The fluorescnce yield, ϕ_f, decreases with the solvent polarity much more than the fluorescence lifetime, τ_f, as seen from Fig. 4. The fluorescence yield in polar solvents is expressed by $\phi_f=k_4\cdot(k_4+k_5+k_2)^{-1}\cdot\tau_f\cdot k_f$. Based on the same reason as above, the decrease of (ϕ_f^{rel}/τ_f) with the solvent polarity must also be attributed to the increase of (k_2+k_5). Since the absolute value of k_2 is very small, as seen from the small absolute photo-current yield ($\sim10^{-5}$ at 30.3 kK in ether), the decrease of (ϕ_f^{rel}/τ_f) is mostly attributed to the increase of k_5. Thus, we can conclude that a large part of molecules excited to the Rydberg-like states near 30 kK in ether pass directly or *via* the fluorescent state into the solvated cation-electron pairs and only a small fraction turns to the free charge carriers or fluoresces. With increasing solvent polarity, process (2) will become more important.

The Photo-ionization of Other Organic Molecules in Polar Solvents. The ionization thresholds of organic molecules in nonpolar solvents are found to be 1.1—1.8 eV lower than the gas-phase ionization potentials, depending on the molecular size of solute and the molecular sphericity of solvent.[7,14-16] According to the scheme of the photo-electron ejection proposed in the present work, the ionization threshold in a polar solvent is expected to be further lowered, down to the lowest vertical Rydberg-like state.

The ionization threshold of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in hexane is measured to be about 5.0 eV,[15,16] 1.2 eV lower than the gas-phase ionization potential, 6.20 eV.[17] Richard and Thomas showed that TMPD was photo-ionized in water by illumination even at a photon energy of 3.57 eV.[4] The similar conclusion was also derived from an analysis of the fluorescence lifetimes and yields for TMPD in water–ethanol mixed solvents.[18] The lowest Rydberg states of aniline and its alkyl derivatives were reported to lie in the range 4.7—4.2 eV, being parallel to the sequence of decreasing ionization potentials.[19] Thus, the additional lowering of the ionization threshold of TMPD observed in polar solvents can be explained by the electron ejection from the lowest Rydberg-like state.

The ionization thresholds of aromatic hydrocarbons such as anthracene, pyrene and perylene in boric acid glass at room temperature were reported to be about 2.2—2.5 eV lower than the gas-phase ionization potentials.[20] These results can also be regarded as showing the electron ejection *via* the Rydberg-like state in polar solvents.[21]

The authors wish to thank Professor N. Mataga and Dr. T. Okada for letting us use a nitrogen gas laser for measurements of the fluorescence lifetime.

Solid-State Circular Dichroism Spectra of Tris(diamine)cobalt(III) Complexes: Decomposition into E and A_2 Components

Reiko KURODA* and Yoshihiko SAITO

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received October 15, 1975)

Solid-state circular dichroism spectra of some tris(diamine)cobalt(III) complexes were measured. Each CD band region was decomposed into E and A_2 components by combining the CD spectra in uniaxial single-crystals and in microcrystalline states. The observed values of $R(E)$ and $R(A_2)$ were compared with the theoretical calculation of Mason and Seal based on dynamic coupling method. The agreements are generally good for those complexes with five-membered chelate rings, however, there are some discrepancies for six- and seven-membered chelate ring cases.

Tris(diamine) cobalt(III) complexes usually exhibit two circular dichroism bands with opposite signs in the first absorption region ($A_{1g}\rightarrow T_{1g}$). The two bands correspond to the E and A_2 components of O_h parentage in D_3 environment. However, they are considered to be residual wing absorption resulting from extensive cancellation of the rotatory strengths of the two transitions, since the trigonal splitting is small. Single-crystal CD spectra are generally attended by difficulty of double refraction. Uniaxial crystals are usually employed for the measurement of single-crystal CD spectra. With the aid of the known crystal structures, an attempt has been made to decompose the CD spectra into two components by combining the single-crystal and the microcrystalline CD spectra of uniaxial crystals.

Principle of the Method

Figure 1 illustrates the interaction of circularly polarized light with the complex ion in a uniaxial crystal. The light propagates along the optic axis OZ. The direction of a threefold axis of the complex ion is indicated by a small closed triangle. The threefold axis is inclined at an angle of α with respect to the optic axis. Let OY be a projection of the threefold axis on a plane perpendicular to OZ. OX is chosen in such a way that OX, OY and OZ form a right-handed Cartesian coordinate system. When the circularly polarized light propagates along OZ, its electric vector $\boldsymbol{E}$ rotates on the XY plane. E component can be excited with the light whose electric vector is perpendicular to the threefold axis of the complex ion, whereas A_2 component can be excited when the electric vector is parallel to the threefold axis. At a given moment, let the electric vector $\boldsymbol{E}$ make an angle of φ with OX. The intensities of E and A_2 components excited at this moment will be proportional to

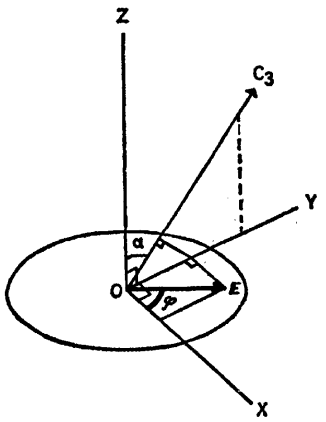

Fig. 1. Illustrating the interaction of circularly polarized light with the complex ion in a uniaxial crystal.

$$E^2\cos^2\alpha\sin^2\varphi + E^2\cos^2\varphi \quad \text{for E} \tag{1}$$

and

$$E^2\sin^2\alpha\sin^2\varphi \quad \text{for } A_2 \tag{2}$$

respectively. The averaged intensity over a period of rotation of the $\boldsymbol{E}$ vector will be obtained as follows:

$$1/2\pi\int_0^{2\pi}(E^2\cos^2\alpha\sin^2\varphi + E^2\cos^2\varphi)\mathrm{d}\varphi = E^2(1+\cos^2\alpha)/2 \quad \text{for E} \tag{3}$$

and

$$1/2\pi\int_0^{2\pi}(E^2\sin^2\alpha\sin^2\varphi)\mathrm{d}\varphi = E^2(\sin^2\alpha)/2 \quad \text{for } A_2 \tag{4}$$

Since E level is doubly degenerate, the difference between ε_l and ε_r of the single crystal, $\Delta\varepsilon_s$, can be written as a sum of the $\Delta\varepsilon(E_X)$, $\Delta\varepsilon(E_Y)$ and $\Delta\varepsilon(A_2)$ as follows:

$$\Delta\varepsilon_s = (1+\cos^2\alpha)/4\Delta\varepsilon(E_X) + (1+\cos^2\alpha)/4\Delta\varepsilon(E_Y) + (\sin^2\alpha)/2\Delta\varepsilon(A_2) \tag{5}$$

On the other hand, in microcrystalline state the threefold axes of the complex ions are randomly oriented, hence $\Delta\varepsilon$ in microcrystalline state, $\Delta\varepsilon_m$, can be written as

$$\Delta\varepsilon_m = 1/3\Delta\varepsilon(E_X) + 1/3\Delta\varepsilon(E_Y) + 1/3\Delta\varepsilon(A_2) \tag{6}$$

where 1/3 is a random orientation factor. Since $\Delta\varepsilon(E_X)=\Delta\varepsilon(E_Y)$, Eqs. (5) and (6) become

$$\Delta\varepsilon_s = (1+\cos^2\alpha)/2\Delta\varepsilon(E_X) + (\sin^2\alpha)/2\Delta\varepsilon(A_2) \tag{7}$$

and

$$\Delta\varepsilon_m = 2/3\Delta\varepsilon(E_X) + 1/3\Delta\varepsilon(A_2) \tag{8}$$

Now we obtain the two simultaneous Eqs. (7) and (8) involving $\Delta\varepsilon(E_X)$ and $\Delta\varepsilon(A_2)$ as two unknowns. Using $\Delta\varepsilon_s$ and $\Delta\varepsilon_m$ measured at an arbitrary wavelength, $\Delta\varepsilon(E_X)$ and $\Delta\varepsilon(A_2)$ can be easily calculated by Eqs. (7) and (8). In this way the observed CD spectra can be decomposed into E and A_2 components.

* Present address: Department of Chemistry, University of London, King's College, Strand, London WC2R 2LS, England.

Experimental

By the procedure described above, CD spectra of the following seven tris(diamine)cobalt(III) complexes of known crystal structures were decomposed.

Abbreviations: en ethylenediamine; pn propylenediamine; chxn *trans*-1,2-diaminocyclohexane; cptn *trans*-1,2-diaminocyclopentane; ptn 2,4-diaminopentane; tmd 1,4-diaminobutane.

These are all uniaxial crystals and the values of α are also shown.

The CD spectra of these D_3 complexes were measured for single-crystal and microcrystalline states except those of Δ-[Co(*R*,*R*-cptn)$_3$]Cl$_3$·4H$_2$O. For this complex Toftlund and Pedersen[8] measured the single-crystal CD spectra by diluting the complex ion in Δ-[Rh(*R*,*R*-chxn)$_3$]Cl$_3$·4H$_2$O. Though the crystal structure of this Rh(III) complex is not yet known, it is highly probable that the compound is isostructural with Δ-[Co(*R*,*R*-cptn)$_3$]Cl$_3$·4H$_2$O, in view of the fact that they belong to the same space group P6$_1$22 and form mixed crystals. Accordingly α was assumed to be 22° based on the known crystal structure of the cobalt complex[5].

The crystals of Λ-2[Co(en)$_3$]Cl$_3$·NaCl·6H$_2$O, Λ-[Co(en)$_3$]Br$_3$·H$_2$O, Δ-[Co(*R*-pn)$_3$]Br$_3$ and Λ-[Co(*S*,*S*-chxn)$_3$]Cl$_3$·5H$_2$O were prepared according to the method described by Nakatsu, Shiro, Saito and Kuroya[9], Werner[10], Iwasaki and Saito[3] and Jaeger and Bijkerk[11], respectively. The crystals of Δ-[Co(*R*,*R*-ptn)$_3$]Cl$_3$·2H$_2$O and Δ-[Co(tmd)$_3$]Br$_3$ were kindly supplied by Professor J. Fujita of Nagoya University.

CD Spectra. *a) Single-crystal CD Spectra*: Crystals were cut with a thin razor blade perpendicular to the optic axis and then they were polished on a filter paper moistened with water to the required thickness (0.01—0.08 mm). The thickness was measured by using a microscope fitted with a microscale. Direction of the optic axis for each specimen was checked by observing conoscopic figure under a polarizing microscope. The single-crystal CD spectra were measured over the range 300—650 nm by means of JASCO J-20 and partly by J-40, with the light beam parallel to the optic axis of the crystal. The measurements were repeated at least twice by employing different specimen in order to check the reproducibility except for Δ-[Co(tmd)$_3$]Br$_3$. For the latter case, the crystal was brittle and hard to manipulate. A specimen with suitable thickness for the measurement could not be obtained.

b) Preparation of KBr Disk and Measurement of CD Spectra in Microcrystalline State: About 180 mg of dry KBr and the required amount of complexes(*ca.* 1 mg) were weighed and powdered in a dental amalgam mill (Amalgamator) together with a stainless steel ball for about 150 s. In order to prevent from diffused reflections at grain boundaries, samples must be powdered elaborately. Dependence of CD spectra on duration of grinding was examined. $\Delta\varepsilon$ increases with the duration of grinding and tends to a constant value. The optimum duration of grinding was determined. The powdered samples were pressed in a standard KBr press at 9 t/cm^2 for five to ten minutes. The pellet was, after weighing, mounted on a KBr disk holder and placed normal to the light beam. CD spectra were measured over the range 300—650 nm by JASCO J-20. It was established that there exists a linear relationship between the circular dichroism deflection and the sample concentration, if the latter is less than 1% by weight.[12] Accordingly $\Delta\varepsilon$ values were calculated in the usual way.

The CD spectra under the second absorption band were recorded for those complexes containing chloride ions. The intensities were very weak, since the involved transitions are magnetically forbidden. The results are less reliable as compared to those under the first absorption band.

Results and Discussion

Figure 2 represents two typical CD spectra in single crystal and in microcrystalline state: Λ-[Co(*S*,*S*-chxn$_3$]Cl$_3$·5H$_2$O and Δ-[Co(*R*,*R*-ptn)$_3$]Cl$_3$·2H$_2$O. Table 1 gives the observed $\Delta\varepsilon_{max}$ and the peak positions for Λ-2[Co(en)$_3$]Cl$_3$·NaCl·6H$_2$O, Λ-[Co(*S*,*S*-chxn)$_3$]Cl$_3$·5H$_2$O and Δ-[Co(*R*,*R*-ptn)$_3$]Cl$_3$·2H$_2$O. In Fig. 3 are shown the results of decomposition into E and A_2 components of the CD spectra shown in Fig. 2. Table 2 summarizes the peak positions and $\Delta\varepsilon_{max}$ of the decomposed E and A_2 components in the first absorption region for all the seven D_3 complexes. Trigonal splitting param-

eters $K(\equiv 2/3(\tilde{\nu}_E - \tilde{\nu}_{A_2}))$ are also included. Single-crystal CD spectra of some D_3 complexes with $\alpha=0°$ were reported by McCaffery and Mason[13] and Judkins and Royer[14]. General features of the spectra and peak positions obtained by these authors agree well with those of the present study. However, the $\Delta\varepsilon$ values are somewhat different, reflecting the experimental difficulties of this kind of measurement. The CD spectra of Λ-$[Co(S,S\text{-chxn})_3]Cl_3\cdot 5H_2O$ are broadly similar to those of Λ-$2[Co(en)_3]Cl_3\cdot NaCl\cdot 6H_2O$. The CD spectra in KBr matrix of Λ-$[Co(en)_3]^{3+}$ and Λ-$[Co(S,S\text{-chxn})]_3^{3+}$ are not so much different from their solution CD spectra. However, it is not true for Δ-$[Co(R,R\text{-ptn})_3]Cl_3\cdot 2H_2O$: in its microcrystalline state, it gives a weak negative peak at a longer wavelength side and a large positive peak at shorter wavelength side of the first absorption band and a very weak negative peak in the second absorption region, whereas in solution the peak heights in the first absorption region are inverted, suggesting a conformational change in solution.[15] From Table 2, it can be easily seen that $R(E)$ is positive and $R(A_2)$ is negative for the absolute configuration Λ, while $R(E)$ is negative and $R(A_2)$ is positive for Δ configuration, in agreement with the well-known empirical rule for the solution CD spectra. The sign of K is always negative throughout the series of the complexes. For the complexes with five-membered chelate rings, K ranges from -250 to $-130\ cm^{-1}$, while $\tilde{\nu}_{max}$ of the two bands nearly coincide and the sign of K is

Λ-[Co(*S*,*S*-cptn)$_3$]Cl$_3$·4H$_2$O[b]	+57.3	−54.5	+2.8	+69.3	−65.4	+3.9	−4.3
Λ-[Co(*S*,*S*-ptn)$_3$]Cl$_3$·2H$_2$O[a]	+12.5	−14.5	−2.0	+57.7	−55.3	+2.4	+1.9
Λ-[Co(tmd)$_3$]Br$_3$[a]	+31.1	−38.7	−7.6	+93.0	−89.3	+3.7	−4.9

a) Experiments were carried out for the enantiomers. b) These values are based on the CD spectra measured by Toftlund and Petersen[8]. $R(T_1)=R(E)+R(A_2)$. $R(T_1)_{expt}$ are values observed for solution CD spectra.[16].

ambiguous in the six-membered chelate ring case. The K value for Δ-[Co(tmd)$_3$]$^{3+}$ was not so reliable and it may not be practicable to discuss further. Rotatory strengths of each component under the first absorption band were obtained from the band areas of the CD spectrum. Table 3 lists the values of $R(E)$ and $R(A_2)$. The net rotatory strengths, $R(T_1)=R(E)+R(A_2)$ are also included. The net rotatory strengths obtained from solution CD spectra are also included in Table 3 under the heading $R(T_1)_{expt}$.[16] For $R(E)$ of Λ-2[Co(en)$_3$]Cl$_3$·NaCl·6H$_2$O values of +52.6[13] and +50.9[14] are reported. +45.3 is given for $R(E)$ of Λ-[Co(en)$_3$]Br$_3$·H$_2$O.[13] All these values are somewhat smaller than those of the present study. $R(E)$ of −41.5 for Δ-[Co(*R*-pn)$_3$]Br$_3$ by Judkins and Royer[14] agrees well with −38.1 of the present study. As can be seen from Table 3, the absolute values of the observed rotatory strengths of the E and A_2 bands possess nearly the same magnitudes and opposite signs in conformity with the theoretical prediction. $R(E)$ and $R(A_2)$ are unequal: $|R(E)|>|R(A_2)|$ for the complexes with five-membered chelate rings, whereas $|R(E)|<|R(A_2)|$ for the complexes with six- and seven-membered chelate rings. $R(T_1)$'s obtained from solid state CD spectra generally agree well in magnitude and sign with those obtained from solution CD spectra except for Λ-[Co(*S*,*S*-cptn)$_3$]$^{3+}$, Λ-[Co(*S*,*S*-ptn)$_3$]$^{3+}$ and Λ-[Co(tmd)$_3$]$^{3+}$. For the latter three cases, some change in the conformation of the complex ion or in the mode of ion association may be expected in solution.[8,15]

Recently Mason and Seal calculated the d-electron optical activity of tris(diamine) cobalt(III) complex ions based on dipole-coupling ligand-polarization model.[16,17] All the computations are based on the crystal structures determined by us.[1-7] The results are listed in Table 3. The theoretical calculations correctly predict all the signs of $R(E)$ and $R(A_2)$. Moreover, theoretical values of $R(T_1)$ agree well in sign and magnitudes with those observed in solid-states for the complexes with five-membered chelate rings. Theoretical values of $R(E)$ and $R(A_2)$ for Λ-[Co(en)$_3$]$^{3+}$ agree satisfactorily with the observed values. For five-membered ring cases $R(E)$ and $R(A_2)$ agree pretty well with the observation. For the six- and seven-membered chelate ring cases, the agreement is less satisfactory. No explanation can be offered at present.

Unlike solution CD spectra, crystal CD spectra are free from the effect of conformational change which sometimes occurs in solution, on the other hand the effect of neighboring anion in the crystal cannot be ignored. This latter effect might not be of a primary importance, as can be seen from Table 3.

The authors wish to thank Professor C. E. Schäffer of University of Copenhagen for suggesting the method for decomposing solid-state CD spectra into E and A_2 components and for helpful discussion. They also thank Professor S. F. Mason of University of London for the theoretical results in advance of publication. Part of the cost of this reseach was met by a Scientific Research Grant from the Ministry of Education, to which the authors' thanks are due.

Triplet Excimer of Phenanthrene in Fluid Solution. Dynamic Analysis of Time-Resolved Phosphorescence

Masayuki AIKAWA, Takeshi TAKEMURA, and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received October 27, 1975)

The excimer phosphorescence of phenanthrene in isooctane at temperatures over a range of 300—77 K has been studied by means of a photon-counting technique. At temperatures above the melting point of isooctane a broad emission spectrum with its intensity maximum at 525 nm was obtained, which is essentially different from the structured phosphorescence spectrum obtained in rigid media at 77 K. The time dependence of the spectral shape and intensity of the phosphorescence emission affords strong evidence that the broad emission spectrum originates from the triplet excimer. A scheme of the triplet excimer formation involving a self-quenching pathway of the triplet monomer is proposed to interpret the time and concentration dependence of the monomer and excimer phosphorescence.

Although there have been many studies on the triplet excimer of aromatic hydrocarbons, the occurrence of excimer phosphorescence in solution has not yet been established.[1-4] In previous papers we have confirmed the existence of the triplet excimer for naphthalene and 1-chloronaphthalene in 2,2,4-trimethylpentane (isooctane) at 293 K through the photostationary and transient phosphorescence measurements.[5,6]

Langelaar *et al.* first reported the excimer phosphorescence of phenanthrene in viscous solution, but they have subsequently shown that the emission was due to an impurity.[7,8] They have also shown, however, kinetic evidence in favor of triplet excimer formation in some aromatic hydrocarbons including phenanthrene in fluid solutions.[9,10] On the other hand, in a study on the photo-dissociation of the *cis* dimer of 9-(hydroxymethyl)phenanthrene and other phenanthrene derivatives in a rigid matrix at 77 K, Chandross and Thomas have concluded that phenanthrene does not form a triplet excimer as well as a singlet excimer even under favorable conditions.[11] Thus, it is necessary to further study the phenanthrene triplet in fluid solution in order to settle the question whether the triplet excimer does exist.

In the present work, we have observed a broad phosphorescence spectrum with a maximum near 525 nm for phenanthrene in isooctane solution at 187 or 293 K. This spectrum is essentially different from the structured phosphorescence spectrum of phenanthrene obtained in EPA at 77 K. The broad spectrum may be attributed to emission either from an impurity triplet produced by T–T energy transfer or from the triplet excimer of phenanthrene. In order to elucidate this problem we measured time-resolved spectra of phenanthrene phosphorescence in fluid solution. An analysis of the time-dependent behavior of the phosphorescence after flash excitation leads to strong evidence that the phenanthrene triplet excimer exists even in fluid solution.

Experimental

A sample of commercial phenanthrene was purified carefully by the following successive processes. To remove a small quantity of anthracene from phenanthrene, the sample was refluxed with maleic anhydride in spectro-grade benzene for 20 hours. The mixture was filtered, the filtrate was shaken with a sodium hydroxide solution, and phenanthrene contained in the organic layer was freed from the solvent by distilling the latter under reduced pressure.[12,13] The sample was then recrystallized several times from spectro-quality ethanol, passed through a silica-gel column with petroleum benzine as the solvent, and finally sublimed *in vacuo*. Spectro-grade isooctane was also treated with a silica-gel column. The solution of phenanthrene in 1 cm square quartz cell was fully degassed by repeated freeze-thaw cycles (7 or 8 times).

Emission and excitation spectra were measured with a high-resolution, high-sensitivity photon-counting emission spectrophotometer constructed in our laboratory. The time-resolved phosphorescence spectra, as well as the intensity of phosphorescence or delayed fluorescence emission as a function of time, were measured with the aid of a spectro-phosphorimeter which was designed, on the basis of the photon-counting method, for obtaining emission decay curves in a time range of 10^2 to 10^{-5} s. In this phosphorimeter, either a continuous Xe arc lamp combined with a light-chopping system or a Xe flash lamp was used as a pulsed light source. The design and performance of these two apparatuses have been described in a previous paper.[6]

The phosphorescence spectra were corrected for the spectral sensitivity of the monochromator-photomultiplier system after the method reported in a previous paper[14] using a standard tungsten filament lamp. The phosphorescence quantum yields were determined by comparing the corrected phosphorescence spectra with a corrected fluorescence spectrum of quinine sulfate in 0.5 M sulfuric acid, which has a fluorescence quantum yield of 0.51.

Results

Figure 1 shows the phosphorescence spectra of phenanthrene in isooctane at 77 K and 187 K. In the spectrum at 187 K a broad emission band is seen near 525 nm which is absent at 77 K. A phosphorescence spectrum similar to that at 187 K was also obtained at 293 K. The structured phosphorescence band at 187 K or at 293 K in a region near 470 nm, which is practically identical with the spectrum at 77 K in location and band shape, can be attributed to the monomer phosphorescence emission of phenanthrene. The excitation spectrum in fluid solution monitored at the 520 nm emission peak (Fig. 1), as well as that monitored at 465 nm, is in good agreement with the absorption spectrum. This suggests that the broad emission band originates from phenanthrene itself.

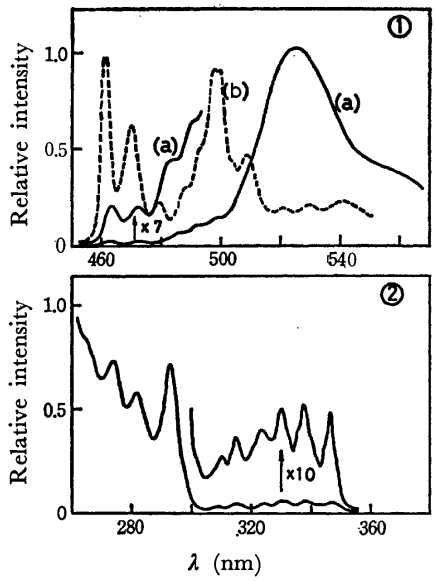

Fig. 1. Corrected phosphorescence and excitation spectra of phenanthrene in isooctane (2.5×10^{-5} M). (1) Phosphorescence spectrum: **a**, at 187 K; **b**, at 77 K. (2) Excitation spectrum at 187 K, monitored with respect to the 520 nm phosphorescence peak.

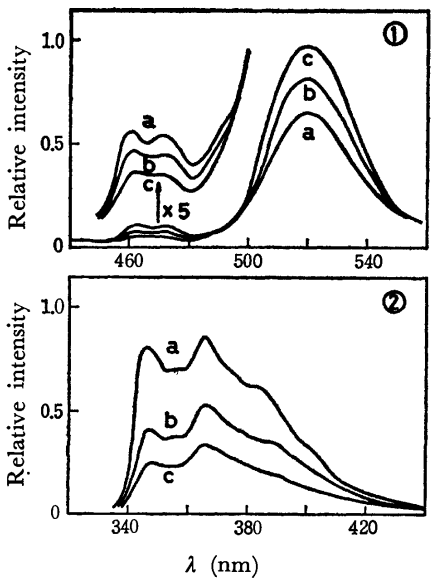

Fig. 2. Time-resolved phosphorescence (1) and delayed fluorescence (2) spectra in isooctane (1×10^{-4} M) at 293 K (uncorrected for instrumental response). The spectra denoted by **a**, **b**, and **c** were observed at 140, 305, and 635 μs, respectively, after flash excitation.

The time-resolved phosphorescence and delayed fluorescence spectra in isooctane at 293 K are shown in Fig. 2. The intensities of both the phosphorescence at about 465 nm and the delayed fluorescence decrease monotonously with time after flash excitation, whereas the broad structureless band with its maximum at about 525 nm grows with time.

The emission intensity as a function of time after flash excitation, monitored at a given wavelength, will be denoted by $I(t)$. Figure 3 illustrates the $I(t)$

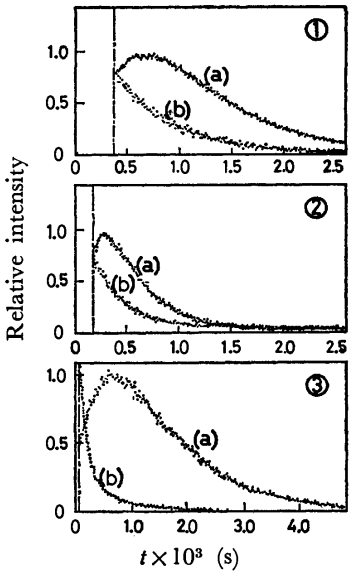

Fig. 3. Some representative $I(t)$ curves for phenanthrene in isooctane. Temperatures and solute concentrations: (1) 293 K, 1.8×10^{-4} M; (2) 293 K, 1.24×10^{-3} M; (3) 187 K, 2.1×10^{-3} M. Monitoring wavelengths: **a**, 465; **b**, 520 nm. Dashed lines show the time width of pulsed light source.

curves for phosphorescence in isooctane at 293 and 187 K. The $I(t)$ curve observed at 465 nm and at 187 K is composed of two exponential decays but that at 293 K represents a first order decay within our experimental errors. On the other hand, the $I(t)$ curve detected at 520 nm shows a rise for small values of t and decay for large t. It is also seen that the value of t at which $I(t)$ reaches a maximum becomes much smaller on increasing the phenanthrene concentration. We can thus assign the broad emission band with the intensity maximum at about 525 nm to the triplet excimer of phenanthrene on the basis of the following considerations.

Under our experimental conditions where the excitation intensity is low and the solution is of very low viscosity, the kinetic scheme for the deactivation of the triplet states involving the triplet excimer formation may be expressed in general as follows:[9,15]

$$^3M^* + {}^1M \underset{\overleftarrow{k}}{\overset{\overrightarrow{k}}{\rightleftharpoons}} {}^3D^* \qquad (1)$$

$^3M^*$ → k_{1r}, k_{1q}; $^3D^*$ → k_{2r}, k_{2q}

Here, ^1M, $^3M^*$, and $^3D^*$ stand for the ground singlet monomer, excited triplet monomer, and excited triplet dimer (triplet excimer), respectively; k_{1r}, k_{1q}, k_{2r}, and k_{2q} are the radiative (r) and non-radiative (q) decay constants for the triplet monomer and excimer; and $\overrightarrow{k}$ and $\overleftarrow{k}$ denote the rate constants for the formation and dissociation of the triplet excimer, respectively.

Delayed fluorescence could be observed because of its high intensity. The triplet–triplet annihilation, however, need not be considered in the scheme, since

the triplet concentration in our experiments was so low that the annihilation should not contribute appreciably to the triplet decay. The decay rate constant for the delayed fluorescence observed is twice the rate constant obtained from the tail portion of the phosphorescence $I(t)$ curve at 465 nm (see Fig. 2).

Solution of the rate equations for the kinetic scheme (1), under the appropriate initial conditions, yields the following expressions for the quantum intensity of the monomer and excimer phosphorescence at time t.

$$I_m(t) = \frac{k_{1r}(\theta_2 - X)}{(\theta_2 - \theta_1)}\{e^{-\theta_1 t} + Ae^{-\theta_2 t}\} \quad (2)$$

$$I_d(t) = \frac{k_{2r}\vec{k}[^1M]}{(\theta_2 - \theta_1)}\{e^{-\theta_1 t} - e^{-\theta_2 t}\} \quad (3)$$

where

$$\theta_{1,2} = \frac{1}{2}[X + Y \mp \{(Y-X)^2 + 4\vec{k}\overleftarrow{k}[^1M]\}^{1/2}] \quad (4)$$

and

$$A = (X-\theta_1)/(\theta_2 - X)$$
$$X \equiv k_1 + \vec{k}[^1M] \qquad k_1 = k_{1r} + k_{1q} \quad (5)$$
$$Y \equiv k_2 + \overleftarrow{k} \qquad k_2 = k_{2r} + k_{2q}$$

Equations (2) and (3) predict that the monomer should display a curve consisting of two exponential decays and that the excimer phosphorescence should yield a rise-and-decay curve. The $I(t)$ curves monitored at 465 and 520 nm correspond well to $I_m(t)$ given by Eq. (2) and $I_d(t)$ given by Eq. (3), respectively. This provides the conclusive evidence that the emission at 520 nm is due to the triplet excimer of phenanthrene.

For both $I(t)$ curves monitored at 465 and 520 nm, the plot of log $I(t)$ *vs.* t at long times after flash excitation gives the first-order decay constant, θ_1. The value of θ_2 can be obtained from the difference between the $I(t)$ curve observed for the excimer emission and the first order decay curve extrapolated towards shorter times by the use of θ_1. The θ_2 value can also be obtained by using the initial part of the $I(t)$ curve for the monomer.

The initial decay related to θ_2 was observed in the monomer $I(t)$ curve at 187 K, but not at 293 K. This is because the excitation pulse used was not sufficiently short to monitor the fast decay at 293 K.

There may be a possibility that the broad phosphorescence is ascribed to an impurity emission. Energetically, however, reversible energy transfer is not likely to occur[16,17] owing to a large energy difference between the phosphorescence 0–0 band at 463 nm and the phosphorescence maximum at 520 nm. Therefore, if the emission assigned to the excimer phosphorescence were to be due to an impurity triplet, $^3Q^*$, the broad phosphorescence should arise from irreversible triplet–triplet energy transfer from phenanthrene to the impurity. In this case, the kinetic scheme (1) is modified by substituting ^1Q for ^1M and $^3Q^*$ for $^3D^*$, and the following expression is obtained for the time dependence of the intensity of monomer emission:

$$I_m(t) = C\exp\{-(k_1 + \vec{k}[^1Q])t\} \quad (6)$$

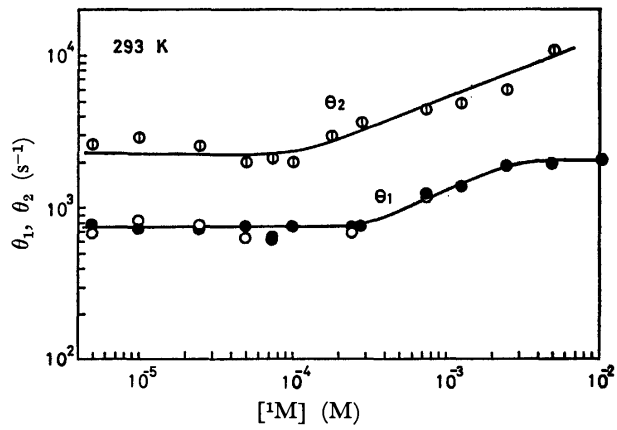

Fig. 4. Plots of θ_1 and θ_2 against the concentration of phenanthrene in isooctane at 293 K. The values of θ_1 are obtained from the $I(t)$ curves monitored at 465 (○) and 520 nm (●), and the values of θ_2 are obtained at 520 nm (ⓓ).

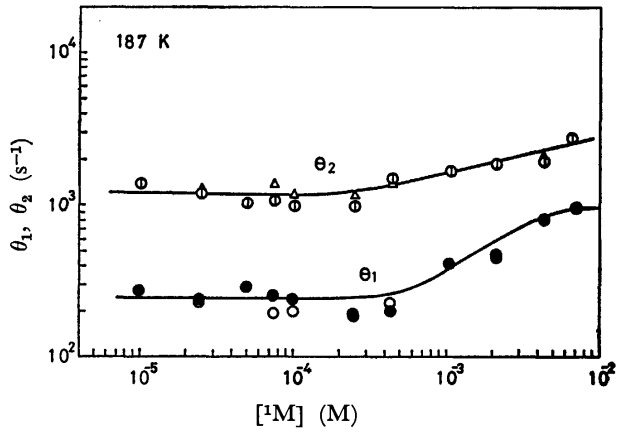

Fig. 5. Plots of θ_1 and θ_2 against the concentration of phenanthrene in isooctane at 187 K. The symbol (△) refers to the values of θ_2 which are obtained from the $I(t)$ curves monitored at 465 nm, and the other symbols are the same as in Fig. 4.

The $I(t)$ curve for the monomer phosphorescence observed at 465 nm is then expected to show a single exponential decay with a rate constant $k_1 + \vec{k}[^1Q]$. This expectation contradicts the experimental fact that the initial fast decay was observed in the monomer $I(t)$ curve at 187 K, and therefore the possibility of impurity emission is ruled out. Thus additional evidence is obtained that the emission at 525 nm is due to the triplet excimer of phenanthrene.

The plots of θ_1 and θ_2 obtained at 293 K and 187 K against [^{1}M] are shown in Figs. 4 and 5, respectively. As [^{1}M] increases, θ_1 first increases and then reaches a constant value at relatively high values of [^{1}M], while θ_2 increases monotonously. It is also seen from Fig. 5 that the monomer and the excimer $I(t)$ curves at 187 K lead to consistent values both for θ_1 and for θ_2.

The rate constants $\vec{k}$, $\overleftarrow{k}$, k_1, and k_2 at a given temperature can be evaluated from the data on θ_1 and θ_2 as a function of [^{1}M] by using the following limiting properties,[15] (i) As [^{1}M] becomes small, θ_1 and θ_2

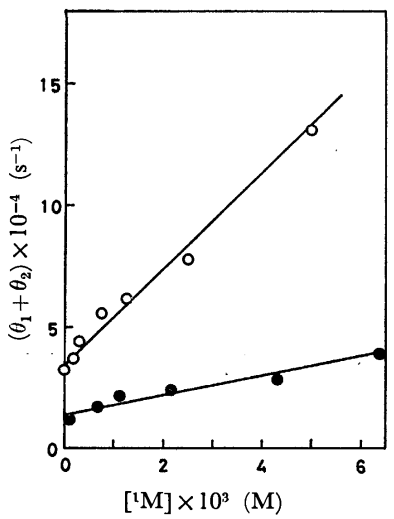

Fig. 6. Plots of $\theta_1+\theta_2$ against the concentration of phenanthrene at 293 (○) and 187 K (●).

TABLE 1. RATE CONSTANTS FOR PHENANTHRENE IN ISOOCTANE SOLUTION

Temperature K	$k_1\times10^{-2}$ s^{-1}	$k_2\times10^{-3}$ s^{-1}	$\vec{k}\times10^{-6}$ $M^{-1}s^{-1}$	$\overleftarrow{k}\times10^{-3}$ s^{-1}
187	2.5	1.0	0.4	0.2
293	7.5	1.9	2.0	0.6

approach constant values which represent k_1 and $k_2+\overleftarrow{k}$. As shown in Figs. 4 and 5, θ_1 and θ_2 become constant in the concentration range of 10^{-6}—10^{-4} M. (ii) At higher concentrations ($>10^{-2}$ M in the case of phenanthrene), θ_1 becomes k_2. (iii) At any value of $[^1M]$, Eq. (4) yields the following relation:

$$\theta_1+\theta_2=k_1+k_2+\overleftarrow{k}+\vec{k}[^1M] \quad (7)$$

As expected from Eq. (7), the plots of $\theta_1+\theta_2$ against $[^1M]$ (Fig. 6) give good straight lines with slopes, $\vec{k}$ equal to 2.0×10^6 and 0.4×10^6 $M^{-1}s^{-1}$, respectively, at 293 and 187 K. The behavior of θ_1 and θ_2 as predicted from the limiting conditions (i) through (iii) is consistent with our experimental results. The rate constants, $\vec{k}$, $\overleftarrow{k}$, k_1, and k_2 at 293 and 187 K thus determined are summarized in Table 1.

Discussion

The equilibrium constant of the excimer formation reaction (1) in the triplet state is defined as $K_e=\vec{k}/\overleftarrow{k}$, which is calculated to be 3.3×10^3 M^{-1} at 293 K and 2.0×10^3 M^{-1} at 187 K. The energy difference (ΔE) between the 0–0 phosphorescence band of the monomer at 463 nm and the phosphorescence maximum of the triplet excimer at 525 nm is about 2600 cm^{-1} (7.3 kcal). The value of K_e is much the same as those observed in singlet excimers, but the ΔE value is very small compared with the corresponding values for singlet excimers of aromatic hydrocarbons, in which ΔE is nearly constant and equal to ~6000 cm^{-1}.[16] The entropy change, ΔS, accompanying the triplet excimer formation is obtained from K_e and ΔE after the manner in which ΔS was estimated for the singlet excimer.[15] The absolute value of ΔS thus determined seems to be too small (less than 1 cal mol^{-1} deg^{-1} at 293 K).

In view of those circumstances, we introduce a self-quenching pathway of $^3M^*$ into the scheme (1):

$$^3M^* + {}^1M \underset{\overleftarrow{k}}{\overset{k_d}{\rightleftharpoons}} {}^3D^* \quad (9)$$

$^3M^*$ → k_1, $k_1'[^1M]$; $^3D^*$ → k_2

Evidently the rate constants k_1 and $\vec{k}$ defined in the scheme (1) correspond, respectively, to $k_1+k_1'[^1M]$ and k_d in the scheme (9). The values of $\vec{k}$ as determined from the dependence of $\theta_1+\theta_2$ on $[^1M]$ (Eq. (7) and Fig. 6) must then be identified as the values for $k_1'+k_d$. It is conceivable that most of the encounters of the triplet-state monomer with the ground-state lead to the quenching of the former, and thus it is possible that k_1' may be ten times as large as k_d. The rate constant k_d will then be smaller than $\vec{k}$ by a factor of 10; in other words, the photoassociation equilibrium constant, $K_a=k_d/\overleftarrow{k}$ in the scheme (9) may become far smaller than K_e. Thus, if we tentatively assume that $K_a=10^2$ M^{-1} at 300 K, we can obtain reasonable values for ΔS, the enthalpy of the triplet excimer formation ΔH, and the repulsion energy between two unexcited monomer molecules I_G, using $\Delta E=7.3$ kcal mol^{-1}. The results are: $\Delta S=-10$ cal mol^{-1} deg^{-1}, $\Delta H=-5.5$ kcal mol^{-1}, and $I_G=2$ kcal mol^{-1}.

We believe that the triplet excimer formation of aromatic hydrocarbons is a general phenomenon as in the case of the singlet excimer formation. It is probable that the stabilization responsible for the triplet excimer is due to the charge resonance interaction,[4,17,18] which depends critically on the distance, R, and the orbital overlap between the triplet and ground state molecules contrary to the dipole-dipole interaction.[19] Thus, the triplet excimer formation requires a specific arrangement between the two molecules within the solvent cage. This seems to correspond to the fact that the formation rate constant is much smaller than the diffusion-controlled rate constant, as is shown by our experimental results (Table 1). It may be concluded that the difference between those two rate constants results from the frequency factor.

It is well known that the T–T energy transfer rate in fluid solution is very nearly the diffusion-controlled rate when the triplet level of donor lies higher than that of the acceptor by 3—4 kcal/mol or more.[20-22] T–T energy transfer distance, 6—10 Å between donor and acceptor in fluid solution[23] is much larger than the interaction distance of triplet excimer which may be 3—3.5 Å on the analogy of singlet excimer. The difference between the T–T energy transfer and triplet excimer formation, though both processes require overlaps of the orbitals of the two molecules, is that the former can occur even within one or two encounter

with very weak interaction, in comparison with the latter which depends on the suitable overlap. There have been many negative results about the problem whether or not the orientation is detectable for the T–T energy transfer in solution.[24,25] Our result suggests, however, that the triplet excimer formation needs specific and critical requirement for the orientation between two molecules.

In the concentration range used in our experiments, the precursor of the triplet excimer is very likely the triplet monomer rather than the singlet excimer. In higher concentration region, the possibility of the latter cannot be ruled out.

Sum Rule Consideration of Molecular Photoelectron Spectra: s-Type Bands of Butenes

Shunji KATSUMATA and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received November 17, 1975)

The s-type photoelectron bands of *cis*-, *trans*-2-butene, and 2-methylpropene in the gaseous phase have been measured in the region 17—27 eV by a He(II) resonance lamp which was constructed for the present purpose. The vertical ionization energies obtained here from the s-type bands have been interpreted with the Hückel method involving the Coulomb integrals of carbon 2s atomic orbitals which were estimated on the basis of the idea of sum rule from the available He(II) data of many other hydrocarbons reported by Potts *et al.*

In previous He(I) photoelectron studies of many aliphatic compounds,[1-5] total and partial sums of vertical ionization energies in the p-type region have been interpreted by Kimura *et al.* in terms of the empirical energies selected on the basis of the photoelectron data of simple molecules. The sum rule has also been applied to all the ionization energies obtained in the p- and s-type regions in mono-, di-, and trimethylamines,[6] using Hall's equivalent orbitals.[7] From the sum rule considerations of various chloro-substituted compounds[4] and ethylene derivatives,[5] the following substitution effects have been pointed out on the total sums of the p-type vertical ionization energies: 1) The total sum increases approximately linearly with number of substituents. 2) The total sums of the isomers are nearly the same. 3) The total sum may be approximately reproduced with the sums of the p-type empirical ionization energies. In connection with our previous studies, we have attempted to extend our study to the s-type region of butenes in the present He(II) photoelectron study.

Potts *et al.*[8-10] have published He(II) photoelectron spectra of many saturated and unsaturated hydrocarbons, together with the resulting complete sets of vertical ionization energies in the s-type region. They have interpreted the s-type ionization energies in terms of the Coulomb integrals of carbon 2s atomic orbitals on the basis of a simple Hückel theory. In the present work, we tried to employ their experimental data for a test of our sum rule in the present work. We wish to point out here that: 1) the total sums of the available s-type vertical ionization energies in the individual hydrocarbons may be reproduced by the sums of Coulomb integrals associated with the carbon skeletons of the hydrocarbons and 2) the He(II) bands of butenes which have not been published so far may be interpreted by the Hückel method with the Coulomb energies estimated from other hydrocarbons.

Experimental

Measurements of He(II) photoelectron spectra were carried out in the region up to about 27 eV with a high-resolution photoelectron spectrometer previously used,[1,2] a DC discharge He lamp of hollow-cathode type being used as a He(II) resonance source (304 Å) which was constructed for the present purpose. The cathode of the He(II) lamp was made of aluminum. During the photoelectron measurements, the He lamp was discharged at a pressure of about 0.06 Torr at a voltage of 700 V (0.4 A). Calibrations of ionization energies were carried out with Xe and He as internal standards. In the region below about I_1+17 in eV units, where I_1 represents the first ionization energy, He(II) spectra may be observed without overlapping with He(I) spectra. In the higher region the ionization bands produced by He(I) lines (584, 537, 522 Å, *etc.*) are mixed with those produced by He(II) line. No filter films were used here for separating He(II) line from He(I) line. Commercial gaseous samples of propene and *cis*- and *trans*-2-butene, and 2-metyhlpropene were used without further purification.

Results and Discussion

The photoelectron spectra of propene and *cis*- and *trans*-2-butene, and 2-methylpropene obtained here in the region 17—27 eV are shown in Fig. 1, suggesting three ionization bands indicated by vertical lines with the numbering. The propene spectrum in Fig. 1(a) is essentially the same as that reported by Potts *et al.*[10] It may be pointed out from the photoelectron spectra of butenes that the separations of the second and third

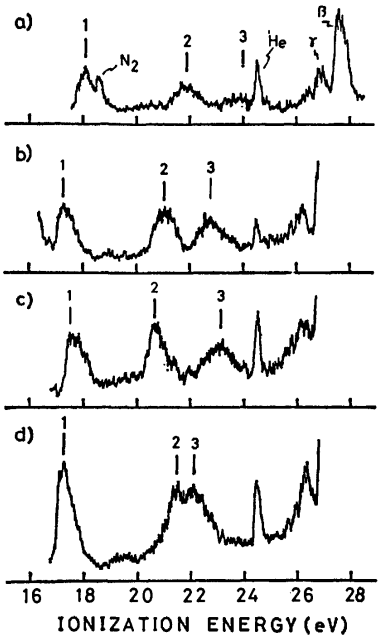

Fig. 1. The He(II) photoelectron spectra of (a) propene, (b) *cis*-2-butene, (c) *trans*-2-butene, and (d) 2-methylpropene in the region 17—27 eV. The peaks indicated by He are due to the ionization of helium gas by a He(II) line and those indicated by β and γ are due to the ionization of the samples by the 537- and 522-Å lines of He(I), respectively.

a) Ref. 10.

s-type bands remarkably differ from one another among the three isomers. The first s-type bands of the isomers are located approximately at the same position. The vertical ionization energies obtained from these photoelectron bands are summarized in Table 1. For *cis*- and *trans*-2-butene, and 2-methylpropene there are no available He(II) spectra for comparison.

In the previous He(I) photoelectron studies,[3,5] it has been indicated that all the p-type bands of methyl-substituted ethylenes appear below about 17 eV and may be interpreted in terms of p-type localized MO's. In the present work, we discuss only s-type bands in the photoelectron spectra. The number of such s-type MO's in a hydrocarbon is equal to that of carbon atoms. Propene has three carbon s-type MO's which probably correspond to the three bands in Fig. 1(a). Butene isomers show three bands, the remaining bands being not clear in Fig. 1(b—d). The theoretical treatments mentioned later suggest that the fourth bands may be located at about 24.5 eV.

Potts *et al.*[8-10] have indicated in their He(II) photoelectron studies that the s-type bands of hydrocarbons may be interpreted in terms of carbon 2s atomic orbitals. They estimated the Coulomb integrals of the C-2s orbitals on the basis of the He(II) data, and suggested that the Coulomb integrals depend on the number of hydrogen atoms attached to the carbon atoms. However, no formulas have been given for correlating the Coulomb integrals to the number of hydrogen atoms.

Using the ionization energy data of Potts *et al.*,[9,10] we found that there may be an approximately linear relationship between the Coulomb integrals ($\alpha_{CH_{4-m}}$) and the number (m) of hydrogen atoms lost from CH_4,

$$\alpha_{CH_{4-m}} = a + bm \qquad (1)$$
$$m = 0—4$$

where a means the Coulomb integral of CH_4 and bm a correcting term due to the change of CH_4 to CH_{4-m}. The Coulomb integrals α_{CH_i} (i=0—4) are hereafter represented by α_i for simplicity.

In the present work, we first estimated Coulomb integrals α_i's from the available s-type ionization energies of several hydrocarbons; $CH_{4-m}(CH_3)_m$ (m= 0—4), ethylene, and butadiene. From least squares calculations, we found that a=−22.90 eV and b= 0.73 eV. The Coulomb energies thus determined are summarized in Table 2, which are used in the present study of propene and butenes. Before going into the analysis of the He(II) spectra of the compounds studied, we examined how the α_i's in Table 2 can reproduce the experimental total sums of s-type vertical ionization energies for various other hydrocarbons.

Table 2. Coulomb integrals (in eV) of the carbon s-type orbitals in CH_i (i=0—4), estimated from the sum rule

α_0	α_1	α_2	α_3	α_4
−19.98	−20.71	−21.44	−22.17	−22.90

The traces of the Hückel determinants and their numerical values for fourteen hydrocarbons are given in Table 3, compared with the corresponding experimental sums (T_{expt}) based on the s-type ionization energies reported by Potts *et al.*[9,10] As seen from Table 3, excellent agreements are obtained between calculation and experiment, except for cyclopropane and benzene.

Applying the above sum rule to butenes, we may

C_6H_6	$6\alpha_2=6a+12b$	124.4	125.3

Table 4. The traces of the Hückel determinants and the calculated total sums (eV) for *cis*- and *trans*-2-butene, and 2-methylpropene

Compound	Trace		$-T_{calcd}$
cis-CH_3-CH=CH-CH_3	$2\alpha_3+2\alpha_1$		
trans-CH_3-CH=CH-CH_3	$2\alpha_3+2\alpha_1$	$=4a+8b$	85.7
$(CH_3)_2C$=CH_2	$2\alpha_3+\alpha_2+\alpha_0$		

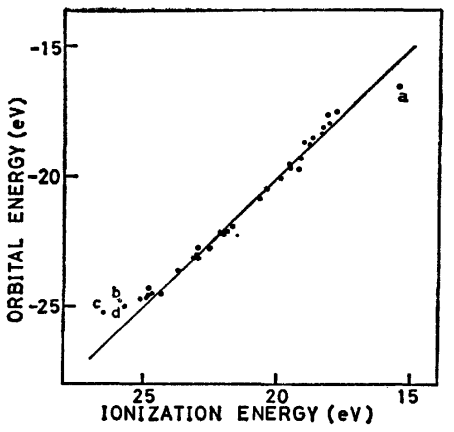

Fig. 2. A plot of the calculated (Hückel) orbital energies against the experimental vertical ionization energies in the s-type region for fourteen hydrocarbons given in Table 3. The solid line is drawn to show Koopmans' theorem. Points a and b are for the benzene b_{1u} and a_{1g} MO's, respectively; point c for the cyclopropane a_1 MO; and point d for the cyclohexane a_{1g} MO.

predict that the remaining s-type bands may appear at about 24.1—24.5 eV as shown in brackets in Table 1. The traces of the Hückel determinants of *cis*- and *trans*-2-butene, and 2-methylpropene are summarized in Table 4 which may be given simply by $4a+8b$.

In addition to the sum rule considerations mentioned above, we also calculated orbital energies by solving secular equations containing off-diagonal elements given by resonance integrals

$$\beta_{\mu\nu} = kS_{\mu\nu}(\alpha_\mu + \alpha_\nu) \qquad (2)$$

where $S_{\mu\nu}$ is the overlap integral between the nearest neighboring C-2s atomic orbitals and $k=0.12$ is used which was selected so as to reproduce the separation (3.48 eV) between two s-type vertical ionization energies of ethane. In order to test the validity of the parameter value (k) in Eq. (2), we calculated the orbital energies of s-type MO's for all the hydrocarbons given in Table 3. The resulting orbital energies are plotted against the available experimental ionization energies in Fig. 2, from which it may be seen that agreements between the orbital energies and the negative ionization energies are excellent except a few cases.

Similarly, solving secular equations, we also calculated the orbital energies of s-type MO's for *cis*- and *trans*-2-butene and 2-methylpropene. The calculated Koopmans' theorem ionization energies are also shown in Table 1, compared with the experimental ionization energies. Good agreements may be seen between experiment and theory.

The most interesting conclusions obtained in the present work are the following. 1) The sum rule of ionization energies approximately holds in the s-type region for the various hydrocarbons studied. 2) The s-type ionization energies in each of the hydrocarbons may well be interpreted in terms of the constant parameters a, b, and k. 3) The separation between the second and third s-type bands of 2-methylpropene is much smaller compared with that of *cis*-2-butene (or *trans*-2-butene) and such difference may be explained mainly with the difference in the Coulomb integrals of the C-2s atomic orbitals between the two isomers.

Further applications of the sum rule to many other organic compounds not only in the p-type region but also in the s-type region will be interesting subjects to be studied.

We would like to express our gratitude to Professor S. Kiyono, Dr. N. Ueno, and Dr. Y. Hayashi of Tohoku University for their valuable suggestions for the design of the He(II) lamp.

Substitution Reactions of Several Lead(II)–Polyamine-*N*-polyacetate Complexes with Indium(III) in Aqueous Solutions

Toru NOZAKI and Nagao SUEMITSU

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama-shi 790

(Received January 13, 1975)

The kinetics of the substitution reactions of the lead(II) complexes of EDTA, EDTA·OH, CyDTA, and DTPA with the indium(III) ion have been studied in the pH range from 1.8 to 4.8 at 20 °C and at an ionic strength of 0.1 in the presence of an excess of lead(II) ions. The reaction for the CyDTA system seems to proceed through only the dissociative process, while those for the EDTA, EDTA·OH, and DTPA systems proceed through both the steps forming a binuclear intermediate and the dissociative steps, in which the reactions forming indium complexes proceed mainly through the paths involving $InOH^{2+}$.

Many of the substitution reactions of divalent metal complexes of ethylenediamine-*N,N,N',N'*-tetraacetate (EDTA) and 1,2-cyclohexanediaminetetraacetate (CyDTA) with other divalent metal ions have been reported. However, only a few substitution reactions of divalent metal complexes with trivalent metal ions have been studied. Recently, the reaction paths of this type of substitution reaction have been shown by Takahashi and his co-workers.[1]

In the same way as in the previous work,[2] the kinetics of the substitution reactions of the lead(II) complexes of EDTA, *N*-(hydroxyethyl)ethylenediamine-*N,N',N'*-triacetate (EDTA·OH), CyDTA, and diethylenetriamine-*N,N,N',N'',N''*-pentaacetate (DTPA) with the indium(III) ion, which has the same electronic configuration as the gallium(III) ion, have been studied in the pH range from 1.8 to 4.2 at 20 °C and at an ionic strength of 0.1 in order to investigate the effects of the ligand and of the species of the indium(III) ion on the rate and the reaction process, and in order to compare the rates with those for gallium(III). In the present paper the rate equations will be presented on the basis of the kinetic results, and the mechanisms of the reactions will be discussed by relating the terms in the observed rate constants of the reactions to the rate constants of the reaction paths of a known type.[1]

Experimental

Stock solutions of indium(III) and lead(II) were prepared by dissolving a weighed amount of metallic indium (99.99%) in perchloric acid, and by converting lead(II) nitrate into the perchlorate with perchloric acid, respectively. The solutions were diluted to a constant volume with redistilled water and were standardized by chelatometric titration with EDTA. Standard solutions of polyamine-*N*-polyacetate were prepared by dissolving a weighed amount of EDTA, EDTA·OH, CyDTA, or DTPA (Dotite reagent), which had been dried at 80 °C for 3 hr without further purification, in redistilled water containing equimolar quantities of sodium hydroxide.

The pH values of the solutions of the lead(II) complexes and indium(III) were adjusted to given values with sodium hydroxide and perchloric acid, using a pH meter equipped with a calomel electrode in which sodium chloride was substituted for potassium chloride to avoid potassium-perchlorate interference. After mixing, the pH of the resulting solutions was constant during the reactions. The ionic strength of each of the solutions was adjusted to 0.1 with sodium perchlorate. The initial concentrations of PbX_t, where X_t denotes all the species of the polyamine-*N*-polyacetate anions, In(III), and Pb^{2+} were 5.0×10^{-6}, 5.0×10^{-6}, and $(1.0-8.0)\times10^{-3}$ M respectively. The substitution reactions were run in the pH range from 1.8 to 4.2 at 20 °C and at an ionic strength of 0.1 in the presence of an excess of lead(II) ions and in the absence of a buffer solution.

The reactions were followed by measuring the changes in the percent transmittances of the mixed solutions of the lead(II)-EDTA, -EDTA·OH, -CyDTA, and -DTPA complexes at maximum absorption wavelengths[3] of 240, 240, 225, and 250 nm respectively. The reacted amount of PbX_t with In(III), x, in the molar concentration for the initial reaction time, t (min), can be expressed as follows:

$$x = \frac{a\cdot\varepsilon_{PbX_t} + b\cdot\varepsilon_{In} + c\cdot\varepsilon_{Pb} - D}{(\varepsilon_{PbX_t} - \varepsilon_{Pb}) - (\varepsilon_{InX_t} - \varepsilon_{In})}$$

where a, b, c are the initial concentrations of the lead complexes PbX_t, the In(III) ions, and Pb^{2+} respectively, and where ε_{PbX_t}, ε_{Pb}, ε_{InX_t}, and ε_{In} are the molar extinction coefficients for PbX_t, Pb^{2+}, all the species of the indium(III) complexes, InX_t, and the In(III) ions, again respectively, at the maximum absorption wavelengths of the lead complexes, and where D refers to the measured absorbance of the mixed solution.

Results and Discussion

Reaction Orders. The reaction orders with respect to the lead complexes and the indium(III) ions were examined by changing the concentration of the complexes from 2.0×10^{-6} to 9.0×10^{-6} M and that of the indium ions from 2.0×10^{-6} to 1.1×10^{-5} M in the presence of excessive lead ions at a constant pH. The reactions were found to be first-order in both $[PbX_t]$ and [In(III)].

Effects of an Excess of Lead(II) Ions. Using the Bydalek and Margerum method,[4] the effects of excessive lead ions on the rates were investigated. The rates for all the systems decreased with an increase in the concentration of added lead ions, as is shown in Fig. 1.

pH Dependences. The effects of the pH on the initial rates are shown in Fig. 2. The rates were too fast and too slow to be measured below and above the pH ranges from 2.6 to 4.1, from 3.2 to 4.3, from 2.6 to 3.6, and from 1.8 to 2.3 for the EDTA, EDTA·OH, CyDTA, and DTPA systems respectively. The slopes suggest that the rate equations involve the terms of $1/[H^+]$ and $[H^+]$ for the EDTA and EDTA·OH systems, $[H^+]$ for the CyDTA system, and $1/[H^+]$ for the DTPA system.

Initial Rate Equations. In order to obtain the rate equations, the initial rates were measured by changing the pH in the presence of a large excess of lead(II) ions of 1.0×10^{-3} M and 2.0×10^{-3} M for the EDTA and EDTA·OH systems, 1.0×10^{-3} M for the CyDTA system, and 8.0×10^{-3} M and 4.0×10^{-2} M for the DTPA system. The concentrations of In^{3+}, PbX, and PbH_2X were calculated from the total concentrations of In(III) and PbX_t by use of the following equations: $[In^{3+}]=[In(III)]/(1+K_h/[H^+])$, $[PbX]=[PbX_t]/(1+K_H[Pb^{2+}])$, and $[PbH_2X]=[PbX_t]/(1+1/K_{2H}[H^+])$ respectively, and the values of $K_h=10^{-3.70}$M,[5] $K_H=66.1$,* 0, and 77.1 M^{-1} for EDTA, EDTA·OH, and CyDTA,[3] again respectively, and $K_{2H}=3.87\times10^4$ M^{-1} for DTPA.[3] The results are shown in Figs. 3, 4, and 5, and in Table 1. From the results and a consideration of the reaction orders and the effects of an excess of lead(II) ions and the pH dependence mentioned above, the initial rate equations can be

expressed as follows:

For the EDTA and EDTA·OH systems:

$$R=\{(k_1+k_4/[Pb^{2+}])/[H^+]+(k_2+k_5/[Pb^{2+}])+(k_3+k_6/[Pb^{2+}])[H^+]\}[PbX][In^{3+}] \quad (1)$$

for the CyDTA system:

$$R=\{k_5+k_6[H^+]\}[PbX][In^{3+}]/[Pb^{2+}] \quad (2)$$

for the DTPA system:

$$R=\{(k'_3+k'_6/[Pb^{2+}])/[H^+]+(k_7+k_8/[Pb^{2+}])\}[PbH_2X][In^{3+}] \quad (3).$$

As has been concluded by previous workers,[1] such reactions proceed through simultaneous reaction paths of the electrophilic substitution reaction and the dissociation reaction of the metal complexes. From a consideration of the species of the indium(III) ions[5] and the lead and indium complexes in an equilibrium state, the following reaction paths from Eqs. (1a) to (6c) for the EDTA, EDTA·OH, and CyDTA systems, and from (2a) to (3b), (5a) to (6c), and (7a) to (8c) for the DTPA system may be considered:

$$PbX^{(n-2)-}+In^{3+}\xrightarrow{k_{1a}^+}InX^{(n-3)-}+Pb^{2+} \quad (1a)$$

$$PbX^{(n-2)-}+InOH^{2+}\xrightarrow{k_{1b}^+}In(OH)X^{(n-2)-}+Pb^{2+} \quad (1b)$$

$$PbHX^{(n-3)-}+In^{3+}\xrightarrow{k_{2a}^+}InHX^{(n-4)-}+Pb^{2+} \quad (2a)$$

$$PbHX^{(n-3)-}+InOH^{2+}\xrightarrow{k_{2b}^+}InX^{(n-3)-}+Pb^{2+}+H_2O \quad (2b)$$

$$PbH_2X^{(n-4)-}+In^{3+}\xrightarrow{k_{3a}^+}InH_2X^{(n-5)-}+Pb^{2+} \quad (3a)$$

$$PbH_2X^{(n-4)-}+InOH^{2+}\xrightarrow{k_{3b}^+}InHX^{(n-4)-}+Pb^{2+}+H_2O \quad (3b)$$

$$PbX^{(n-2)-}\underset{k_{4a}^-}{\overset{k_{4a}^+}{\rightleftharpoons}}Pb^{2+}+X^{n-} \quad (4a)$$

$$X^{n-}+In^{3+}\xrightarrow{k_{4b}^+}InX^{(n-3)-} \quad (4b)$$

$$X^{n-}+InOH^{2+}\xrightarrow{k_{4c}^+}In(OH)X^{(n-2)-} \quad (4c)$$

$$PbHX^{(n-3)-}\underset{k_{5a}^-}{\overset{k_{5a}^+}{\rightleftharpoons}}Pb^{2+}+HX^{(n-1)-} \quad (5a)$$

$$HX^{(n-1)-}+In^{3+}\xrightarrow{k_{5b}^+}InHX^{(n-4)-} \quad (5b)$$

$$HX^{(n-1)-}+InOH^{2+}\xrightarrow{k_{5c}^+}InX^{(n-3)-}+H_2O \quad (5c)$$

$$PbH_2X^{(n-4)-}\underset{k_{6a}^-}{\overset{k_{6a}^+}{\rightleftharpoons}}Pb^{2+}+H_2X^{(n-2)-} \quad (6a)$$

$$H_2X^{(n-2)-}+In^{3+}\xrightarrow{k_{6b}^+}InH_2X^{(n-5)-} \quad (6b)$$

$$H_2X^{(n-2)-}+InOH^{2+}\xrightarrow{k_{6c}^+}InHX^{(n-4)-}+H_2O \quad (6c)$$

$$PbH_2X+In^{3+}\xrightarrow{k_{7a}^+}InH_3X^{+}+Pb^{2+} \quad (7a)$$

$$PbH_3X+InOH^{2+}\xrightarrow{k_{7b}^+}InH_2X+Pb^{2+}+H_2O \quad (7b)$$

$$PbH_3X\underset{k_{8a}^-}{\overset{k_{8a}^+}{\rightleftharpoons}}Pb^{2+}+H_2X^{2-} \quad (8a)$$

$$H_3X^{2-}+In^{3+}\xrightarrow{k_{8b}^+}InH_3X^{+} \quad (8b)$$

$$H_3X^{2-}+InOH^{2+}\xrightarrow{k_{8c}^+}InH_2X+H_2O \quad (8c)$$

where X^{n-} denotes the polyamine-*N*-polyacetate anion.

According to Margerum's method,[6] the application of a steady-state approximation to $[X^{n-}]$ gives:

$$[X^{n-}]=\frac{k_{4a}^+[PbX]}{k_{4a}^-[Pb^{2+}]+k_{4b}^+[In^{3+}]+k_{4c}^+[InOH^{2+}]}.$$

From a consideration of the rate constants[6-10] for the exchange of water molecules from the first coordination spheres of metal ions and the experimental conditions,

the relation of $k_{4a}\cdot[Pb^{2+}] \gg k_{4b}\cdot[In^{3+}]+k_{4c}\cdot[InOH^{2+}]$ holds. Therefore, the above equation can be transformed to:

$$[X^{n-}] = (k_{4a}\cdot/k_{4a}\text{-})[PbX]/[Pb^{2+}].$$

Since the overall rate, R, is considered to be the sum of the rates of the individual reactions, the initial rate equations are derived as follows:

$$\begin{aligned}R &= k_{1a}\cdot[PbX][In^{3+}] + k_{1b}\cdot[PbX][InOH^{2+}] \\ &\quad + k_{2a}\cdot[PbHX][In^{3+}] + k_{2b}\cdot[PbHX][InOH^{2}] \\ &\quad + k_{3a}\cdot[PbH_2X][In^{3+}] + k_{3b}\cdot[PbH_2X][InOH^{2+}] \\ &\quad + k_{4b}\cdot\cdot k_{4a}\cdot[PbX][In^{3+}]/k_{4a}\text{-}[Pb^{2+}] \\ &\quad + k_{4c}\cdot\cdot k_{4a}\cdot[PbX][InOH^{2+}]/k_{4a}\text{-}[Pb^{2+}] \\ &\quad + k_{5b}\cdot\cdot k_{5a}\cdot[PbHX][In^{3+}]/k_{5a}\text{-}[Pb^{2+}] \\ &\quad + k_{5c}\cdot\cdot k_{5a}\cdot[PbHX][InOH^{2+}]/k_{5a}\text{-}[Pb^{2+}] \\ &\quad + k_{6c}\cdot\cdot k_{6a}\cdot[PbH_2X][In^{3+}]/k_{6a}\text{-}[Pb^{2+}] \\ &\quad + k_{6c}\cdot\cdot k_{6a}\cdot[PbH_2X][InOH^{2+}]/k_{6a}\text{-}[Pb^{2+}] \\ &= \{(k_1+k_4/[Pb^{2+}]/[H^+]+(k_2+k_5/[Pb^{2+}]) \\ &\quad +(k_3+k_6/[Pb^{2+}])[H^+] \\ &\quad +(k_3{*}+k_6{*}/[Pb^{2+}])[H^+]^2\}[PbX][In^{3+}]\end{aligned}$$

where

$$k_1 = k_{1b}\cdot\cdot K_h,\ k_2 = k_{1a}\cdot + k_{2b}\cdot\cdot K_H\cdot K_h$$

$$k_3 = k_{2a}\cdot\cdot K_H + k_{3b}\cdot\cdot K_{2H}\cdot K_h,\ k_4 = k_{4c}\cdot\cdot k_{4a}\cdot\cdot K_h/k_{4a}\text{-}$$

$$k_5 = k_{4b}\cdot\cdot k_{4a}\cdot/k_{4a}\text{-} + k_{5c}\cdot\cdot k_{5a}\cdot\cdot K_H\cdot K_h/k_{5a}\text{-}$$

$$k_6 = k_{5b}\cdot\cdot k_{5a}\cdot\cdot K_H/k_{5a}\text{-} + k_{6c}\cdot\cdot k_{6a}\cdot\cdot K_H\cdot K_{2H}\cdot K_h/k_{6a}\text{-}$$

$$k_3{*} = k_{3a}\cdot\cdot K_{2H}\cdot K_H,\ k_6{*} = k_{6b}\cdot\cdot k_{6a}\cdot\cdot K_H\cdot K_{2H}/k_{6a}\text{-}$$

$$K_h = [InOH^{2+}][H^+]/[In^{3+}],\ K_H = [PbHX]/[PbX][H^+]$$

$$K_{2H} = [PbH_2X]/[PbHX][H^+].$$

Neglecting the term of $[H^+]^2$, since it is not included in the above equations, Rate Equation (1) can be derived for the EDTA and EDTA·OH systems. For the CyDTA system, furthermore, considering that the plot of the rate, R, *vs.* $1/[Pb^{2+}]$ gives a straight line which passes through the point of origin of the coordinates, as may be seen in Fig. 1, and considering that the term of $1/[H^+]$ is not included, as has been mentioned above, Rate Equation (2) is obtained. In the same way, the rate equation for the DTPA system can be deduced as Equation (3), where $K_{3H}=[PbH_3X]/[PbH_2X][H^+]$

$$k_3' = k_{2a}\cdot/K_{2H} + k_{3b}\cdot\cdot K_h,$$

$$k_6' = k_{5b}\cdot\cdot k_{5a}\cdot/k_{5a}\text{-}\cdot\cdot K_{2H} + k_{6c}\cdot\cdot K_{6a}\cdot\cdot K_h/k_{6a}\text{-}$$

$$k_7 = k_{3a}\cdot + k_{7b}\cdot\cdot K_{3H}\cdot K_h,$$

$$k_8 = k_{6b}\cdot\cdot k_{6a}\cdot/k_{6a}\text{-} + k_{8c}\cdot\cdot k_{8a}\cdot\cdot K_{3H}\cdot K_h/k_{8a}\text{-}.$$

Reaction Mechanisms. The contribution of each reaction path to the overall rate of the reaction was estimated, the results are shown in Fig. 6, where the numbers of the curves, I, II, III, V, VI, VII, and VIII, denote Reaction Paths (1b), (1a)+(2b), (2a)+(3b), (4b)+(5c), (5b)+(6c), (3a)+(7b), and (6b)+(8c) respectively. For the EDTA, EDTA·OH, and DTPA systems the reactions proceed through the paths forming binuclear intermediate complexes, PbX_tIn, and the dissociative paths. For all the systems, the contribution of the dissociative path of PbX without acid is not found, while those of the other paths change with

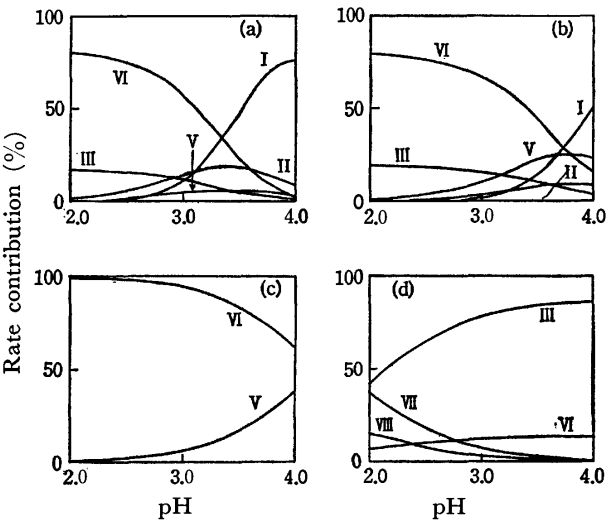

Fig. 6. The rate contribution of each path to the reaction rate.
(a): EDTA, (b): EDTA·OH, (c): CyDTA, (d): DTPA, $[Pb^{2+}]=2.0\times10^{-3}$ M
Number of curves, I, II, III, VI, VII, and VIII denotes reaction path (1b), (1a)+(2b), (2a)+(3b), (4b)+(5c), (5b)+(6c), (3a)+(7b), and (6b)+(8c), respectively.

the pH variation. Since the dissociation of the protonated lead complexes is rapid, the contributions of Paths (5b) and (6c) are predominant in the lower pH range for the EDTA and EDTA·OH systems, but the contribution decreases, and that of Path (1b) increases, with an increase in the pH, as the fractions of PbHX and PbH_2X decrease and those of PbX and $InOH^{2+}$ increase. For the CyDTA system only the contribution of the dissociative path is found, because the formation of a binuclear intermediate becomes difficult as a result of the steric hindrance of the cyclohexane ring, as Margerum and his co-workers have suggested in their study.[6] For the DTPA system the contributions of Paths (2a) and (3b) become predominant with an increase in the pH, since it is easier for the DTPA complex containing free coordinating groups to form a binuclear intermediate than for the complexes of the other ligands. From a consideration of the effect of the concentration of the lead ions, it is found that, in the dissociative paths, the rapid dissociative equilibria precede the formation of the indium complexes, as may be seen in the substitution reaction[11] of the lead(II)–EDTA complex with copper(II), for the systems other than the CyDTA system the contribution of the path forming a binuclear intermediate increases with an increase in the concentration of the lead(II) ions.

In order to determine the contribution of each path involving $InOH^{2+}$ to the rate of the formation of the indium complex through the dissociative step, the rate constants for the formation of InX, InHX, and InH_2X, k_5 and k_6 in Eqs. (1) and (2) for the EDTA, EDTA·OH, and CyDTA complexes, k'_6 and k_8 in Eq. (3) for the DTPA complexes, are rewritten as follows:

$$k_5 = k_{4b}\cdot/K_{PbX} + k_{5c}\cdot\cdot K_h/K_{PbX}\cdot K_{an} \qquad (4')$$

$$k_6 = k_{5b}\cdot/K_{PbX}\cdot K_{an} + k_{6c}\cdot\cdot K_h/K_{PbX}\cdot K_{an}\cdot K_{a(n-1)} \qquad (5')$$

for the EDTA, EDTA·OH and CyDTA systems and:

$$k_6' = k_{5b'}/K_{PbHX}\cdot K_{2H} + k_{6c'}\cdot K_h/K_{PbH_2X} \quad (6')$$

$$k_8 = k_{6b'}/K_{PbH_2X} + k_{8c'}\cdot K_h/K_{PbH_2X}\cdot K_{a3} \quad (7')$$

for the DTPA system, where K_{an}, K_{PbX}, K_{PbHX}, and K_{PbH_2X} represent the acid dissociation constants of the ligands and the stability constants of the lead complexes respectively. By a comparison of the values of the first terms and those of the second terms in Eqs. (4'), (5'), (6'), and (7'), using the values of K_h[5], K_{an},[12-15] K_{PbX},[12)16)] K_{PbHX},[17)] and K_{PbH_2X}[17)] obtained by the authors, and the products of the rate constants for the substitution of water molecules from the first coordination spheres of the In^{3+} and $InOH^{2+}$ ions and of the association constants[18)] of the ion-pairs according to Eigen,[19)] the first terms were found to be negligibly small. Therefore, the above equations are expressed as:

$$k_5 = k_{5c'}\cdot K_h/K_{PbX}\cdot K_{an} \quad (4)$$

$$k_6 = k_{6c'}\cdot K_h/K_{PbX}\cdot K_{an}\cdot K_{a(n-1)} \quad (5)$$

for the EDTA, EDTA·OH, and CyDTA systems, and as:

$$k_6 = k_{6c'}\cdot K_h/K_{PbH_2X} \quad (6)$$

$$k_8 = k_{8c'}\cdot K_h/K_{PbH_2X}\cdot K_{a3} \quad (7)$$

for the DTPA system.

As an example, the rate constants for the formation of the InHX of EDTA and CyDTA, and the InH_2X of DTPA and the InHX of EDTA·OH from $InOH^{2+}$ were calculated by means of Eqs. (5) and (7) to be 2.0×10^7, 2.9×10^7, 3.0×10^7, and 4.9×10^6 M^{-1} s^{-1} respectively. The rate constants for EDTA, CyDTA, DTPA, and EDTA·OH were in good agreement with the values of 2.5×10^7 and 5.0×10^6 M^{-1} s^{-1} of the complexes of $InOH^{2+}$ with SO_4^{2-} and of $InOH^{2+}$ with the semixylenol orange anion H_3SXO^-, which have the same charges as H_2X^{2-}, H_3X^{2-}, and H_2X^- respectively. This shows that the rate equations from (1) to (3) and the rate constants and the reaction mechanisms are suitable.

In addition, the reaction rate of indium(III) is 160 times faster than that of gallium(III) for the CyDTA system at pH 2.0. This may be attributed to the difference in the rate constants with regard to the substitution of the water molecules of the $InOH^{2+}$ and $GaOH^{2+}$ ions resulting from the difference in the effective nuclear charge.

The authors wish to thank Professor D.W. Margerum of Purdue University, U.S.A., for his useful discussions.

Composition of Single Crystals of Chromium Chalcogenide Spinels Grown by Chemical Vapor Transport

Kohei AMETANI

RCA Research Laboratories, Inc., Zushi-machi, Machida-shi, Tokyo 194-02

(Received May 15, 1975)

Compositional analyses using atomic absorption spectrophotometry were carried out on the vapor-phase grown single crystals of copper-based spinels with the nominal formulas such as $CuCr_2S_3Cl$, $Cu_{1-x}Fe_xCr_2S_4$ ($x \leq 1$), $Cu_{0.5}In_{0.5}Cr_2S_4$, $CuCr_2Se_3Cl$, and $CuCr_2Se_3Br$, and the cadmium-based spinels of $CdCr_2S_4$ and $CdCr_2Se_4$, including crystals doped with indium, silver, and copper. The grown crystal usually had a composition different from the nominal formula and a tetrahedral-site deficiency of the copper-based spinels is reported for the first time. All crystals of $Cu_{1-x}Fe_xCr_2S_4$ and $Cu_{0.5}In_{0.5}Cr_2S_4$ were contaminated with a considerable amount of chlorine and some of the crystals had a substantial cation deficiency on the tetrahedral sites; the cation deficiency increases with increasing copper or chlorine content. For the $CuCr_2S_3Cl$ and $CuCr_2Se_3Br$ crystals, a large copper deficiency was also found while the halogen content was close to that expected for the nominal compositions, or somewhat higher. Of all the copper-based spinels, the least tetrahedral-site deficiency was observed in the $CuCr_2Se_3Cl$ crystals, but the chlorine content was much less than the stoichiometric content. The cadmium-based spinels usually satisfied the stoichiometric formula $CdCr_2S_4$ or $CdCr_2Se_4$.

The magnetic, electrical, and optical properties of chromium chalcogenide spinels have been extensively investigated. In spinels with the general formula ACr_2X_4, the A sites are usually filled with bivalent metal ions (M^{2+}) or a mixture of uni- and trivalent cations ($M^{+}_{0.5}M^{3+}_{0.5}$–). The X sites are occupied by a single chalcogen anion (–X^{2-}_4) or a combination of chalcogen with halogen anions (–$X^{2-}_3Y^{-}$; Y=halogen); in the latter case, the effective cation valence of the A sites is reduced to univalent. Single crystals are usually grown by the chemical vapor-transport method, using a halogen as a transport agent.[1-3] The crystals obtained are, at most, 3—4 mm on edge and weigh only several mg. A number of workers have spent a lot of time and effort to grow large single crystal using the chemical vapor-transport method and other methods, but the crystals obtained are size limited. Therefore, some of published papers reported the physical properties of the crystals without chemical analysis, or only a partial chemical analysis of impurities[4-11] and some of the main components[10-16] of the crystals has been made. Very little has been published about the compositional analysis of all the major constituents.[9,17] Most of the published papers described only the results of the analysis without details of the procedures for the analysis. In the present paper, we describe a method of chemical analysis to determine the composition of some single crystals of chromium chalcogenide spinels using AAS (Atomic Absorption Spectrophotometry) technique and present a serious problem regarding the composition of various samples; the grown crystals usually had compositions different from their nominal formula. The AAS technique provides a high sensitivity and selectivity so that the sample weight can be reduced to a minimum amount, and the major as well as minor constituents or impurities can be determined continuously or simultaneously from the same small sample. The use of the same sample would be recommended to obtain consistent analytical data. The present analytical method was developed from our previously reported procedures for chlorine[10] and sulfur.[15] Using 10 mg samples, the metallic elements were determined directly from their atomic absorptions. Chlorine and sulfur were determined indirectly from the silver and barium atomic absorptions after being captured in the form of silver chloride[10] and barium sulfate,[15] respectively.

The materials to be analyzed were the copper-based spinels with nominal formulas such as $CuCr_2S_3Cl$, $Cu_{1-x}Fe_xCr_2S_4(x \leq 1)$, $Cu_{0.5}In_{0.5}Cr_2S_4$, $CuCr_2Se_3Cl$, and $CuCr_2Se_3Br$, and the cadmium-based spinels of $CdCr_2S_4$ and $CdCr_2Se_4$, including crystals doped with indium, silver, and copper. Of these materials, the chlorine content for some of the copper-based and cadmium-based spinels,[10,11] the sulfur content of $CuCr_2S_3Cl$ and $CdCr_2S_4$ crystals,[15] and the content and site preference of dopants in $CdCr_2X_4$ crystals,[11] were reported previously. The single crystals, except for the halochalcogenides, were grown by the closed-tube vapor transport, where the starting materials with the above-described compositions were mixed with a solid transport agent $CrCl_3$, usually in ratio of 10 : 1. The halochalcogenide crystals were grown by transport either with an intrinsic copper halide present in the starting materials or an extra copper halide added as the halogen source. The details of the growth conditions can be found elsewhere.[1,11,18-20] All the crystals were prepared in these laboratories and the physical properties of some of the crystals have been reported.[18-23]

Experimental

Apparatus. Atomic absorption measurements were made in an air–acetylene flame using a Hitachi model 208 Atomic Absorption Spectrophotometer and Hitachi hollow-cathode lamps HLA-3, except the lamp used for the selenium measurement, which was obtained from Westinghouse. The analytical lines used were Cr 357.9 nm, Fe 372.0 nm, Cu 324.7 nm, Se 204.0 nm, Ag 328.1 nm, Cd 228.8 nm, In 303.9 nm, and Ba 553.5 nm.

Standard Solutions. (1) Solutions of metal chlorides: The chromium and iron solutions were prepared by dissolving metals (99.9%) in hydrochloric acid and diluting with deionized water. The copper, cadmium, and indium solutions were prepared by dissolving metals (99.9—99.99%) in nitric acid, removing the excess nitric acid by evaporation with hydrochloric acid, and then dissolving the residue in de-

a) Solutions (5—7) and (8—11) also contained 3.50 and 4.00 mg of S, respectively, as Na_2SO_4.

ionized water. All the solutions were stocked as 0.1 M hydrochloric acid solutions with a concentration of 1 mg analyte/ml. (2) Solutions of metal nitrates: The chromium and iron solutions were prepared by dissolving the respective nitrates in deionized water and then standardizing by chelatometry using EDTA. The copper, cadmium, and indium solutions were prepared by dissolving metals (99.9—99.99%) in nitric acid and diluting with deionized water. All the solutions were stocked as 0.1 M nitric acid solutions with a concentration of 1 mg analyte/ml. (3) Other solutions: The selenium solution was prepared by dissolving elemental selenium (99.9%) in nitric acid and diluting with deionized water. The stock solution had a concentration of 1 mg Se/ml with 0.1 M nitric acid. The silver solutions (1, 0.5, or 0.25 mg Ag/ml) were prepared by dissolving silver nitrate (dried at 110 °C) in a minimum amount of deionized water, and then diluting with concentrated nitric acid. The silver solutions were used to dissolve samples as described below. The solutions containing 1 mg Ag/ml were also prepared from silver nitrate and stocked as 0.1 M nitric acid solutions. The barium solution (5 mg Ba/ml) was prepared by dissolving barium chloride dihydrate in deionized water and standardizing by chelatometry using EDTA. The sulfur and chlorine solutions (1 mg analyte/ml) were prepared by dissolving sodium sulfate and sodium chloride (dried at 110 °C), respectively, in deionized water. Reagents used were of analytical reagent grade.

Procedure (A). Pulverized crystals weighing 10 mg (usually 5—6 crystals) were dissolved in nitric acid containing excess silver ions of a known quantity and chlorine was simultaneously precipitated as silver chloride. For a sample containing several hundred μg to about 1 mg of chlorine, 5 ml of nitric acid containing 1 mg Ag/ml was used, and the solution was then diluted to about 50 ml. However, if the expected chlorine content in the sample was less than 100 μg, 2 ml of nitric acid containing 0.5 or 0.25 mg Ag/ml was used and the solution diluted to about 20 ml. The solution was aged for 30 min over a hot water bath. After the solution was cooled in ice water, the precipitated silver chloride was filtered and washed with six 5-ml portions of cold nitric acid (1 : 50), and dissolved in an aqueous ammonia solution. Both the ammoniacal solution and the filtrate were diluted to an appropriate concentration of analytes and the atomic absorptions measured. For the measurements, the concentrations of nitric acid and ammonia were adjusted to 0.05—0.3 M and 3%, respectively, because the interference effects of coexisting foreign elements at these concentrations were found to be negligible.[10,11] The chlorine content, except for the silver-doped $CdCr_2S_4$ and $CdCr_2Se_4$ crystals, was determined indirectly from the silver content, usually, in both the ammoniacal solution and the filtrate. For the silver-doped crystals, chlorine was determined from the silver content in the ammoniacal solution. Metallic elements, such as chromium, iron, copper, cadmium, and indium, and also selenium, were determined from the filtrate. The silver content in the silver-doped crystals was determined by comparing the total amount of silver in both the filtrate and the ammoniacal solution with the amount of silver contained in the nitric acid solution used to dissolve the crystals. The results obtained were corrected by the blank test in all cases.

Procedure (B). This procedure is applicable for the sulfides only, and not for the selenides. Pulverized crystals weighing 10 mg were dissolved in 2 ml of concentrated nitric acid containing bromine in order to oxidize the sulfurs into sulfate ions. The sample solution was evaporated nearly to dryness. After removal of the nitric acid by evaporation with hydrochloric acid, the residue was dissolved in deionized water. The sample solution was diluted to about 20 ml and warmed to about 80 °C. If iron was present in the solution, the iron(III) ions were reduced to iron(II) ions by adding a minimum amount of ascorbic acid. The acidity of the solution was adjusted to 0.05 M hydrochloric acid, and 5 ml of the standard barium solution (5 mg Ba/ml) was slowly added to the solution. The precipitated barium sulfate was allowed to settle for 1 hr over a hot water bath. After aging more than 20 hr, the precipitate was filtered and washed with six 5-ml portions of boiling water. The filtrate was diluted to an appropriate concentration of analytes and the atomic absorptions measured. For the measurements, the concentration of hydrochloric acid was adjusted to 0.05—0.2 M because the interference effects of coexisting foreign elements are negligible at these concentrations.[11,15] Metallic elements, except for silver, were determined directly by their atomic absorptions, and sulfur, indirectly by the atomic absorption of an excess of barium in the filtrate. Silver was not determined by this procedure.

The procedures (A) and (B) were confirmed by using mixtures of the standard solutions. Table 1 shows typical results for procedures (A) and (B). The tabulated values

a) "X" designates S or Se and "Y" designates Cl or Br. b) The ratio expected for the formula is 2 for each sample, where "A" is Cu, Fe, and/or In. c) "M" designates cationic elements (Cu, Fe, In, and Cr) and the expected value of the ratio is 0.75 for each sample. d) Average of at least five determinations with the standard deviation 0.003—0.005 Å. e) Both sets of crystals were grown in the same batch. The first set was analyzed by procedure (A) of the present work and the second set was analyzed by the alternative method.[29]

for chlorine are the average of values obtained from the filtrate and the ammoniacal solution. Most of the observed values are in agreement with the added amounts, within 1—2%.

Results and Discussion

The results of analyses are presented as mole ratios of the analytes, as calculated from the observed wt% values, in order to easily understand the chemical composition of the present materials. Most of the results for metallic elements are the average of values obtained by the procedures of both (A) and (B). Table 2 shows the results for the copper-based chromium chalcogenide spinels. Table 3 compares the compositions determined by chemical analysis with those estimated from lattice parameters for crystals of the system $Cu_{1-x}Fe_xCr_2S_4$ ($x \leq 1$). Table 4 gives the results for the cadmium-based spinels including crystals doped with indium, silver, and copper.

$CuCr_2S_3Cl$. Samples grown in three different batches were analyzed. As can be seen in Table 2, all the results indicate that the crystal did not have the stoichiometric formula $CuCr_2S_3Cl$; the chlorine content is much higher than the stoichiometric amount.[10] The cation-to-anion ratio, (Cu+Cr)/(S+Cl), also shows that the total amount of the anionic elements was higher and that of the cations was lower than the expected amount. This is due to an insufficient amount of copper as shown in Table 2. Therefore, it can be concluded that the crystal has a copper deficiency on the tetrahedral sites in the spinel structure and the formula is written as $Cu_{1-x}\square_xCr_2S_{4-y}Cl_y$, where $\square$ designates the copper deficiency. When the mole ratios in Table 2 are normalized by the value of 2 for chromium, the empirical formulas for these crystals can be expressed as follows;

sample (1) $Cu_{0.86}\square_{0.14}Cr_2S_{2.91}Cl_{1.08}$,

sample (2) $Cu_{0.84}\square_{0.16}Cr_2S_{2.87}Cl_{1.12}$,

sample (3) $Cu_{0.85}\square_{0.15}Cr_2S_{2.80}Cl_{1.19}$.

Actually, Wada[24] of these laboratories successfully prepared polycrystalline powders of the copper-deficient chlorosulfospinels, $Cu_{1-x}\square_xCr_2S_3Cl$ ($x \leq 0.3$), by firing mixtures of copper(I) chloride, copper(II) chloride, chromium metal, elemental sulfur at high temperatures. He found that compounds with $x=0.2$—0.3 were the most pure of all the compositions, whereas the stoichiometric compound ($x=0$) always had a minor second phase of hexagonal $CuCrS_2$ as determined by X-ray diffraction; the degree of contamination by the second phase increased with the decreasing x. Another example of such metal-deficiencies are the trivalent metal-based sulfospinels $M_{16/9}\square_{3/9}Cr_{8/9}S_4$ with M= Al or In.[25]

The lattice constants of these crystals range from 9.902 to 9.907 Å, as given in Table 2. These values are nearly the same as those for single crystals with the composition close to $CuCr_2S_3Cl$ reported by Sleight and Jarrett.[12] They used a chemical analysis to determine the composition of crystals, but did not give the data for elements other than chlorine nor did they present the details of their chemical analysis. Presumably the crystal composition is dependent on the growth conditions.

$Cu_{1-x}Fe_xCr_2S_4$. For the system, samples with the nominal composition $x=0.2$, 0.4, 0.6, 0.8, or 1.0 were analyzed. For all of the crystals analyzed, the copper content was higher and the iron content much lower than the nominal amount, especially for the lower values of x. Colorimetric methods[26] also showed similar results. It seems that copper is transported more preferentially than iron during the vapor transport reaction, while, in the case of the $Cd_{1-x}Fe_xCr_2S_4$

system ($0 \leq x \leq 1$),[16] iron is incorporated more readily than the nominal content in the vapor-phase grown crystals. As can be seen in Table 2, a deficiency in the tetrahedral-site was also found for the crystals. For crystals containing the higher amount of iron, however, the degree of this deficiency was small; both ratios of chromium-to-copper and iron, Cr/(Cu+Fe), and cation-to-anion, (Cu+Fe+Cr)/(S+Cl), are closer to the expected values than those of crystals with the lower amount of iron. On the other hand, when the copper content increases or the iron content decreases, the tetrahedral-site cation deficiency increases when chlorine is easily incorporated in the crystals (see results for the $Cu_{0.8}Fe_{0.2}Cr_2S_4$ and $Cu_{0.6}Fe_{0.4}Cr_2S_4$ crystals). The $FeCr_2S_4$ crystal even seems to have a small deficiency on the tetrahedral sites as shown in Table 2. A similar result was reported by Goldstein *et al.*,[9] where the $FeCr_2S_4$ crystal was grown by use of $HCl+Cl_2$ gas as the transport agent. They found about 1% deviation in the chromium-to-iron ratio, Cr/Fe, but our result was about 3.5%. The discrepancy between the two results may be related to a variation of the chlorine content in the crystal; the mole ratio of chlorine presented in Table 2 corresponds to 0.8 wt%, whereas Goldstein *et al.*[9] reported only 0.01 wt%.

Haacke and Beegle[27] prepared polycrystalline samples in the entire composition range of the system $Cu_{1-x}Fe_xCr_2S_4$ ($0 \leq x \leq 1$), and found that the curve of lattice parameters *vs.* composition obeys Vegard's law. They used Vegard's law to determine the copper and iron content in single crystals grown by chemical vapor transport using HCl gas as the transport agent; the reported compositions ranged from $Cu_{0.59}Fe_{0.41}Cr_2S_4$ to $FeCr_2S_4$. However, the present results suggest that Vegard's law seems to be unsuitable for the determination of the copper and iron content in vapor-phase grown crystals of this system because of the tetrahedral-site deficiency and the observed higher incorporation of chlorine, (as described previously), which, in turn, cause the compositional variation of components other than copper and iron.

Table 3 compares the compositions determined by Vegard's law and our chemical analysis using this AAS technique for crystals of the system $Cu_{1-x}Fe_xCr_2S_4$. The compositions determined by chemical analysis are normalized by the value of 2 for chromium while those by Vegard's law are determined by the lattice constants, 9.819 and 9.989 Å for polycrystalline $CuCr_2S_4$ and $FeCr_2S_4$,[13] respectively. As can be seen in Table 3, the iron content determined by Vegard's law is usually much higher, particularly for crystals with a lower iron content than that obtained by chemical analysis. Banus[13] also obtained similar results for single crystals of this system by determining the copper, iron, and chromium content, using chemical analysis of crystals grown by transport with $CrCl_3$ as the transport agent. He found that the lattice constants of single crystals are 0.005 to 0.025 Å higher than those of polycrystals, assuming that both polycrystalline and single-crystal samples have the same value of x. This tendency indicates that the iron content determined by Vegard's law is apparently higher than the actual content because the lattice constant of $FeCr_2S_4$ is larger than that of $CuCr_2S_4$. In addition, Vegard's law does not suggest anything about components other than copper and iron. Our results for the $Cu_{0.2}Fe_{0.8}Cr_2S_4$ crystal showed that the composition of crystals of this system comes closer to the general formula $Cu_{1-x}Fe_xCr_2S_4$ when the iron content increases and the chlorine content decreases.

Table 3. Comparison of compositions determined by Vegard's law and chemical analysis for single crystals of the system $Cu_{1-x}Fe_xCr_2S_4$

Sample, nominal composition	Determined composition	
	by Vegard's law	by chemical analysis
$Cu_{0.8}Fe_{0.2}Cr_2S_4$	$Cu_{0.52}Fe_{0.48}Cr_2S_4$	$Cu_{0.73}Fe_{0.06}Cr_2S_{3.39}Cl_{1.04}$
$Cu_{0.6}Fe_{0.4}Cr_2S_4$	$Cu_{0.64}Fe_{0.36}Cr_2S_4$	$Cu_{0.81}Fe_{0.07}Cr_2S_{3.32}Cl_{0.76}$
$Cu_{0.4}Fe_{0.6}Cr_2S_4$	$Cu_{0.57}Fe_{0.43}Cr_2S_4$	$Cu_{0.64}Fe_{0.29}Cr_2S_{3.50}Cl_{0.45}$
$Cu_{0.2}Fe_{0.8}Cr_2S_4$	$Cu_{0.31}Fe_{0.69}Cr_2S_4$	$Cu_{0.31}Fe_{0.70}Cr_2S_{3.62}Cl_{0.23}$
$FeCr_2S_4$	——	$Fe_{0.96}Cr_2S_{3.93}Cl_{0.07}$

The reason Vegard's law gives apparent higher values for iron is due to the incorporation of chlorine in the crystals. Incorporating chlorine in the system $Cu_{1-x}Fe_xCr_2S_4$ will result in a chemical reduction of cationic species and give an increase in effective cation size so that there is an increase in unit cell volume. This tendency occurs because the lattice constant of crystals for the system $Cu_{1-x}Fe_xCr_2S_4$ decreases upon annealing in a sulfur atmosphere,[13] where the relative sulfur and chlorine content increases and decreases, respectively. Therefore, the present $FeCr_2S_4$ crystal has a lattice constant (10.083 Å) higher than that of the polycrystalline sample (9.989 Å),[13] where the former contains a substantial amount of chlorine, while the latter is believed to be a chlorine-free sample.

$Cu_{0.5}In_{0.5}Cr_2S_4$. The results for samples grown in three different batches showed that the anionic element content is higher than the expected content, as shown by the ratio of (Cu+In+Cr)/(S+Cl) in Table 2. The chlorine content is small when the indium content is large and/or the copper content is small. The copper-to-indium ratio, Cu/In, always exceeds unity, indicating a higher preferential incorporation of copper, as compared to indium, in crystals. This is consistent with the previous result obtained by X-ray fluorescence spectroscopy.[14] The ratio of chromium-to-copper and indium, Cr/(Cu+In), is lower than the expected value of 2 for the crystal with the relatively higher content of indium (sample (1)) but the ratio is higher than 2 for other crystals with a lower indium content (samples (2) and (3)). This indicates that indium in sample (1) may substitute partially for chromium on the octahedral sites in addition to occupancy of tetrahedral sites, just as was found for $CdCr_2S_4$ crystals heavily doped with indium.[11] For samples (2) and (3) a tetrahedral-site deficiency, as described earlier for $CuCr_2S_3Cl$ and $Cu_{1-x}Fe_xCr_2S_4$ crystals, was found. Among these crystals, sample (1) has the copper-to-indium ratio (Cu/In) nearest to unity and the lowest chlorine content. Samples (2) and (3) have a composition relatively similar to each other but the lattice constants of the samples differ as

shown in Table 2; the values of 10.089 Å (sample (2)) and 10.016 Å (sample (3)) bracket the 10.057 Å of sample (1), while the lattice constant of the polycrystalline sample is reported to be 10.065 Å.[28]

$CuCr_2Se_3Cl$ and $CuCr_2Se_3Br$. The $CuCr_2Se_3Cl$ crystal shows a tendency to have a different composition than the $CuCr_2S_3Cl$ crystal. The chlorine content is much less than the stoichiometric content, as shown in Table 2. This may be due to the difference between the chalcogenide elements sulfur and selenium. A comparison of the ionic radii of these elements indicates that the sulfur ionic size (S^{2-}; 1.84 Å) is nearly the same as chlorine (Cl^-; 1.81 Å) while selenium (Se^{2-}; 1.91 Å) is somewhat larger. This large difference in ionic radii is responsible for the reduced incorporation of chlorine in the $CuCr_2S_3Cl$ crystal, while chlorine is more easily incorporated in the $CuCr_2S_3Cl$ crystal as described previously, because the sulfur- and chlorine-ion sizes are comparable. However, the ratios of chromium-to-copper, Cr/Cu, and cation-to-anion, (Cu+Cr)/(Se+Cl), are close to the expected values as shown in Table 2. The formula, normalized by the value of 2 for chromium, is $Cu_{0.97}Cr_2Se_{3.66}Cl_{0.32}$. Similar results for crystals grown in different batches were found, while Miyatani *et al.*[19] reported without chemical analysis that the composition of crystals always ranged from $CuCr_2Se_{3.6}Cl_{0.4}$ to $CuCr_2Se_{3.5}Cl_{0.5}$. They determined the composition by comparing the lattice constant (Vegard's law) and the magnetic property of single crystals with those of polycrystalline samples having a known composition.

In the case of the $CuCr_2Se_3Br$ crystal, the compositional problem is expected to be similar to that of the $CuCr_2S_3Cl$ crystal because for both crystals the ionic size of the chalcogen is nearly equal to that of the corresponding halogen (Br^-; 1.96 Å). Although the present method of chemical analysis was established for materials containing chlorine, the use of procedure (A) to analyze the $CuCr_2Se_3Br$ crystal seems reasonable because the solubility of silver bromide in aqueous media is much smaller than that of silver chloride. For the analysis, 10 mg of the sample was dissolved in 5 ml of nitric acid containing 1 mg Ag/ml. The results showed that the total amount of the anionic elements is higher, and that of the cations lower, than the expected amount. As in the case of the $CuCr_2S_3Cl$ crystal, this is due to the tetrahedral-site deficiency of copper. An alternative method[29] showed a similar result for a crystal grown in the same batch as shown in Table 2. For another crystal grown in a different batch, the composition was found to be $Cu_{0.80}Cr_{2.01}Se_{3.06}Br_{1.13}$ by the alternative method.

The present crystal is one of samples for the system $CuCr_2Se_{4-x}Br_x$ reported by Miyatani *et al.*[19] The alternative method was used to analyze their both polycrystalline and single-crystal samples at that time. They reported that the actual compositions of their polycrystalline samples are found to be the same as those intended within 1% by chemical analysis but did not give the data of chemical analysis for single crystals; the composition of single crystals was determined by comparing the lattice constant (Vegard's law) and the magnetic property (the Curie temperature) of single crystals with those of polycrystalline samples. They concluded as follows: (1) No excess-bromine compounds ($x>1$) can be synthesized. (2) The ionic configuration assumed is $Cu^{1+}_{1-x}Cu^{+}_{x}Cr^{3+}_{2}Se^{2-}_{4-x}Br^{-}_{x}$. (3) The physical properties of crystals can be explained in terms of the x-value dependence; for example, both the Curie temperature and electrical resistivity vary drastically over the small range $0.98 \leq x \leq 1.0$.

From the present results, however, it is revealed that the physical properties of crystals cannot be explained in terms of the compositional (x-value) dependence. Near $x=1$, they considered that the Cu^{2+} ions concentration is negligibly small but the present results indicated that the Cu^{2+} ions concentration is larger than that of Cu^+ ions. When the values in Table 2 (the first set) are normarized by the value of 2 for chromium, taking into account the electroneutrality of crystal, the present crystal can be expressed by the ionic configuration $Cu^{2+}_{0.63}Cu^{+}_{0.15}Cr^{3+}_{2}Se^{2-}_{3.19}Br^{-}_{1.03}$, while they regarded the crystal as one of samples with the composition close to $CuCr_2Se_3Br$ and the effective copper valence as monovalent. Moreover, their experiments to determine the composition are clearly found to be very careless because the composition of the crystal with the lattice constant 10.414 Å was reported to be $CuCr_2Se_{3.5}Br_{0.5}$; the lattice constant for the system $CuCr_2Se_{4-x}Br_x$ increased linearly from 10.325 to 10.405 Å as x increased from 0 to 1. Therefore, we can now understand that their conclusions are very suspicious and a complete analysis for the composition is necessary to interpret the physical properties of crystals.

$CdCr_2S_4$ and $CdCr_2Se_4$. We have already described the chlorine contamination,[10,11] and the actual content and site preference of dopants such as indium, silver, and copper for the $CdCr_2S_4$ and $CdCr_2Se_4$ crystals.[11] To provide a review of all the constituents, data for the minor elements are summarized with the major constituents in Table 4. All the crystals are contaminated with chlorine, but the chlorine content is much less than that of the copper-based spinels. The chlorine content increases in the following order; indium-doped, undoped, silver-doped, and copper-doped crystals. The content of dopants is usually less than the nominal content, especially, in $Cd_{0.95}Ag_{0.05}Cr_2S_4$ and $Cd_{0.9}Ag_{0.1}Cr_2S_4$ crystals. There seems to be a solubility limit for dopants in the single crystals.[30] The tetrahedral-site deficiency was not usually observed, although the undoped $CdCr_2Se_4$ and $Cd_{0.99}Ag_{0.01}Cr_2Se_4$ crystals had a somewhat lower value for cadmium in comparison with the chromium content. The stoichiometric formula $CdCr_2X_4$ is more closely satisfied for $CdCr_2S_4$ than for $CdCr_2Se_4$.

In summary, for the copper-based spinels, single crystals with the nominal formula $Cu_{1-x}Fe_xCr_2S_4 (x \leq 1)$, $Cu_{0.5}In_{0.5}Cr_2S_4$, or $CuCr_2X_3Y$ (X=S or Se, and Y=Cl or Br) were not found. In crystals of the halo-chalocogenides, combinations such as S–Cl and Se–Br on the anionic sites caused a substantial cation deficiency on the copper sites, while the halogen content was close to stoichiometric, or somewhat higher, because in both cases chalcogens and halogens are of nearly the same ionic size. The combination of Se–Cl on the

TABLE 4. RESULTS OF ANALYSIS FOR $CdCr_2S_4$ AND $CdCr_2Se_4$ SINGLE CRYSTALS

Sample, nominal composition	Analyte, mole ratio

$Cd_{0.9}Cu_{0.1}Cr_2Se_4$	0.94_7	0.05_3	1.99_7	3.98_0	0.02_1

a) "M" designates dopants (In, Ag, and Cu) and "X" designates S or Se. b) Annealed in vacuum at 600 °C for 48 hr. c) The crystal was dissolved in concd HNO_3 without Ag^+ ions. The intrinsic Ag and Cl present in the material were reacted with each other to form AgCl precipitates during the dissolution Only metals such as Cd, Ag, and Cr were determined subsequently using procedure (A) so that the observed Ag value was the sum of the Ag content in both the filtrate and precipitates.

anionic sites did not give the copper deficiency, but the chlorine content was much less than the stoichiometric content. The halochalocogenides, contrary to the general understanding, seem to contain a considerable amount of bivalent copper ions. For other crystals of the copper-based spinels, it was often observed that the total amount of metals was lower than that expected for the nominal composition and the amount of chlorine was high. The lower amounts of metals are mainly due to an insufficient amount of tetrahedral-site elements. The composition of single crystals of cadmium-based spinels, compared to that of the copper-based spinels, more closely approximated the nominal formula ($CdCr_2X_4$) but all the crystals were contaminated with a small amount of chlorine. The chlorine content was much less than that of the copper-based spinels and increased in the order of indium-doped, undoped, silver-doped, and copper-doped crystals. The content of dopants was usually less than the nominal content. From the present results, it can be concluded that Vegard's law is not useful to determine the intermediate composition of the vapor-phase-grown single-crystals of multicomponent systems such as $Cu_{1-x}Fe_xCr_2S_4$ and $CuCr_2X_{4-x}Y_x$, and that a complete analysis, including the determination of both major and minor constituents or impurities, is necessary to interpret the physical properties of crystals; a partial analysis fails to notice a compositional variation of components other than elements of interest. The present work also indicates that individual crystals in a growth batch can be characterized by AAS techniques if somewhat large crystals are grown.

The author would like to express his sincere appreciation to Drs. Bernard Hershenov and Fumio Okamoto for critical reading of the manuscript, and to Mr. Katsuhiro Kato for measurements of the lattice constants and discussions during the course of this work. He is also indebted to Drs. Fumio Okamoto and Yasuo Wada, and Messrs. Katsuhiro Kato and Takao Oka for providing samples. All the above-mentioned personnel are with RCA Research Laboratories, Inc., Tokyo.

26) Analyses were performed for one crystal in the individual growth batches. Pulverized crystals weighing 1 mg were dissolved in concentrated nitric acid. The sample solution was evaporated nearly to dryness. After removal of the nitric acid by evaporation with hydrochloric acid, the residue was dissolved in deionized water. Copper was determined by colorimetry using cupferazone as a color-producing reagent, where the absorbance was measured at 600 nm. Iron was determined by the absorbance at 470 nm using the colorimetric thiocyanate method.

29) Two hundred mg of the sample was dissolved in concentrated nitric acid in a distillation flask and steam-distillation simultaneously performed until the sample completely dissolved, whereupon the distillate containing bromine was absorbed by a solution mixed with sodium hydroxide and hydrogen peroxide. Bromine in the distillate was determined by iodometry after removal of the excess hydrogen peroxide. The nitric acid solution remaining in the distillation flask was converted to hydrochloric acid solution and elemental selenium was precipitated by adding sulfurous acid. The precipitated selenium was filtered and determined by gravimetry. From the filtrate, copper and chromium were determined by chelatometry with EDTA using PAN and Zincon, respectively, as indicators. The procedure was confirmed using polycrystalline samples with the composition of $CuCr_2Se_{3.2}Br_{0.8}$ or $CuCr_2Se_3Br$, and satisfactory results were obtained.

Magnetic Circular Dichroism of the Iron(III) Porphins

Hiroshi KOBAYASHI, Tadatoshi HIGUCHI, and Ken EGUCHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 5, 1975)

Magnetic circular dichroism(MCD) spectra were measured of some low-spin and high-spin Fe(III) porphins in a rigid matrix of polymethyl methacrylate(PMMA) for a variety of temperature. Some of the most prominent MCD extrema of the low-spin Fe(III) porphins showed a remarkable enhancement of the intensity at reduced temperatures, while no appreciable increase was observed in the absorption intensity. The temperature dependence of the MCD dispersion of the low-spin Fe(III) porphins arises, in principle, from a change in the Boltzmann distribution between the ground Kramers doublet splitting in a magnetic field, however, the MCD enhancement observed in the Soret region can correctly be interpreted only when the excited states described by a product wave function of the porphin B state and the spin-orbit coupling substates of low-spin iron(III) d^5 system are split by a configuration interaction with the "porphin to iron(III)" charge-transfer excited states.

The visible and near-ultraviolet absorption spectra of metalloporphyrins arise from the lowest spin-allowed (π, π^*) excitations.[1-3] The role of the central metal ion in the absorption spectra is of relatively minor in most metalloporphyrins, whereas the lifetime of the excited metalloporphyrins depends upon the structure of interactions between the π-electron system of porphyrin and the central transition metal ion.[4-9] In some metalloporphyrins with dπ-open shell such as high-spin iron(III) porphyrins and high-spin manganese(III) porphyrins, a participation of "porphyrin to metal" charge-transfer (CT) excited states in the lowest electronic excited states gives rise to an observable anomaly in the absorption spectra.[10]

The temperature-dependent *C*-term extrema in the (π, π^*) transitions of the ligand coordinated to a metal ion in a degenerate ground state should be observed only when an appreciable interaction between the π-electron system of the ligand and the open-shell orbital of the central metal ion is present. In this paper, a study of temperature changes of the MCD spectra in the lowest excitations of the iron-(III) porphyrins is presented.

Experimental

Synthesis of the Metal-free Base of Tetraphenylporphin (H_2TPP). H_2TPP was synthesized by the method of Adler *et al.*[11] Chromatographic purification was repeated on activated alumina columns using chloroform as solvent and also as eluent. The elute was concentrated, and then excess methanol was added. Purple needle crystals thus obtained were identified by elemental analysis.

Found: C, 86.18; H, 4.61; N, 8.96%. Calcd for $C_{44}H_{30}N_4$: C, 85.97; H, 4.92; N, 9.11%.

Synthesis of Tetraphenylporphinatoiron(III) Chloride (TPPFe(III)Cl). TPPFe(III)Cl was prepared in dimethylformamide (DMF). H_2TPP (0.3 g) and $FeCl_2 \cdot 4H_2O$ (1.5 g) were dissolved in DMF (200 ml) and refluxed for 3 hr. When the solution was cooled, portions of dilute hydrochloric acid were added by a small amount. The dark purple crystals thus precipitated were collected by filteration. The complex was recrystallized twice from a mixture of 1,2-dichloroethane and hexane.

Found: C, 74.94; H, 3.85; N, 7.92; Fe, 7.97; Cl, 5.10%. Calcd for $C_{44}H_{28}N_4FeCl$: C, 75.07; H, 4.01; N, 7.96; Fe, 7.93; Cl, 5.04%.

Synthesis of Bisimidazoletetraphenylporphinatoiron(III) Perchlorate ([TPPFe(III)(Im)$_2$]ClO$_4$). TPPFe(III)Cl (35 mg) was dissolved in benzene (5 ml). $AgClO_4$ (10 mg) was added to the solution. After reflux for 4 hr, AgCl was filtered off and then imidazole (6 mg) was added. Just after the addition of imidazole, reddish purple crystals precipitated. When the precipitation was completed, unreacted $AgClO_4$ and imidazole were dissolved by adding ethyl ether (5 ml). The residue was dissolved in 1,2-dichloroethane and then filtered for separation of the contaminating $AgClO_4$. The filtrate was condensed under reduced pressure and then benzene was added to it for precipitation. Pure crystals were obtained by recrystallization from a mixture of 1,2-dichloroethane and benzene.

Found: C, 66.18; H, 3.67; N, 12.50; Fe, 6.08%. Calcd for $C_{50}H_{36}N_8FeClO_4$: C, 66.42; H, 4.01; N, 12.39; Fe, 6.18%.

Synthesis of the Metal-free Bases of Octaethylporphin (H_2OEP). H_2OEP was prepared by refluxing 3,4-diethyl-5-hydroxymethylpyrrole-2-carboxylic acid and potassium ferricyanide in glacial acetic acid according to the method of Inhoffen *et al.*[12] Octaethylporphin thus obtained was recrystallized from a mixture of chloroform and methanol and purified by column chromatography.

Found: C, 80.55; H, 8.51; N, 10.44%. Calcd for $C_{36}H_{46}N_4$: C, 80.85; H, 8.67; N, 10.48%.

Synthesis of Octaethylporphinatoiron(III) Chloride (OEPFe(III)Cl). OEPFe(III)Cl was prepared by a method similar to the preparation of TPPFe(III)Cl. H_2OEP (250 mg) was dissolved in refluxing dimethylformamide (100 ml). $FeCl_2 \cdot 4H_2O$ (1.5 g) was added to the refluxing solution of the free base. After reflux for 3 hr, portions of dilute hydrochloric acid were added by a small amount when the refluxed solution was cooled. The product was recrystallized twice from a mixture of 1,2-dichloroethane and hexane.

Found: C, 68.60; H, 6.88; N, 9.16; Fe, 8.55; Cl, 6.00%. Calcd for $C_{36}H_{44}N_4FeCl$: C, 69.29; H, 7.11; N, 8.98; Fe, 8.95; Cl, 5.68%.

Synthesis of Bisimidazoleoctaethylporphinatoiron(III) Perchlorate ([OEPFe(III)(Im)$_2$]ClO$_4$). [OEPFe(III)(Im)$_2$]ClO_4 was prepared by the method of Ogoshi *et al.*[13] OEPFe(III)Cl (150 mg) was dissolved in benzene (50 ml), and $AgClO_4$ (200 mg) was added. The reaction mixture was refluxed for 3 hr. After imidazole (80 mg) dissolved in benzene (15 ml) was added, the reaction mixture was refluxed continuously until the solution became transparent. The precipitates were separated by filteration, and extracted with 1,2-dichloroethane. Crude crystals were obtained by removing the solvent under reduced pressure. Dark brown pure crystals were obtained by recrystallization from a mixture of 1,2-dichloroethane and benzene.

Other metal porphins TPPMn(III)Cl, TPPCo(II), and TPPZn(II) used in the present measurements were prepared

in our previous works[10,14,15] and used without further purification.

Measurements of Absorption and Magnetic Circular Dichroism Spectra. The electronic absorption spectra were recorded on a Shimadzu recording spectrophotometer Model MPS-50. Solvents were benzene and 1,2-dichloroethane purified by fractional distillation using a 1.5 m Dixson-ring packed column and dried by the usual procedure.[16]

The circular dichroism under an external magnetic field (MCD) was measured by a JASCO automatic recording spectropolarimeter Model ORD/UV-5 with its CD attachment and electromagnet. The magnetic field was set at 10000 gauss.

A cryostat was adopted for measurements of the spectra at liquid-nitrogen temperature and dry ice–methanol temperature. For the low-temperature measurements, the porphins were dispersed in an appropriate polymer film. In the case of TPPFe(III)Cl, OEPFe(III)Cl, [TPPFe(III)-$(Im)_2]ClO_4$, [OEPFe(III)$(Im)_2]ClO_4$, TPPMn(III)Cl, and TPPZn(II), polymethyl methacrylate was used for matrices. By spontaneous evaporation of a viscous solution, which was obtained by dissolving polymethyl methacrylate and porphin in 1,2-dichloroethane, a transparent film dispersing porphin was prepared on a clean glass plate. In the case of TPPFe-(III)Cl and TPPZn, polystyrene was also used. A polystyrene film was made on a glass plate by spontaneous evaporation of a viscous solution, which was obtained by dissolving polystyrene and porphin in 1,2-dichloroethane. After evacuation, the film was melted in a glass tube at about 200 °C under nitrogen atmosphere which was used for polystyrene not to be oxidized. The bubbles in polystyrene were eliminated by recycling evacuation of the atmosphere in the glass tube and introduction of nitrogen gas. The polystyrene gave a rigid glass without cracks and distortion when slowly cooled. The sample was cut in a disk and its faces were polished so as to make optical measurements possible. Since TPPCo(II) might be oxidized during preparation of the rigid glass sample, TPPCo(II) was directly fused in polystyrene under nitrogen atmosphere.

ESR Spectra. The ESR spectra were obtained by a Japan Electron Optics Laboratory spectrometer Model JES ME3X. The static magnetic field was calibrated by means of a proton-resonance gaussmeter.

Results and Discussion

The MCD spectra of TPPFe(III)Cl and OEPFe-(III)Cl, which are typical iron(III) porphins in the high spin state $S=5/2$, were observed in benzene. The results are presented in Figs. 1 and 2. The similar spectra were obtained in polystyrene. Quantitative spectrum, however, could not be obtained, since the back-ground absorption of polystyrene increased so fast in the higher wave number region that a reproducible calibration was impossible. In the case of PMMA matrices, reproducible spectra of the porphins were obtained. In fact, the spectra of the rigid polymer glass at room temperature were coincident with the solution spectra. The absorption and MCD spectra of TPPFe(III)Cl and OEPFe(III)Cl in PMMA were measured for a variety of temperature as shown in Figs. 3 and 4.

The MCD spectra of [TPPFe(III)$(Im)_2]ClO_4$ and [OEPFe(III)$(Im)_2]ClO_4$, which are typical iron(III) porphins in the low spin state $S=1/2$, were

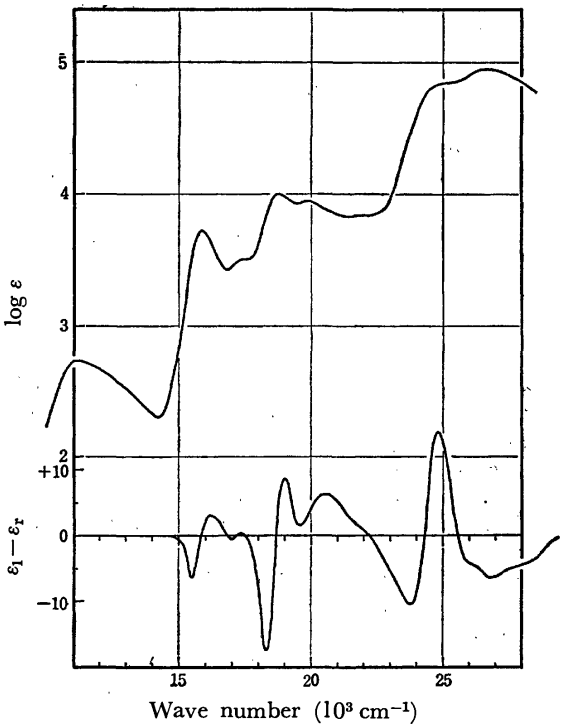

Fig. 2. The absorption and MCD spectra of OEPFe-(III)Cl in C_6H_6.

observed in $C_2H_4Cl_2$, and in PMMA for a variety of temperature. The results are presented in Figs. 5, 6, 7, and 8. The similar spectra were also obtained for [TPPFe(III)$(Im)_2]Cl$ and [TPPFe(III)$(Im)_2]ClO_4$ in chloroform which consists of ten times or more excess imidazole. La Mar and Walker also ob-

served in their NMR studies that the proton signals of the low-spin species were detected only in the presence of eight times excess imidazole in deutero-chloroform.[17] In chloroform, however, the dissociation of coordinated imidazole gives rise to a drift of the spectrum even in the presence of excess imidazole. In 1,2-dichloroethane, on the other hand, a spectrum characteristic of the low-spin iron(III) porphins did not change for a few days after the solid sample was dissolved in the absence of excess imidazole. The spectra obtained for TPPMn(III)Cl in PMMA, TPPCo(II) in polystyrene, and TPPZn(II) in PMMA are also shown in Figs. 9, 10, and 11.

A most remarkable enhancement of MCD extrema was observed in the low-spin iron(III) porphins when

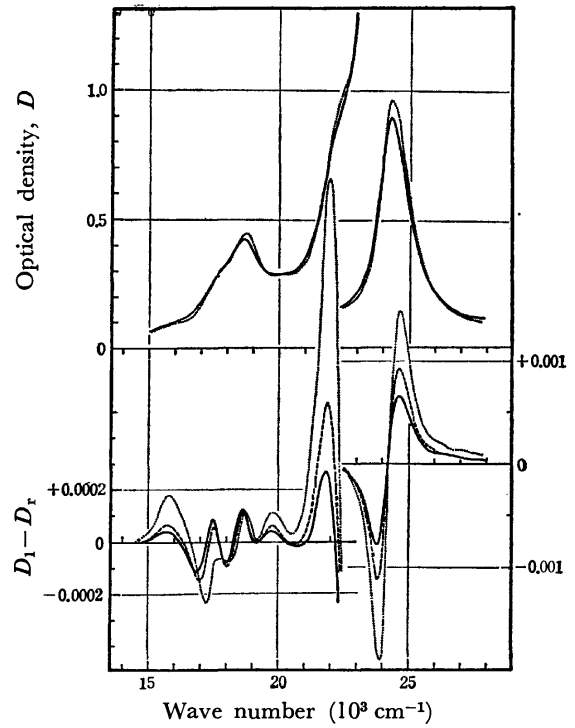

Fig. 7. The absorption and MCD spectra of [TPPFe(III)$(Im)_2$]ClO_4 in PMMA. ——: 310 K; ----: 196 K; ·····: 79 K.

the temperature is reduced. At the liquid-nitrogen temperature, two MCD peaks in the lower energy region of the B band increase their intensity up to several times greater than those at room temperature.

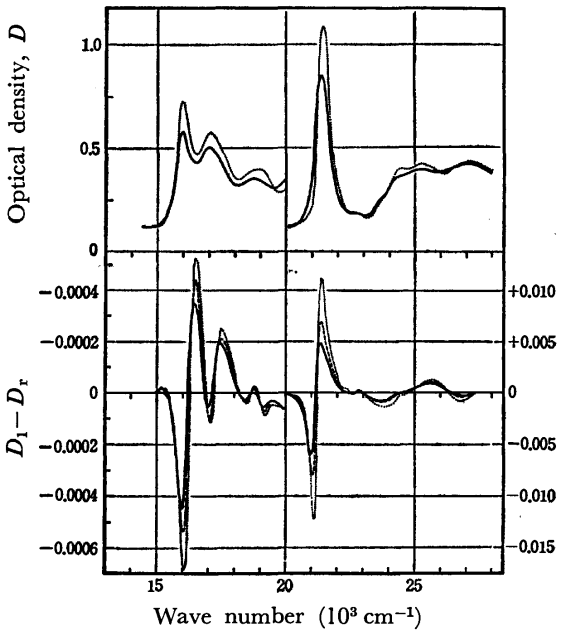

Fig. 9. The absorption and MCD spectra of TPPMn(III)Cl in PMMA. ——: 310 K; ----: 196 K; ·····: 79 K.

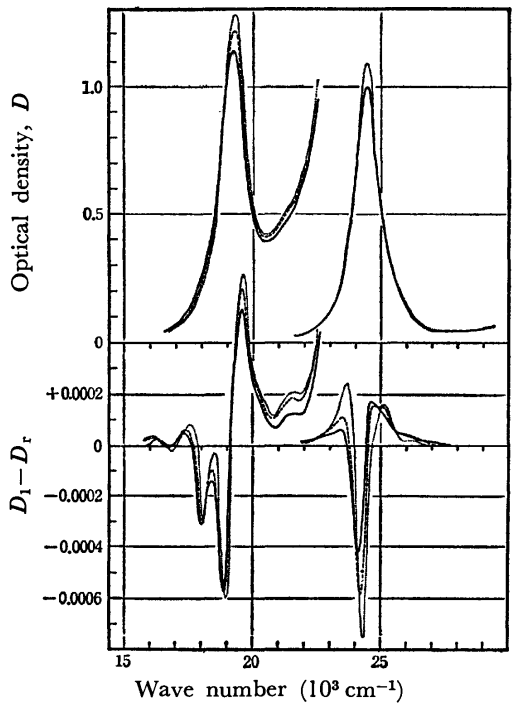

Fig. 10. The absorptioon and MCD spectra of TPPCo(II) in PMMA. ——: 310 K; ---- 196 K; ·····: 79 K.

The MCD extrema in the B band also increase their intensity at reduced temperatures. TPPCo(II) and TPPMn(III)Cl also exhibit the similar enhancement.

The absorption band is simulated by a damped oscillator or Gaussian spectral shape function.[18] Supposed that other factors are unchanged, the intensity of *A*-term dispersion extrema is inversely proportional to a square of the line width, while the intensities of *B*-term extrema and of absorption maxima are in-

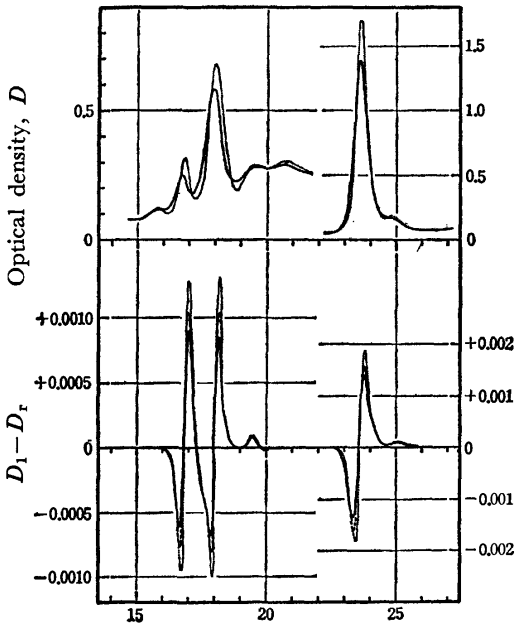

Fig. 11. The absorption and MCD spectra of TPPZn-(II) in PMMA. ——: 310 K; ----: 196 K; ……: 79 K.

versely proportional to the line width,

$$\theta^A_{max} \propto (1/\Gamma(T))^2,\ \theta^B_{max} \propto 1/\Gamma(T) \text{ and } \varepsilon^B_{max} \propto 1/\Gamma(T),$$

where Γ is the line width and a function of temperature T. Thus a ratio of the intensities of MCD extrema observed at two different temperatures is correlated with a ratio of the absorption intensities at the corresponding temperatures as follows:

$$\theta^A_{max}(T_2)/\theta^A_{max}(T_1) = \{\varepsilon_{max}(T_2)/\varepsilon_{max}(T_1)\}^2$$

and

$$\theta^B_{max}(T_2)/\theta^B_{max}(T_1) = \varepsilon_{max}(T_2)/\varepsilon_{max}(T_1).$$

Here it is noted that the ratio R_θ of the intensities of MCD extrema at liquid-nitrogen temperature and at ambient temperature is equal to or less than the square of the corresponding ratio R^2_ε of the absorption maxima. When R_θ is much greater than R^2_ε, a mechanism other than temperature-broadening of the line width should be working. The R_θ's and R^2_ε's observed for the samples studied in the present work are summarized in Fig. 12. The R_θ of TPPZn(II), in which only a small interaction between metal and porphin is present, is in good agreement with its corresponding R^2_ε. This implies that the MCD dispersions observed in the absorption bands of TPPZn(II) are assigned to A-term dispersions. A greater deviation was found in the case of two low-spin iron(III) porphins, TPPCo(II), and TPPMn(III)Cl. Here it is noted that a change of R_θ over the observed wave numbers was analogous in two different low-spin iron(III) porphins.

The ground state of the low-spin iron(III) porphin is described as a composite system of the ground state of porphin π system and the lowest Kramers doublet of low-spin iron d^5 system as follows:

$$A^+(+1) = |+4+\bar{4}-4-\bar{4}\,\zeta\,\bar{\zeta}+1+\bar{1}-1|,$$

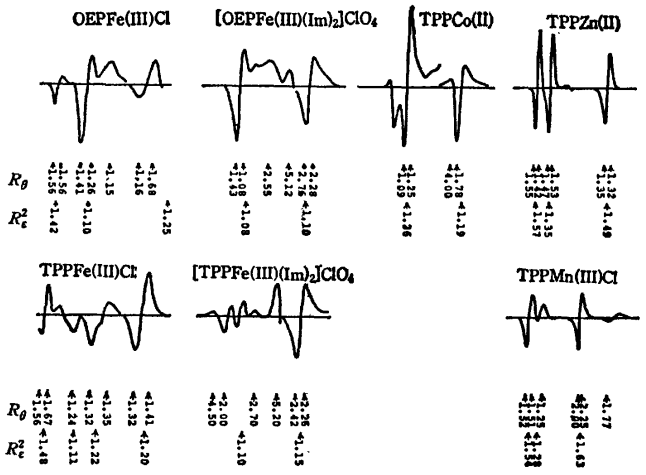

Fig. 12. $R_\theta = \left\{\dfrac{\theta_{max}(79\text{ K})}{\theta_{max}(310\text{ K})}\right\}$ and $R^2_\varepsilon = \left\{\dfrac{\varepsilon_{max}(79\text{ K})}{\varepsilon_{max}(310\text{ K})}\right\}^2$.

and

$$A^-(-1) = |+4+\bar{4}-4-\bar{4}\,\zeta\,\bar{\zeta}-1-\bar{1}+\bar{1}|,$$

where the numbers ±1 given in the parentheses are the orbital angular momenta, the superscripts $\pm$ indicate the α- and β-components of the Kramers doublet, ±4 are the highest occupied porphin π orbitals, ζ is iron xy orbital, ±1 are iron $d_{\pm1}$ orbitals, no bar implies spin α and a bar implies spin β. Thus the spin-allowed excited states of the low-spin iron(III) porphin should be spin-doublets. The composite doublets arise from products of the Kramers doublets of low-spin iron d^5 system and the porphin-localized lowest (π, π^*) excited states, not only of spin-singlet but also of triplet. The doublets given by the product wave funtions of the lowest Kramers' doublet of low-spin iron d^5 system and the porphin-localized Soret excited state B are denoted by $B^+(+2)$, $B^-(-2)$, $B^+(0)$, and $B^-(0)$:

$$B^+(+2) = \frac{1}{\sqrt{2}}\{|-4-\bar{4}+4+\bar{5}\,\zeta\,\bar{\zeta}+1+\bar{1}-1| - |-4-\bar{4}+\bar{4}+5\,\zeta\,\bar{\zeta}+1+\bar{1}-1|\}$$

$$B^-(-2) = \frac{1}{\sqrt{2}}\{|+4+\bar{4}-4-\bar{5}\,\zeta\,\bar{\zeta}-1-\bar{1}+\bar{1}| - |+4+\bar{4}-\bar{4}-5\,\zeta\,\bar{\zeta}-1-\bar{1}+\bar{1}|\}$$

$$B^+(0) = \frac{1}{\sqrt{2}}\{|+4+\bar{4}-4-\bar{5}\,\zeta\,\bar{\zeta}+1+\bar{1}-1| - |+4+\bar{4}-\bar{4}-5\,\zeta\,\bar{\zeta}+1+\bar{1}-1|\}$$

$$B^-(0) = \frac{1}{\sqrt{2}}\{|-4-\bar{4}+4+\bar{5}\,\zeta\,\bar{\zeta}-1-\bar{1}+\bar{1}| - |-4-\bar{4}+\bar{4}+5\,\zeta\,\bar{\zeta}-1-\bar{1}+\bar{1}|\}$$

Here the numbers given in the parentheses are the orbital angular momenta, the superscripts $\pm$ indicate the α- and β-components of the Kramers doublet, and ±5 are the lowest vacant porphin π orbitals. The excitations $A^+(+1)\rightarrow B^+(+2)$ and $A^-(-1)\rightarrow B^-(0)$ are left-handed circularly polarized, while the excitations $A^-(-1)\rightarrow B^-(-2)$ and $A^+(+1)\rightarrow B^+(0)$ are right-handed circularly polarized. An MCD dispersion occurs in the excitations $A^+(+1)\rightarrow B^+(+2)$ and $B^+(0)$

and also in the excitations $A^-(-1)\rightarrow B^-(-2)$ and $B^-(0)$. When the temperature is reduced, $A^-(-1)$ is more populated than $A^+(+1)$. However no practical change in MCD happens even at reduced temperatures if the B_1 states ($B^+(+2)$ and $B^-(-2)$), in which an orbital angular momentum induced upon excitation is in the direction of the resultant momentum of spin-orbit coupling at the central iron(III) ion, and the B_2 states ($B^+(0)$ and $B^-(0)$), in which an orbital angular momentum induced upon excitation is against the iron momentum, are degenerate.

Since the vacant $d\pi$ orbital and the lowest vacant porphin π^* orbital are equivalent in symmetry and thus, an electron-delocalization is possible between the $d\pi$ and π^* orbitals, the low-energy "porphin to iron(III)" CT excited states exhibit a configuration interaction against the lowest porphin-localized (π, π^*) excited states.[10] A difference in the configuration interactions of the "porphin to iron(III)" CT excited states against the porphin (π, π^*) excited states arises between the B_1 and B_2 states from a difference in symmetry of the doublet eigenfunctions of spin-orbit coupling in the low-spin iron(III) ion embedded in the excited porphin. The $B^+(0)$ and $B^-(0)$ states interact with the CT excited states $CT^+(+4)=|+4+\bar{4}-4\ \zeta\ \bar{\zeta}+1+\bar{1}-1-\bar{1}|$ and $CT^-(-4)=|-4-\bar{4}+\bar{4}\ \zeta\ \bar{\zeta}+1+\bar{1}-1-\bar{1}|$, respectively, while there is no such CT excited states interacting with the $B^+(+2)$ and $B^-(-2)$ states in a first-order approximation.

		$B^+(0)$ ($B^-(0)$)	$-CT^+(+4)$ ($CT^-(-4)$)
$B^+(0)$	($B^-(0)$)	$E+2K_1-\frac{1}{2}a$	$\frac{\sqrt{2}}{2}X$
$-CT^-(+4)$	($CT^-(-4)$)	$\frac{\sqrt{2}}{2}X$	E_{CT}

Here $E+2K_1$ and E_{CT} are the diagonal energies of the B state and the CT state, a is the spin-orbit coupling constant and X is the resonance integral between porphin ±5 orbital and iron $d_{\pm1}$ orbital. Since the "porphin to iron(III)" CT excited states in low-spin iron(III) porphins are lower than the B states,[10] the CT states raise the $B^\pm(0)$ states. The empirical values $E=13070\ cm^{-1}$, $K_1=4600\ cm^{-1}$, $X=-3000\ cm^{-1}$ [10] and $a=435\ cm^{-1}$ [19] predict an energy gap ΔE between $B^\pm(0)$ and $B^\pm(\pm2)$ as a function of E_{CT} as follows:

$E_{CT}=10000\ cm^{-1}$	$\Delta E=360\ cm^{-1}$
$E_{CT}=12500\ cm^{-1}$	$\Delta E=450\ cm^{-1}$
$E_{CT}=15000\ cm^{-1}$	$\Delta E=590\ cm^{-1}$

The mixing of the "porphin to iron(III)" CT excited states to B_1 states occurs to a less extent than the interaction to B_2 states even if in a higher approximation. In fact, the B band of low-spin iron(III) porphins is evidently broad as compared with the B band observed for a typical (π, π^*) transition in TPPZn(II). An MCD dispersion experimentally observed in the Soret region, however, indicates that a gap between the B_1 and B_2 states should be less than the band width ($1000\ cm^{-1}$) of each component absorption band. Since $A^-(-1)$ is more populated than $A^+(+1)$ at reduced temperatures, the low-energy component transition $A^-(-1)\rightarrow B^+(-2)$ which is right-handed circularly polarized and the high-energy component transition $A^-(-1)\rightarrow B^-(0)$ which is left-handed circularly polarized enhance their absorption intensities. An apparent dispersion is thus obtained by superposing two temperature-dependent *C*-term extrema with opposite sign for a small energy gap of the excitations to B_1 and B_2 states.

The ESR spectrum of powder $[TPPFe(III)(Im)_2]ClO_4$ at 77 K exhibits three different *g*-values at $g_{zz}=2.87$, $g_{yy}=2.26$, and $g_{xx}=1.65$. The *g*-values of powder $[TPPFe(III)(Im)_2]Cl$ prepared in the present work were $g_{zz}=2.91$, $g_{yy}=2.31$, and $g_{xx}=1.54$ and in good agreement with the values $g_1=2.9$, $g_2=2.3$, and $g_3=1.5$ reported for $[TPPFe(III)(Im)_2]Cl$ in a frozen chloroform solution containing excess imidazole.[20] These anisotropic *g*-values insist that the iron $d_{\pm1}$ orbitals are split by the π-interaction due to the axial ligands and the lowest Kramers doublet is predominantly made of a degenerate configuration ((xy) ($\overline{xy}$) (zx) ($\overline{zx}$) (yz); (xy) ($\overline{xy}$) (zx) ($\overline{zx}$) ($\overline{yz}$)). The lowest component of the spin-orbit coupling sublevels of low-spin d^5 system is about 99.3% occupied even at 300 K.[19] For such a ground state, the arguments similar to those given for the ground state $A^\pm(\pm1)$ can be applicable and predict a temperature-dependent MCD dispersion. As revealed by X-ray studies, two coordinated imidazole molecules are in almost coplanar in the crystal.[21,22] However an internal rotation of the coordinated imidazoles is not so hindered in solution and then the anisotropy becomes smaller than expected from three *g*-values observed for the solid sample.

In the course of the present work, an independent observation on the temperature-dependent MCD spectra of the low-spin iron(III) porphyrins in hemoproteins was informed the authors before its publication by Dr. T. Nozawa, Tohoku University. The authors' thanks are due to Dr. H. Ogoshi, Kyoto University, for his advice concerning the preparation of porphyrinatoiron(III) perchlorates. The authors are also indebted to Professor J. Higuchi and Dr. T. Ito for the measurements of ESR spectra.

Cyanoalkyl Complexes of Transition Metals. IV. Geometry and Spectroscopic Properties of Cyanomethyl Complexes of Palladium(II) and Platinum(II)

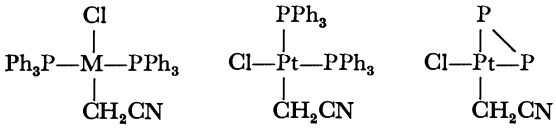
Keinosuke SUZUKI, Junichi OOYAMA, and Masami SAKURAI

Inorganic Chemistry Laboratory, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received August 11, 1975)

A number of cyanomethyl complexes of palladium(II) and platinum(II) were prepared and characterized by proton nuclear magnetic resonance and infrared spectroscopy. It was shown that the methylene resonance, phenyl resonance, and a strong band at 550 ± 5 cm^{-1} are acceptable criteria for deducing the geometry of the complexes $MX(CH_2CN)(PPh_3)_2$ (M=Pd, Pt). The criteria allow us to assign the *cis* geometry to the bromo and iodo complexes of platinum(II) both of which showed an unusual methylene resonance. An approximately linear relationship holds between ^2J(Pt-H) of *trans*-$PtX(CH_2CN)(PPh_3)_2$ and that of *trans*-$PtX(CH_3)(PPh_3)_2$ (X=Cl, Br, I, N_3, NO_2, NO_3).

It has been well established that the stereochemistry of square-planar bis(phosphine)-transition metal complexes can be determined by ^{1}H NMR if the phosphines contain methyl or methylene groups attached to the phosphorus atom.[1-8] However, this method is inadequate when the phosphine is triphenylphosphine. Recently we reported the synthesis and spectroscopic properties of $PdCl(CH_2CN)(PPh_3)_2$[9] (**1a**), *trans*- and *cis*-$PtCl(CH_2CN)(PPh_3)_2$[10] (**1b**, **2**) and demonstrated that the gross geometry of these complexes could be determined by the ^{1}H NMR spectrum of the cyanomethyl protons. The methylene resonance of **1a** and **1b** appeared as a triplet due to spin-spin coupling with two equivalent phosphorus atoms. On the other hand the same resonance of **2** occurred as a 1 : 1 : 1 : 1 doublet of doublets because of the two non-equivalent phosphorus atoms. The cyanomethyl protons of PtCl(diphos) (**3**, diphos=$Ph_2PCH_2CH_2PPh_2$) also



1a, M=Pd **2** **3**, P-P=diphos
1b, M=Pt

gave a doublet of doublets in accordance with *cis* geometry. The methylene resonance seems to be useful as a criterion for determining the stereochemistry of the complexes $MX(CH_2CN)(PPh_3)_2$. However, we found in the course of studies on cyanomethyl complexes that care should be taken in making deductions about the geometry of $MX(CH_2CN)(PPh_3)_2$ solely from the methylene resonance. In this paper we describe the preparation of several cyanomethyl complexes of palladium(II) and platinum(II) and discuss the method of establishing their geometry on the basis of IR and ^{1}H NMR spectral data.

Experimental

High frequency infrared spectra (4000—700 cm^{-1}) were recorded on a JASCO-DS-402G spectrometer with samples prepared as Nujol or hexachlorobutadiene mulls. Low frequency spectra (700—200 cm^{-1}) were recorded on a HITACHI EPI-L2 spectrometer with samples as Nujol mulls. The ^{1}H NMR spectra were recorded on a JEOL-C60H spectrometer with TMS as an internal standard.

Starting Materials. Chlorocyanomethylbis(triphenylphosphine)-palladium (II) **1a**, *trans*- and *cis*-chlorocyanomethylbis(triphenylphosphine)platinum(II) **1b** and **2**, were prepared as reported previously.[9,10] Commercial reagents and solvents were used without purification. Microanalyses were performed by Wako Pure Chemical Industries, Ltd.

Preparation of $PdX(CH_2CN)(PPh_3)_2$ (X=NCO, N_3, I, NO_2, $N(CO)_2C_6H_4$, CN). Potassium cyanate (0.07 g, 0.86 mmol) was added to a solution of **1a** (0.50 g, 0.71 mmol) dissolved in 150 ml of acetone and stirred for 3 hr at room temperature. The yellow color of the solution disappeared and a small amount of white solid was obtained. It was filtered off and the filtrate was concentrated to give a white precipitate of $Pd(NCO)(CH_2CN)(PPh_3)_2$. The precipitate was filtered, washed with acetone and dried *in vacuo*. The azido, iodo, nitro, and phthalimido complexes were prepared similarly in acetone (sodium azide, potassium iodide) or methanol (sodium nitrite, potassium phthalimide).

A suspension of potassium cyanide (0.046 g, 0.73 mmol) and **1a** (0.50 g, 0.71 mmol) in 150 ml of methanol was heated at 55—60 °C for 2 hr. The resulting yellow solution was allowed to stand at room temperature to afford pale yellow crystals of $Pd(CN)(CH_2CN)(PPh_3)_2$ containing two molecules of methanol.

Preparation of trans-*$PtX(CH_2CN)(PPh_3)_2$ (X=NCO, N_3, NO_2, $N(CO)_2C_6H_4$, NO_3, CH_3COO),* Potassium cyanate (0.045 g, 0.55 mmol) and **1b** (0.35 g, 0.44 mmol) were suspended in a mixed solvent of benzene (100 ml) and ethanol (50 ml) and refluxed for 5 hr. The resulting yellow solid was filtered and recrystallized from chloroform–diethyl ether to give *trans*-$Pt(NCO)(CH_2CN)(PPh_3)_2$. Similarly *trans*-$Pt[N(CO)_2C_6H_4](CH_2CN)(PPh_3)_2$ was prepared by the reaction of **1b** with potassium phthalimide in a mixed solvent of acetone and ethanol (1 : 1). *trans*-$Pt(N_3)(CH_2CN)(PPh_3)_2$ was synthesized by the reaction of **1b** with sodium azide in ethanol at room temperature.

A suspension of **1b** (0.50 g, 0.63 mmol) and silver nitrate (0.107 g, 0.63 mmol) in 150 ml of acetone was stirred for 12 hr at room temperature in the dark. The silver chloride formed was removed by filtration and the filtrate was concentrated to dryness *in vacuo*. The white residue was recrystallized from dichloromethane–diethyl ether to give white crystals of *trans*-$Pt(NO_3)(CH_2CN)(PPh_3)_2$. It contained one molecule of dichloromethane. *trans*-$Pt(CH_3COO)(CH_2CN)(PPh_3)_2$ was prepared in the same way with the use of silver acetate. *trans*-$Pt(NO_2)(CH_2CN)(PPh_3)_2$ was prepared by the reaction of *trans*-$Pt(NO_3)(CH_2CN)(PPh_3)_2$ with potassium nitrite in acetone.

Preparation of cis-*$PtX(CH_2CN)(PPh_3)_2$(X=NCO, N_3, NO_2, Br, I).* Lithium bromide (0.04 g, 0.46 mmol) and **2**

a) All complexes melted with decomposition. b) The existence of one mole of dichloromethane and acetone and two moles of methanol was confirmed by ^1H NMR.

(0.20 g, 0.25 mmol) were dissolved in a mixed solvent of methanol (30 ml) and bromoform (15 ml). The solution was refluxed for 0.5 hr and then concentrated *in vacuo*. Addition of diethyl ether to the solution caused the precipitation of a pale yellow solid, which was recrystallized from dichloromethane–petroleum ether to afford pale yellow crystals of *cis*-$PtBr(CH_2CN)(PPh_3)_2$. It contained one molecule of dichloromethane.

A suspension of **2** (0.50 g, 0.63 mmol) and lithium iodide trihydrate (0.15 g, 0.80 mmol) in methanol (20 ml) was stirred for 5 hr at room temperature. The white suspension turned into a yellow solid. It was filtered and recrystallized from dichloromethane–diethyl ether to give yellow crystals of *cis*-$PtI(CH_2CN)(PPh_3)_2$. *cis*-$Pt(NCO)(CH_2CN)(PPh_3)_2$ and *cis*-$Pt(NO_2)(CH_2CN)(PPh_3)_2$ were synthesized by the reaction of **2** with potassium cyanate or potassium nitrite in a similar manner, after being stirred for 24 hr at room temperature. *cis*-$Pt(N_3)(CH_2CN)(PPh_3)_2$ was similarly prepared by the reaction of **2** with sodium azide. Heating under reflux for 5 hr was necessary.

Physical properties and analytical data of new cyanomethyl complexes are given in Table 1.

Results and Discussion

Most of the cyanomethyl complexes were prepared by simple metathesis according to

$$MCl(CH_2CN)(PPh_3)_2 + X^- \rightarrow MX(CH_2CN)(PPh_3)_2 + Cl^-$$

For the nitrato and acetato complexes of platinum(II), it was necessary to utilize silver nitrate or silver acetate in order to abstract the chloride ion. However, application of this method to **1a** and **2** was unsuccessful.

An interesting property of the palladium complexes is photochromism. In the solid state, all palladium complexes except the cyano derivative change color (B) when exposed to light, but revert to the original color (A) in the dark. This color change is reversible but not observed in solution. The observed color changes are summarized in Table 2. In contrast to the palladium complexes, neither *cis*- nor *trans*-$PtX(CH_2CN)(PPh_3)_2$ showed similar color changes. Thus the phenomenon seems to be characteristic of the cyanomethyl complexes of palladium(II), but the cause has not been clarified.

Table 2. Photochromism of $PdX(CH_2CN)(PPh_3)_2$

X	N_3	NCO	NO_2	$N(CO)_2C_6H_4$	I
A	yellow	pale yellow	white	white	yellow
B	orange	pale orange	pale orange	red	brown

All the complexes are stable in the air both in the solid state and in solution. They are soluble in chloroform and dichloromethane but sparingly soluble in diethyl ether.

Spectroscopic Features of $MX(CH_2CN)(PPh_3)_2$. ^1H NMR spectral data are given in Table 3. They show that the methylene resonance of complexes prepared from **1a** and **1b** consists of a 1 : 2 : 1 triplet without exception while the same resonance of azido, cyanato, and nitro complexes derived from **2** occurs as a 1 : 1 : 1 : 1 doublet of doublets. For the platinum complexes of the same composition, the triplet always appeared at much higher field relative to the doublet of doublets (*ca.* 0.6 ppm). The coupling constants, ^2J(Pt–H) of the triplets (90.0—109.5 Hz) are much larger than those for the doublet of doublets (76.5—79.5 Hz). The methylene resonance of two azide complexes of platinum (II) illustrates these spectroscopic features (Fig. 1). The results confirm the previous observation based on the spectral data of the chloro complexes and suggest that the methylene resonance, if it satisfies the conditions mentioned above, will provide a method to distinguish *cis*-$MX(CH_2CN)(PPh_3)_2$ from the corresponding *trans* isomer. The difference of the chemical shift of the methylene protons (0.6 ppm) is larger than

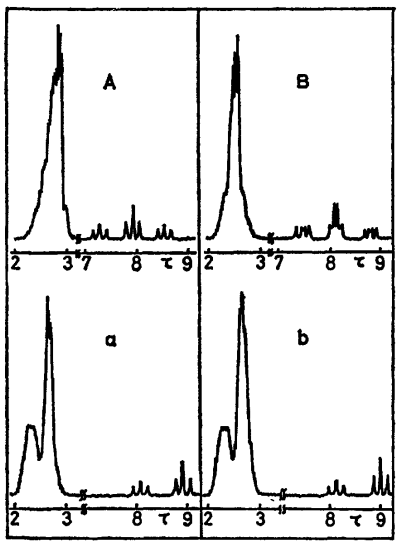

Fig. 2. ^{1}H NMR spectra of the bromo and iodo complexes of platinum(II). (A) *cis*-$PtI(CH_2CN)(PPh_3)_2$, (a) *trans*-$PtI(CH_2CN)(PPh_3)_2$, (B) *cis*-$PtBr(CH_2CN)(PPh_3)_2$, (b) *trans*-$PtBr(CH_2CN)(PPh_3)_2$.

that of the methyl protons for *cis*- and *trans*-$PtX(CH_3)(PEt_3)_2$[11] (*ca.* 0.2 ppm). The larger difference found in the cyanomethyl complexes might be due to the ring current of the coordinated triphenylphosphine.

Nelson *et al.*[12] showed that when two phenylphosphines, in square-planar complexes, are *trans* to one another the phenyl resonance occurs as two broad multiplets, whereas if they are *cis*, only one broad multiplet is usually observed. Figure 1 indicates this is true for the complexes we studied. The phenyl resonance of the cymplexes which exhibited a triplet occurred as two broad multiplets centered at τ 2.3 and 2.5—2.7 while only one multiplet was found for the complexes accompanied by a doublet of doublets. Thus the phenyl resonance of $MX(CH_2CN)(PPh_3)_2$ also provides identification of the stereochemistry of the cyanomethyl complexes.

Recently, Mastin[13] gave a convenient method for directly determining the stereochemistry of the complexes $PtXY(PPh_3)_2$ and proposed the use of the intensity of a band at 550±5 cm^{-1} as a simple criterion for assignment of their stereochemistry. The complexes which showed a doublet of doublets and one multiplet gave a strong absorption at 550±5 cm^{-1} without exception (Table 4). On the other hand, none of the complexes to which the *trans* geometry was assigned on the basis of the methylene and phenyl resonance showed any strong absorption in this region. Thus Mastin's proposal is a useful tool for determining

the geometry of $MX(CH_2CN)(PPh_3)_2$.

For the cyanomethyl complexes discussed so far, one of the three criteria was consistent with the other two, suggesting each of them is normally a reliable criterion in determining the stereochemistry of the complexes $MX(CH_2CN)(PPh_3)_2$.

Geometry of $PtX(CH_2CN)(PPh_3)_2$ (X=Br, I). ^1H NMR spectra of the bromo and iodo complexes of platinum(II) prepared from **2** are shown in Fig. 2, which includes the spectra of the corresponding *trans* isomers for the sake of comparison. The splitting pattern of the methylene resonance differs from that expected for the *cis* geometry. In particular the NMR spectrum of the iodo complex is of interest in that the methylene resonance appeared as a 1 : 2 : 1 triplet which is typical of *trans*-$PtX(CH_2CN)(PPh_3)_2$ (Figs. 1 and 2). However, this triplet is not due to the formation of *trans*-$PtI(CH_2CN)(PPh_3)_2$ since its chemical shift (τ 7.91) and the coupling constant ^2J(Pt-H) (79.5 Hz) are quite different from those of the *trans* isomer[10] (τ 8.88, ^2J(Pt–H)=102.0 Hz). Thus, in order to deduce their geometry, the other criteria were considered. First, the methylene resonance of the bromo (τ 8.19) and iodo (τ 7.91) complexes in question appear at much lower fields than those of the *trans* isomers (τ 8.98 (Br), τ 8.81(I)) and rather close to those of the diphosphine complexes (τ 8.27 (Br), τ 8.03(I)).[10] Furthermore, the coupling constant ^2J(Pt–H) of both complexes (Br= 78.0, I=79.5 Hz) is also comparable with the values found for the other *cis* isomers (Table 3) but smaller than those obtained for the *trans* isomers. Second, the phenyl resonance exhibits only one broad multiplet centered at τ 2.6 (Br) and 2.7 (I), while *trans* isomers gave two broad multiplets (Fig. 2). A strong absorption was observed at 545 cm^{-1} for both bromo and iodo complexes but not for the corresponding *trans* isomers. These spectroscopic data led us to assign the *cis* geometry to the bromo and iodo complexes, although their methylene resonance showed no expected nultiplets. This demonstrates that the spectral pattern of the methylene protons alone is insufficient for deducing the geometry of $MX(CH_2CN)(PPh_3)_2$.

The methylene resonance of *cis*-$PtBr(CH_2CN)(PPh_3)_2$ shows different multiplet structures in the side bands and in the center band (Fig. 2). Similar unusual spectra have been reported for some hydride complexes of platinum(II)[14] and interpreted on the basis of the relative magnitude of the chemical shift difference of two phosphorus atoms and the coupling constant J(Pt–P). Although we could not analyze the spectrum, the observed anomaly might be explained in a similar manner.

Recently, Ros *et al.*[15] have measured the proton decoupled ^{31}P NMR spectrum of *cis*-$PtCl(CH_2CN)(PPh_3)_2$ and observed two sets of doublet with equal intensity. Therefore we assumed an AMX_2 spin system (A=M=P, X=H) for the *cis* complexes which showed a doublet of doublets. The coupling constants ^3J(P–H) for these complexes are listed in Table 3. The unusual methylene resonance of the bromo and iodo complexes cannot be explained in terms of the same spin system. Instead of the ^3J(P–H) we tentatively report a separation between the two inside strong peaks (*ca.* 2.5 Hz) and one between the two outside peaks (*ca.* 14.5 Hz) for the bromo complex, and a separation between the central peak and one of the two outside peaks (*ca.* 7.5 Hz) for the iodo complex.

The methylene resonance of *cis*-$PtX(CH_2CN)(PPh_3)_2$ changes from a doublet of doublets (X=Cl)[10] to a triplet (X=I) through an intermediate pattern (X=Br), but no similar variations have been observed for $PtX(CH_2CN)(P\text{–}P)$ (X=Cl, Br, I). X-Ray structural analysis of $[Rh(P\text{–}P)_2]^+$ [16] and $[Ir(PMePh_2)_4]^+$ [17] indicates that the steric crowding around the central metal atom is larger for the latter. Since triphenylphosphine is more bulky than methyldiphenylphosphine, it is likely that greater distortion from the planar configuration is found in $PtX(CH_2CN)(PPh_3)_2$ than $PtX(CH_2CN)(P\text{–}P)$ and enhanced with increase in the size of a halogen atom. Thus, the observed variation in the methylene resonance might be partially due to this distortion.

^2J(Pt–H). The coupling constant, ^2J(Pt–H) of *trans*-$PtX(CH_2CN)(PPh_3)_2$ is larger than that of *trans*-$PtX(CH_3)(PPh_3)_2$.[18] These two coupling constants are related to one another by a reasonably linear relationship (Fig. 3). The dependence of ^2J(Pt–H) on the substituent R in the Pt–CH_2R moiety is not clear at present, but it is evident that the nitrile group increases the absolute value of ^2J(Pt–H) as is found for the coupling constant ^2J(H–H).[19]

The coupling constant ^2J(Pt–H) of *trans*-$PtX(CH_2CN)(PPh_3)_2$ increases in the order

$$NO_2 < N(CO)_2C_6H_4 < N_3,\ I < NCO,\ Br < Cl < CH_3CO_2 < NO_3^-$$

This is in line with the NMR *trans*-influence order given by Appleton, Clark, and Manzer.[20]

Infrared Spectra. All the complexes studied showed a sharp strong band due to ν(CN) at *ca.* 2200 cm^{-1}. The band is useful in identifying the presence of the CH_2CN group but gives little information on the geometry of the cyanomethyl complexes.

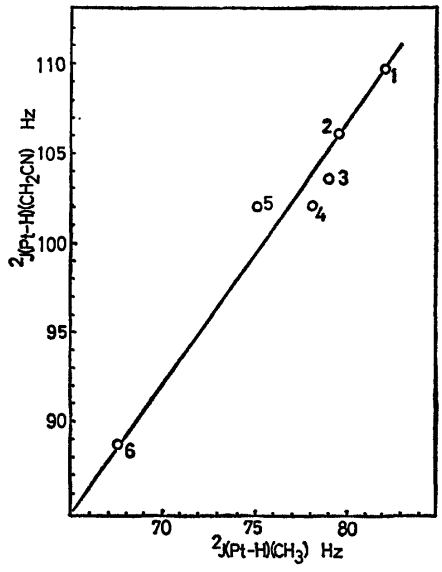

Fig. 3. A plot of ^2J(Pt–H) of *trans*-$PtX(CH_2CN)(PPh_3)_2$ *vs.* ^2J(Pt–H) of *trans*-$PtX(CH_3)(PPh_3)_2$. X=NO_3 (1), Cl (2), Br (3), I (4), N_3 (5), NO_2 (6).

	CN	2210 s		

a) See text.

A comparison between ν(Pt–X) of *cis*- and *trans*-$PtX(CH_2CN)(PPh_3)_2$ (X=N_3, NCO, NO_2) indicates that the *trans*-influence of the CH_2CN group is slightly higher than that of triphenylphosphine.

We could not prepare *cis*-$PdX(CH_2CN)(PPh_3)_2$ and examine the presence or absence of a strong band at 550±5 cm^{-1}. Thus, for the palladium complexes, the validity of Mastin's criterion is uncertain, although none of the *trans*-$PdX(CH_2CN)(PPh_3)_2$ complexes showed a strong absorption in this region.

Metal Complexes of EDTA and Its Related Compounds. II.[1] Geometric Isomers of [Co(X)(trimethylenediamine-*N,N,N'*-triacetate)] Complexes with X=H_2O, NH_3, Cl^-, and CN^-

Myung-Ki Doh,* Hiroshi Ogino, Junnosuke Fujita,** and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received August 25, 1975)

Three geometric isomers, equatorial-skew, polar-chair and polar-skew, of [Co(X)(trdtra)] ($trdtra^{3-}$=trimethylenediamine-*N,N,N'*-triacetate) have been prepared for each X=H_2O, NH_3 and Cl^-, and the structures assigned mainly by comparing their electronic spectra with those of the equatorial-skew and the polar-chair isomers of *N*-methyl-trdtra complexes reported previously. The cyano complex gives only the polar-chair isomer.

Cobalt(III) complexes containing a quinquedentate trimethylenediamine-*N,N,N'*-triacetate($trdtra^{3-}$) or its *N*-substituted derivatives can have three probable geometric isomers as shown in Fig. 1.[1] Of these, the equatorial-skew and the polar-chair isomers were found for aqua, ammine and chloro complexes of *N*-methyl-trimethylenediamine-*N,N',N'*-triacetate(*N*-Me-$trdtra^{3-}$).[1] In the present study, all the three isomers have been obtained for the aqua, ammine and chloro complexes with trdtra in place of *N*-Me-trdtra.

Experimental

Preparation of Sodium Trimethylenediamine-N,N,N'*-triacetate (Na₃trdtra).* This ligand was prepared by a method similar to that for Na_3*N*-Me-trdtra.[1] An aqueous solution containing 0.3 mol of chloroacetic acid, 0.1 mol of trimethylenediamine and 0.7 mol of sodium hydroxide was heated at 80 °C for 40 min, concentrated under a reduced pressure at 70 °C and filtered to remove sodium chloride. The filtrate was used for the preparation of cobalt(III) complexes without isolating the free ligand.

Preparation of Complexes. [$Co(H_2O)$(trdtra)]: The aqua complex was prepared from cobalt(II) nitrate and the aqueous Na_3trdtra solution and separated into geometric isomers by a method similar to that for [$Co(H_2O)$(*N*-Me-trdtra)]·H_2O.[1] On the separation of three isomers by column chromatography, the order of elution was bluish violet(polar-chair), reddish violet(polar-skew) and violet(equatorial-skew) isomer. Each eluate was evaporated to dryness under a reduced pressure below 40 °C. Pure isomers were obtained by dissolving the residues in a small amount of water and by adding ethanol. The solubility in water increases in the order of the bluish violet, the reddish violet and the violet isomer. Total yield of the three isomers based on trimethylenediamine was about 20% and the ratio of the bluish violet, the reddish violet and the violet isomer was 1 : 1 : 8.

[($Co(NH_3)$(trdra)]: Violet(equatorial-skew), reddish violet(polar-skew) and red(polar-chair) isomers of the complex were obtained by a similar method to that for [$Co(NH_3)$(*N*-Me-trdra]·$2H_2O$.[1] The isomers were eluted from the column in the order given above. The solubility in water increases in the order of the red, the reddish violet and the violet isomer.

H[(Co(Cl)(trdra)]: The violet(equatorial-skew), reddish violet(polar-skew) and bluish violet(polar-chair) isomers of [$Co(H_2O)$(trdtra)] were converted to bluish green(A)(equatorial-skew), bluish green(B)(polar-skew) and greenish blue (polar-chair) isomers, respectively, by a method similar to that for H[Co(Cl)(*N*-Me-trdtra)].[1] The greenish blue isomer includes one mole of crystalline ethanol which can hardly be removed by usual methods.

H[Co(CN)(trdra)]·$2H_2O$: The complex was prepared from the violet aqua complex by a method similar to that for H[Co(CN)(*N*-Me-trdtra)]·$2H_2O$.[1] The reactions with the other isomers of aqua complex gave also the same red cyano complex(polar-chair).

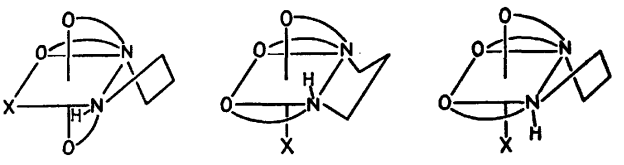
The analytical data for the complexes prepared in this work are summarized in Table 1.

Measurements. Visible and ultraviolet absorption spectra were recorded on a Hitachi 323 recording spectrophotometer. PMR spectra were obtained on a Varian HA-100 spectrometer in a D_2O solution containing sodium 3-trimethylsilyl-1-propanesulfonate(TMS*) as the internal standard. All the measurements were made at room temperature.

Results and Discussion

Figure 1 shows three geometric isomers of the complex [Co(X)(trdtra)]. This complex could have further possible geometric isomers than the three. They have two acetate groups on the tertiary nitrogen coordinated *trans* to each other. Such a form was found in [$Co(NO_2)$((*R*)-pdtra)]$^-$ [2] ((*R*)-pdtra=(*R*)-1,2-propanediaminetriacetate) and [Co(en)((*R*)-H_2pdta)]$^+$ [3] (en = ethylenediamine, (*R*)-pdta = *R*-1,2-propanediaminetetraacetate). However, this form is expected to be stable only for complexes of diamine-tri- or -tetraacetate with bulky groups on carbon atoms of the diamine moiety.[2] In fact, no indication for the presence of more than three isomers was found in the present syntheses of trdtra complexes. Thus, the three isomers for each aqua, ammine and chloro trdtra complex obtained here may have all the *cis* form in which two acetate groups on the tertiary nitrogen are coordinated *cis* to each other as shown in Fig. 1.

Both violet and bluish violet isomers of the aqua complex isomerize to each other in an acid aqueous



equatorial-skew polar-chair polar-skew

Fig. 1. Three geometric isomers of [Co(X)(trdtra)].

sh: shoulder band.

solution on warming. The equilibrium constant between the two isomers was 0.12 at 63 °C and pH 3, the violet isomer being predominant. On the other hand, the reddish violet isomer shows no spectral change under a similar condition. We reported that the isomerization between the equatorial-skew and the polar-chair isomer takes place more easily than do those between the polar-skew and the other two isomers.[1] Therefore, the violet and the bluish violet isomer can be assigned to either the equatorial-skew or the polar-chair, and the reddish violet isomer to the polar-skew. The assignment for the first two isomers was made by comparing the absorption spectra with those of the corresponding *N*-Me-trdtra complexes. As Fig. 2 and the Table 2 show, the bluish violet isomer exhibits a sharp first absorption band at longer wave length and an intense second absorption band as compared with those of the violet isomer. Such spectral differences resemble those between the two isomers of the aqua *N*-Me-trdtra complex, and the bluish violet isomer can be assigned to the polar-chair, and the violet isomer to the equatorial-skew.

Tanaka *et al.*[4] obtained the violet isomer by thermal decomposition of $K[Co(trdta)]\cdot 2H_2O$ ($trdta^{4-}$=trimethylenediaminetetraacetate) at 250 °C, but they did not describe its structure.

The absorption spectra of three isomers of the ammine complex are shown in Fig. 2. The equatorial and the polar structure correspond to *mer*- and *fac*-$[CoN_3O_3]$ type, respectively.

The red isomer shows a sharp first absorption band and can be assigned to *fac* type.[5] On the other hand, the violet and the reddish violet isomers give broad first absorption bands, indicating *mer* type, although only one *mer* type is expected. To assign the structure of these two isomers, PMR spectrum of the violet isomer was measured in deuterium oxide. The spectrum shows three AB patterns with coupling constants, 16.0, 18.3 and 18.5 Hz (Fig. 3). The AB pattern with 16.0 Hz is attributed to the in-plane acetate protons and those with 18.3 and 18.5 Hz to the out-of-plane acetate protons.[6] Thus, the violet isomer can be assigned to the equatorial-skew (*mer*) and hence, the reddish violet isomer to the *fac*. Of the two *fac* isomers, the red isomer can be assigned to the polar-chair structure, since its absorption spec-

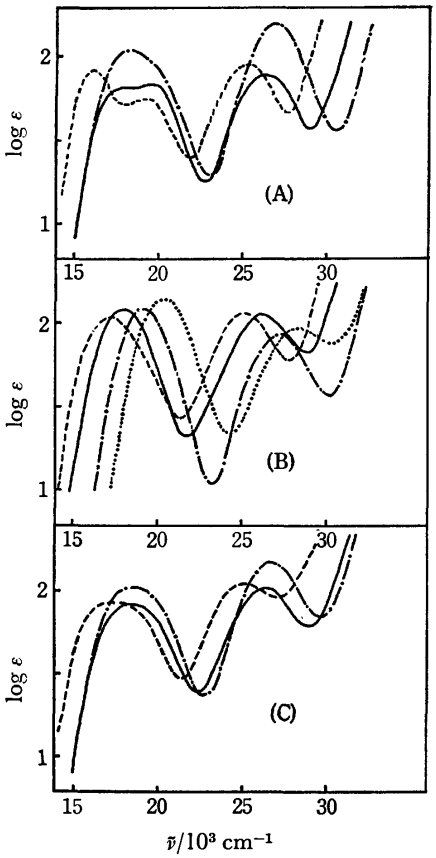

Fig. 2. Absorption spectra of (A): equatorial-skew, (B): polar-chair and (C): polar-skew isomers of [Co(X)(trdtra)] in water except chloro complexes (in 1 M HCl). ——: aqua, – – –: ammine, – – –: chloro, and ·····: cyano complexes.

trum resembles very closely that of the corresponding *N*-Me-trdtra complex. The remaining reddish violet isomer, therefore should have the polar-skew structure, although it gives a broad first absorption band. The broadening of the first absorption band seems to be characteristic of trdtra and its related complexes with a skew conformation in the trimethylenediamine moiety. The [Cotrdta]$^-$ in which the trimethylenediamine moiety takes a skew conformation[7] shows also a broad first absorption band.[8]

The chloro complexes were prepared from the aqua complexes by treating with hydrochloric acid. Since the substitution reactions would be configuration retention[1] under the present experimental condition, the bluish green(A), the bluish green(B) and the greenish blue isomer would have the structure of the equatorial-skew, the polar-skew and the polar-chair, respectively. The absorption spectra of these isomers are shown in Fig. 2. The first absorption bands of the two skew isomers are broader than that of the chair isomer, as seen in the aqua and ammine complexes. The equatorial-skew isomer shows the first absorption band split apparently into two components.

The cyano complex gives always only one red isomer

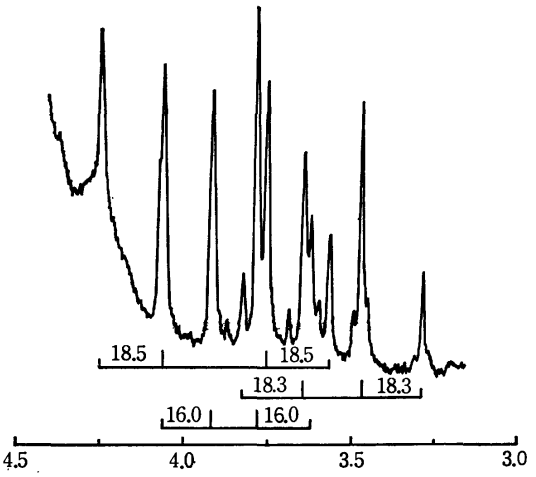

Fig. 3. PMR spectrum of violet (equatorial-skew) [Co(NH_3)(trdtra)] in D_2O (100 MHz). Numerical values in the figure indicate coupling constants in Hz for acetate protons.

on the reactions of any isomer of aqua complex with potassium cyanide. It exhibits a sharp and symmetrical first absorption band which is almost identical with that of the corresponding *N*-Me-trdtra complex (Fig. 2). Thus, the complex would have the same structure as that of the *N*-Me-trdtra complex, the polar-chair.

The absorption spectra of all the complexes obtained in the present study are compared in Fig. 2. As stated previously, the first absorption bands of the skew isomers are broader than those of the chair isomers. The equatorial-skew isomers of the aqua and the chloro complex give the first absorption band split into two components. When the kind of unidentate ligand is changed, the lower frequency components shift to a greater extent than do the higher frequency components, although all the bands shift in accordance with the spectrochemical series.

Metal Complexes of Amino Acids. IX.[1] Carbon-13 Nuclear Magnetic Resonances of Cobalt(III) Complexes

Tomoharu AMA and Takaji YASUI

Faculty of Arts and Sciences, Kochi University, Asakura, Kochi 780

(Received September 8, 1975)

The ^{13}C NMR spectra of cobalt(III) complexes containing various amino acids as unidentate or bidentate ligands were measured. The relation between the coordination types and the changes of the chemical shifts was clarified. The changes of chemical shift on coordination of α-amino acid to cobalt(III) (NH_3^+-R-COOH→ NH_3^+-R-COOCo) were about 7 and 1 ppm for the carboxy-carbon and α-carbon, respectively. On the other hand, those on chelation (NH_3^+-R-COOH→chelated amino acid) were about 15 and 5 ppm for each carbon, respectively. However, the changes of chemical shift on chelation of β-alanine were different from those of α-amino acids.

There have been numerous reports containing the application of ^{13}C NMR to organic compounds, and the technique has proven to be a very powerful tool for the structural investigation of organic compounds.[2,3] However, there have been few reports of application of the technique to transition metal complexes, except for organometallic compounds. As octahedrally coordinated Co(III) complexes (Werner type) are diamagnetic and there are no direct bonds between cobalt and carbon atoms in the complexes, many results in organic researches are applicable to these complexes with little modification.[4-10]

Previously we reported the ^{13}C NMR of the *trans(O)*-[Co en_2(aaH)$_2$]X_3 complexes containing various amino acids,[1,11] which were bound to cobalt(III) ion as unidentate ligands through their carboxylate groups, the $-NH_3^+$ groups being free. In the present paper, we wish to describe not only more detailed ^{13}C NMR study of the *trans(O)*-[Co en_2(aaH)$_2$]X_3 complexes, but also new ^{13}C NMR study of the [Co(NH_3)$_4$(aa)]X_2 complexes containing amino acids bound to cobalt(III) ions as bidentate ligands. The relation between the coordination types and the changes in the ^{13}C chemical shifts of amino acid-cobalt(III) complexes will be clarified from the results of ^{13}C NMR spectra.

Experimental

Preparation of Complexes. The *trans(O)*-[Co en_2(aaH)$_2$]-(ClO_4)$_3$ (aaH=glyH, L-alaH, L-valH, L-leuH, L-serH, L-thrH, L-proH, L-hyproH, β-alaH, and γ-ambH (γ-aminobutyric acid)) complexes were prepared by the procedure similar to those described in previous papers.[12,13]

trans(O)-[*Co en_2(ac)$_2$*]*Cl·0.5 NaCl·3.5 H_2O*: This complex was obtained by the modification of Linhard's method.[14] To an aqueous solution containing 5 g of [Co en_2(OH_2)$_2$]-(ClO_4)$_3$ in 10 ml of water, 5 ml of 1 M aqueous solution of NaOH and 10 ml of acetic acid (acH) were added. The mixture was evaporated almost to dryness on steam-bath. After cooling, the resultant was dissolved in 50 ml of water. The solution was poured into a SP-sephadex column (C-25, Na^+ form) and eluted with 5% aqueous solution of NaCl. The first eluted solution (reddish violet) was concentrated in vacuum evaporator till a large excess of NaCl was deposited out. The deposited NaCl was removed off by filtration. A dark red complex, *trans(O)*-[Co en_2(ac)$_2$]Cl, contaminated with some sodium chloride, was obtained by adding ethanol and ether to the filtrate. The crude product was recrystallized from water by adding ethanol and ether.

Found: C, 22.92; H, 6.83; N, 12.95%. Calcd for $C_8H_{29}N_4O_{7.5}Cl_{1.5}Na_{0.5}Co$: C, 22.61; H, 6.88; N, 13.19%.

trans(O)-[*Co en_2(pr)$_2$*]*Cl·0.5 H_2O*: This complex was prepared by a similar method to that for the acetato complex except for using propionic acid (prH).

Found: C, 32.64; H, 7.37; N, 15.26%. Calcd for $C_{10}H_{27}N_4O_{4.5}ClCo$: C, 32.48; H, 7.36; N, 15.15%.

trans(O)-[*Co en_2(bu)$_2$*]*ClO_4·0.5 H_2O*: The complex of butyric acid (buH) was prepared by a procedure similar to those described above. However, this complex was obtained directly from the reacted solution as crystals of perchlorate salt without using SP-sephadex column. The crude product was recrystallized from warm water.

Found: C, 31.34; H, 6.78; N, 11.75%. Calcd for $C_{12}H_{31}N_4O_{8.5}ClCo$: C, 31.20; H, 6.75; N, 12.13%.

[*Co(NH_3)$_4$gly*]*Cl_2·0.5 H_2O*: To an aqueous solution containing 6 g of [Co(NH_3)$_6$]Cl_3 and 1.5 g of glycine in 100 ml of water, about 2 g of activated carbon was added. The mixture was warmed at 60 °C for 30 min with stirring. After filtering off a large amount of insoluble materials, the filtrate was poured into a column containing SP-sephadex (C-25, Ca^{2+} form) and eluted with 3% aqueous solution of calcium chloride. The eluted solution from the orange band was evaporated to about 5 ml in vaccum evaporator. To the concentrated solution 200 ml of ethanol was added, and the desired complex deposited was filtered. The complex was recrystallized from water by adding ethanol.

Found: C, 8.38; H, 6.08; N, 24.54%. Calcd for $C_2H_{17}N_5O_{2.5}Cl_2Co$: C, 8.55; H, 6.10; N, 24.93%.

[*Co(NH_3)$_4$(aa)*]*SO_4 (aa=*L-*ala*, L-*val*, L-*leu*, L-*ser*, L-*thr*, L-*pro*, and L-hypro)*: These complexes were prepared by modification of the methods described in previous papers.[12,15]

[*Co(NH_3)$_4$(β-ala)*]*Cl_2·H_2O*: To an aqueous solution containing 5 g of [Co(NH_3)$_5$(β-alaH)](ClO_4)$_3$[13] in 50 ml of water, 2 g of activated carbon was added. The mixture was warmed at 60 °C for 5 min with stirring. After the solution was filtered, the filtrate was poured into SP-sephadex column. The adsorbed band was eluted with 3% calcium chloride solution, and the solution eluted from the orange band was concentrated by using a vacuum evaporator. The crude complex was deposited by adding ethanol to the concentrated solution. The complex was recrystallized from water by adding ethanol.

Found: C, 11.82; H, 6.59; N, 23.13%. Calcd for $C_3H_{20}N_5O_3Cl_2Co$: C, 11.85; H, 6.64; N, 23.03%.

Measurements. ^{13}C NMR spectra at 25.15 MHz were recorded on a JEOL MFT-100 spectrometer with JEC-6 spectrum computer, in pulsed Fourier transform/proton noise decoupled mode. The field frequency ratio was stabilized by locking to internal D_2O. Peak positions were measured relative to external benzene (capillary). Chemical shifts in

a) $\Delta_{-H}(C_\alpha)=\delta_{-H}(C_\alpha)-\delta(C_\alpha)$. b) $\Delta_{-H_2}(C_\alpha)=\delta_{-H_2}(C_\alpha)-\delta(C_\alpha)$. c), d) and e); see Table 1.

Figures and Tables are reported relative to TMS using the relation $\delta_{TMS}=\delta_{benzene}-128.5$ ppm.

Amino acids, of which concentrations in D_2O, 10% NaOD-D_2O and 10% DCl-D_2O were 2 mmol/ml, were used for NMR measurements. However, L-alaH, L-thrH and L-valH were sparingly soluble in D_2O, so that these amino acids were measured with saturated solutions in D_2O. Acetic and propionic acids which were dissolved in equivolumes of D_2O containing small amount of DCl, and butyric acid which was saturated in D_2O containing small amount of DCl were used. For the measurements of fatty acidate anions, the saturated solutions of their sodium salts in D_2O containing small amount of 10% NaOD were used.

The perchlorate or sulfate salts of the complexes were converted to the more soluble chlorides by treating with anion-exchange resin (Cl^- form). The saturated solutions of the *trans(O)*-$[Co\,en_2(aaH)_2]Cl_3$ complexes which have free $-NH_3^+$ groups were acidified with a small amount of 20% DCl to obtain the complete protonation of free amino groups. The other complexes were examined in saturated solutions. Experimental errors were within ± 0.1 ppm.

Results and Discussion

The ^{13}C chemical shifts of carboxy-carbons (C_0) and α-carbons (C_α) of amino acids and fatty acids are summerized in Tables 1 and 2. The symbols of

$\delta(C_0)$ and $\delta(C_\alpha)$ represent the chemical shifts of the carbons of C_0 and C_α of NH_3^+–R–COOH or R–COOH (in acidic solution), $\delta_{-H}(C_0)$ and $\delta_{-H}(C_\alpha)$ those of NH_3^+–R–COO^- or R–COO^-, and δ_{-H_2} (C_0) and δ_{-H_2} (C_α) those of NH_2–R–COO^-. The chemical shifts of C_0 and C_α of unidentate ligands in *trans(O)*-[Co en_2-$(acid)_2]^+$ and -[Co $en_2(aaH)_2]^{3+}$ complex ions are given by the symbols of $\delta_{Co}(C_0)$ and $\delta_{Co}(C_\alpha)$, respectively. The chemical shifts of C_0 and C_α of the chelated amino acidates in $[Co(NH_3)_4$(amino acidato)$]^{2+}$ complex ions are denoted in the symbols of $\delta_{ch}(C_0)$ and $\delta_{ch}(C_\alpha)$, respectively.

The $\delta(C_0)$ values for α-amino acids were found in the range of 171—174 ppm. However, those for β- and γ-amino acids and fatty acids were observed at a furthermore lower magnetic field region (175.9—180.4 ppm).

The resonances for C_α were observed over a fairly wide region, 18.9—60.0 ppm, for the fatty acids and amino acids having various α-substituted groups.[16,17]

trans*(O)*-[*Co* en_2*(OCO-R)*$_2$] *Type Complexes.* It is known that a large number of amino acids and fatty acids form inert complexes in which they coordinate to cobalt(III) with only carboxyl-groups. When the proton attaching to the carboxyl group was substituted with Co(III), down-field shift was observed in the resonance of carboxy-carbon ($\Delta_{Co}(C_0)$: $\delta_{Co}(C_0)$ minus $\delta(C_0)$). Similar down-field shifts were also observed when the corresponding carboxylate anions were formed. It is interesting that the chemical shifts of coordinated carboxy-carbon ($\delta_{Co}(C_0)$) are closer to those of the deprotonated carboxy-carbon ($\delta_{-H}(C_0)$) than to those of the protonated carboxy-carbon($\delta(C_0)$), (though the $\delta_{Co}(C_0)$ located at lower field region than the $\delta_{-H}(C_0)$) (Table 1).

The $\Delta_{Co}(C_0)$ values of α-amino acids were 7.0± 0.3 ppm. Those of the β- and γ-amino acids and fatty acids were rather diverse, showing 7.8—10.3 ppm. These $\Delta_{Co}(C_0)$ values increase with increasing $\delta_{-H}(C_0)$ values, and it appears that there are linear correlation between them (Fig. 1). For the practical purpose in predicting the $\Delta_{Co}(C_0)$ value, we propose the following relation (Eq. (1)).

$$\Delta_{Co}(C_0) = 0.268\,\delta_{-H}(C_0) - 40.00 \quad (1)$$

We could also obtain linear correlation between Δ_{Co}-(C_0) and $\delta(C_0)$ values in a similar manner as above, though the deviation of the data from the calculated straight line was larger than those in Fig. 1.

The resonances of the C_α in α-amino acids appear over the wide region, compared with those of the carboxy-carbons. This is caused by the different character of the groups attaching to the α-carbon in α-amino acid. In spite of the fairly large difference of the chemical shifts ($\delta(C_\alpha)$), the $\Delta_{Co}(C_\alpha)$ values ($\delta_{Co}(C_\alpha)$ minus $\delta(C_\alpha)$) were approximately constant in α-amino acids, showing 1.0±0.2 ppm.

Similarly to the C_0, the chemical shifts of the C_α in the unidentate coordination form ($\delta_{Co}(C_\alpha)$) are closer to those in the deprotonated form ($\delta_{-H}(C_\alpha)$) than to those in the protonated form ($\delta(C_\alpha)$) (Table 2). In the α-amino acids, the chemical shifts, $\delta_{Co}(C_\alpha)$, appear in a field higher than $\delta_{-H}(C_\alpha)$. This behavior

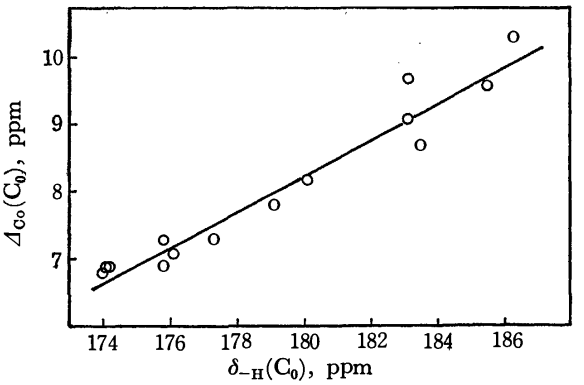

Fig. 1. Variation of $\Delta_{Co}(C_0)$ for the unidenate complexes with $\delta_{-H}(C_0)$ for the fatty acids and amino acids. The line is determined by Eq. (1).

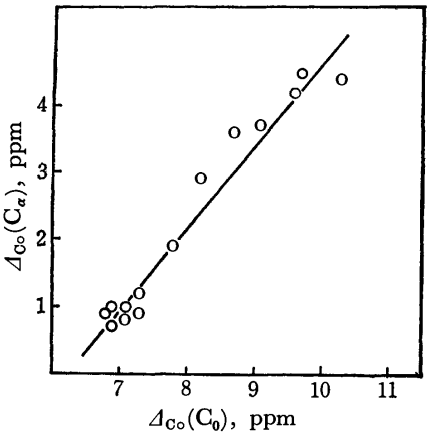

Fig. 2. Variation of $\Delta_{Co}(C_\alpha)$ with $\Delta_{Co}(C_0)$ for the unidentae complexes. The line is determined by Eq. (2).

is different from that of carboxy-carbon, that is, $\delta_{Co}(C_0)$ appears in a field lower than $\delta_{-H}(C_0)$. On the other hand, in β- and γ-amino acids and fatty acids, the $\delta_{Co}(C_\alpha)$ values were observed in a field lower than $\delta_{-H}(C_\alpha)$.

Figure 2 shows the relationship between the $\Delta_{Co}(C_0)$ and $\Delta_{Co}(C_\alpha)$ values. It is evident from the figure that the acid showing a large $\Delta_{Co}(C_0)$ value possesses a large $\Delta_{Co}(C_\alpha)$ value. It is probable that the change in chemical shift of α-carbon, which is neighboring to the carboxy-carbon, becomes larger as the change in chemical shift of carboxy carbon becomes larger. It appears that there are a simple linear correlation between the $\Delta_{Co}(C_0)$ and $\Delta_{Co}(C_\alpha)$ values (Eq. (2)).

$$\Delta_{Co}(C_\alpha) = 1.228\,\Delta_{Co}(C_0) - 7.67 \quad (2)$$

If the extrapolation of linear plot to the smaller value is correct, the following results will be obtained. In the case where the $\Delta_{Co}(C_0)$ value is equal to 0 ppm, that is, in the case where the chemical shift of the coordinated carboxy-carbon is equal to that of the protonated carboxy-carbon, the $\Delta_{Co}(C_\alpha)$ value will be about −8 ppm. Some portion of the −8 ppm may be caused by the direct interaction between the α-carbon and Co(III).

$[Co(NH_3)_4$*(amino acidato)*$]^{2+}$ *Type Complexes.* It is well known that the α-amino acid also forms an

inert complex chelated to Co(III) with both carboxyl and amino groups. The chemical shifts of the carboxy-carbon in the chelated α-amino acids were observed in a field lower than those of the carboxy-carbons in the protonated α-amino acids, that is, the $\Delta_{ch}(C_0)$ values ($\delta_{ch}(C_0)$ minus $\delta(C_0)$) are 15.0±1.0 ppm. The chemical shifts of the chelated carboxy-carbons of α-amino acids are closer to those of their carboxy-carbons in basic solution rather than in acidic and neutral solutions (Table 1).

Figure 3 shows the plots of $\Delta_{ch}(C_0)$ against $\delta(C_0)$ for some α-amino acids. It appears that the $\Delta_{ch}(C_0)$ values decrease with increasing $\delta(C_0)$ values. On the contrary, $\Delta_{Co}(C_0)$ values increase with increasing $\delta(C_0)$ values, as previously described.

Chemical shifts of C_α in chelated α-amino acids, $\delta_{ch}(C_\alpha)$, are closer to $\delta_{-H_2}(C_\alpha)$ than $\delta(C_\alpha)$, $\delta_{-H}(C_\alpha)$ and $\delta_{Co}(C_\alpha)$. The $\Delta_{ch}(C_\alpha)$ ($\delta_{ch}(C_\alpha)$ minus $\delta(C_\alpha)$) values are 4.8±1.0 ppm and independent from $\delta_{ch}(C_0)$, $\delta(C_\alpha)$ and $\delta_{ch}(C_\alpha)$ values. Difference of the interaction between substituting group on the C_α of α-amino acids and the other ligands in the complex, and difference among the natures of amino-nitrogen will be responsible for the variance of the $\Delta_{ch}(C_\alpha)$ values. The α-amino acids with pyrrolidine ring, *i.e.*, L-proline and hydroxy-L-proline, show larger $\Delta_{ch}(C_\alpha)$ values than the other α-amino acids (except for glycine). This may be caused by the large steric interactions between the pyrrolidine ring and the other ligands in the complex, and/or by the coordination of the secondary amino-nitrogen to cobalt(III). However, the $\Delta_{Co}(C_\alpha)$ values of L-proline and hydroxy-L-proline in the complexes in which the amino acids are coordinated to Co(III)

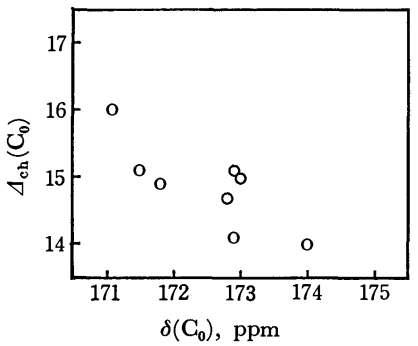

Fig. 3. Plots of $\Delta_{ch}(C_0)$ for the chelated α-amino acids *vs.* $\delta(C_0)$ for the α-amino acids.

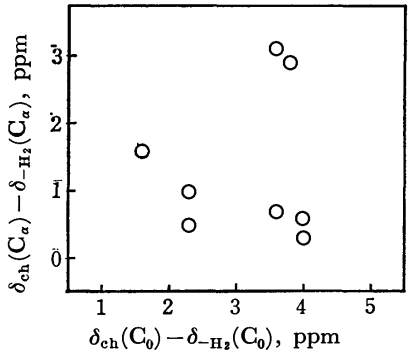

Fig. 4. Plots of $\delta_{ch}(C_0)-\delta_{-H_2}(C_0)$ *vs.* $\delta_{ch}(C_\alpha)-\delta_{-H_2}(C_\alpha)$ for the α-amino acids.

a) Preparation; Ref. 18.

with their carboxyl groups as unidentate ligands are nearly equal to those of the other amino acids in the corresponding complexes. This means that there are no steric interactions in these unidentate complexes.

Figure 4 illustrates plots of $\delta_{ch}(C_0)$ minus $\delta_{-H_2}(C_0)$ *versus* $\delta_{ch}(C_\alpha)$ minus $\delta_{-H_2}(C_\alpha)$. It is evident from the figure that L-proline and hydroxy-L-proline differ from the other α-amino acids. It appears that the values of $\delta_{ch}(C_\alpha)$ minus $\delta_{-H_2}(C_\alpha)$ decrease with increasing values of $\delta_{ch}(C_0)$ minus $\delta_{-H_2}(C_0)$, except for L-proline and hydroxy-L-proline.

Table 3 shows the chemical shifts of carboxy-carbons in chelated glycinato complexes. It is interesting that these values (187.3±1.3 ppm) were observed in a considerably narrow range, in spite of the difference of the net charge among the complex ions and the difference among the other ligands.

Chemical shift-changes of chelated β-alanine deviated largely from those of the α-amino acids. The $\delta_{ch}(C_0)$ of β-alanine was observed in higher magnetic field region than $\delta_{-H_2}(C_0)$ and $\delta_{Co}(C_0)$, while the $\delta_{ch}(C_0)$ of the α-amino acids were observed in a field lower than $\delta_{-H_2}(C_0)$ and $\delta_{Co}(C_0)$. Similar result was obtained for the $\delta_{ch}(C_\alpha)$. The factors affecting them could be as follows; size of the chelate ring of β-alanine being larger than that of the α-amino acid; carboxy-carbon and α-carbon of β-alanine being remote from the amino-group, compared with those of the α-amino acids; the absence of amino-group on α-carbon of β-alanine. Since there are insufficient data, it is not clear which factor is a most dominant one.

In summary, we obtained the following results for the Co(III) complexes. The $\Delta_{Co}(C_0)$ and $\Delta_{Co}(C_\alpha)$ values for α-amino acids were about 7 ppm and 1 ppm, respectively. On the other hand, those values for β- and γ-amino acids and fatty acids were 8—10 ppm and 2—4 ppm, respectively. The changes in chemical shifts of carboxy- and α-carbons caused by the chelation of α-amino acids, $\Delta_{ch}(C_0)$ and $\Delta_{ch}(C_\alpha)$, were 14—15 ppm and 4—6 ppm, respectively. The $\Delta_{ch}(C_0)$ and $\Delta_{ch}(C_\alpha)$ values of β-alanine were different from those of the α-amino acids and were 5.8 ppm and 2.2 ppm, respectively.

Selective Activation of Methylene or Methine Groups of Tripeptide-Schiff Bases Coordinated around Nickel(II)

Mamoru FUJIOKA, Yasuo NAKAO, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received October 16, 1975)

Nickel(II) chelates of the Schiff bases derived from salicylaldehyde and tripeptides such as glycylglycylglycine, glycyl-DL-α-alanylglycine, glycylglycyl-DL-α-alanine, and DL-α-alanylglycylglycine have newly been prepared. The reactivity of methylene or methine groups in the tripeptide moieties of those Schiff base chelates has been studied by PMR spectra in D_2O. It has been found that the methylene or methine protons of the N-terminal amino acid residues are most effectively activated by the coordination around nickel(II) as compared with those of the C-terminal and central amino acid residues.

It is well known that the coordination of amino acids or oligopeptides to metal ions results in activations of their methylene or methine protons of the α-positions.[1,2] In a previous paper,[3] we reported that deuteration of the methylene or methine groups in tripeptides coordinated around nickel(II) occurred most easily for those of the C-terminal as compared with those of the N-terminal and central amino acid residues.

The present paper deals with the preparation of nickel(II) chelates of the Schiff bases derived from salicylaldehyde and tripeptides containing glycine and/or DL-α-alanine, and the results of PMR study of those chelates in view of the selective activation of methylene or methine protons in coordinated tripeptide moieties. The general discussions on the relative reactivity of the methylene or methine protons of oligopeptides and amino acids in coordination are also described on the basis of our recent findings as well as the present investigation.

Experimental

Glycylglycylglycine was purchased from the Protein Research Foundation. Tripeptides[3] containing DL-α-alanine residue and bis(salicylaldehydato)nickel(II)[4] were prepared according to the directions described previously.

Preparation of Nickel(II) Chelates of the Schiff Bases Derived from Salicylaldehyde and Tripeptides. To a mixture of 0.004 mol of each tripeptide and 20 ml of water was added 0.004 mol of bis(salicylaldehydato)nickel(II). The reaction mixture was adjusted to pH 8—10 with concentrated potassium hydroxide solution. After it had been stirred at 30—40 °C for about half an hour, the reaction mixture was filtered. The *N*-salicylidene-glycylglycylglycinato- and -DL-α-alanylglycylglycinato-nickelate(II) were deposited respectively as orange crystals from the filtrate upon the addition of a large quantity of ethanol with vigorous stirring, and were recrystallized from water–ethanol. The *N*-salicylidene-glycyl-DL-α-alanylglycinato- and -glycylglycyl-DL-α-alaninato-nickelate(II) were isolated as orange crystalline products by adding a mixture of ethanol and ether(1 : 1 by volume) with constant stirring. The products were dissolved in a small quantity of water, and then recrystallized by dropwise addition of a mixture of ethanol and ether(1 : 1 by volume). For elemental analysis the products were dried at 70 °C over P_4O_{10}. The results of elemental analysis are shown in Table 1.

Measurements. The visible and ultraviolet absorption spectra were obtained with a Union Giken SM-401 high-sensitivity recording spectrophotometer. The PMR spectra were recorded with a JEOL MH-100 spectrometer and Varian EM-360 60 MHz NMR spectrometer and deuterium oxide was used as a solvent. The chemical shift was measured relative to the sodium salt of trimethylsilylpropane sulfonic acid taken as an internal standard. The pD-adjustment was carried out by the addition of concentrated NaOD–heavy water solution. A Hitachi-Horiba M-5 pH meter equipped with a No. 6026 combined electrode was used after standardization with a Nakarai standard buffer solution (pH 6.86 and 9.18 at 25 °C).

Results and Discussion

We have newly prepared four nickel(II) complexes of the Schiff bases obtained from salicylaldehyde and glycylglycylglycine, glycyl-DL-α-alanylglycine, glycylglycyl-DL-α-alanine, and DL-α-alanylglycylglycine. The complexes were prepared by reactions of each tripeptides with bis(salicylaldehydato)nickel(II) in the pH range 8—10. The visible and ultraviolet absorption spectrum for potassium *N*-salicylideneglycylglycylglycinatonickelate(II) in aqueous solution is shown in Fig. 1. Similar absorption spectra were found also for the nickel(II) complexes of *N*-salicylidene-glycyl-DL-α-alanylglycine, -glycylglycyl-DL-α-alanine, and -DL-α-alanylglycylglycine. Their absorption curves resemble those observed for the nickel(II) complexes which are considered to have the square planar structure.[4,5] On the basis of this finding as well as the results of the elemental analyses (Table 1), it is inferred that the

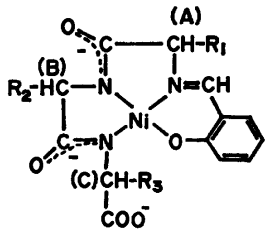
structural formulas of nickel(II) complexes produced from salicylaldehyde and each tripeptide can be represented as **1**, in which the symbols (A), (B) and (C)



1

indicate methylene or methine protons in the N-terminal, central and C-terminal amino acid residue, respectively.

The PMR spectra at 1—4 ppm of those nickel(II) chelates in deuterium oxide under various conditions are illustrated in Figs. 2—5. The peak identification of the methylene or methine protons for the four chelates, [Ni(Sal=Gly·Gly·Gly)]$^{2-}$, [Ni(Sal=DL-α-Ala·Gly·Gly)]$^{2-}$, [Ni(Sal=Gly·Gly·DL-α-Ala)]$^{2-}$ and [Ni(Sal=Gly·DL-α-Ala·Gly)]$^{2-}$, were carried out on the basis of a comparative inspection of Figs. 2-, 3-, 4- and 5-(a), which were recorded within an hour after preparing each solution. The results of peak assignment necessary for the discussion are inserted in each figure. It is interesting to note that the assignment

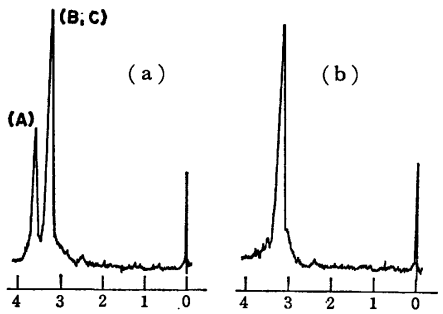


Fig. 2. PMR spectra of [Ni(Sal=Gly·Gly·Gly)]$^{2-}$: (a) pD 11.0, room temp., after 1 h; (b) pD 13.5, 40 °C, after 7 days.

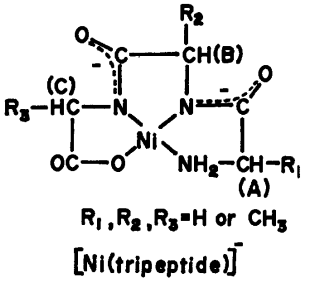

2

for the (A)- and (C)-methylene peaks of the coordinated tripeptide-Schiff bases **1** is the inverse of that for the same peaks of the coordinated simple tripeptides **2**.[3]

It is clearly shown from a comparison of Figs. 2(a) and (b) that the peak at 3.50 ppm arising from the N-terminal methylene protons of triglycine moiety for nickel(II) chelate **1**($R_1=R_2=R_3=H$) almost disappears on allowing the solution to stand at 40 °C, pD 13.5 for 7 days. On the other hand, the peak (3.12 ppm) for the central and C-terminal methylene protons were unchanged under the same condition, though the decrease of the peak(3.12 ppm) was observed in a more severe condition (40 °C, pD 13.5, after 22 days).

In case of [Ni(Sal=DL-α-Ala·Gly·Gly)]$^{2-}$, the doublet methyl signals (1.22 and 1.30 ppm) collapsed on allowing the solution to stand at 40 °C, pD 13.7 for a day, producing a singlet on account of the deuteration of the methine proton of (A), whereas the signals due to the methylene protons of (B) and (C) were almost unchanged (Fig. 3(b)).

Fig. 4(b) illustrates the PMR spectrum of [Ni(Sal=Gly·Gly·DL-α-Ala)]$^{2-}$ recorded after standing the solution at 40 °C and at pD 13.3 for a day, which indi-

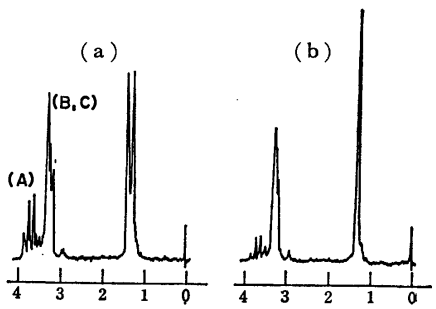

Fig. 3. PMR spectra of [Ni(Sal=DL-α-Ala·Gly·Gly)]$^{2-}$: (a) pD 11.2, room temp., after 1 hr; (b) pD 13.7, 40 °C, after 1 day.

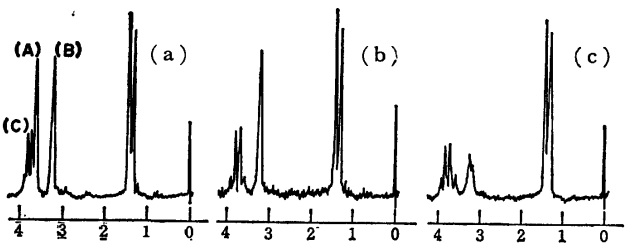

Fig. 4. PMR spectra of [Ni(Sal=Gly·Gly·DL-α-Ala)]$^{2-}$: (a) pD 11.5, room temp., after 1 h; (b) pD 13.3, 40 °C, after 1 day; (c) pD 13.1, 40 °C, after 12 days.

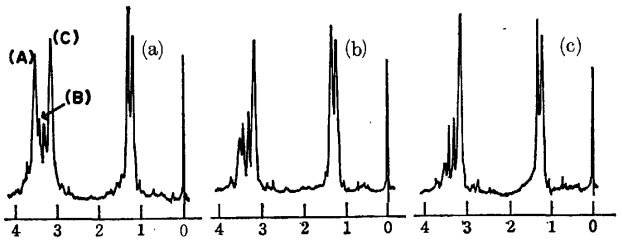

Fig. 5. PMR spectra of [Ni(Sal=Gly·DL-α-Ala·Gly)]$^{2-}$: (a) pD 11.3, room temp., after 1 h; (b) pD 12.5, 40 °C, after 1 day; (c) pD 10.7, 40 °C, after 31 days.

cates that the deuteration is going on (A) methylene groups, whereas the (B) methylene protons do not show any tendency of activation under the condition. However, at 40 °C and at pD 13.1 after 12 days the signal (3.20 ppm) for the (B) methylene group almost disappeared. Even under this condition the methyl doublet at 1.37 ppm remains unchanged, as is seen from a comparison of Fig. 4(a)—(c). The fact suggests that the exchange reaction does not occur at (C) methine group in the *N*-salicylideneglycylglycyl-DL-α-alaninatonickelate(II).

Figure 5(a) shows the PMR spectrum of [Ni(Sal=Gly·DL-α-Ala·Gly)]$^{2-}$, which was recorded within an hour after the preparation of the solution. In this spectrum the signals for the methylene or methine protons of (A), (B) and (C) are not well-separated. The resonance signals at 3.55 ppm and 3.17 ppm are supposed to arise from the methylene protons of (A) and (C), respectively. The signals at 3.33 ppm and 3.43 ppm are attributed to the (B) methine proton, and the remaining two peaks for the (B) methine proton are possibly considered as overlapping with peaks for the (A) and (C) methylene protons. After a day at 40 °C (pD 12.5), the signal at 3.55 ppm due to the (A) methylene proton decreased, but not that at 3.17 ppm (Fig. 5(b)). The methyl doublet at 1.23 ppm and 1.33 ppm remained unchanged under the same condition. Further deuteration of the (A) methylene proton could also be observed, on allowing the solution to stand at 40 °C and pD 10.7 for 31 days. Here the doublet methyl signals exhibited an indication of collapsing to give a singlet, indicating that deuteration began to occur at the (B) methine proton.

The foregoing description on the results of PMR study of nickel(II) chelates of Schiff bases derived from salicylaldehyde and tripeptides can be summarized as follows: (i) the N-terminal methylene or methine protons are more easily activated than the others; (ii) the C-terminal methylene or methine protons cannot be activated in the range of our experimental condition. The former, (i), can be explained by taking into consideration the electron-withdrawing effect of nickel(II) through the azomethine nitrogen atom. And the latter, (ii), may be interpreted as resulting from the absence of the electron-withdrawing effect of nickel(II) through the terminal carboxylate group.

Of interest is the fact that the preferential activation of the methylene or methine protons of tripeptides occurs in the different position (N-, C-terminal or central amino acid residue, respectively) depending upon the modes of tripeptides (chelate **1**, **2** or uncoordinated triglycinate **3**,[6] respectively).

$$\underset{(A)}{NH_2CH_2}CONH\underset{(B)}{CH_2}CONH\underset{(C)}{CH_2}COO^-$$

3

The results of our series of investigations on the selective activation of dipeptides[2,8] and tripeptides[9] in different structures can be summarized as follows: (i) in order to activate the C-methylene or -methine protons of oligopeptides, the coordination of the terminal carboxylate groups of peptides to metal ions is necessary; (ii) in order to activate the N-methylene or -methine groups, the terminal nitrogens of peptides have to be coordinated to metal ions in the form of Schiff bases.

The validity for the foregoing conclusion is also demonstrated by the fact that all the methylene protons in the tetraglycine-nickel(II) chelate **4** shows no tendency of activation after 4 days at 40 °C (pD 13.0).[10]

An INDO Molecular Orbital Approach to the Proton Affinity of Oxygenated Compounds

Katsutoshi OHKUBO, Kohji TSUCHIHASHI, Toshiaki YOSHIDA, and Masahide OKADA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received June 19, 1975)

The correlation between the gas-phase proton affinities of aliphatic oxygenated compounds (alcohols, acids, and esters and their electronic structures was investigated by means of an INDO-MO theory. There appears to be a satisfactory linear-dependence of the proton affinities with the energy difference between the parent molecule and the energetically most stable protonated species and with the bond energy of the oxygen-proton bond, although the above energies are overestimated in comparison with the proton affinities. The proton affinities are also predicted with a sufficient accuracy using the first ionization potential and the electron density of the oxygen atom (especially, the % p-character in the oxygen lone-pairs) of the parent molecule.

Mass spectroscopic investigations of ion-molecule reactions have recently centered around the determination of the relative proton affinities (Brønsted base strengths) of nitrogenated[1–5] and oxygenated[6–12] compounds, with a particular view to the dependence of the proton affinities on their molecular structures, especially on their substituents and functional groups.[2,5,12] From the trends observed experimentally for a correlation between the proton affinity and the molecular structure, it has already been noted that the proton affinities for similar molecules depend directly on the ionization potentials of the parent molecules.[13]

There have also appeared the extended Hückel[14] and *ab initio*[15–17] MO-theoretical treatments of the proton affinities of small molecules; the former MO-calculations gave energies which are of the correct order of magnitude but are too small, while the latter MO-calculations indicated appreciable percentage errors of estimated proton affinities with respect to the experimental values. Very recently, a potential model based on the Hellmann-Feynman theorem[18] combined with CNDO/2 wave functions has been proposed by Davis and Rabalais[19] for relating the proton affinities to inner-shell electron binding energies.

Recently, the authors began a semi-empirical INDO-MO study on the gas-phase proton affinities of several oxygenated compounds (aliphatic alcohols, acids, and esters) to investigates how the proton affinities depend on the electronic properties of the molecule. In this paper, the calculated results are reported with particular reference to the correlations between the proton affinities and various calculated energies such as theoretical proton affinities, bond energies for the oxygen-proton bond, ionization potentials, *etc.*

Method of Calculation

The gas-phase proton affinities (*PA*) of the following five series of aliphatic oxygenated compounds were investigated in this work: (a) formates, HCO_2R (R= H, CH_3, CH_3CH_2, and $CH_3CH_2CH_2$), (b) methyl esters, RCO_2CH_3 (R=H, CH_3, and CH_3CH_2), (c) acetates, CH_3CO_2R (R=H, CH_3, CH_3CH_2, and $CH_3CH_2CH_2$), (d) acids, RCO_2H (R=H, CF_3, CH_3, and CH_3CH_2), and (e) alcohols, ROH (R=H, CH_3, CH_3CH_2, and $CH_3CH_2CH_2$) (see Table 1). All calculations for the above compounds and their protonated species were performed using the INDO-MO method[20] which is relatively reliable for bond angles, although less so for bond lengths.[21] The approximations involved in the INDO are not repeated here, because they have been described in detail in Ref. 20.

The energy, ΔE, for the calculated proton affinity was obtained from the energy difference between the protonated species (BOH^+) and the parent molecule (BO):

$$BO + H^+ \longrightarrow BOH^+ \quad (1)$$

Since the energy of the proton is zero, the ΔE value can be given by:

$$\Delta E = E(BO) - E(BOH^+) \quad (2)$$

where the ΔE value is positive because $E(BOH^+)$ is normally a larger negative number than $E(BO)$.

The bond index of E_{OH^+} for the oxygen-proton bond of the protonated species was evaluated by means of a method of energy partitioning:[22]

$$E_{OH^+} = E^R_{OH^+} + E^V_{OH^+} + E^J_{OH^+} + E^K_{OH^+} + E^N_{OH^+} \quad (3)$$

where each energy term represents, respectively, the resonance, potential, electronic repulsion, electronic exchange interaction, and nuclear repulsion energies, which can be obtained by the usual manner described in detail in Ref. 22.

Results and Discussion

Geometries of Parent Molecule and Protonated Species. First, the geometries used for the parent molecules are discussed by comparing calculated dipole moments (μ_{calcd}) and first ionization potentials (I_{calcd})[23] with measured experimentally (μ_{obsd} and I_{obsd}). The dipole moments and ionization potentials are summarized in Table 2. Although exact agreements were not found between calculated and experimental dipole moments and ionization potentials, the approximate agreement between the calculated and observed dipole moments suggests that the charge distributions in the parent molecules appear to be plausible, while an almost constant ratio of I_{obsd}/I_{calcd} (around 0.8) indicates a systematic deviation of the calculated results from the experimental results. The deviations found for the dipole moments and ionization potentials may not be due to an inadequacy of the geometries but to the approximations involved in the INDO method, because it is well known that the INDO calculation trends to give an incomplete evaluation of the dipole

a) All values except those in parentheses were commonly used for the parent and protonated compounds, but the values in the parentheses were given only for the protonated species.

moments and an overestimation of the ionization potentials.

With regard to the geometries of the protonated compounds, it is noteworthy that the C=O bond length of the parent molecule is lengthened by the protonation so that it is nearly equal to the single C–O bond length,[16,17,24)] while the O–C–O bond angle is not so different for the parent molecule and the protonated species. For protonated formic acid, R_{CO}=1.31 Å ($R_{OH}=R_{OH^+}$=0.979 Å) and ∠OCO=124 ° have been given by Ros,[24)] and R_{CO}=1.279 Å ($R_{OH}=R_{OH^+}$= 0.96 Å) have been assumed by Csizmadia *et al.*[16)] The INDO optimization of the geometry for the above compound gave R_{CO}=1.30 Å and ∠OCO=118 °, together with ∠COH=∠COH$^+$=120 °, R_{CH}=1.12 Å, and $R_{OH}=R_{OH^+}$=1.04 Å. For simplicity of computation in the present work, the bond lengths and angles for the protonated compounds were taken to be the same as those (supplied by a standard compendium[25)]) for the parent molecules, as shown in Table 1. Regarding the values of R_{CO}, R_{OH^+}, and ∠COH$^+$, for the protonated species, they were taken to be as follows on the basis of the R_{CO}, R_{OH}, and ∠COH (or ∠COR) values of the parent molecules: R_{CO} of C–OH$^+$=R_{CO} of C–OH or C–OR, $R_{OH^+}=R_{OH}$, and ∠COH$^+$= ∠COH or ∠COR. If we assume the geometries listed in Table 1 to be equilibrium geometries, the force constants (K_{AB})[26)] for the protonated compounds are evaluated to be K_{CO}=4.04–6.65 mdyn/Å and K_{OH}=7.62 mdyn/Å; the former value is somewhat small in comparison with K_{CO}=8.11 mdyn/Å given by Ros[24)] for protonated formaldehyde. Furthermore, the INDO calculations gave the following relative stabilities of the protonated conformers in the case of R=H, although the difference in the total energies of the isomers is very small: I(−43.834 a.u.)>II (−43.830 a.u.)>III(−43.827 a.u.) in the protonated formates; IV(−52.238 a.u.)>V(−52.225 a.u.) in the protonated acetates; VI(−52.285 a.u.)>VII(−52.284 a.u.)>VIII(−52.283 a.u.)>IX(−52.278 a.u.) in the protonated methyl esters. The INDO calculation tends to underestimate the electron-electron repulsions,[20,27)] so that the *trans-trans* isomer, VII, was calculated to be more stable than the *cis-cis* isomers such as IX. As a matter of fact, alkoxy-protonated isomers such as X and XI are less stable than such keto-protonated isomers as I, II, and III. For example,

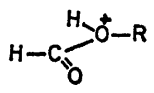
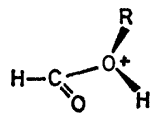
in the case of R=H (the bond lengths and angles of X and XI were taken to be the same to those of I, II, or III), the planar species, X, is less stable than I by 8.79 kcal/mol, and the nonplanar species, XI, is



planar

X



nonplanar

(H-OH plane perpendicular to O-C=O plane)

XI

12.55 kcal/mol higher than I. Although the relative stabilities of the protonated isomers on the basis of the INDO calculation results produce some discrepancies in connection with those determined by NMR observations,[28] the energetically most stable *cis-trans* conformers, I, IV, and VI which were predominantly detected by NMR spectroscopy[28] will be used in the discussions developed below.

Ionization Potential vs. *Proton Affinity.* The calculated first ionization potentials (I_{calcd}) for the protonated compounds in Table 1 were evaluated to be higher by 0.25—0.43 a.u. than those for their parent molecules. This trend can be well explained by the decrease in the electron densities of the oxygen lone-pair orbitals due to the protonation, which causes a lowering of the HOMO (the highest-occupied MO) localized by the so-called lone-pairs. If the nonbonding lone-pair orbitals play a predominant role in the protonation, the I_{calcd} values for the parent molecules may directly correlated with the proton affinities (*PA*). This consideration is related to the fact that the proton affinity corresponds to the Brønsted base strength which is inversely proportional to the ionization potential. As shown in Fig. 1, the *PA* values are satisfactorily linearly dependent on the reciprocal values of I_{calcd} ($1/I_{calcd}$) throughout the series investigated:

$$PA = a_1/I_{calcd} + b_1 \quad (4)$$

where a_1 and b_1 are constants specified by a least squares error analysis, and are listed in Fig. 1.

Equation (4) is particularly useful, because it predicts the proton affinities within a relative error of 2% of the experimental values.

We should here mention the limit of the linear cor-

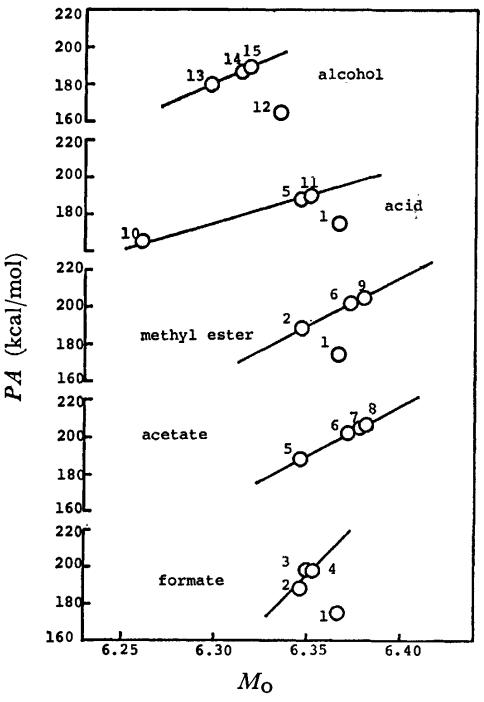

Fig. 2. Plots of PA *vs.* M_O.

relation between the PA and I_{calcd} values. The approach to a constant PA or I_{calcd} value with increasing chain length of R was observed for all the series investigated, especially for the formates, acetates, and alcohols. This may coincide with the fact that oxygenated compounds with a chain length greater than C_3 have a limited proton affinity.[12]

Electron Density of the Oxygen Atom vs. *Proton Affinity.* The electron density of the oxygen atom of BO in reaction(1), M_O, should be a measure of the proton affinity, because the electron density of such hetero-atoms as nitrogen and oxygen relates directly to the base strength.[29] As expected, the M_O values for the parent molecules are in satisfactory agreement with their PA values with some exceptions (H_2O and HCO_2H). A similar correlation with almost the same degree of accuracy as that in Eq. (4) can be seen from Fig. 2.

In connection with the linear correlation between the M_O and PA values, the electron densities of the oxygen p-orbitals (denoted as N_p; $N_p=N_{p_x}+N_{p_y}+N_{p_z}$) may correlate more directly with the proton affinities. In this respect, the linear correlations between the PA and N_p values throughout the series are found to be more satisfactorily established than those between the PA and M_O values, as may be seen from Table 3.

It is of interest here to notice the contributions of the electron densities of the oxygen s and p lone-pairs in the parent molecule to the proton affinity: the nonbonding lone-pair p-orbital expands perpendicularly to the C–O bond axis in the direction of the plane on which almost all the atoms (except the H atoms of the substituent R) are located. Although the electron densities of the lone-pair s-orbital ($N(s)_{lp}$)

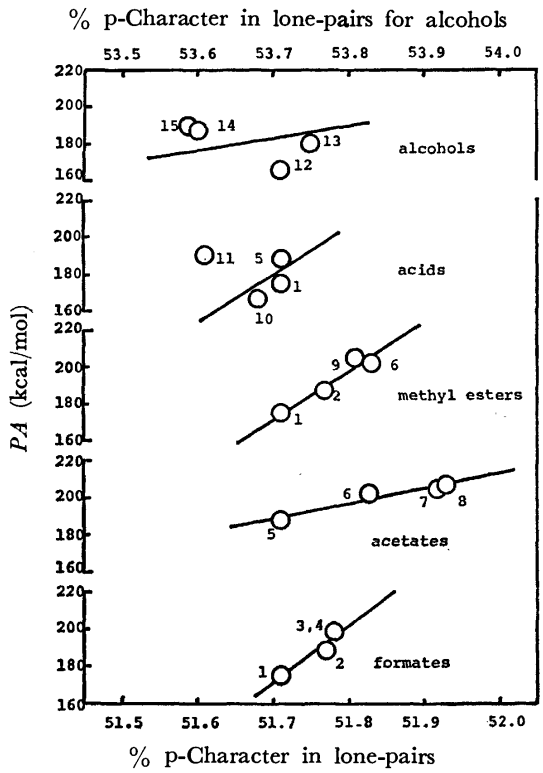

Fig. 3. Plots of % p-character in lone-pairs of parent molecule *vs.* proton affinity.

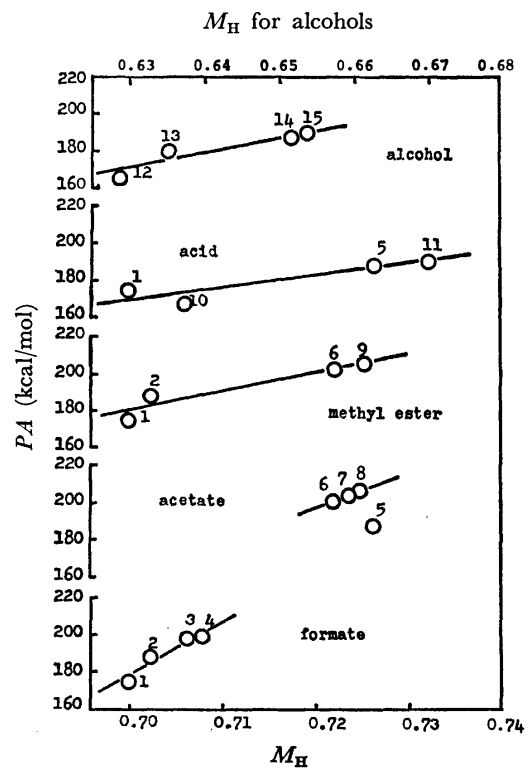

Fig. 4. Plots of *PA vs.* M_H.

and of the lone-pair p-orbital ($N(p)_{lp}$) are not linearly well related to the *PA* values (see Table 3), the % p-character in the lone-pairs, which is defined by $10^2N(p)_{lp}/(N(s)_{lp}+N(p)_{lp})$, correlates directly with the proton affinity, as shown by Fig. 3. Unfortunately, the % p-character of the lone-pairs of the alcohols, which are not completely accurate because of an unsufficient estimation of the $N(p)_{lp}$ values, showed marked deviations from the straight line. This linear relationship between the % p-character of the lone-pairs and the *PA* value coincides with the fact that nitrogen and oxygen bases with a high s-character of their lone-pairs have small *PA* values.[30]

Bearing in mind that the *PA* values correlate well with the I_{calcd} values, the electron density of the oxygen atom or of the nonbonding lone-pair p-orbital at the HOMO (denoted respectively as M_0^{HO} and $N(p)_{lp}^{HO}$) may correlate directly with the *PA* values. However, as may be seen from Table 3, the *PA* values depend inversely on the M_0^{HO} values which correspond roughly to the $N(p)_{lp}^{HO}$ values. This suggests that the proton affinity cannot be explained simply by the electron density at the HOMO of the parent molecule, that is, electrons at lower MOs (next to the HOMO, *etc.*) may participate in the protonation reaction.

We will now examine the possibility of a correlation between the proton affinities and the electron densities about the proton of the protonated compounds, M_H. As can be seen from Fig. 4, there exists a sufficiently linear correlation between them throughout the series. This is well explained by the following reasons: (a) the proton affinity correlates with the proton 1s chemical shift,[19] and (b) the proton chemical shift has also a correlation with the M_H values, as has been found in the NMR results for halomethanes.[31]

Calculated Proton Affinity. As shown in Table 3, the calculated proton affinities, ΔE, obtained from Eq. (2) are larger than the experimental proton affinities and increase with an increase in the chain length of the alkyl substituent (R). The *PA* values of all the oxygenated compounds investigated are roughly linearly correlated with the ΔE values:

$$PA = 0.388\Delta E + 75.65 \text{ kcal/mol} \quad (5)$$

However, Eq. (5) is incomplete, because a least-squares error analysis of the relation expressed by Eq. (5) has a maximum relative error of 8.2%. As shown in Fig. 5, completely linear lines can be obtained from the plots of *PA vs.* ΔE for each series and can be expressed by the following equation with a maximum error of 3%:

$$PA = a_2\Delta E + b_2 \text{ kcal/mol} \quad (6)$$

where a_2 and b_2 are constants specified in Fig. 5. The slopes of the straight lines are almost unity for the formates, methyl esters, and alcohols but are smaller than unity for the acids and acetates. In the latter two compounds, an overestimation can be seen for the effect of the substituents (R) on the calculated proton affinities, that is, a change in the ΔE values with an increase in the carbon number of the substituents is more significant than that in the corresponding *PA* values, while, in the other series, the difference between the ΔE values corresponds almost exactly to that between the *PA* values (see Table 3). Therefore, in the acids and acetates, the settled geometries, especially for those of the substituents, appear incomplete in the approximate INDO-MO method.

Bond Index of E_{OH^+} vs. Proton Affinity. Now, we examine the total bond energy (E_{OH^+}) and the resonance

a) Defined by % O(p)-H$^+$(s) overlap population = oxygen-p and hydrogen-s overlap populations in the O–H$^+$ bond $\times 10^2$/total overlap population in the O–H$^+$ bond.

energy ($E^R_{OH^+}$), which indicates the covalent bond strength, for the O–H$^+$ bond of the protonated species, in connection with the relation to the proton affinity. It can be seen from Table 4 that the absolute values of E_{OH^+}, which correspond to the bond strength of O–H$^+$, are about twice as large as the proton affinities. This may be mainly attributed to the approximations in the INDO-MO method. It is also noteworthy that index of E_{AB} indicates a static property of the A–B bond and cannot be directly compared with experimental energies such as the dissociation energy.[22] However, good correlations are observed in each series with some exceptions (H_3O^+ and $HCO_2H_2^+$) if both the kinds of energies, *PA* and E_{OH^+}, are plotted against each other. In this respect, it is also noticeable that the % O(p)-H$^+$(s) overlap population defined in Table 4 correlates well with the *PA* values with some exceptions (H_3O^+ and $HCO_2H_2^+$). This coincides with the fact that the % p-character in the oxygen lone-pairs of the parent molecule plays a predominant role in the proton affinity.

