12) Methyl benzyloxyacetate and methyl ethoxyacetate are both "displaced" products but are formed in a completely different fashion. The duality has not been fully recognized. Furthermore cage disproportionation is apparently able to produce a displaced product, though its occurrence is doubtful in the present case as judged from the failure to observe CIDNP due to methyl ethoxyacetate.

the quenching of benzonitrile by triethylamine was accompanied by the appearance of a new emission at longer wavelength (Fig. 1), which may be assigned to an exciplex formed between the two components, while no exciplex emission was observed in the quenching of benzonitrile by diethylamine in benzene.

Hydrogen Isotope Exchange in Benzonitrile. Irradiation of a mixture of benzonitrile and diethylamine-[N^2H] with a 1 kW high pressure mercury arc lamp for 20 h resulted in minor amounts of deuterium incorporation (0.9%) in the recovered benzonitrile as determined by mass spectrometry. When a solution of benzonitrile in acetonitrile was irradiated in the presence of diethylamine[N^2H] under the same conditions, the amino-deuterium is transferred to benzonitrile to the extent of 4.5%. A labelling experiment of benzonitrile with triethylamine in acetonitrile was carried out in the presence of deuterated water to elucidate the mechanism. It is of interest to note that the deuterium was involved in the starting material recovered (4.1%).

In view of the incorporation of deuterium in benzonitrile the light induced tritiation of benzonitrile was undertaken with diethylamine[N^3H] or with triethylamine–tritiated water to determine the tritium distribution in the nucleus and the relative rate of tritiation.

A mixture of diethylamine[N^3H], benzene, and benzonitrile was irradiated with a high pressure mercury arc lamp. After a usual work-up, the aromatic compounds were recovered by distillation. Benzene fraction was purified by fractional distillation and submitted to tritium assay. Benzonitrile was degraded by the known procedures[8] in order to determine the tritium distribution. Similarly, a solution of benzonitrile in acetonitrile was irradiated with a high pressure mercury arc lamp in the presence of triethylamine and tritiated water. The benzonitrile was recovered in a similar way and degraded.

The tritium distribution in the recovered benzonitrile and the relative rate of tritiation (per C–H bond) are shown in Table 2 together with related data. The tritium distribution pattern is very similar to that obtained with 1-propanethiol[S^3H] and acetic acid[O^3H],[3] but differs greatly from that reported for the addition of tritium atoms[2] (Table 2). The order of reactivity among the nuclear positions is *para*$\gg$*ortho*$>$*meta* in the present study, whereas it is *meta*$\approx$*ortho*$>$*para* for the addition of tritium atoms.[2] The relative rate of the tritiation on benzonitrile to benzene is extremely high with diethylamine[N^3H] and its value is larger than that with 1-propanethiol-[S^3H] by a factor of seven, although the tritium distribution is similar in patterns in both reagents. The decrease in the relative rate with 1-propanethiol could readily be accommodated in terms of a slight inclusion of tritium atoms generated by the photolysis of the thiol in the tritiation process, since tritium atoms add more easily to benzene than to benzonitrile.

The observed difference in results between tritiation with 1-propanethiol and that reported by Pryor[2] using benzenethiol requires some discussion. Benzenethiol would be photolyzed more easily than 1-propanethiol, because the former has a much smaller S–H bond strength (75 *versus* 88 kcal/mol).[9] In addition, the high pressure mercury arc lamp in a Pyrex immersion well was employed in this work, whereas Rayonette lamps (nominally 300 nm) were used in the earlier experiments,[2] in which hydrogen atoms could be produced more efficiently. In order to confirm this view the photolysis of benzenethiol[S^3H] in a mixture of benzonitrile and benzene was re-examined under the present conditions and the results are listed in Table 2. The tritium distribution takes intermediate values between those with 1-propanethiol and those reported by Pryor[2] with benzenethiol, and the relative rate is decreased to 21. These observations suggest that the tritiation by tritium atoms in the present study occurs moderately with benzenethiol, but not so seriously as in the photolysis using the Rayonette lamps. Thus, it is probable that the values of tritium distribution reported by Pryor are evaluated as the results for the hydrogen atom reactions.

TABLE 2. LIGHT INDUCED TRITIATION OF BENZONITRILE

Triton donor	Tritium distribution (%)[a]			k_{rel}[b]
	Ortho	*Meta*	*Para*	
Diethylamine[N^3H]	18.9	1.4	79.7	1740
Triethylamine and tritiated water	10.0	0.2	89.8	
1-Propanethiol[S^3H][c]	17.4	2.0	80.8	254
Acetic acid[O^3H][c]	12.4	1.0	86.7	
Benzenethiol[S^3H]	31.0	5.0	64.0	21
Benzenethiol[S^3H][d] (Pryor *et al.*)	42.0	45.2	12.8	

a) Average values of data obtained by duplicate runs. b) Rate (per C–H bond) of nuclear tritiation relative to benzene. c) Data taken from Ref. 3. d) Data taken from Ref. 2.

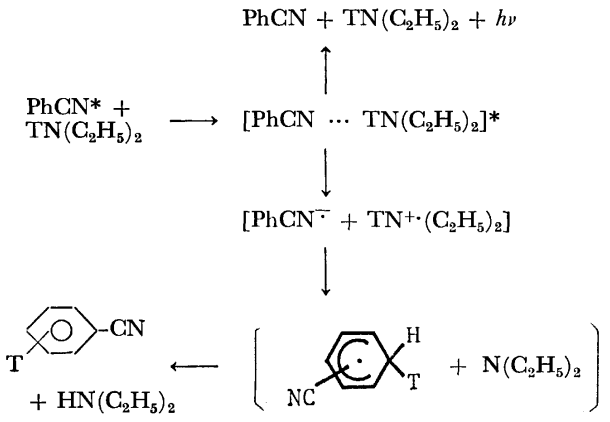
Mechanism for Hydrogen Isotope Exchange. In recent years light induced hydrogen isotope exchange of aromatic compounds has been investigated in acidic media.[10] The previous studies[10] showed that the excited states are much more basic than the ground states, and the exchange takes place through prototropic equlibria of the excited state. As to the multiplicity of the excited state,[10] the first excited singlet states were suggested to be responsible for the exchange from fluorescence quenching experiments, but in some cases a triplet state or a higher excited singlet state was demonstrated to participate in the reaction. Previously, we have shown that the rate of tritium incorporation into benzonitrile is lower in tritiated acetic acid than in tritiated 1-propanethiol by a factor of 10^{-3} in spite of the higher acidity of acetic acid.[3] This fact indicates that proton transfer is not involved in the rate determining step and the basicity of the excited states is irrelevant to the exchange.

The UV spectra of benzonitrile–diethylamine and –triethylamine mixture in hexane were the sums of the absorption spectra of each component, indicating that charge-transfer interaction in the ground state is absent or very weak. Thus, a possible role of a charge-transfer complex in the ground state is ruled out.

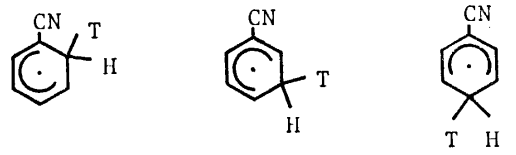
As mentioned above, fluorescence of aromatic

nitriles was quenched efficiently by the amines and the quenching of benzonitrile by triethylamine was accompanied by the appearance of a new exciplex emission (Fig. 1). In view of these findings the most plausible mechanism for the exchange reaction seems to involve an exciplex possessing charge-transfer nature between singlet excited benzonitrile and the amines.[11]

The exciplex either deactivates to each component in the ground state *via* exciplex emission or undergoes electron transfer from the quencher to the quenchee to give a radical cation and a radical anion, respectively. With diethylamine[N^3H], the radical cation contains an acidic triton and the triton transfer from the radical cation to the radical anion may occur to give a radical pair, which may disproportionate to result in the hydrogen exchange. On the other hand, the radical cation from triethylamine does not contain an acidic proton (triton) and tritiated water in the system functions as a triton donor to the anion radical.



The suggested reaction pathway is compatible with the observation that the order of the tritiation among the nuclear positions is *para*≫*ortho*>*meta*. The triton transfer to the anion radical of benzonitrile occurs to the *ortho*- and *para*-positions to give cyclohexadienyl radicals, I_o and I_p, in preference to the *meta*-positions to give I_m, because the greater electronic stabilization is achieved in I_o and I_p than I_m. This trend is kept in the subsequent disproportionation reactions to give the *ortho*- and *para*-tritiated benzonitrile in higher portion than the *meta*-substituted one.



I_o I_m I_p

Inspection of the tritium distribution pattern in Table 1 indicates that there is an overall similarity between 1-propanethiol, acetic acid, and the amines. It is, therefore, suggested that similar intermediates participate in the distribution determining step. The decrease in the rate of the tritiation with acetic acid and scarce quenching of benzonitrile fluorescence by acetic acid are rationalized as a reflection of the difference in ionization potential between acetic acid,[12] 1-propanethiol,[13] and the amines.[7] The formation of the charge transfer exciplex and following electron transfer from quencher to aromatic substrate would be hard in quenchers having higher ionization potential such as acetic acid.

Experimental

Materials. Benzene, diethylamine, triethylamine, and benzonitrile were purified by distillation or vacuum distillation. Terephthalonitrile was recrystallized three times from benzene. α-Naphthonitrile was purified by distillation under reduced pressure followed by twice recrystallizations from ligroin.

Diethylamine[N^2H]: Diethylamine was fractionally distilled from deuterated water. The distillation was repeated until no signal due to the amino proton was observed in the NMR spectrum.

Diethylamine[N^3H]: Diethylamine (15.0 ml) was mixed with tritiated water (0.1 ml, 5 Ci/ml), stirred for 30 min, dried over artificial zeolite, and purified by bulb to bulb distillation to give the tritiated amine (2.90 Ci/mol).

Benzenethiol[S^3H]: benzenethiol was tritiated in a way similar to the above and purified by distillation.

Deuteration of Benzonitrile. *(a) With Diethylamine*[N^2H]: A mixture of benzonitrile (19.4 mmol) and diethylamine-[N^2H] (58.4 mmol) was irradiated for 20 h under nitrogen atmosphere with a 1 kW high pressure mercury arc lamp (RIKO Rotary Photochemical Reactor, Model RH 400—10W). After irradiation, the deuterated benzonitrile was recovered by fractional distillation under reduced pressure. Irradiation of a solution of benzonitrile (9.7 mmol) and the amine (19.5 mmol) in 10 ml of acetonitrile was carried out under the same conditions and benzonitrile was recovered by distillation.

(b) With Triethylamine and Deuterated Water: A solution of benzonitrile (9.7 mmol), triethylamine (14.3 mmol), and deuterated water (100 mmol) in 10 ml of acetonitrile was irradiated for 15 h with the high pressure mercury arc lamp and the deuterated benzonitrile was fractionated.

The isotopic content was determined by mass spectral analysis using a Hitachi RMU-6 mass spectrometer.

Tritiation of Benzonitrile with Diethylamine[N^3H]. Tritiated diethylamine (42.0 mmol, 6.38×10^{12} dpm/mol), benzonitrile (218 mmol), and benzene (218 mmol), all of which were degassed by the usual freeze-thaw cycles, were mixed in Pyrex tubes under nitrogen atmosphere. Irradiation was carried out for 20 h under nitrogen atmosphere with the 1 kW high pressure mercury arc lamp. The reaction mixture was washed with 1 M sulfuric acid and water to remove the amine and the aromatic compounds were recovered by distillation. Benzene was further purified by fractional distillation and submitted to tritium assay. Benzonitrile (17.5 g) recovered was hydrolyzed by refluxing with a solution of potassium hydroxide (14.5 g) in 68 ml of water for 5 h. After the usual work-up, the tritiated benzoic acid isolated was purified by recrystallization from water until reproducible specific activities were obtained and submitted to tritium assay.

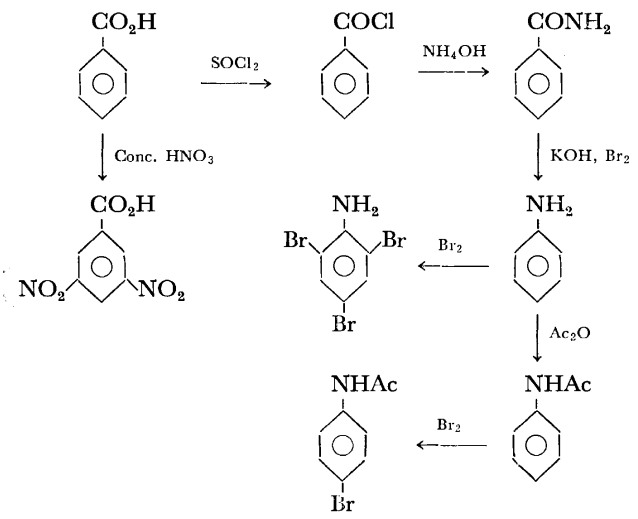
A reference solution, identical to the irradiated solution but stored in the dark for the corresponding period, was subjected to the same procedure and the incorporation of tritium in the substrate was confirmed to be negligible.

Tritiation with Triethylamine and Tritiated Water. A solution of benzonitrile (291 mmol), triethylamine (43 mmol), and tritiated water (6.0 ml, 3.61 mCi/ml) in 30 ml of acetonitrile was placed in Pyrex tubes, deoxygenated by purging with argon, and irradiated for 10 h with the 1 kW lamp.

After the irradiation, triethylamine and water were removed by distillation. The residue was washed with water and hydrolyzed as described above.

Tritiation with Benzenethiol[S^3H]. A mixture of benzenethiol[S^3H] (99 mmol, 4.45×10^{11} dpm/mol), toluene (501 mmol), and benzonitrile (486 mmol) was placed in Pyrex tubes, degassed by the usual freeze-thaw cycles, and irradiated for 6 h with the 1 kW lamp. After irradiation, benzenethiol was removed by washing with 10% NaOH and water, and the aromatic compounds were recovered by fractional distillation. Toluene was oxidized to benzoic acid by refluxing with aq. $KMnO_4$. Benzonitrile was converted to benzoic acid as described above.

The relative rate of nuclear tritiation of benzonitrile to toluene was determined as 5.9 from the specific activities of each benzoic acid derived from benzonitrile and toluene. The relative rate of benzonitrile to benzene (per C-H bond) was calculated to be 21 using the reported value of toluene (3.6),[3] which was obtained by competitive tritiation of toluene and benzene with 1-propanethiol[S^3H]. Since the relative rate of toluene to benzene for the addition of hydrogen atoms (1.7)[14] is small and photolysis of benzenethiol is supposed to generate much more amounts of hydrogen atoms than that of 1-propanethiol under the present condition, the relative rate of toluene would be diminished if it were determined with benzenethiol[S^3H]. Thus, the estimated value for benzonitrile would be larger than the value determined experimentally.



Degradation. The tritiated benzoic acid was diluted, if necessary, with inactive specimen for convenience in chemical manipulations, and then degraded in order to determine the tritium distribution according to the preceding schemes.[8]

The degradation products were purified by means of recrystallization until reproducible specific activities were obtained. Tritium activity was measured with a Packard Tri-Carb liquid scintillation spectrometer Model 3380. Each sample was counted for a period sufficient to reduce the randam error to 1% or less.

Quenching studies. Fluorescence measurements were made on a Hitachi fluorescence spectrophotometer MPF-2A.

Preparation of Matsutake Alcohol (1-Octen-3-ol) from a Butadiene Telomer

Jiro TSUJI, Katsuhiko TSURUOKA, and Keiji YAMAMOTO

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 15, 1976)

A simple preparation of 1-octen-3-ol so called Matsutake alcohol using a butadiene telomer is described: selective hydrogenation of the terminal double bond of 2,7-octadienyl acetate gave 2-octenyl acetate which was converted *via* palladium-catalyzed allylic rearrangement and hydrolysis into 1-octen-3-ol.

Naturally occurring *l*-1-octen-3-ol is known as Matsutake alcohol.[1] The racemic form of this alcohol has been prepared by a reaction of pentylmagnesium bromide with acrylaldehyde, and resolved.[1,2] Two other procedures have been reported which involve Friedel-Crafts reaction of hexanoyl chloride with ethylene[3] and Grignard reaction of vinyl bromide with hexanal.[4]

As part of studies on the utilization of butadiene telomers[5] for organic synthesis, we wish to describe a simple preparation of *dl*-1-octen-3-ol starting from 2,7-octadienyl acetate(**1**), which is readily obtained, along with 1-vinyl-5-hexenyl acetate(**2**), by the palladium-catalyzed telomerization of butadiene with acetic acid (Eq. 1).[6]

$$2CH_2{=}CH{-}CH{=}CH_2 + AcOH \xrightarrow{(Pd)} CH_2{=}CHCH_2CH_2CH_2CH{=}CHCH_2OAc \quad \mathbf{1}$$
$$+ CH_2{=}CHCH_2CH_2CH_2CH(OAc)CH{=}CH_2 \quad \mathbf{2} \qquad (1)$$

The compound **2** seemed to be the most suitable precursor of 1-octen-3-ol. However, attempted homogeneous hydrogenation of **2** catalyzed by chlorotris(triphenylphosphine)rhodium(I) in a benzene solution did not proceed selectively, and a mixture of three possible hydrogenation products was formed even at 40% conversion.

It has been found that **1** is readily equilibrated with **2** in a ratio of *ca.* 3 : 1 by way of an allylic rearrangement under the influence of the palladium catalyst. Therefore, **1** may be a suitable starting material for 1-octen-3-ol, if a sequence of partial hydrogenation and the rearrangement of the acetoxyl group shown below is possible.

$$CH_2{=}CH(CH_2)_3CH{=}CHCH_2OAc \longrightarrow \mathbf{1}$$
$$CH_3(CH_2)_4CH{=}CHCH_2OAc \quad \mathbf{3}$$
$$CH_3(CH_2)_4CH(OAc)CH{=}CH_2 \quad \mathbf{5}$$

Thus **1** was hydrogenated at room temperature in the presence of chlorotris(triphenylphosphine)rhodium(I) (0.5—1.0 mol%) in purified benzene under hydrogen pressure (17.5 kg/cm² initial pressure). Analysis of the reaction mixture by GLC showed the formation of 2-octenyl acetate(**3**) as a main product and octyl acetate(**4**) as a minor product in a ratio of 80 : 20 at about 90% conversion. This result is satisfactory for preparative purpose.

The selectivity for partial hydrogenation of **1** apparently depends on the conversion as shown in Table 1. The results indicate that the rate difference is rather small in the consecutive hydrogenation of the terminal and the internal olefinic bonds of **1**. Attempts to improve the selectivity for partial hydrogenation of **1** by using a cationic rhodium complex, $[(NBD)Rh(PPhMe_2)_2]^+ClO_4^-$ (NBD=norbornadiene),[7] were fruitless.

The distilled product containing both **3** and **4** was then subjected to allylic 1,3-shift of the acetoxyl group. When palladium acetate (3 mol%) combined with three equivalents of triphenylphosphine was used as a catalyst in the presence of potassium acetate in *t*-butyl alcohol, **3** was readily equilibrated with 3-acetoxy-1-octene(**5**) in 3 h at 70 °C in a ratio of 1.9 : 1.0 on the basis of GLC, while **4** remained intact. The lower boiling **5** was isolated by distillation, further purified by preparative GLC and characterized by NMR and IR spectra (see Experimental). The mixture of **3** and **4** undistilled was again subjected to the conversion into **5** under the same conditions as above. In preparative scale synthesis, the lower boiling product **5** can be continuously distilled out by fractionation, while the rearrangement of the higher boiling **3** to **5** proceeds in the vessel containing the active catalyst system to completion.

Finally, **5** was hydrolyzed in aqueous methanolic alkali to give 1-octen-3-ol in a high yield.

TABLE 1. SELECTIVE PARTIAL HYDROGENATION OF 2,7-OCTADIENYL ACETATE (**1**) CATALYZED BY $ClRh(PPh_3)_3$ AT ROOM TEMPERATURE

Conditions		Conversion of **1** (%)	Product ratio[a]	
Catalyst concentration (mol%)	Initial pressure of H_2 (kg/cm²)		**3**	**4**
1.0	6.0	39	96	4
1.0	17.5	47	92	8
1.0	—[b]	52	94	6
0.5	17.5	79	85	15
0.5[c]	17.5	89	82	18
0.5	17.5	91	79	21
0.5	17.5	95	75	25

a) Determined by GLC. b) Normal pressure. c) $(1/2[(C_6H_{10})RhCl]_2 + Ph_2PCH_2CH_2PPh_2)$ prepared *in situ*.

Experimental

Materials. Fractionally distilled 2,7-octadienyl acetate(**1**) (bp 106.5 °C/24 mmHg) was still contaminated with a small amount (*ca.* 6%) of unidentified material,

whereas 1-vinyl-5-hexenyl acetate(**2**) (bp 92.0 °C/24 mmHg) was pure by GLC.

GLC Analysis. A column (3 mm×3 m) packed with 20% UCON oil (50 HB-2000) on Celite (60—80 mesh) was used at 140 °C with 0.8 kg/cm² (40 ml/min) of hydrogen as a carrier gas. Under these conditions, **1** eluted in 11.3 min while **2** in 5.7 min, and all hydrogenation products were satisfactorily separated from each other.

Attempted Partial Hydrogenation of 2. In a 100 ml glass vessel flushed with dry nitrogen was placed a solution of 0.45 g (2.7 mmol) of **2**, 25 mg (2.7×10^{-2} mmol) of $ClRh(PPh_3)_3$ in 5 ml of purified benzene. The mixture was shaken at room temperature under hydrogen atmosphere for 4 h. GLC analysis showed that the product contains **2**, **5** (and/or 1-ethyl-5-hexenyl acetate, and 1-ethylhexyl acetate in the ratio 62 : 21 : 18. 3-Octyl acetate was obtained independently by thorough hydrogenation of **2** using 5% Pd-C in benzene–ethanol solution.

Partial Hydrogenation of 1. The following is typical: In a 100 ml-micro autoclave were placed 9.09 g (54 mmol) of **1**, 250 mg (0.27 mmol, 0.5 mol%) of $ClRh(PPh_3)_3$, and 30 ml of pure benzene. Hydrogen (17.5 kg/cm²) was charged after purging air twice with hydrogen and the mixture was magnetically stirred for 5 h. GLC analysis of the reaction mixture indicated the presence of **3** and **4** in a ratio of 75 : 25 at 95% conversion of **1**. Two other very minor unidentified products were detected by GLC. Another run under 40 kg/cm² of initial hydrogen pressure gave exactly the same results as above. The product ratio of **3** to **4** decreased with the increasing conversion of **1** as shown in Table 1. Benzene was removed by evaporation and the residue was distilled *in vacuo* to give 7.52 g of a mixture of **3** and **4**, bp 96—97 °C/17 mmHg.

Rearrangement of 3 to 5. To a mixture of 0.297 g (1.3 mmol) of palladium acetate, 1.04 g (4.0 mmol) of triphenylphospine, 4.32 g (44 mmol) of potassium acetate and 2.65 g (44 mmol) of acetic acid in 50 ml of *t*-butyl alcohol was added 7.52 g of the above distillate in one portion. The mixture was heated at 70 °C with stirring for 3 h, during which time **3** gradually rearranged into **5** to attain an equilibrium. The reaction mixture was poured into 50 ml of water, extracted three times with hexane. GLC showed the extracts to contain **5** and **3**, in the ratio 1 : 1.9, in addition to **4**. The acetates (5.20 g) were obtained by flush-distillation (~60 °C/4 mmHg). The combined distillate (10.38 g) of two runs was fractionally distilled to give 2.50 g of almost pure **3**, bp 82—84 °C/13 mmHg, which was further purified by preparative GLC. NMR(CCl_4, δ) 0.89 (deformed t, 3H, $\underline{CH_3}CH_2$), 1.34 (br, s, 8H, $(\underline{CH_2})_4$), 1.99 (s, 3H, $\underline{CH_3}CO$), and 4.97—6.04 ppm (m, 4H, $\underline{CH}OAc$ and $\underline{CH}=\underline{CH_2}$). IR (film) 1750($\nu_{CO}$) and 1240 cm^{-1}(δ_{CO}).

The remainder in the pot-still (7.50 g), containing **3**, **4**, and **5** in a ratio of 53 : 40 : 7, was again treated with palladium acetate (3 mol%) in the same manner as indicated above to give **3** by equilibration. Higher temperature (90 °C) for the catalyzed 1,3-shift was found to cause considerably the elimination of the acetoxyl group from **5** to form 1,3-octadiene.

Hydrolysis of **5** with 1 M potassium hydroxide in aqueous methanol (1/1) gave nearly quantitatively 1-octen-3-ol, which was purified by preparative GLC. NMR and IR spectra of 1-octen-3-ol were in good accord with those reported previously.[4] NMR (CCl_4, δ) 0.90 (deformed t, 3H, $\underline{CH_3}$-CH_2), 1.36(br.s, 8H, $(\underline{CH_2})_4$), 2.15 (s, 1H, $\underline{OH}$), 4.00 (m, 1H, $\underline{CH}OH$), 4.95—5.25 (m, 2H, $\underline{CH_2}$=), and 5.56—6.10 ppm (m, 1H, -$\underline{CH}$=). IR(film) 3400 (ν_{OH}) and 920 cm^{-1} ($\delta_{CH_2=}$).

A Study of the Removal of Oily Soil by Rolling up in Detergency

Keizo OGINO and Wataru AGUI

Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received December 11, 1975)

The removal of simply constituted oily soil from a low-energy surface such as polypropylene (PP) has been examined in aqueous solutions of sodium dodecylbenzenesulfonate and its builders. Oleic acid, olive oil, lauryl alcohol, oleyl alcohol, and liquid paraffin were used as model oily soils. Rolling-up was observed in all the soils except oleyl alcohol and liquid paraffin. The rolling-up of the soil occurred in the contact angle range of $0°<\theta<90°$(θ is contact angle) when the soil was removed incompletely from PP. Apparent activation energies for rolling-up were derived, *i.e.*, 8 kcal/mol for oleic acid and 11.9 kcal/mol for olive oil. Complexes were formed for oleic acid, lauryl alcohol, and oleyl alcohol. The effects of the surfactant in various concentrations at various temperature, and with various builders were studied in view of the interfacial tension and the contact angle.

Although cleaning systems have in practice, complicated constitutions (*i.e.*, multicomponent soils in multiphase adhering to substrates which are immersed in a multicomponent cleaning both), it is known that there are three basic mechanisms by which liquid oily soil may be removed in detergent solutions: rolling-up, emulsification, and solubilization.[1,2]

Adam first pointed out that oily soil originally present as a thin layer coating the substrate is pushed into a sphere, together with the substrate, when immersed in a detergent solution; then, it can be removed from the substrate.[3] He also adopted Young's equation to relate the contact angle to the interfacial tension. Thereafter, many investigators reported microscopic studies of similar processes with various kinds of textile fibers and oily soils in the surfactant solutions.[4-7] Kling *et al.* showed some quantitative results on a process using nonpolar oily soil such as liquid paraffin.[8-10]

In the present paper, oleic acid (*cis*-9-octadecanoic acid), olive oil, lauryl alcohol(1-dodecanol), oleyl alcohol(*cis*-9-dodecen-1-ol), and liquid paraffin were used as model oily soils, and the removal of these oily materials from low-energy solid surfaces was studied.

Experimental

Materials. *Substrate*: Sheets of polypropylene (Mitsui Nobulene JHG) ($100\times40\times1.2$ mm) were prepared under a projecting pressure of 475/cm² at 250 °C and were pressed with a pressure of 200 kg/cm² at 180 °C. The sheets were then cut into specimens of $10\times10\times1.2$ mm: the surface was cleaned with a commercial detergent solution at 35 °C several times, rinsed with distilled water for 60 min, soaked in absolute ethanol for 5 min, dried in a vacuum for 3 h, and stored in a desiccator at room temperature before use.

Surfactant: The sodium dodecylbenzenesulfonate (NaDBS) was of an extra pure reagent grade, purchased from the Tokyo Kasei Co., and was purified by extraction with absolute ethanol.

Builders: The anhydrous sodium sulfate and sodium carbonate were of a guaranteed reagent grade, obtained from the Hikotaro Shudzui Co. and the Showa Chemical Co. respectively. The sodium tripolyphosphate was from the Mitsui Toatsu Chem. Co., it was the commercial grade.

Model Oily Soils: The oleic acid and lauryl alcohol were of a reagent grade from the Tokyo Kasei Co. The oleyl alcohol and liquid paraffin of an extra pure reagent grade were from the Wako Pure Chem. Co. The olive oil was commercially purchased from the Kozakai Seiyaku Co.

Apparatus and Procedure. An oily soil droplet of 1.5 μl was put on the surface of PP by means of a microsyringe connected with a micrometer. The sheet of PP was then set in a glass cell ($40\times25\times15$ mm). The glass cell was placed on the table of the Goniometer, M-2010, A-a, G-I type of the Erma Kogaku Co. Ltd., and then the detergent solution was poured slowly onto it. The contact angle of the droplet, its change, and the radius of the contact area between the droplet and the PP plate were measured in the solution, and the appearance of the droplet was photographed.

A polarizing microscope with crossed nicols (PFM type of the Nippon Kogaku Co. Ltd.) was used to observe the state of the droplets in the solution at 30 °C. The time required to remove oily soils from the PP by rolling-up was measured at 25, 30, 40, 50, and 55±1 °C. The interfacial tension of the system was measured by a Wilhelmy-type Surface Tensiometer, ST-1, of the Shimadzu Seisakusho Co. at 30 °C.

Results and Discussion

Observation of the Rolling-up Process. Figure 1 shows the behavior of oily soils adhering on PP in the

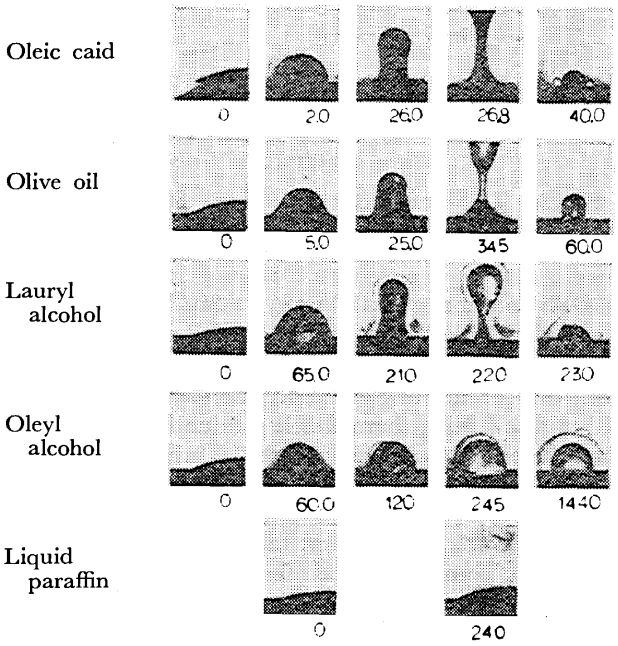

Fig. 1. Behavior of oily soils in 0.150% NaDBS solution at 30 °C. (Numbers show the time in minutes after immersion into the solution.)

Table 1. Removal of oily soils

Oily soil	Contact[a] angle in air	Contact angle in water	In NaDBS 0.150% solution			
			Contact[b] angle	Complex[c] formation	Rolling up[d]	Rolling up[e] time
Oleic acid	27.5°	7.0°	81.7°	○	○	26.9
Olive oil	28.3°	5.0°	81.0°	×	○	34.5
Lauryl alcohol	17.0°	38.0°	67.0°	○	○	222.2
Oleyl alcohol	26.8°	6.9°	54.5°	○	×	—
Liquid paraffin	18.0°	0.0°	26.5°	×	×	—

a) Measured in air at room temperature. b) Angle quoted is final contact angle in the surfactant solution. c) ○: Complex formed visibly, ×: No complex formed visibly. d) ○: Rolling up occured, ×: No rolling up occured. e) The figures show the time (min), required to remove soils by rolling up.

NaDBS solution of 0.150 wt% at 30 °C. The contact angle of the oleic acid droplet on PP was 27.5° in air. As soon as the droplet came into the surfactant solution, the contact angle rapidly increased from 27.5° to 68° in a few min; thereafter it gradually increased with the time until it reached 81° after 20 min. Accordingly, the contact area between the droplet and PP decreased, and the droplet was constricted and floated away after about 26 min. Thereafter, a transparent layer, the so-called "complex," was formed at the remaining droplet/solution interface after about 40 min.

The olive oil droplet was removed incompletely from the PP surface after 34.5 min by the same process as that used for the oleic acid droplet, but in this case the complex was not formed. Lauryl alcohol behaved

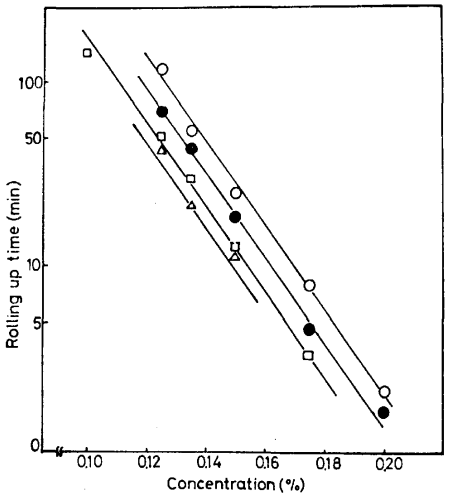

Fig. 4. The effect of NaDBS concentration of the time required for rolling up of oleic acid droplet.
○: 30 °C, ●: 40 °C, □: 50 °C, △: 55 °C.

like oleic acid in the earlier stages, but the complex was formed on the surface of the droplet after 60 min and the droplet coated with the complex gradually grew and then was incompletely detached and floated away after 220 min. The oleyl alcohol droplet was kept for 50 h. The complex began to form after 150 min; it grew gradually with the time and covered the droplet, but no rolling-up occurred. A rigid complex seemed to form between oleyl alcohol and NaDBS. On liquid paraffin, little change was recognized within 50 min.

Figure 2 shows the dependence of the contact angle of oleic acid on PP on the time in the solutions of NaDBS at various concentrations. Similar relations were also obtained for olive oil, lauryl alcohol, and oleyl alcohol, but, as is shown in Fig. 3 no distinct change was recognized with the time for liquid paraffin in the solutions of NaDBS. Table 1 summarizes the results obtained above.

The contact angle of the soils in air decreased in this order: olive oil > oleic acid > oleyl alcohol > liquid paraffin>lauryl alcohol. These results agree approximately with Zisman's;[11] that is, the contact angle of the same series of organic liquids on a low-energy surface decreases with the decrease both the molecular weight and the surface tension. However, when oily soils are placed in the NaDBS solution, the

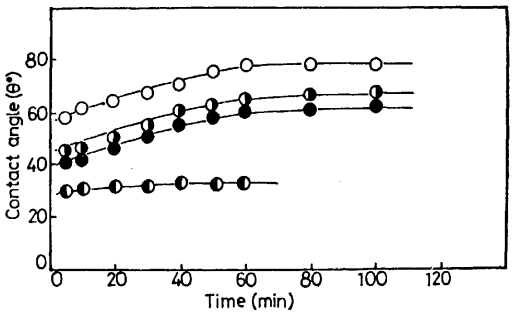

Fig. 6. The contact angle of oleic acid droplet in NaDBS–Na_2SO_4 solution (total solid 0.100%, at 30 °C). Surfactant: builder ratio, ●; 1 : 0, ○; 3 : 1, ◑; 1 : 1, ◐; 1 : 3.

contact angle of the oil/substrate interface gradually increases, and substantially the contact angle increases with the increase in the surfactant concentration. The rolling-up was observed in all the soils except oleyl alcohol and liquid paraffin; the time required for the rolling-up of soils from PP decreased in this order: lauryl alcohol>olive oil>oleic acid. Visible complexes were formed for oleic acid, lauryl alcohol, and oleyl alcohol at the surface of the droplets.

Effect of Concentration of NaDBS and Temperature. Figure 4 shows the effect of the concentration of the NaDBS solution on the time required for the rolling-up of an oleic acid droplet between 30 and 55 °C. It may be seen in Fig. 4 that the time required for the removal of the oleic acid droplet by rolling-up becomes shorter exponentially with the increase in the concentration at each temperature. A similar result was also obtained for olive oil.

In Fig. 5, the logarithms of the reciprocal rolling-up time (log X) are plotted as functions of the reciprocal absolute temperature($1/T$) for oleic acid. The relation gives a straight line. Consequently, the apparent activation energies for rolling-up are derived, *i.e.*, 8 kcal/mol for oleic acid and 11.9 kcal/mol for olive oil.

Effect of Neutral Builders. Figure 6 shows the time dependence of the contact angle of oleic acid against PP in the surfactant solutions containing

neutral builder sodium sulfate (0.100 wt%). Similar figures were also obtained for olive oil, lauryl alcohol, and oleyl alcohol, but, as is shown in Fig. 7, no distinct change was observed for liquid paraffin. It was found that, when the ratio of NaDBS to Na_2SO_4 was 3 to 1 by weight, the increase in the contact angle with the time became the largest at each oily soil. The effect of the total concentration of NaDBS and Na_2SO_4 on the rolling-up of the oily soils was further studied. The results are shown in Tables 2 and 3 for oleic acid and olive oil droplets respectively at 30 °C. As is evident from these results, the time required for rolling-up decreases most remarkably in the solution containing NaDBS and Na_2SO_4 at the ratio of 3 to 1, while the time required for the rolling-up of oleic acid was shorter than that of olive oil in the solution containing the neutral builder Na_2SO_4, but the result was the inverse in the surfactant solution

Table 4. Removal of oily soils

buoyancy of the oily soil, the cohesive force of the oil itself, and the adhesive force between oil and substrate. When these three forces are unbalanced and the buoyancy overcomes the other forces as a result of the adsorption and the desorption of surfactant molecules at the substrate/soil/solution interfaces under the hydrodynamic fluctuation or the convection of the solution, the incomplete detachment and floatation of the oily soil, the process from Stage 5 to Stage 7 in Fig. 8 will take place. We assume that the complex formation may also contribute to the rolling-up of lauryl alcohol [Fig. 8(b)].

Observation of Liquid Crystals. As is shown in Fig. 1, we observed complexes on the surface of soils, especially a distinct complex layer on lauryl and oleyl alcohol droplets. Figure 11 shows the appearance of complexes for oily soils in a 0.150 per cent NaDBS solution; we made the observation by means of the polarizing microscope with crossed nicols. Complexes from oleic acid (remaining droplet after rolling-up), lauryl alcohol, and oleyl alcohol show optical anisotropy around the original oily soil. Therefore, we assumed that these complexes might be regarded as ternary liquid crystalline phases composed of an oil–water–surfactant.[4,12]

We studied further the behavior of oily soils in the NaDBS solution containing builders. Table 4 summarizes the results. With respect to oleic acid, in the solution containing only NaDBS and NaDBS with Na_2SO_4, rolling-up occurred before the formation of the liquid-crystalline phase. As is shown in Fig. 12(a), though in the solution containing NaDBS and alkaline builders such as sodium tripolyphosphate(STPP) or sodium carbonate, no rolling-up occurred. Oleic acid is considered to react with the alkaline builder to form sodium oleate at the solution/soil interface; as a result, the oleic acid would be removed from the PP surface by a spontaneous emulsification.

Olive oil forms no liquid crystal; nevertheless, it is remarkably rolled up by the addition of builders to a surfactant. For higher alcohols, such as lauryl and oleyl alcohol, the time required to form a liquid crystal is shorter in the solution of NaDBS containing an alkaline builder than in the other solutions. As is shown in Fig. 12(b), lauryl alcohol was removed continuously in small droplets from PP in the solution of NaDBS containing STPP, while oleyl alcohol showed a myelinic appearance after about 900 min in the solution of NaDBS containing Na_2CO_3 [Fig. 12(c)]. With respect to liquid paraffin, no distinct change was recognized, not even in the solution of NaDBS containing builders.

The Crystal Structure and the Absolute Configuration of (+)-2,3 : 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-diyl Bis(*p*-bromobenzoate)

Tsuguhiro KANEDA, Chuji KATAYAMA, and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received February 26, 1976)

Synopsis. The crystal and the molecular structure of the titled compound was investigated by the X-ray diffraction method. The absolute configuration was determined by the Bijvoet method as 1*R*4*S*5*R*8*S*.

The titled compound was synthesized, optically resolved, and crystallized by Tatemitsu, Ogura, Nakagawa, Nakagawa, Naemura, and Nakazaki.[1] The optical properties of related compounds to it were investigated, and it was desired to determine the absolute configuration of the compound by the X-ray method.

Experimental

The space group of the crystal was determined from oscillation and Weissenberg photographs. The cell dimensions were determined by the least-squares method, using 12 reflections which had been carefully measured on a Hilger-Watts four-circle diffractometer with Ni-filtered Cu$K\alpha$ radiation (λ=1.5418 Å). Crystal data : $C_3H_{22}O_4Br_2$, *M. W.* =618.34, orthorhombic $P2_12_12_1$, a=12.391(1), b=19.802(1), c=10.595(1)Å, z=4, D_m=1.576, D_c=1.580 g·cm^{-3}, μ=46.79 cm^{-1} (for Cu$K\alpha$ radiation). Intensity data were collected with the diffractometer in the θ-2θ scanning mode ($2\theta \leqq 144°$) with the same radiation using a crystal whose size was 0.2×0.2×0.4 mm. No correction was made for absorption or extinction.

Structure Determination

The structure was determined by the symbolic addition method using the program coded by Dr. Furusaki in Hokkaido University. An E-map revealed all the atoms except hydrogen atoms. The block-diagonal least-squares refinement was proceeded with anisotropic thermal parameters for all non-hydrogen atoms by using 1929 independent reflections with $|F^\circ| > 3\sigma$. The final R-index was converged to 0.062 with an equal weight for each reflection. The program HBLS-IV coded by Prof. Ashida was utilized for the block-diagonal least-squares refinement. The final atomic parameters with their standard deviations are shown in Table 1.

The atomic scattering factors for all atoms and $\Delta f'$ and $\Delta f''$ values for bromine atom were taken from International Tables for X-ray Crystallography.[2] The computations were carried out on a FACOM 230-60 computer at Nagoya University Computation Center. The table of the observed and calculated structure factors is kept at the office of this Bulletin. (Document No. 7623).

Results and Discussion

Figure 1 shows the atomic labelings, bond distances and angles with their standard deviations. The molecule has a bicyclo[3.3.1]nonadiene ring skeleton, and the bicyclo ring seems to be distorted by the

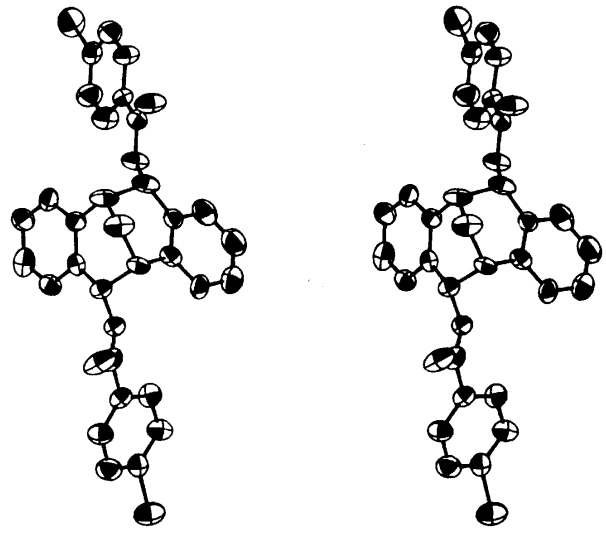

Fig. 3. Stereoscopic view of the molecule. The atoms are represented as thermal ellipsoids of a size such that the vibrating atoms have a 50% probability of being found within them.

presence of the bridge. Bond angles C(2)–C(1)–C(8) and C(4)–C(5)–C(6) are larger by 4.5° and 5.5°, respectively, than the normal tetrahedral angle. On the other hand, C(8)–C(1)–C(9) and C(4)–C(5)–C(9) are both smaller by 5.5° than the normal value. The planarities of two benzene rings, A and B, are good with the maximum deviations by 0.02 and 0.01 Å, respectively, while C(4) deviates by 0.16 Å from the A plane and C(8) by 0.19 Å from the B plane. These considerable deviations are not noticed in (−)-argemonine methiodide which also has bicyclo[3.3.1]nonadiene skeleton.[3] The bond distances and the remaining bond angles show the normal values for the respective bond types. Dihedral angle between the A and B planes is 86.9°, which was 90.4° in (−)-argemonine methiodide. Projection of the structure along the c axis is shown in Fig. 2. No particularly short intermolecular contact was found in this crystal.

The absolute configuration was determined by the Bijvoet method using the anomalous scattering by the bromine atom. The observed and calculated intensity differences between 8 pairs are listed in Table 2. The signs of observed values are in good agreement with those calculated based on the positional parameters of Table 1 in the right-handed coordinate system. The absolute configuration thus determined is 1*R*4*S*5*R*8*S* for (+)-enantiomer (Fig. 3).

Viscosity *B* Coefficients for Di- and Trialkylammonium Chlorides in Aqueous Solutions

Kunio TAMAKI, Mitsuyoshi KUSHIDA, and Yōko ŌHARA
Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236
(Received March 11, 1976)

Synopsis. The viscosity *B* coefficients of the Jones-Dole equation for di-*n*-alkylammonium chlorides (methyl to butyl) and tri-*n*-alkylammonium chlorides (methyl to propyl) in water at 25 °C were determined, and the effect of structural changes in the solvent water induced by the alkyl-substituted ammonium ions is discussed.

The behavior of electrolytes with nonpolar groups in water may be interpreted approximately by a balance of two types of interaction; hydrophobic hydration due to the nonpolar parts, and electrostrictive hydration due to the ionic parts.[1] In a previous paper,[2] the role of the alkyl groups in the coordination of the charge-bearing nitrogen atom in the series of *n*-alkylammonium salts RNH_3X, di-*n*-alkylammonium salts R_2NH_2X, tri-*n*-alkylammonium salts R_3NHX, and tetra-*n*-alkylammonium salts R_4NX was discussed on the basis of the changes in the heat capacity upon dissolution in water. The study of the viscosity of aqueous electrolyte solutions provides a useful method of obtaining information on ion-solvent interactions.[3,4] The viscosity *B* coefficients for RNH_3X[1,5] and R_4NX[6-9] are found in the literature. In this paper, we will report our experimental study of the viscosity *B* coefficients for R_2NH_2Cl (methyl to butyl) and R_3NHCl (methyl to propyl) in aqueous solutions.

Experimental

R_2NH_2Cl and R_3NHCl salts used in this work were the same samples as those described in a previous paper.[2] The viscosities were measured at 25±0.007 °C by a method similar to that described in our previous papers.[1,10]

Results and Discussion

The viscosity of aqueous electrolyte solutions is given by the Jones-Dole equation:[11]

$$\eta/\eta_0 = 1 + Ac^{1/2} + Bc \quad (1)$$

where η and η_0 are the viscosity of the solution and the solvent respectively; c, the molar concentration; A, the constant arising from the interaction between the ions, and B, the viscosity *B* coefficient. Equation 1 may be converted to:

$$(\eta/\eta_0-1)/c^{1/2} = A + Bc^{1/2} \quad (2)$$

By plotting $(\eta/\eta_0-1)/c^{1/2}$ against $c^{1/2}$, as is shown in Fig. 1, the *B* coefficient can be determined from the slope of the straight line. The values of the *B* coefficient so determined are summarized in Table 1.

The *B* value obtained in this procedure is considered to be the sum of the contributions from a cation and an anion. Taking the ionic *B* value, B_{ion}, of Cl^- ion to be −0.007 according to the separation basis of Gurney,[3] the B_{ion} values of $R_2NH_2^+$ and R_3NH^+ ions

Bu	0.687	0.694	170.7	147.5	0.325
			R_3NHCl		
Me	0.110	0.117	90.59	67.3	−0.051
Et	0.378	0.385	138.6	115.4	0.097
Pr	0.681	0.688	186.8	163.6	0.279

can be obtained; they are listed in Table 1.

The viscosity *B* coefficient is usually interpreted as consisting of two terms; the first is the effect of the ionic size, B_{size}, and the second is the contribution arising from the ion-solvent interaction, B_{solv};[4]

$$B_{ion} = B_{size} + B_{solv} \quad (3)$$

If we assume that the Einstein equation derived for the case of spherical colloid may be applied approximately to the aqueous electrolyte solutions, B_{size} may be obtained from this equation:

$$B_{size} = 0.0025\,\overline{V}^\circ_{ion} \quad (4)$$

where $\overline{V}^\circ_{ion}$ is the ionic partial molal volume expressed in cm³/mol. Thus, B_{solv} can be derived by ths use of this equation:[7]

$$B_{solv} = B_{ion} - 0.0025\overline{V}^\circ_{ion} \quad (5)$$

The values of the partial molal volume, $\overline{V}^\circ$, of R_2NH_2Cl and R_3NHCl salts have been reported by Conway and

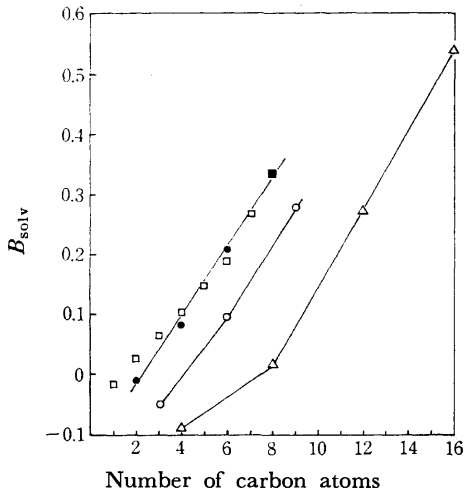

Fig. 2. Plots of B_{solv} against number of carbon atoms in the ions. □ RNH_3^+, ● $R_2NH_2^+$, ○ R_3NH^+, △R_4N^+.

his collaborators.[12,13] The $\overline{V}^\circ_{ion}$ values of $R_2NH_2^+$ and R_3NH^+ ions may be obtained by subtracting 23.2 cm^3/mol, the $\overline{V}^\circ_{ion}$ value of Cl^- ion[14], from the $\overline{V}^\circ$ values of R_2NH_2Cl and R_3HNCl salts. The B_{solv} values obtained for $R_2NH_2^+$ and R_3NH^+ ions are summarized in Table 1.

As may be seen in Table 1, the B_{solv} values of $Me_2NH_2^+$ and Me_3NH^+ ions are negative; both the methyl salts are, then, to be classified as simple salts. This implies that the interaction of the charge-bearing nitrogen atom with water surpasses the hydrophobic hydration due to methyl groups; thus, the overall behavior of these methyl salts in water is governed by electrostrictive hydration.

Table 1 indicates the positive B_{solv} values for $Et_2NH_2^+$, $Pr_2NH_2^+$, $Bu_2NH_2^+$, Et_3NH^+, and Pr_3NH^+ ions; they are all classifiable as the hydrophobic structure-making ions in water.

The B_{solv} values of RNH_3^+ and R_4N^+ ions may also be obtained using the viscosity and partial molal volume data in the literature.[1,5–9,15] Thus, in the cases of RNH_3^+, $R_2NH_2^+$, R_3NH^+, and R_4N^+ series, the dependence of the B_{solv} values on the total number of carbon atoms in the ions is shown in Fig. 2. It is found that the B_{solv} values for the alkyl-substituted ammonium ions with the same number of carbon atoms will be in this order: $RNH_3^+ \fallingdotseq R_2NH_2^+ > R_3NH^+ > R_4N^+$. The Behavior of the B_{solv} values obtained in this paper for the alkyl-substituted ammonium ions is consistent with the inclination of the changes in the heat capacity upon dissolution of these salts in water reported in a previous paper.[2]

The Catalytic Hydroboration of Ethylene with Diborane in the Gas Phase — The Acidity of Catalysts and the Reaction Activity —

Tsuneo MATSUDA, Isao SETO,* and Toyosuke TANAKA

Faculty of Engineering, Saitama University, Shimoohkubo, Urawa, Saitama 338

**Bridgestone Tire Co. Ltd., Kyobashi, Chuo-ku, Tokyo 104*

(Received December 8, 1975)

Synopsis. The catalytic hydroboration of ethylene with diborane to triethylborane in the gas phase was studied in the presence of various catalysts. The acidity of catalysts and the reaction activity were measured; the increase in the activity can be related to surface acidity of the catalysts.

The hydroboration of olefin in the liquid phase using diglyme (diethylene glycol dimethyl ether), tetrahydrofuran (THF), diethyl ether and so on as solvent was widely investigated.[1] Very few investigations of the noncatalytic hydroboration in the gas phase have, however, been reported.[2-5] We previously found that Pd–carbon was a active catalyst for the vapor-phase hydroboration of ethylene.[6] In this paper the activity of various catalysts in the hydroboration of ethylene was investigated, and it was found that the surface acidity of catalysts is correlated with its activity.

Experimental

The reaction was carried out in a closed circulation apparatus equipped with two small traps in which the product was collected. One of the traps was cooled with a salt–ice bath during the reaction.

Diborane was produced by allowing $NaBH_4$ in a diglyme solution or $LiAlH_4$ in an ether solution to react with $BF_3 \cdot C_2H_5OC_2H_5$ at room temperature under a nitrogen atmosphere.[7] The diborane was purified by freezing it with liquid nitrogen, by then pumping off any impurities, and finally by distilling it. The ethylene was also purified by low-temperature distillation. The catalysts used were Pd-carbon (Pd 3 wt.%), α- and γ-Al_2O_3 (kindly provided by Kawaken Fine Chemicals and the Tōkai Kōnetsu Co., Ltd.), active carbon, Ni-γ-Al_2O_3, and silica gel and its pretreated species with an acidic or alkaline medium. Before the reaction the catalysts were treated at 450 °C for 1 h under a vacuum (about 10^{-3} mmHg). The reaction conditions were as follows: molar ratio: 6 (C_2H_4; 4.58, B_2H_6; 0.758 mmol); catalyst used: 0.5 g; temperature: 50 °C, and time: 1 h. After the reaction, the residual gases in the apparatus were condensed by the liquid nitrogen into another trap containing THF, which was then isolated from the reactor system during the reaction, in order to recover the unreacted diborane. Then the dry nitrogen was admitted into the apparatus and the reaction vessel, and the traps in which the product had condensed were removed from the reactor system. Immediately the catalyst in the reaction vessel was washed with the purified ether several times in order to extract the reaction product adhering on the catalyst, after which the extract was added to the trap containing the product. The product thus collected was analyzed by gas chromatography, with a 10 wt% Silicone oil on Celite 545 column,[8] and using toluene as the internal standard. The unreacted diborane in THF was converted to boric acid with water. The boric acid was then titrated with a sodium hydroxide solution in the presence of glycerol, using phenolphtalein as an indicator.

The surface acidity of the catalysts was determined by the measurement of the irreversibly adsorbed amount of ammonia at 50 °C.

Results and Discussion

The only hydroboration product of ethylene under the conditions described above was triethylborane. It has been reported that, in a high molar ratio of diborane to olefins, mono- and dialkylborane were produced in the gas phase without any catalyst,[4] but in this study no such products were detected. The pressure changes during all the catalytic reactions were almost the same as in the previous paper;[6] an induction period in the initial stage was observed in every case. The catalyst properties and the results of the hydroboration of ethylene on the various catalysts are summarized in Table 1. A good correlation between the catalytic activity (yield) and the acidity was found, as is indicated in Fig. 1.

The γ-Al_2O_3, both supported and non-supported, was active, and in the hydroboration with the Ni-γ-Al_2O_3 catalyst tributylborane was detected in a small yield as well as triethylborane. The tributylborane may be formed by the reaction of diborane and the butenes which are produced by the dimerization of ethylene, since Ni or NiO supported on a silica and (or) an alumina catalyst showed catalytic activity in the dimerization of ethylene.[9] The addition of nickel

SiO_2 (B)	0	0.064	0

to γ-Al_2O_3 increases the acidity by the interaction of the nickel with the support, as was also indicated by Aonuma *et al.*[10] In order to further ascertain the effect of the acidity on the catalytic activity, hydroboration with silica gel treated with acid or alkali was carried out. As is shown in Table 1 and Fig. 1, the acid-treated silica gel caused increases in the yield and the acidity. The percentage yield of the product with respect to the admitted amount of diborane at the initial stage are shown in Table 1. On the basis of the results of the titration of the boric acid, the conversion of diborane was calculated to be as is shown in Table 1.

The greater conversion on the Pd–C and active carbon than on the other catalysts may be ascribed to the large surface area of the former, much unreacted diborane being adsorbed.[6] This is probably the reason for the great discrepancy between the percentage yield and the conversion of diborane. As another reason, the reacted diborane calculated on the basis of the results of the titration does not always proceed to triethylborane, because a gas (perhaps H_2) uncondensable by liquid nitrogen, which may be due to the reaction of diborane with the hydroxylic surface of γ-Al_2O_3 and Ni-γ-Al_2O_3,[12] was detected. Because of the small surface area of α-Al_2O_3, the supported and non-supported α-Al_2O_3 would have little of either activity of acidity.

The distribution of the acidic strength of several catalysts was measured by the titration of the butylamine–benzene solution, using Netral Red (pK_a=6.8), 1-phenylazo-2-naphtylamine (pK_a=4.0), and dicinnamylideneacetone (pK_a=−3.0) as indicators.[11] Table 2 indicates the results of the distribution with respect to the strength of the acidity. As is shown in Table 2, relatively weak acidic sites seem to catalyze the hydroboration.

The hydroboration proceeds with the migration of the hydrogen atom in diborane to olefin and the B–C bond being newly constructed. It is known that diborane dissociatively absorbs on the catalyst surface.[6, 12] The acidic site on the catalysts seems to be related to the migration of the hydrogen of BH_3, by which the olefin atom can easily attack the boron atom.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (6), 1715—1716 (1976)

The Reaction of a Stable Free Nitrogen-centered Radical, 3,4-Dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl, with Organolithium Compounds

Yozo MIURA, Yuzo MORIMOTO, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received December 5, 1975)

Synopsis. 3,4-Dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**) reacted with ethyl- and butyllithiums to give 1-ethyl- and 1-butyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazines respectively. On the other hand, biphenyl and 1-benzyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine were given by the reaction of **1** with phenyllithium in toluene. Thus, the results indicate that these reactions proceed through a homolytic process.

In a previous report it was shown that the reactions of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**, 1,3,5-triphenylverdazyl) with Grignard reagents[1] or organoaluminum compounds[2] in toluene or in THF proceed through a homolytic process, affording 1-alkyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazines (**2**) and biaryls.

In the course of the preparation of polymers containing stable free radicals,[3] the reaction of **1** with butyllithium used as an initiator was examined, and it was found that a coupling compound (**2b**) was formed. In this report, the reactions of **1** with several organolithium compounds are studied, and a reasonable reaction mechanism is presented.

Experimental

All the melting points are uncorrected. Butyllithium in hexane was obtained from the Mitsuwa Pure Chemicals Co., Ltd. Ethyllithium was prepared by treating diethylmercury with lithium in anhydrous ether,[4] while phenyllithium was prepared by treating bromobenzene with lithium in the same solvent.[5] The concentrations of the reagents were determined by the method of Gilman.[6] 3,4-Dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazine-1-yl (**1**) was prepared according to the procedure of Kuhn and Trischmann,[7] and was recrystallized from methanol, mp 141—142 °C (lit,[7] 139—140 °C). THF and toluene were distilled from $LiAlH_4$ before use.

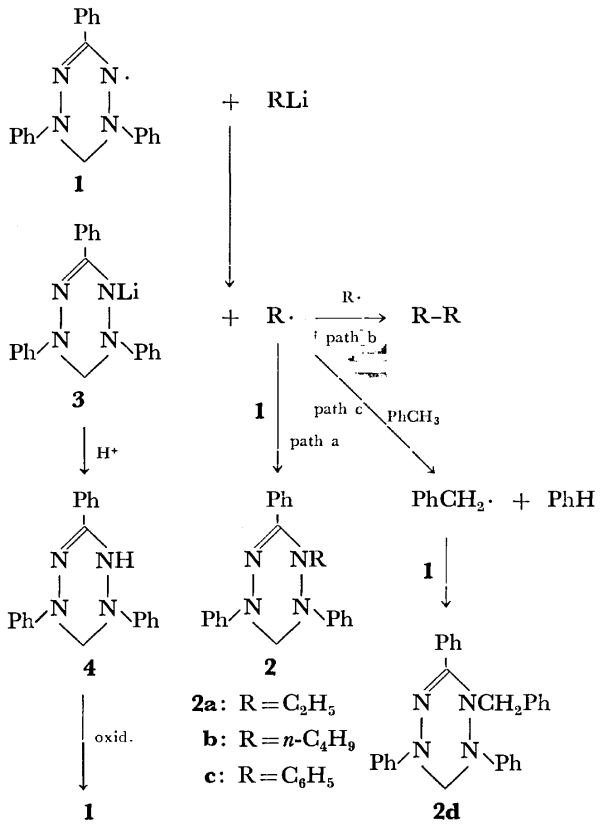
The reactions of **1** with organolithium compounds were performed in THF and in toluene according to a procedure similar to that described in a previous report.[1] The amounts of **1** recovered and the coupling compounds (**2**) formed in the reactions with alkallithiums were determined by a similar procedure.[1] The coupling compounds were recrystallized from methanol. 1-Ethyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine (**2a**): 0.19 g (0.55 mmol); mp 133—134 °C (lit,[1] 133—134 °C). 1-Butyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine (**2b**): 0.21 g (0.57 mmol); mp 109—111 °C (isolated from the reaction in THF); 0.26 g (0.70 mmol); mp 108—110 °C (from the reaction in toluene, lit,[1] mp 109—111 °C).

The compounds formed in the reaction of **1** with phenyllithium were isolated by column chromatography, using benzene/hexane (1/1 in volume) as the eluent. The isolated compounds were as follows: biphenyl 0.15 g (0.79 mmol), mp 69—71 °C (lit,[7] 71 °C); 1-benzyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine (**2d**) 0.060 g (0.15 mmol), mp 167—169 °C (recrystallized from methanol, lit,[8] 172 °C), and two unidentified compounds (0.058 and 0.010 g).

The amount of biphenyl which arose from the preparation procedure of phenyllithium was determined by a procedure similar to that used for the arylmagnesium bromides,[1] to be 0.047 g (0.31 mmol, 0.53% based on the amount of bromobenzene used for the preparation of phenyllithium). The yield of biphenyl described in Table is corrected for the amount in the starting phenyllithium solution.

Results and Discussion

When an organolithium compound was added to a THF or toluene solution of **1** at 0 °C, the dark green color of **1** faded rapidly to be replaced with light brown. This brown solution maintained its color in the absence of moisture. However, when the solution was poured into water, its color immediately returned to green, indicating the regeneration of **1**. This reaction behavior is similar to that of the reaction of **1** with Grignard reagents or organoaluminum compounds, but the reactions with organolithium compounds proceed more rapidly than those with Grignard



Scheme.

Table. The results of the reactions of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**) with organolithium compounds

Organolithium compound	mmol[a]	**1**[b] mmol	Recovered **1** %	Isolated coupling compounds	
				2 (%)[c]	Other (%)[c]

Butyllithium[d]	1.5	1.6	39	**2b** (36)	
Butyllithium[e]	1.4	1.6	30	**2b** (44)	
Phenyllithium[f]	4.0	3.2	70	**2d** (5)	Biphenyl(42)

a) Molar amount required for the completion of the reaction. b) Molar amount used in the reaction. c) Based on the amount of **1** used. d) Solvent, tetrahydrofuran: 15 ml. e) Toluene: 20 ml. f) Toluene: 30 ml.

reagents.

The amounts of **1** recovered were determined by the measurement of the absorbance at 720 nm in a benzene solution extracted from the reaction mixture. Next, the benzene solution was concentrated and subsequently subjected to column chromatography to give the coupling products (**2**) and biphenyl. The results are given in Table.

The results of the reactions with the alkyllithiums are similar to those of the reactions with alkylmagnesium halides or alkylaluminums. In the reaction with phenyllithium in toluene, however, the corresponding coupling compound (**2c**) was not isolated, though biphenyl and a small amount of 1-benzyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine (**2d**) were isolated. The formation of biphenyl was expected from the results of the reaction of **1** with arylmagnesium bromides. It is very interesting that **2d** was isolated from the reaction mixture, because the formation of this compound indicates the presence of benzyl radical in the reaction system.

On the basis of these results, a reasonable reaction mechanism may be illustrated as is shown in Scheme. In the reaction of **1** with alkyllithiums, **1** and an alkyllithium are converted into the corresponding lithium salt (**3**) and an alkyl radical. The radical is captured exclusively by another **1** to give **2** (path a). The salt (**3**) is stable under anhydrous conditions, and it decomposes immediately in contact with water to give a leuco compound (**4**), which is the oxidized gradually by atmospheric oxygen to **1**.

On the other hand, the phenyl radical formed in the reaction of **1** with phenyllithium is not captured by **1**; it either couples with itself to give biphenyl (bath b) or abstracts a hydrogen from the solvent (toluene) to give benzene and a benzyl radical (path c). The benzyl radical is captured immediately by **1** to give **2d**.

The Thermal Decomposition of Cyanodiphenylmethyl *t*-Butyl Peroxide: An Example of C–O Bond Scission

Masao Ōkubo, Emiko Iba-Imai, Hiroko Mizuta, and Takumi Kawamoto

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received June 9, 1975)

Synopsis. The thermal decomposition of cyanodiphenylmethyl *t*-butyl peroxide was investigated. The peroxide is abnormally stable and decomposes slowly at 130—135 °C, and the main reaction product is tetraphenylsuccinonitrile. A main reaction path including the C–O bond scission, in contrast to the case of triphenylmethyl *t*-butyl peroxide, is proposed.

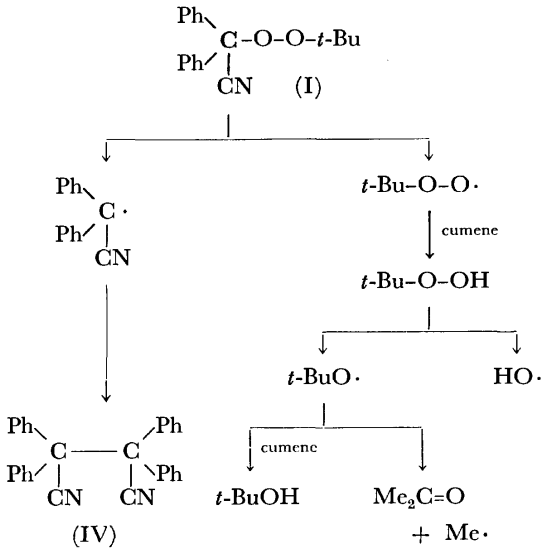
It has been reported that cyanodiphenylmethyl *t*-butyl peroxide(I)[1] is unaffected by treatment with two molar equivalents of phenylmagnesium bromide.[2] The stability of the α-cyano group and that of the O–O bond of I attracted our attention. This peroxide resembles triphenylmethyl *t*-butyl preoxide(II) in its molecular structure as well as its stability towards the Grignard reagent. Upon thermal decomposition in cumene, II yields 1-phenoxy-1,1,2-triphenyl-2-methylpropane (60%) as a result of the rearrangement of the triphenylmethoxyl radical, followed by recombination with the cumyl radical.[3] The preferential migration of the *p*-nitrophenyl group in *p*-nitrophenyldiphenylmethoxyl radical has also been reported.[3,4] These facts led the present authors to study the thermal decomposition of I.

Peroxide I was also unaffected by treatment with iodide ions in both the absence[5] and presence[6] of ferric ions at room temperature.[2] Treatment in boiling acetic acid[7] liberated iodine, but the thiosulfate-titer went up to extraordinarily high values (250—500 mol%) and fluctuated seriously. Thus, no iodometric search for the decomposition course of I was not made in this work.

When peroxide I was decomposed in some alkylbenzenes (toluene, ethylbenzene, *p*-xylene, mesitylene, and cumene) at their boiling temperatures, acetone and *t*-butyl alcohol were produced. The manner of the variation in the molar ratio of the two products (Table 1) is consistent with the reactivities of these aromatics towards the hydrogen abstraction by the *t*-butoxyl radical.[8]

After a solution of I(1.0 M) in cumene had been heated at 130—135 °C for 5 h, the yields of acetone and *t*-butyl alcohol were 5 and 16% respectively. From the viscous oily mixture obtained after the complete evaporation of cumene under reduced pressure, a large amount of unreacted I (53%) and a small amount of dicumyl(III) were detected by NMR spectroscopy on the basis of the *t*-butyl- and methyl-proton signals. Tetraphenylsuccinonitrile(IV), the main reaction product, was separated from the unreacted I by the elution of the mixture with petroleum ether–benzene through a silica-gel column. A small amount of benzophenone (V, 7%), accompanied by a trace of benzhydrol (VI), was detected by GLC. The yields of III and IV were estimated to be 9 and 31% respectively from the integrated NMR spectrum of the mixture (See Experimental Section).

The results of the product analysis imply that I is remarkably stable and that it decomposes in a novel manner. The stability of I is evident in comparison with II; it was reconfirmed that the latter decomposed completely after 5 h under the same reaction conditions.[3] The substantially high yield of IV (67%) suggests that the main reaction path begins with the cleavage of the C–O bond (Scheme 1).



Scheme 1.

Table 1. Variation of the molar ratio of *t*-butyl alcohol and acetone with aromatics

Aromatics	[*t*-BuOH]/[Acetone]
Mesitylene	0.1
Cumene	3.1
Fluorene (ArH/I=1.0)[a]	1.1
(ArH/I=2.0)	1.6

a) Peroxide I and fluorene (0.004 mol), dissolved in chlorobenzene (50 ml), were heated in an oil bath maintained at 180—185 °C.

The yield of V did not exceed 7 mol% in any of the aromatics used. Hydrogen cyanide (VII) was detected by the use of a piece of test paper impregnated with an aqueous solution of cupric acetate–benzidine acetate.[9] The formation of V, VI, and VII suggests a concurrent minor reaction path beginning with the ordinary O–O bond scission, as is shown in the following:

$$\underset{\text{(I)}}{Ph_2C(CN)-O-O-t\text{-}Bu} \longrightarrow Ph_2\dot{C}(CN) + t\text{-}BuO\cdot$$

$$Ph_2C(CN)-O\cdot \longrightarrow [Ph_2\dot{C}-OCN] \longrightarrow \underset{\text{(V)}}{Ph_2C=O} + \underset{\text{(VII)}}{\cdot CN(\rightarrow HCN)}$$

Though no direct evidence was obtained, the migration of the cyano group in the cyanodiphenylmethoxyl radical should be taken into account.[3,4]

Another example of the C–O bond scission of organic peroxide has been found in the thermal decomposition of *N*-cyclohexyl-1-*t*-butylperoxycyclohexylamine, which afforded the corresponding imine by the loss of *t*-butyl hydroperoxide,[10] but this manner of decomposition is probably due to the existence of the neighboring NH group. Though the reason for the unexpected stability of peroxide I remains obscure, its C–O bond scission can be ascribed to the stabilization of the cyanodiphenylmethyl radical by the spin-delocalization[11]; this is consistent with the absence of diphenylacetonitrile, which shows the low hydrogen-abstracting ability of the radical.

Experimental

Materials. The peroxide I was prepared by the treatment of diphenylacetonitrile with *t*-butyl hydroperoxide; mp 52 °C.[1] The peroxide II was prepared by the reported method.[3] Dicumyl(III) was prepared by the thermal decomposition of di-*t*-butyl peroxide in cumene.[12] Tetraphenylsuccinonitrile(IV) was prepared from diphenylacetonitrile.[1]

Procedures. Thermal decomposition was carried out using 1.0 M solution of I under a N_2 atmosphere. After the oil bath had been removed, a few milliliters of the aromatic solvent of the reaction mixture were distilled into an ice-cooled receiver and the ratio of the contents of acetone and *t*-butyl alcohol in the distillate was then determined by means of GLC.

In order to obtain a mixture of high-boiling products for the NMR measurement, the cumene was completely removed by the repeated dissolution of the oily mixture into CCl_4 and by evaporation under reduced pressure; the resulting pale yellow viscous oil was free from cumene (checked by GLC) and could be analyzed by the integration of the NMR spectrum. The contents of I and III were estimated on the basis of the intensities of the *t*-butyl- and methyl-proton signals; the intensities corresponding to the phenyl-protons of I and III were substracted from the overall intensity in the same region. The result gave the sum of the contents of IV and V, the latter of which had been determined by the use of GLC.

A Proton Magnetic Resonance Study of the Molecular Configurations of 2′,5′-Dichloroacetoacetanilide in Various Solvents

Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received September 25, 1975)

Synopsis. It has been found by ^{1}H NMR spectroscopy that 2′,5′-dichloroactoacetanilide (**1**) exists predominantly in the *keto* form containing an intramolecular hydrogen bond between the amide proton and the carbonyl oxygen at the γ-position in chloroform solutions. In pyridine, the line broadening of signals suggests a rapid interconversion between the *keto* and *enol* forms. Configurations of the *enol* form are discussed.

It is well known that β-diketones undergo *keto-enol* tautomerism in solution. ^{1}H NMR studies of such tautomerism have been carried out for a number of derivatives of acetylacetone and acetoacetic acid,[1] but only a few studies have been done on acetoacetamide derivatives.[2]

The *keto-enol* equilibrium is sensitive to many factors, such as the temperature, the concentration, and the solvent, as well as to the presence of substituents. Acetylacetone, *N*,*N*-dimethylacetoacetamide, and ethyl acetoacetate show a successively decreasing contribution of *enol* form.[1,2]

It is an interesting subject to determine which of the many possible conformations are actually reallized in the case of each compound. This paper will be concerned with the molecular configuration of 2′,5′-dichloroacetoacetanilide (**1**), which is revealed to exist predominantly in the *keto* form in $CDCl_3$.

Experimental

Commercial 2′,5′-dichloroacetoacetanilide (**1**) was purified by recrystallization from CCl_4.

The ^{1}H NMR spectra were recorded on a Varian T-60A spectrometer, using TMS as the internal standard. The concentrations of the samples were 6% (w/v) unless otherwise noted.

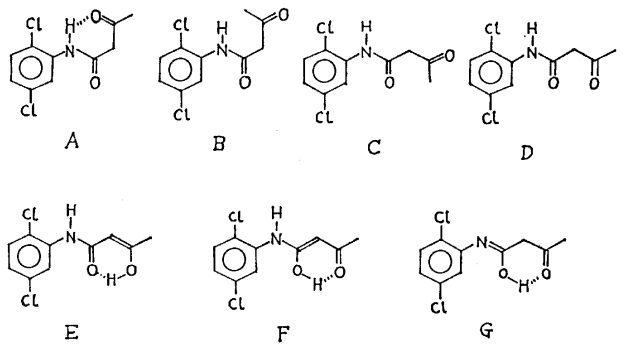
The IR and UV spectra were measured on a Hitachi infrared spectrophotometer, Model G-3, and a Hitachi spectrophotometer, Model 356, respectively.

Results and Discussion

The ^{1}H NMR spectra of **1** in various solvents are relatively simple and seem to be composed of two kinds of signals. Raising the temperature of a DMSO solution of **1** up to 100 °C caused no new signals to appear, but there was a slight upfield shift of the amide proton signal.

The signal at δ 3.64 (in $CDCl_3$, for example) corresponding to *ca.* 2H can be ascribed to the methylene protons in *keto* forms on the basis of its chemical shift. The broad signal at δ 9.77 corresponding to *ca.* 1H may be attributed to the amide proton. The alternative assignment of this signal to an enolic OH in the G structure can be eliminated on the basis of the close resemblance in the IR spectra of **1** and 2′, 5′-dichloroacetanilide (**2**) in $CDCl_3$ (Table 1). The amide bands at about 1600 and 1700 cm^{-1} were clearly observed at about same positions. The UV spectra of **1** and **2** in 1,2-dichloroethane solutions are very similar to each other. These facts seem to allow us to rule out the contribution of G in the present case.

The ABX spectral pattern of the aromatic ring protons permits an unequivocal assignment of H-6′ because of the presence of two chlorine atoms. The similarity in the δ values for the ring protons of **1** and **2** enables us to assign forms A to D with the *trans* configuration about the amide bond to *keto* tautomers for **1**, because the *trans* configuration of **2** has been proved on the basis of the diagnostic acetylation-deshielding shift.[3] The corresponding *cis* configurations were dificult to realize, judging from the generally known fact that amide bonds (or peptide bonds) predominantly exist in the *trans* form.[4]



The amide proton of **1** resonates at a field lower by about 2.14 ppm than does that of **2**. This pronounced downfield shift can be interpreted in terms of the A configuration, wherein an intramolecular hydrogen bond is formed between the amide proton and the γ-carbonyl oxygen, though the contributions of B, C, and D can not be neglected. The concentration dependence of the amide proton signal was negligible, as was to be expected from the intramolecular hydrogen bond formed. The broad band at 2900—3400 cm^{-1} in the IR spectrum of **1** may also be ascribed to the amide proton intramolecularly hydrogen-bonded.

An analogous situation was observed in CCl_4 solutions. In DMSO, it is not clear from only the position of the amide proton signal whether or not this configuration remains unchanged, because that of **2** also resonates at a low field due to the intermolecular hydrogen bonding with a DMSO molecule. However, the molecular planarity is considered to be lowered in DMSO, as suggested by the diagnostic upfield shift of the H-6′ signal as compared with that in $CDCl_3$.[5]

a) Saturated solution. b) Shoulder. c) Lower frequency bands are omitted.

In pyridine it is noted that the linewidths of the signals of the methyl and methylene protons are much broader than those in chloroform. Although no apparent signal ascribable to *enol* forms were observed, the broadening in the methylene proton signal suggests a rather rapid interconversion between the *keto* and *enol* forms. This could be ascribed to catalytic actions of pyridine.[1d]

The population of the *keto* form is much greater in this compound than in *N,N*-dimethylacetoacetamide.[2] The intramolecular hydrogen bonding between the amide proton and the γ-carbonyl oxygen may be responsible for this.

It is possible to imagine four configurations (E and F and the corresponding *cis* forms, E′ and F′) as *enol* forms. The fact that the chemical shift of H-6′ in the *enol* tautomer is very close to that for the *keto* tautomer favors the E and F structures, which have the oxygen atom in close proximity to H-6′, rather than E′ and F′, which have the olefinic proton in such proximity. The methyl signals of the *enol* tautomers were observed at fields higher than those of the *keto* tautomers in the solvents examined, as was also observed for a series of β-diketones and β-keto esters.[1e] The difference between the chemical shifts of the two tautomers of **1** is almost the same as that in the case of ethyl acetoacetate, but it is clearly larger than that of acetylacetone. If the *enol* molecule assumes the F form, the chemical shift of the acetyl protons should not be very different from that in the *keto* form. Furthermore, if a rapid interconversion between E and F is supposed, the chemical shift difference between the *keto* and *enol* forms should be equal to the corresponding difference in acetylacetone. The argument given above leads one to the conclusion that the molecular configuration of the *enol* tautomer is E.

The olefinic proton signal of the *enol* tautomer was observed at δ 5.07 in $CDCl_3$, higher by -0.51 ppm than that of acetylacetone, but almost the same as that of ethyl acetoacetate. The enolic OH proton resonates at δ 13.3 in $CDCl_3$. The corresponding values for acetylacetone and ethyl acetoacetate are δ 15.6 and 12.2 in pure liquid respectively.[1e] These facts also support the argument presented above.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (6), 1721—1722 (1976)

Reaction of Thiocarbonyl Compounds with Tributylphosphine[1)]

Yoshiro OGATA, Mitsuji YAMASHITA, and Makoto MIZUTANI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received October 6, 1976)

Synopsis. The reaction of thiobenzophenone (**1**) with tributylphosphine (**3**) gives an oligomer at room temperature, but it gives tributylphosphine sulfide (**4**), 1,1,2,2-tetraphenylethane, and tetraphenylethylene (**6**) at 100 °C. The reaction of thiofluorenone with **3** gives **4**, bifluorenylidine (**8**), and bifluorenyl (**9**) at room temperature. These possible mechanisms are discussed by carbene intermediates.

The deoxygenation and desulfurization of organic compounds by trivalent phosphorus compounds is well known.[2)] Some of these reactions may proceed *via* carbene intermediates, but there have been only a few attempts to identify carbenes in the reaction with trivalent phosphorus compounds.[3)] The reaction of benzophenone with triisopropyl phosphite to give a mixture of diisopropyl benzhydrylphosphonate, triisopropyl phosphate, tetraphenyl–ethylene, and propylene, probably proceeds *via* an ionic path.[4)]

On the other hand, it was postulated[5)] that hexafluoroacetone reacts with phosphite *via* a carbene intermediate to give trialkoxybis(trifluoromethyl)methylene phosphorane. The reaction of cyclic 1,2-thiocarbonates with trimethyl phosphite gives olefinic product, together with a small amount of orthoformate derivative formed by carbene reaction.[6)] Also the formation of fluorene, bifluorenyl, and tribiphenylenepropane by the reaction of fluorene with tributylphosphine in hydrogen donating solvents[7)] suggests the intermediacy of carbene.

The thiophilicity of trivalent phosphorus compounds should be higher than the oxophilicity in the reaction of ketonic compounds, and we reported previously the facile reaction of thiobenzophenone with phosphite.[8)] This paper deals with evidence for carbene formation during the desulfurization of some thioketones by phosphine, and their higher reactivities.

Results and Discussion

No reaction of thiobenzophenone (**1**) with triphenylphosphine (**2**) occurred even at 160 °C for 24 h. An apparent reaction of **1** on addition of tributylphosphine (**3**) proceeds at room temperature, but the reaction gave only an oligomer of **1** in good yield without desulfurization. When the oligomer was dissolved in inert solvents, the dark blue color of the monomer was reappeared, and it strongly suggests that the formation of the oligomer is reversible.

The acid-catalyzed dimerization and trimerization of thioaldehydes, dialkyl thioketones, and alkyl aryl thioketones are well known.[9,10)] On the other hand, cyclization of monothiobenzil and dithiobenzil derivatives to four-membered ring including one or two sulfur atoms was recently reported.[11,12)]

But only a few report was known concerning the formation of polymeric thiobenzophenone.[13)] This is the first report on the reversible formation of oligomer.

$$n\text{-}Ph_2CS(\mathbf{1}) \xrightarrow{n\text{-}Bu_3P} (Ph_2CS)_n \qquad (n=2 \text{ or } 3)$$

However, the reaction of **1** with **3** under N_2 at 100 °C for 10 h gives mainly tributylphosphine sulfide (**4**, 89%), 1,1,2,2-tetraphenylethane (**5**, 65%), and tetraphenylethylene (**6**, 28%). The formation of **5** and **6** suggests the intermediacy of carbene in the reaction, i.e., these products may be produced by the coupling of diphenyl carbene or diphenylmethyl radical arising from abstraction of sulfur from **1** by phosphine, followed by hydrogen atom abstraction.

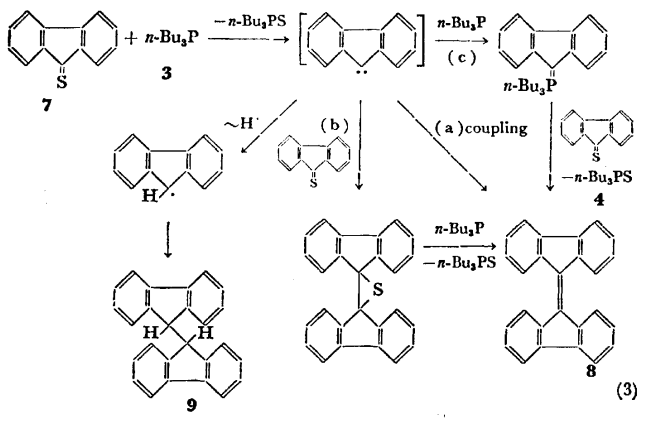
$$\underset{\mathbf{1}}{Ph_2CS} + \underset{\mathbf{3}}{n\text{-}Bu_3P} \rightarrow \underset{\mathbf{4}}{n\text{-}Bu_3PS} + \underset{\mathbf{5}}{(Ph_2CH\text{-})_2} + \underset{\mathbf{6}}{Ph_2C{=}CPh_2} \quad (2)$$

The photochemical reaction of diphenyldiazomethane in some solvents gives benzophenonazine and tetraphenylethane, those yields depending upon solvents used[14)] where the formed diphenylcarbene couples with starting material to give benzophenonazine, and/or abstracts hydrogen atom from the solvent followed by coupling to give tetraphenylethane. In our present reaction, the formed carbene may react with thiobenzophenone to give tetraphenylethylene, and/or may abstract a hydrogen atom from phosphine followed by coupling to give tetraphenylethane. (See Scheme 1).

The reaction of thiofluorenone (**7**) with tributylphosphine (**3**) proceeds at room temperature. The products are mainly **4** (95%), bifluorenylidine (**8**, 63%), and bifluorenyl (**9**, 23%). It is known that the reaction of fluorenone with tributylphosphine at 155—165 °C for 76 h affords bifluorenylidene (40%),[7)] and that the photochemical reaction of diazofluorene in cyclohexane affords bifluorenyl (24%).[14)] Hence following reaction pathways are conceivable for our reaction of thiofluorenone to form **4**, **8** and **9**.

Fluorenyl carbene abstracts a hydrogen atom from tributylphosphine (**3**), then couples each other to form bifluorenyl (**9**), because **9** was obtained even in the reaction in neat. Three pathways are concievable for the formation of **8**, i.e., (i) coupling of two molecules of fluorenyl carbene (path a), (ii) formation of episulfide followed by desulfurization (path b), and (iii) formation of phosphorane followed by Wittig reaction with thiobenzophenone (path c).[3b,15)] Phosphines have been utilized as carbene acceptors,[16)] but path c is less probable in this reaction because of the little effect on the product distribution by adding benzaldehyde to the reaction mixture.[17)] The desulfurization from episulfide by phosphine and coupling of carbene is very fast, so that both paths a and b cannot be ruled out. The analogous reaction mechanism may be applicable for the reaction of **1** with **3**.

The facile reaction of thiofluorenone with tributylphosphine at room temperature for 3 h in comparison



Scheme 1.

with the reaction of thiobenzophenone, which required 10 h reaction at 100 °C, is attributable to the driving force due to the stability of the formed carbene; *i.e.* fluorenyl carbene may be more stable than diphenyl carbene in view of its resonance forms. Gas phase reaction of diphenyl carbene gives about 30% yield of fluorene.[18]

The thiophilicity of trivalent phosphorus compounds towards thiocarbonyl compounds surpasses the oxophilicity towards the corresponding carbonyl compounds.[8,19] The reaction of **7** with **3** proceeds at room temperature, while the reaction of fluorenone with **3** necessitates the higher temperature of 155—165 °C,[7] and the reaction of benzophenone with triisopropyl phosphite needs more drastic conditions, *i.e.*, 72 h reaction at 170 °C, while those of thiobenzophenone with trialkyl phosphites can proceed at 100 °C for 10 h.[4,8]

Experimental

All melting points and boiling points were uncorrected. A Yanagimoto GCG 550F and Hitachi K53 gas chromatographs were used with a 1 m×3 mm column packed with Silicone GE SE 30 (8%) coated on Chromosorb W. IR spectra were measured by a Perkin-Elmer Model 337 spectrophotometer. NMR spectra were measured by a JNM-C60-HL NMR instrument of Japan Optics Laboratory. Mass spectra were measured by a Hitachi RMS-4 mass spectrometer.

Reaction of Thiobenzophenone with Tributylphosphine. The reaction of thiobenzophenone (**1**) with excess tributylphosphine (**3**) (*ca.* 3 equivalents) at room temperature for 10 min gave oligomer of **1** (quantitative), which was dissociated to its monomer on dissolving in benzene and chloroform, mp 130 °C.

The NMR spectra show only aromatic protons (δ= 7.18—7.72), and IR spectra show C-S absorption (651 cm^{-1}), but no C=S absorption. The reported mp of polymeric thiobenzophenone is 146.5 °C[13]

The mixture of **1** (0.67 g) and **3** (1.7 g) was heated under N_2 for 10 h at 100 °C. The products were tetraphenylethylene (28%), tetraphenylethane (65%), and tributylphosphine sulfide (89%), which were identified by NMR, IR, VPC. and mp by comparison with the authentic samples. In addition to these compounds, other two minor unidentified products were obtained.

Reaction of Thiofluorenone (7) with Tributylphosphine(3). The reaction of thiofluorenone (**7**) with **3** was carried out for 3 h at room temperature. Bifluorenylidine (63%), bifluorenyl (23%), and tri-*n*-butylphosphine sulfide (95%) were separated from the reaction mixture by TLC (Kiesel gel G/benzene) and identified by VPC analysis by comparison with the authentic samples. The formation of 9-diphenylenephenanthrone was also observed, and was identified by IR (KBr, C=O, 1700 cm^{-1}), NMR ($CDCl_3$, δ=6.2—7.9, aromatic protones), mp 201.5—203 °C (recrystallized from petroleum ether–benzene), and elemental analysis. Found: C, 90.90; H, 5.06%. Calcd for $C_{26}H_{16}O$: 90.70; H, 5.13%.

Reaction of **1** *with* **2**. A mixture of **1** (0.71 g) with **2** (3.71 g) was heated in a sealed tube under N_2 for 24 h at 160 °C, but no reaction product was observed by VPC analysis.

The Photochemical Reaction of Iron Pentacarbonyl and 1,3-Butadiene-1,1,4,4-d_4. The Lack of Secondary Isotope Effects

Ryoji Noyori and Keiichi Yokoyama

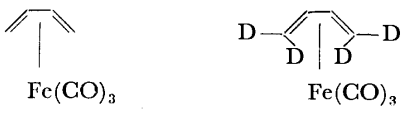
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received March 2, 1976)

Synopsis. No significant deuterium isotope effects have been noticed in the formation of the 1,3-butadiene–iron tricarbonyl complex, in contrast to the olefin complexation of Ag^+ or Rh(I) species.

Deuterated olefins and 1,3-dienes are known to form complexes with silver nitrate more readily than their undeuterated analogs.[1] The same trend has been observed with the reaction of Rh(I) complexes.[2] In connection with a mechanistic study of the iron carbonyl-promoted reaction of 1,3-dienes and α,α'-dibromo ketones,[3] we have now examined the reaction of a deuterated butadiene and iron pentacarbonyl [$Fe(CO)_5$].

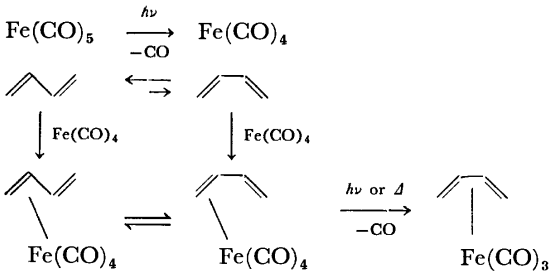
Intermolecular competition experiments were carried out using an approximate 1 : 1 mixture of 1,3-butadiene (**1**) and 1,3-butadiene-1,1,4,4-d_4 (**2**). A mixture of $Fe(CO)_5$ and a 10-fold excess of **1** and **2** was placed in a sealed Pyrex tube and exposed to a high-pressure mercury arc. The resulting iron carbonyl complexes, **3** and **4**, were isolated, and the isotopic composition



3 **4**

was analyzed carefully on a 100 MHz NMR machine with a CAT system. The correction of the rate constant of the d_4 substrate to a per deuterium basis was done in order to determine the secondary deuterium isotope effect, k_H/k_D. The results, given in Table 1, indicate that the deuterium substitution does not exert any significant influence on the rate of butadiene–iron tricarbonyl complex formation.

The photochemical reaction between $Fe(CO)_5$ and butadiene is considered to proceed through the pathway outlined in Scheme 1.[4] Since the butadiene ligand in **3** is not displaced by free butadiene under the present reaction conditions, the negligible deuterium isotope effect is associated with the stage of iron tetracarbonyl–butadiene (as a monoolefinic ligand) complex formation. In iron carbonyl–olefin complexes, the σ-donative ability of the olefinic ligand is less



Scheme 1.

Table 1. Secondary deuterium isotope effect in the formation of butadiene–$Fe(CO)_3$ complex

Run	Butadiene composition, d_4/d_0[a]	$Fe(CO)_3$ complex composition, d_4/d_0[a,b]	(k_H/k_D)[4], obsd	k_H/k_D
1	0.898[c]	0.899	0.999	1.00
2	1.19[d,e]	1.24	0.964	0.992
3	1.19[d]	1.21	0.983	0.996
			Av 0.982	0.996

important than the π-acceptor capacity;[5] accordingly, unlike the cases of Ag^+ and Rh(I),[1,2] subtle difference in electronic properties between deuterium and protium does not affect the relative complex stabilities. In addition, this observation may imply that carbon atoms of the butadiene–iron tetracarbonyl complex are little distorted from the sp^2-hybridized structures.[6]

Experimental

The NMR spectra were recorded on a Varian Associates Model HA-100D spectrometer equipped with a Model C-1024 time-averaging computer. 1,3-Butadiene (**1**) (Tokyo Kasei) was used after distillation. 1,3-Butadiene-1,1,4,4-d_4 (**2**) was prepared by the method of Cope[9] and stored at −20 °C on Molecular sieves 3A before use. The NMR spectrum (CCl_4 solution, tetramethylsilane as the internal standard) exhibited a very small signal due to $=CH_2$ protons, indicating that the butadiene was *ca.* 96% labeled. An approximate 1 : 1 mixture of **1** and **2** was prepared, and the ratio of the d_0 substrate to the d_4 substrate was determined on the basis of integrated relative intensities for the $=CH_2$ (δ 5.10) and =CH– (δ 6.25) signals in the NMR spectrum (CCl_4 solution), using factors obtained from the spectrum of undeuterated diene, **1**. The values in Table 1 are averages of 39 or 100 integrations. The isotopic composition of the iron tricarbonyl adduct was determined in the same manner; **3** (benzene-d_6 solution) showed signals at δ (benzene signal taken as δ 7.37) 0.09, 1.55 ($=CH_2$), and 4.88 (=CH–).

A typical experiment was executed as follows. A Pyrex tube (1 cm × 20 cm) equipped with a rubber septum was flushed with nitrogen and cooled at −78 °C. To this vessel we then introduced $Fe(CO)_5$ (Strem Chemicals, 79 mg, 0.4 mmol) and a mixture of **1** and **2** (220 mg, 4 mmol, $d_0/d_4=1.00/0.898$) by means of microsyringes. The tube was sealed, warmed to room temperature, and exposed to a 200 W high-pressure mercury lamp from a distance of 2 cm. After a 40-min irradiation, the tube was opened and the unreacted butadiene was removed under atmospheric pressure. The short-path distillation of the residue (20 mmHg; bath

temperature, 70—100 °C) gave a mixture of **3** and **4** as a yellow oil (61 mg, 78% yield). The product was recrystallized from pentane at −90 °C under nitrogen and immediately subjected to the NMR analysis under an argon atmosphere (benzene-d_6); this analysis indicated the production of **3** and **4** in a 1 : 00 : 0.999 ratio.

The Cycloaddition of 1,2,4,5-Tetrazines with Indoles. The Formation of 5*H*-Pyridazino[4,5-*b*]indoles

Masahiko TAKAHASHI, Hiroyuki ISHIDA, and Masao KOHMOTO

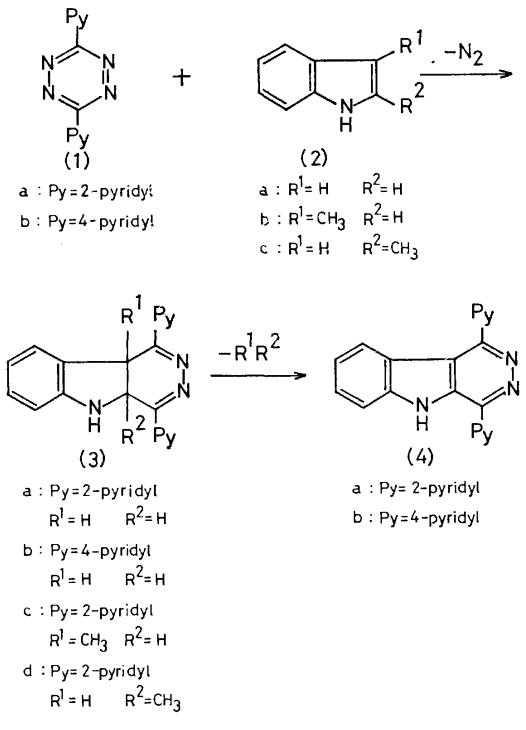
Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316

(Received March 13, 1976)

Synopsis. The cycloaddition of 3,6-disubstituted 1,2,4,5-tetrazines (**1**) with indoles (**2**) gave 1,4-disubstituted 5*H*-pyridazino[4,5-*b*]indoles (**4**).

It is well known[1] that indoles add at the C_2 or C_3 position to certain olefins and acetylenes substituted by electron-withdrawing substituents. On the other hand, the cycloaddition at the C_2 and C_3 positions of indoles with some dipolarophiles has been reported. The cycloaddition of indoles with acetylenedicarboxylate[2] has been studied in detail, and the ring-expansion of the adducts has been observed to give benzoazepines. The 1 : 2 adducts were obtained by the reaction with *p*-benzoquinone and 1,4-naphtoquinone.[3] 1,3-Dipolar cycloaddition to indoles has been reported in the cases of azides[4] and nitrilimines.[5]

Previously, we have described the reaction of 1,2,4,5-tetrazines with 2-phenyl-1-azirine.[6] In this paper we wish to report the cycloaddition of 1,2,4,5-tetrazines with indoles. Heating a toluene solution of 3,6-di-(2-pyridyl)-1,2,4,5-tetrazine (**1a**) and indole (**2a**) gave a crystalline product (35% yield). The elemental analysis and the mass spectral measurement supported the molecular formula of $C_{20}H_{13}N_5$. The IR spectrum showed an NH absorption at 3220 cm^{-1}, but the NMR spectrum did not show the methine protons anticipated for compound (**3a**). From these data it was concluded that the product was not the expected compound, **3a**, but the further-dehydrogenated compound, 1,4-di(2-pyridyl)-5*H*-pyridazino[4,5-*b*]indole (**4a**). The same product, **4a**, was also obtained in a low yield by the treatment of **1a** with 3-methylindole (**2b**). When **1a** was treated with 2-methylindole (**2c**), two products were obtained. One product was identical with **4a**, while the other was (**3d**), an intermediate to **4a**. From these results it has become apparent that the primary cycloadducts, **3a—d**, immediately aromatize on the extrusion of R^1R^2 (H_2, CH_4) to form **4a—b**. Similar results have been reported recently by Seitz *et al.*[7] for the reaction of dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate with thiophene, *N*-methylimidazole, 2,5-dimethylfuran, or *N*-methylpyrrole.



Experimental

The IR, UV, and NMR spectra were measured with a JASCO Model IRA-2 spectrometer, a Shimadzu Model MPS-501 spectrometer, and a Hitachi Model R-20 spectrometer respectively. A Shimadzu Model UM-3B apparatus was used for the elemental analysis.

*Reaction of **1a** with **2a**.* A toluene solution (20 ml) of **1a** (1.44 g, 6.1 mmol) and **2a** (0.68 g, 5.8 mmol) was refluxed for 3 h. After cooling, the precipitates were filtered off and then washed with methanol to remove a by-product, 3,5-di(2-pyridyl)-1,2-dihydro-1,2,4,5-tetrazine, to give 1,4-di-(2-pyridyl)-5*H*-pyridazino[4,5-*b*]indole **4a** (0.65 g, 35% yield). Recrystallization from benzene afforded pale yellow prisms; mp 202—204 °C. Found: C, 74.11; H, 3.76%. Calcd for $C_{20}H_{13}N_5$: C, 74.29; H, 4.05%. IR (KBr, cm^{-1}): 3220, 1615, 1587, 1579, 1538. UV (MeOH, nm (log ε)): 270 (sh, 4.45), 286 (4.52), 358 (3.85). NMR ($CDCl_3$, δ): 11.95 (s, 1H, NH), 7.10—9.15 (m, 12H, aromatic H). MS *m/e* (%): 323 (M^+, 90), 322 (100), 294 (7.8), 293 (11), 266 (5.4), 245 (30), 219 (4.6), 192 (3.5), 161 (11).

*Reaction of **1b** with **2a**.* 1,4-Di(4-pyridyl)-5*H*-pyridazino [4,5-*b*]indole **4b** (0.88 g, 24% yield) was obtained by refluxing a xylene solution (30 ml) of **1b** (2.4 g, 10 mmol) and **2a** (2.7 g, 23 mmol) for 7h. Recrystallization from pyridine afforded pale yellow prisms; mp>300 °C. Found: C, 74.22; H, 4.40%. Calcd for $C_{20}H_{13}N_5$: C, 74.29; H, 4.05%. IR (KBr, cm^{-1}): 3360, 3030, 2930, 2880, 2780, 1600, 1585, 1566, 1549. UV (MeOH, nm (log ε)): 224 (4.54), 272 (4.45), 352 (3.58).

