dominant. Thus, in the first place, a β-spin electron is transferred from methane to methylene; next, back transfer of an α-spin electron from methylene to methane takes place; and finally, local excitation in the bond to be broken becomes appreciable. The first stage can be termed the electrophilic stage of the reaction. From the viewpoint of spin properties, the first and second stages may be envisaged as the "spin delocalization" stage, which operates to drive the two reactant molecules close to each other, thus forming a three-center bond over C^1, H^4, and C^2. Cleavage of the old bond is effected primarily by the last stage, *i.e.*, the "spin polarization" stage. The spin polarization is in effect equivalent to the "triplet excitation" noted in the intermolecular configuration interaction treatments.[1,20]

In connection with the above statement, we briefly consider the reaction of the triplet methylene with CH_3X (X=F or Cl). Triplet methylene attacks substrates containing both hydrogen and halogen atoms in a selective manner; it abstracts a hydrogen atom rather than a halogen atom.[21] The calculated triplet excitation energies[22] from the bonding (C–H) to antibonding (C–H)* orbital are 17.1 and 17.3 eV for CH_3F and CH_3Cl, respectively. Those from (C–F) and (C–Cl) to (C–F)* and (C–Cl)* are 24.0 and 19.1 eV, respectively. Thus, we may anticipate the spin polarization effect to be larger in the C–H bond rather in the C–F or C–Cl bond. Spin density distributions in

the reaction systems lend support to this view (Fig. 6). Apparently, the distributions are $\overset{\alpha}{C}\cdots\overset{\alpha}{X}\cdots\overset{\alpha}{C}$ in the case of the halogen abstraction and $\overset{\alpha}{C}\cdots\overset{\beta}{H}\cdots\overset{\alpha}{C}$ for the hydrogen abstraction. Thus, the triplet excitation energy in the bond as well as the spin density distribution may be a useful guide for predicting the relative ease of the bond cleavage.

C. Addition Reaction. The reaction here studied is the addition of triplet methylene to the double bond of ethylene. Characteristics of this particular reaction was already investigated by Hoffmann[23] in terms of the extended Hückel molecular orbitals. The reaction path was more thoroughly examined by Bodor *et al.*[14] using the MINDO/2 method. We here choose to employ the path similar to that of Bodor *et al.* for our purpose.

The relative positions of methylene and ethylene during the reaction are specified as shown in Fig. 7. The middle of the ethylene double bond was taken as the origin of the coordinate. The carbons C^1 and C^2 of ethylene are put on the x axis, and the carbons C^1, C^2 and C^3 are placed on the xz plane. The entire system is assumed to be symmetric with respect to this plane. The geometry of the system is characterized by the notation $(r, \theta, \psi, \omega)$ in units of Å and degree. The path points considered are A(3.5, 90, 90, 0), B(2.4, 85, 90, 0), C(2.0, 80, 80, 0), D(1.9, 65, 75, 0), E(1.9, 50, 60, 0), and F(1.9, 50, 60, 30).

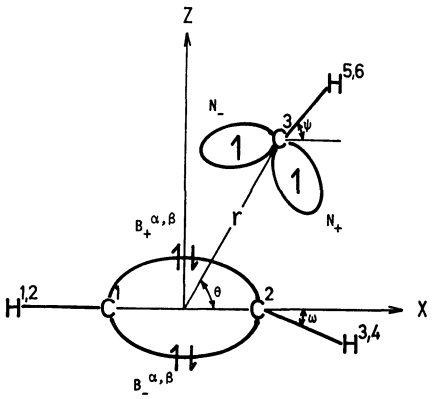

Fig. 7. Coordinate system (side view) for describing the relative position of $CH_2(^3B_1)$ and $CH_2{=}CH_2$.

The LMO calculations for the ethylene molecule provide two equivalent banana bonds for the description of the double bond; one (B_+) lies above the molecular plane while the other (B_-) below it. The banana bonds associated with the α- and β-spin electrons are specified as $B_\pm^\alpha$ and $B_\pm^\beta$, respectively. The triplet methylene has two unpaired orbitals N_+ and N_- as has been mentioned earlier.

When reaction takes place, these particular LMO's suffer the greatest deformation. Table 4 gives the results of the LMO mapping analysis at path points (B)

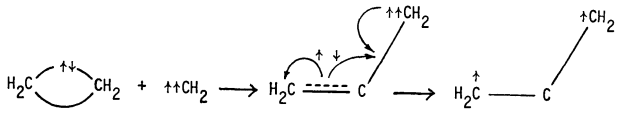
to (E). As is naturally expected, the B$_-^{\alpha}$, B$_-^{\beta}$, B$_+^{\alpha}$, and N$_-$ bonds are responsible primarily for the intramolecular bond rearrangement, while the B$_+^{\beta}$ and N$_+$ orbitals, for the intermolecular bond formation. Here also, the mixing of the B$_+^{\alpha}$ and B$_+^{\beta}$ bonds with the anti-bonding B$_+$* and B$_-$* bonds takes place with opposite signs, a situation which is equivalent to an inducement of triplet excitation in the double bond.[1]

The addition reaction of triplet methylene also conforms to a three-stage mechanism. As can be inferred from Table 4, triplet methylene initially approaches ethylene as a β-spin acceptor. Next, it comes to behave as an α-spin donor. Finally, local excitation in the ethylene molecule becomes appreciable. The β- and α-spin electron transfers must be the major origin of the formation of the new C^2–C^3 bond. The local excitation, *i.e.*, spin polarization in the C^1—C^2 bond should be a factor most effective to the cleavage of the B$_+$ bond.

The results described above can be illustrated pictorially by the schematic representation of the centroids of LMO charge distributions (Fig. 8). Again, the schematic description is in accord with the conventional scheme:



The paired electrons which existed in the B$_-$ bond are slightly decoupled and migrate toward the mid-point of the carbons C^1 and C^2 to form a single bond. The paired electrons which existed in the B$_+$ bond are highly decoupled; the α-spin electron migrates onto the carbon C^1 to form a radical center there, while the β-spin electron migrates toward the mid-point of the carbons C^2 and C^3 to make a pair with one of the two unpaired electrons of methylene, leaving the other unpaired electron to form another radical center on C^3.

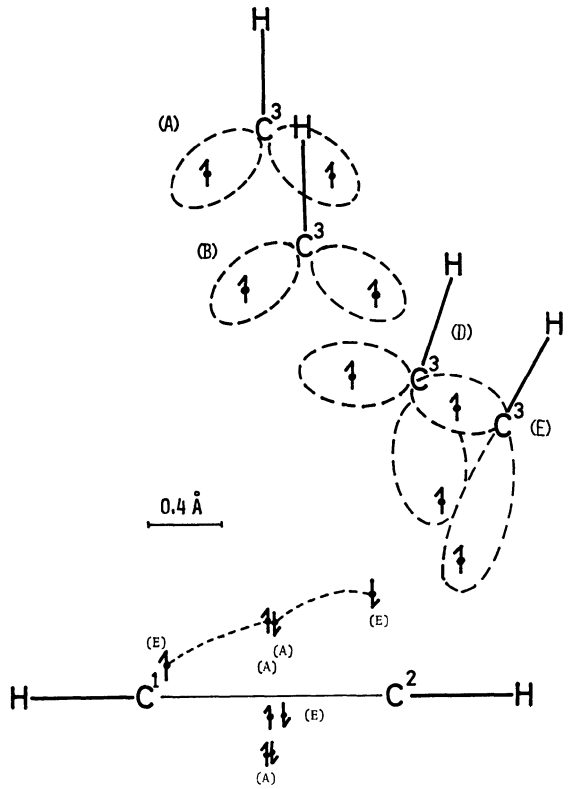


Fig. 8. Schematic representation of the centroids of LMO charge distributions at path points (A)—(E) in the addition reaction of triplet methylene to ethylene.

Listed in Table 5 are the total weights $\sum_i C_{Ki}^2$ of various types of configurations K contributing to Φ_{UHF} at different reaction path points. That the reaction proceeds by the three-stage mechanism can be perceived here even more clearly. Thus, the most dominant configuration to be mixed with Φ_G at initial stages of reaction is Φ_{CT}, the β-spin delocalization from ethylene to CH_2. This is followed up by the mixing of Φ_{BCT}, the α-spin delocalization from CH_2 to ethylene. Finally, the contribution of Φ_{LE} due to the α-spin, and hence triplet, excitation on ethylene becomes appreciable.

Table 5. Total weights of the composite configurations in the addition of triplet methylene (M) to ethylene (E)

	β		0.008	0.179	0.001	0.008
(D)[a]	α	0.354	0.082	0.005	0.178	0.001
	β		0.019	0.176	0.001	0.009

a) Other highly-transferred and highly-excited configurations are also mixed into the ground configuration.

If triplet methylene approached ethylene by way of the least motion with the C_{2v} symmetry ($\theta=\psi=90°$), no new pairing of opposite spins would be possible between them and the bonded electron pair in B$_+$ could not be decoupled with ease. This was in fact confirmed by separate calculations. The situation is much the same as in the addition of methyl radical to ethylene, which has been discussed previously.[1] The steric course of reaction should thus be dependent upon how smoothly the interchange of pairing of opposite spins can take place.

The Crystal and Molecular Structure of 1-(2-Thiazolylazo)-2-naphthol

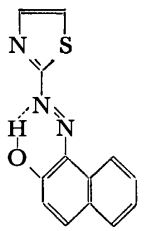
Masayasu KURAHASHI

National Research Institute for Metals, 3-12, 2-Chome, Nakameguro, Meguro-ku, Tokyo, 153

(Received May 14, 1976)

The crystal structure of 1-(2-thiazolylazo)-2-naphthol, $C_{13}H_9N_3OS$, has been determined from three-dimensional X-ray data collected by counter methods. The crystals are monoclinic with space group $P2_1/a$; cell dimensions: $a=17.721(1)$, $b=28.366(2)$, $c=4.699(1)$ Å, $\beta=91.78(1)°$, and $Z=8$. The structure was solved by the symbolic addition procedure and refined by the least-squares method to give an R value of 0.051 for 2150 observed reflections. There are two crystallographically independent molecules in an asymmetric unit; both of the molecules show a generally similar shape and size, but their structural details differ in planarity and distribution of the bond lengths. Both molecules have the azo and hydrazone character, but the equilibrium is shifted toward the azo tautomer.

The compound 1-(2-thiazolylazo)-2-naphthol (abbreviated as Htan) forms colored complexes with various metals, and has therefore been used as an analytical reagent. As part of a series of investigations of the structure of Htan and its metal chelates, the X-ray determination of Htan has been undertaken. The main purpose of the investigation is to establish the configuration of the ligand molecule; this will help to elucidate the structural change involved in the chelate ring formation.



Htan

There is also interest in the tautomerism of this compound. It is well known that the azo and hydrazone tautomers frequently coexist in *ortho*-azophenol compounds.[1-5] An IR spectral study has suggested the azo-hydrazone tautomerism of Htan;[6] however, an explicit interpretation has never been made. Since the phenomenon of the tautomerism seemed to be important for understanding the reactions of this compound with metals, a detailed analysis of the structure has been undertaken. A preliminary note of this work has already been published.[7]

Experimental

The crystals of Htan were obtained from an ethanolic solution by slow evaporation. A crystal of dimensions $0.15\times0.3\times0.4$ mm was chosen for data collection. The crystal data are summarized in Table 1. The cell parameters were determined by the least-squares procedure from the 2θ values of 40 reflections measured on a diffractometer using monochromated Cu $K\alpha$ radiation. The density was determined by flotation in an aqueous solution of sodium iodide.

TABLE 1. CRYSTAL DATA

$C_{13}H_9N_3OS$	M. W. 255.3
Monoclinic	Space group $P2_1/a$
$a=17.721(1)$ Å	$D_m=1.44$ g cm^{-3}
$b=28.366(2)$ Å	$D_x=1.436$ g cm^{-3}
$c=4.699(1)$ Å	$Z=8$
$\beta=91.78(1)°$	$\mu=2.64$ cm^{-1} (for Mo $K\alpha$)
$V=2360.8$ Å^3	

The integrated intensities of the reflections were measured on a Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation monochromated by a graphite plate. The ω-2θ scan technique was employed at a scan speed of 4°/min in ω, and scanning was repeated up to four times when the $\sigma(|F|)$ due to the counting statistics was larger than 3% of $|F|$. The scan width was determined according to the formula $1.5°+0.6°\times\tan\theta$. Background was counted for 10 s at both sides of each peak. Three standard reflections were measured every fifty reflections during the data collection. The intensities of unique reflections with 2θ values less than 55° were collected and a total of 2150 reflections with $|F|>3\sigma(|F|)$ were obtained. The data were corrected for Lorentz and polarization factors, but no correction was made for absorption ($\mu r<0.1$).

Solution of the Structure and Refinement

The structure was determined by the symbolic addition procedure.[8] The distribution and statistics of $|E|$'s agree well with the theoretical values for the centrosymmetric case. Signs of 386 reflections could be determined by the usual symbolic addition procedure using three origin reflections and three symbols, and the resulting E map revealed the location of all 36 non-hydrogen atoms. Several cycles of least-squares refinement of the coordinates and isotropic temperature factors resulted in an $R(=\sum||F_o|-|F_c||/\sum|F_o|)$ of 0.092. Anisotropic thermal parameters were then introduced for all non-hydrogen atoms, and the R factor was reduced to 0.075. All the hydrogen atoms were located on the difference map. This map also revealed that the phenolic hydrogen atoms (H(O) and H(O')) are disordered or oscillate violently, especially the H(O') atom; the contour lines corresponding to the H(O') are elongated toward both O' and N(2') atoms. A second difference map, computed after three cycles of refinement in which all the hydrogen atoms except H(O) and H(O') were included with an isotropic temperature factor, showed the same tendency. Then various least-squares calculations were made, assuming the internal hydrogen bonding of the double minimum type [O–H(O)···H(N)–N]. For example, when the occupancy factors [H(O) to H(N) ratio] of 7 to 3 and 6 to 4,

estimated from the N(1)–N(2) and C(2)–O distances, were given to A (unprimed molecule) and B (primed molecule) respectively, R dropped to 0.052. However, the lowest R value, 0.051, was obtained when the single minimum model of the type O–H(O)···N(2) was assumed. Unit weight was given to all 2150 reflections. The atomic scattering factors used for S, O, N, and C were taken from International Tables for X-ray Cry-

stallography,[9] for H, those of Stewart, Davidson, and Simpson were used.[10] The final atomic parameters based on the single minimum model are listed in Table 2. The observed and calculated structure factors are compared in Table 3.*

Description of the Structure and Discussion

The structure consists of two chemically similar but crystallographically independent molecules (referred to as A and B). The configuration of these molecules viewed normal to the naphthalene plane is shown in Fig. 1. The thermal ellipsoids are drawn at 50% probability. Both molecules show a generally similar shape and size, but some structural details are different, as described below. Each azo group adopts a *trans* conformation, and the phenolic oxygen atom, O, is linked to the azo nitrogen atom, N(2), by intramolecular hydrogen bonding; the O···N(2) distances are 2.548(6) and 2.556(6) Å for A and B, respectively.

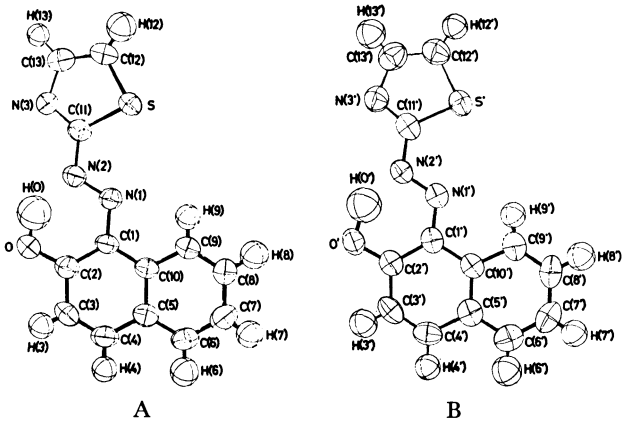

Fig. 1. The molecular structures viewed normal to each naphthalene plane. The thermal ellipsoids are drawn at 50% probability.

N(1) and N(3) are in *trans* positions with respect to the C(11)–N(2) bond. A similar conformation was observed for a bromo-derivative of Htan, 1-(2-thiazolylazo)-6-bromo-2-naphthol.[11] This will imply that the observed conformation is the most stable one for these molecules. A relatively short non-bonded distance of 2.87 Å, as shown in Fig. 2a, is observed between N(1) and S (and N(1′) and S′).

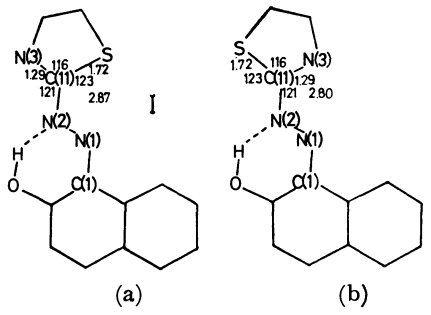

Fig. 2. Two possible planar configurations for Htan. (a) *trans* (b) *cis* (N(1)–N(2)–C(11)–N(3)).

If the thiazole ring is rotated by 180° around the C(11)–N(2) bond, that is, when N(1) and N(3) are in *cis* positions, the N(1)···N(3) distance will be about 2.80 Å (Fig. 2b). Inspection of MO calculations for this molecule[12] reveals that such a conformation is less stable in view of the electrostatic interaction, because the formal charges on N(1) and N(3) are both negative. On the other hand, the N(1)···S interaction in the observed conformation (Fig. 2a) is of the attractive type, since the formal charges on N(1) and S are negative and positive, respectively.

Bond lengths and angles are shown in Table 4 with their e.s.d.'s. The most significant differences between A and B are in the N(1)–N(2) and C(1)–C(10) distances; the other distances of both molecules agree well, within the limit of three times their corresponding e.s.d.'s.

The observed N(1)–N(2) distance of 1.278(7) Å lies between the standard distance of the azo form (–N=N–), 1.24±0.01 Å,[13–18] and that of the hydrazone form (–NH–N=), 1.39±0.01 Å,[16,19,20] and is closer to the value corresponding to the azo form. On the other hand, the observed value of 1.306(7) Å for N(1′)–N(2′) is almost intermediate between the azo and hydrazone

forms, but is slightly closer to the value corresponding to the azo form.

The C(2)–O and C(2′)–O′ distances of 1.325(7) and 1.317(7) Å observed for A and B respectively are congruent with neither the standard distance of the phenolic form (C–OH), 1.38±0.01 Å,[21,22] nor with that of the quinoid form (C=O), 1.22±0.01 Å.[21,23,24] The distances lie intermediate between these two values, but are slightly closer to the value corresponding to the phenolic C–OH distance.

Somewhat similar behaviors were observed in 1-(*p*-nitrophenylazo)-2-naphthol,[25] 4-chloro-2,5-dimethoxyanilide of 1-(2,5-dichlorophenylazo)-2-hydroxy-3-naphthoic acid,[26] and 1,2-naphthoquinone 1-(2-nitro-4-chlorophenylhydrazone).[27] In these compounds N–N (–N=N– or –NH–N=) and C–O (C=O or C–OH) distances range from 1.32 to 1.34 Å and from 1.25 to 1.26 Å, respectively. These reported values correspond more nearly to the hydrazone tautomer than to the azo tautomer.

In view of the bond length distribution for Htan, azo-like (phenol) character is predominant rather than the hydrazone-like (quinone) character in both A and B. However, B has more of a hydrazone-like character than A, since the N(1)–N(2) and C(1)–C(10) are longer and C(2)–O and N(1)–C(1) are shorter in B than in A.

The azo-hydrazone tautomerism of Htan was better established by the location of the relevant hydrogen

atoms. The positions of H(O) and H(O'), which were located from the difference map (higher than 0.3 e Å^{-3}), were refined by the least-squares method as mentioned above. The observed O–H(O) and O'–H(O') distances are 1.04(6) and 1.17(6) Å respectively (the N(2)···H(O) and N(2')···H(O') distances are 1.65(6) and 1.55(6) Å respectively), indicating O–H(O)···N(2) [and O'–H(O')···N(2')] hydrogen bonding. This fact is sufficient to establish the azo form as the predominant tautomer in both A and B. It can also be seen from the hydrogen positions that B has more of a hydrazone-like character than A.

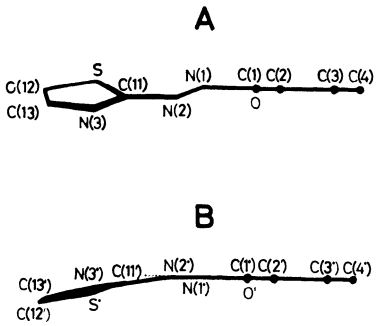

Fig. 3. Side view of the A and B molecules. The vertical scale is approximately eight times greater than the horizontal scale.

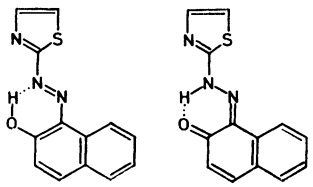
In studying the problem of the tautomerism, it is of interest to see the planarity of the molecules. The equations of the best planes through various sets of atoms in the respective molecules are presented in Table 5(a). The displacement of atoms from the planes and the angles between these planes are given in Tables 5(b) and 5(c). A view of the molecules which illustrates the planarity is shown in Fig. 3. The vertical scale is approximately eight times greater than the horizontal scale. Naphthol and thiazole rings of both molecules are planar within the experimental error. The A and B molecules are roughly planar within the deviations of $\pm$0.08 and $\pm$0.06 Å respectively, and each breaks the planarity in a different way, as can be seen in Figs. 1 and 3. The molecule A is twisted along the N(1)–C(1) bond, with 4.2° as the angle between the planes of the thiazole and naphthol rings. On the other hand, the molecule B is slightly folded at the N(2) atom and the thiazole ring plane makes an angle of 3.5° with the naphthol ring plane. The slight rotation along the N(1)–C(1) bond will indicate the single bond character, and accordingly the pronounced azo-like character in A. The slight pyramidal configuration (C(11')–N(2')$<^{N(1')}_{H(O')}$) around the N(2') atom is indicative of some hydrazone-like character in B.

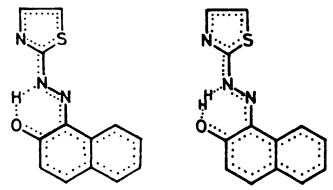
From the X-ray evidence mentioned above, the following two models can be proposed for the real molecular structure of Htan. The first is to assume that the azo (I) and hydrazone (II) tautomers coexist in the crystals of Htan, but the azo tautomer predominates.



(I) (II)

Accordingly the molecules as a whole are disordered; the azo and hydrazone tautomers occupy statistically two slightly different positions with unequal probability. Elongation of the thermal ellipsoids, especially in the molecule B, along the N(1)–N(2), N(1)–C(1), C(2)–O, *etc.*, suggests this model. However, it seems that more elongated ellipsoids should appear in such a case.

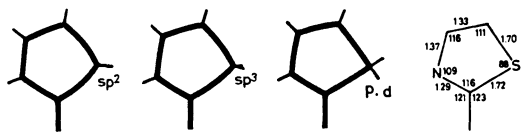
The second is that there exists only one type of molecule, whose electronic structure is intermediate between the azo and hydrazone tautomer, but the contribution of the azo form is more pronounced. If the potential curve of the hydrogen bonding is of the single minimum type (IIIa), the hydrogen atom would vibrate violently in the potential well. If the potential is of the double minimum type (IIIb), only the hydrogen



(IIIa) (IIIb)

atoms would be disordered. X-Ray evidence cannot distinguish these two cases. The potential well is clearly not the symmetric double minimum nor the symmetric single minimum type.

The average values of bond distances and angles in the thiazole ring are: S–C(11)=1.724, S–C(12)=1.701, N(3)–C(11)=1.290, N(3)–C(13)=1.374, and C(12)–C(13)=1.329 Å. C(11)–S–C(12)=88.3, C(11)–N(3)–C(13)=109.2, S–C(11)–N(3)=115.7, S–C(12)–C(13)=110.6, and N(3)–C(13)–C(12)=116.4°. Both S–C(11) and S–C(12) distances are significantly shorter than the standard distance of the paraffinic C–S bond, 1.817(5) Å.[28] This indicates that both C–S bonds have some double bond character and that the hybridization state of S is not sp^3.



(a) (b) (c) (d)

Fig. 4. Framework molecular models (a, b, c) for thiazole and observed geometry (d). For S atom (a) sp^2, (b) sp^3 and (c) p (or d_{xy}) orbital skeleton was used.

Figure 4 shows the molecular models of a thiazole ring in which the valence state of S is assumed to be (a) sp^2, (b) sp^3, and (c) p (or some other orthogonal orbitals like d_{xy}). The observed distribution of bond angles, (d), corresponds more to that of model (c) than to (a) or (b). This may suggest that the valence state of S is not sp^2 either. In the case of thiophene, the C–S distance and the C–S–C angle are reported to be 1.718 Å and 92.2(1)° respectively,[29] and the d-electron orbitals are thought to be involved in the hybridization.[30] The observed values of C–S bond length and C–S–C angle for Htan are very close to the values for thiophene. Therefore, d-electron orbitals may be connected with the hybridization in the case of thiazole as well. If the hybridization state is purely sp^2 or sp^3, and if the accuracy of the analysis is high enough, lone pair electrons will appear in a residual map. An attempt to locate the relevant lone pair electrons for the sulfur atom in the final difference map failed; A more detailed analysis will be necessary to discuss this problem.

If the thiazole sulfur atom does not have lone pair electrons pointing to the bisector of C(11)–S–C(12), the sulfur atom will not participate in any chelate ring formation. Actually, there is no example of the participation of the thiazole sulfur atom in metal binding. X-Ray determinations of Fe(II)-, Co(III)-, Ni(II)-, Cu(II)-, and Pd(II)-chelates of the 1-(2-thiazolylazo)-2-naphtholato (tan) group have established that tan is coordinated to the metal through the phenolic oxygen atom, the azo nitrogen atom adjacent to the naphthol ring, and the thiazole nitrogen atom so as to form two five-membered chelate rings.[31–35]

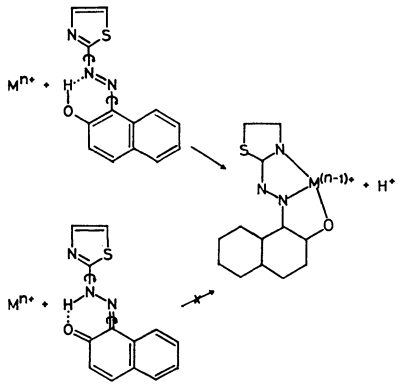


Fig. 5. Conformational changes on chelate ring formation.

Comparison of the structures of Htan and tan indicates that both thiazole and naphthol rings are rotated by 180° around the N(2)–C(11) and N(1)–C(1) bonds, as illustrated by Fig. 5. It should be noted that the rotation around the N(1)–C(1) bond will not usually occur when the N(1)–C(1) is a double bond (*i.e.* hydrazone form). Thus the reaction of the type $Htan+M^{n+}\longrightarrow M^{(n-1)+}\text{-tan}+H^+$ will occur through the azo tautomer.

The crystal structure projected along the c axis is shown in Fig. 6. Intermolecular distances shorter than 3.5 Å are given in Table 6. All distances are consistent with the van der Waals contacts, and there is no evidence of intermolecular hydrogen bonding.

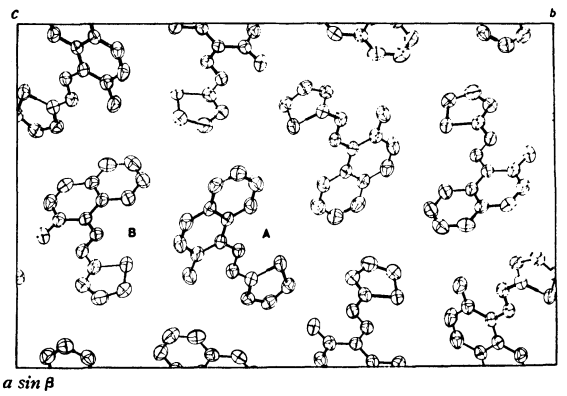

Fig. 6. Crystal structure projected along the c axis. The thermal ellipsoids are drawn at 50% probability.

The Penetration of Disodium Hexadecyl Phosphate to the Monolayers of Cholesterol and its Esters from the Underlyning Aqueous Solutions

Masayuki NAKAGAKI and Tetsurou HANDA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received May 15, 1976)

The surface pressure of the monolayers of cholesterol (CH), cholesteryl acetate(CA), and cholesteryl propionate (CP) on the aqueous solutions of disodium hexadecyl phosphate (SHP) was measured. The monolayer exhibited a more expanded state on the solution than on pure water. The curves showing the surface pressure against the area per molecule of each monolayer had a kink point, which was considered to indicate the collapse of the monolayer. The amount of SHP penetrating into the insoluble monolayer was calculated by means of the Gibbs adsorption equation. It was found that the relation between the penetration amount and the activity of SHP in the aqueous solution could be expressed by a modification of the Langmuir adsorption equation. It was also found that the saturated amount of the penetration decreased, and the Langmuir coefficient increased, with the compression of the monolayer.

To study the penetration of a physiologically active substances from its aqueous solution into an insoluble lipid monolayer is important and interesting. Many papers on this subject have been published on, *e.g.*, the penetration of surfactants into the cholesterol or long-chain alcohol monolayers,[1-3] the penetration of anesthetics into the phospholipid monolayers,[4] and the penetration of various proteins into the phospholipid monolayers.[5-7] These papers have presented valuable discussion related to the fundamental aspect of the drug action, the biomembrane structure, the interaction of antibodies with lipid antigens, the enzyme activation, and so forth.

When an insoluble monolayer is spread on an aqueous solution of a surface-active substance, the latter penetrates into the insoluble monolayer and a mixed monolayer of these components is formed. In our laboratory, the thermodynamics of mixed monolayers of insoluble components have been studied and the miscibility of components in the monolayer and the phase transition of the monolayer have been explained by applying the phase rule and the theory of regular solution to the monolayer.[8-9] Moreover, the surface tension of aqueous solutions of disodium dodecyl, tetradecyl, and hexadecyl phosphates have been measured. On the basis of the surface tension measurement, it has been found that the adsorption to the solution surface and the formation of micelles of these bi-valent anionic surfactants could be explained satisfactorily by using the activity, instead of the concentration, of these compounds in the solutions,[10] and also that, on the basis of the measurement of the surface tension of a mixed solution of these compounds, the mixed adsorption and the formation of the mixed micelle could be explained by assuming an ideal mixing at the adsorption layer and the micelle phase.[11] The penetration of the soluble component into the insoluble monolayer will be discussed here, with reference to the results of our previous papers.[8-10]

In order to discuss the above subjects quantitatively, the calculation of the penetration amount (the adsorption amount) of the soluble component into the insoluble monolayer is indispensable. The adsorption equation of the soluble component was presented by B. A. Pethica and applied to the system of cholesterol and sodium dodecyl sulfate (SDS).[2]

In this work, the surface pressure of the cholesterol (CH), cholesteryl acetate (CA), and cholesteryl propionate (CP) spread as monolayers on an aqueous solution of disodium hexadecyl phosphate (SHP), was measured by the Wilhelmy method at 25 °C, and the penetration amounts of SHP into the monolayers of cholesterol and its esters were calculated.

Experimental

Materials. The specimen of CH was from the Sigma Chemical Co. and the CP, from The Aldrich Chemical Co. Inc. the CA, from the Nakarai Chemical Co., was recrystallized from acetone. The specimen of SHP was the same as that used in a previous paper, which had been synthesized and dissolved in water, as was reported there.[10]

Surface-pressure Measurement. On the aqueous solution of SHP in a trough, the monolayer of CH, CA, or CP was spreaded by using benzene as the spreading solvent. The curves of the surface pressure against the area per molecule (the *F–A* curve) was measured by the Whilhelmy plate method by compressing the monolayer with a barrier, that means, by the surface-area-decreasing method (SAD method). Otherwise, *F–A* curve was obtained by dropping a benzene solution of an insoluble component onto a constant area, that means, by the insoluble-component-addition method (ICA method). The area per molecule, A, is S/nN_A, where S is the area of the aqueous surface between two barriers, n is the mole of the insoluble component spread in this area, and N_A is the Avogadro number. Therefore, A can be decreased either by decreasing S (SAD method) or by increasing n (ICA method). Details of the surface pressure measurement have been reported in a previous paper.[12]

Results

F–A Curves and γ–c_2 Curves of the Monolayers of CH on the Aqueous Solution of SHP. The surface pressure, F, was measured by changing the area per molecule of the insoluble component, A, on the aqueous solution of SHP at various concentrations, c_2. Both the SAD method and the ICA method were applied. The *F–A* curves of the CH monolayers are shown in Fig. 1, where the surface pressure, F, is defined as usual by:

$$F = \gamma_w - \gamma \quad (1)$$

where γ is the surface tension of the SHP solution, whose

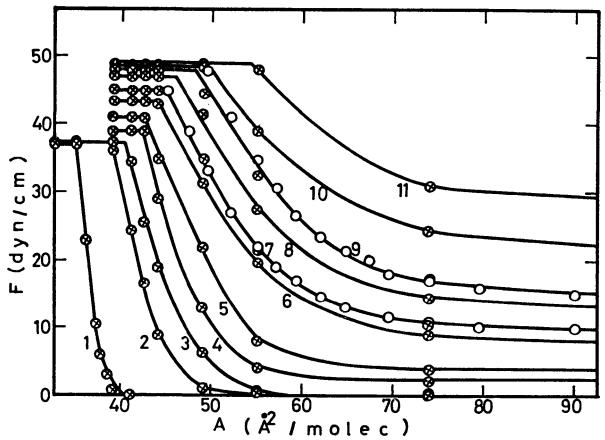

Fig. 1. *F–A* curves of the CH monolayers on the SHP solutions.
○: SAD method, ⊗: ICA method,
c_2: (1) 0 mM, (2) 0.02 mM, (3) 0.05 mM, (4) 0.1 mM, (5) 0.2 mM, (6) 0.4 mM, (7) 0.5 mM, (8) 0.8 mM, (9) 1 mM, (10) 2 mM, (11) 3 mM.

surface is covered with an insoluble monolayer, and γ_w is that of pure water. It is found that the monolayer is more expanded and is shifted to a higher surface pressure on a solution with a higher concentration of SHP, c_2. Even if the practical surface pressure, F', is calculated by subtracting the surface pressure of the SHP solution, the curves of F' against the area per molecule are also more expanded on a solution with a higher value of c_2.[9] This phenomenon is due to the penetration of the soluble component, SHP, into the insoluble monolayer. On the other hand, each curve in Fig. 1 has a kink point. It was found in our previous paper that this point indicates the collapse of the monolayer.[9]

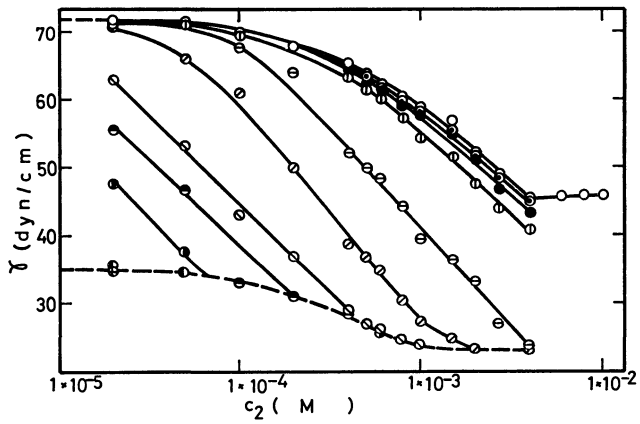

Fig. 2. The relations of surface tension, γ, and the concentration of SHP, c_2, at various values of A of CH.
A (Å²/molec): ○ no insoluble monolayer, ⊙ 220, ● 110, ⓘ 74, ⊖ 55, ⊘ 49, ⊗ 44, ◓ 42.5, ◑ 41, ◐ 39, ⊕ 35.

In Figure 2, the surface tension, γ, is plotted against the SHP concentration, c_2. Each line is drawn at a constant area per molecule of the insoluble component (CH), A. The data in Fig. 2 can be transcribed into the data in Fig. 1. The critical micelle concentration of SHP is 6 mM, and the insoluble monolayers were spread on a SHP solution of less than 6 mM. It was found that, at a constant value of A, the surface tension, γ, decreases with c_2, and that at a constant value of c_2, γ increases with A. The collapse points are shown by the broken line in Fig. 2.

γ–c_2 Curves of the Monolayer of CA. The *F–A* curves and the *F'–A* curves of CA on aqueous solutions of SHP with various values of concentration, c_2 were presented in our previous paper.[9] Both the SAD method and the ICA method were applied; the data based on these two methods were in good agreement. Each *F'–A* curve had a kink point, which was considered to be the collapse point, and the practical surface pressure of this point (the collapse pressure) was independent of c_2. As well as the monolayer of CH, the monolayer of CA was the more expanded on the SHP solution with a higher concentration.

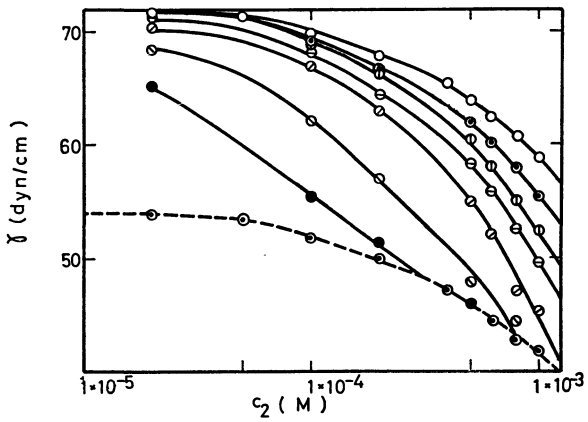

Fig. 3. The relations of surface tension, γ, and the concentration of SHP, c_2, at various values of A of CA.
A (Å²/molec): ○ no insoluble monolayer, ⊙ 100, ⓘ 80, ⊖ 70, ⊘ 60, ⊗ 50, ● 45, ◎ 40.

Figure 3 shows the relation between the surface tension, γ, and the SHP concentration, c_2, at various values of the area per molecule of CA, A. The collapse points of the monolayers are shown by the broken line. The general features of the CA monolayers on the SHP solutions are identical with those of the CH monolayers.

γ–c_2 Curves of the Monolayers of CP. The *F'–A* curves of the CP monolayer on the aqueous solution of SHP were also presented in our previous paper.[9] Both the SAD method and ICA method were applied here also. It is noticeable that the data based on these two methods were not in agreement. The monolayers of CP on the SHP solutions were easily supercompressed when the SAD method was applied. The value of the surface pressure of the kink point decreased with the time and was constant at $F'=7.5$ dyn/cm. On the other hand, the *F'–A* curves based on the ICA method showed no change with the time, agreed well with the curves obtained by the SAD method in the region of low F' values, and gave the collapse pressure $F'=7.2$ dyn/cm, which is practically equal to the above-mentioned value of the "equilibrium" collapse pressure obtained by the SAD method.

In Fig. 4, the relation between the surface tension, γ, and the SHP concentration, c_2 of the equilibrium

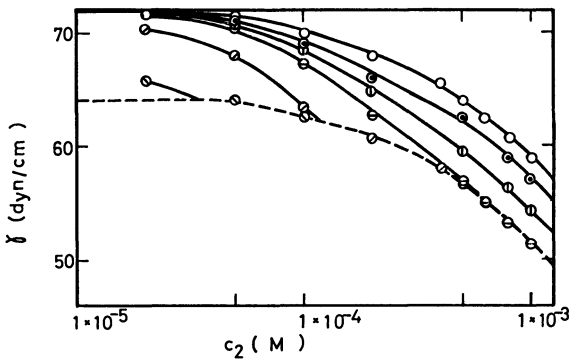

Fig. 4. The relations of surface tension, γ, and the concentration of SHP, c_2, at various values of A of CP. A (Å²/molec): ○ no insoluble monolayer, ⊙ 100, ⊕ 80, ⊖ 70, ⊘ 60, ⊗ 50.

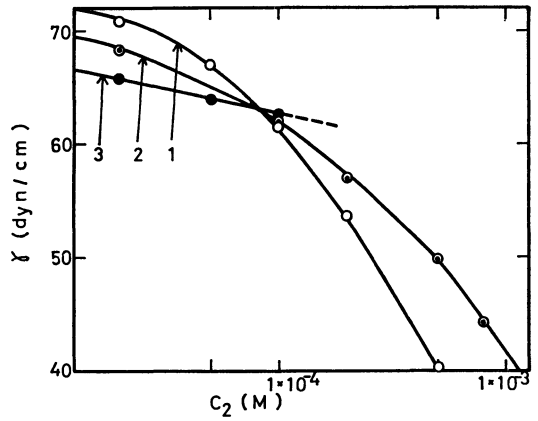

Fig. 5. The relations of surface tension, γ, and the concentration of SHP, c_2, at $A=50$ Å²/molec. Insoluble component: 1. CH, 2. CA, 3. CP.

monolayers of CP are shown. The equilibrium collapse points are shown by the broken line. The general features of the CH, CA, and CP monolayers on the SHP solution are similar. However, there is one noticeable aspect: in comparing at a constant area per molecule of the insoluble components, A, the surface tension is higher in the region of the lower value of c_2 in the order of CH, CA, and CP whereas the surface tension is lower in the region of the higher values of c_2 in the order of CH, CA, and CP. This aspect is shown in Fig. 5, at $A=50$ Å²/molec., as an example. This must affect the penetration isotherms of SHP into the insoluble monolayers of CH, CA, and CP.

Discussion

Mixed Monolayers of an Insoluble Component and a Soluble Component. Into the insoluble monolayer, the surface-active soluble component, SHP, penetrates and a mixed monolayer of these components is formed. The molecular interaction between the insoluble (CH, CA, or CP in this case) and soluble (SHP in this case) components is important in helping one to decide the general features of the mixed monolayer. Three typical cases, shown in Fig. 6, can be expected.

a) If these two components are completely miscible in the monolayer, the F–A curve of the mixed monolayer takes the shape of Type a. b) If these two components are only partially miscible, the F–A curve takes the shape of Type b. In the plateau region, two monolayer phases of different compositions co-exist under a constant pressure, a constant temperature, and a constant concentration of SHP, c_2. According to the surface-phase rule, the freedom of the system becomes zero and the surface pressure, F, does not change.[13,14] By the compression of the monolayer, one monolayer phase diminishes, after the complete disappearance of this monolayer phase, the surface pressure again increases. c) When the insoluble and soluble components are completely immiscible, the general feature of the F–A curve is Type c. The surface pressure does not change from F_{SHP} by the compression of the monolayer until the p point. At this point, the F–A curve is the same as that on pure water (the broken line in in Fig. 6).

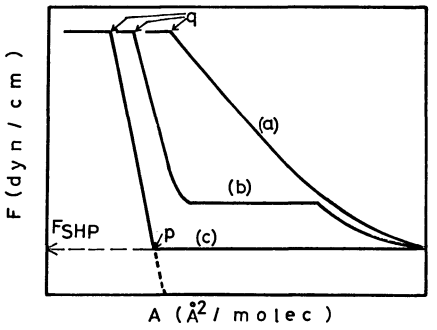

Fig. 6. The general features of F–A curves of the penetrated monolayers.

On the basis of the above discussion, all of the systems in this paper (CH–SHP, CA–SHP, and CP–SHP) can be identified as of Type a. Therefore, in the monolayers, the insoluble component and the soluble component are miscible. The q point is the collapse point of the monolayer.

The Calculation of the Amount of Penetration of SHP into the Insoluble Monolayer. SHP and the insoluble component (CH, CA, or CP) are designated as Components 2 and 3 (Component 1 is water). The Gibbs adsorption equation is given as:

$$\begin{aligned} dF &= \Gamma_2 d\mu_2 + \Gamma_3 d\mu_3^s \\ &= \Gamma_2 RT \, d\ln a_2 + \Gamma_3 d\mu_3^s \end{aligned} \quad (4)$$

where Γ_2 is the penetration amount (the adsorption amount) of SHP (mol/cm²), a_2 is the activity of SHP in the aqueous solution, Γ_3 is the mole of the insoluble component in the monolayer of 1 cm² and is equal to $1/AN_A$, and μ_3^s is the chemical potential of the insoluble component in the monolayer. The activity of SHP in the solution, a_2, is defined as:

$$a_2 = \gamma_\pm^3 c_2 (2c_2 + c')^2 \quad (5)$$

where $\gamma_\pm$ is the mean ionic activity coefficient, the latter can be calculated from the Güntelberg approximation of the Debye-Hückel theory:

$$\log \gamma_\pm = \frac{-B\sqrt{J}}{1+\sqrt{J}} \quad (6)$$

Here, J is the ionic strength, and B is a constant whose value is 1.022 for SHP at 25 °C.[15] c' is the concentration of the added electrolyte (in this case, $c'=0.01$ M NaOH). With respect to the chemical potential of the insoluble component in the monolayer, μ_3^s, we give the following equation:

$$d\mu_3^s = N_A\omega_3 dF + RT d\ln X_3 \quad (7)$$

Here, N_A is the Avogadro number, ω_3 is the partial molecule area of component 3, which is obtained from the F–A curve of the monolayer on pure water at the corresponding value of the surface pressure, and X_3 is the mole fraction of the insoluble component in the monolayer. X_3 is defined as:

$$X_3 = \frac{\Gamma_3}{\Gamma_2+\Gamma_3} \quad (8)$$

Because the surface-pressure measurement is performed by changing the concentration of SHP, c_2 (the activity of SHP, a_2), and the area per molecule of the insoluble component, A, under a constant temperature and constant pressure, F and X_3 are functions of $\ln a_2$ and A respectively.

$$dF = \left(\frac{\partial F}{\partial \ln a_2}\right)_A d\ln a_2 + \left(\frac{\partial F}{\partial A}\right)_{a_1} dA \quad (9)$$

$$dX_3 = \left(\frac{\partial X_3}{\partial \ln a_2}\right)_A d\ln a_2 + \left(\frac{\partial X_3}{\partial A}\right)_{a_1} dA \quad (10)$$

Under the constant area per molecule of the insoluble component, A, Eqs. 4, 7, 9, and 10 give the following equation:

$$\Gamma_2 = \frac{(1-\omega_3/A)(\partial F/\partial \ln a_2)_A}{1-(\partial \ln X_2/\partial \ln a_2)_A} \quad (11)$$

Because the value of $(\partial \ln X_2/\partial \ln a_2)_A$ is not directly known from the data (Figs. 2 and 4), we start the calculation of Γ_2 with an approximate equation and revise succesively. For this purpose, the following equation may be used instead of Eq. 11:

$$\Gamma_2 = (1-\omega_3/A)(\partial F/\partial \ln a_2)_A \quad (12)$$

if the following equation is used instead of Eq. 7:

$$d\mu_3^s = N_A\omega_3 dF \quad (13)$$

The same equation as Eq. 12 was used by Pethica[2] and other investigators[16] for the systems of cholesterol and SDS and of octadecanol and hexadecyl-trimethyl ammonium bromide. The calculation of Γ_2 from Eq. 11 is performed as follows:

1. Γ_2 is calculated by applying Eq. 12 to, for example, Fig. 3. 2. $\ln X_2$ is calculated by means of Eq. 8. 3. $(\partial \ln X_2/\partial \ln a_2)_A$ is calculated graphically. 4. Now, Γ_2 is recalculated by means of Eq. 11. 5. The successive approximation is repeated until the value of Γ_2 converges to a difined value.

In Fig. 7, the values of Γ_2 calculated from Eqs. 11 and 12 are shown for the $A=220$ Å^2/molec of CH as an example. In the region of low concentrations of SHP, c_2, an appreciable difference is recognized between the values calculated from these equations. This is caused by the comparatively large value of $(\partial \ln X_2/\partial \ln a_2)_A$ in this region of c_2. In Fig. 8, the converged values of Γ_2 are shown against the concentration of SHP at various values of the A of CH. The following points are found: 1. The relation of Γ_2 and c_2 at each value of A are, in appearance, those of the Langmuir adsorption. 2. The saturated amount of the penetration is larger at a larger value of A. 3. The initial increment of Γ_2 against c_2 is larger at a small value of A.

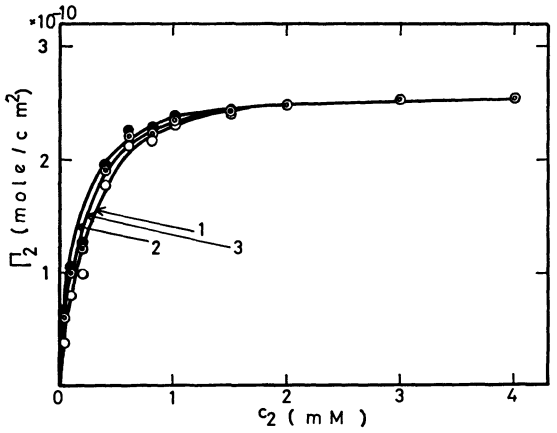

Fig. 7. The relations of the penetration amount, Γ_2, and the concentration of SHP, c_2, for $A=220$ Å^2/molec of CH. ○ 1st approximation by Eq. 12, ● 2nd approximation, ◎ the converged values by Eq. 11.