In regard to the $E^R_{OH^+}$ values, the slopes of the straight lines obtained from the plots of *PA vs.* $E^R_{OH^+}$ were not constantly positive throughout the series. This may be due to the fact that the resonance energy $E^R_{OH^+}$ is not meaningful for such an ionic oxygen-proton bond in the protonated species. In this respect, the contributions of the electronic exchange term ($E^K_{OH^+}$) and the repulsive electrostatic interactions ($E^V_{OH^+}+E^J_{OH^+}+E^N_{OH^+}$) to the proton affinity are here noted. As may be seen from Table 4, the negative $E^K_{OH^+}$ values become more negative with an increase in the *PA* values, while the positive values of the repulsive terms ($E^V_{OH^+}+E^J_{OH^+}+E^N_{OH^+}$) decrease with an increase in the *PA* values. These observations are in harmony with the fact that the more negative the $E^K_{OH^+}$ value becomes (or the smaller the above sum of the repulsion terms becomes), the stronger becomes the O–H$^+$ bond. There exists on approximate relation between them with some exceptions (H_3O^+ and $HCO_2H_2^+$). Then, we can say that the above exchange and repulsion terms can also be useful as a measure of the *PA* value.

In conclusion, it is worthy of emphasis that the experimental gas-phase proton affinities for the oxygenated compounds investigated cannot be compared directly with the calculated proton affinities or the bond energies obtained by the INDO calculations, but are in satisfactory agreement with them. The proton affinities can also be predicted with a sufficient accuracy from the first ionization potentials and the electron densities of the oxygen atoms of the parent molecules.

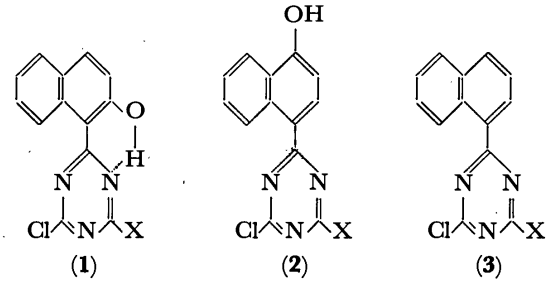
(Received July 8, 1975)

The nucleophilic substitution reactions of 2-methoxy- and 2-diethylamino-4-chloro-6-(2-hydroxy-1-naphthyl)-1,3,5-triazines (**1**) with aniline, diethylamine, sodium azide, and sodium methoxide were carried out and compared with the reactions of the corresponding derivatives of 4-chloro-6-(4-hydroxy-1-naphthyl)-1,3,5-triazine (**2**) and 4-chloro-6-(1-naphthyl)-1,3,5-triazine (**3**). Compound **1** was found to be more reactive than the corresponding (**2**) and (**3**), not only in the reactions of a neutral molecule, but also in those of anionic species. The results of the reactions of neutral species are interpreted in terms of the difference in solvation toward the substrates; however, the loss of coplanarity between the naphthalene and triazine nuclei may be responsible for the high reactivity of Compound **1** in the reactions of anionic species.

It is well known that, in nitrogen heteroaromatic compounds possessing an *O*-hydroxyaryl group in the 2-position, an intramolecular hydrogen-bond formation between the ring nitrogen and the hydroxyl group takes place.[1] In these cases, the reactivity of the heteroaromatic compound is expected to be affected more or less by the chelate formation. If the compound has an active halogen atom in the heteroaromatic nucleus, its reactivity towards nucleophiles will be different from that of the corresponding non-chelated compound. However, no such effect of chelation upon the reactivity has yet been revealed. This paper will report on the nucleophilic substitution reactions of 2-substituted 4-chloro-6-(2-hydroxy-1-naththyl)-1,3,5-triazines with some nucleophiles as examples; the experiments were undertaken in order to reveal the effect of chelate formation on the reactivity of nitrogen heteroaromatic compounds.

Results and Discussion

Preparation of Triazine Derivatives. The nucleophilic substitution reactions of 2-methoxy- and 2-diethylamino-4-chloro-6-(2-hydroxy-1-naphthyl)-1,3,5-triazines (**1**) were carried out and compared with the reactions of the corresponding derivatives of 4-chloro-6-(4-hydroxy-1-naphthyl)-1,3,5-triazine (**2**) and 4-chloro-6-(1-naphthyl)-1,3,5-triazine (**3**).



(**1**) (**2**) (**3**)

X: $-OCH_3$, $-NEt_2$

Compounds **1** and **2**, containing the methoxy group in the triazine nucleus, were prepared by the Friedel-Crafts reaction of 2,4-dichloro-6-methoxy-1,3,5-triazine with 1- and 2-naphthol in the presence of aluminium chloride, while compounds containing the diethylamino group were obtained by the condensation of cyanuric chloride with 1- and 2-naphthol in the presence of aluminium chloride,[2] followed by treatment with diethylamine. (1-Naphthyl)-1,3,5-triazine derivatives (**3**) were obtained by the reaction of cyanuric chloride with 1-naphthylmagnesium bromide, followed by treatment with methanol in combination with sodium carbonate. Table 1 lists the compounds thus obtained.

In order to estimate the structural effects upon the reactivity, kinetic measurements of the reactions of Compounds **1**, **2**, and **3** with some nucleophilic reagents were carried out. Diethylamine and aniline were used as the neutral nucleophilic reagents, while sodium azide and sodium methoxide were used as the anionic ones.

It is well known that the ordinary reactions of chloro-1,3,5-triazines with such nucleophilic reagents as amines[3] and alkoxides[4] take place very readily. The reactions in this paper were also found to take place without any appreciable side reactions by checking the reaction mixtures by tlc after the reactions had been completed; in every case, the substitution product was obtained in an almost quantitative yield, showing that these reactions are well suited to kinetic measurements. Table 2 lists the substitution products thus obtained.

Kinetics of the Reactions of 2-Substituted 4-Chloro-6-(2-hydroxy-1-naphthyl)-1,3,5-triazines with Diethylamine, Aniline, and Sodium Azide. In this study, only the derivatives of α-naphthyl-1,3,5-triazine were investigated, because the effect of the α-naphthyl group upon the reactivity of the chlorine atom is assumed to differ appreciably from that of the β-naphthyl group.[5] However, some structural differences which would affect the reactivities of these compounds can be seen between Compounds **1** and **2**. For example, there is a difference in the position of the naphthalene nucleus where the hydroxyl group is attached, and a chelate ring is formed in Compound **1**, but not in the case of Compound **2**.

In 6-substituted 2-aryl-4-chloro-1,3,5-triazines, it is generally considered that the strong electron-donating hydroxyl group in the aryl group lowers the reactivity of the active chlorine atom, not only in the *para* but also in the *ortho* position, by increasing the electron density of the triazine nucleus. Thus, if the chelation were ineffective with regard to the reactivity of the chlorine atom, both 2-hydroxy-1-naphthyl- and 4-hydroxy-1-naphthyl groups would lower the reactivity in a similar manner and the difference in substituent

Table 3. Rate constants for the nucleophilic reactions of 2-substituted 4-chloro-6-(hydroxy-1-naphthyl)-1,3,5-triazines

Compound	k_2 ($l \cdot mol^{-1} \cdot s^{-1}$)
With aniline at 35 °C	
1-2	4.28×10^{-3}
2-2	2.28×10^{-5}
With diethylamine at 20 °C	
1-3	2.36×10^{-2}
2-3	2.12×10^{-4}

effect between the two groups would not be large. However, as is apparent from Tables 3 and 4, the hydroxyl group was found to affect the reactivity of chloro-triazinyl-naphthalene in very different manners depending upon its position in the naphthalene nucleus. As compared with the case of Compound **3**, it is apparent that the hydroxyl group in the *para* position lowered the reactivity, as was to be anticipated. The hydroxyl group in the *ortho* position, on the contrary, raised the reactivity in spite of its powerful electron-donating character; in every case, the reactivity varied in the following order:

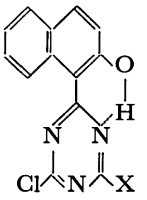
Compound **1** > **3** > **2**

Therefore, it may be reasonable to assume that the high reactivity of *O*-hydroxy compounds is mainly ascribable to the presence of the chelate ring in these compounds.

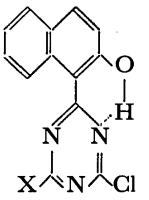
The hydroxyl group of these compounds can dissociate into anions whose reactivities should be different from those of the neutral species. Therefore, it may be necessary to ascertain the actual species in the above reactions. As the absorption spectra of these compounds are different from those of their anions, the dissociation can be checked spectrophotometrically to determine that Compounds **1** and **2** react practically like the neutral molecule in every case under the present reaction conditions.

The activation by the intramolecular hydrogen bond seems in this case to be a phenomenon similar to the acid catalysis in the reactions of chloro-triazines.[6]

However, from the activation parameters for the reactions with sodium azide, it is clear that the high reactivity of Compound **1** does not depend on the energy of activation, but results mainly from the difference in the entropy of activation. Thus, even if the chelation raised the reactivity by reducing the electron density of the triazine nucleus in a manner similar to the acid catalysis, this would not be the major reason for the high reactivity of the *O*-hydroxy compound; the assumption may also be supported by the fact that the differences in rate constant were rather larger in the cases of the derivatives containing the methoxyl group than in those of the derivatives having the diethylamino group, in spite of the fact that the order of the stability of chelation is known to be **1-2**<**1-4**.[7] In these derivatives, the two types of chelate-ring formation shown below are possible. Although it is obscure at present which is the true chemical species in the actual reactions under the present experimental conditions, the results can be reasonably explained as follows.



(1)′



(1)″

In these cases, a difference in solvation between two compounds is assumed to be responsible for the difference in reactivity.

In the initial state of the reaction (in the reaction with sodium azide, a mixture of dioxane and water was used as the solvent), the hydroxyl group and the ring nitrogen atoms of the substrates would be the principal centers for solvation. Thus, in the case of Compound **1** the solvation may be hindered by the chelate formation, because by the chelate formation the two centers for solvation should partially negate each others abilities to solvate.

In the transition state, a negative charge poured into the triazine nucleus from the reagent (N_3^-) would spread over the three ring nitrogen atoms, and the solvation would increase with an increase in the electron density of the triazine nucleus. However, in the transition state of Compound **1** the chelation would become stronger; thus, the increase in solvation in this case would be inferior to that of the case of Compound **2**.

Table 4. Rate constants for the reactions of 2-substituted 4-chloro-6-(1-naphthyl)-1,3,5-triazines with sodium azide

Compound	k_2 ($l \cdot mol^{-1} \cdot s^{-1}$)			Activation parameters	
	35 °C	45 °C	55 °C	ΔE kcal/mol	$\Delta S^{\neq}$ cal/deg·mol (35 °C)
1-3	0.85×10^{-4}	1.77×10^{-4}	4.70×10^{-4}	16.7	−25.3
2-3	1.39×10^{-5}	2.26×10^{-5}	5.59×10^{-5}	13.5	−39.1

Compound	k_2 ($l \cdot mol^{-1} \cdot s^{-1}$)				Activation parameters	
	15 °C	25 °C	35 °C	45 °C	ΔE kcal/mol	$\Delta S^{\neq}$ cal/deg·mol (25 °C)
1-2	1.29×10^{-2}	2.77×10^{-2}	7.03×10^{-2}	——	15.3	−15.7
2-2	——	0.77×10^{-3}	1.94×10^{-3}	4.20×10^{-3}	15.4	−23.1
3-2	——	4.38×10^{-3}	9.15×10^{-3}	2.05×10^{-2}	14.5	−22.5

In other words, although Compound **2** would solvate water more strongly than Compound **1** during the full course of the reaction, the difference in solvation degree between the two would be larger in the transition state than in the initial one.

Thus, in spite of the advantage in the energy of activation, Compound **2** was less reactive because of the disadvantage in the entropy term, as can be seen by comparing the reactions of **1–3** and **2–3**. A similar relation is also seen in the reactions of **1–2** and **2–2**.

Kinetics of the Reactions with Sodium Methoxide. The reactions of Compounds **1** and **2** with sodium methoxide were carried out in a mixture of methanol and acetone (1 : 1, by volume); the rate constants for the reactions are listed in Table 5.

Table 5. Rate constants for the reactions of 2-substituted 4-chloro-6-(hydroxy-1-naphthyl)-1,3,5-triazines with sodium methoxide

Compound	k_2 ($l \cdot mol^{-1} \cdot s^{-1}$) at 20 °C	Compound	k_2 ($l \cdot mol^{-1} \cdot s^{-1}$) at 30 °C
1–2	2.03	**1–3**	4.85×10^{-3}
2–2	4.55×10^{-2}	**2–3**	4.46×10^{-4}

In these reactions, Compound **1** was again found to be more reactive than **2**. In the reactions with sodium methoxide, the substrates are assumed to dissociate into their anions. In fact, most of the substrates were found to react practically as their anions, as can be seen in Table 6.[8] It is obvious from Table 6 that the rate constants of the two compounds are of an anionic species, regardless of the substituent in the triazine nucleus. However, in the case of Compound **1–3** about 3% of the substrate was found to remain as an undissociate form in the solution. Thus, the rate constant of Compound **1–2** was practically that of the anionic species; however, when the substituent is $-NEt_2$ the rate constant probably results from the reactions of anionic and neutral substrates. Therefore, the apparent rate constant may vary with the concentration of sodium methoxide. In fact, when the apparent rate constants were plotted against the concentration of sodium methoxide, a curve converging to a constant value with an increase in the concentration of the base was obtained, as is shown in Fig. 1.

Table 6. Ratios of anion to neutral molecule of 2-substituted 4-chloro-6-(hydroxy-1-naphthyl)-1,3,5-triazines in methanol

Compound	C^-/C	Compound	C^-/C
1–3	32	**1–2**	120
2–3	1000	**2–2**	3900

C^-: Concentration of ionized molecule.
C: Concentration of non-ionized molecule.

The results indicate that the anion is less reactive than the neutral substrate, and that the converged value (about 2.9×10^{-3} l/mol·s) in the high-base-concentration region is the true rate constant of the anionic species. Thus, in the reaction of anionic species, Compound **1** was also more reactive than the corresponding Compound **2**; it may be of interest that Compound **1** is more reactive even in the absence of an intramolecular hydrogen bond.

Table 7. Effect of concentration of $NaOCH_3$ on apparent rate constant of compound **1–3**

$[NaOCH_3]$ (mol/l)	k_2' ($l \cdot mol^{-1} \cdot s^{-1}$) at 30 °C
18.67×10^{-2}	2.90×10^{-3}
14.58×10^{-2}	3.14×10^{-3}
9.65×10^{-2}	4.07×10^{-3}
9.14×10^{-2}	4.85×10^{-3}
7.18×10^{-2}	6.04×10^{-3}
4.96×10^{-2}	1.08×10^{-2}

[Substrate] : 2×10^{-2} mol/l.

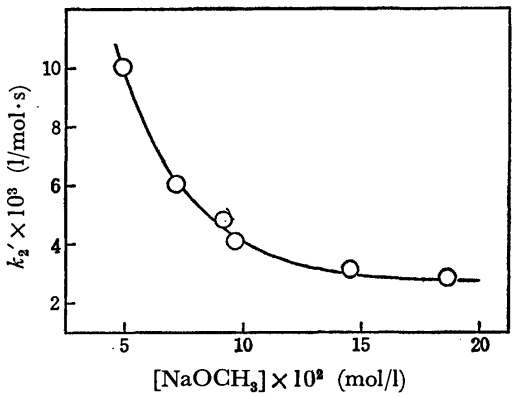


Fig. 1. Dependence of apparent rate constants of Compound **1–3** on concentration of sodium methoxide.

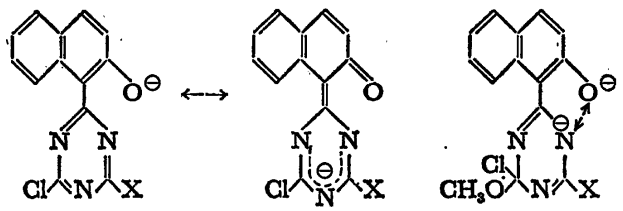
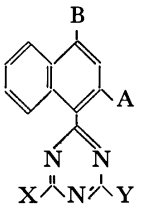
In the case of Compound **1**, one of the ring nitrogen atoms and one of the naphthoxide oxygen atom are assumed to be located very close to each other. Therefore, in the transition state there should be a repulsion between two atoms of same kinds of negative charge, leading to a loss of coplanarity between the naphthalene and triazine nuclei.



In the reaction of anionic species, the negative charge poured into the triazine nucleus from the naphthoxide anion should lower the reactivity of the substrate, regardless of the type of compound. However, in the case of Compound **1**, this lowering of reactivity should be prevented in some degree by the loss of copolanarity between the aromatic rings. Thus, Compound **1** would be more reactive than Compound **2** even in the reaction with sodium methoxide. As a whole, in the reactions with nucleophiles, Compound **1** was more reactive than the corresponding Compound **2**, regardless of the nucleophile used. The chelation

TABLE 8. pK_a VALUES OF (HYDROXY-1-NAPHTHYL)-1,3,5-TRIAZINES IN METHANOL AT 20 °C



X	Y	A	B	pK_a' [a]	Indicator[c]	Buffer

$-NEt_2$	$-NEt_2$	-H	-OH	13.6	Phenol Red	SBA+SBE

SBA=Sodium barbiturate. SBE=Sodium benzoate.

a) pK_a' denotes the ionization constant of (hydroxy-1-naphthyl)-1,3,5-triazine in methanol. b) Calculated using a linear relation between pK_a' and $\sum\sigma_m$ values of two substituents in the 1,3,5-triazine nucleus [Y. Ohto, Y. Hashida, S. Sekiguchi, and K. Matsui, *Bull. Chem. Soc. Japan*, **47**, 1301 (1974)], because the compound was found to be too unstable to measure an accurate pK_a' value in an alkaline solution; in this calculation the substituent constant of $-NMe_2$ was substituted for that of $-NEt_2$. c) Indicator employed for the measurement of pK_a' of triazines as the primary standard.

in Compound **1** surely plays an important role in the high reactivity; however, it has become apparent that the function of chelation is not a mere lowering of the electron density of the triazine nucleus.

Experimental

All melting points are uncorrected.

Materials. *2,4-Dichloro-6-(2-hydroxy-1-naphthyl)-1,3,5-triazine (**1-1**)*: Compound **1-1** was prepared by the reaction of cyanuric chloride with 2-naphthol in the presence of aluminium chloride in benzene.[2)]

*2,4-Dichloro-6-(4-hydroxy-1-naphthyl)-1,3,5-triazine (**2-1**)*: A solution of 40.6 g (0.22 mol) of cyanuric chloride and 32.1 g (0.22 mol) of 1-naphthol in 350 ml of benzene was added, drop by drop, into a mixture of 30.7 g (0.23 mol) of aluminium chloride in 200 ml of benzene at room temperature. After stirring for 2 h under reflux, the mixture was poured into 1 l of ice water containing 200 ml of a concd hydrochloric acid solution. The precipitate thus formed was filtered, dried, and purified by column chromatography on silica gel using a mixture of benzene and acetone (10 : 1 by volume) to give an analytical sample. Mp 239 °C (decompn.). This product gave 2,4-dimethoxy(4-hydroxy-1-naphtnyl)-1,3,5-triazine (mp 204—205 °C)[2)] upon treatment with an excess of sodium methoxide in methanol.

*2-Diethylamino-4-chloro-6-(2-hydroxy-1-naphthyl)-1,3,5-triazine (**1-3**) and 2-Diethylamino-4-chloro-6-(4-hydroxy-1-naphthyl)-1,3,5-triazine (**2-3**)*: A typical preparation is shown in the case of Compound **1-3**. A solution of 7.5 g (0.1 mol) of diethylamine in 100 ml of acetone was added, drop by drop, into a solution of 14.6 g (0.05 mol) of Compound **1-1** in 250 ml of acetone at 0 °C. After stirring for 3 h at 0—5 °C, the reaction mixture was poured into 1 l of ice water. The precipitate was then filtered and dried to give a crude product in an almost quantitative yield. The recrystallization of the product from ligroin gave an analytical sample of Compound **1-3**. Mp 104.5—105.5 °C.

*2-Methoxy-4-chloro-6-(2-hydroxy-1-naphthyl)-1,3,5-triazine (**1-2**) and 2-Methoxy-4-chloro-6-(4-hydroxy-1-naphthyl)-1,3,5-triazine (**2-2**)*: A typical preparation is shown in the case of Compound **1-2**. A solution of 10.5 g (0.073 mol) of 2-naphthol in 200 ml of benzene was added, drop by drop, into a mixture of 13.1 g (0.073 mol) of 2,4-dichloro-6-methoxy-1,3,5-triazine and 9.7 g (0.073 mol) of aluminium chloride at room temperature. After stirring at 40—50 °C for 8 h, the mixture was poured into ice water containing hydrochloric acid as has been described above. The precipitate thus formed was filtered and washed with dilute hydrochloric acid, with cold water, and then with a small amount of acetone to give a crude product in a yield of 80%. The recrystallization of the product from ligroin gave an analytical sample. Mp 168—169 °C.

*2,4-Dichloro-6-(1-naphthyl)-1,3,5-triazine (**3-1**) and 2-Methoxy-4-chloro-6-(1-naphthyl)-1,3,5-triazine (**2-3**)*: A solution of 36.9 g (0.2 mol) of cyanuric chloride in 300 ml of dry ether was added all at once into a mixture of Grignard reagent prepared from 41.4 g (0.2 mol) of 1-bromonaphthalene and 5.0 g (0.2 mol) of magnesium in 200 ml of dry ether. After the mixture had been stirred overnight at room temperature, the precipitate was filtered and washed with cold dilute hydrochloric acid and then with water to give a crude product of Compound **3-1** in a 55% yield.

A solution obtained by dissolving 1.2 g (0.05 mol) of sodium in 150 ml of methanol was added, drop by drop, into a solution of 13.8 g (0.05 mol) of Compound **3-1** in a mixture of 450 ml of dioxane and 200 ml of methanol at 0 °C. After stirring for 3 h, the solution was poured into 1.5 l of ice water. The precipitate was filtered and dried to give Compound **3-2** in an almost quantitative yield.

Kinetic Measurements. Runs were carried out with an excess of the nucleophile (the substrate and the nucleophile were used in a molar ratio of about 1 : 5; the initial concentration of the former was about 0.02 mol/l). In the reaction with aniline, acetone was used as the solvent; the reaction in aliquot portions was stopped by dilution with

cold acetone (−20 °C), followed by a titration of the hydrochloric acid with a standard acetone solution of triethylamine, using Neutral Red as the indicator.

In the reaction with diethylamine (solvent : acetone), the reaction in aliquote portions was stopped by pouring in an excess of an acetone solution of hydrochloric acid of a known concentration; the reagent consumed was estimated by back-titration with a standard acetone solution of triethylamine, using Neutral Red as the indicator.

In the reaction with sodium azide (solvent: a mixture of dioxane and water in a ratio of 4 : 1 by volume), reaction in aliquot portions was stopped by pouring in a mixture of carbon tetrachloride and water; the chloride in the water layer was estimated by titration with silver nitrate by the Volhard method in the presence of a small amount of nitrobenzene.[9]

In the reaction with sodium methoxide (solvent: a mixture of acetone and methanol in a ratio of 6 : 4 by volume), reaction in aliquot portions was stopped by pouring in an excess of a hydrochloric acid solution of a known concentration, followed by back-titration with a standard sodium hydroxide solution, using Methyl Red as the indicator. For the reactions with aniline and diethylamine, the rate constants were calculated from Eq. (1):

$$k_2t = 2.303/b-2a \cdot \log a(b-2x)/b(a-x) \quad (1)$$

where a and b are the initial concentrations of the substrate and the nucleophile respectively, and where x is the concentration of the product at time t. On the other hand, in the cases of sodium azide and sodium methoxide Eq. (2) was used:

$$k_2t = 2.303/b-a \cdot \log a(b-x)/b(a-x) \quad (2)$$

However, in the reactions of Compounds **1** and **2** with sodium methoxide, the rate constants were calculated using b-a as the initial concentration of nucleophile, because equimolar proportions of the substrate and the nucleophile should combine to form an anion of the substrate prior to the substitution reaction.

The mean values of not less than four separately determined values of k_2, which agreed within 5%, were taken as the rate constants for these reactions; they are listed in Tables 3, 4, 5, and 7.

*p*K$_a$ *Measurements.* The pK_a values of naphthol derivatives in methanol were determined by the indicator method using Eq. (3);[10] the ratio of the acidic to the basic form of an indicator and naphthol derivatives was determined spectrophotometrically:

$$pK_a' = pK_I + \log C_{Ib} \times C_{Na}/C_{Ia} \times C_{Nb} \quad (3)$$

where pK_a'=pK_a value of naphthol derivative, pK_I=the pK_a value of an indicator; C_{Ia} and C_{Ib} are the concentrations of the acidic and basic forms of an indicator respectively, and C_{Na} and C_{Nb} are the concentrations of the acidic and dissociated forms of the naphthol derivative respectively. The results obtained are summarized in Table 8.

The Metal-Ion-Catalyzed Alcoholysis of β-Dicarbonyl Compounds[1]

Kaku UEHARA, Fujio KITAMURA, and Makoto TANAKA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received July 11, 1975)

The alcoholysis of β-dicarbonyl compounds of the type $CH_3COCHRCOR'$ is catalyzed by a variety of metal ions. In the presence of a large excess of β-diketone compared with metal ions, the rate is given by the expression: rate$=k_{obsd}[M^{2+}][ROH]$. The values of k_{obsd} decrease with M^{2+} in the order $Zn^{2+}>Co^{2+}>Ni^{2+}>Cu^{2+}$. The reaction rate is remarkably affected by the substituents (R,R'), the kinds of alcohol and solvent used, the addition of a chelating agent, and also by the counter anion of the metal ion. The alcoholysis proceeds more slowly in CH_3OD than in CH_3OH by a factor of 1.4. These are interpreted in terms of a mechanism in which the β-dicarbonyl compound coordinated to a metal ion is attacked by the alcohol which is also coordinated to the metal ion to cleave the C^2–C^3 or C^3–C^4 bond of the dicarbonyl compound. A convenient method for the preparation of β,γ-unsaturated ketones and esters is provided by the alcoholysis of alkenyl substituted β-dicarbonyl compounds in the presence of zinc acetate.

Acid- and base-catalyzed cleavages of β-diketones and ketoesters are well known.[2] Alkaline alcoholysis of acetylacetone has been previously studied by Kutz and Adkins,[2d] and Pearson and Sandy.[2h] Recently, we have found that certain metal salts and chelates catalyze the alcoholysis of 3-(1-alkenyl)-2,4-pentanediones to give β,γ-unsaturated ketones.[3]

It has been shown that the β-diketo compounds react with a metal ion to form a certain type of chelate and consequently are activated toward the electrophilic attack of various reagents.[4–9] On the other hand, it has been reported that metal complexes containing both methoxy and β-dicarbonylate ions as ligands, [M(acac) (CH_3O) $(CH_3OH)_x$],[10–12] effectively catalyze the ester exchange reactions of ethyl picolinate, ethyl 2-pyridylacetate, and ethyl esters of α-amino acids.[13]

In this paper, the metal-ion-catalyzed alcoholysis of 3-substituted β-dicarbonyl compounds will be discussed in more detail; we will propose a possible mechanism involving an intermediate in which both β-dicarbonyl compound and alcohol are coordinated to a metal ion.

Results and Discussion

Kinetic Studies. The dependences of the reaction rate on the concentration of zinc acetate, 3-(1-butenyl)-2,4-pentanedione, and methanol have been investigated. The results are shown in Table 1 and Fig. 1. It is seen that the metal-ion-catalyzed alcoholysis of 3-substituted β-diketones follows the rate equation: rate$=k_{obsd}$ [Metal ion] [Alcohol]. The rate of alcoholysis is independent of [β-diketone] under the present condition of [β-diketone]≫[metal ion]. This may be due to the fact that the metal ion exists only as a metal chelate of β-diketone and the reaction species is not the metal ion itself but the metal chelate. The band of 3-(1-butenyl)-2,4-pentanedione at 288 nm was found to shift to 303 nm by the addition of $Zn(OAc)_2$, as shown in Fig. 2. The large red shift should be ascribed to the zinc enolate formation.

TABLE 1. ALCOHOLYSIS OF 3-(1-BUTENYL)-2,4-PENTANEDIONE BY ZINC ACETATE IN METHANOL AT 70 °C (reflux)

Run No.	$[Zn(OAc)_2]\times10^3$ (M)	[β-Diketone]×10 (M)	Rate×10^3 (M s^{-1})
1	20.8	13.1	4.41
2	20.1	13.1	4.76
3	13.9	13.1	3.48

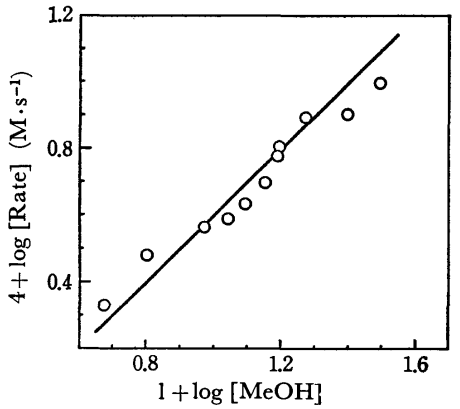

Fig. 1. Plot of log (Rate) *vs.* log [CH_3OH] in dioxane at 70 °C [$Zn(OAc)_2$]$=7.0\times10^{-3}$ M, [β-Diketone]$=$ 1.31 M.

Effect of 3-Substituent. The effect of the substituent at the 3-position of acetylacetone is shown in Table 2. The rate of alcoholysis of 3-substituted 2,4-pentanediones was found to be markedly affected by the property of the substituent. 3-(1-Butenyl)-2,4-pentanedione showed the highest reactivity and 3-benzyl- or 3-butyl-2,4-pentanedione showed a moderate reactivity. Acetylacetone, however, was inactive toward the alcoholysis. The rate of reaction increases with decrease in activation energy E_a. 3,3-Dimethyl-, 3-benzylidene-, and 3-furfurylidene-2,4-pentanedione which have no labile hydrogen to form the metal enolate showed less or no reactivity in the metal-ion-catalyzed alcoholysis, in contrast to the very high reactivity in alkaline alcoholysis of the 3,3-dialkyl

a) 1.58×10^{-2} M of triethylenetetramine was added.

substituted β-diketone.[2d]

Solvent Effects. The methanolysis of 3-(1-butenyl)-2,4-pentanedione by zinc acetate was carried out using benzene, ethyl acetate, dioxane, and acetonitrile as diluents. The solvent effects on the reaction are summarized in Table 3. It is clear that the rate is much greater in a nonpolar solvent than in a polar solvent, in spite of the unfavorable activation energy for the former. The reaction cannot be facilitated in a nonpolar solvent. In fact, from the data of Table 1, k_{obsd} in methanol is calculated to be 9.5×10^{-3} $M^{-1} s^{-1}$, which is larger than in benzene. The solvent effect in Table 3 may be explained as follows: The polar solvent should compete with the alcohol for the occupation of the coordination site of the metal chelate so as to depress the formation of the intermediate (c) as described below.

Effect of Chelating Agent. Addition of a small amount of triethylenetetramine (Trien), which is known as a more effective chelating agent than β-diketone, induces a marked decrease in the reaction rate, as shown in Table 3. This effect may be accounted for by a reduction of the net concentration of the metal ion acting as catalyst.

Effect of Alcohol. As shown in Table 4, the rates of alcoholysis varied with the kind of alcohol used. The order of the reactivity was anti-parallel to that of the basicity as follows: methanol>ethanol>propan-2-ol>*t*-butyl alcohol. The observed reactivity order of the alcohols is attributable to the steric effect rather than the activation energy. This effect and the data of Table 3 seem to suggest that the reaction proceeds *via* the coordination of alcohol to the metal of the β-diketone complex.

TABLE 4. EFFECTS OF ALCOHOL ON THE ALCOHOLYSIS OF 3-(1-BUTENYL)-2,4-PENTANEDIONE IN DIOXANE

[β-Diketone] = 1.30 M, $[Zn(OAc)_2] = 7.0 \times 10^{-3}$ M

TABLE 5. EFFECTS OF METAL SALTS ON THE ALCOHOLYSIS OF 3-(1-BUTENYL)-2,4-PENTANEDIONE IN METHANOL

[β-Diketone] = 3.25×10^{-1} M, at 70 °C (reflux)

Metal salt	$k_{obsd} \times 10^4$ (s^{-1})
Cu(OAc)	1.02
$Ni(OAc)_2$	1.93
$Co(OAc)_2$	7.44
$Zn(OAc)_2$	48.7
$Zn(acac)_2$	33.4
$ZnSO_4$	1.83
$ZnCl_2$	1.19

Deuterium Isotope Effect. The alcoholysis of 3-(1-butenyl)-2,4-pentanedione in a large amount of monodeuteriomethanol (CH_3OD) by zinc acetate gave 3,3-dideuterio-4-hepten-2-one, which was identified by means of mass spectra (parent peak, *m/e* 114) and NMR spectra (a practical disappearance of the signal of 4-hepten-2-one at 6.98 τ(2H, d, $-C\underline{H}_2COCH_3$)). The alcoholysis proceeds more slowly in CH_3OD than in CH_3OH by a factor of $k_H/k_D = 1.4$. The isotope effect may be caused by a rapid and reversible reaction, which involves breakage of the O–H (or O–D) bond and is followed by the slow rate-determining step.[15] The catalysis of divalent metallic ions for the exchange of alcohol hydroxyl protons has been reported.[16]

Effects of Metal Salts. The activities of metal salts used as the catalyst of the alcoholysis are shown in Table 5. The order of the activity of metal acetates ($M(OAc)_2$) was as follows: Zn(II)>Co(II)>Ni(II)>Cu(II). The observed activity order of $M(OAc)_2$ was anti-parallel with the stability constants[14] of metal acetylacetonates ($M(acac)_2$). The catalytic activity of a metal ion is altered by its counter anion. The rate constant of $Zn(OAc)_2$ is 40-fold larger than that of $ZnCl_2$. The lower activity of $ZnCl_2$ may be attributed to a reluctance to form metal enolate(A). Kawaguchi *et al.*[17] reported the presence of a zinc(II) complex, $ZnCl_2(acacH)$, which has a tetrahedral structure containing a ketonic molecule of acetylacetone (B). As already shown in Fig. 2, the small change in the absorption spectra of 3-(1-butenyl)-2,4-pentanedione by the addition of $ZnCl_2$ also gives evidence for the reluctance of $ZnCl_2$ to form metal enolate (A). The higher activity of $Zn(OAc)_2$ compared with that of $ZnCl_2$ or $ZnSO_4$ seems to be because the HOAc liberated by chelation is a much weaker acid than HCl or H_2SO_4 and consequently $Zn(OAc)_2$ is more likely to form the metal enolate(A).

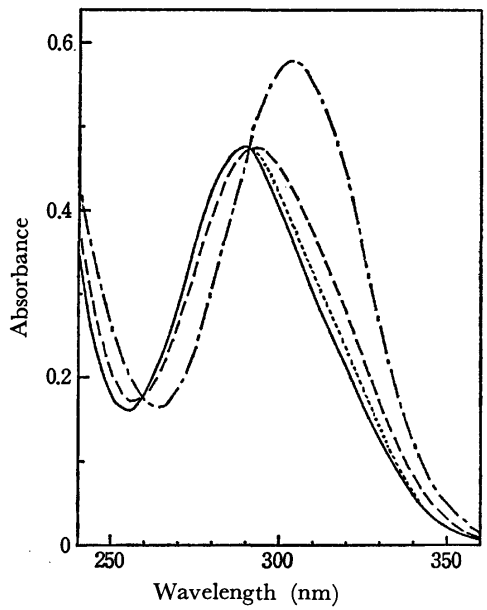

Fig. 2. Absorption spectra of 3-(1-butenyl)-2,4-pentanedione (1.03×10^{-4} M) in the absence and presence of zinc salt in methanol.
——: Absence of zinc salt,
— — —: $[Zn(OAc)_2]=5.11\times10^{-4}$ M,
— — —: $[ZnSO_4]=5.18\times10^{-4}$ M,
……: $[ZnCl_2]=6.31\times10^{-4}$ M.

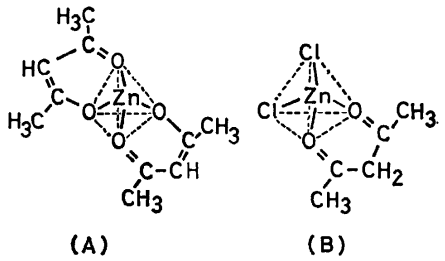

Fig. 3.

The observed effects of metal salts suggest that the formation of metal enolate is essential for a high catalytic activity. However, an extremely stable O–M bond is unfavorable, because the present catalysis presumably proceeds *via* the dissociation of the O–M bond followed by the protonation to carbonyl oxygen to form the intermediate(d) as described below.

Alcoholysis of Unsymmetrical β-Diketones. Unsymmetrical β-diketones, RCO-CHR'-COR", can be cleaved in either of two ways.[2a,2c,2e] Metal-ion-catalyzed alcoholysis of several 3-(1-butenyl)-4-substituted-2,4-butanediones was carried out in order to find the direction of the cleavage. The results are shown in Table 6, where k_1 is the rate constant of the alcoholysis of the C–$COCH_3$ bond (deacetylation) and k_2 is that of the C–COR bond (deacylation).

An electron-donating substituent increases the rate ratio k_1/k_2. Except for 3-(1-butenyl)-4-phenyl-2,4-butanedione, the direction of cleavage is found to be determined by the strength of the carboxylic acid of the two possible esters: the stronger acid is formed in a larger proportion as in the alkaline hydrolysis reported by Bradley and Robinson.[2a] The effect of

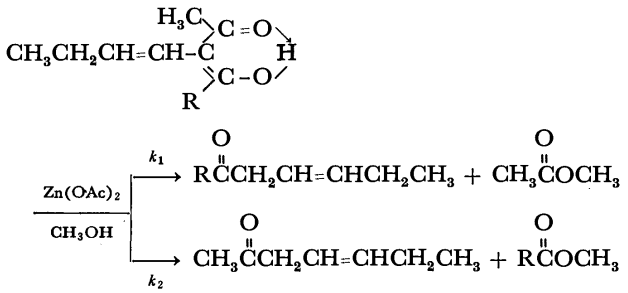

Table 6. Effects of 4-substituent in the methanolysis of 3-(1-butenyl)-4-substituted-2,4-butanedione by $Zn(OAc)_2$

4-Substituent	k_1 (70 °C)$\times10^5$ ($M^{-1}s^{-1}$)	k_2 (70 °C)$\times10^5$ ($M^{-1}s^{-}$)	k_1/k_2
CH_3-	41.9	41.9	1.0
$(CH_3)_2CH$-	27.1	4.09	6.63
	36.3	14.2	2.56
CH_3O-	6.14	0.414	14.8

phenyl substitution resulting in the k_1/k_2 value of 2.56 may be explained from the viewpoint of steric hindrance.

Mechanism. On the basis of the experimental results described above, a possible mechanism for the metal-ion-catalyzed alcoholysis of β-diketone may be proposed as follows:

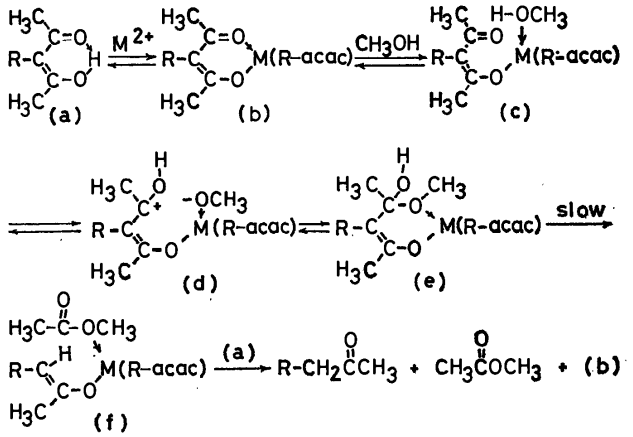

Fig. 4.

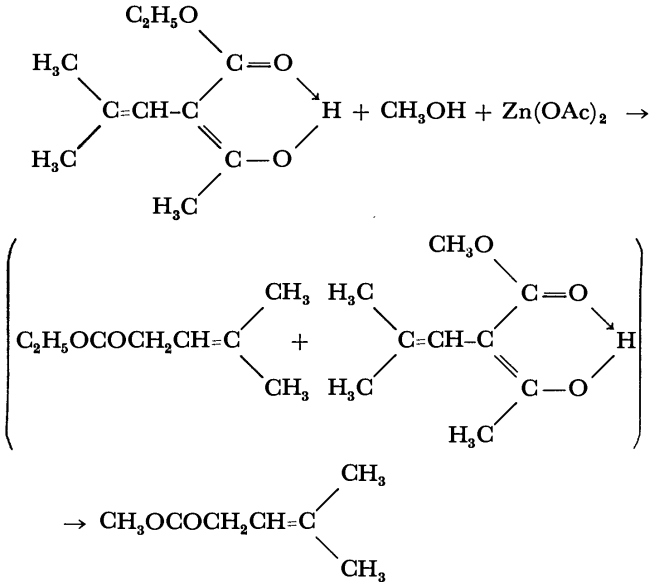
The mechanism is consistent with the observed kinetic results and the reaction products. The independence of the rate of alcoholysis from β-diketone concentration, the small or absent reactivity of 3,3-disubstituted-2,4-pentanedione, and the lower activity of zinc chloride suggest that the metal enolate(b) is the reactive species in the present alcoholysis. The presence of a pre-equilibrium (b)$+CH_3OH\rightleftarrows$(e) is supported by the observed kinetic isotope effect and the effects of the kinds of solvent and alcohol on the rate of the alcoholysis. The effects of 3-substituents and solvents on the activation energy E_a may be explained in terms of the stabilization of the intermediate in the transition state of the rate-determining step (e)→(f). The effect of 4-substituents on the rate

ratio k_1/k_2 in unsymmetrical β-diketones shows that the cleavage occurs at the more electron-deficient C–C bond. Monoketone and acetate are liberated from the coordinated site by the ligand exchange with another β-diketone(a) to re-form the metal chelate of β-diketone (b) and the cycle recurs many times.

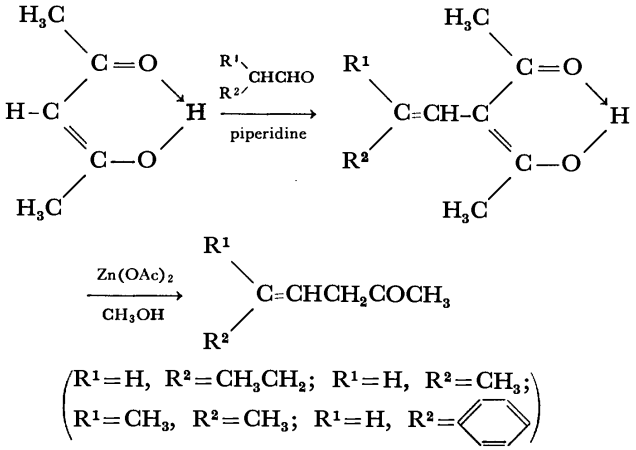
Alcoholysis of 1-Alkenyl Substituted β-Ketoesters. It was found that in the presence of metal acetate 1-alkenyl substituted β-ketoesters underwent alcoholysis involving an ester exchange to give esters of β,γ-unsaturated carboxylic acid. For example:



The metal-ion-catalyzed ester exchange of β,γ-unsaturated carboxylates formed by the deacetylation was found to proceed much more slowly than that of the parent β-ketoesters. Thus, in the initial stage of the methanolysis, ethyl esters of 1-alkenylacetic acid were formed predominantly as the alcoholysis product. The initial rate of the deacetylation of ethyl (2-methyl-1-propenyl)acetoacetate by the various metal acetates is shown in Table 7.

The order of the activities of metal acetates used as the catalyst is as follows: Mn(II)>Cd(II)>Zn(II)>Co(II)>Ni(II)>Cu(II). The observed activity order of $M(OAc)_2$ was again anti-parallel to the stability constants of $M(acac)_2$.

Synthesis of β,γ-Unsaturated Ketones and Esters. It has been known that β,γ-unsaturated ketones are prepared by the steam distillation of an aqueous acidic solution of 3-alkene-2,5-diols,[18] by the acid catalyzed isomerization of α,β-unsaturated ketones,[19] and by several other methods.[20–23] The present reaction seems to be interesting as a general synthetic method of β,γ-unsaturated ketones of the type $RR'C{=}CHCH_2COCH_3$ starting from aldehyde and acetylacetone, because of the ease of isolation of the β,γ-unsaturated ketone from its reaction mixture by fractional distillation with high purity and a fair yield. Zinc acetate is an efficient catalyst for the alcoholysis of 3-(1-alkenyl)-2,4-pentanediones without catalyzing side reactions such as rearrangements of double bond and alcohol additions.



It is known that β,γ-unsaturated carboxylic acids are prepared by the condensation of malonic acid with aldehyde followed by decarboxylation[24] and that the esterification of β,γ-unsaturated carboxylic acids is carried out by the reaction of its Ag salt with alkyl iodide.[25] The present reaction seems to provide a more convenient route to the ester of β,γ-unsaturated carboxylic acid in spite of its lower yield.

Table 7. Effects of metal ion on the deacetylation of ethyl (2-methyl-1-propenyl)acetoacetate in methanol

[β-Ketoester] = 2.73×10^{-1} M, [$M(OAc)_2$] = 7.00×10^{-3} M

Metal acetate	k_{obsd} (70 °C) $\times 10^5$ (s^{-1})
$Mn(OAc)_2$	19.1
$Cd(OAc)_2$	9.42
$Zn(OAc)_2$	7.20
$Co(OAc)_2$	2.80
$Ni(OAc)_2$	0.535
$Cu(OAc)_2$	<0.1

Experimental

Materials. 3-Substituted-2,4-pentanedione was prepared by the method described in the previous paper.[26] 3,3-Dimethyl-2,4-pentanedione was prepared by the method of Pearson:[2g] bp 68—68.5 °C/18 mmHg, n_D^{23} 1.4283 (lit,[2g] bp 170—173 °C, n_D^{25} 1.4330). Benzoylacetone,[27] isobutyrylacetone,[28] and *p*-methoxybenzoylacetone[29] were allowed to react with butyraldehyde in the presence of piperidine to give Knoevenagel condensates: 3-(1-butenyl)-4-phenyl-2,4-butanedione, bp 107—110 °C/1 mmHg, n_D^{18} 1.5487, yield 52.5%; 3-(1-butenyl)-4-isopropyl-2,4-butanedione, bp 106—117 °C/16 mmHg, n_D^{17} 1.4724, yield 54%: Copper chelate, Found: C, 61.59; H, 7.99%. Calcd for $C_{22}H_{34}O_4Cu$: C, 62.02; H, 8.04%. 3-(1-Butenyl)-4-*p*-methoxyphenyl-2,4-butanedione, bp 133—141 °C/1 mmHg.

The Knoevenagel condensates of ethyl acetoacetate with aldehydes were prepared by a similar method. Ethyl (1-butenyl)acetoacetate, bp 117—120 °C, yield 41%. Ethyl (2-methyl-1-propenyl)acetoacetate, bp 115—117 °C/20 mmHg, yield 33%. Ethyl (1-propenyl)acetoacetate, bp 110—115 °C/20 mmHg, yield 21%.

Metal acetates and other metal salts were G. R. -grade reagents. Alcohols and solvents were purified by the ordinary methods and were distilled before use. Monodeuteriomethanol was supplied by E. Merck Co. and used without

further purification.

Kinetic Measurements. An alcoholic solution of β-dicarbonyl compound was allowed to undergo alcoholysis in the presence of a metal salt at the desired temperature. Aliquots of the reaction mixture were withdrawn at regular intervals and analyzed by means of gas-liquid chromatography on a column packed with Apiezone grease L (30%) on chromosorb. A Shimadzu GC-4APT gas chromatograph equipped with an integrator, model ITG-2A, was used as the analyzer. Toluene was usually employed as an internal standard, but in some experiments, cumene, ethyl benzoate, propyl benzoate, or diethyl phthalate was also used. The increase of products was measured as a function of time for various β-dicarbonyl compounds.

Spectral Measurements. The IR spectra were measured as a liquid film by means of a Hitachi Model EPI-G2 infrared spectrometer. The UV spectra were measured using a Shimadzu recording spectrophotometer model UV-200. The NMR spectra were determined by means of a Hitachi Model R-20 spectrometer. Tetramethylsilane was used as the internal standard, and carbon tetrachloride was used as the solvent. The mass spectra were recorded on a Hitachi Model RMU-6E mass spectrometer under the following conditions: chamber voltage 80 V, total emission current 80 μA, vacuum 2×10^{-6} mmHg, sample temp. 160 °C.

Synthesis of β,γ-Unsaturated Ketones. 80 g (0.52 mol) of 3-(1-butenyl)-2,4-pentanedione[26] and 0.8 g (0.0036 mol) of zinc acetate in 150 ml of methanol were heated under reflux at 70 °C for 16 h. The reaction mixture was subjected to fractional distillation. The volatile fraction is a mixture of methanol, methyl acetate, and a small amount of acetic acid. From the second fraction (bp 60—62 °C/25 mmHg), 4-hepten-2-one[30] was obtained in a yield of 64% (37 g); its purity was found to be above 99% from glc-analysis by double fractional distillation.

The following 4-alken-2-ones were obtained by the Zn-$(OAc)_2$-catalyzed methanolysis of the Knoevenagel condensates of acetylacetone with propionaldehyde, isobutyraldehyde, and phenylacetaldehyde in a similar manner to that described above (yield 60—80%): 4-Hexen-2-one, bp 61—62 °C/52 mmHg (lit,[18] 45 °C/29 mmHg). n_D^{21} 1.4265. IR spectrum (liquid film): $\nu_{C=O}$ 1710 cm^{-1}. λ_{max}^{MeOH}(C=O) 275 nm. Mass spectrum: *m/e* 98, 83, 55, 43. Semicarbazone (mp 142—143 °C), Found: C, 54.53; H, 8.31; N, 27.32%. Calcd for $C_7H_{13}ON_3$: C, 54.17; H, 8.44; N, 27.07%. 5-Methyl-4-hexen-2-one: bp 61—62 °C/25 mmHg, n_D^{28} 1.4384. IR spectrum(liquid film): $\nu_{C=O}$ 1705 cm^{-1}. λ_{max}^{MeOH} (C=O) 278 nm. Semicarbazone (mp 155—156 °C), Found: C, 56.17; H, 8.65; N, 25.28%. Calcd for $C_8H_{15}ON_3$: C, 56.17, H, 8.65; N, 25.28%. Calcd for $C_8H_{15}ON_3$: C, 56.78; H, 8.93; N, 24.83%. 5-Phenyl-4-penten-2-one: bp 85—87 °C/1 mmHg. n_D^{27} 1.5472. IR spectrum(liquid film); $\nu_{C=O}$ 1708 cm^{-1}. Semicarbazone (mp 151—152 °C), Found: C, 66.97; H, 6.97; N, 19.66%. Calcd for $C_{12}H_{15}ON_3$: C, 66.35; H, 6.91; N, 19.35%.

Synthesis of Esters of β,γ-Unsaturated Carboxylic Acids. The following 1-alkenylacetates were obtained by the $Zn(OAc)_2$-catalyzed ethanolysis or methanolysis of the Knoevenagel condensates of ethyl acetoacetate with butyraldehyde, isobutyraldehyde, and propionaldehyde in a similar manner to that described above: Ethyl 1-butenylacetate, bp 71—72 °C/20 mmHg, yield 14%. n_D^{24} 1.4228. IR spectrum ($\nu_{C=O}$), 1735 cm^{-1}. NMR spectrum (δ, ppm): 1.0 (3H,t), 1.2 (3H, t), 2.0 (2H, m), 2.9 (2H, t), 4.1 (2H, m), 5.5 (2H, m). Benzyl amide (mp 251—252 °C), Found: C, 77.15; H, 8.14; N, 7.03%. Calcd for $C_{13}H_{17}ON$: C, 76.85; H, 8.37; N, 6.90%. Methyl 1-butenylacetate, bp 61—62 °C/20 mmHg, yield 46%. Ethyl (2-methyl-1-propenyl)acetate, bp 67.5—68 °C/18 mmHg, yield 24%. n_D^{24} 1.4286. IR spectrum ($\nu_{C=O}$): 1730 cm^{-1}. NMR spectrum (δ, ppm): 1.2 (3H, t), 1.7 (6H, t), 2.9 (2H, t), 4.1 (2H, m), 5.2 (1H, m). Methyl (2-methyl-1-propenyl)acetate: bp 62—63 °C/18 mmHg, yield 40%. Ethyl propenylacetate: bp 64—66 °C/20 mmHg, yield 6%. n_D^{24} 1.4209. IR spectrum ($\nu_{C=O}$): 1735 cm^{-1}. NMR spectrum (δ, ppm): 1.2 (3H, t), 1.7 (3H, t), 2.9 (2H, t), 4.1 (2H, m), 5.5 (2H, m). Mass spectrum: *m/e* 128, 85, 55, 45.

The authers wish to thank Mr. Tetsuo Akutsu for his assistance in carrying out a part of the reported experiments.

Photooxygenation of α,β- and β,γ-Unsaturated Enamines in 17-(1-Formylethyl)etiojervanes[1]

Akio MURAI, Chizuko SATO, Hiroshi SASAMORI, and Tadashi MASAMUNE

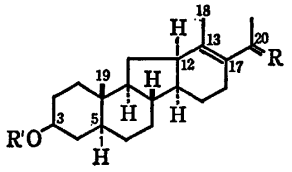
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

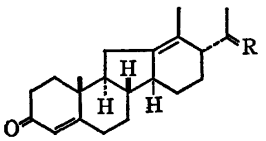
(Received July 11, 1975)

Photooxygenation of α,β(13,17)- and β,γ(12,13)-unsaturated morpholine enamines (I and II) in 17-(1-formylethyl)etiojervanes by singlet oxygen was carried out under irradiation with fluorescent bulbs. Oxidation of the former (I) afforded the corresponding α,β-unsaturated ketone (III) as the only product which could be isolated, while that of the latter gave two products, one (IV) being a normally oxidized β,γ-unsaturated ketone and the other (VIII) an α,β-unsaturated ketone with the D-ring contracted. Compound (VIII) was not obtained by treatment of IV under the same photooxygenation conditions as for II, indicating that the formation of VIII would not involve IV as an intermediate.

The photooxygenation of enamines by singlet oxygen has been demonstrated to be useful for synthesis.[2] We describe further examples which involve transformation of the enamines (I) and (II) into the corresponding unsaturated ketones. These α,β-[3] and β,γ-unsaturated ketones[4] (III and IV) are not readily obtainable by the standard chemical procedures.[5]

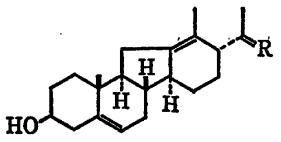
The enamines (I) and (II) were prepared as follows. 17-(1-Formylethyl)-5α,12α-etiojerv-13(17)-en-3β-ol[3] (V) was converted into the acetate (Va), oil, which was treated with morpholine[6] to give the α,β-unsaturated morpholine enamine (I), oil, in good yield; NMR, δ 1.68 and 1.74 (each 3H, s, 21- and 18-$C_3\underline{H}$ or *vice versa*). On the other hand, 17α-(1-formylethyl)etiojerva-5,12-dien-3β-ol[4] (VI) was transformed *via* a three-step process (acetalization of the formyl group, the Oppenauer oxidation and deacetalization) into the corresponding Δ^4-3-ketone (VII), oil, in good yield; UV, λ_{max} 238 nm (ε 10500), which smoothly formed the morpholine 20-enamine (II), oil, in the same manner as Va; NMR, δ 1.46 and 1.50 (each 3H, s, 18- and 21-$C\underline{H}_3$ or *vice versa*).

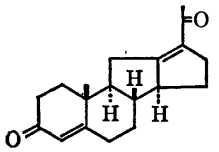




I R=CH(NC_4H_8O), R'=Ac
III R=O, R'=Ac
V R=H, CHO, R'=H
Va R=H, CHO, R'=Ac

II R=CH(NC_4H_8O)
IV R=O
VII R=H, CHO





VI R=H, CHO
IX R=O

VIII

Photooxygenation of the α,β-unsaturated enamine (I) in benzene with Rose Bengal as a sensitizer was carried out in a Pyrex tube irradiated externally with four 15-watt fluorescent bulbs at room temperature for 7.5 h, when all the starting enamine had been brought to reaction. The resulting tarry product was purified by preparative tlc to give 13, 17-unsaturated 20-ketone (III), oil, in 40% yield as the only main product which could be isolated; Mass, 358 (M^+) and 255; UV, λ_{max} 249 nm (ε 13000); IR, ν_{max} 1730, 1674, 1612, 1255, and 1210 cm^{-1}; NMR, δ 0.78, 1.89, 2.04, and 2.25 (each 3H, s, 19-, 18-, acetoxy, and 21-$C\underline{H}_3$), and 4.71 (1H, br W_H=21 Hz, $\underline{H}$ at C_3). Since α,β-unsaturated enamines have been reported to undergo autooxidation and form the cooresponding 1,4-diones,[7] photooxygenation is practicable, since ketone (III) had not been obtained by hydrolysis of the corresponding oxime[3] even under mild conditions. The α,β-(13,17)-unsaturated 20-ketone (III) was found to be very unstable as compared with the other α,β-(16,17)-unsaturated 20-ketone.[6] Double bond migration[4,8] followed by hydrooxygenation probably takes place under the conditions.

Photooxygenation of β,γ-unsaturated enamine (II) under the comparable conditions (22 h) afforded a tarry mixture, from which two products (IV) and (VIII) were isolated by preparative tlc in 11 and 22% yields, respectively. (IV), mp 131—133 °C and $[\alpha]_D$ +198°, showed the following spectra: Mass, *m/e* 312 (M^+) and 269; UV, λ_{max} 238 nm (ε 11500); IR, ν_{max} 1700, 1655, and 1603 cm^{-1}; NMR, δ 1.18, 1.57, and 2.14 (each 3H, s, 19-, 18-, and 21-$C\underline{H}_3$) and 5.78 (1H, s, $\underline{H}$ at C_4). The assigned structure of (IV) was consistent with these spectra and confirmed by the Oppenauer oxidation of the corresponding etiojerv-5-en-3β-ol[4] (IX) to IV. On the other hand, (VIII), mp 196—198 °C and $[\alpha]_D$ +110°, was identified on the basis of the spectral data to be α,β-unsaturated ketone with the D-ring contracted: Mass, *m/e* 284 (M^+), 269(M^+–CH_3), 241 (M^+–$COCH_3$), and 161 (base); UV, λ_{max} 247 nm (ε 20000); IR, ν_{max} 1654 and 1614 cm^{-1}; NMR, δ 1.22 and 2.28 (each 3H, s, 19-$C\underline{H}_3$ and $COC\underline{H}_3$) and 5.79 (1H, s, $\underline{H}$ at C_4). This ring-contracted product (VIII) was not obtained by treatment of IV under the same oxygenation conditions, most of the starting material being recovered unchanged. Its formation might involve initial oxygenation of the isolated 12,13-double bond[9] followed by the usual oxidation of the enamine double bond[10] and subsequent deacetylation (Norrish Type I and/or II). The same reaction of II in methanol resulted in the predominant formation of IV. Compounds IV and VIII were isolated in 24 and 3% yields. This result was in good accord with the solvent dependency

with respect to product formation in the photooxygenation of enamines.[11]

Experimental

All the mps were uncorrected. The homogenity of each compound was always checked by tlc on silica gel (Wakogel B-5), various solvent systems being used, and the spots were developed with ceric sulfate in dil sulfuric acid and/or iodine. The optical rotations and UV, IR and NMR spectra were measured in chloroform, ethanol, chloroform, and deuteriochloroform, respectively. The abbreviations "s, d, br, and m" in the NMR spectra denote "singlet, doublet, broad, and multiplet," respectively.

α,β-Unsaturated Enamine (I). 17-(1-Formylethyl)-5α, 12α-etiojerv-13(17)-en-3β-ol[3a] (V, 240 mg) was treated with acetic anhydride (5 ml) and pyridine (5 ml) at room temperature overnight. The mixture was diluted with chloroform, washed with 1 M hydrochloric acid and 5% aqueous sodium bicarbonate, dried, and evaporated to leave an oily residue (255 mg), which was purified by column chromatography (cc) over silica gel to give the 3β-acetate (Va, 180 mg), oil; Mass *m/e* 372 (M^+) and 343 (M^+—CHO); IR, ν_{max} 1728, 1252, and 1208 cm^{-1}; NMR, δ 0.76, 1.72, and 2.05 (each 3H, s, 19-, 18-, and acetoxy-C$\underline{H}_3$), 1.14 (3H, d J= 7 Hz, 21-C$\underline{H}_3$), and 3.44 (1H, br W_H=21 Hz, $\underline{H}$ at C_3), and 9.52 (1H, s, C$\underline{H}$O). This was used for the next reaction without further purification.

A solution of Va (108 mg) in a mixture of benzene (20 ml) and morpholine (0.1 ml) containing *p*-toluenesulfonic acid (PTS, 1 mg) was refluxed under nitrogen for 6 h, water being removed by means of a Dean-Stark apparatus. After removal of the solvents below 30 °C, the residue was worked up as usual to give α,β-unsaturated enamine (I, 119 mg), oil; Mass, *m/e* 441 (M^+), 426 (M^+–CH_3), and 398 (M^+—$COCH_3$); IR, ν_{max} 1720, 1644, 1256, and 1115 cm^{-1}; NMR, δ 0.81 (3H, s, 19-C$\underline{H}_3$), 2.05 (3H, s, OCOC$\underline{H}_3$), and 2.84 and 3.70 (each 4H, m W_H=13 Hz, N$C_2\underline{H}_4C_2\underline{H}_4$O), and 4.70 (1H, br W_H=21 Hz, $\underline{H}$ at C_3).

Oxygenation of I. A solution of I (108 mg) in benzene (15 ml) containing Rose Bengal (5 mg) in a Pyrex tube was bubbled with oxygen at room temperature under external irradiation with four 15-watt fluorescent bulbs (standard desk lamps) for 7.5 hr, when the starting material had disappeared on tlc. After removal of benzene, the residue was treated with water and chloroform. The chloroform extracts were worked up as usual to leave tarry material (100 mg), which was purified by preparative tlc over silica gel (Wakogel B-5) with a 1 : 1 mixture of benzene and ether to give α,β-unsaturated ketone (III, 40 mg), oil, showing a single spot; Mass, UV, IR and NMR are given in the text.

β,γ-Unsaturated Enamine (II). To a methanol solution (54 ml) of 17α-(1-formylethyl)etiojerva-5,12-dien-3β-ol[4] (VI, 605 mg) was added boron trifluoride etherate (2.0 ml) under cooling with ice, and the mixture was stirred at room temperature for 62 h under nitrogen. The solution was neutralized with 5% aqueous sodium bicarbonate and evaporated to leave an oily residue, which was worked up as usual to give the 20-aldehyde dimethyl acetal (585 mg), oil; Mass, *m/e* 342 (M^+—CH_3OH), 310 (M^+—$2CH_3OH$), and 270 [base, M^+—$CH(CH_3)CH(OCH_3)_2$]; NMR, δ 0.68 (3H, d J=7 Hz, 21-C$\underline{H}_3$) 0.98 and 1.53 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.34 (6H, s, OC$\underline{H}_3$), 4.24 (1H, d J=8 Hz, $\underline{H}$ at C_{22}), and 5.40 (1H, br W_H=9 Hz, $\underline{H}$ at C_6).

The acetal (575 mg) was dissolved in a mixture of toluene (72 ml) and cyclohexanone (3.9 ml); 30 ml of the toluene was then distilled off to remove water. Aluminium isopropoxide (530 mg) was added and, after removal of 10 ml of the toluene by distillation, the mixture was refluxed for 2.5 h and then distilled with steam to remove the organic solvents. The residue was extracted with chloroform, and the chloroform solution was washed with water, dried, and evaporated to give the corresponding Δ^4-3-ketone (569 mg), oil; UV, λ_{max} 238 nm (ε 10500); IR, ν_{max} 1666 and 1616 cm^{-1}; NMR, δ 0.69 (3H, d J=7 Hz, 21-C$\underline{H}_3$), 1.16, 1.54 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.35 (6H, s, 2OC$\underline{H}_3$), 4.22 (1H, d J= 8 Hz, $\underline{H}$ at C_{22}), and 5.80 (1H, s, $\underline{H}$ at C_4).

A solution of the α,β-unsaturated ketone (569 mg) in a mixture of acetone (170 ml) and water (30 ml) was refluxed with PTS (117 mg) for 4 h under stirring. After removal of most of the acetone, the residue was extracted with chloroform, washed with water, dried and evaporated to give 20-formyl-Δ^4-3-ketone (500 mg), oil; IR, ν_{max} 1721, 1656, and 1609 cm^{-1}; NMR, δ 0.90 (3H, d J=7 Hz, 21-C$\underline{H}_3$) 1.16 and 1.60 (3H, s, 19- and 18-C$\underline{H}_3$), 5.78 (1H, s, $\underline{H}$ at C_4), 9.68 and 9.73 (total 1H, each s, C$\underline{H}$O).

The 20-formyl-Δ^{12}-3-ketone (84 mg) in benzene (10 ml) and morpholine (0.1 ml) was treated with PTS (1 mg) in the same manner as for Va to give the 20-morpholine enamine (II, 99 mg), oil; Mass, *m/e* 395 (M^+), 380 (M^+—CH_3), 268 [M^+—(H+17-side chain)], and 127 [base, (H+17-side chain)]; IR, ν_{max} 1660, 1616, and 1116 cm^{-1}; NMR, δ 1.16 (3H, s, 19-C$\underline{H}_3$), 2.66 and 3.76 (each 4H, m, W_H=12 Hz, N$C_2\underline{H}_4C_2\underline{H}_4$O), and 5.49 and 5.82 (each 1H, s, 2$\underline{H}$ at C_{22} and C_4).

Oxygenation of II. A solution of II (337 mg) in benzene (20 ml) was oxygenated in the same manner (60 watt, 22 h, and room temperature) as for I. The reaction mixture was worked up as usual to leave an oily residue (250 mg), showing two main spots on tlc, which was separated by cc over silica gel with a 1 : 1 mixture of benzene and ether to give two crystalline compounds (IV and VIII). The former (IV, 27 mg), mp 131—133 °C on recrystallization from acetone–isopropyl ether, showed the spectra as described. The compound (IV) was also obtained by treatment of the corresponding etiojerv-5-en-3β-ol[4] (IX) under the same Oppenauer conditions as the acetal of VI. Found: C, 80.90; H, 9.15%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%. The latter (VIII, 52 mg) had mp 196—198 °C (acetone–isopropyl ether); Mass, UV, IR, and NMR in the text. Found: C, 80.36; H, 8.52%. Calcd for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51%.

Compound II (330 mg) was oxygenated in methanol (20 ml) under almost the same conditions (60 watt, 3.5 h, and room temperature) as for benzene and gave IV (63 mg), mp 129—131 °C, and VIII (15 mg), mp 189—191 °C.

The Reactions of the Dimers of Hexafluoropropene with *O*-Nucleophiles

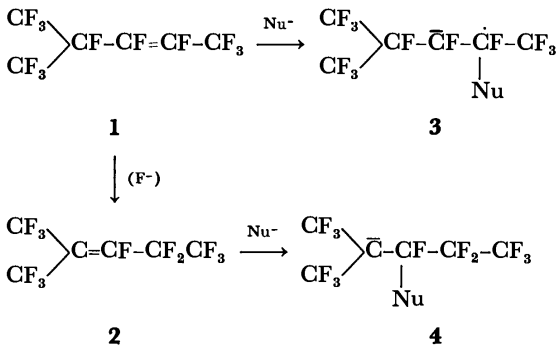
Nobuo ISHIKAWA and Akira NAGASHIMA

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received July 14, 1975)

The reactions of the dimers of hexafluoropropene with alcohols and phenol in the presence of triethylamine, and with sodium alkoxides and phenolate were carried out. Of the two dimers, perfluoro-2-methyl-2-pentene (Dimer **2**) was much more reactive than perfluoro-4-methyl-2-pentene (Dimer **1**). While the dimer **2** and *O*-nucleophiles gave various addition and substitution products very easily, the dimer **1** reacted only with sodium alkoxides to give trialkoxylated products.

Hexafluoropropene is known to oligomerize readily in the presence of a base or a fluoride ion, giving a mixture of its dimers and trimers.[1-4] The dimers are composed of perfluoro-4-methyl-2-pentene (**1**) and perfluoro-2-methyl-2-pentene (**2**), the former being predominant. However, because of the negative hyperconjugation and the electron-withdrawing inductive effect of the trifluoromethyl groups adjacent to the double bond, **2** is thermodynamically more stable than **1**, and the latter is converted into **2** by heating with potassium fluoride.[2-5] Further, **2** is likely to be more susceptible to the nucleophilic attack than **1**, because the supposed anionic intermediate, **4**, must be more stable than another intermediate, **3**.



We wish to report several results derived from the reactions of these dimers with alcohols and phenol.

Results and Discussion

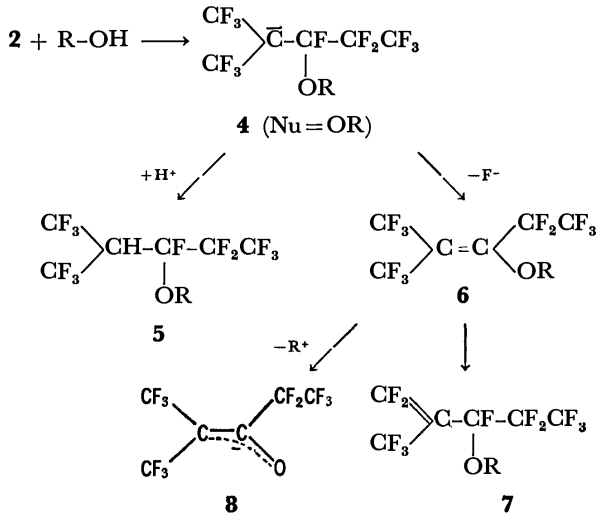
Reactions with Alcohols and Phenol in the Presence of Triethylamine. While the dimer **1** was unsusceptible to methanol under basic conditions, even when heated for a prolonged time, the dimer **2** and methanol in the presence of an equimolar amount of triethylamine reacted readily at −10—0 °C. They gave a mixture of addition and substitution products [**5** : **6** (R=Me) = 1 : 1; total, 44%], together with highly boiling products. These by-products seem to have resulted from further reactions of **6**. For example, a reactive terminal olefin, **7**, or a dealkylated ambident anion, **8**, might be formed[6] and might then react further with alcohol to give other products.

When a catalytic amount of triethylamine was used in the above reaction, the adduct, **5**, was obtained in a good yield (69%), together with a trace of the substituted product, **6**.

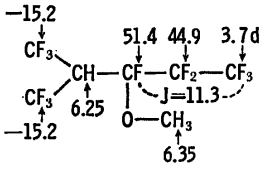
Ethanol reacted with the dimer **2** more moderately. In the presence of an equimolar amount of triethylamine, they gave a mixture of addition and substitution products, **5** and **6** (R=Et), in a ratio of 2 : 5; the total yield was rather good (71%). When the mixture was treated with aqueous potassium hydroxide, **6** was obtained as a pure product.

With a catalytic amount of triethylamine, ethanol and the dimer **2** did not react at low temperatures. At room temperature, however, they gave the substitution product (**6**) and that alone. The prevailing formation of **6** in this case is presumed to be due to the bulky OEt group, which prefers the sp^2 carbon of **6** rather than the sp^3 carbon of **5**.

This was supported by the results of the reaction between the dimer **2** and phenol. This weak and bulky nucleophile, in the presence of triethylamine, also reacted readily with **2** in diethyl ether, thus giving the substitution product, **6** (R=Ph), exclusively (65%).

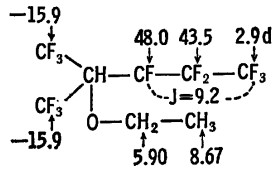


The structures of the products described above were established from various spectral data, especially the ^{19}F NMR. The chemical shifts and some of the coupling constants were as follows:*

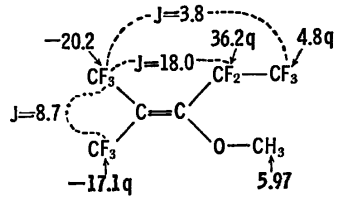


5 (R=Me)

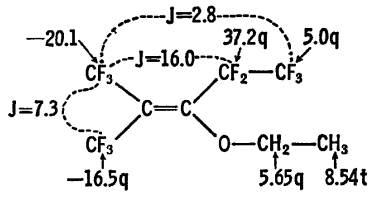
* All the ^{19}F NMR chemical shifts throughout this article are given in δ ppm from external trifluoroacetic acid. The PMR chemical shifts and the coupling constants are given in τ and Hz, as usual. All were taken in neat.



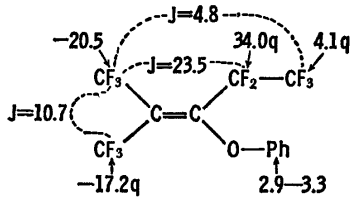
5 (R=Et)



6 (R=Me)

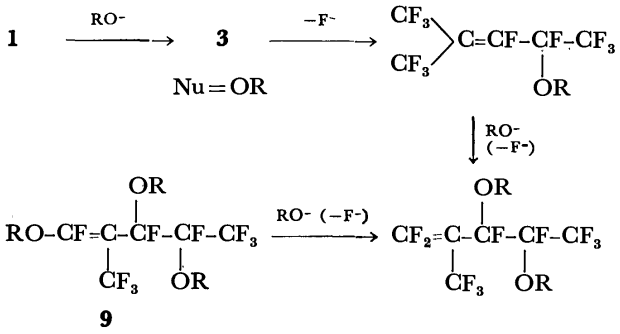


6 (R=Et)



6 (R=Ph)

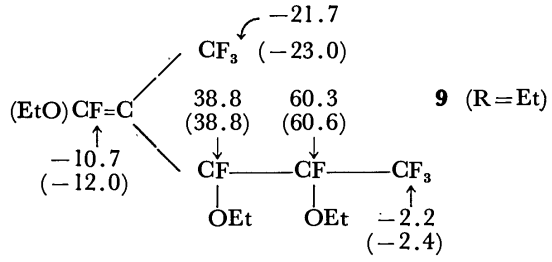
The Reactions with Sodium Alkoxides and Phenoxide. Althouth the dimer **1** did not react with alcohols in the presence of a base, it was readily attacked by sodium alkoxides at low temperatures from −10 to 0 °C. When three moles of sodium ethoxide in ethanol were used, a triethoxy-substituted product, **9**, was obtained. The reaction seemed to proceed according to an S_N2'-like mechanism as follows:



9

The crude product of this reaction partly decomposed on distillation *in vacuo*, probably because it contains a small amount of an addition product containing the EtO–CF_2–CH< group, which is hydrolyzed easily to an ester, EtO–C(=O)–CH<.

The crude product was then treated with an aqueous potassium hydroxide solution prior to distillation. The yield of the purified product thus obtained was 32%. This triethoxylated product was composed of two isomers in a ratio of 2 : 3; they were separated by means of a preparative gas chromatography. These isomers gave almost identical patterns in their IR, ^{19}F, and ^1H NMR and mass spectra. In the IR spectra, both compounds gave a strong absorption band at 1675 cm^{-1} due to the C=C double bond. In the mass spectra, strong peaks at *m/e* 333 (M^+—OEt), 233 (M^+—CF(OEt)–CF_3), and 137 ($O{=}\overset{+}{C}$–C(CF_3)=C=O)were observed for each isomer. The ^{19}F NMR chemical shifts are shown below. From these results, we assigned for the *E* and *Z* isomers to them, though we could not ascertain which was which.



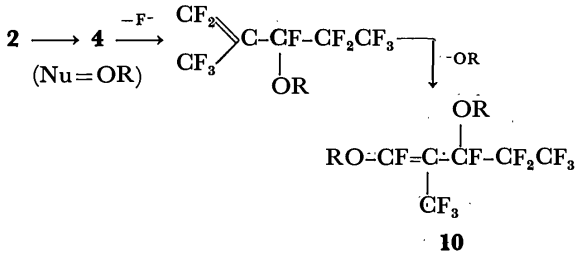
9 (R=Et)

(The values in parentheses are of the minor component)

Even when the reaction was carried out using an equimolecular amount of sodium ethoxide, the triethoxy compound was formed. This means that the second and the third steps of the above scheme proceed very fast, and that the first alkoxylation is the rate-determining step.

In the same manner, the dimer **1** and sodium methoxide gave similar trimethoxylated products, also composed of two isomers. Although the attempt to separate them from each other was unsuccessful, even by means of preparative gas chromatography, the IR and NMR spectra of the mixture supported the structure **9** (R=Me).

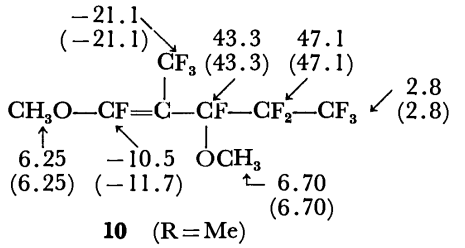
The dimer **2**, in contrast with **1**, gave dialkoxy compounds in a reaction with sodium alkoxide. The dimer **2** with a 2.2-molar amount of sodium ethoxide in ethanol below 0 °C yielded a diethoxy substituted product, **10** (R=Et). Vacuum distillation after treatment with an aqueous sodium hydroxide solution gave a pure compound in a 52% yield. The reaction path seemed to be as follows:



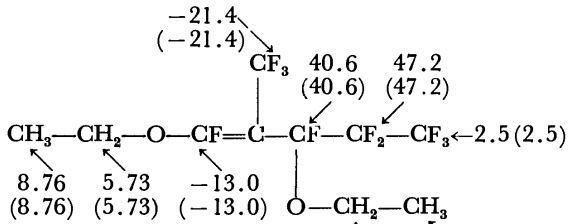
10

This ethoxylated product was also a mixture of two isomers in a ratio of 1 : 3. Since the IR, NMR and mass spectra of the mixture strongly supported the structure **10**, these two compounds are also presumed to be *E* and *Z* isomers. Sodium methoxide gave a similar dimethoxy substituted product in a 51% yield. This was also a mixture of two isomers (1 : 3). The

^{19}F NMR spectra for these products are shown below.



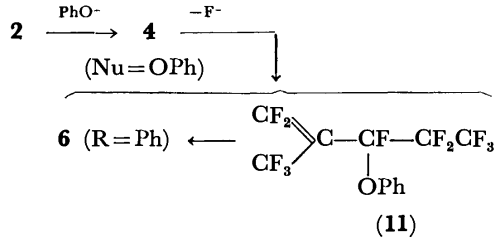
10 (R=Me)



10 (R=Et)

(The values in parentheses are of the minor component)

Sodium phenoxide, a weaker nucleophile than sodium alkoxide, was unreactive to the dimer **1**. However, the dimer **2** in diethyl ether reacted even below 0 °C, giving a mixture of monophenoxylated internal and terminal olefins, **6**(R=Ph) and **11**(2 : 11), in a total yield of 70%.



(**11**)

These phenoxylated olefins were separated from each other by means of preparative gas chromatography, and their structures were elucidated from their IR and ^{19}F NMR spectra. The IR spectrum for **11** revealed the presence of the terminal double bond by its absorption at 1725 cm^{-1}, whereas that for **6** (R=Ph) showed the absorption due to the internal double bond at 1647 cm^{-1}. As for the ^{19}F NMR spectra, **11** gave the characteristic signals for CF_2=, which appeared at −15.0 and −17.7 ppm.

When a mixture of these two isomers (**6** : **11**= 3 : 1) was treated with a catalytic amount of triethylamine in diethyl ether at room temperature, only **6** (R=Ph) was obtained. This means that the internal olefin (**6**) is thermodynamically more stable than the terminal olefin (**11**), as was previously known, and that the latter is easily converted into the former.

Experimental

Reaction of Perfluoro-2-methyl-2-pentene (Dimer 2) with Methanol in the Presence of Triethylamine. Into a mixture of the dimer **2** (9.0 g, 0.03 mol) and methanol (15 ml), was added dropwise a solution of triethylamine (3.03 g, 0.03 mol) in methanol (15 ml) at −10—0 °C. After 10 min of stirring at 0 °C, the reaction mixture was poured into dilute hydrochloric acid; the oily matter thus separated was washed with water and dried over magnesium sulfate. Distillation at an ordinary pressure gave an oil (4.2 g, 44%), bp 96—102 °C, which was a mixture of 2-trifluoromethyl-3-methoxy-1,1,1,3,4,4,5,5,5-nonafluoropentane (**5**, R=Me) and 2-trifluoromethyl-3-methoxy-1,1,1,4,4,5,5,5-octafluoro-2-pentene (**6**, R=Me) in a ratio of 1 : 1, based on the ^{19}F NMR spectrum.

When a catalytic amount of triethylamine (0.5 g, 0.005 mol) was used in this procedure, the addition product **5** (6.8 g, 69%), bp 98—99 °C, was obtained exclusively.

Found: F, 68.4%. Calcd for $C_7H_4F_{12}O$: F, 68.7%. IR: 2980 (C-H), 1150—1300 (C-F) cm^{-1}. MS: *m/e* 313 (M^+-F), 293 (M^+-HF_2), 259 ($M^+-CH_4F_3$), 213 ($M^+-C_2F_5$), 193 ($M^+-C_2HF_6$).

Reaction of the Dimer 2 with Ethanol in the Presence of Triethylamine. When ethanol instead of methanol was used in the procedure described above, it gave a mixture of 2-trifluoromethyl-3-ethoxy-1,1,1,3,4,4,5,5,5-nonafluoropentane (**5**, R=Et) and 2-trifluoromethyl-3-ethoxy-1,1,1,4,4,5,5,5-octafluoro-2-pentene (**6**, R=Et) (2 : 5), bp 110—115 °C (71%).

After the mixture (6.11 g, **5** : **6**=2 : 3) had been stirred with diethyl ether (20 ml) and a 30% aqueous potassium hydroxide solution (7 ml) for 5.5 h at room temperature, the ethereal layer was separated and washed with dilute hydrochloric acid and water successively. After being dried over magnesium sulfate, the solvent was removed and the residue was subjected to distillation, giving pure **6** (R=Et), bp 113—116 °C, in a yield of 58% (3.5 g).

Found: F, 64.2%. Calcd for $C_8H_5F_{11}O$: F, 64.1%. IR: 1635 (C=C), 1100—1400 (C-F) cm^{-1}.

Reaction of the Dimer 2 with Phenol in the Presence of Triethylamine. Into a solution of the dimer **2** (6.0 g, 0.02 mol) in diethyl ether (15 ml) was added portionwise a solution of phenol (1.88 g, 0.02 mol) and triethylamine (2.23 g, 0.022 mol) in diethyl ether (15 ml) at 0 °C. After 3 h of stirring at room temperature, the reaction mixture was washed with dilute hydrochloric acid, and then with water, and dried over magnesium sulfate. The solvent was then removed, and the residue was subjected to distillation *in vacuo*, giving 2-trifluoromethyl-3-phenoxy-1,1,1,4,4,5,5,5-octafluoro-2-pentene (**6**, R=Ph) (4.8 g, 65%); bp 69—71 °C/19 mmHg.

Found: F, 56.3%. Calcd for $C_{12}H_5F_{11}O$: F, 55.9%. IR: 1647 (C=C), 1100—1400 (C-F) cm^{-1}. MS: *m/e* 374 (M^+), 305 (M^+-CF_3), 186 (305−C_2F_5), 77 (C_6H_5).

Reaction of Perfluoro-2-methyl-2-pentene (Dimer 1) with Sodium Alkoxides. Into a mixture of the dimer **1** (9.0 g, 0.03 mol) and ethanol (15 ml), an ethanolic solution of sodium ethoxide (Na, 2.3 g, 0.01 mol and EtOH, 30 ml) was added dropwise, in a course of 1 h, while the temperature was kept at −10—0 °C. After stirring at 0 °C and then at room temperature, both times for 0.5 h, the resulting precipitate of sodium fluoride was filtered off, and the filtrate was poured into water. The separated oily matter was washed with water and refluxed for 16 h with a 15% aqueous potassium hydroxide solution in order to complete the elimination of HF from the contaminated addition product. The oily matter was separated, washed with water, and then dried over magnesium sulfate. Vacuum distillation gave a mixture of two isomers (3 : 2) of 1,3,4-triethoxy-2-trifluoromethyl-1,3,4,5,5,5-hexafluoro-1-pentene (**9**, R=Et) (3.6 g, 32%); bp 111—114 °C/16 mmHg.

Found: F, 45.2%. Calcd for $C_{12}H_{15}F_9O_3$: F, 45.2%. IR: 1675 (C=C), 1000—1400 (C-F) cm^{-1}.

A similar reaction with sodium methoxide in methanol gave an oil, bp 94—97 °C/17 mmHg, in a 57% yield. This was also a mixture of two isomers (3 : 1) of 1,3,4-trimethoxy-

2-trifluoromethyl-1,3,4,5,5,5-hexafluoro-1-pentene (**9**, R=Me). In this case, no treatment with an aqueous alkali solution was necessary.

Found: F, 50.7%. Calcd for $C_9H_9F_9O_3$: F, 50.9%. IR: 1675 (C=C), 1100—1400 (C-F) cm^{-1}.

Reaction of the Dimer 2 with Sodium Ethoxide. An ethanolic solution of sodium ethoxide (Na, 1.0 g, in EtOH, 20 ml) was vigorously stirred into the dimer **2** (6.0 g, 0.02 mol), the temperature being kept at −10—0 °C. After 30 min of stirring at 0 °C, the reaction mixture was poured into water; the resulting oily matter was separated, washed with water, and then subjected to refluxing with a 15% aqueous potassium hydroxide solution for 16 h. After washing and drying, distillation *in vacuo* gave a mixture of two isomers (3 : 1) of 1,3-diethoxy-2-trifluoromethyl-1,3,4,4,5,5,5-heptafluoro-1-pentene (**10**. R=Et), bp 81—82 °C/20 mmHg, in a yield of 52%.

Found: F, 54.0%. Calcd for $C_{10}H_{10}F_{10}O_2$: F, 54.0%. MS: *m/e* 352 (M^+), 307 ($M^+-OC_2H_5$), 233 ($M^+-C_2F_5$), 205 ($233-C_2H_4$).

The reaction with methanolic sodium methoxide was carried out in a similar manner. A mixture of two isomers of 1,3-dimethoxy-2-trifluoromethyl-1,3,4,4,5,5,5-heptafluoro-1-pentene (**10**, R=Me), bp 66—68 °C/20 mmHg, was obtained in a 51% yield.

Found: F, 59.9%. Calcd for $C_8H_6F_{10}O_2$: F, 58.6%.

Reaction of the Dimer 2 with Sodium Phenoxide. Sodium phenoxide (2.55 g, 0.02 mol) was added portionwise to a solution of the dimer **2** (6.0 g, 0.02 mol) in diethyl ether (30 ml), while the temperature was kept between −15 and 5 °C. Stirring was continued at 0 °C for 30 min and then at room temperature for 1 h. The sodium fluoride thus precipitated was removed by filtration, and the filtrate was distilled *in vacuo*. A mixture, bp 59—61 °C/15 mmHg (5.3 g, 70%), of 3-phenoxy-2-trifluoromethyl-1,1,1,4,4,5,5,5-octafluoropentene-2 (**6**, R=Ph) and 3-phenoxy-2-trifluoromethyl-1,1,3,4,4,5,5,5-octafluoro-1-pentene (**11**) (2 : 11) was thus obtained. These components were separated from each other by means of preparative gas chromatography.

(**11**): Found: F, 56.6%. Calcd for $C_{12}H_5F_{11}O$: F, 55.9%. IR: 1725 (C=O), 1100—1400 (C-F) cm^{-1}. MS: *m/e* 374 (M^+), 305 (M^+-CF_3), 281 (M^+-OPh), 255 ($M^+-C_2H_5$).

Palladium-catalyzed Decomposition of Azides. I. Formation of Nitriles

Hiroshi HAYASHI, Atsuyoshi OHNO, and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto-Fu 611

(Received July 16, 1975)

Palladium metal catalyzes the decomposition of benzyl azide affording benzonitrile, benzylamine, and *N*-benzylidenebenzylamine. The presence of a suitable hydrogen-acceptor improves the yield of benzonitrile at the sacrifice of benzylamine, whereas the yield of *N*-benzylidenebenzylamine remains constant. The reaction is applied to the preparation of other nitriles.

Azide group possesses many qualities that enable it an excellent starting group for organic synthesis. It can be introduced into an organic moiety by several convenient methods, even in the presence of various other functional groups.[1] The dipolar character and the reactivity (or instability) of the azide group make it react in a variety of fashions.[2] However, surprisingly little is known on its application to organic syntheses except for the syntheses of amines by reduction, carbonyl compounds by acid-catalyzed decomposition, and heterocyclic compounds by 1,3-dipolar addition. Some other transformations are restricted to azides of limited structures.[2]

In the course of our studies on the chemistry of the azide group,[3] we have found that a primary azide can be transformed into the corresponding nitrile by catalysis of palladium metal under such a mild condition as below 80 °C in neutral solutions. In this paper will be reported the procedure, scope, and limitation of the reaction.

It should be emphasized that the present procedure provides a method to obtain various nitriles *without* elongating the skeletal carbon-chain.

Results and Discussion

When a mixture of benzyl azide (**1**) and a catalytic amount of palladium black in benzene was refluxed for 30 min, benzonitrile (**2**), benzylamine (**3**), dibenzylamine (**4**), and *N*-benzilidenebenzylamine (**5**) were obtained in 43, 29, 2, and 27% yields, respectively.

$$\underset{\mathbf{1}}{PhCH_2N_3} \xrightarrow[PhH]{Pd^0} \underset{\mathbf{2}}{PhCN} + \underset{\mathbf{3}}{PhCH_2NH_2} + \underset{\mathbf{4}}{(PhCH_2)_2NH} + \underset{\mathbf{5}}{PhCH{=}NCH_2Ph}$$

The same, but a little bit slower, reaction took place at temperatures as low as 40 °C provided the mixture was set under an atmosphere of nitrogen. Ethanol could be replaced for benzene, whereas amines retarded the reaction appreciably. High-dilution technique, employed to avoid unnecessary bimolecular reaction of **1**, did not alter the yields of products. The results are summarized in Table 1.

Contrary, in the presence of a suitable compound such as 2,5-dimethyl-3-hexyne-2,5-diol or diphenylacetylene increased the yield of the nitrile greatly at the sacrifice of that of the amine (Table 2). Apparently these compounds play a role of a hydrogen-acceptor. Table 2 also shows that the high-dilution technique is effective when the reaction is run in the presence of a hydrogen-acceptor. Although in order to extend the scope of the reaction, one has to deal with azides of various types, some (especially low-molecular-weight aliphatic) azides are, unfortunately,

explosive and hazardous to be isolated.[4] Therefore, we have investigated a procedure to transform a halide into the corresponding nitrile without isolating the intermediate azide. Namely, benzyl chloride was reacted with sodium azide in dimethylformamide (DMF) at 70 °C for 2 h and the benzene-extract of the reaction mixture was subjected to the palladium-catalyzed decomposition. The results are listed in Table 3 together with those from substituted benzyl halides. Since the maximum yield of benzonitrile from benzyl azide was 75—76%, the present result is satisfactory. The distribution of the yield for *p*-methoxy-, *p*-chloro-, and unsubstituted benzonitrile may be accounted for by the different yields of the corresponding azides. The situation of *p*-nitrobenzonitrile is somewhat different: the reaction of *p*-nitrobenzyl bromide with sodium azide takes place more smoothly than those of other benzyl halides.

a) Reaction in DMF. b) See footnote (b) in Table 3. c) See footnote (c) in Table 3. d) See footnote (d) in Table 3. e) A controlled experiment. f) Reaction in water. g) Reaction with 100 mg of palladium on charcoal.

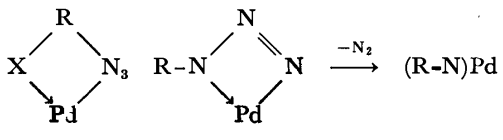
However, the *p*-nitro group behaves as a hydrogen-acceptor, which has been confirmed by a controlled experiment with benzyl azide and nitrobenzene, yielding a complex mixture of products. Palladium on charcoal was more effective catalyst than palladium black for this particular compound.

In Table 3 are also listed results on the reaction of phenethyl chloride and its analogs. It is interesting to note that the reaction of 3-azido-1-phenyl-1-propene proceeded without appreciable reduction of the internal double bond, whereas about 30% of styrene, *cis*- or *trans*-stilbene was reduced to the corresponding alkylbenzene when used as a hydrogen-acceptor for the decomposition of benzyl azide. This fact suggests that, unlike the nitro group, nonpolar carbon-carbon double bond has less facility to coordinate onto palladium than the polar azido group.

The decomposition of neophyl (2-methyl-2-phenylpropyl) azide is quite normal in the sense that it affords 2-phenyl-2-propyl cyanide in 47 and 77% yields in the absence and presence of a hydrogen-acceptor, respectively, whereas neophyl chloride gives the corresponding result only when it is subjected to the decomposition catalyzed by palladium on charcoal in the absence of a hydrogen-acceptor. Pre-treatment of the benzene extract by activated charcoal did not improve the yield when palladium black was used as a catalyst. The yield of neophyl azide from neophyl chloride was found to be 92%. Thus the factor(s) which affects the reaction starting from neophyl chloride is unpredictable.

The procedure has also been applied to aliphatic halides and the results are summarized in Table 4. Halides that have *n*-alkyl chain gave satisfactory results, whereas these branched at the β-position reacted less readily. Since neophyl azide reacts normally, the present result cannot be accounted for by steric effect, which is proposed for explaining the difference in reactivity of primary and secondary alkyl halides toward palladium.[5]

When a halide is substituted by a polar functional group, the reaction is greatly retarded and the yield of nitrile is reduced. The most extreme example can be seen in the reaction of *vic*-diazides: in spite of an expectation that the reaction of *vic*-diazides might afford α-amino nitriles, no decomposition of the azido group took place. This fact may be interpreted by the coordination of the functional group onto palladium (**6**) preventing the bidentate coordination of the azido group (**7**).[6] The latter coordination is necessary to loose the nitrogen-nitrogen bond to form an active species **8**.



6 **7** **8**

Experimental

Materials. Benzyl azide (bp 86—87 °C/20 mmHg (*lit*,[7] 82.5 °C/16.5 mmHg), n_D^{14} 1.5407), *p*-chlorobenzyl azide (bp 80—82 °C/1.5 mmHg, n_D^{15} 1.5600),[8] and diphenylacetylene (mp 60—61 °C (*lit*,[9] mp 60—61 °C)) were prepared according to the literature, respectively. Halides, obtained from commercial sources or by well known methods, were purified by distillation or recrystallization prior to use. Solvents were distilled and kept over Molecular Sieves 4A. Other reagent-grade chemicals were used without further purification unless otherwise indicated.

2-Ethylhexyl Azide. A mixture of 2-ethylhexyl bromide (9.7 g, 0.05 mol) and sodium azide (6.5 g, 0.1 mol) in DMF (25 ml) was stirred at 70 °C for 15 h. The reaction mixture was poured into 250 ml of water and organic materials were extracted with one 100 ml portion of ether. The extract was washed with three 50 ml portions of water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The residual oil was distilled yielding 5.8 g (74% yield) of 2-ethylhexyl azide: bp 81—82 °C/20 mmHg; n_D^{16} 1.4430; ν_{N_3} 2100 cm^{-1}. Found: C, 62.11; H, 11.10; N, 27.02%. Calcd for $C_8H_{17}N_3$: C, 61.89; H, 11.04; N, 27.07%.

Neophyl Azide. Starting from 8.4 g (0.05 mol) of neophyl chloride, 6.5 g (0.1 mol) of sodium azide, and 35 ml of hexamethylphosphoric triamide (HMPA), 6.1 g (70% yield) of neophyl azide was obtained: bp 90—91 °C/3 mmHg; n_D^{22} 1.5266; ν_{N_3} 2100 cm^{-1}. Found: C, 68.34; H, 7.73; N, 24.18%. Calcd for $C_{10}H_{13}N_3$: C, 68.54; H, 7.48; N, 23.98%.

Procedure. Method A. A mixture of benzyl azide (2.0 mmol) and palladium black (10 mg) in benzene (4.0 ml) was refluxed for 30 min or stirred for 1.5 h at 40 °C under an atmosphere of nitrogen. It was necessary to exclude air from the system when the reaction was carried out without refluxing, otherwise no reaction took place even after 12 h.

To the reaction mixture were added 200 mg of biphenyl as an internal standard, 4 ml of ether, and 10 ml of water.

The ether extract was subjected to vpc analyses on Yanagimoto G1800 with a column of Silicon DC-200 (1 m, 150 °C, H_2 0.4 kg/cm^2) or BDS (1 m, 120 °C, H_2 0.2 kg/cm^2).

Method B. Into a refluxing mixture of palladium black (10 mg) and benzene (4.0 ml) was infused benzyl azide (2.0 mmol) over a period of 2 h. The whole mixture was refluxed for additional 15 min and the products were analysed as described above.

In some experiments 100 mg of palladium on charcoal (5%) was employed in place of palladium black yielding similar results. Ethanol could be substituted for benzene, but amines were not good solvents for the reaction (Table 1).

Method C. In a typical run, 20 mmol of a halide and 40 mmol of sodium azide in 10 ml of a solvent were stirred. The solvent, reaction temperature, and reaction period are shown in Tables 3 and 4. The reaction mixture was poured into water (100 ml) and 2.0 g of biphenyl (an internal standard for vpc analyses) was added. The organic materials were extracted with one 20 ml portion of benzene. The extract was washed with three 25 ml portions of water and dried over anhydrous sodium sulfate. A 2.0 ml aliquot of the benzene solution was subjected to palladium-catalysis with the Method A or B and the products were analyzed on vpc as described above. When the reaction required more than an hour, only the Method A was employed.

Identification of Products. In a typical run 3.3 g (0.02 mol) of *p*-chlorobenzyl azide was added to a refluxing mixture of 2,5-dimethyl-3-hexyne-2,5-diol (2.8 g, 0.02 mol) and palladium black (0.1 g) in benzene (20 ml) over a period of 1 h and the whole mixture was refluxed for additional 10 min. The reaction mixture was filtered and the filtrate was washed with four 25 ml portions of water. The organic layer was dried over $CaCl_2$ and the solvent was evaporated *in vacuo* The residue was distilled at a bath temperature of 95 °C under a pressure of 20 mmHg.

The distillate was recrystallized from cyclohexane giving 1.6 g (60% yield) of *p*-chlorobenzonitrile: mp 91—93 °C (*lit*,[10] mp 89—91 °C).

The nonvolatile substance was recrystallized from hexane giving 0.5 g (20% yield) of *N*-(*p*-chlorobenzyliden)-*p*-chlorobenzylamine: mp 58—60 °C (*lit*,[11] mp 62—65 °C).

The aqueous layers were combined and extracted with 50 ml of ether. The ether layer was washed with three 25 ml portions of water and dried over $CaCl_2$. The solvent was evaporated *in vacuo* and the residue was recrystallized from benzene yielding 1.0 g (40% yield) of *cis*-2,5-dimethyl-3-hexene-2,5-diol: mp 68—69 °C (*lit*,[12] mp 68—69 °C).

Stereoselective and Stereospecific Reactions. III.[1] Benzoylation, Cyclization, and Epimerization of Diols

Oyo MITSUNOBU, Junji KIMURA, Ken-ichi IIZUMI, and Noboru YANAGIDA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received July 19, 1975)

The benzoylation of various classes of diols by means of diethyl azodicarboxylate (**1**) and triphenylphosphine (**2**) was carried out at room temperature. When primary-secondary diols were treated with an equimolar amount of benzoic acid (**3**) in the presence of 1.5 molar equivalents of **1** and **2**, reaction mainly occurred at their primary hydroxyl functions. Secondary-secondary diols gave mono- and dibenzoylated products or cyclic ethers. The course of the reactions depends on the structure of diols used. Thus, intermolecular displacement giving benzoates is a favorable process for 1,3-butanediol, 2,4-pentanediol and *trans*-1,2-indanediol, while 2,5-hexanediol and *trans*-1,2-cyclohexanediol afford the cyclized products.

For the past several years studies have been carried out on the intermolecular dehydration between alcohols and active hydrogen compounds by means of diethyl azodicarboxylate (**1**) and triphenylphosphine (**2**). The reaction of nucleosides with dibenzyl hydrogen phosphate and with benzoic acid (**3**) in the presence of **1** and **2** predominantly gave 5'-*O*-phosphorylated and 5'-*O*-benzoylated products, respectively.[2] Stereospecificity and functional selectivity were also observed in the alkylation of imides.[3] Bose *et al.*[4] reported that the present system could be utilized in the inversion of unhindered sterol configuration. In this paper, we wish to report the benzoylation of simple diols by the use of **1** and **2**.

Primary, Secondary-Diols. When 1,3-butanediol was allowed to react with an equimolar amount of **3** in the presence of 1.5 molar equivalents of **1** and **2** at room temperature, 3-hydroxybutyl benzoate was formed in a 70% yield. A small amount (7%) of dibenzoylated product was also isolated. Similarly, 1-phenyl-1,2-ethanediol or 3-chloro-1,2-propanediol predominantly gave monobenzoate. When 1.5 molar equivalent of **3** was used in the benzoylation of 1,3-butanediol, the yields of 3-hydroxybuthyl benzoate and 1,3-bis(benzoyloxy)butane increased to 80% and 10%, respectively. The results are summarized in Table 1.

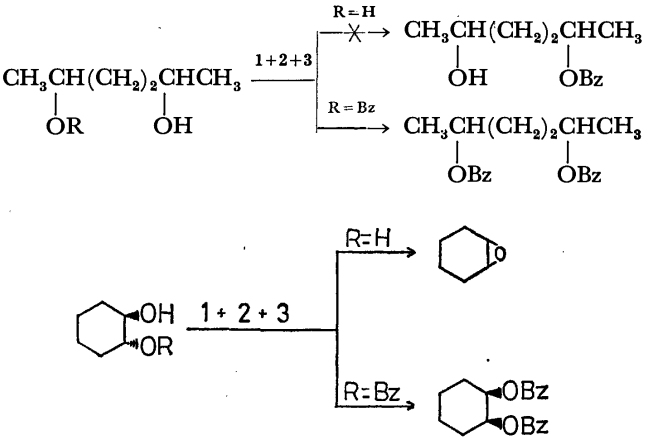
a) Solvent systems used for separation of products. See Table 1. b) The ratio of the 1-benzoylated and 2-benzoylated products is 1.4 : 1.

3-Hydroxybutyl benzoate and 3-chloro-2-hydroxypropyl benzoate reacted smoothly with **3** under the above conditions to give 1,3-bis(benzoyloxy)butane and 1,2-bis(benzoyloxy)-3-chloropropane in good yields.

Primary, Primary-Diols and Secondary, Secondary-Diols. Under the same conditions as for the reaction of primary–secondary diols, 1,3-propanediol gave 3-hydroxypropyl benzoate and 1,3-bis(benzoyloxy)propane in 65% and 12% yields, respectively. 1,4-Butanediol afforded monobenzoate and dibenzoate in 66% and 15% yields, respectively.

The benzoylation of secondary–secondary diols was then attempted. The reaction of 2,4-pentanediol with 1.5 molar equivalents of **1**, **2** and **3** proceeded with ease giving 4-hydroxy-2-pentyl benzoate and bis(benzoyloxy)pentane in 57% and 20% yields, respectively. *trans*-1,2-Indanediol gave a mixture of 1-hydroxy-2-benzoyloxy- and 1-benzoyloxy-2-hydroxyindanes in a 50% yield. 2,3-Butanediol, 2,5-hexanediol or *trans*-1,2-cyclohexanediol hardly gave benzoylated products. On the other hand, 5-benzoyloxy-2-hexanol and *trans*-2-benzoyloxycyclohexanol reacted smoothly with **3** in the presence of **1** and **2** to give 2,5-bis(benzoyloxy)hexane and 1,2-bis(benzoyloxy)cyclohexane in good yields. The results are summarized in Table 2.

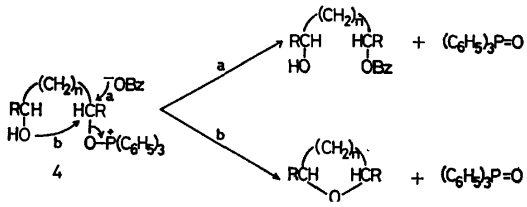
Secondary–secondary 1,2- and 1,4-diols gave no corresponding benzoates, while monobenzoates of these diols were converted into dibenzoates. The contrast between these reactions can therefore be explained by assuming the facile formation of three- and five-membered cyclic ethers. In order to confirm cyclization, the mixture resulting from the reaction of *trans*-1,2-cyclohexanediol with **1**, **2** and **3** was subjected to gas chromatography(glc). The resulting chromatogram revealed the formation of cyclohexene oxide in an 82% yield.



Scheme 2

The cyclization reaction would be rationalized in terms of intramolecular participation by a neighboring hydroxyl group in the initial alkoxyphosphonium salt (**4**) presumed as an intermediate of the present reaction.[5] If steric crowding renders intermolecular displacement slow and the hydroxyl group in the substrate molecule is at a suitable distance from the carbon site of substitution, three- or five- membered ring formation takes place predominantly. Somewhat related cases of cyclization have been observed in the reaction of

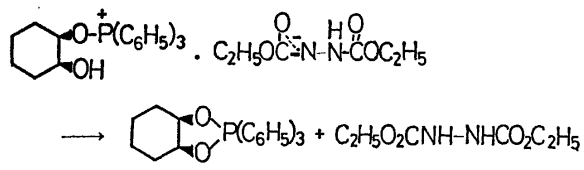
nucleosides.[6]



Scheme 3.

When 2,5-hexanediol was allowed to react with **1** and **2** in the absence of **3** at room temperature, 2,5-dimethyloxolane was formed in a 48% yield as determined by glc. The 2,5-dimethyloxolane was isolated by preparative glc and identified by comparison of its NMR spectrum with that of an authentic sample. Similarly, *trans*-1,2-cyclohexanediol and 1-phenyl-1,2-ethanediol were converted into the corresponding oxiranes.

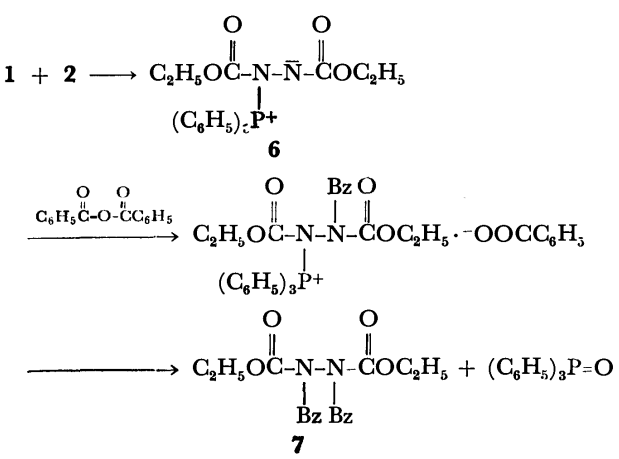
Compared with the benzoylation of acyclic diols, *cis*-1,2-cyclohexanediol gave the benzoate in low yield (22%). The difference would be ascribed in part to conformational strain.[7] Although no direct evidence could be obtained, the formation of 1,2-*O*-(triphenyl)-phosphoranylcyclohexane (**5**) can not be ruled out.[8]



5

Scheme 4.

In some cases, for example in the benzoylation of *trans*-2-benzoyloxycyclohexanol, a small amount of *N,N'*-dibenzoyl-*N,N'*-bis(ethoxycarbonyl)hydrazine (**7**) was isolated. The formation of **7** would be explained as follows. Intermolecular dehydration between alcohols and carboxylic acids by means of **1** and **2** proceeds through initial activation of the alcohol.[5] In the reaction using sterically crowded alcohols, however, it is most likely that activation of carboxylic acid occurs to some extent giving the corresponding acid anhydride.[9] The anhydride fomed in turn reacts with the phosphonium salt (**6**) to afford **7**. In order to confirm this process, **1** was allowed to react with **2** in the presence of benzoic anhydride, **7** being isolated in an 80% yield.

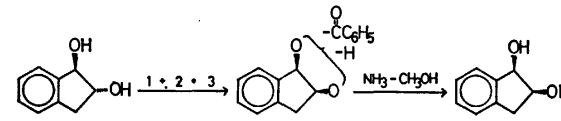


6

7

Scheme 5.

Stereochemistry. In order to examine the stereochemistry of the benzoylation of diols using a combination of **1** and **2**, a mixture of 1-hydroxy-2-benzoyloxy- and 1-benzoyloxy-2-hydroxyindanes, prepared from *trans*-1,2-indanediol, was treated with ammonia saturated in methanol affording *cis*-1,2-indanediol in a 60% yield. That 2-benzoyloxycyclohexanol derived from *cis*-1,2-cyclohexanediol by the present procedure has *trans*-configuration was proved by comparison of its NMR and IR spectra with those of an authentic sample.



Scheme 6.

Experimental

Nuclear magnetic resonance spectra were measured on a Hitachi R-20 spectrometer using tetramethylsilane as an internal standard. Mass spectra were obtained at 70 eV on a Hitachi 6M-GC gas-chromatogram-mass spectrometer, infrared spectra on a JASCO-IRG. Gas-chromatographic analyses were performed on a Hitachi 063 instrument with a flame ionization detector, and 1 m×3 mm column of 20% SE-30 on Celite 545 (60—80 mesh). Preparative separation of cyclic ethers was made on a Shimadzu GC-1C gas chromatograph with a 1.82 m×1 cm column of 20% SE-30 on Celite 545 (60—80 mesh). Thin layer separation was carried out on silica gel PF_{254} (Merck: 20 cm×20 cm or 20 cm×30 cm) and visualization was by UV light.

Diethyl azodicarboxylate,[10] 2,4-pentanediol,[11] 1-chloro-3-benzoyloxy-2-propanol,[12] *cis*- and *trans*-1,2-cyclohexanediols,[13,14] and *trans*-1,2-indanediol[15] were prepared by procedures in literature. *cis*-2-Benzoyloxycyclohexanol was prepared in a yield of 54% by the reaction of *cis*-1,2-cyclohexanediol (348 mg, 3 mmol) with benzoic anhydride (678 mg, 3 mmol) in pyridine for 12 hr. The product was isolated by preparative tlc (ether–petroleum ether 1 : 1). Similarly, *trans*-2-benzoyloxycyclohexanol was prepared in a 63% yield. 5-Benzoyloxy-2-hexanol was prepared in a 33% yield by the reaction of 2,5-hexanediol (354 mg, 3 mmol) with benzoic anhydride (678 mg, 3 mmol) in pyridine at room temperature for 4 hr, followed by tlc separation (ether–petroleum ether 1 : 5).

General Procedure of Benzoylation of Diols and their Monobenzoates. A solution of **1** (261 mg, 1.5 mmol) in tetrahydrofurane (THF, 2 ml) was added dropwise over a period of 1 hr to a solution of primary-primary diol or primary-secondary-diol (1 mmol), **2** (393 mg, 1.5 mmol) and **3** (122 mg, 1 mmol) in THF (2 ml) with stirring at room temperature. After 12—14 hr, the mixture was fractionated by preparative tlc.

In the case of benzoylation of secondary-secondary diols, 1.5 molar equivalent of **3** was used.

Benzoylation of trans-*1,2-Indanediol.* A solution of **1** (261 mg, 1.5 mmol) in 2 ml of THF was added dropwise to a solution of *trans*-1,2-indanediol (150 mg, 1 mmol), **2** (393 mg,

1.5 mmol) and **3** (183 mg, 1.5 mmol) in THF (3 ml) under reflux. After the solution had been refluxed for 5 hr, a mixture of 1-benzoyloxy-2-hydroxyindane and 1-hydroxy-2-benzoyloxyindane was isolated by tlc (benzene) in a 50% yield. The ratio was calculated to be 1.4 : 1 from the integration of NMR absorption. When the reaction was carried out at room temperature, the yield of the mixture of the monobenzoates decreased to 30%.

cis-*1,2-Indanediol.* The mixture of monobenzoates obtained by the reaction of *trans*-1,2-indanediol with **1, 2** and **3** was treated with methanol saturated with ammonia at room temperature for 24 hr. After removal of the solvent, *cis*-1,2-indanediol was isolated in a 60% yield by preparative tlc. The *cis*-diol was recrystallized from ethyl acetate–petroleum ether, mp 94—96 °C (lit.[15] mp 98 °C).

Cyclization of Diols. Cyclohexene Oxide. A solution of **1** (1.74 g, 10 mmol) in ether (8 ml) was added dropwise over a period of 2 hr at room temperature to a solution of *trans*-1,2-cyclohexanediol (1.16 g, 10 mmol) and **2** (2.62 g, 10 mmol) in ether (12 ml). After the mixture had been kept stirring overnight, white precipitates were removed by filtration (1.40 g). The filtrate was distilled and the fraction boiling at 80—130 °C was collected. The distillate was then subjected to preparative glc to yield pure cyclohexene oxide. Cyclohexene oxide isolated was identical (IR, NMR and mass spectra) with that prepared by independent synthesis.

By a separate experiment, the yield of the cyclohexene oxide was determined to be 68% by glc analysis using tetraline as an internal standard. Similarly, 2,5-hexanediol and 1-phenyl-1,2-ethanediol were converted into 2,5-dimethyloxolane and 2-phenyloxirane in 48% and 27% yields, respectively.

Reaction of Benzoic Anhydride with 1 and 2. To a solution of benzoic anhydride (226 mg, 1 mmol) and **2** (262 mg, 1 mmol) in THF (2 ml) was added dropwise over a period of 1 hr at room temperature a solution of **1** (174 mg, 1 mmol) in THF (1 ml). After the solution had been kept stirring overnight, **7** was isolated in an 80% yield by preparative tlc (ether–petroleum ether 1 : 1). The material was recrystallized from ether–petroleum ether, mp 82—83 °C: IR (KBr) cm^{-1} 1750, 1710 (C=O); NMR (CCl_4) δ 1.05 (t, 6H), 4.13 (q, 4H), 7.1—8.0 (m, 10 H).

Anisotropy of Needle Cokes

Isao MOCHIDA, Masashi OGAWA, and Kenjiro TAKESHITA
Research Institute of Industrial Science, Kyushu University, Fukuoka 812
(Received July 30, 1975)

The anisotropic properties of several lump needle cokes were studied by means of a X-ray diffractometer, a dilatometer, and a reflected microscope in order to evaluate the anisotropic factors of the needle cokes and to discuss the relations among them. Among them several relations were found, which were well understood on the basis of the structure of the uniaxial arrangement of the crystallites. The change in these factors upon heat treatment was also investigated in order to find how these factors depended on the crystal-growth of the needle coke. Some anisotropic properties of the extruded sample were compared with those of the filler coke, which were observed in a lump shape. The results indicate that the extruded sample had its anisotropic properties considerably lowered. The structure and crystal-growth of the needle cokes are discussed based on these observations.

The carbons used for the ultra-high-power electrodes have been required to be so-called needle-like cokes, which should have not only a good crystallinity but also a highly oriented structure.[1] It is recognized that the needle cokes exhibit high anisotropy in various properties, such as thermal expansion, thermal and electric conductivity, and Hall current.[2]

Mrozowski[3] and other researchers[4] described the structure of the needle cokes. The anisotropic properties of needle cokes in extruded or molded samples have been extensively studied, and the relations among them have been discussed.[2,5] However, some problems regarding the nature and structure of the needle cokes seem to be still open. A study of lump cokes may help us to understand the needle cokes, because there is no disturbance brought about by binder cokes and different degree of preferred orientation at the shaping.

In the present study, the anisotropy of lump needle cokes has been observed by means of microscopic observation, CTE measurement, and X-ray diffraction,[6-8] and the relations among the anisotropy factors have been studied on cokes heat-treated at graphitizing temperatures. The methods of measuring the anisotropy of powdered cokes have also been surveyed because the small batch reactors often give powdered cokes, even though they are needle-like. We also intend to discuss the structure of needle cokes on the basis of these data.

Experimental

Sample Cokes. Five kinds of filler cokes (A, B, C, D, E) and three kinds of extruded samples (B, F, G) were used in the present study. They were all commercially available; some of their properties are summarized in Table 1.

TABLE 1. DESCRIPTION OF COKES USED IN THE PRESENT STUDY

Sample	Source	Starting pitch	Structure	Shape
A	Petro Cokes Ltd.	petroleum	needle	lump
B	GLW	petroleum	mosaic	lump, extruded
C	Koa Petro Co.	petroleum	needle	lump
D	Nittetsu Chem Co.	coal tar	mosaic	lump
E	Nittetsu Chem Co.	coal tar	needle	lump
F	Petro Cokes Ltd.	petroleum	needle	extruded
G	Petro Cokes Ltd.	petroleum	needle	extruded

Experimental Procedure. Calcination and Graphitization: Cokes were calcined at 1300 °C under a nitrogen flow. The calcined cokes were further graphitized at 2000 °C or 2500 °C for 0.5 hr under an argon flow. The heating rates were 20 °C/min up to 2000 °C and 10 °C/min up to 2500 °C.

Microscopic Observation and Measurement of Thermal Expansion: The optical structure of cokes and the graphites were observed using a Leitz Ortholux microscope with reflected polarized light under crossed nicols. The cokes were cut both parallel and perpendicular to the direction of the needle. They were then mounted in a cylinder of epoxy resin in order for the desired plane to be fixed on the surface of the cylinder, and were ground with several grades of alumina. As for mosaic cokes, the direction of cutting made no difference in the value of CTE or the features of microscopic observation, so each specimen was cut arbitrarily.

Thermal expansion was measured between 350° and 450 °C with a specimen heated at the rate of 10 °C/min in a vacuum. A dilatometer of a comparative type referring to the standard sample of silica (Shinku-Riko DL-1500H) was used. A cylindrical specimen 8 mm in diameter and 20 mm long was cut both parallel and perpendicular to the direction of the needle-like texture in order to obtain values of CTE parallel and perpendicular to the texture.

X-Ray Diffraction Analysis. Measurement of Crystallographic Parameters:[9] The calcined cokes and graphitized carbons were analyzed by X-ray powder diffraction Cu$K\alpha$ produced at 30 KV and 15 mA being used. The lattice constant (C_0) and the average crystallite thickness (L_c) were determined from the (002) diffraction peak. Silicon was used as the internal standard.

Measurement of Degree of Preferred Orientation: 1) Bacon Anisotropy Factor (BAF): The preferred orientation of both filler and extruded samples was measured by transmission X-ray diffraction according to the method proposed by Bacon.[6] A rectangular specimen 1 mm thick and 1 cm square was cut parallel to the direction of the needle-texture of the cokes. The intensity of the (002) reflection, $I(\phi)$, was observed at angles of every ten degrees from the normal direction of the texture. The area which was exposed to the X-ray was a circle 3 mm in diameter. BAF was calculated by the numerical integration of $I(\phi)$ based on the following equation:[6]

$$\mathrm{BAF} = \frac{1}{2}\frac{\int_0^{\pi/2} I(\phi)\sin^3\phi\,\mathrm{d}\phi}{\int_0^{\pi/2} I(\phi)\cos^2\phi\sin\phi\,\mathrm{d}\phi}$$

A random distribution of the crystallites will give equal intensities of (002) peaks against every ϕ, so that BAF is unity.

2) Method proposed by Noda and Inagaki[7] and Walker

et al.[8]: The following equation of the anisotropy factor (γ_1) was used in the present study:

$$\gamma_1 = \frac{I(002)_{/\!/}}{I(002)_{/\!/}+K\{I(100)_{/\!/}+I(101)_{/\!/}\}} \Big/ \frac{I(002)_{\perp}}{I(002)_{\perp}+K\{I(100)_{\perp}+I(101)_{\perp}\}}$$

where $I_{/\!/}$, and $I_{\perp}$ represent the intensities from the (002), (100) and (101) diffraction peaks in the planes parallel and perpendicular to the direction of the needle texture respectively. The constant, K, was fixed at 5.56 so as to set the γ_1 of the completely non-oriented sample as unity. Because the intensities of the (004) and (110) peaks were as weak as for cokes calcined below 2000 °C, the (002), (101), and (100) peaks were used instead, modifying the equation proposed by Noda and Inagaki.[7] The area exposed to X-ray in the reflection method was roughly 1 cm square.

Results

Comparison of Filler Cokes. The reflected micrographs and physical and structural properties of five cokes calcined at 1300 °C are shown in Photo 1 and Table 2 respectively. Cokes A, C, and E consisted of a flow-pattern structure, small values of CTE parallel to the direction of the texture, and large values of the anisotropic factors of both BAF and γ_1. In contrast, Cokes B and D, which showed a disordered mosaic unit-structure of several ten microns, have large CTE values and anisotropic factors near unity. The CTE values seem related to the anisotropy factors, although CTE should depend not solely on the anisotropy factor. The similar values of L_c and C_0, regardless of the kind of coke, might play some roles for such a relation, because Engle,[5a] Matsumoto and Sasaki[10] showed a slight dependence of CTE on *Lc*. Closed porosity should also be taken into account, as has been pointed by several researchers.[11] Thus, the microscopic observations and the values of BAF, γ_1, and CTE may be considered to be indications of the needle-like structure of the cokes.

Dependence of Properties of the Needle Coke on the Calcination Temperatures. Because Table 2 indicates that A coke is the best needle coke in regard to CTE, BAF, and γ_1, the dependence of its properties on the calcination temperatures was investigated in order to clarify the relation among these properties. The reflected microscopic photographs of the plane parallel or perpendicular to the direction of the needle texture are shown in Photo 2. The preferred orientation of the crystallites is clearly observed on the parallel plane, whereas a disordered mosaic structure is shown on the perpendicular plane. No essential change in the visible structure was observed upon further heat treatment up to 2500 °C, except for the development of cracks along the needle texture on the parallel plane at higher calcination temperatures. The orientation of the cracks was not observed at all on the perpendicular plane, although they run along the anisotropic boundary.

The CTE values of the cokes calcined at 600 °C were still very large on both the parallel and perpendicular planes, as is shown in Table 3, although the anisotropic nature ($\alpha_{\perp}/\alpha_{/\!/}>1$) had previously been observed. As the shrinkage of the needle texture and cracks parallel to the texture appeared at the calcination temperature of 1300 °C, the CTE value

decreased. The value, however, did not decrease appreciably upon further heat treatment. Although the ratios of $\alpha_\perp/\alpha_{//}$ had a rather poor accuracy because of the difficulty of accurately measuring small $\alpha_{//}$ values of cokes calcined at higher temperatures, a significant increase in $\alpha_\perp/\alpha_{//}$ was observed at 1300 °C as the marked decreases of $\alpha_\perp$ and $\alpha_{//}$ occurred. In contrast, only slight changes were observable in the values of C_0, L_c, and BAF between 600 °C and 1300 °C, as is shown in Table 3. However, the background around 23°(2θ) in the X-ray diffraction pattern decreased for the sample calcined at 1300 °C, indicating that the amorphous part decreased upon heat treatment at this temperature. No more evolution of gas was observed above 1300 °C.

C_0 (Å)	6.884	6.762	6.725	6.891	6.747
L_c (Å)	28	540	810	27	655

The two anisotropy factors obtained in turn by X-ray diffraction changed considerably between 1300 and 2000 °C, and both settled above 2000 °C. The crystal growth of the carbon continued up to 2500 °C, as is indicated by the increasing $L_c(002)$ value and the decreasing $C_0(002)$ value. The relation among these properties of cokes calcined at different temperatures will be discussed later.

The needle-like cokes, C and E, showed increases in the anisotropic factor and the crystal growth similar to those of the A coke (Table 4), although their starting pitches were different. In contrast, mosaic cokes showed no improvement in anisotropic factors at all up to 3000 °C, at which point a significant crystal growth was observed much as with needle-like cokes (Table 5).

The X-ray observations indicate that the anisotropy, one of important qualities of the needle-like cokes, is a property connected with the preferred orientation of the crystallites as well as with the crystallographic nature of the simple crystallite. Such a conclusion

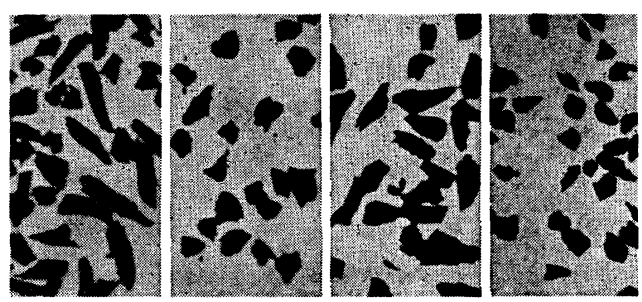

Photo. 3. Optical micrographs (×60) of the ground cokes calcined at 1300 °C. Particle size; 65—100 mesh. (a) A coke, (b) B coke, (c) C coke, (d) D coke.

has also been obtained in the discussion of the carbonized products from naphthalene and pyrene.[12]

Shape Factors of Ground Cokes. Microscopic photographs of ground samples from A, B, C, and D cokes are shown in Photo 3. Obviously, the needle cokes A and C were broken into elongated pieces in which the needle-textures ran lengthwise, as Mrozowski[3] and Walker *et al.*[8] recongnized. In contrast, the B and D cokes with the mosaic structure, gave rather spherical pieces. Walker *et al.*[8] proposed to define the shape factor, k, by the following equation;

$$k = S_v \mu$$

where S_v is the geometric surface area per unit of value and where μ is the arithmetic-average sieve-size diameter of the sample; they reported the relation between the shape factor and the anisotropic factors. Because their factors seem to have some ambiguity concerning the pore surface area, the ratios of the shortest and longest lengths of the particles were averaged for one hundred particles in the present study. We could not find any clear difference in the averaged ratios of ground cokes of A, B, C, and D, although distinct difference in shapes could be recognized at a glance.

Comparison of Anisotropic Factors between Filler Cokes and Their Extruded Products. The anisotropy factors of filler cokes and their extruded products were compared in an attempt to discuss how well the extrusion aligned the particles of needle cokes parallel to the axis of extrusion, and whether or not the anisotropy factor of the extruded products could represent that of filler cokes, because the elongated pieces of the needle cokes were expected to be arranged parallel to the direction of extrusion. The anisotropy factors measured by two ways of X-ray diffraction are summarized in Table 6. As for the needle cokes (F and G), a decreased anisotropy upon the extrusion was shown by both methods, although the extent of decrease was a little smaller by the reflected method (γ_1) than in the Bacon method(BAF). The arrangement of the needle coke particles in the extrusion products is shown by the micrograph[Photo 4]. When compared with the photographs of the fillers themselves, they could be easily distinguished from the binder cokes in the extrusion products, however, this arrangement was far from an uniaxial one along the extrusion axis. The disordered arrangement probably brings about the decrease in the anisotropic facors. Thus,

Table 6. Comparison of anisotropic factors between filler and extruded cokes

	B coke[a]		F coke[b]		G coke[c]	
	Filler	Ext.	Filler	Ext.	Filler	Ext.
BAF	1.2	1.1	2.5	1.4	2.2	1.4
γ_1	1.1	1.2	3.4	2.0	2.6	2.3

a) Calcined at 3000 °C. b) Calcined at 1300 °C.
c) Calcined at 3000 °C.

the usual extrusion could not be expected to be sufficient to reproduce the anisotropic factors of filler cokes. The extrusion which forces the uniaxial arrangement of filler cokes more strictly is required for this purpose. In the case of cokes of the mosaic structure, the filler cokes were difficult to distinguish by the microscopic observation, and the X-ray data shown in Table 6[B Coke] indicate the unchanged isotropic natures of both filler and extruded cokes.

The different degree of decrease in the anisotropic factors observed by the two ways of X-ray diffraction measurement may be explained as follows. The values of BAF fluctuated with the exposed location, and sometimes the plots of $I(\phi)$ *vs.* ϕ gave a quite unsymmetrical curve. These facts may be the result of the small area exposed to X-rays, and may mean that the Bacon method is not suitable for the measurement of the extruded sample the fillers of which are not uniformally arranged. In contrast, the reflection method gave constant and reproducible values, perhaps because of the larger exposed area, as has been pointed out by Noda and Inagaki.[6] This method may give the averaged anisotropic factor against the filler cokes distributed in the area exposed to the X-rays.

Discussion

There have been several proposals with regard to the structures of the needle cokes. Franklin[13] considered the needle coke to be a platelet-like arrangement of crystallites with the crystallites parallel on a large plate. Mrozowski[3] defined the needle-coke in which the crystallites of carbon were well aligned with normals to the planes distributed in all directions, but approximately parallel to the axis of the needle, so that the crystallites were not at all parallel to each other. Photo 2 clearly supports such a structure. This structure can be compared to a paper-roll.[4b] On the basis of this structure, the fact that the profiles of Bacon plots are equal in two planes perpendicular to each other, but parallel to the axis of the needle, is understandable.

The data shown in Table 3 are of value in a discussion because they seem to indicate interesting relations among crystal growth, the orientation of the crystallites, and the physical properties of the needle coke. The significant decrease of CTE value between the calcination temperatures of 600 °C and 1300 °C is considered to be the result of the crystal growth of the incorporation of the disorganized phase,[3] as is indicated by the marked decrease in the amorphous part in the X-ray diffraction, although no real crystal growth such as is shown by L_c or C_0 was observed. The disappearance of amorphous carbon may improve the CTE of the carbon.

Above 1300 °C no amorphous part was present any more, but real crystal growth may occur, as is indicated by the significantly increased L_c and C_0. The small gas evolution or the small decrease in the H/C ratio may also indicate the crystal growth in this region at the expense of other crystallites, as was mentioned by Mrozowski.[3]

Microcrystallites of carbon calcined at 1300 °C (their average L_c was as small as 21 Å) may have a CTE value similar to that of complete graphite (L_c is several hundred Å) if the chemical bonds are the most important factor in the thermal expansion, because microcrystallines already consist exclusively of carbon–carbon bonds, as does complete graphite. This might indeed be the case, although many other factors should be considered to play some role in the thermal expansion. Several researchers have studied the relation of CTE or other anisotropic properties to the crystal size, as in shaped cokes. Engle[5a] claimed the dependence of CTE and its anisotropic ratio on the mean apparent crystallite size L_c. Matsumoto and Sasaki[10] investigated similar relations. The latter authors claimed a slight dependence of CTE on the crystal size (the size has no effect on the CTE value over 700 Å) and a linear relation between the CTE anisotropic ratio and the crystal size. According to the opinion of the present authors, however, there are some problems in the study of extruded or molded samples because shaped cokes may not always represent the filler cokes and because the factor brought about at the shaping probably often has significant effects. Furthermore, the mechanism how the crystal size influences the CTE is worth further study.

Although the CTE values did not change at the calcination of 2000 °C, where essential crystal growth was also noticed, a significant increase in anisotropic factors as measured by X-ray diffraction was observed. The anisotropic factor showed no increase at 2500 °C in spite of the marked crystal growth. These facts may mean that a critical value of the crystal size may be necessary to give the leveled anisotropy factor observed for the cokes calcined at 2000 or 2500 °C, because the intensity of the (002) diffraction is influenced very much by the crystal size. It is evident from Photo 2 that the alignment of the crystallites is already formed at the temperature of the solidification of the cokes and that is persists essentially unchanged up to the highest-temperature. In this sense, the anisotropy factor may be constant regardless of the later heat treatment; however, other anisotropy factors based on the other physical properties of cokes seem to change because of the dependence of the property on characteristics of the cokes other than alignment of crystallites.

The needle cokes produced by the reactor of an experimental size are often pulverized so that their anisotropic properties are difficult to measure, although the measurement is important in evaluating the quality of the needle cokes. There are two possible ways of measurement. First, an attempt is made to measure the anisotropic properties of a particle itself. Second, powdered cokes are molded or extruded into a lump of a suitable size with binders, and the properties of the filler cokes are estimated from those of the shaped sample. The first approach is possible by the use of a strong X-ray source and an automatic full-circle goniometer; however, it is still difficult to set the sample in the right direction, parallel to the needle-axis. The reflective index, as measured by a polarized light microscope, may also give the anisotropic factor of powdered cokes.[14]

In the second method, filler cokes should be arranged in the shaped sample, with the same symmetry as the filler cokes themselves have. The needle cokes are in an uniaxial arrangement in which the axis of the powdered needle is within a plate; however, this symmetry is completely different from the uniaxial one. Although the extrusion is considered a possible way to achieve this arrangement, the results shown in Table 6 and Photo 4 indicate that the present extrusion is not sufficient to arrange the powdered needle cokes in an uniaxial direction to the same extent as was observed in an original lump coke. Ubbelohde[15] succeeded in obtaining a highly anisotropic arrangement of cokes by applying compression and sherring forces to the cokes in a shaped binder-polymer at the same time. An extrusion with a large compression ratio seems to be an expedient way to obtain a lump composed of uniaxially arranged cokes which can represent the individual coke-particle; furthermore, it is interesting because anisotropic properties superior to those of original cokes can be realized in such a way.

Our thanks are due to Professor Ryohei Takahashi of our University and Mr. Juji Furumi, The Nittetsu Chemical Industrial Co., for providing the experimental facilities. The authors are also gratefull to the Japan Securities Scholarship Foundation for its financial support.

Photochemical Cycloaddition Reactions of α,β-Unsaturated Lactones with Olefins, and Application to Synthesis of Natural Products[1]

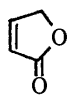
Hiroshi KOSUGI, Shizuo SEKIGUCHI, Ryû-ichi SEKITA, and Hisashi UDA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2, Sendai 980

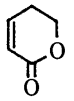
(Received August 18, 1975)

The photochemical cycloaddition reactions of five- and six-membered α,β-unsaturated lactone derivatives with unsaturated substrates (ethylene, acetylene, 1,1-dimethoxyethylene *etc.*) have been studied. The parent α,β-unsaturated lactone (γ-crotonolactone) and the β-,γ-, or δ-alkyl substituted derivatives add to ethylene and acetylene in the acetone solutions and to 1,1-dimethoxyethylene in the benzene solutions in so good yields as to utilize them practically for synthesis. α-Phenyl-γ-crotonolactone and β-phenyl-γ-crotonolactone also add to ethylene and acetylene, whereas, α-methyl, β-hydroxy, and β-methoxy derivatives do not. As the synthetic applications of the reactions, the synthesis of (±)-grandisol has been achieved, and the synthetic approach to (±)-canadensolide has also been described.

Despite many examples of the photochemical cycloaddition reactions of cyclic α,β-unsaturated ketones with a variety of unsaturated substances[2,3] and of the fruitful applications in total syntheses of natural products,[4] the use of α,β-unsaturated lactones such as **1** and **2** has so far been very limited.[5-7] Tada



1



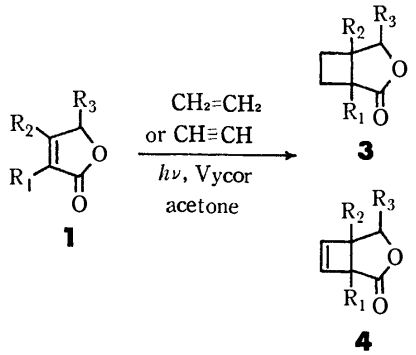
2

and his co-workers[6] reported, in mechanistic points of view, that γ-crotonolactone (**1**) underwent photocycloaddition reaction with cyclopentene or cyclohexene to give the cycloadduct in 36—42% yield and that the reaction was sensitized by acetone and quenched by 1,3-pentadiene and, therefore, the reaction proceeded through the triplet excited state of **1**. Furthermore, it is one of the most significant findings in their work that 1,1-dimethoxyethylene, which is one of the most reactive olefins in the photocycloaddition of cyclic enones,[2] did not give the cycloadduct with **1**, but quenched the photocycloaddition reaction between **1** and cyclopentene in acetonitrile. As the example of a six-membered α,β-unsaturated lactone, the acetophenone-sensitized cycloaddition of 5,6-dihydro-4-methyl-2*H*-pyran-2-one (**2b**), β-methyl derivative of **2**, to ethylene has been successfully applied to the stereoselective synthesis of (±)-grandisol by Gueldner and his co-workers.[7] We have simultaneously and independently investigated the photochemical cycloaddition reactions of **1** and the simply substituted derivatives of **1** and **2** with unsaturated substrates, especially ethylene, acetylene, and 1,1-dimethoxyethylene, for the actual synthetic purpose including the synthesis of (±)-grandisol, rather than the mechanistic view points. This work was undertaken with several goals in mind: (1) to clarify and generalize the reaction conditions and the effects of the substituents in both lactone and olefin components, (2) to elucidate the structures, including orientations, of the products obtained, (3) to apply the cycloaddition reaction to the synthesis of natural products, (4) to compare the photochemical reactivities of unsaturated lactones with those of enones.

Results and Discussion

Photochemical results are described first, followed by synthetic applications.

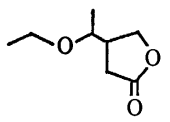
Photochemical Cycloadditions. All of the photochemical reactions described herein were conducted in ordinary solvents and with a 500-W high pressure mercury arc lamp fitted with or without a filter (Vycor or Pyrex cooling jacket of a lamp), in contrast with the peculiar conditions (in acetonitrile, 10-W low pressure mercury arc lamp) employed by Tada, *et al.*[6] Described below are studies on the photochemical cycloaddition reactions of γ-crotonolactone (**1a**) and the following derivatives: β-methyl (**1b**), β-phenyl (**1c**), α-methyl (**1d**), α-phenyl (**1e**), and γ-methyl (**1f**), and 5,6-dihydro-6-methyl-2*H*-pyran-2-one, parasorbic acid (**2a**).



a : $R_1=R_2=R_3=H$
b : $R_1=R_3=H$, $R_2=Me$
c : $R_1=R_3=H$, $R_2=Ph$
d : $R_1=Me$, $R_2=R_3=H$ (no reaction)
e : $R_1=Ph$, $R_2=R_3=H$
f : $R_1=R_2=H$, $R_3=Me$

The photocycloaddition of **1a** to ethylene in acetone (Vycor) proceeded readily and cleanly, and afforded the cycloadduct **3a** in high yield (70% at room temperature; >80% at −50 °C). The analytical and spectral data indicate that **3a** is the expected 1 : 1 cycloadduct. Acetone was the best solvent among other solvents examined in the photocycloaddition of **1a** to ethylene and appears to play a role as the sensitizer, as suggested by Tada, *et al.*[6] For example,

the photocycloaddition of **1a** to ethylene in ether or in ether–acetone (fivefold molar excess amount of **1a**) resulted in lowering remarkably the yield of **3a**, 22 and 6%, respectively. In this case, the major product was a mixture of the diastereomers of the ether addition product **5**. This result suggests that the excited species of **1a** abstracts preferentially a hydrogen atom from ether rather than the photocycloaddition to ethylene, being quite different from the feature of the excited species of enones since enones added satisfactorily to ethylene and other olefins by irradiation in ether without the formation of the ether addition product.[8] However, the abstraction of a hydrogen atom from ether was not always the preferential pathway in the photocycloaddition of **1a** in ether; **5** was obtained as the minor component in

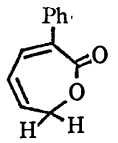


5

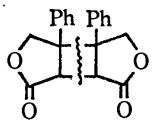
the photocycloaddition with cyclohexene (see below). Propyl bromide–acetone (−50 °C) was also not a suitable solvent system for the photocycloaddition of **1a** to ethylene, giving **3a** in 53% yield. Also, benzene, which is one of the very common solvents for the photocycloaddition of enones,[9] was unsatisfactory for the present reaction due to the relatively low solubility of **1a**: a solution of **1a** in benzene (the same concentration as in acetone) became emulsion by the saturation of ethylene, and in fact, no reaction occurred even in prolonged irradiation.

Similarly, the photocycloaddition of **1b**, **1c**, **1e**, and **1f** to ethylene in acetone afforded products, **3b**, **3c**, **3e**, and **3f** (44, 49, 52, and 35%) whose analytical and spectral data indicated they were the expected cycloadducts. The adduct **3f** and others derived from **1f** were obtained always as a *ca.* 1 : 1 mixture of the stereoisomers. From these experiments, although the reactions proceeded smoothly under the conditions examined (acetone, −50 °C for **1b** and **1f**; room temperature for **1c** and **1e**, Vycor filter for **1b** and **1c**; Pyrex filter for **1e**; no filter for **1f**), it was observed that prolonged irradiation caused to increase the amount of by-products which presumably arose from the participation of acetone, and therefore, in practice for preparation of the adducts it would be better to conduct the photocycloaddition reaction without a filter, resulting in making the reaction much faster. It should be noted that α-methyl derivative **1d**, contrary to the phenyl analog **1e**, did not undergo the photocycloaddition to ethylene, being similar to the observation on the photocycloaddition of 2-methyl-2-cyclohexenone.[2] On the photoeffectiveness of **1e**, the electronic effect of the conjugated phenyl group may play an important role in the reaction.

Contrary to the photochemical unreactivity of 2-cyclohexenone with acetylene (in acetone at −70 °C) observed by Owsley and Bloomfield,[10] we have found that the unsaturated lactones **1a-f** except **1d** underwent actually the photocycloaddition with acetylene under the standard conditions (acetone, −50 °C, Vycor filter for **1a-c**; Pyrex filter for **1e**; no filter for **1f**). The noteworthy features of the reactions are the slowness relative to the cases with ethylene and the formation of a large amount of by-products at the end of the reaction periods. Consequently, for the actual isolation of the desired adducts the progress of the reactions should be carefully followed by glpc or tlc analysis and intermitted at appropriate reaction periods. Thus, the corresponding acetylene adducts **4a**, **4b**, **4c**, **4e**, and **4f** were obtained in 54, 29, 8, 23, and 14% yields, respectively. Again, no reaction was observed in **1d**. The structures of the adducts were established on the basis of analytical and spectral grounds, and among them **4e** was further identified by comparison with the authentic sample obtained from the photocyclization of 3-phenyl-2(7*H*)-oxepinone (**6**).[11] In the case of **1c**, the yield of adduct **4c** was extremely low and the major product (35%) was found to be the dimer **7** which was quantitatively formed by irradiation of **1c** alone. The structure of **7** was assigned on the basis of the analytical and spectral results but the *syn*/*anti* and *cis*/*trans* natures could not be determined.

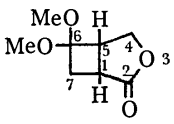


6

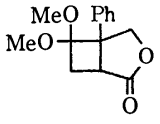


7

It should be noteworthy that the compound **1a** as well as **1c** effectively adds to 1,1-dimethoxyethylene, contrary to the observation by Tada, *et al.*[6] Thus, irradiation of **1a** or **1c** in the presence of excess 1,1-dimethoxyethylene in the benzene solution without a filter gave the cycloadducts **8** or **9** in 62 or 37% yield, respectively. Acetone was not used as a solvent in these reactions because of the easy formation of the oxetane derivative with 1,1-dimethoxyethylene.[6,12] The presence of excess 1,1-dimethoxyethylene increased the solubility of **1a** in benzene, and now the reaction proceeded smoothly. Furthermore, it was observed that the photoaddition proceeded very slowly by irradiation through a Vycor filter and that a large amount of by-products arising from 1,1-dimethoxyethylene (dimethyl succinate *etc.*) were produced by prolonged irradiation. For example, the ratio of **1a** and **8** reached to about 7 : 2 after 19 hr irradiation through a Vycor filter and did not change considerably on further irradiation, despite of a remarkable consumption of 1,1-dimethoxyethylene. The product **8** was apparently single, being *cis* fused, and the 6,6-dimethoxy structure follows from 100 MHz NMR coupling multiplicity of the methine proton (H-1) at the ring juncture; that is, the signal of H-1 appears as eight lines with the following coupling constants: J_{1-5}= 8.4, J_{1-7}^{trans}=5.1, J_{1-7}^{cis}=9.0. The coupling patterns of the protons in **9** also support the position of the dimethyl acetal grouping, and furthermore, the orientation of the photoaddition of 1,1-dimethoxyethylene was confirmed by chemical transformation of another adduct **24** described in the later section. Hence,



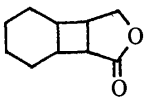
8



9

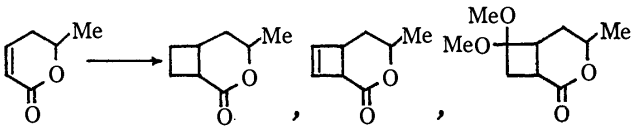
the orientational mode of the photocycloaddition of α,β-unsaturated lactones to 1,1-dimethoxyethylene is apparently the same as the case of cyclic enones.[2,8a] Interestingly, **1e**, which added effectively to ethylene and acetylene as mentioned above, was found to be photochemically unreactive to 1,1-dimethoxyethylene.

In order to gain more informations on the effect of an olefin-solvent combination in these photochemical processes, the reaction of cyclohexene with **1a** was performed in an ether solution. The reaction proceeded well to afford the expected product **10**[6] in 72% yield. This product appears to be a mixture of stereoisomers; however, the aspect of stereochemistry was not investigated further. In this case the by-product **5** was a minor component in a yield of less than 10%.



10

Furthermore, parasorbic acid (**2a**) was selected for study as an example of a six-membered α,β-unsaturated lactone. The photocycloadditions of **2a** to ethylene and acetylene in acetone and to 1,1-dimethoxyethylene in ether equally proceeded readily and gave the adducts, **11** (70%), **12** (66%), and **13** (64%), each of which was a mixture of stereoisomers, and the analytical and spectral data were consistent with the assigned structures.



2a **11** **12** **13**

Finally, we also examined the photoreactions using acrylonitrile as an olefinic substrate and tetronic acid as an unsaturated lactonic one. It has been known that acrylonitrile is one of the good olefinic substrates for the photocycloaddition of enones and actually adds to 2-cyclohexenones;[2,8a] however, any of α,β-unsaturated lactones examined in the present work did not give the photocycloadduct with acrylonitrile.

Furthermore, in contrast with the successful photoadditions of 3-hydroxy-[13] and 3-methoxy-[8a] cyclohexenones to olefins, the photoreactions of tetronic acid (**14**) with ethylene or cyclohexene and of the methyl ether **15** with ethylene under the various conditions (solvent, Vycor or no filter *etc.*) did not entirely give the cycloadducts, resulting in recovery of the starting materials **14** and **15** or formation of an intractable mixture.

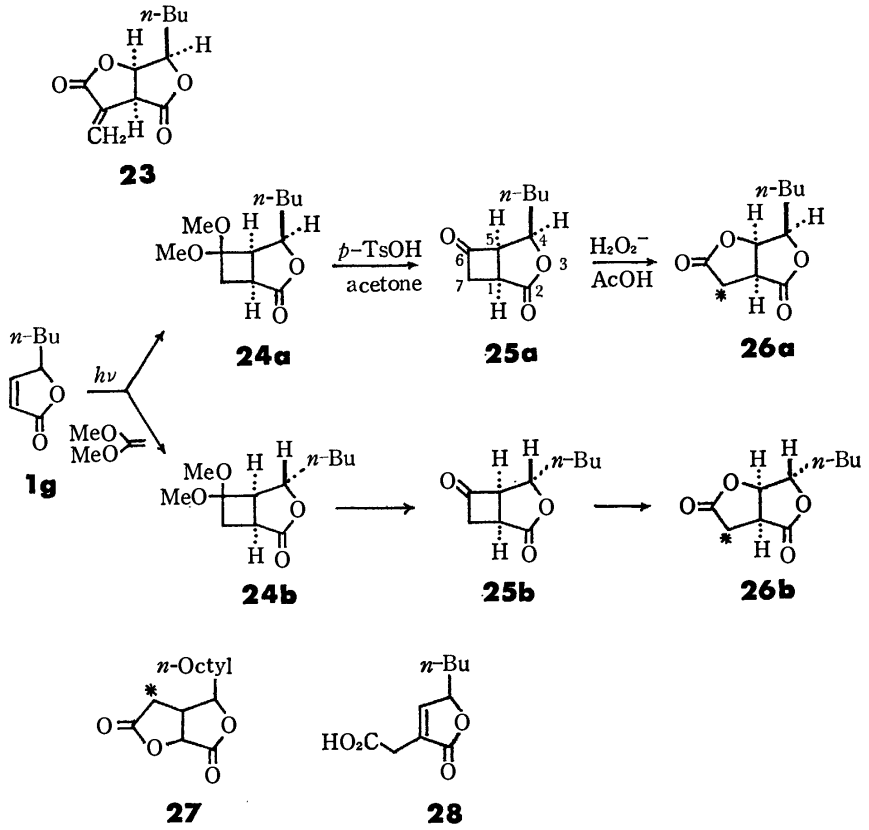
Scheme 1.



Scheme 2.

excited species o. α,β-unsaturated lactones has not been investigated precisely in the present work. However, from the experimental results, it could be pointed out that there are apparently the several different features of the excited species of unsaturated lactones from those of enones; that is, hydrogen abstraction from ether, photoaddition to acetylene, inertness for the photoaddition to acrylonitrile, and unreactive effect of 3-hydroxy and alkoxy groups.

As is clear from the several examples cited above the photocycloaddition reactions of α,β-unsaturated lactones with olefins, especially ethylene, acetylene and 1,1-dimethoxyethylene, should be of considerable utilities for the preparation of a wide variety of four-membered ring fused γ- and δ-lactone derivatives.

Synthetic Applications. (±)-Grandisol. Grandisol (**16**), one of the four components of the male boll weevil sex pheromone,[14] has been previously synthesized in racemic form,[7,9e,14] and additionally, three alternative synthetic courses have very recently been reported.[15] Among these reported synthetic sequences, the photocycloaddition reaction of 5,6-dihydro-4-methyl-2*H*-pyran-2-one (**2b**) with ethylene has been successfully applied as the initial step by Gueldner, *et al.* (**2b**→**17**→**18**→**16** in the scheme 1).[7] In this section we will describe briefly our independent synthetic work of (±)-**16** starting from **2b** and the reaction sequence is outlined in the scheme 1.

Irradiation of a solution of **2b** in acetone at room temperature through a Vycor filter with moderately rapid introduction of ethylene gave a 70% yield of the cycloadduct **17** (the reported conditions:[7] benzene, acetophenone as a sensitizer, a medium-pressure mercury-vapor lamp, no filter, yield of **17**: 56%).

The addition of **17** to excess sodium methylsulfonylcarbanion[16] at 55 °C resulted in the formation of the acetal **19**, mp 103.5—104.5 °C, (75%). For the introduction of one carbon unit the use of sodium methylsulfinylcarbanion[16,17] was unsatisfactory, affording a low yield of non-crystalline product. Reduction of **19** with aluminum amalgam in aqueous tetrahydrofuran gave an equilibrium mixture of the acetal **20** and the methyl ketone **21**, which were apparently separable on silica gel tlc but not obtained in pure form.

Acetylation of the mixture of **20** and **21** with acetic anhydride–pyridine at room temperature afforded in a 40% yield (based on **19**) of the single acetate **22** which is transformed by the Wittig process, methylenetriphenylphosphorane–dimethyl sulfoxide,[18] followed by alkaline hydrolysis to (±)-grandisol (**16**) identical with an authentic sample prepared by Zurflüh, *et al.*[9e]

(±)-Canadensolide. Canadensolide (**23**) is a mould metabolite produced by *Penicillium canadense*[19] and the total synthesis in racemic form and the revision of the stereochemistry has been reported by Yoshikoshi, *et al.*[20] The orientation of the dimethyl acetal grouping in the photocycloadduct **8** from **1a** and 1,1-dimethoxyethylene as mentioned earlier is well suited for the construction of the second lactone ring in the canadensolide bislactone ring system, and hence, the photo-

cycloaddition of γ-butyl-γ-crotonolactone (**1g**) to 1,1-dimethoxyethylene would appear to provide an alternative synthetic route leading to (±)-**23**. This part deals with this synthetic approach to (±)-**23** from **1g** (Scheme 2).

Irradiation of **1g** in the presence of excess 1,1-dimethoxyethylene in benzene gave a mixture of the stereoisomers of the adduct which were easily separated by column chromatography on silica gel into *endo* and *exo* isomers, **24a** and **24b**, in respect of the butyl side chain in 30 and 40% yields, respectively. The orientation of the dimethyl acetal grouping and the configuration of the butyl group were rigorously established on the basis of the NMR coupling pattern of H-5 in the hydrolysis product **25**.

Treatment of each isomer **24a** and **24b** with *p*-toluenesulfonic acid in acetone afforded the corresponding keto lactone **25a** and **25b**. The signals of H-5 in both isomers appear as a doublet of doublets, suggesting the position of the keto group at C-6, with the following coupling constants: $J_{4-5}=7.0$ in **25a** (assignable to *cis* coupling), $J_{4-5}=1.7$ in **25b** (assignable to *trans* coupling) respectively. Thus, the configuration of the butyl group is *endo* in the **a**-series compounds, while *exo* in the **b**-series, as shown in Scheme 2. On treatment with hydrogen peroxide–acetic acid **25a** and **25b** were transformed into the bislactone derivatives **26a** and **26b** which were identified by direct comparison with the authentic samples prepared by Yoshikoshi, *et al.*[20]

Unfortunately, however, in this bislactone ring system the introduction of a carboxylic group (or its equivalent) at the α-methylene position (asterisked) of the newly formed lactone ring failed, in contrast to the successful introduction in the case of the avenaciolide bislactone ring system **27**.[21] All attempts to introduce one carbon unit at the α-methylene position in both **26a** and **26b** under a wide variety of conditions (MMC–DMF–dioxane, *iso*-Pr_2NLi–CO_2–THF, Et_2NH–aq HCHO *etc.*) were unsuccessful; the abstraction of a proton from C-1 occurred exclusively to produce the ring opened product **28**. This problem is still unresolved.

Experimental

All melting points were determined in an oil bath and are uncorrected. Distillation of the liquid products was usually carried out evaporatively using a modified sublimation apparatus and the oil bath temperatures were recorded. IR spectra were taken on a Hitachi EPI-S2 or G2 spectrometer. NMR spectra were obtained on a JEOL Model C-60HL (60 MHz) or PS-100 (100 MHz) instrument using TMS as an internal standard and CCl_4 as the solvent unless otherwise indicated. Reported values are on the cm^{-1} in IR and δ scales in NMR, respectively. Coupling constants are given in Hz. Glpc analyses were performed on a JEOL Model JGC-750 or 1100 instrument using the following columns: A (20% Carbowax 20 M on Chromosorb W, 2 m×3 mm), B (20% Carbowax 20 M on Chromosorb W, 3 m×3 mm), and C (20% SE-30 silicone rubber on Chromosorb W, 2 m×3 mm). Elemental analyses were performed in the microanalytical laboratory of this institute.

General Procedure for Irradiation. The apparatus consisted of an irradiation vessel fitted with a Vycor, Pyrex or quartz (for experiments without a filter) immersion type cooling jacket for a lamp serving a filter as well, a rubber stopple in one side arm, and a gas inlet tube or a three-way stopcock on the other side arm. In the cases of small scale experiments, a quartz reaction tube (3×30 cm) having a glass sponge gas inlet part at the bottom was employed and irradiated externally. The entire apparatus was immersed in a dry-ice—methanol or a running water bath (for room temperature experiments). The gaseous olefinic substrates, ethylene and acetylene, were saturated at appropriate temperatures and continuously bubbled through the solutions as a finely dispersed state throughout irradiation. For the other olefins the irradiations were performed under the nitrogen atmosphere. The solutions were irradiated by a Taika immersion type 500-W high pressure mercury arc lamp and the progress of the reactions was generally monitored by removing aliquots with a syringe and examination by glpc or tlc means. The yields of the photoadducts are based on the starting unsaturated lactones.

*Photoadditions of γ-Crotonolactone (**1a**).* *(a) To Ethylene in Acetone*: A solution of γ-crotonolactone (**1a**)[22] (1.02 g) in freshly distilled acetone (400 ml) was irradiated at −50 °C for 2.5 hr through Vycor with introduction of ethylene. Evaporation of the solvent under reduced pressure and distillation (110—120 °C/15 mmHg) of the residual liquid gave 1.10 g (80%) of the single product, 3-oxabicyclo[3.2.0]-heptan-2-one (**3a**)[23], with a retention time of 24 min on column B (200 °C, He 2.0 kg/cm²). IR (CCl_4) 1780, 1150; NMR 1.90—2.70 (m, 4H), 2.88—3.34 (m, 2H), 4.12 (dd, J=10 and 2, 1H), 4.29 (dd, J=10 and 6, 1H). Found: C, 64.71; H, 7.19%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%.

When the reaction was carried out at room temperature, **3a** was isolated in 70% yield.

(b) To Ethylene in Ether: A solution of **1a** (0.94 g) in dry ether (500 ml) was irradiated at room temperature for 2.5 hr through Vycor with introduction of ethylene. Glpc analysis (column A, 180 °C) of the crude photolysate indicated the product contained two components with the retention times of 10.8 min (*ca.* 22% of area) and 18.8 min (*ca.* 54% of area). Pure sample of each component was collected by preparative glpc. The faster moving component was identified to be **3a** and the slower moving one was found to be the ether addition product, β-(1-ethoxyethyl)-γ-butyrolactone (**5**): IR (CCl_4) 1780; NMR around 1.13 (d, J=7, 3H), around 1.16 (t, J=7, 3H) (these are splitted small due to a mixture of diastereomers), 2.20—2.60 (m, 3H), 3.20—3.70 (m, 3H), 4.20 (m, 2H). Found: C, 60.38; H, 8.70%. Calcd for $C_8H_{14}O_3$: C, 60.78; H, 8.92%.

(c) To Acetylene: A solution of **1a** (1.58 g) in acetone (500 ml) was irradiated at −50 °C through Vycor with introduction of acetylene. After 5 hr the amount of by-products gradually increased, presumably arising from photoreaction of acetylene and/or acetone, and therefore, the reaction was stopped after 5 hr irradiation. At this stage the ratio of **1a** (retention time of 2.6 min) and the main product (4.6 min) was about 31% and 54%, in addition to 15% of by-products, respectively, determined from glpc on column C (150 °C, He 1.0 kg/cm²). After removal of the solvent under reduced pressure, the gas-chromatographically homogeneous product, 3-oxabicyclo[3.2.0]hept-6-en-2-one (**4a**), (470 mg, 23%) was collected by column chromatography on silica gel (70 g) using 7 : 3 petroleum ether–ether as eluent. The analytical sample was purified by distillation (110—125 °C/10 mmHg). IR (CCl_4) 3020, 1780, 1160; NMR 3.50—3.70 (m, 2H), 4.20—4.40 (m, 2H), 6.32 (s, 2H). Found: C, 65.79;

H, 5.49%. Calcd for $C_6H_6O_2$: C, 65.44; H, 5.49%.

(d) To Cyclohexene: A solution of **1a** (1.02 g, 12 mmol) and cyclohexene (10.5 g, 116 mmol) in dry ether (500 ml) was irradiated at room temperature for 5 hr through Vycor. Analysis of the crude photolysate by glpc (column C, 190 °C, He 1.5 kg/cm²) indicated the photoproduct consisted of three components eluted at 3.1 min, 5.7 min, and 6.8 min in the area ratio of about 1 : 1.5 : 3, respectively. After removal of the solvent under reduced pressure, the residual liquid was separated into 72 fractions of *ca.* 50 ml portion by chromatography on silica gel (60 g) using initially petroleum ether alone and then a mixture of petroleum ether and ether (gradually increasing the amount of ether, the final ratio of petroleum ether and ether was about 7 : 3) as eluting agent. Fractions 32—39, consisting of the single compoment corresponding to 6.8 min eluate on glpc, were combined and concentrated under reduced pressure to give 302 mg of one stereoisomer of 4-oxatricyclo[5.4.0.$0^{2,6}$]undecan-3-one (**10**). Purified sample by distillation (125—130 °C/6 mmHg) was gradually crystallized on standing, mp 41—45 °C. IR (CCl_4) 1775, 1150; NMR 0.90—3.20 (m, 12H), 4.20—4.40 (m, 2H). Found: C, 72.58; H, 8.75%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%. Fractions 40—49 amounting 452 mg were found to be a mixture of the 5.7 min and 6.8 min eluates, and the IR and NMR spectra were almost identical with those of the above mentioned pure sample. Therefore, the 5.7 min eluate was another stereoisomer of **10**. Total yield was *ca.* 50%.

The product obtained from the fractions 55—65, which was the 3.1 min eluate, was identified to be **5** (132 mg, 7%).

(e) To 1,1-Dimethoxyethylene: A solution of **1a** (0.84 g, 10 mmol) and freshly distilled 1,1-dimethoxyethylene (8.8 g, 0.1 mol) in dry benzene (50 ml) was irradiated at room temperature for 15 hr without a filter. Evaporation of the solvent under reduced pressure left 2.69 g of oily residue. From the glpc analysis (column A, 230 °C, He 2.3 kg/cm²) the starting material **1a** (retention time of 2.5 min) still remained and the ratio of **1a** and the photoproduct (retention time of 8.8 min) was about 1 : 3. Many other peaks due to by-products (totally comparable area with **1a** and the product) were also observed around 1—3 min and 4—6 min. The crude mixture was chromatographed on silica gel (75 g) using initially hexane and then a mixture of hexane and ether (gradually increasing the amount of ether, the final ratio of hexane and ether was about 7 : 3) as eluting agent to give 435 mg (26% based on **1a** used) of 6,6-dimethoxy-3-oxabicyclo[3.2.0]heptan-2-one (**8**), which was purified by distillation (95 °C/3 mmHg). IR(CCl_4) 2810, 1778; NMR (100 MHz) 2.29 (dd, J= 13.0 and 5.1, 1H), 2.50 (ddd, J= 13.0, 9.0, and 2.0, 1H), 2.83 (ddd, J=9.0, 8.4, and 5.1, 1H), 3.09 (s, 3H), 3.15 (s, 3H and m, 1H), 4.22 (dd, J=9.3 and 7.8, 1H), 4.48 (dd, J=9.3 and 2.6, 1H). Found: C, 55.79; H, 6.88%. Calcd for $C_8H_{12}O_4$: C, 55.84: H, 7.08%.

Photoadditions of β-Methyl-γ-crotonolactone (1b). *(a) To Ethylene*: A solution of β-methyl-γ-crotonolactone (**1b**)[24] (250 mg) in freshly distilled acetone (600 ml) was irradiated at −50 °C for 8 hr through Vycor with introduction of ethylene. Evaporation of the solvent under reduced pressure and chromatography of the residual liquid on silica gel (30 g) using 5 : 1 petroleum ether–ether as eluent gave 150 mg (48%) of 5-methyl-3-oxabicyclo[3.2.0]heptan-2-one (**3b**), which was homogeneous on glpc (column A, 200 °C, He 1.6 kg/cm²). Analytical sample was purified by distillation (80—120 °C/12 mmHg). IR (CCl_4) 1780, 1150; NMR 1.35 (s, 3H), 1.70—2.70 (m, 5H), 3.86 and 4.14 (AB type q, J=9.0, 1H each). Found: C, 66.42; H, 7.84%. Calcd for $C_7H_{10}O_2$: C, 66.64; H, 7.99%.

(b) To Acetylene: A solution of **1b** (600 mg) in acetone (800 ml) was irradiated at −50 °C through Vycor with introduction of acetylene. After 9 hr glpc analysis (column A, 200 °C, He 1.5 kg/cm²) indicated the ratio of **1b** (retention time of 6.2 min) and the photoadduct (4.2 min) was about 3 : 1. After an additional 1 hr irradiation the ratio reached to 1 : 1 but the amount of by-products considerably increased. Therefore, for convenience of the isolation of the product, the reaction was intermitted at 9 hr irradiation. Removal of the solvent under reduced pressure and chromatography of the residual liquid (1.1 g) on silica gel (50 g) using 5 : 1 petroleum ether–ether as eluting agent gave 86 mg (29%) of homogeneous 5-methyl-3-oxabicyclo-[3.2.0]hept-6-en-2-one (**4b**). Analytical sample was purified by distillation (80—83 °C/15 mmHg). IR (CCl_4) 1785, 1770, 1160; NMR 1.42 (s, 3H), 3.10 (s, 1H), 3.89 and 4.19 (AB type q, J=9.7, 1H each), 6.27 and 6.38 (AB type q, J=2.8, 1H each). Found: C, 67.56; H, 6.42%. Calcd for $C_7H_8O_2$: C, 67.73; H, 6.50%.

Photoadditions of β-Phenyl-γ-crotonolactone (1c). *(a) To Ethylene*. A solution of β-phenyl-γ-crotonolactone (**1c**)[25] (500 mg) in acetone (800 ml) was irradiated at room temperature for 3 hr through Vycor with introduction of ethylene. In this case the progress of the reaction was monitored by tlc instead of glpc. Removal of the solvent under reduced pressure and chromatography of the residue (972 mg) on silica gel (50 g) using 4 : 1 petroleum ether–ether as eluent gave 250 mg (50%) of 5-phenyl-3-oxabicyclo[3.2.0]heptan-2-one (**3c**). Analytical sample was purified by distillation (120—140 °C/3 mmHg). IR (CCl_4)1785, 1170; NMR 1.80—2.80 (m, 4H), 3.10—3.40 (m, 1H), 4.05 and 4.40 (AB type q, J=9.0, 1H each), 7.22 (s, 5H). Found: C, 76.42; H, 6.73%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

(b) To Acetylene: A solution of **1c** (500 mg) in acetone (800 ml) was irradiated at −50 °C through Vycor with introduction of acetylene. After 2 hr **1c** was completely consumed. Evaporation of the solvent and chromatography of the residue (806 mg) on silica gel (40 g) using 5 : 1 petroleum ether–ether as eluent gave two products. The faster moving minor product (46 mg, 8%) was purified by distillation (140—150 °C/3 mmHg) and identified to be the expected photoadduct, 5-phenyl-3-oxabicyclo[3.2.0]hept-6-en-2-one (**4c**): IR ($CHCl_3$) 1765, 1180; NMR 3.50 (br. s, 1H), 4.27 and 4.48 (AB type q, J=9.4, 1H each), 6.47 and 6.77 (AB type q, J=2.8, 1H each), 7.30 (s, 5H). Found: C, 77.08; H, 5.41%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

The crystalline major product (173 mg, 35%) isolated from the slower eluted fractions was recrystallized from hexane–chloroform, mp 192—194 °C, and found to be the dimer **7** of the starting lactone **1c**: IR ($CHCl_3$) 1790, 1180; NMR ($CDCl_3$) 3.82 (s), 4.10 (s), 7.00—7.60 (m) with area ratio of 1 : 2 : 5. Found: C, 74.86; H, 5.17%. Calcd for $(C_{10}H_8O_2)_n$: C, 74.99; H, 5.03%.

The almost identical result was obtained when a Pyrex filter instead of a Vycor one was employed. After 4 hr irradiation, the yields of **4c** and the diner **7** was 8% and 55%, in addition to 10% recovery of **1c**, respectively.

The dimer **7** was quantitatively obtained by irradiation of **1c** in acetone without introduction of acetylene.

(c) To 1,1-Dimethoxyethylene. A solution of **1c** (300 mg, 1.9 mmol) and 1,1-dimethoxyethylene (2.5 g, 28 mmol) in dry benzene was irradiated at room temperature for 21 hr through quartz. After removal of the solvent and excess olefin under reduced pressure, the residue (600 mg) was chromatographed on preparative thin layer of silica gel using 1 : 1 petroleum ether–ether as developing agent to give 172 mg (37%) of 6,6-dimethoxy-5-phenyl-3-oxabicyclo-

[3.2.0]heptan-2-one (**9**). Analytical sample was purified by distillation (110—120 °C/1 mmHg). IR ($CHCl_3$) 2810, 1765; NMR (100 MHz, $CDCl_3$) 2.52 (dd, J=13.0 and 5.0, 1H), 2.87 (dd, J=13.0 and 10.0, 1H), 2.84 (s, 3H), 3.28 (s, 3H), around 3.28 (m, 1H), 4.55 and 5.18 (AB type q, J=9.0, 1H each), 7.20—7.40 (m, 5H). Found: C, 67.43; H, 6.56%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

*Photoadditions of α-Phenyl-γ-crotonolactone (**1e**).* *(a) To Ethylene*: α-Phenyl-γ-crotonolactone (**1e**) was prepared essentially according to Swain's procedure[26] and the yield was somewhat improved by slightly modified operations. A solution of **1e** (500 mg) in acetone (700 ml) was irradiated at room temperature through Pyrex with introduction of ethylene. After 3.5 hr of the irradiation period, the solvent was removed under reduced pressure and the residue (673 mg) was chromatographed on silica gel (40 g) using 4 : 1 petroleum ether–ether as eluent to yield 305 mg (52%) of 1-phenyl-3-oxabicyclo[3.2.0]heptan-2-one (**3e**), in addition to the recovery of **1e** (100 mg, 20%). Analytical sample was purified by distillation (105—110 °C/2 mmHg). IR ($CHCl_3$) 1765, 1160; NMR ($CDCl_3$) 1.70—2.68 (m, 4H), 3.41 (m, 1H), 4.27 (dd, J=9.8 and 1.5, 1H), 4.49 (dd, J=9.8 and 5.8, 1H), 7.38 (s, 5H). Found: C, 76.66, H, 6.38%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

(b) To Acetylene: A solution of **1e** (500 mg) in acetone (700 ml) was irradiated at −50 °C for 4.5 hr through Pyrex with introduction of acetylene. After removal of the solvent under reduced pressure, the resulting oily residue (814 mg) was chromatographed on silica gel (50 g) using 4 : 1 petroleum ether–ether as eluent to give 131 mg (23%) of 1-phenyl-3-oxabicyclo[3.2.0]hept-6-en-2-one (**4e**). The IR and NMR spectra were identical with those of the authentic specimen[11] in every respect.

*Photoadditions of γ-Methyl-γ-crotonolactone, β-Angelica Lactone (**1f**).* *(a) To Ethylene*: A solution of γ-methyl-γ-crotonolactone (**1f**)[27] (1.0 g) in acetone (700 ml) was irradiated at −50 °C for 2 hr through quartz with introduction of ethylene. Glpc analysis (column A, 210 °C, He 1.4 kg/cm²) of the reaction mixture indicated the photoproduct consisted of two components eluted at 4.2 min and 4.9 min with the area ratio of about 1 : 1. After evaporation of the solvent under reduced pressure, the residual liquid (1.7 g) was chromatographed on silica gel (60 g) using 4 : 1 petrolum ether–ether as eluent. From the rapidly eluted fractions, 266 mg (21%) of *exo*-4-methyl-3-oxabicyclo[3.2.0]heptan-2-one (**3f**), corresponding to the 4.2 min eluate on glpc, was obtained. Analytical sample was purified by distillation (90—100 °C/20 mmHg). IR (CCl_4) 1775, 1155; NMR 1.25 (d, J=6.3, 3H), 1.90—2.60 (m, 4H), 2.65—3.50 (m, 2H), 4.47 (dq, J=6.3 and 1.0, 1H). Found: C, 66.76; H, 8.12%. Calcd for $C_7H_{10}O_2$: C, 66.64; H, 7.99%.

From the slowly eluted fractions, 183 mg (14%) of the *endo*-methyl isomer, corresponding to the 4.9 min eluate on glpc, was isolated. Analytical sample was purified by distillation (90—100 °C/20 mmHg). IR (CCl_4) 1775, 1170; NMR 1.32 (d, J=6.1, 3H), 1.70—2.70 (m, 4H), 2.80—3.30 (m, 2H), 4.56 (dq, J=6.1 and 5.6, 1H). Found: C, 66.75; H, 8.15%. Calcd for $C_7H_{10}O_2$: C, 66.64; H, 7.99%.

(b) To Acetylene: A solution of **1f** (1.5 g) in acetone (800 ml) was irradiated at −50 °C through quartz with introduction of acetylene. At the reaction period of 4.5 hr, the ratio of **1f** and the product to 9 : 11 as determined by glpc on column A (210 °C, He 1.4 kg/cm²) and the product consisted of the *exo*- and *endo*-methyl isomers with the ratio of 6 : 5 (retention times of 3.3 min and 4.1 min, respectively) similar to the case of the ethylene adduct **3f**. At this stage, the reaction was intermitted and the mixture was evaporated *in vacuo*. The residual liquid (2.7 g) was chromatographed on silica gel (60 g) using 9 : 1 petroleum ether–ether as eluent to give the homogeneous *exo*-methyl (134 mg, 7%) and *endo*-methyl (130 mg, 7%) isomers of 4-methyl-3-oxabicyclo[3.2.0]hept-6-en-2-one (**4f**), and the analytical samples were purified by distillation (80—90 °C/20 mmHg). *Exo*-**4f**: IR (CCl_4) 1775, 1170; NMR 1.30 (d, J=6.7, 3H), 3.17 (dd, J=1.7 and 3.5, 1H), 3.61 (d, J=3.5, 1H), 4.50 (dq, J=6.7 and 1.7, 1H), 6.39 (br. s, 2H). Found: C, 67.79; H, 6.65%. Calcd for $C_7H_8O_2$: C, 67.73; H, 6.50%. *Endo*-**4f**: IR (CCl_4) 1770, 1170; NMR 1.38 (d, J=6.2, 3H), 3.20—3.70 (m, 2H), 4.55 (quint, J=6.2 and 6.2, 1H), 6.37 (br. s, 2H). Found: C, 67.27; H, 6.65%.

*Photoaddition of γ-Butyl-γ-crotonolactone (**1g**) to 1,1-Dimethoxyethylene.* A solution of γ-butyl-γ-crotonolactone (**1g**)[27] (1.46 g, 10 mmol) and 1,1-dimethoxyethylene (9.4 g, 107 mmol) in dry benzene (25 ml) was irradiated for 19 hr at room temperature through quartz. The solvent and excess olefin were evaporated under reduced pressure to give 3.5 g of brown liquid which consisted mainly of two components in a ratio of about 1 : 1 as determined by glpc analysis (column B, 218 °C He 2.4 kg/cm²). Chromatography of the residue on silica gel (80 g) using 7 : 3 hexane–ether as eluent gave 650 mg (28%) of *endo*-4-butyl-6,6-dimethoxy-3-oxabicyclo-[3.2.0]heptan-2-one (**24a**) and 900 mg (38%) of the *exo*-butyl isomer (**24b**), in addition to a small amount of the unreacted lactone. The analytical samples were purified by distillation (70—90 °C/3 mmHg). *Endo*-**24a**: IR (CCl_4) 2850, 2820, 1760; NMR (100 MHz) 0.93 (t, J=6.0, 3H), 1.20—1.80 (m, 6H), 2.10—2.50 (m, 2H), 2.70—3.00 (m, 2H), 3.10 (s, 3H), 3.12 (s, 3H), 4.26 (m, 1H). Found: C, 63.26; H, 8.88%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%. *Exo*-**24b**: IR (CCl_4) 2850, 2820, 1760; NMR (100 MHz) 0.96 (t, J=6.0, 3H), 1.20—1.80 (m, 6H), 2.20—2.50 (m, 2H), 2.70—2.95 (m, 2H), 3.12 (s, 3H), 3.17 (s, 3H), 4.68 (br. t, J=6.0, 1H). Found: C, 63.26; H, 8.58%.

*Photoadditions of Parasorbic Acid (**2a**).* *(a) To Ethylene*: A solution of parasorbic acid (**2a**)[28] (1.06 g) in acetone (500 ml) was irradiated at room temperature for 3 hr through quartz with introduction of ethylene. Evaporation of the solvent under reduced pressure, followed by chromatography of the residue on silica gel (60 g) using chloroform as eluent gave 260 mg of a mixture of the stereoisomers (at least two isomers) of 4-methyl-3-oxabicyclo[4.2.0]octan-2-one (**11**) as indicated by glpc on column C (170 °C, He 0.65 kg/cm²) Analytical sample was purified by distillation (120—130 °C/10 mmHg). IR (CCl_4) 1740, 1080; NMR 1.29—1.35 (two pairs of doublet, 3H), 1.50—3.20 (m, 8H), 4.00—4.30 (m, 1H). Found: C, 68.97; H, 8.79%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

(b) To Acetylene: A solution of **2a** (0.5 g) in acetone (250 ml) was irradiated at room temperature for 5 hr through quartz with introduction of acetylene. Analysis of the reaction mixture by glpc (column C, 180 °C, He 1.1 kg/cm²) apparently indicated a single peak due to the photoadduct eluted at 3.5 min with about 66% of area. Spectral sample of the product, 4-methyl-3-oxabicyclo[4.2.0]oct-7-en-2-one (**12**), was collected by preparative glpc using an SE-30 column (3 m×6 mm) at 230 °C. IR (CCl_4) 1740, 1060; NMR 1.29 (d, J=6.0, 3H), 1.60—2.40 (m, 2H), 3.40—3.70 (m, 2H), 4.20—4.40 (m, 1H), 6.00—6.20 (m, 2H).

(c) To 1,1-Dimethoxyethylene: A solution of **2a** (240 mg, 2.1 mmol) and 1,1-dimethoxyethylene (1.15 g, 13.1 mmol) in dry ether (80 ml) was irradiated at room temperature for

10 hr through Vycor. Analysis of the photolysate by glpc (column A, 155 °C, He 1.2 kg/cm²) indicated a main peak eluted at 3.0 min (*ca.* 66% of area) due to the photoproduct, along with the peaks of **2a** and by-products. Spectral sample of the product, 7,7-dimethoxy-4-methyl-3-oxabicyclo-[4.2.0]octan-2-one (**13**), was collected by glpc using a preparative SE-30 column (3 m×6 mm) at 230 °C and then passed through a short column of silica gel with anhydrous ether. IR (CCl_4) 2850, 1740, 1250; NMR 1.34 (d, J= 6.8, 3H), 1.50—3.00 (m, 5H), 3.10 (s, 3H), 3.15 (s, 3H), 3.60—3.80 (m, 1H), 4.20—4.40 (m, 1H).

*Photoaddition of 5,6-Dihydro-4-methyl-2H-pyran-2-one (**2b**) to Ethylene.* A solution of 5,6-dihydro-4-methyl-2*H*-pyran-2-one (**2b**) (344 mg), prepared by dehydration of mevalonic acid lactone with potassium bisulfate, in acetone (600 ml) was irradiated at room temperature for 3 hr through Vycor with introduction of ethylene. At the end of the irradiation period the solvent was removed by distillation under reduced pressure. The residue (770 mg) was chromatographed on preparative layer of silica gel using 1 : 2 petroleum ether–ether as developing agent to give 300 mg (70%) of 6-methyl-3-oxabicyclo[4.2.0]octan-2-one (**17**). Analytical sample was purified by distillation (85—95 °C/4 mmHg). IR (CCl_4) 1740, 1075; NMR (100 MHz) 1.26 (s, 3H), 1.50—3.00 (m, 7H), 4.20—4.60 (m, 2H). Found: C, 68.35; H, 8.45%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

*2-Hydroxy-6-methyl-2-methylsulfonyl-3-oxabicyclo[4.2.0]octane (**19**).* Sodium methylsulfonyl carbanion was prepared according to the reported manner[16] from sodium hydride (100 mg, 4.2 mmol), dimethylsulfone (495 mg, 4.2 mmol), and dimethyl sulfoxide (3 ml), and diluted with anhydrous tetrahydrofuran (3 ml). Then, a solution of **17** (270 mg, 2.0 mmol) in anhydrous tetrahydrofuran (3 ml) was added at room temperature with stirring and under nitrogen; the mixture turned immediately to deep red, and then heated at 50—60 °C for 1 hr. After cooling, the resulting solution was poured into ice-water, neutralized to pH 4—5, and extracted with chloroform five times. The combined extracts were successively washed with water and saturated salt solution, dried over anhydrous sodium sulfate, and freed from solvent to give 450 mg of crude product. Purification by chromatography on silica gel (15 g) using chloroform afforded 270 mg (76%) of crystalline **19**. Analytical sample was recrystallized from 1 : 1 petroleum ether–ether, mp 103.5—104.5 °C. IR (KBr) 3520, 1315, 1300; NMR ($CDCl_3$) 1.20 (s, 3H), 1.90—2.30 (m, 7H), 2.92 (finely splitted d, J=15.0, 1H), 3.32 (d, J=15.0, 1H), 3.40 (finely splitted s, 3H), 3.65 (ddd, J=11.8, 5.0, and 2.5, 1H), 4.03 (dt, J=11.8, 11.8, and 3.0, 1H). Found: C, 51.62; H, 8.11%. Calcd for $C_{10}H_{18}O_4S$: C, 51.27; H, 7.75%.

*cis-2-(β-Acetoxyethyl)-2-methylcyclobutyl Methyl Ketone (**22**).* To a solution of **19** (770 mg, 3.3 mmol) in 10% aqueous tetrahydrofuran (70 ml) was added aluminum amalgam prepared from 1.0 g of aluminum foil, and the mixture was refluxed for 8 hr. After removal of the insoluble material by filtration, the filtrate was concentrated under reduced pressure and extracted with ether twice. The combined extracts were washed with water and then saturated salt solution, and dried over anhydrous sodium sulfate. Evaporation of the solvent gave 500 mg (96%) of the equilibrium mixture of the methyl ketone **20** and the acetal **21** as indicated by tlc and NMR analyses. The mixture, without further purification, was treated with a mixture of pyridine (3 ml) and acetic anhydride (3 ml) at room temperature overnight. The reaction mixture was poured into ice-water and extracted with ether three times. The combined extracts were washed successively with dilute hydrochloric acid, sodium bicarbonate solution, water, and saturated salt solution, dried over anhydrous sodium sulfate and concentrated. The crude product (500 mg) was purified by passing through a silica gel column (20 g) with 1 : 4 petroleum ether–ether and distilled (100—105 °C/10 mmHg) to give 255 mg (40%) of **22** as a sole product. IR (CCl_4) 1740, 1708, 1235; NMR 1.32 (s, 3H), 1.95 (s, 3H), 2.00 (s, 3H), 2.97 (t, J=7.5, 1H), 1.40—2.40 (m, 6H), 4.00 (t, J=7.5, 2H). Found: C, 66.71; H, 9.47%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

*cis-2-Isopropenyl-1-methylcyclobutaneethanol = (±)-grandisol (**16**).* The Wittig reagent, methylenetriphenylphosphorane, was prepared in dimethyl sulfoxide as reported in the literature[18] and this solution (1.5 equiv, *ca.* 4 ml) was added dropwise to a solution of **22** (100 mg, 0.5 mmol) in anhydrous tetrahydrofuran (3 ml) at room temperature. The resulting mixture was stirred at room temperature for 3 hr under nitrogen and poured into a separatory funnel containing ice-water. The resulting yellow solution was extracted with petroleum ether three times. The combined extracts were washed successively with 1 : 1 dimethyl sulfoxide–water, water, and then saturated salt solution, dried, and concentrated under reduced pressure to give crude product (125 mg) which consisted of two components, being presumably **16** and the acetate. The mixture was dissolved in methanol (2 ml) containing five drops of 1M sodium hydroxide solution and heated at 60—70 °C for 3 hr. The cooled reaction mixture was diluted with water and extracted with ether three times. Evaporation of the solvent, followed by distillation (100—110 °C/17 mmHg) of the residual liquid gave 67 mg (87%) of (±)—**16**, the IR and NMR spectra of which were completely indistinguishable from those of the authentic (±)-grandisol synthesized through an alternative route.[9e] Found : C, 78.02; H, 11.93%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%.

*Hydrolysis of **24a** and **24b**.* A solution of **24a** (400 mg) in acetone (14 ml) containing a catalytic amount of *p*-toluenesulfonic acid was stirred at 60 °C overnight. Usual work-up gave 330 mg of oily product. Chromatography on silica gel (10 g) using 3 : 7 petroleum ether–ether afforded 261 mg (82%) of *endo*-4-butyl-3-oxabicyclo[3.2.0]heptane-2,6-dione (**25a**).

In the same manner *exo*-isomer **25b** was obtained in 94% yield (76 mg) from 100 mg of **24b**. Analytical samples were purified by distillation (110—120 °C/1 mmHg). **25a**: IR (CCl_4) 1790, 1780; NMR 0.95 (t, J=6.0, 3H), 1.20—1.90 (m, 6H) 3.00—3.80 (m, 3H), 4.00 (m, 1H), 4.54 (dq, J= 8.0 and 7.0, 1H). Found: C, 65.62; H, 7.81%. Calcd for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74%. **25b**: IR (CCl_4) 1790, 1780, 1170; NMR 0.95 (t, J=6.0, 3H), 1.20—1.80 (m, 6H), 3.10—3.80 (m, 4H), 4.58 (dt, J=6.0 and 1.7, 1H). Found: C, 65.66; H, 7.81%.

*Baeyer-Villiger Oxidation of **25a** and **25b**.* To a solution of **25a** (217 mg, 1.19 mmol) in acetic acid (4 ml) was added 30% aqueous hydrogen peroxide (520 mg), and the reaction mixture was allowed to stand at room temperature overnight. The mixture was neutralized with saturated sodium carbonate solution and extracted with ether three times. The combined extracts were washed with water and saturated salt solution and evaporated to dryness to give 216 mg (92%) of crystalline residue. Recrystallization from petroleum ether–ether–chloroform (2 : 2 : 1) gave colorless needles of *endo*-4-butyl-3,6-dioxabicyclo[3.3.0]octane-2,7-dione (**26a**), mp 85.0—85.5 °C:[20] IR (KBr) 1770, 1200, 1150; NMR ($CDCl_3$) 0.96 (t, J=6.5, 3H), 1.20—1.70 (m, 4H), 1.70—2.10 (m, 2H), 2.93 (d, J=6.0, 2H), 3.53 (q, J=6.0, 1H), 4.59 (dt, J=7.0 and 4.0, 1H), 5.10 (dd, J=6.0 and 4.0, 1H). Found: C, 60.26; H, 7.26%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H,

7.12%.

According to the identical manner using 112 mg of **25b**, crystalline *exo*-isomer **26b** was obtained in 88% yield (106 mg). Recrystallized sample from carbon tetrachloride had mp 85.0—85.5 °C.[20,29] IR (KBr) 1775, 1200; NMR ($CDCl_3$) 0.96 (t, J=6.5, 3H), 1.20—1.90 (m, 6H), 2.94 (d, J=6.2, 2H), 3.47 (q, J=6.4, 1H), 4.70 (t, J=6.5, 1H), 4.88 (d, J=6.4, 1H). Found: C, 60.53; H, 6.77%. The structures of **26a** and **26b** were further confirmed by comparison of the IR and NMR spectra with those of the samples provided by Professor Yoshikoshi.

The authors are grateful to Drs. C. A. Henrick and J. B. Siddall, Zoecon Corporation, for providing the copies of IR and NMR spectra of (±)-grandisol and to Professor A. Yoshikoshi, our Institute, for the identification of bislactones **26a** and **26b**. The authors also thank Miss Shukuko Suzuki for her technical assistance in part. Financial support from the Ministry of Education of Japan and Asahi Glass Foundation is gratefully acknowledged.

(Received September 12, 1975)

Some derivatives of pseudo-geminal ketone of tris[2.2.2]paraxylylene (I) were prepared and their spectral properties were investigated in connection with their structural characteristics. The stereochemistry of two isomers of pseudo-geminal carbinols of tris[2.2.2]paraxylylene (III and V) was determined on the basis of chemical shifts of benzhydryl protons and H_o protons in NMR spectra and also of ν_{O-H} bands in IR spectra. The difference in chemical shifts of H_p protons of the two alcohols was explained in terms of the change in electron densities of *para* carbon atoms.

In the preceding paper,[1] the authors reported the high yield preparation of pseudo-geminal ketone of tris[2.2.2]paraxylylene (I) and its spectral properties in connection with its structure. The remarkable high frequency shift of $\nu_{C=O}$ band in the IR spectrum and the large hypochromic effect of intramolecular charge-transfer absorption on the electronic spectrum of I compared with the corresponding spectral characteristics of 5*H*-10,11-dihydrodibenzo[*a*,*d*]cycloheptene-5-one [VI] indicate the lack of coplanarity between carbonyl and benzene planes, and the presence of angle strain about the carbonyl.

Taking these characteristics into consideration, some derivatives of I were prepared in order to elucidate relationships between structures and spectral properties. In this paper, the authors describe some interesting NMR spectral characteristics in the pseudo-geminal tris[2.2.2]paraxylylene derivatives.

Results and Discussion

Preparation. Pseudo-geminal ketone (I) was prepared from tris[2.2.2]paraxylylene by acetylation, bromoform reaction and intramolecular Friedel-Crafts acylation.[1] Reduction of I with sodium tetrahydroborate(−1) in dioxane or with zinc powder in alkaline aqueous ethanol gave 92% or 71% yield, respectively, of "equatorial" alcohol (III), mp 181.0 °C, exclusively. The Wolff-Kishner reduction of I with aqueous hydrazine and sodium hydroxide at 195 °C yielded 44% of pseudo-geminal methanotris[2.2.2]paraxylylene (II) and 46% of III. III was converted into the corresponding trifluoromethanesulfonate (IV) on treatment with butyllithium and trifluoromethanesulfonyl chloride in ether. IV was hydrolyzed in aqueous dioxane to give the stereoisomeric "axial" alcohol (V), mp>300 °C, in quantitative yield.

Determination of Stereochemistry of Pseudo-Geminal Carbinols of Tris[2.2.2]paraxylylene. Based on molecular model (Dreiding and CPK), the pseudo-geminal bridged tris[2.2.2]paraxylylenes are regarded to have appreciably rigid structures, where conformation change between "equatorial" and "axial" positions about pseudo-geminal bridge carbon seems to be difficult and environments of these positions seem to differ remarkably. The stereochemistry of the two isomeric

a) Ref. 1.

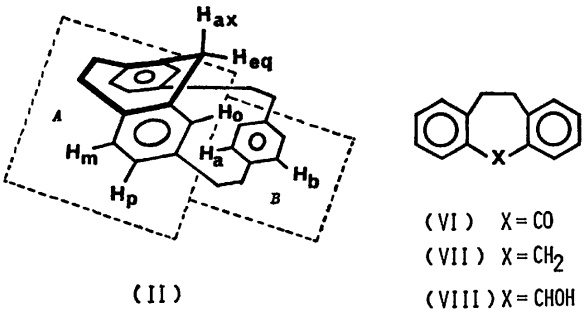

Fig. 2

alcohols (III and V) was investigated mostly by means of NMR spectra. The NMR spectral data of the two alcohols are given in Table 1 along with those of the related compounds. Absorptions of the aromatic and benzhydryl protons are shown in Fig. 1.

The seven membered ring of II (bold line, Fig. 2) is forced to be in a boat conformation due to the remarkably large barrier to the expected conformation change, as shown by the NMR spectra of II in hexachlorobutadiene which shows no substantial temperature dependence up to 180 °C. Irradiation at δ 2.88 caused increase in area intensity of the H_o signal (δ 6.12) of II by 22±1%, while only a very small increase (2.7±0.1%) was observed upon irradiation at δ 4.12. From this nuclear Overhauser effect[2] the higher field signal (δ 2.88) was determined to be H_{eq}, "equatorial" about pseudo-geminal carbon, and the lower (δ 4.12) to be H_{ax}, "axial". Since the chemical shift of a proton α to hydroxyl was reported to be not remarkably affected by the change in stereochemistry of the group,[3] assignments of stereochemistry of the present carbinols are made as shown in Fig. 1. Deshielding of the H_o protons of III (by 0.41 ppm lower field than those of V) is, thus, mainly attributed to anisotropic effect of the "equatorial" oxygen atom in a close proximity.

The low field absorption of the "axial" proton in the present system is consistent with those reported for the 3,4-homotropylidenes,[4] dihydropleiadenes[5] or dihydroanthracenes.[6]

A marked difference between observed ν_{O-H} of these two isomeric alcohols in also in line with the present stereochemistry. The ν_{O-H} values of III, V and VIII (dilute solutions in carbon tetrachloride)

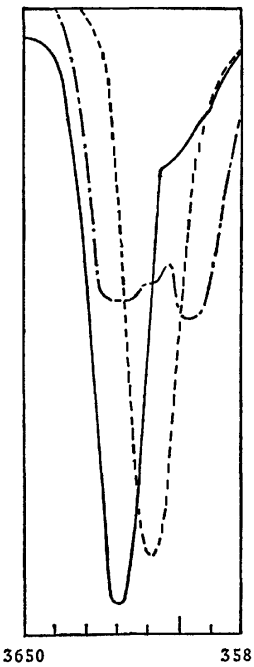

Fig. 3. ν_{O-H} absorptions of III (——), V (- - -) and VIII (— - —) in CCl_4. Concentration 5×10^{-4} M, cell thickness 2.5 cm.

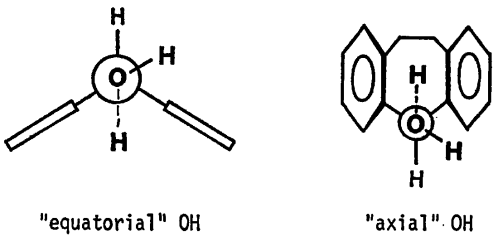

Fig. 4.

are shown in Fig. 3. The "axial" hydroxyl group is expected to interact with a phenyl group (Fig. 4), known as the π-hydrogen bonding,[7] shifting the ν_{O-H} of V to a relatively low frequency, 3608 cm^{-1}. On the other hand, the ν_{O-H} of III appears at relatively high frequency, 3619 cm^{-1}, again in line with the sterochemistry, where the "equatorial" hydroxyl group does not seem to interact with phenyl group. The above consideration is supported by IR spectra of structurally related compounds, 9-fluorenol (3591

cm^{-1}, only the "axial" conformation is allowed) and VIII (3620, 3609^{sh} and 3597 cm^{-1}, more than two conformations are allowed due to its flexible structure). The stereochemistry of the alcohols (III and V), therefore, suggests highly stereoselective attacks (*anti* to the *B* benzene ring) of nucleophiles such as hydride or hydroxide, toward the carbonyl carbon.

Chemical Shift of Pseudo-Geminal Bridged Tris[2.2.2]-*paraxylylene.* A remarkable characteristic appearing in the NMR chemical shifts (Table 1) of the pseudo-geminal bridged tris[2.2.2]paraxylylenes is the absorption of H_o and H_a protons at a considerably high field. All of the H_a protons of the four derivatives (I, II, III and V) are observed by 1.5 ppm upfield (δ from 5.51 to 5.57) than *p*-xylene. We come across a similar situation in the aromatic protons of 4,5 : 7,8-dibenzo[2.2]paracyclophane (IX, Fig. 5)[8] showing absorption at δ 5.50, which is located just above (*ca.* 3.0 Å) the aromatic ring. Thus, for the H_a protons of our present compounds, considered to be located just above (3.1 Å) the "face"[1] benzene rings (*A*) judging from molecular models, the observed high field shifts are attributed to a transannular shielding effect of the *A* rings (see II).

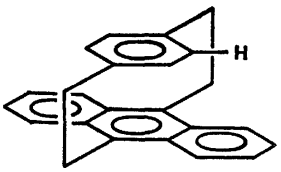

Fig. 5.

Since the absorption of the H_o protons of II appears at δ 6.12, a field higher than the corresponding noncyclic VII by 0.97 ppm, the transannular shielding of the *B* ring is estimated to be 0.82 ppm assuming a 0.15 ppm[9] upfield shift due to the inductive effect of the *meta* methylene bridges. This reduced transannular shielding is responsible for deviation (1.6 Å by the model) of location of the H_o proton from the center of the *B* ring.

The H_p protons of II appear at a field only 0.21 ppm higher than VII. This relatively small shift is mostly attributable to the *meta* methylene bridges. Only a negligibly small transannular shielding seems to be present at this position.

An interesting difference (0.06 ppm) between the chemical shifts of the H_p protons is seen for V as compared with III.[10] Since the distance between the H_p hydrogen and the hydroxyl oxygen atoms is estimated to be 6.0—6.1 Å, at most a 0.2 ppm difference is responsible for the change in the chemical shift due to anisotropic shielding and electrostatic field effect.[11,12] The main part of the difference is, therefore, interpreted in terms of the change in electron densities of the *para* carbon atoms. Linear correlations of chemical shifts of aromatic protons with electron densities of ring carbon atoms have been well established.[13] The CNDO/2[14] calculations were carried out for two conformations, where the hydroxyl was perpendicular or coplanar to the phenyl plane, of benzyl alcohol taken as a model compound. The calculated electron density of the *para* carbon was lower (by 0.003 *e*, which caused by 0.04 ppm down field shift according to the equation[13b]) for the perpendicular form. This is clearly in line with the observed lower chemical shift in V.

Experimental

Measurements and Calculations. All the melting points were uncorrected. NMR spectra were recorded with a Varian HA-100 or a Varian EM-360 spectrometer. The former was also employed for the variable-temperature and the nuclear Overhauser experiments. The sample for the latter experiment was degassed. Mass spectra were determined with a Hitachi RMU-6C mass spectrometer with ionization current 70 eV. Electronic spectra were measured with a Hitachi EPS-3T recording spectrophotometer, the IR spectra being taken on a Hitachi EPI-G3 grating infrared spectrophotometer. Theoretical calculations were carried out by use of the FACOM 230-75 computer at the Data Processing Center of Kyoto University.

Pseudo-Geminal "Equatorial" Carbinol of Tris[*2.2.2*]*paraxylylene (III).* *a) Zinc Reduction*: To a hot solution of 520 mg of I in 70 ml of ethanol was added a mixture of 7 g of zinc powder, 7 g of sodium hydroxide and 10 ml of water. The mixture was refluxed for 2 hr and concentrated to half volume. After being cooled to room temperature, the mixture was filtered. The filtrate was extracted six times with ether. The combined ether extract was washed with saturated aqueous sodium chloride, dried over anhydrous magnesium sulfate, and the solvent was evaporated. The residual solids were recrystallized with benzene-dichloromethane (6/1 vol/vol) to give 370 mg (71%) of III as colorless prisms; mp 181.0 °C. MS *m/e* (rel intensity): 340 (M^+, 88), 322 (36), 311 (54), 218 (100), 205 (31), 193 (32), 133 (47), and 104 (36). IR (KBr): 3470, 3000, 2930, 2840, 1495, 1440, 1155, 1045, 1040, 805, 620, and 455 cm^{-1}. UV (cyclohexane) λ_{max}: 279^{sh} (ε 800), 265 (900), 272^{sh} (930), 274 (1000), and 281 nm (910). Found: C, 88.48; H, 7.05%. Calcd for $C_{25}H_{24}O$: C, 88.19; H, 7.11%.

b) Sodium Tetrahydroborate (−1) Reduction: To a stirred solution of 430 mg (1.27 mmol) of I and 0.5 ml of 0.1 M aqueous sodium hydroxide in 10 ml of dioxane was added 242 mg (6.35 mmol) of sodium tetrahydroborate (−1) at room temperature, stirring being continued for 3 hr. Excess tetrahydroborate (−1) was removed by boiling the solution for 5 min. The solution was then cooled and extracted three times with chloroform. The combined chloroform extract was washed with saturated aqueous sodium chloride and dried over anhydrous sodium sulfate, the solvent being evaporated. The residual solids were chromatographed on a silica gel column with benzene to give 397 mg (92%) of III.

Pseudo-Geminal Methanotris[*2.2.2*]*paraxylylene (II).* A mixture of 50 mg of I, 200 mg of sodium hydroxide, 10 drops of hydrazine hydrate (abt. 80%) and 4 ml of diethylene glycol was refluxed for 40 min. After being cooled, the mixture was extracted with ether. The extract was washed with aqueous sodium chloride and dried over anhydrous magnesium sulfate. The solvent was evaporated and the residue was chromatographed on a silica gel column with hexane-dichloromethane (1 : 1) and then dichloromethane. The first fraction gave 21 mg (44%) of II, and the second fraction gave 23 mg (46%) of III which was identified with an authentic III by NMR and IR spectra. Recrystallization of II from hexane-chloroform gave colorless plates; mp 189.5—190.5 °C. MS *m/e* (rel intensity): 324 (M^+, 100), 220

(26), 219 (40), 205 (61), 129 (26), 104 (21), and 83 (28). IR (KBr): 3000, 2930, 2850, 1500, 1440, 1100, 810, 590, and 460 cm^{-1}. UV (cyclohexane) λ_{max}: 258^{sh} (ε 650), 261^{sh} (690), 266 (860), 274 (1060), 279 (830), and 282 nm (1070). Found: C, 92.42; H, 7.48%. Calcd for $C_{25}H_{24}$: C, 92.54; H, 7.46%.

The Trifluoromethanesulfonate of III (IV). To a stirred solution of 190 mg of III in 5 ml of dry ether was added 0.3 ml of abt. 20% butyllithium in hexane at room temperature, stirring being continued for 10 min. A few drops of trifluoromethanesulfonyl chloride were then added, and stirring was continued for 10 min at room temperature. The solvent was removed under reduced pressure and the residue was chromatographed on a silica gel column with benzene. The crystals from the major fraction were recrystallized from petroleum ether to give 180 mg (68%) of IV as colorless needles; mp 158.5—159.0 °C (dec). IR (KBr): 2930, 1415, 1250, 1215, 1200, 950, 890, 805, 635, 605, 580, 515, and 460 cm^{-1}. NMR ($CDCl_3$): δ 2.0—3.5 (m, 12H, $-CH_2-$), 5.56 (m, 2H, H_a), 6.39 (m, 2H, H_0), 6.93 (d, 2H, J=8.0 Hz, H_m), 7.00 (s, 1H, H_{ax}), 7.01 (dd, 2H, J=8.0 Hz, J=1.5 Hz, H_p), and 7.12 (m, 2H, H_b). Found: C, 66.18; H, 5.19%. Calcd for $C_{26}H_{23}F_3O_3S$: C, 66.09; H, 4.91%.

Pseudo-Geminal "Axial" Carbinol of Tris[2.2.2]paraxylylene (V). A solution of 52 mg of IV in 9 ml of dioxane and 6 ml of water in a sealed tube was placed in a bath kept at 110.6±0.1 °C for 23 hr. After being cooled, the reaction mixture was diluted with water and extracted with ether–benzene (1 : 1). The ether–benzene extract was washed with aqueous sodium hydrogencarbonate and then with saturated aqueous sodium chloride, and dried over anhydrous sodium sulfate. The solvent was evaporated to yield 39 mg (100 %) of colorless crystals of V, which was recrystallized from benzene to give colorless needles; mp> 300 °C. MS *m/e* (rel intensity): 340 (M^+, 6), 322 (45), 218 (46), 202 (19), 104 (100), 103 (27), and 78 (32). IR (KBr): 3430, 3000, 2930, 2840, 1500, 1440, 1045, 1030, 810, 630, 580, and 460 cm^{-1}. UV (cyclohexane) λ_{max}: 244^{sh} (ε 4940), 265^{sh} (1240), 274 (1320), and 284 nm (1110). Found: C, 88.42; H, 7.26%. Calcd for $C_{25}H_{24}O$: C, 88.19; H, 7.11%.

Chemical Synthesis of *N*-Acetylmuramyl Peptides with Partial Structures of Bacterial Cell Wall and Their Analogs in Relation to Immunoadjuvant Activities[1)]

Shoichi KUSUMOTO, Yuzo TARUMI, Kazuhiro IKENAKA and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received September 16, 1975)

N-Acetylmuramyl peptides of successive length corresponding to the partial structures of cell wall in *Staphylococcus aureus* were synthesized in order to elucidate the minimum effective structure responsible for immunoadjuvant activity of bacterial cell walls. In view of the finding that *N*-acetylmuramyl-L-alanyl-D-isoglutamine was the least structure moiety for exhibition of the activity, nine analogs of either *N*-acetylmuramyl amino acid or *N*-acetylmuramyl dipeptide were also synthesized.

The fact that mycobacterium cell exhibits the immunoadjuvant activity had been first described by Freund in 1956.[2)] He observed the significant stimulation of both humoral and cellular immune responses to a protein antigen, when the antigen was administered together with killed cell of this bacterium. Successive investigations have revealed that this activity is not restricted to mycobacterium cells but manifests in many other bacterial cells commonly, and that water soluble fragments involving peptidoglycan are responsible for the activity.[3)] Meanwhile, the chemical structure of such bacterial peptidoglycan was clarified by many investigators.[4)] For example, the main chain of peptidoglycan in *Staphylococcus aureus* is composed of *N*-acetylglucosamines and *N*-acetylmuramic acids alternately, and tetrapeptide subunits of L-alanyl-D-isoglutaminyl-L-lysyl-D-alanine are linked to the carboxyl groups of *N*-acetylmuramic acids. The carboxyl group of *C*-terminal D-alanine in one peptide subunit is connected to the ε-amino group of L-lysine in the another unit through a pentaglycine bridge, thus completing the network structure of cell wall. The peptidoglycans of many other bacteria have fundamentally similar structures, though the lysine residue is often replaced with α,ε-diaminopimelic acid and glycine residue in the bridge also with other amino acids.

Recently, Kotani *et al.*[1,5)] found the fact that *N*-acetylmuramyl peptides obtained by enzymatic digestion of cell wall, *i.e.*, N^{α}-(*N*-acetylmuramyl-L-alanyl-D-isoglutaminyl)-N^{ε}-(glycyl-glycyl)-L-lysyl-D-alanine from *S. aureus* and *N*-acetylmuramyl-L-alanyl-D-isoglutaminyl-*meso*-diaminopimelyl-D-alanine and/or *N*-acetylmuramyl-L-alanyl-D-isoglutaminyl-*meso*-diaminopimelic acid from *Lactobacillus plantarum*, showed definite adjuvant activities. These muramyl peptides seemed to be the smallest chemical entities possessing adjuvant activity in the cell wall structure. Lederer *et al.*[6)] as well as Fleck *et al.*[7)] also reported that the monomeric subunit is enough essential for the adjuvant activities of peptidoglycan from their result of enzymatic degradations.

However, there seemed to remain still some ambiguity on possible disturbance by inevitable impurities which contaminated the enzymatic digests and caused the adjuvant activity. Furthermore, the method of enzymatic degradation has a limitation for the determination of the minimal structure for exhibition of the activity. In view of the above situation, the chemical synthesis would be expected to have obvious advantage particularly in this case, as one can prepare not only a satisfactory pure substance of natural structure but also tailor-made analogs to investigate a relation between the structure and the activity. We therefore synthesized several *N*-acetylmuramyl peptides corresponding to the partial structures of peptidoglycan in *S. aureus*, and could thus demonstrate clearly that *N*-acetylmuramyl-L-alanyl-D-isoglutamine is the least structure required for the adjuvant activity.[8)] The experimental results on the biological tests of these synthetic substances were already reported.[1,9)] In the present paper, we report the full details of the synthesis of the muramyl peptides.

As muramyl peptides of natural type structure involved in the *S. aureus* peptidoglycan, the following four compounds of successive length were prepared by total synthesis, *i.e.*, *N*-acetylmuramyl-L-alanine (**1d**), *N*-acetylmuramyl-L-alanyl-D-isoglutamine (**2d**), *N*-acetylmuramyl-L-alanyl-D-isoglutaminyl-L-lysine (**3d**) and *N*-acetylmuramyl-L-alanyl-D-isoglutaminyl-L-lysyl-D-alanine (**4d**).

These compounds were all preprared in principle by coupling of a protected *N*-acetylmuramic acid, *i.e.*, benzyl 2-acetamido-4,6-*O*-benzylidene-3-*O*-(D-1′-carboxyethyl)-2-deoxy-α-D-glucopyranoside (**5**)[10)] with suitably protected peptide portions followed by deprotection. The all protecting groups were so selected as to be removed simultaneously by mild hydrogenolysis at the final synthetic step.

Each peptide portion was synthesized by conventional method using *t*-butoxycarbonyl (Boc) and benzyloxycarbonyl (Z) groups for α- and ε-amino protections respectively and benzyl ester for carboxyl protection. Although the synthesis of Boc-L-alanyl-D-isoglutamine benzyl ester (**2a**) and N^{α}-(Boc-L-alanyl-D-isoglutaminyl)-N^{ε}-Z-L-lysyl-D-alanine benzyl ester (**4a**) had been already described by Bricas *et al.*,[11)] synthetic procedure and yield of the products were eventually improved in this investigation. Thus, the dipeptide (**2a**) was prepared by coupling of Boc-L-alanine with *D*-isoglutamine benzyl ester using dicyclohexylcarbodiimide–*N*-hydroxysuccinimide. Hydrogenolysis of **2a** gave Boc-L-alanyl-D-isoglutamine, which was then coupled with benzyl N^{ε}-Z-L-lysinate or N^{ε}-Z-lysyl-L-D-alanine benzyl ester by means of mixed anhydride method to afford the protected tripeptide (**3a**) or

tetrapeptide (**4a**). The Boc group in **2a** was removed with hydrogen chloride in acetic acid, while trifluoroacetic acid was employed for deprotection of those in **3a** and **4a**. The di-, tri- and tetrapeptides (**2b**, **3b**, and **4b**) with free amino terminals were thus obtained and then subjected to condensation with the muramic acid moiety (**5**).

Synthesis of muramyl peptides was first reported by Lanzilotti *et al.*[12] who prepared *N*-acetylmuramyl-L-alanyl-D-α- and γ-glutamyl-L-lysyl-D-alanyl-D-alanine by the same strategy mentioned above. They used Woodward's reagent K for coupling of **5** with peptides

a) All these compounds except **13d** are colorless hygroscopic powder and do not show definite melting points. b) This compound was recrystallized from water—methanol—ether; mp 198 °C (decomp.). c) *c* 0.5 in H_2O at 15—17 °C.

without mention of the yield of the reaction. Thereafter, Chaturvedi *et al.*[13] reported the synthesis of *N*-acetylmuramyl-L-alanine, *N*-acetylmuramyl-L-alanyl-D-glutamic acid and several their analogs again by the same procedures and reagents. In our study, more convenient and simple methods generally applicable to the synthesis of muramyl peptides were investigated for this coupling.[14] Coupling of **5** with peptides by the active ester method was first examined using benzyl L-alaninate (**1b**). When the 1-succinimidyl ester of **5** was prepared using dicyclohexylcarbodiimide and allowed to react with **1b**, the fully protected *N*-acetylmuramyl-L-alanine (**1c**) was obtained in a fairly good yield. Its structure was confirmed by elemental analysis and NMR spectrum, in which two doublet signals of methyl groups attributed to the alanine and the muramic acid residues were clearly observed. The protected *N*-acetylmuramyl peptides **2c**, **3c** and **4c** were also obtained using the similar procedure by coupling of **5** with **2b**, **3b** and **4b**. In the latter two cases, 1-succinimidyl ester of **5** was isolated and recrystallized before the coupling.

Furthermore, it was found that this coupling proceeds also by the mixed anhydride method in a comparable yield.

The hydrogenolytic removal of the protecting groups in **1c** was carried out with palladium black in acetic acid. Although addition of hydrochloric acid increased the reaction rate considerably, it caused a formation of several by-products and removal of them required laborious process. Thus, **2c** was hydrogenolyzed in acetic acid without hydrochloric acid to afford pure **2d**. However, complete deprotections of **3c** and **4c** were only accomplished by addition of 0.5 equivalent of hydrochloric acid forming **3d** and **4d** in pure states, and use of 1 equivalent or more of the acid resulted in a formation of much amount of a by-product in each case. All the free *N*-acetylmuramyl peptides (**1d**—**4d**) precipitated as hygroscopic powder on addition of anhydrous ether to their ethanol or methanol solution. The powders thus obtained were found to contain considerable amount of the solvent alcohol from the results of elemental analyses and NMR spectra. The alcohol-free compounds adequate to biological tests and elemental analyses were prepared by lyophilization.

The *N*-acetylmuramyl amino acids and peptides of unnatural structures (**6d**—**14d**) were also synthesized by the similar procedures. The peptide portions were prepared by dicyclohexylcarbodiimide–*N*-hydroxysuccinimide method using Boc and benzyl groups for protections. After removal of Boc group, the products (**6b**—**14b**) were coupled with **5** by means of either the active ester or the mixed anhydride method, and the final hydrogenolysis afforded each *N*-acetylmuramyl peptide (**6d**—**14d**).

The free di-, tri- and tetrapeptides without sugar part, *i.e.*, L-alanyl-D-isoglutamine (**2e**), L-alanyl-D-isoglutaminyl-L-lysine (**3e**) and L-alanyl-D-isoglutaminyl-L-lysyl-D-alanine (**4e**) were also prepared in order to know the significance of *N*-acetylmuramyl moiety for the adjuvant activity. The dipeptide (**2e**) was obtained by hydrogenolysis of **2a** followed by removal of Boc group with trifluoroacetic acid. Dihydrochloride and bistrifluoroacetate of **3e** and bistrifluoroacetate of **4e**[11] were also prepared similarly from **3a** and **4a**, respectively.

Experimental

All melting points are uncorrected. Silica gel G according to Stahl, Merck, was used for thin-layer chromatography (tlc). Paper electrophoresis (PEP) was carried out using Toyo filter paper No. 51 in a pyridine–acetic acid–water (30 : 4 : 966 v/v/v) buffer solution.

1-α-O-Benzyl-4,6-O-benzylidene-N-acetylmuramyl-L-alanine Benzyl Ester (1c). Dicyclohexylcarbodiimide (0.82 g, 4.0 mmol) was added to an ice-cooled solution of benzyl 2-acetamido-4,6-*O*-benzylidene-3-*O*-(D-1'-carboxyethyl)-2-deoxy-α-D-glucopyranoside (**5**)[10] (1.88 g, 4.0 mmol) and *N*-hydroxysuccinimide (0.57 g, 5.0 mmol) in tetrahydrofuran (40 ml). The mixture was stirred in an ice bath for 3 hr and then at room temperature for 1 hr. Dicyclohexylurea formed was filtered off and washed with tetrahydrofuran. The combined filtrate and washings were again cooled in an ice bath and there were added benzyl L-alaninate *p*-toluenesulfonate (1.54 g, 4.4 mmol) and triethylamine (0.62 ml, 4.4 mmol). The mixture was stirred overnight at room temperature. After evaporation of the solvent, the residue was dissolved in chloroform, worked up as usual and the product was recrystallized from ethanol; yield, 1.89 g (75%); mp 211.5—216.5 °C. A sample for elemental analysis was recrystallized again from ethanol; mp 215.5—217 °C; $[\alpha]_D^{20}+85.6°$ (*c* 2.1, *N*,*N*-dimethylformamide). NMR (in $CDCl_3$): δ1.37 and 1.44 (each 3H, d, $J=7$ Hz), 1.90 (3H, s; CH_3CO) and 7.2—7.5 (15H; aromatic).

Found: C, 66.47; H, 6.42; N, 4.65%. Calcd for $C_{35}H_{40}O_9N_2$: C, 66.44; H, 6.37; N, 4.43%.

N-Acetylmuramyl-L-alanine (1d). A solution of **1c** (1.26 g, 2.0 mmol) in acetic acid (100 ml) containing 6M hydrochloric acid (1 ml) was hydrogenolyzed in the presence of palladium black at room temperature for 31 hr. The solvent was removed *in vacuo*, the syrupy residue was dissolved in water and subjected to column chromatography on a mixture of Darco G-60 active charcoal (30 g) and Hyflo Super-Cel (90 g). Elution with water–ethanol (9 : 1) afforded a fairly pure product, which was passed through a column of Dowex 50×8 (H^+ form) to remove the ninhydrin-positive impurity. The eluate was evaporated *in vacuo* and the residue was dissolved in absolute ethanol. Hygroscopic solid was formed on addition of absolute ether; yield, 0.490 g (67%). This product was dissolved in water and lyophilized to give colorless hygroscopic solid, which was subjected to biological test and elemental analysis. $[\alpha]_D^{17}+35.6°$ (after 3 min), +30.9 ° (after 19 hr) (*c* 0.51, H_2O).

Found: C, 46.08; H, 6.76; N, 7.54%. Calcd for $C_{14}H_{24}O_9N_2$: C, 46.15; H, 6.64; N, 7.69%.

t-Butoxycarbonyl-L-alanyl-D-isoglutamine Benzyl Ester (2a). *N*-Hydroxysuccinimide (2.25 g, 19.6 mmol) and dicyclohexylcarbodiimide (4.04 g, 19.6 mmol) were added to an ice-cooled solution of Boc-L-alanine (3.71 g, 19.6 mmol) in tetrahydrofuran (70 ml). After stirring for 10 min, there was added a cold mixture of benzyl D-isoglutaminate hydrochloride (5.33 g, 19.6 mmol) and triethylamine (2.70 ml, 19.6 mmol) in tetrahydrofuran (100 ml), and the mixture was stirred in an ice bath. Stirring was continued overnight, allowing the temperature of the mixture to reach to room temperature. Triethylamine hydrochloride and dicyclohexylurea formed were filtered off and the filtrate was worked up as usual. Recrystallization was effected from ethyl acetate–hexane; yield, 7.28 g (91%); mp 137.5—138.5 °C (lit,[11] 133—134 °C); $[\alpha]_D^{28}-8.1°$ (*c* 1.0, methanol).

Found: C, 58.64; H, 7.15; N, 10.41%. Calcd for $C_{20}H_{29}O_6N_3$: C, 58.95; H, 7.17; N, 10.31%.

L-Alanyl-D-isoglutamine Benzyl Ester (2b) Hydrochloride. Dry hydrogen chloride was passed through a solution of **2a** (3.70 g, 9.1 mmol) in acetic acid (50 ml) for 1 hr. After evaporation of the solvent *in vacuo*, the syrupy residue crystallized on trituration with ether. Recrystallization was effected from ethanol–ether; yield, 2.76 g (89%); mp 149.5—151 °C; $[\alpha]_D^{23}+10.8°$ (*c* 2.1, ethanol).

Found: C, 51.68; H, 6.41; N, 11.91; Cl, 9.97%. Calcd for $C_{15}H_{21}O_4N_3Cl\cdot 1/4H_2O$: C, 51.87; H, 6.24; N, 12.10; Cl, 10.21%.

1-α-O-Benzyl-4,6-O-benzylidene-N-acetylmuramyl-L-alanyl-D-isoglutamine Benzyl Ester (2c). i) *Dicyclohexylcarbodiimide–N-hydroxysuccinimide Method*: The procedure is similar to that described above for **1c**. Compound **5** (2.83 g, 6.0 mmol) was converted into its 1-succinimidyl ester with dicyclohexylcarbodiimide (1.24 g, 6.0 mmol) and *N*-hydroxysuccinimide (0.69 g, 6.0 mmol) in tetrahydrofuran (80 ml) and then treated with **2b** hydrochloride (2.06 g, 6.0 mmol) and triethylamine (0.85 ml, 6.0 mmol). The insoluble material

was collected by filtration, and dissolved in *N,N*-dimethylformamide. After filtration of insoluble triethylamine hydrochloride, the product was precipitated on addition of ether; yield, 3.43 g (75%). Recrystallization was effected from *N,N*-dimethylformamide–95% ethanol; mp 226.5—227.5 °C (decomp.); $[\alpha]_D^{25}$ +88.5 ° (*c* 2.1, *N,N*-dimethylformamide).

Found: C, 62.36; H, 6.39; N, 7.23%. Calcd for $C_{40}H_{48}O_{11}N_4 \cdot 1/2H_2O$: C, 62.40; H, 6.42; N, 7.28%.

ii) *Mixed Anhydride Method*: Compound **2a** (408 mg, 1.0 mmol) was dissolved in trifluoroacetic acid (2 ml). After standing at room temperature for 15 min, excess trifluoroacetic acid was removed *in vacuo*, and the remaining **2b** trifluoroacetate was dried over potassium hydroxide *in vacuo*. Ethyl chloroformate (0.10 ml, 1.0 mmol) and *N*-methylmorpholine (0.11 ml, 1.0 mmol) were added to a solution of **5** (472 mg, 1.0 mmol) in tetrahydrofuran (10 ml) at −19 °C. The mixture was stirred at this temperature for 15 min, then a cold solution of **2b** trifluoroacetate above obtained and *N*-methylmorpholine (0.11 ml, 1.0 mmol) in tetrahydrofuran (10 ml) was added. The mixture was stirred at room temperature for 22 hr. Then, water (100 ml) was added and the product was collected by filtration; yield, 600 mg (79%). It was reprecipitated from *N,N*-dimethylformamide–ether; mp 224—225 °C (decomp.); $[\alpha]_D^{15}$ + 83.4 ° (*c* 2.5, *N,N*-dimethylformamide). The IR spectrum of this compound was identical with that of the product in (i).

N-Acetylmuramyl-L-alanyl-D-isogultamine (2d). A solution of **2c** (1.52 g, 2.0 mmol) in acetic acid (50 ml) was hydrogenolyzed in the presence of palladium black at room temperature for 2 days. After removal of the catalyst by filtration, the filtrate was diluted with water (300 ml) and then evaporated *in vacuo* at 35 °C. After the residue was dissolved in methanol and the solvent was evaporated *in vacuo*, the final residue was dissolved in a small amount of absolute ethanol. Addition of absolute ether afforded colorless hygroscopic powder; yield, 918 mg (94%). This substance was further subjected to lyophilization. $[\alpha]_D^{15}$ +36.9° (after 3 min), +33.1° (after 25 hr) (*c* 0.51, H_2O).

Found: C, 45.73; H, 6.81; N, 11.36%. Calcd for $C_{19}H_{32}O_{11}N_4 \cdot 1/4H_2O$: C, 45.92; H, 6.59; N, 11.27%.

t-Butoxycarbonyl-L-alanyl-D-isoglutamine. This compound was prepared by hydrogenolysis from **2a** (7.34 g, 18.0 mmol) according to Bricas *et al.*[11]; yield, 6.87 g (94%); mp 99.5—101 °C (lit,[11] 94—98 °C); $[\alpha]_D^{28}$ −8.2° (*c* 1.0, methanol).

Found: C, 49.97; H, 7.70; N, 10.11%. Calcd for $C_{13}H_{23}O_6N_3 \cdot CH_3CO_2C_2H_5$: C, 50.36; H, 7.71; N, 10.37%.

Nα-(t-Butoxycarbonyl-L-alanyl-D-isoglutaminyl)-Nε-benzyloxycarbonyl-L-lysine Benzyl Ester (3a). Triethylamine (0.82 ml, 5.8 mmol) and ethyl chloroformate (0.56 ml, 5.8 mmol) were added to a solution of Boc-L-alanyl-D-isoglutamine (2.35 g, 5.8 mmol) in *N,N*-dimethylformamide (15 ml) at −23 °C. After the mixture was stirred at this temperature for 15 min, a cooled solution of benzyl *Nε*-Z-L-lysinate *p*-toluenesulfonate (3.15 g, 5.8 mmol) and triethylamine (0.82 ml, 5.8 mmol) in *N,N*-dimethylformamide (15 ml) was added and the mixture was stirred at room temperature for 15 hr. The precipitate of triethylamine hydrochloride was filtered off, the solvent was evaporated *in vacuo*. The residue was then dissolved in ethyl acetate and worked up as usual. The product was recrystallized from 99% ethanol–hexane; yield, 3.13 g (81%); mp 130—137 °C; $[\alpha]_D^{25}$ −13.8° (*c* 1.8, *N,N*-dimethylformamide).

Found: C, 60.53; H, 7.04; N, 10.06%. Calcd for $C_{34}H_{47}O_9N_5 \cdot 1/2C_2H_5OH$: C, 60.67; H, 7.27; N, 10.11%.

1-α-O-Benzyl-4,6-O-benzylidene-N-acetylmuramic Acid 1-Succinimidyl Ester. To an ice-cooled solution of **5** (4.72 g, 10 mmol) in tetrahydrofuran (60 ml) were added *N*-hydroxysuccinimide (1.38 g, 12 mmol) and dicyclohexylcarbodiimide (2.06 g, 10 mmol). After stirring in an ice bath for 3 hr, the mixture was worked up as usual and the product was recrystallized from ethyl acetate–hexane; yield, 4.52 g (79%); mp 178—179 °C.

Nα-(1-α-O-Benzyl-4,6-O-benzylidene-N-acetylmuramyl-L-alanyl-D-isoglutaminyl)-Nε-benzyloxycarbonyl-L-lysine Benzyl Ester (3c). Trifluoroacetic acid (4 ml) was added to **3a** (1.34 g, 2.0 mmol) and the mixture was stirred at room temperature. After 10 min, absolute ether was added to the resulting solution and the precipitate of free amino tripeptide derivative (**3b**) trifluoroacetate was collected by filtration (1.24 g). 1-Succinimidyl ester of **5** (1.14 g, 2.0 mmol) was added to an ice-cooled solution of **3b** trifluoroacetate thus obtained and triethylamine (0.28 ml, 2.0 mmol) in a mixture of tetrahydrofuran (20 ml) and *N,N*-dimethylformamide (20 ml). The mixture was stirred at room temperature for 15 hr. The gelatinous solid was collected by filtration, washed with ethyl acetate and dried (1.00 g). By addition of ether to the mother liquor followed by recrystallization from *N,N*-dimethylformamide–water, further amount of the product was recovered (0.46 g); total yield, 1.46 g (79%); 221—224 °C (decomp.); $[\alpha]_D^{25}$ +53.9 ° (*c* 1.9, *N,N*-dimethylformamide).

Found: C, 62.00; H, 6.51; N, 8.36%. Calcd for $C_{54}H_{66}O_{14}N_6 \cdot H_2O$: C, 62.29; H, 6.58; N, 8.07%.