*Reaction of **1a** with **2b**.* A toluene solution (40 ml) of **1a** (0.94 g, 4.0 mmol) and **2b** (0.84 g, 6.4 mmol) was refluxed for 68 h. After cooling, the precipitates were filtered, washed with methanol, and recrystallized from methanol to give a pale yellow product (0.18 g, 15% yield). Its mp and IR spectrum were identical with those of **4a**.

*Reaction of **1a** with **2c**.* A toluene solution (30 ml) of **1a** (0.71 g, 3.0 mmol) and **2c** (0.57 g, 3.6 mmol) was refluxed for 22 h. After cooling, the precipitates were filtered, washed with methanol, and recrystallized from methanol to give **4a** (0.13 g, 13% yield). The filtrate was concentrated *in vacuo* to give a small amount of precipitates, which were then recrystallized from methanol to afford red needles;

mp 177—183 °C. Found: C, 74.33; H, 4.80%. Calcd for $C_{21}H_{17}N_5$: C, 74.31; H, 5.05%. MS *m/e* (%): 339 (M^+, 9.3), 325 (25), 324 (100), 261 (11), 78 (12).

The authors wish to express their thanks to Dr. Masatoshi Hirayama for the NMR measurements and to the Sankyo Co., Ltd., for the mass measurements.

In order to highly selectively remove and recover heavy metals, usually harmful, from wastewater, a modified foam-separating method using a fatty compound, *i.e.* *N*-monodecanoyl diethylenetriamine, was investigated on real and model wastewater, containing several kinds of metals. This agent forms soluble and foamy complexes with the metals.

As methods for removing harmful heavy metals from wastewater, precipitation, floatation after deposition, absorption, extraction, *etc.* have been employed. However, these methods are accompanied by difficult problems, especially, in the case where a small amount of heavy metals is dissolved in a large quantity of wastewater.[1] Therefore, in order to solve these problems, the authors proposed an effective method[2] based on the foam-separating principle.[3]

Generally, such compounds as fatty acid amido-amines which contain amino- or imino-groups in the molecule react with heavy metal salts and produce organic complexes.[4] The authors have found that, if a fatty acid amino-amine having a suitable structure is added to an aqueous solution of heavy metal salts, even in a very dilute solution, the amido-amine reacts instantly with the metal ions and produces complexes which are considerably water-soluble, very foamy and very absorbable in bubbles.[2,5] Also, the authors have successfully applied this to the removal and recovery of harmful heavy metals from wastewater.[2] In the present paper, the results for an effective typical amido-amine type agent, *N*-monodecanoyl diethylenetriamine hydrochloride, are reported.

Experimental

N-Monodecanoyl diethylenetriamine hydrochloride (C_{10}-ODT) was prepared by the direct aminolysis of methyl decanoate with diethylenetriamine and neutralization with hydrochloride.

After C_{10}ODT was added to the aqueous solution containing heavy metal ions, the pH of the solution was adjusted. Then, the foam treatment was carried out by bubbling air, passed through a water-washing bottle, into the solution at a constant flow rate (200—250 ml/min) until foaming almost ceased.

The batch foaming column consisted of a glass tube (28 mm i.d., 500 mm long) with a glass filter (2G, 20 mm i.d.) fixed in a rubber stopper at the bottom of tube. Into this column, 50 ml of the solution for foam treatment was poured. The foam which ran over the top of the column was recovered and the amount of metal ions in the residual water was analysed after the treatment.

The continuous multistage foam treatment was carried out using a trial apparatus (Fig. 1). After the treatment, the amount of metal ions in the residual water was analyzed.

Solutions containing 10 ppm of single metal ions were prepared with sulfates, chlorides or acetates of copper, lead, zinc and iron.

Solutions containing mixtures of 10 ppm of each metal ion were prepared with copper sulfate, lead nitrate, zinc sulfate, and calcium sulfate or with copper sulfate, zinc sulfate, lead nitrate, cadmium chloride, cobalt sulfate, and manganese sulfate.

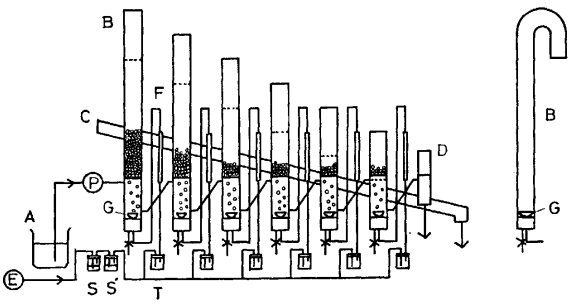

Fig. 1. The trial apparatus for the multistage foam treatment.
C_{10}ODT was added into the wastewater and the pH of the solution was adjusted. This solution was sent by the fluid pump P from the beaker A to the first foaming column B. Every column also consists of glass tube (ϕ 32, L 360—220 mm) with a glass filter G fixed in the rubber stopper at the bottom of tube, and the top of the column is bent in a shape of a half circle and is connected to the foam assembling pipe C. The six foaming columns are all connected in series and the last column is connected to the fluid level meter D. Air is blown into B at the flow rate of about 300 ml/min through the blower E, the humidity chamber S, S', the trap T, the flow meter F and G. The water is sent at the flow rate of 23—25 ml/min.

For application to real wastewater, several kinds of wastewater were sampled at non-ferrous metal mines, an electroplating factory, a spinning factory and an antiseptic factory.

The amounts of heavy metals in the solutions were analyzed for hydrochloric acidity with an atomic absorption spectrophotometer (Shimadzu-AA600).

Results

The result of the elementary analysis of C_{10}ODT is as follows. Found: C, 51.00; H, 9.94; N, 12.44%. Calcd for $C_{14}H_{33}N_3OCl_2$: C, 51.00; H, 10.33; N, 12.60%.[5]

Foaming Ability of the Solution Containing a C_{10}ODT–Metal Complex. An aqueous solution of C_{10}ODT has little foaming ability, but when C_{10}ODT is added to a dilute aqueous solution containing heavy metal ions, the foaming ability of the solution greatly increases due to the rapid formation of water-soluble and foaming C_{10}ODT–metal complex over a suitable pH range (Fig.

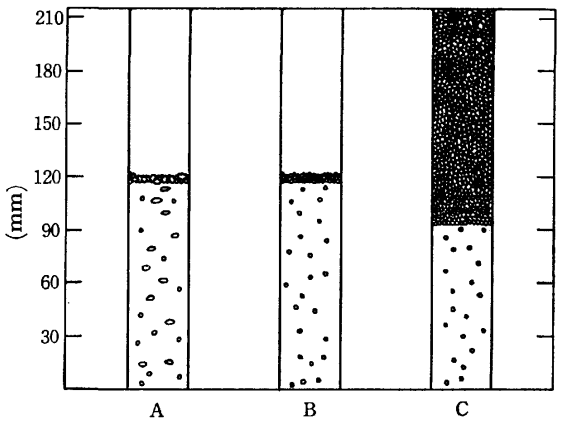

Fig. 2. The foaming ability of the solution of C_{10}ODT–metal complex.
A: Air was blown at the flow rate of 250 ml/min into the aqueous solution of ferrous sulfate at pH 7.
B: Air was blown into the aqueous solution of C_{10}-ODT on the same conditions as A.
C: After C_{10}ODT was added to the aqueous solution of ferrous sulfate at the addition ratio of 2 mol of C_{10}ODT/ gram-atom of iron, air was blown into this solution on the same conditions as A.

2). The foaming ability of the C_{10}ODT–metal complex differs according to the kind of heavy metal, with the C_{10}ODT–copper complex having a particularly high foaming ability.

The effect of the addition of C_{10}ODT to an aqueous solution containing an amount of ferrous sulfate equivalent to 10 ppm of iron is shown in Fig. 2. C_{10}ODT and ferrous sulfate solutions have little foaming ability separately, but a solution of the C_{10}ODT–iron complex has a great foaming ability.

Foam Treatment of Prepared Solution. As an example of batch foam treatment of solutions containing a single kind of metal ion with C_{10}ODT, the case of a solution containing copper ions is shown in Fig. 3.[5]

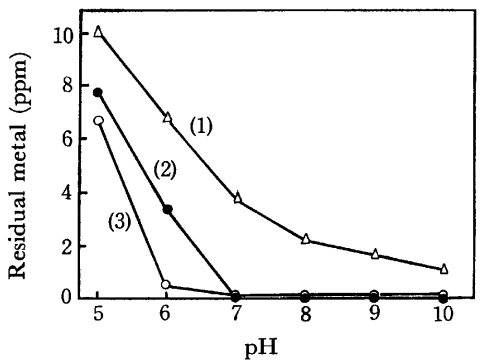

Fig. 3. The result of the batch foam treatment of the aqueous solution of copper sulfate equivalent to 10 ppm of copper with C_{10}ODT.
(1): 1/1; (2): 2/1; (3): 3/1 (C_{10}ODT/Cu).

For the foam treatments of aqueous solutions of copper sulfate, copper chloride, and copper acetate, there was no significant difference between the removing and recovering effects of copper ions. In each case, with a proportional addition of 2 mol of C_{10}ODT/gram-atom of copper, the residual copper after foam treatment at pH 7—10 was 0.05—0.4 ppm.

In the case of zinc, at a proportional addition ratio of more than 2 mol of C_{10}ODT/gram-atom of zinc, the residual zinc after foam treatment at pH 9—10 was less than 1 ppm (Fig. 4).

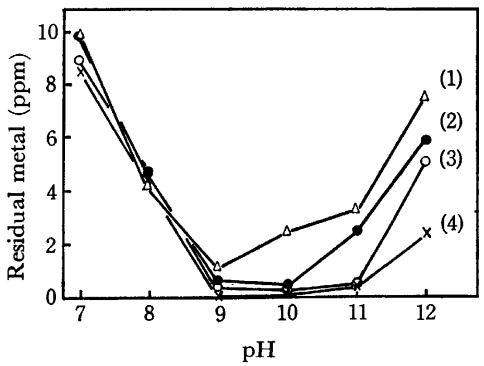

Fig. 4. The result of the batch foam treatment of the aqueous solution of zinc sulfate equivalent to 10 ppm of zinc with C_{10}ODT.
(1): 1/1; (2): 2/1; (3): 3/1; (4): 4/1 (C_{10}ODT/Zn).

As is shown in the above instances, it is seen that the optimum pH value for foam treatment with C_{10}ODT is considerably different for each heavy metal.

In the case of an equimolar mixed solution of several kinds of heavy metal ions, the metal ion content in the residual water after foam treatment differed for each metal (Figs. 5—7).

The results of Figs.5—7suggest that, if the proportional addition of C_{10}ODT to metal ions is selected properly, the specific metal may be removed and recovered over a definite pH range. Thus, by utilizing such properties of C_{10}ODT, the specific metal ion can be removed and recovered selectively (Fig. 8). Thus,

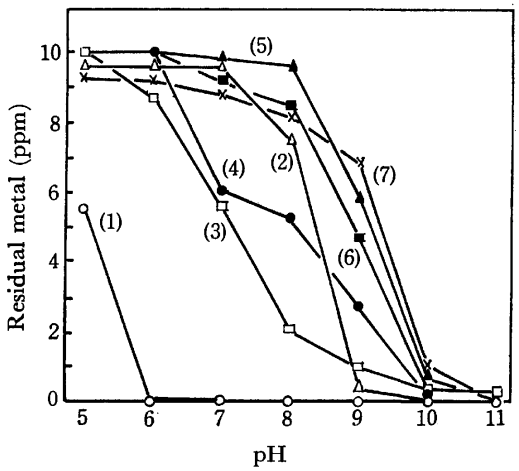

Fig. 5. The result of the foam treatment of the mixed aqueous solution of heavy metal ions.
After C_{10}ODT was added to the solution at the addition ratio of 0.5 mol of C_{10}ODT/ gram-atom of each metal, the pH of the solution was adjusted and the foam treatment was carried.

after 200 ppm of C_{10}ODT was added to a mixed solution of copper sulfate, lead nitrate, and zinc sulfate which was equivalent to a mixture of 10 ppm of each metal ion, batch foam treatment was carried at various pH values of the solution. Consequently, at first, nearly 100% of the copper ions at pH 6, next, about 70% of the lead ions at pH 7 and finally, about 98% of the zinc ions at pH 9 were selectively removed and recovered. However, for a foam treatment beginning at pH 9 resulted in the simultaneous recovery of more than 96% of all heavy metal ions. Calcium sulfate (equivalent to 200 ppm of calcium) did not influence these results.

Foam Treatment of Real Wastewater. Batch foam treatment was carried out on wastewater from a mine A (Table 1), after the addition of C_{10}ODT to the water at ratios of 0.5, 1.0 or 2.0 mol/gram-atom of zinc and copper with the pH of the solution adjusted. The result is shown in Table 1. 100% of the copper and zinc were removed and recovered by the foam treatment at pH 9 for a proportional addition of 1—2 mol of C_{10}ODT/gram-atom of copper and zinc.

Table 1. Batch foam treatment of a sample from a non-ferrous metal mine A

Treated A	9.0[a)]	1/1	0.15	0.00	0.00
		2/1	0.00	0.00	0.00

a) pH directly before foam treatment.

The batch foam treatment was carried on wastewater from a mine B (Table 2) for a proportional addition of 0.1 mol of C_{10}ODT/gram-atom of zinc and the results are shown in Table 2. All heavy metals were completely removed and recovered within limited values, and moreover, no reduction of the efficiency of the treatment by the coexisting abundant calcium ions was observed.

Table 2. Batch foam treatment of samples from a non-ferrous metal mine B

Sample	pH	(ppm) Zinc	Cadmium	Copper	Lead	Iron	Calcium
B	2.3	679.39	4.02	0.18	1.29	111.69	250.0

a) pH directly before foam treatment.

After C_{10}ODT was added to the wastewater from a mine C (Table 3) for a proportional addition of 1 mol of C_{10}ODT/gram-atom of each metal, the foam treatment was carried at pH 6. As shown in Table 3, about 99% of the copper was removed and recovered selectively. The cadmium and zinc in the residual water were removed and recovered within limited values by

a) pH directly before foam treatment.

the form treatment of the residual water at pH 9 (Table 3).

After C_{10}ODT was added to the wastewater of an electroplating factory E (Table 4) for a proportional addition of 1 or 1.5 mol of C_{10}ODT/gram-atom of each metal, the pH of the solution was adjusted and continuous multistage foam treatment was carried out. A better removal and recovery yield of the metal ions was obtained when 1.5 mol of C_{10}ODT was added (Fig. 9). When the foam treatment was applied at pH 6, 99.5% of the copper was removed and recovered selectively, but 90.1% of the zinc and 100% of the nickel remained in the residual water. When the foam treatment was carried out initially at pH 9, the copper, zinc and nickel were removed and recovered simultaneously with a yields of 100, 93.6, and 93.7%, respectively.

When C_{10}ODT was added to the wastewater from a spinning factory S (Table 4) for a proportional addition of 0.5 mol of C_{10}ODT/gram-atom of zinc and continuous multistage foam treatment was applied at pH 10, 99.7% of the zinc ions were removed and recovered.

Of course, by bubbling air into the real wastewater and the model solution, both without C_{10}ODT, almost no foam was produced, and consequently, none of the metal dissolved in the water could be removed and recovered.

Discussion

For the foam treatment of aqueous solutions containing heavy metal ions, the optimum pH for good foaming varies with the metal. This may be due to the differences of the conditional stability constant[6)] of the C_{10}ODT–metal complex.

Also, when the C_{10}ODT addition ratio was varied, even when good foaming was observed upon the application of the foam treatment, in some cases the residual metal concentration varies considerably. For instance, for the foam treatment of copper sulfate (Fig. 3), at pH values above about 6.5, good foaming was observed. But in this foam treatment for a proportional addition ratio of 1 mol of C_{10}ODT/gram-atom of copper, the removal and recovery yield of the copper was lower in comparison with other cases. Such differences due to the variation of the C_{10}ODT ratio were similarly observed in cases involving other heavy metals and were thought to be due to the structural differences of the complexes.

When a tridentate ligand co-ordinates over a suitable pH range to a copper ion having a co-ordination number of four, one of two types of complexes, *i.e.*, a 1 : 1 hydroxo chelate (A) or a 2 : 1 chelate (B), is obtained[7)] and one of the copper co-ordination bonds in the former complex A co-ordinates with the water.[7)] Thus, C_{10}-ODT, a tridentate ligand, may co-ordinate with copper ions similarly in the above-mentioned case. The authors have previously determined that when C_{10}ODT was added exessively to a solution containing copper ions, a 2 : 1 chelate was produced.[5)] The difference in the structures of the complexes which are formed by adding 1 or 2 mol of C_{10}ODT per gram-atom of copper may be inferred by the fact that the colors of the solutions in these two cases are considerably different from each other, that is, the color in the former case is blue and that of the latter is purple. However, concerning the structures of the complexes, no further investigation was attempted.

As mentioned above, in the case of a small amount of harmful heavy metals dissolved in a large quantity of wastewater, by applying the usual methods, especially, the precipitation method, it is not easy to remove effectively the metals. But, by the present simple method utilizing complex formation of the amido-amines, the problem can be solved.

If necessary, from the complexes recovered by this method, almost all the amido-amine can be easily regenerated by electrolysis.[8)]

The structure of the ligand of a metal complex has influence on not only the solubility,[7] but also the effect of the foam treatment. The authors found that among the acyl groups of C_8–C_{12} involved in these water-soluble metal complexes, the decanoyl group acted as the most desirable hydrophobic group for the foam treatment.[9]

It is interesting that for wastewater containing a high concentration of heavy metal ions, even with a small amount of C_{10}ODT, the foam treatment can be applied (Table 2). The reason for this may be that the complexes formed by the co-ordination of the metal ions with C_{10}ODT are also water-soluble and foamy, and the foam absorbs not only the dissolved complexes but also the deposited particles consisting of the hydroxides of the heavy metals and the complexes which have formed beyond their solubilities.

(September 5, 1974, reported at the 12th World Congress of the International Society for Fat Research in Milano, Italy)

The Catalytic Reduction of Nitrogen Oxide by Carbon Monoxide over Metal Oxide Catalysts —The Correlation of the Activities with the Surface States of Metal Oxides—

Katsumi SAKURAI, Yasuaki OKAMOTO, Toshinobu IMANAKA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received July 21, 1975)

In the catalytic NO–CO reaction over metal oxide catalysts, the surface states of reduced metal oxides were studied with ESCA, and the correlation of the activities of the reduced metal oxide catalysts for the NO–CO reaction with their surface states was investigated. The surfaces of the catalysts were studied with ESCA after treatments *in situ*. It was revealed that the surface states of the metal oxides did not always agree with their bulk constituents. For example, it was found that the oxygen in the surface layer of the cobalt oxide after a proper reduction treatment by CO was richer than in its bulk. Moreover, the correlation between the surface states and the activities of those oxides was successfully explained. It was also concluded that, in the NO–CO reaction, the metal states were most active for the cobalt, iron, and nickel oxides, while the Cu^+ state was more active than the Cu metal state for the copper oxide.

The investigation of the catalytic reduction of NO by CO has advanced as part of an effort to prevent the air pollution caused by automobile exhaust, for this reaction can simultaneously change two noxious species, that is, nitrogen oxide and carbon monoxide, to innoxious species, that is, nitrogen and carbon dioxide. Many studies of catalyzed reactions over metal oxide catalysts have been reported.[1–4] However, the study of the correlation of the activities of the metal oxide catalysts with their surface states has rarely been reported. Therefore, it would be very interesting to investigate such a correlation. In the NO–CO reaction, great interest is focussed on what the surface states of the catalysts are during the reaction and on what valence states of the metal ions in the catalysts are most active. Accordingly, the surface states of the metal oxides were studied with ESCA in an attempt to solve these problems.

The phenomenon that the surface of the catalysts was reduced after the NO–CO reaction was observed, so the metal oxides were treated with CO gas in order to reduce them to some degree. Subsequently, the surface states of those reduced oxides were studied with ESCA in order to investigate the correlation of the activities of the catalysts for the NO–CO reaction with the surface states of the catalysts, and also the correlation of their surface states with the degree of reduction of the bulk catalysts.

Experimental

Fe_2O_3, Co_2O_3, Ni_2O_3, and CuO were used as metal oxide catalysts. The Co_2O_3 and Ni_2O_3 were supplied by Nakarai Chemicals, Ltd., while the CuO was supplied by Wako Pure Chemical Industries, Ltd. Only the Fe_2O_3 was prepared by the decomposition, at 600 °C for 4 h in air, of $Fe(OH)_3$, which had itself been produced from iron(III) nitrate and aqueous ammonia. The BET surface areas of Fe_2O_3, Co_2O_3, and Ni_2O_3 were 4.7, 24.8, and 141.3 m^2/g respectively.

The reduction of these catalysts and the reactions between CO and NO were carried out in a usual closed circulating system apparatus, the volume of which was about 340 cm^3. The amount of the catalyst used in each run was 0.020 g for Co_2O_3, Ni_2O_3, and CuO, and 0.100 g for Fe_2O_3. The catalyst, set in the closed circulating apparatus, was evacuated for 4 h at 400 °C, and then it was reduced by CO for a given time at 300 °C. Subsequently, after the evacuation, a reactant gas was introduced into the system, and the reaction between CO and NO was carried out at 300 °C. The partial pressures of NO, CO, and Ar in the gas mixture at about 4.7 cmHg were 1.8, 1.9, and 1.0 cmHg respectively. The product gas mixture was analyzed by means of a Hitachi RMS-4 mass spectrometer calibrated for pure gases. The concentrations of the product gas constituents (CO_2, N_2, and so on) were calculated by comparing their peak intensities with that of Ar. The reaction rates were calculated from the rates of the increases in the peak intensity at $m/e=44$.

The degree of reduction of the bulk catalysts, which is represented by x, is defined by the ratio of the amount of oxygen in the catalyst lost by reduction to that of oxygen in the catalyst before reduction. That is, $M_2O_{3(1-x)}$ shows the composition of the bulk at x for sesquioxides, and $MO_{(1-x)}$, that for monoxides. The conversion of CO into CO_2 was estimated by means of analysis with the mass spectrometer. The CO disproportionation ($2CO \rightarrow CO_2 + C$) occurred at the same time in the reduction by CO. The extent of the disproportionation can be estimated by the amount of the pressure decrease in the closed system. Thus, the above reduction degree was corrected.

The photoelectron spectra were measured on a Hitachi 507 photoelectron spectrometer using Al $K\alpha_{1,2}$ radiation. Powdered samples were mounted on a sample holder made of stainless steel. The oxide catalysts were reduced by CO in a closed treatment chamber which was directly linked to the analysis part. After evacuation, the reduced catalysts were immediately introduced into the adjacent analysis part and were measured with ESCA. Also, in this case the reduction degree was determined in the same way as in the above closed circulating system. The binding energies were corrected by using the value of 285.0 eV for the C 1s level resulting from the contaminated carbon. The reproducibility of this value was within ± 0.2 eV.

Results and Discussion

Figure 1 shows the dependence of the initial reaction rate on the degree of reduction of the catalysts. Initial reaction rates were used to represent the activity, since the catalysts were reduced by the progress of the reaction. Figure 1 indicates that the activities increase as the degree of reduction increases for three oxides of Fe,

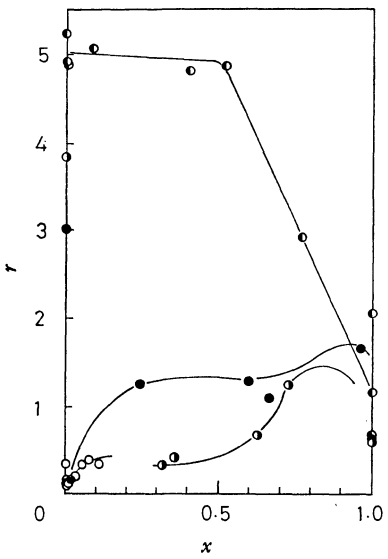

Fig. 1. Dependence of the initial reaction rate on the degree of the reduction.
x: Degree of reduction; $M_2O_{3(1-x)}$ for Fe, Co, and Ni; $MO_{(1-x)}$ for Cu.

Co, and Ni, and that no very marked change occurs at a moderate degree of reduction (x=0.2—0.6) for the cobalt oxide. The oxides of Co and Ni have comparably high activities near the degree of x=1. That is, they are supposed to have high activities near the metal state. At the degree of x=1, the oxides of both Co and Ni have low activities; this may be caused by the deposited carbon produced by the incidental CO disproportionation. The oxides of Co and Ni, which were not reduced before the reaction, have considerably high activities. These high activities are considered to be attributable to the excess oxygen adsorbed originally on the surfaces of the oxides used. That is, in the case of these catalysts, CO rapidly reacts with the excess oxygen in the initial stage of the reaction; hence, the formation

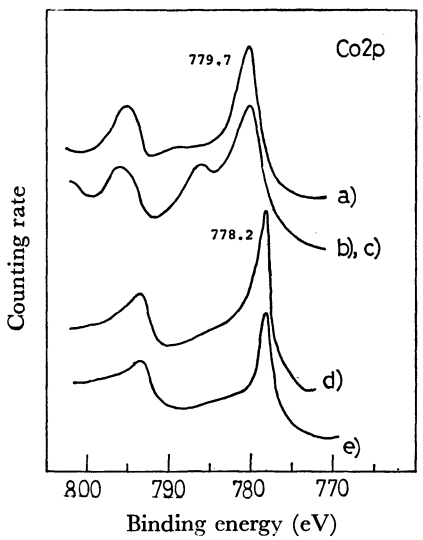

Fig. 2. Co2p ESCA spectra of Co_2O_3 reduced by CO.
a) x=0, b) x=0.37, c) x=0.65, d) x=0.99, e) x=1.

of CO_2 increases upon the additional reaction. Therefore, the activities are considered to be very high.

The behavior of the copper oxide is markedly different from the other three oxides. In Fig. 1 the curve for the copper oxide shows a break at the degree of x=0.5; below this point a high activity is maintained. while above it the activity descends linearly with the degree of reduction. It is obvious that the activity of the copper oxide is higher than those of the other three oxides used in almost all the range of the degrees of reduction.

Table 1. Assignment of the ESCA spectra of the metal oxides in Figs. 2, 4, 5, and 7

Oxide	Spectra	x (Degree of reduction)	Bulk constituent	Surface species
Co_2O_3	a)	0	$CoO_{1.5}$	Co^{3+}
	b)	0.37	$CoO_{0.95}$	Co^{2+}

	c)	0.16	$CuO_{0.84}$	Cu^{2+}, Cu^{+}
	d)	0.40	$CuO_{0.60}$	Cu^{+}
	e)	0.76	$CuO_{0.24}$	Cu^{0}

Then we studied, by means of ESCA, the correlation of the surface states of the metal oxides with the reduction degree of the bulk oxides. Figure 2 shows the ESCA spectra of Co 2p for the cobalt oxide. The a), b), and c) spectra in Fig. 2 roughly correspond to Co_2O_3, CoO, and $CoO_{0.5}$ respectively in terms of bulk. Therefore, both the d) and e) spectra correspond to the metal state in bulk. The assignment of the spectra of the cobalt oxide and of the other metal oxides is shown in Table 1. In Fig. 2, it may be observed that the b) spectrum is the same as the c) spectrum, though the degree of the bulk reduction of the former (x=0.37) is different from that of the latter (x=0.65). The b) and c) both spectra correspond to CoO.[5] From these facts it may be considered that the surface state of the cobalt oxide remains CoO over a considerably wide range of the degree of reduction and that the oxygen in the surface layer is richer than in the bulk at a moderate degree of reduction. This fact is consistent with the constant activity at a moderate degree of reduction for the cobalt oxide in Fig. 1. Figure 3 shows the dependence of the peak intensities of O1s and C1s on the cobalt oxide surface upon the degree of reduction. This dependence agrees well with the above facts that the intensity of the O1s peak on the surface is constant at a moderate degree of reduction. When the cobalt oxide at the degree of x=1 was further reduced, it was found

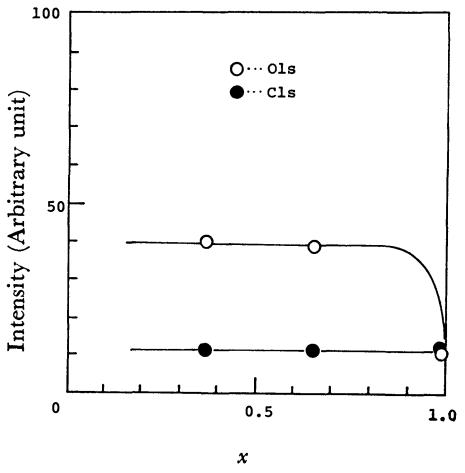

Fig. 3. Dependence of the peak intensity of O1s and C1s for Co_2O_3 on the degree of reduction.
x: Degree of reduction.

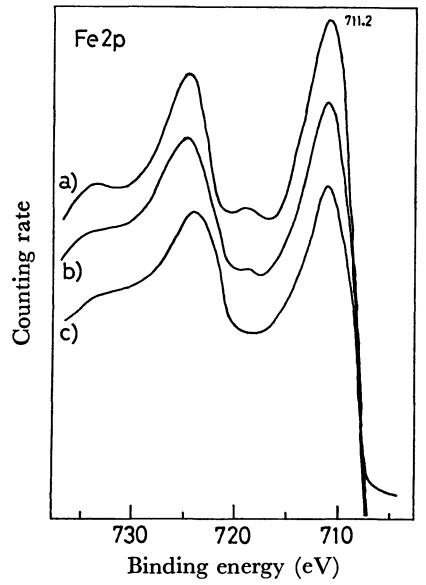

Fig. 4. Fe 2p ESCA spectra of Fe_2O_3 reduced by CO.
a) $x=0$, b) $x=0.04$, c) $x=0.11$.

that the intensity of the C1s peak on the cobalt surface increased suddenly; this suggests that the disproportionation of CO occurs when the oxygen in the cobalt oxide is exhausted.

Fe_2O_3 is more difficult to reduce than Co_2O_3. The spectra of the iron oxide show no remarkable change, as is shown in Fig. 4, but the main peaks of Fe2p tend to become broader and its satellite peaks disappear as the oxide is reduced. It may be supposed that the spectra accompanied by the satellite peaks correspond to Fe^{3+} and that the spectra without them correspond to the mixed state of Fe^{2+} and Fe^{3+} in Fe_3O_4. Therefore, it may be concluded that, in the case of the iron oxide, the divalent and trivalent states of iron can not definitely be differentiated on the basis of the Fe 2p-spectral data.

As is shown in Fig. 5, the spectra of Ni 2p vary around the degree of $x=0.5$. It may be considered from Fig. 5 that the surface constituent of the nickel oxide is NiO

x: Degree of reduction.

below the degree of $x=0.5$ and is a mixture of NiO and nickel metal above the degree of $x=0.5$. Figure 6 shows the dependence of the intensity of the O1s and C1s spectra for the nickel oxide surface on the degree of reduction. The amount of the surface oxygen is roughly constant below the degree of $x=0.5$, while it decreases sharply near the degree of $x=0.5$; this coincides with the above reduction tendency of the nickel oxide. Figure 1 indicates that the activity of the nickel oxide is roughly constant below the degree of $x=0.5$ and increases above the degree of $x=0.5$; this increase in the activity corresponds with the appearance of nickel metal on the catalyst surface. Thus, the behavior of the nickel oxide is similar to that of the cobalt oxide, except that the former produces the metal states at a lower reduction degree than does the latter.

In Fig. 5, the a) spectrum at the degree of $x=0$ after the evacuation treatment, which is accompanied by satellite peaks, may be supposed to correspond to the Ni^{2+} state in spite of the Ni^{3+} bulk constituent, but the binding energy of the Ni $2p_{3/2}$ peak of the spectrum (854.5 eV) is considerably smaller than that of NiO (855.4 eV). This finding suggests that the surface of the oxide may be almost covered with the noncrystal

a) $x=0$, b) $x=0.02$, c) $x=0.16$, d) $x=0.40$, e) $x=0.76$.

Ni^{2+} oxide with defects upon evacuation at a high temperature.

Figure 7 shows the ESCA spectra of Cu 2p for the copper oxide, while the Cu LMM Auger spectra are shown in Fig. 8. The spectra of Cu 2p start to vary around the degree of $x=0.16$, and the satellite peaks almost disappear at the degree of $x=0.40$, as is shown in Fig. 7. The a) and b) spectra, with the satellite peaks, are assigned to the Cu^{2+} state.[6] In Fig. 7, the ESCA d) spectrum is almost the same as e), while, as is shown in Fig. 8, the kinetic energy of the $L_3M_{4,5}M_{4,5}$ peak of the corresponding Auger spectrum, d), is smaller than that of e) by 1.8 eV. Accordingly, the ESCA spectra in Fig. 7, d) and e), can be assigned to the Cu^+ and Cu metal states respectively.[7] This fact indicates that CuO on the oxide surface may decrease as Cu_2O increases below the degree of about $x=0.40$, and that CuO may almost disappear at the degree of $x=0.40$. Therefore, it may be supposed that the copper oxide catalyst has a high activity when CuO coexists with Cu_2O on the catalyst surface, and that the activity decreases as the copper metal increases above the degree of about $x=0.5$, where CuO disappears entirely. In conclusion, for the copper oxide the active species in the NO–CO reaction is mainly Cu^+, and the Cu metal is a much lower active species than Cu^+.

It may be concluded that, in the NO–CO reaction, the metal states are most active for the cobalt, iron, and nickel oxides, while the Cu^+ state is more active than the Cu metal state for the copper oxide. As has been mentioned above, the differences between the bulk constituents and the surface states of some reduced metal oxides were revealed by ESCA. Moreover, the correlation between the surface states and the activities of those metal oxides was successfully explained. By using ESCA, useful information on the above problem could also be obtained for other metal compounds which are not dealt with in this paper.

A Study on the Anode Effect in KF-2HF System. II. Difference in Anodic Behavior between Edge Plane and Layer-plane of Pyrolytic Graphite

Hiroki IMOTO and Nobuatsu WATANABE

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyoku Kyoto 606

(Received August 18, 1975)

The anodic behavior of pyrolytic graphite has been studied by voltammetry and ESCA analysis in the molten KF-2HF system at 100 °C, attention being given to the difference in anodic behavior between the edge plane and layer-plane of the pyrolytic graphite. The polarization current obtained by a linear potential sweep experiment decreased rapidly with increasing potential after the onset of the anode effect. When the edge plane was used as a working electrode surface the current density was recovered on the subsequent sweep toward negative potentials, whereas the current density was hardly recovered on the layer-plane surface of the electrode. The difference in polarization behavior was interpreted on the basis of the difference in the rate of decomposition reaction of graphite fluoride, $(CF)_n$, formed on the electrode surface. ESCA spectra of the electrodes polarized at various potentials indicate that $(CF)_n$ was formed even at 2.0 V *vs.* Pt, below the fluorine evolution potential, on the edge plane of the pyrolytic graphite and that its amount did not increase appreciably with increasing potential. On the layer-plane, however, no formation of $(CF)_n$ was observed at 2 V *vs.* Pt, its amount increasing appreciably with potential at the potentials above 3 V *vs.* Pt.

The anodic behavior of graphite and carbon in molten fluorides is of importance since the cell operation during the course of electrolysis at high current density is remarkably restricted by the occurrence of anode effect.[1-3] In the preceding paper,[4] it was reported that the onset of the anode effect is due to a significant decrease in the wettability of the anode surface by the electrolyte caused by the formation of graphite fluoride, $(CF)_n$, having very low surface energy, and that the compound is formed even under normal electrolysis conditions. In the present investigation, the anodic behavior of the two distinct planes of pyrolytic graphite, edge plane and layer-plane, was studied by the potential sweep and potentiostatic methods, and by ESCA analysis of the electrodes polarized potentiostatically at various potentials and the electrodes after the anode effect.

The following reactions are considered to occur simultaneously on the anode surface.

1) Fluorine evolution

$$2F^- \longrightarrow F_2 + 2e^- \quad (1)$$

2) Formation of $(CF)_n$ film

$$nF^- + nC \longrightarrow (CF)_n + ne^- \quad (2)$$

3) Decomposition of $(CF)_n$ film

$$(CF)_n \longrightarrow C + CF_4,\ C_2F_6,\ etc. \quad (3)$$

The results obtained were interpreted by considering the kinetic balance between the formation and the decomposition reaction of the $(CF)_n$ film on the anode surface.

Experimental

Voltammetry and preparation of the samples for ESCA analysis were carried out in the cell shown in Fig. 1. The cell was made of iron and its temperature was maintained at 100 °C in an oil bath. The wall of the cell was used as a cathode and the bottom of the cell was covered with a Teflon plate. The brass leads and all parts of the electrodes A, B, and C directly in contact with the vapor of hydrogen fluoride or KF-2HF melt were coated with Teflon. The molten KF-2HF was dehydrated by pre-electrolysis by using the carbon electrode

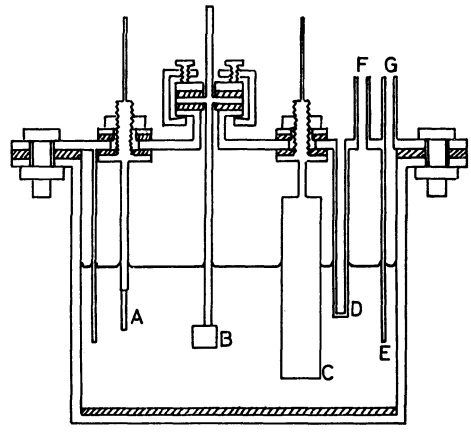

Fig. 1. Electrolytic cell.
A: Reference electrode (Pt), B: anode, C: carbon electrode for dehydration, D: well for thermometer, E: skirt, F: anode gas outlet, G: cathode gas outlet. The hatched parts are made of Teflon.

C. The potentials of working electrode B were measured with respect to the reference electrode A of a Pt rod. The pyrolytic graphite used was supplied by Nihon Carbon Co., Ltd.. The pyrolytic graphite was heat-treated at 2200 °C for 1 h before use. Its crystallographic properties determined by X-ray analysis were as follows: lattice parameters $a=2.457$ Å and $c=6.831$ Å, crystallite size La (110)$>$1000 Å, crystallite height Lc (002)$=$240 Å, degree of crystalline alignment P (Franklin's *P*-value)*$=0.84$. The apparent density was 2.08 g/cm^3. The specific resistances parallel and perpendicular to the c axis were 0.52 and 3.9×10^{-5} ohm·cm, respectively. The layer-plan electrode was *ca.* 14 mm$\times$ *ca.* 9 mm and *ca.* 1 mm in thickness. The edge plane electrode was *ca.* 10 mm$\times$5 mm and *ca.* 6 mm in thickness. The apparent surface area was used for the calculation of current density. The surface of the edge plane electrode was polished with fine sandpaper Emery #600, the powder of graphite being removed by washing with distilled water.

* *P*-value was calculated by the equation

$$d(002) = 3.340 - 0.086(1-P^2),$$

where P is a ratio of the misoriented parts to the sum of the oriented and misoriented parts.

The electrodes were connected with the brass leads by winding fine copper wire on to them. Only one face of the pyrolytic graphite, the edge plane or the layer-plane, was used as a working electrode surface, the other faces being covered with Teflon tape. The edge plane electrodes polarized at various potentials were washed with anhydrous hydrogen fluoride in order to remove KF-2HF before ESCA analysis.

Results and Discussion

Polarization Curves. Figure 2 shows a polarization curve obtained by sweeping potential 1—10 V *vs.* Pt for the layer-plane electrode. Three peaks were observed on the *I—V* curve. An explanation for these peaks was given in a previous paper[5] in which the anodic behavior of carbon, graphite, and glassy carbon electrodes was dealt with. The first peak corresponds to the discharge reaction of trace water in the electrolyte and the second and third peaks to the discharge reaction of fluoride ion. Current density decreased rapidly at 5 V due to the onset of the anode effect. Restoration of the current density was hardly observed on the subsequent sweep from 10 to 3 V. The observed current density was as small as 2 mA/cm², when the anode potential was swept again from 3.5 to 10 V at the same sweep rate. Thus it is indicated that

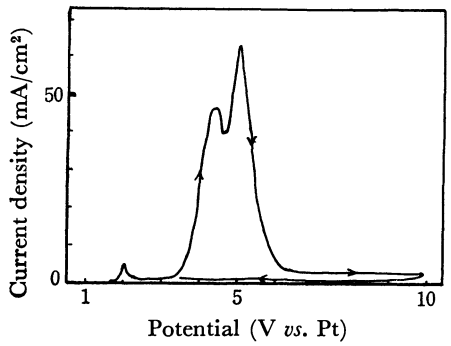

Fig. 2. *I—V* curve (potential sweep) in KF-2HF at 100 °C. Anode: layer-plane of pyrolytic graphite, sweep rate: 12.5 mV/s.

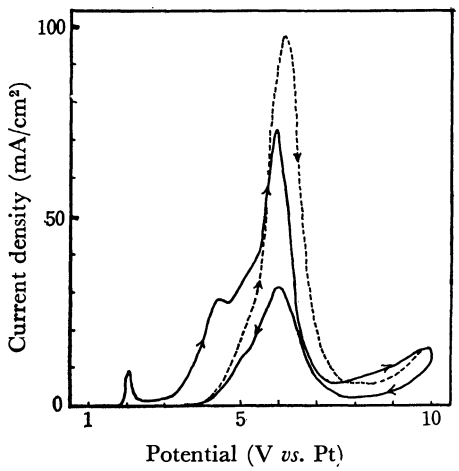

Fig. 3. *I—V* curves (potential sweep) in KF-2HF at 100 °C. Anode: edge plane of pyrolytic graphite, sweep rate: 12.5 mV/s.
——: First sweep, ------: second sweep.

if $(CF)_n$ film is once formed on the layer-plane of pyrolytic graphite by reaction (2), the anode surface is hardly restored.

Figure 3 shows the polarization curves obtained by the potential sweep method for the edge plane electrode. On the first sweep from 1 to 10 V, the polarization curve for the edge plane electrode was similar to that for the layer-plane electrode. However, in contrast to the case for the layer-plane electrode, the restoration of current was observed on the subsequent sweep toward negative potentials, the peak current density on the second sweep toward positive potentials (a dotted line) being comparable to the third peak on the first sweep. The restoration in current indicates that the decomposition of $(CF)_n$ takes place much faster on the edge plane than on the layer-plane.

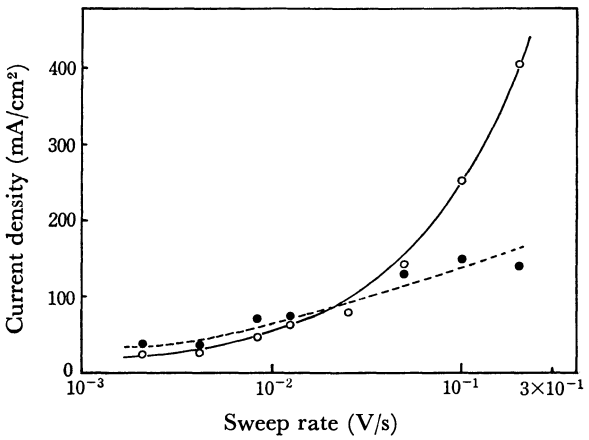

Fig. 4. Dependence of peak current densities on sweep rate.
○: Layer-plane of pyrolytic graphite,
●: edge plane of pyrolytic graphite.

The third peak current density in the polarization curve on the first sweep toward positive potential depends upon the rates of reactions (2) and (3). The peak current densities are plotted against the sweep rate for both layer-plane and edge plane electrodes in Fig. 4. The peak current density increased noticeably with increasing sweep rate for the layer-plane electrode, while it increased only slightly for the edge plane electrode. It is supposed in general that the peak current density becomes less dependent on the sweep rate with an increase in the rate of deactivation of electrode surface, since the relatively fast deactivation reaction of electrode surface with respect to the sweep rate leads to a nearly steady-state condition of the electrode surface irrespective of the sweep rate. Thus, it might be suggested that the rate of deactivation of the anode surface, which depends upon the difference in rates between reactions (2) and (3), is smaller at the layer-plane electrode than at the edge plane electrode, if it is assumed that the potential dependence of the current density due to the fluorine evolution reaction (1) at both the plane is equal to each other.

When the layer-plane and edge plane electrodes were polarized potentiostatically at various potentials, the current densities reached stationary values within 30

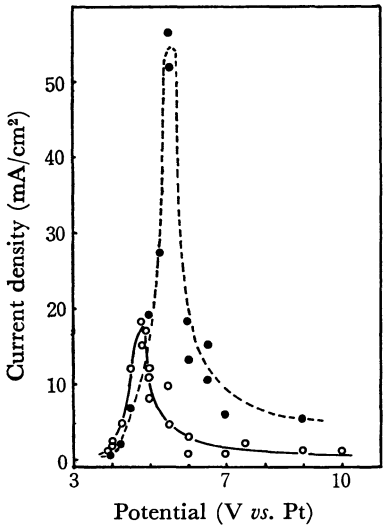

Fig. 5. *I—V* curves (potentiostatic) in KF-2HF at 100 °C.
○: Layer-plane of pyrolytic graphite,
●: edge plane of pyrolytic graphite.

min. These values are plotted against potentials in Fig. 5. Maximum current densities are observed at 4.8 V and 5.5 V for the layer-plane and edge plane, respectively. Since the maximum current densities are observed at 5.5 V for carbon and graphite,[4] it seems that the critical current densities at graphite and carbon anodes are attributable to those at their edge plane.

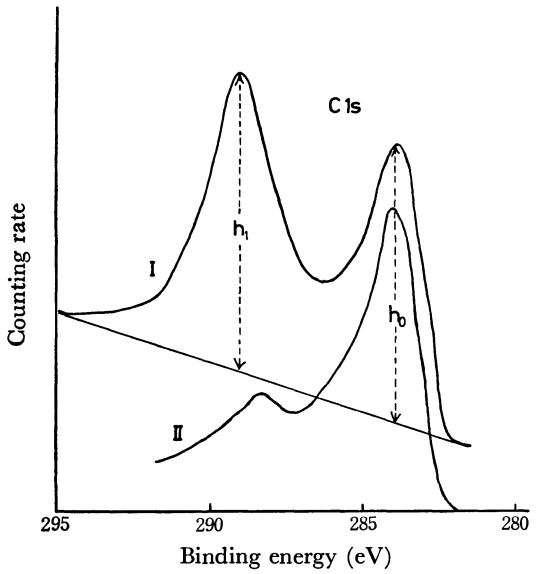

Fig. 6. ESCA spectra of pyrolytic graphite anodes immediately after the anode effect.
I: Layer-plane,
II: edge plane.

ESCA Spectra. When the layer-plane and edge plane electrodes were polarized at a constant current density of 400 mA/cm², the anode effect took place within 10 s and the circuit was opened immediately after the onset of the anode effect. Figure 6 shows the ESCA spectra of the carbon 1s electron for the above samples. The peak at 284 eV corresponds to the binding energy of the carbon 1s electron for the carbon which has only the C–C bond. The peak at 288.5 eV corresponds to the one for the carbon atom with the C–F bond.[4] The height of the peaks at 284 eV and 288.5 eV is denoted by h_0 and h_1, respectively.

In order to investigate the potential dependence of the amount of $(CF)_n$ on the anode surface, the ESCA spectra of the fluorine 1s electron as well as carbon 1s electron were obtained for the layer-plane and edge plane electrodes polarized potentiostacitally at various potentials for 30 min. The height of the peaks at 688

●: edge plane of pyrolytic graphite.

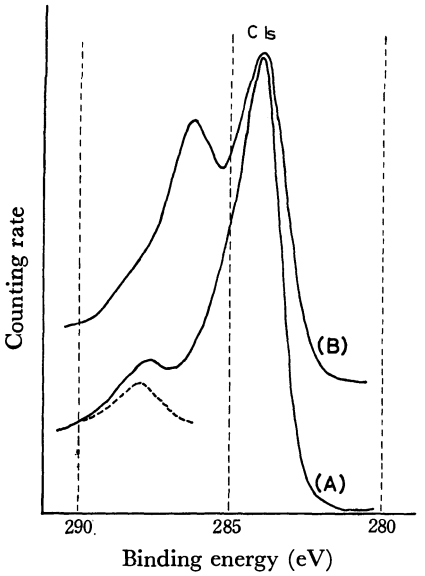

Fig. 9. ESCA spectra of anode surfaces.
(A): Edge plane of pyrolytic graphite polarized at 2.0 V *vs.* Pt in KF–2HF at 100 °C.
(B): Graphite polarized at constant current density of 500 mA/cm^2 in 2M-H_2SO_4 at room temperature.

eV corresponding to the binding energy of F 1s electron is represented by h_2. The ratios h_1/h_0 and h_2/h_0 plotted against potentials are illustrated in Figs. 7 and 8, respectively.

The equilibrium potential of reaction (1) is 3.4 V *vs.* Pt in KF–2HF at 100 °C.[6] A peak was observed at 288.5 eV in the carbon 1s spectra for the edge plane electrode polarized at 2 V, at a more negative potential than 3.4 V. The following experiments were carried out in order to confirm the view that the peak at 288.5 eV observed for the edge plane electrode polarized at 2 V is attributable to the C–F bond, but not to the C–O bond formed by the discharge reaction of the trace water.

Sample A: the edge plane electrode polarized at 2.0 V for 30 min at 100 °C in KF–2HF.

Sample B: the graphite anodically polarized at constant current density of 500 mA/cm^2 in 2M-H_2SO_4, for 10 min at room temperature.

Figure 9 shows the ESCA spectra of C 1s electron for samples A and B. A peak was observed at 286 eV for sample B, which is identical with that for the graphite oxide in the binding energy.[7] Since the peak at 288.5 eV for sample A is attributable to the C–F bond, but not to the C–O bond, it becomes apparent that reaction (2) proceeds at a more negative potential than the equilibrium potential of reaction (1).

The same tendency is shown in Fig. 7 as in Fig. 8. It is thus evident that the peak at 288.5 eV is associated with the carbon bound with fluorine atom. No detectable amount of $(CF)_n$ exists on the layer-plane electrode polarized at 2 V in Fig. 7, but the amount of $(CF)_n$ increases noticeably as the potential becomes higher than 2 V. On the other hand, a considerable amount of $(CF)_n$ is detected on the edge plane electrode polarized at 2 V, above which the amount of $(CF)_n$ increases slightly with increasing potential.

The values of h_1/h_0 for the layer plane electrode are much larger than those for the edge plane under the conditions of the anode effect, which is in line with the view that the rate of the decomposition of the $(CF)_n$ film is larger on the edge plane than on the layer-plane.

It is concluded that the amount of $(CF)_n$ formed on the surface of carbon and graphite anode increases with an increase in the polarization potential and that the restoration of current at these electrodes during the polarization toward negative potentials after the onset of anode effect is attributed to the fast decomposition reaction of the $(CF)_n$ film on the portions of these electrodes where the edge plane is in contact with the electrolyte.

The authors are greatly indebted to Shimadzu Seisakusho Co., Ltd. for permission to use their electron spectrometer.

ESR Study of γ-Ray Irradiated Potassium Hexacyanocobaltate $K_3[Co(CN)_6]$

Naoki FURUTA,* Tokuko WATANABE, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 2, 1975)

ESR results for γ-irradiated $K_3[Co(CN)_6]$ in powder and single crystal forms are reported. The main paramagnetic species detected at 77 K were diisocyanide $[Co^{II}(CN)_4(NC)_2]^{4-}$ and pentacyanocobaltate(II) $[Co^{II}(CN)_5]^{3-}$. On annealing, diisocyanide was lost and pentacyanocobaltate was formed. In Part I the reaction mechanism is discussed from the results of the powdered sample and in Part II the noncollinear structure is presented as the plausible molecular form of diisocyanide from the results of the single crystal.

The central diamagnetic transition metal ions in inorganic complex compounds are transformed into paramagnetic ones by high energy radiation, leaving the mother lattice almost unchanged. The products have been referred to as the hot ions.[1] Hot ions of Zn and Cd in cyanocomplexes have recently been investigated extensively as single crystals.[2-5] The cyanocomplexes are useful as the samples of the investigation of hot ions because they easily form good single crystals and show interesting features, such as the dimer formation and the high ligand lability; thus, cyanocobaltate(III) has been taken as the sample of the present experiment. The cyanocabaltate(II) complexes are dimerized when synthesized by the usual chemical methods, forming a diamagnetic compound. Also, the hot ion Co(II) presents ESR data which refer to the low spin state of d^7, in contrast to the usual method. It has been reported that the paramagnetic diisocyanide $[Co^{II}(CN)_4(NC)_2]^{4-}$, (to be referred to as species I),** and the pentacyanocobaltate $[Co^{II}(CN)_5]^{3-}$ (species II) are produced by the high energy irradiation of cyanocobaltate.[6-9] However, those investigations in the literature are preliminary and leave several problems to be investigated. For example, when the sample is annealed from 77 K to room temperature, only species II can be observed, and not I. Also, the mechanisms of the formation and the temperature dependence of the stability of these species have not been clarified. Hence, we decided to investigate these problems more in detail; we found that species I and species II are stable at 77 K, but, on annealing, an electron is released from species I resulting in the formation of species II. The first part of this paper is concerned with the investigation of the powdered sample, and the second part, that of the single crystal.

Part I Powdered Sample

Experimental

Potassium hexacyanocobaltate(III) was prepared with cobalt(II) chloride hexahydrate and potassium cyanide.[10] The reagents used were of the reagent grade and no further putification was done. The purity of the synthesized sample was checked by elemental analyses: Calcd for $K_3[Co(CN)_6]$: C, 21.68; H, 0; N, 25.29%. Found: C, 21.65; H, 0; N, 25.74 % mol wt 332.25. The powdered samples were exposed to γ-rays from a ^{60}Co source of the University of Tokyo at room temperature and at 77 K. ESR spectra were obtained with a JEOL 3BS Type X-band spectrometer using 100 kHz field modulation. The magnetic field was calibrated by Mn^{2+} (doped in MgO) and the resonance position of DPPH (g= 2.0036). The ESR spectrum was measured for each specimen before irradiation and it was confirmed that the sample did not contain any ESR-active paramagnetic species. The number of the hot ions was determined by comparing the integrated intensity of hot ions with that of the standard sample $[Co^{III}(NH_3)_6]$ $[Cu^{II}Cl_5]$ which contained 1.3×10^{18} Cu(II) ions. The sample was sealed *in vacuo* (4.2×10^{-6} Torr), and this was compared to the sample in air in order to see the atmospheric effect. The sample irradiated at 77 K was annealed gradually, and ESR was measured during this procedure. The effect of the total dose applied to the sample was also examined. When the sample was kept at constant temperature, species I decayed and II was formed. The rate of this decay and that of the formation were also measured.

Results

Figure 1 shows the ESR spectra of the sample after irradiation at 77 K (referred to as I in the figure) and that at room temperature (II). In both spectra $g_{//}$ and $g_{\perp}$ are split into eight lines by Co(II) with a nuclear spin of 7/2. The spectral patterns are different, with the different parameters shown in Table 1. Apparently,

Table 1. ESR parameters of hot ions formed in γ-irradiated powder $K_3[Co(CN)_6]$.

	$g_{//}$	$A_{//}$(G)	$g_{\perp}$	$A_{\perp}$(G)
Irradiated at 77 K (Spectrum I)				
$[Co^{II}(CN)_4(NC)_2]^{4-}$	2.001 (±0.002)	61.7 (±0.3)	2.091 (±0.001)	−70.0 (±0.3)
$[Co^{II}(CN)_5]^{3-}$	2.004 (±0.005)	89 (±2)	2.170 (±0.003)	−29.3 (±1)
Irradiated at room temperature (Spectrum II)				
$[Co^{II}(CN)_5]^{3-}$	2.004 (±0.005)	89 (±2)	2.170 (±0.003)	−29.3 (±1)

the features of the spectrum in Fig. 1 are complicated and cannot be analysed by simple observation. After the analysis of the angular dependence of the ESR spectra of the single crystal, it was revealed that the tensors of g and A for species I were orthogonal to each other, and $g_{//}$ was split by $A_{\perp}$ and $g_{\perp}$ by $A_{//}$ and $A_{\perp}$. More details of the latter finding will be described in Part II of this article. For species II the $A_{//}$ can be observed as

* Present address: Department of Chemistry and Physics, National Institute for Environmental Studies, P. O. Yatabe, Tsukuba, Ibaraki 300-21.

** With respect to the real form of the molecule, it is not clear whether two of the cyanide ligands are inversed[14] or twisted.[8,9] We use the formula $[Co^{II}(CN)_4(NC)_2]^{4-}$ for convenience.

5×10^7	171	50	87	(134)	215

the split of the $g_{//}$ part, as usual. Species I can be assigned to the hexacoordinated species $[Co^{II}(CN)_4(NC)_2]^{4-}$ and species II to the pentacoordinated one $[Co^{II}(CN)_5]^{3-}$, by the comparison of the g and A values with those of the alkylisocyanide complexes.[11,12] The temperature dependence of the two species was noticeable. As the sample which has been irradiated at 77 K was annealed to room temperature, the formation of the species II was observed by ESR. During annealing both species I and II were observed simultaneously: I decreased and II increased. The results are shown in Fig. 2. Species I decreases and II increases with time. Besides species I and II, an ESR signal of narrow linewidth was observed in the center of the spectrum; this was attributed to the radical produced by irradiation. Since the intensity of the radical species was independent of the decay of I, hence, it was not taken into the consideration of the reaction mechanisms of I and II. No sizable difference was observed between the samples sealed *in vacuo* and that in the air.

The magnitudes of the total dose exerts a large influence on the yield of hot ions, as seen in Table 2. The experimental results can be summarized as: i) on irradiation of the same dosage, the total yield of I and II is independent of the temperature, and ii) on annealing, some part of species I changes into the diamagnetic species. Figures 3 and 4 present the process of the decay and formation of hot ions. The formations of species II and the diamagnetic species are second order reactions, and the activation energies of the two reactions were measured as 9 and 8 kcal/mol, respectively.

Discussion

Electronic States of Hot Ions. From the crystal field approximation, the ESR parameters of the d^7-low spin state in the C_{4v} (or D_{4h}) symmetry may be expressed as follows:[13]

$$g_{//} = 2.0023 \tag{1}$$

$$g_{\perp} = 2.0023 + 6\frac{\lambda}{\Delta} \tag{2}$$

$$A_{//} = P\left[-\kappa + \frac{4}{7} - \frac{6}{7}\frac{\lambda}{\Delta}\right] \tag{3}$$

Table 3. Some parameters derived from ESR measurements (using crystal field approximation)

	λ/Δ	$P(cm^{-1})$	κ	$\lambda(cm^{-1})$	$\Delta(cm^{-1})$	χ	$A_{iso}(G)$	$A_{aniso}(G)$
Species I	0.0148	0.0168	0.215	340	23000	0.04	−36.5	100
Species II	0.0279	0.0173	0.0654	352	12600	0.06	−9.8	103

$$A_{\perp} = P\left[-\kappa+\frac{2}{7}-\frac{45}{7}\frac{\lambda}{\Delta}\right] \quad (4)$$

where $\Delta=E(z^2)-E$ (xz or yz), κ is an isotropic term, and λ is the spin-orbit coupling constant. The values calculated for λ/Δ, P, and κ from the experimental results listed in Table 1 are shown in Table 3, where $A_{//}$ and $A_{\perp}$ are assumed to have opposite signs. A comparison of the value of P (see Table 3) to that of the free ion P_0 (0.0254 cm^{-1}) suggests that the unpaired electron is delocalized considerably in the orbital of the cyanide ligands (33%). This also gives rise to a smaller value of λ (see Table 3) than that for the free ion λ_0 (515 cm^{-1}). With the consideration of the delocalization, the value of Δ for hot ions can be estimated from λ/Δ. Values of A_{iso} and A_{aniso} can also be calculated from $-P\kappa$ and $4/7P$, respectively. Symons and Wilkinson[14] gave an equation to derive the spin density χ in Co(4s): $A_{iso}(G)=1320\chi-90\leftarrow(1-\chi)$, where 1320 G is the theoretical value of A_{iso} from Co(4s) and 90 G is the $3d_{z^2}$ contribution to A_{iso} *via* spin polarization. χ was calculated by applying this relation. The values of χ, A_{iso}, and A_{aniso} are shown in Table 3. From the molecular orbital approximation, the ESR parameters of the d^7-low spin state in a C_{4v} (or D_{4h}) symmetry can be obtained as follows:[15]

$$g_{//} = 2.0023 \quad (5)$$

$$g_{\perp} = 2.0023 + 6\frac{\alpha^2\beta^2\lambda_0}{E(^2E)-E(^2A_1)} \quad (6)$$

$$A_{//} = P_0\left[-\kappa+\frac{4}{7}\alpha^2-\frac{6}{7}\frac{\alpha^2\beta^2\lambda_0}{E(^2E)-E(^2A_1)}\right] \quad (7)$$

$$A_{\perp} = P_0\left[-\kappa+\frac{2}{7}\alpha^2-\frac{45}{7}\frac{\alpha^2\beta^2\lambda_0}{E(^2E)-E(^2A_1)}\right] \quad (8)$$

The molecular orbitals are

$$^2A_1(e^4b_2^2a_1^1) = \alpha d_{z^2} - d'\Phi_1(z^2) \quad (9)$$

$$^2E(e^3b_2^2a_1^2) = \beta d_{xz}\ (\text{or } d_{yz}) - \beta'\Phi_1\ (\text{xz or yz}) \quad (10)$$

The values of P_0 and λ_0 for a free Co ion are calculated from atomic spectral data. They depend on their Co charge[16-18] (Table 4). From the optical spectrum[13]

Table 4. The values of P_0 and λ_0 for a Co ion they depend on the charge on the Co ion

Assumed Co charge	$P_0(cm^{-1})$	$\lambda_0(cm^{-1})$
Co^0	0.022[16]	390[18]
$Co^{+0.52}$	0.0224	424
Co^+	0.0228[17]	455[18]
Co^{2+}	0.0254[17]	515[18]

of $[Co^{II}(CN)_5]^{3-}$, $E(^2E)-E(^2A_1)$ has been determined to be 10350 cm^{-1}. By substituting $E(^2E)-E(^2A_1)$, $\alpha^2\beta^2$, and the experimentally observed $g_{\perp}$ value into Eq. 6, λ_0, the charge of Co, and P_0 of hot ions are evaluated as 424 cm^{-1}, +0.52, and 0.0224, respectively. With the values of $E(^2E)-E(^2A_1)$, P_0, λ_0, and $\alpha^2\beta^2$ thus fixed, the orbital coefficients α^2 and β^2 and the isotropic hyperfine interaction $-P_0\kappa$ can be calculated from Eqs. 7 and 8.

In the case of the hot ion $[Co^{II}(CN)_4(NC)_2]^{4-}$, substituting $\alpha^2\beta^2$, λ_0, and the experimentally obtained $g_{\perp}$ value into Eq. 6, $E(^2E)-E(^2A_1)$ is evaluated as 18900 cm^{-1}. With the values of $E(^2E)-E(^2A_1)$, P_0, λ_0, and $\alpha^2\beta^2$ thus obtained, the orbital coefficients α^2 and β^2 and the isotropic hyperfine interaction $-P_0\kappa$ can be calculated from Eqs. 7 and 8. The calculated results are summarized in Table 5.

Table 5. Some parameters derived from ESR measurements (using molecular orbital approximation)

	$E(^2E)-E(^2A_1)$	α^2	β^2	$-P_0\kappa(cm^{-1})$
Species I	18900	0.783	0.847	−0.00395
Species II	10350	0.826	0.826	−0.00171

According to the results shown in Tables 3 and 5, it is concluded that: i) the λ values for penta and hexa coordinated species are the same (about 350 cm^{-1}); ii) the energy difference between the ground and the excited states is different for the two salts (about 10000 cm^{-1} for the pectacoordinated hot ion and about 20000 cm^{-1} for the hexacoordinated hot ion); and iii) the spin densities of hot ions are calculated as Co($3d_{z^2}$) 0.78 and Co(4s) 0.04 for species I, and Co($3d_{z^2}$) 0.83 and Co(4s) 0.06 for species II.

Mechanism of the Changes of Species I and II. *At 77K*: The mechanism of the reactions which take place in the γ-irradiated solid sample is assumed to take the scheme shown in Fig. 3. The secondary electrons which are formed by the γ-ray irradiation will hit Co^{III} in the complex of $[Co^{III}L_6]^{3-}$(1) in Fig. 3. With respect to the subsequent reactions, several different possible paths can be assumed. The first one is the case where the species(1) kicks out an electron, leaving itself as an positive hole. If the hole is stable, it will persist (3). If it is unstable, it may release one of the cyanide ligands,

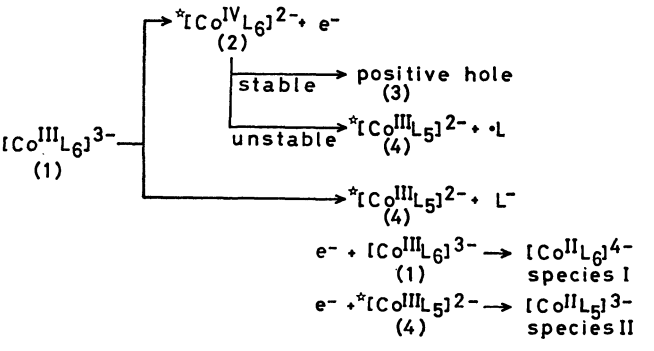

Fig. 3. The reaction mechanism at 77 K.
☆ stands for an excited species.

thus forming species (4). The latter can also be produced from species (1) directly. The active electron which is produced by the irradiation or by the process of the formation of (2) is trapped by (1) or (4), and produces hot ions.

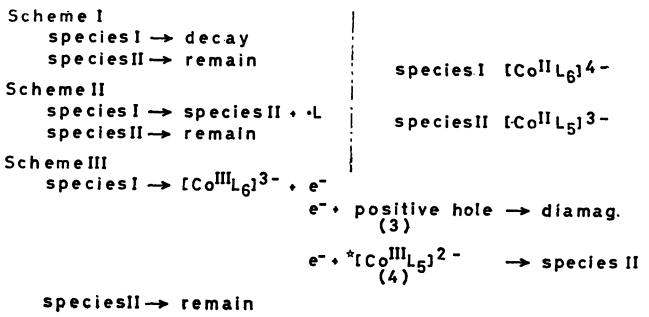

Fig. 4. The reaction mechanism on annealing.
☆ stands for an excited species.

On Annealing: From the experimental results, three processes of annealing can be imagined, as shown in Fig. 4. Among the processes shown in Fig. 4, we take scheme III as the most plausible. Scheme I cannot explain why the intensity of species II increases with temperature. Scheme II cannot explain the fact that some part of species I changes into the diamagnetic species. And of scheme II is the actual case, the formation of species II must be a first order reaction. In fact, this is against the experimental findings that both the formation of species II and that of the diamagnetic species are second order. But scheme III can explain the observed facts fairly well. According to this scheme, species I $[Co^{II}L_6]^{4-}$ releases an electron and returns to the original complex $[Co^{III}L_6]^{3-}$, and the electron thus released is trapped by another Co complex ion, such as $[Co^{IV}L_6]^{2-}$ (3) or $[Co^{III}L_5]^{2-}$ (4), forming either the diamagnetic ion or species II $[Co^{II}L_5]^{3-}$. Furthermore, the originally formed species II is kept unchanged according to this scheme.

Part II Single Crystal Experimental

Potassium hexacyanocobaltate(III) was prepared in the same way as in Part I from cobalt(II) chloride hexahydrate and potassium cyanide. Single crystals of $K_3[Co(CN)_6]$, approximately $3\times3\times1$ mm^3 in size, were obtained by slow evaporation of the aqueous solution. They were irradiated at 77 K with ^{60}Co γ-rays. 1×10^6 rads of γ-rays in total were applied to the sample at the rate of 5×10^4 rads/h. All conditions of the ESR measurements were the same as those in Part I. The crystals of $K_3[Co(CN)_6]$ exhibit polytypism.[19,20] Two unit cells occur in the structure of $K_3[Co(CN)_6]$: one, which is dominant, is orthorhombic (20 r) and the other monoclinic (1M,3M,7M). The ESR spectra observed in the present refer to the orthorhombic symmetry. The orthorhombic axes b and c of the crystal were easily identified with the aid of the crystallographic data,[21] and the axis of the right-handed orthorhombic system was unambiguously assigned. The ESR spectra were observed by rotating the sample at 15° intervals with the external magnetic field in the ab, ac, or bc plane.

Results

A typical example of the spectrum is shown in Fig. 5. It consists of one strong line due to the unidentified radicals, two wing lines (arrows) due to hydrogen atoms produced in the sample tube, and eight wing lines due to the Co(II) hot ions with a nuclear spin of 7/2. Two groups of octets are seen in the figure, which refer to two non-equivalent directions of the hyperfine tensor of the Co(II) hot ion. Each hyperfine line of cobalt is, furthermore, split into five lines, suggesting the coupling of cobalt with two equivalent nitrogen atoms. When the magnetic field was set parallel to the bc, ca, or ab planes, each spectrum became simple and revealed that it was formed of the two spectra shown in Figs. 5 and 6. Moreover, when the spectra taken at the arbitrary positions were analysed, taking this result into consideration, it was found that the spectra were produced by species I of the Co(II) hot ion located in four different sites in the unit cell. This means the produced hot ion is assigned as species I, which has been referred to in Part I, and is located at four sites in the unit cell of the mother lattice. The g-tensor was evaluated by measuring the central position between the first and the eighth peaks. The hyperfine coupling tensor was obtained as one-seventh of the separation between the first and eighth peaks. These results are shown in Fig. 7.

Discussion

Three different coordinate systems must be considered for the crystal of the sample: i) the crystallographic coordinate system (a, b, c), ii) the principal axis system of the g-tensor (α, β, γ), and iii) the principal axis system of the A-tensor (1, 2, 3). From the direction consines with respect to the magnetic field, the g values, and the hyperfine splitting K, the principal values and the principal of axes the g-tensor and the A-tensor are determined by the least-square method. The principal axes of the g-tensor do not necessarily coincide with those of the A-tensor. In the coordinates (α, β, γ), the g-tensor is diagonalized by

$$g^2 = (l_\alpha, l_\beta, l_\gamma) \begin{pmatrix} G_{\alpha\alpha} & 0 & 0 \\ 0 & G_{\beta\beta} & 0 \\ 0 & 0 & G_{\gamma\gamma} \end{pmatrix} \begin{pmatrix} l_\alpha \\ l_\beta \\ l_\gamma \end{pmatrix}$$

where $G_{\alpha\alpha}=g^2_{\alpha\alpha}$, $G_{\beta\beta}=g^2_{\beta\beta}$ and $G_{\gamma\gamma}=g^2_{\gamma\gamma}$
In the coordinates (1, 2, 3), the A-tensor can be diagonalized, but the g-tensor cannot.

$$g^2K^2 = (l_1, l_2, l_3) \begin{pmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{pmatrix} \begin{pmatrix} B_{11} & 0 & 0 \\ 0 & B_{22} & 0 \\ 0 & 0 & B_{33} \end{pmatrix} \begin{pmatrix} g_{11} & g_{21} & g_{31} \\ g_{12} & g_{22} & g_{32} \\ g_{13} & g_{23} & g_{33} \end{pmatrix} \begin{pmatrix} l_1 \\ l_2 \\ l_3 \end{pmatrix}$$

where $B_{11}=A^2_{11}$, $B_{22}=A^2_{22}$, and $B_{33}=A^2_{33}$.
In the crystallographic coordinates, the principal values

and the principal axes were determined (Table 6). The direction of the $A_{//}(A_3)$ axis coincides with Co–C_3 and the direction of the $g_{\parallel}(g_3)$ axis coincides with Co–C_2. Since $g_1 \simeq g_2 \simeq g_{\perp}$, the direction cosines of g_1 and g_2 cannot be determined exactly. Under the condition that the g-tensor and the A-tensor are axially symmetric, the parallel directions are orthogonal to each other. From the angular dependence of the superhyperfine splitting of nitrogen it is known that two cyanide ligands are inversed or twisted along the parallel direction of the g-tensor ($A^N_{//}=3.92$ G, $A^N_{\perp}=2.95$ G). Accordingly, the structure of the hot ion is axially symmetric along the $g_{//}$ axis. On the other hand, the distribution of the electron density is axially symmetric along the $A_{//}$ axis, *i. e.*, perpendicular to the $g_{//}$ axis. Similar noncollinear examples have been found in radicals,[22–24] but very rarely in metal complexes. Only five cases have been reported in the literature.[4,25–28] When the principal values and the principal axes of the g-tensor and the A-tensor are determined, the powder ESR spectrum can be assigned. As the parallel components of the g-tensor and the A-tensor are orthogonal, the $A_{\perp}$ can be seen at the $g_{//}$ part, and the $A_{//}$ and $A_{\perp}$ can be seen at the $g_{\perp}$ part (Fig. 8). Empirically it is known that $|A_{//}|<|A_{\perp}|$ for the hexacoordinated d^7-low spin complex, whereas $|A_{//}|>|A_{\perp}|$ for the pentacoordinated one.[1] Symons and his co-workers[8] reported that the g-tensor is

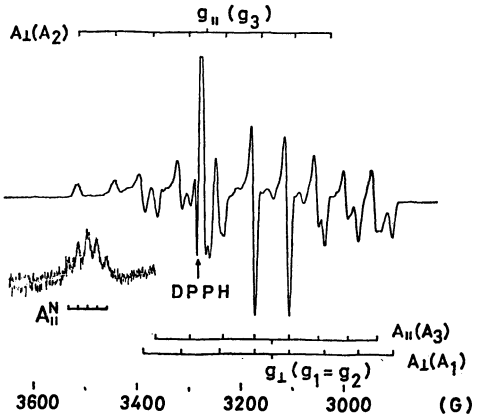

Fig. 8. An ESR powder spectrum of $[Co^{II}(CN)_4(NC)_2]^{4-}$. ESR parameters assigned by using the single crystal data. The superhyperfine structure at the $g_{//}$ part is caused by two equivalent nitrogen atoms of ligands.

axially symmetric ($g_x=g_y$) but the A-tensor is anisotropic ($A_x \neq A_y$). However, this statement is not right; both the g-tensor and the A-tensor are axially symmetric, and hence the principal axes do not coincide.

Other alkali metals were used instead of $3K^+$ to examine the effect of the mother lattice (Fig. 9). Species I can be measured only in the cases of $3K^+$ and $3Rb^+$.

The Theory of the Reverse Diffusion of Ions in Mixed Electrolyte Solutions and Experimental Results on the HCl-$CaCl_2$-H_2O Ternary System[1)]

Masayuki NAKAGAKI and Shuji KITAGAWA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyoku, Kyoto 606

(Received October 13, 1975)

Reverse diffusion is the migration of solutes in the direction opposite to that expected from the concentration gradient, that is, from a portion with a lower concentration to that with a higher concentration. This type of diffusion of ions in mixed electrolyte solutions was studied theoretically on the basis of nonequilibrium thermodynamics. For a solution containing two kinds of cations and one kind of anion, it has been concluded that the reverse diffusion occurs when the mobilities of the coexisting ions differ largely, because the effect of the diffusion potential is pronounced in such a case. It has also been concluded that the practical diffusion coefficient of an ion varies linearly with the ratio of the concentration gradient of a coexisting ion to that of the diffusing ion when the average concentration ratio of the ions is fixed. Moreover, the range of the concentration-gradient ratio, where the practical diffusion coefficient is negative, has been determined. These theoretical conclusions were tested experimentally for the HCl-$CaCl_2$-H_2O ternary system. The results satisfactorily verified that reverse diffusion actually occurred and that the relationship between the diffusion coefficient and the concentration-gradient ratio was linear, as has been expected.

The Fick law of diffusion predicts that a solute will migrate from a portion with a higher concentration to one with a lower concentration at a rate proportional to the concentration gradient. The diffusion through a membrane, that is, the so-called passive transport, also proceeds in the same direction. In contradiction to this, the active transport in biological membranes is transport against the concentration gradient. However, an ion can migrate against its concentration gradient passively in a system of mixed electrolytes, at least under certain limited conditions. This has already been pointed out theoretically in our previous paper.[2)]

According to nonequilibrium thermodynamics, the flux of the ion (i), J_i, is proportional to the gradient of the total potential of the component, $\tilde{\mu}_i$, which is the electrochemical potential in the present case. Thus, the rate of the diffusion of each ion is modified by the effect of the electric potential, the so-called diffusion potential, and, under certain conditions, the reverse diffusion of an ion can proceed, as has already been predicted both qualitatively[3)] and quantitatively.[2,4)] However, no precise experimental support of the reverse diffusion has so far been given. For the KCl-$MgCl_2$-H_2O system and the K(HAsp)-$Mg(HAsp)_2$-H_2O system, where $HAsp^-$ indicates the hydrogen aspartate anion, it has been reported[5)] that the diffusion coefficient of a cation becomes smaller with the addition of a faster cation, but the diffusion coefficient has not reached a negative value.

Theoretical

Practical Diffusion Coefficient of Ions. According to nonequilibrium thermodynamics, the flux of the ion (i), $[J_i]$ (mg-ion·cm^{-2}·s^{-1}), through a diffusion layer between two aqueous solutions, I and II, is given by the following equation,[2,4,6,7)] after the term of the electric potential gradient has been eliminated by using the condition that the diffusion current is zero in the steady state:

$$[J_i] = -D_i\left(\frac{\partial[i]}{\partial x}\right) + \frac{z_i B_i [i]}{\sum_j z_j^2 B_j [j]} \sum_j z_j D_j \left(\frac{\partial [j]}{\partial x}\right) \quad (1)$$

Here, $[i]$ (g-ion·l^{-1}) is the concentration of the i ion, while x is the coordinate taken in the direction of the flux. Moreover, B_i is the mobility of the ion, i, which is related to the radius of the ion, a_i, and the viscosity of the medium, η, by the Stokes law if the ion is considered to be spherical;

$$B_i = 1/6\pi\eta a_i \quad (2)$$

and D_i is the diffusion coefficient related to the mobility by the following equation:

$$D_i = kTB_i h_i \quad (3)$$

where k is the the Boltzmann constant, T is the absolute temperature, and h_i is the coefficient;

$$h_i = 1 + (\partial \ln f_i / \partial \ln [i]) \quad (4)$$

with f_i being the activity coefficient of the ion, i. If the concentration dependence of the activity coefficient can be neglected so that $h_i = 1$, then Eq. 3 is simplified to:

$$D_i = kTB_i \quad (5)$$

which gives the Einstein equation when Eq. 2 is used together with it.

The actual rate of diffusion of the ion, i, in a solution, however, can not be determined by D_i or, in other words, by the ionic radius and the solvent viscosity only, because of the electrostatic interaction between ions, or, we could say, because of the effect of the diffusion potential. The practical diffusion coefficient of the ion (i), D'_i, may then be defined by:

$$[J_i] = -D_i'(\partial[i]/\partial x) \quad (6)$$

Its theoretical expression is given by the following equation, which has been derived from Eq. 1, in the same approximation as was used for Eq. 5:

$$D_i' = kTB_i\left\{1 - \frac{z_i[i]\sum_j z_j B_j (\partial[j]/\partial x)}{(\sum_j z_j^2 B_j [j])(\partial[i]/\partial x)}\right\} \quad (7)$$

In the case of an electrolyte solution containing one cation, 1, and one anion, 3, only, Eq. 7 gives the Haskell

equation:

$$D_1' = D_3' = kT(z_1+|z_3|)B_1B_3/(z_1B_1+|z_3|B_3) \quad (8)$$

If, however, the electrolyte solution contains two cations, 1 and 2, and one anion, 3, the practical diffusion coefficients are given, on the basis of Eq. 7 and the equation of electrical neutrality;

$$z_1[1] + z_2[2] = |z_3|[3] \quad (9)$$

by the following equations:

$$D_1' = kTB_1\left\{1-z_1\frac{F(1/2)}{G(1/2)}H\right\} \quad (10a)$$

$$D_2' = kTB_2\{1-z_2H\} \quad (10b)$$

$$D_3' = kTB_3\left\{1+|z_3|\frac{1+G(1/2)}{1+F(1/2)}H\right\} \quad (10c)$$

where:

$$H = \frac{(B_2-B_3)+(B_1-B_3)G(1/2)}{(z_2B_2+|z_3|B_3)+(z_1B_1+|z_3|B_3)F(1/2)} \quad (10d)$$

Here, $F(i/j)$ is the ratio of concentrations (g-equiv$\cdot l^{-1}$);

$$F(i/j) = |z_i/z_j|\cdot[i]/[j] \quad (11)$$

and $G(i/j)$ is the ratio of the concentration gradients, the concentration being expressed again in g-equiv$\cdot l^{-1}$:

$$G(i/j) = |z_i/z_j|\cdot(\partial[i]/\partial x)/(\partial[j]/\partial x) \quad (12)$$

Equations 10a—d show that the practical diffusion coefficient, D'_i, is a function of the concentration ratio and the concentration-gradient ratio, and that D'_2 is linear and D'_1 and D'_3 are hyperbolic against $G(1/2)$ at a fixed $F(1/2)$. As for the 3 anion, Eqs. 10c, d may be rewritten, by using Eq. 9, as follows:

$$D_3' = kTB_3\left\{1+|z_3|[1+F(1/2)]\right.$$
$$\left.\times\frac{(B_2-B_3)+(B_1-B_2)G(1/3)}{(z_2B_2+|z_3|B_3)+(z_1B_1+|z_3|B_3)F(1/2)}\right. \quad (13)$$

Therefore, D'_3 is linear with $G(1/3)$ at a fixed $F(1/2)$.

Reverse Diffusion. As is obvious from Eq. 6, the reverse diffusion of the ion, i, takes place when the practical diffusion coefficient, D'_i, is negative; the condition for it is readily obtained from Eqs. 10a—d:

When the 1 cation is also present, the reverse diffusion of the 2 cation proceeds when Eq. 14 is fulfilled if $B_1>B_3$, or when Eq. 15 is fulfilled if $B_1<B_3$:

$$G(1/2) > \frac{(z_1/z_2)(B_1/B_3)+(|z_3|/z_2)}{(B_1/B_3)-1}F(1/2) + \frac{(|z_3|/z_2)+1}{(B_1/B_3)-1}$$
$$(B_1>B_3) \quad (14)$$

$$-G(1/2) > \frac{(z_1/z_2)(B_1/B_3)+(|z_3|/z_2)}{1-(B_1/B_3)}F(1/2) + \frac{1+(|z_3|/z_2)}{1-(B_1/B_3)}$$
$$(B_1<B_3) \quad (15)$$

Since the right side of Eq. 15 is positive, the reverse diffusion of the 2 ion can occur, if $B_1<B_3$, only in the case of counter diffusion, that is, in the case where the concentration gradients of the 1 and 2 cations are in the opposite direction so that $G(1/2)<0$.

Equation 14 will be fulfilled if $G(1/2)$ is large enough or if $F(1/2)$ is small enough and (B_1/B_3) is large enough, while Eq. 15 will be fulfilled if $-G(1/2)$ is large enough or if $F(1/2)$ is small enough and (B_1/B_3) is small enough. Therefore, both Eqs. 14 and 15 predict that the reverse diffusion of the 2 cation will be observed when the coexisting cation, 1, is at a smaller concentration but is of a greater concentration gradient and when the mobility of the coexisting cation, 1, differs more from that of the anion, 3.

This may be interpreted as follows: If the coexisting cation, 1, moves faster than the anion, 3, as in the case of Eq. 14, the diffusion potential is generated in such a way that the front part of the diffusion layer is positive and the rear part negative, so that the 2 cation is pulled back by this electric potential, even against its concentration gradient, if the latter is not very large. On the other hand, if the coexisting cation 1 moves much slower than the anion, 3, as in the case of Eq. 15, the direction of the diffusion potential will be opposite to the previous case, so that the 2 cation is pushed forth by this potential, irrespective of the direction of its concentration gradient; the reverse diffusion of the 2 cation results if the direction of its concentration gradient is opposite to those of the 1 cation and the anion, 3.

As for the reverse diffusion of the anion, 3, D'_3 of Eq. 10c or 13 becomes negative when Eq. 16 or 17 is fulfilled, where the use of the suffix 1 for the cation of greater mobility does not lose any generality:

$$1 > -G(1/2) > \frac{\{(z_2/|z_3|)+1\}+\{(z_1/|z_3|)(B_1/B_2)+1\}F(1/2)}{\{(B_1/B_2)+(z_2/|z_3|)\}+\{(z_1/|z_3|)+1\}(B_1/B_2)F(1/2)}$$
$$(B_1>B_2) \quad (16)$$

$$-G(1/3) > \frac{\{(z_2/|z_3|)+1\}+\{(z_1/|z_3|)(B_1/B_2)+1\}F(1/2)}{\{(B_1/B_2)-1\}\{1+F(1/2)\}}$$
$$(B_1>B_2) \quad (17)$$

According to Eqs. 16 and 17, it may be concluded that the reverse diffusion of the anion, 3, may be observed only when the concentration gradient of the faster cation, 1, is in the direction opposite to those of the coexisting cation, 2, and of the anion, 3.

Numerical Calculations on the HCl–$CaCl_2$–H_2O System. The numerical values of D'_i have been calculated for

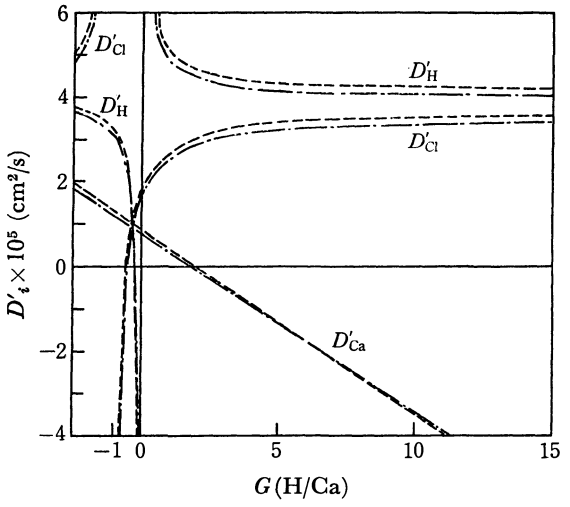

Fig. 1. Calculated values of D'_i against $G(H^+/Ca^{2+})$ at $F(H^+/Ca^{2+})=2$.
The broken lines indicate the values at $h_i=1$, while chain lines indicate the values obtained by using the Güntelberg equation.

the HCl–$CaCl_2$–H_2O system according to Eqs. 10a—d, with 1=H^+, 2=Ca^{2+} and 3=Cl^-. The results for the case of $F(H/Ca)=2$ as an example are shown in Fig. 1, where the concentration-gradient ratio $G(H/Ca)$ is taken on the abscissa.

The broken lines in Fig. 1 are the results obtained for $h_i=1$ by neglecting the concentration dependence of the activity coefficient, while the chain lines are the results obtained by using Eq. 4 and the Güntelberg approximation:[8]

$$\ln f_i = -Az_i^2\sqrt{J}/(1+\sqrt{J}) \quad (18)$$

where A is a constant at a given temperature:

$$A = \sqrt{2\pi N_A/1000}\cdot(e/\sqrt{D_0kT})^3 \quad (19)$$

Here, N_A is the Avogadro Number, e is the elementary charge, D_0 is the dielectric constant of the solvent, and J is the ionic strength:

$$J = (1/2)\sum_i z_i^2[i] \quad (20)$$

By comparing these curves, it may be concluded that the effect of the concentration dependence of the activity coefficient is small, at least in the concentration range studied in this paper.

The values of mobility, B_i, used in these calculations were obtained from the values of the equivalent conductance at an infinite dilution, λ^0_i, given in the literature[9], according to the well-known equation:

$$B_i = \lambda_i^\circ N_A/(|z_i|F_A^2) \quad (21)$$

The values of kTB_i and kTB_ih_i thus obtained are shown in Table 1.

Table 1. Values of D_i ($=kTB_ih_i$) in aqueous HCl–$CaCl_2$ solutions at 25 °C

Ion	λ_i° ($\Omega^{-1}\cdot cm^2\cdot g\text{-}eq^{-1}$)	$D_i\times10^5$ ($cm^2\cdot s^{-1}$)	
		($h_i=1$)	(Güntelberg)
H^+	349.82	9.315	8.990
Ca^{2+}	59.50	0.792	0.682
Cl^-	76.35	2.033	1.928

For the HCl–$CaCl_2$–H_2O system, Fig. 1 shows that the diffusion coefficients, D'_H, D'_{Ca}, and D'_{Cl}, become negative in their respective regions, so that each ion would cause a reverse diffusion in these regions. Figure 1 shows that D'_{Ca} decreases linearly with $G(H/Ca)$, as is to be expected from Eqs. 10b, d, and that D'_{Ca} becomes negative when $G(H/Ca)$ is greater than a certain value, as is to be expected from Eq. 14, since $B_H>B_{Cl}$, as is shown in Table 1.

Figure 1 also shows that the change in D'_H with $G(H/Ca)$ is hyperbolic, as is to be expected from Eqs. 10a, d, and that D'_H becomes negative in the region, which can be expected from Eq. 15a, since $B_{Ca}<B_{Cl}$, as is shown in Table 1. The region of $G(1/2)$, in which D'_1 is negative in the presence of the 2 cation, is derived readily from Eq. 15:

$$0<-G(1/2)<F(1/2)\Big/\left\{\frac{(z_2/z_1)(B_2/B_3)+|z_3|/z_1}{1-(B_2/B_3)}+\frac{1+(|z_3|/z_1)}{1-(B_2/B_3)}F(1/2)\right\} \quad (B_2<B_3) \quad (15a)$$

Instead of $G(H/Ca)$, however, if $G(Ca/H)$ is taken on the abscissa, as is shown in Fig. 5, D'_H is linear, as is to be expected from Eqs. 10b, d, with 1=Ca^{2+} and 2=H^+, and becomes negative when $-G(Ca/H)$ is greater than a certain value, as is to be expected from Eq. 15.

As for the Cl^- anion, the curves shown in Fig. 1 are hyperbolic, as is to be expected from Eqs. 10c, d, with 1=H^+, 2=Ca^{2+}, and 3=Cl^-. The value of D'_{Cl} becomes negative, as is shown in Fig. 1, in the region where $G(H/Ca)$ is negative but greater than -1, as is expected from Eq. 16, since $B_H>B_{Cl}$, as is shown in Table 1. If, however, $G(H/Cl)$ is taken on the abscissa, as is shown in Fig. 6, D'_{Cl} is linear at a fixed value of $F(H/Ca)$, as is to be expected from Eq. 13, and becomes negative when $-G(H/Cl)$ is large enough, as is to be expected from Eq. 17, since $B_H>B_{Cl}$.

Experimental

Diffusion Measurements. McBain's porous-plate method[10] was used for the diffusion measurements, with a diffusion cell modified as has been reported previously.[11] A glass cell divided into two compartments by a porous plate, as is shown in Fig. 2, was held vertically in a thermostat at 25±0.1 °C after each compartment had been filled with a mixed solution of HCl and $CaCl_2$. The solution with the higher density was placed in the upper compartment, I, and that with the lower density, in the lower one, II, in order to keep the concentration distribution in each compartment homogenous by means of convectional flow.[10]

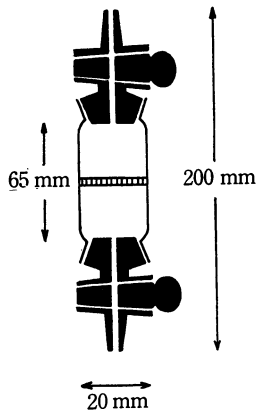

Fig. 2. Diffusion cell.

After a certain time, t, had passed, the concentration in each compartment was measured, and the practical diffusion coefficient, D_i', defined by Eq. 6, was calculated according to the following equations:

$$D_i' = (\langle m_i\rangle/Kt)/\langle[i]_I-[i]_{II}\rangle \quad (22)$$

where K is the cell constant, which depends on the porosity, area, and thickness of the porous plate, and where

$$\langle m_i\rangle = (1/2)\{V_I([i]_I^\circ-[i]_I^t)+V_{II}([i]_{II}^t-[i]_{II}^\circ)\} \quad (23)$$

$$\langle[i]_I-[i]_{II}\rangle = (1/2)\{([i]_I^\circ-[i]_{II}^\circ)+([i]_I^t-[i]_{II}^t)\} \quad (24)$$

where $[i]_I^\circ$ and $[i]_{II}^\circ$ are the initial concentrations of the ion, i, in the upper and lower compartments, $[i]_I^t$ and $[i]_{II}^t$ are those after the time, t, and V_I and V_{II} are the volumes of the compartments.

The diffusion time, t, was set at about 30 h. The values

Table 2. Constants of the diffusion cells used

Cell No.	V_I (ml)	V_{II} (ml)	K (cm)
1	6.9994	7.1516	0.626_1
2	6.4548	6.3961	0.404_5
3	6.6927	6.7142	0.553_4

of V_I and V_{II} are given in Table 2 together with the values of K measured with 0.05 N KCl, the diffusion coefficient of the latter being 1.863×10^{-5} ($cm^2 \cdot s^{-1}$), as is given in the literature.[12]

For the solutions containing only one electrolyte, the diffusion equation (6) can be integrated to obtain the equation to be used for the calculation of the diffusion coefficient.[2,5,11] Instead of this, however, the average amount of diffusion, $<m_i>$, and the average concentration difference, $<[i]_I-[i]_{II}>$, were used in this study, and the diffusion coefficient was calculated by means of Eq. 22, because the integration with time is complicated for mixed electrolyte solutions.[7] The discrepancy between the diffusion coefficients obtained by Eq. 22 and the usual integrated equation was not more than 10% for the one-electrolyte solutions used.

Parameter Values. In order to compare the experimental D_i' values with the theoretical ones, the values of $F(i/j)$ and $G(i/j)$ defined by Eqs. 11 and 12 are needed. The experimental values of $F(i/j)$ were calculated from:

$$F(i/j) = |z_i/z_j| \cdot \frac{([i]_I^\circ + [i]_{II}^\circ) + ([i]_I^t + [i]_{II}^t)}{([j]_I^\circ + [j]_{II}^\circ) + ([j]_I^t + [j]_{II}^t)} \quad (25)$$

where $([k]_I^\circ+[k]_{II}^\circ)$ and $([k]_I^t+[k]_{II}^t)$, k being i or j, take almost the same values, since V_I and V_{II} have almost the same value. The value of $F(i/j)$ is, therefore, kept almost contant during the diffusion experiment. For the experimental values of $G(i/j)$, the following equation was used with Eq. 24, since the concentration distribution in a diffusion layer had been found to be almost linear:[7]

$$G(i/j) = |z_i/z_j|\langle[i]_I-[i]_{II}\rangle/\langle[j]_I-[j]_{II}\rangle \quad (26)$$

Concentration Determination. The concentration of the H^+ ion was determined by titration with NaOH as the standard solution and with phenolphthalein as the indicator. The concentration of the Ca^{2+} ion was determined by chelatometry, with disodium-EDTA as the standard solution and Eriochrome Black T as the indicator. The concentration of the Cl^- ion was determined by precipitation titration, with $AgNO_3$ as the standard solution and fluorescein as the indicator.

Results and Discussion

Examples of Reverse Diffusion. Some examples of the data are shown in Table 3. Since the parameter values of the three cells used in the experiments are not the same, as is shown in Table 2, the values of $|z_i|[i]_I$ and $|z_i|[i]_{II}$ differ from cell to cell; only the average values are given in Table 3 in order to shorten the listing. The values of D'_i given in the Table are the averages of the values obtained for individual cells. A comparison of data for different cells is given in Figs. 3—6.

It may be seen from Table 3 that the reverse diffusion actually takes place; that is, the concentration increases in the solution with the higher concentration and decreases in that with the lower concentration, for Ca^{2+} in Example 1, for H^+ in Example 2, and for Cl^- in Example 3; the diffusion coefficients, D'_i, are negative in all these cases.

Table 3. Examples of data on the reverse diffusion

Ion	t (h)	$\|z_i\|[i]_I$ (mN)	$\|z_i\|[i]_{II}$ (mN)	$D'_i\times10^5$ ($cm^2 \cdot s^{-1}$)
		Example 1		
H^+	0	148.6	52.1	3.66
	30	125.8	74.5	
Ca^{2+}	0	52.6	48.4	−2.68
	30	53.7	47.1	
Cl^-	0	200.7	100.4	3.15
	30	179.7	121.3

	30	155.3	144.6	

Reverse Diffusion of Ca^{2+}. The experimental D'_{Ca} values are plotted against G(H/Ca) in Fig. 3 for F(H/Ca) $=0.5$, 1, and 2. This figure also shows that the deviation of the experimental data due to the use of different cells is not large.

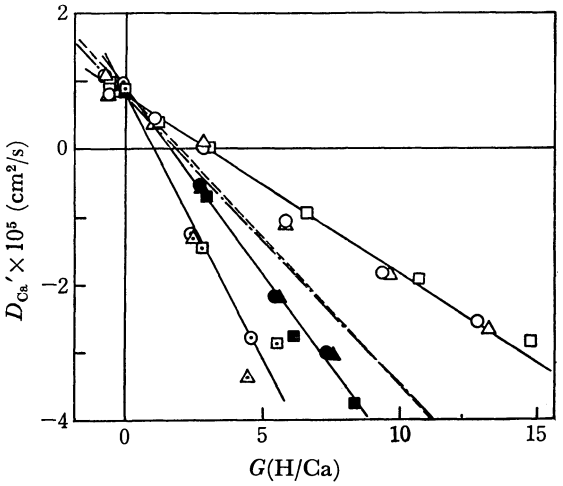

Fig. 3. Diffusion coefficient of Ca^{2+} at 25 °C as a function of G(H/Ca) when F(H/Ca) is fixed.
F(H/Ca)=0.5 (Cell #1, ⊙; #2, ⊡; #3, △), 1.0 (#1, ●; #2, ■; #3, ▲), and 2.0 (#1, ○; #2, □; #3, △).
Theoretical values for F(H/Ca)=2 are shown by a broken line for $h_i=1$, and by a chain line for Güntelberg approximation.

Figure 3 gives the experimental verifications of the theoretical conclusions that D'_{Ca} will be linear to G(H/Ca) and that the inclination will be the steeper when the value of F(H/Ca) is the smaller, as is to be expected from Eqs. 10b, d, with $1=H^+$, $2=Ca^{2+}$, and

3=Cl^-, and that the reverse diffusion of Ca^{2+} will proceed when G(H/Ca) is large, as is to be expected from Eq. 14.

The theoretical curves for F(H/Ca)=2 are also shown in Fig. 3. Neither of the theoretical curves fits in quantitatively with the experimental straight lines. This will be discussed later. It is, however, noticeable that the experimental results are in agreement, qualitatively, with the theoretical expectations mentioned above.

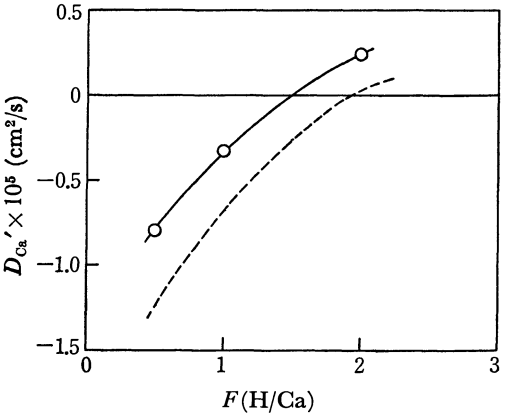

Fig. 4. Dependency of D_{Ca}' on F(H/Ca) for G(H/Ca)=2 at 25 °C.
The broken line is theoretical for $h_i=1$.

The dependency of D'_{Ca} on F(H/Ca) is shown in Fig. 4 for G(H/Ca)=2, where the experimental values are obtained by the interpolation of Fig. 3. It may be seen from Fig. 4 that the experimental curve satisfies qualitatively the trend of the theoretical broken line drawn for $h_i=1$. This result verifies that the reverse diffusion of Ca^{2+} takes place when F(H/Ca) is small, as is to be expected from Eqs. 10b, d.

Reverse Diffusion of H^+ and Cl^-. The dependency of D'_H on G(Ca/H) is shown in Fig. 5 for F(H/Ca)=2, that is, for F(Ca/H)=0.5. The results verify the theoretical conclusions that D'_H will be linear to G(Ca/H) at a fixed F(Ca/H), according to Eqs. 10b, d with

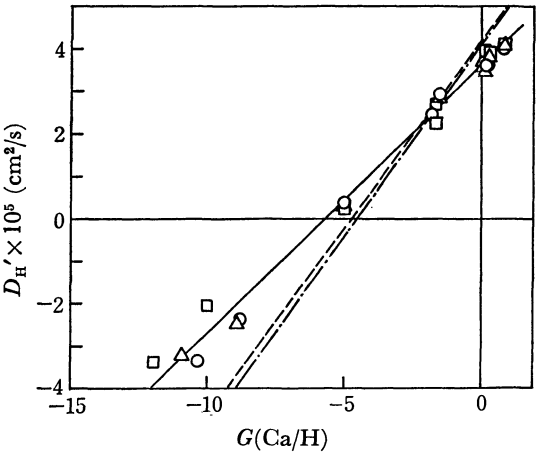

Fig. 5. Dependency of D_H' on G(Ca/H) for F(H/Ca)=2 at 25 °C.
Cell #1, ○; #2, □; #3, △.
Theoretical curves are shown by a broken line for $h_i=0$ and by a chain line for Güntelberg approximation.