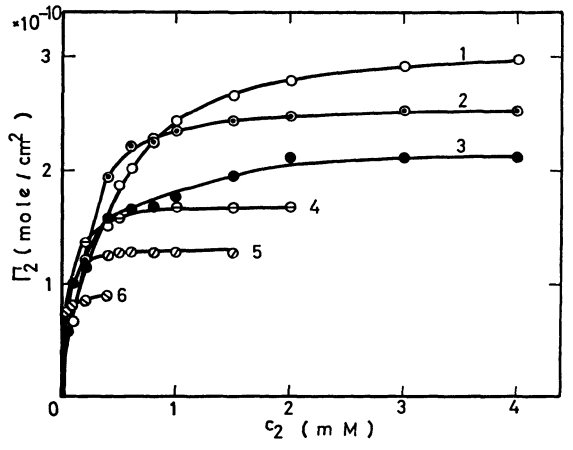

Fig. 8. The relations of the penetration amount, Γ_2, and the concentration of SHP, c_2.
The converged values, A (Å^2/molec): 1. no insoluble monolayer, 2. 220, 3. 110, 4. 55, 5. 49, 6. 44. the insoluble component is CH.

Because SHP is an electrolyte, we assumed the modified Langmuir adsorption equation by using the activity, a_2, instead of the concentration, c_2:

$$\Gamma_2 = \frac{\Gamma_s K a_2}{1+Ka_2} \quad (14)$$

where Γ_s is the saturated amount of the penetration of SHP and K is the modified Langmuir coefficient. If we, therefor, plot the value of (a_2/Γ_2) against a_2, a straight line is obtained: the values of Γ_s and K are obtained from the slope and the intersection in relation to the ordinate. In Fig. 9, (a_2/Γ_2)-a_2 plots for CH are shown for several values of A. All the plots shown a linear relation: the values of Γ_s and K thus obtained are shown in Fig. 10. The data of CA and CP as well as CH are shown in this figure.

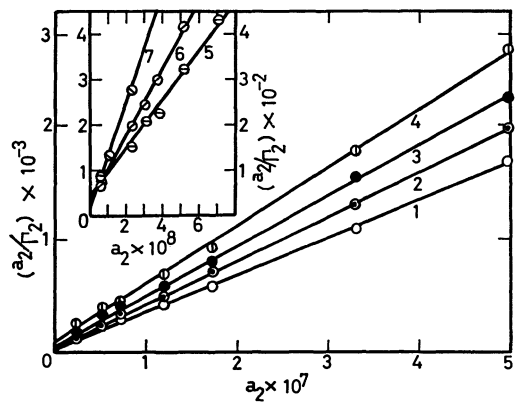

Fig. 9. The Langmuir plots, (a_2/Γ_2) *vs.* a_2.
The insoluble component is CH. A (Å²/molec): 1. no insoluble monolayer, 2. 220, 3. 110, 4. 74, 5. 55, 6. 49, 7. 44.

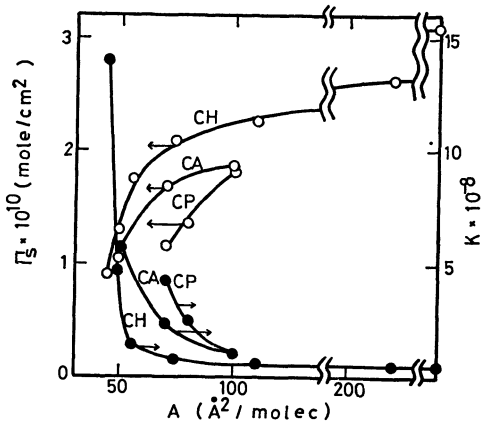

Fig. 10. The saturated penetration amount, Γ_s, or the modified Langmuir coefficient, K, *vs.* the area per molecule of the insoluble component, A.

The value of the saturated amount of the penetration, Γ_s, is 3.1×10^{-10} mol/cm² when surface is free from the insoluble component, and it decreases with a decrease in the value of A. At a constant value of A, the value of Γ_s is larger in the order of CH, CA, and CP. On the other hand, the value of K is nearly constant at the large value of A (A>100 Å²/molec); it is 0.5—1.0×10^8, which agrees with the value of 0.5×10^8 for the solution surface free from the insoluble component. When the value of A decreases further, the value of K steeply increases. The value of K is correlated with the strength of the penetration, and the increase in the value of K means a larger strength of the penetration of SHP into the insoluble monolayer and is caused by the greater amount of intermolecule interaction. The value of K for the system of CP–SHP is the largest, and that for the system of CH–SHP is smallest. This is caused by the hydrophobic nature of these compounds; the noticeable difference in Figs. 2, 3, 4, and 5 directly indicate these effect of the K and Γ_s of CH, CA, and CP.

X-Ray Photoelectron Spectroscopy of Chloromethanes and Chloroethanes

Toshiaki OHTA and Haruo KURODA

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo 113

(Received May 15, 1976)

X-Ray photoelectron spectra of chloromethanes ($CH_{4-n}Cl_n$, n=2,3,4) and chloroethanes ($CH_3CH_{3-n}Cl_n$, n=1,2,3) in vapor phase were observed employing Mg $K\alpha$ radiation. The observed Cls binding energies were analyzed by means of Siegbahn's electrostatic potential model and charge densities calculated by the CNDO/2 method, and the effects of inclusion and exclusion of Cl 3d atomic orbitals in the basis set of the CNDO/2 calculation is critically investigated. The assignment of all valence electron levels of above molecules were performed with the aids of the CNDO/2 calculations incorporated with Gelius' intensity model and the reported data of ultraviolet photoelectron spectroscopy.

X-Ray photoelectron spectroscopy (XPS) of free molecules in gas phase provides various useful informations concerning molecular electronic structures. By means of XPS, one can directly determine core-electron binding energies, which reflect charge distribution in molecule. As for valence-electron levels, XPS offers informations complementary to those obtainable by ultraviolet photoelectron spectroscopy (UPS) which employs the He I or He II line as the stimulating radiation; deep valence-electron levels, out of reach of UPS, are able to be studied by XPS, and, from the comparison between XPS and UPS spectra, one can obtain information concerning the s- and p-characters of ionizing molecular orbitals.

From the above point of view, we have previously investigated the gas-phase X-ray photoelectron spectra of mono-substituted benzenes,[1] and those of a series of molecules containing the C≡N group.[2]

In the present paper, we will describe the results obtained by gas-phase XPS of chloromethanes, $CH_{4-n}Cl_n$ (n=2, 3, and 4) and chloroethanes, $C_2H_{6-n}Cl_n$ (n=1, 2, and 3). On those series of chlorine-containing molecules, UPS studies have been carried out by other authors,[3-7] but no systematic investigation by gas-phase XPS has been hitherto reported.

We examined the correlation of the chemical shifts of Cls levels and charge distributions calculated by the CNDO/2 method. Discussion will be given on the effects of inclusion and exclusion of vacant 3d atomic orbitals of chlorine in the CNDO/2 calculations. We also intended to elucidate all of the valence-electron levels in these molecules from the analysis of XPS spectra with the aids of the reported UPS data and the CNDO/2 calculations.

Experimental

All materials used here were commercially obtained, and purified by distillation.

The gas-phase XPS spectra were measured with McPherson ESCA 36 electron spectrometer, equipped with a gas-iozination cell and gas-control system, by employing Mg $K\alpha$ (1253.6 eV) as the stimulating radiation. Details of experimental procedure were the same as those described in our previous papers.[1,2]

Binding energies of core-electron peaks were calibrated by using the Nls peak of nitrogen gas (409.9 eV) mixed in sample vapors as the reference. The weak Al $K\alpha$ radiation (1486.6 eV) which came out as the secondary X-ray from the Al window of the gas-ionization cell, gave weak core-electron peaks at the kinetic energies exactly higher by 233.0 eV than the kinetic energies of the corresponding peaks by Mg $K\alpha$. Some of them are located closely to the valence-electron spectrum due to Mg $K\alpha$. For example, Cl 2s peak induced by Al $K\alpha$ appears at the position corresponding to the binding energy of about 45 eV in the spectrum by Mg $K\alpha$. Thus we used this peak as a subsidiary reference for the calibration of binding energies of valence-electron peaks.

Measurement was carried out at least twice for each sample. Binding energies thus determined were reproducible within ±0.1 eV.

Results

For each material, we carried out measurement both for core- and valence-electron regions. In order to illustrate the general features of the XPS spectra of the chlorine-containing molecules studied here, three regions of the spectrum of chloroform are shown in Fig. 1. Note that the Cl 2s peak is apparently broader than C 1s peak, and that the C 1s and Cl 2s peaks induced by Al $K\alpha$ appear in the spectrum of valence-electron region.

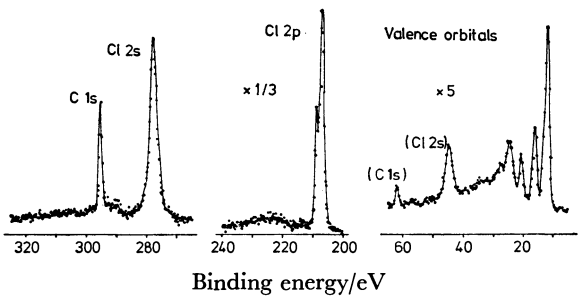

Fig. 1. Core and valence electron spectra of chloroform.

The C 1s spectra of chloromethanes and chloroethanes, observed with a higher resolution, are shown in Fig. 2. In the case of chloromethanes, the C 1s peak is markedly shifted to higher binding energy on increasing the number of chlorine atoms in a molecule, as it is expected from the high electronegativity of chlorine. In the case of chloroethanes, C 1s spectrum splits into two peaks of equal intensity, in which the one at higher binding energy (C 1s (a)) is attributable to the carbon atom of chlorine-substituted methyl group (hereafter, we denote this carbon atom as C(a)), and the one at lower binding energy (C 1s (b)) to the other carbon atom (we denote it as C(b)). C 1s (a) peak shows a marked shift

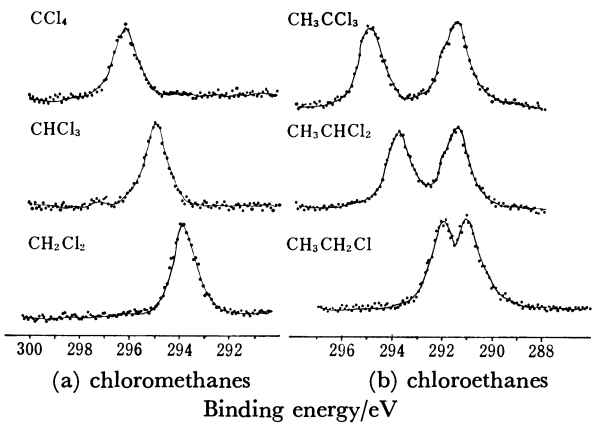

Fig. 2. C 1s spectra of (a) chloromethanes and (b) chloroethanes.

to higher binding energy on increasing the number of substituted chlorine atoms. The extent of this shift is almost the same as that found for the corresponding chloromethane.

As compared with the above change of C 1s binding energy, the changes of Cl2s and Cl2p binding energies are quite small, although these binding energies slightly increase with the number of chlorine atoms. The determined binding energies of core-electron levels are listed in Table 1.

TABLE 1. OBSERVED CORE ELECTRON BINDING ENERGIES OF CHLOROMETHANES AND CHLOROETHANES (eV)

	C 1s	Cl 2s	Cl $2p_{3/2}$
CH_3Cl	(292.4)*	(277.2)*	
CH_2Cl_2	294.0 (293.9)	277.6 (277.6)	206.7
$CHCl_3$	295.1 (295.1)	277.8 (277.7)	206.8
CCl_4	296.3 (296.3)	278.0 (278.0)	207.0
CH_3CH_2Cl	292.1, 291.1	276.8	206.0
CH_3CHCl_2	293.8, 291.5	277.2	206.4
CH_3CCl_3	295.0, 291.5	277.3	206.5

*) Figures in parentheses are from Thomas (Ref. 8).

Full width of half maximum (ΔE_{fwhm}) of C 1s peak was observed to be 1.2, 1.05, and 1.05 eV for dichloromethane, chloroform, and carbon tetrachloride, respectively. ΔE_{fwhm} of 1.05eV is likely to be the resolution limit under the present experimental condition, so that, among the above three cases, the C 1s peak of dichloromethane only can be concluded to be broader than the instrumental broadening. In the case of chloroethanes, ΔE_{fwhm} of C 1s (*a*) peak is almost constant at 1.1 eV, which is close to the resolution limit, but C 1s (*b*) peak is markedly asymmetric with ΔE_{fwhm} of about 1.3 eV, exhibiting a shoulder at about 0.4 eV from the main peak. The above asymmetry of C 1s (*b*) peak is very similar to that of the C 1s peak of methane reported by Gelius,[9] who explained the above asymmetry of the C 1s peak of methane as the effect of vibrational structure. It is also noteworthy that ΔE_{fwhm} of Cl 2s is as large as 2.6 eV. This can be attributed to the life-time broadening associated with the Coster-Kronig process.

It is of large value to know relative photoionization cross sections of core-electron levels, both from theoretical interest and from the interest to use XPS as a tool of quantitative analysis. However, as it has been pointed out by Siegbahn *et al.*,[10] relative intensities of photoelectron peaks could change, more or less, depending on the pressure of sample vapor, because of the effect of inelastic scattering. This pressure dependence of relative intensity is significant at higher sample pressure, but becomes almost negligible at sufficiently low pressure. We previousely observed the pressure dependence of the intensity ratio of the O 1s and C 1s peaks of methanol,[11] and found that the ratio was independent of sample pressure within the pressure region usually used in our experiments. By adopting such an experimental condition, we compared the integrated intensities of Cl 2s, Cl 2p, and C 1s peaks in the XPS spectra of chloromethanes and chloroethanes, and found that the relative intensities of these peaks can be quantitatively interpreted by assuming the ratios of apparent cross sections as follows;

$$\text{Cl 2s/C 1s} = 1.14$$
$$\text{Cl 2p/C 1s} = 2.02$$

The observed spectra of valence-electron region are shown in Figs. 3 and 4, where the observed data are shown by points, the solid lines being the calculated spectra which will be discussed later. The spectra of chloromethanes are very similar to each other. The same can be said also for the spectra of chloroethanes. We can roughly divide each spectrum into three parts; (1) The most intense peak at about 12 eV, which seems to be predominantly associated with Cl 3p lone pairs, (2) the peaks in the region of 15—22 eV, which are likely to be due to the orbitals associated with chemical bonds, and (3) the very broad bands with long tails in the region of 22—35 eV, where the peaks seem to be attributable to the molecular orbitals mainly associated with Cl 3s and C 2s atomic orbitals, possibly the long tails being due to shake-up or shake-off processes.

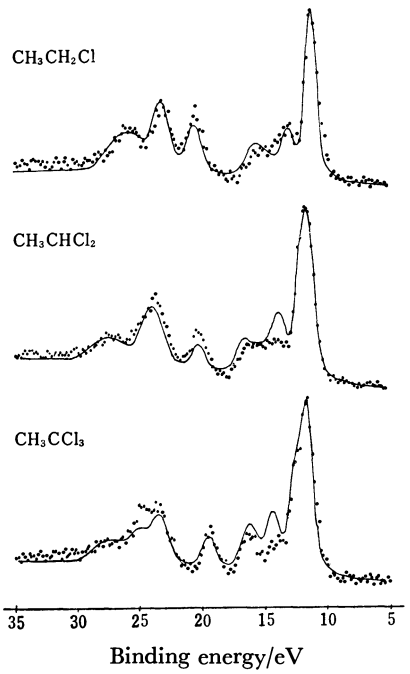

Fig. 4. Valence electron spectra of chloroethanes. Solid lines denote the calculated spectra.

Discussion

Binding Energies of Core-electron Levels. According to the electrostatic potential model, developed by Siegbahn and his co-workers,[10] core-electron binding energies can be correlated with charge distribution in molecule by the following relation;

$$E_i = E_0 + kq_i + \sum_{j \neq i}(q_j/R_{ij}) \qquad (1)$$

where E_i is the binding energy of a core-electron level of the atom i, q_j is the charge on the atom j, R_{ij} is the interatomic distance, and k is a constant characteristic of the kind of atom. In this equation, the second term gives the energy shift due to the charge on the atom i, and the third one is the contribution of the electrostatic potential due to surrounding atoms. This electrostatic potential model has been successfully used in conjunction with the charge density calculated by the CNDO/2 method.

Although the CNDO/2 method is widely used for a variety of organic molecules, the procedures of treating chlorine-containing molecules by the CNDO/2 method has not yet wholly established. There remains a problem concerned with the suitable extent of including vacant 3d atomic orbitals of chlorine in the CNDO/2 calculation of chlorine-containing molecules. In the present study, we carried out calculations by the two extreme methods; Method (a) is that proposed by Santry and Segal,[12] where the 3d orbitals of chlorine are included in the basis set, assuming their orbital exponents the same as those of the 3s and 3p atomic orbitals of chlorine, and Method (b) is the one which completely neglects the 3d orbitals of chlorine. The charge densities obtained by the above two methods are compared in Table 2. It should be noted that there is a significant difference between the charge distributions predicted by these two methods.

According to Eq. 1, we shall obtain a straight line when we plot $E_i - \sum_{i \neq j}(q_j/R_{ij})$ against q_i for a given kind of core-electron level, for example, for C 1s levels. The inclination of the line corresponds to the constant k and its intercept at $q_i=0$ gives the E_0 value. In Fig. 5, we have plotted $E_i(\text{obsd}) - \sum_{i \neq j}(q_j/R_{ij})$ against q_i, using the

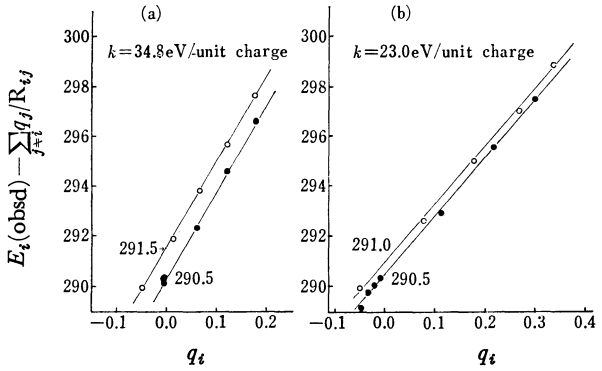

Fig. 5. Correlation between $E_i(\text{obsd}) - \sum_{j \neq i} q_i/R_{ij}$ and q_i.
(a) CNDO/2 including 3d orbitals.
(b) CNDO/2 excluding 3d orbitals.
Open and filled circles are for chloromethanes and chloroethanes, respectively.

observed binding energies of C 1s levels and calculated charge densities. The plots fall on a straight line for the charge densities obtained by Method (a) as well as for those by Method (b), but the inclination of line significantly differs between the two cases, giving the following k values, respectively;

Method (a); k(C 1s) = 34.8 eV/*unit charge*

Method (b); k(C 1s) = 23.0 eV/*unit charge*

In our previous paper, we obtained 22.67 eV/*unit charge* for k(C 1s) from the analysis of observed C 1s binding energies of benzene derivatives using CNDO/2 charge densities.[1] The k value of 23.0 eV/*unit charge* obtained here for the charge densities by the calculations with Method (b), is in good agreement with the above result, but the k value of 34.8 eV/*unit charge*, which was obtained for the charge densities calculated by Method (a), seems to be too large. The same conclusion has been derived recently by Clark *et al.*[13] from the study of XPS spectra of chlorobenzenes in solid phase. The equation of electrostatic potential model, (Eq. 1), can be reinterpreted quantum-mechanically for CNDO scheme.[14] According to this interpretation, the constant k corresponds to the Coulomb repulsion potential between a core electron and an electron in the valence shell, so that it can be theoretically calculated. When such a calculation is done for carbon atom by use of Slater AO's, we obtain 22.0 eV/*unit charge* for k(C 1s), which is close to the k value obtained here for the charge densities calculated by Method (b). However it should be noted that the point charge approximation, on which Siegbahn's electrostatic potential model has been derived, has a serious problem in the case of molecules which contain large atoms such as chlorine, because there can be a relatively large contribution of polarization in the electrostatic potential. At the same time, we have to consider that relaxation energy may appreciably increase by replacing hydrogen with chlorine.[15] Both of these effects are expected to reduce the apparent k value. In other words, the k value experimentally determined by the electrostatic potential model must be smaller than the theoretical value if the above effects are significant. When this situation is taken into account, the k value of 23.0 eV/*unit charge* seems to be already a little too large, and the k value of 34.8 eV/*unit charge* is apparently unreasonable. Therefore, we can conclude that Method (b), which neglects 3d orbitals of chlorine, gives better results than Method (a), at least for charge densities.

It should be noted in Fig. 5 that the plots for chloromethanes and those for chloroethanes are on separate lines with the same inclination. From the intercepts of these lines at $q_i=0$ in Fig. 5 (b), we obtain the following values for E_0 (Cls);

E_0(C 1s) = 291.0 eV for chloromethanes

E_0(C 1s) = 290.5 eV for chloroethanes

It is noteworthy that almost the same values are obtainable from Fig. 5 (a) which has used the charge densities calculated by Method (a).

We have previousely obtained 290.2 eV for E_0(C 1s) in the case of benzene derivatives.[1] As compared with this value, the E_0 value for chloromethanes is larger by 0.8 eV and that for chloromethanes is larger by 0.3 eV. Presumably, the above differences of E_0 values reflect the differences concerned with relaxation energy.

The binding energies of Cl 2s and Cl 2p levels slightly increase with the number of chlorine atoms. This change corresponds qualitatively to the decrease of the negative charges on chlorine atoms. However, the number of available data is so limited that it is not possible in these cases to quantify the correlation between binding energy and charge density.

Analysis of Valence-electron Spectra. The photoionization cross section of a molecular orbital is approximately given by the overlap integral between the molecular orbital and the photoelectron final-state wave function which can be expressed as a plane wave orthogonalized to the initial state. In the case of XPS, this overlap integral is almost entirely determined by the contributions from the parts very close to the nuclei, because of the short de Broglie wavelength of photoelectron. On the basis of this idea, Gelius[16] proposed that the molecular orbital cross section may be expressed as a sum over contributions from each atomic centers, as follows;

$$\sigma_j \propto (2+\beta/2)\sum_{A\lambda} P_{A\lambda}^{(j)}\sigma_{A\lambda} \qquad (2)$$

where $P_{A\lambda}^{(j)}$ denotes the probability of finding the electron in the j-th molecular orbital in an atomic orbital $A\lambda$, $\sigma_{A\lambda}$ is the cross section of the atomic orbital $A\lambda$, and β is the asymmetry parameter, $-1\leqq\beta\leqq 2$. In the case of chloromethanes and chloroethanes, one may use an average value of β instead of the true asymmetric parameters without significant influence on the calculated intensities. Thus, using relative atomic cross section $\sigma(A\lambda/\mathrm{C2s})=\sigma_{A\lambda}/\sigma_{\mathrm{C2S}}$, we can express the intensity of the peak associated with the photoionization of the j-th molecular orbital, as follows;

$$I_j \propto \sum_{A\lambda} P_{A\lambda}^{(j)}\sigma(A\lambda/\mathrm{C\,2s}) \qquad (3)$$

The simulation of valence-electron spectra, by use of the above intensity model, is useful for the analysis of valence-electron spectra.[16-20] In the present study, we carried out spectrum simulation adopting the following procedures:

(1) $P_{A\lambda}^{(j)}$ was calculated by CNDO/2 with neglect of 3d orbitals of chlorine (Method (b)). Incidentally, the CNDO/2 calculations including 3d orbitals of chlorine (Method (a)) gave the values of $P_{A\lambda}^{(j)}$ which are not significantly different from those obtained by Method (b).

(2) The shape of each photoelectron peak was assumed to be the one that is expressed by the modified Lorentzian function (Eq. 4).

$$f_j(\chi) = 0.5I_j\left\{\frac{1}{1+\left(\frac{2\chi}{w_j}\right)^2}+\frac{1}{1+\left(\frac{2\chi}{w_j}\right)^4}\right\} \qquad (4)$$

where χ is the energy measured from the center of the peak and w_j is the half-width. The value of w_j was fixed as 1.1 eV for peaks in the Cl 3p lone-pair region, and as 1.3 eV for those in the chemical-bonding region, but it was treated as an adjustable parameter for peaks in the Cl 3s region.

(3) The order of valence-electron levels was assumed the same as that predicted by the CNDO/2 calculation

a) Ref. 7.

with a few exceptions.[21] For the orbitals within reach of UPS, we used the binding energies reported by Pott *et al.*[4] for chloromethanes, and by Katsumata and Kimura[7] for chloroethanes. For the peaks at binding energies above 17 eV, we adjusted peak positions so as to give the best agreement between calculated and observed spectra.

In order to calculate the valence-electron spectra of chloromethanes and chloroethanes, we need to know three relative atomic cross sections, σ(C 2p/C 2s), σ(Cl 3s/C 2s) and σ(Cl 3p/C 2s), parametrized for CNDO/2 orbitals.[22] Banna *et al.*[20] has determined σ(C 2p/C 2s) from the analysis of the XPS spectrum of methane using CNDO/2 orbitals. Since the remaining two relative cross sections have not been known, we treat them as parameters, and found that the following values give the best over-all agreement between calculated and observed spectra for all chloromethanes and chloroethanes;[23]

$$\sigma(\text{Cl 3s/C 2s}) = 0.50$$

$$\sigma(\text{Cl 3p/C 2s}) = 0.50$$

The final results of spectrum simulation are shown by solid lines in Figs. 3 and 4 for chloromethanes and chloroethanes, respectively. The agreement with observed spectrum is very satisfactory in every case.

The binding energies and half-widths of photoelectron peaks finally employed in the above simulations are listed in Tables 3 and 4, together with the results of CNDO/2 calculations. It should be noted that the peaks at binding energies of 22—35 eV are very much broadened, having a width of 2.5—3.5 eV. These peaks are due to the molecular orbitals mainly associated with Cl 3s and C 2s atomic orbitals. Seemingly, the above phenomena are due to the life-time broadening, since a hole in these molecular orbitals is expected to decay rapidly by the Coster-Kronig process.

The photoelectron bands of chloromethanes at binding energies of about 20 eV were also studied by Potts *et al.* by means of UPS with He II resonance line.[4] The

binding energies reported by them are considerably different from our values, the discrepancies being as large as 1 eV. However, very recently, Katsumata and Kimura[24] carefully measured the UPS spectra of chloromethanes employing the He II line, and obtained the values which agree well with our XPS data.

Figure 6 shows the correlation diagram of valence electron levels of chloromethanes and chloroethanes. By examining the atomic populations, given in Tables 3 and 4, molecular orbitals can be roughly divided into three groups; (1) Cl 3p lone-pair orbitals (2) chemical-bonding orbitals, and (3) orbitals predominantly associated with Cl 3s and C2s. As it is naturally expected, Cl 3p lone-pair levels split wider on increasing the number of chlorine atoms in the case of chloromethanes as well as in the case of chloroethanes. The main features of this splitting are nearly the same between the two cases.

In Fig. 7, we have plotted the observed binding energies against the corresponding orbital energies obtained by CNDO/2 calculations. Most of the plots are on a straight line for each series of compounds, so that we can derive the following empirical relations between binding energy E_B and CNDO/2 orbital energy $\varepsilon_{CNDO/2}$; For chloromethanes,

$$E_B = 0.78(-\varepsilon_{CNDO/2}-2.9) \text{ eV},$$

and, for chloroethanes,

$$E_B = 0.72(-\varepsilon_{CNDO/2}-2.9) \text{ eV}.$$

Extended Hückel type (EHT) calculation is often used in the analysis of photoelectron spectrum. In Fig. 7(a), we have also plotted the observed binding energies against the orbital energies obtained with EHT calculation.[25] It should be noted that orbital energies by EHT calculations do not show such a simple correlation with observed binding energies as we have obtained for CNDO/2 orbital energies.

21) There are some ambiguities in the assignment of MO's in the Cl 3p region. Although several possible cases were tried in the course of spectra simulation, we could not find a clear difference in these simulated curves. Accordingly, we have adopted the same assignment as those proposed by Hopfgarten and Manne (Ref. 25) for chloromethanes.

As for 1,1,1-trichloroethane, it would be reasonable to assign the first ionization potential to 5*a*, instead of 5*e* from the consideration of UPS spectral intensity. This assignment is contradicted with the CNDO/2 result.

22) As the cross section of H ls is much smaller than those of C 2s, 2p, Cl 3s, 3p in the XPS region, the contribution of H ls was neglected in the spectral simulation. (See for example, V. I. Nefedov *et al.*, *J. Electron Spectrosc.*, **2**, 383 (1973).

23) Most recently Berndtsson *et al.* (*Physica Scripta*, **12**, 235 (1975)) has measured XPS valence electron spectra of chloroethylenes and performed the spectral simulation by using extended Hückel type MO's. They determined the experimental relative cross sections for Cl 3s and Cl 3p, as follows,

$$\sigma(\text{Cl } 3s/\text{C } 2s) = 0.69$$

$$\sigma(\text{Cl } 3p/\text{C } 2s) = 0.58$$

These values are slightly higher than ours.

Epoxide Rearrangement. VIII. The Acidic and Basic Properties of TiO_2-SiO_2-MgO and Its Catalytic Activities

Teruaki YAMADA, Kazushi ARATA,* Masayoshi ITOH, Hideshi HATTORI, and Kozo TANABE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
**Department of Chemistry, Hokkaido University of Education, Hachimancho, Hakodate 040*

(Received May 18, 1976)

Four kinds of TiO_2–SiO_2–MgO having different molar ratios, TiO_2–SiO_2–MgO (1: 1: 1, 10: 10: 1, 1: 10: 10, and 10: 1: 10), were prepared, their acidic and basic properties being examined by titration with butylamine and benzoic acid in benzene, respectively. The acidity of TiO_2–SiO_2–MgO was attributed to that of TiO_2–SiO_2 and SiO_2–MgO. The amount of strong acid sites of $H_0 \leqq -5.6$ decreased with the addition of MgO to TiO_2–SiO_2. The basicity of TiO_2–SiO_2–MgO was attributed to that of TiO_2–MgO and decreased with the increase in SiO_2 content. Catalytic activities for the isomerization of 1-butene and the decomposition of 4-hydroxy-4-methyl-2-pentanone are correlated with the acidity and basicity, respectively. For isomerization of 1-methylcyclohexene oxide and *d*-limonene oxide, TiO_2–SiO_2–MgO and TiO_2–SiO_2 showed high activities for the preferential formation of ketones except TiO_2–SiO_2–MgO (10: 1: 10) over which allyl alcohols were produced preferentially. The selectivities for the isomerization of two epoxides were interpreted in terms of the acidic and basic properties of the catalysts.

Binary metal oxides such as SiO_2–Al_2O_3,[2] TiO_2–Al_2O_3,[3] TiO_2–ZrO_2,[3] TiO_2–SiO_2,[4] SiO_2–MgO,[2,5] and TiO_2–MgO[6] have been investigated on acidic and basic properties and on their catalytic actions. Among the binary metal oxides, TiO_2–SiO_2 showed the highest acidic property; the acidity and acid strength of TiO_2–SiO_2 of a certain composition were found to be higher than those of SiO_2–Al_2O_3.[4] SiO_2–MgO is known to possess acid and base sites of moderate strength on the surface.[2,5] Recently, TiO_2–MgO has been found to show higher basicity than each component oxide. Thus, a mixed material of these three metal oxides, TiO_2–SiO_2–MgO, is expected to have both acid and base sites, the amount and strength of which may depend on the ratio of the three components.

No systematic investigation concerning both acidic and basic properties of multicomponent metal oxides except binary metal oxides has been performed, though many multicomponent metal oxides are often used as solid catalysts for many reactions. We have attempted to examine acidic and basic properties of TiO_2–SiO_2–MgO having different molar ratios and their relations to the catalytic actions for the isomerization of 1-butene, the decomposition of 4-hydroxy-4-methyl-2-pentanone and the isomerization of 1-methylcyclohexene oxide and *d*-limonene oxide.

Experimental

Catalyst Preparation. TiO_2–SiO_2–MgO with various compositions were prepared by kneading TiO_2–SiO_2 having different molar ratios of Ti to Si and magnesium hydroxide with a proper amount of water for 2 h, followed by drying at 120 °C for a day. TiO_2–SiO_2 was prepared by co-precipitation from a mixed solution of ethyl orthosilicate and titanium tetrachloride with aqueous ammonia.[4] The precipitate was aged over a water bath for 1 h, washed with distilled water until no chloride ion was detected and dried at 100 °C for a day. Magnesium hydroxide was prepared by the hydrolysis of magnesium chloride, followed by washing and drying as above.

All the catalysts were calcined in air at 500 °C for 3 h prior to reactions or measurements of surface properties.

Surface Area and X-Ray Analysis. A specific surface area was determined by applying the BET equation to the adsorption isotherm of nitrogen at −196 °C. X-Ray powder diffraction diagrams were recorded over the range of $2\theta = 20$—70° with an X-ray diffractometer (Toshiba ADG-301) by using nickel filtered Cu $K\alpha$ radiation.

Measurement of Acidic and Basic Properties. Acidity and basicity of catalysts at various strengths were measured by titrating with butylamine and benzoic acid in benzene, respectively, indicators of different pK_a's and pK_{BH} being used.[7,8]

Reaction Procedure. Isomerization reaction of 1-butene was carried out in a closed circulation system having a volume of about 900 ml at 200 °C.[4] 50 mg of a catalyst was placed in a reactor and evacuated at 200 °C for 2 h. The reactant (200Torr) was introduced and the products were analyzed periodically by gas chromatography. The analysis was carried out at 0 °C on a 4 m column containing 30 wt % propylene carbonate on Uniport C.

Decomposition of 4-hydroxy-4-methyl-2-pentanone to acetone was carried out at 30 °C for 10 min.[9] A mixture of 25 ml of 4-hydroxyl-4-methyl-2-pentanone and 0.5 g of a catalyst was stirred in a reaction vessel with a magnetic stirrer. For the analysis of products, a column packed with 10 wt% polyethylene glycol on chromsorb W and thermostated at 0 °C was used.

Isomerization of 1-methylcyclohexene oxide was carried out in the presence of toluene as a solvent at 108 °C for 2 h.[10] A mixture of 0.5 ml of the epoxide, 2.5 ml of toluene and about 0.3 g of a catalyst was stirred in a reaction vessel. The products were analyzed by gas chromatography, a 3 m column of polyethylene glycol 20M on Celite 545SK being used at 150 °C. For separation of two allyl alcohols, a 45 m capillary column of Ucon LB-500-X was used at 100 °C.

The procedure of reaction and analysis of products for the isomerization of *d*-limonene oxide[11] were similar to those for the isomerization of 1-methylcyclohexene oxide, except that a mixture of 1 ml of the epoxide and 5 ml of toluene was used.

Results and Discussion

Surface Area and X-Ray Analysis. Specific surface areas of catalysts are listed in Table 1. The values of

* Part VII; see Ref. 1

Table 1. Specific surface areas of catalysts

mixed oxides were larger than those of single component oxide except SiO_2.

According to X-ray diffraction pattern, TiO_2–SiO_2–MgO (1:1:1 and 10:10:1) were amorphous and TiO_2–SiO_2–MgO (1:10:10 and 10:1:10) showed only weak diffraction lines of TiO_2 (anatase) and MgO. Since no diffraction lines of the hydroxides were detected, calcination in air at 500 °C is considered to cause the dehydration to form TiO_2–SiO_2–MgO.

Acidic and Basic Properties. Acidity at various acid strengths of TiO_2–SiO_2–MgO calcined at 500 °C is given in Table 2, together with that of TiO_2–SiO_2 and TiO_2–MgO. The acidity at $H_0 \leqq -5.6$ and -8.2 of TiO_2–SiO_2 (10:1 and 1:1) could not be determined by the titration method, since the color of the acidic forms of indicators of $pK_a \leqq -5.6$ and -8.2 is yellow and that of the above mentioned TiO_2–SiO_2 is of the same tone. However, it was confirmed that TiO_2–SiO_2 (10:1 and 1:1) has high acidity at $H_0 = -5.6$ and -8.2 from experimental results which showed that larger amounts of basic molecules (ammonia, butylamine, and pyridine) remain after evacuation at high temperatures on TiO_2–SiO_2 than SiO_2–Al_2O_3 which shows high acidity at $H_0 \leqq -5.6$ and -8.2.[4]

The distribution of acidity on TiO_2–SiO_2 (1:1) and TiO_2–SiO_2–MgO (10:10:1 and 1:1:1) indicates that the acidity at lower acid strength of $-3.0 < H_0 \leqq +3.3$ increases with an increase in the Mg content. This is considered to be due to the acidity of SiO_2–MgO resulting from the mixing of MgO with TiO_2–SiO_2 (1:1). On the other hand, the acidity at $-3.0 < H_0 \leqq +3.3$ of TiO_2–SiO_2 (10:1) decreases with the addition of MgO. This may be attributed to the fact that TiO_2–MgO which has no acidity occupies the main part in TiO_2–SiO_2–MgO (10:1:10). Similarly, the acidity of TiO_2–SiO_2–MgO (1:10:10) might be explained in terms of the acidic characters of SiO_2–MgO and TiO_2–SiO_2. The acidity at higher acid strengths of $H_0 \leqq -5.6$ and -8.2 of TiO_2–SiO_2 (1:1 and 10:1) decreases with the addition of MgO. In all TiO_2–SiO_2–MgO systems, only TiO_2–SiO_2–MgO (10:1:10) showed no acidity at $H_0 \leqq -3.0$.

Table 3. Basicity and catalytic activity for decomposition of 4-hydroxy-4-methyl-2-pentanone (diacetone alcohol) at 30 °C

Catalysts	Mole ratio	Basicity[a] (μmol m^{-2})	Activity[b] ($\times 10^2$%m^{-2} min^{-1})

	(10:10:1)	0	0
	(10:1:10)	1.6	1.0
	(1:10:10)	2.0	1.8

a) 2,4-Dinitroaniline ($pK_{BH} = 15.0$) was used as an indicator. b) Mole percentage of the product at 10 min of a reaction time per unit surface area of catalyst (m^{-2}) per unit time (min^{-1}). c) Cited from Ref. 6.

The basicity of TiO_2–SiO_2–MgO and TiO_2–MgO calcined at 500 °C is given in Table 3. The high basicity of TiO_2–MgO (1:2 and 1:18) greatly decreased with the addition of SiO_2, TiO_2–SiO_2–MgO (10:10:1) showing no basicity.

Isomerization of 1-Butene. The activity and selectivity (the ratio of *cis*- to *trans*-2-butene) of TiO_2–SiO_2–MgO, TiO_2–SiO_2, and MgO for the isomerization of 1-butene are given in Table 4. The active sites of TiO_2–SiO_2 for the reaction were ascribed to acid sites. In the reaction, the *cis*-/*trans*- ratios were 1—2 and the reaction proceeds *via* a butyl cation.[4] The ratio over TiO_2 was reported to be 4.2, suggesting a base-catalyzed isomerization *via* a π-allyl carbanion intermediate.[4] The ratios over TiO_2–SiO_2–MgO (1.7—2.1) indicate that the same acid-catalyzed isomerization as over TiO_2–SiO_2 takes place, the activity being correlated with acidity (see Table 2) and not basicity.

TABLE 4. CATALYTIC ACTIVITY AND SELECTIVITY (RATIO OF *cis*- TO *trans*-2-BUTENE) FOR ISOMERIZATION OF 1-BUTENE AT 200 °C

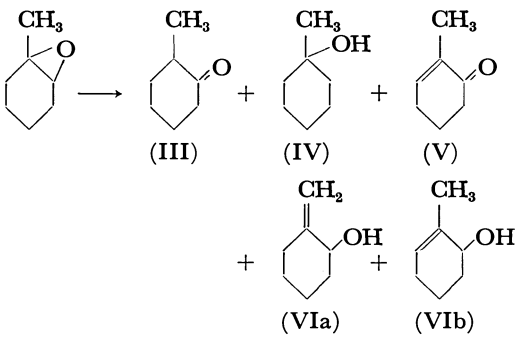
	(1: 10: 10)	1.1	1.7

a) Initial conversion per unit surface area of catalyst (m^{-2}) per unit time (min^{-1}).
b) Obtained by extrapolation to zero conversion.

Decomposition of 4-Hydroxy-4-methyl-2-pentanone. Catalytic activity as well as basicity of the catalysts are given in Table 3. A good correlation was observed between activity and basicity. Although TiO_2–SiO_2–MgO had acidic sites, the activity was small as compared with that of TiO_2–MgO which has no acidic sites. Thus, it is suggested that only basic sites are considered to be operative, and that the reaction proceeds as in the case of other solid base catalysts.[9]

Isomerization of 1-Methylcyclohexene Oxide. The reaction of 1-methylcyclohexene oxide over TiO_2–SiO_2–MgO, TiO_2–SiO_2, TiO_2, SiO_2, and MgO gave five main products: 2-methyl-cyclohexanone (III), 1-methylcyclohexanol (IV), 2-methyl-2-cyclohexene-1-one (V), 2-methylenecyclohexanol (VIa), and 2-methyl-2-cyclohexene-1-ol (VIb), with a small amount of 1-methylcyclohexene (I) and unidentified compound (II).



The activity and selectivity of catalysts in 2 h at 108 °C are shown in Table 5. The activity of three TiO_2–SiO_2 was higher than that of single component oxides. This fact is interpreted by taking into consideration the higher acidity of the former. It is of interest that TiO_2 formed the allyl alcohol (VI), but TiO_2–SiO_2 formed the ketone (III). Since formation of the ketone and the allyl alcohol is explained by isomerization over strong acid sites and acid-base bifunctional sites, respectively,[10] it is considered that comparatively weak acid sites and base sites exist on TiO_2 and strong acid sites exist on TiO_2–SiO_2.

Over TiO_2–SiO_2–MgO (1: 1: 1, 10: 10: 1, and 1: 10: 10), a high activity for the preferential formation of the ketone was observed. Although some basic sites were observed on TiO_2–SiO_2–MgO (1: 1: 1 and 1: 10: 10), they do not seem to be active. Only strong acid sites of $H_0 \leqq -3.0$ seem to be active. On the other hand, TiO_2–SiO_2–MgO (10: 1: 10) showed high activity and selectivity for the formation of the allyl alcohol. This suggests that TiO_2–SiO_2–MgO (10: 1: 10) has both base and acid sites at the proper acid strength to act as acid-base bifunctional sites; TiO_2–SiO_2–MgO (10: 1: 10) showed no acidity at higher acid strength of $H_0 \leqq -3.0$ (see Table 2).

Isomerization of d-*Limonene Oxide.* Isomerization of *d*-limonene oxide over the present catalysts gave the following products: cymene (II), 1-methyl-3-isopro-

TiO_2[b]		0.32	25	0	0	0	0	0	6	58	25
MgO[b,d]		0.24	1								
TiO_2–SiO_2	(1: 1)[c]	0.26	100	7	2	18	3	4	48	0	0
	(9: 1)[c]	0.35	98	3	1	17	1	3	30	21	19
	(1: 9)[c]	0.28	98	2	1	15	2	5	41	8	14
TiO_2–SiO_2–MgO	(1: 1: 1)[c]	0.18	98	4	1	19	1	4	44	11	11
	(10: 10: 1)[c]	0.28	100	6	2	22	1	4	47	9	2
	(10: 1: 10)[b]	0.17	31	0	0	0	0	4	22	30	41
	(1: 10: 10)[b]	0.21	90	5	0	30	2	4	43	6	9
	(1: 10: 10)[c]	0.21	51	0	0	21	4	5	48	7	12

a) See text. b) Reaction time: 75 min. c) Reaction time: 10 min. d) Cited from Ref. 11.

penyl-1-cyclopentanecarbaldehyde (III), 1-methyl-3-isopropylidene-1-cyclopentanecarbaldehyde (IV), carvone (V), dihydrocarvone (VI), *exo*-carveol (VII), *endo*-carveol (VIII), and an unidentified compound (I).

The activity and selectivity of TiO_2–SiO_2–MgO, TiO_2–SiO_2, TiO_2, SiO_2, and MgO in 10 or 75 min at 108 °C are listed in Table 6. TiO_2–SiO_2–MgO (1: 1: 1, 10: 10: 1, and 1: 10: 10) and all TiO_2–SiO_2 showed surprisingly high activity for the ketone (VI) formation, as in the case of SiO_2–Al_2O_3 and $LiClO_4$.[11] TiO_2–SiO_2–MgO (10: 1: 10) was less active than any other mixed oxide, the allyl alcohols (VII and VIII) being preferentially produced. The selectivity for the reaction is similar to that for the isomerization of 1-methylcyclohexene oxide in the sense that the ketone was produced over acidic sites and the allyl alcohols over bifunctional sites. The selectivity in the isomerization of *d*-limonene oxide can be explained by the acidic and basic properties of the catalysts, as in the case of 1-methylcyclohexene oxide.

The products of II and IV were obtained in small amounts on the present catalysts, though large amounts were formed over SiO_2–Al_2O_3[11] which have strong acid sites of the Brönsted type. Thus, TiO_2–SiO_2–MgO and TiO_2–SiO_2 are considered to have no strong Brönsted acid sites.

Deactivation of Triplet 2-Naphthol and 1-Anthrol by Aromatic *N*-Heterocycles

Sada-aki YAMAMOTO, Koichi KIKUCHI, and Hiroshi KOKUBUN

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received May 20, 1976)

A flash-photolytic investigation was carried out on the hydrogen bonding interaction of triplet 2-naphthol and 1-anthrol with aromatic *N*-heterocycles such as 4-methylpyridine, quinoline, and benzo[*h*]quinoline. The deactivation of triplet 2-naphthol and 1-anthrol by aromatic *N*-heterocycles was found to be due to the hydrogen atom transfer reaction. The relationship between the reactivity and the reduction potential of aromatic *N*-heterocycles suggests that the electron transfer from the triplet to the quencher is the primary process of the hydrogen atom transfer reaction.

Previously, we studied the hydrogen bonding interaction of the π-electronic system such as 2-naphthol–pyridine, 1-anthrol–pyridine, and 1-anthrol–quinoline in the ground, the triplet and the excited singlet states.[1] On the basis of the results obtained, it was concluded that the hydrogen atom transfer reaction plays an important role in the dynamic deactivation through the hydrogen bonding interaction in the excited states and that the efficiency of the hydrogen atom transfer reaction in the excited state is affected by the acidity of the proton donor. In addition, the investigation of the triplet-triplet energy transfer from a suitable sensitizer to the hydrogen bonded species revealed that the triplet state of the hydrogen bonded species (^{3}DH–A) and the non-relaxed encounter complex (^{1}DH*···A) in the excited singlet state are the reaction state.[2]

$$^1\mathrm{DH}^* + \mathrm{A} \rightleftharpoons {}^1\mathrm{DH}^* \cdots \mathrm{A} \longrightarrow \dot{\mathrm{D}} + \dot{\mathrm{HA}}$$

$$^3\mathrm{DH} + \mathrm{A} \rightleftharpoons {}^3\mathrm{DH\text{–}A} \longrightarrow \dot{\mathrm{D}} + \dot{\mathrm{HA}}$$

However, the difference in the reactivity between the excited singlet state and the triplet state is still not fully elucidated.

To clarify the reaction mechanism, it is of prime importance to find out the factors which govern the reactivity. In the present paper, we have investigated the effect of the reduction potential of the quenchers on the reactivity by a conventional flash apparatus.

Experimental

Materials. 2-Naphthol (G. R. grade, Tokyo Kasei) was recrystallized twice from the water–ethanol mixture, and sublimed twice *in vacuo*. 1-Anthrol used was the same as described before.[1] Benzo[*h*]quinoline (G. R. grade, Tokyo Kasei) was recrystallized three times from the water–ethanol mixture, treated by thin-layer chromatography and sublimed *in vacuo*. 4-Methylpyridine (G. R. grade, Tokyo Kasei) was dried over barium oxide, distilled under reduced pressure and stored *in vacuo*. Quinoline (G. R. grade Tokyo Kasei) was distilled under reduced pressure and stored *in vacuo*. Cyclohexane was purified by the standard method.

Apparatus and Procedure. Absorption spectra were measured with a Hitachi EPS-3T spectrophotometer. The input energy of flash lamps was 65—130 J and its FWHM was about 10 μs. The combination of a Toshiba V-V40 and two plastic filters (cut off $\approx$380 nm) for the excitation of 1-anthrol and the combination of a Toshiba UV-D25 and a photographic plate glass for the excitation of 2-naphthol were used. Cyclohexane solutions were degassed by freeze-pump-thaw cycles. All measurements were made at about 25 °C.

Results and Discussion

A flashing of the deaerated cyclohexane solution of 2-naphthol gives the triplet-triplet absorption.[3] Both the decay rate of the triplet 2-naphthol and the yield of the 2-naphthoxyl radical ($\dot{\mathrm{D}}$) increase with increasing quinoline concentration [Qu] up to 10^{-4} M, where neither the formation of hydrogen bond in the ground state nor the interaction of the excited singlet 2-naphthol with quinoline occurs. Since the triplet level of quinoline (21800 cm^{-1})[4] is higher than that of 2-naphthol (21100 cm^{-1}), the deactivation of the triplet 2-naphthol is not due to the energy transfer but the hydrogen atom transfer reaction. The observed first order decay rate constant k_{obsd} is linear with respect to [Qu].

$$k_{\mathrm{obsd}} = k_{\mathrm{dt}} + k_{\mathrm{qt}}[\mathrm{Qu}] \qquad (1)$$

From the slope, the quenching rate constant k_{qt} was obtained as 3.3×10^9 M^{-1} s^{-1}. The reaction scheme is described as follows.

$$\mathrm{DH} \xrightarrow{I_{\mathrm{ab}}} \mathrm{DH}^* \xrightarrow{\phi_{\mathrm{st}}} {}^3\mathrm{DH} \underset{k_{-1}^{\mathrm{t}}}{\overset{k_1^{\mathrm{t}}[\mathrm{A}]}{\rightleftharpoons}} {}^3\mathrm{DH\text{–}A} \xrightarrow{k_{\mathrm{r}}^{\mathrm{t}}} \dot{\mathrm{D}} + \dot{\mathrm{HA}}$$

$$^3\mathrm{DH} \xrightarrow{k_{\mathrm{dt}}} \mathrm{DH} \qquad {}^3\mathrm{DH\text{–}A} \xrightarrow{k_{\mathrm{dt}}^{\mathrm{t}}} \mathrm{DH\text{–}A}$$

Reaction scheme 1.

where DH and A stand for the proton donor and acceptor, respectively.