N-Acetylmuramyl-L-alanyl-D-isogultaminyl-L-lysine (3d). A solution of **3c** (256 mg, 0.25 mmol) in acetic acid (15 ml) was hydrogenolyzed in the presence of 1 M hydrochloric acid (0.12 ml, 0.12 mmol) and palladium black. After the catalyst was removed, the mixture was diluted with water (100 ml) and evaporated *in vacuo* at 35 °C. After this procedure had been repeated, the aqueous solution was passed through a column of Amberlite IR-45 (OH^- form) to remove hydrogen chloride. The eluate was evaporated *in vacuo* and the residue was dissolved in absolute methanol. Colorless hygroscopic powder was obtained on addition of absolute ether; yield, 134 mg (86%). It was reprecipitated from absolute methanol–absolute ethanol and then lyophilized. $[\alpha]_D^{28}$ +18.3 ° (after 3 min), +14.7° (after 19 hr) (*c* 1.0, H_2O).

Found: C, 47.23; H, 7.12; N, 13.27%. Calcd for $C_{25}H_{44}O_{12}N_6 \cdot H_2O$: C, 47.01; H, 7.26; N, 13.16%.

Nα-t-Butoxycarbonyl-Nε-benzyloxycarbonyl-L-lysyl-D-alanine Benzyl Ester. To an ice-cooled solution of *Nα*-Boc-*Nε*-Z-L-lysine (2.89 g, 7.6 mmol) in tetrahydrofuran (10 ml), there were added dicyclohexylcarbodiimide (1.56 g, 7.6 mmol) and then a solution of triethylamine (1.07 ml, 7.6 mmol) and benzyl D-alaninate *p*-toluenesulfonate (2.66 g, 7.6 mmol) in tetrahydrofuran (10 ml). The mixture was allowed to stand at room temperature for 20 hr. The product was recrystallized from ethyl acetate–hexane; yield, 2.91 g (71%); mp 103.5—104.5 °C (lit,[11] 96—100 °C); $[\alpha]_D^{28}$ +6.4 ° (*c* 1.1, methanol).

Found: C, 64.33; H, 7.26; N, 7.68%. Calcd for $C_{29}H_{39}O_7N_3$: C, 64.30; H, 7.26; N, 7.76%.

Nε-Benzyloxycarbonyl-L-lysyl-D-alanine Benzyl Ester p-Toluenesulfonate. This compound was prepared from *Nα*-Boc-*Nε*-Z-L-lysyl-D-alanine benzyl ester according to Bricas[11]; yield, 13.0 g (98%); mp 122—123 °C (lit,[11] 122—124 °C).

Nα-(t-Butoxycarbonyl-L-alanyl-D-isoglutaminyl)-Nε-benzyloxycarbonyl-L-lysyl-D-alanine Benzyl Ester (4a). Ethyl chloroformate (0.77 ml, 8.0 mmol) and triethylamine (1.13 ml, 8.0 mmol) were added to a solution of Boc-L-alanyl-D-isoglutamine (3.24 g, 8.0 mmol) in *N,N*-dimethylformamide (20 ml) at −18 °C. After stirring at −18 °C for 15 min,

a cold solution of N^{ε}-Z-L-lysyl-D-alanine benzyl ester *p*-toluenesulfonate (4.91 g, 8.0 mmol) and triethylamine (1.13 ml, 8.0 mmol) in *N,N*-dimethylformamide (20 ml) was added and the mixture was stirred at room temperature for 15 hr. Triethylamine hydrochloride was filtered off and the solvent was evaporated *in vacuo*. The residue was dissolved in ethyl acetate saturated with water, worked up as usual, and the product was recrystallized from *N,N*-dimethylformamide–ether; yield, 4.65 g (78%), mp 191—194.5 °C (lit,[11] 196—198 °C); $[\alpha]_D^{26}$ −10.8° (*c* 2.2, acetic acid).

Found: C, 60.11; H, 7.11; N, 11.08%. Calcd for $C_{37}H_{52}O_{10}N_6$: C, 59.98; H, 7.08; N, 11.35%.

*N^{α}-(1-α-O-Benzyl-4,6-O-benzylidene-N-acetylmuramyl-L-alanyl-D-isogultaminyl)-N^{ε}-benzyloxycarbonyl-L-lysyl-D-alanine Benzyl Ester (**4c**).* This compound was prepared in a similar way to that described for **3c**. Trifluoroacetic acid salt of **4b**, obtained from **4a** (1.41 g, 1.9 mmol), was neutralized with triethylamine (0.26 ml, 1.9 mmol) and treated with 1-succinimidyl ester of **5** (1.02 g, 1.8 mmol) in a mixture of tetrahydrofuran (40 ml) and *N,N*-dimethylformamide (20 ml). The product was recrystallized from *N,N*-dimethylformamide–water, then from *N,N*-dimethylformamide–ether; yield, 1.24 g (63%); mp 221 °C (decomp.); $[\alpha]_D^{25}$ +50.4° (*c* 2.1, *N,N*-dimethylformamide).

Found: C, 61.64; H, 6.56; N, 8.74%. Calcd for $C_{57}H_{71}O_{15}N_7 \cdot H_2O$: C, 61.55; H, 6.62; N, 8.82%.

*N-Acetylmuramyl-L-alanyl-D-isoglutaminyl-L-lysyl-D-alanine (**4d**).* This compound was prepared from **4c** (547 mg, 0.50 mmol) by the same procedure described for **3d**. The final product was precipitated from absolute methanol–absolute ether; yield, 295 mg (85%). A sample after lyophilization showed the following data: $[\alpha]_D^{15}$ +14.9° (after 3 min), +15.4° (after 25 hr) (*c* 0.51, H_2O).

Found: C, 47.42; H, 7.13; N, 13.75%. Calcd for $C_{28}H_{49}O_{13}N_7 \cdot H_2O$: C, 47.38; H, 7.24; N, 13.82%.

*t-Butoxycarbonyl-L-alanyl-L-isoglutamine Benzyl Ester (**8a**) and the Analogous Protected Dipeptides (**9a—14a**).* These compounds as shown in Table 1 were all prepared in similar manners to that described for **2a**. The yields and physical constants are summarized in Table 2.

*Protected N-Acetylmuramyl Amino Acids (**6c** and **7c**) and N-Acetylmuramyl Dipeptides (**8c—14c**).* These compounds were prepared by coupling of **5** with the corresponding amino acid benzyl esters (**6b** or **7b**) or dipeptides having free amino groups (**8b—14b**) using either dicyclohexylcarbodiimide—*N*-hydroxysuccinimide or ethyl chloroformate as described for **2c**. While **8b** hydrochloride was prepared from **8a**[15] just as described for **2b**, compounds **9b—14b** were obtained as their trifluoroacetic acid salt by treating **9a—14a** with trifluoroacetic acid at room temperature. The yields and the physical constants of the products (**6c—14c**) are summarized in Table 3.

*N-Acetylmuramyl Amino Acids (**6d** and **7d**) and N-Acetylmuramyl Dipeptides (**8d—14d**).* Compounds **6c—14c** were hydrogenolyzed in acetic acid in the presence of palladium black at room temperature. The product was isolated as described for **2d** and lyophilized. The yields, $[\alpha]_D$ and the results of elemental analyses are summarized in Table 4.

*L-Alanyl-D-isoglutamine (**2e**).* Boc-L-alanyl-D-isoglutamine (300 mg, 0.74 mmol) was dissolved in trifluoroacetic acid (1.5 ml), and the solution was set aside at room temperature for 30 min. On addition of absolute ether to the solution, trifluoroacetate of **2e** precipitated as hygroscopic powder. Removal of trifluoroacetic acid with a column of Amberlite IR-45 (OH^- form) followed by lyophilization afforded hygroscopic solid; yield, 132 mg (81%).

Found: C, 43.40; H, 7.01; N, 19.14%. Calcd for $C_8H_{15}O_4N_3 \cdot 1/4H_2O$: C, 43.33; H, 7.05; N, 18.95%. It was recrystallized from water–ethanol; mp 83 °C (decomp); $[\alpha]_D^{28}$ +14.4° (*c* 0.96, H_2O).

*L-Alanyl-D-isoglutaminyl-L-lysine (**3e**).* i) *Dihydrochloride*: Compound **3a** (0.50 g, 0.75 mmol) was dissolved in ethanol (50 ml) and hydrogenolyzed in the presence of palladium black. After removal of the solvent *in vacuo*, the residue was dissolved in methanol. Addition of ether afforded Boc-L-alanyl-D-isoglutaminyl-L-lysine (0.33 g, 99%). To a solution of this compound (190 mg) in acetic acid (6 ml) was added acetic acid (10 ml) previously saturated with dry hydrogen chloride. After standing at room temperature for 15 min, absolute ether was added to the mixture and the precipitate was collected and dried over phosphorus pentaoxide and potassium hydroxide *in vacuo*. Reprecipitation from absolute methanol–absolute ether afforded very hygroscopic powder; yield, 136 mg (76% from **3a**). This was further purified by treatment with charcoal and lyophilized for elemental analysis. $[\alpha]_D^{28}$ +2.06° (*c* 4.5, H_2O).

Found: C, 39.90; H, 7.08; N, 16.34; Cl, 16.95%. Calcd for $C_{14}H_{29}O_5N_5Cl_2$: C, 40.19; H, 6.99; N, 16.74; Cl, 16.95%.

ii) *Bistrifluoroacetate*: Compound **3a** (67 mg, 0.1 mmol) was hydrogenolyzed in acetic acid (5 ml) in the presence of palladium black. After evaporation of the solvent *in vacuo*, the residue was treated with trifluoroacetic acid (2 ml) at room temperature for 60 min. Addition of absolute ether to the mixture afforded hygroscopic powder, yield, 45 mg (76%). This compound showed a single ninhydrin-positive spot identical with the product obtained in (i) on tlc (1-butanol–acetic acid–water, 4 : 1 : 2) and PEP.

*L-Alanyl-D-isoglutaminyl-L-lysyl-D-alanine (**4e**) Bistrifluoroacetate.* This compound was prepared from **4a** (185 mg, 0.25 mmol) according to Bricas *et al.*[11] The procedure is similar to that described for **3e** (ii). Yield, 155 mg (96%); $[\alpha]_D^{19}$ +2.24° (*c* 0.45, H_2O) (lit,[11] $[\alpha]_D^{25}$ +1.6±0.5° (*c* 0.45, H_2O).

Found: C, 39.35; H, 5.60; N, 12.85%. Calcd for $C_{21}H_{34}O_{10}N_6F_6$: C, 39.13; H, 5.32; N, 13.04%.

The authors wish to express their sincere thanks to Professor Shozo Kotani and his collaborators of Osaka University Dental School for their cooperations and invaluable discussions.

Nucleophilic Ion Pairs. I. Enhanced Esterolytic Reactivity of Hydrophobic Ion Pairs in Micellar Systems*

Toyoki KUNITAKE, Seiji SHINKAI, and Yoshio OKAHATA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received September 22, 1975)

The reaction of the dodecyl(2-hydroxyimidophenethyl)dimethylammonium bromide(DHDB) and *N*-methylmyristohydroxamate (MMHA) anion with *p*-nitrophenyl acetate was studied mostly in the presence of aqueous nonionic micelles. Addition of a hydrophobic ammonium ion, TMAC, considerably enhanced the reactivity of MMHA but not that of DHDB (a zwitterion). The rate enhancement for MMHA-TMAC and DHDB in nonionic micelles were almost comparable to those in cationic(CTAB) micelles. It was proposed that the large enhancement observed for some anionic nucleophiles in cationic micelles is to a great extent caused by the formation of hydrophobic, desolvated ion pairs.

The importance of micellar catalyses which influence rates and equilibria of organic reactions and yield data pertinent to enzyme-catalyzed reactions has been reported.[1,2] Anionic nucleophiles such as alkoxide,[3,4] oximate,[5,6] hydroxamate,[7-10] thiolate[11,12] and imidazole anions[13,14] are considerably activated in the presence of cationic micelles and cationic polysoaps. The reactions studied involve nucleophilic attack toward phenyl esters,[1-8, 10, 11, 13, 14] nucleophilic substitution of 2,4-dinitrofluorobenzene[12] and hydrogen abstraction from carbon acids.[9] The nucleophilicity of some hydroxamate anions toward *p*-nitrophenyl acetate(PNPA) is enhanced by two or three orders of magnitude as compared with those predicted from the Brönsted relationship, the reaction rate exceeding even that of α-chymotrypsin and PNPA.[7,8] In contrast, the activation does not occur in anionic micelles,[15] and neutral nucleophiles such as amines and imidazoles are not subjected to activation by cationic micelles.[16]

In an attempt to elucidate the mechanism of these micellar effects, we investigated the reaction of *N*-methylmyristohydroxamic acid(MMHA) and dodecyl-(2-hydroxyimidophenethyl)dimethylammonium bromide (DHDB) with PNPA in nonionic micelles. The latter nucleophile was specially designed to allow ready formation of the intramolecular ion pair between the oximate anion and the ammonium moiety on the basis of the CPK model building. The use of nonionic micelles as the reaction environment can avoid complicating influences of the high charge density at the surface of cationic micelles.

MMHA: $CH_3(CH_2)_{12}CONOH$

(1)

Reaction of MMHA with PNPA. The reaction of MMHA and PNPA was first carried out in the presence of nonionic micelles (Tween 80, Triton X-100, POOA**, Brij-35) above their cmc.[1] The influence of addition of quaternary ammnoium salts was also evaluated. If the $k_{a,obsd}$ value of MMHA in the absence of a nonionic micelle is approximated by that of aqueous *N*-methylisobutyrohydroxamic acid,[18] the presence of nonionic micelles results in a 2—9 time increase of $k_{a,obsd}$ (Table 1). The rate enhancement is much greater in cetyltrimethylammonium bromide(CTAB) micelle (more than 200 fold)[7]. In contrast, anionic sodium dodecyl sulfate(SDS) suppressed the reactivity of MMHA. The reactivity of MMHA can be further enhanced in nonionic micelles by addition of trioctylmethylammonium chloride(TMAC) (Fig. 2). The reaction rates increased almost linearly with increasing TMAC and then gradually levelled off. Maximal augmentation of 18-fold was brought about by addition of TMAC. Addition of $Et_4N^+Br^-$ and $Bu_4N^+Br^-$ caused no effect. TMAC, typical phase transfer catalyst, is much more hydrophobic than the latter two, but cannot form a micelle by itself. In fact, it exists as an oily suspension in as aqueous medium without nonionic micelles. Thus, TMAC should be trapped in and/or on the nonionic micelles. The micelle consisting of a nonionic surfactant plus TMAC can be envisioned as an analogue of cationic micelles which possesses a much lower positive-charge density. On the contrary, addition of an inorganic salt inhibited the reaction (*vide post*). It is noteworthy that a minute amount of TMAC caused the rate enhancement of more than one-order of magnitude and that only the hydrophobic ammonium salt was effective.

The $k_{a,obsd}$ values at a constant surfactant concentration are recorded for comparison in Table 1. The reactivity of MMHA in the presence of nonionic micelles which contain TMAC is enhanced up to

** Polyoxyethylene(n=10) oleyl alcohol.

POOA was not added.

20—70 times as compared with that for the nonmicellar system, the maximum value (280 M^{-1} s^{-1} in Triton X-100) amounting to one-third of that in CTAB.

Reaction of DHDB with PNPA. Similar experiments were carried out for a zwitterionic nucleophile. The reaction was quenched by SDS micelle and enhanced in the presence of CTAB micelle(*ca.* 200 times), as is the case for the reaction of MMHA and PNPA. On the other hand, considerable rate enhancements (10—60 times) were readily achieved

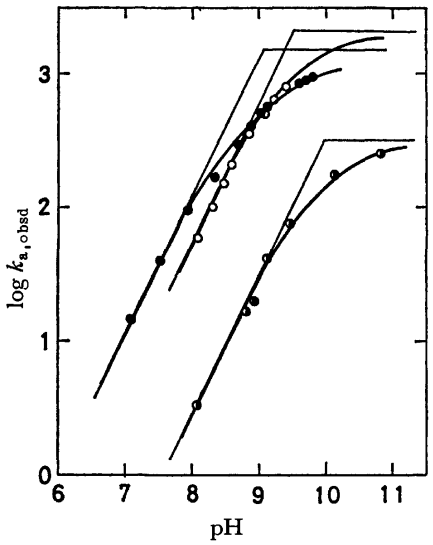

Fig. 5. pH Dependence.
30 °C, μ=0.01 with KCl, 3 v/v% ethanol, [POOA]=1.0×10^{-3} M.
○; [MMHA]=1.0×10^{-5} M, [PNPA]=2.62×10^{-4} M, [TMAC]=1.0×10^{-4} M. ●; [DHDB]=(0.8—5.6)$\times10^{-4}$ M, [PNPA]=(1.7—8.5)$\times10^{-5}$ M. ◑; POOA was not added. [DHDB]=(2.8—5.6)$\times10^{-4}$ M, [PNPA]=(4.3—8.5)$\times10^{-5}$ M.

in the presence of nonionic micelles alone. Addition of TMAC caused no increase in the reaction rate. The maximum rate constant observed for DHDB (306 M^{-1} s^{-1} in POOA) is about one-third of the value in the CTAB micelle. Other additives such as poly(ethyleneimine), β-cyclodextrin and poly(*N*-vinylpyrrolidone) were found to be ineffective.

Influence of Surfactant Concentration and Ionic Strength. The dependence of the reactivities of MMHA-TMAC and DHDB on the concentration of POOA is given in Fig. 3. The cmc of POOA is estimated to be 10^{-6} M.[1] The $k_{a,obsd}$ value for the MMHA-TMAC system first increased and then decreased gradually with increasing POOA concentrations, the maximum $k_{a,obsd}$ value being observed at [POOA]=1.5×10^{-3} M. On the other hand, the reactivity of zwitterionic nucleophile rapidly increased and reached a constant value. The difference reflects the intermolecular *vs.* intramolecular nature of these ion pairs.

The reactivities of MMHA-TMAC and DHDB toward PNPA were also examined at different ionic strength (Fig. 4). The $k_{a,obsd}$ value for DHDB in the nonmicellar system was hardly affected by the salt(KCl) concentration. On the other hand, the enhanced reactivities of these catalytic systems attained in the presence of nonionic micelles were gradually lost with increasing salt concentrations. The largest rate decrease was about 4-fold. Similar results are frequently obtained in micellar catalysis.[1]

pH Dependence. The micellar reaction of MMHA-TMAC and DHDB with PNPA was carried out in the pH range 7—10. The log $k_{a,obsd}$ values are plotted against pH, which show linear increase with slope 1.0 followed by gradual saturation in the high pH region (Fig. 5). The reaction rates were found to

be too great to be measured in the pH region higher than that in Fig. 5. The acid dissociation constants (K_a) and the true second-order rate constants (k_a) were determined by two methods: (a) fitting of the theoretical curves (Eq. (2)) to the experimental plots, and (b) finding pK_a values which give straight lines for α(degree of dissociation$=K_a/(K_a+a_H)$) *vs.* $k_{a,obsd}$ plots by trial-and-error computation. The values of K_a and k_a calculated by both methods were found to be agree within 5%.

$$k_{a,obsd} = k_a \frac{K_a}{K_a + a_H} \quad (2)$$

The results are given in Table 2, together with data we obtained recently.

Table 2. Second-order rate constants for the reactions of hydroxamates and oximates with PNPA at 30 °C

Catalyst		pK_a	k_a $M^{-1}s^{-1}$

a) k''_a (the true second-order rate constant for MMHA paired with TMAC). b) DBHA (N-dodecylbenzohydroxamic acid)[10]; 3 v/v% ethanol, μ=0.5 (KCl). c) 1.4 v/v% CH_3CN, μ=0.1 (KCl).[18]

Discussion

Reactions performed in the presence of ionic micelles are influenced by various micellar effects.[1,2] Straightforward kinetic analysis is often difficult because of complications characteristic of ionic micelles. One may simplify this situation by appropriate use of nonionic micelles, as independently shown by Brown *et al.* for a general-base catalyzed reaction toward phenyl phosphate.[19] The nucleophilicity of some anions such as hydroxamates and oximates is highly enhanced in cationic micelles. We have attempted to elucidate the mechanism of these rate enhancement. We assumed that the rate enhancement of anionic nucleophiles in cationic micelles could be reduced to the problem of nucleophilic ion pairs. An anionic nucleophile forms an ion pair with a cationic surfactant molecule in a highly hydrophobic environment of micelles, the high charge density at the surface of cationic micelles playing only a secondary role. Nonionic micelles are convenient systems for testing the hypothesis, since nucleophilic ion pairs can be studied as species isolated from other charged species.

The nucleophilicity of MMHA anion as expressed by the $k_{a,obsd}$ value (Table 1) is enhanced in cationic and nonionic micelles relative to the nonmicellar system. Although the observed rate enhancement is much greater in the cationic(CTAB) micelle than in nonionic micelles, the difference can be made smaller by adding 1.0×10^{-4} M of TMAC, which is highly hydrophobic and not much soluble in water. Thus, the highly increased nucleophilicity of MMHA can be related to the formation of hydrophobic ion pairs solubilized in nonionic micelles. The absence of rate increase upon addition of less hydrophobic $Et_4N^+Br^-$ and $Bu_4N^+Br^-$ supports this view.

The apparent rate constant showed a maximum when the POOA concentration was varied. Supposedly, the hydrophobicity of POOA micelles increases with increasing POOA concentrations, and the formation of hydrophobic ion pairs becomes increasingly favorable. Further increase in the POOA concentration causes dissociation of MMHA-TMAC, resulting in rate decrease. This is consistent with the fact that no rate decrease was observed with increasing POOA concentrations in the case of intramolecular ion pair DHDB.

$k_{a,obsd}$ in the POOA micelle simply increased with increasing TMAC concentration (Fig. 2). This kinetic situation can be quantitatively treated by the following equation, provided that MMHA anion and TMAC cation form a 1 : 1 ion pair only, and that addition of TMAC does not change the micellar structure such as to affect the reaction rate.

$$\text{MMHA} + \text{TMAC} \overset{K}{\rightleftharpoons} \text{MMHA-TMAC} \quad (3)$$

$$\text{MMHA} \xrightarrow{k'_{a,obsd}\cdot[\text{PNPA}]} \text{products} \quad (4)$$

$$\text{MMHA-TMAC} \xrightarrow{k''_{a,obsd}\cdot[\text{PNPA}]} \text{products} \quad (5)$$

where K is the association constant for MMHA–TMAC, $k'_{a,obs}$ is the apparent second-order rate constant for MMHA which is not paired with TMAC and $k''_{a,obs}$ is that for MMHA paired with TMAC.

According to Mollica and Connors,[20] the following equation is derived for [MMHA]$\ll$[TMAC].

$$\frac{k'_{a,obsd}}{k_{a,obsd}-k'_{a,obsd}} = \frac{1}{q\cdot K[\text{TMAC}]} + \frac{1}{q} \quad (6)$$

where $k_{a,obsd}$ is the rate constant obtained at a given TMAC concentration and $q=(k''_{a,obsd}/k_{a,obsd})-1$.

K and q were determined by plotting $k'_{a,obsd}/(k_{a,obsd}-k'_{a,obsd})$ against 1/[TMAC], which gives a straight line (r=0.99) for [TMAC]$>1.0\times10^{-3}$ M: K=104 M^{-1} and q=0.0225. The $k''_{a,obsd}$ value thus determined (447 $M^{-1}s^{-1}$) is more than 50% of the corresponding value in the CTAB micelle (821 $M^{-1}s^{-1}$, Table 1). The reactivity of MMHA increased from 36.8 to 447 $M^{-1}s^{-1}$ upon pairing with TMAC, if the other changes which may be caused by the addition of TMAC (*e.g.* micellar structure) are negligible.

The rate-enhancing effect of a countercation trapped in the hydrophobic environment is more clearly shown by using a zwitterionic nucleophile with a long alkyl group, DHDB. The $k_{a,obsd}$ value of DHDB in a nonmicellar system does not differ much from that expected from Brönsted relationship (see below), but it is enhanced in nonionic micelles (Table 1 and Fig. 3) more effectively than that of MMHA. This means that the presence of an intramolecular countercation

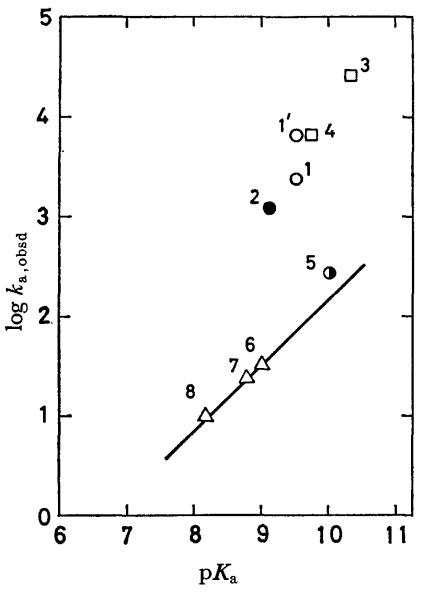

Fig. 6. Brönsted plots.
Numbers indicate those recorded in Table 2.

does not result in the increased reactivity of anionic nucleophiles unless they are placed in a hydrophobic environment. The addition of TMAC did not affect the reactivity of DHDB, reflecting the fact that DHDB forms a stable intramolecular ion pairs, as also inferred from the CPK model building.

It is thus concluded that the reactivity of an anionic nucleophile (hydroxamate and oximate) undergoes considerable augmentation in the presence of a hydrophobic countercation in a hydrophobic environment.

Figure 6 shows the Brönsted relationship for the data of Table 2. The plot for nonmicellar DHDB is located fairly close to the relationship obtained for simple hydroxamic acids. The data obtained in the CTAB micelle are placed above the Brönsted line by two orders of magnitude, though they are scattered due to varying reaction conditions. The polts for MMHA and DHDB in the nonionic micellar system are placed not far below those in the CTAB micelle.

The data (Tables 1 and 2) clearly indicate that the reactivity enhancement for intermolecular(MMHA–TMAC) and intramolecular(DHDB) ion pairs in nonionic micelles is almost comparable to those in cationic micelles. The remarkable rate enhancement in the cationic micelles has been attributed to concentration effect, proximity effect, peculiar environments of the micellar surface, desolvation of nucleophiles and to other factors, in the absence of definitive experimental evidence.

The entropic factors such as concentration effect and proximity effect cannot contribute to the large enhancement, since this has been observed not only in cationic micelles but also in anionic and conventional noninoic micelles. Characteristics peculiar to cationic micelles such as high charge density at the micellar surface do not appear to be a prerequisite for the rate enhancement, since the present investigation showed that the presence of a single countercation causes a sufficiently large enhancement. Thus, it is proposed that the rate acceleration observed for anionic nucleophiles in cationic micelles is largely derived from the formation of hydrophobic ion pairs between anionic nucleophile and cationic surfactant in a highly hydrophobic environment. The anion included in a hydrophobic ion pair will attain its high reactivity from desolvation, as already known for other nucleophilic reactions.[9,12]

The importance of hydrophobic (dehydrated) ion pairs in the nucleophilic attack is also suggested by other data obtained recently. The reaction rate of the MMHA anion and PNPA in an aqueous system increased by 100-fold in the presence of partially benzylated poly(4-vinylpyridine).[21] The polymer can provide a hydrophobic environment but cannot form a micellar structure. Kirsh *et al.*[22] reported that the reactivity of the *N*-(2-hydroxyimidophenethyl)-pyridinium unit anchored to poly(4-vinylpyridine) is higher by a factor of 100 than for the monomeric analog. The micellar structure is not required for the activation of anionic nucleophiles in these cases.

We have found that tetraethylammonium *N*-methylmyristohydroxamate(MMHA–NEt_4) shows very large reactivities toward PNPA in dry, aprotic solvents, the reaction being efficiently suppressed (*ca.* 100 times rate decrease) by the addition of 10^{-3}—10^{-4} M of H_2O.[23] The result shows the importance of the hydration term in considering the nucleophilic reactivity of some anions.

In conclusion, a remarkable rate enhancement of some anionic nucleophiles observed in cationic micelles arises from the formation of hydrophobic ion pairs (both intermolecular and intramolecular) in highly hydrophobic environments. The reactivity of these ion pairs is enhanced probably by desolvation of the anion. The micellar effect would constitute a part of a more general microenvironment effect, which is conceivably a major source of enzymatic efficiency.

We wish to express our appreciation to Miss R. Ando for her technical assistance. The present research was financially supported by the Ministry of Education.

Reversible CO Insertion into an Ni-C Bond of Alkyl(acetylacetonato)-(triphenylphosphine)nickel(II)

Toshio SARUYAMA, Takakazu YAMAMOTO, and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, O-okayama, Tokyo 152

(Received October 23, 1975)

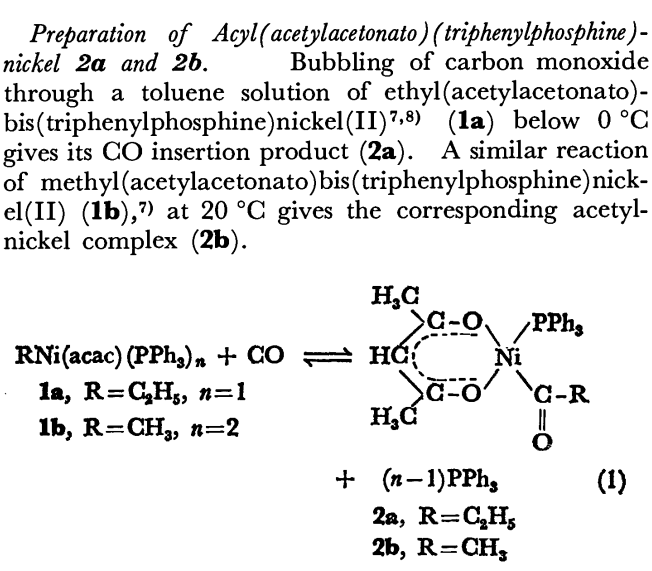
Reaction of alkyl(acetylacetonato)(triphenylphosphine)nickel(II), RNi(acac)(PPh_3)n (R=C_2H_5, n=1 (**1a**); R=CH_3, n=2 (**1b**)) with carbon monoxide gives acyl(acetylacetonato)(triphenylphosphine)nickel(II) RCONi(acac)(PPh_3) (R=C_2H_5 (**2a**); R=CH_3 (**2b**)). Elemental analysis, IR and NMR spectra, and chemical properties of the acylnickel complexes support the structure. A variable temperature NMR spectroscopic study has revealed that the acac ligand in the acyl complexes exchanges rapidly in solution on NMR time scale. The acylnickel complexes **2a** and **2b** tend to decarbonylate at room temperature, the decarbonylation tendency of **2b** being greater than **2a**. They undergo further disproportionation according to the stoichiometry: 3RCONi(acac)(PPh_3)→ RCOR+Ni(CO)$_2$(PPh_3)$_2$+Ni(acac)$_2$+RNi(acac)(PPh_3). The mechanism involving the cross coupling of the acylnickel complex with the alkylnickel complex is proposed for the reaction on the basis of formation of $CH_3COC_2H_5$ on reaction of **2a** with **1b**.

Insertion of carbon monoxide into a transition metal-carbon bond to give an acyltransition metal complex and its reverse process, decarbonylation from an acyltransition metal complex to an alkyl complex, consitute crucial elementary steps in industrially important processes such as carbonylations of olefins[1] and methanol[2] and in synthetically important decarbonylation reactions.[3] However, studies of the carbonylation and decarbonylation processes dealing with well characterized complexes are relatively limited.[4] Particularly, the study with an acylnickel complex has received less attention because of its unstable nature,[5] and only recently the first stable acylnickel complex $CH_3CONiCl(PMe_3)_2$ has been isolated by Klein.[6]

We report here the preparation of new stable acylnickel complexes RCONi(acac)(PPh_3) from the corresponding alkylnickel complexes and describe their properties in solutions including facile decarbonylation and ketone formation.

Results and Discussion

Preparation of Acyl(acetylacetonato)(triphenylphosphine)-nickel 2a and 2b. Bubbling of carbon monoxide through a toluene solution of ethyl(acetylacetonato)-bis(triphenylphosphine)nickel(II)[7,8] (**1a**) below 0 °C gives its CO insertion product (**2a**). A similar reaction of methyl(acetylacetonato)bis(triphenylphosphine)nickel(II) (**1b**),[7] at 20 °C gives the corresponding acetylnickel complex (**2b**).



It is necessary to carry out the reaction at the low temperature for obtaining the propionyl complex **2a**, since **2a** is thermally unstable and the reaction at room temperature readily gives its decomposition products, Ni(CO)$_2$(PPh_3)$_2$ and diethyl ketone (*vide infra*).

Although the acylnickel complexes are unstable in solution, they are stable in the solid state once it is isolated. The IR spectrum of **2a** shows a ν(C=O) band of the nickel-bonded acyl group at 1665 and that of **2b** at 1680 cm^{-1} which may be compared with the ν(C=O) bands of acylplatinum, palladium and nickel complexes in the region of 1610 to 1675 cm^{-1}.[6,9] The IR bands due to the acetylacetonato and triphenylphosphine ligands in **2a** and **2b** are similar to those of the starting alkylnickel complexes **1a** and **1b**.

NMR Spectrum and Chemical Properties of 2a. The NMR spectrum of **2a** in toluene-d_8 at 20 °C (Fig. 1A) shows a triplet at δ 0.70 (3H, CH_3 of the propionyl group), a quartet at δ 2.85 (2H, CH_2 of the propionyl

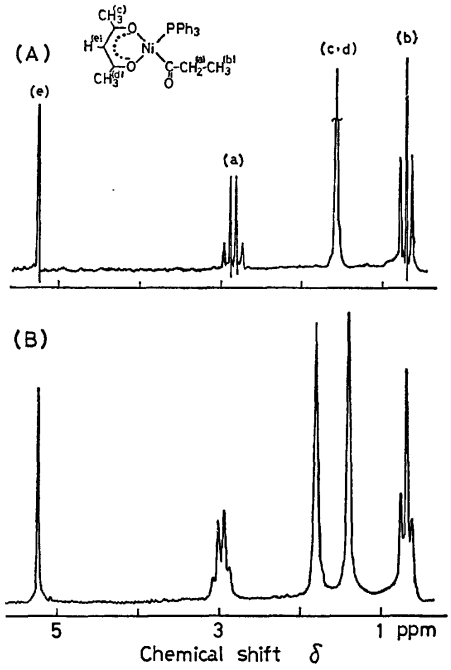


Fig. 1. NMR spectra of $C_2H_5CONi(acac)(PPh_3)$ in toluene-d_8 at (A) 20 °C and (B) −40 °C.

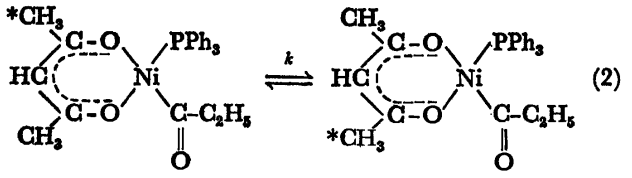
Table 1. The rate constants of the acac interchange in **2a** in toluene-d_8

Temp (°C)	Rate constant (s^{-1})
−40	7±2
−30	16±2
−20	70
−10	140
0	500

group), a singlet at δ 1.56 (6H, two CH_3 groups of acac) and a singlet at δ 5.25 (1H, CH of acac). Although the two CH_3 groups of the acac ligand in **2a** give a sharp singlet peak at room temperature, the singlet peak becomes broad on cooling the toluene-d_8 solution of **2a** and then separates on further cooling into two peaks indicating a rapid exchange of the acac ligand in the square planar nickel complex at room temperature on NMR time scale. Figure 1B shows the NMR spectrum of **2a** at −40°C, where the exchange is very slow. The rate constants of the exchange of the acac ligand calculated from the temperature variation of the NMR spectrum are tabulated in Table 1.



(2)

The rate constant of the acac exchange is expressed as,

$$k = 2.5 \times 10^{13} \exp(-13400/RT) \quad (3)$$

In the parent ethylnickel complexes **1a**, on the other hand, the exchange of the acac ligand is much slower in benzene, toluene, acetone and tetrahydrofuran. The methyl protons of the acac ligand in **1a** are observed as magnetically non-equivalent signals at room temperature which coalesce at elevated temperatures (~−70 °C). The higher exchange rate of the acac ligand in the propionylnickel complex may be due to the electron-withdrawing effect of the acyl group bonded to nickel.

When **2a** was allowed to stand in solution for 1 week at room temperature, it underwent disproportionation reaction to give $C_2H_5COC_2H_5$ (24 mol % per **2a**), **1a**, $Ni(CO)_2(PPh_3)_2$ and $Ni(acac)_2$. Figure 2 shows the NMR spectrum of the solution of **2a** observed after the disproportionation reaction. Each of peaks with an arrow (a,c,e, and g) is due to **1a**.[7] The ethyl group of **1a** gives rise to a singlet peak as previously reported.[7] The amount of **1a** formed is about 30 mol % per **2a**. The triplet and quartet peaks in Fig. 2 (b, d) are assigned to the methyl and methylene groups of $C_2H_5COC_2H_5$ by comparison of the spectrum with that of the authentic sample. Formation of $Ni(CO)_2(PPh_3)_2$ and $Ni(acac)_2$ was confirmed by elemental analyses and IR spectra of the complexes isolated from the reaction mixture. Heating the reaction solution further for 6 hr at 70 °C caused a slight increase in the amount of $C_2H_5COC_2H_5$ (29 mol % per **2a**) with a partial thermal decomposition of

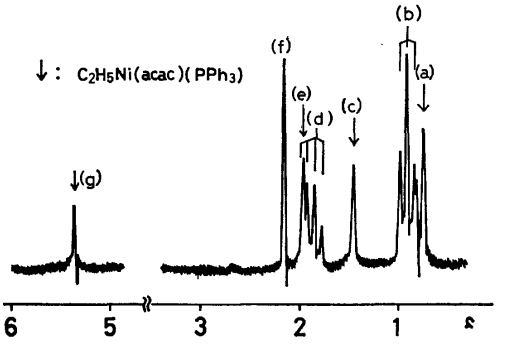


Fig. 2. NMR spetrum of the disproportionation products of **2a** in benzene. A peak (f) at δ 2.10 is due to toluene contained in C_6H_6. For assignment of the peaks (a~g) see the text.

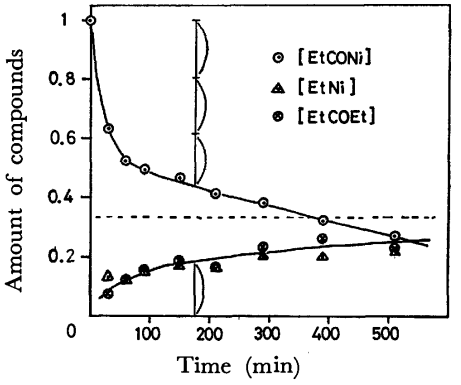

Fig. 3. Time curves for disappearance of **2a** and formation of **1a** and diethylketone during the disproportionation of **2a**. Units of the amounts of the compounds are arbitrary (calculated from areas in the NMR spectrum).

1a to give ethane (7 mol % per **2a**) and ethylene (23 mol % per **2a**).

The decrease of **2a** and the accompanying increases of $C_2H_5COC_2H_5$ and **1a** with time were followed by the NMR spectroscopy. Figure 3 shows the time curves of the amounts of **2a**, $C_2H_5COC_2H_5$ and **1a**. It is seen in Fig. 3 that the amount of **1a** produced is equal to that of $C_2H_5COC_2H_5$ produced within experimental error and 1 mol equivalent of C_2H_5-COC_2H_5 is formed with the consumption of 3 mol of **2a**. These facts suggest that the following reaction is taking place in the solution.

$$3Ni(COC_2H_5)(acac)(PPh_3) \rightarrow \underset{\textbf{2a}}{C_2H_5COC_2H_5} + \underset{\textbf{1a}}{NiC_2H_5(acac)(PPh_3)} + Ni(CO)_2(PPh_3)_2 + Ni(acac)_2 \quad (4)$$

A detailed kinetic analysis of the reaction has been unsuccessful due to the complexity of the reaction process. However, the following disproportionation mechanism seems to be most probable. (1) The first step of the reaction is the decarbonylation of **2a** to give **1a**.

$$Ni(COC_2H_5)(acac)(PPh_3) \rightarrow Ni(C_2H_5)(acac)(PPh_3) + CO \quad (5)$$

(2) The second step is the formation of $C_2H_5COC_2H_5$,

$Ni(acac)_2$ and $Ni(PPh_3)_2$ from **2a** and **1a** presumably *via* a binuclear interaction between **2a** and **1a**.

$$Ni(COC_2H_5)(acac)(PPh_3) + Ni(C_2H_5)(acac)(PPh_3) \rightarrow C_2H_5COC_2H_5 + Ni(acac)_2 + Ni(PPh_3)_2 \quad (6)$$

$Ni(PPh_3)_2$ produced will immediately accept carbon monoxide liberated from **2a** by equation 5, thus completing Eq. 4.

In order to test the assumption that the ketone is formed by interaction of the acylnickel complex with alkylnickel complex the reaction of the propionyl complex **2a** with the ethyl complex **1a** in a 1 : 1 molar ratio was examined. The amount of $C_2H_5COC_2H_5$ produced increased to 47 mol % per **2a** compared with 24 mol % produced in the absence of **2a**. The reaction was accompanied by the evolution of ethane (22 mol % per **2a**) and ethylene (22 mol % per **2a**) which may be formed from an intermediate unstable ethylnickel complex produced in the process of the disproportionation reaction.

Assumption of coupling of the acylnickel complex with the alkyl complex was further supported by formation of $CH_3COC_2H_5$ in the reaction of the propionyl complex **2a** with the methyl complex **1b**. The reaction was accompanied by formation of $C_2H_5COC_2H_5$ probably produced by coupling of the propionyl group in **2a** with the ethyl complex **1a** generated by decarbonylation of **2a**. Some methane, ethylene and ethane were also formed, which may be produced by decomposition of unstable intermediate methyl and ethynickel complexes generated during the disproportionation process as in the reaction of **2a** with **1a**.

In relation to Eq. 6 a somewhat analogous disproportionation of $NiC_2H_5(acac)(PPh_3)$ in pyridine producing $Ni(acac)_2$, $Ni(C_2H_4)(PPh_3)_2$ and ethane according to a second-order reaction kinetics has been observed.[7]

NMR Spectrum and Chemical Properties of 2b. Although **2b** is stable in the solid state and the IR spectrum of **2b** in the solid state indicates that the compound is not contaminated with **1b**, the NMR spectrum of **2b** (Fig. 4) shows not only the peaks assignable to **2a** (δ 2.23 (3H, CH_3 of CH_3CO), δ 1.60 (6H, CH_3 of acac), δ 5.26 (1H, CH of acac)) but also peaks of **1b**[7] (shown with an arrow) which is formed by the decarbonylation of **2b**. This fact suggests that **2b** readily liberates CO in solution reverting itself to **1b** in a greater decarbonylation tendency than **2a** and that **1b** and **2b** are in equilibrium in the solution. The presence of equilibrium in solution accounts for the experimental fact that **2b** was isolable from solution only under an atmosphere of CO. Attempts to isolate **2b** under an atmosphere of nitrogen were unsuccessful and **1b** was recovered from the solution.

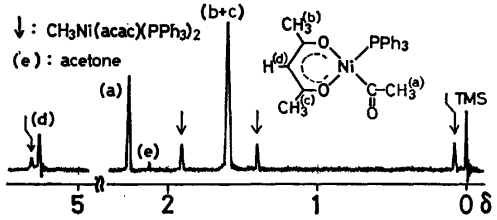

Fig. 4. NMR spectrum of $CH_3CONi(acac)(PPh_3)$ in benzene at 25 °C. The assignment of each signal (a—d) is indicated on the spectrum with reference to the formula of **2b**. Each of peaks with an arrow is due to $CH_3Ni(acac)(PPh_3)$.[7] Formation of a small amount of acetone by the disproportionation of **2b** is seen (peak e).

When the reaction of CO with **1b** in toluene was carried out at room temperature in a closed system, 0.7 mol equivalent of CO was absorbed per mol of **1b** but the complex recovered from the solution turned out to be **1b**.

As in the propionyl complex **2a**, the NMR spectrum of the acetyl complex **2b** shows that the acac ligand exchanges rapidly at room temperature in benzene as indicated by appearance of the methyl signal of the acac ligand as a sharp singlet which splits on lowering the temperature. An accurate value of the rate constant of the acac exchange in **2b** could not be obtained, since the split peaks of CH_3(acac) group in **2b** were overlapped with the CH_3(acac) peaks of **1b** at the low temperatures. Roughly estimated values for the rate constants were of the same magnitude as those obtained for **2a**. When the benzene solution of **2b** was allowed to stand at room temperature for 1 week, **2b** underwent the disproportionation reaction to give CH_3COCH_3 (20 mol % per **2b**), $Ni(CO)_2(PPh_3)_2$, **1b** and $Ni(acac)_2$. The products of the disproportionation reaction suggest that a similar reaction expressed by Eq. 4 takes place with **2b**.

It is known that some acyltransition metal complexes give biacyls.[4e,5,11] However, no biacyl has been detected in the disproportionation of **2a** and **2b**.

The work was supported by a Scientific Research Grant from the Ministry of Education Japan.

Experimental

Materials. $C_2H_5Ni(acac)(PPh_3)$, **1a**, and $CH_3Ni(acac)(PPh_3)_2$, **1b**, were prepared as described in our previous paper.[7] Solvents were dehydrated, purified and stored under nitrogen.

Preparation of $C_2H_5CONi(acac)(PPh_3)$ 2a. Dehydrated carbon monoxide was bubbled into a toluene solution (6 ml) of **1a** (0.98 g, 2.2 mmol) for an hour at −20 °C. Hexane (25 ml) was added to the red solution under an atmosphere of CO at −78 °C and the orange crystals which separated were collected by filtration to yield 0.91 g (85%) of **2a**. Found: C, 65.4; H, 6.1%. Calcd for $C_{26}H_{27}NiO_3P$: C, 65.6; H, 5.8%. IR(KBr): 1665 cm^{-1} (C=O), 595 cm^{-1} (tentatively assigned to Ni–C). NMR(benzene, 25 °C): δ: 0.77 (3H, CH_3 of propionyl, t, J=7 Hz), 2.92 (2H, CH_2 of propionyl, q, J=7 Hz), 1.60 (6H, CH_3 of acac, s), 5.38 (1H, CH of acac, s).

The same product was obtained in a closed system by the reaction of **1a** (0.43 g, 0.96 mmol) with carbon monoxide (*ca.* 60 ml, 2.5 mmol) in toluene (10 ml) at 0 °C for 1 hr; yield=70%. However, bubbling of CO into a toluene solution of **1a** at room temperature for 3 hr did not give **2a** but yellow crystals and $C_2H_5COC_2H_5$. The yellow crystals were identified as $Ni(CO)_2(PPh_3)_2$ by the IR spectrum (2000 and 1935 cm^{-1}, ν(CO))[5] and elemental analysis. Found: C, 71.8; H, 4.8%. Calcd for $C_{38}H_{30}NiO_2P_2$: C, 71.4;

H, 4.7%.

Preparation of $CH_3CONi(acac)(PPh_3)$ 2b. Dehydrated carbon monoxide was bubbled into a toluene (50 ml) solution of **1b** (1.7 g, 2.4 mmol) for an hour at 20 °C. Hexane (50 ml) was added slowly to the red solution under an atmosphere of CO at −78 °C and the orange crystals which separated were collected by filtration to give 0.98 g (55%) of **2b**. Found: C, 65.3; H, 5.4%. Calcd. for $C_{25}H_{25}NiO_3P$: C, 64.9; H, 5.4%. IR(KBr): 1680 cm^{-1} (C=O), 580 cm^{-1} (tentatively assigned to Ni–C). Since an absorption peak of **1b** at 605 cm^{-1} (tentatively assigned to Ni–C) was not observed in the IR spectrum, the product is considered not contaminated with **1b**. Prolonged bubbling of CO into the toluene solution of **1b** resulted in the formation of $Ni(CO)_2(PPh_3)_2$ (confirmed by IR and elemental analysis) and acetone, but **2b** was not obtained.

Reaction of 2a with Methyl Iodide. CH_3I (1.33 g, 9.3 mmol) was added to a flask containing 0.145 g (0.30 mmol) of **2a** by a trap-to-trap distillation in vacuum. The mixture was allowed to stand for 1.5 days at room temperature. $CH_3COC_2H_5$ (0.130 mmol), ethylene (0.062 mmol), methane (0.018 mmol) and a trace amount of C_2H_6 were obtained from the reaction mixture. When the reaction time was shorter (4 hr), a smaller amount of $CH_3COC_2H_5$ (20 mmol % per **2a**) was formed.

Disproportionation Reaction of 2a and 2b. On allowing **2a** (0.42 g, 0.87 mmol) to stand in benzene for 1 week at room temperature, the color of the solution changed from red to yellow. The gas-chromatographic analysis of the solution indicated the formation of $C_2H_5COC_2H_5$ (0.20 mmol. Trace amounts of C_2H_6 and C_2H_4 were detected. Heating the obtained solution at 70 °C for 6 hr caused an increase in the amount of $C_2H_5COC_2H_5$ (0.25 mmol) with a thermal decomposition of **1a** to give ethane and ethylene.

On adding hexane to the reaction mixture a mixture of a yellow precipitate and a green precipitate was obtained. IR spectrum of the mixture indicated that it was a mixture of $Ni(CO)_2(PPh_3)_2$[5] and $Ni(acac)_2$. $Ni(CO)_2(PPh_3)_2$ was isolated by recrystallization from hexane. Similar results were obtained from the disproportionation of **2b**.

Reaction of **2a** (0.15 g, 0.32 mmol) with **1a** (0.13 g, 0.29 mmol) was carried out in benzene (1.5 ml). After allowing the mixture to stand at room temperature for 3 days 0.13 mmol of $C_2H_5COC_2H_5$, 0.07 mmol of ethane and 0.07 mmol of ethylene were obtained. Heating the reaction mixture further at 70 °C for 5 hr caused an increase in the amount of $C_2H_5COC_2H_5$ (0.15 mmol, 47 mol % per **2a**).

Reaction of **2a** (0.14 g, 0.29 mmol) with **1b** (0.23 g, 0.33 mmol) was carried out in benzene-d_6 (1.70 g) at 50 °C. After 5 hr 0.08 mmol of $CH_3COC_2H_5$, 0.09 mmol of $C_2H_5COC_2H_5$, 0.07 mmol of CH_4, 0.13 mmol of ethylene and 0.04 mmol of ethane were obtained. When the molar ratio of **1b** to **2a** was smaller (1 : 1.8), the molar ratio of $CH_3COC_2H_5$ to $C_2H_5COC_2H_5$ decreased to 1 : 2.5.

Spectral Measurements and Analysis. The IR spectra were obtained by using Hitachi Model EPI-G3 spectrometer. NMR spectra were measured by Mr. Y. Nakamura of our laboratory with a Japan Electron Optics Laboratory PS-100 spectrometer. Solvent and TMS were added by a trap-to-trap distillation in vacuum into an NMR tube containing **2a** or **2b** and the NMR tube was sealed. Chemical shifts are referred to internal TMS (down field positive).

The microanalysis of carbon and hydrogen was performed by Mr. T. Saito of our laboratory with a Yanagimoto CHN Autocorder Type Mr-2. The amounts of gases and ketones formed by the reactions of **2a** and **2b** were measured by gas chromatography with Shimadzu GC-3B gas chromatograph.

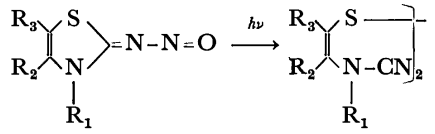
Chemistry of Nitrosoimines. XIV.[1] Photolysis of 5-Nitrosoimino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine

Kin-ya AKIBA, Tohru TSUCHIYA, Isaburo FUKAWA, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received October 29, 1975)

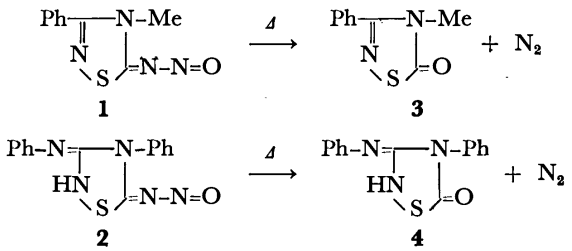
Photolysis of 5-nitrosoimino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine proceeded through π-π^* excitation and gave phenylcyanamide and 5-imino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine as primary products. It was found that other products were produced by the reactions of the primary products. The formation mechanisms have been discussed briefly.

In a previous paper,[2] we reported that photolysis of 2-nitrosoimino-2,3-dihydro-1,3-thiazoles gave the corresponding disulfides *via* π-π^* excitation.



As the extention of these works, this paper describes photolysis of 4-methyl-5-nitrosoimino-3-phenyl-1,2,4-thiadiazoline (**1**) and 5-nitrosoimino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine (**2**).

Similarly to other nitrosoimines,[3] the nitrosoimines **1** and **2** decomposed thermally to give 4-methyl-3-phenyl-1,2,4-thiadiazolin-5-one (**3**) and 4-phenyl-3-phenylimino-1,2,4-thiadiazolidin-5-one (**4**), respectively, in almost quantitative yields.



Photolysis of **1** was very slow in benzene or dichloromethane–acetone under an irradiation with a 100 W medium-pressure mercury lamp and gave a lot of products in small quantities, some of them containing cyano group (determined by IR). Therefore, the further investigation was given up, but this fact presumably supports that the photolyses of the nitrosoimino substituted heterocycles proceed through the π-π^* excitation, because the π-π^* absorption (317.5 nm) of **1** does not overlap effectively with 334.1 nm of the mercury arc.

The photolysis of **2** was carried out under several conditions. The results are summarized in Table 1.

The reaction products were **5**—**11** and phenylcyanamide, depending on the reaction conditions. The compound **5** was identical with 5-imino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine, the denitrosation product of **2**. The compound **6** was the same as the 1 : 1 adduct of **5** and phenylcyanamide.[4] The compound **7** was determined to be 3,5-dianilino-1,2,4-thiadiazole by comparison with an authentic sample.[5] The compound **8** was identical with the reaction product of **5** with cyanic acid, 5-carbamoylimino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine. The compounds **9** and **10** were determined to be phenylurea and phenylisomelamine, respectively. The structure of **11** remains

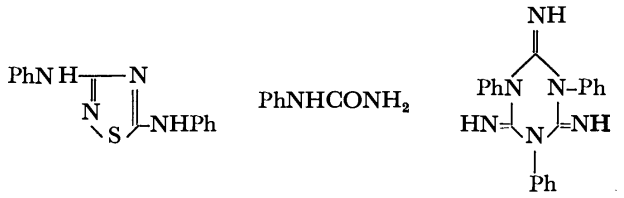
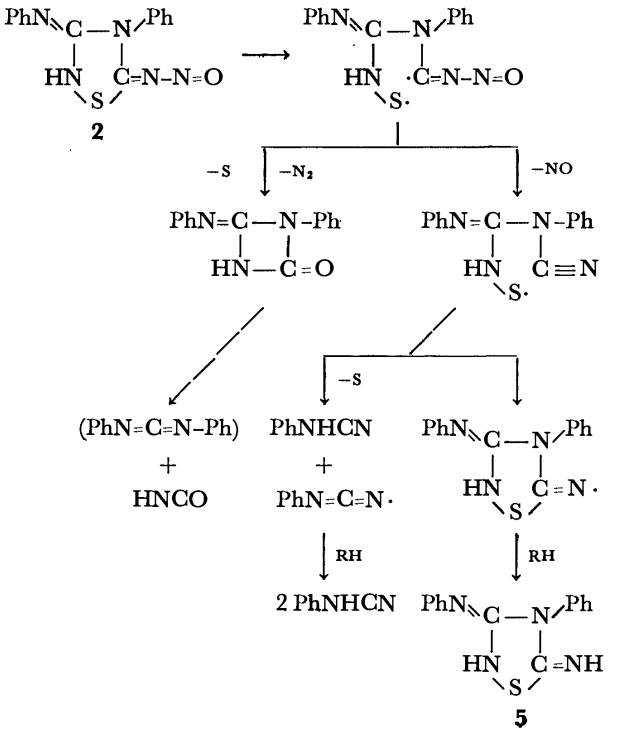
8

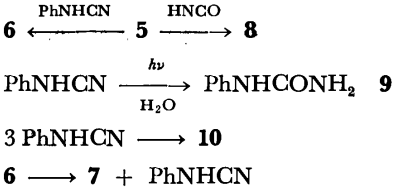


7 9 10

Since the isolation of pure reaction products was difficult, the material balance was not sufficient for quantitative discussion. However, as seen in Table 1, the reaction in a shorter irradiation time gave **5** in a considerable amount and the amount of **6** increased as a reaction time became longer (Runs 1 and 2). Moreover, a shorter irradiation time with a stronger arc gave phenylcyanamide in a fairly good yield (Run 4). Thus, the initial products are **5** and phenylcyanamide and the others are considered to be secondary products. Although **7** is an isomer of **5**, **5** could not be isomerized to **7** by acid or adsorption on silica gel. **9** is the photolysis product of phenylcyanamide with water, being contained in the solvent.

Furthermore, it is shown by experiments using a filter solution that the photolysis of **2** proceeds through π-π^* excitation, similarly to the previous results[2] (see Runs 3 and 4). Therefore, the photolysis is considered to proceed as follows.





Thus, photolysis of **2** is apparently more complicated than that of 2-nitrosoimino-2,3-dihydro-1,3-thiazoles due to the character of the ring.

Experimental

Materials. 4-Methyl-5-nitrosoimino-3-phenyl-1,2,4-thiadiazoline was prepared according to the method of Goerdeler *et al.*,[6] mp 157—158 °C (dec), λ_{max} (C_6H_6): 317.5 (ε 9.08×10^3) and 429 nm (100). 5-Nitrosoimino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine was prepared from 5-imino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine according to the Hector's method,[7] mp 183.3 °C (dec), λ_{max} (C_6H_6): 359 (ε 4.0×10^3) and 433 nm (200).

Thermal Decomposition of 4-Methyl-5-nitrosoimino-3-phenyl-1,2,4-thiadiazoline (1). A suspension of 4.0 g (18.1 mmol) of **1** in 200 ml of toluene was refluxed under stirring for 7 hr. After removal of toluene, the residue was chromatographed on silica gel. Elution with benzene–chloroform gave 2.8 g (80%) of 4-methyl-3-phenyl-1,2,4-thiadiazolin-5-one (**3**), mp 76.0—76.5 °C, IR (KBr): 1680 cm^{-1} (C=O).

Found: C, 56.09; H, 4.21; N, 14.43%. Calcd for $C_9H_8N_2OS$: C, 56.23; H, 4.19; N, 14.57%.

Thermal Decomposition of 5-Nitrosoimino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine (2). The decomposition was carried out qualitatively. A suspension of **2** in xylene was refluxed for 5 hr. After removal of the solvent and addition of petroleum ether to the residue, the resulting crystals were recrystallized from ethanol to give 4-phenyl-3-phenylimino-1,2,4-thiadiazolidin-5-one (**4**) as white needles, mp 165.0—165.3 °C (lit,[8] 162 °C); IR(KBr): 3330 (NH) and 1670 cm^{-1} (C=O). The compound was identical with a sample prepared by nitric acid-catalyzed hydrolysis of 5-imino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine.

Photolysis of 2. The reactions were carried out under nitrogen.

1) A solution of 1.80 g (6.1 mmol) of **2** in 900 ml of dichloromethane was irradiated through Pyrex filter with a 100 W medium pressure mercury lamp at 20—25 °C for 6 hr, and the solvent was removed. The residue was chromatographed on alumina. Elution with benzene–ether and ether afforded 0.27 g (0.7 mmol, 17.2%) of **6**, mp 192—194 °C (lit,[4] 196—198 °C). IR(KBr): 3480, 3420, 3380, 1660, 1560, and 1535 cm^{-1}; MS: *m/e* 386 (M^+, trace). The spectral data were in agreement with those of an authentic sample[4] (see below).

Elution with ether gave 80 mg (0.3 mmol, 5%) of 5-imino-4-phenyl-3-phenylimino-1,2,4-thiadiazolidine (**5**), mp 179—180 °C (lit,[7] 180—181 °C).

2) A solution of 10.22 g (34.4 mmol) of **2** in 1400 ml of benzene-*N*,*N*-dimethylformamide (DMF) (2 : 1) was irradiated through pyrex filter with the same lamp at 5—10 °C for 40 hr. After the solvent was removed *in vacuo* at 90 °C, the residue was chromatographed on silica gel. Fractions eluted with benzene–dichloromethane (3 : 1—1 : 1) and dichloromethane were evaporated. The residue was dissolved in benzene and addition of hexane gave 1.71 g (4.4 mmol, 19.2%) of **6**, mp 183—185 °C, as precipitates. Fractions eluted with dichloromethane–ether (3 : 1) were evaporat-

ed and rechromatographed on a silica gel dry column with dichloromethane to afford **7** (0.74 g), mp 218—219 °C (from chloroform) (lit,[9] 220—222 °C). Eluate with dichloromethane–ether (1 : 1–1 : 3) was rechromatographed on silica gel to afford 0.26 g of **7** (1.00 g, 3.7 mmol, 10.8% in total) with benzene and chloroform and 0.60 g (1.9 mmol, 11.0%) of **8** with chloroform and ether–ethyl acetate, mp 208—209 °C; IR (KBr): 3480, 3400, 3320 (NH), 1760, 1640, 1610, and 1590 cm^{-1}. The spectral data of **8** were in agreement with those of an authentic sample prepared by another route (see below).

Fractions eluted with acetone and acetone–methanol (1 : 1) were rechromatographed on silica gel. Elution with dichloromethane gave 0.42 g (1.1 mmol, 3.3%) of **11**, mp 201—202 °C (from acetone), and elution with chloroform and ethyl acetate gave 1.02 g of crystalline material. The soluble part in ethyl acetate gave 0.82 g (6.0 mmol, 8.8%) of **9**, mp 148—149 °C (from ethyl acetate) (lit,[10] 148—149 °C). The insoluble part was unidentified.

11 : IR (KBr) : 3420, 3360, 3280, 3100 (NH), 1630, and 1590 cm^{-1}; MS: *m/e* 373 (0.7%), 347 (11), 311 (49), 295 (55), 293 (25), 268 (48), 195 ($PhNHCNPh^+$, 28), 150 (100), 122 (44), 119 (59), and 118 (58). The structure of **11** was unidentified.

3) As a filter solution for 340–360 nm and a coolant, a solution of 490 g of $CoSO_4 \cdot 7H_2O$ and 100 g of $CuSO_4 \cdot 5H_2O$ in 900 ml of water was used.[2] A solution of 6.09 g (20.5 mmol) in 850 ml of benzene–DMF–2-propanol (5 : 7 : 5) was irradiated with the same lamp through the filter solution at 5—10 °C for 20 hr. After evaporation of the solvent, the residue was chromatographed on silica gel. Eluates with benzene–dichloromethane (1 : 1) were treated with dichloromethane and water to afford 0.10 g (0.28 mmol, 2.1%) of **10**, mp 202.5—203.5 °C (lit,[11] 210 °C); IR (KBr): 3330 (NH), 1620, and 1590 cm^{-1}, NMR ($CDCl_3$): δ 5.4 (s, 3H, NH) and 7.35 (s, 15H, Ph); MS: *m/e* 354 (M^+), 236, and 118. Evaporation of the organic layer and washing with dichloromethane gave 0.10 g of **7**. The filtrate was treated with preparative thin layer chromatography (tlc) on silica gel with dichloromethane–ether to give 0.44 g (1.1 mmol, 8.1%) of **6**.

Eluates with benzene–dichloromethane (1 : 1) and dichloromethane were rechromatographed on silica gel. Elution with dichloromethane–ether gave 0.64 g of a mixture, which was separated by preparative tlc with ether to give 20 mg of **7** (in total, 0.12 g, 0.45 mmol, 2.2%). Elution of dichloromethane gave 1.04 g (2.8 mmol. 13.7%) of **11**. Elution of ethyl acetate afforded 0.38 g (2.8 mmol, 6.8%) of **9**.

The products were identified by the melting points and spectral data.

4) A solution of 8.84 g (29.8 mmol) of **2** in 1100 ml of DMF–2-propanol (1 : 1) was irradiated with a 400 W medium-pressure mercury lamp at 10—15 °C using the same filter solution for 3 hr. The UV spectrum of the solution indicated that about 5 mmol of **2** remained unchanged. The solvent was removed below 40 °C *in vacuo* and the residue was chromatographed on silica gel.

Elution with dichloromethane and dichloromethane–ether gave 1.42 g (12 mmol, 20.2%) of phenylcyanamide (identified by IR) and other materials which were rechromatographed on alumina. The fractions eluted with benzene–chloroform (3 : 2—2 : 3) was again chromatographed on silica gel dry column with chloroform to give 90 mg of **6**.

Fractions eluted with dichloromethane–ether and ether were purified by preparative tlc with ethyl acetate–ether to give 0.70 g of **6** (in total, 0.79 g, 2 mmol, 10.1%). Elution with ethyl acetate gave 0.59 g of **9** (4.3 mmol, 7.2%). Other fractions could not be identified.

Preparation of ***7***. Ammonia gas was bubbled to 3.0 g (11 mmol) of **5** in 40 ml of ethanol for 2 min and the mixture was heated at 135—140 °C for 3 hr in a sealed tube. After evaporation of the solvent, a small amount of dichloromethane was added to dissolve the residue and ether was added to the solution to precipitate 1.0 g (33%) of **7**, mp 220—221 °C (from ethanol) (lit,[5] 220—222 °C).

Reaction of ***5*** *and Phenylcyanamide.* A mixture of 5.0 g (18.7 mmol) of **5** and 2.0 g (17 mmol) of phenylcyanamide in 50 ml of chloroform was refluxed for 3 hr. After removal of the solvent, the residue was washed with a small amount of dichloromethane to obtain **6**. The washing was allowed to stand after addition of benzene to precipitate **6**. The total amount was 6.0 g (92%), mp 196—198 °C.

Found: C, 65.09; H, 4.56; N, 21.73; S, 8.10%. Calcd for $C_{21}H_{18}N_6S$: C, 65.25; H, 4.70; N, 21.75; S, 8.29%.

Reaction of ***5*** *and Cyanic Acid.* A mixture of 3.0 g (11.2 mmol) of **5**, 5 ml of 10% sulfuric acid, and 1.0 g (15.4 mmol) of sodium cyanate was stirred at 120 °C for 20 min to precipitate 2.5 g (72%) of **8**, mp 208—209 °C (from acetone). MS: *m/e* 311 (M^+, 100%), 295 ($M^+ - NH_2$, 16), and 268 ($M^+ - HOCN$, 63).

Found: C, 57.97; H, 4.19; N, 22.51; S, 9.93%. Calcd for $C_{15}H_{13}N_5OS$: C, 57.85; H, 4.22; N, 22.50; S, 10.30%.

2-Chloro-1,3,5-trithiane and 2-Chloro-1,3-dithiane. Their Ionic Dissociation and Reactions with Nucleophiles

Kazutaka Arai and Michinori Ōki

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received October 29, 1975)

2-Chloro-1,3,5-trithiane and 2-chloro-1,3-dithiane have been prepared by chlorination of the corresponding polythianes with *N*-chlorosuccinimide. These chlorides afford various substitution products when treated with nucleophiles, whereas nuclear substitution of the aromatic ring occurs when the chlorides are treated with phenol or *N*,*N*-dimethylaniline. ^{1}H NMR spectra of these chlorides show remarkable solvent dependence which is explained by assuming ionic dissociation of the chlorides to produce polythianyl cation and chloride anion. Free energies of activation for the dissociation in various solvents indicate that the dissociation of 2-chloro-1,3,5-trithiane is more sluggish than that of 2-chloro-1,3-dithiane. The results are attributed to the difference in availability of electrons on the sulfur atoms in two systems.

Derivatives of 1,3,5-trithiane and 1,3-dithiane have been found to show interesting stereoselectivities in reactions.[2-5] 2-Benzoyloxy-1,3,5-trithiane derivatives exhibited strong preference for the axial attack of nucleophiles and solvent-dependence of the stereoselectivity was partially attributed to the intermediacy of ion pairs.[3] Chloride ion, being a more effective leaving group than benzoate ion, may modify the reactivity and stereoselectivity of the trithiane and dithiane derivatives. And, if the reactivity is enhanced, there is a chance that an unusual phenomenon is observed.

Thus, 2-chloro-1,3,5-trithiane (**1**) and 2-chloro-1,3-dithiane (**2**) were prepared and their reactivities were examined. This paper describes the results of such studies together with a study on anomeric effect in these compounds as an extension of previous works[6-8] with the polythiane derivatives.

(**2**)

Experimental

NMR Measurement. The ^{1}H NMR spectra were recorded on a Hitachi R 20B spectrometer, operating at 60 MHz, with a temperature variation accessory. Temperature was read by the chemical shift differences between protons of methanol for lower temperatures and by those of ethylene glycol protons for higher temperatures than 34 °C. ^{13}C NMR spectra were obtained on a Varian CFT-20 spectrometer with a temperature variation accessory.

Kinetic Parameters. The rate constants of the exchange processes at the coalescence temperature were obtained by applying the following equation[9]

$$k_c = \frac{\pi}{\sqrt{2}}\sqrt{6J_{AB}^2+\nu_{AB}^2}$$

where J_{AB} is the coupling constant of the AB protons in positions 4 and 6 and ν_{AB} the chemical shift difference of those protons. The coalescence of the AB type signals was observed for compound **2** by irradiating the signals due to protons in position 5. Free energies of activation were obtained by the usual method.

Chlorination. To a suspension or solution of 0.5 g of 1,3,5-trithiane or 1,3-dithiane in 10 ml of benzene, which had been dried over sodium, powdered *N*-chlorosuccinimide (1.1 equivalents) was added during a 15 min period at 20 °C with stirring under a nitrogen atmosphere. Stirring was continued for 15 min after completion of the addition. The reaction mixture was filtered to remove insoluble materials, contact with moisture being avoided as completely as possible. Since attempted isolation of the resulting chlorides failed because of their high reactivities, the filtrate was directly submitted to some reactions. Spectra of chlorides in other solvents were obtained after evaporation of the filtrate *in vacuo* followed by dissolving the residue in appropriate solvents.

Benzenethiolysis. The benzene solution was treated with 2—3 equivalents of benzenethiol at room temperature for 2—3 hr and the resulted mixture was evaporated *in vacuo*. Recrystallization from hexane gave 2-phenylthio-1,3,5-trithiane (**3**), mp 122—123 °C (lit. 123.0—123.5 °C)[6] and 2-phenylthio-1,3-dithiane (**4**), mp 58—59 °C (lit. 59 °C),[10] in 80 and 90% yields, respectively.

Reaction with Imidazole. The benzene solution of the chloride was treated with 2 equivalents of imidazole and the mixture was allowed to stand overnight. The whole was washed with water, and the benzene layer dried over magnesium sulfate. Chromatography on silica gel afforded 2-(1-imidazolyl)-1,3,5-trithiane (**5**), mp 174.5—175.5 °C, and 2-(1-imidazolyl)-1,3-dithiane (**6**), mp 139.5—140.5 °C, in 75 and 90% yields, respectively.

5. Found: C, 35.22; H, 3.99; N, 13.79; S, 47.10%. Calcd for $C_6H_8N_2S_3$: C, 35.27; H, 3.95; N, 13.71; S, 47.07%. ^{1}H NMR (δ $CDCl_3$); 4.17 and 4.25 (4H, q, J=15.5 Hz), 6.27 (1H, s), 7.14 (1H, m), 7.27 (1H, m), 7.86 (1H, m).

Reaction with Succinimide. To a reaction mixture obtained by treating polythianes with *N*-chlorosuccinimide as above, was added 3—5 equivalents of triethylamine and the whole was allowed to stand overnight. The mixture was washed with water and the benzene layer separated. The solution was dried over magnesium sulfate and evaporated *in vacuo*. Chromatography of the residue on silica gel afforded 2-(*N*-succinimidyl)-1,3-5,trithiane (**7**), mp 148—149 °C, and 2-(*N*-succinimidyl)-1,3-dithiane (**8**), mp 101—101.5 °C, in 70 and 75% yields, respectively.

Reaction with Phenol. The benzene solution of the crude chloride was mixed with 7 ml of phenol at 41 °C and allowed to stand at room temperature overnight. The volatile materials were removed by distillation *in vacuo* and the residue was recrystallized from chloroform or acetone to give 2-(*p*-hydroxyphenyl)-1,3,5-trithiane (**9**), mp 183—184 °C, and 2-(*p*-hydroxyphenyl)-1,3-dithiane (**10**), mp 149—150 °C, in 50 and 75% yields, respectively.

Reaction with N,N-*Dimethylaniline.* The benzene solution of crude **2** was mixed with 2.5 ml of *N,N*-dimethylaniline and the mixture was allowed to stand at room temperature overnight. The volatile materials were distilled off *in vacuo* and the residue was recrystallized from acetone to give 2-(*p*-*N,N*-dimethylaminophenyl)-1,3-dithiane (**11**), mp 115.5—116.5 °C, in 30% yield. Found: C, 59.99; H, 6.86; N, 5.95; S, 26.89%. Calcd for $C_{12}H_{17}NS_2$: C, 60.21; H, 7.16; N, 5.85; S, 26.78%. ^{1}H NMR (δ, $CDCl_3$): 1.7—2.3 (2H, m), 2.85—3.1 (4H, m), 2.92 (6H, s), 5.11 (1H, s), 6.77 and 7.32 (4H, q, J=8.5 Hz).

Results

Preparation and Conformation of Chloropolythianes. Chlorinations of 1,3,5-trithiane and 1,3-dithiane were carried out with the use of *N*-chlorosuccinimide in benzene under the conditions of α-chlorination of sulfides.[11] Since **1** and **2** were found to react readily with the atmospheric moisture, the reaction mixture was used after filtration of succinimide for spectral measurement and for reactions. The purity of **1** and **2** was checked by ^{1}H NMR spectra and found to be 90—95%. The yield was estimated to be 90—95% from the ^{1}H NMR spectra. The following ^{1}H NMR data were recorded at room temperature (δ, C_6H_6): **1**, 5.52 (1H, s), 2.91 and 4.56 (4H, q, J=15.0 Hz); **2**, 5.76 (1H, s), 2.64 (4H, m), 1.58 (2H, m).

The ^{1}H NMR spectra of these chlorides were obtained at −80 °C to avoid possible complexity of various origins. A carbon disulfide solution of **1** exhibited signals at δ 6.21 (1H, s) and 5.08 and 3.72 (4H, q, J=15 Hz), whereas that of **2** complex signals

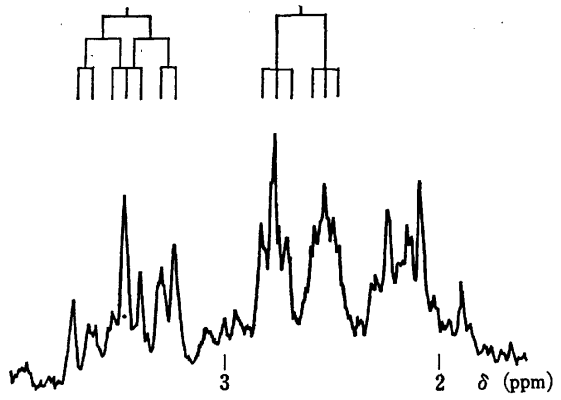

Fig. 1. First-order analysis of ^{1}H NMR signals due to 4,6-protons of **2** in carbon disulfide at −80 °C.

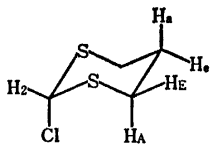
Table 1. ^{1}H NMR data of **2** in carbon disulfide at −80 °C, as analyzed in Fig. 1.



2

Coupling constants		Chemical Shifts	
Assignment	Hz	Assignment	δ
J_{aE}	3	H_E	2.66
J_{eE}	3	H_A	3.49
J_{aA}	10.5∼11		
J_{eA}	3.5		
J_{AE}	14		

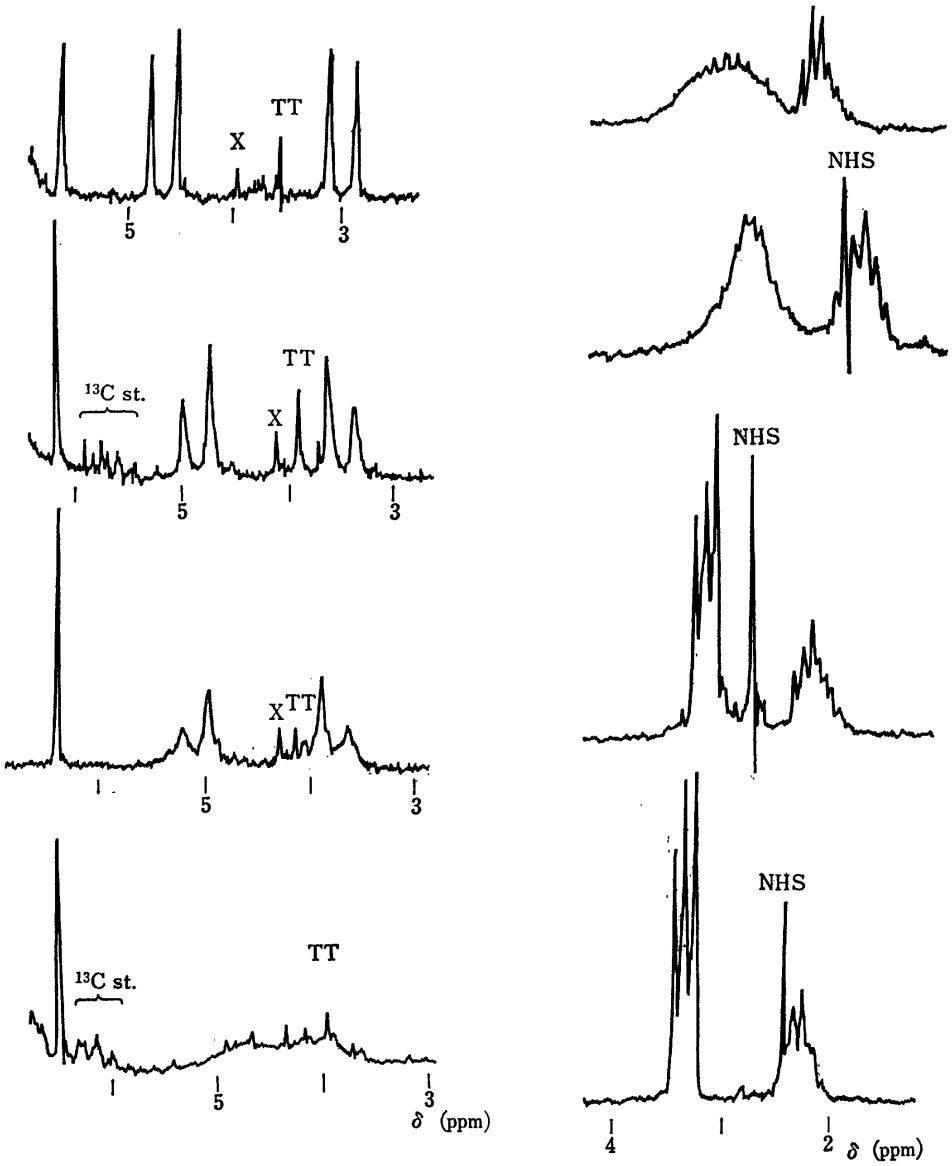
(Fig. 1) and a singlet at δ 6.02 (1H, position 2). The coupling constants and chemical shifts involving the protons in 4 and 6 positions obtained by the first order analysis are given in Table 1. The spectra of **1** and **2** in carbon disulfide at −30 °C were essentially the same with those at −80 °C.

Solvent and Temperature Dependence of NMR Spectra. ^{1}H NMR spectra of **1** and **2** were remarkably affected by the solvent. Some of the typical results are shown in Fig. 2. With sulfur dioxide solutions of **2**, the following NMR data were obtained at −50 °C: ^{1}H NMR (ppm from external TMS), 2.27 (2H, m),

Table 2. ^{1}H NMR data and thermodynamic parameters for the ionic dissociation of **1** and **2**

Compound	Solvent	J_{AB}(Hz)	$\Delta\nu_{AB}$(Hz)	T_c(°C)	k_c(s^{-1})	$\Delta G_c^{\ddagger}$(kc al/mol)
1	C_6H_6	15	98	>80	1.9×10^2	>17.1
	o-$Cl_2C_6H_4$	15	78	106	1.9×10^2	18.5
	$CDCl_3$	14.5	74	>60[a]	$1.7_5\times10^2$	>16.2
	$C_6H_5NO_2$	14	72	40	1.8×10^2	15.1
	$(CH_3)_2SO$	—	—	<20	—	<14.2[b]
2	CS_2	14	51	33±3	$1.3_0\times10^2$	15.0
	C_6H_6	—	—	≤ 0	—	≤13.5[b]

a) From the line-broadening, the coalescence temperature was roughly estimated to be 85 °C. Then $\Delta G_c^{\ddagger}$ becomes *ca.* 17 kcal/mol. b) These values are derived by using coupling constants and chemical shifts in other solvents: the data used for **1** are those obtained with *o*-dichlorobenzene solution.



a) **1** at 35 °C. From top to bottom: in C_6H_6, in o-$Cl_2C_6H_4$, in $CDCl_3$, and in $C_6H_5NO_2$. Signals marked X and TT are due to impurities and 1,3,5-trithiane, respectively, and ^{13}C st signals are carbon-13 satellites of the solvents.

b) **2** at 32 °C, except for sulfur dioxide solution (at −40 °C). From top to bottom: in CS_2, in C_6D_6, in $CDCl_3$, and in SO_2. The signals marked NHS are due to succinimide.

Fig. 2. Solvent dependence of ^1H NMR spectra.

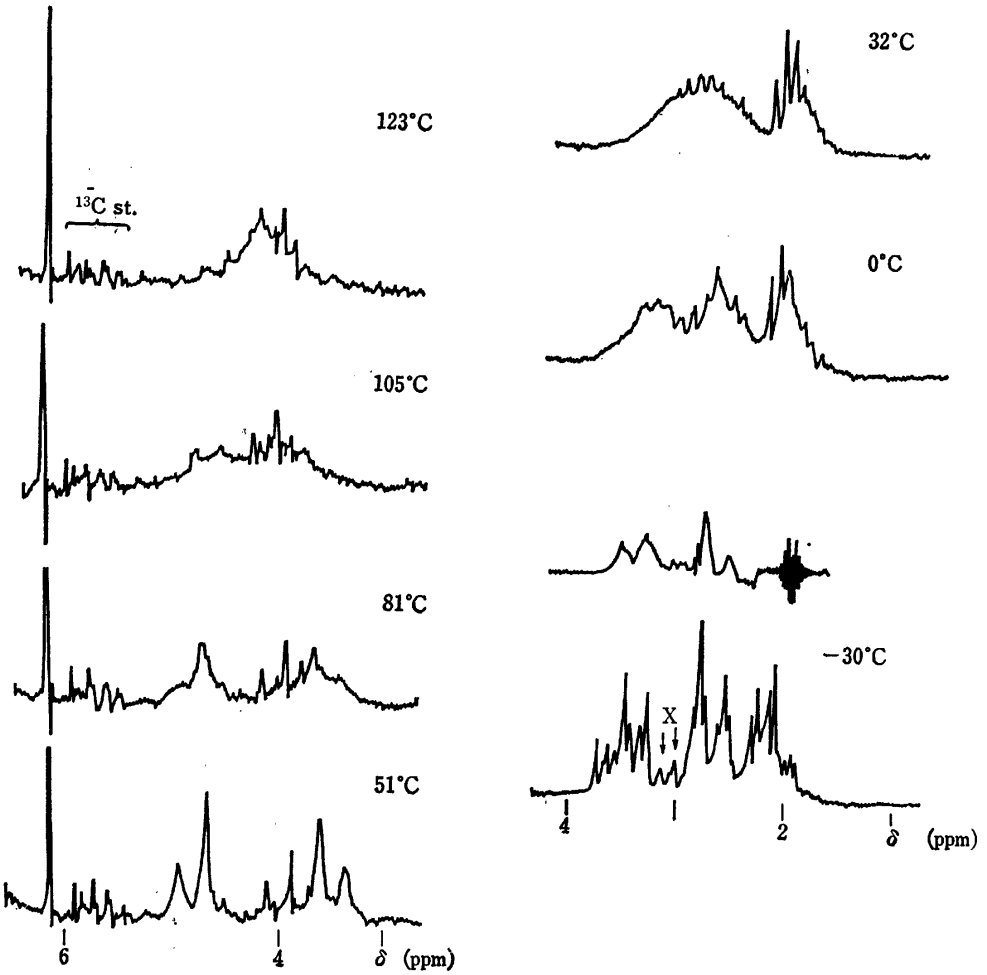
3.30 (4H, m), 10.65 (1H, s); ^{13}C NMR (ppm from external TMS), 16.0 (5-C), 30.5 (4, 6-C), 184.5 (2-C). The ^{13}C NMR spectra were essentially the same within the temperature range of −50∼0 °C.

In general, there seems to be an exchange process for both compounds and the process is faster in more polar solvents.

On raising the temperature, we observe spectra to become simplified (see Fig. 3), although decomposition takes place to some extent and lines due to impurities appear. The spectra at low temperatures are roughly reproducible when the temperature is lowered again. The results suggest that the exchange process becomes fast at the higher temperature. The coalescence temperatures (T_c), exchange rate constants at T_c (k_c) and the free energies of activation at T_c ($\Delta G_c^{\neq}$) obtained with various solvents are given in Table 2.

The process is unimolecular because the spectra were little affected by concentration in the range of 0.08—0.65 M. The process is not quenched by addition of potassium carbonate to remove a minute amount of hydrogen chloride which is produced by hydrolysis of **1** or **2** by moisture.

Reactions. Since the chlorides **1** and **2** were not stable, these were treated with nucleophiles and the products were analyzed and characterized. As expected, reaction with benzenethiol led to the formation of 2-phenylthio derivatives and those with imidazole and succininimide afforded the corresponding 1-

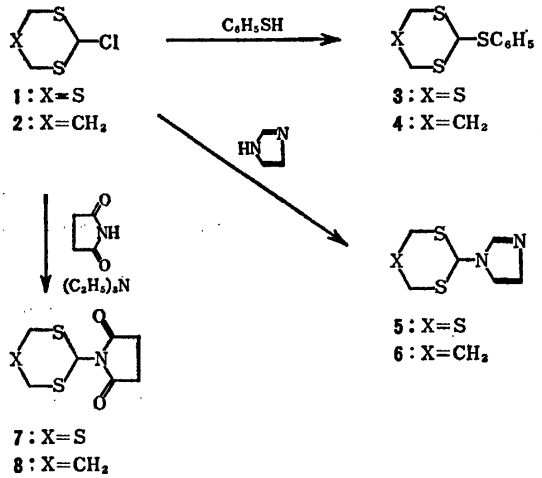


a) **1** in *o*-dichlorobenzene. Signals marked X and TT are due to impurities and 1,3,5-trithiane, respectively, and those marked ^{13}C st are carbon-13 satellites of the solvent.

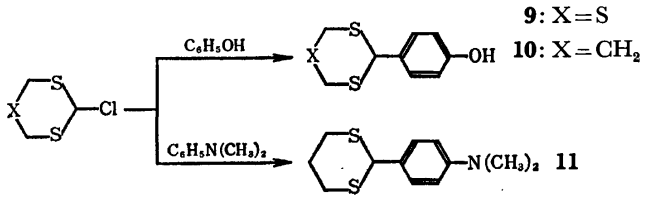
b) **2** in carbon disulfide. Signals marked X are due to impurities. The second spectrum from the bottom is obtained by irradiating signals due to 5-methylene protons at −30 °C.

Fig. 3. Temperature dependence of ^{1}H NMR spectra.

imidazolyl and succinimidyl derivatives respectively.

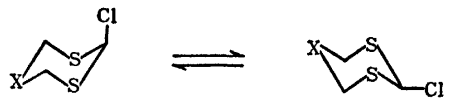


Of interest were the reactions with aromatic compounds which are rich in electron densities. Reactions with phenol and *N*,*N*-dimethylaniline in benzene afforded nuclear substitution products: polythianyl group entered in the *para* position of the electron-donating groups.



Discussion

Observed solvent and temperature effect on the ^{1}H NMR spectra might be explained by the normal ring inversion leading to an equilibrium (Eq. 1) between equatorial and axial isomers of the chloro compounds. Thus it is necessary to discuss the conformation of these compounds.



(1)

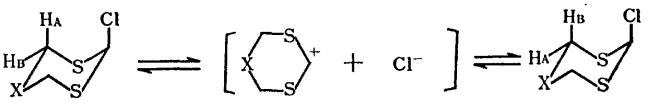
Inspection of the ^1H NMR spectral data of **1** and **2** in carbon disulfide at −80 °C reveals that there is only one stable conformer for each compound under the conditions: although the temperature of −80 °C is usually low enough to freeze the ring inversion of the trithiane ring,[12] no signals attributable to another conformer are found. The complex spectrum of **2** is the reflection of freezing of the inversion of the dithiane ring. The conformer can either be equatorial or axial, in principle. However, for the following reasons, the conformer will best be assigned to the axial.

Firstly, it is known that strong anomeric effect operates in trithianes.[6,7] 2-Benzoyloxy-1,3,5-trithiane exists as an axial conformer exclusively. The chloro group, being more effective in giving anomeric effect than the benzoyloxy,[13] must destablize the equatorial form to a greater extent. Secondly, assuming the axial conformer explains the ^1H NMR data better.[14] In 1,3,5-trithianes, an equatorial proton in 2-position, where a substituent is borne, is known to give a signal height of 0.8—1.2 if an average height of the AB quartet signals due to protons in 4- and 6-positions is taken as unity. The relative height of a signal due to an axial form, on the other hand, is 1.4—1.6. This owes to the presence of the long-range W-letter coupling by which the equatorial proton gives a broader signal. The observed relative signal height of 0.8 for the 2-proton of **1** is consistent with the conformation which has the proton equatorially and the chloro group axially. It is also known that, in 1,3,5-trithiane series, if a substituent in 2-position is axially oriented, the axial protons in 4- and 6-positions are deshielded by the anisotropy effect of the axial bond and the difference in chemical shifts of the AB protons in 4- and 6-positions amounts to 1.20 ppm or more. On the other hand, the equatorial substituent gives little effect to the chemical shifts of 4- and 6-protons. As a result, the difference in chemical shifts of AB protons in the equatorial conformer is less than 0.65 ppm. The observed difference of 1.36 ppm must be an indication that the conformation is axial.

^1H NMR spectrum of **2** showed complex signals but could be analyzed by the first order approximation. It must have been impossible to analyze by a conventional method if the two conformers coexisted. The chemical shifts of the axial and equatorial protons in 4- and 6-positions listed in Table 1 are consistent with the presence of the axial conformer, the difference being 0.83 ppm. It is also more plausible to assume the overwhelming presence of the axial isomer from the analogy of the trithiane compound **1**.

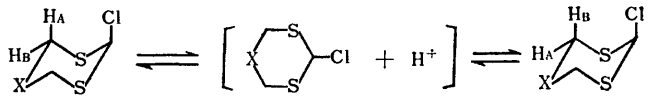
Since raising the temperature did not give any sign of the presence of the equatorial isomer but causes sudden broadening of the signals in NMR spectra, the conformational equilibrium may be taken to be one-sided in favor of the axial isomer. That essentially the same ^1H NMR spectra were obtained at −80 °C and at −30 °C is a support for the presence of one isomer only because the ring inversion of 1,3,5-trithianes usually causes coalescence of signals at about −60∼−40 °C. Since the equatorial isomer is not detected by the present technique, the free energy difference between the axial and the equatorial conformations must be over 1.7 kcal/mol at −50 °C.

Then it becomes necessary that the cause for the line-broadening of the ^1H NMR signals be sought in other processes than the ring inversion (Eq. 1). The exchange is not a kind of ionic process catalyzed by proton since the addition of potassium carbonate to the system did not affect the rate. Yet, the solvent effect that the rate of exchange is larger in polar solvents strongly suggests the process is of ionic nature. Two possibilities arise to account for the phenomenon. The first is the dissociation of the chloride into the polythianyl cation (**12**) and chloride ion (Eq. 2) and the second is that into the chloropolythianide anion (**13**) and proton (Eq. 3). The second possibility cannot be ruled out without convincing evidence because the anion (**13**) must be stable due to delocalization of the negative charge over chlorine and two sulfur atoms.[15]



12

(2)



13

(3)

NMR spectra of the ionic species, if we could generate it to, at least, a significant extent, should shed light on this problem. Sulfur dioxide was chosen as a solvent, because it is strongly ionizing. Both the ^1H NMR and ^{13}C NMR spectra of **2** at −50 °C exhibited a signal at a very low field, 10.65 and 184.5 ppm from external TMS, respectively. The results unambiguously indicate that the dissociation according to Eq. 2 takes place in sulfur dioxide solution at −50 °C. As to the extent of the dissociation, we feel it is almost complete because the spectra are essentially the same although the temperature was varied between −50 °C and 0 °C and the features of the ^1H NMR spectra are very similar to those reported for 1,3-dithian-2-yl tetrafluoroborate in nitromethane-d_3.[16] The situation is reminiscent of the case of triphenylmethyl chloride[17] which is known to show first-order kinetics for chloride exchange in benzene solution.[18]

The conclusion drawn from the spectral data is also supported by the chemical properties. Substitution of aromatic rings of high electron density with an easily ionizing halides such as triphenylmethyl chloride is known.[19] Formation of phenol and dimethylaniline derivatives (**9**—**11**) can therefore be taken as an indication that the polythianyl chloride dissociates easily according to Eq. 2.

As auxiliary evidence, the behavior of polythianes bearing a methoxycarbonyl group may be cited. Although the methoxycarbonyl group is a more anion-stabilizing group than the chloro group, the barriers to proton exchange of 2-methoxycarbonyl-1,3-dithiane

and -1,3,5-trithaine were too large to be detected by the dynamic NMR technique.

The kinetic data of the benzene solutions in Table 2 indicate that the free energies of activation for the ionic dissociation of **1** is smaller than those of **2**. It generally appears that the more polar solvent is needed to effect the dissociation of **1** to a similar extent with **2**. The results are in harmony with the facts that anomeric effect is larger in 1,3-dithanes than in 1,3,5-trithianes[6-8] and benzenethiolysis of 2-benzoyloxy-1,3-dithiane is much faster than that of 2-benzoyloxy-1,3,5-trithiane.[10] Since the level of highest occupied molecular orbital of the trithiane system is more effectively lowered than the dithiane system because of the delocalization over the three sulfur atoms,[20] stabilization of the cation in question will be less effective. It seems a general tendency that the phenomenon concerned with the donation of electrons from sulfur atoms is more favored in the 1,3-dithiane system than in the 1,3,5-trithiane system. To the contraty, a phenomenon concerned with acceptance of electrons to these systems is expected to be more facilitated in the latter than in the former, although the comparison has not been made.

We wish to thank Ministry of Education for Grant in Aid for Fundamental Research which supported this work. We are also indebted to Mr. Kiyoshi Aoki of Nippon Electric-Varian Ltd. for the measurement of the ^{13}C NMR spectra.

Hydroquinone and Quinone Derivatives of the (*Z*)- and (*E*)-β-Thiocrotonates[1]

E. CAMPAIGNE and Yasuo ABE[2]

Chemistry Laboratories, Indiana University, Bloomington, Indiana 47401, U.S.A.

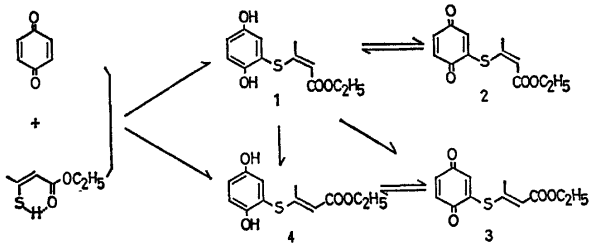
(Received November 4, 1975)

Addition of ethyl thioacetoacetate to *p*-benzoquinone and 1,4-naphthoquinone gave satisfactory yields of the expected ethyl(*Z*)-β-(2,5-dihydroxyphenylthio)crotonate and ethyl(*Z*)-β-(1,4-dihydroxynaphthyl-2-thio)crotonate respectively. In the latter case, at higher temperatures the isomeric ethyl(*E*)-β-(1,4-dihydroxynaphthyl-2-thio)-crotonate was the major product. Oxidation of these compounds with chromic acid gave the corresponding *Z*- and *E*-isomeric quinone derivatives, but oxidation of the *Z*-isomer of the phenyl compound at higher temperatures gave the (*E*)-quinone derivative. All eight isomers in these two series have been isolated, characterized and identified by NMR assignment.

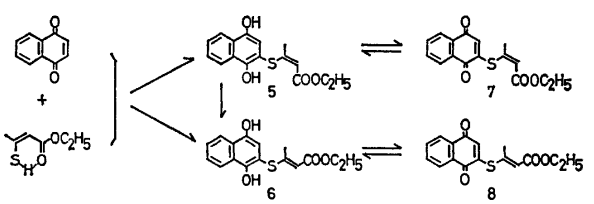
The addition of thiols to *p*-quinones is complicated by the oxidizing power of the quinones, which can oxidize the thiols to disulfides, and oxidize the product hydroquinone to quinone derivatives. This reaction has been discussed in some detail by Snell and Weissberger[3] who found that by deliberately using an excess of quinone, the product could be isolated as the alkyl or arylthioquinone in satisfactory yields from an alcohol solution without added catalyst. Grinev, *et al.*[4] attempted the addition of ethyl thioacetoacetate to *p*-benzoquinone, using zinc chloride as a catalyst, and obtained the desired ethyl β-(2,5-dihydroxyphenylthio)crotonate, in low yield, melting at 176—177 °C. No attempt was made by the authors to assign steric structure to this product. We have reinvestigated the addition of ethyl thioacetoacetate to both *p*-benzoquinone and 1,4-naphthoquinone, and examined the steric structure of products, and also that of the quinones obtained by further oxidation.

Results and Discussion

In Schemes 1 and 2 the reactions and products are outlined. When ethyl thioacetoacetate was mixed with one equivalent of *p*-benzoquinone in ethanol at room temperature a good yield (58%) of ethyl β-(2,5-dihydroxyphenylthio)crotonate of the same melting point as reported by Grinev, *et al.*[4] was obtained. However, concentration of the mother liquors led to the isolation of second isomer, melting at 139—140 °C, in low yield. These two compounds must have the structures shown in Scheme 1 as **1** and **4**. The higher melting compound was assigned the *Z*-configuration **1** on the basis of NMR (see later).



Scheme 1.



Scheme 2.

Oxidation of **1** with chromic acid at 60 °C gave a quinone **2**, whose NMR was consistent with the *Z*-configuration also. The structural relationship of **1** and **2** was confirmed by reduction of **2** with zinc and acetic acid, giving the higher melting isomer **1** again. Surprisingly, oxidation of **1** with chromic acid at 75 °C led to the formation of a mixture which contained a different, higher melting isomeric quinone, the NMR of which indicated the *E*-configuration **3**. This compound was reduced to the lower melting isomeric ethyl β-(2,5-dihydroxyphenylthio)crotonate, assigned the *E*-configuration **4**, consistent with its NMR spectrum. Oxidation of **4** gave a nearly quantitative yield of **3**.

Finally, heating **1** in acetic acid containing a catalytic amount of hydrochloric acid produced a mixture of **1** and **4**. The reverse isomerization did not occur under these conditions, nor was **2** converted to **3** under these conditions. Nevertheless, it seems reasonable to assume that **1** is the kinetically favored product of the addition of the (*Z*)-thioacetoacetic ester (stabilized by hydrogen bonding) to the quinone, but that the *E*-form, **4**, is thermodynamically favored.

Similar observations were made when ethyl thioacetoacetate was allowed to react with 1,4-naphthoquinone in alcohol solution. If care was taken to keep the solution below 40 °C, even during concentration, the crystalline product, melting at 172.5—173 °C, obtained in satisfactory yield, had the *Z*-configuration (**5**) by NMR (Scheme 2). The configuration of pure **5** was maintained at the reflux condition in alcohol. Alternatively, if a similar solution was heated with steam during work-up, and recrystallized from alcohol then a different product melting at 170—171 °C, assigned the *E*-configuration **6** was obtained as a major product. The nearness of melting points of these two isomers complicated the experimental work. However, NMR characteristics are distinctive, and the melting points of the oxidation products are quite different.

Oxidation of **5** with chromic acid at 60 °C gave the corresponding naphthoquinone **7**, also having the *Z*-configuration, and melting at 97—98 °C, while similar treatment of **6** gave a nearly quantitative yield of

TABLE 1. NMR δ VALUES FOR SELECTED PROTONS OF (*Z*)- AND (*E*)-β-THIOCROTONATES

A. β-Arylthio Derivatives

		R=benzyl[a]	R=2,5-dihydroxyphenyl	R=1,4-dihydroxynaphthyl
	*d*	2.15 (d, 3H, J=1.0)	1.86 (d, 3H, J=1.0)	1.85 (d, 3H, J=1.4)
	c	5.72 (q, 1H, J=1.0)	5.83 (q, 1H, J=1.0)	6.01 (q, 1H, J=1.4)
	*d*	2.39 (d, 3H, J=0.9)	2.34 (d, 3H, J=1.0)	2.43 (d, 3H, J=1.1)
	c	5.61 (broad)	5.17 (q, 1H, J=1.0)	5.23 (q, 1H, J=1.1)

a) Values from Ref. 5. b) Isopropylthiobenzoquinone shows this proton (*e*) at δ 6.36 (d, 1H, J=2.1 Hz). See Experimental.

ethyl(*E*)-β-(1,4-naphthoquinonyl-2-thio)crotonate, **8**, melting at 119—120 °C. Oxidation of **5** at 75—85 °C gave **7**, but did not give **8** in contrast with the reaction of **1** at the same condition. The reduction of **7** to **5** with zinc dust was quantitative, and **8** did produce **6**, but the reduction was much less facile than with the other quinones. Finally, heating **5** in acetic acid with added hydrochloric acid gave a mixture of isomers, in which **6** predominated, by NMR spectra.

Z- and *E*-isomers of *S*-alkyl derivatives of thioacetoacetic ester, have been examined by Hedegaard, Mortensen, and Lawesson.[5] Alkylation of ethyl thioacetoacetate gave a mixture of the (*Z*)- and (*E*)-β-alkylthiocrotonates, separable by distillation, in a ratio of about 3 to 1. The NMR chemical shifts for the vinyl methyl and vinyl protons of the *Z*- and *E*-isomers of the benzyl derivatives, as assigned by these authors, are shown in Table 1 as reference points. The values are consistent with values assigned to the *cis* and *trans* methyl groups in β,β-dimethylacrylic acid by Anet and Bourn[6] using Nuclear Overhauser effects. These authors assigned the upfield doublet (δ 1.42) to the methyl group *cis* to hydrogen, and the downfield doublet (δ 1.97) to the methyl group *cis* to carboxyl, as predicted by deshielding effects of the carboxyl group.

We have tabulated the significant δ values for our compounds in Table 1. The chemical shifts for the vinylic methyl groups and protons for the arylthio derivatives are shown in part A. Note that the deshielding effect of the *cis*-carboxyl group shows quite well, as the *E*-isomers both show chemical downfield shifts of approximately 0.50 ppm for the vinyl methyl group. On the other hand, a strong shielding effect of the arylthio group on the vinylic protons is observed in the *E*-isomers, which show upfield chemical shifts of about 0.70 ppm over values for this proton in the *Z*-series.

The *p*-quinone derivatives are compared in part B of Table 1. The chemical shifts for the vinylic methyl groups are consistent with the expected deshielding effect of a *cis* carboxyl group over that of a *trans* carboxyl, equal to about 0.36 ppm in each pair of isomers. However, in this case the vinylic hydrogens in the *E*-isomers show a weak deshielding, (0.06±0.01 ppm) probably the effect of the adjacent *p*-quinone, held partially coplanar by conjugation through the sulfur atom. The adjacent thiocrotonic ester exerts an interesting effect on the protons at the 3-position of the quinone (labeled *e* on Table 1B). These protons in the *Z*-isomers appear consistently 0.28 ppm downfield from the absorption of their counterparts in the *E*-isomers, due, apparently, to a deshielding of this proton by the carboxylic ester group in the *Z*-structures, not possible in the *E*-configuration. To confirm our identification of this proton, a sample of isopropylthiobenzoquinone, previously reported[3] was synthesized and its NMR spectra determined. The ring proton at the upfield position at δ 6.36 is clearly the 3-proton, shielded by the adjacent alkylthio group. The assignment of the 3-proton in the naphthoquinone series is simpler, since it is the only possible singlet.

Experimental

Melting points were obtained on a Mel-Temp capillary melting point apparatus and are uncorrected. NMR spectra were determined on a Varian Associates EM 360 spectrometer (60 MHz) using TMS as an internal standard, and mass spectra on a Varian Associates MAT CH-7 spectrometer. IR spectra were determined on a Perkin-Elmer Model 137-B Infracord Spectrometer using potassium bromide disks. Elemental analyses were performed by Midwest Microlabs, Inc., Indianapolis, Indiana, U.S.A.

Ethyl (Z)-β-(2,5-Dihydroxyphenylthio)crotonate (1). *a)* To a solution of 15.0 g (0.14 mol) of *p*-benzoquinone in 200 ml of ethanol was gradually added, with stirring, an ethanol solution of 22.8 g (0.16 mol) of ethyl thioacetoacetate, prepared by the method of Mitra.[7] The reaction mixture turned red and became warm, but after 30 min the color faded to pale brown or tan. Ethanol was removed on a flash evaporator, and the residual oil taken up in warm ethyl acetate. Addition of warm benzene to cloudness and

cooling produced 20.4 g (58%) of **1** as white crystals, mp 174—175 °C (lit,[4] 176—177 °C). NMR (Acetone-d_6): δ 1.23 (t, 3H, J=7 Hz), 1.86 (d, 3H, J=1 Hz), 4.10 (q, 2H, J=7 Hz), 5.83 (q, 1H, J=1 Hz), 6.81—6.89 (m, 3H), 7.84 (s, 2H).

Concentration of the mother liquor gave 5.4 g of crude oily solid which NMR analysis showed was a mixture of **1** and the corresponding *E*-isomer **4**, in a ratio of 1 : 4. This was then taken up in hot benzene and recrystallized, giving 2.1 g (6%) of **4**, mp 138—139 °C (see later).

b) A solution of 1.0 g of ethyl (*Z*)-β-(*p*-benzoquinonylthio)-crotonate (**2**, see later) in 25 ml of glacial acetic acid was stirred while 1.0 g of zinc dust was added in portions. After 45 min the colorless solution was concentrated to a syrup and water added. The white precipitate was collected and recrystallized from benzene–ethyl acetate, giving 1.0 g (98%), of crystals melting at 171—173 °C, shown to be identical to **1**, above, by congruent IR and NMR spectra.

Ethyl (Z)-β-(p-Benzoquinonylthio)crotonate (2). Chromic acid (1.0 g, 10 mmol) was added all at once to a stirred solution of 2.54 g (10 mmol) of **1** in 50 ml of glacial acetic acid at 60 °C. The temperature was maintained at 60 °C for 10 min, after which the orange solution was poured over 300 g of ice. The precipitate was collected and washed with water, then taken up in benzene and washed again. The benzene extract was dried ($MgSO_4$), evaporated, and the solid recrystallized from ethanol to give 1.1 g (44%) of **2**, mp 71—71.5 °C. IR: 1680, 1653, 1640 (C=O), 1567, 1587 (C=C), 1189 cm^{-1} (C–O). NMR: ($CDCl_3$): δ 1.25 (t, 3H, J=7 Hz), 2.09 (d, 3H, J=1 Hz), 4.14 (q, 2H, J=7 Hz), 6.16 (q, 1H, J=1 Hz), 6.70 (dd, 1H, J=2.5, 10.5 Hz), 6.73 (d, 1H, J=2.5 Hz), 6.82 (d, 1H, J=10.5 Hz). MS (*m/e*): 252 (M^+). Found: C, 57.36; H, 4.92; S, 12.94%. Calcd for $C_{12}H_{12}O_4S$: C, 57.13; H, 4.79; S, 12.71%.

Ethyl(E)-β-(p-Benzoquinonylthio)crotonate (3). *a)* Chromic acid (2.0 g, 20 mmol) was added all at once to a stirred solution of 5.1 g (20 mmol) of **1** in 100 ml of glacial acetic acid maintained at 70—75 °C. After 10 min the hot solution was poured directly over ice and the orange precipitate collected and washed with water. The crude product was chromatographed on acidic alumina (Giulini activity Grade 1) eluted with benzene, forming two orange bands. The first fraction gave **3** (0.8 g, 16%) recrystallized from ethanol, mp 83.5—84 °C. IR: 1709, 1645, 1629 (C=O), 1555 (C=C), 1186 cm^{-1} (C–O). NMR ($CDCl_3$): δ 1.28 (t, 3H, J=6.9 Hz), 2.45 (d, 3H, J=0.9 Hz), 4.16 (q, 2H, J=6.9 Hz), 6.23 (q, 1H, J=0.9 Hz), 6.45 (d, 1H, J=2.8 Hz), 6.67 (dd, 1H, J=9.5, 2.8 Hz), 6.81 (d, 1H, J=9.5 Hz). MS (*m/e*): 252 (M^+). Found: C, 57.37; H, 4.88; S, 12.92%. Calcd for $C_{12}H_{12}O_4S$: C, 57.13; H, 4.79; S, 12.71%.

The second fraction from the column worked up in the same way, gave 1.5 g (30% of **2**, identical by melting point and congruent NMR spectra. A mixture melting point of **2** and **3** was depressed.

b) When 0.37 g (1.45 mmol) of ethyl (*E*)-β-(2,5-dihydroxyphenylthio)crotonate (**4**, see later) was oxidized with an equivalent of chromic acid at 60 °C, as described above for the preparation of **2**, the orange precipitate was collected and recrystallized once from ethanol to give 0.31 g (84%) of **3**, mp 80—81 °C, identical with the authentic sample of **3** by IR and NMR spectra without further purification.

Ethyl (E)-β-(2,5-Dihydroxyphenylthio)crotonate (4). Reduction of 1 g (4 mmol) of **3** with zinc dust in glacial acetic acid, as described for the preparation of **1** (*b*) gave 0.97 g (96%) of white crystals from benzene, mp 139—140 °C. IR: 3356 (OH), 1686 (C=O), 1603 cm^{-1} (C=C). NMR (Acetone-d_6): δ 1.13 (t, 3H, J=7 Hz), 2.34 (d, 3H, J=1 Hz), 3.98 (q, 2H, J=7 Hz), 5.17 (q, 1H, J=1 Hz), 6.83 (m, 3H), 7.80 (s, broad, 1H), 7.99 (s, broad, 1H). MS (*m/e*): 254 (M^+). Found: C, 56.50; H, 5.68; S, 12.88%. Calcd for $C_{12}H_{14}O_4S$: C, 56.32; H, 5.58; S, 12.67%.

Ethyl (Z)-β-(1,4-Dihydroxynaphthyl-2-thio)crotonate (5). To a solution of 20 g (137 mmol) of ethyl thioacetoacetate in 100 ml of ethanol was added 15.0 g (91 mmol) of finely ground 1,4-naphthoquinone all at once with stirring at room temperature. The deep red solution was let stand three days, then evaporated under reduced pressure, taking care to keep the temperature below 40 °C. Cold benzene was added, and the slurry so obtained was filtered, washed with cold benzene, and dried under reduced pressure, recrystallization of the product from ethanol gave 18 g (63%) of white crystals, mp 172.5—173 °C. IR: 3322 (OH), 1667 (C=O), 1590 (C=C), 1198 cm^{-1} (C–O). NMR (Acetone-d_6): δ 1.26 (t, 3H, J=7.2 Hz), 1.85 (d, 3H, J=1.4 Hz), 4.20 (q, 2H, J=7.2 Hz), 6.01 (q, 1H, J=1.4 Hz), 6.96 (s, 1H), 7.65 (m, 2H), 8.33 (m, 3H), 8.77 (s, broad, 1H). MS (*m/e*): 304 (M^+). Found: C, 63.12; H, 5.33; S, 10.34%. Calcd for $C_{16}H_{16}O_4S$: C, 63.14; H, 5.30; S, 10.53%.

Ethyl (E)-β-(1,4-Dihydroxynaphthyl-2-thio)crotonate (6). The above experiment was repeated, except that after all of the naphthoquinone had dissolved, the red solution was refluxed on a steam bath for an hour, then the ethanol evaporated on a steam bath and the residue crystallized by the addition of benzene. On cooling, the white crystals were collected and recrystallized from ethanol, giving 13.2 g (46%) of **6**, mp 170—171 °C. IR: 3333 (OH), 1686 (C=O), 1603 (C=C), 1200 cm^{-1} (C–O). NMR (Acetone-d_6): δ 1.08 (t, 3H, J=7.3 Hz), 2.43 (d, 3H, J=1.1 Hz), 4.00 (q, 2H, J=7.3 Hz), 5.23 (q, 1H, J=1.1 Hz), 6.90 (s, 1H), 7.57 (m, 2H), 8.22 (m, 3H), 8.28 (s, broad, 1H). MS (*m/e*): 304 (M^+). Found: C, 62.86; H, 5.00; S, 10.79%. Calcd for $C_{16}H_{16}O_4S$: C, 63.14; H, 5.30; S, 10.53%.

Ethyl(Z)-β-(1,4-Naphthoquinonyl-2-thio)crotonate (7). Oxidation of 3.1 g (10 mmol) of **5** with an equivalent of chromic acid below 60 °C, as previously described for the conversion of **1** to **2**, gave 2.8 g (94%) of orange crystals (from ethanol), mp 97—98 °C. IR: 1698, 1656 (C=O), 1592, 1565 (C=C), 1200 cm^{-1} (C–O). NMR ($CDCl_3$): δ 1.28 (t, 3H, J=7.1 Hz), 2.19 (d, 3H, J=1.3 Hz), 4.23 (q, 2H, J=7.1 Hz), 6.37 (q, 1H, J=1.3 Hz), 7.01 (s, 1H), 7.85 (m, 2H), 8.15 (m, 2H). MS (*m/e*): 302 (M^+). Found: C, 63.25; H, 4.76; S, 10.32%. Calcd for $C_{16}H_{14}O_4S$: C, 63.56; H, 4.67; S, 10.61%.

Oxidation of **5** at 75—85 °C gave orange crystals **7** in 60% yield. The NMR spectra of mother liquor did not show the presence of *E*-isomer **8**.

Reduction of 7. The zinc dust reduction mixture of 1.0 g of **7** in acetic acid (25 ml) was stirred for 40 min, and worked up in the usual manner to give 0.8 g (80%) of **5**, mp 169—171 °C, identified by congruent NMR spectra.

Ethyl (E)-β-(1,4-Naphthoquinonyl-2-thio)crotonate (8). Oxidation of 1.0 g (2.9 mmol) of **6** with an equivalent of chromic acid in glacial acetic acid at 60 °C, as previously described, gave 0.92 g (92%) of yellow crystals after one recrystallization from ethanol, mp 119—120 °C. IR: 1710, 1658 (C=O), 1592, 1563 (C=C), 1198 cm^{-1} (C–O). NMR ($CDCl_3$): δ 1.33 (t, 3H, J=7.2 Hz), 2.55 (d, 3H, J=1.1 Hz), 4.27 (q, 2H, J=7.2 Hz), 6.42 (q, 1H, J=1.1 Hz), 6.73 (s, 1H), 7.83 (m, 2H), 8.32 (m, 2H). MS (*m/e*): 302 (M^+). Found: C, 63.77; H, 4.76; S, 10.33%. Calcd for $C_{16}H_{14}O_4S$: C, 63.56; H, 4.67; S, 10.61%.

Reduction of 8. The zinc dust reduction mixture of 1.0 g of **8** in acetic acid was stirred for several hours, and worked up in the usual manner to give 0.30 g (30%) of **6**,

mp 169—170 °C, identified by congruent NMR spectra. Concentration of the benzene mother liquors gave 0.63 g (63%) of recovered **8**.

Isomerization of Z-Isomers in Acid Solution. A solution of 1.0 g of **1** in 20 ml of glacial acetic acid, to which 0.5 ml of 1 M HCl had been added, was heated to 75 °C for 10 min, then diluted with water and extracted with ether. After drying and concentrating, the residue was subjected to thin layer chromatography on Silica gel G, using chloroform. The R_f range of 0.18—0.37 was collected and extracted with ether, giving 280 mg of crude **4**, mp 130—133 °C. Recrystallization from benzene gave **4**, mp 138—139 °C, identical to an authentic sample by congruent IR and NMR spectra. Extraction of the R_f 0.37—0.59 range gave approximately 500 mg of crude **1**, having a distinct thiolic odor, indicating some decomposition had occurred.

Similar treatment of **4** resulted only in recovery of 95% of **4** unchanged. Likewise, similar treatment of **2** and **3** led to recovery of starting materials in nearly quantitative yields.

A solution of 1.0 g of **5** was heated to 75 °C in 20 ml of glacial acetic acid containing 0.5 ml of 6 M HCl. After 10 min the mixture was poured over 100 g of ice, the precipitate collected, washed with water and dried, giving 0.60 g of crude solid with a definite thiolic odor. Several recrystallizations from ethanol gave a white solid melting at 167—169 °C which by NMR showed the spectrum of **6**, with traces of **5** still present.

Isopropylthiobenzoquinone. Following the procedure of Snell and Weissberger[3] a mixture of isopropylthiol and two equivalents of *p*-benzoquinone were stirred in ethanol at room temperature for 30 min, and worked up as described to yield 32% of yellow crystals, mp 74—76 °C. NMR ($CDCl_3$): δ 1.39 (d, 6H, J=6.6 Hz), 3.27 (m, 1H, J=6.6 Hz), 6.36 (d, 1H, J=2.1 Hz), 6.63 (dd, 1H, J=10, 2.1 Hz), 6.75 (d, 1H, J=10 Hz).

Epoxide Rearrangement. IV.[1] Isomerization of Cyclohexene and 1-Methylcyclohexene Oxides over Solid Acids and Bases in Gas Phase

Kazushi ARATA, Kiyoshi KATO, and Kozo TANABE*

Hokkaido University of Education, 1-2 Hachiman-cho, Hakodate 040

**Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060*

(Received May 29, 1975)

Synopsis. A large amount of diene compounds was found to form in the isomerizations of cyclohexene and 1-methylcyclohexene oxides catalyzed by solid acids and bases in gas phase. The catalysts which were quite inactive in liquid phase showed unexpectedly high activities in gas phase, indicating the different catalytic actions.

We have recently studied the isomerization of 1-methylcyclohexene oxide catalyzed by solid acids and bases in a heterogeneous solid-liquid system and observed the markedly different selectivities which depended on the type of catalysts.[1-3] In order to elucidate the electronic and steric effects of methyl group of the oxide on the reactivity and selectivity, the isomerization of cyclohexene oxide together with 1-methylcyclohexene oxide was studied in a solid-gas system in the present work, since the reaction rate of cyclohexene oxide was extremely low in a solid-liquid system.[3] The catalytic action of solid acids and bases in a solid-gas system was also compared with that in a solid-liquid system.

Experimental

Catalysts and Materials. Cyclohexene and 1-methylcyclohexene oxides, supplied from Takasago Perfumery Co., were fractionally distilled to purify to more than 98%. $NiSO_4$ and $FeSO_4$ were prepared by calcining their heptahydrates (G. R.). Al_2O_3, KAT6 of Nishio Chemical Co., was calcined at 500 °C. TiO_2, TiO_2·ZrO_2, ZrO_2, and ZnO were prepared by thermal decompositions of H_4TiO_4, H_4TiO_4·$Zr(OH)_4$, $Zr(OH)_4$ and $Zn(OH)_2$, respectively, which were produced by the same procedure as that described previously.[1,3] The preparations of $LiClO_4$ and $NaOH/SiO_2$ were also followed by the previous experiment.[3] CaO and MgO were prepared by calcining their hydroxides at 550 °C. All the catalysts were heat-treated in air and stored in sealed ampoules until use.

Procedures. The isomerization of oxides was carried out at 150 °C in a conventional pulse reactor in N_2 carrier. The catalysts (40 mg, 100—200 mesh) were heat-treated again in the reactor at their preparation temperatures in air for 3 hr before reaction. The amount of reactant injected was 0.3—0.4 μl. The products were analyzed and identified by gc comparison with the authentic samples using a 3 m column of 20% polyethylene glycol 20 M on Celite 545 SK (150 °C; N_2, 27 cc/min; FID).

Results and Discussion

The catalytic activity and selectivity for the isomerization of cyclohexene oxide are summarized in Table 1. The main products were cyclohexanone, cyclohexenol and 1,3-cyclohexadiene. Cyclohexanol and cyclohexenone, which are formed by hydrogenation and dehydrogenation of cyclohexene oxide, respectively, were almost negligible or not produced at all, though those corresponding compounds were considerably produced in the rearrangement of 1-methylcyclohexene oxide in the heterogeneous liquid phase.[1-3]

Table 1. Catalytic activity and selectivity for isomerization of cyclohexene oxide

Catalyst[a]	Conversion %	Products (%)[b]		
$NiSO_4$ (250 °C)	58.9	42.0	7.2	7.2
$NiSO_4$ (400 °C)	25.8	11.5	3.3	7.5
$FeSO_4$ (200 °C)	24.5	8.5	2.7	8.6
$FeSO_4$ (400 °C)	49.1	25.6	6.3	13.0
Al_2O_3	79.1	56.4	9.1	9.2
TiO_2	36.8	21.8	2.2	8.2
TiO_2-ZrO_2[c]	59.5	43.7	2.2	9.0
ZrO_2	22.4	5.2	2.0	8.3
ZnO (400 °C)	18.7	5.5	1.5	7.0
$LiClO_4$ (150 °C)	16.0	4.3	1.5	6.4
$NaOH/SiO_2$	18.7	5.1	1.5	6.7
MgO (550 °C)	19.3	5.2	1.8	7.4

a) Calcined at 500 °C unless noted. b) About 3% of an unidentified compound was found right before the epoxide in glc in every reaction. c) Molar ratio= 1 : 1.

The relative activities of $NiSO_4$, Al_2O_3, TiO_2, TiO_2–ZrO_2 and ZrO_2 were similar to those for 1-methylcyclohexene oxide in a liquid phase;[1-3] namely, (1) the activities were higher when calcined at low temperature for $NiSO_4$ and at high temperature for $FeSO_4$, (2) the activity of Al_2O_3 was highest, which gave the outstanding activity for the allyl alcohol formation in the liquid phase reaction, and (3) the activity of TiO_2–ZrO_2 was higher than that of TiO_2 or ZrO_2 due to its higher acidity created by combining both oxides.

Comparatively high activities were shown by ZnO, $NaOH/SiO_2$ and MgO, which were quite inactive in our previous work,[3] where it was considered that basic catalysts such as $NaOH/SiO_2$,[4] CaO and MgO[5] did not cause the rearrangement of 1-methylcyclohexene oxide. ZnO and CaO showed unexpectedly high activities for 1-methylcyclohexene oxide (Table 2). These high activities in the present investigation are considered to be due to the different reaction condi-

Table 2. Catalytic activity and selectivity for isomerization of 1-methylcyclohexene oxide

Catalyst[a]	Conversion %	Products (%)[b]		
		Dienes		Allyl[c] alcohols
$NiSO_4$ (250 °C)	72.4	35.2	35.2	0
Al_2O_3	74.2	44.8	27.3	0
TiO_2	62.9	32.1	12.6	16.3
TiO_2-ZrO_2[d]	71.3	43.3	15.3	7.0
ZrO_2	46.2	12.9	14.4	15.0
ZnO (400 °C)	45.0	12.0	16.5	14.3
CaO (550 °C)	43.6	11.0	14.9	15.5

a) Calcined at 500 °C unless noted. b) The amounts of 1-methylcyclohexanol and 2-methyl-2-cyclohexene-1-one produced in the liquid phase reaction were almost negligible. c) 2-Methyl-2-cyclohexene-1-ol and 2-methylenecyclohexanol. d) Molar ratio=1 : 1.

tions; 40 °C higher in reaction temperature, absence of solvent and gas phase.

The activity of $LiClO_4$, which was surprisingly active for the formation of ketone in the liquid phase reaction,[3] was relatively low. The fact seems to support our previous conclusion that the high activity of $LiClO_4$ in a solid-liquid system is due to the partial dissolution of the catalyst or the complex formation with the epoxide.[3]

The most unexpected observation was the formation of a large amount of the diene compound, 1,3-cyclohexadiene, which was probably formed by the dehydration of cyclohexenol, though the amounts of the corresponding dienes were almost negligible in the liquid phase reaction.[1-3] Since there is a report that cyclohexene oxide is pyrolyzed to form cyclohexanone and cyclohexenol with the negligible amount of 1,3-cyclohexadiene at 407—467 °C,[6] the readsorption of cyclohexenol on the catalyst surface is supposed to cause the dehydration. This interpretation is also supported from another experimental fact that the conversion of cyclohexenol into 1,3-cyclohexadiene was 80% over $NiSO_4$ (400 °C) under the present reaction conditions.

The similar conversion to dienes was also observed for the isomerization of 1-methylcyclohexene oxide as shown in Table 2. The dienes were not identified by comparison with the authentic samples, but the identification is unquestionable from the quite similar selectivities to those of cyclohexene oxide and the additional experimental results: that is, (1) allyl alcohols (a mixture of 2-methylenecyclohexanol and 2-methyl-2-cyclohexene-1-ol in 1 : 1.5) converted into their dienes over $NiSO_4$ (250 °C) in almost 100% under th esame reaction conditions, (2) the oxide isomerized to form 18.8% of dienes, 11.9% of ketone and 25.5% of allyl alcohols over TiO_2 (500 °C, 23 mg) in faster carrier gas (twice as fast as the flow rate in general runs), indicating the decrease of dienes from allyl alcohols and (3) relative retention time in glc between the oxide and dienes was quite close to that in the case of cyclohexene oxide.

There have not been reports concerning the considerable diene formation by the catalyzed isomerization of epoxides, with the exception of the 1,3-cycloheptadiene formation from cycloheptene oxide catalyzed by lithium diethylamide.[7] The conversion of propylene[8,9] and ethylethylene oxides[10,11] over solid acids or bases in gas phase were also not reported to yield their dienes.

We are grateful to Dr. Tadashi Nakamura for his offering a sample of cyclohexenol.

ESR Spectra of Nitric Oxide Adsorbed on ZrO_2, CeO_2, and ThO_2

Miki NIWA, Takashi MINAMI, and Yuichi MURAKAMI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 9, 1975)

Synopsis. ESR spectra of nitric oxide adsorbed on ZrO_2, CeO_2, and ThO_2 were measured at -196 °C, and $g_\perp$, $g_{//}$ and splitting constants were determined.

Nitric oxide is a rare paramagnetic compound stable in the gas phase. However, the ESR spectrum of gaseous NO is not observed with an ordinary X-band spectrometer. Adsorption of NO allows us to observe the adsorbed radical, since the orbital momentum is quenched by the surface fields. The spectra of radicals formed by NO adsorption have been reported only for MgO, ZnO, Al_2O_3, zeolite, Molecular Sieve 4A, TiO_2, SnO_2, and Cr_2O_3–Al_2O_3.[1-10] These spectra have hyperfine structures owing to the nuclear spin of nitrogen, and are easily removed by evacuation for a short time, except for that on Cr_2O_3–Al_2O_3.[10] Lunsford determined the anisotropy of NO radical by utilizing ^{14}NO and ^{15}NO, and discussed its relationship to catalytic activity.[1-5] In the present work, an attempt was made to observe the hyperfine structure for the system of NO on ZrO_2, CeO_2, and ThO_2.

Experimental

Samples. The ZrO_2 sample was prepared by calcination of the powder in air stream at 450 °C for 2 hr. The CeO_2 and ThO_2 samples were made by thermal decomposition of nitrates at 500 °C for 4 hr. Nitric oxide (Takachiho Chemical Ind. Co. Ltd.) was used without further purification.

Measurements. The samples were placed in Pyrex glass ampules for ESR measurements, and dehydrated at 250 °C during a period of 1 hr in a vacuum of 10^{-6} Torr. Nitric oxide was adsorbed at a pressure of *ca.* 5 Torr. ESR measurements were carried out at -196 °C with a JEOL Spectrometer (JES-ME-1X). *g*-Values and hyperfine splitting constants were calculated by comparison with the value for the Mn^{2+} impurity in MgO.

Results and Discussion

The obtained spectra on ZrO_2, CeO_2, and ThO_2 are shown in Figs. 1, 2, and 3, respectively. These spectra were easily removed by evacuation for a short time. They are similar to those obtained for ZnS by Lunsford[2] and TiO_2 by Imelik *et al.*[9] This corresponds to the case in which an unpaired electron of NO (nuclear spin of nitrogen = 1) lies in a crystal field such that $g_\perp > g_{//}$. The anisotropy of spectrum is thus determined

TABLE 1. *g*-VALUES AND HYPERFINE SPLITTING CONSTANTS

Material	$g_\perp$	$g_{//}$	a (G)	Δ (eV)
ZrO_2	2.000	1.92	27.5±0.3	0.36
CeO_2	1.993	1.90	28.4±0.3	0.29
ThO_2	1.991	1.95, 1.93	27.6±0.3	0.57, 0.42

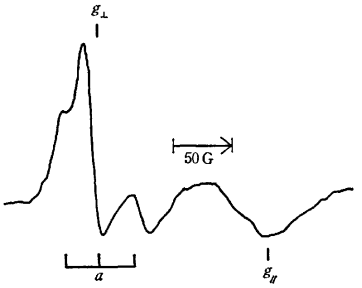

Fig. 1. ESR spectrum of NO adsorbed on ZrO_2.

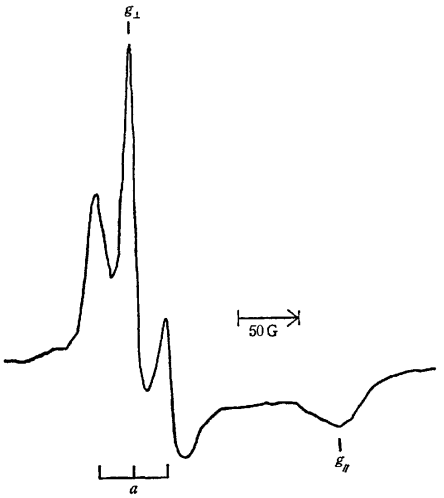

Fig. 2. ESR spectrum of NO adsorbed on CeO_2.

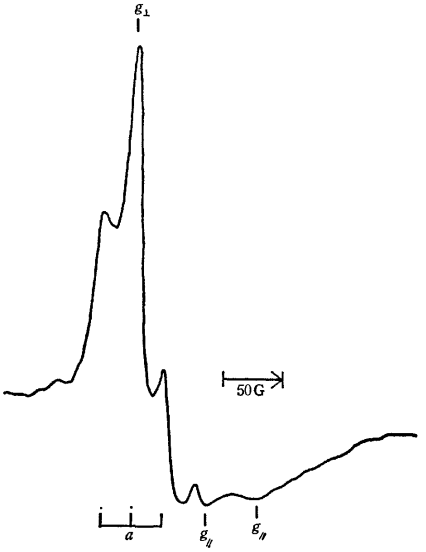

Fig. 3. ESR spectrum of NO adsorbed on ThO_2.

as shown in Table 1.

The spectrum on ThO_2 has two high-field minima as observed on silica-magnesia.[4] The anisotropy of this spectrum remained unchanged when the sample was evacuated at 665 °C under 10^{-6} torr or at 450 °C under 10^{-3} torr. It seems that two types of sites contribute to the adsorption of NO.

The splitting (Δ) of $2p\pi^*$ orbital of NO by the crystal field given by Kanzig and Cohen[11] is as follows,

$$\Delta = \frac{2\lambda}{g_e - g_{//}}$$

where λ is the spin-orbit coupling constant (0.015 eV for NO), and g_e is the g-value of free electron (2.003). The values of Δ for ZrO_2, CeO_2, and ThO_2 are given in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49(2), 567—568 (1976)

A Study of Catalysis by Metal Phosphate. III.[1] The Dehydrogenation of Alcohols over Cadmium Phosphate and the Influence of CCl_4 Addition on the Catalytic Reaction

Fumio NOZAKI and Yutaka IIMORI

Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received June 28, 1975)

Synopsis. Various alcohols were selectively dehydrogenated over the $Cd_3(PO_4)_2$ catalyst. The addition of CCl_4 during the reaction resulted in a rapid decrease in dehydrogenation activity and in an increase in dehydration activity, accompanied by an evolution of CO_2.

In a previous paper,[1] we have reported a kinetic study of the dehydrogenation of 2-propanol over $Cd_3(PO_4)_2$ and an investigation of the acid-base character of the catalyst. In this paper, we will describe an additional result concerning the relative reactivities of various alcohols. In addition, the results of the influence of CCl_4 addition upon the catalytic reaction will be reported and the observations will be discussed.

Experimental

The catalyst was prepared by the same method as has been described in the previous paper[1]. Before use in the tests, the catalyst was calcined at 400 °C for 2 hr in an air stream. The six kinds of alcohols, C_4H_9OH (to be subsequently referred to as *n*-BtOH), $(CH_3)_2CHCH_2OH$ (*i*-BtOH), $CH_3CH_2CH(OH)CH_3$ (*s*-BtOH), C_3H_7OH (*n*-PrOH), $CH_3CH(OH)CH_3$ (*i*-PrOH), and C_2H_5OH (EtOH), were used after they had been dehydrated and distilled in a routine manner.

The procedures for the catalytic tests and for analyzing the reaction products were practically the same as those described in the previous paper[1], except that a 12-m gas-chromatographic column of 30% DMS-chromosorb operating at room temperature was additionally used in this work for the separation and determination of CO_2, 1-butene, *trans*-2-butene, and *cis*-2-butene.

Results and Discussion

For the cases of all alcohols in so far as we have investigated, the catalyst exceeded 95% in selectivity for dehydrogenation and olefine formation attributable to the dehydration was very slight. The conversion data of alcohols were found to be approximately expressed in the zero-th order kinetics. Arrhenius plots for the rate constants are shown in Fig. 1.

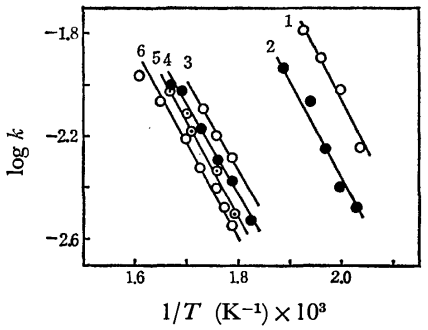

Fig. 1. Arrhenius plots for the rate constants.
1: *s*-BtOH, 2: *i*-PrOH, 3: *i*-BtOH, 4: *n*-BtOH, 5: *n*-PrOH, 6: EtOH.

Figure 1 indicates that the reactivities of the alcohols decrease in this order: *s*-BtOH>*i*-PrOH>*i*-BtOH>*n*-BtOH>*n*-PrOH>EtOH and that the apparent activation energy is about 20 kcal/mol for all the alcohols. The secondary alcohols are much more reactive than the primary alcohols. The observed sequence and regularity in reactivity are similar to that reported in the paper in which the dehydrogenation of alcohols was investigated over metallic catalysts.[2] This fact leads to the speculation that the rate-determining step of the dehydrogenation reaction is an α-hydrogen elimination process.

The changes in catalytic activity upon the addition of CCl_4 are illustrated in Fig. 2, with *i*-PrOH as the example. As CCl_4 had been placed on the catalyst surface, the dehydrogenation to acetone was rapidly retarded and was almost eliminated after the reaction had been continued for about 20 min. In contrast, a dehydration to propylene was generated, with some time-lag. The lag in the appearance of dehydration activity might be a slow response to the acidic sites generated by the reaction of the catalyst with CCl_4. As is shown by Curve 3 in Fig. 2, CO_2 was gradually produced by the addition of CCl_4, although the amount of evolution was so slight that it was difficult to make a quantitative determination. As has previously been reported,[1] the organic acid without a Cl atom, *e.g.*,

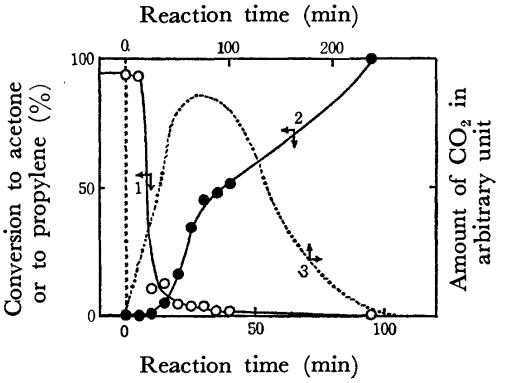

Fig. 2. Influence of CCl_4 addition on the reaction of *i*-PrOH.
1: conversion to acetone, 2: conversion to propylene, 3: relative amount of CO_2.
Reaction temperature: 300 °C, Catalyst weight: 2.0 g, Feed rate of *i*-PrOH and N_2: 0.229 mol/hr, Mol-fraction of *i*-PrOH in feed: 0.24, CCl_4 concentration in the feed: 0.1 mol/l of *i*-PrOH.

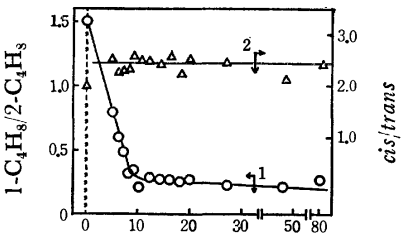

Fig. 3. Changes in the selectivity for dehydration of *s*-BtOH to butene isomers during the course of CCl_4 addition.
1: 1-butene/2-butenes ratio, 2: *cis/trans* ratio in 2-butenes. Reaction conditions are the same as for Fig. 2.

C_6H_5COOH, also retarded the dehydrogenation activity of the catalyst, but there was no enhancement of the dehydration activity. In the case of C_6H_5COOH addition, there was absolutely no such evolution of CO_2 as was observed upon the addition of CCl_4.

The influence of CCl_4 addition upon the reaction of *s*-BtOH was quite similar to that shown in Fig. 2; the dehydrogenation to 2-butanone was rapidly retarded, while the dehydration to butene isomers was much enhanced. A characteristic aspect of the behavior to be noted here is that the distribution of butene isomers changes appreciably upon the addition of CCl_4, as is shown in Fig. 3. Before the addition of CCl_4, the 1-butene/2-butenes ratio in butene isomers was about 1.5. In contrast, as CCl_4 is added the ratio decreases rapidly and leads to a value of about 0.25, a value which is quite close to the value of 0.24 in an equilibrium state.[3] The *cis/trans* ratio in 2-butenes remains almost unaltered and is kept nearly constant in the range from 2.0 to 2.5. In other words, the most abundant isomer varied from 1-butene to *cis*-2-butene upon the addition of CCl_4. Both the 1-butene/2-butenes and *cis/trans* ratios were almost independent of the *s*-BtOH conversion. This indicates that no further isomerization of the butene isomers produced by dehydration is involved.

According to the paper reported by Tanabe *et al*,[3] the change in the 1-butene/2-butenes ratio during the course of CCl_4 addition suggests that the reaction pathway of the dehydration has been altered from an acid-base bifunctional mechanism to an *E*-1 mechanism *via* the carbonium-ion intermediate.

The exact mechanism of the CO_2 formation directly attributable to the admission of CCl_4 is still not yet completely elucidated, but we have speculated that the following reaction is involved:

$$CCl_4 + 2OH^- \longrightarrow CCl_2(OH)_2 + 2Cl^- \longrightarrow 2HCl + CO_2 + 2Cl^-$$

where OH^- is the basic site of the catalyst and plays an important role in the dehydrogenation of alcohol. The acidic action of HCl is a likely cause of the appearance and enhancement of the dehydration activity upon the addition of CCl_4. None of the catalyst poisoned with CCl_4 regained its activity for dehydrogenation when the catalytic reaction of alcohol without CCl_4 was continued or when it was passed through N_2 at 300 °C. By a long period of heating in contact with a N_2 stream containing H_2O at 300 °C, the dehydrogenation activity was substantially regenerated. The introduction of CO_2 had no effect on the reaction. A definite correlation between the loss of the dehydrogenation activity upon the addition of CCl_4 and the formation of CO_2 gives a basis for speculation that OH^- is the active site for the dehydrogenation; however, further experimental evidence is necessary to clarify this postulation.

Preparation and Properties of Cobalt(II) and -(III) Complexes of (2-Aminoethylthio)acetic Acid

Kiichi Hori

Department of Chemistry, Faculty of Science, Yamagata University, Yamagata 990

(Received April 21, 1975)

Synopsis. The cobalt(II) and -(III) complexes of (2-aminoethylthio)acetic acid (HL), $[CoL_2]\cdot H_2O$, *trans*-(*N*)-$[CoL_2]Cl$ and *cis*(*N*)-$[CoL_2]Cl\cdot 2H_2O$ were prepared and characterized. These complexes are octahedral in which the ligand is coordinated through the N, S and O atoms as a terdentate ligand.

As a part of a study on the cobalt(III) complexes containing sulfides as a ligand, the complexes of bis-(2-aminoethyl)sulfide[1] and 2,2'-thiodiacetic acid[2] have been reported. For the former ligand, only tri-valent complexes were obtained, while for the latter, di-valent complexes were generally obtained. This work was undertaken to prepare cobalt(III) complexes of (2-aminoethylthio)acetic acid and to compare the results with the previous ones.

Experimental

Preparation. *Bis[(2-aminoethylthio)acetato]cobalt(II) monohydrate,* $[Co(NH_2CH_2CH_2SCH_2COO)_2]\cdot H_2O$ ***(1)***. A solution of 4.05 g (0.03 mol) of (2-aminoethylthio)acetic acid in 50 ml of water was adjusted to about pH 11.5 with a sodium hydroxide solution. 2.67 g (0.01 mol) of hexaamminecobalt(III) chloride was added to the solution. The solution was heated at 70—75 °C until ammonia gas evolution ceased, and was filtered. On standing, pinkish crystals were precipitated. Recrystallization was carried out from water.

Found: C, 27.67; H, 5.02; N, 8.06; Co, 17.02%. Calcd for $C_8H_{18}O_5N_2Co$: C, 27.82; H, 5.26; N, 8.11; Co, 17.06%.

trans(N)- *and* cis(N)-*bis[(2-aminoethylthio)acetato]cobalt(III) chloride,* trans(N)-$[Co(NH_2CH_2CH_2SCH_2COO)_2]Cl$ ***(2)*** *and* cis(N)-$[Co(NH_2CH_2CH_2SCH_2COO)_2]Cl\cdot 2H_2O$ ***(3)***. To an aqueous solution of 3.37 g (0.025 mol) of (2-aminoethylthio)-acetic acid adjusted to about pH 9 was added 2.38 g (0.01 mol) of cobalt(II) chloride hexahydrate. The solution was gradually concentrated at 70 °C until it became sticky. Adding 2 ml of 30% hydrogen peroxide, the color of the solution turned to red-purple. The solution was allowed to stand for several days to precipitate the mixture of complexes **2** and **3**. In order to separate the two complexes, a part of the mixture was dissolved in a small volume of warm water and filtered. When the filtrate was cooled, purple crystals of complex **3** were precipitated. The remaining portion of the mixture was dissolved in warm water, and the same volume of ethanol was added. On cooling, red-purple crystals of complex **2** were precipitated. Both of the complexes **2** and **3** were recrystallized from a small amount of water by adding ethanol.

Found for (**2**): C, 26.52; H, 4.64; N, 7.83; Co, 15.67%. Calcd for $C_8H_{16}O_4N_2S_2ClCo$: C, 26.49; H, 4.45; N, 7.72; Co, 16.24%. Found for (**3**): C, 24.05; H, 5.39; N, 7.11; Co, 14.75%. Calcd for $C_8H_{20}O_6N_2S_2ClCo$: C, 24.09; H, 5.06; N, 7.03; Co, 14.78%.

Apparatus. The same instruments as those described previously were used.[1,2]

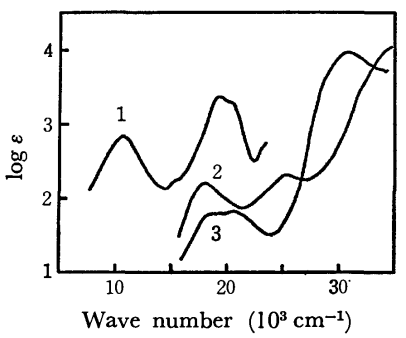

Fig. 1. Electronic spectra of complexes.
1: Reflection spectrm of (**1**) (arbitrary scale), 2: Absorption spectrum of (**2**), 3: Absorption spectrum of (**3**).

Results and Discussion

The reflectance spectrum of complex **1** is similar to those of well-known octahedral cobalt(II) complexes such as $[Co(H_2O)_6]^{2+}$ in the near-infrared and visible regions (Fig. 1).[3] Furthermore, the magnetic moment value of 5.18 B.M. obtained falls within the range of 4.7—5.2 B.M. usually found for regular high-spin octahedral complexes.[4] Therefore, complex **1** is concluded to be a high-spin octahedral cobalt(II) complex.

From the infrared spectral data, it is proven directly that both amino and carboxylate groups are coordinated in the ligand. When the S atom with both N and O terminals is present in a straight chain ligand molecule around the central cobalt(II) ion, it will be useful to promote the coordinating effect of the sulfur. Finally, since all N, O and S atoms in the ligand can be coordinated potentially on chelation, it seems more practical to consider the existence of a terdentate ligand in this case.

On the other hand, both complexes **2** and **3** are diamagnetic and their molar extinction coefficients are appropriate for the cobalt(III) complexes (Fig. 1). Therefore, they are concluded to be octahedral cobalt-(III) complexes. The ligand in these complexes is concluded to function as a terdentate ligand from a consideration analogous to the case of complex **1**.

The absorption spectrum of complex **2** shows a splitting in the first band while that of complex **3** does not. The patterns of the absorption spectra of complexes **2** and **3** are similar to those of *trans*- and *cis*-$K[Co(ida)_2]$,[5] respectively, in the visible region. Such a similarity indicates that these complexes of the $N_2S_2O_2$ type may be similar to cobalt(III) complexes of iminoacetic acid of the N_2O_4 type in the strength of crystal field splitting. It is, therefore, suggested that complex **2** which has a splitting in the first band is the

trans form with respect to the nitrogen atoms and complex **3** which shows no splitting is the *cis* form, as in the case of $K[Co(ida)_2]$. For these cobalt(III) complexes, six geometrical forms are possible: two species with a *trans(N)-fac* configuration, one with a *cis(N)-mer* configuration and three with a *cis(N)-fac* configuration. However, the detailed coordination structures is not known because no NMR data are available, owing to the poor solubility of the complexes. Considering the reduced yield of the *mer* configuration in the complexes with iminodiacetic acid or the related ligand,[5,6] the *mer* configuration does not seem to be contained in these complexes.

The infrared spectral data of the complexes are summerized in Table 1, together with those of nickel(II) and copper(II) complexes of (2-aminoethylthio)-acetic acid. The assignments of the bands are tentative and were made with reference to the spectra of related complexes,[7] considering deuteration effects. The ν(Co(III)–N) bands for complexes **2** and **3** were assigned to slightly higher wave numbers, because no corresponding bands could be found the bands appearing in the 480—520 cm^{-1} region. In the complexes containing the bond of thioether-type sulfur and metal, the ν(M–S) bands have been assigned to the 210—260 cm^{-1} region for the cobalt(II), nickel(II) and copper(II) complexes with (alkylthio)acetic acid,[8] and to 307 and 316 cm^{-1} for the palladium(II) and platinum(II) complexes with dimethyl sulfide, respectively.[9] It was therefore expected that the ν(Co(II)–S) and ν(Co(III)–S) bands for the present complexes would appear in the 210—250 cm^{-1} and 250—300 cm^{-1} regions, respectively. The appropriate bands appearing in this region and corresponding to the nickel and copper complexes shown in Table 1 are unique for each of the complexes **1**, **2** and **3**. These were assigned to the ν(Co(II)–S) and ν(Co(III)–S) bands, respectively.

The Spectrophotometric Determination of Beryllium with Chromazurol S and Polyoxyethylenedodecylamine

Hiroshi NISHIDA, Taeko NISHIDA, and Hiroshi OHTOMO
Faculty of Engineering, Iwate University, Ueda, Morioka 020

(Received August 23, 1975)

Synopsis. A sensitive and selective method for the spectrophotometric determination of beryllium with Chromazurol S (CAS) and polyoxyethylenedodecylamine(POEDA) in the presence of EDTA and perchlorate is proposed.

Sensitive methods for the spectrophotometric determination of beryllium with several triphenylmethane dyestuffs and cationic surfactants have been developed.[1-5] These methods are, however, subject to interferences from large anions, such as nitrate (above 4×10^{-2} mol/l) and perchlorate (above 4×10^{-4} mol/l), which precipitate easily by forming ion-pairs with the cationic surfactant.[2] In the present work, it is found that the effects of these anions can be appreciably eliminated by the use of a surfactant with a large polarity, such as polyoxyethylenedodecylamine {*N,N*-bis-(polyethylene glycol)-dodecylamine, abbreviated as POEDA}, and perchlorate in the spectrophotometric determination of beryllium with Chromazurol S(abbreviated as CAS).

Reagents and Apparatus. The standard beryllium solution (Be 1.00 mg/ml), the CAS solution (0.25%), the ethylenediaminetetraacetic acid disodium salt (abbreviated as EDTA) solution (1%), and the sodium acetate solution (1 mol/l) used in this work were the same as those described in previous papers.[2-4] POEDA solution (0.5%): the reagent (0.5 g) was dissolved in water containing 0.5 ml of 2 mol/l hydrochloric acid. The solution was adjusted to pH 4.5 with the sodium acetate solution and diluted to 100 ml with water. All the other chemicals used were of an analytical reagent grade. A Hitachi 139 spectrophotometer and 10-mm cells were used to measure the absorbance.

Recommended Procedure. A solution containing less than about 2 μg of beryllium was transferred into a beaker, there after 1 ml of the EDTA solution and 5 ml of a sodium perchlorate solution (5 mol/l) were added. The pH was adjusted to 4.5 with the sodium acetate solution, and the solution was evaporated to 5—10 ml.[3] By this procedure, interference from aluminum can be avoided by the easy complexing with EDTA. After cooling to room temperature, 1 ml of the CAS solution and 2 ml of the POEDA solution were added. The solution was transferred into a 25-ml volumetric flask and made up to volume with water. After the solution had then stood for 15 minutes, its absorbance was measured in a 10-mm cell at 605 nm against a reagent blank.

Effects of pH and Reagent Concentrations. The absorption maximum of the beryllium–CAS complex in the presence of POEDA is at 605 nm. The maximum absorbance is about four times higher than that in the absence of POEDA. The absorbance of the complex is almost constant over the pH range from 4.2 to 4.9.

A constant absorbance is obtained by the addition of more than 0.8 ml of the CAS solution (in the presence of 2 ml of the POEDA solution) and more than 1.5 ml of the POEDA solution (in the presence of 1 ml of the CAS solution). The addition of 1 ml of the CAS solution and 2 ml of the POEDA solution at pH 4.5 is, therefore, recommended.

A constant absorbance is also obtained by the addition of more than 0.8 ml of the EDTA solution. The maximum absorbance is obtained within 10 minutes after the color development and then remains constant for at least 10 hours.

Effect of the Concentration of the Perchlorate. A turbidity does not appear in the CAS–POEDA solution, even when 10 ml of a 5 mol/l sodium perchlorate solution are added. In the previous work, since the absorbance of the CAS–zephiramine solution increases with an increase in the ionic strength in the sample solution, the concentration of anions in the sample solution has to be held constant.[4] The effect of the concentration of anions on the absorbance of the CAS–POEDA solution is, therefore, examined. The effect of the concentration of perchlorate on the absorbance of the solution at pH 4.5 is shown in Table 1. The absorbance does not vary with the variation

TABLE 1. EFFECT OF THE CONCENTRATION OF SODIUM PERCHLORATE ON THE ABSORBANCE OF CAS-POEDA SOLUTION AT pH 4.5

	Concentration of sodium perchlorate (mol/l)			
	0	0.5	1.0	2.0

in the concentration of perchlorate. Up to 2 mol/l of nitrate and up to 1 mol/l of chloride in the presence of 1 mol/l of perchlorate also have no effect on the absorbance of the solution. The effect of the concentration of perchlorate on the absorbance of the complex is shown in Table 2. A constant absorbance is obtained by the addition of less than 10 ml of a 5 mol/l sodium perchlorate solution. The addition of 5 ml of the sodium perchlorate solution is, therefore, recommended.

Table 3. Effects of anions

Ion added (g)		Added as	Be found (μg)	Error (μg)

V^{5+}	0.1	NH_4VO_4	1.03	+0.03

Be taken: 1.00 μg.

Effects of Diverse Ions. The effect of anions on the beryllium determination is shown in Table 3. Up to 2.5 g of perchlorate, 3 g of nitrate, 2 g of chloride, 0.7 g of sulfate, and 0.1 g of acetate do not interfere, but fluoride interferes seriously. The effect of cations on the beryllium determination is shown in Table 4. One mg of calcium, barium, manganese, zinc, cadmium and lead, 0.5 mg of nickel and copper, 0.3 mg of iron, 0.2 mg of aluminum, and 0.1 mg of molybdemum(VI) and vanadium(V) can be tolerated for the determination of 1 μg of beryllium, with a relative error of 3%.

Calibration Curve. As a result of the examinations described above, a procedure for the beryllium determination may be proposed. In the calibration curve obtained by the recommended procedure, Beer's law is obeyed over a concentration range up to at least 0.08 μg/ml and the apparent molar absorptivity at 605 nm is 9.0×10^4 l mol^{-1} cm^{-1}, which is 12% lower than that in the CAS–zephiramine method.[4]

The proposed method has the following merits compare with the CAS–zephiramine method:[4] it is adaptable to the beryllium determination in the sample solution containing perchlorate and nitrate as well as chloride, and it is unnecessary to hold the concentration of these anions constant within the range of concentrations described above.

Synthetic Reacions by Complex Catalysts. XXXVIII. A New Preparation of Copper(I) Isocyanate(Alkyl Isocyanide) and Its Reactions

Yoshihiko Ito, Yoshinori Inubushi, Shun-ichi Matsumura, and Takeo Saegusa
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received June 23, 1975)

Synopsis. Reaction of ethyl carbamate with Cu_2O in the presence of *t*-butyl isocyanide produces copper(I) isocyanate(*t*-butyl isocyanide) complex, $Cu(NCO)(t\text{-}C_4H_9NC)_{2.5}$ (**1**), in 93% yield. Complex **1** is also produced in high yield by the reaction of ethyl *N*-trimethylsilylcarbamate with Cu_2O in the presence of *t*-butyl isocyanide. Complex **1** reacts with alkyl halides in alcohols and with acyl chlorides to afford *N*-alkylcarbamate (**2**) and acyl isocyanate (**3**), respectively, in moderate yields.

It was already reported that organocopper(I)(alkyl isocyanide) complexes[1] and copper(I) carboxylate (alkyl isocyanide) complexes[2] have been successfully prepared by the reactions of Cu_2O/RNC system with carbon acids such as cyclopentadiene, acetylacetone, and malonate (Eq. (1)), and with carboxylic acid (Eq. (2)).

$$\begin{matrix}X\\Y\end{matrix}\!\!>CH_2 + Cu_2O/RNC \xrightarrow{-H_2O} \begin{matrix}X\\Y\end{matrix}\!\!>CHCu(RNC)_n \qquad (1)$$

$$RCO_2H + Cu_2O/RNC \xrightarrow{-H_2O} RCO_2Cu(RNC)_n \qquad (2)$$

We have now found that the treatment of ethyl carbamate with Cu_2O/RNC produces copper(I) isocyanate (alkyl isocyanide) complex in high yields. This reaction presents a convenient one-step preparative method of Cu(I) isocyanate complex(**1**)[3]

$$NH_2CO_2C_2H_5 + Cu_2O/RNC \xrightarrow[-H_2O]{-C_2H_5OH} \underset{\mathbf{1}}{Cu(I)(NCO)(RNC)_n} \qquad (3)$$

The preparation of Cu(I)isocyanate(*t*-butyl isocyanide) complex (**1a**) was carried out as follows. Under nitrogen, a mixture of ethyl carbamate, Cu_2O, and *t*-butyl isocyanide in benzene was refluxed for 6 hr, water and ethyl alcohol produced being removed by azeotropic distillation. The complex of Cu(I)(NCO)-$(t\text{-}C_4H_9NC)_{2.5}$ (**1a**) was obtained as a white crystalline solid in 93% yield based upon the starting carbamate. Complex **1a** is not very sensitive to air in solid form, but is readily oxidized in solution. The identity of **1a** has been established by elemental analysis, IR and NMR spectra, and a chemical transformation. Complex **1a** was treated with ethyl alcohol containing dry HCl to produce ethyl carbamate and Cu(I)Cl(t-C_4H_9-NC) complex. It is of interest that complex **1** was also produced in high yields by the reaction of ethyl *N*-trimethylsilylcarbamate[4] with Cu_2O/RNC.

$$(CH_3)_3SiNHCO_2C_2H_5 + Cu_2O/RNC \longrightarrow \underset{\mathbf{1}}{Cu(I)(NCO)(RNC)_n} \qquad (4)$$

A detailed understanding of the reaction mechanism for the formation of copper(I)isocyanate complex **1** must await further studies.

Complex **1a**, which is soluble in most organic solvents, is conveniently utilized for the preparation of urethane derivatives and acyl isocyanates. Complex **1a** did not react with any alkyl halides but reacted with the halides in the presence of alcohol to afford *N*-alkylcarbamate (**2**) in moderate yields (Eq. (5)). Also, complex **1a** reacted with acyl chlorides to produce acyl isocyanates (**3**) in good yields (Eq. (6)). Results are summarized in Table 1.

$$\mathbf{1a} + RBr + R'OH \longrightarrow \underset{\mathbf{2}}{RNHCO_2R'} \qquad (5)$$

$$\mathbf{1a} + RCOCl \longrightarrow \underset{\mathbf{3}}{RCONCO} \qquad (6)$$

a) Reaction conditions: **1a** (1 mmol), halide (1.5 mmol), alcohol (1.7 mmol).

t-butyl isocyanide (30 mmol), and benzene (20 ml) was refluxed for 6 hr, water and ethyl alcohol produced being removed by azeotropic distillation. Then, the solvents were removed *in vacuo*, and the residue was recrystallized from benzene to give complex **1a** as a white crystalline solid (mp 103 °C) in 93% yield based upon the carbamate. [**1a**: Found: C, 51.68; H, 7.40; N, 15.78%. Calcd for $Cu(NCO)(C_4H_9NC)_{2.5}$: C, 51.74; H, 7.24; N, 15.64%. IR(KBr) 2220, 2200, 2180, 2140, 1200 cm^{-1}. NMR($CDCl_3$) δ 1.20 (s).]

Complex **1a** was also prepared in 90% yield by the reaction of ethyl *N*-trimethylsilylcarbamate (10 mmol)[4] with Cu_2O (12 mmol) and *t*-butyl isocyanide (50 mmol) at 80 °C for 2 hr. Hexamethyldisiloxane was also isolated.

Reaction of ***1a*** *with Alkyl Halide and Alcohol.* A mixture of **1a** (1 mmol), butyl bromide (1.5 mmol), and *t*-butyl alcohol (1.7 mmol) was heated at 75 °C for 5 hr under nitrogen. The reaction mixture was triturated with ether, and filtered to remove copper(I) bromide (*t*-butyl isocyanide) complex. The filtrate was subjected to distillation *in vacuo*. The product was identified as *t*-butyl *N*-butylcarbamate (61%) by comparison of its IR and NMR spectra with those of an authentic sample.

Reaction of ***1a*** *with Acyl Halide.* To a solution of **1a** (10 mmol) in benzene (10 ml), benzoyl chloride (10 mmol) was added dropwise with stirring, and then heated at 50 °C for 5 hr. The reaction mixture was triturated with hexane and filtered. The filtrate was subjected to distillation. The product was identified as benzoyl isocyanate (bp 95 °C/21 mmHg) by comparison of its IR spectrum with that of an authentic sample[5].

The Acidities of Substituted α-Phenylsulfinylacetophenones

Norio KUNIEDA, Yoichi FUJIWARA, Junzo NOKAMI, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 26, 1975)

Synopsis. The acidities of eleven *meta*- and *para*-substituted α-phenylsulfinylacetophenones (**1**) were determined potentiometrically in a 50% ethanol solution. pK_a values (10.22—12.01) which can be nicely correlated with Hammett's σ-values were obtained.

In recent years, many chemists have examined β-keto sulfoxides as key synthetic intermediates. During the course of our research concerned with the reactions of β-keto sulfoxides and their derivatives at the α-carbon atom with electrophiles in the presence of a base,[1] we became interested in the acidities of β-keto sulfoxides, synthesized eleven substituted α-phenylsulfinylacetophenones (**1**), and determined their acidities, which may shed light on the problem of their reactivity.

The β-keto sulfoxides (**1**) were prepared by treating *meta*- or *para*-substituted ethyl benzoates with α-sulfinylcarbanions derived from the corresponding *meta*- or *para*-substituted methyl phenyl sulfoxides;[2] their pK_a values were measured potentiometrically with 0.1 M potassium hydroxide in a 50% ethanol solution. The pK_a values thus obtained are listed in Table 1. The data reveal that the β-keto sulfoxides possess rather strong acidities.

Recently, Amel and Marek[3] determined the acidities of substituted phenyl phenacyl sulfones in a 95% ethanol solution, and gave pK_a values which can be correlated with Hammett's σ-values. Furthermore, the basicities of phenacyl-substituted phosphonium,[4,9a] sulfonium,[5,9a] and pyridinium[6] ylides have been determined in order to confirm the stability and reactivity of these ylides in terms of the substituent effect.

The pK_a values of the phenacyl-substituted active methylene compounds hitherto reported are summarized in Table 2, together with our results for comparison. One finds in Table 2 that the β-keto sulfoxides(**1**) are less acidic than the other active methylene compounds. This fact is compatible with the relatively weak electron-withdrawing character of sulfinyl group in comparison with those of the sulfonyl, sulfonium, and ammonium groups.[7]

When the pK_a values for the β-keto sulfoxides (**1**) thus obtained were plotted against Hammett's σ-values, a good straight line was obtained. For the substituents (X) on the phenylsulfinyl aromatic ring, $\rho=1.32$, and for the substituents (Y) on the phenacyl aromatic ring, $\rho=2.68$. The electron-withdrawing substituents on both the aromatic rings increase the acidity of **1**. As is revealed in Table 2, the magnitude of the ρ-value for the phenacyl substituents, Y, closely resembles those of phenacyl sulfones(**2**), arylmethylphenacylsulfonium salts(**3**), dimethylphenacylsulfonium

salts(**4**), triphenylphenacylphosphonium salts(**5**), and phenacyl pyridinium salts(**6**), suggesting that the carbanions generated from these compounds, 1—6, are stabilized by a $p_\pi-p_\pi$ delocalization system with a carbonyl group (such as: $-CH=\overset{\ominus}{C}-\overset{O}{\overset{\|}{C}}-C_6H_4-Y$) with the same tendency. On the other hand, the magnitude of ρ-values for the phenylsulfinyl substituents, X, is considerably small in comparison with that for phenacyl sulfones(**2**) and is comparable with that for phenacylsulfonium salts(**3**). The σ-correlation for X suggests that the demand for the resonance effect of the substituent would be negligible; hence, the inductive effect of X can cause a change in electronegativity only at the sulfinyl sulfur. In addition, since the sulfur atom can expand its valence shell beyond an octet using 3d orbitals,[8] perhaps a substantial $p_\pi-d_\pi$ interaction may operate between the sulfinyl sulfur and the carbanion carbon to stabilize the carbanion of **1**, in a fashion analogous to the cases of phosphonium and sulfonium ylides and sulfones.[3,5,6,9] Of course, this interaction should result in a large inductive effect of the substituent, together with an increase in the acidity. However, the smaller ρ-value for **1**, as well as the higher pK_a values, seems to suggest that the $p_\pi-d_\pi$ interaction in the β-keto sulfoxide system stabilizes the carbanion to a less extent than in the phenacyl sulfone system(**2**).

Experimental

Preparation of α-Phenylsulfinylacetophenones (1). The β-keto sulfoxides (**1**) were prepared according to a method analogous to that developed by Russell *et al.* and by Corey *et al.*[2]

A *meta-* or *para*-substituted ethyl benzoate was treated with 2 equiv of an α-sulfinylcarbanion, derived from the corresponding *meta-* or *para*-substituted methyl phenyl sulfoxide and lithium diethylamide(prepared from 0.1 g/ml solution of butyl lithium in hexane and diethylamine in tetrahydrofuran), at 0 °C. The reaction mixture was then stirred for 1 hr. After the addition of water, the solution was acidified with 10% hydrochloric acid (*ca.* pH 3) and extracted with chloroform. The concentration of the chloroform layer, followed by the crystallization of the residue from carbon tetrachloride or ether, yielded the β-keto sulfoxide in sufficient yields. Satisfactory IR, NMR, and elemental analyses were obtained for all the β-keto sulfoxides described here. Table 1 summarizes their melting points and NMR data.

Measurement of pK_a. The pK_a value of the β-keto sulfoxides(**1**) in a 50% ethanol solution was determined potentiometrically by the titration of 0.100 M potassium hydroxide in 50% ethanol at 25 °C, according to the usual method.[10]

Photochemical Ligand Substitution in Hexakis(aryl isocyanide)-chromium(0)–Olefin Systems

Kazuhito IUCHI, Shintaro ASADA, Takashi KINUGASA, Koji KANAMORI, and Akira SUGIMORI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7, Chiyoda-ku, Tokyo 102

(Received August 8, 1975)

Synopsis. Isocyanide chromium(0) complexes coordinated by dimethyl fumarate, fumaronitrile and maleic anhydride were prepared photochemically by the irradiation of hexakis(aryl isocyanide)chromium(0) with the corresponding olefin. Tetracyanoethylene reacts with hexakis(aryl isocyanide)chromium(0) thermally without illumination, while acrylonitrile and dimethyl maleate do not react even with irradiation.

The chemistry of isocyanide metal complexes coordinated by olefins is a newly developing field. Otsuka *et al.* studied the thermal ligand substitution of *t*-butyl isocyanide metal complexes and prepared nickel and palladium isocyanide complexes coordinated by electron poor olefins.[1] They presumed that the reaction proceeds by S_N1 mechanism. Kawakami *et al.* concluded that tetrakis(aryl isocyanide)rhodium-(I) perchlorates form TCNE adducts of square pyramidal structure, in which TCNE rotates freely.[2]

Although the photochemical ligand substitution of metal carbonyls has been extensively investigated,[3] the photochemical method has rarely been applied to the preparation of isocyanide metal complexes. We found that some aryl isocyanide chromium(0) complexes coordinated by electron poor olefins are formed under irradiation.[4]

Experimental

Materials. Aryl isocyanides were prepared by the carbylamine reaction according to Weber *et al.*[5] Phenyl isocyanide; bp 64 °C/20 mmHg. *p*-Tolyl isocyanide; bp 70 °C/8 mmHg. *p*-Anisyl isocyanide; bp 80 °C/20 mmHg. Hexakis(aryl isocyanide)chromium(0) (**1**) were synthesized by the reaction of aryl isocyanide and chromium(II) salt according to Malatesta *et al.*[6]

Commercial GR grade dimethyl fumarate, dimethyl maleate, fumalonitrile, maleic anhydride and EP grade TCNE were used.

Irradiation. **1** ($7—8\times10^{-5}$ mol) and olefin ($7—10\times10^{-5}$ mol) were irradiated in benzene (in the case of NMR measurement in benzene-d_6) or THF solutions (10 ml) in quartz vessels with a high pressure mercury lamp under a nitrogen atmosphere. The color of the solution changed from red to dark brown during the course of irradiation.

Product. Some of the photo-products were stable and isolated by means of alumina chromatography. They were identified as pentakis(aryl isocyanide)(olefin)chromium-(0). Spectral data and the results used for identification are listed in Table 1. Some of the photo-products could not be isolated, but the IR and NMR spectra of the reaction mixtures showed characteristic absorption due to the complex coordinated by olefin. IR and NMR spectra assigned to the olefin-coordinated complexes are shown in Table 1.

Results and Discussion

Hexakis(aryl isocyanide)chromium(0) (**1**) undergoes ligand exchange with electron-poor olefins either thermally or photochemically. Fumaronitrile, dimethyl fumarate and maleic anhydride react with [Cr-(ArNC)$_6$] (Ar=phenyl, *p*-tolyl, and *p*-anisyl) photochemically, affording the corresponding [Cr(ArNC)$_5$-(olefin)]. Among them three complexes are stable enough to be isolated by means of alumina chromatography in the air. Other complexes were identified spectroscopically in the irradiated reaction mixture.

$$[Cr(ArNC)_6] + \text{olefin} \xrightarrow{h\nu} [Cr(ArNC)_5(\text{olefin})] + ArNC$$

The reactivity of olefins for the ligand substitution depends principally on the electron affinities of the olefins and secondarily on the steric factor. Acrylonitrile, a weaker electron acceptor, does not undergo photochemical ligand substitution. TCNE, a stronger electron acceptor, reacts with **1** without illumination to give pentakis(aryl isocyanide) (TCNE)chromium(0).

The difference between the reactivities of dimethyl fumarate and dimethyl maleate can not be explained in terms of their electronic character. The electron affinity values are similar: E_a for dimethyl maleate, 0.60 eV; E_a for dimethyl fumarate, 0.59 eV.[7] Dimethyl fumarate reacts photochemically with **1**, whereas dimethyl maleate undergoes no ligand substitution, but isomerization to the *trans* isomer. In the photoreaction of hexakis(phenyl isocyanide)chromium(0)–dimethyl fumarate system, no *trans-cis* isomerization was observed.

UV-irradiation of **1** with dimethyl acetylenedicarboxylate and phenylacetylene gave decomposition products, but no substitution products.

IR and NMR spectra of the isocyanide–chromium(0) complexes coordinated by olefins clearly show electron transfer from the central metal to the olefins. A similar phenomenon is observed in nickel and palladium complexes.[1] NC-stretching frequencies of the chromium complexes increase with the introduction of olefins. On the other hand, the CN-stretching frequencies of coordinated TCNE and fumaronitrile are lower than those of free TCNE and fumaronitrile. Analogous shift was observed for the CO-stretching vibration of dimethyl fumarate and maleic anhydride. NMR peaks due to olefinic protons of coordinated olefins are found in a lower δ region than those of free olefins.

The photochemical ligand substitution occurs also with solar light in a glass vessel.

For the ligand substitution of metal carbonyls, the

S_N1 mechanism has been established. S_N1 mechanism was kinetically confirmed for the exchange reaction between hexakis(phenyl isocyanide)chromium(0) and ^{14}C-labeled phenyl isocyanide.[8] However, the substitution of aryl isocyanide by TCNE is much faster (the reaction is completed immediately after the chromium complex and TCNE are mixed) than what would be expected for a S_N1 mechanism. The first order rate of the ligand exchange by ^{14}C-labeled phenyl isocyanide is very small; $\tau_{1/2}$, the half life of the reaction, is reported to be hundred hours at 20 °C. This indicates that the substitution of aryl isocyanide by TCNE can not proceed by a simple S_N1 mechanism. The fact that electron-poor olefins are reactive both in thermal and in photochemical substitution suggests that charge transfer interaction between olefins and **1**, in either the ground or the excited state, plays an important role in the ligand substitution reaction.

The Mercury-photosensitized Reaction of Hydrogen with Nitric Oxide

Kohji TADASA,* Naomi IMAI, and Tetsuo INABA

Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Sakai, Osaka 591

(Received June 9, 1975)

The Hg-photosensitized reaction of a mixture of H_2 and NO has been studied mainly at room temperature. The quantum yield of the H_2O formation is nearly unity, independent of the pressures of both H_2 and NO. The quantum yield of the N_2 formation is proportional to the NO pressure, while that of N_2O decreases with the NO pressure; both of them are independent of the H_2 pressure. In order to interpret the results concerning the H_2O formation, the following process is proposed:

(i) $NO_3 + NO \longrightarrow 2NO_2$

$NO_2 + HNO \longrightarrow OH + 2NO$

$OH + HNO \longrightarrow H_2O + NO$

in addition to the well-established H_2O-forming process:

(ii) $2HNO \longrightarrow H_2O + N_2O$

NO_2, one of the reactants in Process (i), is formed by the chain process proposed by Arden and Phillips:

(iii) $H + NO + M \longrightarrow HNO + M$

$HNO + 2NO \longrightarrow N_2 + H + NO_3$

The (ii) and (iii) processes also coincide with the results of the N_2O and N_2 formations respectively.

In this laboratory, the effect of nitric oxide on the photochemical decomposition of formaldehyde has been studied.[1] The photolysis of formaldehyde has been known to proceed by means of the free-radical-chain mechanism, where the hydrogen atom is one of the chain carriers. The addition of nitric oxide to the photolysis was found to cause an inhibition of the chain decomposition of formaldehyde. In order to elucidate the kinetics of the inhibited photolysis, it is desirable to study reactions containing the hydrogen atom and nitric oxide. Thus, in this work, the mercury-photosensitized reaction of a mixture of hydrogen and nitric oxide was investigated. This photosensitized reaction has already been studied by several workers,[2-5] but no satisfactory interpretation has been given for the kinetics of the overall reaction.

Experimental

Materials. The nitric oxide and hydrogen used were obtained from the Takachiho Kagaku Co., Ltd.; they had research-grade purities of 99.6% and 99.95% respectively. They were used without further purification.

Apparatus. A cylindrical reaction cell of quartz was used; it had a volume of 262 ml. The lamp used was a 2537-source of a spiral type.

Procedure. The reactants, H_2 and NO, were successively expanded into the reaction vessel, in which they were then kept for more than two hours in order to reach the diffusion equilibration and then saturated with mercury for the same period at room temperature. Most runs were carried out at room temperature with 15-min irradiation (0.2—2% conversion). One series of runs, however, was carried out at various temperatures up to 250 °C. For all the experiments, the absorbed light intensity was approximately the same. Its value was determined to be 8.3×10^{-7} einstein l^{-1} min^{-1} by propane actinometry, assuming the quantum yield of hydrogen to be unity at a low intensity, a low temperature, a high propane pressure, and a very low conversion.[6]

Analysis. The mixture of decomposition was then separated and collected by means of cold traps (at −78 °C, for H_2O and −196 °C for N_2O) and a Toepler gauge (N_2), and analyzed quantitatively by means of a gas-chromatograph. The water, one of the products, was converted to hydrogen by treating it with the sodium evaporated as a thin layer onto the surface of a glass trap; then its amount was determined (though the measurement was not very accurate). The hydrogen and nitrogen were analyzed on a 2 m Molecular Sieve 5A column at room temperature, and the nitrous oxide, on a 4 m Porapak Q column at room temperature. Identification was achieved by using IR and a mass spectrometer.

Results

The products of the Hg-photosensitized reactions were N_2, N_2O, H_2O, and unidentified nitrogen oxides

a) Pressure in the cell at room temperature.

which might react with mercury in the system. After some runs, some of a white solid was found trapped in the cold U tube. On heating *in vacuo*, it turned yellow and released mercury. Strausz *et al.*[3] found a similar substance in their experiment and identified it as predominantly $Hg_2(NO_2)_2$. Because of the reaction of NO_2 with Hg both in the reaction cell and in the analysis part, the amount of NO_2 could not be measured.

The experimental results are listed in Table 1.

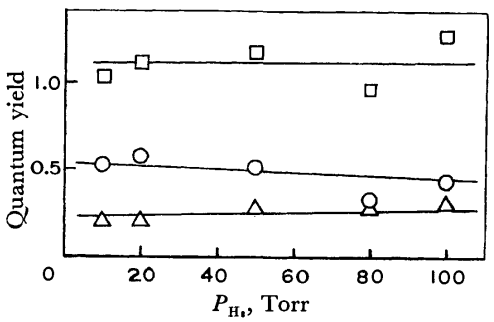

Fig. 2. Plot of quantum yield *vs* H_2 pressure.
T=room temperature, P_{NO}=20 Torr, irradiation time=15 min.
○: N_2, △: N_2O, □: H_2O.

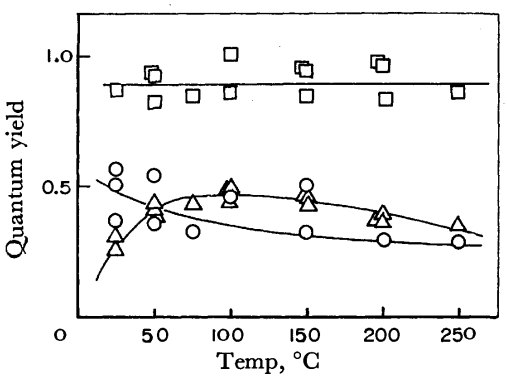

Fig. 3. Temperature dependencies of quantum yield.
P_{NO}=20 Torr, P_{H_2}=20 Torr, irradiation time=20 min.
○: N_2, △: N_2O, □: H_2O.

Figure 1 shows the effect of the NO pressure on each product formation, while Fig. 2 shows that of the H_2 pressure. These figures indicate the quantum yield of H_2O formation to be nearly unity over wide pressure ranges of reactants except for the low NO pressure range, though the accuracy of the quantitative analysis of H_2O is very low. Figure 3 shows the temperature dependencies of the yields of the products.

Discussion

The mercury-photosensitized reaction of H_2 has been studied by many workers. The primary reactions of the photosensitization were found to be as follows:[7]

$$Hg + h\nu(2537\,Å) \longrightarrow Hg^* \quad (1)$$

$$Hg^* + H_2 \longrightarrow HgH + H \quad (2)$$

$$\longrightarrow Hg + 2H \quad (3)$$

where $Hg^*=Hg(6^3P_1)$. In the presence of NO, Hg^* should be largely quenched by NO, because of its high quenching cross section[8]:

$$Hg^* + NO \longrightarrow NO^* \quad (4)$$

where $NO^*=NO(^4\Pi)$.[9]

Since the formation of H_2O, which is a measure of the rate of the primary steps, as will be described later, is constant against the amount of H_2 and NO, the following step should occur:

$$NO^* + H_2 \longrightarrow HNO + H \quad (5)$$

The hydrogen atoms formed by (2), (3) or (5) should combine with NO as:

$$H + NO + M \longrightarrow HNO + M \quad (6)^{10}$$

The HgH radicals were shown to react with NO very rapidly[5]:

$$HgH + NO \longrightarrow Hg + HNO \quad (7)$$

One Hg^* atom, therefore, leads to the formation of two HNO species.

It is well known that the HNO species combine with each other as:

$$2HNO \longrightarrow N_2O + H_2O \quad (8)^{2,3,10,11}$$

This reaction, however, is probably not the main reaction of HNO under the present conditions, since the N_2O yield is quite low compared with that of H_2O.

In the study of the H_2–NO pyrolysis at 500 °C carried out in this laboratory,[12] it was suggested that most of the HNO species react as:

$$2HNO \longrightarrow 2OH + N_2$$

and that the OH radicals thus formed react as:

$$OH + H_2 \longrightarrow H_2O + H$$

resulting in the H_2O–N_2 ratio in the product of 2: 1. In this study at room temperature, however, the N_2 formation is of the first order in NO pressure and the H_2O formation is of the zeroth order in NO pressure, showing that they are formed by reactions different from those in the pyrolysis.

Since the H_2O quantum yield equals unity within the limits of experimental error over wide pressure ranges of the reactant gases, the rate of H_2O formation seems to exhibit that of the primary process. On the other hand, N_2 may be supposed to be formed by the chain reaction containing NO, because its quantum yield exceeds unity and its formattion is of the first-order with respect to NO.

Arden and Phillips have proposed that HNO induces the chain disproportionation of NO to N_2 and NO_2.[13]

$$HNO + 2NO \longrightarrow N_2 + H + NO_3 \quad (9)$$

$$NO_3 + NO \longrightarrow 2NO_2 \quad (10)$$

These reactions do not consume the HNO, however, since H atoms formed by (9) regenerate the HNO by means of (6). Thus, N_2 is formed by the chain reaction carried out by means of (6) and (9). Strausz and Gunning[3] has proposed a HNO–NO reaction scheme alternative to (9):

$$HNO + 2NO \longrightarrow N_2 + HNO_3\dagger$$

If it is followed by this reaction:

$$HNO_3 + NO \longrightarrow HNO + NO_3$$

it leads to the same results as (9).

As the mechanism of H_2O formation, when the NO pressure is not low, the following reactions may be proposed in addition to (8):

$$NO_2 + HNO \longrightarrow OH + 2NO \quad (11)$$

$$OH + HNO \longrightarrow H_2O + NO \quad (12)$$

Thus, one H_2O molecule is formed by consuming two HNO species by means of (11) and (12) as well as (8). The rate of the H_2O formation should equal that of the absorption of the light quanta:

$$R_{H_2O} = I_a \quad (I)$$

This has been clearly proved by the results, $\phi_{H_2O}=1$, shown in Figs. 1 and 2. This equation is not affected by the occurence of the chain disproportionation of NO carried out by means of (6) and (9).

The H_2O formation by this reaction:

$$OH + H_2 \longrightarrow H_2O + H$$

instead of (12) seems to be improbable at low temperature, since its activation energy is 5.2 kcal mole^{-1} ($E_{12}\sim0$).[14] If this reaction, nevertheless, occurrs appreciable, the H atom would be regenerated and (6) and (11) would follow it. In this case, H_2O would be formed by the chain reaction, and, accordingly, ϕ_{H_2O} should depend on the H_2 pressure; this is not consistent with the results shown in Fig. 2.

Accepting the reaction scheme (1)—(12), the rates of N_2 and N_2O formations in the steady state may be expressed as:

$$R_{N_2} = k_9[HNO][NO]^2 \quad (II)$$

and:

$$R_{N_2O} = k_8[HNO]^2 \quad (III)$$

where [HNO] can be obtained from this equation:

$$I_a = k_8[HNO]^2 + k_{11}[NO_2][HNO] \quad (IV)$$

From Rate Equations (II) and (III), we obtain:

$$\phi_{N_2}^{1/2}/\phi_{N_2O}^{1/4} = k_9^{1/2}[NO]/I_a^{1/4}k_8^{1/4} \quad (V)$$

This equation is tested in Fig. 4, which shows that this relation holds, although the plots do not fall on a straight line very clearly.

If $R_8 \ll R_{12}(=R_{11})$ (this reaction holds when [NO] is not low), the first term on the right-hand side of Eq. (IV) can be neglected. Thus,

$$\phi_{N_2} = k_9[NO]^2/k_{11}[NO_2] \quad (VI)$$

and

† This reaction was shown experimentally to be of the first order with respect to both HNO and NO, while (9) is of the first order with respect to HNO and of the second order with respect to NO.

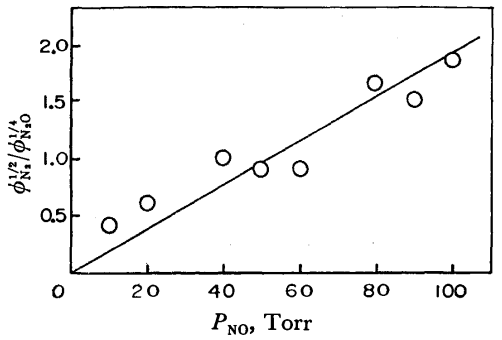

Fig. 4. Plot of $(\phi_{N_2}^{1/2}/\phi_{N_2O}^{1/4})$ value *vs.* NO pressure.
T=room temperature, P_{H_2}=20 Torr

$$\phi_{N_2O} = k_8 I_a / k_{11}^2 [NO_2]^2 \qquad \text{(VII)}$$

As NO_2 is consumed by the reaction with Hg,

$$NO_2 + Hg \longrightarrow (1/2)Hg_2(NO_2)_2$$

its concentration could not be measured. If $[NO_2]$ is assumed to be proportional to the added NO pressure, $\phi_{N_2} \propto [NO]$ and $\phi_{N_2O} \propto I_a/[NO]^2$. Figures 1 and 2 seem to indicate these relations to hold, even though very roughly.

Figure 3 shows that ϕ_{H_2O} does not vary, while ϕ_{N_2} decreases and ϕ_{N_2O} reaches a maximum, with the rise in the temperature to 250 °C. These tendencies are quite the same of those in the CH_2O–NO photolysis.[1] The decrease in the rate of the termolecular reaction (9) is supposed to cause the decrease of ϕ_{N_2} at higher temperatures. The increase of ϕ_{N_2O} with the temperature up to 100°C may be attributed to the occurence of Reaction (13):

$$HNO + NO \longrightarrow N_2O + OH \qquad (13)$$

in addition to (8). At temperatures higher than 100°C, Reaction (14) takes place:

$$2HNO \longrightarrow 2OH + N_2 \qquad (14)$$

Thus, HNO is consumed by (14) and (12) to a great extent, so that the rate of the N_2O formation by (8) and (13) should decrease above 100°C. It was suggested that these reactions occur in the H_2–NO[12] and CH_2O–NO[15] pyrolyses. The latter reaction, especially, was indicated to be predominant compared with (8) at 400 and 500 °C in these experiments. The occurence of these reactions, however, does not affect the (I) relation. Consequently, ϕ_{H_2O} holds constant over the temperature range examined.

Magnetic Two-dimensionality and Antiferromagnetism in the DANO Crystal

Osamu TAKIZAWA

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received August 13, 1975)

An organic free radical crystal, the di-*p*-anisyl nitric oxide (DANO) crystal, was found to exhibit the characteristics of the two-dimensional Heisenberg spin system in its magnetic susceptibility at low temperatures and in its angular dependence of the ESR line width at room temperature. A distinct minimum of magnetic susceptibility due to a phase transition to antiferromagnetic spin ordering was observed at 1.67 K; this is consistent with the results of the NMR measurements, while another unexplainable anomaly was found near 2.7 K. The magnetic anisotropy field, H_A, along the a-axis, perpendicular to the magnetic easy-plane, was determined to be $(3\pm1)\times10^2$ Oe at 0 K from the analysis of the antiferromagnetic resonance; it was attributed to the magnetic field originating from the spin magnetic dipoles distributed over the radical molecules. The ratio of the anisotropy field to the exchange field within the magnetic two-dimensional plane, H_A/H_E, and that of the Néel temperature to the Weiss temperature, T_N/θ, were found to be 5×10^{-3} and 0.34 respectively. The ratio of the inter-plane exchange interaction to the intra-plane one, J'/J, was estimated therefrom to be of the order of 10^{-3}.

Recently, a number of magnetic studies of organic free radical crystals have been performed in spite of difficulties in the purification of the samples and the complexity of the structure; these studies have revealed the magnetic-ordering phenomena at low temperatures in some typical crystals.[1-4] Above the magnetic-ordering temperatures they generally exhibit the characteristics of low-dimensional magnetic systems.[5-8] The low-dimensional characteristics of these organic radical crystals are a consequence of the crystal structures with a pile of plane radical molecules. The magnetic moment originates from an unpaired electron spin in a 2pπ-orbital stretched perpendicularly to the molecular plane. When each molecule is stacked plane-to-plane in the crystal, an unpaired electron spin interacts magnetically with those of only a few neighboring molecules through an overlapping of the 2pπ-orbitals; this causes the low-dimensional magnetic characters of these organic radical crystals.

The magnetically one-dimensional systems[5-8] have been extensively studied in organic radical crystals. Radical crystals with a two-dimensional character can be formed only under favorable conditions with regard to the crystal structure. These crystals, if ideal, can be expected to show interesting magnetic behavior; that is, as is well known, the ideal two-dimensional Heisenberg spin system cannot exhibit a long-range ordered state. In the real systems, a small deviation from the ideal system, such as the existence of a weak anisotropy and/or of interlayer interaction, gives rise to three-dimensional ordering at a finite temperature.[9]

The crystal of the di-*p*-anisyl nitric oxide radical, $(CH_3OC_6H_4)_1NO$ (hereafter abbreviated to DANO), may be possibly regarded as a two-dimensional magnetic system, judging from its crystal structure[10] and from thermal and magnetic properties of the powdered sample studied by Duffy *et al.*[11] However, they found a weak anomaly around 2.7 K and ascribed it to the three-dimensional magnetic ordering. Recently, we also found that the DANO crystal undergoes the antiferromagnetic transition at 1.67 K from the results of NMR measurements of its single crystal.[12] The cause of the magnetic phase transition in this crystal was not clarified in the previous study.

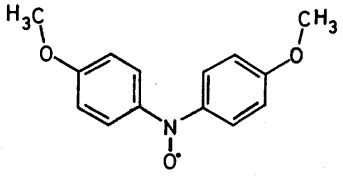

Fig. 1. DANO.

This paper will deal with the results of magnetic susceptibility and ESR measurements of powdered and single crystal of DANO. The measurements were undertaken in order to examine the magnetic two-dimensionality and to study the magnetic ordering of this crystal.

Structural Consideration

The DANO radical shown in Fig. 1 is a nitroxide radical. The ESR[13] and ENDOR[14] spectra of the DANO in solution revealed that the unpaired electron is distributed mainly on a 2pπ-orbital of the N–O group and partially on 2pπ-orbitals of the two phenyl rings. The 2pπ-orbital of the N–O group is stretched perpendicularly to the plane made of the –C–NȮ–C– group.

An X-ray analysis of the DANO crystal by Hanson[10] showed that the crystal structure belongs to the orthorhombic space group Aba2 and that a unit cell with four molecules has dimensions of $a=7.33$ Å, $b=26.8$ Å, and $c=6.25$ Å. Ignoring the twist of the two phenyl rings, it can be said that all the molecules in the unit cell occupy crystallographically equivalent sites and make the plane formed by the –C–NȮ–C– group parallel to the bc-plane and the axis of the N–O bond to the c-axis, resulting in the 2pπ-orbital of the N–O group being stretched along the a-axis. The distances from an N-atom to the first, second, and third nearest neighboring molecules in the ac-plane are 4.8 Å, and 6.2 Å, and 7.3 Å respectively. The layer of the molecules parallel to the ac-plane is separated from the adjacent one by 13.4 Å. Figure 2 is a schematic drawing of the crystal structure, which is simply assumed to be face-

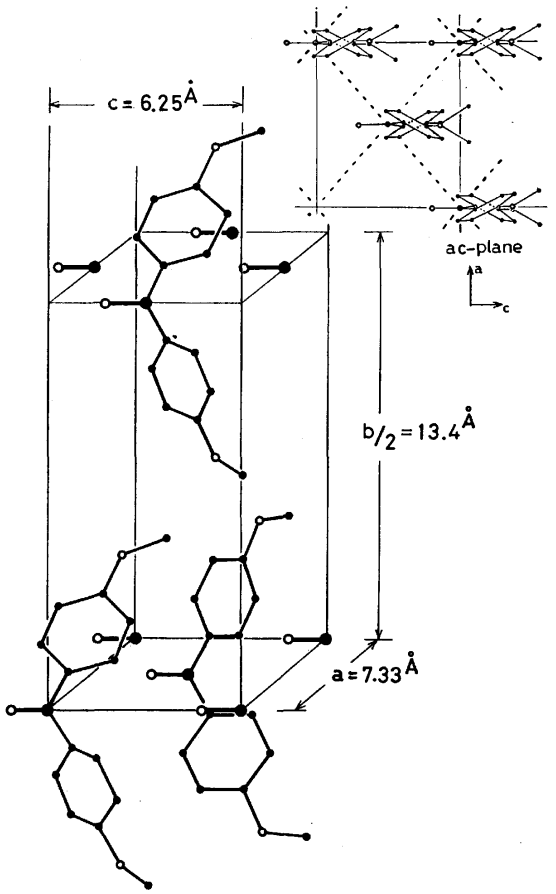

Fig. 2. Crystal structure of DANO crystal. The inset shows the projection to (010) plane.

centered orthorhombic.

Generally, the overlapping of the orbitals of magnetic electrons gives a measure of the magnitude of the exchange interaction. One can assume from the above-mentioned directional configuration of the 2pπ-orbital of the N–O group that the magnitude of the exchange interaction with nearest neighbors much exceed those with the second and the third nearest neighbors in the ac-plane, while the exchange interaction between the ac-planes is much weaker than those in the ac-plane. As a consequence, the DANO crystal may be regarded as forming a two-dimensional magnetic lattice with a nearly quadratic network.

Experimental

Fine copper-colored powder of the DANO crystal was synthesized by the method of Meyer *et al.*[15] After it has been recrystallized several times from ethanol, dark brown platelets with (010) crystal faces were obtained. Elementary analysis gave these values: C, 68.92; H, 5.79; N, 5.75% (calcd: C, 68.84; H, 5.79; N, 5.73%). Its crystallographic axes were determined with a polarized microscope.

The magnetic susceptibility was measured from 1.55 K to 300 K by means of a magnetic torsion balance[16] under magnetic fields of 8 kOe to 11 kOe, calibrated with that of Mn–Tutton salt. The ESR absorptions were observed by means of a conventional spectrometer with operating frequencies of 9.5 GHz and 35.5 GHz. The magnetic field was calibrated using Mn^{2+} doped in MgO (1/2000) after correction by DPPH recrystallized from ether ($g=2.0036$).

Results

Magnetic Susceptibility. At high temperatures, the magnetic susceptibility of a powdered sample obeys the Curie–Weiss law $\chi=C/(T-\theta)$, with $\theta=-4.9\pm0.3$ K and $C=0.377$,* determined in the temperature range between 300 and 63 K; from these results the radical concentration was evaluated to be more than 97%. The diamagnetic correction, -1.35×10^{-4} emu/mol, estimated from Pascal's law[17] was used in this evaluation.

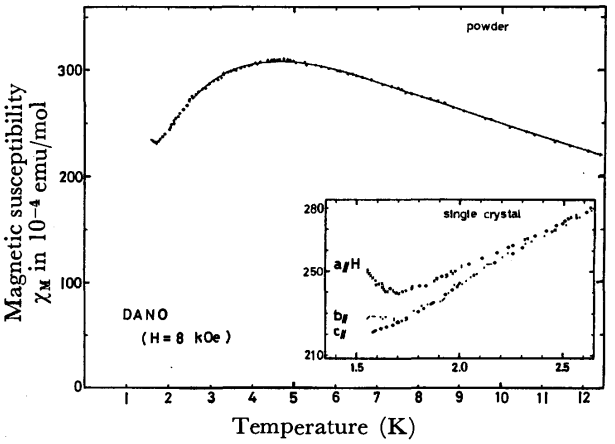

Fig. 3. Temperature dependence of the magnetic susceptibility of DANO crystal. Solid line indicates the results of the HTS calculation for $J/k=-2.45$ K.

With a lowering of the temperature, a broad maximum of the magnetic susceptibility, $\chi_{max}=304\times10^{-4}$ emu/mol, appears at 4.6 ± 0.2 K, as is shown in Fig. 3. Besides a vague anomaly near 2.7 K, reported by Duffy *et al.*,[11] a distinct minimum of the magnetic susceptibility was observed at 1.67 ± 0.02 K.

The inserted figure in Fig. 3 shows the magnetic susceptibility of a single crystal along three crystallographic axes. On account of inaccuracy in the sample weight, the observed values were scaled to that of the powdered sample at 4.2 K; the correction for the diamagnetic anisotropy, less than -1.1×10^{-4} emu/mol, was neglected. The susceptibility is clearly anisotropic below about 2.5 K, and only the susceptibility along the a-axis exhibits a distinct minimum at 1.67 K. This minimum in susceptibility of the single crystal can not be attributed to the origin in impurity but is attributable to the existence of the magnetic ordering of spins.

ESR Absorption. The ESR absorption of a single crystal was measured in order to study variations in the g-value and in the linewidth between 1.3 K and 300 K. Only a single absorption line was observed in the field from 0.5 kOe to 13.0 kOe at all temperatures. At room temperature the g-tensor coincides with that of the isolated radical,[18] and its principal

* The small disagreement between the θ, C, and χ_{max} values in the present work and those in Ref. 11 is probably due to the existence of an impurity, judging from the fact that, in the latter, the authors used a fitting parameter of magnetic susceptibility; $p=0.93$ or 0.95.

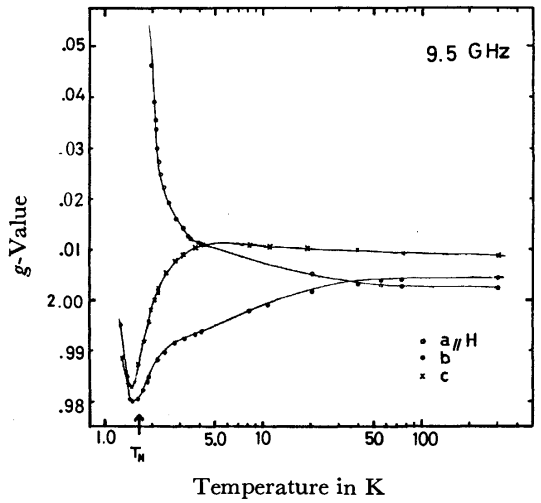

Fig. 4. Temperature dependence of g-values.

axes are parallel to the crystal ones. The g-value shown in Fig. 4 is strongly dependent on the temperature but not on the sample size. Above 2 K, the g-values observed at 9.5 GHz and 34.4 GHz are in agreement with each other within an error of ± 0.0002, and they shift monotonically with the temperature. Below 2 K, but above T_N, a marked shift of the g-value was observed; this is attributable to the shortr-ange magnetic ordering, as has been demonstrated for typical one-dimensional antiferromagnets.[19]

At room temperature the line width shows its maximum when the external field, H_0, is applied parallel to the b-axis and shows its second extremum when H_0 is applied parallel to the a- or c-axes, while it has its minimum value when H_0 and the b-axis make an angle of about 55°, as is indicated in Fig. 5.

Figure 6 shows the temperature dependence of the line width. The line width observed at 9.5 GHz is anomalously broadened up to more than 500 Oe at 1.3 K as compared with the width of less than 20 Oe

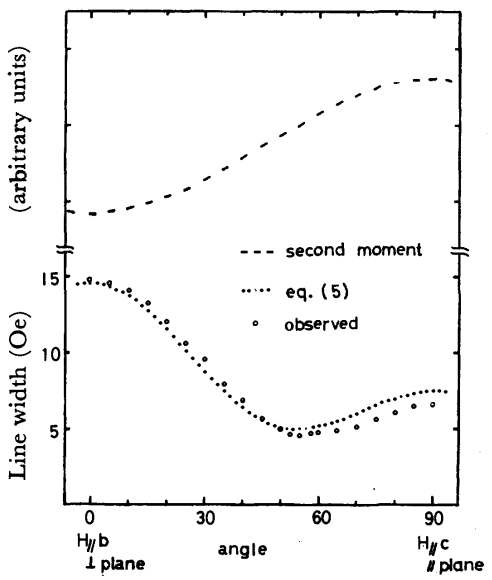

Fig. 5. Angular dependence of ESR line width at room temperature in the bc-plane.

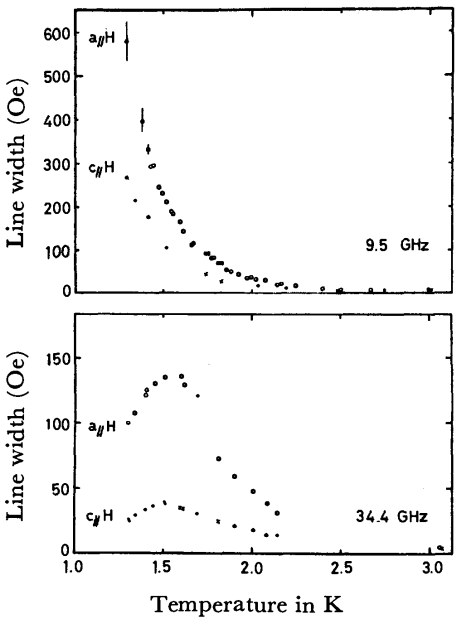

Fig. 6. Temperature dependence of ESR line width at low temperatures measured at a) 9.5 GHz and b) 34.4 GHz.

at 3 K. On the other hand, the linewidth observed at 34.4 GHz shows its maximum at about 1.6 K. With a lowering of the temperature, the absorption line can be observed continuously across the transition temperature, accompanied by a gradual shift of the resonance field although the paramagnetic resonance switches over to the antiferromagnetic resonance (AFMR) at T_N; below this temperature, the resonance position is determined by the AFMR condition.

Discussion

Magnetic Two-dimensionality. The DANO crystal can be expected to be an isotropic two-dimensional antiferromagnetic spin system, with $S=1/2$, coupled with four nearest neighboring spins, on the following grounds: 1) The unpaired electron distributed in the $2p\pi$-orbital has a spin with $S=1/2$. 2) As the observed g-tensor is almost isotropic and is nearly equal to that of the free electron, the magnetic exchange interaction is considered to be approximately isotropic, that is, of the Heisenberg type. 3) From structural considerations, the radical spins may be supposed to interact predominantly with those in the two-dimensional plane. 4) The dominant exchange interaction, J, within the two-dimensional plane is considered to be negative, judging from the negative Weiss temperature.

According to the high-temperature-series expansion (HTS) method applied to the two-dimensional Heisenberg spin system, the magnetic susceptibility is expanded as a function of $x=kT/2JS(S+1)$ as;

$$Ng^2\mu_B^2/\chi\cdot|J| = 3x + \sum_n C_n/x^{n-1} \quad (n=1, 2, \cdots) \qquad (1)$$

where C_n are the HTS coefficients.[20,21] By utilizing the first ten terms for the $S=1/2$ system, the broad maximum in the curve of the magnetic susceptibility *versus* the temperature can be reproduced. The

temperature of the susceptibility maximum, T_{max}, and the maximum value of the susceptibility, χ_{max}, are, respectively, given as;[22]

$$\left.\begin{aligned} kT_{max}/|J| \cdot S(S+1) &= 2.53 \pm 00.5 \text{ for } S = 1/2 \\ \chi_{max} \cdot |J|/Ng^2\mu_B^2 &= 0.0469 \pm 0.0001. \end{aligned}\right\} \quad (2)$$

The combination of these two equations gives a parameter independent of J;

$$\chi_{max} \cdot T_{max}/C = 0.356. \quad (3)$$

The observed values, $\chi_{max}=304\times10^{-4}$ emu/mol and $T_{max}=4.6\pm0.2$ K, yield $\chi_{max} \cdot T_{max}/C=0.36\pm0.01$, which is consistent with the two-dimensional character of the DANO crystal. The solid line in method for Fig. 3 shows the susceptibility calculated by the HTS $J/k=-2.45$ K. In the temperature range of $T>0.9 \cdot S(S+1) \cdot |J|/k$, where the HTS method is valid, the present model explains satisfactorily the magnetic susceptibility of the DANO crystal. In the molecular-field theory, the Weiss temperature is given by;

$$\theta = (2/3) \cdot z \cdot S(S+1) \cdot J/k, \quad (4)$$

which yields $J/k=-2.45\pm0.1$ K, in excellent agreement with the value obtained by the HTS method.

In the recent ESR studies, the effects of magnetic low-dimensionality on the line width have been the topics of great interest.[23] Experimental studies have revealed that, in the two-dimensional system, the angular dependence of the ESR line width, ΔH, at high temperatures cannot be explained by either the three-dimensional-exchange narrowing theory or the dipolar width obtained by the second moment, but is roughly of the form:[24]

$$\Delta H = A(3\cos^2\varphi - 1)^2 + B. \quad (5)$$

Here φ is the angle of the external magnetic field with respect to the normal direction of the two-dimensional plane. The angular dependence of this form was interpreted successfully by the theory taking into account the spin diffusion in the plane.[25] The theory predicts that the angular dependence observed in the two-dimensional system is different from both that in the one-dimensional system and that in the three-dimensional system. In Fig. 5 the angular dependence calculated from Eq. (5) and the dipolar width obtained by the second moment are compared with the line width in the ab-plane observed at 9.5 GHz. Hence, the angular dependence of the line width observed here indicates the two-dimensional characteristics of the magnetic system.

Antiferromagnetism and Magnetic Anisotropy. To investigate the ordered state of the DANO crystal, the results of ESR measurements in 34.4 GHz at 1.39 K ($T/T_N=0.83$) are discussed in terms of the antiferromagnetic resonance (AFMR).[26] The AFMR in an organic free radical crystal was recently reported with regard to the *p*-Cl-BDPA crystal,[27] in which the AFMR was observed in the vicinity of the paramagnetic resonance field because of the very small magnetic anisotropy in contrast with the cases of the antiferromagnets of ionic crystals.[26] In the case of the DANO crystal, the resonance field begins to shift remarkably around 2 K and finally shifts to almost 1 kOe at 1.3 K,

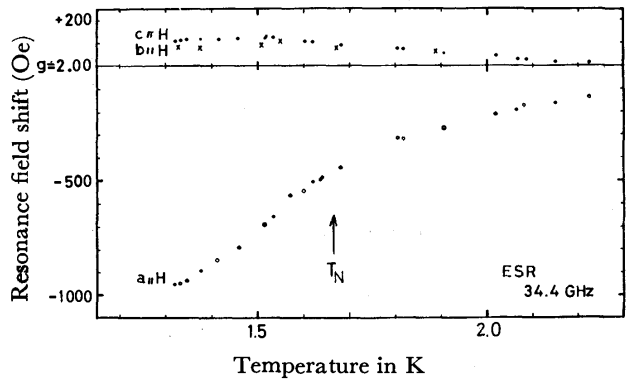

Fig. 7. Temperature dependence of the resonance field at 1.39 K measured at 34.4 GHz.

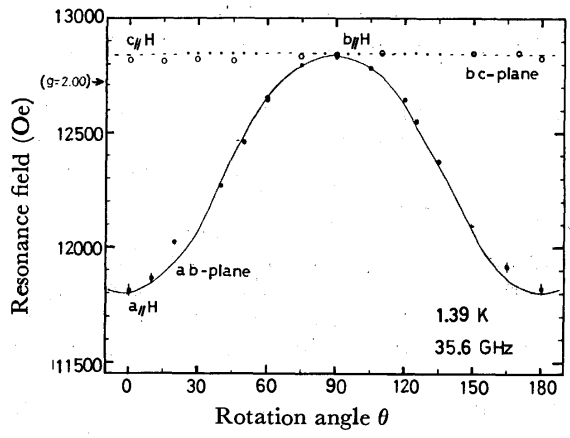

Fig. 8. Angular dependence of AFMR line field at 1.39 K measured at 34.4 GHz.

but no indication of anomaly appears at $T_N=1.67$ K, as is shown in Fig. 7. Fig. 8 shows that the resonance field at 1.39 K has predominantly a uniaxial symmetry around the a-axis and takes the minimum field along the a-axis. The downward shift of the resonance field in the a-axis suggests that this axis is perpendicular to the spin-easy axis.[26] The most remarkable feature of the DANO crystal is the following; its AFMR is observed continuously on the rotation of the external field from the spin-easy axis to the spin-hard axis, indicating the absence of spin flipping; this is confirmed by magnetic torque measurements.[28] These results can be understood reasonably by the model that the DANO crystal is a collinear antiferromagnet with a spin-easy plane perpendicular to the a-axis.[29] It must be noted here that the spin-easy plane (bc-plane) is prependicular to the two-dimensional plane (ac-plane). When the external field, H_0, is applied along the a-axis nearly perpendicular to the sublattice magnetization, the resonance condition is given by:[29]

$$H_0^2 = (\omega/\gamma)^2 - C, \quad C = 2H_AH_E, \quad (6)$$

where H_A and H_E are the anisotropy field along the hard axis and the effective exchange field respectively, ω and γ are calculated from the resonance frequency, 34.4 GHz, and $g=2.0055$ as usual.

According to the molecular field theory, $\sqrt{C}$ is in proportion to the sublattice magnetization, M, which is given by the Brillouin function as a function of the

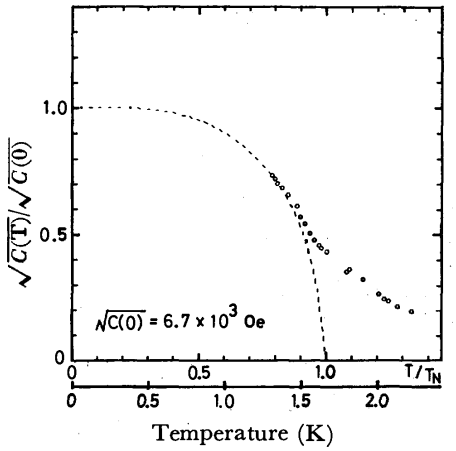

Fig. 9. Temperature dependence of $\sqrt{C}$.

temperature. Figure 9 shows the observed temperature dependence of $\sqrt{C}$ fitted to the Brillouin function for $S=1/2$ at 1.3 K. By the extrapolation of $\sqrt{C}$ along the Brillouin function to $T=0$ K, $\sqrt{C}(0)=(6.7\pm1.0)\times 10^3$ Oe is obtained. In the molecular-field theory, the exchange field is expressed by

$$H_E = 2z|J|\cdot S_z/g\mu_B. \quad (7)$$

Numerical calculations for $z=4$ and $J/k=-2.45$ K yield $H_E=7\times10^4$ Oe at 0 K. From this value, together with $\sqrt{C}(0)$, $H_A=(3\pm1)\times10^2$ Oe at 0 K is obtained.

In the orthorhombic crystals, the magnetic anisotropy energy, F_A, can be generally expressed by the following formula:

$$F_A = (1/2)(K_a\cos\theta_a + K_c\cos\theta_c) \quad (8)$$

where K_a and K_c are the anisotropy constants in the direction of the a-axis and the c-axis respectively with reference to the b-axis. θ_a and θ_c are the angles which the sublattice magnetization makes with the a-axis and the c-axis respectively. Then the effective anisotropy field in each direction, H_A^i, is derived by means of the following equation:

$$H_A^i = K_i/M \quad (i=a, c).$$

In an $S=1/2$ spin system with isotropic-g such as the DANO crystal, the magnetic anisotropy is mainly caused by the magnetic dipolar interaction. The magnitude of the classical magnetic dipolar anisotropy energy was calculated by the direct sum method, taking into account the magnetic dipoles within a diameter of 60 Å. For the examination of the effect of the spin delocalization in the molecule, numerical calculations were performed for the following two cases: 1) the case where the whole magnetic moment ($1\,\mu_B$) is localized at the center of the N–O bond, and 2) the case where the magnetic moment is delocalized over the molecular frame according to the spin density distribution, as calculated by a simple Hückel molecular orbital theory, as is shown in Table 1. In the course of the calculation of the magnetic dipole field, a collinear two-sublattice antiferromagnetic ordering was assumed. The contribution from the spins in the neighboring two-dimensional plane was found to be negligibly small for any spin configuration.

Table 1 summarizes the numerical values of H_A^i.

Table 1. Observed and calculated anisotropy fields with reference to the b-axis in the antiferromagnetic state

	Anisotropy observed from AFMR (Oe)	Dipolar field anisotropy (Oe)	
		Case 1	Case 2
H_A^a	300	216	195
H_A^c	0	106	10

Case 1: spin localized at the center of the N–O bond, Case 2: spin density 0.42 at N, 0.22 at O, 0.06 at *ortho*-C and 0.06 at *para*-C.

In the case 1, the anisotropy field, H_A^c, which should be equal to H_A^a in the case of an ideal quadratic lattice, becomes about 1/2 of H_A^a in the actual lattice shown in Fig. 2. When the delocalization of the spin over the entire molecule is taken into consideration, H_A^a becomes about 1/20 of H_A^a, and the a-axis becomes a unique spin-hard axis (case 2). This corresponds to the experimental result that the system is almost isotropic around the a-axis; *i.e.*, $H_A^c=0$. The observed anisotropies, $H_A=H_A^a=300$ Oe and $H_A^c=0$ Oe, can be approximately explained by the contribution from the magnetic dipoles delocalized over the DANO molecule.

Magnetic Phase Transition. The temperature of the magnetic phase transition of the DANO crystal was determined to be $T_N=1.67$ K from the magnetic susceptibilities of the single crystal and the powdered samples; this value is compatible with the results of the NMR experiments. The resonance-field shift of the ESR spectra, however, shows no anomaly at the transition temperature; thus, no clear distinction was found between the paramagnetic and the antiferromagnetic resonances. This unusual result may be attributed to the well-developed short-range magnetic ordering near T_N. No anomaly was observed either at T_N in the specific heat measurements reported by Duffy *et al.*[11] Bloembergen *et al.* showed that, in the two-dimensional system, the specific heat anomaly is expected to be vanishingly small even if a magnetic ordering occurs as a result of a deviation from the ideal system.[30] The absence of any anomaly at the magnetic-phase-transition temperature in the specific heat and the ESR spectra suggests that the two-dimensionality of the DANO crystal is nearly ideal.

The phase-transition temperature of the two-dimensional system is greatly raised by the interplane exchange interaction, J', and the magnetic anisotropy field, H_A.[9] As a result, J'/J can be evaluated from T_N/θ and H_A/H_E. Table 2 lists the H_A/H_E, T_N/θ, and J'/J

Table 2. Magnetic properties in some two-dimensional magnetic systems with $S=1/2$.

Sample	T_N/θ	H_A/H_E	J'/J
DANO	0.34	5×10^{-3}	10^{-3} a)
Rb_2CuCl_4	0.37	10^{-4}	8×10^{-3}
$Rb_2CuBrCl_3$	0.43	10^{-4}	1.6×10^{-2}

a) Estimated from the data T_N/θ and H_A/H_E of DANO in comparison with those of other samples in this table.

values of some typical two-dimensional magnets with $S=1/2$ listed in a review paper by De Jongh *et al.*,[9] together with those of the DANO crystal. From a comparison of these data, a plausible J'/J value for the DANO crystal is less than 10^{-3}. The three-dimensional magnetic ordering at 1.67 K of the DANO crystal is, therefore, caused by deviations from the ideal two-dimensionality, the existence of J' or H_A, even though these are very small.

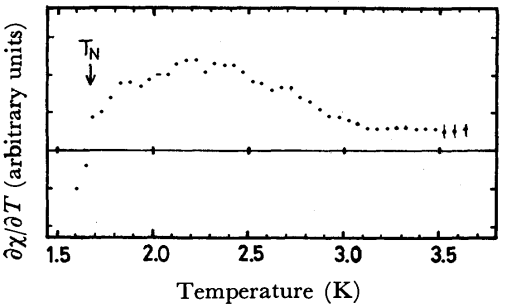

Fig. 10. Temperature derivative of magnetic susceptibility of powdered sample.

Duffy *et al.*[11] assigned weak anomalies in both the magnetic susceptibility and the specific heat near 2.7 K to a three-dimensional magnetic phase transition. In the present experiment, a slight anomaly in the $\partial\chi/\partial T$ spread in the temperature range between 2.4 and 2.9 K was found, as is shown in Fig. 10, while, by the measurements of single crystals, we could hardly detect the anomaly since the accuracy of the measurements is poor for the small single-crystal. In the ESR absorption, nothing anomalous—only a gradual change—was observed at 2.7 K. The shift of the proton-NMR lines also changes gradually and loses its proportionality to the magnetic susceptibility below about 2.7 K. These results do not support the model of the three-dimensional magnetic phase transition at 2.7 K, but they indicate the occurrence of some change, in the short-range magnetic ordering. Further study is necessary to clarify this phenomenon around 2.7 K.

In conclusion, 1) the DANO crystal is an isotropic, nearly two-dimensional spin system with a 10^{-3} ratio of the interplane exchange interaction to the intraplane interaction, 2) the absence of the anomaly in the ESR spectra at T_N is the direct consequence of the short-range magnetic ordering, and 3) the magnetic dipoles distributed over the molecule mainly yield the anisotropy in the ordered state, which orientates the magnetic moment perpendicularly to the a-axis.

The author would like to express his appreciation to Professors Hideo Takaki, Ikuji Tsujikawa, and Yasuo Deguchi for their continual encouragements. He also wishes to thank Drs. Mamoru Mekata, Hiroaki Ohya-Nishiguchi, Yoshitami Ajiro, and Jun Yamauchi for their illuminating discussions. The numerical calculations have partly been done at the Data Processing Center of Kyoto University.

Dynamic Behavior of Acetylacetonato, Triphenylphosphine and Alkyl Ligands in NiR(acac)$(PPh_3)_n$ (R=C_2H_5, CH_3) in Solution and Disproportionation of the Alkylnickel Complexes in Pyridine

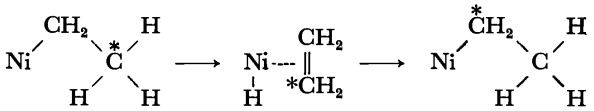
Takakazu YAMAMOTO, Toshio SARUYAMA, Yoshiyuki NAKAMURA, and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo 152

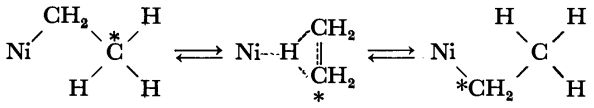
(Received August 18, 1975)

Dynamic behavior of acetylacetonato (acac), triphenylphosphine (PPh_3) and ethyl (in the case of **1**) ligands of NiR(acac)$(PPh_3)_n$ (R=C_2H_5, n=1 (**1**); R=CH_3, n=2 (**2**)) in solution has been studied. PPh_3 ligand(s) in **1** and **2** exchange rapidly on NMR time scale with free PPh_3 in solution. Addition of excess PPh_3 makes the exchange rate much faster and an S_N2 mechanism is proposed to explain the acceleration effect. ^{31}P-NMR spectrum of **1** in pyridine shows that the PPh_3 ligand is replaced by the solvent molecule. Acac ligands in **1** and **2** also undergo rapid interchange on NMR time scale. The activation energy for the acac interchange is about 10 kcal/mol. On standing a specifically deuterated ethylnickel complex, Ni(CH_2CD_3)(acac)(PPh_3) **1**-d_3 in solution, the hydrogens and deuteriums in the ethyl group were scrambled. Appearance of the methyl proton signals in the ^{1}H-NMR spectrum of the deuterated ethylnickel complex after the treatment in solution demonstrates the occurrence of the H–D scrambling in solution. Both **1** and **2** undergo disproportionation reactions in pyridine. The rate of the disproportionation is second-order with respect to the concentration of **2**.

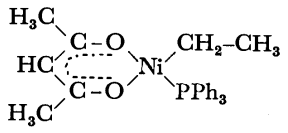
Ethyl(acetylacetonato)(triphenylphosphine)nickel(II), **1**, provides an interesting object for study of its dynamic behavior in solution. The preliminary NMR study of this complex has led us to suggest that all the ligands including ethyl, acetylacetonato and triphenylphosphine may have dynamic properties in solution.[1] The prime attention was focussed on the NMR spectrum of the ethyl group which appeared as a singlet in benzene, toluene, tetrahydrofuran and acetone and as a pair of a triplet and a quartet in pyridine (at 220 MHz). The observation of the nickel-bound ethyl group as a singlet in particular solvents appeared to suggest that this complex might afford a unique example that the ethyl group undergoes rapid reversible processes involving β-elimination and its reverse reaction such as:



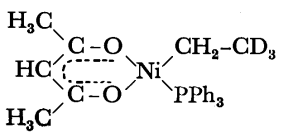
or an alternative process such as:



where the intermediacy of the ethylene-coordinated nickel hydride of any significant life time is not involved but the abstracted hydrogen is rapidly transferred in a concerted manner back and forth between two carbon atoms bonded to nickel.[12] If this should be the case the complex may be regarded as a model system for the active species of catalysts promoting various olefin catalyses such as isomerization and oligomerization. The particular feature of the complex has immediately caught attention of Cotton and coworkers who refuted the non-rigid nature of the ethyl group on the basis of ^{13}C-NMR study as well as X-ray examination of **1** which was shown to possess a normal molecular structure with a square planar configuration of the ethyl group, bidentate acetylacetonato and triphenylphosphine ligands around nickel.[2]



1



1-d_3

Our subsequent ^{13}C-NMR study of the complex also confirmed the normal ^{13}C-NMR spectrum for the ethyl group. The observation of the normal ^{13}C-ethyl signal recorded by a PFT method, however, does not warrant the complete exclusion of the possibility of proton scrambling of the ethyl group. If the chemical shift difference between CH_2 and CH_3 groups in ^{13}C-NMR is much larger than that in ^{1}H-NMR, and the relaxation of ^{13}C's of the ethyl group should be much faster than the rate of scrambling, the non-decoupled ^{13}C-NMR may still exhibit the triplet and quartet feature with the concomitant scrambling process taking place. In order to get an unequivocal information regarding the suspected proton scrambling process we prepared a specifically deuterated ethylnickel complex Ni(CH_2CD_3)(acac)(PPh_3) **1**-d_3 and examined its behavior by spectroscopic as well as chemical means. The NMR examination of **1**-d_3 revealed that the H–D scrambling is not taking place on NMR time scale but a chemical study of **1**-d_3 in solution indicated that slow scrambling process does occur.

In addition to the ethyl group, other ligands coordinated to nickel in **1** including the acetylacetonato and triphenylphosphine ligands show dynamic behavior amenable to NMR study. We describe here the detailed study of the dynamic behavior of **1** in solution and compare it with its methyl analog, NiCH_3(acac)$(PPh_3)_2$, **2**.

These alkylnickel complexes behave differently in pyridine and undergo a disproportionation reaction. This paper includes the kinetic study of the reaction in pyridine as followed by ^{1}H-NMR spectroscopy.

Experimental

Materials. $NiC_2H_5(acac)(PPh_3)$ **1**[1] was prepared by stirring 15 g (58 mmol) of $Ni(acac)_2$, 18.6 g (71 mmol) of PPh_3 and 36 ml (240 mmol) of $Al(C_2H_5)_2(OC_2H_5)$ in 90 ml of deoxygenated and dehydrated toluene at −40 °C for 40 hr under nitrogen. The yellow-brown complex can be recrystallized from toluene, benzene, acetone or ether. Yield: about 65%; mp 93 °C (decomp.). Found: C, 66.9; H, 6.1%. Calcd for $NiC_2H_5(acac)(PPh_3)$: C, 66.9; H, 6.0%; mol wt, 449; mol wt, (cryoscopic in benzene), 450.

$NiCH_3(acac)(PPh_3)_2$ **2**[1] was prepared and recrystallized in a similar manner by using $Ni(acac)_2$, PPh_3 and $Al(CH_3)_2(OC_2H_5)$ in a molar ratio of 1:2:4: mp 102—103 °C. Found: C, 72.5; H, 6.0%. Calcd for $NiCH_3(acac)(PPh_3)_2$: C, 72.3; H, 5.8%.

Deuterated triethylaluminum $Al(CH_2CD_3)_3$ was prepared by using commercially available CD_3COOD (150 g, 2.38 mol) as the starting material for the preparation of $Ni(CH_2CD_3)(acac)(PPh_3)$ **1**-d_3. CD_3COOD was reduced to CD_3CH_2OH by $LiAlH_4$, and the deuterated ethanol was converted to CD_3CH_2Br by treatment with PBr_3. Deuterated triethylaluminum etherate, $Al(CH_2CD_3)_3(O(C_2H_5)_2)$, was prepared and purified by distillation (91—93 °C/10 mmHg) by the method described in literature.[3] Yield, 10.3 g (0.16 mmol, 6.6%). $Al(CH_2CD_3)_2(O(C_2H_5)_2)$ was prepared from the deuterated triethylaluminum and ethyl alcohol (1:1) and used without purification. Acidolysis of the deuterated triethylaluminum by H_2SO_4 gave 92% of CH_3CD_3 and 8% of CH_2DCHD_2 as analyzed by mass spectroscopy, suggesting a slight H–D scrambling took place during the preparation (presumably during the distillation of $Al(CH_2CD_3)_3(O(C_2H_5)_2)$. The deuterated ethylnickel complex $NiCH_2CD_3(acac)(PPh_3)$ was prepared both in toluene, as described above, and in diethyl ether by the method described by Cotton and coworkers.[2] Cotton's method, in which the reaction was carried out at room temperature, was modified for avoiding the possible scrambling of the ethyl group and the reaction temperature was kept below —10 °C throughout the preparation of **1**-d_3.

The mass spectrum of the ethane released by acidolysis of the deuterated ethylnickel complex with H_2SO_4 and the ^{1}H-NMR spectrum of **1**-d_3 in pyridine indicated that the H–D scrambling of the ethyl group during the preparation was negligible (see the results and discussion). The IR spectrum (KBr) of the deuterated ethylnickel complex showed ν_{C-D} at 2190, 2160, 2100, and 2040 cm^{-1}. When the preparation was carried out at room temperature (in toluene, 1 day), hydrogens and deuteriums of the ethyl group were scrambled during the preparation as proved by the evolution of CH_3CD_3 and CH_2DCHD_2 in a ratio of about 1:1 on acidolysis of the complex by H_2SO_4.