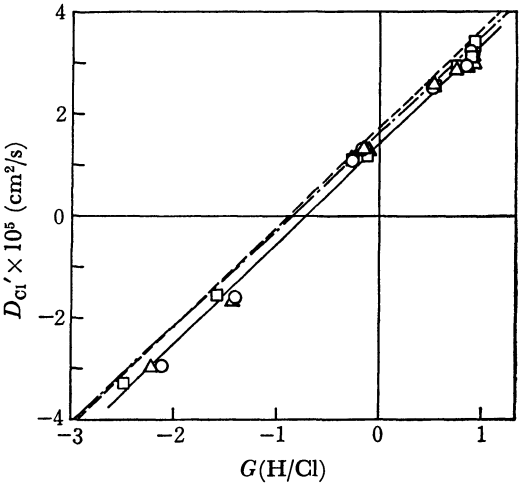

Fig. 6. Dependency of D'_{Cl} on G(H/Cl) for F(H/Ca)=2 at 25 °C.
Cell #1, ○; Cell #2, □; Cell #3, △.
Theoretical curves are shown by a broken line for $h_i=0$ and by a chain line for Güntelberg approximation.

1=Ca^{2+} and 2=H^+, and will be negative when $-G$-(Ca/H) is large, according to Eq. 15, where $B_{Ca}<B_{Cl}$, as is shown in Table 1. The theoretical curves shown in Fig. 5 show the same trend as the experimental results.

The result for D'_{Cl} against G(H/Cl) shown in Fig. 6 is quite similar to that shown in Fig. 5. The relation is linear at a fixed F-value, F(H/Ca)=2, as is to be expected from Eq. 13, and D'_{Cl} becomes negative when $-G$(H/Cl) is large, as is to be expected from Eq. 17, where $B_H>B_{Ca}$, as is shown in Table 1. The discrepancy between experimental and theoretical lines is not large in this case.

Approximation of a Constant Cation Ratio. In our previous papers,[2,4] theoretical equations have been derived, and compared with experimental data, by assuming the fraction of the cation concentrations to be constant throughout the diffusion layer. For a mixed electrolyte solution containing 1 and 2 cations and an anion, 3, the fraction of the equivalent concentration of the 2 cation, ξ_2, defined by:

$$\xi_2 = z_2[2]/(z_1[1]+z_2[2]) \tag{27}$$

may be used in place of $F(1/2)$ and $G(1/2)$ in Eqs. 10a—d, since

$$F(1/2) = G(1/2) = (1-\xi_2)/\xi_2 \tag{28}$$

according to the present assumption. Then, the following equation, which has been given in our previous paper,[4] is obtained:

$$D_2' = kTB_2\frac{(z_1-z_2)B_1(1-\xi_2)+(z_2+|z_3|)B_3}{z_1B_1(1-\xi_2)+z_2B_2\xi_2+|z_3|B_3} \tag{29}$$

The value of D'_2 becomes negative if $z_2>z_1$ and if ξ_2 is small enough, as is shown by the following equation:

$$\xi_2<1-(B_2/B_1)(1+|z_3|/z_2)/(1-z_1/z_2) \quad (z_1<z_2) \tag{30}$$

As for the HCl–$CaCl_2$–H_2O system, the experimental values of D'_i against average ξ_2-values are shown in Fig. 7, together with theoretical broken lines. It may be seen from Fig. 7 that the diffusion coefficient of the slower cation, D'_{Ca}, decreases, both experimentally

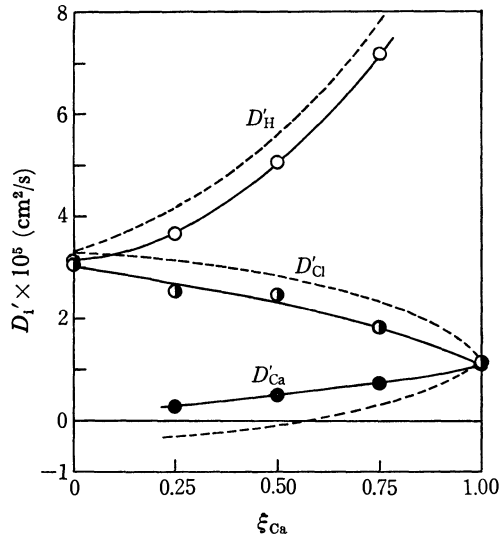

Fig. 7. Relation between D'_i and ξ_{Ca} for aqueous HCl–$CaCl_2$–H_2O solutions at 25 °C.
Experimental data for H^+, ○; Ca^{2+}, ●; Cl^-, ◑.
Broken lines are theoretical for $h_i=1$.

and theoretically, with the decrease in ξ_{Ca}, and that the theoretical curve goes down to negative, as has already been stated,[2,4] although the experimental data do not. This is because the condition $F(1/2)=G(1/2)$ in Eq. 28 is too severe for the accuracy of the present experiments, as may seen from Figs. 3 and 4, which show that D'_{Ca} takes distinctly negative values only in the region where $G(H/Ca)$ is larger than $F(H/Ca)$.

Phenomenological Coefficients. The phenomenological equations of the nonequilibrium thermodynamics are often written as follows for a mixed solution of two electrolytes, A and B[2,3,7,13]:

$$\left.\begin{aligned}[J_A] &= -D_{AA}\left(\frac{\partial[A]}{\partial x}\right) - D_{AB}\left(\frac{\partial[B]}{\partial x}\right)\\ [J_B] &= -D_{BA}\left(\frac{\partial[A]}{\partial x}\right) - D_{BB}\left(\frac{\partial[A]}{\partial x}\right)\end{aligned}\right\} \quad (31)$$

where x is the coordinate in the direction of the diffusion. If the A electrolyte consists of the 1 cation and the anion, 3, and the B electrolyte consists of the 2 cation and the anion, 3, the phenomenological coefficients, D_{AA}, D_{AB}, D_{BA}, and D_{BB}, are related to the mobilities of ions, B_i, according to Eq. 1, since

$$[J_1] = \nu_1[J_A],\quad [J_2] = \nu_2[J_B]$$
$$[1] = \nu_1[A],\quad [2] = \nu_2[B] \quad (32)$$

where ν_1 and ν_2 are the numbers of the respective cations contained in one mole of the electrolytes. The results are given by Eqs. 24—27 of Ref. 7.

This treatment is, however, rather formalistic, because what really exist in the solution of strong electrolytes are not the electrolytes, A and B, but the ions, 1, 2, and 3. For each ion, the phenomenological equation may be written as follows:

$$[J_i] = \sum_j L_{ij}(\partial[j]/\partial x) \quad (33)$$

According to Eq. 1, therefore,

$$L_{ii} = -D_i$$
$$L_{ij} = z_i z_j B_i D_j [i]/(\sum_k z_k^2 B_k [k]) \quad (34)$$

If, however, the phenomenological equations are written on the basis of the physico-chemical potentials of the ions, $\tilde{\mu}_i$, as in the following equation,[14]

$$[J_i] = -\sum_j l_{ij}(\partial\tilde{\mu}_j/\partial x) \quad (35)$$

then Eq. 1 corresponds to the case of $l_{ij}=0$ $(i\neq j)$. This means that the cross terms have not yet been taken into consideration, even though the L_{ij} of Eq. 34 and the D_{AB} and D_{BA} of Eq. 31 are not zero.

The possibility that the cross terms, l_{ij}, are not zero might be important in explaining the discrepancy seen in the quantitative comparisons between the theoretical and experimental results, as shown in Figs. 3—7 of this paper. In order to discuss this point further, however, the experimental problems which are related to taking the averages of the concentration gradients between the initial and final values must be settled first, although these expedients do not affect the facts that ions migrated from the lower to the higher concentrations and that the reverse diffusion was actually observed experimentally. Further studies will be reported separately.

Solvation Effects on the Electron-Transfer Reaction of TCNQ Anion Radical and 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone

Akihiko YAMAGISHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 15, 1975)

Rate constants were obtained with a temperature-jump apparatus for the electron-transfer reaction between 7,7,8,8-tetracyanoquinodimethane anion radical and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in acetonitrile/tetrahydrofuran (MeCN/THF) and in acetonitrile/water (MeCN/H_2O) mixtures. In MeCN/THF, the forward rate constant (k) was determined in three kinds of mixed solvents: $k=(5\pm2)\times10^9$ $M^{-1}s^{-1}$ (pure MeCN), $(2.2\pm0.2)\times10^9$ $M^{-1}s^{-1}$ (1:2 MeCN/THF), and $(6\pm2)\times10^8$ $M^{-1}s^{-1}$ (1:10 MeCN/THF) at 25 ± 2 °C. In MeCN/H_2O the forward rate constant increases with the square of the H_2O concentration in the range of $[H_2O]=2$—10 M; $k=k_0[H_2O]^2$ with $k_0=(1.0\pm0.2)\times10^6$ $M^{-3}s^{-1}$ at 25 ± 2 °C. The results are discussed in terms of the specific solvation and the ion-pairing of ion radicals.

Recent studies of electron-transfer reactions of ion radicals demonstrate that the solvation structure of an ion radical affects the reaction rate drastically.[1] The specific solvation and ion-pairing with counter ions reduce the electron-transfer rate by a few orders of magnitudes.[1] The conclusion has been deduced mostly from ESR studies of the electron exchange between an ion radical and its parent molecule.

$$R^{\ddagger}\ (\text{or } R^{-}) + R \rightleftharpoons R + R^{\ddagger}\ (\text{or } R^{-})$$

For a reaction of this kind, the free energy change of reaction, $\Delta F°$, is zero.

The present paper gives the results of the temperature-jump study of the reaction between 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ).

$$TCNQ^{-} + DDQ \rightleftharpoons TCNQ + DDQ^{-}, \qquad (1)$$

The electron affinity of DDQ is much greater than that of TCNQ, indicating that $\Delta F°$ of Reaction 1 is largely negative.[2,3] It was intended to see whether the specific solvation and the ion-pairing still cause an additional energy barrier even under the conditions of a negative free energy change, $\Delta F°<0$.

Experimental

Sodium (Na^+) and tetraethylammonium (NEt_4^+) salts of TCNQ and DDQ were prepared by the reduction with NaI and NEt_4I, respectively. $NaClO_4$ and $NaB(C_6H_5)_4$ were used without purification. NEt_4ClO_4 was prepared by the reaction of NEt_4OH with $HClO_4$. MeCN and THF were distilled with a distillation column of *ca.* 30 cm length, H_2O contents being 0.5 mg/ml (MeCN) and 1.7 mg/ml (THF). Both were stored under $CaCl_2$. H_2O was distilled after being deionized.

The instruments for equiliblrium, conductivity and rate measurements were described elsewhere.[4] As regards the temperature-jump apparatus, the rise time of temperature was determined by following the decrease of a DDQ^- dimer at 700 nm after the temperature-jump; *e.g.* for 1:10 MeCN/THF solvent containing 0.01 M NEt_4ClO_4 and *ca.* 10^{-3} M NEt_4^+-DDQ^-, the 90% temperature rise was attained within 10 μs. Equilibrium measurements were carried out at 25 ± 1 °C. For temperature-jump measurements, samples were kept at 20 ± 1 °C. The difference in temperature between static and kinetic results was neglected.

Results

Reactions in MeCN/THF. The apparent equilibrium constant of Reaction 1 in MeCN/THF was determined in the same way as for MeCN solvent.[5]

$$K_{ap} = [TCNQ][DDQ^-]_t/[TCNQ^-]_t[DDQ]$$

where $[\ ]_t$ denotes the total concentration of each ion radical, since an ion radical is present as either a free ion or an ion-paired ion. $[TCNQ^-]_t$ is calculated from the absorbance at 842 nm, assuming $\varepsilon=4.33\times10^4$ for all the solvents. $[DDQ^-]_t$ is equated to $[DDQ^-]_t=[DDQ^-]^0+\Delta[TCNQ^-]$, where $[DDQ^-]^0$ is the initial concentration of DDQ^- and $\Delta[TCNQ^-]$ the decrease of $TCNQ^-$ when DDQ is added. K_{ap} thus obtained is plotted against the volume percent of THF (Fig. 1).

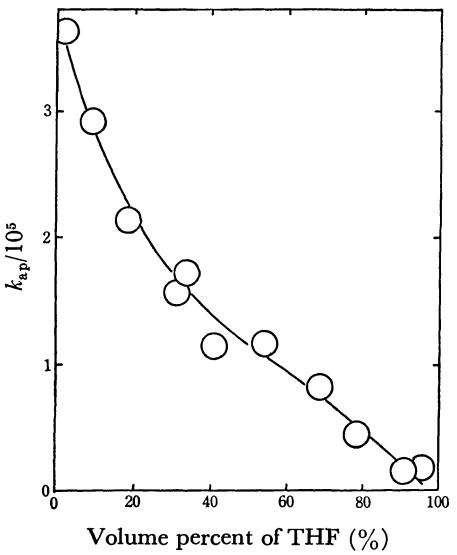

Fig. 1. K_{ap} obtained in MeCN/THF mixtures.

K_{ap} was also obtained in the presence of various amounts of added salts. The results are given in Table 1. The addition of $NaClO_4$ gives a negligible effect on K_{ap} in pure MeCN. In 1:2 MeCN/THF, however, K_{ap} increases as $[NaClO_4]$ increases. In 1:10 MeCN/THF, the small amount of $NaB(C_6H_5)_4$ increases K_{ap} remarkably, while further addition of the salt decreases K_{ap}.

Table 1. The effect of Na^+ on K_{ap}

a) In MeCN; $K^0_{ap}=3.6\times10^5$ [a]				
$[NaClO_4]$/M	0.012	0.041	0.12	0.21
K_{ap}/K^0_{ap} at 25 °C	1.0	1.0	1.0	1.0
b) In 1:2 MeCN/THF; $K^0_{ap}=8.2\times10^4$ [a]				
$[NaClO_4]$/M	0.0072	0.025	0.057	0.087
K_{ap}/K^0_{ap}	1.3	1.5	1.5	1.7
c) In 1:10 MeCN/THF; $K^0_{ap}=1.0\times10^4$ [a]				
$[NaB(C_6H_5)_4]$/M	0.0011	0.0022	0.0043	0.01
K_{ap}/K^0_{ap}	1.5	1.5	1.4	1.1

a) K^0_{ap} denotes K_{ap} at $[Na^+]=0$.

Table 2. The molar conductivity, λ, of $NEt_4^+TCNQ^-$ and $NEt_4^+DDQ^-$

a) $NEt_4^+TCNQ^-$ in MeCN				
$[NEt_4^+TCNQ^-]\times10^6$/M	2.2	4.5	8.8	14
λ	145	132	123	111
b) $NEt_4^+TCNQ^-$ in 1:2 MeCN/THF				
$[NEt_4^+TCNQ^-]\times10^6$/M	5.3	10	21	
λ	112	112	107	
c) $NEt_4^+TCNQ^-$ in THF				
$[NEt_4^+TCNQ^-]\times10^6$/M	2.1	3.7	5.9	9.1
λ	65.5	61.7	60.7	57.0
d) NEt_4^+ DDQ^- in MeCN				
$[NEt_4^+DDQ^-]\times10^5$/M	6.3	9.5	14	32
λ	240	238	240	232
e) $NEt_4^+DDQ^-$ in THF				
$[NEt_4DDQ^-]\times10^5$/M	1.2	2.5	4.9	9.3	16
λ	123	91.8	66.9	49.5	40.1

In order to obtain the dissociation constants of ion radical salts, the molar conductivities of $NEt_4^+TCNQ^-$ and $NEt_4^+DDQ^-$ were measured in MeCN/THF (Table 2). The dissociation constant, K_D, for

$$NEt_4^+R^- \rightleftharpoons NEt_4^+ + R^-$$

is roughly estimated by means of the equation.

$$K_D = \frac{C\lambda^2}{\lambda_\infty^2}. \quad (2)$$

Where C is the total concentration of an ion radical salt and λ_∞ the molar conductivity at infinite dilution. For $NEt_4^+DDQ^-$ in THF, K_D is obtained to be $(4.9\pm1.0)\times10^{-5}$ M at 25 ± 2 °C. In the other solvents, however, K_D defined by Eq. 2 gives no constant value, making the estimation of K_D impossible.

Temperature-jump studies were performed in MeCN, 1:2 MeCN/THF, and 1:10 MeCN/THF in order to obtain the rate constans of Reaction 1. With a temperature-rise, the trasient increase of $TCNQ^-$ is observed at 745 nm in all the solvents. k_{obs} defined by

$$-\frac{d\Delta[TCNQ^-]}{dt} = k_{obs}\Delta[TCNQ^-] \quad (3)$$

is related to the forward rate constant as follows.[5]

$$k_{obs} = k\{[TCNQ^-]_{t,e}+[DDQ]_e\}, \quad (4)$$

where $[\ ]_e$ denotes the equilibrium concentration at an elevated temperature. The k values determined at various concentrations of supporting electrolytes are given in Table 3.

Table 3. k at various concentrations of counter ions at 25 °C

a) MeCN				
$[NEt_4ClO_4]$/M	0.012			
$k\times10^{-9}/M^{-1}s^{-1}$	5 ± 2			
b) 1:2 MeCN/THF				
$[NEt_4ClO_4]$/M	0.0012	0.0024	0.0050	0.010
$k\times10^{-9}/M^{-1}s^{-1}$	2.6 ± 0.5	2.2 ± 0.5	2.2 ± 0.5	2.2 ± 0.5
c) 1:10 MeCN/THF				
$[NaB(C_6H_5)_4]$/M	0.006	0.012	0.024	
$k\times10^{-8}/M^{-1}s^{-1}$	7 ± 2	5 ± 2	6 ± 2	

Reactions in MeCN/H_2O: The apparent equilibrium constant of Reaction 1 in MeCN/H_2O was determined in the same way as in MeCN/THF. A large uncertainty in K_{ap} arises in the higher concentration of H_2O, since DDQ^- decomposes gradually in such regions and DDQ is reduced to DDQ^-. K_{ap} thus obtained is plotted against the volume percent of H_2O (Fig. 2).

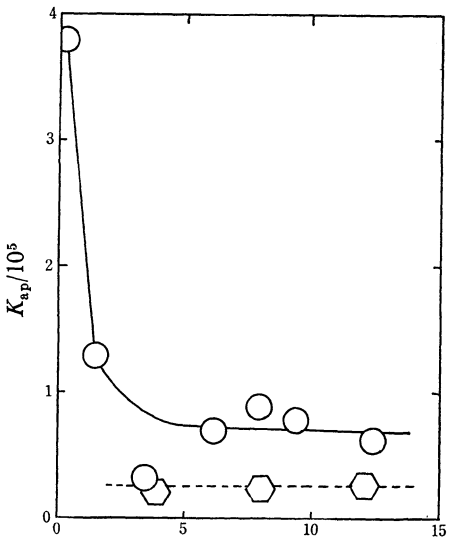

Fig. 2. K_{ap} obtained in MeCN/H_2O mixtures; A solid line is determined by spectrophotometric measurements and a dotted line by rate measurements.

The rates of Reaction 1 in MeCN/H_2O mixtures were determined using a temperature-jump apparatus. In MeCN/H_2O, the trasient increase of $TCNQ^-$ is observed at 745 nm with temperature-rise. k_{obs} defined by Eq. 3 is determined by varying the concentrations of $TCNQ^-$ and DDQ at constant concentrations of TCNQ and DDQ^-. Under these conditions, Eq. 4 is transformed into

$$k_{obs} = k\{[TCNQ^-]_e + C/[TCNQ^-]_e\}, \quad (5)$$

where C is a constant given by

$$C = [TCNQ]_e[DDQ^-]_{t,e}/K_{ap}.$$

The dependence of k_{obsd} on $[TCNQ^-]_e$ is shown in Fig. 3. As expected from Eq. 5, k_{obsd} becomes minimum for a certain value of $[TCNQ^-]_e$. This concentration is denoted by $[TCNQ^-]_e^*$. It is apparent from Eq. 5 that $[TCNQ^-]_e$ is equal to $[DDQ]_e$ at $[TCNQ^-]_e^*$. Using

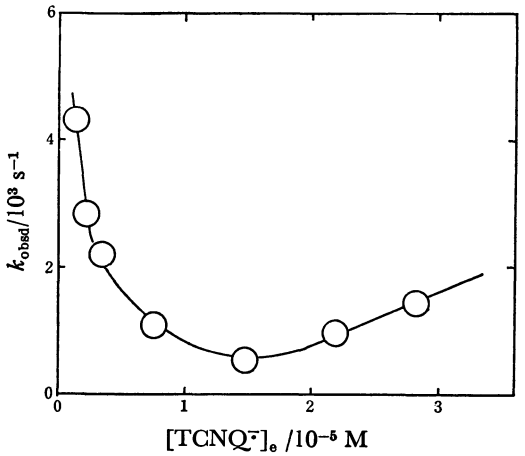

Fig. 3. Dependence of k_{obsd} on [TCNQ$^-$]$_e$ in 9: 1 MeCN/H_2O; [TCNQ] 1.1×10^{-3} M and [NEt_4^+DDQ$^-$] 4.1×10^{-4} M.

the value of [TCNQ$^-$]$_e$*, K_{ap} is determined by

$$K_{ap} = [TCNQ]_e[DDQ^-]_{t,e}/[TCNQ^-]_e{}^{*2}.$$

K_{ap} obtained in this way agrees with the one obtained by the equilibrium measurements within a factor of 5 (a dotted curve, Fig. 2).

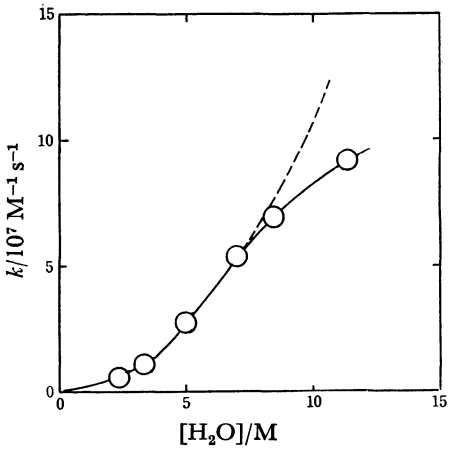

Fig. 4. Dependence of k on the H_2O concentration. A dotted curve denotes the calculated values according to Eq. 6.

Figure 4 gives the dependence of k on the concentration of H_2O. It is concluded that k increases with the square of the H_2O concentration from 2 to 10 M.[6]

$$k = k_0[H_2O]^2$$
$$k_0 = (1.0\pm0.2)\times10^6\ M^{-3}\ s^{-1} \text{ at } 25\pm2°C. \quad (6)$$

Discussion

The effect of THF on the equilibrium and the rates of Reaction 1 is interpreted in terms of the ion-pairing of ion radicals.

$$\begin{array}{ccc} TCNQ^- + DDQ & \overset{k_1}{\rightleftharpoons} & TCNQ + DDQ^- \\ M^+ \uparrow\downarrow & & \uparrow\downarrow M^+ \\ M^+TCNQ^- + DDQ & \underset{k_2}{\rightleftharpoons} & TCNQ + M^+DDQ^- \end{array} \quad (7)$$

K_{ap} is expressed in terms of the dissociation constants of M$^+$TCNQ$^-$ and M$^+$DDQ$^-$, K_D^T and K_D^P, respectively, as follows.

$$K_{ap} = K_0(1+[M^+]/K_D^P)/(1+[M^+]/K_D^T) \quad (8)$$

where K_0 is the equilibrium constant for the electron-transfer reaction of free ions.

$$K_0 = \frac{[TCNQ][DDQ^-]}{[TCNQ^-][DDQ]}$$

K_{ap} in MeCN only slightly varies with the addition of $NaClO_4$ (Table 1). This indicates that K_D^T is nearly equal to K_D^P previously determined to be 0.40 M.[4] On the other hand, K_{ap} in 1 : 10 MeCN/THF increases rapidly until it reaches a constant value. According to Eq. 8, this implies that K_D^P is smaller than K_D^T in this medium. From the limiting value of $K_{ap}/K^0_{ap}=1.5$ at the region of [$NaB(C_6H_5)_4$]=0.0011—0.0022 M, K_D^T is equated to 1.5 K_D^P. Assuming that K_D^P in 1 : 10 MeCN/THF does not differ from K_D^P in THF ($4.9\pm1.0\times10^{-5}$ M), K_D^P and K_D^T are roughly estimated to be 5×10^{-5} M and 8×10^{-5} M, respectively.

Under the scheme of Eq. 7, k is expressed in terms of K_D^T and K_D^P as follows.

$$k = k_1\left(\frac{K_D^T}{[M^+]+K_D^T}\right) + k_2\left(\frac{[M^+]}{[M^+]+K_D^T}\right), \quad (9)$$

where k_1 and k_2 are the forward rate constants for the reactions between TCNQ$^-$ and DDQ and between M$^+$TCNQ$^-$ and DDQ, respectively. In deriving the equation, the rate of ion-pairing of TCNQ$^-$ with M$^+$ is assumed to be much greater than that of electron-transfer. Taking [Na^+]≈[$NaB(C_6H_5)_4$]≈10^{-2} M and $K_D^T\approx8\times10^{-5}$ M in 1 : 10 MeCN/THF, k is simply equated to k_2 in this solvent. k_2 in 1 : 10 MeCN/THF is about one order smaller than in MeCN. It is concluded that the transfer process of Na^+ causes an additional energy barrier even under the conditions of a negative free energy change, $\Delta F° < 0$.

The effects of H_2O on the equilibrium and rate constants are most likely ascribed to the capacity of H_2O for hydrogen-bonding. As regards DDQ and its anion radical, the formation of hydrogen bond with H_2O has been confirmed by polarographic investigations.[3] The decrease of K_{ap} in MeCN/H_2O indicates that the free energy change of reaction, $\Delta F°$, becomes less negative. This seems closely related to the fact that the electron affinity of DDQ decreases in hydroxylic solvents like H_2O and ethanol.[3] The specific solvation of DDQ and DDQ$^-$ by H_2O is thus concluded from Fig. 2 to be completed at the concentration of [H_2O]= 6 vol. %.

The kinetic result shown in Fig. 4 implies that H_2O acts catalytically in electron-transfer. From the dependence of the forward rate on [H_2O] (Eq. 6), it is suggested that a part of DDQ is solvated by two H_2O molecules to form DDQ(H_2O)$_2$, and that electron-transfer takes place through this species.

$$TCNQ^- + DDQ(H_2O)_2 \rightleftharpoons TCNQ + DDQ^-(H_2O)_2 \quad (8)$$

It is assumed herewith that TCNQ does not form hydrogen-bond with H_2O in the investigated region of

[H_2O] since a carbon atom is a weaker proton acceptor than an oxygen atom.[7]

The author thanks Prof. Masatoshi Fujimoto for his encouragement. This work was supported by the ministry of Education.

Photolysis of Formaldehyde in the Presence of Nitric Oxide

Kohji TADASA,* Naomi IMAI, and Tetsuo INABA

Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Sakai, Osaka 591

(Received October 31, 1975)

The photolysis of CH_2O has been studied in the absence and presence of NO from room temperature to 300 °C. In the photolysis of CH_2O alone, the CO and H_2 formation rates increase greatly with temperature. When NO is added, these rates vary and reach constant values with an increase in the amount of NO. These limiting rates are independent of the temperature to within the experimental error, in contrast to the rates observed for CH_2O alone. It is suggested that the limiting rate of CO formation corresponds to the sum of the rates of the two primary processes, the molecular and radical reactions, and that that of H_2 formation corresponds to the rate of the molecular process. For photolysis totally inhibited by NO, the rates of formation of CO, H_2, N_2, and N_2O were examined and a reaction mechanism is proposed which is consistent with that for the photosensitized reaction between hydrogen and nitric oxide previously studied in this laboratory.

The effect of the addition of nitric oxide on the pyrolysis of formaldehyde has been investigated in this laboratory and it was found that nitric oxide very effectively inhibits the radical chain process, while nitric oxide reacts with formaldehyde at high temperature forming CHO radicals.[1] Thus, NO has both inhibitive and accelerative effects on the free radical process, rendering the elucidation of the overall reaction mechanism very difficult.

In the work reported here, the photolysis of CH_2O was investigated in the presence of NO at lower temperatures, for which the thermal reaction between NO and CH_2O is negligible and NO reacts only with radicals formed photochemically.

Experimental

Materials. Formaldehyde was prepared from paraformaldehyde. The method of preperation and purification are same as those in a previous paper.[1] Nitric oxide was obtained from Takachiho Kagaku Co., Ltd. with a research-grade purity of 99.6%, and subjected to several trap-to-trap distillations.

Apparatus. The reaction was studied in a conventional static system, and was carried out in a cylindrical quartz vessel of 262 ml placed in an electric furnace, which was wrapped in asbestos and placed inside a cylindrical alminum collar 20 cm long and 9 cm in diameter with walls 1.6 cm thick, for the purpose of maintaining a constant temperature.

The light source was a medium pressure mercury arc. A glass filter was used to remove light of wavelength less than 2700 Å.

Procedure. Formaldehyde and nitric oxide were introduced into the vessel, which was maintained at the experimental temperature. For all experiments, the incident light intensity was the same. The photolytic products were separated by means of cold traps and a Toepler pump, and analyzed quantitatively by means of a gas chromatograph. The separation and analysis techniques are similar to those described in a previous paper.[1]

Results

The amounts of CO, H_2, N_2, and N_2O produced during the photolysis of CH_2O with NO were measured. A large amount of H_2O was found, but it was not measured. An unmeasurable amount of CO_2 was observed at room temperature. No methanol was detected, although it is important in the pyrolysis.

The yields of CO, H_2, N_2, and N_2O were measured at different reaction times during the uninhibited and inhibited photolysis. Some results are given in Fig. 1, which shows that the amount of each product increases linearly from the beginning of the photolysis. The initial rate of formation of each product, in all experiments, was determined by the amount produced after 10 min of photolysis.

Figure 2 shows the results of a series of runs carried out at a constant pressure of formaldehyde (100 Torr) and various pressures of NO (0—100 Torr) at (a) room temperature, (b) 100 °C, (c) 200 °C, and (d) 300 °C. On the other hand, Fig. 3 shows the effect of the CH_2O pressure (20—120 Torr) on the photolysis for a fixed amount of NO (50 Torr) at (a) 100 °C and (b) 200 °C.

Discussion

The photodecomposition of CH_2O has been studied by a number of workers and it is well established that the photolysis occurs *via* two primary processes.[2-4]

$$CH_2O + h\nu \longrightarrow H + CHO \quad (I)$$
$$\longrightarrow H_2 + CO \quad (II)$$

Sperling and Toby[4] observed that the quantum yields of the H_2 and CO formations do not vary with temperature between 80 and 120 °C. On the other hand, Akeroyd and Norrish,[2] and Calvert and Steacie[5] have found the quantum yield of CH_2O photolysis to increase with temperature at high temperatures, *e.g.*, $\phi_{CO}=1.0$ at 101 °C, 5.4 at 196 °C, and 69 at 295 °C.[5] In this work, the results shown in Fig. 2 (NO=0 Torr) indicate that the rates of H_2 and CO formation increase with temperature in a manner similar to that observed by them. Such a temperature dependency of the quantum yields, together with the fact that nearly equal amounts of H_2 and CO are produced in the photolysis indicates that Process I is followed by the chain process, which is assumed to proceed mainly *via* the following reactions:

$$H + CH_2O \longrightarrow H_2 + CHO$$
$$CHO + M \longrightarrow CO + H + M$$
$$CHO + (wall) \longrightarrow products + (wall)$$

When NO is added to the CH_2O during photolysis, the rates of CO and H_2 formation vary and attain limiting values for increasing amounts of NO, as is shown in Fig. 2. The limiting rates of CO and H_2

formation are approximately independent of the temperature, contrary to those for the photolysis of CH_2O alone.

Since, in the CH_2O pyrolysis, H_2 formation is almost totally inhibited by a small amount of NO, the rate of H_2 formation which occurs for photolysis with NO added can be attributed to the molecular Process II. The difference between the limiting rates of the CO and H_2 formations should be regarded as the rate of CO formation caused by Process I. The following discussion will, therefore, concern the radical process caused by Reaction I under conditions of sufficient inhibition by NO ($P_{NO}>30$ Torr).

The Hg-photosensitized reaction of H_2 and NO[6] has been studied in this laboratory in order to study the reactions in a system containing H atoms and NO at low temperature. In this photosensitization, it was found that the main products are H_2O and N_2, with the H_2O formation being of the zeroth order and the N_2 formation of the first order with respect to NO at room temperature. A third product is N_2O and its rate of formation decreases with the amount of NO. Although the amount of H_2O in the products was not measured in the work reported here, stoichiometry predicts that

$$R_{CO} - R_{H_2} = R_{H_2O}$$

i.e., the same amounts of CO and H_2O are formed by the radical process. The reaction orders of the H_2O, N_2, and N_2O formations with respect to NO are quite similar both for H_2–NO photosensitization and for the photolysis studied at room temperature, indicating that these products are formed by similar processes in both cases.

Thus, the following reaction scheme is proposed for the radical process of CH_2O–NO photolysis at room temperature, the scheme being consistent with that of H_2–NO photosensitization:

$$CH_2O + h\nu \longrightarrow CHO + H \quad (I)$$
$$CHO + M \longrightarrow CO + H + M \quad (1)$$
$$CHO + HO \longrightarrow CO + HNO \quad (2)$$
$$H + NO + M \longrightarrow HNO + M \quad (3)$$
$$2HNO \longrightarrow H_2O + N_2O \quad (4)$$
$$HNO + 2NO \longrightarrow N_2 + H + NO_3 \quad (5)$$
$$NO_3 + NO \longrightarrow 2NO_2 \quad (6)$$
$$NO_2 + HNO \longrightarrow OH + 2NO \quad (7)$$
$$OH + HNO \longrightarrow H_2O + NO \quad (8)$$

This reaction scheme leads to the following rate equations:

$$R_{CO} = R_1 + R_2 = I_{a(I)}$$
$$R_{H_2O} = R_4 + R_8 = I_{a(I)},$$

where $I_{a(I)}$ refers to the rate of the primary Reaction I.

The extinction coefficient of CH_2O has been estimated to be ε=4.84,[4] 1.87,[4] and 0.07[7] mol^{-1} l cm^{-1} at 313, 334, and 366 nm, respectively. In Fig. 3, the dotted lines are drawn since the rate is proportional to the intensity of light absorbed by CH_2O using the value of the extinction coefficient given above at 313 nm. Although the curvatures of the observed values are larger than those calculated, the differences are not as large. Thus, Figs. 2 and 3 show that R_{CO} and R_{H_2O} in the radical process ($=R_{CO(total)}-R_{H_2}$) are proportional to I_a and are independent of the NO pressure, supporting the above rate equations.

According to the above reaction scheme, N_2 is produced by the chain disproportionation of NO, Reactions 5 and 3,[8] and N_2O is produced by the disproportionation of HNO, Reaction 4.[9] Hence,

$$R_{N_2} = k_5[HNO][NO]^2$$
$$R_{N_2O} = k_4[HNO]^2,$$

where [HNO] can be obtained from the following equation

$$I_{a(I)} = k_4[HNO]^2 + k_7[NO_2][HNO].$$

As discussed in a previous paper on H_2–NO photosensitization,[6] the following relations hold if $R_4 \ll R_7 (= R_8)$** and $[NO_2] \propto [NO]$***, NO_2 being consumed by reaction with Hg in the reaction cell, the amount of which it is not possible to measure accurately:

$$R_{N_2} \propto I_a[NO]$$
$$R_{N_2O} \propto I_a^2/[NO]^2$$

Figure 2(a) indicates that these relations are approximately valid at room temperature.

At higher temperatures, however, the above rate expressions for N_2 and N_2O do not hold as is shown in Figs. 2(b), (c), and (d). As the temperature rises up to 200 °C, moreover, R_{N_2} decreases and R_{N_2O} increases, with the latter decreasing for temperatures above 200 °C. Such dependencies on the temperature were also observed for H_2–NO photosensitization and can be explained by a similar reaction mechanism. Since Reaction 5 is a termolecular reaction, its rate should decrease for a rise in temperature, causing a decrease of R_{N_2}. The increase of R_{N_2O} with the temperature increase is assumed to be caused by the following reaction:

$$HNO + NO \longrightarrow N_2O + OH \quad (9)$$

in addition to Reaction 4, which appears to have a small activation energy and a rate that should not depend greatly on the temperature. At temperatures higher than 200 °C, the following reaction will proceed:

$$2HNO \longrightarrow 2OH + N_2 \quad (10)$$

Thus, a great amount of HNO is consumed by Reactions 10 and 8, with the R_{N_2O} being decreased by Reactions 4 and 9. The relations $R_{CO}=I_{a(I)}$ and $R_{H_2O}=I_{a(I)}$, however, are valid even for the reaction scheme at high temperature.

Excited-State Dipole Moments of Azulene and 3,5-Dimethylcyclopenta[*ef*]heptalene

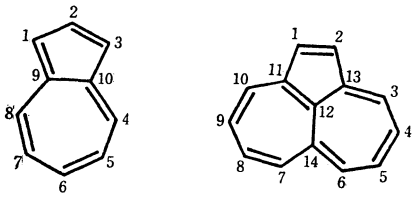
Hiroyuki YAMAGUCHI, Teruki IKEDA,* and Hiroaki MAMETSUKA**

Department of Chemistry, Kumamoto University, Kumamoto 860

(Received November 6, 1975)

The dipole moments of the lower two singlet excited states of azulene (I) and 3,5-dimethyl derivative of cyclopenta[*ef*]heptalene (II) have been determined from the frequency shift of the absorption and emission spectra in various solvents. The direction of the excited-state dipole moments of molecules I and II is opposite to the direction of the ground-state dipole moments. The dipole moments of the two excited states of molecules I and II have been calculated by using the semi-empirical SCF-π-MO CI method. There is a general agreement between the theoretical results and the experimental results. This agreement shows that the polarization effect of the σ-electrons is almost identical in the ground and excited states of both molecules.

Many phenomena occurring in the electronically-excited states of molecules, such as photochemical reactions, are dependent on the changes in the electronic structures. Electronic excitation in molecules usually leads to a new electron density distribution and, consequently, to changes in dipole moments. Pariser[1] has calculated the dipole moments for the singlet excited states of azulene (I) and found that they increase in magnitude and reverse in sign with respect to the ground state. This behavior has been used to interpret the blue shift of the longest absorption band going from a nonpolar solvent to a polar solvent.



I II

Fig. 1. Numbering of carbon atoms.

The change in dipole moment for the excited state of a polar molecule could be measured by observing the absorption and emission spectra, as suggested by Mataga *et al.*,[2] Lippert,[3] and McRae.[4] By using the equations developed by McRae, Robertson *et al.*[5] have experimentally investigated the values of the change in dipole moment for each of the singlet excited states of I. However, they have not obtained the definitive values of the change in dipole moment for each of the excited states of I.

The electronic structures of cyclopenta[*ef*]heptalene (II) have been of interest since Hafner and Schneider[7] prepared its dimethyl derivative in 1958—59. The electronic spectra of II may be considered to be well understood as a result of the work of Ali and Coulson,[8] Julg and Francois,[9] and others.[10] Recently, Eaton *et al.*[11] have shown that the observed emission in the case of 3,5-dimethylcyclopenta[*ef*]heptalene corresponds to anomalous fluorescence due to a transition from the second excited singlet, as in the case of I.

The purpose of our research was to determine experimentally the dipole moments in the lower two electronic excited states of I and the dimethyl derivative of II and to compare the experimental results with the theoretical results obtained by using the semi-empirical SCF-π-MO CI method.[12,13] It may be possible to use the results of such investigations to deepen our understanding of the electronic properties for excited states of nonbenzenoid aromatic hydrocarbons containing an azulene nucleus.

Experimental

Chemicals. Substance I was purchased from Tokyo Kasei Chemicals Co. The 3,5-dimethyl derivative of II was received from Professor K. Hafner. These Substances were carefully purified by recrystallization from hexane and by subsequent sublimation *in vacuo*. Both compounds were spectroscopically pure, from comparison with published spectra.[11] The solvents used were carefully purified according to the descriptions in Ref. 14. The purity of solvents was established by checking for emission before use.

Measurements. The dielectric constants were determined with a home-made resonance-method apparatus. A dielectric constant measurement cell with cylindrical platinum electrodes was used. The refractive indices were measured by means of a Pulfrich refractometer. The static dielectric constant (ε) and the refractive index (n) at the sodium D line of the solvents agreed with the values cited in Ref. 14. The densities of the solutions were measured by the use of a pycnometer for volatile liquids. The absorption spectra were obtained with a Cary Model 14 recording spectrophotometer equipped with a thermostated cell holder. The fluorescence spectra were taken with a Shimadzu RF-502 recording spectrophotometer equipped with a thermostated cell holder. The wave numbers of the emission-band maxima were determined from the emission spectra, as corrected for the spectral sensitivity of the instrument. The concentration of I and 3,5-dimethyl derivative of II was kept less than 10^{-4} mol/l for all solutions prepared, so that the system was free from any undersired concentration quenching. All measurements were made on deaerated samples at 20 °C.

Determination of Excited-state Dipole Moments. If we ignore any changes in the solute polarizability on excitation, the solvent shifts can be written as follows:[4] for the wave number of the band maxima of absorption spectra (ν_a)

$$\nu_a = K\left[\frac{n^2-1}{2n^2+1}\right] + C\left[\frac{\varepsilon-1}{\varepsilon+2} - \frac{n^2-1}{n^2+2}\right] + \text{Const.}, \quad (1)$$

* Present address: Japan Spectroscopic Co. Ltd., Hachioji, Tokyo 192

** Present address: Research Institute of Industrial Science, Kyushu University, Fukuoka 812

and for the difference ($\Delta\nu_{af}$) between ν_a and the wave number ν_f of the corresponding fluorescence

$$\Delta\nu_{af} = C'\left[\frac{\varepsilon-1}{\varepsilon+2} - \frac{n^2-1}{n^2+2}\right] + \text{Const.} \quad (2)$$

The constants C and C' are given by Eqs. 3 and 4, respectively,

$$C = \frac{2m_0(m_0-m_i)}{a^3hc} \quad (3)$$

$$C' = \frac{2(m_0-m_i)^2}{a^3hc} \quad (4)$$

where a is the cavity radius in Onsager's theory[6] of the reaction field, and m_0 and m_i are the dipole moments of the ground state and the ith excited state of the solute molecule, respectively.

For the hydrocarbon solvents, the second term of Eq. 1 is zero and the constant K is the least-squares slope of the curve of ν_a against $(n^2-1)/(2n^2+1)$. It remains to evaluate the constants C and C' of Eqs. 1 and 2 for the lower two transitions observed in a range of polar solvents. By using the constant K determined from the nonpolar solvents, the constants C and C' are chosen to give the best reproduction of the observed frequency shifts. From the constants C and C', the excited-state dipole moments, m_i, for each transition of I and the 3,5-dimethyl derivative of II can be calculated using Eqs. 3 and 4 and the dipole moments m_0 determined experimentally.

MO Calculation

The method of calculation used for obtaining the energetically most stable structure in a conjugate molecule is the SCF formalism of the Pariser-Parr-Pople semiempirical MO method,[15,16] taken together with the variable bond-length technique. The C–C bond distances and, correspondingly, the resonance and Coulomb repulsion integrals are allowed to vary with bond orders at each iteration until self-consistency is achieved. Bond lengths are correlated with bond orders by the aid of the following formula:[17]

$$r_{\mu\nu}\,(\text{Å}) = 1.520 - 0.186p_{\mu\nu} \quad (5)$$

The Coulomb repulsion integrals are evaluated using the Mataga-Nishimoto formula.[18] The resonance integral is assumed to be of exponential form $\beta=A\exp(-br)$, the value of exponent b being taken as 1.7Å^{-1}.[12]

As the starting geometries for iterative calculation, we take all the possible structures in which bond lengths are distorted so that the set of displacement vectors may form a basis of an irreducible representation of the full symmetry group of a molecule.

In order to discuss the geometrical structures of electronically excited states, the procedure described above is used, except for the use of a different value, 3.3 Å^{-1}, for exponent b in the exponential form of the resonance integral.[13] This value of b was determined so that the predicted fluorescence energy from the lowest singlet excited state ($^1B_{2u}$) in benzene may fit the experimental value.

In discussing the properties of excited states, configuration mixing of all the singly excited states is included.

Results and Discussion

For the hydrocarbon solvents, the constants K for the first electronic transitions of I and the dimethyl derivative of II were obtained from the least-squares slopes of the curves of ν_a against $(n^2-1)/(2n^2+1)$ (see Figs. 2 and 3). By using the constants K, the constants C for these transitions were chosen to reproduce the frequency shifts observed in a range of polar solvents (see Figs. 4 and 5). The observed $\Delta\nu_{af}$ for the second electronic transitions against $[(\varepsilon-1)/(\varepsilon+2)-(n^2-1)/(n^2+2)]$ rela-

tions are shown in Figs. 6 and 7. The straight lines in the figures were obtained by the least-squares method. The C' values for both molecules were determined by using the slopes of these lines. It was evident that the alcohol solvents had to be separated from the other polar solvents for Eqs. 1 and 2 to represent the frequency shifts successfully. These different results in the alcohol solvents are attributed to hydrogen bonding and to the resulting erroneous value of the local field expressed in terms of the solvent dielectric constant and refractive index in Eqs. 1 and 2. Thus, the constants C and C' were determined from frequency shifts observed in nonalcoholic solvents; these values are listed in Table 1. From Eqs. 3 and 4, the excited-state dipole moments, m_i, for each transition were obtained by using the constants C and C', the experimentally-determined m_0, and the value of a estimated from the apparent molal volume. The results are given in Table 2. Using $a=3$ Å and $a=4$ Å, Robertson *et al.*[5] have obtained the dipole moments for each transition of I. The agreement with the present results in the case of $a=4$ Å is satisfactory, but in the case of $a=3$ Å is less satisfactory.

Table 1. Constants of frequency shifts

Molecule	a (Å)[a]	Excited state	K (cm^{-1})	C (cm^{-1})	C' (cm^{-1})
I	3.65[b]	S_1	499	476	
		S_2			530
II	4.29[b]	S_1	509	399	
		S_2			351

a) Estimated from the apparent molal volume ϕ_v. The ϕ_v is defined by the relation: $\phi_v=1000(d_2-d_1)/(m_1d_2d_{12})+M_1/d_{12}$, where d_2 and d_{12} are the densities of the solvent and the solution of molality m_1 of the solute having molecular weight M_1, respectively. b) Measured in cyclohexane.

Table 2. Excited-state dipole moments

Molecule	Dipole moment (D)[a]	
	S_1	S_2
I	−1.30	−0.60
II	−1.13	−0.37

a) The negative sign represents the fact that the direction of the dipole moment is opposite to that of the ground-state dipole moment.

For molecules I and II, the starting bond distortions belonging to the irreducible representation, a_1 and b_2, of the full symmetry group, C_{2v}, are taken as the starting bond distortions for iterative calculation. It turns out that, in the ground state (S_0) and the two lower excited states (S_1 and S_2) of both molecules, all the starting bond distortions converge into a unique self-consistent set of electronic structures corresponding to C_{2v}. The dipole moments for S_0, S_1, and S_2 states of both molecules are calculated by using the theoretical electron densities and bond lengths. The calculated dipole moments for S_0, S_1, and S_2 of I are 2.82, −3.55, and −2.65 D, respectively, and those of II are 3.08, −3.27, and −1.30 D, respectively. The calculated dipole moment for S_0 of I is somewhat larger than the experimental value 1.0 D.[19] A similar difficulty has been met with in case of II: the calculated value is somewhat larger than the observed value 1.29 D for its 3,5-dimethyl-derivative.[20] Pariser[1] has shown that the disagreement between the theoretical and experimental values is attributable to the polarization effect of the σ-electrons. If the calculated dipole moment for S_0 of II is multiplied

by the correction factor, 1.0/2.82, which is derived from the fact that the calculated dipole moment for S_0 of I must agree with the experimental value, the dipole moment for II is predicted to be 1.09 D, in agreement with the experimental value. If the same procedure is carried out for the dipole moments of the excited states, the dipole moments for S_1 and S_2 states of molecules I and II become −1.26 and −0.94 and −1.16 and −0.46 D, respectively. Such obtained-theoretical values are in general agreement with the experimental values, except that the theoretical values of S_2 for I and II are slightly larger than the observed values. This discrepancy between the experimental moments and the theoretical moments indicates that the σ core is much more polarized in the second excited state than in the first. The methyl groups would not play any decisive role in the equilibrium structures of molecule II.[8]

Since the direction of the dipole moments of the excited states of I and II is opposite to the direction of the dipole moments of the ground states, it may be expected that in the excited states of both molecules the nucleophilic substitution occurs on the five-membered ring and the electrophilic substitution occurs on the seven-membered ring. Recently, Vink *et al.*[21] have shown that with molecule I a reaction starting from the excited state with a nucleophile leads to substitution at the same positions as an electrophilic substitution in the ground state.

One of the present authors (H. Y.) especially wishes to thank Professor T. Nakajima of Tohoku University for his fruitful discussions and to thank Professor K. Hafner of Technische Hochschule Darmstadt for the supply of 3,5-dimethylcyclopenta[*ef*]heptalene. The investigation was supported in part by a Scientific Research Grant from the Ministry of Education.

Infrared Absorption Spectrum of Gaseous CF_3CO Radical; Recording on a Rapid-Scan Infrared Spectrometer

Muneteru KOZUKA and Taro ISOBE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980

(Received November 27, 1975)

A rapid-scan infrared spectrometer capable of scanning the region from 5000 to 650 cm^{-1} in 200 μs was constructed and successfully applied to study CF_3CO radical produced by flash photolysis. Four absorption bands of the radical were detected at 1574, 1338, 1115, and 1024 cm^{-1} for scanning started 25 μs after the firing of a Xe flash tube. They were tentatively assigned to the CO stretching, CF_3 stretching (a species), CF_3 stretching (e species), and CC stretching vibrations, respectively.

The powerful technique of flash photolysis kinetic (UV-visible) spectroscopy, developed by Norrish and Porter[1] and Herzberg and Ramsey,[2] has been extended to the infrared spectral region by Pimentel and his collaborators.[3] They employed, for the first time, a zinc-doped germanium semiconductor detector[4] in their rapid-scan infrared spectrometer. The instrument was capable of scanning the region from 5000 to 650 cm^{-1} in several hundred micro-seconds. The scanning speed corresponded to about 100 times the speed of preceding systems developed by other workers.[5] Using this instrument, they succeeded not only in recording infrared absorption spectra of several new transient intermediates produced by flash photolysis,[3,6-8] but also in developing the first chemical laser[9] and the first photodissociation laser.[10] These new techniques have been successfully used for studying vibrational relaxation processes.[11]

Therefore, it is now possible to record vibrational spectra of tetratomic or larger transient intermediates, and consequently, to elucidate the mechanisms of many complex reactions. Nevertheless, such studies in the infrared spectral region are very few and many interesting chemical systems remain to be examined, while studies in the UV and visible regions are quite numerous.

The present authors constructed a rather conventional rapid-scan infrared spectrometer and succeeded in detecting CF_3CO radical produced by the flash photolysis of CF_3COI. It is hoped that this instrument will be successively improved by introducing the various new techniques developed in recent years.

Experimental

Materials. NH_3, $COCl_2$, and CO_2 gases were obtained commercially and purified by trap-to-trap distillations. CF_3COI (bp 7 °C) was prepared by a reaction of CF_3COBr (bp 2 °C) with KI. CF_3COBr was obtained by a reaction of CF_3COOH and PBr_3. Immediately before recording the spectra, CF_3COI was decolorized with Cu powder and distilled to eliminate the I_2 released.

Instrument. The instrument consists of a monochromator with a high-speed rotating Littrow mirror, a copper-doped germanium detector (Fujitsu Corp.), a Globar source, a 40-cm quartz gas cell, photolysis flash circuitry and a time base pulse control circuit.

The spectrometer optical path is shown in Fig. 1. In order to protect the detector from the discharge noise of the Xe flash tube, the optical bench of the detector and monochromator sections is separated from that of the Globar source and sample cell sections. This also facilitates the exchange of the light source unit and the sample cell. The collimator mirror, M_8, is an off-axis paraboloidal mirror 60 mm in diameter and with a 280-mm focal length. The rotating Littrow mirror which is made of glass in the form of a tetragonal prism (JASCO Corp.), is used for rapid scanning of the wavelength. Each of the four faces is 50 mm high and 60 mm wide; the face-to-face angles and the face-to-shaft angle are accurate to 6″ and 10″, respectively. The reflecting surfaces are aluminized. The mirror housing is installed on the spectrometer table, while, in order to reduce mechanical vibration, the drive motor (Matsushita Denki Corp., Model SCD-W 150) is set on an independent frame, and both are connected by means of a slender rubber tube (10 mm o.d., 8 mm i.d. and 30 mm long). Rotation at 3000 min^{-1} produces a slight mechanical vibration of the spectrometer table, while rotation at 6000 min^{-1} is well balanced on a frame for adjustment. The mirror scans the 4000—650 cm^{-1} region with a rotation of about 3.3°, so that a speed of 2750 min^{-1} permits the region to be scanned in about 200 μs.

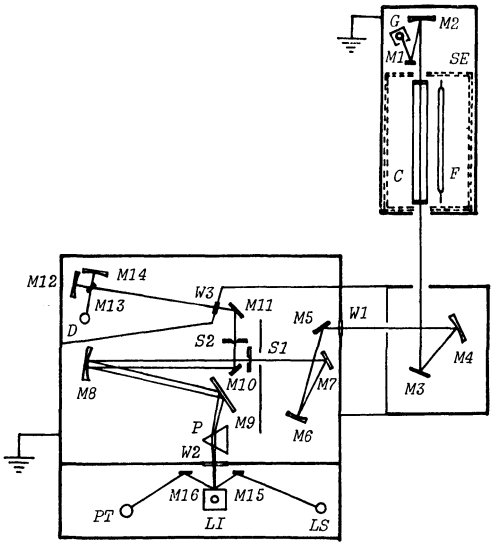

Fig. 1. Optical layout of rapid-scan infrared spectrometer. G: Globar source; SE: electro-magnetic shield; F: Xe flash tube; C: 40 cm quartz gas cell; W_1, W_2, and W_3: NaCl Windows; S_1: entrance slit; S_2: exit slit; P: NaCl prism; M_1, M_3, M_5, M_7, M_{10}, M_{11}, M_{13}, M_{15}, and M_{16}: planar mirrors; M_2, M_4, and M_{12}: spherical mirrors; M_6: troid; M_8: off-axis paraboloid; M_{14}: paraboloid; LI: littrow mirror (tetragonal prism); LS: trigger source (tungsten bulb); PT: phototransistor (OS-14). The light path length from the source to the detector is 4.4 m.

A copper-doped germanium crystal was chosen as the detector on the basis of three criteria: response time, sensitivity, and frequency range. The size is $2.5\times5.0\times6.0$ mm. One of the faces of area 5.0×6.0 mm is soldered onto a copper cooling holder in specially-designed helium cryostat,[12] using indium and Wood's metal (mp 75 °C). A detector temperature of 4 K was routinely maintained using 1.1 l of liquid helium at reduced pressure (15 mmHg) for 8 h. The temperature was measured with a gold-doped germanium resistor, Cryo Resistor Model CR-1000 (Cryo Cal. Inc.). The background radiation was minimized with a silver film shield maintained at 4 K, an outer copper-plate shield at 77 K, and a KBr plate filter at 77 K. The detector element is visible from the room temperature side through an angle of about 35°. The measured response time was less than 0.05 μs,[13] the detectivity D* (500 K, 1800) 3×10^{10} cm·$Hz^{1/2}\cdot W^{-1}$,[13] the dark resistance 160 kΩ at DC bias current of 50 μA, and the sensitive frequency range approximately 6000—350 cm^{-1}, with maximum sensitivity at about 500 cm^{-1}. The detector leads pass through insulated feed throughs to a small circuit board mounted on the outer wall of the cryostat. This circuit, designed to minimize lead capacitance, contains a power supply (22.5 V dry-cell battery), and a load resistor (100 kΩ carbon-deposited resistor). The signal is fed to a Keithley 102-B wide band preamplifier (2—1.7×10^6 Hz and 0.5—150×10^3 Hz bandpasses available), and then to a synchroscope (Iwasaki Tsushinki Corp., Model SS-5102) equipped with a *Multi-Trace* preamplifier plug-in unit (Iwasaki Tsushinki Corp., Model SP-05M-B). The detector system is shilded with copper and mu-metal screens in order to reduce the discharge noise.

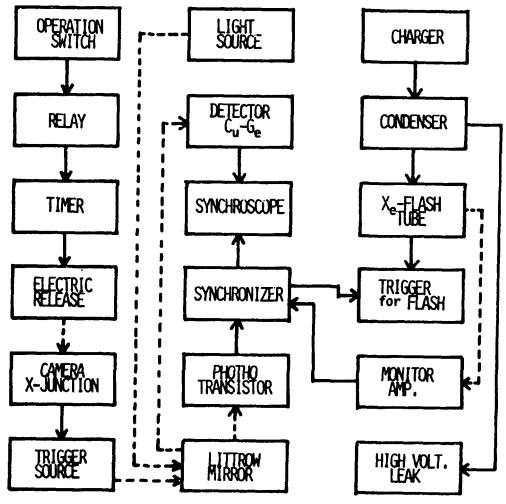

Fig. 2. Block diagram of whole electric system. Real and dotted lines denote electric and optical connections, respectively.

The flash photolysis lamp is a 10 i.d. × 440 mm quartz tube with concentric tungsten electrodes 2 mm in diameter. The lamp is filled with Xe to a pressure of 25 mmHg. The unit is capable of dissipating 600 J in about 20 μs. This energy is supplied by six 8.0 μF condensers charged to 5 kV.

A block diagram of the entire electrical system is shown in Fig. 2. Operation on a micro-second time scale raises special synchronization and recording problem. Firstly, the flash photolysis lamp must be fired, and, after a 25-μs delay for detector recovery, the Littrow mirror must be at the correct angular position to begin the spectral scan. During the next 200 μs, the voltage trace must be recorded. This is accomplished with the specially-designed time-base pulse-control

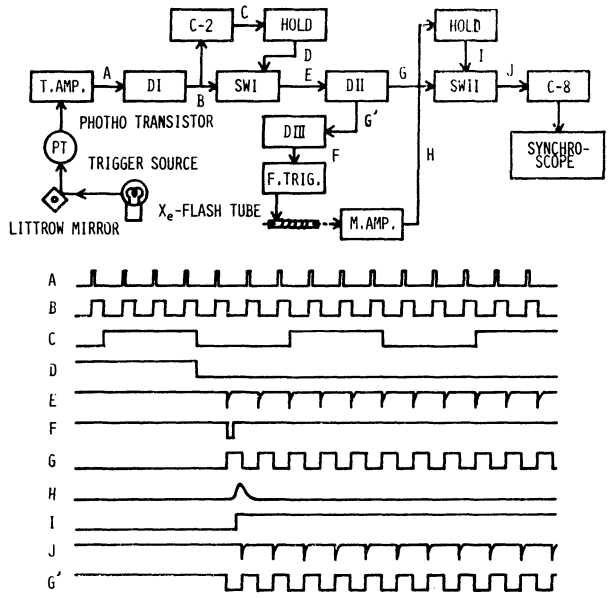

Fig. 3. Block diagram of time base pulse control system (synchronizer) and its timing chart. T. Amp.: amplifier for trigger pulse, F. Trig.: trigger for flash, M. Amp.: monitor amplifier.

circuit, *Synchronizer*, shown in Fig. 3. When the *Operation Switch* (in Fig. 2) is turned on, the *Electrical Release*, which is made of a speaker magnet coil, pushes the shutter of the camera. The *Trigger Source* bulb connected to the *X-junction* of the camera is lightes. The light beam is reflected by the rotating Littrow mirror and focused onto a silicon phototransistor (OS-14) which produces a pulse each time the mirror passes a given rotational position. The resulting pulse train is amplified, and fed to the *Synchronizer* circuit, where it is used to trigger the synchroscope and the Xe flash tube (point A in Fig. 3). Here, the infrared light and the light for the triggering pulse reflect on the same face of the Littrow mirror for synchronization. The phase relationship between the trigger pulse and the spectral wave length can be adjusted by changing the positions of the phototransistor and the bulb, or alternatively, by changing the delay time in the first delay circuit, DI, in Fig. 3 (point B). In order to obtain stable operation, the first three pulses (point A in Fig. 3) are discarded with the counter circuit, C-2 (point C). The fourth pulse releases the HOLD circuit from clamping (point D) and the fifth passes through the first switching circuit, SWI, to the second delay circuit, DII (point E). The voltage drop in one of the DII collectors (point G') forces the third delay circuit, DIII, to generate a delayed pulse (point F), and the voltage rise of the pulse, in turn, induces a 2 μF condenser (in *Trigger for Flash* circuit in Fig. 2) to discharge through a thyratron (Toshiba Corp., 1G50A). A fly-back transformer (Chuo Musen Corp., TV-304 CD 3) connected to the thyratron generates a trigger pulse of about 20 kV which fires the charged Xe flash tube. A portion of the flash light is fed to a photomultiplier (Hamamatsu Televi Corp., R-252) in the *Monitor Amp.* circuit in Fig. 2. The resultant signal is amplified and used to release the second switching circuit, SW-II, from clamping (point H and I in Fig. 3). Finally, the output signal of the DII (point G) arrives at the synchroscope either *via* a counter circuit, C-8, or directly (point J). The C-8 is used to thin out some pulses in the train for the purpose of recording the spectra of fairly long-lived intermediates (life time: 0.1—1.0 s). By adjusting the delay times of DII and DIII, one can set the sweep of the synchroscope to the moment desired after the flash terminates.

Results and Discussion

Instrument Performance. Reference spectra of air, $COCl_2$ and NH_3 were recorded on the instrument equipped with an NaCl prism and a Globar source. Immediately before every run, the light source was adjusted to a white glow (1300—1600 °C), and the Littrow mirror was set to high-speed rotation (about 3000 min^{-1}). Dried N_2 gas was blown through the light path, as necessary.

The 1.7 MHz amplifier bandpass increases the noise level by a factor of 1000 over that of narrow bandpass amplifiers normally used in thermocouple spectrometers. Therefore, reducing this noise is essential to rapid-scan infrared spectroscopy. To facilitate the estimation of the absolute value of this noise in various recording conditions, the narrowest possible slit width and the highest possible gain of the detector system were used throughout the experiment. Because of the resultant low S/N, it became very difficult to quantitatively control the influence of the following factors which dominate the spectral resolution, the band shape and the band intensity: the brightness of the light source, the rotating speed of the Littrow mirror, the selection of the wavelength region, the gain of the detector system, the sweep speed of the synchroscope, *etc.* The S/N may be estimated from the ratio of the intensity to the thickness of the voltage trace. Throughout the experiment, it was 38—43 at 3000 cm^{-1} and 4—8 at 1000 cm^{-1}.

The thickness of the voltage trace was investigated using a *wave analyser* (General Radio Company Concord, USA, Type 1900-A). It was found that the thickness was due to white noise of about 100 μV and not due to any hum. The noise increased exponentially below 100 Hz. This agrees well with the noise characteristics of a CuGe detector. The Keithley 102-B preamplifier has a noise level of 20 μV in case of short-input circuit, a gain of 60 dB and a 1.7 MHz bandpass. The noise signal appears as high as 50—60 μV on the synchroscope. This would build up the 100 μV white noise along with the noise contributions due to the CuGe detector and load resistor. Besides this high frequency noise, there was a microphonic noise of 50—100 μV and of about 100 Hz, which is caused by the mechanical vibration accompaning the rotation of the Littrow mirror.

Although the time constant of the entire detector system could not be measured precisely because of the microphonic noise, it was observed that the intensity of the voltage trace at a scanning speed of 1000 min^{-1} did not decrease at speeds up to 3000 min^{-1}.

Figure 4 shows the atmospheric absorption spectrum due to ν_{OH} (3654)* and δ_{OH} (1595) of H_2O, and due to ν_{CO} (2349) of CO_2. Each of the four voltage traces corresponds to scanning by each of the four faces of the Littrow mirror. Under the conditions, it may be said that the spectral resolution is independent of the face. The microphonic noise slightly shifts the starting point of the first (lowest) sweep in Fig. 4 with respect to the starting points of the other sweeps. Wave

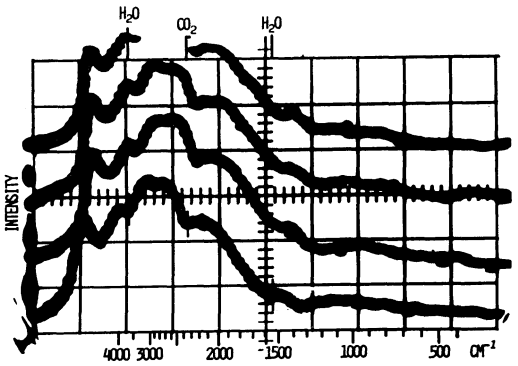

Fig. 4. Atmospheric absorptions. 150 μ slits, sweep 20 μs/div., 0.5 mV/div. The evacuated 40 cm qurtz gas cell was set in the light path.

number calibration was carried out on the basis of the absorption bands for which vertical short lines were drawn. Because the reflecting faces of the Littrow mirror are separated from the rotating axis by 25 mm, the nonlinearity in the wave number scale is emphasized, as compared with that in the case of a planar Littrow mirror. Figure 5 shows the absorption bands due to $COCl_2$. In addition to the two fundamental frequencies,

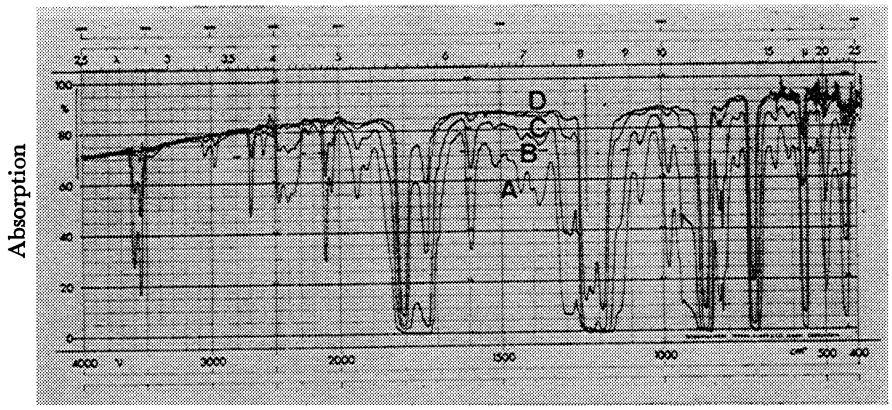

Fig. 7. Infrared spectrum of CF_3COI recorded on a Perkin-Elmer Model 125 Spectrometer with use of 10 cm gas cell: (A) 25 mmHg, (B) 15 mmHg, (C) 8 mmHg, (D) 3 mmHg.

ν_2 (1827) and ν_4 (849), five combination bands, $2\nu_4$ (1677), $\nu_1+\nu_4$ (1412), $\nu_4+\nu_6$ (1276), $2\nu_1$ (1159) and $\nu_1+\nu_6$ (1011), are recorded. Figure 6 shows the HNH deformation mode, ν_4 (1627.5), and the umbrella mode, ν_2 (931.58 and 968.08), of NH_3.[14]

From these spectra, it is seen that the instrument is quite adequate for qualitative low-resolution detection of transient intermediates with half-lives as short as 50 μs.

Application. CF_3COI was chosen as the first chemical system for exploration on the basis of the following criteria: (1) high infrared absorption coefficients of the CF and CO stretching vibrations, (2) a high photolytic yield for the breaking of the CI bond, (3) its chemical interest, and (4) an adequate vapor pressure at room temperature. Prior to the experiment, INDO calculations were carried out to estimate the minimum CC-bond distances for CF_3COF, CF_3COH, CF_3CN, and CF_3CO radicals, since sufficient information about these molecular parameters could not be obtained in other ways. The following assumptions were made: CF (in CF_3) 1.34 Å, CO 1.19 Å, CH 1.09 Å,[15] CN 1.15 Å, ∠FCF (in CF_3) 109°28′,[15] and ∠HCO 120°.[15] The calculated values were 1.50, 1.49, 1.47, and 1.42 Å, respectively. These values suggest that the CC stretching vibration in the CF_3CO radical couples strongly with the CF and CO stretching vibrations, and consequently the fundamental frequencies of the radical are fairly different from those of CF_3COI.

Since no IR spectrum of CF_3COI has yet been published, the one recorded on the Perkin-Elmer 125 spectrometer is shown in Fig. 7. Absorption bands at 1806, 1240, 1190, and 870 cm^{-1} were approximately assigned to ν_{CO}, ν_{CF_3}, $\nu_{FCF_2}(a')$, $\nu_{FCF_2}(a'')$, and ν_{CC}, respectively. When the sample pressure is high, the absorption maxima are shifted from the fundamental frequencies. This was taken into account in the wave number calibration in Fig. 8. Spectra (A), (B) and (C) in Fig. 8 were recorded on the instrument before, immediately after, and about two seconds after photolysis, respectively. ν_{CO} of CO_2 was recorded in (A), besides ν_{CO}, ν_{CF}'s, and ν_{CC} of CF_3COI. The first and the second traces are slightly shifted with respect to each other. This could also be because of microphonic noise as in the case of Fig. 4. In (B), dried N_2 gas was

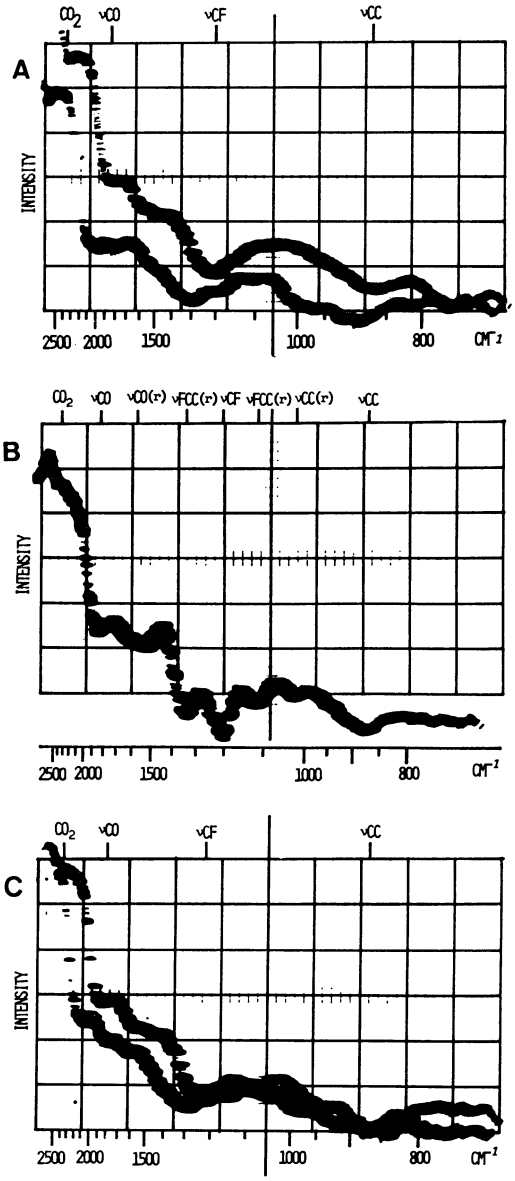

Fig. 8. Flash photolysis of CF_3COI: 200 μ slits, sweep 20 μs/div., 0.2 mV/div., 40 cm gas cell, 40 mmHg CF_3COI, N_2 700 mmHg, (A) Before Photolysis, (B) Immediately after photolysis, (r) denote radical, (C) About 2 s after photolysis.

* denote absorption due to C_2F_5I.

blown through the optical path. Spectrum (B) was swept 25 μs after trigger pulse was fed to the charged Xe flash tube. Although the *Multi Trace* unit was set to sweep twice, only one voltage trace was recorded. This could be caused by tailing of the flash noise. Prior to this experiment, it was ascertained that any single sweep, for which the *Multi Trace* unit acts only as an ordinary preamplifier, was performed normally and consistently at 25 μs after photolysis, but not at 13 μs. Therefore, the trace in (B) is undoubtedly the first sweep, but not the second (about 5 ms later). In addition to the absorption bands due to CO_2 and CF_3COI, four new absorption bands were detected at 1574, 1338, 1115 and 1024 cm^{-1}. They did not appear in (C). Their absolute intensities were difficult to estimate because of the microphonic noise, but the sensitivity of this instrument in the relevant spectral region is confirmed in Figs. 5 and 6. The CF_3CO radical population should be smaller than the $COCl_2$ and NH_3 populations, while the absorption coefficient of the radical should be larger than those of the combination bands and of the umbrella mode in the molecules. Therefore, it is thought that the data are quite adequate for qualitative discussion. The decomposition products were transfered into a 10 cm gas cell, and the infrared spectrum was recorded on a Perkin-Elmer 125 spectrometer (Fig. 9). The CF_3COI pressure decreased to one tenth of the value before photolysis. The absorption in the 1800 cm^{-1} region suggests that there is no perfluorobiacetyl, $(CF_3CO)_2$. The absorption bands at 1321, 1113, and 923 cm^{-1} should be due to C_2F_5I. In addition, there are uncondensed molecular species at liquid N_2 temperature. They are CO (2100), C_2F_6 (1113), CF_4, CF_3I, *etc.* The light intensity of the Xe flash tube has the peak in the wavelength region of 300—400 nm. The CI bond is usually ruptured by the light, but the CF, CC and CO bonds are not. All of these suggest that the photolysis produces, first, a CF_3CO radical in the electronic ground state, and then the radical decomposes into a CF_3 radical and CO, either due to room light or thermal collisions. This explanation is in good agreement with the results of Noda *et al.*[16] that the CH_3CO radical in an isolated matrix at liq. N_2 temperature is easily decomposed by visible light into a CH_3 radical and CO.

Consequently, it is concluded that the four weak and transient absorptions in Fig. 8 (B) are due to the CF_3CO radical. They were tentatively assigned to ν_{CO} (1574), ν_{CF_3} (1338, a species), ν_{CF_3} (1115, e species), and ν_{CC} (1024). They should be coupled strongly to each other.

The authors wish to thank the Ministry of Education for financial support for this study. They also wish to express their gratitude to the (late) Prof. Kozo Kamiryo, Dr. Katsuhiko Ishida, Messrs. Kiichi Sato and Setsuo Tamagawa of the Research Institute of Electrical Communication of this university, and to Messrs. Minoru Takahashi and Eijiro Yamazaki of this institute, who assigned in the construction of the liquid He cryostat. The authors also gratefully acknowledge Prof. Tsuneo Ikenoue and his collaborators of this institute for assistance in constructing the electric circuits, and the (late) Professors Susumu Kinumaki and Tetsuo Hata, Mr. Shinji Onodera and Mrs. Hamako Sato of this institute for their assistance in earlier stages of this work.

Heat of Adsorption from Solution. II. The Heat of Adsorption of Pyridine on Silica-Alumina from the Hexane Solution

Hiromitu NAONO,* Kazuko MOORI, and Tetsuo MORIMOTO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received December 19, 1975)

The amounts of physisorbed and chemisorbed pyridine on silica–alumina in the hexane solution were measured at 30 °C, and found to be 1.25 and 0.25 molecules/100 Å^2 respectively. The number of strong acid sites determined by Benesi's method are in good agreement with the chemisorbed molecules, which indicates that the ratio of the number of chemisorbed pyridine molecules to that of the strong acid sites on the surface of silica–alumina is equal. The adsorption calorimetry was carried out on the same system by means of a flow microcalorimeter which permits us to differentiate the heats of physisorption and chemisorption: the results showed that the heats of physisorption and chemisorption of pyridine are 11.3 ± 0.3 and 22 ± 4 kcal/mol respectively.

It is well known that silica–alumina is a typical solid acid; a number of efforts have been devoted to clarify the interaction between the silica–alumina surface and basic molecules.[1] The infrared spectroscopic studies using ammonia, butylamine, and pyridine as adsorbates have made it possible to distinguish the acid sites on silica–alumina into two types, *i.e.*, those of Brönsted and Lewis acid.[2,3] On the other hand, no exact measurements of the interaction energy between the acid surface and basic molecules have satisfactorily been carried out.[4–7]

The present work was undertaken in order to determine precisely the heat of adsorption of pyridine on silica–alumina from the hexane solution. For the calorimetric measurements, a flow microcalorimeter is used; it was found in the preceding paper to be suitable for the exact measurement of a small heat evolved in a solid–liquid system.[8] The present paper will also show the advantage of using flow calorimetry in order to differentiate the heat of the chemisorption of an adsorbate from that of the physisorption; this can be done by combining the heat of adsorption data with the chemisorbed and physisorbed amounts of the adsorbate.

Experimental

Materials. Silica–alumina powder (13 wt % alumina) presented by the Shokubaikasei Co., Ltd., was washed forty times by hot distilled water (*ca.* 80 °C) until the conductivity of the supernatant liquid was brought to a limiting value, 5×10^{-6} Ω^{-1}cm^{-1}. The powder was then dried at 100 °C in the atmosphere, and finally degassed at room temperature for 4 h at a reduced pressure of 10^{-3} Torr. The guaranteed-grade reagents of hexane, benzene, and pyridine were purified by passing them through a silica gel column. On the other hand, the guaranteed-grade reagent of butylamine and such indicators as anthraquinone, benzylideneacetophenone, 4-(phenylazo)diphenylamine, and *p*-dimethylaminoazobenzene were used without further purification.

Surface Area and Porosity of Silica–Alumina. The adsorption and desorption isotherms of nitrogen on silica–alumina were measured at −196 °C by the volumetric method. The surface area was calculated by the BET method, where the adsorbed area of a nitrogen molecule was assumed to be 16.2 Å^2. The pore volume of silica–alumina was estimated from the adsorbed amount of nitrogen at the saturated pressure. The pore-size distribution was calculated from the desorption branch of the isotherms by the method reported by Barret *et al.*, where the shape of pores was assumed to be cylindrical.[9]

Water Content of Silica–Alumina. The surface water content of silica–alumina was determined by the successive-ignition-loss method reported previously.[10]

Acidity of Silica–Alumina. The measurement of the surface acidity of silica–alumina was carried out by Benesi's method by using the indicators mentioned above.[11] Ten milliliters of a 4—12% solution of butylamine dissolved in benzene were mixed with 0.15—0.27 g of silica–alumina which had been pretreated *in vacuo* at room temperature. The mixture was shaken for 10 h at 30 °C. A few drops of a 0.1% indicator solution were then added to the mixture, and the color change of the silica–alumina was observed. The acidity was determined from the minimum amount of butylamine which did not bring about a color change.

Adsorption of Pyridine on Silica–Alumina from the Hexane Solution. The amounts of pyridine adsorbed on silica–alumina from the hexane solution were determined from the difference between the concentrations of the solution before and after the adsorption. Ten milliliters of the pyridine solution were poured into a 15 ϕ centrifugal tube with a cap, containing 0.35—0.65 g of silica–alumina. The tube was then shaken for 10 h at 30 °C. The equilibrium concentration of the pyridine was determined by means of absorption spectroscopy at the wavelength of 220 nm. In this experiment, the adsorption measurement of pyridine was carried out on the fresh and pyridine-chemisorbed surfaces. The latter surface was prepared by immersing the silica–alumina into a 0.1 M pyridine solution and by then washing the sample in a column with a sufficiently large quantity of hexane until no pyridine was detected in the hexane. The wet sample was then transferred to the centrifugal cell. After the residual hexane in the cell had been pipetted out, the pyridine solution of a known concentration was again poured into the cell. The effect of dilution due to the residual hexane was within an experimental error of adsorption (2%).

Adsorption Calorimetry of Pyridine on Silica–Alumina. A flow microcalorimeter was used for the adsorption calorimetry.[8] Silica–alumina (0.10—0.12 g) was set into the calorimeter. Hexane was forced to flow through at the flow rate of 0.21 ml/min by means of the pump. After a stable base line with no slope had been recorded, the hexane was replaced by a 0.1 M pyridine solution. A solution of the same concentration was then allowed to flow through until no heat evolved by the adsorption was detected; the temperature went

* Present address: Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya 662.

down to the same level as the original base line (Fig. 6). In this stage, the adsorption equilibrium was established. In this calorimetry, the measurement was carried out at 30 °C; the two surfaces mentioned above were also used.

Results and Discussion

Characterization of Silica-Alumina Powder. Prior to the measurement of the interaction energy between the silica-alumina surface and the pyridine molecules, such properties of silica-alumina as the surface area, the pore volume, the pore-size distribution, the water content, and the surface acidity were examined.

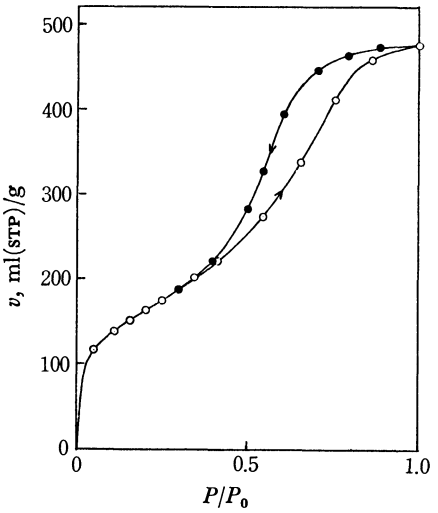

Fig. 1. Adsorption isotherm of nitrogen on silica-alumina at −196 °C. Pretreatment at 25 °C. ○: adsorption, ●: desorption.

Figure 1 shows the adsorption isotherm of nitrogen gas on silica-alumina. The facts that a distinct hysteresis appears in the isotherm and that the isotherm is of Type IV[12] reveal the sample used to be porous. From the isotherm, the BET surface area and the pore volume were estimated to be 596 m^2/g and 0.74 ml/g respectively. Assuming that the pores are cylindrical, we can calculate the average radius of the pores, $\bar{r}_p$, from the $\bar{r}_p=2v_p/S$ relation, where v_p is the pore volume, and S, the surface area. The calculated value of $\bar{r}_p$ is found to be 25 Å. The pore-size distribution curve given in Fig. 2 shows a peak at 21 Å, representing an asymmetric distribution extending to larger pores. It should be noted that most pores in silica-alumina are remarkably larger than the molecular size of butylamine or pyridine; this suggests that these molecules can easily diffuse into pores.

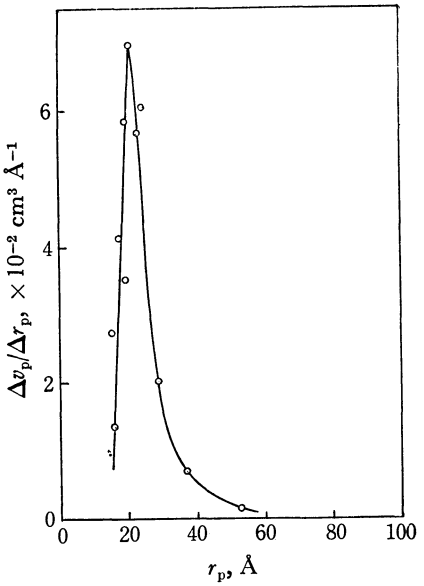

Fig. 2. Pore size distribution of silica-alumina.

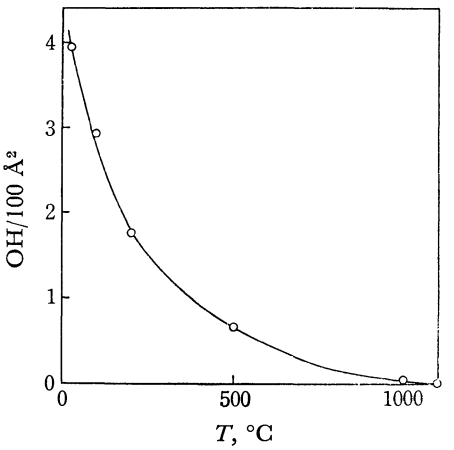

Fig. 3. Water content of silica-alumina.

In Fig. 3, the water content of silica-alumina, expressed by the number of surface hydroxyl groups per 100 Å², is given as a function of the pretreatment temperature. It may be seen from Fig. 3 that the water content of the silica-alumina used in the present experiment approximates that of pure silica,[13-15] but the dehydration behavior is greatly different from that in silica; that is, the surface water content of silica-alumina decreases rapidly with an increase in the pretreatment temperature.

In Fig. 4, the acidity is given as a function of the acid strength (H_0), expressed by the number of acid sites per 100 Å². The fact that the acidity goes nearly parallel to the abscissa leads to the conclusion that all the acid sites on silica-alumina are strongly acidic. Benesi reported a similar result for silica-alumina calcined at 550 °C.[11] On the other hand, the average

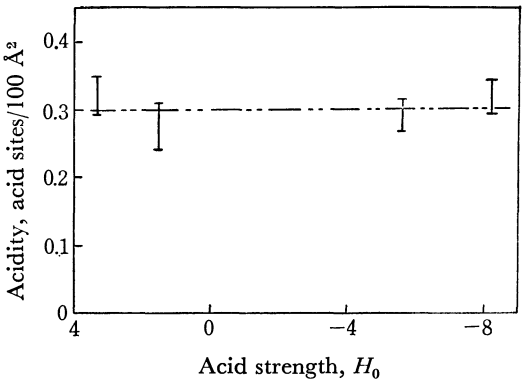

Fig. 4. Acidity *vs.* acid strength for silica-alumina.

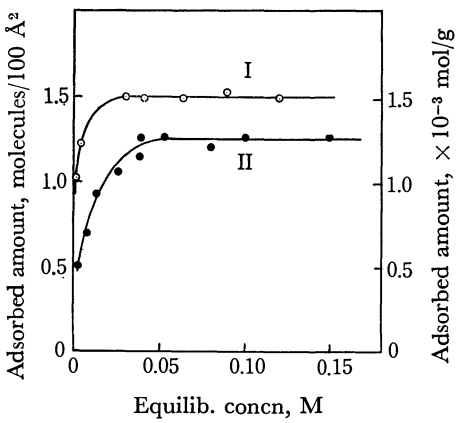

Fig. 5. Adsorption isotherm of pyridine on silica–alumina from *n*-hexane solution at 30 °C. I: fresh surface, II: pyridine-chemisorbed surface.

surface population of acid sites is only 0.3 sites/100 Å² (Fig. 4), indicating that the acid sites are very sparse on silica–alumina.

Adsorption of Pyridine on Silica–Alumina from the Hexane Solution. The adsorption isotherm of pyridine measured on silica–alumina from the hexane solution is shown in Fig. 5. Curves I and II correspond to the adsorption of pyridine on fresh and pyridine-chemisorbed surfaces of silica–alumina respectively; both curves are found to be of the Langmuir type. The difference between the two curves at saturation is read to be 0.25 molecules/100 Å² from Fig. 5, which indicates the amount of strongly adsorbed pyridine which could not be removed by washing the pyridine-preadsorbed surface with a large quantity of hexane, while the II isotherm represents the physisorption of pyridine, 1.25 molecules/100 Å² as a maximum (Fig. 5). Taking account of the magnitude of the heat of adsorption to be given later, these pyridine molecules may be considered to be chemisorbed on the surface of silica–alumina. Here, it is interesting to note that the acidity mentioned above is in fairly good agreement with the quantity of chemisorbed pyridine; this enables us to conclude that one molecule of chemisorbed pyridine interacts with one acid site.

One further question remains to be solved, whether pyridine molecules are chemisorbed on the Brönsted or Lewis acid sites. Shiba *et al.* determined both Brönsted and Lewis acid on silica-alumina as a function of the silica content.[16] On silica–alumina containing 13 wt % alumina, the amounts of Brönsted and Lewis acid were found to be *ca.* 80 and 20% respectively when treated at 500 °C. In our sample, the pretreatment temperature is 25 °C. As may be seen from Fig. 3, the water content decreases remarkably with the increase in the temperature from 25 to 500 °C. It is expected that, in the present silica–alumina, the greater part of the acid sites are of the Brönsted type, because the Brönsted acid sites increase with the water content. Thus, it may reasonably be considered that, in the present investigation, pyridine molecules react with the Brönsted sites to form pyridinium ions.[3]

Adsorption Calorimetry of Pyridine on Silica–Alumina. Figure 6 shows the response of the flow microcalorimeter to the adsorption of pyridine on silica–alumina from the hexane solution. Peaks I and II were obtained by the adsorption of pyridine on the fresh and pyridine-chemisorbed surfaces respectively. After Peak I was measured, the flowing liquid was converted from the solution to the solvent. In order to wash away the physisorbed pyridine, the solvent was forced to flow through the calorimeter for a prolonged period (15—20 h), until no pyridine was detected in the solvent flowing out of the calorimeter. Again, a pyridine solution of the same concentration was introduced into the calorimeter. Peak II was thus obtained. Pyridine molecules adsorbed on silica–alumina are composed of two part, *i.e.*, reversible and irreversible parts, as has been stated above; the corresponding heats of adsorption can be analyzed from the areas of the two peaks. As a matter of course, Peak II arises from the reversible or physical adsorption of pyridine, while Peak I should involve both kinds of adsorption. First, the reliability of adsorption calorimetry was confirmed by the measurements of twelve runs at the concentration of a 0.1 M pyridine solution; the data were calibrated by using electrical energy. The results obtained are listed in Table 1, giving the average values of 19.6 ± 0.2 and 14.1 ± 0.2 cal/g for Peaks I and II respectively.

Table 1. Calorimetric results on the pyridine adsorption on silica–alumina from 0.1 M solution at 30 °C

Run no.	Fresh surface (cal/g)	Pyridine-chemisorbed surface (cal/g)
1	18.3	13.5
2	19.0	12.6
3	19.8	14.2
4	20.2	15.7
5	20.2	14.6
6	19.6	13.7
7	18.7	12.3
8	19.9	14.9
9	20.5	15.8
10	19.8	14.3
11	18.8	13.0
12	20.1	14.4
av.	$19.5_8\pm0.2_1$	$14.0_8\pm0.2_0$

Next, on the basis of the calorimetric data (Table 1) and the adsorption isotherms (Fig. 5), the heat of adsorption of pyridine can be computed to be 11.3 ± 0.3 and 22 ± 4 kcal/mol for the physisorbed and chemisorbed pyridine respectively. In the present calorimetric measurements, the heat of dilution should be a factor in addition to the heat evolved by adsorption. The heat of dilution can be estimated from the dependence of the heat-of-mixing, ΔH_{mix}, on the concentration of the solution. The calorimetric measurement of ΔH_{mix} was carried out at 30 °C in a pyridine–hexane system by means of an adiabatic calorimeter. In the concentration range from 0.03 to 0.1 M pyridine, ΔH_{mix} was found to be 2.10 ± 0.02 kcal/mol. The fact that ΔH_{mix} is independent of the concentration indicates that the heat of dilution is less than the limits of experimental

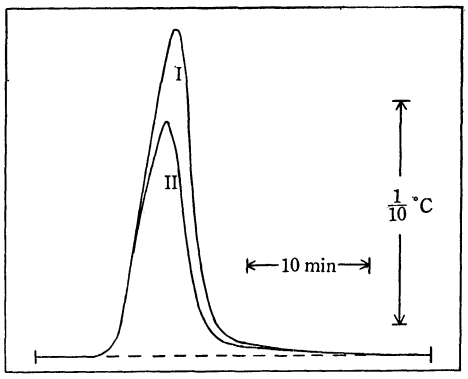

Fig. 6. Adsorption peaks of pyridine on silica–alumina from 0.1 M solution at 30 °C. I: fresh surface, II: pyridine-chemisorbed surface.

error, *i.e.*, ±0.02 kcal/mol. Accordingly, the heat of dilution is neglected compared with the heats of adsorption mentioned above.

The larger heat of chemisorption may be attributed to the strong interaction of strong Brönsted acid sites with pyridine molecules through the relation of 1: 1 between the site and molecule. In other words, the heat of chemisorption is considered to be the heat of the formation of pyridinium ions on the silica–alumina surface. On the other hand, the heat of the physisorption of pyridine is probably due to the interaction of the physisorbed molecules with possible surface sites other than the strong acid sites, *i.e.*, with surface silanol groups.

So far, several investigators have reported on the heat of adsorption in systems of basic molecules silica–alumina.[4–7] However, the direct calorimetric heats of physisorption and chemisorption in the system of pyridine–silica–alumina have not been measured. Roca *et al.* estimated indirectly the heats of physisorption and chemisorption of pyridine on silica–alumina by utilizing the adsorption isosters and the temperature-programmed desorption technique;[17] they obtained 8 kcal/mol for the heat of physisorption and 33 and 39 kcal/mol for the heat of chemisorption on two different sites. Their heat of physisorption is slightly lower than ours, while their heat of chemisorption is fairly larger than ours.

In considering the discrepancy between the two sets of data, it is necessary to compare the pretreatment conditions. In our sample degassed at 25 °C, there is a great possibility that the surface includes physisorbed water molecules, because of the remarkable decrease in water content with the temperature (Fig. 3), while in Roca's sample degassed at 400 °C, physisorbed water molecules are considered to be almost entirely removed from the surface. It may, therefore, be considered that the heat of chemisorption of pyridine may be greatly reduced by the existence of physisorbed water, while the heat of physisorption may not be influenced significantly by the existence of physisorbed water.

^{13}C-NMR Study of Aerosol OT in Chloroform

Masaharu UENO, Hiroshi KISHIMOTO, and Yoshimasa KYOGOKU*

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

**Institute for Protein Research, Osaka University, Suita, Osaka 565*

(Received December 24, 1975)

The dynamic structure of Aerosol OT molecules in micellar state was studied by measurements of ^{13}C-NMR spin-lattice relaxation time (T_1) and the effect of a lantanide shift reagent Yb(fod)$_3$ in chloroform at 25 MHz and 40 °C. The results were analyzed on the basis of the conformation and segmental motions of Aerosol OT molecules in micellar state, with the following conclusions: Aerosol OT molecules in the micellar state associate with each other by the polar head groups; their hydrocarbon chains are flexible; the mobility of side chain is restricted to a greater extent than that of the main chain; carbonyl carbon-(2′) is located nearer to the polar group than carbon-(2) in steric conformation.

Studies on the state of surface active agents in solution are of interest from a biological viewpoint, since the amphiphilic behavior of surface active agents such as micelle formation and hydrophobic interaction can also be observed in biological systems. As a suitable substance for the study, Aerosol OT was chosen and thermodynamical studies were carried out on its solution state in water[1] or in organic solvents[2] and also its two-phase distribution between water and an organic solvent.[3] Spectroscopic studies, however, are necessary for more extensive and detailed information.

Recently, solution states of surface active agents in water or organic solvents have been studied by means of NMR.[4] The dynamic structure of molecules have been studied in the last few years, since the use of Fourier transform NMR made the measurement of relaxation time practicable. Clifford and Pethica studied the properties of micellar solutions of sodium alkyl sulfates in D_2O by ^{1}H-NMR T_1 measurement.[5] Henriksson and Ödberg studied the micellar structure of heptafluorobutyric acid and sodium pentadecafluorooctanoate in H_2O and D_2O by ^{19}F-NMR T_1 measurement.[6] Podo *et al.* studied the dynamical structure and hydration of micelle by ^{1}H-NMR T_1 measurement.[7] However, the study of local mobility or segmental motions by means of ^{1}H- or ^{19}F-NMR is difficult because of the overlap of proton signals and the simplicity of the ^{19}F signal. For this study, ^{13}C-NMR would be most useful. Williams *et al.* and Levy *et al.* studied the local mobility of surface active agents in water and several organic solvents by ^{13}C-NMR.[8,9] We have applied it to the study of Aerosol OT molecules in the micellar state in chloroform.

Experimental

Materials. Aerosol OT (sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethane-1-sulfonate, American Cyanamid Co., Ltd.) was used. The anhydrous material is claimed to be 99% pure and to contain about 1% of methanol insoluble impurity. The procedure by Higuchi and Misra[10] was used for purification. The solvents used were as follows: chloroform was distilled twice; chloroform-d_1 (Merck Co., Ltd.) was dried by passing through an alumina gel column. Yb(fod)$_3$ (tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato) ytterbium, Nagoya Katayama Kagaku-Kogyo KK).

Methods. ^{13}C nuclear magnetic resonace spectra were recorded on a JEOL-PFT-100 pulse Fourier transform NMR spectrometer at 25 MHz locked on deuterium using 10-mm sample tubes. Chemical shift, δ, was measured relative to tetramethyl silane used as an internal standard by data reduction. For ordinary FT NMR experiments (proton decoupled), pulse angle: 45°, repetition: 2.0 s, data point: 8192, frequency range: 6250 Hz, numbers of scans: 400 (time domain accumulation). For T_1 measurements (proton decoupled), pulse angle: 180°-τ-90°, repetition: 20.0 s, data point: 8192, frequency range: 6250 Hz, numbers of scans: 400. For off resonance experiment, pulse angle: 45°, repetition: 3.0 s, data point: 4096, frequency range: 1000 Hz, numbers of scans: 5000.

Vapor pressure depressions were measured with a molecular weight apparatus (Hitachi Perkin-Elmer Type 115) based on a thermister method.[11]

Results and Discussion

Vapor Pressure Depression Measurement. Vapor pressure depressions of the solvent were measured for the determination of CMC (critical micelle concentration) and association number of Aerosol OT in chloroform. The thermister bridge reading, ΔR, is plotted against solute concentration (molality) in Fig. 1. Open circles correspond to Benzil as a standard substance and solid circles to Aerosol OT. The insert shows the result of measurement in low concentration. The arrow indicates CMC, 4×10^{-4} M (mol kg^{-1}). By comparison of the slopes of the two straight lines for Benzil and for Aerosol OT, the number average association number was calculated to be 5.

^{13}C-NMR Spectra. ^{13}C-NMR spectra were measured for a solution at 2×10^{-1} M. We see from the results that a large part of Aerosol OT at this concentration is in a micellar state. Spectrum (a) was taken under ^{1}H noise decoupling conditions and spectrum (b) under ^{1}H partial decoupling conditions. Spectrum (c) shows the effect of the addition of a shift reagent and spectrum (d) that of 2-ethyl-1-hexanol whose signals were already assigned.[12] Almost all the signals in spectrum (a) were assigned to each carbon with reference to spectra (b), (c) and (d). Two peaks of carbonyl carbons at lower fields, however, could not be assigned to either C(2) or C(2′) from only the above reference. We took, therefore, the off resonance spectrum. If the two protons of methylene(1′) are assumed to be magnetically equivalent, it is expected

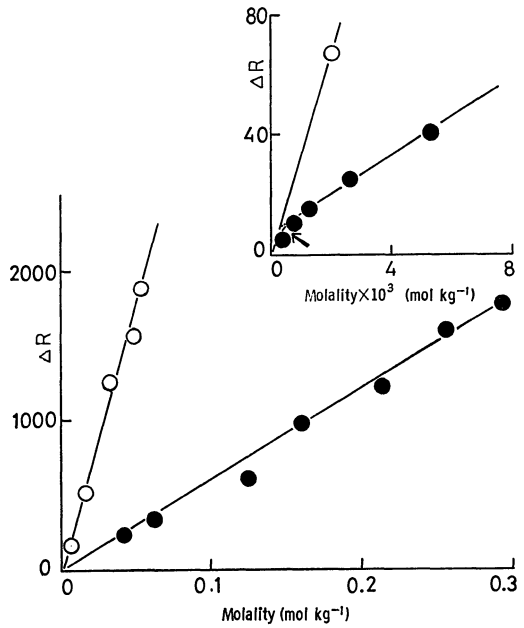

Fig. 1. Thermister bridge reading (ΔR) *vs.* solute concentration in $CDCl_3$.

The figure inserted in upper right is the result of measurements in dilute concentration. The arrow in the figure indicates CMC.

that under the off resonance conditions the peak of C(2) is split into two peaks by the one proton of methine (1), and that of C(2′) into three peaks by the two protons of methylene (1′). As shown in Fig. 3, the lower-field signal of the two is split into two peaks and is assignable to C(2), while the higher-field signal is split into three peaks and assignable to C(2′). The two methylene carbons (3) and (3′) (Fig. 2-a) also exist in magnetic nonequivalence. However, it is difficult to assign the two signals. It was tentatively assumed that the peak at the lower-field is assigned to C(3) and that at the higher-field to C(3′), by taking into consideration the fact that the carbonyl-carbon peak near a polar group such as ($-SO_3^-$) appears at lower field.