The absorbance of the 2-naphthoxyl radical measured at the end of a flash, $D_{\mathrm{R}}{}^0(\lambda)$, is given by

$$\frac{1}{D_{\mathrm{R}}{}^0(\lambda)} = \frac{1}{\varepsilon_{\mathrm{R}}(\lambda)\mathrm{d}\phi_{\mathrm{ST}}I_{\mathrm{ab}}^0\phi_{\mathrm{R}}}\left(1+\frac{k_{\mathrm{dt}}}{k_{\mathrm{qt}}[\mathrm{Qu}]}\right) \qquad (2)$$

where $\phi_{\mathrm{R}}=k_{\mathrm{r}}{}^{\mathrm{t}}/(k_{\mathrm{r}}{}^{\mathrm{t}}+k_{\mathrm{dt}}{}^{\mathrm{t}})$ and $k_{\mathrm{qt}}=(k_{\mathrm{r}}{}^{\mathrm{t}}+k_{\mathrm{dt}}{}^{\mathrm{t}})\cdot k_1{}^{\mathrm{t}}/(k_{\mathrm{dt}}{}^{\mathrm{t}}+k_{\mathrm{r}}{}^{\mathrm{t}}+k_{-1}{}^{\mathrm{t}})$. The plot of $1/D_{\mathrm{R}}{}^{\mathrm{o}}$ (470 nm) *vs.* 1/[Qu] is linear, from which the ratio $k_{\mathrm{qt}}/k_{\mathrm{dt}}$ was found to be 2.0×10^5 M^{-1}. Since $k_{\mathrm{dt}}=1.5\times10^4$ s^{-1} is known,[3] k_{qt} was determined to be 3.0×10^9 M^{-1} s^{-1}, which agrees well with $k_{\mathrm{qt}}=3.3\times10^9$ M^{-1} s^{-1} obtained from the effect of quinoline concentration on the triplet decay. The reaction of the triplet 2-naphthol with quinoline yielding the 2-naphthoxyl radical occurs at one forth of the diffusion controlled rate; 1.1×10^{10} M^{-1} s^{-1} in cyclohexane.[5]

The triplet 2-naphthol also reacts with 4-methylpyri-

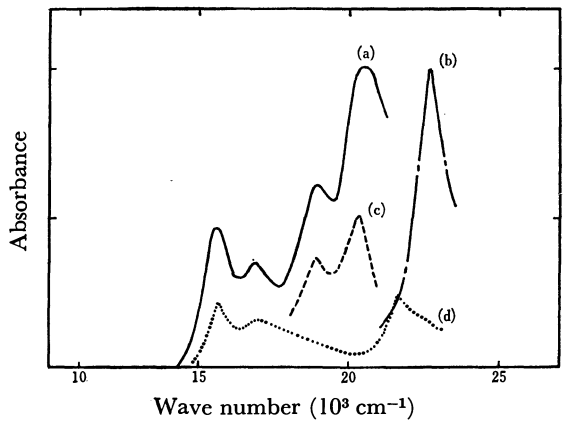

Fig. 1. Transient absorption spectra of 1-anthrol in cyclohexane. (a) [1-anthrol] = 1.0×10^{-4} M, [benzo[*h*]quinoline] = 1.0×10^{-3} M. (b) T-T absorption spectrum of 1-anthrol. (c) The spectrum of 1-anthroxyl radical. (d) The spectrum of benzo[*h*]quinoline radical.

Table 1. Quenohing rate constants of triplet 1-anthrol and 2-naphthol

Quencher	pK_a	k_{qt}/M^{-1} s^{-1}	Reduction potential in DMF[c]/V
		1-Anthrol	
Pyridine	5.23[a]	—	−2.76
Benzo[*h*] quinoline	4.25[a]	1.6×10^7	−2.23
Quinoline	4.94[a]	$(1.1—1.4)\times10^9$ [1]	−2.175
Acridine	5.5[a]	3.4×10^9 [1]	−1.62
		2-Naphthol	
4-Methylpyridine	6.02[b]	4.0×10^8	−2.86
Pyridine	5.23[a]	$(1.5—1.9)\times10^9$ [3]	−2.76
Quinoline	4.94[a]	$(3.0—3.3)\times10^9$	−2.175

a) A. Albert, R. Goldacre, and J. Phillips, *J. Chem. Soc.*, **1948**, 2240. b) H.C. Brown and X. Mihm, *J. Am. Chem. Soc.*, **77**, 1723 (1955). c) B. J. Tabner and J. R. Yandle, *J. Chem. Soc., A*, **1968**, 381.

dine to produce the 2-naphthoxyl radical. The value of k_{qt} was determined as 4.0×10^8 M^{-1} s^{-1} from both the 4-methylpyridine concentration effect on the triplet decay and the yield of the 2-naphthoxyl radical. This value is smaller than that for the 2-naphthol-quinoline pair by about one order of magnitude.

The investigation was extended to the triplet 1-anthrol and benzo[*h*]quinoline (BQ) pair. With the addition of BQ, the decay rate of the triplet 1-anthrol increases and the transient absorption spectrum shown in Fig. 1(a) appears. This spectrum seems to be the superposition of the spectrum of the 1-anthroxyl radical[1] and that of the BQ radical[6] (Fig. 1(c), (d)). The observed first order decay rate constant of the triplet 1-anthrol is linear with respect to BQ concentration (*cf.* Eq. 1) and the quenching rate constant was found to be 1.6×10^7 M^{-1} s^{-1}. It is obvious that the hydrogen atom transfer reaction occurs between the triplet 1-anthrol and BQ. However the rate constant is smaller by about three orders of magnitude than the diffusion controlled rate constant.

In Table 1 are collected the quenching rate constants for the triplet 1-anthrol and the triplet 2-naphthol, together with reduction potentials and acid dissociation constants of the proton acceptors.

In a previous paper, the difference in the reactivity of 1-anthrol and 2-naphthol in the excited singlet state was explained by the difference of their acidities;[1] the hydrogen atom transfer is suppressed in the systems where the proton transfer is considered to occur easier. In the triplet state, however, the reaction rate constant has no correlation with the acidity of the proton acceptor. But reduction potential is associated with the quenching rate constant, which increases with the lowering of reduction potential. The reaction rate seems to be dependent on the easiness of the electron transfer in the encounter complex.

Therefore it seems plausible that the hydrogen atom transfer reaction occurs initially by the electron transfer followed by the proton transfer.

$$^3DH\cdots A \longrightarrow {}^3\overset{+}{D}H\cdots \bar{A} \longrightarrow \dot{D} + H\dot{A}$$

The Effect of Pressure on the Dissociation of Weak Acids in Aqueous Buffers

Motoyuki TSUDA, Ichimin SHIROTANI,* Shigeru MINOMURA,* and Yoshio TERAYAMA

Department of Physics, Sapporo Medical College, Sapporo 060

**Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo 106*

(Received May 24, 1976)

The effect of pressure on the dissociation of boric acid, imidazole HCl, and $H_2PO_4^-$ in aqueous buffers has been investigated up to 6 kbars, using as optical indicators *p*-nitrophenol and Cresol Red. The limiting volume change on ionization at atmospheric pressure ($\Delta\bar{V}°$) and the compressibility change ($\Delta\bar{\kappa}°$) for these weak acids were obtained. The values of $\Delta\bar{V}°$ ($cm^3\ mol^{-1}$) and $\Delta\bar{\kappa}°$ ($cm^3\ mol^{-1}\ kbar^{-1}$) are -10.1 and -0.4 for Cresol Red, -30.2 and -4.3 for boric acid, and -2.4 and -0.6 for imidazole H^+.

A large number of measurements have been made of the dissociation constants of weak electrolytes under pressure using the method of the concentration cell e.m.f., and density and conductivity measurements.[1,2] They have shown that the dissociation of a weak acid HA in water, to form H^+ and A^- ions, is increased by pressure. Pressure lowers the free energy of solvation of the ions, because it is accompanied by a contraction, or electrostriction, of the surrounding solvent; water is much more densely packed around the ions than around the corresponding undissociated molecules. One important consequence of this is that the pH of aqueous buffer solutions varies with the pressure.[3] Biochemical systems are best studied under buffered conditions, and the conformation of biomolecules is sensitive to the pH. For the study of the pressure dependence of conformational change in biomolecules,[4-8] a detailed knowledge of pressure-induced changes in the buffer pH is required. The results obtained in this study have been extensively used in an investigation of pressure effects on the spectral changes in heme proteins and invertebrate rhodopsin.[9]

Gibson and Loeffer[10] attempted to measure the effects of pressure on the pH by the use of an optical indicator; however, no quantitative results were reported. Recently Newman *et al.*[3] extensively studied the pressure effects of weak acid ionization in aqueous buffers using as optical pH indicators 2,5-dinitrophenol and *p*-nitrophenol; they gave the values of the limiting volume change ($\Delta\bar{V}°$) and the compressibility change ($\Delta\bar{\kappa}°$) upon ionization for acetate, cacodylate, phosphate, and tris buffer. Here we wish to report on the effect of pressure on the acid dissociation of dihydrogen phosphate ($H_2PO_4^-$), boric acid, and imidazole HCl, using as optical pH indicators *p*-nitrophenol and Cresol Red up to 6 kbars. No data have been available for Cresol Red and imidazole HCl. However, the values of $\Delta\bar{V}°$ at atmospheric pressure for the ionization of boric acid have been reported on the basis of limited pressure studies utilizing a glass electrode;[11] they will serve as reference data for the optical experiments reported here.

Experimental

The *p*-nitrophenol was recrystallized from ethanol–water and given long needles were filtered and dried *in vacuo*. The Cresol Red was titrated with 0.1 M NaOH to pH 11 and filtered. The filtrate was then neutralized with 0.1 M HCl. The suspension was filtered, and the residue was washed with water. This procedure was repeated. The residue was then dried at 60 °C overnight. The imidazole, recrystallized from ethanol, was neutralized with hydrochloric acid. The other reagents, sodium borate, boric acid, sodium phosphate, and potassium dihydrogenphosphate, were reagent-grade chemicals, and were used without further purification. A stock solution of *p*-nitrophenol (0.01 M) was prepared by weighing it and by dissolving it in distilled deionized water. Solutions of this indicator in the various buffers were prepared just prior to use by diluting 1.2 ml of the stock to 10 ml with the appropriate buffer. A stock solution of Cresol Red (0.001 M) was prepared in water containing an equivalent amount of sodium hydroxide. Solutions of this indicator in various buffers were prepared just prior to use in the way described above.

The highpressure optical bomb is shown in Fig. 1(a). This bomb was constructed from hardened-steel and had three sapphire windows and a electrode for thermocouples. A

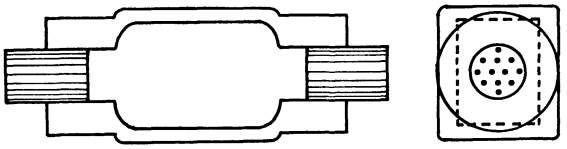

Fig. 1(b). The micro optical cell of quartz with Teflon piston.

hydrostatic pressure up to 6 kbars was applied by means of the pressuring fluid (silicone oil) through a pressure intensifier.

The pressure was determined by a Harwood manganine resistance gauge and a Heise Bourdon tube gauge. The indicator solutions were contained in an internal micro optical cell of quartz (0.3 cm path length and 1.0 cm overall length of the cell). The travelling Teflon piston in the separator served as a physical barrier to the mixing of the indicator solution with the pressuring fluid. The micro optical cell is exhibited in Fig. 1(b).

A thermostatting jacket was constructed for the high-pressure vessel. This was made of brass and was machined to fit snugly along the entire length of the highpressure vessel. The vessel, with its thermostatting jacket, was securely fastened into a metal supporting frame which was itself positioned directly into the sample compartment of a Shimadzu SV-50 spectrophotometer. The frame was designed so that the optical aperture of the cell automatically coincided with the light beam when the frame was in place.

The method of operating was to equilibrate the sample at a low pressure. After the data were obtained, the pressure was raised slightly and the system was allowed to reequilibrate. After the highest pressure had been attained, the system was returned to the initial low pressure to check for reversibility. The pH values of the buffers and the other solutions studied were measured using a Radiometer pH meter and Radiometer electrodes.

The absorbance of any solution in the optical cell of a fixed length will increase with an increase in the pressure due to compression. Before two-state equilibrium constants can be determined, the experimentally determined absorbances must be corrected for this effect. This correction** can be achieved by multiplying the experimental values by $OD_{I.P.}$ (1 atm)/ $OD_{I.P.}$ (P) for the isosbestic point of the absorption spectra of the indicator holds in its acid-base equilibrium. $OD_{I.P.}$-(P) implies the absorbance values at the wavelength at the isosbestic point under the pressure, P.

Methods

The molar equilibrium constant (K_a) for the ionization of weak acids is pressure- or volume-dependent. When the buffer concentration is sufficiently high, as it is these studies (0.05—0.10 M), pressure-induced changes in the pH of buffer solutions do not significantly alter the concentration ratio of the acid, HA, and its conjugate base A^-.

$$\frac{\partial \mathrm{pH}}{\partial P} = \frac{\partial \mathrm{p}K_a}{\partial P} + \frac{\partial}{\partial P}(\log([A^-]/[HA]) \simeq \frac{\partial \mathrm{p}K_a}{\partial P} \quad (1)$$

The pHs of solutions can be determined by an examination of the absorption spectra of pH indicators, using the following equation:

$$\mathrm{pH} = \mathrm{p}K_I - \log\left(\frac{\Delta OD}{OD}\right), \Delta OD = OD_I - OD \quad (2)$$

where pK_I is the dissociation constant of the acid form of the indicator, OD_I is the optical density at λ_{max} corresponding to the complete conversion of the indicator to its conjugate base, and OD is the observed optical density at the same wavelength due to the conjugate base of the indicator acid. The relation of the pressure dependence of pK_a and pK_I can thus be determined using Eq. 3, which arises from a combination of Eqs. 1 and 2.

$$\frac{\partial(\mathrm{p}K_a)}{\partial P} = \frac{\partial(\mathrm{p}K_I)}{\partial P} - \frac{\partial \log(\Delta OD/OD)}{\partial P} \quad (3)$$

The effect of the pressure on pK_I can be determined if the pressure dependence of pK_a is known. Equation 1 shows that the pressure-induced changes in pK_a can be attributed directly to changes in the pH. Thus, changes in the pH of the buffer with the pressure can be determined from the pressure dependence of the OD of the indicator.

The pressure dependencies of pK_a for boric acid and imidazole HCl were determined using as optical indicators p-nitrophenol (pK_I=7.05) and Cresol Red (pK_I= 8.3). The pressure dependence of pK_I for p-nitrophenol was determined but that of pK_I for Cresol Red is not known. Accordingly the pressure dependence for Cresol Red was calculated from data available for $H_2PO_4^-$.[3)]

The limiting volume change for the weak acid at atmospheric pressure ($\Delta\bar{V}°$) and the compressibility change ($\Delta\bar{\kappa}°$) during ionization may be readily obtained by means of thermodynamics. The change in the partial molar volume can be determined from the pressure derivative of the free energy, *i.e.*:

$$\left(\frac{\Delta\partial F°}{\partial P}\right) = -\left(\frac{\partial RT\ln K}{\partial P}\right)_T = \bar{V}°(H^+ + A^-) - \bar{V}°(HA) = \Delta\bar{V}° \quad (4)$$

where $\bar{V}°$ (HA) and $\bar{V}°$ ($H^+ + A^-$) are the partial molar volumes of acid and ionized forms of the weak acid. On the other hand, V varies with the pressure, the derivative

$$\left(\frac{\partial \Delta V°}{\partial P}\right)_T = -\Delta\bar{\kappa}° \quad (5)$$

being termed the standard partial molar isothermal compressibility on ionization. It follows that

$$\frac{RT\ln(K_p/K_o)}{P} = -\Delta\bar{V}° + \frac{1}{2}\Delta\bar{\kappa}°P, \quad (6)$$

where the $\Delta\bar{\kappa}°$ term accounts for the pressure dependence of $\Delta\bar{V}°$. Using the experimental data, the values of $\Delta\bar{V}°$ and $\Delta\bar{\kappa}°$ were obtained from the slope and intercept of $\log(K_p/K_o)/P$ *vs.* P (Eq. 6).

Results and Discussion

The absorption spectra of p-nitrophenol and Cresol Red in phosphate, borate and imidazole (Im) buffer were recorded at various pressures from 1 bar to 6 kbars. The absorption band of the alkali form of the indicators (λ_{max}; 570 nm for Cresol Red and 400 nm for p-nitrophenol) in phosphate and borate buffers increased in intensity and shifted slightly to a higher wavelength, but that of the indicator in the imidazole buffer decreased in intensity when it also shifted slightly to a higher wavelength under pressure. These changes were completely reversible upon the release of the pressure. An example is given in Fig. 2, which shows the absorption spectra of Cresol Red in the borate buffer (pH=8.4) recorded as a function of the pressure up to 6 kbars. The spectra are not corrected for contraction. The absorption band of

** As the pressure-induced shift of absorption maximum (λ_{max}) is small, this treatment may be correct for the present experimental accuracy.

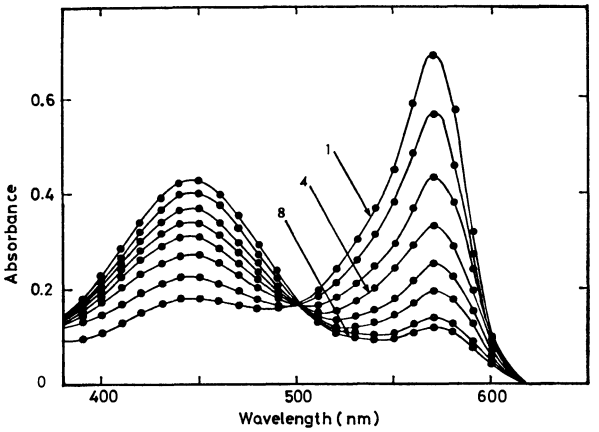

Fig. 2. The effect of pressure on the absorption spectrum of Cresol Red in the borate buffer (0.05 M, pH 8.4) and at appropriate pressures at 25 °C.
1: 1 bar, 2: 706 bar, 3: 1570 bar, 4: 2420 bar, 5: 3340 bar, 6: 4180 bar, 7: 5000 bar, 8: 5480 bar.

the alkali form of Cresol Red decreased, while that of the acid form increased, in intensity and shifted slightly to higher wavelength under pressure. The isosbestic point of the spectra shifted. This is due to the contraction of the sample under pressure. After the correction of the values of OD, the values of log (ΔOD/OD) were calculated for each buffer-indicator system; a summary of these data is presented in Fig. 3. These values of Δlog (ΔOD/OD) are equal to $\Delta pK_I - \Delta pK_a$, where the Δ symbol indicates the difference between the quantity at 1 bar and at a high pressure, P.

The values of Δlog(ΔOD/OD) for *p*-nitrophenol in the borate buffer and the imidazole buffer in conjunction with previously available data for the pressure dependence of pK_I for *p*-nitrophenol permitted the determination of the pressure dependence of pK_a for boric

acid and imidazole HCl. Further, the pressure dependence of the pK_a of boric acid and imidazole HCl was examined using Cresol Red as the indicator. The pressure dependence of the pK_I for the Cresol Red was calculated from the data available for $H_2PO_4^-$.[3] These pK_I values in conjunction with the data for Cresol Red in the borate and imidazole buffers, gave an alternate determination of ΔpK_a values for boric acid and imidazole HCl. The results are given in Fig. 4. With the exception of imidazole HCl, the dissociation of the acids is favored by pressure. The increases in the ΔpK_a value for Cresol Red are very similar to those for *p*-nitrophenol. The changes in the pK_a for boric acid are much greater. The results show that the pH of boric acid changes by more than two units up to the pressure of 6 kbars. On the other hand, the pH of imidazole HCl is almost pressure-insensitive up to 6 kbars.

The values of $\Delta\bar{V}°$ and $\Delta\bar{\kappa}°$ were calculated, using Eq. 6, from the experimental values of $\log(K_p/K_o)$ for *p*-nitrophenol, boric acid, and imidazole HCl. They are given in Table 1, along with the approximate values of $\Delta\bar{V}°$ for the imidazole HCl obtained. The values of $\Delta\bar{V}°$ for Cresol Red is close to the values previously

Table 1.

Weak acid	$\Delta\bar{V}°$(cm³/mol)	$\Delta\bar{\kappa}°$(cm³mol/kbar)	Coupled acid	pH
Cresol Red (CR)	−10.1	−0.4	$H_2PO_4^-$	7.60
Imidazole H^+	−2.4	−0.6	CR	7.84
	−2.0	−0.4	PNP	7.25
Boric acid	−30.2	−4.3	CR	8.26
	−30.9	−4.6	PNP	7.52
	(−31.4)[a]			
p-Nitrophenol (PNP)	(−11.3)[b]	(−1.43)[b]		

a) Observed by means of electrodes by A. Distèche and S. Distèche.[11] b) Observed by R. C. Neuman *et al.*[3]

reported for other phenols, that is, -11.3 cm^3 mol^{-1} [3] and -10.3 cm^3 mol^{-1} [2] for *p*-nitrophenol and -11.8 cm^3 mol^{-1} [13] and -11.3 cm^3 mol^{-1} [3] for 2,5-dinitrophenol. This fact supports the validity of the procedures used.

The value of $\Delta\bar{V}°$ for boric acid is considerably larger than those of the acids. The reason for the large $\Delta\bar{V}°$ value for the amine bases is that the positive charges of the cations are localized on the small nitrogen atoms.[1] Distèche[2] has suggested that this is probably also the reason why $\Delta\bar{V}°$ is very small for boric acid. We suggest that another contributive factor may be the existence of a preliminary hydration equilibrium for boric acid;

$$H_3BO_3 + H_2O \rightleftarrows H_3BO_3 \cdot H_2O$$

$$K_1 = \frac{[H_3BO_3 \cdot H_2O]}{[H_3BO_3]} \quad (7)$$

$$H_3BO_3 \cdot H_2O \rightleftarrows B(OH)_4^- + H^+$$

$$K_2 = \frac{[H^+][B(OH)_4^-]}{[H_3BO_3 \cdot H_2O]} \quad (8)$$

The dissociation constant, K, is based on the total concentration of boric acid, both free and hydrated, so that

$$K = \frac{[B(OH)_4^-] \cdot [H^+]}{[H_3BO_3] + [H_3BO_3 \cdot H_2O]} = \frac{K_1K_2}{1+K_1} \quad (9)$$

It follows that, when K_1 is very small, $K=K_1K_2$ and $\Delta\bar{V}°=\Delta\bar{V}°_1+\Delta\bar{V}°_2$, where the subscripts 1 and 2 refer to the hydration and ionization reactions, 7 and 8 respectively. Ellis correctly pointed out that the abnormally large values of $\Delta\bar{V}°$ for carbonic acid and sulforous acid can be ascribed to the contribution of $\Delta\bar{V}°_1$ since, at the atmospheric pressure, CO_2 and SO_2 are only slightly hydrated in solution.[14]

In striking contrast to these results is the fact that the pH of an imidazole buffer solution is almost pressure-insensitive, below 6 kbars. This is understandable in terms of the ionization equilibrium. Substances that are stronger bases than water are able to extract protons from water molecules, whereupon the conjugate acid of the base, BH^+, is formed, together with hydroxide ions:

$$Im + H_2O \rightleftarrows ImH^+ + OH^- \quad (10)$$

In an analogous way, acids such as BH^+ are able to react with water molecules, which then function as a base;

$$ImH^+ + H_2O \rightleftarrows Im + H_3O^+ \quad (11)$$

Reaction 10 may be taken as the basic dissociation of the base, Im, and the corresponding equilibrium constant is K_b. Reaction 11 is the acidic dissociation of acid BH^+, and the corresponding equilibrium constant is K_{bn}. K_b and K_{bn} are related by means of the ion-product constant of water, K_w:

$$K_w = K_bK_{bn}$$

Amines are usually characterized in terms of K_{bn}, because of the emphasis upon the hydrogen-ion concentration. The large volume changes for boric acid and amine bases with connected with Reaction 11 and with the effect of the pressure on K_b. The determinations of the pH yield $K_{bn}=K_w/K_b$, so that the effect of the pressure on K_b is cancelled by the corresponding effect on K_w, $\Delta\bar{V}°$ value for water being -20.4 cm^3 mol^{-1}. This explains why, for the imidazole buffer, the observed $\Delta\bar{V}°_{bn}$ value is -4.2 cm^3 mol^{-1}, which means that the $\Delta\bar{V}°_b$ value for Reaction 10 is -16.2 cm^3 mol^{-1}.

The authors wish to express their deep thanks to Mr. Tatsuo Takeda of the Institute for Solid State Physics, University of Tokyo, who constructed the delicate micro optical cell of quartz. We wish to express our thanks to Professor Hideo Yabu for his encouragement.

The γ-Radiolysis of a Cyclohexene-Carbon Dioxide Mixture in the Liquid Phase at −18 °C

Laszlo WOJNAROVITS,* Shun-ichi HIROKAMI, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 27, 1976)

The γ-radiolysis of a cyclohexene–carbon dioxide mixture in the liquid phase at −18 °C has been studied. When the mole fraction of carbon dioxide was low, carbon dioxide behaved as an electron scavenger and slightly suppressed the formation of the hydrogen and hydrocarbon products: 2,2′-bicyclohexenyl, cyclohexane, 3-cyclohexylcyclohexene, bicyclohexyl, 1-cyclohexylcyclohexene, and 1,3-cyclohexadiene. Along with this suppression, the formation of cyclohexanol was observed. At the high mole fraction of carbon dioxide, the main products were carbon monoxide and the oxygen atom-addition products: cyclohexene oxide, cyclohexanone, and cyclopentanecarbaldehyde. The material balance for oxygen atoms was good. The formation ratio of the addition products suggests that the precursors of the addition products are the ground-state oxygen atoms. These oxygen atoms are probably produced by the direct radiolysis of carbon dioxide. As the CO_2 mole frcation approached unity, the *G*-values of the addition products and other oxygenated compounds including 2-cyclohexenone and 2-cyclohexenol sharply increased. This suggests that there is another source of oxygen atoms which is suppressed by the presence of cyclohexene. The reactions may be $CO_2^+ + CO_2^- \rightarrow CO + O + CO_2$ and $CO_2^+ +$ cyclohexene$\rightarrow CO_2 +$ cyclohexene$^+$. The formation of 2-cyclohexenone and 2-cyclohexenol may be explained in terms of the reaction between the cyclohexenyl radicals and oxygen molecules eventually produced. To support the elucidation of the reaction mechanism, the radiolysis in the solid phase at 77K and the mercury-photosensitized reaction of a nitrous oxide–cyclohexene mixture in the gas phase have also been studied.

Carbon dioxide was used as an electron scavenger in the radiolysis of liquid hydrocarbon.[1,2] The formation of hydrogen was suppressed by the addition of carbon dioxide, but the yield of carbon monoxide was found to be very small.[1] In the radiolysis of pure liquid carbon dioxide, the observed products were carbon monoxide, oxygen, and ozone.[3] The oxygen atoms produced as intermediates were assumed to be in the ground state, $O(^3P)$. In the liquid-phase γ-radiolyses of benzene–CO_2[4] and of toluene–CO_2[5] mixtures at 0 °C, the main oxygenated products observed were phenol in the case of the benzene–CO_2 mixture and *o*-, *m*-, and *p*-cresols in the case of the toluene–CO_2 mixture. As the precursors of these oxygenated compounds, O^- and CO_3^- ions were considered because the addition of a small amount of SF_6 inhibited the formation of the oxygenated compounds. Sakurai *et al.* studied the γ-radiolysis of olefin–CO_2 mixtures and showed that the oxidizing species must be the ground-state oxygen atoms.[6]

The reactions of the ground-state oxygen atoms with simple olefins in the gas phase were extensively studied by Cvetanović and his co-workers, and a general reaction mechanism has been established.[7] The reaction of $O(^3P)$ atoms with simple olefins in the liquid and solid phases at cryogenic temperatures has also been studied.[8–10] These experimental results show that the general reaction mechanism proposed for the gas-phase reaction can equally apply to the liquid- and solid-phase reactions, although there are some ambiguities in the solid-phase reaction.

The reaction of O^- radical ions with simple olefins in the gas phase has been studied by Bohme and Young,[11] and a general reaction mechanism has been proposed, one which involves either the abstraction of a hydrogen atom to yield a hydroxide ion or the abstraction of a proton to yield a carbanion. The reaction of O^- radical ions in the liquid phase, however, has not been established. Neta and Schuler studied the reaction of O^- ions with organic compounds containing a double bond in an aqueous solution and concluded that the addition of O^- to the double bond is relatively slow, so that abstraction dominates addition.[12]

As has been described above, the reactions of $O(^3P)$ atoms and of O^- radical ions with cyclohexene may produce different types of products. With this prospect in mind, we have investigated the γ-radiolysis of the cyclohexene–CO_2 mixture in the liquid phase at −18 °C and in the solid phase at 77 K.

Experimental

Carbon dioxide and nitrous oxide supplied by the Takachiho Shoji Co. were used after thorough degassing and distillation. Cyclohexene supplied by the Tokyo Kasei Co. was distilled before use. The impurity was less than 1/200.

A conventional vacuum system was used for sampling. The measured amount of cyclohexene was introduced into a Pyrex tube (about 3 ml) with a breakable seal and was thoroughly degassed at the temperature of liquid nitrogen. Then a known amount of carbon dioxide was condensed in the tube, and the tube was sealed. The sample thus prepared was left for thirty minutes in a Dewar flask containing ice-sodium chloride slush at -18 ± 1 °C so that the carbon dioxide and cyclohexene were well mixed. The γ-irradiation was carried out at −18 °C or 77 K at the dose rate of 1.40×10^6 R h^{-1} usually for 3 or 6 h. The absorbed dose was estimated by Fricke dosimetry on the assumption of a proportionality between the absorbed dose and the electron fraction.

The gas noncondensable at the temperature of liquid nitrogen was collected in a gas buret by means of a Toepler pump. After the amount had been measured, the gas was introduced into a copper oxide furnace at about 270 °C, where CO and H_2 were converted into CO_2 and H_2O respectively.

* IAEA fellow 1975—76. Permanent address: Institute of Isotopes of the Hungarian Academy of Sciences, H-1525 Budapest, P. O. B. 77.

Both of them were trapped at 77 K. The amount of CO was measured by recovering CO_2 from the trap at −80 °C. In the radiolysis at 77 K, the formation of oxygen was observed; this was confirmed by using a gas chromatograph equipped with a 6 m column of a 5A molecular sieve at 40 °C.

The analysis of the condensable products was made by gas chromatography. The seal of the irradiated sample tube was broken in the atmosphere, and a certain amount of mesitylene was added as a standard. Two columns were used for the analysis; one was a 2-m PEG-600 column of 20% w/w on celite for C_6 hydrocarbons, while the other was a 2-m PEG-600 column connected in series with a 50-cm silicone SE-52 column for the C_{12} hydrocarbons and the oxygenated compounds. The identification of the products was made by seeding the gas chromatograph with authentic samples when available.

Results

γ-Radiolysis of Liquid CO_2–Cyclohexene Mixture at −18 °C. The *G*-values of the noncondensable products, hydrogen and carbon monoxide, are shown in Fig. 1 as a function of the electron fraction of CO_2. The small change in $G(H_2)$ from 1.25 to 0.75 at the low electron fraction of CO_2 and the rapid increase of $G(CO)$ in the range from 0.8 to 1.0 of the electron fraction of CO_2 are

noticeable. It is also recognized that $G(H_2)$ does not linearly approach zero as the electron fraction of CO_2 approaches unity. These results suggest that some energy or charge-transfer processes between CO_2 and cyclohexene are involved in the formation of H_2 and CO. Figures 2 and 3 show the *G*-values of the hydrocarbon products. All of the curves are similar to one another. Figures 4 and 5 show the *G*-values of the oxygenated compounds. The rapid increase in the *G*-values of cyclohexene oxide, cyclohexanone, 2-cyclohexenone, and 2-cyclohexenol above 0.8 of the electron fraction of

CO_2 corresponds to the rapid increase in $G(CO)$ in the same region. Cyclohexanol seems to be quite different from the other oxygenated products in the mechanism of its formation.

γ-Radiolysis of Solid CO_2–Cyclohexene Mixture at 77 K. Figures 6 and 7 summarize the data obtained at 77 K. In the noncondensable products, oxygen was found; this was confirmed by gas chromatography but no quantitative measurement could be made. As Fig. 7 shows, the *G*-value of cyclohexene oxide was very small. This is quite different from the data obtained in the liquid phase. In the solid-phase radiolysis, it seems that there is no or very little interaction between CO_2 and cyclohexene.

Mercury-photosensitized Reaction of the Nitrous Oxide–Cyclohexene Mixture. In order to obtain the relative yield of the oxygen-atom-addition products, the mercury-photosensitized decomposition of nitrous oxide in the presence of cyclohexene was carried out. The experimental procedure was the same as that reported previously.[13] The relative yields obtained were as follows: cyclohexene oxide, 0.76; cyclohexanone, 0.19, and cyclopentanecarbaldehyde, 0.05.

Discussion

Radiolysis of Cyclohexene. The radiolysis of cyclohexene in the liquid phase at room temperature has been studied by several groups.[14–17] The most important reactions and the formation of products may be described as follows:

$$c\text{-}C_6H_{10} \rightsquigarrow c\text{-}C_6H_{10}^+ + e^- \quad (1a)$$
$$\searrow\ c\text{-}C_6H_{10}^* \quad (1b)$$
$$c\text{-}C_6H_{10}^+ + e^- \rightarrow c\text{-}C_6H_9 + H \quad (2a)$$
$$c\text{-}C_6H_{10}^* \rightarrow c\text{-}C_6H_8 + H_2 \quad (2b)$$
$$\rightarrow c\text{-}C_6H_{10} \quad (2c)$$

$$c\text{-}C_6H_{11} + c\text{-}C_6H_{10} \longrightarrow (c\text{-}C_6H_{11})\text{-}(c\text{-}C_6H_{10}) \quad (7)$$

Hydrogen is formed by Reactions 2b and 3a. Wakeford and Freeman showed that Reaction 2b is less important than Reaction 3a in the formation of hydrogen. The radical formed by the abstraction of a hydrogen atom from cyclohexene is presumably of the allylic type. The disproportionation-combination ratio for allylic-type radicals has been measured in the condensed phase at 90 K by Klein and Kelly.[18] The combination takes place exclusively.

On the basis of the reaction mechanism proposed above and on the assumption that Reaction 7 is not important, we can estimate the *G*-values of the intermediate radicals, $c\text{-}C_6H_9$ and $c\text{-}C_6H_{11}$, by using these disproportionation-combination ratios: $k_{5a}/k_{5b}=1.2$ and $k_{6a}/k_{6b}=0.2$.[19,20] Here, the correction for the temperature of −18 °C has been made by using the activation-energy difference of 300 cal mol^{-1} between the combination and disproportionation established for ethyl and propyl radicals.[21] The radical yields thus calculated are shown in Fig. 8. If the reaction mechanism proposed above is correct, a half of the difference between $G(c\text{-}C_6H_9)$ and $G(c\text{-}C_6H_{11})$ should be equal to the *G*-value of hydrogen produced through the atomic reaction (3a). A comparison of $G(H_2)$ in Fig. 1 and $G(c\text{-}C_6H_9)$

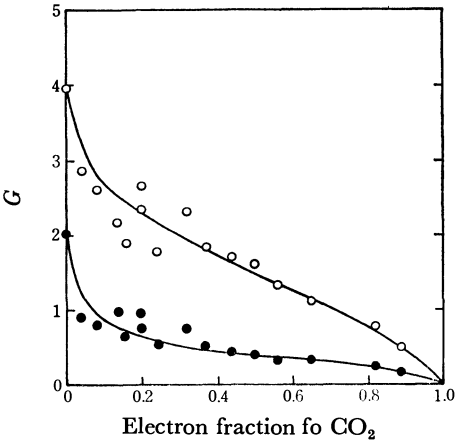

Fig. 8. *G*-values of cyclohexenyl (○) and cyclohexyl radicals (●) calculated from the data obtained at −18 °C in the liquid phase.

and $G(c\text{-}C_6H_{11})$ in Fig. 8 shows that most of hydrogen is produced through the atomic reaction; in other words, the formation of hydrogen by the unimolecular reaction (2b) is not important in the radiolysis of cyclohexene, as was suggested by Wakeford and Freeman.[15]

The formation of 2,2'-bicyclohexenyl, bicyclohexyl, 3-cyclohexyl-cyclohexene, 1,3-cyclohexadiene, and cyclohexane may be explained by Reactions 4—6b. The formation of a small amount of 1-cyclohexylcyclohexene may be explained in terms of the following disproportionation reaction:

$$(c\text{-}C_6H_{11})\text{-}(c\text{-}C_6H_{10}) + c\text{-}C_6H_{11} \longrightarrow \text{3-cyclohexylcyclohexene or 1-cyclohexylcyclohexene} + c\text{-}C_6H_{12} \quad (8)$$

Electron Scavenging by Carbon Dioxide. Upon the addition of a few mole percents of carbon dioxide to cyclohexene, the G-value of hydrogen and the G-values of the hydrocarbon products were reduced. This reduction may be explained in terms of the electron-scavenging reaction of carbon dioxide:

$$CO_2 + e^- \longrightarrow CO_2^- \quad (9)$$

$$CO_2^- + c\text{-}C_6H_{10}^+ \longrightarrow \text{no hydrogen} \quad (10)$$

As Fig. 5 shows, the formation of cyclohexanol was observed in place of the decrease in $G(H_2)$. This suggests that a part of Reaction 10 probably leads to the formation of the hydroxyl radical:

$$CO_2^- + c\text{-}C_6H_{10}^+ \longrightarrow CO + OH + c\text{-}C_6H_9 \quad (10a)$$

and that the OH radicals thus produced react with cyclohexene as follows:

$$OH + c\text{-}C_6H_{10} \longrightarrow c\text{-}C_6H_{10}OH \quad (11a)$$

$$\searrow\ H_2O + c\text{-}C_6H_9 \quad (11b)$$

Söylemez and Schuler studied the reaction of OH radicals with hydrocarbons in an aqueous solution[22] and reported that the addition-abstraction ratio for the reaction of OH radicals with cyclopentene is 4.0. Almost the same value may be applied to Reactions 11a and 11b. The $c\text{-}C_6H_{10}OH$ radicals thus formed will react with other radicals in the system through the disproportionation or combination reaction:

$$c\text{-}C_6H_{10}OH + c\text{-}C_6H_{11} \begin{cases} \nearrow\ c\text{-}C_6H_{11}OH + c\text{-}C_6H_{10} & (12a) \\ \longrightarrow\ c\text{-}C_6H_{10}O + c\text{-}C_6H_{12} & (12b) \\ \searrow\ (c\text{-}C_6H_{11}OH)\text{-}(c\text{-}C_6H_{11}) & (12c) \end{cases}$$

Similar reactions may occur between $c\text{-}C_6H_{10}OH$ and $c\text{-}C_6H_9$ radicals. A small part of cyclohexanone, the main process of the formation of which will be discussed below, must be produced by Reaction 12b.

Formation of Cyclohexene Oxide, Cyclohexanone, and Cyclopentanecarbaldehyde. As Fig. 4 shows, the most abundant oxygenated compound observed is cyclohexene oxide. If oxygen atoms in the ground state are produced in the present system, the formation of cyclohexene oxide can easily be explained, because it is well known that the main product between oxygen atoms and olefins is this type of oxide.[7] Since Cvetanović did not report the formation ratio of the oxygen atom-addition products—cyclohexene oxide, cyclohexanone, and cyclopentanecarbaldehyde, we have measured them, as was

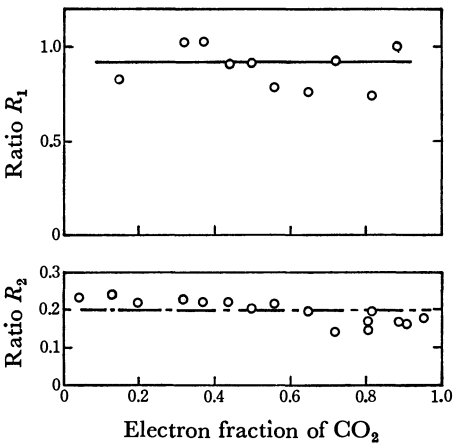

Fig. 9. The ratios of R_1 and R_2. R_1 is the ratio between the sum of the G-values of oxygenated compounds and the G-value of carbon monoxide. R_2 is the ratio between the G-value of cyclohexanone and the sum of the G-values of cyclohexene oxide and cyclohexanone. The dashed line shows the ratio, R_2, obtained in the mercury photosensitized decomposition of nitrous oxide in the presence of cyclohexene.

stated in the Results section. Figure 9 shows the ratio of cyclohexanone/(cyclohexene oxide+cyclohexanone). The ratios obtained in the radiolysis are in good agreement with that obtained in the photolysis. The small deviation at the low concentration of CO_2 may be due to the formation of cyclohexanone by other processes, such as Reaction 12b.

When the electron fraction of carbon dioxide is above 0.8, the amount of oxygen atom-addition products increases with the increase in the electron fraction. This suggests that there are two processes for the formation of oxygen atoms, and that one of them is suppressed by the presence of cyclohexene. They may be written as follows:

$$CO_2 \rightsquigarrow CO_2^* \longrightarrow CO + O \quad (13a)$$

$$\searrow\ CO_2^+ + e^- \quad (13b)$$

$$e^- + CO_2 \longrightarrow CO_2^- \quad (9)$$

$$CO_2^+ + CO_2^- \longrightarrow CO + O + CO_2 \quad (14a)$$

$$\searrow\ 2\,CO + O_2 \quad (14b)$$

$$CO_2^+ + c\text{-}C_6H_{10} \longrightarrow CO_2 + c\text{-}C_6H_{10}^+ \quad (15)$$

$$O + c\text{-}C_6H_{10} \longrightarrow \text{  } \quad (16)$$

Formation of 2-Cyclohexenol and 2-Cyclohexenone. At the high concentrations of carbon dioxide, the formation of 2-cyclohexenol and 2-cyclohexenone has been observed. These compounds may be explained in terms of the reaction of cyclohexenyl radicals with the oxygen molecules produced.

$$c\text{-}C_6H_9 + O_2 \longrightarrow c\text{-}C_6H_9O_2 \quad (17)$$

$$2\,c\text{-}C_6H_9O_2 \longrightarrow c\text{-}C_6H_9OH + c\text{-}C_6H_8O + O_2 \quad (18)$$

Material Balance for Oxygen Atoms. As Fig. 9 shows, the ratio between the sum of the oxygenated compounds and carbon monoxide was about 93%

throughout the range of the electron fraction of CO_2. The ratio between the sum of the oxygen-atom-addition products and carbon monoxide was about 74%.

γ-Radiolysis at 77 K. As Figs. 6 and 7 show, the interaction between CO_2 and cyclohexene at the temperature of liquid nitrogen seems to be very little. The formation of cyclohexene oxide was very small. According to the experiment by Hughes *et al.*,[10] the reaction of oxygen atoms, which are produced in the gas phase, with olefins in the solid state is similar to that in the gas phase. This discrepancy might be due to the inhomogeneity in the solid in the present system or to the melting of the solid olefin surface by the collision of gas molecules in the experiment of Hughes *et al.* This problem is obviously subject to further investigations.

Charge-Transfer Bands of the Mixed Molecular Complex, (Anthracene)$_{1-x}$(Phenanthrene)$_x$(1,2,4,5-Tetracyanobenzene)

John D. WRIGHT,* Toshiaki OHTA, and Haruo KURODA

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 29, 1976)

A series of crystalline mixed molecular complexes of composition, (anthracene)$_{1-x}$(phenanthrene)$_x$(TCNB), with $0.17 \leq x \leq 0.63$, has been prepared from solutions containing mixtures of the three components. A linear relationship is observed between solution and solid composition, and the melting point data and powder X-ray diffraction patterns suggest the formation of a continuous series of mixed molecular complexes of closely related crystal structure. Polarized crystal spectra of these crystals show two charge-transfer bands characteristic of the interaction between anthracene and TCNB and that between phenanthrene and TCNB, respectively. Their intensity ratio is linearly dependent on composition, and constant for different crystals of the same composition. Discussion is given on these results by using the results of semi-empirical SCF-MO-CI calculations on the three-molecule model, anthracene/TCNB/phenanthrene.

Although physical properties of mixed molecular crystal composed of aromatic hydrocarbons have been widely studied, relatively little work has been reported[1,2] on crystals of mixed molecular complexes of the type (Donor 1)$_x$(Donor 2)$_{1-x}$(Acceptor). Extensive studies of the crystal structures of molecular complexes suggest that the relative orientation of donor and acceptor is influenced by lattice packing requirements in addition to intermolecular attractive forces.[3] Therefore, for a given donor/acceptor pair, the relative orientation of the donor and acceptor molecules can be different from the one found in the crystal of the pure molecular complex, if the pair is incorporated in the crystal lattice of mixed molecular complex. Thus, one could examine the effects of relative orientation of donor and acceptor on charge-transfer interaction by comparing the structures and properties of the crystals of mixed molecular complexes with those of pure molecular complexes.

The present work is an investigation of the crystal spectra and other physical properties of the mixed molecular complex system which involves anthracene and phenanthrene as the donors and 1,2,4,5-tetracyanobenzene (TCNB) as the acceptor, undertaken primarily to elucidate the nature of this mixed complex system. We were able to confirm that anthracene–TCNB and phenanthrene–TCNB complexes form a homogeneous solid-solution over the whole composition range. Discussion will be given on the nature of the charge-transfer bands which were observed in the single crystals of mixed molecular complexes.

Experimental

Anthracene was purified by chromatography and multiple zone refining. Phenanthrene, purified by successive treatment with maleic anhydride, KOH and sodium, followed by sublimation and multiple zone-refining,[4] was kindly supplied by Professor Y. Matsunaga. TCNB was synthesized from pyromellitic dianhydride,[5] and purified by recrystallization and sublimation. Crystals of the anthracene–TCNB and phenanthrene–TCNB (pure) complexes were grown by slow cooling of glacial acetic acid and 2-methoxyethanol solutions, respectively, containing 100 mg of each component in 5 ml of solvent. Crystalline powders of the apparent compositions, (anthracene)$_x$(phenanthrene)$_{1-x}$(TCNB) with $0.17 \leq x \leq 0.63$, were obtained from 2-methoxyethanol solutions containing 100 mg TCNB with varying ratios of anthracene and phenanthrene. The anthracene and phenanthrene contents of those powders were determined by ultraviolet spectrophotometry of their ethanol solutions: The optical densities of several solutions of different known concentrations in ethanol were measured at 356, 339, and 282 nm, for each sample of mixed complex, using a Hitachi EPS-3 recording spectrophotometer, and the data were interpreted assuming 1 : 1 mol ratio of (phenanthrene+anthracene)/TCNB, using previously determined values of the extinction coefficients of anthracene, phenanthrene and TCNB at these wavelengths.

X-Ray powder diffraction patterns were recorded for all samples using a diffractometer, Geigerflex, quartz being used as the internal standard. Differential scanning calorimetry (DSC) was carried out by means of a Rigaku TG-DSC apparatus on powdered samples sealed in small aluminium capsules.

The polarized absorption spectra in the visible region, were measured on small plate crystals, typically 20×10 μ in size and less than 1 μ thick, by using a microspectrophotometer, Olympus MSP-IV. The details of the apparatus and the procedures of measurement were described elsewhere.[6]

Results and Discussion

Structural Aspects of the Mixed Molecular Complex.
The anthracene/phenanthrene ratio of a crystalline powder of mixed complex varied depending on the anthracene/phenanthrene ratio initially mixed in the solution from which the sample was prepared. In Fig. 1, we have plotted the mol fraction of anthracene, x= [anthracene]/{[anthracene]+[phenanthrene]}, in the powder sample against the corresponding value for the solution. This plot shows a linear relationship, indicating that anthracene and phenanthrene form a continuous series of mixed molecular complexes with TCNB, with no particularly stable phase of fixed stoichiometric ratio of two donors.

In Fig. 2, the melting point is plotted against the composition. Accurate determination of melting point was not possible because of the thermal decomposition which was apparent at temperatures far below the melting point. The data shown in Fig. 2 were obtained by means of a conventional method of melting-point measurement with visual observation using a rapid heating

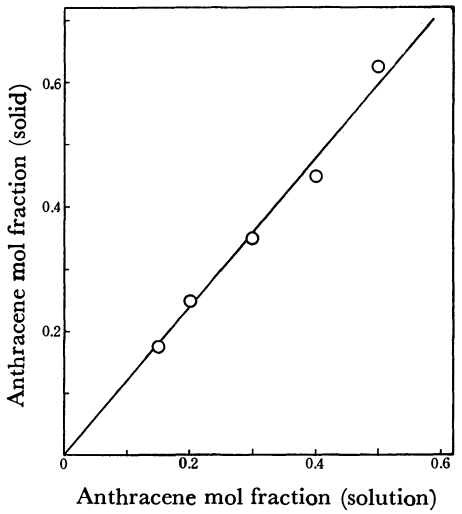

Fig. 1. Mol fraction of anthracene of mixed crystalline complexes, $(\text{Anthracene})_x(\text{phenanthrene})_{1-x}(\text{TCNB})$, as a function of composition of the solutions used to obtain the complexes.