Reaction of **1** *with Deuterium.* On treating **1** (0.75 mmol) with D_2 (2.1 mmol) in toluene (18 °C, 3 days) variously deuterated ethanes (4 mol % per **1**) were formed, whose mass spectrum (70 eV) showed the following pattern: m/e=36 (relative peak height=37), 35 (51), 34 (108), 33(143), 32(670), 31 (635), 30 (819), 29 (643), 28 (890), 27 (265), 26 (127). The isotopic purity of the deuterium gas employed decreased from 0.995 to 0.966 after the treatment of **1** with the deuterium gas.

Spectral Measurements and Analysis. The IR spectra of complexes were obtained by using Hitachi Model EPI-G3 spectrometer. IR spectra of deuterated ethylene evolved on standing **1**-d_3 in pyridine were recorded on Perkin Elmer Model 125. The IR spectra of specifically deuterated ethylene are given in literature.[11] ^{1}H-, ^{31}P-, and ^{13}C-NMR spectra were measured with a Japan Electron Optics Laboratory PS-100 spectrometer. ^{31}P- and ^{13}C-NMR were obtained in the pulsed Fourier transform mode at 40.50 and 25.15 MHz, respectively. Measuring temperature of the NMR spectra was not corrected. Deuterated solvents were used as purchased from Merck and Co., Inc. The solvent and tetramethylsilane were added to an NMR tube containing $NiR(acac)(PPh_3)_n$ by a trap-to-trap distillation in vacuum and the NMR tube was sealed. ^{1}H- and ^{13}C-NMR chemical shifts are referred to internal TMS (downfield positive) and ^{31}P-NMR signals to external triphenylphosphine (downfield positive).

Mass spectra of gases were obtained with a Hitachi type RMU-5B Spectrometer. The distribution of deuterated ethanes evolved on acidolysis of the deuterated ethylnickel complex was calculated from the mass spectra. The mass spectra of specifically deuterated ethanes are given in literature.[4]

The microanalysis of carbon and hydrogen was performed by Mr. T. Saito of our laboratory with a Yanagimoto CHN Autocorder Type Mt-2.

Results and Discussion

Dynamic Behavior of Ligands in $NiC_2H_5(acac)(PPh_3)$ **1** *and* $NiCH_3(acac)(PPh_3)_2$ **2**. *Triphenylphosphine (PPh_3) Ligand*: ^{31}P-NMR spectra of **1** in toluene and pyridine with and without addition of excess triphenylphosphine are shown in Fig. 1. In toluene, without excess PPh_3, a sharp singlet peak due to the coordinated PPh_3 ligand is observed at 44 ppm downfield from external free PPh_3 at −60 °C. At higher temperatures the singlet becomes broad with slight shift to higher field. With excess PPh_3 ([**1**]/[PPh_3]=1) the ^{31}P-NMR spectrum at −80 °C shows two broad signals at 44 ppm and at the position of free PPh_3 in an area ratio of *ca.* 1:1. These results indicate that liberation of PPh_3 from **1** at −60 °C is negligible whereas raising the temperature enhances the liberation of PPh_3 from **1** and

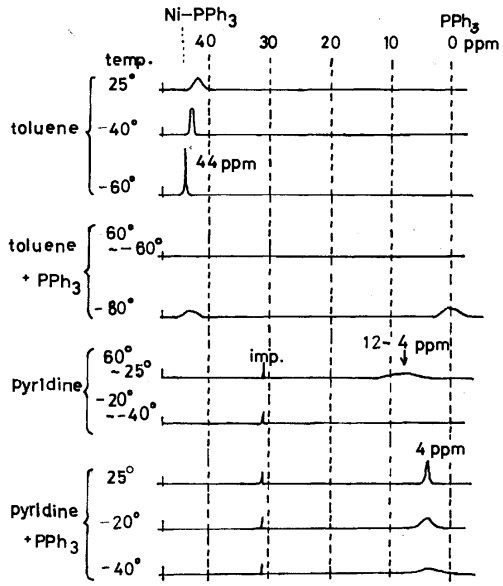


Fig. 1. ^{31}P-NMR spectra of $NiC_2H_5(acac)(PPh_3)$ under various conditions. A peak near 30 ppm which appears in pyridine is due to $Ni(C_2H_4)(PPh_3)_2$ formed by the disproportionation of **1** in pyridine (see the text).

accelerates the PPh_3 exchange of **1** with the liberated PPh_3, although the degree of dissociation is not extensive even at room temperature as revealed by the ^{31}P-NMR in toluene and molecular weight measurement of **1** in benzene. In the presence of added PPh_3, ligand exchange takes place more rapidly even at −80 °C suggesting an S_N2 mechanism, although no definite sign for the formation of $NiC_2H_5(acac)(PPh_3)_2$ corresponding to the methyl analog **2** was observed. The more rapid ligand exchange between **1** and the added PPh_3 at higher temperatures than −60 °C causes collapse of the separated two peaks.

The rate constants of the dissociation of PPh_3 from **1** (the reciprocal of the life time of PPh_3 in **1**, $1/\tau_{Ni-p}=k$ in Eq. 1) calculated

$$Ni(C_2H_5)(acac)(PPh_3) \underset{k'}{\overset{k}{\rightleftharpoons}} Ni(C_2H_5)(acac) + PPh_3 \quad (1)$$

from the half widths of the ^{31}P-NMR signals are summarized in Table 1, which includes the rate constants of dissociation of PPh_3 from **1** in acetone and pyridine and those from **2** in toluene.

Table 1. The rate constants of dissociation of PPh_3 from $NiR(acac)(PPh_3)_n$

Compound	Solvent	[Added PPh_3]/[1]	Temp (°C)	Rate constant (s^{-1})
1	Toluene	0	25	1.6×10^2
	Toluene	0	−40	4.0×10
	Toluene	1	−80	4.2×10^2
	Acetone	0	25	2.2×10^2
	Pyridine	3.4	25	1.0×10^5
	Pyridine	3.4	−20	2.6×10^4
	Pyridine	3.4	−40	1.9×10^4
			E_a=4 kcal/mol	
2	Toluene	0	25	2.8×10^3
	Toluene	0	−60	2.1×10^2

In pyridine the dissociation of **1** to liberate the coordinated triphenylphosphine ligand is more extensive as shown in Fig. 1. The exchange rate seems to be also high and only a broad signal was observed at 25 °C and above at a position between the coordinated PPh_3 and free PPh_3, but much closer to that of free PPh_3. Decrease of the temperature obscured the spectrum and no distinct signal was observed at −20∼ −40 °C. Addition of PPh_3 to the pyridine solution containing **1** gives rise to a somewhat sharp singlet observed at 25 °C downfield from that of free PPh_3. Suppression of the exchange by lowering the temperature from 25 °C down to −40 °C makes the signal broader.

If one assumes that the chemical shift of the coordinated PPh_3 ligand of **1** in pyridine does not differ so markedly from that in toluene, the ratio of undissociated complex to the completely dissociated complex solvated with pyridine can be computed from the chemical shift of the broad signal observed in the absence of added PPh_3 as 1/10 to 1/4 in the temperature range of 60 °C to 25 °C.

The ^{31}P-NMR spectrum of the pentacoordinated methylnickel complex **2** shows somewhat different temperature dependence pattern from that of the ethyl

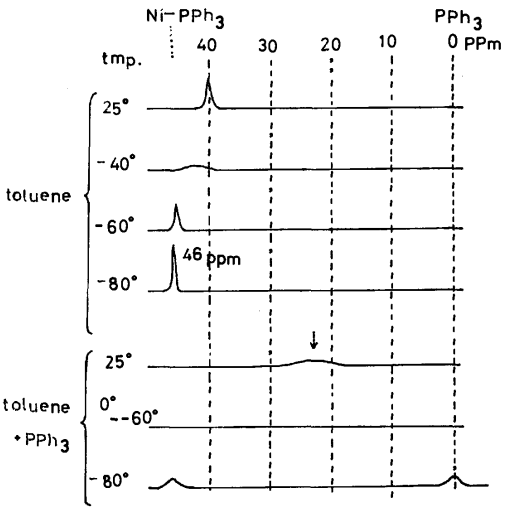

Fig. 2. ^{31}P-NMR spectra of **2** in toluene with and without addition of PPh_3.

analog **1** (Fig. 2). The single resonance which is observed as a reasonably sharp signal at −80 °C in toluene at 46 ppm downfield from free PPh_3 may be ascribed to the coordinated PPh_3 ligands in **2**. With raising the temperature to −40 °C the signal broadens and shifts to higher field indicating the exchange of the coordinated PPh_3 ligands with PPh_3 liberated from **2**. At 25 °C the signal shifts further upfield and sharpens indicating the more rapid exchange taking place. ^{31}P-NMR spectrum of the mixture of **2** and added PPh_3 in a 1 : 0.6 ratio in toluene is similar to the system of (**1**+PPh_3) showing broad peaks of the coordinated PPh_3 and free PPh_3 exchanging each other even at −80 °C. Raising the temperature causes collapse of the peaks and at 25 °C building up of a broad single peak can be noticed as an indication that exchange rate is enhanced by raising the temperature.

The activation energies for dissociation of PPh_3 from **1** and **2**, roughly estimated from the data in Table 1 are in the range of 4—6 kcal/mol which are much less than the values reported for dissociation of tertiary phosphines from nickel complexes.[5]

Acetylacetonato(acac) Ligand: The ^1H-NMR spectra of **1** and **2** have been summarized in our preliminary report.[1] The ^1H-NMR spectra of **1** in acetone-d_6 and benzene-d_6 at various temperatures have been also observed by Cotton, *et al.*[2] At room temperature or below the ^1H-NMR shows two acac(CH_3) peaks. On heating **1** in the solvents these peaks undergo a continued broadening, coalescence, and then sharpening as a result of a time averaging of the two CH_3 groups. A similar temperature dependence of ^1H-NMR spectra is observed in toluene-d_8 and tetrahydrofuran-d_8. In pyridine, however, only one sharp acac(CH_3) peak appears at room temperature. On cooling the pyridine solution the peak becomes broad and then separates into two broad peaks.

TABLE 2. THE RATE CONSTANTS OF THE acac INTERCHANGE IN **1**

Solvent	Additive	[Additive]/[1]	Temp (°C)	Rate Constant (s^{-1})
Toluene	—	—	60	1.3×10^{2}
Toluene	—	—	40	1.1×10
Toluene	PPh_3	4.3	70	2.1×10^{2}
Toluene	PPh_3	4.3	60	1.3×10^{2}
Toluene	PPh_3	4.3	40	1.1×10
Benzene	Ethylene	2.0	60	4.3×10^{2}
Benzene	Ethylene	2.0	40	9.3×10
Benzene	Ethylene	2.0	25	6.8×10
Pyridine	—	—	20	3.9×10^{3}
Pyridine	—	—	0	1.0×10^{3}
Pyridine	—	—	−20	3.0×10^{2}
Pyridine	—	—	−40	1.4×10^{2}
Pyridine	PPh_3	1.7	25	5.0×10^{3}
Pyridine	PPh_3	1.7	0	9.0×10^{2}
Pyridine	PPh_3	1.7	−20	2.1×10^{2}
Pyridine	PPh_3	1.7	−40	1.3×10^{2}

The rate constants of the acac interchange in **1** (Eq. 2) under various conditions are summarized in Table 2.

Since the addition of excess PPh_3 does not affect the rate constant, the acac interchange is independent of the exchange of PPh_3 whose exchange rate depends on the excess PPh_3 in the solutions. The mechanism for the interchange is not clear at the moment. However, a mechanism involving M–O bond rupture to form a monodentate acac complex has been proposed for the mechanism of the exchange of acac ligand in some acetylacetonato complexes,[6] and the rupture of Ni–O bond followed by a rotation of the monodentate acac around the Ni–O bond and formation of a new Ni–O bond will be one of the most probable mechanisms for the present acac interchange.

Replacement of PPh_3 in **1** by pyridine and addition of ethylene cause the acceleration of the interchange. Since attempts to obtain an ethylene-coordinated complex from a mixture of **1** and ethylene failed, the interaction between **1** and ethylene seems to be weak. However, such a weak interaction (presumably π-type interaction) makes the rate faster by a factor of 4—9. A similar acceleration effect was observed when one added stryrene or acrylonitrile into the solution of **1**.

The activation energy for the acac interchange (about 10 kcal/mol) is of the same magnitude as those obtained for various acac complexes.[6]

The ^{1}H-NMR spectra of **2** at room temperature show two separate peaks for the acac CH_3 groups in toluene-d_8 and a single peak in pyridine-d_5, similarly to the ^{1}H-NMR spectra of **1** in these solvents. On cooling the pyridine solution the singlet becomes broad. However, since the acac interchange of **2** in pyridine is faster than that of **1**, separation of the peak was not observed even at the low temperatures, in contrast to the case of **1**.

Ethyl Group in **1**: We prepared deuterated ethylnickel complexes from $Ni(acac)_2$, PPh_3 and $Al(CH_2CD_3)_2(OC_2H_5)(O(C_2H_5)_2)$ at −40~−10 °C. The following three facts indicate that the H–D scrambling did not take place during the preparation. (1) The acidolysis of the complex by H_2SO_4 gives 91% of CH_3CD_3 and 9% of CH_2DCHD_2 which coincides, within experimental

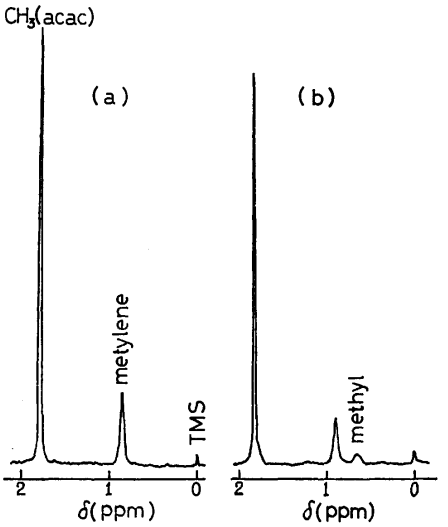

Fig. 3. ^{1}H-NMR spectra of the deuterated ethylnickel complex in pyridine (a) without treatment in solution and (b) after treatment in toluene (Room temp., 2 hr).

error, with the composition of ethane released on the acidolysis of the deuterated triethylaluminum used for the preparation. (2) The ^{1}H-NMR of the deuterated ethylnickel complex in pyridine shows a strong methylene peak, and methyl peak is not observable (Fig. 3a). (3) The ^{1}H-NMR spectrum of propionyl(acetylacetonato)(triphenylphosphine)nickel[7] prepared by the reaction of the deuterated ethylnickel complex with CO clearly demonstrates that it is composed mainly of $NiCOCH_2CD_3$ (Fig. 4a).

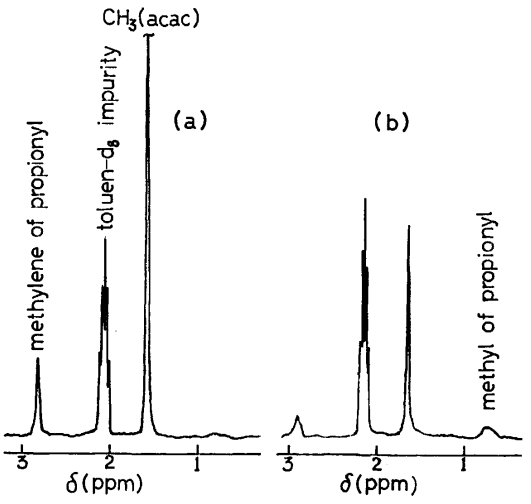

Fig. 4. ^{1}H-NMR spectra of the propionyl (acetylacetonato)(triphenylphosphine)nickel in toluene-d_8 prepared by the reaction of **1**-d_3 and CO. (a) Without treatment of **1**-d_3 in solution. (b) After treatment of **1**-d_3 in acetone (Room temp., 1.5 days).

Since the preparation of $Ni(CH_2CD_3)(acac)(PPh_3)$ **1**-d_3 was carried out at −40~−10 °C where the ethyl signal appears as a sharp singlet in less basic solvents, the H–D scrambling should have taken place during the preparation if the rapid scrambling on NMR time scale should occur and, consequently, we can completely rule out the rapid proton scrambling on NMR time

TABLE 3. COMPOSITION OF THE DEUTERATED ETHANES EVOLVED ON ACIDOLYSIS OF THE DEUTERATED ETHYLNICKEL COMPLEX

No	H–D Scrabling conditions			Composition of deuterated ethanes formed on acidolysis					
	Solvent	Temp (°C)	Time	C_2HD_5	$C_2H_2D_4$	CH_3CD_3	CH_2DCHD_2	$C_2H_4D_2$[a]	C_2H_5D[a]
1	Without treatment					91	9		
2	Toluene	25.6	7.5 min			86.5	13.5		
3	Toluene	25.6	16 min			83	17		
4	Toluene	25.6	31 min			78	22		
5	Toluene	25.6	82 min			71	29		
6	Acetone	24.4	47 min		1	74	24	1	
7	Acetone	24.4	111 min	1	16	22	42	16	1
8	Acetone	Room temp.	a few hrs	2	16	12	52	16	2
9	Pyridine	Room temp.	2.5 days		3	38	56	3	

a) The following relation was assumed: the amounts of $C_2H_4D_2$ and C_2H_5D are equal to the amounts of $C_2H_2D_4$ and C_2HD_5, respectively.

scale based on the facts described above.

Although the rapid scrambling on NMR time scale does not take place, a slow H–D scrambling does occur when one allows the deuterated ethylnickel complex to stand in solutions.

Table 3 summarizes the composition of ethane evolved on acidolysis of the deuterated ethylnickel complex with H_2SO_4 after treatments in solutions.

Through an intramolecular H–D scrambling the specifically deuterated ethylnickel complex is expected to become a mixture of Ni–CH_2CD_3, Ni–$CHDCHD_2$ and Ni–CD_2CH_2D complexes; the first one will evolve CH_3CD_3 on acidolysis with H_2SO_4 and the last two CH_2DCHD_2. Therefore, an increase of CH_2DCHD_2 fraction in Table 3 is regarded as an indication of increase of the degree of internal H–D scrambling.

The random distribution of H and D without isotope effect will result in the formation of Ni–CH_2CD_3, Ni–$CHDCHD_2$ and Ni–CD_2CH_2D complexes in a ratio of 1 : 6 : 3. Such a mixture of the Ni–$C_2H_2D_3$ complexes will evolve CH_3CD_3 and CH_2DCHD_2 in a ratio of 1 : 9 on the acidolysis.

It is shown in Table 3 that the degree of the H–D scrambling increases with time. In toluene formation of Ni-ethyl-d_4 and Ni-ethyl-d_5 species is negligible and the CH_2DCHD_2 fraction increases linearly with time in the early stage (7.5—31 min). In the case of the treatments in acetone the degree of the H–D scrambling at 47 min is of the same extent as that achieved in toluene. However, after allowing the solution containing **1**-d_3 to stand for 111 min or more, considerable amounts of Ni-ethyl-d_4 and Ni-ethyl-d_5 species were formed as proved by evolution of $C_2H_2D_4$ and C_2HD_5 on acidolysis with H_2SO_4. Since the Ni-ethyl-d_4 and Ni-ethyl-d_5 species are not formed at the early stage, they may be formed through a intermolecular interaction of the deuterated ethylnickel complex catalyzed by an unknown compound which is formed during standing the complex in acetone. The H–D scrambling in pyridine is somewhat slower than in acetone and in toluene. In pyridine the ethylnickel complex undergoes disproportionation reaction (*vide infra*) and more than half of the ethylnickel complex is decomposed in a day at room temperature. Therefore most of the Ni–$C_2H_2D_3$ bond had been cleaved before the acidolysis and the data given in Table 3 (No. 9) is for the remaining ethylnickel-d_3 complex resistant to the disproportionation.

Further evidence for the H–D scrambling was provided as follows. (1) The ^{1}H-NMR spectrum of the toluene-treated (Room temp., 2 hr) ethylnickel-d_3 complex in pyridine shows methylene and methyl peaks in an area ratio of 1 : 0.35 (Fig. 3b). (2) The ^{1}H-NMR spectra of propionyl(acetylacetonato)(triphenylphosphine)nickel prepared by the reaction of the acetone-treated (room temp, 1.5 days) ethylnickel-d_3 complex with CO shows methylene and methyl peaks of the propionyl group in an area ratio of 1 : 1.3 (Fig. 4b).

Although it has been known that the H–D scrambling in some deuterated alkylplatinum complexes occurs during their thermal decomposition,[8] this is the first report concerning the H–D scrambling in deuterated alkyltransition metal complex without its decomposition.[12]

Another feature of a dynamic behavior of hydrogens in the ethyl group was demonstrated when **1** was treated with D_2. Although the ethylnickel complex **1** reacts very slowly with D_2 at room temperature, mass spectroscopic examination of ethane gas formed revealed that it contained considerable amounts of C_2D_6, C_2D_5H, $C_2D_4H_2$, $C_2D_3H_3$ and $C_2D_2H_4$ in addition to C_2H_5D which was expected as the sole product in the absence of H–D exchange during the reaction of **1** by D_2 (see the experimental section).[9] Since the ethyl group in the remaining ethylnickel complex **1** was not deuterated at all, this type of H–D exchange is considered to take place only at the moment when the ethyl-nickel bond is cleaved by the reaction with D_2.

Disproportionation of NiR(acac)$(PPh_3)_n$ in Pyridine.

Although **1** and **2** are stable in less basic solvents (benzene, toluene, acetone, *etc.*), the complexes undergo an intermolecular reaction in pyridine. The NMR spectral change of **1** and **2** in pyridine is shown in Fig. 5. The ethyl signals of the ethylnickel complex **1** decrease with time and signals assignable to C_2H_6 and Ni$(C_2H_4)(PPh_3)_2$ increase (the molar ratio of C_2H_6 : Ni$(C_2H_4)(PPh_3)_2 \fallingdotseq 1 : 1$), although the signal of the ethylene in Ni$(C_2H_4)(PPh_3)_2$ is somewhat broadened due to exchange with uncoordinated ethylene in the solution.[10]

In the methyl complex, the methyl signal decreases and peaks assignable to CH_4 and C_2H_6 increase with time. After completion of the reaction one can isolate

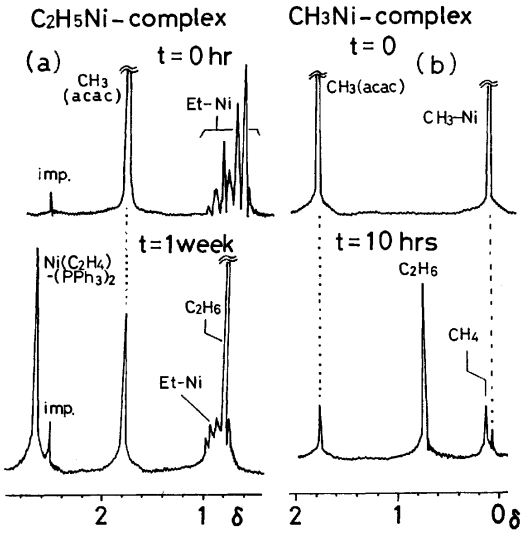

Fig. 5. Changes of ^{1}H-NMR spectra of **1** and **2** with time in pyridine. (a) $NiC_2H_5(acac)(PPh_3)$; (b) $NiCH_3(acac)(PPh_3)_2$.

$Ni(acac)_2(pyridine)_2$ from the both systems. These results suggest that the following disproportionation reaction *via* formation of an unstable dialkylnickel complex may be taking place in pyridine.

$$2NiR(acac)(PPh_3)_n \xrightarrow{2Py} Ni(acac)_2\cdot 2Py + [(PPh_3)_2NiR_2]$$

$$R=C_2H_5 \swarrow \qquad \downarrow R=CH_3$$

$$Ni(C_2H_4)(PPh_3)_2 + C_2H_6 \qquad Ni(PPh_3)_n' + CH_4 + C_2H_6 \ (1:2)$$

Although the rate of the disproportionation of **1** is very slow, that of **2** is reasonably fast and the disproportionation reaction of **2** was followed by NMR spectroscopy. Figure 6 shows the decrease of **2** with time and the second-order plot for the reaction. If we take into account the kinetic result as well as the observation of the fluxionality of the acac ligand, a partial dissociation of acac ligand from nickel and a following coordination of the partially dissociated acac ligand with another alkylnickel complex to form a binuclear complex seem to be the most probable process for the disproportionation reaction.

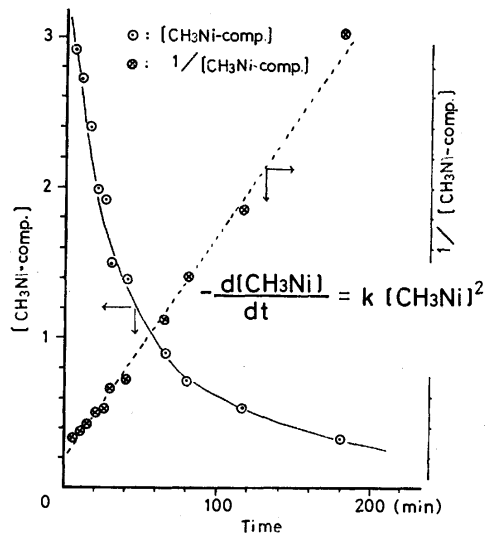

Fig. 6. Disproportionation of $NiCH_3(acac)(PPh_3)_2$ in pyridine followed by ^{1}H-NMR spectroscopy. The unit of the concentration of **2** is arbitrary (peak area).

When **1**-d_3 was employed for the disproportionation reaction in pyridine, the ethylene evolved in a day at room temperature was $CH_2=CD_2$ and other deuterated ethylene was not detected (IR spectrum). This suggests that the scission of the Ni–C_2H_5 bonds in the supposed unstable diethylnickel complex proceeds through a β-elimination mechanism.

2) F. A. Cotton, B. A. Frenz, and D. L. Hunter, *ibid*, **96**, 4820 (1974). In the literature they claimed that the ethylene ligand formed by the β-elimination of the ethyl group should have rotated about the axis from Ni to the center of the ethylene in order to lead to scrambling of hydrogens. However, we think that the rotation of ethylene is not necessary and the reversible processes involving the β-elimination and its reverse reaction is enough to lead to scrambling of hydrogen.

(Received August 22, 1975)

$C_{21}H_{12}O_6Cl_3Zn_2OH \cdot 2H_2O$ crystallizes in the monoclinic space group $P2_1/c$: $a=12.779$, $b=23.732$, $c=14.749$ Å, $\beta=147.98°$, and $Z=4$. The structure was determined by the usual heavy atom method and refined to $R=0.039$. The complex forms polymeric complex chains in the crystalline state. The ligands around two independent zinc atoms form an unusual trigonal bipyramid and an octahedron, respectively; the coordination geometry apparently differs from that found in the crystal structure of bis(2-chlorobenzoato) zinc(II). The correlation between coordination geometry and catalytic action of zinc atom is also discussed.

Two different forms of zinc complex of 2-chlorobenzoic acid were found.[1] In this paper, we report the detailed crystal and molecular structure of the second crystal, a reactive form, as regards the coordination around central zinc atom differing from that in the first crystal, an inactive form. From the results, a mechanism for complex formation and catalytic reactivity of zinc atom is discussed.

Experimental

The complex was prepared by mixing three-molar sodium 2-chlorobenzoate and two-molar zinc chloride in aqueous or acetone-aqueous solution at room temperature. By recrystallization from a mixed solvent of acetone and water 9: 1 ratio, a hexagonal pillar-shaped single crystal was obtained, which was cut to approximately $0.12\times0.11\times0.55$ mm for X-ray study. The density was measured by the flotation method in a carbon tetrachloride and ethylene dibromide mixture. The cell dimensions were obtained on a Rigaku-Denki four-circle diffractometer with Cu$K\alpha$ radiation (Table 1). From the systematic absence of reflections ($h0l$: $l=2n+1$, $0k0$: $k=2n+1$), the space group was determined to be $P2_1/c$. The intensity data were collected on the diffractometer with Cu$K\alpha$ radiation

using the ω-2θ scan technique. A total of 2472 independent reflections were collected in the range $\sin\theta/\lambda \leqq 0.55$ Å^{-1}. A Wilson plot was then made to place the observed intensities on an absolute scale. No correction was made for absorption.

Structure Determination and Refinement

The structure was solved by application of the usual heavy atom method. Except for three water molecules, all the positions of thirty-two nonhydrogen atoms were determined by the first Fourier synthesis with phases based on zinc and chlorine atoms. The coordinates of oxygen atoms in three water molecules were then found (R=0.26). After several cycles of block-diagonal least-squares refinement, a difference Fourier synthesis was carried out in order to determine the location of hydrogen atoms. Twelve hydrogen atoms bound to carbon atoms and three hydrogen atoms (HW1, HW2, and HW3, see Fig. 1) attached to water molecules were satisfactorily located at proper positions with reasonable peak heights. Only one hydrogen atom peak was found around the water oxygen atom OW2, almost on the line connecting OW1 and OW2 to form a hydrogen bond. However, the positions of the remaining two hydrogen atoms bound to the oxygen atoms (OW1 and OW3) were obscure, and were omitted in further refinement. The final least-squares refinement including fifteen hydrogen atoms with isotropic temperature factors (B=2.0~7.0 Å^2) reduced the R-value to 0.041. The final atomic parameters with their estimated standard deviations except those for the two undetectable hydrogen atoms are given in Tables 2 and 3. The observed and calculated structure factors are listed in Table 4.[2] The atomic scattering factors and all the numerical calculation procedures were the same as given previously.[1]

TABLE 3. THE FINAL TEMPERATURE FACTORS AND THEIR STANDARD DEVIATIONS ($\times 10^4$)

The anisotropic temperature factors are in the form of $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$

Results and Discussion

Numbering of molecule is made by use of two letters and two numbers. The first letter corresponds to the kind of atom, and the second to one of the three independent 2-chlorobenzoic acid ligands (A, B and C) or water molecule (W). The first number corresponds to the

individual atom number in a ligand and the second one to the unit number (Table 7), those corresponding to unit No. 1 being omitted (Fig. 1).

The bond lengths and angles are listed in Tables 5 and 6 with their estimated standard deviations. Two of the exocyclic bond angles increase from the normal value of 120° to 122.5° and 122.8° for A, to 123.1° and 128.6° for B, and to 123.1° and 124.8° for C. This might be due to repulsion between the adjacent chlorine atom and carboxyl group. The dihedral angles between carboxyl plane and benzene-ring plane in three independent 2-chlorobenzoic acid ligands are 35° for A, 30° for B and 35° for C, whereas the values in bis(2-chlorobenzoato)zinc(II) are 9° and 41°,[1] and 23° in 2-chloro-5-nitrobenzoic acid.[3]

The coordination geometry around two independent zinc atoms is of interest. Znl is surrounded by five ligands to form a distorted trigonal bipyramid, and Zn2 by six ligands to form a distorted octahedron (Fig. 2 and Table 7). Znl shifts by 0.015 Å toward OA1 from the trigonal plane formed by OC2, OB1 and OW2, and the directions of two bonds, Znl–OW2-4 and Znl–OA1, deviate by 9.2° and 6.6° from the normal to the trigonal plane, respectively. Similarly, the bonds, Zn2–OW1

The coordinates of Zn1 and Zn2 are those belongoing to unit No. 1

Unit No. 1 ($0.0+x, 0.0+y, 0.0+z$)
Unit No. 2 ($1.0-x, 0.0-y, 1.0-z$)
Unit No. 3 ($-1.0+x, 0.0+y, -1.0+z$)
Unit No. 4 ($0.0-x, 0.0-y, 0.0-z$)

and Zn2-OW2-2, deviate by 5.5° and 8.8° from the least-squares plane consisting of OA2, OA2-2, OB2-2, and OCl. These unusual coordinations, especially a distorted trigonal bipyramidal coordination, which is probably the first case in zinc complexes,** might give important information on catalytic function of the zinc atom. The interatomic distances between adjacent zinc atoms are 3.06 Å for Zn1 to Zn1-4, 3.22 Å for Zn2 to Zn2-2, and 3.28 Å for Zn1 to Zn2-2. The values are much smaller than those in bis(2-chlorobenzoato)-zinc(II), 3.77 Å.[1] From density measurement, it seems that three water molecules are involved in an asymmetric unit. However, the difference Fourier map indicates that one of these water molecules should be of anionic form, OH^-, that is, only one peak for hydrogen atom around OW2 was found. This is reasonable for the balance of charge in crystal, provided that four units of positive charge are supplied by $2Zn^{2+}$ and four units of negative charge by three $C_6H_4ClCOO^-$ and one OH^- ions. This was confirmed by counting the number of OH-proton in NMR spectra. As shown in Fig. 3, OW2 coordinates to three neighboring zinc atoms, Zn1, Zn1-4 and Zn2-2, and the OH^- (*i.e.*, OW2-HW2) bond directs to one remaining apex of tetrahedron to form a hydrogen bond with OW1 (2.94 Å). Two water molecules participate in hydrogen bonding of OW1-HW1···OW3 (2.70 Å) and OW3-HW3 ···OC2 (2.77 Å), but the remaining two hydrogen atoms bound to OW1 and OW3 do not take part in hydrogen-bond formation, their positions being obscure. The molecular arrangements projected along the a- and b-axes are given in Figs. 4(a) and 4(b), respectively. They show the formation of a complicated infinite chain through coordinations and hydrogen bonds.

In comparison with the coordination geometry around two independent zinc atoms, the infrared spectra reported previously and herewith were measured by KBr disk technique. As in the case of metal complex of acetic acid, the zinc complex of 2-chlorobenzoic acid has characteristic strong absorption bands associated with the stretching of carboxyl group; for this complex, the bands appear at 1610 cm^{-1} and 1545 cm^{-1} for ν_{as} (OCO), and 1410 cm^{-1} and 1375 cm^{-1} for ν_s(OCO), while the corresponding bands of bis(2-chlorobenzoato)-zinc(II) appear at 1540 cm^{-1} for ν_{as}(OCO) and at 1410 cm^{-1} for ν_s(OCO). The splitting of bands in this complex supports the X-ray evidence of the antisymmetrical chelation around two independent zinc atoms, Zn1 and Zn2.

The difference in the coordination geometry of the two zinc complexes of 2-chlorobenzoic acid described in the present and previous papers might be strongly

** M. Bonamico *et al.* report that the coordination geometry around the zinc atom is considered to be a distorted trigonal bipyramidal in the crystal structure of zinc diethyldithiocarbamate.[4]

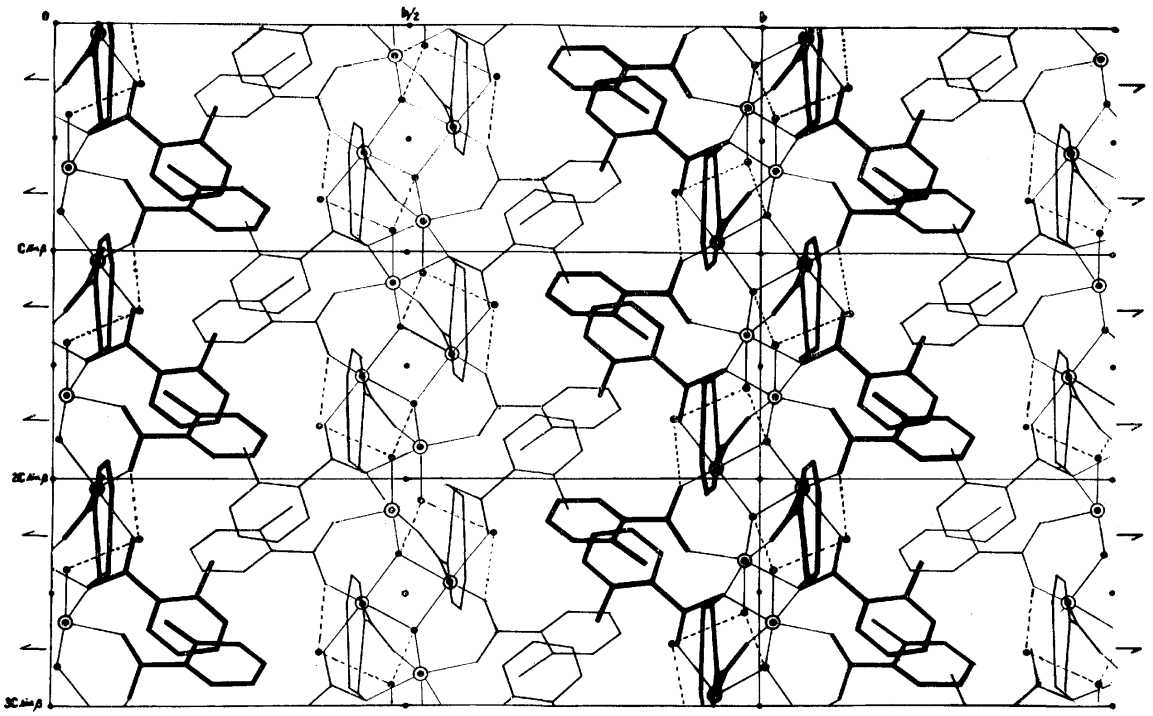

Fig. 4(a). The view of the structure looking down the a-axis.

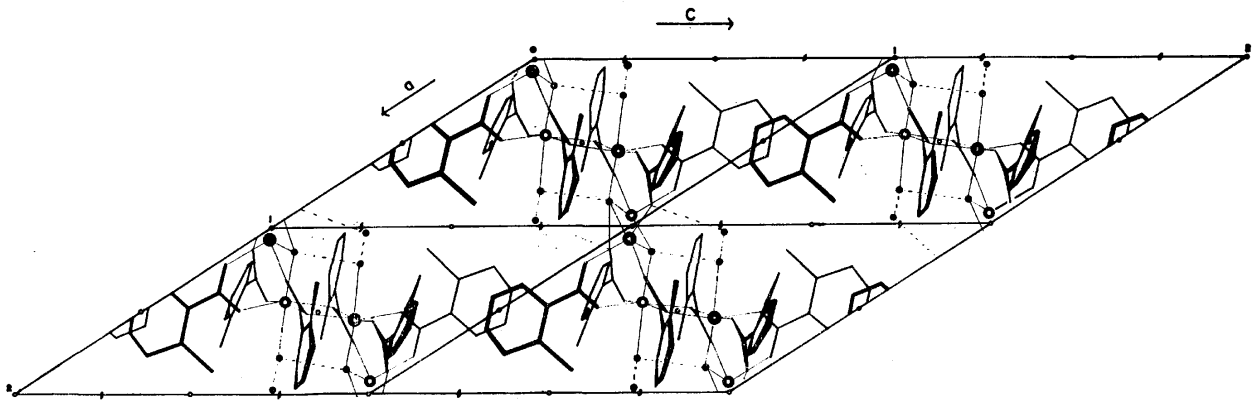

Fig. 4(b). The view of the structure looking down the b-axis.

correlated with the difference in their catalytic actions, *i.e.*, the former is active but the latter is inactive for the following condensation reaction with 2,3-xylidine. The distorted trigonal bipramidal coordination around the zinc atom found in this crystal is probably the first example as a zinc complex so far determined by the X-ray method. By the difference thermal analysis, it was confirmed that two water molecules disappeared at 60—70 °C and 140 °C, respectively, but the remaining OH^- ion was tightly bound to zinc atoms even at the condensation reaction temperature, 170—180 °C (Fig. 3). The overall coordination geometry might be retained at the condensation reaction except two water molecules. At the first step of the condensation reaction, it seems that a reactive group, the amino group of 2,3-xylidine, is fixed by coordination to the zinc atom, and the other reactive atom, the chlorine atom attached at C-2 position of benzoic acid, adjoins the amino group as much as possible. Let us suppose that the amino-nitogen of 2,3-xylidine coordinates to Zn2 in place of OW1 on addition of 2,3-xylidine to the non-aqueous solution of this complex. The nearest chlorine atom to OW1 is ClB-2 in the molecule B of 2-chlorobenzoic acid coordinated to Zn1-2 with a distance of 3.42 Å. The reaction mechanism is still obscure, but probably these amino groups and the chlorine atom react to synthesize mefenamic acid.

The Radiolysis of Anthraquinone Dye in Aqueous Solutions

Nobutake SUZUKI, Takeshi NAGAI, Hiroshi HOTTA, and Masamitsu WASHINO

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma 370-12

(Received September 5, 1975)

The decoloration yields of an Acid Blue 40 neutral aqueous solution, G(-Dye), obtained from the optical density at 610 nm for the nitrogen-, oxygen-, and N_2O-saturated solutions, equaled 0.18, 0.29, and 0.51 in the respective early stages. In view of the effects of NCS^- and NO_3^- on the G(-Dye), the decoloration is attributable to the attacks of the OH radicals and hydrated electrons on the dye. The rate constants for the reactions of the OH radical and the hydrated electron with Acid Blue 40, obtained from competition reactions with various additives, were $(6.6\pm1.2)\times10^9$ $M^{-1}s^{-1}$ and 1.5×10^{10} $M^{-1}s^{-1}$ respectively. In the nitrogen-saturated solutions, the G(-Dye) increased markedly upon the addition of alcohols-for example, up to 1.25 upon the addition of 2 mM butyl alcohol. In this case, at the same time, a new absorption band which is attributable to the formation of the reduction products by the attacks of the hydrated electrons and alcohol radicals on the dye appeared at 460—490 nm. This new absorption band disappeared slowly in the presence of oxygen; the rate of this disappearance was 2.8×10^{-5} s^{-1}. On the other hand, in the oxygen-saturated solutions, the G(-Dye) decreased markeld upon the addition of even a small amount of alcohol.

In a preceding paper,[1] we studied the radiation-induced decoloration of azo dye (Acid Red 265) in aqueous solutions and found that the decoloration is attributable to the attack of OH radicals and is promoted markedly by the addition of alcohols in the nitrogen-saturated solutions. On the other hand, it is known that quinones react easily with hydrated electrons as well as with OH radicals.[2,3] The radiolysis of quinones in aqueous solutions is also interesting from the point of view of biochemistry.[4-6]

In this paper, a study of anthraquinone dye (Acid Blue 40) was carried out as part of a series of radiolysis of dyes in aqueous solutions. This dye was not only decolored at 610 nm, but also gave a new absorption band at 460—490 nm as a result of the reduction reactions with the hydrated electrons and alcohol radicals. The behavior of the new absorption band will be clarified in this study.

Experimental

The experimental procedures were the same as in the preceding work[1] except for those described below.

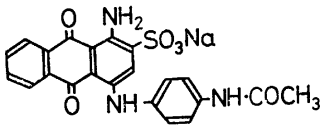

Fig. 1. Schematic diagram of the sodium salt of Acid Blue 40.

The Acid Blue 40 (Kayacyl Blue AGG, see Fig. 1), obtained from the Nippon Kayaku Co., Ltd., was further purified by recrystallization from a methyl alcohol–ethyl alcohol mixture.

When the irradiation was continued over 1 hr without any bubbling of oxygen, the dye solution began to lack oxygen. Therefore, in the case of an irradiation for over 1 hr, oxygen was bubbled in during the irradiation through a porous plate at the bottom of a Pyrex reaction vessel (5 cm in diameter and 16 cm in height).

The absorption spectra were measured with a Shimadzu spectrophotometer, UV-200. The decoloration yield was determined by the measurement of the optical density at 610 nm.

Results

Decoloration of Acid Blue 40 in Aqueous Solutions. The absorption spectra, shown in Fig. 2 as measured for the oxygen-saturated 0.1 mM Acid Blue 40 solution, indicate that the absorption bands at 250, 285, and 610 nm disappeared with the dose, and that these bands almost disappeared at 1.1×10^6 rad (Curve 7). The number of the curves is in common in Figs. 2 and 3 for the same dose.

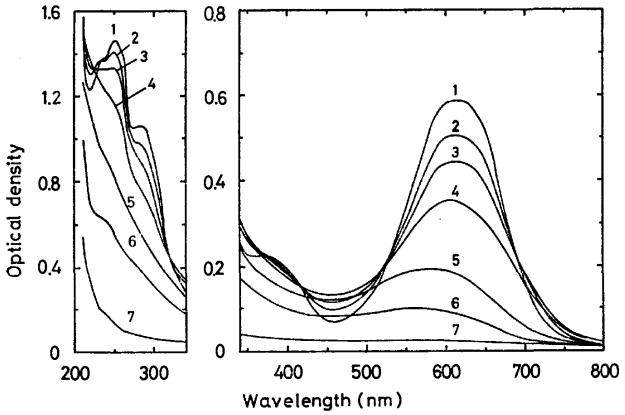

Fig. 2. Absorption spectra of irradiated oxygen-saturated Acid Blue 40 aqueous solutions.
Dye concentration: 0.1 mM. Dose (rad): 0 (Curve 1), 3.7×10^4 (Curve 2), 7.4×10^4 (Curve 3), 1.7×10^5 (Curve 4), 3.9×10^5 (Curve 5), 5.5×10^5 (Curve 6), and 1.1×10^6 (Curve 7).

The absorption spectra for the nitrogen-saturated solution are shown in Fig. 3. The absorption bands at 250 and 285 nm did not disappear with the dose so much as that at 610 nm. An interesting fact is that a new absorption band appears at 460—490 nm at 5.5×10^5 rad (Curve 6). This new absorption band hardly appeared for the N_2O-saturated solution, and the optical density at 250 and 285 nm decreased more efficiently for the N_2O-saturated solution than for the nitrogen-saturated solution.

Since the Acid Blue 40 solutions have a strong absorption band at 610 nm (Figs. 2 and 3), the degrees

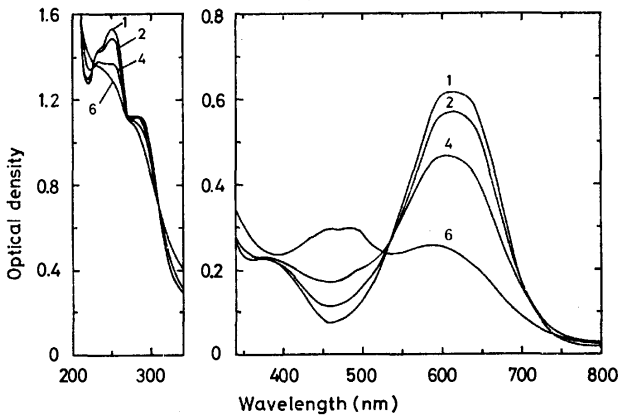

Fig. 3. Absorption spectra of irradiated nitrogen-saturated Acid Blue 40 aqueous solutions.
Dye concentration: 0.1 mM. The number of the curves is the same with Fig. 2.

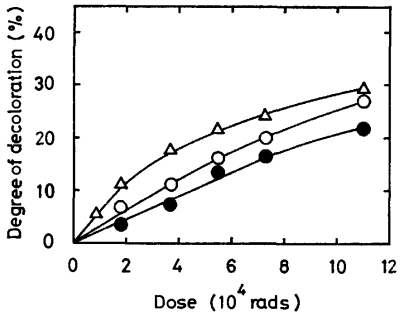

Fig. 4. Effects of inorganic gases on degree of decoloration.
Dye concentration: 0.1 mM. ●: N_2 saturation, ○: O_2 saturation, and △: N_2O saturation.

of decoloration were estimated from the reduction of the optical density. As may be seen in Fig. 4, the degrees of decoloration for the nitrogen-, oxygen-, and N_2O-saturated 0.1 mM Acid Blue 40 solutions increased with the dose. The decoloration yields, G(-Dye), obtained from the linear part in the early stage, are 0.18, 0.29, and 0.51 for the nitrogen-, oxygen-, and N_2O-saturated solutions respectively. These values were independent of the dose rate in the range from 5.3×10^4 to 1.9×10^5 rad/hr and of the initial dye concentration from 0.05 to 0.4 mM.

When the initial pH of the solutions was changed by the addition of sulfuric acid, the G(-Dye) was independent of the initial pH between 6.3 and 5.1; it increased from 0.29 to 0.35 for the oxygen-saturated solution and from 0.18 to 0.24 for the nitrogen-saturated solution at initial pH values between 5.1 and 2.4. This tendency may be attributable to the pH dependence of the yields of the primary species formed from the radiolysis of water.[7] The pH of the nitrogen- and oxygen-saturated solutions used in the present study changed from 6.3 to 6.0 and to 5.1 at 6.7×10^4 rad respectively. Therefore, the G(-Dye) is hardly affected by this pH change during irradiation.

Effects of NCS^- and NO_3^-. The G(-Dye) for the nitrogen-saturated 0.1 mM Acid Blue 40 solution containing NCS^- at 5.5×10^4 rad is shown as a function

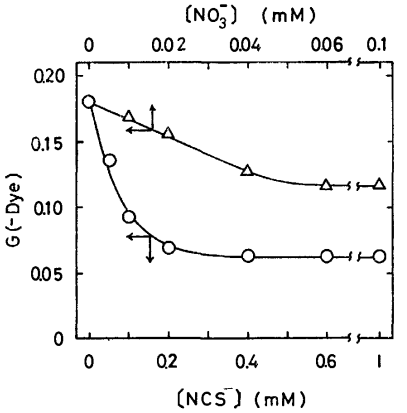

Fig. 5. Effects of NCS^- and NO_3^- on G(-Dye).
Dye concentration: 0.1 mM. Dose: 5.5×10^4 rad.
Additives: NCS^-(○) and NO_3^-(△).

of the NCS^- concentration in Fig. 5. The G(-Dye) decreased to 0.06 upon the addition of NCS^- and became constant above 0.4 mM. The reduction upon the addition of NCS^- was G(-Dye)=0.12 above 0.4 mM. On the other hand, the G(-Dye) decreased to 0.12 upon the addition of NO_3^- and became constant above 0.06 mM. The reduction upon the addition of NO_3^- was G(-Dye)=0.06 above 0.06 mM. The sum of the two reductions equals the original G(-Dye)=0.18 without these solutes.

Dye concentration: 0.1 mM. Dose: 5.5×10^4 rad.
◇: methyl alcohol, □: ethyl alcohol, △: propyl alcohol, ○: butyl alcohol, and ▽: *t*-butyl alcohol.

Effects of Alcohols. The G(-Dye) for the nitrogen-saturated 0.1 mM Acid Blue 40 solutions containing normal alcohols (C_1—C_4) and *t*-butyl alcohol at 5.5×10^4 rad is shown as a function of the alcohol concentration in Fig. 6. The G(-Dye) increased steeply with an increase in the alcohol concentration to 2 mM. The G(-Dye) at 2 mM alcohols is shown in Table 1. The increase in the G(-Dye) upon the addition of alcohols was in the order of:

butyl alcohol > propyl alcohol > ethyl alcohol > methyl alcohol > *t*-butyl alcohol (1)

The G(-Dye) increased to 1.25 upon the addition of

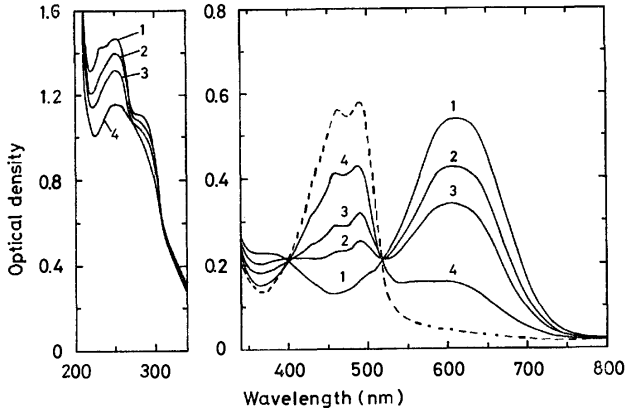

Fig. 7. Absorption spectra of irradiated nitrogen-saturated Acid Blue 40 aqueous solution containing methyl alcohol.
Dye concentration: 0.1 mM. Dose: 5.5×10^4 rad. Methyl alcohol concentration (mM): 0 (Curve 1), 0.5 (Curve 2), 1 (Curve 3), and 10 (Curve 4). Dotted curve represents the spectrum of the irradiated solution containing 10 mM butyl alcohol.

2 mM butyl alcohol from 0.18 for the non-alcoholic solution.

The absorption spectra, shown in Fig. 7 as measured for the nitrogen-saturated solution containing methyl alcohol, indicate that the absorption band at 610 nm disappears with an increase in the alcohol concentration, while, at the same time, the new absorption band at 460—490 nm appears more clearly than that for the non-alcoholic solution (Fig. 3). Similar results were obtained for the solutions containing other alcohols. In Fig. 7, the spectrum of the irradiated solution containing 10 mM butyl alcohol is shown by the dotted curve as a typical result. The intensity in the new absorption bands at 490 nm was in the same order (1) as the increase in the G(-Dye) for the nitrogen-saturated solutions for the same dose.

On the other hand, the G(-Dye) for the oxygen-saturated solutions containing normal alcohols (C_1—C_4) and *t*-butyl alcohol at 5.5×10^4 rad decreased with an increase in the alcohol concentration, in contrast with that for the nitrogen-saturated solutions, much like the curves in Fig. 5 in the preceding paper.[1] The decrease in the G(-Dye) upon the addition of 2 mM alcohol, as is shown in Table 1, was in the same order (1) as the increase in the G(-Dye) for the nitrogen-saturated solutions.

Discussion

The Nitrogen-saturated Solutions. As may be seen in Fig. 5, the G(-Dye) in the nitrogen-saturated solution decreased from 0.18 to 0.06 upon the addition of NCS^-, which is an efficient scavenger of OH radicals.[8] This means that the reduction (0.12) in the G(-Dye) is due to the contribution of the OH radical to the decoloration. On the other hand, the G(-Dye) decreased from 0.18 to 0.12 upon the addition of NO_3^-, which is an efficient scavenger of hydrated electrons.[9,10]

$$e_{aq}^- + NO_3^- \xrightarrow{k_2} NO_2 + 2OH^- \qquad (2)$$

This means that the reduction (0.06) in the G(-Dye) is due to the contribution of the hydrated electron to the decoloration. The sum of the two contributions equals the original G(-Dye) (0.18) without these solutes. It may be concluded from these results that the decoloration reaction of Acid Blue 40 in the nitrogen-saturated solution is mainly attributable to the attacks of the OH radicals and hydrated electrons, and that the contribution of the H atom to the decoloration reaction is minor.

The primary yields[11] of the OH radical and the hydrated electron formed from the radiolysis of water are 2.74 and 2.76 respectively for neutral water. These primary yields are much larger than the above G(-Dye) value. This fact indicates that the most of the primary species are consumed by reactions other than the decoloration reaction.

On the basis of these results, as postulated previously for azo dye,[1] the radiation-induced decoloration reaction of Acid Blue 40 at 610 nm in the nitrogen-saturated solutions may be represented as follows:

$$AB + OH \xrightarrow{k_3} ABOH \text{ (decolored product)} \qquad (3)$$

$$AB + OH \longrightarrow ABOH' \text{ (colored product)} \qquad (4)$$

$$AB + e_{aq}^- \xrightarrow{k_5} AB_{red} \text{ (decolored product)} \qquad (5)$$

$$AB + e_{aq}^- \longrightarrow AB'_{red} \text{ (colored product)} \qquad (6)$$

where AB, ABOH, and AB_{red} are Acid Blue 40, its OH adduct, and its reduction product by the hydrated electron respectively.

The dye molecule has three kinds of reaction sites for Reactions 3—6: (a) the anthraquinone ring, (b) the carbonyl group in the anthraquinone ring, and (c) the substituted benzene ring, not conjugated to the carbonyl group in the anthraquinone ring. The attacks of the OH radical and hydrated electron on Site c are independent of the decoloration reaction and cause little change in the absorption spectrum at 610 nm. This is represented by Reactions 4 and 6.

In Fig. 3, the absorption band at 285 nm is attributable to the carbonyl group, and that at 610 nm, to an auxochromic effect on the anthraquinone.[12,13] The

absorption band near 250 nm is attributable to substituted aromatic rings.[12,13] The optical density at 250 nm does not decrease with the dose so much as does that at 610 nm. This suggests that the decoloration reaction is not necessarily accompanied by the destruction of the skeleton of the dye molecule.

According to Broadbent and Newton,[14] the reaction of sodium 9,10-anthraquinone-2-sulfonate with Fenton's reagent gives the hydroxylation products. In this case, the OH radical does not react with the carbonyl group, but with the anthraquinone ring. This rate constant is 5.6×10^9 $M^{-1}s^{-1}$.[3] On the other hand, according to Hulme *et al.*,[3] the pulse radiolysis of sodium 9,10-anthraquinone-2-sulfonate in an aqueous solution gives its radical anion. This means that the hydrated electron reacts with the carbonyl group. The rate constant of the reduction is 2.8×10^{10} $M^{-1}s^{-1}$.[3]

Therefore, it may be concluded that Site a is attacked by the OH radical, and Site b, by the hydrated electron. These processes reduce the absorption band at 610 nm. The OH radical and the hydrated electron also react with the part (Site c) not conjugated to Site b. Furthermore, since the ABOH and the AB_{red} from Reaction 3 and 5 can react with the OH radicals and hydrated electrons, the dye molecule is degraded to the lower molecular weight compounds by consuming many primary species formed from the radiolysis of water. Therefore, the G(-Dye) is much less than the primary yields of the OH radical and the hydrated electron.

The absorption band at 460—490 nm is attributable to the reaction of the dye with the hydrated electron (Reaction 5), which will be interpreted in detail after discussing Reaction 3.

The Oxygen-saturated Solutions. As may be seen in Fig. 2, the absorption bands at 250, 285, and 610 nm in the oxygen-saturated solution decrease more efficiently than in the nitrogen-saturated solution. Curve 7 in Fig. 2 suggests that the skeleton of the dye molecule in the oxygen-saturated solution is almost destroyed at 1.1×10^6 rad. The G(-Dye) (0.29) in the oxygen-saturated solution is higher than that (0.18) in the nitrogen-saturated solution. This may be attributable to the contribution of the HO_2 radical, which is formed from the reaction of oxygen with the hydrogen atom. Peroxides formed by the degradation of the dye molecule may also accelerate the decoloration reaction.

The N_2O-saturated Solutions. The $G(\text{-Dye})_{N_2O}$ (0.51) for the N_2O-saturated solution is larger than that (0.18) for the nitrogen-saturated solution. N_2O reacts rapidly with the hydrated electron to form the OH radical:[10]

$$e^-_{aq} + N_2O \longrightarrow OH + OH^- + N_2 \qquad (7)$$

Therefore, such a large G(-Dye) is attributable to an increase in the OH radical.

As has been already described, the absorption band at 250 nm in the N_2O-saturated solution disappears more efficiently than in the nitrogen-saturated solution. This suggests that the skeleton of the dye molecule is mainly destroyed by the attack of the OH radical.

The Solutions Containing Alcohols. The increase in the G(-Dye) upon the addition of alcohols in the nitrogen-saturated solution (Fig. 6) means that the alcohol radical ($R\dot{C}HOH$) destroys the dye chromophore more efficiently than the OH radical does.[1]

$$RCH_2OH + OH \xrightarrow{k_3} R\dot{C}HOH + H_2O \qquad (8)$$

The values of the G(-Dye) in Table 1 correspond to the order of the rate constants for the reaction of alcohols with OH radicals, as measured by the pulse-radiolysis technique; these rate constants are listed in Table 2.[8,15]

Table 2. Rate constants for reactions 3 and 8

Additives	k_3[a] ($M^{-1}s^{-1}$)	k_8[b] ($M^{-1}s^{-1}$)
Methyl alcohol	5.5×10^9	4.8×10^8
Ethyl alcohol	6.6×10^9	1.1×10^9
Propyl alcohol	6.7×10^9	1.5×10^9
Butyl alcohol	7.4×10^9	2.2×10^9
t-Butyl alcohol	5.3×10^9	2.5×10^8
NCS^-	7.8×10^9	6.6×10^9

a) Initial pH 6.3. b) Rate constants for reaction of OH radical with additives from Ref. 8 and 15.

On the basis of these results, the radiation-induced decoloration reaction of Acid Blue 40 at 610 nm in the nitrogen-saturated solution containing alcohols may be represented as follows:

$$AB + R\dot{C}HOH \longrightarrow ABH\ (\text{decolored product}) + RCHO \qquad (9)$$

where AB and ABH are Acid Blue 40 and its reduction product respectively. It is known that quinones are reduced by alcohol radicals, leading to the formation of reduction products.[6,16]

On the other hand, in the oxygen-saturated solution, the alcohol radicals react rapidly with oxygen prior to Reaction 9 and are degraded to lower molecular weight compounds.[1] Therefore, the G(-Dye) for the oxygen-saturated solution decreased upon the addition of alcohols, in contrast with that for the nitrogen-saturated solution.

Rate Constant for Reaction 3. The rate constant for Reaction 3 can be determined by using a competition reaction method with additives from the following equation:[1]

$$\frac{1}{G(\text{-Dye})} = \frac{1}{G_r}\left(1+\frac{k_8[RCH_2OH]}{k_3[AB]}\right) \qquad (10)$$

where G_r is the yield of the OH radicals consumed by Reactions 3 and 8, and where [AB] and [RCH_2OH] are the initial concentrations of Acid Blue 40 and alcohols respectively.

The plots of $1/G$(-Dye) are linear against the alcohol concentration, in good agreement with Eq. (10). From Eq. (10), the slope of the curve gives the k_8/k_3 ratio and the intercept gives the G_r value by means of the least-squares method. The k_3 values listed in Table 2 were obtained from the observed k_8/k_3 ratio by using the corresponding k_8 values in Table 2. The average k_3 value is $(6.6\pm1.2)\times10^9$ $M^{-1}s^{-1}$. This value is in good agreement with the rate constant of the additional reaction of the OH radical with sodium 9,10-anthraquinone-2-sulfonate (5.6×10^9 $M^{-1}s^{-1}$),[3] as obtained by the pulse-radiolysis technique. The k_3 value is

also near to the rate constant of the similar reaction with Acid Red 265 (azo dye, 9.3×10^9 $M^{-1}s^{-1}$).[1] The rate constant, obtained by using a competition reaction with NCS^-, is listed in Table 2.

Rate Constant for Reaction 5. Similarly, the rate constant for Reaction 5 (k_5) can be determined from the results shown in Fig. 5.

The plots of $1/G$(-Dye) are linear against the NO_3^- concentration. The k_5 value can be obtained from the observed k_2/k_5 ratio by using the k_2 value (1.1×10^{10} $M^{-1}s^{-1}$).[9] The k_5 value is 1.5×10^{10} $M^{-1}s^{-1}$. This value is near to the rate constant of the reduction reaction of the hydrated electron with sodium 9,10-anthraquinone-2-sulfonate (2.8×10^{10} $M^{-1}s^{-1}$).[3]

Appearance of Absorption Band at 490 *nm.* As may be seen in Fig. 3, in the nitrogen-saturated solution a new absorption band appears clearly at 460—490 nm at 5.5×10^5 rad (Curve 6). This new absorption band appears hardly at all in the presence of oxygen and N_2O, which react rapidly with hydrated electrons, leading to the formation of the O_2^- and OH radicals (Reaction 7) respectively. Furthermore, as may be seen in Figs. 3 and 7, this new absorption band appears more clearly for the solution containing alcohols than for the non-alcoholic solution, while the absorption band at 610 nm disappears more efficiently in the presence of alcohols as a consequence of Reaction 9.

It may be concluded from these facts that the formation of the reduction product from Reactions 5 and 9 reduces the absorption band at 610 nm; at the same time, it causes new absorption bands with maxima at about 460 and 490 nm, and also with a shoulder at about 430 nm, to appear, as may be seen in Fig. 7.

The final reduction product through Reactions 5 and 9, whose half-life is about 7 hr, as will be discussed in the next section, is appreciably stable. Therefore, this product is considered to be a permanent product even if it is unstable chemically. Then, the final reduction product is assumed to be the hydroquinone of AB. In fact, the Acid Blue 40 solution was immediately reduced to the leuco-form with alkaline sodium dithionite, and then recovered by oxygen. The leuco-base solution at pH 8.2 had two bands with maxima at about 460 and 485 nm, while the solution at pH 13.2 had two bands with maxima at about 430 and 480 nm. These bands are in good agreement with those in Fig. 7.

According to Phillips *et al.*,[16] the flash photolysis of the sodium 9,10-anthraquinone-2-sulfonate (A) alcoholic aqueous solution gives absorption bands at 275 and 385 nm for the semiquinone radical (AH·), and at 395 and 505 nm for the semiquinone radical anion ($A\cdot^-$). Both transients are long-lived (several millisec.). On the other hand, sodium 9,10-anthrahydroquinone-2-sulfonate (AH_2), a permanent reduction product of A, has two bands with maxima at about 265 and 385 nm, and the corresponding dianion (A^{2-}) has two bands with maxima at about 435 and 505 nm. The AH_2 and A^{2-} are produced through the disproportionation reaction from the semiquinone radical (AH·) and from the semiquinone radical anion ($A\cdot^-$) respectively.[16]

The reduction product may be dissociated in the aqueous solution as follows:

$$ABH\cdot \rightleftarrows AB\cdot^- + H^+ \qquad (11)$$

where ABH· is the semiquinone radical of AB. The pK values of the semiquinone radical are 4 for benzoquinone,[2] 4.5 for menaquinone,[6] and 3.25 for sodium 9,10-anthraquinone-2-sulfonate.[16] Since the pH is about 5—6 for the present experiments, as has been already described, ABH· may be rather dissociated to the right side. Since the pH values of the above leuco-base solutions are higher than the pH of the solution shown in Fig. 7, the spectra at the high pH must correspond to the dianion, and the spectra in Fig. 7 must contain the spectra of the undissociated form.

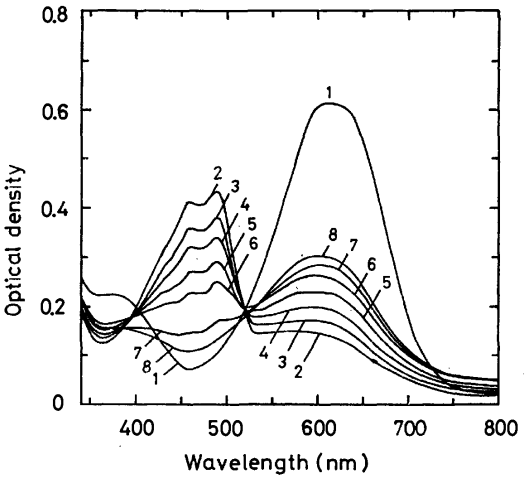

Fig. 8. Effect of oxygen on the spectra of the nitrogen-saturated Acid Blue 40 aqueous solution containing 10 mM methyl alcohol after irradiation of 5.5×10^4 rad. Dye concentration: 0.1 mM. Bubbling time of oxygen (hr): 0 (Curve 2), 1 (Curve 3), 2 (Curve 4), 4 (Curve 5), 7 (Curve 6), 24 (Curve 7), and 45 (Curve 8). Curve 1 represents the spectrum of the solution before irradiation.

Disappearance of Absorption Band at 490 *nm by Oxygen.* As may be seen in Fig. 8, the absorption spectra for the irradiated nitrogen-saturated solution containing methyl alcohol changed gradually upon the bubbling-in of oxygen after irradiation. The spectrum after 70 hr was almost identical with the curve after 45 hr. At the same time, about one-half of the intensity of the original absorption band at 610 nm was recovered finally. The other half of the intensity is attributable to the degradation of the dye by, for example, through Reaction 3. This recovery of the absorption band at 610 nm may be represented as follows:

$$AB_{red,f} + O_2 \xrightarrow{k_{12}} AB \text{ (colored product at 610 nm)} + O_2^- \text{ (or } HO_2) \qquad (12)$$

where $AB_{red,f}$ is the final reduction product.

Thus, the rate of Reaction 12 can be represented in terms of the rate constant, k_{12}, as follows:

$$-\frac{d[AB_{red,f}]}{dt} = k_{12}[O_2][AB_{red,f}] \qquad (13)$$

When the oxygen concentration dissolved is assumed to be constant, Eq. (13) can be rewritten by using the rate of the disappearance of the absorption band at 490 nm (k_{12}') as follows:

$$-\frac{dx}{dt} = k_{12}'(a-x) \quad (14)$$

that is;

$$-k_{12}'t = \ln\frac{(a-x)}{a} \quad (15)$$

where a is the initial intensity of the absorption band at 490 nm, and where x is the intensity of the absorption band which disappears in time t. The plots of $\ln(a-x)/a$ are linear against the time, in good agreement with Eq. (15). From the slope of the curve, the k_{12}' value is 2.8×10^{-5} s^{-1}. Then, the half-life of $AB_{red,f}$ is 6.8 hr. Similarly, the rate of the recovery of the absorption band at 610 nm, k_{12}'', can be estimated. When the intensity of the absorption band at 610 nm for the dye solution after 45 hr is assumed as the initial concentration, the k_{12}'' value is 2.6×10^{-5} s^{-1}. Since the value of $[O_2]$ is 1.2×10^{-3} M in the oxygen-saturated solution,[17] the k_{12} value becomes 2.3×10^{-2} M^{-1} s^{-1}.

Spectroscopic Study of Concentration Fluctuation and Intermolecular Interaction in Liquid

Tsunetake FUJIYAMA, Masao KAKIMOTO,* and Tetsuo SUZUKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

** Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113*

(Received September 19, 1975)

The band widths of the infrared absorption spectra were observed for binary solutions of methyl iodide, methyl cyanide, chloroform, and carbon disulfide. The observed bands are: the ν_1 fundamental of chloroform in carbon disulfide and in carbon tetrachloride; the ν_2 fundamental of methyl iodide in methyl cyanide, nitromethane, benzene, carbon disulfide, and carbon tetrachloride; the $2\nu_2$ band of methyl iodide in methyl cyanide, and the ν_8 and $2\nu_8$ bands of methyl cyanide in methyl iodide. The concentration dependence of a band width was explained in terms of the concentration fluctuation. The theory was compared with the observed band widths, together with the light-scattering data. A fluctuation volume was related with the intermolecular interactions in these binary solutions.

Gordon[1] and Shimizu[2] have shown that a shape of an infrared absorption band of a liquid or a solution can be interpreted as the Fourier transform of a time-correlation function of a transition dipole moment. The time-correlation function of a transition dipole moment is considered to be determined mainly by the reorientational motion of molecules. Many reports have been published which have determined the rate of molecular reorientation in liquids or solutions from measurements of the shapes of infrared-absorption bands.[3–6] However, the time-correlation function of a transition moment may be affected by many other factors than the reorientational motion of molecules. Among these factors, two important factors, namely, the vibrational relaxation and the vibration-rotation interaction, have been shown to affect the observed band shape considerably in some cases.[7,8] The former of the two factors is concerned with the decay of an excited vibrational level, and the latter, with the fact that a transition moment is not fixed to a molecular frame in the case of a degenerate-type vibration of a symmetric top molecule. Taking into account the effects of these factors, the present authors have succeeded in explaining the abnormal behavior of the half-band width of carbon disulfide[7] and of methyl cyanide[8] in liquid and in solutions. Recently, Bondarev and Mardaeva[9] have suggested that the concentration fluctuation affects the half-band width of the spectra of solutions.

The present report will be concerned with the observation of the half-band widths of the infrared-absorption spectra for a few binary solutions and with the introduction of concentration fluctuation to the explanation of the band widths. A consideration of the nature of the concentration fluctuation observed from the infrared spectra will be given, together with a detailed description of the relation between the half-band width of the infrared absorption spectra and the concentration fluctuation.

Experimental

All the chemicals used in the present study were commercial products. The methyl iodide was distilled just before the observation to remove its pale yellowish color. The other samples were used without further purification, although the infrared spectra of methyl cyanide showed a small amount (about 0.5 wt %) of water in it, the presence of water in methyl cyanide seems to cause no serious error.

The binary solutions were prepared just before the observation in order to attain the appropriate concentration by measuring the weight of each component. The mole percentage was calculated by the use of the density data.[10]

The infrared absorption spectra were measured with a Perkin-Elmer 112G single-beam infrared spectrometer (the ν_1 band of chloroform, and the ν_2 and $2\nu_2$ bands of methyl iodide). A Perkin-Elmer 12C single-beam infrared spectrometer mounted with a CsBr prism was used to measure the ν_8 band of methyl cyanide in a methyl iodide solution. A Hitachi EPI-G2 double-beam infrared spectrometer was used to measure the $2\nu_8$ band of methyl cyanide in a methyl iodide solution.

The spectrometers were operated under a resolution of about 1 cm^{-1} except for the case of the ν_8 and $2\nu_8$ bands of methyl cyanide, where the resolution was about 2—3 cm^{-1}. The effect of the finite slit width on the observed spectra was found to be very small. All the measurements were carried out at room temperature (25 °C). The frequencies were calibrated by the use of atmospheric water-vapor or carbon dioxide lines for the 112G spectrometer, and by the use of atmospheric water-vapor or methanol-vapor lines for the 12C spectrometer.

The observed spectra were reduced to the absorption index curve, $k(\nu)$. We fitted a Lorentzian curve to the observed $k(\nu)$ curve by the method of least-squares. The half-width and peak frequency of a band were determined as the parameters of the Lorentzian curve.

Results and Discussion

Half-band Width and Concentration Fluctuation. Consider the case where a peak frequency of a spectral line varies according to the concentration variation. We will confine our discussion to a binary solution. The two components of a binary solution will be denoted hereafter as 1 and 2. All the symbols suffixed by 1 and 2 correspond to the 1 or 2 component, respectively. When a sample of the binary solution is prepared to give a mole fraction of one component, x_1°, the actual mole fraction, x_1, is not always the same as x_1°, but has a distribution around x_1°. The difference between x_1 and x_1° is denoted as Δx_1:

$$x_1 = x_1^\circ + \Delta x_1 \tag{1}$$

Corresponding to the distribution of x_1, the peak frequency, ν_1, also has a distribution:

$$\nu_1 = \nu_1^\circ + \Delta\nu_1 \tag{2}$$

where ν_1° corresponds to a peak frequency at a mole fraction of x_1°, and where $\Delta\nu_1$ is expressed as:

$$\Delta\nu_1 = \frac{\partial\nu_1}{\partial x_1}\Delta x_1 \tag{3}$$

A spectral band of a 1 component directly reflects the distribution of $\Delta\nu_1$. If there is no broadening factor for the spectral band other than the concentration fluctuation, and if a Gaussian distribution is assumed to be the distribution of $\Delta\nu_1$, a normalized intensity distribution, $I(\Delta\nu_1)$, of the band may be expressed as:

$$I(\Delta\nu_1) = \frac{1}{\sqrt{2\pi\langle\Delta\nu_1^2\rangle}}\exp\left[-\frac{\Delta\nu_1^2}{2\langle\Delta\nu_1^2\rangle}\right] \tag{4}$$

where $\langle\ \rangle$ means a statistical average. Then, a half-band width, $\Delta\nu_{1/2}$, of the band is:

$$\Delta\nu_{1/2} = 2\sqrt{2\ln 2}\sqrt{\langle\Delta\nu_1^2\rangle} = 2\sqrt{2\ln 2}\left|\frac{\partial\nu_1}{\partial x_1}\right|\sqrt{\langle\Delta x_1^2\rangle} \tag{5}$$

Let the N_1 and N_2 molecules of the components be contained in a volume in which the concentration fluctuation takes place. We call this volume the "fluctuation volume." Then, we can write:

$$x_1 = \frac{N_1}{N_1+N_2} \tag{6}$$

and:

$$\Delta x_1 = \frac{N_2}{(N_1+N_2)^2}\Delta N_1 \tag{7}$$

It is derived by the method of statistical mechanics that

$$\langle\Delta N_1^2\rangle = kT\Big/\left(\frac{\partial\mu_1}{\partial N_1}\right)_{T,P} \tag{8}$$

where k is the Boltzmann constant; T, the absolute temperature; P, the pressure, and μ_1, the chemical potential. The chemical potential is expressed as:

$$\mu_1 = kT\ln x_1 \tag{9}$$

if the solution is considered to be an ideal solution. A straightforward calculation using Eqs. (6) through (9) leads to:

$$\langle\Delta x_1^2\rangle = \frac{x_1(1-x_1)}{N_1+N_2} \tag{10}$$

which, combined with Eq. (5), gives:

$$\Delta\nu_{1/2} = \sqrt{2\ln 2}\left|\frac{\partial\nu_1}{\partial x_1}\right|\sqrt{\frac{x_1(1-x_1)}{N}} \tag{11}$$

where:

$$N = N_1 + N_2 \tag{12}$$

is the number of molecules contained in the fluctuation volume. Equation (11) tells us that the necessary conditions for the appearance of the broadening of this type are a large change in a peak frequency and a small number of molecules in the fluctuation volume. When these conditions are satisfied, the broadening appears to a measurable extent; the maximum width occurs at $x_1=0.5$.

Comparison with Observed Data. Figure 1 shows the half widths, γ's, of the infrared absorption band of the ν_1 fundamental of chloroform observed in the carbon disulfide and carbon tetrachloride solutions. It may be seen from the figure that the concentration dependence of γ is quite different in the two solutions. In the carbon disulfide solution, γ increases in magnitude as the concentration decreases down to 50 mole percent, and then it decreases as the concentration decreases. This is just the same as what the factor, $\sqrt{x_1(1-x_1)}$, of Eq. (11) predicts. In the carbon tetrachloride solution, on the other hand, γ takes an almost constant value over the whole concentration range. As is shown in Fig. 2, the concentration dependence of the peak frequency of the ν_1 band of chloroform has a strong dependency on the concentration in the carbon disulfide solution at all the concentrations. This fact is consistent with the result of Eq. (11) namely, the line broadening due to the concentration fluctuation is proportional to the magnitude of the change in the peak frequency

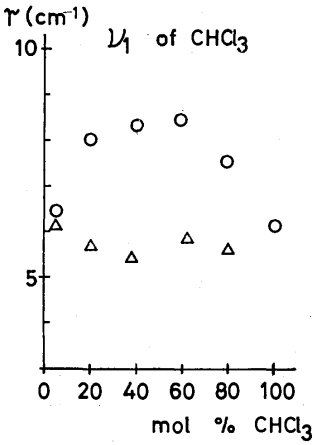

Fig. 1. Concentration dependence of the half width, γ, of the infrared absorption band of the ν_1 fundamental of chloroform. The circles and triangles correspond to those observed in carbon disulfide solutions and in carbon tetrachloride solutions, respectively.

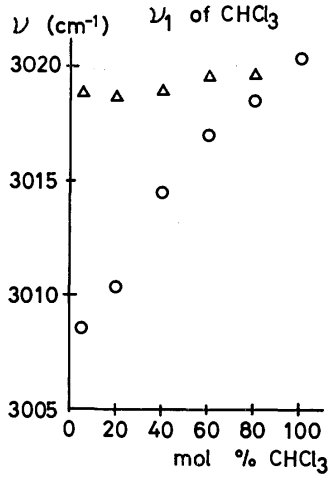

Fig. 2. Concentration dependence of the peak frequency of the infrared absorption band of the ν_1 fundamental of chloroform. The circles and triangles correspond to those observed in carbon disulfide solution and in carbon tetrachloride solution, respectively.

against the concentration. Similar phenomena were observed for the ν_2 band of methyl iodide in nitromethane, methyl cyanide, carbon tetrachloride, benzene, and carbon disulfide solutions. The results are given in Figs. 3 and 4. It may be seen from the figures that a broadening of this type is observed for the ν_2 band in methyl cyanide or nitromethane solutions, and that the shifts of the peak frequencies are very large in these solutions. Figure 4 shows that the frequency shift of the $2\nu_2$ band is about two times that of the ν_2 band in methyl cyanide solutions. In Eq. (11), all the factors except $|\partial\nu_1/\partial x_1|$ should be the same for these two absorption bands. Thence, the broadening of the $2\nu_2$ band should be about two times that of the ν_2 band, which is seen to be true in Fig. 3.

The observed band widths are composed not only

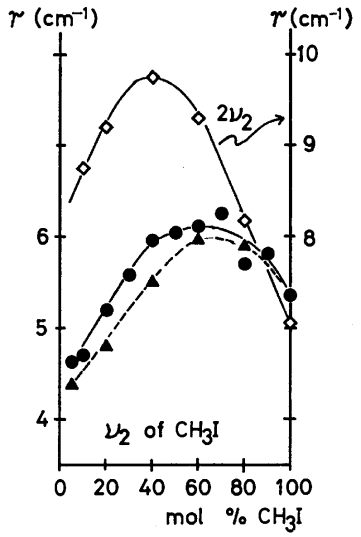

Fig. 3-a. Concentration dependence of the half width, γ, of the infrared absorption band of the ν_2 and $2\nu_2$ of methyl iodide. The open squares correspond to the $2\nu_2$ band observed in methyl cyanide solutions. The closed circles and closed triangles correspond to the ν_2 band observed in methyl cyanide solutions and in nitromethane solutions, respectively.

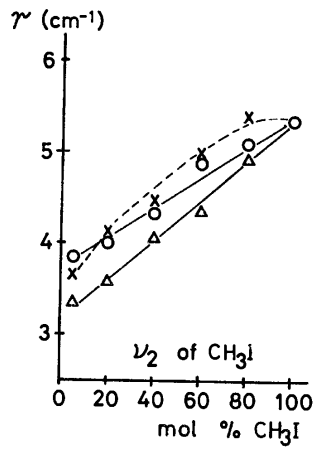

Fig. 3-b. Concentration dependence of the half-width, γ, of the infrared absorption band of the ν_2 band of methyl iodide. Used solvents are: ×; benzene, ○; carbon disulfide, △; carbon tetrachloride.

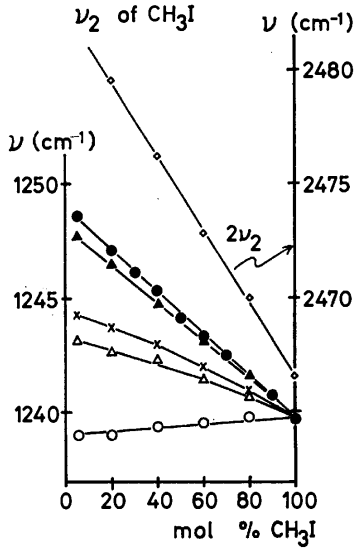

Fig. 4. Concentration dependence of the peak frequencies of the ν_2 and $2\nu_2$ infrared absorption bands of methyl iodide. The open squares correspond to the $2\nu_2$ band in methyl cyanide solutions. Used solvents are: ●; methyl cyanide, ▲; nitromethane, ×; benzene, △; carbon tetrachloride, ○; carbon disulfide.

of the width due to concentration fluctuation, but also of those due to the other factors the reorientational motion of molecules, vibrational relaxations, and so on. When $|\partial\nu/\partial x|$ is small, an observed band width is thought to be independent of the concentration; an example of this is the ν_1 band of chloroform in the carbon tetrachloride solution (see Fig. 2).[11] Therefore, the part of the band-width caused by the concentration fluctuation, γ_f, is expressed as:

$$\gamma_f = \gamma - \gamma' \tag{13}$$

where γ is an observed band width, and where γ' is a width caused by the other factors. We consider that γ' is expressed as:

$$\gamma' = \gamma_0 + x(\gamma_1 - \gamma_0), \tag{14}$$

where x is a mole fraction; γ_1 and γ_0 are the observed band widths at $x=1$ and $x=0$ respectively. Thus, $\Delta\nu_{1/2}$ of Eq. (11) is defined as:

$$\Delta\nu_{1/2} = 2\gamma_f. \tag{15}$$

In the case of the $2\nu_8$ band of methyl cyanide, which is shown in Fig. 5, no reliable change in the half-band width due to concentration fluctuation was observed, although the peak-frequency change due to concentration is considerably large. This can probably be explained by the fact that the width of the band is very broad, while the width can be explained by γ' of Eq. (13). The accuracy of the band-width measurement was not satisfactory enough to detect the width change due to concentration fluctuation from γ. Fig. 5 shows the results obtained for the ν_8 and $2\nu_8$ bands of methyl cyanide in the methyl iodide solution. The $|\partial\nu/\partial x|$ values for the ν_8 and $2\nu_8$ bands are 6 and 11 cm^{-1} respectively.

Comparison with Light-scattering Data. So far the relation between the concentration fluctuation and the

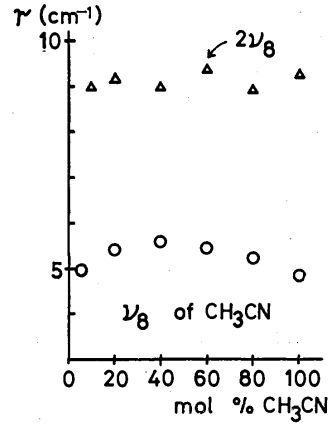

Fig. 5. Concentration dependence of the half width, γ, of the ν_8 and $2\nu_8$ infrared absorption bands of methyl cyanide observed in methyl iodide solutions.

band widths of the infrared spectra has been discussed. A light-scattering measurement is also an useful method to determine the concentration fluctuation. We cannot, however, compare the results obtained by these two methods directly. A band width affords information about the concentration fluctuation in the $\langle \Delta x^2 \rangle$ form. On the other hand, an intensity measurement of the Rayleigh scattering affords information about the concentration fluctuation in the form of $\langle \Delta x^2 \rangle \times V^*$, where V^* is the fluctuation volume, that is, the volume in which the concentration fluctuation is observed. We call this product, $\langle \Delta x^2 \rangle \times V^*$, the "fluctuation ability."[12]

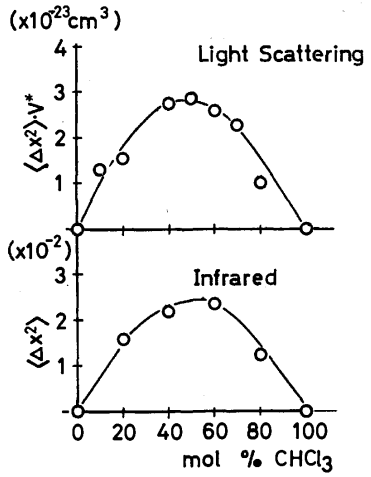

Fig. 6. Comparison of the concentration fluctuation obtained from infrared absorption spectra with that from light scattering data (chloroform–carbon disulfide system).

For the chloroform–carbon disulfide system, a fluctuation ability was observed by the intensity measurement of the Rayleigh scattering.[12] Figure 6 shows a comparison of the $\langle \Delta x^2 \rangle_{IR}$ obtained from the infrared data with the $[\langle \Delta x^2 \rangle \times V^*]_{LS}$ obtained from the light-scattering data. They show quite an analogous dependency on the change in concentration, indicating a qualitative consistency between the two sets of experimental results.

Attention should be paid to the fact that the $\langle \Delta x^2 \rangle_{IR}$ values are obtained, in the case of the infrared spectra, regardless of the dimensions of the fluctuation volume. It is important, therefore, to examine the dimensions of the fluctuation volume from which a band width of the infrared spectrum receives information about the concentration fluctuation. In order to examine the fluctuation volume quantitatively, the number of molecules contained in a fluctuation volume, N, was calculated in two ways. One was to calculate N directly from Eq. (11), using the observed spectral data, $\Delta\nu_{1/2}$ and $|\partial\nu_1/\partial x_1|$. In this procedure, the system was assumed to be an ideal solution. The other way was to calculate N from the observed scattering data, $[\langle \Delta x^2 \rangle \times V^*]_{LS}$, and the absorption spectral data, $\langle \Delta x^2 \rangle_{IR}$, as:

$$N = \frac{[\langle \Delta x^2 \rangle \times V^*]_{LS}}{\langle \Delta x^2 \rangle_{IR}} \times \frac{N_a}{x_1\left(\frac{M_1}{\rho_1}\right) + x_2\left(\frac{M_2}{\rho_2}\right)} \qquad (16)$$

where M was the molecular weight; ρ, the density, and N_a, the Avogardro number. The additivity of volumes on mixing is assumed in the procedure. If the infrared data correctly reflect the concentration fluctuation of the binary solution, and if the binary solution can be regarded as an ideal solution, the N values calculated by the two different ways should be identical. The calculated results are summarized in Table 1. The agreement between these two sets of N values is quite good; this in turn indicates that the proposed mechanism of line broadening as being due to concentration fluctuation is quite reasonable.

Table 1. Comparison of N and $\langle \Delta x^2 \rangle$ obtained from infrared absorption data with those from infrared and light scattering data, for chloroform–carbon disulfide system

Fluctuation Volume and Intermolecular Interaction. The problem of spectral-line broadening due to concentration fluctuation has now been reduced to the problem of the shift of the peak frequency in the solutions. It is necessary, for a complete understanding of the spectral-line broadening due to concentration fluctuation, to understand why a peak frequency changes its magnitude according to the concentration variation. This is a quite difficult problem indeed, and no satisfactory answer has yet been given. The deter-

mination of the N values, however, seems to give some useful information regarding this problem.

Considering the mechanism through which the concentration fluctuation causes broadening in a spectral line, the N value or the dimensions of the fluctuation volume corresponding to $\langle \Delta x^2 \rangle_{IR}$ indicates the region in which the surrounding molecules are confined, which can affect the peak frequency of a central molecule through intermolecular interactions.

It is established in the preceding paragraph that N can reasonably be estimated using only the infrared spectral data and Eq. (11), if the solution can be considered to be an ideal solution. Now, let us proceed further in the calculation of N through Eq. (11) for the other absorption bands observed. The results are summarized in Table 2. It may be seen from Table 2 that the N values are almost the same for the three bands observed in the methyl iodide–methyl cyanide system. If we compare the results of Table 2 with those of Table 1, we see, however, a difference between these two sets of N values; that is the N value is larger for the methyl iodide–methyl cyanide system than for the chloroform–carbon disulfide system. The N values of Table 1 are around 10. This may indicate that the intermolecular interaction, which effectively affects the peak frequency of the ν_1 band of chloroform in the carbon disulfide solution, arises from about 10 surrounding molecules. In other words, the peak-frequency change reflects the intermolecular interaction between a given molecule and the nearest neighbor molecules. The larger N values for methyl iodide–methyl cyanide system indicate the existence of a different type of intermolecular interaction. The peak-frequency change or the band-width change, in this case, may afford information about the intermolecular interaction between a given central molecule and the nearest and next nearest neighbour molecles.

Conformation of Thymidine 3′,5′-Cyclic Phosphate in Aqueous Solution. Compatibility of the Information from the Lanthanide-Ion Probe and the Spin-Coupling Constants

Fuyuhiko INAGAKI, Seizo TAKAHASHI, Mitsuo TASUMI, and Tatsuo MIYAZAWA

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received October 4, 1975)

The Pr(III)- and Eu(III)-induced shifts of ^{1}H nuclear magnetic resonances of thymidine 3′,5′-cyclic phosphate were observed in D_2O solution. The results indicated that the induced shifts were primarily of dipolar origin and that the magnetic susceptibility tensor had effective axial symmetry. The ratios of shifts intrinsic to the lanthanide-substrate 1:1 complex were determined after correcting for the contributions of the complex formation shifts (diamagnetic terms). The Gd(III)-induced perturbations of the spin-lattice relaxation times were also observed, and the ratios of relaxation rates were obtained. A computer search was then performed to find out the molecular conformation of this cyclic nucleotide which best fitted the shift and relaxation ratios. As a result the phosphate-ring part was found to have a typical chair conformation. The effective symmetry axis of the magnetic susceptibility tensor coincided with the bisector of the OPO angle almost completely. It was rather difficult, however, to establish the conformation of the deoxyribose ring from the shift and relaxation ratios alone. The use of the additional information from the vicinal ^{1}H—^{1}H coupling constants ($J_{1'2'}$ and $J_{1'2''}$) was necessary for obtaining a reasonable conformation of the entire molecule. The compatibility of the information from the lanthanide-ion probe and the spin coupling constants ($^3J_{HH}$ other than $J_{1'2'}$ and $J_{1'2''}$ and $^3J_{HP}$) is discussed along with the limitations of both methods.

The chemical shift and relaxation perturbations induced by paramagnetic lanthanide cations[1–6] have been increasingly utilized for the determination of conformations of biologically important molecules.[7,8] The advantage of this lanthanide-ion probe method lies in its potentiality of yielding information on relative arrangements of nuclei located within a relatively long distance (approximately 10 Å) and in various directions from the bound lanthanide cation. The information obtainable by this method is particularly valuable when the molecule under study has a portion for which neither vicinal nor long-range spin-coupling data are available. For the phosphodiester linkage in dinucleoside monophosphates no spin coupling is present and accordingly, no information is obtainable as to the torsional angles about the P–O bonds. It seems therefore interesting to apply the lanthanide-ion probe method to conformation studies of this class of molecules. However, such flexible molecules should be treated with caution. For 5′-nucleotides the results obtained by this method[9–11] are not quite consistent with the conclusions derived from the spin-coupling constants.[12–14] Therefore, it is important to check the compatibility of these two methods with an appropriate molecule related to dinucleoside monophosphates. For such a purpose it has been found that thymidine 3′,5′-cyclic phosphate (3′,5′-cTMP) is particularly suited on the following grounds. (a) The binding of the lanthanide cation to 3′,5′-cTMP and to a dinucleoside monophosphate would be similar, since either has a phosphodiester linkage as the binding site. (b) Unlike other 3′,5′-cyclic nucleotides, the analysis of ^{1}H and ^{13}C NMR spectra of 3′,5′-cTMP has given an exceptionally complete set of the ^{1}H–^{1}H, ^{1}H–^{31}P, and ^{13}C–^{31}P coupling constants.[15,16] From the analysis of these coupling constants it has been concluded that the deoxyribose and cyclic phosphate rings of 3′,5′-cTMP are locked in a rigid conformation. Consequently, the result from the lanthanide-ion probe may be compared easily with that from the spin-coupling constants.

Experimental

Materials and Preparation of Sample Solutions. Thymidine 3′,5′-cyclic phosphate (3′,5′-cTMP) was purchased from Sigma Chemical Co. and was used without further purification. The nitrates of Eu(III), Pr(III), Gd(III), and La(III) (purity better than 99.9%) obtained from Nakarai Chemical Co. were used for measuring the induced shifts or the relaxation-time perturbations.

The shifts induced by Pr(III) and the "complex formation" shifts induced by La(III)[17,18] were observed in D_2O solutions by the successive dilution method.[19,20] The concentrations of 3′,5′-cTMP in the initial solutions were 0.307 and 0.253 M for the measurements with Pr(III) and La(III), respectively. The molar ratio of a lanthanide ion to the substrate was kept constant [1.186 for Pr(III) and 1.185 for La(III)] throughout a series of dilution measurements. The shifts induced by Eu(III) were also observed but unfortunately the resonance peaks due to $H_{5'}$ and $H_{5''}$ were overlapped with the HDO peak as a result of the shift and the peaks arising from $H_{2'}$ and $H_{2''}$ could not be separated clearly. The "pH" (uncorrected pH meter reading) was adjusted to about 2.0. Precipitation occurred at higher pH. A Radiometer PHM 26 pH meter was used with a long thin Ingold combination electrode (Catalog No. 6030—04). For the measurements of Gd(III)-perturbed proton relaxation times, a small amount of Gd(III) nitrate solution was added successively to the 0.19 M solution of 3′,5′-cTMP. Thus the concentration of Gd(III) was varied from 20 to 140 μM in steps of 20 μM.

NMR Measurements. The NMR spectra were obtained with a Hitachi R-22/FT spectrometer operating at 90 MHz for ^{1}H. The probe temperature was kept at 37 °C. The chemical shifts were determined by a frequency counter using a frequency-sweep mode. Sodium 4,4-dimethyl-4-silapentane-1-sulfonate (DSS) was used as an internal standard. Spin-lattice relaxation times (T_1) were obtained by means of a standard 180°—τ—90° pulse sequence.

Data Analysis. Computer programs were developed to derive a conformation which best fitted not only the chemical

shift and relaxation perturbations induced by lanthanide ions but also the conformation-dependent coupling constants. The main features of the programs are described in the Appendix. Computations were carried out with a HITAC 8800/8700 system at the Computer Centre of the University of Tokyo.

Results and Discussion

Lanthanide-Induced Shifts. The induced chemical shifts of all the protons of 3',5'-cTMP could be observed only with Pr(III), whereas the results with Eu(III), Nd(III), and Yb(III) were incomplete because of unfavorable line overlappings and/or line broadenings. The Pr(III)-induced shifts observed by the successive dilution method were corrected for the complex formation shifts which were determined using diamagnetic La(III). Next the ratios of the Pr(III)-induced shifts of protons $H_{5'}$, $H_{5''}$, $H_{4'}$, $H_{2'}$, $H_{2''}$, $H_{1'}$, H_6, and H_{Methyl} relative to that of H_3, were calculated and extrapolated to zero substrate concentration [as for the numbering of protons, see Fig. 1(a)]. Such a procedure was previously shown to be appropriate for obtaining experimentally the shift ratios intrinsic to the 1:1 complex between the substrate molecule and the lanthanide ion.[19,20] The shift ratios thus obtained with Pr(III) are listed in Table 1, together with the results with Eu(III). Although the Eu(III)-induced shifts were observed only for $H_{3'}$, $H_{5'}$, $H_{4'}$, $H_{1'}$, H_6, and H_{Methyl} the shift ratios derived from them were not much different from the corresponding ones obtained with Pr(III). This means that the induced shifts for these protons are mainly of dipolar origin and that the susceptibility tensor has effective axial symmetry. Therefore, the shift ratios for the above six protons could be used for conformation

a) As for the notations of the protons, see Fig. 1(a). b) The values in the columns A and B were obtained, respectively, from Conformations A and B of Table 2. c) The weights for these values were 1/10 of those for the other data. d) An average position of the methyl protons was assumed to be the center of the triangle formed by them.

studies with the McConnel-Robertson equation.[21] Since only the Pr(III)-induced shifts were obtained for $H_{5''}$, $H_{2''}$, and $H_{2'}$, the shift ratios for these three protons were used in the conformation search with a weight factor of 1/10 relative to the other protons.

Gd(III)-Induced Relaxation Rate Enhancement. The relaxation rates for the nuclei of a Gd(III)-bound molecule are to a good approximation proportional to $\langle r_i^{-6} \rangle$, where r_i refers to the distance between Gd(III) and the ith nucleus.[7,9] In the present study the change of the spin-lattice relaxation time (T_1) with successive addition of a small amount of Gd(III) was followed. The observed spin-lattice relaxation rates ($1/T_1^{obsd}$) are plotted against the concentrations of Gd(III) in Fig. 2. As shown in a previous paper,[22] the slope of each plot is proportional to the relaxation rate of each nucleus in the Gd(III)-bound molecule. Using the data thus obtained, the relaxation ratios were calculated as listed in Table 1, where the relaxation rate for $H_{3'}$ was chosen as a reference.

Spin-Coupling Constants. The ^1H–^1H and ^1H–^{31}P coupling constants of 3',5'-cTMP at pD 7.2 were obtained by Blackburn *et al.*[15] No appreciable varia-

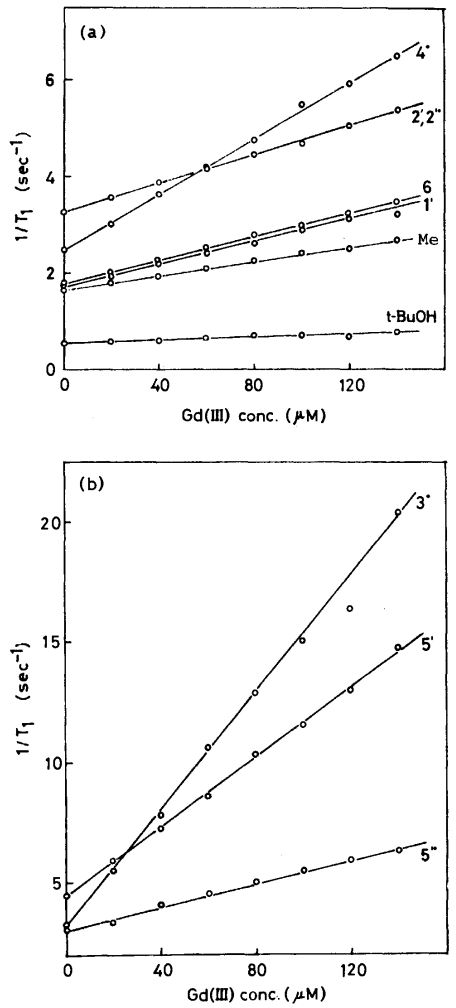

Fig. 2. Dependence of the spin-lattice relaxation rate ($1/T_1^{obsd}$) on the concentration of Gd(III). (a), $H_{1'}$, $H_{2'}$, $H_{2''}$, $H_{4'}$, $H_{6'}$, and H_{Methyl}; (b), $H_{3'}$, $H_{5'}$, and $H_{5''}$. The concentration of 3',5'-cTMP was 0.19 M. *t*-BuOH (*ca.* 20 mM) was used as an internal standard.

tions of the spin-coupling constants from these values were found with the addition of approximately equimolar La(III) at pD 2.0. This indicated that the conformation of 3',5'-cTMP remained unchanged upon complex formation with the lanthanide cation. It is also known that for 3',5'-cTMP no protonation occurs between pH 2.0 and 7.2. Therefore, the spin-coupling constants given by Blackburn *et al.* will be used in the following discussion.

Conformation Search. A search for the conformation of 3',5'-cTMP which best fitted all the observed data was carried out in the following way. A conformation based on the structure of uridine 3',5'-cyclic phosphate in a crystal was assumed at first. This model was employed because no crystallographic data were available for 3',5'-cTMP itself. By modifying this initial model a conformation was obtained which gave the best fit between the observed and calculated values of the shift and relaxation ratios. Finally a further adjustment of molecular parameters was performed by taking a few key spin-coupling constants into consideration. Such a process and the results obtained will be described below in more detail.

From the crystal data of uridine 3',5'-cyclic phosphate (molecule A)[23] all the necessary parameters, *viz.*, bond lengths, bond angles, ring-puckering angles, and the torsional angle around the glycosidic bond, were obtained and transferred to 3',5'-cTMP. The four ring-puckering angles $\omega_1-\omega_4$ [shown in Fig. 1(b)] as well as the torsional angle around the glycosidic bond were chosen as variable parameters[24] in the iteration process of fitting the calculated shift and relaxation ratios to the observed values. These are defined as the dihedral angles between the two planes, each of which is indicated below by the three atoms in a parenthesis: ω_1 ($PO_{5'}O_{3'}$) and ($O_{5'}O_{3'}C_{3'}$); ω_2 ($O_{3'}O_{5'}C_{3'}$) and ($O_{5'}C_{3'}C_{5'}$); ω_3 ($O_{5'}C_{3'}C_{5'}$) and ($C_{2'}C_{5'}C_{4'}$); ω_4 ($C_{4'}C_{2'}$-$O_{1'}$) and ($C_{2'}O_{1'}C_{1'}$). Since each dihedral angle is equivalent to the torsional angle around the imaginary bond XY in the atomic sequence A–X–Y–B as given in Table 2, its sign was given according to the IUPAC-IUB conventions on the definition of a torsional angle.[25] The torsional angle χ around the glycosidic bond is defined with respect to the sequence $O_{1'}$–$C_{1'}$–N_1–C_6. To describe the conformation of a five-membered ring two puckering angles are generally needed. However, only one (ω_4) was sufficient for the deoxyribose ring of 3',5'-cTMP because of the interlocking of this and the phosphate rings. In Table 2 the initial values of $\omega_1-\omega_4$ and χ are given as Conformation I.

Table 2. Molecular parameters of thymidine 3',5'-cyclic phosphate

Molecular Parameter[a]	Conformation		
	I	A	B
ω_1(P–$O_{5'}$–$O_{3'}$–$C_{3'}$)	−135°	−116°	−114°
ω_2($O_{3'}$–$O_{5'}$–$C_{3'}$–$C_{5'}$)	−179°	−189°	−189°
ω_3($O_{5'}$–$C_{3'}$–$C_{5'}$–$C_{4'}$)	−121°	−121°	−126°
ω_4($C_{4'}$–$C_{2'}$–$O_{1'}$–$C_{1'}$)	−160°	−187°	−152°
χ($O_{1'}$–$C_{1'}$–N_1–C_6)	77°	135°	84°
θ		4°	4°
τ		−101°	−66°

a) As for the definitions of ω, χ, θ, and τ, see the text and Fig. 1(b).

The shift and relaxation ratios were calculated on the assumption that the lanthanide cation was located on the bisector of the OPO angle. This assumption was substantiated by previous studies,[9-11,24,26] particularly for the early members of the series of lanthanide cations like Pr(III) and Eu(III).[27] The direction of the symmetry axis of susceptibility tensor was made variable. Two parameters θ and τ were used to specify this direction, the former being the angle between the symmetry axis and the OPO bisector and the latter the dihedral angle between the plane involving the symmetry axis and the P atom and the plane defined by Ln, P, and O* [see Fig. 1(b)]. The angle τ could be regarded as the torsional angle around the Ln–P linkage in the sequence formed by a point on the symmetry axis–Ln–P–O* and, therefore, its sign was given in the same way as for ω's and χ. The distance between Ln(III) and P was fixed to 3.0 Å (corresponding

to the Ln–O distance of 2.6 Å) which is in the range generally accepted.

The agreement factor (R_1)[28] defined below is a useful measure for evaluating the degree of fit between the observed and the calculated values.

$$R_1 = \left\{ \frac{\sum_i v_i (p_i^{\text{obsd}} - p_i^{\text{calcd}})^2 + \sum_i w_i (q_i^{\text{obsd}} - q_i^{\text{calcd}})^2}{\sum_i v_i (p_i^{\text{obsd}})^2 + \sum_i w_i (q_i^{\text{obsd}})^2} \right\}^{1/2} \quad (1)$$

Here p_i and q_i refer to the shift ratio and the relaxation ratio for the ith nucleus, respectively, and v_i and w_i are the corresponding weights (both set to unity unless otherwise mentioned). After minimizing the R_1 value by varying ω_1–ω_4, χ, θ, and τ, Conformation A of Table 2 was obtained as the best-fit model. The shift and relaxation ratios calculated for Conformation A are listed in Table 1 as Calcd A. The R_1 value for Calcd A was 0.048 [using the shift ratios observed by Pr(III)], which is comparable with the value (0.037) obtained for hydroxy-L-proline.[22] The R_1 value was found rather insensitive to ω_4 since it is related only to $H_{1'}$, H_6, and H_{Methyl} which have small shift and relaxation ratios. Therefore, the two spin-coupling constants $J_{1'2'}$ and $J_{1'2''}$ were included in the conformational search in order to add further information for determining ω_4. The Karplus-type equation derived by Altona and Sundaralingam[29] was used for this purpose. The agreement factor (R_2) defined below was used in this search.

$$R_2 = \left\{ \frac{\left(\sum_i v_i (p_i^{\text{obsd}} - p_i^{\text{calcd}})^2 + \sum_i w_i (q_i^{\text{obsd}} - q_i^{\text{calcd}})^2 \right) + \sum_k u_k (J_k^{\text{obsd}} - J_k^{\text{calcd}})^2}{\sum_i v_i (p_i^{\text{obsd}})^2 + \sum_i w_i (q_i^{\text{obsd}})^2 + \sum_k u_k (J_k^{\text{obsd}})^2} \right\}^{1/2} \quad (2)$$

In this equation p_i, q_i, v_i, and w_i are the same as in Eq. (1), and J_k and u_k refer to the coupling constant and the corresponding weight, respectively. The ratio of u_k to v_i (except those for $H_{5''}$, $H_{2''}$, and $H_{2'}$ as indicated in Table 1) or w_i was set to 0.004 somewhat arbitrarily. With this value, shift ratios, relaxation ratios, and coupling constants contributed almost equally to the structure determination. The resultant best-fit conformation is indicated as Conformation B in Table 2, and the shift and relaxation ratios calculated for this model are listed in the column Calcd B of Table 1. The R_1 value (*not* R_2) for Calcd B was 0.070. A stereoscopic drawing of Conformation B is shown in Fig. 3.

The following points may be noted from the results described above. (1) The conformation of the phosphate ring could be determined by the lanthanide-ion probe method. There is no significant difference between phosphate-ring conformation determined here (Conformations A and B) and that of 3′,5′-cUMP in a crystal. Both may be called a chair form (see Fig. 3). (2) The small value of θ as determined for either Conformation A or B indicates the virtual coincidence of the symmetry axis of susceptibility tensor with the bisector of the OPO angle. Such a result ensures the validity of assuming this coincidence in the studies of other molecules having a phosphodiester bond. (3) It was difficult to obtain definite information on the positions of $H_{1'}$, H_6, and H_{Methyl} by the lanthanide-ion probe method alone. This is mainly because the distances between the lanthanide cation and these protons are relatively long (8.1, 7.0, and 9.0 Å for $H_{1'}$, H_6, and H_{Methyl}, respectively). (4) A reasonable conformation of the entire molecule could be obtained by the use of $J_{1'2'}$ and $J_{1'2''}$ in addition to the shift and relaxation data. The conformation of the deoxyribose ring may be described as 4′-*exo* (Fig. 3) in agreement with the conclusion of Blackburn *et al.*[15] However, it should be remembered that the parameters in the Karplus-type equation used here were based on the data of ribosylnucleosides and ribosylnucleotides.[29] If a different set of parameters is found to hold for the deoxyribose ring of 3′,5′-cyclic phosphates, the deoxyribose part of Conformation B should be modified accordingly. The conformation of the phosphate and deoxyribose rings determined here is roughly similar to the corresponding one of adenosine 3′,5′-cyclic phosphate reported by Barry *et al.*[24] According to these authors, the distance between Ln and $H_{4'}$ calculated from the relaxation data was not consistent with the structure determined from the shift ratios. Such discrepancy was not encountered in our case, since both the shift and relaxation ratios were used simultaneously. (5) In Conformation B the torsional angle around the glycosidic bond χ is close to that of molecule A of 3′,5′-cUMP in a crystal[23] and is in the anti range.[30] The value of χ in Conformation A seems less reliable. (6) If R_1 has a shallow minimum with respect to a variable parameter (*e.g.*, ω_4), a minor decrease in R_1 does not necessarily reflect a closer approach to the true conformation. Therefore, such

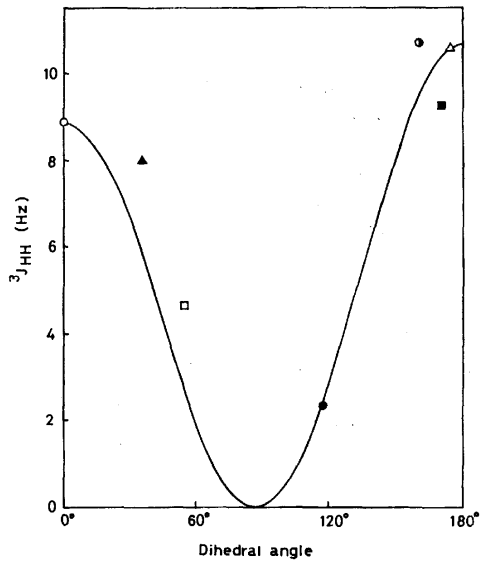

Fig. 4. The vicinal ^1H—^1H coupling constants $^3J_{HH}$ of thymidine 3',5'-cyclic phosphate plotted against the corresponding H–C–C–H dihedral angles in Conformation B. ○, $J_{1'2''}$; ▲, $J_{2'3'}$; □, $J_{4'5'}$; ●, $J_{1'2'}$; ◑, $J_{2''3'}$; ■, $J_{3'4'}$; △, $J_{4'5''}$. The solid curve indicates the variation of $^3J_{HH}$ with the dihedral angle as expressed by the Karplus-type equation with the coefficients of Altona and Sundaralingam.[29]

a case should be treated with caution.

In Fig. 4 the vicinal ^1H–^1H coupling constants ($^3J_{HH}$) are plotted against the H–C–C–H dihedral angles in Conformation B. Although the observed $^3J_{HH}$'s qualitatively follow the trend expressed by the Karplus-type equation (solid curve), there are considerable deviations of $J_{2'3'}$ and $J_{4'5'}$ from the curve. It is likely that these deviations reflect the limitations of the semi-empirical Karplus-type equation rather than the errors in the dihedral angles of Conformation B. Any possible torsional angle about the $C_{2'}$–$C_{3'}$ bond cannot give good fits of both $J_{2'3'}$ and $J_{2''3'}$ with the curve in Fig. 4. Blackburn *et al.* also noted using another Karplus-type expression that the observed $^3J_{HH}$ values were not in satisfactory agreement with the values calculated for a 4'-*exo* conformation, though it gave better fits than the other conformations.

Blackburn *et al.* determined three vicinal ^1H–^{31}P coupling constants ($^3J_{HP}$), namely $J_{3'P}$, $J_{5'P}$, and $J_{5''P}$, to be 1.7, 2.2, and 20.4 Hz, respectively.[15] The corresponding H–C–O–P dihedral angles (ϕ_{HP}) in Conformation B are 46°, 63°, and 179°, respectively. Such a relationship between $^3J_{HP}$ and ϕ_{HP} is in agreement with the results obtained earlier by Tsuboi and coworkers,[31–33] White and Verkade,[34] and Hall and Malcolm[35] from the spectral studies of some molecules containing the H–C–O–PO_2^- system. This gives another support to the use of the $^3J_{HP}$–ϕ_{HP} relationship to structural studies of dinucleoside monophosphates.[36]

Conclusion

The lanthanide-ion probe method is useful for determining the conformation of the phosphate ring of thymidine 3',5'-cyclic phosphate. The resultant phosphate ring conformation is compatible with what is expected from the vicinal ^1H–^1H and ^1H–^{31}P coupling constant. The direction of the symmetry axis of magnetic susceptibility tensor virtually coincides with the bisector of the OPO angle. If two ^1H–^1H coupling constants $J_{1'2'}$ and $J_{1'2''}$ are used in the conformation search to supplement the shift and relaxation data, a reasonable conformation of the entire molecule (Conformation B depicted in Fig. 3) is obtained.

Appendix

Conformation search based on the shift and relaxation ratios requires a considerable amount of computation when the molecule under study has many degrees of internal freedom, *e.g.*, the internal rotation around a single bond and the puckering of a ring. Although the outlines of computer programs developed by other workers have been published,[6,9,28] it would be still worth while to describe the main procedure of our program which we believe has some unique aspects.

Our program consists of two parts, namely, PCS-I and PCS-II. PCS-I is used to compute internal coordinates from atomic coordinates when the latter data are available from a crystallographic analysis. The bond length, bond angle, internal-rotation (torsional) angle, and ring-puckering angle are adopted as internal coordinates. As described in the text, the latter two angles are defined in accord with the IUPAC-IUB conventions. The internal coordinates thus obtained are used as an initial set of parameters for the conformation search by PCS-II. If no crystal data are available, an initial set of internal coordinates is assumed appropriately by referring to the data of analogous molecules.

PCS-II has the functions of computing (1) the space-fixed Cartesian coordinates of atoms from the internal coordinates (the reversal of the process carried out by PCS-I), (2) the shift and relaxation ratios using the McConnel-Robertson equation and the first term in the Solomon-Bloembergen equation, respectively, and (3) the agreement factor (R). It is also possible to calculate the spin-coupling constants from the Karplus equation (or its modification) and to include the spin-coupling terms in the agreement factor. PSC-II is also used to minimize the R value by varying the internal coordinates. This is performed in the following manner.

(a) According to user's instructions the internal coordinates are divided into two groups, variable and invariable. The former usually includes the position of the lanthanide ion and the direction of the principal axis of magnetic susceptibility tensor in addition to internal-rotation and ring-puckering angles. Bond lengths are almost always invariable (fixed to the initial values), and bond angles are varied only in some special cases.

(b) The R values are computed for the conformation with the initial set of variable parameters (ϕ_1^0, ϕ_2^0, ···, and ϕ_n^0) and the $2n$ conformations with the new sets ($\phi_1^0 \pm h_1$, ϕ_2^0, ···, and ϕ_n^0), ···, and (ϕ_1^0, ϕ_2^0, ···, and $\phi_n^0 \pm h_n$). Here, h_1, h_2, ···, and h_n are the variable increments which should be set appropriately by the user. If the smallest one among the R values for the new conformations is smaller than that for the initial conformation, the initial set is replaced by the set corresponding to the smallest. The same process is repeated until no further variations of internal coordinates reduce the R value. In order to gain fast convergence it is advantageous to use large h_i values in the first

search and to make h_i values smaller and smaller in the subsequent searches. This can be performed either automatically or stepwise at user's option.

Recently we extended PCS-II to treat the flexible molecules which exist in two or more conformers with various populations. The application of such a function of PCS-II will be reported separately.

Optical Activity of Biphenyl Derivatives: The π-π^* and n-π^* Transitions of *o,o'*-Dinitrobiphenyls

Ichiro HANAZAKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received October 20, 1975)

The optical rotatory power for the lower electronic transitions of several *o,o'*-dinitrobiphenyl derivatives is examined on the basis of a theoretical method previously developed and applied to metal chelate compounds and binaphthyl derivatives. The theoretical energy, absorption intensity, and rotational strength are shown to be in reasonable agreement with the observed absorption and circular dichroism spectra, confirming the applicability of the theory to the optical activity of this simple type of dissymmetric molecules. In addition, the origin of the rotational strength for the n-π^* transition is examined in detail. The results indicate that the n-π^* transition gains its intensity and rotatory power through the interaction of the nonbonding electrons in a nitro group with the π electron system in the other nitrobenzene ring.

The optical rotatory dispersion (ORD) and circular dichroism (CD) of organic compounds and of metal complexes have been a subject of increasing interest in relation to their importance in biology as well as in the fundamental theory of molecular electronic structure. Although the general theory for the phenomenon has been established,[1-3] a more extensive study of the electronic origin of the optical activity for each optically active molecule seems to be necessary. It is also desirable to examine in more detail the reliability of the approximations employed in the calculation of the optical activity.

Some years ago, we first tried to use semiempirical electronic wave functions in the calculation of the rotatory strength accompanying the lower electronic transitions in transition-metal chelate compounds and in some binaphthyl derivatives.[4,5] For these two typical types of optically active molecules, the method was revealed to be satisfactory in explaining the observed CD spectra. It was also noticed that the method is capable of treating the rotational strength fully for the "charge-transfer" transition between two chromophors, as well as for the "locally excited" transition in each chromophor, which may be related to the well-known polarizability theory of Kirkwood.[6]

Recently, the optical activity of the biphenyl derivatives, one of the simplest optically active molecules, has been studied in our laboratory in order to clarify the origin of the interaction responsible for the optical activity and in order to examine the applicability of the theoretical method more extensively. Two difficulties have been found in the case of weakly substituted biphenyls (*e.g.*, alkyl- or halogeno-substituted ones); one of them is the vibrationally enhanced electric and magnetic transition moments, which seem to be responsible predominantly for some CD bands. The other is the interaction between the σ and π electrons in a benzene chromophor induced through the interaction with the other. In view of these results, it seems to be desirable to study a biphenyl compound with a strong substituent, for which the above-mentioned effects do not contribute predominantly to the rotational strength.

In the present paper, a theoretical study is presented for *o,o'*-dinitrobiphenyl, and the results are compared with the experimental CD spectra of its derivatives.[7] It is also interesting to study the origin of the CD band accompanying the n-π^* transition since, in this type of compounds, it is not clear whether the n-π^* transition gains its intensity through the vibronic interactions, as in the case of nitrobenzene, or through a purely electronic interaction.

Method of Calculation

The π-π Interaction. Details of the theoretical treatment were given in previous papers.[4,5] Here we will give only an outline of the method and some parameter values characteristic of the compound studied.

The electronic structure of the π electron system of nitrobenzene is calculated by means of the Pariser-Parr-Pople SCFCI method[8] for the geometry given by Trotter.[9] Since there are some ambiguities in the choice of parameter values concerning the nitro group, several choices of the core resonance integrals between nitrogen and oxygen and between nitrogen and carbon are examined in order to determine the best values (see Results and Discussion). The wave functions are then used in the composite-molecule calculation[10] of *o,o'*-dinitrobiphenyl with various dihedral angles (θ). The geometry and coordinate system employed are shown in Figs. 1 and 2. The core resonance integral over the 2pπ AO's (atomic orbitals), $\chi_1{}^a$ and $\chi_1{}^b$ is expressed as a function of θ:

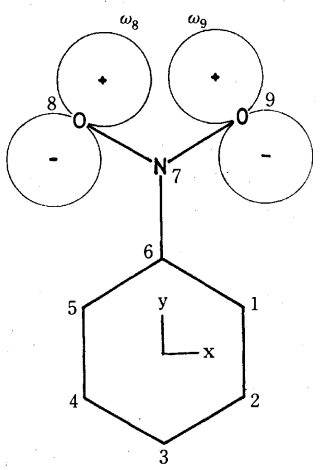

Fig. 1. Numbering of atomic orbitals in nitrobenzene.

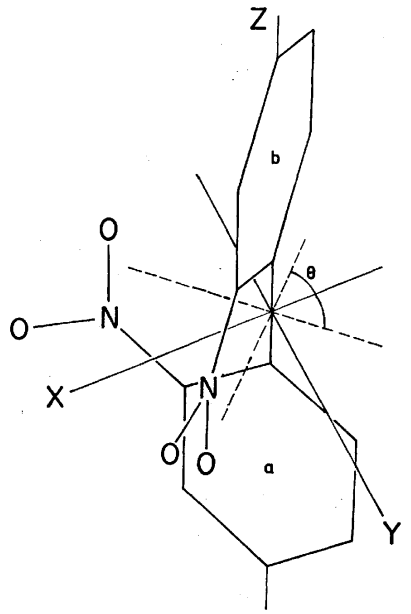

Fig. 2. Numbering and coordinate system for *S-o,o'*-dinitrobiphenyl.

$$\beta(\chi_1^a, \chi_1^b) = -\beta_0 \cos\theta \quad (1)$$

Assuming 1.50 Å for the distance between atoms 1a and 1b, β_0 is calculated to be -1.99 eV by means of its proportionality to the benzene value.[8]

The composite-molecule calculation is performed with 14 LE(locally excited) electron configurations in the electron system of each nitrobenzene fragment and 24 CT (charge transfer) configurations between two π electron systems. The effect of the σ electron in each fragment is neglected.[11]

The rotational strength[1,2] for the n-th excited state is given by the following formula:

$$R_{0-n} = -1.187\times 10^{2}\bar{\nu}^{-1}\langle 0|\boldsymbol{\nabla}|n\rangle\cdot\langle n|\boldsymbol{\lambda}|0\rangle \ (\text{Å}^2) \quad (2)$$

assuming real wave functions. Here, $\boldsymbol{\lambda}=\mathbf{r}\times\boldsymbol{\nabla}$, and the gradient, $\boldsymbol{\nabla}$ and the excitation energy, $\bar{\nu}$, are expressed in units of Å^{-1} and cm^{-1} respectively. The integrals, $\langle 0|\boldsymbol{\nabla}|n\rangle$ and $\langle n|\boldsymbol{\lambda}|0\rangle$, are reduced to the integrals over AO's (only the nearest neighbour integrals are retained), the latter being evaluated for nitrobenzene to be[12]:

$$\nabla_{CC} = -0.417,\ \nabla_{CN} = -0.314 \text{ and}$$
$$\nabla_{NO} = -0.412\ (\text{Å}^{-1}) \quad (3)$$

The integral of $\boldsymbol{\lambda}$ over AO's χ_p and χ_q can also be expressed by ∇_{pq}:

$$\begin{aligned}\langle p|\boldsymbol{\lambda}|q\rangle &= \langle\chi_p|\mathbf{r}\times\boldsymbol{\nabla}|\chi_q\rangle \\ &= \langle\chi_p|\mathbf{R}_q\times\boldsymbol{\nabla}|\chi_q\rangle + \langle\chi_p|\mathbf{r}_q\times\boldsymbol{\nabla}|\chi_q\rangle \\ &= \mathbf{R}_q\times\langle\chi_q|\boldsymbol{\nabla}|\chi_p\rangle \\ &= \nabla_{pq}\cdot(\mathbf{R}_q\times\boldsymbol{\sigma}_{pq}) \end{aligned} \quad (4)$$

where $\mathbf{r}$ and $\mathbf{r}_q$ are the position vectors of an electron measured from a common origin, O, and atom q respectively. $\mathbf{R}_q$ is a vector directed from O to q.

The integrals between two fragments are expressed as:

$$\langle\chi_1^b|\nabla_z|\chi_1^a\rangle = -\nabla_0\cos\theta,$$
$$\langle\chi_1^b|\lambda_z|\chi_1^a\rangle = S_0\sin\theta \text{ (for } S \text{ configuration)}, \quad (5)$$

where the X and Y components are all vanishing. The quantity ∇_0 is calculated to be -0.359 Å^{-1} by means of the Slater AO.

The n-π Transition.* In the calculation of the rotational strength accompanying the n-π* transition, it is assumed that the non-bonding AO's (ω_8 and ω_9) are the 2p AO's of oxygen lying in the molecular plane and with their axes perpendicular to the N–O bond. They are taken as their positive directions towards one another (Fig. 1). Taking the symmetry orbitals as:

$$\omega_S = \frac{1}{2}(\omega_8+\omega_9)$$
$$\omega_A = \frac{1}{2}(\omega_8-\omega_9), \quad (6)$$

one obtains two n-π* states in nitrobenzene corresponding to the transitions from ω_S and ω_A to the lowest vacant MO(molecular orbital) φ_6. Thus, the following four n-π* wavefunctions can be constructed for dinitrobiphenyl:

$$\Psi_\tau^{\pm} = (2)^{-1/2}(\Psi_\tau^a \pm \Psi_\tau^b) \quad (\tau = \text{S or A})$$

where Ψ_τ^μ corresponds to transition $\omega_\tau\rightarrow\varphi_6$ in the μ-th fragment. The average transition energy for these n-π* transitions is evaluated to be 3.2 eV on the basis of the ionization potential of the oxygen non-bonding AO, the semiempirical two-center repulsions, and the calculated orbital energy of φ_6. This value is in reasonable agreement with the observation (3.6 eV).[13]

The n-π* transitions have an intrinsic (one-center) transition magnetic moment in a direction parallel with the N–O bond. On the basis of ω_S and ω_A, theyare calculated to be:

$$\langle\varphi_6|\lambda_x|\omega_S\rangle = -(3/2)^{1/2}C_{68}$$
$$\langle\varphi_6|\lambda_y|\omega_A\rangle = (2)^{-1/2}C_{68} \quad (7)$$

where the coordinates, x and y, correspond to those in Fig. 1, and where C_{68} is the coefficient of 2pπ AO χ_8 in MO φ_6. The effect of the mixing of the π-π* transition on λ can safely be neglected since the one-center magnetic moment is very large. On the other hand, the n-π* transition may gain ∇ from the π-π* transition. In the present work, it is proposed that the n-π* state gains ∇ through the mixing with the π-π* CT states. In fact, the n-π* state, $\omega_9^a\rightarrow\varphi_6^a$, interacts appreciably with the CT state, $\varphi_i^b\rightarrow\varphi_6^a$, through the resonance interaction between ω_9^a and φ_i^b (i=1, 2,···,5). The

same holds for the interaction between $\omega_9^b \rightarrow \varphi_6^b$ and $\varphi_i^a \rightarrow \varphi_6^b$. The schematic drawing of the interaction is given in Fig. 3. The core resonance integrals between ω_9^a and the $2p\pi$ AO's, χ_1^b, χ_2^b, and χ_6^b, and those between ω_9^b and χ_1^a, χ_2^a and χ_6^a, are evaluated on the basis of their proportionality to the overlap integral and the valence-state ionization potential.[14,15] They are summarized in Table 1 for several dihedral angles. The effects of the mixing are calculated by the first-order perturbation treatment.

Results and Discussion

Nitrobenzene. The transition energies and oscillator strengths for some lower electronic transitions of nitrobenzene calculated by means of the SCFCI method are given in Table 2, together with the observed values obtained by Nagakura and his coworkers[16] and by Labhart.[17] The theoretical results given in the table are calculated with $\beta_{CN}=-2.4$ and $\beta_{NO}=-2.7$ eV, which seem to give a reasonable agreement with the experimental results. It should be noted that the oscillator strength for nitrobenzene shown in Table 2 is calculated on the basis of the transition dipole moment:

$$f_m = 1.085\times 10^{-5}\bar{\nu}|\langle 0|\mathbf{r}|n\rangle|^2 \quad (8)$$

whereas the f value for the dinitrobiphenyls given below (Tables 4, 5, and 6) is calculated by means of the dipole velocity:

$$f_v = 4.16\times 10^{4}\bar{\nu}^{-1}|\langle 0|\boldsymbol{\nabla}|n\rangle|^2 \quad (9)$$

It has been pointed out that f_m generally gives a considerably larger value, whereas f_v gives a favorable agreement with the experimental results.[18] In view of this, the present result for nitrobenzene is fairly satisfactory.

o,o'-Dinitrobiphenyl (Type I). There are two types of *o,o'*-dinitrobiphenyl derivatives for which the CD spectra have been measured by Mislow *et al.*;[7] one has a bridge between the 2 and 2′ positions (Type I), and the other has substituents at the 2 and 2′ positions (Type II). The compounds for which the CD measurement was made are summarized in Table 3. The dihedral angle for the latter compounds is not known and may fluctuate around a stable position. On the other hand, the former compounds have a well-defined dihedral angle. It seems reasonable to take $\theta\approx 60°$ for the compounds studied here.[19]

Table 3. *o,o'*-Dinitrobiphenyls

Type	Compound	X
I	Ia	$=C(COOC_2H_5)_2$
	Ib	=CHOH
	Ic	$=N^+\cdot Br^-$
II	IIa	CH_3
	IIb	CH_2Br
	IIc	CH_2OH
	IId	COOH
	IIe	$COOCH_3$

The calculated results for the *S*-isomer with $\theta=60°$ are summarized in Table 4, together with the CD and absorption spectra observed by Mislow *et al.* for Ia. Since the methylene bridge is expected to work as a very weak substituent, the experimental results for this compound can be compared with the theoretical results in which the effect of bridge is not taken into account. This conclusion is also supported by the fact that the CD spectra for the related compounds with different X are almost the same in their shape, indicating that the rotational strength is predominantly determined by the nitrobenzene groups and their relative orientation.

Except for the n-π^* transition, which will be discussed below, the characteristic features of the CD spectrum seem to be explained by the present calculation—that is, a positive Cotton effect around 35000 cm^{-1} and a stronger negative one in the higher-energy region. The experimental rotational strength for the latter is -2.7×10^{-4} (Å^2), whereas the calculated one is -5.62×10^{-4} (Å^2). The calculated rotational strength for the lower-energy transition is correct in its sign. It is, however, too large compared with the corresponding CD band, although the mixing with the n-π^* transition reduces the theoretical rotational strength to some extent (see below). One reason for this inconsistency may lie in the fact that the nitro group twists to some extent. The first LE state in nitrobenzene is of a CT character (benzene to the nitro group). The first three calculated rotational strengths for dinitrobiphenyl, which have the LE_1 state as main components, are sensitive to the twist. In fact, the X-ray crystal analysis of nitromesitylene[20] shows that the nitro group twists by 66° from the

benzene plane. The angle of twist must be much smaller in the present case, since the steric hindrance due to the *ortho* substituent (in the present case, a phenyl group) is expected to be much weaker than that for nitromesitylene.

Another point to be discussed here is the origin of the peak at 43500 cm^{-1} in the absorption spectrum. The band is very intense ($f\approx0.6$) if it is considered as a single transition. The strong transitions predicted to appear between 47000—50000 cm^{-1} are unlikely to be responsible for the observed peak; they are mainly composed of LE_3, LE_4, and LE_5 in nitrobenzene (see Table 2), the calculated energies of which are somewhat lower than the observed one. Since we have calculated the electronic structure of dinitrobiphenyl on the basis of the calculated energies for nitrobenzene, the predicted energies (47000—49000 cm^{-1}) for the LE transitions must be somewhat lower than the actual energies. The most reasonable interpretation is that the peak is due to the CT transition predicted to appear at 43910 cm^{-1} overlapping on the tail of the strong absorption bands in the higher-energy region. It is desirable to extend the absorption and (especially) CD measurements to a higher-energy region in order to clarify this point.

o,o'-Dinitrobiphenyl (Type II). The calculated results for the (*S*)-*o,o'*-dinitrobiphenyl with $\theta=91°$ are summarized in Table 5, together with the observed results[7] for (*S*)-2,2'-dimethyl-6,6'-dinitrobiphenyl (IIa). Again, the lowest CD band at 29000 cm^{-1} is the n-π^*

transition, and the remaining two CD bands with opposite signs are qualitatively consistent with the theoretical third and fourth transitions, which are of an LE_2 character. The sum of the theoretical oscillator strengths for the first four transitions ($f \approx 0.38$) is also in reasonable agreement with the observed one ($f \approx 0.3$). However, the magnitude of the two CD bands ($R = -1.00 \times 10^{-3}$ and 7.25×10^{-4} Å^2) are too large compared with the corresponding observed CD bands ($R \approx -4.4 \times 10^{-5}$ and 3.8×10^{-5} Å^2 respectively). In view of the agreement between the theoretical and experimental f values, the most probable reason for this discrepancy is the mutual cancellation of the positive and negative CD bands. The effect of the cancellation should be remarkable for the dihedral angle of ~90°, since the energy separation becomes smaller. This viewpoint may also be supported by the fact that the rotational strength of the n-π^* transition, in which the algebraic sum of R's for four transitions is responsible for the observed single peak, is in reasonable agreement with the observation (see below).

The n-π^* Transition. Before discussing the rotational strength of the n-π^* transition, it is necessary to consider the splitting of the n-π^* excited states. McEwen[21] has calculated the n-π^* states of nitromethane by taking account of the interaction of two nonbonding AO's (ω_8 and ω_9) with the nitrogen σ AO's. The results show that the orbital energy of ω_S is higher than that of ω_A by about 400 cm^{-1}. The result of configuration interaction predicts that the n-π^* state in which an electron has been removed from ω_S will lie at an energy lower by 1200 cm^{-1}. In view of these results, it may be reasonable to assume that the energies of these n-π^* transitions are very close to each other. The remarkable asymmetry observed by Labhart[17] for the n-π^* band of nitrobenzene may be taken as an indication of the overlapping of these two bands.[22] The splitting into the Ψ_τ^+ and Ψ_τ^- states (τ=S or A) in dinitrobiphenyls is very small and can safely be neglected for the present purposes.

The rotational strengths and oscillator strengths for the n-π^* transitions are summarized in Table 6 for several dihedral angles. In view of the calculated R values for four n-π^* transitions, the observed single CD band is predominantly accounted for by the transition to Ψ_S^-, while those to Ψ_A^+ and Ψ_A^- must give small negative contributions on the longer-wavelength tail of the spectrum. The calculated total rotational strength for $\theta = 60°$ is 2.85×10^{-4} Å^2, which is in reasonable agreement with the observation, 1.8×10^{-4} Å^2, given in Table 4.

Table 6. Calculated results for the n-π^* transitions of (*S*)-*o*,*o*'-dinitrobiphenyl

	n-π^* State	θ (deg.)[a] 60	80	91	100

	total	16.2	2.3	0.03	4.1

a) Dihedral angle. b) Rotational strength. c) Oscillator strength calculated from Eq. (9).

The calculated total oscillator strength for $\theta = 60°$ is 0.016. Comparing this value with that of nitrobenzene ($f \approx 0.004$[17]; presumably of vibronic origin), one can conclude that the present mechanism of the interaction between the nonbonding AO and the π electron system determines predominantly the intensity of the n-π^* transition for this compound, although the vibronic intensity borrowing may give rise to an additional effect. Unfortunately, the n-π^* band is much weaker than the nearby π-π^* transitions and cannot be observed as distinct peaks in the absorption spectrum. However, the very long tail on the longer-wavelength side of the absorption spectrum of Ia can be taken as an indication of the overlapping of absorption bands with $\varepsilon \approx 10^3$, which is in order-of-magnitude agreement with the calculated intensity (f=0.016).

The observed n-π^* rotational strength for Compound IIa is -7.9×10^{-6} Å^2. If one supposes that the observation corresponds to a pure optical isomer, this result indicates that the dihedral angle for this compound is only slightly larger than 90°. In fact, the calculated result, $R = -1.3 \times 10^{-5}$ Å^2 for $\theta = 91°$, is in reasonable agreement with the observation.[23] This conclusion is also consistent with the above discussion of the π-π^* transition bands.

In view of these results, it can be concluded that the rotational strength and oscillator strength for the n-π^* transition are due to direct interaction between the non-bonding AO of the nitro group and the π electrons in the adjacent benzene ring.

The rotational strength of the π-π^* type transition is also affected by the interaction with the n-π^* states. This is caused by the mixing of the intrinsic transition magnetic moment of the n-π^* transition into the π-π^* transition. For instance, the rotational strengths for the first, third, and fifth transitions for Compound Ia change from 3.82, 3.37, and 0.49×10^{-4} Å^2 to 1.93, 4.20, and -0.19×10^{-4} Å^2 respectively, while the second and fourth transitions remain unchanged. This brings the theoretical results in Table 4 into better agreement with the observed CD spectrum, although the effect of the twisting of nitro groups mentioned above may also be responsible.

The unoccupied orbitals, φ_7 and φ_8, of nitrobenzene lie at higher energies than φ_6 by 1.82 and 2.35 eV respectively. Hence, the second and third n-π^* transitions to these π^* orbitals may appear in the 45000—50000 cm^{-1} region. Although, in the present treatment, we focus on the lowest n-π^* transition at 30000 cm^{-1}, these higher n-π^* transitions may have some effect on the calculated rotational strengths.

Related Compounds. The CD spectra of two additional compounds of Type I (Ib and Ic) have been recorded by Mislow *et al.*[7] Their spectra resemble that of Ia quite well, so their electronic structures can

be regarded as almost the same as that of Ia. The result also indicates that the substituent on the bridge does not bring about any significant effect on the optical activity. Among the Type II compounds (IIb—IIe), IIb and IIc show CD spectra similar to that of IIa, while a remarkable deformation is observed for IId and IIe. The latter is undoubtedly due to the strong substituent effect of carboxyl groups at the 2 and 2′ positions. Finally, the present theoretical results for the *S* configuration are consistent with the observed CD spectra for the optical isomers, determined to have the same absolute configuration on the basis of the chemical correlation.[7,24] This confirms the reliability of the present theoretical treatment in determining the absolute configuration in this type of compound.

21) K. L. McEwen, *J. Chem. Phys.*, **32**, 1801 (1960).
22) On the other hand, a recent photoelectron study [T. Kobayashi and S. Nagakura, *Chem. Lett.*, **1972**, 903; *Bull. Chem. Soc. Jpn.*, **47**, 2563 (1974)] shows that the third peak at 11.01 eV for nitrobenzene corresponds to the ionization from ω_S, whereas the energy of the ionization from ω_A is not lower than 12.65 eV Since the splitting between the n-π^* excited states is not the same as that between the non-bonding orbitals, this result cannot be taken as definite evidence for a large separation between the n-π^* states. Even if the splitting is large, our conclusion will not be altered essentially, since the main contribution to the rotational strength arises from Ψ_S^-, one of the lower n-π^* states.
23) Since two benzene rings are not fixed in this compounds, the dihedral angle may fluctuate over a considerably wide range. The estimated value of θ corresponds to a weighted mean value.
24) When the actual spectrum is shown for the *R* optical isomer, the same spectrum with a reversed sign is taken for the *S* isomer.

Hydration of Pyridine Bases in Benzene

Katsumi HIROSE and Motoharu TANAKA*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Nagoya 464

(Received October 30, 1975)

Hydration of pyridine bases in benzene has been studied by partition at 25 °C, the total concentration of pyridine bases being less than 1.0 M in benzene. The studied pyridine bases include pyridine, 2-methylpyridine, 4-methylpyridine, 2,6-dimethylpyridine, 3,5-dimethylpyridine, 2,4,6-trimethylpyridine, 2-chloropyridine, 2-bromopyridine, 3-bromopyridine and 2,6-dibromopyridine. Hydrated species with different composition are formed: the composition of the hydrated species (base to water ratio) is as follows: (1:2) for 2,6-dibromopyridine, (1:1) and (1:2) for 2-chloro- and 2-bromopyridine, (1:1) and (2:1) for 3-bromopyridine, (1:1), (1:2) and (2:1) for 4-methylpyridine and pyridine itself, and (1:1), (1:2), (2:1) and (2:2) or (2:3) for the other methyl derivatives. A linear free energy relationship has been observed between the hydration in benzene for the monomer monohydrate and the protonation in water of the corresponding base.

There have been numerous investigations on the hydrogen-bonded complex of polar organic compounds in nonpolar solvents. Studies on hydration are of importance among them because of the unique ability of water to act as a bridge binding two base molecules. Christian *et al.* have studied the hydration of various organic compounds in nonpolar solvents[1–4] and reviewed on the interaction of polar solutes with water.[5]

In order to study in detail the extraction mechanism, it should be important to determine the hydration equilibrium of extractants and/or synergists in the organic solvents. A study along this line has been carried out by Li *et al.*,[6] who determined the hydration of TBP in the organic solvent. In many cases, however, little attention has been paid to the hydration of extractants and synergists in the organic solvents.

Among various organic bases the hydration of pyridine in nonpolar solvents has been extensively studied by infrared spectroscopy and partition technique.[7–10] An analysis of pyridine water hydrogen-bonded system using Hückel theory has been published recently by Adam *et al.*[11] In the present paper, we shall describe the hydration of several pyridine bases with special reference to the effect of substituents.

Experimental

Materials. All pyridine bases, *i.e.* pyridine, 2-methylpyridine, 4-methylpyridine, 2,6-dimethylpyridine, 3,5-dimethylpyridine, 2,4,6-trimethylpyridine 2-chloropyridine, 2-bromopyridine, 3-bromopyridine and 2,6-dibromopyridine, were of G. R. grade. Pyridine bases except for 2,6-dibromopyridine were purified by distilling and by collecting a fraction distilled at constant temperature. 2,6-Dibromopyridine was purified by twice recrystallization in alcohol. Benzene (G. R.) washed successively with sodium hydroxide, sulfuric acid and water was finally distilled. Calcium chloride of G. R. grade was purified by recrystallization.

Procedure. The method of Christian *et al.*[12] was used for equilibrating the organic phase with solutions of known water activity. 50 ml Centrifuge tubes were utilized for the partition. Equilibrium is known to be reached within less than 12 h.[12] The water activity was controlled by $CaCl_2$–H_2O mixtures of known water activity.[13] It was confirmed that no calcium ion was extracted in the organic phase: 15 ml of 1 M solution of a pyridine base in benzene was equilibrated with the same volume of 5.5 M aqueous calcium chloride. The organic phase was separated and then shaken with 10 ml of distilled water, in which we were not able to detect calcium ion with 3,3′-bis[*N*,*N*-di(carboxymethyl)aminomethyl]-*o*-cresolphthalein. The partition was carried out at 25±0.1 °C. After standing for at least 24 h for complete phase separation, the total concentration of water in the organic phase was determined by the Karl-Fischer method with the Coulometric generation of iodine. The method allows to determine the water content with an error of less than 1%. The total concentration of pyridine base in the organic phase was determined by the colorimetry for the halogen derivatives of pyridine, while for the other pyridine bases it was determined by the acid-base titration in glacial acetic acid with Crystal Violet as an indicator.

Results and Discussion

Equilibrium Treatment. Hydrates of pyridine base, $B_m(H_2O)_n$, being assumed to be formed in benzene, the hydration equilibrium of a pyridine base B is written as follows:

$$mB_o + n(H_2O)_o \rightleftarrows (B_m(H_2O)_n)_o \qquad (1)$$

where the subscript o denotes the organic phase. Under the experimental conditions, Henry's law is assumed to be valid for both hydrated and non-hydrated species. The vapor pressure measurement has revealed the ideal behavior of non-hydrated pyridine and 2-methylpyridine in benzene at least up to 0.1 mole fraction (1 M).[14] The concentration equilibrium constant, $\beta_{m,n}$, for hydrated species $(B_m(H_2O)_n)_o$ remains constant.

$$\beta_{m,n} = [B_m(H_2O)_n]_o/[B]_o^m[H_2O]_o^n \qquad (2)$$

Water in the organic solvent may be present as monomeric and/or polymeric species, such as dimer, trimer and so on.[15–18] It is known, however, that only monomeric water is present in benzene. Therefore, the partition equilibrium of water is given as follows:

$$(H_2O)_w \rightleftarrows (H_2O)_o$$

$$K_{D,H_2O} = [H_2O]_o/a_w$$

where a_w is the activity of water in the aqueous phase and the subscript w denotes the aqueous phase.

When a pyridine base is partitioned between the aqueous and organic phases, the total concentration

* To whom correspondence should be addressed.

of the pyridine base in the organic phase, $C_{B,o}$, is given as follows:

$$C_{B,o} = \sum_{m=0} \sum_{n=1} m[B_m(H_2O)_n]_o \quad (3)$$

Since the increase in the formal solubility of water in the presence of the pyridine base in the organic phase at a given water activity is due to the formation of hydrated pyridine bases, the total concentration of water in the organic phase, $C_{H_2O,o}$, is given as follows:

$$C_{H_2O,o} = \sum_{m=0} \sum_{n=1} n[B_m(H_2O)_n]_o \quad (4)$$

The composition of the hydrated species and the hydration equilibrium are determined on the basis of Eqs. (2), (3), and (4).

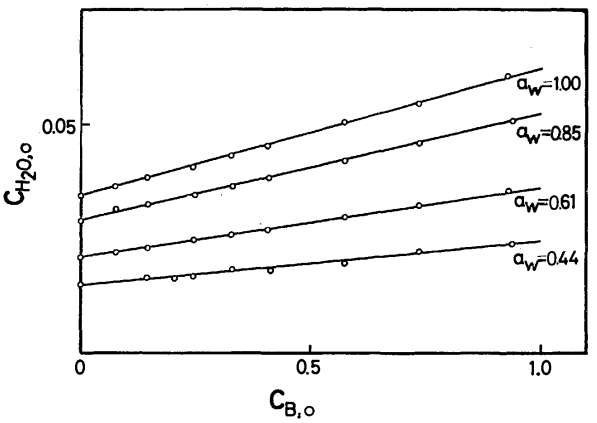

Fig. 1. The total concentration of water as a function of the total concentration of pyridine base in benzene for 2-bromopyridine. Curves are calculated with the constants given in Table 1.

Determination of the Composition of the Hydrated Species. In order to determine the composition of the hydrated species, the total concentration of water, $C_{H_2O,o}$, was plotted against the total concentration of pyridine base $C_{B,o}$ at various water activities. The result for 2-bromopyridine is shown in Fig. 1 as an example. Similar plots were obtained for 2-chloropyridine and 2,6-dibromopyridine. The linear relationship between $C_{B,o}$ and $C_{H_2O,o}$ points to the fact that the hydrated species are monomeric in the organic phase. Then the following expression is obtained from Eqs. (2), (3), and (4).

$$C_{H_2O,o} = (\sum_{n=1} n\beta_{1,n}[H_2O]_o^n)(1+\sum_{n=1} \beta_{1,n}[H_2O]_o^n)^{-1}C_{B,o} + [H_2O]_o \quad (5)$$

The composition of the hydrated species is determined from the relation between the water concentration in benzene and the slope of the plot of $C_{B,o}$ *vs.* $C_{H_2O,o}$. Monomer monohydrate and monomer dihydrate are both present in benzene for 2-chloropyridine and 2-bromopyridine, while monomer monohydrate was hardly detected for 2,6-dibromopyridine, that is, $\beta_{1,1}<0.1$. The hydration constants thus obtained are given in Table 1. The plot of $C_{H_2O,o}$ against $C_{B,o}$ for pyridine is different from these halogen derivatives as shown in Fig. 2. Similar plots were obtained for the other pyridine bases. Non-linearity of the plot points to the presence of the hydrated species involving

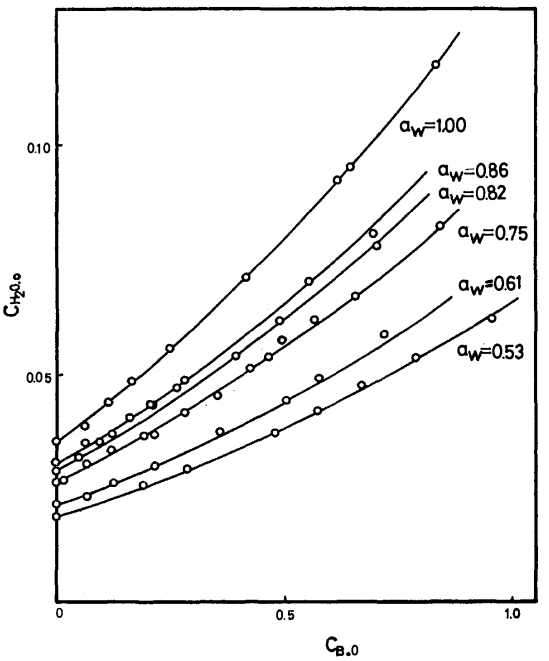

Fig. 2. The total concentration of water as a function of the total concentration of pyridine base in benzene for pyridine. Curves are calculated with the constants given in Table 1.

more than one molecule of pyridine base in benzene for 3-bromopyridine, pyridine and its methyl derivatives. If the number of pyridines involved in the hydrated species is two or less, the total concentration of the pyridine base is given by Eq. (6) and the increment of water in the organic phase due to the presence of the pyridine base, $\Delta C_{H_2O,o}$, is given by Eq. (7).

$$C_{B,o} = \alpha_1[B]_o + \alpha_2[B]_o^2 \quad (6)$$

$$\Delta C_{H_2O,o} = \alpha_3[B]_o + \alpha_4[B]_o^2 \quad (7)$$

with

$$\alpha_1 = 1 + \sum_{n=1} \beta_{1,n}[H_2O]_o^n$$

$$\alpha_2 = \sum_{n=1} 2\beta_{2,n}[H_2O]_o^n$$

$$\alpha_3 = \sum_{n=1} n\beta_{1,n}[H_2O]_o^n$$

$$\alpha_4 = \sum_{n=1} n\beta_{2,n}[H_2O]_o^n$$

where $\Delta C_{H_2O,o}=C_{H_2O,o}-[H_2O]_o$, and α_1, α_2, α_3 and α_4 are constant when the activity of water is kept constant. The composition of hydrated species and these hydration constants are determined from Eqs. (6) and (7). This calculation was carried out on a computer, FACOM 230-60, by use of the least squares method. The result is given in Table 1. For 3-bromopyridine we have monomer monohydrate and dimer monohydrate, although we have hardly detected monomer dihydrate. For pyridine and 4-methylpyridine we have monomer monohydrate, dimer monohydrate and monomer dihydrate, while for the other methyl derivatives we should take into account dimer dihydrate or dimer trihydrate in addition. Thus the following equilibria are relevant to the hydration of pyridine bases in benzene:

$$B_o + (H_2O)_o \rightleftarrows (BH_2O)_o$$

$$B_o + 2(H_2O)_o \rightleftarrows (B(H_2O)_2)_o$$

a) Standard deviation. b) Ref. 10. c) Dimer dihydrate and dimer trihydrate interpret the experimental results equally well.

$$2B_o + (H_2O)_o \rightleftarrows (B_2(H_2O))_o$$
$$2B_o + n(H_2O)_o \rightleftarrows (B_2(H_2O)_n)_o$$
$$n = 2 \text{ or } 3$$

The hydrated species obtained for pyridine are in accord with the results reported by Christian *et al.*[10] except for monomer trihydrate which was not found in our case. The presence of the monomer monohydrate and dimer monohydrate are consistent with the results by the infrared spectroscopy for pyridine.[7-9] On the basis of our results and others, the fundamental types of the hydrated organic base are the monomer monohydrate B···H–O–H and thedime r monohydrate B···H–O–H···B in a nonpolar solvent as pointed out by Josien[19] when any specific effect such as steric hindrance is not present. Monomer dihydrate and dimer monohydrate are formed as a result of a competition of water with pyridine base for the monomer monohydrate.

For the *o*-halogen derivatives of pyridine, dimer monohydrate cannot be detected under the experimental conditions, and the sequence of the hydration constant for monomer dihydrate is not parallel with the basicity of pyridine bases. Very low basicity and the steric effect of the *o*-halogen should prevent the formation of dimer monohydrate, whereas the hydogen-bond formation with *o*-halogen favors the formation of monomer dihydrate.

The hydration of pyridine bases is considered as an acid-base reaction in benzene. Recently the formation of molecular complexes involving phenol, alcohol, and so on, in inert solvents has been reported.[20-22] The formation constant of the hydrogen-bonded complex is linearly related with the basicity of bases involved. In Fig. 3 the hydration constant $\beta_{1,1}$ for monomer monohydrate is plotted against pK_a of corresponding pyridinium. This figure includes the plot of the hydration constant of triethylamine in benzene.[4] The correlation is obviously good: the stronger the base, the more extensive the hydration. The following two Hammett equations (8) and (9) may be written[23] for the hydration of pyridines in benzene and the dissociation of pyridinium ion in water, respectively:

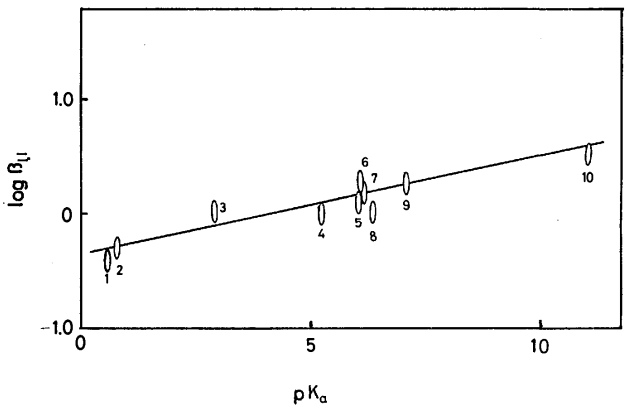

Fig. 3. Correlation of hydration constant $\beta_{1,1}$ with the basicity. 1) 2-chloropyridine, 2) 2-bromopyridine, 3) 3-bromopyridine, 4) pyridine, 5) 4-methylpyridine, 6) 2-methylpyridine, 7) 3,5-dimethylpyridine, 8) 2,6-dimethylpyridine, 9) 2,4,6-trimethylpyridine, 10) triethylamine. Data of pK_a's taken from Refs. 24 and 25.

$$\log \beta_{1,1} = \log \beta^\circ_{1,1} + \rho\Sigma\sigma_x \quad (8)$$
$$pK_a = pK_a^\circ + \rho'\Sigma\sigma_x \quad (9)$$

where $\beta_{1,1}$ and $\beta^\circ_{1,1}$ refer to the formation constants of the 1:1 hydrates of substituted and non-substituted pyridines, respectively, pK_a and pK_a° denote the acid dissociation constants of the substituted and non-substituted pyridiniums, respectively. σ_x is the substituent constant for x in pyridines and ρ and ρ' are the reaction constants for the hydration and the acid dissociation, respectively. From Eq. (8) and (9), we have immediately

$$\log \beta_{1,1} = \frac{\rho}{\rho'} pK_a + \text{constant.} \quad (10)$$

This is a linear free energy relationship as shown in Fig. 3. Water, being a very week acid, discriminates the basicity of these pyridines to an extent much smaller than proton does: ρ' is much greater than ρ. Thus the hydration constant is not very sensitive to the basicity as seen from Fig. 3.

Stereochemical Studies of Elimination Reactions of 2-Bromobutane and 2,3-Dibromobutane over Alkali-Ion Exchanged Silica Gels

Makoto Misono, Yukio Aoki, and Yukio Yoneda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 6, 1975)

The stereochemistry (*anti* or *syn* mode) of elimination reactions of 2-bromobutane and 2,3-dibromobutane over alkali-ion exchanged silica gels (Li, Na, K, and Cs) was determined at 100—300 °C from the products of the diastereomeric isomers of each alkyl bromide. They were *erythro*- and *threo*-2-bromobutanes-3-d_1 and *meso*- and *dl*-2,3-dibromobutanes. The steric course of dehydrobromination of 2-bromobutane changed nearly reversibly between *syn* and *anti* mode by the partial exchange of a surface proton with K^+ or Cs^+ ion, although the surface structure seemed to remain unchanged by the exchange procedure. On the other hand, the exchange with Na^+ or Li^+ ion did not change the steric course. Dehydrobromination of 2,3-dibromobutane proceeded by *anti* mode over Na–, K–, and Cs–SiO_2, while SiO_2 and Li–SiO_2 were not active. The poisoning effect of acidic and basic reagents as well as the indicator test revealed that basic sites played important roles over K– and Cs–SiO_2 where *anti* elimination prevailed, and that weakly acidic sites were responsible for *syn* elimination.

Study of the stereochemistry of reactions over solid catalysts is a useful tool for the elucidation of reaction mechanisms and for the characterization of surface active sites. The knowledge of the stereochemistry of liquid-phase elimination reactions seems well accumulated.[1,2] However, relatively few studies have been reported for heterogeneous systems. Although various factors such as the steric effect, the timing of bond breakings, and the shape of the transition state have been suggested,[3–7] the problem of what is the essential factor controlling the steric course of a reaction still remains unsettled.

We reported previously that the steric course of dehydrohalogenation of 2-bromobutane over silica gels varied markedly by the alkali-treatment, and proposed a postulate that the prime factor determining the stereochemistry is not the surface geometry but the acid-base properties of both catalyst and reactant in these systems; *syn* elimination prevalied over an acidic surface and *anti* over a basic one, regardless of the wide variation of surface area. This postulate was applicable to other basic solids such as alkaline-earth metal oxides, which are known to be strongly basic and to have substantially different surface structures.[8] We further suggested that the elimination reaction proceeded by a concerted mechanism over a basic surface and *via* a carbonium-ion like intermediate over an acidic surface.

In the present work, we studied the stereochemistry of dehydrobromination over silica gels containing different cations, since the previous results indicated that the cation species played important roles. For example, similar *anti*-selectivity was observed for KOH–SiO_2 and for K_2CO_3–SiO_2.[6] If the surface structure remains unchanged, it is expected that only the role of the acid-base properties of the surface would be important, as we reported preliminarily.[9] The silica gels studied were prepared carefully by means of ion-exchange, so as to keep the surface structure as constant as possible.

The acid-base properties of these silica gels were clarified from the indicator test and the poisoning effect of acidic and basic reagents. The correlations of these properties with the stereochemistry and the reaction mechanism are discussed.

Experimental

Apparatus and Procedure. A conventional pulse technique described previously was utilized.[6] The carrier gas was hydrogen or helium, which was deoxygenated and dried by a "DEOXO" column and a molecular-sieve trap kept at liquid N_2 temperature. Catalysts (100—500 mg) were ordinarily preheated at 300 °C for 1 h in the stream of carrier gas. After they were cooled to the reaction temperature, 1 or 2 μl of alkyl halide was injected into the gas stream with aid of a microsyringe. All the reactants submitted for elimination reactions in this study gave different stereoisomeric products depending on the steric course of reaction (*anti* or *syn*, *cf.* Scheme I). The stereochemistry of each reaction was determined from the product distribution. No isomerization of butenes of 2-bromo-2-butenes took place under the present reaction conditions.

The analysis of products followed the same procedure as before.[6] The deuterium content of each butene isomer was determined by use of a mass spectrometer (Hitachi, RMU-S) after gas chromatographic separation.

Catalysts. Silica gel was prepared from the hydrolysis of tetraethoxysilane, as before.[6] Ordinarily it was used after being calcined at 500 °C for 6 h and washed with dilute HCl aqueous solution and then with water. Alkali-exchanged silica gels, M–SiO_2 (M=Li, Na, K, or Cs), were prepared by soaking SiO_2 three times in an aqueous solution (N/20) of alkali chloride and carbonate (*ca.* 2: 1) with vigorous shaking for several hours each time at room temperature. The initial pH of the solutions was adjusted every time to 8.0 or 10.0 (low or high alkali content, respectively) by the addition of a small amount of hydrochloric acid. They were then washed and dried at 110 °C. Decationized M–SiO_2 was prepared by repeated washing with aqueous HCl solution (pH=4). The alkali ion contents were determined by flame photometry.

Reagents. 2-Bromobutane (C_4Br), 2-bromobutane-3-d_1 and *meso*- and *dl*-2,3-dibromobutanes (C_4Br_2) were prepared and purified as described previously.[6] The purity of 2-bromobutane-3-d_1 was determined more strictly in the present work, as described in the following section.

Results

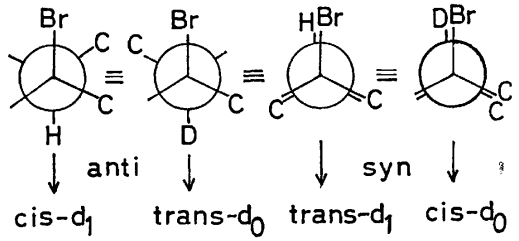
Determination of Diastereoisomeric Purity of 2-Bromobutane-3-d_1. Two kinds of 2-bromobutane-3-d_1 which differed in the compositions of *erythro*-d_1, *threo*-d_1, and d_0 species were prepared from *trans*- and *cis*-2-butene as

described above. The compositions were determined by the following method from the butene compositions and the contents of d_1-species in each butene isomer formed from the stereospecific dehydrobromination in liquid phase. The rates of *trans*- and *cis*-2-butene formation from 2-bromobutane-d_0 can be represented as (*cf.* Refs. 4 and 6)

$$v_t^0 = k_t^a + k_t^s \quad (1)$$

$$v_c^0 = k_c^a + k_c^s \quad (2)$$

normalizing the rate of 1-butene formation to unity. Then, since 1-butene formation is little affected by the deuterium atom at C-3 position, the rates of butene formation from 2-bromobutane-3-d_1 (*erythro*: *threo*: d_0= x: y: $1-x-y$) are, referring to Scheme I,



Scheme 1. Stereochemistry and butenes produced in the dehydrobromination of *erythro*-2-bromobutane-3-d_1.

$$v_t(d_0) = xR_t^a k_t^a + yR_t^s k_t^s + (1-x-y)(k_t^a + k_t^s) \quad (3)$$

$$v_t(d_1) = xr_t k_t^s + yr_t k_t^a \quad (4)$$

$$v_c(d_0) = xR_c^s k_c^s + yR_c^a k_c^a + (1-x-y)(k_c^a + k_c^s) \quad (5)$$

$$v_c(d_1) = xr_c k_c^a + yr_c k_c^s \quad (6)$$

where $v_i(d_m)$ is the relative rate of formation of butene i (*trans* or *cis*) with d_m (m=0, 1), R_i^j and k_i^j are the reciprocals of the primary deuterium isotope effect and the relative rate of formation of butene i by j mode (*anti* or *syn*), and r_i is the reciprocal of the secondary isotope effect for butene i formation. Since the reaction utilized for analysis is known to be 100% *anti* elimination (k_t^s, k_c^s=0),[11] the composition (x and y) of 2-bromobutane-3-d_1 can be determined from these equations. The compositions of butenes and their deuterium contents obtained from the reaction in EtOK–EtOH and KOH–ethylene glycol systems at 70 °C are given in Table 1. The content of d_1 species ($x+y$) was 94%, as seen from the d_1 content of 1-butene and confirmed by NMR. The position of deuterium atom was exclusively at 3-position, as evidenced by the microwave spectroscopic analysis of the 1-butene-d_1 formed.[10] Values of x and y are determined for each system by the method of least squares* using Eqs. (1) to (6) as given in the same table. The butene compositions in the case of the EtOK–EtOH system almost agreed with those in the literature, so that 100% *anti* elimination was reasonably assumed in the calculation (k_t^s=k_c^s=0). The compositions of two bromobutane-3-d_1 (**A** and **B**) are as follows, by taking the average of the values from the two systems.

	erythro	*threo*	d_0	
A	77%	17%	6%	(*erythro* rich)
B	28	66	6	(*threo* rich)

The primary isotope effects ($1/R$) for *trans*- and *cis*-2-butene formations were respectively 3.7 and 4.0 (EtOK–EtOH), and 3.0 and 3.5 (KOH–ethylene glycol).

Dehydrobromination of 2-Bromobutane over Silica Gels. Dehydrobromination of 2-bromobutane over Na– and Li–SiO_2 as well as SiO_2 seemed to proceed catalytically, as indicated by the small change in the rate from the repeated pulses. On the other hand, Cs– and K–SiO_2 showed rapid deactivation, and the reaction seemed stoichiometric at the initial stage, as in KOH–SiO_2.[6] However, catalytic elimination by *anti* mode at a stationary rate was possible also over Cs–SiO_2 in the later stage (Fig. 1). The butene compositions changed little in most cases from pulse to pulse. They were

a) pH of ion exchange. b) See Table 2. c) Butene compositions from 2-bromobutane-d_0 and contents of d_1 species in butenes from 2-bromobutane-3-d_1 (**A**). d) See text. e) Preheated at 400 °C for 1.5 h. f) Reaction temperature was 100 °C. g) Rate and butene composition varied depending on pH of HCl solution used for SiO_2 washing.

determined from the first four pulses. It was ascertained that the conversion increased proportionally to the amount of catalyst, while the butene composition remained constant.

The absence of butene isomerization** and of d_2 species in butenes from 2-bromobutane-3-d_1, together with the agreement of the d_1 content of 1-butene to that of the starting 2-bromobutane-3-d_1, makes possible a reasonable application of Eqs. (1) to (6) for the determination of the stereochemistry. In practice, it was mostly determined only from the reaction of 2-bromobutane-3-d_1 (**A**), with the approximation that *anti*-selectivity is the same for *trans*- and *cis*-2-butene formations, as well as $r=1$ and $R_t=R_c$. These approximations may be rationalized by the results obtained in the cases of SiO_2 and KOH–SiO_2.[6]

The ratio $(trans/cis)_0/(trans/cis)_1$, which is the ratio of the *trans*-/*cis*-2-butene from 2-bromobutane-d_0 to that from 2-bromobutane-3-d_1 (**A**, *erythro* rich), is also a measure of the stereochemistry. This ratio becomes larger than unity for *anti* mode and smaller than unity for *syn* mode, since one of the 2-butene formations decreases substantially by the introduction of deuterium atom at 3-position, owing to the primary isotope effect.[6]

The effect of K exchange is given in Table 2. *Syn* elimination was favored over SiO_2, as reported previously.[6] The favored steric course of the reaction changed to *anti* mode by the partial exchange of surface protons with K^+ ion. When K^+ ion was reexchanged with H^+ by washing with dilute acid, the steric course returned to *syn* mode almost reversibly. During this exchange procedure the surface area changed little (particularly in the $K^+ \rightarrow H^+$ treatment). The same change in the stereochemistry was observed with Cs exchange, as well as the K exchange of SiO_2 calcined at 1000 °C, which had surface area of 100 m^2/g.***

The effect of alkali-ion species is demonstrated by the results given in Table 3. *Syn* elimination was favored over Li– and Na–SiO_2 and *anti* over K– and Cs–SiO_2,

** Besides the absence of reaction of butenes before and after the pulse of 2-bromobutane, it was also confirmed that pentenes pulsed together with 2-bromobutane did not isomerize.

*** SiO_2 calcined at 1000 °C showed appreciable activity after being washed with dilute HCl solution.

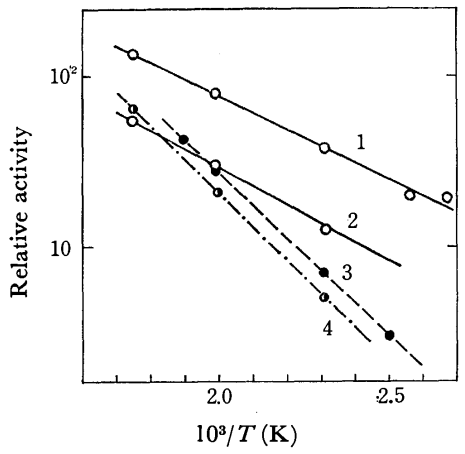

Fig. 2. Arrhenius plots of dehydrobromination of 2-bromobutane over several silica gels.
1. Cs-SiO_2 (*ca.* 0.5 mg-ion/g): E_A=4.4 kcal/mol,
2. Cs-SiO_2 (0.41 mg-ion/g): E_A=4.8 kcal/mol,
3. SiO_2: E_A=8.6 kcal/mol,
4. Li-SiO_2 (0.04 mg-ion/g): E_A=8.7 kcal/mol.

with *anti*-selectivity in the order of Cs>K>Na~Li. It is worthwhile to note that nearly 100% *anti* elimination was observed over the solid surface. The 2-/1-butene ratio was in the order of Cs>K>Na<Li and the *trans/cis* ratio of 2-butene formed increased as Li≦Na<K<Cs.

The dependences of the reaction rates on the reaction temperature are shown in Fig. 2. The predominant steric course did not change for each silica gel at the temperature range studied, as far as judged from the $(trans/cis)_0/(trans/cis)_1$ ratio. The apparent activation energy for Cs-SiO_2 (*anti*) was smaller by about 4 kcal/mol than those for SiO_2 and Li-SiO_2 (*syn*), but the frequency factor for *anti* elimination was about 50 times less favorable.

Dehydrobromination of 2,3-Dibromobutanes over Silica Gels. 2-Bromo-2-butenes formed from dehydrobromination at 2,3-position were the only products over K- and Cs-SiO_2. This reaction proceeded very stereospecifically by *anti* mode; *e.g.*, *meso* isomer produced almost exclusively *cis*-2-bromo-2-butene (Table 4). Over Na-SiO_2, debromination took place besides the dehydrobromination. This debromination proceeded also by *anti* mode. Li-SiO_2 and SiO_2 were almost inactive for the dehydrobromination at this temperature.

a) See Table 2.

Acid-Base Properties of Alkali-Ion Exchanged Silica Gels. The effect of preadsorbed pyridine (a basic reagent which will poison the acidic sites) on the activity was investigated. As the typical results given in Table 5 show, the rate remained unchanged or increased slightly with Cs-SiO_2, while it decreased significantly with Li-SiO_2 and SiO_2. The deactivation by the repeated pulses, which is probably due to HBr (an acidic reagent) formed by the reaction, and, therefore, reflects the basicity of the active sites, was large with Cs- and K-SiO_2, but small with the others. Although these silicas were not as strongly basic as the alkaline-earth oxides nor as strongly acidic as silica alumina, observation of the color changes of indicators (methyl red, bromothymol blue, and cresol red) shows that the acidity increases (or basicity decreases) in agreement with the order of the electronegativity, as Cs<Na<Li (Table 6). The acid strength of silica was comparable with or a little less than Li-SiO_2. Methyl red turned to pink over SiO_2. All of these results demonstrate that the basic sites play important roles over *anti*-prevailing Cs- and K-SiO_2, and the acidic sites over *syn*-prevailing ones.

Table 6. Indicator test of alkali-ion exchanged silica gels[a]

Indicator	Li-SiO_2	Na-SiO_2	Cs-SiO_2
Methyl red	red	yellow	yellow
Bromothymol blue	(bluish) yellow	yellowish blue	blue
Cresol red	yellow (-red)	red	red

a) Ion-exchanged at pH 10. Pretreated at 300 °C for 2 h.

The results of thermogravimetric analysis (TGA) of SiO_2, Li- and Cs-SiO_2 are given in Fig. 3. Prior to TGA analysis, samples were equilibrated with water vapor for 3 days in a desiccator which contained 50% sulfuric acid. The rate of temperature increase was 10 °C/min.

a. Temperature was kept at 600 °C for 1 h.

Discussion

Stereochemistry of Dehydrobromination and Acid-Base Properties. The present results obviously show that a close correspondence exists between the prevailing steric course of dehydrobromination and the acid-base properties of the catalyst surface. In the case of 2-bromobutane, *anti* mode prevailed over basic surface (Cs– and K–SiO_2) and *syn* mode over acidic surface (SiO_2, Na– and Li–SiO_2).

The steric effect or the geometry of the surface must influence the steric course, in the general case. In *anti* elimination, the two leaving groups or atoms must be released from the opposite sides of a reactant molecule. Therefore, the number of active sites and/or the shape of transition state for *anti* mode may be more restricted by geometrical reasons than those for *syn* elimination. The apparent frequency factor of Cs–SiO_2 was actually much smaller than that over SiO_2 or Li–SiO_2, while activation energy was favorable for *anti* elimination. Thus, it may be expected that *anti* elimination is more sensitive to the surface structure. However, as far as the present systems are concerned, the surface structure is not important from the following reasons in addition to those described before.[6,8]

(i) By the exchange of a small portion of surface silanols by K^+ or Cs^+ ion and then by H^+ (SiOH→SiOM→SiOH), the stereochemistry changed reversibly between *syn* and *anti* mode. During this exchange procedure (particularly in the $K^+ \rightarrow H^+$ treatment), the surface seemed to remain unchanged except for the cation species, as indicated by the small change in the surface area.

(ii) A marked effect of the alkali-ion species on the stereochemistry was observed, although it is unlikely that the surface structures were much different among the four alkali-ion exchanged silicas.

It is difficult to clarify the reason why the stereochemistry seems insensitive to the surface structure and how H and Br can be moved onto the surface from the opposite sides of a reactant molecule. Probably the surface of the silica gel is rough and irregular enough in the dimension of a reactant molecule so as to satisfy the geometrical requirements both for *anti* and *syn* elimination. Therefore, either mode can occur depending on the acid-base properties of surface and reactant. Possible explanations are also found in the proposals by Kibby, Lande, and Hall[4] and Knözinger, Bühl, and Kochloefl.[12]

Acidic and Basic Centers Created by Alkali-ion Exchange of Surface Silanols. The results of many investigations by various methods agree in general as regards the density of silanol groups on the silica surface.[13,14] Adsorbed water on silica gel is desorbed by the evacuation at room temperature. Water adsorbed by hydrogen bonding to silanols is also desorbed by the evacuation at as low as 150 °C. The surface density of silanols after evacuation at 150—300 °C is *ca.* 5/100 $Å^2$. Heating at higher temperature causes surface dehydroxylation, and "free" silanols of 1/100—2/100 $Å^2$ remain after evacuation at 600—800 °C. TGA of SiO_2 (Fig. 3) agreed in general with those reported.[14f]

The introduction of alkali ions increased the amount of adsorbed water, which was retained on the surface more tightly, as indicated by the TGA curves in the range of 100—300 °C. However, there was little difference between Cs and Li, if one takes into account the difference in surface area. It has been reported that Na-doped silica retained no water after evacuation at 170 °C, as evidenced by the absence of the combination mode of stretching and bending of water in the IR spectrum.[14e] Therefore, heating at 300 °C probably eliminated almost all of the adsorbed water on the alkali-ion exchanged silica gels. Then it may be irrational to assume the existence of a liquid water phase only on the surface of Cs–SiO_2 for the explanation of the *anti* elimination. In conformity with this, Cs–SiO_2 preheated at 400 °C and 300 °C showed no significant difference in *anti*-selectivity and butene composition (Table 3).

Surface silanol exchanges its proton with alkali ion as

$$\geqslant SiOH + M^+ \rightleftarrows \geqslant SiOM + H^+ \qquad (7)^{15}$$

According to Boehm,[13] the extent of the exchange with Na^+ ion increases with pH and almost 100% exchange is attained at pH 9—10. However, surface siloxane bonds open and silica starts to dissolve at high pH. In fact, the surface area considerably decreased by the exchange at pH 10, but the decrease was small at pH 8 and negligible at pH 4 (Table 2). In support of Eq. (7), the pH changes during exchange at lower pH were in good agreement with those expected from Eq. (7) and the alkali content determined by flame photometry. If one takes 5/100 $Å^2$ as the density of surface silanols, the extents of exchange in the present work are, for example, 4% for Cs–SiO_2 (Cs: 0.08 mg-ion/g) and *ca.* 50% for Cs–SiO_2 (Cs: 0.41 mg-ion/g).

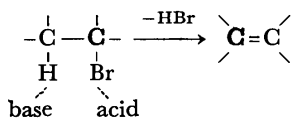
Usually alkali-ion exchange acts as a poison to the surface acidity and catalytic activity in the case of strongly acidic silica alumina or zeolite. Cs exchange decreased the activity for dehydrobromination of 2-bromobutane at low Cs content, but further exchange increased the activity. Since the stereochemistry was opposite to SiO_2, even for Cs– and K–SiO_2 with low activity, it is obvious that the exchange with these alkali ions created new active sites, besides acting as a

poison. An increase in the activity with the extent of exchange was observed also in the case of Li–SiO_2. However, the change was small in this case and was negligible for Na–SiO_2. Therefore, it is not certain whether or not the exchange created new sites in these cases, besides acting as a poison. From the indicator test and the catalytic activity, the weak acidity or basicity of the sites of the original silica surface and those created by the exchange seems sufficient for the reaction to occur.

The electronegativity or the acid strength of alkali ions increases in the order of Cs<K<Na<Li.[16] The active sites responsible mainly for *syn* elimination, which is acidic, may be the alkali ion and/or the protonic sites of silica. The *anti*-selectively increased in the reverse order. The basic strength of the oxide ion will increase by the coordination of the alkali ion in the decreasing order of the electronegativity (OCs>OK>ONa>OLi), so that this oxide ion may play essential roles in *anti* elimination. As a result, the activity order including both steric modes becomes Cs>K~Na<Li, as observed. The active basic sites on Cs–SiO_2 which was deactivated quickly in the initial stage was roughly 20—40% of the total Cs ions. It has been suggested by Imanaka, Hayashi, and Teranishi that K or Cs exchange of porous glass creates basic sites.[17] Yashima *et al.*[18] reported that K- or Cs-exchanged zeolites exhibit a basic character, although Li-zeolite is acidic. Malinowski and coworkers[19] have measured acidic and basic sites on NaOH-treated SiO_2 and correlated its catalytic activity with them.

The marked change in the catalytic action from one alkali ion to another seems to be one of the remarkable characteristics of the solid surface. In aqueous solutions, there is little difference expected among alkali ions owing to the levelling effect of water. Even in aprotic solvent, although the rate changed, the selectivity remained essentially the same in the isomerization of an olefin.[20]

Reaction Mechanisms, Stereoselectivity, and Stereochemistry. In the dehydrobromination, the surface acts as an acid-base bifunctional catalyst; the acid site abstracts a bromide ion and the basic center a β-proton. The reaction mechanism, therefore, may be classified by the timing of the C–H and C–Br bond breaking,



although it is very difficult to determine strictly whether the two bonds break simultaneously or not.[21]

A carbanion mechanism in which the C–H bond breaks (or becomes loose) in the first step seems unlikely because of the observed relative reactivity (*sec*-butyl>isopropyl>ethyl) and the butene composition from C_4Br (2->1-butene). The primary isotope effect and the stereospecificity observed suggest a concerted mechanism where two bonds break in a single concerted step. A carbonium-ion mechanism may also be applied in some cases, if the turnover of the ion on the surface is restricted.

The present results are reasonably explained as in the previous papers by the application of the extended Bunnett's hypothesis of the variable transition state,[2] which was originally proposed for concerted elimination reactions in the liquid phase. The reaction mechanism of elimination varies from an ideally concerted to a carbonium-ion like mechanism, as a reagent attacking the C–H bond becomes less basic or that attacking the C–Br bond becomes more acidic. A variation of the mechanism of the elimination reaction consistent with this idea has been reported also in solid catalysis.[5,22]

When the surface basicity decreases as in Li– and Na–SiO_2, it will become difficult for the surface to abstract a β-proton. But it may be removed to a bromide ion which is already or nearly released, so that *syn* elimination results.[6] The opposite stereochemistry observed with Na–SiO_2 between C_4Br and C_4Br_2 is attributed to a similar variation of mechanism caused by the much higher tendency of β-proton of dihalide to dissociate as a proton, which enables *anti* elimination even over a weak base like Na–SiO_2. The higher reactivity of dibromide than of monobromide (C_4Br_2>C_4Br), as well as the elimination of HBr exclusively from 2,3-position (not from 1,2-position), is explained similarly by the strong acidity of β-proton of dihalide. These trends are well recognized in the liquid-phase elimination.[2,23,24] The C–Br bond breaking, on the contrary, is retarded by β-halogen. These effects explain the reversed reactivity of alkyl bromide over Li–SiO_2 (C_4Br>C_4Br_2) and the activity order for C_4Br_2 of Cs>K>Na>Li.

The fact that the relative reactivity of C_4Br to isopropyl bromide was about 4 over Cs–SiO_2 but about 10 over Li–SiO_2 also supports the idea that the transition state exhibits a more carbonium-ion character in the latter surface. Changes in the rate and butene composition with acid-base properties are also consistent with the mechanisms described here. For example, increases in 2-/1- and *trans*/*cis* ratios from Li to Cs are expected, when the mechanism becomes more concerted[2,25] and the stability of the transition state reflects more that of the products.

The authors are indebted to Prof. Y. Saito and Dr. J. Take for helpful discussions and to Dr. H. Matsumoto for analysis of alkali content. They also gratefully acknowledge Prof. M. Tsuchiya and Dr. S. Saito for mass spectrometric and microwave spectroscopic analyses, respectively.

Acidic Nature of Chemisorption Sites on Silica-Alumina and Alumina Catalysts. Characterization by UV Spectra of Adsorbed *p*-Nitroaniline

Koichi MIZUNO, Jun-ichiro TAKE, Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 12, 1975)

Chemisorbed *p*-nitroaniline (PNA) gives two bands at 245 and 445 nm on silica-alumina and one band at 450 nm on alumina. The present paper deals with the nature of these chemisobed species and of the chemisorption sites. Kinetic studies of PNA chemisorption onto silica-alumina from cyclohexane solution revealed that the chemisorbed species responsible for the 245 nm band was formed with an activation energy by 0.9 kcal/mol smaller than that responsible for the 445 nm band. The two bands on silica-alumina are due conclusively to two different chemisorbed species. Comparison among UV absorption spectra of PNA in various solutions and on various solid surfaces led to the conclusion that the 245 nm band is ascribable to PNA chemisorbed on Brønsted acid sites and the 445 and 450 nm bands to PNA chemisorbed on Lewis acid sites (*i.e.* surface Al^{3+} ions).

The characterization of the surface acid sites of solid catalysts has provided information useful for the clarification of solid acid catalysis. A variety of techniques have been proposed for determining acid properties.[1] Most of them, however, scarcely give information on the type of surface acid sites (Brønsted or Lewis acid). Such information must also be required for the elucidation of reaction mechanism. In recent years, the distinguishment between both types of surface acid sites has been attempted in IR spectroscopic studies of chemisorbed bases. Ammonia,[2] pyridine,[3] and 2,6-dimethylpyridine[4] were employed successfully because their protonated species exhibit IR absorption bands definitely different from those of the species coordinated to Lewis acid sites.

If an indicator is available which shows UV absorption bands distinct from each other when it interacts with Brønsted and Lewis acids, all of the acid strength of acid sites, their content, and their type are possibly determined as an extension of the butylamine titration method. In a previous study,[5] we found that *p*-nitroaniline (PNA) shows two bands at 245 and 445 nm upon chemisorption on silica-alumina catalyst and concluded that these two bands may be due to two different chemisorbed species.

The present study was undertaken in order to confirm further the previous conclusion and to understand the nature of the chemisorbed species and hence of the chemisorption sites. Kinetic studies of PNA chemisorption onto silica-alumina from cyclohexane solution revealed that the chemisorbed species responsible for the 245 nm band was formed with an activation energy by 0.9 kcal/mol smaller than that responsible for the 445 nm band, demonstrating that these two bands are due unambiguously to two different chemisorbed species. Comparison among UV absorption spectra of PNA in various systems (*i.e.*, in solutions and on surfaces) led to the conclusion that the 245 and 445 nm bands are ascribable to PNA coordinated to Brønsted acid sites and to Lewis acid sites (*i.e.* surface Al^{3+} ions), respectively.

Experimental

Materials. The silica-alumina (SA-1, 13% Al_2O_3) and the silica gel (S-3) were used earlier.[6] Alumina (A-1) was prepared by the neutral hydrolysis of aluminum isopropoxide distilled twice immediately before use.[7] Its surface area was 170 m^2/g. Silica gel impregnated with sulfuric acid (SS-3) was prepared by soaking a thin S-3 wafer calcined in air at 550 °C for 4 h in a diluted aqueous solution of sulfuric acid (20%) and then dried in air at about 80 °C overnight. *p*-Nitroaniline (PNA) was a GR grade reagent and dissolved in cyclohexane without further purification. Cyclohexane used was exhaustively dried and degassed as previously described.[6]

Kinetic Adsorption and UV Studies. Procedures were essentially the same as in a previous study,[6] except that a single wafer was used in all experiments.

A wafer of SA-1, after mounted on the rectangular quartz cage, was treated in a dry oxygen stream at 550 °C for 2.5 h and then in a wet oxygen stream at 150 °C for 0.5 h. The wafer was activated at 450 °C and 10^{-4} mmHg for 2 h in the specially designed UV-cell which is transparent in all sides. Back-ground spectra were determined for both the wafer and the solvent, after introduction of cyclohexane (about 3 ml) followed by that of dry nitrogen. A small amount of PNA (2×10^{-7} mol) was added in a dry nitrogen stream onto frozen cyclohexane in the cell kept at 0 °C, in order to prevent the chemisorption of PNA onto the wafer during the course of addition. The capped cell was rapidly warmed on a water bath thermostatted at temperatures of 10 to 80 °C under stirring with a magnetic stirrer. Separate experiments proved that the frozen PNA almost instantaneously reached adsorption temperature with this procedure. The change of PNA concentration with time was followed by UV spectrophotometry for both the wafer and the solvent.

Wafers of A-1 and S-3 were treated in a dry oxygen stream at 500 °C for 2 h and then activated *in situ* under identical conditions with those employed for SA-1 wafers. A wafer of SS-3 was evacuated briefly *in situ* at room temperature immediately after preparation.

UV spectra over the range of 220 to 600 nm were recorded on a Shimadzu multipurpose recording spectrometer Model MPS-50L at room temperature with a control of atmospheric air.

ESR Studies. A 494 mg sample of powdered SA-1 was activated in an adsorption vessel equipped with a conventional ESR-tube. Experimental conditions for oxygen-treatment and activation were the same as employed in kinetic studies. After addition of cyclohexane and PNA (3.9×10^{-6} mol), the vessel was kept at 62 °C for 2 h. The solvent was removed by evaporation under a vacuum, and then the catalyst was trans-

ferred into the ESR-tube. ESR spectra were recorded on a JES-3BS-X spectrometer at room temperature.

Results and Discussion

UV Spectra of PNA. UV absorption spectra of PNA on various solid surfaces are shown in Fig. 1 and, together with those in various solutions, are summarized in Table 1. PNA chemisorbed on SA-1 shows two bands at 245 (Band I) and 445 nm (Band II), whereas PNA adsorbed on A-1, S-3 and SS-3 gives a single band.

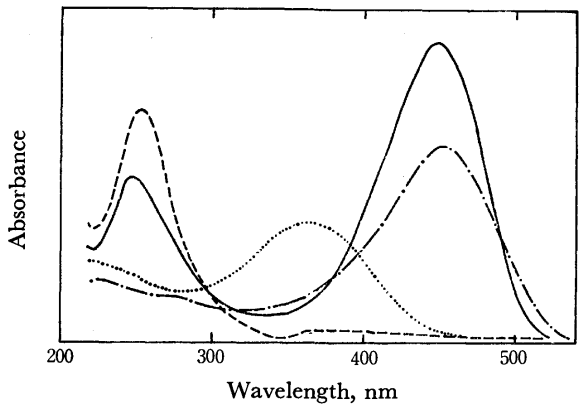

Fig. 1. UV spectra of PNA adsorbed on SA-1 (——), A-1 (-·-), SS-3 (------), and S-3 (·····).

Table 1. UV absorption spectra of PNA on various catalysts and in various solutions (nm)

System		Species		
	Acidic nature	Protonated	Neutral	Coordinated to Al^{3+} ion
on SA-1	L[a] and B[a]	245 (Band I)		445 (Band II)
on A-1	L			450
in $AlBr_3$–$(C_2H_5)_2O$	L			440[b]
in $AlCl_3$–$(C_2H_5)_2O$	L			440[c]
on SS-3	B	252		
in aq H_2SO_4 (20%)	B	255		
on S-3	Nonacidic		365	
in C_2H_5OH	Nonacidic		370	
in cyclo-C_6H_{12}	Nonacidic		322

Chemisorption of PNA onto SA-1 from Cyclohexane. Chemisorption of PNA onto SA-1 from cyclohexane solution was kinetically investigated in order to determine whether Bands I and II over SA-1 are due to two different chemisorbed species. Figure 2 shows an example of the change of PNA concentration with time. Both Bands I and II increased in intensity with decreasing intensity of the 322 nm band due to PNA in cyclohexane. After initial 2—3 h the 322 nm band completely disappeared and both Bands I and II reached stationary intensities, indicating that the chemisorption was completed. The disappearance of PNA from cyclohexane solution obeyed well a first-order kinetics with

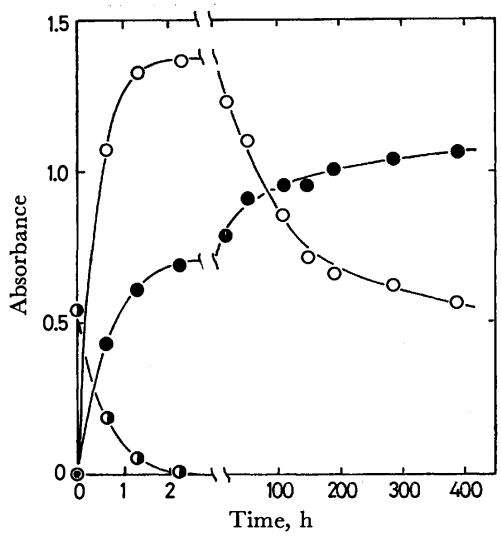

Fig. 2. Change of absorption intensity during chemisorption at 70 °C.
245 (●), 322 (◑), and 445 nm (○) band.

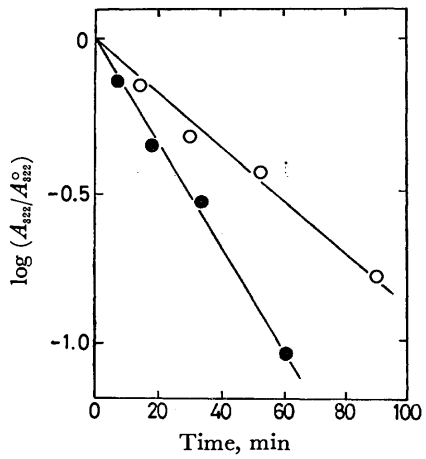

Fig. 3. Disappearance rates of PNA from cyclohexane at 10 (○) and 65 °C (●).

respect to the concentration of PNA, as shown in Fig. 3. From the temperature dependence of rate constants for the disappearance of PNA, the overall activation energy was evaluated to be 1.4 kcal/mol for the chemisorption from cyclohexane.

At every temperature, linear correlations were observed between the increment in intensity of both Bands I and II and the decrement in intensity of the 322 nm band: *i.e.*, $\Delta A_{\mathrm{I}} = -\alpha_{\mathrm{I}} \Delta A_{322}$ and $\Delta A_{\mathrm{II}} = -\alpha_{\mathrm{II}} \Delta A_{322}$, where ΔA_i is the increment in absorbance of Band I, α_i its proportionality constant, as exemplified in Fig. 4. The ratio of the proportionality constants ($\alpha_{\mathrm{II}}/\alpha_{\mathrm{I}}$) *i.e.*, the ratio of the increments in intensity of Bands I and II ($\Delta A_{\mathrm{II}}/\Delta A_{\mathrm{I}}$) at a given time, however, changed depending upon adsorption temperature, as is shown in Fig. 5. If Bands I and II were ascribed to identical chemisorbed species, this ratio would correspond simply to the ratio of the molar extinction coefficients of Bands I and II independent of adsorption temperature. Therefore, the temperature dependence observed demonstrates that Bands I and II are ascribable unambiguously to two different chemisorbed species. As will be described in

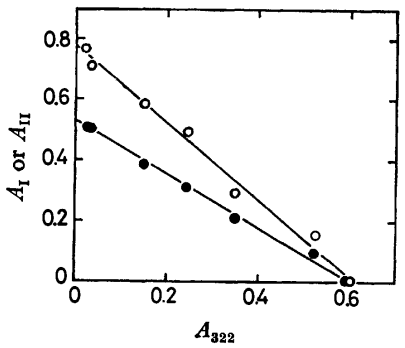

Fig. 4. Ratio of increment in absorbance of Band I (●) or II (○) over decrement in absorbance of 322 nm band (40 °C).

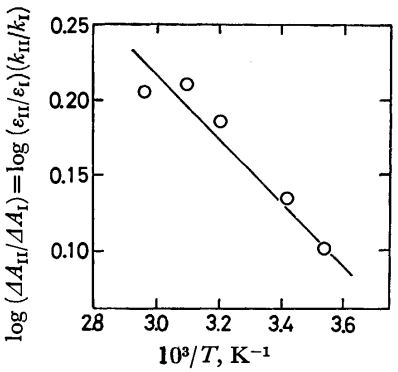

Fig. 5. Difference between activation energies for chemisorption of PNA onto Brønsted acid sites and onto Lewis acid sites.

detail later, these two chemisorbed species correspond to PNA chemisorbed on two types of acid sites different in nature (Sites I and II).

After the completion of chemisorption above 40 °C, the intensity of Band II decreased very slowly with an accompanying increase in intensity of Band I (see Fig. 2), indicating that Band II was just replaced by Band I. This observation provides additional evidence supporting the conclusion that there exist two different chemisorbed species. The observed slow replacement of Band II by Band I is best explained by the following postulation: because the apparent stationary state is far from an equilibrium, the system gradually approaches a true adsorption equilibrium by the migration of less stable chemisorbed species on Site II (responsible for Band II) onto Site I, producing more stable chemisorbed species responsible for Band I. This explanation is in line with the expectation by Polanyi's rule that less stable species become less unfavorable at kinetically controlled stage than at equilibrium. Also, the explanation is consistent with our previous conclusion that the establishment of an adsorption equilibrium of indicators and *n*-butylamine is seriously difficult under the ordinary conditions employed in the butylamine titration method.[10]

Accordingly, the ordinate of Fig. 5 corresponds to the product of the ratio not of equilibrium constants but of the rate constants for chemisorption onto Sites I and II (k_{II}/k_I) and the ratio of molar extinction coefficients for Bands I and II ($\varepsilon_{II}/\varepsilon_I$). The temperature dependence in Fig. 5 thus indicates that the activation energy of the chemisorption of PNA is by 0.9 kcal/mol higher for Site II than for Site I.

Nature of Chemisorption Sites. Inspection of Table 1 will provide interesting information on the nature of the chemisorbed species on SA-1 and hence of the chemisorption sites. The solutions and solid acids employed in the present study can be devided into four groups according to their acidic nature.

As regards the solutions, it has been well established that the acidity of a diluted aqueous solution of sulfuric acid is of the Brønsted type, whereas aluminum bromide and chloride in diethyl ether behave as Lewis acids, and also that ethanol having hydrogen-bonding ability and cyclohexane are both nonacidic. With regard to the solid except for SS-3, the characterization of the surface acidity by means of the IR spectra of adsorbed pyridine indicated that SA-1 has both Lewis and Brønsted acid sites while on A-1 only Lewis acid sites are present, and that S-3 is nonacidic though it has hydrogen-bonding ability,[12] in accord with the results in the literature.[3] SS-3 probably has Brønsted acidity alone.

A noteworthy feature in UV absorption spectra of PNA is that maximal absorption takes place in one or two of three different wavelength regions, depending upon the acidic nature of environments: the first region (240—260 nm), the second (320—370 nm), and the third (440—450 nm) are characteristic for environments of Brønsted acidity, for nonacidic environments, and for environments containing Al^{3+} ions as a Lewis acid, respectively. The second region can be further classified in two subregions: one is the 370 nm region characteristic for environments having hydrogen-bonding ability and the other the 320 nm region characteristic for nonpolar environments.

These considerations lead reasonably to the conclusion that Bands I and II on SA-1 are due to PNA chemisorbed on the Brønsted acid sites and Lewis acid sites (surface Al^{3+} ions), respectively. The 450 nm band on A-1 is ascribed, of course, to PNA chemisorbed on the Lewis acid sites. Reportedly the bathochromic shift from 322 nm in cyclohexane to 370 nm in ethanol is due to the formation of intermolecular hydrogen bonds with the solvents.[12] The 365 nm band on S-3 is therefore ascribed to PNA hydrogen-bonded with the surface, probably with surface hydroxyl groups and oxide ions.

From spectral and reaction-mechanistic evidence, it has been established that besides acidic sites, various sites such as an oxidizing, reducing, and basic site coexist on silica-alumina and alumina surfaces.[13–16] On oxidizing and reducing sites PNA may be converted to radical cations and anions, respectively, by one-electron transfer. In strongly basic media, PNA which is a weak acid of $pK_a=18.9$ is ionized with the loss of a proton from the amino group to produce an anion giving rise to absorption at 467 nm.[17] This wavelength is close to that of Band II or of the 450 nm band on A-1. Such an ionization may also take place over basic sites on SA-1 and A-1. However, we ruled out the formation of either ionic radicals or anions as a main chemisorbed species responsible for Band II on the

following grounds: (a) the presumption that a system of $AlBr_3$ (or $AlCl_3$)–$(C_2H_5)_2O$ has neither a strong basicity nor the ability of oxidation or reduction is quite reasonable, (b) Band II, as well as Band I, was unaffected by the introduction of gaseous oxygen, which enhances the ability of oxidation of silica-alumina and alumina,[18] (c) the surface concentration of the chemisorbed species responsible for Band II on SA-1 was estimated to amount to about 500 times that of reducing sites of silica-alumina with an alumina content of 13%,[14] (d) the ESR spectrum of PNA chemisorbed on SA-1 (g-value=2.00) indicates that the surface concentration of radical species amounts to 5×10^{15} spins/g and corresponds to about one thousandth of that of chemisorbed PNA, and (e) the surface basicities of SA-1 and A-1 are both too weak to ionize PNA, as evidenced by the experimental fact that both catalysts exhibited no absorption peaks around 500 nm upon adsorption of 2,4-dinitroaniline,[19] which is a less weak acid of $pK_a=15.0$ and produces in strongly basic media an anion giving rise to absorption at 388 and 535 nm.[20] This statement is also applicable to Band I characteristic of an anilinium-ion type of species.

Mohammad and Satchell[8] have attributed the 440 nm band observed in their system, PNA–$AlBr_3$ (or $AlCl_3$)–$(C_2H_5)_2O$, to a charge-transfer type of absorption by the complex, and proposed a structural model in which the aluminum ion coordinates weakly to the amino nitrogen atom of PNA. Consistent with this model is our interpretation that the chemisorbed species on Lewis acid sites (*i.e.*, surface Al^{3+} ions) is less stable than that on Brønsted acid sites. It is not obvious why Lewis acid sites of SA-1 should interact less strongly with PNA than do Brønsted acid sites, in contrast with the fact that pyridine coordinates more strongly to Lewis acid sites than to Brønsted acid sites of SA-1.[11]

The authors are indebted to Drs. Yasukazu Saito, and Toshio Uchijima for valuable discussions, to Dr. Makoto Misono for helpful discussion and ESR data, and to Mr. Haruyuki Kawai for kind assistance in the preliminary stage of this work.

Molecular Structures of 5-Thiabicyclo[2.1.1]hexane and 7-Thianorbornane as Studied by Gas Electron Diffraction

Tsutomu FUKUYAMA, Kazuko OYANAGI, and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received November 22, 1975)

Molecular structures of 5-thiabicyclo[2.1.1]hexane and 7-thianorbornane (7-thiabicyclo[2.2.1]heptane) were studied by gas electron diffraction. For 7-thianorbornane the rotational constants obtained by Hirota *et al.* by microwave spectroscopy were also taken into account. Least-squares analyses gave the following r_g bond distances and valence angles (r_a for 5-thiabicyclo[2.1.1]hexane and r_{av} for 7-thianorbornane): for 5-thiabicyclo[2.1.1]-hexane, $(C_1-C_2,\ C_2-C_3)_{av}=1.539\pm0.016$ Å, $C_1-C_6=1.564\pm0.024$ Å, $C-S=1.865\pm0.004$ Å, $(C-H)_{av}=1.110\pm0.008$ Å, $\angle C-S-C=69.5\pm0.6°$ and the dihedral angles (C_1SC_4)-$(C_1C_2C_3C_4)=115.2\pm1.7°$ and $(C_1C_6C_4)$-$(C_1C_2C_3C_4)=116.1\pm2.4°$; for 7-thianorbornane, $C_1-C_2=1.538\pm0.006$ Å, $C_2-C_3=1.561\pm0.015$ Å, $C-S=1.837\pm0.004$ Å, $(C-H)_{av}=1.115\pm0.008$ Å, $\angle C-S-C=80.2\pm0.8°$, the dihedral angle $(C_1C_2C_3C_4)$-$(C_4C_5C_6C_1)=115.0\pm1.2°$ and $\angle H-C-H=106\pm5°$. The uncertainties represent the estimated limits of experimental error. The C–S bond length in 5-thiabicyclo[2.1.1]hexane is longer than that in dimethyl sulfide by 0.06 Å and that in 7-thianorbornane by 0.03 Å. The C–S–C angle in 5-thiabicyclo[2.1.1]hexane is smaller than that in dimethyl sulfide by about 30° and that in 7-thianorbornane by about 11°. The C_1-C_6 bond in 5-thiabicyclo[2.1.1]hexane is longer than the weighted average of the C_1-C_2 and C_2-C_3 bond lengths. The C_1-C_2 bond in 7-thianorbornane is longer than the C_2-C_3 bond.

Bicyclic compounds provide important clues for understanding the relationship between the geometry of molecules and intramolecular forces, since their bond lengths and angles are often very different from the corresponding values in open-chain molecules. When a heteroatom is introduced into a bicyclic system, the system is further distorted. As one of such systems, the structure of 7-oxanorbornane[1] was recently studied. The present paper is concerned with the structures of two thiabicyclic compounds, 5-thiabicyclo[2.1.1]hexane (TBH) and 7-thianorbornane (TN) (Fig. 1). After our

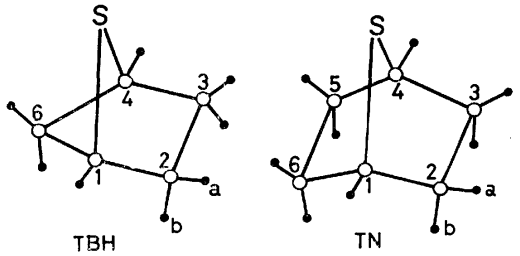

Fig. 1. 5-Thiabicyclo[2.1.1]hexane (TBH) and 7-thianorbornane (TN).

preliminary report on their structures[2] was published, a further refinement was made, particularly for the latter molecule, since a set of rotational constants for TN became available.[3] By means of a joint analysis of electron diffraction and spectroscopic data the two non-equivalent C–C distances, C_1-C_2 and C_2-C_3 have been determined independently.

Experimental

The samples were prepared by the procedures described in the literature[4] and were purified by sublimation and recrystallization. By using a high-temperature nozzle[5] the samples were vaporized at about 60 °C (TBH) and 105 °C (TN), and diffraction photographs were taken with nozzle-to-plate distances of about 249.07 and 114.39 mm. The accelerating voltage of the electrons, about 40 kV, was stabilized within ±0.01% during the experiment.

The scale factors of the diffraction patterns taken with the short camera length were calibrated with reference to the r_a(C=O) distance[6] of carbon dioxide measured under essentially the same experimental conditions as those for the sample gases. In the experiment with the long camera length, nitrogen was used as a reference gas. Other experimental details are described in Refs. 6 and 7.

Three photographic plates taken with each camera length were selected for the analysis, and their optical densities were measured by means of a microphotometer and an integrating digital voltmeter.[8] After correction for imperfection in the r^3-sector and drawing smooth background curves,[7] molecular scattering intensities were obtained in the ranges $s=2.8$—20.1 Å^{-1} and $s=7.9$—34.6 Å^{-1} from the long distance and the short distance data, respectively, at intervals of $s=$

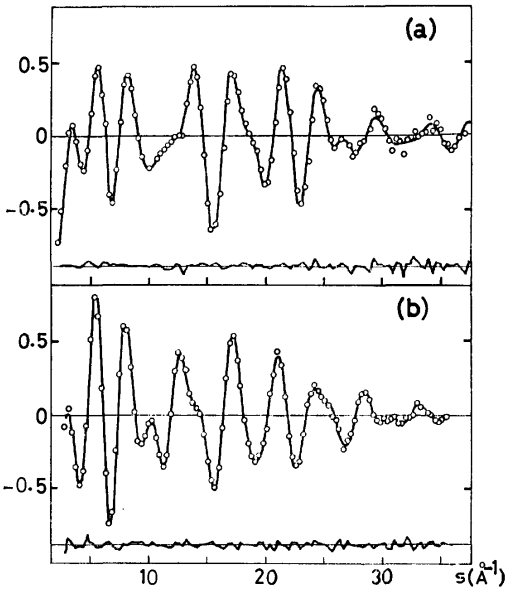

Fig. 2. Molecular intensities. a) 5-Thiabicyclo[2.1.1]-hexane. b) Thianorbornane. Observed values are shown as open circles, and the solid curves represent the best-fit theoretical intensities. The lower solid curves represent the residuals.

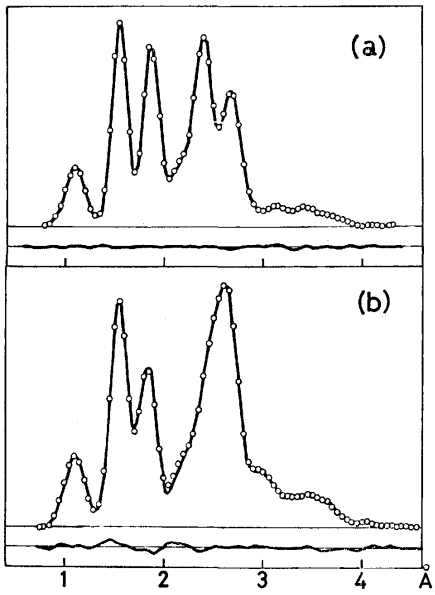

Fig. 3. Experimental (open circles) and the theoretical radial distribution curves. a) 5-Thiabicyclo[2.1.1]-hexane. b) 7-Thianorbornane. Damping factors, $\exp(-0.0016s^2)$ for a) and $\exp(-0.0018s^2)$ for b), were used. The residuals are shown below in the same scale.

$\pi/10$. Since the intensities from the two camera lengths agreed in their overlapping region, they were joined at $s=$ 11.9 Å^{-1}. The elastic and inelastic scattering factors and the phase shifts used for correction of the non-nuclear scattering were taken from the tables prepared by Schäfer *et al.*[9] Typical molecular intensity curves are shown in Fig. 2,[10] and the corresponding radial distribution curves are shown in Fig. 3. Most of the calculations were carried out on a HITAC 8800/8700 in the Computer Center of the University of Tokyo.

Analysis

Analysis of Electron Diffraction Data. The molecular intensities were analyzed by a least-squares method. In order to limit the variable parameters to a tractable number, the following assumptions were made.

1) TBH and TN have C_s and C_{2v} symmetry, respectively.

2) The H–C–H plane in the methylene group is perpendicular to the C–C–C plane, and bisectors of the C–C–C angle and the H–C–H angle are colinear.

3) The C–C–H angles and the S–C–H angle at the bridgehead are equal to one another, *i.e.*, $\angle C_2$–C_1–H$=$ $\angle$S–C_1–H$=\angle C_6$–C_1–H.

4) All the C–H bond lengths are equal.

5) All the H–C–H bond angles are equal. For TBH the angles are assumed to be 110° and are not varied in the analysis.

6) The C_1–C_2 and C_2–C_3 bond lengths are equal. With these assumptions, the structure of TBH is defined by seven parameters: the weighted average of C_1–C_2 and C_2–C_3 bond lengths, the C_1–C_6, and C–S bond lengths, the weighted average C–H bond lengths, the C–S–C angle and the two dihedral angles: $\angle(C_1SC_4)$-$(C_1C_2C_5C_4)$ and $\angle(C_1C_6C_4)$-$(C_1C_2C_3C_4)$. TN For the following six parameters are taken as variables: the weighted average C–C and C–H bond lengths, C–S–C and the weighted average H–C–H angles, and the dihedral angle $\angle(C_1C_2C_3C_4)$-$(C_4C_5C_6C_1)$. In the analysis of the TN structure the last assumption 6) was released by the joint use of diffraction and spectroscopic data, whereas the other constraints were maintained throughout.

Table 1. Estimated force constants for 5-thiabicyclo[2.1.1]hexane and 7-thianorbornane[a]

Y(C–C)$_c$	0.11[b]	H(C–C–H)	0.21	F(C–C–H)	0.47
Y(C–S)	0.05	H(H–C–H)	0.40	F(H–C–H)	0.18

a) Estimated force constants taken from cyclohexane[11] and ethyl methyl sulfide.[12] The torsional force constants (Y) are in mdyn·Å and the others are in mdyn/Å units. b) Symbols g and c represent the C–C axes which have *gauche* and *cis* C···C atom pairs, respectively.

In addition to the geometrical parameters, a number of mean amplitudes were determined by the least-squares analysis: the average C–H, bonded C–S and nonbonded C_2–S and C_6–S amplitudes for TBH, and the average C–C, C–H amplitudes, bonded C–S and nonbonded C_2–S amplitudes for TN. The rest of the mean amplitudes were fixed to values calculated by the use of Urey-Bradley force constants. Since the vibrational spectra of TBH and TN have not been observed, the force constants transferred from cyclohexane[11] and ethyl methyl sulfide[12] were used without further refinement. They are given in Table 1. In order to apply assumption 1), corrections for the shrinkage effects, r_a–r_α,[13,14] were also calculated on the basis of this force field for all the internuclear distances. The calculated mean amplitudes and the shrinkage corrections are shown in Tables 2 and 3. The asymmetry parameter κ for the C–H bond was estimated to be 1.2×10^{-5} Å^3 by a diatomic approximation.[15] The κ parameters for the other atom pairs were assumed to be zero.

Table 2. Mean amplitudes (l_{ij}) and shrinkage corrections (r_a-r_α) for 5-thiabicyclo-[2.1.1]hexane[a] (in 10^{-4} Å)

a) Calculated at 105 °C.

The r_α structures were determined by a least-squares analysis of the molecular intensities. A conventional diagonal weight matrix[16] with unit elements in the range $6.3 \leq s \leq 26.7$ and smaller for smaller and larger scattering angles was used. The results are listed in Tables 4 and 5. The r_g bond lengths derived from the r_α structure are also shown.

The error limits quoted in Tables 4 and 5 were estimated from random and systematic errors from various sources,[1,17] including those originating from preceding assumptions. The structure of TBH given in Table 4 is regarded as the final result of the present study. The corresponding error matrix is listed in Table 6.

Joint Analysis of Electron Diffraction Intensities and Rotational Constants for TN. The rotational constants for the normal species of TN were reported by Hirota *et al.* from microwave spectroscopy.[3] Their rotational constants for the ground vibrational state, A_0, B_0, and C_0, were transformed into A_z, B_z and C_z by making vibrational corrections.[18] The electronic and centrifugal corrections were ignored. The uncertainties in the vibrational corrections were tentatively assumed to be 20%, and the uncertainties in the A_0, B_0, and C_0 constants were also taken into account in the total uncertainties in A_z, B_z and C_z.

In order to check the consistency of the diffraction data with the spectroscopic data, the r_α structure determined from the diffraction data was extrapolated to zero kelvin[13,14] by calculating the difference $r_\alpha^0 - r_\alpha$. The anharmonic contribution to the difference was estimated on the basis of a diatomic approximation,[15] while the harmonic contribution was derived from the force constants mentioned in the preceding subsection. The temperature effect on the bond angles was ignored.

As shown in Table 7, the rotational constants, A_α^0, B_α^0 and C_α^0 calculated from the r_α^0 structure agreed with their spectroscopic equivalents, A_z, B_z and C_z within their uncertainties. In general, if two bonds in a molecule with nearly equal distances are approximately parallel to different principal axes, the rotational constants with respect to these axes can be used for discriminating these bond lengths. For 7-thianorbornane, like 7-oxanorbornane,[1] the rotational constants A_z and B_z are sensitive to the C_2–C_3 and C_1–C_2 bond lengths, respectively. Therefore, the rotational constants were taken into the least-squares analysis to complement the

Uncertainties represent 2.5 times the estimated standard deviations.

diffraction data.

For each least-squares calculation the standard deviations in the rotational constants were estimated from those in the r_α^0 parameters by using the law of propagation of errors. The relative weights for the rotational constants were then adjusted in such a way that 2.5 times their standard deviations were approximately equal to their estimated uncertainties. The weights assigned in this way were 4×10^8, 1×10^9 and 3×10^9 for A_z, B_z and C_z respectively, in comparison with unit weights assigned to the molecular intensities from s=6.3 to 26.7 $Å^{-1}$. It was possible to release the constraint 6) on the C–C bond lengths by the joint use of the rotational constants and the electron diffraction

a) k_1, k_2=indices of resolution for the long and short camera length data (1.03±0.08, 1.03±0.09), respectively, $x_1=r(C_1-C_2)$, $x_2=r(C_2-C_3)$, $x_3=r(C-S)$, $x_4=r(C-H)$, $x_5=\angle C-S-C$, $x_6=\angle(C_1C_2C_3C_4)$-$(C_4C_5C_6C_1)$, $x_7=\angle H-C-H$, $l_1=l(C-C)$, $l_2=l(C-S)$, $l_3=l(C-H)$ and $l_4=l(C\cdots S)$. Units ($\times 10^{-4}$) for the distances and mean amplitudes are Å, those for the angles are rad, and those for the indices are dimensionless.

intensities. Including the indices of resolution for the long and short distance data, thirteen parameters were refined. The final structural parameters and mean amplitudes with estimated error limits are shown in Tables 8 and 9. The observed mean amplitudes for TBH and TN agree with the calculated mean amplitudes to within the limits of their uncertainties. The corresponding error matrix is given in Table 10.

Discussion

The final structures of TBH and TN are compared with the structures of bicyclo[2.1.1]hexane,[19,20] norbornane,[21] 7-oxanorbornane,[1] tetrahydrothiophene[22] and dimethyl sulfide[23] in Table 11.

C–S Bond Lengths and Sulfur Valence Angles. The present study demonstrates unusual bond lengths and

angles in bicyclic compounds. The C–S bond length in TBH is longer than that in dimethyl sulfide[23] by 0.06 Å, and the C–S–C angle is smaller by about 30°. On the other hand, the C–S bond length and the C–S–C angle in TN are shorter by about 0.03 Å and larger by about 11°, respectively, than the corresponding values in TBH. This trend implies that intramolecular strain is much greater in TBH than in TN.

The present study also demonstrates a systematic decrease in the C–S–C angle in a series of sulfur substituted hydrocarbons: (a) acyclic, (b) five-membered ring and (c) bicyclic. The corresponding series of unsubstituted and oxygen substituted hydrocarbons showed a similar systematic trend in the C–C–C and C–O–C angles.[1] The C–S lengths do not show regular increases in the series of sulfur substituted hydrocarbons,[24] as do the C–C and C–O lengths in the series of unsubstituted and oxygen substituted hydrocarbons.[1] (See Table 11.)

C–C Bond Lengths. The essential features regarding the C–C bond lengths are the following:

1) The C_1–C_6 bond in TBH is longer than the weighted average of the C_1–C_2 and C_2–C_3 bond lengths. Similar trends were reported for norbornane.[21]

2) The average values of the C_1–C_2 and C_2–C_3 distances in TN, 7-oxanorbornane and norbornane are equal to one another to within their limits of error and about 0.01 Å longer than the normal single C–C bond length, whereas the corresponding average C–C bond length in TBH seems to be shorter and approximately equal to the normal C–C bond length.

3) For TN and 7-oxanorbornane the C_1–C_2 and C_2–C_3 bonds were separated by use of the rotational constants. The corresponding distances in these molecules are essentially equal to each other. The C_1–C_2 distances are similar to the normal single bond length, while the C_2–C_3 distances are about 0.02 Å longer and close to the C_1–C_6 distance in TBH or the C_1–C_7 distance in norbornane. The trend that the C_2–C_3 bond is longer than the C_1–C_2 bond has also been suggested for norbornane and bicyclo[2.2.2]octane.[25]

4) The C–C bond lengths in the six-membered rings in norbornane, 7-oxanorbornane and TN are remarkably similar in spite of the very different bond lengths and valence angles in the C–C–C, C–O–C and C–S–C bridges.

Angles in the Rings. The dihedral angles in norbornane and 7-oxanorbornane are nearly equal to each other and are about 2° smaller than that in TN. The C_1–C_6–C_4 angle in TBH seems to be essentially equal to that in bicyclo[2.1.1]hexane.[19] The C_1–C_2–C_3 angle in TN is about 5° larger than that in 7-oxanorbornane and about 3° larger than that in norbornane.

The authors are indebted to Professor Zen-ichi Yoshida, Professor Iwao Tabushi, and Dr. Yoshinao Tamaru for preparation of the samples and to Professor Robert K. Bohn and Dr. Ken-ichi Karakida for their helpful comments.

The Crystal and Molecular Structure of Tris-(2,2,6,6-tetramethylheptane-3,5-dionato)lutetium(III)

Shigeki ONUMA, Hironao INOUE,* and Shuzo SHIBATA
Department of Chemistry, Shizuoka University, Oya, Shizuoka 422
(Received December 22, 1975)

The crystal and molecular structure of tris-(2,2,6,6-tetramethylheptane-3,5-dionato)lutetium(III) has been determined by X-ray diffraction method. The space group is $Pmn2_1$, and the unit cell is orthorhombic with $a=17.713(4)$, $b=10.638(2)$, $c=9.973(3)$ Å, and $Z=2$. The structure is isomorphous with the erbium analogue. The atomic parameters of the molecule (except for hydrogen atoms) were refined by the block-diagonal least-squares method to an R of 0.053. Three chelate rings are planar. One of them lies in the crystallographic mirror plane, and the other two rings are symmetrically related to each other with respect to this mirror plane. Six oxygen atoms of the three β-diketones form a distorted trigonal prism around the central lutetium ion, the average Lu–O distance being 2.19 Å.

The anhydrous lanthanide complexes of 2,2,6,6-tetramethylheptane-3,5-dione, H(thd), are volatile.[1] Among them the complexes of La to Dy are monoclinic and those of Ho to Lu are orthorhombic.[2,3] Crystal structure analyses were carried out on the tris-thd chelates of praseodymium[3] and erbium;[4] the praseodymium chelate is dimeric and each Pr atom is surrounded by seven oxygen atoms in a monocapped trigonal prism, while the erbium chelate is monomeric and the coordination polyhedron is approximately trigonal prismatic, giving a sixfold coordination. The present study was undertaken to determine the crystal and molecular structure of the anhydrous tris-thd chelate of the most heavy element of lanthanides.

Experimental

Single-crystals of anhydrous tris-thd chelate of lutetium were prepared by sublimation. They are transparent prisms. It was, however, noticed that the crystals become opaque and amorphous slowly when exposed to X-rays in the atmosphere. The crystal was, therefore, sealed in a glass capillary tube to avoid such changes.

Approximate cell constants were determined from Weissenberg photographs, and they were refined by a least-squares method using 23 higher angle reflections measured on a Rigaku Denki automatic four-circle single-crystal diffractometer with Mo$K\alpha_1$ radiation ($\lambda=0.70926$ Å). They are given in Table 1 with other crystal data.

The intensity data were collected on a single-crystal diffractometer using Zr-filtered Mo$K\alpha$ radiation at room temperature. The ω–2θ scan technique was employed at a speed of 2°/min in 2θ. The intensities of three reflections (002, 010 and 400) were checked every 50 reflection measurements. The fluctuations were less than 1%, and no appreciable decomposition of crystal was observed. A total of 2360 accessible reflections with $2\theta<55°$ were measured. The data were corrected for the Lorentz and polarization factors, but not corrected for absorption. Reflections whose amplitude $|F|$ were less than three times their standard deviations were not included in the subsequent calculations. The number of observed reflections was 1731.

TABLE 1. CRYSTAL DATA

$Lu(thd)_3$, $LuC_{33}H_{57}O_6$
Molecular weight 724.8
Orthorhombic
$a=17.713(4)$
$b=10.638(2)$
$c=9.973(3)$ Å
Space group $Pmn2_1$
Volume of a unit cell 1879.2(8) Å^3
Density, calculated for $Z=2$: 1.286 g cm^{-3}
Number of electrons per unit cell $F(000)=634$ (without hydrogen atoms)

Structure Determination and Refinement

The crystal structure of $Lu(thd)_3$ was supposed to be isomorphous with that of $Er(thd)_3$[4] because the cell constants and systematic absences are similar. Therefore, the atomic parameters of $Er(thd)_3$ were used as initial values and they were refined by a block-diagonal least-squares method. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, where the weighting function w was unity. Positional and anisotropic thermal parameters

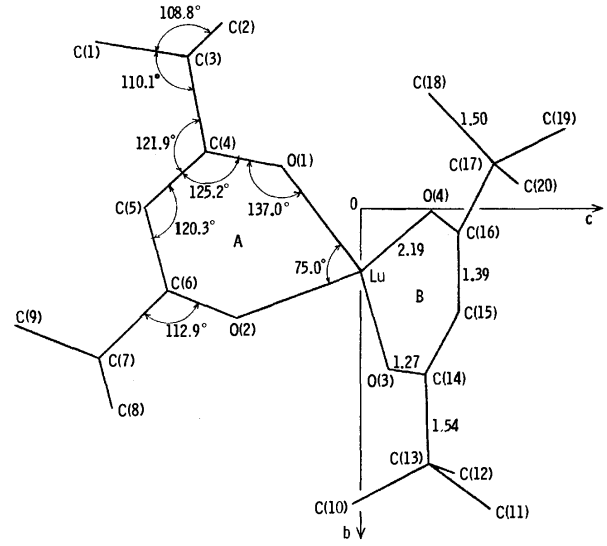

Fig. 1. Projection of the molecular skeleton along the a-axis.
The numbering system of atoms and average bond lengths (l/Å) and angles (φ/°) are also indicated.

of atoms except hydrogen were refined until all the parameter shifts became less than one tenth of the estimated standard deviations. The conventional R was 0.053 for the observed reflections.** At this final stage of refinement the difference Fourier map was flat and unreasonable electron density regions were not found, though no evidence of the hydrogen atoms were obtained.

The atomic scattering factors for carbon and oxygen atoms were taken from Ref. 5, and those for lutetium ion were from the table of Cromer and Waber.[6] The calculations were carried out using UNICS programs[7] at the Computer Center of the University of Tokyo. The refined parameters of atoms, the numbering of which is indicated in Fig. 1, are listed in Table 2.

Results and Discussion

The crystal consists of monomeric Lu(thd)$_3$ units, and in this unit there are two crystallographically independent chelate rings A and B. All the atoms of the forming the ligand A lie in the crystallographic mirror plane except two methyl carbon atoms of C(2) and C(8), which are accompanied with symmetrically related methyl carbon atoms. Projection of the unit along the a-axis (on the mirror plane) was shown in Fig. 1. The other two chelate rings of B are symmetrically related to each other. The angle between the A and B planes is about 117°. The chelate ring is nearly planar as indicated in Table 3 and the folding is about 3.5°. The interatomic distances and angles are listed in Table 4 and the average values are shown in Fig. 1. A comparison of the average values with those for other lanthanide complexes (Table 5) seems to indicate that the structure of the skeleton remains unchanged independent of the atomic number of the central atom and that the structure of the acetylacetonato ring is nearly the same as that reported by Lingafelter and Braun.[8]

The oxygen atoms coordinated to the central lutetium ion form a distorted trigonal prism as shown in Fig. 2, and this coordination polyhedron is the same as that found in Er(thd)$_3$. Metal-oxygen and oxygen-oxygen (bite) distances of β-diketone lanthanide complexes are summarized in Table 6. A constant bite cannot be found. The oxygen-oxygen distances widely range in these complexes probably because of the molecular

** The table of the observed and calculated structure factors ($\times 10$) is kept as Document No. 7610 at the Chemical Society of Japan.

Primed and unprimed atoms of the same number are related by the mirror plane.

constraints. The metal-oxygen distances, however, remarkably correlate with the atomic number of the metal. The distances are nearly equal to the sum of the ionic radii[9] of the metal (+3 for six coordination) and oxygen. The deviations are probably dependent on the kind of ligands (acac, thd and fod), and the coordination number of the metal (6 to 9). For example, the M–O lengths in fod complexes are generally smaller than those in thd complexes and the M–O lengths in six coordination complexes are smaller than those for seven coordination complexes (monohydrate or anhydrous dimer).

The four crystallographically independent *t*-butyl groups of the chelate rings A and B have nearly the same orientation with respect to the corresponding chelate rings. It is interesting to note that this orientation is the same as that in $Ni(thd)_2$[10] but is the opposite of $Zn(thd)_2$[11] (180° rotation about the C_3 axis of *t*-butyl group). To check the rotational configuration of the *t*-butyl group, the least-squares calculations were examined using the same structural parameters as listed

a) Oxygen atoms of M–O and O–O means carbonyl oxygen atoms. b) fod: 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione, dpp:1,3-diphenyl-1,3-propanedione.

in Table 2 except 180° rotation of *t*-butyl groups of the ring A and/or B. In these cases the *R* values did not increase significantly (~0.07), but the C_t–C_m lengths became unreasonably small (1.0—1.3 Å). However, uncertainty concerning the positions of the methyl groups may remain, if the high temperature factors observed for the methyl carbon atoms are interpreted as static disorder rather than as thermal motion.[3)]

All the intermolecular distances are about twice the van der Waals radius for a methyl group or longer, except a distance of 3.65 Å between C(12)(x,y,z) and C(2)$(0.5-x, -y, 0.5+z)$.