The Influence of a Shift Reagent. The influence of a lantanide shift reagent, $Yb(fod)_3$, on the spectra was examined. Figure 2-(c) shows the spectrum of Aerosol OT on addition of $Yb(fod)_3$ at 0.1 mole ratio. Some peaks become broader and are shifted down field. The chemical shift is plotted against the ratio (La)/(AOT), the molal concentration ratio of lantanide shift reagent to Aerosol OT, in Fig. 6. The $Yb(fod)_3$-induced shift increases in the order of carbons-(2′>1>1′>2>3>3′). For the carbons-(4,4′, 5,5′, 6,6′, 7,7′, 8,8′, 9,9′, 10,10′), no induced shifts were observed. It is probable that the shift reagent coordinates to the polar group, and that carbons nearer the polar group in a spacial distance are more influenced by the shift reagent. It might be

presumed that carbonyl carbon-(2') is located nearer the polar group in spacial distance than carbonyl carbon-(2) in spite of the longer distance through chemical bonds. On the contrary, methylene C(3) is nearer to the polar group than C(3'), as expected from the chemical sequence. Carbon-(4,4', 5,5', 6,6', 7,7', 8,8', 9,9', 10,10') are far from the polar group.

T_1 *Measurement.* Spin-lattice relaxation time T_1 was measured by the 180°-τ-90° pulse sequence method. The sample was dissolved in chloroform-d_1, and the

* N: The number of protons attached to carbon.

solution was degassed. The concentration was 200 mg/ml, which is sufficiently high to neglect the existence of monomer. Repetition time was 20 s and the peaks were accumulated 400 times in time domain. The results are shown in Fig. 5. In the pulse sequence method, the relative peak intensity A is given by

$$A = A_e(1-2\exp(-\tau/T_1))$$

where τ is the interval between the 180° and 90° pulses and A_e is the limited peak intensity when interval τ is long enough (20 s). In Fig. 6, log (A_e-A) are plotted against τ. T_1 can be calculated from the slopes. The results are given in Table 1 with the corresponding chemical-shift values. The estimated errors in the T_1 measurement were within 10%. We found that when the relaxation was caused by magnetic dipole interaction, most of it was affected by the protons bonded directly to carbon. The relaxation becomes faster with an increase in the number of attached protons. In order to correlate relaxation time to segmental motion, the number of the proton time T_1, *i.e.*, NT_1, is more useful than T_1 itself.

With respect to the main chains, T_1 of carbons gradually becomes greater as they become located far from the polar group ($-SO_3Na$). This implies that segmental mobility increases as the segment becomes located farther from the polar group of the molecule in the miecllar state in chloroform. This is in line with the fact that Aerosol OT in chloroform forms reverse micelles with the aid of dipole interaction among intermolecular polar groups, the hydrocarbon parts far from the micellar core moving freely. This is interesting when compared with the behavior of micelle in water. The relaxation times of main and side chains were compared with each other. T_1 of C(8) is greater than that of C(10), the same relation holding for C(5) and C(9). This indicates that the side chains are restricted in mobility to a greater extent than the main chains in micellar state. It is concluded that (1) Aerosol OT molecules in the micellar state associate with each other by the polar head groups, hydrocarbon chains being flexible, (2) the mobility of side chains is more restricted than that of the main chain, and (3) carbonyl carbon-(2′) is located nearer in spacial distance to the polar group than carbonyl carbon-(2).

Chemisorption of Nitrogen Oxide and Nitrogen on Tungsten

Teijiro TAMURA and Takuya HAMAMURA

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606

(Received December 25, 1975)

The chemisorption of nitrogen oxide and nitrogen on a polycrystalline tungsten filament was studied using flash desorption mass spectroscopy. The saturation coverage for nitrogen oxide and nitrogen on tungsten is 8.8×10^{14} molecules/cm^2 and 1.9×10^{14} molecules/cm^2, respectively. These saturation coverages on tungsten are about 1.7 times those on rhenium. The initial sticking probability of nitrogen oxide is very high compared with other gases. It is assumed that the nitrogen oxide adsorption is non-dissociative on tungsten, while the nitrogen is adsorbed dissociatively. When the temperature of the tungsten filament saturated with nitrogen oxide is raised, a small amount of nitrogen oxide molecules desorb at about 475 K, and dissociation occurs at more elevated temperatures. The greater part of the nitrogen desorbs before the temperature reaches 1500 K. No oxygen desorption was detected upon heating the tungsten saturated with nitrogen oxide. It appears that oxygen probably desorbs as tungsten oxide. Three states of nitrogen desorption, designated α, β_1, and β_2, on tungsten appeared at room temperature. The activation energy of the desorption for the strongly chemisorbed nitrogen of the β_1 and β_2 states on tungsten are 78 kcal/mol and 80.5 kcal/mol, respectively.

Fundamental to the understanding of heterogeneous reactions, such as catalytic reactions, is the determination of the role of the surface and the dependence of the reaction variables on the properties of the solid. Recently, detailed data of chemisorption studies have been presented taking advantage of the progress of ultra-high vacuum techniques and the development of modern methods,[1-5] such as the use of flash filaments, isotopic mixing, FEM, FIM, LEED and AES.

Many studies of chemisorption of common gases on tungsten have been made, but there have been only a few studies of the chemisorption of nitrogen oxide.[6-9]

In the present investigation, the chemisorption of nitrogen oxide and nitrogen on a tungsten filament was studied using flash desorption mass spectroscopy.

Experimental

The ultra-high vacuum apparatus used in this study is similar to that used in previous work[10,11] except that the reaction vessel with a volume of 1.0 l contained a polycrystalline tungsten filament with a geometrical surface area of 1.26 cm^2. The tungsten filament was analyzed spectroscopically. (Found: Mo, 0.08%; Mg, 0.004%)

The total pressure was measured by means of a Pirani gauge with a sensitivity of 7.2×10^{-8} Torr/μV for N_2 and NO, and 7.5×10^{-8} Torr/μV for O_2. An omegatron mass spectrometer was used for analyzing the gaseous component and for measuring the partial pressure in the reaction vessel; it has a sensitivity of 12 Torr^{-1} and 11.8 Torr^{-1} for N_2 and NO, respectively. A B-A gauge was used only for the ultimate-pressure measurement, because the nitrogen oxide was dissociated by the hot filament of the gauge.

The temperature of the tungsten filament was measured by the same method as that reported in a previous paper.[10] The nitrogen oxide and nitrogen were also prepared by the method described in that paper, and no impurities up to mass 200 were detected by means of the omegatron mass spectrometer.

The ultimate pressure, read on a B-A gauge, was 3×10^{-10} Torr in the reaction system after rigorous outgassing. Before the experiment, the tungsten filament was heated to 2200 K in an oxygen atmosphere of about 1×10^{-6} Torr for a long time, in order to remove carbonaceous surface contamination.

The procedure used for the present experiments are also similar to that previously described.[10] The number of molecules of nitrogen oxide or nitrogen that strike the tungsten filament during the adsorption process is calculated from the recorder trace of the omegatron or the Pirani gauge. The amount of adsorbed molecules is calculated from the pressure and the volume of the reaction vessel when the filament is flashed at 2200 K in the closed system. In the case of the adsorption of nitrogen oxide, the number of molecules adsorbed is twice the number of molecules desorbed, because the desorbed gas is nitrogen.

After the adsorbed layers were formed, the temperature of the tungsten filament was raised slowly with an approximately linear sweep rate while the system was being evacuated. During that period, the ion currents of the omegatron mass spectrometer for each mass were recorded on a chart recorder.

Results and Discussion

Sticking Probability and the Amount of Adsorbed Nitrogen Oxide and Nitrogen on Tungsten. The relation between the number of molecules impinging on the filament, $N_{(e)}$(exposure), at various temperatures and those adsorbed, N, is shown in Fig. 1. The saturation coverage for nitrogen oxide is 8.8×10^{14} molecules/cm^2 at 300 K, which is much higher in comparison with that on rhenium. For adsorption on a tungsten filament at elevated temperatures, the saturation coverage of nitrogen oxide decreases as shown in Fig. 1. There are 8.2×10^{14} and

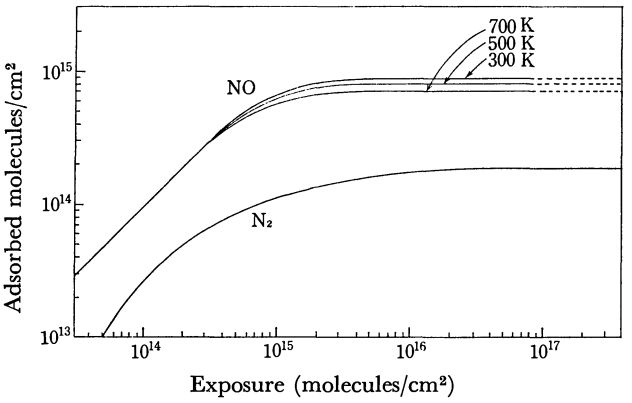

Fig. 1. Surface coverage as a function of exposure.

7.0×10^{14} molecules/cm^2 at 500 K and 700 K, respectively.

For the sake of comparison with nitrogen oxide adsorption, the adsorption of nitrogen was studied on the same tungsten filament. The saturation coverage of nitrogen on tungsten is 1.9×10^{14} molecules/cm^2, as is shown in Fig. 1. The saturation coverage for nitrogen oxide is 4.6 times as much as that for nitrogen. This ratio agrees with that on rhenium.[10] Assuming that the number of metal surface atoms is 1.5×10^{15} atoms/cm^2, this is equivalent to a W: NO ratio of about 2: 1. Yates *et al.*[6] state that the saturation coverage for nitrogen oxide on tungsten is 1.4×10^{15} molecules/cm^2, which is obtained from the ratio of the areas of the desorption spectrum of the nitrogen oxide monolayer to that of the nitrogen monolayer and from Ehrlich's data[12] for the adsorption of nitrogen on tungsten. Since saturation coverages of nitrogen on polycrystalline tungsten of 1.25 to 3.0×10^{14} molecules/cm^2 have been found by many investigators, as listed in Table 1, a comparison of the saturation coverage for nitrogen oxide and nitrogen should be made using the same tungsten filament.

Table 1. Comparison of initial sticking probabilities, saturation coverages and activation energies for nitrogen desorption

Investigator	s (initial)	Saturation coverage (molecules/cm^2)	E_d (kcal/mol)	Ref.
Schlier	0.42	1.8×10^{14}	—	13
Ehrlich	0.3	2.8×10^{14}	—	14
Hickmott	0.26	1.8×10^{14}	β: 81	15
Oguri	0.2	1.25×10^{14}	ε: 84 ζ: 69	16
Rigby	0.4	1.5×10^{14}	β_1: 73 β_2: 75	17
Yates, Jr.	—	1.6×10^{14}	β_1: 82 β_2: 84	18
Madey	—	—	β_1: 80 β_2: 82, 89	19
King	0.61	3.0×10^{14}	—	20
Tamura	0.35	1.9×10^{14}	β_1: 78 β_2: 80.5	This work

From the curve in Fig. 1, the sticking probability, s, can be calculated by means of the following equation:

$$s = \mathrm{d}N/\mathrm{d}N_{(e)}.$$

The relationship between the sticking probability and the surface coverage for nitrogen oxide is shown in Fig. 2. The initial sticking probability for nitrogen oxide adsorption on tungsten is close to unity up to $\theta\simeq0.4$ (θ is the monolayer fraction). This value agrees well with that found for the 110 surface of tungsten single crystals.[9] The initial sticking probability for nitrogen adsorption on tungsten obtained from Fig. 2 is 0.35, which is reasonable value in comparison with those of other papers.[13-17] Furthermore, the result obtained by the usual method, using flash desorption at a constant flow rate,[21] also agree with those of the present method. As in the case of the Re–NO system, one of reasons for such a high value of the initial sticking probability is that the ionization potential of nitrogen oxide (9.5 eV)[22] is lower than those of nitrogen ($\approx$16 eV), oxygen ($\approx$15 eV) and carbon monoxide ($\approx$14 eV).

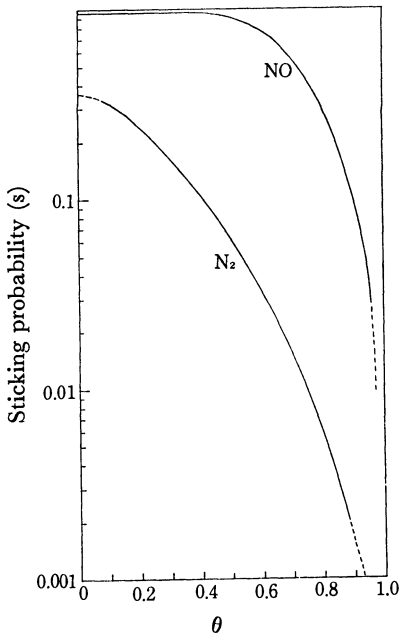

Fig. 2. Sticking probability as a function of surface coverage.

Rate of Adsorption and Desorption of Nitrogen Oxide and Nitrogen on Tungsten. It was confirmed that the rate of adsorption depends on the first power of the pressure. The rate of adsorption at constant pressure and temperature may, then, written as:

$$\mathrm{d}N/\mathrm{d}t = K\cdot P(1-\theta)^n,$$

where K and n are constants and P is the pressure of the nitrogen oxide or nitrogen. It was found that the rate of nitrogen oxide adsorption is proportional to $(1-\theta)$ as is shown in Fig. 3, and it seems that nitrogen oxide molecules are adsorbed non-dissociatively on tungsten. Nevertheless, for nitrogen adsorption, it may be shown that the adsorbed nitrogen was present in a dissociated form, because the rate of adsorption was proportional to $(1-\theta)^2$, as is shown in Fig. 3.

On the other hand, when the nitrogen oxide adsorbed is desorbed at definite temperature in a closed system,

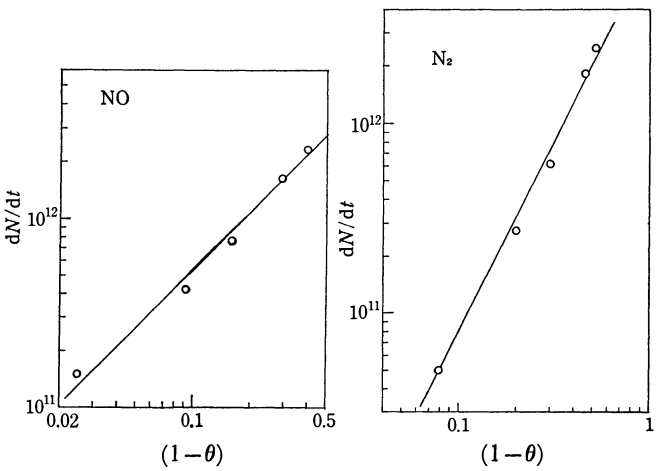

Fig. 3. The relation between the rate of adsorption and $(1-\theta)$.

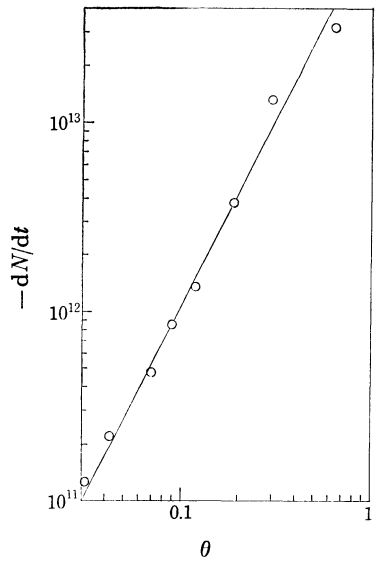

Fig. 4. The relation between the rate of nitrogen desorption and θ.

the rate of desorption may be expressed simply as:

$$-dN/dt = K'\theta^{n'},$$

where K' $[=\nu\exp(-E/RT)]$ is a constant and n' is the order of the desorption. In the W–NO system, the nitrogen oxide is decomposed for an increase in the tungsten temperature and is desorbed as in the case of nitrogen. The relation between the desorption rate and the surface coverage is shown in Fig. 4. As can be seen, the nitrogen desorption rate from a nitrogen oxide layer is roughly proportional to θ^2. At such high temperature, re-adsorption can be neglected.

Desorption Spectra. *1) Desorption from a Nitrogen Oxide Monolayer on Tungsten*: When tungsten saturated with nitrogen oxide was heated, nitrogen oxide and nitrogen from the tungsten surface due to decomposition of the nitrogen oxide desorbed, but neither molecular nor atomic oxygen were detected by means of the omegatron mass spectrometer. The desorption spectra from a nitrogen oxide monolayer on tungsten are shown in Fig. 5.

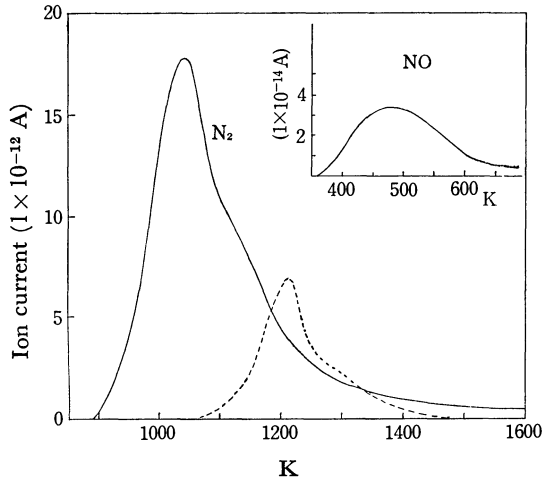

Fig. 5. The desorption spectra from nitrogen oxide monolayer. Dashed curve denotes nitrogen from nitrogen monolayer.

Table 2. The T_p of NO and N_2, and the amount of desorbed gas from a monolayer
(The percentages being calculated in terms of adsorbed NO)

	T_p (K)	%
NO	475	0.3
N_2	1045	99.7

The temperature of the desorption-peak maximum, T_p, for nitrogen oxide and nitrogen in each desorption spectrum, and the percentage calculated in terms of the adsorbed nitrogen oxide are shown in Table 2. Desorption of nitrogen oxide began at about 350 K, and above 900 K no further desorption of nitrogen oxide was observed. Moreover, when the initial coverage of nitrogen oxide was changed, no desorption of nitrogen oxide was observed below 0.75 nitrogen oxide monolayer. The greater part of the nitrogen from the nitrogen oxide monolayer desorbed before the temperature reached 1500 K. The T_p of the nitrogen desorption from a nitrogen oxide monolayer was lower than that from a nitrogen monolayer by about 170 K. Although Yates *et al.*[6] have observed the desorption of oxygen from a nitrogen oxide monolayer on tungsten, no oxygen desorption was seen in the present experiment. It appears that the oxygen from the nitrogen oxide monolayer evaporates as tungsten oxide.

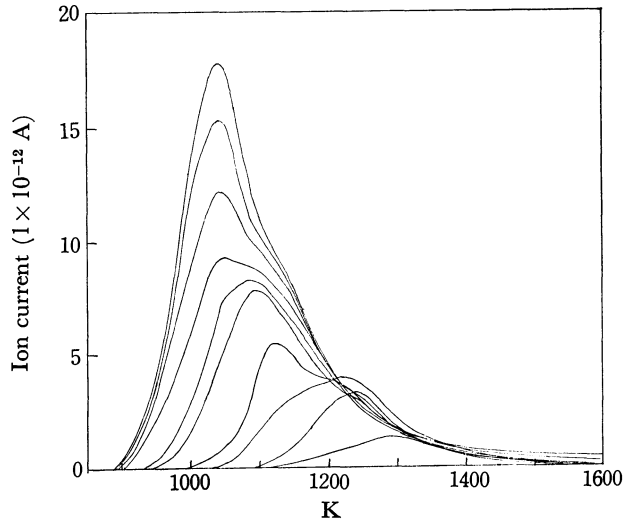

Fig. 6. The desorption spectra of nitrogen from various initial coverages of nitrogen oxide.

2) Desorption of Nitrogen from Various Initial Coverages of Nitrogen Oxide on Tungsten: The desorption spectra as a function of initial coverage of nitrogen oxide at 300 K are shown in Fig. 6. The desorption spectra for very low coverages of nitrogen oxide ($\theta<0.1$) resemble those for very low coverages of nitrogen. The T_p at $\theta=0.1$ and $\theta=0.2$—0.3 for nitrogen oxide adsorption correspond to the β_2 and β_1 peaks of the nitrogen desorption spectrum for a nitrogen layer on tungsten, respectively.

This behavior is reasonable, since the dissociation of nitrogen oxide for a very low coverage would produce a dilute layer of adsorbed nitrogen and oxygen (or oxide),

the desorption of nitrogen should be unaffected by the small amount of oxygen (or oxide) coverage. When the coverage of nitrogen oxide is increased, two new modes, ω_2(T_p: $\approx$1100 K) and ω_1 (T_p: 1045 K) peaks as designated by Yates *et al.*,[18] appeared which were formed beginning at about θ=0.3 and 0.7, respectively. However, no retrograde temperature behavior for the T_p of the ω_1 peak was observed in the present experiment.

Peng and Dawson, [23,26] and Matsushita and Hansen[24,25] have stated that these ω peaks resemble those for nitrogen desorption (λ state) from an adsorbed layer of ammonia on tungsten heated to 800 K or from that of activated nitrogen by electron bombardment, and that the number of total nitrogen atoms adsorbed is 8.6×10^{14} atoms/cm^2 because one nitrogen atom occupies a single vacancy site. Since one nitrogen oxide molecule may occupy a single vacancy site, a nitrogen oxide monolayer of 8.8×10^{14} molecules/cm^2 agrees with 8.6×10^{14} sites/cm^2 in the λ state of nitrogen adsorption.

The processes of adsorption, dissociation and desorption may be expressed as follows:

$$NO_{(g)} \longrightarrow NO_{(a)} \quad (1)$$
$$NO_{(a)} \longrightarrow N_{(a)} + O_{(a)} \quad (2)$$
$$2N_{(a)} \longrightarrow N_{2(g)} \quad (3)$$

Equations 2 and 3 are the reactions during the heating process. It is believed that the rate of process 2 is faster than that of process 3, since the rate of nitrogen desorption is roughly proportional to θ^2.

3) Desorption of Nitrogen from a Nitrogen Layer on Tungsten: The desorption spectra for various coverages of nitrogen are shown in Fig. 7. For nitrogen adsorption on tungsten at room temperature, three states, α, β_1, and β_2, were found in the desorption spectrum as has

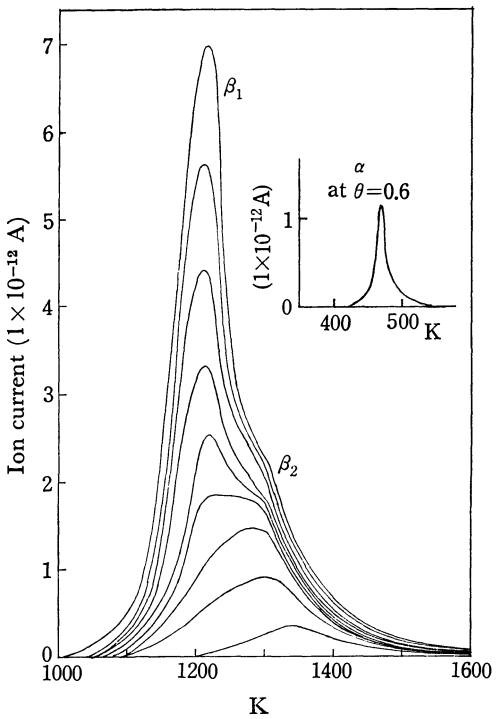

Fig. 7. The desorption spectra from various initial coverages of nitrogen.

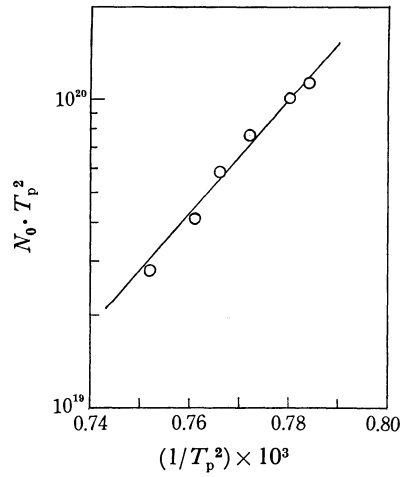

Fig. 8. A plot of log $N_0T_p^2$ *vs.* $1/T_p$.

been reported by other investigators.[16,17] The α state exhibits a maximum peak height (T_p: 470 K) at θ=0.6, and the α peak disappears for saturation coverage of nitrogen. The amount of α nitrogen desorbed corresponds to 5% of the β nitrogen at $\theta\simeq$0.6 (corresponding to 3% of a monolayer). Since the nitrogen from the α state desorbs at very low temperatures, it appears that the bond strength of W–$N_2(\alpha)$ is considerably weaker than those of the β states.

The β_1 peak appears beginning at $\theta\simeq$0.3. The T_p of the β_1 peak does not shift from the value of 1205 K as the coverage increases. According to Redhead's report,[27] and assuming that the desorption of the β_1 state follows first order kinetics and that the pre-exponential factor is 10^{13}/s, we obtain a value of 78 kcal/mol as the activation energy of β_1 nitrogen desorption.

On the other hand, the T_p of the β_2 peak shifts to a lower temperature with an increase in the coverage. Also, according to Redhead, when the desorption kinetics are 2nd order, the following equation should be valid:

$$E/RT_p^2 = (N_0\nu/\bar{\beta})\exp(-E/RT_p),$$

where N_0 is the initial coverage, ν is the rate constant, E is the activation energy for β_2 nitrogen desorption, and $\bar{\beta}$ is the rate at which the filament temperature is raised. A plot of $\log(N_0T_p^2)$ *vs.* $1/T_p$ is shown in Fig. 8. From the slope, the activation energy for desorption in the β_2 state is 80.5 kcal/mol. Data for the activation energy for nitrogen desorption on tungsten by other investigators are shown together in the Table 1.

Finite Element Approach to the Vibrational Schrödinger Equation of Diatomic Species

Hideyuki ARAI, Isao KANESAKA,* and Yukio KAGAWA**

Computer Center of Toyama University, Toyama University, Gofuku, Toyama 930

(Received January 5, 1976)

The finite element approach was successfully applied to the vibrational Schrödinger equation of diatomic species. An O_2 molecule with a harmonic potential and an Ar_2 molecule with a Lennard-Jones potential were examined and their eigen values and the associated eigen function were obtained. The calculated eigen values of the O_2 molecule agree with those expected. In the case of the Ar_2 molecule the calculated eigen values agree with those experimentally obtained when Lennard-Jones parameters are $\varepsilon=115.1$ (cm^{-1}) and $\sigma=3.35$ (Å). This verifies the validity of the present approach.

The finite element method was originally developed for the analysis of structures and has been widely applied to various problems in engineering science because of its versatility.

The method has been successfully applied to the analysis of the field problems, Laplace, Poisson and Helmholts equations.[1,2] It is a variant of the Rayleigh-Ritz procedure, turning a continuum field discrete with the best possible approximation by means of variational calculus which minimizes the functional corresponding to the governing differential equation. The present procedure might be an extended approach of the variational calculus widely used in wave mechanics.[3]

The purpose of this paper is to present the finite element method for the vibrational Schrödinger equation with two body potential V which is expressed as follows:

$$\frac{d^2\Psi}{dQ^2}+\frac{2\mu}{\hbar^2}(E-V)\Psi=0 \tag{1}$$

where Ψ is a wave function, Q a normal coordinate, μ a reduced mass, and E an eigen value.

If V is given by

$$V(Q)=\frac{1}{2}kQ^2 \tag{2}$$

where k is a force constant, Eq. 1 is the Schrödinger equation of harmonic oscillator.

In the case of the Lennard-Jones potential, which is of interest to us, V is given by

$$V(Q)=4\varepsilon\left\{\left(\frac{\sigma}{r_e+Q}\right)^{12}-\left(\frac{\sigma}{r_e+Q}\right)^{6}+0.25\right\} \tag{3}$$

where ε is a potential energy in equilibrium distance r_e and σ a distance of two bodies at $V=\varepsilon$.

The eigen values and their associated wave functions for harmonic oscillators as well as those under the Lennard-Jones potential were numerically calculated by means of the finite element approach. The results are compared with those obtained analytically and experimentally.

Functional and Finite Element Formulation

According to variational calculus the solution of Eq. 1 is equivalent to finding the function Ψ which minimizes the following functional:[3]

$$\chi=\int_Q\left\{\frac{1}{2}\left(\frac{d\Psi}{dQ}\right)^2-\frac{1}{2}\frac{2\mu}{\hbar^2}(E-V)\Psi^2\right\}dQ \tag{4}$$

where the integration is taken over the whole region under consideration.

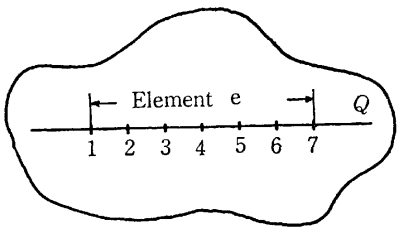

Fig. 1. The division of the region into the elements.

The region is divided into small elements (Fig. 1) for which the trial function was assumed to be:

$$\Psi=\sum_k^7\alpha_kQ^{k-1}=\mathbf{N}\boldsymbol{\alpha} \tag{5}$$

where the components of $\mathbf{N}$ are spatial functions and the α_s are seven unknown constants to be chosen so as to satisfy the nodal values at the element nodes.

Thus the function Ψ is uniquely specific within the element by the nodal values Ψ_1, Ψ_2, Ψ_3,……, Ψ_7, their associated coordinates being

$$\Psi^{(e)}=[\mathbf{N}_1\mathbf{N}_2\cdots\mathbf{N}_7]^T\boldsymbol{\alpha}=\mathbf{C}^{(e)}\boldsymbol{\alpha} \tag{6}$$

where (e) refers to the element and $\Psi^{(e)}$ indicates the values of Ψ at the nodes and is given by

$$\Psi^{(e)}=[\Psi_1\Psi_2\cdots\Psi_7]^T \tag{7}$$

T denotes transposition, and $\mathbf{N}_i$ consists of the coordinate value corresponding to node i, and is given by

$$\mathbf{N}_i=[1\,Q_i\,Q_i^2\cdots Q_i^6] \tag{8}$$

Premultiplying each side of Eq. 6 by $\mathbf{C}^{(e)-1}$ (inverse of $\mathbf{C}^{(e)}$ matrix) and substituting $\boldsymbol{\alpha}$ into Eq. 5, we obtain the trial function

$$\Psi=\mathbf{N}\mathbf{C}^{(e)-1}\Psi^{(e)} \tag{9}$$

Substituting Eq. 9 into Eq. 4, we get the functional for the element

$$\chi^{(e)}=\frac{1}{2}\Psi^{(e)T}(\mathbf{C}^{(e)-1})^T(\mathbf{P}^{(e)}-\mathbf{E}\mathbf{R}^{(e)})\mathbf{C}^{(e)-1}\Psi^{(e)} \tag{10}$$

where

$$\mathbf{P}^{(e)}=\int_e\frac{d}{dQ}\mathbf{N}^T\frac{d}{dQ}\mathbf{N}dQ+\frac{2\mu}{\hbar^2}\int_e V\mathbf{N}^T\mathbf{N}dQ \tag{11}$$

* *Faculty of Literature and Science, Toyama University, Gofuku, Toyama* 930.

** *Faculty of Engineering, Toyama University, Nakagawa, Takaoka* 933.

$$\mathbf{R}^{(e)} = \frac{2\mu}{\hbar^2}\int_e \mathbf{N}^T\mathbf{N}dQ \tag{12}$$

where the integration is taken over the element.

In order to minimize the functional $\chi^{(e)}$, we take the partial derivative with respect to $\Psi^{(e)}$ and obtain

$$\frac{d\chi^{(e)}}{d\Psi^{(e)}} = (\mathbf{C}^{(e)-1})^T\mathbf{P}^{(e)}\mathbf{C}^{(e)-1}\Psi^{(e)} - \mathbf{E}(\mathbf{C}^{(e)-1})^T\mathbf{R}^{(e)}\mathbf{C}^{(e)-1}\Psi^{(e)} = 0 \tag{13}$$

The equation holds for all the elements which divide the space.

The values of Ψ_1 at the interconnecting nodes between adjoining elements should be the same. Under these condition we obtain a linear algebraic equation of the form

$$(\mathbf{A}-\mathbf{EB})\Psi = 0 \tag{14}$$

The eigen values and the wave functions are calculated from Eq. 14.

Numerical Examples

The functional of Eq. 4 is defined in unbounded space where the integration should be carried out. This can not be achieved by numerical analysis. Since the lower eigen values are of interest, the potential is calculated for the lower well region, which is divided into elements.

The first example for calculation is of the O_2 molecule with harmonic potential. That is, Eq. 1 is to be solved under the conditions of Eq. 2. The eigen values and their eigen functions are resolved analytically.

Six elements divided the integrated region which was chosen so as to cover lower eigen values. Two schemes were considered for the method of division: Case 1, equal space division; Case 2, finer division employed for the vicinity of the potential well.

Table 1. The observed and calculated eigen values (cm^{-1}) of the O_2 and Ar_2 molecules

v	O_2			Ar_2		
	Anal[a]	Calcd		Obsd[b]	Calcd	
		Case 1	Case 2		[I]	[II]
0	791.3	794.0	791.2	15.1	13.9	14.7
1	2374.0	2458.6	2373.9	40.6	37.6	40.1
2	3956.7	4220.3	3959.0	60.7	56.4	60.7
3	5539.4	5984.7	5545.5	75.8	68.6	76.8
4	7122.0	9444.3	7169.9	86.4	79.3	87.3

a) Obtained from $k=11.8$ (mdyn/Å). b) From Refs. 4 and 6.

The calculated lower six eigen values are given in Table 1. The values obtained by the finite element approach agree reasonably with the analytical ones obtained on the basis of $\kappa=11.8$ (mdyn/Å). The results are not independent of the division method. Elements are not enough because of the limitation of the capacity of the computer. However, the present approach is promising if the division is proper by chosen (Case 2); the spacing of the i-th element from the origin is as follows: $\Delta Q^{(e_i)}=0.025|i|$, $i=\pm1$, ±2, ±3. The potential function used is shown in Fig. 2 with the eigen functions (not normalized) corresponding to the six lower eigen values.

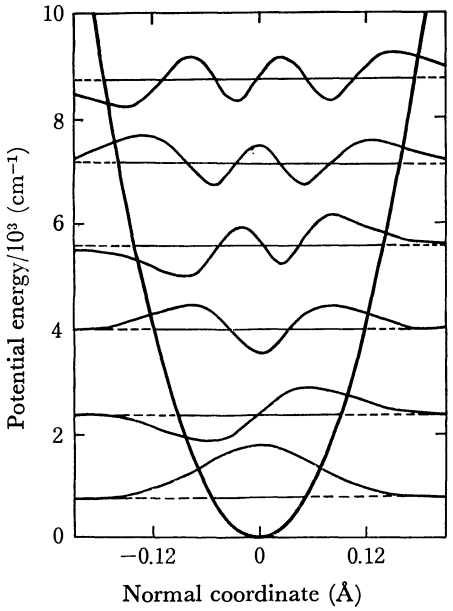

Fig. 2. The potential function and the calculated eigen functions (arbitrary unit) of the O_2 molecule. The solid horizontal lines show the level of the eigen values.

The next example of calculation is for the case with Lennard-Jones potential; it is to solve Eq. 1 under the conditions of Eq. 3. In this case the Ar_2 molecule is taken as an example. The experimental eigen values obtained by spectroscopic[4] and molecular beam[5] methods are given in Table 1. From the results we obtain: ε in Eq. 3 is 98.7 cm^{-1} and r_e 3.85 Å which gives the value of σ, 3.35 Å.

The region where the potential is negative in the

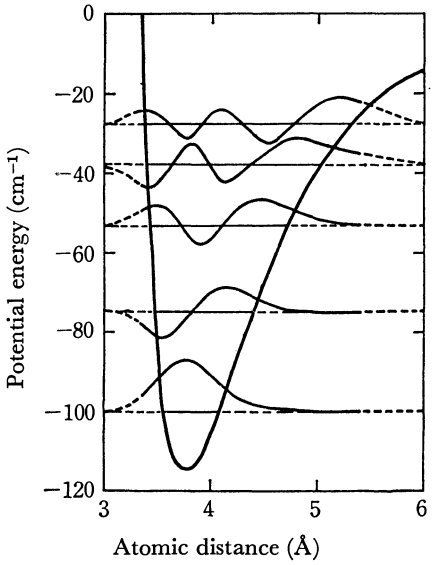

Fig. 3. The potential function and the calculated eigen functions (arbitrary unit) of the Ar_2 molecule. The solid horizontal lines show the level of the eigen values. The dotted lines are hypothetically drawn.

ordinary Lennard-Jones potential form was chosen for integration. Finer division was used for the vicinity of the potential well (Case 2); the spacing of the i-th element from the potential minimum is as follows: $\Delta Q^{(e_i)} = 2^{|i|-1}\{(2)^{1/6}\sigma - \sigma\}/3$, $i = \pm 1, \pm 2, 3, 4$. The calculated eigen values (Calcd I) are also given in Table 1. The agreement between the observed and calculated values is not satisfactory, the calculated ones being as a whole lower than the observed ones. We thus varied the value of ε. When ε is 115.1 cm^{-1}, the values of Calcd II are obtained, agreeing with those observed. This shows that since the Lennard-Jones potential explained the spectroscopic result,[4] this potential is proper for the bound state, though it has been unfavorable for the collision data.[5,6]

The potential function and the eigen functions for the Ar_2 molecule in the case of Calcd II are given in Fig. 3. The dotted lines for the eigen functions out of the region of integration are hypothetical.

Conclusion

The finite element approach is successfully applied to the vibrational Schrödinger equation. Simple examples of diatomic species are considered for verification of the approach. The method is promissing and seems to deserve further application.

The numerical calculations were performed at the Computer Center of Toyama University.

We wish to thank Professor K. Kawai, the Faculty of Literature and Science, Toyama University, for his valuable suggestions, and Professor S. Tanaka and Mr. S. Ishida of the Computer Center, Toyama University, for their help in the computation.

Nature of Catalytically Active Sites over Solid Acids. I. Selective Poisoning of Lewis Acid Sites on Silica-Alumina with Pyridine and Its Application to Olefin Polymerization

Koichi MIZUNO, Masanori IKEDA, Toshiaki IMOKAWA, Jun-ichiro TAKE, and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 4, 1976)

When pyridine chemisorbed on silica–alumina was evacuated at 350 °C, the 1460 cm^{-1} band due to Lewis-bound pyridine (LPY) remained while the 1540 cm^{-1} band due to Brønsted-bound pyridine (BPY) completely disappeared. This disappearance of the BPY band was revealed to accompany a loss of the Brønsted acid sites themselves besides their liberation. However, the lost Brønsted acid sites were regenerated by allowing the sample to stand overnight at 110 °C. Thus, strong Lewis acid sites of silica–alumina were able to be selectively poisoned by pyridine without any damage to the Brønsted acid sites. By poisoning catalysts *in situ* by controlled amounts in this way, the nature of the active site was investigated for polymerization of propylene or *cis*-2-butene at a low temperature of 30 °C. The initial activity declined sharply as the extent of pyridine poisoning of the Lewis acid sites increased. Therefore, it was concluded that strong Lewis acid sites (25—30% of the total Lewis acid content) were active in polymerization over silica–alumina.

The catalytic activities and selectivities in solid acid catalysts may be governed by the type of acid site, the acid strength, and the acid content. One of the characteristics of solid catalysts is that, in general, they have many kinds of chemisorption sites of different nature. Therefore, the determination of the role of these sites in reactions, especially the nature of catalytically active sites may be essential to the elucidation of reactions over solid acid catalysts. Infrared spectroscopy of chemisorbed pyridine has been recently proposed as a method for distinguishing between Brønsted and Lewis type surface acid sites.[1] Of a variety of methods so far proposed for the determination of the acidic properties of solid surfaces, this method is probably the most reliable. Only in a few studies[2,3] has this technique been applied to determine the nature of catalytically active sites. Even these determinations, however, require correlations between IR data on the acidic properties and reaction data, both obtained in separate experiments, and therefore, are rather indirect. If only a certain type of acid sites can be selectively poisoned with a base, the use of such a poisoned catalyst should permit a more direct determination of the nature of catalytically active sites. It has been found that upon evacuation at above 300 °C some Lewis-bound pyridine (LPY) over silica–alumina remains, whereas Brønsted-bound pyridine (BPY) disappears completely.[4,5] In the present study, it was attempted first, on the basis of this experimental fact, to prepare silica–alumina whose Lewis acid sites were selectively poisoned by pyridine without any poisoning of the Brønsted acid sites, and second, by using *in situ* such catalysts, to elucidate the nature of active sites for polymeric olefin formation reactions.

It is well known that an olefin such as propylene or butene forms an adsorbed residue giving rise to IR bands characteristic of a saturated hydrocarbon over silica–alumina[6] and deamminated ammonium Y (or HY) zeolite[7] at room temperature. Deuterium-tracer studies of butene isomerization over silica–alumina revealed that the residue is the active site for the isomerization.[8,9] Recently, the residue proved to consist of oligomers (about four monomer units, on the average).[10–12] However, the nature of active sites in the polymeric olefin formation has been controversial because of the lack of conclusive evidence. Ozaki and Kimura[8] have speculated that olefin was chemisorbed on Lewis acid sites as a monomer. Hirschler[10] concluded that Brønsted acid sites were active over silica–alumina on the basis of the similarity in composition of polymeric species formed over silica–alumina and those formed over deamminated Y zeolite. On the contrary, Weeks *et al.*[7] concluded that the active sites were dehydroxylated (surface Al^{3+} ions, *i.e.*, Lewis acid sites) over Y zeolite because no significant difference was found between products over deamminated and dehydroxylated zeolites. Peri[6] regarded an α-site, a pair consisting of an Al^{3+} ion (Lewis acid) and an oxide ion, to be active. Holm, Bailey, and Clark[13] and Sato, Aonuma, and Shiba[14] have reported that the catalytic activity of silica–alumina for propylene polymerization at an elevated temperature varied in proportion to the Brønsted acid content. However, reasonable objections have been presented to their determinations of the Brønsted acid content.[15] The present study employing silica–alumina, whose Lewis acid sites were selectively poisoned, revealed that the catalytic activity for the polymeric olefin formation declined sharply as the extent of pyridine poisoning of the Lewis acid sites increased. Therefore, it is concluded that strong Lewis acid sites are active in polymerization over silica–alumina.

Experimental

Materials. The silica–alumina (SA-1, 13% Al_2O_3, 540 m^2/g) was used in a previous study.[16] Pyridine distilled from a GR reagent was dried over KOH under vacuum, and finally vacuum-distilled into a vessel containing molecular sieve 5A evacuated at 350 °C before use. Propylene and *cis*-2-butene (Matheson Co.) were dried by circulation for 1.5 h over anhydrous magnesium perchlorate prepared freshly by evacuation up to 240 °C, and then were thoroughly degassed by the freeze-pump-thaw technique.

Sample Preparation. Self-supporting 20 mm diameter wafers of SA-1 were formed by pressing the oxide powder at 6200 kg/cm^2 in a conventional KBr die. For each wafer, 20—80 mg of sample was used.

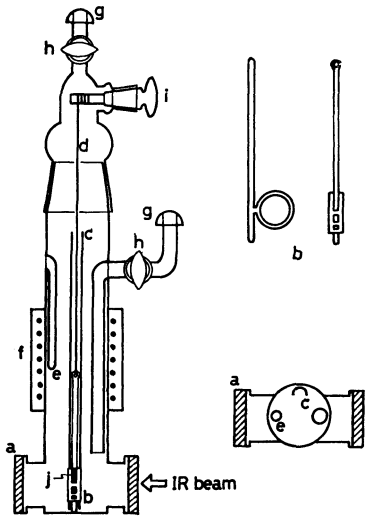

Fig. 1. Sketch of infrared cell. (a) CaF_2 window; (b) sample holder; (c) guideway; (d) Pt wire (0.2 mmϕ); (e) thermowell; (f) furnace; (g) ball joint; (h) stopcock; (i) reel; (j) sample wafer.

Infrared Cell. The cell used for IR-spectral measurements and as the reactor in reaction runs is shown in Fig. 1. The body was made of Pyrex or quartz, and equipped with CaF_2 windows (a) 40 mm in diameter and 5 mm thick. The middle of the cell was surrounded by a thermostatically controlled furnace (f).

A Pyrex or quartz sample holder (b), in which the wafer was mounted, was suspended with a Pt wire (d) from a reel (i), and could be moved through a guideway (c) up and down by winding up and off the Pt wire. This permitted reproducible positioning of the wafer in the analytical beam of the infrared spectrometer.

The cell could readily be connected through two ball joints (g) to a conventional vacuum manifold or to a closed circulation system (about 570 ml including the cell) for reaction runs.

Procedures. The wafer was inserted between two rings of the sample holder, pretreated in an oxygen stream as described earlier,[17] and finally activated in the cell by evacuation at 450 °C and about 10^{-4} mmHg usually for 15 h.

The amounts of Brønsted and Lewis acid sites were determined on the basis of IR absorption spectra of chemisorbed pyridine. The wafer was dosed with about 0.2 mmol/g of pyridine for 0.5 h at room temperature, and then evacuated for 1 h at 110 °C (referred to as the standard pyridine treatment) in order to eliminate hydrogen-bonded pyridine (HPY) which gives rise to the 1438 cm^{-1} band. The peak absorbances of the bands at 1540 and 1460 cm^{-1} (ascribable to BPY and LPY, respectively) were taken as the amount of acid sites of the corresponding type. The amount of acid sites thus obtained proved to agree excellently with that determined by means of the usual method in which a wafer was exposed to a large excess of pyridine vapor. By the use of such a small amount of pyridine, we were able to protect the wafer from surface contaminations with pyridine dissolved in the grease, as was evidenced, for example, by the absence of the slow reappearance of the HPY band after the 110 °C evacuation.

The polymeric olefin formation reaction was carried out in the closed circulation system provided with the cell at an initial olefin pressure of 10 mmHg and 30 °C. Its progress was followed by observing the IR spectrum of the polymeric species formed over the wafer after gaseous and physically-adsorbed olefin had been removed with a liquid nitrogen trap. During the course of this removal, the spectra of the polymeric species showed no significant change. The pressure decrease of the olefin was negligibly small for the period of the reaction.

Infrared spectra over the range of 4000 to 1300 cm^{-1} were recorded on a model DS-401G grating spectrometer (Japan Spectroscopic Co.) at room temperature. Attenuation of the reference beam with specially-designed screens was necessary to compensate for the energy loss due to light scattering by the wafer. Spectral slit widths were ~3 cm^{-1} at 1500 cm^{-1} and ~10 cm^{-1} at 3000 cm^{-1}.

Peak absorbances are all normalized so as to indicate the absorbance per unit optical thickness of the wafer. This normalized absorbance, AS/W (cm^2/g), corresponds to the quantity $\varepsilon M/W$, where A and ε are respectively the absorbance and the absorption coefficient of a band, M is the amount (mmol) of the responsible species, and S and W are the cross section (cm^2) and weight (g) of the wafer, respectively.

Results

Selective Poisoning of Lewis Acid Sites over Silica–Alumina. Figure 2 shows the IR spectra of pyridine chemisorbed on SA-1. The standard pyridine treatment of SA-1 produced spectrum (a), in which three bands appear at 1540, 1490, and 1460 cm^{-1} in accordance with spectra in the literature.[1,18] The bands at 1540, 1460, and 1490 cm^{-1} are ascribed to BPY, LPY, and to both species, respectively. Every band decreased in intensity when the wafer was evacuated at higher temperatures. On evacuation at 350 °C for 1 h (spectrum (b)), the LPY band remained while the BPY band completely disappeared. Seemingly this disappearance of the BPY band may indicate the desorption of BPY and hence mere liberation of the Brønsted acid sites. If this were true, the BPY band should reappear with the same intensity as the original when the standard pyridine treatment is repeated after the 350 °C evacuation.

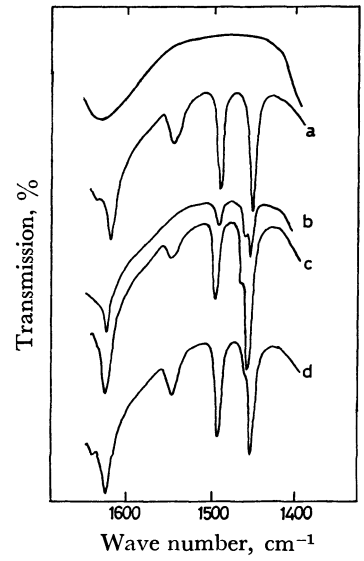

Fig. 2. IR-spectral changes of adsorbed pyridine induced by 350 °C-evacuation: (a) original; (b) after 350 °C evacuation for 1 h; (c) immediate standard pyridine treatment of (b); (d) standard pyridine treatment of (b) after 110 °C standing overnight.

a) cm^2g^{-1}. b) Overnight at 110 °C. c) Overnight at room temperature. d) After standing for 2 days.

Table 1 summarizes the results of an examination of this problem. The acid content of a fresh wafer, which is labelled "original," was determined first for both acid types. After the wafer had been successively evacuated at 350 °C for 1 h and allowed to stand under the conditions given in Table 1, its acid contents were determined again. Acidity data obtained from several cycles of this procedure, in which the conditions for standing were altered in the sequence cited, are given in the lines indicating the corresponding treatment. The arrows indicate the particular treatments that were not followed. The immediate standard pyridine treatment after the 350 °C evacuation ("none" in Table 1 and spectrum (c)) revealed that the intensity of the BPY band decreased definitely while the intensity of the LPY band did not significantly change. This indicates that evacuation at 350 °C gives rise to the loss of some Brønsted acid sites themselves over SA-1, in addition to the liberation of these sites resulting from the desorption of BPY. On the other hand, when the wafer was allowed to stand overnight at 110 °C after the 350 °C evacuation, spectrum (d) was observed to be identical to spectrum (a). This fact demonstrates that the Brønsted acid sites lost are regenerated by allowing the wafer to stand overnight at 110 °C. These observations are reproducible as is seen in Table 1. In conclusion, the selective poisoning of Lewis acid sites over silica–alumina is attainable without any damage to the Brønsted acid sites when the following treatment is employed: the wafer is dosed with pyridine, evacuated at 350 °C, and allowed to stand overnight at 110 °C.

The mechanism of the loss and regeneration of Brønsted acid sites is not completely clear at present. In view of the same absorption coefficients for the BPY and LPY bands,[19–21] inspection of Table 1 indicates that the total number of acid sites (Brønsted plus Lewis) remains sensibly constant at all stages. The loss of Brønsted acid sites is compensated with the generation of Lewis acid sites, and the regeneration of the former with the loss of the latter. This observation may be associated with the well-known interconversion of Brønsted and Lewis acid sites on silica–alumina:[5,18] the conversion of Brønsted to Lewis acid sites occurs on dehydration and the reverse occurs on hydration. Some empirical evidence was reported to suggest that the presence of bases such as pyridine facilitates dehydration or dehydroxylation of the surface.[22,23] However, the regeneration, especially of an exact amount, of the lost Brønsted acid sites after standing overnight at 110 °C is surprising in view of the experimental procedure employed in which no water was added. The hydroxylation may result from the action of water from the bulk of the catalyst. Table 1 also suggests that this regeneration includes a slow chemical process.

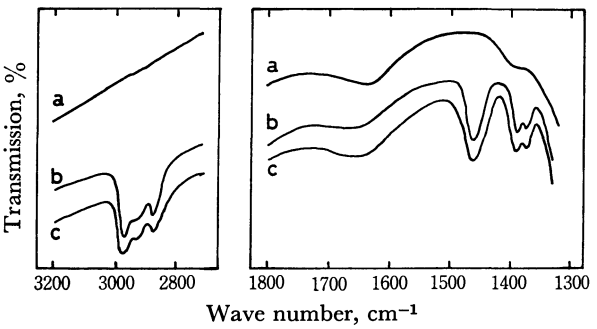

Fig. 3. IR spectra of polymeric *cis*-2-butene over SA-1. Background spectra (a); spectra of polymeric *cis*-2-butene 2 (b) and 20 h (c) after the reaction at 30 °C and 10 mmHg.

Polymeric Olefin Formation. Introduction of propylene or *cis*-2-butene onto SA-1 immediately produced the irreversibly adsorbed species giving rise to IR absorption bands at 2970—2960, 2930, and 2870 cm^{-1} in the C–H stretching region and at 1470, 1385, and 1370 cm^{-1} in the C–H deformation region. Figure 3 shows some spectra recorded, which are characteristic of saturated hydrocarbons. Each band grew steadily and reached a constant intensity 1—2 days after the introduction of the olefin (see Fig. 4). At any stage of the reaction, no olefinic species was detected, as evidenced by the absence of absorption in the unsaturated C–H stretching (3300—3000 cm^{-1}) and C=C stretching regions (1700—1600 cm^{-1}). The adsorbed species was not desorbed on evacuation at room temperature, and was desorbed by about 50, 80, and 95% on evacuation at 100, 200, and 450 °C, respectively, indicating that it is strongly held to the surface. Recently, the adsorbed species have been proven to be oligomers.[10–12]

The amount of polymeric propylene formed and its

Table 2. Distribution of desorption products of polymeric propylene (100 °C)

Reaction time, min	Amount of polymeric propylene,[a] μmol/g	H/C Ratio	Desorption products, mol %						
			C_3	C_4	C_5	C_6	C_7	C_8	C_9
1	70	1.9	26	44	18	7	1	1	2
5	142	—	19	46	21	11	1	1	1
30	223	1.9	6	52	22	14	2	1	3

a) On propylene basis.

H/C ratio were determined by means of the combustion method. The results are given in Table 2. The experiments were carried out in a separate closed circulation system (ordinarily, 1300 ml) with SA-1 powder (*ca.* 1 g) which had been pretreated and activated in the same manner as in the IR study. After exposure to olefin for the times described and removal of gaseous and physically-adsorbed hydrocarbons with a liquid nitrogen trap, dry oxygen at about 500 mmHg was circulated over the wafer at 450 °C overnight. The carbon dioxide and water produced were separated with a liquid nitrogen trap and a dry ice/ethanol trap, and the corresponding amounts were determined volumetrically. The amount of the polymeric species obtained by means of the present method, which is given on the olefin monomer basis, agreed well with that from the pressure decrease of the gaseous olefin. With either propylene or *cis*-2-butene, the peak intensity at 2970—2960 cm^{-1} was found to be proportional to the amount of the polymeric species. The intensity of this peak was therefore taken to be the amount of the polymeric species formed.

The distribution of desorption products of the polymeric propylene are also given in Table 2. After removal of gaseous and physically-adsorbed hydrocarbons with a liquid nitrogen trap, the sample was inserted into a furnace previously regulated thermostatically at 100 °C and maintained at the same temperature for 1 h. The desorbed products were collected into a trap maintained at −196 °C with or without evacuation, and analyzed with two FID gas chromatographs equipped with a VZ-7 column operating at room temperature and with a silicon DC-11 column temperature-programmed from room temperature to 150 °C at 6 °C/min, respectively. No hydrocarbons other than reactant propylene were detected in the gas phase. Neither C_1- nor C_2-hydrocarbons were detected in the desorption products. The C_3-hydrocarbons consisted only of propylene and the C_4-hydrocarbons contained mainly 1-butene and/or isobutylene. Although the VZ-7 column used could not separate 1-butene from isobutylene, this GLC peak may be due to isobutylene because of the absence of 2-butene. The C_4-, C_5-, C_7-, and C_8-hydrocarbons are probably cracking products of polymeric propylene. As the reaction proceeded, the amount of propylene (a C_3-hydrocarbon) decreased, whereas the amount of higher (C_4—C_9) hydrocarbons increased, suggesting that monomeric olefin changes successively into dimer, trimer, and higher oligomers over the surface.

Selective Poisoning Study of Polymeric Olefin Formation. Preliminary experiments revealed that the catalytic activity of SA-1 decreased in a drastic way when its Lewis acid sites were selectively poisoned with an amount of pyridine (*ca.* 0.2 mmol/g) similar to that in the acid content measurements, strongly suggesting that Lewis acid sites are active in the polymerization. Confirmation of this suggestion required that a series of more active, selectively poisoned wafers were prepared by using smaller amounts of pyridine. For this reason, it was necessary to determine the acid contents of a wafer after activity tests, assuming that the acid content was conserved for each acid type before and after the reaction.

Table 3. Conservation of acid contents before and after reaction

	Peak intensity, $cm^2\ g^{-1}$		
	BPY (1540)	LPY (1460)	BPY+LPY (1490)
Before reaction:			
a. acid content	2.2	20.7	7.4
b. selectively poisoned	0	5.6	1.6
After reaction:			
c. removal of gaseous propylene with a liq. N_2 trap	0	—	1.7
d. acid content	2.3	18.3	8.0

As is shown in Table 3, the validity of the assumption was confirmed by an examination with one wafer poisoned selectively with about 0.2 mmol/g of pyridine. The acid contents after reaction (d), which were determined by a method described below, agree with those before reaction (a) to within the experimental error. Table 3 also shows that no pyridine held on the Lewis acid sites migrates onto Brønsted acid sites during the course of the reaction (b and c). This is evidenced by the absence of the BPY band after the reaction and the invariability of the intensity of the 1490 cm^{-1} band. After the reaction, the LPY band overlapped with the strong 1470 cm^{-1} band assigned to the CH_2 and asymmetrical CH_3 deformations of the polymeric olefin.

On the basis of these results, the following procedure was employed for reaction experiments. An activated wafer was dosed with a small amount of pyridine for 0.5 h at room temperature, evacuated for 1 h at 350 °C, and allowed to stand overnight at 110°C. The poisoned state of the wafer surface was ascertained on the basis of its IR spectra. The reaction was conducted as described above. After the polymeric olefin had been removed by evacuation for 1 h at 350 °C, the wafer was dosed with about 0.2 mmol/g of pyridine, allowed to stand overnight at 110 °C, and finally evacuated

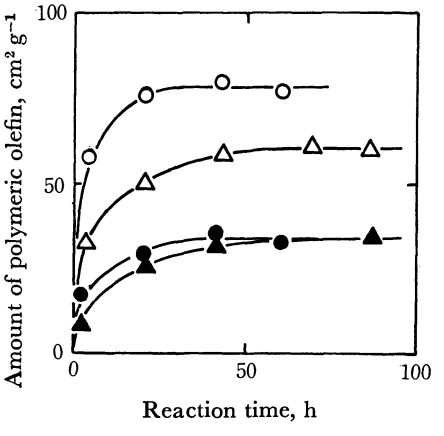

Fig. 4. Time-course of the formation of polymeric olefin: propylene over clean (△) and selectively poisoned (▲) SA-1; *cis*-2-butene over clean (○) and selectively poisoned (●) SA-1.

for 1 h at the same temperature, in order to determine its acid contents.

Figure 4 shows the time evolution of the formation of the polymeric olefin over a clean and a selectively poisoned wafer. On both wafers, the formation of the polymeric olefin took place rapidly in the early stage of the reaction, slowed down gradually, and finally ceased after 1—2 days. At any stage of the reaction, the amount of polymeric olefin formed was smaller on a selectively poisoned wafer than on a clean wafer. The amount of the polymeric olefin formed after 1 min was taken as the initial activity.

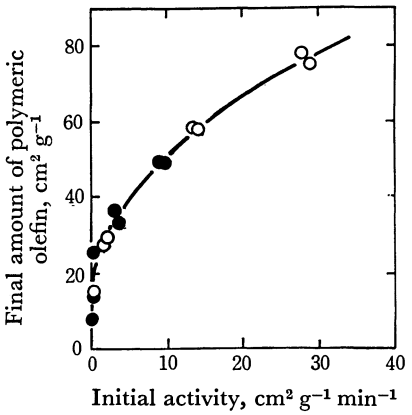

Fig. 5. Correlation between the initial activity and the final amount of formation of polymeric olefin: propylene (●) and *cis*-2-butene (○).

Figure 5 shows a correlation of the initial activity with the amount of polymeric olefin formed after 20 h (the final amount of formation). The final amount of formation of the polymeric olefin increased with an increase in the initial activity.

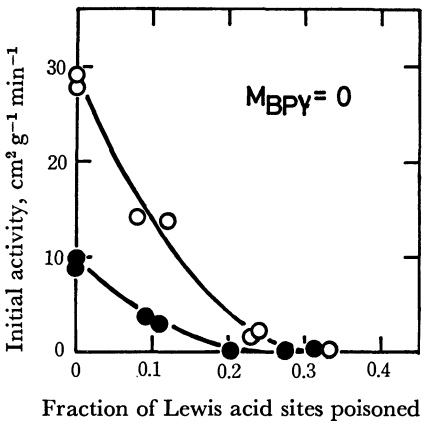

Fig. 6. Effect of pyridine poisoning on the initial activity for the formation of polymeric olefin: propylene (●) and *cis*-2-butene (○).

Figure 6 illustrates a relationship between the initial activity and the fraction of Lewis acid sites poisoned. The fraction of Lewis acid sites poisoned was calculated for each wafer from the amount of Lewis acid sites poisoned (the intensity of the LPY band) before the reaction and the Lewis acid content determined after the reaction. It should be noted here that for all the wafers used no Brønsted acid sites are poisoned, *i.e.*, $M_{BPY}=0$.

Discussion

Nature of the Polymeric Species. The polymeric species have characteristics of saturated hydrocarbons, as characterized in their IR spectra by the absence of unsaturated =C–H and C=C stretching bands and by the presence of saturated C–H stretching and bending bands. Unlike an adsorbed paraffin, however, the species is strongly held to the surface. Such characteristics are also evidenced by the finding that the H/C ratio is close to 2 for the polymeric species (Table 2) and that no materials other than reactant olefins were detected in the gas phase. This, as well as the absence of a band around 1600 cm^{-1} arising from a conjugated polyene structure, indicates that no dehydrogenation of the polymeric species occurs under the experimental conditions employed. It has been reported that dehydrogenation occurs at higher temperatures.[24-26]

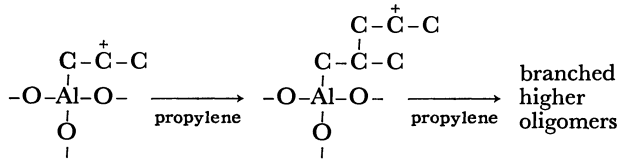
IR bands in the C–H deformation region provide, in general, valuable structural information about hydrocarbons. Hirschler[10] characterized the extracted polymeric species as a mixture of highly-branched polymeric monoolefin on the basis of its IR spectrum. In the symmetrical CH_3 deformation region, the doublet at 1385 and 1370 cm^{-1} is an indication of the presence of a $(CH_3)_2CH$–, $(CH_3)_2CR$–, or $(CH_3)_3C$– group in the species.[27] Therefore, the polymeric species probably is branched and consists of saturated oligomers with a cationic property. Recent Raman and IR spectra[28] of butyl cations show that in the relevant frequency regions no significant difference is found between butyl cations and the corresponding neutral butyl groups. A cationic property of the polymeric species is also suggested by difference in the reactivity of various olefins (isobutylene$\gg$*cis*-2-butene$>$propylene $\gg$ethylene).

Nature of Active Sites. Figure 6 indicates that the initial activity of SA-1 declines sharply for polymeric olefin formation as the fraction of Lewis acid sites poisoned increases, in spite of the fact that the Brønsted acid sites remain unpoisoned for all the samples. Since the initial activity should depend directly upon the number of active sites, these results unequivocally demonstrate that some of the Lewis acid sites (25—30% of the total Lewis acid content) play a vital role in initiating the reaction over silica–alumina. The pyridine molecules held to Lewis acid sites of all samples are those which remain unremoved on the Lewis acid sites even by evacuation at a temperature as high as 350 °C. It can be stated, therefore, that such Lewis acid sites are strongly acidic. Consequently, the conclusion is drawn that strong Lewis acid sites are active in the formation of the polymeric olefin over silica–alumina. This conclusion is consistent with our recent results that added-back water sharply decreases the initial activity of SA-1 and to a slight extent the Lewis acid content, in spite of an increase in the Brønsted acid content.[21] Although the catalysts of Friedel-Crafts type have been thought to require a co-catalyst such as water

and alcohol,[29] recent studies of isobutylene polymerization in the liquid phase revealed that $AlBr_3$[30] and $AlCl_3$[31] both catalyzed the reaction even in the absence of a co-catalyst.

As expected from Fig. 5, a correlation similar to that in Fig. 6 was found between the final amount of formation of the polymeric olefin and the extent of pyridine poisoning of the Lewis acid sites. This correlation indicates that the final amount of formation decreases with a decrease in the number of the active sites. If polymeric olefin migrated onto sites other than the active sites, where it was formed, and liberated them, the final amount of formation of the polymeric olefin should ultimately become essentially the same for all the samples, independent of the number of unpoisoned active sites. Therefore, the above correlation is easily explained on the assumption that the polymeric olefin grows on the active sites that initiated the reaction and remains on them.

In view of this interpretation as well as the nature of the polymeric olefin described above, the formation of the polymeric olefin may be visualized as follows:



Polymerization may accompany isomerization resulting in further branching of the oligomers. Since the distribution of products shown in Table 3 is substantially the same as that found in the gas phase in the olefin polymerization over silica–alumina at higher temperatures,[25,26] the high-temperature polymerization may proceed *via* a polymeric olefin intermediate.

The authors are indebted to Drs. Yasukazu Saito, Toshio Uchijima, and Makoto Misono for valuable discussions.

The Primary Process of the Photochemical Isomerization of Azanaphthalene *N*-Oxides

Norisuke HATA and Isao ONO

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya, Tokyo 157

(Received February 12, 1976)

The quantum yields for the photochemical isomerization of azanaphthalene *N*-oxides, such as quinoline *N*-oxide and isoquinoline *N*-oxide, into lactam (Process I) or oxazepine (Process II) were determined in benzene (or carbon tetrachloride), in methanol, and in mixtures of the two solvents. Consequently, the reaction was revealed to be closely related to whether or not the *N*-oxide oxygen atom forms a hydrogen bond with the solvent molecule; that is, a strong hydrogen-bonding interaction between the excited singlet *N*-oxide and alcohol is essential for Process I, but not for Process II. It was further demonstrated that Process II occurred with the formation of powerful oxidants (probably oxaziridines) from the excited singlet *N*-oxide, whereas such an oxidizing species was not involved in Process I. The reaction mechanisms of Processes I and II were also discussed on the basis of the present experimental results.

It has been well established that the photochemical isomerization of quinoline *N*-oxide or isoquinoline *N*-oxide into lactam (Process I) or oxazepine (Process II)[1] occurs from the lowest excited singlet state (S_1).[2,3] In order to account for such a photoisomerization, oxaziridines have been customarily postulated as the primary photoproduct from which all the products were derived.[4] However, several experimental data conflicting with this idea have recently been documented in the literature. Lohse has concluded from the results of his laser photolysis and quantum-yield measurements of isoquinoline *N*-oxides that there was no common intermediate leading to both Processes I and II.[2] In view of the photochemical behavior of isoquinoline *N*-oxide in water at different pH values, we have also indicated that the intervention of an oxaziridine intermediate is extremely doubtful in Process I.[3]

In the present paper, we wish to report some new observations and interpretations of the primary process of the photochemical isomerization of azanaphthalene *N*-oxides, such as quinoline *N*-oxide and isoquinoline *N*-oxide.

Experimental

2-Phenyl-, 3-phenyl-, and 2-cyano-quinoline *N*-oxides, and isoquinoline *N*-oxide were synthesized and purified according to the method given in the literature.[5,6] In the irradiation experiments, reagent-grade benzene, methanol, and ethanol of Wako Pure Chemical Industries Co. and also spectro-grade carbon tetrachloride (Dojindo Co.) were used without further purification. The photolytic procedure was quite similar to that described in a previous paper.[3] Small-scale photolyses for the determination of the quantum yield were performed in a quartz cylindrical cell (5-cm in diameter and 1-cm in length), using a 250 W high-pressure mercury lamp (USH-250D) equipped with a filter combination of a nickel sulfate solution with UV-31 and UVD-25 Toshiba filters, while the light intensity was determined by means of a potassium tris-(oxalato)ferrate(III) actinometer. Large-scale photolyses were carried out in a Pyrex vessel (70 ml) using a 100 W high-pressure immersion mercury lamp (Riko Kagaku Sangyo Co.). All the photolytic experiments were undertaken in a nitrogen atmosphere. The UV absorption spectra were measured with a Hitachi recording spectrophotometer EPS-3T.

Results and Discussion

The photochemical isomerization of azanaphthalene *N*-oxides in solution is well known to be very sensitive to the nature of the solvent or substituent group.[4] That is, isoquinoline *N*-oxide **1**, quinoline *N*-oxide **2**, or 3-phenylquinoline *N*-oxide **3** isomerizes predominantly to the corresponding lactam, **1a**, **2a**, or **3a**, in a hydroxylic solvent, such as alcohol and water (Process I), whereas in a nonhydroxylic solvent, such as benzene and acetone, these *N*-oxides are primarily converted into the corresponding oxazepines **1b**, **2b**, and **3b** (Process II). In the case of 2-phenylquinoline *N*-oxide **4** or 2-cyanoquinoline *N*-oxide **5**, having an electron-withdrawing group at the 2-position of a quinoline nucleus, however, Process II occurs preferentially to give rise to a stable oxazepine, **4b** or **5b**, irrespective of the nature of the solvent, whether hydroxylic or nonhydroxylic. Table 1 lists the chemical yields of the main products of the photolyses of **1**—**5** in various solvents. Meanwhile, the intermolecular hydrogen-bonding in heterocyclic *N*-oxides has been investigated spectroscopically in detail.[12] It has been thus proved that the oxygen atom of the $N\rightarrow O$ group in **1**, **2**, or **3** formed a strong hydrogen bond to alcohol or water, whereas such a hydrogen-bonding interaction was negligibly small in the case of **4** or **5** because of the electron-withdrawing group at the 2-position of a quinoline nucleus.

It is inferred from the foregoing that the remarkable dependence of the photochemical isomerization of azanaphthalene *N*-oxides on the nature of the solvent or substituent is closely related to whether or not the *N*-oxide oxygen atom can form a hydrogen bond with a hydroxylic solvent. In order to clarify this point, we determined the qunatum yield of both the disappearance of *N*-oxide (Φ_{dis}) and the formation of lactam or oxazepine (Φ_{lac} or Φ_{oxa}) for **1**, **3**, and **4** in benzene (or carbon tetrachloride), in methanol, and in mixtures of the two solvents at room temperature.

Figure 1 shows the results when the quantum yield for the disappearance of **1** or **4** was plotted against the concentration of methanol in a carbon tetrachloride

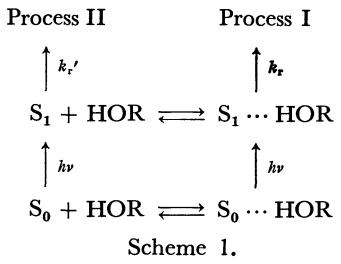
or benzene solution, from which the quantum yield was noticed to decrease with an increase in the concentration of methanol.

Figure 2 shows the quantum yield of the formation of lactam or oxazepine determined as a function of the concentration of methanol in a benzene solution. As can be seen from Curve (a) or (b) in the figure, the value of Φ_{lac} in a benzene solution of **1** or **3** increased steeply upon the addition of a small amount of methanol until it became approximately a constant value at a concentration of methanol greater than 5 vol%. On the other hand, **4** showed a continuous decrease in Φ_{oxa} as the concentration of methanol increased (Curve (c) in Fig. 2).

As is shown in Scheme 1, such a dependence of the quantum yield on the concentration of the alcohol could be interpreted in terms of a hydrogen-bonding equilibrium between the *N*-oxide and alcohol;[13,14] in

this scheme it was assumed that Process I proceeds from the excited singlet *N*-oxide hydrogen-bonded to alcohol ($S_1\cdots HOR$), while the nonhydrogen-bonded excited singlet *N*-oxide (S_1) undergoes Process II.



Scheme 1.

Assuming photostationary state conditions, the quantum yield for the formation of oxazepine or lactam is given by Eq. 1 or 2;

$$1/\Phi_{oxa} = K_e(k_r+k_d)[ROH]/k_{r'} + (k_{r'}+k_{d'})/k_{r'} \quad (1)$$

$$1/\Phi_{lac} = (k_{r'}+k_{d'})/K_e k_r[ROH] + (k_r+k_d)/k_r \quad (2)$$

where k_d or $k_{d'}$ is the sum of the rate constants of the deactivation of $S_1\cdots HOR$ or S_1 other than the reaction, k_r or $k_{r'}$ is the rate constant of the reaction of $S_1\cdots HOR$ or S_1 to give products responsible for Process I or Process II, and K_e is the equilibrium constant between $S_1\cdots HOR$ and S_1. Accordingly, if this scheme is correct, the reciprocal of Φ_{oxa} or Φ_{lac} should be directly proportional to the alcohol concentration or its reciprocal. In fact, as is shown in Figs. 3 and 4, the plot of Φ_{oxa} or Φ_{lac} against [MeOH] or its reciprocal was found to be linear, which was consistent with Eq. 1 or 2. This means that Process I proceeds through the S_1-species hydrogen-bonded to methanol, while the nonhydrogen-bonded S_1-species is responsible for Process II.

The first step in the photochemical isomerization of heterocyclic *N*-oxides has been supposed to be the formation of an oxaziridine intermediate common to both Processes I and II. However, all attempts to observe oxaziridine intermediates have been unsuccessful, except for the case of 9-cyano- or 9-chloroacridine *N*-oxide, where the isolation of oxaziridine has been effected in the form of the valence-tautomer.[15] If the photochemical isomerization of quinoline *N*-oxide or isoquinoline *N*-oxide proceeds *via* an oxaziridine intermediate, irradiations of the *N*-oxides in the presence of the iodide ion would have to bring about the liberation of iodine and the formation of parent amine at the same

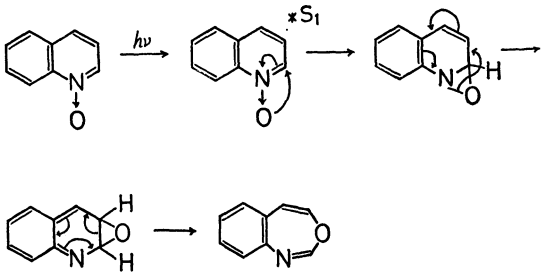
5	0 M	**5b** (73), 2-Quinolinecarbonitrile (trace)
	1.0 M	2-Quinolinecarbonitrile (68)

Concentration of *N*-oxide; 5×10^{-3}M. Solvent; 40 ml of ethanol–water (1: 1). Irradiation Time; 20 min.

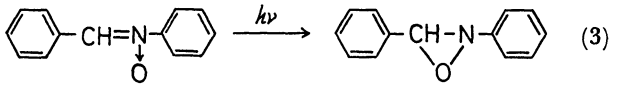
time, for oxaziridines are normally powerful oxidants. Figure 5 and Table 2 show the results when the photolysis of **1** or **5** was performed in aqueous ethanol containing potassium iodide in a nitrogen atmosphere, where iodine release was followed iodometrically as a function of the irradiation time. As may be seen from Fig. 5, iodine was detected in quantity in the case of **5**, but not in the case of **1**. In addition, in the case of **5** there was observed a complete quenching of the photoisomerization and a marked increase in the yield of the deoxygenation product (2-quinolinecarbonitrile), whereas the photochemical reaction of **1** was scarcely affected by iodide ions (Table 2). These results suggest that Process II takes place with the formation of a powerful oxidant (probably oxaziridine) from the excited singlet *N*-oxide, whereas such an oxidizing intermediate is not involved in Process I.

From the experimental results presented above, the following conclusions can be obtained regarding the primary process of the photochemical isomerization of azanaphthalene *N*-oxides: (i) When the *N*-oxide oxygen atom does not form a hydrogen bond with solvent molecules, the azanaphthalene *N*-oxide excited into the S_1 state may be initially converted into the oxaziridine and thereafter transformed into the oxazepine (Process II). This is quite consistent with the mechanism given by earlier investigators (Scheme 2).[4] (ii) When there



Scheme 2.

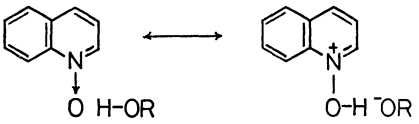
is a strong hydrogen-bonding interaction between the *N*-oxide oxygen atom and the solvent molecule, the azanaphthalene *N*-oxide may undergo photochemical rearrangement to the lactam without the formation of an oxaziridine intermediate (Process I), as we have deduced in a previous paper.[3] These conclusions also imply that the formation of oxaziridine from the excited singlet *N*-oxide is greatly diminished by the hydrogen-bonding interaction between the *N*-oxide oxygen atom and the hydroxylic solvent. A very similar conclusion has also been obtained by Tanaka *et al.* in the case of the photochemical isomerization of α,*N*-diphenylnitrone to oxaziridine (singlet reactions) in solution



(3)

(Eq. 3),[16] where the drop in the quantum yield of the reaction has been shown to be produced either by changing the solvent from cyclohexane to ethanol or by introducing a hydroxyl group to the *ortho*-position of an α-phenyl ring.

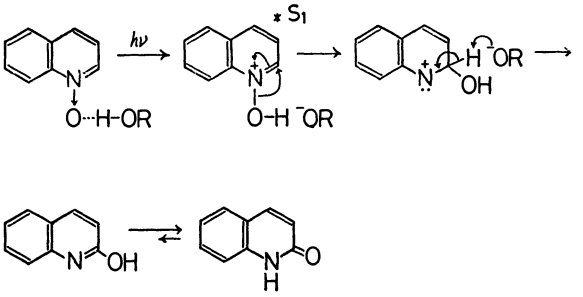
As to the mechanism of Process I, Kaneko and Buchardt have independently presented the idea that the primary photoproduct was an oxaziridine which can be postulated to undergo a heterolytic cleavage to give a carbonium ion or a zwitterion[4] (*cf.* Schemes 1 and 2 in Ref. 3), but such a mechanism evidently conflicts with the conclusion described above. Therefore, we propose the following mechanism to account for Process I (Scheme 3): According to the concept of electron donor-acceptor interaction, hydrogen bond formation is generally accepted to be due to the stabilization caused by resonance interaction between the no-bond structure and the CT structure, *e.g.*, Eq. 4, which is shown for quinoline *N*-oxide, and the contribution of the CT structure may be important in strong



(4)

no-bond structure CT structure

hydrogen-bonding.[12c] Therefore, as is shown in Scheme 3, the photoexcitation of such a hydrogen-bonded *N*-oxide is presumed to cause a protonation of the N→O group to give ion-pairs, through which a conversion to the lactam could occur.[17]



Scheme 3.

In conclusion, the authors wish to thank Professor Oyo Mitsunobu for his kind discussion and Miss Michiko Maniwa for her assistance.

The Crystal Structure of the Intermolecular Complex between 9-Ethyladenine and Indole

Tsuguhiro KANEDA and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received February 12, 1976)

The crystal structure of a 1: 1 complex of 9-ethyladenine and indole has been determined by the X-ray method. The crystal system is monoclinic with the space group of $P2_1/c$. The cell dimensions are $a=15.712(2)$, $b=8.098(1)$, $c=11.838(1)$Å, and $\beta=103.90(1)°$. Adenines form walls made of double layer. An overlap of adenines is found between layers. The adenine molecule in the front layer is found to be joined by the hydrogen bond with the molecule in the back layer. An intermolecular hydrogen bond is found between adenine and indole rings. The significance of these observations in the interaction of adenine with tryptophan in biological systems is discussed.

The crystal structures of adenine derivatives and its complexes with uracil or thymine have been studied in order to find the intermolecular forces between DNA bases and other related molecules.[1-6] Adenine is also important as a constituent of many biologically significant molecules such as ATP, NAD and FAD. Voet and Rich,[7-9] and Tomita and his group[10] studied the structure of intermolecular complexes between adenine with other molecules such as riboflavin, barbiturate and nicotinic acid derivatives. The aim of these investigations is to find a specific interaction in enzymatic or biological reactions involving adenine group.

Helene and his co-workers[11-14] studied the interaction of aromatic residues of proteins with nucleic acids and their model system spectroscopically, and suggested the formation of complexes between purine or pyrimidine with aromatic amino acids, *e.g.*, adenosine with tryptophan. Morita *et al.*[15-17] studied a specific interaction between ATP with an enzyme, myosine-ATPase, and its model system by the UV absorption measurement. They suggested that a charge transfer force exists between adenine and indole rings through the stacking of molecules. The charge transfer force may be important between the donor and acceptor molecules. However, no such interaction has been confirmed in the crystal of the complex composed of adenine and indole. An X-ray study is desirable on the complex of these molecules.

In the present paper we give the crystal structure of a 1: 1 9-ethyladenine-indole complex. It was found that the hydrogen bonding is most important as an intermolecular force between adenine and indole rings as well as between adenines.

Experimental

Equimolar amounts of 9-ethyladenine and indole were dissolved in methanol. Pale yellow crystals were obtained by slow evaporation at room temperature. The ultraviolet spectrum of the dissolved crystals shows that they contain approximately equimolar amounts of 9-ethyladenine and indole.

The space group was determined from oscillation and Weissenberg photographs. The density was measured by the flotation method in the mixed solution of cyclohexane and carbon tetrachloride. The cell dimensions were determined by the least-squares method, using twelve reflections carefully measured on a Hilger-Watts four circle diffractometer with Zr-filtered Mo$K\alpha$ radiation ($\lambda=0.71069$ Å). The crystal was found to be not so unstable while being left to stand in the air, but the color changed to light brown. It was therefore mounted in a glass capillary for the X-ray measurements. Intensity data were collected with the same diffractometer in the ω-2θ scanning mode ($2\theta \leqq 52°$) with the same radiation. The size of the crystal used was $0.3\times0.3\times0.2$ mm. No absorption or extinction correction was made because of the smallness of the crystal. In order to confirm the stability of the crystal and the counter system, the intensities of three standard reflections were measured every 50 reflections. The fluctuation and the decay of standard reflections was within 5%. The crystal data are given in Table 1.

Table 1. Crystal data

$C_7H_9N_5 \cdot C_8H_7N$
F.W.: 280.33
Crystal system: monoclinic
Space group: $P2_1/c$
$a=15.712$ (2), $b=8.098$ (1),
$c=11.838$ (1) Å; $\beta=103.90$ (1)°,
$D_m=1.274$, $D_c=1.273$ g·cm^{-3}
$\mu=1.05$ cm^{-1} (for Mo$K\alpha$ radiation).

Determination and Refinement of the Structure

The structure was solved by the direct method with the program MULTAN[18] using 415 reflections with $|E| \geqq 1.20$. An E-map computed from the phase set with the highest figures of merit ($FOM=1.448$) revealed the positions of non-hydrogen atoms. The block-diagonal least-squares method was applied to the refinement of the structure parameters by using 1106 independent reflections with $|F^\circ| \geqq 5\sigma$. An R-index was reduced to 0.107. At this stage, a difference Fourier synthesis was performed. Two other peaks could be assigned to the disordered ethyl group of 9-ethyladenine, and eleven hydrogen atoms, other than those belonging to the ethyl groups, were found in this map. The occupancies for the differently oriented ethyl groups were also refined as a group by the least-squares method to be 0.65 and 0.35, respectively. Subsequent refinement was carried out with anisotropic thermal parameters for non-hydrogen atoms, and with isotropic ones for hydrogen atoms. The final R-index converged to 0.074 with an equal weight for each reflection.

The atomic scattering factors were taken from the work of Stewart, Davidson and Simpson[19] for the

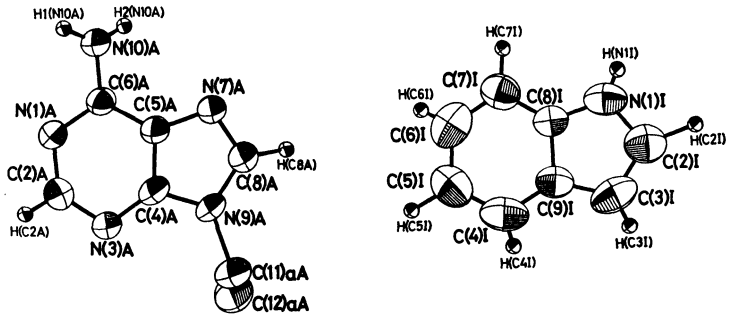

Fig. 1. The atomic labelings of 9-ethyladenine and indole. Nonhydrogen atoms are represented as thermal ellipsoids of a size such that the vibrating atoms have a 50% probability of being found within them. Hydrogen atoms are represented as spheres that are defined by the artificial isotropic thermal factor B of 1.0 Å^2.

hydrogen atom and from the International Tables for X-ray Crystallography[20] for other atoms. The program HBLS-IV coded by Ashida and the program written by Katayama and Wada were utilized for the block-diagonal least-squares refinements. The program ORTEP coded by Johnson was utilized for the drawings in Figs. 1, 4 and 5. All the computations were performed on a FACOM 230-60 computer at the Nagoya University Computation Center. The observed and calculated structure factors are listed in Table 2.[21]

Results and Discussion

The atomic labelings and thermal ellipsoids are shown in Fig. 1. The positional and thermal parameters with their standard deviations for non-hydrogen atoms are given in Tables 3 and 4, respectively. The coordinates and isotropic thermal parameters for hydrogen atoms, except for those belonging to ethyl groups, are given in Table 5.

Molecular Structure. The bond distances and bond angles with their standard deviations involving only heavy atoms are given in Tables 6 and 7, respectively. The covalent bond distances and angles of 9-ethyladenine are in good agreement with values found in other crystals.[2,8] The bond distances and angles around the disordered ethyl groups show somewhat abnormal values because of the disordered structure. The adenine molecule is highly planar with a maximum deviation of 0.028 Å for C(5)A from the least-squares plane (Table 8).

The bond distances and angles of indole agree with values found in crystals of L-tryptophan hydrobromide,[24] tryptamine picrate and D,L-tryptophan picrate.[25] The only exception is in the C(7)I–C(8)I bond distance, which is smaller by *ca.* 0.06 Å as compared with the values in the literature.[24,25] The indole molecule is also highly planar with a maximum deviation of 0.011 Å for C(5)I from the least-squares plane.

Crystal Structure. The crystal structure projected along the b axis is shown in Fig. 2. Adenines form walls consisting of a double layer. An overlap of adenines, related to a center of symmetry, is observed between the layers. Four hydrogen bonds are found between adenine molecules which connect the molecule in the front layer with the molecule in the back one (Fig. 3).

a) The symbols a and b were used for the disordered carbons, C(11) and C(12), to discriminate the major and the minor sites.

The hydrogen bond network is developed along the b axis. All the amino NH bonds participate in hydrogen bonds, N(10)A-H···N(7)A($1-x$, $1/2+y$, $1/2-z$) and N(10)A-H···N(1)A($1-x$, $-1/2+y$, $1/2-z$). The intermolecular distances and angles for the hydrogen bonds are given in Table 9. The overlapping mode of adenine molecules is shown in Fig. 4. The interplanar distance between adenine rings is 3.50 Å. A more extensive overlapping of adenine rings is found in 9-methyladenine,[1] ATP,[6] and (9-ethyladenine)-(1-methyl-5-fluorouracil) complex.[3] The interplanar distance is 3.31—3.40 Å.

The stacking and hydrogen bondings may influence the conformation of the ethyl group, namely the structure of methylene carbons. C(11)aA and C(11)bA bend

away to the opposite side from the adenine plane by 0.32 and 0.71 Å, respectively. A similar deviation from the plane of the adenine ring is observed for the carbon atoms of glycosidic bonds in adenosine-5′-phosphate[22] and deoxyadenosine[23] crystals, where the hydrogen bond network is developed extensively and the molecular packing is favorable to the bent conformation. Hydrogen bonds are also formed in the present crystal, the region around the disordered ethyl groups being crowded by the neighboring molecules. The distance between the terminal methyl carbon (C(12)aA) and the atoms of indole rings (C(4)I and C(5)I) is *ca.* 3.50 Å, and that between C(12)bA and hydrogen atoms of adenine rings, (H1(N10A) and H(C8A)), is *ca.* 2.60 Å (Table 9).

Indole molecules are sandwiched by the adenine

walls, sticking to the wall by the hydrogen bonding. A stereoscopic view along the a axis is shown in Fig. 5. No stacking interaction is found between indoles, nor between adenine and indole. Their arrangement in the crystal may be favored by the hydrogen bonding and the dipole-dipole interaction between neighboring molecules.

The most interesting feature of the crystal structure is the hydrogen bonding between adenine and indole. The N(1)I–H···N(3)A distance is 3.03 Å, which is not

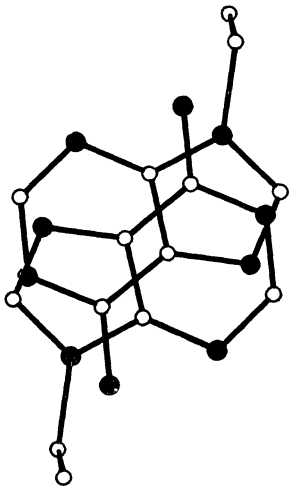

Fig. 4. A stacking pattern of the 9-ethyladenine pair. Carbon atoms are depicted as open circles and nitrogen atoms are filled circles.

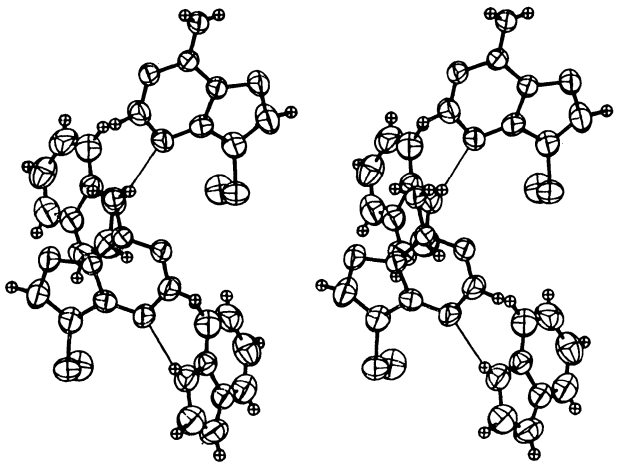

Fig. 5. A stereoscopic view of the 9-ethyladenine-indole pair. The criterion to thermal ellipsoids of nonhydrogen atoms and that of hydrogen atoms are the same in Fig. 1. The hydrogen bond between H(N1I) and N(3)A is represented in a thin solid line.

particularly small as compared with other NH···N hydrogen bond distances.[9] The molecular plane of indole tilts to that of the adenine ring with a dihedral angle of 74.7°. No particular stacking of adenine-indole pair is found in the crystal. It is therefore unlikely that the molecular association for this pair occurs through the overlapping of two rings.

The result is biologically significant in that the same mode of interaction is expected to exist between adenine and tryptophan in the biological system. It can be suggested that the hydrogen bonding is more important than the stacking of two rings in the pair. This seems reasonable since both molecules have an electron donating character contrary to the case in which one is electron donating and the other accepting. An alternative interpretation on the spectral change found in model biological systems should be worth considering by the result in this study.

(Received February 19, 1976)

A detailed conformation study of the polypeptide (Pro–Pro–Gly)$_{10}$, synthesized as a collagen model, has been done using X-ray diffraction. Several structures having the observed helical parameters (unit height=8.61 Å, unit twist=51.4°) together with standard bond lengths and angles were generated and tested in terms of an existence of intermolecular van der Waals contacts and least squares calculations using 49 equatorial reflections. It was found from these studies that three polypeptide chains make a three-stranded rope of which the helical parameters are similar to but significantly different from those of the collagen models proposed so far. There exist two possible models for (Pro–Pro–Gly)$_{10}$ according to the type of hydrogen bonding. One is the model having a hydrogen bond so-called 'standard' structure type, and the other has a hydrogen bond of collagen II type. The two-dimensional electron density map, synthesized with the observed structure factors, agrees well with these models. In the least squares calculations, atomic scattering factors were modified by taking into account of effects of amorphous water between the three-stranded ropes.

The first three-stranded coiled coil model for collagen was that suggested by Ramachandran and Kartha.[1] Since then, this structural model has been widely accepted as correct at least in its general features. The structure was derived from a prototype structure, shown in polyglycine II and polyproline II structures, by the introduction of a right handed rope twist so that the individual chains had a coiled coil conformation. It is almost impossible, however, to determine the detailed molecular structure from only the poor X-ray fiber patterns of native collagen; so various models for the molecular conformation have been suggested from the X-ray data. In order to obtain more decisive information to determine the structure of collagen precisely, a number of polypeptide models have been synthesized.[2,3] Since the features of the chemical compositions of the collagen are the occurrence of glycyl residues at every third positions in the sequence and a relatively high contents of proline and hydroxyproline residues, many of these synthetic polypeptides have the sequence in the form of (Gly–Pro–X)$_n$, in which X is a variety of amino acids. A number of structure analyses of these synthetic polypeptides have been reported so far,[4] although X-ray diffraction patterns obtained from these were also poor fiber patterns similar to those from collagen.

In the case of (Pro–Pro–Gly)$_{10}$, single crystals available for X-ray diffraction study were obtained by a dialysis from 10% acetic acid.[5] This is the first one that could be crystallized among the polypeptides belonging to collagen group proteins. The crystal is orthorhombic, space group $P2_12_12_1$, with twelve molecules per unit cell of dimensions: a=26.93, b=26.42 and c=100.4 Å. The crystal has a subcell structure with the c' dimension of one-fifth of the true period, c'=100.4/5=20.08 Å. Intensity data of 787 reflections (exclusive of reflections with $l \neq 5n$) were collected. It was given in the previous paper[6] that the crystal of (Pro–Pro–Gly)$_{10}$ consists of a three-stranded coiled coil structure, of which the helical parameters are similar to but significantly different from those of collagen models proposed so far. The long extended helix of the polypeptides lies parallel to the c axis. In this paper we will describe more detailed molecular structures found by a systematic evaluation of possible molecular conformations and crystal structures derived by a method of two-dimensional least squares refinement.

Structure Analysis

At the beginning of this study, we tried to crystallize a heavy atom derivative of (Pro–Pro–Gly)$_{10}$, that is 4-bromoprolylprolylglycyl-(Pro–Pro–Gly)$_9$. Although crystals of this derivative were obtained by a dialysis from acetic acid, these had a disorder along the c axis, and they were not suitable for X-ray study. Therefore, we built molecular models systematically as in fibrous protein research. These models were tested for acceptable intra- and intermolecular van der Waals contacts and also hydrogen bonds which stabilize the three-stranded coiled coil structure. Finally the structures were refined by the least squares calculations.

Relations among the Individual Chains in Triple Helix. As mentioned earlier,[6] the helical parameters of (Pro–Pro–Gly)$_{10}$ are considerably different from those of collagen models proposed so far.[7–9] There are 21 amino acid residues in one pitch of (Pro–Pro–Gly)$_{10}$ (Fig. 1, left). The vector from the first amino acid residue to the

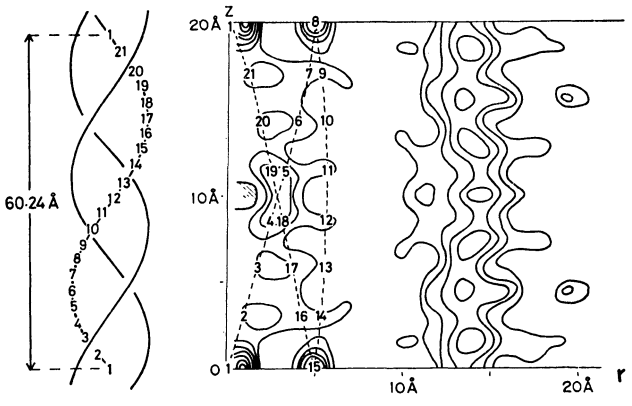

Fig. 1. Left: Three stranded helices. Each helix has 21 amino acid residues in one pitch. Right: Cylindrical Patterson map of (Pro–Pro–Gly)$_{10}$.

n-th amino acid residue is represented as a symbol n in the cylindrical Patterson map (Fig. 1, right). These vectors are connected with dashed lines. Peaks in the range of $0 \leq r \leq 10$ Å in this map are well interpreted by these 21 vectors.

The structure of $(Pro\text{–}Pro\text{–}Gly)_{10}$ consists of three equivalent helical molecules, and each of them has the above mentioned conformation. If these three chains are arranged in an antiparallel fashion, the repeat distance along the chain axis coincides with a pitch, 60.24 Å, rather than a pseudoperiod of 20.08 Å (=60.24/3), which is clearly shown in the $(0kl)$ precession photograph.[6] Therefore, these three are arranged in a parallel fashion. Electron microscopic study of this polypeptide has shown the same result.[10]

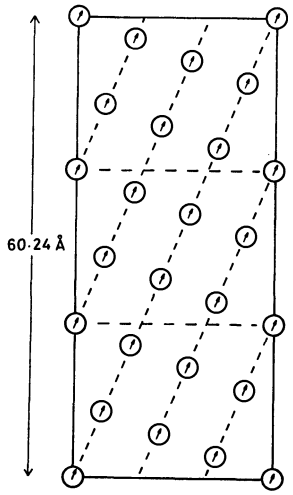

Fig. 2. Radial projection of $(Pro\text{–}Pro\text{–}Gly)_{10}$.

A radial projection of a right handed helix of $(Pro\text{–}Pro\text{–}Gly)_{10}$ is shown in Fig. 2, where an open circle represents a repeating unit, Pro–Pro–Gly, and an arrow in the circle represents a direction of the unit. It is easily shown that in order to have a pseudoperiod of 20.08 Å, the chains must be all parallel and also shifted by a distance of 2.87 Å or 5.74 Å which correspond to the heights of one-third or two-thirds of the unit along the chain axis, from the neighboring chains. Consequently, it is clear that the relation of the atomic coordinates of one chain and those of the corresponding in the other two chains are as follows;

$$(r,\ \phi,\ z)$$
$$(r,\ \phi-102.9°,\ z+2.87)$$
$$(r,\ \phi-205.8°,\ z+5.74)$$

If the polypeptide chain is a left handed helix, its radial projection is a mirror image of that of a right handed one and the relation of the atomic coordinates are as follows;

$$(r,\ \phi,\ z)$$
$$(r,\ \phi+102.9°,\ z+2.87)$$
$$(r,\ \phi+205.8°,\ z+5.74)$$

Analytical Procedure. Figure 3 (a) shows the structural formula of a tripeptide unit of $(Pro\text{–}Pro\text{–}Gly)_{10}$, together with its nine internal rotations. In

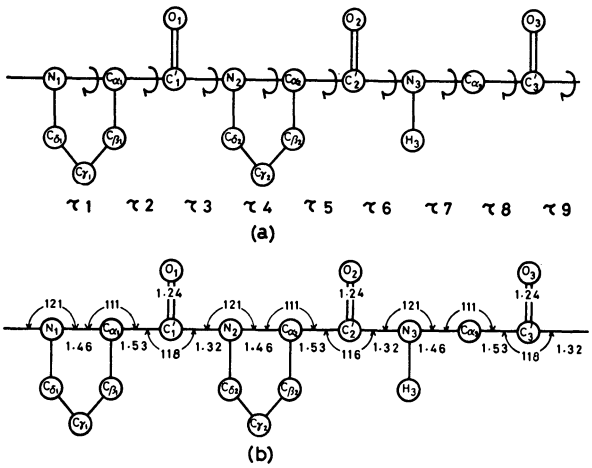

Fig. 3. (a) Structural formula and the notation of internal rotation angles in one tripeptide unit of $(Pro\text{–}Pro\text{–}Gly)_{10}$. (b) Standard stereochemistry of $(Pro\text{–}Pro\text{–}Gly)_{10}$.

building the various possible molecular conformations, we have made several stereochemically reasonable assumptions. Bond distances and angles of peptide backbone were fixed to the values shown in Fig. 3 (b). These are the mean values obtained from the results of structure analyses of oligopeptides. The value of $C_\alpha\text{–}C'\text{–}N$ angle is 118° in the peptide group followed by the prolyl residue, and 116° in that followed by the glycyl residue, because of the steric repulsion between the C_α atom of the preceding residue and the bulky C_δ methylene group of the pyrrolidine ring.[11] For the glycyl residue we have taken the values of 1.0 Å, 1.07 Å, 120° and 109.5° for the bond lengths of N–H and C–H and bond angles of $C_\alpha\text{–}N\text{–}H$ and $H\text{–}C_\alpha\text{–}H$, respectively. For the prolyl residue we have taken the dimension of *p*-bromocarbobenzoxy-glycyl-prolyl-leucyl-glycine.[12] It is known that *cis* as well as *trans* conformations are possible for the peptide bond of proline residues (*e.g.*, the structures of polyproline I and II). However, on the triple helix of $(Pro\text{–}Pro\text{–}Gly)_{10}$ at the lower temperatures, the study of proton magnetic spectra made it clear that the peptide bonds in Pro–Pro and Gly–Pro are all in *trans* conformations.[13] So, we also assumed that the six atoms of the peptide group in all three residues are coplaner, that is, $\tau 3 = \tau 6 = \tau 9 = 180°$. In this study, dihedral angles of the polypeptide chain are taken to be zero for a *cis* conformation and are taken to be positive for an anticlockwise rotation looking along the peptide backbone from the amino terminal to the carboxyl terminal. (This definition is different from that of a standard nomenclature[14] in the direction of rotation.)