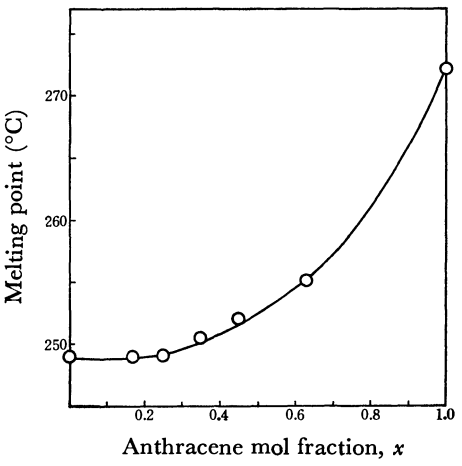

Fig. 2. Dependence of melting point on composition.

condition to minimize thermal decomposition. For each sample, melting occurred rapidly over a temperature range of about 1 °C, suggesting that all crystals in a given sample of mixed complex have almost identical composition. The plot of melting point *vs.* composition is a smooth curve, as shown in Fig. 2, with no evidence for a eutectic. None of the samples of (anthracene, phenanthrene)/TCNB showed any indication of a phase transition in their DSC curves, at least in the range above room temperature. Melting point can be determined also from DSC curves. The melting point data obtained by this method were 2—4 °C higher than those shown in Fig. 2, but their dependence on composition was essentially the same as found for the latter.

The X-ray powder diffraction patterns of mixed complexes and those of the two pure complexes are all very similar (see Fig. 3). Although the positions and intensities of several diffraction peaks are dependent on the composition, they vary continuously with the anthracene/phenanthrene ratio without showing any indication of discrete change of crystal lattice. We can also con-

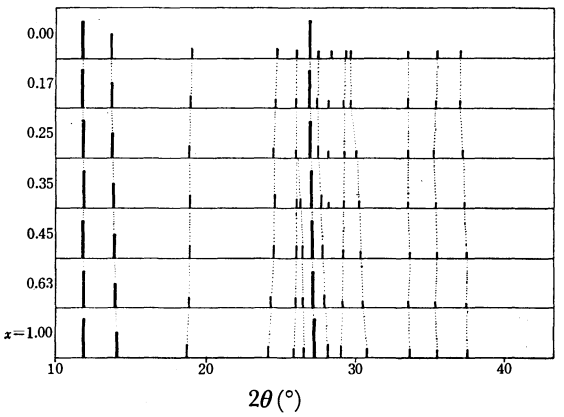

Fig. 3. X-Ray powder diffraction patterns of mixed complexes.

clude from the X-ray powder diffraction patterns that each powder sample of mixed complex in a given preparation is composed of crystals of almost uniform composition and structure.

All of the results mentioned above indicate that the $(\text{anthracene})_x(\text{phenanthrene})_{1-x}(\text{TCNB})$ system is indeed a homogeneous solid solution over the whole composition range, $0 \leq x \leq 1$.

The crystal structure of anthracene–TCNB complex was determined by Tsuchiya *et al.*[7] The crystal is monoclinic with space group C*m*, the lattice parameters being $a=9.505$ Å, $b=12.748$ Å, $c=7.417$ Å, and $\beta=92.45°$. Anthracene and TCNB molecules are alternately stacked on each other to form molecular columns parallel to the c-axis. It was pointed out that there exists a disorder concerning the orientation of anthracene molecule; Anthracene molecules are taking, with equal probability, one of the two orientations rotated by $\pm 8.6°$ within their molecular plane from the mean position. We are currently determining the crystal structure of phenanthrene–TCNB complex. The crystal data have been found to be as follows: monoclinic with possible space group C2/*m* or C2 and the lattice parameters, $a=9.413$ Å, $b=13.104$ Å, $c=7.260$ Å, and $\beta=93.06°$. Phenanthrene and TCNB molecules are alternately stacked along the c-axis and phenanthrene molecules are disordered so as to conform to the apparent site symmetry required for the space groups mentioned above. Thus the crystal lattice of phenanthrene–TCNB is very similar to that of anthracene–TCNB. This similarity of lattice structures suggests that the donor sites in the mixed complexes can be occupied with equal facility by anthracene or phenanthrene, and this may be a requirement for the formation of a continuous series of mixed molecular complexes.

Crystal Spectra of Anthracene–TCNB and Phenanthrene–TCNB. The polarized absorption spectra of single crystals of the two pure complexes are shown in Fig. 4.[8] In the crystal spectrum of anthracene–TCNB (Fig. 4a), the first absorption band at 20.5×10^3 cm^{-1} is almost completely polarized in the direction parallel to the c-axis, along which anthracene and TCNB are alternately stacked on each other. This absorption band can be assigned to the charge transfer from the highest occupied orbital of anthracene to the lowest vacant orbital of

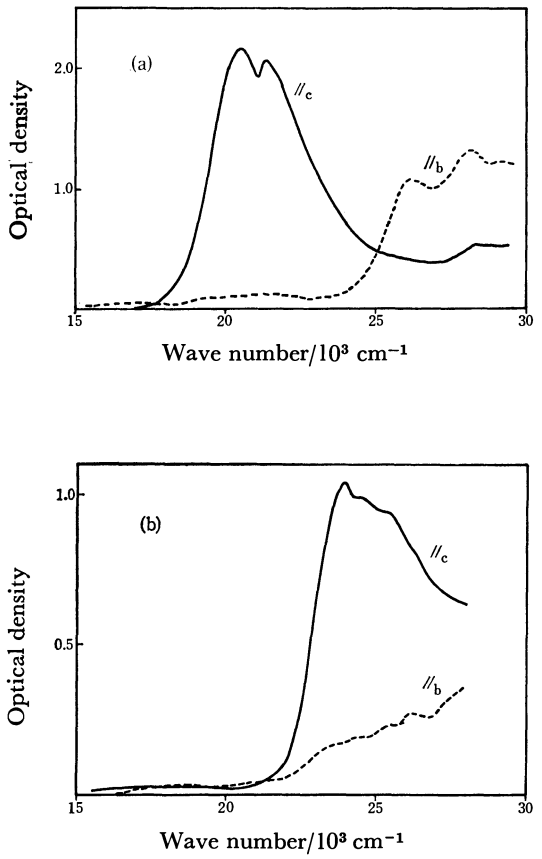

Fig. 4. Polarized absorption spectra of single crystals of pure complexes; (a) Anthracene–TCNB, (b) Phenanthrene–TCNB

TCNB. Incidentally, the corresponding charge-transfer band appears at 20.1×10^3 cm^{-1} in the case of the anthracene–TCNB (1:1) complex in chloroform solution.[9] In the crystal spectrum shown in Fig. 4a, there is another absorption band, polarized in the b-axis direction in the region above 25×10^3 cm^{-1}. This absorption band can be attributed to the local-excitation band mainly associated with the $^1B_{2u}\leftarrow{}^1A_g$ (short-axis polarized) transition of anthracene. Since the short-axis of the anthracene molecule is almost parallel to the b-axis, the above absorption band is expected to be strongly polarized in the b-axis direction. This is consistent with the observed results.

In the case of phenanthrene–TCNB, only one absorption band is found in the observed region (below 28×10^3 cm^{-1}) of crystal spectrum (see Fig. 4b). This absorption band shows its maximum at 23.8×10^3 cm^{-1}, and is strongly polarized in the c-axis direction. Since no local-excitation band is expected to appear in this region, we can safely attribute it to a charge-transfer band. The phenanthrene–TCNB (1:1) complex in chloroform solution exhibits a charge-transfer band at 25.0×10^3 cm^{-1}.[9] When it is compared with the charge transfer band of the anthracene–TCNB (1:1) complex in chloroform solution, the energy difference between them, 0.41 eV, closely agrees with the difference of the first ionization potentials of phenanthrene and anthracene, which have been determined as 7.86 and 7.47 eV, respectively, by means of photoelectron spectroscopy.[10] Thus the 25.0×10^3 cm^{-1} band of the solution spectrum of phenanthrene–TCNB complex can be assigned to the charge transfer from the highest occupied orbital of phenanthrene to the lowest vacant orbital of TCNB, although, in phenanthrene, the second highest occupied orbital is located rather close to the highest occupied orbital. Seemingly, the 23.8×10^3 cm^{-1} band of the crystal of phenanthrene–TCNB complex is also attributable to the charge transfer from the highest occupied orbital of phenanthrene to TCNB.

In measuring the crystal spectra of anthracene–TCNB and phenanthrene–TCNB complexes, we noted that the extinction coefficient of the charge-transfer band is very much lower in the latter than in the former, although we were not able to carry out a quantitative comparison because of the difficulty of determining crystal thickness. As we will describe later, this was confirmed to be the case from the studies of the crystal spectra of mixed molecular complexes.

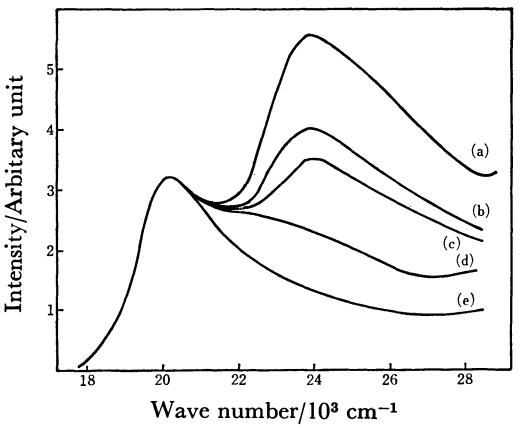

Fig. 5. Charge-transfer bands in the single-crystal spectra of mixed complexes, (Anthracene)$_x$(Phenanthrene)$_{1-x}$(TCNB); (a) $x=0.17$, (b) $x=0.25$, (c) $x=0.35$, (d) $x=0.45$, (e) $x=0.63$.

Charge-transfer Bands of Mixed Complexes. The crystals of mixed complexes all show broad absorption bands extending from 18×10^3 to 28×10^3 cm^{-1}, when the spectra are measured with light polarized parallel to the elongated direction of crystal, which is the crystal axis along which donor and acceptor molecules are alternately stacked on each other. The observed spectra are shown in Fig. 5, where the ordinate (optical density) has been scaled so that all spectra coincide in the region of the first absorption maximum (at about 20×10^3 cm^{-1}). As can be seen in Fig. 5, the observed spectra exhibit two absorption maxima, one at about 20×10^3 cm^{-1} and the other at about 24×10^3 cm^{-1}, and their intensity ratio varies as a function of anthracene/phenanthrene ratio. We have confirmed that the above intensity ratio is almost the same for all crystals in a given preparation of mixed complex. The intensity ratios observed for three different crystals taken from the crystalline powder whose apparent composition is (anthracene)$_{0.25}$(phenanthrene)$_{0.75}$(TCNB), agreed within 5%, indicating that the composition of the crystals in any given preparation is indeed uniform.

The positions of the two absorption maxima mention-

Table 1. Intensity ratios of the two charge-transfer bands in the crystal spectra of mixed complexes, $(\text{Anthracene})_x$-$(\text{Phenanthrene})_{1-x}(\text{TCNB})$

Composition x	Melting point [°C]	Intensity ratio[a] I_2/I_1
0.17	249	1.47
0.25	249	0.94
0.35	251	0.82
0.45	252	0.38
0.63	255	0.18

a) I_1 and I_2 are the integrated intensities of the 20×10^3 cm^{-1} and 24×10^3 cm^{-1} bands, respectively (see text).

ed above correspond closely to those of the first charge-transfer bands of the two pure complexes. This fact, together with the dependence of their intensity ratio on composition, suggests that the 20×10^3 cm^{-1} maximum is due to the charge transfer from anthracene to TCNB, and the 24×10^3 cm^{-1} maximum is due to the charge transfer from phenanthrene to TCNB. The observed charge-transfer bands of the mixed complexes can be reproduced well by superposing the charge-transfer bands of the crystals of the two pure complexes, assuming an appropriate intensity ratio. Table 1 includes the intensity ratios of the two bands of mixed complexes, obtained by the graphical decomposition of observed spectra.

If we assume that the intensities of the two charge-transfer bands of a mixed complex are simply proportional to the probabilities of finding anthracene/TCNB and phenanthrene/TCNB pairs in the crystal, the following relation is expected for the intesnity ratio,

$$\frac{I_2}{I_1}=\frac{I_{\text{phen/TCNB}}}{I_{\text{anth/TCNB}}}\cdot\frac{1-x}{x} \qquad (1)$$

where I_1 and I_2 are the intensities of the bands at 20×10^3 and 24×10^3 cm^{-1}, respectively, and $I_{\text{anth/TCNB}}$ and $I_{\text{phen/TCNB}}$ are the constants corresponding to the extinction coefficients of the charge-transfer bands of anthracene/TCNB and phenanthrene/TCNB pairs, respectively. In Fig. 6, we have plotted the observed intensity ratio against $(1-x)/x$. The points can be fitted well by a single straight line, showing that the intensity ratio is actually proportional to the phenanthrene/anthracene ratio, with $I_{\text{phen/TCNB}}/I_{\text{anth/TCNB}}=0.3$.

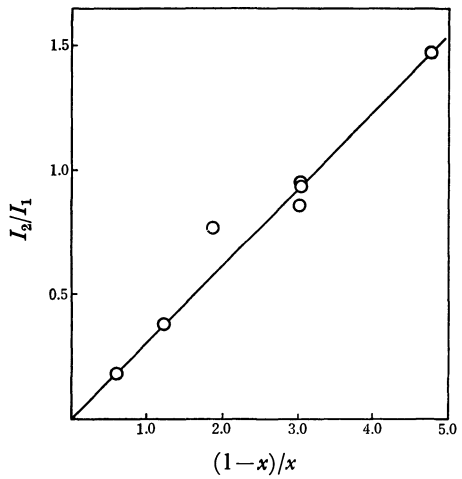

Fig. 6. Intensity ratio of the two charge transfer bands as a function of mol ratio of the two donors.

Molecular-orbital Calculations. Since the oscillator strength of a charge-transfer transition is usually quite small, charge-transfer excitons in a molecular complex crystal can be regarded as rather localized in nature, so that one may neglect the effects of long-range interaction between them. However, it should be noted that, in the crystal of mixed complex, there are sites where an acceptor molecule is sandwiched between two different donors, and, at those sites, the charge-transfer states associated with the two donors could appreciably interact with each other. Therefore, a crystal of mixed molecular complex could exhibit charge-transfer bands considerably different from those observed in pure complexes. However, the crystals of mixed complexes show two charge-transfer bands corresponding very well to those of anthracene–TCNB and phenanthrene–TCNB complexes, and their intensity ratio is simply proportional to the anthracene/phenanthrene ratio.

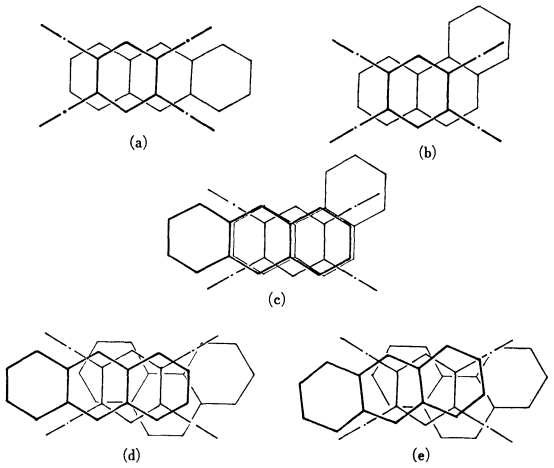

Fig. 7. Relative orientations of donor and acceptor, assumed for the models used in MO calculations. (The mean interplanar spacing between electron donor and acceptor molecules is 3.43 Å in all cases).

In order to examine the nature of charge-transfer bands of the crystals of (anthracene, phenanthrene)/TCNB mixed complexes, we carried out molecular-orbital calculations. Since the main purpose is to examine the short-range interactions of donor and acceptor molecules, calculations were made on simplified models, which are the three-molecule system, anthracene/TCNB/phenanthrene, and the two-molecule systems, anthracene/TCNB and phenanthrene/TCNB. The relative arrangements of donor and acceptor molecules assumed for these models are shown in Fig. 7. For the anthracene/TCNB pair (Fig. 7(a)) the relative orientation and mean separation were taken as those found in the crystal structure analysis of anthracene-TCNB complex, with the anthracene molecule occupying a position corresponding to the mean of the observed disordered arrangement. A model for the phenanthrene/TCNB pair (Fig. 7(b)) retained an orientation of TCNB relative to two of the aromatic rings of phenanthrene similar to

that in the crystal of anthracene–TCNB complex, with the same intermolecular spacing. The first trial model for anthracene/TCNB/phenanthrene (the model (c) in Fig. 7) consists of a combination of the models (a) and (b). However, since the experimental data suggest that anthracene and phenanthrene can be readily interchanged without appreciably disturbing the crystal lattice, two further models (d) and (e) (see Fig. 7) were adopted, in which phenanthrene molecule was rotated and translated so as to occupy a space as similar as possible to that occupied by the anthracene molecule. The two models, (d) and (e), differ only in that the latter contains anthracene occupying one of its extreme positions in the disordered model, rotated in the molecular plane by 8.6° from the orientation in model (d). Seemingly, model (e) is the most realistic one for the relative arrangement of molecules in the crystal of mixed complex.

We carried out calculations on the models described above, by the semiempirical molecular orbital method which was essentially the same as that previously described by Ohta, Kuroda, and Kunii,[11] but extended to permit calculation of a three-molecule system. In this calculation, the orbitals of the system composed of three molecules, D_1, A, and D_2, are calculated as linear combinations of 2p AO's of the atoms in the system as follows;

$$\psi_i = \sum_{\mu}^{(D_1)} c_{i\mu}\phi_\mu + \sum_{\mu'}^{(A)} c_{i\mu'}\phi_{\mu'} + \sum_{\mu''}^{(D_2)} c_{i\mu''}\phi_{\mu''} \qquad (2)$$

where the first, second and third summations are those over the AO's in D_1, A and D_2, respectively. In order to see the character of each orbital, we calculated the following quantities;

$$D_1^{(i)} = \sum_{\mu}^{(D_1)} c_{i\mu}^2, \quad A^{(i)} = \sum_{\mu'}^{(A)} c_{i\mu'}^2, \quad D_2^{(i)} = \sum_{\mu''}^{(D_2)} c_{i\mu''}^2 \qquad (3)$$

These show the contribution of each molecule in the i-th orbital of the system. The results of the calculation on model (e) are partly listed in Table 2. It should be noted that the highest three occupied orbitals are strongly localized on one of the three constituent molecules, although deeper occupied orbitals are considerably delocalized over the whole system. We can see also that vacant orbitals are localized on individual molecules. Similar results were obtained for other models.

Table 2. Characters of molecular orbitals of the three-molecule system, anthracene/TCNB/phenanthrene (Model (e))

a) Defined by Eq. 3 in the text.

We calculated the transitions in the three-molecule system by taking into account the lowest forty singly-excited configurations in the configuration interaction calculation. The results obtained for charge-transfer transitions using different models are compared in Table 3. For the three models of anthracene/TCNB/phenanthrene, (models (c), (d), and (e) of Fig. 7), the calculations gave nearly the same results. In all cases, the lowest-energy transition is predicted at 17.1×10^3—17.7×10^3 cm^{-1} with the character almost entirely associated with the charge transfer from the highest occupied orbital of anthracene to the lowest vacant orbital of TCNB, and the next transition is predicted at about 21×10^3 cm^{-1} with the character of the charge transfer from the highest occupied orbital of phenanthrene to the lowest vacant orbital of TCNB. There is little interac-

Table 3. Energies and oscillator strengths of charge-transfer bands, obtained from the calculations for different models

Model[a]	$\tilde{\nu}$ 10^3 cm^{-1}	f[b]	Contribution of HOMO(A)→LUMO(T)[c] %	$\tilde{\nu}$ 10^3 cm^{-1}	f[d]	Contribution of HOMO(P)→LUMO(T)[e] %
(a)	17.13	0.155(0.144)	97.9			
(b)				20.64	0.055	97.4
(c)	17.72	0.174(0.161)	97.9	21.57	0.041	97.2
(d)	17.45	0.164(0.155)	97.9	21.11	0.024	97.6
(e)	17.12	0.146(0.133)	98.0	20.99	0.028	97.1

(a) See Fig. 7. b) The transition moment of this transition has a small component (5—10%) parallel to the short-axis of anthracene molecule. The oscillator-strength component perpendicular to the molecular plane is given in the parenthesis. c) Contribution of the charge transfer from HOMO of anthracene to LUMO of TCNB, estimated by the procedure given in Ref. 11. d) The component parallel to the molecular plane is negligible. e) Contribution of the charge transfer from HOMO of phenanthrene to LUMO of TCNB.

tion between these two charge-transfer states.

Since model (c) has been formed simply by combining model (a) of the anthracene/TCNB pair and model (b) of the phenanthrene/TCNB pair, it is interesting to compare the results obtained for model (c) with those obtained separately for models (a) and (b). We can see in Table 3, that the two charge-transfer transitions predicted for model (c) of the anthracene/TCNB/phenanthrene very closely correspond to the charge-transfer transition predicted for the anthracene/TCNB pair and that for the phenanthrene/TCNB pair, respectively, although there are small differences as regards the predicted energies and oscillator strengths.

All of the results of the above calculations suggest that the nature of charge-transfer transitions in the mixed complex system should not differ appreciably from those found in the crystals of pure complexes.

TABLE 4. $I_{\text{phen·TCNB}}/I_{\text{anth·TCNB}}$ ESTIMATED FROM THE CALCULATIONS ON THE TWO- AND THREE-MOLECULE MODELS

	$I_{\text{phen·TCNB}}/I_{\text{anth·TCNB}}$
Model (b)/Model (a)	0.38
Model (c)	0.25
Model (d)	0.15
Model (e)	0.20
Expl.	0.30

The intensity ratio of the two charge-transfer bands of anthracene/TCNB/phenanthrene system can be calculated from the predicted oscillator strengths. As shown in Table 4, the predicted ratios[12] fall in the range of 0.15—0.25. If the intensity ratio is estimated by using the results calculated separately for the anthracene/TCNB and phenanthrene/TCNB pairs, (models (a) and (b) of Fig. 7), it becomes 0.38, which is a little larger than the values obtained by the calculations on the three-molecule models. The intensity ratios mentioned above correspond to $I_{\text{phen/TCNB}}/I_{\text{anth/TCNB}}$ in Eq. 3. As we have already mentioned, we obtained 0.3 as the experimental value of $I_{\text{phen/TCNB}}/I_{\text{anth/TCNB}}$ from the observed linear relationship between intensity ratio of two charge-transfer bands and composition of mixed complex. This experimental value is in reasonable agreement with the results of calculations.

Conclusion. The studies reported above show that anthracene and phenanthrene form a particularly ideal series of mixed molecular complexes with TCNB. This may be a consequence of the similar overall size of the three molecules. One interesting consequence of this ideality of (anthracene, phenanthrene)/TCNB solid solution is that it is possible to introduce a large amount of second donor, having different electronic properties, into the crystal lattice of a molecular complex without introducing appreciable lattice perturbations. In this respect the crystals of (anthracene, phenanthrene)/TCNB mixed complex seem to be of particular interest for the purpose of investigating energy transfer and electron transfer in molecular crystals. Studies of the electrical conductivity of this mixed molecular complex are now planned from the above point of view.

(Received May 31, 1976)

The absorption and fluorescence spectra and the fluorescence decay times were measured at 77 K for the photo-irradiation products of the 1,2,4,5-tetracyanobenzene (TCNB) complexes with hexamethylbenzene (HMB), durene, mesitylene, and toluene. The absorption spectra of the photoproducts are similar in shape to that of the TCNB anion and have maxima at 469, 467, 466, and 465 nm for the TCNB complexes with HMB, durene, mesitylene, and toluene, respectively. The fluorescence maximum wavelengths and decay times of the photoproducts are also similar to those of the TCNB anion (505 nm, 19.6 ns for the TCNB–mesitylene system; 505 nm, 20.7 ns for the TCNB-toluene system). The red shift of the absorption maximum and the decrease in the fluorescence decay time by changing the electron donors from toluene to HMB are discussed in terms of ion-pair formation.

Only a few electron donor–acceptor (EDA) complexes have been found to emit fluorescence in fluid solutions and even those which are fluorescent in nonpolar fluid solutions become nonfluorescent in polar fluid solutions.[1,2] In connection with the fluorescence quenching, the ionic dissociation of EDA complex in their excited states has been studied.[3] Sofue and Nagakura[4] reported that flash irradiation of 1,2,4,5-tetracyanobenzene (abbreviated hereafter to TCNB) in such polar solvents as diethyl ethyl ether and acetonitrile at room temperature produces the TCNB anion. Achiba *et al.*[5] studied in more detail the TCNB complexes with tetrahydrofuran and other complexes (in dichloromethane) and observed charge-transfer (CT) bands. Furthermore, they found that the ionization takes place by the excitation in the CT band. Masuhara *et al.*[6] reported that such weak CT complexes as the TCNB–toluene system dissociate spontaneously into ions in their excited CT singlet states in polar solvents.

In the present paper, we report that TCNB complexes with methyl substituted benzenes in diethyl ether–isopentane (1: 1) mixed solvent produce stable ion-pairs at 77 K by excitation in their CT bands.[7] Subsequent to our study, Achiba and Kimura also obtained similar results for TCNB–2-methyltetrahydrofuran.[8]

Experimental

Commercially available TCNB (Frinton, GR grade) used as an electron acceptor was purified by sublimation *in vacuo*. Hexamethylbenzene (abbreviated hereafter to HMB) (Tokyo Kasei, GR grade) was purified by repeated recrystallizations and thereafter by sublimation *in vacuo*. Durene (Tokyo Kasei, GR grade) was purified by repeated recrystallizations from ethanol, and thereafter by repeated zone refinings (about 50 times). Spectrograde toluene (Dotite) was used without further purification. Commercially available mesitylene (Tokyo Kasei, GR grade) was purified by distillation. Diethyl ether and isopentane were purified by the usual methods. The samples in a mixed solvent of diethyl ether–isopentane (1: 1) (hereafter abbreviated to EP) were excited by a 100 W high-pressure mercury lamp at 77K. By using appropriate filters, the samples were exposed to and excited by light with a frequency corresponding to the CT band. The absorption spectra of the photoproducts were measured by the use of a Cary recording spectrophotometer, model 14R. The fluorescence spectra were measured with a grating monochromator (Spex model 1704) with an EMI 9558B photomultiplier as a detector and a 100 W high-pressure mercury lamp as the excitation source. Fluorescence lifetimes were measured by using a dye laser (4-methylumbelliferone; 460 nm) pumped by an Avco Everett model 950 nitrogen laser (peak power, 100 kW; pulse width, 10 ns) as a pulsed excitation light source and by using an HTV 1P28 photomultiplier combined with an oscilloscope (Hitachi, model V1000) as a detector.

Results and Discussion

TCNB in EP at 77 K was directly irradiated by a 100 W high-pressure mercury lamp. Several minutes after the excitation, the irradiated portion of the sample was colored. The absorption and emission spectra of the photoproduct are shown in Figs. 1 and 2, respectively. The absorption spectrum with a maximum at 460 nm[9] and with a vibrational structure is quite similar to that of the TCNB anion in acetonitrile.[4] Therefore the photoproduct can safely be assigned to the TCNB anion. The fluorescence spectrum is broad and structureless, with a maximum at 500 nm. The fluorescence lifetime was found to be 21.3 ns.

The TCNB–HMB system in EP was irradiated at 77 K by a 100 W high-pressure mercury lamp through a Toshiba UV-39 filter and a TCNB (in methylene chloride) solution filter. With these filters, the complex was

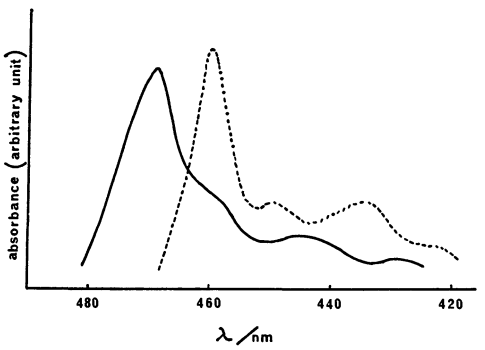

Fig. 1. The absorption spectra of the irradiated EP solution of TCNB (---) and the TCNB–HMB complex (—) at 77 K.

excited only in its CT band. After the irradiation of the sample for several minutes, we obtained a photoproduct with an absorption maximum at 469 nm (Fig. 1). The absorption spectrum of the photoproduct resembles that of the TCNB anion, although the former slightly shifts to longer wavelengths and is a little broader than the latter. The concentrations of the photoproducts were found to be proportional to the exciting light intensity. Therefore, the photo-process is a one photon process.

TABLE 1. THE MAXIMUM WAVELENGTHS OF THE ABSORPTION AND FLUORESCENCE SPECTRA (λ_a AND λ_f, RESPECTIVELY), STOKES SHIFTS ($\Delta\nu$), AND THE FLUORESCENCE LIFETIMES (τ_f) OBSERVED WITH THE TCNB ANION AND THE ION-PAIRS OF THE TCNB ANION AND THE METHYL SUBSTITUTED BENZENE CATIONS

Donor	λ_a(nm)	λ_f(nm)	$\Delta\nu(10^3\,cm^{-1})$	τ_f(ns)
HMB	469			
Durene	467			
Mesitylene	466	505	1.66	19.6
Toluene	465	505	1.70	20.7
TCNB anion only	460	500	1.74	21.3

Similar measurements have been made with the systems containing TCNB as an electron acceptor and durene, mesitylene, and toluene as electron donors; their absorption maxima were observed at 467, 466, and 465 nm, respectively (see Table 1). Thus, the absorption maxima of the photoproducts shift to longer wavelengths with the increasing number of the methyl groups in the donor.

The photoproducts have another common feature: they emit intense fluorescence. The fluorescence spectra and decay times of the photoproducts were measured for the TCNB–mesitylene and TCNB–toluene systems.[10] The observed fluorescence spectra are shown in Fig. 2, and the maximum wavelengths, Stokes shifts, and decay times are given in Table 1. The fluorescence spectra of the photoproducts[11] shift only slightly to longer wavelengths and their fluorescence decay times are only a little shorter compared with the corresponding quantities of the TCNB anion in EP. The Stokes shifts obtained from the absorption and emission spectra of the photoproducts are 1660 and 1700 cm^{-1} for the TCNB–mesitylene and TCNB–toluene systems, respectively. These values are similar to the value for the TCNB anion, 1740 cm^{-1}. The fluorescence excitation spectra were measured with the TCNB–mesitylene and TCNB–toluene systems. Their maximum positions agree well with those of absorption spectra of the respective systems within the limitations of experimental error and their vibrational structures are similar to that of the corresponding absorption spectra.

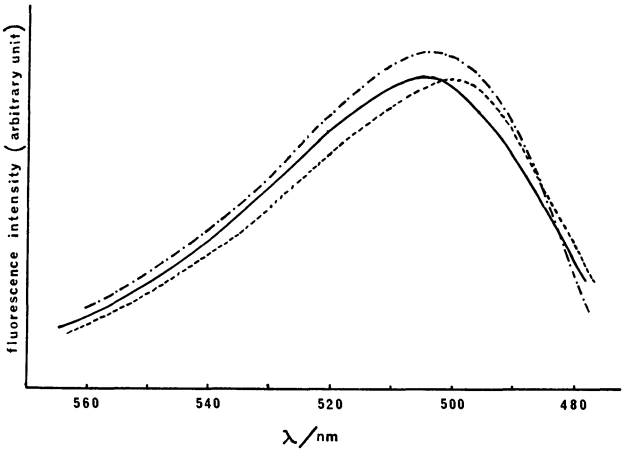

Fig. 2. The fluorescence spectra of the TCNB anion (------) and of the ion-pairs: $TCNB^-$–$toluene^+$(——) and $TCNB^-$-$mesitylene^+$(-·-·-) at 77 K.

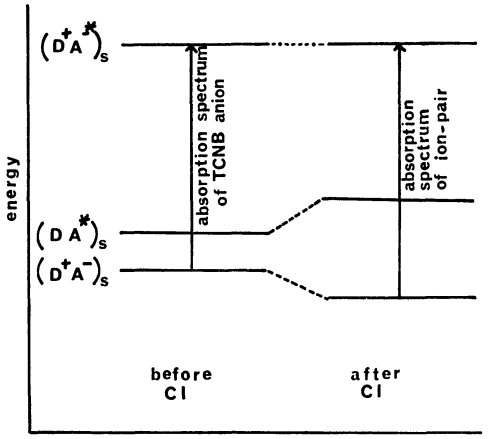

Fig. 3. The schematic energy diagrams of the ion-pair before and after configuration interaction.
( )s indicates the state after solvation.

The above-mentioned results for the absorption and fluorescence spectra, the fluorescence decay times, and the fluorescence excitation spectra show that the photoproducts are the TCNB anion perturbed by some chemical species. From the fact that a counter cation is formed in a pair with the TCNB anion for the electron-donor-acceptor system at 77 K in the rigid medium, it is reasonable to consider that the perturbing chemical species is the donor cation which forms an ion-pair with the TCNB anion. The identification of the photoproducts is supported by the following considerations about the peak wavelengths of the absorption spectra and the fluorescence decay times.

(i) In the ion-pair, the zero-order locally (within TCNB) excited state (DA*) is probably located above the zero-order ion-pair state (D^+A^-), and the two can interact. This interaction stabilizes the ion-pair state and increases the transition energy of the absorption band of the TCNB anion (see Fig. 3). The interaction depends on the energy separation, ΔE, and overlap, S, between the appropriate orbitals belonging to D and A. With the decreasing ionization potential, I_p, of the donor, namely, with the increase in the number of the methyl groups on the donor, $n(CH_3)$, the D^+A^- state becomes lower and ΔE increases. Furthermore, with the increase in $n(CH_3)$, the distance between the TCNB anion and the donor cation may increase because of the increasing steric hindrance, and S is expected to decrease.[12] Thus, we can expect that the stabilization of

the D^+A^- state due to the interaction with the DA* state decreases with the increase in $n(CH_3)$. From this we can explain the observed shift of the absorption maximum with $n(CH_3)$ of the donor.[13]

(ii) The decrease in the fluorescence decay time with the decreasing I_p of the donor may be tentatively explained in the following way: The radiative transition moment may decrease with the increasing DA* character of the ion-pair in the ground state, which is represented by D^+A^-, since the observed fluorescence corresponds to an allowed transition of the TCNB anion. As described above, the contribution of the DA* state to the ground state of the ion-pair increases with the decrease in $n(CH_3)$. Thus, the decrease in the radiative lifetime of S_1 with the decreasing I_p of donor can be explained. A similar tendency was also observed for the TCNB complexes with methyl substituted benzenes in both fluid and rigid nonpolar solvents, and was explained in the same way.[2]

Thus the TCNB complexes with methyl substituted benzenes produce stable ion-pairs at 77 K by excitation in their CT bands.

8) Y. Achiba and K. Kimura, *Chem. Phys. Lett.*, **36**, 65 (1975).

9) The absorption band at 460 nm shifts to 462 nm at room temperature (295 K) for a degassed solution.

10) The fluorescence spectra of the photoproducts could not be measured for the TCNB–HMB and TCNB–durene systems. It is difficult to separate them from the fluorescence spectra of the corresponding molecular complexes because of the large overlap.

11) The fluorescence spectra are broad (bandwidth 1700—1800 cm^{-1}) and structureless while the corresponding absorption spectra show a vibrational structure. This implies that a rather large change in the geometrical configuration of the photoproduct and in the orientation of the surrounding solvent molecules takes place in the excited state.

12) Since the ion-pair is formed by the excitation in the charge-transfer absorption band of the complexes in the rigid solvents, it is reasonable to consider that no solvent molecule intervenes between the TCNB anion and the donor cation. The molecular planes of the components in the ion-pair may be parallel with each other as are those in the parent complex. The exchange interaction between the components may exist in both the ion-pair and the parent CT complex, although it may decrease in the former.

13) The fact that the photoproduct of the TCNB–EP system shows its absorption maximum at a shorter wavelength (460 nm) than the TCNB–toluene complex can be explained by the interaction between D^+A^- and DA*. The ΔE value may conceivably be larger for the TCNB–diethyl ether than for the TCNB–toluene. The finding that the fluorescence decay time is longer for the TCNB–EP system than for the TCNB–toluene system can be explained along the same lines.

Selective Hydrogen Atom Abstraction by Hydrogen Atoms in Photolysis and Radiolysis of Alkane Mixtures at 77 K

Tetsuo MIYAZAKI,* Kazuhisa KINUGAWA, Masao EGUCHI, and Selma M. L. GUEDES**

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
***Coordenadoria de Radioquimica, Instituto de Energia Atômica, C.P. 11049 (Pinheiros), 01000 São Paulo, SP, Brazil*

(Received June 1, 1976)

A selective hydrogen atom abstraction reaction by H atoms, which are produced at 77K by radiolysis of alkane or photolysis of hydrogen halides, has been found in isobutane, 2,2,3,3-tetramethylbutane (TMB), and cyclopropane matrices as well as in the neopentane matrix. The selective hydrogen atom abstraction reaction is caused by H atoms which have initial kinetic energies in the range from 15 to 67 kcal/mol. The reaction is caused also by D atoms. The competitive reaction between *c*-C_6H_{12} and HI for H atoms has been studied in the radiolysis and photolysis of *neo*-C_5H_{12}–*c*-C_6H_{12}–HI mixture at 77K. The rate constants of these reactions in the neopentane matrix are quite different from those of a thermal H atom reaction, but similar to those of a hot H atom reaction. The importance of the selective hydrogen atom abstraction reaction by H atoms is pointed out in the radical formation in the radiolysis of pure TMB at 77K.

We can easily investigate solid-state reactions at 77 K by irradiation with ultraviolet light or γ rays. Recently quite interesting phenomena have been found in the radiolysis of a neopentane–alkane mixture in the solid phase at 77 K.[1] When neopentane containing a small amount of alkane is γ-irradiated at 77 K, alkyl radicals from solute alkanes rather than neopentyl radicals are selectively formed.

Since the formation of the solute alkyl radical is not affected by the addition of an electron scavenger or a hole scavenger, it was concluded that the alkyl radical is formed by a nonionic process.[1b] The following observations obtained previously showed that the solute alkyl radical is not formed by the excitation transfer from the irradiated neopentane to the solute, but by the selective hydrogen atom abstraction from the solute by H atoms.[1c] (1) The mechanism of excitation transfer promotes the formation of D_2 in the radiolysis of *neo*-C_5H_{12}–*i*-C_4H_9D at 77 K. Though much HD is formed in this system, D_2 is not formed at all.[1c] (2) When a *neo*-C_5H_{12}–*c*-C_6H_{12} (1 mol %) mixture is irradiated at 77 K by γ-rays, cyclohexyl radicals are mainly formed. When propylene is added to the mixture, the formation of the cyclohexyl radicals is suppressed, while C_3H_7 radicals are produced complementarily by the addition of H atoms to propylene.[2] (3) H atoms, which are produced by the photolysis of hydrogen iodide in neopentane containing a small amount of alkane, react selectively with the solute slkane at 77 K.[1c,3]

The selective hydrogen atom abstraction reaction by H atoms has new problems in its reaction kinetics in the solid phase at 77 K. When H atoms are hot, we must assume that they migrate a long distance at 77 K through the neopentane crystal without losing their kinetic energies. When H atoms are thermal, we must assume that the activation energy for hydrogen atom abstraction is nearly zero in the neopentane matrix at 77 K, though the value amounts to 7—10 kcal/mol in the gas phase.[4,5] The research described herein was undertaken in order to obtain further information about the nature of the reactive H atoms.

* All correspondence should be addressed.

The previous studies of the selective hydrogen atom abstraction have been limited only to the neopentane matrix and to the reactions of H atoms. In the present paper the study will be extended to other alkane matrices, such as isobutane, 2,2,3,3-tetramethylbutane (TMB), and cyclopropane, and to the reactions of H and D atoms.

The formation of radicals in the radiolysis of pure TMB and of a TMB–alkane mixture is discussed here in terms of the selective hydrogen atom abstraction by H atoms.

Experimental

Neopentane, isobutane, and propane were more than 99.9 mol% pure, while cyclopropane and ethane were respectively more than 99.0 and 99.7% pure. Spectrograde cyclohexane was passed through a 1-m column packed with silica gel and then distilled on a vacuum line before use. 2,2,3,3-Tetramethylbutane (TMB) was of a high purity and purified by sublimation on a vacuum line before use. To prepare hydrogen halides (HX), such as HI, HBr, DBr, and HCl, the aqueous solution of each hydrogen halide was passed through P_2O_5 and subjected to several trap-to-trap sublimations on the vacuum line.

UV illumination was provided by Toshiba medium-pressure or low-pressure mercury lamps. γ-Irradiation was done by Co-60 at a dose rate of 4.2×10^{19} eV/h.

The free radicals were measured at 77 K with a JES-3BX ESR spectrometer.

Results

Table 1 shows the yields of radicals by the reaction of hydrogen (or deuterium) atoms in the radiolysis or photolysis of alkane mixtures in the solid phase at 77 K. *t*-C_4H_9 radical is mainly formed in the photolysis of *neo*-C_5H_{12}(or TMB)–*i*-C_4H_{10}–hydrogen halide(HX), while a small amount of *i*-C_4H_9 radical is also produced. Since the ratio of the amounts of *i*-C_4H_9 radicals to those of *t*-C_4H_9 radicals increases with increasing the illumination time of ultraviolet light, *i*-C_4H_9 radical is formed by the isomerization of *t*-C_4H_9 radical, which absorbs ultraviolet light.[6] The amounts of C_4H_9 radicals re-

a) Yields are averages of two or more runs. b) Alkane mixtures in the absence of hydrogen halide were irradiated at 77 K with γ-rays. H atoms are produced by the radiolysis of solvent alkane. c) H (or D) atoms are produced by the photolysis of hydrogen halide with ultraviolet light. Concentrations of hydrogen halide in *neo*-C_5H_{12}, *i*-C_4H_{10}, TMB, and *c*-C_3H_6 matrices are 0.5, 0.2, 0.5, and 0.5 mol/100 mol of solvent alkane. The yield of the radical in HI system is taken as 10. Illumination times of *neo*-C_5H_{12}, *i*-C_4H_{10}, TMB, and *c*-C_3H_6 matrices with UV light from a low-pressure mercury lamp are 5, 5, 20, and 30 min respectively. d) Unit of concentration is mol/100 mol of solvent alkane. e) ESR spectra are shown in Ref. 1a. f) ESR spectra are shown in Figs. 3 and 4.

present a sum of *t*-C_4H_9 and *i*-C_4H_9 radicals, and are measured by double integration of the first-derivative ESR signal of the radicals. Since only C_4H_9 radicals are formed selectively in the photolysis of *neo*-C_5H_{12}(or TMB)–*i*-C_4H_{10}–HX, overlapping of the spectra of the solute radical and the neopentyl radical does not occur. *neo*-C_5H_{11}, C_3H_7, *i*-C_4H_9, and C_2H_5 radicals do not isomerize under the illumination by ultraviolet light. Therefore the relative yields of these radicals are obtained from the heights of their peaks in the ESR spectrum. The yields of solute radicals increase linearly with increasing irradiation time. The yield of radical in the photolysis of HI is much higher than that in the photolysis of HBr, DBr, or HCl. This is because the absorbance of the ultraviolet light by HI is stronger than that by other hydrogen halides.[7)] H atoms in the previous studies have been produced only by the photolysis of HI with 253.7 nm. The present study has been undertaken in order to obtain qualitative information as to whether H atoms with various energies produced from different compounds also react selectively with solute alkanes or not. Since the absolute yields of radicals was not necessary, the effect of HX concentration on the radical yields has not been studied systematically, except for a few runs of different concentrations. The results of the photolysis in Table 1 have been obtained by the illumination in the air with UV light from a low pressure Hg lamp. It was found by using a filter that the photolysis of HI is caused mainly by light of 253.7 nm, while that of HBr or DBr is caused by light of 184.9 nm along with 253.7 nm.

In order to examine the effect of different wavelengths on the photolysis of HBr, two experiments have been undertaken. First, a filter which completely cuts off any light shorter than 190 nm has been used, and thus the photolysis was caused only by light of 253.7 nm. Second, the illumination with a low pressure Hg lamp has been done in the vacuum. The photolysis is caused mainly by light of 184.9 nm, because the decomposition of HBr by light of 253.7 nm is much smaller than that by light of 184.9 nm. Both H atoms, produced by the photolysis of HBr with the light of 184.9 nm or 253.7 nm, react selectively with the solute alkane in the *neo*-pentane matrix at 77 K.

The photolysis of HI has been done with a medium-pressure Hg lamp through a Toshiba UV31 filter, which cuts off all light shorter than 305 nm. The yields of radicals in the photolysis with the UV31 filter are much higher than those in the photolysis with a glass filter which cuts off all light shorter than 330 nm. Therefore the photolysis with the UV31 filter is caused mainly by the light from 330 nm to 305 nm. H atoms produced by the photolysis with the light from 330 nm to 305 nm also react selectively with the solute alkanes in the *neo*-pentane matrix at 77 K.

Figure 1 shows the effect of HI on the formation of cyclohexyl radicals in the radiolysis of *neo*-C_5H_{12}–*c*-C_6H_{12}–HI at 77 K. When *neo*-C_5H_{12} containing *c*-C_6H_{12} of 0.5, 1.0, and 2.0 (mol/100 mol of *neo*-C_5H_{12}) is γ-irradiated in the absence of HI, the yields of cyclohexyl radicals are approximately the same in the three systems; they are taken as 10.

Figure 2 shows the effect of HI on the formation of cyclohexyl radicals in the photolysis of *neo*-C_5H_{12}–*c*-C_6H_{12}–HI at 77 K. The yields of cyclohexyl radicals at HI concentration of 0.25 (mol/100 mol of *neo*-C_5H_{12}) are taken as 10

Figure 3a shows the ESR spectrum of γ-irradiated

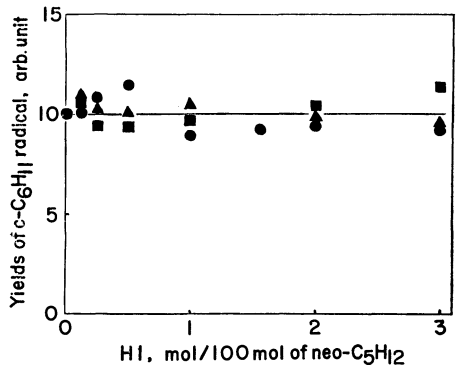

Fig. 1. Effect of HI on the yield of c-C_6H_{11} radicals in the radiolysis of *neo*-C_5H_{12}–c-C_6H_{12} mixture at 77 K with a dose of 2.1×10^{19} eV/g.
■, Concentration of c-C_6H_{12} is 0.5 mol/100 mol of *neo*-C_5H_{12}.
●, Concentration of c-C_6H_{12} is 1.0 mol/100 mol of *neo*-C_5H_{12}.
▲, Concentration of c-C_6H_{12} is 2.0 mol/100 mol of *neo*-C_5H_{12}.

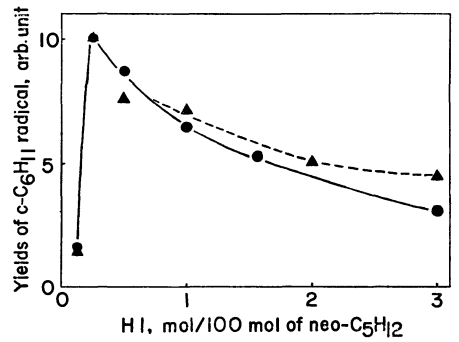

Fig. 2. Effect of HI on the yield of c-C_6H_{11} radicals in the photolysis of *neo*-C_5H_{12}–c-C_6H_{12}–HI mixture at 77 K.
●—●, c-C_6H_{12} concentration is 1.0 mol/100 mol of *neo*-C_5H_{12}.

pure TMB at 77 K. The spectrum is similar to that reported by Gerola *et al.*[8] The spectrum of three broad lines, indicated by ⇩, is ascribed to the $(CH_3)_3CC(CH_3)_2\dot{C}H_2$ (TMB·) radical. The other unidentified spectrum, indicated by ⇣, has been ascribed to an isomerized radical, *i.e.* $(CH_3)_3CCH_2\dot{C}(CH_3)_2$,[8] or a mixture of t-C_4H_9 and $(CH_3)_3C\dot{C}(CH_3)_2$ radicals.[9] When TMB containing a small amount of isobutane or cyclohexane are γ-irradiated at 77 K, quite different spectra are obtained (Figs. 3b and c). The spectrum in Fig. 3b consists of three broad lines, which are attributable to the TMB· radical, and eight narrow lines, indicated by ↓, with a splitting constant of 22 G. The spectrum of the eight lines is consistent with the reported spectrum for the t-C_4H_9 radical.[10,11] The spectrum in Fig. 3c consists of three broad lines, which are attributable to the TMB· radical, and six broad lines, indicated by ↓, with a splitting constant of 22 G. The spectrum of the six lines is consistent with the reported spectrum

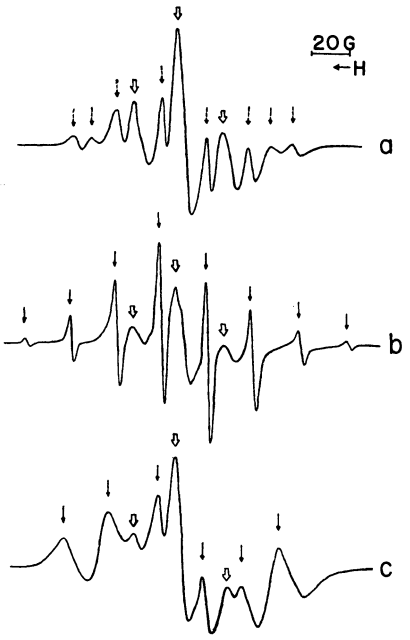

Fig. 3. ESR spectra of γ-irradiated TMB and TMB-alkane mixtures at 77 K with a dose of 1.8×10^{19} eV/g. Relative sensitivities of spectrometer for a, b, and c are approximately the ratios of 2: 1: 1.5 respectively. a, pure TMB; b, TMB–i-C_4H_{10}(5.4 mol/100 mol of TMB); c, TMB–c-C_6H_{12} (5.8 mol/100 mol of TMB).