We are indebted to Dr. R. E. Sievers for providing the crystals of $Lu(thd)_3$.

(Received November 20, 1975)

A high-resolution vacuum spectrometer for the near and medium infrared has been designed and built with capability of resolving 0.03 cm^{-1}. The spectrometer consists of the fore-optics with a built-in White cell, a 2.5 m Littrow-McCubbin type monochromator which utilizes a 31.6 lines/mm echelle grating with the ruled area of 102 mm × 206 mm, and an order-sorter which is essentially a prism spectrometer of Wadsworth mount. Details of the design, construction, and performance of the instrument are described.

There are three types of method available for a construction of a high-resolution infrared spectrometer at present. They are dispersion type infrared spectrometer with a large grating, a Michelson type Fourier spectrometer and a spectroscopy using a laser source.

Recently, laser sources have been introduced to infrared spectroscopy and recognized to be very useful sources to obtain magnificient resolution. However, observable spectral regions are confined to the frequency ranges very close to particular laser lines. In order to correlate laser lines to molecular absorption lines, the laser frequencies must be tuned by appropriate methods, *e.g.*, a Zeeman shift technique, or the molecular absorption lines must be moved to the laser frequencies using a Stark effect, a spin-magnetic resonance effect, and so on. These methods can cover very narrow frequency regions, say, ± 1 cm^{-1} from laser frequencies. In the case where a molecule has no dipole moment or electric spin moment, it is impossible to move molecular absorption lines by the above techniques. Although recent developments of dye lasers and semiconductor lasers make it possible to extend the tunable regions considerably, it is not wide enough to use the laser elements in a system for general purposes.

In principle, Fourier spectrometer using Michelson interferometer is the most preferable spectrometer in the respects of a resolution and of observable spectral regions. A resolution which has been actually obtained by the method is about 0.005 cm^{-1} and an observable spectral region 2830—10000 cm^{-1} with a PbS detector.[1] Since a resolution of an interferometer is inversely proportional to a path difference of two interfering beams, one must translate one of the plane mirrors over a long distance with a high accuracy. Suppose the mirror is translated 200 cm, a resolution obtained is 0.005 cm^{-1} so long as an apodization procedure is perfect. During the translation of the mirror, the path differences must be measured with a high accuracy and the direction of the mirror must be kept definitely constant. The other difficulty is a treatment of interferograms. In order to transform an interferogram to a usual spectrum, a computer with large memories must be used, because a number of observed points of a interferogram is numerous.

On the other hand, a large grating high-resolution spectrometer is the most general method and its construction is comparatively easier than the other two methods. Though a resolution obtainable by a large grating spectrometer is much lower than those of the other two methods, this type of spectrometer is more convenient to use than the others in the respect of its construction and its operation. A wide frequency region can be covered by the use of suitable gratings and detectors. Therefore, we decided to construct a large grating spectrometer. Our wishes to study rotational fine structures of vibrational transitions for usual interesting molecules dictated the basic design requirements. Briefly, these were that the instrument should cover the spectral region 600 to 4000 cm^{-1}, that the resolution should be the order of 0.03 cm^{-1} at all wave numbers, that we should be able to handle samples of ordinary interests conveniently, and that the operation and calibration of the instrument should be relatively straightforward. The following items have been mainly taken into account in the design and construction of the present spectrometer, *viz.*,

(1) the resolution is better than 0.04 cm^{-1},

(2) the frequency region covers from 600 to 4000 cm^{-1},

(3) the accuracy of frequency measurement is better than 0.001 cm^{-1},

(4) the accuracy of intensity measurement is better than $\pm 1\%$,

(5) the whole spectrometer system is stable enough to do continuous measurements, and

(6) the lines of atmospheric carbon dioxide and water vapour should be eliminated sufficiently.

A resolution, $\Delta\nu$, of a spectrometer is expressed as

$$\Delta\nu = \frac{d\cdot\cos\theta}{p\cdot n}\cdot\frac{s_1+s_2}{f}\nu^2+\frac{1}{p\cdot 2W\cdot\sin\theta} \qquad (1)$$

where d is a grating constant, p a number of optical paths to the grating, s_1 and s_2 mechanical slit widths of entrance and exit slits, respectively, f a focal length of a collimating mirror, and W a ruled width of the grating. On the other hand, radiant power which arrives at a detector for a particular frequency and a slit width is given by

$$E = \frac{BThAD}{f}\cdot(\Delta\nu)^2 \qquad (2)$$

where B denotes source radiance, T transmittance of a whole spectrometer, h a slit height, A an effective area of a collimating mirror which usually corresponds to a ruled area of a grating, and D angular dispersion of a grating. Equations (1) and (2) show that a resolution is higher as a focal length increases, while energy arrives at a detector decreases as a focal length increases. In order to increase a focal length to realize the required resolution without losing too much energy, an effective area of a collimating mirror, A, and a slit height, h, should be increased at the same time, which leads to the increase of the whole dimensions of a spectrometer.

Most of the large grating spectrometers reported so far have been designed for special uses in the regions above 2800 cm^{-1} and have been used for the observations of the C–H stretching fundamental bands and other summation bands. We referred to the spectrometer constructed in the University of Minnesota,[2] because it satisfies most of the required items for our spectrometer.

Removal of atmospheric carbon dioxide and water vapor was essentially important, because their existence makes it impossible to measure absorption spectra in the regions where these molecules show strong absorption lines, *e.g.*, 2200—2400 cm^{-1} region, 1300—1800 cm^{-1} region, and so on. Therefore a vacuum spectrometer has been considered and the problem of vacuum has been one of the most troublesome problems at all stages in the building.

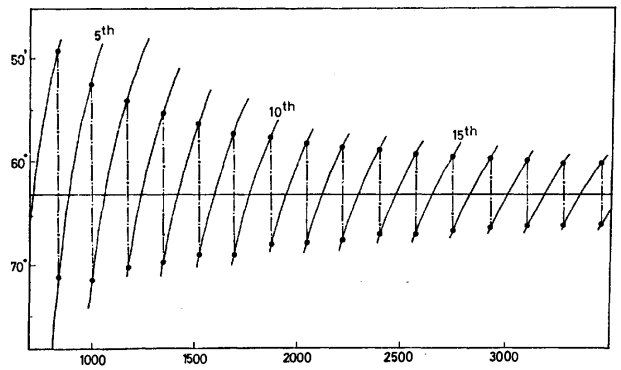

Fig. 1. Relation between angle of incidence on grating and frequency for various grating orders. Actual frequency scanning is performed along the real lines.

A grating is the most important component of an optical system, so we must decide a desirable grating at first to construct the spectrometer. A grating finally chosen is an echelle type plane replica grating made by Bausch and Lomb Co., Ltd. The grating has a ruled area of dimensions 206 mm × 102 mm with 31.6 lines per mm and a blaze angle of 63°26′. This type of grating is superior, in the respect of linear dispersion and brightness, to that of fine echellette, because the latter has a small grating constant, d, and a small blaze angle of about 30°. By the use of the above grating of echelle type, the frequency region of 600—4000 cm^{-1} can be covered by changing a grating order. Figure 1 shows relations between an angle of incidence on the grating and frequencies for various grating orders. The horizontal line corresponds to the blaze angle and, therefore, an actual frequency scanning is performed along the real lines of the figure. It is seen from the figure that the lower a grating order the more angular change is necessary for scanning of the same frequency interval.

Optical Systems

The main part of the monochromator is of Littrow-McCubbin type with an optical system of 2500 mm focal length as shown in Fig. 2. The whole optical system may be classified into three parts, namely, fore-optics with a sampling system, a grating monochromator, and an order sorter.

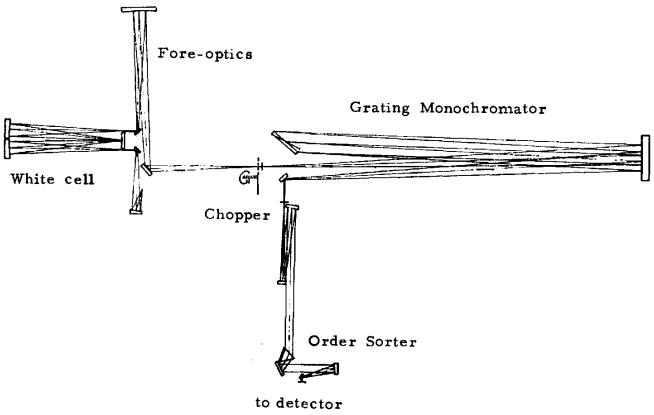

Fig. 2. Optical layout of spectrometer.

Grating Monochromator. A grating monochromator is the most essential of all, because it governs a resolution and an accuracy of frequency measurement. According to Eq. (1), the theoretical resolution for the grating described in the preceding section is 0.027 cm^{-1}

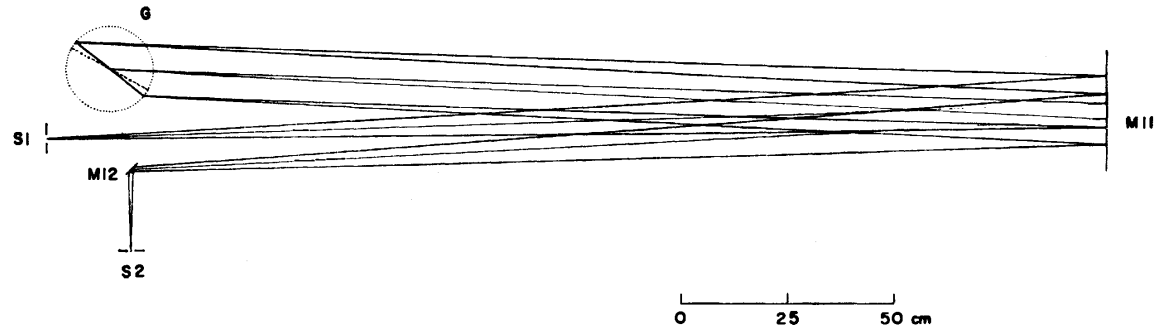

Fig. 3. Optical layout of grating monochromator for single pass operation.

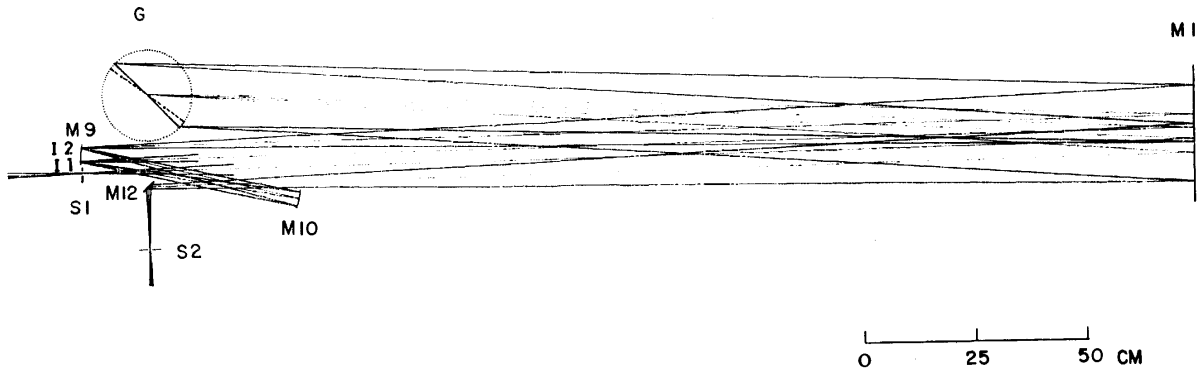

Fig. 4. Optical layout of grating monochromator for double pass operation.

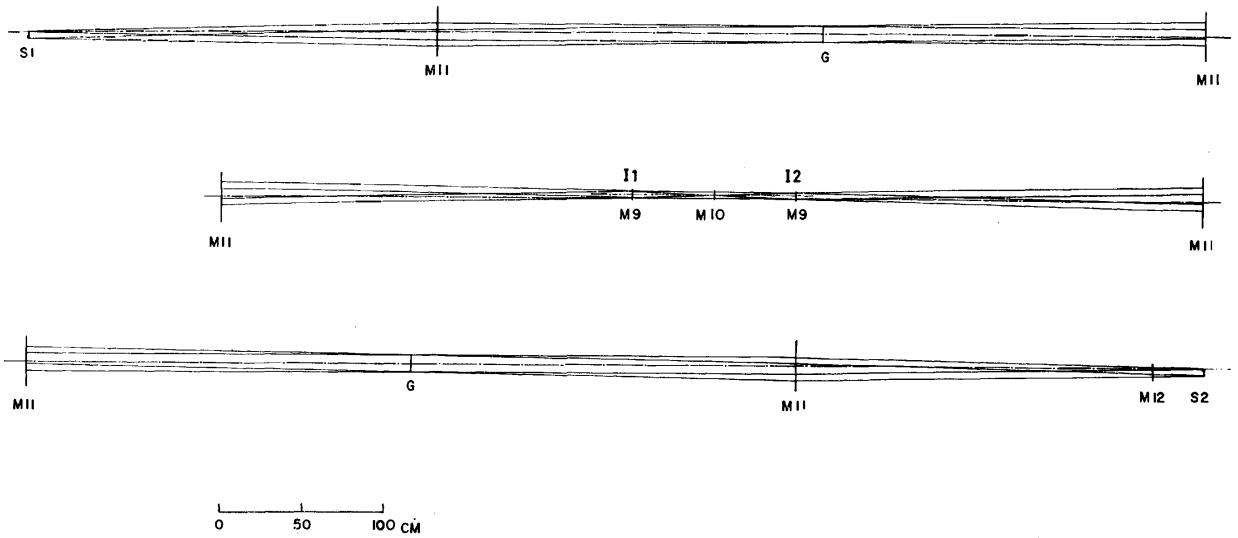

Fig. 5. Vertical tracing of monochromator optics for double pass operation. Single pass component is separated by masking upper halves of entrance and exit slits.

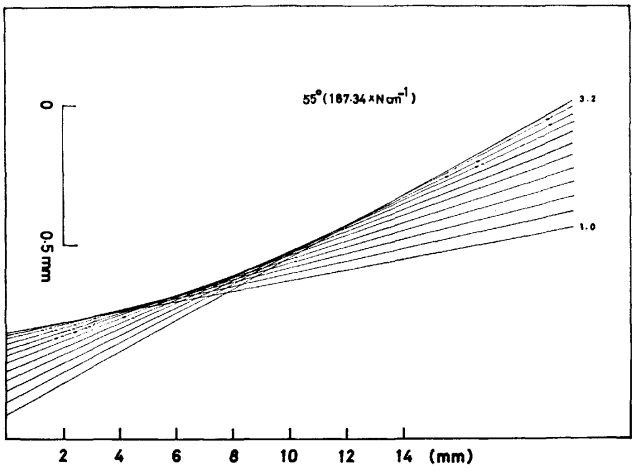
and 0.014 cm^{-1} at the blaze angle with single path ($p=1$) and double path ($p=2$) operations, respectively. The optical layouts are shown in Fig. 3 for a single path operation and in Figs. 4 and 5 for a double path operation. The collimating mirror M11 has a focal length of 2500 mm and a diameter of 300 mm. The f-number of the monochromator is about 25. For the double path operation, the light beam from the entrance slit S1 illuminates the grating G, after being collimated by the mirror M11. The reflected light from G is focused upon the spherical mirror M9 ($R=1000$ mm) at I1. The image at I1 is transformed to I2 by the spherical mirror M10 ($R=500$ mm). After being collimated and reflected by M11 and G once more, the light beam is finally focused upon the exit slit S2 (see Figs. 4 and 5).

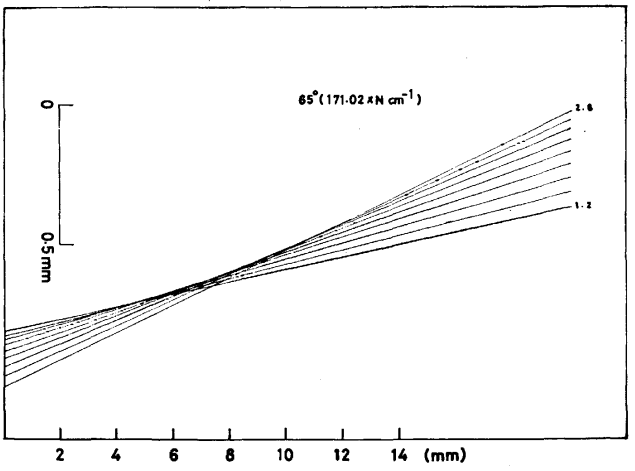
Since the light beam is chopped just before the entrance slit S1, the single-pass radiation and the double-pass radiation must be separated optically. If the upper half of the entrance slit is masked, the image at S1 is transferred to the lower half of S2 with respect to the optical axis in the case of double pass operation. For the case of single pass operation, on the other hand, the upper half image at S1 is transferred to the lower half image at S2. Therefore, a double pass component can be definitely separated from a single pass component by masking either upper or lower halves of the entrance and exit slits. The situation is illustrated in Fig. 5, where the dotted line corresponds to the optical axis and the image I1 of double pass operation corresponds to the image S2 of single pass operation. The points at I1 and I2 are conjugated with respect to M10, while the points at S1 and S2 are conjugated with respect to M10. The grating pupil is focused upon the field mirror M10 and, therefore, M10 can be as small as 20×20 mm^2.

The slits S1 and S2 have the heights of 80 mm, but only the lower halves of about 30 mm are used for a double path operation. For the double path operation, both entrance and exit slits[3] have a radius of curvature of 640 mm. For the single path operation, S1 is a straight slit and S2 has a curvature. The curvature of 640 mm is based upon the sagittal curvature calculated at the blaze angle. Although the curvature is slightly different at the other angles, the difference is negligible because relatively small range of angle is used for the actual scanning (see Fig. 1). Moreover, if half of the slit is masked, effect of the different angles becomes much smaller.

The aberration which arises from the use of a spherical mirror for M11 is examined carefully by the beam tracing method using a large electronic computer. A few results are illustrated in Figs. 6a and 6b. In this



6a. Incident angle to the grating is 55°.



6b. Incident angle to the grating is 65°.

Fig. 6. Results of beam tracing by computer. The entrance slit is put at the origin which is 2500 mm apart from the collimating mirror. Spindle axis parallel to optical axis. Small figures of the right side show angles of the ray at entrance slit. Note that scales of the spindle and cross axes are different.

calculation, the entrance slit is put at the origin which is 2500 mm apart from M11. The diffuseness at the focal point is about 0.06 or 0.04 mm for the incidental angle of 55° or 65°, respectively. Because the mechanical slit width used for the ordinary spectral measurements is 0.4—0.2 mm, the effect of the aberration is negligibly small. Figure 6 shows that the focal point at the exit slit is about 8 mm forward. Therefore, the entrance and exit slits are simultaneously moved about 4 mm forward along the optical axis, because S1 and S2 must be optically conjugated.

Fore-optics and White Cell. For a measurement of high-resolution infrared spectrum, it is necessary to use a long path cell, for the line width due to pressure broadening often exceeds the spectral width of a monochromator even under low sample pressure. Thus, we designed the fore-optics with a long-path cell of White type[4] optically matched to the monochromator.

Figure 7 shows the optical layout of the fore-optics with a White cell. The light from the source S0 is focused by an ellipsoidal mirror M1 at the point very

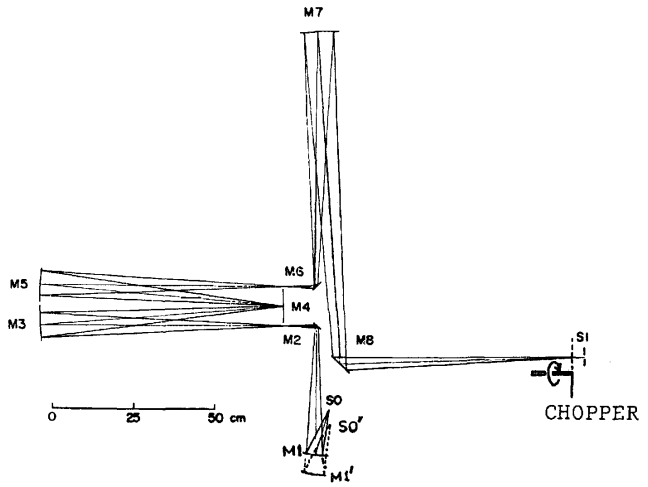


Fig. 7. Optical layout of fore-optics with White cell.

close to the KBr window of the White cell. After being reflected multiple times in the White cell between the spherical mirrors M3, M4, and M5, the light beams are focused on the entrance slit S1. The *f*-number is matched to 25 which is the same with that of the grating monochromator. As the *f*-number at the source S0 is about 3.75, the source image is magnified by about 6.6 at S1. The ellipsoidal mirror M1 and the spherical mirror M7 are used for the *f*-number matching.

The White type long-path cell has three spherical mirrors with a focal length of 757.9 mm and has two KBr windows with diameters of 70 mm. This cell is optically matched with the spectrometer. The light beam is guided into the cell by the plane mirror M2. The White cell has a physical length of about 75 cm between the mirrors M3 and M4, or M5 and M4, giving path length up to 30 m. The sampling system of a vacuum line is always combined with the White cell, which guarantees the vacuum of about 10^{-5} Torr when there is no sample in the system.

The White cell can be removed and mirrors M2 and M6 are used to bring the radiation out to an external sampling device and return it to the vacuum instrument. Mirrors M2 and M6 can be removed, giving a sample space for a short cell use. In this case, it is necessary to translate a mirror M1 and a source S0 to the positions M1' and S0'. Both components are mounted on a single plate which slides along the rail parallel to the optical axis.

The source S0 is a Nernst glower purchased from Perkin-Elmer with an active length of 20 mm. The source is covered with a brass mantle. The electric circuit involves a 60 W balast lamp. The conditions of the source operation are 0.3—0.45 A and 80—100 V. The stability of the light source is quite satisfactory in the vacuum, because there is no convection of air in the vacuum.

Order Sorter. The optical layout of the order sorter is shown in Fig. 8. The order sorter is essentially a prism spectrometer of Wadsworth mount and separates the order of a grating. The prism P and the Wadsworth mirror M15 are mounted on a single plate and is rotated so as to keep the angle of minimum deviation.

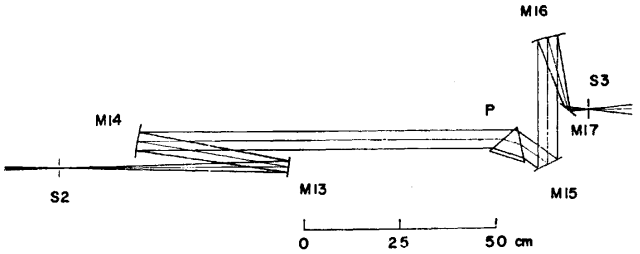

Fig. 8. Optical layout of order sorter.

Three different prisms of KBr, NaCl, and CaF_2 are used for the different frequency ranges. They are 60° prisms with 70 mm in height and with 100 mm base length.

The light beam from the exit slit S2 of the grating monochromator is collimated by the parabolic mirror M14 which has a focal length of 1000 mm. After being separated into grating orders by the prism P, the light beam is focused on the exit slit S3 of the order sorter by the parabolic mirror M16 of a focal length of 250 mm. Therefore, the image at S3 is one fourth of the image at S2. A straight slit is used for S3, because the prism P is oriented so that the curved image at S2 is changed into the straight image at S3. The position of P is at an exit pupil of the grating. The mirror M16 is positioned to give another exit pupil of the grating at about 300 mm behind the exit slit S3.

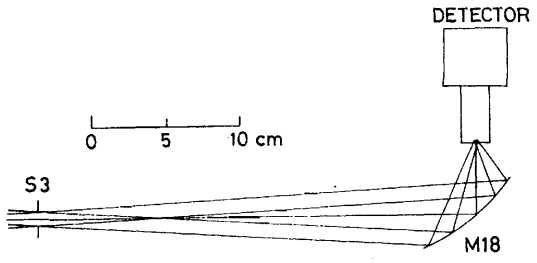

Fig. 9. Optical layout between exit slit and detector (vertical).

In order to collect the radiation to the detector, we used an ellipsoidal mirror M18 by which the light beam is vertically reflected and focused upon the detector element (see Fig. 9). The exit slit S2 is finally imaged upon the detector with a magnification of about one twenty-fourth. The detector is positioned out of the vacuum tank and the distance from the exit window of

TABLE 1. DETAILS OF MIRRORS

Name	Type	Dimension (mm)	Remarks
M1	ellipsoidal	150×78	a=325.0, b=269.5, α=22°
M2, M6	plane	80×50	
M3, M5	spherical	160×125	R=757.9
M4	spherical	60×110	R=757.9
M7	spherical	230 ϕ	R=1207.43
M8	plane	150×90	
M9	spherical	55×55	R=1000
M10	spherical	40×40	R=500
M11	spherical	300 ϕ	R=5000
M12	plane	80×25	
M13	plane	180×50	
M14	parabolic	150×80	f=1000, α=6°
M15	plane	100×90	
M16	parabolic	100×70	f=250, α=15°
M17	plane	80×35	
M18	ellipsoidal	80×70	a=175.0, b=86.6, α=19°

R: Radius of spherical mirror (mm), f: focal length of parabolic mirror (mm), a: a half of longer axis of ellipsoidal mirror (mm), b: a half of shorter axis of ellipsoidal mirror (mm), α: off-axis angle.

the vacuum spectrometer to the mirror M18 is about 15 cm. One can use this space to put a short path gas cell for the calibration purpose or the usual spectral measurement.

Mirrors. All the mirrors used are made on BK7 glasses and the thickness is greater than one fifth a diameter. Aliminum surface is coated with silicon monoxide. An accuracy of a surface is better than $\lambda/2$ (λ=546 nm). The dimensions of the mirrors are determined by drawing the plane figures (see Figs. 2, 3, 4, 7, and 8) and the vertical figures (see Figs. 5, 9, 10, and 11) of the optical layout. In Table 1, the mirrors used are summarized with the types and dimensions.

Detection System

The detection system adopted in this spectrometer is a phase sensitive detection system. The schematic diagram of the whole system is shown in Fig. 12. A mechanical chopper of a rotating circle is positioned just in front of the entrance slit S1 and chops the signal and reference signal beams simultaneously. The rotating circle has six wings made of a pasteboard and is jointed to the direct current vacuum motor[6] which rotates

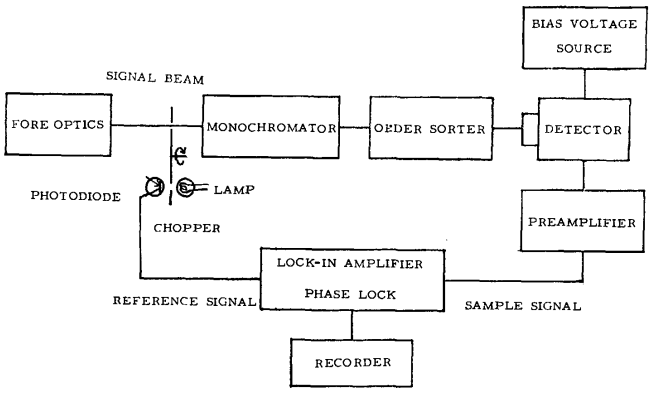

Fig. 12. Detection system (schematic).

about 100 Hz in vacuum. Therefore, the light beams arrive at the detector is a 600 Hz alternating pulse signal. After being amplified by a preamplifier,[7] the signal from the detector is put into the lock-in amplifer[8] and compared with the reference signal. The 6.3 V midget lamp is used as the reference light source and the light energy is transformed into electric current by the phototransistor OS14. The final output from the lock-in amplifier is direct current and is sent to recorder.[9]

Detector and Preamplifier. As an actual resolution of a spectrometer is governed by a signal to noise ratio, detectivity of a detector is the most important problem for the construction of a spectrometer. In our spectrometer, an InSb semiconductor detector is used for the region around 2000 cm^{-1}, a Ge: Au detector below 1800 cm^{-1} region, and a PbS detector above 3000 cm^{-1} region. The detectivity of InSb detector is higher than that of Ge: Au detector about one order of magnitude at 2300 cm^{-1} region. The ν_2 band of carbon dioxide is measured by use of these two different types of detectors under the same instrumental conditions. The S/N ratio of the spectra for InSb detector is about ten times better than that for Ge: Au detector. Although at the longer wavelength region, there are a few detectors which are superior in detectivity to Ge: Au detector, they must be cooled by liquid helium. At the present situation of our laboratory, it is rather inconvenient and troublesome to use liquid helium. Thus we decided to use a Ge: Au detector for the longer wavelength region.

The preamplifiers suitably designed to the individual detectors are made by ourselves. The amplification factors are limited to 20—50 dB.

The InSb detector was purchased from JEOL, Ltd.,[10] with the sensitive area of 1×1 mm^2. The preamplifier and the bias voltage supplier were constructed according to the data sheet, the amplification degree being about 30 dB.

The Ge: Au detector was purchased from Barnes Co.,[11] with the sensitive area of 2×2 mm^2. The magnitudes of bias voltage and load registor are adjusted to the recommended values from the detector manufacturer. The preamplifier was made by the use of an operational amplifier of Burr-Brown model 3503A.[12] The amplification degree is about 50 dB.

The PbS detector was purchased from Infrared Industries[13] with the sensitive area of 2×2 mm^2.

Vacuum System and Room

The elimination of atmospheric carbon dioxide and water vapor is essentially important, because they have strong absorption bands in the infrared regions. Since the optical pathlength of the entire system is about 30 m long, it is desired to build a spectrometer in vacuum.

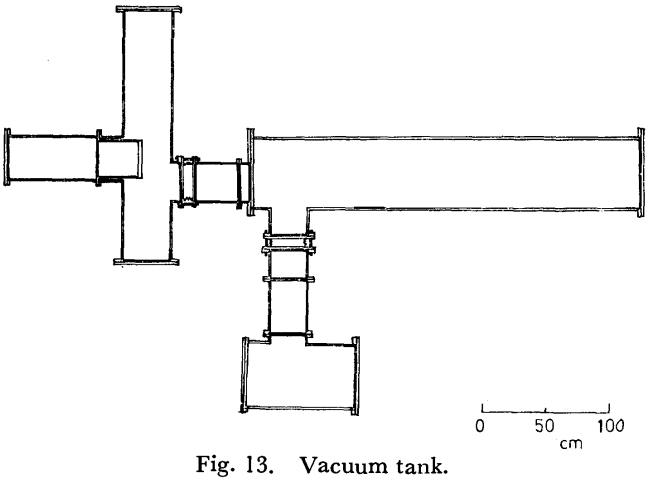

Fig. 13. Vacuum tank.

Figure. 13 shows a plane tracing of a vacuum tank system. The tank system is conveniently separated into three parts in accordance with the optical system, *i.e.*, a main tank, a fore-optics tank, and an order sorter tank. These three parts are connected with each other by bellows flanges which can be collapsed and removed without disturbing the optical system, since there are no internal optical benches inside of the bellows sections. This system is beneficial to avoid the spread of distortions of the individual tank due to temperature changes and to evacuation. All the flanges and end covers are sealed with O-rings. Removing these covers and bellows sections, we can set and adjust all the necessary optical elements effectively.

A rotary pump[15] is used to evacuate the vacuum tank with evacuation speeds of 3000 l/min. As the total volume of the tank is about 1000 l, we can reach pressures of about 10^{-3} torr within a few minutes. Using an oil diffusion pump,[16] we have actually reached pressures of 10^{-4} Torr, although it is not always necessary to operate the spectrometer under such low pressure. In order to avoid the mechanical vibration transferred from the main rotary pump, we can use a supplementary pump of 450 l/min evacuation speed[17] after the spectrometer is evacuated by the main pump.

The detector system is placed out of the vacuum tank and, therefore, nitrogen gas is flashed to remove atmospheric carbon dioxide and water vapour. Actually the detector system is confined in an aluminum box. The disturbing absorption lines of these molecules were reduced to about one twentieth by flashing dry nitrogen gas inside of the box.

In order to avoid the effect of mechanical vibrations of room floors, the spectrometer base is fixed rather loosely to the floor by the use of sand and mortar as illustrated in Fig. 14. In addition, optical benches

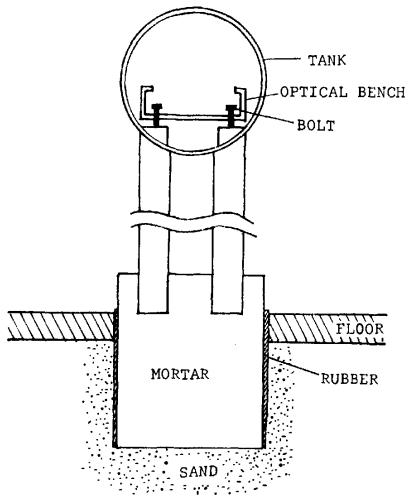

Fig. 14. Schematic figure for spectrometer base. Optical bench is mounted on vacuum tank kinematically.

are kinematically mounted so that the distortion and vibration of the tanks would not directly disturb the optical set-up.

The room is airconditioned,[18] which keeps the temperature and humidity of the room within 23±0.5 °C and 45±5%. The variation of the temperature will cause the thermal expansions of optical benches and vacuum tanks, which will disturb the optical alignment of the spectrometer.

Mechanical System[19]

Driving Mechanism of Grating. The most principal part of all the mechanisms is a driving mechanism of a grating, because it governs an accuracy of frequency measurements. Figure 15 shows the plane figure for the grating drive mechanism. Figure 16 is the cross section of the rotatory shaft of the grating drive. The mechanism is arranged to give both fine and coarse drives. The former is used for the precise measurements under optimum resolution, while the latter is used for the survey works and for setting the instrument to a suitable wavelength range. The coarse driving mechanism is extremely convenient and indispensable for actual measurements.

As shown in Figs. 15 and 16, the rotatory shaft is composed of three coaxial cylinders made of stainless steel. The outer cylinder is fixed to the optical bench. The intermediate cylinder is equipped with a 400 mm tangent arm and rotates inside the outer cylinder. The weight of this cylinder is supported by a ball bearing which is set upon the outer cylinder. Since the cylinder faces are carefully polished, the rotation is very smooth. The tangent arm is pushed by a stainless steel rod which is connected to a 50 mm micrometer head.[20] The micrometer is driven through a gear box external to the vacuum tank. The rotatory rod which connects the micrometer and the gear box is sealed by O-rings as shown in Fig. 17. The gear box is designed to give six scanning speeds from about $(5n/2)$ to $(5n/64)$ cm^{-1}/h, where n is the grating order.

The inner cylinder, upon which the grating is mounted, is rotated by a worm and wheel of about 160 mm diameter. This part is placed upon the tangent arm and is designed for coarse driving purpose. The inner cylinder is driven by a second gear box which is set out of the vacuum tank. Scanning speed is changeable from $20n$ to $640n$ cm^{-1}/h, where n is the grating order. The diameters of these three cylinders are 120, 80, and 40 mm.

In order to determine the frequencies with the

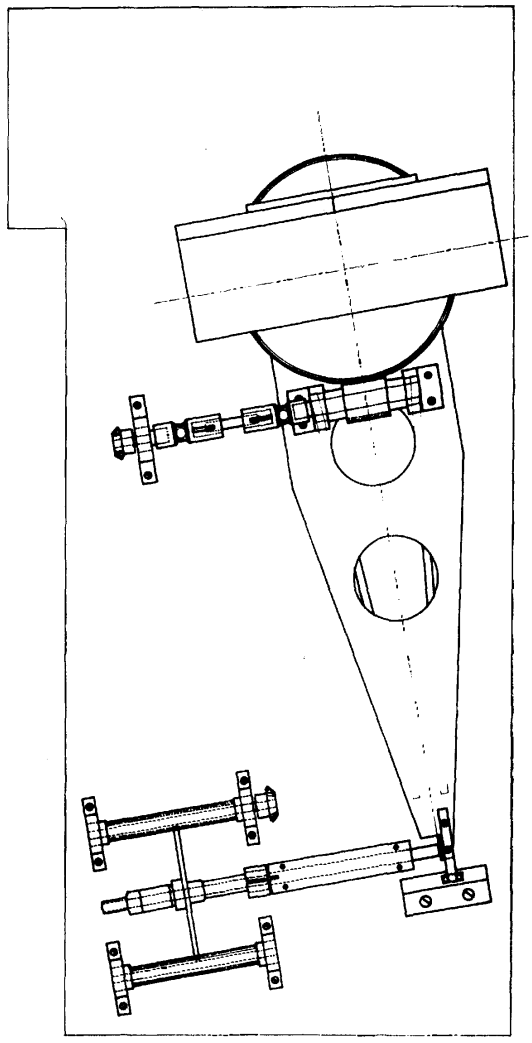

Fig. 15. Plane figure of grating drive mechanism.

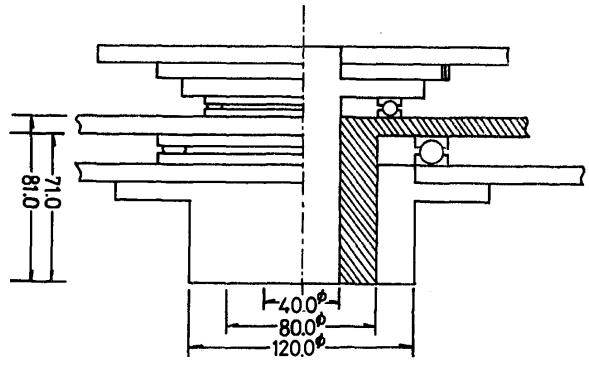

Fig. 16. Cross section of rotating shaft of grating drive mechanism.

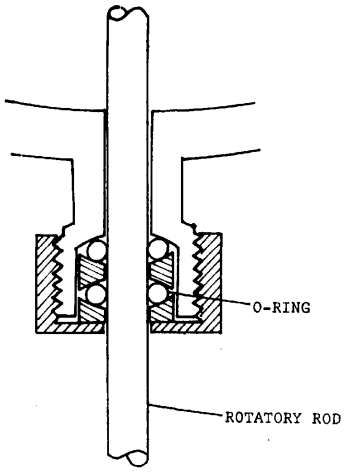

Fig. 17. Sealing of rotatory rod.

accuracy of 0.002 cm^{-1}, the grating must be rotated with the accuracy of 1 second of arc. As mentioned above, the fine drive mechanism consists of a 400 mm tangent arm and a 50 mm micrometer head. The required accuracy can be satisfied, because the accuracy of the micrometer drive is ascertained to be better than 0.01 mm.

Driving Mechanism of Prism. The prism drive mechanism is essentially the same as that of grating drive. A bearing of 30 mm diameter is connected to the nut which, in turn, slides along the screw. We manually drive the screw from outside the vacuum tank. No provision is made for coupling the prism rotation with that of the grating mechanically, because the setting of prism rotation must be changed only about once an hour under normal running conditions.

Mirror Holders. Modified Perkin-Elmer mount has been applied for the design of all the mirror holders, except for the spherical mirrors, M7 and M11. The holders for M7 and M11 can slide along a guiding rod by a screw and a nut which is fixed to the mirror mount (see Fig. 28). We can accurately adjust the position of the mirror by driving the screw.

Performance

As mentioned earlier, a particular order of an echelle type grating has a narrow frequency region. Using a few orders, however, we can cover the wider frequency region (see Fig. 1). Firstly we have to know the relation between the grating order and the rotating angle of a prism. The grating is fixed at a particular position and the prism is rotated slowly by hand. As shown in Fig. 18, we can observe the successive intensity maxima along the angle of prism rotation. The grating order can be determined from the cut off frequency of the detector and the atmospheric CO_2 absorption. The 4.5 μ absorption band of carbon dioxide is observed in the 13-th order.

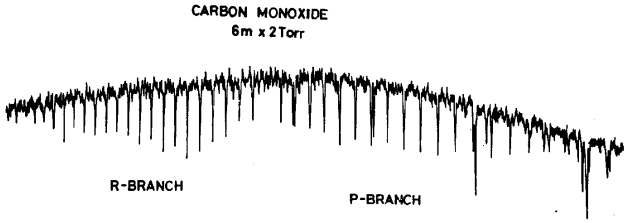

Fig. 19. Rapidly scanned spectra for CO.

Next procedure is to determine the relation between the coarse drive counter and the frequency. The carbon monoxide has absorption lines in fairly wide region with regular spacing. Fixing the prism angle at 12-th order of the grating, we scan the coarse driving mechanism without moving the fine drive. We obtain the CO spectrum as shown in Fig. 19. As the frequencies of CO lines are accurately known,[21] the calibration diagram for the coarse drive can be obtained.

It is necessary to know the relation between the mechanical slit width and the counter number of slit drive mechanism. The entrance slit S1 is fixed about 4 mm wide, and the width of exit slit S2 is changed from 2.00 mm to zero. Since the energy which reaches at the detector is proportional to the width of S2, we can calibrate the mechanical slit width against the counter number of the slit S2. The same method is applied to the entrance slit S1.

The resolving power of the spectrometer is checked by observing the ν_3 band of NNO, $2\nu_3$ band of CH_3F, 10 μm CO_2 laser lines and so on. The line width of CO_2 laser line is about 0.002 cm^{-1} for the multimode operation, which corresponds to a Doppler breadth. Since the diffraction limit of the grating of this spectrometer is about 0.027 cm^{-1} for single pass operation, the line width of the CO_2 laser is negligibly small. In Fig. 20 shows the observed spectrum of CO_2 laser

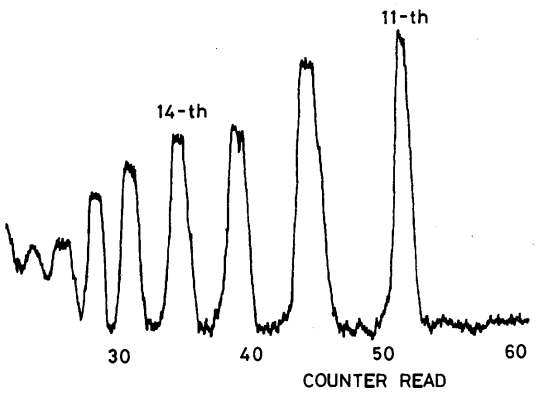

Fig. 18. Grating orders and prism counter.

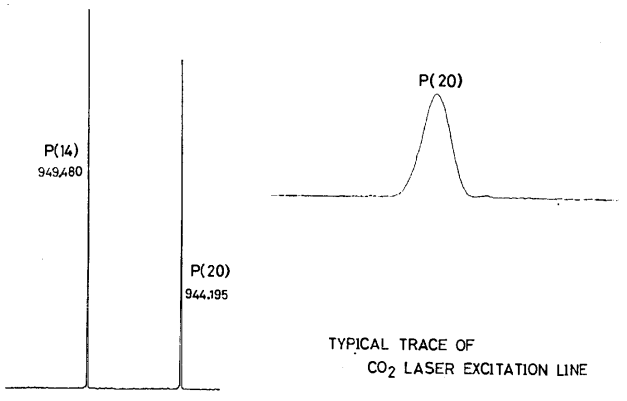

Fig. 20. Typical trace of CO_2 laser line.

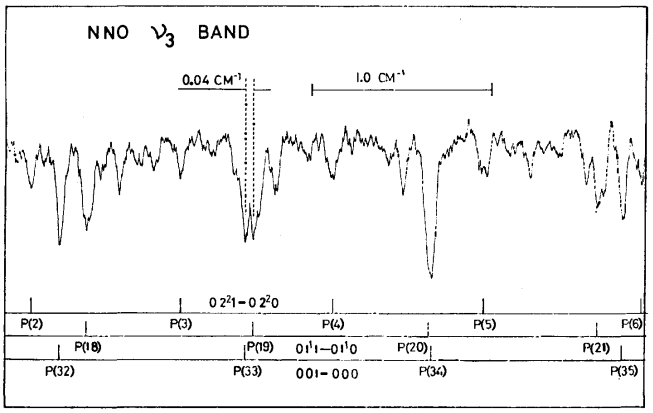

Fig. 22. Resolution check by ν_3 band of NNO. Double pass operation, InSb detector.

line. The half width of the observed line is about 0.03 cm^{-1}, which corresponds to the resolution limit for the single pass operation.

For usual measurements, the resolution is limited by a signal to noise ratio which is governed by the detectivity of a detector. As the ν_3 band of NNO has a number of hot band series, the absorption lines have various separation. Figure 28 shows the observed spectra of the ν_3 band of NNO with a single pass operation using an InSb detector. The resolution is better than 0.07 cm^{-1}, although this region is far from the blaze angle of the grating. In Fig. 22, the spectra of ν_3 band of NNO observed with a double pass operation is shown with their assignments. These lines are seen to be measured with good S/N ratio and the resolution is ascertained to be better than 0.04 cm^{-1}.

The ^QQ-branch of $2\nu_3$ band of CH_3F is completely resolved into its J-components and the individual J-component is resolved into a lot of K-components. From the spacing of the resolved lines, the resolution is ascertained to be better than 0.04 cm^{-1}. The detailed analysis of the band has been given in elsewhere.[22]

An accuracy of a frequency measurement is estimated from the standard deviation of the CO calibration lines fitted with the quartic equation. The standard deviation of the actually observed CO lines is about 0.005 cm^{-1}. The value of 0.005 is obtained from a single measurement and the error arises mainly from the reading ambiguity of the line positions.

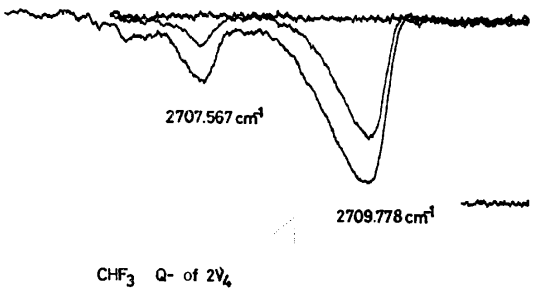

Fig. 23. Q branch of $2\nu_4$ and related hot bands of CHF_3.

The intensity accuracy is checked by observing relative intensities of the Q branch of the $2\nu_3$ band of CHF_3, the observed result of which is shown in Fig. 23. The three Q branches are assigned to one main band and two hot bands. As the intensity of the Q branch is proportional to the Boltzmann factor, we can ascertain the accuracy of the intensity measurements by comparing the theoretical and observed intensity ratios of the three Q branches. The result indicates that the accuracy along an intensity axis is better than $\pm 3\%$ of the full-scale disregarding to the effect of the S/N ratio.

Photographs of the Spectrometer

Photographs of the spectrometer are summarized in Figs. 24—29. In Fig. 24 a part of the monochromator tank is seen at the right hand side and the order sorter tank at the lower left. These two tanks are combined with bellows flanges. The fore-optics tank is seen at the middle of the picture. The vacuum lines which is seen at the upper side is the sampling system. Figure 25 shows the fore-optics with a long path cell of White type. Behind the fore-optics tank, the flange of the monochromator is seen. The U-pipe leads to the vacuum pump. Figure 26 shows the top view of the grating monochromator. The grating and the coarse driving mechanism are clearly seen. At the upper left we see the entrance slit S1 and double pass mirror M9.

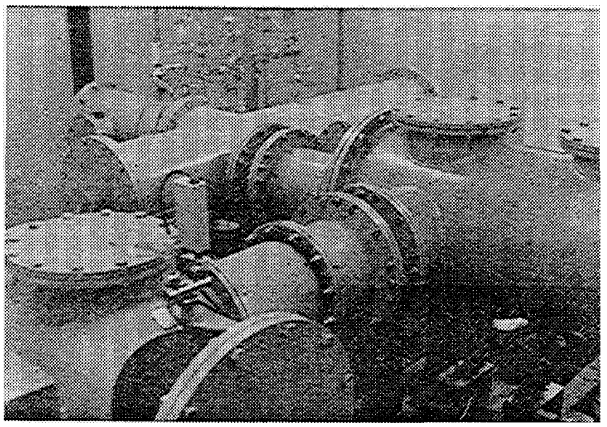

Fig. 24. Vacuum tank (whole view).

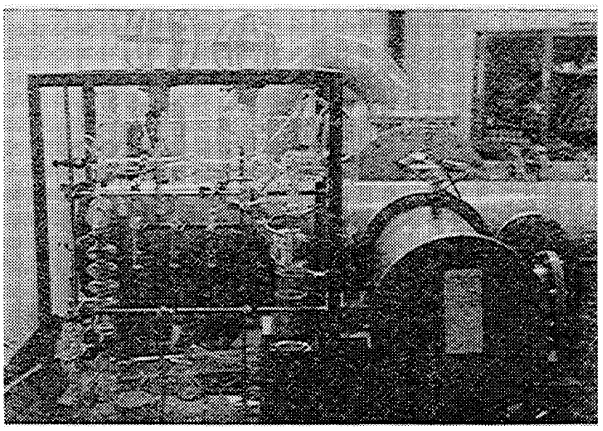

Fig. 25. Sampling system.

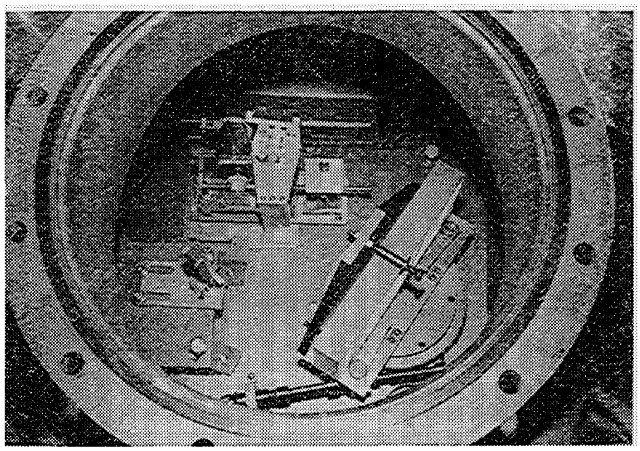

Fig. 26. Top view of grating monochromator.

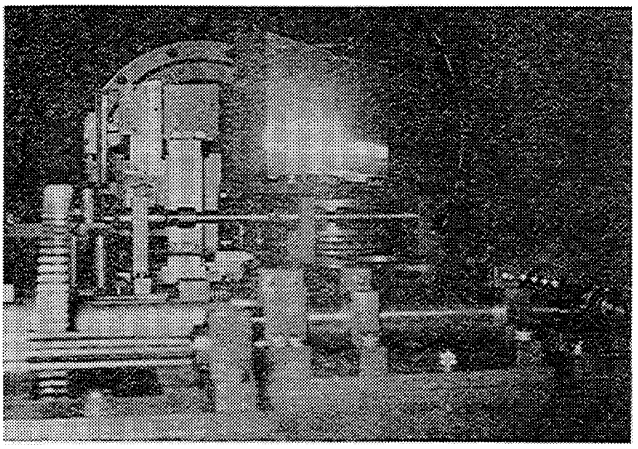

Fig. 27. Side view of grating monochromator.

The coarse driving mechanism consists of a worm and wheel. The side view of this part seen from the direction of the collimator mirror is shown in Fig. 27. The grating strongly reflects the flash-lamp light. Behind the grating, the entrance slit and double pass mirror M9 are seen. The fine drive mechanism which consists of the micrometer and the tangent arm is seen before the grating. In Fig. 28, we can see the optical bench and the mirror holder inside the main tank. Note that the optical bench is supported by bolts and is not fixed to the tank directly. The order sorter part is

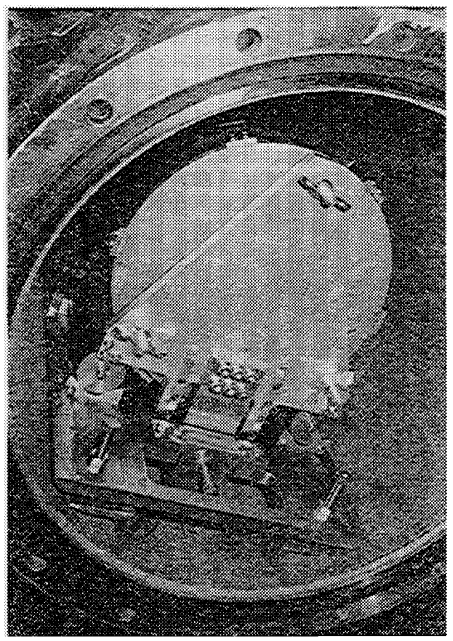

Fig. 28. Collimating mirror.

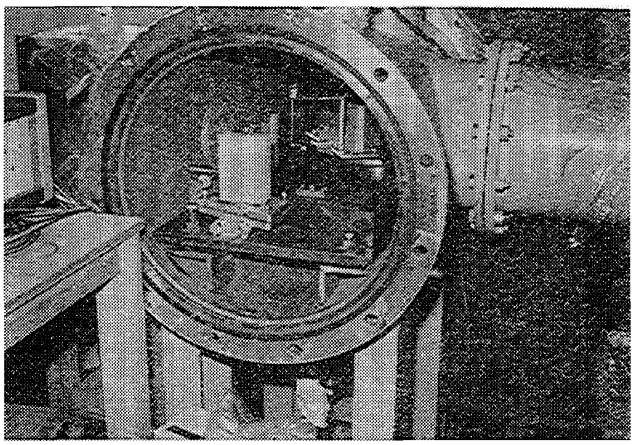

Fig. 29. Order sorter.

seen in Fig. 29. The prism and M15 are placed on the same rotatory holder.

Effect of Temperature on the Infrared Spectroscopic Parameters of Hydrogen Bonds between Some Phenols and Nitriles

Inam JAWED*

Department of Physical Chemistry, Peshawar University, Peshawar, Pakistan

(Received March 18, 1975)

The effect of temperature on the infrared spectroscopic parameters of hydrogen bonds between a number of phenol-nitrile systems has been studied. The infrared frequency shift always decreases with increase in temperature. The variation of half width of the hydrogen bonded band, however, is not regular and is within the error of measurement. The intensity of the bonded band shows a general decrease with rise in temperature. All these variations are interpreted as being indicative of the weakening of the hydrogen bond with increase in temperature.

The effect of temperature on the infrared spectroscopic parameters of hydrogen bonds has long been recognized.[1] The present study was undertaken to investigate this effect for some hydrogen bonded systems of phenols and nitriles in the temperature range 20—60 °C and is concerned with stretching vibration of the hydroxyl group, ν(OH), involved in the hydrogen bond. The phenols and nitriles were chosen so as to give a rather wide range of acidities and basicities respectively as shown by the pK_a values and Hammett substituent constants of phenols and Taft substituent factors of nitriles (Table 1). Taft factor, being a measure of the inductive effect of the substituent group, can be conveniently considered to be directly related to the basicity of the nitrile group. Para-substituted phenols were preferred to avoid any complications arising from intramolecular associations and steric effects.

Experimental

The spectra were recorded on a Perkin-Elmer Model 125 infrared spectrophotometer using an expanded scale (1 cm=5 wave nos.). Tetrachloroethylene was used as the solvent which was dried carefully and fractionally distilled. The phenols and nitriles were also purified by the usual methods of drying, recrystallization and fractional distillation. Quartz cells, 20 mm long, were used.

The use of rather large cells enabled us to use very dilute solutions which is very desirable, but, on the other hand, required a special heating arrangement. Hence a special heating jacket was designed for the cells. It consisted of two solid brass pieces carefully cut from inside so that when the two pieces were brought into contact with each other by means of a screw, they formed a round hole in the centre of which the cell fitted almost exactly. The brass pieces were fitted, through an asbestos insulator, onto a brass backing plate. Copper tubes were soldered round the brass pieces through which water could be circulated continuously from a thermostat maintaining the cells at any desired temperature. Both the sample and reference cells were heated or cooled simultaneously to avoid any base line error due to differences in the background spectra which appear when only the sample cell is heated or cooled. The temperature of the solution in the cell was measured by means of an iron-constantan thermocouple.

* Present Address: Department of Inorganic Materials, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo, Japan,

Results and Discussion

In fact, both the free and bonded ν(OH) stretching frequencies have been found to be temperature dependent and shift towards higher values with increase in temperature. However, the frequency of the bonded band changes much more markedly than that of the free band with the result that the frequency shift, $\Delta\nu$, decreases with rise in temperature. This variation of $\Delta\nu$ with temperature is generally linear (Fig. 1). Tables 2 and 3 give some of the results from our present study.

Finch and Lippincott,[2] on the basis of a potential function for hydrogen bond suggested by Lippincott and Schroeder,[3] have predicted the temperature coefficient of the bonded frequency, $d\nu_b/dt$, to fall within the range 0.20—0.64. However, vapour phase measurements of the bonded ν(OH) have shown that the bonded frequency remains virtually unchanged over a wide range of temperature.[4,5] Jones and Watkinson,[6] from their studies of hydrogen bonds between substituted phenols and heptyl halides in solvent tetrachloroethylene, conclude that, since both the free as well as bonded frequencies behave similarly with regard to temperature effect, the 'free' ν(OH)

band arises from phenol molecules bonded to solvent tetrachloroethylene. The difference in behaviour of the two frequencies is only in magnitude but there is no qualitative difference as both result from the same type of interaction, namely, hydrogen bonding. In other words, two types of hydrogen bonded species, phenol–solvent and phenol–heptyl halides, are present in the solution both of which are weakened with a rise in temperature. Present results for the temperature coefficients of the bonded frequency, $d\nu_b/dt$, are seen to fall within the range predicted by Finch and Lippincott.[2] However, an examination of our data for temperature coefficients of free ν(OH) band, $d\nu(OH)_f/dt$, for a series of phenols reveals that this coefficient for *p*-nitrophenol and *p*-cyanophenol is somewhat larger than that for *p*-methoxyphenol or phenol. This could mean that the more acidic the phenol, the stronger is its interaction with the solvent, thus supporting the conclusions of Jones and Watkinson.[6]

The effect of temperature on the half width of the bonded band is not straightforward. (Fig. 2) Some systems show an increase in the half width, $(\Delta\nu_{1/2})_b$, with temperature, others a decrease while some hardly any change. In any case, the variation is only slightly larger than the experimental error. Similar results have been reported by other workers.[7–9] A theoretical treatment by Buckingham[10] shows a linear relationship between $(\Delta\nu_{1/2})_b$ and $\sqrt{T}$. This is, however, not verified by our results. Moreover, Buckingham's treatment does not explain the change of sign of the slopes as our results show. Table 4 summarises our results for the effect of temperature on $(\Delta\nu_{1/2})_b$.

It is not quite clear whether absence of any definite trend is due to the differences in the proton acceptor concentrations employed. The half-width seems to have a positive coefficient for the complexes of *t*-butyl cyanide where much less cyanide concentration was required for measurements, while the complexes of trichloroacetonitrile have generally a negative temperature coefficient where much higher concentration was necessary.

The product $(\varepsilon_{max}\cdot\Delta\nu_{1/2})_b$ has been taken, for convenience, as a measure of intensity of the bonded band. This quantity was first used by Gramsted and Askenes[11] as a relative measure of intensity. Table 5 shows our results. There is a general decrease in the intensity parameter $(\varepsilon\cdot\Delta\nu_{1/2})_b$ with temperature (Fig. 3). ε_b is found to decrease with increase in temperature, while $(\Delta\nu_{1/2})_b$ shows no definite pattern. However, the product decreases to some extent with increased temperature. This observation is consistent with the previous findings that for absorption bands in liquids

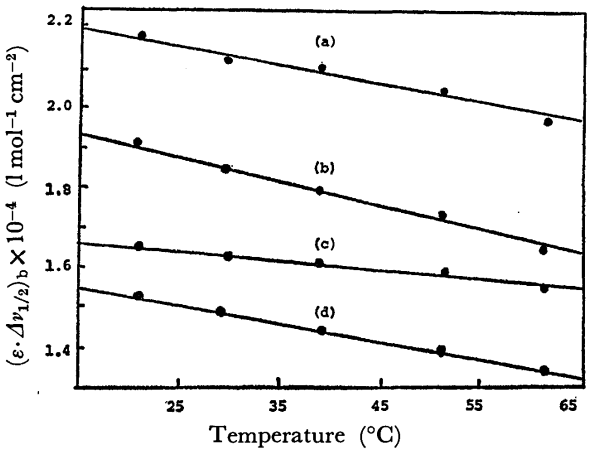

Fig. 3. Intensity of the bonded band *vs.* temperature. (a): *p*-Cyanophenol + CH_3CN, (b): *p*-methoxyphenol + C_6H_5CN, (c): phenol + $(CH_3)_3CCN$, (d): *p*-nitrophenol + Cl_3CCN.

and solutions, ε_{max} decreases more rapidly than the integrated intensity with increase in temperature. Similar results have been reported by other workers also.[1,12,13]

If the intensity of the bonded band is related to the strength of the hydrogen bond, then the observed decrease with temperature is indicative of the weakening of the bond. Satisfactory explanations of the decrease of intensity with temperature have been suggested by various authors. Finch and Lippincot's explanation,[2] based on the charge transfer model of the hydrogen bond suggested by Tsubomura[14] seems most satisfactory.

The author is grateful to Professor Sir Harold Thompson for helpful advice and to Dr. R. J. L. Popplewell for constructing the cell heating jacket. An award of a research fellowship by the Ministry of Education, Government of Pakistan, is also gratefully acknowledged.

Dielectric Relaxation in *p*-Substituted Thiophenols in the Liquid State

Subir K. Roy, Kamalendu Sengupta, and S. B. Roy

Optics Department, Indian Association for the Cultivation of Science, Calcutta-32, India

(Received April 21, 1975)

The dielectric absorption in 4-methylthiophenol and 4-chlorothiophenol in the liquid state has been studied in 0.8, 1.25, 1.62 and 3.49 cm microwave regions. Molecular and intramolecular relaxation times, their relative weight factors and the heats of activation have been determined. The results have been discussed and compared with other related molecules.

Intramolecular rotation of various polar groups in aromatic molecules[1-3] in dilute solutions and in pure liquids has been studied extensively. Such studies of intramolecular rotation of SH group in organic molecules are rather few. Fong and Smyth[4] reported the intramolecular rotation of SH group in naphthalenethiol in dilute benzene solution. Recently, Hasan *et al.*,[5] from studies of dielectric relaxation in benzenethiol and benzylthiol in the liquid state reported that intramolecular rotation of the SH group was the main relaxation process in both the thiophenols. From a comparison of the values of SH group relaxation time τ_2 and its weight factor C_2 in the thiophenols, with the corresponding τ_2 and C_2 values for OH group rotation in phenols and substituted phenols reported by Aihara and Davies,[6] Hasan *et al.*[5] concluded that the intermolecular hydrogen bonding S–H···S are negligible in the thiophenols even in the liquid state.

The object of the present investigations was to extend similar studies in the case of *p*-substituted thiophenols in the liquid state and compare the results with the corresponding *p*-substituted phenols. The results obtained in the case of 4-methylthiophenol and 4-chlorothiophenol are presented and discussed in this paper.

Experimental

The apparatus for the measurements of dielectric permittivity ε', dielectric loss ε'' in the region 0.8, 1.25, 1.62 and 3.49 cm microwaves were described earlier.[7] The static dielectric constant ε_0 was measured at 1 MHz, the refractive index n_D was determined with an Abbe refractometer, the viscosity η was measured with an Ostwald viscometer and the density d with a pycnometer. The temperature in each experiment was kept constant within ± 1 °C by means of a thermostat. The estimated errors in ε' and ε'' are about 2% and 4% respectively.

Results

The experimental values of ε' and ε'' at different microwave frequencies together with the values of ε_0 at different temperatures are given in Table 1. These data were then fitted in Cole-Cole arc plots (Fig. 1). The high frequency dielectric constant $\varepsilon\infty$ and the distribution parameter α were obtained as usual from the arc plots. The values of $\varepsilon\infty$ in each case was found much higher than that of n_D^2. The values of the distribution parameter were appreciably high at all temperatures, indicating the presence of more than one relaxation process. This was confirmed by the non linear plots of ε' vs $\varepsilon''\omega$. The dielectric data were

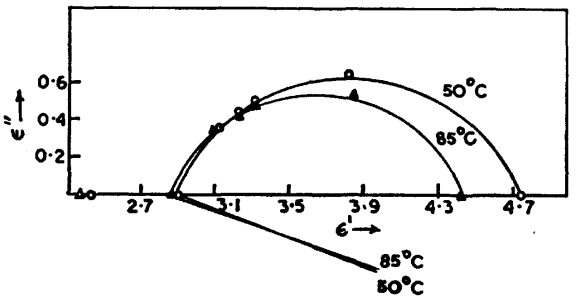

Fig. 1. Cole-Cole arc plot of 4-thiocresol.

then analysed in terms of two relaxation processes following the equations of Bergmann *et al.*[8] and as simplified by Bhattacharyya *et al.*[9] for straightforward calculations.

Bergmann's equations are

$$a = \frac{\varepsilon' - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \frac{C_1}{1+\omega^2\tau_1^2} + \frac{(1-C_1)}{1+\omega^2\tau_2^2} \tag{1}$$

and

$$b = \frac{\varepsilon''}{\varepsilon_0 - \varepsilon_\infty} = \frac{C_1\omega\tau_1}{1+\omega^2\tau_1^2} + \frac{(1-C_1)\omega\tau_2}{1+\omega^2\tau_2^2} \tag{2}$$

The simplified equation[9] is

$$\frac{1-a}{b\omega} = \tau_1 + \tau_2 - \frac{a\omega}{b}\tau_1\tau_2 \tag{3}$$

which can be written in the form

$$\sum_{i=1}^{n} Sx_i - Py_i - 1 = 0 \tag{4}$$

where

$$S = \tau_1 + \tau_2,\ P = \tau_1\tau_2,\ x = \frac{b\omega}{1-a} \text{ and } y = \frac{a\omega^2}{1-a}$$

Eq. (4) is a linear equation and can be solved by the method of least squares. From the principle of least square, it can be easily shown from Eq. (4) that

$$S = \frac{\sum_{i=1}^{n} y_i \sum_{i=1}^{n} x_i y_i - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i^2}{\left(\sum_{i=1}^{n} x_i y_i\right)^2 - \sum_{i=1}^{n} x_i^2 \sum_{i=1}^{n} y_i^2} \tag{5}$$

$$P = \frac{\sum_{i=1}^{n} y_i \sum_{i=1}^{n} x_i^2 - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} x_i y_i}{\left(\sum_{i=1}^{n} x_i y_i\right)^2 - \sum_{i=1}^{n} x_i^2 \sum_{i=1}^{n} y_i^2}. \tag{6}$$

Solving Eqs. (5) and (6), τ_1 and τ_2 can be calculated. The value of C_1 is then determined from the equation given below, obtained from Eqs. (1) and (2) by applying the least square principle.

The value of ε_∞ as obtained from Cole-Cole plot may not coincide with the actual value in Eqs. (1) and (2), but it will lie between the n_D^2-value and ε'-value obtained at the highest microwave frequency used. So, to start with, any value for ε_∞ within the above limit is assumed and τ_1, τ_2 and C_1 values are determined. With these values of τ_1, τ_2 and C_1, the values of ε' and ε'' are calculated from Eqs. (1) and (2). The value of ε_∞ is then varied and the process is repeated till the mean square deviation A, from the relation

$$A = \sum (\varepsilon''_{obsd} - \varepsilon''_{calcd})^2 + \left\{\frac{\varepsilon'_{obsd} - \varepsilon'_{calcd}}{n}\right\}^2,$$

is found to be minimum. The 'n' is a scaling factor to reduce the error in ε', to the same magnitude of the error in ε''. A value of $n=3$ is used in the present case. The values of ε_∞, τ_1, τ_2 and C_1 are given in Table 2. All the calculations were carried on the IBM Computer 1130. The calculated values of ε' and ε'' are included in Table 1.

The activation energies for dielectric relaxation and viscous flow were obtained from the straight line plots of $\log \tau T$ *vs.* $1/T$ and $\log \eta$ *vs.* $1/T$ respectively. The dipole moment in the case of 4-methylthiophenol was calculated from ε_0 and density d using Onsager's equation. The values of α, n_D^2, $\Delta H\tau_1$, $\Delta H\eta$ and μ are included in Table 2.

Discussion

It can be seen from Table 2 that the molecular and intramolecular relaxation times in both the *para* substituted thiophenols, decrease with increase in temperature as is generally observed in polar liquids, so also the distribution parameter α decreases with increase of temperature.

The intramolecular relaxation time τ_2 for SH group rotation in both the liquids are of the same order ($\approx$3ps) and compares well with the τ_2-values in thiophenol (2.6 ps) and in benzylthiol (3.1 ps) in the liquid state reported earlier[5] as also in naphthalenethiol (2.5 ps) in dilute solution in benzene reported by Fong and Smyth.[4] Thus it is found that the SH group relaxation times in pure liquids as also in dilute benzene solution are almost the same, showing thereby that the intermolecular hydrogen bondings S–H···S of the type hydroxyl hydrogen bonding, observed in phenol and substituted phenols,[10] are negligible in the thiophenols even in the liquid state.

It would be interesting to compare the τ_1 and τ_2 values of the present liquids, with those of *p*-substituted phenols reported by Magee and Walker.[10] Though the molecular relaxation time τ_1 of 29.7 ps at 50 °C in 4-methylthiophenol compares well with the value of $\tau_1=32$ ps at 25 °C in 4-methylphenol in *p*-xylene solution, the SH group relaxation time of 2.85 ps in the former, is definitely much smaller than the OH group relaxation time $\tau_2=8.4$ ps in the latter. The molecular relaxation time $\tau_1=17.7$ ps at 65 °C in 4-chlorothiophenol in the liquid state is almost half the value of $\tau_1=39$ ps in 4-chlorophenol in *p*-xylene solution and the τ_2-value of 2.8 ps for SH group rotation in the former is about our fourth the τ_2-value of 12.7 ps

for OH group rotation in the latter. The unusual lengthing of the OH group relaxation of *p*-substituted phenols in *p*-xylene solution was attributed by Magee and Walker[10] to association among the solute molecules, in addition to the effects of solvents. The lengthing of molecular relaxation time (τ_1=39 ps) in 4-chlorophenol in dilute *p*-xylene solution to double the τ_1-value of 17.7 ps in 4-chlorothiophenol, seems to suggest that a dimer has been formed in *p*-chlorophenol molecule by association with other solute molecule probably through H-Cl hydrogen bond. Similar bond formation is not observed in 4-methylphenol in the *p*-xylene solution.

Weight factors: It is seen from Table 2 that the weight factor C_1 for 4-methylthiophenol and 4-chlorothiophenol are about 0.79 and 0.63 respectively. An estimate for the weight factors for both the thiophenols can be made from consideration of bond moments. Assuming the moments of μ_{CH_3}=0.37D, μ_{C-S}=0.9D, μ_{H-S}=0.7D, μ_{C-Cl}=1.5D and $\angle$CSH=135°,[11] and remembering that the CH_3 group moment is directed towards the benzene ring, the moment components responsible for SH group rotation are μ_2=0.49D in both the molecules, while the moment components responsible for molecular reorientations are μ_1=0.8 D in methyl thiophenol and μ_1=1.1D in 4-chlorothiophenol. From the above values of μ_1 and μ_2, the ratio of the weight factors in the two cases are,

$$\frac{C_2}{C_1}=\left(\frac{0.49}{0.8}\right)^2=\frac{0.24}{0.64} \text{ or } C_1=0.73$$

in 4-methylthiophenol and

$$\frac{C_2}{C_1}=\left(\frac{0.49}{1.1}\right)^2=\frac{0.24}{1.21} \text{ or } C_1=0.83$$

in 4-chlorothiophenol. Thus the weight factors C_1 for molecular reorientation in both the liquids are larger than that for group rotation. The is in conformity with the values obtained experimentally. It may be noted here that some uncertainty may arise in the calculated value of the dipole moment in 4-chlorothiophenol, due to appreciable mesomeric charge shift occurring across the molecule.[12]

The activation energy $\Delta H\tau_1$ for molecular relaxation in 4-methylthiophenol is about 1.3 kcal/mol which, as usual, is less than the corresponding activation energy of $\Delta H\eta$=2 kcal/mol for viscous flow. In the case of 4-chlorothiophenol, the dielectric data could be taken only for two temperatures and therefore activation energy $\Delta H\tau_1$ may not be reliable in this case.

The values of ε_∞ in both the *p*-substituted thiophenols are appreciably larger than the value of n_D^2 at all temperatures. This indicates the presence of a third dispersion region of the 'Poley type' in the high frequency region.

The dipole moment of 4-methylthiophenol has been determined from ε_0 and density *d*, using Onsager's equation and is found to be 1.4D, which agrees well with the value of 1.46D obtained from bond moment calculation of the CH_3 group in the *para* postition of thiophenol (μ=1.22D).

The authors express their sincere thanks to Professor G. S. Kastha for helpful discussions and to Mr. D. Bhowmic for his help in making the computer programme.

(Received July 28 1975)

$K_6[Co_2(CN)_{10}(N_2O_2)]\cdot 2H_2O$ (orange salt) was prepared by reaction of $[Co(NO)(NH_3)_5]Cl_2$ with an aqueous solution of potassium cyanide. $K_6[Co_2(CN)_{10}(N_2O_2)]\cdot 4H_2O$ (yellow salt) was obtained by adding an aqueous solution of the orange salt to methanol. On the basis of IR and Raman spectra for their ^{14}NO- and ^{15}NO-salts, and of IR spectra for their gaseous decomposition products, the orange salt is considered to be a linkage isomer of the yellow salt with respect to the *trans*-hyponitrito bridge. It is presumed that the orange salt is potassium μ-(*trans*-hyponitrito-*N,N'*)-bis{pentacyanocobaltate(III)}, the yellow salt being potassium μ-(*trans*-hyponitrito-*O,O'*)-bis{pentacyanocobaltate(III)}.

Toyuki[1] and Jezowska-Trzebiatowska *et al.*[2] prepared $K_6[Co_2(CN)_{10}(N_2O_2)]\cdot 4H_2O$ with a *cis*- or *skew*-hyponitrito bridge by the method given by Nast and Rohmer.[3] On the other hand, Raynor[4] prepared $K_6[Co_2(CN)_{10}(N_2O_2)]\cdot 4H_2O$ with a *trans*-hyponitrito group, according to the method given by Nast, Mesche and Neubauer.[5] While investigating the method of Nast and Rohmer,[3] we prepared two new isomers with a *trans*-hyponitrito group, $K_6[Co_2(CN)_{10}(N_2O_2)]\cdot nH_2O$ (n=2 or 4 for orange and yellow salts, respectively).[6]

This paper describes studies on the two isomers with respect to IR and Raman spectra, UV spectra, and thermal decomposion. The product prepared according to the method of Nast and Rohmer[3] is also discussed by comparing its IR absorption bands with those of the two isomers.

Experimental

Preparation. Synthetic procedures and elementary analyses for the orange and the yellow salts were reported in detail.[6] From 1 to 3 g of $[Co(NO)(NH_3)_5]Cl_2$ was used for preparing the orange salt. Powdered $[Co(NO)(NH_3)_5]Cl_2$ was added little by little to a 30% aqueous solution of potassium cyanide with stirring in order to keep the reaction vessel at constant temperature (−10 °C). The procedure differs from that reported by Nast and Rohmer.[3] Yield, 0.6—2 g. χ_g (at 293K) $=-0.45\times 10^{-6}$ (c.g.s.). One gram of the orange salt was used for preparing the yellow salt. Yield, 0.8 g. χ_g (at 293K) $=-0.36\times 10^{-6}$ (c.g.s.).

Thermal Decomposition and Decomposition with 10% Potassium Cyanide Aqueous Solution. Decomposition was carried out in a vacuum line. A reaction vessel containing the salt (*ca.* 0.5 g) was heated *in vacuo* in an electric furnace at a rate of *ca.* 1—2 °C min^{-1}. Both the orange and the yellow salts decomposed violently at *ca.* 155 and 116 °C, respectively, to give gray powders. About 0.5 g of the salt was added in a reaction vessel containing 5 ml of 10% KCN solution frozen with the aid of liquid nitrogen, and the reaction vessel was evacuated. When the frozen solution was melted, both the salts decomposed by contact with the aqueous solution. The gaseous products thus obtained were dehydrated with P_4O_{10} and transferred to a gas cell with windows of calcium difluoride.

Measurements. The magnetic susceptibility was measured by the Gouy method. The IR spectra of the salts were measured as Nujol and hexachlorobutadiene mulls in the region 200—4000 cm^{-1} on JASCO 402G and JASCO model IR-F spectrometers. The Raman spectra of the powdered samples were recorded in the region 100—1500 cm^{-1} on a JASCO R-300 spectrometer equipped with He–Ne laser. The gaseous products were identified by means of their IR spectra.[7] The mole ratio of the liberated NO to N_2O was determined.[8] The diffuse reflection spectra of the salts were measured with a Hitachi EPS-3T spectrometer. The UV spectra in aqueous solution were recorded with a Hitachi 124 spectrometer.

Results and Discussion

Raman and IR Spectra for the Orange and Yellow Salts. Wave numbers of the IR and Raman bands and their assignments are summarized in Table 1.

Raman Spectra: Upon ^{15}NO-substitution (^{15}N atom% =95), the bands at 1257 and 1165 cm^{-1} for the orange salt shifted downwards by 31 and 39 cm^{-1}, respectively and, the bands at 1412 and 1070 cm^{-1} for the yellow salt shifted downwards by 43 and 18 cm^{-1}, respectively. Upon ^{15}NO-substitution (^{15}N atom %=50), the 1257 cm^{-1} band for the orange salt shifted and split into three peaks at 1253, 1242, and 1226 cm^{-1} (their intensity ratio 1:2:1). The same phenomenon was observed with the yellow salt; the 1412 cm^{-1} band shifted and split into three peaks, 1414, 1392, and 1369 cm^{-1} (their intensity ratio 1:2:1). This indicates that N–N bond is present in both the orange and yellow salts. For other bands, no isotopic shifts upon ^{15}NO-substitution could be observed. The bands in the region *ca.* 400—550 cm^{-1} are considered to be due to the $Co(CN)_5$ group.[9]

IR Spectra: The bands at 1157, 609, and 299 cm^{-1} for the orange salt shifted downwards by 21, 14, and 2 cm^{-1} upon ^{15}NO-substitution (^{15}N atom %=95), respectively, while the bands at 987, 630, and 329 cm^{-1} for the yellow salt shifted downwards by 15, 6, and 6 cm^{-1}, respectively.

The 1630 and 3580 cm^{-1} bands for the orange salt

and the 1643 and 3620 cm^{-1} bands for the yellow salt are considered to be due to the water of crystallization. The sharp bands at 2127 cm^{-1} with two shoulders for the orange and yellow salts are assigned to the C–N stretching vibrations. Many absorption bands were observed in the region 200—600 cm^{-1}. Some of them in the region *ca.* 400—550 cm^{-1} are considered to be due to the skeletal vibrations between the cobalt atom and the CN group.[9]

Assignments of the Bands due to the Bridged Hyponitrito Group: The Raman and IR bands for the orange and yellow salts can be explained on the basis of the bands due to the hyponitrito group. Raman and IR studies on $M_2N_2O_2$ (M=Na and K) containing a *cis*- or *trans*-hyponitrite ion show that one band at 1380—1420 cm^{-1} is assigned to the N–N stretching and two bands at 830—1120 cm^{-1} to the N–O stretching vibrations.[10-14]

Of the three bands in the region 990—1400 cm^{-1} observed on the IR and Raman Spectra for the orange and yellow salts, two bands are Raman active, and one band is IR active. The mutual exclusion rule holds for the set of the three bands as observed on the *trans*-hyponitrite ion.[11] It can be considered that both the orange and yellow salts contain a *trans*-hyponitrite ion but not a *cis*-one. On the basis of the mutual exclusion rule and the ^{15}N-isotopic shifts, the 1257 cm^{-1} band for the orange salt and the 1412 cm^{-1} band for the yellow salt can be assigned to the N–N symmetric stretching vibrations, the 1165 cm^{-1} band for the orange salt and the 1070 cm^{-1} one for the yellow salt to the N–O symmetric stretching, and the 1157 cm^{-1} band for the orange salt and the 987 cm^{-1} band for the yellow salt to the N–O antisymmetric stretching vibrations.

For the bands in the region 200—800 cm^{-1} for *trans*-hyponitrite ion, Millen *et al.*[11] and McGraw *et al.*[12] assigned the Raman band at 485 or 698 cm^{-1} to the in-plane NNO symmetric deformation, the IR band at *ca.* 370 cm^{-1} to the in-plane NNO antisymmetric one, and the IR band at *ca.* 500 cm^{-1} to the out-of-plane ONNO distortion. McGraw *et al.*[12] also reported that the bands due to both the in-plane NNO antisym-

metric deformation and the out-of-plane ONNO distortion shifted downwards by *ca.* 10 cm^{-1}, but the band due to the in-plane NNO symmetric deformation hardly shifted upon ^{15}NO-substitution (^{15}N atom %= 95).

As for complexes other than the cyano complexes with hyponitrito group, $[(C_6H_5)_3M]_2(N_2O_2)$ (M=Sn and Pb),[15] $\{[MoCl_2(NO)(das)]_2N_2O_2\}Cl_2$ (das=*o*-phenylene-bis(dimethylarsine)),[16] $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4 \cdot H_2O$,[17] and $Pt(N_2O_2)(PPh_3)_2$ (PPh_3=triphenylphosphine)[18] have been reported. IR study on *μ*-(*trans*-hyponitrito-*O,O'*)-bis{triphenyltin(II)} and its lead(II) analog has shown that the band at 580—620 cm^{-1} is due to the metal–O antisymmetric stretching, the band at 370—380 cm^{-1} to the out-of-plane ONNO distortion, and the band at 310—360 cm^{-1} to the in-plane NNO antisymmetric deformation.[15] IR study on *μ*-(*cis*-hyponitrito-*N,O*)-bis{pentaamminecobalt(III)} nitrate has shown that the band at 616 cm^{-1} is due to the NNO bending, the band at 577 cm^{-1} to the Co–NO stretching, the band at 536 cm^{-1} to the ONNO out-of-plane bending, the band at 374 cm^{-1} to another NNO bending, and the band at 247 cm^{-1} to the O_2N_2–Co–NH_3 bending vibrations.[17] On the other hand, IR study on $K_6[Co_2(CN)_{10}(N_2O_2)] \cdot 4H_2O$ with a *cis*- or *skew*-hyponitrito bridge has shown that the bands at 599, 537, 450, and 281 cm^{-1} are assigned to the Co–N stretching, the NNO bending, the Co–O stretching, and the N–Co–C or the Co–NO bending vibrations, respectively.[2] However, the bands other than the N–N and N–O stretching vibrations due to the hyponitrito bridge have not yet been definitely assigned.

From studies by means of IR and nitrogen-15, the 299 cm^{-1} band for the orange salt and the 329 cm^{-1} band for the yellow salt can probably be assigned to the in-plane NNO antisymmetric deformation, and the 609 cm^{-1} band for the orange salt and the 630 cm^{-1} band for the yellow salt to the out-of-plane ONNO distortion. The bands are considered to be coupled with the skeletal vibrations between the cobalt atom and the hyponitrito group. The Raman bands at 704 cm^{-1} for the orange salt and at 760 or 650 cm^{-1} for the yellow salt can be assigned to the in-plane NNO symmetric deformation.

N_2O and NO Liberated by the Decompositions of the Orange and Yellow Salts. The results are shown in Table 2. The IR spectra of the gaseous products show that NO and N_2O were liberated as major products by the thermal decomposition, while the decomposition, with 10% KCN aqueous solution, milder than the thermal decomposition, gave N_2O only. The amount of the N_2O formed in the thermal decomposition was greater than that of the NO for both the orange and the yellow salts. The mole ratio of the NO to N_2O from the orange salt was greater than that from the yellow one. The results obtained by isotopic analyses of the N_2O suggest that the hyponitrito group is present in both the orange and yellow salts, and that the N_2O is formed without a cleavage of the N–N bond in the hyponitrite group.

UV Spectra for the Orange and Yellow Salts. The diffuse reflection spectrum for the yellow salt was the same as the spectrum for its fresh aqueous solution (Fig. 1). On the other hand, the diffuse reflection spectrum for the orange salt was different from that

a) The values in parentheses indicate the relative mole ratio.

for the yellow one. The spectrum for the fresh aqueous solution of the orange salt was almost equal to that for the yellow one. The orange species is considered to change rapidly to the yellow one on dissolution as expected from the synthetic method of the yellow salt.[6] The aqueous solution of the yellow salt was unstable; intensity of a shoulder at *ca.* 24 Kcm^{-1} due to the yellow species decreased to give a peak at 26 Kcm^{-1} after the solution had been allowed to stand for 2 weeks at room temperature. UV study on $K_3[Co(CN)_5(OH)]$ in an aqueous solution has shown that the $[Co(CN)_5(OH)]^{3-}$ decomposes to give $[Co(CN)_4(OH)_2]^{3-}$ and $[Co(CN)_6]^{3-}$ upon standing.[19] The spectrum obtained for the yellow salt solution which had been allowed to stand was the same as that for the solution of the mixture of $[Co(CN)_4(OH)_2]^{3-}$ and $[Co(CN)_6]^{3-}$. It is suggested that the complex anion of the yellow salt decomposes in water to give $[Co(CN)_4(OH)_2]^{3-}$ and $[Co(CN)_6]^{3-}$ through $[Co(CN)_5(OH)]^{3-}$:

$$[Co_2(CN)_{10}(N_2O_2)]^{6-} + H_2O \longrightarrow 2[Co(CN)_5(OH)]^{3-} + N_2O$$

$$2[Co(CN)_5(OH)]^{3-} \longrightarrow [Co(CN)_4(OH)_2]^{3-} + [Co(CN)_6]^{3-}.$$

Comparison of Compounds Prepared by the Method of Nast and Rohmer with the Orange and the Yellow Salts. For the compound with a *cis*- or *skew*-hyponitrito bridge reported by Jezowska-Trzebiatowska *et al.*, IR bands at 1340—1400 (the N–N stretching vibration), 1043 (the N–O one), and 831 cm^{-1} (the N–O one) have been observed.[2] IR spectra in the region 800—1400 cm^{-1} for the "yellow product," prepared by the authors according to the method of Nast and Rohmer[3] on *ca.* 1/10 scale, gave broad bands at 1393(s), 1373(s), 1155(m), 1054 (m), 982(m), and 910(s) cm^{-1}, which shifted downwards by 31, 31, 25, 32, 13, and 17 cm^{-1}, respectively, upon ^{15}NO-substitution (^{15}N atom %=95). On the other hand, the IR spectra for the compound reported by Toyuki gave the bands at 1389(sh), 1333(w), 1158(w), 1058(w), and 984(w) cm^{-1}.[1] The bands at *ca.* 1160 and 980 cm^{-1} for the "yellow product" might correspond to the N–O antisymmetric stretching vibrations due to the orange and yellow salts, respectively. The residual three components at 1393—1373, 1054, and 910 cm^{-1} for the "yellow product" might be due to a new linkage isomer of the compounds with a *cis*-hyponitrito group since wave numbers of these residual bands observed on the "yellow product" are different from those of the bands observed on the compounds with the *cis*-hyponitrito group reported by Toyuki[1] and Jezowska-Trzebiatowska *et al.*,[2] and also since all the N–N and the N–O stretching vibrations due to the *cis*-hyponitrito bridge are IR active. The IR study by Raynor on the compound prepared according to the method of Nast, Mesche and Neubauer[5] has shown that the N–O stretching vibration is observed at 1120 cm^{-1}.[4] However, it seems that this compound has not yet been well characterized.

The "yellow product" might be a mixture of the yellow salt, the orange salt, and an unknown compound with a *cis*-hyponitrito group. New linkage isomers with a *cis*-hyponitrito group can be expected to be isolated by subtle changes in the preparative conditions.

The yellow salt can be considered to be a linkage isomer of the orange salt. The N–N bond strength for the orange salt might be weaker than that for the yellow one. On the other hand, the N–O bond strength for the orange salt might be stronger than that for the yellow one. The mole ratio of NO to N_2O formed in the thermal decomposition for the orange salt is greater than that for the yellow one. This suggests that the N–N bond strength for the orange salt is weaker than for the yellow one as expected from the Raman spectra. Thus, it is presumed that the anion of the orange salt is μ-(*trans*-hyponitrito-*N,N'*)-bis{pentacyanocobaltate(III)} (A), that of the yellow salt being μ-(*trans*-hyponitrito-*O,O'*)-bis{pentacyanocobaltate(III)} (B) as shown in Fig. 2.

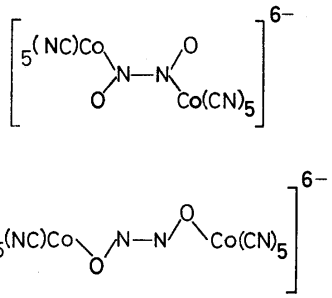

Fig. 2. Probable structures of the orange (A) and yellow (B) salts.

The authors are indebted to Mr. M. Arita and Mr. T. Takakuwa of the Japan Spectroscopic Co., Ltd., for the measurements of the Raman spectra. The present work was supported in part by a Grant for Scientific Research from the Ministry of Education.

Formation of Oxygen Deficient Pyrochlore Solid Solutions $Pb_2Ta_{2-2x}M_{2x}O_{7-x}$(M=Ti, Sn and Zr) and Their Optical and Dielectric Properties

Yasuyoshi TORII and Hideo MATSUMOTO*

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received July 29, 1975)

It was found that oxygen deficient pyrochlore solid solutions $Pb_2Ta_{2-2x}M_{2x}O_{7-x}$ with M=Ti, Sn, and Zr exist over wide ranges. The formation of oxygen deficient pyrochlore structure results from the occupancy of Pb^{2+} ions in the A position, which have a high polarizability. Their reflectance and infrared absorption spectra, and dielectric constants were measured. With the increase of M^{4+} ions, the color turned lemon yellow to reddish yellow, and the dielectric constants increased. The infrared absorption spectra in their pyrochlore solid solutions were similar to those in $PbTiO_3$ and $PbZrO_3$. The infrared properties of two strong absorption bands observed were discussed in comparison with those in the perovskites.

Pyrochlore type compounds are represented by the general formula $A_2B_2O_7$ and exhibit interesting physical properties such as ferroelectricity in $Cd_2Nb_2O_7$[1,2] and electrooptic effect in $Ca_2Nb_2O_7$.[3] Compounds of this type have a face-centered cubic structure with a unit cell of *ca.* 10 Å. The structural framework is a three-dimensional array of BO_6 octahedra, all sharing corners, and the framework thus has the composition $(B_2O_6)_\infty$. The seventh set of oxygen ions and the A ions occupy open spaces in the framework as the large ions do in the perovskite structure. The mixed oxides consisting only of oxygen octahedra can generally yield a large internal field for ferroelectricity to occur. Both perovskite and pyrochlore are furnished with such a structural condition. There are, however, essential differences between the two structure types. In the ABO_3 perovskite, the O–B–O chains lie on straight lines parallel to the cubic axis. In the pyrochlore structure the configuration of the BO_6 octahedra is much more complicated, the O–B–O chains lying on zig-zag lines along the <110> directions. The zig-zag structure of O–B–O chains seems to be unfavorable for the occurrence of ferroelectricity since few[4,5] have been found to be ferroelectric among pyrochlores. Nikiforov *et al.*[6,7] concluded that oxygen deficient pyrochlores with more loose structure than pyrochlores of the type $A_2B_2O_7$ are favorable for its occurrence from a crystallochemical analysis of the conditions for a spontaneously polarized state in pyrochlores. Among perovskites, a number of ferroelectric substances have been found.[8] $PbTiO_3$ is ferroelectric with a Curie point of 490 °C and $PbZrO_3$ is antiferroelectric below 230 °C. It is of interest to see if a binary system consisting of pyrochlore and perovskite as end members exists in the form of oxygen deficient pyrochlore. In the present study, the formation of solid solutions $Pb_2Ta_{2-2x}M_{2x}O_{7-x}$ with M=Ti, Sn and Zr was examined and their optical and dielectric properties were investigated.

Experimental

Specimens were prepared from PbO, Ta_2O_5, TiO_2, SnO_2, and ZrO_2 of high purity. In particular, an electronic grade sample (>99.99%) was used for SnO_2. Mixtures of various compositions were ground together in an agated mortar, pressed into a disk and then ignited on platinum foil in the air at *ca.* 1050 °C. The resulting materials were reground, repressed and re-ignited at 1100—1200 °C for 3 h. They were then left to cool in the furnace.

Phase identification was carried out by X-ray diffraction technique using a X-ray diffractometer with nickel filtered Cu $K\alpha$ radiation. Calibration of goniometer was made using high purity silicon as a standard. Their lattice constants were determined from the reflection line of (662). The spectral reflectance between 400—760 nm was recorded with a spectrophotometer to pursue the displacement of absorption. Infrared absorption measurements between 4000—250 cm^{-1} were made for powder specimens dispersed in a pressed KBr disk, using a Perkin-Elmer infrared spectrophotometer model 457. The dielectric constants were measured on a capacitance bridge employing a frequency of 1000 cps. Fired-on silver electrodes were used for the measurements. No correction was made as regards the porosity of specimen.

Results and Discussion

Formation of Oxygen Deficient Pyrochlore Solid Solutions.

* Present Address: Yamatsu China Mfg. Co., Ltd.

Powder X-ray diffraction analyses show that cubic pyrochlore solid solutions exist in wide ranges. The variation of lattice constants for the solid solutions $Pb_2Ta_{2-2x}M_{2x}O_{7-x}$ with M=Ti, Sn and Zr are shown in Fig. 1. The part drawn by solid line represents the compositional range in which a single phase of cubic pyrochlore is observed in the powder X-ray patterns. $Pb_2Ta_2O_7$ is known to be rhombohedrally distorted pyrochlore with the unit cell with dimensions, $a=10.700$ Å and $\alpha=88°25'$. Partial substitution of M^{4+} ions for Ta^{5+} ions makes it possible for the cubic pyrochlore to form. In the case of Ti-containing system, the crystal distortion disappears when $x=0.15$. The unit cell dimension of cubic pyrochlore phase becomes smaller with a further increase in x, but remains much the same when the value of x, exceeds *ca.* 0.50. From the result, the substitutional limitation of Ti^{4+} ions to form the cubic pyrochlore phase is *ca.* $x=0.50$. According to Ahrens's radii,[9] the ionic size of Ti^{4+} ion is 0.68 Å and is the same as that of Ta^{5+} ion. The unit cell dimension in this system, however, decreases with the increase of x in the substitutional range of Ti^{4+} ions. This affords an experimental proof for the formation of pyrochlore structure with oxygen deficiencies.

In the case of Sn- and Zr-containing systems, similar series of solid solutions exist in the form of cubic oxygen deficient pyrochlore. Their unit cell dimensions, however, increased with the increase of x in the compositional ranges in which cubic oxygen deficient pyrochlore is formed as a single phase. The regions of their solid solutions were narrower than that in the Ti-containing system. This is because the ionic sizes of Sn^{4+} ion (0.71 Å) and Zr^{4+} ion (0.79 Å) are larger than that of Ta^{5+} ion.

When Ta^{5+} ions were substituted partially with Ti^{4+} ions in cubic pyrochlore $Ca_2Ta_2O_7$, a series of oxygen deficient pyrochlore solid solution was not formed as in the case of the pyrochlore with Pb^{2+} ions in the A position. The partial substitution of Y^{3+} ions plus Ti^{4+} ions for Ca^{2+} ions plus Ta^{5+} ions gave a pyrochlore. The formation of the oxygen deficient pyrochlore structure seems to be related with the occupancy of Pb^{2+} ions in the A position. The structure with oxygen deficiency is derived from the pyrochlore structure by the removal of oxygen ions located in the tetrahedral interstices of the cationic array of Pb ions.[10] The oxygen ions removed do not contribute to the framework structure even though they are necessary in the structure. Pb^{2+} ion has an eigthfold coordination (nearly an hexagonal bipyramid) in the pyrochlore structure. However, Pb^{2+} ion has a coordination less than eightfold in the oxygen dificient pyrochlore structure. The removal of oxygen ions located in the tetrahedral interstices results in an increase in the oxygen polarization. Since Pb^{2+} ion has a high polarizability due to its electronic configuration ($6s^2$), the occupancy of Pb^{2+} ions in the A position is favorable for the formation of oxygen deficient pyrochlore structure. It is understandable that oxygen deficient pyrochlores have often been formed, as in the examples of $Pb_2Ti_{1.5}W_{0.5}O_{6.5}$[11] and $Bi_2Zn_{4/3}Ta_{2/3}O_6$,[6] when Pb^{2+} or Bi^{3+} ion occupies the A position. Consequently the occupancy of Ca^{2+} ions in the A position seems unfavorable for the formation of oxygen deficient pyrochlore structure.

Reflectance Spectra. Samples of cubic oxygen deficient pyrochlore prepared were yellowish powder, a slight difference in the tone of color being found. Figure 2 shows the reflectance spectra in the range 400—760 nm for the Ti-containing system. The curves show strong absorption extending over violet and blue parts of visible light. The strong absorption is responsible for the yellowish color development. $Pb_2Ta_2O_7$ is white powder. With the increase in the amount of substituted Ti^{4+} ions, the reflectance curve shifts towards higher wavelength side, the color changing from lemon yellow to reddish yellow. Similar results were obtained for Sn- and Zr-containing systems. Each reflectance in the vicinity of the blue part increased in the order of Sn-, Ti-, and Zr-containing oxygen deficient pyrochlores under the condition of equimolecular substitution of M^{4+} ions. It seems that the color development can be ascribed to a significant contribution of covalent character in the Pb-O bond of these oxygen deficient pyrochlores. The Pb-O distances in $Pb_2Ta_{1.4}Ti_{0.6}O_{6.7}$ were calculated as an example, using its lattice constant ($a=10.518$ Å) and atomic coordinate parameters of cubic pyrochlore structure[12] (oxygen parameter $u=5/16$). It was found that each Pb atom has two close oxygen neighbors at 2.28 Å and six close oxygen neighbors at 2.69 Å. Of the two kinds of Pb-O distance, the former is a little smaller than that in tetragonal PbO, which is a reddish color. The latter distance is nearly the same as that (2.70 Å) in $Pb(NO_3)_2$ with a typical ionic character. Pb^{2+}, Ta^{5+}, Ti^{4+}, or O^{2-} alone causes no visible absorption, but the combination gave a yellowish color. In the shorter Pb-O distance, consideration must be given to the fact that the outer electron orbits and energy levels are affected by the neighboring ions of oxygen. This is the electron band in which color-producing transition occurs as known in Cu_2O (red) and tetragonal PbO (reddish).[13] The development of yellowish color is attributed to visible absorption in the vicinity of the violet part, by which the nonbonding electrons of O^{2-} ions are transferred to the outer orbits of Pb^{2+} ions. The volume of rhombohedral $Pb_2Ta_2O_7$ was larger by 2.8% than that of cubic $Pb_2Ta_2O_7$ (actually not existing at room temperature) estimated from the curve of lattice constant *vs.* composition in the solid solution $Pb_2Ta_{2-2x}Ti_{2x}O_{7-x}$. The atomic coordinates of each atom in rhombohedral $Pb_2Ta_2O_7$ have not been determined yet. The crystal distortion would cause the shorter Pb-O distance to enlarge, since rhombohedral $Pb_2Ta_2O_7$ is colorless.

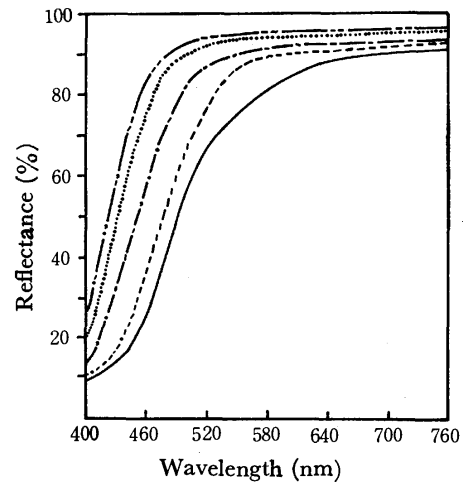

Fig. 2. Reflectance spectra of pyrochlore solid solution $Pb_2Ta_{2-2x}Ti_{2x}O_{7-x}$.
-·-·-: $x=0.1$, ·····: $x=0.2$, -·-; $x=0.3$, ----: $x=0.4$, ——: $x=0.5$.

The pyrochlores were stable without dissolution in the lead glaze and the yellowish color remained unchanged when about 5% of them by weight were well dispersed in the lead glaze and their mixtures were ignited at 900 °C. These pyrochlore solid solutions might be used as a pigment in ceramics.

Infrared Absorption Spectra. Figure 3 shows infrared spectra of the solid solution $Pb_2Ta_{2-2x}Ti_{2x}O_{7-x}$. Two strong absorption bands were observed in all the specimens. Their

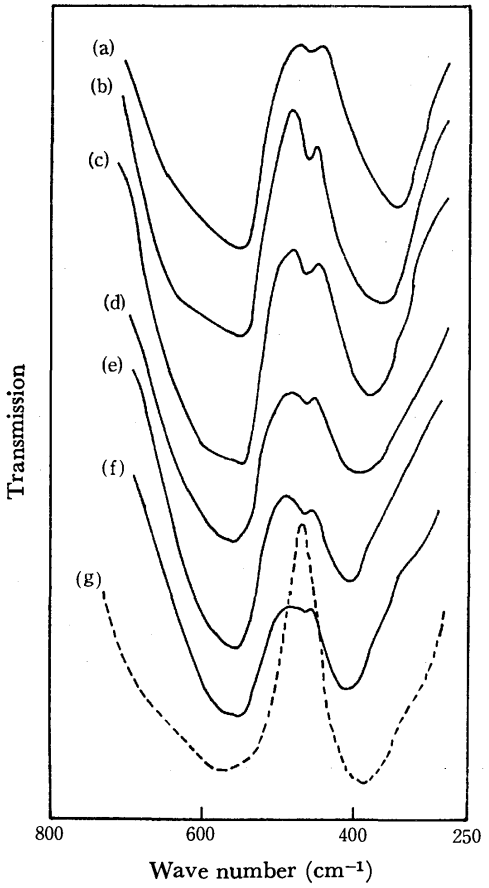

Fig. 3. Infrared absorption spectra of pyrochlore solid solution $Pb_2Ta_{2-x}Ti_{2x}O_{7-x}$ and $PbTiO_2$.
(a): $x=0.0$, (b): $x=0.1$, (c): $x=0.2$, (d): $x=0.3$, (e); $x=0.4$, (f): $x=0.5$, (g): $PbTiO_3$ ($x=1.0$).

spectra were all similar in general features. The higher frequency bands, ν_1, extend from *ca.* 800 to 490 cm^{-1}, with a peak of *ca.* 550 cm^{-1}. They are asymmetric, with a high-frequency tail. The lower frequency bands, ν_2, extend from *ca.* 490 cm^{-1} to the limit of the experimental range at 250 cm^{-1}, with a peak of 350—400 cm^{-1}. With the increse of Ti^{4+} ions, band locations of ν_1 remained nearly unchanged, these bands becoming slightly sharper. The band locations of ν_2 shifted towards high frequency side. Except two strong absorption bands, a weak absorption band was observed at *ca.* 460 cm^{-1}. The infrared spectra of pyrochlore solid solution were similar to that of $PbTiO_3$ except for the band locations (Fig. 3). The two absorption band peaks ν_1 and ν_2 observed in $PbTiO_3$ are 585 and 390 cm^{-1}. These values are in good agreement with Last's data.[14] Similar absorption spectra were obtained for two series of Sn- and Zr-containing systems. Assignment of infrared spectrum has been done on perovskite,[15-17], but not on pyrochlore. It should be noted that the infrared absorption spectra observed in these pyrochlore solid solutions were similar to those of the perovskites. The infrared absorption spectra between metastable pyrochlore $K_{1.5}(Ta_{0.65}Nb_{0.35})_2O_{5.75}$ and perovskite $K(Ta, Nb)O_3$ are similar.[18] Thus it is of significance to compare the infrared absorption spectra of pyrochlore with those of perovskite, since they have analogous structural frameworks. According to the study by Perry *et al.*,[15,16] the vibrations ν_1 and ν_2 observed in the ABO_3 perovskite are assigned to the B–O stretching mode and the B–O_3 torsional mode, respectively. Figures 4 and 5 show the compositional dependence of ν_1 and ν_2 for three series of oxygen deficient pyrochlore solid solutions.

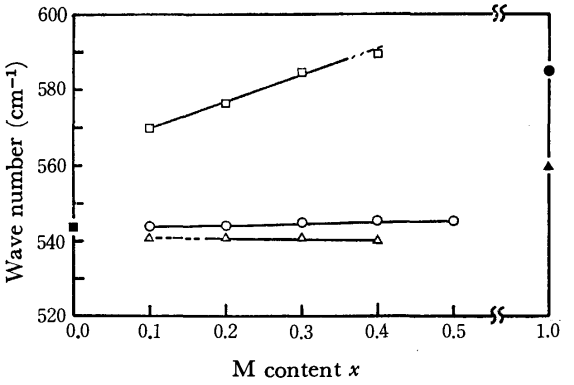

Fig. 4. Compositional dependence of ν_1 for the solid solutions of pyrochlore $Pb_2Ta_{2-2x}M_{2x}O_{7-x}$ (M=Ti, Sn, and Zr).

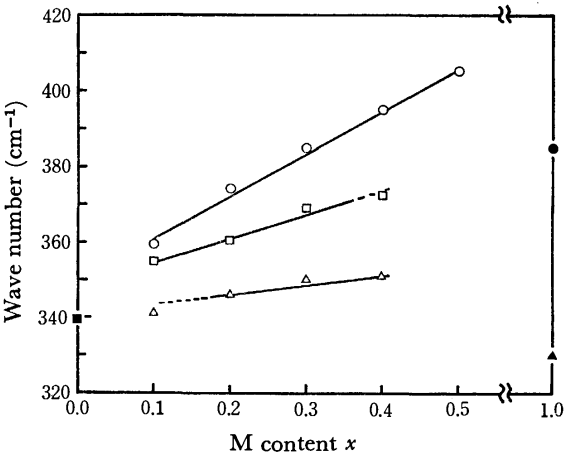

Fig. 5. Compositional dependence of ν_2 for the solid solutions of pyrochlore $Pb_2Ta_{2-2x}M_{2x}O_{7-x}$ (M=Ti, Sn, and Zr).
○: Ti-containing system, □: Sn-containing system, △: Zr-containing system, ■: rhombohedral $Pb_2Ta_2O_7$, ●: perovskite $PbTiO_3$, ▲: perovskite $PbZrO_3$.

The band locations of ν_1 remain nearly unchanged, except for Sn-containing system. On the other hand, all the band locations of ν_2 for three systems shift linearly towards high frequency side with the increase of M^{4+} ions. The values and slopes for ν_2 increase in the order of Ti-, Sn-, and Zr-containing systems. The observed band locations of ν_2 seem to have an inverse relationship between atomic masses and vibrational frequencies. Such a tendency appeared in the perovskites with the same cation in the A position. For example, the band locations of ν_1 for $BaTiO_3$, $BaSnO_3$, and $BaZrO_3$ are 578, 635, and 573 cm^{-1}, respectively, and the band locations of ν_2 for $BaTiO_3$, $BaSnO_3$, and $BaZrO_3$ are 410, 400, and 420 cm^{-1}, respectively.[19] Similar results were obtained for $PbTiO_3$ and $PbZrO_3$ (Figs. 4 and 5). That the vibrational frequencies of ν_1 for Ti- and Zr-containing systems remain nearly unchanged is probably because both effects of reduced mass and force constant on them are cancelled out. The band locations of ν_1 for Sn-containing system, however, shift towards high frequency side, the values being larger than those observed in Ti- and Zr-containing systems. It will be attributed to larger force constants of ν_1 in Sn-containing

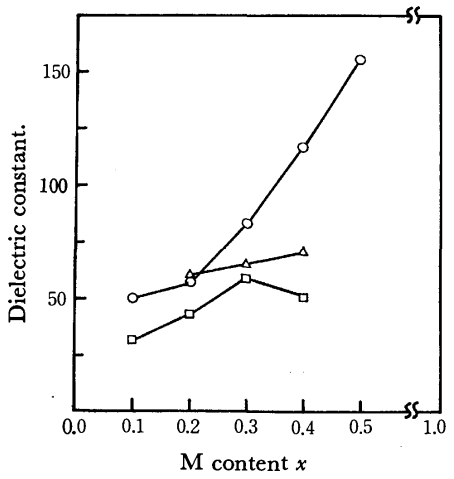

Fig. 6. Compositional dependence of dielectric constant for the solid solutions of pyrochlore $Pb_2Ta_{2-2x}M_{2x}O_{7-x}$ (M=Ti, Sn, and Zr).

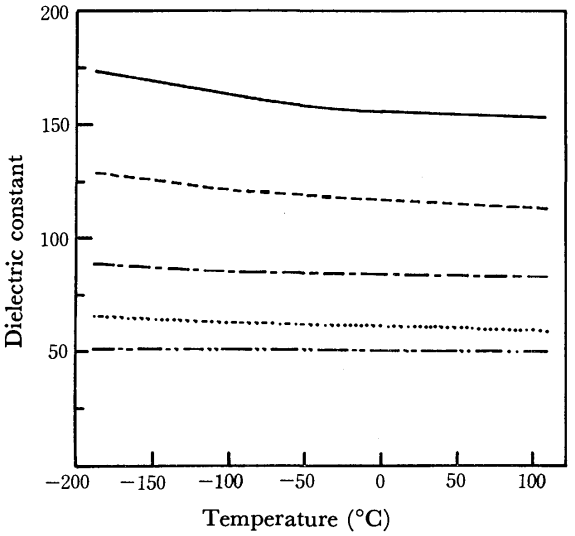

Fig. 7. Temperature dependence of dielectric constant for the pyrochlore solid solution $Pb_2Ta_{2-2x}Ti_{2x}O_{7-x}$. -·-·-: $x=0.1$, ·····: $x=0.2$, -·-: $x=0.3$, ——: $x=0.4$, ——: $x=0.5$.

system than in Ti- and Zr-containing ones. The band locations of ν_1 for pyrochlores of compositions $PbTiO_3$ and $PbZrO_3$ (actually not existing), estimated from the compositional dependence of frequency (Fig. 4), are larger than those observed in the perovskites of $PbTiO_3$ and $PbZrO_3$. This is because force constants of ν_1 in these pyrochlores are larger than those in the perovskites, assuming that the higher frequency ν_1 observed in these pyrochlore solid solutions corresponds to the perovskite B–O stretching mode. The weak absorption band located at 460 cm^{-1} would result from the splitting of degeneracy in the vibrational mode of ν_2. The qualitative similarity of infrared absorption spectra between pyrochlore and perovskite can be expected in view of the assignment based on the vibrations of oxygen octahedron, since they have an analogous structural framework. Further investigation is necessary to confirm whether two absorption bands ν_1 and ν_2 observed in pyrochlores correspond to the B–O stretching mode and the $B–O_3$ torsional mode, respectively, or not.

Dielectric Constant. The compositional dependence of dielectric constant for the solid solutions at room temperature is shown in Fig. 6. The dielectric constants are relatively high, but small as compared with those of titanates or zirconates of typical perovskite. They increase with the increase of M^{4+} ions. In particular, a marked increase of dielectric constant was observed in the Ti-containing system. The temperature dependence of dielectric constant for the Ti-containing system from −190 to 110 °C is shown in Fig. 7. The dielectric constants tend to increase slightly with the decrease in temperature. Such a tendency also appeared in Sn- and Zr-containing systems. If ferroelectric phases occur among these oxygen deficient pyrochlores, the dielectric anomalies would be below liquid nitrogen temperature.

The authors wish to thank Dr. Tetsuo Noguchi of this Institute for his discussions and encouragement.

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

** Niigata Prefectural Center of Industrial Science and Technology, Abumi, Niigata 950*

(Received August 8, 1975)

Fundamental research into the treatment of the chromic plating rinse by reverse osmosis were carried out with Loeb-type skinned membranes. The effect of the pH on the transport of chromic acid was quantitatively investigated. With the increase in pH, chromic acid dissociates to form a divalent ion, CrO_4^{2-}, and the rejection by the membrane increases. For example, the rejection of 0.01 M chromic acid at pH 3 was 83%, while it was 96% at pH 7.25, both at 40 atm. The permeation behavior of additives such as sodium hexafluorosilicate and chromium (III) sulfate was also examined, mainly in connection with their dissociation in the solution. In the case of the concentration of chromic acid, the rejection remained constant up to about 15000 ppm, while the flux decreased considerably with an increase in the concentration.

In Japan as well as other developed countries, concern with pollution has been growing remarkably, and legislative restrictions on discharged harmful effluents are becoming stricter. In addition to national regulations, some more restrictions have been imposed in some local communities. At the same time, it is well recognized among the people concerned that pure water can no longer be treated as limitless natural resource.

The plating rinse effluents are regarded as among the most harmful wastes which contain numerous toxic constituents. In these circumstances, some studies[1,2] have been made on the application of reverse osmosis to the treatment of plating rinses with a view to the recovery of harmful substances and the reuse of the water. These experimental data give us much information for practical use. However, there have been few reports describing the relation between the state of the species in the solution and their permeation behavior. It may be necessary to consider even such a basic problem for a feasibility study. Therefore, simulated chromic plating rinse was chosen here and fundamental experiments were performed in order to clarify the relation mentioned above.

These fundamental experiments were carried out under the following conditions; a three-stage countercurrent rinse system had been chosen in which the concentration of the total dissolved solid in the first stage rinse was 2000 ppm. The concentrated solution (15000 ppm) of the first-stage rinse was returned to the plating bath for balance and the permeated water was used as the rinse. Golomb reported a scheme for the rinse system and the mass-balance of the Watts nickel plating rinse and should be referred to for the details.

Experimental

The modified cellulose acetate (E-398-3) membranes were prepared by the method reported by Loeb and Manjikian.[3] The casting solution was composed of 25 wt. % cellulose acetate, 65 wt. % acetone, and 10 wt. % phosphoric acid. The annealing temperatures of the Loeb-type membranes were 60, 65, 70, 75, and 78 °C. The evaporation temperature was 20±1 °C and the evaporation time was 40 s for all Loeb-type membranes. The membranes thus prepared had approximately 20% more fluxes, with the same rejections, as compared with standard (formamide-type) membranes. The effective membrane area in the desalination cell was 12.6 cm^2. The pressurized (40 atm) solution was circulated along the surface of the membrane at 1.2 l/min to reduce the concentration polarization.

Aqueous solutions of 0.01 M—0.2 M chromic acid, 0.005 M sodium-hexafluorosilicate, and 0.004 M chromic (III) sulfate were tested. Their pH was controlled by adding a suitable amount of 0.1 M NaOH or 0.1 M HCl to the solution. In all the experiments the permeated water was collected one hour after the beginning of the operation. The analysis of the chromic acid was performed by photo-absorption at 274 nm after adjusting the pH of the solution to 8. Sodium hexafluorosilicate was supposed to dissociate in the solution to form various species, so sodium, fluorine, and silicon were analyzed individually.

The sodium was determined by flame photo-absorption at 589 nm. The fluorine was measured by photo-absorption at 620 nm after color developing by a Dotite reagent, "Alfusone." The silicone was also analyzed by photo-absorption at 334 nm after treatment with ammonium molybdate. The properties of the membrane were shown by water flux ($m^3/m^2 \cdot day$) and salt rejection. The salt rejection is shown by;

$$R_e = (1 - C_p/C_f) \times 100 \quad (1)$$

where C_p and C_f are the salt concentrations of the product and feed solutions respectively.

Results

Rejection of Chromic Acid. It is well known[4,5] that, in the case of electrolytes, fluxes of a given solute through the membrane are closely related to the charged state of the molecules in the solution. Since chromic acid dissociates in the solution, chromic acid solutions with pHs of 2, 3, 5, 6, and 7 were tested in order to clarify the effect of pH on the permeation of chromic acid. The rejection of chromic acid was considerably influenced by the pH of the solution, as had been expected. For instance, the rejection of chromic acid was 83% and 96% at pH 3 and 7.25 respectively for the membrane annealed at 70 °C, as is shown in Fig. 1. As it is known that the cellulose acetate membrane is deteriorated rapidly, with a loss

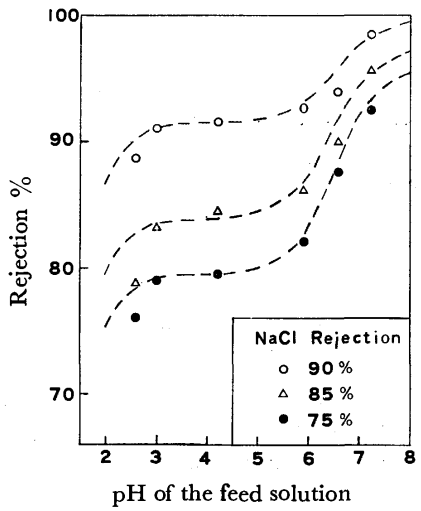

Fig. 1. The effect of pH on the rejection of chromic acid.

of performance, by a strong acidic solution,[6] experiments were carried out as rapidly as possible. That there was no loss of performance of the membrane during the experiment was verified by the fact that there was no change in the water flux or NaCl rejection between before and after the experiment, as is shown in Table 1.

Table 1. Membrane performance before and after experiment

	Memb. ●[a] NaCl rej. %	● Water flux m³/m²·day	△ NaCl rej. %	△ Water flux m³/m²·day	○ NaCl rej. %	○ Water flux m³/m²·day
Before	74.0	1.55	85.3	1.14	90.0	1.07
Intermediate	76.2	1.55	84.1	1.18	90.6	1.09
After	76.8	1.52	84.4	1.18	90.5	1.09

a) Symbols in Table 1 correspond to those in Fig. 1.

Rejection of Additives. The permeation behavior of chromium(III) sulfate and sodium hexafluorosilicate as additives was also examined.

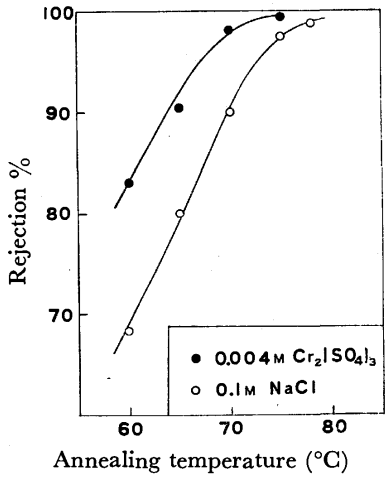

Fig. 2. Rejections of $Cr_2(SO_4)_3$.

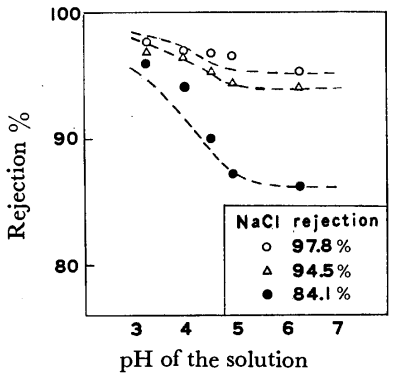

Fig. 3. Rejection of Si in Na_2SiF_6.
------: Calculated rejection.

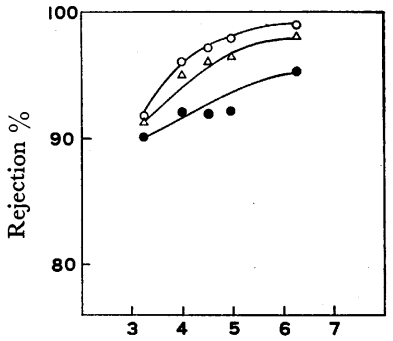

Fig. 4. Rejections of F in Na_2SiF_6.

In the case of inorganic salts, the order of separation is usually consistent with the order of the lyotropic property.[7] In that sense, the rejection of chromium (III) sulfate, which is composed of cations and anions with a high valency, was remarkably higher than that of NaCl, as is shwon in Fig. 2. Since sodium hexafluorosilicate was supposed to dissociate to form various type of species, the rejection was calculated by taking into account the existence of each species.

The analytical data of silicon and fluorine indicate that the rejection of species which contain silicon decreased with the increase in pH, while in the case of species which contain fluorine the opposite is true, as is shown in Figs. 3 and 4.

Discussion

Rejection of Chromic Acid. Chromic acid dissociates in an aqueous solution as follows.

$$H_2CrO_4 \overset{K_1}{\rightleftharpoons} H^+ + HCrO_4^- \quad (2)$$

$$HCrO_4^- \overset{K_2}{\rightleftharpoons} H^+ + CrO_4^{2-} \quad (3)$$

The literature values[7] of the dissociation constants K_1 and K_2 are 1.8×10^{-1} and 3.2×10^{-7} respectively.

The amounts of H_2CrO_4, $HCrO_4^-$, and CrO_4^{2-} in 0.01 M chromic acid solution were calculated using the values of K_1 and K_2. The calculation indicated that at pH 3, most of the chromic acid exists in the solution in the form of $HCrO_4^-$, while at pH 7.25, $HCrO_4^-$ and CrO_4^{2-} exist in the solution in portions of 14.8% and 85.2% respectively. Over the pH range from 2 to

7, the amount of H_2CrO_4 is too small to affect the rejection of chromic acid. Based on the calculation, the expected values of rejection were calculated in the following manner:

(1) The rejection of chromic acid at pH 3 was supposed to be the rejection of $HCrO_4^-$.

(2) Taking into account the existence ratio of CrO_4^{2-} and $HCrO_4^-$, the rejection of CrO_4^{2-} was calculated from the observed rejection at pH 7.25 by using the calculated rejection of $HCrO_4^-$.

(3) The rejection at pH values from 2 to 8 was expressed by the following equation:

$$R = \frac{a(H_2CrO_4) + b(HCrO_4^-) + c(CrO_4^{2-})}{(H_2CrO_4) + (HCrO_4^-) + (CrO_4^{2-})} \quad (4)$$

where a, b, and c are the expected rejections of H_2CrO_4, $HCrO_4^-$, and CrO_4^{2-} respectively. As the amount of H_2CrO_4 was insignificantly small, the value of a is not very important and is supposed to be zero here.

The calculated values of a, b, and c for each membrane are shown in Table 2.

Table 2. Calculated values of a,b, and c

Membrane		a[a)]	b	c
NaCl Rej.	75%	0	79.5	96.0
	85%	0	84.0	97.6
	90%	0	91.5	99.7

a) Not calculated but determined in advance.

The calculated rejections are thus in fair agreement with the experimental values, as is shown in Fig. 1.

At pH 2.5 the observed rejections were several percent lower than the ones expected for each membrane. It can be considered that the amount of species with no charge, H_2CrO_4, became richer at the surface of the membrane, when the concentration of chromic acid increased there due to concentration polarization thereby displacing the equilibrium.

Rejection of Sodium Hexafluorosilicate. The dissociation of sodium hexafluorosilicate is expressed as follows:

$$Na_2SiF_6 \rightleftarrows 2Na^+ + SiF_6^{2-} \quad (5)$$

$$SiF_6^{2-} \overset{K_1}{\rightleftarrows} SiF_4 + 2F^- \quad (6)$$

$$SiF_4 + 2H_2O \overset{K_2}{\rightleftarrows} SiO_2 + 4HF \quad (7)$$

$$HF \overset{K_3}{\rightleftarrows} H^+ + F^- \quad (8)$$

where K_1, K_2, and K_3 are the dissociation constants; their literature values[9] are 1.0×10^{-6}, 1.0×10^{-8}, and 4×10^{-4} respectively.

In this case, the dissociation is so complex that it is very difficult to explain the rejction of each species. The species were, therefore, classified into three groups, containing sodium, fluorine, and silicon respectively.

There are numerous reports[7] seeking to explain the permeation behavior of sodium ions, and so nothing will be mentioned about it here. The species which contain silicon are SiF_6^{2-}, SiF_4, and SiO_2. Calculations based on Eqs. (6), (7), and (8) suggest that at pH 6, the amounts of SiF_6^{2-} and SiF_4 are vanishingly small, while at pH 3 suggests that SiO_2 and SiF_6^{2-} exist in the solution in portions of 30.0 mol.% and 66.6 mol.%. Considering the charged state of the species, SiF_6^{2-} seems to have a much higher rejection rate than the other two species. Just as in the previous section, the rejection of SiO_2 was calculated assuming the amount of SiO_2 to be 5×10^{-3} M at pH 6.25.

Then the rejections of SiF_6^{2-} were calculated considering the existence ratio of each species at pH 3.15. In calculating, it was assumed that the rejection of SiF_4 was almost the same as that of SiO_2, since both of them are the same type of nonelectrolyte. The rejections thus calculated are shown by dotted lines in Fig. 3, and they agree with experimental values. In the case of the separation of the species containing fluorine, it is very difficult to describe the permeation behavior of each species, since there are too many species in the solution.

It may be said, however, that, with an increase in the pH of the solution, HF was enhanced to produce charged species, H^+ and F^-, and that the rejection of the fluorine-containing species became higher, as is shown in Fig. 4. As is shown in this case, the species in the permeated solution are sometimes different from those in the feed solution.

Particular attention should be paid to the cases when species with small solubilities are concentrated or produced in the feed or permeated solution.

Concentration of Chromic Acid. Experiments on the concentration were carried out using a batched-type cell with an effective membrane area of 12.6 cm^2. To avoid concentration polarization, an impeller was rotated over the membrane at 300 r.p.m. The cell was initially charged with 4 l of a chromic acid solution; then it was pressurized with nitrogen gas, which was maintained at 40 atm during the experiment. The permeated solution was collected every hour by using a fraction collector. The initial concentrations of the chromic acid solutions were 0.01—0.05, and each solution was concentrated by a factor of 3—4.

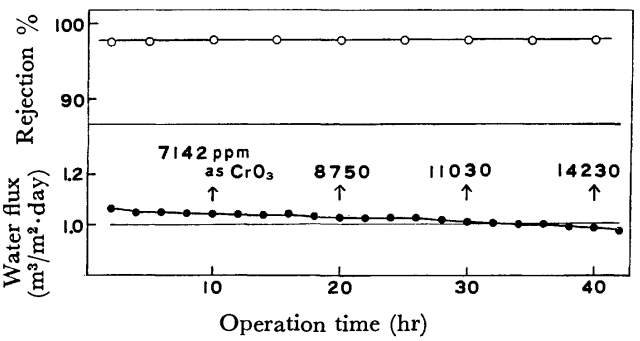

Fig. 5. Concentration of chromic acid. Initial concentration of the feed; 4560 ppm, pH of the feed; 7.1.

Results obtained with an initial concentration of 0.05 M are shown in Fig. 5. Figure 5 indicates that water flux decreased with the increase in the concentration of the feed, while the rejection of chromic acid remained approximately constant. According to those results, the concentration of the permeate was in linear propor-

tion to that of the feed.

When the rejection remains constant, the extent of the concentration can be calculated from the following equation,[10] which corresponds to the concentration process by evaporation:

$$C/C_0 = (V_0/V)^R \quad (9)$$

where C is the concentration of the feed and V is the residual volume of the feed. C_0 and V_0 indicate the initial concentration and volume of the feed.

Later, hexavalent chromium in the permeate should be removed by a method such as ion-exchange resin if the permeate is to be drained off.

The addition of NaOH to control the pH of the feed may be troublesome in that the concentrated solution must be returned to the plating bath. A new type of membrane which has a high resistance to chemicals is expected to be developed.

Influence of Added Alcohols on the Pfeiffer Effect of Tris-(1,10-phenanthroline)zinc(II)-*l*-Malic Acid and -*d*-Tartaric Acid Systems in Water

Katsuhiko MIYOSHI, Yasushige KURODA, Yuji ISOE, and Hayami YONEDA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Hiroshima 730

(Received August 15, 1975)

Influence of lower alcohols (methanol to butanol) was examined on the Pfeiffer effect of the $[Zn(phen)_3]^{2+}$-*l*-malic acid and -*d*-tartaric acid systems in water at 25 °C (phen=1,10-phenanthroline). It was found that the Pfeiffer rotation α_p decreases linearly with molar concentration C_A of added alcohols for both systems, and that the logarithm of the rate of the decrease in α_p with C_A is a linear function of the number of methylene groups in added alcohol molecules. This is well interpreted on the assumption that added alcohol molecules adhere to $[Zn(phen)_3]^{2+}$ ion, thereby preventing the complex and chiral acid from coming into contact with each other. The enthalpy change per methylene group on passing from the alcohol environment to the complex environment was estimated to be *ca.* 0.7 *RT*.

When a racemic mixture of a certain labile complex is added to a solution containing a chiral compound which is not subject to usual racemization, additional optical activity is developed. This phenomenon is called the Pfeiffer effect[1] and is usually ascribed to spontaneous enantiomerization of the complex in favor of either the *dextro-* or *levo*-form, depending on the spacial demand of the chiral compound present.[2] Partial resolution of some complexes was successfully performed by utilizing this phenomenon,[3] which provides so far the strongest evidence for the occurrence of the enantiomerization in the Pfeiffer-active systems.[4] However, little is known yet as regards the nature of the interaction of the complex with the chiral environment compound.[1]

The Pfeiffer systems are classified into three groups according to their charge types: (1) systems of the same charge, *e.g.*, $[Zn(phen)_3]^{2+}$-*l*-stryH$^+$ and -cinchoH$^+$ systems in water (phen=1,10-phenanthroline, *l*-stryH$^+$ =*l*-strychninium, and cinchoH$^+$=cinchoninium), (2) systems of the opposite charge, *e.g.*, $[Zn(phen)_3]^{2+}$-*d*-BCS$^-$ system in water (*d*-BCS$^-$=*d*-α'-bromocamphor-9-sulfonate), and (3) systems containing nonelectrolytes, *e.g.*, $[Zn(phen)_3]^{2+}$-*l*-malic acid and -*d*-tartaric acid systems in water.[5] The influence of some additives was examined on the systems of the first group and the hydrophobic bonding was proposed as one of the essential driving forces by which $[Zn(phen)_3]^{2+}$ cation could associate with cationic environment compounds such as *l*-stryH$^+$ and cinchoH$^+$ against mutual electrostatic repulsion.[6] In this paper, we report the results of an investigation of the influence of some lower alcohols, dioxane, and urea on the systems of group (3). Zinc-complex systems were chosen since they exhibit an instantaneous Pfeiffer rotation.

Experimental

A stock solution of $[Zn(phen)_3]SO_4$ was prepared by dissolving $ZnSO_4 \cdot 7H_2O$ and phen$\cdot H_2O$ in water in a mole ratio of 1:3. Sample solutions containing $[Zn(phen)_3]SO_4$ and *l*-malic acid or *d*-tartaric acid were prepared by diluting respective stock solutions appropriately in volmetric flasks (25 ml). To these solutions were added methanol, ethanol, 1- and 2-propanol, 1- and 2-butanol, *iso-* and *tert*-butyl alcohol, dioxane, and urea, all of which were of reagent grade. Optical rotations were measured in a 5-cm cell at 405 nm with a Union-Giken PM-71 polarimeter kept at 25±0.1 °C.

Results and Discussion

In Table 1 are listed the observed optical rotations of the $[Zn(phen)_3]^{2+}$-*l*-malic acid and -*d*-tartaric acid systems without additives, where code numbers are attached to identify the systems. In Figs. 1—4 is plotted the Pfeiffer rotation α_p, defined as the observed rotation of the Pfeiffer system minus that of the chiral environment compound α_e, as a function of molar concentration

Table 1. Observed rotations in degrees at 405 nm of the Pfeiffer systems[a]

System	Racemic complex	Chiral compd	Rotation of chiral compd, α_e	Obsd Rotation, α_{obsd}	Pfeiffer Rotation, α_p
	$[Zn(phen)_3]SO_4$				
		l-malic acid

1b	0.02M	0.03M	−0.003	−0.335	−0.332
	$[Zn(phen)_3]SO_4$				
		d-tartaric acid			
2a	0.02M	0.02M	+0.034	+0.453	+0.419
2b	0.01M	0.03M	+0.049	+0.379	+0.330

a) In a 5 cm cell at 25 °C.

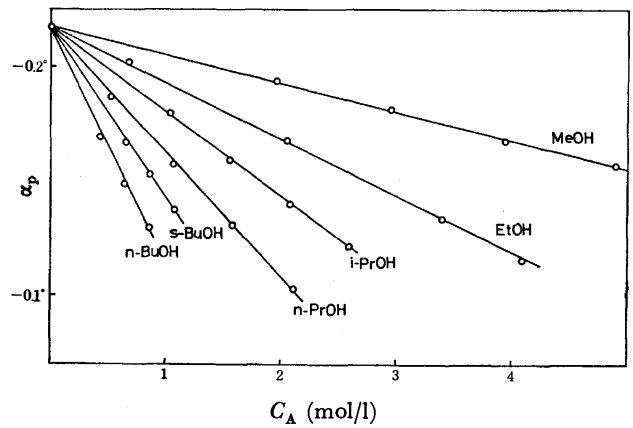

Fig. 1. Plots of α_p as a function of molar alcohol concentration C_A for the $[Zn(phen)_3]^{2+}$ (0.02 M)-*l*-malic acid (0.02 M) system (system 1a).

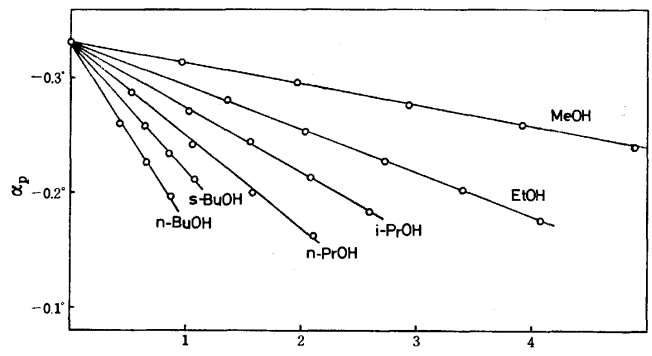

Fig. 2. Plots of α_p as a function of molar alcohol concentration C_A for the $[Zn(phen)_3]^{2+}$ (0.02 M)-*l*-malic acid (0.03 M) system (system 1b).

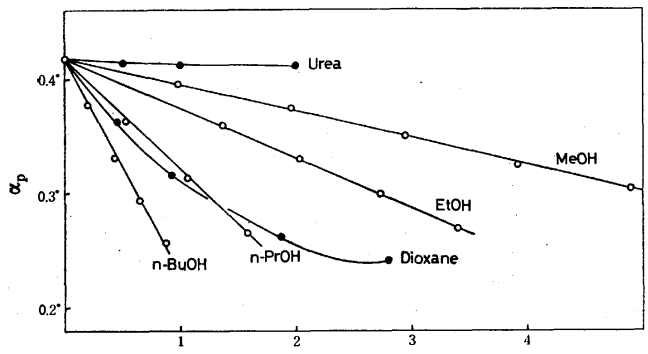

Fig. 3. Plots of α_p as a function of molar concentration of additives C_A for the $[Zn(phen)_3]^{2+}$ (0.02 M)-*d*-tartaric acid (0.02 M) system (system 2a).

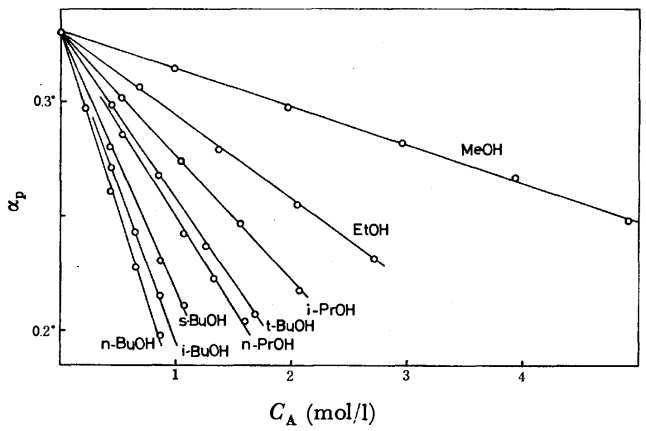

Fig. 4. Plots of α_p as a function of molar alcohol concentration C_A for the $[Zn(phen)_3]^{2+}$ (0.01 M)-*d*-tartaric acid (0.03 M) system (system 2b).

of additives. Since α_e was somewhat affected by the additives, all the α_p's plotted are corrected values as regards small changes in α_e. It is seen that α_p decreases linearly with molar alcohol concentration C_A for both systems, and that the longer the carbon chain of the alcohol molecules, and the greater the Pfeiffer rotation, the steeper the slopes. We are thus led to suppose that added alcohol molecules intervene between the complex and chiral acid, thereby preventing them from coming into contact with each other. In other words, it is assumed that added alcohol molecules are distributed between aqueous phase and the aggregate composed of the complex and chiral acid, the latter being called the Pfeiffer aggregate.[7]

According to the regular solution theory,[8] the chemical potential of the alcohol transferred to water, μ_w, is given by

$$\mu_w = \mu^\circ + RT\ln x_w + m\omega_w^{CH_2} + \omega_w^{OH} \quad (1)$$

where x_w is mole fraction of the alcohol in water, $\omega_w^{CH_2}$ and ω_w^{OH} represent the enthalpy change of CH_2- and OH-groups, respectively on passing from the alcohol environment to water, and m is the number of CH_2-groups in the alcohol molecule.[9] The corresponding chemical potential in the Pfeiffer aggregate, μ_p, is given in a similar manner by

$$\mu_p = \mu^\circ + RT\ln x_p + m\omega_p^{CH_2} + \omega_p^{OH} \quad (2)$$

where x_p is mole fraction of the alcohol in the Pfeiffer aggregate, and $\omega_p^{CH_2}$ and ω_p^{OH} represent the corresponding enthalpy changes from the alcohol environment to the Pfeiffer aggregate. In distribution equilibrium, μ_w must be equal to μ_p. Then, from Eqs. (1) and (2),

$$\ln(x_p/x_w) = m(\omega_p^{CH_2}-\omega_p^{CH_2})/RT + (\omega_w^{OH}-\omega_p^{OH})/RT \quad (3)$$

It seems reasonable to assume that α_p is proportional to the concentration of the Pfeiffer aggregate, and its decrease upon the addition of alcohols is in turn proportional to that of the alcohols in the Pfeiffer aggregate. Then, x_p is expressed as

$$x_p = K_i d\alpha_p/\alpha_p \quad (4)$$

where K_i is a proportionality constant and $d\alpha_p$ is the decrease in α_p when added alcohol concentration is dC_A. On the other hand, x_w is approximated to $C_A/55.5$, since C_A is sufficiently low and the amount of the alcohol transferred to the Pfeiffer aggregate is at most equal to or less than that of the complex or chiral acid present. Substituting the above relations, Eq. (3) is rearranged into

$$\ln(d\alpha_p/\alpha_p dC_A) = m(\omega_w^{CH_2}-\omega_p^{CH_2})/RT + (\omega_w^{OH}-\omega_p^{OH})/RT + C_i \quad (5)$$

where C_i is a constant for a given Pfeiffer system. Equation (5) indicates that a linear relationship holds between $\ln(d\alpha_p/\alpha_p dC_A)$ and m.

a) Omitted in the calculation because of somewhat large deviation. b) Calculated using the values for normal alcohols only.

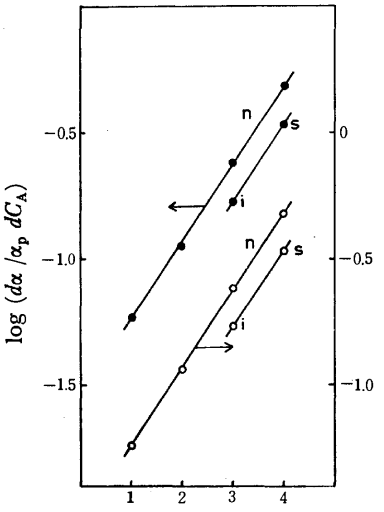

Fig. 5. Plots of $\log(d\alpha_p/\alpha_p dC_A)$ *vs.* m for the $[Zn(phen)_3]^{2+}$-*l*-malic acid system. Filled circles (system 1a) and open circles (system 1b) correspond to left- and right-hand scales, respectively.

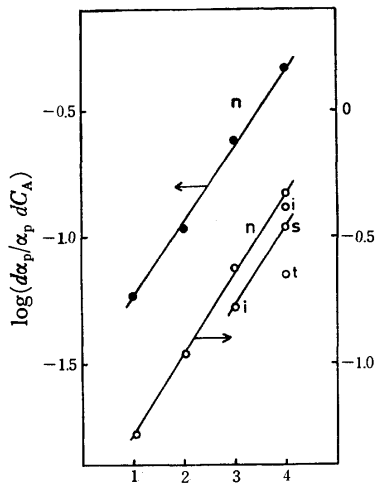

Fig. 6. Plots of $\log(d\alpha_p/\alpha_p dC_A)$ *vs.* m for the $[Zn(phen)_3]^{2+}$-*d*-tartaric acid system. Filled circles (system 2a) and open circles (system 2b) correspond to left- and right-hand scales, respectively.

In Table 2 are listed the values of $(d\alpha_p/\alpha_p dC_A)$, where code numbers correspond to those in Table 1. It is seen that for a given alcohol, these values are almost constant for a given system irrespective of the magnitude of its Pfeiffer rotation. This supports the validity of Eq. (5). In Figs. 5 and 6 is plotted log $(d\alpha_p/\alpha_p dC_A)$ *vs.* m for the $[Zn(phen)_3]^{2+}$-*l*-malic acid and -*d*-tartaric acid systems, respectively. We see that a good linearity holds, as expected from Eq. (5), and that the slope for *n*-alcohols is nearly equal to that for 2-propanol and 2-butanol. The α_p-decreasing order of butanol isomers is found to follow the order of their solubility in water. From these figures, the value of $(\omega_w^{CH_2}-\omega_p^{CH_2})$ corresponding to the enthalpy change per CH_2-group of the alcohol molecule on passing from the Pfeiffer aggregate to water, was estimated by the least squares method

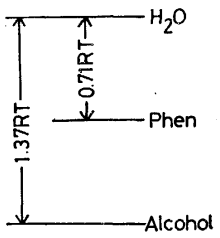

Fig. 7. Energy diagram for the CH_2-group in different environments.

and is included in Table 2.

The value of $\omega_w^{CH_2}$ was estimated by Kinoshita *et al.*[10] to be 1.37 RT from the solubility measurement of higher alcohols in water. The energy diagram for the CH_2-group in different environments is established as shown in Fig. 7. The value of $(\omega_w^{CH_2}-\omega_p^{CH_2})$ for the $[Zn(phen)_3]^{2+}$-*l*-malic acid and -*d*-tartaric acid systems is nearly equal to the value (0.67 RT) found for the $[Zn(phen)_3]^{2+}$-*l*-stryH$^+$ and -cinchoH$^+$ systems, but somewhat different from that (0.57 RT) for the $[Zn(bipy)_3]^{2+}$-cinchoH$^+$ systems (bipy=2,2'-bipyridine).[6,11] The value depends on the kind of racemic complexes but not the chiral environment compound. This suggests that added alcohol molecules adhere to the complex, rather than being distributed between the Pfeiffer aggregate and aqueous phase, thereby diminishing the Pfeiffer effect. It seems necessary for the complex and chiral acid to come into direct contact with each other in order to exhibit additional optical activity.

The influence of dioxane and urea on the $[Zn(phen)_3]^{2+}$-*d*-tartaric acid system is shown in Fig. 3. The striking feature is that the system is considerably affected by dioxane but not appreciably by urea, though both additives diminish the Pfeiffer effect of the first group greatly.[6] This implies that the driving force in developing the Pfeiffer effect in the third group differs from that in the first group[6] for which we have proposed the hydrophobic bonding.[1b,13] For the system of the third group Kirschner[2,12] proposed the hydrogen bonding between the hydrogen in the –COOH and –OH groups of the environment substance and the complex's pi electrons of the aromatic rings. The present result in which addition of urea has little influence on the Pfeiffer effect clealy contradicts the hydrophobic bonding mechanism. We are inclined to assume the hydrogen bonding as the probable cause of the Pfeiffer effect in the system of the third group.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

Transition-metal Complexes of Pyrrole Pigments. XIII. Reduction and Coordination Behaviors of the Cobalt(II) Complexes of 1,19-Disubstituted Tetradehydrocorrins as Demonstrated by the Presence of Various Bases*

Yukito MURAKAMI and Yasuhiro AOYAMA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 27, 1975)

The interaction of various bases with the cobalt(II) complexes of 1,19-disubstituted tetradehydrocorrins (Co(II)-TDHC) was investigated. The parent cobalt(II) complexes were shown to undergo ready reduction at the nuclear cobalt(II) with the unsolvated hydroxide ion as well as with bulky triethylamine. A relatively large positive reduction potential of Co(II)-TDHC is responsible for these novel electron transfer reactions. Less hindered amines (B), on the other hand, failed to show such electron transfer reactions with the cobalt(II) complexes and Co(II)-TDHC became the pentacoordinated complex by taking up an amine base in the axial position: Co(II)-TDHC+B$\rightleftharpoons$B-Co(II)-TDHC. For the interaction of 4-substituted pyridines with the cobalt(II) complex, the general behavior of the equilibrium constants was interpreted in terms of the amine basicity and the Hammett equation by referring to the corresponding behavior of the porphyrin complexes. The weaker coordination tendency of some aliphatic amines and hindered pyridines toward Co(II)-TDHC was attributed to their electronic and steric effects in the coordination process. The intrinsic correlation between electronic and stereochemical characteristics pertaining to the tetradehydrocorrin skeleton and the nature of nuclear cobalt(II) was discussed on the basis of these observations.

In order to provide the chemical basis for the enzymatic functions of naturally occurring macrocyclic complexes such as metal corrinoids and porphyrins, extensive investigations have been carried out on the redox properties of a series of synthetic macrocyclic complexes of various electronic characters.[1-4] Among the biological redox systems, vitamin B_{12}, which involves a corrin framework (**1**), has attracted particular attention from the viewpoint of its unique ability to form a Co(III)-C σ bond.[5,6] The cobalt(I) species has been widely recognized as the key intermediate in the alkylation of vitamin B_{12} and a number of synthetic cobalt complexes have been shown to undergo alkylation *via* nucleophilic reactions of the cobalt(I) intermediates generated by reduction of the parent cobalt(II) or cobalt(III) complexes.[6-12] The redox property of a cobalt complex would be controlled by several factors, such as the cavity size provided by a macrocyclic skeleton which incorporates a cobalt ion, the electronic structure of a macrocyclic ligand, and so on. Attempts have been made to clarify the structural characteristics of these macrocycles which lead to the formation of stable Co(III)-C bonds,[1,11,12] but no satisfactory explanation has been given so far for the significance of the corrinoid structure. In connection with the chemistry of corrinoids, the tetradehydrocorrins (**2**), which have a macrocyclic framework closely related to the corrins (**1**), have been prepared and their metal complexes have been investigated from several structural viewpoints.[13-15] On the basis of these structural studies, the interaction of the hydroxide ion and various organic bases with the cobalt(II) complexes of 1,19-disubstituted tetradehydrocorrins was investigated in the present study. This work, therefore, may elucidate the effects of electronic and stereochemical structures pertaining to the tetradehydrocorrin skeleton on the reactivity of nuclear cobalt(II).

Experimental

Electronic spectra were taken on a Hitachi EPS-2 recording spectrophotometer. NMR spectra were recorded on a Varian A-60 spectrometer. Solvents for spectroscopic measurements were prepared by the standard procedures.[16] Sodium hydroxide and potassium hydroxide of analytical grade were obtained from commercial sources. Diethylammonium chloride was recrystallized twice from ethanol–ether and dehydrochlorinated with sodium hydroxide. Free diethylamine was recovered by fractional distillation after being dried over potassium hydroxide. Similarly, triethylamine was obtained from triethylammonium chloride recrystallized twice from ethanol. Other liquid amines (pyridine, 2-methyl- and 4-methylpyridine, 2,4,6-trimethylpyridine, butylamine, and piperidine) were refluxed with potassium hydroxide and then fractionally distilled. Commercially available 4-cyanopyridine and imidazole were recrystallized from aqueous ethanol and benzene, respectively. 4-Aminopyridine was prepared by ammonolysis of (4-pyridyl)pyridinium dichloride[17] and recrystallized twice from benzene. The purity of these organic amines was checked by gas chromatographic analysis. Dibenzo-18-crown-6 and its potassium hydroxide complex were prepared after Pedersen.[18]

*Tetradehydrocorrinatocobalt(II) Perchlorates (**7a** and **7b**).* 8,12-Diethyl-1,2,3,7,13,17,18,19-octamethyltetradehydrocorrinatocobalt(II) perchlorate (**7a**) was prepared after Johnson *et al.*[19,20] with slight modifications. First, 2,4-dimethyl-3-

acetyl-5-ethoxycarbonylpyrrole was converted to 2,4-dimethyl-3-ethyl-5-ethoxycarbonylpyrrole (**3**, yield 90%) by essentially the same procedure as applied for the synthesis of 2,3,4-triethyl-5-ethoxycarbonylpyrrole.[21] Then, **3** was brominated at the 2-methyl group and further converted to 3,3′-diethyl-4,4′-dimethyl-5,5′-diethoxycarbonyldipyrromethane (**4**, yield 87%) *via* solvolytic coupling of the resulting 2-bromomethyl derivative.[22] The dipyrromethane (**4**) was recrystallized from aqueous ethanol (mp 123.5—125 °C; lit,[23] 126 °C) and hydrolyzed quantitatively with sodium hydroxide to give 3,3′-diethyl-4,4′-dimethyl-5,5′-dicarboxydipyrromethane (**5**). 2-Formyl-3,4,5-trimethylpyrrole underwent condensation with **5** in the presence of hydrogen bromide to afford 1,19-dideoxy-8,12-diethyl-1,2,3,7,13,17,18,19-octamethylbiladiene-ac dihydrobromide (**6**) according to the general procedure of Johnson *et al.*[19] (yield 30—65%). Aeration of a mixture of biladiene-ac dihydrobromide **6** and cobalt acetate tetrahydrate in ethanol followed by addition of sodium perchlorate afforded the tetradehydrocorrinatocobalt(II) perchlorate (yield 35—40%); recrystallized from acetone–benzene. The preparation of 2,8,12,18-tetrakis(2-ethoxycarbonylethyl)-1,3,7,13,17,-19-hexamethyltetradehydrocorrinatocobalt(II) perchlorate (**7b**) has been described previously.[15]

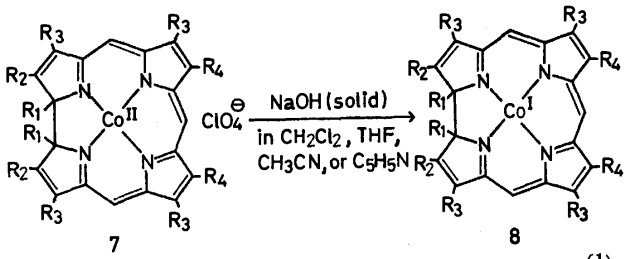
NMR Spectrum of Tetradehydrocorrinatocobalt(I) (8b). To a dichloromethane solution (5 ml) of **7b** (50 mg) was added solid sodium hydroxide (1.0 g) under nitrogen atmosphere, and the mixture was stirred for 2 hr at room temperature. Sodium hydroxide was then removed by filtration. The electronic spectrum of the filtrate indicated the complete conversion of **7b** to **8b**. Most of the solvent was carefully removed under dry nitrogen. The NMR spectrum of the residue (**8b**): δ 1.49 (6H, s, 1,19-C$\underline{H}_3$), 1.85 and 2.45 (both 6H, s, 3,7,13,17-C$\underline{H}_3$), 9.78 (2H, s, 5-$\underline{H}$ and 15-$\underline{H}$), 10.82 (1H, s, 10-$\underline{H}$), 1.27 (12H, t, $CO_2CH_2C\underline{H}_3$), 3.6—4.5 (16H, multi, $CH_2C\underline{H}_2CO_2C\underline{H}_2CH_3$) and 2.9—3.4 (8H, multi, $C\underline{H}_2CH_2$-$CO_2CH_2CH_3$).

Reduction of 7a with the Potassium Hydroxide Complex of Dibenzo-18-crown-6. Into a benzene solution of **7a** (1×10^{-5} M) was added the potassium hydroxide complex of dibenzo-18-crown-6 in an excess amount. The mixture was stirred for 5 min under nitrogen. The electronic spectrum of the mixture showed that **7a** was completely converted to the tetradehydrocorrinatocobalt(I) (**8a**). Controlled experiments were carried out by addition of a calculated amount of a benzene solution of the potassium hydroxide complex (1.5×10^{-2} M).

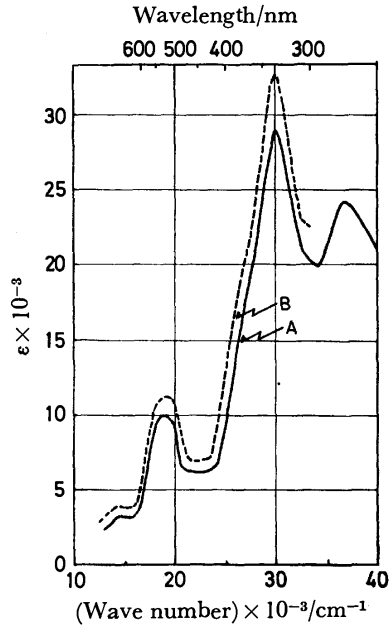
Determination of Equilibrium Constants for the Complex Formation Between 7a and Amine Bases. The interaction of **7a** with an amine base was investigated by measuring the visible spectra of a series of solutions in which the concentration of an amine was varied in about 10^2-fold range on one side and that of **7a** maintained constant (3×10^{-5} M) on the other. According to the Benesi-Hildebrand relationship, the equilibrium constant for the complex formation between **7a** and an amine base was determined on the basis of spectral changes observed upon addition of an amine.

Results and Discussion

Reduction of Tetradehydrocorrinatocobalt(II) Perchlorates with Hydroxide Ion. The reaction of tetradehydrocorrinatocobalt(II) perchlorates (**7a** and **7b**, Co(II)–TDHC hereafter) with sodium hydroxide was investigated at room temperature. When the reaction was carried out in an aprotic solvent (dichloromethane, THF, acetonitrile, or pyridine) with solid sodium



hydroxide, the product was identified as the tetradehydrocorrinatocobalt(I) complex (**8a** or **8b**, Co(I)–TDHC hereafter, refer to Eq. (1)) due to the following facts: (1) the electronic spectrum of the product (**8a**) was almost identical with that of 1,19-diethoxycarbonyl-8,12-diethyl-2,3,7,13,17,18-hexamethyltetradehydrocorrinatocobalt(I) (**8c**) obtained by reduction of the corresponding cobalt(II) complex with sodium film[13] (Fig. 1); (2) the product (**8b**) was diamagnetic and showed a sharp NMR spectrum, suggesting the d^8 configuration of cobalt(I); and (3) the product was oxidized by oxygen only slowly back to the parent cobalt(II) complex, but instantaneously upon treating with iron(III) chloride, as observed for **8c**.[13]



Fug. 1. Electronic spectra of 8,12-diethyl-1,2,3,7,13,17,-18,19-octamethyltetradehydrocorrinatocobalt(I) (**8a**) at room temperature: A, in dichloromethane; B, in pyridine.

As shown in Fig. 2, the electronic spectrum of the parent cobalt(II) complex (**7a**) shows an appreciable solvent dependence. This spectral behavior seems to indicate a further coordination of one pyridine molecule at the axial position of the complex, which is consistent with the corresponding ESR data.[13,15] In contrast, the electronic spectrum of the cobalt(I) species (**8a**) does not show any significant change upon changing the solvent from dichloromethane to pyridine. This fact

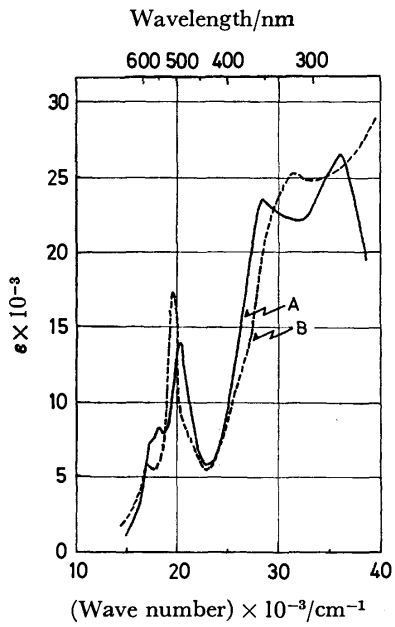


Fig. 2. Electronic spectra of 8,12-diethyl-1,2,3,7,13,17,-18,19-octamethyltetradehydrocorrinatocobalt(II) perchlorate (**7a**) at room temperature: A, in dichloromethane; B, in pyridine.

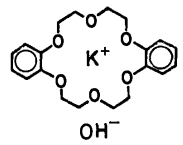
indicates that the reduced complex has no further ability to coordinate with an organic base. The reduction of Co(II)–TDHC failed in both dichloromethane and methanol solutions, even though the saturation level of sodium hydroxide concentration was maintained. These results indicate that the novel electron transfer from sodium hydroxide to Co(II)–TDHC takes place on the solid surface of the base. In marked contrast, the ready reduction of Co(II)–TDHC was again observed in an aprotic solvent (acetonitrile, THF, or benzene) with potassium hydroxide solubilized *via* complex formation with a cyclic polyether, dibenzo-18-crown-6 (**9**). Controlled experiments showed that Co(II)–TDHC was completely reduced to Co(I)–TDHC with less than 3 equivalents of the crown complex, indicating that the active reducing reagent was certainly the hydroxide ion and not any impurity which may exist in alkaline hydroxide. The observed successful reduction of Co(II)–TDHC may be attributed to the absence of any solvation effects for the hydroxide ion. The hydroxide ion at the solid surface or in an aprotic solvent may exist in a naked state without any significant solvation, and is consequently active enough to transfer an electron to an appropriate acceptor, *i.e.* Co(II)–TDHC. The activation of inorganic anions through the complex formation with crown polyethers has been reported for some nucleophilic and oxidation reactions.[24–26]



9

The electron-transfer mechanism for the hydroxide–Co(II)–TDHC system is not fully understood. Gillard has suggested that an unstable intermediate cobalt(II) species is present in the ligand substitution of a cobalt(III) complex, as promoted with a hydroxide ion (Eq. (2)).[27]

$$L_5Co(III)\text{-}Br + OH^- \longrightarrow (L_5Co(II)\cdot OH) + Br^- \longrightarrow L_5Co(III)\text{-}OH + Br^- \quad (2)$$

Cobalt(II) corrinoids[28,29] as well as bis(dimethylglyoximato)cobalt(II)[28,30] have been known to undergo disproportionation in alkaline solutions to the corresponding cobalt(I) and cobalt(III) complexes. A mechanistic distinction, however, should be made between those reactions and the present novel reduction of Co(II)–TDHC. The hydroxide ion transfers an electron to the cobalt(II) complex in the present reaction without its final coordination to or causing disproportionation of Co(II)–TDHC. Such a strong oxidizing power of Co(II)–TDHC is consistent with its higher positive reduction potential relative to other analogous cobalt complexes (Table 1).

There are a number of papers which have reported the successful preparation of coordination compounds containing Co(III)–C σ bonds.[6–12] The nucleophilic attack of a cobalt(I) species on an appropriate alkyl donor seems to provide the most suitable method for such preparative purposes. The present Co(I)–TDHC appears to be an exception for this kind of reaction. Addition of methyl iodide to a solution of Co(I)–TDHC did not result in the formation of a Co(III)–C bond, and no other reaction was detected as proceeding in the system. This result can be understood in the light of the electrochemical data listed in Table 1. The nucleophilicity of various cobalt(I) complexes seems to follow the order of the Co(II)–Co(I) reduction potential.[6,31] The Co(I)–Bae complex, among the complexes listed in Table 1, reacts even with bromobenzene, while Co(I)[(DO)(DOH)pn]P(C_6H_5)$_3$ does not show any reactivity toward propyl bromide even after a prolonged time.[9] Thus, the lack of any nucleophilicity of Co(I)–TDHC appears to be reasonable on the basis of its reduction-oxidation trend, as listed in Table 1. In conclusion, the effects of the corrin and tetradehydrocorrin rings on the reduction-oxidation

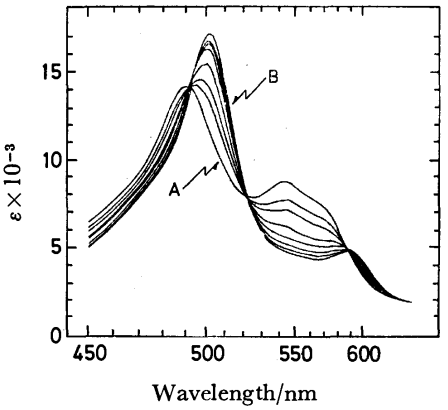

Fig. 3. Electronic spectra of the tetradehydrocorrinatocobalt(II) perchlorate (**7a**) (3.47×10^{-5}M) in dichloromethane at various concentrations of 4-methylpyridine: 0, 7.93×10^{-5}, 1.59×10^{-4}, 3.97×10^{-4}, 7.93×10^{-4}, 1.59×10^{-3}, and 3.02×10^{-3} M (read from A to B).

behavior of the nuclear cobalt are not so alike as would be judged from the similarity in their skeletal structures.

Interaction of Tetradehydrocorrinatocobalt(II) Perchlorates with Amine Bases. The electronic spectrum of Co(II)–TDHC dissolved in dichloromethane underwent variation upon addition of any of the following amine bases: substituted pyridines (4-NH_2, 4-CH_3, 4-CN, 2-CH_3, and 2,4,6-$(CH_3)_3$), imidazole, and aliphatic amines (butyl, diethyl, and piperidine). Since the spectral feature is almost identical with that for the pyridine adduct shown in Fig. 2, the cobalt(II) ion becomes pentacoordinated by having an amine base in the axial position as the fifth ligand. The spectral variations upon addition of 4-methylpyridine are shown in Fig. 3 as an example. The effect of amine concentration on the spectral change was consistent with the following solution equilibrium:

$$\text{Co(II)-TDHC} + \text{B} \overset{K}{\rightleftharpoons} \text{B-Co(II)-TDHC} \qquad (3)$$

where B stands for an amine base. The observations of isosbestic points at 491, 523, and 590 nm and the unit slope for the plots of log([B–Co(II)–TDHC]/[Co(II)–TDHC]) *vs.* log[B] are further evidence for the 1 : 1 complex formation for each of the amine ligands treated, in contrast to the case of the cobalt(II) porphyrin system for which the ESR data suggested the formation of 1 : 2 (metal complex to base) complexes.[32] The equilibrium constants (K) were obtained from the intensity change at 502 nm by adopting the Benesi-Hildebrand-type relation[33] (Eq. (4)).

$$\frac{[\text{Co(II)-TDHC}][\text{B}]}{\Delta A} = \frac{1}{\Delta\varepsilon \cdot K} + \frac{[\text{B}]}{\Delta\varepsilon} \qquad (4)$$

In this equation, [Co(II)–TDHC] and [B] stand for the total concentrations of **7a** and amine, respectively, $\Delta\varepsilon$ is the difference in molar extinction coefficient between Co(II)–TDHC and B–Co(II)–TDHC, and ΔA represents the extent of the absorbance change upon addition of amine bases. A good linear correlation based on Eq. (4) is observed, as shown in Fig. 4 for the Co(II)–

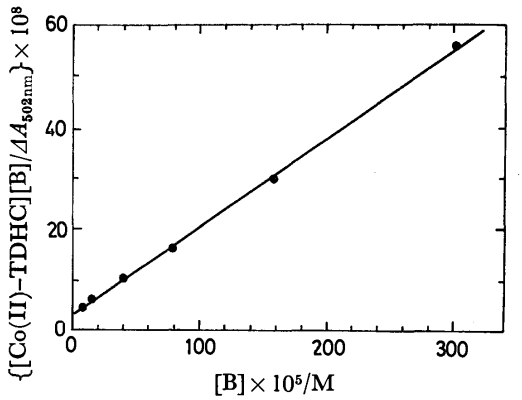

Fig. 4. Benesi-Hildebrand plot for the complex-forming equilibrium between 4-methylpyridine (B) and Co(II)–TDHC (**7a**).

TDHC–4-methylpyridine system: $K=5.90\times10^3\,M^{-1}$ and $\Delta\varepsilon=0.578\times10^4$. This $\Delta\varepsilon$ value is in good agreement with that obtained upon addition of a large excess of 4-methylpyridine (0.584×10^4). Equilibrium constants for other amines were obtained in a similar manner, and are summarized in Table 2.

The equilibrium constants for the formation of pyridine and imidazole adducts of **7a** are comparable in magnitude to those for the porphyrin complexes, but significantly larger than those for the Schiff base complexes, as shown in Table 3. This is consistent with the prediction based on the electrochemical data, *i.e.*, the more negative the cobalt(II)-cobalt(I) reduction potential the smaller the equilibrium constant. Apparently, there exists no systematic correlation between log K and amine basicity, as shown in Fig. 5, without considering the structural characteristics of the amine bases. However, if the 4-substituted pyridines are taken up, the following correlation is established by a least squares analysis, where $a=0.24$ and $b=2.1$:

$$\log K = apK_a + b \qquad (5)$$

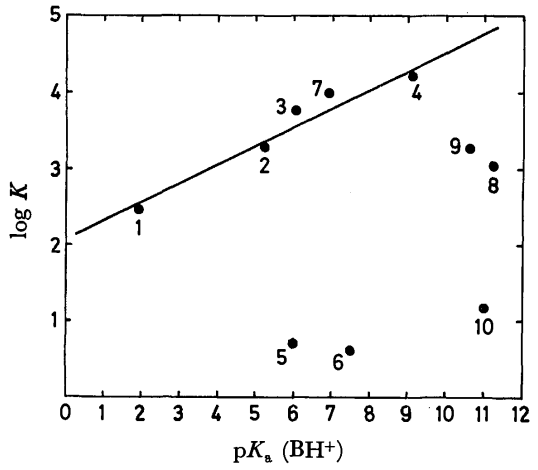

Fig. 5. Correlation between log *K* and amine basicity. Amines: 1) 4-cyanopyridine; 2) pyridine; 3) 4-methylpyridine; 4) 4-aminopyridine; 5) 2-methylpyridine; 6) 2,4,6-trimethylpyridine; 7) imidazole; 8) piperidine; 9) butylamine; 10) diethylamine.

This is due to the fact that these 4-substituted pyridines exert the least and a constant steric effect on Co(II)–TDHC among the amine bases. The equilibrium data for the present set of 4-substituted pyridines can be referred to the Hammett equation with $\rho=1.6$ (Eq. (6)):

$$-\log K/K_0 = \rho\sigma \qquad (6)$$

where K is for a substituted pyridine and K_0 for pyridine, and σ is the Hammett substituent constant. Such a linear free energy relationship has been reported for the complex-forming equilibria between 4-substituted pyridines and metalloporphyrins.[34-38] It is interesting to note that both *a* and ρ values for the present Co(II)–TDHC (**7a**) system are considerably larger than the corresponding values for the cobalt(II) complexes of protoporphyrin ($a=0.09$, $\rho=0.6$)[38] and tetrakis(*p*-methoxyphenyl)porphyrin ($a=0.19$, $\rho=1.0$).[37] The current interpretation of *a*[39] and ρ values may lead to an important conclusion that the nuclear cobalt in Co(II)–TDHC is more electronegative than in cobalt(II) porphyrins, and the pyridine nitrogen in X–C_5H_4N–Co(II)–TDHC is much more electron deficient than in the corresponding cobalt(II) porphyrin complexes. This is again what might be expected from the extremely positive cobalt(II)–cobalt(I) reduction potential of Co(II)–TDHC (Table 1).

A large decrease in K value was observed for some hindered pyridines, such as 2-methylpyridine and 2,4,6-trimethylpyridine (Fig. 5). This may be attributed to the front strain exerted between these amines and Co(II)–TDHC in the coordination process. The coordination of pyridines to metalloporphyrins is also subject to a similar steric effect.[34,35,37] The formation constant of the 2,4,6-trimethylpyridine complex of cobalt(II) tetrakis(*p*-methoxyphenyl)porphyrin is 1.5 log unit less than that expected from the basicity of the amine.[37] This effect is even larger in the present system and the formation constants for 2-methyl- and 2,4,6-trimethylpyridine are reduced by 3 log units more than expected (Fig. 5). In addition to the repulsion between the in-plane π-electron system of the macrocyclic ligand and the 2- and/or 6-methyl groups of the substituted pyridines, another steric interaction seems to interfere greatly with the coordination of 2-methyl- and 2,6-dimethylpyridines to Co(II)–TDHC. This other significant steric effect may arise from the interaction of the angular methyl groups placed at the 1- and 19-positions of the macrocyclic ligand and the substituted pyridines.

Aliphatic amines form complexes with Co(II)–TDHC which are less stable than those derived from substituted pyridines, on the basis of the basicity scale shown in Fig. 5. The extra stabilization observed for the pyridine complexes may be attributed to the π-back bonding from the nuclear cobalt to the pyridine moiety. It is interesting to note that imidazole has an affinity toward Co(II)–TDHC which falls relatively well on the $\log K - pK_a$ correlation line for the 4-substituted pyridines. It has been generally realized, on the other hand, that imidazole behaves as a better π-electron acceptor relative to pyridine.[37] The present result indicates, therefore, that π-back donation from the nuclear cobalt to the π*-orbital of the fifth ligand such as imidazole and pyridine derivatives would not be so marked as predicted for the porphyrin complexes,[40] due to the significant electronegative character of cobalt in Co(II)–TDHC.

Because of the bulkiness of triethylamine, it demonstrates the least coordination tendency toward Co(II)–TDHC among the amine bases used in this work. The spectrum of Co(II)–TDHC (**7a**) (2×10^{-5}M in dichloromethane) remained unchanged upon addition of triethylamine (up to 10^{-2} M.) However, when the concentration of the amine was adjusted to the 10^{-1} to 1 M range, the reduction of **7a** took place to afford Co(I)–TDHC (**8a**). The reduction product gave a spectrum identical with that observed for the cobalt(I) complex obtained upon treating with sodium hydroxide. The observed electron transfer from triethylamine to Co(II)–TDHC is of considerable interest since the less hindered amines resulted not in electron transfer but

in coordination to Co(II)–TDHC.[41] These results may be interpreted in a consistent manner as follows: (1) the electron transfer takes place appreciably in a long range scheme (outer sphere mechanism), since triethylamine has the least tendency of coordination toward Co(II)–TDHC due to its sterically hindered structure; (2) less hindered amines donate two electrons in a stepwise manner to Co(II)–TDHC microscopically and the first electron is transferred to the Co(II)–TDHC through the outer sphere mechanism. The resulting Co(I)–TDHC intermediate and the electron defficient amine may couple together to give the corresponding coordination compound. The entire mechanistic scheme is given by Eq. (7).

$$\begin{array}{c} \text{Co(II)-TDHC} + \text{NR}^1\text{R}^2\text{R}^3 \\ \Updownarrow \\ [\text{Co(I)-TDHC} + \cdot\overset{+}{\text{N}}\text{R}^1\text{R}^2\text{R}^3] \qquad (7) \\ \swarrow \qquad\qquad \searrow \\ \begin{array}{ll} \text{Co(I)-TDHC} + \cdot\overset{+}{\text{N}}\text{R}^1\text{R}^2\text{R}^3 & \text{R}^1\text{R}^2\text{R}^3\text{N-Co(II)-TDHC} \\ (\text{R}^1, \text{R}^2, \text{R}^3\text{: alkyl}) & (\text{R}^1\text{: H and} \\ & \text{R}^2, \text{R}^3\text{: H or alkyl}) \end{array} \end{array}$$

(Received August 28, 1975)

Oxygen in zinc compounds was determined by a modification of the method of Schütze. Oxygen in some zinc compounds such as zinc oxide, zinc acetate and zinc oxalate could not be determined by the usual method. The carrier gas method of adding carbon was employed for the determination of total oxygen. Total oxygen could be determined by the addition of 5 mg of carbon to a sample boat and heating at 1000 °C. The determination was also carried out by the carrier gas method by addition of 2 mg naphthalene. As a result, total oxygen could be determined by the addition of 2 mg of naphthalene.

Determination of oxygen in zinc compounds was first reported by Schütze in 1939.[2)] Carbon was placed in a sample boat in an atmosphere of nitrogen, the boat was heated at 1000 °C, and determination of oxygen in zinc oxide was carried out. Oxygen determination in zinc oxide by the method of inert gas fusion was reported by Engelsman *et al.*,[3)] who employed a platinum bath, heating being carried out at 2000 °C. Merz[4)] reported that oxygen in zinc oxide could be determined by the addition of ammonium chloride or an indulin base.

In spite of the publication of several reports, little is known about the determination of oxygen in zinc compounds other than zinc oxide.

We have studied oxygen determination in compounds containing metals such as silver, arsenic, mercury, tin and copper. The present paper deals with the determination of oxygen in zinc compounds.

Experimental

Samples. The following samples were employed for the experiments: zinc oxide, ZnO; zinc acetate, $Zn(CH_3COO)_2 \cdot 2H_2O$; ammonium zinc sulfate, $(NH_4)_2Zn(SO_4)_2$; zinc anthranilate, $Zn(C_7H_6NO_2)_2$; zinc benzoate, $Zn(C_7H_5O_2)_2$; zinc 4-cyclohexylbutyrate, $Zn(C_{10}H_{17}O_2)_2$; zinc formate, $Zn(CHO_2) \cdot 2H_2O$; zinc lactate, $Zn(C_3H_5O_3)_2 \cdot 3H_2O$; zinc nitrate, $Zn(NO_3)_2 \cdot 6H_2O$; zinc oxalate, $ZnC_2O_4 \cdot 2H_2O$; zinc perchlorate, $Zn(ClO_4)_2 \cdot 6H_2O$; zinc *p*-phenolsulfonate, $Zn(C_6H_5O_4S)_2 \cdot 8H_2O$; zinc stearate, $Zn(C_{18}H_{35}O_2)_2$; zinc salicylate, $Zn(C_7H_5O_3)_2$; zinc sulfate, $ZnSO_4 \cdot 7H_2O$; zinc tartrate, $ZnC_4H_4O_6$; bis[bis(2-hydroxyethyl)dithiocarbamato]zinc, $Zn(C_5H_{10}NO_2S_2)_2$; bis(2,4-pentanedionato)zinc, $Zn(C_5H_7O_2)_2$; bis(2-quinolinecarboxylato)zinc, $Zn(C_{10}H_6NO_2)_2 \cdot H_2O$; bis(8-quinolinolato)zinc, $Zn(C_9H_6NO)_2$; *p*-[N-ethyl(2-hydroxyethyl)amino]benzenediazonium tetrachlorozincate, $C_{20}H_{28}Cl_4N_6O_2Zn$. The results of the determination of carbon and hydrogen are given in Table 1. They are in fair agreement with the corresponding calculated values.

Reagents and Apparatus. The reagents and apparatus used were the same as those previously reported.[5)]

Procedure. *(1) Usual Method of Oxygen Determination in Organic Compounds:* Nitrogen was passed throughout the apparatus as a carrier gas at a rate of 10—15 ml/min. Nitrogen was purified by passing through a silica gel drying tube, a deoxidation tube filled with porous copper heated at 550 °C and two tubes one containing sodium hydroxide and the other magnesium perchlorate. The temperatures of the combustion furnace, desulfurization furnace and heating furnace were maintained at 900, 550, and 150 °C, respec-

TABLE 1. ANALYTICAL RESULTS OF CARBON AND HYDROGEN IN ZINC COMPOUNDS

Sample	Carbon(%)		Hydrogen(%)	
	Found	Calcd	Found	Calcd
Zinc oxide ZnO	0.05	0.00	0.02	0.00
Zinc acetate $Zn(CH_3COO)_2 \cdot 2H_2O$	21.94	21.89	4.60	4.59
Ammonium zinc sulfate $(NH_4)_2Zn(SO_4)_2$	0.12	0.00	2.89	2.75

p-[*N*-Ethyl(2-hydroxyethyl)-amino]benzenediazonium tetrachlorozincate $C_{20}H_{28}Cl_4N_6O_2Zn$	40.73	40.60	4.51	4.77

tively. A boat containing a weighed sample was put into a pyrolysis tube through a sample inlet, nitrogen being flushed at the sample inlet lest air should come into the pyrolysis tube. The boat was moved up to a sample heated by means of an iron ball and a magnet, and the sample was pyrolized over a period of 15 min. Oxygen contained in the sample was completely converted into carbon monoxide by means of platinum-carbon heated at 900 °C. The carbon monoxide was oxidized to carbon dioxide by iodine petaoxide, and the resulting carbon dioxide was allowed to be absorbed into an absorption tube packed with sodium hydroxide. Thirty minutes after the beginning of pyrolysis, the absorption tube of carbon dioxide was disconnected from the apparatus and weighed. The content of oxygen in the sample was calculated as follows:

$$\text{The content of oxygen (\%)} = \frac{0.3636\times(a-b)}{s}\times 100$$

where s=sample weight (mg); a=increase in weight of the absorption tube of carbon dioxide (mg); and b=blank value (mg). The determination took *ca.* 40 min.

(2) Determination by Means of a Solid Reaction Agent: This method was approximately the same as that described in (1) except that carbon powder was sprinkled on the sample boat prior to and after placement of the sample.

(3) Determination by Addition of a Reaction Agent: Purification of the carrier gas and the procedure after oxygen in a sample had been converted into carbon monoxide were the same as those described in (1), except for insertion of the sample boat and pyrolysis of the sample which were carried out as follows. A weighed sample was placed in the sample boat which was then put in the sample inlet after the apparatus was ventilated reversely. An iron ball and then a boat with a weighed reaction agent (2 mg of naphthalene) were inserted into the apparatus, and the apparatus was ventilated reversely for 3—5 min. The direction of the ventilation was then changed and the sample boat was moved up to a sample heater by means of the iron ball and a magnet. During the course of pyrolysis, the iron ball was brought back to the boat with the reaction agent and the boat was moved up to a place about 2—3 cm from the sample heater. The reaction agent was gasified by the heat from the sample heater and the gas was allowed to flow along with the carrier gas toward the sample heater. The sample or oxidation products remaining in the sample boat were allowed to react directly with the gas or the pyrolysis products of the reaction agent. The oxygen compounds resulting from the reaction of the pyrolysis gas produced by the heating of the sample or of the oxygen remaining in the sample boat with the reaction agent were allowed to react with platinum carbon heated at 900 °C in order to convent the oxygen in the sample into carbon monoxide.

Results and Discussion

Determination of Oxygen in Zinc Compounds by the Usual Method. Oxygen in zinc compounds was determined according to the method for determination of oxygen in organic compounds. The results are shown in Table 2. Heating was carried out at 900 °C. The values for oxygen in zinc oxide, zinc acetate, zinc ammonium sulfate, zinc formate, zinc nitrate, zinc oxalate, zinc perchlorate and zinc sulfate was 3—18% lower than the corresponding calculated values. Oxygen in the other 13 compounds, however, could be determined more accurately. Since zinc oxide has a high

melting point, we supposed that oxygen in zinc oxide could not be determined at all by the method for determination of oxygen in organic compounds. However, we have found that heating of zinc oxide at 900 °C in an atmosphere of nitrogen is likely to lead to the dissociation of zinc oxide, and we were able to determine about 1% of oxygen in this compound although the calculated content of oxygen was 19.66%. The residue left in the sample boat after determination of oxygen in zinc acetate was white and seemed to be zinc oxide. We see from the analytical results that 5.5 oxygen atoms out of 6 in zinc acetate could be determined. The residue in the sample boat after determination of oxygen in zinc ammonium sulfate, zinc formate, zinc nitrate, zinc oxalate, zinc perchlorate or zinc sulfate was white and seemed to be zinc oxide. The analytical results show that the value found was approximately the same as the calculated value obtained by subtracting one oxygen atom left as zinc oxide from all the oxygen atoms in each sample.

Determination of Total Oxygen in Zinc Compounds by the Carrier Gas Method with a Solid Reaction Agent. Total oxygen in some of the zinc compounds can not be determined by the usual method. We therefore used the carrier gas method with carbon as a solid reaction agent. In order to examine the influence of temperature on oxygen determination, 5 mg of carbon was placed in a sample boat and the temperature was measured according to the carrier gas method with a solid reaction agent. Zinc oxide was used as the

sample. The analytical results are given in Table 3. It was found that oxygen in zinc oxide can be determined fairly accurately when the sample is heated at 1000 °C or above. With compounds the oxygen of which can not be determined by the usual method, determination of oxygen was also carried out at 1000 °C. The results are given in Table 4. We see that oxygen in zinc compounds can be determined quite accurately by the addition of carbon to a sample boat.

Determination of Total Oxygen in Zinc Compounds by the Carrier Gas Method with a Reaction Agent. The total oxygen in zinc compounds can be determined by the addition of carbon to a sample boat and by heating at 1000 °C. We also attempted the addition of naphthalene (2 mg) instead of carbon. The results are given in Table 5. It was found that total oxygen in the zinc compounds can be determined accurately even in the presence of naphthalene.

The authors are indebted to Dr. Nobuo Suzuki of Pharmaceutical Laboratory, Hoechst Japan Limited, for his encouragement. Thanks are also due to Miss Motoko Kanda for her assistance in the early stage of the present experiments.

Preparative Thin-Layer Chromatography of Semi-Xylenol Orange and Xylenol Orange by Development with Solvents Giving Discrete pH Change on the Plate*

Mutsuo YAMADA and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 1, 1975)

A new procedure is proposed to obtain pure Semi-Xylenol Orange (SXO) and Xylenol Orange (XO) from *ca.* 100 mg of synthetic mixture using preparative thin-layer chromatography on cellulose layer *ca.* 2 mm thick. Development with a composite solvent, 55—60 ml of 1-butanol saturated with 25% aqueous acetic acid-0.6—0.8 ml of 28% aqueous ammonia, forms two discrete zones of different pH values on the layer. The zones favor a sharp separation of polybasic Brønsted acids with structures similar to those of SXO and XO.[1] SXO and XO are in the protonated forms corresponding to the pH values of the given zones. XO is located near the starting line in the lower zone of higher pH and SXO migrates through the layer in the upper part of the same zone. Both SXO and XO constitute the compact and concentrated bands. Each run takes only 3 hr. 18 mg of SXO and 36 mg of XO are obtained as sodium salts from 100 mg of the synthetic mixture.

Semi-Xylenol Orange, 3-[*N*,*N*-bis(carboxymethyl)-aminomethyl]-*o*-cresolsulfonphthalein, is an appropriate chelating agent for spectrophotometric determination of zirconium(IV)[2] and for interpreting the kinetic behavior for the metal complex formation in a strongly acid medium.[3]

Xylenol Orange, 3,3′-bis[*N*,*N*-bis(carboxymethyl)-aminomethyl]-*o*-cresolsulfonphthalein, is a well-known metallochromic indicator.[4] However, there has been considerable disagreement in the results obtained by different authors on the solution chemistry of the metal complex formation.[5] The disagreement is caused by the use of "*impure*" XO containing iminodiacetic acid (IDA) and SXO with complexing properties and the lack of attention to the existence of metal complex species other than mononuclear 1 : 1 complex.[6]

Two methods have been reported for the purification of XO and/or SXO: (1) Selective precipitation of XO with ethanol from a saturated aqueous sodium acetate solution containing the mixture,[7] and (2) column chromatography on cellulose powder with the eluent, 1-butanol–acetic acid–water.[2,8] By the former, XO is partly decomposed[2,8] and cannot sufficiently be separated from SXO and IDA.[8] The latter causes serious tailing and cross-contamination of XO and SXO.

In the present paper we propose a new procedure to obtain "*pure*"[9] SXO and XO from a synthetic mixture. The procedure is preparative thin-layer chromatography with a developing solvent, 55—60 ml of 1-butanol saturated with 25% aqueous acetic acid-0.6—0.8 ml of 28% aqueous ammonia. The solvent yields on the cellulose layer two distinct zones I and II with stepwise different pH values. Zones I and II correspond to the regions of lower and higher pH values, respectively. Development with the composite solvent satisfactorily separates SXO, XO and *o*-Cresol Red (*o*-CR). SXO is thus concentrated in the upper part of zone II, while XO near the starting line in the same zone. *o*-CR moves much faster than both SXO and XO and is located in zone I at the top of the plate. The band of XO partly overlaps that of IDA and further separation is required. Development with the solvent, acetone–water–1 M hydrochloric acid (160/59/1, v/v/v), is found to be very effective for this purpose. "*Pure*" specimens of SXO and XO in the forms of free acid are prepared by cation exchange.

Experimental

Materials. Reagents: All the chemicals used were of analytical grade, unless otherwise specified. Water was deionized and distilled. *n*-BuOH was distilled.

SXO and XO: These compounds were synthesized by Mannich condensation.[4] 1.91 g (0.5×10^{-2} mol) of *o*-CR, 1.33 g (1.0×10^{-2} mol) of IDA and 1 g of NaOH were dissolved in 50 ml of glacial acetic acid followed by dropping 1 ml of 37% HCHO and kept at 65 °C for 10 h with stirring. The solvent was distilled off under reduced pressure to give a dry sample.

Cellulose Powder: Toyo-Roshi cellulose powder (300 or 200—300 mesh) was suspended in 0.5 M HCl and left to stand overnight. The suspension was sucked off, washed with water until washings became free from chloride, washed with acetone and dried in an oven at 80 °C for 2 h.

Ion Exchanger: A macroreticular strongly acid cation-exchange resin of low cross-linkage, Diaion PK-204 (Mitsubishi Kasei, Ltd.), was treated with HCl to remove trace of metal impurities and used in the hydrogen-form.

Preparative Thin-Layer Chromatography. Adsorbent Layer: A slurry was prepared by adding 90 ml of water to 30 g of the pretreated cellulose powder. A layer was obtained by the pouring procedure:[10] The slurry was rapidly poured on the middle of a glass plate (20×20 cm) and uniformly distributed over the plate by gentle tilting and shaking. The layer was sufficiently dried in the air at room temperature to avoid cracking during the course of heating. The plates were heated in an oven at 110 °C for 80 to 100 min, and stored in a desiccator over silica gel. Fairly uniform layers *ca.* 2 mm thick were usually prepared.

Chromatographic Chamber: A sandwich chamber ($20\times20\times$ 0.3 or 0.6 cm) was used. The terminal edge of the chamber was kept open during the development in order to allow free evaporation of the solvent at the top of the plate.[10]

Application of the Sample: About 100 mg sample powder was dissolved in 0.36 ml of water and successively applied with a 0.06 ml band-pipet (2.6 cm wide) in a line *ca.* 15 cm wide on

* Presented in part at the IUPAC International Congress on Analytical Chemistry, Kyoto, April 7, 1972, Abstracts, p. 183.

the layer 1.5 cm apart from the solvent surface in a sandwich chamber trough. After the application of the sample the plate was stored in a desiccator over silica gel until the water of the sample solution evaporated.

Developing Solvents: *Fifty-five* to *sixty* milliliters — a volume sufficient for one run — of *n*-BuOH saturated with 10, 20, or 25% aqueous HOAc was poured into a sandwich chamber trough (19×207×23 mm), and 0.6—0.8 ml of 28% aqueous NH_3 was added drop by drop so as to form an emulsion as uniformly as possible. Developing was started immediately after the preparation of the emulsion.

Identification of Each Band on the Chromatogram: The bands of *o*-CR, SXO and XO were readily identified by their intense coloration on the plate. It was necessary to confirm a position of the colorless band of IDA under similar experimental conditions beforehand, otherwise the band was inevitably covered with the intense coloration of XO. The band of IDA was detected by spraying a copper(II) acetate solution on the layer.

Transfer of SXO and XO from the Adsorbent to Solutions: The bands of SXO and XO on the layer were carefully scraped off with a glass rod, extracted with a small amount of water and dried *in vacuo*.

Ion Exchange. The extracts of SXO and XO were subjected to cation exchange to yield their free acids.

H_4SXO: About 50 mg of the sodium salt of purified SXO was dissolved in 25 ml of water, passed through a column containing 4 ml of pretreated cation-exchange resin, and eluted with 25 ml of water. A small part of SXO remaining on the resin phase was thoroughly washed out with a small amount of *n*-BuOH saturated with water.

H_6XO: About 50 mg of the sodium salt of purified XO was dissolved in 25 ml of water, passed through a column containing 9.5 ml of resin, and eluted with 75 ml of water. A small part of XO retained on the resin was washed out with a small amount of *n*-BuOH saturated with water.

Each effluent was evaporated to dryness at room temperature under reduced pressure and further kept *in vacuo* for 3 days to yield a dried sample. For the XO portion a further separation from IDA was required.

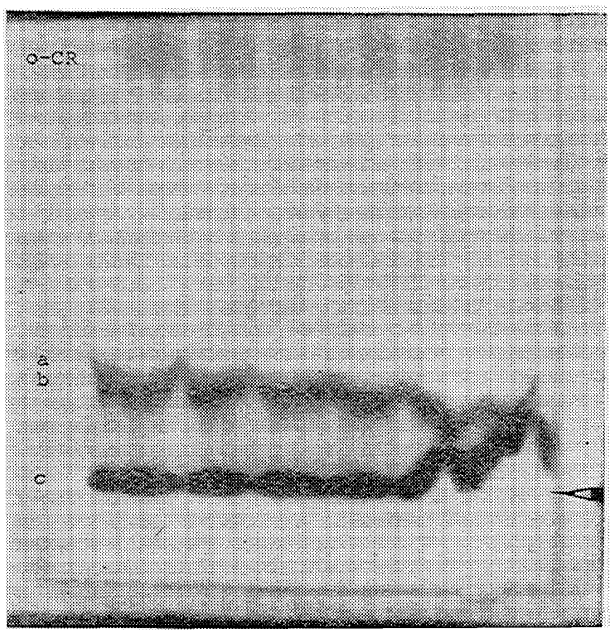

Fig. 1. Chromatogram developed for 3 hr with 60 ml of *n*-BuOH satd. with 10% HOAc–0.6 ml of 28% NH_3. a) NH_4-front, b) SXO, and c) XO.

Results

Separation of SXO and XO. Figure 1 shows a chromatogram with the developing solvent, 60 ml of *n*-BuOH saturated with 10% HOAc–0.6 ml of 28% NH_3.

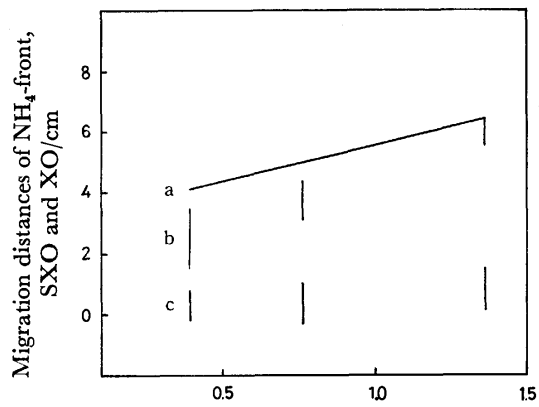

Fig. 2. Dependence of the migration distances of SXO, XO, and NH_4-front on the concentrations of HOAc contained in the *n*-BuOH satd. with 10, 20, and 25% HOAc.
The developing solvents used are 60 ml of *n*-BuOH saturated with 10, 20, and 25% HOAc–0.6—0.8 ml of 28% NH_3. a) NH_4-front, b) SXO, and c) XO.

Figure 2 shows the dependence of the migration distances of SXO, XO and NH_4-front on the concentrations of HOAc contained in *n*-BuOH saturated with 10, 20 and 25% HOAc. The developing solvents are 60 ml of *n*-BuOH saturated with 10, 20 and 25% HOAc–0.6—0.8 ml of 28% NH_3. It is found that as far as the experimental conditions are concerned the greater the concentration of HOAc, the better the

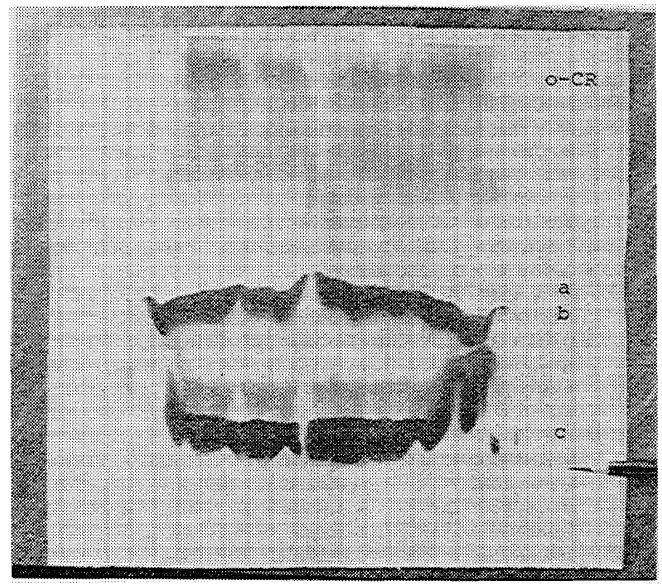

Fig. 3. Chromatogram developed for 3 hr with 60 ml of *n*-BuOH satd. with 25% HOAc–0.8 ml of 28% NH_3. a) NH_4-front, b) SXO, and c) XO.

separation of SXO and XO. Figure 3 gives the chromatogram obtained in the case of 25% HOAc and 0.8 ml of 28% NH_3 added.

SXO is finely separated from XO under the following conditions: The sample is applied on the layer 1.5 cm apart from the solvent surface in the trough, and developed with an emulsion freshly prepared in the trough by adding 0.6—0.8 ml of 28% NH_3 drop by drop to 55—60 ml of *n*-BuOH saturated with 25% HOAc.

The solvent, 55—60 ml of *n*-BuOH saturated with 10, 20 and 25% HOAc–0.6—0.8 ml of 28% NH_3 forms zones I and II with discrete different pH values, the zones being divided by a distinct boundary. After 3 hr development using 60 ml of *n*-BuOH saturated with 25% HOAc–0.8 ml of 28% NH_3 without the sample applied, three acid-base indicators, Bromophenol Blue, Bromocresol Green and Bromothymol Blue, are sprayed on the layer. They exhibit uniform visible colorations on the layer corresponding to the pH value of both zones I and II as shown in Table 1.

Table 1. The coloration of the layer sprayed with acid-base indicators

Zone	Acid-base indicators		
	BPB[a)]	BCG[b)]	BTB[c)]
I	Yellow	Yellow	Yellow
II	Blue	Blue	Bluish green

a) Bromophenol Blue. b) Bromocresol Green.
c) Bromothymol Blue.

Uniformity of the sensitive coloration indicates that the given solvent forms two distinct zones of discrete pH values as defined by the acid-base indicators. The pH of zone I is estimated to be lower than 3.0 and that of zone II between 5.4 and 6.0.

Separation of XO and IDA. In this stage of separation the band of XO is inevitably contaminated with IDA. Acetone–water (8/2, v/v) is useful for the separation of the sodium salts of aminopolycarboxylic acids by paper chromatography.[11] *Seventy* milliliters of a solvent, acetone–water–1 M HCl (160/59/1, v/v/v) was found to be effective to separate 5 mg mixture a band-pipet. The mixture contains *ca.* 90% XO and *ca.* 10% IDA in free acid form. It is necessary to confirm a position of the band of IDA under similar experimental conditions beforehand. In Fig. 4 the band of IDA is schematically reproduced by d, where 10 mg of pure IDA in the acid form is applied. *Thirty* milligrams of the mixture in the free acid form was applied on the layer (prepared from cellulose powder of 200—300 mesh) 1.0 cm apart from the solvent surface in a trough and developed with 70 ml of the solvent, acetone–water–1 M HCl (160/59/1, v/v/v) (Fig. 4), each run taking 1 hr. A sandwich trough (34×205×29 mm) was used.

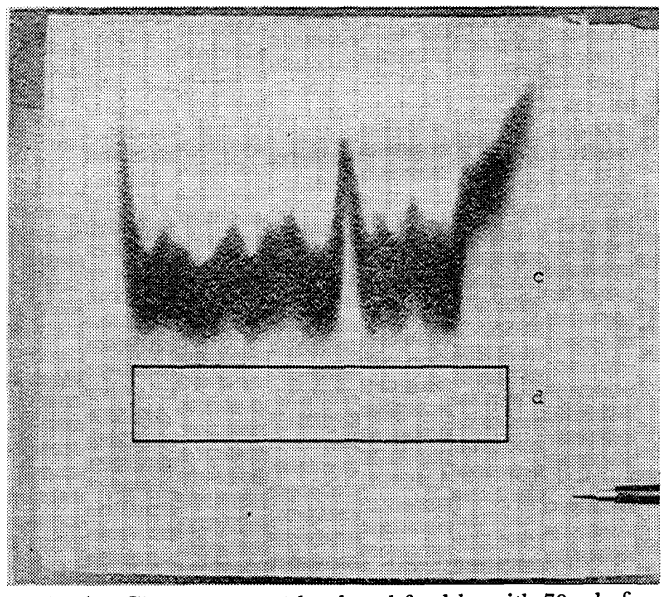

Fig. 4. Chromatogram developed for 1 hr with 70 ml of acetone–water–1M HCl (160/59/1, v/v/v).
c) XO and d) IDA.

Elemental Analysis. Table 2 gives the results of elemental analyses together with the decomposition points for the purified specimens of SXO and XO in free acid form, which have no melting points. The decomposition points were determined by a Rigaku Denki Differential Scanning Calorimeter Model 8001 SL/C. The temperature was calibrated with anthracene (216 °C) and anthraquinone (286 °C).

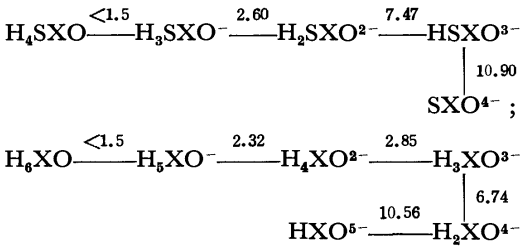
Discussion

The solvent *n*-BuOH–HOAc–H_2O–NH_3 forms on the layer two zones I and II with stepwise different pH values. Zone I consists of *n*-BuOH–HOAc–H_2O system which primarily acts as an organic phase for the solute species. Zone II consists of NH_4OAc–HOAc–*n*-BuOH–H_2O system which primarily acts as an aqueous phase for solutes.

The polybasic Brønsted acids SXO and XO dissociate to the species corresponding to the pH of zone II. They dissociate in aqueous solution with acid dissociation constants, pK_a,[8] as follows.

Table 2. Analytical data of the purified specimens of SXO and XO

Compound	Formula	Dp (°C)		Elemental analyses				
				C, %	H, %	N, %	S, %	C/N
SXO	$C_{26}H_{25}O_9NS \cdot H_2O$	201	Calcd	57.24	4.99	2.57	5.87	22.3
			Found	56.05	4.97	2.53	5.68	22.2
XO	$C_{31}H_{32}O_{13}N_2S \cdot 2H_2O$	281	Calcd	52.54	5.12	3.95	4.52	13.3
			Found	52.40	4.93	3.95	4.20	13.3



Since there is a discrete change in pH value between zones I and II, SXO exists only as a diprotonated species H_2SXO^{2-} in zone II, and cannot migrate through zone I; it constitutes a concentrated "*one*" band completely separated from the band of *o*-CR. XO is concentrated near the starting line as H_3XO^{3-} and H_2XO^{4-} in zone II. Thus SXO is satisfactorily separated from XO and *o*-CR.

In the chromatography using *n*-BuOH saturated with 10% aqueous HOAc without aqueous NH_3, the band of SXO lengthens due to the increasing number of species in protolytic equilibria and causes serious cross-contamination with XO and *o*-CR.[1)]

The best conditions for the separation of SXO and XO in preparative thin-layer chromatography (p-tlc) differ from those in thin-layer chromatography (tlc).[1)] In tlc, XO migrates through zone II beneath the NH_4-front and SXO migrates through zone I. In p-tlc, both XO and SXO migrate through zone II. The difference is due to the fact that the amount of NH_4OAc formed in zone II is in large excess relative to that of the solute species applied. Thus NH_4OAc forms a saturated adsorption band in zone II and XO migrates through zone II beneath the NH_4-front. In p-tlc, however, the NH_4OAc cannot form a saturated adsorption band in zone II under the conditions mentioned above owing to the increased amount of the solutes applied. Therefore, both SXO and XO remain in zone II. With increase in the amount of NH_3 added the chromatographic behavior of p-tlc approaches that of tlc.

However, in the deeper portion of the layer the band of SXO becomes considerably overlapped with that of XO.

With a thick layer some substances show different rates of migration in the surface and the deeper portion of the layer.[12)] We observed that the band of SXO moves faster in the surface of the layer than in the deeper layer, but this is not the case for XO. Under the given conditions, the band of SXO is not contaminated with XO and IDA either in the surface or in the deeper layer.

The authors wish to thank Professor Y. Matsunaga for aid in the DSC measurements. They also thank Miss H. Kakizaki, Faculty of Pharmacology, for elemental analysis.

One of the authors (M. Y.) is indebted to Professor S. Abe, Tokyo University of Agriculture and Technology, for instruction in tlc.

Mössbauer Studies of the Thermal Decomposition of Tris(2,2'-bipyridine)iron(II) Chloride and the Structures of the Isomers of 2,2'-Bipyridineiron(II) Chloride

Haruo SATO and Takeshi TOMINAGA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received September 30, 1975)

The thermal decomposition of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$ in nitrogen was investigated by means of Mössbauer spectroscopy. Two isomers of $Fe(bipy)Cl_2$ were found to occur in the decomposition sequence; one of them appears to be identical with the rose-red form of $Fe(bipy)Cl_2$ prepared by the wet process. The structures of the two isomers were determined on the basis of the Mössbauer spectra, the infrared and Raman spectra, the powder X-ray patterns, and the magnetic moments of these compounds. It has been concluded that tris(2,2'-bipyridine)-iron(II) chloride presumably decomposes in the following sequence:

$[Fe(bipy)_3]Cl_2 \cdot 5H_2O \longrightarrow Fe(bipy)_2Cl_2 \longrightarrow$ orange $Fe(bipy)Cl_2$ (monomeric, tetrahedral) $\longrightarrow$ rose-red $Fe(bipy)Cl_2$ (polymeric, octahedral) $\longrightarrow FeCl_2$

Earlier papers of this series[1-3] have demonstrated that the structural changes during the step-by-step pyrolysis of iron(II) pyridine complexes and the ^{57}Co-labeled cobalt(II) pyridine complex can be monitored by Mössbauer spectroscopy. As a part of the Mössbauer studies of iron complexes with multidentate ligands, we have recently investigated the thermal decomposition of tris(2,2'-bipyridine)iron(II) chloride in nitrogen and found that two isomers of 2,2'-bipyridineiron(II) chloride arise in the pyrolysis sequence.[4] Since the structures of these isomers have not been known, however, we have now attempted to determine their structures by means of Mössbauer spectroscopy, together with other physicochemical methods.

The object of the present article is to give a more complete report on our work concerning the thermal decomposition process of tris(2,2'-bipyridine)iron(II) chloride and the structures of the two isomers of 2,2'-bipyridineiron(II) chloride obtainable as decomposition products.

Experimental

Materials. *Tris(2,2'-bipyridine)iron(II) Chloride*: A concentrated aqueous NaCl solution was added to an aqueous solution containing a 1:3 mixture (mole ratio) of iron (II) sulfate and 2,2'-bipyridine, and the separated crystals were washed and stored over P_2O_5 in a desiccator. The compound thus prepared was pentahydrate.[5] Found: C, 52.5; H, 4.7; N, 12.4%. Calcd for $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$: C, 52.6; H, 5.0; N, 12.3%.

2,2'-Bipyridineiron(II) Chloride (Rose-red Form): This compound was prepared from iron(II) chloride and 2,2'-bipyridine in an aqueous HCl solution in the manner described by Broomhead and Dwyer.[6] Found: C, 42.5; H, 2.9; N, 10.1%. Calcd for $Fe(bipy)Cl_2$: C, 42.5; H, 2.9; N, 9.9%.

Measurements. The thermogravimetric analysis and differential thermal analysis were performed in a nitrogen stream at a heating rate of 1, 2 or 5 °C/min. The powder X-ray patterns of the isomers of $Fe(bipy)Cl_2$ and $Co(bipy)Cl_2$ were made using a Rigaku Denki Geigerflex and Fe-$K\alpha$ radiation. The infrared spectra of $Fe(bipy)Cl_2$ isomers were recorded on a Hitachi EPI-L Spectrophotometer (for the 200—700 cm^{-1} region) or on a Hitachi EPI-G2 Spectrophotometer (for the 400—4000 cm^{-1} region). The Raman spectra were measured by means of a Spectra Physics 166-01 Spectrophotometer using the 6471 Å exciting line of a Kr-ion laser. The magnetic susceptibilities were determined at room temperature by the Faraday method.

The Mössbauer spectra of the parent complex, the decomposition products (including those obtained at intermediate stages), and the 2,2'-bipyridineiron(II) chloride prepared by the wet method (rose-red form) were taken at 78, 195, and 293 K by using a Shimadzu MEG-2 Mössbauer Spectrometer with a ^{57}Co source diffused into copper foil.

Results and Discussion

Thermal Decomposition of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$.

In Fig. 1 are represented the TGA and DTA curves for tris(2,2'-bipyridine)iron(II) chloride, $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$. Three phases, II, III, and IV, can be observed distinctly during the thermal decomposition of this compound (Phase I). Based on the TGA curve, the II, III, and IV phases were assumed to indicate the products which were obtainable by the loss of all the water and one molecule of 2,2'-bipyridine from the parent complex in the first step, and then by the successive loss of an additional molecule each of 2,2'-bipyridine: the II, III, and IV phases correspond to $Fe(bipy)_2Cl_2$, $Fe(bipy)Cl_2$, and $FeCl_2$ respectively. The results of elementary analysis were also in good agreement with the values expected for the assumed compounds. Found for the product at Phase II: C, 54.7; H, 3.7; N, 12.7%. Calcd for $Fe(bipy)_2Cl_2$: C, 54.7; H,

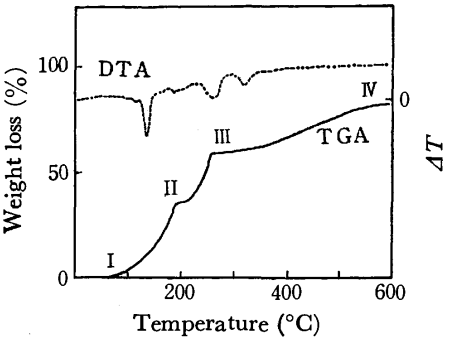

Fig. 1. TGA and DTA curves of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$ (heating rate: 2 °C/min).

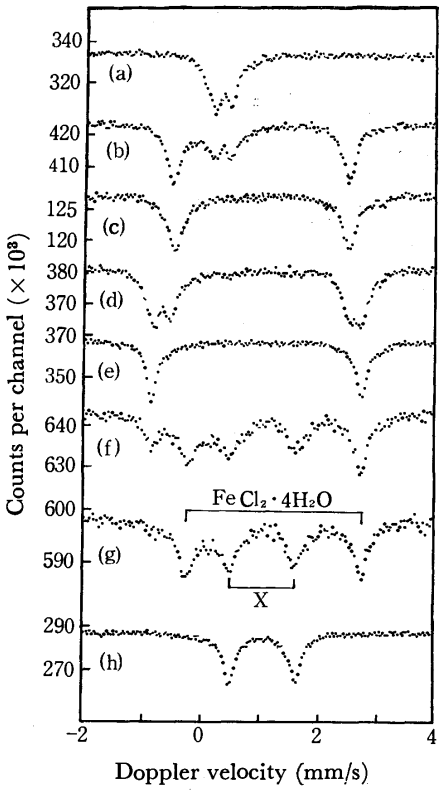

Fig. 2. Mössbauer spectra at 293 K of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$ and thermal decomposition products: (a) phase I ($[Fe(bipy)_3]Cl_2 \cdot 5H_2O$); (b) intermediate stage, phase I→phase II; (c) phase II ($Fe(bipy)_2Cl_2$); (d) intermediate stage, phase II→phase III; (e) phase III (orange $Fe(bipy)Cl_2$); (f) intermediate stage obtained at about 400 °C, phase III→phase IV; (g) intermediate stage obtained at 460 °C, phase III→phase IV; (h) rose-red $Fe(bipy)Cl_2$ prepared by the wet process.

3.7; N, 12.8%. Found for the product at Phase III: C, 42.5; H, 2.8; N, 9.9%. Calcd for $Fe(bipy)Cl_2$: C, 42.5; H, 2.9; N, 9.9%.

Figure 2 reveals some typical Mössbauer spectra at 293 K of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$, the products at the II and III phases, and the products (mixtures) obtained at intermediate stages between the distinct phases. The Mössbauer parameters of tris-, bis-, and mono-(2,2′-bipyridine)iron(II) chloride are summarized in Table 1. The detailed process of thermal decomposition can be elucidated by comparing the Mössbauer spectra taken at various stages of the reactions, as will be done below.

Phase I: The Mössbauer spectrum of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$ (Phase I) consists of a doublet with δ and ΔE_Q values indicating low-spin iron(II) (Fig. 2a). The anhydrous salt, $[Fe(bipy)_3]Cl_2$, prepared by dehydration in an Abderhalden's dryer, reveals a spectrum identical with the pentahydrate's.

Intermediate Stages between Phases I and II: The intermediate products obtained at 140 °C between Phases I and II indicate a composite spectrum composed of the Mössbauer peaks of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$ (Phase I) and $Fe(bipy)_2Cl_2$ (Phase II), as is shown in Fig. 2b. However, the spectrum of the products obtained at 130 °C was identical with that of Phase I, while the spectrum of the products obtained at 150 °C was identical with that of Phase II. While Phase II is attained at about 200 °C on the TGA curve, the large endothermic peak due to the *Phase I→Phase II* transition appears at 140 °C on the DTA curve. No plateau for the anhydrous $[Fe(bipy)_3]Cl_2$ phase was detectable on the TGA curve. These observations imply that the dissociation of one 2,2′-bipyridine molecule occurs quickly at about 140 °C before dehydration is completed, but that the volatilization of the dissociated 2,2′-bipyridine molecules from crystals proceeds rather slowly below 200 °C.

Phase II: The Mössbauer spectrum of $Fe(bipy)_2Cl_2$ (Phase II) consists of a doublet with large δ and ΔE_Q values corresponding to high-spin iron(II) (Fig. 2c). The Mössbauer parameters of this compound at room temperature were reported by König *et al.*;[7] they are in agreement with the values obtained in the present work.

Intermediate Stages between Phases II and III: In the stages between Phases II and III, mixtures of the absorption peaks of $Fe(bipy)_2Cl_2$ (Phase II) and $Fe(bipy)Cl_2$ in the orange form (Phase III) were observed (Fig. 2d); the intensity of the $Fe(bipy)Cl_2$ peaks relative to that of the $Fe(bipy)_2Cl_2$ peaks increased with the increase in the reaction temperature.

Phase III: The spectrum of $Fe(bipy)Cl_2$ in the orange form (Phase III) is composed of a doublet with an even larger quadrupole splitting than that of $Fe(bipy)_2Cl_2$, characteristic of high-spin iron(II) (Fig. 2e).

Intermediate Stages between Phases III and IV: The Mössbauer spectrum of the intermediate products obtained between Phases III and VI indicates a new doublet of high-spin iron(II) in addition to the peaks ascribable to known products expected at Phases III and IV (Figs. 2f and 2g). In the meantime, the color of the mixture of products changes from orange to dark red upon the formation of the new compound. Since the new rose-red compound (hereafter designated as X)

TABLE 1. MÖSSBAUER PARAMETERS OF TRIS(2,2′-BIPYRIDINE)IRON(II) CHLORIDE, THERMAL DECOMPOSITION PRODUCTS AND ROSE-RED FORM OF 2,2′-BIPYRIDINEIRON(II) CHLORIDE PREPARED BY THE WET PROCESS

Compound	Isomer shift[a] δ(Fe) (mm/s)			Quadrupole splitting[a] ΔE_Q (mm/s)		
	78K	195K	293K	78K	195K	293K
$[Fe(bipy)_3]Cl_2 \cdot 5H_2O$	0.39	0.36	0.33	0.34	0.31	0.28
$Fe(bipy)_2Cl_2$	1.11	1.04	1.01	3.40	3.29	2.98
$Fe(bipy)Cl_2$ (orange form)	1.08	1.00	0.93	3.71	3.65	3.58
Compound X[b]	1.1_8	1.0_7	1.0_4	1.7_8	1.4_4	1.0_9
$Fe(bipy)Cl_2$ (rose-red form)	1.18	1.09	1.07	1.76	1.38	1.14

a) Errors: ±0.02 mm/s. b) Because of the uncertainty due to the complexity of overlapping peaks and to the counting statistics, parameters of compound X involve relatively large errors of ± 0.06 mm/s.

could not be isolated as a pure product, but was usually found as mixtures with the other decomposition products corresponding to Phases III and IV (*i.e.*, $Fe(bipy)Cl_2$ in the orange form, $FeCl_2$, and its hydrates),[8] it was not readily identified by ordinary physicochemical methods of analysis. Although Compound X was observed distinctly in the Mössbauer spectra of the reaction products obtained above the temperature range of Phase III, the weight loss was negligible and its formation was not detectable on the TGA curve. Therefore, it is unlikely that Compound X is a product formed by the further decomposition of $Fe(bipy)Cl_2$ (orange form).[9] The Mössbauer parameters at 78, 195, and 293 K of the rose-red Compound X are entirely different from those of the orange-form $Fe(bipy)Cl_2$ obtained by thermal decomposition, whereas they are in agreement with those of the rose-red form of $Fe(bipy)Cl_2$ prepared by the wet process in hydrochloric acid (Table 1 and Fig. 2h). Thus, we may presume that the rose-red Compound X formed in the intermediate stages between Phases III and IV is identical with the rose-red form of $Fe(bipy)Cl_2$ prepared by the wet process, which appears to be isomeric with the orange form of $Fe(bipy)Cl_2$ obtained by the thermal decomposition (Phase III).

Phase IV: In the Mössbauer spectra of the products at Phase IV we often observed the hydrates of iron(II) chloride, $FeCl_2 \cdot 2H_2O$, and $FeCl_2 \cdot 4H_2O$, since anhydrous iron(II) chloride is so hygroscopic that it is partially hydrated before the Mössbauer measurements.

Structures of $Fe(bipy)Cl_2$ Isomers. Both $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$ (Phase I) and $Fe(bipy)_2Cl_2$ (Phase II) are octahedral monomers. Although a marked discrepancy has been reported between the magnetic moments of $Fe(bipy)Cl_2$ samples prepared by different methods,[6,10] the structures of the two isomers of $Fe(bipy)Cl_2$ have never been studied before. According to the following data of the Mössbauer spectra, powder X-ray patterns, infrared and Raman spectra, and magnetic moments of the orange $Fe(bipy)Cl_2$ obtained by the thermal decomposition and the rose-red $Fe(bipy)Cl_2$ prepared by the wet process, we may conclude that the orange-form $Fe(bipy)Cl_2$ is monomeric and tetrahedral, while the rose-red form $Fe(bipy)Cl_2$ (or the compound, X, obtained between Phases III and IV) is polymeric and octahedral, with chloride bridges.

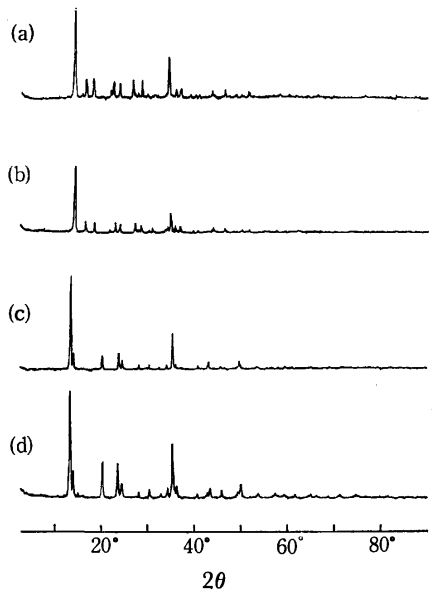

Fig. 3. Powder X-ray patterns of (a) orange $Fe(bipy)Cl_2$, (b) β-$Co(bipy)Cl_2$, (c) rose-red $Fe(bipy)Cl_2$, and (d) α-$Co(bipy)Cl_2$.

Mössbauer Spectra: It has been found for high-spin iron(II) complexes that a tetrahedral complex generally gives a smaller isomer shift as compared with the octahedral complex containing similar ligands.[11-13] Since the isomer shift of the rose-red $Fe(bipy)Cl_2$ is larger than that of $Fe(bipy)_2Cl_2$, which is octahedral, the former may not be tetrahedral, but octahedral (Table 1). Accordingly, the orange form of $Fe(bipy)Cl_2$, with a smaller isomer shift, is probably tetrahedral.

Powder X-Ray Patterns: The structures of the α and β isomers of $Co(bipy)Cl_2$ have been reported as an octahedral polymer and a tetrahedral monomer respectively on the basis of their electronic and infrared spectra.[14,15] As is shown in Fig. 3, the two isomers of $Fe(bipy)Cl_2$ (or $Co(bipy)Cl_2$) give different powder X-ray patterns, while the pattern of each isomer of $Fe(bipy)Cl_2$ is quite similar to that of the corresponding analogue of $Co(bipy)Cl_2$. Hence, a comparison of their powder X-ray patterns reveals that the orange $Fe(bipy)Cl_2$ and β-$Co(bipy)Cl_2$ are isomorphous and tetrahedral, while the rose-red $Fe(bipy)Cl_2$ and α-$Co(bipy)Cl_2$, octahedral: these results confirm the conclusion derived from the Mössbauer data.

Infrared and Raman Spectra: In a number of transition-metal complexes, the metal-halogen stretching vibrations are affected by whether or not the halogen is bridging.[16-18] Hence, the region of iron-chlorine stretching vibrations of FeL_2Cl_2 (L=py, 1/2bipy, *etc.*) can be expected to shift to lower frequencies in the polymeric octahedral isomer (in the vicinity of 200 cm^{-1}),[18,19] as compared with the region for the monomeric tetrahedral isomer (in the vicinity of 300 cm^{-1}).[20] In the infrared and Raman spectra of the orange form of $Fe(bipy)Cl_2$ we observed a band at 360 cm^{-1} (Fig. 4) which can be ascribed to the Fe–Cl stretching vibrations, in accordance with the assignment by Strukl *et al.* of the 361/369 cm^{-1} region of this compound as such.[21] In the case of the rose-red $Fe(bipy)Cl_2$, no strong band was observed in the 270—340 cm^{-1} region, while the

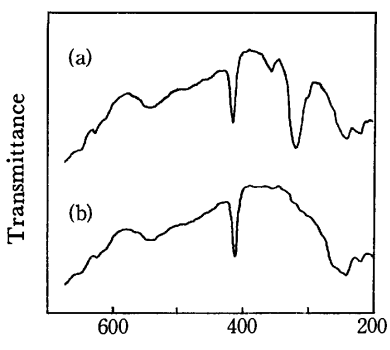

Fig. 4. Infrared spectra of (a) orange $Fe(bipy)Cl_2$, and (b) rose-red $Fe(bipy)Cl_2$.

band occurring at 152 or 187 cm^{-1} in the Raman spectrum may possibly correspond to the Fe–Cl streching vibrations. Therefore, the infrared and Raman spectra of these isomers also support the structures presumed on the basis of the Mössbauer and powder X-ray data.

Magnetic Moments: There has been a considerable disagreement among the reported values of the magnetic moments of Fe(bipy)Cl_2: 1.8 B.M.[10] and 4.8 B.M.[6] for the Fe(bipy)Cl_2 samples prepared by decomposition in a vacuum, and 5.72 B.M.[6] for the Fe(bipy)Cl_2 prepared by the wet process. The magnetic moments obtained in the present work are 4.9 ± 0.1 B.M. for the orange Fe(bipy)Cl_2 and 5.3 ± 0.1 B.M. for the rose-red Fe(bipy)-Cl_2. Hence, it may be concluded that the low value of 1.8 B.M. reported by Basolo *et al.*[10] is in error, as has been suggested.[6] This is further confirmed by the fact that no low-spin iron(II) was observed in the Mössbauer spectra of the products from the pyrolysis of [Fe(bipy)$_3$]$Cl_2\cdot5H_2O$ in nitrogen or a vacuum. The observation that the magnetic moment of the rose-red Fe(bipy)Cl_2 is larger than that of the orange Fe(bipy)Cl_2 is compatible with the assignment of the rose-red isomer as octahedral and the orange isomer as tetrahedral.[22]

In conclusion, we can say that the thermal decomposition of tris(2,2'-bipyridine)iron(II) chloride in nitrogen presumably proceeds as follows:

$$[Fe(bipy)_3]Cl_2\cdot5H_2O \longrightarrow Fe(bipy)_2Cl_2 \longrightarrow$$
orange Fe(bipy)Cl_2 (monomeric, tetrahedral) $\longrightarrow$
rose-red Fe(bipy)Cl_2 (polymeric, octahedral) $\longrightarrow$
$FeCl_2$

The authors wish to express their thanks to Professor Nobufusa Saito for his encouragement and support. They are also indebted to Dr. Hiroo Hamaguchi for the measurements of the Raman spectra, and to Dr. Toshiaki Ohta and Mr. Tadashi Sugano for the measurements of the magnetic susceptibilities.

8) The Mössbauer peaks of Compound X, orange Fe(bipy)Cl_2, and hydrates of $FeCl_2$ were observed in the spectrum of the reaction products obtained at about 400 °C (Fig. 2f), while the peaks of the orange Fe(bipy)Cl_2 disappeared in the products obtained at 460 °C (Fig. 2g).
9) The small endothermic peak at 330 °C on the DTA curve may not be related to the conversion of the orange Fe(bipy)Cl_2 into the rose-red isomer, since a similar endothermic peak is also observable on the thermal decomposition of the rose-red form and an exothermic peak appears at about the same temperature on the cooling of the orange form. The Mössbauer spectra indicate the presence of mixtures of both forms over a fairly wide temperature range between Phases III and IV.

X-Ray Diffraction Studies of the Structures of Hydrated Divalent Transition-Metal Ions in Aqueous Solution*

Hitoshi OHTAKI, Toshio YAMAGUCHI, and Masunobu MAEDA

Laboratory of Solution Chemistry, Department of Electronic Chemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received October 21, 1975)

X-ray scattering measurements have been carried out for concentrated aqueous solutions of divalent transition-metal perchlorates of manganese(II) to zinc(II). The radial distribution curves showed that each central metal ion was octahedrally surrounded by six water molecules at the distances of 2.20 Å for Mn^{2+}–OH_2, 2.12 Å for Fe^{2+}–OH_2, 2.08 Å for Co^{2+}–OH_2, 2.04 Å for Ni^{2+}–OH_2, and 2.08 Å for Zn^{2+}–OH_2. The results from the radial distribution curves were confirmed by the direct analysis of reduced intensities. Concentrated aqueous solutions of copper(II) and zinc(II) sulfates have also been measured. The bond distances of 1.94 Å for the Cu^{2+}–OH_2 (equatorial), 2.38 Å for the Cu^{2+}–OH_2 (axial) and 2.08 Å for Zn^{2+}–OH_2 were consistent with those obtained for the perchlorate solutions. No evidence for the contact ion pairs of metal and sulfate ions was found by the present X-ray measurements. The bond energies between metal ions including copper ion[26] were discussed by application of the Garrick model with a slight modification.

In crystals, divalent transition-metals of various salts are coordinated by 2 to 6 water molecules and the vacant apices of the octahedral structure of the metal ions are occupied by other ligands. The bond distance between a central metal ion and a water molecule is affected by counter-anions.

The manganese(II) ion in the $Mn(NH_4)_2(SO_4)_2 \cdot 6H_2O$ crystal combined with water molecules at the distance of 2.18 Å.[1] For iron(II) salts the Fe^{2+}–OH_2 distance varied from 1.96 Å to 2.15 Å[2-6] depending on anions in salts. The Co^{2+}–OH_2 distance in crystals changed over the range of 2.08 Å to 2.23 Å,[7-10] which was longer than the Ni^{2+}–OH_2 distance; the latter was found to be 2.04—2.07 Å.[10-14] In copper salts were found two different Cu^{2+}–OH_2 bond lengths due to the Jahn–Teller distortion. The shorter bond length was in the order of 1.97 Å[15-19] except the bond within $Cu(H_2O)_6(ClO_4)_2$ in which the length was 2.125 Å,[20] and the longer one was about 2.3—2.8 Å.[15-20] The zinc(II) ion had a regular octahedral structure and the Zn^{2+}–OH_2 distance was about 2.08—2.10 Å.[10,21,22]

In contrast to a number of crystallographic studies of divalent transition-metal salts, only a few studies by X-ray diffraction have been reported on the structures of hydrated divalent transition-metal ions in solution. According to Shapovalov *et al.* who measured X-ray scatterings of sulfate solutions,[23,24] divalent transition-metals were hydrated with six water molecules and the bond lengths were about 2.15 Å independent of the metal ions except the Mn^{2+}–OH_2 distance of 2.20 Å and the longer Cu^{2+}–OH_2 distance of 2.5 Å. Bol *et al.* reported shorter bond lengths for hydrated Co^{2+}, Ni^{2+}, and Zn^{2+} ions in nitrate solutions[25] than those by Shapovalov *et al.* Our previous results for a copper perchlorate solution[26] showed that the Cu^{2+}–OH_2 distance in the equatorial position was 1.94 Å and that in the axial position was 2.43 Å, both of them being shorter than the distances reported by Shapovalov and Radchenko[23] in a sulfate solution.