Thus, the variable parameters reduced to only six dihedral angles, *i.e.*, $\tau 1$, $\tau 2$, $\tau 4$, $\tau 5$, $\tau 7$ and $\tau 8$. If we take into account of our finding that the structure of $(Pro\text{–}Pro\text{–}Gly)_{10}$ has 7 units (*i.e.*, 21 amino acid residues) in one turn of a single chain, there become not six but five independent parameters.[15] In our program the five parameters were varied systematically and a number of molecular models were built for each combination.[16] Intramolecular atomic coordinates for each model are

transformed into the cylindrical coordinates by using **T** and **L** matrices.[17] The unit height h and one of the six dihedral angles, which was $\tau 2$ in our calculations, were obtained simultaneously. The molecular conformations, whose h and $\tau 2$ are out of the ranges of criterion listed in Table 1, were eliminated in each stage. For the remaining conformations the atomic coordinates of the neighboring chains were given by the relations among the three-stranded chains. Further, the models which do not have a hydrogen bond, judged from a distance b(N, O) and an angle θ(H, N, O), were excluded. Finally the remainders were tested against intra- and intermolecular van der Waals contacts. The minimum van der Waals contacts are based on the "outer limit" values cited by Ramakrishnan and Ramachandran.[18] The various stages of the analysis and the regions found to have the reasonable structures are described in Table 1.

The validities of the molecular structure were tested by the two-dimensional least squares refinements using 49 equatorial reflections. The parameters are the position of the molecular axis (x, y), a rotation angle of a molecule about it, an over all temperature factor and a scale factor. In these calculations we have taken into account of the scattering by water molecules in the unit cell as described in the following section.

Effects of Water Molecules. The water content of (Pro–Pro–Gly)$_{10}$ crystals is 46% (by weight). Although several water molecules may be held at the definite positions by hydrogen bonds to the carbonyl oxygens of polypeptides, these positions may be clarified as the structure analysis proceeds. We took into account of the only water molecules which can be assumed to be uniformly distributed between the three-stranded ropes. For the first approximation we have assumed that all the atoms are spheres with van der Waals radii, 1.60, 1.35 and 1.40 Å for C, N and O, respectively. Each of the atomic scattering factors shown in Fig. 4 is calculated from the ordinary atomic scattering factors minus the scattering factor of water molecules which occupy uniformly the atomic volume with an electron

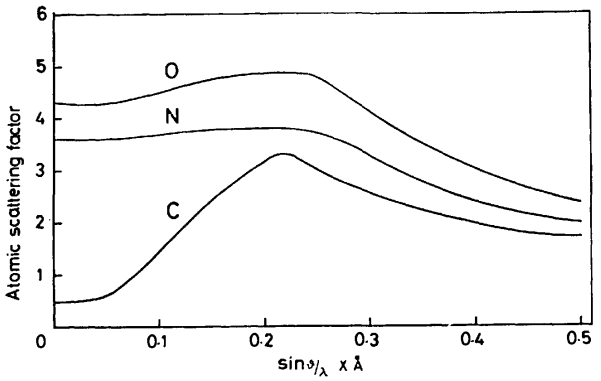

Fig. 4. Atomic scattering factors for atoms immersed in water.

density of 0.33 electrons/Å^3. This correction of atomic scattering factors decreased the R index about 10% in the least squares calculations. The temperature factor was not decreased so immediately as the cases without a correction. A similar method of correcting for background has been used already in the structural studies of DNA.[19]

Results of Analysis. Structures of the left handed helices as well as those of the right handed ones were examined. However, none of the structures of the left handed helices was acceptable in view of their intra- and intermolecular atomic contacts. As shown in Table 1, the ranges of five independent internal rotation angles became narrow at each cycle. In cycle 1, the dihedral angles, $\tau 1$ and $\tau 4$ in pyrrolidine rings were fixed to 60°, while the dihedral angles of glycine, $\tau 7$ and $\tau 8$, were searched over all ranges. From structure analyses of oligopeptides[11,20] and the energy calculations of prolyl oligomers,[21] the dihedral angles of C_α–C′ in proline residue, $\tau 2$ and $\tau 5$, were assumed to be in the ranges of 170~260°. There are some structures in which these angles are in the range of −50~40°, but the range is for the α-helix type dihedral angles.[11] Increments of the three parameters, $\tau 5$, $\tau 7$ and $\tau 8$, were 10° at the first cycle. The structures in the range of

	$\tau 5$	170—260°	180—200°	185—200°	185—188°	194—197°
	$\tau 7$	−20—140°	80—100°	80—95°	92—95°	83—86°
	$\tau 8$	180—240°	180—210°	185—210°	198—210°	183—192°

6.61～10.61Å of the unit height were selected in all combinations of these three parameters. After the first cycle it was shown that the angles of $\tau 7$ and $\tau 8$ of glycine residue were in the range of −20～140° and 180—240°, respectively. These ranges show that the glycyl residue has the left handed polyglycine II type structure, as in the collagen models. Therefore, taking into account of energy map of diglycine,[22] the range of $\tau 7$ was restricted to 40～100° at the second cycle.

In cycles 2, 3 and 4, structures without NH···O hydrogen bonds were eliminated. In the case of $(Pro–Pro–Gly)_{10}$, there were two possible types of hydrogen bonds, that is, $N_3(Gly)\cdots O_2(Pro)$ and $N_3(Gly)\cdots O_1(Pro)$. We call hereafter the structure having the former type hydrogen bond model 1 and that having the latter model 2. The ranges of parameters for model 1 and 2 at cycle 4 are shown in the last column of Table 1. Illustrations of a hydrogen bond between neighboring chains of each model are shown in Fig. 5.

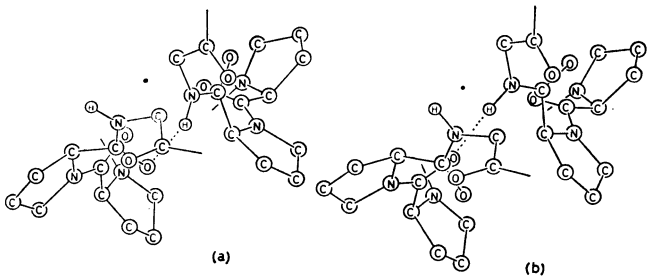

Fig. 5. An axial projection of segments of the two $(Pro–Pro–Gly)_{10}$ models. (a) Model 1, (b) Model 2. The filled circle represents the axis of the molecule for each model. The dashed line represents a hydrogen bond.

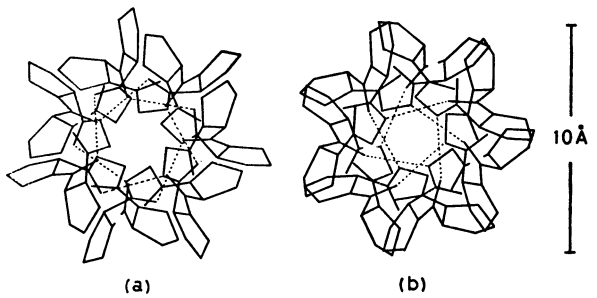

Fig. 6. The molecular structure viewed down the c axis. (a) Model 1, (b) Model 2.

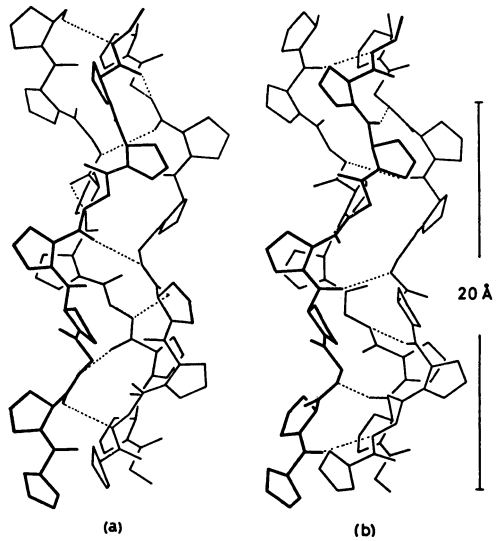

Fig. 7. The molecular structure viewed down the b axis. (a) Model 1, (b) Model 2.

Fifteen structures, which were chosen from different parts of regions for each model, have been tested by the two-dimensional least squares refinements. The R index $(\Sigma||F_o|^2-|F_o|^2|/\Sigma|F_o|^2)$ was calculated after three cycles with the same initial setting parameters for each structure. The dihedral angles and the hydrogen bond parameters of all the fifteen structures are listed in Table 2, together with their R indices.

As typical structures, the structure of No. 4 in Table 2 for model 1 and that of No. 13 for model 2 are shown in Figs. 6 and 7, since they had small R indices and good hydrogen bond parameters. Atomic coordinates for the repeating unit are given in Table 3. The intermolecular short contacts (less than 3.5 Å) of the structures are as follows;

$O_1\cdots C\delta_1$ 3.27, $N_3\cdots O_1$ 3.14, $N_3\cdots O_2$ 3.09, $C\alpha_3\cdots C\alpha_3$ 3.49, $C'_3\cdots C\alpha_3$ 3.38, $O_3\cdots C\alpha_3$ 3.28, $O_3\cdots C\delta_1$ 2.90, $O_1\cdots C\alpha_3$ 2.99 and $O_1\cdots C\delta_1$ 2.27 Å in model 1 (No. 4). $C\alpha_2\cdots O_1$ 2.96, $C\beta_2\cdots O_1$ 3.42, $C_2'\cdots O_1$ 3.41, $N_3\cdots O_1$ 2.97 and $O_3\cdots C\alpha_3$ 2.99 Å in model 2 (No. 13).

Since the molecule has 7 units in one turn (7/1 helix), there is a 7-fold rotational symmetry in Fig. 6. At the molecular center of this figure, there exists a hole surrounded by glycyl residues. The dimension of this

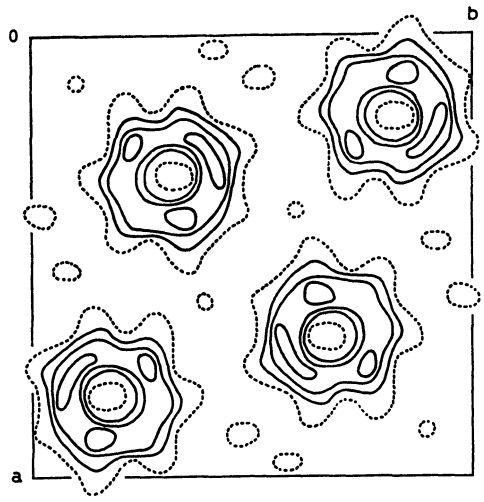

Fig. 8. Electron density map projected along the c axis.

hole is 2.0~2.5 Å for model 1 and 2.7~3.1 Å for model 2. The R index of the least squares refinements decreases as the dimension of this hole increase.

The electron density map, calculated from the observed structure factors $|F_o|$ and phases calculated by the fifteen structures of Table 2, is shown in Fig. 8. Only 38 ($hk0$) reflections whose signs were the same in all the fifteen structures were used in this calculation. In this map, the center portion of the triple helix has low electron density, and high electron density parts are distributed cylindrically with about 5.7 Å in diameter. Further, there are seven projections of electron density from this cylinder.

Discussion

It can be seen from the systematic study of molecular conformations that there exist two possible structures distinguished by hydrogen bonding. The structure of model 1 has the so called "standard" structure type hydrogen bond and that of model 2 has the collagen 11 type hydrogen bond. The difference between these two structures is illustrated in Fig. 5 and the values of hydrogen bond parameters are listed in Table 2. The angle θ(H, N, O), between N-H and H···O, is 20~30° in model 1 and 27~30° in model 2. The angle θ'(180−NOC'), between C=O and O···N, is about 70~80° in model 1 and 20~30° in model 2. These values as well as the hydrogen bond lengths are not extreme cases of hydrogen bonding parameters.[23]

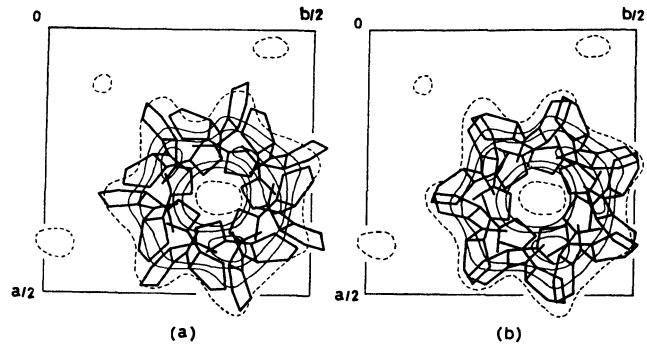

Fig. 9. Comparison of the electron density in an asymmetric unit with the molecular structures of (a) model 1 and (b) model 2 for (Pro-Pro-Gly)$_{10}$.

The two structures are supported by the electron density map as seen from Fig. 9. There is a remarkable coincidence, seven knobs of pyrrolidine rings being well fitted to those of the electron density distribution. The position of the molecular axis of the triple helix obtained from least squares refinements is x=8.57±0.06 Å and y=8.42±0.06 Å. Then, the distance between nearest neighbours of the triple helix is 13.7~12.9 Å, which agrees well with the peaks lined up at about r=14 Å in the cylindrical Patterson map (Fig. 1). The electron density map calculated from all the 49 ($hk0$) reflections for each model was somewhat different from the map in Fig. 8 if examined in detail. This may be due to the neglect of the water molecules which are at the definite positions in the unit cell. At this stage it cannot be decided which is more plausible for (Pro-Pro-Gly)$_{10}$, model 1 or 2.

A comparison of the hydrogen bond type and the helical parameters of (Pro-Pro-Gly)$_{10}$ with those of the several collagen models[7,9] and of a synthetic polypeptide (Pro-Gly-Pro)$_n$[4] is shown in Table 4. The amino acid sequence of (Pro-Gly-Pro)$_n$ is the same as that of (Pro-Pro-Gly)$_{10}$. The molecular weight is about 15000 for the former and 2528 for the latter. Our sample was practically monodispersed,[24] and single crystals available for X-ray study were obtained. On the other hand, molecular weights of (Pro-Gly-Pro)$_n$ seem to be polydispersed and only the fiber patterns similar to those of collagen could be obtained. Collagen 1 and "standard" structures can not be considered as good models for collagen because imino acids could not be incorporated in position R_3 or R_2, respectively,[25] while it is known that the amino acid sequence of collagen

Table 4. Comparisons of features for several collagen models and collagen model synthetic polypeptides

	Amino acid sequence $(Gly_1–R_2–R_3)_n$	Types of hydrogen bond	Helical parameters
Collagen I[7]	R_2 any residue R_3 Gly only	$N(Gly_1)\cdots O(Gly_1)$	10/1 helix, $h=2.86\times3$Å, $t=36°$
Collagen II[7]	R_2 any residue R_3 any residue	$N(Gly_1)\cdots O(R_2)$	10/1 helix, $h=2.86\times3$Å, $t=36°$
'Standard' structure[9]	R_2 Pro or Hypro imposible R_3 any residue	$N(Gly_1)\cdots O(R_3)$ $N(R_2)\cdots O(R_2)$	12/1 helix, $h=2.91\times3$Å, $t=30°$
$(Pro–Gly–Pro)_n$[4]	R_2 Pro R_3 Pro	$N(Gly_1)\cdots O(R_2)$	10/1 helix, $h=2.87\times3$Å, $t=36°$
$(Pro–Pro–Gly)_{10}$	R_2 Pro R_3 Pro	$N(Gly_1)\cdots O(R_2)$ or $N(Gly_1)\cdots O(R_3)$	7/1 helix, $h=2.87\times3$Å, $t=51.4°$

proteins obtained from several sources has many tripeptide sequences of Gly–Pro–X. Structures of collagen II and $(Pro–Gly–Pro)_n$ have the same type hydrogen bond and the same helical parameters with each other. And the structure of collagen II is considered to be the most favorable model for collagen so far.[25] In the model 1 of $(Pro–Pro–Gly)_{10}$, the hydrogen bond is the same type as that in "standard" structure and the other (model 2) is the same as that of collagen II structure, although the helical parameters of this polypeptide are significantly different from those of collagen models. The major difference of these structures is in the pseudoperiod along the fiber axis. The pseudo period of $(Pro–Pro–Gly)_{10}$ is 20.08 Å, which is clearly shown in the (0*kl*) precession photograph.[6] On the other hand, that of collagen II structure was considered to be 28.6 Å, since the meridional reflection with 2.86 Å spacing was considered to be 10 th order reflection. Bear[26] thought, however, that the pseudoperiod of kangaroo tail tendon collagen was 20.0 Å. He ascribed the meridional reflection of 2.86 Å as the 7-th, although the molecular structure suggested was incorrect. If this is true, the helical parameters of $(Pro–Pro–Gly)_{10}$ are the same as those of collagen.

During this study we have assumed that the molecule is an infinite chain, but actually the dimension of the molecules is 86.1 Å (2.87×30) and the number of turns in this peptide chain is only 1.4. Therefore, it should be taken into account of this molecular terminal effects in the least squares refinements. However, the results at this stage are the same, whether the molecule is assumed to be finite or infinite.

We are grateful to Prof. M. Takayanagi of Kyushu University for his encouragement throughout this work. We are indebted to Drs. S. Sakakibara and Y. Kishida of Protein Research Foundation for suppling the valuable samples. All the numerical computations were done on a FACOM 230-75 of the Computer Center of Kyushu University.

Topological Index as Applied to π-Electronic Systems. IV. On the Topological Factors Causing Non-Uniform π-Electron Charge Distribution in Non-Alternant Hydrocarbons*

Ivan GUTMAN,** Tamiё YAMAGUCHI,*** and Haruo HOSOYA***§

**Institute "Ruđer Bošković," Zagreb, Croatia, Yugoslavia

***Department of Chemistry, Ochanomizu University, Bunkyo-Ku, Tokyo 112

(Received February 25, 1976)

The topological factors which cause non-uniform π-electron charge distribution in non-alternant hydrocarbons (NAH's) are discussed. For estimating and analyzing the net-charge density a novel topological index, topological charge density, Q_r^T, is proposed. It is defined as $Q_r^T=\mathrm{Re}(F_{G,r}(1))$, the real part of $F_{G,r}(y)=\Delta_{r,r}(iy)/\Delta(iy)$, where $\Delta(x)$ is the secular determinant of graph G and $\Delta_{r,r}(x)$ is its adjunct with row r and column r struck out. This quantity Q_r^T, corresponding to the Coulson net charge density $Q_r=1-q_r$, is related with the topological indices $\tilde{Z}_G$ and $\tilde{Y}_G$ which are defined in terms of the coefficients of the characteristic polynomial of graph G. As all the newly proposed indices can be enumerated graphically, one can easily estimate the net-charge densities of NAH's.

Coulson and Rushbrooke[1] have proved that the Hückel MO theory predicts uniform π-electron charge distribution in all the alternant hydrocarbons (AH's). Although the structural requirements for uniform π-charge distribution are presently well understood,[1,2] it is not much known[3-6] on the same problem for non-alternant hydrocarbons (NAH's). A number of empirical rules which relate the π-electron charge distribution of NAH's with their structure are collected in Ref. 3, but with an incomplete mathematical justification.[4,7] In Ref. 5 some general consequences of the Coulson integral formula for charge density are presented.

Until recently it has not been recognized[5-11] that useful topological information can be deduced from the Coulson integral representation[12] of several π-electron characteristics of conjugated systems, although parallelism among the several reactivity indices derived from the Hückel MO theory were already proved.[13,14] According to Ref. 12, the total π-electron energy E_π, the bond order p_{rs} between atoms r and s and the charge density Q_r (not the π-electronic but net-charge density) on atom r can be expressed as:

$$E_\pi = \frac{1}{\pi}\int_{-\infty}^{+\infty} F_G(y)\mathrm{d}y, \tag{1}$$

$$p_{rs} = \frac{1}{\pi}\int_{-\infty}^{+\infty} F_{G,rs}(y)\mathrm{d}y, \tag{2}$$

$$Q_r = \frac{1}{\pi}\int_{-\infty}^{+\infty} F_{G,r}(y)\mathrm{d}y, \tag{3}$$

where

$$F_G^*(y) = N - iy\Delta'(iy)/\Delta(iy) \tag{4a}$$

$$F_{G,rs}(y) = -\Delta_{r,s}(iy)/\Delta(iy) \tag{5}$$

$$F_{G,r}(y) = \Delta_{r,r}(iy)/\Delta(iy). \tag{6}$$

Here $i=\sqrt{-1}$ is the imaginary unit and $\Delta(x)\equiv P_G(x)=\det(xI-A)$ is the characteristic polynomial of the molecular graph G with N vertices.[15] A and I are the adjacency matrix and the unit matrix, $(-1)^{r+s}\Delta_{r,s}$ denotes Δ with row r and column s struck out. Note that $\Delta_{r,r}=P_{G\ominus r}$, where $G\ominus r$ is the graph obtained by deletion of vertex r and all the edges incident to it from graph G. Equation 1 holds also for the integrand[9,10]

$$F_G^{**}(y) = y^{-2}\ln|y^N P_G(1/iy)|. \tag{4b}$$

A proof of this relation will be given in Appendix I.

Let us write $P_G(x)$ in the form

$$P_G(x) = \sum_{k=0}^{N} a_k x^{N-k}. \tag{7}$$

Since the relations between the coefficients a_k and the structure of the molecular graph G are nowadays completely elucidated,[16,17] by means of Eqs. 1—3 one can get insight into the topological factors determining E_π, p_{rs} and Q_r. However, this analysis is not simple[14] because of the complicated form of Eqs. 4—6.

We have shown that E_π of a number of conjugated hydrocarbons can be approximated fairly well by $\log\tilde{Z}_G$,[8]

$$E_\pi \doteq c\log\tilde{Z}_G \tag{8}$$

where

$$\tilde{Z}_G = \sum_{k=0}^{m}(-1)^k a_{2k} \tag{9}$$

with $m=[N/2]$. It was also found that the value of F_G^{**} for $y=1$ has an analogous behavior as $\tilde{Z}_G$.[18] In particular, numerical analysis shows that E_π is nearly linearly related to $F_G^{**}(1)$. The similar is valid for the function $F_{G,rs}$. That is, $F_{G,rs}(1)$ is shown to be used as a good index for bond orders.[11] This suggests[6] that $F_{G,r}(1)$ may also possess interesting properties for the study of Q_r. In the present paper we would like to demonstrate that this is indeed the case. In order to analyze this problem two different kinds of the topological indices for a given graph are to be defined.

Topological Indices $\tilde{Z}_G$ and $\tilde{Y}_G$

Let us consider the polynomial $P_G(x)$ for $x=i$. According to Eq. 7,

$$P_G(i) = i^N(\tilde{Z}_G + i\tilde{Y}_G) \tag{10a}$$

and

$$P_G(-i) = (-i)^N(\tilde{Z}_G - i\tilde{Y}_G), \tag{10b}$$

where two topological indices are defined as

$$\tilde{Z}_G = \sum_{k=0}(-1)^k a_{2k}^{8)} \tag{11a}$$

$$\tilde{Y}_G = \sum_{k=0}(-1)^{k+1} a_{2k+1}. \tag{11b}$$

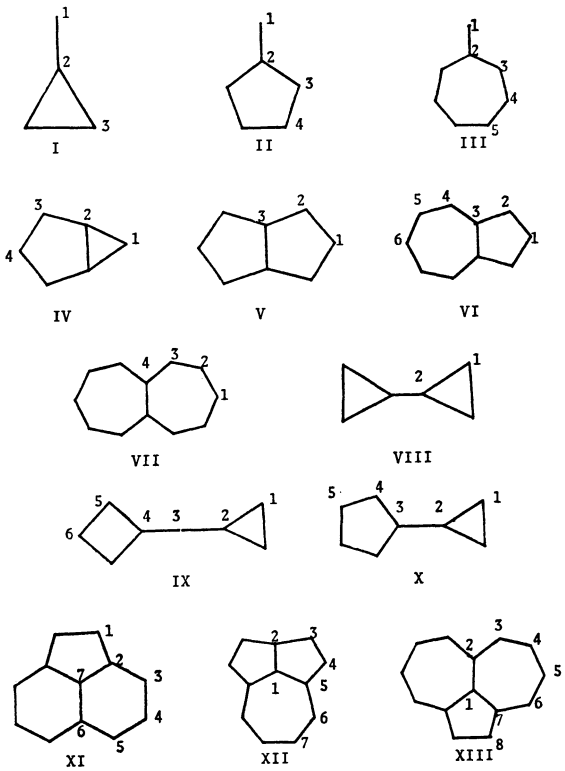

Chart 1

Hence we have

$$F_G^{**}(1) = \ln (\tilde{Z}_G^2 + \tilde{Y}_G^2)^{1/2}. \tag{12}$$

Note that $\tilde{Z}_G$ is always positive,[19] whereas $\tilde{Y}_G$ is zero for an AH and may take a positive or negative value according to the topology of a NAH as shown in Table 1, where the characteristic polynomial and the topological indices $\tilde{Z}_G$ and $\tilde{Y}_G$ for the typical NAH's are given. The following relation can be shown for almost all the NAH's (See the later discussions):

$$\tilde{Z}_G \gg |\tilde{Y}_G|. \tag{13}$$

Thus for an AH we have

$$F_G^{**}(1) = \ln \tilde{Z}_G \qquad (\boldsymbol{G}\in\mathrm{AH}) \tag{14}$$

and for a NAH the relation

$$F_G^{**}(1) \doteq c \ln \tilde{Z}_G \qquad (\boldsymbol{G}\in\mathrm{NAH}) \tag{15}$$

holds as expected.[8,18]

As the Sachs theorem states that[17]

$$a_0 = 1$$
$$a_n = \sum_{S_n}(-1)^{c(s)} \qquad (N\geq n\geq 1), \tag{16}$$

it follows that

$$\tilde{Z}_G = 1 + \sum_{k=1}^{m}(-1)^k \sum_{S_{2k}}(-1)^{c(s)}$$
$$= 1 + \sum_{S_{2k}}(-1)^{n(s)/2+c(s)}. \tag{17}$$

Here $c(s)$ and $n(s)$ denote the number of components and the number of vertices of the directed Sachs graph s. The summation in Eq. 16 runs over the set S_n of all the Sachs graphs with $n(s)=n$ vertices which are contained in the molecular graph $\boldsymbol{G}$, while in Eq. 17 over the set S_{2k} of all the Sachs graphs with even

number of vertices which are contained in G. In another terminology[21] a directed Sachs graph is called a linear graph.

If graph G has no cycle, namely if G is a tree, or an acyclic hydrocarbon, $n(s)=2c(s)$ and Eq. 17 leads to

$$\begin{aligned}\tilde{Z}_G &= 1+\sum_{k=1}\begin{pmatrix}\text{number of Sachs graphs}\\ \text{with } k \text{ disjoint edges}\end{pmatrix}\\ &= \sum_{k=0}^{m} p(G,k) \qquad (G\in\text{Tree})\\ &= Z_G, \end{aligned} \tag{18}$$

where $p(G, k)$ is the non-adjacent number and Z_G the orignal version of the topological index.[22]

For a non-tree graph Eq. 17 is expressed as

$$\tilde{Z}_G = Z_G + \Delta Z_G \tag{19}$$

$$\Delta Z_G = \sum_{S^{\circ}_{2k}}(-1)^{n(s)/2+c(s)}, \tag{20}$$

where S°_{2k} runs over all the even Sachs graphs containing at least one cycle, and ΔZ_G is called as the aromaticity index.[8] Figures 1 and 2 summarize all the indices,

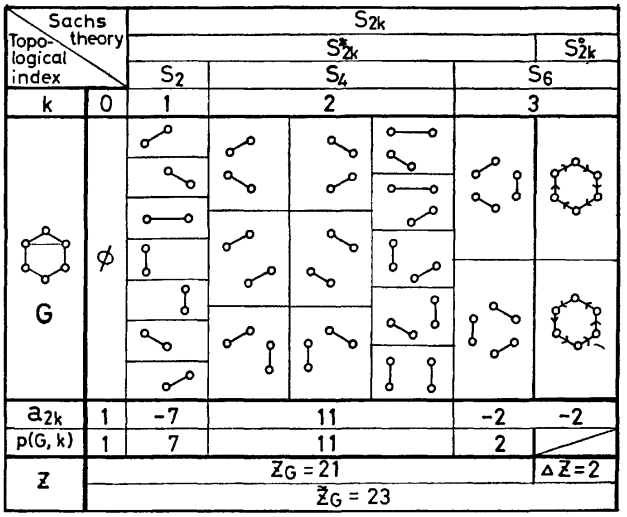

Fig. 1. Relation between the Sachs theorem and the topological indices. Even-Sachs graphs S_{2k} of graph $G\equiv$IV are given, which are divided into cycle-including (S°_{2k}) and cycle-excluding (S^{*}_{2k}) graphs. The symmetric part of $P_G(x)=(x^6-7x^4+11x^2-4)+(-2x^3+2x)$ is obtained from this figure. See Table 1 and Fig. 2.

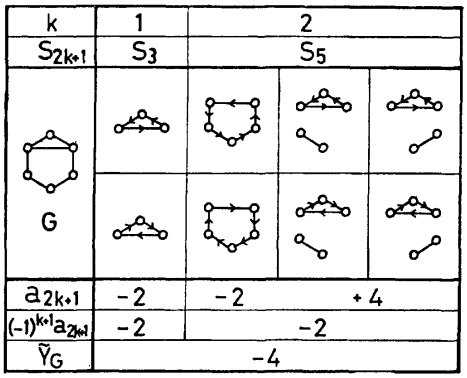

Fig. 2. Relation between $\tilde{Y}_G$ and odd-Sachs graphs, S_{2k+1}, of graph $G\equiv$IV. Note that the anti-symmetric part of $P_G(x)=(x^6-7x^4+11x^2-4)+(-2x^3+2x)$ is obtained from this figure. See Fig. 1 and Table 1.

Z_G, ΔZ_G, $\tilde{Z}_G$ and $\tilde{Y}_G$, and illustrates the relation between the Sachs theorem and the topological indices with graph IV as an example. In Ref. 8 it is shown how a combination of two or more cycles contributes to the sign of ΔZ_G. Here analysis will be developed in line with the Sachs formula.

Let s contain $p_0(s)$, $p_1(s)$, $p_2(s)$, and $p_3(s)$ cycles of the size, $4m$, $4m+1$, $4m+2$, and $4m+3$, respectively. Then[10]

$$n \equiv p_1 + 2p_2 + 3p_3 \pmod 4$$

$$c \equiv p_0 + p_1 + p_2 + p_3 \pmod 4$$

from which one deduces

$$n/2 + c \equiv p_0 + (p_3-p_1)/2 \pmod 2$$

or

$$\tilde{Z}_G = \sum_{S_{2k}}(-1)^{p_0+(p_3-p_1)/2} \tag{21}$$

One sees that $\tilde{Z}_G$ is closely related with the cycles contained in the molecular graph. For example, a couple of disjoint $4m$-membered cycles increase the $\tilde{Z}_G$ value as well as a combination of $(4m+1)$- and $(4m+3)$-membered cycles, whereas a couple of $(4m+1)$- or of $(4m+3)$-membered cycles decrease $\tilde{Z}_G$.[8]

If one uses the linear relation (8) the above statement is nothing else but the stability criterion, *i.e.* an extended Hückel rule,[8] for an arbitrary network of conjugated hydrocarbons.

As mentioned earlier, for AH's $a_{2k+1}=0$ for all k and we have $\tilde{Y}_G=0$. If the size of the smallest odd-cycle in G is $2g+1$, one gets $a_1=a_3=\cdots=a_{2g-1}=0$ and $a_{2g+1}=-2n_{2g+1}$, where n_{2g+1} is the number of such cycles.[15,16] Therefore the sign of $\tilde{Y}_G$ is equal to the sign of the term $(-1)^{g+1}a_{2g+1}$. That is,

$$\tilde{Y}_G = \begin{cases} >0 & \text{if the smallest odd cycle in } G \text{ is of the size } 4m+1\\ <0 & \text{if the smallest odd cycle in } G \text{ is of the size } 4m+3, \end{cases} \tag{22}$$

as shown in Table 1. Hence, $\tilde{Y}_G$ presents a topological index which in a particular way reflects the non-alternant character of a π-electron network. It is important to emphasize that $\tilde{Y}_G$ distinguishes the $(4m+1)$-rings from $(4m+3)$-ones, which seems to be the most important structural factor in determining Q_r.

A consideration analogous to that used for the derivation of Eq. 21 gives

$$\tilde{Y}_G = \sum_{S_{2k+1}}(-1)^{p_0+(p_3-p_1+1)/2} \tag{23}$$

showing that the indices $\tilde{Z}_G$ and $\tilde{Y}_G$ are algebraically closely related. S_{2k+1} is the set of all the directed Sachs graphs with odd number of vertices, which are contained in graph G. However, it is not necessary to draw all these graphs in order to determine the value of $\tilde{Y}_G$. A simple graphical method for the enumeration of $\tilde{Y}_G$ is given in Appendix II.

Topological Charge Density

Following the discussion above it is natural to use the $F_{G,r}$ value for $y=1$ as a kind of topological index for representing the net charge density on atom r in hydrocarbon G.

Substitution of Eq. 10a into Eq. 6 yields

$$F_{G,r}(1) = (\tilde{Z}_{G\ominus r}+i\tilde{Y}_{G\ominus r})/(i\tilde{Z}_G-\tilde{Y}_G), \quad (24)$$

whose real part is expressed as

$$Q_r^{\mathrm{T}} = \mathrm{Re}(F_{G,r}(1)) = \frac{\tilde{Z}_G\tilde{Y}_{G\ominus r}-\tilde{Y}_G\tilde{Z}_{G\ominus r}}{\tilde{Z}_G^2+\tilde{Y}_G^2} \quad (25)$$

and will be called as the topological (net-) charge density. Although all the quantities in the right-hand side of Eq. 25 are derived from the characteristic polynomial, they can easily be obtained graphically by hand calculation as in Appendix II even without knowing the characteristic polynomial.

TABLE 2. TOPOLOGICAL CHARACTERISTICS OF SUBGRAPHS OF GRAPH IV AND ITS TOPOLOGICAL CHARGE DENSITIES

r	$P_{G\ominus r}(x)$	$\tilde{Z}_{G\ominus r}$	$\tilde{Y}_{G\ominus r}$	Q_r^{T} a)	Q_r b)
1	x^5-5x^3+5x-2	11	2	0.165	0.300
2	x^5-4x^3+3x	8	0	0.059	0.073
3	$x^5-5x^3+4x-2x^2+2$	10	−4	−0.095	−0.215
4	$x^5-5x^3+3x-2x^2$	9	−2	−0.018	−0.072

a) $Q_r^{\mathrm{T}}=\frac{\tilde{Z}_G\tilde{Y}_{G\ominus r}-\tilde{Y}_G\tilde{Z}_{G\ominus r}}{\tilde{Z}_G^2+\tilde{Y}_G^2}$. b) $Q_r=1-q_r$, where q_r is the Coulson charge density calculated from the HMO's.

Examples are shown in Table 2 for graph IV, for which the topological charge density Q_r^{T} is correlated fairly well with the charge density calculated from the Hückel MO's. It is to be noted that the sign of the Q_r value is correctly predicted by Q_r^{T}. Correlation between Q_r and Q_r^{T} was extensively studied for typical NAH molecules. The results are summarized in Table 3, from which the following conclusions are drawn.

TABLE 3. COMPARISON BETWEEN THE TOPOLOGICAL CHARGE DENSITY Q_r^{T} AND THE HÜCKEL CHARGE DENSITY Q_r FOR TYPICAL NON-ALTERNANT HYDROCARBONS

a) $\tilde{Z}_G\tilde{Y}_{G\ominus r}-\tilde{Y}_G\tilde{Z}_{G\ominus r}$. $\tilde{Z}_G$ and $\tilde{Y}_G$ are given in Tabe 1.
b) $Q_r=1-q_r$.

(1) The topological charge density Q_r^{T} is useful for estimating the relative magnitudes of Q_r in an individual NAH.

(2) The correlation gets worse but still satisfactory for the following three groups of NAH's with i) an NBMO (non-bonding) (V, VII, and IX), ii) an anti-bonding HOMO (highest occupied) (VIII), and iii) a

bonding LUMO (lowest unoccupied).

(3) For relatively small NAH's (I-IV, VI, X) excluding the above groups, both the relative orders and the signs of Q_r values are correctly predicted by Q_r^{T}.[23]

Discussion

As the mathematical form of Q_r^{T} is fairly simple a number of general conclusions are drawn straightforwardly. Equation 25 suggests one to consider Q_r^{T} as a competition between the two terms $\tilde{Z}_G\tilde{Y}_{G\ominus r}$ $(=A_r)$ and $-\tilde{Y}_G\tilde{Z}_{G\ominus r}$ $(=B_r)$. Inspection of Table 3 shows that for almost all the cases, the former term predominates over the latter. Since $\tilde{Z}_G$, as well as $\tilde{Z}_{G\ominus r}$, is always positive and the largest number among the four indices in the expression of Q_r^{T}, the relative magnitude of $\tilde{Y}_{G\ominus r}$ is in parallel with the Q_r^{T} value and hence Q_r. In this sense the first term A_r is local or atomic factor determining the Q_r value. On the other hand, the second term B_r is a global or molecular factor, since its sign is already determined by that of $\tilde{Y}_G$, *i.e.*, by the topology of G (See Eq. 22).

By using this logic one can prove that for a network G in which the only entry of $(4m+3)$-cycle is a triangle, this triangle is positively charged. Choose a vertex r in the triangle. According to Eq. 22 $\tilde{Y}_G$ is negative and B_r positive. If there is no other odd cycle in G, $\tilde{Y}_{G\ominus r}$ is zero and so is A_r. Thus Q_r^{T} is positive. If there is at least one $(4m+1)$-cycle, $\tilde{Y}_{G\ominus r}$ is positive and so are A_r and Q_r^{T}. Thus Q_r^{T} is always positive. If a heptagon or a higher-member of $(4m+3)$-cycle coexists with a triangle in network G, it can be shown that the electron repulsive power of a triangle is stronger than that of a larger $(4m+3)$-cycle.[24] Then unless the conflict between two or more triangles occurs a triangle is shown to be always positive. Although this is a well-known conjecture in the MO theory based on a huge collection of numerical data, there has never been given a general proof for an arbitrary network by conventional perturbation treatment. In order to make the proof complete it will be analyzed in detail in the forthcoming paper that the signs of Q_r^{T} and Q_r are expected to be the same for almost all the cases with a very few exceptions as XIII. Similarly one can conclude that a pentagon is negatively charged in almost all the cases.

In conclusion it will be worth noting that by using the relations (8), (13), and (25), one can get a novel relation

$$Q_r^{\mathrm{T}} \doteq \exp(-E_\pi(G)/c)[\tilde{Y}_{G\ominus r} - \tilde{Y}_G \exp(-L_r/c)]$$

where $L_r = E_\pi(G) - E_\pi(G\ominus r)$ is the localization energy[25,26] of atom r. This interesting relation shows that the value of Q_r is not independent of the stability of the molecule (E_π) and the reactivity of its considered site (L_r).

Appendix I

Proof of Eq. 4b

Given two different functions $F_G^*(y)$ and $F_G^{**}(y)$ for an AH as

$$F_G^*(y) = N - iy\Delta'(iy)/\Delta(iy) \tag{4a}$$

$$F_G^{**}(y) = y^{-2}\ln|y^N P_G(1/iy)|. \tag{4b}$$

and we will show the following equality

$$\int_{-\infty}^{+\infty} F_G^*(y)\mathrm{d}y = \int_{-\infty}^{+\infty} F_G^{**}(y)\mathrm{d}y. \tag{A1}$$

Integration of $F_G^{**}(y)$ by parts one gets

$$\begin{aligned} I &= \int_{-\infty}^{+\infty} F_G^{**}(y)\mathrm{d}y \\ &= [yF_G^{**}(y)]_{-\infty}^{+\infty} - \int_{-\infty}^{+\infty} y\{\mathrm{d}F_G^{**}(y)/\mathrm{d}y\}\mathrm{d}y \\ &= -\int_{-\infty}^{+\infty} y\{\mathrm{d}F_G^{**}(y)/\mathrm{d}y\}\mathrm{d}y \end{aligned} \tag{A2}$$

by noting that $F_G^{**}(y)$ is an even function for AH's.

Differentiation of $F_G^{**}(y)$ with respect to y gives

$$\begin{aligned} \mathrm{d}F_G^{**}(y)/\mathrm{d}y &= -2y^{-3}\ln|y^N P_G(1/iy)| + y^{-3}A(y) \\ &= -2y^{-1}F_G^{**}(y) + y^{-3}A(y), \end{aligned} \tag{A3}$$

where

$$A(y) = N - P_G'(1/iy)/\{iyP_G(1/iy)\}. \tag{A4}$$

Substitution of Eq. A3 into Eq. A2 gives

$$I = 2I - \int_{-\infty}^{+\infty} y^{-2}A(y)\mathrm{d}y. \tag{A5}$$

Thus we have

$$I = \int_{-\infty}^{+\infty} y^{-2}A(y)\mathrm{d}y \tag{A6}$$

Transformation of $y = -Y^{-1}$, $\mathrm{d}y = Y^{-2}\mathrm{d}Y$ gives the relation

$$\begin{aligned} \int_{-\infty}^{+\infty} y^{-2}\mathrm{d}y &= \left[\int_{-\infty}^{0} + \int_{0}^{+\infty}\right] y^{-2}\mathrm{d}y \\ &= \left[\int_{0}^{+\infty} + \int_{-\infty}^{0}\right]\mathrm{d}Y \\ &= \int_{-\infty}^{+\infty}\mathrm{d}Y. \end{aligned} \tag{A7}$$

From Eqs. A4, A6, and A7 one gets

$$I = \int_{-\infty}^{+\infty} F_G^*(y)\mathrm{d}y. \tag{A8}$$

(Q.E.D.)

Appendix II

Graphical enumeration of $\tilde{Y}_G$ value.

The coefficients of the characteristic polynomial $P_G(x)$ are related with the topological index of the parent graph G and its subgraphs $\{G\ominus R_i\}$, where R_i is a cycle or a set of r_i disjoint cycles with a total of n_i vertices, as[11,16]

$$\begin{aligned} P_G(x) = &\sum_{k=0}^{m}(-1)^k p(G, k)x^{N-2k} \\ &+ \sum_{i}^{R_i\subset G}\sum_{k=0}^{m_i}(-1)^k(-2)^{r_i}p(G\ominus R_i, k)x^{N-n_i-2k}. \end{aligned} \tag{A9}$$

Since the $\tilde{Y}_G$ value is a collection of the coefficients of the terms x^{N-2k-1}, only the contribution by the odd-membered cycles are counted. Then it is straightforward to have

$$\begin{aligned} \tilde{Y}_G &= \sum_{i}^{\substack{n_i=2l_i+1\\ R_i\subset G}}(-1)^{l_i+1}(-2)^{r_i}\sum_{k=0}^{m_i}(-1)^k p(G\ominus R_i, k) \\ &= \sum_{i}^{\substack{n_i=2l_i+1\\ R_i\subset G}}(-1)^{l_i+1}(-2)^{r_i}Z_{G\ominus R_i}, \end{aligned} \tag{A10}$$

which is to be compared with the expression for $\tilde{Z}_G$[8]

$$\tilde{Z}_G = Z_G + \sum_{i}^{\substack{n_i=2l_i\\ R_i\subset G}}(-1)^{l_i}(-2)^{r_i}Z_{G\ominus R_i}. \tag{A11}$$

ESR of Hot Ions: Ni(I) Complex Ions Produced in Rigid Solutions by UV-Exposure

Chikara AMANO* and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 8, 1976)

It has been shown that univalent nickel complex ions are produced in rigid solutions by electrons released on photo-ionization of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine. These complexes have the same *g*-values as those obtained by γ-irradiation, suggesting that the univalent nickel complex ions produced on γ-irradiation can be formed as a result of the capture of near-thermal electrons by bivalent nickel complexes. Upon UV-exposure at various sample temperatures between -196 °C and -70 °C, a new chemical species with $g_{//}$ of 2.37 and $g_{\perp}$ of 2.128 has been observed, which appears to be an exchange-coupled dimer of the univalent hexaaqua nickel complex ions.

Paramagnetic ions which are produced in diamagnetic inorganic metal complexes upon γ-ray irradiation, are referred to as the hot ions.[1,2] Investigations have been carried out in this laboratory on metal ions such as Co, Ni, Pd, Pt, Rh, Ir, Cu, Zn, Cd, Hg, and Tl, in order to clarify the distortion of the lattice structure of the host compounds, which is caused by the formation of reduced or oxidized metal complex ions.

This paper deals with the hot ion of nickel which will be compared with the case of Pd and Co. From the viewpoint of the distortion of the ligand field, Pd(II), which takes a square planar structure, presents an extreme case where the hot ion is stabilized without appreciable change of the symmetry of ligand field in the process of one electron reduction. In the case of Ni(II), however, the original octahedral structure becomes distorted to the tetragonal one by the formation of Ni(I), which may be caused by the Jahn-Teller effect. The technique of investigation adopted in this experiment is almost the same as that in the case of Pd(II), *i.e.* the reaction of Ni(II) complex ions with the photoelectrons from *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in rigid solutions. We have also examined the effect temperature of the rigid solutions on the formation of Ni(I) complex ions during and after UV-exposure.

Experimental

Nickel(II) chloride hexahydrate, purified by the anion exchange method, was dissolved into a glassy solvent, a mixture of ethylene glycol and water (2: 1 v/v). Ethylenediamine (en), 2,2'-bipyridyl (bpy), or 1,10-phenanthroline (phen) was added to the nickel(II) solution as a ligand. The molar ratio of nickel(II) chloride to each ligand was varied in the same way as in a previous experiment.[3] The concentration of nickel(II) complex ions was between 0.01 and 0.1 mol/l. *N,N,N',N'*-tetramethyl-*p*-phenylenediamine hydrochloride (TMPD·HCl) was added to the above solutions in an equal molar ratio to nickel(II) complex ions. Xylene, a mixture of *o*-, *m*-, and *p*-xylene, was also used as a glassy solvent in the case of nickel(II) ethyl xanthate complex, where hydrochloric acid free TMPD was used. Each solution was placed in the sample tube for ESR measurements and immersed in liquid nitrogen. The sample was exposed to UV-light through a quartz lens window of the ESR cavity for 10—60 min. An Ushio mercury lamp UI-501C (500 W) was used as a UV source. In order to suppress short wavelength light, a Corning color filter 7-54 was used which does not transmit UV-light with a wavelength smaller than 230 mμ. In the case of hexaaqua nickel(II) complexes, the effect of temperature during and after UV-exposure was closely checked by examining the relative amount of products. ESR experiments were performed in the temperature range -196 °C to -50 °C.

* Present address: Department of Engineering Physics, The University of Electro-communications, Chofugaoka, Chofu, Tokyo 182

Results and Discussion

Upon exposure to UV-light the sample turned blue, due to the formation of a TMPD cation radical. At the same time, two ESR signals became observable, one at the position of usual organic radicals, and the other at a few hundred gauss lower field (Fig. 1, 3). The

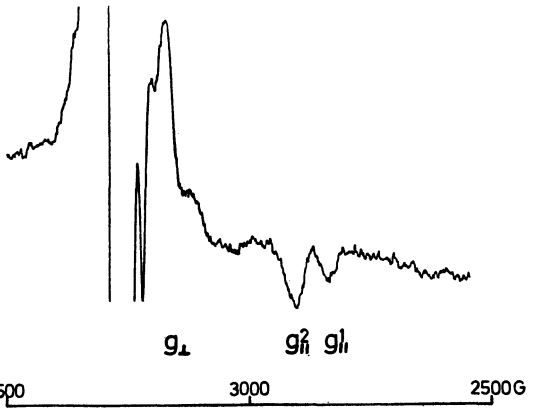

Fig. 1. ESR spectra of $[Ni(bpy)(H_2O)_4]^+$ ($g'_{//}$) and $[Ni(bpy)_2(H_2O)_2]^+$ ($g^2_{//}$). $NiCl_2 \cdot 6H_2O$: dipy = 1: 1.

line shape of the former signal suggests that some unidentified organic radicals are superimposed on the TMPD cation radical. By raising the temperature of the sample, the signal intensity decreased, only one signal with a characteristic structure remaining observable above -50 °C. The signal is identical with that of the TMPD cation radical which can be easily produced by adding sodium nitrite or lead tetracetate to a TMPD·HCl solution (Fig. 2). On the other hand, the latter signal can be assigned to a univalent nickel complex ion since the *g*-values are characteristic of the complex ion with d^9 electron configuration.[3] The results suggest

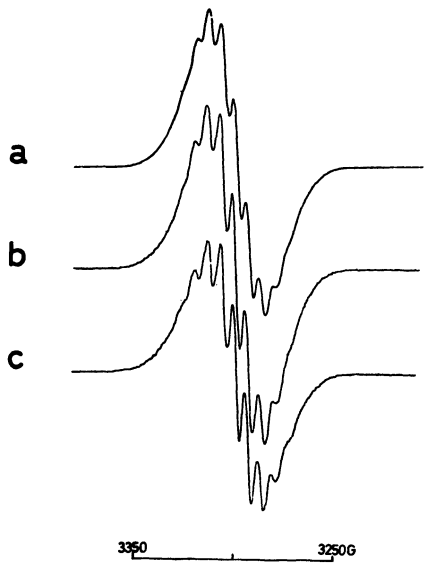

Fig. 2. ESR spectra of TMPD·H^{2+}. a) −196 °C. b) −160 °C. c) −90 °C. The strength is arbitrary.

a possible reaction scheme as follows:

$$TMPD\cdot H + h\nu\ (318\ m\mu) + h\nu\ (380\ m\mu) \longrightarrow TMPD\cdot H^{2+} + e^-$$

$$Ni^{2+}\ comp. + e^- \longrightarrow Ni^{+}\ comp.$$

$$H_2O \text{ or ethylene glycol} + e^- \longrightarrow \text{radicals}$$

The g-values of the univalent nickel complex ions are shown in Table 1. By comparing the g-values obtained in this experiment with those in the case of γ-irradiation, it can be concluded that the electronic state of the univalent nickel complex ions obtained in both these experiments are identical. This might suggest that the univalent nickel complex ions formed on γ-irradiation are produced by the capture of near-thermal electrons in a later stage of radiation-chemical processes. It seems that TMPD·H^+ does not participate in ligation to the nickel(II) ion, and the univalent nickel complex ions retain the ligand molecules originally bonded to the nickel(II) ions. ESR signals of the univalent nickel complex ions disappear above −50 °C and do not appear even if the sample temperature is lowered again.

$[Ni(H_2O)_6]_2^{2+}$	EG–H_2O	2.37	2.128

a) ±0.005. b) The g-values in parentheses are those obtained in the previous γ-irradiation experiment. c) ±0.01 (for g-values with two figures below decimal point).

In a previous experiment on γ-irradiation, an isotropic ESR signal with g-value of 2.308 which was tentatively assigned to a tervalent nickel complex ion was observed along with the univalent nickel complex ion having d^9 electron configuration. The isotropic signal observed in the present experiment on UV-light exposure gives the same g-value. In order to examine these signals more closely, rigid sample solutions were exposed to UV-light at several temperatures. Between −130 °C and −196 °C, a univalent nickel complex ion with g-values of 2.468($g_{//}$) and 2.078($g_\perp$) is strong in intensity. This is named low temperature signal. The isotropic signal with g-value of 2.308 is weak (Fig. 3). Between −125 °C and −100 C°, a new signal (a high temperature signal) with the g-values 2.37($g_{//}$) and 2.128($g_\perp$) appears and grows gradually at the expense of the low temperature signal, while the isotropic signal reaches the maximum strength at −115 °C and decays gradually beyond this temperature. The low temperature signal is not observed above −115 °C. In the range −95 °C to −70 °C, only the high temperature signal remains observable. The high temperature signal does not change to the low tempera-

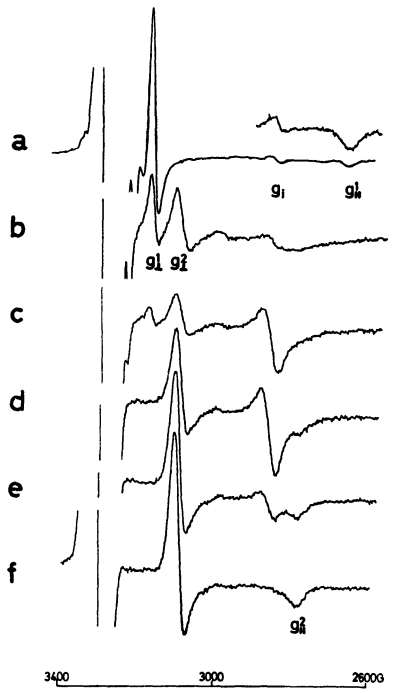

Fig. 3. Three ESR spectra are observed, as the temperature is raised: low temperature signal ($g^1_{//}$ and $g^1_\perp$), isotropic signal (g_i), and high temperature signal ($g^2_{//}$ and $g^2_\perp$). a) UV-exposure at −140 °C. b) −125 °C. c) −120 °C. d) −115 °C. e) UV-exposed at −115 °C and raised to −100 °C. f) UV-exposed at −115 °C and raised to −90 °C.

ture signal by cooling the rigid solution again to −150 °C, indicating two different chemical species.

The thermal stability of these species is in the order: high temperature signal>isotropic signal>low temperature signal. The low temperature signal and isotropic one are also observed in the previous γ-irradiation experiment. The high temperature signal appears to be due to nickel complex ion because of its relatively large g-shift. A large g-shift, say greater than 0.2, would be most likely caused by strong spin-orbit interaction, and is typical of heavy atoms, *i.e.* nickel ion in this case. From the relation $g_{//}>g_{\perp}>2$, which is characteristic of a d^9 electron configuration with D_{4h} symmetry elongated along one of the four fold axes of O_h, it can be concluded that the paramagnetic center is due to a univalent nickel complex ion. Since the average g-value $(g_{//}/3+2g_{\perp}/3)$ is nearly the same in both low and high temperature signals, these two species do not seem to differ much in electronic state. However, each component of the principal g-values differs a great deal. Copper(II) sulfate does not show one of its principal g-values in any direction in the crystalline state because of the presence of exchange interaction between the neighboring ions in the same unit cell.[4] Thus the apparent g-values differ in the rigid solution state from those in the crystalline state. It appears that the high temperature signal is due to an exchange-coupled dimer of the univalent nickel complex ions.

We would like to thank Dr. Yoji Arata for valuable discussions in the preparation of this paper.

Silver Ion Catalysed Oxidation of Primary Aliphatic Amines by Potassium Peroxydisulfate — A Kinetic Study

J. Sreekantha Babu, Km. Veena Joshi, and A. K. Bhattacharya
School of Studies in Chemistry, Vikram University, Ujjain, India

(Received May 28, 1974)

A detailed kinetic study of the oxidation of propyl-, isopropyl-, butyl- and isobutylamines by potassium peroxydisulfate in presence of silver ions has been carried out in aqueous medium. The effects of silver ion concentration and various neutral salts have been detected and the variation of the order of reaction with respect to amine had been explained. The activity of Ag^+ ion has been correlated with the amine structure and probable rate law and the mechanism has been proposed.

Marshall[1] observed the catalytic action of silver ions in the oxidation by peroxydisulfate. Agrawal and Mushran[2] and Srivastava and Hambir Singh[3] reported the silver ion catalysed oxidation of certain amides by peroxydisulfate while Khare and Bhattacharya[4] studied kinetically the morpholine–persulfate reaction. Beileryan *et al.*[5] studied certain aspects of the peroxydisulfate oxidation of some simple primary and secondary amines and amino alcohols. In the present investigation silver ion catalysed oxidation of propyl-, isopropyl-, butyl-, and isobutylamines has been studied kinetically and the effect of amine structure on the catalytic activity of silver ions has been discussed.

Experimental

All the chemicals used were of AnalaR or E. Merck's G. R. quality. The amines were distilled before use. The solutions were always freshly prepared in redistilled water. The amine solution and peroxydisulfate solution along with other required solutions were separately thermostated to attain constant temperature (accuracy ± 0.1 °C). The amine solution is added to peroxydisulfate to start the reaction. Aliquots (5 ml) of the reaction mixture were pipetted out in ice cold water to quench the reaction. The progress of the reaction has been studied by estimating the unreacted peroxydisulfate with use of Kolthoff and Carr's[6] iodometric method with necessary modifications.

Preliminary experiments showed that all the reactions follow pseudo first order kinetics in the presence of silver ion when the concentration of amine has been taken in excess. The self decomposition of peroxydisulfate was found to be negligible and therefore not taken into consideration. Since the boiling point of isopropylamine is 34 °C, all the results of the silver ion catalysed oxidation of isopropylamine have been given at 20 °C, while the oxidation of the other three amines have been carried out at 30 °C. The rate of uncatalysed oxidation was found to be quite small for all the four amines.

Results and Discussion

Effect of Silver Ion Concentration on the Rate of Oxidation. We see that the rate of reaction increases with increase in the concentration of Ag^+ ions for all the four reactions. Straight lines were obtained for the plots of pseudo first order rate constant k *versus* (Ag^+) and the values of intercepts are in good agreement with the rate of uncatalysed reaction (k_o).

Order with Respect to Each Reactant. Since the values of pseudo first order rate constants were found to be fairly constant during all the sets, the order with respect to peroxydisulfate is unity.

The values of order of reaction with respect to amine at different silver ion concentrations in each case are given in Table 2.

The order with respect to amine decreases with the increase in silver ion concentration.

According to Moelwyn-Hughes[7] the uncatalysed and catalysed reactions proceed simultaneously in the presence of a catalyst, and the relation $k=k_o+k_c$ (catalyst), holds, where in k is observed overall pseudo first order rate constant in the presence of catalyst silver ion.

k_o is pseudo first order rate constant for uncatalysed reaction and k_c, is catalytic constant.

The above relation holds for all the four amines, the k_c values for different concentrations of (Ag^+) being fairly constant within the limits of experimental error (Table 3).

Effect of Neutral Salts. The values of rate constants in the presence of different concentrations of

neutral salts are given in Table 4.

Table 4 indicates that the rate of oxidation decreases with the addition of neutral salts, *i.e.* with increase in ionic strength.

The order of reaction with respect of amine was found to change with the amine concentration as well as with the temperature and it was not possible to calculate the over all rate constant and hence the energy parameters.

Rate Laws and Discussion. The experimental results show that all the four amines behave similarly. Hence, the following general rate law is proposed for all the four amines.

$$\frac{-d(S_2O_8^{2-})}{dt} = k_s(Am)(S_2O_8^{2-}) + k_c(Ag^+)(S_2O_8^{2-}) \quad (8)$$

Uncatalysed path Catalysed path

where k_s is second order rate constant for uncatalysed reaction and k_s (Am) $=k_o$ pseudo first order rate constant for uncatalysed reaction. The rate law suggests that in the presence of catalyst both uncatalysed and catalysed reactions proceed simultaneously. In the absence of a catalyst the reaction proceeds through the path involving the first term only and the order with respect to amine should be one. Similar results were reported by Chaltykyan and Beileryan,[8] during the course of their study of the uncatalysed oxidation of some simple primary and secondary amines. In the presence of high concentration of Ag^+ ions, k_o is negligible as compared with k_c (Ag^+), *i.e.* the reaction proceeds entirely along the second path and the order with respect to amine would be zero. Naturally, at moderate concentrations of Ag^+ which have been used in the present investigation, the order with respect to amine is fractional. This was found to be actually the case. With further increase

in silver ion concentration the order should decrease, approaching zero. This is also in agreement with the observed data (Table 2).

The second term in the rate law also suggests that the reaction proceeding *via* catalysed path occurs between two oppositely charged ions, and negative salt effect should be observed. This was found also to be the case.

In the presence of excess amine as in the present study, Eq. 1 is reduced to

$$\frac{-d(S_2O_8^{2-})}{dt} = [k_o + k_c(Ag^+)](S_2O_8^{2-}) \quad (2)$$

At particular Ag^+ concentration,

$$[k_o + k_c(Ag^+)] = k, \text{ the over all rate constant} \quad (3)$$

Equation 3 is similar to that proposed by Moelwyn-Hughes, which has been experimentally found to hold good.

Effect of Amine Structure on the Oxidation Rate. Since the rate constants for the uncatalysed oxidation of all the four amines are of similar magnitude, the catalytic activity of Ag^+ ion has been compared for the values of k_c. To compare the results of isopropyl amine with propylamine, the value of k_c of propylamine was determined at 20 °C under identical conditions and found to be 47.52 l mol^{-1} min^{-1}.

Chaltykyan and Beileryan[9] suggested that the catalytic activity of silver ions in the oxidation of amines with peroxydisulfate increases with decreasing basicity of amines. Nikolaev and Sychev[10] and other workers have reported that the catalytic activity of the metal ion is directly proportional to the instability of metal amine complex.

The order of stability of the silver amine complex and P_{kb} values of the four amines are: butyl-<isobutyl-[11] and propyl-<isopropyl-. The catalytic activity of Ag^+ ions should therefore be in the reverse order which was actually the case.

Mechanism. Taking into consideration all the experimental evidences, the following mechanism has been proposed. Firstly Ag(III)[12,13] will form (rate determining step) which will readily oxidizes the amine to hydroxyl amine derivative

$$S_2O_8^{2-} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} 2SO_4^{\cdot-} \quad (3a)$$

$$\frac{(SO_4^{\cdot-})^2}{(S_2O_8^{2-})} = k_o \text{ (Equilibrium constant)} \quad (3b)$$

$$2SO_4^{\cdot-} + Ag^+ \xrightarrow[\text{Rate determining step}]{\text{slow}} 2SO_4^{2-} + Ag^{3+} \quad (4)$$

$$Ag^{3+} + R\cdot NH_2 + H_2O \xrightarrow{\text{Rapid}} R\cdot NHOH + Ag^+ \quad (5)$$

This explains the rate law proposed for the catalysed path,

$$\frac{-d(S_2O_8^{2-})}{dt} = k_2(Ag^+)(SO_4^{\cdot-})^2$$

from Eq. 3b.

$$(SO_4^{\cdot-})^2 = k_e(S_2O_8^{2-}), \text{ then}$$

$$\frac{-d(S_2O_8^{2-})}{dt} = k_2k_e(Ag^+)(S_2O_8^{2-})$$

$$= k_c(Ag^+)(S_2O_8^{2-})$$

where $k_c = k_2k_e$ is catalytic constant.

The stoichiometric ratio determined for all the four amines is 1 : 1, showing that one molecule each of the oxidant and reductant have been consumed in the reaction.

The oxidation products have been isolated from the reaction mixture using solvent extraction technique. The presence of two compounds other than the excess of amine have been found by thin layer chromatography. From the samples obtained hydroxyl amine derivative and oxime have been detected.[14,15] The oximes formed were due to autooxidation of hydroxylamine derivatives[16,17] as the pH of the systems is above 7. This might be due to reduction of catalyst Ag^+ ion left in the system to Ag by the hydroxylamine derivatives.[18] Black particles of silver were observed when the system was left for a long time.

Lebedev and Kazarnovskii[19] also found oximes, hydroxyl amines of hydroxyamic acids as end products in their study on the catalytic oxidation of aliphatic amines with hydrogen peroxide. Bacon and Stewart[20] also reported aldoximes as the products of oxidation of the silver catalysed peroxydisulfate oxidation of amine.

The authors are thankful to Prof. M. M. Bokadia, Head, School of Studies in Chemistry, Vikram University, Ujjain, for providing laboratory and other research facilities. They are grateful to the Council of Scientific and Industrial Research, India for the award of Junior research fellowship to Km. Veena Joshi and Junior and Postdoctoral fellowships to J. Sreekantha Babu.

Dielectric Study of the Intermolecular Association of Alcohols in Solutions of Benzene

Buta SINGH and J. K. VIJ
Department of Physics, Punjabi University, Patiala-147002, India
(Received September 2, 1975)

The relative permittivity at 1 MHz, the refractive index at the wavelength of sodium D-line and density of the nine alcohols, 1-propanol (A), 2-propanol (B), 1-butanol (C), 2-methyl-1-propanol (D), 1-pentanol (E), 1-hexanol (F), 1-heptanol (G), 3-methyl-2-hexanol (H), 3-methyl-3-hexanol (I), have been measured at 25 °C in benzene in the entire concentration range. The measurements for 1-dodecanol (J) have been made in dilute solutions only. The dipole moments of these molecules in dilute solutions, using Higasi's equation, and the apparent dipole moment for various solute concentrations, using Kirkwood-Fröhlich equation, have been calculated. The results suggest that at low concentrations the alcohols associate to form weakly polar multimers. At high concentrations and in pure liquids, the isomers in which the hydroxyl group is relatively free, favour the formation of highly polar multimers, whereas the isomers in which the hydroxyl group is sterically blocked by the methyl group, favour the formation of closed or ring dimers having low dipole moment.

The low frequency relative permittivity, the electric dipole moment, the Kirkwood correlation factor and dielectric relaxation measurements are useful for studying liquid structure.[1,2] Alcohols have probably been studied more extensively than any other group of compounds and their dielectric absorption is well established. Nevertheless a complete molecular model of the liquid structure capable of explaining the experimental results in alcohols is as yet incomplete. The position of the hydroxyl and the methyl groups on the hydrocarbon chain in alcohols greatly influence the relative permittivity and the correlation factor and consequently the degree and type of hydrogen bonding in these liquids.[3-5] In 1929, Smyth and Stoops[3] reported on the temperature dependence of the relative permittivity of twenty-two isomeric alcohols and also the dilute solution studies of two of these compounds in benzene. They concluded that there is a possibility of both parallel and antiparallel alignments of near-neighbour dipoles. The particular type depends on the molecular geometry, temperature and dilution in nonpolar solvents. Dannhauser made systematic studies on the temperature dependence of the relative permittivity of eight lower alcohols[6] and eight isomeric octanols.[4] He explained the results in terms of the alcohol association into highly polar linear chain n-mers ($n=1,2,3,4....$) and ring dimers having small or zero dipole moment.

Hydrogen bonding in aliphatic alcohols in dilute solution has also received considerable attention. However, most of the data available to date is limited to low concentrations only.[7-9] Rajala and Crossley[10] studied the association of butanols and 1-decanol in the concentration range from 0.2 to 1.0 mol fraction in different solvents and concluded that alcohol association is initially dominated by the formation of small, weakly polar multimers, and eventually large highly polar multimers predominate.

The present work reports the data of the relative permittivity for several alcohols in benzene as a nonpolar solvent in the entire concentration range. In these alcohols the alcohol molecular size and the steric environment of the hydroxyl group are the variables. The data is analysed in terms of the Kirkwood correlation factor, the liquid structure of these alcohols being discussed.

Experimental

Materials. The name and the specifications of the alcohols as given by the manufacturer are given in parentheses after each sample.

(A) 1-propanol (E. Merck A. G., pure grade),
(B) 2-propanol (B. D. H., A. R.),
(C) 1-butanol (B. D. H., A. R.),
(D) 2-methyl-1-propanol (B. D. H., A. R.),
(E) 1-pentanol (Riedel A. G.),
(F) 1-hexanol (Eastman, for chemical purposes),
(G) 1-heptanol (Fluka A. G., practical grade),
(H) 3-methyl-2-hexanol (Fluka A. G., purum),
(I) 3-methyl-3-hexanol (Fluka A. G., purum),
(J) 1-dodecanol (Eastman, for chemical purposes).

Alcohols A—E and G were all dried and distilled and the middle fraction for each sample was collected for use. Alcohols F and H—J were used as such. Benzene (B. D. H., A. R.) which was previously dried by passing sodium wire was subsequently distilled and the middle fraction thus obtained was used. The refractive indices of all the alcohols (except for 1-dodecanol) and of benzene were measured. The values were found to compare well with those given in literature. The melting point of 1-dodecanol was found to be distinct, its value of 23 °C coinciding closely with the literature value of 22.6 °C.

Measurements. Relative permittivity measurements at the frequency of 1 MHz were made with a dielectrometer based on the heterodyne beat method.[11] A two-terminal dielectric cell (type DFL 2, made in Germany), with air capacitance of 17.9 pF, was used. The refractive indices at the wavelength of the sodium D-line were measured with Abbey's refractometer (Andhra Scientific Company Ltd., Machilipatnam, India). The desity measurements were, made with a pycnometer having a volume of 11.563 ml. Temperature was maintained at 25 °C within 0.1 °C. The accuracy in the relative permittivity measurements was estimated to be $\pm 0.5\%$. The accuracy in the refractive indices measurements was estimated upto the fourth decimal place and that for the density measurements 0.03%.

Results of the Measurements. The values of the low frequency relative permittivity ε_0, the relative permittivity at infinite frequency ε_∞, and the square of refractive index n_D^2, at each concentration (mole fraction) for the alcohols C, G, H,

and I, are given in Table 1. For the rest of the alcohols the data are not given here.

ε_∞ has been calculated by first calculating a_∞ by the method reported elsewhere[12,13] and then using the relation:

$$\varepsilon_\infty = \varepsilon_{1\infty} + a_\infty w_2 \quad (1)$$

Here $\varepsilon_{1\infty}$ is the relative permittivity of benzene and w_2 is the weight fraction of the solute. The effective dipole moment at each concentration was calculated using the Kirkwood-Fröhlich equation:[14]

$$\mu_{eff}^2 = g\mu_0^2 = \frac{9kT(\varepsilon_0-\varepsilon_\infty)(2\varepsilon_0+\varepsilon_\infty)}{4\pi N\varepsilon_0(\varepsilon_\infty+2)^2} \quad (2)$$

where kT is the thermal energy and N is the number of solute molecules per ml. The Kirkwood correlation factor g was estimated by taking the dipole moment of the alcohol molecules in vacuum μ_0 to be 1.68 D.[5] The values of μ_{eff} and g for the alcohols C, G, H, and I are given in Table 1.

The dipole moments of these molecules in dilute solutions were calculated using the modified Higasi equation[15] given below:

$$\mu = B\sqrt{(a_0-a_\infty)}, \quad (3)$$

where a_0 is given by the relation:

$$\varepsilon_0 = \varepsilon_1 + a_0 w_2 \quad (4)$$

Table 2. Values of ε_0 (pure liquid), a_0, a_∞, the dipole moment μ calculated by Higasi's method[15] in benzene and the values of μ_{eff} in the pure liquid calculated using the Kirkwood-Fröhlich equation at 25 °C

3-Methyl-3-hexanol (I)	3.248	—	2.125	−0.240	1.58	—	1.16	—
1-Dodecanol (J)	—	—	1.515	−0.157	1.69	1.52	—	—

Values of μ_{eff} in the pure liquid form are calculated by taking the values of g at 27 °C and using the relation $\mu_{eff}^2 = g\mu_0^2$; $\mu_0 = 1.68$ D.

ε_0 and ε_1 are the relative permittivity of the solution and the solvent respectively, and w_2 is the weight fraction of the solute. a_∞ is the same as defined by Eq. 1. The constant B is given by:

$$B = \frac{1}{2(\varepsilon_1+2)}\sqrt{\frac{27kTM_2}{\pi N_A d_1}} \qquad (5)$$

where the different symbols have their usual meaning. Values of the dipole moment are given in Table 2.

Discussion

The values of the relative permittivity of alcohols in the pure liquid form are given in Table 2. There is a close agreement between the experimental and literature values. There is also an agreement between our values of the dipole moments calculated using Higasi's equation[15] in dilute solutions of benzene and the literature values (Table 2) except for the case of 1-dodecanol. For this alcohol our value of the dipole moment is 1.69 D whereas the literature value is 1.52 D. However, our value is quite close to the value of 1.68 D of the alcohol molecule in a vacuum. The values of the dipole moments for 3-methyl-2-hexanol and 3-methyl-3-hexanol are not found in literature. The dipole moments in the pure liquid for all the alcohols except 1-dodecanol are given in Table 2. These values compare within 3% to the literature value of the dipole moment for the alcohols where available.

The concentration dependence of the relative permittivity for the first nine alcohols is shown in Fig. 1. The curves for 1-butanol and 2-methyl-1-propanol almost overlap each other. The plots of the correlation factor g *versus* the alcohol mole fraction are shown in Figs. 2 and 3.

Effect of ε_∞ *on the Dipole Moment and the Correlation Factor.* Our results yield dipole moments μ_{eff} calculated using the Kirkwood-Fröhlich relation.[14] The values are listed in Table 1. The dipole moments are

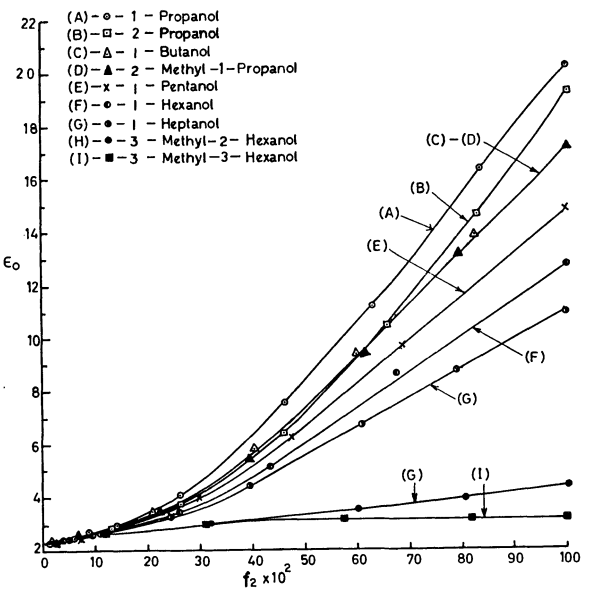

Fig. 1. Plots of ε_0 *versus* f_2 for the alcohols A—I in benzene at 25 °C.

compared with the literature values when available. Our values for 1-butanol in the concentration range 0.019—0.065 mole fraction lie within the range 1.68—1.75 D. It has been found that the discrepancy is due to different values of ε_∞ obtained by using different methods for its evaluation. Several authors[7-9] have calculated the value of ε_∞ by fitting the permittivity data to the Cole-Cole plots using a digital computer. We have calculated the values of ε_∞ using Eq. 1. On using the values of ε_∞ as given by Johari and Smyth[19] for 1-butanol in benzene in the same concentration range, we find that our values of dipole moments at about the same concentration range lie within 1.48—1.60 D and therefore, compare well with the values given by Crossley.[9] The comparison is shown in Table 3. The dipole moments calculated by using our values, are, therefore, higher by a factor of about 0.2 D at low concentrations in all the alcohols. Consequently, g values are also higher than those quoted in literature. For higher concentrations and in pure liquids the difference in the dipole moments is expected to be less for the alcohols A to G since the relative permittivity at infinite frequencies ε_∞ makes dipole moments less sensitive to slight changes in ε_∞. Since the relative permittivity of the alcohols H and I is of the order of magnitude as the square of refractive index, a small uncertainty in the

value of ε_∞ will greatly affect the values of the dipole moment, and consequently, the value of g.

Behaviour of alcohols A—G and effect of Chain-length. The correlation factor g is a measure of those short-range intermolecular forces that lead to the specific dipole-dipole orientations. According to the Kirkwood-Fröhlich theory[14] $g\mu_0^2$ is the square of the dipole moment of the spherical cavity so that its size is macroscopically small and microscopically large. The size should be such that the surroundings can be assumed to have relative permittivity of the liquid. The value of g greater than unity is interpreted in terms of predominantly parallel alignment of the near-neighbour dipoles and g less than unity corresponds to a structure such that its dipole moment is less than that of the monomer. A more specific interpretation depends on the introduction of a molecular model of the liquid structure.

The plots of g against the alcohol mole fraction for alcohols A—G are shown in Figs. 2 and 3. In the absence of the association of the neighbouring molecules, g should be unity for all concentrations. Strong self association is evident for large alcohol concentrations in benzene and in pure liquids. As concentration of alcohols increases from 0.15 to 0.90 mole fraction, values of g increase in the order 1-heptanol<1-hexanol<1-pentanol<2-methyl-1-propanol<1-butanol<1-propanol. Propanols and butanols attain almost the same value in pure liquid. The trend shows that self association (with the exception of 2-propanol) decreases with increase in the length of hydrocarbon chain.

Taking into account the effect of ε_∞ as discussed above, we can say that the values of g are about 20—25% less than unity at the concentration range of *ca.* 0.2 mole fraction. With the increase of alcohol concentration the values of g increase and approach unity at the concentration of *ca* 0.20 mole fraction. This leads us to the conclusion that the initial association involves the formation of multimers having smaller dipole moments than the free monomer. These multimers may be closed or open dimers and timers.[4,20,21] Above the concentration of 0.2 mole fraction g increases rapidly with the increase of the alcohol concentration for the alcohols. (Figs. 2 and 3). Dannhauser[4] and also, Gold and Perrine[22] suggest the association into linear chains as mechanism responsible for the large values of g. Some authors support the existence of highly polar cyclic tetramers.[23,24] In 2-propanol the values of g are lower (Fig. 2) than 1-propanol, 1-butanol and 1-pentanol in the concentration range 0.15—0.90 mole fraction. This is probably due to the chain-branching close to the –OH group which presents steric factors for the formation of large multimers.

Behaviour of 3-Methyl-2-hexanol and 3-Methyl-3-hexanol. The values of g decrease with the increase of the alcohol concentration for 3-methyl-3-hexanol in the entire concentration range. Whereas in the case of 3-methyl-2-hexanol it decreases initially with the increase of concentration in the range 0.10—0.35 mole fraction above which it again starts increasing with comparatively less slope. In these alcohols the –OH group is so effectively screened due to the presence of the neighbouring $-CH_3$ group that association is restricted to small weakly polar multimers, preferably ring dimers, the values of g for pure liquids being less than unity. Association into higher open chain n-mers or highly polar cyclic tetramers is not possible because of steric effects. The results are in agreement with those given by Dannhauser[4] and Crossley *et al.*[25] for 2-methyl-3-heptanol, 3-methyl-3-heptanol, and 4-methyl-3-heptanol in pure liquids.

It is evident that in a liquid alcohol for a given temperature and concentration, one has to assume equilibrium between different structures. The equilibrium constants between the various structures are strongly dependent on the nature of alcohol and its concentration in an inert solvent.

The research project was financed by the Department of Atomic Energy. One of the authors (Buta Singh) is grateful to Professor B. S. Sood, Head, Department of Physics, for the encouragement during the work.

Determination of the Dissociation Constants of Salicylic Acid in Water-Ethanol Mixtures by Modified Conductometric Methods

A. K. MANDAL and S. C. LAHIRI
Department of Chemistry, University of Kalyani, Kalyani, Nadia, West Bengal, India
(Received September 9, 1975)

The dissociation constants of salicylic acid in water and ethanol–water mixtures (8—87.6 wt % of ethanol), have been determined by the modified conductometric method as suggested by Gelb. The results have been checked independently from the plot ΛC *vs.* $1/\Lambda$ of salicylic acid in mixed solvents. $\Lambda^{\circ}_{HClO_4}$ and $\Lambda^{\circ}_{\text{salicylic acid}}$ have also been determined.

The importance and limitations of the determinations of the dissociation constants of acids and bases in mixed solvents have been well-discussed.[1-4] In order to explore a suitable method for the determination of the dissociation constants in mixed solvents which could avoid the uncertainties due to liquid-junction potential and changed sensitivity of the glass electrode, we found the conductometric method as suggested by Gelb[5] with suitable modification can be utilized with success. The method is handy and less time consuming and ensures high accuracy. The method involves the assumption of complete dissociation of $HClO_4$ in mixed solvents—an assumption on which the measurement of H^+ ion concentration in mixed solvents is generally based. Until now the assumption has been regarded as being valid in mixed solvents containing fairly high percentages of organic solvents.

We report in this communication the dissociation constants of salicylic acid in a series of ethanol–water mixtures by the modified conductometric method. We are particularly interested in the determination of pK values of comparatively weak acids which may be useful for the preparation of suitable buffers, the lack of which is one of the strong handicaps for the measurement of H^+ ion concentrations in mixed solvents.

Experimental

Absolute ethanol was treated with the requisite quantity of calcium oxide, kept overnight, and then distilled. The middle fraction was collected and used without further treatment. The slight traces of water, if any, in the organic solvents were neglected. The weight percentages of the organic solvent and the relative permittivities of the solvent mixtures were determined in the same way as described before.[6] Salicylic acid (G. R. E. Merck) was recrystallized from alcohol. Perchloric acid and other reagents used for standardization were of E. Merck's reagent grade.

Conductance measurements were done with the aid of a Leeds and Northrup Model 4959 conductance bridge with a sensitivity of $\pm 0.1\%$. A 50—60 cycle signal was employed. A dip-type Philips conductance cell with a cell-contant, $\theta = 0.815\ cm^{-1}$ was utilized. The cell constant was determined using accurately measured KCl (G. R. E. Merck) solutions and using the conductance values from the literature[7] and the value of the cell-constant was repeatedly checked during the course of the experiment. The measurements were done at 25 ± 0.05 °C.

The initial conductance of a certain amount of the acid solution was measured. Definite amounts of perchloric acid in appropriate solvents were added at regular intervals. The mixtures were allowed sufficient time to attain equilibrium and the conductance of each solution was measured. The experiment was repeated with different concentrations of the salicylic acid and also in different percentages of mixed solvents. The ionic strengths of the solutions were kept as low as practicable ($\approx 10^{-3}$ M) so that the ionic strength correction was almost negligible. The blank titrations were performed in the same way as described above, the experimental solutions being replaced by the same amount of the appropriate solvent. The conductances of the solvents were taken to apply appropriate corrections.

Results and Discussion

The dissociation constant K for the reaction

$$HA \rightleftharpoons H^+ + A^- \tag{1}$$

can be represented as

$$K = \frac{[H^+][A^-]}{[HA^-]} \times f_{\pm}^2 \tag{2}$$

(f_{HA} may be regarded as unity).

However, if we take a mixture of completely dissociated $HClO_4$ and partly dissociated HA, Eq. 2 can be written as

$$K = \frac{\alpha(\alpha C_{HA} + C_{HClO_4}) \times f_{\pm}^2}{(1-\alpha)} \tag{3}$$

C_{HA} = total concentration of HA
C_{HClO_4} = concentration of $HClO_4$ in the mixture
$f_{\pm}$ = mean activity coefficient
α = the degree of dissociation of HA in presence of $HClO_4$

The conductances of the mixtures (containing HA and $HClO_4$) and the blank solutions (containing $HClO_4$ only) are given by

$$\frac{1}{R} = \frac{1}{1000\theta}[C_{HClO_4}\Lambda'_{HClO_4} + \alpha C_{HA}\Lambda'_{HA}] \tag{4}$$

[where $\Lambda'_{HA} = \lambda_{H^+} + \lambda_{A^-}$ at the appropriate ionic strength and $\Lambda = \alpha\Lambda'$, $\alpha = 1$ in the case of $HClO_4$] and

$$\frac{1}{R^*} = \frac{1}{1000\theta} C^*_{HClO_4}\Lambda^{*\prime}_{HClO_4} \tag{5}$$

(* indicates quantities for blank solutions)

θ = cell constant.

When $1/R = 1/R^*$, we have

$$C^*_{HClO_4}\Lambda^{*\prime}_{HClO_4} = C_{HClO_4}\Lambda'_{HClO_4} + \alpha C_{HA}\Lambda'_{HA} \tag{6}$$

Since C_{HClO_4} and $C^*_{HClO_4}$ do not differ considerably and the ionic strengths of the solutions are equal, one can write $\Lambda'_{HClO_4}=\Lambda^{*\prime}_{HClO_4}$. However, approximations are made that $\Lambda'_{HClO_4}=\Lambda'_{HA}$ in aqueous as well as in mixed solvents. This is quite reasonable in view of the closeness of the mobility of ClO_4^- and anions on which the difference in equivalent conductances of $HClO_4$ and organic acids ultimately depends. Thus,

$$C_{HClO_4} + \alpha C_{HA} = C^*_{HClO_4} \quad (7)$$

from which α is obtained.

Modified equations[8] can be used to take into account the variations of Λ'_{HClO_4} and Λ'_{HA} due to variations in ionic strengths; this, however, is not necessary in our case as the ionic strengths are kept low ($\approx 10^{-3}$ M) and the variation of ionic strengths is also too small to vitiate the assumption $\Lambda^{*\prime}_{HClO_4}=\Lambda'_{HClO_4}$ to a measurable accuracy.

Further modifications of K values are possible taking

$$\alpha = (C^*_{HClO_4}-C_{HClO_4})/\beta C_{HA} \quad (8)$$

where $\Lambda'_{HClO_4}=\Lambda^{*\prime}_{HClO_4}$ and $\beta=\Lambda'_{HA}/\Lambda'_{HClO_4}$.
We have calculated β as suggested by Gelb but found the alternative procedure given below to be superior.

Equivalent conductance values of perchloric acid at different dilutions (5.0×10^{-2} M to 5.0×10^{-4} M) were obtained from conductance measurements. At low concentrations, Λ'_{HClO_4} values when plotted against $C^{1/2}$ gave good straight lines in aqueous as well as in mixed solvents. $\Lambda^\circ_{HClO_4}$ values were obtained by extrapolation to zero dilution. Λ_{HA}° and K values were obtained from the plot of $C\Lambda$ against $1/\Lambda$ of a number of dilute solutions of HA utilizing the equation[9]

$$C\Lambda = -K\Lambda^\circ + K\Lambda^{\circ 2}/\Lambda \quad (10)$$

where the intercept gives $(-K\Lambda^\circ)$ and the slope $(K\Lambda^{\circ 2})$. This, however, gives us an independent method of checking K values free from any assumption.

The β values were evaluated from $\Lambda^\circ_{HClO_4}$ and Λ°_{HA} values. Since the ionic strengths are very low, the slight differences of Λ' from Λ° values would not affect the value of β to any measurable extent. β value in water comes to be 400/415=0.96. The β values in mixed solvents also lie within 0.90 to 0.96, deviations occurring at higher percentages. However, evaluation of K and Λ° of the acid by the dilution method is liable to be erroneous at higher percentages of alcohols, where the dissociation constant decreases enormously.

The average values of $\Lambda^\circ_{HClO_4}$, $\Lambda^\circ_{salicyclic\ acid}$, and p$K$ measured from several sets of experiments (using both the titration method and the dilution method) for each percentage of organic solvent are given in Table 1. The agreement of the K values suggests the accuracy of the titration method. The activity correction term from the Debye-Hückel limiting equations, making appropriate corrections for the change in the dielectric constant values, comes out to be about 0.02 (in 8 wt % of alcohol) to 0.09 (87 wt% of alcohol).

The values from the spectrophotometric measurements were also incorporated in Table 1 for comparison.[10] The results are found to agree fairly well. The results obtained by the spectrophotometric method utilizing a glass–calomel electrode for measurement of H^+ ions give higher values at higher percentages of alcohol. This may be due to uncertainties in H^+ ion concentration measurements. The association of ions may be increasingly greater as the percentage of alcohol increases. However, it is noted that the pK values obtained by the modified conductivity method, when plotted against weight percentages and mole fractions of organic solvent, give excellent straight lines (up to 0.6 mole fraction); the plot of pK *vs.* $1/\varepsilon$ (ε=relative permittivity) gives deviations only at higher percentages of organic solvent.

The method however, cannot be used when the pK values are rather high (more than 4 or so). It is known that the dissociation constant is considerably suppressed with the addition of $HClO_4$; as a result α becomes too small. For such cases, however, it is possible to take a large number of $1/R$ values from fairly concentrated to dilute solutions of HA (as dilute as measurable without impairing the accuracy). Suitable blank curves are obtained by addition of a dilute solution of perchloric acid to the appropriate solvents and the interpolated values of $1/R^*$ are determined from these blank curves. Under this condition, the equation reduces to $\alpha C_{HA}=$

$C^*_{HClO_4}$, from which α and hence pK values are calculated. Further refinements as suggested above are possible.

The method has the advantage that the accurate determination of cell constants is not at all necessary, provided the same cell is used, as the θ terms cancel.

The $\Lambda^\circ_{HClO_4}$ in water has been found to be 415, in good agreement with the values in the literature ($\lambda^\circ_{H^+}$= 349.8 and $\lambda^\circ_{ClO_4^-}$=64.6[11] or 67.32)[12] at 25 °C. The $\Lambda^\circ_{HClO_4}$ values decrease with increasing percentages of alcohol, as expected. The reliability of the results may be obtained from the comparison of $\Lambda^\circ_{HClO_4}$ and Λ°_{HCl} values ($\lambda^\circ_{Cl^-}$=76.34 at 25 °C). The values of Λ°_{HCl} in ethanol reported in the literature vary from 81.7 to 89.1[13] where $\Lambda^\circ_{HClO_4}$ at 87.6 wt % of alcohol is 92.00. The values thus appear to be reasonable. The $\Lambda^\circ_{\text{salicylic acid}}$ (in water) comes out to be 400 ($\lambda^\circ_{\text{salicylate ion}}$= 35 at 25 °C).[11] A slight disagreement is thus apparent. It is, however, difficult to suggest the extent of reliability of the $\lambda^\circ_{\text{salicylate ion}}$ value. It is as yet inopportune to say something positively about the modified conductometric method. In comparison to the pH-metric method the assumptions involved in the determination of pK values by this method should not vitiate the result appreciably, even if association of $HClO_4$ takes place at higher percentages of alcohol, as we are concerned with the conductivities.

Systematic studies by different techniques are necessary to make a definite statement about the reliability of this method in different mixed solvents.

π-Electron Structure of Some Nonbenzenoid Hydrocarbons Using β-Variable Method

Subrata CHATTERJEE and Nanda K. DAS GUPTA*

Department of Chemistry, Visva-Bharati University, Santinikentan, West Bengal, India
**Department of Chemistry, The University of Alberta, Edmonton, Alberta, Canada*

(Received October 14, 1975)

The molecules pentaleno[*def*]heptalene, cyclohept[*fg*]acenaphthylene, naphth[*cde*]azulene and cyclohept[*bc*]-acenaphthylene have been studied using β-variable methods proposed by Dewar *et al.* and Yamaguchi *et al.* The predicted results are compared with experimental values and with other theoretical results.

The Pariser-Parr-Pople (PPP) semiempirical self-consistent antisymmetrized molecular orbital (SCF ASMO) method[1] is very useful in predicting the electronic structure of conjugated systems. From time to time the semiempirical nature of the method has been changed by several authors by changing the mode of evaluation of certain integrals. Among these are Nishimoto and Forster[2], Yamaguchi *et al.*[3] and Dewar and co-worker[4] who used exchange integrals $\beta_{\mu\nu}$ as functions of bond order $p_{\mu\nu}$ or bond length $r_{\mu\nu}$. These methods are known as the "β-variable" method. The former two methods were developed to calculate the electronic transitions and the latter one to calculate the ground state properties of conjugated systems. But we[5] have successfully applied the β-variable technique of Yamaguchi *et al.*[3] and Dewar *et al.*[4] to predict the electronic transitions of many nonbenzenoid hydrocarbons. In this paper we are going to report the results of calculations on some nonbenzenoid hydrocarbons shown in Fig. 1. However, these molecules were studied by several authors[6] using a different set of parameters. Our aim is to see how far the results calculated by the "β-variable" technique are in agreement with the experimental results.

Geometry of the Molecules. Although the β-variable technique is insensitive to the assumed geometry of the molecule, still for molecules **1**[7] and **2**[8] we used the actual structure and for the other two we assigned the

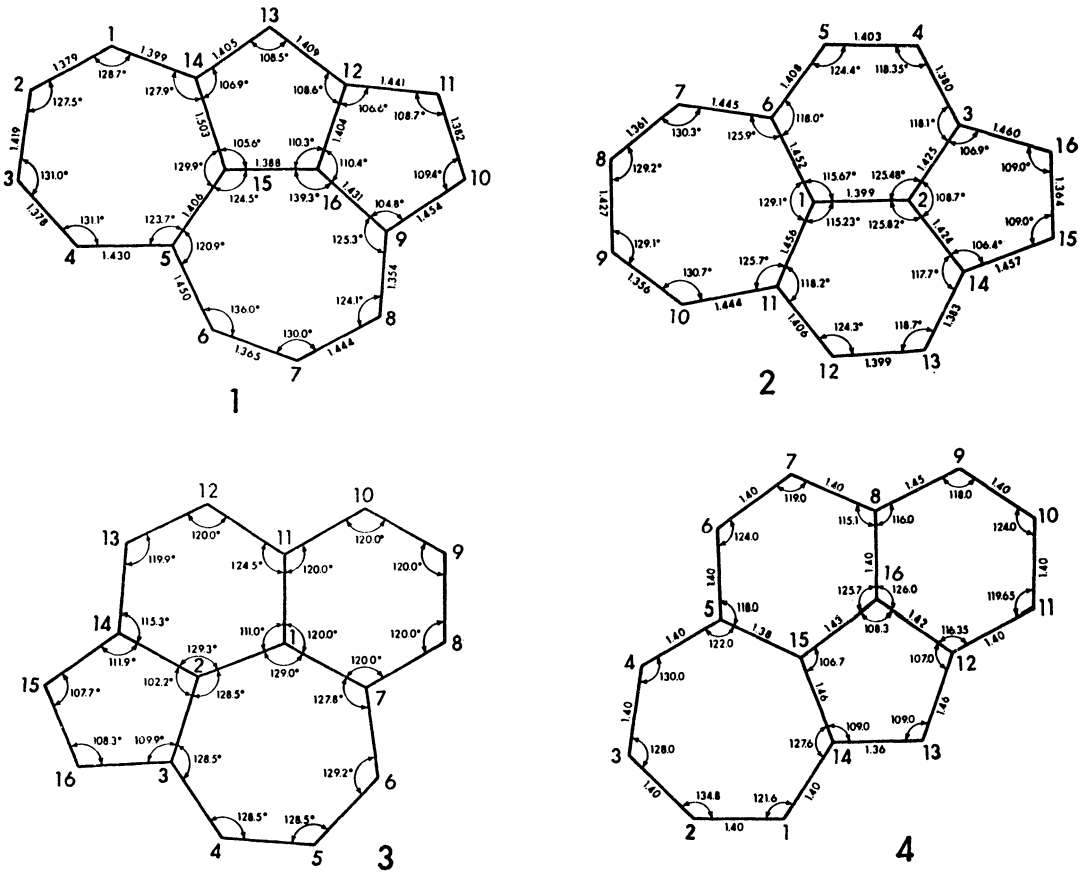

Fig. 1. Molecules.

geometry shown in Fig. 1 for our calculation.

Parameters. As usual the two-centre, two-electron repulsion integrals $\gamma_{\mu\nu}$ were computed from the initial geometry of the molecules using the formula of Ohno[9] for the method of Dewar and Harget and for the method of Yamaguchi *et al.* the formula of Mataga and Nishimoto[10] was used. For both the methods the integrals between non-bonded atoms were not varied throughout the calculation.

The one-centre, two-electron repulsion integrals were evaluated from the valence-state ionization energy I_μ (11.16 eV)[11] and electron affinity A_μ (0.026 eV)[11] of the carbon atom using the relation

$$\gamma_{\mu\mu} = I_\mu - A_\mu = 11.134 \text{ eV}.$$

For bonded atoms, $\gamma_{\mu\nu}$ and core resonance integrals $\beta_{\mu\nu}$ were adjusted at each iteration on the basis of bond-order bond length relations. For the method of Yamaguchi *et al.* the relations are

$$r_{\mu\nu}(\text{Å}) = 1.520 - 0.186 p_{\mu\nu}$$

and

$$\beta_{\mu\nu} = \beta_0 \exp\left[a(r_0 - r_{\mu\nu})\right]$$

where r_0 is the bond length of benzene, a is equal to 1.7 Å^{-1} and β_0 has been taken to be equal to -2.15 eV.[5] For the method of Dewar and Harget the relations are

$$\beta_{\mu\nu} = -6.927 S_{\mu\nu}$$

and

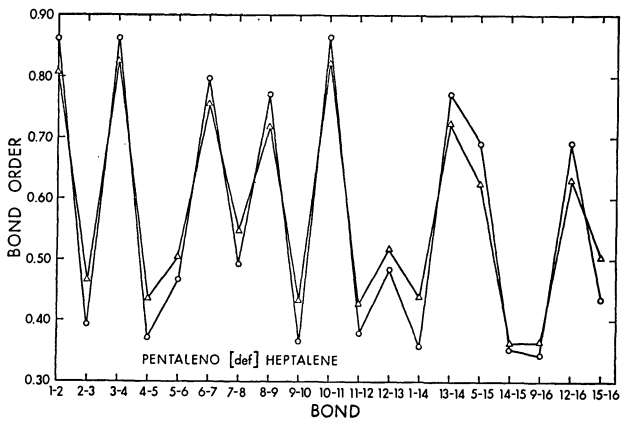
$$r_{\mu\nu}(\text{Å}) = 1.512 - 0.174 p_{\mu\nu}$$

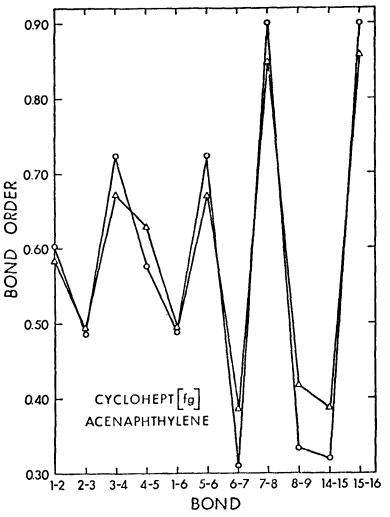
where $S_{\mu\nu}$ is the overlap integral between two π_{2p} orbitals with orbital exponent 1.59. In both the methods $\beta_{\mu\nu}$ for non-bonded atoms was equal to zero.

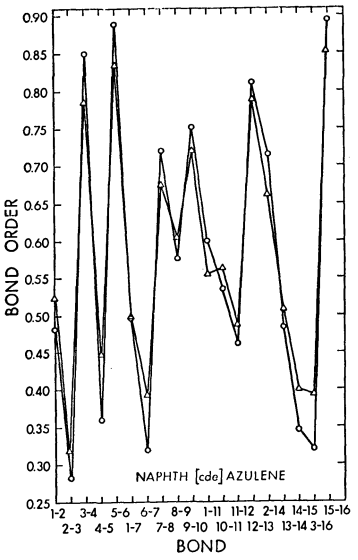
The starting vectors were Hückel MO coefficients and the interation was continued until the self-consistency was achieved within the desired degree of accuracy.

Results and Discussion

Table 1 contains the calculated $\pi^* \leftarrow \pi$ transitions along with the oscillator strengths and experimental results. For comparison we have also included in the table the other theoretical results. Since the molecules are not simple it is very difficult to make point-to-point correlations. However, attempts have been made to do so. It is clear that except for a few cases the present work in which case no configuration interaction was performed is in good agreement with experiment and is also comparable to other theoretical results where, in some cases, configuration interaction was done.







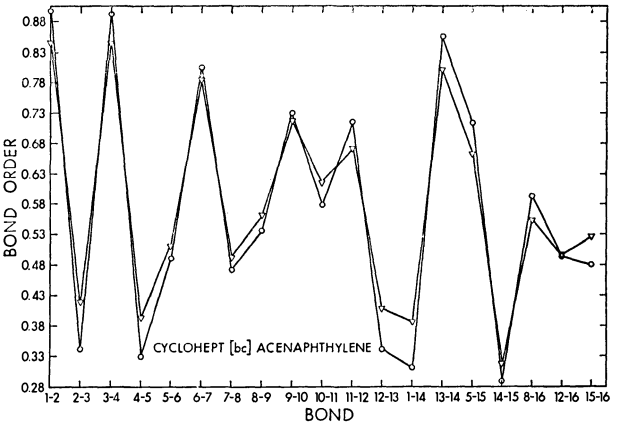


Fig. 2. Variation of bond order with bonds (SCF(a)—○; SCF (b)—△).