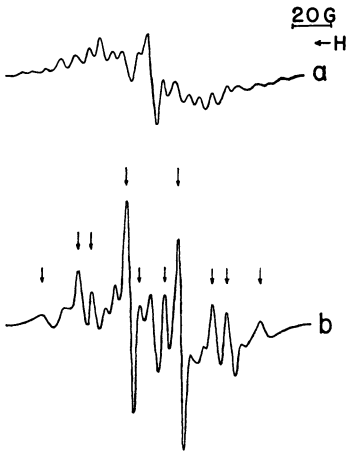

Fig. 4. ESR spectra of γ-irradiated c-C_3H_6 and c-C_3H_6–C_2H_6 mixtures at 77 K with a dose of 1.8×10^{19} eV/g. Sensitivities of spectrometer for a and b are approximately the same. a, pure c-C_3H_6; b, c-C_3H_6–C_2H_6 (4 mol/100 mol of c-C_3H_6).

for the cyclohexyl radical.[10,12] When TMB containing a small amount of C_3H_8, i-C_4H_8, or C_3H_6 is γ-irradiated at 77 K, C_3H_7, t-C_4H_9, or C_3H_7 radical is clearly observed.

Figure 4a shows the ESR spectrum of γ-irradiated pure cyclopropane at 77 K. The spectrum may be ascribed to C_3H_5 radical.[10] When cyclopropane containing a small amount of ethane is γ-irradiated at 77 K, a typical spectrum of an ethyl radical,[10,11] indicated by ↓, is clearly observed, as in Fig. 4b.[13]

Discussion

Selective Formation of Solute Radicals in the Radiolysis and Photolysis of Alkane Mixtures at 77 K. Table 1 shows that the selective formations of solute radicals in the radiolysis of alkane mixtures are observed also in isobutane, 2,2,3,3-tetramethylbutane (TMB), and cyclopropane matrices as well as in the neopentane matrix. All of the matrix alkanes are polycrystalline at 77 K. H atoms, produced by the photolysis of HI or HBr, react selectively with a small amount of the solute alkane in the *neo*-C_5H_{12}, *i*-C_4H_{10}, and TMB matrices. It is concluded that the selective hydrogen atom abstraction reaction is not limited to the neopentane matrix, but can be found also in other polycrystalline alkanes.

When H atoms are produced by the photolysis of HI with light of 330—305 nm, they react selectively with the solute alkane in the neopentane matrix. The 330—305 nm radiation corresponds to 86.6—93.7 kcal/mol, while the bond strength of HI is 71.3 kcal/mol.[14] To conserve momentum essentially all of the energy from the primary process in excess of that used in bond rupture must appear as translational energy of the H atom, because I atoms produced by the photolysis with 330—305 nm are mainly in the ground state.[15] Therefore the energies of the H atoms are 15—22 kcal/mol. The bond strength of HBr is 87.6 kcal/mol.[14] When H atoms are produced by the photolysis of HBr with light of 184.9 nm, the energies of the H atoms are 67 kcal/mol, because Br atoms produced by the photolysis are mainly in the ground state.[16] The H atoms also react selectively with the solute alkanes in the neopentane matrix. It is concluded that the H atoms, which have initial kinetic energies ranging from 15 to 67 kcal/mol, migrate a long distance through the neopentane matrix without reacting with the neopentane molecules and react selectively with the solute alkanes.

Though the C_2H_5 radical is mainly formed in the radiolysis of *c*-C_3H_6–C_2H_6 (Fig. 4), it is not observed in the photolysis of *c*-C_3H_6–C_2H_6–HI (HBr or DBr). Since the concentration of HX in cyclopropane and the method of illumination with UV light are the same as those in neopentane, the condition of the absorption of the light in cyclopropane must be the same as in neopentane, where the formation of radicals by the photolysis can be observed clearly. At present we cannot give a suitable explanation for the phenomenon that radicals are not formed by the photolysis in cyclopropane. One plausible reason would be as follows: that the amount of the H atoms produced by the photolysis of hydrogen halide in cyclopropane is extremely small. This might be because the ultraviolet light is reflected at the surface of the cyclopropane crystal and does not penetrate into the crystal, or because the decomposition of HX is suppressed by the cage effect in the cyclopropane crystal. The following results were observed during our experiments. Firstly, neither the C_3H_5 radical nor any other radical is produced by the illumination of *c*-C_3H_6–HX, where C_2H_6 does not exist, with ultraviolet light at 77 K. Secondly, when *c*-C_3H_6–C_2H_6–HI is illuminated with ultraviolet light, the color of I_2, produced by the decomposition of HI, is observed only at the surface of the crystal.

Table 1 shows that D atoms, produced by the decomposition of DBr, also react selectively with the solute alkanes. Therefore the selective hydrogen atom abstraction reaction is not limited only to H atoms.

Nature of Reactive Hydrogen Atom. In order to elucidate the mechanism of the selective hydrogen atom abstraction reaction by H atoms, it is important to get some information about the nature of the H atoms.

(I) Competitive reaction of H atoms with HI and *c*-C_6H_{12} in the *neo*-C_5H_{12} matrix at 77 K.

Figure 1 shows that the yields of cyclohexyl radicals in the radiolysis of *neo*-C_5H_{12}–*c*-C_6H_{12} mixtures are not affected by the addition of HI. As described in the Introduction, the previous studies[1] of the radiolysis of neopentane–alkane mixtures at 77 K have concluded that excited neopentane, formed by γ-irradiation, produces a H atom and a neopentyl radical. The H atom migrates through the neopentane matrix and reacts selectively with the solute cyclohexane. The ionic process and the excitation transfer are not responsible for the formation of *c*-C_6H_{11} radicals.[1] When HI is

$$\textit{neo}\text{-}C_5H_{12} \rightsquigarrow \textit{neo}\text{-}C_5H_{11} + H \quad (1)$$

$$H + c\text{-}C_6H_{12} \xrightarrow{k_{c\text{-}C_6H_{12}}} c\text{-}C_6H_{11} + H_2 \quad (2)$$

present in the *neo*-C_5H_{12}–*c*-C_6H_{12} system, occurrence of Reaction 3 is expected, because both hot and thermal H atoms react easily with HI in the gas phase. H

$$H + HI \xrightarrow{k_{HI}} I + H_2 \quad (3)$$

atoms produced by the radiolysis of *neo*-C_5H_{12} at 77 K, however, do not react with HI, but with *c*-C_6H_{12} (Fig. 1). It can be estimated from the results in Fig. 1 that $k_{HI}/k_{c\text{-}C_6H_{12}}$ is less than 0.05; the value is given in the first line in Table 2.

Figure 2 shows that the yields of cyclohexyl radicals in the photolysis of the *neo*-C_5H_{12}–*c*-C_6H_{12}–HI mixture reach a maximum at the HI concentration of 0.25 (mol/100 mol of *neo*-C_5H_{12}) and then decrease gradually with increasing concentration of HI. Such results can be explained in terms of competitive reactions between HI and cyclohexane for H atoms. A possible kinetic scheme is as follows:

$$HI \xrightarrow{h\nu} H + I \quad (4)$$

$$H + c\text{-}C_6H_{12} \xrightarrow{k_{c\text{-}C_6H_{12}}} c\text{-}C_6H_{11} + H_2 \quad (5)$$

$$H + HI \xrightarrow{k_{HI}} I + H_2 \quad (6)$$

If the rate of Reaction 4 is represented by r, the following kinetic equation is obtained:

$$\frac{1}{[c\text{-}C_6H_{11}]} = \frac{1}{r} + \frac{k_{HI}[HI]}{r\,k_{c\text{-}C_6H_{12}}[c\text{-}C_6H_{12}]}$$

The linear relationship between $1/[c\text{-}C_6H_{11}]$ and $[HI]/[c\text{-}C_6H_{12}]$ is obtained for the HI concentrations higher than 0.25 (mol/100 mol of *neo*-C_5H_{12}). When concentrations of *c*-C_6H_{12} are 1.0 and 2.0 (mol/100 mol of *neo*-C_5H_{12}), $k_{HI}/k_{c\text{-}C_6H_{12}}$ are 1.2 and 1.0 respectively. The mean value for $k_{HI}/k_{c\text{-}C_6H_{12}}$ is given in the second line in Table 2.

There are many studies of the reaction of hot atoms produced by the photolysis of hydrogen halides in the gas phase. Carter *et al.*[17] reported that $k_{DI}/k_{C_2H_6}$ is

Table 2. Competitive reaction between HI and c-C_6H_{12} for H atoms at 77 K

Species of H atom	$k_{HI}/k_{c-C6H12}$
H atom produced by radiolysis of *neo*-C_5H_{12} at 77 K	<0.05
H atom produced by photolysis of HI in *neo*-C_5H_{12} matrix at 77 K	1.1
Hot H atom[a]	0.23—1.1
Thermal H atom (A)[b]	10^{20}—10^{23}
Thermal H atom (B)[c]	10^{11}—10^{14}

a) Hot H atoms were produced by photolysis of HI in the gas phase. b) $k_{HI}/k_{c-C_6H_{12}}$ was estimated from the data in the gas phase. c) $k_{HI}/k_{c-C_6H_{12}}$ was estimated from the reaction of the thermal methyl radical in the solid phase at 77 K.

1.45 for reactions of hot D atoms with DI and C_2H_6. Hong *et al.*[18] reported that $k_{HI}/k_{C_2D_5H}$ is 7.0 for reactions of hot H atoms with HI and C_2D_5H. Rebbert *et al.*[19] reported that $k_{C_2D_6}/k_{c-C_6D_{12}}$ is 0.16 for reactions of hot CH_3 radicals with C_2D_6 and c-C_6D_{12}. Therefore $k_{HI}/k_{c-C_6H_{12}}$ ranges approximately from 1.45×0.16 (=0.23) to 7.0×0.16 (=1.1). These values are given in the third line in Table 2.

Thermal H atoms react quite easily with HI in the gas phase. According to the study by Sullivan,[20] the rate constant of this reaction can be expressed by $k_{HI}=10^{12.05}T^{0.5}\exp(-E/RT)$. The activation energy (E) is nearly zero, 0.48 kcal/mol. The activation energy for a reaction of thermal H atoms with cyclohexane is, however, about 8 kcal/mol.[4,5] If it is assumed that the pre-exponential factor of $k_{c-C_6H_{12}}$ is approximately the same as that of k_{HI} and that the activation energy for the reaction of H atoms with HI is 0—1 kcal/mol, $k_{HI}/k_{c-C_6H_{12}}$ at 77 K amounts to 10^{20}—10^{23}; this is given in the 4th line in Table 2.

Recently it has been reported that a thermal CH_3 radical abstracts H atoms from CH_3OH[21] and 3-methylpentane[22,23] at 77 K by quantum mechanical tunneling. The rate constant of the reaction can be estimated from the decay time of the CH_3 radical to be about 10^{-1} mol^{-1} ml s^{-1} at 77 K. Assuming that the thermal H atom reacts with cyclohexane by the quantum mechanical tunneling and that the rate constant of the thermal H atom is the same order of magnitude as that of the thermal CH_3 radical, $k_{HI}/k_{c-C_6H_{12}}$ at 77 K may be 10^{11}—10^{14}; this is given in the 5th line in Table 2.

Though a number of studies of the reaction rate have been undertaken in the gas and liquid phases at temperatures higher than room temperature, studies in the solid phase at 77 K are quite few. At present we have no information about the possibility that the activation energy changes drastically in the solid alkane at 77 K, as compared with the gas or liquid phases. If the activation energy obtained in the gas phase may be used also in the solid phase, the following discussion may be fruitful. The results in Table 2 show that $k_{HI}/k_{c-C_6H_{12}}$ of H atoms produced by the radiolysis or photolysis in the neopentane matrix at 77 K are quite different from the values expected from the reaction of thermal H atoms, but approximately similar to the value expected from the hot H atom reaction.

If the activation energy in the gas phase is quite different from that in the solid phase at 77 K, we cannot exclude the possibility that the H atoms produced by the radiolysis or photolysis in the neopentane matrix at 77 K are thermal. In this case, the thermal H atoms react more easily with cyclohexane than with hydrogen halide, though the activation energy for the former reaction is 8 kcal/mol and that for the latter reaction is nearly zero.

(II) Possibility of H atom abstraction by a thermal radical in the neopentane matrix at 77 K.

Since the activation energies for the hydrogen atom abstraction reaction from alkanes by thermal atoms or radicals are 7—10 kcal/mol,[4,5] it may be concluded from the previous theory of reaction kinetics that the reaction does not occur at all at 77 K.

Recent findings,[21-23] however, indicate that thermal methyl radicals abstract hydrogen atoms from the solvent molecules even at 77 K. We have examined here the possibility that thermal methyl radicals react in *neo*-C_5H_{12}–alkane mixtures at 77 K. When *neo*-C_5H_{12}–C_2H_6(2 mol/100 mol of *neo*-C_5H_{12})–CH_3Br(0.1 mol/100 mol of *neo*-C_5H_{12}) is irradiated with UV light at 77 K, a CH_3 radical is formed by the photolysis of CH_3Br. The thermal CH_3 decays very slowly at 77 K. The half-life for decay is about 150 h, which is extremely long as compared with 0.2—0.3 h in 3-methylpentane at 77 K.[22,23] When the CH_3 radicals decrease, the formation of *neo*-C_5H_{11} or C_2H_5 radicals cannot be observed at all, while unknown radicals increase complementarily. Therefore it is concluded that the hydrogen atom abstraction reaction from alkane by thermal methyl radicals does not occur in the *neo*-C_5H_{12}–C_2H_6 mixture at 77 K.

(III) Selective hydrogen atom abstraction by H atoms in the i-C_4H_{10}–C_3H_8 mixture at 77 K.

When i-C_4H_{10} containing HI is irradiated with UV light at 77 K, the H atom produced by the photolysis of HI abstracts a hydrogen atom from the primary C–H bond of i-C_4H_{10} to form an i-C_4H_9 radical. When a small amount of C_3H_8 is added to the mixture, the H atom react selectively with the solute propane (Table 1 and Ref. 3) and the formation of the i-C_4H_9 radical is suppressed.

$$HI \xrightarrow{h\nu} H + I \quad (4)$$

$$H + i\text{-}C_4H_{10} \longrightarrow i\text{-}C_4H_9 + H_2 \quad (7)$$

$$H + C_3H_8 \longrightarrow C_3H_7 + H_2 \quad (8)$$

The H atom produced by the photolysis of HI has an initial kinetic energy of 20 or 41 kcal/mol, depending on whether the iodine atom is produced in the excited state or in the ground state. In the radiolysis of i-C_4H_{10}–HI, it was found that the H atom, which is produced by dissociative electron attachment to HI, preferentially abstracts the tertiary H atom from i-C_4H_{10}.[24]

$$e^- + HI \longrightarrow H + I^- \quad (9)$$

$$H + i\text{-}C_4H_{10} \longrightarrow t\text{-}C_4H_9 + H_2 \quad (10)$$

The H atom produced by dissociative electron attachment has a kinetic energy of 5—6 kcal/mol, if HI captures a thermal electron. Therefore it can be concluded that the hot H atom with high energy abstracts a pri-

mary H atom from i-C_4H_{10}, while the H atom with low energy abstracts a tertiary H atom. The hot H atom reacts selectively with C_3H_8 when C_3H_8 is present in the system.

(IV) Migration of H atoms in the crystal.

It can be summarized from the present and previous studies[1] that the reactive H atoms in the crystalline alkane at 77 K have the following characteristics: (a) The activation energy for the reaction of the H atoms with solute alkane is nearly zero, though that in the gas phase is 7—10 kcal/mol. The H atoms produced by radiolysis of neopentane at 77 K do not react with HI, though the activation energy for this reaction is nearly zero in the gas phase. (b) The selective reaction of H atoms in the neopentane–isobutane mixture occurs efficiently in the solid phase at 77 K, while it does not occur at all in the liquid phase.[1c] The selective reaction has been found only in polycrystalline matrices (Table 1).

At present we cannot give a clear answer to the question whether the reactive H atoms are thermal or hot. Though the possibility of hot H atoms cannot be excluded a priori, only the reaction of thermal H atoms has been discussed in the previous paper.[1c] The possibility of hot H atoms will be described here in order to supplement the previous discussion.[1c]

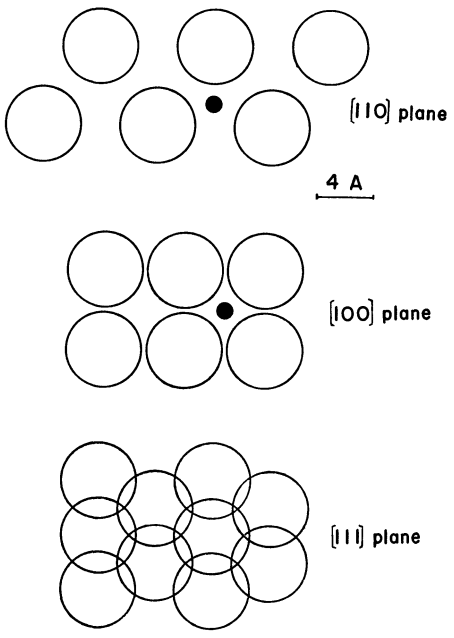

Fig. 5. Molecular arrangement of the three principal planes of fcc lattice of crystalline neopentane at 77 K.

One plausible explanation will be given by the idea of "channeling."[25-27] The crystalline structure of neopentane at 77 K consists of face-centered cubic unit cells with a lattice constant of 11.4 Å.[28] Since the chemical structure of neopentane is symmetrical, the structure is depicted here as a sphere. Projections of the molecular arrangements of the three principal planes of the fcc lattice of neopentane are shown in Fig. 5. A neopentane molecule is represented by a large circle, where a line of the circle is the most probable position of the electrons of H atoms in neopentane molecules. Top and second layers are depicted in the projections of the [110] and [100] planes, because the third and fourth layers are repetitions of the top and second layers. Top, second, and third layers are depicted in the projection of the [111] plane. A smaller circle, depicted by ●, represents a hot hydrogen atom with a Bohr radius. It is clear that the surface layers of the [110] and [100] orientations exhibit transparent regions to the incident hot H atoms. When hot H atoms produced by the radiolysis of neopentane or by the photolysis of hydrogen halide are incident upon the transparent regions of [110] and [100] planes, the hot H atoms may travel a long distance by a succession of glancing collisions with the channel walls of neopentane molecules and then react with a solute alkane which may exist as a defect in the neopentane crystal.

The selective hydrogen atom abstraction reaction by hot H atoms in neopentane–alkane mixtures is not observed in the liquid phase.[1c] This phenomenon can be explained by the channeling hypothesis. Since a random arrangement of molecules in the liquid phase does not contain transparent regions, *i.e.* channels, the hot H atom collides head-on with a solvent molecule in the liquid phase and loses its energy by chemical reaction or deactivation. It is expected from this hypothesis that the selective reaction will be found in the crystal, but not in the glass.

Radical Formation in the Radiolysis of Pure 2,2,3,3-Tetramethylbutane (TMB) and TMB–Alkane Mixture at 77 K. Gerola *et al.*[8] reported the ESR spectrum of γ-irradiated TMB at 77 K. Since $(CH_3)_3CC(CH_3)_2\dot{C}H_2$ (TMB·) and $(CH_3)_3CCH_2\dot{C}(CH_3)_2$ radicals are formed, they considered that first a C–H bond rupture occurs in the radiolysis of TMB and then the isomerization of the TMB· radical produces the $(CH_3)_3CCH_2\dot{C}(CH_3)_2$ radical. Shiraishi *et al.*[9] reported t-C_4H_9, $(CH_3)_3C\dot{C}$-$(CH_3)_2$, and TMB· radicals in the radiolysis of solid TMB. They considered that the free radicals are formed by C–C bond ruptures as well as C–H bond ruptures in the radiolysis of TMB.

The ESR spectrum in Fig. 3a consists of TMB· and an unidentified radical which has been ascribed to $(CH_3)_3CCH_2\dot{C}(CH_3)_2$[8] or a mixture of t-C_4H_9 and $(CH_3)_3C\dot{C}(CH_3)_2$.[9] When a small amount of alkane or olefin is added to TMB, the formation of the unidentified radical is suppressed and the solute alkyl radical is formed complementarily (Fig. 3b and c). Therefore it seems that the unidentified radical is neither formed by the isomerization of the TMB· radical nor by the direct C–C bond rupture, but by a secondary process of some active species which reacts also with the solute alkane or olefin.

The following observations obtained here show that the solute alkyl radical is not formed by the energy transfer from the irradiated TMB to the solute, but by the selective hydrogen atom abstraction by H atoms from the solute alkane.

(1) When TMB containing a small amount of propane is γ-irradiated at 77 K, the propyl radical is formed. The ionization potential of TMB has not been reported previously. But if we assume that the value is approximately the same as that of 2,2,4-trimethyl-

pentane, which is an isomer of TMB and has a structure similar to that of TMB, the ionization potential of TMB may be 9.86 eV,[29] which is lower than the ionization potential (11.07 eV)[29] of propane. The energy level of the first excited state of TMB is 8.0 eV,[30] which is lower than that (8.9 eV)[30] of propane. Therefore, assuming that the relative magnitude of the ionization potential and the first excited state is kept in the solid phase, the ordinary charge or excitation transfer from TMB to C_3H_8 cannot occur.

(2) When TMB containing a small amount of isobutene or propylene is irradiated with γ-rays at 77 K, the formation of the unidentified radical is suppressed, while t-C_4H_9 or C_3H_7 radical is produced complementarily by the addition of H atoms to isobutene or propylene.

(3) When TMB–i-C_4H_{10} (5 mol/100 mol of TMB)–HX (0.5 mol/100 mol of TMB) is irradiated with UV light at 77 K, the H atoms produced by the photolysis of hydrogen halide react selectively with i-C_4H_{10} to form the t-C_4H_9 radical (Table 1).

Therefore the mechanism of radical formation in the radiolysis of TMB at 77 K can be represented as follows:

$$\text{TMB} \rightsquigarrow \text{TMB}\cdot + \text{H} \quad (11)$$

$$\text{H} + \text{S} \longrightarrow (CH_3)_3CCH_2\dot{C}(CH_3)_2,\ t\text{-}C_4H_9, \text{ or } (CH_3)_3C\dot{C}(CH_3)_2 \quad (12)$$

$$\text{H} + \text{RH} \longrightarrow \text{R}\cdot + H_2 \quad (13)$$

Reactive H atoms produced by the decomposition of TMB (Reaction 11) react selectively with impurities (S) to form $(CH_3)_3CCH_2\dot{C}(CH_3)_2$, t-C_4H_9, or $(CH_3)_3C\dot{C}(CH_3)_2$ in the radiolysis of pure TMB. When an alkane (RH), such as C_3H_8, i-C_4H_{10}, or c-C_6H_{12}, is added to TMB, the H atoms react selectively with the solute to form an alkyl radical (R·).

The authors wish to express their appreciation to Professor Fausto W. Lima of Instituto de Energia Atômica in São Paulo for his encouragement. The authors also wish to express their appreciation to Professor Noriaki Ito and Dr. Kenji Morita of Nagoya University for their fruitful discussions.

Relation between Amounts of Chemisorbed Water and Ammonia on Zinc Oxide

Mahiko NAGAO and Tetsuo MORIMOTO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received June 7, 1976)

The adsorption isotherm of NH_3 was measured at 25 °C on ZnO surfaces with a controlled amount of surface hydroxyls. It was found that NH_3 can be chemisorbed at 25 °C on the dehydroxylated sites of ZnO in a 1:1 molecular ratio of adsorbed NH_3 to desorbed H_2O. H_2O can be chemisorbed for prechemisorbed NH_3 through exchange reaction to form surface hydroxyls and gaseous NH_3. The physisorption of NH_3 at 25 °C can take place only on a limited part of ZnO surfaces which were fully hydroxylated or ammoniated.

Adsorption studies with the use of NH_3 as a basic adsorbate provide valuable information on the acidic properties of solid surfaces. Many workers have endeavored to investigate the surface properties of silica–alumina and related compounds.[1-6] The principal technique employed was the infrared spectroscopy of NH_3 adsorbed on solid surfaces, giving information on the adsorbed state of the molecules. H_2O molecules are chemisorbed on metal oxides and form surface hydroxyls even at room temperature. They can be desorbed gradually by heating.[7-14] Thus, the surface acidity of a solid is expected to be considerably affected by the existence of surface hydroxyls.[1,15]

The amount of NH_3 adsorbed on hydrated surfaces of MgO or SiO_2 is larger than that on dehydrated ones, since the surface hydroxyls act as the adsorption sites for NH_3.[16,17] Blyholder and Richardson[18] concluded from infrared studies that the sites for chemisorption of NH_3 on α-Fe_2O_3 are the same as those for the chemisorption of H_2O. However, no quantitative relation between the amounts of chemisorbed NH_3 and desorbed hydroxyl has been given.

We have investigated the infrared spectroscopy of NH_3 and H_2O adsorbed on ZnO surfaces with controlled amount of surface hydroxyls.[19] It was found that the adsorbed state of NH_3 depends largely upon the amount of hydroxyls on the surface. We found that the chemisorption of CO_2 occurs on the dehydrated sites of ZnO in such a way that one molecule of CO_2 can be chemisorbed for the removal of two hydroxyls.[20,21] The surface hydroxyls on the fully hydroxylated $(10\bar{1}0)$ planes of ZnO having a wurtzite structure give rise to closed hydrogen bondings with each other, resulting in the appearance of discontinuity in the adsorption isotherm of H_2O because of weakened adsorption force of the surfaces for coming H_2O molecules.[22]

The present work has been undertaken to investigate quantitatively the adsorption of NH_3 on ZnO in connection with the amount of surface hydroxyls, *i.e.*, to investigate the relation between the amounts of chemisorbed NH_3 and dehydroxylated sites on the surfaces of ZnO with controlled amount of surface hydroxyls.

Experimental

Materials. The ZnO sample mainly used was Kadox15 (ZnO–K), prepared by the New Jersey Zinc Co., being the same as that used for infrared studies.[19] Another sample (ZnO–S) prepared by the Sakai Chemical Co. and employed for various examinations,[10,13,22-25] was used for the sake of comparing the data with those of ZnO–K. Both samples gave almost the same adsorption data (Table 1), though their transmittance for infrared beam differs substantially.[19,21]

Measurement of Specific Surface Area. The specific surface area of the samples was measured by the BET method with N_2 adsorption at the temperature of liquid N_2; assumption for the cross-sectional area of a molecule of N_2 was made to be 16.2 Å^2.

Measurement of Adsorption Isotherm. For samples pretreated at 450 °C in a vacuum of 10^{-5} Torr for 4 h, the adsorption isotherms of H_2O and NH_3 were determined volumetrically at 25 °C with a conventional adsorption apparatus equipped with greaseless cocks for NH_3 adsorption and oil-manometer for H_2O adsorption. The pretreatment of the sample at 450 °C *in vacuo* resulted in the removal of almost all the chemisorbed CO_2 and H_2O, leaving only a small amount of chemisorbed H_2O (1.00 OH groups/100 Å^2). The sample was then exposed to saturated H_2O vapor at 25 °C for 12 h, followed by evacuation at 25 °C, which left the fully hydroxylated surfaces with little amount of physisorbed H_2O.[10,13] The last sample was subjected to evacuation at various temperatures from 100 to 400 °C in order to obtain samples of different degrees of hydroxylation, which were used for the measurement of adsorption isotherms of NH_3.

Measurement of Surface H_2O and NH_3 Content. The amount of H_2O or NH_3 chemisorbed was determined by the successive-ignition-loss method.[11] The vapor liberated by heating the NH_3-adsorbed sample was analyzed in the following way. All the vapor evolved in a given temperature range, *e.g.*, 300—400 °C, was condensed in a trap kept in liquid N_2, reevaporated in a closed system at room temperature for measurement of the total pressure, and recondensed in a trap cooled at the dry ice–ethanol temperature at which the pressure of uncondensed gas of NH_3 was measured. After the sample was reevacuated at the dry ice–ethanol temperature, the remaining condensed H_2O, if present, was measured after reevaporation at room temperature. The same procedure was repeated by raising the temperature at appropriate intervals from 25 to 1000 °C. The surface H_2O content, which implies the amount of chemisorbed H_2O remaining on the surface, was calculated by summing the amount of H_2O evolved over the temperature indicated and by assuming that the H_2O content of the sample treated at 1000 °C is nil. The surface NH_3 content was similarly calculated.

Results and Discussion

Adsorption Isotherms of H_2O and NH_3 on ZnO. Figure 1 shows the adsorption isotherms of H_2O and NH_3 on the ZnO–K sample. Curves a and b are the adsorption isotherms of H_2O on the dehydroxylated and fully

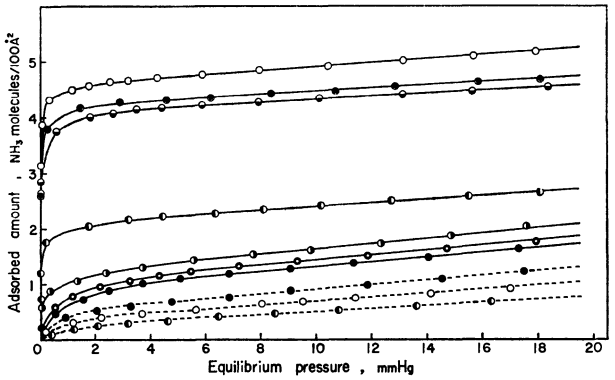

Fig. 3. Adsorption isotherms of NH_3 at 25 °C on differently hydroxylated ZnO prepared by degassing at various temperatures: ●, 25 °C; ◎, 100 °C; ◑, 200 °C; ◐, 300 °C; ◒, 350 °C; ⊙, 400 °C; ○, 450 °C. Solid line, first adsorption; broken line, second adsorption.

Recently, a similar exchange reaction was discovered on a system including H_2O vapor and the ZnO surface covered with chemisorbed CO_2, where CO_2 vapor was liberated from the surface in contact with H_2O vapor.[21]

Adsorption of NH_3 on ZnO with Controlled Amount of Surface Hydroxyls. The calculations (Table 1) suggest that one molecule of NH_3 can be chemisorbed on the sites formed by the desorption of H_2O. Figure 3 shows the adsorption isotherms of NH_3 at 25 °C on the ZnO samples on which the amount of surface hydroxyls was controlled by degassing the fully hydroxylated surfaces at different temperatures. Solid lines indicate the first adsorption isotherms and broken lines the second ones; some of the latter are omitted but they are all in this narrow range of adsorption amount. The results show that the amount of adsorbed NH_3 increases with increasing temperature of degassing and therefore with decreasing amount of the remaining hydroxyls. We can calculate the monolayer capacity of NH_3, $V_{m(h)}$, by applying the Langmuir equation to the isotherms (Fig. 3), and the amount of chemisorbed NH_3 by substracting the $V_{m(h)}$ value of the second adsorption from that of the first adsorption. The results obtained for the chemisorbed amount of NH_3 are plotted against the degassing temperature (Fig. 4), where the H_2O content of the same sample is also given. We see that the chemisorption of

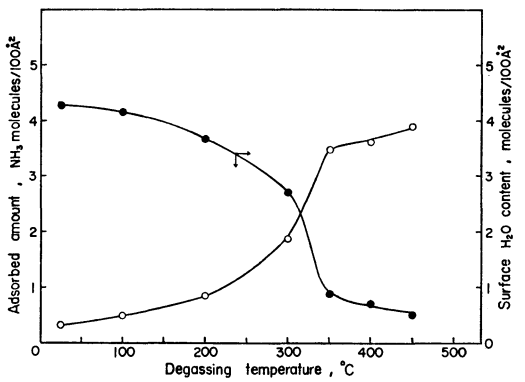

Fig. 4. Dependence of the amount of chemisorbed NH_3 and the surface H_2O content on degassing temperature.

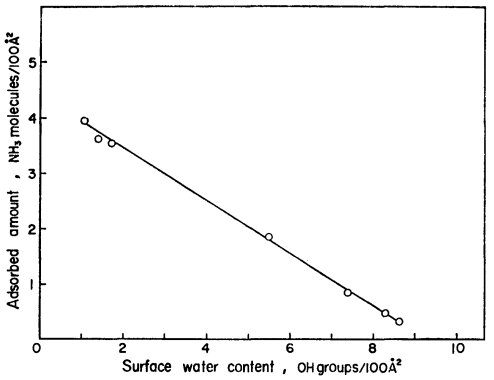

Fig. 5. Relation between the amount of chemisorbed NH_3 and the surface H_2O content.

NH_3 increases with the degassing temperature of the hydroxylated sample, a sharp increase being observed near 300—350 °C which corresponds to a sharp decrease in H_2O content of the sample, and that the sum of the H_2O content and the amount of chemisorbed NH_3 is almost kept constant. This can be seen more clearly from Fig. 5, where the amount of chemisorbed NH_3 is plotted against the remaining surface H_2O content, the linear relationship being observed between the two quantities. This strongly suggests that the chemisorption of NH_3 occurs on the dehydroxylated sites of ZnO in the ratio of one molecule of adsorbed NH_3 to one molecule of desorbed H_2O. A similar relation has been discovered on the chemisorption of CO_2 on ZnO surfaces.[20,21]

Physisorption of NH_3 on ZnO Surfaces. It might be of interest to infer the nature of a small number of physisorption sites for NH_3 at room temperature. The number of H_2O molecules physisorbed in the first layer on ZnO (Table 1) is identical to that of underlying hydroxyls,[13,22,25] while the number of physisorbed NH_3 molecules is less than half the number of underlying chemisorbed NH_3. For the surface hydroxyls, the number of physisorbed NH_3 molecules can be calculated from curve e (Fig. 1). This was found to be 1.50 molecules/100 Å^2, which is approximately the same as 1.35 for the surface with chemisorbed NH_3 (Table 1).

Infrared spectroscopy shows that the adsorption of NH_3 on the fully hydroxylated surface of ZnO takes place through hydrogen bonding and formation of NH_4^+ ions.[19] The hydroxylated (0001) or (000$\bar{1}$) planes of ZnO will be more active for physisorption of H_2O than the hydroxylated (10$\bar{1}$0) planes,[22] since they have isolated hydroxyls in contrast to the latter which have closed hydrogen bonding between surface hydroxyls. The former will also be more active for the physisorption of NH_3 than the latter, the sites on the surface defects such as corners, edges and steps being still more active. It seems that the adsorption of NH_3 occurs through hydrogen bonding on the isolated hydroxyls and through formation of NH_4^+ ions on the more active sites as stated above.

A Consideration on the Energy Efficiency of Agitation in Emulsion

Hisao HIDAKA, Shun'ichi NORO*, Akira TAKAMURA,* and Masumi KOISHI**

Department of Science and Engineering, Meisei University, Hodokubo, Hino-shi, Tokyo 191
**Meiji College of Pharmacy, Yato-cho, Tanashi-shi, Tokyo 188*
***Faculty of Pharmaceutical Science, Science University of Tokyo, Ichigaya Funakawara-machi, Shinjuku-ku, Tokyo 162*

(Received June 9, 1976)

The effects of mechanical factors on the energy efficieucy of agitation in o/w-type emulsions were investigated. The impeller diameters used were 49.0, 65.0, 80.1, and 89.9 mmϕ and the number of revolution was set at 200, 330, 400, 530, 660, or 812 rpm. The viscosity ratios (μ_d/μ_c) were 0.836: 1, 0.0861: 1, 0.000777: 1, and 0.000173: 1. The size of the dispersed liquid droplets was measured by the microphotographic method. The mean diameter of the droplets, their size distribution, and the agitation torque were determined, and the energy efficiency of agitation was evaluated. When the viscosity ratio was near 0.00861: 1, the energy efficiency of agitation showed a maximum. Furthermore, the energy efficiency decreased as the mean surface-volume diameter became smaller.

Agitation is one of the most important factors affecting the formation of emulsions when a specific emulsification method and specific emulsifying equipment are used:[1,2] more efficient agitation gives better emulsions. Now, the energy consumption related to agitation is considered to be due not only to the creation of new interfaces but also to setting the liquid in motion against viscous resistance in an emulsifying machine.[3,4] That is, the required input power of an agitator will depend upon various factors,[5] so it is very difficult to give a complete theoretical formula for agitation power. Even if the flow pattern is unknown, however, the relationship between agitation power and many mechanical factors may be formulated by the method of dimensional analysis, if the latter can be expressed in terms of such physical parameters as the diameter of the impeller and its rate of revolution.[6]

In this study, therefore, agitation power is first calculated from the torque value[7] and then the agitation energy[8] is evaluated as the product of agitation power and agitation time in the case of a liquid-liquid dispersion.[9] Secondly, the total interfacial energy of the emulsion is calculated as the product of the interfacial area and the interfacial tension.[8] The interfacial area is considered to be the most important factor[10] in the formation of emulsions and it is strongly affected by mechanical stirring. If the total interfacial energy and the agitation energy are calculated, the energy efficiency of agitation is then defined as the ratio of these two quantities.[8]

In this paper, therefore, the energy efficiency of agitation in the emulsion formation will be experimentally examined in relation to the impeller diameter, the revolution number, agitation torque, agitation power, the mean diameter of the dispersed phase, and interfacial tension.

Experimental

Equipment. The apparatus employed was the same one as described in our previous report.[11] The clear acrylate resin agitation tanks with 4 baffles were 150—200 mmϕ in diameter and 120—200 mm in depth. The stainless-steel agitation impeller (49.0—89.8 mmϕ) was of the standard Rushton-type with 6 blades. The tank was surrounded by a water jacket in order to keep the temperature of the liquid in it at 20.0 °C. The values of the tank diameter, the impeller diameter, and the number of revolution are summarized in Table 1.

TABLE 1. VALUES OF D_T, D_h, D_I, D_A, AND D_B OF THE APPARATUS EMPLOYED AND OF THE REVOLUTION NUMBER USED IN AGITATION

Tank size		Impeller size			Revolution number
D_T (mm)	D_h (mm)	D_I (mm)	D_A (mm)	D_B (mm)	N (rpm)
150	120	49.0	13.3	9.5	200, 330, 400,
		65.0	17.0	12.9	530, 660, 812
		80.1	19.9	15.9	
		89.8	24.9	17.1	
200	160	49.0	13.3	9.5	200, 330, 400,
		65.0	17.0	12.9	530, 660, 812
		80.1	19.9	15.9	
		89.8	24.9	17.1	
250	200	49.0	13.3	9.5	200, 330, 400,
		65.0	17.0	12.9	530, 660, 812
		80.1	19.9	15.9	
		89.8	24.9	17.1	

Measurement of Agitation Torque. The rotary torque meter used was of the Yamazaki SS-IR type (Yamazaki Seiki Laboratories) and was equipped with a stroboscope of the Sugawara PS-240 type (Sugawara Laboratory). The torque meter was tightly bound to the middle of the rotary shaft of the agitator, to prevent any precessional motion. Shortly after a liquid-liquid dispersion was formed, the torque was directly read with the light beam the stroboscope, which was exactly synchronized with the revolution of the impeller.

Measurement of Physical Properties. Mixtures of sodium silicate (Kishida Chemical Co.) and distilled water in varying ratios were used as the continuous phase. The total concentration of sodium silicate in the mixture ranged from 52.0 to 96.3% (w/w). The dispersed phase was made by mixing n-C_7H_{16} and CCl_4 in various volume ratios; the density was adjusted so as to be the same as that of the continuous phase (1.000—1.610 g/cm^3). Tween-20 (Tōhō Chemical Industry Co.) was employed as the emulsifying agent; its concentration was 0.1% (w/w). Interfacial tensions were measured by the ring method, and the viscosities of the liquid were measured by a rotating viscometer at 20.0±0.1 °C. The viscosity ratio, μ_d/μ_c, was widely varied, from 0.836: 1 to 0.000173: 1. The concentration of sodium silicate, the density of the continuous phase, the density ratio, the viscosity of the continuous phase,

the viscosity ratio, and the interfacial tension are summarized in Table 2.

Experimental Procedure. The experiments were carried out under the following conditions:

(1) The viscosity ratios, μ_d/μ_c, used were 0.836: 1, 0.0861: 1, 0.00861: 1, 0.000777: 1, and 0.000173: 1.

(2) The tank diameters were 150, 200, and 250 mmϕ.

(3) The impeller diameters were 49.0, 65.0, 80.1, and 89.8 mmϕ.

(4) The revolution numbers of 200, 330, 400, 530, 660, and 812 rpm were employed.

The agitation tank was filled with 1960 ml of an aqueous sodium silicate solution, the continuous phase, containing Tween-20 as an emulsifying agent. The impeller was set at the center of the tank. In the middle of the impeller were gently placed 40 ml of a mixed solvent, the dispersed phase, to form a spherical drop.

The concentration of the dispersed phase was kept at 2.0% (w/w). Sixty minutes after agitation started, the liquid was sampled with a glass tube (5 mmϕ).

Each sample was photographed with a Nikon AFM camera equipped with a microscope. The diameters of the droplets were measured with a micrometer scale which had been photographed and enlarged under the same conditions. The number of droplets measured was one thousand in all cases. The mean length diameter, the mean surface diameter, the mean volume diameter, the standard deviation, and the particle size distribution were calculated by means of a Seiko-301 computer.

Calculation of Agitation Torque and Agitation Energy. The agitation power, P, can generally be represented, as shown below, by a function of the impeller diameter (D_I), revolution number (N), density of continuous phase (ρ_c), and viscosity of continuous phase (μ_c), when the dimensional analysis is applied to the case of turbulent flow.[12]

$$P = N_p(\rho_c N^3 D_I^5) \tag{1}$$

Here N_p is called the power number and is a function of impeller shape and Reynolds number.[13]

When the angular velocity of the impeller and the agitation torque are ω (rad/s) and T (kgw m), respectively, the agitation power P (kgw m/s) can be written as:

$$P = \omega T \tag{2}$$

Since the angular velocity is given by

$$\omega = 2\pi N \tag{3}$$

the agitation power can be written as:

$$\omega = 2\pi NT \tag{4}$$

Accordingly, if the agitation torque and the revolution number are exactly measured, the agitation power can be evaluated from Eq. 4.

When the agitation power is expressed in watts, the agitation energy E_A is given as the product of agitation power P and agitation time θ:

$$E_A = P\theta \tag{5}$$

Combining Eqs. 4 and 5,

$$E_A = 2\pi NT\theta \tag{6}$$

Consequently, the agitation energy can be obtained explicitly from Eq. 6.

Determination of the Energy Efficiency of Agitation. When the total interfacial area of the emulsion increases from S_1 to S_2, the increase in the total interfacial energy is calculated by the following equation:

$$E_s = \gamma(S_2-S_1) = \frac{6\gamma}{\rho_d}\left(\frac{1}{d_{sv_2}}-\frac{1}{d_{sv_1}}\right) \tag{7}$$

In order to investigate to what extent the agitation energy affects the increase in the total interfacial energy, the energy efficiency of agitation is defined as:

$$\eta = \frac{E_s}{E_A} = \frac{\gamma(S_2-S_1)}{P\theta} \tag{8}$$

Equation 8 gives the ratio of the total interfacial energy to the agitation energy, this is named the energy efficiency of agitation in mechanical dispersion. If the energy efficiency can be calculated under a certain agitation condition, it will be very useful for the research which looks for the optimum physical and mechanical conditions to obtain a good emulsion.

Results and Discussion

Relationship between Agitation Torque and Agitation Intensity. Agitation torques were measured at various impeller sizes and revolution numbers for two tank diameters, under a constant viscosity ratio in the range of μ_d/μ_c=0.836: 1—0.000173: 1. Figure 1 gives the relation between the agitation torque and the value of $\rho_c N^2 D_I^5$. The viscosity of the continuous phase was in the range of 1.005—4860 centi-poise, and its Reynolds number ranged from 2.63 to 110000. The log-log plot gives roughly the following experimental equation:

$$\log T = \alpha \log(\rho_c N^2 D_I^5) + \beta \tag{9}$$

where α is the slope of the straight line and β is the intercept on the ordinate.

From the data of previous reports, it is also quite certain that the agitation torque is approximately proportional to the agitation intensity,[14] $\rho_c N^2 D_I^5$, as obtained above. Table 3 gives the values of α and β calculated from Eq. 9 by the least-squares method. The interrelation coefficients are also listed in the same table. From Fig. 1, it is found that the agitation torque has a slightly higher value over the whole range of agitation

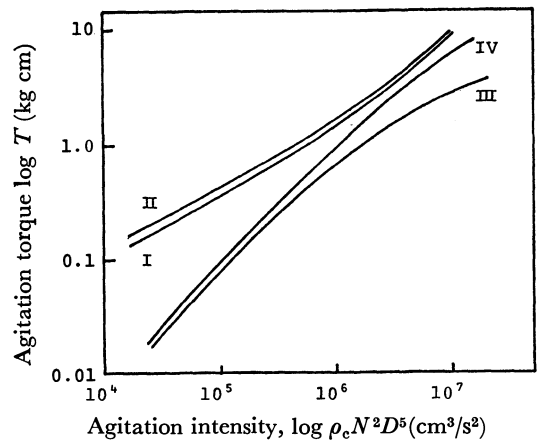

Fig. 1. Relation between agitation torque and agitation intensity at two tank diameters.
I: μ_c=4860 C.P., D_T=150 mmϕ, II: μ_c=4860 C.P., D_T=250 mmϕ, III: μ_c=1.005 C.P., D_T=150 mmϕ, IV: μ_c=1.005 C.P., D_T=250 mmϕ, Tween-20: 0.1% (w/w).

Table 3. The values of α and β calculated from Eq. 9 and of the interrelation coefficient

Viscosity ratio μ_d/μ_c	Tank diameter D_T (mm)	Slope α	Intercept at $\rho_c N^2 D_I^5=1$ β	Interrelation coefficient
8.36×10^{-1}	150	0.793	−5.003	0.991

	200	0.668	−3.740	0.997
	250	0.678	−3.788	0.996

intensity in the tank having a larger diameter. Furthermore, the agitation torque increases noticeably with increasing viscosity of the continuous phase, indicating that it is greatly affecting by the viscosity.

Effect of the Impeller Diameter on the Particle Size Distribution. The particle size distributions after 60 min of agitation, calculated from the length diameters of particles at three different impeller diameters, are shown in Fig. 2. At each impeller diameter, the size distribution had only one peak, at a particle size of about 12.5 μm. However, as the impeller diameter became smaller, the size distribution spread over a wider range of 5 to 50 μm.

Figure 3 shows changes in the mean surface-volume diameter of droplets at four impeller diameters and at three different viscosity ratios. At two viscosity ratios, 0.00861: 1 and 0.000173: 1, a plot of the mean surface-volume diameter against the impeller diameter gave

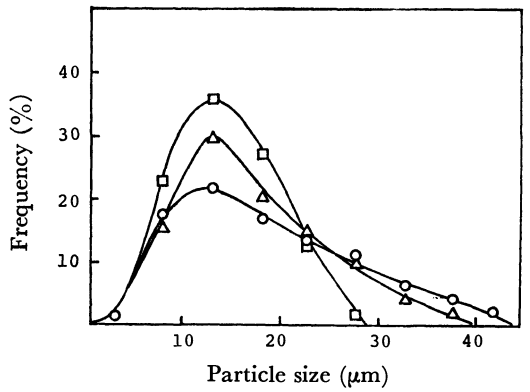

Fig. 2. Particle size distributions at three different impeller diameters.

approximately a straight line, while a convex curve was obtained at 0.836: 1, as illustrated in Fig. 3. The mean surface-volume diameter as measured at the same impeller diameter showed the smallest value when the viscosity ratio was 0.00861: 1. The relation between the mean surface-volume diameter and the diameter ratio of impeller to tank, D_I/D_T, is shown in Fig. 4. It was generally found that the mean surface-volume diameter decreased linearly with increase in the value of D_I/D_T. However, the slope of the straight line became smaller as both the impeller diameter and the viscosity of the continuous phase increased.

Effect of the Revolution Number on the Particle Size Distribution. The particle size distributions calculated by using the length diameters measured at three different revolution numbers are shown in Fig. 5. At each revolution number, the size distribution had only one peak, at a particle size of about 12.5 μm. However, the size distribution took a narrower and sharper shape with increase in the revolution number.

Figure 6 shows the relation between the mean surface-volume diameter of the droplets and the revolution number. When the continuous phase consisted of distilled water (μ_d/μ_c=0.836: 1) alone, a convex curve was observed. On the contrary, when the continuous phase consisted of a mixture of distilled water and sodium silicate (μ_d/μ_c=0.00861: 1 or 0.000173: 1), concave curves could be seen in the figure. In addition, the dependency of the mean surface-volume diameter on the viscosity ratio decreased remarkably at the highest revolution number (N'=812 rpm).