In the present investigation we aim at determining the structures of a series of divalent transition-metal ions from Mn^{2+} to Zn^{2+} in aqueous perchlorate solutions by means of X-ray diffraction and discussing the change in the M^{2+}–OH_2 bond length with varying metal ions. The structures of hydrated copper(II) and zinc(II) ions in sulfate solutions are also determined in order to examine if the bond distances of metal and water molecules would really be affected by anions even in solutions.

Preparation and Analysis of Sample Solutions

Mn(II), Co(II), and Ni(II) Perchlorate Solutions. Manganese, cobalt, and nickel perchlorates were prepared by dissolving the metal chlorides (Wako reagent grade), which had been recrystallized twice from water, in dilute perchloric acids. Hydrochloric acid formed in solution was removed by repeated evaporation. After recrystallizing twice from water, crystals thus obtained were dissolved in water to prepare sample solutions. The concentrations of these metal ions were determined by two different methods; gravimetry as pyrophosphate $Mn_2P_2O_7$ and titration with EDTA for Mn^{2+}, electrogravimetry and titration with EDTA for Co^{2+}, and electrogravimetry and gravimetry as the dimethylglyoximate for Ni^{2+} ions.

Fe(II) Perchlorate Solution. A stoichiometric amount of $Ba(ClO_4)_2$ crystals (Wako reagent grade) was dissolved into an aqueous solution of $FeSO_4 \cdot 7H_2O$ (Wako reagent grade) containing perchloric acid and then either $Ba(ClO_4)_2$ or sulfuric acid solution was added dropwise from burets to attain the exact stoichiometric ratio of Ba^{2+} to SO_4^{2-} ions in the mixture. The equivalent point was detected by the naked eye. A solution of iron (II) perchlorate was obtained by removing the $BaSO_4$ precipitates through G4 glass filters and No. 5C filter papers. All the treatments were performed under an atmosphere of nitrogen gas. The sample solution thus prepared was tested for Ba^{2+} and SO_4^{2-} ions by the addition of drops of sulfuric acid and a $Ba(ClO_4)_2$ solution, respectively. A check for Fe^{3+} ion with a KSCN aqueous solution was negative. The content of Fe^{2+} was determined by titration with a $KMnO_4$ solution.

Zn(II) Perchlorate Solution. Zinc perchlorate crystals were prepared by dissolving zinc oxide (Wako reagent grade)

* A part of the work has been submitted to The Prof. Ringbom Memorial Volume, to be published from Pergamon Press.

Table 1. Compositions of the sample solutions (in g-atoms·dm^{-3})

	$Mn(ClO_4)_2$	$Fe(ClO_4)_2$	$Co(ClO_4)_2$	$Ni(ClO_4)_2$	$Cu(ClO_4)_2$[26]	$Zn(ClO_4)_2$	$CuSO_4$	$ZnSO_4$
M	2.612	2.173	2.672	2.491	3.550	2.886	1.368	2.797
S	—	—	—	—	—	—	1.371	2.809
Cl	5.818	4.499	5.710	5.430	7.357	6.179	—	—

in a hot perchloric acid and recrystallizing twice from water. A solution of the zinc perchlorate was prepared by dissolving the crystals in water. The content of Zn^{2+} was determined both by gravimetry as $ZnHg(SCN)_4$ and by titration with EDTA.

The amounts of perchlorate and hydrogen ions in the solutions were determined as described in the previous papers.[26,27]

Cu(II) and Zn(II) Sulfate Solutions. Copper and zinc sulfate crystals (Wako reagent grade) were recrystallized once from water. The content of Cu^{2+} in the copper sulfate sample solution was determined by electrogravimetric analysis and by titration with EDTA. The concentration of zinc in the sample was analyzed by the same method as used for the zinc perchlorate solution. The content of SO_4^{2-} ions in the solutions was determined gravimetrically as $BaSO_4$.

The results of analysis for metal ions made by two different methods agreed each other within 0.2%. A small amount of perchloric or sulfuric acid was added to all the sample solutions in order to prevent the hydrolysis of the metal ions.

The density of the solutions was determined pychnometrically.

The compositions of the solutions investigated are given in Table 1, together with that of the $Cu(ClO_4)_2$ solution previously reported.[26]

X-Ray Scattering Measurements

X-Ray scattering measurements were carried out on a θ–θ X-ray diffractometer (JEOL Co., Tokyo) in a room thermostated at 25±1 °C. In the case of the iron(II) perchlorate solution, the measurements were carried out under an atmosphere of nitrogen gas in order to prevent the oxidation of the iron(II) ion by air.

Mo$K\alpha$ radiation (λ=0.7107 Å) was diffracted at the sample solution and then monochromatized by reflection on a curved surface of an LiF crystal. A Philips PW 210500 X-ray tube was employed. The observed range of scattering angles (2θ) was 2° to 140°, corresponding to the range 0.31 Å^{-1}<s<16.6 Å^{-1} ($s=4\pi\sin\theta/\lambda$). Times required to accumulate 40000 counts at each angle were recorded. The whole angle range was scanned twice. The details of the measurements are described elsewhere.[26,27]

Symbols

$D(r)$	The radial distribution function
ρ_0	The bulk electron density in the stoichiometric unit volume
s_{max}	The maximum value of s accessible in the experiments
$i(s)$	The reduced intensity
$M(s)$	The modification function
$I(s)$	The scaled intensities after correction for background, polarization, and absorption in the sample
n_i	The number of atom "i" in the stoichiometric volume containing one metal atom
$f_i(s)$	The scattering factor for atom "i" corrected for the real part of the anomalous dispersion
$\Delta f_i''$	The imaginary part of the anomalous dispersion correction for atom "i"
$\Phi(s)$	The fraction of the total incoherent scattering reaching the counter
$I_i^{inco}(s)$	The incoherent scattering of atom "i"
k	The damping factor
r_{ij}	The distance between the atoms "i" and "j"
b_{ij}	The temperature factor of the atoms "i" and "j"

Treatment of Intensity Data

The measured intensities were corrected for background, polarization,[28] and absorption in the sample,[28] and then scaled to absolute intensities by the conventional methods.[26,29,30] The coherent scattering factors used for Mn, Fe, Co, Ni, Cu, Zn, Cl, S, and O were those given by Cromer and Waber.[31] The values for H were those given by Stewart *et al.*[32] The incoherent scattering factors cited from Cromer[33] for Fe, Co, Ni, O, S, and Cl, from Cromer and Mann[34] for Mn, Cu, and Zn, and from Compton and Allison[35] for H were corrected for the Breit–Dirac factors. Values of anomalous dispersion corrections for all atoms were taken from Cromer and Lieberman.[36]

The radial distribution functions $D(r)$ were calculated by means of the Fourier transform according to Eq. 1:

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_0^{s_{max}} si(s)M(s)\sin(rs)ds \qquad (1)$$

where the reduced intensities $i(s)$ are written as[26,27]

$$i(s) = I(s) - \sum_i n_i(f_i^2(s) + (\Delta f_i'')^2 + \Phi(s)I_i^{inco}(s)) \qquad (2)$$

and the modification function $M(s)$ used in this study was $(\sum_i n_i f_i^2(0)/\sum_i n_i f_i^2(s))\exp(-ks^2)$ with the damping factor k of 0.015 Å^2 except the $CuSO_4$ case for which k=0.01 Å^2 was used.

Spurious peaks below 1 Å which appeared in the $D(r)$ curve were corrected since these spurious peaks did not correspond to any interatomic distances.[26,27] The reduced intensities $i(s)$ multiplied by s and the $D(r)$ curves thus deduced are shown in Figs. 1 and 2, respectively, for all the solutions, those for $Cu(ClO_4)_2$ solution previously reported[26] being also included.

Theoretical intensities due to interatomic interactions were calculated according to Eq. 3:

$$i(s)_{calc} = \sum_i\sum_j n_i f_i(s) f_j(s)\frac{\sin(r_{ij}s)}{r_{ij}s}\exp(-b_{ij}s^2) \qquad (3)$$

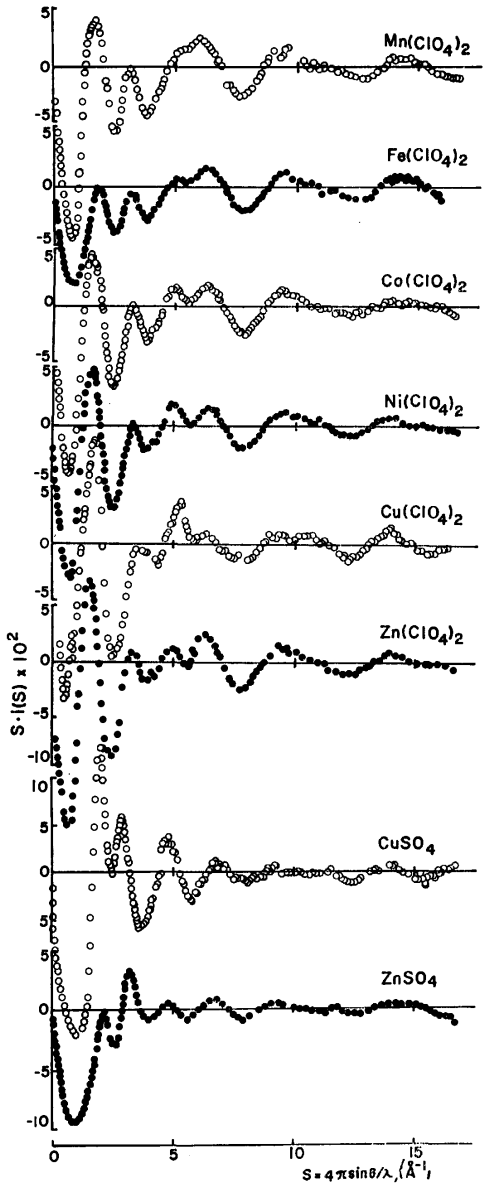

Fig. 1. Observed $s \cdot i(s)$ values of the solutions.

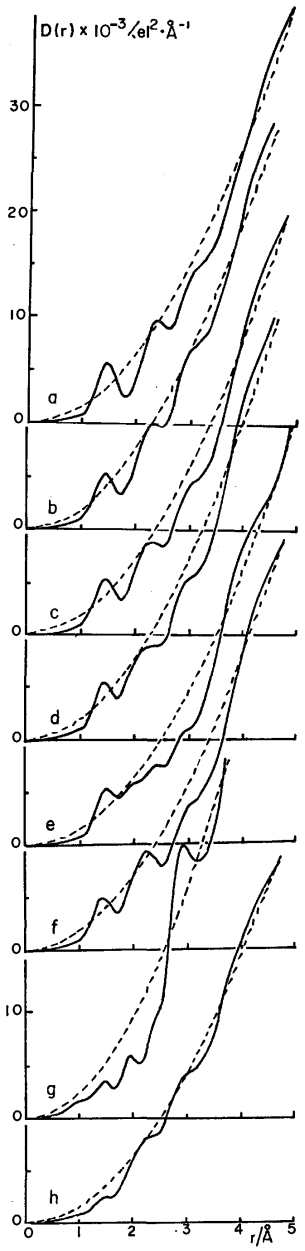

Fig. 2. Radial distribution curves $D(r)$'s (solid line) and $4\pi r^2\rho^0$ (dashed line) for the solutions. a. $Mn(ClO_4)_2$, b. $Fe(ClO_4)_2$, c. $Co(ClO_4)_2$, d. $Ni(ClO_4)_2$, e. $Cu(ClO_4)_2$, f. $Zn(ClO_4)_2$, g. $CuSO_4$, h. $ZnSO_4$.

All calculations were carried out on a HITAC 8700 computer at the Computer Center of our Institute by means of the KURVLR program.[37]

Analysis of Intensity Data and Results

a) Solutions of Manganese, Iron, Cobalt, Nickel, and Zinc Perchlorates. The $D(r)$ curves for these solutions are shown in Fig. 2 (a, b, c, d, and f); the $D(r)$ curve (Fig. 2e) for the $Cu(ClO_4)_2$ solution reported in the previous paper[26] being also contained for comparison. The $D(r)$ curves represented the first peak at around 1.4 Å, which corresponded to the Cl–O distance within the ClO_4^- ion according to previous investigations.[26,27] The second peak appeared in the region 2.0—2.2 Å which was expected to correspond to both the distance between the metal ions and neighboring water molecules and the O–O distance ($\simeq 1.4$ Å $\times\sqrt{8/3}=2.3$ Å) within the ClO_4^- ion which is known to form a regular tetrahedron. In order to deduce the peaks corresponding to the distances between metal ions and water molecules, the contributions from the Cl–O bond and the O–O

Table 2. Parameter values for the Cl–O, O–O atom pairs within ClO_4^-, the S–O, O–O atom pairs within SO_4^{2-}, and the O–H atom pair within H_2O

		r_{ij}/Å	b_{ij}/Å²	n_{ij}
ClO_4^-	Cl–O	1.43	0.001	4
	O–O	2.34	0.002	6
SO_4^{2-}	S–O	1.47	0.001	4
	O–O	2.40	0.002	6
H_2O	O–H	1.01	0.001	2

interactions within the ClO_4^- ion were theoretically subtracted from the $D(r)$ curves. Calculations of these contributions were carried out according to Eqs. 1 and 3. Values of parameters attributed to the structure of the ClO_4^- ion used for the calculations are listed in Table 2.[38] Theoretical peak shapes thus calculated are shown in Fig. 3 with a special reference to the zinc perchlorate solution. The distance between the metal ion and water molecules was obtained from the residual peak shown in Fig. 3a. The number of water molecules bonded to the metal ion was roughly estimated from the peak area (shown by the dotted line in Fig. 3a) according to procedures described in a previous paper.[27] Final values for the structure of the aqua complex were determined by the method of trial and error so that the subtraction of the calculated peak due to the M–OH_2 bond from the $D(r)$ curve led to a smooth background curve with no indication of residual intramolecular interaction. (Fig. 3b).

The distances between metal ions and water molecules were found to be 2.20 Å for Mn^{2+}, 2.12 Å for Fe^{2+}, 2.08 Å for Co^{2+}, 2.04 Å for Ni^{2+}, and 2.08 Å for Zn^{2+}, and the numbers of water molecules in the first hydration sphere and the temperature factors were about 6 and 0.004 $Å^2$, respectively, for all the solutions.

In order to confirm the results obtained by the analysis of $D(r)$ curves, the distances, the temperature factors, and the frequency factors for the hydrated metal ions as well as for the perchlorate ions were refined by a least squares method in which the minimum of the function $U=\sum s^2(i(s)-i(s)_{calc})^2$ was sought. Various subsets of the reduced intensities from different s regions were used in order to check experimental errors in the data and errors in the parameter values introduced by contributions from intermolecular interactions which largely contribute to the reduced intensities at low s regions. The calculations were carried out by the use of the program NLPLSQ, which is a modified program of the algorithm described by Marquardt.[39]

b. Comparison between observed $s \cdot i(s)$ (circle) and the calculated $s \cdot i(s)$ (solid line) for the atom pairs considered using the refined parameter values given in Table 3.
c. Difference between observed and calculated $s \cdot i(s)$ values.

Table 3. The results of least squares refinements of the $Zn(ClO_4)_2$ solution by program NLPLSQ. The units of r and b are Å and Å^2, respectively. Standard deviations are listed in parentheses.

	$3.22<s/Å^{-1}<14.95$	$6.01<s/Å^{-1}<14.95$	$10.70<s/Å^{-1}<14.95$
r_{Zn-O}	2.083(4)	2.081(2)	2.080(6)
b_{Zn-O}	0.0047(3)	0.0042(1)	0.0043(2)
n_{Zn-O}	5.84(4)	5.92(6)	5.7(2)
r_{Cl-O}	1.427(2)	1.430(1)	1.428(2)
b_{Cl-O}	0.0008(2)	0.0010(1)	0.0010(1)
n_{Cl-O}	4.06(3)	3.98(3)	4.07(7)
r_{O-O}	2.376(1)	2.339(7)	2.338(1)
b_{O-O}	0.0025(7)	0.0013(3)	0.0013(4)
n_{O-O}	5.97(1)	6.3(2)	6.8(4)
U	0.126×10^7	0.101×10^6	0.409×10^5

The results calculated in various s ranges are shown in Table 3 with a reference to the $Zn(ClO_4)_2$ solution. The refined parameter values of a given hydrated metal ion were almost the same for different s regions, and did not differ significantly from the values estimated from the $D(r)$ curve. The $s\cdot i(s)_{calc}$ values are compared with the values of $s\cdot i(s)$ in Fig. 4 for the $Zn(ClO_4)_2$ solution as an example. From Fig. 4 it is seen that the agreement is good except at a low s region where various interactions including intermolecular interactions, which are not taken into account in the present refinements, significantly contribute to the $s\cdot i(s)$values.

b) Copper Sulfate Solution. The $D(r)$ curve for the copper sulfate solution (Fig. 2g) showed three peaks at 1.5 Å, 1.95 Å, and 2.9 Å and shoulders at about 1 Å and 2.4 Å. The shoulder at 1 Å was ascribed to the intramolecular O–H interaction within H_2O. The peak at 1.5 Å could be identified as being due to the S–O bond within the SO_4^{2-} ion.[40–42]

Table 4. Parameter values of the hydrated copper ion

	r_{ij}/Å	b_{ij}/Å^2	n_{ij}
$Cu-O_{eq}$	1.94	0.002	4
$Cu-O_{ax}$	2.38	0.004	2
cis-$O_{eq}-O_{eq}$	2.70	0.01	4
$O_{eq}-O_{ax}$	3.05	0.01	8

The distances and the numbers of equatorial and axial Cu^{2+}–OH_2 bonds were determined by the same procedures as those made for the copper perchlorate solution[26] after subtraction of interactions of the S–O and O–O bonds within the SO_4^{2-} ion and the O–H bond of H_2O from $D(r)$. Calculations are illustrated in Fig. 5a. Figure 5b shows the difference curve $(D(r)-4\pi r^2\rho_0)$ on which the peaks are better distinguishable. Values for the structure of the SO_4^{2-} ion given in Table 2 were used.[38] From the peak positions of the residual curve (Fig. 5a, b), it was found that the distance of the equatorial Cu^{2+}–OH_2 bond was 1.94 Å and that of the axial Cu^{2+}–OH_2 bond was 2.38 Å. The area for Cu^{2+}–OH_2 interaction in the equatorial position was found to correspond to four Cu^{2+}–OH_2 bonds by an analogous calculation to that in the perchlorate systems. Interactions within the hydrated

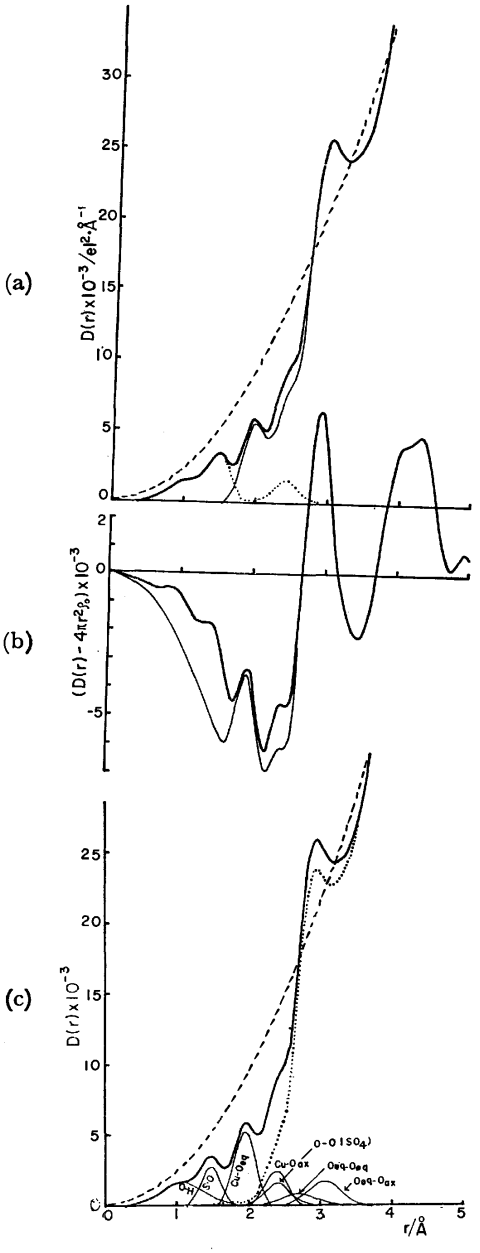

Fig. 5. a. The residual curve (fine solid line) obtained after subtraction of the theoretical peak(dotted line) of the S–O, O–O atom pairs within SO_4^{2-} and the O–H atom pair within H_2O from $D(r)$.
b. $D(r)-4\pi r^2\rho_0$ curve (upper) and the residual curve given in $a-4\pi r^2\rho_0$ (lower).
c. The smooth curve (dotted line) obtained by subtraction of theoretical peak shapes from $D(r)$.

copper ion which formed a distorted octahedron were calculated using the values listed in Table 4 and are shown in Fig. 5a. The subtraction of these interactions from the residual curve in Fig. 5a led to a smooth curve, which showed no dominant peak in the region below 2.8 Å (Fig. 5c). The sharp peak at 2.9 Å may be due to both adjacent O–O interactions of bulk water[43] and the interaction between water molecules and the oxygen atom of the SO_4^{2-} ion.[41]

c) Zinc Sulfate Solution. The $D(r)$ curve in Fig. 2h showed three peaks at around 1.5 Å, 2.1 Å, and 3 Å.

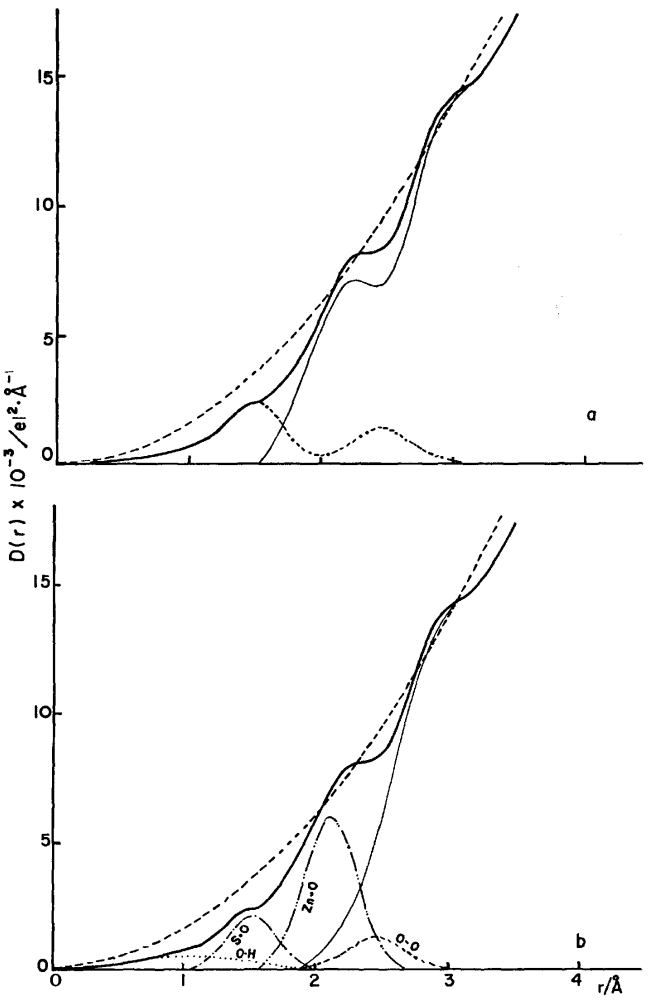

Fig. 6. a. The residual curve (fine solid line) obtained by subtraction of the theoretical peak (broken line) of the S–O and O–O atom pairs within SO_4^{2-} from $D(r)$. b. The smooth curve(fine solid line) gives the residual distribution function obtained after subtraction of the S–O, O–O, and Zn–OH_2 atom pairs from $D(r)$.

The peak at 1.5 Å corresponded to the S–O distance within the SO_4^{2-} ion. The second peak at around 2.1 Å was due to both Zn^{2+}–OH_2 and O–O interactions within the SO_4^{2-} ion. Parameter values for the Zn^{2+}–OH_2 bond within the hydrated Zn^{2+} ion were estimated according to the same procedures as those in the perchlorate system after subtraction of the contributions from the S–O and O–O interactions within the SO_4^{2-} ion from the $D(r)$ curve. These procedures are illustrated in Fig. 6. From the analysis, the Zn^{2+}–OH_2 distance was found to be 2.08 Å, and the number of the Zn^{2+}–OH_2 bonds was about 6, and the corresponding temperature factor was estimated to be 0.004 Å^2.

Discussion

In the aqueous perchlorate solutions of divalent transition-metal ions, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, and Zn^{2+}, the M–OH_2 bond distances were found to be 2.20 Å, 2.12 Å, 2.08 Å, 2.04 Å, and 2.08 Å, respectively, and all the metal ions were octahedrally hydrated with six water molecules. The measurements for interatomic distances of zinc and copper sulfate solutions resulted in the same values as those obtained in the perchlorate solutions. Values of the cation–water distances obtained in this study are summarized in Table 5, along with those reported in the literature.[23–25] As is seen in Table 5, the present results were in excellent agreement with those found by Bol *et al.* in the metal nitrate solutions.[25] The distance of the longer Cu^{2+}–OH_2 bond in the copper sulfate solution differed slightly from that in the copper perchlorate solution, but this difference in the distance could not be significant in view of uncertainties in the present investigation. From the results obtained in this work and those reported by Bol *et al.*,[25] we concluded that the anions cause no change in the bond distances between cation and water molecules. This conclusion agreed with that obtained by Andreev *et al.*[44] and by Holmes and McClure[45] from the visible and ultraviolet spectra of the transition-metals in aqueous solution, who reported that the atmosphere around central metal ions was not affected by anions such as sulfate and nitrate ions. Values by Shapovalov *et al.*[23,24] are too large for the distances between transition-metal ions and neighboring water molecules.

In metal sulfate solutions, metal ions tend to form complexes with the sulfate ion. From infrared spectrophotometric measurements of divalent transition-metal ions in aqueous sulfate solutions, Larsson[46] estimated that the degree of inner-sphere complexity was about 10%. On the contrary, Hester and Plane[47] reported, using the Raman spectroscopy, that there was no evidence for the contact ion-association between transition-metal ions and sulfate ions in aqueous solution. According to the association constants reported in aqueous solution[48] of as high an ionic strength as of the sample solution, about 50% of the sulfate ions in our sample solutions were estimated to be bound as complexes. If 50% of the sulfate ions were directly coordinated to the metal ions through the M–OSO_3

Table 5. The distances between the metal ions and water molecules

	Anion	Mn^{2+}	Fe^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}	
r_{M-OH_2}/Å	Perchlorate	2.20	2.12	2.08	2.04	1.94 2.43	2.08	This work
	Sulfate	—	—	—	—	1.94 2.38	2.08	This work
	Sulfate	2.20	—	2.15	2.15	2.15 2.50	2.15	Shapovalov *et al.*[23,24]
	Nitrate	—	—	2.06	2.06	—	2.09	Bol *et al.*[25]

bond, the peaks ascribed to the M–O bond in the sulfate solutions would become broader and more or less asymmetrical compared with those in the perchlorate solutions, because it is expected that the M–OSO_3 bond within metal sulfate compounds is a little shorter than the M–OH_2 bond.[49] However, such evidence could not be observed in both copper and zinc sulfate solutions. Therefore, we concluded that the association of copper and zinc ions with sulfate ions was solvent-separated and the hydration sphere of the ions was not affected by the associated sulfate ions in the outer-sphere.

Estimation of the M–OH_2 Bond Energies. Bond energies for aqua complexes with the regularly symmetric configuration have so far been calculated on the basis of several models.[50–52] However, no calculation for the hydrated copper(II) ion has been carried out, because of its asymmetric structure due to the Jahn–Teller effect.

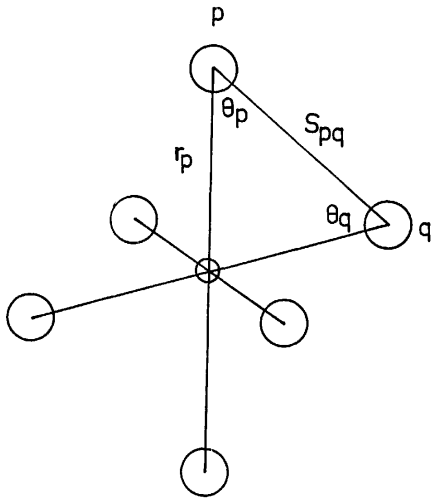

Fig. 7. The model of octahedral hydration.

We calculated the bond energies for the hydrated divalent transition-metal ions by application of the electrostatic model proposed by Garrick[52] and Basolo and Pearson[53] with a modification for a distorted octahedral structure. The bond energy in vacuum $-\Delta H_{\text{bond}}$ for a model of the octahedral hydration (Fig. 7) may be written as follows.

$$-\Delta H_{\text{bond}} = U_{\text{ed}} + U_{\text{dd}} + U_{\text{id}} + U_{\text{vw}} \quad (4)$$

Here subscripts ed, dd, id, and vw refer to the interaction between the ion and the dipole, that between the dipole and dipole, polarization of ligands to form induced dipoles, and the van der Waals repulsion. Each energy term is given as follows.

$$U_{\text{ed}} = -\sum_{p=1}^{N}(ze)(\mu_0+\mu_{\text{i}.p})/r_p^2 \quad (5)$$

$$U_{\text{dd}} = 1/2\sum_{p=1}^{N}\sum_{q=1}^{N}(\mu_0+\mu_{\text{i}.p})(\mu_0+\mu_{\text{i}.q}) \times(\sin\theta_p\sin\theta_q+2\cos\theta_p\cos\theta_q)/s_{pq}^3 \quad (6)$$

$$U_{\text{id}} = \sum_{p=1}^{N}\mu_{\text{i}.p}^2/2\alpha \quad (7)$$

$$U_{\text{vw}} = \sum_{p=1}^{N}B_p/r_p^9 \quad (8)$$

where r_p denotes the distance between a central metal ion and a water molecule p, ze the charge of the central metal ion, μ_0 the permanent dipole moment of the water molecule (1.85×10^{-18} esu·cm), $\mu_{\text{i}.p}$ and $\mu_{\text{i}.q}$ the induced dipole moments of the water molecules p and q at a distance s_{pq}, α the polarizability of water (1.48 Å^3), and N the hydration number which is 6 in this case. The dipole moment of the water molecule p induced by another water molecule q was calculated by Eq. 9.

$$\mu_{\text{i}.p} = \frac{\mu_0+(ze)/r_p}{1+\sum_{q=1}^{N-1}\alpha s_{pq}^{-3}(\sin\theta_p\sin\theta_q+2\cos\theta_p\cos\theta_q)} - \mu_0 \quad (9)$$

The constant B_p in the repulsion term was estimated according to the procedures proposed by Basolo and Pearson[53] on the assumption of spherical hydrated ions. For a copper ion both $B_{p\cdot\text{eq}}$ and $B_{p\cdot\text{ax}}$ were estimated on the assumption of spherically hydrated ions having radii of $r_{p\cdot\text{eq}}$ and $r_{p\cdot\text{ax}}$. This approximation may be acceptable in calculating the interaction energies because of the relatively small value of van der Waals repulsion energies.

Each interaction energy calculated by the use of Eqs. 4—9 is tabulated in Table 6 and the total bond energies for the hydrated metal ions ($-\Delta H_{\text{bond}}$) thus calculated are graphically represented in Fig. 8, together with the experimental values of the enthalpy change of hydration ($-\Delta H_{\text{h}}$) of these ions in solution.[54]

The curves of $-\Delta H_{\text{bond}}$ and $-\Delta H_{\text{h}}$ were parallel and the maxima of both curves appeared at Cu^{2+}. The differences between the two curves were about 150 kcal·mol^{-1} independent of the ions, which was approximately equal to the sum of the free energy change in transfer of one mole of a hydrated divalent ion with an ionic radius of about 3.5 Å ($\simeq$ an average $r_{\text{M–OH}_2}+$ the radius of a water molecule) and the energy change of vaporization of six moles of water. The dotted lines show the enthalpy change expected after the correction

Table 6. The bond energies ($-\Delta H_{\text{bond}}$) calculated by the use of the Garrick model[52] and the enthalpy change of hydration ($-\Delta H_{\text{h}}$)[54] for the hydrated divalent transition-metal ions (in kcal·mol^{-1})

Ion	$r_{\text{M–OH}_2}$/Å	U_{ed}	U_{dd}	U_{id}	U_{vw}	$-\Delta H_{\text{bond}}$	$-\Delta H_{\text{h}}$
Mn^{2+}	2.20	+617.4	−124.8	−89.4	−95.4	+307.8	+459.0

Zn^{2+}	2.08	+708.6	−155.4	−99.6	−105.6	+348.0	+506.6

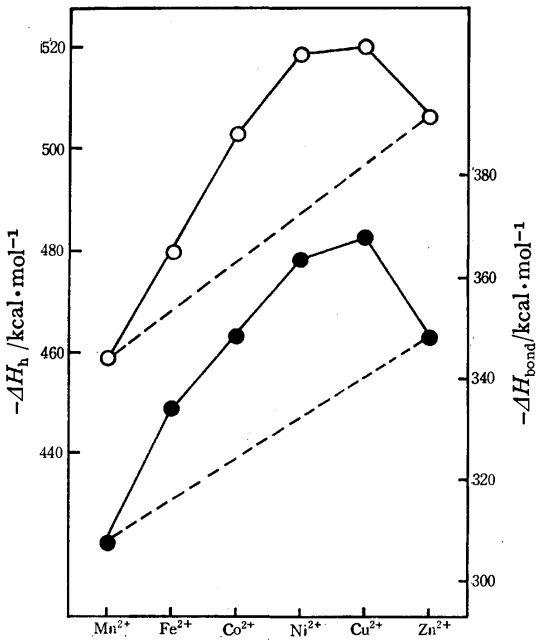

Fig. 8. $-\Delta H_{bond}$ (full circle) and $-\Delta H_h$ (open circle) for Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}. The dashed line shows the enthalpy change expected after correction of the crystal field stabilization.

for the effect of the crystal field. From these results we see that the crystal field largely contributes to the bond distances between a central metal ion and ligands in complexes.

The Polymorphic Crystallization of TiO_2 under Hydrothermal Conditions. I. The Effect of Phosphate Ions on the Selective Crystallization of Anatase[1)]

Fujio IZUMI and Yoshinori FUJIKI

National Institute for Researches in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received October 30, 1975)

The hydrothermal growth of anatase has been investigated at 480—650 °C and 500—1000 atm. Only rutile was formed in KF solutions. On the other hand, anatase was found to crystallize in solutions containing 5 wt% KF+0.1—10 wt% K_2HPO_4 at temperatures up to 600 °C, accompanied by small amounts of $K_2Ti_6O_{13}$ on the addition of 5—10 wt% of K_2HPO_4. The optimum growth conditions were: mineralizer solution, 5 wt% KF+1—2.5 wt% K_2HPO_4; temperature, 550—600 °C; pressure, 1000 atm. Anatase crystals were found as irregular aggregates of dipyramidal grains, blue and transparent. Individual crystals grown at a low supersaturation were characterized by well-developed {101} and {103} faces. The observed habit agrees with the expectations based on Hartman's PBC theory. The presence of phosphate ions favored anatase formation in NH_4F solutions as well, and the retrograde solubility of TiO_2 was observed. The reaction scheme for anatase formation has been proposed. The polymorphic crystallization of TiO_2 under hydrothermal conditions has been shown to be greatly affected by the complexing anions, such as fluoride or phosphate, in mineralizer solutions.

Natural TiO_2 exhibits three structural modifications, the rutile(tetragonal), brookite(orthorhombic), and anatase(tetragonal) minerals. In each of these, the Ti^{4+} ion is surrounded by an irregular octahedron of O^{2-} ions. The number of edges shared by other octahedra increases, from two in rutile to three in brookite and four in anatase, which implies that the free energies of the three forms increase in the above order.[2)] In nature rutile is much more common than brookite and anatase, being formed as a rule at high temperatures. Brookite and anatase transform, exothermally and irreversibly, to rutile over a wide range of temperatures. The rate and activation energy of the anatase–rutile transformation are greatly affected by the concentration of oxygen vacancies or interstitials.[3)] Navrotsky and Kleppa[4)] have demonstrated that anatase is metastable with respect to rutile under all conditions of temperature and pressure.

It is well known that the polymorphic crystallization of TiO_2 from aqueous solutions is influenced by some inorganic anions.[5)] The crystallization of amorphous TiO_2 under hydrothermal conditions leads to brookite in the presence of Na^+ ions.[6,7)] As for natural minerals,[8)] rutile formation is facilitated by the presence of Fe. A lack or deficiency in Fe leads to anatase formation, whereas brookite is preponderantly formed in the presence of Nb.

The only practical method for growing single crystals of rutile in large sizes is that of Verneuil. Other means include solution growth from molten salts,[9–11)] vapor-phase growth by chemical-transport reactions,[9,12)] and the hydrothermal method.[13–16)] Single crystals of brookite can be prepared hydrothermally in NaOH[6)] and NaF[7)] solutions. On the other hand, no authenticated reports have been published on the crystal growth of anatase.

The present study was undertaken in order to establish the optimum conditions for the hydrothermal growth of anatase on a small scale. The hydrothermal method should provide the highest probability of growing large crystals of anatase, since it combines a low temperature and a reasonable solubility. However, it may suffer from the defect that the temperature of the conversion of anatase to rutile is markedly lowered under hydrothermal conditions.[17)] It has now been shown that spectroscopically pure anatase crystals can be successfully grown in KF–K_2HPO_4 solutions. The reaction scheme for anatase formation, as well as some properties and morphology of crystals, has now been investigated.

Experimental

The TiO_2 (rutile) used was obtained commercially and was 99.99% pure. All the other materials used were of a guaranteed reagent grade. The hydrothermal reactions were carried out in sealed Au capsules in cold-seal-type pressure vessels with a capacity of 5.5 cm^3 and an inner diameter of 1/4 inch. About 0.1 g of TiO_2 was packed into a nutrient capsule 4 mm in diameter and 15 mm long, with a small hole. This was then placed, together with 0.5 ml of a mineralizer solution, in a larger capsule 5 mm in diameter and 70 mm in length, and sealed by crimping and welding one end shut. This double capsule was placed in the pressure vessel set horizontally with a temperature gradient between the dissolution and crystallization zones. The TiO_2 in the nutrient capsule fixed at one end of the larger one was dissolved, transported by convection to the other end, and recrystallized spontaneously through supersaturation. The nutrient capsule serves as both a container of the starting material and a baffle controlling the growth rate. The reaction temperature was measured by means of a chromel–alumel thermocouple on the outside of the vessel,[18)] while the pressure was measured with a Bourdon gauge. The experiments were conducted at temperatures between 480 and 650 °C and at pressures between 500 and 1000 atm. The temperature difference between the hot and cold zones was 40—90 °C. The duration of the runs was 4—15 days in most cases, but some lasted 25 days.

The reaction products were identified by the X-ray powder diffraction technique. The directions of the crystallographic axes of anatase crystals were found by means of the Wissenberg method. The Miller indices of the crystal faces were determined by use of a reflecting goniometer. The pH values before and after the hydrothermal reactions were measured by Toyo Roshi pH test papers.

Results and Discussion

The experimental conditions and the products of the hydrothermal reactions are summarized in Table 1. In these runs, KF and NH_4F solutions were used with or without additives. Keesmann[6] has suggested that anatase formation under hydrothermal conditions requires both a pH value around neutrality and a temperature below *ca.* 600 °C. The pH values of the 5 wt % solutions of KF and NH_4F were 8.6 and 6.3 respectively, and the hydrothermal solubilities of TiO_2 in these solutions are large enough to effect its crystal growth.[14,15] Therefore, each solution is expected to be advantageous for the hydrothermal growth of anatase.

Effect of Inorganic Ions on the Selective Crystallization of Anatase. The starting material was transported from the hot to the cold zone of the large capsule in KF solutions. Only rutile was formed in 10 wt % KF solutions at 500 °C and 800 atm. Kuznetzov[14,16] also prepared rutile crystals hydrothermally from NaF and KF solutions at 470—585 °C. Judging from the previous finding that, in the presence of F^- ions, rutile crystals grow at the expense of anatase at temperatures as low as 250 °C,[17] anatase would not be formed even if the reaction temperature was lowered to below 500 °C.

It is generally recognized that when TiO_2 is precipitated from an aqueous solution, the presence of a large amount of sulfate or phosphate ions favors anatase formation very strongly.[5] We, therefore, performed hydrothermal reactions in which several materials were added to the KF solution, expecting a similar effect under supercritical conditions (Runs No. 3—No. 7). However, only the addition of K_2HPO_4 proved to be effective in crystallizing anatase. It is worth noting that the presence of Na_2SO_4 did not aid anatase formation; this will be discussed later.

Hydrothermal Reactions in KF–K_2HPO_4 Solutions. Anatase was found to crystallize by adding 0.1—10 wt% of K_2HPO_4 at temperatures up to 600 °C. However, the rate of the transport of TiO_2 fell sharply when only 0.1 wt% of K_2HPO_4 was added. The highest temperature that allows the exclusive formation of anatase lies between 600 and 650 °C because rutile was formed in Runs No. 12 and No. 14. This corresponds well to the temperature of anatase–rutile conversion under hydrothermal conditions.[17]

Small amounts of needle or filamentary crystals, though not more than the minimum detection limit of X-ray powder diffraction analysis, were observed under a microscope in the products formed in solutions containing 5—10 wt% of K_2HPO_4. X-Ray diffraction study showed these crystals to be $K_2Ti_6O_{13}$ elongated along the b axis. The crystallization of the titanate was enhanced by a higher pH value as well as by a higher concentration of K^+. For instance, the addition of 5 wt% of $K_3PO_4 \cdot nH_2O$ (n=2—4) resulted in the formation of only $K_2Ti_6O_{13}$ (Fig. 1). The initial pH of this solution was 12.8. After the hydrothermal reaction, however, the pH was reduced to 6.6. These results can be explained in terms of the following reaction:

$$6TiO_2 + 2K^+ + OH^- \longrightarrow K_2Ti_6O_{13} + H^+$$

As is shown in Table 1, the pH values of KF–K_2HPO_4

Table 1. Transport of TiO_2 in fluoride solutions

Run No.	Mineralizer solution (wt %)	Temperature (°C)	Pressure (atm)	Duration (h)	Change in pH	Products[a]
1	5% KF	525	875	238		Ru

a) Ru, rutile; An, anatase; Ti, $K_2Ti_6O_{13}$. b) No transport of TiO_2 occurred.

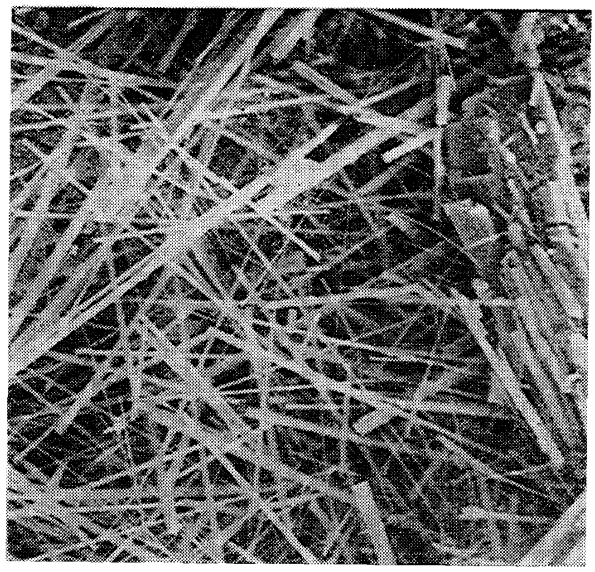

Fig. 1. Needle crystals of $K_2Ti_6O_{13}$.

solutions before and after the hydrothermal reactions did not deviate much from neutrality, since dissolution–crystallization reactions of TiO_2 occurred almost exclusively in these solutions.

In conclusion, the best growth of anatase is achieved under the following conditions: mineralizer solution, 5 wt% KF+1—2.5 wt% K_2HPO_4; temperature, 550—600 °C; pressure, 1000 atm.

Characterization of Anatase Crystals Grown in KF–K_2HPO_4 Solutions. Anatase crystals grown in KF–K_2HPO_4 solutions were usually found as irregular aggregates of dipyramidal grains, blue and transparent (Fig. 2). Upon continued heating at 1000 °C in air, these crystals turned opaque brown.

Individual crystals with maximum dimensions of 1 mm were mostly subhedral, although those grown at a low supersaturation were characterized by well-developed {101} and {103} faces. Hartman's PBC theory[19] predicts the (101) face in anatase to be an F-face and all the other (*h*0*l*) faces to be of the S type. The S-face in the zone [010] with the longest d_{hkl} value is (103). In view of these structural features, the appearance of the {101} and {103} faces on the anatase crystals grown hydrothermally seems to be quite reasonable. The observed habit of the synthetic anatase is in accord with expectations based on the description in the literature[20] that natural anatase occurs in crystals usually showing a simple dipyramid of the second order {101} or, less commonly, {103}.

No impurities could be detected by either the emission spectral analysis or the EPMA analysis of the anatase crystals. The tetragonal unit-cell constants determined by the powder technique are: $a=3.783\pm0.001$ Å; $c=9.508\pm0.002$ Å, which are in good agreement with the data published for anatase. The temperature of the anatase–rutile transformation was measured to be 975 °C by the high-temperature X-ray diffraction method.

Hydrothermal Reactions in NH_4F Solutions. TiO_2 showed retrograde solubility in NH_4F solutions; that is, the transport of the starting material proceeded from the cold to the hot zone of the capsule. From 5 wt% NH_4F solution, only rutile crystallized at 480 °C, and hardly any transport of TiO_2 was observed at 370 °C. On the other hand, anatase was obtained in the presence of 2 wt% of $(NH_4)_2HPO_4$, accompanied by unknown by-products which were found as brownish and translucent solids that formed an aggregate with anatase crystals (Fig. 3) and as a white powder dispersed throughout the whole capsule. The EPMA analysis of the former showed the main constituents to be Ti and P, indicating that it is a kind of titanium phosphate. However, no further effort was devoted to examining this phase in detail. The anatase crystals obtained

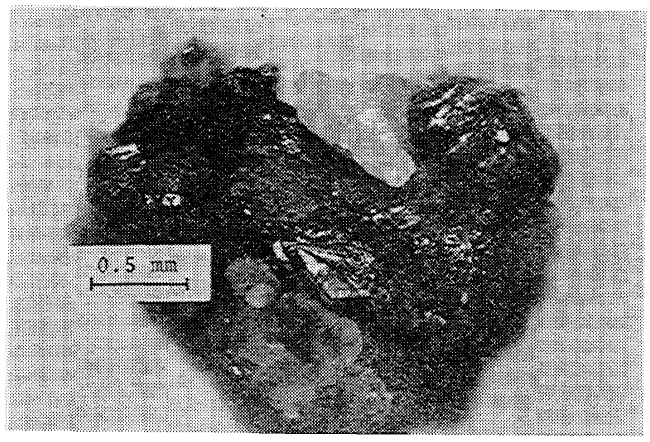

Fig. 3. Anatase crystals accompanied by an unknown phosphate.

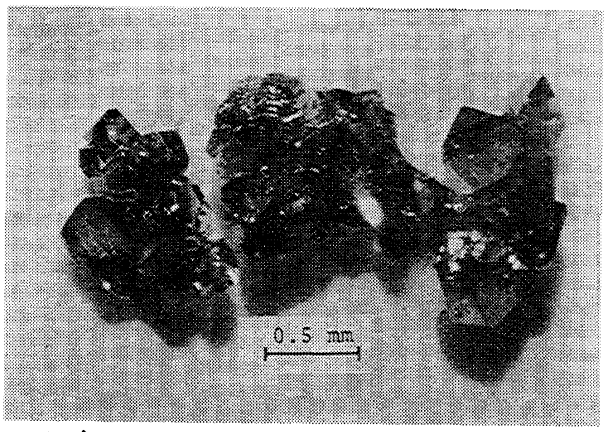

Fig. 2. Aggregates of anatase crystals (Run No. 19).

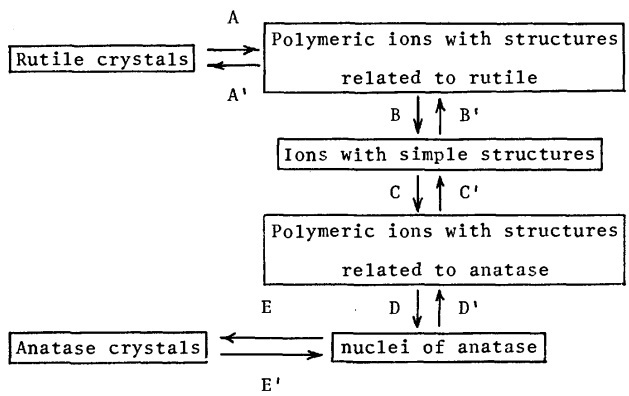

Fig. 4. The reaction scheme for anatase formation under hydrothermal conditions.

were in the form of opaque black grains with an average size of 0.3 mm. These results revealed that the presence of phosphate ions favors anatase formation in NH_4F solutions as well.

The Reaction Scheme for Anatase Formation under Hydrothermal Conditions. The reaction scheme for anatase formation assumed on the basis of the work by Yamaguchi *et al.*[21,22] is illustrated schematically in Fig. 4. The starting material (rutile) reacts with F^-, H_2O, and other species to form polymeric ions with structures related to the lattice of rutile; these ions undergo further cleavage and form ions with simple structures. The resulting ions are unstable under supersaturated conditions; they are hydrolyzed to give polymeric ions with structures related to anatase. Further hydrolysis leads to the formation of the nuclei of anatase, which grow into anatase crystals. Processes A and B should take place in the dissolution zone, whereas Processes C and D are predominant in the crystallization zone.

Caglioti *et al.*[23] have revealed that the $TiOF^+$, $TiOF_2$, $TiOF_3^-$, and $TiOF_4^{2-}$ species exist in aqueous solutions of Ti^{4+} and F^- ions. These mononuclear and/or polynuclear oxyfluoro-complexes are probably formed in the hydrothermal solutions of KF and NH_4F as well, which leads to the selective formation of rutile-like polymeric ions through Process B'. On the other hand, the above species are assumed to be further complexed by phosphate ions in the presence of K_2HPO_4 or $(NH_4)_2HPO_4$, with the result that only polymeric ions with structures related to anatase can be formed through Process C. Complexing between Ti^{4+} and phosphate is quite likely to occur since Ti^{4+}, one of the hardest acids, has a very strong affinity for the oxygen donor.[24] The decrease in the concentration of K_2HPO_4 lowers the rate of Process C, but favors Process B' (Runs No. 8 and No. 9). Above 600 °C, polymeric ions and/or nuclei with the anatase structure are partially transformed into the denser rutile-type structures.

The emission spectral analysis of the anatase crystals grown in KF–K_2HPO_4 solutions indicates that the phosphorus content does not exceed 10 ppm, which supports the idea that phosphate ions do not enter the crystal lattice of anatase, but are released almost completely into an aqueous environment during Processes C, D, and E. This is understandable in view of the large difference in ionic radius between Ti^{4+} and P^{5+} (Ti^{4+}, 0.69 Å; P^{5+}, 0.25 Å).[25] The failure to crystallize anatase in the presence of Na_2SO_4 may be ascribed to the weaker complexing ability of the sulfate ion compared with that of the phosphate ion.[26]

The detailed mechanism by which the nucleation of anatase occurs in the presence of phosphate ions is still a matter of speculation. However, the data presented in this paper suggest that the polymorphic crystallization of TiO_2 under hydrothermal conditions is greatly affected by the complexing anions, such as fluoride or phosphate, in mineralizer solutions. Work is now under way to investigate this problem in detail.

The authors wish to thank Drs. Mamoru Watanabe and Takefumi Mitsuhashi for helpful discussions and technical assistance during this work. Thanks are also due to Dr. Hiroshi Kawamoto, Faculty of Technology, Gunma University, for the emission spectral analysis.

25) This seems to exclude the possibility for P^{5+} to substitute Ti^{4+} in the anatase structure.[3]
26) For example, when concentrated H_3PO_4 was added to the solution of titanium sulfate, a white precipitate of titanium phosphate was immediately formed.

The Photo-Enolization of β-Disubstituted αβ-Unsaturated Ketone

Masaru TADA and Kyo MIURA

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received May 27, 1975)

γ-Methyl groups of mesityl oxide (I), dypnone (II), 2-isopropylidenecyclopentanone (III), and pulegone (IV) were deuterated by ultra-violet irradiation in methanol-*d*. It has been claimed that these ketones are not enolized by photo-excitation, but the formation of enol by irradiation was proved by infrared spectroscopy at a low temperature and was correlated to the photo-deuteration. The photo-enolization was deduced to occur from an n–π* singlet excited state.

It has previously been reported that several β-disubstituted α,β-unsaturated ketones such as mesityl oxide(I) do not isomerize to β,γ-unsaturated ketones upon ultraviolet irradiation;[1-4] Yang and Jorgensen[1] attributed the photo-stability of mesityl oxide (I) to the π–π* nature of the lowest triplet excited state, which was proposed to have no ability to abstract γ-hydrogen.[5] This conclusion was drawn on the basis of a comparison with the behavior of the *ortho*-alkylated aromatic ketone, in which an n–π* triplet state has been proved to be responsible for photo-enolization by flush photolysis.[6] This deduction does not, however, seem proper since the nature of the excited state is very different between aliphatic and aromatic ketones, especially in the efficiency of intersystem crossing. A recent publication by Turro *et al.*[7] has demonstrated that the n–π* singlet and triplet excited states of adamantanone have the same degree of reactivity toward intermolecular hydrogen abstraction and that the lower effectiveness of the singlet excited state is attributable to its short life-time.

In this paper we wish to report on the general photo-enolization of β-disubstituted α,β-unsaturated ketones, which have no tendency to isomerize to β,γ-unsaturated ketones; an n–π* singlet state is responsible for the hydrogen transfer.

Experimental

Materials. Commercially available mesityl oxide (I) (bp 130 °C) and pulegone (IV) (bp 103 °C/17 mmHg) were purified by distillation. Dypnone (II) (bp 141—144 °C/0.3 mmHg) was prepared by the base-catalyzed condensation of acetophenone.[8] 2-Isopropylidenecyclopentanone (III) (bp 90—91 °C/14 mmHg) was prepared by the condensation of acetone with cyclopentanone.[9] The purity of these materials was checked by glc analysis (SE-30 and Carbowax 20 M on Chromosorb W, N_2) before use. UV λ nm (ε): I, 252 (3600), 314 (60); II, 295 (15800); III, 252 (3650), 325 (68); IV, 252 (6450), 324 (40). NMR (JEOL ps-100 spectrometer) of ketones (I, III, and IV) in MeOD show two signals due to *syn* and *anti*-methyls at 1.83 and 2.05 ppm for I, at 1.78 and 2.12 ppm for III, and at 1.72 and 1.98 ppm for IV, respectively, by using TMS as an internal reference. Dypnone (II) originally showed one signal at 2.53 ppm due to the methyl group of the *E*-form, but rapid photo-equilibration between *E* and *Z*-forms occurred upon irradiation and another signal appeared at 2.25 ppm.

Deuterium Exchange. Each ketone (I, II, III, or IV) was dissolved (2%) in MeOD containing 1% of TMS as an internal reference for the chemical shift and the signal intensity. The solution was then sealed in a Pyrex NMR sample tube and irradiated by a 450-W medium-pressure Hg lamp—the distance between lamp and tube was *ca.* 1 cm. The NMR spectrum of the irradiated sample was inspected periodically. The relative intensities of the signals of the methyl groups to that of TMS were decreased by irradiation, as is shown by Figs. 1 and 2 in the text. Another sample tube wrapped with aluminum foil was placed in the irradiation apparatus as a reference. The reference sample did not show any change in its NMR spectrum. The solutions of the ketones in MeOH instead of MeOD were also irradiated under the same conditions, but their NMR spectra were identical with those of the non-irradiated solutions. Glc analyses of the samples also showed a quantitative recovery of the starting ketones.

Acid-catalyzed Deuteration. A solution of a ketone (I, II, III, or IV) in MeOD containing HCl (0.01 mol/l) was sealed in an NMR sample tube and kept under the same conditions as in photodeuteration, but without irradiation; the NMR spectra were taken periodically. The spectra showed no decrease in the signal intensities of the γ-methyl groups, but the signal intensities of the α-methyl group of mesityl oxide (I) at 2.05 ppm and of the α-methylene groups of the III and IV ketones at around 2.5 ppm were decreased—a 50% decrease within 15 hr for the I ketone.

Triplet Quenching of the Photo-deuteration. The solutions (2%) of dypnone (II) and pulegone (IV) in MeOD containing 0.0 and 0.1 mol/l of 3,3,4,4,-tetramethyl-1,2-diazetine 1,2-dioxide[10] were placed in a merry-go-round-type irradiation apparatus and were irradiated by means of a 450-W medium-pressure Hg lamp—the distance between lamp and tube was 5 cm—for 35 min (II) and 5 hr (IV). The irradiation caused the deuteration of γ-methyl groups (*ca.* 15% for II and *ca.* 30% for IV), and the quencher did not show any effect on the rate of deuteration of the γ-methyl groups.

Low Temperature Infrared Spectra. Pulegone (IV) dissolved in the mixed solvent of methyl cyclohexane and 2-methyltetrahydrofuran (2: 1) was placed in an infrared cell of CaF_2 plate, and the cell was mounted in the ditch of a brass block connected to a container of liquid nitrogen. The sample was hang in a glass case with a window of CaF_2 and was cooled by liquid nitrogen, with an occasional evacuation of the system. After a tight matrix of the sample has been obtained, the system was evacuated continuously (*ca.* 10^{-3} mm Hg). Pulegone (IV) in the cold matrix showed the absorptions at 1675 and 1615 cm^{-1} due to the carbonyl group and the carbon-carbon double bond respectively. An external irradiation of the matrix through the window was carried out by means of a 500-W high-pressure Hg lamp mounted in a lamp house equipped with an optical system of a quartz lens and a Pyrex filter. Irradiation caused a diminuation of the original absorptions, with a concomitant increase in new absorptions at 1664 and 1596 cm^{-1} due to the enol form of IV (see Fig. 3); the photo-equilibrated state was attained after 2 hr.

In the case of mesityl oxide (I), the solvent system of methyl-

cyclohexane-2-methyltetrahydrofuran-isopentane (1 : 1 : 2) was superior to the system used for pulegone (IV). The original absorptions at 1695 and 1622 cm^{-1} due to the *s-cis* form of ketone I, and at 1690 and 1645 cm^{-1} due to the *s-trans* form of I, decreased, with a concomitant increase in the absorptions at 1655 and 1602 cm^{-1} due to the enol form of I. The spectral change in mesityl oxide (I) was slower than that of pulegone (IV); it required irradiation for 10 hr to reach the photo-equilibrated state. The samples were warmed slowly after irradiation, and the spectral measurements were repeated during the period of warming up. Only the original absorptions were observed in the infrared spectrum of the warmed sample; the absorptions due to the enol form disappeared completely.

Results and Discussion

We found that, upon ultraviolet irradiation, β-disubstituted α,β-unsaturated ketone enolizes to dienol, and that the lack of the isomerization of the dienol to a β,γ-unsaturated ketone accounted for the nominal inertness of such a ketone. This result was established by the following experimental results. Each solution of mesityl oxide (I), dypnone (II), 2-isopropylidenecyclopentanone (III), and pulegone (IV) in methanol-*d* was irradiated, and the photo-deuteration of the γ-methyl groups was examined by NMR. The relative intensities of the signals *versus* irradiation period are shown in Figs. 1 and 2 A reference experiment in the dark did not show deuteration to any detectable extent, and the irradiations of I—IV the ketones in methanol resulted in a quantitative recovery of the starting materials. There is a possibility that a kind of acidic compound formed by the irradiation of methanol-*d* containing a trace amount of oxygen[11] would catalyze the deuteration of γ-methyl groups. The addition of hydrochloric acid (0.01 mol/l) to the solution, however, caused only the deuteration of the α-methylene or α-methyl groups; no deuteration of γ-methyl groups was observerd.

The photo-enolization was proved more directly by the infrared spectrum the dienol isolated in a cold matrix.

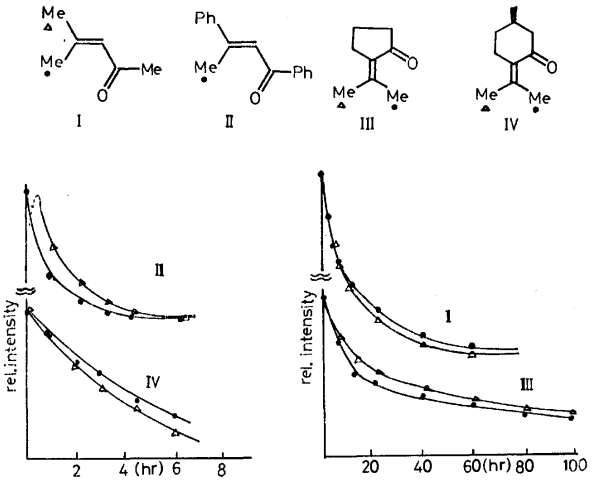

Fig. 1 Fig. 2

Fig. 1 and 2. Decrease of NMR signal-intensities of α-methyls *versus* irradiation period.

Pulegone (IV) dissolved in methylcyclohexane-2-methyltetrahydrofuran (2: 1) was solidified to a clear matrix under cooling by liquid nitrogen. The irradiation of the matrix caused a distinct change in its infrared spectrum, as is shown in Fig. 3. The absorptions due to the starting pulegone (IV) at 1675 ($\nu_{C=O}$) and 1615 cm^{-1} ($\nu_{C=C}$) decreased, with a concomitant increase in the absorptions at 1664 ($\nu_{C=O}$) and 1596 cm^{-1} ($\nu_{C=C}$, strong) due to the enol form of pulegone. The same spectroscopic behavior was observed with mesityl oxide (I), in which the absorptions at 1655 ($\nu_{C=O}$) and 1602 cm^{-1} ($\nu_{C=C}$, strong) increased, with a concomitant decrease in the absorptions at 1695 ($\nu_{C=O}$) and 1622 cm^{-1} ($\nu_{C=C}$) for the *s-cis* form of I and at 1690 ($\nu_{C=O}$) and 1645 cm^{-1} ($\nu_{C=C}$) for the *s-trans* form of I.[12] In accordance with the difference in the rate of photo-deuteration between the I and IV ketones, the photo-equilibrium state of IV was attained after 2 hr, whereas that of I required 10 hr. The original absorptions for I and IV were regenerated by warming up the sample after the termination of the irradiation.

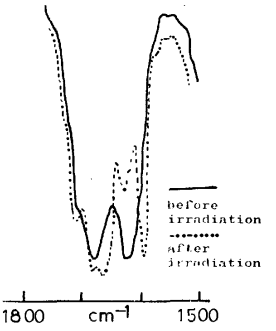

Fig. 3. Infrared spectra.

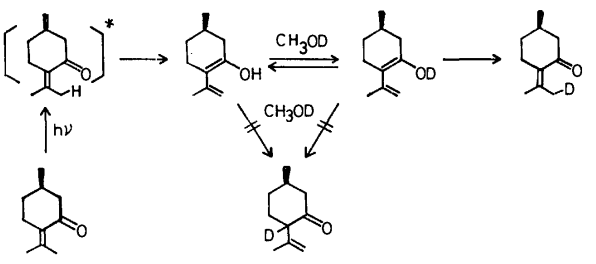
These experimental findings are compatible with Scheme 1. The deuterium exchange of the hydroxy group of the enol and the hydrogen return to the γ-carbon explain the photo-stability in the non-deuterated methanol and the deuterium exchange of the γ-methyl groups of these ketones. It is worthwhile to point out that the prototropy in these ketones, upon ketonization, takes the 1,5-migration instead of the 1,3-migration path to give β,γ-unsaturated ketone. This behavior can be explained by considering that the prototropy is completely intramolecular and that the 1,5-transfer is more favorable in the energy surface of the reaction. Dypnone (II) and pulegone (IV) isomerize to β,γ-unsaturated isomers upon irradiation in the presence of hydrochloric acid[13]; this feature can be accounted for by the intermolecular prototropy



Scheme 1

placing a proton at the α-position of the enol.[14,15]

We deduced the excited state responsible for the photo-enolization to be the n–π^* singlet. This conclusion is based on a consideration of the relation between the rate of enolization and the geometry of the ground state of these ketones, and by triplet-quenching experiments. The deuterations of dypnone (II) and pulegone (IV) are much faster than those of mesityl oxide (I) and 2-isopropylidenecyclopentanone (III); this property is considered to be a reflection of the geometry of the ground state.[16,17] Judging from the Dreiding molecular model, the shortest distance between carbonyl oxygen and one of the hydrogens of γ-methyl is 1.9 Å for the III ketone and 1.5 Å for the IV ketone when the conjugate system takes a planar conformation. The influence of the ground-state geometry on the reaction rate can be expected only in the singlet state immediately after excitation. In the case of acyclic ketone, we propose that the difference in the rates of the deuteration of the I and II ketones is a reflection of the coplanarity of the enone system. The II ketone is more coplanar than the I ketone due to the conjugate effect of the aromatic ring. Another possibility is the consequence of the difference in absorbance (ε: I, 60 at 314 nm; II, 15800 at 295 nm). The large absorption coefficient of the II ketone indicates that both the lowest singlet and triplet states are π–π^* in nature, but the efficiency for hydrogen abstraction by the π–π^* state is, in general, very low. Therefore, we feel that the higher-lying n–π^* state instead of the π–π^* state is responsible for the photo-enolization of II, and that the coplanarity of the system is more crucial.

The photo-deuterations of dypnone (II) and pulegone (IV) were not quenched by a triplet quencher, 3,3,4,4-tetramethyl-1,2-diazetine 1,2-dioxide (E_T=*ca.* 40 kcal/mol);[10] therefore, the photo-deuteration *via* photo-enolization must be a singlet or an extremely fast triplet process. It has been established that an n–π^* singlet state abstracts hydrogen as fast as an n–π^* triplet state does.[7] The fast formation of a photo-equiliblium mixture of the *E* and *Z* forms of dypnone (II), as well as the deuteration of both methyl groups of the I, III, and IV ketones at a similar rate, shows the existence of fast geometrical isomerization from the excited state with a triplet manifold. This free rotor effect[18-20] must be responsible for the dissipation of the triplet excited energy, and the present phot-deuteration must be a singlet process.

In conclusion, it follows from the present results that the isomerization of an α,β-unsaturated ketone into a β,γ-unsaturated ketone is not a definite guide for the usefulness of photo-enolization, as has previously been reported, and that the γ-hydrogen abstraction in the I—IV ketones is a fast process from the singlet n–π^* state, retaining the geometry of the ground state.

The authors are indebted to Professor T. Sato of Waseda University for disclosing his unpublished data to them and for his discussions. Financial support by the Matsunaga Science Foundation is also acknowledged.

The Air Oxidation of Catecholamines by Flavin Mononucleotide

Fujio TAKAHASHI, M. B. RAHMAN,* and Hirotoshi MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

** Department of Chemistry, University of Rajshahi, Raishahi, Bangladesh*

(Received June 7, 1975)

Polarographic studies of the aerobic oxidation of catecholamines under the influence of FMN in various concentrations, and spectrophotometric investigations of the formation of FMN–catecholamine complexes, have been carried out. By following the course of the oxidation reaction polarographically, the rate constants have been found. The oxidation of catecholamines by air was found to be disturbed through complex formation and to be facilitated by light illumination. The equilibrium constants for the formation of some catecholamine complexes with FMN have been calculated.

It has been established that such flavins as flavin mononucleotide (FMN) and flavin adenine dinucleotide can form charge transfer (CT) complexes with tryptophane, purines, and catechol.[1] These flavins act as catalysts for the redox reactions in flavin enzymes. The oxidation of ethylenediamine tetraacetate or reduced nicotinamide adenine dinucleotide (NADH) in the presence of flavins has been reported to be facilitated by light exposure.[2] This oxidation reaction is inhibited if the donor compounds coexist in the systems.[3] Such acceptors as methyl viologen do not inhibit the reaction. Menadiol diphosphate is oxidized by oxygen in the presence of riboflavin with light exposure.[4]

It was expected that such catecholamines as 3,4-dihydroxyphenylalanine (DOPA), 3-hydroxytyramine (dopamine), and adrenaline, which are susceptible to be oxidized by oxygen,[5] might form the CT complex as donors. No papers on the study of the flavin-sensitized photooxidation of catecholamines have yet been found, however. Both catecholamines and flavins are biochemicals utilized as medicines. Therefore, it is important to clarify the interaction between flavins and catecholamines. For this purpose, we studied the formation of CT complexes in FMN-catecholamine systems and the oxidation of catecholamines in the presence of FMN. In this paper we will present the results obtained by the polarographic and spectrophotometric methods.

Experimental

The determination of FMN was carried out by spectrophotometry at 450 nm. L-DOPA, dopamine hydrochloride, and L-adrenaline bitartrate were used as catecholamines. All the sample solutions were prepared in a 0.1 mol/l phosphate buffer (pH 7.0).

Anode polarograms were obtained by using a Yanaco platinum rotating electrode equipped with a Hokuto Denko linear scanning unit LS-1D and potentiostat HA101, and a Toa Electronics Ltd. X-Y recorder SYR-1A. The platinum rotating electrode used was 1 cm long, with a diameter of 0.1 cm, and had a rotation of 600 rpm. The sweep speed for recording polarograms was set at 3 V/min. The accuracy of the half-wave potentials obtained was estimated to be within ± 0.01 V. The intensity of the illumination and the dissolved oxygen were measured by means of a Tokyo Koden illumination meter ANA-300 and an Anal Instrument Co DO meter respectively. The absorption spectra were determined with a Shimadzu UV-200 spectrophotometer.

Results

Polarography. In several 50 ml beakers, 40 ml portions of solutions containing FMN and catecholamines were prepared and shaken under the air at 30 °C with illumination (400—3000 lx). Polarograms were measured at desired intervals. Some results are shown in Fig. 1. In the case of adrenaline, the half-wave potential, $E_{1/2}$, of the anodic wave was found to shift from +0.14 to +0.16 V *vs.* SCE with an increase in the FMN concentration from 2.5 to 20 mmol/l. Towards the end of the oxidation process, the waveheight at each $E_{1/2}$ gradually reduced and finally disappeared overnight, but another anodic wave became predominant, its $E_{1/2}$ value being clearly determined to be at +0.28 V *vs.* SCE. The waveheight at the first $E_{1/2}$ changed with the lapse of time. It increased measurably during the first 30 min and then decreased. After that, the oxidation seemed to occur in the first order

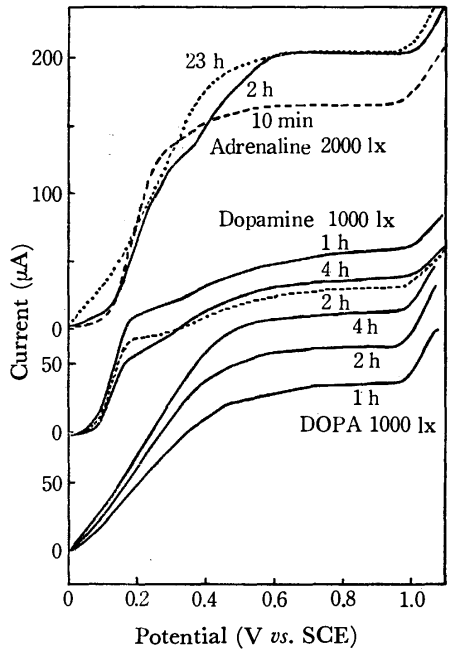

Fig. 1. Polarograms of catecholamine–FMN systems.
Catecholamine: 1 mmol/l
FMN: 20 mmol/l (Adrenaline)
5 mmol/l (Dopamine or DOPA)
pH 7.0, 30 °C

Table 1. Equilibrium constants and velocity constants

	Equilibrium Constant (1/mol)	Velocity Constant (h^{-1})			
		400 lx	1000 lx	2000 lx	3000lx
Adrenaline	19±4	0.12	0.18	0.25	0.24
DOPA	11±4	—	—	—	—
Dopamine	89±10	—	0.14	0.068	—

with respect to adrenaline. The reaction velocity was found to be independent of the FMN concentration and to be influenced by illumination. The velocity constants were obtained from the slopes in Fig. 2; they have been summarized in Table 1.

The reaction velocity in the case of dopamine was smaller than that in adrenaline and was also independent of the FMN concentration. The value of the first $E_{1/2}$ of dopamine fell on +0.12 V *vs.* SCE when the FMN concentration varied from 2.5 to 20 mmol/l. The second $E_{1/2}$ was apparent in the region between 0.38 and 0.43 V, but the exact value could not be obtained because the waveheight at the first $E_{1/2}$ still remained after 22 h. The velocity constant obtained from the slope in Fig. 2 is recorded in Table 1.

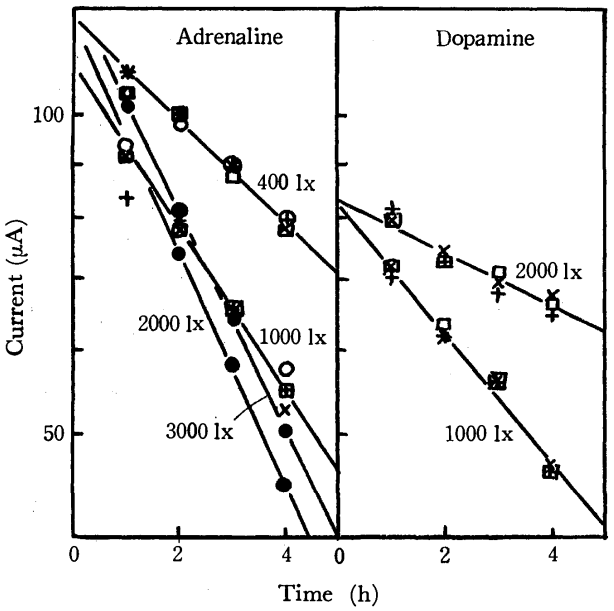

Fig. 2. Air oxidation of catecholamines.
Adrenaline or dopamine: 1 mmol/l, FMN: +; 2.5, ■; 5, ×; 10, ○; 20 mmol/l ●; average in each concentration of 2.5—10 mmol/l.

In the case of DOPA, $E_{1/2}$ was found to be centered in the region of 0.2—0.3 V. However, the definite position of $E_{1/2}$ and the waveheight at $E_{1/2}$ could not be obtained. The waveheight at about 0.6 V was found to increase considerably with the lapse of time (Fig. 1).

Spectrophotometry. The absorbances of the FMN–catecholamine systems at 505 nm were measured in a way similar to that described in a previous paper.[6] Dissolved oxygen from the sample solutions was removed by bubbling in nitrogen gas. The results plotted according to Benesi–Hildebrand's equation are shown in

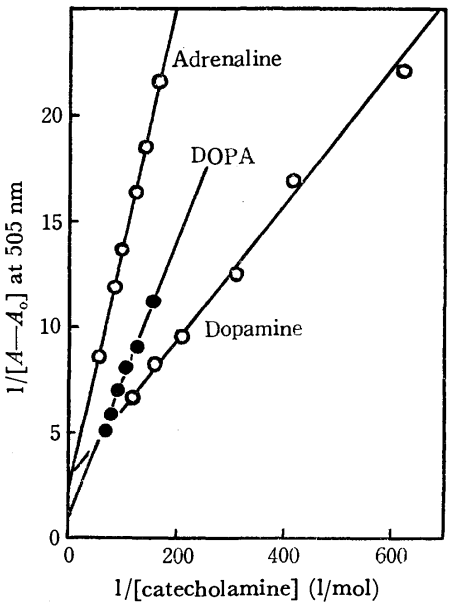

Fig. 3. Benesi–Hildebrand's plots of FMN–catecholamine systems.
FMN: 8.0×10^{-4} mol/l Oxygen free, pH 7.0, 25 °C

Fig. 3. The equilibrium constants calculated from the results in Fig. 3. are summarized in Table 1.

In a 100-ml beaker a 20 ml solution containing 3.2 mmol/l DOPA with or without 8.0×10^{-2} mmol/l FMN was prepared and stirred on a waterbath at 25 °C with illumination. The absorbance change at 340 nm was determined[7] and found to increase linearly with the lapse of time within an hour. The initial velocities (v_0's) were calculated from the absorbance change (340 nm)-time curves. The v_0's of DOPA oxidation were compared with different strengths of illumination (Figs. 4 and 5). DOPA oxidation was found to be facilitated in the presence of FMN and with stronger illumination. The plots of $1/v_0$–1/DOPA concentration fall on a straight line. Its oxidation was very slow without light exposure, even when FMN was present in the solution. In another experiment, when nitrogen gas was bubbled through a solution, the absorbance at 450 nm diminished to 82% after illuminating for 16

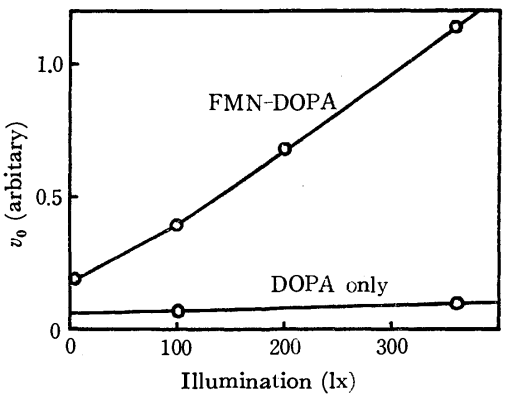

Fig. 4. Influence of illumination to the initial velocity of DOPA oxidation reaction.
FMN: 8.0×10^{-5} mol/l, DOPA: 3.2×10^{-3} mol/l, Oxygen: 2.7×10^{-4} mol/l, pH 7.0, 25 °C.

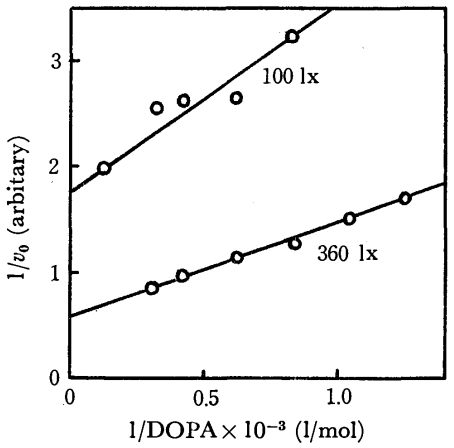

Fig. 5. Plots of 1/DOPA *vs.* $1/v_0$. FMN: 8.0×10^{-5} mol/l, Oxygen: $2{,}7 \times 10^{-4}$ mol/l, pH 7.0, 25 °C.

h at 1300 lx. Similar results were obtained when dopamine and adrenaline were used in place of DOPA. The ratios of the absorbance change of dopamine and adrenaline against DOPA were 0.4 and 1.2 respectively at 360 lx.

Discussion

It seemed that the complex formation might disturb the oxidation, as the velocity constant in the FMN–dopamine system was smaller than that in the FMN–adrenaline system. The illumination was found to enhance the air oxidation reaction in the case of adrenaline.

The reaction by which FMN oxidized NADH to form NAD, which has been reported by Radda and Calvin,[2] is a downhill reaction, because the redox potentials of NADH/NAD and $FMNH_2$/FMN are −0.32 and −0.22 V *vs.* NHE, respectively. The redox potential of adrenaline is known to be +0.80 V *vs.* NHE.[8] It is not probable that adrenaline or other catecholamines can be oxidized directly by FMN. Moore and Song[4] have reported that the energy transfer occurred from a photoexcited FMN to oxygen to attain a singlet state and that, in turn, the oxygen in the singlet state oxidized menadiol diphosphate. This oxidation reaction seems similar as that in the case of catecholamines.

It has been recently reported that a preequilibrium complex must react directly with oxygen in the process of lumiflavin reduction by *N*-methyl-1,4-dihydronicotinamide.[9] A similar reaction was observed in the FMN–DOPA reaction in Fig. 5, which showed the following Michaelis–Menten-type reaction:

$$\begin{array}{ccccc} F + D & \rightleftharpoons & FD & \rightleftharpoons & FH_2 + \text{Product} \\ & & \downarrow O_2 & & \downarrow O_2 \\ & & \text{Product} + F + H_2O_2 & & F + H_2 \end{array} \quad (1)$$

F: FMN D: Catecholamine

The fact that the reaction proceeded without illumination (Fig. 4) might be explained as a result of the oxidation of a trace amount of FH_2 produced in the equilibrium. The reduced flavin is known to be easily oxidized by oxygen.[10] It is plausible that the light reaction and the dark reaction proceed together.

It is known that catecholamine-oxidized can form a cyclic compound, III,[5] which may accumulate through the reaction if the velocity constant, k_1, is larger than k_2. This assumption is considered to be justified, because the reaction proceeds by the first order with respect to catecholamines. The half-wave potential of leucoadrenochrome is known to be +0.44 V *vs.* NHE at pH 7.[8] This is almost in accord with the second half-wave potential in adrenaline (+0.28 V *vs.* SCE) if some interaction between FMN and adrenaline is considered. Therefore, the second half-wave potentials in adrenaline and dopamine solutions can be assigned to III. Then the fact of the waveheight increase Fig. 1 seems reasonable because III is oxidized faster than I at the anode to limiting currents of the III and I of adrenaline, as shown in Fig. 1, are 205 and 165 μA respectively.

	R_1	R_2	R_3
Adrenaline	OH	H	CH_3
DOPA	H	COOH	H
Dopamine	H	H	H

The Catalytic Action of a Mixed Micelle of Lauroylamino Acid and a Detergent

Tohru INOUE,* Kazuo NOMURA,** and Hideo KIMIZUKA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received June 12, 1975)

The catalytic effect of the mixed micelles of lauroylamino acids (LauAm) and detergents on the hydrolysis of *p*-nitrophenyl acetate has been studied. The amino acids used for the synthesis of LauAm were glycine, serine, histidine, tyrosine, lysine, and arginine. Cetyltrimethylammonium bromide (CTAB), polyoxyethylene dodecyl ether ($C_{12}E_6$) and sodium dodecyl sulfate (SDS) were used for the preparation of the mixed micelles with LauAm. Among the detergents used, only CTAB remarkably enhanced the catalytic activity of LauAm. A reaction scheme was proposed, and the rate constant for the catalytic activity of LauAm was estimated from the kinetic data. The effect of pH was also studied. Discussions were given of the mechanism of the catalytic action on the basis of the present study.

In general, it is thought that the detergent micelle is roughly spherical and that the hydrophilic groups occupy the micellar surface and are exposed to the solvent phase, while the hydrophobic groups occupy the interior and form the hydrophobic region. In this respect, micelles resemble globular proteins, which have a structure in which the nonpolar amino acid residues are inside and the polar ones are outside. On the other hand, it has been known that several organic reactions are accelerated or inhibited when they occur in solutions containing detergent micelles and that this catalytic action shows a pattern similar to that of the Michaelis–Menten type. For these reasons, the study of the reaction rates in micellar system is useful as a model of enzymatic reaction, and recently many investigations in this area have been carried out.[1,2]

Gitler *et al.* found that the mixed micelle of N^{α}-myristoyl-L-histidine and cetyltrimethylammonium bromide (CTAB) remarkably enhanced the rate of the liberation of *p*-nitrophenol by the hydrolysis of *p*-nitrophenyl acetate (PNPA).[3] Heitman observed a similar enhancement of the reaction rate in the presence of sodium dodecanoylcysteinate in the micelle.[4] It has been regarded that the acylation reaction accompanies the liberation of *p*-nitrophenol in these systems.

When amino-acid side chains are in the vicinity of the micellar surface or the boundary between apolar and polar regions, their properties might be different from those in an aqueous environment. Thus, it is interesting to investigate the catalytic action of amino-acid residues in micelles in comparison with that of the enzyme. Thus, the effect of the mixed micelle of *N*-long chain acylamino acid and a detergent on the rate of the hydrolysis of PNPA has been studied.

Experimental

Materials. N^{α}-lauroylamino acid (LauAm) was prepared by the method of Lapidot *et al.*[5] The amino acids used for the synthesis of LauAm were glycine, serine, histidine, tyrosine, lysine, and arginine. To a solution of amino acid (20 mmol) and sodium hydrogencarbonate (20 mmol) in 200 ml of water we added a solution of the *N*-hydroxysuccimid ester of lauric acid (20 mmol) in 200 ml of tetrahydrofuran. The mixture was stirred for 16 h at room temperature and then acidified with 1 M HCl to pH 2—3, and the organic solvent was removed *in vacuo*. After the addition of 100 ml of water, the precipitate was filtered and recrystallized from the methanol–water mixture three times. In the cases of N^{α}-lauroyllysine (LauLys) and N^{α}-lauroylarginine (LauArg), two protective groups were removed by the catalytic hydrogenation of palladium black after the coupling of ε-benzyloxycarbonyl-L-lysine (or N^{ω}-nitro-L-arginine) with lauric acid. The products were recrystallized from the methanol–ether mixture or ethanol. Each compound moved as a single spot on a thin-layer chromatogram. The results of the elementary analysis of LauAm are given in Table 1.

The cetyltrimethylammonium bromide (CTAB), *p*-nitrophenyl acetate (PNPA), tris(hydroxymethyl)aminomethane (Tris), 2-amino-2-methyl-1,3-propanediol, potassium hydrogenphosphate, and disodium hydrogenphosphate were of a guaranteed grade and were used without further purification. A purified specimen of polyoxyethylene dodecyl ether, $C_{12}H_{25}O(CH_2CH_2O)_6H$, ($C_{12}E_6$), was obtained from the Kao Soap Co., Ltd. The sodium dodecyl sulfate (SDS) was purified by recrystallization from 95% ethanol.

The experiments were carried out at detergent concentrations well above the critical micelle concentration (CMC) of the detergent. Gitler *et al.* reported that N^{α}-myristoyl-L-histidine and CTAB formed a mixed micelle.[3] Although LauAm is insoluble in water at a neutral pH, it is easily solubilized by detergent micelles. In this study, sample solutions were prepared by solubilizing LauAm into the detergents in a buffer solution where the molar ratio of LauAm to detergents was less than 1/5. The micellar solutions were transparent for a long time at room temperature. The pH of the sample solution was adjusted with a 1/20 M Tris buffer unless otherwise stated.

Kinetic Measurements. An absorption cell was filled with 3.0 ml of a sample solution containing a mixed micelle of LauAm and a detergent, and was then placed in the thermostated chamber (25 °C) of a HITACHI 124 spectrophotometer. 15 min later, 20 μl of an acetonitrile solution of PNPA was added to the sample solution, and the two were mixed by stirring. The initial concentration of PNPA in the system was maintained at 10^{-5} M throughout. Then, the increase with time in the absorbance at 400 nm (at pH 6 and above) or 317 nm (below pH 6) due to the liberated *p*-nitrophenol was recorded. The pseudo-first-order kinetics were

a) Ref. 5). b) Ref. 6).

observed under the present experimental condition: [detergent]>[LauAm]≫[PNPA]. The pseudo-first-order rate constants, k_ψ, were calculated from $(1/t)\cdot\ln a/(a-x)$, where a and x are the absorbances at an infinite time (about ten half-lives) and at time t respectively. The duplicate values of k_ψ agreed within 4%.

Results and Discussion

Effect of Detergent on the Rate of Hydrolysis of PNPA. The rate constant, k_ψ, was measured with detergent solutions at pH 8.7, 25 °C. SDS and $C_{12}E_6$ did not appreciably alter k_ψ as compared with the non-micellar system, whereas in the presence of CTAB greater values of k_ψ were observed.

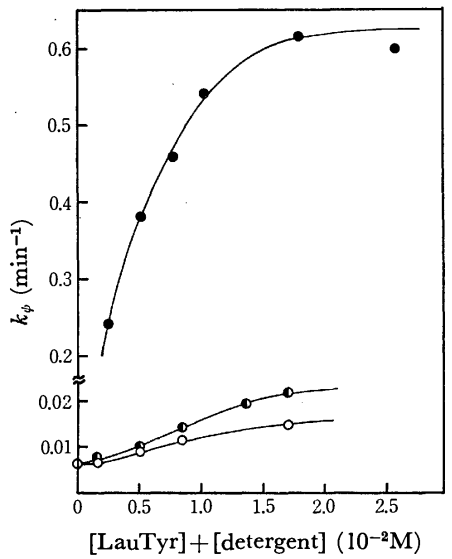

Fig. 1. Catalytic action of LauTyr.
●: CTAB, ◐: SDS, ○: $C_{12}E_6$. The molar ratio of LauTyr to detergent is 1: 16. $[PNPA]_0=10^{-5}$ M.

A series of experiments were carried out with a constant molar ratio of LauAm to the detergent. The results for LauTyr are shown in Fig. 1. This figure indicates that CTAB remarkably accelerates the rate of the hydrolysis of PNPA and that SDS causes a small increase in the reaction rate. However, in the presence of SDS the reaction rate is somewhat lower than that in the absence of SDS or in the presence of LauTyr alone. This indicates that SDS suppresses the reaction rate to some extent. Similar effects of CTAB and SDS were observed with LauHis, LauLys, LauSer, and LauArg. It may be noted that the acceleration by CTAB is small for mixed micelles with LauSer and LauArg. $C_{12}E_6$ tends to decrease the catalytic activity of LauAm except in the case of LauHis.

On the other hand, the mixed micelle of LauGly and a detergent showed a smaller catalytic activity than the detergent solution itself.

Change in the Reaction Rate with the Detergent Concentration. The catalytic effect of the mixed micelles of CTAB and LauAm has been studied as a function of the concentration with a fixed molar ratio of LauAm to CTAB. It may be seen, *e.g.*, in Fig. 1, that the rate constant, k_ψ, increases with the concentration and approaches a saturation value. The concentration dependence showed a similar pattern regardless of the composition of the mixed micelle. However, the saturation value becomes greater as the fraction of LauTyr becomes larger. This can be attributed to the increase in the number of the active sites of a mixed micelle. Similar results were obtained with LauHis, LauLys, LauArg, and LauSer.

Kinetics. The micellar concentration dependence of the rate constant can be explained by assuming the following reaction scheme:

$$S \xrightarrow{k_b} P$$

$$S + M \underset{}{\overset{K}{\rightleftharpoons}} MS \xrightarrow{k} P \qquad (1)$$

where S denotes the substrate (PNPA); M, the micelle; MS, the micelle–substrate complex and P, the product (*p*-nitrophenol); k_b and k are the rate constants of the product formation in the bulk and at the micellar surface respectively; K represents the dissociation constant of the micelle–substrate complex.

This scheme differs from that proposed by Gitler *et al.*[3] in the catalytic action of the mixed micelle of N^{α}-myristoyl-L-histidine and CTAB. The application of their theory to the results of present study showed that the dissociation constant of the inactive micelle-substrate complex changed appreciably with the kind of LauAm in the mixed micelle. This disagrees with their assumption that the dissociation constant is independent of the kind of LauAm.

In the present study, the experiments were carried out under these conditions: [detergent]≫CMC, and [detergent]>[LauAm]≫[PNPA]. According to Scheme (1), the pseudo-first-order rate constant, k_ϕ, is given by:

$$k_\phi = \frac{k_b + k \cdot \frac{[M]}{K}}{1 + \frac{[M]}{K}} \qquad (2)$$

where [M] denotes the sum of the initial concentrations of detergent and LauAm. By rearranging Eq. (2) we obtain:

$$\frac{1}{k_\phi - k_b} = \frac{K}{(k-k_b)[M]} + \frac{1}{k-k_b} \qquad (3)$$

Thus, $(k-k_b)$ and K can be evaluated from the plot according to Eq. (3); an example is shown in Fig. 2. For estimating k and K, the value of k_b is necessary. It was found that k_b increased with the pH. The values of k_b at pH's, 7.5, 8.7, and 9.7 were found to be 7.02×10^{-4}, 6.55×10^{-3}, and 2.23×10^{-2} min^{-1} respectively.

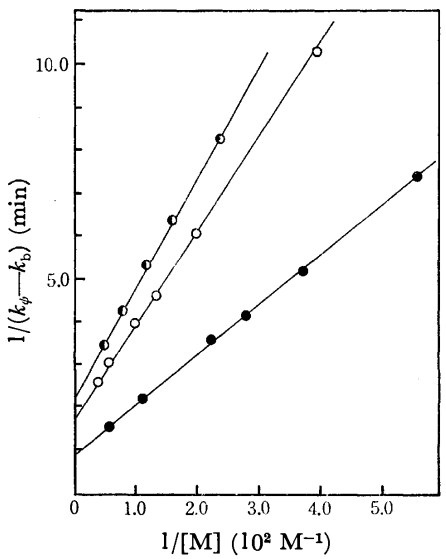

Fig. 2. $1/(k_\phi - k_b)$ *vs.* 1/[M]. The molar ratios of LauHis to CTAB are 1:8 (●), 1:16 (○), and 1:20 (◐), respectively. [M]=[LauHis]+[CTAB].

a) in phosphate buffer. b) in 2-amino-2-methyl-1,3-propanediol–HCl buffer.

The k and K values for mixed micelles are summarized in Table 2, together with those for CTAB micelle. It may be seen in this table that the mixed micelles consisting of the same components yield almost a constant K, regardless of the molar ratio of LauAm to CTAB. This may imply that the micelle–substrate complex formation takes place without electrical processes, since changes in the molar ratio of LauAm to CTAB should alter the micellar charge. This may be attributed to the fact that the substrate, PNPA, is electrically neutral.

It may also be seen in this table that the K value is a characteristic constant for each LauAm. If the micelle-substrate complex formation is regarded as a solubilization of PNPA into the interior of the micellar hydrocarbon phase, the K value should be a constant, regardless of the kind of LauAm in the mixed micelle. Thus, it is likely that the complex formation takes place near the micellar surface or the palisade layer of the micelle.

The treatment given in the present paper assumes that the molar ratio of the micellar substance to the substrate is 1:1. When n molecules bind with a substrate molecule, K in Eqs. (2) and (3) should be replaced by nK. However, no information on n could be obtained from the present data.

On the other hand, k increases as the fraction of LauAm increases, as is shown in Table 2. Since the surface layer of mixed micelles consists of CTAB and LauAm, the rate constant, k, may be expressed as:

$$k = k_a \frac{[\text{LauAm}]}{[M]} + k_c \frac{[\text{CTAB}]}{[M]} \qquad (4)$$

or:

$$k = (k_a - k_c)\frac{[\text{LauAm}]}{[M]} + k_c$$

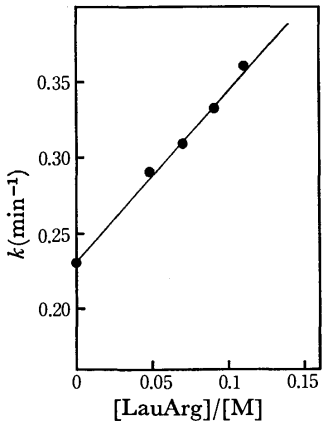

Fig. 3. Plot of k *vs.* [LauArg]/[M]. [M]=[LauArg]+[CTAB]

where k_a denotes the rate constant for the active site (LauAm), and k_c, that for the nonspecific site (CTAB).

For the LauArg–CTAB system, the variation in k with the molar ratio of LauArg to CTAB obeys Eq. (4), as is shown in Fig. 3. The intercept of the ordinate agrees well with the value of k for the CTAB micelle. It may be seen in Table 2 that the k's are much greater in mixed micelles than in the CTAB micelle and that k_c may be ignored as compared with k except in the case of LauArg. Thus, the k_a values for the other systems were estimated according to this relation:

$$k_a = k[\mathrm{M}]/[\mathrm{LauAm}]$$

which is found to be almost independent of the composition of the mixed micelles, as is shown in Table 2.

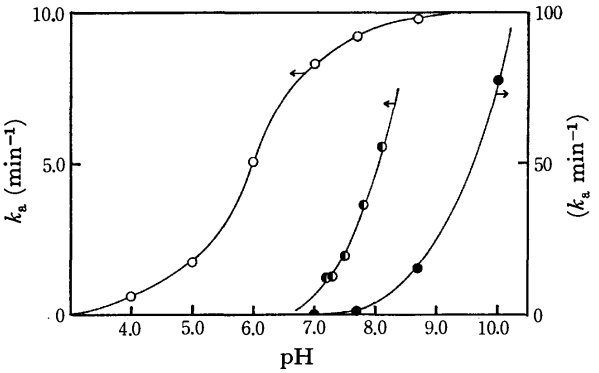

Fig. 4. pH dependence of k_a.
○: LauHis, ◐: LauLys, ●: LauTyr.
Buffer; 1/30 M phosphate (for LauLys), 1/20 M acetate pH 4—6 (for LauHis), 1/20 M Tris pH 7—8.7 (for LauHis and LauTyr), 1/20 M sodium carbonate-sodium hydrogencarbonate (for LauTyr).

The pH Dependence of k_a. The pH dependence of the catalytic activity has been measured; the results are shown in Fig. 4. The values of k_a varied with the pH to a great extent, in contrast to the small change in K. In mixed micelles of LauHis and CTAB, a sigmoidal curve was obtained. This suggests that k_a is proportional to the concentration of the dissociated form of the group with a pK_a value of *ca.* 6.0. Since the pK_a value of the imidazolium group of histidine in protein is 5.6—7.0,[7] the catalytic activity may be ascribed to the imidazolium group of LauHis.

For the mixed micelle of LauTyr and CTAB, it can be predicted from Fig. 4 that phenolate ions, the dissociated form of the side group of tyrosine, possess catalytic activity. The UV spectra of LauTyr were observed in order to find out evidence of dissociation. Two absorptions are found around 245 nm and 300 nm at pH 8.7; they are more enhanced at pH 10.0, while at pH 7.7 they disappear. These two absorptions correspond to those of tyrosine in an alkaline solution.[8] Therefore, it can be concluded that the dissociation of the *p*-hydroxyphenyl group of tyrosine is small at pH 7.7 and that it becomes appreciable at pH 8.7. Thus, it is evident that the catalytic activity of LauTyr is ascribable to the dissociated form of the *p*-hydroxyphenyl group. However, in the mixed micelles of LauTyr and SDS or $C_{12}E_6$ as well as the LauTyr solution without a detergent, the catalytic effect was very small, even at pH 8.7, where the absorption spectra associated with the phenolate ion were not observed. The dissociation of the *p*-hydroxyphenyl group of LauTyr incorporated into the micelle may be promoted by a positive charge at the surface of the CTAB micelle. Probably, the actual pH is higher in the vicinity of the surface of the mixed micelle than in the bulk phase because of an accumulation of hydroxide ions, which are responsible for the dissociation of the *p*-hydroxyphenyl group.

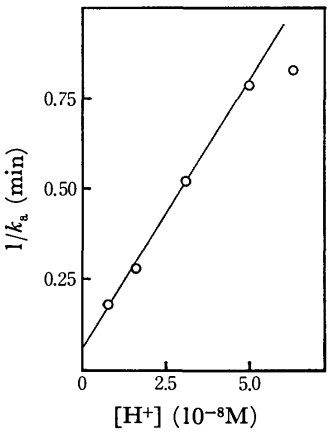

Fig. 5. $1/k_a$ *vs.* [H$^+$] for the mixed micelle of LauLys and CTAB.

From Fig. 4, it can be presumed that the dissociated form of the ε-amino group of N^{α}-lauroyllysine (LauLys) possesses catalytic activity. On this assumption, k_a is expressed by:

$$k_a = k_a^* \cdot \frac{K_a}{[\mathrm{H}^+]+K_a} \tag{6}$$

where k_a^* denotes the rate constant, which is independent of the pH, and K_a, the apparent dissociation constant of the functional group in the mixed micelle. By rearranging Eq. (6) we obtain:

$$\frac{1}{k_a} = \frac{[\mathrm{H}^+]}{k_a^* \cdot K_a} + \frac{1}{k_a^*} \tag{7}$$

The results for the mixed micelle of LauLys and CTAB obey Eq. (7), as is shown in Fig. 5. From the slope and

intercept of the plot, pK_a and k_a* were found to be 8.8 and 37 (min^{-1}) respectively. The value of pK_a determined from the kinetic data is somewhat smaller than that of the ε-amino group of lysine in an aqueous solution.[9] However, it may be thought that this smaller value of pK_a is caused by electrostatic interaction with a positive charge at the surface of the mixed micelle. Such an effect has already been shown in the mixed micellar system of N^{α}-myristoyl-L-histidine and CTAB.[3] A detailed study of the effect of the pH will be required in order to elucidate the mechanism underlying the catalytic action of the functional groups in mixed micelles.

Substituent Effects in the Ionization of *trans*-2-Substituted Cyclopropanecarboxylic Acids

Yoshiaki KUSUYAMA and Yoshitsugu IKEDA

Department of Chemistry, Wakayama University, Masagocho, Wakayama 640

(Received July 16, 1975)

The ionization constants of *trans*-2-substituted cyclopropanecarboxylic acids were determined in water and 50% aqueous ethanol at 25 °C. The substituent effects thus obtained were interpreted by the use of the four parameter equations presented by Yukawa and Tsuno. The transmitting resonance effect of *trans*-cyclopropylene is about a quarter that of *trans*-vinylene and a half that of *p*-phenylene.

There have been a number of reports on the analogy between a cyclopropane ring and a double bond. Previous investigations based on linear free-energy relationships (LFER) have suggested almost exclusively the possibility of the transmission of a resonance effect through a cyclopropane ring.[1] However, the degree of transmission of the resonance effect is still uncertain because of the use of limited data and the variety of treatments of the LFER. In connection with the previous study of the estimation of the electronic effects of the cyclopropane ring,[2] a definite answer has been sought concerning the degree of the transmission of conjugation through a *trans*-cyclopropylene. The ionization constants of *trans*-2-substituted cyclopropanecarboxylic acids have been determined in water and in 50% ethanol at 25 °C, and the substituent effects thus obtained have been interpreted in terms of the LFER reported by Yukawa and Tsuno.[3]

Results and Discussion

The pK_a values measured are listed in Table 1. The effects of the substituents in the two solvents were in the usual order and were correlated with each other, as is illustrated in the figure. The plot of the ΔpK_a values against the substituent constants, σ', σ^0, σ_p, σ^-, or σ^+, fails to give a linear relationship. The correlation coefficients proved to be from 0.885 to 0.94. However, an excellent correlation with a ρ value of 1.99 was obtained by means of σ_m with the correlation coefficient of 0.999 (in water), while the ionization of acrylic acids was correlated with the σ_p constants.[4] In the case of ionization in 50% ethanol, ρ and the correlation coefficient for σ_m were 2.92 and 0.998 respectively.

Yukawa and Tsuno successfully separated the polar effects of the substituent into inductive and resonance effects,[3] they expressed σ_m and σ_p as $0.87\sigma'+0.21\Delta\bar{\sigma}_R$ and $0.74\sigma'+0.685\Delta\bar{\sigma}_R$ respectively, where σ' is a polar substituent constant presented by Roberts[5] and where $\Delta\bar{\sigma}_R$ measures the capacities of the substituents to supply electrons by resonance.[3] Thus, the substituent effects (ΔpK_a) for the ionization of *trans*-2-substituted cyclopropanecarboxylic, *trans*-β-substituted acrylic, β-substituted propionic, and *p*-substituted benzoic acids are expressed by the equations given in Table 2. In the sets of the same structural type, such as XZCOOH, it seemed reasonable to assume that the ratio (*fr*) of the coefficient of $\Delta\bar{\sigma}_R$ to that of $\Delta\bar{\sigma}_R$ of the reference system is a measure of the ability of the Z group to transmit the resonance effect to the reaction site, *i.e.*, COOH, under the same reaction conditions. The *fr* values of (1) and (2) to (4) were 0.62 and 2.7 respectively. Thus,

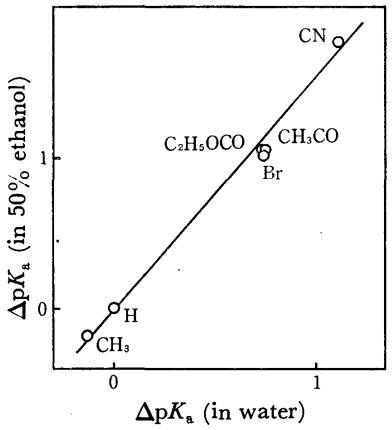

Fig. 1. Linear free energy relation for dissociation of *trans*-2-substituted cyclopropanecarboxylic acids at 25 °C.

the transmitting-resonance effect of *trans*-cyclopropylene is about a quarter that of *trans*-vinylene and a half that of *p*-phenylene.[6] Three models (a trigonally hybridized model,[7] a bent-bond model,[8] and a molecular orbital model[9]) for the bonding in cyclopropane, previously presented, have led to a prediction of the *p* orbital character of C–C bonds. Since there is no steric interaction between the substituent and the carboxy group in *trans*-2-substituted cyclopropanecarboxylic acids, the substituent and the carboxy group can both overlap with the cyclopropane ring. Thus, it is revealed that cyclopropylene is a transmitter of the resonance effect, although its action is rather poor.

The ratios(f_i) of the coefficients of σ' of (1) and (2) to that of σ' of (3) were 1.0 and 1.1 respectively, indicating that the transmission of the inductive effect was practically equal in all three series.

Experimental

The materials were identified on the basis of spectroscopic and gas-chromatographic measurements and elemental analysis. The NMR spectra were measured on a JEOL JNM-C-60HL (60 MHz) spectrometer, with tetramethylsilane employed as the internal standard. The structure assignments for the geometrical isomers were made by means of the NMR spectra of ring protons by means of shift reagents based on a generalization that the tendency of the shift of the signal of the *cis* proton to ethoxycarbonyl is larger than that of the shift of the *trans* protons.[10] Unsubstituted,[11] *trans*-2-methyl,[12] ethoxycarbonyl,[13] methoxycarbonyl[13] and bromocyclopropanecarboxylic[13] acids were synthesized by the methods described in the literature. The syntheses of other substituted cyclopropanecarboxylic acids will be described below.

Ethyl trans-2-*Ethoxycyclopropanecarboxylate.* To a mixture of commercial ethyl vinyl ether (100 g) and an anhydrous copper (I) sulfate catalyst (1 g), ethyl diazoacetate was added over a period of 1 h with rapid stirring. The mixture was then cooled to room temperature, and the catalyst was removed by filtration. The remaining ethyl vinyl ether was removed *in vacuo*, and the residue was distilled to give a main fraction boiling at 95—105 °C at 35 mmHg. Yield, 75 g. Pure ethyl *trans*-2-ethoxycyclopropanecarboxylate was obtained by fractional distillation; bp 66 °C/9 mmHg. NMR (CCl_4) δ 0.72—1.86 (3H, m, ring), 1.24 (3H, t, J=7 Hz, CH_3), 1.16 (3H, t, J=7 Hz, CH_3), 3.16—3.5 (1H, m, ring), 3.54 (2H, q, J=7 Hz, $COCH_2$), 4.06 (2H, q, J=7 Hz, ester CO_2CH_2), Found: C, 59.56; H, 9.04%. Calcd: C, 60.74; H, 8.92%.

trans-2-*Ethoxycyclopropanecarboxylic Acid.* Ethyl *trans*-2-ethoxycyclopropanecarboxylate (20 g) was saponified by refluxing with 6 g of sodium hydroxide in 40% ethanol to yield, after acidification, extraction with 50 ml of ether, and distillation *in vacuo*, 13 g of *trans*-2-ethoxycyclopropanecarboxylic acid; bp 119 °C/10 mmHg. NMR (CCl_4) δ 1.0—1.4 (2H, m, ring), 1.16 (3H, t, J=7 Hz, CH_3), 1.49—1.82 (1H, m, ring), 3.35—3.6 (1H, m, ring), 3.35—3.75 (2H, q, (J=7 Hz); neut. equiv. Found 132, Calcd 130.

Ethyl trans-2-*Methoxycyclopropanecarboxylate.* To a stirred mixture of 100 g of methyl vinyl ether and 1 g of anhydrous copper (I) sulfate in 100 ml of hexane at 35 °C, we added, drop by drop, 110 g of ethyl diazoacetate. After the reaction has been completed, the catalyst was removed by filtration. The solvent and unreacted methyl vinyl ether were removed *in vacuo*, and the residue was distilled to give 65 g of crude products; bp 75—100 °C/15 mmHg. The fractional distillation afforded 5 g of pure ethyl *trans*-2-methoxycyclopropanecarboxylate; bp 61—63 °C/15 mmHg. NMR (CCl_4) δ 0.80—1.80 (3H, m, ring), 1.23 (3H, t, J=7 Hz, CCH_3), 3.32 (3H, s, OCH_3), 4.6 (2H, q, J=7 Hz, CO_2CH_2C). Found: C, 56.36; H, 8.40%. Calcd: C, 58.31; H, 8.39%.

trans-2-*Methoxycyclopropanecarboxylic Acid.* Ethyl *trans*-2-methoxycyclopropanecarboxylate (6 g) was hydrolyzed by refluxing with sodium hydroxide (2.6 g) in 70 ml of water to yield, after a routine treatment, *trans*-2-methoxy-cyclopropanecarboxylic acid (2 g); bp 116 °C/16 mmHg. NMR ($CDCl_3$) δ 1.16—1.45 (2H, m, ring), 1.60—1.90 (1H, m, ring), 3.41 (3H, s, CH_3), 3.3—3.8 (1H, m, ring). neut. equiv: Found 117, Calcd 116.

trans-2-*Cyanocyclopropanecarboxylic Acid.* The saponification of ethyl *trans*-2-cyanocyclopropanecarboxylate (8 g)[14] with potassium carbonate (4 g) in water (20 ml) gave crude *trans*-2-cyanocyclopropanecarboxylic acid (1.5 g). Pure acid was obtained by recrystalization from benzene; mp 127—128 °C. NMR ($CDCl_3$) δ 1.80—2.45 (2H, m), 0.92—1.70 (2H, m). neut. equiv: Found 112, Calcd 111.

Ethyl trans-2-*Acetylcyclopropanecarboxylate.* This ester was obtained by the reaction of *trans*-2-ethoxycarbonylcyclopropanecarbonyl chloride (25 g) with dimethyl cadmium in benzene prepared by the treatment of methyl magnesium bromide (about 0.17 mol) with cadmium chloride (20 g); bp 105 °C/19 mmHg. IR (in CS_2) 1730 cm^{-1} (C=O, ketone), 1710 cm^{-1} (C=O, ester), NMR (CCl_4) δ 1.25 (3H, t, J=7 Hz, $OCCH_3$), 1.25—1.45 (2H, m, ring), 1.8—2.15 (1H, m, ring), 2.16—2.6 (1H, m, ring), 2.23 (3H, s, $COCH_3$), 4.05 (2H, q, J=7 Hz, CO_2CH_2C). Found: C, 60.72; H, 8.07%, Calcd: C, 61.51; H, 7.74%.

trans-2-*Acetylcyclopropanecarboxylic Acid.* Ethyl *trans*-2-acetylcyclopropanecarboxylate (6.2 g) was hydrolyzed with sodium hydroxide (1.6 g) in 80% ethanol (35 ml) to yield *trans*-2-acetylcyclopropanecarboxylic acid (4 g); bp 122—124 °C/3 mmHg, mp 56—57 °C. NMR (CCl_4) δ 1.88—2.60 (2H, m, ring), 1.20—1.55 (2H, t, J=6 Hz, ring), 2.26 (3H, s, CH_3). neut. equiv: Found 128, Calcd 128.

The ionization constants were determined by a potentiometric titration of substituted cyclopropanecarboxylic acids (0.005 M) with sodium hydroxide (0.02 M) according to the previously outlined procedure.[2]

The authors wish to thank Professor Yasuhide Yukawa and Professor Yuho Tsuno for their many helpful discussions and suggestions during this work.

The Reaction of Tris(diethylamino)bismuthine with Carbonyl Compounds and the Reactivity Comparison of Several Metal Amides

Fumio ANDO, Kumao OHASHI, and Jugo KOKETSU

Department of Chemistry, Chubu Institute of Technology, 1200 Matsumoto, Kasugai, Aichi 487

(Received July 28, 1975)

Tris(diethylamino)bismuthine (I) reacted with the sterically unhindered carbonyl compounds to give the corresponding enamines. The reactivity of the metal amides $M(NR_2)_n$ (M=As, Sb, Bi, and Ti; R=Me and Et) toward the carbonyl compounds was examined. The order of reactivity: Bi>Sb>Ti>As was observed for the addition reaction that took place as the first step in the reaction. On the other hand, the order of enamine formation was Sb>Ti>As>Bi. The effectiveness of the amination reaction depends both on the reactivity of metal amides to carbonyl groups and also on the affinity for oxygen of metal atoms. Although bismuth amide gives the addition product very rapidly, because of its poor affinity for oxygen, the addition products decompose thermally on prolonged standing or on distillation giving large amounts of starting carbonyl compounds along with small amounts of enamines.

The preparation and reactions of tris(dialkylamino)-bismuthines with heterocumulenes have been reported.[1] The reactions of these reagents with acetic anhydride and heterocumulenes were found to be much easier than those of arsine amide or stibine amide, and the reagents could be expected to be useful for aminating carbonyl compounds. The reactions of various carbonyl compounds with the following organometallic compounds have been reported: tributylmethylaminotin,[2-4] tris-(dimethylamino)borane,[5,6] tris(dimethylamino)-arsine,[7-9] tetrakis(dimethylamino)titanium,[4,7,10-13] and tris(dimethylamino)stibine.[14,15] The amination ability order of metal amides, $M(NR_2)_n$, towards carbonyl compounds has been found to be Ti>As>B>Sn.[7] Tris(dimethylamino)stibine was proved to have an amination ability towards carbonyl compounds comparable to that of tetrakis(dimethylamino)titanium.[14,15] Amination of carbonyl compounds by metal amides is known to be a very easy way for obtaining the versatile synthetic intermediate enamines, because the reaction is very fast and the by-product (metal oxide) can be separated easily. Therefore it is of significance to find out the factors which control the amination reactions. This paper reports the reaction of tris(diethylamino)bismuthine (I) with carbonyl compounds along with a comparison of the reactivity of various metal amides.

Experimental

General Remarks. All reactions were carried out under argon. IR and NMR spectra were taken on a JASCO A-1 spectrometer and a JEOL-C 60 HL spectrometer respectively. Glc analyses were carried out on a Shimadzu GC 6A apparatus, using PEG 6000 (10%) on Shimalite W-301 (1.0 m) and helium as a carrier gas.

Reagent. The preparation of tris(diethylamino)bismuthine (I), was reported previously.[1] Tris(diethylamino)-arsine (II), -stibine (III), and tetrakis(diethylamino)titanium (IV) were prepared by the same method reported in the preparation of their dimethylamino derivatives; II: bp, 47—50 °C/0.08 mmHg; yield, 72%, III: bp, 59—62 °C/0.02 mmHg; yield, 82% and IV: bp, 96—98 °C/0.12 mmHg; yield, 64%.

The other commercial reagents were dried over calcium hydride and distilled before use.

Reaction of I with Benzaldehyde. To a solution of I (3.0 g, 7.07 mmol) in 10 ml of ether, benzaldehyde (0.74 g, 7.00 mmol) was added slowly with stirring. A slightly exothermic reaction took place giving a yellowish solution. After removal of the solvent, a viscous yellowish liquid remained. IR spectra of the liquid showed no absorption of carbonyl group and a new absorption at 1060 cm^{-1} (ν_{C-O}). NMR also showed no reasonance of aldehyde-proton but a new reasonance of -OCH-N moiety at δ 4.10. On distillation of the liquid under reduced pressure, benzaldehyde was recovered almost completely (0.65 g). The distillation residue was a dark black solid whose structure was not identified. Hydrolysis of the reaction mixture, and the following extraction with ether gave mostly (90%) benzaldehyde with several materials detected on a TLC. These materials was not identified.

Reaction of I with Reactive Carbonyl Compounds. A typical

a) Coated on NaCl Crystal. b) In $CHCl_3$ (V, VI and VII), in $CDCl_3$ (VIII).

reaction (with cyclohexanone) is described.

Details are given in Tables 1 and 2. To a solution of (I) (2.82 g, 5.92 mmol) in 10 ml of ether, cyclohexanone (0.87 g, 8.4 mmol) was added slowly with stirring. A slightly exothermic reaction took place giving a small amount of a yellowish grey precipitate. The precipitate was removed by filtration and the filtrate was condensed on a rotary evaporator. Distillation of the remaining viscous liquid which showed no carbonyl absorption on its IR spectra gave a large amount (0.44 g, 50% recovery) of cyclohexanone and the aminated product; *N,N*-diethylcyclohex-1-enylamine in 49% yield (0.39 g); bp, 74.0—75.0 °C/10 mmHg, NMR (in $CHCl_3$) δ 4.49 (m, 1H), 2.92 (q, 4H), 2.04 (m, 4H), 1.59 (m, 4H) and 0.37 (t, 6H), IR 1630 cm^{-1} ($\nu_{C=O}$). These spectroscopic data coincide with those of the reaction product of cyclohexanone with III[14,15] or IV.[4,7,10-13]

Reaction of Acetophenone with Various Metal Amides. The reactions of acetophenone with I—IV as well as with their dimethyl amino homologues were carried out under the same reaction conditions. To a solution of metal amide (5 mmol) in 10 ml of ether, acetophenone (0.9 g, 7.5 mmol) was added slowly with stirring. The reaction mixture was kept at 20 °C for 24 hr. The same treatment as above gave α-dimethylaminostyrene or α-diethylaminostyrene. The yields of the substituted styrenes are given in Table 3.

Measurements of the Rate of Carbonyl Compounds Consumption on the Reactions with I—IV. An equimolar (0.05 mol/l) reaction between metal amide and carbonyl compounds at an appropriate temperature was started by mixing each reagent dissolved in chlorobenzene containing a constant amount of *o*-dichlorobenzene as an internal standard. Aliquots of the reaction mixture were withdrawn at appropriate time intervals and the remaining amounts of the carbonyl compounds were determined by GLC analyses. The results are shown in Figs. 1 and 2.

Results and Discussion

The amination of various carbonyl compounds with tris(dimethylamino)stibine has been studied,[14] and the amination ability is found to be comparable to that of tetrakis(dimethylamino)titanium which has been known as the most effective amination reagent so far.[7] Bismuth amide has labile bonds and could be expected to be an effective amination reagent. In fact bismuth amides are very reactive towards acetic anhydride and heterocumulenes and also towards moisture and oxygen in air.[1] Contrary to expectation, I gave only poor yields of amination products even in the reactions with reactive carbonyl compounds such as cyclohexanone, cyclopentanone, diethyl ketone and acetophenone (Table 1). The structures of the amination products were determined by comparison of their IR and NMR spectra with those of the reaction products obtained in the reaction between III or IV and the corresponding carbonyl compounds.[4,7,10-15] The reaction mixture of I with these carbonyl compounds shows no carbonyl absorption on their IR spectra. This result together with that of the reaction of I with benzaldehyde indicate that I could react with such carbonyl compounds quantitatively. Distillation of the reaction mixture under reduced pressure, however, gave only small amounts of aminated product and large amounts of starting carbonyl compounds (Table 1). Table 2 shows the yields of the enamines in the reaction of acetophenone with various metal amides. Bismuth amides gave the least amounts of the enamines among the metal amides examined. These unexpected observations prompted us to compare the reactivity of several

metal amides. Figure 1 shows the consumption curves of benzaldehyde (A), acetophenone (B), and di-isopropyl ketone (C), in the reaction with compounds I—IV. The corresponding consumption curves of DMF with the same metal amides are shown in Fig. 2. They show only the consumption of the carbonyl compounds and not the formation of aminated products. It has been proposed that the reaction mechanism includes an addition step of metal–nitrogen bond to carbonyl groups (step A), followed by a deoxygenation step of carbonyl oxygen by metal moieties forming metal oxides (step B).[7,14] The results (Figs. 1 and 2) reveal that the bismuth amide has the highest reactivity in the addition step (step A) and reactivity order of $M(NEt_2)_n$ ($n=3$ or 4) is Bi>Sb>Ti>As in this step. The effectiveness of amination reaction is Sb>Ti>As>Bi based on the yield of the amination products (Table 3). This result can be explained in terms of the affinity for oxygen of the metal atoms. The properties of group Va metals have not been compared, but they could be parallel to factors such as the metal–oxygen bond energies, and the tendency of the quarternary onium salt formation. The σ-bond energies for the phosphorus–, arsenic–, and stibine–oxygen bonds have been reported to be 86,[16] 72 and 71 kcal/mol,[17] respectively. There have been several observations of the fact that the stability order of quinqivalence state of group Va metal is P>As>Sb>Bi.[18] Because of the poor affinity of bismuth atom for oxygen, the addition products decomposed thermally giving mostly original carbonyl compounds and unidentified decomposition products of bismuth amide. This is shown in the reaction of I with benzaldehyde (Fig. 1-A). Reappearance of benzaldehyde from the reaction mixture was observed at a high temperature (100 °C). In the reaction with amide carbonyls, group Va metal amides are apparently inferior to titanium amide from a preparative viewpoint.[14] Figure 2 shows, however, I could add to the amide carbonyl group much faster than IV, but the thermal decomposition of the addition products occurred again easily, giving the starting amide carbonyl. The reason why titanium amide could have a large reactivity towards amide carbonyl is not known but it may be partly ascribed to the fact that the titanium atom is a transition metal and has vacant d orbitals which increase the interactions with the lone pairs of the oxygen atom.

Elimination and Nucleophilic Substitution on Nitrogen Atom. Reactions of *O*-Aroyl-*N*,*N*-di(*p*-substituted benzyl)- and *O*-Aroyl-*N*-benzoyl-*N*-benzylhydroxylamines with Various Nucleophiles in Dipolar Aprotic Solvents[1]

Shigeru OAE and Tadamitsu SAKURAI*

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

* *Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Osaka 552*

(Received July 31, 1975)

The reactions of the title compounds with various nucleophiles were found to proceed through either elimination or nucleophilic substitution on the nitrogen atom depending on both the structure of the substrate and the nature of nucleophiles used. The effect of substituent and the primary isotope effect (k_H/k_D of 7.6 and 8.1 with NaN_3 and LiCl at 30 °C) on the elimination of *O*-(*p*-nitrobenzoyl)-*N*,*N*-dibenzylhydroxylamine revealed that the reaction is an E2 process involving the rate-determining proton abstraction by base and proceeds *via* an ionic transition state of an ideal concerted type. Nucleophilic substitution on the trivalent nitrogen atom has been inferred for the reactions with such nucleophiles as diethyl sulfide, *p*-toluenethiol and sodium cyanide on the basis of product distribution.

The nucleophilic substitution and elimination reactions on carbon atom have been studied extensively in the past and well understood.[2] However, no systematic study concerning the nature of both nucleophilic substitution and elimination reactions on the trivalent nitrogen atom has been attempted, though there have been some investigations on the nucleophilic substitution[3] and elimination[4] reactions at oxygen atom. A careful literature survery reveals that there are a few reactions which appear to be the nucleophilic substitution[5] and elimination[6] reactions on the nitrogen atom. Very recently, the occurrence of S_N2 type reaction on nitrogen atom has been well confirmed on the basis of both detailed kinetic study and product analysis by us[7b] and Krueges *et al.*[7a] However, as to the elimination reaction on the trivalent nitrogen atom giving either C–N double bond or C–N triple bond, a more critical examination would be necessary.

Thus, we have prepared *O*-aroyl-*N*,*N*-di(*p*-substituted benzyl)- and *O*-aroyl-*N*-benzoyl-*N*-benzylhydroxylamines as model compounds, and allowed them to react with various nucleophiles in dipolar aprotic solvents for studying both nucleophilic substitution and elimination reactions on the nitrogen atom.

Results and Discussion

Reactions of (I) (X=CH_2; Y=CO; R^1=CH_3, H, Cl; R^2=p-NO_2, 3,5-$(NO_2)_2$) with Charged Nucleophiles. The reactions of (I) with charged nucleophiles in dimethyl sulfoxide (DMSO) gave substituted benzaldehydes, substitutted benzylamines and substituted benzoate ions in good yields respectively, as indicated in Table 1. There are two conceivable mechanisms to explain the product distribution. Although the formation of substituted benzaldehydes could be interpreted as a modification of the Kornblum reaction,[8] this mechanism may be ruled out since benzaldehyde (R^1=H) was also obtained (85% yield) when *N*,*N*-dimethylformamide (DMF) was used as a solvent. Formation of the aldehyde and the amine can be explained by assuming the imine (IV) as the precursor of which intermediacy was confirmed by direct hydrolysis of the authentic imine (IV) in the presence of HCl in DMSO.

Moreover, the imine (IV, R^1=H) was actually isolated from the reaction with NaOH as a nucleophile probably because of lower acidity of HNu (Nu=OH) than other HNu (Nu=N_3, Cl, I). Interestingly, the

a) as carboxylic acid. b) Reaction was carried out in DMF. c) as *S*-benzylthiuronium salt. d) Isolation was not carried out.

reaction of I (R^1=H; R^2=*p*-NO_2) with sodium *p*-chlorobenzenecarbothioate gave the addition product along with the expected products, indicating clearly that the imine (IV) is involved during these reactions.

On the other hand, there are two conceivable processes to give the imine (IV). The one is the base-catalyzed elimination of the carboxylate ion from the starting material (Path A) and the other, the decomposition of the initial product (II), which was formed by the nucleophilic substitution on the nitrogen atom, due to the instability of the N–Nu bond of II and then the nitrenium ion (III) will easily decompose to afford the imine (IV).[9]

Isolation of the imine (IV) in the reaction of I (R^1=Cl; *p*-R^2=NO_2) with NaN_3 may be due to the increased stability of the imine (IV) intermediate, bearing electron-withdrawing *p*-chloro substituent.

Kinetics of the Reactions of I (X=CH_2; Y=CO; R^1=CH_3, H, Cl; R^2=p-NO_2, 3,5-$(NO_2)_2$) with NaN_3 and LiCl in DMSO. In order to make a choice between the two mechanisms (Path A and B) and to know the nature of these reactions in detail, we carried out the kinetic experiments using some substituted hydroxylamines (I) under pseudo-first order conditions with a large excess of nucleophiles. The over-all reaction rate was measured spectrophotometrically by following the increase in absorbance of *p*-nitro- and 3,5-dinitrobenzoate ions at 290 nm. Hydrogen–deuterium kinetic

a) Concentration of nucleophiles is 12 times excess, *i.e.*, [Substrates]$=6.9\times10^{-3}$ mol/l, [Nucleophiles] $=8.3\times10^{-2}$ mol/l. b) Pseudo-first order rate constants and error limits are standard deviation.

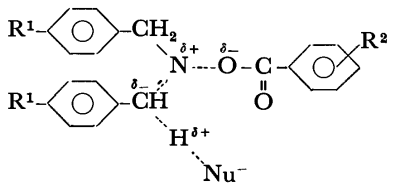
isotope effect was measured using the substrate which was labeled with D at the benzylic position of I under the same condition.

Good pseudo-first order kinetic behaviors were observed and the kinetic results are summarized in Table 2. As seen from Table 2, the isotope effects are 7.6 and 8.1 for the reactions of I (R^1=H; R^2=p-NO_2) with NaN_3 and LiCl as nucleophiles at 30 °C, respectively.

On the other hand, it has been generally known that secondary hydrogen isotope effects are $k_H/k_D=1.00$ for S_N2 reaction and $k_H/k_D=1.15$ for S_N1 reaction.[10] The isotope effect, thus, clearly indicates that the reaction is of base-catalyzed elimination (Path A). The order of the reactivities of the halide ions, $Cl^->Br^->I^-$, deduced from the recovered amounts of the starting material and the reaction times, also support that the reaction involves the rate-determining proton abstraction by the base.

The substituent effect (R^1) gave hardly any correlation with Hammett σ value. Apparently, an electron-withdrawing substituent such as Cl accelerated the reaction, while an electron-donating substituent (CH_3) could not retard it. On the other hand, the substituent effect (R^2) indicates the reaction rate to increase with the increase in electron-withdrawing ability of the substituent. This is also supported by the observation that the staring material was recovered in 63% yield for the reaction of I (R^1=H; R^2=p-OCH_3) with NaN_3, while no starting material was recovered in the reaction of I (R^1=H; R^2=p-NO_2) under the same condition. The activation parameters for the reaction of I (R^1=H; R^2=p-NO_2) with NaN_3 in DMSO are $\Delta H^{\ddagger}$, 17.4 kcal/mol and $\Delta S^{\ddagger}$, −20.2 *e.u.* respectively.

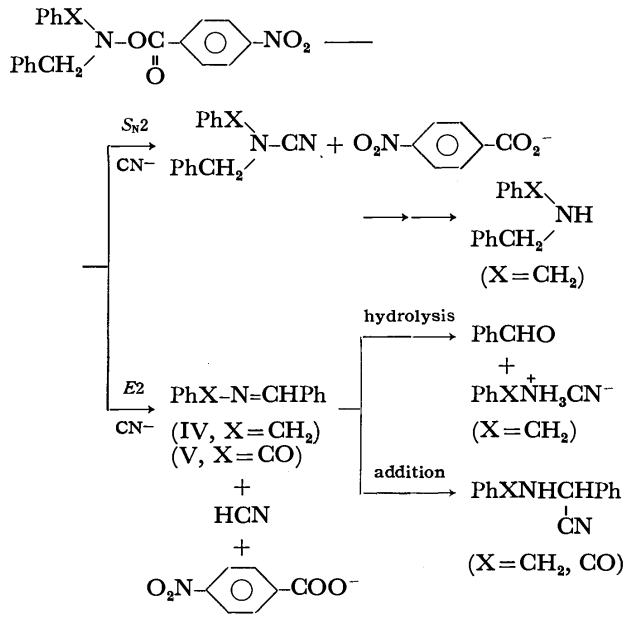
On the basis of these experimental observations, one can assume that the elimination reaction on the trivalent nitrogen atom involves the ionic transition state of an ideal concerted type like in the carbonyl-forming



elimination reaction of benzyl and 9-fluorenyl nitrates where primary hydrogen isotope effects are 5.94 for the former nitrate and 4.3 for the latter nitrate at 30 °C.[4b]

Reactions of I (X=CH_2, CO; Y=CO, SO_2; R^1=H; R^2=p-NO_2, p-Cl, p-OCH_3, 2,4,6-$(CH_3)_3$) with NaCN and KCN. The reaction of (I) (X=CH_2; Y=CO; R^2=p-NO_2) with NaCN in DMSO unexpectedly gave the dibenzylamine which may be formed *via* *N,N*-dibenzylcyanamide as the precursor in a substantial yield along with the products which were produced by the elimination (Path A). Among these products, the α-aminonitrile must be formed by the addition of HCN to the imine (IV). Although in a previous experiment[1] we have reported that the above reaction yields the *N,N*-dibenzylcyanamide, a careful reexamination revealed the cyanamide to be a mixture of dibenzylamine and an unidentified product bearing cyano group, which could not be separated from the other.

Meanwhile, a mechanism involving the nucleophilic attack of cyanide ion upon oxygen atom of the N-O bond in (I) seems to be unlikely since the anion of dibenzylamine is a very poor leaving group in DMSO.



Therefore, the scheme of the reaction with cyanide ion is depicted as follows.

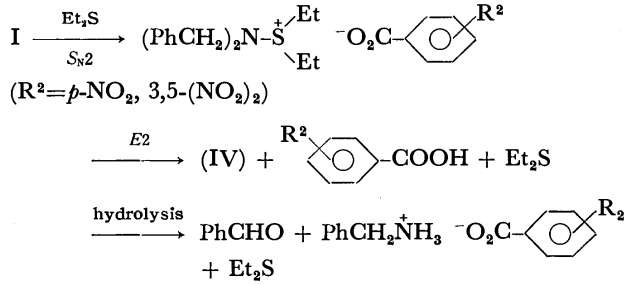
Neither α-aminonitrile nor dibenzylamine was found among the products when the leaving group changes from *p*-nitrobenzoyloxy to 3,5-dinitrobenzoyloxy groups as seen in Table 1. In this reaction, a Meisenheimer-type complex would be formed in the main route like in the reaction of *O*-(3,5-dinitrobenzoyl)-*N*-aroyl-*N*-arylhydroxylamines with cyanide ion in DMSO[11] since a strong absorption band appeared at 602 nm immediately upon addition of NaCN. Furthermore, the final products were those which are expected by a minor path, *i.e.*, Path A.

Here, it is interesting to examine the effect of substituents X, Y and R^2 on the product distribution, namely, the Substitution/Elimination ratio, since only the reaction with cyanide ion affords both substitution and elimination products on the nitrogen atom. The elimination-addition product, *i.e.*, α-benzoylamino-α-phenylacetonitrile, was obtained in a good yield by replacing a methylene group by a carbonyl group for the substituent X when substituents Y and R^2 are carbonyl and *p*-nitro groups. The yield of α-aminonitrile is better in DMSO than in DMF.

A similar tendency was observed in the reaction with I (X=CO; Y=SO_2; R^2=2,4,6-$(CH_3)_3$). Further inspection of the results in Table 1 reveals that introduction of more electron-donating substituents such as Cl and OCH_3 for R^2 in place of NO_2 group resulted in a predominant elimination according to Path A. Thus, the substitution product was shown to be obtained only when the substituents X, Y and R^2 are methylene, carbonyl and *p*-nitro groups, respectively. No formation of benzaldehyde in the reaction of I (X=CO; Y=CO; R^2=*p*-NO_2) with NaCN may be ascribed to the difference in stabilities of either the imine (IV) and (V) or the addition products which are obtained by the addition of HCN to the imine (IV) and (V). Accordingly, in the reaction with cyanide ion, the product distribution seems to be sensitive to the substituents R^2, X and Y.

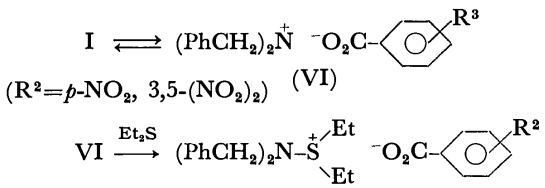
Reactions of I (X=CH_2; Y=CO; R^1=H; R^2=p-NO_2, 3,5-$(NO_2)_2$) with Diethyl Sulfide and p-*Toluenethiol.* The reaction of I with nucleophiles such as sulfide and thiol is expected to proceed *via* nucleophilic substitution on the nitrogen atom at the initial step due to the very low proton affinity of these nucleophiles because the occurrence of elimination requires a high proton affinity of nucleophiles.

As indicated in Table 1, the reactions of I (R^2=*p*-NO_2, 3,5-$(NO_2)_2$) with an excess of diethyl sulfide were found to give the products which are same as those in



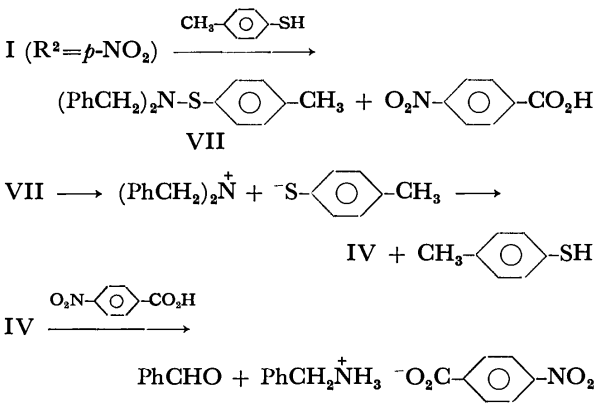
the reaction with NaN_3. Therefore, the following mechanism involving the initial nucleophilic substitution and the subsequent elimination appears to be the most plausible, judging from the nature of the nucleophile used.

These results suggest the initial step of the reaction to proceed *via* a S_N2 path on the nitrogen atom like in the reaction of *O*-2,4-dinitrophenylhydroxylamine with phenyl methyl sulfide.[7a] One can also assume that these reactions proceed through the S_N1 path, namely, by forming dibenzylnitrenium ion as an intermediate because of the bulky benzyl groups, as shown below. If the ion-pair intermediate (VI) would exist, this very

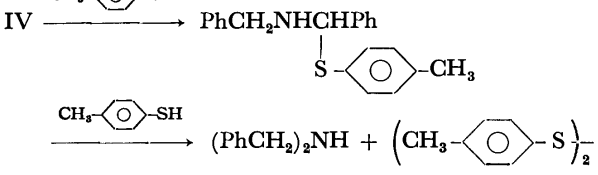


reactive nitrenium ion must yield benzaldehyde and benzylamine *via* the imine (IV). The starting material, however, was recovered nearly quantitatively when it was allowed to stand for 50 hr at room temperature in the absence of any nucleophile. Therefore, the S_N1 path seems to be unlikely, though no detailed mechanism for this reaction can be elucidated at present.

In the reaction with *p*-toluenethiol, a same reaction scheme as above may be applied on the basis of product distribution in Table 1. The sulfenamide (VII) which was produced by a S_N2 reaction on the trivalent



nitrogen atom at the initial step will decompose to give the nitrenium ion and *p*-toluenethiolate ion. No formation of dibenzylamine excludes the following two possibilities, namely, the nucleophilic attack of the thiol upon the sulfur atom of the sulfenamide (VII) giving dibenzylamine and the disulfide, and the addition of the thiol to the imine affording dibenzylamine and the disulfide as shown below. The



disulfide obtained may be formed by the oxidation of the thiol in DMF. This is confirmed by the control experiment independently.

Recently, Krueger *et al.*[7b] have shown that for substitution on the trivalent nitrogen atom polarizability of the nucleophile plays a major role, with basicity making a minor contribution. Their results support the earlier prediction by Edwards and Pearson.[12]

In the reactions of (I) (X=CH_2; Y=CO; R^1=H; R^2=*p*-NO_2) with various nucleophiles in DMSO, proton affinity (basicity) of the nucleophiles plays an important role, since the elimination can compete with the nucleophilic substitution on the nitrogen atom in this model compound (I). Thus, reactions with charged nucleophiles such as N_3^-, X^- (X=Cl, Br, I) and OH^- underwent elimination reaction, while reactions with sulfide and thiol underwent nucleophilic substitution at the initial step despite the presence of a bulky benzyl group.

Experimental

Materials. *N,N*-Dibenzylhydroxylamine was prepared according to the method of L. W. Jones and C. N. Sneed, mp 123—124 °C (lit, 124 °C).[13] *N*-Benzoyl-*N*-benzylhydroxylamine was prepared by the reaction between benzoyl chloride (1 mol) and *N*-benzylhydroxylamine (2 mol), which was synthesized according to the method of L. W. Jones and C. N. Sneed, in dry ether at 0 °C. Recrystallization from ethanol–water gave white needles, mp 107—108 °C. *O*-Aroyl-*N,N*-di(*p*-substituted benzyl)- and *O*-aroyl-*N*-benzoyl-*N*-benzylhydroxylamines were obtained by the reactions of aroyl chlorides with *N,N*-di(*p*-substituted benzyl)hydroxylamines, and with *N*-benzoyl-*N*-benzylhydroxylamine respectively under usual Schotten-Baumann conditions. The physical properties of these hydroxylamines are listed in Table 3.

Solvents. Dichloromethane was distilled after drying over calcium chloride and acetonitrile was distilled over phosphorus pentoxide. Dimethyl sulfoxide was distilled twice over activated alumina and *N,N*-dimethylformamide was distilled under reduced pressure.

Nucleophiles. Alkali-metal azide, halides, hydroxide and cyanide were all commercial products which were used without further purification other than drying at 100—120 °C overnight *in vacuo*. Sodium *p*-chlorobenzenecarbothioate was prepared from the reaction of *p*-chlorothiobenzoic acid with sodium hydroxide and was used without further purification after drying *in vacuo*. Diethyl sulfide and *p*-toluenethiol were used after purification by distillation.

General Procedure for the Reactions of O-*Aroyl*-N,N-*di*(p-*substituted benzyl)hydroxylamines with Nucleophiles such as* NaN_3, *LiCl, NaI, NaOH, and* $NaSCOC_6H_4Cl$-p. A small excess of a nucleophile (2.3—3.0 mmol) was added into DMSO (8 ml) solution of the hydroxylamine (2.0—2.3 mmol) in a reaction vessel and the whole solution was stirred with magnetic stirrer at room temperature for 15—50 h. After the reaction had subsided, the reaction mixture was poured into water (120 ml) and then products were extracted twice with dichloromethane (40 ml). The dichloromethane solution was washed with water several times and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded the residual oil, which was then chromatographed on silica gel, eluting with dichloromethane. The aqueous layer was acidified slightly with dil-HCl aqueous solution and extracted twice with chloroform (60 ml), which was then washed with water several times. After drying over anhydrous sodium sulfate, evaporation of chloroform gave the crude *p*-nitro- and 3,5-dinitrobenzoic acids. Next, the acidic aqueous solution was made alkaline with sodium carbonate and extracted twice with dichloromethane (40 ml), and dried over anhydrous sodium sulfate. Removal of solvent *in vacuo* gave *p*-substituted benzylamines.

Structures of the products isolated were identified by comparing their physical properties with those of the authentic compounds.

N-Benzylidenebenzylamine, which was obtained in the reaction with NaOH, was hydrolyzed to give benzaldehyde and benzylamine when the imine obtained was passed through silica gel column. Therefore, yields of the imine and benzaldehyde were determined before separation by means of NMR spectroscopy.

Addition product, i.e., α-benzylaminobenzyl p-chlorobenzenecarbothioate, which was isolated in the reaction with sodium *p*-chlorobenzenecarbothioate, was recrystallized from benzene–hexane to give colorless needles, mp 162—163 °C; IR (KBr) 3300, 1640 cm^{-1}; NMR ($CDCl_3$) δ 4.51 (s, 1H), 4.61 (s, 2H), 6.86 (broad s, 1H), 7.13—7.90 (m, 14H); Anal. Found: C, 68.60; H, 4.77%. Calcd for $C_{21}H_{18}NOSCl$: C, 68.56; H, 4.93%.

Reactions of O-(p-Substituted Benzoyl)-N,N-dibenzylhydroxylamines with Cyanide Ion. A typical run was as follows: to the *O*-(*p*-nitrobenzoyl)-*N,N*-dibenzylhydroxylamine (2.6 mmol) in DMSO (7 ml) was added NaCN (2.7 mmol) at room temperature. After 15 h, the reaction mixture was poured into water (120 ml) and then products were extracted twice with dichloromethane (40 ml). After drying over anhydrous sodium sulfate, solvent was evaporated *in vacuo*. The resulting residue was subjected to column chromatography packed with silica gel using dichloromethane as eluent, and three fractions, benzaldehyde (7%), α-benzylamino-α-phenylacetonitrile (22%) and dibenzylamine (58%) were obtained respectively. *p*-Nitrobenzoic acid (87%) and benzylamine (8%) were isolated by similar work-up as above. Structures of the products were determined in comparison with authentic samples. The α-aminonitrile was colorless oily liquid; IR (neat) 3330, 2225 cm^{-1}; NMR ($CDCl_3$) δ 1.80 (s, 1H), 3.83 (s, 2H), 4.58 (s, 1H), 7.09—7.63 (m, 10H). This α-aminonitrile was allowed to react with an equimolar amount of *p*-nitrobenzoyl chloride to afford α-*p*-nitrobenzoylbenzyl-α-phenylacetonitrile in 87% yield, which was recrystallized from benzene to give pale yellow needles, mp 148—149 °C; IR (KBr) 1645, 1525, 1350 cm^{-1}, ν_{CN} was too weak to detect; NMR ($CDCl_3$) δ 4.52 (dd, 2H), 6.73 (s, 1H), 6.86—7.42 (m, 5H), 7.47 (s, 5H), 7.92 (dd, 4H); Anal. Found: C, 71.76; H, 4.56; N, 11.24%. Calcd for $C_{22}H_{17}N_3O_3$: C, 71.15; H, 4.61; N, 11.31%.

Reactions of O-Aroyl-N-benzylhydroxylamines with Cyanide Ion. For a typical run, a mixture of *O*-(*p*-nitrobenzoyl-*N*-benzoyl-*N*-benzylhydroxylamine (2.2 mmol) and NaCN (2.7 mmol) was dissolved in DMSO (8 ml) in a reaction vessel, and the mixture was stirred for 15 h at room temperature. The contents were then poured into water (120 ml), the solution was extracted, and the products were separated by column chromatography through silica gel using dichloromethane as eluent. The product obtained was α-benzoylamino-α-phenylacetonitrile (58%) which was recrystallized from benzene–hexane, mp 147.5—148.5 °C; IR (KBr) 3250, 2220, 1640 cm^{-1}; NMR ($CDCl_3$) δ 6.32 (d, 1H), 7.24—8.04 (m, 11H); Mass spectrum *m/e* 236 (parent); Anal. Found: C, 76.46; H, 5.06; N, 11.84%. Calcd for $C_{15}H_{12}N_2O$: C, 76.25; H, 5.12; N, 11.86%. Acid-catalyzed methanolysis of this product in refluxing methanol–HCl gave methyl α-benzoylamino-α-phenylacetate (90%) which had mp 113.5—114.5 °C; IR (KBr) 3280, 1760, 1635 cm^{-1}; NMR ($CDCl_3$) δ 3.76 (s, 3H), 5.80 (d, 1H), 7.05—7.98 (m, 11H). The aqueous layer was acidified with dil-HCl aqueous solution and extracted twice with chloroform (60 ml). The chloroform solution was dried over anhydrous sodium sulfate after washing with water several times, followed by evaporation of chloroform afforded crude *p*-nitrobenzoic acid in 27% yield, identical with the authentic sample.

Reactions of O-(p-Nitrobenzoyl)- and O-(3,5-Dinitrobenzoyl)-N,N-dibenzylhydroxylamines with Diethyl Sulfide and p-Toluenethiol. A typical run was as follows: to *O*-(*p*-nitrobenzoyl)-*N,N*-dibenzylhydroxylamine (2.2 mmol) in DMSO (7 ml) was added diethyl sulfide (3.0 mmol) at room temperature and the whole solution was allowed to stand for 48 h. A similar work-up as in the above experiment gave recovered starting material (28%), benzaldehyde (49%), *p*-nitrobenzoic acid (38%) and benzylamine (33%).

In the reaction with *p*-toluenethiol, two molar amount of *p*-toluenethiol was allowed to react with the hydroxylamine in DMF at room temperature. Separation and identification of the products obtained were carried out similarly.

O-(p-*Nitrobenzoyl*)-N,N-*di(benzyl-α-d_2)hydroxylamine* was prepared according to the following reaction steps.

$$PhCOC_2H_5 \xrightarrow[\text{in dry ether}]{LiAlD_4} PhCD_2OH \xrightarrow[\text{in dry ether}]{SOCl_2,\ \text{pyridine}} PhCD_2Cl \xrightarrow[\text{in } C_2H_5OH\text{–}H_2O]{NH_2OH\cdot HCl,\ Na_2CO_3} (PhCD_2)_2N\text{–}OH \xrightarrow[\text{Pyridine in } CH_2Cl_2]{p\text{-}NO_2C_6H_4COCl} (PhCD_2)_2N\text{–}OCC_6H_4NO_2\text{-}p$$

O-(*p*-Nitrobenzoyl)-*N,N*-di(benzyl-α-d_2)hydroxylamine obtained was recrystallized twice from benzene–hexane to give pale yellow needles, 700 mg (total yield, 11%) which had mp 108—109 °C. The NMR showed no proton of the methylene groups.

Procedure for Kinetic Runs. Each kinetic run was carried out by monitoring the UV absorbance of *p*-nitro- and 3,5-dinitrobenzoate ions liberated during the reaction at 290 nm. At first the solution of *O*-aroyl-*N,N*-di(*p*-substituted benzyl) hydroxylamines in 10 ml of DMSO (13.8×10^{-3} mol/l) was placed in a reaction vessel and immersed in a constant temperature bath which was kept at 30.0±0.1 °C. The solution of a nucleophile such as NaN_3 or LiCl in 10 ml of DMSO (16.6×10^{-2} mol/l), which was previously kept at 30.0±0.1 °C in a same constant temperature bath, was added to the DMSO solution of the hydroxylamine. The reaction was followed by taking out 0.5 ml aliquot at suitable time intervals, diluting the aliquot with 50 ml of acetonitrile–water (2:1 in volume), and finally subjecting the solution for measurement of the optical density of the resulting solution at 290 nm. All the pseudo-first order rate constants were determined from following rate equation and the extent of reaction studied was *ca.* half-life.

$$\log(a_\infty - a_0) - \log(a_\infty - a_t) = (k/2.303)t$$

a_∞; the final absorbance at 290 nm,
a_0; the initial absorbance at 290 nm,
a_t; the absorbance at 290 nm after t.

For a typical run, molar extinction coefficients of *O*-(*p*-nitrobenzoyl)-*N,N*-dibenzylhydroxylamine, sodium *p*-nitrobenzoate, benzaldehyde, *N*-benzylidenebenzylamine and benzylamine in acetonitrile–water (2:1 in volume) were 4400, 7200, 1000, 400 and 0 at 290 nm respectively. Effect of the absorbance of benzaldehyde seems to be negligibly small since a good pseudo-first order kinetic behavior was observed in each case.

(Received August 4, 1975)

A compound, 6-methoxy-2a,3,4,5-tetrahydro-2*H*-naphtho[1,8-*bc*]furan-5-one (XX), was prepared in a 72% yield by heating 3-(5-methoxy-2,3-dihydrobenzofuran-3-yl)propionic acid (XIX) with polyphosphoric acid. However, when 3-(5-methoxybenzofuran-3-yl)propionic acid (IX) or 3-(2-benzoyl-5-methoxybenzofuran-3-yl)-propionic acid (XIII) were treated with polyphosphoric acid, the product was 7-methoxy-2,3-dihydro-1*H*-cyclopenta[*b*]benzofuran-3-one (XI) rather than the corresponding naphtho[1,8-*bc*]furan derivatives, Also, neither naphtho[1,8-*bc*]furan nor cyclopenta[*b*]benzofuran derivatives were obtained from 3-(2-benzyl-5-methoxybenzofuran-3-yl)propionic acid (XIV) or 3-(2-ethyl-5-methoxybenzofuran-3-yl)propionic acid (XVII).

Naphtho[1,8-*bc*]furans (IV) have been prepared[1] by the two methods shown in Scheme 1. The yields of carboxylic acids (II) based on tetralones (I) were almost the same as one another (40—50%), regardless of the kind of the substituents (R_1 and R_2) on the benzene ring. The yields of naphtho[1,8-*bc*]furans (IV) based on carboxylic acids (III) were found in the region of 40—70%, according to kind of substituent (R_1 and R_2). We attempted to devise a novel method to synthesize naphtho[1,8-*bc*]furans from 3-(5-methoxybenzofuran-3-yl)propionic acid (IX), as the yields of II or IV (based on I or III respectively) were not very good.

Results and Discussion

The important intermediate compound 3-(5-methoxybenzofuran-3-yl)propionic acid (IX) was obtained, as is shown in Scheme 2, according to the method of Hallmann *et al.*[2] It was expected that the naphtho-[1,8-*bc*]furan derivative (X) would be produced from IX by intramolecular cyclization. When IX was treated with polyphosphoric acid, cyclization took place[3] to give a crystalline product. However, the product was 7-methoxy-2,3-dihydro-1*H*-cyclopenta[*b*]-benzofuran-3-one (XI) rather than X. This result suggests that the furan ring is more reactive than the benzene ring. The structure of XI was determined from the spectral properties. The IR and UV spectra showed absorptions due to a conjugated-carbonyl group at 1698 cm^{-1} and at 284 (ε 24600) and 289 nm (24000) respectively. The NMR spectrum exhibited no peak corresponding to a hydrogen atom on the furan ring. The structure of XI was also supported by the catalytic hydrogenation of XI with 5% palladium–charcoal to give 7-methoxy-2,3,3a,8b-tetrahydro-1*H*-cyclopenta[*b*]benzofuran-3-ol (XII).

The formation of XI rather than X in the cyclization mentioned above required us to make further attempts to prepare such benzofuran derivatives as XIII, XIV, and XVII, all of which have substituents on the 2-position of the furan ring. For this reason, the XIII compound 3-(2-benzoyl-5-methoxybenzofuran-3-yl)-propionic acid was prepared from VII and phenacyl bromide.[1] When XIII was treated with polyphos-

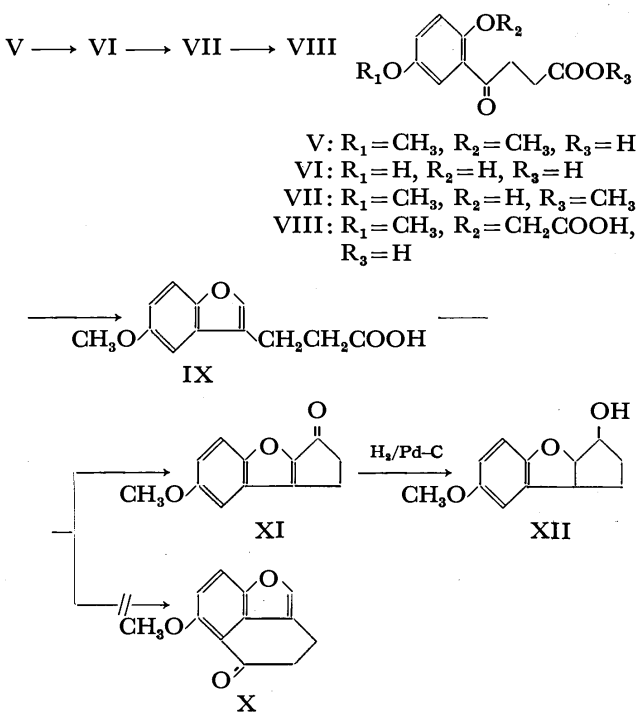
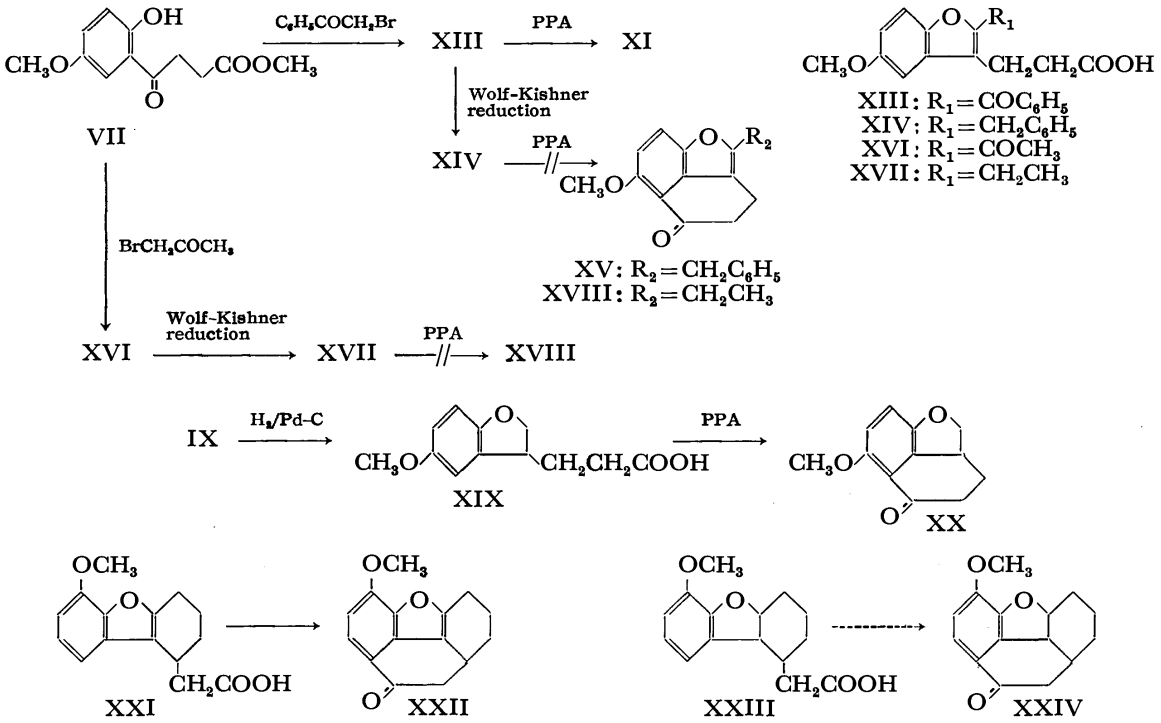


Scheme 2.



Scheme 3.

phoric acid, a carbonyl compound was produced along with benzoic acid. The carbonyl compound was identical in its IR spectra with the product (XI) obtained from the reaction between IX and polyphosphoric acid. Therefore, XIII was converted to 3-(2-benzyl-5-methoxybenzofuran-3-yl)propionic acid(XIV) by a Wolf-Kishner reduction,[4] as the benzoyl group tended to be eliminated under acidic reaction conditions and so XIV was treated with polyphosphoric acid. Nevertheless, only a tarry material was produced; the desired naphtho[1,8-*bc*]furan derivative (XV) was not obtained. Similarly, 3-(2-acetyl-5-methoxybenzofuran-3-yl)propionic acid (XVI) was prepared by the reaction between VII and bromoacetone and was reduced to 3-(2-ethyl-5-methoxybenzofuran-3-yl)propionic acid (XVII). Also, the corresponding naphtho[1,8-*bc*]furan derivative (XVIII) was not obtained by the treatment of XVII with polyphosphoric acid.

From these results, it appears difficult to convert benzofuran derivatives (IX, XIII, XIV, and XVII) where furan rings remained fully unsaturated to naphtho[1,8-*bc*]furan derivatives by intramolecular cyclization. We made a further examination of a partially saturated benzofuran derivative. The IX compound was reduced to 3-(5-methoxy-2,3-dihydrobenzofuran-3-yl)propionic acid (XIX) by catalytic hydrogenation with 10% palladium–charcoal. When XIX was treated with polyphosphoric acid,[5] the desired 6-methoxy-2a,3,4,5-tetrahydro-2*H*-naphtho[1,8-*bc*]furan-5-one (XX) was obtained in a 72% yield. Compound XX showed an absorption corresponding to the carbonyl group at 1670 cm^{-1} in the IR spectrum and peaks corresponding to two adjacent aromatic hydrogen atoms on the benzene ring at δ 6.90 (d, 1H, J=8 Hz) and 6.68 (d, 1H, J=8 Hz) in the NMR spectrum.

These results suggest that the presence of the carbon–carbon double bond of the furan ring hinders intramolecular cyclization because of the formation of by-products, but partially saturated benzofuran derivatives readily undergo cyclization to the corresponding naphtho[1,8-*bc*]furan derivatives. Dendy *et al.*[6] obtained a phenanthro[4,5-*bcd*]furan derivative (XXII) in a very poor yield from a benzofuran derivative (XXI). They ascribed this difficulty of cyclization to a strain in the fused-ring system. However, the above results suggest that the dihydrobenzofuran derivative (XXIII) may be converted to a phenanthro[4,5-*bcd*]furan derivative (XXIV) in a good yield. The reactivities of naphtho[1,8-*bc*]furans will be further investigated.

Experimental

All the melting points are uncorrected. The column chromatography was performed on silica gel (WAKOGEL C-200). The polyphosphoric acid (PPA) was prepared from 85% phosphoric acid (100 ml) and phosphorus pentoxide (125 g) by heating them at 160—165 °C for 5 h. Unless otherwise stated, anhydrous sodium sulfate was employed as the drying agent. The infrared absorption spectra were determined with a JASCO Model DS 402 G infrared spectrophotometer. The ultraviolet absorption spectra were determined with a Shimadzu Model UV-200 spectrophotometer. The nuclear magnetic resonance spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as the internal standard.

3-(2,5-Dihydroxybenzoyl)propionic Acid (VI). A mixture of 3-(2,5-dimethoxybenzoyl)propionic acid (V, 20 g)[7] and pyridinium chloride (100 g) was heated for 40 min at 200 °C.[8] After cooling, the mixture was poured into dilute hydrochloric acid and extracted with ether. The ethereal layer was washed with 1M hydrochloric acid and water, dried, and then evaporated. The residue was recrystallized from 35% aqueous

methanol to give 11.1 g (63%) of VI as orange prisms; mp 181—182 °C. IR(KBr): 3200 (OH), 1700 (COOH), 1635 (C=O), 1175 (OH), and 830 cm^{-1} (two adjacent aromatic hydrogen atoms). Found: C, 57.03; H, 4.80%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

Methyl 3-(2-Hydroxy-5-methoxybenzoyl)propionate (VII). A mixture of VI (15.0 g), dimethyl sulfate (13.0 g), potassium carbonate (17.0 g), and acetone (50 ml) was refluxed for 2.5 hr at 62 °C.[9] After the decomposition of the dimethyl sulfate with water, the reaction mixture was extracted with ether. The ethereal layer was washed with a 1M potassium carbonate solution and water, dried, and then evaporated. The residue was chromatographed over silica gel and eluted with benzene (95)–ether (5); the first fraction gave 16.5 g (48%) of crystals. Recrystallization from ether–hexane gave yellow plates of VII; mp 41—42 °C. IR (KBr): 1726 ($COOCH_3$), 1642 (C=O), 1042 cm^{-1} (OCH_3). NMR ($CDCl_3$): δ 2.75 (t, 2H, J=7 Hz, $-CH_2-$), 3.35 (t, 2H, J=7 Hz, $-CH_2-$), 3.72 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 6.90 (d, 1H, J=9 Hz, Ar–H), 7.10 (d, d, 1H, J=3 Hz and 9 Hz, Ar–H), 7.20 (d, 1H, J=3 Hz, Ar–H), 11.60 (s, 1H, OH). Found: C, 60.66; H, 6.06%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

The yield of VII was not good because of the formation of methyl 3-(2,5-dimethoxybenzoyl)propionate and methyl 3-(2,5-dihydroxybenzoyl)propionate.

3-(2-Carboxymethoxy-5-methoxybenzoyl)propionic Acid (VIII). Compound VIII was prepared (84%) according to the method of Hallmann *et al.* Colorless prisms (from tetrahydrofuran–benzene); mp 188—189 °C. (lit,[2] mp 189—190 °C)

3-(5-Methoxybenzofuran-3-yl)propionic Acid (IX). Compound IX was also prepared (67%) according to the method of Hallmann *et al.* Colorless plates (from benzene–hexane); mp 124—125 °C. (lit,[2] mp 126—127 °C) IR (KBr): 1681 (COOH), 1620 (C=C), 792 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR (CD_3COCD_3): δ 2.73 (t, 2H, J=7 Hz, $-CH_2-$), 2.98 (t, 2H, J=7 Hz, $-CH_2-$), 3.85 (s, 3H, OCH_3), 6.90 (d, d, 1H, J=3 Hz and 8 Hz, Ar–H), 7.19 (d, 1H, J=3 Hz, Ar–H), 7.35 (d, 1H, J=8 Hz, Ar–H), 7.60 (s, 1H, furan H). UV (EtOH): λ_{max} 210 (ε 23800), 252 (8300), 304 (4100), 302 nm (3700). Though a mixture of VIII (200 mg), sodium acetate (500 mg), and acetic anhydride (7 ml) was heated for 1 h at 145 °C and for 10 min at 160 °C, only a tarry material was produced.

7-Methoxy-2,3-dihydro-1H-cyclopenta[b]benzofuran-3-one (XI). A mixture of IX (0.5 g) and polyphosphoric acid (70 g) was heated for 4 h at 80 °C with stirring. The reaction mixture was decomposed with ice–water, and the resulting precipitates were extracted with ether. The ethereal layer was washed with a 1M potassium carbonate solution and water, dried, and then evaporated. The residue was chromatographed over silica gel and eluted with benzene(92)–ether(8) to give 0.2 g (43%) of crystals; mp 136—138 °C. Recrystallization from benzene–hexane gave colorless needles of XI; mp 138—139 °C. IR (KBr): 1695 (C=O), 810 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR (CD_3COCD_3): δ 3.87 (s, 3H, OCH_3), 7.12 (d, d, 1H, J=2 Hz and 9 Hz, Ar–H), 7.28 (d, 1H, J=2 Hz, Ar–H), 7.52 (d, 1H, J=9 Hz, Ar–H). UV (EtOH): λ_{max} 219 (ε 14400), 284 (24600), 289 (24000), 325 nm (5600). Found: C, 71.09; H, 4.92%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

7-Methoxy-2, 3, 3a, 8b-tetrahydro-1H-cyclopenta[b]benzofuran-3-ol (XII). A mixture of XI (200 mg), palladium chloride (50 mg) in 0.1 M hydrochloric acid (5 ml), charcoal (100 mg), and ethanol (60 ml) was shaken under a hydrogen atmosphere for 1.5 h at room temperature. After the removal of the catalyst, the ethanol was evaporated. The residue was chromatographed over silica gel and eluted with benzene (9)–ether (1) to give 150 mg (74%) of crystals; mp 66—67 °C. Recrystallization from methanol gave XII as colorless plates; mp 68—69 °C. IR (KBr): 3530 (OH), 1100 (C–OH), 1030 cm^{-1} (OCH_3). NMR (CCl_4): δ 1.20—1.95 (m, 4H, $-CH_2-$+ $-CH_2-$), 2.35 (s, 1H, OH), 3.67 (s, 3H, OCH_3), 3.70 (m, 1H, =CH–), 4.87 (d, d, 1H, J=5 Hz and 7 Hz, a hydrogen atom on the 3a carbon atom), 6.53 (s, 3H, Ar–H). UV (EtOH): λ_{max} 204 (ε 14300), 230 (4200), 300 nm (2900). Found: C, 69.73; H, 6.74%. Calcd for $C_{12}H_{14}O_3$: C, 69.89; H, 6.84%.

3-(2-Benzoyl-5-methoxybenzofuran-3-yl)propionic Acid (XIII). A mixture of VII (1.5 g), phenacyl bromide (6.1 g), and potassium carbonate (4.4 g) was heated for 3 h at 140 °C. The reaction mixture was then extracted with acetone, and the acetone was evaporated. The residue was dissolved in a small amount of ethanol and hydrolyzed with a 3M potassium hydroxide solution. The alkaline solution was acidified with 6M hydrochloric acid, and the resulting precipitates were extracted with ether. The ethereal layer was then extracted with a 1M potassium carbonate solution, and the alkaline solution was acidified with 6M hydrochloric acid. The resulting precipitates were extracted with ether, and the ethereal layer was washed with water, and then evaporated. The residue was triturated with benzene to give 0.8 g (57%) of crystals; mp 169—170 °C. Recrystallization from methanol gave colorless needles of XIII; mp 171—172 °C. IR (KBr): 1720 (COOH), 1637 (C=O), 1027 (OCH_3), 810 cm^{-1} (two adjacent aromatic hydrogen atoms). UV(EtOH): λ_{max} 207 (ε 33000), 257 (9300), 317 nm (20900). Found: C, 70.39; H, 5.13%. Calcd for $C_{19}H_{16}O_5$: C, 70.36; H, 4.98%.

The Formation of XI from XIII. A mixture of XIII (100 mg) and polyphosphoric acid (10 g) was heated with stirring for 4 hr at 90 °C. The reaction mixture was then decomposed with ice–water and extracted with ether. The ethereal layer was washed with a 1M potassium carbonate solution and water, dried, and then evaporated. The residue was chromatographed over silica gel and eluted with benzene (92)–ether (8) to give 20 mg (33%) of crystals; mp 135—136 °C. Recrystallization from benzene–hexane gave colorless needles of XI; mp 138—139 °C. The compound was identical in its IR spectra with the sample prepared from IX and polyphosphoric acid.

3-(2-Benzyl-5-methoxybenzofuran-3-yl)propionic Acid (XIV). A mixture of XIII (500 mg), 80% hydrazine hydrate (2.5 g), potassium hydroxide (7.0 g), and triethylene glycol (25 ml) was heated for 1 h at 140 °C; the temperature was thereafter gradually raised to 190 °C, after which the mixture was kept for 4 h at that temperature. The reaction mixture was poured into ice–water, acidified with 6M hydrochloric acid, and then extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The residue was chromatographed on silica gel and eluted with benzene (9)–ether (1) to give 220 mg (46%) of crystals; mp 116—117 °C. Recrystallization from ether–hexane gave colorless needles of XIV; mp 117—118 °C. IR (KBr): 1700 (COOH), 1624 (C=C), 803cm^{-1} (two adjacent aromatic hydrogen atoms). NMR ($CDCl_3$): δ 2.66 (d, 2H, J=7 Hz, $-CH_2-$), 2.92 (d, 2H, J=7 Hz, $-CH_2-$), 3.80 (s, 3H, OCH_3), 4.06 (s, 2H, $-CH_2-$), 6.79 (d, d, 1H, J=2 Hz and 8 Hz, Ar–H), 6.93 (d, 1H, J=2 Hz, Ar–H), 7.22 (s, 5H, Ar–H), 7.25 (d, d, 1H, J=1 Hz and 8 Hz, Ar–H), 9.66 (broad s, 1H, COOH). UV (EtOH): λ_{max} 210 (ε 31400), 255 (14000), 292 (5600), 302 nm (5000). Found: C, 73.51; H, 5.85%. Calcd for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85%. Though a mixture of XIV (100 mg) and polyphosphoric acid (14 g) was heated with stirring for 4 h at 90 °C, XV was not obtained.

3-(2-Acetyl-5-methoxybenzofuran-3-yl)propionic Acid (XVI).

A mixture of VII (2.0 g), bromoacetone (7.0 g), and potassium carbonate (7.0 g) was refluxed for 4 h at 120 °C. The reaction mixture was then extracted with acetone, and the acetone was evaporated. The residue was dissolved in a small amount of ethanol and hydrolyzed with a 3M potassium hydroxide solution. The alkaline solution was acidified with 6M hydrochloric acid, and the resulting precipitates were extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The residue was chromatographed on silica gel and eluted with benzene (8)–ether (2) to give 1.0 g (44%) of crystals; mp 124—126 °C. Recrystallization from aqueous methanol gave colorless needles of XVI; mp 124—126 °C. IR (KBr): 1710 (COOH), 1675 (C=O), 800 cm^{-1} (two adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 205 (ε 21500), 296 nm (17800). Found: C, 63.90; H, 5.31%. Calcd for $C_{14}H_{14}O_5$: C, 64.11; H, 5.38%.

3-(2-Ethyl-5-methoxybenzofuran-3-yl)propionic Acid (XVII). Compound XVII was obtained (54%) by a method similar to the preparation of XIV from XIII. Recrystallization from ether–hexane gave colorless prisms; mp 86—87 °C. IR (KBr): 1713 (COOH) and 813 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR ($CDCl_3$): δ 1.25 (t, 3H, J=7 Hz, CH_3), 2.50—3.00 (m, 6H, $-CH_2-$), 3.82 (s, 3H, OCH_3), 6.80 (d, d, 1H, J=2 Hz and 8 Hz, Ar-H), 6.92 (d, 1H, J=2 Hz, Ar-H), 7.26 (d, d, 1H, J=1 Hz and 8 Hz, Ar-H), 9.91 (broad s, 1H, COOH). Found: C, 67.79; H, 6.50%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%. Though a mixture of XVII (100 mg) and polyphosphoric acid (8 g) was heated with stirring for 6 h at 90 °C, XVIII was not obtained.

3-(5-Methoxy-2,3-dihydrobenzofuran-3-yl)propionic Acid (XIX). A mixture of IX (300 mg), 10% palladium–charcoal (200 mg), and ethanol (70 ml) was shaken under a hydrogen atmosphere for 20 h at room temperature. After the subsequent removal of the catalyst, the ethanol was evaporated to give 280 mg (92%) of crystals; mp 94—96 °C. Recrystallization from benzene–hexane gave colorless plates of XIX; mp 96—97 °C. IR (KBr): 1692 (COOH), 1033 (OCH_3), 800 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR ($CDCl_3$): δ 2.00 (m, 2H, $-CH_2-$), 2.42 (t, 2H, J=6 Hz, $-CH_2-$), 3.47 (m, 1H, =CH–), 3.77 (s, 3H, OCH_3), 4.20 (d, d, 1H, J=5 Hz and 9 Hz, $-CH_2-$), 4.60 (t, 1H, J=9 Hz, –OCH–), 6.70 (s, 2H, Ar-H), 6.76 (s, 1H, Ar-H), 10.90 (broad s, 1H, COOH). UV (EtOH): λ_{max} 204 (ε 16400), 230 (6300), 299 nm (4800). Found: C, 64.66; H, 6.22%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

6-Methoxy-2a,3,4,5-tetrahydro-2H-naphtho[1,8-bc]furan-5-one (XX). A mixture of XIX (300 mg) and polyphosphoric acid (30 g) was heated with stirring for 4 h at 80 °C. The reaction mixture was then decomposed with ice–water, and the resulting precipitates were extracted with ether. The ethereal layer was washed with a 1M potassium carbonate solution and water, dried, and then evaporated to give 200 mg (72%) of crystals; mp 102—103 °C. Recrystallization from benzene–hexane gave colorless prisms of XX; mp 104—105 °C. IR (KBr): 1670 (C=O), 832 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR ($CDCl_3$): δ 3.72 (m, 1H, =CH–), 3.88 (s, 3H, OCH_3), 4.10 (d, d, 1H, J=9 Hz and 10 Hz, –OCH–), 4.84 (t, 1H, J=9 Hz, –OCH–), 6.80 (d, 1H, J=8 Hz, Ar-H), 6.91 (d, 1H, J=8 Hz, Ar-H). Found: C, 70.37; H, 6.05%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

The authors wish to thank Mr. Yoshiaki Takahashi for the elemental analyses, Mr. Hideo Saisu for the infrared analyses, and Mr. Takao Ono for the nuclear magnetic resonance analyses.

(Received August 5, 1975)

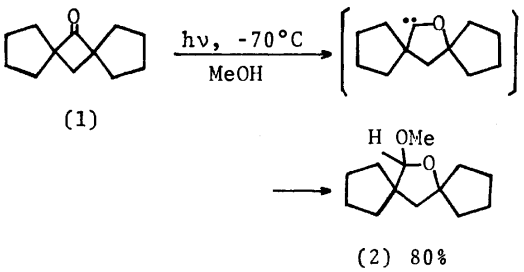
The photochemical ring expansion of dispiro substituted cyclobutane-1,3-diones in methanol has been investigated. The formation of ring expansion product was strongly dependent on the spiro ring size of dispiro substituent. The ring expanded acetal was obtained in a low yield when the spiro ring of dispiro substituted cyclobutane-1,3-diones was a five- or seven-membered ring. This is the first example of photochemical ring expansion from cyclobutane-1,3-diones. A mechanism is postulated.

Three primary photochemical processes, (**a**) decarbonylation (α-cleavage) (**b**) cycloelimination(β-cleavage) and (**c**) ring expansion, are usually observed in the photochemistry of simple cycloalkanones such as cyclobutanones[1] and cyclopentanones.

Recently extensive studies have been carried out from an interest in photochemical ring expansion *via* an oxacarbene intermediate(**c**).[1a,b,2,3] However, in the photochemistry of cyclobutane-1,3-diones,[4] no photochemical ring expansion seems to have been found.[1c,d] In a previous communication,[5] a report was given on the first example of ring expansion in the photochemical reaction of dispiro[4.1.4.1]dodecane-6,12-dione. We now report the effect of the ring size on the photochemical ring expansion of spiro substituted cyclobutanones and cyclobutane-1,3-diones in methanol, and suggest a plausible mechanism.

Results and Discussion

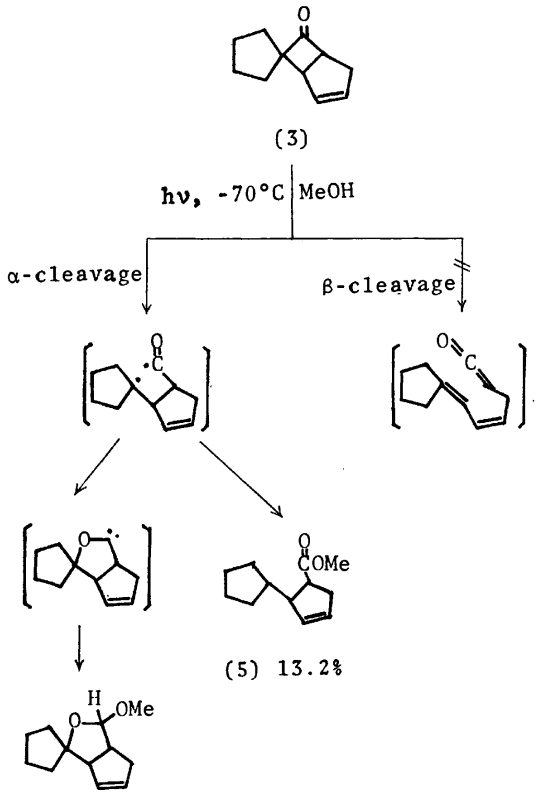
The photochemical reaction of cyclobutanone derivatives substituted by a spiro five-membered ring has been carried out to clarify the effect of spiro ring substituent on the photochemical processes. When dispiro[4.1.4.1]-dodecane-6-one (**1**) was irradiated in methanol at —70 °C for 10 hr with a Pyrex filter, a photochemical ring expansion *via* an oxacarbene intermediate took place smoothly to give ring expanded acetal (**2**) predominantly.



(1) (2) 80%

When 7-tetramethylene-bicyclo[3.2.0]hept-2-en-6-one (**3**) was irradiated in methanol, α-cleavage into only one of two possible directions occurred preferentially to yield a large quantity of ring expanded acetal (**4**) and an ester (**5**) without any formation of β-cleavage product.

In both cases, the ring expanded acetals were obtained predominantly. This is of great interest as compared with the cases of bicyclo[3.2.0]hept-2-en-6-one[6] and



(5) 13.2%

(4) 68.3%

its 7,7-dimethyl derivative,[7] accompanied by comparable amounts of β-cleavage. This enhancement of ring expansion in **1** and **3** may be interpreted in terms of the nucleophilicity and stability of the carbon atom migrated to electron defficient oxygen atom. In connection with the stability of migratory carbon atom, it is not unreasonable to presume that the spiro five-membered ring substituent affects the stability of 1,4-biradical derived from initial α-cleavage in a striking manner. It can be anticipated that photo ring expansion would occur depending upon the selection of certain spiro substituents, even in the photochemical reaction of dispiro substituted cyclobutane-1,3-diones. A spiro five-membered ring substituent was chosen as a suitable substituent. As expected, irradiation of degassed methanolic solution of dispiro[4.1.4.1]dodecane-6,12-dione (**6a**) at —70 °C for 2 h through a Pyrex filter gave ring expanded acetal (**7a**) in 6.1% yield.[5] The formation of **7a** represents the first example of photo-

TABLE 1. PER CENT YIELDS OF PRODUCTS DERIVED FROM PHOTOLYSES OF CYCLOBUTANE-1,3-DIONES IN METHANOL

Compd	Irrad Temp	Acetal(%)	Other Products(%)			
6a	−70°C	**7a** (6.1)	**8a** (55.5)	**9a** (3.9)	**10a**[a] (1.1)	**11a** (3.6)
	0°C	(2.0)	(4.2)	(45.5)	(2.3)	(4.2)
	30°C	(1.4)	(1.6)	(54.6)	(3.8)	(3.6)
6b	−70°C		**8b** (3.4)		**10b'** (12.5)[b]	**11b** (41.7)
6c	−70°C		**8c** (54.9)		**10c** (5.6)	**11c** (4.9)

Besides the above products, cyclopentanone and cyclohexanone were obtained for both **6a** and **6b**, but not quantified. a) Compound (**10a**) was also produced by further irradiation of isolated compound(**8a**) in methanol. b) Methyl 1-(1-cyclohexenyl)cyclohexanecarboxylate.

chemical ring expansion from cyclobutane-1,3-diones. In analogy with cyclobutanones, the formation of **7a** from **6a** can be satisfactorily explained by a photochemical ring expansion reaction by way of an oxacarbene intermediate. As the major nongaseous product other than **7a**, methyl 1-(cyclopentylcarbonyl)cyclopentanecarboxylate (**8a**) was obtained in 55.5% yield, together with small amounts of α-methoxy dicyclopentyl ketone (**9a**), methyl 1-(cyclopentyl)cyclopentanecarboxylate (**10a**) and methyl cyclopentanecarboxylate (**11a**).

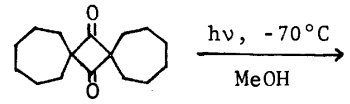
(10)

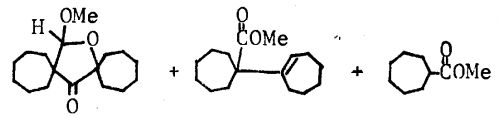
On the other hand, in a similar irradiation of dispiro-[5.1.5.1]tetradecane-7,14-dione (**6b**) and dispiro[3.1.3.-1]decane-5,10-dione (**6c**), no ring expansion product could be detected by vapor phase chromatography. In these reactions, either β- or α-cleavage took place predominantly and, as the major products in each case, methyl cyclohexanecarboxylate (**11b**) and methyl 1-(cyclobutylcarbonyl)cyclobutanecarboxylate (**8c**) were obtained in 41.7% and 54.9% yields, respectively. It has been confirmed, however, that all or most of keto ester (**8c**) is easily formed by the dark reaction. This is perhaps due to the release of internal ring strain. The yields of photolysis products are given in Table 1.[8]

The effect of spiro ring size on the photochemical processes of cyclobutane-1,3-diones is remarkable. With the increase in temperature in the case of **6a**, the formation of **7a** and **8a** decreases and that of **9a**, which appears to be derived from intermediary unstable dispirocyclopropanone, increases markedly (Table 1). 1,3-Pentadiene is ineffective for the formation of **7a**, an attempt to sensitize with benzophenone being unsuccessful. It is thus assumed that a reactive species of **6a** is an n–π* singlet (or unquenchable triplet). From this excited state, the molecule undergoes α-cleavage to give a spin-conserved singlet biradical (1,4-acyl cycloalkyl biradical) (**A**). In these photochemical reactions, there are three primary photoprocesses (decarbonylation, β-cleavage, and ring expansion) which compete for the short-lived 1,4-acyl cycloalkyl biradical.[9] We would like to postulate that the stability of 1,4-acyl cycloalkyl biradical intermediate (**A**) is of importance in determining the subsequent path, though there is little evidence for the existence of 1,4-acyl cycloalkyl biradical. Increasing stability of intermediary biradical might increase the efficiency of ring expansion. The main path which describes the photochemical transformation of dispiro cyclobutane-1,3-diones is given in the Scheme.

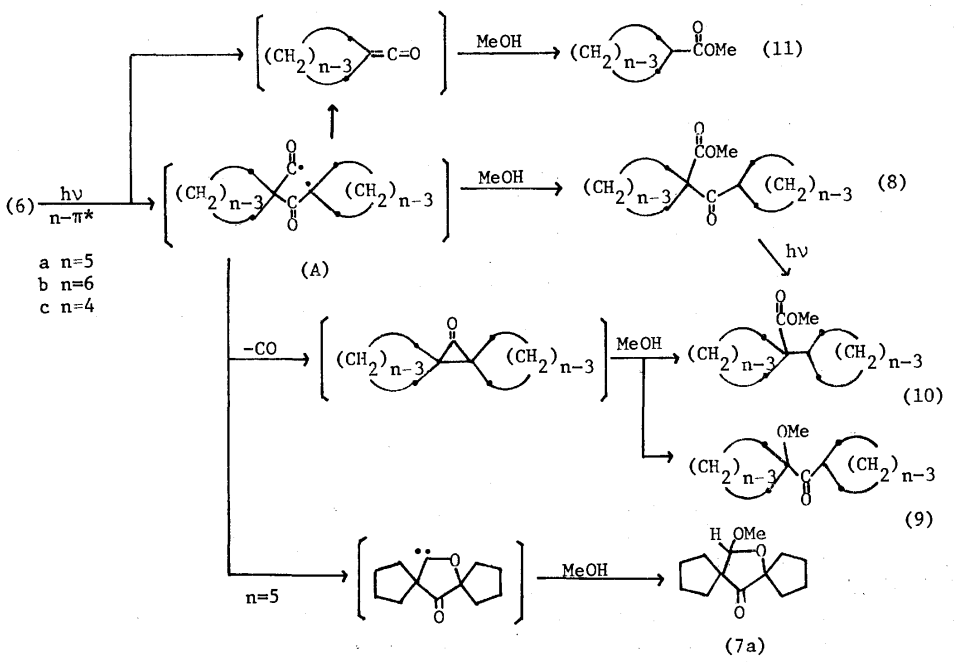
Since cycloalkyl radicals are stable in the sequence $\cdot C_5 \sim \cdot C_7 > \cdot C_6 > \cdot C_4$,[10] it may be reasonable to consider that an acyl cyclopentyl biradical derived from initial α-cleavage of excited **6a** is stable enough to undergo electronic rearrangement, and that the bonding between the carbonyl oxygen atom and cyclopentyl radical center in the biradical intermediate produces the oxacarbene intermediate. Dispiro[6.1.6.1]hexadecane-8,16-dione (**6d**) would undergo photochemical ring expansion, since the stability of an acyl cycloheptyl radical intermediate derived from initial α-cleavage may be comparable to that of an acyl cyclopentyl radical. As expected, ring expanded acetal (**7d**) was



(6d)



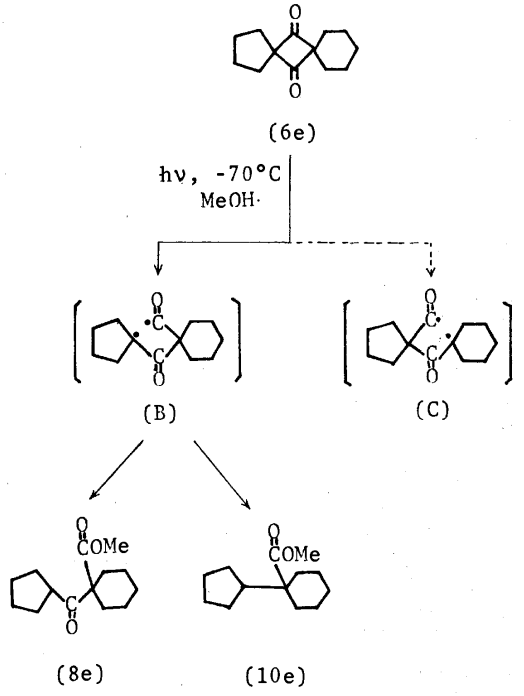
(7d) 3.8% (10d') 21.1% (11d) 9.3%



Scheme

obtained in 3.8% yield.

In order to obtain precise information on the effect of two different spiro ring sizes on the photochemical processes and, in particular, the direction of initial α-cleavage, the photolysis of dispiro[4.1.5.1]tridecane-6,13-dione (**6e**) in methanol has been examined.



The above reaction led to the preferential formation of methyl 1-(cyclopentylcarbonyl)cyclohexanecarboxylate (**8e**). The result can be explained by the difference in the stability of two 1,4-acyl cycloalkyl biradical intermediates (**B**) and (**C**) derived from the different directions of α-cleavage.

Experimental

All the melting points and boiling points are uncorrected. Infrared spectra were measured with a JASCO IR-G spectrometer, UV spectra with a Hitachi Two-wavelength Double Beam Spectrophotometer 356, and NMR spectra with a JEOL JNM-3H-60 or JEOL JNM-PS-100 spectrometer, tetramethylsilane being used as an internal standard. Mass spectra were taken on a Hitachi RMU-6E spectrometer. Gas chromatography was carried out on a Hitachi gas chromatograph 063 and on a Varian aerograph model 90-P.

Dispiro Substituted Cyclobutane-1,3-dione. Dispiro cyclobutane-1,3-diones (**6a,b,c,d**) were prepared by the procedure given by Erickson *et al.*[11] Dispiro[4.1.5.1]tridecane-6,13-dione (**6e**) was synthesized by the following procedure. To a stirred solution of cyclopentanecarbonyl chloride (7.6 mmol) and cyclohexanecarbonyl chloride (23.2 mmol) in 50 ml of ether under nitrogen was added triethylamine (46.5 mmol) over a period of 0.5 hr. The reaction mixture was stirred and refluxed for 24 hr, then worked up as usual to give dione (**6e**) in 37.7% yield, together with **6a** and **6b**. After diones had been chromatographed on silica gel, recrystallization from pentane gave white needles (**6e**). Dione (**6e**) was obtained in maximum yield, when the molar ratio of cyclopentanecarbonyl chloride to cyclohexanecarbonyl chloride was 1 : 3. The

properties and spectral data for these dispiro cyclobutane-1,3-diones are given in Table 2. The ultraviolet absorption of the dispiro cyclobutane-1,3-diones showed two distinct n-π^* transitions due to 1,3 π interactions in the excited states and a small, regular increase in each absorption maximum with decreasing spiro ring size.

General Irradiation Procedure. A solution degassed by bubbling nitrogen slowly for 30 min was irradiated through a Pyrex filter using 500W high pressure mercury lamp. The reaction progress was monitored periodically by glpc analysis. Upon termination of the irradiation, the solvent was evaporated and the residue was purified by glpc. The yields were determined by glpc analysis (Poly Ethylene Glycol 20-M).

Synthesis of Dispiro[4.1.4.1]dodecane-6-one (1). A mixture of Raney nickel (80 g), ethanol (200 ml) and 12,12-di-(ethylthio)dispiro[4.1.4.1]dodecane-6-one (2.5 g, 8.4 mmol)[12] was refluxed for 8 hr. Distillation of the residue gave **1** (753 mg, 50%), bp 81—82 °C/3 Torr; IR (neat) 2950, 2900, 1760, 1440, 1110, 1015 cm^{-1}; NMR (CCl_4) δ 1.32—1.90 (m, 16H), 1.98 (s, 2H); Mass *m/e* 178 (M^+), 150, 96, 83, 68. Found: C, 80.62; H, 10.38%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

Photolysis of Dispiro[4.1.4.1]dodecane-6-one (1) in Methanol. A degassed solution of (**1**) (537 mg, 3.0 mmol) in 250 ml of methanol was irradiated at −70 °C for 10 hr. Preparative glpc afforded cyclic acetal (**2**) (80%): IR (neat) 2980, 2910, 1450, 1330, 1190, 1160, 1095, 1030, 960 cm^{-1}; NMR (CCl_4) δ 1.35—2.00 (m, 16H), 2.02 (s, 2H), 3.25 (s, 3H), 4.28 (s, 1H); Mass *m/e* 210 (M^+), 178, 160, 149, 137, 96, 81, 67.

Synthesis of 7-Tetramethylene-bicyclo[3.2.0]hept-2-en-6-one (3). Triethylamine (0.12 mol) was added to a solution of cyclopentanecarbonyl chloride (0.1 mol) and cyclopentadiene (0.7 mol) in 200 ml of dry ether under an atmosphere of nitrogen, and the resulting suspension was stirred and refluxed for 20 hr. The amine salt was removed by filtration. After distillation of the residue three times, spiro ketone (**4**) was obtained in 74.4% yield, bp 68—69 °C/9.5 Torr; IR (neat) 1775, 1600 cm^{-1}; NMR (neat) δ 1.60 (m, 8H), 2.38 (m, 2H), 3.19 (d, 1H), 3.58—4.00 (three d or two t, 1H), 5.80 (m, 2H); Mass *m/e* 162 (M^+), 134, 119, 105, 96, 91, 68, 66. Found: C, 81.24; H, 8.78%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

Photolysis of Spiro Ketone (3) in Methanol. A solution of **3** (18.5 mmol) in 300 ml of methanol was irradiated at −70 °C for 10 hr. Preparative glpc afforded acetal (**4**) in 68.4% yield, together with methyl 2-(cyclopentyl)-3-cyclopentene-1-carboxylate (**5**) (13.2%). For **4**, IR (neat) 3075, 2900, 1615, 1445, 1190 cm^{-1}; NMR (neat) δ 1.60 (m, 8H), 2.48—2.80 (m, 2H), 3.08 (m, 1H), 3.20 (s, 3H), 4.30 (m, 1H), 4.50 (s, 1H), 5.60 (m, 2H); Mass *m/e* 194 (M^+), 162, 144, 133, 110, 105, 91, 79, 77, 67, 55. Found: C, 74.17; H, 9.32%. Calcd for $C_{12}H_{18}O_2$: C, 74.10; H, 9.34%. For **5**, IR (neat) 3075, 2900, 1725, 1615, 1445, 1360, 1190, 1100 cm^{-1}; NMR (CCl_4) δ 1.40—2.10 (m, 8H), 2.20—2.80 (m, 4H), 3.10 (m, 1H), 3.25 (s, 3H), 5.60 (m, 2H); Mass *m/e* 194 (M^+), 163, 134, 120, 106, 91, 79.

Photolysis of Dispiro[4.1.4.1]dodecane-6,12-dione (6a) in Methanol. A degassed solution of **6a** (18 mmol) in 200 ml of methanol was irradiated using a Pyrex filter at −70 °C for 2 hr. Analysis of the photolysate by glpc revealed the following products: ring expanded acetal (**7a**, 6.1%), methyl 1-(cyclopentylcarbonyl)cyclopentanecarboxylate (**8a**, 55.5%). In addition, α-methoxydicyclopentyl ketone (**9a**, 3.9%), methyl 1-(cyclopentyl)cyclopentanecarboxylate (**10a**, 1.1%) and methyl cyclopentanecarboxylate(**11a**, 3.6%) were detected. Methyl cyclopentanecarboxylate (**11a**) was identified by comparison of glpc retention time with that of an authentic sample. For **7a**, IR (neat) 2950, 2890, 1742, 1445, 1090, 1015, 975 cm^{-1}; NMR (CCl_4) δ 1.77 (b, 16H), 3.35 (s, 3H), 4.60 (s, 1H); Mass *m/e* 224 (M^+), 193, 165, 112, 96, 84, 67, 55, 41. Found: C, 69.34; H, 9.01%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%. For **8a**, IR (neat) 2960, 2890, 1740, 1707, 1447, 1435, 1335, 1230, 1160, 1120, 1080, 1010 cm^{-1}; NMR (CCl_4) δ 1.30—2.30 (m, 16H), 2.50—3.30 (b, 1H), 3.68 (s, 3H); Mass *m/e* 224 (M^+), 193, 165, 128, 97, 69, 41. The structure of **8a** was confirmed also by its identity with an authentic sample prepared by treating **6a** with methanol containing a catalytic amount of sodium methoxide. For **9a**, IR (neat) 2950, 2870, 1700, 1440, 1360, 1070 cm^{-1}; NMR (CCl_4) δ 1.70—2.00 (m, 16H), 2.50 (m, 1H), 3.05 (s, 3H); Mass *m/e* 196 (M^+), 164, 149, 135, 99, 67. For **10a**, IR (neat) 2950, 2890, 1724, 1440, 1155 cm^{-1}; NMR (CCl_4) δ 1.40—2.30 (m, 17H), 3.60 (s, 3H); Mass *m/e* 196 (M^+), 194, 166, 137, 111, 97, 81, 69. Irradiation of **6a** at 0 °C and 30 °C gave the same photoproducts in somewhat different yields (Table 1).

Quenching with 1,3-Pentadiene. Three samples were prepared, each containing 250 ml of methanol solution of **6a** (18 mmol). One also contained 1,3-pentadiene (0.1 mol) and another contained 1,3-pentadiene (0.01 mol). All the samples were irradiated at −70 °C for 2 hr. 1,3-Pentadiene has no quenching effect on the formation of cyclic acetal (**7a**).

Photolysis of Dispiro[5.1.5.1]tetradecane-7,14-dione (6b) in Methanol. A solution of **6b** (41 mmol) in 300 ml of methanol was irradiated at −70 °C for 5 hr. Isolation of products by preparative glpc afforded methyl cyclohexanecarboxylate (**11b**, 41.7%), dimethyl (bicyclohexyl)-1,1′-dicarboxylate (**12**, 15.4%), methyl 1-(1-cyclohexenyl)cyclohexanecarboxylate (**10b′**, 12.5%), and methyl 1-(cyclohexylcarbonyl)cyclohexanecarboxylate (**8b**, 3.4%). Methyl cyclohexanecarboxylate (**11b**) was identified by comparison of glpc retention time with that of an authentic sample. For **12**, mp 117—118 °C (lit,[13] 116 °C); IR (KBr) 3030, 2970, 2900, 1720, 1450, 1435, 1350, 1300, 1210, 1130, 1060, 1030, 985 cm^{-1}; NMR (CCl_4) δ 1.0—2.2 (m, 20H), 3.60 (mc, 6H); Mass *m/e* 282 (M^+), 251, 223, 169, 163, 142, 113, 109, 81. For **10b′**, IR (neat) 2950, 2890, 2700, 1728, 1450, 1298, 1260, 1212, 1200, 1175, 1155, 1130, 995 cm^{-1}; NMR (CCl_4) δ 0.9—2.0 (m, 14H), 2.07 (m, 4H), 3.58 (s, 3H), 5.50 (m, 1H); Mass *m/e* 222 (M^+), 190, 163, 142, 95, 83, 81. For **8b**, IR (neat) 2940, 2820, 1730, 1703, 1445, 1365, 1210, 1130, 1110, 980 cm^{-1}; NMR (CCl_4) δ 1.0—2.1 (m, 20H), 2.2—2.6 (b, 1H), 3.65 (s, 3H); Mass *m/e* 252 (M^+), 221, 193, 142, 111, 83, 55. The structure of **8b** was confirmed also by its identity with an authentic sample.

Photolysis of Dispiro[3.1.3.1]decane-5,10-dione (6c) in Methanol. A solution of **6c** (8.2 mmol) in 250 ml of methanol was irradiated at −70 °C for 2 hr. Preparative glpc gave methyl 1-(cyclobutylcarbonyl)cyclobutanecarboxylate (**8c**, 54.9%), dimethyl (bicyclobutyl)-1,1′-dicarboxylate (**14**, 17.1%), methyl 1-(cyclobutyl)cyclobutanecarboxylate (**10c**, 5.6%) and methyl cyclobutanecarboxylate (**11c**, 4.9%). For **8c**, IR (neat) 2950, 1734, 1700, 1430, 1350, 1273, 1245, 1220, 1118, 968 cm^{-1}; NMR(CCl_4) δ 1.5—2.6 (m, 12H), 3.30 (m, 1H), 3.68 (s, 3H); Mass *m/e* 196 (M^+), 165, 141, 113, 83, 55. For **14**, IR (neat) 2970, 1728, 1430, 1283, 1215, 1195, 1120, 1070, 970 cm^{-1}; NMR (CCl_4) δ 1.6—2.6 (m, 12H), 3.58 (mc, 6H); Mass *m/e* 226 (M^+), 194, 170, 166, 153, 139, 114, 107, 83, 79, 59, 55. Methyl cyclobutanecarboxylate (**11c**) was identified by comparison of glpc retention time with that of an authentic sample. However, when a solution of dione (**6c**) (100 mg) in methanol (20 ml) was allowed to stand at room temperature for 5 hr, **6c** underwent a facile ring opening to produce **8c** quantitatively. On the other hand, diones (**6a**, **b**,**d**,**e**) were stable in refluxing methanol.

Photolysis of Dispiro[6.1.6.1]hexadecane-8,16-dione (6d) in Methanol. A solution of dione (**6d**) (5.1 mmol) in 250 ml

of methanol was irradiated using a Pyrex filter at −70 °C for 2 hr. Analysis of the photolysate by glpc revealed the following products: ring expanded acetal (**7d**, 3.8%), methyl 1-(1-cycloheptenyl)cycloheptanecarboxylate (**10d'**, 21,1%) and methyl cycloheptanecarboxylate (**11d**, 9.3%). Methyl cycloheptanecarboxylate (**11d**) was identified by comparison of glpc retention time with that of an authentic sample. For **7d**, IR (neat) 2930, 2850, 1725, 1440, 1100, 970 cm^{-1}; NMR (CCl_4) δ 1.50—1.90 (m, 24H), 3.36 (s, 3H), 4.62 (s, 1H); Mass *m/e* 280 (M^+), 220, 140, 124, 108, 95. For **10d'**, IR (neat) 2930, 2850, 1725, 1440, 1240, 1190, 1170, 1060 cm^{-1}; NMR (CCl_4) δ 1.30—1.80 (m, 18H), 1.94—2.20 (m, 4H), 3.56 (s, 3H), 5.62 (t, 1H); Mass *m/e* 250 (M^+), 191, 180, 156, 109, 95.

Photolysis of Dispiro[4.1.5.1]tridecane-6,13-dione (6e) in Methanol. A solution of **6e** (1.84 mmol) in 300 ml of methanol was irradiated at −70 °C for 1 hr. Preparative glpc afforded keto ester (**8e**) and methyl 1-(cyclopentyl)cyclohexanecarboxylate (**10e**) in 20.5% and 15.2% yields, respectively. For **8e**, IR (neat) 2950, 2900, 1730, 1705, 1445, 1295, 1220, 1120 cm^{-1}; NMR (CCl_4) δ 1.27—2.30 (m, 18H), 2.50—2.78 (b, 1H), 3.66 (s, 3H); Mass *m/e* 238 (M^+), 206, 195, 178, 142 (vs), 110, 96, 85, 67. For **10e**, IR (neat) 2950, 2900, 1725, 1450, 1200, 1170, 1130, 1000 cm^{-1}; NMR (CCl_4) δ 1.20—2.65 (m, 19H), 3.64 (s, 3H); Mass *m/e* 210 (M^+), 208, 176, 151, 149, 142, 128, 95, 87, 83, 81, 69.

The Catalytic Effect of Crown Ethers on Benzoin Condensation

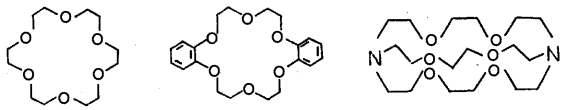
Sadatoshi AKABORI,* Michiko OHTOMI, and Katsuhiko ARAI

Department of Chemistry, Faculty of Science, Tōho University, Funabashi, Chiba 275

(Received August 9, 1975)

Aromatic aldehydes were treated with potassium cyanide in the presence of a crown ether in water or in aprotic solvents to give benzoins in high yields, although similar reactions in the absence of the crown ether proceeded sluggishly in general. The catalysis is believed to be due to the ability of the crown ether to bring anions into the organic phase.

In recent years there have been reported several synthetic applications of crown ethers, such as 18-crown-6 (I) and dibenzo-18-crown-6 (II), which possess the ability to form complexes with a variety of inorganic salts and also the ability to solubilize these salts in aprotic solvents. The following reactions are reported to be enhanced by the crown ether: substitution reactions,[1-6] elimination reactions,[7,8] a condensation reaction,[9] oxidation reactions,[3,10] a reduction reaction,[3] and an addition reaction.[11]

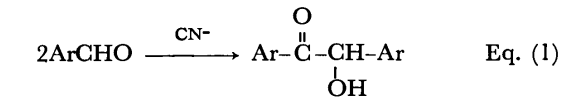


(I) (II) (III)

In a previous paper,[12] we have reported on the reaction of potassium alkanoate with alkyl halide in an aprotic solvent. Although the reaction of potassium alkanoate with alkyl halide does not proceed in aprotic solvents such as benzene, the reaction with the same starting materials in the presence of catalytic amounts of a bicyclopolyether such as III affords alkyl esters in high yields. As an extension of our previous work, we have been interested in seeking examples of the enhancement of the reaction by crown ethers in the field of condensation, which has been little studied.[9] Benzoin condensation was taken as our target. Generally benzoins are generated by the action of sodium cyanide or potassium cyanide on aromatic aldehydes in aqueous ethanol.[13] We now wish to report that dramatic results can be achieved by the addition of crown ethers (I and II) to benzoin condensations in water and in aprotic solvents at appropriate temperatures.

Results and Discussion

Benzoin Condensation in Water. The condensation reactions represented by Eq. 1 were run in heterogeneous systems by the use of crown ethers (I and II) as anion-transfer catalysts:



$$2\mathrm{ArCHO} \xrightarrow{\mathrm{CN^-}} \mathrm{Ar{-}C(=O){-}CH(OH){-}Ar} \qquad \text{Eq. (1)}$$

IV: Ar=C_6H_5–, V: Ar=*p*-CH_3-C_6H_4–,
VI: Ar=furyl

The reagent is prepared by dissolving potassium cyanide in water and by then adding 18-crown-6. After the mixture has been stirred for 30 min, the organic substrate is added and the resulting heterogeneous mixture is stirred for 15 min to 6 hr at appropriate temperatures. The results are shown in Table 1. The reaction conditions are relatively mild (at 25 or 60 °C), and the conversions are high at 60 °C; in the presence of *ca.* 7% of crown ether, benzoin was obtained in more than 78% yields within 15 min from benzaldehyde, *p*-toluoin (99%) in 3 hr from *p*-tolualdehyde, and furoin (66%) in 15 min from 2-furaldehyde.

Table 1. Reactions of aromatic aldehydes with potassium cyanide

Substrate	Solvent[a]	Reaction temp (°C)	Reaction time (hr)	Product[b]	Yield(%)[c] Crown ether present	Yield(%)[c] Crown ether absent
IV	H_2O	25	1.5	Benzoin	73.9	3.1
IV	H_2O	60	0.25	Benzoin	78.0	3.3
V	H_2O	25	6.0	*p*-Toluoin	44.3	0.0
V	H_2O	60	3.0	*p*-Toluoin	99.0	1.9
VI	H_2O	25	1.5	Furoin	35.6	24.4
VI	H_2O	60	0.25	Furoin	66.2	48.0
IV	CH_3CN	25	3.0	Benzoin	78.4	1.1
IV	CH_3CN	60	1.5	Benzoin	73.6	9.0
IV	C_6H_6	25	3.0	Benzoin	70.9	0.1
IV	C_6H_6	60	3.0	Benzoin	95.9	0.5
V	CH_3CN	25	6.0	*p*-Toluoin	56.4	2.7
V	CH_3CN	60	3.0	*p*-Toluoin	99.0	6.0
V	C_6H_6	25	6.0	*p*-Toluoin	29.1	0.0
V	C_6H_6	60	3.0	*p*-Toluoin	90.8	0.0
VI	CH_3CN	25	3.0	Furoin	65.0	3.7
VI	CH_3CN	60	0.25	Furoin	43.6	3.6
VI	C_6H_6	25	3.0	Furoin	52.7	0.3
VI	C_6H_6	60	3.0	Furoin	53.0	0.0

a) 2.7 ml of water or 9.0 ml of aprotic solvents were used. b) All product show the same retention time with authentic sample and mass spectra were consistent with the proposed structure. c) The values are those obtained by GLC.

In sharp contrast, benzoin and *p*-toluoin were obtained in less than 3% yields in the absence of the crown ether, although furoin was obtained in a good yield from 2-furaldehyde under similar conditions. These results can be accounted for in terms of the solubility of aldehydes in water; 2-furaldehyde is fairly soluble in water, whereas benzaldehyde and *p*-tolualdehyde are soluble in water to only a limited extent. Generally a reaction between two substrates located in different phases of a mixture is often inhibited because of the inability of reagents to come together. However, this reaction is brought about by the use

of small quantities of a reagent, which transfers one reactant across the interface into the other phase. Although potassium cyanide is an excellent catalyst for benzoin condensation at 90 °C in 95% ethanol,[14] it exhibits hardly any catalytic ability in water at room temperature.[15] However, as is shown in Table 1, complexes of crown ether with potassium cyanide afford benzoin in high yields even when the reaction was run at room temperature. Thus, in the benzoin condensation of aromatic aldehydes, it is most likely that crown ethers transport cyanide into the organic phase, although the possibility of transforming the aromatic aldehyde into the aqueous phase can not be ruled out.

Benzoin Condensation in Aprotic Solvents. The crown ethers are known to form complexes with alkali and other metal salts to increase the solubility and to increase the reactivity of anions in aprotic solvents. The potassium cyanide complex of 18-crown-6 was prepared *in situ* by dissolving a catalytic amount of 18-crown-6 in *ca.* 9 ml of a dry aprotic solvent (benzene or acetonitrile) and by then adding appropriate amounts of potassium cyanide, most of which remained insoluble. After the heterogeneous system had been stirred for 30 min, the aromatic aldehyde was added at once; the resulting mixture was stirred for from 15 min to 6 hr at 25 or 60 °C. In the absence of the crown ether, potassium cyanide does not have any detectable solubility in benzene and hardly no reaction occurs; benzaldehyde gives less than a 0.5% yield of benzoin after 3 hr at 60 °C when it is treated with potassium cyanide in the absence of 18-crown-6, whereas benzoin is formed in a 95.9% yield within 3 hr when a trace amount of 18-crown-6 is present. The reaction was found to be faster in acetonitrile than benzene.

In summary, these experimental results in water indicate that crown ethers may be at least as useful as onium salts in reactions which proceed by means of phase-transfer. It has been shown that crown ether (I) effectively solubilizes potassium cyanide in aprotic solvents and that the reagent produces benzoins in high yields from a variety of organic substrates. The catalytic activity of dibenzo-18-crown-6 is almost the same as that of 18-crown-6.

Experimental

Analysis. The products were analyzed by gas chromatography. The gas chromatograms were obtained on a Hitachi 023 gas chromatograph, using 10% FFAP on Chromosorb W AW/DMCS 1 m×3 mm. The mass spectra were recorded on a Shimadzu LKB 9000 gas-chromatograph-mass-spectrometer at an ionizing voltage of 70 eV.

Materials. 18-Crown-6[16] and dibenzo-18-crown-6[17] were prepared according to the procedures described in the literature. Authentic samples (benzoin[14], *p*-toluoin[18] and furoin[19]) were also prepared according to the procedures described in the literature. Potassium cyanide of Koso Co., Ltd., and aromatic aldehydes of the Tokyo Kasei kogyo Co., Ltd., were used without further purification. The solvents used were purified by distillation.

Benzoin Condensation of Benzaldehyde in Water. The following procedure for the preparation of benzoins is representative. A mixture of potassium cyanide (20.0 mmol), 18-crowm-6 (1.22 mmol), and 2.7 ml of water was stirred for 30 min at 60 °C. Benzaldehyde (41.7 mmol) was then added at once, and the mixture was stirred for a further 15 min. A yellow precipitate, which gradually formed, was collected by filtration, and the filtrate was extracted with chloroform. The yellowish solid was dissolved in the chloroform extract, and then the solution was subjected to gas-chromatographic analysis.

Benzoin Condensation of Benzaldehyde in Aprotic Solvents. A mixture of potassium cyanide (20.7 mmol), 18-crown-6 (1.40 mmol), and *ca.* 9 ml of benzene was stirred for 30 min at 25 °C. Benzaldehyde (49.9 mmol) was then added at once, and the mixture was stirred for a further 3 hr. The work-up and analysis were performed analogously with the case cited above.

Benzoin Condensation with the Aid of Dibenzo-18-crown-6. The reaction was carried out similarly. The results were usually quite similar, although results a little inferior were sometimes obtained.

The authors wish to express their gratitude to Professor Michinori Ōki, the University of Tokyo, for his valuable discussions and suggestions.

Double 1,3-Dipolar Cycloaddition Reaction of 3-Phenylsydnone with 1,3-Dienes

Akira HANEDA, Takeshi IMAGAWA, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

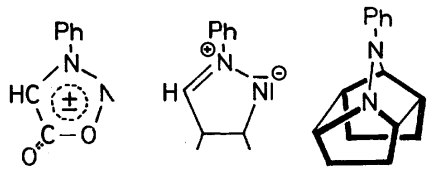
(Received August 14, 1975)

Thermal reaction of 3-phenylsydnone with isoprene or 2,3-dimethylbutadiene gave 2-methyl- or 2,6-dimethyl-7-phenyl-1,7-diazatricyclo [2.2.1.$0^{2,6}$]heptane, together with 3-isopropenyl-1-phenylpyrazole. The former is the product of the double 1,3-dipolar cycloaddition. A similar reaction with 1,3-butadiene gave only 3-vinyl-1-phenylpyrazole.

3-Phenylsydnone (**1**) and other sydnone derivatives have been found by Huisgen and his co-workers[1] to undergo 1,3-dipolar cycloaddition with both electron-deficient and -abundant olefins and acetylenes.

Of the many reactions reported by Huisgen, there is only one case in which one molecule of **1** adds to two molecules of dipolarophile, *i.e.*, acenaphthylene. The intermediate of this reaction is thought to be the azomethine-imine (**2**), which has been known to behave as a 1,3-dipole.

Recently, the intramolecular case of this double 1,3-dipolar cycloaddition reaction has been reported by Weintraub[2]; he used 1,5-cyclooctadiene as the dipolarophile. The tetracyclic product (**3**) is composed of four rings, two of which are formed by the two 1,3-dipolar cycloadditions; the other two, indicated by the bold lines, may be considered to be due to the concomitant cyclization reactions.



(1) (2) (3)

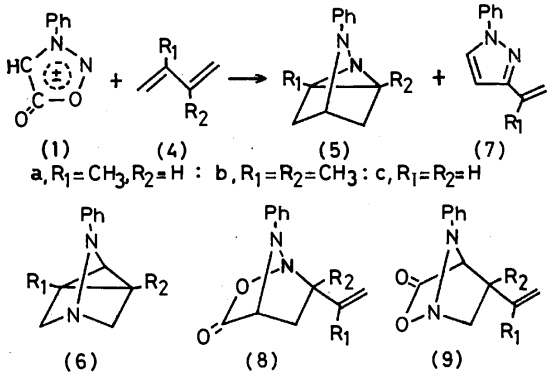
Formulas.

The formation of alicyclic rings has been discussed in terms of two kinetic factors: energy (strain) and entropy (probability) factors.[3] The above-mentioned cyclization forming the five-membered rings is governed mainly by energy factor.[4] The other factor contributes to the case of cyclopropane-ring formation. Therefore, if we utilize 1,3-dienes as the diene component, the intramolecular capture of the reactive intermediate can be expected to be easily done by the concomitant cyclopropane-ring formation. This prediction[5] was substantiated in the case of the Diels-Alder reactions of 2-pyrone derivatives with 1,3-dienes.[6]

The aim of the present study is to apply this principle to the 1,3-dipolar cycloaddition reaction and to obtain the diazanortricyclenes.

Heating of a solution of **1** and isoprene (**4a**) in ethyl acetate at 150 °C for 24 hr, followed by flash distillation, gave an oily mixture which was shown by GLC analysis to consist of two components present in the ratio of about 1: 1. Preparative GLC separation allowed their isolation.

The faster-moving fraction (**5a**) gave the correct



(1) (4) (5) (7)

a, R_1=CH_3, R_2=H : b, R_1=R_2=CH_3 : c, R_1=R_2=H

(6) (8) (9)

Scheme.

analysis for $C_{12}H_{14}N_2$. In the NMR spectrum, the absence of any signal of olefinic protons except those of aromatic protons indicates the tricyclic structure, while the absence of any prominent coupling pattern indicates the diazanortricyclyl system, since the reported coupling constants in the nortricyclyl system[7] are small (1.5 Hz at most). The two methine protons adjacent to nitrogen atom clearly exclude the alternative structure, **6a**.

The slower-moving fraction (**7a**) showed the NMR signals of only aromatic and olefinic protons, except for the methyl protons. The magnitude of the coupling constants and the chemical shifts of the pyrazole ring protons revealed the 3-substituted 1-phenylpyrazole structure.[8] The isopropenyl substituent could be derived from the olefinic proton signals, exhibiting patterns characteristic of *exo*-methylene signals.[9]

A similar reaction of **1** and 2,3-dimethylbutadiene (**4b**) at 150 °C for 6.5 hr gave, after distillation, an oily mixture consisting of two components in the ratio of 4: 1.

The isolation of the major component by preparative GLC revealed the major component to be identical with the pyrazole, **7a**, obtained in the reaction with **4a**. The formation of **10a** in the present reaction is explained by the elimination of a methane molecule after the first decarboxylation. This apparently unusual reaction is not without precedent in the 1,3-dipolar cycloaddition reaction.[10]

The minor product was proved to have a tricyclic structure (**5b**).

In the reaction of **1** with butadiene (**4c**), prepared *in situ* from sulfolene, at 150 °C for 47 hr, we could not obtain the tricyclic product (**5c**); only 1-phenyl-3-vinylpyrazole (**7c**) could be isolated.

From these structures of the products, it was concluded

that the first 1,3-dipolar addition step gave, regioselectively, the adduct (**8**) and that no product originating from an alternative intermediate (**9**) was found. This regioselectivity is in the same line as the 1,3-dipolar cycloaddition reaction of **1** with stilbene[1] and is not in conflict with the prediction made by the perturbation molecular orbital methods of Bastide[11] and of Houk.[12]

Our initial attempt has been successful, although the yield is far from satisfactory. In these reactions it was not possible to by-pass the formation of tarry material, and no optimization of the yield of the tricyclic products was undertaken.

Experimental

The NMR spectra were measured in CCl_4 solution, using TMS as the internal standard. The mass spectra (MS) were obtained at 70 eV. GLC was performed at the column temperature of 130 °C with a Shimadzu GC-4AIT apparatus with a 3 mm × 1 m column packed with 10% High Vacuum Silicone Grease on Chromosorb W (80—100 mesh).

Reaction of 1 with Isoprene (4a). A solution of 1.00 g (6.18 mmol) of **1** and 0.48 g (12.4 mmol) of isoprene (**4a**) in ethyl acetate (10 ml) was heated in a pressure bottle at 150 °C for 24 hr. After evaporation of the solvent, bulb-to-bulb distillation (oven temperature 150—180 °C, 3 mm) gave an oily mixture (1.15 g) which consisted of two components in the ratio of about 1: 1. These substances were separated by preparative GLC.

The first eluate (**5a**); IR: 1601, 1500, 752, and 690 cm^{-1}. NMR: δ 7.0 (m, 5H, Ph), 1.48 (s, 3H, CH_3), 1.4 (m, 4H, 2× CH_2). 2.24 (s, 1H, CH–N), and 3.83 (broad s, 1H, CH–N); MS: *m/e* 186 (M^+, 31), 105 (57), 81 (67), 79 (36), 77 (100%). Found: C, 77.34; H, 7.56; N, 14.84%. Calcd for $C_{12}H_{14}N_2$: C, 77.38; H, 7.58; N, 15.04%.

The second eluate (**7a**): IR; 1516, 1500, 1341, 1280, 1146, 942, 891, 750, 692 cm^{-1}; UV: λ_{max}^{MeOH} 276 nm (ε 18000); MS: *m/e* 185 (M^++1, 21), 184 (M^+, 100), 183 (43), 169 (23), 81 (20), 77 (38); NMR: δ 7.77 (d, 2.5 Hz, 1H), 6.47 (d, 1H, 2.5 Hz) (pyrazole), 7.0—7.9 (m, 5H, Ph–), 5.47 (m, 1H), 5.05 (m, 1H) (CH_2=), and 2.20 (s, 3H, CH_3) ppm. Found: C, 78.15; H, 6.72; N, 15.14%. Calcd for $C_{12}H_{12}N_2$: C, 78.23; H, 6.57; N, 15.21%.

Reaction of 1 with 2,3-Dimethylbutadiene (4b). A solution of 1.00 g of **1** (6.18 mmol) and 1.01 g (12.4 mmol) of **4b** in ethyl acetate (10 ml) was heated in a pressure bottle at 150 °C for 6.5 hr. Distillation gave an oily mixture (441 mg) which consisted of two components in the ratio of 4: 1. These substances were separated by preparative GLC.

The major substance was identified as **7a**, by comparison of its IR, NMR, MS, and the retention time of GLC with those of the afore-mentioned product.

The minor substance, **5b**: MS: *m/e* 200 (M^+, 33), 105 (35), 95 (100), 77 (83), 67 (40%); NMR: δ 7.0 (m, 5H, Ph–), 3.80 (m, 1H), 1.4 (m, 4H, 2× CH_2), 1.42 (s, 6H, 2× CH_3) ppm. Found: C, 77.67; H, 7.91; N, 13.71%. Calcd for $C_{13}H_{16}N_2$: C, 77.96; H, 8.05; N, 13.99%.

Reaction of 1 with Butadiene (4c). A solution of 231 mg (1.42 mmol) of **1**, 252 mg (2.14 mmol) of 3-sulfolene and a trace of hydroquinone in ethyl acetate was heated in a pressure bottle at 150 °C for 47 hr. Distillation gave an oily mixture (102 mg; 1: 1). One components was **7c**. The other was an unidentified hydrocarbon, probably originating from **4c**.

7c; MS: *m/e* 170 (M^+, 100), 169 (78), 152 (27), 149 (45), 77 (36%); NMR: δ 7.1—7.7 (m, 5H, Ph–), 7.80 (d, 3.1 Hz, 1H) and 6.48 (d, 3.1 Hz, 1H) (pyrazole), 6.76 (q, 11.0 and 17.8 Hz, 1H), 5.70 (q, 17.8 and 1.6 Hz, 1H), 5.30 (q, 11.0 and 1.6 Hz, 1H). Found: C, 77.66; H, 5.78; N, 16.70%. Calcd for $C_{11}H_{10}N_2$; C, 77.62; H, 5.92; N, 16.46%.

Cyclopentadienylsodium and Phenylethynylsodium as Cocatalysts in Olefin Metathesis

Kazuaki ICHIKAWA, Toru TAKAGI,* and Kazuo FUKUZUMI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa, Nagoya 464

(Received August 29, 1975)

Cyclopentadienylsodium and phenylethynylsodium are effective cocatalysts with WCl_6 in the homogeneous olefin metathesis. The optimum mole ratios of C_5H_5Na and $PhC{\equiv}CNa$ to WCl_6 ranged more widely—from 1.5 to 3.0 and from 1.5 to 2.5 respectively—than that of BuLi to WCl_6. The formation of the Friedel-Crafts products was extremely small—such as 1—%, if the cocatalyst/WCl_6 ratio was about 2. The new catalyst systems were less poisoned by ether than the other catalyst systems and were hardly deactivated in the course of the reaction. The characteristics of these catalyst systems were discussed.

In olefin metathesis, the alkylidene moieties of olefins are redistributed as follows:

$$\begin{matrix} R_1CH{=}CHR_2 \\ + \\ R_3CH{=}CHR_4 \end{matrix} \rightleftharpoons \begin{matrix} R_1CH \\ \| \\ R_3CH \end{matrix} + \begin{matrix} HCR_2 \\ \| \\ HCR_4 \end{matrix}$$

For the homogeneous metathesis, binary catalyst systems, such as WCl_6, $MoCl_5$ or $ReCl_5$–R_4Sn,[1] RMgX,[2] RLi,[3] or $R_{3-n}AlCl_n$,[4] in which R is an alkyl or an aryl group, have been used *in situ*. Also, hydridic agents, such as lithium aluminum hydride and sodium borohydride, have been used as cocatalysts with WCl_6.[5] This reaction is unique and useful, but it has the faults that the catalysts are unstable and easily deactivated.

This study of cyclopentadienylsodium and phenylethynylsodium as cocatalysts was carried out in order to improve these faults and in order to investigate the scope and the limitations of the cocatalysts.

Results and Discussion

Dependence of Conversion on the Cocatalyst/WCl_6 Ratio. The dependence of the conversion on the Na/W mole ratio in the metathesis with catalyst systems of WCl_6–C_5H_5Na and WCl_6–$PhC{\equiv}CNa$ is shown in Table 1. Good conversions were obtained at a Na/W ratio near 2 in both cases. Wang and Menapace have reported that the optimization at Li/W=2 strongly suggests a W^{IV} catalytic intermediate in the metathesis with a binary catalytic system of WCl_6 and *n*-BuLi.[3]

In the WCl_6–$PhC{\equiv}CNa$ system the formation of diphenyldiacetylene was confirmed by GLC analysis. This fact suggests that the active catalyst species, $W^{IV}Cl_4$, forms as follows:

$$WCl_6 + 2PhC{\equiv}CNa \xrightarrow{-2NaCl} (PhC{\equiv}C)_2WCl_4 \longrightarrow WCl_4 + PhC{\equiv}C\text{-}C{\equiv}CPh$$

In the NMR study, when WCl_6 was added to the C_5H_5Na benzene solution, the proton signal of $C_5H_5^-$ (1.7 ppm to high fields of the benzene reference, a singlet) disappeared and a new peak assignable to the vinyl protons of cyclopentadiene (about 0.85 ppm to high fields of the benzene reference, a multiplet) appeared. Also, in the WCl_6–C_5H_5Na system, it is speculated that the catalyst formation proceeds by a mechanism similar to that of the WCl_6–$PhC{\equiv}CNa$ system.

Table 1. Effect of cocatalyst/WCl_6 ratio[a]

Cocatalyst (M)	M/W ratio	Products, mol%[b]			
		C_4	C_7	C_{10}	F.C.[c]

a) The reactions of 2-heptene (1.2 mol/l) with WCl_6 (2.4×10^{-2} mol/l) and the listed cocatalysts were carried out in benzene at room temperature for 15 h. b) Mol% of each product to the total amounts of 2-butene, 2-heptene, 5-decene, and Friedel-Crafts products. c) Friedel-Crafts products.