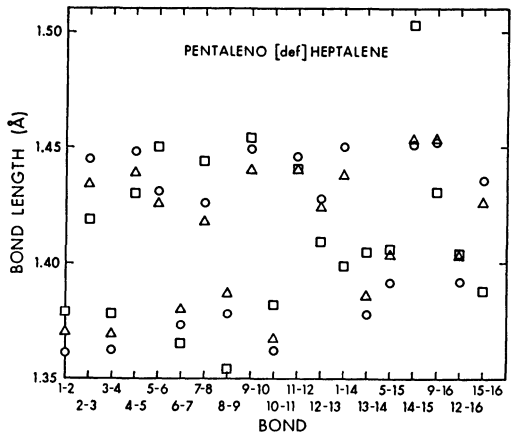
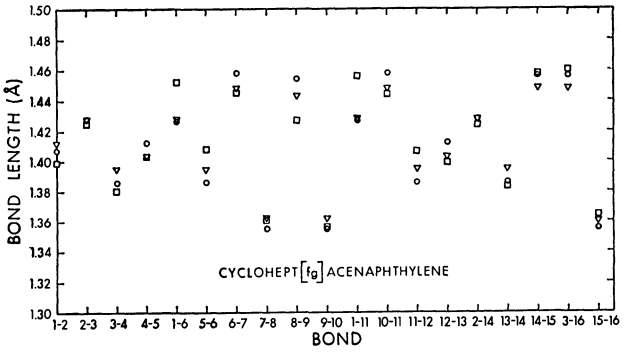
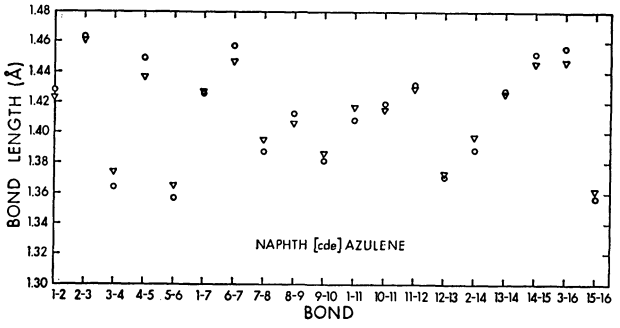
Figure 2 represents the variation of bond order with







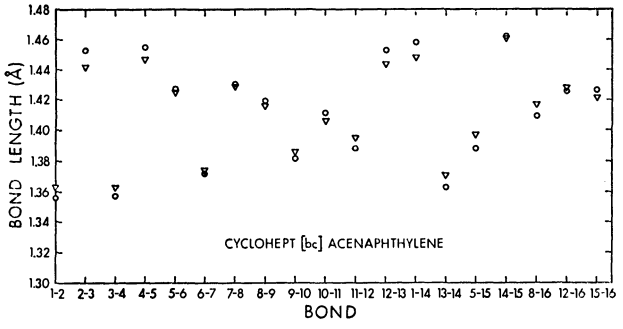


Fig. 3. Comparison between predicted bond lengths and experimental bond lengths (SCF (a)—○; SCF (b)—△; experimental—□).

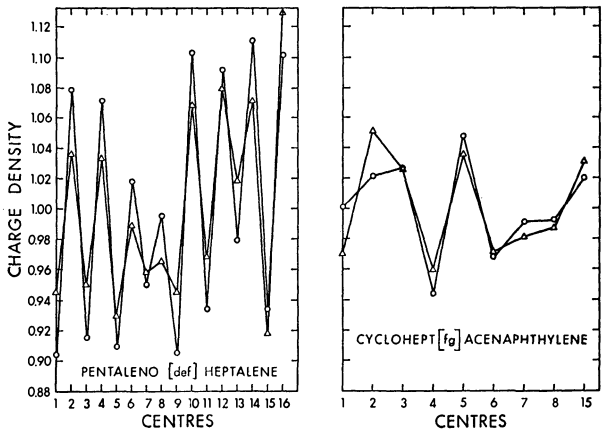

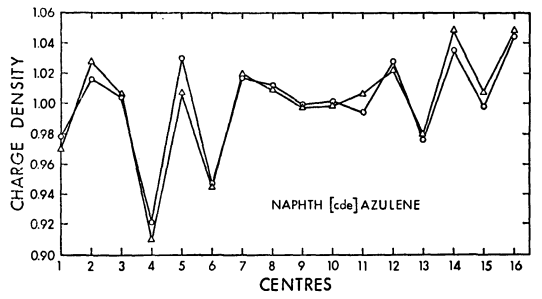

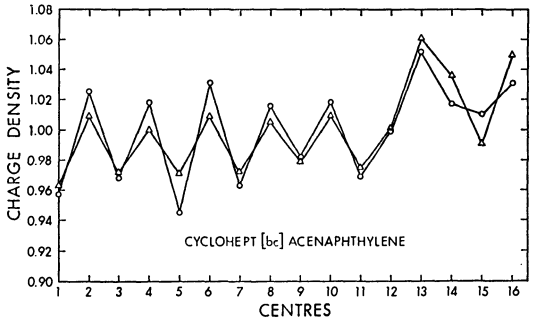

Fig. 4. Variation of charge density with centres (SCF(a) —○; SCF (b)—△).

bond. It is seen that the two methods maintain almost the same trend of variation in all the cases. Figure 3 compares the bond length calculated by the different methods. Experimental values, where available are also included in the figure. It is evident from Fig. 3 that in all the molecules the bond lengths calculated by the two methods are in very good agreement with each other. Except for a few cases, the agreement between the predicted bond lengths and the experimental values are good. Figure 4 represents the variation of charge density with different centres. Here also the two methods maintain the same trend.

It will be clear from the predicted bond lengths that when a bond is common to two different types of rings then the bond has a tendency to have single bond character. This is pronounced when the bond is common to five and seven membered rings and less pronounced when the bond is common to a six membered ring and seven or five membered ring. The range is from 1.43 to 1.46 Å. But the bond C_{15}–C_{16} of the molecule cyclohept[*bc*]acenaphthylene has a value of 1.422 Å calculated by the method of Yamaguchi *et al.* Although the bond is common to two different types of

TABLE 2. CALCULATED VALUES OF IONIZATION POTENTIAL, ELECTRON AFFINITY AND DIPOLE MOMENT

Molecule	Ionization potential (eV)				Electron affinity (eV)				Dipole moment (D)		
	Uncorrected		Corrected		Uncorrected		Corrected

rings, still its single bond nature is not exhibited as much. A similar situation is also seen in the case of C_1–C_2 bond, the value being 1.423 Å calculated by the method of Yamaguchi *et al.* of molecule **3**. This may be due to the fact that these molecules have three consecutive bonds, common to two different types of rings. As a result the tendency of single bond character for the middle one, C_1–C_2 for molecule **3** and C_{15}–C_{16} for molecule **4**, is not so pronounced. Again when a bond is in common to two of the same type of rings such as two seven membered, five membered and six membered rings the bond has a predicted bond length almost equal to that of an aromatic C–C bond. The examples are C_5–C_{15} (1.392, 1.404 Å) and C_{12}–C_{16} (1.392, 1.403 Å) of pentaleno[*def*]heptalene, C_1–C_2 (1.407, 1.412 Å) of molecule **2**, C_1–C_{11} (1.408, 1.417 Å) of naphth[*cde*]-azulene and C_8–C_{16} (1.409, 1.417 Å) of cyclohept[*bc*]-acenaphthylene. Moreover if we examine the predicted peripheral bond lengths of all the molecules, an interesting feature will be observed. The predicted peripheral bond lengths of one of the seven and five membered rings of pentaleno[*def*]heptalene has alternate single bond and double bond character. Thus the bonds C_{14}–C_1, C_2–C_3, C_4–C_5, C_9–C_{10}, and C_{11}–C_{12} have single bond character whereas the bonds C_1–C_2, C_3–C_4, and C_{10}–C_{11} have double bond character. The peripheral bonds of the other seven membered ring (C_5–C_6, C_6–C_7, C_7–C_8, and C_8–C_9) and five membered ring (C_{12}–C_{13} and C_{13}–C_{14}) have more or less bond length equal to an aromatic C–C bond length. Thus the peripheral bonds of this molecule are of two types— in one case the bonds are localized and in the other case they are delocalised. This is more clearly observed in the method of Yamaguchi *et al.* A similar situation is also seen in the case of other molecules. Thus the peripheral bonds of the naphthalene ring of molecule **2** are delocalised whereas those of five and seven membered rings are localized. In the case of naphth[*cde*]-azulene and cyclohept[*bc*]acenaphthylene the peripheral bonds of five and seven membered rings have alternate single and double bond character. Moreover the peripheral bonds of naphthalene moiety of these molecules are not predicted to be of similar type. It is found that the peripheral bonds of one of the benzene rings of the naphthalene nucleus is more delocalised than the other one which is joined with both five and seven membered rings. Thus the peripheral bonds of these molecules are either aromatic or polyolefinic in nature. Hence any definition of aromacity based on the global π-electron properties such as delocalization energy, magnetic properties or the standard deviation of bond length[12] is not adequate for these types of molecules.

Ionization Potential, Electron Affinity and π-Dipole Moment. According to Koopmans' theorem[13] the highest occupied orbital energy and the lowest unoccupied orbital energy represent ionization potential and electron affinity respectively of a molecule. But ionization potential and electron affinity calculated in this way is 1 or 2 eV higher than the true value. Hence we have used a relation of Kunii and Kuroda[14] for the calculation of ionization potential (I.P.) and electron affinity (E.A.). The relations are

$$\text{I.P.} = -(\varepsilon_i + 1.06)\ \text{eV}$$

and

$$\text{E.A.} = -\varepsilon_j - 1.90\ \text{eV}$$

where ε_i and ε_j are respectively the highest occupied and lowest unoccupied orbital energy. Table 2 contains uncorrected and corrected ionization potential and electron affinity respectively along with other theoretical values calculated in a similar way. It is seen that the present work is in good agreement with other theoretical results.

Table 2 also contains calculated values of π-dipole moment of these molecules along with other results. The dipole moment of molecule **2** has been determined experimentally and it is 0.49 D.[15] Theoretical values for the π-dipole moment have been obtained by Birss and Das Gupta,[6a] 1.15 and 2.06 D, by Pullman *et al.*,[16] 1.0 D, and by Francois *et al.*,[17] 0.9 D, compared with the present value of 1.26 and 2.27 D.

The authors express their gratitude to Professor F. W. Birss for many stimulating discussions and financial support. They are also thankful to the Computing Services, University of Alberta, for computational facilities.

Effect of Solvent on Dipole Moment of Aliphatic Mercaptans

A. N. SRIVASTAVA and P. R. TALESARA
Chemistry Department, University of Jodhpur, Jodhpur-342001, India
(Received December 18, 1975)

Evidence of donor-acceptor complexes as a result of interaction between thiols and carbon tetrachloride has been obtained from the studies of dipole moment at 30 °C. Our polarisation data in other solvents except benzene are new. The results obtained have been discussed in terms of the influence of solvent on dipole moments in the light of general theory of Higasi.[1-3]

A survey of the literature reveals that only a few workers[4-6] have determined the dielectric-polarisation of alkanethiols, either to examine the equations derived from current theories of dielectric polarisation or to study the effect of sulfur replacing oxygen in an alcoholic group. The dipole moment value available[4,5] for these compounds are widely divergent. The present work has therefore been undertaken to re-examine the value of dipole moment as well as to assist in understanding the application of general theory of Higasi in case of aliphatic mercaptans.

Experimental

The method and technique have been described earlier.[7]

Purification. All the alkanethiols were purified[8] before use by distilling over anhydrous sodium sulfate in a quick fit apparatus where there was no possibility for the liquid to be in contact with atmospheric moisture or carbon dioxide. Table 1 contains the physical quantities experimentally measured for the liquids studied in the present paper.

The non polar solvents, benzene and carbon tetrachloride of grade E. Merck (G.R.) and dioxane of grade B.D.H. (A.R.) were used as such as the measured dielectric constants of these solvents agreed within ± 0.001 unit with the literature values.[6]

Table 1. Experimental physical constants

Name of substance	Density	Refractive index	Boiling point
Propyl mercaptan	0.82995	1.4330	66.1 °C
Butyl mercaptan	0.83134	1.4375	96.2 °C
Isobutyl mercaptan	0.82334	1.4340	40.0 °C
t-Butyl mercaptan	0.78888	1.4175	61.0 °C

Cyclohexane (B.D.H. Laboratory reagent) was distilled twice and the fraction boiling at 78 °C was used.

The solution moment values have been evaluated from the usual expression

$$\mu_S = 0.01281 \times 10^{-18}(P_{2\infty} - P_e)^{1/2} T^{1/2} \quad (1)$$

The solute-polarisation at infinite dilution *i.e.* $P_{2\infty}$ has been calculated by the method of Halverstadt and Kumler.[9] The values of the constants α, β, ε_1 and V_1 in Halverstadt and Kumler equation have been evaluated by the method of least squares and are given in Table 2. The electronic polarisation (P_e) is the same as molecular refraction for sodium D line and has been taken from literature.[10] Atomic polarisation (P_a) has not been taken into consideration according to the suggestion of Debye,[11] *viz.* the electronic polarisation calculated from sodium D line partly compensates the neglect of atomic polarisation.

Results and Discussion

The solvent effect in mercaptan can be understood with reference to the structure of H_2S. Hydrogen sulfide is an asymmetrical top molecule and has two-fold axis of symmetry. The molecule may be considered to consist of two ellipsoids with a common axis 'c' and with a dipole in its axis of symmetry at a distance a_1 from one end of the diameter and a_2 from the other end (diameter along axis of symmetry $2a=a_1+a_2$). The value of a_1, a_2, and c have been calculated from the spectroscopic[12] data for the H–S bondlength (1.328 Å) and ∠HSH (92°2′). Thus

$$c = 0.9568\,\text{Å}, \quad a_1 = 0.0544\,\text{Å}, \quad a_2 = 0.8663\,\text{Å}$$

According to the theory of Higasi[1-3] if $a<c$, $a_1<c$ and $a_2<c$, the induced moment is evaluated by the expression

$$\mu_1 = 2\pi n\alpha\mu(B_1+B_2) \qquad (2)$$

where the value of B_1 and B_2 may be obtained from the expression

$$B = \frac{k'^2}{k'^2-1}\left|1-\frac{1}{(k'^2-1)^{1/2}}\sin^{-1}\frac{(k'^2-1)^{1/2}}{k'}\right|-\frac{1}{3} \qquad (3)$$

(where $k'=c/a>1$) by substituting $k'=c/a_1$ and $k'=c/a_2$ respectively. From the calculated values of $B_1=+0.5833$ and $B_2=0.0286$, it is observed that B_1 and B_2 are both positive and therefore as suggested by Higasi, the solvent effect would be positive *i.e.* $\mu_s>\mu_v$. Literature value[13] 0.97 D for μ_s of H_2S in benzene, appears to be much convincing and is greater than 0.93 D,[14] a value in the vapour state. The observed ratio for μ_s/μ_v is therefore 1.04. The value calculated for μ_s/μ_v on the basis of Higasi's treatment comes to be 1.09. This shows that theory of Higasi is correctly applicable[7] in case of H_2S molecule. If one of the hydrogen atom of H_2S is replaced by an alkyl group, this will lead to an increase in the value of 'c' and c would be further greater than a_1 and a_2. Therefore it is expected that k' would be greater than one and μ_s would be greater than μ_v in case of mercaptans studied here. Unfortunately the data in vapor state are not available in case of alkanethiols. However, in case of positive solvent effect, according to the suggestion of Higasi, the solution moment should be greater in the solvent having higher dielectric constant and as such μ_s (benzene) should be greater than μ_s in the other three solvents.

The unexpected higher values for last two mercaptans (Table 4) in dioxan than the values in benzene may be regarded due to hydrogen bonding between hydrogen atoms of the solute and the donor oxygen atoms of the solvent molecules, an effect which would give rise both to the lengthening of the S–H bond and polarisation of solvent molecules. The high values are therefore best considered as due to an "interaction polarisation." This is further supported by the observation of Taylor[15] reporting that smaller is the ionisation constant of the acid, the stronger is the hydrogen bond. The ionisation constant values,[16] 2.26×10^{-11}, 2.21×10^{-11} and 0.89×10^{-11} for propyl mercaptan, butyl mercaptan and *t*-butyl mercaptan respectively suggest therefore that the possibility of hydrogen bonding in the last case is more and as such a high value is expected. The decreasing order of ionisation constant leads to anticipate that isobutyl mercaptan (the ionisation constant of which is not available) has a greater tendency of hydrogen bonding in dioxane than the first two thiols. Consequently the solution moment value of isobutyl mercaptan happens to be greater than that in benzene but the value is certainly less than that of butyl mercaptan in dioxane, as expected.

The moment values in carbon tetrachloride has been examined in the light of Earp and Glasstone[17] theory. Accordingly it has been shown in Fig. 1 (data shown in Table 3) that for these systems the excess polarisation P^E is a linear function of f_1f_2 and passes through the origin, confirming that the contact pairs are exclusively

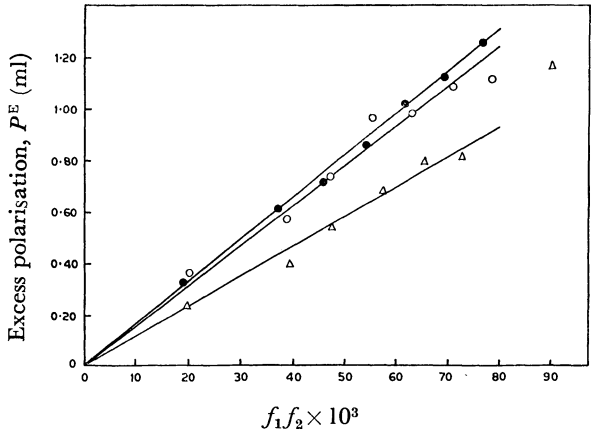

Fig. 1. P^E *vs.* f_1f_2.
Solvent: carbon tetrachloride.
●: Propyl mercaptan, ○: butyl mercaptan, △: isobutyl mercaptan.

formed. The unexpected higher values for all the four thiols in carbon tetrachloride than those in benzene may therefore be due to the formation of donor-acceptor type complexes. Praunitz and coworkers[18] have also adduced evidence that carbon tetrachloride behaves as an electron acceptor. Besides, the support for complex formation between benzene and carbon tetrachloride (acceptor) is recently[19] reported. Literature[20] also reports the behavior of mercaptans as donor.

The dipole moment value determined by Hunter and Partington[4] in Table 4 appears to be low. This observation is further supported by the data of Walls and Smith[21] and Mathias[5] who have found higher values. It is expected that with larger atoms or groups in place of hydrogen in H_2S, the bond angles would be larger and as such the dipole moment value for butyl mercaptan should be higher than that of propyl mercaptan. This contention is also supported by Mathias,[5] who observed that the dipole moment calculated by Debye's equation increases with the extention of the carbon chain in the normal thiols. It is pertinent to mention that out moment values fairly agree with those obtained by Mathias.[5] Our data in Table 4 amply demonstrate the above facts.

The authors are thankful to Prof. R. C. Kapoor, Head, Department of Chemistry for providing the necessary facilities. One of us (P.R.T.) is grateful to C.S.I.R. and U.G.C., Govt. of India for financing the project.

Chromium(III) Complexes with Amino Acids. I. Chromium(III) Complexes with Glycine and *dl*-α-Amino Acids

Hisaya Oki and Kiyoe Otsuka

Department of Chemistry, Faculty of Education, Fukui University, Fukui 910

(Received September 10, 1975)

A comparison has been made between the synthesis carried out by the isothermal matrix method in solid state and that by the usual method in solution for chromium(III) complexes with glycine and *dl*-α-amino acids (alanine, aminobutyric acid, norvaline, norleucine, valine, isoleucine and leucine). The effect of the length of the skeletal carbon chain or the presence of the side chain in α-amino acids on the formation of complexes was investigated. The complexes with α-amino acids which have a normal chain were obtained in *fac*-structure except for norleucine complexes, whereas the complexes with α-amino acids which have a side chain were obtained only in dimer-type by the matrix method in solid state. The chromium(III) complexes with *dl*-α-amino acids were all prepared as tris-type structure, except for α-aminobutyric acid and valine, whereas all the complexes of dimer-type structure were prepared in solution, except for alanine and norleucine.

A number of chromium(III) complexes with natural amino acids are known.[1-10] However, no systematic studies have been carried out on the effect of the length of the skeletal carbon chain or the presence of a side chain in α-amino acids upon the formation of complexes. No studies have been reported on the difference between racemic- and L-amino acids in the complexation. All the tris-type chromium(III) complexes with the natural α-amino acids are of *fac*-structure, no *mer*-form being obtained as crystals. The preparation of purple *mer*-$[Cr(gly)_3]$ has been claimed by Israily.[11] However, Gillard *et al.* reported that this purple fraction is a hydrated dihydroxobridged dimer, $[Cr_2(gly)_4(OH)_2]\cdot 6H_2O$.[12] In the present work, attempts were made to prepare chromium(III) complexes with glycine and racemic amino acids (where racemic amino acids= alanine, aminobutyric acids, norvaline, norleucine, valine, isoleucine and leucine) by the isothermal matrix method in solid state and by the method in solution where hexaamminechromium(III) nitrate was used as the starting material.

Experimental

Preparation of Chromium(III) Complexes. There are two methods for the preparation of chromium(III) complexes with natural α-amino acids according to the mode of starting.

a) Preparation by Solid State Reaction: Hexaamminechromium(III) nitrate was mixed with α-amino acids in a mortar. The mixture was heated at 135±1 °C in a Toyoroshi electronic drying oven. The mole ratios of the amino acids to the starting complex and the heating time applied are given in Table 1.

Table 1. Mole ratios of amino acids to the starting complex and the reaction times at 135±1 °C

α-Amino acid	Mole ratio	Reaction time (min)
Glycine	3	45
α-Alanine	2.5	60
α-Aminobutyric acid	3	60
Norvaline	4	60
Valine	3	60
Isoleucine	2	50
Leucine	3	40

The reaction products containing glycine and *dl*-α-alanine were dissolved in water and kept standing at room temperature overnight. $[Cr(gly)_3]\cdot H_2O$ and $[Cr(\alpha\text{-ala})_3]$ were obtained as red or pink crystals. The reaction products containing *dl*-α-alanine, *dl*-α-aminobutyric acid and *dl*-norvaline were dissolved in methanol. After removal of residues by filtration, the filtrates were kept standing at room temperature for one or two days. $[Cr(\alpha\text{-ala})_3]$, $[Cr(\alpha\text{-ambut})_3]\cdot H_2O$ and $[Cr(norval)_3]\cdot H_2O$ were gradually deposited as pink crystals. When the reaction products containing *dl*-valine, *dl*-isoleucine and *dl*-leucine were dissolved in methanol, the complexes could not be crystallized. However, when water was used as a solvent, *dl*-μ-hydroxo-tetrakis(amino acidato)dichromium(III) complexes were obtained as light purple crystals, where amino acids are *dl*-α-aminobutyric

Table 2. Analytical data (by the solid state reaction)

acid, *dl*-norvaline, *dl*-valine, *dl*-isoleucine and *dl*-leucine. The reaction product containing *dl*-norvaline was washed with water and the residue was dissolved in DMF. After filtration, the filtrate was evaporated until its volume was reduced to one-third. To this was added water until pink crystals began to appear. The crystals have the same composition as that of the product deposited from the methanolic solution, but the amount of the water of crystallization contained is two, instead of one mole. The analytical data are given in Table 2.

b) *Preparation by the Reaction in Solution*: Hexaamminechromium(III) nitrate (345 mg) and glycine (225 mg) were dissolved in water (10 ml) and the mixture was heated on a waterbath until a small quantity of purple crystals began to appear. The purple crystals formed were removed by filtration while hot. When the filtrate was cooled to room temperature, red crystals were precipitated, which were contaminated by some amount of purple crystals. The red compound was separated by decantation in ethanol. The red and the purple crystals are considered to be tris- and binuclear-type chromium(III) complexes, respectively.

By the same method as described above, the complex with *dl*-alanine was precipitated only as of tris-type. The complexes with *dl*-aminobutyric acids, valine and isoleucine were precipitated as hydroxo bridging dimer complexes. The complexes with *dl*-norvaline was first precipitated as pink crystals. After they had been removed by filtration, water was added to the filtrate until the volume became equal to the original one. By heating the resulting solution on a waterbath, pink and purple crystals were precipitated. Pure $[Cr(OH)(dl\text{-norval})_2]_2\cdot 2H_2O$ was precipitated by repeating the same procedure. Pink crystals were dissolved in DMSO because of contamination by a small quantity of the purple crystals. After filtration, the filtrate was added dropwise to water, causing instant precipitation of $[Cr(dl\text{-norval})_3]\cdot 3H_2O$ as pink crystals. The complexes with norleucine and leucine were precipitated as red-purple crystals. The crystals were dissolved in DMF and after removal of residues by filtration, the filtrate was added dropwise into water. $[Cr(dl\text{-norleu})_3]\cdot 2H_2O$ and $[Cr(dl\text{-leu})_3]\cdot 2H_2O$ were precipitated almost instantly. The analytical data of these complexes are given in Table 3.

Apparatus. The UV spectra were measured with a Hitachi 139 spectrophotometer. The IR spectra were measured with a Hitachi EPI-G3 infrared spectrophotometer in Nujol mull.

Results and Discussion

UV Absorption Spectra. Mizuochi *et al.*[10] measured all the UV absorption spectra of the chromium(III) complexes of tris-type with amino acids in a 20% perchloric acid solution except the spectrum of tris(L-leucinato)chromium(III) complex which was measured in methanol and DMF. Gillard *et al.*[12] reported that the values found for the absorption maxima of *fac*-tris(glycinato)chromium(III) complex in solid state (530 nm) and in 70% $HClO_4$ solution (539 nm) differ from each other, suggesting the occurrence of some chemical reactions during the course of dissolution.

The UV absorption spectra of chromium(III) complexes of tris-type with glycine, alanine and aminobutyric acid were measured in both solid state and in perchloric solution. The absorption spectra of chromium(III) complexes with other amino acids of tris-type were measured in DMF or DMSO. Their maxima are summarized in Table 4. The spectra of tris(glycinato)chromium(III) complex in 60% perchloric acid and in solid state are shown in Fig. 1. These data suggest that this complex undergoes acid hydrolysis or chemical reaction on dissolution in perchloric acid. The spectra of tris(norvalinato)-chromium(III) complex in DMSO and in solid state are shown in Fig. 2. It can be seen that the absorption curve in DMSO is similar to that in solid state except for slight shifts of the peak to longer wave number region in solid state. This indicates that the latter complex is significantly stable even in DMSO solution.

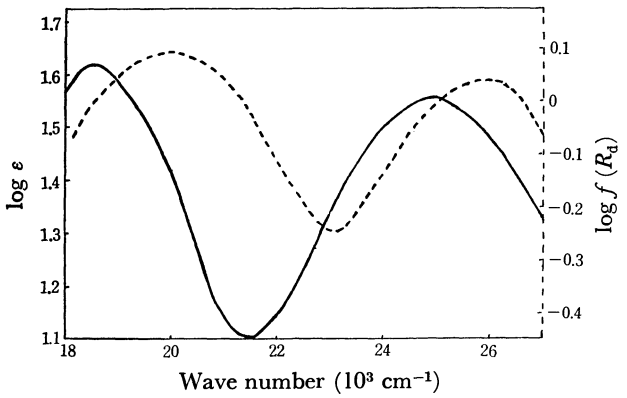

Fig. 1. The absorption spectra of tris-glycinatochromium(III) complex in 60% $HClO_4$ solution (—) and in solid state (---).

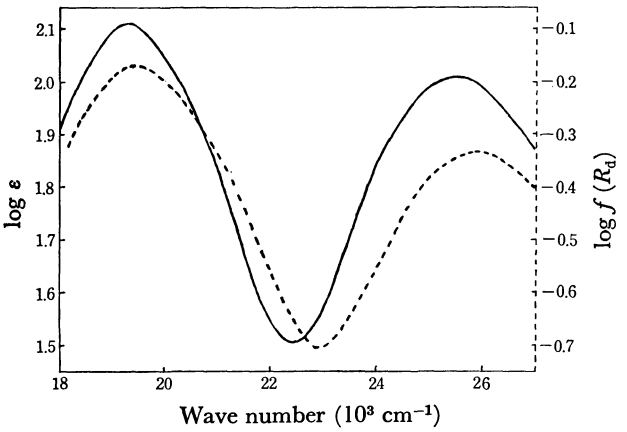

Fig. 2. The absorption spectra of tris-norvalinatochromium(III) complex in DMSO solution (—) and in solid state (---).

For all the $[Co(O)_n(N)_{6-n}]$ series, the predicted shift of the first and second absorption bands has been discussed by Matsuoka *et al.*[13] In the present paper, their calculations were applied to these chromium(III) complexes. The value 21.9×10^3 cm^{-1} and 28.3×10^3 cm^{-1} were obtained for the maxima of the first and the second bands, respectively, in the $[Cr(en)_3]^{3+}$ complex, and 17.5×10^3 cm^{-1} and 23.8×10^3 cm^{-1} for those in the $[Cr(ox)_3]^{3-}$ complex. The maxima of the first and the second absorption bands in *fac*-$[Cr(O)_3(N)_3]$ were calculated to be 19.7×10^3 cm^{-1} and 26.1×10^3 cm^{-1}, respectively. The absorption maxima of these chromium(III) complexes in solid state and in DMF or DMSO solution (Table 4) coincide with the wave numbers obtained by the above calculation. This suggests that the tris-type chromium(III) complexes we prepared have the *fac*-form. Although the absorption maxima of tris-glycinato, alaninato and aminobutyrato complexes in perchloric acid differ from those predicted, the values obtained by Gillard *et al.*,[12] Nakahara[14] (glycine) and Mizuochi *et al.*[10] (alanine and aminobutyric acid) agreed with those obtained in perchloric acid solution (Table 4).

The results indicate that *fac*-tris(amino acidato)-chromium(III) complexes are unstable in acid solution, the stability differing substantially from that of the corresponding cobalt(III) complexes in acid. Tris-(amino acidato)chromium(III) complexes become easily soluble in organic solvent, with increase in the length of the skeletal carbon chain of α-amino acid.

IR Spectra. Infrared absorption spectra were measured in the range 4000—400 cm^{-1}. The spectra of tris-type chromium(III) complexes with glycine, α-alanine and α-aminobutyric acid agree with those of the corresponding chromium(III) complexes of *fac*-form as reported by Mizuochi *et al.*[10] No *fac*-form of chromium(III) complexes with norvaline and norleucine could be found. The preparation of purple chromium-(III) complex with α-aminobutyric acids was reported but no spectrum. The spectrum of purple chromium(III) complex with aminobutyric acid agrees with that for the corresponding chromium(III) complex, *cis*-$[Cr(OH)(ambut)_2H_2O]$, which they prepared. However, it is doubtful whether the assignment of this structure is correct, since, the di-μ-hydroxotetrakis(glycinato)-dichromium(III) shown by X-ray diffraction analysis and magnetic measurement,[15] was assigned to hydroxo-aquo complex. The purple crystals with glycine and L-phenylalanine were confirmed to have the dimer structure by magnetic measurement.[16]

L=amino acid.
● Complexes prepared by the solid method.
◑ Complexes prepared by both methods.
○ Complexes prepared by the solution method.

The chromium(III) complexes with various *dl*-amino acids of the type $[CrL_3]$ and $[Cr(OH)L_2]_2$, where L denotes amino acid, were synthesized in the solid state and in solution (Table 5). Preparation of chromium(III) complexes with natural *dl*-α-amino acids carried out by the two methods may be charactrized as follows: i) Solid State Reaction. The complexes with *dl*-α-amino acids which have no side chain were prepared as tris-type structure, except for *dl*-norleucine. The complexes of dimer-structures were prepared with α-aminobutyric acid and norvaline. Taking account of the carbon skeleton in *dl*-amino acids, when the reaction product is dissolved in water, complexes with glycine and α-alanine are obtained as tris-type, but those with α-aminobutyric acid and norvaline in which the length of carbon chain is longer than that of alanine are obtained as the dimer type. When the reaction product is dissolved in methanol, the complex with glycine can not be crystallized, but the complexes with other amino acid are obtained as tris-type. The preparation of tris-type chromium(III) complex with norleucine

was not successful. However, the solid state reaction of norleucine was similar to that of other amino aicds. Thus, the complexes of *fac*-structure can be easily separated from the dimer type, when the solvent is changed. This is advantageous for the preparation of tris-type complexes in a solid method than in the solution method. The complexes with valine, isoleucine and leucine which have a side chain were obtained only as the dimer-type. ii) Solution State Reaction. The chromium(III) complexes with racemic α-amino acids have all been prepared with tris-type structure, except for α-aminobutyric acid and valine. All the complexes with dimer-structure have been prepared, except for alanine and norlecine. Preparation in solution method seems more convenient than that in solid state. A mixture of tris- and dimer-complexes is prepared by the solution method. It should be separated into components by another method.

Taking account of the carbon skeleton in racemic amino acids, we obtained dimer-type complexes containing glycine and α-aminobutyric acid and tris-type complexes containing α-alanine and norvaline. Complexes with racemic α-amino acids appear predominantly with dimer- and tris-structures, alternatively, depending on the length of the carbon skeleton. However, this can not always be applied to complexes with norleucine, since it gave only a tris-type structure.

Complexes with isoleucine and leucine which have a side chain were obtained with tris- and dimer-type structures. However, the complex with valine which has a methyl group in the β-position, as well as isoleucine, was obtained with only a dimer-type structure.

The present method in solution state using hexaamminechromium(III) nitrate is very simple as compared with the usual method in the same state, using chromium(III) hydroxide and chromium(III) chloride as a starting material. It is necessary to remove unreacted hydroxide using chromium(III) hydroxide and to neutralize the reactant solution in the method using chromium(III) chloride, but it is not necessary to separate unreacted substance in the dissolved state and the reactant solution naturally neutralized in the method using hexaamminechromium(III) nitrate.

No circular dichroism was observed for tris-type. All tris-type chromium(III) complexes were in *fac*-structure, no *mer*-form being obtained.

The authors wish to thank Professor R. Tsuchiya, Kanazawa University, for valuable discussions and suggestions.

(Received October 20, 1975)

The isomerization of two of the three possible geometrical isomers for the (D-aspartato)(L-2,4-diaminobutyrato)cobalt(III) complex afforded the residual third isomer which has not here to fore been obtained. The equilibrium mole fractions of these isomers in water in the presence of activated carbon were found for D-*cis*O_5*cis*N_5, D-*trans*O_5*trans*N_5, D-*fac* to 0.68, 0.11, 0.21, respectively. As the two ligands coordinated are considered to involve no intermolecular hydrogen bonding or steric hindrance, the relative positions of the six coordinated atoms around a cobalt atom may cause these unequal isomer ratios. These isomerisms are dealt with by means of a network of first-order reversible reactions and the relative values of the rate constants are determined.

The preparation and absorption and PMR spectra of [Co(L- or D-asp)(L-2,4-dba)] (asp=aspartate ion and dba=diaminobutyrate ion) have already been reported.[1] Though three possible isomers of [Co(L-asp)-(L-dba)] could be obtained, only two isomers of [Co(D-asp)(L-dba)] could be obtained (Figs. 1-a and c). The residual isomer (Fig. 1-b) could not be obtained though several preparative methods were attempted. The two ligands coordinated are considered to involve no intermolecular hydrogen bonding or steric hindrance. It is interesting to study the difficulty encountered in obtaining the third isomer of [Co(D-asp)(L-2,4-dba)]. In the work reported here, the present authors studied whether the third isomer of [Co(D-asp)(L-2,4-dba)] could be obtained by equilibrating the complex obtained earlier in the presence of activated carbon.

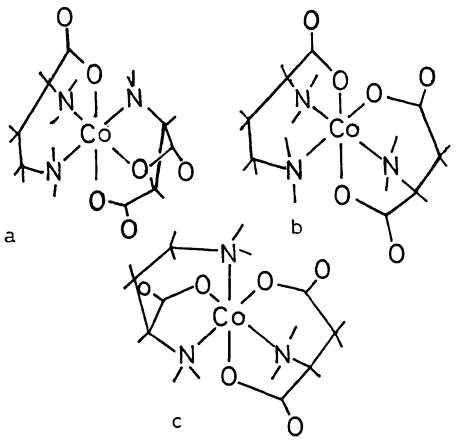

Fig. 1. The three possible geometrical isomers of the [Co(D-asp)(L-2,4-dba)] a: *cis*O_5*cis*N_5, b: *trans*O_5*trans*-N_5, c: *fac*. The isomers are named by considering 5-membered N and O atoms.

Experimental

The [Co(D-asp)(L-2,4-dba)] was prepared as described in a previous paper.[1] Two isomers were obtained and named D1 and D2 in their order of elution using a cation exchange column (Dowex 50 w X8, Na form). Activated carbon was purchased from Takeda-Yakuhin, Ltd, which was "Shirasagi," and dried at 100 °C before use.

The isomerization of D1 (D-*cis*O_5*cis*N_5) and D2 (D-*fac*) isomers using the activated carbon as a catalyst afforded the third isomer D3 (D-*trans*O_5*trans*N_5). When the resulting mixture was loaded on a cation exchange column (Dowex 50 w X8, 100—200 mesh Na form) the D3 isomer was found to closely follow the D1 isomer. As the D3 isomer was relatively less soluble, this fraction was concentrated and kept in a refrigerator overnight. A small quantity of the D3 isomer was precipitated. Found D3: C, 28.73; H, 5.26; N, 12.07%. Calcd for $CoC_8H_{14}O_6N_3 \cdot 1.5H_2O$: C, 28.75; H, 5.13; N, 12.57%.

A starting isomer (80 mg, 0.0024 mol) was dissolved in 100 ml water at 50 °C. To this solution, 20 mg of activated carbon was added. A reflux condensor was attached to the flask. The solution was stirred and maintained at 50 °C in a temperature-controlled reaction vessel. The reaction was timed with a stop clock whenever the carbon was introduced into the sample in the vessel. Since the isomerization is "frozen" upon the removal of the carbon from the sample solutions, rapid filtration is an excellent way to stop the reaction. The method adopted requires 7 mm glass tubing packed with a cotton filter. The packed tubes were placed, using a specially-prepared fitting, on the end of a 5 ml hypodermic syringe. The solution was examined for optical rotation immediately after withdrawal and at the end of the run. No loss of optical activity was noted. Sampling was continued for 24 h at intervals of 30 and 60 min. The concentrations of all isomers after sampling were determined as follows. First, the concentration of the D2 isomer was determined using high-speed liquid chromatography in comparison with a known concentration of the D2 isomer. The concentrations of the D1 and D3 isomers were determined using the molar rotation $[\phi]$ at 489 and 540 nm.

	489 nm	540 nm
D1	44.53	0.0
D2	8.20	−4.82
D3	0.0	−80.20

The concentrations of the D1 and D3 isomers were calculated using the following equation:

$$[\phi]_{D1}x + [\phi]_{D2}y + [\phi]_{D3}(1-x-y) = \alpha/c,$$

where $[\phi]_{D1}$, $[\phi]_{D2}$, and $[\phi]_{D3}$ are the molar rotations, x and y are the concentrations of the D1 and D2 isomers, respectively and c is the initial concentration of the isomer which is isomerized. α is the rotation of the plane of polarization, expressed in degrees. Since the concentration loss of the complex due to adsorption on the surface of the carbon and due to other reactions was less than 2 percent, it was possible

to treat the complex concentration as constant throughout a run. The concentration of cobalt was determined using nitrosonaphthol.

Measurements. The electronic absorption spectra and the optical rotatory dispersion spectra were measured with a JASCO ORD-UV-5 spectrometer. The wavelength correction was cheked using neodymium glass which is absorping at 589 nm. The chromatographic separation was carried out with a JASCO LCP-350 high-speed liquid chromatograph. A 500×2.3 mm glass column containing 50 w X8 Dowex and a 200—400 mesh Na form was used for all measurements. The complexes were eluted with water at a flow rate of 1.0 ml/min at a pressure of *ca.* 40 kg/cm^2.

Results and Discussion

Figure 1 shows the possible isomers of [Co(D-asp)(L-dba)]. The D-*trans*O_5*trans*N_5 isomer (Fig. 1 (b)) has not previously been prepared. Figure 2 shows the results of high-speed liquid chromatography for the equilibrated mixture, starting from the D2 isomer. The D-*mer* isomer was found to appear in front of the D2 isomer. After the isomerization of more than 2 grams of the D1 or D2 isomer in 100 ml of H_2O in the presence of activated carbon, the equilibrated mixture was loaded on a cation exchange column (30×700 mm Na form) and eluted with water. The fractions were taken in a fraction collector. The optical rotatory dispersion and visible spectra of the rear part of the D-*mer* fractions did not agree with those of the D-*cis*O_5*cis*N_5 isomer. These fractions were collected, concentrated and kept under refrigeration overnight. A small amount of precipitate appeared. The optical rotatory dispersion and visible spectra of the filtrate agreed well with those of the D-*cis*O_5*cis*N_5 isomer. The elemental analysis of this precipitate coincided with those of the other two isomers. This isomer was named D3, with the possible

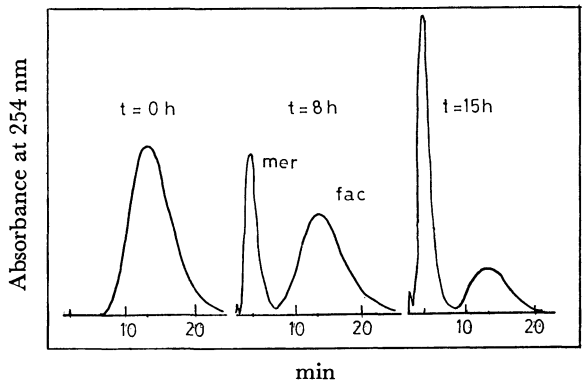

Fig. 2. High speed liquid chromatogram indicating the result of the isomerization for the D2 isomer (UV detector).

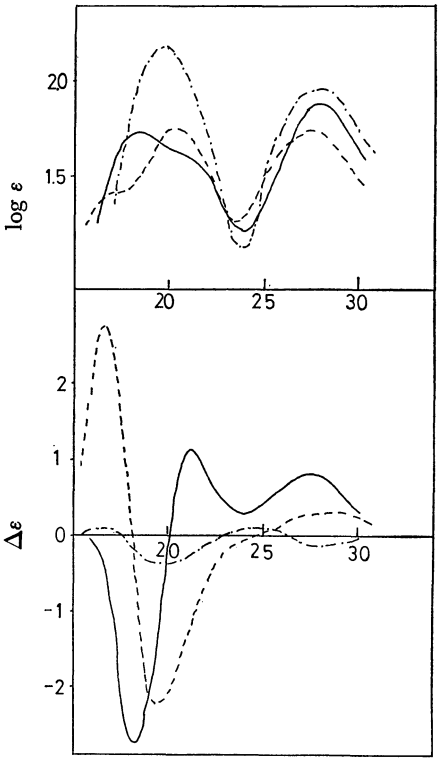

Fig. 3. The visible (upper) and the CD (lower) spectra of the [Co(D-asp)(L-2,4-dba)], —, D1 (*mer*); ---D3 (*mer*); -·-D2 (*fac*). The D3 isomer is eluted faster than the D2.

configuration D-*trans*O_5*trans*N_5. Figure 3 shows the visible absorption and circular dichroism spectra of the [Co(D-asp)(L-2,4-dba)] complex. All numerical data together with those obtained for [Co(L-asp)(L-2,4-dba)] are listed in Table 1. The visible absorption spectrum of the D-*fac* isomer is similar to that of L-*fac*. This shows that for these complexes which are diastereoisomers of each other, whether D-asp or L-asp is coordinated does not seriously affect the electronic absorption patterns. The first absorption bands for all the *mer* isomers exhibit splittings, though that for the L1 isomer is not obvious.[1] The intensity of the lower energy side of the first absorption band for D3 is smaller than that of the higher energy side. But in the case of D1, this relation is reversed. The L2 spectrum pattern is almost the same as that of the D3 isomer. In order to study the above findings, molecular models are considered. When the L-2,4-dba coordinated for all the *mer* isomers are placed in the same coordinates, the positions of the carboxylate and amino groups of the D-asp of the *trans*O_5*trans*N_5 isomer are quite similar to those of L-asp of the *cis*O_5-*trans*N_5 isomer for [Co(L-asp)(L-2,4-dba)]. The only difference between the complexes lies in the alteration of the 5-membered and 6-membered chelate rings for the asp ligand. The same situation occurs in the relation between the coordinated ligands of the *cis*O_5*cis*N_5 and *trans*O_5*cis*N_5 isomers. From the visible spectra, the assignment of one series, for example, [Co(L-asp)(L-2,4-dba)], is found to serve as an assignment for the other diastereoisomeric series, for example, [Co(D-asp)(L-2,4-dba)]. The circular dichroism spectra of [Co(D-asp)-(L-2,4-dba)] can not at present be correlated with those of [Co(L-asp)(L-2,4-dba)].[2] The PMR spectrum of the D3 isomer was not compared with those of the other isomers because this isomer was only slightly soluble in water. The racemization of $[Co(en)_3]^+$ (en=ethylenediamine) and of $[Co(edta)]^-$ (edta=ethylenediaminetetraacetate ion) using activated carbon as a catalyst has been studied.[3-8] Particularly, the racemization of $[Co(edta)]^-$ has been examined in detail by Cooke *et al.* and Erdmann and Douglas.[6-8] In the present work, the isomerization of [Co(D-asp)(L-2,4-dba)] was studied using activated carbon. The optical rotatory dispersion spectral changes in the isomerization of [Co(D-asp)(L-2,4-dba)] are shown in Fig. 4. This

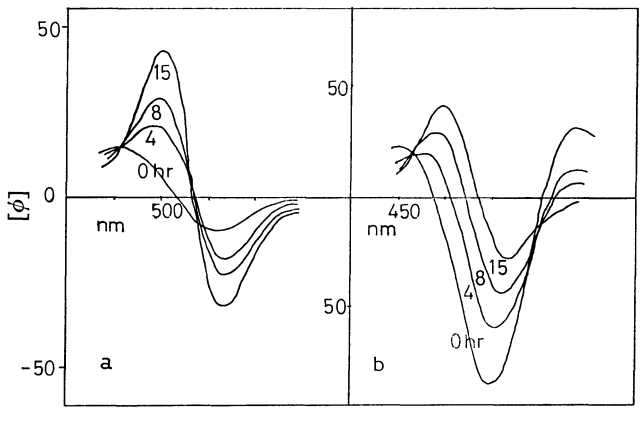

Fig. 4. The ORD spectral changes due to the isomerization for the D2 (left) and the D3 (right) isomers.

indicates that the last equilibrating molar fraction were equal for all kinds of isomers used as the starting material. The rate of isomerization was found to essentially follow second-order kinetics, first order for the complex and first order for the carbon. The activated carbon once used was washed with water and dried at 100 °C for 3 h. This activated carbon was not deactivated in contrast with the experiments reported Erdmann *et al.*[4] Isomerization without activated carbon was very difficult. Since no direct measure of the effective concentration of activated carbon was available, this isomerization was treated as first-order kinetics in the complex only. This isomerization was considered to occur for the three possible isomers. Consequently, the system of differential equations representing the behavior of this system is:

$$da_1/dt = -(k_{12}+k_{13})a_1 + k_{21}a_2 + k_{31}a_3$$
$$da_2/dt = k_{12}a_1 - (k_{23}+k_{21})a_2 + k_{32}a_3$$
$$da_3/dt = k_{13}a_1 + k_{23}a_2 - (k_{31}+k_{32})a_3,$$

where a_i is the molar fraction, and the rate constant of the reaction, for which the notation of the $D_i(i=1, 2, 3)$ isomers is transformed into D_j, is represented by k_{ij}. A method was easily applicable for obtaining the relative value of the rate constant but it was difficult to obtain absolute values. If k_{31} is taken to be unity, all the rate constants were determined as shown in Fig. 5. The values of the rate constants of this system

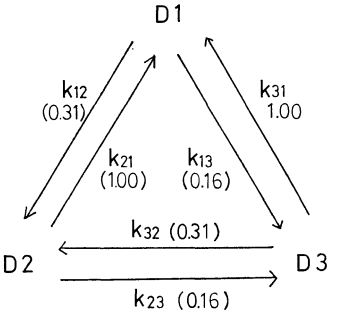

Fig. 5. A network of the isomerization system.

decrease in the order $k_{31},k_{21}>k_{12},k_{32}>k_{13},k_{23}$. D3 is isomerized most rapidly of the three isomers. The molar fractions at equiliblium are: a_1, a_2, a_3=0.68, 0.21, 0.11, respectively. Since these complexes are considered to involve no hydrogen bonding or steric hindrance between asp and 2,4-dba coordinated on the basis of the molecular model concept, such a distribution in favor of the D1 isomer is surprising. The free energy differences at 25 °C are as follows: $\Delta G_{12}=G(D1)-G(D2)=-RT\ln 68/21=-0.69$ kcal/mol and $\Delta G_{13}=-RT\ln 68/11=-1.08$ kcal/mol. The reason for this distribuion in favor of the D1 isomer may be ascribed to the relative site of the atoms coordinated (α- and γ-amino nitrogens and α- and γ-carboxylate oxygens, as is shown in Fig. 1). Recently, investigations of the *trans* effect for the cobalt(III) complex containing S-bonded sulfite ligands have been reported.[10] In cobalt(III) chemistry, S-bonded sulfite produces a specific and dramatic labilization of the ligands situated the *trans* position relative to it. This electronic effect which is transmitted through

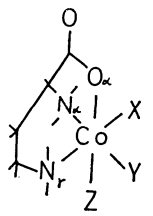

Fig. 6. Coordination axes to which L-2,4-dba ligand fixes.

the bonds may apply to our study. For example, L-2,4-dba coordinated axes (Fig. 6). The α-amino nitrogen seems to affect the atom of the D-asp which confirmly combines at the site y (Fig. 6). Similar relations arise for the other cases (N_γ-Co-site x and O_α-Co-site z). It cannot at present be estimated whether any of these bond relations affect the partial mole fraction because of the lack of data. Only a small amount of the *trans*N isomer of $[Co(L\text{-asp})_2]^-$ [11] could be prepared. In addition to the above results and the low molar fraction of the D-*trans*O_5*trans*N_5 isomer of [Co(D-asp)(L-2,4-dba)] in equilibrium using activated carbon, it is suggested that the two α-nitrogen atoms avoid the *trans* position.

This work was supported by a special grant from Kogakuin University.

Preparative and Magnetic Studies of Several Binuclear Copper(II) Alkanoate Complexes with Salicylideneamines

Tadashi Tokii and Yoneichiro Muto

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

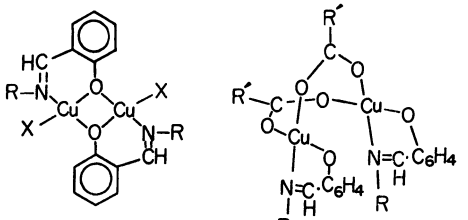
(Received October 27, 1975)

Compounds with the stoichiometry of Cu(5-R″-sal·N–R)R′COO (5-R″-sal·N–= ·$\overset{2}{O}$·C_6H_3($\overset{5}{R''}$)·$\overset{1}{C}$H=N–; R= methyl, phenyl, *o*-tolyl and *p*-tolyl; R′=ethyl, monochloromethyl and dichloromethyl; R″=H, CH_3 and Cl) have been prepared, and their magnetic and spectral properties have been studied. The magnetic and IR spectral data of the compounds where R=methyl and *o*-tolyl, R′=dichloromethyl, and R″=H indicate that they have phenolic oxygen-bridged dimer units in their crystals. On the other hand, a carboxylate-bridged binuclear structure is postulated for the other complexes on the basis of magnetic and IR spectral data. It has been observed that, in the latter group of complexes, both the $-2J$ (singlet-triplet separation) and ν_{max} (ligand-field transition energy) values decrease in the order of Cu(Sal·N–R)C_2H_5COO>Cu(Sal·N–R)$ClCH_2COO$>Cu(Sal·N–R)Cl_2CHCOO, where Sal·N–= ·$\overset{2}{O}$·C_6H_4·$\overset{1}{C}$H=N–. The preparation and characterization of the Cu(Sal·N–R)HCOO·DMF compounds (R=*p*-tolyl and *p*-chlorophenyl; DMF=*N*,*N*-dimethylformamide) are also reported.

Bis(N-R-salicylideneaminato)copper(II), Cu(Sal·N–$R)_2$, reacts with copper(II) halide or nitrate to yield binuclear complexes with the structure shown in I, $[Cu(Sal\cdot N\text{–}R)X]_2$, in which the phenolic oxygen atoms act as bridges, where R=alkyl or aryl and X=Cl,[1,2] Br[3] or NO_3.[4,5] These binuclear complexes display antiferromagnetic behavior, in conformity with the Bleaney-Bowers equation (1)[6] formulated for the magnetic susceptibility of an isolated pair of interacting ions of spin 1/2:

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha \qquad (1)$$

where $-2J$ is equal to the energy separation between the singlet and triplet states, which gives the degree of strength of the magnetic interaction.



I

II

In the course of our studies of binuclear complexes of the I type, we found that, by the reaction of copper(II) alkanoates, $Cu(R'COO)_2$, with $Cu(Sal\cdot N\text{–}R)_2$, complexes with the Cu(Sal·N–R)R′COO stoichiometry were isolated when R=phenyl and *p*-tolyl and R′=ethyl.[7] On the basis of the magnetic and IR spectral data of these complexes, it was concluded that they possess the carboxylate-bridged binuclear structure represented in II.[7] It is noteworthy that the antiferromagnetic interaction in these propionate complexes ($-2J$=101 cm^{-1})[7] is much weaker than that in the corresponding chloride complexes ($-2J\approx$350 cm^{-1}),[7,8] $[Cu(Sal\cdot N\text{–}R)Cl]_2$, where R=phenyl and *p*-tolyl.

As a continuation of those studies, we have newly prepared seven compounds with the Cu(Sal·N–R)-R′COO stoichiometry and two compounds with the Cu(Sal·N–R)HCOO·DMF stoichiometry, where DMF =*N*,*N*-dimethylformamide. These new compounds have been characterized on the basis of elemental analyses, the IR and visible spectra, and the temperature dependences of the magnetic susceptibilities. Since no reasonable relationship between the magnitude of the antiferromagnetic interaction in dimeric copper(II) carboxylates and the acidity of the parent carboxylic acids has yet been established,[9–13] the observation of the $-2J$ values in the newly prepared complexes of the II type is of particular interest.

Experimental

Syntheses. Cu(Sal·N–R)R′COO Complexes: A typical synthetic method is as follows. A solution of an anhydrous copper(II) alkanoate (12 mmol) in ethanol (50 ml) was added, through a quantitative filter paper, to one of the parent $Cu(Sal\cdot N\text{–}R)_2$ complexes (10 mmol). The solution was stirred at *ca.* 70° C for 1/2 h and then concentrated to one-third of its volume. After the solution had been allowed to stand overnight at *ca.* 5 °C in a freezer, the separated crystals were collected and washed twice with a small quantity of ethanol and once with ether. They were all green in color.

Cu(Sal·N–R)HCOO·DMF Complexes: To a solution of the parent $Cu(Sal\cdot N\text{–}R)_2$ complex (10 mmol) in DMF (30 ml), we added copper(II) formate tetrahydrate (10 mmol). The mixture was stirred on a hot plate for 1/2 h. The green crystals thus precipitated were collected and recrystallized from DMF.

The data of the elemental analyses of the new compounds are summarized in Table 1.

Physical Measurements. The magnetic susceptibilities were determined by the Gouy method in the range from the temperature of liquid nitrogen to room temperature. The effective magnetic moments per copper ion at room temperature were calculated from this expression:

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N\alpha)\cdot T} \qquad (2)$$

where χ_A is the molar magnetic susceptibility corrected for the diamagnetism of the constituted atoms using Pascal's constant[14] and where $N\alpha$ is the temperature-independent paramagnetism per gram-ion of copper(II). The $N\alpha$ was assumed to be 60×10^{-6} emu.[15] The results are given in Table 2. The ESR (X-band) spectra of polycrystalline samples were measured with a JEOL ESR-apparatus, model JES-ME-1X, at room temperature. The IR spectral measurements were made with a Hitachi EPI-G2 IR spectro-

photometer in the 400—4000 cm^{-1} region on Nujol mulls. The reflectance spectra were measured with a Hitachi EPS-3T recording spectrophotometer.

Results and Discussion

Synthesis. It was observed that the dichloroacetate complexes, 8 and 9, listed in Table 1 were most readily obtainable, even though dichloroacetic acid has the lowest pK_a value among the parent carboxylic acids employed in the preparation in this study.[10,16,17] It was also found that, in the reaction of copper(II) formate with Cu(Sal·N-ph-Y)$_2$, where ph-Y=a monosubstituted phenyl group with the Y substituent, no formate complexes were isolated when Y=*o*-CH_3, *o*-Cl, *m*-CH_3, and *m*-Cl. This finding is in accord with the previous observation that, in a preparation of DMF adduct complexes of the [Cu(Sal·N-ph-Y)X·DMF]$_n$ type, where X=Cl[2] or NO_3,[5] the complexes with Y at the *p*-position of the phenyl ring were easily obtained, while a synthesis of complexes with Y at the *o*- or *m*-position was unsuccessful; *i.e.*, the Y substituent attached at the *o*- or *m*-position hinders the coordination of the DMF molecule to the central metal ion much more than the one at the *p*-position, since the former is present at a position closer to the metal ion than the latter.

Magnetic Susceptibility. The magnetic susceptibilities of the complexes were determined over the temperature range of 80—300 K; the data are shown in Figs. 1—3 as plots of the molar magnetic susceptibility (χ_A) *vs.* the temperature (T). The magnetic data for the complexes, except for Compound 4, are well represented by Eq. 1 (*cf.* Figs. 1 and 3). The $-2J$ and g values listed in Table 2 were evaluated from the best fit of the cryomagnetic data to Eq. 1, assuming $N\alpha = 60\times10^{-6}$ emu.[15] The g values for some of the complexes were in good agreement with the average g values determined from ESR measurements of the polycrystalline samples (*cf.* Table 2). The close agreement between the observed and calculated temperature dependences of the magnetic susceptibility is powerful evidence for a binuclear structure of these complexes. For Compound 4, the observed magnetic data could not satisfactorily fit Eq. 1 when the following values were used: J was estimated from the $-2J\approx1.6\,kT_C$ relation, where k is the Boltzmann constant, and T_C, the temperature of the maximum susceptibility; g ranged

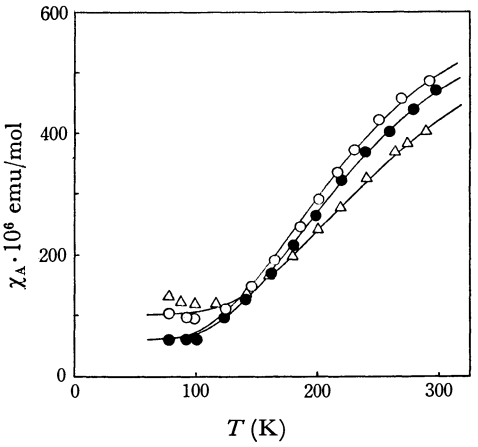

Fig. 1. Temperature dependence of magnetic susceptibilities of (○) Cu(Sal·N-*p*-tol)HCOO·DMF, (●) Cu(Sal·N-*p*-Clph)HCOO·DMF, and (△) Cu(Sal·N-CH_3)Cl_2CHCOO.
The solid curves represent the Bleany-Bowers equation.

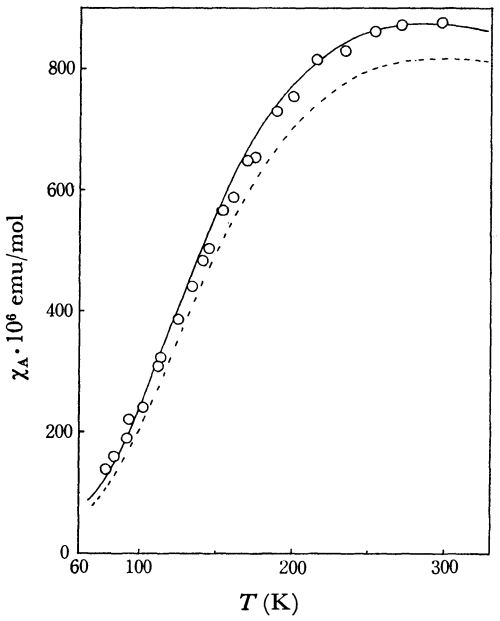

Fig. 2. Temperature dependence of magnetic susceptibilities of (○) Cu(Sal·N-*o*-tol)Cl_2CHCOO.
The broken curve was calculated from the Bleaney-Bowers equation (1) with $-2J=335$ cm^{-1}, $g=2.20$, and $N\alpha=60\times10^{-6}$ emu. The solid curve was calculated from the modified equation (3) with $-2J=335$ cm^{-1}, $g=2.20$, $N\alpha=60\times10^{-6}$ emu and $\theta=+20$ K.

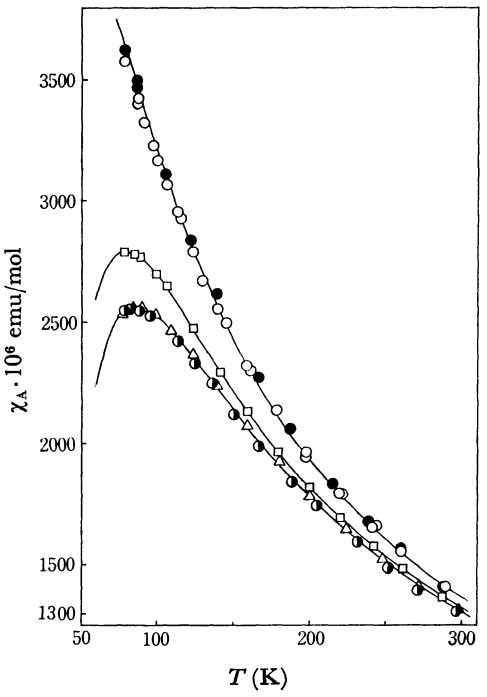

Fig. 3. Temperature dependence of magnetic susceptibilities of (△) Cu(5-CH_3sal·N-ph)C_2H_5COO, (◑) Cu(5-Clsal·N-ph)C_2H_5COO, (□) Cu(Sal·N-*p*-tol)-$ClCH_2$COO, (●) Cu(Sal·N-ph)Cl_2CHCOO, and (○) Cu(Sal·N-*p*-tol)Cl_2CHCOO.
The solid curves represent the Bleaney-Bowers equation.

from 2.10 to 2.20, and $N\alpha$ was 60×10^{-6} emu (*cf.* Fig. 2). However, a better fit was obtained for the data to the theoretical curve drawn based on a modification of the Bleaney-Bowers equation (3):[18]

$$\chi_A = \frac{Ng^2\beta^2}{3k(T-\theta)}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha \qquad (3)$$

where the Weiss constant, θ, allows for intermolecular interaction between dimers (*cf.* Fig. 2). From a best-fitting procedure of the experimental data to Eq. 3, the $-2J$ and g values listed in Table 2 and the value of $\theta=+20$ K were evaluated. The positive value for θ suggests the presence of ferromagnetic spin interaction between the dimers.

The complexes described here can be classified into two groups based on the magnetic data. Group (A): in Compounds 1—4, the effective magnetic moments at room temperature are definitely smaller than the spin-only value, 1.73 B.M., for one unpaired electron, and the $-2J$ values are larger than 300 cm^{-1}. Group (B): in Compounds 5—9, the moments are close to the spin-only value, and the $-2J$ values are smaller than 100 cm^{-1}.

Electronic Spectra. The electronic spectra of all the complexes investigated were recorded by the diffuse reflectance technique. The frequencies of the ligand-field band maxima are collected in Table 3. Some of the spectral curves of the Group (A) and (B) complexes are shown in Fig. 4 and Fig. 5 respectively. It is apparent from Table 3 and Figs. 4 and 5 that there is a marked difference in the spectra between Group (A) and (B) complexes. This is indicative of a structural difference between them. The spectra of the Group (A) complexes are similar to one another and closely resemble those of DMF adducts of the I type complexes, [Cu(Sal·N-R)X·DMF]$_2$, to which a five-coordinated square pyramidal configuration with axially coordinated DMF molecules was assigned.[2,5] For comparison, the reflectance spectral curve of [Cu(Sal·N-*p*-tol)NO_3·DMF]$_2$, where *p*-tol=*p*-tolyl,[5] is given in Fig. 4. Group (B) complexes have a ligand-field band in an energy region ((15—16)$\times10^3$ cm^{-1}) much higher than that of Group (A) complexes. As can be seen in Fig. 5, the spectral features of Group (B) complexes are very similar to one another, indicating that they are isostructural.

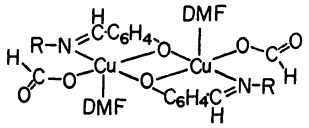
IR Spectra. For the present complexes and the previously reported propionate complexes, $Cu(Sal\cdot N\text{-}R)C_2H_5COO$, where R=phenyl and *p*-tolyl,[7] the absorption near 1540 cm^{-1}, and those due to antisymmetric($\nu_{as}CO_2$) and symmetric(ν_sCO_2) carboxylate stretching vibrations were measured to obtain information concerning the coordination mode of the phenolic oxygen atoms and carboxylate groups in the complexes. The assignment of the observed bands was made by comparing the bands of these complexes with those of the parent $Cu(Sal\cdot N\text{-}R)_2$ complexes and the corresponding binuclear chloro and nitrato complexes of the I type. The results are listed in Table 3, together with the data reported for the related alkanoate compounds.

Although there have been tentative assignments for the absorption near 1540 cm^{-1} in $Cu(Sal\cdot N\text{-}R)_2$ (*e.g.*, to $\nu C{=}N$,[19] $\nu C\text{–}O$(phenolic)[1,20] or to the skeltal vibration of the aromatic ring[21]), no definite conclusion has yet been reached as to the origin of the band. However, a shift of the band to higher energies by 10—20 cm^{-1} near 1540 cm^{-1} is now at least taken as an unambiguous criterion of the formation of a phenolic oxygen-bridging between metal ions in polymeric salicylideneamine complexes.[1-3,7,8,20,21] As is shown in Table 3, the band shift was observed for all the complexes of Group (A), indicating the presence of phenolic oxygen-bridges between the copper(II) ions in these complexes. On the other hand, no significant band shift was observed for any of the complexes of Group (B), indicating that, in these complexes, no phenolic oxygen-bridge exists.

For the carboxylate coordination, a comparison of the carboxylate stretching frequencies in the present complexes with those in the related copper(II) alkanoates is informative. All the propionate complexes described here exhibit $\nu_{as}CO_2$ and ν_sCO_2 bands in an energy region very similar to that reported for anhydrous copper(II) propionate,[22] $Cu(C_2H_5COO)_2$, which has a copper(II) acetate monohydrate type of binuclear structure[23] (*cf.* Table 3). The close similarity in absorption energy leads to the conclusion that the propionate complexes have carboxylate bridges of a syn-syn arrangement[16] between copper(II) ions, as is shown in II. In the case of the dichloroacetate complexes, the frequencies of $\nu_{as}CO_2$ and ν_sCO_2 and the separation between them, Δ_{as-s}, in the complexes belonging to Group (A), 3 and 4, markedly differ from those in the complexes belonging to Group (B), 8 and 9. The $\nu_{as}CO_2$, ν_sCO_2, and Δ_{as-s} in the Group (A) complexes are nearly the same as those reported for the purple isomer of bis(α-picoline)copper(II) dichloroacetate, $Cu(Cl_2CHCOO)_2(\alpha\text{-pic})_2$, for which the carboxylate coordination was identified as intermediate between a strictly unidentate type and a strictly bidentate-chelate type.[24] It seems, therefore, reasonable to conclude that, in the dichloroacetate complexes of Group (A), no carboxylate bridges of the syn-syn type

exist. No unambiguous assignment for carboxylate coordination in the dichloroacetate complexes, 8 and 9 (Group (B)), and in the monochloroacetate complex, 7, could be drawn from their IR data. However, the magnetic and reflectance spectral features of these chloroacetate complexes (7, 8 and 9) are very similar to those of the propionate complexes. The appearance of IR bands at *ca.* 1540 cm^{-1} indicates that the magnetic interaction in the chloroacetate complexes probably takes place through carboxylate bridging rather than through phenolic oxygen bridging. These facts suggest that the carboxylate coordination mode in these chloroacetate complexes is of a syn-syn bridging type, as is seen in the propionate complexes.

Structure and Magnetic Interaction. The magnetic and IR spectral data for Group (A) complexes clearly indicate that the complexes have phenolic oxygen-bridged dimer units of the I type in crystals. The reflectance spectra showed them to have a penta-coordinated square pyramidal configuration. Accordingly, the most probable structure for the formate complexes, 1 and 2, seems to be III, in which the DMF



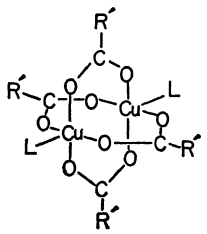
III

molecule occupies the fifth coordination site of the copper ion. The penta-coordination in the dichloroacetate complexes, 3 and 4, seems to be possible when the carboxylate group acts as a bidentate chelate or a bridging group (triatomic –O–C–O– or monoatomic –O(CO)–) between the dimer units. The presence of inter-dimer magnetic interaction observed for the Cu(Sal·N–*o*-tol)Cl_2CHCOO complex, 4, is indicative of the carboxylate bridges between the dimer units in this complex.

The $-2J$ values determined for Group (A) complexes are considerably larger than those reported for the I type complexes with a pseudo-tetrahedral configuration,[2,25] but they are comparable with those reported for the I type complexes with a square pyramidal configuration.[2] This can be seen in Table 4.

The carboxylate-bridged binuclear structure shown in II may be assigned to Group (B) complexes on the basis of their magnetic and spectral data. An analogous dimeric structure bridged by two carboxylate groups in the syn-syn manner exists in crystals of the *p*-toluidine adduct of copper(II) propionate, $[Cu_2(C_2H_5COO)_4(p\text{-toluidine})_2]_n$, the structure of which has recently been determined by X-ray analysis.[26] The structure is basically composed of carboxylate-bridged dimers which are linked into one-dimensional polymeric chains by relatively long monoatomic Cu–O(CO)–Cu carboxylate bridges. Yawney *et al.*[26] have interpreted the magnetic data conforming to Eq. 1 with $-2J=105$ cm^{-1} in terms of a superexchange interaction between copper ions through bridging two carboxylate groups of Cu–O–C–O–Cu linkages rather than in terms of a direct metal–metal interaction, since the Cu–Cu separation (3.197 Å) is too large to allow any significant interaction between them. The $-2J$ values (96—101 cm^{-1}) of the present propionate complexes, 5 and 6, and Cu(Sal·N–R)C_2H_5COO complexes, where R=phenyl and *p*-tolyl, are practically identical with that reported for $[Cu_2(C_2H_5COO)_4(p\text{-toluidine})_2]_n$. This also supports the assignment of the II structure for the present propionate complexes.

The magnetic properties of Group (B) complexes significantly differ from those of the corresponding dimeric carboxylates, $Cu_2(R'COO)_4$, or their adduct complexes with the structure shown in IV, $Cu_2(R'COO)_4L_2$, where L is an additional unidentate ligand:



IV

(1) The magnitude of antiferromagnetic interaction observed in Group (B) complexes is considerably smaller than those found in $Cu_2(C_2H_5COO)_4$ ($-2J=300$ cm^{-1})[27] and $Cu_2(ClCH_2COO)_4(\alpha\text{-pic})_2$ ($-2J=322$ cm^{-1}).[24] Such a decrease in magnetic interaction can

be explained in terms of a decrease in the number of the bridging carboxylate groups through which superexchange interaction is operative, from four in these dimeric copper(II) carboxylates[23,28] to two in the Group (B) complexes. (2) The degree of antiferromagnetic interaction in the Group (B) complexes is apparently reduced according as the number of the substituted chlorine atoms on the acetate group is increased; the order of decrease in $-2J$ is Cu(Sal·N–R)C_2H_5COO> Cu(Sal·N–R)$ClCH_2COO$> Cu(Sal·N–R)Cl_2CHCOO. This is the same as the order of decrease in the ligand-field transition energies observed for these complexes (*cf.* Table 3 and Fig. 5); *i.e.*, there exists a good linear relation between the $-2J$ and ν_{max} values. The effect of the chloro-substituent on the magnetic and spectral properties may be attributed to the electron-withdrawing nature of the substituent; *i.e.*, the electron-withdrawing effect causes a decrease in the overlap between the metal-ion orbitals and the orbitals of the bridging carboxylate oxygen atoms and, hence, leads to a weaker magnetic interaction and a lower ligand-field band energy. However, the same type of polar effect of the substituents does not appear in the dimeric copper(II) carboxylates as in $Cu_2(F_3C\text{-}COO)_4$(quinoline)$_2$ ($-2J=310$ cm^{-1}),[13] $Cu_2(ClCH_2\text{-}COO)_4$(α-pic) ($-2J=322$ cm^{-1}),[24] and $Cu_2(CH_3C\text{-}OO)_4(py)_2$ ($-2J=325$ cm^{-1}).[29] These complexes all show almost the same magnitude of $-2J$ values regardless of the nature of the substituents. Therefore, there must exist some different conditions in these two types of complexes which make the II-type complexes more sensitive to substitution than the IV-type compounds. The insensitivity of the IV complexes to substitution seems to be linked to the rigid framework of the dimer structure, composed of four carboxylate bridges. This is apparent in the Cu–O–C–O–Cu superexchange path length, which is almost the same for these adduct complexes, *ca.* 6.45 Å.[13,28,30] Such an extremely inflexible path length may lead to constancy in the magnitude of superexchange interaction. On the other hand, the II-type complexes, whose dimer structure is constructed by connecting a pair of copper(II) ions with two carboxylate bridges, is more flexible than that of the IV complexes; thus, it should be more sensitive to any change upon substitution. The different sensitivities could cause the different electronic states in these flexible and inflexible dimer systems, leading to the observed difference in the magnetic interaction. Another probable explanation can perhaps be given in terms of the steric effect of substituents. The flexible framework of the II complexes is considered to be more sensitive to any type of steric conditions than the inflexible framework of the IV compounds. Such steric conditions may come from the repulsion force between the electronegative halogen atoms on the adjacent dimeric molecules or some others. At present, it is difficult to decide which reason is the more important for the observed substituent effect. However, the authors hope that their observation of the effect will lead to the resolution of the unsolved problems regarding the magnetic interaction in copper(II) carboxylate systems.

Conditions for the Formation of Compounds Consisting of BaO and Fe_2O_3 from Aqueous Suspensions

Masao KIYAMA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received December 4, 1975)

Suspensions containing either iron(III) hydroxide or hydroxide oxide and barium ions were subjected to autoclaving at various temperatures from 100 to 300 °C, and the properties of the resulting products were studied. A ferromagnetic precipitate, $BaO \cdot 6Fe_2O_3$, consisting of hexagonal plate-like particles, was obtained by suitable combination of temperature, kind and particle size of iron(III) hydroxide oxide, and concentration of $Ba(OH)_2$. Nonferromagnetic precipitates, $BaO \cdot 4.5Fe_2O_3$ and $BaO \cdot 2Fe_2O_3$, were also formed depending on the conditions. The mechanism of their formation is discussed. The magnetic properties of the $BaO \cdot 6Fe_2O_3$ precipitates are investigated.

$BaO \cdot 6Fe_2O_3$ is widely used as a permanent magnet, and its properties have been thoroughly investigated.[1] The compound can be obtained as a polycrystalline substance when a mixture of iron(III) oxide and barium carbonate is ignited at high temperatures (>800 °C) in an oxidizing gas.[2] The hydrothermal synthesis of $BaO \cdot 6Fe_2O_3$ was achieved for the first time in 1969.[3] It was found that iron(III) hydroxide or hydroxide oxide can react with the barium ion in a suspension to form $BaO \cdot 6Fe_2O_3$ if we choose the proper pH, concentration of barium ion, and temperature; nonferromagnetic precipitates, $BaO \cdot 4.5Fe_2O_3$ and $BaO \cdot 2Fe_2O_3$, are also obtained depending on the conditions.[3]

This paper will deal with the conditions for the formation of compounds consisting of BaO and Fe_2O_3 and with the magnetic properties of $BaO \cdot 6Fe_2O_3$.

Experimental

Material. Chemicals of an analytical grade were used except for the iron(III) hydroxide oxides and oxide. α- and γ-FeO(OH), consisting of needle-like particles of different mean sizes, were prepared by the seed method. Acidic suspensions of very fine, needle-like particles of α- and γ-FeO(OH) (used as seeds) were obtained by the air oxidation of $Fe(OH)_2$ at 40 °C in a $FeSO_4$ solution and of $Fe(OH)_2$ at 15 °C in a $FeCl_2$ solution respectively.[4] A 20-g of iron powder (size<140 μm) was added to 1 l of the suspension. Oxidation to α-FeO(OH) was carried out at 70 °C and to γ-FeO(OH) at 50 °C by bubbling air into the suspension at the rate of 500 l/h.[5] In order to obtain α- and γ-FeO(OH) with different mean particle sizes, the particle growth of FeO(OH) in suspension was controlled by the amount of seed added.

β-FeO(OH), consisting of needle-like particles, was prepared by the air oxidation of mixtures of $FeCl_2$, $FeCl_3$ and NH_4Cl solutions at 70 °C with different concentrations with respect to the total amount of iron.[6] The mean particle size increased with an increase in the concentration.

Needle-like particles, each consisting of very fine particles of α-Fe_2O_3, were prepared by the calcination of α-FeO(OH) particles in air at 300 °C for 2 h.

Procedure. Suspensions containing barium ions and one of iron(III) hydroxide, hydroxide oxide, or oxide were prepared as follows: (1) An acidic solution was prepared in a cylindrical tetrafluoethylene bottle (40 ml) by mixing 12.8 mmol of iron(III) nitrate and 1.6 mmol of barium nitrate in 10—15 ml of conductivity water. To the acidic solution the required amount of NaOH was added in various mol ratios of NaOH to the total nitrate. Water was then added to make the total volume 25.0 ml. (2) Starting suspensions containing either iron(III) hydroxide oxide or oxide, and $Ba(OH)_2$ were also prepared in the cylindrical bottles by mixing 36.0 mmol of iron(III) hydroxide oxide or 18.0 mmol of oxide, and different amounts of $Ba(OH)_2 8H_2O$ in 25.0 ml of water.

In order to prevent carbonation, the preparation was carried out in a nitrogen atmosphere. The bottles containing the suspensions were stoppered with tetrafluoethylene caps and dipped in water contained in an autoclave* to prevent the reduction of the volume of the suspension during the course of autoclaving. Four suspensions were subjected to autoclaving in each run. The suspensions were heated to the desired temperature at the rate of 4 °C/min, and then kept at this temperature for 5 h.

The products were separated from the solution by filtration, treated with a dilute $HClO_4$ solution to remove the remaining $Ba(OH)_2$, washed thoroughly with water, treated with acetone, and dried at 80 °C.

Examination. The products and the iron(III) hydroxide oxides used as the starting materials were examined by means of X-ray powder diffraction using Mn filtered Fe$K\alpha$ radiation. The products and the iron(III) hydroxide oxides which were found to consist of only one phase were subjected to BET surface measurements and to optical or electron microscopic observation. Products consisting of only one phase were further washed with 3M-$HClO_4$ to remove the adsorbed barium ion. After they had been dissolved in a HCl solution by heating, the barium and iron(III) ion contents were determined by means of gravimetric analysis.

Results and Discussion

Conditions for the Formation of $BaO \cdot 6Fe_2O_3$. A brown precipitate was formed when the NaOH solution was added to an acidic solution containing iron(III) and barium nitrates. When the NaOH/total NO_3^- in mol ratio ($=R$) was 0.8, most of the iron(III) ions precipitated, the pH of the resulting suspension becoming 2.4—2.8. When $R \geqq 0.9$, the pH of suspensions became> 7 as a result of the formation of $Ba(OH)_2$ (no precipitation). By autoclaving, it turned out that pH≧11 for the suspensions with $R \geqq 0.9$ and pH≦1.1 for those with $R=0.8$.

The formation of the products is shown in Fig. 1 in terms of R and temperature. The concentration of

* Constructed of stainless steel.

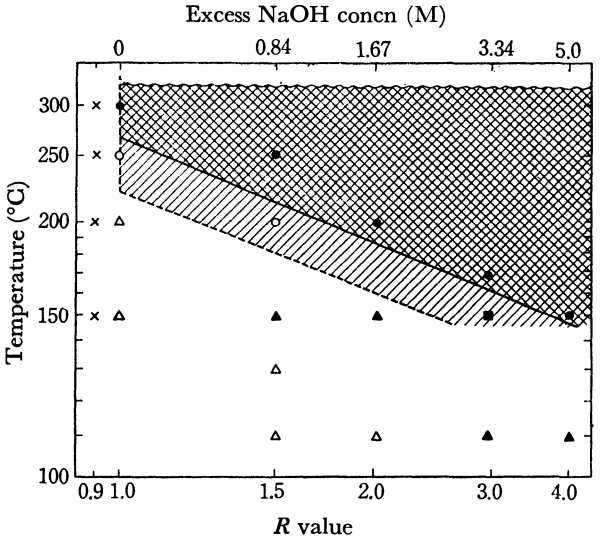

Fig. 1. Conditions for the formation of $BaO \cdot 6Fe_2O_3$ from suspensions containing 0.514 M-$Fe(NO_3)_3$, 0.064 M-$Ba(NO_3)_2$, and vairous amounts of NaOH.
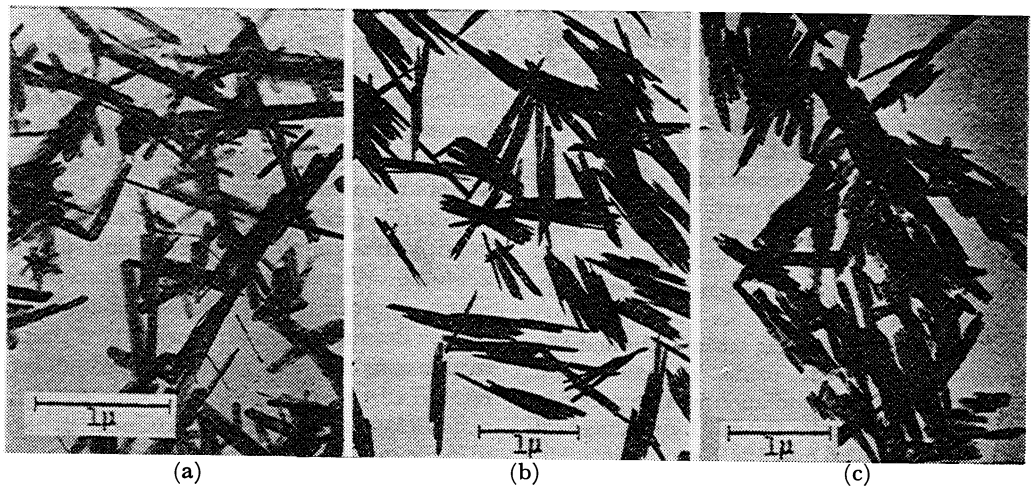
● $BaO \cdot 6Fe_2O_3$, ○ $BaO \cdot 6Fe_2O_3 + \alpha\text{-}Fe_2O_3$, ▲ $BaO \cdot 4.5Fe_2O_3$, ■ $BaO \cdot 6Fe_2O_3 + BaO \cdot 4.5Fe_2O_3$, × $\alpha\text{-}Fe_2O_3$, △ $BaO \cdot 4.5Fe_2O_3 + \alpha\text{-}Fe_2O_3$.

excess NaOH in the suspension, as calculated from the R value, is also given. $BaO \cdot 6Fe_2O_3$, a brown ferromagnetic precipitate, is formed in the range of $R > 1.0$ at temperatures higher than those for the formation of $BaO \cdot 4.5Fe_2O_3$, a brown nonferromagnetic precipitate, or a mixture of $\alpha\text{-}Fe_2O_3$ and $BaO \cdot 4.5Fe_2O_3$. The temperature at which $BaO \cdot 6Fe_2O_3$ is formed decreases with the increase in R. When similar experiments were carried out with chlorides in place of nitrates, no remarkable difference were found in the conditions for the formation of $BaO \cdot 6Fe_2O_3$.

The physical and chemical properties of iron(III) hydroxide, formed by the addition of an alkaline solution to an iron(III) salt solution, were studied in detail by van der Giessen.[7] The precipitate consists of superfine particles (30—40 Å in size) stable in a neutral suspension medium. In an alkaline medium, however, the precipitate is transformed into α-FeO(OH) or $\alpha\text{-}Fe_2O_3$, or their mixture, depending on the temperature of aging.[8-10] $\alpha\text{-}Fe_2O_3$ is formed at temperatures higher than those at which α-FeO(OH) is formed. The temperature at which $\alpha\text{-}Fe_2O_3$ is formed depends on the time elapsed during the course of aging at room temperature and on the concentration of the excess alkali. It seems that $BaO \cdot 6Fe_2O_3$ is formed at such temperatures that iron(III) hydroxide is transformed into $\alpha\text{-}Fe_2O_3$, provided that the amount of $Ba(OH)_2$ in the suspension is suitable for $BaO \cdot 6Fe_2O_3$ formation. The content of barium ions in the product increases with the decrease in the solubility of $Ba(OH)_2$ at a given concentration of the total barium ions. The solubility might decrease with a rise in the temperature and with an increase in the NaOH concentration.[11]

Iron(III) hydroxide oxides in alkaline suspension media can be transformed into $\alpha\text{-}Fe_2O_3$ by autoclaving, the rate of transformation depending on the crystal structure of the iron(III) hydroxide oxides as well as on the particle size and shape. In order to examine the effects of the modification and particle size of iron(III) hydroxide oxide on the formation of $BaO \cdot 6Fe_2O_3$ in the presence of $Ba(OH)_2$, the following experiments were carried out by the use of iron(III) hydroxide oxides and oxide, similar in particle shape and size (Fig. 2). The suspensions containing 4.5 mmol of $Ba(OH)_2$ and either iron(III) hydroxide oxide or oxide were subjected to autoclaving at 150, 200, 250, and 300 °C. The products are given in Table 1, together with the BET surface area, S, of the starting material. We see that the temperature required for the transformation of α-, β-, and γ-FeO(OH) into $\alpha\text{-}Fe_2O_3$ decreases in this order, and that the use of α-FeO(OH) at higher temperatures favors the formation of $BaO \cdot 6Fe_2O_3$. The contents of $BaO \cdot 4.5Fe_2O_3$ and $BaO \cdot 6Fe_2O_3$ in the products obtained by autoclaving β-FeO(OH) suspensions at 200 and 300 °C were much smaller than those in the products from γ-FeO(OH) suspensions at corresponding temperatures. When $\alpha\text{-}Fe_2O_3$ was used as the starting material, autoclaving gave rise to the growth of fine particles in needle-like particles. A very small amount of hexagonal plate-like particles of $BaO \cdot 2Fe_2O_3$ besides $\alpha\text{-}Fe_2O_3$ was, however, found in the product obtained by autoclaving at 300 °C.

Similar experiments were carried out using powders



(a) (b) (c)

a) Obtained from α-FeO(OH) with 23.2 m^2/g.

of α- and γ-FeO(OH) with different mean particle sizes. The results indicate that the decrease in the apparent density (g/ml) of iron(III) hydroxide oxide in the starting suspension was favorable for the formation of $BaO \cdot 6Fe_2O_3$. The apparent density decreased with a decrease in the mean particle size down to a size corresponding to about 20 m^2/g in S. When the size was too small (S>40 m^2/g), the apparent density increased as a result of the aggregation of very fine needle-like particles caused by drying during the course of the preparation of iron(III) hydroxide oxides.

In order to study the effect of the $Ba(OH)_2$ concentration on the formation of $BaO \cdot 6Fe_2O_3$, alkaline suspensions containing α-FeO(OH) particles (Table 1) and different amounts of $Ba(OH)_2$ (0.32—72 mmol, corresponding to 0.015—2.88 M $Ba(OH)_2$), were subjected to autoclaving at 300, 250, and 200 °C. The contents of $BaO \cdot 6Fe_2O_3$ in the products were determined by comparing the relative intensities of X-ray diffraction peaks of d(006) 3.86 Å for $BaO \cdot 6Fe_2O_3$, and d(104) 2.69 Å for α-Fe_2O_3, and d(103) 3.19 Å for $BaO \cdot 2Fe_2O_3$. The contents are plotted against the $Ba(OH)_2$ concentration at three reaction temperatures (Fig. 3). The content of $BaO \cdot 6Fe_2O_3$ in the products consisting of $BaO \cdot 6Fe_2O_3$ and α-Fe_2O_3 increases with an increase in the $Ba(OH)_2$ concentration and reaches 100% with 0.18—0.24 M $Ba(OH)_2$ for autoclaving at 300 °C, 0.24—0.28 M at 250 °C, and 0.36 M or more at 200 °C. A further increase in $Ba(OH)_2$ concentration at 300 and 250 °C resulted in the formation of $BaO \cdot 2Fe_2O_3$ besides $BaO \cdot 6Fe_2O_3$ and the content of $BaO \cdot 2Fe_2O_3$ reached 100% with 1.44 M $Ba(OH)_2$. At 200 °C, a further increase in $Ba(OH)_2$ concentration caused no formation of $BaO \cdot 2Fe_2O_3$, but only hindered the growth of $BaO \cdot 6Fe_2O_3$ particles.

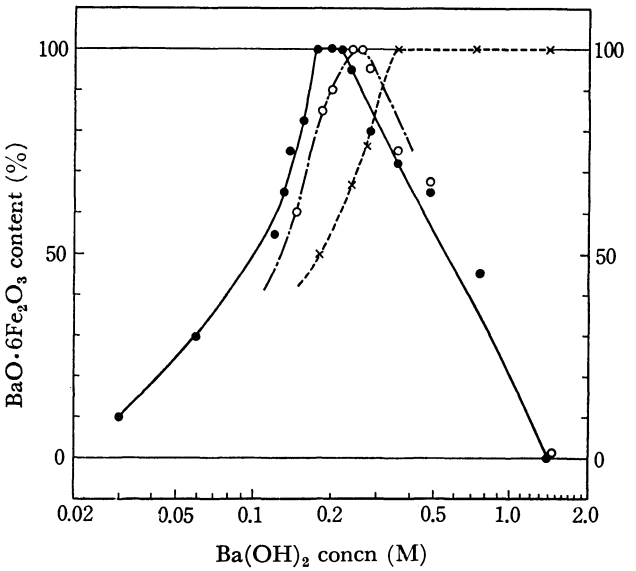

Fig. 3. Effect of $Ba(OH)_2$ concentration on $BaO \cdot 6Fe_2O_3$ formation at 200(×), 250(○), and 300 °C(●).

In order to examine the effect of reaction time on the content of $BaO \cdot 6Fe_2O_3$ in the product, the suspensions containing α-FeO(OH) (Table 1) and 0.14, 0.18, and 0.29 M $Ba(OH)_2$ were subjected to autoclaving at 250 and 300 °C for 5 min, 1/2, 2, and 8 h. In all cases, except for the reaction at 250 °C with 0.14 M $Ba(OH)_2$, α-FeO(OH) was completely transformed into $BaO \cdot 6Fe_2O_3$ or a mixture of $BaO \cdot 6Fe_2O_3$ and $BaO \cdot 2Fe_2O_3$ or α-Fe_2O_3 in 5 min. Under the conditions of 250 °C and 0.14 M $Ba(OH)_2$, $BaO \cdot 6Fe_2O_3$ was hardly formed in 5 min; however, α-FeO(OH) was completely transformed into a mixture of $BaO \cdot 6Fe_2O_3$ and a small amount of α-Fe_2O_3 in 2 h. The contents of $BaO \cdot 6Fe_2O_3$ in the products at complete transformation were not determined by the reaction time, but by the concentration of $Ba(OH)_2$ and the temperature, as is shown in Fig. 3.

γ-FeO(OH) as well as iron(III) hydroxide is unstable

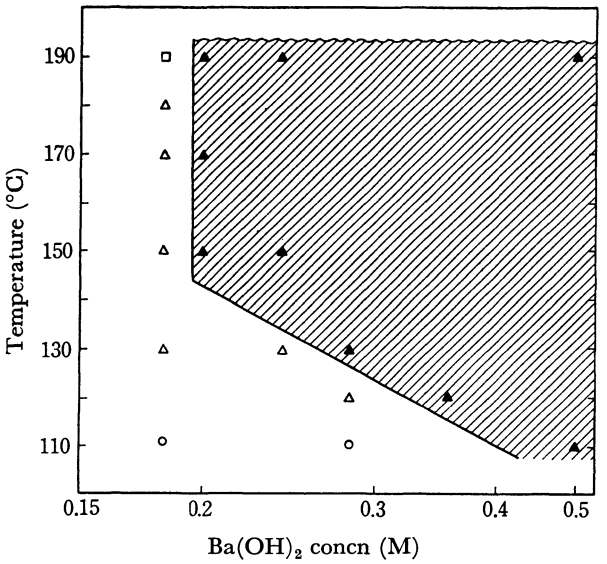

Fig. 4. The transformation products of γ-FeOOH in suspension media with various amounts of $Ba(OH)_2$. ▲ $BaO \cdot 4.5Fe_2O_3$, △ $BaO \cdot 4.5Fe_2O_3$+α-FeO(OH), ○ $BaO \cdot 4.5Fe_2O_3$+γ-FeO(OH), □ $BaO \cdot 4.5Fe_2O_3$+α-Fe_2O_3+α-FeO(OH).

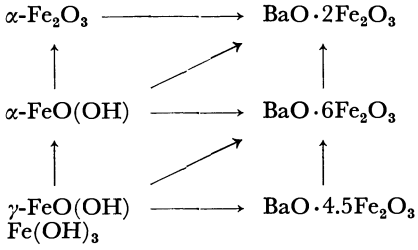
in an alkaline medium and is transformed into α-FeO(OH) at temperatures lower than those needed for the transformation into α-Fe_2O_3.[12,13] The precipitate of $BaO \cdot 4.5Fe_2O_3$ seems to be formed in the presence of $Ba(OH)_2$ at temperatures at which γ-FeO(OH) is transformed into α-FeO(OH) (Table 1). In order to confirm this assumption, the following experiments were carried out using γ-FeO(OH) (Table 1). Alkaline γ-FeO(OH) suspensions containing different amounts of $Ba(OH)_2$ were subjected to autoclaving at temperatures in the range of 110—190 °C. The products are shown in Fig. 4 in relation to the temperature and the $Ba(OH)_2$ concentration (in M). Products consisting only of $BaO \cdot 4.5Fe_2O_3$ can be obtained by choosing the $Ba(OH)_2$ concentration and temperature.

In order to examine if $BaO \cdot 6Fe_2O_3$ is formed by the dissolution of the barium ion in the particles of $BaO \cdot 2Fe_2O_3$ or $BaO \cdot 4.5Fe_2O_3$ into a solution, two suspensions of $BaO \cdot 2Fe_2O_3$ (2 g) and $BaO \cdot 4.5Fe_2O_3$ (2 g) in water (25 ml) were subjected to autoclaving at 300 °C for 5 h. Some particles of $BaO \cdot 2Fe_2O_3$ were transformed into α-Fe_2O_3, while $BaO \cdot 4.5Fe_2O_3$ was completely transformed into a mixture of $BaO \cdot 6Fe_2O_3$ and α-Fe_2O_3. When 0.14 M-$Ba(OH)_2$ containing $BaO \cdot 4.5Fe_2O_3$ was used, the product consisted of only $BaO \cdot 6Fe_2O_3$. It may be considered from the experimental results that some or all of the $BaO \cdot 6Fe_2O_3$ particles in the products obtained from β- and γ-FeO(OH) suspensions are formed *via* $BaO \cdot 4.5Fe_2O_3$.

The transformation processes could be summarized as follows:



No direct transformations, such as α-$Fe_2O_3 \rightarrow BaO \cdot 6Fe_2O_3$ and α-FeO(OH)$\rightarrow BaO \cdot 4.5Fe_2O_3$, take place. Since β-FeO(OH) did not favor the formation of $BaO \cdot 6Fe_2O_3$, its yield being very small as compared with those of α-FeO(OH) and γ-FeO(OH), experiments using β-FeO(OH) were not sufficiently carried out.

The change in the shape and size of the particles before and after the transformation was observed in electronmicrographs. The change in particle shape and size suggests that the mechanism of formation takes place in the suspension medium. The barium ions in the alkaline suspension medium might react either with iron(III) ions on the surface of the particle of the intermediate product (the precursor of each product) or with iron(III) complexes formed by the dissolution of the intermediate product particle in the suspension medium to form a nucleus of $BaO \cdot 6Fe_2O_3$, $BaO \cdot 4.5Fe_2O_3$, or $BaO \cdot 2Fe_2O_3$. It is probable that the product formation takes place by the dissolution, followed by crystallization on suitable nuclei.

Properties of Precipitates. The ferromagnetic products, $BaO \cdot 6Fe_2O_3$, with a hexagonal crystal structure (a=5.88 and c=23.2 Å),[14] consisted o hexagonal plate-like particles. Their size increased with a rise in the reaction temperature; it depended also on the size of the particles in the starting suspension (Fig. 5). The diameter and thickness of the hexagonal plate-like particles obtained from the suspensions of iron(III) hydroxide did not exceed 1 and 0.05 μm respectively. The diameter of the particles obtained from the suspensions of α-FeO(OH) was 1—2 μm, the thickness depending on the conditions under which they were formed. These products** contained greater amounts of barium ions than those calculated from the $BaO \cdot 6Fe_2O_3$ formula. The relative heights of the X-ray diffraction peaks vary with the sample (Figs. 6(a)—(c)). This is because the hexagonal plate-like particles in the pressed powdery sample for X-ray measurement undergo alignment to some extent. The degree of alignment, F, depends on the thickness, d, of the particles (1—2 μm in diameter) and on the packing density P (Table 2). The d values were calculat-

S (m^2/g)	d (μm)	10 kg/cm^2		100 kg/cm^2		1000 kg/cm^2	
		F	P	F	P	F	P
9.65	0.041	0.09	0.98	0.26	1.64	0.37	2.67
6.75	0.060	0.23	1.09	0.48	2.06	0.56	2.72
5.25	0.079	0.26	1.27	0.36	1.90	0.49	2.72
2.69	0.168	0.09	1.50	0.21	2.20	0.35	2.78

$F = I_{d(008)}/I_{d(008)} + I_{d(107)}$, where $I_{d(008)}$ and $I_{d(107)}$ are relative intensities of X-ray diffraction on (008) and (107) crystal faces, respectively, of $BaO \cdot 6Fe_2O_3$.

ed by means of this formula;

$$d(\mu m) = 3(3)^{1/2}/1.5\rho S(3)^{1/2} - 6$$

assuming that the diameter of the circle circumscribing the hexagon is 2 μm, where $\rho = 6.3$ is the specific gravity of the $BaO \cdot 6Fe_2O_3$ crystal.

Since the c axis of the $BaO \cdot 6Fe_2O_3$ crystal is the easy direction of magnetization, all the hexagonal plate-like particles can be aligned by magnetic field when they are free to rotate. A brown suspension prepared by mixing the $BaO \cdot 6Fe_2O_3$ precipitates with an adequate amount of a liquid such as oil, water, or ethanol in a test tube, loses its color when brought near a magnet since light is reflected by the aligned basal planes perpendicular to the direction of the magnetic field.

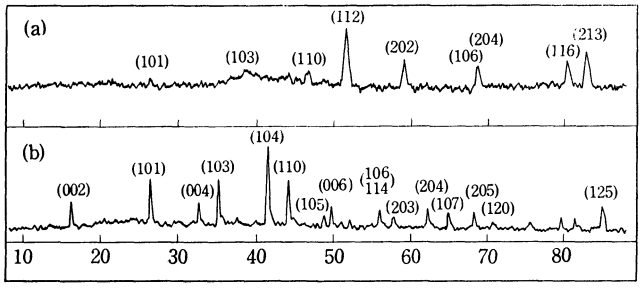

Fig. 7. X-Ray diffraction patterns of $BaO \cdot 4.5Fe_2O_3$ (a) and $BaO \cdot 2Fe_2O_3$ (b).

X-Ray diffraction patterns of the non-ferromagnetic products consisting of only one phase are shown in Figs. 7(a) and (b). Samples (a) and (b) contained barium and iron(III) ions in the Fe_2O_3/BaO mol ratios of 4.4—4.6 and 1.9—2.2 respectively. $BaO \cdot 4.5Fe_2O_3$ is estimated to have a hexagonal crystal structure with $a = 4.8$ and $c = 11.3$ Å. The particles were spherical (maximum size, 0.05 μm). It was difficult to obtain large particles. Particles of $BaO \cdot 2Fe_2O_3$ remarkably increase in size with increases in the temperature and in the concentration of $Ba(OH)_2$. Large particles with a hexagonal crystal structure with $a = 5.12$ and $c = 13.8$ Å were easily obtained by autoclaving at 300 °C. Their properties were then studied.[3,15]

When heated at 800 °C in the air for 4 h, the $BaO \cdot 4.5Fe_2O_3$ particles were decomposed into $BaO \cdot 6Fe_2O_3$ and a small amount of $BaO \cdot Fe_2O_3$, whereas the $BaO \cdot 2Fe_2O_3$ particles, 20—40 μm in diameter, were hardly decomposed at all. This difference might be due to the difference in their particle size.