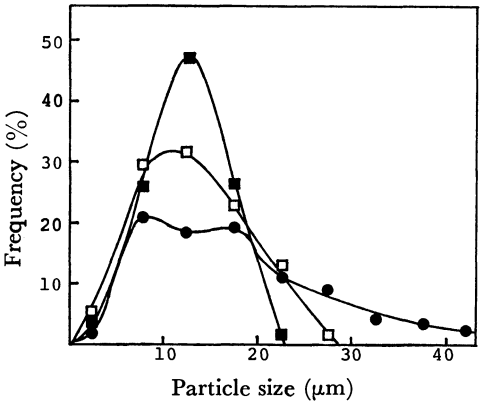

Fig. 5. Particle size distributions at three different revolution numbers.

○: μ_d/μ_c=0.836: 1, △: $\mu_d/\mu_c=8.61\times10^{-3}$: 1, □: $\mu_d/\mu_c=1.73\times10^{-4}$: 1.

Effect of the Viscosity Ratio on the Particle Size Distribution. Changes in the mean surface-volume diameter with viscosity ratio are shown in Fig. 7. At each revolution number, the mean surface-volume diameter increased abruptly as the viscosity ratio approached unity. This tendency was particularly notable at two low revolution numbers, 330 and 400 rpm. On the other hand, the curves had a minimum value at a viscosity ratio of 10^{-2}: 1. In the region where the viscosity ratio is below 10^{-2}: 1, the curves were almost flat.

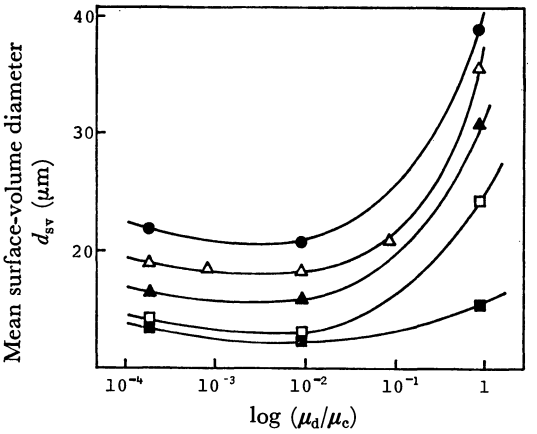

Fig. 7. Relation between mean surface-volume diameter and viscosity ratio.
D_I: 65.0 mm, D_T: 150 mm, θ: 60 min, Tween-20: 0.1% (w/w).
●: 330 rpm, △: 400 rpm, ▲: 530 rpm, □: 660 rpm, ■: 812 rpm.

Energy Efficiency of Agitation in Emulsion. In the present study, the agitation torque, the agitation power, and Reynolds number are as given below:

T: 0.025—8.5 (kgw cm), P: 0.045—73 (watt)

N_{Re}: 2.6—110000 (—)

Under the above conditions, we can now discuss the relation between the energy efficiency of agitation and the agitation conditions in order to obtain a valuable guide for finding the optimum conditions for making emulsions. In this study, the parameters characterizing agitation are chosen to be the viscosity ratio, the mean surface-volume diameter, and the agitation power.

First, the effect of the viscosity ratio on the energy efficiency is shown in Fig. 8. As can be seen from the figure, the relation gave a convex curve at each revolution number and each of the curves had a maximum value near μ_d/μ_c=0.00861: 1, except for the case of the high revolution number of 812 rpm. This means that the agitation power increases and, therefore, the agitation energy becomes higher as the viscosity of the conti-

nuous phase rises. On the other hand, the cohesion and coalescence of droplets during the agitation are obstructed by the high viscosity of the continuous phase, since subdivision of droplets occurs frequently and easily. Accordingly, when the viscosity ratio aproaches 0.00861: 1, the agitation energy and the interfacial energy are balanced.

Secondly, Fig. 9 shows the relation between the mean surface-volume diameter and the energy efficiency. It was found that the value of energy efficiency (μ_d/μ_c= 0.00861: 1 and 0.000173: 1) decreased linearly as the mean surface-volume diameter became smaller, while a concave curve was obtained at a viscosity ratio of 0.836: 1. This tendency can be interpreted as follows. For large droplets, break-up may be possible by only weak shear forces of agitation, while in small ones break-up may be impossible unless the droplets are subjected to strong shear forces of agitation. Thus, the probability for small droplets to burst may be low.

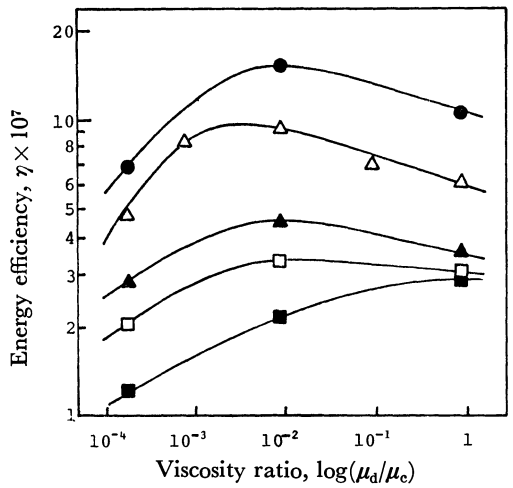

Fig. 8. Relation between energy efficiency and viscosity ratio.
D_I: 65.0 mm, D_T: 150 mmϕ, θ: 60 min, Tween-20: 0.1% (w/w).
●: 300 rpm, △: 400 rpm, ▲: 530 rpm, □: 660 rpm, ■: 812 rpm.

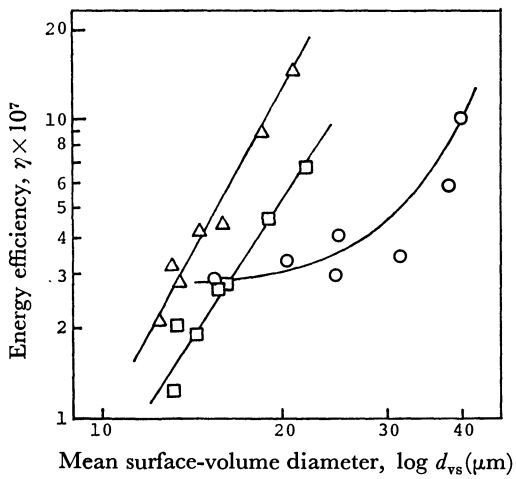

Fig. 9. Relation between energy efficiency and mean surface-volume diameter.
D_I: 65.0 mm, D_T: 150 mmϕ, θ: 60 min, Tween-20: 0.1% (w/w).
○: μ_d/μ_c=0.836: 1, △: $\mu_d/\mu_c=8.61\times10^{-3}$: 1, □: $\mu_d/\mu_c=1.73\times10^{-4}$: 1.

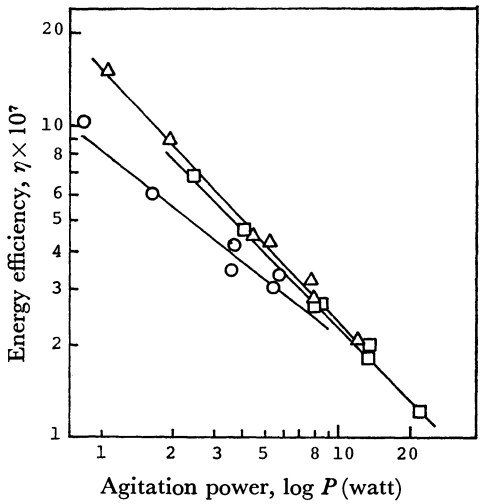

Fig. 10. Relation between energy efficiency and agitation power.
D_I: 65.0 mm, D_T: 150 mmϕ, θ: 60 min, Tween-20: 0.1% (w/w).
○: μ_d/μ_c=0.836: 1, △: $\mu_d/\mu_c=8.61\times10^{-3}$: 1, □: $\mu_d/\mu_c=1.73\times10^{-4}$: 1.

Finally, the relation between the energy efficiency and agitation power is shown in Fig. 10. The agitation power ranged from 1 to 20 watts. The energy efficiency decreased linearly as the agitation power increased. Thus, it is preferable to use as low an agitation power as possible in the formation of emulsions. In addition, the energy efficiency increased in the order of the viscosity ratios, μ_d/μ_c=0.00861: 1>μ_d/μ_c=0.000173: 1>μ_d/μ_c= 0.836: 1. Consequently, the effect of increasing the viscosity ratio is to decrease the rate of cohesion of the droplets, thereby raising the stability of the emulsions.

Copper Nuclear Quadrupole Resonance Spectra of Tris(tetramethylthiourea)copper(I) Tetrafluoroborate and Perchlorate

Yukio HIYAMA, Noriyuki WATANABE, and Eiji NIKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 10, 1976)

^{63}Cu, ^{65}Cu NQR spectra of tris(tetramethylthiourea)copper(I) tetrafluoroborate ($[Cu(tmtu)_3]BF_4$) and tris(tetramethylthiourea)copper(I) perchlorate ($[Cu(tmtu)_3]ClO_4$) have been observed. The resonance frequencies are 27.390 MHz and 25.341 MHz in the BF_4 compound, 27.390 MHz and 25.340 MHz in the ClO_4 compound (23.0 °C). These results indicate that the crystal structure of $[Cu(tmtu)_3]ClO_4$ is very similar to that of $[Cu(tmtu)_3]BF_4$ and the copper valence has sp^2 hybridization with $p\pi$–$d\pi$ bonding. The temperature dependence of ^{63}Cu NQR of $[Cu(tmtu)_3]BF_4$ has been studied from −100 to +100 °C. A discontinuous point has been discovered at −11 °C.

Recently, copper(I) coordination compounds have been studied because of biochemical or stereochemical interest.

Tris(thiourea)copper(I) tetrafluoroborate[4] is a sulfur-bridged dimer with tetrahedral Cu(I), while bis(thiourea)copper(I) chloride contains trigonal planar CuS_3 in a chain structure. Several copper NQR spectra[1-3] of these compounds, for example $KCu(CN)_2$, have been studied. $[Cu(tmtu)_3]BF_4$ is a trigonal planar Cu(I) monomer,[4] and its chemical bonding is also very interesting. So we synthesized $[Cu(tmtu)_3]BF_4$ and $[Cu(tmtu)_3]ClO_4$, and measured the copper NQR of these compounds. Furthermore, the temperature dependence of the resonance frequency in the BF_4 complex was carefully studied.

Experimental

Materials. Tetramethylthiourea and copper(II) tetrafluoroborate were commercially obtained. Copper(II) perchlorate was prepared from copper(II) carbonate and perchloric acid.

Preparation of Compounds. $[Cu(tmtu)_3]BF_4$ was prepared by a method given by Weininger and Amma.[4] $[Cu(tmtu)_3]ClO_4$ was prepared by the same method except for copper(II) perchlorate. These compounds are quite pale and polycrystalline.

Analysis. The composition of these compounds was ascertained by C–H–N analysis. $[Cu(tmtu)_3]BF_4$—Found: C, 33.22; H, 6.90; N, 15.69%. Calcd for C, 32.94; H, 6.63; N, 15.36%. $[Cu(tmtu)_3]ClO_4$—Found: C, 32.15; H, 6.57; N, 14.92%. Calcd for: C, 32.19; H, 6.48; N, 15.01%.

Spectrometer. The search spectrometer was a noise-controlled superregenerative spectrometer that was built in our laboratory. The frequency measurement was made by use of the regenerative spectrometer that has been described[5] by Tsukada *et al.* The total error may amount to approximately 2 KHz.

Results and Discussion

^{63}Cu NQR spectra of $[Cu(tmtu)_3]BF_4$ are shown in Fig. 1. The observed resonance frequencies of the two compounds at 23.0 °C are given in Table 1.

Since ^{63}Cu or ^{65}Cu has a nuclear spin $I=3/2$, only a single NQR frequency $\nu=(e^2Qq/2h)(1+(\eta^2/3))^{1/2}$ is observed. Thus we cannot determine the coupling constant and the asymmetric parameter independently without a Zeeman study.

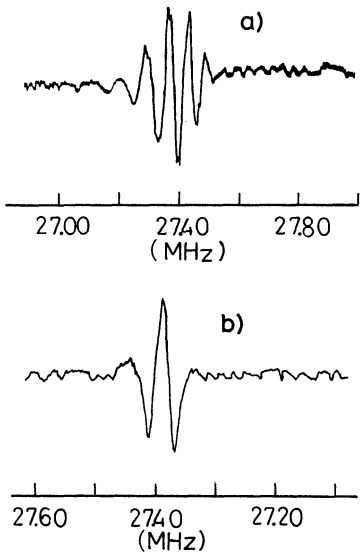

Fig. 1. ^{63}Cu NQR spectra of $[Cu(tmtu)_3]BF_4$. a) superregenerative spectrometer, b) regenerative spectrometer.

Table 1. Resonance frequency (MHz)

Compound	Temp	^{63}Cu	^{65}Cu
$[Cu(tmtu)_3]BF_4$	23.0°C	27.390	25.341
$[Cu(tmtu)_3]ClO_4$	23.0°C	27.390	25.340

According to the X-ray analysis by Weininger and Amma,[4] $Cu(tmtu)_3^+$ is distorted from a trigonal configuration. But we assume the asymmetric parameter η is zero for simplicity. On this assumption, we calculated the EFG (electric field gradient; q) of these compounds in Table 2. The EFG due to a 4p electron

Table 2. Value of the observed EFG

Compound	$q(\times 10^{15}$ esu cm$^{-3})$	
$[Cu(tmtu)_3]BF_4$	4.80	$Q(^{63}Cu)=-0.16$ barn
$[Cu(tmtu)_3]ClO_4$	4.80	
4p electron[6,a]	3.1	

a) determined from the constant of the magnetic hyperfine splitting, using the nuclear moment obtained by the nuclear induction method.

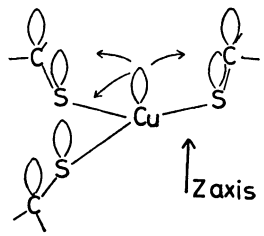

Fig. 2. $p\pi$—$d\pi$ bonding in $Cu(tmtu)_3^+$ ion. $3d_{z^2}$ (Cu) electron backdonates to π orbital (tmtu).

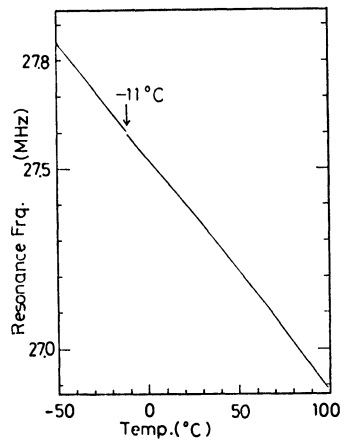

Fig. 3. Temperature dependence of ^{63}Cu NQR in $[Cu(tmtu)_3]BF_4$ (−50 to +100 °C). 28.763 MHz (−196 °C).

of the copper atom calculated by Korol'kov[6] is also shown in Table 2. So the EFG due to a sp^2 configuration (4s, 4p, $S=33\%$) is 3.1×10^{15} esu cm^{-3}. Since the BF_4^- ion is well separated from the copper atom, the EFG due to the negative ion is negligibly small.

The EFG observed around the copper atom in the $Cu(tmtu)_3^+$ is greater than that calculated for the sp^2 hybrid, quite covalent bond. We explain this by saying that the $3d_{z^2}$ electron of the copper backdonates to the π orbital of the ligands, and as a result the vacant $3d_{z^2}$ orbital enhances the EFG around the copper atom. Consequently we conclude that the EFG observed is due to sp^2 hybridization with $p\pi$–$d\pi$ bonding (Fig. 2).

The crystal structure of $[Cu(tmtu)_3]ClO_4$ has not yet been resolved. But we suggest that the crystal structure of the ClO_4 complex is close to that of the BF_4 complex, because of the similarity between the two EFG's.

Temperature Dependence. The temperature dependence of ^{63}Cu NQR in $[Cu(tmtu)_3]BF_4$ is shown in Fig. 3. The observed frequency gradient is very large ($d\nu/dT=-6.5$ kHz/°C) compared with that of Cu_2O (−3.3 kHz/°C). A discontinuous point has been discovered at −11 °C, but we could not ascertain any phase transition.

Associated Complex Formation in a Binary Solution and the Concentration Fluctuation: The Chloroform–Diethyl Ether System

Kenji IWASAKI, Yumiko KATAYANAGI, and Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received June 12, 1976)

The relations between the associated complex formation and the concentration fluctuation in a binary solution were derived. The concentration fluctuation of a chloroform–diethyl ether system was determined by observing light-scattering spectra at various concentrations. The theoretical values of the concentration fluctuation of this system were calculated from the proposed relation by the use of the shape and the number population of the associated complex, as determined from the infrared absorption intensity measurements. The observed and calculated concentration fluctuations agreed quite well.

The local fluctuation of the concentration is considered to afford information which is useful in understanding *mixing* from a molecular point of view. Based on this belief, a series of studies have been planned on analyses of the concentration dependence of the concentration fluctuation in solution through observation of the light-scattering spectra.[1)]

First, the relation between the concentration fluctuation and the Rayleigh intensities has been theoretically established.[2)] The concentration fluctuations for the chloroform–carbon disulfide system observed by this light-scattering method were compared with those obtained from the band-width of the infrared spectrum for the ν_1 fundamental of chloroform.[3)] The observed concentration dependence of the concentration fluctuation in the chloroform–carbon disulfide system indicated an associative tendency between the chloroform and carbon disulfide molecules.[2)]

The present report will concern itself with a study of the concentration dependence of the concentration fluctuation for a binary solution of the chloroform–diethyl ether system through the observation of light-scattering and infrared-absorption spectra. This system was chosen because (1 : 1)-complex formation between chloroform and diethyl ether has been well established with this dissociation equilibrium:

$$CHCl_3 : (C_2H_5)_2O \rightleftarrows CHCl_3 + (C_2H_5)_2O$$

Our main interest lies in the relation between the complex formation and the concentration fluctuation.

Theoretical

Ideal Solution. We start by considering the concentration fluctuation in an ideal binary solution whose components, A and B, behave as simple particles. In order to express the concentration fluctuation in terms of the number fluctuation of Component A, the volume area containing a constant quantity of Component B is to be considered. The volume of such an area changes in magnitude momentarily around its mean value. Therefore, the fluctuation of the mole fraction, x_A, of Component A arises from two factors: The exchange of A molecules between the inside and the outside of the area due to thermal motion of A molecules and the volume change in the area due to thermal motion of the B molecules. As the molecular number, n_B, of Component B is constant within the area under consideration, the fluctuation of x_A is expressed by the fluctuation of n_A. The mean fluctuation in n_A, $\langle(\Delta n_A)^2\rangle$, has been given as:[4)]

$$\langle(\Delta n_A)^2\rangle = \frac{kT}{(\partial\mu_A/\partial n_A)_{T,P}} \tag{1}$$

where k is the Boltzmann constant; T, the temperature; μ_A, the chemical potential of Component A, and P, the pressure. By definition,

$$x_A = \frac{n_A}{n_A + n_B} \tag{2}$$

Therefore,

$$dx_A = \frac{x_B}{n_A + n_B} dn_A \tag{3}$$

because n_B is constant. If the mixture of Components A and B is considered to be ideal, the chemical potential of Component A is given by:

$$\mu_A = \mu_A^\circ + kT \ln x_A \tag{4}$$

where μ_A° is the standard chemical potential. Equations 1, 3, and 4 are combined to become:

$$N\langle(\Delta x_A)^2\rangle = x_A(1 - x_A) \tag{5}$$

where

$$N = n_A + n_B$$

is the total number of molecules in the area under consideration.

Associated Complex Model. In the above discussion for an ideal solution, all the molecules in the solution are assumed to behave independently. In actual solutions, however, molecular species may be affected by a molecular species of the central molecule under consideration. This arises from the intermolecular interactions between the component molecules. In order to simplify the theoretical treatment, we wish to introduce the concept of an associated complex instead of considering intermolecular interactions explicitly. We will consider the formation of an associated complex, such as B_l or AB, in a binary solution of A and B components, where the suffix l indicates the number of molecules which form an associated complex. The associated complex, B_l or AB, is assumed to behave independently from the species A or B. In other words, the associated complex formation is considered to arise from strong intermolecular interactions, and the resultant complex is considered to have no interaction abilities with the other molecular species, A and B. Under these assumptions, we first calculate the concent-

ration fluctuation in a system of complete association, because such a system can be treated as a two-component system of A and B_l or A and AB.

Case I (A and B_l): Consider a case where strong intermolecular interactions are expected between B molecules in a binary solution of A and B molecules. We assume that a mixture of Components A and B is a two-component system of A molecules and associated complex molecules, B_l. If the effect of the volume difference between A and B_l is neglected, the binary mixture of A and B_l is an ideal solution. Therefore, the following relation is obtained directly from Eq. 5:

$$N'\langle(\Delta x_A')^2\rangle = x_A'(1-x_A') \tag{6}$$

where:

$$x_A' = \frac{n_A}{n_A+n_{B_l}} \tag{7}$$

and:

$$N' = n_A + n_{B_l} \tag{8}$$

and where n_A is the mean quantity of Component A in a small volume area which contains a constant number, n_{B_l}, of the B_l complex. As the $\Delta x_A'$, x_A', and N' which appear in Eqs. 6—8 are fictitious quantities, we have to rewrite these quantities in terms of real quantities, like Δx_A, x_A, and N. The true mole fraction, x_A, of Component A and the total number of molecules, N, in the volume range under consideration are expressed by these relations:

$$x_A = \frac{n_A}{n_A+ln_{B_l}} \tag{9}$$

and:

$$N = n_A + ln_{B_l} \tag{10}$$

From Eqs. 7—10, we obtain:

$$x_A' = \frac{lx_A}{(l-1)x_A+1}$$

or:

$$dx_A' = \frac{l}{\{(l-1)x_A+1\}^2}dx_A$$

and:

$$N' = \frac{(l-1)x_A+1}{l}N$$

Substituting the last three relations into Eq. 6, we finally obtain this relation:

$$N\langle(\Delta x_A)^2\rangle = -(l-1)x_A^3 + (l-2)x_A^2 + x_A \tag{11}$$

In Fig. 1 the results obtained from Eq. 11 are illustrated for various l values. The result for $l=1$ is identical with the result for an ideal binary solution of Eq. 5. It may be seen from the figure that the concentration fluctuation increases in magnitude as the association number, l, increases. The maximum of the fluctuation curve moves to the larger-mole-fraction side as the association number increases, until it arrives at $x_A=2/3$ for an infinite l. This may be understood reasonably by the following intuitive image. When x_A is large, that is, when n_B is small, a local concentration fluctuates mainly as a result of thermal motion of associated species in and out of the volume area. When x_A is small, on the other hand, a local concentration fluctuates mainly as a result of motion of non-associated species. The effect on the local concentration of the coming in and going out of one species may be supposed to be much larger in the former case than in the latter.

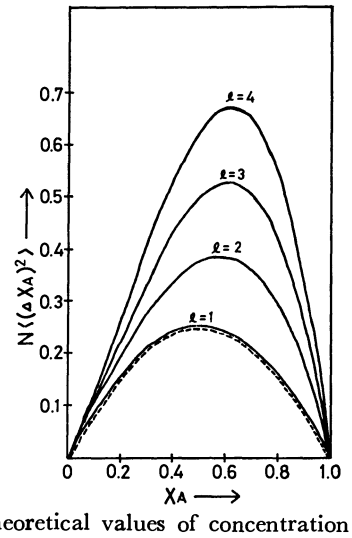

Fig. 1. Theoretical values of concentration fluctuation calculated from Eq. 11 for $l=1, 2, 3, 4$. The dashed line corresponds to the concentration fluctuation expected for an ideal binary solution.

Case II (A_l and B_l): Consider a case where strong intermolecular interactions are expected between A molecules and between B molecules. We assume that a mixture of Component A and B is a two-component system of associated complex molecules, A_l and B_l. Then, the calculation procedure is the same as that of Case I and the result is:

$$N\langle(\Delta x_A)^2\rangle = lx_A(1-x_A) \tag{12}$$

In Fig. 2 the results obtained from Eq. 12 are illustrated for various l values. In this case, the value of the concentration fluctuation is l times as large as that for an ideal binary solution.

Case III (A and AB): Consider a case where (1: 1) association between different species occurs in a binary mixture of Components A and B. The binary mixture of

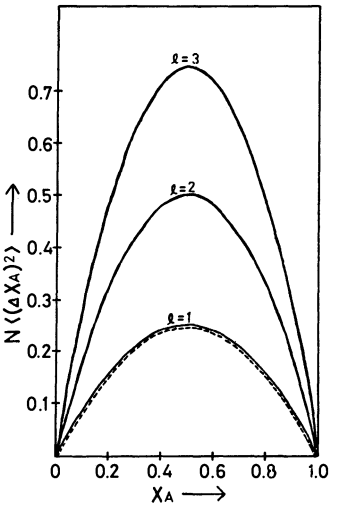

Fig. 2. Theoretical values of concentration fluctuation calculated from Eq. 12 for $l=1, 2, 3$. The dashed line corresponds to the concentration fluctuation expected for an ideal binary solution.

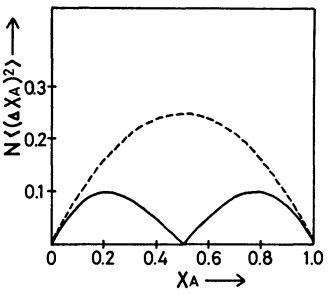

Fig. 3. Theoretical values of concentration fluctuation calculated from Eq. 13. The dashed line corresponds to the concentration fluctuation expected for an ideal binary solution.

A and B is composed of A and AB molecules for $x_A>0.5$ and of B and AB molecules for $x_A<0.5$. $N\langle(\Delta x_A)^2\rangle$ can be calculated similarly:

$$N\langle(\Delta x_A)^2\rangle = -2x_A{}^3 + 3x_A{}^2 - x_A \tag{13}$$

The results of Eq. 13 are shown in Fig. 3. It may be seen from the figure that the magnitude of the concentration fluctuation is smaller than that of an ideal solution for all the x_A values and that the concentration fluctuation has two maxima and takes a zero value at $x_A=1/2$.

Thus, we can understand roughly the relation between the shape of the associated complex and the concentration dependence of $N\langle(\Delta x_A)^2\rangle$ from the calculation of $N\langle(\Delta x_A)^2\rangle$ for the system of complete association. Association between the same species brings a larger $N\langle(\Delta x_A)^2\rangle$ than that of an ideal solution, while association between different species brings a smaller $N\langle(\Delta x_A)^2\rangle$.

Complex Formation with Association Equilibrium. Thus far we have discussed the concentration fluctuation for the system of complete association. In actual solutions, however, we have to take into account the association equilibrium between an associated complex and the component molecules. Consider a case where an association equilibrium of the form:

$$A + B \rightleftarrows AB$$

exists in a binary mixture of Components A and B. We assume that Components A and B and the AB complex behave as simple particles in the mixture. In other words, we consider an ideal ternary solution of A, B, and AB molecules. Under this assumption, we calculate the number fluctuation in the three-component system, and the result is reduced to the concentration fluctuation $N\langle(\Delta x_A)^2\rangle$.

Consider the fluctuations of the quantities, n_A and n_B, of A and B species in a small volume area which contains a constant number, n_{AB}, of the AB complex. The total number of molecules, N, in the volume area under consideration and the mole fraction, x_A, of Component A are expressed as:

$$x_A = (n_A+n_{AB})/N \tag{14}$$

and:

$$N = n_A + 2n_{AB} + n_B \tag{15}$$

From Eq. 14,

$$(\partial x_A/\partial n_A)_{n_B} = x_B/N \tag{16}$$

$$(\partial x_A/\partial n_B)_{n_A} = -x_A/N \tag{17}$$

Therefore,

$$\begin{aligned} dx_A &= (\partial x_A/\partial n_A)_{n_B}dn_A + (\partial x_A/\partial n_B)_{n_A}dn_B \\ &= (x_B/N)dn_A - (x_A/N)dn_B \end{aligned} \tag{18}$$

From Eq. 18, the mean square value of Δx_A is given as:

$$\langle(\Delta x_A)^2\rangle = \frac{x_B{}^2}{N^2}\langle(\Delta n_A)^2\rangle - 2\frac{x_Ax_B}{N^2}\langle\Delta n_A\Delta n_B\rangle + \frac{x_A{}^2}{N^2}\langle(\Delta n_B)^2\rangle, \tag{19}$$

In order to calculate $\langle(\Delta n_A)^2\rangle$, $\langle\Delta n_A\Delta n_B\rangle$, and $\langle(\Delta n_B)^2\rangle$, we define three imaginary mole fractions:

$$x_A' = n_A/N',\ x_B' = n_B/N',\ x_{AB}' = n_{AB}/N' \tag{20}$$

and:

$$N' = n_A + n_{AB} + n_B$$

In an ideal ternary solution of A, B, and AB, the corresponding chemical potentials are given as:

$$\mu_A = \mu_A{}^\circ + kT\ln x_A',$$

$$\mu_B = \mu_B{}^\circ + kT\ln x_B',$$

and:

$$\mu_{AB} = \mu_{AB}^\circ + kT\ln x_{AB}' \tag{21}$$

where $\mu_A{}^\circ$, $\mu_B{}^\circ$, and μ_{AB}° are the standard chemical potentials. Using the chemical potentials of Eq. 21, the number fluctuations are calculated to be:

$$\begin{aligned} &\langle\Delta n_A\rangle = \langle\Delta n_B\rangle = 0 \\ &\langle(\Delta n_A)^2\rangle = kTF_{BB}/(F_{AA}F_{BB}-F_{AB}{}^2) \\ &\langle(\Delta n_B)^2\rangle = kTF_{AA}/(F_{AA}F_{BB}-F_{AB}{}^2) \\ &\langle\Delta n_A\Delta n_B\rangle = -kTF_{AB}/(F_{AA}F_{BB}-F_{AB}{}^2) \end{aligned} \tag{22}$$

where:

$$F_{AA} \equiv \frac{\partial\mu_A}{\partial n_A},\ F_{BB} \equiv \frac{\partial\mu_B}{\partial n_B},\ F_{AB} \equiv \frac{\partial\mu_A}{\partial n_B} \tag{23}$$

Substituting Eq. 21 into Eq. 23, we obtain:

$$F_{AA} = \frac{kT(n_{AB}+n_B)}{n_AN'}$$

$$F_{BB} = \frac{kT(n_{AB}+n_A)}{n_BN'}$$

$$F_{AB} = \frac{-kT}{N'}$$

$$F_{AA}F_{BB}-F_{AB}{}^2 = \frac{(kT)^2n_{AB}}{n_An_BN'} \tag{24}$$

Now Eq. 22 can be rewritten as:

$$\langle(\Delta n_A)^2\rangle = \frac{n_A(n_A+n_{AB})}{n_{AB}}$$

$$\langle(\Delta n_B)^2\rangle = \frac{n_B(n_B+n_{AB})}{n_{AB}}$$

$$\langle\Delta n_A\Delta n_B\rangle = \frac{n_An_B}{n_{AB}} \tag{25}$$

The combination of Eq. 19 and 25 leads to:

$$\langle(\Delta x_A)^2\rangle = \frac{1}{N}x_A(1-x_A)(1-2n_{AB}/N)$$

Using the $x_{AB}=n_{AB}/N$ relation, we finally obtain the expression for the concentration fluctuation:

$$N\langle(\Delta x_A)^2\rangle = x_A(1-x_A)(1-2x_{AB}) \tag{26}$$

The x_{AB} can take the values from 0 to 0.5. When no complexes are formed, x_{AB} should be zero. Put $x_{AB}=0$, then Eq. 26 becomes:

$$N\langle(\Delta x_A)^2\rangle = x_A(1-x_A)$$

which is identical with Eq. 5. In the case of a complete (1:1) complex formation, x_{AB} can be replaced by either x_A or x_B. Then Eq. 26 is reduced to:

$$N\langle\Delta(x_A)^2\rangle = x_A(1-x_A)(1-2x_A)$$

which is identical with Eq. 13.

Experimental

In order to check the validity of the present theory, we have to observe the concentration fluctuation from the light-scattering spectra and the association equilibrium constant from infrared-absorption intensities.

Light-Scattering Measurements. The light-scattering spectra were recorded with a spectrometer designed and constructed in our laboratory.[1] The spectrometer is composed of a He-Ne gas laser source (NEC, GLG 108) and a pressure-scanning Fabry-Perot interferometer. The spacer between the interferometer etalons is 6 mm thick, giving a free spectral range of 0.82 cm^{-1} and an over-all instrumental half-width of about 0.042 cm^{-1}. The temperature inside the sample cell was maintained at 25.0±1.0 °C. The samples used in this experiment were commercially available reagents: Diethyl ether used without further purification and chloroform purified by column chromatography on alumina. The binary solutions of diethyl ether and chloroform were made dust-free by the use of a Millipore-filter FG (0.2 μm). The dust-free state was checked by comparing the observed L-P ratio of diethyl ether with the standard L-P ratio; the ratio of 0.41 was obtained by the present experiment, and that of 0.35 by Cummins.[5] The preparation (filtration and injection of a sample into cell) of the sample was repeated three times or more, and the sample which showed the best L-P ratio was used for further experiments. The refractive index of the sample was measured by means of a Shimadzu-Bausch-Lomb-Abbe refractometer 3L. The composition derivative of the refractive index at the mole fraction x was estimated from the difference between refrative indices measured at $x\pm0.05$.

Infrared-absorption Measurement. The chloroform-*d* was purchased from the Merck and Co., Ltd., and was dehydrated by zeorite A-3. The diethyl ether was purified by distillation with calcium hydride after the elimination of water by the use of zeorite A-3. The infrared-absorption spectra were recorded with a Perkin-Elmer 180 infrared spectrometer at the temperature of 25±1 °C. A sample cell with NaCl windows was used, and the thickness of a sample was determined by the interference-fringe method. The absorption spectra of the C-D stretching vibration for the frequency region of 2100—2400 cm^{-1} were measured under the resolution of 0.5 cm^{-1} and at the scanning speed of 7.0 cm^{-1}/min.

Results and Discussion

Light-scattering Spectra. The observed spectra for chloroform–diethy lether system are given in Fig. 4. It may be seem from the figure that the intensity of a Rayleigh line increases on passing from pure liquids to the binary solutions. The intensity of Brillouin lines, on the other hand, is largest for pure diethyl ether and smallest for pure chloroform. The intensity of a Rayleigh wing is weak and nearly constant along the frequency axis.

Concentration Fluctuation. Since the concentration fluctuation contributes only to a Rayleigh line, we can determine the concentration fluctuation from a Rayleigh intensity in a binary solution. In the previous report[2] we have shown the relation between the Rayleigh intensity of the light-scattering spectrum and the concentration fluctuation. The Rayleigh ratio for a Rayleigh line, $(R_{90})_R$, can be written approximately as:

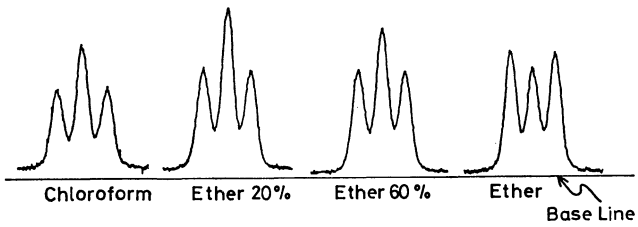

Fig. 4. Observed spectra for chloroform–diethyl ether system at 25 °C.

$$(R_{90})_R = \begin{pmatrix}\text{entropy-fluctuation}\\ \text{term}\end{pmatrix} + \begin{pmatrix}\text{concentration-}\\ \text{fluctuation term}\end{pmatrix}$$

Therefore, the concentration fluctuation, $V^*\langle(\Delta x_2)^2\rangle$, is given by:

$$V^*\langle(\Delta x_2)^2\rangle = (\lambda_i^4/\pi^2)\frac{1}{4n^2(\partial n/\partial x_2)^2_{T,P}}\{(R_{90})_R-(R_{90})_S\}, \quad (27)$$

where V^* is the fluctuation volume; x_2, the mole fraction of Component 2; λ_i, the wavelength of the incident light, and n, the refractive index. $(R_{90})_S$ is the Rayleigh ratio for entropy fluctuation and is given by:

$$(R_{90})_S = (\pi^2/\lambda_i^4)\frac{4kn^2T^2}{C_{Pg}\rho}(\partial n/\partial T)^2_{P,x_i} \quad (28)$$

where C_{pg} is the isobar heat capacity per gram, and ρ, the density.

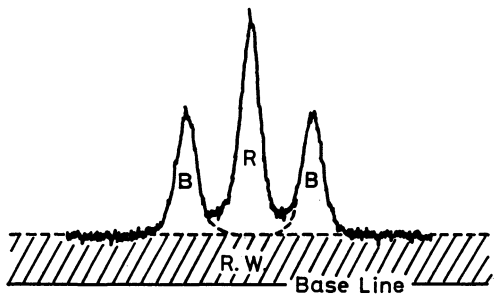

Fig. 5. Separation of Rayleigh line from light scattering spectra (schematic). R: Rayleigh line. B: Brillouin line. R.W.: Rayleigh wing.

The procedure of separating a Rayleigh line from Brillouin lines and a Rayleigh wing is illustrated in Fig. 5. A Rayleigh wing is assumed to be almost flat along a frequency axis. The outer halves of the Brillouin lines are assumed to be equal to non-overlapping line shapes. Thus, the intensity of a Rayleigh line was determined by eliminating the areas corresponding to the Rayleigh wing and the Brillouin lines.

Since the observed Rayleigh intensities are relative values, we have to express the observed relative intensities, I_R, in terms of Rayleigh ratios. A Rayleigh ratio is defined as Ir^2/I_0V_S, where I_0 is the incident-light intensity; I, the scattered-light intensity; r, the distance from scattering point to observing point, and V_S, the scattering volume. We first calculate $(R_{90})_S^{CHCl_3}$ for pure

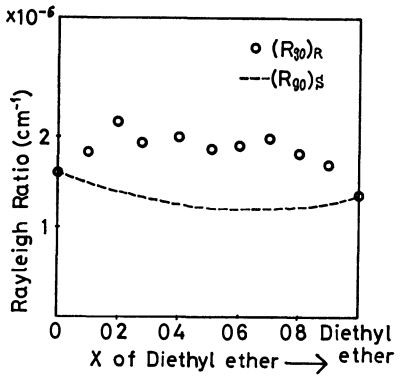

Fig. 6. Concentration dependence of Rayleigh intensity of chloroform–diethyl ether system. The open circles corresponds to $(R_{90})_R$ and the broken line $(R_{90})_S$.

chloroform by the use of Eq. 28. Then, the Rayleigh ratio for binary mixtures, $(R_{90})_R$, is calculated to be:

$$(R_{90})_R = I_R \times \frac{(R_{90})_S^{CHCl_3}}{I_R^{CHCl_3}} \tag{29}$$

where $I_R^{CHCl_3}$ is a relative Rayleigh intensity for pure chloroform. The calculated Rayleigh ratios are plotted by open circles in Fig. 6.

The theoretical values of $(R_{90})_S$ at each mole fraction were calculated by substituting the observed values of λ_i, n, T, ρ, and $(\partial n/\partial T)_{p,x_2}$, and C_{pg} values from the

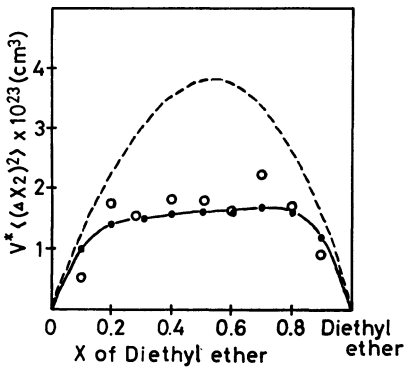

Fig. 7. Concentration dependence of concentration fluctuation for chloroform–diethyl ether system at 25 °C: ---; expected for an ideal binary solution, ○; observed by light scattering spectra, —●—●—; calculated from Eq. 26 by the use of the infrared data.

standard table[6] into Eq. 28 (see Table 1). Then, the fluctuation ability, $V^*\langle(\Delta x_2)^2\rangle$, was calculated at each concentration from Eq. 27. The calculated $V^*\langle(\Delta x_2)^2\rangle$ values are plotted by open circles in Fig. 7. The dashed line of Fig. 7 corresponds to the concentration fluctuation expected for an ideal binary solution. The procedure of converting $N\langle(\Delta x_2)^2\rangle$ into $V^*\langle(\Delta x_2)^2\rangle$ will be described later. It may be seen from the figure that the observed concentration fluctuation is smaller than that expected for an ideal binary solution throughout all concentrations. This tendency indicates the existence of molecular association, not between the same species (see Case I and II), but between different species (see Case III), in this mixture. Therefore, we will try to explain the observed concentration-fluctuation curve by the use of Eq. 26, because association equilibrium is taken into account in Eq. 26.

Determination of the Relative Population of (1: 1) Complex by Infrared-Absorption Measurements. The relative population of (1: 1) complex, x_{AB}, can be determined from the infrared-absorption-intensity measurement of the C-D stretching band (ν_1) of chloroform-*d*, because the ν_1 band increases in intensity in a diethyl ether solution by the formation of hydrogen bonding between chloroform-*d* and diethyl ether. The relative intensity of the ν_1 band of the chloroform-*d* in solution is defined as:

$$I_S = \frac{f_d}{l}\int_{band} \ln(I_0/I)\,d(\ln\nu) \tag{30}$$

in cm^{-1}, and the absolute intensities of the ν_1 bands of free and bonded chloroform-d are defined, respectively, as:

$$\Gamma_F = \frac{f_d}{C_F l}\int_{band} \ln(I_0/I)\,d(\ln\nu) \tag{31}$$

and:

$$\Gamma_B = \frac{f_d}{C_B l}\int_{band} \ln(I_0/I)\,d(\ln\nu) \tag{32}$$

in (cm^2/mole), where l is the thickness of the sample; C_F and C_B, the concentrations in moles per cm^3; I_0, the energy of the incident light; I, the energy of the transmitted light, and ν, the frequency of the light, and where the integration covers the whole band area. The subscript "B" refers to the chloroform-*d* forming a complex or to an associated complex. The f_d factor is

introduced to consider the intensity correction for the local-field effect,[7] which is defined as:

$$f_d = \frac{9n_D}{(n_D^2+2)^2} \tag{33}$$

where n_D is the refractive index of the sample. The three intensity parameters, I_S, Γ_F, and Γ_B, are related with each other as:

$$I_S = C_F\Gamma_F + C_B\Gamma_B \tag{34}$$

When chloroform-*d* and diethyl ether form a (1:1) complex, the analytical concentrations of free chloroform-*d* and diethyl ether, C_F° and C_E°, are related to the equilibrium concentrations by:

$$C_F = C_F^\circ - C_B \tag{35}$$

$$C_E = C_E^\circ - C_B \tag{36}$$

where C_E is the equilibrium concentration of diethyl ether. Notice that weak hydrogen bonding between chloroform-d molecules is neglected. Equations 34 and 35 are then combined to give:

$$I_S = C_F^\circ\Gamma_F + (\Gamma_B - \Gamma_F)C_B \tag{37}$$

Γ_F is directly measured in pure chloform-*d*, and I_S, in solution. As the frequency shift of the ν_1 band due to hydrogen bonding is about 10 cm^{-1}, ν_1 bands corresponding to the free and the bonded states overlap greatly with each other. Therefore, Γ_B cannot be determined directly from the intensity measurement of the ν_1 band corresponding to the bonded state. The value of Γ_B was obtained from the slope of the plots of I_S against C_F° in the low-concentration range of C_F° (see Fig. 8). It is assumed here that all the chloroform-*d*

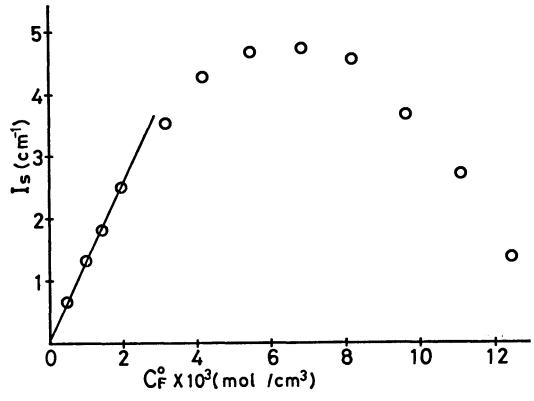

Fig. 8. I_S *vs.* C_F° plot for the chloroform-*d*-diethyl ether system.

molecules are hydrogen-bonded in the low-concentration range of C_F°. The Γ_B value of 1360 (cm^2/mol) and the Γ_F value of 109 (cm^2/mol) were obtained in the present work. As C_F° is known, C_B can be determined from I_S, Γ_F, Γ_B, and C_F° with the help of Eq. 37. C_B is reduced to x_{AB} as:

$$x_{AB} = \frac{C_B}{C_F^\circ + C_E^\circ} \tag{38}$$

Thus, we determined the relative population of the x_{AB} complex from the infrared-absorption measurements (see the 2nd column of Table 2).

a) The subscript "A" refers to diethyl ether.

Comparison of Observed and Calculated $V^*\langle(\Delta x_2)^2\rangle$. As x_{AB} is obtained experimentally, $N\langle(\Delta x_2)^2\rangle$ can be calculated from Eq. 26. $N\langle(\Delta x_2)^2\rangle$ is related to $V^*\langle(\Delta x_2)^2\rangle$ by this relation:

$$V^*\langle(\Delta x_2)^2\rangle = \frac{N}{\rho_n}\langle(\Delta x_2)^2\rangle = \frac{N}{(\rho/M_{AV.})N_A}\langle(\Delta x_2)^2\rangle \tag{39}$$

and:

$$M_{AV.} = x_{ether}M_{ether} + x_{CHCl_3}M_{CHCl_3} \tag{40}$$

where ρ_n is the number density; N_A, Avogadro's number; x_{ether} and x_{CHCl_3}, the mole fractions of diethyl ether and chloroform respectively, and M_{ether} and M_{CHCl_3}, the molecular weights. In Fig. 7 the $V^*\langle(\Delta x_2)^2\rangle$ values calculated from Eqs. 39 and 40, using x_{AB} values determined by the infrared-intensity measurements, are compared with those obtained from the light-scattering data. It may be seen from the figure that these two sets of $V^*\langle(\Delta x_2)^2\rangle$ values agree quite well; this shows the validity of the present theoretical treatment of the concentration fluctuation.

Concluding Discussion. The present theoretical study has shown that the concentration dependence of the concentration fluctuation in a binary solution is quite sensitive to the formation of local structures or intermolecular interactions. If molecules of same chemical species have a tendency to get together, the concentration fluctuation takes larger values than those in an ideal binary solution. On the other hand, if molecules of different chemical species have a tendency to get together, the concentration fluctuation takes smaller values than those in an ideal binary solution. For a binary solution of chloroform–diethyl ether, the theoretical treatment corresponds to the calculation of the concentration fluctuation in a ternary solution. The pivotal point of the theory is the introduction of the shape and the number population of an associated complex. In the case of a chloroform–diethyl ether system, the shape and the number population can be determined by means of the infrared-absorption spectra. The very good agreement between the concentration fluctuation observed by the light-scattering spectra and the concentration fluctuation calculated using the infrared data shows that intensity measurements of light-scattering spectra can determine the shape and the number population of an associated complex which is

formed in a binary solution. It must be emphasized that the concept of an associated complex was introduced so as to simplify the theoretical treatment; therefore, the concept of complex formation is a rather fictitious concept. In other words, the present theory postulates the usefulness of light-scattering measurements for the study of local structures which are formed in solutions by intermolecular interactions between component molecules.

The Primary Process of the Photochemical Formation of 1-Nitrenopyrene

(Received June 18, 1976)

The primary process of the photo-decomposition of 1-azidopyrene (Py–N_3) was studied with the aid of nanosecond time-resolved laser photolysis. An excited singlet 1-nitrenopyrene (Py–N) was identified as an intermediate for the formation of the ground triplet nitrene. The direct photo-decomposition of 1-azidopyrene occurs through Py–N_3* (singlet)→Py–N* (singlet)→Py–N (triplet). The lifetime of the excited singlet nitrene was found to be 22 ns at room temperature in benzene and was found to be slightly longer at 77 K.

Organic azides decompose photochemically or thermochemically to corresponding nitrenes which are known as intermediates in various kinds of reactions; cyclization, reduction, oxidation, and dimerization.[1,2] The ground states of the nitrenes produced by the photo-decomposition of the azides are known to be in the triplet state;[3-5] the eliminated nitrogen molecule is in the singlet state.[6] The existence of the triplet nitrenes as reaction intermediates has been confirmed by flash-photolysis experiments[7-11] and also by measurements of the electronic absorption and ESR spectra of the rigid solutions at low temperature.[3-5,12-16] From the spin conservation rule for the reaction, two paths are conceivable for triplet nitrene formation. One of them is the "singlet mechanism" occurring through the excited singlet nitrene (R–N*(singlet)) and the other is the "triplet mechanism" through the excited triplet azide (R–N_3(triplet)).

$$\begin{array}{ccccc} \text{R–N}_3 & \xrightarrow{h\nu} & \text{R–N}_3\text{*(singlet)} & \longrightarrow & \text{R–N*(singlet)} + \text{N}_2 \\ & & \downarrow & & \downarrow \\ & & \text{R–N}_3\text{ (triplet)} & \longrightarrow & \text{R–N (triplet)} + \text{N}_2 \\ & & \text{azide} & & \text{nitrene} \end{array}$$

From quenching experiment Reiser and Leyshon[17] showed that phenyl azide in the excited singlet state directly decomposes to the singlet nitrene and nitrogen before it is transferred to the triplet azide by intersystem crossing. In the flash-photolysis experiment Lehman and Berry[11] found that the decay time from the excited singlet state to the ground triplet state was shorter than 6 μs for some organic nitrenes, but they could not detect any singlet nitrenes. The excited singlet nitrenes spectroscopically observed so far are limited to such simple nitrenes as NH, NF, and NCN[18-23] in the gaseous state.