In Fig. 1 the conversions are plotted against the cocatalyst/WCl_6 mole ratio. The optimum ranges of the cocatalyst/WCl_6 ratio decreased as follows:

C_5H_5Na, 1.5—3.0 > $PhC{\equiv}CNa$, 1.5—2.5 > BuLi, 2

In the WCl_6–BuLi system, the sharp decrease in the conversion at Li/W>2 suggests that the Bu^- from BuLi easily displaces more than two Cl^- on WCl_6 because of the strong nucleophilicity of the carbanion, that is, the $W^{IV}Cl_4$ formed is easily attacked further by the excess BuLi to be destroyed. On the other hand, the wide optimum range of the Na/W ratio in the WCl_6–C_5H_5Na system suggests that $C_5H_5^-$ from C_5H_5Na does not destroy the active W^{IV} species to any considerable extent, because of the weaker nucleophilicity of the carbanion. As the optimum range of the Na/W ratio

in the WCl_6–PhC≡CNa system lies in between that in WCl_6–C_5H_5Na and that in WCl_6–BuLi, the nucleophilicity of $PhC{\equiv}C^-$ may be stronger than that of $C_5H_5^-$ and weaker than that of Bu^-. These cocatalysts are different from any other cocatalyst reported in that, in C_5H_5Na, the negative charge of the cyclopentadienide anion is delocalized on all the five carbon atoms, while in PhC≡CNa the anion is composed of the carbon atoms of the sp hybridization. The weak nucleophilicity may be attributable to this unique character.

The higher activity of the WCl_6–C_5H_5Na and WCl_6–PhC≡CNa systems than the WCl_6–BuLi system in the region of cocatalyst/$WCl_6<2$ may be explained by either one or both of the following reasons: (1) the slower deactivation of the WCl_6–C_5H_5Na and WCl_6–PhC≡CNa systems than the WCl_6–BuLi system, as will be described later, and (2) BuLi reacts completely and irreversibly with water, but C_5H_5Na and PhC≡CNa do so only reversibly and incompletely. Moreover, the hydroxide anion resulting from the reactions may be a more powerful inhibitor than water itself. Water is presumed to be the main inhibitor, since the deactivation of the metathesis catalyst was observed upon the addition of water and trace amounts of water are inferred to exist in the solvent and olefin, and on the wall of the reaction tube, though it was excluded as much as possible. Similarly, the higher activity of these catalyst systems than that of the WCl_6–BuLi system in the cocatalyst/$WCl_6\geqq2$ region may be attributable to the slower deactivation of these catalyst systems and the weaker nucleophilicity of the carbanions of the cocatalysts.

Because of the highly acidic character of the hydrogens of the cyclopentadiene and phenylacetylene, these cocatalysts are easily synthesized. Moreover, they are less hazardous and more stable than most other cocatalysts and less toxic than R_4Sn.

Phenylsodium and 1-hexynylsodium were also effective as cocatalysts of metathesis. However, triphenylmethylsodium and diphenylmethylsodium were not effective. These facts can be explained by the difficulties of the displacement of Cl in WCl_6 with the carbanions from triphenylmethylsodium and diphenylmethylsodium due to their weak nucleophilicity, itself attributable to the steric hindrance and the electronic effect.

Dependence of Conversion on the Reaction time.

Figure 2 shows the dependence of the conversion on the reaction time in the metathesis of 2-heptene with a catalyst system of WCl_6–C_5H_5Na, together with the reaction by the WCl_6–BuLi, WCl_6–Bu_4Sn, or WCl_6–Et_3Al system. The catalyst from WCl_6–C_5H_5Na required preformation periods to reach its maximum activity toward metathesis. In Curve A of Fig. 2, WCl_6 and C_5H_5Na had been allowed to stand for half an hour at room temperature before the olefin was added. The two reactions of A and B were identical in all other respects. The S shape of Curve B may be attributed to the incompleteness of the formation of active species at the initial stage of the reaction without standing, whereas the catalysts from WCl_6–BuLi, WCl_6–Bu_4Sn, and WCl_6–Et_3Al do not require the preformation periods. These facts suggest that, in the WCl_6–C_5H_5Na system, the catalyst formation, that is, the nucleophilic attack of carbanion on WCl_6 and/or the reductive elimination of carbanion from R_2WCl_4, proceeded more slowly than in WCl_6–BuLi, WCl_6–Bu_4Sn, or WCl_6–Et_3Al. Moreover, Fig. 2 shows that the initial rates increased in the following order:

$$C_5H_5Na \sim BuLi < Bu_4Sn < Et_3Al.$$

The fact that alkali salts of carbanions afford the active metathesis catalysts with WCl_6 suggests that the central metals of the cocatalysts need not be Lewis acids. However, the order of the initial rates suggests that the reduced tungsten component was activated by the presence of acidic aluminum and tin species. Aluminum capable of binding to tungsten through Cl bridges might be a constituent of the catalyst and might modify the distribution of the electron density of the reduced tungsten component and/or might accelerate the formation of an active *cis* intermediate, *cis*-WCl_4-$(Olefin)_2$.[6] Also, the possibility of Sn–W coordination bond formation in the WCl_6–Bu_4Sn system can not be denied, since several compounds containing tin-transition metal bonds have been reported.[7] Tin might function as the electron modifier of the reduced tungsten component.

Table 2. Friedel-Crafts products[a]

Cocatalyst (M)	M/W ratio	Olefin/W ratio	Products, mol%[b]			
			C_4	C_7	C_{10}	F.C.[c]
C_5H_5Na	2	100	25	49	25	1
PhC≡CNa	2	100	25	49	25	1
Bu_4Sn	1	100	20	52	21	7
Et_3Al	1	100	23	46	23	8

a) The reactions of 2-heptene with WCl_6 (2.4×10^{-2} mol/l) and the listed cocatalysts were carried out in benzene at room temperature for 15 h. b) Mol% of each product to the total amounts of 2-butene, 2-heptene, 5-decene and Friedel-Crafts products. c) Friedel-Crafts products.

Friedel-Crafts Products. The yield of the Friedel-Crafts products was 1% in the metathesis of 2-heptene by WCl_6–C_5H_5Na and by WCl_6–PhC≡CNa, whereas it was 7—8% in the metathesis reaction of 2-heptene by WCl_6–Bu_4Sn and by WCl_6–Et_3Al, as is shown in Table 2. These facts, that the WCl_6–acidic cocatalyst system favors the Friedel-Crafts reaction more than the WCl_6-basic cocatalyst system, may be attributable to the influence of aluminum and tin on the reduced tungsten component through the W–Cl–Al or W–Sn bond.

Stability of Catalysts. In the olefin metathesis, the conversion of olefin should attain the equilibrium conversion, 50%. The failure to reach the equilibrium value results from catalytic deactivation, as has been described in our previous paper.[1,2] As is shown in Fig. 2, when BuLi or Bu_4Sn was used as a cocatalyst, the conversion leveled off within 3 h. On the other hand, in the WCl_6–C_5H_5Na system, the increase in conversion continued and the equilibrium conversion was reached. This result and those shown in Table 3 show that the deactivation of the WCl_6–C_5H_5Na system proceeded more slowly than those of the WCl_6–BuLi and WCl_6–Bu_4Sn systems.

The deactivation of the metathesis catalyst not only has been reported in the literature but has also been observed in our laboratory by the addition of heteroatom compounds, such as water, alcohols, ethers, carbonyl compounds, carboxylic acids, esters, amines, nitriles, amides, phosphines, thiophene and thiophenol, as has previously been reported.

Table 3. Stability of catalyst[a]

Cocatalyst (M)	M/W ratio		Products, mol%[b]		
			C_4	C_7	C_{10}

		1	9	80	10	1
		2	2	95	2	1
		4	0	100	0	0
Bu_4Sn	1	0	23	47	23	7
		1	22	53	22	3
		2	11	76	12	1
		4	4	92	4	0

a) The reactions of 2-heptene (1.2 mol/l) with WCl_6 (2.4×10^{-2} mol/l) and the listed cocatalysts were carried out in benzene at room temperature for 15 h. b) Mol% of each product to the total amounts of 2-butene, 2-heptene, 5-decene and Friedel-Crafts products. c) Friedel-Crafts products.

In the metathesis using C_5H_5Na or PhC≡CNa with WCl_6, also, the effect of ether on the conversion was investigated; the results are shown in Table 4. The fact that the WCl_6–C_5H_5Na and WCl_6–PhC≡CNa systems were less poisoned by ether than the WCl_6–BuLi and WCl_6–Bu_4Sn systems suggests that the former systems are less deactivated by the water present in the reaction systems. The deactivation of the catalysts by ether may be explained by the following inferences: (1) the coordination of the inhibitor at its heteroatom to tungsten, which interrupts the formation of active intermediates, such as diolefin complexes; (2) the decomposition of the bimetallic catalyst system by the coordination of the basic inhibitor to the cocatalyst metal,[6] though no evidence for the formation of the tungsten-lithium or sodium binary complex has been reported in the olefin metathesis, and (3) the decomposition of the cocatalysts by a reaction with ether, such as a Wittig rearrangement.

The WCl_6–Bu_4Sn and WCl_6–BuLi systems showed the optimum conversion when 2—3 equivalent moles of dicyclopentadiene, cyclopentadiene, or phenylacetylene to WCl_6 were added. This suggests that the stability of the catalyst from the WCl_6–C_5H_5Na or PhC≡CNa system is also attributable to the organogroups from the cocatalysts, which may interrupt the coordination of the inhibitor, water, to tungsten by means of the coordination at the cyclopentadienyl ring or the triple bond.

Experimental

Materials. The cyclopentadienylsodium was prepared according to a modification of the method given in the literature.[8] Sodium-dried benzene and a sodium–naphthalene

dispersion containing 15 wt% sodium were used instead of xylene and sodium metal. The supernatant solution was stored in a sealed Schlenk tube. The concentration of the reagent was determined by titration with aqueous sodium hydroxide after the addition of excess hydrochloric acid to the reagent. The preparation and the analysis of phenylethynylsodium were carried out in a similar way.[9] The triethylaluminum and butyllithium (both 15 w/v % hexane solutions) and tetrabutyltin (extra pure reagent) were purchased and used without further purification. The tungsten hexachloride was purified by the sublimation of the more volatile contaminants, WO_2Cl_2 and $WOCl_4$, under nitrogen at about 200 °C, leaving a residue of pure tungsten hexachloride. The benzene was distilled over sodium wire under nitrogen. After having been dried over anhydrous calcium sulfate (Drielite), 1,2,4-trichlorobenzene was distilled under nitrogen. The mixed 2-heptene (*cis* content, 75%; Tokyo Kasei; extra pure reagent) was dried by sodium wire and distilled over sodium hydrogensulfite under nitrogen.

Procedure. A typical procedure for the metathesis of 2-heptene will now be described. To a dried glass tube sealed with a neopren rubber cap, 2-heptene (0.28 ml, 2.4×10^{-3} mol, 1.2 mol/l), a benzene solution of WCl_6 (4.8×10^{-5} mol, 2.4×10^{-2} mol/l), and a benzene solution of C_5H_5Na (9.6×10^{-5} mol, 4.8×10^{-2} mol/l) were injected, in this order, by means of hypodermic syringes. The total volume of the reaction mixture was 2.0 ml. The reaction mixture was oscillated vigorously at room temperature for 15 h, and then analyzed by gas-liquid chromatography, which was performed with a Shimadzu-GC-4APF or a JEOL-GC-1100 chromatograph, using an 1 m×3 mm column packed with 10% SE30 on 80—100 mesh Chromosorb W.

The Friedel-Crafts products were identified by gas-liquid chromatography using authentic samples which had been prepared by the alkylation of benzene with olefin catalyzed by sulfuric acid and aluminum chloride respectively. The identity of diphenyldiacetylene was determined by gas-liquid chromatography using an authentic sample prepared according to the method given in the literature.[10]

The NMR spectra were obtained by means of a Japan Electron Optics Lab. JEOL 60 HL apparatus operating at 60 MHz.

The Thermal Reaction of Azoxybenzenes

Ichiro SHIMAO and Hirokazu HASHIDZUME

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi, Toyama 933

(Received September 1, 1975)

Azoxybenzenes (**1**) were heated at 245—250 °C to give azobenzenes (**2**), 2-hydroxyazobenzenes (**3**), 2-hydroxyazoxybenzenes (**4**), 4-hydroxyazobenzenes (**5**), and 4-hydroxyazoxybenzenes (**6**). Compounds **4** and **6** were mostly composed of α-isomers. In the reaction of azoxytoluenes, their methyl groups were oxidized to formyl groups. It was proposed that **4** and **6** were the intermediates of the thermal rearrangement of **1** to **3** and **5**.

The Wallach rearrangement[1] and photorearrangement[2] of azoxybenzenes (**1**) have been extensively investigated, and it is well known that azobenzenes (**2**) can be prepared by a dry distillation of **1**. Recently, Feinstein and Fields[3] have investigated the reaction of azoxybenzene with benzene at elevated temperatures. However, only one work on the thermal rearrangement has been done. About seventy years ago, Knipscheer[4] reported that **1** decomposed thermally to give **2**, 2-hydroxyazobenzenes (**3**), and 4-hydroxyazobenzenes (**5**) at 240—250 °C in a carbon dioxide atmosphere. Azoxybenzenes gave mostly **5** in a Wallach rearrangement, and exclusively **3** in a photorearrangement, but they gave **3** and **5** in a thermal reaction. Consequently, it seemed that the thermal rearrangement may proceed by a mechanism different from those presented for the other rearrangements of **1**. In this paper, we will deal in detail with the thermal reaction of unsubstituted, 4-bromo-, 3,3′-, and 4,4′-disubstituted azoxybenzenes.

Results and Discussion

It was found by the differential thermal analysis that the exothermic reaction occurred when **1** was heated at 245—250 °C. The thermal decomposition of **1** at 245—250 °C gave **2**, **3**, 2-hydroxyazoxybenzenes (**4**), **5**, and 4-hydroxyazoxybenzenes (**6**), while the formation of **2**, **3**, and **5** has previously been reported by Knipscheer.[4] The results are shown in Table 1.

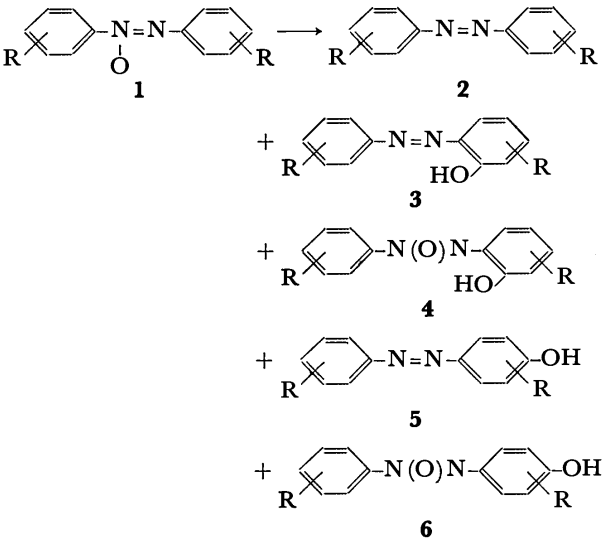
a) Reaction temperature, 245—250 °C. b) Crude product, mixture of **5** and **6**. c) Mixture of 2-hydroxy compound and 6-hydroxy compound. d) Tolylazobenzaldehyde was obtained. e) Mixture of 5-bromo-2-(phenylazo)phenol and 2-(4-bromophenylazo)phenol.

Significant amounts of black resinous substances were also formed as by-products.



After long heating **4** and **6** were not isolated, because of their lability under these conditions. Figure 1 shows the influence of the heating time on the yields of **2**, **3**, and **4** for the thermal reaction of azoxybenzene. The 2-hydroxyazoxybenzenes obtained by the thermal reaction were exclusively 2-(phenyl-ONN-azoxy)phenols (α-isomers). The α- and β-isomers of **4** were easily distinguished by their NMR spectra. The OH proton signal of the β-isomer appeared in a lower magnetic field than that of the α-isomer (2-hydroxyazoxybenzene: β-isomer, δ 11.73 ppm; α-isomer, δ 7.66 ppm). This may be attributed to the formation of an intramolecular hydrogen bond between the hydroxyl group and the

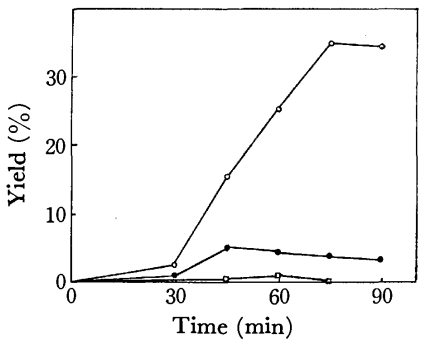


Fig. 1. The effect of the heating time on the yield of products, **2**, **3**, and **4**, for thermal reaction of azoxybenzene. At 245—250 °C.
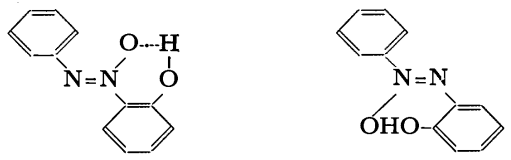
○: **2**, ●: **3**, □: **4**.

oxygen atom of the azoxy group in the β-isomer. On the other hand, in the α-isomer the formation of the analogous intramolecular hydrogen bond is impossible, because of a steric strain present in its coplanar seven-membered ring. Those results agreed with those postulated by Digiavi[5] from the fact that the α-isomer is more liable to undergo oxidation with a potassium permanganate solution than is the β-isomer. In addition, the presence of the intramolecular hydrogen bond in the β-isomer was also shown by an absorption near 3400 cm^{-1} in its IR spectrum and by a higher R_f value in TLC on silica gel.



β-isomer α-isomer

The ratio of 2-(3-chlorophenylazo)-4-chlorophenol to 2-(3-chlorophenylazo)-6-chlorophenol was determined by gas chromatography to be 1:1. 2-(3-Methoxyphenylazo)-4-methoxyphenol and 2-(3-methoxyphenylazo)-6-methoxyphenol were separated by column chromatography on silica gel, and the ratio of the 4-methoxy isomer to the 6-methoxy isomer was 1:2.1. Those ratios were analogous to that in the photorearrangement of the corresponding **1**. Tanikaga[6] reported that the substituents on 3,3'-positions do not have a steric effect on the isomer ratios upon the photorearrangement. Interestingly, it was found that, on the irradiation of an ethanolic solution of 3,3'-dimethoxyazoxybenzene, the oxygen atom rearranged preferentially to the *o*-position of methoxy group (4-methoxy isomer: 6-methoxy isomer=1:2.5).

The 2-hydroxyazoxybenzenes obtained from 3,3'-dichloro- and 3,3'-dimethoxyazoxybenzenes were a mixture of the α-isomers; however, because of difficulties in the separation, the ratios of the 2-hydroxy isomer to the 6-hydroxy isomer could not be determined. The mixture of 3,3'-dichloro-**4** was reduced with lithium aluminum hydride in ethyl ether to give the corresponding **2** and a mixture of the corresponding substances **3**. It was presumed, by a comparison of the retention time in high-speed liquid chromatography with that of the authentic samples,[7] that 4-hydroxyazoxybenzene was composed mostly of α-isomers.

The thermal reactions of 3,3'- and 4,4'-azoxytoluenes gave 3-(*m*-tolylazo)benzaldehyde (yield, 2.1%) and 4-(*p*-tolylazo)benzaldehyde (yield, 2.5%) respectively. The methyl group was oxidized to only the formyl group, and the hydroxymethyl and carboxyl groups have not been found in the reaction products, which did not show a characteristic absorption of the carboxyl group in the IR spectra or a signal of the benzyl methylene proton in the NMR spectra.

The ratios of 2-phenylazo-5-bromophenol to 2-(4-bromophenylazo)phenol obtained from 4-bromo-ONN- and 4-bromo-NNO-azoxybenzenes were 2.5:1 and 1:3 respectively. These ratios were determined by means of the strength of the OH proton signal of the mixture on the NMR spectra (2-phenylazo-3-bromophenol, δ 13.30 ppm; 2-(4-bromophenylazo)phenol, δ 12.88 ppm). The hydroxyl group was preferentially introduced in the benzene ring remote from the oxygen atom of the azoxy group; however, the selectivity was significantly lower than that in the photorearrangement. 4-Bromo-ONN-azoxybenzene reacted faster than the NNO-isomer, and the **1** was recovered from the reaction mixture without isomerization to the other azoxy isomer.

In order to examine the pathway of the formation of **4** and **6**, mixtures of **1** and **3**, or **5** (1:1), were heated at 245—250 °C for 30 min. If **3** or **5** were oxidized to **4** or **6**, a large quantity of **4** or **6** should be formed in this condition. Azobenzene was formed in a larger quantity than when azoxybenzene was heated alone (yield of azobenzene: azoxybenzene+2-hydroxyazobenzene, 44%; azoxybenzene+4-hydroxyazobenzene, 53%; azoxybenzene alone, 2.6%); however, **4** or **6** were not isolated. These results show that **4** or **6** is not formed by the oxidation of **3** or **5** with **1**. The absence of **4** or **6** may be attributed to the fact that **1** was readily reduced with **3** or **5** to give **2**. This is reflected by the increasing yield of **2**. On the other hand, azoxybenzene was easily reduced to azobenzene on heating with phenols, such as naphthols; the resinous material and water were then formed.

Since **1** served as oxidizing agent at high temperatures and was converted to **2**, the *o*- or *p*-position of **1** was oxidized to the hydroxyl group. The formation of **4** or **6** is a novel reaction in which the aromatic nucleus is directly oxidized to phenols. The formation of the α-isomer of **4** or **6** is due to the ready oxidation of the benzene ring apart from the oxygen atom of the azoxy group. This may be explained in terms of the resonance of **1** and the nucleophilic attack.

In addition, 2-hydroxyazoxybenzene and 3,3'-dichloro-4-hydroxyazoxybenzene gave 2-hydroxyazobenzene (yield, 17%) and 3,3'-dichloro-4-hydroxyazobenzene (yield, 18%) respectively on heating at 245—250 °C for 5 min. Thus, we may conclude that the thermal rearrangement of **1** to **3** or **5** involves the disproportionation of **1** to **2** and **4** or **6** (oxidation and reduction), and then the reduction of **4** or **6** to **3** or **5**:

$$2C_6H_5N(O)NC_6H_5 \longrightarrow C_6H_5N_2C_6H_5 + C_6H_5N(O)NC_6H_4(OH)\ (o\text{- or } p\text{-})$$

$$C_6H_5N(O)NC_6H_4(OH) \xrightarrow{\text{Reduction}} C_6H_5N_2C_6H_4(OH)\ (o\text{- or } p\text{-})$$

However, it is possible that the thermal rearrangement proceeds partly by the pathway[8] proposed for the Wallach rearrangement, which includes protonation and a symmetrical intermediate ion, or by the intramolecular pathway[9] proposed for the photorearrangement.

Experimental

The IR spectra were recorded with a JASCO IRA-1 spectrometer. The NMR spectra were obtained with a JEOL MH-100 spectrometer, using TMS as the internal standard. The gas-chromatographic analysis was carried out using a Shimadzu GC-2C apparatus on a 1.5 m×3 mm column packed with 5% SE-52. The high-speed liquid-chromato-

graphic analysis was carried out using a JASCO-FLC 150 apparatus on a 0.5 m×2.1 mm column packed with JASCO-DAC SV-02 (solvent: methanol–water). The differential thermal analysis was carried out using a Mitamura-Riken 2-100 DTA-S apparatus with a sample packed as a layer in α-alumina. The melting points are uncorrected.

The azoxybenzenes were prepared by the methods described in the literature.[10-12]

Thermal Reaction of 1. General Procedure: About a 0.2 g portion of **1** was placed in a small glass tube and heated at 245—250 °C in a silicone oil bath. After cooling, the reaction mixture was extracted with benzene, and then the extract was further extracted with a dilute sodium hydroxide solution. The alkali extract was acidified with hydrochloric acid, and the resulting precipitate was collected and chromatographed on silica gel by the use of chloroform as the solvent. The elution was in the following order: **3**, **4**, **5**, and **6**.

The alkali-insoluble material was chromatographed on alumina by the use of benzene as the solvent; the elution was in the following order: **2** and **1**.

Each eluent was evaporated and recrystallized from hexane or ehanol. These products were identified by a comparison of their mp and their IR and NMR spectra with those of the corresponding authentic samples, or by chromatographic analysis.

Tolylazobenzaldehydes: These compounds were obtained as second fractions in chromatography, on silica gel, of the alkali-insoluble parts in the reaction of azoxytoluenes. 4-(*p*-Tolylazo)benzaldehyde was recrystallized from acetone and sublimed under reduced pressure; mp 177—178 °C (lit,[13] 177.5 °C). 3-(*m*-Tolylazo)benzaldehyde, obtained as an oil (IR: 1700 cm^{-1}, NMR: δ 9.82 ppm (COH)), was oxidized with silver oxide to the carboxylic acid. The acid was esterified with methanol in the presence of sulfuric acid; subsequent recrystallization from petroleum ether gave methyl 3-(*m*-tolylazo)benzoate; mp 66.5—68 °C; Found: C, 70.85; H, 5.40; N, 10.97%. Calcd for $C_{15}H_{14}N_2O_2$: C, 70.85; H, 5.55; N, 11.02%.

Preparation of the Authentic Samples. The compounds **3**, except for 2-(3-chlorophenylazo)-6-chlorophenol, were synthesized by the photorearrangement of **1**, or by the coupling of the corresponding phenols and diazonium salts. 2-(3-Methoxyphenylazo)-4-methoxyphenol; mp 80.5—81.5 °C. Found: C, 64.82; H, 5.25; N, 11.08%. Calcd for $C_{14}H_{14}N_2O_3$: C, 65.10; H, 5.46; N, 10.85%. 2-(3-Methoxyphenylazo)-6-methoxyphenol, mp 128.5—129.5 °C. Found: C, 65.07; H, 5.31; N, 10.68%. Calcd for $C_{14}H_{14}N_2O_3$: C, 65.10; H, 5.46; N, 10.85%.

The compounds **5** were prepared by diazo-coupling in the usual method. 4-(3-Chlorophenylazo)-2-chlorophenol, mp 127—128 °C. Found: C, 54.17; H, 2.81; N, 10.67%. Calcd for $C_{12}H_8Cl_2N_2O$: C, 53.95; H, 3.02; N, 10.49%. 4-(3-Methoxyphenylazo)-2-methoxyphenol, mp 88—89 °C. Found: C, 64.91; H, 5.24; N, 10.88%. Calcd for $C_{14}H_{14}N_2O_3$: C, 65.10; H, 5.46; N, 10.85%.

2-(3-Chlorophenylazo)-6-chlorophenol: This compound was formed during the irradiation of 3,3′-dichloroazoxybenzene; however, its separation from its isomer was difficult. Consequently, the following synthesis was carried out. A mixture of 2-chloro-6-nitrophenol (9.1 g), benzyl chloride (13.3 g), and 3% sodium hydroxide solution (186 ml) was stirred for 4 hr at 50—60 °C. A subsequent recrystallization of the oily substance from methanol gave *benzyl 2-chloro-6-nitrophenyl ether*; mp 49 °C (yield, 17%). Found: C, 59.66; H, 3.85; N, 5.35%. Calcd for $C_{13}H_{10}ClNO_3$: C, 59.50; H, 3.70; N, 5.39%.

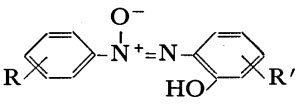
The catalytic hydrogenation of the benzyl ether (2.4 g) in ethanol using the Pt catalyst gave *3-chloro-2-benzyloxyaniline*. The treatment of the aniline with hydrochloric acid gave the amine hydrochloride (yield, 83%). The *acetanilide*; mp 84—85 °C. Found: C, 69.20; H, 5.27; N, 5.13%. Calcd for $C_{15}H_{14}ClNO_2$: C, 69.36; H, 5.43; N, 5.39%.

A mixture of the amine hydrochloride (2.4 g), 3-chloronitrosobenzene (1.1 g), and anhydrous sodium acetate (0.1 g) in acetic acid (11 ml) and benzene (10 ml) was stirred for 15 hr at room temperature. The reaction mixture was then steam-distilled, and the residue was collected. After purification by column chromatography on alumina, recrystallization from ethanol gave *3-chloro-2-benzyloxy-(3-chlorophenylazo)-benzene*; mp 74—75 °C (yield, 21%). Found: C, 63.63; H, 3.79; N, 7.86%. Calcd for $C_{19}H_{14}Cl_2N_2O$: C, 63.88; H, 3.95; N, 7.84%.

A mixture of the benzyloxyazobenzene (0.6 g), acetic acid (3.7 ml), and 47% hydrobromic acid (3.7 ml) was stirred for 8 hr at 45 °C. The mixture was then poured into cold water. The recrystallization of the resulting precipitate from ethanol gave 6-chloro-2(3-chlorophenylazo)phenol; mp 143.5—145 °C (yield, 74%); lit,[6] mp 144 °C.

α-2-Hydroxyazoxybenzenes: The 2-hydroxyazobenzenes were oxidized by 30% hydrogen peroxide in acetic acid according to the usual method.[14] The product was chromatographed on silica gel, using petroleum benzine–benzene as the developing solvent, to separate the α-isomer from the β-isomer and the unchanged azo compound, and then recrystallized from petroleum benzine. The results are shown in Table 2.

TABLE2. PREPARATION OF α-2-HYDROXYAZOXYBENZENES,



R	R′	Yield (%)	Mp (°C)	Found (Calcd) C %	H %	N %

Role of Amine in Arylation of Ethylene with Iodobenzene Catalyzed by Rhodium Trichloride

Kunio Mori, Tsutomu Mizoroki, and Atsumu Ozaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received September 5, 1975)

Rhodium trichloride effectively catalyzes the arylation of ethylene with iodobenzene in the presence of an amine to give styrene, although neither rhodium-powder nor chlorotris(triphenylphosphine)rhodium(I) is effective. The efficacy of the amine in increasing the yield of styrene is remarkable with tertiary and secondary amines but negligible with a primary amine. The difference among these amines in their interaction with rhodium trichloride is explained by their steric hindrance based on the isolation of the Rh(III)–amine complex only with primary amine.

The oxidative addition of an organic halide to Rh(I) complexes is well known. Alkyl, allyl, or acyl halide, for example, can be added to chlorotris(triphenylphosphine)rhodium(I) to give the corresponding σ-organorhodium(III) complex.[1] One of the well-known catalytic reactions using oxidative addition of an organic halide to Rh(I) complex is the acetic acid synthesis from methanol and carbon monoxide, of which the rate determining step is admittedly the oxidative addition of methyl iodide to Rh(I).[2] The oxidative addition of an aryl halide to Rh(I), however, is rarely found, except that iodobenzene reacts with methyltris(triphenylphosphine)rhodium(I) to give toluene.[3]

In the preceding paper, it was reported that, in the presence of a base, palladium-black effectively catalyzes the arylation of olefins with iodobenzene[4] as well as the carbonylation of iodobenzene.[5] These reactions are considered to take place *via* σ-arylpalladium(II) intermediate formed by the oxidative addition of iodobenzene to Pd(0) complex. As an extention of these studies, the oxidative addition of an aryl halide to rhodium has been examined. It has been found that the arylation of ethylene takes place smoothly in toluene when rhodium trichloride, $RhCl_3 \cdot 3H_2O$, is used as the catalyst together with a tertiary amine, whereas the primary amine is not very effective. The present paper is mainly concerned with the effect of the amine, and an interpretation is given for the reason why a tertiary amine is most effective in this catalytic reaction.

Experimental

Reaction Procedure. Rhodium trichloride ($RhCl_3 \cdot 3H_2O$, 0.5 mmol), iodobenzene (30 mmol), amine (0~30 mmol), and toluene (30 ml) were placed in a titanium-alloy autoclave (100 ml) equipped with a magnetic stirrer. Ethylene was introduced up to 20 kg/cm² at room temperature. The temperature was then raised up to 120 °C within 20 min, and kept constant for 3 hr. The autoclave was then cooled to room temperature with water, and the gaseous materials were discharged. The liquid products were quantitatively determined by gas chromatography, using a DC-550 column and bromobenzene as an internal standard.

Preparation of Rhodium Complexes. (a) Wilkinson's complex. $RhCl(P\phi_3)_3$ was prepared according to the literature[6] (Found: C, 70.46; H, 5.01; Cl, 4.23%. Calcd: C, 70.1; H, 4.9; Cl, 3.8%). (b) Penta(butylamine)chlororhodium(III)dichloride, $[RhCl(C_4H_7NH_2)_5]Cl_2$. $RhCl_3 \cdot 3H_2O$ (0.5 mmol) and butylamine (15 mmol) were placed in toluene (30 ml), and the solution was heated under reflux for 1 h. The solution turned yellow, giving a pale-yellow crystalline precipitate, which was recrystallized from methanol–water, and dried *in vacuo* (Found: C, 42.1; H, 10.0; N, 12.1; Cl, 19.3%. Calcd: C, 41.8; H, 9.58; N, 12.2; Cl 18.5%). (c) Tetra(butylamine)dichlororhodium(III)chloride, $[RhCl_2(C_4H_7NH_2)_4]Cl$. $[RhCl(C_4H_7NH_2)_5]Cl_2$ was treated with iodobenzene in the presence of butylamine under the conditions (Table 2) employed in the arylation of ethylene. No iodobenzene was consumed, while a precipitate was formed after the reaction. The precipitate was recrystallized from methanol and water (Found: C, 39.2; H, 9.6; N, 11.3; Cl, 19.0%. Calcd: C, 38.2; H, 8.8; N, 11.2; Cl 21.2%). (d) Tetra(benzylamine)dichlororhodium(III)chloride, $[RhCl_2(C_6H_5CH_2NH_2)_4]Cl$. The treatment of $RhCl_3 \cdot 3H_2O$ with benzylamine under the conditions employed in the arylation (Table 2) gave a crystalline yellow complex which was recrystallized from methanol and water (Found: C, 51.6, H, 5.9, N, 8.5, Cl, 17.5%. Calcd: C, 52.7, H, 5.7, N, 8.9, Cl, 16.7%). In this reaction, no arylation was observed, as in (c). (e) Phenyl rhodium(III) complex, $C_6H_5Rh(P\phi_3)_2(Cl)$(I). $RhCl(P\phi_3)_3$ (1 mmol) and iodobenzene (30 mmol) were placed in dried and degassed toluene (40 ml) under nitrogen. The solution was heated under reflux for 4 h. $RhCl(P\phi_3)_3$ was gradually dissolved, and the solution changed from reddish brown to dark brown, giving a dark brown crystalline precipitate on cooling. The precipitate was washed with hexane and dried *in vacuo* (Found: C, 57.9; H, 4.3; Halogen, 17.6%. Calcd: C, 58.1; H, 4.0; Halogen 18.7%). By treating a toluene solution of this complex with atmospheric hydrogen at room temperature for 3 h, benzene was quantitatively obtained. $RhCl(P\phi_3)_3$, however, was practically inactive for the formation of styrene. (f) Phenylrhodium(III)carbonyl complex, $C_6H_5Rh(P\phi_3)_2(CO)(Cl)$(I). A greenish yellow precipitate was obtained by treatment of iodobenzene (30ml) with a methanol solution (30 ml) of $RhCl_3 \cdot 3H_2O$ (0.5 mmol) in the presence of $P\phi_3$ (1.5 mmol) and butylamine (15 mmol) under ethylene pressure (20 kg/cm²) at 120 °C for 3 h, although no styrene was detected. The precipitate was recrystallized from benzene and methanol, and a yellow crystal was obtained(Found: C, 57.2; H, 3.9; Halogen, 18.0%. Calcd: C, 57.8; H, 4.0; Halogen, 17.2%. ν_{CO} 1965 cm^{-1}). Treatment of a chlorobenzene solution of this complex with dry hydrogen chloride at room temperature gave benzene quantitatively.

Results

General Features of the Reaction. From the reaction of iodobenzene (30 mmol) with ethylene (20 kg/cm²) at 120 °C for 3 h in methanol (30 ml) using $RhCl_3 \cdot 3H_2O$ (0.5 mmol) as the catalyst in the presence of butylamine (15 mmol) or tributylamine (15 mmol), a

small amount of styrene (8.0 and 0.96 mmol, respectively) was obtained; most of the catalyst was found in the form of metallic rhodium after the run. The addition of triphenylphosphine (1.5 mmol, $P\phi_3/Rh=3$ in mol) to this catalyst system completely inhibited the formation of styrene, and no iodobenzene was consumed. From the reaction mixture, σ-phenylrhodium(III)-carbonyl complex, $C_6H_5Rh(P\phi_3)_2(CO)(Cl)$(I), as described in the experimental section, was isolated. Carbon monoxide seems to be supplied from methanol.

Table 1. Arylation of ethylene catalyzed by Rh-catalyst

Catalyst 0.5 mmol, Iodobenzene 30 mmol, Tributylamine 15 mmol, Toluene 30 ml, P_{C_2}' 20 kg/cm² at room temp, Temp, 120 °C, and Time 3 h.

Rh-Catalyst	$P\phi_3$ (mmol)	Conv[a)] (%)	Select (%)
Rh-powder	0	0	0
$RhCl(P\phi_3)_3$	0	61	4
$RhCl_3\cdot 3H_2O$	0	86	80
$RhCl_3\cdot 3H_2O$	0.75	72	78
$RhCl_3\cdot 3H_2O$	1.5	7	0
$RhCl_3\cdot 3H_2O$	3	5	0

a) Based on iodobenzene.

The yield of styrene, however, was considerably increased by using a toluene–tributylamine mixture instead of methanol as the solvent. The results are summarized in Table 1. Rh-powder[7] showed no activity, and $RhCl(P\phi_3)_3$ gave only a small amount of styrene in spite of a considerable consumption of iodobenzene. Even in the case of $RhCl_3\cdot 3H_2O$, which proved to be effective for the arylation, the addition of triphenylphosphine($P\phi_3/Rh\geq 3$ in mol) also inhibited almost completely the formation of styrene.

The Effect of Amine. The effect of the amount of tertiary amines on the conversion of iodobenzene and selectivity to styrene is shown in Fig. 1. In the absence of tertiary amine, no styrene was formed and a substantial amount of metallic rhodium was found after the run. It is clear in Fig. 1 that the conversion of iodobenzene increases with increase in the amount of tertiary amine, while the selectivity to styrene decreases when a larger amount of the amine is added. Neither stilbene nor 1,1-diphenylethylene was detected.

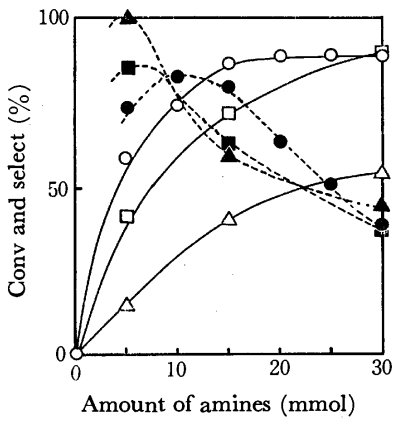

Fig. 1. Effect of the amount of tertiary amines. $RhCl_3\cdot 3H_2O$ 0.5 mmol, toluene 30 ml, iodobenzene 30 mmol, P_{C_2}' 20 kg/cm², Temp. 118 °C, and Time 3 h.
— Conv and --- Select
○ Tributylamine, □ Tripropylamine, and △ Triethylamine.

Separate experiments showed that iodobenzene remained unchanged in the absence of $RhCl_3\cdot 3H_2O$ under the condition specified in Fig. 1, while a considerable amount of iodobenzene was consumed even in the absence of ethylene when $RhCl_3\cdot 3H_2O$ was added. Although the reaction products were unidentified, this suggests that the rhodium catalyst catalyzes also a reaction of iodobenzene with the tertiary amine.

The effects of primary, secondary, and tertiary amines are summarized in Table 2. The yield of styrene decreases in the order, tertiary≥secondary≫primary amine. Practically no arylation takes place when primary amine or pyridine is added. The steric effect of primary amine was examined under the same

reaction condition. Monotertiarybutylamine and 1,1,3,-3-tetramethylbutylamine selectively gave styrene, although the conversions were low (9 and 10% respectively). The arylations in the presence of both tributylamine and butylamine were carried out to define their effects more clearly. The results are described in Table 3. It is clear that even when a large amount of tributylamine is present, the addition of butylamine remarkably decreases the yield of styrene. When butylamine was added through a high pressure injector during the course of arylation in the presence of tributylamine, it also terminated the formation of styrene (the last line of Table 3).

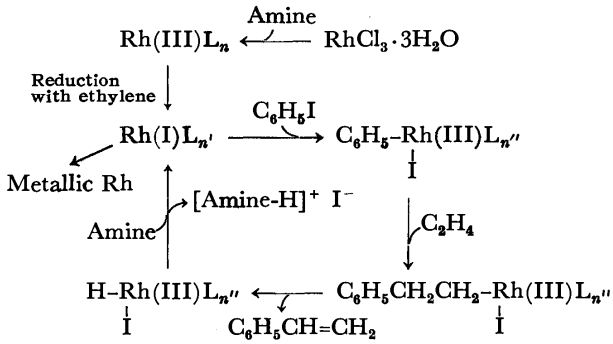
The isolation of rhodium–amine complex was carried out as described in the experimental section. The treatment of $RhCl_3 \cdot 3H_2O$ with butylamine gave $[RhCl(C_4H_9NH_2)_5)_5]Cl_2$, which changed into another complex, $[RhCl_2(C_4H_9NH_2)_4]Cl$, under the arylation condition. The treatment of $RhCl_3 \cdot 3H_2O$ with benzylamine under the arylation condition gave $[RhCl_2(C_6H_5CH_2NH_2)_4]Cl$, which has an analogy with the Rh(III)–butylamine complex. The primary amine is known to give stable Rh(III) complexes.[8] Practically no metallic rhodium was formed after the arylation in the presence of tertiary amine; all attempts to isolate a rhodium–tertiary amine complex, however, were unsuccessful.

Discussion

The treatment of $RhCl(P\phi_3)_3$ with iodobenzene in toluene under reflux gives a stable σ-phenylrhodium(III) complex, $C_6H_5Rh(P\phi_3)_2(Cl)(I)$, as described in the experimental section. $RhCl(P\phi_3)_3$ is catalytically inactive for the arylation of ethylene in spite of a considerable consumption of iodobenzene by the reaction with amine, as shown in Table 1. This suggests that the oxidative addition of iodobenzene to Rh(I) takes place readily, while $P\phi_3$ prevents the coordination of ethylene. When $RhCl_3 \cdot 3H_2O$ is used as the catalyst, the addition of a catalytic amount of $P\phi_3$ prevents not only the formation of styrene, but also the consumption of iodobenzene, as shown in Table 1. In this case, $P\phi_3$ presumably stabilizes the Rh(III) complex as $RhCl_3(P\phi_3)_3$,[6] because, if Rh(I) were formed during the reaction, iodobenzene should be consumed, as observed with $RhCl(P\phi_3)_3$. In the absence of $P\phi_3$, however, $RhCl_3 \cdot 3H_2O$ is fairly active for the arylation of ethylene with iodobenzene in the presence of tertiary amine. From the above consideration, it is postulated that the arylation reaction proceeds *via* a Rh(I) complex which is formed by reduction of a Rh(III) complex, although all attempts to isolate the Rh(I) complex in the absence of $P\phi_3$ were unsuccessful. Possible reducing agents were separately examined for their effectiveness under relevant conditions. Practically no reduction of Rh(III) was observed with amine or toluene. The treatment of $RhCl_3 \cdot 3H_2O$ with ethylene in the absence of iodobenzene, however, gave a black precipitate, presumably metallic rhodium, demonstrating some reducing ability for ethylene. Accodingly, it seems likely that Rh(III) is reduced by ethylene[9] during the course of arylation.

A question arises why the primary amines are almost ineffective for the arylation in spite of the fact that their basicities are almost the same as those of the secondary and tertiay amines, as shown in Table 2. The most plausible explanation may be a steric hindrance of the amine, because a bulky primary amine, for example, monotertiarybutylamine or 1,1,3,3-tetramethylbutylamine, gave styrene selectively, although the conversion was low. The less crowded primary amine tightly coordinates to Rh(III) to give a highly stable Rh(III)–primary amine complex, thus stabilizing the Rh(III) state. On the other hand, tertiary amines, which are sterically more crowded, are likely to coordinate weakly to Rh(III), giving rise to only slight inhibition of the reduction from Rh(III) to Rh(I). In fact, no Rh(III)–tertiary amine complexes have been isolated.

The active species may be a weakly bonded Rh(I)–tertiary amine complex, to which iodobenzene is oxidatively added to give σ-phenylrhodium(III) complex, followed by insertion of ethylene and elimination of β-hydrogen to give styrene as follows:



L: Hologen, Amine, Olefin, and Solvent.

Scheme.

The more tight coordination of the primary amine to Rh(III) than of the tertiary amine is also supported by the result that the formation of styrene is almost completely inhibited by the injection of butylamine during the course of the arylation described in Table 3. This means that the primary amine stabilizes the Rh(III) intermediate, resulting in a lack of regeneration of Rh(I) complex.

Since iodobenzene is consumed in the interaction with $RhCl_3 \cdot 3H_2O$–tributylamine mixture even in the absence of ethylene, σ-phenylrhodium(III) complex seems to react with tributylamine to give $[C_6H_5N(C_4H_9)_3]^+I^-$, although its isolation was unsuccessful. This may be the reason why the selectivity to styrene decreases with the increase in the amount of tributylamine, as shown in Fig. 1.

Synthesis of 2,5-Diaryltetrazoles from *N*-Phenylsulfonylbenzhydrazidoyl Chlorides and Arylhydrazines[1]

Suketaka Ito, Yumo Tanaka, and Akikazu Kakehi

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received September 11, 1975)

A new synthesis of 2,5-diaryltetrazoles is given by the reaction of *N*-phenylsulfonylbenzhydrazidoyl chlorides with arylhydrazines and the action of potassium carbonate on the intermediate product formed in the initial reaction. Thirty tetrazoles carrying H, CH_3, Cl, Br, or NO_2 as the *para*-substituent of the 2-phenyl group, and H, CH_3, Cl, CH_3O, CN, or NO_2 as that of the 5-phenyl group, were synthesized in 70—16% yields, respectively. The reaction may proceed *via* the concerted elimination of benzenesulfinate ion from the intermediate 1,3-diaryl-5-phenylsulfonylformazanide anion taking a quasi-aromatic configuration.

N-Phenylsulfonylbenzonitrilimine derived from the corresponding hydrazidoyl halide does not undergo 1,3-dipolar cyclo-addition but dimerizes easily to 1,4-dihydro-3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,2,4,5-tetrazine.[2] This behavior which differs from that of *N*-phenylbenzonitrilimine should be attributed to the strong electron-withdrawing nature of the arylsulfonyl group. Since arylsulfonyl groups can be eliminated[3] and hydrazidoyl halides are a kind of imidoyl halide, the parent *N*-phenylsulfonylbenzhydrazidoyl halides can be utilized as a starting material for the synthesis of heterocycles.

The present paper gives a new synthesis of 2,5-diaryltetrazoles[4] by the reaction of *N*-phenylsulfonylbenzhydrazidoyl chlorides with arylhydrazines and the action of base such as potassium carbonate on the intermediate product formed in the initial reaction. Previously we described an alternative procedure for the synthesis of 2,5-disubstituted tetrazoles from phenylsulfonylhydrazones of aromatic aldehydes and benzenediazonium salt, in which formazan was postulated as an intermediate.[5]

Results and Discussion

The reactions were carried out without isolation of intermediates. *N*-Phenylsulfonylbenzhydrazidoyl chlorides, prepared from the corresponding hydrazides and thionyl chloride,[2,6] were allowed to react with two equivalents of an arylhydrazine in tetrahydrofuran. In cases of reactants carrying a nitro group, it was necessary to reflux or warm the mixture of the reactant materials in the solvent. After removal of the precipitated arylhydrazine hydrochloride by filtration,[7] the tetrahydrofuran solution was stirred with excess potassium carbonate for 24 h at room temperature. From the reaction mixture, 2,5-diaryltetrazole was isolated by extraction with chloroform–water and by subsequent chromatographic treatment of the chloroform extract. The results are summarized in Table 1.

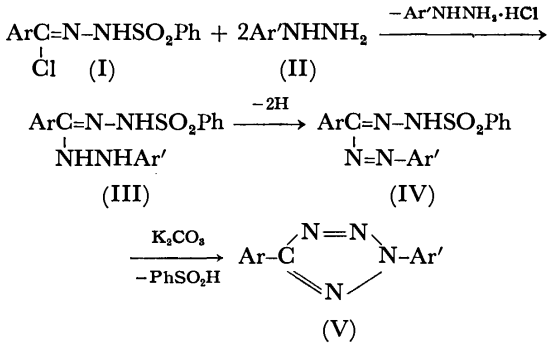
The use of a tertiary amine such as triethylamine or pyridine with one equivalent of arylhydrazine in the first step of reaction caused the predominant formation of 1,4-dihydro-3,6-diaryl-1,4-bis(phenylsulfonyl)-1,2,4,5-tetrazine, and it was therefore unsuitable as the trapping agent of hydrogen chloride. Tetrahydrofuran was the most suitable solvent in this reaction; the use of benzene, chloroform, or diethyl ether as the solvent reduced the yields of the tetrazoles. Prolonged stirring with potassium carbonate brought about an increase in yield. Pyridine could serve as a substitute for potassium carbonate, giving tetrazoles in slightly lower yields. After removal of arylhydrazine hydrochloride from the reaction mixture, the filtrate was concentrated under reduced pressure below 30 °C. The resulting oily residue was stirred for 24 h at room temperature with the same volume of pyridine as that of the tetrahydrofuran removed to afford tetrazoles (Table 2). Stirring without a base in the second step of reaction gave a small amount of tetrazoles (7%, in the case of 2,5-diphenyltetrazole).

From the water layer in the chloroform–water extraction, benzenesulfinic acid was extracted with dichloromethane and confirmed to be phenyl benzhydryl sulfone.

Identification of tetrazoles was carried out by their analytical and spectral data and, in the case of known compounds, by comparison with authentic specimens. The spectral data of the products are listed in Table 3.

In the IR spectra, the absorptions due to the *para*-substituted phenyl groups at 2- and 5-position of the tetrazoles were additive and constitutive with minor changes. The absorption at 1260—1290 cm^{-1} may be assigned to the cyclic N–N=N group in analogy with other tetrazoles and triazoles.[8] The absorptions at near 1070, 1010, and 990 cm^{-1} can be attributed also to the tetrazole ring system: absorptions in the 1100 to 990 cm^{-1} region observed in tetrazole,[9a] 5-substituted tetrazoles,[9a] and 1,5-disubstituted tetrazoles[9b,c] have been assigned to the tetrazole ring system.

The reaction route can be illustrated as follows:



It is known that the reaction of *N*-arylbenzhydrazidoyl halide with phenylhydrazines yields formazans.[10]

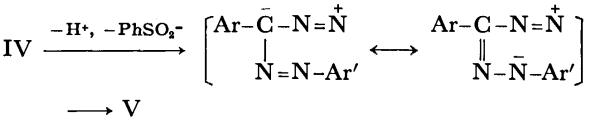
26	33

Although no reaction intermediates were isolated in this study,[11] the intermediacy of formazan in this reaction is undoubted from the reaction process and our other tetrazole synthesis.[5] The process, hydrazidine to formazan(III→IV), should be an autoxidation by air.

As a possible mechanism for the formation of tetrazole from formazan(IV→V), the following three can be given:

(1) Mechanism involving the Bamford-Stevens type α-elimination of benzenesulfinic acid followed by 1,5-dipolar cyclization[12] of the resultant arylazoaryldiazomethane:



Scheme 1.

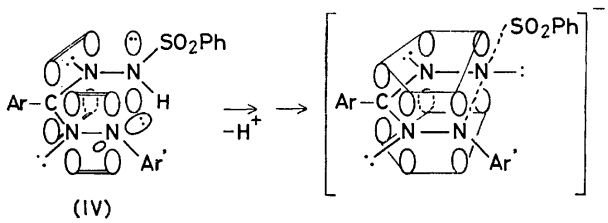
a) Absorptions other than those given in the table are omitted. b) The two peaks at 1266—1286 and 1062—1077 cm^{-1} are weak, and the others are strong to medium. c) Shoulder.

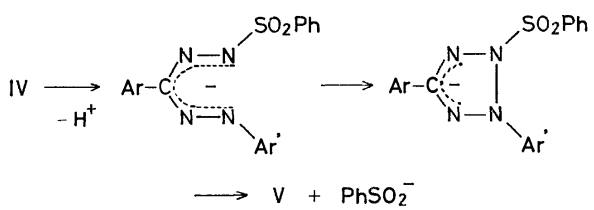
(2) Concerted elimination of benzenesulfinate ion from the intermediate formazanide anion taking a quasi-aromatic configuration:



$\longrightarrow$ V + $PhSO_2^-$

Scheme 2.

(3) Polar cyclization of formazanide anion to tetrazolinide anion and its subsequent release of benzenesulfinate ion:



$\longrightarrow$ V + $PhSO_2^-$

Scheme 3.

The elimination of arenesulfinic acid occurs far more readily in the present reaction as compared with that in the Bamford-Stevens reaction[13] and in the pyrazole synthesis from α,β-unsaturated aldehydes tosylhydrazones.[14] Thus, the second mechanism (Scheme 2) is most probable: the greater facility of eliminating of benzenesulfinate ion may be due to the increased delocalization of π-electrons and the participation of a lone-pair orbital of nitrogen in the transition state.

Formazan and formazanide anion are isoelectronic with pentadienyl anion, and their most favored configuration would therefore be the planar U-shaped form.[15,16] The U-shaped form may possess some quasi-aromatic character.[17,18] Thus, keeping the U-shaped quasi-aromatic configuration, the formazanide anion might pass into the transition state, in which a three-center four-electron orbital-interaction arises between 1-*N*, 5-*N*, and the phenylsulfonyl group (analogous to S_N2 reaction) with a more stabilized 6π-electron structure (Scheme 2).

Arylazoaryldiazomethane can also cyclize easily to tetrazole, keeping its quasi-aromatic configuration by participation of the lone-pair orbital of the nitrogen atom adjacent to aryl group.[19] No matter how the azodiazomethane is involved in the reaction, it should be merely

a transition species.

The third mechanism may be improbable, since tetrazolinide ions lack the aromatic stabilization.

The lower yields of the tetrazoles with *para*-nitro-substituent, especially in the *N*-phenyl group, should be correlated to the electron-withdrawing nature of the substituent. *p*-Nitrophenylhydrazine reacted with the hydrazidoyl chlorides with difficulty because of its weak nucleophilicity, and 2,4-dinitrophenylhydrazine did not react with them. The nitro group in the *N*-phenyl group, and presumably in the *C*-phenyl group, may stabilize the hydrazidine to prevent oxidation to formazan.

The present method is comparable to others[4] as regards yield and utility for preparative purpose.

Experimental

Melting points were determined with a Yanagimoto micro-melting point apparatus Model MP-S3 and are uncorrected. The microanalysis was performed on a Perkin-Elmer elemental analyzer Model 240. Molecular weights were determined with a Hitachi Perkin-Elmer molecular weight apparatus Model 115. The IR and UV spectra were recorded with a JASCO DS-301 spectrometer and a Hitachi EPS-3 spectrometer, respectively.

1-Aroyl-2-phenylsulfonylhydrazines. General Procedure: Benzenesulfonyl chloride (0.1 mol) was added dropwise to a solution of an aroylhydrazine[20] (0.1 mol) in pyridine (50 ml)[21] with stirring and external cooling. The reaction mixture was allowed to stand at room temperature for 30 min and then poured into cold water. The resulting precipitates were collected by filtration, washed with dilute hydrochloric acid and water in succession, and dried; yield: almost quantitative. The product was purified by crystallization from methanol. The results are summarized in Table 4.

N-Phenylsulfonylbenzhydrazidoyl Chlorides. Typical Procedure: A mixture of 1-benzoyl-2-phenylsulfonylhydrazine (5.5 g, 0.02 mol) and thionyl chloride (10 ml) was refluxed for 1.5 h. After removal of excess thionyl chloride *in vacuo*, the resulting residue was crystallized from benzene to give colorless prisms; yield: 4.2 g (71%). The results are summarized in Tables 5 and 6.

2,5-Diaryltetrazoles. General Procedure: A solution of an arylhydrazine[22] (0.01 mol) in tetrahydrofuran (15 ml) was added dropwise to a solution of a *N*-phenylsulfonylbenzhydrazidoyl chloride (0.005 mol) in tetrahydrofuran (15 ml) at room temperature. With reactants carrying a nitro group, the mixture was warmed or refluxed for 10—60 min. The separated arylhydrazine hydrochloride was filtered and washed with tetrahydrofuran (20—30 ml). The filtrate combined with the washings was then stirred with potassium carbonate (2.5 g) for 24 h at room temperature using a magnetic instrument. The reaction mixture was concentrated and extracted with chloroform and water. After removal of the solvent from the chloroform extract, the resulting residue was chromatographed on a silica gel column using benzene as the eluent to give the corresponding tetrazole, which was purified by recrystallization from an appropriate solvent (ethanol,

Structure of C-2801X, a New Cephamycin-type Antibiotic

Hiroshi FUKASE and Hidesuke IWASAKI

Medicinal Research Laboratories, Central Research Division, Takeda Chemical Industries, Ltd. Jūso, Yodogawa-ku, Osaka 532

(Received September 29, 1975)

The C-3 side chain moiety of C-2801X, a new cephamycin-type antibiotic, was almost quantitatively obtained by Dowex 50-catalyzed hydrolysis, and its structure was established as 3,4-dihydroxy-α-methoxycinnamic acid (I) by spectroscopic analyses and synthesis. The full structure of C-2801X was also assumed to be XIII by NMR analysis.

In the course of screening for new antibiotics, two new species of *Streptomyces*, *S. heteromorphus* and *S. panayensis*, were found to produce a new cephamycin-type antibiotic C-2801X[1] together with cephamycins A and B.[2,3]

As described in detail in the paper[1] on characterization, C-2801X (Na salt: $C_{25}H_{28}N_3O_{12}SNa$) was regarded as a 7-(5-amino-5-carboxyvaleramido)-7-methoxycephem (cephamycin-type) antibiotic from the following facts: (1) C-2801X was inactivated by cephalosporinase; (2) it exhibits an IR absorption at 1760 cm^{-1} due to β-lactam, as shown in Fig. 1; (3) a signal corresponding to C-7 methoxyl group was observed in the NMR spectrum; and (4) glycine and α-aminoadipic acid in the hydrolyzate of C-2801X were determined to be 1:2 in molar ratio, as reported in cephamycin-type antibiotics.[3,4] The IR (Fig. 1) and UV [$\lambda_{max}^{H_2O}$ 234 nm (ε 12800), 318 (16900), $\lambda_{sh}^{H_2O}$ 295(15700)] spectra and paper chromatography indicated that C-2801X is a new antibiotic differing from known cephem antibiotics.

This paper describes first the elucidation of structure of the C-3 side chain moiety, and then presents evidence for the full structure for C-2801X.

Structure of C-3 Side Chain Moiety

C-2801X was almost quantitatively hydrolyzed at the C-3 side chain by treatment with Dowex 50 W×8 in methanolic solution. The hydrolysis products having amino groups were separated by adsorption on Dowex 50, and the methanolic solution containing a neutral or acidic substance was concentrated *in vacuo* to give I. The UV absorption (Table 2) was similar to that of C-2801X. Therefore, I was assumed to be the C-3 side chain moiety. The IR spectrum (Fig. 2) shows the presence of hydroxyl (3450, 1190 cm^{-1}), α,β-unsaturated carboxylic acid (1660, 1630) and aromatic ring (1605, 1510, 905). A phenolic hydroxyl group is probably present, as judged by the IR absorption and a positive color reaction with $FeCl_3$–$K_3Fe(CN)_6$ reagent.[5] The NMR spectrum in CD_3OD shows the signals of 1,2,4-*tri*-substituted benzene (δ, ppm: 7.35, 1H, d, J=1.5 Hz; 7.03, 1H, dd, J=1.5, 8 Hz; 6.75, 1H, d, J=8 Hz), a single vinylic proton (6.90, 1H, s), and methoxyl protons (3.70, 3H, s). These spectroscopic analyses suggest that I is a cinnamic acid derivative having two hydroxyl (at least one hydroxyl group is phenolic) and one methoxyl group.

Mass spectral fragmentations of I are shown in Table 1 and compared with those of *p*-hydroxy-α-methoxycinnamic acid (II) obtained from cephamycin B by hydrolysis in a similar manner. Peaks corresponding to M^+, M−15, M−32, M−43, M−60, M−87, M−88, and M−89 were observed in both mass spectra of I and II at a difference of *m/e* 16. As the peaks at *m/e* 107, 106, and 105 of II are due to fragments IIIa, IVa, and Va, the corresponding peaks at *m/e* 123, 122, and 121 of I were assigned to IIIb, IVb, and Vb, respectively. This fact indicates that I has two phenolic hydroxyl groups and that the methoxyl group is located at the α-position. A characteristic peak at M−33, observed

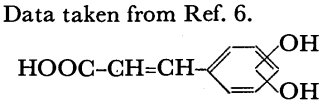
a) Data taken from Ref. 6.



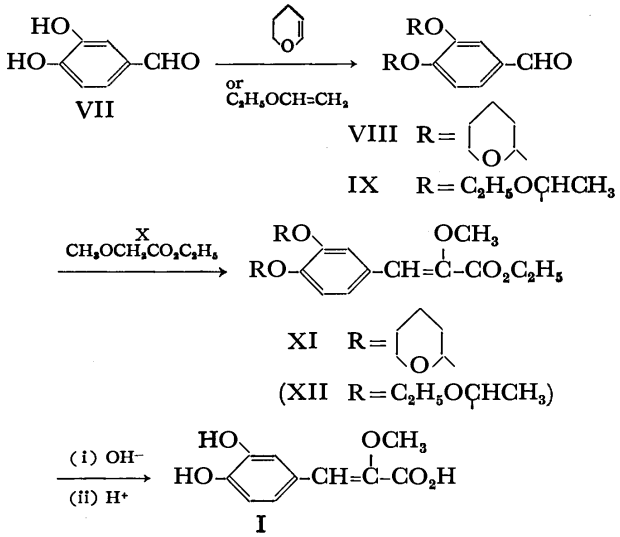
VI

only in the spectrum of I, is consistent with the structure having two hydroxyl groups.

To confirm the positions of the two hydroxyl groups on the benzene nucleus, UV absorption maxima[6] of six isomers of dihydroxycinnamic acid (VI) were compared with that of I (Table 2). The absorption maxima of I are obviously similar to that of 3,4-dihydroxycinnamic acid (caffeic acid).

From these data the chemical structure of I was assumed to be 3,4-dihydroxy-α-methoxycinnamic acid (I).

Since I is a hitherto unreported compound, 3,4-dihydroxy-α-methoxycinnamic acid was synthesized from protocatechualdehyde (VII) and ethyl methoxyacetate (X) as shown in the Scheme. As I is considerably labile in an alkaline solution, the two hydroxyl groups of VII were protectedby converting into hemiacetals which revert easily to hydroxyl by mild acidic hydrolysis. The addition reaction of dihydropyran[7] and ethyl vinyl



Scheme. Synthesis of 3,4-dihydroxy-α-methoxycinnamic acid.

ether[8] onto VII in the presence of phosphoric acid yielded VIII and IX, respectively. Condensation of VIII and IX with ethyl methoxyacetate (X) was carried out in toluene in the presence of metallic sodium to give XI and XII (not isolated), respectively.

Saponification of ester XI or XII and subsequent acid hydrolysis of the acetals gave 3,4-dihydroxy-α-methoxycinnamic acid (I). NMR, Mass, UV, and IR spectra (Fig. 2) of the synthetic compound were identical with those of the natural specimen (I).

Full Structure of C-2801X

In the Dowex 50-catalyzed hydrolysis described above, compounds adsorbed on the resin were eluted with 1 M sodium acetate. The investigation by paper chromatography of the eluate revealed that it contains α-aminoadipic acid and 7-methoxycephem moieties showing the same R_f values as those of hydrolysis products obtained by the same treatment of cephamycin B.

2″-C**H**$_2$	2.4—2.7 (m)	2.4—2.7 (m)	2.4—2.7 (m)
3″,4″-(C**H**$_2$)$_2$	1.7—2.2 (m)	1.6—2.2 (m)	1.7—2.3 (m)
5″-C**H**	4.0—4.2 (m)	4.0—4.2 (m)	4.0—4.3 (m)

a) Tentative assignment. The figures in parentheses are coupling constants. s=singlet, d=doublet, dd=double doublet, m=multiplet

The NMR assignments of C-2801X are shown in Table 3, for comparison with those of cephamycin A and B. The chemical shifts, multiplicity, and coupling constants of each proton of C-2801X except the aromatic protons of the C-3 side chain were in fair agreement with those of cephamycin A and cephamycin B; *i.e.* 7-OC**H**$_3$, 6-C**H**, and 2-C**H**$_2$ of methoxycephem nucleus, α-OC**H**$_3$ of the C-3 side chain, and 2″-C**H**$_2$, 3″,4″-(C**H**$_2$)$_2$, and 5″-C**H** of the C-7 aminoadipoyl moiety. The chemical shifts of the aromatic protons of the C-3 side chain were assigned as shown in Table 3, in comparison with the NMR of I. The C-3′ of C-2801X has no proton, so the 2′-benzene proton does not show any *ortho*-coupling in J=8 Hz, but has a *meta*-coupling with the 6′-benzene proton in J=1.5 Hz. As the chemical shifts of the 2′-C**H**, 5′-C**H**, and 6′-C**H** are closer to those of cephamycin B than to those of cephamycin A, the two phenolic hydroxyl groups were supposed to be free. UV absorption and phenolic color reaction[5] of C-2801X also support this structure. Consequently, C-2801X was assumed to have the chemical structure shown as XIII.

Among C-2801X, cephamycin A, and cephamycin B, C-2801X (having two phenolic hydroxyl groups) shows the strongest activity against gram-negative bacteria, although their activities against gram-positive bacteria are almost indistinguishable.[1] This phenomenon is very interesting from the viewpoint of the structure-activity relationship.

Experimental

Hydrolysis of C-2801X. In a suspension of Dowex 50W×8 (H^+) (1 ml) in methanol (3 ml), the sodium salt (3 mg) of C-2801X was dissolved and the mixture was stirred at room temperature for 3 h. After filtration, the resin was washed with methanol (10 ml). The filtrate and the washings were combined and concentrated *in vacuo* to dryness. Addition of benzene to the residue, followed by standing at 10 °C overnight, afforded colorless prisms (1.1 mg) of I, mp 215 °C (dec.).

Found: C, 57.22; H, 4.67%; (M^+) *m/e* 210. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%; mol wt, 210.18.

To Dowex resin separated by filtration was added 1M sodium acetate solution (5 ml), and the mixture was stirred for 30 min. The mixture was poured into a glass column (0.9×10 cm) and additional 1M sodium acetate solution (3 ml) was passed over the resin. The resulting eluates were combined and concentrated to *ca.* 1 ml. Ascending paper chromatography of the concentrate was carried out using 1-butanol–acetic acid–water (4: 1: 5) as a developing solvent. By spraying ninhydrin reagent, spots corresponding to α-aminoadipic acid and 7-methoxycephem moieties were observed, showing the same R_f values as those of the hydrolysis products of cephamycin B.

3,4-Bis(tetrahydropyranyloxy)benzaldehyde (VIII). A few drops of 80% phosphoric acid was added to a suspension of VII (2.7 g) in dihydropyran (10 ml) and the mixture was stirred at room temperature until in solution. After stirring at room temperature for an additional 3 h, the reaction mixture was poured into ice water (500 ml). The oily substance which separated out was extracted with ether, and after washing with 5% sodium hydrogencarbonate solution, the ether extracts were dried over anhydrous sodium sulfate and concentrated *in vacuo* to dryness. The residue was dissolved in ethyl acetate–benzene (1: 1) (10 ml) and charged to a column containing Merck's silica gel (250 ml). The column was developed with ethyl acetate–benzene (1: 1) and the eluate was evaporated *in vacuo* to give VIII (4.3 g) as an oil (yield: (72%).

Found: C, 66.79; H, 7.28%. Calcd for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24%.

3,4-Bis(α-ethoxyethyloxy)benzaldehyde (IX). A few drops of 80% phosphoric acid was added with stirring and cooling

below 5 °C to a suspension of VII (2.7 g) in ethyl vinyl ether (10 ml). The suspension was stirred below 10 °C overnight and the resulting clear reaction mixture was poured into ice water (500 ml). The mixture was extracted with ether and the extracts, after washing with 5% sodium hydrogencarbonate solution, were dried over anhydrous sodium sulfate and concentrated *in vacuo*. The oily residue was purified by vacuum distillation, bp 134—137 °C/1 mmHg, to give IX (3.0 g) as a colorless oil (yield: 43%).

Found: C, 63.71; H, 7.86%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

Ethyl 3,4-Bis(tetrahydropyranyloxy)-α-methoxycinnamate (XI). To a mixture of metallic sodium (2.5 g), anhydrous toluene (50 ml), and VIII (3.0 g), anhydrous ethanol (0.1 ml) was added with stirring. Under cooling with ice and stirring, X (3.6 g) was added dropwise to the mixture. The condensation reaction was performed by stirring the whole mixture under ice-cooling for 2 h and then at room temperature for an additional 6 h. The reaction mixture was poured into ice water (200 ml) and the product was extracted with benzene. After washing with 0.1 M hydrochloric acid and 5% sodium hydrogencarbonate solution, the benzene extracts were dried over anhydrous sodium sulfate and concentrated *in vacuo* to dryness. The residue was purified by column chromatography using Merck's silica gel (250 ml) as adsorbent and ethyl acetate–benzene (1: 9) as developer to obtain XI (1.8 g) as a colorless oil (yield: 43%).

Found: C, 64.94; H, 7.57%. Calcd for $C_{22}H_{30}O_7$: C, 65.01; H, 7.44%.

3,4-Dihydroxy-α-methoxycinnamic Acid (I). (i) Aqueous 1 M sodium hydroxide solution (50 ml) was added to a solution of XI (1.0 g) in methanol (50 ml) and the mixture was stirred overnight at room temperature. The reaction mixture was concentrated (*ca.* 20 ml) under reduced pressure. After acidification of the concentrate with 1 M hydrochloric acid, the resulting oil was extracted with ethyl acetate, and the extracts were concentrated *in vacuo*. The residue obtained was dissolved in methanol (20 ml) and, after addition of 0.2 M hydrochloric acid (20 ml), the mixture was warmed at 60 °C for 15 min. The reaction mixture was adjusted to pH 4 with 0.1 M sodium hydroxide solution on cooling with ice-water, and concentrated to dryness under reduced pressure. The residue was extracted with ethanol and the ethanol extracts were concentrated to dryness. The residue was crystallized from water to yield I (310 mg) as colorless prisms (yield: 60%), mp 215 °C (dec.).

Found: C, 57.40; H, 4.78%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

(ii) The condensation reaction of IX with X was carried out in a similar manner to that described in the preparation of XI to obtain XII (*ca.* 3.5 g) in a crude oil. Without further purification, a mixture of a solution of XII in methanol (100 ml) and aqueous 1M sodium hydroxide solution (100 ml) was stirred overnight at room temperature. The reaction mixture was concentrated (30 ml) *in vacuo*, neutralized with hydrochloric acid, and evaporated to dryness. The residue was dissolved in acetic acid (50 ml) and the solution was warmed at 60 °C for 10 min. The reaction mixture was concentrated to dryness and the residue was extracted with ethanol. The ethanol extracts were evaporated to dryness, and the residue was crystallized from water to obtain I (1.0 g) as colorless prisms (yield 48%), mp 215 °C (dec.).

Found: C, 56.88; H, 4.74%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

We are indebted to Drs. R. Takeda, A. Miyake, K. Mizuno, and M. Yoneda for their encouragement and advice throughout this work. Thanks are also due to Drs. T. Yamano, T. Hasegawa, and their co-workers for fermentation and to the members in charge of elemental analysis and physicochemical measurements.

The Synthesis of Cubebol from (−)-Carvone by Introducing the Electrochemical Acetoxylation Reaction

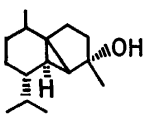
Sigeru Torii and Tsutomu Okamoto

Department of Industrial Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

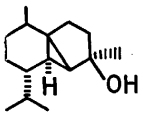
(Received October 2, 1975)

The synthesis of cubebol and the related compounds from (−)-carvone is described. In the preparation of the key intermediate, 7,10-*trans*-2,6-epi-2-acetoxy-7-isopropyl-10-methyltricyclo[4.4.0.0^{1,5}]decan-4-one (**10**) the electrochemical acetoxylation reaction could be used as an effective method for introducing the acetoxy group at C-2 carbon atom instead of the carboxy function of 7,10-*trans*-2,6-epi-4-oxo-7-isopropenyl-10-methyltricyclo-[4.4.0.0^{1,5}]decan-2-carboxylic acid (**6a**). The condensation of (+)-*p*-menth-8-en-2-one (**2a**) prepared from (−)-carvone with dimethyl succinate afforded Stobbe half-ester **3**, which provided the diazoketone **4** smoothly. Thermal decomposition of **4** in benzene gave intramolecular adducts **5a** and **5b** (4: 1). Hydrolysis of **5a** afforded **6a** in *ca.* 40% yield. Electrolysis of **6a** in AcOH–*t*-BuOH–Et_3N (2: 1: 0.1) using platinum electrodes gave **10** in 72% yield. Elimination of acetic acid gave two isomers **11a** and **11b** (3: 1) in 87% yield and subsequent methylation of **11a** afforded 7-isopropyl-4,10-dimethyltricyclo[4.4.0.0^{1,5}]deca-2-en-4-ol (**12**) in 82% yield, which on hydrogenation gave the desired product **1a** (36.5%) along with the epimer **1b** (36.5%).

For the synthesis of complex sesquiterpenes, principal components in essential oils, cubebol (**1a**) and its related compounds, α- and β-cubebenes, isolated from the essential oil of the fruits of cubeb (*Piper cubeba* L.)[1] and citrus oils[2] are of interest as regards their synthesis.



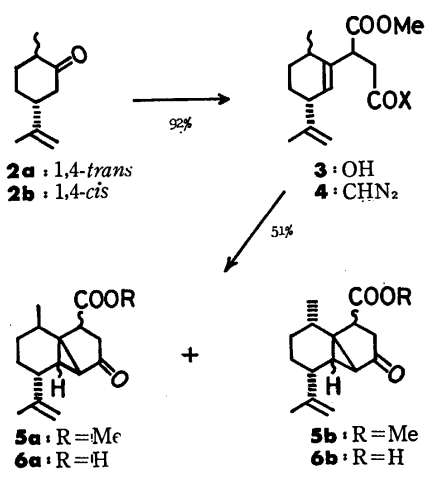
1a



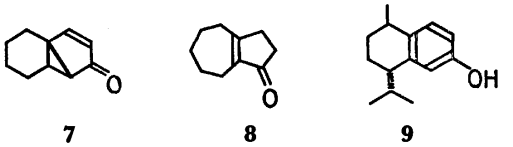
1b

Recently, Yoshikoshi *et. al.*,[1c] reported the preparation of **1a**, elucidating the stereochemistry of the related sesquiterpenoids. The present work deals with a convenient synthesis of **1a** from (−)-carvone by means of an electrochemical method. An electrochemical procedure for the replacement of carboxyl function to acetoxy group at the C-2 carbon atom of tricyclo[4.4.0.0^{1,5}]-decan-4-one system was reported.[3] In order to utilize electrochemical acetoxylation in cubebol synthesis it is desirable to find an intermediate which is easily prepared and stable during the course of electrolysis. We chose 7,10-*trans*-2,6-epi-7-isopropenyl-10-methyl-4-oxo-tricyclo[4.4.0.0^{1,5}]decan-2-carboxylic acid (**6a**) for the present synthesis.

The Stobbe condensation of (+)-8-*p*-methen-2-one (**2a**), contaminated with 24% of 8-*p*-isomenthen-2-one (**2b**),[4] with dimethyl succinate afforded the starting material **3** in 92% yield. In order to obtain the tricyclo[4.4.0.0^{1,5}]decan-4-one skeleton, intramolecular addition of keto-carbene to the double bond of **3** was attempted.[5] The diazoketone **4** obtained by the reaction of acid chloride of **3** with diazomethane was subjected to thermal decomposition in benzene at 80—81 °C using bis(*N*-propylsalicylideneaminato)copper(II) as a soluble catalyst.[6] This afforded 51% yield (based on **3**) of a C-10 isomeric mixture of the adducts **5a** and **5b**, which was separated by column chromatography over alumina to afford 40% of **5a** and 11% of **5b**. Hydrolysis of **5a** in 5% aqueous methanolic potassium hydroxide afforded **6a** quantitatively.

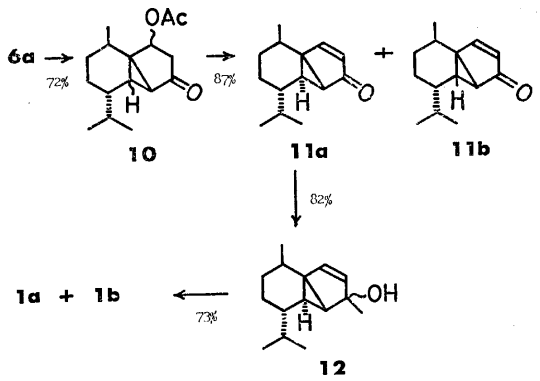


Mc Murry and Blaszczak[7] reported a new method for the synthesis of the cyclic enones from β-carboxy ketones by oxidative decarboxylation with lead tetraacetate in the presence of cupric ion. However, the method could only be applied to γ-methyl-β-carboxy ketones. It seems that application of stepwise reactions and mild reaction conditions is particularly suitable for the complex acid **6a**. We have encountered some difficulties in obtaining the enones **7** selectively from

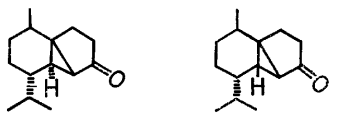


7 **8** **9**

4-oxotricyclo[4.4.0.0^{1,5}]decan-2-carboxylic acid by electrolytic decarboxylation directly, a mixture of **7** and **8** being obtained.[3] Under similar electrolysis conditions, the acid **6a** afforded a mixture of the enone **11** and the aromatic compound **9**. The synthesis of the enone **11** was successfully accomplished on treatment of the acetate **10** with triphenylmethylenephosphorane.[8] Thus, electrolytic acetoxylation of **6a** in a mixed solvent of acetic acid-*t*-butyl alcohol-trimethylamine (2:1:0.1) using platinum electrodes with a constant current of 0.08 A/cm^2, applied voltage *ca.* 20 V (1.6—1.7 *vs.* SCE) at 10 °C for 20 h afforded 72% of the acetate **10** as the sole product.[3] Under these electrolytic conditions,



hydrogenation to the isopropenyl function of **6a** occurred spontaneously. The conversion of **10** into an epimeric mixture of α,β-unsaturated ketones **11a** and **11b** (3: 1) was accomplished in 87% yield on treatment with a benzene solution containing a slightly excess amount of triphenylmethylenephosphorane at 0—4 °C. Separation of the epimers **11a** and **11b** was carried out by preparative glpc to afford the desired **11a** in 65% yield (based on **10**). The Grignard reaction of **11a** with methyl magnesium iodide resulted in the formation of C-4 isomeric mixtures **12** in 82% yield. Without separation of the isomers, **12** was hydrogenated over platinum oxide to afford cubebols **1a** and **1b** (1: 1) in 73% yield. Separation of the isomers could be achieved by column chromatography over silica gel.



13a **13b**

Norcubebanone **13a**[9] prepared from hydrogenation of **11a** could be used for the preparation of **1a** by the reaction with methylmagnesium iodide.[1c] The coupling of alkylmetals with the carbonyl group of the bicyclo[3.1.0]hexan-2-ones occurred mainly on the side opposite the cyclopropane ring.[1c,10] However, the Grignard reactions of **11a** and/or **13a** with methyl magnesium iodide provided a small amount of the epimer **1b** together with **1a**.

Experimental

Melting points and boiling points are uncorrected. NMR spectra were determined with a Hitachi R-24 instrument. IR spectra were recorded on a Hitachi EPI-S2, only the major absorptions being cited. Mass spectra were obtained on a Hitachi RMS-4 mass spectrometer at 70 eV, the molecular and major fragment ions being cited: *m/e* (relative intensity).

Electrolysis Apparatus. The electrolytic vessel was a water-jacketed beaker, diam. 2.5 cm, height 10 cm, fitted with a gas lead pipe, thermometer and magnetic stirrer, two smooth platinum electrodes (3 cm^2) being placed parallel to each other 3 mm apart. The current was controlled by adjusting the voltage. The direction of current was changed every 30 s by means of a commutator.

Preparation of Stobbe Half-ester (3). A solution of (+)-8-*p*-menthen-2-one (**2**), $[\alpha]_D^{14}$ +18.8° (*c* 3.03, $CHCl_3$)[4] (500 mg, 3.3 mmol) and dimethyl succinate (720 mg, 4.9 mmol) was treated with *t*-BuOK (from 200 mg of K metal) in 5 ml of dry *t*-BuOH. The mixture was heated at *ca.* 90 °C for 3 h with stirring. After being cooled to 0 °C the mixture was acidified with ice-cold 10% HCl. The organic phase was extracted with ether–benzene (1: 1). The extracts were washed with water, dried (Na_2SO_4), and concentrated. The residue (920 mg) was chromatographed over silica gel. Elution with 70 ml of hexane–ether (9: 1, monitored by TLC) gave a fraction of R_f 0.26—0.62. Subsequent elution with *ca.* 60 ml of acetone gave 805 mg (92%) of **3** (R_f 0.19): IR (neat) 3400—2500 (COOH), 1740 (ester), 1715 (COOH), 1645 (C=C), and 892 cm^{-1}; NMR ($CDCl_3$) δ 0.95—1.14 (m, 3H, CH_3), 1.68 (s, 3H, CH_3C=C), 3.64 (s, 3H, CH_3O), 4.45—4.80 (m, 2H, H_2C=C), and 5.41 (m, 1H, HC=C); $[\alpha]_D^{13}$ +54.75° (*c* 2.56, $CHCl_3$).

Found: C, 67.48; H, 8.29%. Calcd for $C_{15}H_{22}O_4$: C, 67.65; H, 8.33%.

2,6,10-Epi-2-methoxycarbonyl-7-isopropenyl-10-methyltricyclo-[4.4.0.0^{1,5}]decan-4-ones (5a and 5b). To a stirred suspension of 72 mg of NaH (50% mineral oil dispersion, washed with anhydrous hexane before use) in 10 ml of dry benzene, was added dropwise 266 mg (1 mmol) of **3** in 3 ml of dry benzene. The mixture was stirred for 1 h at room temperature and 0.2 ml of oxalyl chloride was added at 5 °C. Stirring was continued for 1 h at room temperature and the mixture was filtered under N_2. The residual acid chloride was dissolved in 2 ml of dry benzene. The benzene solution was treated with excess diazomethane at 0 °C. The mixture was stirred overnight at 0—5 °C. Removal of the solvent under reduced pressure at 10 °C and subsequent chromatography over alumina with CH_2Cl_2 gave 210 mg of the diazo ketone **4**, a yellow oil: IR (neat) 2075 (CN_2), 1737 (ester), and 1645 cm^{-1} (diazo ketone); NMR ($CDCl_3$) δ 0.95—1.18 (m, 3H, CH_3), 1.67 (s, 3H, CH_3C=C), 3.43 (s, 3H, CH_3O), 4.45—4.80 (broad d, 2H, H_2C=C), 5.20 (s, 1H, $COCHN_2$), and 5.38 (m, 1H, HC=C). Without further purification, the diazo ketone (210 mg, 0.72 mmol) was added to a mixture of 40 ml of benzene and 20 ml of bis(*N*-propylsalicylideneaminato)-copper(II), dried in an oven at 80—100 °C for 10 min before use, and dissolved in 5 ml of dry benzene with vigorous stirring at 80—81 °C for 4 hr. The solvent was then removed on a rotoevaporator and the residue was chromatographed over alumina. Elution with 20 ml of hexane–ether (2: 1, monitored by tlc) gave 105 mg (40%) of **5a** (R_f 0.77) and subsequent elution with 20 ml of hexane–ether (1: 1) gave 29.1 mg (11%) of **5b** (R_f 0.53). The spectral data along with elemental analyses are as follows: *7,10-trans-2,6-epi-2-methoxycarbonyl-7-isopropenyl-10-methyltricyclo[4.4.0.0^{1,5}]decan-4-one (5a)*: IR (neat) 3080, 1732 (C=O), and 1648 cm^{-1} (C=C); NMR ($CDCl_3$) δ 0.95—1.18 (m, 3H, CH_3), 1.75 (s, 3H, CH_3C=C), 3.72 (s, 3H, CH_3O), and 4.86 (broad, 2H, H_2C=C); mass spectrum (*m/e*) 262 (M^+, 14), 247 (14), 234 (15), 203 (22), 181 (21), 175 (20), 161 (25), 159 (29), 147 (39), and 135 (100); $[\alpha]_D^{24}$ +6.1° (*c* 3.68, $CHCl_3$).

Found: C, 73.13; H, 8.51%. Calcd for $C_{16}H_{22}O_3$: C, 73.25; H, 8.45%.

7,10-cis-2,6-Epi-2-methoxycarbonyl-7-isopropenyl-10-methyltricyclo[4.4.0.0^{1,5}]decan-4-one (5b): IR (neat) 3080, 1737 (C=O), and 1647 cm^{-1} (C=C); NMR ($CDCl_3$) δ 0.47—1.18 (m, 3H, CH_3), 1.78 (broad, 3H, CH_3C=C), 3.66 (s, 3H, CH_3O), and 4.75 (m, 2H, H_2C=C); mass spectrum (*m/e*) 262 (M^+, 9), 247 (13), 234 (8), 203 (26), 181 (13), 175 (19), 161 (26), 159 (22), 147 (44), and 135 (100); $[\alpha]_D^{24}$ −8.5° (*c* 2.64, $CHCl_3$).

Found: C, 73.08; H, 8.60%. Calcd for $C_{16}H_{22}O_3$: C, 73.25; H, 8.45%.

7,10-trans-2,6-Epi-7-isopropenyl-10-methyl-4-oxotricyclo-[4.4.0.0^{1,5}]decene-2-carboxylic Acid (6a). A mixture of

330 mg (1.26 mmol) of **5a** and 700 mg (12.5 mmol) of KOH in 20 ml of 5% aqueous MeOH was stirred at room temperature overnight. The solvent was removed on a rotoevaporator. The residual alkaline solution was washed with hexane–benzene and neutralized with aqueous tartaric acid under cooling with an ice-water bath and then extracted with ether. The combined extracts were washed with water, dried (Na_2SO_4), and concentrated. The residue (312 mg) was chromatographed over silica gel using hexane–ether (1: 1) to give 305 mg (98%) of **6a**: IR (neat) 3500—2500 (COOH), 1728 (C=O), 1705 (COOH), and 1645 cm^{-1}; NMR ($CDCl_3$) δ 1.02—1.19 (d, J=6.5 Hz, 3H, CH_3), 1.74 (s, 3H, CH_3C=C), 3.15—3.60 (m, 1H, HCC=O), 4.73 (broad, 2H, H_2C=C), and 10.63 (broad, 1H, COOH); $[\alpha]_D^{24}$ +7.7° (*c* 2.92, $CHCl_3$).

Found: C, 72.44; H, 8.38%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Electrolytic Acetoxylation of ***6a***. The acid **6a** (150 mg, 0.61 mmol) was dissolved in a mixed solution of AcOH (6 ml), *t*-BuOH (3 ml), and Et_3N (20 mg). The mixture was electrolyzed at a constant current of *ca.* 0.25 A (*ca.* 20 V) at 10 °C for 20 h. The solvent was removed on a rotoevaporator and the residue was taken up in benzene–ether (1: 1). The organic phase was washed with water and saturated $NaHCO_3$ and dried (Na_2SO_4), and concentrated. The residue was chromatographed over silica gel using hexane–ether (2: 1) to give 115 mg (72%) of **10**, bp 129—130 °C (0.005 mmHg).[3]

7,10-trans-*6-Epi-7-isopropyl-10-methyltricyclo*[*4. 4. 0. 0*^{1,5}]-2-*decen-4-ones* (***11a and 11b***). A salt free benzene solution (10 ml) of triphenylmethylenephosphorane prepared from triphenylmethylphosphonium bromide (210 mg, 0.59 mmol) was added dropwise with cooling in an ice-water bath to a stirred solution of **10** (119 mg, 0.45 mmol) in 2 ml of benzene. The mixture was diluted with 20 ml of hexane and the precipitate was filtered off. The filtrate was concentrated. The residual oil was chromatographed over silica gel tlc plate (Merck PF-254, hexane–ether, 1: 1) to give 80 mg (87%) of **11a** and **11b** (R_t 0.64—0.72). Separation of the epimers was carried out by preparative glpc to give **11a** and **11b** in a 3: 1 ratio (polyneopentyl glycol succinate, 10% coated on Chromosorb W, 4 mm×2 m column, carrier gas H_2 32 ml/min, 169 °C, R_t (min) **11a** (11.00), **11b** (15.00).

6,7-cis-*7,10*-trans-*7-Isopropyl-10-methyltricyclo*[*4. 4. 0. 0*^{1,5}]-2-*decen-4-one* (***11a***): IR (neat) 3020, 1702 (C=O), and 1571 cm^{-1} (C=C); NMR ($CDCl_3$) δ 0.60—1.07 (10H, $3CH_3$, CH), 1.10—2.40 (m, 8H, CH_2, CH), 5.55 (d, J=9 Hz, 1H, CH=C), and 7.46 (d, J=9 Hz, 1H, HC=C); mass spectrum (*m/e*) 204 (M^+, 39), 189 (50), 161 (100), 149 (56), 148(53), 147 (57), 133 (84), 121 (50), 109 (62), 105 (75), and 91 (94); $[\alpha]_D^{24}$ −136.7° (*c* 1.88, $CHCl_3$).

Found: C, 82.15; H, 10.02%. Calcd for $C_{14}H_{20}O$; C, 82.30; H, 9.87%.

6,7-trans-*7,10*-trans-*7-Isopropyl-10-methyltricyclo*[*4. 4. 0. 0*^{1,5}]-*decene-4-one* (***11b***): IR (neat) 3080, 1706 (C=O), and 1568 cm^{-1} (C=C); NMR ($CDCl_3$) δ 0.60—1.10 (10H), 1.10—2.40 (8H), 5.48 (d, J=9 Hz, 1H, HC=C), and 7.62 (d, J=9 Hz, 1H, HC=C); mass spectrum (*m/e*) 204 (M^+, 39), 189 (38), 161 (83), 149 (54), 148 (25), 147 (48), 133 (56), 121 (46), 109 (34), 105 (58), and 91 (100); $[\alpha]_D^{24}$ +77.4° (*c* 0.23, $CHCl_3$).

Found: C, 82.26; H, 9.82%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

7-Isopropyl-4,10-dimethyltricyclo[*4. 4. 0. 0*^{1,5}]*deca-2-en-4-ol* (***12***). A solution of **11a** (26 mg, 0.13 mmol) in ether (3 ml) was added for 10 min to a stirred solution of MeMgI prepared from MeI (50 mg, 0.35 mmol) and Mg metal (5 mg, 0.21 mg atom) under N_2 and cooling with ice. The solution was gently refluxed for 2 h. After being cooled to room temperature the mixture was poured into aqueous 20% NH_4Cl (5 ml) and extracted with benzene. The extracts were washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed over silica gel with benzene to give **12** (23.0 mg, 82%): IR (neat) 3400 (OH), 3050 (shoulder), 1370, 1027, 917, and 756 cm^{-1}; NMR (CCl_4) δ 0.60—1.20 (m, 14H, $3CH_3$, CH_2, CH), 1.40 (d, 3H, CH_3), 1.40—1.80 (m, 5H, CH_2, CH), 5.00—5.24 (m, 1H, HC=C), and 5.52—5.76 (m, 1H, HC=C); mass spectrum (*m/e*) 220 (M^+, 7), 207 (32), 202 (28), 177 (56), 161 (53), 159 (78), 145 (29), 135 (43), 131 (58), 121 (58), 119 (57), 118 (100), 117 (58), 105 (63); $[\alpha]_D^{24}$ −91.5° (*c* 0.87, $CHCl_3$).

Found: C, 81.50; H, 11.04%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

Hydrogenation of ***12***. To a solution of **12** (34.0 mg, 0.15 mmol) in 5 ml of AcOEt was added 5 mg of platinum dioxide. The mixture was flushed with H_2 gas and stirred efficiently under H_2. After 1 h the theoretical amount of H_2 was absorbed. The mixture was filtered and the solvent was rotoevaporated to afford a residue which was immediately chromatographed over silica gel (2.5 g). Careful elution with benzene gave 4-epicubebol (**1b**, 12.5 mg, 36.5%) as an oil contaminated with a small amount of **1a**. The following elution with benzene gave cubebol (**1a**) (12.5 mg, 36.5%) as crystals. Repeated chromatography of the products over silica gel using benzene gave analytical samples: cubebol (**1a**), mp 58—59 °C (lit,[1a,1c] 61—62 °C, 64 °C); IR (Nujol) 3300 (OH), 1385, 1370, 1300, 1223, 1155, 1134, 1080, 1032, 980, 970, 928, and 890 cm^{-1}; NMR ($CDCl_3$) δ 0.89 (d, J=7 Hz, 6H, CH_3), 0.95 (d, J=6.5 Hz, 3H, CH_3), and 1.27 (s, 3H, CH_3); mass spectrum (*m/e*) 222 (M+,2), 207 (39), 204 (29), 189 (4), 179 (8), 161 (100), 121 (32), 119 (58), 105 (72), and 91 (55); $[\alpha]_D^{15}$ −44.7° (*c* 0.85, $CHCl_3$) (lit,[1c,1a] −48.3 °, −61.6 °).

4-Epicubebol (***1b***): IR (neat) 3400 (OH), 1370, 1321, 1152, 1123, 1040, 1008, 980, and 915 cm^{-1}; NMR (CCl_4) δ 0.87—1.05 (m, $3CH_3$), and 1.25 (s, 3H, CH_3); mass spectrum (*m/e*) 222 (M^+, 3), 207 (53), 204 (26), 189 (6), 179 (21), 161 (100), 121 (54), 120 (55), 119 (58), 105 (67), and 91 (64); $[\alpha]_D^{14}$ −4.0° (*c* 1.25, $CHCl_3$).

7,10-trans-*7-Isopropyl-10-methyltricyclo*[*4.4.0.0*^{1,5}]*decan-4-one* (*norcubenbanone*) (***13a***). Hydrogenation of 44 mg (0.22 mmol) of **11a** was carried out in 3 ml of absolute EtOH with 40 mg of 10% Pd-carbon until 4.8 ml of H_2 gas was absorbed. The mixture was filtered and the solvent was evaporated to afford an oil. The crude product was chromatographed on silica gel, eluted with benzene, to give 44 mg (99%) of **13a**, mp 57.0—57.5 °C (lit,[1c] mp 57—58 °C); mass spectrum (*m/e*) 206 (M^+, 42), 191 (10), 164 (78), 163 (45), 149 (32), 134 (31), 122 (100), 93 (77), and 79 (92); $[\alpha]_D^{24}$ −22.8 ° (*c* 0.12, MeOH). (lit,[1c] $[\alpha]_D^{24}$ −23.9° (*c* 0.16, MeOH)). IR and NMR spectra of **11a** were identical with those of an authentic sample.[9]

Cubebol (***1a***) *from Norcubebanone* (***13a***). To an ether solution of MeMgI, prepared from MeI (80 mg, 0.56 mmol) and Mg metal (10 mg, 0.42 mg atom), was added 33 mg (0.16 mmol) of **13a** in 5 ml of ether over a period of 5 min. The stirred mixture was refluxed for 2 h and poured into ice-cold aqueous 20% NH_4Cl (5 ml). The organic phase was extracted with ether. The extracts were washed with brine, dried (Na_2SO_4), and concentrated. The residue was chromatographed over silica gel using benzene to give **1a** (17.3 mg, 49%). Compound **1a** melted at 58—59 °C. IR and NMR spectral data were identical with those of an authentic sample.

The Bromination and Mercuration of bis-Dimethylglyoxymato-(alkyl)pyridinecobalt(III), Alkyl Cobaloxime[1]

Hiraku SHINOZAKI, Hiroki OGAWA, and Masaru TADA

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received October 2, 1975)

The bromination and mercuration of *cis*-2-methoxycyclohexyl(pyridine)cobaloxime (I) gave *trans*-1-bromo-2-methoxycyclohexane (V) and *trans*-2-methoxycyclohexylmercury(II) chloride (VII), along with other by-products derived from the cyclohexene formed by β-elimination. β-Elimination is an exclusive degradation path with *trans*-2-hydroxycyclohexyl(pyridine)cobaloxime(II). The reaction of *cis* and *trans*-4-*t*-butylcyclohexyl(pyridine)cobaloximes (III and IV) gave *trans* and *cis*-1-bromo-4-*t*-butylcyclohexanes (X and XI), and *trans* and *cis*-4-*t*-butylcyclohexylmercury(II) chloride, with an exculsive or preferential inversion at the reaction center. These results show that the S_E2 reaction of alkyl cobaloxime takes a stereochemical course of inversion.

The electrophilic rupture of the alkyl group from cobalamine, the coenzyme B_{12} derivative,[2] is considered to be a simple metabolic pathway to produce methane, acetic acid, and methyl mercurial. Especially, methyl cobalamine has been recognized to be responsible for the transformation of mercury(II) ion into dimethylmercury in the sludge of river and sea, which causes a serious pollution problem.[3] Schrauzer[4] demonstrated that bis-dimethylglyoxymato(alkyl)pyridinecobalt(III) (the conventional name, alkyl cobaloxime, will be used hereafter) constituted a superior model system for the alkyl derivative of the B_{12} coenzyme. Much attention has been paid to the stereochemistry of the electrophilic displacement of alkyl σ-metal complexes, and the steric courses of both retention and inversion have been reported.[1,5-12] Kinetic studies have established the nature of these electrophilic reactions of alkyl cobaloximes to be a bimolecular substitution, a S_E2 reaction.[13,14] We reported in preliminary form about the steric consequence of the bromination and mercuration of alkyl cobaloxime;[1] in this paper we wish to report the details of our study.

Experimental

Preparation of cis-*2-Methoxycyclohexyl(pyridine)cobaloxime (I) and* trans-*2-Hydroxycyclohexyl(pyridine)cobaloxime (II).* Cobaloxime I was synthesized by the reaction of *trans*-1-bromo-2-methoxycyclohexane (5.0 g) with the cobaloxime anion prepared *in situ* from $CoCl_2 \cdot 6H_2O$ (5.95 g), dimethylglyoxime (5.80 g), sodium hydroxide (2.0 g), pyridine (2.0 g), and sodium tetrahydroborate (200 mg)under nitrogen in methanol (90 ml) at 0 °C for 1 h and at room temperature for 12 h. The reaction mixture was condensed to *ca.* 30 ml under reduced pressure, and the residue was extracted with chloroform (30 ml×3) after the addition of water (30 ml). The condensation of the extract after drying over sodium sulfate gave a residue containing cobaloxime I. The separation of I from the residue was achieved by column-chromatography on Florisil (30 g), eluting with benzene (unreacted 1-bromo-2-methoxycyclohexane) and chloroform (cobaloxime I). The repeated chromatography of the latter fraction on Florisil gave 3.85 g (32%) of the pure I.

The cobaloxime, II, was synthesized from cyclohexene oxide by a similar method, but using hydrogen as the reducing agent, in a 24% yield. Spectroscopic data showed the I and II cobaloximes to be identical with the compounds described by Jensen *et al.*[15]

I, NMR ($CDCl_3$): 8.7—7.1 (5H, pyridine), 3.30 (broad singlet, $W_{1/2}$=9 Hz, 1H), 3.15 (singlet, 3H), 2.10 (singlet, 12H), and 2.1—0.9 ppm (δ) (multiplet, 9H).

II, NMR ($CDCl_3$): 8.7—7.1 (5H, pyridine), 3.05—2.70 (sextet, $W_{1/2}$=19 Hz, 1H), 2.07 (singlet, 6H), 2.13 (singlet, 6H), and 2.1—0.8 ppm (δ) (multiplet, 9H).

Preparation of cis-*4-t-Butylcyclohexyl(pyridine)cobaloxime (III) and* trans-*4-t-Butylcyclohexyl(pyridine)cobaloxime (IV).* Cobaloxime III was synthesized in essentially the same way as cobaloxime I, using *trans*-4-*t*-butylcyclohexyl tosylate. The reaction period was prolonged to 21 h, and the crude product was chromatographed on Florisil to give the unreacted tosylate in a benzene eluate and the cobaloxime III in a chloroform eluate. The yield was poor (7.7%), but it was fruitless to continue the reaction further because of the deterioration of the cobaloxime anion. The reaction of *cis*-4-*t*-butylcyclohexyl tosylate with the cobaloxime anion in the same manner for 13 h gave the cobaloxime IV in a higher yield (40.7%).

III, mp 110—120 °C (dec.). Found: C, 54.47; H, 7.40; N, 13.59%. Calcd for $C_{23}H_{38}N_5O_4Co$: C, 54.43; H, 7.55; N, 13.80%. IR(KBr): 2690, 1600, 1550, 1448, 1365, 1232, 1090, and 520 cm^{-1}. NMR ($CDCl_3$): 8.5—7.0 (5H, pyridine), 2.10 (singlet, 12H), 1.9—0.8 (10H), and 0.77 ppm (δ) (singlet, 9H).

IV, mp 150—160 °C (dec.). Found: C, 54.34; H, 7.48; N, 13.92%. Calcd for $C_{23}H_{38}N_5O_4Co$: C, 54.43; H, 7.55; N, 13.80%. IR (KBr): 2940, 1595, 1550, 1445, 1360, 1230, 1082, and 515 cm^{-1}. NMR ($CDCl_3$): 8.4—7.0 (5H, pyridine), 2.10 (singlet, 12H), 1.9—0.8 (10H), and 0.76 ppm (δ) (singlet, 9H).

Bromination of the Cobaloximes (I and II). To a solution of the I cobaloxime (120 mg) in dichloromethane (50 ml) we added, drop by drop, a solution of bromine (42 mg, 1.0 equivalent) in benzene (3 ml) under cooling to −70 °C. After stirring for 3 h under argon, the reaction mixture was passed through a column of Florisil (20 g) to remove the inorganic complex formed. The subsequent evaporation of the eluate gave a mixture (11 mg) of *trans*-1-bromo-2-methoxycyclohexane (V), *trans*-1,2-dibromocyclohexane (VI), and cyclohexanone, whose GLC analysis (OV-17 on Chromosorb W, N_2) showed signal intensities of *ca.* 2:1:2 respectively. The treatment of the II cobaloxime (500 mg) under the same reaction conditions, but at the reaction temperature of 0 °C, gave the VI dibromide (169 mg, 65%).

Bromination of the Cobaloximes (III and IV). The III cobaloxime (25 mg) in dichloromethane (1 ml) was cooled in an ice-water bath to −5 °C and then treated with 22 mg of bromine (2.6 equivalents) in dichloromethane. The reaction mixture was subsequently stirred for 6 h under nitrogen.

After the careful evaporation of the solvent, the product was chromatographed on Florisil (1 g), using hexane as the eluent. The careful evaporation of the eluate yielded *ca.* 10 mg of a product (*ca.* 92%). GLC analysis (Carbowax 20 M on Chromosorb W, N_2) showed the product to be a 1:3 mixture of *cis* and *trans*-1-bromo-4-*t*-butylcyclohexanes, XI and X, which were identical with authentic samples. The same treatment of the IV cobaloxime gave exclusively the XI bromide in a *ca.* 90% yield.

Mercuration of the Cobaloximes (I and II). To a solution of the I cobaloxime (360 mg) in ethanol (30 ml) containing acetic acid (0.02 mol/l), we added solid mercuric acetate (360 mg, 1.48 equivalents), after which the reaction mixture was refluxed for 2.5 h under nitrogen. Excess sodium chloride was added to the cooled mixture, which was then further stirred for 2.5 h at room temperature. The filtrate of the mixture was condensed and extracted with chloroform after the addition of water to the condensate. The passing of the extract through Florisil gave products in benzene eluate, while the I cobaloxime (73 mg) was recovered in the chloroform eluate. The chromatography of the products on silica gel eluted with dichloromethane gave a mixture of *trans*-2-methoxycyclohexylmercury(II) chloride (VII) and *trans*-2-ethoxycyclohexylmercury(II) chloride (VIII) (77 mg, 36% based on the I cobaloxime consumed). The ratio of VII to VIII was determined by the transformation of these mercurials into *trans*-1-bromo-2-methoxycyclohexane (V) and *trans*-1-bromo-2-ethoxycyclohexane (IX) by bromine in pyridine at −20 °C. The V and IX bromides, obtained in 40 mg after chromatography on alumina eluted by hexane, were found by analysis to exist in the ratio of 3:2.

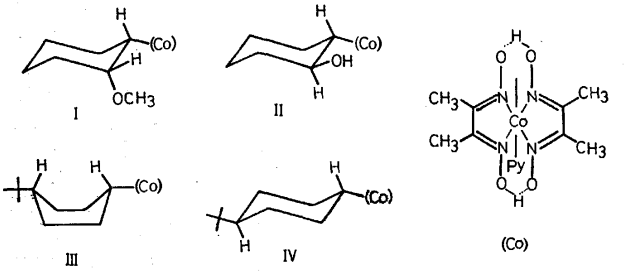
The treatment of the II cobaloxime (467 mg) with mercuric acetate in methanol under essentially the same reaction conditions, but at the reaction temperature of 20 °C, gave *trans*-2-methoxycyclohexylmercury(II) chloride (VIII) in a 70% yield; this substance was identified with an authentic sample obtained by the methoxymercuration of cyclohexene.

Mercuration of the Cobaloximes (III and IV). To a solution of cobaloxime III (204 mg) in methanol (20 ml) we added powdered mercuric nitrate hydrate (274 mg), after which the solution was stirred for 120 h under nitrogen at room temperature. The reaction mixture was further stirred for 2.5 h after the addition of excess sodium chloride. The product was extracted with chloroform after the evaporation of methanol under reduced pressure and the addition of water to the condensed mixture. The extract was chromatographed on Florisil (6 g) to give the product as a benzene eluate and the recovered cobaloxime as a chloroform–methanol (9:1) eluate. The chromatography of the product on silica gel (2 g) gave *trans*-4-*t*-butylcyclohexylmercury(II) chloride, XII (3 mg, 2.0%), in a benzene eluate; this substance was identified with an anthentic sample synthesized from *trans*-4-*t*-butylcyclohexylmagnesium(II) bromide[16] and, further, by the transformation of XII into *trans*-1-bromo-4-t-butylcyclohexane (X) in the same way as was used for the transformation of mercurial VII and VIII into the V and IX bromides.

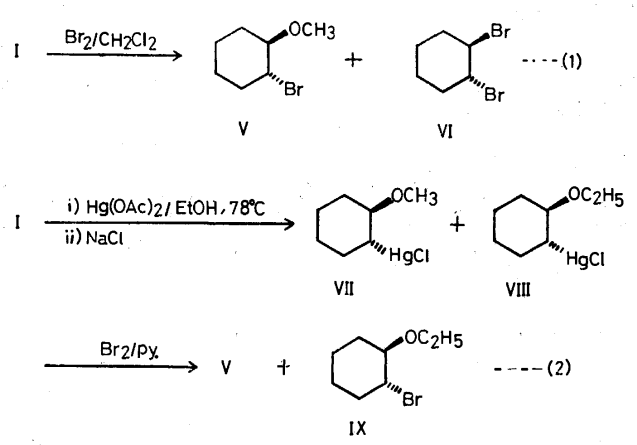
The mercuration of the IV cobaloxime (127 mg) was carried out in the same manner, but for 5 h at 50 °C. The chromatography of the products on Florisil (5 g) gave the products as the benzene eluate and the recovered IV cobaloxime (66 mg) as the chloroform eluate. Repeated chromatography of the products on silica gel (6 g) gave a mixture of *cis* and *trans*-4-*t*-butylcyclohexylmercury(II) chloride. The structure and ratio of the isomers were determined, by the transformation of the mercurials into bromides as has been described above, to be *cis*(XI): *trans*(X)=3:2.

Results and Discussion

cis-2-Methoxycyclohexyl(pyridine)cobaloxime (I) was synthesized by the substitution of *trans*-1-bromo-2-methoxycyclohexane with the cobaloxime anion, $(Co)^-$, prepared *in situ* by the sodium tetrahydroborate reduction of the complex from dimethylglyoxime, cobalt(II) chloride, and pyridine. The steric course of this reaction has been proved to proceed with an inversion at the reaction center, and the *trans* arrangement of the methoxy group and the cobaloxime moiety was confirmed by the NMR spectrum of I. The signal due to the hydrogen attached to the carbon bearing methoxy group is at 3.30 ppm (δ), with a half-band width of 9 Hz, which shows a lack of diaxial coupling and the axial conformation of the methoxy group. This feature unequivocally limits the stereochemistry of the I cobaloxime to *cis*, since the large steric requirement of the ligand enforces the cobaloxime group to take an equatorial conformation.[15] *trans*-2-Hydroxycyclohexyl(pyridine)cobaloxime (II), prepared from cyclohexene oxide and the cobaloxime anion, $(Co)^-$, has an NMR signal at 3.05—2.70 ppm as a diffused sextet with a half-band width of 19 Hz (J=10, 10, and 5 Hz), indicating the presence of two diaxial coupling and one axial-equatorial coupling. *Cis* and *trans*-4-*t*-butylcyclohexyl(pyridine)cobaloxime (III and IV) were prepared by the S_N2 displacement of *trans* and *cis*-4-*t*-butylcyclohexyl tosylate respectively. The reaction of the *trans* tosylate to give the *cis*-cobaloxime (III) was sluggish, and the yield was poor, 7.7%, even after a prolonged reaction period. This behavior can be accounted for by the steric hindrance on the approach of the cobaloxime anion from the axial direction when the S_N2 mechanism operates.[17] The large substituents at the 1,4-position of the cyclohexane ring suggest that the conformation of III is a boat form. The spectroscopic data do not discriminate the stereochemistry of III and IV, but the S_N2 nature of the reaction suggests the stereochemistry of the cobaloximes to be *cis* and *trans* respectively.[15] This reasoning was proved by the bromination of III and IV giving different products, as will be described below.

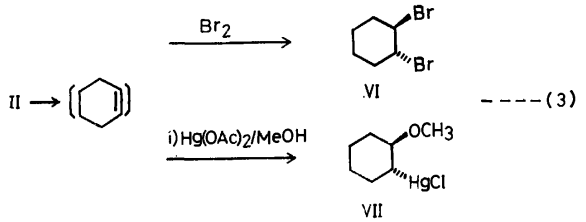


The bromination of *cis*-2-methoxycyclohexyl(pyridine)cobaloxime (I) in dichloromethane gave a complex mixture at an ambient temperature, but the reaction at a lower temperature (−70 °C) yielded *trans*-1-bromo-2-methoxycyclohexane (V) in a poor yield, besides *trans*-1,2-dibromocyclohexane (VI) and cyclohexanone (Eq. 1). The formation of V, in spite of the low yield, clearly shows that the reaction proceeds



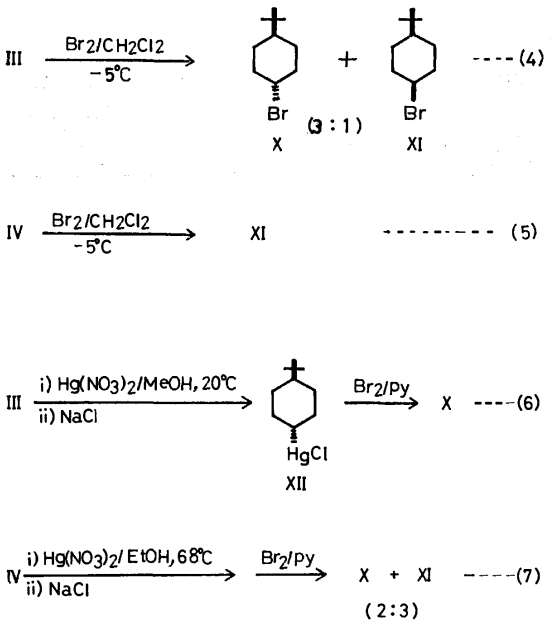
with an inversion of the configuration, though the formation of VI indicates the side reaction *via* cyclohexene as an intermediate. The mercuration of I with mercuric acetate was attempted under the conditions in which Schrauzer *et al.*, determined the kinetic property of the reaction to be second order.[13] In our preliminary report, we errornously recorded the formation of *trans*-2-methoxycyclohexylmercury(II) chloride (VII) when *cis*-2-hydroxycyclohexyl(pyridine)cobaloxime was treated with mercuric acetate in methanol; we attributed this result to a mercury-assisted corbonium ion. A detailed analysis of the NMR spectrum, however, clarified that the cobaloxime in some synthetic lots contained varying amounts of II due to the intervention by cyclohexene oxide when *cis*-2-hydroxycyclohexyl-(pyridine)cobaloxime was prepared under the basic conditions. The mercuration of the I cobaloxime was sluggish at an ambient temperature, but gave a mixture of *trans*-2-methoxycyclohexylmercury(II) chloride (VII) and *trans*-2-ethoxycyclohexylmercury(II) chloride (VIII) when the ethanol solution of I and mercuric acetate was refluxed. The bromination of the resulting mixture in pyridine gave a mixture of *trans*-1-bromo-2-methoxyhexane (V) and *trans*-1-bromo-2-ethoxyclohexane (IX) in the ratio of 3: 2—the yield of the mixture from I was 36% (Eq. 2). The bromination of organo-mercurial in pyridine has been determined to proceed with a retention of the configuration;[18] hence, the mercuration of *cis*-2-methoxycyclohexyl(pyridine)-cobaloxime (I) clearly proceeds with inversion. The formation of the by-product, 1-bromo-2-ethoxycyclohexane, must be accounted for by the intermediate formation of cyclohexene upon mercuration as in the case of bromination.

The bromination and mercuration of *trans*-2-hydroxycyclohexyl(pyridine)cobaloxime (II), under the same reaction conditions as were used for the reaction of the I cobaloxime, gave *trans*-1,2-dibromocyclohexane (VI)



(65%) and *trans*-2-methoxycyclohexylmercury(II) chloride (VII) (70%) (Eq. 3). This implies that the *trans* arrangement of the hydroxy and cobaloxime groups in II brings about a facile β-elimination to give cyclohexene, and that the bromination or mercuration of the resulting cyclohexene takes place efficiently.

The bromination of *cis*-4-*t*-butylcyclohexyl(pyridine)cobaloxime (III) in dichloromethane at −5 °C gave a mixture of *trans*-1-bromo-4-*t*-butylcyclohexane (X) and its *cis* isomer, XI, in the ratio of 3: 1 and in a 92% yield (Eq. 4). The same treatment of *trans*-cobaloxime IV gave exclusively the XI *cis* isomer in a 90% yield (Eq. 5). The incompleteness of the stereospecificity in the bromination of III may arise from the intrusion of the radical process, since the back-side attack of III, in boat-like conformation, by bromine is hardly allowed. The mercuration of III and IV with mercuric acetate is sluggish, so the reaction was attempted by using the more reactive mercuric nitrate in methanol (Eqs. 6 and 7). The product from the reaction of III was identified with authentic *trans*-4-*t*-butylcyclohexylmercury(II) chloride (XII) prepared from the corresponding Grignard reagent.[16] The mercuration itself was a rather smooth process and the complete disappearance of III and IV was observed by the thin-layer chromatography of the reaction mixture. The addition of sodium chloride to convert the resulting organo-mercurial into the more stable organo-mercuric chloride, or the condensation of the reaction solution for isolation reverted the reaction and regenerated the III and IV cobaloximes.[19] This behavior was also suggested by observing the NMR spectrum of the reaction solution of IV. The signal at 2.17 ppm (δ) in methanol due to the four methyl groups of the dimethylglyoxymato-ligand of IV was displaced to 2.22 ppm by the addition of the mercuric ion. The addition of powdered sodium chloride to this solution regenerated the original signal. Several efforts to isolate the resulting mercurial in a practical yield from III and IV were unsuccessful in this situation. The stereochemistry of



the mercurials thus obtained in poor yields was determined by the transformation of these mercurials into bromides by the action of bromine in pyridine. GLC analyses of the resulting bromides revealed that the bromide from III was exclusively *trans*-1-bromo-4-*t*-butylcyclohexane (X), while the bromide from IV was a 3:2 mixture of *cis* and *trans*-1-bromo-4-*t*-butylcyclohexanes. The latter result may be due to the incomplete stereospecificity upon the bromination of the *cis*-4-*t*-butylcyclohexylmercury(II) chloride derived from IV, since the *cis* mercurial can be expected to have a mercuric chloride group in the axial conformation;[20] the bromination with retention may not be favored.

In general, the S_E2 reaction is known to proceed with retention at the reaction center.[21] Reactions with inversion, however, have been reported in several instances, such as the brominations of tri-norbornyl borane in the presence of sodium methoxide,[22] alkyl tin,[23] and the alkyl iron complex.[5] Jensen *et al.*,[24] and Johnson *et al.*,[25] showed in preliminary reports, independently from ours, that the bromination of cobaloxime took a reaction path with an inversion at the reaction center; our results described in the preliminary report[1] and in the present paper are in good accordance with the results by those authors.

The bromination and mercuration of the II cobaloxime were found not to be suitable for the test of stereospecificity because of the reaction path of β-elimination. The equilibrium between 4-*t*-butylcyclohexyl(pyridine)cobaloxime and the mercuric ion, as proved by TLC and NMR analyses, may confuse the stereochemical course of the mercuration, but the reverse reaction must take the same stereochemical course as that of mercuration since the transition state is common to both the reactions in the equilibrium (Eq. 8).

$$Hg^{2+} + \rangle R\text{-}(Co) \rightleftharpoons [Hg\cdots C\text{-}(Co)]^{2+} \rightleftharpoons Hg\text{-}R + (Co)^{+} \cdots (8)$$

transition state

The discussions in this paper define the stereochemical nature of the bromination and mercuration as involving inversion, despite some incomplete stereospecificity in the systems with difficult geometries to take a penta valent transition state for the S_E2 reaction.

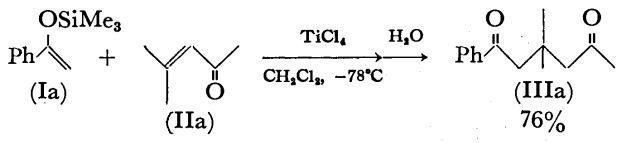
(Received November 4, 1975)

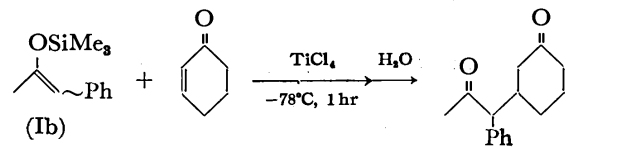
Silyl enol ethers react with α,β-unsaturated ketones and esters in the presence of $TiCl_4$ or in the coexistence of $TiCl_4$ and $Ti(O^i\text{-}Pr)_4$ to give 1,5-dicarbonyl compounds in good yields. The reactions of acetals derived from α,β-unsaturated ketones with silyl enol ethers in the coexistence of $TiCl_4$ and $Ti(O^i\text{-}Pr)_4$, followed by successive addition of 1,2-ethanedithiol, give the Michael products, δ-keto ethylene thioacetal, in good yields. The reaction of silyl enol ethers with acetals derived from α,β-unsaturated aldehydes also gives the Michael products when $Ti(OCEt_3)_4$ is employed instead of $Ti(O^i\text{-}Pr)_4$ in the above experiment and is successfully applied to the simple synthesis of dihydro rose oxide.

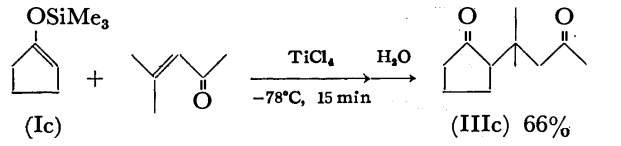
The Michael reaction of silyl enol ethers with various α,β-unsaturated ketones was briefly reported in the previous paper.[1] In this report, the reaction is explained in detail with additional results.

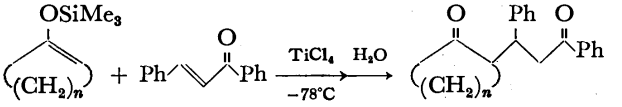
During the investigation on the cross-aldol reaction of silyl enol ethers with carbonyl compounds,[2] it was found that $TiCl_4$-promoted reaction of α,β-unsaturated ketones with silyl enol ethers results in the formation of 1,5-dicarbonyl compounds (the Michael products) instead of aldol products. For example, equimolar amounts of mesityl oxide (IIa) and α-trimethylsiloxystyrene (Ia) were treated with an equimolar amount of $TiCl_4$ in methylene chloride at −78 °C, and the mixture was quenched with aqueous K_2CO_3 after 2 min. Following purification by preparative tlc(silica gel), the Michael product, 3,3-dimethyl-1-phenyl-1,5-hexanedione (IIIa), was isolated in 76% yield.



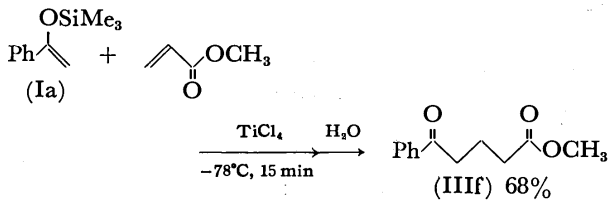
The reactions of various silyl enol ethers with a variety of α,β-unsaturated carbonyl compounds were tried in the presence of an equimolar amount of $TiCl_4$ and the corresponding Michael products were obtained in good yields as shown in the following equations.



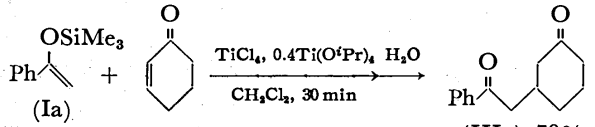


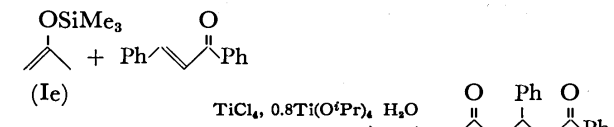


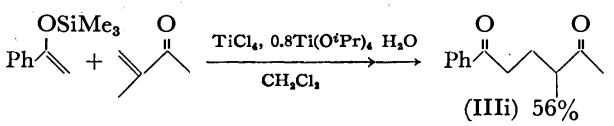
n=2 (Ic) n=2, 45 min 85% (IIId)
n=3 (Id) n=3, 60 min 95% (IIIe)



As shown in the above equations, 1,5-dicarbonyl compounds were generally obtained in good yields by the $TiCl_4$-promoted reaction of silyl enol ethers with α,β-unsaturated ketones. When $TiCl_4$-sensitive compounds such as isopropenyl trimethylsilyl ether (Ie) or 2-cyclohexen-1-one and isopropenyl methyl ketone were employed as a nucleophile or the Michael acceptors, the yields of the products became vary low. However, when the same reaction was carried out at —78 °C in the coexistence of $TiCl_4$ and $Ti(O^iPr)_4$, 1,5-diketones (IIIg, h, i) were obtained in fairly good yields.



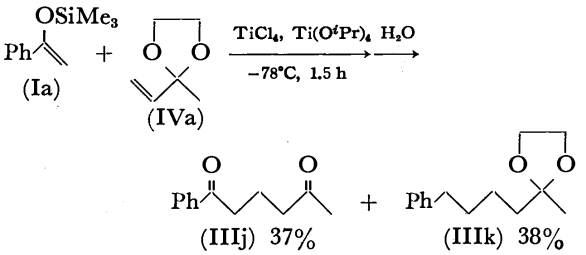




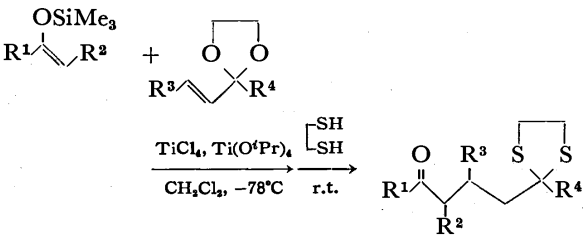
In general, the Michael reaction of an α,β-unsaturated carbonyl compound with a ketone is carried out under basic conditions and the product, a 1,5-dicarbonyl compound, frequently tends to undergo further transformation in the presence of a base.[3] Furthermore, when α,β-unsaturated ketones are used as the Michael acceptors, there are many possibilities leading to a variety of side reactions such as self-condensation reactions and the Michael reaction followed by aldol reaction.[4] On the other hand, a few examples are known concerning the acid catalyzed Michael reaction,

but in these cases, none of the 1,5-dicarbonyl compounds can be isolated bacause of further transformations of initially formed 1,5-dicarbonyl compounds.[5] In contrast to these known methods, the present Michael reaction proceeds under a very mild condition (−78 °C) to afford 1,5-dicarbonyl compounds exclusively without accompanying any by-product.

In addition, an advantage of this acid catalyzed Michael reaction is that an α,β-unsaturated acetal is able to be used as the Michael acceptor. When methyl vinyl ketone ethylene acetal (IVa)[6] was treated with α-trimethylsiloxystyrene (Ia) in the presence of equimolar amounts of $TiCl_4$ and $Ti(O^iPr)_4$ in methylene chloride at −78 °C, 1-phenyl-1,5-hexanedione (IIIj) and its monoacetal (IIIk) were isolated in 37% and 38% yields, respectively, after hydrolysis with aqueous K_2CO_3.



However, it was found that the subsequent treatment of the reaction mixture with 1,2-ethanedithiol gives the corresponding δ-keto thioacetal as the Michael product. For example, dropwise addition of a methylene chloride solution of equimolar amounts of Ia and IVa to a mixture of equimolar amounts of $TiCl_4$ and $Ti(O^iPr)_4$ in methylene chloride at −78 °C followed by stirring at −78 °C for 1 h. After addition of 1,2-ethanedithiol (1.1 molar amount) to the mixture, it was allowed to stand overnight at room temperature. δ-Keto thioacetal (Va) was isolated in 78% yield by preparative tlc (silica gel). Similarly, several δ-keto thioacetals were prepared and, in all cases, the carbonyl group originated from the starting acetal was selectively protected as an ethylene thioacetal.



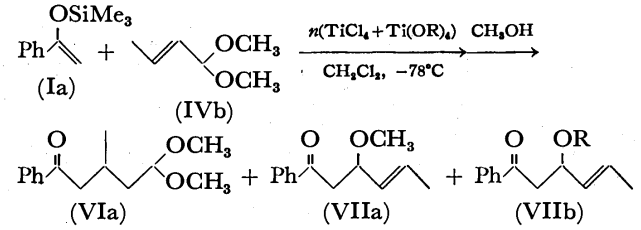
Va: R^1=Ph, R^2=H, R^3=H, R^4=Me 78%
Vb: R^1=Me, R^2=Ph, R^3=H, R^4=Me 61%
Vc: R^1=Ph, R^2=H, R^3, R^4=$-(CH_2)_3-$ 70%
Vd: R^1=Me, R^2=Ph, R^3, R^4=$-(CH_2)_3-$ 58%

Acetals derived from α,β-unsaturated aldehydes were also used as the Michael acceptors in order to prepare δ-ketoaldehyde derivatives. The reaction of crotonaldehyde dimethyl acetal (IVb) with α-trimethylsiloxystyrene (Ia) was carried out by using equimolar amounts of $TiCl_4$ and $Ti(O^iPr)_4$, but the desired Michael product (VIa) was not obtained and the β-alkoxyketones (VIIa, VIIb R=^{i}Pr) were isolated in 83% yield in total after quenching with methanol.

The preferential formation of β-alkoxyketones (VIIa, b) may be attributable to the decrease of steric hindrance around the acetal group as compared with that derived from ketones. According to this assumption, the formation of β-alkoxyketones (VIIa, b) may be suppressed by the use of aldehyde acetal having sterically large alkoxy groups instead of the methoxy group to result in the predominant formation of the Michael product (VIa).

On the other hand, it was found in our laboratory that on treatment with $Ti(O^iPr)_4$ and $TiCl_4$, 3-phenylpropionaldehyde dimethyl acetal is readily converted into the corresponding diisopropyl acetal at low tem-

Table 1. Effect of titanium alkoxides



$Ti(OR)_4$	n	Yield (%) VIa[a]	VIIa	VIIb
$Ti(O^iPr)_4$	1	0	33	50
$Ti(O^tAm)_4$	1	46	28	18
	3	59	10	19
$Ti(OCEt_3)_4$	3	70	—	—

a) The Michael product was isolated as dimethyl acetal since the resulted mixture was quenched with a large amount of methanol.

Table 2. The reaction of silyl enol ethers with aldehyde acetals

	Silyl enol ether	Acetal R^3	Yield (%) VI	VII
b		CH_3	46	trace
c		CH_3	42	trace
d		n-C_3H_7	52	9
e		n-C_3H_7	47[a]	trace

a) In this case, the reaction mixture was quenched with water instead of methanol, and the product was isolated as aldehyde.

perature,[7] and this fact indicates that an acetal having sterically hindered alkoxy group would be readily prepared *in situ* by the reaction of the corresponding dimethyl acetal with titanium alkoxides such as $Ti(OCEt_3)_4$ and $Ti(O^tAm)_4$[8] derived from sterically hindered alcohols.

Based on this assumption, crotonaldehyde dimethyl acetal (IVb) was treated at −78 °C with $Ti(OCEt_3)_4$ or $Ti(O^tAm)_4$ and $TiCl_4$ prior to the addition of the silyl enol ether (Ia) in order to replace at least one of the methoxy group with sterically hindered alkoxy group originated in $Ti(OCEt_3)_4$ or $Ti(O^tAm)_4$. In fact, it was found that when Ia was added to the above reaction mixture, the Michael product (VIa) predominated over the formation of β-alkoxyketones (VIIa, b) as the steric hindrance of the alkoxy group increased. Especially, when 3 molar amounts of $Ti(OCEt_3)_4$ and $TiCl_4$ were employed, the Michael product (VIa) was isolated almost exclusively as summarized in Table 1.

The reactions of crotonaldehyde dimethyl acetal (IVb) and (*E*)-2-hexenal dimethyl acetal (IVc) with several silyl enol ethers were tried using 3 molar amounts of $Ti(OCEt_3)_4$ and $TiCl_4$, and the results are shown in the Table 2.

The present method for the synthesis of δ-keto aldehyde acetal was successfully applied to the simple syn-

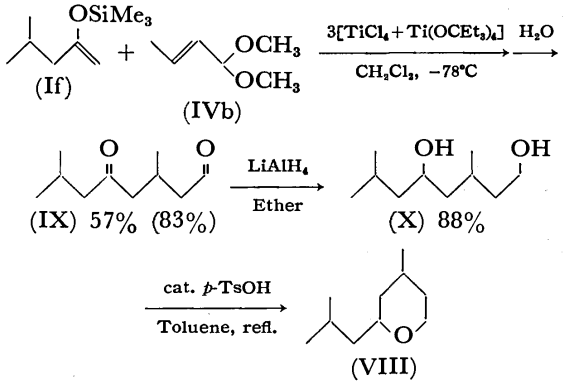
thesis of dihydro rose oxide (VIII). The reaction of 4-methyl-2-trimethylsiloxy-1-pentene (If) with crotonaldehyde dimethyl acetal (IVb) was carried out using 3 molar amounts of $TiCl_4$ and $Ti(OCEt_3)_4$ at −78 °C in methylene chloride. After hydrolysis, the ketoaldehyde (IX) was obtained in 57% yield (83% when 2 molar amounts of If was employed). Reduction of IX with $LiAlH_4$ in ether readily afforded the corresponding diol (X) in 88% yield and the dehydration of the diol (X) according to literature[9] gave a *cis* and *trans* mixture of dihydro rose oxide (VIII), which was identical by glc analysis with the authentic sample prepared by the hydrogenation of a *cis* and *trans* mixture of rose oxide over palladium.



Experimental

Materials. Commercially available $TiCl_4$ and $Ti(O^iPr)_4$ were distilled under an argon atmosphere before use. Trimethylsilyl enol ethers of carbonyl compounds, α-trimethylsiloxystyrene (Ia), 1-phenyl-2-trimethylsiloxy-1-propene (Ib), 1-trimethylsiloxy-1-cyclopentene (Ic), 1-trimethylsiloxy-1-cyclohexene (Id), were prepared according to the procedures described in the literature[10] and purified by distillation: Ia, bp 89—91 °C/12 mmHg (lit, bp 89—91 °C/12 mmHg); Ib, bp 103 °C/8 mmHg (lit, bp 106 °C/10 mmHg); Ic, bp 155 °C/760 mmHg (lit, bp 158—159 °C/760 mmHg); Id, bp 97—99 °C/65 mmHg (lit, 74—75 °C/20 mmHg). In a similar manner, isopropenyl trimethylsilyl ether (Ie) was prepared from acetone, trimethylsilyl chloride and triethylamine and 4-methyl-2-trimethylsiloxy-1-pentene (If) was prepared from the corresponding ketone, trimethylsilyl chloride and lithium diisopropylamide: Ie, bp 94.5—95.5 °C, NMR(CCl_4); δ 3.96 (s, 2H, vinyl CH_2), δ 1.75 (s, 3H, CH_3), δ 0.19 (s, 9H, $Si(CH_3)_3$); If, bp 58—60 °C/35 mmHg, NMR(CCl_4); δ 3.97(s, 2H, vinyl CH_2), δ 0.19(s, 9H, $Si(CH_3)_3$).

Reaction of α-Trimethylsiloxystyrene (Ia) with Mesityl Oxide (IIa) in the Presence of $TiCl_4$. A solution of $TiCl_4$ (2 mmol) in 8 ml of CH_2Cl_2 was cooled to −78 °C and stirred under an argon atmosphere. A solution of mesityl oxide (IIa, 2 mmol) in CH_2Cl_2 (3 ml) and a solution of α-trimethylsiloxystyrene (Ia, 2 mmol) in CH_2Cl_2 (3 ml) were added successively to the above solution. After stirring for 2 min at −78 °C, the mixture was quenched with aqueous K_2CO_3 (0.7 g in 15 ml of water), and resulting precipitate was filtered off. The filtrate was extracted with ether and the extract was washed with water and brine. After removal of the solvent, 3,3-dimethyl-1-phenyl-1,5-hexanedione (IIIa, 76%) was separated by preparative tlc (silica gel) using hexane–ether 2: 1) as eluent.

Reaction of α-Trimethylsiloxystyrene (Ia) with 2-Cyclohexen-1-one in the Presence of $TiCl_4$ and $Ti(O^iPr)_4$. To a CH_2Cl_2 (4 ml) solution of $TiCl_4$ (1.0 mmol) and $Ti(O^iPr)_4$ (0.4 mmol) [$TiCl_4$ and $Ti(O^iPr)_4$ must be mixed at −78 °C] was added a mixture of α-trimethylsiloxystyrene (Ia, 1.0 mmol) and 2-cyclohexen-1-one (1.0 mmol) in CH_2Cl_2 (6 ml) at −78 °C with stirring under an argon atmosphere. After being stirred for 30 min, the mixture was hydrolyzed with 12 ml of aqueous K_2CO_3 (0.75 g) and extracted with ether. The extract was washed with brine, dried over anhydrous Na_2SO_4 and condensed under reduced pressure. By preparative tlc (silica gel), 3-phenacylcyclohexan-1-one (IIIg) was isolated in 70% yield.

Reaction of α-Trimethylsiloxystyrene (Ia) with Methyl Vinyl Ketone Ethylene Acetal (IVa). To a CH_2Cl_2 (4 ml) solution of $TiCl_4$ (1.0 mmol) and $Ti(O^iPr)_4$ (1.0 mmol) was added a mixture of α-trimethylsiloxystyrene (Ia, 1.0 mmol) and methyl vinyl ketone ethylene acetal (IVa, 1.0 mmol) in CH_2Cl_2 (6 ml) at −78 °C with stirring under an argon atmosphere. After stirring the mixture for 1 h, 1,2-ethanedithiol (1.1 molar amounts) was added to the mixture. After being allowed to stand overnight at room temperature, the mixture was quenched with aq. K_2CO_3 (0.7 g in 15 ml of water) and the resulting precipitate was filtered off. The filtrate was extracted with ether and the extract was washed with water and brine, dried over anhydrous Na_2SO_4. After removal of the solvent δ-keto thioacetal (Va, 78%) was isolated by preparative tlc (silica gel) using hexane–ether (2: 1) as eluent. The structure was also established by hydrolysis in the presence of $CuCl_2$[11] to 1-phenylhexane-1,5-dione.

Reaction of α-Trimethylsiloxystyrene (Ia) with Crotonaldehyde Dimethyl Acetal (IVb). To a mixture of $Ti(OCEt_3)_4$(3 mmol) and crotonaldehyde dimethyl acetal (1 mmol) in CH_2Cl_2 (6 ml) was added $TiCl_4$ (3 mmol) in 2 ml of CH_2Cl_2 under an argon atmosphere. After stirring the mixture for 6 min, α-trimethylsiloxystyrene (Ia, 1 mmol in 3 ml of CH_2Cl_2) was added. The mixture was stirred for 1 h, treated with 3 ml of MeOH at 0 °C for 30 min and worked-up in the usual manner. After separation by preparative TLC (silica gel), 5,5-dimethoxy-3-methyl-1-phenylpentan-1-one (VIa) was isolated in 70% yield. (VIa: NMR(CCl_4): δ 0.98 (d, 3H), δ 3.17 (s, 3H), δ 3.20 (s, 3H), δ 4.41 (t, 1H): IR; 2820, 1685 cm^{-1}).

3,5-Dimethyl-5-oxooctanal (IX). To a mixture of 3 mmol of $Ti(OCEt_3)_4$ and crotonaldehyde dimethyl acetal (1 mmol) in CH_2Cl_2 (6 ml) was added $TiCl_4$ (3 mmol) in 2 ml of CH_2Cl_2 at −78 °C under an argon atmosphere. After stirring the mixture for 6 min 4-methyl-2-trimethylsiloxy-1-pentene (If, 1 mmol in 3 ml CH_2Cl_2) was added. The mixture was stirred for 1 h, followed by hydrolysis with aq. K_2CO_3 (0.75 g in 12 ml of water), and extracted with ether. The extract was washed with brine, dried over anhydrous Na_2SO_4 and condensed under reduced pressure. 3,7-Dimethyl-5-oxooctanal (IX) was isolated in 57% (83% when 2 equimolar amounts of If was employed) by preparative tlc (silica gel) using hexane–ether (2: 1) as eluent. (IX: NMR (CCl_4); δ 9.72 (t, 1H): IR; 2725, 1725, 1715 cm^{-1}).

3,7-Dimethyl-1,5-octanediol (X). To a suspension of $LiAlH_4$ (2.4 mmol) in Et_2O (16 ml) was added a Et_2O (12 ml) solution of 3,7-dimethyl-5-oxooctanal (IX, 1.19 mmol) in 7 min at 0 °C. After stirring the mixture for 1 h at room temperature, saturated aqueous solution of Na_2SO_4 was added into the mixture. The resulted precipitate was washed with THF (5 ml×3) by decantation. The THF-Et_2O solution was dried over anhydrous Na_2SO_4. Distillation under reduced pressure gave 3,7-dimethyl-1,5-octanediol (X, 88%). (X: NMR (CCl_4); δ 4.49 (s (broad), 2H), δ 3.40—4.40 (m, 3H), δ 0.79—2.20 (m, 15H): IR; 3330, 1370, 1380 cm^{-1}).

Dihydro Rose Oxide (VIII). Dehydration of 3,7-dimethyl-1,5-octanediol (X) according to literature[9] method gave a *cis* and *trans* mixture of dihydro rose oxide (VIII), which was identical by glc analysis with the authentic sample prepared by the hydrogenation of a *cis* and *trans* mixture of rose oxide over palladium catalyst.

Reactions of Dihydridotetrakis(tertiary phosphine)ruthenium(II) Complexes with Carbon Dioxide, Carbon Disulfide and Sulfur Dioxide

Sanshiro KOMIYA and Akio YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received November 7, 1975)

Carbon dioxide reacts with $RuH_2(PPh_3)_4$ to give its insertion product, hydridoformatotris(triphenylphosphine)-ruthenium(II). The reversibility of the CO_2 insertion has been demonstrated. Insertion products of carbon disulfide and adducts of sulfur dioxide with ruthenium also have been obtained by the reactions of carbon disulfide and sulfur dioxide with various ruthenium dihydride complexes, RuH_2L_4 (L=PPh_3, PPh_2H, PPh_2Me, $PPhMe_2$). These compounds were characterized by IR and NMR spectroscopy, elemental analysis and chemical reactions.

Since the first reports on the reactions of a hydrido-(dinitrogen)cobalt complex with carbon dioxide to yield a cobalt formate complex[1,2] the reactions of CO_2 with transition metal alkyls and hydrides have been attracting increasing attention.[3] As an extension of our preliminary communication[4] we now report the reactions of tertiary phosphine-coordinated ruthenium dihydride complexes (RuH_2L_4) with carbon dioxide and its analogs, carbon disulfide and sulfur dioxide.

Results and Discussion

Reaction of Dihydridotetrakis(phosphine)ruthenium(II) with Carbon Dioxide. The reaction of $RuH_2(PPh_3)_4$ (I) with carbon dioxide in toluene proceeds readily at room temperature to give a diamagnetic complex $RuH(O_2CH)(PPh_3)_3$(toluene) (II) in a high yield.[a]

$$\underset{\text{(I)}}{RuH_2(PPh_3)_4} + CO_2 \xrightarrow{\text{toluene}} \underset{\text{(II)}}{RuH(O_2CH)(PPh_3)_3(\text{toluene})} + PPh_3$$

Complex II is an air-sensitive yellow solid which is stable in a nitrogen atmosphere but decomposes in air in about 1 day releasing 1 mol of carbon dioxide per ruthenium. The IR spectrum of II is in agreement with its formulation as a hydrido-formato complex. Table 1 tabulates relevant IR absorption bands of the hydridoformato complex II with assignments based on comparison with IR spectra of other known formates, $Rb(O_2CH)$[6] and $Co(O_2CH)(PPh_3)_3$.[1]

The reactions of CO_2 with other phosphine-coordinated complexes of a general formula RuH_2L_4 (L=PPh_2H,[7] PPh_2Me,[8] $PPhMe_2$[9]) also have been examined. However, none of these complexes other than I reacted with CO_2 in toluene even at 110 °C and only starting dihydrido complexes were recovered. Presumably, a predissociation of one of the four phosphine ligands from the coordinatively saturated complexes is required for accommodating a coordination site for the reactant to enter into the reaction. Examination of $^{31}P\{^1H\}$-NMR of RuH_2L_4 complexes in polar solvents such as pyridine revealed that complex I is completely dissociated to $RuH_2(PPh_3)_3$(solvent) and PPh_3 whereas other phosphine-coordinated complexes are not dissociated in the polar solvents.[10] In non-polar solvents the dissociation of PPh_3 from I is much less extensive and the dissociative process may constitute a rate determining step as we previously observed in polymerization of vinyl compounds by PPh_3-coordinated complexes.[11,12]

Acidolysis of II in the solid state with sulfuric acid liberated carbon monoxide and hydrogen in addition to carbon dioxide. Complex II readily loses CO_2 on various chemical treatments. Reaction of II with alkyl halides released carbon dioxide and alkanes and gave a quantitative yield of hydridohalotris(triphenylphosphine)ruthenium.[13]

$$\underset{\text{(II)}}{(HCOO)RuH(PPh_3)_3(\text{toluene})} + RX \longrightarrow HRuX(PPh_3)_3 + RH + CO_2 + \text{toluene}$$

(RX=MeI, EtBr, EtI)

M–H stretch		1996 m	

a) Vol'pin *et al.* first reported the reaction claiming that $Ru(OMe)H(PPh_3)_3 \cdot CO_2$ was obtained.[3a] However, subsequent to our communication[4] the complex was reformulated as $RuH(OOCH)(PPh_3)_3$ and its molecular structure with an octahedral configuration containing the formato group as a bidentate ligand has been established by X-ray analysis.[5]

Complex II is thermally fairly stable, and thermolysis of II takes place in two steps. At *ca.* 140 °C II releases about one mol of CO_2 per II leaving a ruthenium hydride complex having a ν(Ru-H) band at 2080 cm^{-1}. The second decomposition takes place at 200 °C, which is very close to the decomposition point of $RuH_2(PPh_3)_4$, and at the temperature hydrogen and a small amount of carbon monoxide are liberated.

The formate Complex II can be also obtained by reactions of carbon dioxide with $RuH_4(PPh_3)_3$ and $RuH_2(N_2)(PPh_3)_3$.[14,15]

A salient feature of the formate complex is the ready release of carbon dioxide in solution. Bubbling of H_2 and N_2 through benzene solutions containing II displaces readily carbon dioxide giving $RuH_4(PPh_3)_3$ and $RuH_2(N_2)(PPh_3)_3$, respectively. Addition of PPh_3 to the benzene solution containing II also liberated CO_2 giving Complex I.

$$RuH(OOCH)(PPh_3)_3 + H_2 \rightleftarrows RuH_4(PPh_3)_3 + CO_2$$

$$RuH(OOCH)(PPh_3)_3 + N_2 \rightleftarrows RuH_2(N_2)(PPh_3)_3 + CO_2$$

$$RuH(OOCH)(PPh_3)_3 + PPh_3 \rightleftarrows RuH_2(PPh_3)_4 + CO_2$$

(I)

Addition of triphenylphosphite and tributylphosphine to II also led to liberation of CO_2 and toluene. The reversibility of the reactions among $RuH_2(PPh_3)_4$, $RuH_4(PPh_3)_3$ and $RuH_2(N_2)(PPh_3)_3$ have been previously demonstrated.[14,15]

Reaction of RuH_2L_4 with Carbon Disulfide. As extension of the reaction of RuH_2L_4 with carbon dioxide the reaction with its isoelectronic compound toward RuH_2L_4 have been examined. Insertion reactions of CS_2 into transition metal-alkyl bonds are known;[16] several examples of CS_2 insertion into transition metal-hydrogen bond have been reported.[16d,17]

In the interium since we started this line of work the reactions of I and $RuH_4(PPh_3)_3$ with CS_2 to afford $Ru(S_2CH)_2(PPh_3)_2$ have been reported by Harris *et al.*[18] We describe here the reactions of CS_2 with RuH_2L_4 including other phosphine ligands (L=PPh_3, PPh_2H, PPh_2Me, $PPhMe_2$).

In contrast to the reaction of CO_2 with RuH_2L_4, where the CO_2 insertion into only one of the two Ru–H bonds in I was observed, the CS_2 insertion into both of the Ru–H bonds proceeds smoothly at room temperature in all of the RuH_2L_4 type complexes examined to afford bis(dithioformato) type complexes. Negligible amounts of hydrogen were evolved in the reactions. One might observe the formation of HCSSH if one molecule of CS_2 should be inserted into one of the two Ru–H bonds to be followed by abstraction of hydrogen from the remaining Ru–H bond. Examination of the volatile reaction products by NMR excluded the formation of HCSSH in the reaction. This was further supported by failure of the formation of silver dithioformate by treating the volatile matters with silver nitrate.

Table 2 shows yields, physical and chemical properties, and analytical data of the isolated bis(dithioformato) complexes obtained by the reactions of RuH_2L_4 with CS_2.

The thermal stability of the dithioformate complex appears to depend on the phosphine ligand. Less basic ligands such as triphenylphosphine and diphenylphosphine gave more stable complexes than more basic ligands such as diphenylmethylphosphine and phenyldimethylphosphine. Pyrolysis of the dithioformate complex containing triphenylphosphine releases carbon disulfide and triphenylphosphine sulfide. Liberation of CS_2 was observed in the pyrolysis of other phosphine-coordinated complexes and the release of a small amount of hydrogen was noted in the pyrolysis of $Ru(S_2CH)_2(PPh_2H)_4$.

Acidolysis of $Ru(S_2CH)_2(PPh_3)_2$ (III) with concentrated sulfuric acid released CS_2 and SO_2. Hydrogen chloride and methyl iodide did not react with (III) at room temperature.

Table 2 includes IR bands which are not observed in the RuH_2L_4 type complexes. Known dithioformate and dithiobenzoate complexes[16] show ν (CS_2) bands in the range of 900—1100 cm^{-1} whereas CS_2-coordinated complexes and carbon-bonded metal dithio acid type (M-CSSR) complexes have $\nu(CS_2)$ bands at much higher frequencies. Therefore the strong new bands in the range of 900—1100 cm^{-1} may be assigned to $\nu(CS_2)$ bands of the dithio formate group. The dithioformate group can act as a bidentate as well as a monodentate ligand. In $Ru(S_2CH)_2(PPh_3)_2$ the $\nu(CS_2)$ band appears at the lowest frequency among the four dithioformate complexes shown in Table 2. This may well arise from its octahedral configuration having two bidentate

Table 2. Reactions of RuH_2L_4 with CS_2

dithioformate groups. Conversely the strong $\nu(CS_2)$ absorption band at 1016 cm^{-1} in $Ru(S_2CH)_2(PPh_2H)_4$ may be ascribed to the monodentate dithioformate group in the octahedral complex, and the strong bands in $Ru(S_2CH)_2(PPh_2Me)_3$ and $Ru(S_2CH)_2(PPhMe_2)_3$ may be due to the presence of two modes of coordination of the two dithioformate ligands in these complexes. All the dithioformate complexes showed a weak band at 1510 cm^{-1} which disappears on drying them in vacuum for a long period. This band may be due to the presence of an S-bonded CS_2 molecule which has a weak interaction with the ruthenium complex. A similar band has been observed in the IR spectrum of $PtMe(I)(CS_2)(PPh_3)_2$.[16d]

Reaction of RuH_2L_4 with Sulfur Dioxide. We have examined further the reactions of RuH_2L_4 type complexes with sulfur dioxide. The reactions of SO_2 with various organometallic compounds have been recently reviewed.[19] The reactions of SO_2 with $RuH_2(PPh_2H)_4$ and $RuH_2(PPh_2Me)_4$ in toluene gave light yellow complexes without evolution of hydrogen, whereas a considerable amount of hydrogen was evolved in the reactions of SO_2 with $RuH_2(PPh_3)_4$ and $RuH_2(PPhMe_2)_4$. We tentatively formulate the sulfinate structures $Ru(SO_2H)(PPh_2H)_3$ and $Ru(SO_2H)(PPh_2Me)_3$ for the products obtained without evolution of hydrogen and SO_2-coordinated structures $Ru(SO_2)_2(PPh_3)_2$ and $Ru(SO_2)(PPhMe_2)_3$ for those obtained with evolution of hydrogen. The latter complexes liberated only SO_2 on acidolysis and pyrolysis whereas the PPh_2H-coordinated complex released H_2 in addition to SO_2 on pyrolysis. No infrared band due to ν(Ru–H) was observed in these complexes. The complexes which may have the sulfinate structure showed a broad NMR signal in the region of δ 5. Formulation of the reaction product of $RuH_2(PPh_3)_4$ with SO_2 as $Ru(SO_2)_2(PPh_3)_2$ has been previously proposed by Eliades *et al.*[18a]

Experimental

All the reactions were carried out under nitrogen or in a vacuum. Infrared spectra were recorded as KBr disks on a Hitachi model EPI-G3 spectrometer. NMR spectra were measured on JNM-PS-100 and JNM-MH-60. Elemental analyses were performed with Yanagimoto CHN Autocorder Type MT2. Gas chromatograms were recorded by using Shimadzu type GC-5A. Solvents were purified by usual methods under nitrogen. Carbon dioxide gas was dried by passing it through a $CaCl_2$ column and carbon disulfide was dried with CaH_2. Sulfur dioxide was obtained on reaction of Cu with concd H_2SO_4 and dried by passing through a concd H_2SO_4 bubbler. RuH_2L_4 (L=PPh_3,[18] PPh_2H,[7] PPh_2Me,[8] and $PPhMe_2$[9]) were synthesized by the methods previously reported.

Hydrido(formato)tris(triphenylphosphine)(toluene)ruthenium(II) (II), $RuH(O_2CH)(PPh_3)_3$(toluene). When carbon dioxide was brought in contact with or bubbled into the toluene solution of I at room temperature, a yellow precipitate was formed in about 1 day. The precipitate was washed with hexane a few times and dried in a vacuum; yield, *ca.* 80%. Anal. Calcd for $RuH(O_2CH)(PPh_3)_3$(toluene): C, 72.6; H, 5.4%. Found: C, 72.8; H, 5.2%.

Attempts of recrystallization led only to decomposition of the formate complex with liberation of CO_2. Reactions of $RuH_2(N_2)(PPh_3)_3$ or $RuH_4(PPh_3)_3$ with carbon dioxide gave the same product.

Reaction of $RuH(O_2CH)(PPh_3)_3$(toluene) (II). i) Acidolysis. Acidolysis of II (159.0 mg, 0.155 mmol) by *ca.* 5 ml of concd sulfuric acid released carbon monoxide (0.08 mmol) and hydrogen (0.03 mmol) at room temperature.

ii) Reaction of II with Alkyl Halide. The reaction of II (162.6 mg, 0.158 mmol) with methyl iodide (*ca.* 2 ml) gave methane (0.15 mmol) and carbon dioxide (0.13 mmol). The resultant complex is considered to be hydridoiodotris(triphenylphosphine)ruthenium $RuHI(PPh_3)_3$ on the basis of IR spectrum showing a ruthenium-hydrogen stretching band at 2020 cm^{-1}. Because a quaternary salt of triphenylphosphine with methyl iodide was also produced in this reaction, the complete purification was not feasible, but in case of the reaction of II with ethyl bromide $RuHBr(PPh_3)_3$ was isolated. Pyrolysis of II (148.5 mg, 0.145 mmol) liberated carbon dioxide (0.15 mmol) at *ca.* 200 °C. Formation of a small amount of benzene was observed.

iv) Reaction of II with Triphenylphosphite. When complex (II) (625.7 mg, 0.610 mmol) was treated with triphenylphosphite (*ca.* 2 ml), toluene was released as identified by gas chromatography in a yield of 52 mg (0.56 mmol, 93%). Hydrogen and carbon dioxide were also evolved. By the reaction of II with tributylphosphine CO_2 and toluene were released.

v) Reaction of II with Hydrogen, Nitrogen and Triphenylphosphine. An excess of hydrogen was brought in contact with a benzene solution of II to precipitate white needles in a few hours. Carbon dioxide was detected in the gas phase. The white needles were washed with hexane a few times and dried in a vacuum, dec. pt. 135°; ν(Ru–H) 1950 cm^{-1}.[14] No particular attempt was made for purification of the complex by recrystallization, but the analytical value was close to that of $RuH_4(PPh_3)_3$. Found: C, 71.8; H, 5.2%. Calcd for $RuH_4(PPh_3)_3$: C, 72.8; H, 5.5%.

Bubbling of nitrogen into the heterogeneous solution of II gave $RuH_2(N_2)(PPh_3)_3$ with the liberation of CO_2; the formation of the dinitrogen complex was confirmed on the basis of its IR spectrum with a $\nu(N_2)$ band at 2143 cm^{-1}. Addition of excess triphenylphosphine into the benzene solution of II liberated carbon dioxide at room temperature forming $RuH_2(PPh_3)_4$. The formation of $RuH_2(PPh_3)_4$ was confirmed by its infrared spectrum with a ν(Ru–H) band at 2080 cm^{-1}.

Reactions of RuH_2L_4 with Carbon Disulfide. The reactions of CS_2 with RuH_2L_4 type complexes were carried out in a similar manner. Excess CS_2 was introduced by a trap-to-trap distillation method to a flask containing RuH_2L_4. The suspension became homogeneous in an hour at room temperature and a yellow or red precipitate was deposited which was washed with hexane a few times and dried *in vacuo* (yield 50—80%). No detectable amount of gas was evolved in the reaction. The product was recrystallized from dichloromethane and ether, or from toluene except for $Ru(S_2CH)_2(PPh_3)_2$ which reacted with dichloromethane.

Pyrolysis of $Ru(S_2CH)_2(PPh_3)_2$ (0.1954 g, 0.251 mmol) at 200 °C liberated carbon disulfide (0.023 mmol, 9%) and triphenylphosphine sulfide. The carbon disulfide was identified by IR and mass spectroscopy and gas chromatography. Triphenylphosphine sulfide was identified on the basis of IR spectrum, ν(P=S) 1105 cm^{-1}, and elemental analysis (Calcd for $C_{18}H_{15}PS$: S, 10.9%; Found: S, 10.8%).

Reactions of RuH_2L_4 with SO_2. The reactions of SO_2 with RuH_2L_4 type complexes were performed by allowing SO_2 gas to contact with toluene solutions containing the hydrido complexes at room temperature. In the reactions of RuH_2-

$(PPh_3)_4$ and $RuH_2(PPhMe_2)_4$ hydrogen evolution (30—40%) was observed. The precipitate was washed with hexane and dried *in vacuo*, and recrystallized from dichloromethane and ether.

$Ru(SO_2)_2(PPh_3)_2$, mp (dec.) 243—251 °C; new IR (KBr disc) peaks not present in $RuH_2(PPh_3)_4$: 1270 (s), 1138 (s), 650 (w), 570 cm^{-1} (w). Found: C, 57.2; H, 4.3; S. 7.4%. Calcd for $Ru(SO_2)_2(PPh_3)_2$: C, 57.4; H, 4.0; S, 7.4%.

$Ru(SO_2)(PPhMe_2)_3$ (tentative formula), mp (dec.) 270—280 °C; new IR (KBr disc) peaks not present in $RuH_2(PPhMe_2)_4$: 1210 (s), 1140 (s), 1010 (m), 652 (m), 610 (w), 455 cm^{-1} (w). Considerable difficulty was encountered in purification due to the formation of $PPhMe_2$–SO_2 adduct. Found: C, 45.7; H, 5.5; S, 5.1%. Calcd for $Ru(SO_2)(PPhMe_2)_3$: C, 49.7; H, 5.7; S. 5.5%.

$Ru(SO_2H)(PPh_2Me)_3$ (tentative formula), mp (dec.) 212—215 °C; IR (KBr disc) not present in $RuH_2(PPh_2Me)_4$: 1260 (m), 1138 (s), 1122 (s), 640 (m), 565 cm^{-1} (w). Found: C, 56.0; H, 4.8; S, 6.8%. Calcd for $Ru(SO_2H)_2(PPh_2Me)_3$: C, 56.3; H, 5.0; S, 7.7%.

$Ru(SO_2H)_2(PPh_2H)_3$ (tentative formula), mp, 146 °C; dec. 226 °C; new IR (KBr) peaks not present in $RuH_2(PPh_2H)_4$: 1238 (m), 1130 (s), 650 (m), 545 cm^{-1} (sh). Found: S, 8.0%. Calcd for $Ru(SO_2H)_2(PPh_2H)_3$: S, 8.1%.

Branched-chain Sugars V. Stereoselective Synthesis of 3-*C*- and 5-*C*-Methyl-D-glucoses, and 5-*C*-Methyl-L-idose Derivatives[1]

Masuo FUNABASHI, Haruo SATO, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received November 18, 1975)

The title compounds were prepared stereoselectively from 1,2: 5,6-di-*O*-isopropylidene-3-*C*-methylene-α-D-*ribo*-hexofuranose (**1**) and 3-*O*-benzyl-1,2-*O*-isopropylidene-5-*C*-methylene-6-*O*-trityl-α-D-*xylo*-hexofuranose (**5b**) by the successive epoxidation and reduction, and from 3-*O*-benzyl-1,2-*O*-isopropylidene-6-*O*-trityl-α-D-*xylo*-hexofuranos-5-ulose (**5a**) by the Grignard reaction, respectively.

The high stereoselectivity of nucleophilic reaction to 2-,[2] 3-,[3] 4-,[4] and 5-[5] keto-sugars has generally been recognized in the synthesis of branched-chain sugars, and as a matter of fact, most of such stereoselectivities (sometimes stereospecificities) have been interpreted in terms of the intrinsic conformational and configurational characters of each keto-sugars.

If this is the case applicable to addition reactions to 2-, 3-, 4-, and 5-*C*-methylene-sugars, which could be obtained from the corresponding uloses by the Wittig reaction, the reversal of the configuration by the similar stereochemical process would be possible to give the desired diastereomeric *C*-substituted sugars not accessible in the conventional manner.

The present paper, therefore, describes the model system applying the above idea to a couple of compounds such as 1,2: 5,6-di-*O*-isopropylidene-3-*C*-methylene-α-D-*ribo*-hexofuranose (**1**)[6] and 3-*O*-benzyl-1,2-*O*-isopropylidene-5-*C*-methylene-6-*O*-trityl-α-D-*xylo*-hexofuranose (**5b**) in order to obtain 3-*C*-methyl-D-glucose and 5-*C*-methyl-L-idose derivatives. A part of which was reported in the preliminary communication.[7]

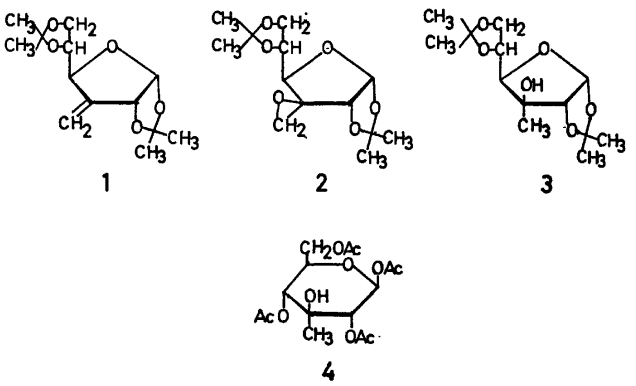
Results and Discussions

The principle of this experiment is to apply epoxidation followed by reduction to compounds **1** and **5b** to get 3-*C*-methyl-D-glucose and 5-*C*-methyl-L-idose derivatives stereoselectively, and we selected as references 1,2: 5,6-di-*O*-isopropylidene-3-*C*-methyl-α-D-allofuranose[8] and newly prepared 3-*O*-benzyl-1,2-isopropylidene-5-*C*-methyl-6-*O*-trityl-α-D-glucofuranose (**7b**) in order to confirm the reversal of the configuration at the branched carbon.

The preparation of 1,2: 5,6-di-*O*-isopropylidene-3-*C*-methyl-α-D-gluco-furanose (**3**) was done in a following way. 3-*C*-Methylene derivative (**1**) obtained from 1,2: 5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose[9] by a modified procedure using butyllithium in tetrahydrofuran in place of sodium amide–liquid ammonia[6a] or sodium hydride–dimethyl sulfoxide[6b] was oxidized with *m*-chloroperbenzoic acid in 1,2-dichloroethane at room temperature to D-*gluco*-epoxide (**2**) in an excellent yield. Compound **2** was also isolated from reaction between **1** and diazomethane in *ca.* 20% yield.[3c] NMR spectrum showed the typical terminal epoxide-methylene protons at δ 3.08 as AB quartet (J=5.0 Hz). The epoxide was then reduced with lithium aluminum hydride in ether to yield a crystalline 1,2; 5,6-*di*-*O*-isopropylidene-3-*C*-methyl-α-D-glucofuranose (**3**) in 85% yield.

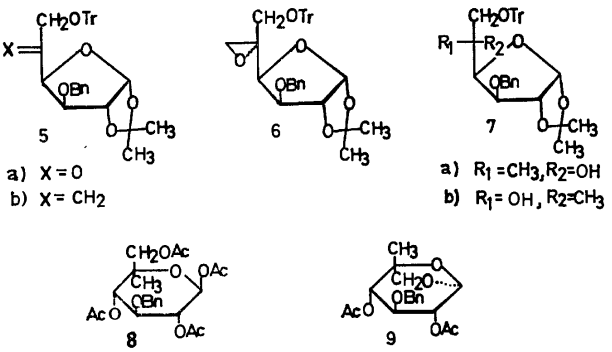
Compound **3** was completely differentiated from the corresponding D-allose isomer.

Removal of isopropylidene group of **3**, followed by acetylation gave 1,3,4,6-tetra-*O*-acetyl-3-*C*-methyl-β-D-glucopyranose (**4**) as a major product.



Scheme 1.

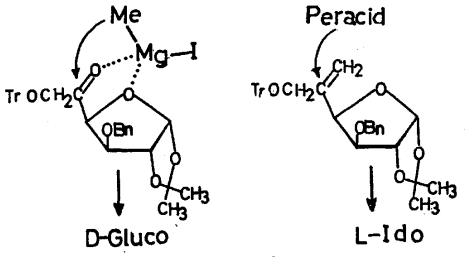
The same techniques were also applied to the compound **5b**, which was newly prepared from 3-*O*-benzyl-1,2-*O*-isopropylidene-5-*O*-trityl-α-D-*xylo*-hexofuranos-5-ulose (**5a**) and methylenetriphenylphosphorane in tetrahydrofuran in 80% yield. **5b** was then oxidized in the same way as in the case of the compound **1** in 1,2-dichloroethane to a mixture of epoxide (**6**: L-*ido* and D-*gluco*), quantitatively. Reduction of **6** with lithium aluminum hydride in ether gave 5-*C*-methyl-hexofuranose derivatives (**7a** and **7b**). The ratio of **7a** to **7b** was estimated to be *ca.* 2: 1 by comparing the intensity of



Scheme 2.

H-6 and H-6′ protons of both compounds in NMR spectrum.

On the other hand, the reference compound, 3-*O*-benzyl-1,2-*O*-isopropylidene-5-*C*-methyl-6-*O*-trityl-α-D-glucofuranose (**7b**) was exclucively prepared by reacting **5a** with an excess amount of methylmagnesium iodide in ether. This stereospecificity must be explained if such a cyclic intermediate (scheme 3) could be possible; the attack of methyl group should take place from the less-hindered site opposite to benzyl group at C-3 to give only D-gluco configuration as was suggested in the case of 3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-xylohexofuranos-5-ulose with phenylmagnesium bromide.[5] The situation would be almost same in the epoxidation of **5b** since the attack by peracid could preferentially from the less-hindered site mentioned above to give L-*ido* configuration predominantly if bulkier trityloxymethyl group situated rather rigidly.



Scheme 3.

As a matter of fact, the configuration of both compounds (**7a** and **7b**) was unambiguously established in the following way. When the compounds **7a** and **7b** were hydrolyzed in hot acetic acid (70%) and followed by acetylation with acetic anhydride in pyridine, 2,4-di-*O*-acetyl-1,6-anhydro-3-*O*-benzyl-5-*C*-methyl-β-L-idopyranose (**9**) from **7a** and 1,2,4,6-tetra-*O*-acetyl-3-*O*-benzyl-5-*C*-methyl-β-D-glucopyranose (**8**) from **7b** were isolated respectively in good yields.

The structure of both compounds (**8** and **9**) was easily established by NMR (see experimental section), comparing the intensity between acetoxy methyl and methyl signals, $J_{1,2}$ (**8**; 7.5 Hz, **9**; 1.5 Hz) and by elemental analysis. It may be noted that similar intramolecular condensation occurrs in a solvolytic process of 3-*O*-benzyl-1,2-*O*-isopropylidene-β-L-idofuranose[10] to yield 1,6-anhydro-3-*O*-benzyl-β-L-idopyranose.

Experimental

Melting points were determined on a Yanagimoto micro-melting point apparatus and uncorrected. NMR spectra were measured with JNM-4H-100 spectrometer in chloroform-*d* using tetramethylsilane as the internal reference. Specific rotations were measured in a 0.5-dm tube with a Carl Zeis photoelectric polarimeter. IR spectra were taken with a Hitachi Model EPI-G2 spectrophotometer. Tlc and preparative tlc was effected on a silica-gel (Merk type 60) plate using solvent systems such as (A) benzene/methanol (25/3), (B) benzene/ether (10/1), (C) benzene/ethyl acetate (8/1), and (D) benzene/ethyl acetate (1/1) respectively by detecting compounds with iodine vapor or with 5% methanolic sulfuric acid spray followed by heating on a hot plate.

1,2: 5,6-Di-O-isopropylidene-3-C-methylene-α-D-ribo-hexofuranose (1b). To an ice-cooled suspension of methyltriphenylphosphonium bromide (25 g, 0.07 mol) in dry THF (150 ml) was added a solution of butyllithium in hexane (15%, w/v, 35 ml) with stirring under a nitrogen atmosphere. A solution of 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1a**) (10 g, 0.04 mol) in THF (50 ml) was then gradually added to the above yellow suspension with keeping cold in an ice-water bath. The stirring was continued for 10 min and the precipitate was filtered off. The filtrate and ether washings were concentrated *in vacuo* to a crude syrup, which was further chromatographed on silica gel column (Wakogel C-200, 150 g), and eluted with ether. Concentration of ether elutes gave a clear oil (6.5 g) pure enough for the next step. A part of which was further purified by preparative tlc, $[\alpha]_D^{22}$ 93° (*c* 2.0, $CHCl_3$) [lit,[5a]); $[\alpha]_D^{23}$ +104° (c, 2, $CHCl_3$), lit,[5b]); $[\alpha]_D^{23}$ +75° (*c* 1.0, $CHCl_3$)] NMR; 1.34, 1.40, 1.43 (6-H, 3-H, 3-H, s, isopropyl methyl), 4.0 (3-H, m, H_5, H_6, H_6'), 4.60 (1-H, m, H_4), 4.89 (1-H, m, H_2), 5.06 (2-H, m, exomethylene), 5.80 ppm. (1-H, d, H_1, $J_{1,2}$=3.8 Hz). (Found: C, 61.12; H, 7.65%)

1,2: 5,6-Di-O-isopropylidene-3-C-hydroxymethyl-3,3′-anhydro-α-D-glucofuranose (2). A solution of **1** (3.5 g, 0.014 mol) and *m*-chloroperbenzoic acid (3.5 g, 85% purity) in dry 1,2-dichloroethane (40 ml) was stirred at room temperature for 18 h. The precipitate was filtered off, and the filtrate was concentrated *in vacuo* to a syrup, which was redissolved in hexane or ether, washed with aqueous sodium hydrogen carbonate and water, dried over anhydrous magnesium sulfate, and concentrated to a clear syrup (3.2 g), $[\alpha]_D^{23}$ +55° (*c* 1.7, methanol). NMR; 1.31, 1.38, 1.54 (3-H, 6-H, 3-H, s, isopropyl methyl), 3.08 (1-H, q, J=5.0 Hz, epoxymethylene), 4.0 (3-H, m, H_5, H_6, H_6'), 4.25 (1-H, d, H_2, $J_{1,2}$=3.8 Hz), 4.3 (1-H, m, H_4), 5.92 ppm. (1-H, d, H_1).

Found: C, 57.26; H, 7.37%. Calcd for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

1,2: 5,6-Di-O-isopropylidene-3-C-methyl-α-D-glucofuranose (3). A mixture of **2** (0.17 g, 0.63 mmol) and lithium aluminium hydride (30 mg) in dry ether (5 ml) was allowed to stand at room temperature for 10 min and refluxed for 30 min. After usual work-up, the filtrate was extracted with ether (10 ml×3), washed with aqueous sodium chloride, dried over anhydrous magnesium sulfate, and concentrated *in vacuo* to a crystalline residue (0.14 g), which was recrystallized from hexane; mp 66—67 °C, $[\alpha]_D^{23}$ +23 °C (*c* 1.0, acetone). NMR; 1.30, 1.34, 1.42, 1.44, 1.50 (3-H×5, CH_3 at C-3 and isopropyl), 2.48 (1-H, broad, OH), 3.75—4.38 (5-H, m, H_2, H_4, H_5, H_6, H_6'), 5.86 ppm. (1-H, d, H_1, $J_{1,2}$=3.7 Hz). Found: C, 56.67; H, 7.99%. Calcd for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08%.

1,2,4,6-Tetra-O-acetyl-3-C-methyl-β-D-glucopyranose (4a). A solution of **3a** (155 mg) in 70% acetic acid (6 ml) was heated at 95 °C for 2 h, and concentrated *in vacuo* to a dry syrup, which was then treated with acetic anhydride (2 ml) and pyridine (3 ml) for 3 h. The crude syrup (180 mg) obtained by the usual work-up was subjected to a preparative tlc (solvent D) to give an amorphous powder (120 mg), $[\alpha]_D^{22}$ −23 °C (*c* 2.34, $CHCl_3$). NMR; 1.29 (3-H, CH_3 at C_3), 2.05, 2.08, 2.09, 2.11 (3-H×4, acetyl), 3.01 (1-H, broad, OH), 3.80 (1-H, o, H_5, $J_{5,6}$=5.0, $J_{5,6'}$=2.5 Hz), 4.10 (1-H, H_6, q, $J_{6,6'}$=12.5 Hz), 4.30 (1-H, q, H_6), 5.03 (1-H, d, H_2, $J_{1,2}$=8.5 Hz), 5.05 (1-H, d, H_4), 5.68 ppm (1-H, d, H_1).

Found: C, 49.43; H, 6.09%. Calcd for $C_{15}H_{22}O_{10}$: C, 49.72; H, 6.12%.

3-O-Benzyl-1,2-O-isopropylidene-5-C-methylene-6-O-trityl-α-D-xylohexofuranose (5b). A solution of **5a** (0.5 g, 1.1 mmol) in dry THF (5 ml) was added to a yellow solution of methylenetriphenylphosphorane prepared from methyltriphenyl-

phosphonium bromide (0.7 g, 2.2 mmol) and butyllithium (15% w/v, 1 ml) in dry THF (10 ml). The stirring was continued at room temperature for 30 min. The precipitate was filtered off and filtrate and ether washings were concentrated *in vacuo* to a crude syrup, which was further subjected to preparative tlc (solvent B) to give a crystalline residue. Recrystallization from ethanol gave fine crystals having mp 113—114 °C, $[\alpha]_D^{23}$ −33 °C (*c* 1.0, $CHCl_3$). NMR: 1.28, 1.48 (3-H×2, isopropylidene), 3.48—3.81 (3-H, m, H_6 and $H_{6'}$), 4.25 (2-H, q, J_{AB}=12.0 Hz, benzyl methylene), 4.50 ppm (1-H, d, $J_{1,2}$=3.8 Hz).

Found: C, 78.91; H, 6.69%. Calcd for $C_{36}H_{36}O_5$; C, 78.80; H, 6.61%.

Oxidation of ***5b*** *with* m-*Chloroperbenzoic Acid.* A solution of **5b** (0.55 g, 1 mmol) and *m*-chloroperbenzoic acid (0.31 g, 1.8 mmol) in dry 1,2-dichloroethane (10 ml) was allowed to stand at room temperature for 24 h. After filtration of the precipitate, the filtrate was washed with dilute sodium hydroxide solution (0.7%, 10 ml) and water, dried over anhydrous magnessium sulfate and concentrated *in vacuo* to a crystalline residue, which was recrystallized from ethanol to give a mixture of 3-*O*-benzyl-1,2-*O*-isopropylidene-5-*C*-hydroxymethyl-5,6′-anhydro-6-*O*-trityl-α-D-gluco- and β-L-idofuranose, mp 179—180 °C, $[\alpha]_D^{23}$ −22.4 °C (*c* 1.0, $CHCl_3$).

Found: C, 76.32; H, 6.45%. Calcd for $C_{36}H_{36}O_6$: C, 76.57; H, 6.43%.

3-O-Benzyl-1,2-O-isopropylidene-5-C-methyl-6-O-trityl-β-L-idofuranose (7a). A mixture of **6** (0.41 g, 0.73 mmol) and lithium aluminum hydride (30 mg) was refluxed in dry THF (5 ml) for 2 h. After the usual work-up, the filtrate was extracted with ether, washed with aqueous sodium chloride, dried over anhydrous magnesium sulfate, and concentrated to a crystalline residue, which was subjected to a preparative tlc (solvent B) to give prismatic crystals (0.2 g) having mp 150—151 °C, $[\alpha]_D^{23}$ −54 °C (*c* 1.37, acetone). NMR: 1.20, 1.34, 1.50 (3-H×3, CH_3 at C-5 and isopropyl methyl), 2.75, 3.45 (1-H ×2, H_6, $H_{6'}$, $J_{6,6'}$=8.7 Hz), 3.64 (1-H, s, OH), 4.15 (1-H, d, H_3, $J_{3,4}$=3.0 Hz), 5.40, 4.60 (1-H×2, dd, benzyl methylene), 4.54 (1-H, d, H_4), 4.60 (1-H, d, H_2, $J_{1,2}$=3.8 Hz), 6.03 ppm (1-H, d, H_1).

Found: C, 76.25; H, 6.88%. Calcd for $C_{36}H_{38}O_6$: C, 76.30; H, 6.76%.

3-O-Benzyl-1,2-O-isopropylidene-5-C-methyl-6-O-trityl-α-D-glucofuranose (7b). A solution of **5a** (0.5 g, 0.9 mmol) in dry tetrahydrofuran (5 ml) was gradually added to a solution of methylmagnessium iodide prepared from magnesium (0.245 g, 10 mmol) and methyl iodide (2 ml, 17 mmol) in dry ether (10 ml). The reaction mixture was then refluxed for 30 min, poured into ice-water containing ammonium chloride (0.535 g, 10 mmol), extracted with ether (20 ml×2), washed with aqueous sodium chloride, dried over anhydrous magnesium sulfate, evaporated to a crystalline residue, which was recrystallized from ethanol, mp 182—183 °C, $[\alpha]_D^{23}$ −5.7 °C (*c* 1.0, $CHCl_3$). NMR: 1.28, 1.52, 1.55 (3-H×3, s, CH_3 at C-5 and isopropyl methyl), 2.93, 3.32 (1-H×2, d, H_6, $H_{6'}$, $J_{6,6'}$=8.5 Hz), 3.05 (1-H, d, H_3, $J_{3,4}$=3.3 Hz), 3.65, 4.20 (1-H×2, d, $C\underline{H}_2Ph$), 4.38 (1-H, d, H_4), 4.43 (1-H, d, H_2, $J_{1,2}$=4.0 Hz), 5.99 ppm (1-H, d, H_1).

Found: C, 76.49; H, 6.65%. Calcd for $C_{36}H_{38}O_6$: C, 76.30; H, 6.76%.

1,2,4,6-Tetra-O-acetyl-3-O-benzyl-5-C-methyl-β-D-gluco-pyranose (8). A suspension of **7b** (300 mg) in 70% acetic acid (10 ml) was refluxed for 2 h, and concentrated *in vacuo* to a syrup, which was then allowed to stand at room temperature in a mixture of acetic anhydride (2 ml) and pyridine (5 ml) for 8 h. The reaction solution was then treated with ice-water containing sodium hydrogen carbonate, extracted with chloroform, washed with aqueous sodium chloride and water, and dried over anhydrous magnesium sulfate. Concentration of the solvent gave fine needles, which was recrystalized from hexane; mp 128—129 °C (100 mg), $[\alpha]_D^{23}$ −18 °C (*c* 1.08, acetone). NMR: 1.34 (3-H, s, CH_3 at C-5), 1.85, 1.97, 2.08 (3-H×2, 3-H×2, s, acetyl methyl), 3.85 (1-H×2, d, H_6, $H_{6'}$, $J_{6,6'}$=12.0 Hz), 4.61 (2-H, s, $C\underline{H}_2Ph$), 5.14 (1-H, q, H_2, $J_{1,2}$=7.5 Hz), 5.33 (1-H, d, H_4), 5.89 ppm (1-H, d, H_1).

Found: C, 58.48; H, 6.26%. Calcd for $C_{22}H_{28}O_{10}$: C, 58.40; H, 6.24%.

1,6-Anhydro-2,4-di-O-acetyl-3-O-benzyl-5-C-methyl-β-L-idopyranose (9). A suspension of **7a** (200 mg) was treated as described above. Fine needles from hexane; mp 118—119 °C, $[\alpha]_D^{23}$ +67 °C (*c* 1.0, acetone). NMR: 1.30 (3-H, s, CH_3 at C-5), 1.98, 2.02 (3-H×2, s, acetyl methyl), 3.35 (1-H, q, $H_{6'}$, $J_{6,6'}$=8.7, $J_{1,6'}$=1.5 Hz), 3.83 (1-H, q, H_3, $J_{2,3}$=7.5, $J_{3,4}$=8.7 Hz), 4.08 (1-H, d, H_6), 4.60 (2-H, s, $C\underline{H}_2Ph$), 4.86 (1-H, q, H_2, $J_{1,2}$=1.5 Hz), 5.13 (1-H, q, H_4, $J_{4,6'}$=1.0 Hz), 5.42 ppm (1-H, H_1).

Found: C, 61.63; H, 6.24%. Calcd for $C_{18}H_{22}O_7$: C, 61.70; H, 6.33%.

Photochemical Reaction of 9,10-Phenanthrenequinone with Hydrogen Donors.[1] Behavior of Radicals in Solution as Studied by CIDNP

Kazuhiro MARUYAMA, Tetsuo OTSUKI, and Yoshinori NARUTA

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received July 15, 1975)

Behavior of radicals produced in the photochemical reaction of 9,10-phenanthrenequinone was investigated by use of CIDNP and ESR technique. By comparison of the sign of CIDNP signals in formation of and in decomposition (photochemical or thermal) of adducts, the rearrangement of adducts, *e.g.*, from the 1,2-adduct to 1,4-adduct and *vice versa*, was proposed. Although the adducts are stable enough to isolate in general, they decomposed photochemically or thermally to give the mixture of 9,10-phenanthrenediol (or its quinhydrone), the dehydrogenated dimer of hydrogen donor, and others as minor product.

Photochemical reactions of 9,10-phenanthrenequinone with hydrogen donors were reinvestigated by means of CIDNP technique.[2] Although the results are rather qualitative, investigation by means of CIDNP technique is quite informative for study of the radical reaction mechanism.

Results and Discussion

The photochemical reaction of 9,10-phenanthrenequinone with hydrogen donors in preparative scale can be classified in the following three types on the basis of the resulting major products. The inspection of the CIDNP spectra, however, reveals that the formation of both 1,2- and 1,4-photoadducts is essential but their stabilities are dependent on the nature of hydrogen donors, solvents used, and reaction temperature. Polarized PMR signals of the protons indicated by Gothic letter were the indices of formations of 1,2- and 1,4-photoadducts. The assignments of polarized signals were straightforward by comparison of the chemical shifts with those of isolated products, and the results

Photochemical Reaction of 9,10-phenanthrenequinone with Hydrogen Donors at 15—20°C.

"1,4-adduct"
ν_{OH}: 3380 cm^{-1}
$\nu_{C=O}$: 1730 cm^{-1} (ester)

could be substantiated by reaction of 9,10-phenanthrenequinone with the corresponding deuterated hydrogen donors.

According to the accepted simple rule for the polarized signal by Kaptein,[3] the absorption polarized signal of methine proton of xanthyl moiety (or methine proton of diphenylmethyl moiety) due to the 1,2-photoadduct (Fig. 1) is reasonable (see Eq. (1)). By the same reason the emission polarized signal due to methyl protons of acetyl moiety of 1,2-adduct (Fig. 2) is con-

$$PQ \xrightarrow{h\nu} PQ^T \xrightarrow{RH} \overline{PQH\cdot\ \cdot R}^T \longrightarrow 1,2\text{-photoadduct} \quad (1)$$

PQ: 9,10-phenanthrenequinone
RH: hydrogen donor
$\overline{PQH\cdot\ \cdot R}^T$: radical pair derived from triplet precursor

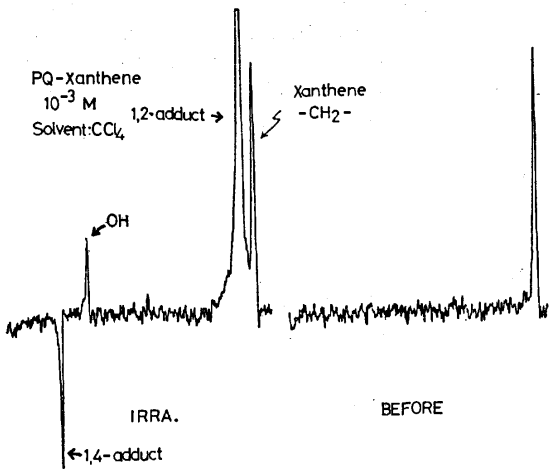

Fig. 1. Polarized PMR spectra observed in the course of the photochemical reaction of PQ with xanthene (Solvent: CCl_4 at room temperature).

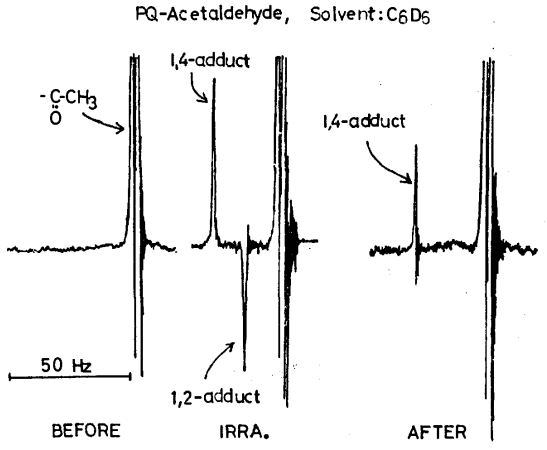

Fig. 2. Polarized PMR spectra observed in the course of the photochemical reaction of PQ with acetaldehyde (Solvent: C_6D_6 at room temperature).

vincible according to the following considerations.

$$\Gamma = \Delta g \varepsilon \mu \alpha \quad (2)$$

if $\Gamma = +$, then absorption polarized signal,
$\Gamma = -$, then emission polarized signal

These parameters have their usual meaning.[3] In the case of the reaction of 9,10-phenanthrenequinone with alkyl aromatics, $\Delta g = -$,[4] $\varepsilon = +$, $\mu = +$, and $\alpha = -$[5] are to be considered on the basis of the preceding reaction mechanism for methine-H and then, $\Gamma = -++-=+$, that is, the absorption polarized signal is expected.

In the case of the reaction of 9,10-phenanthrenequinone with acetaldehyde, for acetyl-H $\Gamma = -+++=-$, then the emission polarized signal is expected. However, the reversely polarized signals due to 1,4-photoadducts compared to those of 1,2-adducts are hard to be explained by the simple route given in Eq. (1) (see Figs. 1 and 2). Since the radical components of the pair for 1,2- and 1,4-adducts are the same, Δg, ε, and α for the formation of 1,4-adducts have the same sign for those of 1,2-adduct. If we postulate the preceding formation of a radical pair which may result from vibrationally excited but singlet molecule of 1,2-adduct in advance of the formation of 1,4-adduct, all of the observed polarized signals for 1,4-adducts may be explicable, because the sign of μ is to be reverse. Further, we can explain the polarized signals due to methine-H of 1,2- and 1,4-adducts (Fig. 3) observed during the course of photochemical reaction of 9,10-phenanthrenequinone with dibenzyl ether (in general, with ethers) taking into consideration of the similar concept described above.

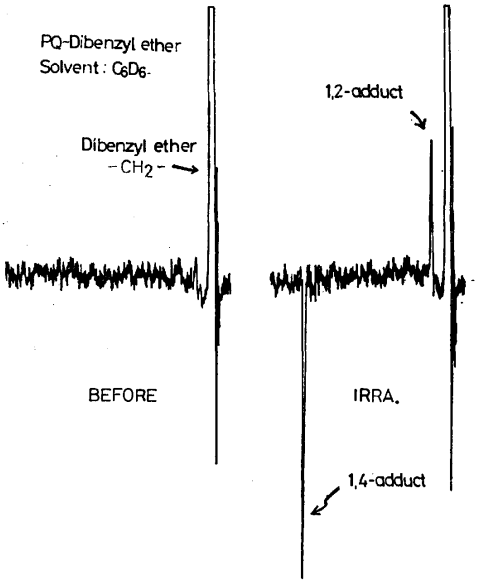

Fig. 3. Polarized PMR spectra observed in the course of the photochemical reaction of PQ with dibenzyl ether (Solvent: C_6D_6 at room temperature).

In fact, the concept was confirmed experimentally. Thermal and/or photo-induced decomposition of the purely isolated 1,2-adducts in suitable solvents was inspected by means of CIDNP. When at slightly elevated temperature (32 °C) isolated pure 1,2-adduct from 9,10-phenanthrenequinone (PQ) and an alkyl aromatic (PQ–*p*-xylene, PQ–*m*-xylene, PQ–*o*-xylene, PQ–mesitylene, PQ–diphenylmethane and PQ–xanthene system), was activated in carbon tetrachloride or benzene-d_6 by light of high pressure mercury arc lamp, two polarized signals due to methine or methylene proton corresponding to 1,2-(absorption in region of δ: 4.0) and 1,4-adducts (emission in region of δ: 6.0) are observed. Although the 1,4-adduct thus derived is too unstable to be isolated in this condition, this is the unambiguous evidence for the rearrangement from 1,2-adduct to 1,4-adduct *via* the radical pair derived from singlet precursor (Fig. 4). ESR inspection of the decomposing system at the same condition in the region of *g*-value=2.00 reveals the presence of no appreciable

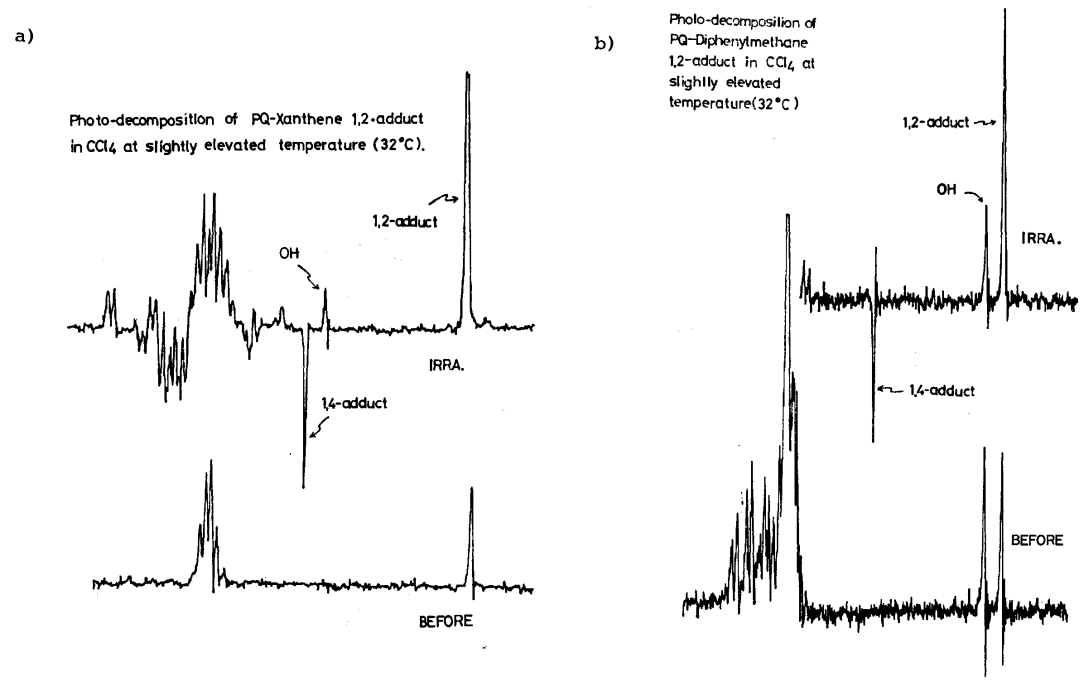

Fig. 4. Polarized PMR spectra observed in the course of the photodecomposition of a) PQ–xanthene 1,2-adduct, b) PQ–diphenylmethane 1,2-adduct (Solvent: CCl_4 32 °C).

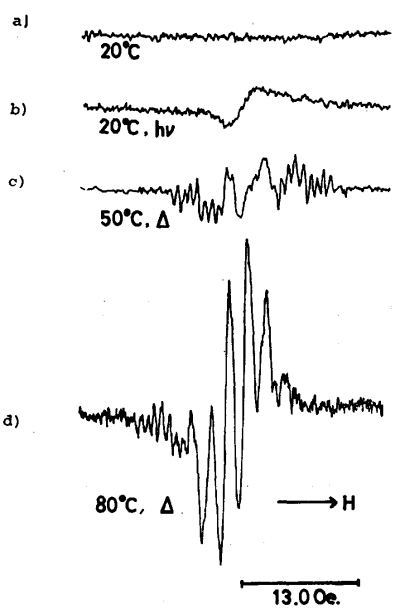

Fig. 5. ESR signals observed in the course of the decomposition of PQ–xanthene 1,2-adduct, a) 20 °C, b) 20 °C, *hν*, c) 50 °C, d) 80 °C (Solvent: CCl_4). Non symmetry of signals indicates that signals are composed of a mixture of radicals.

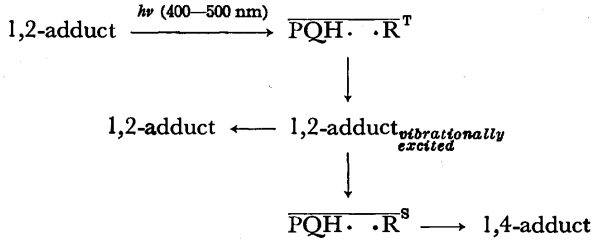
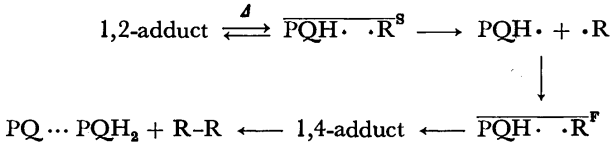
free radical in solution (Fig. 5). On the other hand, when we decomposed 1,2-adduct (from PQ–xanthene and PQ–diphenylmethane) at 80 °C or higher temperature, an absorption polarized and an emission polarized signal each corresponding to 1,4- and 1,2-adducts were observed (Fig. 6). In the decomposing systems of 1,2-adduct at these temperatures were observed, in actual, strong ESR.signals indicating the appearence of *free radicals* in solution (see Fig. 5). We can recognize the polarized signals which were observed during the course of decompositions taking into consideration of the following reaction scheme;

Photodecomposition at lower temperature:



Thermal decomposition at higher temperature:



$\overline{PQH\cdot\ \cdot R^T}$: radical pair derived from triplet precursor
$\overline{PQH\cdot\ \cdot R^S}$: radical pair derived from singlet precursor
$\overline{PQH\cdot\ \cdot R^F}$: radical pair derived from free radical precursor

Thus, the absorption polarized PMR signal corresponding to 1,4-adduct observed in thermally decomposing system of 1,2-adduct at the higher temperature indicates the recombination of the two component radicals *via free radical* state.

On irradiation of 9,10-phenanthrenequinone with ethers by visible light in benzene-d_6 or carbon tetrachloride at about 20 °C, 1,4-adducts (methine-H: in region of δ: 5.7—6.4, emission polarized) are accumu-

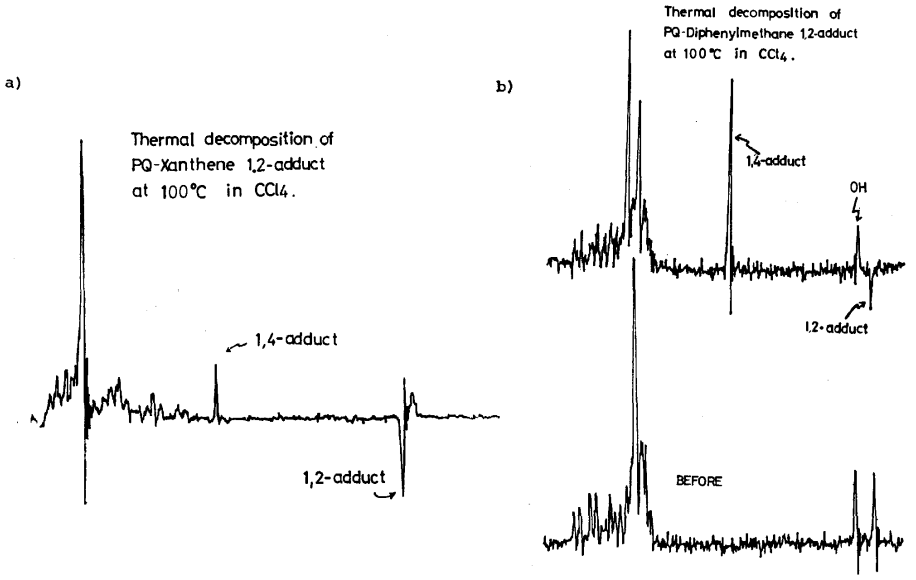


Fig. 6. Polarized PMR spectra observed in the course of the thermal decomposition of a) PQ–xanthene 1,2-adduct, b) PQ–diphenylmethane 1,2-adduct (Solvent: CCl_4 at 100 °C).

lated products in spite that the CIDNP signals indicate the transient formation of 1,2-adducts (methine-H: in region of δ: 4.4—5.1, absorption polarized) accompanying with 1,4-adducts. Irradiation of a 1,4-adduct, for example, 1,4-adduct derived from 9,10-phenanthrenequinone and dibenzyl ether, by UV-light[6] *in situ* exhibits an absorption polarization of methine-H (δ: 5.8) due to 1,4-adduct and an absorption polarization of methine-H (δ: 4.6) due to 1,2-adduct[7] (Fig. 7). This is an indication of rearrangement from 1,4-adduct to 1,2-adduct *via* radical pair produced from triplet precursor. It may be formularized as the followings;

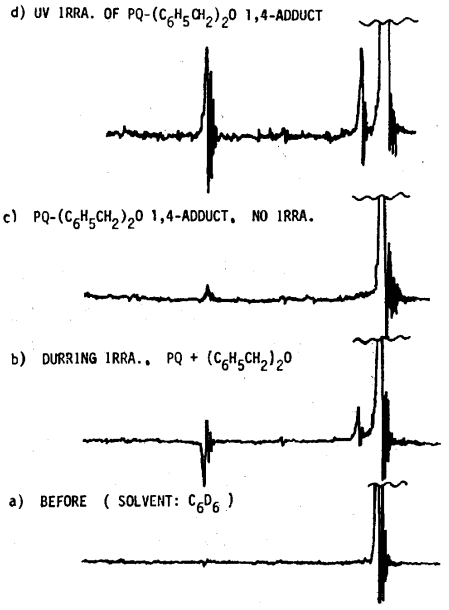

Fig. 7. Polarized PMR spectra observed in the course of the photodecomposition reaction of PQ–dibenzyl ether (Solvent: C_6D_6 at room temperature).

$$PQ^T + R'H \longrightarrow \overline{PQH\cdot\ \cdot R'}^T$$

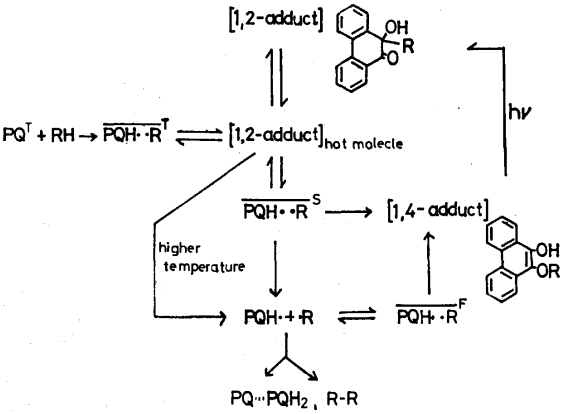
$$\overline{PQH\cdot\ \cdot R'}^T \longrightarrow 1,2\text{-adduct}_{\substack{vibrationally\\ excited}} \longrightarrow 1,2\text{-adduct (H-A)}$$

$$\overline{PQH\cdot\ \cdot R'}^S \longrightarrow 1,4\text{-adduct (H-E)} \qquad (3)$$

$$1,4\text{-adduct} \xrightarrow{\text{UV-light}} \overline{PQH\cdot\ \cdot R'}^T \begin{cases} \nearrow\ 1,4\text{-adduct (H-A)} \\ \searrow\ 1,2\text{-adduct (H-A)} \end{cases} \qquad (4)$$

H-A: polarized absorption signal of methine-H
H-E: polarized emission signal of methine-H

Similarly, the absorption polarized PMR signal due to acyl proton of stable 1,4-adduct (9-acyloxy-10-hydroxyphenanthrene) is comprehensive by assuming the preceding formation of unstable 1,2-adduct, and the subsequent rearrangement to 1,4-adduct *via* singlet radical pair. This is obviously confirmed in the photo-



Reaction scheme.

chemical reaction of PQ with acetaldehyde in benzene-d_6 by use of CIDNP technique (Fig. 2).

Summarizing the behavior of radicals in photochemical reaction of 9,10-phenanthrenequinone we may write schematically the whole reaction as in the preceding reaction scheme.

Experimental

1,2-Adducts. 1,2-Adducts were obtained in preparative scale on irradiation of mixtures of 9,10-phenanthrenequinone and suitable hydrogen donors in neat or in benzene solution. The reaction mixture was kept in a usual glass tube dipped into cool water, and irradiated by high pressure Hg-arc lamp from outside. All the 1,2-adducts of 9,10-phenanthrenequinone with alkyl aromatics have characteristic IR bands due to carbonyl and hydroxyl groups; $\nu_{C=O}$: 1690 cm^{-1}, and ν_{OH}: 3510 cm^{-1} (sharp). Their compositions were confirmed by elemental analysis. PQ–xanthene: mp 103 °C (decomp.), PQ–diphenylmethane: mp 129—132 °C (decomp.), PQ–fluorene: mp 165—167 °C (decomp.), PQ–mesitylene: mp 165—167 °C (decomp.), PQ–*p*-xylene: mp 128—128.5 °C (decomp.), PQ–*m*-xylene: mp 93—94 °C (decomp.), PQ–*o*-xylene: mp 146 °C (decomp.), PQ–anisole: mp 109—111 °C (decomp.). (PQ: 9,10-phenanthrenequinone)

1,4-Adducts. 1,4-Adducts were obtained by procedures analogous to those of 1,2-adducts. They show characteristic IR band due to hydroxyl group; ν_{OH}: 3280 cm^{-1}, and no carbonyl band. PQ–1,4-dioxane: mp 92—94 °C (decomp.), PQ–1,4-dibenzyloxybenzene: mp 143—144 °C (decomp.). Their compositions were confirmed by elemental analysis.

CIDNP. PS-100 type and MH-100 type NMR instruments equipped with PMR probe for irradiation (manufactured by JEOL) were used in CIDNP examinations. For irradiation 1 kW and 500 W high pressure Hg-arc lamps were applied with or without use of filter (Toshiba VY-42).

ESR. ME-3 type ESR machine manufactured by JEOL (X-band) was used in this experiment.

Preparation of Reinforcing Fillers from Japanese Acid Clays with Lime and by Calcination. IV. Investigation on the Structure, Physicochemical Properties and Morphology of M Hard Clay in Relation to the Reinforcing Effect

Hideki Rai and Junkichi Yamada*

The Institute of Industrial Science, The University of Tokyo, 22-1, Roppongi 7 chome, Minato-ku, Tokyo 106

(Received May 21, 1975)

In order to find the optimum conditions for the preparation of satisfactory reinforcing filler from Matsune (**M**) acid clay, two series of fillers of **M** hard clay (CaO 0—9%: drying 110 °C, 5 hr for M-1 series; calcination 600 °C, 1.5 hr for M-2 series: wet ball-milling 6—24 hr) were investigated with respect to their structure, physicochemical properties and morphology. Treatment with hydrated lime (CaO 3%), followed by calcination (600 °C, 1.5 hr) and mechanical disintegration (wet ball-milling 18 hr) was found to give good results. Calcination after the lime treatment gives rise to adequate dehydroxylation as well as dehydration of the montmorillonite, calcium silicate hydrates (CSH) and excess silica remaining. This process helps to restrain the great surface activity of acid clay and facilitate pulverization of the final products combined with the effect of inhibiting polycondensation of the montmorillonite and α-cristobalite due to an even formation of the CSH distributed on the interlayer surfaces and the interfaces of the minute crystallites.

In previous papers we reported on the availability of Nakajo (**N**) and Matsune (**M**) acid clays for preparing a reinforcing filler of elastomers,[1] the optimum conditions of preparation and evaluation of their reinforcing properties.[2] An investigation of the changes in the structure, morphology and physicochemical properties of **N** hard clay derived from **N** with relation to the reinforcement was carried out.[3]

The same treatment as in **N** hard clay (CaO 3—60%; calcination 400—800 °C, 1.5 hr; wet ball-milling 18 hr) revealed that the optimum conditions for preparing a good hard clay from **M** were very close to those of **N**; the requisite amount of alkali less than 10% and calcination at 600 °C for 1.5 hr. The patterns of structural changes in **M** hard clay investigated by X-ray diffraction and IR spectroscopy were found to be similar to those of **N** hard clay. However, a deviation was accompanied by the optimum amount of alkali; 3% for **M** and 6% for **N**.

For the purpose of confirming the optimum conditions, **M** was treated with a less amount of hydrated lime (CaO 0—9%) and then either calcined at 600 °C for 1.5 hr or dried at 110 °C for 5 hr to remove the moisture. Changes in the structure, morphology and physicochemical properties of the fillers were examined as well.

Evidences are given to show the merit of the treatment with alkali followed by calcination and mechanical disintegration for the preparation of a satisfactory reinforcing filler from **M**.

Experimental

Materials. Two series of fillers of **M** hard clay (M-1 and M-2) were used; they were derived from Matsune acid clay with hydrated lime (CaO 0, 1.25, 3, 6 or 9%) followed by thermal treatment (drying 110 °C, 5 hr for M-1; calcination 600 °C, 1.5 hr for M-2) and mechanical disintegration (wet ball-milling 18 hr).[2]

Dixie Clay, Silene EF and the original acid clay **M** which had been ground under 200 mesh and dried at 110 °C for 2 hr without the lime treatment and mechanical disintegration beforehand were utilized as references.

Investigation on Structure, Physicochemical Properties and Morphology. The structure of **M** hard clay was investigated by X-ray diffraction, IR spectroscopy and thermal analyses, DTA and TG. The physicochemical properties were determined by means of hygroscopicity, pH, DPG adsorption, specific gravity and bulk density. The shape, size and particle distribution of the prepared fillers were studied by electron microscopy. The methods, apparatus and conditions of measurement are summarized in Table 1.

The structural feature of the best **M** hard clay (CaO 3%; calcination 600 °C, 1.5 hr; wet ball-milling 18 hr) was studied by selected area electron diffraction (SAD) technique in comparison with that of the best **N** hard clay (CaO 6%; calcination 600 °C, 1.5 hr; wet ball-milling 18 hr).

Results and Discussion

Investigation of Structural Changes. (1) X-ray Diffraction Patterns. Figures 1 (a) and 1 (b) give the X-ray diffraction diagrams showing the difference of structural changes between the M-1 and M-2 fillers, respectively.

(i) M-1 fillers: As the amount of alkali increased, normal montmorillonite, the principal constituent of **M**, still retained its basal reflection[4] (15.37 Å) with a little diminution (less than 5%) in the intensity and a slight, constant shift (1.68 Å) towards a lower spacing (Fig. 1 (a) curves 1—5). The basal shift is smaller than in the case of **N** (about 2 Å) and attributable mainly to the formation of Ca-montmorillonite.

The intensity of α-cristobalite[5] (4.05 Å (101), the most prominent reflection characteristic of **M**, decreased in proportion to the amount of alkali. New but feeble reflections ascribable to tobermolite-like calcium silicate hydrates[6,7] (CSH, 2.97 and 2.81 Å) and calcite[8] (2.45 Å) appeared even in the filler treated with the least amount of alkali, 1.25% CaO. Those prepared with more than 3% CaO showed some weak peaks of unknown significance around 4.85—4.91, 3.20 and 2.65 Å.

The results indicate that the M-1 fillers substantially

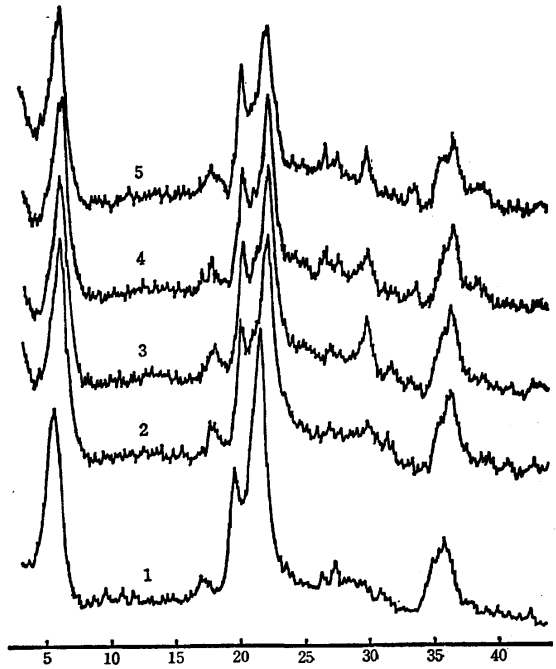

Fig. 1(a). X-Ray powder diagrams of M-1 series fillers in comparison with that of the original acid clay. (Cu$K\alpha$ radiation).
Curve 1: Matsune acid clay pulverized under 200 mesh and dried at 110 °C for 2 hr without lime treatment and calcination beforehand.
Curves 2—5: M-1 series fillers treated with hydrated lime (1.25, 3, 6 or 9% CaO, respectively), disintegrated by wet ball-milling for 18 hr and dried at 110 °C for 5 hr without calcination.

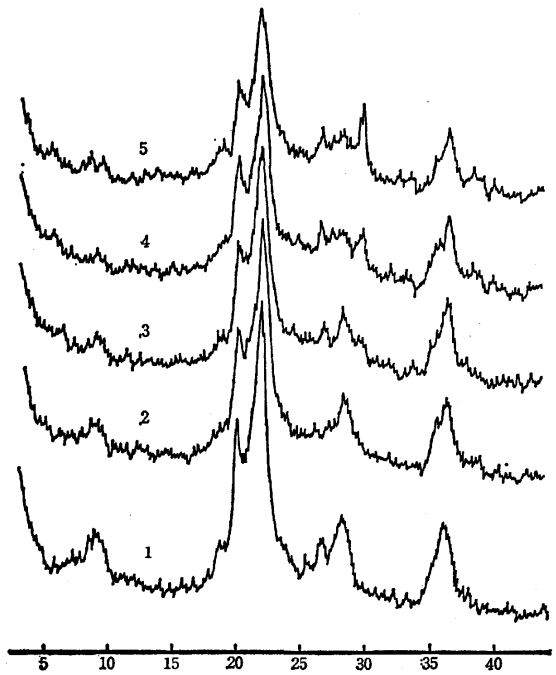

Fig. 1(b). X-Ray powder diagrams of M-2 series fillers. Curves 1—5 show the fillers prepared with or without hydrated lime (0, 1.25, 3, 6 or 9% CaO, respectively) followed by calcination (600 °C, 1.5 hr) and mechanical disintegration (wet ball-milling 18 hr).

retain the montmorillonite lattices with no significant structural changes though the conversion of the crystallite into Ca-montmorillonite, the consumption of the excess silica with alkali and the formation of small amounts of CSH, calcite and unknown crystalline materials were observed.

(ii) M-2 fillers: The basal reflection of montmorillonite almost disappeared. The remaining portion shifted towards lower spacings in the range 1.01—6.12 Å, in which the greatest shift occurred in the filler treated with 3% CaO (Fig. 1 (b) curves 1—5). A close relationship can be suggested with the reinforcing properties of the best **M** hard clay.

The most prominent reflection of α-cristobalite also decreased in proportion to the increase in the amount of alkali. New reflections analogous to those of the M-1 fillers appeared with relatively less intensity. They showed in sharpened mode as the reflections of the distinguished α-cristobalite and remaining montmorillonite.

Consequently, more structural changes occurred in the M-2 fillers than in the M-1 fillers. However, the minute crystallites still retained the montmorillonite lattices with no serious collapse though the capability

	Specific gravity	Pycnometer (10 ml), exhauster and chemical balance	ASTM D 153—39 (1939). Immersion liquid, kerosene (bp 70—100°C/2 mmHg, d_4^{30} 0.7811)
	Bulk density	Graduated, thick-walled test tube (20 ml) and rubber plate as a cushion	S. Kurabayashi, "Methods of Examination for Rubber and Relating Materials," ed. by S. Kunisawa, Soc. Rubber Ind. Japan (1963), p. 651.

of rehydration and rehydroxylation[9–11] disappeared almost completely as in the case of **N** hard clay (CaO less than 10%, calcination 600 °C, 1—1.5 hr; mechanical disintegration 18 hr).

(2) Infrared Spectra. Figures 2(a) and 2(b) illustrate the infrared spectra giving the difference of structural changes between the M-1 and M-2 fillers, respectively.

(i) M-1 Fillers: The diagnostic bands[12] of montmorillonite in the dried **M** varied with the treatment with alkali followed by mechanical disintegration and drying without calcination (Fig. 2(a) curves 1—5).

As the amount of alkali increased, the bands at 3640 (νO–H, free), 3430 (νO–H, hydrogen bonded) and 1630 cm^{-1} (δO–H) in curve 1 first increased and then decreased as a result of the formation of Ca-montmorillonite and CSH (curves 2—5). The latter two bands slightly shifted towards lower frequencies at 3410 and 1620 cm^{-1}, respectively. The bands at 915 (δAl^{3+}–O–H)[13–15] and 853 cm^{-1} (δFe^{3+}–O–H)[13–15] decreased in proportion to the amount of alkali. The uptake of Ca^{2+} ion seems to take place in the outer edges of octahedrons of the montmorillonite. Of the bands characteristic of layer-lattice silicates in the regions 950—1250 (νSi–O) and 400—650 cm^{-1} (not shown), the band at 1100 cm^{-1} related to colloidal silica[16–18] became broad, the intensity considerably increasing, suggesting the progress of ion saturation.[19] However, the bands at 1035 and 472 cm^{-1} (δSi–O)[13–15] related to the skeletal vibrations of the tetrahedrons of montmorillonite and the band at 519 cm^{-1} (Si–O–Al^{VI})[13–15] remained unchanged.

New distinct bands at 1460—1475 and 855 cm^{-1} ascribable to CSH[20,21] increased in proportion to the decrease of the band at 794 cm^{-1} related to hydrated amorphous silica[16–18] with an increase in the amount of alkali. Only feeble bands at 1420, 876 and 715 cm^{-1} attributable to calcite,[22,23] which appeared in the fillers prepared with more than 3% CaO, hardly changed with the variation in the amount of alkali.

The results indicate that no significant alternation occurred in the montmorillonite lattices except for the formation of Ca-montmorillonite, CSH and calcite and the uptake of Ca^{2+} ion in the octahedrons.

(ii) M-2 Fillers: More changes appeared in the diagnostic bands of the montmorillonite than in the case of the M-1 fillers (Fig. 2(b) curves 1—5).

Irrespective of calcination (600 °C, 1.5 hr) for the fillers, the bands at 3430 and 1630 cm^{-1} increased in proportion to the amount of alkali. In view of the abrupt loss and noticeable shift in the basal reflections of calcined fillers, the increase can be attributed mainly to the water of crystallization of CSH. The bands were partially retained after calcination indicating rehydrated during the course of mechanical disintegration. The bands at 1035 and 472 cm^{-1} gradually shifted towards higher frequencies overlapping the adjacent bands at 1100 and 519 cm^{-1}, giving one stronger and broader band around 1060 and 485 cm^{-1}. Some irreversible contraction or condensation might take place in the montmorillonite lattices.

The band at 794 cm^{-1} decreased in intensity and became broader. This suggests the consumption of hydrated amorphous silica and the occurrence of partial polycondensation. The new bands ascribed to CSH and calcite appeared more distinctly than the

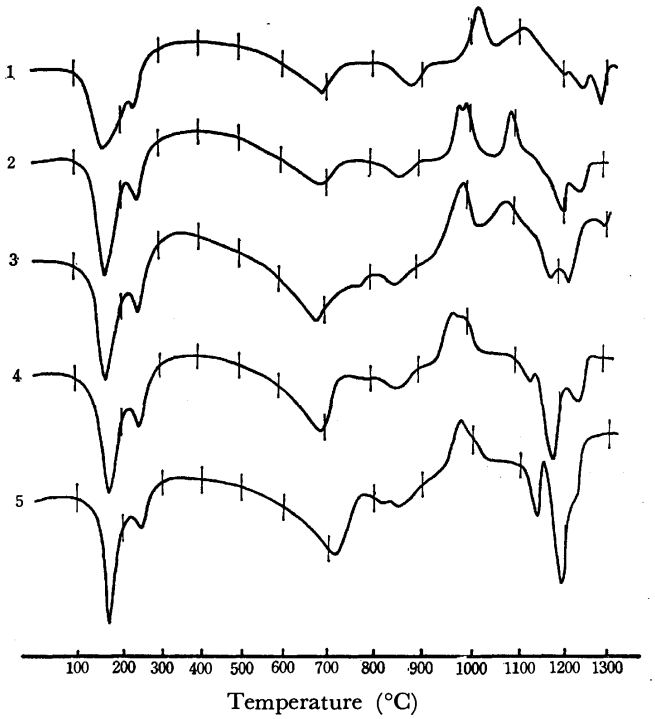

Fig. 3(a). DTA thermograms of M-1 series fillers in comparison with that of the original acid clay.

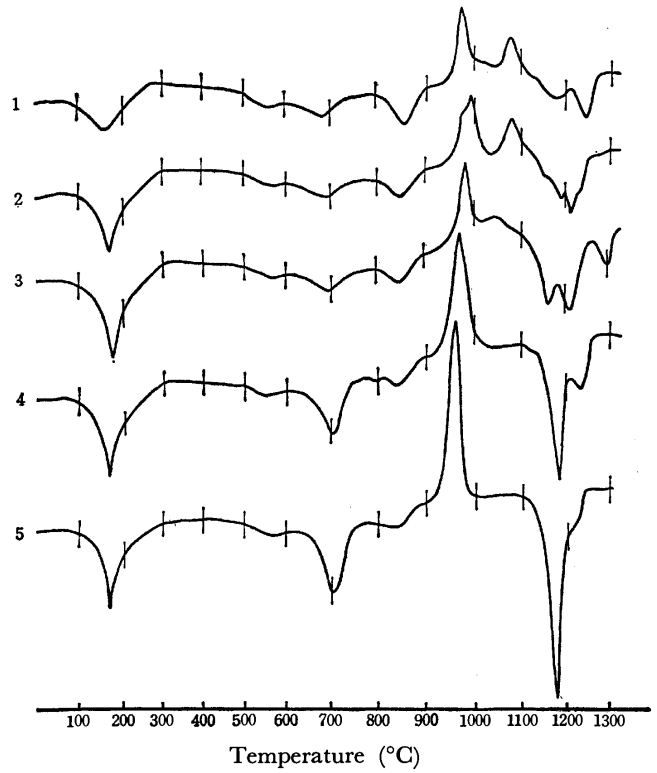

Fig. 3(b). DTA thermograms of M-2 series fillers.
The respective curve corresponds to that of the same number shown in Fig. 1(b).

corresponding bands of the M-1 fillers with an increase in the amount of alkali.

The fillers thus prepared still retained the minute crystallites of montmorillonite structure involving some irreversible contraction in the layer lattices. The consumption of α-cristobalite with alkali and partial polycondensation of the excess silica remained and the formation of new crystalline minerals such as CSH and calcite were observed in the matrix as well. The results agree with those of X-ray investigation.

(3) DTA Thermograms. Figures 3(a) and 3(b) show the DTA thermograms demonstrating the difference of structural changes between the M-1 and M-2 fillers, respectively.

(i) M-1 Fillers: The diagnostic peaks of montmorillonite[24-26] changed with the treatment as follows (Fig. 3(a) curves 1—5).

Endothermic Reactions: With an increase in the amount of alkali, the first two endotherms (152 °C, strong and broad; 225 °C, a medium shoulder) in the dried **M** (curve 1) became greater and gradually shifted towards higher temperatures; the filler treated with 9% CaO gave the endotherms at 173 and 243 °C (curve 5). The major endotherm in curve 1 is ascribable to dehydration[25,26] (100—300 °C) of the water adsorbed on the surfaces and among the interfaces of the minute crystallites of the montmorillonite and α-cristobalite, and the minor one to the water hydrated with the exchangeable cations interposed between the interlayers. With an increase in the amount of alkali, the major endotherm showed increase in the peak temperature, sharpness and symmetry of the profile (curves 2—5). This suggests that the dehydration can be explained in terms of the loss of the water of crystallization due to newly formed minerals CSH besides the adsorbed one.

The endotherm (685 °C, medium and broad) attributable to the dehydroxylation[25,26] (500—780 °C) of the normal montmorillonite and excess silica of the dried **M** showed a considerable rise in temperature around 9% CaO; the endotherm of the filler prepared with 1.25, 3, 6 or 9% CaO appeared at 683, 681, 685 or 709 °C, respectively. It was accompanied by a gradual increase in the area of profile. The results verify the formation of Ca-montmorillonite[25] and CSH[27] together with the appearance of the exotherm (around 970 °C) and endotherms (around 1130 and 1180 °C).

The endotherm (872 °C, medium and broad) due to the phase transition[25,26] (820—920 °C) of montmorillonite in the dried **M** gradually shifted towards lower temperatures, accompanied by a decrease in the area of profile; the filler prepared with 9% CaO gave the endotherm at 848 °C. An appreciable amount of Ca^{2+} ion should have been taken into the octahedrons of montmorillonite during the course of treatment.

The remaining endotherms at 1197 (a weak shoulder), 1237 (small and broad) and 1280 °C (medium and sharp) changed to 1132 (medium and sharp), 1185 (very strong and sharp) and 1222 °C (a medium shoulder), respectively.

The fusion point of the dried **M** (over 1300 °C) is lowered noticeably with the increase in the amount of

alkali; the filler treated with 9% CaO melted at 1185 °C.

No endotherm ascribable to the dehydroxylation of calcium hydroxide (about 570 °C, strong),[27] which would take place during the course of mixing raw materials and subsequent mechanical disintegration, was found in both fillers. However, a weak one (around 772—812 °C) attributable to calcite[28] appeared in almost the same area for the fillers prepared with more than 3% CaO. This indicates that a nearly equal amount of calcite was produced in the fillers; the amount was estimated to be less than 3% from the area of endotherm. The formation resulted from the carbonation of liberated alkali $Ca(OH)_2$ during the course of preparation.

Exothermic Reactions: The exotherms due to β-quartz[24] or spinel[24] (1009 °C, medium and sharp) and β-cristobalite[24] (1102 °C, medium and broad) in the dried **M** showed splitting and sharpening, decreasing in the peak temperatures (979, 993 and 1085 °C) for the filler treated with the least amount of alkali, 1.25% CaO. With an increase in the amount of alkali, the exotherms gradually decreased in the temperatures and overlapped the adjacent peaks. The filler prepared with 9% CaO gave a medium and broad exotherm (972 °C) containing a weak shoulder (998 °C). The formation of some CSH gel in combination with alumina might be suggested.[27]

(ii) M-2 Fillers: The calcined **M** without the lime treatment showed a change in the diagnostic peaks of montmorillonite as follows (Fig. 3(b) curve 1).

Endothermic Reactions: The first two prominent endotherms (152 and 225 °C) in the dried **M** disappeared completely by calcination (600 °C, 1 hr). A medium and broad one (165 °C) appeared by subsequent mechanical disintegration (wet ball-milling 18 hr) and drying (110 °C, 5 hr). The first endotherm is ascribed to the dehydration of the water rehydrated during the course of the wet ball-milling. Disappearance of the minor one (225 °C) indicates that fixation[25] of the exchangeable cations interposed between the interlayers of the montmorillonite took place during the course of calcination.

The endotherm at 685 °C in the dried **M** diminished noticeably just after the calcination, and showed two peaks at 575 °C (small and broad) and 686°C (medium and broad) by the subsequent mechanical disintegration and drying. The endotherms are attributed to the dehydroxylation of the structural water rehydroxylated during the course of the wet ball-milling; the former (575 °C) corresponds to the disorder[10,25] of the montmorillonite lattices resulting from the calcination and mechanical disintegration, and the latter (686 °C) to the residual normal montmorillonite.

The endotherm (872 °C) due to the phase transition of montmorillonite in the dried **M** shifted towards a lower temperature (860 °C) with a slight increase in the area. During the course of calcination, some substitution[25] occurred in the octahedrons of the montmorillonite with the exchangeable cations originally interposed between the interlayers.

The remaining endotherms (1197, 1237 and 1280 °C) in the dried **M** moved to considerably lower temperatures (1130, 1193 and 1251 °C, respectively) with appreciable broadening in the calcined **M**.

Exothermic reactions: The exotherms due to β-quartz (1009 °C) and β-cristobalite (1102 °C) in the dried **M** also shifted towards lower temperatures (983 and 1080 °C, respectively), accompanied by appreciable sharpening in the calcined **M**. A pronounced crystallization would proceed by calcination without previous lime treatment. Additional treatment with hydrated lime caused noticeable changes in the DTA thermograms of the M-2 fillers (Fig. 3(b) curves 2—5).