Magnetic Properties of $BaO \cdot 6Fe_2O_3$ Precipitates. The products were obtained from α-FeO(OH) suspensions containing various amounts of $Ba(OH)_2$ at 200, 250 and 300 °C under the conditions shown in Fig. 3. The samples, consisting of hexagonal plate-like particles 1—2 μm in diameter, were selected, pressed in brass cylinders 15 mm in diameter and 5 mm in height, and sandwiched between the pole pieces of a magnet. After the sample had been magnetized at $H = 17$ kOe, the demagnetization curve was obtained from 5 kOe with a self-recording permeameter. The results are given in Table 3. As the d value increases to 0.044 μm, the values of $4\pi I/P$ and ${}_iH_c$ increase. The d dependence of $4\pi I/P$ and ${}_iH_c$ might indicate the presence of superparamagnetic particles in the samples with $d \leqq 0.044$ μm.

Table 3. Magnetic properties of $BaO \cdot 6Fe_2O_3$ precipitates

Preparation conditions		S (m^2/g)	d (μm)	P (g/ml)	$4\pi I/P$ (G)	${}_iH_c$ (Oe)	I_r/I
Autoclaving temp.	Concn $Ba(OH)_2$ (M)

	0.48	17.5	0.019	1.12	120	606	0.62
	0.36	8.1	0.041	0.86	230	813	0.57
250 °C	0.28	7.6	0.044	1.11	520	973	0.72
	0.24	6.7	0.050	0.95	480	942	0.59
	0.20	6.6	0.051	1.29	480	942	0.63
300 °C	0.20	5.2	0.066	0.93	510	1042	0.55
	0.18	4.1	0.085	0.92	490	1003	0.65

Samples 1—2 μm in diameter and 0.15 μm or less in d were prepared under various conditions. The saturation magnetization, σ_s, at 17 kOe and the ${}_iH_c$ were also measured in the P range of 0.9—2.2 g/ml at room temperature. The values of the samples with $0.05 \leqq d \leqq 0.15$ μm were 55 ± 4 in σ_s (emu/g) and 0.9—1.0 kOe in ${}_iH_c$. The samples were calcined in the air at ≈1000 °C. It was found that no remarkable difference in σ_s and ${}_iH_c$ occurred between the calcined and the original samples.

The author is indebted to Prof. T. Takada, Kyoto University, for suggesting the investigation, to Prof. N. Nakanishi, Konan University, for his valuable discussion, and Mr. T. Asai for his help in the experiments.

Sterically Controlled Substitution of Copper(II) with 3,3′-Bis[*N*,*N*-bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein

Mutsuo YAMADA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 11, 1975)

The rate constants for the formation of the diprotonated bimetallic complex of copper(II) with 3,3′-bis[*N*,*N*-bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein (XO) have been determined by the stoppedflow method. The results are interpreted in terms of the reactions, $Cu+LH_2 \rightleftharpoons CuLH_2 \overset{Cu}{\rightleftharpoons} Cu_2LH_2$ and $Cu+LH_3 \rightleftharpoons CuLH_2+H \overset{Cu}{\rightleftharpoons} Cu_2LH_2+H$. The over-all rate constants, k_1 and k_2 for both reactions are determined to be $k_1=(3.6\pm0.3)\times10^6 M^{-1}s^{-1}$ and $k_2=(8.7\pm1.3)\times10^3\ M^{-1}s^{-1}$ at 25.0 °C and I=0.1 M.

During a search for establishing the solution chemistry on the metal complexes with XO,[1-3] it has been found that copper(II) ion forms the diprotonated bimetallic complex Cu_2LH_2 with XO in solutions containing an excess of copper(II) ion to XO at pH 3.5—5.5. The structure of the complex has been proposed to be four nine-membered and two eight-membered rings.[2]

In the present paper it is examined by the stopped-flow method how the unfavorable large-membered chelate rings affect the complexation reaction of copper(II) ion with XO.

Experimental

Materials. *Reagents*: All chemicals used are of analytical grade, unless otherwise specified. Water is deionized and distilled.

Xylenol Orange: The acid form of the "*pure*" specimen[4,5] is used. 1×10^{-3} M stock solution of XO is prepared by weight.

Copper(II) Perchlorate: Copper(II) perchlorate is prepared from recrystallized copper(II) chloride by heating with a small excess of perchloric acid. Perchlorate is recrystallized twice from water. The solution is standardized by EDTA titration using PAN as indicator.

Sodium Perchlorate: The purified salt[1] is heated at *ca.* 200 °C to prepare anhydrous salt. The concentration of the solution is determined by weight. The ionic strength of the solution is adjusted to 0.1 M with the sodium perchlorate.

Buffer Solutions: They are prepared from 1.0 M acetic acid and 1.0 M sodium acetate.

Measurements. The rates of complexation reaction are measured at 574 nm, the maximum absorption of Cu_2LH_2 complex,[2] with a Union Giken stopped-flow rapid-scan spectrophotometer Model RA 1300 and their signals are stored in an image dissector and then recorded on a Rigaku Denki transient recorder.

The pH values of the solutions are measured with a Radiometer pH Meter 4d (Copenhagen) equipped with a glass electrode Type G 202B and a saturated calomel electrode Type K 401.

All measurements are made at 25.0±0.2 °C by circulating thermostated water from a Lauda Type K 2R Electronic with a circular Duplex pumps.

Results

Figure 1 shows the plot of k_{obsd}, the apparent first-order rate constant, against the total concentration of copper(II) ion for the total concentration of XO,

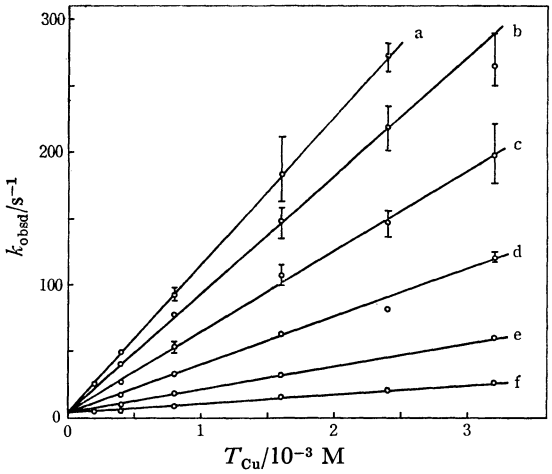

Fig. 1. Plot of k_{obsd} against the total concentration of copper(II) ion at various pH values in the formation of Cu_2LH_2 for $T_L=1.60\times10^{-5}$ M, at 25.0 °C and I=0.1 M. pH: a) 5.36±0.04, b) 5.17±0.03, c) 4.97±0.03, d) 4.70±0.04, e) 4.27±0.07, and f) 3.87±0.09.

$T_L=1.60\times10^{-5}$ M at pH 3.87—5.36 at 25.0 °C and I=0.1 M. As k_{obsd} is the first-order with respect to copper(II) ion at each value of pH, the following equation holds

$$k_{obsd} = k_f[Cu] + k_d, \quad (1)$$

where k_f and k_d are the forward and the reverse rate constants of the reaction, respectively.

In the above pH region, the protolytic equilibria of the ligand are

$$LH_2 + H \rightleftharpoons LH_3; \quad K_1 = 10^{6.74} \quad (2)$$

$$LH_3 + H \rightleftharpoons LH_4; \quad K_2 = 10^{2.85}, \quad (3)$$

where K_1 and K_2 are the acid-association constants[6] of the ligand at 25.0 °C and I=0.1 M.

The kinetic data are consistent with the assumption that the formation of Cu_2LH_2 proceeds *via* two paths in Eqs. 4 and 5 and that the protolytic reactions of Eqs. 2 and 3 reach equilibria much faster than the metal complex reactions

$$Cu + LH_2 \rightleftharpoons CuLH_2 \overset{Cu}{\rightleftharpoons} Cu_2LH_2; \ k_1 \quad (4)$$

$$Cu + LH_3 \rightleftharpoons CuLH_2 + H \overset{Cu}{\rightleftharpoons} Cu_2LH_2 + H; \ k_2, \quad (5)$$

where $CuLH_2$ is a terdentate intermediate **4** in Fig. 3.

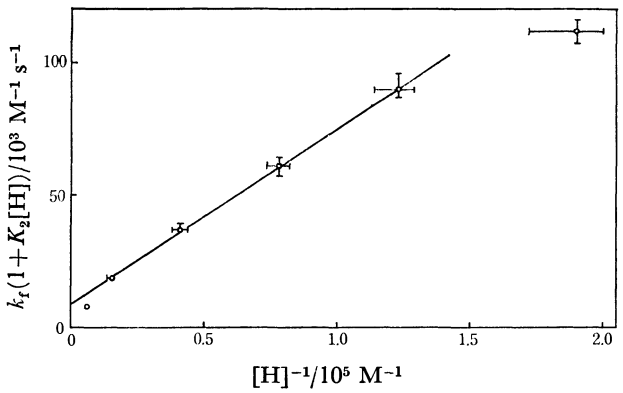

Fig. 2. Plot of $k_f(1+K_2[H])$ against the inverse of hydrogen ion concentration in the formation of Cu_2LH_2 at 25.0 °C and $I=0.1$ M.

The forward rate of the formation of Cu_2LH_2 is given by

$$d[Cu_2LH_2]/dt = k_f[Cu]C_L = k_1[Cu][LH_2] + k_2[Cu][LH_3], \quad (6)$$

where

$$C_L = [LH_4] + [LH_3] + [LH_2], \quad (7)$$

and k_1 and k_2 are the over-all forward rate constants of the reactions for (4) and (5), respectively.

From Eqs. 6 and 7, the formation rate constant k_f is expressed by the equation

$$k_f = (k_1+k_2K_1[H])/(1+K_1[H]+K_1K_2[H]^2). \quad (8)$$

Plot of $k_f(1+K_2[H])\times10^3$ against $[H]^{-1}\times10^5$ gives a straight line (Fig. 2). From Eq. 8 the relation $k_f(1+K_2[H])=k_2+k_1/K_1[H]$ holds in the experimental pH region. The intercept and the slope give the values of k_2 and k_1/K_1, respectively. The values of k_1 and k_2 are evaluated to be $k_1=(3.6\pm0.3)\times10^6\ M^{-1}s^{-1}$ and $k_2=(8.7\pm1.3)\times10^3\ M^{-1}s^{-1}$ at 25.0 °C and $I=0.1$ M.

Discussion

From equilibrium measurements it has been found that copper(II) ion forms the diprotonated *bimetallic* complex with XO,[2] while from kinetic measurements of the complexation reaction of copper(II) ion with XO, k_{obsd} is found to be the first-order with respect to copper(II) ion. These facts indicate that on complexation of copper(II) ion with XO two copper(II) ions do not simultaneously react with two different coordinating sites of XO but successively react with them to form the diprotonated *bimetallic* complex. Thus following mechanisms are considered (Fig. 3).

Using steady-state approximation for species **3** and **4** (**3'** and **4**), and assuming rapid equilibria between species **1** and **2** (**1'** and **2'**), and assuming $k_{45}[Cu]\gg k_{43}$ ($k'_{45}[Cu]\gg k'_{43}$) and $k_{32}\gg k_{34}$ ($k'_{32}\gg k'_{34}$) one gives the expression for the forward rate constant at each value of pH in Eq. 9

$$k_f = k_{34}K_{os}K_{12}K_{23}[Cu][LH_2] + k'_{34}K'_{os}K'_{12}K'_{23}[Cu][LH_3]. \quad (9)$$

From Eqs. 6 and 9,

$$k_1 = k_{34}K_{os}K_{12}K_{23} \quad (10)$$

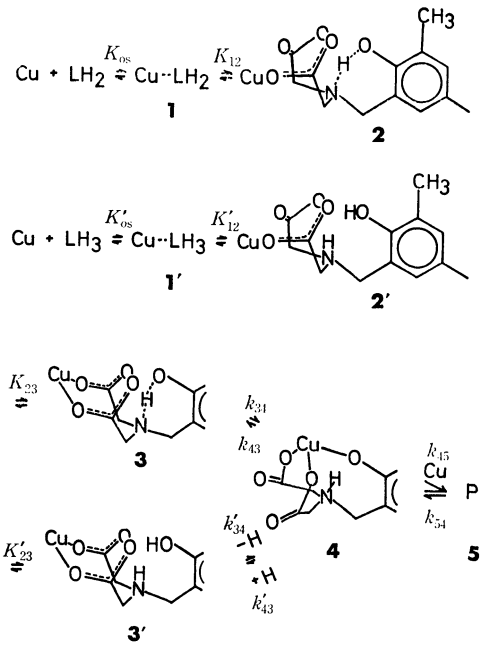

Fig. 3. Proposed mechanisms of the formation of Cu_2LH_2.

$$k_2 = k'_{34}K'_{os}K'_{12}K'_{23}. \quad (11)$$

As the value of the product $K_{os}K_{12}$ is approximately estimated to be 78 M^{-1} from the stability constant of the copper(II) acetate,[7] the value of the product $k_{34}K_{23}$ is calculated to be $4.6\times10^4\ s^{-1}$. If K_{23} is estimated from the ratio of the copper(II) complexes with malonic acid[7] and acetic acid,[7] K_{23} is calculated to be 4.6×10^3. Thus k_{34} is approximately evaluated to be $10\ s^{-1}$.

It is due to the small value of k_{34} that the value of k_1 ($3.6\times10^6\ M^{-1}s^{-1}$) is smaller by approximately 3 orders of magnitude than those of the rate constants of the normal substitution reaction of aquo copper(II) ion with the ligands.

It is found that the formation of large-membered chelate rings reduces the rate of the substitution reaction.

Kustin *et al.* have termed the reactions like this "*sterically controlled substitution,*" the rate has been shown to be ligand dependent.[8]

The author should like to thank Professor M. Fujimoto for general discussion and reading the manuscript.

The Crystal Structure of $(+)_{350}$-Diammine-*N,N,N'*-trimethylethylenediamineplatinum(II) Di-μ-(+)-tartrato-(4-)bis(antimonate(III)) Monohydrate

Keiji Yokoho, Keiji Matsumoto, Shun'ichiro Ooi, and Hisao Kuroya

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi, Osaka 558

(Received January 14, 1976)

X-Ray structure analysis of the title compound has revealed that the asymmetric secondary nitrogen center in the complex cation has the *S* absolute configuration. The crystals are orthorhombic, with the space group $P2_12_12_1$ and with $Z=4$ in a unit cell with dimensions of: $a=18.783(6)$, $b=14.138(4)$, and $c=8.473(2)$Å. The crystal structure has been determined from three-dimensional diffractometer data and refined by the least-squares method to R of 0.030 for 1971 independent reflections with $I>3\sigma(I)$. The Pt atom has a square-planar coordination by four N atoms, and the methyl group bonded to the secondary nitrogen is equatorial with respect to the chelate ring. Each complex cation is surrounded octahedrally by six di-μ-(+)-tartrato(4-)-bis(antimonate(III)) anions.

Although an optical resolution has been made for a large number of octahedral Co(III) complexes, there have been few reports concerning the resolution of the planar Pt(II) complexes. In order to study the correlation between the circular dichroism and the structure in dissymmetric planar metal complexes, we have prepared several Pt(II) chelates of *N*-substituted diamine and have attempted to resolve each of them into enantiomeric forms.

Of these chelates, $[Pt(NH_3)_2(Me_3en)]^{2+}$ (Me_3en, *N,N,N'*-trimethylethylenediamine) exists in two optical isomers: the one has a secondary nitrogen with the *R* configuration, while the other involves *S* asymmetric nitrogen. By the use of silver di-μ-(+)-tartrato(4-)-bis(antimonate(III)) ($Ag_2[Sb_2(+)\text{-tart}_2]$) as the resolving agent, the seemingly diastereoisomeric salt, $(+)_{350}$-$[Pt(NH_3)_2(Me_3en)][Sb_2(+)\text{-tart}_2]\cdot H_2O$, could be obtained as a less soluble fraction in an acidic solution. The circular dichroism of this compound is different from that of $K_2[Sb_2(+)\text{-tart}_2]$ in the 250—350 nm region. Although this indicate that there is some resolution, it is uncertain whether or not the resolution is complete. Fortunately, if the diastereoisomeric salt contains only one antipode of the enantiomeric pair, it is necessary to elucidate the absolute configuration of the complex in order to advance our study. Therefore, an X-ray structure analysis was performed on this compound.

Experimental

Details of the preparation of the title compound will be reported in the near future.

X-Ray Data Measurement. *Crystal Data*: $C_{13}H_{26}N_4O_{13}Sb_2Pt$, $M=884.96$, Orthorhombic, $a=18.783(6)$, $b=14.138(4)$, $c=8.473(2)$Å, $U=2250(1)$Å^3, $Z=4$, $D_m=2.59$ (by flotation), $D_c=2.61$ gcm^{-3}, Mo$K\alpha$ radiation ($\lambda=0.71069$ Å), μ(Mo$K\alpha$) $=89.9$ cm^{-1}. Space group $P2_12_12_1$.

The Laue symmetry and the space group were determined from oscillation and Weissenberg photographs. The unit-cell parameters were obtained by the least-squares treatment of 19 θ values measured on a Philips diffractometer with Mo$K\alpha$ radiation.

Data Collection. The intensities were measured by means of the ω-2θ scan method on a Philips PW 1100 four-circle diffractometer using a graphite monochrometer and Mo$K\alpha$ radiation with a crystal with dimensions of $0.12\times0.13\times0.10$ mm. A scan speed of 0.017° s^{-1}, a scan width of $(0.9+0.2\tan\theta)$°, and two 20 s background counts were chosen. Three standard reflections (400, 0$\bar{6}$0, and 004), monitored every 4 h throughout the data collection, showed no significant

variation in intensity. Of the independent reflections measured in the $5°\leq 2\theta \leq 50°$ range, 1971 reflections with $I>3\sigma(I)$ were considered to be observed and were used for the structure analysis ($\sigma^2(I)=CT+(t_c/t_b)(B_1+B_2)+(pI)^2$; CT, total integrated peak count obtained in a scan time t_c; B_1 and B_2, background counts each obtained in time $t_b/2$; $p=0.04$; $I=CT-(t_c/t_b)(B_1+B_2)$). The intensity data were processed with the computer program of Hornstra and Stubbe.[1] A spherical absorption correction ($r=0.05$ mm) was applied.

Structure Determination and Refinement. The crystal structure was solved by the heavy-atom technique. The positional and thermal parameters were refined by the least-squares method, the function minimized being $\sum w(F_o-|F_c|)^2$. The weight for each reflection, w, was unity in the initial refinement; in the final one $w=0.5$ for $F_o<25.1$, $w=1$ for $25.1\leq F_o\leq 150.8$, and $w=(150.8/F_o)^2$ for $F_o>150.8$. All the parameter shifts in the final cycle of the refinement were $<(1/10)\sigma$. The final R value was 0.030. The atomic scattering factors of the neutral Pt, Sb, O, N, and C were employed from Ref. 2. Real and imaginary parts of the anomalous dispersion correction were applied for Pt and Sb atoms.

The atomic coordinates listed in Table 1 correspond exactly to the absolute crystal structure, which was determined on the basis of the well-established absolute configuration of the $[Sb_2(+)\text{-}tart_2]$ anion. A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7625). All the computations were carried out by means of the FACOM 270-30 computer at Osaka City University. The computer programs used in the calculations were as follows: RSSFR-4 (Fourier synthesis), HBLS-4 (least-squares calculation), and DAPH (interatomic distances and angles, least-squares plane, and coordinates of H atoms), all of which were adapted to the FACOM 270-30 computer.

Results and Discussion

The absolute configuration of the complex cation and the absolute crystal structure viewed down the c axis are shown in Figs. 1 and 2 respectively. The bond lengths and angles in the complex, along with some selected interatomic distances, are presented in Table 2.

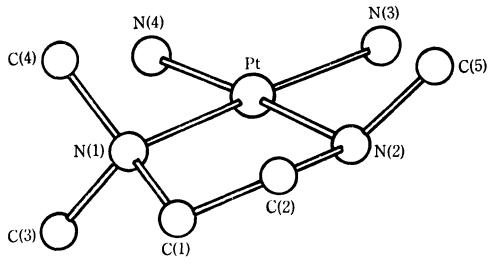

Fig. 1. The absolute configuration of the complex cation in $(+)_{350}$-$[Pt(NH_3)_2(Me_3en)][Sb_2\text{-}(+)\text{-}tart_2]\cdot H_2O$.

From the space group and the number of the formula units in the unit cell, it was inferred that the crystals involve only one antipode of the two optical isomers. The absolute configuration of the secondary nitrogen atom in the complex was elucidated to be *S* by the subsequent crystal structure analysis.

The Pt atom has a square-planar coordination by four nitrogen atoms. The equation of the plane defined by the 4 N atoms is:

$$0.9403X + 0.0138Y + 0.3400Z = 5.484^{3)}$$

The deviations (Å) of atoms from the plane are as follows: Pt, −0.040; N(1), −0.02; N(2), 0.02; N(3), −0.02; N(4), 0.02; C(1), 0.36; C(2), −0.15; C(3), 1.09; C(4), −1.32, and C(5), −0.97. The N–CH_3 bond in the secondary amino group is equatorial with respect to the five-membered chelate ring.

The Pt–NH_3 bond lengths agree with those in *trans*-

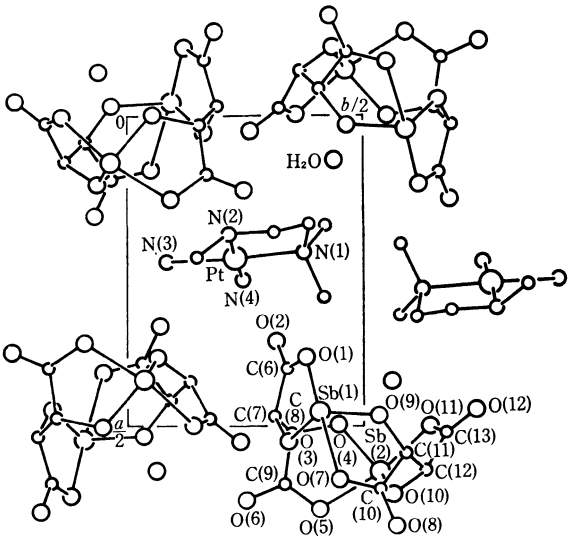

Fig. 2. The crystal structure viewed down the c axis.

Atom		Interatomic distance (Å)	Positions[a] of	
A	B		A	B
H[N(2)][b]	O(3)	2.23	1	3
N(3)	O(5)	3.01(2)	1	2
N(3)	O(8)	3.13(2)	1	3
N(3)	O(10)	2.95(2)	1	5
N(4)	O(6)	2.91(2)	1	2
N(4)	O(8)	2.96(2)	1	5
H_2O	O(4)	3.00(2)	1	4
H_2O	O(6)	2.92(2)	1	2

a) Numerals refer to the following equivalent positions; 1: x, y, z. 2: $-1/2+x, 1/2-y, -z$. 3: $-1/2+x, 1/2-y, 1-z$. 4: $1/2-x, 1-y, 1/2+z$. 5: $1-x, -1/2+y, 1/2-z$. b) The coordinates of H atom linked to N(2) were calculated on the assumption that the N–H bond length is 1.03 Å.

$[PtCl_2(NH_3)_2]$ (2.05(4) Å)[4] and $[Pt(NH_3)_4][Re_2O_3(CN)_8]$ (2.047—2.059(9) Å)[5] within the limits of experimental error, though they seem to be slightly longer than those cited for comparison. The bond lengths of Pt–N(1) (tertiary amino group) and Pt–N(2) (secondary) are almost equal, but are somewhat longer than those of Pt–N (primary) found in $[Pten_2][MoO(H_2O)(CN)_4]\cdot 2H_2O$ (2.024(6) and 2.036(4) Å).[6] The C–C single bond in the complex cation is unusually short. However, all the bond lengths and angles in the $[Sb_2(+)\text{-tart}_2]$ anion are normal and are in good agreement with the corresponding ones in $K_2[Sb_2(+)\text{-tart}_2]\cdot 3H_2O$.[7] The abnormal C–C bond length presumably results from errors in absorption correction for the intensity data.

The complex cation is surrounded octahedrally by six $[Sb_2(+)\text{-tart}_2]$ anions. Since no hydrogen atoms could be located, it is difficult to point out unequivocally the hydrogen bonds in which the NH_3 or H_2O molecule participates. Some possible hydrogen bonds are shown in Table 2. However, the hydrogen bonding in the present crystal seems to be rather weak from the viewpoint of the interatomic distance between proton donor and acceptor.

Proton Magnetic Resonance Spectra of Metal Ammine Complexes. VIII.* Hydrogen Isotopic Exchange in the $[Co(O)_2(N)_4]^+$ Complex Ions

Toshiaki TAURA, Ushio SAKAGUCHI, and Hayami YONEDA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received January 20, 1976)

The rates of amine hydrogen isotopic exchange in the $[Co(O)_2(N)_4]^+$ complex ions, where $(O)_2$ represents carbonate, oxalate, or malonate ions, and $(N)_4$, tetraammine, bis(ethylenediamine), or bis(trimethylenediamine), were measured in D_2O at 35 °C by the PMR technique. It was found that: (1) the rates for *trans* (to oxygen) amines are faster than those for *cis* amines; (2) the rates, especially for *trans* amines, in the carbonato complexes are slower than those in the oxalato and malonato analogs, and (3) the difference between the rates for *cis* and *trans* amines is smaller in the bis(diamine) complexes than in the tetraammine complexes. These results are discussed in terms of the influence of the chelate geometry in the complex on the exchange reaction.

In our previous papers,[1] it was reported that the *trans* amine hydrogen exchange in $[CoCN(NH_3)_5]^{2+}$, $[CoNO_2(NH_3)_5]^{2+}$, and *cis*-$[Co(CN)_2(en)_2]^+$ is unusually decelerated.** In general, coordinated ligand molecules are influenced by the electron-withdrawing effect of the positively charged metal ion. This effect leads to the decrease in the electron density on the nitrogen atom of the coordinated amine ligand and to a concomitant labilization of the hydrogen atom attached to this nitrogen. Therefore, if the Co–N bond is weakened, the electron density on the nitrogen atom will be restored and the amine ligand will approach its free state so that the hydrogen atom bound to this nitrogen atom becomes less labile. This is the reason for the deceleration in the above complexes. Thus, it was thought that the measurement of the rate of hydrogen exchange might serve as a convenient means of obtaining information on the chemical bonding in complexes.

On the other hand, it is known from the results of X-ray studies that the O–Co–O bond angles in the dicarboxylato complexes are *ca.* 70° for the carbonate ion,[2] *ca.* 84° for the oxalate ion,[3] and *ca.* 96° for the malonate ion.[4] The effect of the deviation of these angles from the ideal octahedral value (90°) has been studied through the circular dichroism spectra of the dicarboxylatobis(ethylenediamine) complexes[5] and the aquation reaction of the carbonato$(N)_4$ complexes.[6] Douglas *et al.*[5] reported that the T_{1g} rotatory strength decreases sharply, $CO_3^{2-} > ox^{2-} > mal^{2-}$, with an increase in the size of the carboxylato chelate ring. Dasgupta and Harris[6] discussed the relationship between this deviation and the aquation kinetics. These studies interested us in the effect of this deviation on the rate of amine hydrogen exchange.

To investigate the influence of the geometry of the dicarboxylato chelate, the rates of amine hydrogen exchange in the $[Co(O)_2(N)_4]^+$ complex ions, where $(O)_2=CO_3^{2-}$, ox^{2-}, or mal^{2-} and where $(N)_4=(NH_3)_4$, $(en)_2$, or $(tn)_2$, have been determined by the PMR technique.

* Part VII: U. Sakaguchi, S. Yamazaki, and H. Yoneda, *Bull. Chem. Soc. Jpn.*, **49**, 402 (1976).

** In this paper, en, tn, ox, or mal represent ethylenediamine, trimethylenediamine, the oxalate ion, or the malonate ion respectively.

Experimental

Preparation. The $[CoCO_3(NH_3)_4]Cl\cdot 1/4H_2O$, $[CoCO_3(en)_2]Cl$, and $[Coox(tn)_2]Cl\cdot H_2O$[7] complexes were prepared by the usual methods, and the number of molecules of the water of crystallization was determined by elemental analysis. $[Coox(NH_3)_4]Cl\cdot H_2O$, $[Comal(NH_3)_4]Cl\cdot 3/2H_2O$, and $[Coox(en)_2]Cl\cdot H_2O$ were obtained by adding an equimolar amount of oxalic and malonic acids to the corresponding carbonato complexes and then by heating the mixtures until the effervescence subsided. $[Comal(en)_2]Cl\cdot H_2O$ was obtained from the iodide salt[5] by trituration with AgCl. $[CoCO_3(tn)_2]Cl\cdot H_2O$ was prepared by a method similar to that used for the bis(ethylenediamine) analog. *cis*-$[Co(CH_3CO_2)_2(NH_3)_4]ClO_4$ was prepared by Kuroda's procedure.[8] All these complexes were recrystallized once or twice. The data of the spectrophotometric measurements are summarized in Table 1.

Table 1. First absorption maxima for the $[Co(O)_2(N)_4]^+$ complex ions (nm)

	CO_3	ox	mal	$(CH_3CO_2)_2$
$(NH_3)_4$	522	508	516	522
$(en)_2$	511	497	497	
$(tn)_2$	520	510		

Measurement. The rate of amine hydrogen exchange was determined by following the change in the PMR signal intensity with the time, which was measured at 35 °C with a Varian T-60 spectrometer. An adequate amount of the sample was dissolved in D_2O, and the pD was adjusted by HCl for the dicarboxylato chelate complexes and by $HClO_4$ for the diacetatotetraammine complex so that the exchange might be complete in an appropriate time. The PMR measurement was initiated a few minutes after the sample had dissolved, and the pD of the sample solution was measured at about 30 °C with a Hitachi Horiba Model F-7 pH meter using a microelectrode immediately after the PMR measurement. The absorption spectra were measured with a Shimadzu UV-200 double beam spectrophotometer.

The oxalato tetraammine complex is sparingly soluble in D_2O, and the *cis* and *trans* amine signals overlap.

The influence of counter ions on the rate seemed insignificant, because the change in the concentration of the complexes did not affect the rates, within the limits of experimental errors.

Results and Discussion

The PMR spectra of some samples in D_2O or HCl–D_2O are shown in Fig. 1. We have assigned the higher

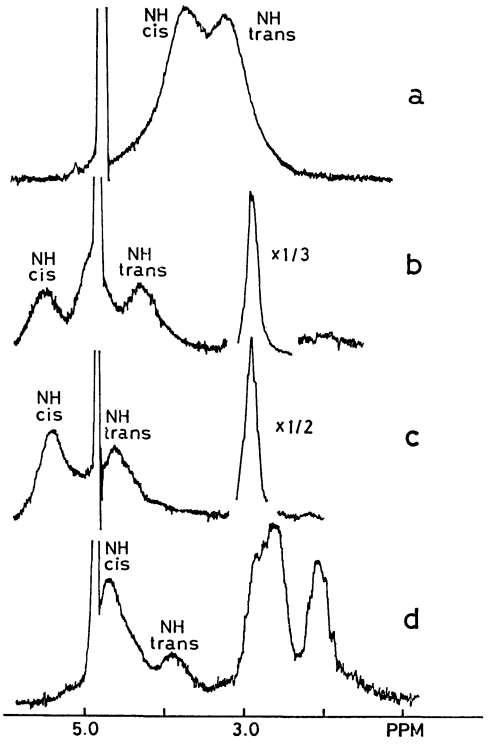

Fig. 1. The PMR spectra of (a) $[CoCO_3(NH_3)_4]^+$, (b) $[CoCO_3(en)_2]^+$, (c) $[Coox(en)_2]^+$, and (d) $[CoCO_3(tn)_2]^+$ in D_2O or HCl–D_2O.

field signal to the *trans* amine and the lower field signal to the *cis* amine based on the magnetic anisotropy of the cobalt ion.[9] In the tetraammine and bis(trimethylenediamine) complexes, both *trans* and *cis* amine proton signals appear at higher fields than the HDO signal, while the bis(ethylenediamine) complexes give the *trans* amine signal at a higher field, and the *cis* one at a lower field, than the HDO signal, except that $[Coox(NH_3)_4]^+$ has only one broad signal at a higher field than HDO.

Figure 2 shows the time change in the amine proton signal intensities for $[Comal(NH_3)_4]^+$ in D_2O. It may be noted in this figure that the *trans* amine signal disappears about ten minutes after dissolution, but the

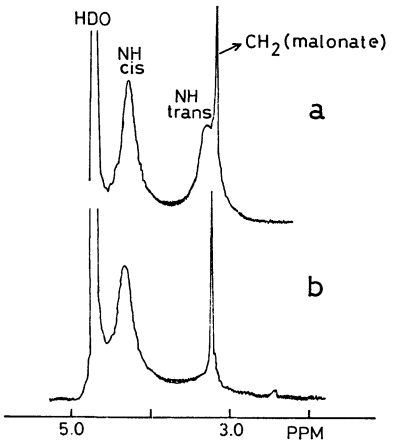

Fig. 2. The PMR spectra of $[Comal(NH_3)_4]^+$ in D_2O (a) immediately after dissolution, and (b) about ten minutes after dissolution.

cis one remains almost unchanged. Therefore, the exchange rate for the *trans* amine hydrogens is much faster than that for the *cis* ones.

The rate constant for the exchange is given by

$$\ln h_t = -kt + c$$

where h_t and k refer to the peak height of an amine proton signal at time t and the rate constant respectively, and where c is a constant. As is shown in Fig. 3, plots

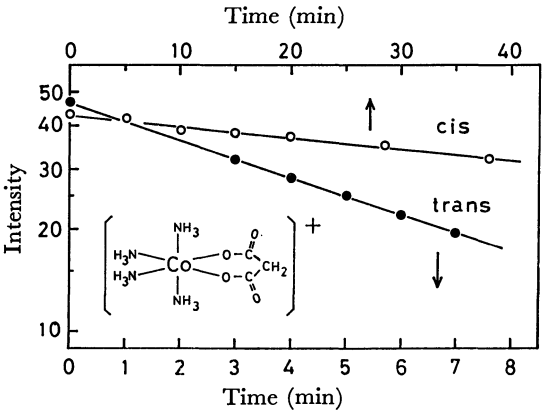

Fig. 3. Plots of log h_t *vs. t.* ●: *trans*, ○: *cis*. *Trans* and *cis* amines correspond to the downward and upward scales respectively.

of log h_t against the time gave straight lines. The rate constants for hydrogen exchange were obtained from the slopes of these plots. It is known[10] that the pseudo-first-order rate constant is directly proportional to the concentration of OD^- ions:

$$k_{obsd} = k_0[OD^-]$$

where k_{obsd} and k_0 refer to the observed and the second-order rate constant respectively.

The rate-constant data obtained in this manner are collected in Table 2. The data are also plotted in Fig. 4. A comparison of these data indicates that: (1) *trans* amine protons are more labile than *cis* ones; (2) the

a) The pD was calculated using the formula pD=pH+0.4, in which pH is a value measured with a usual pH meter in D_2O. b) Not assigned to *cis* or *trans*.

rates for the carbonato complexes are slower than those for the oxalato and malonato analogs; (3) the difference between the rates for the *cis* and *trans* amines is much smaller in the carbonato complexes, and (4) this difference seems to be smaller in the complexes with chelated amines.

As has been mentioned before, the O–Co–O bond angle increases with an increase in the size of the dicarboxylato chelate ring. The deviation of the O–Co–O bond angle from the ideal octahedral value (90°) is greatest in the carbonato complex, and the coplanar N–Co–N bond angle is enlarged in comparison with the octahedral value. This effect will make the Co–N bond less stable, and the hydrogen exchange for *trans* amines will be decelerated. This is considered to be the reason why the rates for *trans* amines in the carbonato complexes are much slower than in the oxalato and malonato analogs. The rates for *trans* amines in the $[Coox(en)_2]^+$ and $[Comal(en)_2]^+$ ions are similar to each other, probably because the deviation of the O–Co–O bond angle is smaller in these complexes. Therefore, the difference in the steric effect between the oxalato and malonato ligands does not seem to be apparent in the hydrogen exchange, though this effect may play an important role in the base hydrolysis of these complex ions.[11]

If *cis* amines are not so much influenced by the carbonato chelate, the difference in the rates for *trans* and *cis* amines necessarily becomes smaller in the carbonato complexes. This seems to be the case with the tetraammine and bis(ethylenediamine) complexes.

The remarkable deceleration of the hydrogen exchange for *cis* amines in $[CoCO_3(tn)_2]^+$ is not clearly explicable. It may be due to the internal hydrogen bonding, as suggested by a study of the carbonate exchange in a basic medium.[12]

The difference between the rates for *trans* and *cis* amine protons is appreciably smaller in the bis(ethylenediamine) and bis(trimethylenediamine) complexes than in the tetraammine analogs. Though the origin of this difference is not known, it is probable that the alkyl bridge links the *cis* to the *trans* amine and imparts a similar bonding property to both amines. Therefore, the rate for *cis* amines will be more similar to the rate for *trans* amines in the chelate amine complexes than in the complexes with no chelated amines.

Factors other than steric ones which affect the rate of hydrogen exchange, will now be examined. The maxima of the first absorption bands are nearly equal. They are positioned at 522, 508, and 516 nm in, for example, the tetraammine complexes of the carbonate, oxalate, and malonate ions respectively, as is shown in Table 1; therefore, the ligand field effect seems insignificant. The ligand field of the carbonato ligand, however, is slightly weaker than that of the others, and one may think that the peculiarity of the rate for the carbonato complex is due to this slight difference in ligand field strength. To make it clear, the rate of amine hydrogen exchange in *cis*-$[Co(CH_3CO_2)_2(NH_3)_4]^+$ was measured, for which λ_{max} is almost equal to that for the corresponding carbonato complex, as is shown in Table 1. In contrast to this similarity in the ligand field strength, the rate for *cis*-$[Co(CH_3CO_2)_2(NH_3)_4]^+$ is much more analogous to that for the malonato complex than for the corresponding carbonato complex. This result supports our expectation that the ligand field effect is less important for the rate of amine hydrogen exchange.

Thus, it can be concluded that the difference in the rate of amine hydrogen exchange arises from the steric source and not from the ligand field effect, and that the peculiarity of the carbonato complexes probably originates from the remarkably strained chelate geometry, where the O–Co–O bond angle is *ca.* 70°. Then, this peculiarity leads us to expect that the *trans*-bond-weakening effect is larger in the carbonato complex than in the oxalato and malonato analogs, although this effect on the Co–N bond length is not clearly apparent in the reported crystal structures.[2] It was also found that the difference in the rate for *trans* and *cis* amines is smaller in the chelate amine complexes than in the complexes with no chelated amines. This suggests that the effect of a dicarboxylato ligand on *trans* and *cis* amines is averaged to some extent through the alkyl bridge of the amine chelate.

Kinetic Study on Dimerization of Chlorotris(triphenylphosphine)-rhodium(I) in Benzene

Yoshimi OHTANI, Masatoshi FUJIMOTO, and Akihiko YAMAGISHI

Department of Chemistry, Fuculty of Science, Hokkaido University, Sapporo 060

(Received March 3, 1976)

The monomer-dimer equilibrium of $RhCl(PPh_3)_3$ in benzene has been studied with a stopped-flow apparatus under He gas pressure. The decomposition rate of a dimer, $[RhCl(PPh_3)_2]_2$, obeys pseudo-first-order kinetics with respect to the concentration of PPh_3, whereas the formation rate of a dimer obtained by diluting an equilibrium solution with benzene depends on the equilibrium concentration of a monomer, a dimer and PPh_3 in a complexed manner. The kinetic results are consistent with the following mechanism; $2RhCl(PPh_3)_3 \rightleftarrows RhCl(PPh_3)_2 + RhCl(PPh_3)_3 + PPh_3 \rightleftarrows [RhCl(PPh_3)_2]_2 + 2PPh_3$.

Chlorotris(triphenylphosphine)rhodium(I) first synthesized by Wilkinson and coworkers has been found to catalyze various kinds of reactions, such as hydrogenation, carbonylation and decarbonylation.[1-3] There have been, however, some disputes over the structures of the complexes in solution. Wilkinson and coworkers proposed the complete dissociation of $RhCl(PPh_3)_3$ into $RhCl(PPh_3)_2$ and PPh_3 on the basis of the molecular weight measurement:

$$RhClL_3 \rightleftarrows RhClL_2 + L \quad (L: PPh_3) \qquad (1)$$

Based on the deviations of the absorbance of $RhCl(PPh_3)_3$ from Beer's law and the effects of added PPh_3 on the spectra, Arai and Halpern estimated the dissociation constant of Reaction 1, K_{dissoc}, to be $(7 \pm 1) \times 10^{-5}$ M.[4] On the other hand, Tolman and coworkers recently observed that the ^{31}P NMR signal of chlorotris(tri-*p*-tolylphosphine)rhodium(I), $RhCl[P(p\text{-tolyl})_3]_3$, in toluene becomes weak on raising temperature with the appearance of other sharp resonances. The new resonances were identical with those of the dimer form of the complex, $[RhCl[P(p\text{-tolyl})_3]_2]_2$, which was prepared independently.[5,6] Thus it was concluded that $RhCl(PPh_3)_3$ reversibly dimerized according to

$$2RhClL_3 \rightleftarrows [RhClL_2]_2 + 2L. \qquad (2)$$

Tolman and coworkers determined the dimerization constant of Eq. 2, K_{dimer}, using the same results of the electronic spectra as obtained by Halpern *et al.*; $K_{dimer} = (3.3 \pm 0.4) \times 10^{-4}$ M in benzene.[6] Although ^{31}P NMR spectra unambiguously showed the reversible interconversion between a monomer and a dimer, a number of kinetic investigations on the catalytic actions of the complexes still suggests the presence of the intermediate, $RhClL_2$.[1] The present work describes the kinetics of the monomer-dimer equilibrium in benzene with the purpose to settle down the problems concerning the origin of the intermediate complex, $RhClL_2$.

Experimental

$RhCl(PPh_3)_3$ was prepared in the usual manner from $RhCl_3 \cdot 3H_2O$ and PPh_3.[1] Found: C, 70.12; H, 4.79; Cl, 3.94%. Calcd for $C_{54}H_{45}ClP_3Rh$: C, 70.10; H, 4.90; Cl, 3.83%. PPh_3 was recrystallized from ethanol. Reagent grade benzene was distilled. The solution was prepared by dissolving $RhCl(PPh_3)_3$ and PPh_3 under vacuum after rigorously excluding oxygen from solvents.

The absorbance of $RhCl(PPh_3)_3$ in benzene was measured by a Hitachi EPS-3T recording spectrophotometer. Ten ml of a PPh_3 solution (9.64×10^{-3} M) was added gradually to 10 ml of a $RhCl(PPh_3)_3$ solution (5.16×10^{-4} M). Equilibrium constant based on the dimerization equilibrium was calculated from the absorbance change at 430 nm. Equilibrium shift due to dilution was so small that it could be neglected.

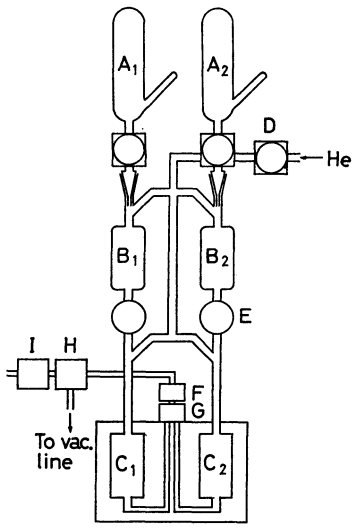

Fig. 1. Schematic diagram of the stopped-flow apparatus. A, B, and C, reservoir; D, Teflon stopcock; E, greaseless valve; F, cell; G, mixing chamber; H, three-way tap; I, air valve.

Kinetic measurements were made using a Union Giken RA 102 stopped-flow apparatus. The mixing part of the apparatus is made of glass and Teflon (Fig. 1). The samples were dissolved in (A) under vacuum. After filled with He gas, (A) was mounted on the body. The body was evacuated and the samples were dropped into (B). After raising the He gas pressure up to *ca.* 2 kg/cm^2, the samples were dropped into (C). The flow was started by opening the air valve. The flow period is about 40 ms. The reaction was followed spectrophotometrically, using a quartz cell of 2 mm optical path. The nominal purity of He gas is 99.8%, thus the effect of O_2 was negligibly small.

Results and Discussion

The variation of the absorbance at 430 nm by the addition of PPh_3 to a $RhClL_3$ solution is shown in Fig. 2. The dissociation equilibrium and the dimerization equilibrium could not be distinguished only from this result.[6] But from the reasons mentioned in the

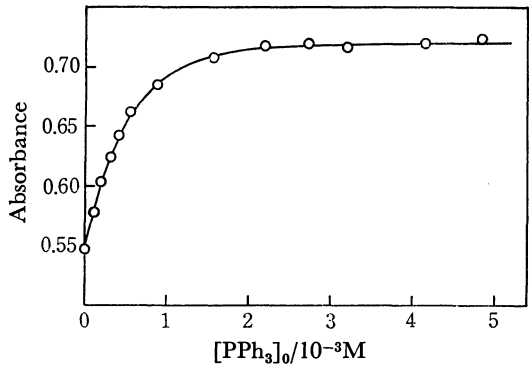

Fig. 2. Effect of added PPh_3 on the absorbance at 430 nm of a 5.2×10^{-4} M $RhCl(PPh_3)_3$ solution in benzene. 20 °C.

introduction, the dimerization equilibrium is considered to be more likely. Assuming equilibrium (2), Eq. 3 is obtained

$$K_{dimer} = [(RhClL_2)_2][L]^2/[RhClL_3]^2 = \frac{(A_\infty - A)\{[L]_0^2\Delta\varepsilon + (A_\infty - A)\}^2}{2\Delta\varepsilon\left\{A - A_\infty\left(1-\frac{\Delta\varepsilon}{\varepsilon_1}\right)\right\}^2} \quad (3)$$

where A is the absorbance, A_∞ the limiting absorbance at high PPh_3 concentrations, ε_1 and ε_2 are the extinction coefficients of $RhClL_3$ and $(RhClL_2)_2$, respectivery, $\Delta\varepsilon=\varepsilon_1-(1/2)\varepsilon_2$ and $[L]_0$ is the concentration of added PPh_3. The value of ε_1 was calculated from $\varepsilon_1 = A_\infty/[RhClL_3]_0$; $\varepsilon_1=1.4\times10^3$ 1 mol^{-1} cm^{-1}. K_{dimer} and $\Delta\varepsilon$ were determined using the curve-fitting method; $K_{dimer}=9\times10^{-5}$ M, $\varepsilon\Delta=7.1\times10^2$ 1 mol^{-1} cm^{-1} and $\varepsilon_2=2(\varepsilon_1-\Delta\varepsilon)=1.4\times10^3$ 1 mol^{-1} cm^{-1}. K_{dimer} is of the same order of magnitude as obtained by Tolman *et al.* $((3.3\pm0.4)\times10^{-4}$ M).[6]

When $RhCl(PPh_3)_3$ and PPh_3 are mixed, the time-course of the absorbance change at 430 nm gives a single exponential curve. The rate of the absorbance change at 430 nm is related to the decomposition rate of the dimer as below.

$$A_{430} = \varepsilon_1[RhClL_3] + \varepsilon_2[(RhClL_2)_2] = \varepsilon_1[RhClL_3]_0 - (2\varepsilon_1-\varepsilon_2)[(RhClL_2)_2] = -2\Delta\varepsilon[(RhClL_2)_2] + \text{const.}$$

Thus,

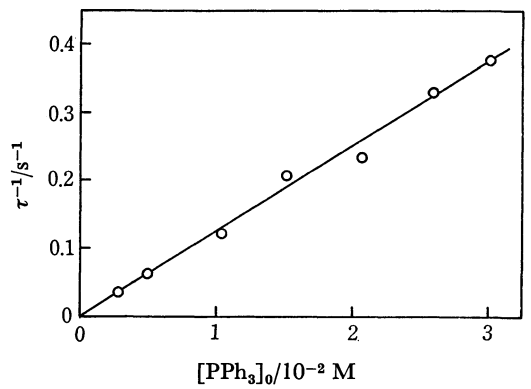

Fig. 3. The dependence of the decomposition rate of a dimer on the concentration of added PPh_3. $[RhCl(PPh_3)_3]_0=5.0\times10^{-4}$ M, at 430 nm and 20 °C.

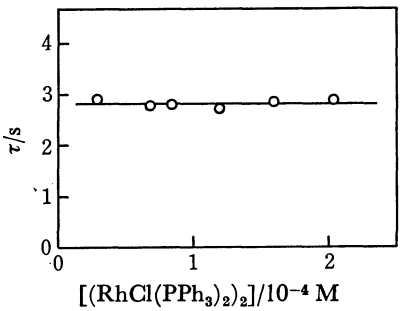

Fig. 4. The dependence of the decomposition rate of a dimer on the initial concentration of $[RhCl(PPh_3)_2]_2$. $[PPh_3]_{add}=3.0\times10^{-2}$ M, at 430 nm and 20 °C.

$$\frac{dA_{430}}{dt} = -2\frac{d[(RhClL_2)_2]}{dt}.$$

Figure 3 shows the dependence of the decomposition rate on the concentration of added PPh_3. Figure 4 shows the dependence of the decomposition rate on the concentration of a dimer. It shows the first-order dependence of the rate on $[RhCl(PPh_3)_2]_2$. Summarizing the above results, the decomposition rate is expressed by Eq. 4.

$$-\frac{d[(RhClL_2)_2]}{dt} = k[(RhClL_2)_2][L] \quad (4)$$

When the solution containing the equilibrium concentrations of a monomer and a dimer is diluted by pure benzene, the equilibrium (2) shifts to the right-hand side. Therefore the formation of a dimer can be followed by mixing the equilibrium solution with pure benzene. Figure 5 shows the dependence

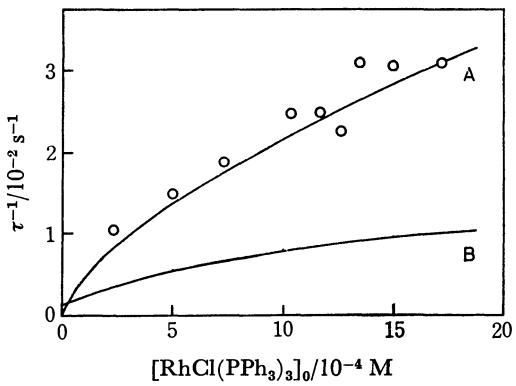

Fig. 5. The dependence of the reciprocal of the relaxation time for dilution experiments on the total concentration of $RhCl(PPh_3)_3$. 20 °C.
Solid lines show calculated curves; A from Eq. 6 and B from dissociation mechanism.

of the formation rate of a dimer on the concentration of added PPh_3. It shows that the formation rate of a dimer increases with the concentration of $RhCl(PPh_3)_3$. Equation 4 suggests that the rate-determining step in the dimer decomposition is the first attack by PPh_3 on a dimer. Thus the following mechanism is proposed in interpreting the present kinetic results:

$$2RhClL_3 \overset{K_1}{\rightleftharpoons} RhClL_2 + RhClL_3 + L \overset{k_2}{\underset{k_{-2}}{\rightleftharpoons}} (RhClL_2)_2 + 2L \quad (5)$$

The above mechanism assumes that the dissociation reaction (1) is present as a pre-equilibrium of the dimer formation. The rate of the concentration change of a dimer is given by Eq. 6.

$$\frac{d[(RhClL_2)_2]}{dt} = k_2[RhClL_3][RhClL_2] - k_{-2}[(RhClL_2)_2] \times \{[L]_0 + [RhClL_2] + 2[(RhClL_2)_2]\} \quad (6)$$

where $[L]_0$ is the added PPh_3 concentration. For the decomposition experiments $[L]_0$ is so large that the second term in Eq. 6 is predominant. That is,

$$\frac{d[(RhClL_2)_2]}{dt} = -k_{-2}[L]_0[(RhClL_2)_2]$$

$$\tau^{-1} = [L]_0 k_{-2}$$

This coincides with Eq. 4, leading to $k_{-2}=k=12\ M^{-1}\ s^{-1}$. As for the dilution experiments $[L]_0$ is zero, and Eq. 6 is modified to Eq. 7.

$$\frac{d[(RhClL_2)_2]}{dt} = k_2[RhClL_3][RhClL_2] - k_{-2}[(RhClL_2)_2] \times \{[RhClL_2] + 2[(RhClL_2)_2]\} \quad (7)$$

Applying the approximation of the vicinity of the equilibrium to each species, the pseudo-first-order rate constant for the rate of the concentration change of a dimer is given by

$$\frac{d\Delta[(RhClL_2)_2]}{dt} = -\tau^{-1}\Delta[(RhClL_2)_2]$$

where $\Delta[\ ]$ is the concentration change at dilution and τ^{-1} is expressed as below.

$$\tau^{-1} = \frac{[RhClL_3]_e\{[RhClL_3]_e + 4[(RhClL_2)_2]_e\}}{2[(RhClL_2)_2]_e^2} K_1 k_2 + 4[(RhClL_2)_2]_e k_{-2} \quad (8)$$

where $[\ ]_e$ denotes the equilibrium concentration of each species and $K_1=k_1/k_{-1}$. The value of τ^{-1} is calculated as a function of $[RhCl(PPh_3)_3]_0$, using Eq. 8. A solid curve in Fig. 5 is a calculated one, showing that Eq. 8 predicts the observed dependence of the rate on $[RhCl(PPh_3)_3]_0$ satisfactorily. Therefore, it is concluded that reaction mechanism (5) describes the monomer-dimer equilibrium of the complexes correctly. The present mechanism implies that an intermediate $RhClL_2$ is produced rapidly in a pre-equilibrium step leading to the dimer formation.

The present work was supported by the grant-in-aid for Scientific Research from the Ministry of Education.

Application of the Zone Melting Technique to Metal Chelate Systems. XII.[1] Computer-assisted Consideration on the Intermittent Zone Melting

Isao YOSHIDA, Hiroshi KOBAYASHI, and Keihei UENO[2]

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 13, 1976)

The solute distribution profile on a columned charge of length L after m-cycles of the intermittent zone melting with j zones of length l, was computed for a range of distribution coefficient, k. The effects of j, l and k upon the separation efficiencies by this method were investigated in terms of the fractional length, α, which was refined to an required purity level, γ, in a limited number of m, and the fractional ratio, σ, of a solute amount which was concentrated into a limited portion of a fractional column length, β. The intermittent method is superior in respect to the separation efficiencies, α as well as σ, over the usual method, if a columned charge was zone-melted with the same number of zones of the same length at the same zone-travelling speed. Results of theoretical calculation were confirmed on systems of azobenzene in naphthalene and those of some metal acetylacetonates in the beryllium chelate of the same ligand compound.

In usual practices of zone melting, more than one molten zone are produced on a columned charge for the sake of time-economy. Two basic modes are useful in the operation with multiple zones.

The first mode, in which all zones traverse through the charge from one end to another, is called a "normal" mode herein, and has been extensively studied in its theory as well as in its practices.[3-5]

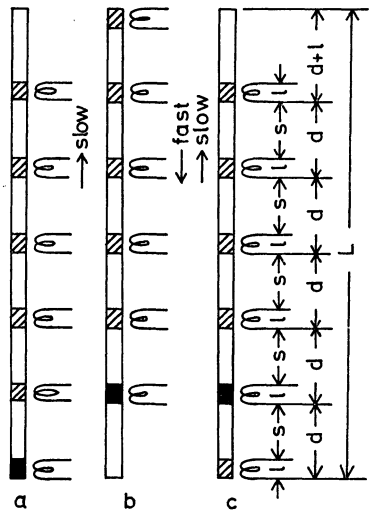

Fig. 1. Reciprocal zone travelling mode in the intermittent zone melting.

The second mode is what is called an "intermittent" method,[6-8] wherein the zones are produced at equal spacings on the charge as shown in Fig. 1(a), and each zone travels in phase to a direction along the charge. After travelling to the distance d between the centers of the nearest neighbor zones, as shown in Fig. 1(b), the heater assembly returns quickly to its initial position as shown in Fig. 1(c). In this cycle, the melt in the first zone is transferred into the second one, meantime the melt initially formed in the second zone transferred into the third one and so forth. In every cycle, the melt in each zone is transferred in a similar manner into its next neighbour in turn.

In the intermittent mode, therefore, the solute distribution is described in terms of the number of reciprocal cycles of the heater assembly, m, and the number of zones produced on a charge, j, in place of the number of zone passes, n, in the normal mode.

In this paper, we consider how the solute distributions vary depending upon m, j and each zone length, l. Also the separation efficiencies are compared between the two modes for systems of a range of distribution coefficient, k.

Results of the theoretical calculation are experimentally confirmed on the system of naphthalene containing azobenzene as a solute and those of bis(acetylacetonato)-beryllium(II), admixed with various metal chelates of the same ligand.

Calculating Procedures of the Solute Distribution. The solute distribution profile on the columned charge of length L after the intermittent zone melting with j zones of l long each, is calculated as follows: The whole columned charge is devided into j divisions of d long except the last one, which is $(d+l)$ long, where d is chosen longer than l. The divisions are assigned with serial numbers, i, in turn from the initial. Since i is defined as

$$i = \{x/d\} + 1$$

and $$L = jd + l, \text{ then } i = 1, 2, 3, \cdots, j,$$

where x is the distance from the initial end along the charge, and $\{x/d\}$ the integer part of the numerical value of x/d. Also variable y is defined as

$$0 \leqq y = (x - \{x/d\}d) = x - (i-1)d \leqq d,$$

where $i=1, 2, 3, \cdots\cdots, (j-1)$,
except the last division, wherein

$$0 \leqq y = x - (j-1)d \leqq d + l$$

In the region of $0 \leqq y \leqq d-l$ on a division, a basic equation in the course of zone melting is represented by Eq. 1 on the basis of mass balance,

$$\frac{dP_{m,i}(y)}{dy} = \frac{k}{l}[C_{m-1,i}(y+l) - P_{m,i}(y)] \qquad (1)$$

where $P_{m,i}(y)$ represents the solute concentration

redistributed into the solid at the position y in the i-th division in the course of m-th cycle, and $C_{m-1,i}(y+l)$ the concentration at $(y+l)$ in the same division after the completion of the $(m-1)$th cycle. The initial conditions for Eq. 1 are

$$P_{m,i}(0) = C_{m-1,i-1}(d)$$

except in the first division, where

$$P_{m,1}(0) = k\int_0^l C_{m-1,1}(y)\mathrm{d}y$$

and $C_{0,i}(y)$ is constant regardless to i and y. In the region of $(d-l)\leqq y\leqq d$ on each division except the j-th one, solute distribution is developed in the basis of distribution profile which has been formed by the preceding zone on the same cycle. A basic equation is, therefore, given by Eq. 2.

$$\frac{\mathrm{d}P_{m,i}(y)}{\mathrm{d}y} = \frac{k}{l}[P_{m,i+1}(y+l-d) - P_{m,i}(y)] \qquad (2)$$

In the corresponding region on the j-th division Eq. 1 is valid, where $C_{m-1,i}(y+l)$ is a constant regardless of y.

When a zone travels to the stroke d, its heating device returns quickly back to the initial position, the molten liquid being left as there it is. Thus after the completion of the m-th cycle, in the region of $0\leqq y\leqq l$ in each division except the first one, $C_{m,i}(y)$ is constant, being equal to the solute concentration of the melt which was equilibrated with the solid at the crystallizing interface therein, and therefore

$$C_{m,i}(y) = P_{m,i-1}(d)/k \qquad (3)$$

where $0\leqq y\leqq l$, $i=2, 3, 4, \cdots\cdots, j$.
Similarly in the region of $d\leqq y\leqq(d+l)$ in the j-th division, the solute concentration in the solid is constant after the completion of m-th cycle as indicated by Eq. 4.

$$C_{m,j}(y) = P_{m,j}(d)/k \qquad (4)$$

When the stroke d is more than twice as long as l, the distribution profile of each division after the completion of the m-th cycle is defined by Eqs. 3 and 5,

$$C_{m,i}(y) = P_{m,i}(y) \qquad (5)$$

in the region of $0\leqq y\leqq l$, and $l\leqq y\leqq d$, respectively, with the exception of the region of $0\leqq y\leqq l$ on the first division and that of $d\leqq y\leqq d+l$ on the j-th one, where the distribution being defined by Eqs. 4 and 5, respectively. If $d\leqq 2l$, then the distribution profile is defined by Eqs. 3 and 5 in the regions of $0\leqq y\leqq l$ and $d-l\leqq y\leqq d$, respectively. Those in the regions of length l at the both ends of the charge are represented by Eqs. 3 and 5 in the similar manner to the above case.

Results and Discussion

Solute Distribution Profile. Some examples of the solute distribution profiles after the intermittent zone melting by use of the six-stage of zones ($j=6$) are shown in Figs. 2, and 3, former of which indicates the effect of cycle number, m for the systems of k equal to 0.4, while the latter the effect of distribution coefficient, k, after 12 cycles of m.

One can readily notice that distribution profiles by the intermittent method are, as a whole, similar to those by the normal method given by Pfann,[3] except

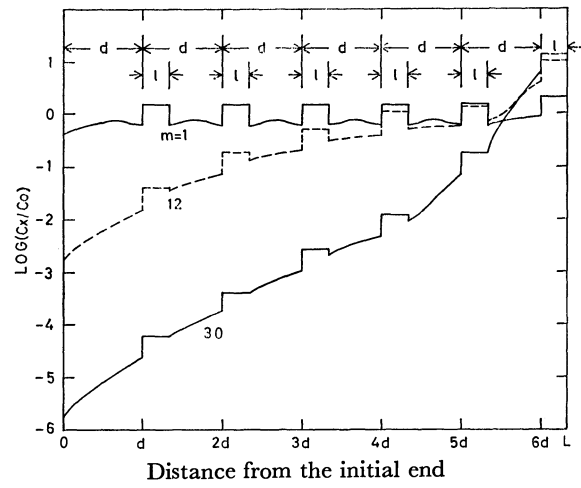

Fig. 2. The solute distributions by the intermittent zone melting after 1, 12, and 30 cyclex of m on the system of $k=0.4$ where $j=6$, $l=0.051L$, and $d=0.16L$. C_x is the solute concentration at x, defined as$C_x=C_{m,i}\{x-(i-1)d\}$ after the m-th cycle.

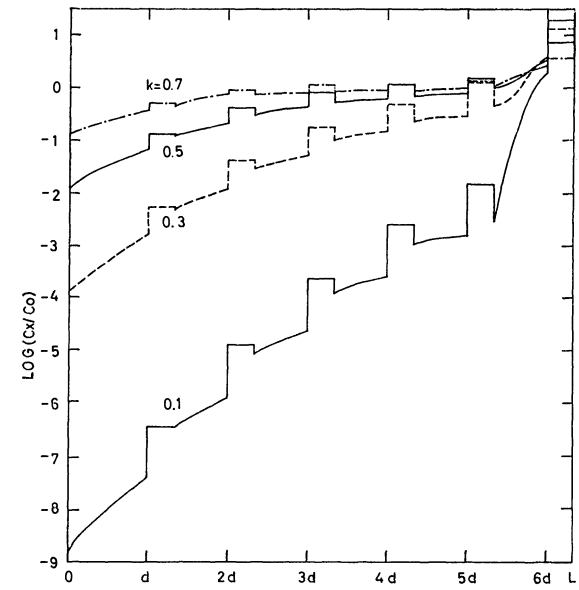

Fig. 3. The solute distributions by the intermittent zone melting after 12 cycles of m on the systems of $k=0.7$, 0.5, 0.3, and 0.1, where $j=6$, $l=0.051$ L, and $d=0.16L$. C_x means the same as in Fig. 2.

protuberant nodes at equal spacings on the curves. The node occurs at the region in which the stroke of a zone overlaps with that of the next neighbor, and the concentration level of a nodal region is equal to that of a molten zone left therein after each cycle. The height or depth of the protuberance decreases with an increase of m, and even in the ultimate stage there remain step-shaped nodes on the distribution curve.

Refining Efficiency. Refining effect can be compared in terms of the length of a refined fraction, of which average concentration decreases to a certain required purity level in a limited period of time. Suppose an α fraction of a columned charge is zone-refined to an average purity, γ, and this value is given as follows:

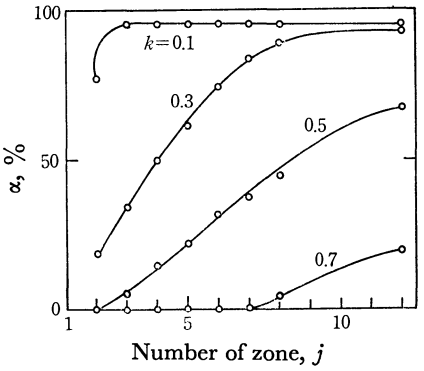

Fig. 4. Relationship between the refining efficiency, α, and the number of zone, j, when $m=2j$, and $l=0.05L$.

$$\gamma = \left[\int_0^{\alpha L} C_m(x)\,dx\right] \Big/ \alpha L C_0 \quad (k<1) \tag{6}$$

$$\gamma = \left[\int_{(1-\alpha)L}^{L} C_m(x)\,dx\right] \Big/ \alpha L C_0 \quad (k>1) \tag{7}$$

where $0 \leqq \alpha \leqq 1$

Figure 4 shows the relationships between the α-value and the zone number, j, when assumed to be $\gamma=0.01$ for a range of k, where m and l are to be $2j$ and $0.05L$, respectively. The higher j-value affords the more efficient refining as expected on the analogy of the effect by the number of zones in the normal mode.

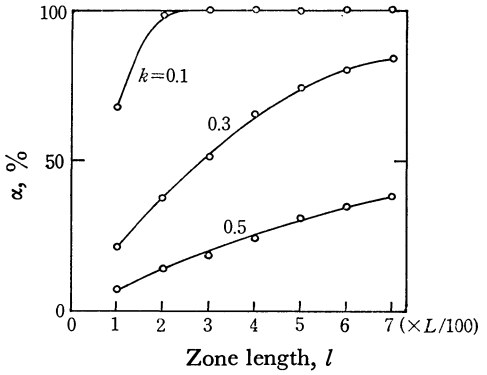

Fig. 5. Relationship between the refining efficiency, α, and zone length, l, when $m=2j$, $j=6$.

On a column of limited length, an increased number of zones leads inevitably to shorter zone-length. However, as shown in Fig. 5, the relationships between α and l indicate that shorter zones do not necessarily give higher refining efficiency in the early stage of the number of m such as in our cases. The column length L is related as $L=l(j+1)+js$, where s means the length of a solid part separating a zone from the next neighbor, and it is practical upon producing more than one zone on a column that the partition solid part is made to be longer than the diameter of the charge for most organic substances. In our case this corresponds to s longer than $0.02L$.

In Fig. 6, α-value after $2j$-cycles of m is plotted against l or j. Although the zone length with which the most efficient refining is attained, varied with k, molten zones of 14—19 stage and 0.03—0.05L long seem to be optimal in general for the range of k.

Concentrating Efficiency. In a similar manner to the

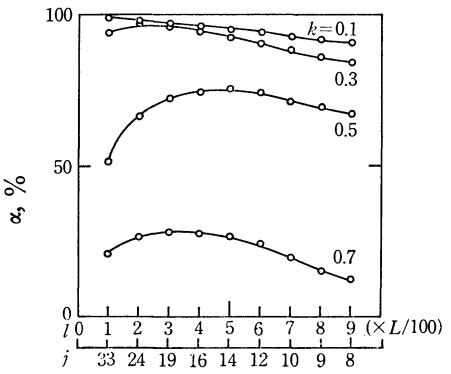

Fig. 6. Dependence of the refining efficiency, α, upon zone length, l, and the number of zone, j, when $m=2j$.

above, concentrating effect can be compared in terms of the fractional amount, σ, of a solute concentrated into the region of length βL as defined in Eqs. 8 and 9:

$$\sigma = \int_{(1-\beta)L}^{L} C_m(x)dx/C_0L \quad (k<1) \tag{8}$$

$$\sigma = \int_0^{\beta L} C_m(x)dx/C_0L \quad (k>1) \tag{9}$$

where $0<\beta<1$.

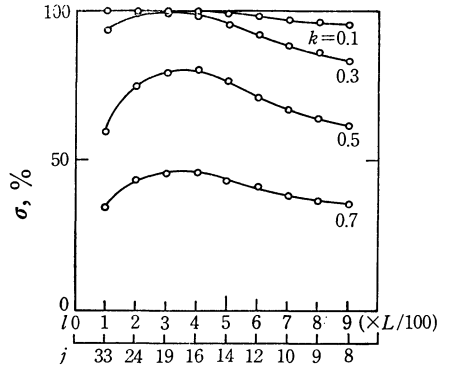

Fig. 7. Dependence of the concentrating efficiency, σ, upon zone length, l, and the number of zone, j, where $m=2j$.

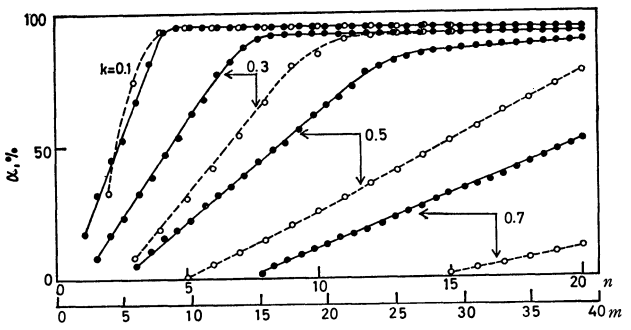
Effects of j and l upon the concentrating efficiency are in a similar manner to those observed in the refining effect, and when s is chosen to be $0.02L$, as shown in Fig. 7, the maximum efficiency is attained with l of $0.03-0.04L$ long and j of between 16 to 19-stage, in accordance with those conditions under which the optimal refining efficiency is afforded.

Comparison of Separation Efficiency between the Normal and Intermittent Zone Melting. In the normal mode the heater assembly arranged as shown in Fig. 1, required the time of $[d(j-1)+L]/v$ to traverse through the whole columned charge, meanwhile j zones pass through, where v is travelling speed of the assembly. An apparent time, t, required for one zone to pass the charge is given as;

$$t = [(j-1)d+jd+l]/jv$$
$$= [(2j-1)d+l]/jv \tag{10}$$

In the intermittent mode, on the other hand, the



Number of zone passes, n, and strokes, m

Fig. 8. The refining effect, α, by the intermittent- (—●—) and normal (---○---) zone melting, where k less than unity, $j=6$, $l=0.051L$, and $d=0.16L$.

time, t', required for travelling to one stroke is

$$t' = d/v \tag{11}$$

When v is chosen to be constant in the both mode, elimination of v from Eqs. 10 and 11 gives

$$\frac{t}{t'} = \frac{(2j-1)d+l}{jd} \tag{12}$$

Using the relation of t/t' the separation efficiencies by the both methods can be compared on the same scale of operation time. Some comparisons in terms of α are illustrated in Fig. 8, in which α is plotted against n and m, when $\gamma=0.1$ for a range of k less than unity.

Evidently one can notice that the intermittent method affords to attain to the ultimate separation (plateau of the curves) much sooner than the normal method. Situation is the same on the systems of k higher than unity. The reverse situation in a system of lower k-value seems practically of no problem, because such a solute can be readily separated from the matrix in any way. Superiority of the former method is retained upon the comparison in terms of the concentrating efficiency, σ.

Intermittent Zone Melting of Azobenzene in Naphthalene and Metal Acetylacetonates in Beryllium Acetylacetonate. Experimental test of the calculations was performed on the systems of azobenzene in naphthalene and some metal acetylacetonates in bis(acetylacetonato)beryllium(II). The length of a zone, l, and of the partition

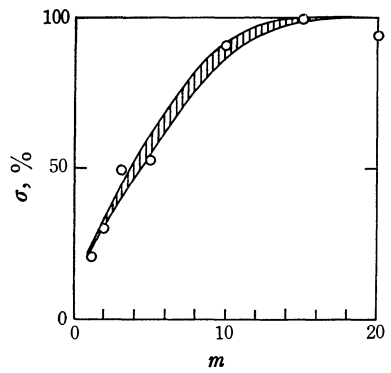


Fig. 9. Concentrated fractions, σ, of azobenzene on a naphthalene column against the number of reciprocal cycles, m. The shaded area indicates the theoretical σ-value for the system of $k=0.22\pm0.02$, when β is chosen to be 0.17.

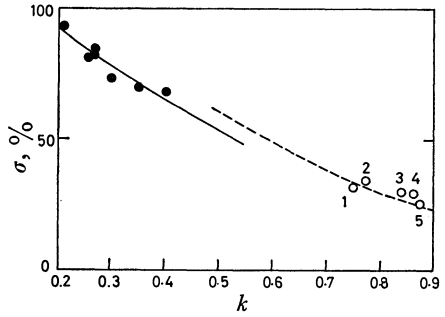

Fig. 10. The σ-value of azobenzene (●) in naphthalene after 10 cycles of m, and those of various metal acetylacetonates (○) in the $Be(AA)_2$ after 12 cycles of m: 1; $Cu(AA)_2$, 2; $Co(AA)_3$, 3; $Al(AA)_3$, 4; $Cr(AA)_3$, and 5; $Fe(AA)_3$, respectively. Dotted- and solid curves indicate the calculated σ-value as the function of k for the corresponding conditions, respectively.

solid part, s, were chosen to be $0.051L$ and $0.107L$, respectively, for procedural convenience. The k-value of azobenzene in naphthalene was determined according to Sorensen,[10] to give 0.22 ± 0.02 under the same operation conditions. The distribution of the solute on a columned charge forms a quite similar curve to those given in Fig. 3. Concentrating effect in terms of σ-value increases with an increased number of m, as shown in Fig. 9, in good agreement with the theoretical calculation for a system of k of 0.22 ± 0.02, which is indicated by a shaded area enclosed with two solid lines.

Figure 10 shows σ-values of the solutes of various k-values, where the effective k of azobenzene could be varied between 0.2 to 0.4 by controlling the stirring effect of molten zones on zone melting as well as the Sorensen's measurement of k-value, and k-values of the metal chelates differ depending upon the kind of the central metal ion. Experimental points stand in good agreement with the respective theoretical curves calculated under the corresponding conditions.

Calculating procedures described above were useful for prediction of experimental results of the intermittent method of zone melting.

Experimental

Materials. Bis(acetylacetonato)beryllium(II) and other metal acetylacetonates were prepared by standard procedures.

Apparatus and Procedures. A high speed zone melting apparatus, operation procedures for the intermittent mode and the determination of k according to Sorensen were essentially same as described previously.[9] A columned charge of 253 mm long and 4 mm in diameter was precessed with 6-stage zones of each 13 mm long, separated with solid parts of each 27 mm long. Zone travelling speed was chosen to be 864 mm/h.

Determination of Solute Concentration. Azobenzene in naphthalene was determined in methanol by use of spectrophotometry[9] on a Hitachi 139 instrument. Metal acetylacetonates were determined, after decomposed in a hot mixture (8 ml) of perchloric acid (3 parts), fuming nitric acid (3 parts) and hydrochloric acid (4 parts), in the form of metal ion by atomic absorption spectrophotometry on a Jarrel-Ash AA-1 instrument.

Computation of the Concentration Profiles. Differential equations (Eqs. 1 and 2) were not solved analytically, and

computed numerically by the Runge-Kutta-Gill method, with the grid spacing of $L/26000$. The computed concentration profile after each intermittent cycle was counterchecked by whether the Simpson's integration of the solute amount over the entire length of the column gave an amount equal to the initial one, where the integration step being equal to the grid spacing. Integral equations (Eqs. 7—10) were also computed in the similar manner. All computations were performed by use of FACOM 230-60 and 230-75 in the Computation Center of Kyushu University.

This work was supported by a grant from the Ministry of Education, to whom the authors are grateful. They are also indebted to Mr. Minato Ookawa for his assistance in FORTRAN programming of the computation.

Isomers of *trans*-Dichlorocobalt(III) Complex with (2*S*,10*S*)-2,10-Diamine-4,8-diazaundecane

Masafumi GOTO,[1] Tadashi MAKINO, Masahiko SABURI, and Sadao YOSHIKAWA[2]

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 15, 1976)

A novel complex, *trans*(*R*,*S*)-[$CoCl_2$((2*S*,10*S*)-Me_2-2,3,2-tet)]ClO_4((2*S*,10*S*)-Me_2-2,3,2-tet=(2*S*,10*S*)-4,8-diazaundecane-2,10-diamine) was prepared from the *trans*(*R*,*R*) isomer in basic methanol. The configuration of the *trans*(*R*,*S*) isomer was determined from the PMR and CD evidences. The equilibrium ratio of the *R*,*S* and *R*,*R* isomers in basic methanol was estimated to be 7.6±0.3: 1 (ΔG_{298}=1.20±0.03 kcal/mol), the former being in preference to the latter.

It has been demonstrated that the linear tetramine 3,7-diazanonane-1,9-diamine, $NH_2(CH_2)_2NH(CH_2)_3NH(CH_2)_2NH_2$ (abbreviated as 2,3,2-tet), tends to coordinate to metal ions with the *trans* geometry more easily than the triethylenetetramine.[3-5] The possible three isomers of *trans*-$CoCl_2$(2,3,2-tet)$^+$ arisen from the difference in the configurations of the asymmetric secondary nitrogen atoms *R*,*S*(*meso*), *R*,*R*, and *S*,*S* have been isolated.[5,7,8] Further, the thermodynamic advantage of the *R*,*S* configuration over the racemic forms (*R*,*R* and *S*,*S*) has been suggested, though any detailed evidences have not been reported yet.[9]

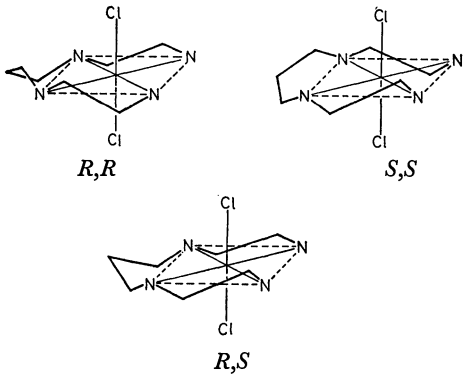

Fig. 1. Possible structures of *trans*-[$CoCl_2$(2,3,2-tet)]$^+$; *R*,*R*, *S*,*S*, and *R*,*S*.

The dominant difference between the *R*,*S* and *R*,*R* (or *S*,*S*) forms consists in the conformation of the central six-membered chelate ring. The chair conformation is adopted in the *R*,*S* form, while the skew-boat conformation in the *R*,*R* and *S*,*S*, as indicated in Fig. 1. The former should be fairly preferred over the latter in a similar manner as in the cyclohexane ring.

Recently, Alexander and coworkers reported some cobalt(III) complexes with (2*S*,10*S*)-4,8-diazaundecane-2,10-diamine (=(2*S*,10*S*)-Me_2-2,3,2-tet[10]), a methyl-substituted derivative of 2,3,2-tet. For the *trans*-dichlorocobalt(III) complex they obtained only one isomer, in which both of the methyl groups adopt the equatorial orientation and the absolute configurations of the secondary N atoms are *R*,*R*.

We have isolated the other *trans*-dichlorocobalt(III) complex of (2*S*,10*S*)-Me_2-2,3,2-tet and assigned the *R*,*S* configuration to it on the proton magnetic resonance (PMR) and other data, the results of which will be reported in the present paper.

Experimental

The ligand (2*S*,10*S*)-Me_2-2,3,2-tet was prepared in a similar way as reported by Harrington, Linke and Alexander,[9] and isolated by distillation. Bp 120—125 °C (4 mmHg).

Preparation of trans-[*$CoCl_2$*((2S,10S)-*Me_2*-2,3,2-tet)]*ClO_4* (*A Mixture of Two Isomers*). (2*S*,10*S*)-Me_2-2,3,2-tet (2.04 g) and $CoCl_2 \cdot 6H_2O$ (2.58 g) were dissolved in 1 M HCl (11 ml) and then water (10 ml) was added. The resultant solution was aerated for 6 h. Concentrated hydrochloric acid (10 ml) was added and the dark wine-red solution was evaporated on a water bath to a volume of 10 ml. To the violet solution was added 60% $HClO_4$ (4 ml), and the green crystals which separated were filtered off after cooling in an ice bath for 1 h, washed with ethanol and ether, and air-dried. Yield, 2.36 g. The product was revealed to be a mixture of two isomers from the PMR measurement.

Preparation of A-β(R,R)-[*$CoCO_3$*((2S,10S)-*Me_2*-2,3,2-tet)]-*$ClO_4 \cdot H_2O$*. The isomeric mixture of *trans*-[$CoCl_2$((2*S*,10*S*)-Me_2-2,3,2-tet)]ClO_4 (0.60 g)was dissolved in 18 ml of water containing 1 ml of 2 M $HClO_4$ with heating and 1.5 g of $NaHCO_3$ were added in small portions. The resultant red solution was concentrated on a water bath to a volume of 10 ml and, then, solid $LiClO_4 \cdot 3H_2O$ (2 g) was added. After cooling wine-red crystals which separated were collected, washed with ethanol and ether, and air-dried. Yield, 0.52 g. Found: C, 28.40; H, 6.29; N, 13.13%. Calcd for [$CoCO_3$-($C_9H_{24}N_4$)]$ClO_4 \cdot H_2O$: C, 28.28; H, 6.17; N, 13.19%.

Preparation of trans(R,R)-[*$CoCl_2$*((2S,10S)-*Me_2*-2,3,2-tet)]-*ClO_4*. *A-β*(*R*,*R*)-[$CoCO_3$((2*S*,10*S*)-Me_2-2,2,2-tet)]-ClO_4 (0.50 g) was added to a mixture of concentrated hydrochloric acid (2 ml) and water (1 ml). After the evolution of carbon dioxide had ceased, 60% $HClO_4$ (2 ml) was added, and the resultant red solution was warmed on a water bath until the separation of green crystals was almost completed. The contents were cooled and the crystals were filtered off, washed with ethanol and ether, and air-dried. Yield, 0.40 g. Found: C, 25.76; H, 5.94; N, 13.32%. Calcd for [$CoCl_2$-($C_9H_{22}N_4$)]ClO_4: C, 25.88; H, 5.80;N, 13.42%.

Preparation of trans(R,S)-[*$CoCl_2$*((2S,10S)-*Me_2*-2,3,2-tet)]-*ClO_4*. *trans*(*R*,*R*)-[$CoCl_2$((2*S*,10*S*)-Me_2-2,3,2-tet)]ClO_4 (0.86 g) was dissolved in 2% 2,6-lutidine in methanol, and the solution was heated under reflux for 2 h. The resultant solution was acidified with methanol saturated with hydrogen chloride gas at room temperature, and then, concentrated to about 10 ml on a rotary evaporator. Solid $LiClO_4$ (2.5 g) was added and the crystals which appeared were filtered off, washed with ethanol and ether, and air-dried. Yield, 0.52 g. A mixture of *trans*(*R*,*S*) and *trans*(*R*,*R*) isomers, thus

obtained, was carefully recrystallized from methanol, and the initial fraction composed of deep green crystals was collected, washed with ethanol and ether, and air-dried. Found: C, 25.74; H, 5.94; N, 13.48%. Calcd for $[CoCl_2(C_9H_{24}N_4)]ClO_4$: C, 25.88; H, 5.80; N, 13.42%.

Measurements. Visible absorption spectra were obtained on a Shimadzu UV-210 spectrophotometer. Circular dichroism spectra were recorded on a JASCO J-20 recording spectropolarimeter. The visible absorption and CD spectra of *trans*-dichloro complexes were obtained in a methanol solution, while the spectra for the carbonato complex was recorded in a aqueous solution. Proton magnetic resonance spectra were obtained on a Hitachi R-20B spectrometer using sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard reference. The spectra of the *trans*-dichloro complexes were obtained in tetradeutetrated methanol immediately after treating with tetraphenylarsonium chloride and filtering the precipitates. The PMR spectrum of the carbonato complex was recorded in deuterium oxide.

Measurements of Isomerization and Equilibrium between the R,R *and* R,S *Isomers of* trans-$CoCl_2((2S,10S)$-Me_2-*2,3,2-tet*$)^+$. A weighed sample (about 15 mg) of *trans*(*R,R*)- or *trans*(*R,S*)-$[CoCl_2((2S,10S)$-Me_2-2,3,2-tet)$]ClO_4$ was dissolved in 8 ml of 2% lutidine in methanol in a 10 ml volumetric flask, and the solution was warmed to 50 °C for 40 min. After cooling to room temperature (25 °C), the solution was acidified by gentle bubbling of dry hydrogen chloride gas. The volume was adjusted to 10 ml by adding methanol and the CD curve of the resultant solution was recorded.

Results and Discussion

Harrington, *et al.* prepared the *trans*(*R,R*)-$[CoCl_2((2S,10S)$-Me_2-2,3,2-tet)$]ClO_4$ from the *Λ-cis-β*-$[CoCl_2((2S,10S)$-Me_2-2,3,2-tet)$]Cl$, which was isolated from the usual air oxidation products by means of cation exchange chromatography technique, and isomerized to the *trans*(*R,R*) in methanol solution.[9] We obtained the *trans*-dichloro complex by adding perchloric acid (60%) directly to a reaction mixture of the air oxidation procedure. The product, thus obtained, was revealed to be an isomeric mixture of two species from the PMR evidence (Fig. 2-a). The overlapped two doublets of unequal intensities were observed in the region of C-methyl resonance (1.3—1.5 ppm).

The isomeric mixture of *trans*-dichloro complex was converted to the carbonato complex, the PMR spectrum of which showed two overlapping methyl doublets (Fig. 3). This indicates that the carbonato complex has no C_2 symmetry axis and is assigned to the *β* topology. The CD curve (Fig. 4) exhibits a dominant positive band in the first absorption band region ($^1A_{1g} \rightarrow {}^1T_{1g}$ (O_h)), demonstrating the *Λ* configuration of the complex.

The *trans*-dichloro complex prepared from the above-mentioned carbonato complex under strongly acidic condition proved to be identical with the *trans*(*R,R*) isomer reported previously.[9] The PMR spectrum shows a single methyl doublet (Fig. 2-b), and coincides with that reported by Alexander *et al.* The CD spectrum is also the same as the curve previously assigned to the *R,R* isomer[9] (Fig. 5). These results indicates that the carbonato complex also adopts the *R,R* configuration with respect to the secondary N atoms, since the conversion from carbonato to *trans*(*R,R*) dichloro complexes should proceed with retention of secondary N configurations under the acidic condition employed.

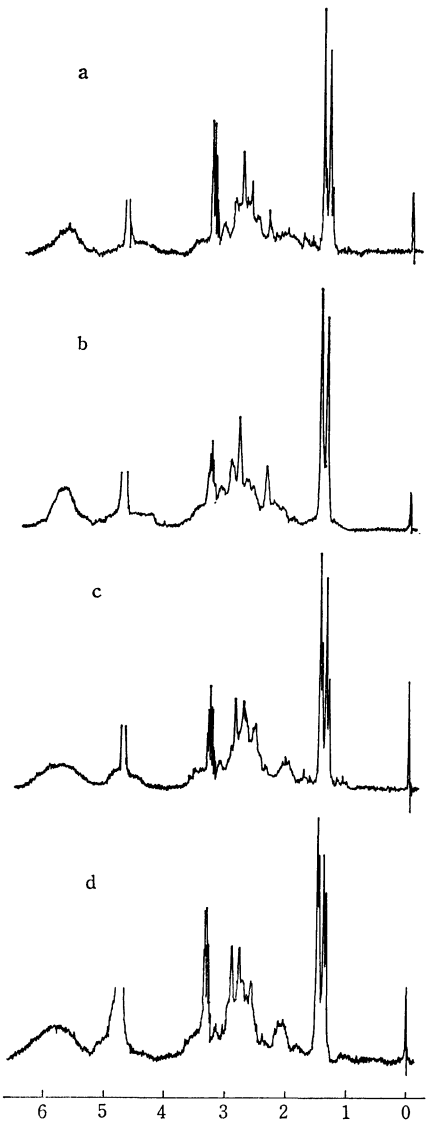

Fig. 2. PMR spectra of *trans*-$[CoCl_2((2S,10S)$-Me_2-2,3,2-tet)$]^+$; (a), a mixture of *R,R* and *R,S* initially obtained: (b), the pure *R,R* isomer; (c), a mixture of *R,R* and *R,S* (*R,R*<*R,S*)) recovered after the equilibration in basic methanol; and (d), the pure *R,S* isomer (in CD_3OD).

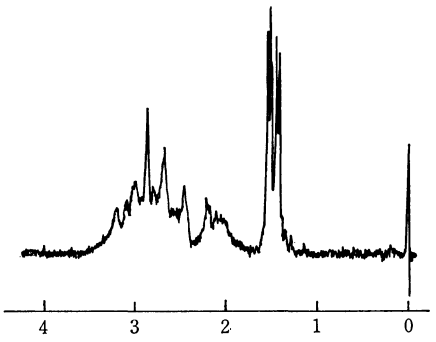

Fig. 3. PMR spectrum of *Λ-β*-$[CoCO_3((2S,10S)$-Me_2-2,3,2-tet)$]^+$ (in D_2O).

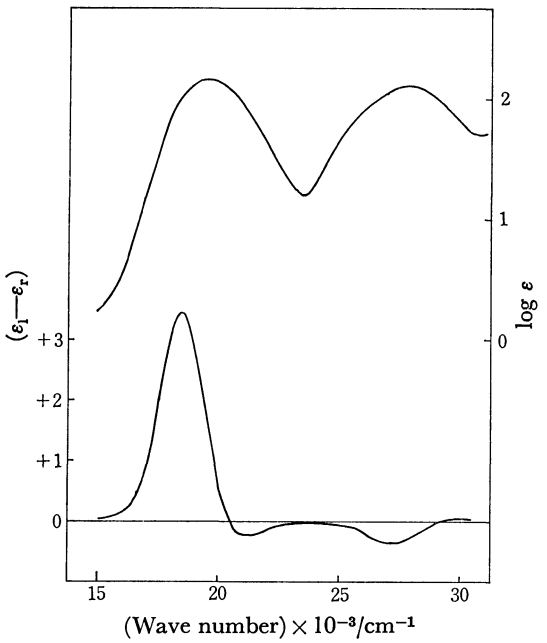

Fig. 4. Visible absorption and CD spectra of Λ-β-[$CoCO_3$((2*S*,10*S*)-Me_2-2,3,2-tet)]ClO_4.

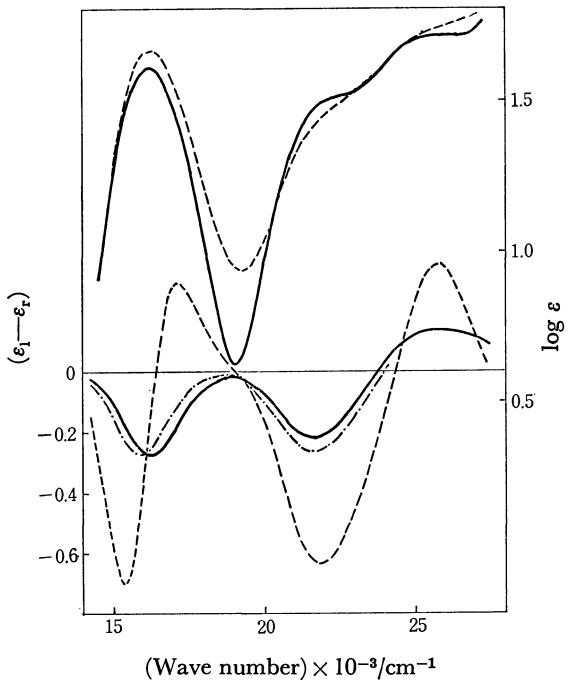

Fig. 5. Visible absorption and CD spectra of *trans(R,R)* (------) and *trans(R,S)* (——) isomers of [$CoCl_2$((2*S*, 10*S*)-Me_2-2,3,2-tet)]$^+$ and CD spectrum of the equilibrated mixture (-·-·-).

It was described that the *trans*(*R*,*R*)-dichloro complex exhibited no evident structural changes in slightly basic methanol solution.[9] We found, however, that the *trans*-dichloro complex obtained directly from an air-oxidation product composed of at least two isomers. So we attempted to isomerize the *trans*(*R*,*R*) form under strongly basic condition such as in 2% 2,6-lutidine in methanol under reflux. The CD curve obtained after the reflux for 2 h was found to be significantly different from the original curve. The *trans*-dichloro complex recovered from the above solution exhibited two methyl doublets with unequal intensities in the PMR spectrum (Fig. 2-c). The *trans*-dichloro isomer different from the *trans*(*R*,*R*) could be purified by carefully repeated recrystallization from methanol as prismatic crystals. The PMR and CD spectra of the present isomer are shown in Figs. 2-d and 5, respectively. The intensities of the two methyl doublets in this PMR can be regarded to be practically equivalent.

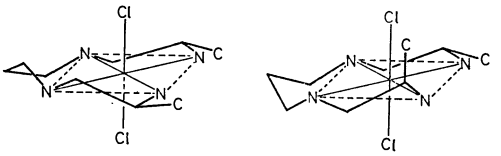

Fig. 6. Possible structures of *trans*-[$CoCl_2$((2*S*, 10*S*)-Me_2-2,3,2-tet)]$^+$: (a) *trans(R,R)*, and (b) *trans(R,S)*.

It is reasonable to consider that the possible structures for the *trans*-$CoCl_2$((2*S*,10*S*)-Me_2-2,3,2-tet)$^+$ ion are those depicted in Fig. 6. The structure shown in Fig. 6-a corresponds to the *trans*(*R*,*R*) configuration, which has the central six-membered chelate ring in the skew-boat conformation and the five-membered rings in the same δ conformation, and further two equivalent methyl groups oriented equatorially. The PMR and CD spectra given in Figs. 2 and 5 for *trans*(*R*,*R*) isomer are in accord with these structural features as described by Harrington, Linke, and Alexander.[9]

The other structure for the *trans*-dichloro complex (Fig. 6-b), which will be designated as *trans*(*R*,*S*) because the secondary nitrogen centers adopt the opposite configuration to each other, has the six-membered ring in the chair conformation and the five-membered rings in the conformation of opposite chirality. One of the methyl groups must have an axial position, while the other in an equatorial position. The PMR spectrum for *trans*(*R*,*S*) isomer should give rise to two methyl doublets of the equal intensities, since the axial methyl group will exhibit, in principle, a different chemical shift from that of the equatorial methyl group. The PMR spectrum of the novel *trans* isomer (Fig. 2-d) is in accord with the requirements from *trans*(*R*,*S*) geometry.

For the *trans*(*R*,*S*) isomer the conformational effects will not contribute to the optical activity for the first approximation because the five-membered rings has the opposite conformation. The vicinal effects from the two methyl groups should primarily be appeared in the CD curve. It is expected from the results on the CD of *trans*-[$CoCl_2(N)_4$]$^+$ type complexes with diamines[11] or tetramines[12] that the equatorial methyl group shows a relatively small vicinal effect. The vicinal effect from an axial methyl group which has not been estimated yet would not be much intense compared with that from the equatorial methyl group.

The CD curve of new *trans*-[$CoCl_2$((2*S*,10*S*)-Me_2-2,3,2-tet)]ClO_4 shown in Fig. 5 is fairly different from and apparently less intense than that of the *trans*(*R*,*R*) isomer. It will be reasonable that the *trans*(*R*,*S*) isomer of $CoCl_2$((2*S*,10*S*)-Me_2-2,3,2-tet)$^+$ gives such a CD

spectrum as indicated above. Consequently, we assign the novel *trans*-dichloro complex to the *R,S* configuration on the ground of characteristics of the PMR and CD data.

The reaction condition employed for obtaining the *trans*(*R,S*) isomer from the *trans*(*R,R*) isomer should promote the reverse change (*R,S*→*R,R*), and establish ultimately an equilibrium between the isomers. The CD curves of both of the *trans*-dichloro complexes obtained after heating under reflux for 1 h in a 2% 2,6-lutidine methanol solution found to agree with each other within the experimental error. The CD curve of the equilibrium mixture at room temperature shown in Fig. 5 crosses at the intersections of the CD curves for the *R,R* and the *R,S* isomer except in the higher energy region where the influences due to 2,6-lutidine are considered to occur. Assuming that only the two isomers, *R,R* and *R,S*, are equilibrated under the above condition, the ratio of these isomers was estimated to be 7.6 ± 0.3: 1 ($\Delta G = -1.20\pm0.03$ kcal/mol) in favor of the *R,S* isomer.

It is very interesting that the *trans*(*R,S*) isomer having the six-membered ring in the chair conformation and one of the methyl groups in an axial location is fairly stable than the *trans*(*R,R*) having the six-membered ring in the skew-boat conformation and both of the methyl groups in the equatorial situation. The energetic advantage of the chair conformation over the skew-boat conformation with respect to the six-membered ring exceeds significantly the disadvantage brought about by an axial methyl group.

Therefore, the most stable configuration for (2*S*,10*S*)-Me_2-2,3,2-tet complexes should be the *Λ-cis-β* geometry, in which the six-membered chelate ring adopts the chair conformation and both of the methyl groups can occupy equatorial positions. This is in accord with the observation that the dominant isomer obtained from the air-oxidation products by means of ion-exchange chromatography is the *Λ-cis-β* dichloro complex.[9]

Recently, an X-ray crystallographic study have demonstrated that the six-membered ring adopts the chair conformation in the *Λ-β*-[Coox(5*R*,7*R*)-Me_2-2,3,2-tet)]$^+$ ion, even though one of the methyl groups occupies an axial orientation at the six-membered ring.[13] On these findings we conclude that metal complexes coordinating methyl-substituted 2,3,2-tet derivatives will often give rise to isomers having an axial methyl group due to the higher preference of the chair conformation for the six-membered ring.

10) Alexander *et al.* abbreviated the ligand 4,8-diazaundecane-2,10-diamine simply as diMe-2,3,2-tet. We consider, however, that it is necessary to designate the positions of the methyl groups on the ligand skeleton for the sake of avoiding the confusions, since the other ligands such as (4*R*,6*R*)-4,6-dimethyl-3,7-diazanonane-1,9-diamine can be also abbreviated as diMe-2,3,2-tet. For convenience the rules we employed for the triethylenetetramine series are introduced in this report to the methyl-substituted 2,3,2-tet ligands regarding the 2,3,2-tet chain as 1,4,8,11-tetraazaundecane as in the case of 5-methyl derivatives: P. W. R. Corfield, J. C. Dabrowiak, and E. S. Gore, *Inorg. Chem.*, **12**, 1734 (1973). The following abbreviations will be used: (5*R*)-Me-2,3,2-tet (=(5*R*)-5-methyl-1,4,8,11-tetraazaundecane or (4*R*)-4-methyl-3,7-diazanonane-1,9-diamine), (5*R*,7*R*)-Me_2-2,3,2-tet (=(4*R*,6*R*)-1,9-diamino-4,6-dimethyl-3,7-diazanonane).

Precise Measurement of Ionic Diffusion Coefficients with a Hanging Mercury Drop Electrode

Haruko IKEUCHI, Yoshimi FUJITA(née AIHARA), Kyoichi IWAI,* and Gen P. SATÔ

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received April 19, 1976)

The diffusion coefficient and the product of the charge number of electrode reaction n and the concentration of depolarizer c can be determined simultaneously from the time dependence of the diffusion limiting current observed at a spherical electrode of known size. Nearly ideal spherical diffusion was realized by means of a mercury drop electrode hanging from the tip of a fine glass capillary (0.2 mm, outer diameter) which was kept at constant size by adjusting the mercury head. The diffusion coefficients of thallium(I), cadmium(II), bismuth(III), and hexamminecobalt(III) ions in 0.1 mol dm^{-3} potassium nitrate aqueous solutions were determined at 25 °C. The experimental nc values agreed with the corresponding known values within 3%.

The present paper deals with a method for determining the diffusion coefficients of ions by using a mercury drop electrode hanging from a thin-walled capillary.

The dropping mercury electrode (DME) has been widely used for measuring the ionic diffusion coefficients in solutions containing excess indifferent electrolytes.[1-6] Ikeuchi[4] measured the diffusion coefficients of amminenitrocobalt(III) complexes in potassium nitrate solutions by means of the instantaneous diffusion current observed at the first drops.[7] The diffusion coefficients in the same systems were measured also by the diaphragm cell method.[8] The two sets of data did not agree with each other except for triamminetrinitrocobalt(III). Similar disagreement has been reported in the cases of hydrogen ion[6] and cadmium ion.[9] Since the reason for such a discrepancy was not clear, further investigation was required to know whether the discrepancy reflected a mere experimental artefact or an essential difference in the physical nature of the diffusion processes in the electrochemical and non-electrochemical methods.

For this purpose, the mass transfer process at DME is not simple enough.[10] The effects of depletion[11] and shielding[12] can be circumvented or reduced by the first-drop method[13,7] and by the use of a thin-walled capillary,[3,7] respectively; but streaming of solution caused by the continuously falling drops is inevitable. The polarographic maximum often interferes and necessitates the addition of surfactants, which may alter the diffusion current in an unpredictable way.[1] Besides these experimental complications, the convective diffusion to DME itself is an involved mathematical problem. In spite of considerable theoretical and experimental work devoted to the subject, no general agreement on the details of the mathematical expression for the diffusion current-time relationship of DME has yet been established[10]; different values of diffusion coefficients may be calculated from the same experimental data by using different equations.