The main purpose of the present study is to observe directly the excited singlet 1-nitrenopyrene (Py–N) by nanosecond laser photolysis and to elucidate the mechanism of the photo-decomposition of 1-azidopyrene (Py–N_3). The compound is suitable for this purpose since the photo-decomposition quantum yield is very large and the absorption peaks characteristic of Py–N_3 and the ground triplet and excited singlet Py–N can easily be distinguished from one another.

**Present address: Institute for Molecular Science, Myodaiji, Okazaki 444.

Experimental

The details of laser photolysis experiment were reported elsewhere.[24] We used a coaxial type N_2 laser (peak power at 337.1 nm, 100 kW; pulse duration, 7 ns FWHM) as a light source for the direct excitation of samples. A monitor light (an EG and G FX-131 flash lamp) was detected with a Hamamatsu TV R666 photomultiplier and a Tektronix 465 oscilloscope.

The sensitized photo-decomposition experiment of Py–N_3 was carried out by using biacetyl as a triplet sensitizer. Biacetyl purified by distillation under a nitrogen atmosphere was excited with a dye laser at 423.0 nm (peak powder, 70 kW; pulse duration, 6 ns FWHM). For the excitation of dye, we constructed a travelling-wave type N_2 laser (peak power, 1 MW; pulse duration, 6 ns FWHM) originally designed by Godard.[25] The dye laser is of a Hänsch type,[26] a Bausch and Lomb grating of 600 grooves per mm and with a blaze wavelength of 500 nm being used. POPOP (1,4-bis(5-phenyl-2-oxazolyl)benzene) in a methanol–dioxane 1:1 mixture was used as a lasing dye. The photolysis system with the dye laser is shown in Fig. 1.

1-Azidopyrene[27] was purified with alumina column chromatography under red light. The effect of oxygen on the reaction was carefully investigated. We observed no oxygen effect on the primary process; therefore, the sample was used

with no deaeration. Since the overall reaction was completed with a single laser shot and gave a final product, sample solutions were either flowed through a sample cell or replaced by a new one at each experiment.

Results and Discussion

Direct Photolysis of Py–N_3 with an N_2 Laser. The time-resolved absorption spectra for the direct photolysis of Py–N_3 (3.6×10^{-4}M) in benzene were measured at room temperature. The results are shown in Fig. 2. We can see that two different absorptions appear at 450 nm and at 415 nm with an isosbestic point at 425 nm and that the 415 nm band increases in intensity with the decay of the 450 nm band. The time dependence of the absorption intensities was measured at various wavelengths. The results measured at 415, 430, and 450 nm are shown as examples in Figs. 3(a), (b), and (c), respectively. The absorption maximum at 415 nm of the long-lived component increases in intensity quickly at first, gradually approaches a constant value, and hardly exhibits any decay in the observed time range of 5 μs (Fig. 3a). On the other hand, the absorption maximum at 450 nm of the short-lived component decays quickly to reach a constant value (Fig. 3c). The intensity at 430 nm near the isosbestic point is almost time-independent (Fig. 3b). The absorptions of both components overlap each other in the observed wavelength region. But, by the deconvolution of oscilloscope traces we could determine the rise-time constant for the long-lived component to be 4.5×10^7 s^{-1} and the decay-time constant for the short-lived component to be 4.4×10^7 s^{-1}. Both values agree well with each other. This leads us to the conclusion that the short-lived component is the precursor of the long-lived component.

The absorption spectrum of the long-lived component

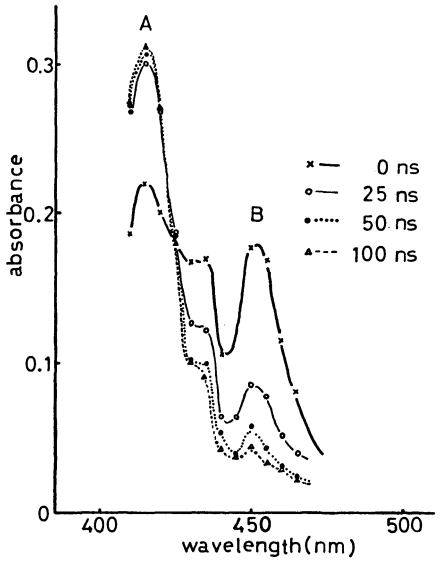

Fig. 2. Time-resolved transient absorption spectra for the direct decomposition of Py–N_3 (3.6×10^{-4} M in benzene): —×—, immediately after; —○—, 25 ns after; ···●···, 50 ns after; and ···△···, 100 ns after an N_2 laser pulse reached its maximum intensity.

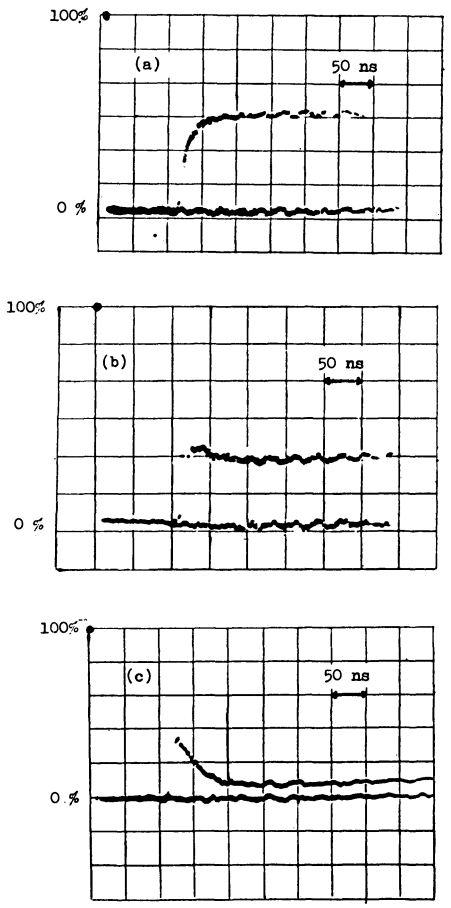

Fig. 3. Oscilloscope traces of transient absorption intensities in the direct photo-decomposition of Py–N_3 observed at (a) 415 nm, (b) 430 nm, and (c) 450 nm.

is the same as that of the ground triplet Py–N observed by Yamaoka *et al.*[10] Therefore it is concluded that the ground triplet Py–N is produced through the short-lived species with the absorption maximum at 450 nm.

The molar extinction coefficient at 450 nm of the short-lived component was determined to be $\approx2\times10^4$ cm^{-1} M^{-1} from comparison with that of the $T_1\leftarrow T_0$ absorption at 415 nm.[10] This value was estimated on the reasonable assumption that all the short-lived component molecules were transferred to T_0.

$T_1\rightarrow T_0$ Fluorescence of Nitrene. At the liquid nitrogen temperature, Py–N was produced photochemically with the N_2 laser and its emission was observed for the solution in the methylcyclohexane–isopentane 1 : 1 mixed solvent with the result shown in Fig. 4. The emission spectrum holds a mirror-image relationship to the $T_1\leftarrow T_0$ absorption spectrum of the ground triplet nitrene. This means that the observed emission is due to the $T_1\rightarrow T_0$ fluorescence of Py–N. The fluorescence-decay time was found to be shorter than 7 ns. Therefore the lifetime of the excited triplet states of Py–N is much shorter than the lifetime of the 450 nm species (22 ns). This clearly demonstrates that the precursor (the 450 nm species) of the ground triplet nitrene is not the excited triplet nitrene.

Quenching Experiment. In order to elucidate the role of the triplet state in the photo-decomposition of

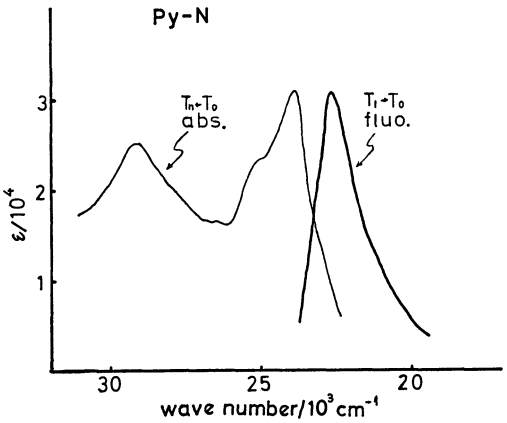

Fig. 4. The $T_1 \rightarrow T_0$ fluorescence (77 K) and absorption spectra of Py-N. The absorption spectrum is taken from Ref. 10.

$Py-N_3$, we examined the effect of triplet quenchers. The lowest triplet state of $Py-N_3$ has never been observed spectroscopically,[28] but its energy may roughly be estimated to be 56—46 kcal/mol. This is because in most of the organic azides the lowest triplet state is located 20—30 kcal/mol lower than the singlet state[29] and the singlet state energy (E_S) is 76 kcal/mol for $Py-N_3$. Thus, 1,3,5-cycloheptatriene ($E_T \approx 50$ kcal/mol), *trans*-stilbene ($E_T = 47$ kcal/mol), and oxygen can be used as triplet quenchers for the photo-decomposition of $Py-N_3$. The quenching experiment using these three molecules as quenchers exhibited no definite effect. Therefore, we concluded that the main reaction path is not *via* the triplet $Py-N_3$ and that the singlet mechanism is applicable to the direct photo-decomposition of $Py-N_3$. Lewis and Saunders[30] also observed no effect of the triplet quencher upon the direct photolysis of some alkyl azides.

Sensitized Photolysis of $Py-N_3$ with a Dye Laser. In order to obtain further support for the singlet mechanism, we induced the N_2 elimination reaction by the selective excitation to the triplet state of $Py-N_3$. Biacetyl ($E_S = 65.0$, $E_T = 56.0$ kcal/mol) is one of the sensitizers for the triplet excitation of $Py-N_3$ (see Fig. 5). We selectively excited biacetyl at 423.0 nm with a dye laser. The reaction occurred and the ground triplet nitrene was produced efficiently. This was confirmed by detecting the $T_1 \leftarrow T_0$ absorption at 415 nm. The oscilloscope trace for this experiment is shown in Fig.

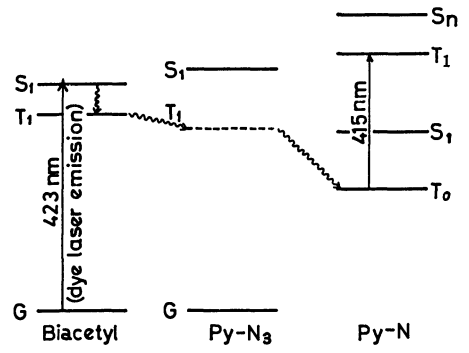

Fig. 5. Energy level diagrams of $Py-N_3$, biacetyl, and Py-N.

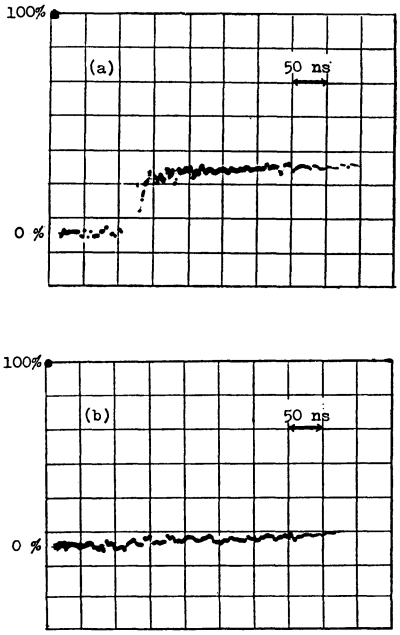

Fig. 6. Oscilloscope traces of transient absorption intensities in the sensitized decomposition of $Py-N_3$ (8.7×10^{-2} M in benzene) observed at (a) 415 nm and (b) 450 nm.

6(a). We can see that in the sensitized photolysis of $Py-N_3$ the short-lived absorption at 450 nm can not be observed (Fig. 6(b)).

The present experimental results of the lifetime of the excited triplet nitrene, the effect of the triplet quenchers on the photo-decomposition, and the sensitized photolysis completely obviate the triplet mechanism for the direct photo-decomposition of $Py-N_3$ and support the singlet mechanism. This means that the short-lived species with the absorption at 450 nm is the excited singlet state of either $Py-N_3$ or Py-N. In general, the lifetime of the excited singlet state of azide can be expected to be much shorter than 7 ns (the limitation of the time resolution of the present experimental apparatus), in view of the fact that it is not fluorescent. The observed lifetime is 22 ns for the 450 nm species. This safely eliminates the possibility that the 450 nm species is the excited singlet state of $Py-N_3$. Thus, the absorption band at 450 nm is due to an excited singlet state of Py-N.

$S_1 \rightarrow T_0$ Fast Intersystem Crossing of Py-N. The excited singlet nitrene is relaxed by the $S_1 \rightarrow T_0$ intersystem crossing to the ground triplet nitrene with a lifetime of 22 ns. The singlet nitrene is known as a strong hydrogen abstracting agent in protic solvents. In benzene, however, we did not detect 1-aminopyrene. The excited singlet Py-N in this solvent dimerizes to form azo compounds (*cis*- and *trans*-azopyrene) after the relaxation to the ground triplet Py-N.[10] Furthermore, we observed that the lifetime becomes longer (34 ns) only slightly in a rigid solution (methylcyclohexane–isopentane = 1 : 1) at 77 K. These results lead us to the conclusion that the lifetime is not determined by the chemical reaction rate but mainly by physical processes such as intersystem crossing. Lehman and Berry[11] estimated the rate of intersystem crossing for the excited singlet phenyl-

nitrene and naphthylnitrene to be faster than 6 μs but could not succeed in observing the nitrenes spectroscopically. The present experiment is the first direct observation of the excited singlet state of organic nitrene in solution.

The authors would like to express their thanks to Dr. Tsuguo Yamaoka, Chiba University, for his kindness in preparing 1-azidopyrene.

Vibration Spectra and Rotational Isomerism of Chain Molecules. I. Methyl Propyl Ether, Ethyl Propyl Ether, and Butyl Methyl Ether

Takehiko SHIMANOUCHI, Yoshiki OGAWA, Masahiro OHTA, Hiroatsu MATSUURA, and Issei HARADA

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 18, 1976)

The Raman and infrared spectra of methyl propyl ether, ethyl propyl ether, and butyl methyl ether were measured for the gaseous, liquid, glassy and crystalline states. The normal vibration frequencies were calculated, a consistent set of force constants explaining the frequencies of basic aliphatic ethers being assumed. The rotational isomerism was studied and the following conclusions were obtained. (1) Only the all-*trans* form exists in the crystalline state. (2) Another form which takes the *gauche* conformation about the OC–CC axis and the *trans* conformation about the CC–CC and CO–CC axes exists in the glassy state. (3) Other forms also exist in the liquid state. These results confirmed that the repulsive force between nonbonded hydrogen atoms was one of the important factors influencing the stability of molecular conformations. The stable conformations of the ether molecules were correlated with those of polyether chains.

The existence of rotational isomers has been clearly shown from the observation of Raman spectral changes on crystallization of 1,2-dichloroethane[1] and the rotational isomerism of small molecules has been studied in detail for various compounds.[2–4] The quantum mechanical treatment has also shown that the approximation of rotational isomerism can be practically applied.[5]

The rotational isomers of longer chain molecules have not yet been fully explored, since infrared and Raman spectra show too many bands to be assigned to each of possible rotational isomers. Recently we succeeded in estimating the force constants of chain molecules consisting of the CH_3, CH_2, O, S, F, Cl, Br, and I units and in calculating the vibrational frequencies of possible rotational isomers accurately enough to give reliable band assignments for longer chain molecules.[6]

This procedure provides us with a reliable method of determining the rotational isomers existing in the solid, liquid and other states. Accordingly, we started a series of research in which the rotational isomerism of longer chain molecules was studied. This paper is the first of this series and deals with the isomerism of methyl propyl ether $CH_3OCH_2CH_2CH_3$, ethyl propyl ether $CH_3CH_2OCH_2CH_2CH_3$ and butyl methyl ether $CH_3OCH_2CH_2CH_2CH_3$ and the results are correlated with those of other ethers[7–11] and the stable conformations of polyether chains.[12,13]

Notation

The conformation of a chain molecule is expressed with respect to the backbone axes and the symbols c, g^+, s^+, t, s^-, and g^- are used for the approximate internal-rotation angles of 0, 60, 120, 180, 240, and 300°, respectively,[3,14,15] where c, g, s, and t are the abbreviations of *cis*, *gauche*, *skew*, and *trans*. For saturated compounds, t, g^+, and g^- are stable.[2,4,16] In this series of papers, we use the generic symbols T, G, and G′ to represent the conformation of rotational isomers, since some of the molecular conformations expressed by t, g^+ and g^- are indistinguishable by vibrational spectroscopy. The symbol T corresponds simply to t, and G and G′ correspond to one and the other of g^+ and g^-. Thus, for example, g^+g^+ and g^-g^- are represented generically as GG, and g^+g^- and g^-g^+ as GG′. The conformations of longer chain molecules are defined by arranging the conformation symbols, T, G, and G′. Table 1 shows the generic names for accessible rotational isomers of the molecules which are studied in this series of papers.

Experimental

Samples of methyl propyl ether, ethyl propyl ether, and butyl methyl ether were purchased from Tokyo Kasei Kogyo Co., Ltd. and were distilled prior to the measurements. The Raman and infrared spectra were measured for the gaseous, liquid, glassy and crystalline states.

The Raman spectra were recorded on a JEOL JRS-400D spectrophotometer with a Coherent Radiation CR-3 argon ion laser in the region below 1600 cm^{-1}. A multireflection accessory and a gas cell with a heater were used for the measurements of the spectra in the gaseous state. The Raman spectra in the liquid state were measured at room and lower temperatures. The glassy state was obtained by putting into liquid nitrogen the sample enclosed in an ampoule and cooling it rapidly, and the crystalline state by inserting a copper wire in the sample and cooling it slowly with liquid nitrogen.

The infrared spectra were recorded on a Hitachi EPI-G2 double beam grating spectrometer in the region 1600—400 cm^{-1} and on a Hitachi EPI-L double beam grating spectrometer in the region 700—250 cm^{-1}. For the measurements in the region 700—250 cm^{-1}, the spectrometer was flushed with dry air to get rid of the interference of water vapor absorptions. The spectra in the gaseous state were measured with a 10 cm gas cell with KBr windows in the region 1600—400 cm^{-1}. For the measurements of the spectra in the liquid state, a 0.025 mm fixed cell with KBr windows and a variable cell with KRS-5 windows were used. The infrared spectra in the glassy and crystalline states were measured by the method previously reported.[17]

Normal Coordinate Treatment

The normal coordinate treatment of the unbranched ethers (see Table 2) was carried out with a computer program NCTB2[6] and a HITAC 8700/8800 computer system at the Computer Center of the University of Tokyo. The calculation made it possible to assign the observed Raman and infrared bands to individual rotational isomers and to determine a consistent set of

The least-squares calculation begins with the simplest ethers given in the first step and the first set of orce constants is determined so as to give the best fit between the observed and calculated frequencies. This set of force constants gives the definite vibrational assignments of the ethers given in the second step and the second set of force constants is subsequently determined from the observed frequencies in this step in addition to those in the first step. By repeating this procedure, the final set of force constants is obtained. The figures in parentheses give the numbers of observed frequencies used for the least-squares calculation.

The observed frequencies of the CH and CD stretching vibrations are not included in the calculation and accordingly the force constants associated with these vibrations are not refined.

a) Refs. 7, 10a, 10b, 11, and 21. b) Refs. 7, 9, 10b, 10c, and 22. c) This study. d) This study and Ref. 7. e) Refs. 10a, 10b, and 11. f) Refs. 10a and 10b. g) Refs. 10a and 11b. h) Refs. 9 and 10c. i) Refs. 9, 10b, and 10c. j) Refs. 10b and 10c. k) Refs. 12, 13, 24, and 25. l) Ref. 13.

The following spectral features are observed for the three ethers in common. (1) The spectra in the various states are distinctly different, especially in the 600—200 cm^{-1} region of the skeletal deformation and torsional vibrations and in the 1200—800 cm^{-1} region of the skeletal stretching and the methyl and methylene rocking vibrations. (2) The spectral pattern of the crystalline state is the simplest and the smallest number of bands is observed. (3) In the glassy state, more bands appear in addition to those which persist in the crystalline state. (4) The liquid-state spectra have further more bands. As temperature is lowered, the intensities of the additional bands decrease rapidly relative to those of the bands which persist in the glassy state. (5) The gaseous-state spectra are essentially the same as the corresponding liquid-state spectra at room temperature.

In the following subsections, the rotational isomerism of the individual ethers is described.

Methyl Propyl Ether. Since this molecule has two internal-rotation axes associated with the rotational isomerism, there are five possible isomers, TT, TG, GT, GG, and GG′, as given in Table 1. The observed and calculated frequencies in the 600—250 cm^{-1} region are compared in Fig. 3.

The spectra in the crystalline state show that only the TT form exists. The number of the observed bands is just what is expected for one form. The frequencies, especially in the region below 600 cm^{-1}, can only be explained by the TT form.

The glassy-state spectra show that the TT and TG forms coexist. The bands at 506, 357, and 308 cm^{-1} which appear newly in the glassy state can only be explained by the TG form.

In the liquid and gaseous states, the observed spectra are explained by the coexistence of the TT, TG, GT and GG forms. The Raman band at 375 cm^{-1} and the infrared band at 495 cm^{-1} are assigned to the GT form, while the weak Raman band at 530 cm^{-1} in the gaseous state and the Raman and infrared bands at 285—292 cm^{-1} in the liquid and gaseous states are assigned to the GG form. The existence of the GG form is also confirmed by the observation of the Raman and infrared bands at 852 cm^{-1} which are assigned only to this form.

It is not likely that the GG′ form exists, since no Raman or infrared bands to be assigned to this form are detected. Furthermore, the distance between the two terminal methyl groups is too short for the GG′ form to be stable.

Ethyl Propyl Ether. This molecule has two C–O axes and a C–C axis which determine the molecular conformation. Accordingly, fourteen rotational isomers listed in Table 1 are derived as possible. Of these, the forms with a sequence of GG′ conformation, *i.e.* TGG′, GG′T, GGG′, GG′G, and GG′G′ are rejected because of the same reason as stated above for the GG′ form of methyl propyl ether.

Figure 6 indicates that the Raman and infrared

a) VS: very strong, S: strong, M: medium, W: weak, VW: very weak, vb: very broad, b: broad, sh: shoulder. The broadness of the band shapes in the gaseous state does not always allow us to correlate the individual bands in the liquid state to those in the gaseous state. Only approximate correlations are made in such cases and in other cases of similar situations. b) The band is assigned preferentially to the isomer(s) given by boldface. For the notation and definition of the local symmetry coordinates, see Ref. 26.

spectra and the calculated results show that the liquid-state spectra are explained by the TGT, TGG, and GTG forms in addition to the TTT and TTG forms which persist in the glassy state.

Existence of the GTT and GTG′ forms is uncertain, since all of their calculated frequencies are almost coincident with those of the other forms mentioned above. The GGT and GGG forms do not seem to exist in the liquid state, since no bands are observed around their characteristic frequencies of about 470 cm^{-1}.

Butyl Methyl Ether. This molecule has two C–C axes and a C–O axis associated with the rotational isomerism. Accordingly, fourteen isomers listed in Table 1 are derived as possible. The GG′T, GG′G and GG′G′ forms are unlikely because of the same reason as stated for methyl propyl ether. However, the TGG′ and GGG′ forms are not ruled out, since unlike the GG′ sequence of the CO–C–CC part in methyl propyl ether or ethyl propyl ether, the GG′ sequence of the OC–C–CC part is not expected to give rise to very large steric hindrance.

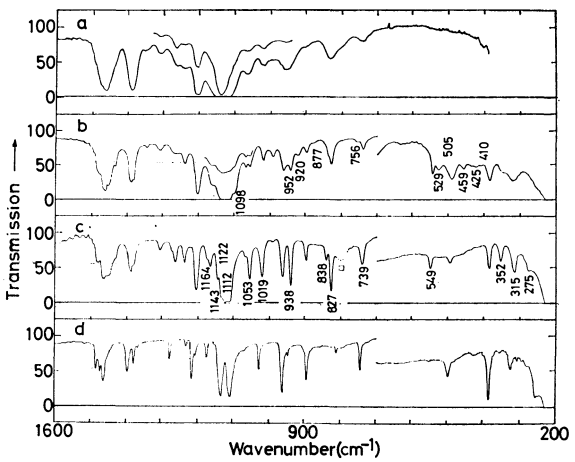

Fig. 8. Infrared spectra of butyl methyl ether.
a: Gas, b: liquid, c: glass, d: crystal.
The symbols are explained in the caption of Fig. 1.

The comparison with the calculated results (Fig. 9) shows that the crystalline-state spectra can be explained only by the TTT form and the glassy-state spectra by the TTT and TGT forms. The spectra in the liquid state have several new bands. Their frequencies are close to the frequencies calculated for the TTG, GTT, and GTG forms. In the liquid-state infrared spectrum,

a: Liquid, b: glass, c: crystal.
The symbols are explained in the caption of Fig. 1.

several weak bands are observed in the region 450—400 cm^{-1}, which are not assignable to the isomers mentioned above. Accordingly, there are possibilities that other forms such as TGG, GGT, TGG' ,GTG', GGG, and GGG' isomers exist in the liquid state. The Raman band at 525 cm^{-1} and the infrared band at 529 cm^{-1} are assigned to either one or both of the TGG and TGG' forms.

Rotational Isomerism. In Table 6, the rotational isomerism of the ethers studied in this work is summarized, together with that of ethyl methyl ether and diethyl ether which has been established in earlier studies.[7,9-11] The symbol $\tilde{G}$ is used to specialize the *gauche* conformation about the C–C axis directly adjoining the O–C axis.

Discussion

The following results were obtained for the three ethers in common. (1) Only the all-*trans* form exists in the crystalline state. (2) An additional form coexists in the glassy state. This form takes the *gauche* conformation ($\tilde{G}$) about the OC–CC axis and the *trans* conformation about other axes. (3) More forms exist in the liquid state than in the glassy state. The temperature dependence of the Raman intensities indicates that the additional forms are much less stable than the two forms which persist in the glassy state, while the energy difference between the latter two is not appreciable. (4) It is likely that the molecules in the gaseous state take the same conformations as in the liquid state.

The stability of the *trans* conformation over the *gauche* conformation may be explained, in a way similar to the case of paraffins, in terms of the weaker nonbonded interactions. In fact, it has been shown that the *trans* conformation about the CO–CC axis is more stable than the *gauche* conformation by 1.1—1.5 kcal/mol as obtained for ethyl methyl ether[10a,11a,11c] and diethyl ether.[9,10c] The existence of the all-*trans* form in the crystal is ascribable also to the requirement of the molecular packing which is determined primarily by intermolecular forces.

In addition to the all-*trans* form, the second isomer with the $\tilde{G}$ conformation exists in the glassy state of the three ethers at liquid nitrogen temperature. This isomer was found to be as stable as the all-*trans* form in the liquid state. The stability of the $\tilde{G}$ conformation is also shown by the fact that ethylene glycol dimethyl ether $CH_3O–CH_2–CH_2–OCH_3$ takes the T$\tilde{G}$T conformation in the crystalline state.[7,23] Thus, it is now established that the $\tilde{G}$ conformation (*gauche* about the OC–CC or OC–CO axis) is much more stable than the *gauche* conformation about other axes such as CC–CC and CO–CC.

The stability of the $\tilde{G}$ conformation is understood in the following way by taking the case of the $C_1–O–C_2–C_3–C_4–C_5$ bond system. When the $C_1O–C_2C_3$ or $C_2C_3–C_4C_5$ axis takes the G conformation, appreciable repulsive forces are expected between the nonbonded hydrogen atoms attached to C_1 and C_3, or between those attached to C_2 and C_5. On the other hand, the $\tilde{G}$ conformation about the $OC_2–C_3C_4$ axis does not give rise to such forces, since the hydrogen atoms attached to C_4 have no counterpart hydrogen atoms. The absence of this type of nonbonded interaction is suggested to be one of the principal factors to stabilize the $\tilde{G}$ conformation.

In connection with the stable $\tilde{G}$ conformation, it is important to examine the structure of polyethers.[12,13]

It has been shown that poly(oxyethylene) $(-OCH_2-CH_2-)_n$ and poly(oxytrimethylene) $(-OCH_2CH_2CH_2-)_n$ have several crystal modifications. In the most stable modification, the molecule takes the $T\tilde{G}T$ conformation for the series of O–C–C–O bonds in the former polymer and the $T\tilde{G}\tilde{G}T$ conformation for the series of O–C–C–C–O bonds in the latter polymer. In other modifications, the poly(oxyethylene) molecule takes the TTT conformation, and the poly (oxytrimethylene) molecule takes the $TT\tilde{G}TTT\tilde{G}'T$ and $(TTTT)_2$ conformations for the series of O–C–C–C–O–C–C–C–O bonds. These facts suggest that the $\tilde{G}$ conformation plays an important role in stabilizing molecular conformations of crystalline polymers.

Carbon Monoxide Oxidation over Chromium Sesquioxide. I. Nature of Oxygen Adsorbed on Cr_2O_3

Masayoshi KOBAYASHI and Haruo KOBAYASHI

Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received August 4, 1975)

The nature of oxygen species adsorbed on Cr_2O_3 surface in the temperature range 131—163 °C was studied in detail by application of the transient response method with simultaneous measurements of the electrical conductivity of the catalyst as a p-type semiconductor. The distribution of oxidation power of the adsorbed oxygen species was also measured. The mode of the distribution curve of oxidation power indicates that the oxygen can be classified into two groups which differ in oxidation power as well as in the catalytic activity for the oxidation of CO. From the comparison between the results of the transient response and the oxidation power measurements, it is concluded that the rapidly and slowly adsorbed oxygen groups observed by the transient response method correspond to those of oxygen species of higher and lower oxidation power, respectively. Kinetic analysis of the conductivity response curve caused by the adsorption of oxygen leads to the conclusion that the dissociative adsorption of oxygen associated with electron transfer from the catalyst takes place simultaneously on two different kinds of adsorption sites at substantially different rates.

The adsorption of oxygen on Cr_2O_3 has been studied by a number of investigators[1,2] with special reference to the nature of adsorbed oxygen. It is widely accepted that the adsorption of oxygen on the surface is dissociative, even at room temperature. However, infrared studies[3,4] of the adsorbed oxygen on Cr_2O_3 revealed that there exist several different adsorption bands due to the different vibrations of bonds between the surface cation and oxygen, produced as a results of the dissociative chemisorption. The existence of the variety of surface oxygen may result in a complexity of reactions in which the surface oxygen takes part.

In order to provide necessary information on the role of adsorbed oxygen participating in the CO oxidation over Cr_2O_3, this paper deals with the nature of surface oxygen species and their activity for this reaction. The transient response method was used together with measurement of the distribution of oxidation power of the surface oxygen species.

Experimental

The chromium sesquioxide was prepared by decomposing chromium trioxide in an air flow at 450 °C for 5 h. The X-ray diffraction analysis of the sample indicated that the sample was in the form of α-Cr_2O_3. The sample used as the catalyst was in 24—32 mesh granule and was found to have a BET surface area of 21 m^2/g. The catalyst is a p-type semiconductor under the whole range of experimental conditions, showing an increase in electrical conductivity with increasing amount of adsorbed oxygen.

The experiments were carried out with either oxidized or reduced catalysts. The oxidized catalyst was prepared by pretreatment in a stream of O_2(20%)-N_2 mixture at 131 °C for more than 24 h and the reduced catalyst was prepared by reduction with a CO(6%)-nitrogen stream at the same temperature until no carbon dioxide in the effluent stream was detected. The electrical conductivity of the oxidized catalyst thus prepared was constant and no change in the conductivity could be observed with prolonged oxidation. The conductivity thus attained was 3.2×10^{-6} ohm^{-1} cm^{-1}. For the reduced catalyst, the electrical conductivity was found to be negligibly small as compared to that of the oxidized catalyst.

Commercial CO, CO_2, and N_2 were carefully purified through a dry ice-methanol trap to remove water vapor. A Pyrex glass tube reactor containing 55.2 g catalyst was immersed in an oil bath. The temperature of the catalyst bed was kept uniform within $\pm$0.1 °C at desired temperatures.

A flow system was employed in all the experiments and the total flow rate of the gas stream was always kept constant at 160$\pm$2 ml/min. In applying the transient response method, the concentration of one or two components in the inlet gas stream was changed stepwise by using nitrogen as a balancing gas. The reaction conditions were always chosen in such a way that the total conversion of carbon monoxide did not exceed ten percent in all the runs.

The gases were analyzed by gas chromatography and the conductivity of the catalyst bed was measured with a d.c. bridge. The amount of surface oxygen species was analyzed with a potassium iodode solution as a reducing agent and the distribution of oxidation power was determined by measurements at various pH's. More detailed descriptions of the transient response method,[5,6] conductivity measurement[5] and the analysis of surface oxygen species[7-9] can be found elsewhere.

Results and Discussion

Nature and Amount of Surface Oxygen Species. The nature of oxygen species adsorbed on the metal oxides varies a great deal with respect to the oxidation power and catalytic activity as in the case of NiO,[8] MnO_2,[5,7] and Pb_3O_4.[10] In order to determine the catalytically active oxygen species on Cr_2O_3 surfaces for carbon monoxide oxidation, the distribution of oxidation power of the surface oxygen species was measured with a potassium iodide solution at various pH for the catalysts exposed to various gas stream. The results are shown in Fig. 1. The amount of oxygen species on the oxidized surface shows a bimodal distribution with respect to the oxidation power similar to those adsorbed on MnO_2[5] and Pb_3O_4[10] (curve I, Fig. 1). One group of oxygen species has an oxidation power (O.P) higher than 9.0 and another with one lower than 9.0. We designate the surface oxygen species in the two groups O_s^h and O_s^l, respectively.

When the oxidized surface was exposed to a stream of CO(6%)-N_2 mixture for 30 min at 163 °C, the

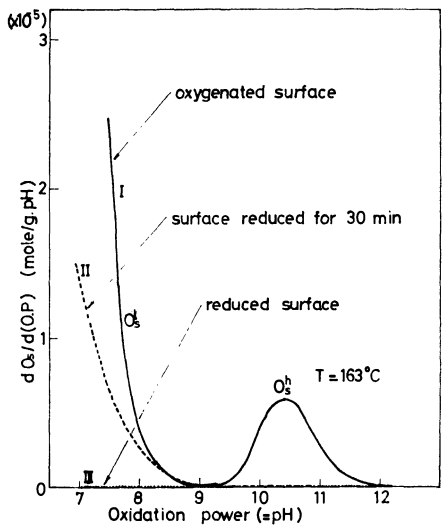

Fig. 1. Variation of the distribution of oxidation power by the reduction with CO.

newly measured distribution curve showed complete disappearance of O_s^h accompanying an appreciable decrease of O_s^l (curve II, Fig. 1). The partly reduced catalyst showed no variation in the amount of O_s^l when it was kept standing in pure nitrogen stream for different periods of time, indicating that no transformation between O_s^l and O_s^h took place.

When the oxidized surface was completely reduced for 24 h by the same gas mixture until no carbon dioxide was detected in the effluent gas stream, no more oxygen species were detected by the KI method on this reduced surface (curve III, Fig. 1).

Based on these results it may reasonably be concluded that both O_s^h and O_s^l are active for the reaction with carbon monoxide and the rate of the reaction is high with O_s^h and low with O_s^l.

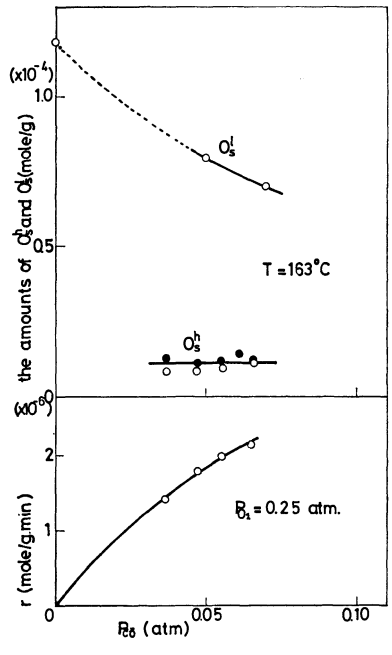

Fig. 2. The amounts of O_s^h and O_s^l and the rate of CO_2 formation on Cr_2O_3 as a function of P_{CO}.

The total amount of the surface oxygen species was determined with hydrazine solution,[7] which is a stronger reducing reagent than potassium iodide solution, and the amount was found to be 1.3×10^{-4} mol/g.

After the steady states of the reaction were attained at 163 °C with the feed streams of various partial pressure of carbon monoxide, the amounts of O_s^h and O_s^l existing on the surface were analyzed. The results are shown in Fig. 2 together with the reaction rate at each steady state. In this case, the amount of O_s^l was determined as the difference between the total amount determined by the hydrazine method and the amount of O_s^h determined by the potassium iodide method. The amount of O_s^h remains constant irrespective of the partial pressure of carbon monoxide in the feed, with which the reaction rate varies considerably (Fig. 2). The open and solid circles for O_s^h curve represent the repeated runs, indicating the satisfactorily good reproducibility of the data. The amount of O_s^l, on the other hand, decreases with increasing partial pressure of carbon monoxide in the feed stream. The results suggest that the rate of the reproduction of O_s^h from gaseous oxygen is sufficiently rapid as compared with the rate at which O_s^h is removed by the reaction with carbon monoxide, while the rate of the reproduction of O_s^l is not great enough and eventually the amount of O_s^l decreases with increasing partial pressure of carbon monoxide, where the reaction rate are higher. The deviation of the reaction rates from the first-order dependence in carbon monoxide can be explained by the diminution of O_s^l.

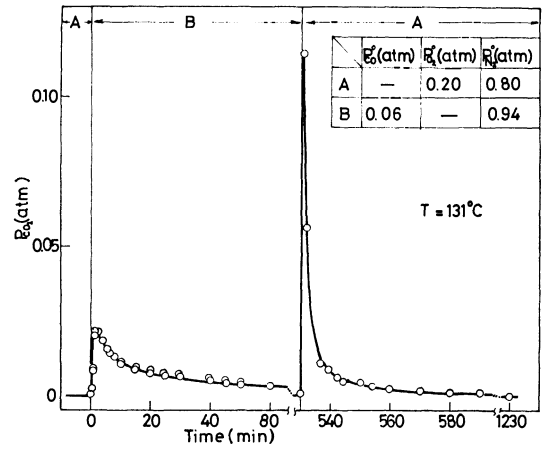

Fig. 3. CO–CO_2 response.

Amount of Surface Oxygen Determined by the Transient Response Method. After the catalyst was completely oxidized in the stream of O_2(20%)–N_2 mixture, the feed was suddenly replaced by the stream of CO(6%)–N_2 mixture and the CO(inc., 0)–CO_2 response was followed for 530 min until no more desorption of carbon dioxide was observed. The results are shown in Fig. 3. Since no oxygen is present in the gas phase after changing the feed composition, the graphical integration of the CO(inc., 0)–CO_2 response curve gives the amount of carbon dioxide produced by the reaction between surface oxygen species and carbon monoxide and then released

from the surface. It is estimated to be 2.5×10^{-4} mol/g.

In the subsequent run, the feed stream of CO(6%)–N_2 mixture was replaced by the stream of O_2(20%)–N_2 mixture and additional outflow of carbon dioxide was observed (Fig. 3, righthand-side). This addional release of carbon dioxide can be attributed to the desorption of irreversibly adsorbed carbon dioxide due to the competitive adsorption of oxygen on the same adsorption site. The behavior of adsorbed carbon dioxide will be discussed in detail in a subsequent paper (part II).[11] The amount of the irreversibly adsorbed carbon dioxide is estimated to be 5.2×10^{-5} mol/g. Hence the total amount of carbon dioxide produced by the reaction between surface oxygen species and carbon monoxide should be 3×10^{-4} mol/g, corresponding to 1.5×10^{-4} mol/g of surface oxygen species. The value is in good agreement with that estimated by the hydrazine method.

On the assumption that the cation layer in the undistorted (001) plane of α-chromia is associated with the surface, the number of surface chromium ions was calculated by McIver and Tobin[12] to be 9.8×10^{14} atom/cm^2. The oxygen adsorption on Cr_2O_3 surface might be dissociative. The amount of oxygen species adsorbed on the surface by the response method corresponds to 8.6×10^{14} atom/cm^2 by using BET surface area of 21 m^2/g. The value is very close to that of surface chromium ions, indicating that each of the dissociatively adsorbed oxygen is bonded to a chromium ion and the surface chromium ions are almost entirely covered with adsorbed oxygen atoms. The fact that the total amount of adsorbed oxygen does not change even when the oxidized surface is exposed to a stream of pure nitrogen at 131 °C for 60 min indicates that the adsorption of oxygen to the surface is fairly strong.

Adsorption of Oxygen on the Reduced Surface. After the reduced catalyst had been kept in a stream of pure nitrogen, the stream was replaced by a stream of O_2(20%)–N_2 mixture and the responce in the oxygen concentration in the effluent stream and the electrical conductivity of the catalyst were followed simultaneously. The results of the response in the conductivity (open circle) are shown in Fig. 4. Owing to the adsorption of oxygen the electrical conductivity of the catalyst

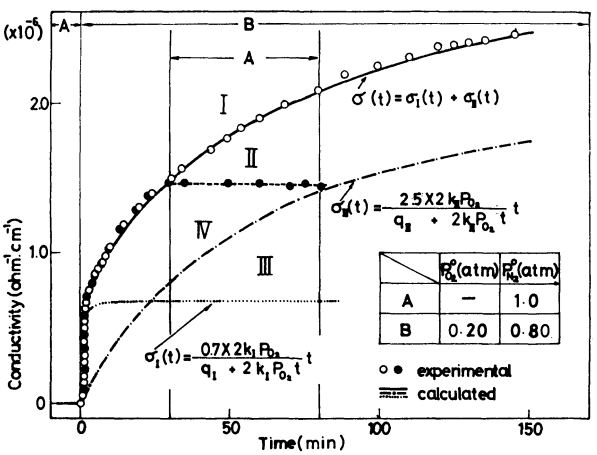

Fig. 4. O_2 (inc., 0)-σ response.

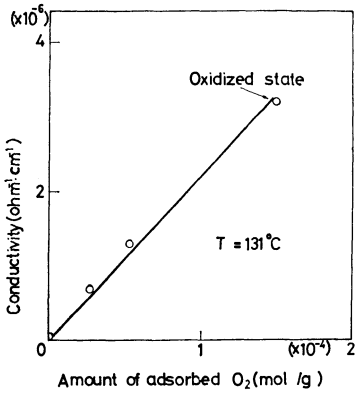

Fig. 5. Linear relationship between the amount of adsorbed O_2 and the conductivity.

increases very rapidly at the initial stage but becomes very slow in the following period of time. Since the catalyst is a p-type semiconductor, the increase in conductivity indicates the shift of electron from the catalyst to the adsorbed oxygen probably bringing about the formation of oxygen anions.

From the response in the oxygen concentration in the effluent stream, we can estimate the amount of adsorbed oxygen at each instant. When the conductivity of the catalyst is plotted against the amount of adsorbed oxygen at each instance, a linear relationship is obtained (Fig. 5). The linearity differs slightly from that obtained by Weller and Voltz,[13] who found that the conductivity was proportional to the 1.2 power of the amount of adsorbed oxygen. Although they stated that the precision of this relationship was not high because of the absolute changes in conductivity observed, the difference in the method of pretreatment of the sample might have caused the disagreement.

The observed response data show at first very rapid and then gradual increases in conductivity. This characteristic behavior of the response curve strongly suggests that the change is due to two different steps. Possible cases are; 1) the successive two-step electron transfer at different rates to the adsorbed oxygen from the catalyst, 2) adsorption of oxygen followed by bulk diffusion into the body of oxide associated with successive electron transfer as suggested by Burwell *et al.*,[2] and 3) the parallel adsorption of oxygen onto two different kinds of active sites at different adsorption rates associated with electron transfer. If 1) or 2) were the case, a gradual increase in the conductivity should be observed when the O_2(20%)–N_2 stream is replaced by a pure nitrogen stream during the course of response measurement. However, the experimental results (solid circles) showed no such changes in conductivity, remaining constant (Fig. 4). Thus the most probable case should be 3). The constancy of the conductivity of the catalyst, which was kept in the pure nitrogen stream, indicates the irreversibility of the oxygen adsorption on both types of active site.

Let us thereby assume the following two parallel elementary steps for the adsorption of oxygen.

$$O_2(g) + S_I \xrightarrow{k_I} O_s^-\cdot S_I \qquad \text{(very fast)} \qquad (1)$$

$$O_2(g) + S_{II} \xrightarrow{k_{II}} O_s^-\cdot S_{II} \qquad \text{(slow)} \qquad (2)$$

where S_I and S_{II} denote the different sites for the adsorption of oxygen with different activities, and O_s^- denotes the negatively charged oxygen spcies. One can roughly estimate the total amounts of $O_s^- \cdot S_I$ and $O_s^- \cdot S_{II}$ by using conductivity data (Fig. 4) and the linear relationship (Fig. 5). Let us suppose that the initial rapid increase in conductivity up to 0.7×10^{-6} ohm^{-1} cm^{-1} is mainly due to the rapid adsorption on site S_I and the gradual increase thereafter results from the slow adsorption on sites S_{II}. Since the conductivity of the catalyst reaches a maximum, 3.2×10^{-6} ohm^{-1} cm^{-1}, with the saturated amount of adsorbed oxygen (Fig. 5), the saturated amounts of $O_s^- \cdot S_I$ and $O_s^- \cdot S_{II}$ are estimated to be 3.3×10^{-5} mol/g and 1.17×10^{-4} mol/g, respectively.

Assuming the dissociative adsorption of oxygen, the rates of adsorption on S_I and S_{II} are given, respectively, by

$$\frac{d\theta_I}{dt} = \frac{2k_I}{q_I}(1-\theta_I)^2 P_{O_2} \quad (3)$$

$$\frac{d\theta_{II}}{dt} = \frac{2k_{II}}{q_{II}}(1-\theta_{II})^2 P_{O_2} \quad (4)$$

where q_I and q_{II} are the saturated amounts of $O_s^- \cdot S_I$ and $O_s^- \cdot S_{II}$, respectively, and θ_I and θ_{II} are the coverage fractions of respective sites.

The rates of oxygen adsorption on sites S_I and S_{II}, respectively, can be easily estimated from the graphical differentiation of the response curve in two portions, from zero to 0.7×10^{-6} ohm^{-1} cm^{-1} and from that to 3.2×10^{-6} ohm^{-1} cm^{-1}. For this purpose, the response curves of P_{O_2} and σ at initial stage are shown in Fig. 6. $d\theta_I/dt$ and $d\theta_{II}/dt$ thus obtained at each instance are plotted against $(1-\theta_I)^2$ and $(1-\theta_{II})^2$, respectively, and linear relationships are obtained (Fig. 7), where $(1-\theta_I)^2$ and $(1-\theta_{II})^2$ are denoted by θ_V^2, indicating Eqs. 3 and 4 fit the data satisfactorily. From the slopes

	$P_{O_2}^0$(atm)	P_{O_2}(atm)	$P_{O_2}^{\infty}$(atm)
A	0.06	-	0.94
B	-	0.20	0.80

Fig. 6. CO(dec., 0) and O_2(inc., 0)-O_2 and σ response; Initial stage.

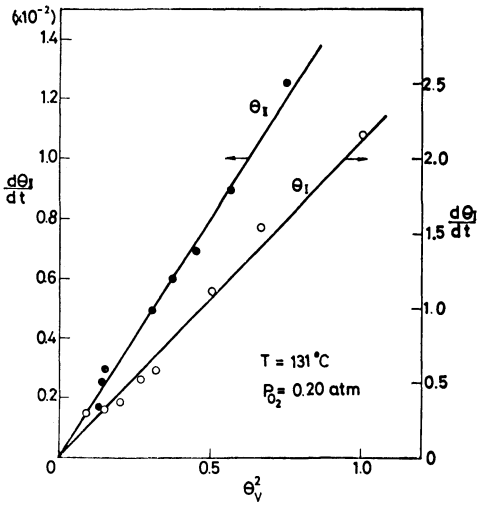

Fig. 7. Plots of $d\theta_I/dt$ and $d\theta_I/dt$ *vs.* θ_V^2.

of both straight lines, two adsorption rate constants, k_I and k_{II}, are calculated, respectively, as

$$k_I = 1.75 \times 10^{-4} \text{ mol/g atm min}$$

$$k_{II} = 4.8 \times 10^{-6} \text{ mol/g atm min}$$

Equations 3 and 4 can be easily integrated with the initial conditions, $\theta_I=0$, $\theta_{II}=0$ at $t=0$, to give

$$\theta_I(t) = \frac{at}{1+at} \quad (5)$$

$$\theta_{II}(t) = \frac{bt}{1+bt} \quad (6)$$

where $a=2k_I P_{O_2}/q_I$ and $b=2k_{II}P_{O_2}/q_{II}$. These equations give the time variation of fractional coverage of sites S_I and S_{II}, and can easily be transformed into the time variation of conductivity owing to the oxygen adsorption on both sites.

$$\sigma_I(t) = \frac{0.7at}{1+at} \quad (7)$$

$$\sigma_{II}(t) = \frac{2.5at}{1+at} \quad (8)$$

σ_I and σ_{II} are the conductivity contribution due to the adsorption of oxygen on sites S_I and S_{II}, respectively. With the values of $q_I=3.3 \times 10^{-5}$, $q_{II}=1.17 \times 10^{-4}$ mol/g and $P_{O_2}=0.2$ atm, Eqs. 7 and 8 are calculated as illustrated by curves III and IV in Fig. 4, respectively. Superposition of curves III and IV gives the calculated curve I, indicating an excellent agreement with the observed data. We might conclude that oxygen is adsorbed dissociatively on two different kinds of adsorption sites with simultaneous charge transfer from the catalyst.