Endothermic Reactions: As the amount of alkali increased, the first endotherm (165 °C) in the calcined **M** appeared around 180 °C. The endotherm gradually increased in the area and sharpness of profile. This can be attributed to the dehydration of the water of crystallization of CSH rehydrated during the course of wet ball-milling besides the readsorbed water distributed on the surfaces and among the interfaces of the minute crystallites.

The endotherm (575 °C) ascribed to the disorder of the montmorillonite lattices in the calcined **M** moved in succession towards a lower temperature (around 560 °C) with no change in the area of profile. However, the adjacent endotherm (686 °C) attributed to the dehydroxylation of the residual normal montmorillonite of the calcined **M** increased in the area, temperature and sharpness of the profile in proportion to the amount of alkali. This indicates a linear formation of CSH with an increase in the amount of alkali in accordance with the increase in the area and sharpness of the peaks observed around 180, 960 and 1180 °C. The filler prepared with 9% CaO gave the endotherm at 708 °C with more than three times area as compared with that of the calcined **M**.

An endotherm (795 °C) ascribable to calcite, easily observable by means of X-ray diffraction and IR spectroscopy, appeared only in the filler treated with 6% CaO.

The endotherm (860 °C) attributed to the phase transition of montmorillonite in the calcined **M** showed a gradual decrease in temperature (835 °C for 9% CaO) and the area (less than 1/3 for 9% CaO) of the profile. This suggests that the consumption of alumina proceeded in the octahedrons of the montmorillonite, resulting in the formation of CSH gel incorporated with alumina.

The endotherms appearing at 1193 and 1251 °C in the calcined **M** varied complicatedly with an increase in the amount of alkali. New peaks accompanied by an increase or a decrease in the area, shifting or overlapping adjacent peaks were observed.

Exothermic Reactions: The exotherm (983 °C) due to β-quartz in the calcined **M** showed a shoulder (975 °C) in the filler treated with the least amount of alkali, 1.25% CaO. The exotherm increased in the area and sharpness of profile, gradually decreased in the peak temperature in proportion to the amount of alkali and finally became one single peak. This suggests the formation of a considerable amount of CSH gel incorporated with alumina. The adjacent exotherm (1080 °C) ascribed to β-cristobalite in the calcined **M** decreased in the temperature and disappeared in the fillers treated with more than 6% CaO.

The greater the amount of alkali, the more advanced the formation of CSH (I, II and gel) and the greater the lowering of the fusion point; the one treated with 9% CaO melted at 1179 °C, about 120 °C lower than that of the dried **M**. Depression in the fusion point due to excess alkali over the optimum amount (CaO 3%) caused agglomeration, sintering or hardening of the minute crystallites of acid clay as in the case of polycondensation observed in the calcined **M** without previous lime treatment or in the fillers treated with alkali less than 3% followed by calcination. The calcined products became too hard to be sufficiently disintegrated. The reinforcing properties were reduced noticeably.

The relative loss in weight corresponds to the net weight loss related to the dehydroxylation of newly formed minerals.
△——△ M-1 series fillers; ○——○ M-2 series fillers.

(4) TG Thermograms. Figures 4(a) and 4(b) illustrate the TG thermograms of the M-1 and M-2 fillers, respectively. Four fractions, *viz.*, dehydration (up to 300 °C), oxidation (300—500 °C), dehydroxylation (500—780 °C) and phase transition (780—1300 °C), can be deduced with reference to the characteristic peaks of corresponding DTA thermograms.

Dehydration caused remarkable changes in weight; 7.8—11.9% and 4.3—6.2% for the M-1 and M-2 fillers, respectively.

Oxidation of adsorbed organic matter and/or the partial dehydration of newly formed minerals CSH (I, II and gel) resulted in a linear loss in weight; the loss varied within the ranges 0.76—1.11% and 0.71—1.57% for the M-1 and M-2 fillers, respectively.

A proportional increase in weight loss due to the dehydroxylation of the prepared fillers took place with an increase in the amount of alkali. The weight loss amounted to 2.59—6.66% and 1.67—5.77% for the M-1 and M-2 fillers, respectively.

The phase transition accompanied by or not by the fusion of specimen showed a linear loss in weight; it changed in the ranges of 0.90—1.39% and 0.74—1.77% for the M-1 and M-2 fillers, respectively.

The total loss in weight, consequently, increased with an increase in the amount of alkali; the M-1 fillers varied from 12.07 (CaO 0%) to 18.38% (CaO 9%) and the M-2 fillers from 7.56 (CaO 0%) to 14.22% (CaO 9%). Irrespective of calcination, the net loss in weight attributable to the dehydroxylation of the new minerals CSH was found to be accurately in proportion to an increase in the amount of alkali (Fig. 4(c)). The value can be estimated from TG thermogram by reducing the weight loss of a corresponding reference specimen, dried or calcined **M**, from that of a M-1 or M-2 filler, respectively. This indicates that the amounts of CSH produced in the fillers are proportional to those of the alkali. This is in line with the results obtained by X-ray diffraction, IR spectroscopy and DTA.

Determination of Physicochemical Properties. Changes in the physicochemical properties such as hygroscopicity, pH, DPG adsorption, specific gravity and bulk density are demonstrated in comparison with those of Dixie Clay, Silene EF and **M**, dried and calcined (Figs. 5(a)—

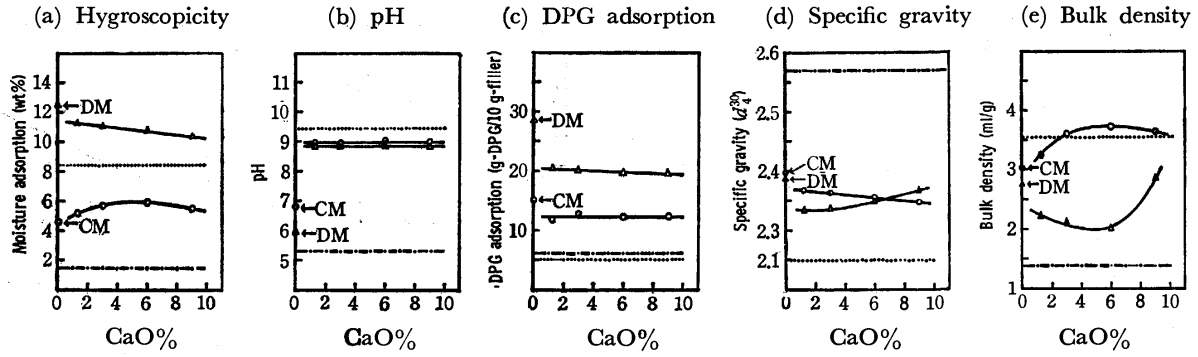

Fig. 5. Changes in the physicochemical properties of **M** hard clay with alkali (CaO 0—9%) and by thermal treatment (110 °C, 5 hr for M-1 series fillers; 600 °C, 1.5 hr for M-2 series fillers) in comparison with those of references, Dixie Clay, Silene EF and the original acid clay **M**, dried (110 °C, 2 hr) and calcined (600 °C, 1.5 hr).
Inscriptions are as follows: (a): Hygroscopicity (wt%), (b): pH, (c): DPG adsorption (g DPG/10^4 g filler), (d): Specific gravity (d_4^{30}), (e): Bulk density (ml/g), DM: Dried **M**, CM: Calcined **M**.
△——△ M-1 series fillers; ○——○ M-2 series fillers, —·—· Dixie Clay; ····· Silene EF.

(e)).

(1) Hygroscopicity: The hygroscopicity of the dried and calcined **M** without lime treatment were found to be 12.44 and 4.53%, respectively (Fig. 5 (a)). The former (12.44%) is much greater than the value of Dixie Clay (1.46%) or Silene EF (8.41%), and the latter (4.53%) is less than the mean value of the reference fillers.

By the lime treatment (CaO 1.25—9%) without subsequent calcination, the hygroscopicity of the M-1 fillers decreased in proportion to an increase in the amount of alkali. However, the value was still greater than that of Silene EF.

The hygroscopicity of the M-2 fillers decreased noticeably by the subsequent calcination (600 °C, 1.5 hr). The hygroscopicity was comparable to the mean value of the reference fillers, accompanied by a maximum around 6% CaO.

(2) pH: The pH of the dried and calcined **M** without previous lime treatment were found to be 5.95 and 6.77, respectively (Fig. 5 (b)). The values are smaller than the value of Silene EF (9.45) but close to that of Dixie Clay (5.30).

Treatment with hydrated lime and without subsequent clacination resulted in a noticeable increase in the pH of the M-1 fillers; a constant value as high as 8.84 was obtained.

Subsequent calcination gave rise to only a small increase (0.12) in the pH values of the M-2 fillers. They were comparable to the pH of Silene EF, deviating from that of Dixie Clay.

(3) DPG Adsorption: The DPG adsorption of **M** (dried 28.57 g DPG/10^4 g filler; calcined 15.03 g DPG/10^4 g filler) was found to be much greater than that of the reference fillers (Dixie Clay 6.05 g DPG/10^4 g filler; Silene EF 5.08 g DPG/10^4 g filler) (Fig. 5 (c)).

The DPG adsorption of the M-1 fillers decreased to a 70% value of the dried **M** by treatment with hydrated lime without subsequent calcination. Irrespective of the variation in the amount of alkali (CaO 1.25—9%), the value remained almost unchanged.

Subsequent calcination caused a further, constant diminution (7.73 g DPG/10^4 g filler) in the DPG adsorption of the M-2 fillers. A reduction to a 57% value of the dried **M**, twice as much as the value of Dixie Clay was observed.

(4) Specific Gravity: The specific gravity of the calcined **M** (2.3957) was found to be a little greater than that of the dried **M** (2.3891) (Fig. 5 (d)). The value of **M**, dried or calcined, is smaller than that of Dixie Clay (2.5684) but greater than that of Silene EF (2.0984).

Treatment with hydrated lime without subsequent calcination caused a noticeable decrease in the specific gravity of the M-1 fillers. The value, however, gradually increased with an increase in the amount of alkali.

Subsequent calcination resulted in a decrease in the specific gravity of the M-2 fillers in proportion to the amount of alkali. Consequently an intersection with the former plots appeared around 7% CaO.

The variation of the specific gravity of the M-1 and M-2 fillers with the amount of alkali remained in the ranges 0.0331 and 0.0203, respectively.

(5) Bulk Density: The bulk density of dried and calcined **M** was found to be 3.02 and 2.75 ml/g, respectively (Fig. 5(e)). The latter (2.75 cc/g) is comparable to the mean value of Dixie Clay (1.38 ml/g) and Silene EF (4.05 ml/g)

Treatment with hydrated lime less than 6% CaO without subsequent calcination caused a gradual decrease in the bulk density of the M-1 fillers. More alkali, however, gave rise to a rapid increase. Consequently a minimum value of the bulk density appeared around 4—6% CaO.

Subsequent calcination afforded a further increase in the bulk density of the M-2 fillers. A maximum exceeding the value of Silene EF was obtained with 5—7% CaO.

The results indicate that not only reduction in the hygroscopicity, DPG adsorption and specific gravity of the original acid clay **M**, but also increase in the pH and bulk density of the fillers can be attained by treatment with hydrated lime (CaO 1.25—9%) followed by calcination (600 °C, 1.5 hr) as compared with a single treatment with alkali or by calcination alone.

Plate 16: **M** hard clay (2) (CaO 6%; calcination 600 °C, 1.5 hr; wet ball-milling 12 hr).
Plate 17: **M** hard clay (3) (CaO 6%; calcination 600 °C, 1.5 hr; wet ball-milling 18 hr).
PlBte 18: **M** hard clay (4) (CaO 6%; calcination 600 °C, 1.5 hr; wet ball-milling 24 hr).

Technique. **M** hard clay gave a greater amount and smaller size of particle than **N** hard clay under the same conditions of preparation (Fig. 6, Plate 1 *cf.* Plate 2). This can be attributed mainly to the difference of mineralogical constituents between the original acid clays, **M** and **N**, *viz.*, the amounts of normal and abnormal montmorillonites as well as excess silica α-cristobalite.

The deviation in the optimum amount of hydrated lime in the best reinforcing fillers (CaO 3% for **M**, 6% for **N**; calcination 600 °C, 1.5 hr; wet ball-milling 18 hr) can be interpreted in the same way. The SAD technique applied to the best reinforcing fillers and others revealed that a distinct diffraction pattern of CSH appeared in **M** hard clay but only a feeble one in **N** hard clay besides the diagnostic reflections of montmorillonite (Plates 3-A, 3-B, 4-A and 4-B *cf.* 5-A and 5-B), and that subsequent calcination affected the formation of CSH noticeably (Plates 4-A and 4-B *cf.* Plates 6-A and 6-B).

The fact that the greater part of hydrated lime added to **N** is combined with the montmorillonite lattices is interpreted as follows: (i) **N** consists of abnormal montmorillonite in a greater amount than normal montmorillonite,[1] (ii) the former reacts with alkali more easily than the latter, (iii) the amount of excess silica involved in **N** (13%) is much less than in **M** (34%),[1] (iv) α-cristobalite contained in the interior of montmorillonite lamellae reacts with alkali with more difficulty than the one distributed on the surface of crystallite or in an isolated state.

The less the content of excess silica involved in the original acid clay, the less the formation of CSH in the fillers prepared with the same amount of alkali. However, the formation of CAH and calcite increased with an increase in the amount of alkali. This agrees with the results obtained by X-ray diffraction and IR spectroscopy.

The indispensability of thermal treatment at an appropriate temperature for the preparation was proved by comparing the morphology of the M-1 and M-2 fillers (Plates 7—10 *cf.* Plates 11—14). After mechanical disintegration in wet state for 18 hr, the particle size and its distribution range of the M-1 fillers were found to be even smaller than those of the corresponding M-2 fillers. During the course of drying, however, the active silanol groups, originally contained and mechanochemically[29,30] generated in the wet ball-milling, and alkali liberated in the matrix cause the recombination of minute crystallites of the fillers, resulting in the formation of much greater and harder agglomerates. Subsequent pulverization with an atomizer to minimize the agglomerates is so difficult that the reinforcing effect of the M-1 fillers on SBR-1502 compounds decreased noticeably.[2]

In the case of the M-2 fillers, calcination (600 °C, 1.5 hr) after lime treatment gives rise to adequate dehydroxylation as well as dehydration of the montmorillonite, CSH and excess silica remaining. This process helps to facilitate the pulverization of the final products and also has the effect of inhibiting polycondensation of montmorillonite and α-cristobalite due to an even formation of the CSH distributed on the interlayer surfaces and the interfaces of the minute crystallites. Thus the great surface activity inducing agglomeration during the course of drying and the great adsorption encountered in compounding can be restrained properly.

The reduction of the particle size and its distribution range of the same-series fillers was found to be proportional to the time of mechanical disintegration up to 18 hr (Plates 15—18).

Conclusion

In spite of the similarity in the constitutional units, fineness and functional groups of montmorillonite and kaolinite, acid clays, hitherto, could not be utilized as a material for reinforcing fillers due to structural factors[31,32] such as substitutions in the tetrahedral and/or octahedral sheet, nonconformity in the layers and lattice defects of montmorillonite which cause too great adsorption, cation exchange, swelling and catalytic activity.

It has been found that treatment with hydrated lime followed by calcination and mechanical disintegration can suppress the great surface activity of acid clay and maintain the fineness and available functional groups of the crystallites properly, turning acid clays into a reinforcing filler.

The reinforcing effect on SBR-1502 compounds was found to be in line with the reduction in both the particle size and its distribution range. The average particle size and its distribution are closely related to the mineralogical constituents of the original acid clays, **K**, **M** and **N**, as well as the conditions of preparation as in the case of the contents of remaining functional groups and newly formed minerals, CSH, CAH and calcite.[1-3] The optimum conditions for the preparation were found to be as follows: Raw materials consist of normal and/or abnormal montmorillonite involving excess silica α-cristobalite as principal constituents. Treatment with hydrated lime (CaO 3% for **M**, 6% for **N**) followed by calcination (600 °C, 1.5 hr) and mechanical disintegration (wet ball-milling 18 hr).

The precise mechanism of the reinforcing effects caused by the prepared fillers has not been clarified. However, it is certain that surface energy, especially the interaction between the hydroxyl radicals distributed on the outer surfaces of filler particles and compounded elastomer molecules play the most important role.[33,34]

The encouragement and support of the late Prof. T. Kuwata, the University of Tokyo, are gratefully acknowledged. Thanks are also due to Prof. J. Kumanotani, the University of Tokyo, for his valuable discussions and Mr. Y. Sugawara, President of Mizusawa Industrial Chemicals Co., Ltd., for the supply of acid clays.

The Many-body Effects in $(N_2)_n$ Systems

Masao HASHIMOTO

The Chemical Research Institute of Tohoku University, Sendai, 980

(Received July 14, 1975)

Synopsis. Many-body effects in $(N_2)_n$ systems are discussed on the basis of CNDO/2-Clementi SCF calculations of the deviation from the pairwise additivity. The many-body effects cancel each other out, and this makes the deviation from the pairwise additivity only a small percentage of the pairwise interaction in the rather high n-mers.

The total energy of an interacting n-molecular system can be described as follows (the so-called multibody expansion[1]):

$$E = \sum_r E_r + \sum_{r<s} E_{rs} + \sum_{r<s<t} E_{rst} + \cdots + \sum_{r<s<t<\cdots<n} E_{rst\cdots n} \quad (1)$$

The first term of Eq. (1) is the summation of the self-energies of individual molecules. The second term is the summation of the two-body interaction energies, the third term is that of the three-body interaction energies, and so on. Rewriting Eq. (1) in terms of the (2) and (3) defintitions, we obtain the defintition for the deviation from the pairwise additivity, $\sigma(n)$:

$$\Delta E_n = E - \sum_r E_r \quad (2)$$

$$\Delta E_2 = \sum_{r<s} E_{rs} \quad (3)$$

$$\sigma(n) = \Delta E_n - \Delta E_2 = \sum E_{rst} + \cdots + \sum E_{rst\cdots n} \quad (4)$$

It is expected that the three-body effects contribute most significantly to $\sigma(n)$.

Recently, there have appeared several papers on SCF calculations of $\sigma(n)$ in various configrations of rare gas trimers and, in a few cases, tetramers.[2] Novaro and Beltran-Lopez made a calculation of the system of $(He)_4$ and found that the four-body effects were not small compared with the three-body effects. Therefore, the superiority of three-body effects in Eq. (4) may be questionable in general.

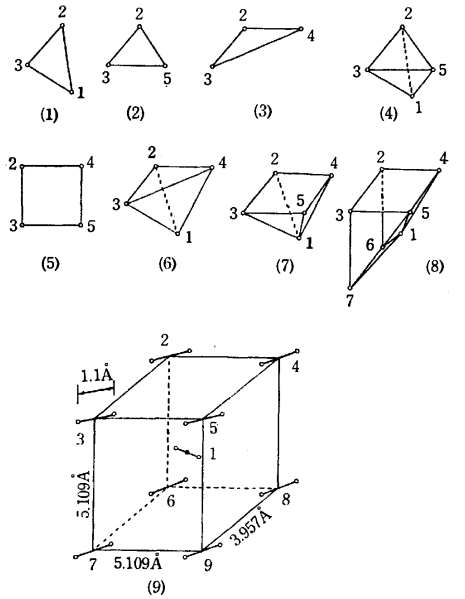

Fig. 2. The configurations of n-mers in γ-N_2 crystal. (1),(2),(3),: 3-mer; (4),(5),(6): 4-mer; (7): 5-mer; (8): 7-mer; (9): 9-mer. In (1)—(8) only the positions of the centers of N_2 molecules are indicated.

In the case of polyatomic molecular n-mer, there have not been any papers reported concerning this point.

In the present paper, we calculate $\sigma(n)$ for $(N_2)_n$ systems in the way previously used[3] for the calculation of $\sigma(3)$ in $(N_2)_3$ systems, and discuss the many-body effects higher than the three-body.

In Tables 1 and 2 the CNDO/2-Clementi SCF LCAO MO results are shown. The configurations of the molecules in n-mers in these Tables correspond to a part of the configurations of molecules in the real crystals, α- and γ-N_2 (see Figs. 1 and 2).[4] The four-body effect in Fig. 1 (4) is calculated as the difference between $\sigma(4)$ and four three-body effects, which can be calculated easily:

$$\begin{aligned} E_{1235} &= \sigma(4) - \sum E_{rst} \\ &= \sigma(4) - (E_{215}+E_{235}+E_{123}+E_{135}) \\ &= -0.00180 - (-0.00140-0.00002 \\ &\quad -0.00606-0.00606) \\ &= 0.01174 \end{aligned} \tag{5}$$

The other four-body effects in Figs. 1 and 2 were calculated in the same way. The five-body effect in Fig. 1(5) was calculated using the four-body effects thus calculated:

$$\begin{aligned} E_{12345} &= \sigma(5) - (E_{2345}+E_{1235}\times 4+E_{123}\times 4+E_{235}\times 4 \\ &\quad +E_{215}\times 2) \\ &= -0.00396 - (0.00006+0.01174\times 4 \\ &\quad -0.00606\times 4-0.00002\times 4-0.00140\times 2) \\ &= -0.02386 \end{aligned} \tag{6}$$

The other five-body and higher-body effects could be calculated in the same way, but the effects higher than five-body were not evaluated since their calculations are rather time-consuming.

The n-body effects obtained throw doubt on the rapid convergence of multibody expansions shown in Eq. (1). However, because the signs of the components in Eq. (4) can be either positive or negative (as may be seen from Tables 1 and 2), there may occur cancellations between them. As a result, the deviations from the pairwise additivity, $\sigma(n)$'s, are of the order of a few percent of ΔE_2 in the n-mers higher than the pentamers. This is another confirmation of the pairwise additivity in molecular crystals.

These discussions are, of course, justified only with respect to the intermolecular distance corresponding to the van der Waals minimum: at larger or smaller distances they are questionable. However, we are not interested in the latter region of distance, because we are concerned exclusively with molecular crystals.

All the numerical calculations were made by means of the NEAC-2200 model 700 computer system at the Computer Center of Tohoku University.

(Received April 5, 1975)

Synopsis. Luminescence spectra and lifetimes are presented for the rare earth ions sensitized by [1]benzopyrano-[3,4-*c*]pyridine-4,5(3*H*)-dione derivatives in dilute solutions. It is to be noted that, among the benzopyranopyridine derivatives investigated, 2-phenyl-[1]benzopyrano[3,4-*c*]pyridine-4,5(3*H*)-dione brings about the most efficient sensitization for the luminescence of europium and terbium ions. Some discussions are made of the energy-transfer processes from these excited benzopyranopyridine derivatives to terbium ions.

Although the phenomenon of intramolecular energy transfer in β-diketone chelates of rare earth ions is well known,[1] the process of intermolecular energy transfer between organic compounds and rare earths has been discussed only recently.[2] This note will give the luminescence characteristics of europium and terbium ions sensitized by 2-phenyl-[1]benzopyrano[3,4-*c*]pyridine-4,5(3*H*)-dione (PBPP), 2-*p*-methoxyphenyl-[1]-benzopyrano[3,4-*c*]pyridine-4,5(3*H*)-dione (*p*-MBPP), and 7-methoxy-2-phenyl-[1]benzopyrano[3,4-*c*]pyridine-4,5(3*H*)-dione (MPBPP) in 1:1 (v/v) ethanol–methanol solutions.

Experimental

Three benzopyranopyridine derivatives, europium nitrate hexahydrate and gadolinium nitrate hexahydrate, and terbium acetate hemihydrate and gadolinium acetate anhydrate were prepared by the methods described by Sakurai *et al.*,[3] Dawson *et al.*,[4] and Witt *et al.*[5] respectively. The luminescence and excitation spectra were measured using the Hitachi Model MPF-2A fluorescence spectrophotometer. Measurements of the lifetimes of the rare earth ion luminescence sensitized by benzopyranopyridine derivatives were made with a photomultiplier located at a 90° angle from the exciting intense ultraviolet beam from a xenon lamp. The flash light given by this lamp had a life-duration of less than 50 μs.

Results and Discussion

The spectra observed at room temperature are presented in Fig. 1. The degree of enhancement in the rare earth ion luminescence at a certain fixed wavelength, *i.e.*, 613 nm for europium and 544 nm for terbium ions, sensitized by donors (benzopyranopyridine derivatives), are shown in Table 1 in terms of the enhancement factor obtained by dividing the relative intensity of the luminescence of the rare earth ions in the presence of the donors by that in their absence, the concentration of the donors being 2.0×10^{-4} M, and that of the acceptors (rare earth salts), 4.5×10^{-3} M. It should be noted that, among the donors investigated, PBPP brings about the most efficient sensitization for the luminescence of europium and terbium ions.

The presence of an acceptor causes a blue shift to the fluorescence and excitation bands of a benzopyranopyridine derivative (Figs. 1 and 2). This result indicates that there is a weak interaction between benzopyranopyridine derivatives and the rare earth ions. Since the excitation spectrum of the rare earth luminescence overlaps appreciably with that of the benzopyranopyridine derivative–rare earth mixed system, a direct excitation of the rare earth should also occur (Fig. 2). However, such an excitation would be

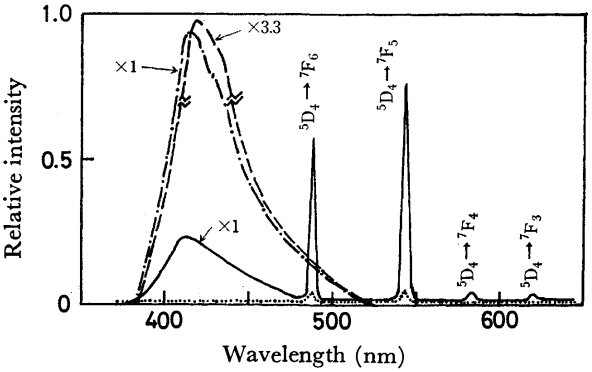

Fig. 1. Luminescence spectra of PBPP (8×10^{-5} M) alone (—), PBPP (8×10^{-5} M)–gadolinium acetate (9×10^{-4} M) system (-·-), PBPP (8×10^{-5} M)–terbium acetate (9×10^{-4} M) system (—), and terbium acetate (9×10^{-4} M) alone (···).

Donor	Excitation wavelength (nm)	Enhancement factor		Triplet level[a]	
		Eu^{3+} (613 nm)	Tb^{3+} (544 nm)	Donor alone (cm^{-1})	Gd^{3+} (cm^{-1})
PBPP	370	40	70	21300	21500
p-MBPP	370	27	32	21200	21400
MPBPP	370	20	55	21100	21600

a) The phosphorescence maxima of the donors.

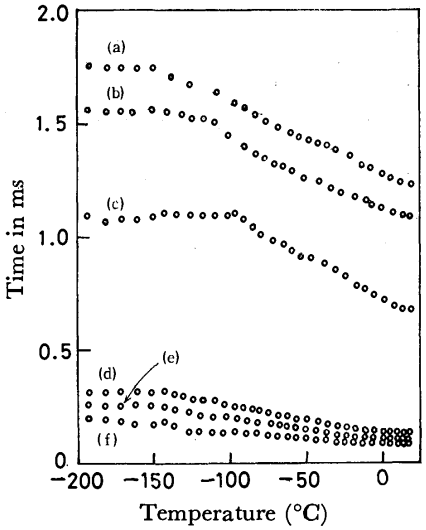

Fig. 3. The lifetimes of terbium $^5D_4$—$^7F_5$ for the *p*-MBPP–Tb (a), PBPP–Tb (b), and MPBPP–Tb (c) systems, and those of the europium $^5D_0$—$^7F_2$ for the *p*-MBPP–Eu (d), PBPP–Eu (e), and MPBPP–Eu (f) systems.

inefficient, because the excitation bands for the luminescence of rare earth ions are weak and very narrow.

As is shown in Fig. 1, the fluorescence intensity of PBPP at room temperature decreases when rare earth ions are present. It is impossible to excite gadolinium ions by energy transfer from either the lowest excited singlet or triplet state of the PBPP, since no transitions in the visible or near-infrared regions exist in the case of gadolinium ions. It can be seen from Fig. 2 that the intensity ratio of the phosphorescence to the fluorescence of the donor at 77 K is much increased by the presence of gadolinium ions. Accordingly, the decrease (about 70%) in fluorescence intensity in the presence of gadolinium ions at room temperature is due to the enhancement in the intersystem crossing (from the lowest excited singlet state to the lowest excited triplet state) of the donor caused by gadolinium ions. The fact that the fluorescence intensity of the donor at room temperature is weakened to about 10% by the presence of terbium (III) ions must be due to the combined effect of the increase in the intersystem crossing of the PBPP caused by terbium ions, with that of the energy transfer from the PBPP to the terbium ions. The excitation of terbium ions by the direct transfer of energy from the lowest excited singlet states of the donors is energetically feasible, but this process would be inefficient because the intersystem crossing of the donors would be enhanced by terbium ions in almost the same degree as by gadolinium ions.

The triplet energy levels of the donors alone and those of the donor–Gd systems at 77 K are listed in Table 1. When the gadolinium ions are present, the triplet levels show a blue shift. The triplet levels of all the donor–Gd systems are nearly 21500 cm^{-1} above the ground energy levels of the donors. The resonance level ($^5D_4$)[6] of terbium ions is 20430 cm^{-1} above the ground level ($^7F_6$). The $^5D_4$ level of terbium ions is, therefore, readily populated by the energy transfer from the triplet state of the donor. Consequently, the luminescence is due to the transition to the ^7F manifold levels from the $^5D_4$ levels of terbium ions. In addition, the intensity ratio of the phosphorescence to the fluorescence decreases with an increase in the concentration of terbium when the donor concentration is kept constant at 77 K, until finally it becomes impossible to observe the phosphorescence spectra of the donors (Fig. 2). From the facts described above, it may be concluded that an energy transfer can be expected from the lowest triplet energy levels to terbium ion levels.

The line emissions due to the transitions from the $^5D_0$ levels of europium and the $^5D_4$ levels of terbium ions sensitized in the mixed systems were so intense that measurements of the lifetimes could be made easily. The observed lifetimes are presented in Fig. 3. Among the mixed systems of the [1]benzopyrano[3,4-*c*]pyridine-4,5(3*H*)-dione derivatives and rare earth ions so far investigated, the duration of the luminescence of the *p*-MBPP–Tb system was found to be the longest.

This work was supported by grants from the Tokyo Electrical Engineering College (T.E.E.C.) Research Fund. The authors wish to express their thanks to Dr. Hiroshi Midorikawa and Dr. Kozo Inuzuka for their kind advice during this study.

The Molecular Motion of Phenyl Groups in Toluene, Diphenylmethane and Triphenylmethane in Solutions of Carbon Tetrachloride by Raman Line Shape Analysis

Hiroyasu NOMURA, Yutaka MIYAHARA, and Shinobu KODA*

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya-shi 464
**Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya-shi 464*

(Received August 12, 1975)

Synopsis. The reorientational correlation times of phenyl groups in the molecules of toluene, diphenylmethane, and triphenylmethane in carbon tetrachloride solutions were measured by the Raman-line-shape analysis. The reorientational relaxation times of the phenyl groups obtained increased in this order: toluene<diphenylmethane<triphenylmethane as a result of the increase in the mutual interaction among phenyl groups themselves in the molecule.

In the Raman spectroscopic study of the molecular dynamics in the liquid state, the most important model-independent quantity obtainable is the reorientational correlation time, τ(OR). When a molecule has a symmetric top, the analysis of the isotropic and anisotropic Raman-line shapes of the nondegenerate vibrations uniquely determines the reorientational correlation time for the tumbling motion of the molecule.

In our previous papers[1-3] it has been shown that the reorientational correlation time of a molecule obtained is an important quantity intimately related to the inter- and intramolecular interaction.

In the present note, the reorientational correlation times of phenyl groups in the molecules of toluene, diphenylmethane, and triphenylmethane dissolved in carbon tetrachloride were determined by Raman-line shape analysis, and the mutual interaction among phenyl groups in the molecule was discussed.

The apparatus used consisted of an argon ion laser (800 mW at 4880 Å) produced by the Coherent Radiation Co. Ltd., and a laser Raman spectrometer of the JRS-Ul type of JEOL, Ltd., Japan. The toluene and carbon tetrachloride used were commercial products of spectra-grade reagents, while the diphenylmethane and triphenylmethane were extra-pure-grade reagents supplied by the Tokyo Kasei (Chemical) Industrial Co., Ltd. The solutions used for the measurements contained such amounts of the solutes that the concentration of phenyl groups was 2 mol per liter of solution.

In order to obtain the orientational correlation times, the Raman-line shape of the ν_2 fundamental of the phenyl group was analyzed. The Raman spectrum was observed at 90 °C with respect to the linearly polarized incident light. With $I_{\parallel}(\omega)$ and $I_{\perp}(\omega)$ representing the strong and weak components of the scattered light, one can write,

$$I_{\parallel}(\omega) = I_{\mathrm{isot}}(\omega) + 4/3 I_{\mathrm{anis}}(\omega) \quad (1)$$

$$I_{\perp}(\omega) = I_{\mathrm{anis}}(\omega) \quad (2)$$

$$\rho_s = \frac{I_{\perp}(\omega)}{I_{\parallel}(\omega)} \quad (3)$$

where ρ_s is the depolarization ratio. $I_{\mathrm{isot}}(\omega)$ represents the intrinsic vibrational line shape, and $I_{\mathrm{anis}}(\omega)$, a convolution of the vibrational line shape and the orientational spectrum.

The line shape of $I_{\parallel}(\omega)$ and $I_{\perp}(\omega)$ of the ν_2 (a_{1g}) fundamental (1002 cm^{-1}) obtained showed Lorentz-type cruves. This fact shows that the vibrational and the rotational motions of the phenyl group are not coupled. We can write;

$$\omega_{1/2}(\mathrm{anis}) = \omega_{1/2}(\mathrm{isot}) + \omega(\mathrm{or}) \quad (4)$$

where the $\omega_{1/2}$ terms are the half-width of the respective line shapes.

In order to eliminate the effect of the slit-width on the shape of the spectrum, the half-width of the spectrum was plotted against the slit-width, the true half-width was then obtained by extrapolating to zero slit-width.

The reorientational correlation time is obtained by means of;

$$\tau(\mathrm{OR})^{-1} = 2\pi c\omega(\mathrm{or}) \quad (5)$$

where τ(OR) is the reorientational correlation time, and c, the velocity of light. The details of the experimental procedures and the data reductions have been reported previously.[1-2]

Table 1.

	$\rho_s \times 10^{-2}$	$\omega_{1/2}$ (isot) cm^{-1}	$\omega_{1/2}$ (anis) cm^{-1}	ω (or) cm^{-1}	τ (OR) $\times 10^{-12} s^{-1}$
Toluene	1.13	1.72	3.56	1.84	2.88
Diphenylmethane	2.32	1.52	2.47	0.95	5.58
Triphenylmethane	3.15	2.37	2.66	0.29	18.6

The experimental results obtained are summarized in Table 1, where the half-width and the correlation time of the reorientational motion are listed in the last two columns. As may be seen in Table 1, the reorientational correlation time increase with an increase in the number of phenyl groups in a molecule; one in toluene, two in diphenylmethane, and three in triphenylmethane. Since the concentration of phenyl groups in the solutions was kept constant, this change in correlation time can be ascribed to the change in the degree of mutual interaction among phenyl groups themselves in a molecule.

The reorientational correlation time of phenyl groups in the dibenzyl molecules dissolved in carbon tetrachloride was 3.80×10^{-12} s^{-1},[2] as has been reported previously. The reorientational correlation time of the phenyl groups in the diphenylmethane molecules is a little larger than that in the dibenzyl molecules. This shows the existence of some interaction between the

phenyl groups themselves in the diphenylmethane molecules, which hinders the orientational motion of the phenyl groups to some extent.

In the triphenylmethane molecules, the rotational motion of phenyl groups are much more strongly hindered by the strong interaction among phenyl groups themselves, such as the steric hinderance and π-coupling. For this reason, the value of the reorientational correlation time of triphenylmethane increased to as much as three times that of free toluene molecules in the solution.

Lumiflavin-sensitized Photooxygenation Accelerated by Adenine. II. The Photolysis of ^{14}C-labeled Reactants

Akio YOSHIMURA and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received August 26, 1975)

Synopsis. Radioactive tryptophan, histidine, methionine, and guanine were photolyzed in the presence of lumiflavin either with or without adenine, and the reaction products were compared chromatographically. Adenine accelerated these lumiflavin-sensitized photooxygenation reactions, and no effect of adenine on the reaction products was shown.

In a previous paper,[1] it was reported that the lumiflavin-sensitized photooxygenation of indoles is greatly accelerated by the addition of adenine when the reactants are present in very low concentrations. At that time, fluorometry was succesfully used as a highly sensitive method to follow the reaction; however, there remained an open question of whether or not adenine simply accelerates the oxygenation of indoles without altering the basic pattern of the reaction. In the present work, the effects of adenine on the lumiflavin-sensitized photooxygenations of tryptophan, histidine, methionine, and guanine, and on the reaction products have been examined by the use of ^{14}C-labeled reactants.

Experimental

The lumiflavin was prepared as has previously been described.[1] *dl*-Tryptophan-3-^{14}C (3.76 mCi/mmol), *l*-histidine-^{14}C (U) (216 mCi/mmol), and *l*-methionine-1-^{14}C (5.81 mCi/mmol) were purchased from the Daiichi Pure Chemicals Co., While guanine-8-^{14}C hydrochloride (5.4 mCi/mmol) was obtained from the New England Nuclear Co.

The photolysis was carried out as has previously been described (at 435.8 nm and 30 °C).[1] After the paper chromatography of the reaction mixtures on Toyo Roshi No. 51A paper, the autoradiograms were prepared by exposing Sakura Industrial X-ray film (type N) (8.4×30.5 cm) for several weeks. The radiochemical counting was carried out using a liquid-scintillation counter (Beckman LS-250) for sections of the paper-chromatograms in 5-ml solutions of 2,5-diphenyloxazole in toluene (4 g/l), or conventionally using a gas-flow counter (Aloka TRM-1) with a paper-chromatogram scanner for each strip of the chromatograms. The initial concentration of tryptophan-3-^{14}*C* was determined by fluorometry,[1] while the other ^{14}C-labeled reactants were measured by the use of the liquid-scintillation counter.

Results and Discussion

The reaction mixtures of the lumiflavin-sensitized photooxygenation of 10 μM tryptophan-3-^{14}*C* in the absence and in the presence of adenine were developed on filter paper with 1-butanol–acetic acid–water (4:1:2). The autoradiograms for the samples at different reaction periods (from 20% to more than 90% decomposition) showed that tryptophan decomposed to several reaction products and that the patterns of the products were not changed with the degree of the decomposition. Therefore, Fig. 1 shows the autoradiograms for the reaction mixtures in which the photolysis was almost completed in the presence and in the absence of adenine. In both chromatograms, six spots of the reaction products were observed; no difference was detected between the patterns of these reaction products with and without adenine. Similar results were obtained when 1-butanol saturated with water was used as the developing solvent. Thus, it was concluded that adenine does not alter the final products in spite of its great accelerating effect on the reaction rate. At pH 8.0, where the reaction quantum yield was about twice as much as that at pH 7.2, the photoproducts also consisted of plural species which were not altered whether adenine was present or not.

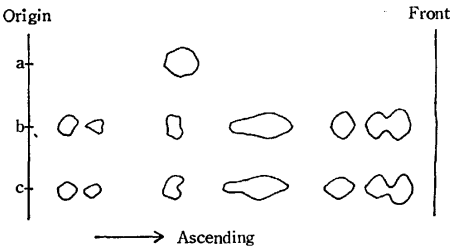

Fig. 1. Autoradiograms for the photoproducts of 10 μM tryptophan-3-^{14}*C* sensitized by 2.5 μM lumiflavin in the absence and presence of adenine.
a) Adenine 0. Before irradiation.
b) Adenine 0. Irradiation 280 min (92% decomp.).
c) Adenine 0.2 mM. Irradiation 82 min (98% decomp.).

In the previous work,[1] the reactions were followed by fluorometry, by which indoles were analyzed with high accuracy even in micromolar concentrations without any interference from adenine. The radioactive-iso-

(8.0 μM)	150	0.56	0.05

Lumiflavin 2.5 μM, phosphate buffer 0.05M, at pH 7.2.
a) Adenine 0.2 mM. b) At pH 6.9.

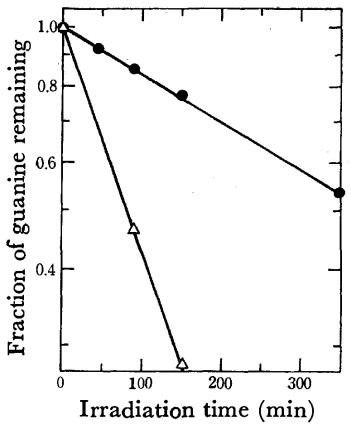

Fig. 2. First order plots for the photooxygenation of 8.0 μM guanine-8-^{14}C sensitized by 2.5 μM lumiflavin in 0.05 M phosphate buffer at pH 6.9.
Adenine: ● 0 mM and △ 0.2 mM.

tope-tracer method is good for the kinetical treatment of the reaction as well as for the product analysis. Therefore, the effect of adenine on the photolysis of nonfluorescent ^{14}C-labeled reactants under dilute conditions was examined. Among the nonfluorescent amino acids which undergo photodynamic action, histidine and methionine were chosen; the effect of the addition of adenine on the lumiflavin-sensitized photooxygenation of these reactants was investigated. The results are summarized in Table 1. The accelerating effect of adenine was observed as in the case of tryptophan.

Besides several amino acids, guanine also undergoes photodynamic action.[2] It was similarly examined whether or not the photodecomposition of this purine derivative, adenine. Since guanine is hard to dissolve in water (5 mg/l), guanine-8-^{14}C hydrochloride was first dissolved in 0.1 M hydrochloric acid and then diluted. The pH value of the sample solution containing 8.0 μM guanine and 2.5 μM lumiflavin was adjusted to 6.9 with a 0.05 M phosphate buffer. The accelerating effect of the addition of 0.2 mM adenine on the photosensitized decomposition of guanine was also observed on the autoradiograms, as is shown in Fig. 2 and Table 1. When guanine was decomposed by equal quantities of both solutions with and without adenine, the effect of adenine on the reaction products was also examined. Successive reactions were observed to occur, but the identity of the products was observed at every stage of the reaction.

On the basis of the results mentioned above, it was concluded that the addition of adenine accelerates the lumiflavin-sensitized photooxygenation of not only tryptophan, but also of many reactants, and that it does not alter the reaction type. Similarly, the enhancement of photodynamic action may take place *in vivo*, because flavin dyes and adenine are general substances in bioorganisms.

The authors wish to express their gratitude to Dr. Sadaaki Komura for his help in the measurements of the radioactivity using the apparatus of the Institute for Protein Research, Osaka University.

Chromatography of Inorganic Ions on TEAE-cellulose Layers in Hydrochloric Acid Media

Rokuro KURODA, Toshiaki TAKAHASHI, and Koichi OGUMA

Laboratory for Analytical Chemistry, Faculty of Engineering, University of Chiba, Yayoi-cho, Chiba 280

(Received August 13, 1975)

Synopsis. The ion-exchange behavior of inorganic ions on TEAE-cellulose was investigated in hydrochloric acid media with and without methanol. Adsorbabilities are low relative to those on strongly basic ion-exchange resin, varying with acid concentration in line with gradual building-up of chlorocomplexes.

Only fragmentary information is available on paper-[1–8] and thin-layer[9]-chromatography of inorganic ions on a strongly basic anion-exchange cellulose with a quarternary ammonium group. Recently we have investigated the adsorption behavior of about 15 metal ions on TEAE-cellulose columns[10] in hydrochloric acid media, revealing markedly weak preference of metal ions to TEAE-cellulose relative to a strongly basic ion-exchange resin. The work was extended in order to obtain individual adsorption characteristics of a number of metal ions on TEAE-cellulose in hydrochloric acid as well as methanol–hydrochloric acid media. The thin-layer-chromatographic method was used throughout, which served to distinguish small differences in weak adsorption among metal ions.

Experimental

Triethylaminoethylcellulose (Serva, Heidelberg, G. F. R., 0.68 meq/g, for column use), a strong base anion-exchange cellulose, was used in the chloride form. Twenty g of swollen TEAE-cellulose was made into a slurry with 65 ml of deionized water, and spread over five 20×20 cm glass plates 500 μm thick. After being dried at 40 °C for several hr it was stored in a desiccator over a saturated potassium bromide solution. Metal ions[11] (1 μl of solution) were developed by the ascending technique for a distance of 15 cm in a rectangular glass tank with ground glass lid, after 1 hr equilibration. They were detected as described previously.[12]

Results and Discussion

In Fig. 1 are illustrated the R_f values of 43 metal ions as a function of hydrochloric acid concentration. The R_f trends against hydrochloric acid concentration are similar to those reported by Lederer and Ossicini[13] for DEAE- and AE-cellulose papers. Chlorocomplexes of noble metals and oxyacids including V(V), Se(IV), Cr(VI), Mo(VI), W(VI), and Re(VII) are adsorbed on a TEAE-cellulose column to a great extent from 0.001 M HCl, showing that K_d(weight distribution coefficient)>100.[10] However, because of the strong preference of chloride ions to ion-exchange sites, the adsorbabilities decreased rapidly with increasing concentration of hydrochloric acid; K_d values for several ions in 0.1 M HCl were Se(IV)<2, Mo(VI) 20, Pd(II) 160, Re(VII) 20, Ir(IV)>100, Pt(IV)>100 and 25 (two bands appeared), Au(III) 80, Hg(II) 90, being mostly insufficient to allow effective column separation. From 6 M HCl these metals were adsorbed with $K_d \leq 10$, being eluted from a 1 g TEAE-cellulose column actually with no adsorption. The column elution study based on the 1 g TEAE-cellulose column[10] did not distinguish the difference in adsorption among *e.g.* Ni(II), Se(IV), Zn(II), and Te(IV) over the 0.10—6 M HCl concentration range, but the tlc chromatograms clearly demonstrate their differences (Fig. 1).

The adsorption of Zn(II), Ga(III), Cd(II), In(III), Sn(IV), and Te(IV) increases with increasing concentration of hydrochloric acid. These metals exhibit a maximum adsorption on a strongly basic resin in the range ~2 to ~8 M HCl.[14] On the other hand, Pd(II), Ag(I), Re(VII), Pt(IV), Au(III), Hg(II), and Bi(III) are adsorbed tightly on the strongly basic resin,

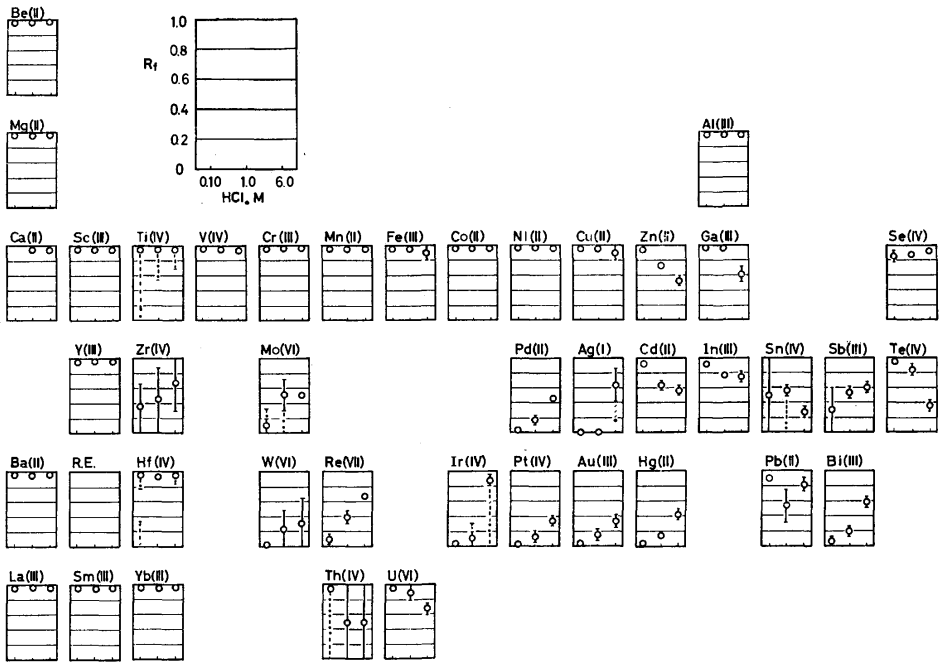

Fig. 1. R_f values of metals on TEAE-cellulose layer (500 μm) in hydrochloric acid media.

showing decreasing adsorption with increasing hydrochloric acid concentration.[14] All these metals show a similar decrease in their adsorption on TEAE-cellulose with increasing hydrochloric acid concentration. In hydrochloric acid media the distribution curve of metals on the strongly basic resin can be described in terms of the gradual building-up of cationic, neutral, and anionic chlorocomplexes with increasing hydrochloric acid concentration, corresponding to positive, zero, and negative slopes of the adsorption curve (log distribution coefficient *vs.* HCl concentration), respectively.[15,16] Closely related adsorption trends, observed in the TEAE-cellulose–hydrochloric acid system, suggest that the dominant factor controlling the R_f values is ion-exchange, but not the partition, which sometimes dominates to control the distribution of metals in chromatography involving the ion-exchange cellulose.[17]

We have also examined the adsorption behavior of metals in methanol–hydrochloric acid media (1 : 1) as a function of hydrochloric acid concentration (1.0, 6.0, and 11.2 M). The R_f values of the metals are summarized in Table 1. Adsorption trends do not change except for Zn(II) and Cd(II), which indicate the decrease in adsorption with increasing concentration of hydrochloric acid. Actually, polar methanol considerably enhances the formation of anionic chlorocomplexes of these metals.

Analytical separation in aqueous hydrochloric acid and mixed methanol–hydrochloric acid media is quite feasible. With 1 M HCl the following separation was accomplished: Hg(8—17)-Cd(58—64)-Zn(69—75); Bi(15—24)-Sb(52—59)-In(72—81)/or Se(77—92); Au(11—16)-Cd(55—65)-Cu(90—100). With 6 M HCl elution the separations Te(35—43)-Cd(56—63)-In(69—78); Sn(26—33)-Cd(57—67)/or Sb(53—63)-In(76—79); Pt(31—43)-Mo(45—51)-Re(65—71); U(57—70)-La(90—100)/or Hf(94—100) were successful. By elution with methanol–6 M HCl (1 : 1) Ba(30—41)-Ca(64—79)-Be(100); Pd(16—27)-Cu(57—66)-Ni(72—100); Pt(12—21)-Au(28—34)-Cu(57—64)-Ni(72—100); Hg(21—28)-Zn(31—40)-Cu(58—66)-Ni(74—100) were separated, respectively. Pt(15—32)-Au(35—43)-Co(46—55)-Ni(69—83); Zr(7—33)-Y(45—58)-Sc(58—71); U(20—30)-Y(43—58)-Ti(58—76); Zr(7—31)/or Th(17—46)-Ti(48—77); Co(46—57)-Mn(69—86) were separated by elution with methanol–11.2 M HCl (1 : 1). The oxidation states of metals separated are the same as listed in Table 1. The values in parentheses indicates the range of R_f ($\times 100$).

The Preparation and Properties of Some Triorgano-(oxinato)antimony Hydroxides

Yoshikane KAWASAKI

Department of Petroleum Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

(Received September 25, 1975)

Synopsis. Some new triorgano(oxinato)antimony hydroxides, $R_3Sb(L)OH$ (R=CH_3, C_6H_5 and *p*-$CH_3C_6H_4$: L=Ox, 2-Me-Ox, and 5-Cl-Ox), have been prepared, and the UV, IR, and NMR spectra of these compounds have been measured. These compounds have a hexa-coordinate configuration around antimony. The effects of the hydroxyl group on the IR and NMR spectra are discussed.

The preparation of the $R_3Sb(OH)X$ type of compounds have been reported by several workers.[1-8] These compounds, however, have been characterized only by chemical analysis, and no IR spectral data such as the O–H stretching band have been reported. Many authors[9-14] have reported that triorganoantimony dihalides, on hydrolysis or on treatment with appropriate silver salts, form stable oxybistriorganoantimony compounds of the $(R_3SbX)_2O$ type. Therefore, there is considerable confusion in the literature regarding the structure of these oxy compounds in the solid state *i.e.*, as to whether they should be regarded as hydroxy compounds, $R_3Sb(OH)X$, or as oxides, $(R_3SbX)_2O$. Doak *et al.*[12] have concluded that compound of the $R_3Sb(OH)X$ type probably do not exist in the solid state.

In the present paper we wish to report on the preparation and spectral data of some new triorgano(oxinato)-antimony hydroxides, $R_3Sb(L)OH$.

Experimental

Preparation of $R_3Sb(L)OH$ (R=CH_3, C_6H_5, and p-$CH_3C_6H_4$; *L=Ox, 2-Me-Ox* and 5-Cl-Ox**).* All of these complexes were prepared in an essentially identical manner, so that only one typical procedure will be given. A benzene solution (70 ml) of trimethylantimony dibromide (10 mmol) was added to sodium methoxide (20 mmol) in methanol (about 10 ml), and the mixture was heated at reflux for 30 min. After distilling off a portion of the solvent, the precipitated sodium bromide was removed by filtration. To the filtrate we then added 8-quinolinol (10 mmol) in benzene (50 ml), and the mixture was heated at reflux for 1 h; the solvent was then removed by distillation under reduced pressure. A mixture of acetone (20 ml) and water (5 ml) was added to the residual, highly viscous yellow liquid. A yellow solid product was obtained by scratching the vessel with a glass rod. The complex was purified by recrystallization from acetone. The analytical data for this and similar compounds are shown in Table 1.

TABLE 1. ANALYTICAL DATA OF TRIORGANO-(OXINATO)ANTIMONY HYDROXIDE

* 2-Methyloxine.
** 5-Chlorooxine.

Spectral Measurements and Analysis of the NMR Spectra. The UV spectra were recorded on a Hitachi model 124 spectrometer with 1-mm quartz cells. The absorption maxima measured in methylene chloride are shown in Table 2. The IR spectra were measured on a Hitachi model 225 grating spectrometer in Nujol mulls or a 5 wt% methylene chloride solution. The NMR measurements were made with a JEOL model JNM-PS-100 spectrometer operating at 100 MHz. The chemical shifts were measured relative to tetramethylsilane as the internal standard. Methylene chloride was used as the solvent. The spectra for the 2-, 3-, and 4-protons of the oxinato ligand were analyzed as a first-order system, and those for the 5-, 6-, and 7-protons as an ABC system by using the method reported by Reilly *et al.*[16] The calculations were carried out on a NEAC 2200 model 700 computer at the Computer Center of Osaka University.

Results and Discussion

The absorption maxima of the longest wavelength for the triorgano(oxinato)antimony hydroxides are found in the region where the chelation of the oxinato ligand is expected.[17-19] From these result, it seems almost certain that the antimony atom is hexacoordinate, as has been reported for triorgano(oxinato)antimony halides.[20,21] The absorption maxima for the triaryl(oxinato)antimony hydroxides appear at longer wavelengths than those for the trimethylantimony analogs. Similar bathochromic shifts upon the substitution of methyl group by aryl groups have been noted for triorgano-(oxinato)antimony halides.[15,20,21]

As has been shown in Table 2, in the solid state all the triorgano(oxinato)antimony hydroxides gave one very broad band, in some cases there was also an additional sharp band in the O–H stretching region. The broad band indicates a hydrogen-bonded hydroxyl group, and the sharp one, a free hydroxyl group. Two similar O–H stretching bands, one sharp and one broad, have been reported for tetraphenylantimony hydroxide.[22] In a methylene chloride solution, triorgano(oxinato)antimony hydroxides show only one sharp O–H stretching band at a somewhat higher wave number than is found for these compounds in the solid state. This result may be attributed to the absence of hydrogen bonding in the methylene chloride solution.

TABLE 2. UV AND IR DATA OF TRIORGANO(OXINATO)ANTIMONY HYDROXIDE

$R_3Sb(L)OH$ R	L	λ_{max}[a] (nm)	ν (O–H) CH_2Cl_2	ν (O–H) solid	ν (Sb–O) solid	ν (Sb–O)(Ox) solid

CH_3–Sb	1.84[d]	1.91[d]	2.07[d]	1.64[d]	1.42	—	—

a) Coupling constants, J_{23}, J_{24}, J_{34}, J_{56}, J_{57} and J_{67}, were found to be 4.2±0.2, 1.5±0.2, 8.0±0.2, 8.1±0.2, 1.1±0.2 and 7.6±0.2 Hz, respectively. b) Sodium oxinate in HMPA (Ref. 26). c) 8-Quinolinol hydrochlordie in HMPA (Ref. 26). d) Ref. 15.

The frequency of the O–H stretching band for triorgano(oxinato)antimony hydroxides is not affected to a large extent by the substituent on the oxinato ligand, but the value is somewhat small for trimethyl(oxinato)antimony hydroxide.

A strong but somewhat broad band in the region of 540—570 cm^{-1} is assigned to the Sb–O stretching band between the hydroxyl group and the antimony atom, because triorgano(oxinato)antimony complexes, $R_3Sb(Ox)X$, X=NO_3, Cl, Br, and OAc show no band in the region. The frequencies observed are almost the same as those assigned to the Sb–O stretching bands in trialkyl-bis(ethoxy)antimony,[23] $R_3Sb(OC_2H_5)_2$ (562, 547, 545, and 540 cm^{-1} for R=CH_3, C_2H_5, n-C_3H_7, and n-C_4H_9 respectively), and $(SbF_5OH)^-(NR_4)^+$ (560 and 554 cm^{-1} for R=C_2H_5 and n-C_4H_9 respectively,[24] but the values are larger than that reported for tetraphenylantimony hydroxide (528 cm^{-1}). [22]Zingaro *et al.*[25] estimated the Sb–O stretching frequency to be 550 cm^{-1} by using Gody's rule.

The Sb–O stretching bands between the oxinato group and the antimony atom for some trimethyl(oxinato)antimony complexes, $(CH_3)_3Sb(Ox)X$, are found to be 525, 520, 520, 516, and 508 cm^{-1} for X=NO_3, Cl, Br, OAc, and OH respectively. The corresponding value for tetramethyl(oxinato)antimony has been reported to be 497 cm^{-1}.[20] The Sb–O bond in the hydroxide complex, therefore, is weaker than those in the nitrate and halide complexes.

Except for the 2-proton of trimethyl(oxinato)antimony acetate, the chemical shifts of the ring protons show a general drift of the low-field shift in the order: NO_3> Cl≳Br>OAc>OH. This order is the same as that for the high-frequency shifts of the Sb–O stretching band between the oxinato group and the antimony atom. These results may indicate that the electron-withdrawing effect of the hydroxyl group is smaller than that of the nitrato group and the halogens.

We wish to express our hearty thanks to Professor Rokuro Okawara for his continuous encouragement throughout this study.

Ligand Isotopic Exchange Kinetics of Tris(acetylacetonato)-titanium(IV) Perchlorate in Acetonitrile

Masato NISHIZAWA, Hiroaki KIDO, Isamu KINOSHITA, Yoshikuni SOMA,* and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai, 980

(Received December 9, 1975)

Synopsis. The rate of isotopic exchange between tris(acetylacetonato)titanium(IV) ions and acetylacetone-$^{14}C_3$ in enol form is measurable at −20 °C in acetonitrile. Water, free ligand and a strong acid catalyse the exchange.

The tris(acetylacetonato)titanium(IV) ion $[Ti(acac)_3]^+$ has been known as salts of various anions[1-3] and the absorption spectrum examined.[4,5] Its dynamic behavior is, however, not known.[6] We have examined the isotopic exchange of this complex ion with free acetylacetone (Hacac) labelled with ^{14}C in acetonitrile and obtained some information concerning the kinetics.

Experimental

Materials. *The Complex Perchlorate*: Dichlorobis(acetylacetonato)titanium(IV)[7] (3.9 g) was dissolved in chloroform (20 ml), mixed with ethanol (10 ml), concentrated to *ca.* 10 ml, and trented with barium perchlorate trihydrate (4.8 g) in ethanol (15 ml). The precipitate was filtered off, washed with chloroform (60 ml) and the filtrate and washings were concentrated to 20 ml together with Hacac (15 ml) at 30 °C and 50 mmHg. Addition of hexane (10 ml) gave $[Ti(acac)_3]ClO_4$, which was recrystallized by dissolving in chloroform and Hacac, and adding hexane. The orange needles decomposed at 180 °C. Anal. Found: C, 40.62; H, 4.83%; Calcd for $C_{15}H_{21}O_{10}ClTi$: C, 40.51; H, 4.76%. IR spectrum in Nujol mull gave a very similar pattern to those of $[Si(acac)_3]ClO_4$[8] and $[Ge(acac)_3]ClO_4$.[9] NMR pattern in deuterochloroform coincided with that in literature.[10] This method gives a higher yield (*ca.* 60%) and a purer product than solvent extraction[3] and direct synthesis from titanium (IV) sulfate and Hacac.[10]

Other Reagents: Acetylacetone-$^{14}C_3$(2,4-pentenedione-1,3,5-$^{14}C_3$) was prepared as in literature.[11] Acetonitrile (AN) was refluxed with phosphorus pentoxide and distilled. The water content was 3 to 5×10^{-3} M. Hexane was washed with sulfuric acid and alkali solution, dried with phosphorus pentoxide and distilled.

Measurements. The UV spectrum was recorded with a Hitachi 323 Spectrometer in the presence of varying amounts of water ($\leq$0.1 M). The radioactivity was recorded with a Unilux IIA of Nuclear Chicago Co., in anisole containing 0.4% *p*-terphenyl and 0.01% POPOP. The enol/keto ratio of free Hacac was determined from UV absorption at 273 nm.[12]

Kinetic Runs. The complex solution ($\simeq10^{-2}$ M) in AN (5 ml) and Hacac-^{14}C ($\simeq10^{-2}$ M) in AN (5 ml) were placed in the two sections of a glass-stoppered test tube with a branched side bottom. The tube was kept in a thermostat at −21.3 °C and both solutions mixed. One ml portions were taken out at appropriate time intervals and poured into chilled hexane (5 ml, −50 °C) in a thin test tube within 10 s. (The UV spectra showed that only the enol tautomer of free Hacac was extracted into the hexane layer while the AN solution flows down.). After 30 s 2 ml portions were pipetted out of the middle part of hexane layer. One ml was dissolved in the anisole scintillator (14 ml) for β-activity counting. The other one ml was diluted with hexane (9 ml) and the extinction measured at 273 nm to find the concentration of Hacac. The water content of the AN solution was determined in the reaction tube by Karl Fischer titration.

Results and Discussion

Absorption Spectrum. The complex perchlorate has three absorption peaks in AN at 364, 257, and 225 nm with log ε values 3.91, 4.34, and 4.30, respectively. When the water content in the solution was $\simeq10^{-3}$ M (the same order as the complex in a 0.1 mm thick cell), the peak heights decreased little (by *ca.* 2% within 30 min.). When the water concentration was $\simeq10^{-1}$ M in $\simeq10^{-5}$ M complex solution, the absorbancy at 364 and 225 nm decreased rapidly, and after several minutes two shoulders were observed with log ε *ca.* 3.4 and 3.6, respectively. Simultaneously a new shoulder appeared at $\simeq$270 nm with log ε *ca.* 3.9, which seemed to be due to free Hacac. The peak at 257 nm gave only a small shift to 259 nm and a very little decrease in absorbancy. When a large excess of Hacac ($\simeq10^{-1}$ M) was added, the log ε at 364 nm increased and the pattern gradually approached that of freshly prepared solution. It seems the change in absorption in the presence of overwhelming amount of water is caused by partial hydrolysis of the complex. The absorption data given in literatures[4,5] may represent those of partially hydrolysed products.

Isotopic Exchange. The experimental results were calculated by McKay's formula,

$$R = -2.3[3ab/(3a+b)][\log(1-F)/t] \quad (1)$$

where a and b are the concentrations of the complex and free Hacac, respectively, and t is the lapse of time. F is the fraction of reaction and is known from $(x_0-x_i)/(x_0-x_\infty)$, where x_0, x_i, and x_∞ are the specific counting rates at time 0, t and infinity, respectively.

Acetylacetone is in tautomeric equilibrium and *ca.* 67% is in enol form in AN at −10 °C. The interchange between keto and enol form is much slower (*ca.* $10^{-5}s^{-1}$) than the present isotopic exchange. The R can be calculated in two ways by considering the participation of either the enol tautomer or total Hacac in the exchange. The experimental x_∞ values come in between the values calculated in the two ways. The x_i *vs.* t diagrams are simulated by considering that the keto tautomer exchanges with the ligand at a much smaller

* Present address: Research Institute, Mitsui Petrochemical Co. Ltd., Iwakuni Yamaguchi-ken.

rate than the enol does (*e.g.* in 0.02 M complex solution containing 0.03 M water and 0.015 M Hacac, the ratio R_{enol}/R_{keto} is *ca.* 30.). Hence the following discussion is made on the assumption that only the enol form exchanges with the ligand. McKay plots made in this way gave straight lines at the initial stage of exchange ($F<$*ca.* 0.5). The UV absorption of the reaction mixture remained unchanged for at least 100 min. These facts indicate that the R values thus calculated give rates of the following isotopic exchange.

$$[Ti(acac)_3]^+ + Hacac(enol)^* \rightleftharpoons [Ti(acac^*)(acac)_2]^+ + Hacac(enol) \quad (2)$$

Attempts have been made to elucidate the influence of various factors upon R. However, only limited information was obtained because of experimental difficulty, especially in adjusting the water concentration, and the discussion is very much limited.

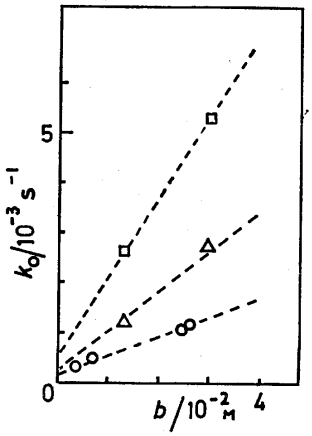

Fig. 1. Dependence of the exchange rate constant on the concentration of Hacac in enol form.
$[H_2O]$=○ 0.016, △ 0.037, □ 0.079 M.

When a was changed as 1.0, 2.0, and 3.4×10^{-2} M at given concentrations of Hacac (0.029 ± 0.001 M) and water (0.016 ± 0.001 M), R increased linearly, and the quotient R/a was almost equal, *i.e.* 1.6, 1.5, and 1.3×10^{-3} s^{-1}, respectively. The quotient k_0 can be the measure of exchange rate. Figure 1 shows the plot R *vs.* b at given concentrations of water. At a water concentration 0.016 ± 0.001 M, the plot is linear. Not many plots were obtained at higher concentrations of water, but both the gradient and the intercept seem to increase. Hence a kinetic formula, Eq. 3 may be appropriate,

$$R = k_0 a = a(k_1+k_2[H_2O]+k_3 b+k_3'b[H_2O]) \quad (3)$$

where b is the concentration of free Hacac in enol form. The dotted lines in Fig. 1 are those calculated on best fitted k values in Eq. 3; *i.e.* $k_1=(1.4\pm0.6)\times10^{-4}$ s^{-1}, $k_2=(5.0\pm1.5)\times10^{-3}$ M^{-1}s^{-1}, $k_3=(7.9\pm2.6)\times10^{-3}$ M^{-1}·s^{-1} and $k_3'=(1.9\pm0.1)$ M^{-2}s^{-1} at −21.3 °C. They do not deviate much from the observed plots, and Eq. 3 can be an adequate expression of the kinetics.

The exchange was catalysed by a strong acid (Fig. 2). As the concentration of trichloroacetic acid increases, k_0 increases and then approaches constant.

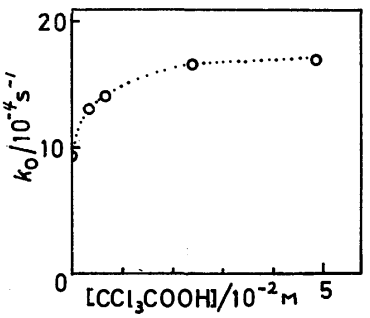

Fig. 2. Influence of the concentration of trichloroacetic acid upon the exchange rate constant.
b=0.024 M $[H_2O]$=0.012 M at −21.4 °C.

Further increase in water and acid concentration caused decomposition of the complex. The saturation may be due to limited formation of H_3O^+ from the acid and water (0.012 M) rather than to the saturation of protonation of complex cation. Weak acids fail to give such a catalytic action, and the influence of Hacac concentration in Eq. 3 cannot be acid catalysis.

It is seen that the isotopic exchange can proceed through several reaction routes. The hydrolysis of $[Ti(acac)_3]^+$ under the given experimental conditions is much slower ($\simeq10^{-5}$ s^{-1} at +20 °C) than the isotopic exchange and the reaction paths should be different. In the k_3 and k_3' path, an associative contribution of enolic Hacac is feasible in the rate-determining step, whereas k_1, k_2 and acid-catalyzed reaction path may involve dissociative rate-determining step. Further elucidation of the reaction mechanism, however, requires more detailed kinetic studies by more sophisticated methods.

The results, however, provides the first example of kinetic studies of intermolecular substitution reaction of titanium(IV) compounds, and it was made clear that $[Ti(acac)_3]^+$ undergoes isotopic exchange much faster than $[Si(acac)_3]^+$ and $[Ge(acac)_3]^+$ do, and the rate is similar to that of $[Sn(acac)_3]^+$.[13]

The Photo-induced Diels-Alder Reaction of 2-Cycloocten-1-one and 2-Cyclohepten-1-one

Hiraku SHINOZAKI, Susumu ARAI, and Masaru TADA

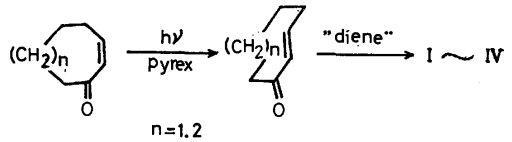
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

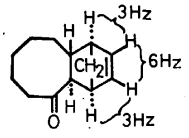
(Received September 24, 1974)

Synopsis. *trans*-2-Cycloocten-1-one and *trans*-2-cyclohepten-1-one, which are supposed to be formed by the ultra-violet irradiation of *cis*-2-cycloocten-1-one and *cis*-2-cyclohepten-1-one, give Diels-Alder addition products with cyclopentadiene and isoprene.

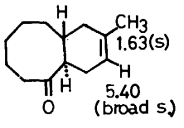
It is well established that the irradiation of a medium ring cycloalkenone, such as 2-cycloocten-1-one and 2-cyclohepten-1-one, induces a *cis-trans* isomerization.[1-3] The *trans* isomer of these enones is highly strained and has been reported to enter into a Diels-Alder addition with some dienes. This facile cycloaddition provides a promising method of constracting a carbocyclic system with a medium ring. Previously *trans*-2-cyclohepten-1-one was found to undergo a photochemically-induced cycloaddition with cyclopentadiene.[1] In this paper we wish to extend the scope of the photo-induced Diels-Alder addition of *trans*-2-cycloocten-1-one and *trans*-2-cyclohepten-1-one with dienes.

The irradiation of a mixture of *cis*-2-cycloocten-1-one and an excess amount of cyclopentadiene or isoprene gave two adducts, I and II, in yields of 66 and 58% respectively. In these runs a large excess of dienes was used to suppress the dimerization of the enone. In the same manner, *cis*-2-cyclohepten-1-one gave the Diels-Alder adducts, III with cyclopentadiene[1,4] and IV with isoprene, in yields of 95%. The 2-cyclohepten-1-one disappeared within 1 hr, while 2-cycloocten-1-one required a longer reaction period—2 hr with cyclopentadiene and 4.5 hr with isoprene. This difference in the reactivity must be a reflection of the strain energy in *trans*-2-cyclohepten-1-one and *trans*-2-cycloocten-1-one.

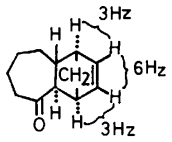




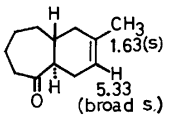
I



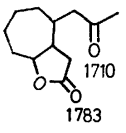
II



III



IV



V

The adducts with 2-cycloocten-1-one were difficult to purify so as to give satisfactory results on elemental analysis due to the *retro*-Diels-Alder reaction which occurred on distillation or gas chromatography. High resolution mass spectrometry, however, defined the molecular formula of the adducts. The mass spectra of these adducts showed base peaks at $m/e=110$ and 124 due to 2-cyclohepten-1-one and 2-cycloocten-1-one cations formed by the fragmentation of the *retro*-Diels-Alder type. The structure of the I adduct, including its stereochemistry, was deduced from a comparison of the spectral data with those of the III adduct between *trans*-2-cyclohepten-1-one with cyclopentadiene. The proton magnetic resonance of the olefinic hydrogens of the I adduct and that of the III adduct show the same signal pattern with the same coupling constants, as is shown in the figures, and the structure of the latter was unambiguously established by chemical degradation.[1] The structures of II and IV adducts were deduced from their spectroscopic data and from their chemical degradation. These two adducts show almost identical NMR signals; the position of the methyl group was assigned by the transformation of the IV adduct into the ketolactone, V. The transformation was achieved by the hydride reduction of the IV adduct, the hydroxylation of the resulting alcohol at the double bond by osmium tetraoxide in pyridine, and successive oxidations by lead tetraacetate and chromic anhydride in acetic acid. The ketolactone, V, had infrared absorptions at 1783 and 1710 cm^{-1} due to γ-lactone and methyl ketone. The *trans*-fusion of the ring system in the II and IV adducts was deduced from its innertness to acid or base treatment and from mechanistic considerations.[5]

Experimental

General Precedure of the Photo-Diels-Alder Reaction. *cis*-2-Cycloocten-1-one or *cis*-2-cyclohepten-1-one (500 mg) and a 20-fold amount of a diene dissolved in 100 ml of hexane were placed in a reaction vessel, after which the mixture was internally irradiated by a 100-W medium-pressure mercury lamp in a Pyrex immersion jacket under an atomosphere of nitrogen. In the case of cyclopentadiene, the mixture was cooled in an ice-salt bath during irradiation. The reaction was monitored by the disappearance of the infrared absorptions due to the conjugate carbonyl groups. After the complete disappearance of the starting ketone–after 2 hr for I adduct, 4.5 hr for the II adduct, and 1 hr for the IV adduct–the solvent and the excess of diene were removed by distillation. The residues were distilled under reduced pressure by using a short-path distillation apparatus, Kugelrohr, to give the adducts in yields of 66% (I), 58% (II), and 95% (IV).

The photo-dimer of 2-cycloocten-1-one contaminated in the fraction with a higher boiling point was removed by chromatography on silica gel eluted with hexane–ether (1: 1); the products were found to be essentially pure by gas-chromatographic analysis (5% SE-30 on Chromosorb W and 5% Carbowax 20M on Chromosorb W).

Adduct I. Bp 75—80 °C/0.7 mmHg. Mass: M^+= 190.138. Calcd for $C_{13}H_{18}O$ m/e=190.135. IR (neat): 1685 and 720 cm^{-1}. NMR (CCl_4): δ=6.34—5.93 (2H, octet, J=3 and 6 Hz), 2.93 (1H, diffused singlet), and 2.7—1.4 ppm (15 H).

Adduct II. Bp 77—82 °C/0.5 mmHg. Mass: M^+= 192.150. Calcd for $C_{13}H_{20}O$ m/e=192.151. IR(neat): 1685, 795, and 780 cm^{-1}. NMR (CCl_4): δ=5.40 (1H, diffused singlet), 1.63 (3H, singlet), and 2.6—1.3 ppm (16 H).

Adduct IV. Bp 90—95 °C/0.2 mmHg. Found: C, 80.80; H, 10.18%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%. IR (neat): 1701 and 785 cm^{-1}. NMR (CCl_4): δ=5.33 (1H, diffused singlet), 1.63 (3H, singlet), and 2.6—1.3 ppm (14H).

Ketolactone V. A solution of the IV adduct (1.10 g) in 20 ml of ethanol was treated with 500 mg of sodium borohydride, after which the mixture was allowed to stand for 14 hr at room temperature (*ca.* 27 °C). After the evaporation of the solvent *in vacuo*, the residue was treated with 10 ml of the saturated solution of tartaric acid to destroy the excess of the hydride. The subsequent ethereal extraction of the mixture gave 1.18 g of crude alcohol. IR (neat): 3470, 1637, 1033, and 785 cm^{-1}. NMR (CCl_4): δ=5.25 (1H, diffused singlet) and 3.87 ppm (1H, diffused doublet, J=5 Hz). The alcohol (450 mg) obtained above in 2 ml of pyridine was treated with 600 mg of osmium tetraoxide in 1 ml of pyridine under cooling in an ice-bath, and the reaction mixture was stirred at room temperature for 12 hr under nitrogen. After the destruction of the osmium complex by adding 20 g of sodium hydrogensulfite in 40 ml of water, the product was extracted with ether to give 171 mg of the triol. IR(neat): 3500, 1117, and 1042 cm^{-1}. The triol (171 mg) in 10 ml of benzene was treated with lead tetraacetate (480 mg) in acetic acid, and the mixture was stirred for 5 hr in a nitrogen atmosphere. The reaction mixture was condensed *in vacuo*, and the condensate was extracted with ether after the addition of a saturated solution of sodium hydrogencarbonate to give a crude oil. The oil in 4 ml of acetic acid was treated with 100 mg of chromic trioxide in 1 ml of water over a 10-min period with cooling, after which the reaction mixture was stirred for 12 hr at room temperature. The product was extracted with ether after the destruction of the excess chromic trioxide by sodium hydrogensulfite to give 71 mg of crude ketolactone. The recrystallization of the product from carbon tetrachloride gave pure V. Mp 68—69 °C. Mass: M^+=210.129. Calcd for $C_{12}H_{18}O_3$ m/e=210.126. IR (neat): 1783, 1710, 1178, and 1010 cm^{-1}.

The authors are indebted to Professor Yasuji Yamada of the Tokyo Colledge of Pharmacy for the measurement of the high-resolution mass spectra.

Heterogeneous Asymmetric Hydrogenation of Benzil Using Bis-(dimethylglyoximato)cobalt Complexes as Catalysts

Hideaki FUJIKOSHI, Riichiro NAKAJIMA, and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602

(Received March 19, 1975)

Synopsis. The asymmetric hydrogenation of benzil in the heterogeneous system was found to proceed not only in the presence of quinine soluble in benzene phase, but also of an optically active amino or ascorbic acids soluble in aqueous phase.

Although the asymmetric hydrogenation of benzil using the complexes of bis(dimethylglyoximato)cobalt and optically active amine(abbreviated to $Co(DMG)_2$–amine) as catalysts was exclusively carried out by Yoshimura *et al.*[1] in the homogeneous system, it was further extended by the authors to the heterogeneous system, which consists of the benzene phase containing benzil and the aqueous phase containing $Co(DMG)_2$–amine complex. The asymmetric hydrogenation of benzil was found to proceed not only in the presence of quinine soluble in benzene phase, but also of an optically active amino or ascorbic acids soluble in aqueous phase. This made possible the use of an optically active and water-soluble base as well as ascorbic acid, which did not react with ammonia and glycine under the experimental conditions,[2] instead of benzene-soluble quinine.

For the hydrogenation of benzil under atmospheric pressure, the conventional apparatus[3] was modified and used. All the reagents used were of guaranteed or purified in advance. Optical rotations were measured in a 1-dm cell with a Union PM-71 polarimeter. The method was as follows unless otherwise stated. In a 100-ml vessel of the hydrogenation apparatus, $CoCl_2 \cdot 6H_2O$ (0.238 g, 0.001 mol) and dimethylglyoxime (0.232 g, 0.002 mol) were placed. The vessel was replaced by nitrogen and added with 10 ml of ethanol solution containing quinine hydrochloride (0.397 g, 0.001 mol) which was previously deaerated by nitrogen, followed by stirring for 5 min. To this solution was added 30 ml of deaerated aqueous solution containing sodium hydroxide (0.004 mol) and base (0.001 mol)

such as ammonia and amino acid, and then 30 ml of deaerated benzene solution containing benzil (0.420 g, 0.002 mol). The vessel was replaced by hydrogen and the solution was stirred under atmospheric pressure of hydrogen at room temperature. The amount of hydrogen absorbed was measured by a gas burette every definite interval. The amount of sodium hydroxide added was controlled, if necessary, so as to give a desired pH.

After absorption of the theoretical amount of hydrogen, the reaction mixture was transferred into a 100-ml separatory funnel and shaken with 30 ml of benzene, followed by separating the aqueous layer. The residual benzene layer was washed with each 50 ml of water, 2M-HCl and water in that order, one, three and four times, respectively. The benzene layer was concentrated *in vacuo*. The resulting product was dried overnight in a desiccator and obtained as white needles, followed by measuring the optical rotation of its acetone solution (c=0.8—1.2). The optical yield was calculated from the specific rotation of the product and that of the optically pure benzoin.[4)] Based on the additional data of melting point and mass spectrum, the above product was identified as (*S*)-benzoin.

As seen from Table 1, the asymmetric hydrogenation of benzil proceeded more or less only if an optically active compound was present in either a benzene phase or aqueous phase. The optical yield depended on the amount of the hydrogen pre-absorbed by $Co(DMG)_2$–NH_3 (Table 2), pH of the aqueous phase (Table 3) and the mole ratio of quinine or L-ascorbic acid to the cobalt complex (Table 4). Though the relationships between the optical yield and the above mentioned factors are interesting, their reasons still remain unknown.

Rearrangement of 4,5-Benzo-3-thiatricyclo[4.1.0.0^{2,7}]heptenes Promoted by Butyllithium: A New Synthetic Route to 3,4-Benzo-2-thiabicyclo[3.2.0]hepta-3,6-dienes

Toshio TATSUOKA and Ichiro MURATA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

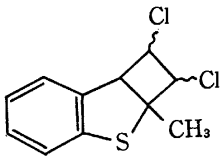
(Received August 18, 1975)

Synopsis. The reaction of 4,5-benzo-3-thiatricyclo-[4.1.0.0^{2,7}]heptenes (**1a—d**) with butyllithium followed by quenching with water or methyl iodide at −60 °C gives the expected bridgehead substituted products, whereas the same reaction conducted at somewhat higher temperature gives the skeletal rearrangement products, 3,4-benzo-2-thiabicyclo-[3.2.0]hepta-3,6-dienes (**2a—f**), almost quantitatively. A mechanism in line with the results is proposed.

The well-known bridgehead deuteration and alkylation of the bicyclo[1.1.0]butanes involve an anion intermediate and electrophilic attack of the corresponding reagents.[1] During the course of our study on 4,5-benzo-3-thiatricyclo[4.1.0.0^{2,7}]heptene (**1a**)[2-6] we found that the deuteration of **1a** with *n*-BuLi/D_2O at 0 °C gives the skeletal rearrangement product, 3,4-benzo-2-thiabicyclo[3.2.0]hepta-3,6-diene-6-*d* (**2a**), exclusively.[3] We report on the generality of this type of rearrangement of **1**.

When 4,5-benzo-3-thiatricyclo[4.1.0.0^{2,7}]heptene (**1a**) was lithiated with *n*-BuLi in ether at −60 °C and then methylated with excess methyl iodide at −30 °C, the expected bridgehead methyl derivative (**1b**)[6] was obtained quantitatively. However, when lithiation was performed at 0 °C in ether, the rearrangement product (**2b**) was obtained quantitatively after methyl iodide quenching at 0 °C. Definite proof of the structure of the product is obtained from its NMR spectrum and synthesis from 4-methyl-1-benzothiepin (**3a**)[6] by photoisomerization. The rearrangement usually took place at 0 °C. However, a lower temperature, −20 °C, also sufficed in the case of methyl substituted substrates, **1b**[6] and **1c**[6] which afforded 1,6-dimethyl-3,4-benzo-2-thiabicyclo[3.2.0]hepta-3,6-diene (**2e**) and 5,6-dimethyl-3,4-benzo-2-thiabicyclo[3.2.0]hepta-3,6-diene (**2f**), respectively. Assignment of structures **2e** and **2f** was based on their spectral data. In addition, **2f** was available from photoisomerization of 4,5-dimethyl-1-benzothiepin (**3b**).[6]

Other examples were also found in the case of water quenching experiments. On treatment with *n*-BuLi/H_2O, **1b** afforded 1-methyl-3,4-benzo-2-thiabicyclo-[3.2.0]hepta-3,6-diene (**2c**). The structure assigned to **2c** follows from its spectral data coupled with an independent synthesis. Thus, dechlorination of the photoadduct (**4**),[7] obtained from irradiation of a mixture of 2-methylbenzo[*b*]thiophene and *cis*-dichloroethylene in the presence of benzophenone as sensitizer, with sodium phenanthrene[8] in THF at 0 °C afforded **2c** in 40% yield.



(**4**)

Furthermore, dimethyl derivative (**1d**) gave 1,5-dimethyl-3,4-benzo-2-thiabicyclo[3.2.0]hepta-3,6-diene (**2d**) on treatment with *n*-BuLi/H_2O at ambient temperature. The NMR spectrum of **2d** was in complete accord with the proposed structure.

In all the cases, we found that the newly introduced methyl or hydrogen is always bonded at C-6 position of **2**. The complete regiospecificity of this rearrangement was interpreted by assuming the intermediacy of a carbene type species (**B**), derived from an initially formed bridgehead anion (**A**), which is subsequently converted into the vinyl anion (**C**). Electrophilic attack of methyl iodide or water would give the observed products. Since **1a** is readily accessible,[1,2] the present reactions provide a useful synthetic route to the substituted 3,4-benzo-2-thiabicyclo[3.2.0]hepta-3,6-dienes (**2**).

Experimental

Generals. The UV spectra were measured with a Hitachi Model 124 spectrophotometer. All the absorptions are given in nm with log ε in parentheses. The NMR spectra were recorded on a Varian XL-100-15 spectrometer with tetramethylsilane as an internal standard.

General Procedure for Rearrangement of 1. To a stirred solution of **1** (0.25 mmol) in 2—5 ml of dry ether was added dropwise a solution of *n*-BuLi (0.25 mmol) in hexane at temperatures indicated in the text [**1a**→**2b**: 0 °C; **1b**→**2e**: −20 °C; **1c**→**2f**: −20 °C; **1d**→**2d**: room temp] under nitrogen atmosphere. The mixture was stirred for 15 min at the specified temperature and treated with 20 fold excess of methyl iodide or water. Excess water was added and the aqueous iayer was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent afforded **2** quantitatively. Analytically pure compounds were obtained by column chromatography on a deactivated (with 5% of water) alumina with light petroleum ether.

Tri(hetero)substituted Carbonium Ions. XI. A Novel Synthetic Route to 2-Dialkylamino-4-alkyl-1,3-dithiolium Salts

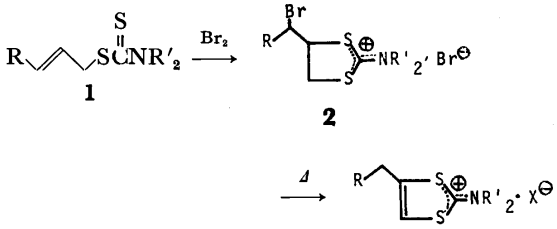
Takeshi NAKAI,* Kazuhisa HIRATANI,[1] and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 30, 1975)

Synopsis. Pyrolysis of 2-dialkylamino-4-(α-bromoalkyl)-1,3-dithiolanylium bromides (**2**) readily prepared by bromination of the β,γ-unsaturated dithiocarbamates (**1**) affords 2-dialkylamino-4-alkyl-1,3-dithiolium salts (**3**) in good yields, providing a useful way to prepare dithiolium salts.

We have shown that bromination of β,γ-unsaturated dithiocarbamates (**1**) results in the quantitative formation of the corresponding 2-dialkylamino-4-(α-bromoalkyl)-1,3-dithiolanylium bromides (**2**) *via* regiospecific (S-5) participation by the dithiocarbamate function.[2] In this Note we wish to report an intriguing thermal transformation of **2** into 2-dialkylamino-4-alkyl-1,3-dithiolium salts (**3**) in good yields. The simple ring transformation is of interest since the dithiolium salt **3** has been an important class of synthetic intermediates[3] for the synthesis of tetrathiofulvalene derivatives which attracted attention in view of the interesting electroconductivity[4] of their charge transfer complexes. The new synthetic route to 4-alkyl-1,3-dithiolium salts is more advantageous than the recently developed methods[3c,5] in view of the operational simplicity and accessibility[6] of the starting materials.



1 **2** **3**

a, R=H, R′=CH_3
b, R=H, R′=C_2H_5
c, R=CH_3, R′=CH_3

When 1,3-dithiolanylium salt (**2**) was heated in bulk at melting point (160—190 °C) in nitrogen under reduced pressure (*ca.* 5—10 mmHg), decomposition took place with the evolution of hydrogen bromide gas which was trapped in an ethanolic solution of triethylamine. The gas evolution ceased after 10—20 min. The resulting bromides, **3b** and **3c**, were converted, on treatment with an aqueous solution of sodium tetraphenylborate, into the tetraphenylborates which were then purified and characterized. The dithiolium salts thus obtained were identified by spectroscopic methods (NMR and UV) and elemental analyses, and/or by spectral comparison with authentic samples. Yields and physical properties of **3** are summarized in Table 1.

From the results it appears that the novel ring transformation involves an initial 1,2-dehydrobromination of **2** giving 4-alkylidene-1,3-dithiolanylium bromides (**4**) which further undergo 1,3-hydrogen shift, ultimately yielding the dithiolium salt **3**.

4 **5**

(1) A similar pyrolysis of 4-bromomethyl-4-methyl-1,3-dithiolanylium bromide (**5**) which does not undergo 1,2-dehydrobromination gave no dithiolium salt, a ring expansion taking place.[7] This indicates that the transformation is initiated by the thermal 1,2-dehydrobromination.

(2) 4-Vinylidene-1,3-dithiolanylium bromide (**4a**; R=H, R′=CH_3) was isolated by the reaction of **2a** with triethylamine (Table 1). When **4a** thus obtained was

TABLE 1. 1,3-DITHIOLIUM SALTS (**3**) AND THE RELATED SALT

Salt (Anion)	Yield %	Mp °C	N, % Found/Calcd	NMR (DMSO-d_6)[a] (δ ppm from TMS)	UV (EtOH)[b] (λ_{max}, nm)
3a	91	178—180[c]		2.54(s, 3H), 3.57(s, 6H)	247.5
(X=Br)				7.58(s, 1H)	303.5
3b	~100	147—150	2.73/2.76	1.23(t, 6H), 2.32(s, 3H)	249
(X=BPh_4)				3.63(q, 4H), 6.5—7.5(m, 21H)	308.5

(X=Br)				5.80—6.10(m, 2H)	

a) All NMR spectra are those of the bromides except for **3b** (X=BPh_4). b) The molar extinction coefficients were not determined. Absorbances of the longer wavelength bands were greater than those of the shorter ones for all the dithiolium salts. c) Lit,[5b] mp 178—180 °C.

* To whom inquiries should be addressed: Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152.

heated under the same conditions as in the pyrolysis of **2a**, the dithiolium salt **3a** was obtained quantitatively, thus providing convincing evidence for occurrence of the 1,3-hydrogen shift of the intermediate **4**. A similar thermal 1,3-hydrogen shift was observed elsewhere.[8]

Experimental

All the melting points are uncorrected. NMR and UV spectra were recorded on Japan Electron Optics spectrometers (PS-100 or MH-60) and a Hitachi EPS-2 spectrometer, respectively.

4-Bromoalkyl-1,3-dithiolanylium Bromides (**2**) were prepared from the corresponding β,γ-unsaturated dithiocarbamates (**1**) following the procedure described previously[2]; **2a**, mp 193—195 °C (lit,[2] 193—195 °C); **2b**, mp 115—116 °C (Found: N, 4.10%. Calcd for $C_8H_{15}NS_2Br_2$: N, 4.01%); **2c**, mp 162—164 °C (lit,[2] 162—164 °C).

Pyrolysis of 2. Bromide **2a** (0.65 g, 2.0 mmol) was placed in a 30-ml distilling flask equipped with a nitrogen balloon. The flask was then connected with a vacuum pump through a trapping tube containing an ethanolic solution of triethylamine placed in a Dry Ice–acetone bath. When the flask was gradually heated up to 190 °C under reduced pressure (5—10 mmHg), the bromide gradually melted, evolution of hydrogen bromide being observed. After heating at 180—190 °C for 10 min, the gas evolution ceased. The flask was then cooled and the solid residue was recrystallized from a mixture of acetone and acetonitrile giving 0.44 g (91%) of the dithiolium bromide (**3a**). The physical data of **3a** (Table 1) are in agreement with the reported values.[5b]

Pyrolysis of **2b** at *ca.* 160 °C for 20 min gave the crude bromide which was further converted, on treatment with a saturated aqueous solution of sodium tetraphenylborate, into the dithiolium salt (**3b**, X=BPh_4); the salt was recrystallized from an aqueous acetone. Similarly, pyrolysis of **2c** at *ca.* 170 °C for 20 min followed by the anion exchange gave **3c** (X=BPh_4) which was then recrystallized from a mixture of acetone and acetonitrile.

Reaction of 2a with Triethylamine. Triethylamine (0.13 g, 1.3 mmol) was added to a solution of **2a** (0.40 g, 1.2 mmol) in dimethylformamide (6 ml) at 0 °C, and the mixture was stirred at room temperature for 1 hr. The solvent was then distilled off under reduced pressure below room temperature giving a white solid. The solid was washed five times with cooled acetone and recrystallized from a mixture of acetone and ethanol to give 0.25 g (83%) of **4a**. The physical properties and the nitrogen analysis of **4a** are given in Table 1. Found: C, 30.32; H, 4.27%. Calcd for $C_6H_{10}NS_2Br$: C, 30.0; H, 4.17%.

Dithiolium bromide **3a** was obtained quantitatively when **4a** was heated in bulk at *ca.* 180 °C for 10 min.

The Reaction of Organic *gem*-Dihalides with Zerovalent Transition Metal Complexes. An Approach to Organic Synthesis

Junji FURUKAWA, Akira MATSUMURA, Yoshihito MATSUOKA, and Jitsuo KIJI

Department of Synthetic Chemistry, Kyoto University, Kyoto 606

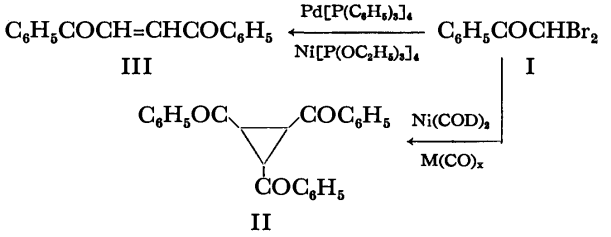
(Received September 11, 1975)

Synopsis. The reaction of ω,ω-dibromoacetophenone with $Ni(COD)_2$ (COD=1,5-cyclooctadiene), $Fe(CO)_5$, or $Co_2(CO)_8$ gave *trans*-1,2,3-tribenzoylcyclopropane, while the reaction with $Pd[P(C_6H_5)_3]_4$ or $Ni[P(OC_2H_5)_3]_4$ gave *trans*-1,2-dibenzoylethylene. Phenyl isocyanide dichloride was dechlorinated by metal carbonyls to give phenyl isocyanide-substituted metal carbonyls.

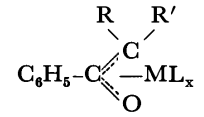
Carbon-carbon bond formation by means of low-valent transition metal complexes is of current interest, and a variety of regio- or stereospecific reactions have been developed.[1] Reactions of *gem*-dihalides with iron carbonyls are known; in them a transiently formed carbenoid is assumed to be the intermediate.[2,3] To find versatile applications of organotransition metals to organic synthesis, several organic dihalides were allowed to react with metal complexes.

Results and Discussion

It has been reported that the reaction of ω,ω-dibromoacetophenone (I) with zinc-copper gives 1,3-diphenyl-2-buten-1-one.[4] The reaction of I with $Ni(COD)_2$, $Fe(CO)_5$, or $Co_2(CO)_8$ in benzene at 80 °C was found to afford *trans*-1,2,3-tribenzoylcyclopropane (II) as the sole organic product. Bis(cyclooctadiene)-nickel, $Ni(COD)_2$, was superior to the metal carbonyls, because $NiBr_2$ was more easily separated from the product by filtration. On the other hand, when dimethyl maleate or methyl sorbate was added to the system, these olefinic compounds did not participate in the reaction, and II was formed. This is a rare example of cyclopropane formation by the dehalogenation of an organic halide by transition metals.



If the debromination occurs by a step-by-step mechanism, an intermediate oxo-allyl complex might be isolated. In fact, the reaction of α-haloketones with $Fe_2(CO)_9$ affords the oxo-allyl complex (IVa).[5] A similar complex (IVb) has been prepared by the reaction of diazoacetophenone with bis(benzonitrile)palladium dichloride.[6] The isolation of the oxo-allyl complex from the reaction of I with tetrakis(triphenylphosphine)palladium $Pd[P(C_6H_5)_3]_4$ was not achieved even at 0 °C, but *trans*-1,2-dibenzoylethylene (III) was obtained in a high yield. The palladium was recovered



IV a; R=R′=H, M=Fe
b; R=H, R′=Cl, M=Pd

as bis(triphenylphosphine)palladium dibromide $PdBr_2[P(C_6H_5)_3]_2$. The reaction with tetrakis(triethyl phosphite)nickel $Ni[P(OC_2H_5)_3]_4$ gave similar results. The presence of donor ligands such as phosphine or phosphite appears to suppress the formation of the cyclopropane. The ligands seem to alter the nature of the intermediate (presumably "carbenoid") electronically or sterically.

In relation to the above reaction, dimethyl dibromosuccinate was treated with $Fe(CO)_5$ with the expectation of gaining insight into the stereochemistry of the dehalogenation, because there is a possibility that II or III is formed by a step-by-step dehalogenation after the coupling of the bromoacetophenone moiety. This debromination proceeded smoothly in benzene at 80 °C. The *dl*(*racemic*)-, and *meso*-isomers gave dimethyl fumarate predominately. Under these conditions, the isomerization of the double bond occurs.[7] Therefore, the specificity, if any, is obscured by the *cis-trans* isomerization.

Contrary to the case with the reaction with I, ethyl dichloroacetate was difficult to be dechlorinated under similar conditions. No appreciable organic product was formed. The dechlorination of phenyl isocyanide dichloride $C_6H_5NCCl_2$ (V) required a higher temperature. On refluxing in toluene, the reaction with 2 mol of $Fe(CO)_5$ gave $(C_6H_5NC)Fe(CO)_4$ in a 67% yield. The reaction with $Ni(CO)_4$ gave pale-yellow solid with IR absorptions at 2040 and 1990 cm^{-1},[8] they are assigned to ν_{NC} of $Ni(C_6H_5NC)_4$.

Experimental

ω,ω-Dibromoacetophenone,[9] *dl*- and *meso*-dimethyl dibromosuccinate,[10] phenyl isocyanide dichloride,[11] $Ni(COD)_2$,[1] $Pd[P(C_6H_5)_3]_4$,[12] and $Ni[P(OC_2H_5)_3]_4$[13] were prepared by the known methods. Commercially available $Fe(CO)_5$, $Co_2(CO)_8$, and $Cr(CO)_6$ were used without further purification. Benzene and toluene were purified by distillation in the presence of sodium ketyl under an atmosphere of argon.

The following procedures are typical examples of the reactions. The amounts of material used are shown in Table 1.

Reaction of I with $Fe(CO)_5$. A test tube fitted with a three-way stopcock was filled with argon by evacuating and filling it with argon several times. To a benzene solution (3 ml) of I (1.0 mmol) was added $Fe(CO)_5$ (1.2 mmol) and the solution was heated at 80 °C with stirring. The precipitate was separated by filtration, and the filtrate was percolated

a) B, In benzene (3 ml); T, in toluene (30 ml). b) II, *trans*-1,2,3-Tribenzoylcyclopropane; III, *trans*-1,2-dibenzoylethylene. c) Based on the dihalides used. d) L, C_6H_5NC. e) In benzene (30 ml).

through a thin layer of alumina. The concentrated solution was poured into petroleum ether. A colorless compound, II, was thus obtained in a 28% yield. It was identified by comparing its spectral data with those of an authentic sample.[14]

Reaction of I with $Pd[P(C_6H_5)_3]_4$. To a benzene solution (3 ml) of I (1.0 mmol) was added $Pd[P(C_6H_5)_3]_4$ (1.2 mmol) under an atmosphere of argon. The reaction mixture was kept at 80 °C with stirring. The precipitate was identified as $PdBr_2[P(C_6H_5)_3]_2$ by comparing its infrared spectrum with that of the reported substance.[15]

The filtrate was concentrated, and the formation of III (in 77% yield) was confirmed by comparing its infrared spectrum with that of an authentic sample.[14]

Reaction of V with Metal Carbonyls. Phenyl isocyanide dichloride (V) was allowed to react with metal carbonyls under the conditions summarized in Table 1. After the reaction, the metal chloride thus precipitate was separated by filtration. The evaporation of the solvent gave isocyanide-substituted metal carbonyls.

The Syntheses of 4- and 5-(α- and β-Naphthyl)tropolones[1]

Josuke TSUNETSUGU, Masaru SATO, and Seiji EBINE

Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama 338

(Received September 16, 1975)

Synopsis. 4- And 5-(α- and β-naphthyl)tropolones have been synthesized *via* naphthyl-tropilidenes, -tropones, and -aminotropones.

Only 3-(α- and β-naphthyl)tropolones in a series of naphthyl-substituted tropolones have ever been reported.[2] This paper describes the syntheses of 4- and 5-(α- and β-naphthyl)tropolones by the successive reactions: tropenylations of naphthalene, transformation of naphthyltropilidenes to naphthyltropones and then to (naphthyl)aminotropones, and hydrolysis to naphthyltropolones.

7-Ethoxytropilidene was allowed to react with α-naphthylmagnesium bromide[3] to produce a mixture of isomeric α-naphthyltropilidenes (Iα, 44%), which was treated with phosphorus pentachloride in carbon tetrachloride, alkali, and acid successively to yield a mixture of isomeric α-naphthyltropones (IIα and IIIα, 85%).[4] Separation of them by chromatography or by fractional recrystallization of their picrates was unsuccessful. The mixture of IIα and IIIα was treated with 80% hydrazine in ethanol to afford three aminonaphthyltropones (IVα, Vα, and VIα; 3.4, 55, and 16%). The position of the amino group on these tropones became partially evident only after independent hydrolysis of each aminotropone with alkali.[5] IVα and VIα were hydrolyzed respectively to yield the same α-naphthyltropolone (VIIα, 86%), while Vα afforded α-naphthyltropolone (VIIIα, 80%). From these results, it is found that VIIα is 4-(α-naphthyl)tropolone and therefore IVα or VIα is 2-amino-4- or 2-amino-6-(α-naphthyl)tropone, although which is which remains unknown, and VIIIα is 5-(α-naphthyl)tropolone and Vα is 2-amino-5-(α-naphthyl)tropone.

For the β-naphthyl series, a mixture of β-naphthyltropilidenes (Iβ, 30%), a mixture of isomeric β-naph-

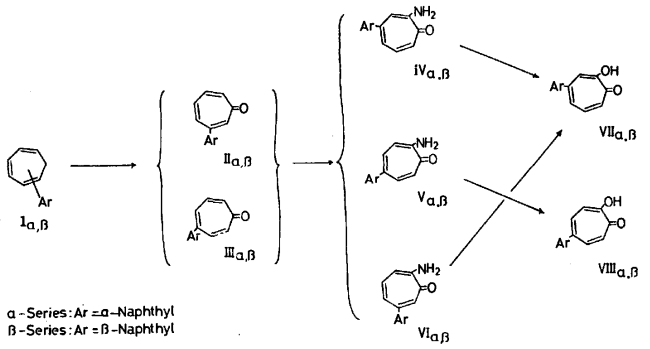
thyltropones (IIβ and IIIβ, 61%), three isomeric amino-β-naphthyltropones (IVβ, Vβ, and VIβ; 31, 41, and 18%), of which IVβ or VIβ is 2-amino-4- or 2-amino-6-(β-naphthyl)tropone, and two β-naphthyltropolones (VIIβ and VIIIβ, 41%) were obtained successively in a similar manner.



Experimental

α-Naphthyltropilidenes (Iα). 7-Ethoxytropilidene (55 g) was added to the Grignard reagent, prepared from α-bromonaphthalene (84.1 g) and magnesium (10.8 g) in dry ether (240 ml), and the ether was evaporated. The reaction mixture was heated for 3 hr at about 130 °C to yield naphthalene (5.6 g) and Iα (37.4 g); δ (CCl_4): 2.15 (t, J=6.8 Hz), 2.19 (t, J=6.8 Hz), 2.69 (d, J=6.8 Hz) and the peak areas of these methylene protons of the tropenyl groups suggest that the ratio between 3-, 2-, and 1-(α-naphthyl)tropilidenes is 3 to 10 to 13; 5.17 (1.65 H, m, tropyl), 6.07 (1.65 H, m, tropyl), 6.42 (1.65 H, m, tropyl), 6.88—8.12 (7H, m, naphthyl).

3- And 4-(α-naphthyl)tropones (IIα and IIIα, mixture). A mixture of phosphorus pentachloride (12.5 g), dry carbon tetrachloride (120 ml), and Iα (6.54 g) was stirred at room temperature overnight. The extraction of the mixture with cold water, neutralization of the water layer and extraction of it with ether afforded a yellow oil (4.55 g). This was hydrolyzed with concentrated hydrochloric acid to give recovered Iα (2.7 g) and a mixture of IIα and IIIα (2.27 g); ν (neat); 1630, 1575 cm^{-1}.

Amino-α-naphthyltropones (IVα, Vα, and VIα). A mixture of IIα and IIIα (590 mg), 80% hydrazine (0.5 ml), and ethanol (10 ml) was refluxed for 6 hr. The reaction mixture was separated through a silica-gel column with benzene–ether to afford three products: VIα (21 mg), IVα (345 mg), and Vα (98 mg), successively.

Acetate of VIα; λ_{max}^{MeOH}, nm (log ε): 220.5 (4.83), 261 (4.33), 290 (3.98 sh), 326 (4.14 sh), 370 (3.97 sh). ν(Nujol): 3230, 1693, 1616, 1220, 837, 808, 783, 730 cm^{-1}.

Acetate of IVα; λ_{max}^{MeOH}, nm (log ε): 221 (4.84), 250—255 (4.34), 324 (4.17), 368 (3.97), 3.88 (3.81 sh). ν(Nujol): 3235, 1692, 1617, 1225, 918, 793, 780, 726 cm^{-1}.

Acetate of Vα; λ_{max}^{MeOH}, nm (log ε): 219 (4.80), 253 (4.31), 280 (4.00 sh), 344 (4.20), 390 (4.01 sh). ν (KBr): 3240, 1693, 1618, 1248, 1220, 1203, 875, 869, 861, 808, 783, 743 cm^{-1}.

4-(α-Naphthyl)tropolone (VIIα). A mixture of IVα (600 mg), potassium hydroxide (660 mg), water (1.5 ml), and ethanol (4 ml) was refluxed for 12 hr and the solvent was evaporated off. The residue was acidified with 3 M sulfuric acid and extracted with chloroform (50 ml) to afford a brown solid of VIIα (518 mg, which was purified from cyclohexane); λ_{max}^{MeOH}, nm (log ε): 220.5 (4.79), 248 (4.42), 319 (4.16), 386 (3.83). ν (KBr): 3200, 1610, 1550, 915, 830, 800, 795, 775 cm^{-1}.

5-(α-Naphthyl)tropolone (VIIIα). This was prepared from Vα (purified from methanol) in a similar manner. λ_{max}^{MeOH}, nm (log ε): 219 (4.80), 346 (4.24). ν (KBr): 3400, 1615, 1550, 862, 805, 785 cm^{-1}.

The compounds of β-naphthyl series were prepared by practically the same treatment as in the α-naphthyl series described above.

The Acid-Catalyzed Rearrangement of 1-Allylindoles. A Hypothesis for the Biogenesis of Echinulin-Type Compounds

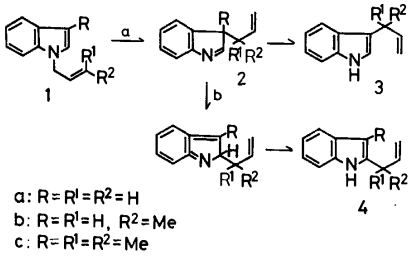
Seisaku INADA, Kunio NAGAI, Yasuo TAKAYANAGI, and Mitsuo OKAZAKI

Department of Chemical Engineering, Faculty of Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received September 18, 1975)

Synopsis. The aluminum chloride-catalyzed rearrangement of 1-allyl- (**1a**) and 1-(*trans*-2-butenyl)indole (**1b**) produced 3-allyl-(**3a**) and 3-(1-methylallyl)indole (**3b**) in 58 and 43% yields, respectively. Based on this, a hypothesis for the biogenetic mechanism of echinulin is proposed.

Recently, Patterson *et al.* showed that the pyrolysis of a mixture of 1-(*trans*- and *cis*-2-butenyl)indole at 450—470 °C gave 3-(1-methylallyl)indole and indole as the major primary reaction products.[1] We wish to report here the exclusive charge-induced [3,3]-shift of 1-allylindoles in connection with our interest in the biogenesis of the mould metabolite echinulin.



The experimental results for the rearrangement of 1-allylindole (**1a**) are summarized in Table 1. The $ZnCl_2$-catalyzed reaction of **1a** afforded an isolable amount of 3-allylindole (**3a**)[2] together with indole and 3-*n*-propyl-1-allylindole (**5**) only under the rather drastic conditions where the reaction was carried out in boiling tetralin. They were separated by preparative GLC and identified, based on analytical and/or spectral data, respectively. In the NMR spectrum of **5**, the presence of absorptions at 6.71 δ (s, 1H) due to 2-H in the indole nucleus and 4.48—4.62 δ (m, 2H) due to the α hydrogens of $N\text{-}CH_2CH{=}CH_2$ indicates the probable location of the propyl group at the 3-position, which may originate from the allyl group of **1a**.

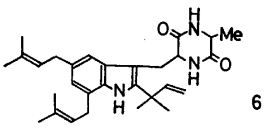
Although the reaction under $SbCl_5$ catalysis formed a fair amount of tarry matter, the $AlCl_3$- and $TiCl_4$-catalyzed reactions were found to give **3a** exclusively, with the exception of a slight formation of tarry matter. The former proceeds with higher reactivity and less formation of tarry products than the latter. Thus, when **1a** and $AlCl_3$ (equimolar amounts) were refluxed in benzene for 4 hr, **3a** was obtained in 58% yield. This was confirmed by GLC to contain no detectable amount of by-products.

TABLE 1. ACID-CATALYZED REACTION OF **1a**

Acid	Solvent	Reaction time(hr)	Relative compositions (glc area %)
$ZnCl_2$	Benzene	24	**1a**, >99; **3a**, trace.
$ZnCl_2$	Tetralin	20	**1a**, 68; **3a**, 14; indole, 4; **5**, 9; unidentified, 5.
$SbCl_5$	Benzene	0.5	
$AlCl_3$	Benzene	1	**1a**, 15; **3a**, 85.
$TiCl_4$	Benzene	3	**1a**, 74; **3a**, 26.

The rearrangement of 1-(*trans*-2-butenyl)indole (**1b**) was similarly performed; heating of **1b** with $AlCl_3$ for 2 hr (**1b** seems more reactive than **1a**) gave 3-(1-methylallyl)indole (**3b**)[1] in 43% yield. This demonstrates that the isomerization is presumably a [3,3]-sigmatropic reaction followed by enamination.

The biogenesis of the mould metabolite echinulin (**6**) and the formally related alkaloids, which involve a



1,1-dimethylallyl group at the 2-position of the indole nucleus, has been of interest.[3] In particular, different biogenetic mechanisms for the process through which the reversed isoprene unit is inserted at the 2-position have been suggested.[4,5] Recently, Casnati *et al.* have found that 3-methyl-1-(3-methyl-2-butenyl)indole (**1c**) rearranged under acid catalysis to give 2-(1,1-dimethylallyl)3-methylindole (**4c**) and 3-methyl-2-(3-methyl-2-butenyl)indole with partial inversion of the migrating group, and stated that this represented a hitherto unobserved type of rearrangement, which might have a biogenetic implication for echinulin-type compounds.[6] However, in view of our experimental results, it seems possible to assume that the reaction affording **4c** (and consequently the process of the biogenesis for echinulin-type compounds also) involves a charge-induced [3,3]-shift to form an intermediate, 3-alkyl-3-allylindolenines (**2**),[7] followed by a [1,5]-shift and subsequent enamination to give 3-alkyl-2-allylindoles (**4**).

It is well-known that 3,3-dialkylindolenines isomerize readily to 2,3-dialkylindoles in an acidic medium, especially when one of the alkyl groups is an allylic group (route b).[5,8] On the other hand, the [3,3]-shift of 1-allylindoles (route a) has not been reported, except for the experiment which was carried out under the rather drastic conditions described above.[1] Our experimental results may be one of primary pieces of evidence supporting the proposed hypothesis.

Experimental

Gas chromatographic analyses were made on a Shimadzu GC 3AH gas chromatograph using a 3 mm×2 m column packed with 25% Apiezon L on Chromosorb W at 220 °C.

For preparative GLC, a Schimadzu GC 1B gas chromatograph having a 6 mm × 1.5 m column packed similarly was employed. 1-Allylindole (**1a**)[9] and 3-allylindole (**2a**)[2] were prepared according to the methods reported in the literature.

1-(trans-2-Butenyl)indole (1b). According to the method of Cardillo *et al.* for preparing **1a**,[9] **1b** (34.5 g, bp 116 °C/2 mmHg) also was prepared from indole (30.0 g, 0.256 mol), sodium hydride (50% dispersion, 12.6 g, 0.262 mol), and *trans*-1-chloro-2-butene (23.2 g, 0.256 mol) in DMF. This was contaminated with a by-product which could not be excluded by distillation. This was treated with picric acid (46.6 g) in methanol (300 ml) and the picrate obtained (51 g) was repeatedly recrystallized from methanol to give red needles (20.4 g) which melted at 73.5—74.5 °C. IR (KBr, cm^{-1}) 3125, 1635, 970. Found: N, 13.76%. Calcd for $C_{18}H_{16}N_4O_7$: N, 13.99%.

The purified picrate was added to 5% aqueous NaOH and extracted with ethyl acetate. The organic solution was washed with water and dried over $MgSO_4$. After removal of the solvent the residue was distilled *in vacuo* and a fraction of bp 91 °C/1.5 mmHg was collected. Yield, 5.0 g (11.4%). The GLC analysis denoted that this fraction consisted of a single product. IR (neat film, cm^{-1}) 3050, 1455, 1320, 970. NMR ($CDCl_3$, δ) 1.59 (br. d, 3H), 4.42 (br. d, 2H), 5.20—5.64 (m, 2H), 6.30 (d, 1H), 6.80 (d, 1H), 6.88—7.14 (m, 3H), 7.36—7.52 (m, 1H). Found: N, 8.10%. Calcd for $C_{12}H_{13}N$: N, 8.18%.

Acid-catalyzed Reaction of 1a. A mixture of **1a** (0.5 g) and a Lewis acid (equimolar amounts) in a solvent (4 ml) was refluxed for an appropriate time. The reaction mixture was poured into 10% aqueous NaOH and extracted with ethyl acetate. The organic layer was washed with water and provided for GLC analysis. The results are shown in Table 1.

1-Allyl-3-n-propylindole (5). Pale yellow oil. IR (neat film, cm^{-1}) 3050, 1465, 990, 920. NMR ($CDCl_3$, δ) 1.00 (t, 3H), 1.44—1.90 (m, 2H), 2.70 (t, 2H), 4.48—4.62 (m, 2H), 4.78—5.08 (m, 2H), 5.60—6.20 (m, 1H), 6.71 (s, 1H), 6.80—7.15 (m, 3H), 7.35 —7.55 (m, 1H). Found: N, 7.00%. Calcd for $C_{14}H_{17}N$: N, 7.03%.

$AlCl_3$-catalyzed Rearrangement. Synthesis of 2a: A solution of **1a** (5.0 g, 32 mmol) and $AlCl_3$ (4.3 g, 32 mmol) in benzene (80 ml) was refluxed for 4 hr. To the cooled solution 2% HCl (100 ml) was added and the organic solution was separated, washed with water, and dried over $MgSO_4$. After removal of the solvent, the residue (4.6 g) was distilled *in vacuo*; a fraction of bp 105 °C/2 mmHg was collected. Yield, 2.9 g (58%). The IR and NMR spectra were completely in accord with those of an authentic sample prepared according to the method of Brown *et al.*[2]

Synthesis of 2b: A mixture of **1b** (3.0 g, 18 mmol) and $AlCl_3$ (2.3 g, 18 mmol) was refluxed in benzene (60 ml) for 2 hr. The reaction mixture was treated similarly and a fraction of bp 111—112 °C/1.5 mmHg was collected. Yield, 1.3 g (43%). The IR and NMR spectra corresponded to those described by Patterson *et al.*[1] This sample was 98% pure (GLC area %), but sensitive to the air; it darkened after standing for a few days.

New A-*nor*-B-*homo*-*ent*-Kauranoids (Grayanotoxin XVI and XVII) from *Leucothoe Grayana Max.*

Shinsei GASA, Ryūzō IKEDA, Nobuyuki HAMANAKA, and Takeshi MATSUMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 18, 1975)

Synopsis. Two physiologically active diterpenoids, grayanotoxin XVI and XVII, have been isolated from *Leucothoe grayana Max.*, and the structures have been determined to be 6-*O*-acetylgrayanotoxin II and 3,6-didehydrograyanotoxin III respectively on the basis of spectral and chemical evidence.

The structures of a number of diterpenoids with an A-*nor*-B-*homo*-*ent*-kaurane skeleton have been elucidated by several groups.[1] In this paper we wish to report on the isolation and characterization of two physiologically active diterpenoids of this type from *L. grayana Max.* These toxic substances, grayanotoxins (hereafter G) XVI and XVII, were obtained as minor constituents by the careful chromatography of alcohol extracts of dried leaves, together with G I,[1] II,[1] III,[1] IV,[2] V,[2] XIV,[3], XV,[3] as well as leucothols A, [4a] B[4b] and C.[4b]

The first compound, G XVI ($C_{22}H_{34}O_6$, mp 116—118 °C, $[\alpha]_D$ +2.8 ° (*c* 1, MeOH) was obtained in a 5×10^{-6}% yield from dried leaves. The IR and NMR spectra indicated the presence of the following groups: two tertiary methyls (δ 0.92 and 1.20), a tertiary methyl on a carbon bearing a hydroxyl group (δ 1.33), two secondary hydroxyls (3511 cm^{-1}, δ 3.57, 1H, q, J_{AX+BX}=3+6 Hz and 4.44, 1H, s), a secondary acetoxyl (1719 cm^{-1}, δ 2.12, 3H, s, and 4.77, 1H, q, J_{AX+BX}= 2+10 Hz), and an exocyclic methylene group (1634 cm^{-1}, δ 5.00 and 5.16, each 1H, s). Since the treatment of this compound with sodium hydroxide in ethanol afforded G II **1**, the new toxin must be either 3-*O*- or 6-*O*-acetyl G III. In order to clarify the position of the acetoxyl group, the toxin was next oxidized with chromium trioxide in pyridine to give an amorphous diketone **7**, whose NMR spectrum indicated a quartet (J_{AX+BX}=4+9 Hz) due to the acetoxyl-bearing methine proton at δ 6.39. The extraordinary large downfield shift of the quartet indicates the steric closeness of the methine proton and the newly-formed carbonyl group (s). Since, on the other hand, **7** seemingly takes a G I-like conformation, **8**,[5] the 6-*O*-acetyl structure was concluded for the diketone and, accordingly, for G XVI also. Supporting evidence for the **2** structure was obtained by means of the INDOR technique. On monitoring the four lines due to the C-6 proton under INDOR conditions, only eight INDOR peaks altogether were observed at δ 2.76. 2.59, 2.52, 2.35, 2.12, 2.08, 1.88, and 1.84, indicating the presence of a **9** moiety (δ_A2.01, δ_B2.53, J_{AB}=−14.4 Hz, J_{AX}= 2.4 Hz, J_{BX}=10.2 Hz) in **7**. Several 6-*O*-acylated grayanoids have been isolated from *Lyonia ovalifolia* D. *elliptica* Hand. -Mazz.,[7a] *Pieris japonica* D. Don,[7b] and *Rhododendron japonicum* Suringer.[7c] However, the new grayanotoxin is the first 6-*O*-acylate to be isolated from *Leucothoe grayana Max.* It causes skin inflammation upon contact.

The second compound, G XVII ($C_{20}H_{30}O_6$, mp 268—270 °C (dec.), $[\alpha]_D$ −157.3 ° (*c* 1, MeOH)), was obtained in a 2.9×10^{-6}% yield from dried leaves and has the following spectral proterties: IR (cm^{-1}, Nujol) 3470 (OH), 1731 and 1712 (C=O); NMR (C_5D_5N, TMS) δ 1.02, 1.19, 1.42, 1.62 (each 3H, s, four tert. methyls), 2.92 (2H, bd, J=~11 Hz, C-2[8]), 3.90 (1H, q, J_{AX+BX}=9+12 Hz, C-1[8]), 2.84 (1H, d, J_{AB}=−13 Hz, C-7Hax), 4.22 (1H, d, J_{AB}=—13 Hz, C-7Heq), 5.27 (1H, s, C-14); ORD *a*=−463 (MeOH). The analytical and mass spectral data indicated that the compound corresponds to a bisdehydro derivative of G III (**3**). A comparison of the above spectral data with those of G III[1] suggested the presence of the C-14 hydroxyl group and two carbonyl groups as well as the absence of C-3 and C-6 protons. Moreover, the appreciable downfield shift of the C-14 proton of G XVII as compared to that of G III (δ 5.10, in C_5D_5N) also suggested the spatial closeness of the C-14 proton and a carbonyl group in G XVII (see **8**). Therefore, the 3,6-didehydro G III structure seemed suitable for G XVII.

This reasoning was proved correct by leading G I (**4**) with chromium trioxide in pyridine to 3,6-didehydro G I[6] (**5**) and by hydrolyzing the diketone with potassium carbonate in ethanol to give a product, which

was, in all respects, (IR, MS, NMR, and tlc) identical with G XVII. The new toxin was, therefore, formulated as 3,6-didehydro G III (**6**).

Two monoketo grayanoids, G V[2] and XIV,[3] were previously isolated and shown to possess no appreciable physiological activity. G XVII is the first grayanoid containing two carbonyl groups, and, in contrast to the monoketo grayanoids, it shows the sneeze-causing activity characteristic of polyhydroxylated grayanoids. The conformation of the central cycloheptane rings of G XVI and G XVII seems quite similar to that of G I on the basis of the NMR evidence presented above.

Experimental

All the mps are uncorrected. The NMR spectra were obtained on a Hitachi R-20B spectrometer, modified for INDOR experiments, in $CDCl_3$ or C_5D_5N, containing TMS as the internal reference. The chemical shifts are reported on the δ scale (s=singlet, q=quartet, d=doublet, bd=broad doublet). The IR spectra were measured on a JASCO Model IR-S spectrophotometer. The ORD curves were obtained on a JASCO ORD/UV-5 spectrometer. The specific rotations were measured in methanol at room temperature.

Isolation of G XVI and XVII. The powder (41 kg) of the leaves, which had been collected on Mt. Tarumae, Hokkaido, in July and dried, was extracted with hot water (*ca.* 4×10^3 l) for 3 days. The extracts were then concentrated under reduced pressure to *ca.* 70 l. An excess sat. lead acetate solution was added to the concentrate, and the ppt. was filtered off. An ammonium hydroxide solution was then added to the filtrate until the solution became alkaline (pH 8), after which the ppt. was filtered off again. H_2S gas was next bubbled through the filtrate to remove the Pb. After filtration and concentration, the solution was extracted with ethyl acetate. The organic phase was then dried over anhydrous sodium sulfate and concentrated under reduced pressure to give a crude mixture consisting mainly of G I and III (368 g). After the removal of the solid material, the mother liquor was chromatographed on silica gel (2 kg, Wako, 100 mesh) and was roughly fractionated into A, B, and C. The first fraction, A (154 g), eluted with ethanol–chloroform (3:97, 2 l), was a mixture of several components and was rechromatographed on silica gel (600 g). A mixture containing G XVII (3 g, subfraction A_1) was first eluted with ethanol–chloroform (3:97, 0.8 l). Further elution with ethanol–chloroform gave, successively, G I, IV, V, and II (85, 13, 3, and 25 g respectively). The second fraction, B (252 g), a semicrystalline solid, was obtained by elution with ethanol–chloroform (5:95, 2 l). After the removal of the crystalline mixture of G I and II (125 g) with ethyl acetate, the filtrate was concentrated and the residue (126 g) was chromatographed on silica gel (800 g). Elution with ethanol–chloroform (3:97, 0.5 l) yielded a mixture (0.7 g, subfraction B_1) of leucothol A, C, and G XVII. Further elution with the same solvent afforded a mixture (5.8 g) of G I and XV, while elution with a more polar solvent system (7:93, 1.8 l) gave a mixture (119 g) of G I, II and V. Later fractions eluted with ethanol–chloroform (7:93, 3 l) contained, altogether, 282 g of G I, II, III, and V.

The above-described subfractions, A_1 and B_1, were then combined, and the mixture (3.7 g) was chromatographed on silica gel (400 g). Elution with ethanol–chloroform (2:98, 0.5 l) gave unknown compounds (268 mg). Further elution with the above solvent (3:97, 0.8 l) afforded leucothol C (53 mg) and then G XVII (118 mg): needles from methanol; mp 268—270 °C (dec.), $[\alpha]_D$ −157.3° (*c* 1, MeOH); ORD $[\phi]^{320nm}_{min}$ −20532 °C, $[\phi]^{275nm}_{max}$ +25752 °C; MS *m/e* 366 (M^+).

Found: C, 65.78; H, 8.27%. Calcd for $C_{20}H_{30}O_6$: C, 65.55; H, 8.25%.

Further elution with the same solvent system (4:96, 0.8 l) gave a mixture of leucothol A and B (390 mg), while elution with the 5:95 solvent system (1.5 l) afforded, successively, crystals of GV (380 mg), XV (185 mg), and XVI (210 mg). The last compound was recrystallized from ether to give plates; mp 116—118 °C, $[\alpha]_D$ +2.8° (*c* 1, MeOH); MS *m/e* 394 (M^+).

Found: C, 66.88; H, 8.69%. Calcd for $C_{22}H_{34}O_6$: C, 66.78; H, 8.44%.

Hydrolysis of G XVI. G XVI (37 mg) was dissolved in a mixture of aqueous sodium hydroxide (5%, 0.5 ml) and ethanol (2 ml), and the solution was heated under reflux for 1 hr. After cooling, the solution was diluted with excess ethyl acetate, washed with water and brine, and dried over anhydrous sodium sulfate. The evaporation of the solvent gave crystals (34 mg) identical (IR, NMR, and tlc) with those of G II.

Oxidation of G XVI. To a chromium trioxide–pyridine complex solution prepared from 90 mg of chromium trioxide and 1 ml of pyridine, a solution of G XVI (30 mg) in pyridine (2 ml) was added, after which the whole solution was left to stand for 1 day at room temperature. An usual work-up gave an amorphous solid (26 mg) which was purified from ethyl acetate. IR (cm^{-1}, film) 3480, 1745 (C=O), 1720 (O_2CCH_3), 1630 (C=C); NMR ($CDCl_3$) 1.08, 1.11, 1.42 (each 3H, s, C–CH_3), 2.06 (3H, s, O_2CCH_3), 5.00, 5.19 (each 1H, bs, C=CH_2), 6.39 (1H, q, J_{AX+BX}=4+9 Hz, C-6); MS *m/e* 390 (M^+).

Hydrolysis of 3,6-Didehydro G I (5).[6] A mixture of **5** (111 mg) and potassium carbonate (17 mg) in ethanol (5 ml) was stirred for 20 min at room temperature. After the evaporation of ethanol under reduced pressure, the residue was dissolved in ethyl acetate and the solution was washed with water and brine and dried over anhydrous sodium sulfate. The subsequent removal of the solvent gave crude crystals which were purified with ethyl acetate to afford prisms (85 mg). The crystalline product was identical with G XVII in all respects (IR, NMR, MS, and tlc).

Substituted Tetrahydropyridine and Dihydropyridobenzoxazine Ring Syntheses

Akio SAKURAI and Hiroshi MIDORIKAWA*

The Institute of Physical and Chemical Research, Wako, Saitama 351

**Department of Domestic Science, Showa Women's University, Setagaya, Tokyo 154*

(Received September 25, 1975)

Synopsis. The ternary condensation of ethyl acetoacetate, 3-methoxysalicylaldehyde, and substituted benzaldehydes in the presence of ammonium acetate gave 1,2,5,6-tetrahydropyridine (**1**) and 6*H*-8,9-dihidropyrido[1,2-*c*][1,3]-benzoxazine (**2**) derivatives.

We have previously shown[1] that the reaction of ethyl acetoacetate with substituted salicylaldehydes gives heterocyclic products which contain two salicylaldehyde residues. However, the ternary condensation of ethyl acetoacetate, 3-methoxysalicylaldehyde, and benzaldehyde derivatives was found to produce compounds containing salicylaldehyde and benzaldehyde residues. In this reaction, the use of *m*-nitrobenzaldehyde as the aldehyde reactant afforded a mixture of **1** and **2** or exclusively **2**, depending on the conditions. Attempts to isolate an intermediate from the reaction of 3-methoxysalicylaldehyde with 2,4-dichlorobenzaldehyde in ethanol gave a yellow crystalline solid. The elemental analysis and NMR spectral data of this substance are compatible with the structure **3** (R_1=R_3=Cl, R_2=H).

The mode of formation of the compound **1** can be concluded as follows. Two molecules of 3-methoxysalicylaldehyde and one of substituted benzaldehyde condense with ammonia to yield **3**. Then, **3** (which undergoes C–N bond cleavage) reacts to ethyl acetoacetate to form **1**. In support of this, treatment of ethyl acetoacetate with **3** (R_1=R_3=Cl, R_2=H) in the presence of ammonium acetate gave the compound **1e**. The compound **2** could be formed by further condensation of **1a** with another molecule of *m*-nitrobenzaldehyde.

Experimental

4-Amino-6-aryl-3-ethoxycarbonyl-2-(2-hydroxy-3-methoxyphenyl)-1,2,5,6-tetrahydropyridines (1). To a mixture of ethyl acetoacetate (0.05 mol), 3-methoxysalicylaldehyde (0.05 mol), and substituted benzaldehyde (0.05 mol) in ethanol (15 ml), ammonium acetate (0.05—0.06 mol) was added and the mixture was refluxed for 1—2 hr. The solid that separated on cooling was recrystallized from ethanol–dimethyl sulfoxide.

10-Amino-11-ethoxycarbonyl-4-methoxy-6,8-bis(3-nitrophenyl)-6H-8,9-dihydropyrido[1,2-c][1,3]benzoxazine (2). Ammo-

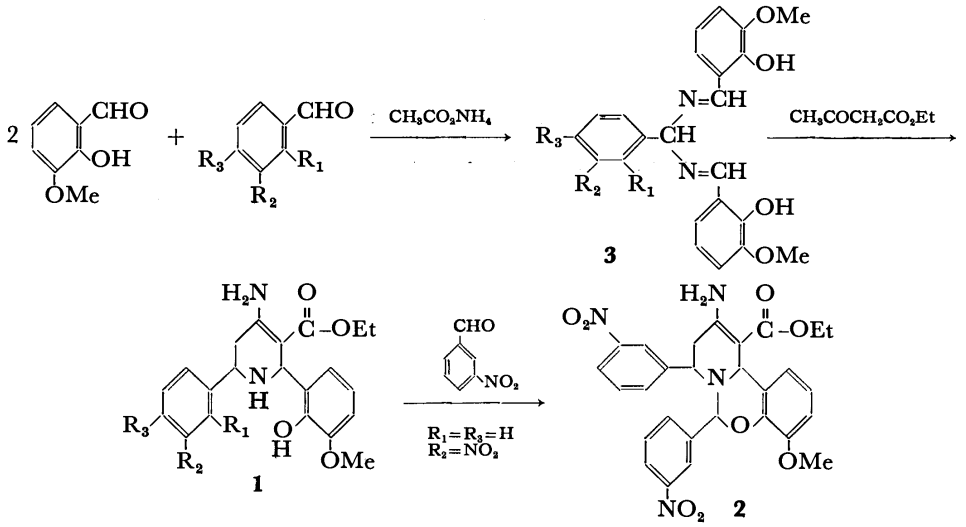
a) IR spectra were recorded for KBr disks. b) NMR spectra were determined in deuteriopyridine with tetramethylsilane as internal reference; s, singlet; d, doublet; t, triplet; q, quartet; b, broad; m, multiplet.



nium acetate (0.06 mol) was added to a mixture of ethyl acetoacetate (0.05 mol), 3-methoxysalicylaldehyde (0.05 mol), and *m*-nitrobenzaldehyde (0.05 mol) in ethanol (10 ml) and the mixture was heated under reflux for 2 hr. The reaction mixture was left at room temperature for several days, when yellow crystals were formed. The same reaction under reflux for 1 hr afforded a mixture of **1a** (13%) and **2** (13.5%). **2** was also prepared in 60% yield from the reaction of **1a** and *m*-nitrobenzaldehyde by refluxing with ammonium acetate in ethanol.

α,α-Bis(3-methoxysalicyclideneamino)-2,4-dichlorotoluene (3, R_1=R_3=Cl, R_2=H). To a mixture of 3-methoxysalicylaldehyde (2.0 g) and 2,4-dichlorobenzaldehyde (2.3 g) in ethanol (15 ml), ammonium acetate (1.0 g) was added and the mixture was heated under reflux for 0.5 hr. After cooling, water (3 ml) was added to the reaction mixture and the solution was left to cool for several days, a crystalline yellow solid separated; yield: 1.0 g; mp 135—136 °C (from ethanol).

Found: C, 59.93; H, 4.74; Cl, 15.26; N, 5.87%. Calcd for $C_{23}H_{20}Cl_2N_2O_4$: C, 60.13; H, 4.35; Cl, 15.45; N, 6.10%. NMR ($CDCl_3$): δ 3.88 (s, 6H, 2 OCH_3), 6.38 (s, 1H, =N-CH-N=), 6.8—7.1 (m, 6H, aromatic), 7.2—7.4 (m, 3H, aromatic), 8.56 (s, 2H, 2 -N=CH-), 12.84—13.24 (broad, 2H, 2 OH).

Heating this product with ethyl acetoacetate and ammonium acetate in ethanol for 1 hr gave the compound **1e** in 42% yield.

Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468
**Chemical Institute, Nagoya University, Chikusa-ku, Nagoya 464*

(Received November 12, 1975)

Synopsis. A zwitterionic alkaloid, the hydration product of daphnilactone-B, has been isolated from the fruits of the plant *Daphniphyllum teijsmanni* Zollinger, and its structure also been determined on the basis of its spectral and chemical properties.

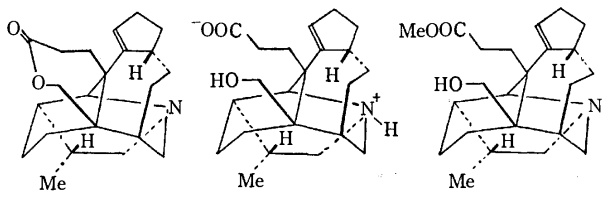
Many alkaloids have been isolated from the bark and leaves of the plant *Daphniphyllum macropodum* Miquel.[1] Further examination of the alkaloidal components in the fruits of the plant *Daphniphyllum teijsmanni* Zollinger led to the isolation of several alkaloids including daphnilactone-B (**1**) as a major product.[1,2] The present paper deals with the zwitterionic alkaloid related with daphnilactone-B.

As described in the previous paper,[2] an oily material containing alkaloidal components was chromatographed on alumina, and eluted successively with hexane, hexane–benzene (1: 1), benzene, benzene–$CHCl_3$ (1: 1) and $CHCl_3$ to give six alkaloids. Further elution with EtOAc–MeOH (9: 1) afforded colorless plates of a new alkaloid (**2**) in 0.00042% overall yield.

This alkaloid (**2**) has a molecular formula [$C_{22}H_{33}O_3N$ (*m/e* 359 (M^+)); mp (decomp) 247—248 °C] with the following spectral data: ν_{max} (Nujol) 3300, 1595, and 1575 sh.cm^{-1}; δ (CD_3OD–D_2O) 1.09 (3H, d, J=6.0 Hz), 3.40—4.05 (5H, complex), 3.70 (1H, d, J=10.5 Hz), 4.27 (1H, d, J=10.5 Hz) and 5.74 ppm (1H, br.s, $W_h \simeq 5$ Hz). The IR and NMR spectra of **2** indicate the presence of a hydroxymethyl group (ν_{max} 3300 cm^{-1}; δ 3.70 and 4.29 ppm). Furthermore, the IR absorption band at 1595 and 1575 sh.cm^{-1} may be due to the CO group of a carboxylate. This is confirmed by the following chemical evidence.

When treated with anhydrous MeOH containing HCl gas (room temp., 5 hr), this alkaloid was readily converted into a mixture of two compounds. The major product was proved to be identical with daphnilactone-B (**1**) (mp, mass and IR spectra), and the remaining one was the expected methyl ester (**3**) which had been already obtained on treatment of **1** with NaOMe.[2] Action of 90% HCOOH on **2** also converted it to daphnilactone-B.

Biogenetically, this zwitterionic alkaloid (**2**) may be regarded as a precursor of daphnilactone-B (**1**), although we can not rule out a possibility, in which the former is produced from **1** in the course of isolation.



1 **2** **3**

Experimental

All mps are uncorrected. The IR and mass spectra were recorded on a JASCO Model IR-S and on a Hitachi RMU 6C mass spectrometer, respectively. The NMR spectra were obtained on a Nihondenshi JNM-PS 100. Chemical shifts are given in ppm from TMS as an internal standard. Only prominent peaks are cited.

Isolation of the Zwitterionic Alkaloid (2). The fruits of the plant *Daphniphyllum teijsmanni* Zollinger (10 kg) were extracted with MeOH (10 l) at room temperature for 2 weeks and treated according to the procedure described in Ref. 2 to give an oil (12 g), which was chromatographed on alumina (Nakarai Chemical Co. Ltd., *ca.* 300 mesh) (60 g) and eluted with hexane, hexane–benzene (1: 1), benzene, benzene–$CHCl_3$ (1: 1) and $CHCl_3$ to afford methyl homodaphniphyllate, daphnilactone-B, daphniphylline, yuzurimine, methyl homosecodaphniphyllate and yuzurimine-B.[2] Further elution with EtOAc–MeOH (9: 1) afforded a crystalline solid, which was recrystallized from water–acetone to give colorless plates of **2**, mp (decomp) 247—248 °C (Found: *m/e* 359.24395. Calcd for $C_{22}H_{33}O_3N$: *m/e* 359.24603).

Formation of Daphnilactone-B (1) and the Methyl Ester (3). To a solution of **2** (50 mg) in anhydrous MeOH (2 ml) was added one drop of ether saturated with HCl gas. The reaction solution was stirred at room temp. for 5 h, and then concentrated under reduced pressure below 5 °C to leave a solid which was dissolved in $CHCl_3$ containing small amounts of $NaHCO_3$ and subjected to preparative tlc (Kieselgel 60 PF_{254}: hexane–Et_2O–Et_2NH (10: 10: 1)]. From the less polar fraction daphnilactone-B (**1**) (30 mg) was isolated (mp, IR and mass spectra), and the methyl ester (**3**) (5 mg) was obtained from the more polar fraction (IR and mass spectra).[2]

Conversion of 2 to Daphnilactone-B (2). A solution of **2** (73 mg) in 90% aq. HCOOH (1 ml) was stirred at 85 °C overnight, and then diluted with small amounts of water. The aqueous solution was made basic with Na_2CO_3 and extracted with $CHCl_3$. The extract was washed with sat. NaCl aq., and then dried over Na_2SO_4. Removal of the solvent gave a colorless oil, which was chromatographed on basic alumina (2 g) and eluted with $CHCl_3$ to afford daphnilactone-B (28 mg) (mp, and IR spectrum).[2]

The Initiation Reaction of Electro-initiated Polymerization of Acrylamide in the Kolbe Electrolysis System*

Zempachi OGUMI, Isao TARI**, Zenichiro TAKEHARA, and Shiro YOSHIZAWA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received May 10, 1975)

The mechanism of electro-initiated polymerization of acrylamide in the Kolbe electrolysis system was investigated in detail and the reaction path of the intermediate radicals was clarified by product analysis and a measurement of the consumption rate of the monomer. The Kolbe intermediate radical, $CF_3\cdot$, reacts first preferentially with the monomer. Next, the radical thus formed reacts with other species to produce $CF_3CH_2CH_2CONH_2$, $CF_3CH_2CH(CF_3COO)CONH_2$ and $CF_3CH_2CH(CONH_2)CH(CF_3CH_2)CONH_2$. The first reaction is fast, but the reaction of $CF_3COO\cdot$ with the monomer appears to be unreasonable. These reactions proceed on the electrode surface and in the layers below the diffusion layer, *i.e.*, in layers of the same order as the depth of unevenness on the platinized platinum electrode.

A few papers have been published concerning the utilization of Kolbe electrolysis as a source of free radicals for initiating polymerization and papers explaining the process of initiating polymerization are very few. The authors have also investigated the production of an oligomer[1,2] and a high polymer[3,4] of acrylamide utilizing the Kolbe reaction in a system of acetate and trifluoroacetate solutions. In a preceding paper[2], they have proposed the following reaction path as the most probable process of initiating polymerization of acrylamide in an aqueous solution of trifluoroacetic acid and potassium trifluoroacetate.

$$R\cdot + M \longrightarrow RM\cdot \quad (1)$$

$$RM\cdot + X \longrightarrow RMX \quad (2)$$

$$2RM\cdot \longrightarrow RMMR \quad (3)$$

$$RM\cdot + R\cdot \longrightarrow RMR \quad (4)$$

$$RM\cdot + M \longrightarrow RMM\cdot \xrightarrow{M} \text{oligomer} \quad (5)$$

where R· represents Kolbe intermediate radical, $CF_3COO\cdot$ and/or $CF_3\cdot$. Reaction (1) was assumed to be very fast. If this assumption is correct, one mol of the monomer will be consumed for every Farady of electricity in addition to that required for oligomer formation. The low current efficiency of oligomer production was ascribed to the fact that reaction (5), which leads to the formation of the oligomer, competes with reactions (2)—(4) which are considered to be fast. Therefore, it is expected that the products with low molecular weight represented by RMX, RMR and RMMR are formed during the oligomer formation. These compounds are examined in this paper in order to verify the above reaction path which was proposed by the authors. Also the kind of radicals taking part in initiating reactions and the manner by which the reactions of the intermediate radicals proceeds are discussed. Furthermore, the site of the polymerization reaction is examined. This is very important from the standpoint of improving of the current efficiency of the oligomer formation and of reaction system for the production of high polymers. This problem may concern the state of the Kolbe intermediate radicals.[5]

The experiments were conducted using a rotating cylindrical electrode and platinized platinum electrodes.

Experimental

The same equipment as that used in previous work was used for the electrolysis[2]. A cylindrical platinum electrode (1.3 cm in diameter, 10 cm^2 in area) was used in the rotating electrode experiment. Platinized platinum electrodes having various degrees of roughness were used. Besides a TFA and TFK 4M solution***, a 2M acetate solution was used, which includes 1 mol acetic acid and 1 mol potassium acetate in 1 liter. The measurement of the acrylamide content in the solution was carried out following the bromate-bromide method, which was modified so that the addition of bromide was performed in a nitrogen atmosphere and in the dark to eliminate the effect of oxygen.

Results

Low Molecular Weight Products. As shown in a preceding paper[2], neither normal Kolbe coupling products nor other gaseous products are formed in a system of electro-initiated polymerization in spite of the low current efficiency of oligomer formation. This fact and the above reaction path imply the existence of products such as RMX, RMR and RMMR in the electrolyte. On the basis of this prediction, the electrolyte was analysed after electrolysis. After electrolysis of a TFA and TFK 4 M solution containing 20 g/100 ml of acrylamide at 400 mA on a platinum electrode (3×3 cm^2), the electrolyte was analyzed using the gel filtration chromatographic technique. Peak b of curve A in Fig. 1 indicates the existence of products with low molecular weight. Peaks a, c and d correspond to products with high molecular weight, monomeric acrylamide and trifluoroacetate, respectively. Curve B corresponds to an aqueous solution of the acrylamide monomer. The following low molecular weight products were detected. $CF_3CH_2CH(CF_3COO)CONH_2$, $CF_3CH_2CH_2CONH_2$ and $CF_3CH_2CH(CONH_2)CH(CF_3CH_2)CONH_2$. These were isolated using the gas-chromatographic technique and identified using mass and infrared spectrophotometric techniques. The gas chromatogram also exhibited traces of products with

molecular weights higher than the above three compounds.

The Amount of Consumed Acrylamide. In order to confirm the participation of the intermediate radical R· in the Kolbe reaction with the monomer forming RM·, the amount of consumed monomeric acrylamide was measured based on the modified bromate-bromide method. The amount of the monomer consumed and of the polymer produced were measured. From these measurements, the amount of monomer consumed for reactions other than oligomer formation was calculated. This value per Faraday is illustrated in Fig. 2. The higher the concentration of acrylamide up to 2.4 M, the more acrylamide is consumed. At concentrations above 2.4 M, about one mol of monomer is consumed per Faraday. At concentrations lower than 2.4 M, the Kolbe dimer, ethane, is formed. In this case, R· produced by charge transfer on the electrode reacts to form the oligomer, ethane and other products. The amount of R· consumed other than that for oligomer

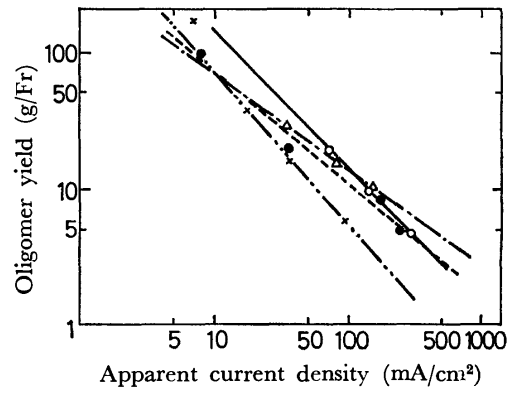

Fig. 3. The effect of surface roughness on the oligomer yield.
Electrolyte: 2 M acetate solution 100 ml+acrylamide 20 g, Electrode: Platinized platinum (1.5×3×2 cm²) r; ○: 1300, △: 175, ●: 60, ×: 45.

and ethane formation were calculated in order to obtain the amount of consumed acrylamide per mol of R· which resulted in products in the electrolyte with lower molecular weight. This amount is illustrated by A in Fig. 2.

The Effect of Electrode Surface Unevenness. The effect of electrode surface roughness was examined in order to obtain information about the area where the oligomer formation occurred. Platinum electrodes (1×2 cm²), coated on one side with silicon resin, were plated with platinum black in a solution of chloroplatinic acid so as to produce a surface of different roughness. The real surface area (A_1) was calculated from the amount of adsorbed hydrogen measured based on the charging curve method in 0.5 M H_2SO_4. The ratio of A_1 to the apparent surface area is designated the roughness factor (r). The relationship between the oligomer yield and the apparent current density on electrodes with different roughness factors was examined. As shown in Fig. 3, the yield increases with roughness factor in the region of relatively high current densities. The effect of roughness, however, is not great. The apparent current density at a given potential increases with r in a 2 M acetate solution without acrylamide but this increase is not great in comparison with the increase of r, and is less than in a solution containing acrylamide. This fact implies that only a part of the surface measured by the hydrogen adsorption method is effective for charge transfer on the electrode.

The Effect of Electrode Rotation. The relation between the area where the polymerization occurs and the thickness of the diffusion layer and the effect of the mass transfer rate to the electrode on oligomer formation were examined using the rotating cylindrical electrode in a 2 M acetate solution. As shown in Fig. 4, below 1500 rpm and above 2000 rpm only a small effect is observed, but there exists a marked increase between 1500 and 2000 rpm. This jump may be ascribed to a change from laminar to turbulent flow.

The Effects of Monomer Concentration and Current Density. The effect of current density was examined at different monomer concentrations in a 2 M acetate solution

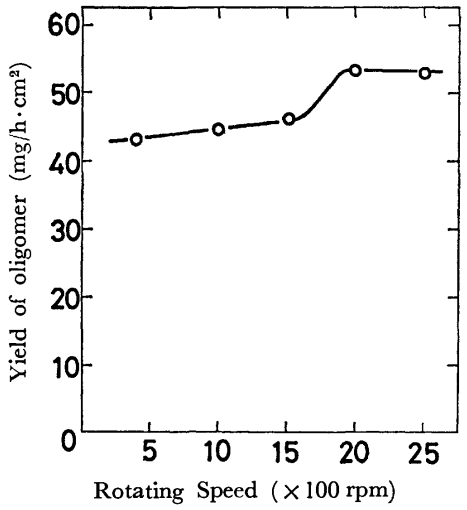

Fig. 4. Dependence of oligomer yield on rotating speed. Electrolyte: 2 M acetate solution 100 ml+acrylamide 20 g, Electrode: Cylinder electrode (10 cm²), Current: 200 mA.

using a cylindrical electrode. Figure 5 shows that at the acrylamide concentrations of 25 g/100 ml and 10 g/100 ml, the yield does not depend on the current density, in agreement with the case of the TFA and TFK 4 M solution[2]. As concentrations of 15 g/100 ml and 20 g/100 ml, however, the yield increases linearly with current density but does not exceed the value at 25 g/100 ml.

Discussion

Three compounds, $CF_3CH_2CH_2CONH_2$, $CF_3CH_2CH(CF_3COO)CONH_2$ and $CF_3CH_2CH(CONH_2)CH(CF_3CH_2)CONH_2$ were detected as products with low molecular weight, RMX, RMR and RMMR. These products indicate the occurrence of reactions (1)—(4). It was observed that 1 mol of the monomer was consumed per Faraday in addition to the consumption required for oligomer formation at high monomer concentrations. This fact supports the assumption that reaction (1) is so fast that almost all of the Kolbe intermediate radicals react with the monomer. In this consideration the current efficiency of the acetate discharge can be considered to be 100%. There exist two kinds of radical species, $CF_3\cdot$ and $CF_3COO\cdot$, as Kolbe intermediates. The fact that $CF_3COOCH_2CH_2CONH_2$ and $CF_3COOCH_2CH(CONH_2)CH(CF_3COOCH_2)CONH_2$ were not detected, but that $CF_3CH_2CH_2CONH_2$ and $CF_3CH_2CH(CONH_2)CH(CF_3CH_2)CONH_2$ were produced clearly shows that $CH_3\cdot$ reacts first with the monomer and the RM· thus formed produces farther reactions. This indicates that the reaction of the radical with the monomer is not as fast as the decarboxylation reaction of $CF_3COO\cdot$. Radical RM· is more active than the monomer and it can react fast with $CF_3COO\cdot$ or RM·, or it can extract hydrogen from other species. From these results we can deduce the reaction path of intermediate radicals as shown in Fig. 6. We have considered that the region where polymerization occurs is just in the vicinity of electrode, but it is still a question as to how far from the electrode this region extends. Some investigators have considered that it occurs on the electrode surface.[6]

The correlation between the height of the rough surface and the thickness of the reaction region in the experiment with the platinized platinum electrode is schematically shown in Fig. 7. In case A, where the thickness is small and the reaction layer is parallel to

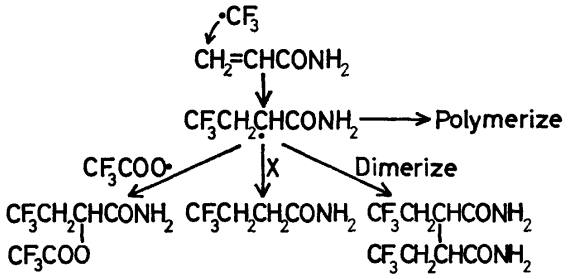

Fig. 6. Reaction path of intermediates.

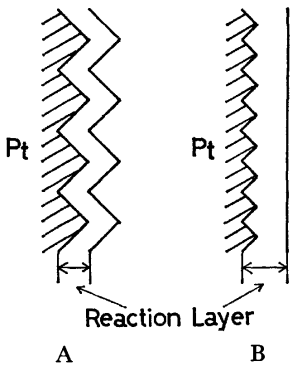

Fig. 7. The relation between surface unevenness and polymerization region.

the uneven surface of the electrode, the volume of the reaction region increases proportionally with an increase of the electrode surface on which the electrode reactions proceed. Thus the radical concentration is this region changes with the surface roughness at the same apparent current density. This causes an increase in the current efficiency of oligomer formation with an increase in surface roughness, because the current efficient of oligomer formation decreases with an increase in current density. In case B, where the reaction layer is thick enough so that the unevenness of the surface does not affect the deepest surface of the layer, the volume of the reaction layer does not increase even if the surface roughness increases. Accordingly, no change in oligomer yield will be caused by a change in the surface roughness. As is shown in Fig. 3, only a slight effect of surface roughness was observed at high current densities, while none was observed at low current densities. This indicates a state between A and B in Fig. 7, *i.e.*, the reaction layer is very thin and that of the same order of thickness as the unevenness of the platinized platinum electrode. Furthermore, this consideration is supported by the results using the rotating cylindrical electrode in which only a slight effect of the rotational speed was observed above 2000 rpm and below 1500 rpm. Namely, the reaction layer is very thin and does not extend into the diffusion layer which is influenced by the electrode rotational speed.

C-13 NMR Chemical Shifts and Charge Densities of Substituted Thiophenes—The Effect of Vacant d^{π} Orbitals

Yoshihiro OSAMURA, Osamu SAYANAGI, and Kichisuke NISHIMOTO
Department of Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 11, 1975)

The effect of vacant d^{π} orbitals on the charge distributions of heteroatomic systems containing sulfur and halogens is discussed. From an appropriate estimation of the Coulomb and resonance integrals associated with the vacant d^{π} orbitals, a linear relationship is obtained between charge density and C-13 chemical shift. For a discussion of the reactivity for electrophilic substitution of thiophene, the contribution of d^{π} orbitals of sulfur atom should be taken into account.

The C-13 NMR chemical shift can be empirically correlated with the charge density on a given carbon atom in a molecule.[1] Since charge density is an important quantity for the study of the chemical reactivity of molecule, an investigation of a relationship between the C-13 chemical shift and the charge density will greatly contribute to theoretical organic chemistry. For aromatic hydrocarbons, substituted benzenes and aromatic heterocyclic compounds containing oxygen or nitrogen atoms, π-electron densities calculated by the MO method have a nearly linear relationship with the C-13 chemical shifts.[1] However, such linear correlation has not yet been obtained for the organic compounds containing halogen and sulfur atoms. The reason for this may be due to the contribution of the vacant d-orbitals to the electronic structure of these compounds. In order to elucidate the effect of vacant d-orbitals of sulfur, chlorine, and bromine atoms on the charge distributions, we carried out a MO calculation based on the σ-included ω-HMO method.[2] We have studied the relationship between C-13 NMR chemical shifts and charge densities for pyrrole, furan, thiophene, and its derivatives.

Theoretical

NMR Chemical Shift and Local Charge Density. The quantum theory of NMR chemical shift was developed by Ramsey.[3] He calculated the shielding parameter σ by means of the second order perturbation theory. However, it is difficult to apply his equation to large molecules. The total shielding constant can be expressed by a sum of local contributions. The expression of shielding constant is divided into the following three terms: 1) The diamagnetic contribution or Lamb term for the atom being considered, σ_d. 2) The paramagnetic term for the same atom, σ_p. 3) The contribution from other atoms, σ'. Thus

$$\sigma = \sigma_d + \sigma_p + \sigma' \tag{1}$$

The diamagnetic term, σ_d, can be given by

$$\sigma_d = \frac{e}{3mc^2}\sum_i \langle r_i^{-1} \rangle \tag{2}$$

where $\langle r_i^{-1} \rangle$ is the mean inverse distance of electron i from the nucleous, and the summation is taken over the electrons in the atom considered.

Karplus and Pople[4] pointed out that in a C-13 NMR chemical shift, σ_d makes no significant contribution. The neighbor atom term, σ', is also very small. Thus, the main contribution to the C-13 chemical shift arises from the paramagnetic term, σ_p. Since the NMR measurement in liquid sample deals with a rotational average, σ_p^A associated with a given atom A can be represented by

$$\sigma_p^A = -\frac{e^2h^2}{2m^2c^2\Delta E}\langle r^{-3} \rangle_{2p} \sum_B Q_{AB} \tag{3}$$

where

$$Q_{AB} = \frac{4}{3}\delta_{AB}(P_{x_Ax_B} + P_{y_Ay_B} + P_{z_Az_B}) - \frac{2}{3}(P_{y_Ay_B}P_{z_Az_B} + P_{z_Az_B}P_{x_Ax_B} + P_{x_Ax_B}P_{y_Ay_B}) + \frac{2}{3}(P_{y_Az_B}P_{z_Ay_B} + P_{z_Ax_B}P_{x_Az_B} + P_{x_Ay_B}P_{y_Ax_B}). \tag{4}$$

ΔE is a mean excitation energy, and $\langle r^{-3} \rangle_{2p}$ is the mean cube inverse distance of a 2p electron from the nucleous. $\sum$ extends over the atom considered and the neighboring atoms, P_{ab} being the element of charge density and bond order matrix in the unperturbed molecule.

For the sake of simplicity, we make the following approximations; 1) σ-AO of carbon atom can be represented by a sp^2 hybridization. Thus, each σ-AO can be expressed as follows.

$$\left.\begin{aligned} \sigma_1 &= \frac{1}{\sqrt{3}}\phi(2s) + \frac{2}{\sqrt{6}}\phi(2p_x) \\ \sigma_2 &= \frac{1}{\sqrt{3}}\phi(2s) - \frac{1}{\sqrt{6}}\phi(2p_x) + \frac{1}{\sqrt{2}}\phi(2p_y) \\ \sigma_3 &= \frac{1}{\sqrt{3}}\phi(2s) - \frac{1}{\sqrt{6}}\phi(2p_x) - \frac{1}{\sqrt{2}}\phi(2p_y) \end{aligned}\right\} \tag{5}$$

2) ΔE is assumed to be constant for each molecule. The assumption does not seem to be unreliable, since the C-13 NMR chemical shifts of aromatic hydrocarbons are almost constant, in spite of the fact that the average excitation energy changes considerably with the size of molecule. 3) Bond order dependence of the chemical shift is neglected. The C-13 chemical shifts should depend on the bond orders. However, Olah and Mateescu[5] showed that in a series of stable carbonium ions the C-13 chemical shifts can be fairly well correlated with only the charge densities, in spite of the fact that their bond orders vary considerably. Let us assign the charge densities q_1, q_2 and q_3 to each σ-AO's, σ_1, σ_2, and σ_3 of a given carbon atom and q^{π} to the π-AO, respectively.

If we use the expression

Table 1. Parameters associated with π and σ AO's

Atom	δ_μ^π	ω	Bond	$k_{\mu\nu}^\pi$	Atom	δ_μ^σ	ω
C·	0.0	0.5	C≡C	1.0	C(sp^2)	0.0	0.25
N·	0.5	0.5	C=C	1.1	C(sp^3)	−0.05	0.25
N:	0.8	0.5	C-C	0.9	O	0.5	0.25
O·	1.0	0.5	C-NO_2	0.9	N	0.25	0.25
O:	1.4	0.5	N≡O	1.1	H	−0.1	0.43
S:	1.0	0.5	C=O	1.2	S	−0.06	0.17
Cl:	1.7	0.5	C-O	0.7	Cl	0.0	0.17
Br:	1.3	0.5	C-S	0.5	Br	−0.2	0.12
			C-Cl	0.6			
			C-Br	0.5		$\beta_{\mu\nu}^\sigma = \beta$	

$$\Delta q_i = q_i - 1 \tag{6}$$

we obtain

$$\left.\begin{aligned} \Delta P_{xx} &= \frac{1}{6}(\Delta q_1 + 4\Delta q_2 + \Delta q_3) \\ \Delta P_{yy} &= \frac{1}{2}(\Delta q_1 + \Delta q_3) \\ \Delta P_{zz} &= \Delta q^\pi \end{aligned}\right\} \tag{7}$$

$$P_{xy}P_{yx} = \frac{(q_3 - q_1)^2}{12}.$$

Assuming Slater's rule, the integral $\langle r^{-3}\rangle_{2p}$ can be easily represented by

$$\langle r^{-3}\rangle_{2p} = \frac{1}{24a_0^3}(3.25 - 0.35\Delta Q)^3 \tag{8}$$

where

$$\Delta Q = \Delta q_1 + \Delta q_2 + \Delta q_3 + \Delta q^\pi$$

a_0 means the Bohr radius. Substituting Eqs. (4), (7), and (8) into Eq. (3), we obtain

$$\sigma_p^A = -K(1 - 0.108\Delta Q)^3\{9 - \Delta q^\pi(\Delta q_1 + \Delta q_2 + \Delta q_3) - (\Delta q_1\Delta q_2 + \Delta q_2\Delta q_3 + \Delta q_3\Delta q_1)\} \tag{9}$$

where

$$K = \frac{e^2h^2}{m^2c^2\Delta E}\frac{3.25^3}{216a_0^3}$$

Since Δq_t is usually very small, we can, to a first approximation, neglect higher terms. Consequently, Eq. (9) can be rewritten as

$$\sigma_p^A = -9K(1 - 0.324\Delta Q) \tag{10}$$

showing a linear relationship between C-13 NMR chemical shift and charge density. The present expression is the same as that obtained by Yonezawa *et al.*[6] for saturated hydrocarbon systems. As Alger *et al.*[7] pointed out, when orbital contraction of σ-AO is considered, Eq. (10) is modified as follows:

$$\sigma_{C^{13}} = a\Delta q^\pi + b\Delta Q - c\Delta P \quad (a = b) \tag{11}$$

B. MO calculation

In the present study, the charge densities were calculated by the σ-included ω-HMO method which is summarized as follows: As σ-bonds are almost localized between two atoms, we can approximately describe them by means of the two center MO. ω-Technique is used in order to take so-called inductive effect of a heteroatom through bonds into account. Thus, the polarized σ-framework is determined by the two center ω-HMO method. The π-electrons are regarded as moving over this σ-framework. The π-densities, then are dependent on the σ- and π-charge densities. We neglect the effect of π-charge densities on the σ-bonds. The net charge ΔQ_μ on the atom μ is given by

$$\Delta Q_\mu = \Delta Q_\mu^\sigma + \Delta q_\mu^\pi. \tag{12}$$

The Coulomb integrals associated with the σ- and π-AO's of the μ-th atom, α_μ^σ and α_μ^π are expressed as follows:

$$\alpha_\mu^\sigma = \alpha_c^\sigma + \delta_\mu^\sigma\beta + \omega^\sigma\Delta Q_\mu^\sigma$$
$$\alpha_\mu^\pi = \alpha_c^\pi + \delta_\mu^\pi\beta + \omega^\pi\Delta Q_\mu$$

The resonance integral for the μ-ν bond, $\beta_{\mu\nu}$, is represented by

$$\beta_{\mu\nu}^\sigma = k_{\mu\nu}^\sigma\beta, \qquad \beta_{\mu\nu}^\pi = k_{\mu\nu}^\pi\beta.$$

The values of ω's, δ_μ's and $k_{\mu\nu}$'s, used are summarized in Table 1.

Since the compounds we considered include sulfur and halogen atoms, the contribution of d-orbitals should be taken into account. We consider only the vacant d^πAO's in our MO calculation. The Coulomb and resonance integrals associated with d^πAO's are estimated with use of atomic energy levels[8] and overlap integrals between $2p\pi$ and $3d\pi$ AO's. Their values are given in Table 2.

Table 2. Parameters associated with d^π orbitals

Atom	$\delta_{\mu d}^\pi$	ω	Bond	$k_{\mu\nu}$
S	−1.0	0.4	C-S	0.5
Cl	−0.8	0.4	C-Cl	0.5
Br	−0.7	0.4	C-Br	0.5

Results and Discussion

Charge Density and C-13 *NMR Chemical Shift.* The effect of substitution on the electron distribution is quite important for discussing the chemical reactivity of a substituted compound. The influence of the heteroatoms on the charge density of a given carbon atom can be described in terms of mesomeric and inductive effects. Takahashi *et al.*[9] reported the C-13 NMR chemical shifts of thiophene and its derivatives and presented some interesting results. However,

they could not obtain inter-relationship between the charge density and the chemical shift. In this paper, the experimental data are quoted from their work. From the NMR measurements, it is expected that in pyrrole and furan the charge densities of C_2 positions are smaller than those of C_3 positions, because of the lower chemical shifts. However, in thiophene the chemical shifts of both positions are almost the same.

In Fig. 1, the charge densities of substituted thiophenes calculated by σ-included ω-HMO method are plotted against the chemical shifts, neglecting the contribution of d-orbitals. The plots deviate considerably from lineality. This might be caused by the neglect of contribution of vacant d-orbitals. The results of thiophene derivatives calculated by CNDO/2 method are shown in Fig. 2. The CNDO/2 method takes explicitly the contribution of d-orbitals into account. However, no improvement could be obtained. This could be attributed to an overestimation of the contribution of d-orbitals at C_3 and C_4 positions. The failure is due to the estimation of parameters associated with d-orbitals.

In our calculations, the resonance integrals between $d\pi$ and $2p\pi$ AO's of non-neighbors are completely neglected. In thiophene, the C–S–C bond angle is known to be almost 90°.[10] We, therefore, assumed σ AO's of sulfur atom are not hybridized but are pure $3p_x$ or $3p_y$ AO's. Thus, $3d_{xz}$ and $3d_{yz}$ should be directed toward each C-S bonds as shown in Fig. 3. We considered only one $d\pi$ AO in a halogen atom, Cl or Br. In Figs. 4 and 5, the charge densities calculated by σ-included ω-HMO method, including

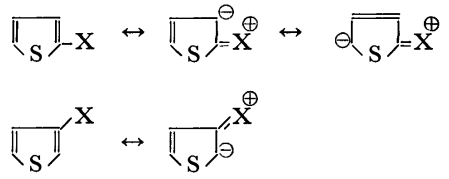
$d\pi$ orbitals, are plotted against the chemical shifts. We see a better correlation than the results without $d\pi$ orbitals. The plots of α-positions of methyl, carbonyl, and cyano derivatives deviated considerably. This deviation may be caused by another factor, such as anisotropy effect.

The mesomeric effect of a substituent on the charge distribution is an important problem in theoretical organic chemistry. The resonance structure of thiophene derivative having an electron donating group can be written as follows:



Thus, the π-electron densities on the β and δ carbons vary a great deal with mesomeric effect of substituent. In the case of δ-carbon of 2-substituted thiophene, a plot of π-electron density against the corresponding C-13 NMR chemical shift has distinct lineality, as shown in Fig. 6. A similar plot shows no lineality, when the contribution of $d\pi$ orbitals is neglected. This fact suggests us that, in order to investigate the mesomeric effect in a heteroatomic system containing S, P, Cl, or Br atoms, the contribution of the vacant $d\pi$ orbitals should be taken into consideration. When we take $d\pi$ orbitals of sulfur atom into consideration, the plots of pyrrole, furan, and thiophene show a better lineality.

Contribution of dπ Orbital to Frontier MO's. The chemical reactivity of conjugated system can be interpreted, to a first approximation, by the frontier MO's, HOMO and LUMO.[11] The MO's and their energies of thiophene are summarized in Table 3. MO spacings are shown in Fig. 8. We see that if dπ orbitals are neglected, ψ_2 and ψ_3 are almost degenerate each other. The frontier electron densities at C_2 and C_3 are calculated to be 0.350 and 0.318, respectively. It is known experimentally that the C_2 position is most reactive. Thus, this tendency can not be interpreted by the calculation of case i) in Table 3. On the other hand, in the calculation of case ii), the orbital degeneracy of HOMO's is removed by the contribution of vacant dπ orbitals. The frontier electron density at C_2 becomes much larger than that at C_3. This shows that in order to explain the reactivity of electrophilic substitution of thiophene, we should consider vacant dπ orbitals. In the discussion of the Diels-Alder reaction, Lert and Trindle[12] pointed out the importance of the contribution of dπ orbitals in thiophene.

ESR Study of Cationic Radicals in Aromatic Compound–Cu–$AlCl_3$ Systems

Sei-ichiro IMAMURA, Kumao HAMANOUE, Seiji FUKUDA, Hiroshi TERANISHI, and Yoshihisa WATANABE*

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

**Department of Hydrocarbon Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606*

(Received June 12, 1975)

The electron spin resonance spectra of several aromatic compound–Cu–$AlCl_3$ systems were observed. When benzene, toluene, and ethylbenzene were used as the aromatic compounds, a singlet with a *g*-value of 2.003 was obtained. In the case of the *o*-, *m*-, and *p*-xylene systems, spectra with well-resolved hfs's resulted. It was suggested that cationic radicals were formed by a transfer of an electron from the benzene ring to Cu(II)–$AlCl_3$.

It has been reported that copper(I) chloride, aluminium chloride, and benzene form a ternary complex, and its structure has been determined by an X-ray diffraction technique.[1] The copper(I) ion has a distorted tetrahedral environment and is located above one of the C–C bonds of the benzene ring by means of a π-type interaction. The distances between the copper(I) ion and the two nearest adjacent carbon atoms are not equivalent; they are 2.15 and 2.30 Å respectively.

When the complex was used in the Friedel-Crafts reaction as a catalyst, the product distribution differed from that in the reaction catalyzed by aluminium chloride alone.[2] For example, in the synthesis of cymene from toluene and isopropyl chloride, the selectivity in *o*- and *m*-products was highly increased by use of the complex. However, the catalytic action of the complex has not been discussed in detail, and it seemed that it would be interesting to study the nature of the aromatic compound–Cu–$AlCl_3$ system (ArH–Cu–$AlCl_3$) by means of the ESR technique from the viewpoint of the interaction of copper with a benzene ring.

Experimental

Materials. The aromatic compounds were carefully purified by the usual method. The anhydrous copper(I) chloride and copper(II) chloride were prepared by the reduction of, and by the dehydration of copper(II) chloride dihydrate respectively. Commercial G. R. grade copper(I) oxide, copper(II) oxide, and aluminium bromide were used without further purification. The aluminium chloride was purified by the sublimation of a commercial G. R. grade reagent.

Preparation of the Samples. The samples were prepared in the following two ways.

Method A: In a 50-ml reaction flask, a mixture of known amounts of copper salt, aluminium salt, and a 5-ml portion of an aromatic compound was stirred under a nitrogen atmosphere at room temperature. The upper layer was put into an ESR sample tube by means of a syringe, and the tube was sealed.

Method B: In a 10-ml reaction vessel equipped with an ESR sample tube, known amounts of copper salt and aluminium salt were placed, and then the vessel was evacuated. About a 5-ml portion of a degassed aromatic compound was distilled into the vessel by the use of a vacuum line, after which the mixture was stirred. An upper layer was decanted into the sample tube and sealed. The concentration of copper salts was 0.1—0.2 mol/l.

ESR Spectra. The electron spin resonance spectra were usually recorded at room temperature with a JEOL-JESPE spectrometer, while the *g*-values were determined by the use of Mn^{2+} as a standard marker. When the measurements at an elevated temperature were necessary, the temperature was maintained by passing hot air through the cavity.

Results and Discussion

ESR Spectra of the Samples Prepared by Method A. While copper salts were insoluble in aromatic compounds, such as benzene or toluene, they were easily dissolved by the addition of aluminium chloride to form brown, purple, yellow, or green homogeneous solution. The rate of the dissolution of copper salts in the aromatic compounds increased in the order of benzene, toluene, ethylbenzene, and *p*-xylene. Copper(II) chloride was the most soluble among the copper salts used.

From Table 1 one can see that all the spectra of ArH–Cu–$AlCl_3$ consist of a singlet with a *g*-value of 2.003 and a ΔH_{msl} value smaller than 10 G, indicating the presence of organic radicals. However, the aluminium bromide systems investigated showed no signal or, if any, a very weak one. In all cases, no spectrum due to the copper(II) ion was observed; this suggests that copper is in the copper(I) state.

TABLE 1. ESR SPECTRA OF AROMATIC COMPOUND–Cu–Al SYSTEMS PREPARED BY METHOD A

		CuO	—	—
Ethylbenzene	$AlCl_3$	CuCl	5.00	2.003

a) very weak

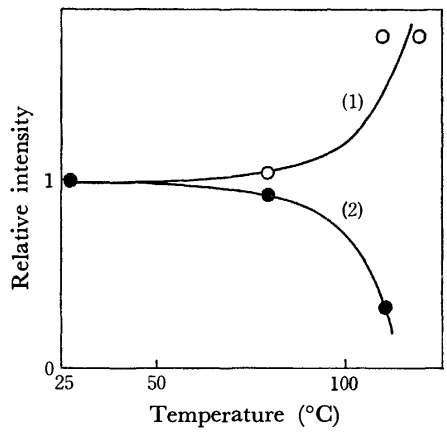

Fig. 1. Temperature dependence of the spectra of (1) toluene-CuCl-$AlCl_3$ and of (2) *p*-xylene-CuCl-$AlCl_3$.

Figure 1 shows an effect of the temperature on the intensities of the signals of ArH-Cu-$AlCl_3$. The ordinate indicates the intensity relative to that of the Mn^{2+} marker. The intensity of the signals of *p*-xylene system does not decrease up to 80 °C, while that of the toluene system increases by heating up to 120 °C. These facts indicate that the radicals are thermally stable to a considerable extent.

They were also found to be stable toward oxygen, and the radical nature still remained under an atmospheric condition when the unreacted aromatic compound was excluded. For example, when excess *p*-xylene was removed by the evaporation from the *p*-xylene-CuCl-$AlCl_3$ system, the spectrum of the residual solid material was observed to be as is shown in Fig. 2.[3] A sharp singlet with a *g*-value of 2.003 is superimposed upon the broad spectrum of the copper(II) ion. It seems that the copper(II) ion was formed by the oxidation of the copper(I) ion by air during the procedure.

ESR Spectra of the Samples Prepared by Method B. As has been mentioned above, the spectra of ArH-Cu-$AlCl_3$ prepared by Method A had no hfs. This may be due to dissolved oxygen, which causes the line broadening of the spectrum. Dissolved oxygen may also affect the valence state of copper; the copper(I) ion may be oxidized to the copper(II) state during the preparation of the samples. Therefore, the effect of oxygen was excluded by preparing the samples under a vacuum. The aromatic compounds used were toluene, *o*-, *m*-, and *p*-xylene, while the copper salts used were copper(I) chloride, copper(II) chloride, and copper(II) oxide.

Copper(I) chloride, although dissolved rapidly in these organic solvents to form brown homogeneous solutions, showed no spectrum. On the other hand, spectra were obtained in all cases where copper(II) salts were used. However, the spectra of the samples prepared in toluene consisted of only a singlet; the same result was obtained in the case of *p*-xylene-$CuCl_2$-$AlCl_3$.

The *p*-xylene-CuO-$AlCl_3$ system gave a dark purple solution; its ESR spectrum, consisting of about eighty lines spaced over thirty gauss, is shown in Fig. 3. As has been mentioned before, Turner has reported that the benzene-CuCl-$AlCl_3$ complex has a π-type copper-benzene ring interaction and that the copper is located above one of the C-C bonds.[1] Taking this into consideration, it appears that the spectrum shown in Fig. 3 is due to a cationic or an anionic radical of Turner's type. If the radical has a symmetrical configuration, and if all the protons on the benzene ring are equivalent, its spectrum will consist of thirty-five lines. An alternate explanation for the unusual complex spectrum may be that there exists a dimer of the ionic radical, as has been reported for a cationic radical of naphthalene.[4] However, the exact assignment of the observed spectrum has not yet been done. This radical was stable in the presence of oxygen. Though line broadening occurred after air was introduced, the hfs could still be observed. The line broadening may be explained by the dipole-dipole interaction with oxygen and/or with the copper(II) ion formed by the oxidation of the copper(I) ion.

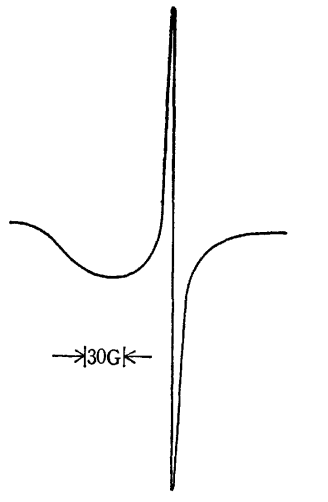

Fig. 2. ESR spectrum of *p*-xylene-CuCl-$AlCl_3$ after evaporation of excess *p*-xylene,

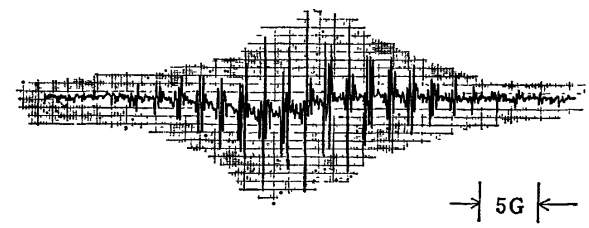

Fig. 3. ESR spectrum of *p*-xylene-CuO-$AlCl_3$.

Figures 4 and 5 show the spectra of *o*-xylene-CuO-$AlCl_3$ and *m*-xylene-CuO-$AlCl_3$ respectively. They are different from that of *p*-xylene-CuO-$AlCl_3$; each consists of about one hundred and fifty lines. It is expected that the hfs of the toluene system as well as of the other systems listed in Table 1 can be obtained by choosing optimum conditions for the preparation of these samples.

The copper(I) systems prepared by Method B yielded no signal. However a signal began to appear when air was introduced into *p*-xylene-CuCl-$AlCl_3$,

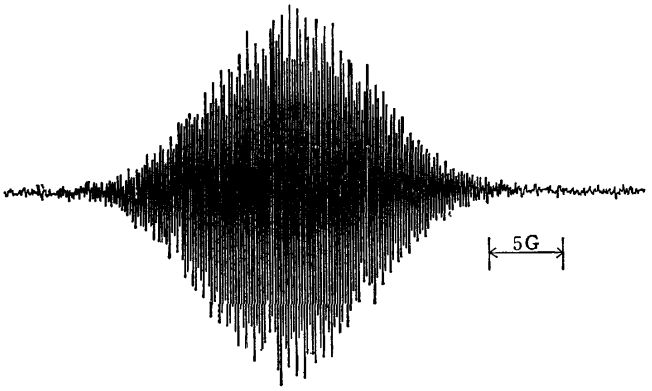

Fig. 4. ESR spectra of *o*-xylene–CuO–$AlCl_3$.

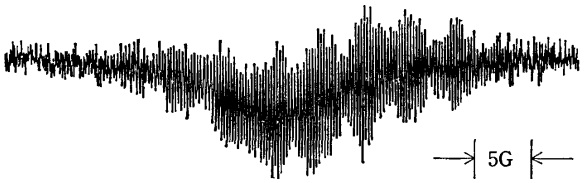

Fig. 5. ESR spectrum of *m*-xylene–CuO–$AlCl_3$.

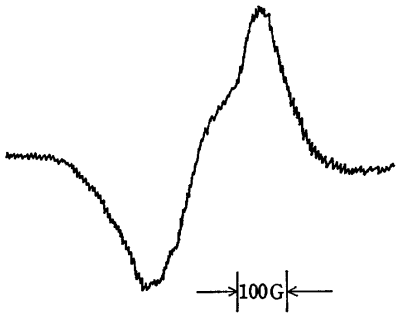

Fig. 6. ESR spectrum of *p*-xylene–CuCl–$AlCl_3$ after an introduction of air and successive addition of tetrahydrofuran.

and, in the presence of an optimum amount of air, a spectrum exactly identical with that shown in Fig. 3 was observed. On the addition of tetrahydrofuran to the system, a precipitate appeared. As is shown in Fig. 6, the spectrum of this precipitate had no signal due to an organic radical; instead, an absorption due to the copper(II) ion was observed. These results suggest that the copper ion in the system is in the copper(I) state and that the copper(II) ion is necessary to produce the organic radical. Therefore, it appears that a transfer of an electron from the benzene ring to the copper(II) ion occurs and that, as a result, the copper(I) ion and an aromatic cationic radical are formed.

It has been known that aluminium halides form complexes with aromatic hydrocarbons.[5-7] Therefore, aluminium chloride alone was dissolved in *p*-xylene under the conditions described in Method B; the spectrum of the resultant pale yellow solution was observed to be as is shown in Fig. 7. The spectrum consists of about sixteen lines, with a hyperfine coupling constant of 1.7 G. The ESR spectra of cationic

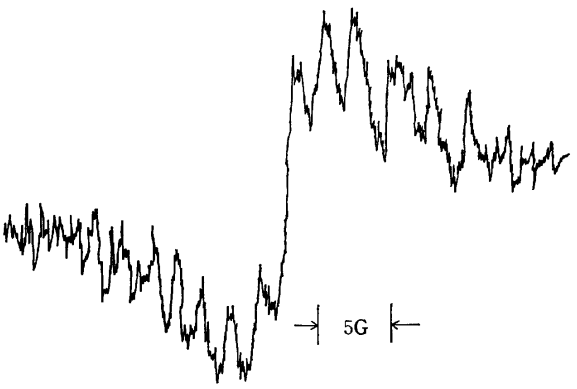

Fig. 7. ESR spectrum of *p*-xylene–$AlCl_3$.

radicals in the complexes of aluminium chloride with aromatic compounds (–anthracene, chrysene, and perylene–) were observed by Rooney *et al.*[8]; our result is very similar to theirs. Therefore, the radical shown in Fig. 7 seems to be a cationic radical produced from *p*-xylene. There is a possibility that the spectra of ArH–Cu–$AlCl_3$ obtained are formed merely by an interaction of aromatic compounds with aluminium chloride. However, this can be excluded on the basis of the following facts: (1) Both the colour and the ESR spectra of ArH–Cu–$AlCl_3$ are different from those of the aromatic compound–$AlCl_3$ systems. (2) The copper(I) ion does not produce any radical species under a vacuum even in the presence of aluminium chloride. Therefore, the cationic radicals in ArH–Cu–$AlCl_3$ are essentially different from those in aromatic compound–$AlCl_3$ systems.

Summary. From the results obtained so far, it can be concluded that a transfer of an electron from the benzene ring to Cu(II)–$AlCl_3$ occurs and that a cationic radical is formed. In this process, the copper(II) ion is reduced to the copper(I) state. The cationic radical thus formed is stabilized by an interaction with Cu(I)–$AlCl_3$:

$$ArH + Cu(II) + AlCl_3 \longrightarrow ArH^+\cdots Cu(I)\cdots AlCl_3$$

However, it is not yet known whether the cationic radical is in a monomer or a dimerized form.

The copper(I) ion produces no cationic radical, although it reacts readily with aluminium chloride and aromatic compounds. On the addition of oxygen to the system, the copper(I) ion is oxidized to the copper(II) ion, which removes a π-electron from the benzene ring and produces the cationic radical:

$$ArH + Cu(I) + AlCl_3 \longrightarrow ArH\cdots Cu(I)\cdots AlCl_3 \xrightarrow{O_2}$$

$$[ArH\cdots Cu(II)\cdots AlCl_3] \longrightarrow ArH^+\cdots Cu(I)\cdots AlCl_3$$

A complete assignment of the hfs of the spectra could not be achieved; a detailed investigation is, therefore, now under way using the ENDOR technique.

(Received June 21, 1975)

$S_n \leftarrow S_1$ absorption spectra of 9,9′-bianthryl in the visible and near infrared regions have been measured by means of picosecond flash spectroscopy. The $S_n \leftarrow S_1$ spectra in hexane measured at 500 ps after the exciting pulse were similar to those of anthracene while those in acetone were similar to the superposition of spectra of anthracene anion and cation. The results of the $S_n \leftarrow S_1$ spectral measurements together with those of the solvent effects upon the fluorescence yield and lifetime indicate an intramolecular electron transfer induced by the interaction with polar solvents in the excited state of 9,9′-bianthryl.

Solvent-induced changes of electronic structures are observed in the excited state of various systems[1–6)] such as *p*-(*N*,*N*-dimethylamino)-benzonitrile,[2)] 9,9′-bianthryl[3)] and some intramolecular heteroexcimer systems.[4–6)] Of these, 9,9′-bianthryl is one of the most important molecules investigated by various methods.

The fact that the two anthracene chromophores of 9,9′-bianthryl in the ground state as well as Franck-Condon(FC) excited state scarcely interact with each other has been shown by the measurements of polarizability,[7)] dipole moment,[7)] half reduction potential,[8)] molecular refraction,[9)] combustion energy,[10)] absorption, and fluorescence spectra.[3)] Moreover, the absorption spectra show no dependence upon the solvent polarity. The fluorescence spectra in rigid matrices and the absorption spectra in rigid as well as fluid solutions remain well structured as in the case of anthracene. Fluorescence spectra in solvents of low viscosity are diffuse compared with those of anthracene, although a slight vibrational structure can be observed in a nonpolar solvent. In polar solvents, the fluorescence spectra are composed of two bands; one shows a slight vibrational structure and is placed at the same wavelength region as in the nonpolar solvent and the other is structureless and shifted towards red.[3,11)] The results indicate a change of the electronic structure of 9,9′-bianthryl in the relaxation process from the FC excited state to the relaxed fluorescent state.[3)] We call the structured band E band and its emitting state E state, and the structureless band P band and its emitting state P state.

The red shift of the fluorescence in a polar solvent indicates that the relaxed fluorescent state has a dipole moment.[3)] It has been concluded on the basis of this fact as well as some quantum chemical calculations that the intramolecular charge transfer from one anthracene nucleus to another caused by the interaction with polar solvent molecules occurs in the excited state.[3,12)] If this is correct, the above result seems to indicate the phenomenon of solvent-induced "broken symmetry,"[13)] *i.e.* the lowering of the symmetry of the solute molecule due to the interaction with polar solvent molecules, resulting in the charge transfer state even if the molecule is composed of two identical chromophores. One of the most direct experimental methods to confirm this would be the measurement of $S_n \leftarrow S_1$ absorption spectra in various solvents of different polarities.

A method of picosecond flash spectroscopy has recently been developed by use of picosecond continuum (pc) as a monitoring light.[14)] We have also established a method of transient absorption measurement by picosecond flash spectroscopy in the visible, near infrared, and uv regions.[1,15,16)] Our method has a resolution of 50 ps in time and 2 nm in wavelength, and can be used for the transient absorption measurement even in the wavelength region of a strong fluorescence. By means of this method, we have measured the $S_n \leftarrow S_1$ absorption spectra of 9,9′-bianthryl in several solvents and have tried to demonstrate that the solvent-induced change of electronic structure is due to the intramolecular charge transfer from one anthracene nucleus to another.

In addition to the $S_n \leftarrow S_1$ absorption measurements, we have investigated the solvent effects upon the fluorescence yield and lifetime of 9,9′-bianthryl. The results seem to give some evidence for the solvent-induced change of electronic structure. Measurements of $T_n \leftarrow T_1$ spectra have also been carried out.

Experimental

Picosecond Flash Apparatus. The details of the method of picosecond flash photolysis and transient spectral measurements used in the present study have been described elsewhere.[1,15,16)] A summary is given herewith.

The sample was pumped with a frequency doubled single picosecond pulse at 347 nm from a mode-locked ruby laser system of JEOL and the transient spectra were monitored by a pc which was generated by collimating a single picosecond pulse at 694 nm into a cell of length 2—20 cm containing polyphosphoric acid (PPA) or water. A single pulse at 694 nm, which was selected from a mode-locked pulse train by a Pockels cell and amplified through a ruby rod, has an energy of *ca.* 100 mJ and a pulse width of 28 ps, and a pulse at 347 nm frequency doubled with KDP an energy of *ca.* 1 mJ. It was first reported by Nakashima and Mataga that the pc from PPA extends from 350 nm to 920 nm and can be used as the most suitable monitoring light in the spectral range 350—650 nm.[16)] The pc probe pulse with *ca.* 50 ps width, determined by an optical Kerr gate, was optically delayed with respect to the exciting pulse (delay time 0—20000 ps).

The 347 nm pump pulse entered the sample cell through one of the two 0.5 mm apertures at the front of the cell. The pc pulse passed through the sample cell from the opposite side was separated into two beams by the apertures. One beam passed through the part of the sample where the mole-

cules were excited. The other passed through the part where the molecules are in the ground state, and was used for correction of shot to shot power variations. The two beams were photographed simultaneously with a Shimadzu GE 100 spectrograph on a Kodak tri-X pan film in the UV~visible wavelength region and on a Kodak high speed infrared 2481 film in the visible near infrared region. We have confirmed that the usual relationship between the photographic density and exposure holds even in the case of the picosecond pulse excitation. Thus, the difference in the photographic densities for the two beams in the spectral range where the ground state absorption is not strong gives transient absorption spectra.

Even in the presence of a strong fluorescence in the same wavelength region as the transient absorption, we can obtain the absorption spectra since the sample cell was set 3 m apart from the spectrograph and the beam divergence of pc is very small (almost the same as that of laser light) in contrast to the fluorescence which becomes very weak after passing the long distance, spreading out in all direction. Our picosecond laser photolysis system was checked by measuring $S_n \leftarrow S_1$ spectra which had been established by the nanosecond laser photolysis method, for example, those of 1,2,4,5-tetracyanobenzene-toluene complex.[17]

Fluorescence Decay Curve Measurements. A 300 kW N_2 gas laser with a half width of 5.5 ns at 337 nm and a Q-switched ruby laser (JEOL, JLR-02A) with an output of *ca.* 100 mJ and a half width of 15 ns at 347 nm were used as the exciting light sources. The fluorescence decay curves were detected through a Nalumi R21 monochrometor with an RCA 1P28 photomultiplier and displayed on a Tektronix 475 oscilloscope. The circuit response time was *ca.* 5 ns. The picosecond pulse at 347 nm from the mode-locked ruby laser was also used for the excitation and the fluorescence was detected with an HTV R617 photodiode and a Tektronix 7912 transient digitizer (0.5 ns time resolution).

Measurements of $T_n \leftarrow T_1$ *Absorption Spectra.* $T_n \leftarrow T_1$ absorption spectra were measured with a conventional μ second flash photolysis apparatus.[18] Both the exciting and monitoring flash lights had a half width of 4 μs. The spectra were photographed with a Shimadzu GE 100 spectrograph.

Measurements of Fluorescence Quantum Spectra. A calibrated Amino-Bowman spectrophotometer was used for the measurements of fluorescence quantum spectra. Fluorescence quantum yields were determined by numerically integrating the areas under the emission curves of both the standard and the sample solutions. Anthracene dissolved in ethanol (2.5×10^{-5} M) was used as a standard, its quantum yield being taken as 0.27.[19]

Synthesis of 9,9'-Bianthryl. 9,9'-Bianthryl was prepared by reduction of anthraquinone in glacial acetic acid with zinc powder.[10] The product was recrystallized from chlorobenzene, washed with ethanol, chromatographed on activated alumina using benzene for elution, and recrystallized twice from glacial acetic acid, mp 312 °C. Found: C, 95.07; H, 4.99%. Calcd for $C_{28}H_{18}$: C, 94.88; H, 5.12%. The absorption and emission spectra in various solvents were identical with those reported.[3]

Solvents. Hexane (Wako, spectrograde), 2-propanol (Wako, spectrograde), diethyl ether (Wako, analytical grade), acetone (Nakarai, spectrograde), ethanol (Wako, analytical grade), methanol (Wako, analytical grade) and acetonitrile (Merck, spectrograde) were used without further purification. Decalin (Wako, analytical grade) was distilled under reduced pressure before use. All samples were deaerated by repeated freeze-pump-thaw cycles.

Results and Discussion

Picosecond Flash Photolysis. Photographs of pc are shown in Fig. 1, and the transient absorption spectra of 9,9'-bianthryl in Figs. 2 and 3. Each point in the visible region of the spectra (Fig. 2c and Fig. 3a) was obtained by taking an average of several measurements and contains an error of only ± 0.05 in the relative optical density unit. The base line of the spectra has an error of $+0.1$ since two beams through the apertures do not always have equal intensities.

(1) $S_n \leftarrow S_1$ *Spectra in Hexane Solution*: The $S_n \leftarrow S_1$ absorption spectra of 9,9'-bianthryl in hexane obtained

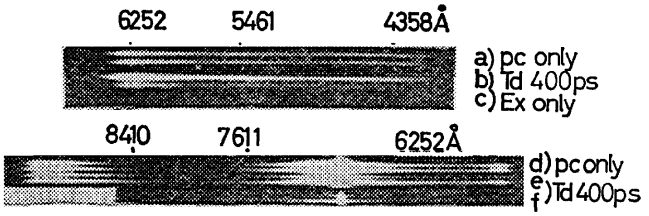

Fig. 1. A photographic display of time-resolved absorption spectra of 9,9'-bianthryl in acetone (5.1×10^{-4} M). a, d; pc without exciting pulse, b; with exciting pulse (lower one) and at 400 ps delay time in the visible region, c; exciting pulse without pc, e; with exciting pulse (upper one) and at 400 ps delay time in the infrared region (over exposure due to exciting Xe flash lamp and ruby fluorescence is observed around 694 nm). f; the same as e except that only the monitoring light intensity was reduced to 1/16. Vertical lines are reference spectra of Hg. The near UV cut off is due to the ground state absorption, and the red or near infrared cut off is due to the low sensitivity of the photographic film.

at the delay time of 500 ps are shown in Fig. 2c. Since only the E band is observed in this solvent, the spectra contain no contribution from the P state. At a delay time of 500 ps, the formation of the triplet state of 9,9'-bianthryl may be negligible since the fluorescence lifetime and quantum yield are 8 ns and 0.55, respectively. We have confirmed by means of μs flash photolysis that 9,9'-bianthryl shows T_n—T_1 absorption at approximately the same position as that of anthracene. Thus, the spectra (Fig. 2c) contain no contribution from the T_n—T_1 spectra. No strong absorption band was observed in the near infrared regions of 15—11 kcm^{-1}. The S_n—S_1 spectra of anthracene in hexane at 250—300 ps delay time[15] as well as those of 9-phenylanthracene in methylcyclohexane measured by the ns laser photolysis method[5] are also given in Fig. 2 for the sake of comparison.

The characteristic band of anthracene at 16.7 kcm^{-1} has been assigned to the $^1A_{1g}^- \leftarrow {}^1B_{2u}^+$ transition and that at 18 kcm^{-1} may be assigned partly to the $^1B_{1g}^- \leftarrow {}^1B_{2u}^+$ transition and partly to the vibrational structure of the $^1A_{1g}^- \leftarrow {}^1B_{2u}^+$ transition.[20] We can see these characteristic bands in the spectra of 9-phenylanthracene although they are a little shifted towards blue. The spectra of 9,9'-bianthryl are also similar to those of anthracene and 9-phenylanthracene, though the former spectra are somewhat broad and further shifted towards blue as compared with the latter. The results suggest that the E fluorescence state with a slight vibrational structure is the locally excited state or exciton resonance state.

(2) *Formation of P State and Estimation of the Equilibrium Constant between E and P States*: We see from Fig. 4 that, with increasing solvent polarity, the intensity of the E band decreases and is accompanied by the appearance of the P band. Schneider and Lippert[3] has shown that the lower the temperature, the stronger the P fluorescence when the viscosity of the solvent is not so high. The results indicate that the P state is formed from the E state. However, it was possible only to observe the single exponential decay of the P as well as E fluorescence. Their lifetimes were almost the same. The result indicates that the P and E states are in equilibrium within 500 ps after the excitation with a picosecond pulse.

Chuang *et al.*[21] showed by the picosecond laser technique that the rise of the intramolecular heteroexcimer formation of *N*,*N*-dimethyl-4-[3-(9-anthryl)-propyl]-aniline in hexane is *ca.* 900 ps. Though there seems to be orientational requirement for the heteroexcimer formation, the rise time becomes much shorter (~60 ps) in the anthracene-DEA(*N*,*N*-diethylaniline) two component system.[22]

In the case of the present system, our results suggest that orientational requirement for the formation of the P state, if any, is slight. The electron transfer would occur far more rapidly than the above intramolecular heteroexcimer formation, presumably competing with the solvent reorientational relaxation.

From the values of fluorescence quantum yields and lifetimes given in Table 1, we can estimate approximately the equilibrium constant between E and P. The yield of the E fluorescence, η_E, can be given by

$$\eta_E = \frac{q_E}{1+(\tau_E/\tau_P)K_e} \qquad (1)$$

where q_E is the fluorescence quantum yield when there is only the E state, τ_E ans τ_P are intrinsic lifetimes of the E and P states, respectively, and $K_e=[P]/[E]$. The value of (η_E/q_E) in acetone was estimated from the spectra (Fig. 4) using the η_E value in hexane for q_E. From the observed values in hexane and acetone for τ_E and τ_P, and the estimated (η_E/q_E) value, K_e was evaluated to be approximately 40.

(3) $S_n \leftarrow S_1$ *Spectra in Acetone Solution*: The $S_n \leftarrow S_1$ spectra of 9,9'-bianthryl in acetone obtained at the delay time of 500 ps are given in Fig. 3a. We have

confirmed that the rise time of the P fluorescence in acetone is shorter than 500 ps, and that the P state is populated predominantly in the excited state.

The $T_n \leftarrow T_1$ spectra of 9,9'-bianthryl in acetonitrile are similar to those in hexane. This indicates that $T_n - T_1$ spectra do not depend on solvent polarity. Thus, the spectra in Fig. 3a contain no contribution from the $T_n \leftarrow T_1$ spectra.

The spectra in acetone differ considerably from those in hexane (Fig. 3). Although the spectra in acetone are a little broad and shifted towards blue as compared with the superposition of those[23,24] of anthracene anion and cation (Fig. 3b), both spectra are rather similar. Considering that the reference spectra were taken for the anthracene ions produced by γ-ray irradiation and measured at 77 K,[23] the observed broadening and blue shift can be ascribed to the effects of counter ions (a charged anthryl group in the present case), substituent, and the temperature of the system. This is supported by the fact that the absorption spectra of 9,9'-bianthryl anion and its dianion are similar to those of Fig. 3a,[25] *i.e.* they are somewhat broad and shifted towards blue as compared with those of anthracene anion and that the spectra of 9,10-diphenylanthracene ions are also broad and shifted towards blue as compared with those of anthracene (Fig. 3b).[26] Similar effects of the spectra of ion radicals of aromatic hydrocarbons being affected by the existence of counterions, *etc.* have been observed in the case of ion radicals of naphthalene[23] and fluorene.[27]

The observed shoulder at 16.7×10^3 cm^{-1} (Fig. 3a) might be assigned to the back CT transition to the same S_n state as that for the transition corresponding to the 17.5×10^3 cm^{-1} band in hexane. However, considering that the fluorescent state of 9,9'-bianthryl in acetone is stabilized due to the reorientation of solvents, the back CT transition in $S_n \leftarrow S_1$ spectra, if any, should be shifted towards blue as compared with the corresponding transition of 9,9'-bianthryl in hexane solution. Therefore, the shoulder at 16.7×10^3 cm^{-1} should be assigned to the ion band at *ca.* 17×10^3 cm^{-1}. Thus, the spectra in acetone can be assigned to the transitions localized in anthryl ions.

The electronic structure of the relaxed S_1 state in acetone as well as in more polar solvents seems to be close to the ion-pair with negligibly small delocalization interaction between the pair. This can be possible if the two anthracene planes are almost perpendicular to each other in the relaxed S_1 state in those polar solvents.

Solvent Effects upon Fluorescence Yields and Lifetimes

(1) *The Structural Change of E State*: We have measured fluorescence quantum yields and lifetimes. The results are listed in Table 1. From these values we can examine the effect of structural change on the radiative lifetime. The value in hexane was obtained as $\tau_f^\circ \simeq 14.5$ ns from the observed fluorescence quantum yield and lifetime. On the other hand, the radiative lifetime evaluated from the absorption spectra by using Strickler-Berg's equation[28] is $\tau_f^\circ \sim 6$ ns. This indicates that, due to the structural change in the relaxation process from the FC excited state to the relaxed fluorescent state, the radiative transition probability is decreased. Namely, two π-electronic systems of 9,9'-bianthryl are oriented perpendicular to each other because of a strong steric hindrance in the relaxed ground state as well as the FC excited state. However, the stable conformation in the excited state may not be the perpendicular one but the oblique one as suggested by Schneider and Lippert.[3] This structural change in the excited state seems to result in the decrease of the radiative transition probability.

Table 1. Fluorescence quantum yields and lifetimes of 9,9'-bianthryl in various solvents[a]

Solvent	ε[b]	$\tilde{\nu}_{a,max}$[c]/ 10^3 cm^{-1}	$\tilde{\nu}_{f,max}$[d]/ 10^3 cm^{-1}	$\phi_{f,rel}$[e]	τ_f/ns[f]
Hexane	1.88	25.7	24.2	1.00 (0.55±0.05)	8
Decalin	2.15	25.5	24.0	1.07	
Benzene	2.28	25.3	23.7[g]		11.8[g]
Diethyl ether	4.34	25.7	23.9	1.08	15
2-Propanol	17.9	25.7	22.8	0.91	
Acetone	20.7	25.6	22.1	0.71	32
Ethanol	24.6	25.7	22.6	0.71	33
Methanol	32.7	25.8	22.0	0.60	
Aceto-nitrile	37.5	25.6	21.3	0.41	35

a) All measurements were carried out at room temperature, the concentration of 9,9'-bianthryl being 2.4 10^{-5} M for all the solutions. b) Dielectric constant of the solvent at room temperature. c) Wave numbers of the absorption maxima quoted from Ref. 3. d) Wave numbers of fluorescence maxima measured in the present work. These values are essentially the same as those of Ref. 3. e) The relative fluorescence quantum yield. The value in parentheses is the absolute value determined by using anthracene as a standard. f) Fluorescence lifetimes were measured at 20×10^3 cm^{-1} through a monochromator except the value of hexane solution. The latter was obtained with the use of Toshiba color filters VV40 and UV39. g) I. B. Berlman, "Handbook of Fluorescence Spectra of Aromatic Molecules", Academic Press, New York, N. Y. (1971), p. 366.

(2) *Solvent-Induced Change of Electronic Structure of P State*: The fluorescence spectra observed in highly polar solvents such as acetone, ethanol, and acetonitrile are almost exclusively due to the P state. We see from Table 1 that the fluorescence lifetimes in these polar solvents are considerably longer than those in nonpolar solvents. Moreover, the lifetime in the polar solvent shows a slight increase with an increase in solvent dielectric constant. However, the fluorescence quantum yield decreases considerably in the strongly polar solvents such as methanol and acetonitrile. In alcoholic solutions, in contrast to the case of aprotic polar solution, specific behaviors in the excited solute-solvent interactions are observed. As has been pointed out already by Schneider and Lippert,[3] as well as by Kosower and Tanizawa,[11] the fluorescence wave number in an alcohol solution is large as compared with the value in an aprotic solvent with almost the same dielectric constant. The fluorescence quantum

yield η_P in alcohol is not smaller than that in acetone though the dielectric constant of the former is larger than that of the latter. Similar effects of solvent polarity as well as alcohol on the behavior of excited molecular composite system are found in the case of aromatic hydrocarbon–amine heteroexcimer.[5,29]

The above results concerning the effects of the solvent dielectric constant upon the fluorescence quantum yield and lifetime of 9,9'-bianthryl indicate the decrease of the radiative transition probability with the increase in the solvent polarity, which can be ascribed to the solvent-induced change in the electronic structure of the P state, just as in the case of some intramolecular heteroexcimers.[5,6]

X-Ray Photoelectron Spectroscopic Studies of Catalysts —Chromia–Alumina Catalysts—

Yasuaki OKAMOTO, Masaki FUJII, Toshinobu IMANAKA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 30, 1975)

The XPS studies of chromia–alumina catalysts were carried out to elucidate the surface of these catalysts. Photoreduction was found to occur during the XPS measurements. Therefore, all spectra were measured rapidly to prevent any photoreduction. It was found that the information about the spin-orbit splitting of the Cr2P level is very useful for determining the valence state of chromium. The surface state of chromium in chromia–alumina catalysts calcined at 500 °C for 5 h is predominantly Cr^{6+} at low chromia concentration catalysts. However, the Cr^{3+} phase appears in catalysts of higher chromium content, and the surface concentration of Cr^{3+} increases with increasing content of supported chromia. The XPS spectra due to Cr^{5+} were observed after mild reduction of the catalysts. Moreover, it was found that almost all surface chromium is present as Cr^{5+} at low chromia content catalysts after mild reductions. Qualitatively, the results obtained by the XPS technique, which gives information about the surface of catalysts, agree well with the results obtained by ESR and other techniques, which gives information about the bulk of catalysts, especially low chromium concentration catalysts. These findings indicate a high dispersion of chromium on γ-Al_2O_3 for low chromium content catalysts.

Since the X-ray photoelectron spectroscopy (XPS or ESCA) measurements reveal both the chemical composition and state of the surface atoms of solids, they provide a new probe for studying the properties of catalysts.[1] From XPS measurements of catalysts, we can obtain three important pieces of information—that is, information about the binding energy, the satellite structure, and the relative intensities of some levels. The information about the binding energy and the satellite structure reveals the chemical and magnetic state of the atom concerned. Recently, the information about the spin-orbit splitting of the 2p level for some transition metals was emphasized to be useful in determining the magnetic state or valence state of the transition metal ions.[2–4] By comparing the XPS peak intensities of different levels, we can obtain knowledge about the surface composition of a catalyst or the surface coverage of supported catalysts on a carrier.

Chromia-alumina catalysts have been studied by many workers[5] using ESR and other techniques, since chromia–alumina catalysts are active in a great variety of reactions such as dehydrocyclization, dehydrogenation, and the polymerization of olefins. On the basis of the results obtained by means of ESR, magnetic susceptibility measurements, titration method, NMR, X-ray diffraction, and optical reflectance spectroscopy, it is revealed that various valence states of chromium are present on chromia–alumina catalysts.[5] However, from these techniques we can only obtain information about the bulk catalysts or thick surface layer of the catalysts.

The advantages of XPS over these techniques are that, in principle, it is capable both of determining the valencies of metal ions on the thin surface layer (~10 Å) of supported oxide and simultaneously of detecting the interaction between catalyst and support.

In this paper, on the basis of the information obtained by XPS measurements for chromia–alumina catalysts, the surface properties of the catalysts will be discussed and compared with the results obtained by other techniques. XPS spectra of some chromium compounds were measured and the spin-orbit splitting of the Cr2p level was emphasized as being very useful for discriminating the valence states of chromium. The first XPS spectra of Cr^{5+} were, to our knowledge, observed in this study. Moreover, it was pointed out that photoreduction phenomena during XPS measurements must be considered in the case of chromia–alumina catalysts.

Experimental

Materials. Chromia–alumina catalysts supported on γ-Al_2O_3 with different compositions were prepared by a conventional impregnation technique using chromium nitrate or chromic oxide. After drying at 120 °C, catalysts were calcined at 500 °C for 5 h in air. In the case of 2 wt% catalysts, the catalysts calcined at 900 °C for 3 h were also investigated. The surface area of γ-Al_2O_3 used in our experiments was 235 m^2/g.

Procedure. Photoelectron spectra were measured on a Hitachi 507 photoelectron spectrometer using Al$K\alpha$ radiation. The power of X-ray radiation was 500 W (10 kV, 50 mA) in all measurements. The spectrometer was linked to a multichannel analyser in the multiscaler mode, which was useful for the study of time dependent spectra. Powdered samples were mounted on a sample holder made of stainless steel mounted with mesh. The spectrometer operating pressure was *ca.* 1×10^{-6} Torr. After the samples were pretreated in a pretreatment chamber (*ca.* 5×10^{-5} Torr), they were introduced into the analyser.

Binding energies were corrected by using the value of 285.0 eV for the ClS level resulting from the contaminated carbon. The reproducibilities of the values thus obtained were within +0.2 eV; the energy differences were determined with an accuracy of ±0.1 eV.

The reduction of the catalysts was carried out in the pretreatment chamber using hydrogen with a pressure of about 10 Torr. The severe reductions were accomplished with a conventional flow system using atmospheric hydrogen.

Results and Discussion

1) XPS Spectra of Chromium Compounds. There have been several reports of X-ray photoelectron spectroscopic measurements of chromium compounds.[6–11] The binding energies of the Cr2p level

for the chromium compounds examined in this study are listed in Table 1. It is clear from Table 1 that Cr^{6+}, Cr^{3+}, and Cr metal can be distinguished by the binding energy alone. However, recently the XPS spectra of Cr^{4+} compounds have been reported by Ikemoto *et at.*[12] According to their results, the binding energies of CrO_2 and CrOOH are 576.3 and 577.0 eV respectively. They also reported the $Cr2p_{3/2}$ binding energies for Cr_2O_3 and $K_2Cr_2O_7$; their values agree very well with our data in Table 1. These values for Cr^{4+} compounds are located around Cr_2O_3. In the case of CrO_2, its binding energy is even lower than that of Cr_2O_3. These facts will be explained in terms of the solid effects which cancel chemical shifts, as has been discussed by Kim and Winograd.[13] The chemical shift data, therefore, are not considered to be useful for determining the valence state of chromium, as in the case of Co,[2] Ni,[14] Pb,[15] and Cu.[16] As for Cr^{5+}, there have been no reports about XPS spectra in spite of its importance in catalysis.

The XPS spectra of the Cr2p level for Cr^{3+} compounds have weak satellites and their satellite splittings ($\Delta\varepsilon$) of the $Cr2p_{1/2}$ level were shown in Table 1, but the Cr^{6+} compounds give no such satellite peak. The $\Delta\varepsilon$ values and satellite intensities agree well with those reported by many workers.[17,18]

Helmer[9] reported that the spin-orbit intensity of the Cr2p doublet of Cr^{6+} is 0.33, instead of the theoretical value of 0.50. Also in our measurements it was found that the intensity ratios (I) ($Cr2p_{1/2}/2p_{3/2}$) for Cr^{6+} compounds are about 0.40, which are samller than 0.50: these are shown in Table 1. The discrepancy between the theoretical value and the observed values may be due to solid effects. In the case of Cr^{3+} compounds, I values are larger than those of Cr^{6+} compounds. This fact can be well understood by recognizing that the satellite peak of $Cr2p_{3/2}$ overlaps with the main peak of $Cr2p_{1/2}$.

The spin-orbit splittings of Cr^{3+} compounds are larger than those of Cr^{6+} compounds, as has been reported.[2,9] The difference of the spin-orbit splitting between Cr^{3+} and Cr^{6+} compounds can be explained in terms of the exchange interaction between 2p electrons and unpaired 3d electrons.[2-4] Such an interaction makes the 2p level spectra broad, as is shown in the last column of Table 1. Similar but larger effects of unpaired 3d electrons on the XPS spectra of 2p levels have been found for cobalt compounds.[2-4]

From these facts, Cr^{3+} and Cr^{6+} compounds and Cr-metal can be distinguished in terms of the binding energy, the satellite structure, the spin-orbit intensity ratio, and the spin-orbit splitting. However, in the studies of supported catalysts, the spectra obtained are usually weak, especially when the concentration of the catalytic component is low. The information about the satellite is sometimes ambiguous for supported transition metals, especially for supported chromium catalysts, since the satellite intensities are rather weak for chromium compounds. Moreover, the measurements of spin-orbit intensity ratios are considered to be difficult because of the uncertainties in the estimation of the base line. Therefore, we use the information about the binding energy and the spin-orbit splitting in order to distinguish the valence states of chromium supported on the carrier. In the case of the XPS studies of the supported cobalt catalysts,[2] such information has been found to be very useful to discriminate Co^{2+} and Co^{3+} species.

2) XPS Spectra of Chromia–Alumina Catalysts. 2—1 Photoreduction of Chromium on Chromia–Alumina Catalysts: The XPS spectra of chromium on the chromia–alumina catalysts were found to be time-dependent. The Cr2p spectra for a 2 wt% chromia–alumina catalyst, which was prepared by impregnation with chromium nitrate and calcined at 500 °C for 5 h, are shown at various irradiation times in Fig. 1. No change in the spectrum was observed within the irradiation time of 12.5 min. But, after 37.5 min-irradiation, an additional peak appeared at the lower binding energy of *ca.* 578 eV. After 80 min-exposure to X-ray flux, the additional and original peaks became comparable. An additional predominant peak appeared after 300 min irradiation, while a peak at 577.8 eV appeared by further irradiation. The peak obtained by the photoreduction has the spin-orbit splitting (ΔE) of 9.0 eV. Therefore, this chromium compound cannot be attributed to a Cr^{3+} compound, which has larger spin-orbit splitting values, as is shown in Table 1. The valence state this chromium compound will be discussed later. In the case of other chromia–alumina catalysts, similar phenomena were observed; the chromium states obtained were: B. E., 577.7 eV and ΔE, 9.5 eV for 5 wt%; B. E., 577.8 eV and ΔE, 9.7 eV for 10 wt%; and B. E., 577.2 eV and ΔE, 9.9 eV for 20 wt% after several hours irradiation. In the 20 wt% catalyst, the final state of chromium can be attributed to Cr^{3+} compound, because it has a energy of 577.2 eV and the ΔE value of 9.9 eV.

Such a pronounced surface reduction of some 3d transition metal compounds has been observed during XPS measurements. Particularly strong effects were found in copper(II) fluoride and potassium hexa-

cyanoferrate (III).[19] No photoreduction phenomena, however, were observed in the chromium compounds examined in our study. These facts indicate that the chromium on the chromia–alumina catalysts can be easily reduced.

2—2 Surface State of Chromium on Chromia–Alumina Catalysts: As has been discussed above, the surface reduction of the catalyst during XPS measurements was found to be negligible within 12.5 min irradiation. Therefore, all spectra were measured within 4—12.5 min exposure to X-ray flux. In Fig. 2, the XPS spectra of the Cr2p level for 1, 2, 5, 10, and 20 wt% chromia–alumina catalysts (impregnated with chromium nitrate and calcined) are shown. The binding energies of the $Cr2p_{3/2}$ level and the spin-orbit splitting (ΔE) for the Cr2p level for these catalysts are listed in Table 2. In the case of 1 and 2 wt% catalyst, the valence state of surface chromium is considered to be almost entirely Cr^{6+} (B. E, 579.7 eV and ΔE, 9.0 eV), whereas the spectrum for a 5 wt% catalyst has a weak shoulder at the lower binding energy side. The shoulder intensity increases with increasing the supported amount of chromia. According to Table 2, the valence state of chromium with lower binding energy can be assigned to Cr^{3+} (B. E., 577.7 eV and ΔE, 9.8 eV). Then, the amount of the Cr^{3+} on the catalyst surface increases with increasing the chromia concentration. This tendency was also ascertained in the bulk analysis of the catalysts examined in our studies† by means of ESR (Cr^{3+}) and chemical analysis (Cr^{6+}; Bunsen-Rupp method). It has been reported by Matsunaga[20] that essentially all of the chromium ions were oxidized at 450 °C to the Cr^{6+} state for low chromia concentration catalysts, which were prepared by impregnation with chromic oxide and reduced in a stream of hydrogen for 5 h at 360 °C after calcination at 350 °C. Poole and MacIver[21] suggested, based on their optical measurements, that the Cr^{6+} detected is probably present on the catalyst surface and not in the catalyst bulk. The surface compositions obtained by XPS techniques support their results for low concentration catalysts. At higher chromium content catalysts, the Cr^{6+} content on the catalyst surface seems to be a little larger than that in a bulk catalyst. For example, in the case of a 20 wt% catalyst about half of chromium was found to be present as Cr^{6+}, according to chemical analysis by Bunsen-Rupp method, whereas the Cr^{3+} peak, as is shown in Fig. 2, is observed only as a shoulder of the Cr^{6+} one.

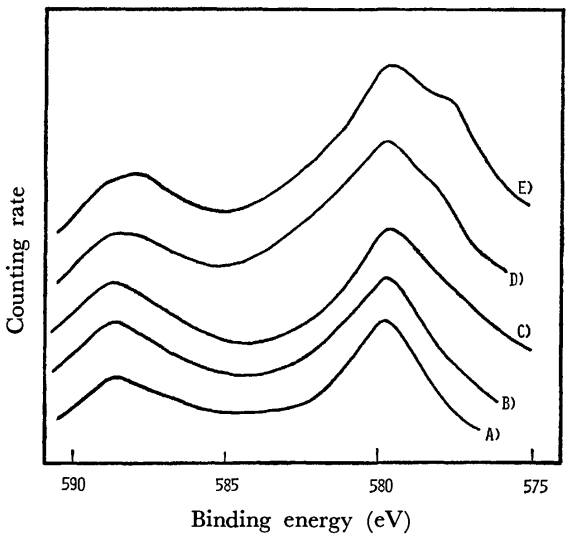

Fig. 2. XPS spectra of Cr2p level for impregnated chromia–alumina catalysts with chromium nitrate, which are calcined at 500 °C for 5 h.
A) 1 wt%, B) 2 wt%, C) 5 wt%, D) 10 wt%, E) 20 wt% catalyst.

Regarding the chromia–alumina catalysts prepared by impregnation with chromic oxide, the spectra were the same as those in Fig. 2 at low concentration of chromia, that is, almost all of the chromium are Cr^{6+}, while in the case of a 20 wt% catalyst the amount of Cr^{6+} is a little larger than that on the 20 wt% catalyst impregnated with chromium nitrate.

The Cr^{6+} binding energies are essentially the same among the calcined catalysts impregnated with different

† The ESR signal intensity of Cr^{5+} decreases with increasing the amount of supported chromium, indicating the maximum at 1 wt% catalyst. This fact suggests that the main valence state of chromium in the bulk is Cr^{5+}, but that the surface of the catalyst calcined in air is covered with Cr^{6+}.

starting compounds and uncalcined catalysts impregnated with chromium(III) oxide. They are slightly lower compared with that of CrO_3. The small changes in the binding energy may be attributed to charging effects, differences in crystal structure, or interactions between chromium and γ-Al_2O_3. Therefore, we cannot determine precisely the chemical state of the Cr^{6+} compound on γ-Al_2O_3 after calcination. However, the binding energies of Cr^{3+} on the surface of chromia–alumina catalysts are considerably increased (1.0—1.4 eV), comparing with that for Cr_2O_3. This fact is considered to indicate the presence of the interaction between small crystallines of Cr_2O_3[5] and γ-Al_2O_3, that is, the electron flow from Cr_2O_3 to γ-Al_2O_3 and be expected.

Before calcination, the valence states of chromium were Cr^{3+} (B. E., 578.0 eV and ΔE, 9.8 eV) for the catalysts prepared from chromium nitrate. This result coincides with that obtained by Poole *et al.*[22] using reflectance spectroscopy. In the case of the catalysts prepared from chromium(III) oxide, the chromium is Cr^{6+} (B. E., 579.8 eV and ΔE, 9.0 eV) before calcination.

The changes in the Cr2p spectra for chromia–alumina catalysts were observed by evacuation at elevated temperature or by reduction with hydrogen. These results are summarized in Table 2. In the case of a 2 wt% catalyst, the binding energy of $Cr2p_{3/2}$ become lower (1.9 eV), while the spin-orbit splitting was invariant (9.0 eV) even after evacuation at 230 °C for 20 min or at 350 °C for 1 h. The binding energy of 577.8 eV is close to that of Cr^{3+} compound, but the ΔE value of 9.0 eV is much smaller than that of Cr^{3+} compound. The XPS spectrum of this chromium was the same as that in Fig. 1 (D), which was observed by photoreduction. We cannot attribute this chromium to Cr^{3+} or Cr^{6+}.

The catalysts are considerably reduced by heating them in a pretreatment vacuum chamber. For example, the pronounced reduction of molybdena–alumina catalysts (Mo^{6+}—Mo^{5+}, Mo^{4+}) were observed by evacuation at 300—400 °C in our sample pretreatment chamber, which is evacuated with a cryogenic pump.[23] Therefore, the sexivalent chromium in the original catalyst is considered to be reduced to the chromium with the binding energy of 577.8 eV and the ΔE of 9.0 eV. In fact, the treatment of the catalyst with hydrogen at the pressure of 7.8 Torr gave the same valence state of chromium produced by the treatment of the evacuation or the photoreduction, as is shown in Table 2.

To determine the state of chromium observed after the evacuation at high temperature or the mild reduction with hydrogen, we consider the correlation between spin-orbit splitting (ΔE) and the number of the 3d unpaired electrons. In Table 3, these correlations are listed. When the number of unpaired 3d electron is one, no or only a small change in ΔE was observed, as for the cases of V, Co, and Cu. But when the unpaired 3d electron number is larger than two, a considerable change in ΔE was observed. The fact that ΔE values increase with increasing the number of 3d unpaired electrons can be explained qualitatively in terms of the exchange interaction between 2p electrons and 3d unpaired electrons.[2] From these facts, we can conclude that the number of 3d unpaired electrons in chromium obtained by the reduction is one or zero. The initial state of chromium is Cr^{6+}, as has been discussed. Therefore, the valence state of chromium is considered to be Cr^{5+}, which has one 3d unpaired electron. As discussed above, the chemical shifts data are not useful for determining the valence

Table 2. Binding energy of $Cr2p_{3/2}$ and spin-orbit splitting of Cr2p level for various chromia–alumina catalysts[a] prepared by impregnation with chromium nitrate

Catalyst (wt%)	Treatment	Binding energy of $Cr2p_{3/2}$ (eV)	ΔE (eV)	Assignment[c]
1	no treatment	579.7	9.0	6+

state of chromium, and ΔE values are considered to be more powerful and reliable in discriminating the valence state of chromium. Therefore, the valence state of chromium obtained by the mild reduction of Cr^{6+} is concluded to be Cr^{5+}, though the binding energy is lower than expected. The low binding energy of Cr^{5+} will be explained in terms of solid effects,[13] as in the case of Cr^{4+}. Moreover, it is considered, based on our assignment, that almost all chromium is present as the Cr^{5+} state after such mild reduction at low chromia concentration catalysts. According to Cossee *et al.*,[24] the mild reductions of chromia–alumina catalysts produce over 95% Cr^{5+} in total chromium in the case of low concentration of chromium. Our XPS results coincide with their ESR results. These facts show that our assignment is reasonable. However, it is not easy to define the chemical state of Cr^{5+} precisely, since there have been no reports, to our knowledge, about the XPS spectrum for Cr^{5+}.

In the case of the high chromia concentration catalysts, the binding energy and ΔE value of the surface state of chromium were 577.5 eV and 9.4—9.6 eV respectively after evacuation at high temperature. The XPS spectra for these chromiums were similar to that in Fig. 1 (D) except for the ΔE value. The spectra containing both Cr^{3+} and Cr^{5+} are deduced to have ΔE of a intermediate value between 9.0 and 9.9 eV, when the spectra of Cr^{3+} and Cr^{5+}, whose binding energies are almost the same, overlap each other. After the evacuation the ΔE values were 9.4, 9.6, and 9.6 eV for 5, 10, and 20 wt% catalysts, respectively. Therefore, it is concluded that these high chromia content catalysts contain both Cr^{3+} and Cr^{5+} after evacuation and that the higher the chromia content is, the larger is the amount of Cr^{3+} produced.

On the basis of a discussion similar to the above, it is considered that the Cr^{3+} phase can be produced at first by severe reductions at low chromia concentration catalysts, as is shown in Table 2. Accordingly, it is concluded that at lower chromia content catalysts, such as a 2 wt% catalyst, Cr^{5+} phase is rather stable, while at higher chromia content catalysts Cr^{3+} phase can be easily produced.

In the case of a 2 wt% catalyst calcined at 900 °C for 3 h, however, chromium was easily reduced by the mild reduction and gave almost entirely Cr^{3+} state, as is listed in Table 2. These findings seem to correlate with the fact that the catalysts calcined at high temperature give a weaker γ-phase intensity in ESR spectra than the catalysts calcined at 500 °C.[5]

On the basis of these results, the assignments for the valence states of surface chromium before and after the treatments were accomplished and listed in the last column of Table 2. Qualitatively, these surface properties of chromia–alumina catalysts obtained by XPS technique agree very well with the results obtained by ESR or other techniques, especially at low chromium concentration catalysts. These facts indicate the good dispersion of chromium on γ-Al_2O_3 at low chromium content catalysts.

Concentration Depolarization of the Fluorescence and Phosphorescence of Acridine Orange Cations

Tomoko KOMIYAMA* and Yuji MORI

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received July 15, 1975)

Concentration depolarization of fluorescence and phosphorescence has been studied for Acridine Orange cations in PVA films. Depolarization can be observed with concentrations above 10^{-6} M. For concentrations ranging from 10^{-6} M to 10^{-4} M both depolarization of fluorescence and of phosphorescence obey the Weber equation. The results indicate that singlet-singlet energy transfer is responsible for depolarization of fluorescence, as well as of phosphorescence. Above 10^{-4} M, the effect of the exchange interaction cannot be ignored due to the formation of higher aggregates.