The results showing that O_s^h is much more quickly reproduced than O_s^l from gaseous oxygen suggest that O_s^h and O_s^l correspond to $O_s^- \cdot S_I$ and $O_s^- \cdot S_{II}$, respectively. q_I (the amount of $O_s^- \cdot S_I$) and q_{II} (the amount of $O_s^- \cdot S_{II}$) correspond fairly well to the amount of oxygen species which produce irreversibly adsorbed CO_2 and reversibly adsorbed CO_2, respectively. The carbon dioxide formed on S_I seems to be adsorbed irreversibly and that formed on S_{II} reversibly.

Davydov, Shchekochikhin and Keier[14] demonstrated

that the reaction of CO takes place primarily with oxygen combined with Cr ions exhibiting the lowest degree of coordinative saturation with respect to oxygen. The surface compounds produced in the process, however, form slightly stronger bonds with the surface than the suface compounds combined with the Cr ions exhibiting the higher degree of coordinative saturation with respect to oxygen. The correspondence mentioned above seems to be reasonable.

Carbon Monoxide Oxidation over Chromium Sesquioxide. II. Adsorption Behavior of CO and CO_2

Masayoshi KOBAYASHI, Tomoyuki DATE, and Haruo KOBAYASHI

Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received August 4, 1975)

The adsorption behavior of carbon monoxide and carbon dioxide on oxidized and reduced surface of α-Cr_2O_3 catalyst was studied experimentally by the application of a transient response method. From the analysis of response curves obtained for the concentration of effluent gas component and for the electrical conductivity of catalysts, it was shown that neither carbon monoxide nor carbon dioxide can be adsorbed on the oxidized surface, but they are adsorbed on the reduced surface without electron transfer between adsorbates and the catalysts. Adsorption of carbon monoxide is almost reversible, but that of carbon dioxide is both reversible and irreversible. Oxygen markedly accelerates the desorption of both carbon monoxide and carbon dioxide. It is concluded that this can be attributed to the effect of adsorbed oxygen in lowering the degree of coordinative unsaturation of Cr^{3+} ions.

The adsorption of carbon monoxide and carbon dioxide on Cr_2O_3 surface has been studied by many investigators.[1-3] It was found that the adsorption behavior of both gases on Cr_2O_3 surface is strongly affected by the oxidation state of the surface as pointed out by Dawden and Garner.[1] In recent years, IR spectroscopy has been successfully applied to reveal the surface properties of Cr_2O_3 and the adsorbed states of CO and CO_2 on its surface.[4,5] It was demonstrated in this line of studies that the degree of coordination unsaturation of Cr^{3+} ions plays as important role in the adsorption behavior of these gases. Zecchina, Colluccia, Guglielminotti and Ghiotti[5] concluded that CO is adsorbed on coordinatively unsaturated (coord. unsatd.) Cr^{3+} ions and CO_2 is adsorbed mainly on Cr^{3+} (coord. unsatd.)–O^{2-} (coord. unsatd.) couples resulting in the formation of bidentate carbonate, and partly on Cr^{3+} (coord. unsatd.) ions or O^{2-}(coord. unsatd.) ions forming linearly bonded CO_2 or monodentate carbonate, respectively. The forms of adsorbed CO_2 and the strength of their bonding to the surface are strongly dependent on the coordination heterogeneity as well as on the ligand heterogeneity. Because of the variety of the adsorbed states it will be worthwhile to reveal the dynamic behavior of the surface complexes and the effect of oxygen on the dynamic behavior.

In the present study, the transient response method[6-8] was utilized for this purpose.

Experimental

α-Cr_2O_3 samples and the method of experiments are the same as described in part I.[9]

The responses of the electrical conductivity, σ, of the catalyst and of the concentration of component Y in the outlet gas stream to a step change in the concentration of component X in the inlet gas mixture are denoted by X-σ and X-Y, respectively. When X is increased from nil, X(inc., 0)-σ and X(inc., 0)-Y; when decreased down to nil, X(dec., 0)-σ and X(dec., 0)-Y.

Results and Discussion

Behavior of CO and CO_2 on the Oxidized Surface

After the catalyst had been completely oxidized in a stream of O_2(20%)–N_2 mixture at 131 °C, CO_2 was introduced stepwise into the feed stream without changing the concentration of oxygen, and the CO_2 (inc., 0)–CO_2 and the CO_2(inc., 0)–σ responses were followed simultaneously. Subsequently, the CO_2 in the feed stream was cut off and the CO_2(dec., 0)–CO_2 and the CO_2(dec., 0)–σ responses were followed. The CO_2–CO_2 responses obtained in both runs were instantaneous and the CO_2–σ responses showed no appreciable change in conductivity (Fig. 1). The CO–CO and the CO–σ responses were also measured in the same way and exactly the same results were observed. The results indicate that neither CO_2 nor CO can be adsorbed on the oxidized surface when prepared in the way used in this experiment. The oxidized sample used in our experiments contains saturated amounts of oxygen on the surface, and hence the oxidized surface has no activity for the additional adsorption of CO and CO_2.

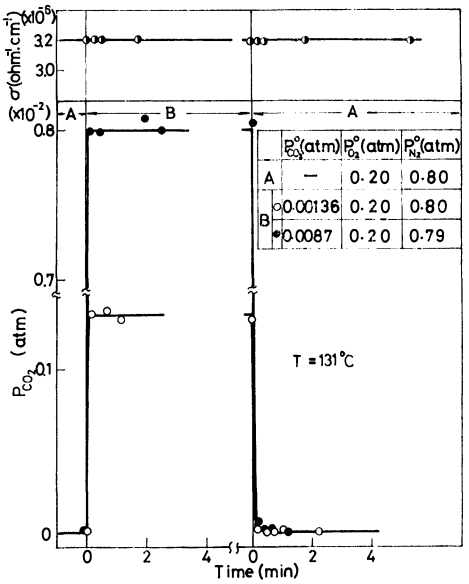

Fig. 1. CO_2–CO_2 response on the oxidized surface.

Behavior of CO_2 on the Reduced Surface. For the preparation of a reduced surface, a stream of CO(6%)–N_2 mixture was allowed to flow through the catalyst bed at 131 °C until no carbon dioxide was detected in the effluent stream. The electrical conductivity of the catalyst fell down to as low as 1×10^{-8} ohm^{-1} cm^{-1}. Carbon dioxide (0.85%) was then introduced into the

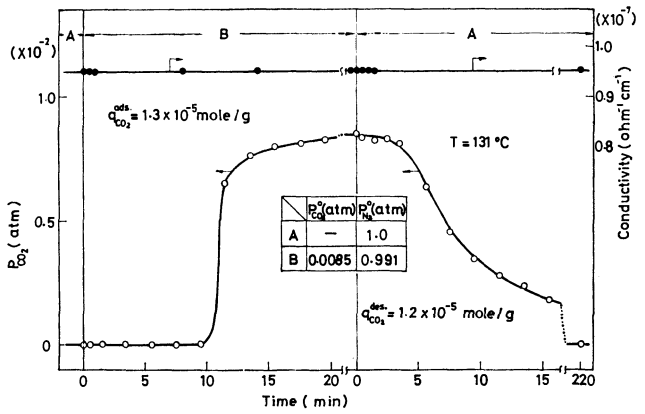

Fig. 2. CO_2–CO_2 response on the reduced surface.

inlet gas stream and the CO_2(inc., 0)–CO_2 and the CO_2(inc., 0)–σ responses were followed until a steady state was reached. Subsequently, the CO_2 in the feed stream was cut off and the CO_2(dec., 0)–CO_2 and the CO_2(dec., 0)–σ responses were followed. The results are shown in Fig. 2. The transient state of the CO_2–CO_2 response was observed in both cases for 30—220 min, indicating the adsorption of CO_2 on the reduced surface. The integrated amount of adsorbed CO_2 is estimated to be 1.3×10^{-5} mol/g from the CO_2 (inc., 0)–CO_2 response and that of desorbed CO_2 is estimated to be 1.2×10^{-5} mol/g from the CO_2(dec., 0)–CO_2 response. Both amounts are nearly the same. It seems that the adsorption of CO_2 under the present conditions is almost reversible.

During these response periods, the electrical conductivity of the catalyst remained constant (Fig. 2), indicating that no electron transfer is accompanied by the adsorption of carbon dioxide, *i.e.* the adsorbed carbon dioxide is electrically neutral.

After the CO_2(inc., 0)–CO_2 response had been followed as described above, the feed stream of CO_2(0.85%)–N_2 mixture was switched over to a stream of O_2(20%)–N_2 mixture instead of pure nitrogen and the CO_2-(dec., 0)–CO_2 response was followed. The results are shown in Fig. 3. A large amount of carbon dioxide was desorbed at the initial period of the response, it decreased steeply and then tailed until no carbon dioxide was detected after 220 min. No carbon monoxide was detected in the effluent stream during the course of response. The integrated amount of the desorbed CO_2 during this run was estimated to be 6.2×10^{-5} mol/g. Since the amount of desorbed CO_2 estimated in the foregoing run was 1.2×10^{-5} mol/g, the desorbed amount of CO_2 estimated in this run is much larger than that in the nitrogen stream. Since the adsorbed CO does not react with gaseous oxygen, the difference in the two amounts can be attributed to the existence of irreversibly adsorbed CO_2 which had been produced during the course of reduction of the surface with CO and remained during the subsequent treatment in the pure nitrogen stream. This suggests that the desorption of the irreversibly adsorbed CO_2 can be attributed to the competitive adsorption of oxygen onto Cr^{3+} (coord. unsatd.) ions. The amount of irreversibly adsorbed CO_2 is estimated to be 5.0×10^{-5} mol/g. This value is in good agreement with that estimated in Part I.

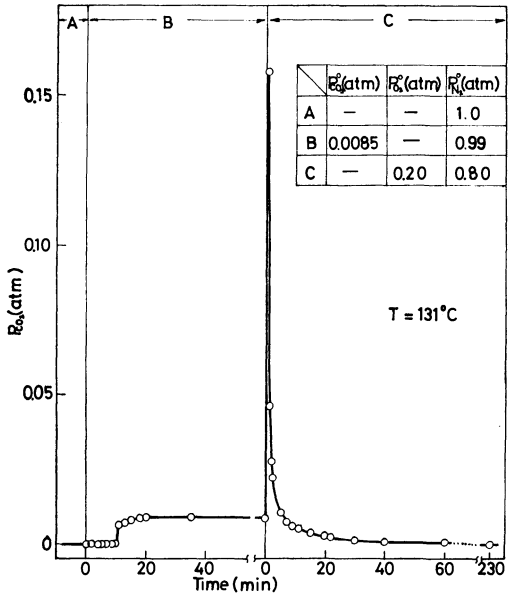

Fig. 3. CO_2–CO_2 response.

It was suggested in Part I that the carbon dioxide produced on site S_I is irreversibly adsorbed while that produced on site S_{II} is reversibly adsorbed. Since the adsorption of oxygen onto site S_I is very rapid, the desorption of the irreversibly adsorbed carbon dioxide from S_I due to the competitive adsorption of oxygen should also be rapid. Comparing the period of the initial rapid desorption of carbon dioxide (Fig. 3) with the time required for the initial rapid adsorption of oxygen (Fig. 6, Part I), we see that the time required for both processes are consistent with each other.

We might conclude that when oxygen is present in the gas phase, the site S_I is always free from retardation by adsorbed carbon dioxide, and $O^-\cdot S_I$, which is very active for CO oxidation, is rapidly regenerated, contributing substantially to the reaction. This might explain the fact that the amount of $O^-\cdot S_I$ remains constant in the steady state of the reaction with a variety of P_{CO}.

The rate of oxygen adsorption on S_{II} is very small and the same effect of oxygen can not be expected for the carbon dioxide produced on S_{II}. Eventually the amount of $O^-\cdot S_{II}$ is lowered at a steady state with higher partial pressure of CO where the rates of CO_2 formation on S_{II} are higher.

According to the results obtained by Zecchina *et al.*[5] the irreversibly adsorbed CO_2 observed in this study will probably be in the form of bidentate carbonate produced by the adsorption of CO_2 on the Cr^{3+} (coord. unsatd.)–O^{-2} (coord. unsatd.) couples which are present on the highly reduced surface. Another possibility is that the bicarbonate ions produced by the adsorption of CO_2 on hydroxyl ions remain on the surface. The reversibly adsorbed CO_2, on the other hand, will mainly correspond to CO_2 coordinated to Cr^{3+} (coord. unsatd.) ions in the linear form which is predominant when the degree of coordinative unsaturation of Cr^{3+} is low.

Behavior of CO on the Reduced Surface. After the

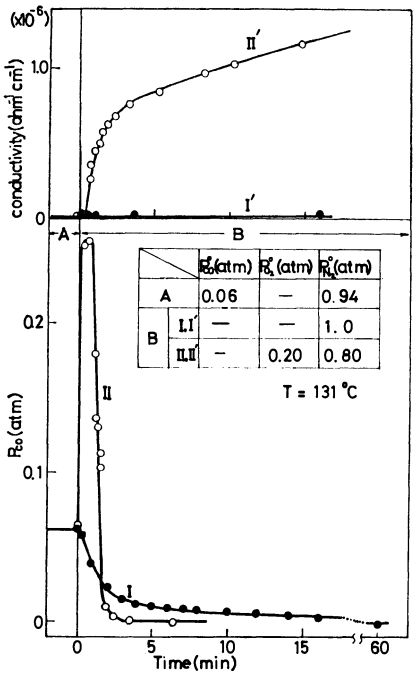

Fig. 4. CO-CO and CO-σ responses.

catalyst had been reduced in the same way as described in the foregoing section, the feed stream was switched over to a stream of either pure nitrogen or a mixture of $O_2(20\%)$–N_2, and the CO-CO and the CO-σ responses were followed simultaneously. The results are shown in Fig. 4.

When the feed stream was replaced by the stream of pure nitrogen, the desorption of CO was observed for about 60 min as shown by curve I in Fig. 4. From the graphical integration of curve I, the total amount of adsorbed carbon monoxide is estimated to be 3.0×10^{-5} mol/g. During the same run, the electrical conductivity of the catalyst was kept entirely constant (line I', Fig. 4). These results imply that CO can be adsorbed on the reduced surface without electron transfer between the adsorbed CO and the catalyst. Since the adsorption of CO can take place only on the reduced surface, the sites for the adsorption should be Cr^{3+} (coord. unsatd.) ions.

When the feed stream was replaced by a stream of $O_2(20\%)$–N_2 mixture, on the other hand, the desorption of a large amount of CO took place at the initial stage of the response and the desorption was completed within 3 min (curve II in Fig. 4). The integrated amount of desorbed CO is estimated to be 3.6×10^{-5} mol/g, being slightly higher than the amount of CO desorbed into the pure nitrogen stream. If the carbon monoxide adsorbed on the surface can react with the oxygen introduced, the amount of the desorbed CO in the $O_2(20\%)$–N_2 stream should be lower than the amount of the desorbed CO in the pure nitrogen stream. The results suggest that the adsorbed CO does not react with the introduced oxygen.

The difference in the amounts of desorbed CO into the $O_2(20\%)$–N_2 stream and the pure N_2 stream may also be ascribed to the same reason as in the case of CO_2.

It has been stated by Zecchina *et al.*[5] that the adsorption of CO on the reduced surface is reversible. Presumably, however, the adsorption of CO under the conditions in this study will not be completely reversible, and the adsorbed CO at a very low coverage will remain on highly coordinatively unsaturated Cr^{3+} ions, and these residual adsorbed CO molecules will be desorbed only by the adsorption of oxygen onto Cr^{3+} (coord. unsatd.) ions, with which the degree of coordinative unsaturation of Cr^{3+} (coord. unsatd.) ions is lowered and eventually the desorption of CO is enhanced.

The change in the electrical conductivity was observed (curve II', Fig. 4). Since no electron transfer takes place in the case of CO desorption into the pure nitrogen stream, the change in the electrical conductivity in this case should be due to the adsorption of oxygen.[9]

So far we have discussed the nature of adsorption sites on the surface only in terms of coordinative heterogeneity of Cr^{3+} ions, but ligand heterogeneity may also play some role in characterizing the nature of those sites. OH^- on the surface might have some effects on the behavior of CO and CO_2 on the surface.

Behavior of CO and CO_2 during the CO Oxidation at Steady States. When a mixture of CO–O_2–N_2 is allowed to flow through the bed of oxidized catalyst, oxidation of CO takes place, the reaction rate varying

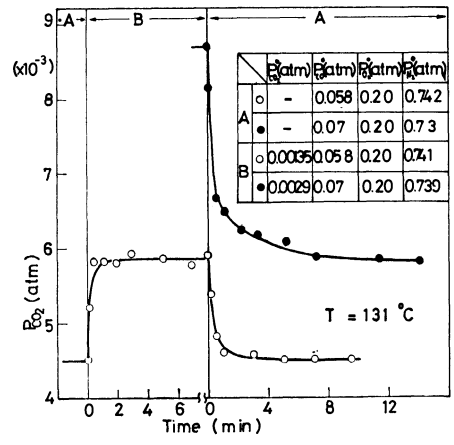

Fig. 5. CO_2-CO_2 response during the reaction.

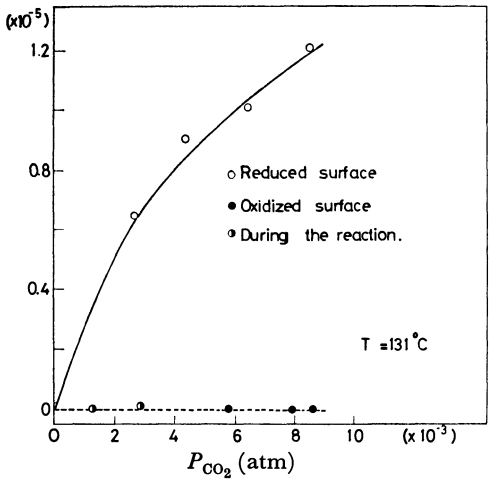

Fig. 6. Adsorption isotherm for CO_2.

very slowly until it reaches a steady state after 15 h. After the steady state was attained, the CO in the feed was cut off and CO(dec., 0)–CO response was followed. The response was instantaneous, indicating that no carbon monoxide was adsorbed on the surface in the steady state during the course of reaction. On the other hand, the CO_2(inc., 0)–CO_2 and the CO_2(dec., 0)–CO_2 responses obtained in the same steady state indicates the occurrence of adsorption and the desorption of CO_2 on the same surface (Fig. 5). The amount of adsorbed CO_2 estimated from the graphical integration of the CO_2(dec., 0)–CO_2 response curve was presented in Fig. 6 with those on the reduced surface and on the oxidized surface. As can be seen from Fig. 6, the amount of CO_2 adsorbed on the surface during the reaction was two orders of magnitude smaller than that adsorbed on the reduced surface and rather close to that on completely oxidized surface. From the result, it can be concluded that the catalyst surface during the course of reaction in the steady state is in highly oxidized state.

Carbon Monoxide Oxidation over Chromium Sesquioxide. III. Kinetics of the Reaction

Masayoshi KOBAYASHI and Haruo KOBAYASHI

Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received August 4, 1975)

Based on the experimental findings in Parts I and II, mechanisms of carbon monoxide oxidation over α-Cr_2O_3 were proposed with which the reaction takes place simultaneously through two parallel reaction paths. Overall reaction consists of five elementary steps, and the rate constants of all ellementary stepes were determined from the analysis of appropriate transient response data. The simulation of transient response with these rate constants proved the validity of these mechansims and the results of kinetic analyses.

The reaction mechanism of carbon monoxide oxidation over Cr_2O_3 has been studied by several investigators and the conclusions reached by these investigators are rather divergent. Winter[1] thought that the rate determining step was the adsorption of oxgen. Tarama, Teranishi, and Hattori[2] worked out the kinetic analysis of the data obtained in a closed recycle reaction system and suggested that the overall reaction was controlled by the reaction between adsorbed carbon monoxide and adsorbed atomic oxygen. Recently, Davydov, Shchekochikhin, and Keier[3] suggested, on the basis of IR spectroscopic study of surface complexes formed on α-Cr_2O_3, that the rate determing step was not the adsorption of oxygen but either the reaction of gaseous carbon monoxide with surface oxygen species or the desorption of surface complexes formed in the course of the reaction.

Voltz and Weller[4] pointed out in early days that the catalytic activity of Cr_2O_3 was affected by the oxidation states of the surface. Recently, the complexity of the characteristics of Cr_2O_3 surface has been revealed in detail by IR spectroscopic studies.[5-9] The divergent conclusions drawn by many investigators for the kinetics of CO oxidation over Cr_2O_3, therefore, may be attributable to the different characteristics of samples, which is highly sensitive to pretreatments, temperature, and ambient gas atmosphere.

In our previous paper, Part I,[10] it was concluded that oxygen is adsorbed dissociatively on coordinatively unsaturated chromium ions forming oxygen anions, and that the oxygen anions consist of two groups, $O^-\cdot S_I$ and $O^-\cdot S_{II}$, the former is very rapidly generated and easily reacts with CO while the latter is produced very slowly and is less active for the reaction with CO. It was also shown[11] that CO could not be adsorbed on α-Cr_2O_3 surface when it was either fully oxidized or in steady states where CO oxidation was taking place. These results lead to a conclusion that the oxidation of CO over α-Cr_2O_3 proceeds through the reaction between gaseous CO and oxygen anions on the surface.

In the present paper, we are concerned with how the different groups of the oxygen anions take part in the oxidation of CO, and also with the detailed kinetic analysis of the reaction.

Reaction Mechanism for Kinetic Analysis

According to the results and the discussion in the previous paper, the mechanism of the oxidation of CO over Cr_2O_3 catalyst can be summarized as follows.

a) Two kinds of dissociatively adsorbed oxygen anions, $O^-\cdot S_I$ and $O^-\cdot S_{II}$, are present on the surface and both are active for the oxidation of CO. $O^-\cdot S_I$ has a higher oxidation power and can be rapidly regenerated by gaseous oxygen. Therefore, S_I is always saturated with adsorbed oxygen anions under the steady states of the reaction at various partial pressure of CO. On the other hand, $O^-\cdot S_{II}$ has a lower oxidation power and the rate of its regeneration is slow and hence the concentration of $O^-\cdot S_{II}$ decreased with higher partial pressure of CO with which the reaction rates are higher.

b) Under the steady states of the reaction, the reaction proceeds through the simultaneous reactions of gaseous CO with both $O^-\cdot S_I$ and $O^-\cdot S_{II}$ with different reaction rates.

c) Carbon dioxide produced by the reaction between CO and $O^-\cdot S_I$ is adsorbed irreversibly on S_I when oxygen is not present in the gas phase, but when oxygen exists in the gas phase the adsorbed CO_2 on S_I is very rapidly desorbed due to the competitive adsorption of oxygen onto S_I. On the other hand, the desorption of carbon dioxide produced by the reaction between CO and $O^-\cdot S_{II}$ is not affected by the presence of oxygen in the gas phase. Under the steady states of the reaction, the amount of adsorbed CO_2 on S_{II} is negligibly small.

d) The adsorbed CO_2 on S_I and S_{II} is not ionized.

The reaction mechanism suggested above for the catalytic oxidation of CO over Cr_2O_3 can be represented in the sequence of the following steps.

Reaction path I:

$$CO(g) + O^-\cdot S_I \xrightarrow{k_1} CO_2\cdot S_I + e \quad (1)$$

$$O_2(g) + 2CO_2\cdot S_I + 2e \xrightarrow{k_2} 2CO_2(g) + 2O^-\cdot S_I \quad (2)$$

Reaction path II:

$$CO(g) + O^-\cdot S_{II} \xrightarrow{k_3} CO_2\cdot S_{II} + e \quad (3)$$

$$CO_2\cdot S_{II} \xrightarrow{k_4} CO_2(g) + S_{II} \quad (4)$$

$$O_2(g) + 2S_{II} + 2e \xrightarrow{k_5} 2O^-\cdot S_{II} \quad (5)$$

Although non-ionized adsorption of CO_2 was suggested in the previous paper[11], one can see another evidence in the results shown in Fig. 1, which indicate that the shift of electrons takes place when gaseous CO reacts with the surface oxygen anions.

Let us examine the results shown in Fig. 1. After the catalyst had been completely oxidized by a stream

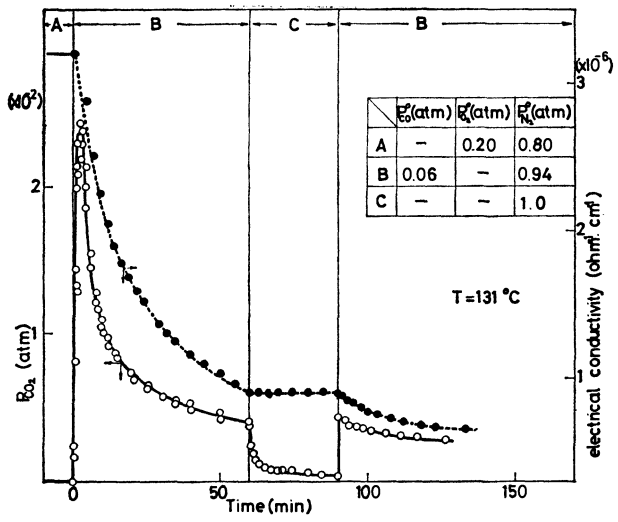

Fig. 1. CO-CO_2 and CO-σ response.

of O_2(20%)-N_2 mixture, the stream was suddenly replaced by a stream of CO(6%)-N_2 mixture and the responses in the outlet CO_2 concentration and in the electrical conductivity of the catalyst were followed for 60 min. The CO_2 concentration reached a maximum in a very short time and then fell down steeply and afterwards it gradually decreased to very low values. The electrical conductivity, on the other hand, decreased monotonously due to the formation of gaseous CO_2 with the expense of oxygen anions on the surface. Since the catalyst is a p-type semiconductor, the picking up of surface oxygen by CO in the form of CO_2 results in the decrease in the conductivity, due to the shift of electrons from the oxygen anions back to the catalyst. After 60 min, the feed was replaced by a stream of pure nitrogen. Even with no carbon monoxide in the feed, CO_2 could be detected for a certain period of time due to the desorption of CO_2 which had been produced and accumulated on the surface during the foregoing reduction period. The electrical conductivity, on the other hand, was kept entirely constant during this run. These results substantiate the Steps (1) and (2) which indicate that the electron transfer back to the catalyst occurs when the surface compounds are formed by the reaction of CO with surface oxygen anions, and not when the surface compound decomposes to give gaseous CO_2 as has been suggested by Matsushita, Nakata[12] and Courtois and Teichner.[13]

Determination of Rate Constants

The rate constants k_2 and k_5 have been already determined in Part I[10] as k_I and k_{II}, respectively.

$$k_2 = k_I = 1.75 \times 10^{-4} \text{ mol/g min atm}$$

$$k_5 = k_{II} = 4.8 \times 10^{-6} \text{ mol/g min atm}$$

Determination of k_4. The value of k_4 can be determined from the CO(dec., 0)-CO_2 response during the reaction under steady states. An example of the CO-(dec., 0)-CO_2 response data is shown in Fig. 2. As has been discussed in Part II,[11] the desorption of CO_2 produced by gaseous CO and $O^- \cdot S_I$ on the surface

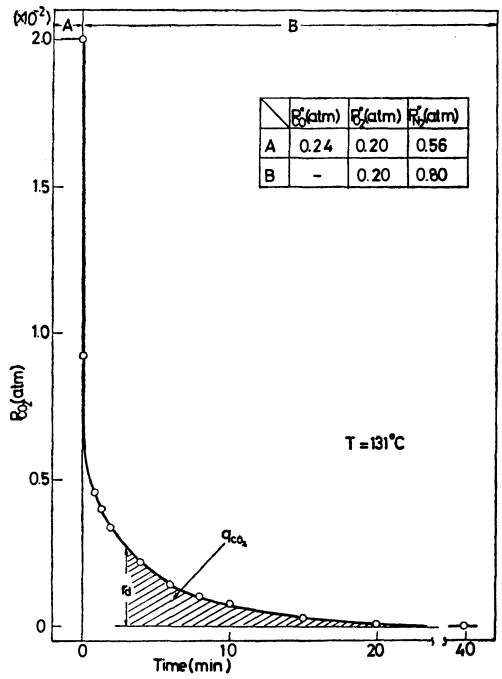

Fig. 2. CO(dec., 0)-CO_2 response during the reaction.

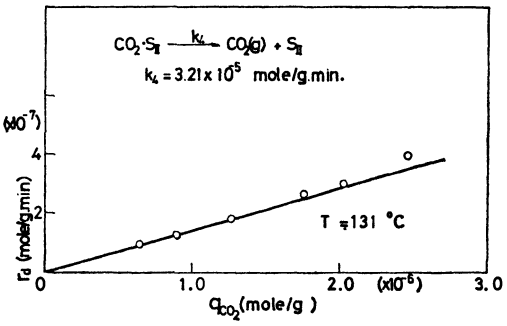

Fig. 3. Plot of the desorption rate of CO_2 *vs.* q_{CO_2} estimated from the graphical analyses of the curve presented in Fig. 2.

is very rapid due to the competitive adsorption of oxygen, then the slow desorption of CO_2 as can be seen in the later part of the response may be attributed solely to the desorption of CO_2 from $CO_2 \cdot S_{II}$. Furthermore, it is known that the amount of CO_2 readsorbed from gas phase on S_{II} during the reaction is negligible.[11] Therefore, the rates of CO_2 desorption measured in the later part of the response can be considered to give true rates of CO_2 desorption from $CO_2 \cdot S_{II}$. From the response data, one can estimate the amounts of adsorbed $CO_2 \cdot S_{II}$ and the corresponding desorption rates of CO_2. A plot of desorption rates against the adsorbed amounts of CO_2 gives a straight line as presented in Fig. 3. The rate of CO_2 desorption from $CO_2 \cdot S_{II}$ can be given by

$$r_d = k_4 \cdot \theta_{II} \cdot CO_2 \qquad (6)$$

where k_4 is the desorption rate constant of CO_2 from S_{II} and $\theta_{II \cdot CO_2}$ is the fractional coverage of S_{II} with CO_2. Assuming linear form of adsorbed CO_2 on S_{II}, as has been discussed in Part II,[11] the saturated amount of $CO_2 \cdot S_{II}$, $q_{CO_2 \cdot max}$, may be taken as equivalent to that of $O^- \cdot S_{II}$ as estimated in Part I, which is equal

		P^0_{CO}(atm)	$P^0_{O_2}$(atm)	$P^0_{N_2}$(atm)

Fig. 4. CO–CO_2 response.

to 2.34×10^{-4} mol/g. Using this value and the slope of the straight line in Fig. 3, one can estimate the value of k_4 as

$$k_4 = 3.21\times10^{-5} \text{ mol/g min}$$

Under the conditions given in Fig. 2, $\theta_{II\cdot CO_2}$ for the catalyst having been operated in the gas mixture A under the steady state was also estimated as

$$\theta_{II\cdot CO_2} = 0.017$$

Determination of k_1. k_1 can be determined from the CO–CO_2 response during the reaction at steady states. An example of such response is given in Fig. 4, which shows an instantaneous increase in P_{CO_2} followed by a gradual increase to a maximum and then approaches a new steady state. The initial instantaneous increase in P_{CO_2} may be ascribed to the rapid desorption of incremental CO_2 produced by the reaction of $O^-\cdot S_I$ and the increment of the partial pressure of CO. Because, as has been discussed in Part II, the CO_2 produced on S_I can be desorbed very rapidly by the competitive adsorption of oxygen while that produced on S_{II} desorbs gradually as we have seen in the foregoing sections. A plot of Δr_1 *vs.* ΔP_{CO} gives a linear relationship as presented in Fig. 5. Thus the initial increase in the production rate of CO_2, namely the rate of Step (1), can be given as

$$\Delta r_1 = k_1\cdot\theta_I\cdot\Delta P_{CO} \tag{8}$$

where θ_I is the fractional coverage of S_I with oxygen. Since it is known that θ_I can be taken to be unity, the valu of k_1 can be estimated from the slope of the straight line in Fig. 5 as

$$k_1 = 4.15\times10^{-6} \text{ mol/g min atm.}$$

Determination of k_3. At the reaction steady state, the rate of CO_2 formation canbe expressed by the sum of both Eqs. 1 and 3 as follows:

$$r_{st} = k_1P_{CO}\theta_I + k_3P_{CO}\theta_{II} = r_I + r_{II} \tag{7}$$

where $r_I=k_1P_{CO}\theta_I$ and $r_{II}=k_3P_{CO}\theta_{II}$. Using the values of k_1 and θ_I estimated in the foregoing section, one can calculate r_I and determine r_{st} from the experimental data at various partial pressures of

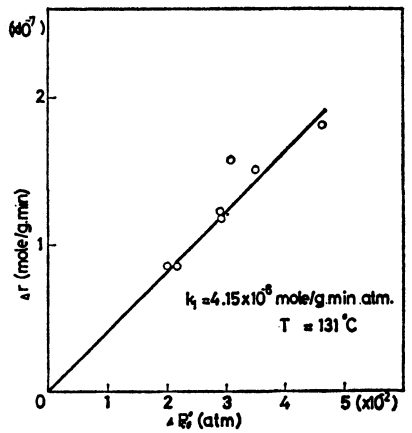

Fig. 5. Plot of Δr *vs.* ΔP^0_{CO}.

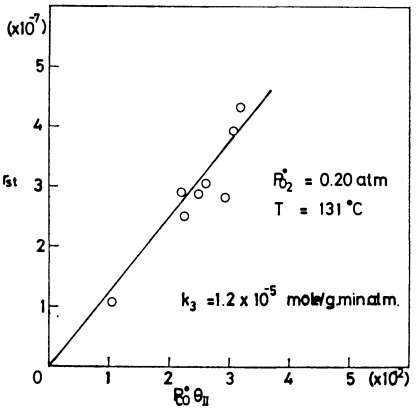

Fig. 6. Plot of r_{st} *vs.* $P^0_{CO}\theta_{II}$.

CO. Therefore, r_{II} at various partial pressures of CO is estimated easily from the difference between r_{st} and r_I at corresponding conditions.

On the other hand, the values of θ_{II} at the corresponding steady states can be roughly estimated from the electrical conductivity at the same conditions, which shows the amount of $O^-\cdot S_{II}$ since S_I is fully occupied by oxygen anions due to its rapid adsorption during the reaction. A plot of r_{II} against θ_{II} gives a straight line as shown in Fig. 6. From the slope of the straight line, the value of k_3 can be estimated as

$$k_3 = 1.2\times10^{-5} \text{ mol/g min atm.}$$

Simulation of Response Data

From the analyses presented in the foregoing section, it is seen that k_2 is very much larger than k_1, *i.e.* the Step (1) is the rate determining step of the reaction path I. Hence the rate of CO_2 formation through reaction path I can be expressed by the following equation.

$$\frac{dP_{CO_2}}{dt} = k_2\theta_IP_{CO} \tag{9}$$

Based on this simplification, the unsteady-state mass balance equations for each component for over-all reaction can be given by[14]

$$\frac{dP_{CO}}{dt} = \frac{2U}{\varepsilon L}(P^0_{CO}-P_{CO}) - \frac{2\rho_cRT}{\varepsilon}(k_1P_{CO}\theta_I+k_3P_{CO}\theta_{II}) \tag{10}$$

$$\frac{dP_{CO_2}}{dt}=\frac{2U}{\varepsilon L}(P^0_{CO_2}-P_{CO_2})+\frac{2\rho_c RT}{\varepsilon}\times(k_1P_{CO}\theta_I+k_4\theta_{II\cdot CO_2}) \quad (11)$$

$$\frac{dP_{O_2}}{dt}=\frac{2U}{\varepsilon L}(P^0_{O_2}-P_{O_2})-\frac{2\rho_c RT}{\varepsilon}\times\left(\frac{1}{2}k_1P_{CO}\theta_I+k_5P_{O_2}\theta^2_{II\cdot v}\right) \quad (12)$$

$$\frac{d\theta_{II}}{dt}=\frac{1}{q_{O_2}}(2k_5P_{O_2}\theta^2_{II\cdot v}-k_3P_{CO}\theta_{II}) \quad (13)$$

$$\frac{d\theta_{II\cdot CO_2}}{dt}=\frac{1}{q_{CO_2}}(k_3P_{CO}\theta_{II}-k_4\theta_{II\cdot CO_2}) \quad (14)$$

where ε abd ρ_c are, respectively, void fraction and apparent density of the catalyst bed, and U is the superficial velocity of the feed, L the length of the catalyst bed. $\theta_{II\cdot v}$ is the fraction of vacant site S_{II} and this is given by

$$\theta_{II\cdot v}=1-(\theta_{II}+\theta_{II\cdot CO_2}) \quad (15)$$

Suppose the reaction system is in the steady state with a feed containing CO and O_2 as the reactants, and the partial pressure of CO in the feed is suddenly increased from P^{io}_{CO} to P^{no}_{CO}, then the inital conditions for the transient response will be given by these equations

$$\left.\begin{array}{l}\left.\begin{array}{l}P^0_{CO}=P^{no}_{CO}\\P^0_{CO_2}=0\\P^0_{O_2}=P^{io}_{O_2}\end{array}\right\}\text{inflow}\\\left.\begin{array}{l}P_{CO}=P^{is}_{CO}\\P_{CO_2}=P^{is}_{CO_2}\\P_{O_2}=P^{is}_{O_2}\end{array}\right\}\text{outflow}\\\left.\begin{array}{l}\theta_{II}=\theta^{is}_{II}\\\theta_{II\cdot CO_2}=\theta^{is}_{II\cdot CO_2}\end{array}\right\}\text{on the surface}\end{array}\right\}\text{at } t=0 \quad (16)$$

In order to examine the validity of the k_j values estimated so far, let us simulate the CO–CO_2 response data given in Fig.4. Although P^{is}_{CO}, $P^{is}_{CO_2}$, and $P^{is}_{O_2}$ can be obtained experimentally, these values are also calculated from initial inflow conditions given in Fig. 4 with k_j values using Eqs. 10—14 under steady state conditions. For this calculation θ^{is}_{II} and $\theta^{is}_{II\cdot CO_2}$ are not known experimentally but can be calculated as follows as a function of P^{is}_{CO} and $P^{is}_{O_2}$.

Under the initial steady state,

$$\frac{d\theta_{II}}{dt}=0 \quad (17)$$

Then from Eq. 13,

$$2k_5P^{is}_{O_2}(1-\theta^{is}_{II}-\theta^{is}_{II\cdot CO_2})^2-k_3P^{is}_{CO}\theta^{is}_{II}=0 \quad (18)$$

Since $\theta_{II\cdot CO_2}$ is very small as has been stated in a previous section, Eq. 18 can be simplified as

$$(\theta^{is}_{II})^2-(2+a)\theta^{is}_{II}+1=0 \quad (19)$$

where

$$a=k_3P^{is}_{CO}/2k_5P^{is}_{O_2} \quad (20)$$

Solving Eq. 19, one can obtain

$$\theta^{is}_{II}=\frac{1}{2}(2+a-\sqrt{a^2+4a}) \quad (21)$$

In the same way, $\theta^{is}_{II\cdot CO_2}$ can be obtained from Eq. 21 and Eq. 14 under steady states.

$$\theta^{is}_{II\cdot CO_2}=\frac{k_3}{2k_4}P_{CO}(2+a-\sqrt{a^2+4a}) \quad (22)$$

By these calculations the initial conditions, Eq. 16, for the response can be obtained. With these initial conditions, Eqs. 10—14 can be solved numerically. The time courses of the P_{CO_2} change thus calculated for four different cases are shown in Fig. 4. The characteristic nature of the response data is simulated fairly well and this would indicate the validity of the proposed mechanisms and the values of k_j estimated so far.

Discussion

Here we shall summerize the values of k_j.

$k_1=4.15\times10^{-6}$ mol/g min atm

$k_2\ (=k_{II})=1.75\times10^{-4}$ mol/g min atm

$k_3=1.2\times10^{-5}$ mol/g min atm

$k_4=3.21\times10^{-5}$ mol/g min

$k_5\ (=k_{II})=4.8\times10^{-6}$ mol/g min atm

It is seen that k_2 is much larger than k_1 and this fact is quite consistent with the conclusion reached experimentally in Part II that the regeneration of $O^-\cdot S_I$ is very rapid and $O^-\cdot S_I$ always contributes to the reaction. It is seen also that k_5 is much smaller than k_3 and k_4. These results are also consistent with the conclusion drawn from the experimental findings in Parts I and II that the regeneration of $O^-\cdot S_{II}$ is slow and the concentration of $O^-\cdot S_{II}$ during the reaction under steady states is lowered when the reaction is opperated under higher partial pressures of CO, where the rates of picking up of $O^-\cdot S_{II}$ are higher.

Since k_1 and k_3 include the total number of $O^-\cdot S_I$ and $O^-\cdot S_{II}$, respectively, the true activity of each oxygen should be compared by the activity of single oxygen. Total amount of $O^-\cdot S_I$ is 3.3×10^{-5} mol/g and that of $O^-\cdot S_{II}$ is 1.17×10^{-4} mol/g and hence the true activity of each oxygen would be

$$k_1'=k_1/3.3\times10^{-5}=1.26\times10^{-1}\ \text{min}^{-1}\ \text{atm}^{-1}$$

$$k_3'=k_3/1.17\times10^{-4}=1.02\times10^{-1}\ \text{min}^{-1}\ \text{atm}^{-1}$$

k_1' is only slightly larger than k_3' and it seems to be not exactly consistent with the experimental findings in Part I, which suggest the higher reactivity of $O^-\cdot S_I$ compared to that of $O^-\cdot S_{II}$. The reason for this inconsistency may be ascribed to the difference in the activation energy of both types of oxygen species because the temperatures of reaction were different in both experiments. At the present moment, however, this problem is still open to the question and will need further investigations.

Nomenclature

a: defined in Eq. 20.

k_j: rate coefficient for step j, arbitrary unit.

L: total length of the catalyst bed (cm).

P_{O_2}, P_{CO}, P_{CO_2}: partial pressure of oxygen, carbon monoxide, and carbon dioxide at the outlet of the catalyst bed at the un-

steady state, respectively (atm).

$P^0_{O_2}$, P^0_{CO}, $P^0_{CO_2}$: partial pressure of oxygen, carbon monoxide, and carbon dioxide at the inlet of the catalyst bed, respectively (atm).

$P^{i0}_{O_2}$, P^{i0}_{CO}: partial pressure of oxygen and carbon monoxide at the inlet of the catalyst bedat initial steady state, respectively (atm).

P^{n0}_{CO}: newly set partial pressure of carbon monoxide at the inlet of the catalyst bed (atm).

$P^{is}_{O_2}$, P^{is}_{CO}, $P^{is}_{CO_2}$: partial pressure of oxygen, carbon monoxide, and carbon dioxide at the outlet of the catalyst bed at initial steady state, respectively (atm).

q_{CO_2}, q_{CO_2}: total amounts of O_2 and CO_2 adsorbed on active site S_{II}, respectively (mol/g).

R: gas constant, consistent units.

S_I, S_{II}: active sites on the surface denoted in earlier paper.[10]

t: time elapsed after the step change of gas composition (min).

T: temperature (K).

U: superficial gas velocity (cm/min).

Greek Symbols

ε: void fraction of packed bed of reactor (—).

θ_{II}, $\theta_{II\cdot CO_2}$: coverage averaged in the catalyst bed for $O^-\cdot S_{II}$ and $CO_2\cdot S_{II}$, respectively (—).

θ^{is}_{II}, $\theta^{is}_{II\cdot CO_2}$: coverage averaged in the catalyst bed for $O^-\cdot S_{II}$ and $CO_2\cdot S_{II}$ at the steady state of reaction, respectively (—).

$\theta_{II\cdot v}$: fraction of vacant active sites S_{II} (—).

ρ_c: catalyst bed density (g/cm^3).

The Complexing of Indium(III) by Cysteine: Evidence for Sulfur-bridged and Protonated Complexes

Nakao KOJIMA, Yukio SUGIURA, and Hisashi TANAKA

Faculty of Pharmaceutical Sciences, Kyoto University, Kyoto 606

(Received October 18, 1975)

The complex formation of the cysteine–In(III) system has been investigated by potentiometric titration and by PMR, IR, and UV spectroscopic measurements. The InL, InL_2, and InLH species are predominantly formed at the metal concentrations from 0.00025 to 0.0005 M. At higher concentrations of the metal ion (0.0025—0.005 M), however, the InL species is negligible and the InL_2, InL_3, InL(LH), and $In(LH)_2$ species are predominant. The formation constants calculated with a non-linear, least-squares program were log $\beta_{110}=14.12$, log $\beta_{120}=27.26$, log $\beta_{130}=32.20$, log $\beta_{11-1}=18.46$, log $\beta_{12-1}=31.78$, and log $\beta_{12-2}=35.74$ for InL, InL_2, InL_3, InLH, InL(LH), and $In(LH)_2$ respectively. The IR and UV spectra revealed that the amino group of the coordinating cysteine was protonated. The $[In_3L_4(OH)(H_2O)]$ complex was isolated.

The study of the complex formation of In(III) with various ligands is needed for the development of new radiopharmaceuticals for clinical diagnosis by the use of ^{113m}In or ^{111}In, which are favorable radioisotopes and which can effectively be used with several chelating agents. We have studied the complex formation of In(III) with penicillamine.[1] In this paper, we will discuss the complex formation of In(III) with cysteine in comparison with that with penicillamine.

Experimental

Materials. All the details of the preparation and standardization of the metal and KOH solutions for pH titration have been reported in a preceding paper.[1] Indium sulfate, $In_2(SO_4)_3 \cdot 9H_2O$, was used for the PMR and UV measurements and for the isolation of the complex. L-Cysteine hydrochloride was dried under a vacuum over diphosphorus pentoxide, and the solution was standardized potentiometrically. The D_2O, DCl, and NaOD (99.5% isotopically pure) were obtained from E. Merck. All the other reagents used were of a reagent grade.

IR Spectra. The IR spectra of the solid were measured in a KBr disk by means of a Hitachi grating infrared spectrophotometer, Model 215. The IR measurements were also made on a D_2O solution of the 0.1 M ligand with or without 0.05 M In(III), in a KRS-5 cell with a light path of 0.1 mm. All the pD values were obtained by the addition of 0.44[2] to the pH values determined using a Hitachi-Horiba pH meter, Model F-7.

PMR Spectra. The PMR spectra were recorded with a Varian A-60 NMR spectrometer at an ambient probe temperature of 33 °C. The concentration of the In(III) ion was 0.052M, and the chemical shifts were measured with sodium 3-(trimethylsilyl)propionate-2,2,4,4-d_4 as the internal standard.

Optical Spectra. The optical spectra were measured in an aqueous solution by means of a Shimadzu recording spectrophotometer, Model Double-40R. Sample solutions were composed of cysteine hydrochloride (0.00016M) and a small amount of 1 M hydrochloric acid, with or without In(III) (0.00008 M), and were neutralized with 1 M potassium hydroxide.

Potentiometric Titrations and Calculations. The potentiometric titrations were performed with standard carbonate-free potassium hydroxide solutions(1.002 M and 0.1001 M) at 21.00±0.05 °C in the presence of 0.1 M potassium nitrate. The total volume was adjusted to 20.00 ml. The apparatus and procedure have been described.[1]

The titrations were carried out for solutions with a wide range of total metal concentrations in order to investigate the formation of hydroxo, protonated, and/or polynuclear species. The system containing polynuclear species does not give coincident formation curves. If hydroxo and/or protonated species are formed, complicated formation curves are to be expected since the free ligand concentration [L] calculated by the usual manner is incorrect. In such cases, a non-linear, least-squares computer program was used for the calculation of the stability constants, β_{lmn}:

$$\beta_{lmn} = [M_lL_mH_{-n}]/[M]^l[L]^m(H^+)^{-n}$$

where n is positive for a hydrolyzed species and negative for a protonated species, and where the parentheses denote activity. The calculations were carried out in a manner previously described[1] by the use of a FACOM 230-75 computer, Kyoto University. This program was also used for the calculation of the dissociation constants of the ligand. The values of $pK_w=14.130$[3] at 21 °C and $[H^+]=10^{-pH}$ were used in the calculation.

Results

Elemental Analysis and IR Spectra of an Isolated In(III) Complex. When a solution containing cysteine hydrochloride (0.1 M) and In(III) (0.052 M) in the ligand-to-metal ratio of 1.9: 1 was titrated with 8 M KOH, a large quantity of a white precipitate which was different from simple In(III) hydrolysate was formed at pH 3.9 and which redissolved at pH 5.2, whereas no precipitation was observed in the system containing the ligand (0.1 M) and In(III) (0.05 M) in the ligand-to-metal ratio of 2: 1. The precipitate formed at pH 4.8 was isolated and dried under a vacuum over diphosphorus pentoxide. Elemental analysis showed that the ligand: metal ratio was 1.3: 1: Found: C, 15.54; H, 3.19; N, 6.12; In, 38.29%. Calcd for $[In_3L_4(OH)(H_2O)\cdot 3H_2O]$: C, 15.83; H, 3.19; N, 6.16; In, 37.85%.

Table 1 shows some significant IR absorption bands of the isolated complex, together with those of the free ligand and the In(III) hydrolysate. In the isolated In(III)-cysteine complex, the coordination of the ligand to In(III) *via* the thiol, amino, and carboxyl groups is assumed on the basis of the disappearance of the SH, NH_3^+, and COOH absorptions, and the presence of NH_2 and COO^- absorptions. The coordina-