With a stationary, hanging mercury drop electrode (HMDE) the situation is much less complicated: the ideal diffusion current-time relationship is strictly described by a simple equation, no polarographic maximum interferes, no streaming of the bulk of solution is caused, and HMDE is as reproducible as DME. A planar electrode may be simpler and, when properly positioned, more stable than HMDE against disturbance due to the convection caused by the density gradient developed in the diffusion layer. However, the spherical electrode has an interesting feature, described below, which is not shared by the planar electrode.

Laitinen and Kolthoff[14] first examined the diffusion current at a spherical platinum electrode. The theoretical equation for spherical diffusion was verified by Shain and Martin[15] with a Gerischer type HMDE. They pointed out the influence of shielding by the glass tip supporting the mercury drop. Kao and Chang[16] made an extensive study on the diffusion at a mercury drop electrode hanging from a fine support and showed that the equation was followed for as long as 20 min in certain particular systems in which the convection due to the density change was expected to be very small. Recently Kojima and Bard[17] also used a fine-tipped Gerischer type HMDE in a.c. polarographic study.

The magnitude of the current $|I_d|$ at time t controlled by the ideal spherical diffusion is given by the following equation:[18,10]

$$|I_d| = FSncD[r^{-1} + (\pi Dt)^{-1/2}] \quad (1)$$

with

$$S = 4\pi r^2, \quad (2)$$

where r is the radius of the electrode; F, the Faraday constant; n, the charge number of the electrode reaction; c and D, the bulk concentration and diffusion coefficient of the depolarizer, respectively. The plot of $|I_d|$ against $t^{-1/2}$ results in a straight line whose intercept A and slope B are given by

$$A = 4\pi FrncD \quad (3)$$

and

$$B = 4\pi^{1/2}Fr^2ncD^{1/2}. \quad (4)$$

If r is known, D and nc can be determined from a single $|I_d|-t$ curve by solving Eqs. 3 and 4. This situation, essentially different from that in the case of the diffusion at DME and planar electrode where these quantities appear always as product $ncD^{1/2}$, implies an interesting application of HMDE.

When n is known or estimated, c and D can be obtained. Hence, the measurement of an $|I_d|-t$ curve

* Present address: Yamato Scientific Co., Ltd., Nihonbashihoncho, Chuo-ku, Tokyo 103.

at HMDE of known size enables one to determine the diffusion coefficient of the species whose concentration is uncertain, or to determine its concentration without referring to any standard solution. Alternatively, n and D can be obtained when c is known, thereby offering a method for evaluating the n values under polarographic conditions. This will be particularly useful in those cases in which the conventional coulometric method fails because of complications due to reactions subsequent to the charge transfer.

The values of n and D can be determined independently by a suitable combination of electrochemical methods; *e.g.*, rotating disk voltammetry and chronopotentiometry,[19] and/or chronoamperometry and stationary electrode voltammetry.[20] However, such a procedure is technically complicated or often limited by the reversibility of the system.

Simultaneous determination of n and D is possible by using a hemispherical[21] or a cylindrical[22] electrode. These methods, however, involve the difficulties inherent to construction of a solid electrode of precise geometry with known surface area. Furthermore, the diffusion current-time relationship at a cylindrical electrode of finite length is too complicated to be described by any simple equation. The usefulness of these electrodes for the accurate determination of diffusion coefficients seems questionable.

In order to realize the ideal spherical diffusion at HMDE, the mercury drop must be small enough to remain practically spherical, and the disturbance of the diffusion layer due to convection and to the shielding by the drop support must be minimized. In other words, the support should be as fine as possible, and the diffusion current should be measured within a relatively short time before the diffusion layer becomes disturbed. These conditions can be satisfied approximately by adequate experimental arrangement.

In the present experiment, the $|I_d|-t$ curves of depolarizer of known n and c were measured, and r was determined from the mass of the mercury drop. By means of Eqs. 3 and 4, D and $(nc)_{obsd}$ were calculated. The value of $(nc)_{obsd}$ should agree with the product of the known n and c. This fact, together with the linearity of the experimental $|I_d|-t^{-1/2}$ plot, provides a test of the extent to which the data are consistent with Eq. 1.

Experimental

Electrode System and Electrolytic Cell. The HMDE and the electrolytic cell system are shown schematically in Fig. 1. The electrode capillary was constructed from a glass capillary, 0.3 mm and 7 mm in inner and outer diameters, respectively. A piece of the capillary was drawn so that a fine capillary tip was formed at one end. The tip was cut at a suitable length. The cut end must be sharp and rectangular when examined under a microscope. A length of the bore of the upper part was constricted in order to provide a suitable slow flow of mercury.[23] A glass sheath with several holes was placed around the fine part. The sheath not only protected the fragile fine tip but also served to reduce mechanical disturbance of the solution in the vicinity of the mercury drop.[3] The mercury reservoir was held by a clamp which could move smoothly between two adjustable stoppers of a heavy stand column. When the electrode was not in use, a minimum

mercury head was applied to keep mercury flowing in order to avoid possible clogging. The characteristics of a typical capillary were as follows: radii of the capillary tip, 0.12 mm (outer) and 0.05 mm (inner); mercury flow rate, 6×10^{-2} mg·s^{-1} at mercury head of 40 cm.

The electrolytic cell (capacity, about 100 cm^3) was all of Pyrex. The counter electrode was a spiral of platinum wire, and the reference electrode was a saturated calomel electrode (SCE), which was connected to the electrolytic solution by means of a potassium nitrate bridge with an agar plug. The cell was placed in a thermostated water bath, the temperature of which was checked with a standard mecury thermometer. The temperature fluctuation in the cell solution was about $\pm$0.01 °C.

Instrumental. A potentiostat with a current follower was used. The output signal of the current follower was recorded by a high speed pen recorder (Riken Denshi Co. Ltd., SP-G3; response time, 0.2 s for full scale of 25 cm with auxiliary pen for recording reference time signal). The chart speed (16 mm s^{-1}) was checked by recording a reference signal (1 Hz) generated from a quartz crystal oscillator. The triangular wave generator for linear-sweep voltammetry was constructed according to Tsuji and Takahashi.[24]

Reagents. The purity of mercury was essential: traces of impurity tended to deposit on the constricted part of the capillary and eventually cause clogging. Mercury for polarographic use was repeatedly washed with 3—5% nitric acid and then with distilled water. After being dried, it was distilled under reduced pressure in an all-quartz distillator: the first two thirds of distillate was collected for use.

Thallium(I) nitrate (>99%: Yamada Kagaku Yakuhin, K. K.) was recrystallized from distilled water and dried in a

vacuum oven at 50 °C. Hexamminecobalt(III) nitrate was prepared according to the usual method,[25] recrystallized from dilute acetic acid, and dried over silica gel. The stock solution was prepared by dissolving a weighed amount of the nitrate. Cadmium(II) nitrate stock solution (10.59_3 mol m^{-3}) was prepared by dissolving 0.5953_5 g of the metal (99.999 % Wako Pure Chemical Industries, Ltd.) in reagent grade nitric acid and by diluting the solution to 500 cm^3. Bismuth-(III) nitrate stock solution (5.117_2 mol m^{-3}) was prepared similarly, from 0.5347_0 g of the metal (99.999%, Wako Pure Chemical Industries, Ltd.); but it contained about 0.7 mol dm^{-3} nitric acid in order to prevent hydrolysis. Potassium nitrate (reagent grade) was recrystallized from distilled water. The water used throughout was deionized water distilled in an all glass apparatus (Kinoshita Rikakogyo Co., Ltd., Model KR-70-AN). All the volumetric operations were performed in a water bath controlled at (25±0.1) °C.

Procedures. The hanging mercury drop was formed by letting a new drop grow at a fixed mercury head h_1 for a certain duration of time and then decreasing the head to h_0, the head necessary to balance the back pressure of the mercury drop. The mercury head h_1 was so chosen that a mercury drop 0.4—0.8 mm in diameter was produced in 5—10 min. The value of h_0 was determined for each capillary. The flow rates of mercury m were measured at several different mercury heads. By extrapolating the m-h plot to $m=0$, h_0 was estimated approximately. Then it was adjusted until the peak current of the linear-sweep voltammogram remained constant for 30 min. Once h_1 and h_0 were determined, the two stoppers on the supporting stand were fixed to these positions so that h_1 and h_0 were reproduced.

The cell solution was deoxygenated with nitrogen gas which had been passed through vanadium(II) sulfate solution and then distilled water; during the measurement nitrogen gas was flushed over the cell solution.

The diffusion current was recorded as follows. After a new mercury drop was formed, the lowest positive potential at which practically no electrolysis occurred was applied on it. Then the potential was switched to that at which the diffusion current was measured. These potentials were found by inspecting the d.c. polarogram of the depolarizer in question. After the current-time curve was recorded, the mercury drop was detached and taken out by means of a glass cup and rod (Figs. 1, 7, and 8). After rinsing and drying, it was weighed on a semimicro-balance. The radius r of the drop was calculated by assuming sphericity. The recorded current-time curve was corrected for the residual current, which was measured by repeating the above procedure with the corresponding supporting electrolyte solution.

The value of $|I_d|$ was plotted against $t^{-1/2}$, and A and B were calculated by the least squares method from the linear portion of the plot; deviating points (*vide infra*) were omitted. By inserting the value of r into Eqs. 3 and 4, D and $(nc)_{obs}$ were determined.

Results and Discussion

Some typical $|I_d|-t$ curves and the corresponding $|I_d|-t^{-1/2}$ plots are shown in Figs. 2 and 3, respectively. Two types of deviation are seen: one at shorter times and the other at longer times. The former, observed at $t<1.5$ s in all cases, was caused by the delay in response of the current measuring system, mainly of the recorder. The latter was dependent on the kind and temperature of the sample solution; for example, at 25 °C it began to appear at about 10 s for thallium ion

(1 mol m^{-3}) and at about 17 s for cadmium and bismuth ions. The values for the thickness of the Nernst diffusion layer** at these time points fell around 0.15 mm, suggesting that the deviation was due to convection of the solution around the electrode: as the electrolysis proceeds, the diffusion layer thickens so that the density gradient in the thickening layer causes convection more easily.[14,1,26] Consequently, this deviation was strongly influenced by the concentration of the depolarizer, temperature fluctuation, and mechanical disturbance.

Apart from the above-mentioned deviations, the linearity of the $|I_d|-t^{-1/2}$ plots (Fig. 3) and the agreement between $(nc)_{obsd}$ and the corresponding known value $(nc)_{calcd}$ (Table 1) were satisfactory. The values of D and $(nc)_{obsd}/(nc)_{calcd}$ are independent of the concentration of the depolarizers at less than 2 mol m^{-3}, as shown for thallium(I) and hexamminecobalt(III) ions. Except for cadmium(II) ion, the values of D and $(nc)_{obsd}/(nc)_{calcd}$ are also independent of the potential at which the diffusion current was measured (at some potentials listed in Table 1, the diffusion current was accompanied by large polarographic maxima when DME was used in the absence of maximum suppressor). For cadmium(II) ion, the measurement was successful only at or near −0.7 V *vs.* SCE. At other potentials the current was not reproducible and in many cases $|I_d|-t^{-1/2}$ plot was not linear; if the plot happened to be linear, the value of $(nc)_{obsd}$ did not agree with $(nc)_{calcd}$. The cause of such behavior is not yet clear.

For the sake of comparison, Table 1 includes some D values in 0.1 mol dm^{-3} potassium nitrate solutions obtained by other methods.

Any actual hanging mercury drop cannot be strictly spherical; it is more or less pear-shaped and shielded by the capillary tip. For a small mercury drop hanging from a thin-walled capillary, however, the error due to these factors is not large. For example, microscopic observation[27] of a mercury drop 0.56 mm in radius hanging from a capillary 0.05 mm in inner radius with a wall thickness of 0.07 mm showed that the actual surface exposed to the solution was larger by 1.0% than that of a perfectly spherical drop of the same mass; the increase in surface area due to distortion of the drop shape outweighed the decrease in surface area due to the fact that a mercury thread is attached to the drop. The capillary tip, in this case, occupied 0.9% of the volume of the solution layer which was 0.15 mm thick. The increase in surface area and the shielding by the capillary tip influence the diffusion current in opposite directions and partially compensate each other. The effect of the change in curvature will be smaller, because the curvature is larger at the bottom of the drop and smaller at the top than that of the ideal sphere. Although quantitative analysis of the total effect of these factors on $(nc)_{obsd}$ and D values was too difficult, the

** The thickness of the Nernst diffusion layer δ for spherical diffusion was calculated by the equation:

$$\delta = \frac{SncFD}{|I_d|} = (\pi Dt)^{1/2} - \frac{\pi Dt}{r+(\pi Dt)^{1/2}}.$$

resultant error might scarecely amount to 1%.

Table 1 shows that the error in $(nc)_{obsd}$ is less than 3%. In view of this value the application of the present method to analytical purposes seems hopeful. The error involved in the D values will likely be of the same order of magnitude.

The data for thallium ion in Table 1 show remarkable agreement among the sets of measurements which were carried out by different experimenters on different solutions with different HMDE's over a long period of time. This fact confirms the validity of the present method.

The research was supported in part by a grant from the Ministry of Education. The financial support granted to H. I. by Matsunaga Science Foundation for the present work is gratefully acknowledged. The authors' thanks are due to Sr. Jean Michalec for correcting the manuscript.

The Electrochemical Fluorination of Aliphatic Primary Monohydric Alcohols and Aldehydes[1]

Takashi ABE, Shunji NAGASE, and Hajime BABA

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

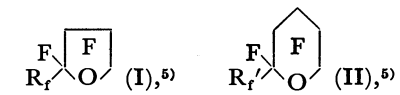
(Received January 27, 1975)

The perfluorocyclic ethers as well as the perfluoroalkanoyl fluorides were obtained by the electrochemical fluorination of primary monohydric alcohols and aldehydes containing 4—8 carbon atoms. The five-membered rather than the six-membered perfluorocyclic ethers were formed as the cyclic products. The over-all yields of the perfluorocyclic ethers and the perfluoroalkanoyl fluorides from the alcohols were in the range of 10—20%, and 3—12% respectively. Those from the aldehydes were poor because of the formation of a considerable amount of tarry by-products. The physical properties of the perfluorocyclic ethers obtained are also described.

The electrochemical fluorination of diols, which resulted primarily in the formation of the six-membered perfluorocyclic ethers, was studied previously.[2]

Commonly, perfluorocyclic ethers (I and II) are known to be formed as the cyclization products in the electrochemical fluorination of straight chain carboxylic acids and their acid halides,[3] or of cyclic ethers directly.[4] The corresponding perfluoroalkanoyl fluorides (III) are also formed in the former case

$$CH_3(CH_2)_nC(O)X \xrightarrow[\text{fluorination}]{\text{Electrochemical}} \left(\begin{matrix} n\geq 2 \\ X=OH, \text{ halogen}\end{matrix}\right)$$



(I),[5] (II),[5]

$\left(R_f=C_{n-2}F_{2n-3},\ n\geq 2\right)$ $\left(R_f'=C_{n-3}F_{2n-5},\ n\geq 3\right)$

$CH_3(CF_2)_nC(O)F$ (III)

To investigate the behavior of alcohols upon electrochemical fluorination in more detail, we examined next the fluorination of several monohydric alcohols. It was found that primary monohydric alcohols also give the perfluorocyclic ethers as well as the perfluoroalkanoyl fluorides in considerable yields, which provides an additional useful route for the preparation of perfluorocyclic ethers.

This paper will deal with the electrochemical fluorination of alcohols and aldehydes having 4—8 carbon atoms, and with the characterization of the products and their related compounds.

Results and Discussion

The reaction conditions and the results of the fluorination of alcohols and aldehydes are shown in Tables 1 and 2 respectively.

The alcohols were dissolved in anhydrous hydrogen fluoride (AHF) to give a colorless electroconductive solution, while the aldehydes (butanal, pentanal, hexanal, heptanal, and octanal) gave a colored solution. The butyric aldehyde–AHF solution had a yellowish tint, and the others had a brownish one.

These solutions containing oxonium ion species were electrolysed smoothly and afforded perfluoroalkanes, perfluorocyclic ethers, and perfluoroalkanoyl fluorides as exhaustive fluorination products. On fluorination of most of the alcohols, only a very small amount of the perfluoroalkanes having the same number of carbon atoms as the starting materials was produced. However, there was a tendency for the formation of an increased amount of the perfluoroalkanes which comprise the same carbon skelton as the sample on fluorination of branched alcohols with an alkyl group on the β carbons, such as 2-ethyl-1-butanol and 2-methyl-1-pentanol.[6] The perfluoroalkanes having one fewer carbon atom than the starting materials and acyl fluorides were invariably formed as the principal cleaved products.

Fluorination of the Alcohols Having Linear Alkyl Groups (Runs 1—7 in Table 1). These alcohols afforded the perfluorocyclic ethers in fair yields. While the yields of the perfluoroalkanoyl fluorides decreased steadily with increase in the length of the carbon chain of the alcohols, the highest yield (21.7%) of the perfluorocyclic ethers was obtained in the case of 1-pentanol (Run 2). This may be due to the availability of the largest number of the C–H bonds on the δ and ε carbons of the alcohol, to create a carbon radical, and also due to the easier mobility of the alkyl group towards the carbonyl oxygen, which occurs intramolecularly, to form a 5-membered or 6-membered ring.

The perfluorocyclic ethers thus obtained consisted almost of the 5-membered and its isomeric 6-membered ring compounds. When the perfluorotetrahydrofurans contain side chains, they were on the 2-position of the ring. However, in the case of the perfluorotetrahydropyrans, ^{19}F NMR revealed that the side chain attached to the 3- or 4-positions of the pyran ring but not to the 2-position as has hitherto been reported.[3a]

The yields of the perfluorotetrahydrofuran from the alcohols with unsaturated bonds at γ carbon (Run 6 and 7) increased slightly, compared with the results in Run 1.

Fluorination of the Alcohols Having Side Chains (Runs 8—12 in Table 1). In Run 8, the perfluoro-2-methyltetrahydrofuran rather than the perfluoro-3-methyltetrahydrofuran was obtained as the major cyclization product. In Run 10, the yield of perfluoro-3,3-dimethyltetrahydrofuran, the expected cyclization product from fluorination of 3,3-dimethyl-1-butanol alcohol, was very poor (<1%), in spite of a sufficient number of available C–H bonds (9) of the starting material for the formation of the 5-membered ring. Instead, perfluoro-2,3-dimethyltetrahydrofuran, perfluoro-3-ethyltetrahydrofuran, perfluoro-2,5-dimethyl-

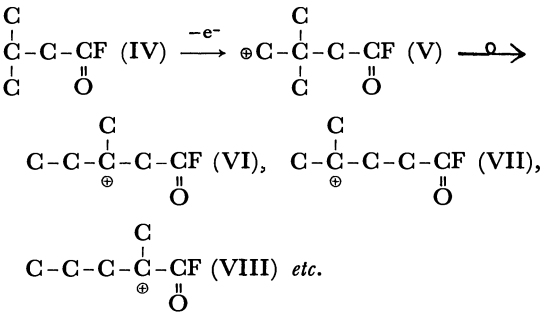
tetrahydrofuran, and perfluoro-4-methyltetrahydropyran were obtained as cyclic products. On the other hand, the fluorination of 3-methyl-1-pentanol (Run 9) afforded almost the same kinds of products as in the case of 3,3-dimethyl-1-butanol (Run 10). Perfluorotetrahydrofurans with perfluoroalkyl groups attached to the expected position of the ring could be obtained satisfactorily in other Runs. Thus, the rearrangement which involves the 1,2-shift of the methyl group of the starting material (3,3-dimethyl-1-butanol) in competition with the cyclization is very likely to take place through the fluorination.

Although an unequivocal explanation has not yet been made of the mechanisms of the electrochemical fluorination,[7] a free radical type reaction is generally accepted. However, so far as the isomerization in the course of the fluorination is concerned, the rearrangement of alkyl groups *via* carbonium ion intermediate is more attractive rather than the free radical type rearrangement,[8] since the alkyl radicals do not generally rearrange.[9] The Hofer-Moest reaction, an example of Kolbe electrolysis, is known to proceed not only in the radical process but also mainly through the carbonium ion process.[9] Similarly, the fluorination by the electrochemical process may be interpreted in terms both of the free radical and the ionic reaction.

Thus, the acyl fluoride formed by the elimination of hydrogen fluoride from unstable α,α-difluoro alcohols (postulated initial fluorination product from alcohols) may be subjected to hydrogen abstraction by fluorine to give a free radical (IV). Then the expected 3,3-dimethyltetrahydrofuran may be created by the intramolecular cyclization. However, the major part of IV may rearrange competitively into other acyl fluorides *via* V, which resulted from further anodic oxidation of the radical of IV. The methyl group on the γ carbon of the intermediate compound (V) migrates favorably in such a way as to produce more stable tertiary carbonium ions. With a highly branched starting material, more opportunities will be given for such an rearrangement than for the cyclization.



The carbonium ion of acyl fluoride (VI) can proceed to the corresponding perfluoroalkanoyl fluoride, but generally it will lead to the cyclic ethers by the intramolecular attack of one of the radicals formed on the three different carbons (denoted by a, b, and c) to the carbonyl oxygen atom. The cyclization which can proceed to the formation of three isomeric perfluorocyclic ethers is formulated as follows:

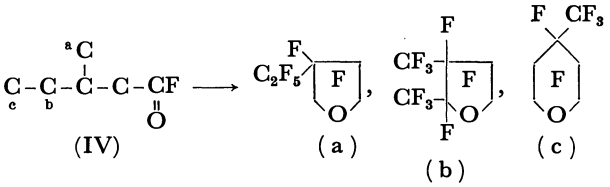


Table 3. Properties of perfluorocyclic ethers and perfluoroalkanoyl fluorides

Compound	Bp (°C)	d_4^{20}	Elemental analysis C (%)	Elemental analysis F (%)

Tullock, and D. D. Coffman, *J. Am. Chem. Soc.*, **84**, 4275 (1962).

The perfluoro-3-methyltetrahydropyran, which is mixed with perfluoro-4-methyltetrahydropyran as an inseparable contaminant, is considered to be produced by the cyclization of VII and VIII. The properties of these perfluorocyclic ethers are shown in Table 3.

It is noteworthy that perfluoro-2-methylbutyryl fluoride $C_2F_5CF(CF_3)C(O)F$, and perfluoro-2-ethylbutyryl fluoride $(C_2F_5)_2CFC(O)F$, obtained in Runs 8 and 11 respectively, were collected safely in cold traps, after passing through a series of washing bottles containing 5% aqueous potassium hydroxide solution.

Some spectral data (^{19}F NMR and IR) of perfluoro-2-methylbutyryl fluoride and perfluoro-2-ethylbutyryl fluoride are shown in Table 4.

Table 4. ^{19}F NMR[a] and IR data of the perfluoro-2-methylbutyryl fluoride and perfluoro-2-ethylbutyryl fluoride

Generally, perfluoroalkanoyl fluorides of the type $R_fC(O)F$ (R_f=linear perfluoroalkyl group) hydrolyze very easily into the corresponding perfluoro carboxylic acids. The anomalies in hydrolytic stability of these perfluoroalkanoyl fluorides with the side chain on the α carbon may be ascribed to the spatial shielding of the carbonyl carbon by two perfluoroalkyl groups.

Fluorination of the Aldehydes. The fluorination of aldehydes gave a formation and distribution of the products similar to that obtained with the alcohols (Runs 1—5 in Table 1). However, the yields both of the perfluorocyclic ethers and the perfluoroalkanoyl fluorides were lower, and the formation of a considerable amount of tarry material in the cell was observed in each run. The polymerization of aldehydes in AHF, which gives a colored liquid of low-molecular weight, has been reported briefly in the literature.[11]

Experimental

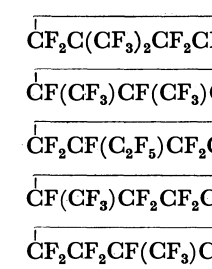
Reagents and Apparatus. All reagents except 3,3-dimethyl-1-butanol, which was prepared by the reaction of 3,3-dimethylbutyryl chloride with lithium aluminium hydride in ether, were available from Tokyo Kasei Co.. Anhydrous hydrogen fluoride (AHF) was more than 99.5% pure. The electrolytic cell used was the same as that described in a previous paper.[12] A standard Pyrex vacuum line was used in the reaction of perfluoro-2,3-dimethyltetrahydrofuran with aluminum chloride for handling the volatile liquids and gaseous materials.

The IR spectrum measurements were made on a Hitachi EPI-G3 spectrometer, using a 6 cm gas cell with KBr windows. The ^{19}F NMR spectra were obtained on a Hitachi Model R-20B high resolution spectrometer operating at 56.46 MHz.

General Procedures for the Electrochemical Fluorination of Alcohols and Aldehydes. A typical example is the case of the fluorination of 3,3-dimethyl-1-butanol (Run 10 in Table 1). A 20.2 g portion of 3,3-dimethyl-1-butanol was dissolved in 1 l AHF in the cell. Then the electrolysis was carried out with an anodic current density of 3.5 A/dm^2, a cell temperature of 5—6 °C, and a cell voltage of 5 V, which rose gradually as the fluorination proceeded. The operation was continued until the voltage reached 10 V. Thus 173 Ahr of electrolysis was conducted.

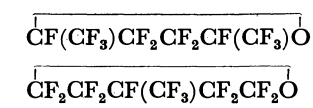
The effluent gases from the cell were passed over NaF pellets, and then bubbled through two consecutive polyethylene bottles containing water (for collection of the perfluorocarboxylic acids resulting from the hydrolysis of the corresponding perfluoroalkanoyl fluorides). The gaseous products which did not react with water were further guided into an alkaline solution of potassium sulfite, and finally collected in traps immersed in liquid nitrogen.

(A) Analysis of the Perfluorocyclic Ethers: The products (30.8 g) condensed in the cold traps were initially subjected to low-temperature distillation, giving two fractions; fraction 1 (bp<0 °C, 3.3 g) and fraction 2 (25.7 g, 15.7 ml). The fraction 1 consisted mainly of CF_4, C_2F_6, and C_3F_8. The fraction 2 was carefully redistilled to collect the volatile compounds. Perfluoropentanes (a mixture of *n*- and isopentane, *n*-C_5F_{12}: *iso*-C_5F_{12}=57: 43) were obtained at about 25 °C as the main low boiling component. The distillation residue (16.7 g, 10.3 ml) was then further subjected to gas chromatographic analysis (compositions were calculated on the basis of chromatographic peak areas, assuming equal weight sensitivities for all components). Thus the following perfluorocyclic ethers were detected:



0.6 g,

6.3 g,



3.8 g,

1.9 g,

1.4 g.

The perfluoro-4-methyltetrahydropyran obtained was found to be mixed with almost an equal quantity of the perfluoro-3-methyltetrahydropyran from the ^{19}F NMR spectrum; 4-CF_3-*cyclo*-C_6F_9O: 3-CF_3-*cyclo*-C_6F_9O=50: 50. In addition to these perfluorocyclic ethers, the formation of perfluorohexamethylene oxide was also observed.[10] With the exception of perfluoro-2,3-dimethyltetrahydrofuran, the isolation and purification of these isomeric perfluorocyclic ethers were accomplished by means of repeated gas chromatography. The preparative-scale columns packed with Silicone QF-1 30% on Chromosorb PAW, diester of hexamethylene glycol with perfluorooctanoic acid 20% on Chromosorb PAW, and 1,6-bis(2,2,3,3,4,4,5,5,6,6,7,7-dodecafluoroheptyloxy)-hexane 30% on Chromosorb PAW were employed. These compounds were characterized by ^{19}F NMR, IR, and mass as well as elemental analyses. The perfluoro-2,3-dimethyltetrahydro furan obtained was found to be contaminated with a small amount of perfluoro-2-ethyltetrahydrofuran, from its spectrometric data (IR and ^{19}F NMR). However, it was not possible to separate them by the preparative gas chromatography. Therefore, the characterization of these compounds was subsequently achieved by converting them into the corresponding perfluoro-2,5,5-trichlorotetrahydrofuran

derivatives followed by the gas chromatographic separation according to a method described in the literature.[13]

Reaction of Perfluoro-2,3-dimethyltetrahydrofuran with $AlCl_3$: In a 30 ml stainless steel bomb, 1.0 g of anhydrous granular $AlCl_3$ and 1.57 g of perfluoro-2,3-dimethyltetrahydrofuran, which contained perfluoro-2-ethyltetrahydrofuran, were kept at 145 °C overnight. Purification was initially conducted by trap-to-trap distillation, using traps immersed in cold baths kept at −78 °C and −196 °C respectively. The gas chromatographic separation of the products which were retained in the −78 °C trap yielded two major fractions along with some unreacted starting material, carbon tetrachloride, and hexachloroethane. These fractions were assigned to be perfluoro-2,5,5-trichloro-2,3-dimethyltetrahydrofuran and perfluoro-2,5,5-trichloro-2-ethyltetrahydrofuran on the basis of their spectroscopic data and elemental analyses.

Perfluoro-2,5,5-trichloro-2,3-dimethyltetrahydrofuran: Yield: 0.82 g (52%), bp 132.5—133.5 °C, n_D^{20} 1.3627, d_4^{20} 1.7977. Found: C, 19.50; F, 46.8%. Calcd: C, 19.70; F, 46.8%.

Perfluoro-2,5,5-trichloro-2-ethyltetrahydrofuran: Yield: 0.21 g (13%), bp 131.0—131.5 °C (lit,: 136 °C),[13] n_D^{20} 1.3605 (lit,: n_D^{25} 1.3566),[13] d_4^{20} 1.7817. Found: C, 19.62; F, 46.7%. Calcd: C, 19.70; F, 46.8%.

(B) Analysis of the Perfluorocarboxylic Acids: The analysis of the perfluoroalkanoyl fluorides produced was performed through their methyl esters. The aqueous solution of the perfluoro carboxylic acids in the polyethylene bottles was neutralized by adding anhydrous Na_2CO_3, and the solution was evaporated to dryness, giving a white solid. It was extracted with alcohols and the extract was evaporated to dryness to give a pure sodium salt. Then the salt was acidified with 10% aqueous H_2SO_4, and free acid was extracted with ether. The ethereal solution of perfluoro carboxylic acid was treated with Ag_2O and filtered, and then the filtrate was evaporated to afford a dry silver salt. In a 50 ml three-necked flask fitted with a reflux condenser, a dropping funnel, and a thermometer, 3.3 g of the fine powdered silver salt and 20 ml of 1,1,2-trichloro-1,2,2-trifluoroethane were placed and heated to 70 °C, with stirring by a magnetic stirrer. Methyl iodide (3 g) was added to the mixture from the dropping funnel over a period of 30 min. The resulting mixture was kept with stirring for an additional 3 h. After removal of silver iodide by filtration, the solvent and unreacted methyl iodide were evaporated. Then, the preparative gas chromatography (column: Kel F #90 26% on Chromosorb PAW; carrier gas: He) of the residue evaporated gave 1.2 g of the mixtures of methyl esters of perfluoro carboxylic acid consisting of $C_3F_7C(O)OCH_3$ (3, peak area %), $C_4F_9C(O)OCH_3$ (2), and $C_5F_{11}C(O)OCH_3$ (95). A few shoulders, which suggested the presence of isomers, appeared on the peak of the gas chromatogram which corresponded to the methyl ester of perfluorohexanoic acid. No further analysis of these isomers was conducted.

The authors wish to thank Dr. Teruo Ueda for his technical assistance in this work and Mr. Kazuo Kodaira for the mass spectrometric measurements.

Solvolytic Ring-opening Reacions of *gem*-Dichloroaziridines in the Presence of Sulfuric Acid

Manabu SENŌ, Shinsaku SHIRAISHI, Yukio SUZUKI, and Teruzo ASAHARA

Institute of Industrial Science, University of Tokyo, Roppongi 7-22, Minato-ku, Tokyo 106

(Received July 1, 1975)

Solvolytic ring-opening reactions of *gem*-dichloroaziridines in the presence of sulfuric acid were investigated. The reaction products from 1-aryl-2,2-dichloro-3-phenylaziridines varied with the kind of substituent at 3-position of the aziridine ring. 2,2-Dichloro-1,3-diphenylaziridine gave α-chloro-α-phenylacetanilide, 2,2-dichloro-3-methyl-3-phenyl-1-(*m*-tolyl)aziridine gave *N*-(*m*-tolyl)atropamide and 2,2-dichloro-1,3,3-triphenylaziridine gave 3,3-diphenyloxindole. 1-Benzyl-2,2-dichloro-3,3-diphenylaziridine and 2,2-dichloro-1-phenethyl-3,3-diphenylaziridine gave 4,4-diphenyl-1,2,3,4-tetrahydroisoquinoline-3-one and 1,1-diphenyl-1,2,3,4,5-pentahydro-3-benzazepine-2-one, respectively. It was found that the substituent on C^3-carbon determines the mode of reaction.

gem-Dichloroaziridines have been prepared by various methods,[1-8] their reactivities being examined for hydrolysis,[1,2,3,6,8] isomerization[2,3] and aminolysis.[8] Ichimura and Ohta reported on the preparation of aromatic ketenimines from the reaction of 1,3,3-triaryl-2,2-dichloroaziridines with sodium iodide.[2] Klamann *et al.* observed that 1-(β-chloroethyl)-3,3-diphenyloxindole was produced by heating benzophenoneanil with chloroform and ethylene oxide in the presence of tetraethylammonium bromide, the reaction proceeding *via* the formation of 1,3,3-triaryl-2,2-dichloroaziridine.[7] On the other hand, Petyunin synthesized various lactams from *N*-aryl-α,α-diaryl-α-hydroxyacetamide in acetic acid in the presence of sulfuric acid.[9,10,11] These reports stimulated us to investigate in detail the reactivities of *gem*-dichloroaziridines in the medium containing sulfuric acid. It was found in the course of this study that atropamide, oxindole, isoquinoline and benzazepine derivatives are obtainable in good yields from the reactions of *gem*-dichloroaziridines in the presence of sulfuric acid. The results and analysis of the reaction scheme are presented in the present paper.

Results and Discussion

gem-Dichloroaziridines were prepared by addition of dichlorocarbene to the corresponding Schiff bases. Schiff bases were prepared by various methods Ph-CH=NPh was prepared from benzaldehyde and aniline, $Ph(CH_3)C{=}NAr$ from acetophenonediethylketal and *m*-toluidine, $Ph_2C{=}NPh$ from the reaction of sodium salt of aniline with benzophenone at 140—160 °C, and $Ph_2C{=}N(CH_2)_nPh$ (where $n=1,2$) by the reaction of $Ph_2C{=}O$ with $Ph(CH_2)_nNH_2$ at 150—180 °C in the presence of hydrobromic acid as a catalyst. *gem*-Dichloroaziridines prepared for the present investigation are listed in Table 1.

The *gem*-dichloroaziridines were treated with sulfuric acid in acetic acid. 2,2-Dichloro-1,3-diphenylaziridine (**1**) gave α-chloro-α-phenylacetanilide (**4**) in a 60% yield. The hydrolysis of **1** in a heterogeneous system

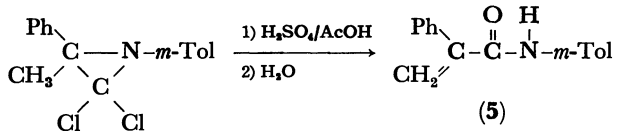
a) Found: C, 65.45; H, 5.21; N, 4.79; Cl, 24.55%. Calcd for $C_{16}H_{15}NCl_2$: C, 65.75; H, 5.13; N, 4.79; Cl, 24.32%. b) This compound shows exothermic peaks at 135—140 °C and 148—153 °C in DTA curve. Found: C, 71.55; H, 4.74; N, 3.87%. Calcd for $C_{21}H_{17}NCl_2$: C, 71.19; H, 4.80, N, 3.95%. c) Found: C, 72.17; H, 5.19; N, 3.66%. Calcd for $C_{22}H_{19}NCl_2$: C, 71.74; H, 5.16; N, 3.80%.

in water affords **4** and the hydrolysis in a water–dioxane homogeneous system gives an equimolar mixture of **4** and α-hydroxy-α-phenylacetanilide.[3]

2,2-Dichloro-3-methyl-3-phenyl-1-(*m*-tolyl)aziridine (**2**) gave *N*-(*m*-tolyl)atropamide (**5**) in a 61% yield. The product showed IR absorption at 1650 and 940 cm^{-1} and NMR absorption (δ value) at 6.24 (singlet) and 5.70 (singlet) which comfirmed the existence of methylene group. The hydrolysis of **2** in water–dioxane (1 : 3) mixture at reflux temperature for 1 h also gave the same product in a 62% yield. These reactions provide a novel convenient synthetic route to obtain atropamide. Meilahn *et al.* reported that 2,2-dichloro-3-ethyl-1,3-diphenylaziridines affords the hydrolysis product *via* a similar reaction.[8]



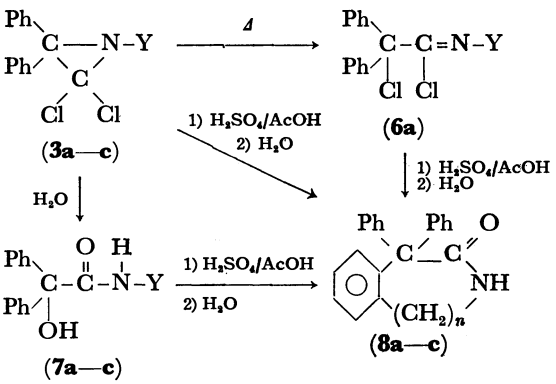
(2) (5)

When concentrated sulfuric acid was added dropwise to a solution of 2,2-dichloro-1,3,3-triphenylaziridine (**3a**) in acetic acid, red coloration appeared instantaneously and disappeared shortly. This indicates the

formation of carbonium ion as an intermediate. Concentrated sulfuric acid was added until no more coloration was observed. Working up the reaction mixture gave 3,3-diphenyloxindole (**8a**) in an 88% yield. On the other hand, by heating **3a** under anhydrous conditions, α-chloro-α,α-diphenyl-*N*-phenylacetimidoylchloride (**6a**) was obtained by thermal isomerization.* Compound (**6a**) thus prepared gave 3,3-diphenyloxindole (**8a**) quantitatively by treatment with sulfuric acid in acetic acid. Hydrolysis of **3a** in aqueous dioxane gave α-hydroxy-α,α-diphenylacetanilide (**7a**),[2] which also gave **8a** quantitatively by treatment with sulfuric acid.

In the presence of sulfuric acid as a catalyst, 1-benzyl-2,2-dichloro-3,3-diphenylaziridine (**3b**) gave 4,4-diphenyl-1,2,3,4-tetrahydroisoquinoline-3-one (**8b**) in a 99% yield. Hydrolysis of **3b** in aqueous dioxane gave *N*-benzylbenzilamide (**7b**),[8] which gave **8b** in an 80% yield by treatment with sulfuric acid. 2,2-Dichloro-1-phenethyl-3,3-diphenylaziridine (**3c**) gave 1,1-diphenyl-1,2,3,4,5-pentahydro-3-benzazepine-2-one (**8c**) in a 67% yield. Hydrolysis of **3c** gave *N*-phenethylbenzilamide (**7c**) in a 74% yield. Treatment of **7c** with sulfuric acid also gave **8c** in a 77% yield.

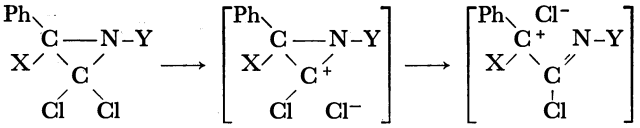
The reactions described above are summarized in the following scheme:



Y=Ph(CH$_2$)$_n$, a) n=0, b) n=1, c) n=2.

Petyunin *et al.* reported on the reaction from **7a** to **8a**[10-11] and Klamann *et al.* presented the reaction scheme to produce thermally oxindole from benzophenoneanil.[7] However, there is no report which gives the direct solvolytic rearrangement reactions of *gem*-dichloroaziridines to produce oxindole, isoquinoline derivatives and benzazepine derivatives. These reaction processes are rather moderate and give higher yields of products, as compared to the pyrolysis reaction at 150 °C reported by Klamann *et al.*

It was revealed from these experiments that the reaction proceeds through the cleavage of C^3–N bond. The existence of **9** and **10** was proposed for intermediates in the ring-opening reaction of *gem*-dichloroaziridines, where the chloride ion shifts intramolecularly, following C^3–N bond cleavage.[3] The nature of the intermediate (**10**) would be dependent on the substituent X.



(**9**) (**10**)

In the case of X=H, Cl$^-$ is substantially bonding at C^3-atom, and the product (**4**) is formed in both the reactions with H_2SO_4–AcOH and aqueous dioxane through α-chloro-*N*-phenylacetimidoylchloride, as reported by Brook *et al.*[3]

In the case of X=CH$_3$, the hydrolysis product is easily converted into compound (**5**) by an elimination pathway in both the reactions with H_2SO_4–AcOH and aqueous dioxane.

In the case of X=phenyl, the C^3-carbonium ion is stabilized through the conjugation of adjacent phenyl groups and the counter Cl$^-$ ion becomes more free. Thus, the attack of carbonium ion to benzene ring at *ortho* position or the displacement of Cl$^-$ by OH$^-$ becomes more feasible. Compounds (**8a**), (**8b**), and (**8c**) are produced by the reaction of parent dichloroaziridine with H_2SO_4–AcOH and *N*-aryl-α-hydroxy-α,α-diphenylacetamide (**7a**), (**7b**), or (**7c**) by the reaction in aqueous dioxane. The difference in the mode of reaction between **1** and **3** is considered to reflect the stability of benzyl cation as compared with that of benzhydryl cation.

Experimental

Preparation of N-*(1-Phenethylethylidene)*-m-*toluidine.* A mixture of 38.8 g (0.2 mol) of acetophenonediethylketal and 21.4 g (0.2 mol) of *m*-toluidine was heated at 80—100 °C for 7 h. The resulting solution was distilled under reduced pressure to give 35 g (84%) of *N*-(1-phenylethylidene)-*m*-toluidine as yellow liquid; bp 150 °C (3 mmHg); IR (KBr) 1634 cm^{-1} (C=N); NMR (CDCl$_3$) δ (ppm) 6.3—8.1 (m, 9, aromatic), 2.30 (s, 3, CH$_3$-aromatic), 2.16 (s, 3, CH$_3$-C=N)

Preparation of N-*(Diphenylmethylidene)phenethylamine.* A mixture of 91 g (0.5 mol) of benzophenone, 60.5 g (0.5 mol) of phenethylamine and two drops of 2M hydrobromic acid was heated at 130—140 °C for 5 h under N$_2$ atmosphere. Distillation under reduced pressure gave 65 g (46%) of *N*-(diphenylmethylidene)phenethylamine as light yellow liquid; bp 190—195 °C (3 mmHg); IR (KBr) 1620 cm^{-1} (C=N); NMR (CDCl$_3$) δ (ppm) 7.75—6.50 (m, 15, aromatic), 3.55 (t, 2, -CH$_2$-N=C-), 2.94 (t, 2, -CH$_2$-phenyl)

Preparation of 2,2-Dichloro-3-methyl-3-phenyl-1-(m-*tolyl)aziridine* (*2*). To a mixture of 28 g (0.25 mol) of potassium *t*-butoxide, 13 g (0.0625 mol) of *N*-(1-phenylethylidene)-*m*-toluidine and 250 ml of hexane, 30 g (0.25 mol) of chloroform was slowly added dropwise under dry N$_2$ atmosphere at 0—5 °C with vigorous stirring. The reaction mixture turned from yellow to brown. Stirring was continued for 2 h at 0—5 °C and then 2 h at room temperature. The solution was filtered and the residue was washed with hexane. The combined solution of the filtrate and the washing was then evaporated in *vacuo* to leave crystals, which gave 11.2 g (61%) of 2,2-dichloro-3-methyl-3-phenyl-1-(*m*-tolyl)aziridine as a colorless crystal by recrystalization from hexane–chloroform; mp 64—65 °C; IR (KBr) 1350 cm^{-1} (symmetry stretching of aziridine ring); 840 cm^{-1} (antisymmetry stretching of aziridine ring); NMR (CDCl$_3$) δ (ppm) 6.6—7.6 (m, 9, aromatic), 2.31 (s, 3, CH$_3$-

* Thermal isomerization of **3b** and **3c** was carried out by heating them in a solvent such as benzene, toluene or *p*-xylene. However, no product like **6a** could be isolated under the limited condition employed.

Table 2. Reaction products of *gem*-dichloroaziridines in the presence of sulfuric acid

a) Mp was not observed. It was found by DTA measurement that this compound decomposes at 280—300 °C.
b) Since this compound was not soluble in the usual organic solvents, NMR was measured in sulfuric acid.

aromatic), 1.73 (s, 3, CH_3-aziridine ring); UV (cyclohexane) λ_{max} 236 nm, ε_{max} 12900.

Preparation of 2,2-Dichloro-1-phenethyl-3,3-diphenylaziridine (3c). To a mechanically stirred mixture of 9 g (0.08 mol) of potassium *t*-butoxide, 8 g (0.028 mol) of *N*-(diphenylmethylidene)phenethylamine, 60 ml of benzene and 60 ml of hexane, 9.5 g (0.08 mol) of chloroform was slowly added dropwise under N_2 atmosphere at 0 °C. The mixture was stirred for 10 h at room temperature and then treated with active carbon for decoloration. After removal of the solid part from the solution by filtration, the filtrate was evaporated *in vacuo* to leave a crystal, which was recrystalized from hexane to leave a crystal, which was recrystalized from hexane to afford 4 g (39 %) of 2,2-dichloro-1-phenethyl-3,3-diphenylaziridine; mp 80—81 °C; IR (KBr) 1322 cm^{-1} (symmetry stretching of aziridine ring), 840 cm^{-1} (antisymmetry stretching of aziridine ring); NMR ($CDCl_3$) δ (ppm) 7.3 (m, 15, aromatic), 3.05 (q, 4, $-CH_2-CH_2-$).

Reaction of gem-*Dichloroaziridine in the Presence of Sulfuric Acid.* The general procedure is as follows: 20 ml of concd H_2SO_4 was slowly added dropwise to a solution of *gem*-dichloroaziridine (0.006 mol) in 20 ml of glacial acetic acid. The solution was heated at 60 °C for 30 min. It was poured into 80 ml of water to precipitate crystals which were collected by filtration. The crystals were dissolved in chloroform and washed with 0.5 M sodium hydrogencarbonate solution and then with water. The chloroform solution was dried on anhydrous sodium sulfate. Evaporation of the solvent and recrystalization from an appropriate solvent gave a pure product. The results are summarized in Table 2.

*Reaction of α-Chloro-α,α-diphenyl-*N*-phenylacetimidoyl Chloride (6a) in the Presence of Sulfuric Acid.* 15 ml of concd H_2SO_4 was slowly added dropwise to a solution of 1.5 g of **6a** in 15 ml of acetic acid and then heated at 60 °C for 30 min. The reaction mixture was poured into 60 ml of water to give precipitates, which were treated as mentioned in the last section. 1.2 g (96%) of 3,3-diphenyloxindole (**8a**) was obtained.

Reaction of N*-Benzylbenzilamide (7b) in the Presence of Sulfuric Acid.* 15 ml of concd H_2SO_4 was added dropwise to a solution of 1.6 g of **7b** in 15 ml of acetic acid. The product was treated similarly as above, 1.2 g (80%) of 4,4-diphenyl-1,2,3,4-tetrahydroisoquinoline-3-one (**8b**) being obtained.

*Hydrolysis of 2,2-Dichloro-3-methyl-3-phenyl-1-(*m*-tolyl) aziridine (2).* A solution of 3 g of **2** in 15 ml of dioxane and 5 ml of water was refluxed for 2 h. Evaporation and recrystalization from ethanol gave 1.5 g (62%) of *N*-(*m*-tolyl)-atropamide.

Hydrolysis of 2,2-Dichloro-1-phenethyl-3,3-diphenylaziridine (3c). A solution of 3 g of **3c** in a mixture of dioxane and 5 ml of water was refluxed for 2 h. After evaporation and recrystallization from ethanol, 2 g (74%) of *N*-phenethylbenzilamide was obtained; mp 144—145 °C (lit. 139 °C); IR (KBr) 3225 cm^{-1} (NH), 1650 cm^{-1} (C=O); NMR ($CDCl_3$) δ (ppm) 7.3 (m, 15, aromatic), 3.93 (s, 1, OH), 3.60 (t, 2, $NH-C\underline{H}_2-CH_2-$), 2.80 (t, 2, $NH-CH_2-C\underline{H}_2-$); found: C, 80.12; H, 6.39; N, 4.26%, calcd for $C_{22}H_{21}NO_2$: C, 79.76; H, 6.34; N, 4.23%.

Pyrolysis of 2,2-Dichloro-1,3,3-triphenylaziridine (3a). A solution of 3.4 g of **3a** in *p*-xylene was refluxed for 1 h. Evaporation and recrystalization from hexane gave 2.4 g (70.6%) of α-chloro-α,α-diphenylacetimidoylchloride (**6a**); mp 68—69 °C (lit, 70—71 °C)[2]; IR (KBr); 1680 cm^{-1} (C=N); found: C, 70.54; H, 4.40; N, 3.94, calcd for $C_{20}H_{15}NCl_2$: C, 70.59; H, 4.41; N, 4.12%.

Asymmetric Hydrogenolysis of Hydrazones. Synthesis of Optically Active α-Alanine

Syun-ichi KIYOOKA, Keiko TAKESHIMA, Hidehumi YAMAMOTO, and Kojiro SUZUKI

Department of Chemistry, Faculty of Literature and Science, Kochi University, Asakura, Kochi 780

(Received July 23, 1975)

Optically active α-alanines have been synthesized by the asymmetric hydrogenolysis of the chiral hydrazones which were derived from chiral amines and ethyl pyruvate. Reduction of the C=N group in the hydrazones was carried out using PtO_2 catalyst in acetic acid at room temperature, followed by hydrogenolysis of the N–N linkage using the same catalyst in 1 M HCl at 100 °C (autoclave). The synthesis using (*S*)-bornylamine as a chiral reagent afforded L-alanine with optical purity of 46.5%. By using (*S*)-1,2-dimethylpropylamine as a simple chiral reagent, L-alanine was also obtained with optical purity of 32.2%. It has become apparent that the synthesis using (*S*)-alkylamine gave L-alanine, while D-alanine was obtained by using (*S*)-α-methylbenzylamine.

A number of methods for the asymmetric synthesis of α-amino acid have been reported and summarized in several reviews.[1] Among these, the reduction of hydrazide and hydrazone derivatives has the advantage of recovering the starting acids and amines without destruction of the optical activity. Akabori and his co-workers[2] reported the synthesis of L-alanine (8% e.e.) and L-phenylalanine (5% e.e.) using hydrazide of (*R*)-2-methyl-3-phenylpropanoic acid. Suzuki[3] also used hydrazide of *d*-tartaric acid to obtain L-alanine (12% e.e.). However, they did not recover the original optically active sources. On the other hand, Kost and his co-workers[4] used the hydrazone (**1**) derived from anabasine to obtain D-alanine (40% e.e., 10% yield) and recovered anabasine with optical purity of 90%. Corey and his co-workers[5] succeeded in an excellent asymmetric synthesis of D-alanine by using the compound (**2**) (96% e.e., 78% yield). Our present study deals with the asymmetric synthesis of α-alanine by the catalytic hydrogenolysis of the hydrazones derived from optically active hydrazines and ethyl pyruvate.

Results and Discussion

The reduction of *d*-camphoroxime with sodium in ethanol afforded the mixture of 70% of bornylamine (Ia) and 30% of isobornylamine (Ib). The mixture was separated into Ia and Ib by the treatment with glacial acetic acid in ether solution, using Hückel's method.[6] The optical purities of Ia and Ib were shown to be 99.7% and 98.6% by comparing their optical rotations with those in the literature.[7] Both amines, Ia and Ib, were respectively converted to the hydrazone derivatives, (Va) and (Vb), by the following procedures. I was condensed with benzaldehyde to give benzaldimine. The imine was treated with methyl iodide, followed by hydrolysis to give *N*-methyl compound (II). II was converted into hydrazine derivative (IV) through the reduction of its nitroso compound (III) with zinc dust. IV was condensed with ethyl pyruvate in a dry ether solution and gave the hydrazone (V). In the asymmetric reductions reported previously, Kost used zinc dust–hydrogen chloride and Corey used aluminum amalgam. Thus far the catalytic hydrogenolysis of the hydrazone has not been successful. The hydrogenation of Va and Vb did not proceed with 5% or 10% of palladium on carbon or platinum oxide in ethanol under the hydrogen pressure of 50 kg/cm² at room temperature or even at an elevated one. However, hydrogen was absorbed when the solvent was replaced with acetic acid using platinum oxide catalyst under atmospheric pressure. The colorless oil isolated from the above reaction was found to be the intermediate (VI) from its IR and NMR spectra. The NMR spectra of the diastereomers VI were so similar in their patterns of peaks that the optical yield of the asymmetric hydrogenation could not be calculated from the proportion of the NMR peaks of the particular protons, even with NMR shift reagents. Further, hydrogen was absorbed in the HCl solution of VI with PtO_2 when the temperature was elevated to 100 °C under a hydrogen

TABLE 1. ASYMMETRIC SYNTHESIS

Hydrazones	Methods	L-Alanine yield	Optical yield
Va (*S*)	Catalytic reduction	34%	46.5%
Va (*S*)	Chemical reduction	21%	10.9%
Vb(*R*)	Catalytic reduction	37%	9.2%

pressure of 50 kg/cm^2. Thus, the cleavage of the N–N linkage leading to α-alanine was carried out, and simultaneously *N*-methyl amine IV was recovered with 95% optical purity (38% yield). The reduction of the bornylhydrazone Va was also performed with zinc dust and hydrogen chloride in ethanol in order to compare the differences between the catalytic reduction and the "chemical" one (Zn–HCl). The resulting α-alanine was isolated by successive columns of an anion exchange resin (Amberlite IRA 410) and a cation exchange resin (Dowex 50W-X8) and the optical rotations of the eluted α-alanines were measured. The results of the asymmetric hydrogenolysis are shown in Table 1. Although the absolute configurations of the starting amines, Ia and Ib, were different at C-2 (asymmetric carbon), the catalytic reductions of Va and Vb, derived from the amines, gave alanines having the same configuration. This fact suggested that the conformation of the molecule adsorbed on the surface of the catalyst could not be predicted because of the difficulty in evaluating the extent of the intramolecular steric repulsions and the interactions between the molecule and the catalyst. What is known as the anchor effect[8] of the lone pair of nitrogen, the adsorption of the lone pair of the amino nitrogen on the surface of the catalyst, may be attributable to the fixing of the conformation of V and the amino nitrogen's tetrahedral character. However, the authors have been unable to find any detailed account of the asymmetric induction mechanism.

Next, as a simple alkylamine, (*S*)-1,2-dimethylpropylamine was chosen. The *dl*-1,2-dimethylpropylamine was synthesized and resolved into (*S*)-amine and (*R*)-amine with *d*-tartaric acid according to a recently reported method.[9] The synthetic method and experimental operation of the asymmetric synthesis using optically active 1,2-dimethylpropylamine was similar to that for (*S*)-bornylamine described above. L-Alanine (32.2% e.e.) was derived from the (*S*)-amine. As expected, from the (*R*)-antipode D-alanine was obtained in reasonable optical yield. Further, in order to examine the effect of an affinity[10] of the phenyl groups for the catalyst, (*S*)-α-methylbenzylamine was chosen and converted into its hydrazone derivative. The hydrazone absorbed two moles of hydrogen (PtO_2–AcOH) at ordinary temperature and pressure. Table 2 shows the results of the asymmetric reduction. Except for R_2= ethyl, the reductions of the hydrazones derived from (*S*)-α-methylbenzylamine gave D-alanine, contrary to the results for (*S*)-1,2-dimethylpropylamine. The cause of the low optical yields seemed to be a complex competition of the adsorption power between the lone pair of nitrogen and the phenyl group to fix the conformation of the molecule on the surface of the catalyst.

Experimental

Optical rotations were measured using an Applied Electric Lab. Automatic Polarimeter Model MP-IT and a Yanaco OR-50. IR spectra were recorded using a JASCO infrared spectrophotometer Model IRA-1. NMR spectra were measured using a JEOL-MH-100 spectrometer. The IR and NMR spectra supported the structures of all compounds used in this paper, but the data have not been written in the experimental section. Nitrogen was analyzed by the Kjeldahl method. Melting and boiling points are uncorrected. The α-alanines given by the asymmetric reductions were identified with pure L-alanine $[\alpha]_D^{21}$ +32.7° (*c* 0.5, acetic acid) by paper chromatography: the IR (KBr) spectra of the products agreed very closely with that of the authentic one.

(S)-*Bornylamine (Ia) and* (R)-*Isobornylamine (Ib).* *d*-Camphoroxime was prepared with *d*-camphor ($[\alpha]_D^{20}$ +44°, *c* 4.0, ethanol) and hydroxylamine.[11] The amines obtained on sodium metal–ethanol reduction[12] of the oxime were purified and separated into two parts (Ia and Ib) by fractional precipitation of their acetates, according to the procedure used by Hückel.[6] Bornylamine hydrochloride, $[\alpha]_D^{20}$ +23.1° (*c* 4.2, ethanol), (lit,[7] [α] +23.3°, *c* 4.0, ethanol) and isobornylamine hydrochloride, $[\alpha]_D^{20}$ −48.6° (*c* 4.0, ethanol), (lit,[7] [α] −49.4°, *c* 4.0, ethanol) were used in the following experiments.

(S)-N-*Methylbornylamine (IIa).* To a cooled solution of the *(S)*-bornylamine hydrochloride (50 g) in ethanol (350 ml), sodium hydroxide (30 g) was added with stirring. Benzaldehyde (30 g) was added to the solution containing the free amine. The mixture was heated under reflux for 4 h with stirring. The solvent was evaporated *in vacuo*. The concen-

a) Using the solvent of acetic acid–ethanol (1: 1), the temperature (0 °C) of the reaction was kept through reduction. In the other cases, the initial addition of one mole of hydrogen was carried out at room temperature using the catalyst of PtO_2 in acetic acid.

trate was cooled and diluted with water (100 ml), followed by extraction with ether. The extract after drying (sodium sulfate), on evaporation, gave the Schiff base quantitatively. The Schiff base obtained was heated with methyl iodide (36 g) in an autoclave (100 °C) for 24 h. The mixture was washed out with aqueous ethyl acetate (200 ml) from the autoclave and then the solution containing aqueous ethyl acetate was heated at 70 °C. The cooled mixture was added into a solution of 1 M hydrochloric acid (200 ml). After separation from the organic layer, the aqueous portion was made basic to litmus with 3 M sodium hydroxide with cooling, and extracted with ether. After drying (sodium sulfate) and evaporating the solvent, the oil obtained was distilled under reduced pressure (22 mmHg) at 95—110 °C (28 g). Found: N, 8.54%. Calcd for $C_{11}H_{21}N$: N, 8.37%.

(S)-N-*Nitroso*-N-*methylbornylamine (IIIa).* *N*-Methylbornylamine hydrochloride (25 g) was dissolved in water (200 ml) containing concd hydrochloric acid (0.5 ml). To the solution obtained, sodium nitrite (13 g) was added little by little at room temperature and then the mixture was heated to 70—80 °C for 3 h. After cooling to room temperature, the floating yellow oil was extracted with ether. The extract after drying (calcium chloride) gave on evaporation a yellow solid (mp 26 °C) (20 g).

(S)-N-*Methylbornylhydrazine (IVa).* To water (40 ml) maintained at 15 °C with zinc (30 g), IIIa (15 g) dissolved in acetic acid (32 ml) was added dropwise over 0.5 h with stirring. After this addition, the reaction mixture was stirred for 1 h at room temperature and heated for 1 more h at 80 °C. The unreacted zinc was filtered from the cooled mixture. Forty per cent solution of sodium hydroxide was added in large excess to the filtrate which was extracted with ether. After drying (potassium hydroxide), the residual oil on evaporation of the solvent was distilled at 195—200 °C to give a colorless oil (13 g). Found: N, 15.21%. Calcd for $C_{11}H_{22}N_2$: N, 15.37%.

Ethyl (S)-2-*(*N-*Methyl*-N-*bornylhydrazono)propionate (Va).* A cooled solution of IVa (4.7 g) in dry ether (300 ml) was added dropwise to a stirred ice-cooled solution of ethyl pyruvate (3 g) in dry ether (500 ml). The solution was kept at 5 °C for 12 h and then at room temperature for 5 h. Anhydrous magnesium sulfate was added to the ethereal solution. After evaporation of the solvent, a deep yellow oil (8 g) was obtained, which had $[\alpha]_D^{22}$ +278° (*c* 2.50, ethanol). Found: N, 9.99%. Calcd for $C_{16}H_{26}O_2N_2$: N, 10.51%.

The General Procedure for Catalytic Reduction. Hydrazone (1 g) and platinum oxide (150 mg) were placed in a 100 ml-round-bottomed flask, which was then filled with hydrogen under ordinary pressure. The solution obtained was hydrogenated at room temperature for 12 h. After filtration of the catalyst, the resulting solution was made alkaline to litmus with 1 M sodium hydroxide solution and extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate. The evaporation of ether afforded a colorless oil (500 mg), which was assigned to a hydrazino compound by IR and NMR data. The hydrazino-compound was successively dissolved in 1 M hydrochloric acid (50 ml) with platinum oxide (100 mg) in a 200 ml-autoclave. The autoclave was then filled with hydrogen at 50 kg/cm² (room temperature) and stirred magnetically at 100 °C for 4 h. After cooling, the catalyst was filtered and the filtrate was evaporated *in vacuo* to dryness. The residue was redissolved in water (100 ml) and basified to pH 9 with 1 M ammonia. The *N*-methyl compound (optically active source) extracted with ether maintained its 95% optically activity (35% yield). The aqueous solution was passed through an ion exchange column packed with IRA-410. The elute was evaporated *in vacuo* to dryness. The residue obtained was redissolved in water (200 ml) and passed through a column packed with Dowex 50W-X8. The amino acid was eluted with 1 M ammonia. The basic solution was concentrated to dryness to give a white solid (30—40% yield). The IR (KBr) spectrum of the synthesized alanine was superimposable with that of an authentic sample. Paper chromatography of the synthesized alanine showed only the one spot having the R_f value as an authentic sample.

L-*Alanine from* (S)-*Hydrazone (Va) by Catalytic Reduction.* One gram of Va gave 109 mg (34% yield) of L-alanine of 46.5 % optical purity, $[\alpha]_D^{22}$ +15.21° (*c* 0.56, acetic acid).

L-*Alanine from Ethyl* (R)-*2*-(N-*Methyl*-N-*isobornylhydrazono) propionate (Vb) by Catalytic Reduction.* One gram of Vb, $[\alpha]_D^{20}$ −293° (*c* 2.7, ethanol), gave 118 mg (37% yield) of L-alanine of 9.2% optical purity, $[\alpha]_D^{22}$ +3.0° (*c* 0.56, acetic acid).

Zn–HCl Reduction of (Va). A mixture of Va (2.2 g), ethanol (40 ml), and zinc dust (2.7 g) was treated slowly with a saturated alcoholic solution of hydrogen chloride at 10 °C. When this zinc was completely dissolved, an additional amount (1.3 g) of zinc was added and the mixture was stirred at room temperature for 1 h. The filtered solution was evaporated *in vacuo* and the residue was dissolved in water. Hydrogen sulfide was introduced into the solution at pH 4. After precipitating ZnS, the mixture was separated by a centrifuge, then the supernatant was made alkaline at pH 9 with 1 M ammonia extracted with ether. The aqueous solution was passed through an ion exchange column packed with IRA-410 and the crude amino acid was eluted with 1 M acetic acid. The dried solid was disolved in water again and treated by passing through a Dowex-50W-X8 column. The L-alanine (140 mg), $[\alpha]_D^{21}$ +3.6° (*c* 0.55, acetic acid) of 10.9% optical purity, was obtained by elution with 1 M ammonia and evaporation.

Catalytic Reduction of Hydrazones (IX—XIV). The same procedure as in the experiment of bornylamine system Va was applied to the hydrazones IX—XIV, which were derived from *(S)*-1,2-dimethylpropylamine (VIIa): $[\alpha]_D^{20}$ −3.4° (neat) (lit,[13] $[\alpha]_D$ −3.45°); *(R)*-(VIIb): $[\alpha]_D^{20}$ +3.2° (neat); and *(S)*-α-methylbenzylamine (VIII): $[\alpha]_D^{22}$ −38.5° (neat).[14]

Iodination Reactions of Ketones in the Reversed Micellar Systems of Dodecylammonium Propionate in Hexane

Manabu SENŌ, Koji ARAKI, and Shinsaku SHIRAISHI

Institute of Industrial Science, The University of Tokyo, Roppongi 7-22, Minato-ku, Tokyo 106

(Received December 8, 1975)

The iodination reactions of ketones in the reversed micellar systems of dodecylammonium propionate (DAP) in hexane were studied at 25.0 °C in relation to the enzymatic function of aldolase or enolase. The reaction rate in the DAP reversed micellar system is 10^6—10^7 times greater than that in the system without DAP, 100 times greater even in comparison with that in DAP aqueous system at pH 6.8. As in the ammonium ion catalyzed reaction in aqueous media, the reaction in the presence of DAP proceeds *via* ketimine formation between ammonium groups of DAP and acetone and subsequent enolization of ketimine to enamine, which reacts very rapidly with iodine. The catalytic effect of DAP reversed micellar system in each reaction step was discussed. Further, this reversed micellar system shows a marked selectivity for acetone as compared with higher analogs.

Recently, Fendler *et al.* reported that the reversed micellar systems in nonpolar solvents catalyze several reactions and provide a favorable model for active sites of enzymes, and that the catalytic effect of these systems is related to the reaction field furnished with water pool in cores of reversed micelles, the polarity of which is lower than that of bulk water.[1,2] We also observed that the reversed micellar system of dodecylammonium propionate (DAP) in hexane shows an enzyme-like behavior in the hydrolysis of adenosine 5'-triphosphate (ATP).[3] We have studied the fundamental properties of this reversed micellar system, and shown that the catalytic effect is closely related to the properties of the water solubilized in the cores of reversed micelles.[4]

The functional groups of enzymes usually show their catalytic activities and specificities through some chemical interaction with substrates. It is of interest to demonstrate the reaction in which the functional groups of surfactant participate through the bond formation with substrate in the reversed micellar system, in order to clarify the enzymatic function.

In this paper, results of the studies on the iodination reaction of ketones in DAP reversed micellar system are given. The reaction is catalyzed by the conjugate acids of primary and secondary amines in aqueous media, proceeding *via* the formation of ketimine intermediate.[5] It has been proposed that at the active sites of aldolase and enolase their amine or ammonium groups participate in the reaction through the ketimine formation with carbonyl groups of a substrate. The ammonium group of DAP is expected to play a similar role in the iodination of ketones.

Experimental

Materials. Preparation and purification of DAP were described previously;[3] mp 55—56 °C (lit, 54—56 °C)[6]; Found (Calcd), C, 70.04 (69.44), H, 12.80 (12.82), N, 5.57 (5.40)%. Acetone was purified by the usual method. The other ketones were of reagent grade.

Iodination Rates of Ketones. A given amount of aqueous solution of iodine, containing a large excess of potassium iodide to suppress the formation of *N*-iodo derivatives,[5] was solubilized in hexane by DAP, the temperature of this reversed micellar solution being maintained at 25.0 °C. After the attainment of thermal equilibrium, the reaction was started by addition of ketone or a ketone/hexane solution in the UV cell of 10 or 2 mm in path length, and the decrease in absorption of triiodide ion at 363 nm was recorded with a Union stopped-flow spectrophotometer model RA-1100 with an RA-108s digital-memory unit. For slow reactions, a Hitachi 124 spectrophotometer was employed.

In DAP aqueous systems, the absorption band due to triiodide ion appears at 353 nm. The reaction in hexane in the absence of DAP, where the solution contains no potassium iodide, was traced by measuring the decrease in absorbance of iodine at 520 nm.

Ketimine Formation Reactions. The UV spectra of mixed solutions of DAP and acetone in hexane were recorded with a Union SM-401 spectrophotometer with an SM-4012 data-analyzer at 25.0 °C, at least half an hour after preparation of the sample solution in order to ensure the attainment of equilibrium. The absorption band of the ketimine intermediate was constructed from the spectra. The rates of ketimine formation were traced by recording the increase in absorption band of ketimine at 250 nm by the stopped-flow method.

Results

Mechanism of Iodination Reaction of Acetone in DAP Reversed Micellar Systems. The iodination reactions of acetone in DAP reversed micellar system were carried out under conditions where acetone concentration was

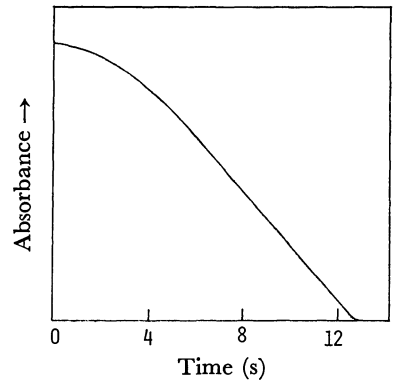

Fig. 1. The decrease in absorbance of triiodide ion at 363 nm. The typical instance of the initial stage and the subsequent steady state of the iodination reaction of acetone in the DAP reversed micellar system at 25.0 °C, where DAP, acetone, iodine and water concentrations are 1×10^{-1}, 5×10^{-4}, 1×10^{-4}, and 1.11×10^{-1} M, respectively.

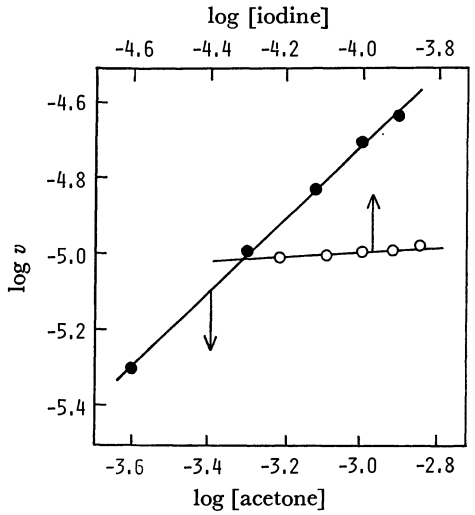

Fig. 2. Dependences of iodination rate of acetone (v) on concentrations of acetone (iodine concentration is 1×10^{-4} M) and iodine (acetone concentration is 5×10^{-4} M) in the DAP reversed micellar system at 25.0 °C, where DAP and water concentrations are 1×10^{-1} and 8.33×10^{-2} M, respectively.

much smaller than DAP concentration so that the reaction caused no large effect on micellar properties. A short induction period was observed, after which the reaction attained a steady reaction rate (Fig. 1). The dependence of the rates of the steady reaction, v, on the concentrations of various components was examined. The rate was proportional to acetone concentration and almost independent of iodine concentration (Fig. 2). A similar behavior was observed in the aqueous system.[7] The results indicate that the iodination step is very fast and the preceding steps, especially the enolization step of substrate, are slow and rate-determining. On the other hand, the dependence of v on DAP and water concentrations is complicated (Figs. 3 and 4). These results suggest that the effect of the reaction field in the reversed micellar system is not as simple as that in the aqueous ammonium ion catalyzed reaction, where the rate is proportional to the ammonium ion concentration

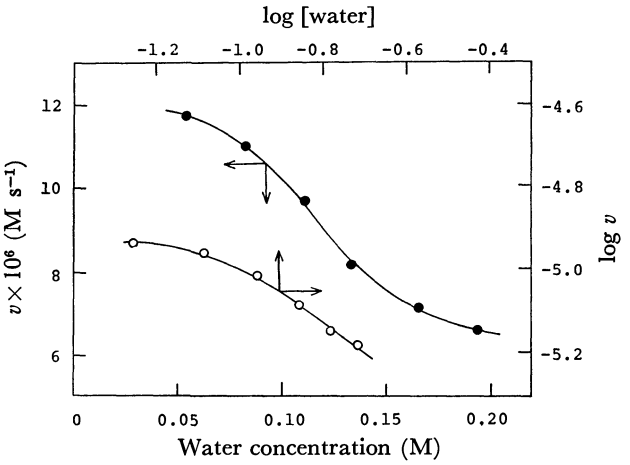

Fig. 3. Dependence of iodination rate of acetone (v) on water concentration in the DAP reversed micellar system at 25.0 °C, where DAP, acetone and iodine concentrations are 1×10^{-1}, 5×10^{-4}, and 1×10^{-4} M, respectively.

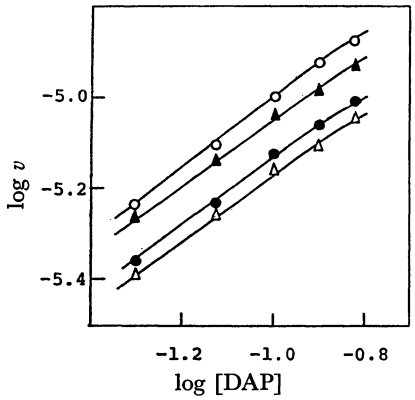

Fig. 4. Dependence of iodination rate of acetone (v) on DAP concentration at various [DAP]/[water] ratios; (○): 1.20, (▲): 0.901, (●): 0.719, and (△): 0.599, where acetone and iodine concentrations are 5×10^{-4} and 1×10^{-4} M, respectively.

together with the acetone concentration.[5]

The above results suggest also the existence of a reaction intermediate. For the sake of confirmation, the UV spectra of the DAP reversed micellar solution were measured in the presence of acetone. The result is shown in Fig. 5. Addition of acetone causes a broad

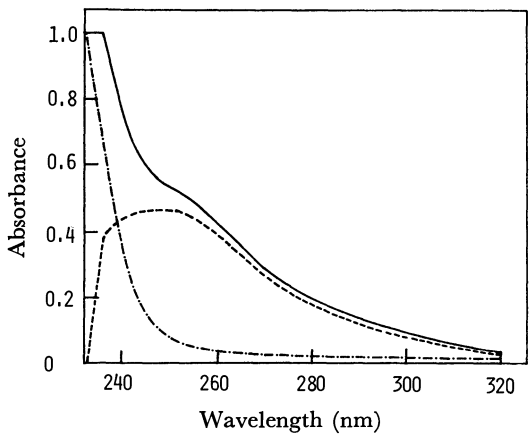

Fig. 5. UV spectra of the DAP reversed micellar solutions at 25.0 °C; (-·-·-): DAP (1.5×10^{-1} M) in the absence of acetone, (——): DAP (1.5×10^{-1} M) in the presence of acetone (7.5×10^{-3} M) and (------): the difference spectra of above two spectra.

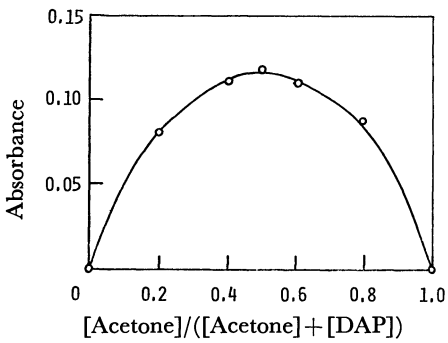

Fig. 6. Continuous variation method applied to the absorption band of the intermediate at 250 nm at 25.0 °C. Total concentration of acetone and DAP is kept constant at 2×10^{-2} M.

absorption band at 240—260 nm (λ_{max}=250 nm) as a shoulder of the DAP absorption band. The continuous variation method applied to this absorption band revealed that it should be ascribed to a 1 : 1 adduct of DAP and acetone (Fig. 6). The equilibrium constants of the formation of this intermediate, K_i, and its molar extinction coefficient, ε, were obtained by means of the equation

$$\frac{[A]_0}{d} = \frac{1}{\varepsilon K_i}\cdot\frac{1}{[D]_0} + \frac{1}{\varepsilon} \quad ([D]_0 \gg [A]_0) \qquad (1)$$

where d is the absorbance of the intermediate at 250 nm, and $[D]_0$ and $[A]_0$ are the initial concentrations of DAP and acetone, respectively. The analysis reveals that the reaction intermediate has an absorption maximum at 250 nm (ε=127), and this spectrum is not so different from that of *N*-isopropylidenebutylamine in cyclohexane (λ_{max}=246 nm, ε=140).[8]

These results, together with a comparison of the results on the aqueous ammonium ion catalyzed reaction, lead us to conclude that the iodination of acetone in DAP reversed micellar system in hexane proceeds *via* the formation of ketimine and subsequent enolization of ketimine, as proposed for the ammonium ion catalyzed reaction in aqueous media. The reaction mechanism can be written as follows.

$$(CH_3)_2C{=}O + DAP \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}}$$

$$[(CH_3)_2C{=}NR \text{ or } (CH_3)_2C{=}\overset{+}{N}(H)R] \xrightarrow{k_2}$$

$$CH_2{=}\overset{CH_3}{\overset{|}{C}}{-}NHR \xrightarrow{I_2} \text{product} \quad (R = n\text{-}C_{12}H_{25}) \qquad (2)$$

where k_1, k_{-1}, and k_2 are the rate constants of formation, decomposition and enolization, respectively, of ketimine. The step of formation of carbinolamine caused by addition of ammonium ion to acetone and the step of dehydration of carbinolamine to form ketimine could not be discriminated from each other. A combined step is given in terms of k_1 and k_{-1} in scheme (2). There is a possibility of direct enolization of acetone catalyzed by DAP. However, this pathway could be neglected, since the reaction rate during the induction period is much smaller than the steady rate. According to the above mechanism, the initial rate, v, and the apparent second-order rate constant, k_{app}, at the steady state are given under the conditions $[D]_0 \gg [A]_0$ as follows:

$$v = k_{app}[D]_0[A]_0 = \frac{k_2[D]_0[A]_0}{K_m + [D]_0} \qquad (3)$$

where $K_m = (k_{-1}+k_2)/k_1$.

Kinetic Analyses of Iodination Reaction of Acetone. The first-order rate constants, $k°$, and the second-order rate constants, k_{app}, in various reaction systems are given in Table 1. The values of K_m and k_2 could be estimated

Table 1. Iodination rate constants of acetone in various systems at 25.0 °C

a) DAP: 1×10^{-1} M, ketone: 5×10^{-4} M, iodine: 1×10^{-4} M, water: 1.67×10^{-1} M. b) DAP: 4×10^{-2} M, ketone: 1×10^{-3} M, iodine: 2.5×10^{-5} M. c) M^{-1} s^{-1}. d) See Refs. 8 and 9.

kinetically from the iodination rate, v. For this purpose, Eq. 3 is transformed into the following equations.

$$\frac{[A]_0}{v} = \frac{K_m}{k_2}\cdot\frac{1}{[D]_0} + \frac{1}{k_2} \quad (4)$$

$$\frac{1}{k_{app}} = \frac{1}{k_2}\cdot[D]_0 + \frac{K_m}{k_2} \quad (5)$$

The plots of $[A]_0/v$ against $1/[D]_0$ and of $1/k_{app}$ against $[D]_0$ give straight lines (Figs. 7 and 8), and the k_2 and K_m values can be determined from their slopes. The [DAP]/[water] ratio was kept constant so as not to affect the state of DAP reversed micelles in these experiments.[3,4]

The values of k_1 and k_{-1} can be determined by the measurements on the ketimine formation reaction between DAP and acetone; the k_1 value was obtained directly from the measurement on the increase in absorption of ketimine at 250 nm, and the k_{-1} value was estimated from k_1 and K_i values. The results are summarized in Table 2. The K_m values can be calculated from k_1, k_{-1}, and k_2 values, and the calculated values are given in Table 2 as K_m^{calcd} in parentheses. The values are close to those obtained experimentally, indicating the validity of the reaction mechanism.

Iodination Reactions of Other Ketones. The iodination rate constants of higher analogs of acetone in the DAP reversed micellar system, k_{app}^{r}, and those in the DAP aqueous system, k_{app}^{w}, are given in Table 3, where k_{rel}^{r} and k_{rel}^{w} represent the relative rates of higher ketones to acetone. For the sake of comparison the reported values of relative rates of higher ketones to acetone in the iodination reaction catalyzed by hydroxide anion, k_{rel}^{OH}, and by hydronium cation, k_{rel}^{H}, in aqueous system are also given.[9,10]

Discussion

Catalytic Effect of DAP Reversed Micellar Systems in Iodination Reaction of Acetone. The results given in Table 1 indicate that the rate constant of iodination of acetone in the DAP reversed micellar system is 10^6—10^7 times greater than that in the system without DAP, and about 100 times greater even in comparison with that in the DAP aqueous system. The second-order rate constants of the iodination reactions in aqueous solutions catalyzed by various catalysts are given in Table 4.[5,11]

Table 4. Iodination rate constants of acetone catalyzed by various acid-base catalysts at 25.0 °C[5,11]

Catalyst	k (M^{-1} s^{-1})
OH^-	1.7×10^{-1}
CH_3COO^-	2.4×10^{-7}
CH_3NH_2	1.9×10^{-2}
H_2O	8.3×10^{-12}
H_3O^+	2.5×10^{-5}
CH_3COOH	1.0×10^{-7}
$CH_3NH_3^+$	3.0×10^{-4}

These reactions proceed *via* prototropic mechanism catalyzed by general acid-base catalysts, the rate constants obeying the Brønsted relationship.[11] However, the ammonium ion catalyzed reaction is much faster than that expected from this relationship. As a reason for this acceleration, the reaction mechanism *via* ketimine formation has been proposed.[5]

Since the pK_a values of methylamine ($pK_a=10.26$) and dodecylamine ($pK_a=10.63$), or those of acetic acid ($pK_a=4.76$) and propionic acid ($pK_a=4.87$) are nearly equal to each other at 25.0 °C, no large difference should exist between them as general acid-base catalysts. Then, it could be anticipated that the contribution of DAP as a general acid-base catalyst would be very small in the DAP aqueous system of pH=6.8. In fact, the catalytic effect of DAP in aqueous media is very high, and the reaction is considered to proceed mainly *via* ketimine formation. This catalytic mechanism could

be applied to the DAP reversed micellar system, although a rate acceleration is enhanced by the micellar effect.

The catalytic effect of reversed micellar system can be discussed in detail by considering the role of micelles in each step of Scheme (2). The K_i value in DAP reversed micellar system is 6.8—6.9 (Table 2). In aqueous system the absorption band of ketimine was not clearly observed. However, the K_i value could be roughly estimated from the decrease in absorption band of acetone at 280 nm, where the absorption due to ketimine and DAP is negligibly small. The K_i value obtained for DAP and acetone in aqueous system is 0.2 ± 0.1 at 25.0 °C, close to the values 0.21—0.23 for methylamine and acetone, and 0.08 for butylamine and acetone.[12,13] The K_i value in aqueous system is much smaller than that in the reversed micellar system. It is therefore concluded that the stabilization of ketimine as a reaction intermediate would be one of the important factors for determining the catalytic effect of the reversed micellar system.

The results on hexadeuterated acetone are included Table 2. An isotope effect is observed only at the enolization step (k_2), ensuring also the reaction mechanism illustrated in Scheme (2).

Dependence of Iodination Rate on Water Concentration. The enolization rate, k_2, of ketimine is affected by water concentration. A major part of water in the DAP reversed micellar system in hexane is solubilized in the cores of reversed micelles,[4] iodine existing in the cores of reversed micelles. The k_2 value is nearly proportional to the [DAP]/[water] ratio (Fig. 9). A similar effect

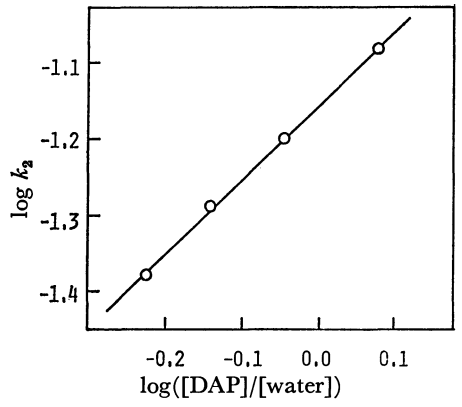

Fig. 9. Dependence of enolization rate constant of ketimine (k_2) on [DAP]/[water] ratio in the DAP reversed micellar system at 25.0 °C, where acetone and iodine concentrations are 5×10^{-4} and 1×10^{-4} M, respectively.

was observed for the ATP hydrolysis and was explained by a change in the microenvironment of substrate solubilized in the cores of reversed micelles.[3] This suggests that the enolization of ketimine occurs in the cores of reversed micelles to afford enamine, to which iodine adds rapidly.

We see from the rate Eq. 3 that, when the k_2 value increases, the K_m value increases and approaches the value of k_2/k_1, the k_{app} value becoming governed mainly by the k_1 value. On the other hand, it is clear from Table 2 that the water concentration largely affects the value of k_2, but not k_1. Therefore, it can be expected that the dependence of the reaction rate on water concentration becomes smaller with the lowering in water concentration or increase in the k_2 value. This expectation agrees with the results shown in Fig. 3.

Iodination Reactions of Other Ketones. It is supposed that the rate-determining step of the base-catalyzed reaction is the proton transfer from ketone, while that of the acid-catalyzed reaction is the proton transfer from protonated ketone.[14] Therefore, it could be expected that the acid-catalyzed reaction would be less affected by the electronic effect of substituents than the base-catalyzed reaction. The reaults in Table 3 show that k^{w}_{rel} values are similar to k^{OH}_{rel} values suggesting that the enolization of ketimine in the DAP aqueous system proceeds *via* proton transfer from the form $(CH_3)_2C{=}NR$.

On the other hand, in the DAP reversed micellar system the k^{r}_{rel} values of higher alkyl ketones are much smaller than the k^{w}_{rel} values. The ratio k^{r}_{app}/k^{w}_{app} is the largest for acetone, and decreases remarkably as the substituents become larger. The selectivity of the iodination reaction catalyzed by the reversed micellar system would be caused by the steric factor rather than the electronic factor of the substituents. Existence of the microscopic heterogeneous phase, *i.e.* a bulk hexane phase and a reversed micellar phase with core water, would play an important role in governing the selectivity through the distribution of substrate or intermediate between these two phases. The results are of interest in relation to the specificity of enzyme.

Reaction of Isocyanides with Mercuric Chloride

Hiroaki SAWAI and Takeo TAKIZAWA

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received November 17, 1975)

Isocyanides reacted with mercury(II) chloride in dry tetrahydrofuran upon heating to afford low molecular weight polymers and oligomers. Isocyanides without bulky groups underwent polymerization catalyzed by mercury(II) chloride. Various heterocyclic oligomers were obtained from the reaction of 2,6-xylyl isocyanide with mercury(II) chloride.

Isocyanides have been reported to polymerize by many kinds of catalysis,[1,2] (a) protonic acids catalysis, (b) certain Lewis acids catalysis, (c) group VIII metal catalysis and (d) ground glass catalysis. On the other hand, little has been known about the oligomerization of isocyanides in spite of its utility for the synthesis of heterocycles and oligomeric derivatives.

In the course of studying the reaction of isocyanides with mercury(II) compounds,[3-5] we found that isocyanides react with mercury(II) chloride to give labile isocyanide complexes, and to afford cyclic oligomers and low molecular weight polyisocyanides upon heating. Here we report the oligomerization and polymerization of isocyanides *via* isocyanide-mercury(II) chloride complexes.

Results and Discussion

Cyclo-oligomerization of 2,6-Xylyl Isocyanide (I). 2,6-Xylyl isocyanide reacted with mercury(II) chloride to give 2,6-xylyl isocyanide-mercury chloride complex (II) at room temperature.[3] When I and mercury(II) chloride in molar ratio of 4: 1 were heated in THF at reflux for 5 h, two heterocyclic tetramers (III and IV) and one pentamer (V) were isolated in 1, 4, and 1% yield based on I, respectively. The complex II was also obtained in good yield. The compound III was converted to IV easily by hydrolysis in aqueous THF solution or in silica gel column chromatography. Elemental analysis and mass spectrum of III indicate that compound III consists of four molecules of I, one chlorine and one hydrogen atom. IR spectrum of III shows absorptions at 3420 due to ν_{NH}, 1670, 1640, and 1625 cm^{-1} due to $\nu_{C=C}$ and $\nu_{C=N}$. NMR spectrum exhibited a singlet at δ 3.76 due to NH proton, four sharp singlets around δ 2.0 due to methyl protons and two broad singlets around δ 7.0 due to aromatic protons. Compound IV was found to have the composition of four molecules of I and one molecule of water on the basis of elemental analysis and mass spectrum. In the IR spectrum, IV shows absorptions at 3370 and 3296 due to two ν_{NH}. The NMR spectrum of IV shows characteristic singlets at δ 4.32 and 5.04 due to NH protons in addition to signals due to methyl protons and aromatic protons. UV absorption pattern is similar to that of pyrrolin-2-one derivatives.[6] From these data,

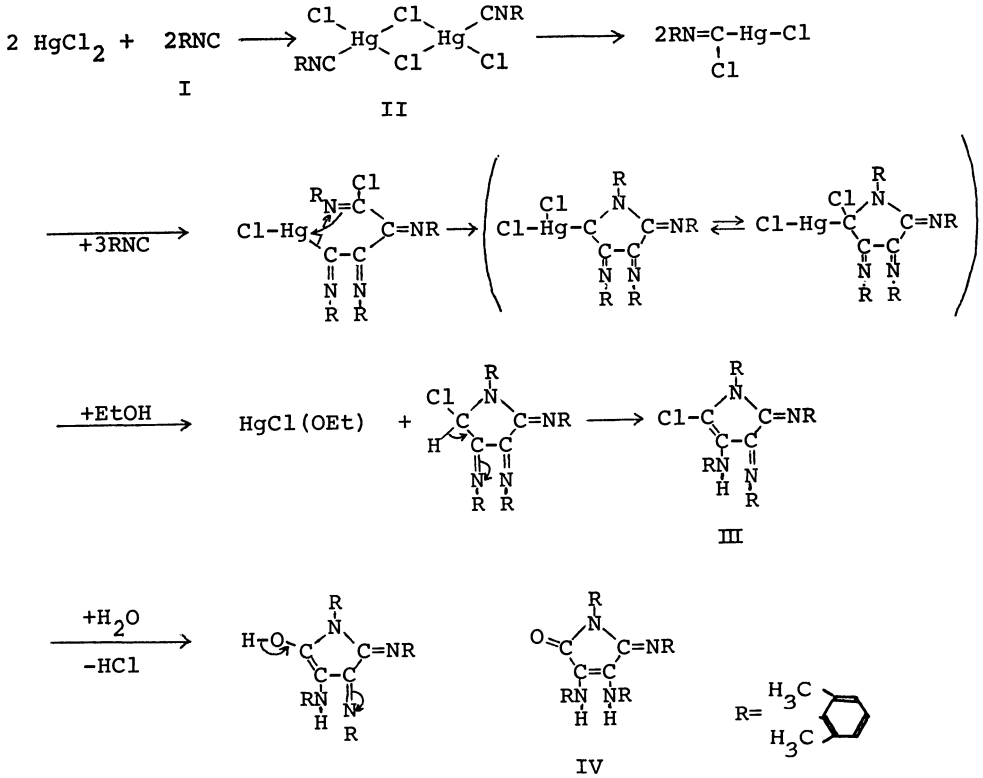

Fig. 1

III and IV were identified as 1-(2,6-xylyl)-2-chloro-3-(2,6-xylylamino)-4,5-bis(2,6-xylylimino)-2-pyrroline and 1-(2,6-xylyl)-3,4-bis(2,6-xylylamino)-5-(2,6-xylylimino)-3-pyrrolin-2-one, respectively. The formation of III and IV could be explained as following scheme. Insertion of I into Hg–Cl bond and successive insertion could form intermediate (A). Further insertion reaction presumably could hardly take place because of steric hindrance of I. Intramolecular addition of Hg–C bond to C=N forms complex (B), which converts to C. Subsequent proton shift of C could give III. The addition of ethanol to the reaction mixture enhanced the oligomerization. Thus, the oligomers III, IV, V, and blue crystalline hexamer (VI) were isolated in 4, 12, 3, and 0.2% yield, respectively. The reaction of phenylisocyanide–mercury(II) chloride complex with I gave small amounts of 1:1 co-oligomer (IV'), whose structure is similar to that of IV.

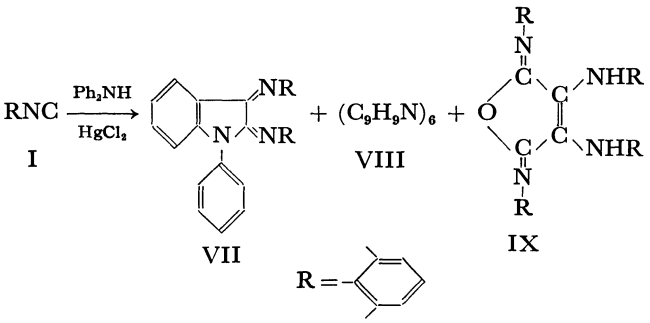

Fig. 2

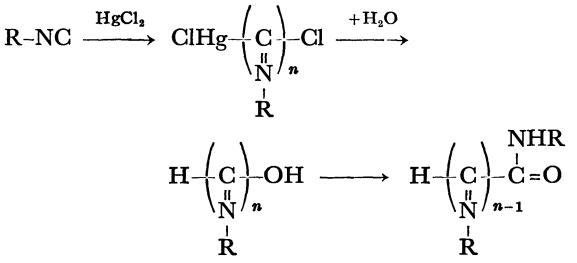
Diphenylamine affected the oligomerization of I, though the role of diphenylamine is unclear. Heating a mixture of I, mercury(II) chloride and diphenylamine in THF solution gave red crystals (VII), brown crystalline hexamer (VIII) and orange yellow crystalline tetramer (IX) in 3, 21, and 31% yield, respectively. Elemental analysis and mass spectrum of VII indicate that VII is a 2:1 adduct of I and diphenylamine. IR and NMR spectra indicate that VII is an isatindiimine derivative. Compound IX was found to be an isomer of IV from elemental analysis and mass spectrum data. NMR spectrum exhibits that IX has a symmetrical molecular structure. Therefore, the compound IX was determined as 2,5-bis(xylylimino)-3,4-bis(xylylamino)furan. The compound I cannnot hold a polymer chain propagation and affords various heterocyclic oligomers.

Polymerization of Isocyanide. Isocyanides without bulky groups can polymerize in the presence of mercury(II) chloride. Heating a mixture of benzyl isocyanide and mercury(II) chloride in THF gave brownish powdery polymer In the similar manner, cyclohexyl and phenyl isocyanide gave brownish polymers. IR spectra of the polymers show absorptions at 1640—1650 and 3260—3370 cm^{-1} (weak) due to $\nu_{C=N}$ and ν_{NH}, respectively. Elemental analysis suggests that the polymers consist mainly of monomer unit and small amounts of water. The molecular weights of these polymers are 720—850. This indicates that the average degree of polymerization is seven to eight. These polymers are soluble in THF and chloroform, but insoluble



$n=(6), 7, 8, (9)$

Fig. 3

in ether. The molecular weights of the polymers are far lower than that of polyisocyanides obtained by $BF_3 \cdot OEt_2$ or $SnCl_4$ catalysis.[2] High reaction temperature and high molar ratio of isocyanides to mercury(II) chloride are also responsible for the low molecular weight.

Experimental

The melting points are uncorrected. The IR spectra were recorded with a JASCO DS-402 spectrometer. The NMR spectra were measured with a JEOL TMN-TS-100 spectrometer. The mass spectra were taken with a JEOL SG-01 apparatus. Molecular weights of the polymers are measured with Hitachi-Perkin Elmer 115 Molecular Weight Apparatus using chloroform solution. Isocyanides were prepared by the method of Ugi and coworkers.[7]

Reaction of I with Mercury(II) Chloride: Mercury(II) chloride (0.68 g, 25 mmol) **I** (1.31 g, 10 mmol) and dry THF (10 ml) were mixed in a 30 ml conical flask under nitrogen and stirred for 5 h at reflux. The reaction mixture was filtered to remove white powder (Hg_2Cl_2, 18 mg). The filtrate was concentrated and treated with 20 ml of ether to remove II (0.89 g) by filtration. The filtrate was concentrated *in vacuo* and subjected to column chromatography on silica gel. The crystalline oligomers, III, IV, and V were isolated by using hexane–ether as an eluent. Recrystallization of III from hexane–ether gave purified reddish purple crystals, (53 mg, 3.8%), mp 195—197°. Found: C, 77.02; H, 6.79; N, 10.16%. Calcd for $C_{36}H_{37}N_4Cl$: C, 77.05; H, 6.65; N, 9.98%. IR (KBr): 3420, 1670, 1645, 1625 cm^{-1}. NMR ($CDCl_3$): δ 1.99 (s, 6H), 2.02 (s, 6H), 2.12 (s, 6H), 2.36 (s, 6H), 3.76 (s, 1H), 6.70—6.90 (broad s, 9H), 7.12 (s, 3H). Mass spectrum: M^+= 561 (561).

Recrystallization of IV from hexane–dichloromethane gave purified orange yellow crystals, (14 mg, 1%), mp 201—203 °C. Found: C, 80.10; H, 7.33; N, 9.83%. Calcd for $C_{36}H_{38}ON_4$: C, 79.67; H, 7.06; N, 10.32%. IR (KBr): 3370, 3296, 1655, 1640 cm^{-1}. NMR ($CDCl_3$): δ 1.88 (s, 6H), 2.05 (s, 6H), 2.23 (s, 6H), 2.36 (s, 6H), 4.32 (s, 1H), 5.04 (s, 1H), 6.63 (s, 3H), 6.66 (s, 3H), 6.93 (s, 3H), 7.22 (s, 3H). UV $\lambda_{max}^{CH_2Cl_2}$: 263 (ε, 26×10^4), 452 nm (4.7×10^3). Mass spectrum: M^+=542 (542).

V was recrystallized from hexane–dichloromethane to give purple crystals, (13 mg, 1%) mp 159—161 °C. Found: C, 82.65; H, 7.14; N, 10.67%. Calcd for $C_{45}H_{45}N_5$: C, 82.40; H, 6.92; N, 10.68%. IR (KBr): 1666, 1612 cm^{-1}. NMR ($CDCl_3$): δ 1.36 (s, 9H), 1.67 (s, 3H), 1.93 (s, 6H), 2.09 (s, 3H), 2.18 (s, 3H), 2.27 (s, 3H), 2.44 (s, 3H), 5.2—5.6 (m, 2H), 6.0—6.15 (m, 1H), 6.60—6.90 (broad s, 9H), 7.05 (broad s, 3H). Mass spectrum: M^+=655 (655).

Reaction of I with Mercury(II) Chloride in the Presence of Ethanol: A mixture of I (2.62 g, 20 mmol), mercury(II) chlo-

ride (1.36 g, 5 mmol), dry THF (20 ml) and ethanol (2 ml) was heated at reflux with stirring for 8 h under nitrogen. Hg_2Cl_2 (150 mg) and II (2.238 g) were removed by filtration. The oligomers, III (334 mg, 11.9%), IV (112 mg, 4.1%), V (81 mg, 3.1%) and VI (5 mg, 0.2%), were isolated from the reaction mixture with a chromatography on silica gel. The compound VI was recrystallized from hexane–dichloromethane to give purified blue crystalline hexamer, mp (decompose) 266—267 °C. Found: C, 81.83; H, 7.05; N, 10.50%. Calcd for $C_{54}H_{54}N_6$: C, 82.40; H, 6.92; N, 10.68%. IR (KBr): 1655, 1580, 1465 cm^{-1}. NMR ($CDCl_3$): δ 1.68 (s, 12H), 2.00 (s, 12H), 2.24 (s, 12H), 6.51 (s, 6H), 6.71 (broad s, 12H). Mass spectrum: $M^+=786$ (786).

Conversion of III to IV: The compound III (101 mg) was heated in aqueous THF at reflux for 0.5 h. The red color of the reaction mixture turned to orange yellow. The reaction mixture was dried over sodium carbonate, concentrated *in vacuo* and chromatographed on silica gel. The compound IV was isolated (92 mg, 94.5%).

The compound III was also completely hydrolyzed to IV, when keeping in silica gel column chromatography for 8 h.

Co-oligomerization of Phenyl Isocyanide with I. Phenyl isocyanide (0.42 g, 4 mmol) and mercury(II) chloride (550 mg, 2 mmol) were mixed in dry THF (10 ml) cooling with Dry Ice–methanol under nitrogen to prepare phenyl isocyanide–mercury(II) chloride complex.

I (1.053 g, 8 mmol) was added to the mixture. The reaction mixture was warmed to room temperature with stirring for 1 h, then heated at reflux for 4 h. The reaction mixture was concentrated *in vacuo*, treated with ether to remove polyphenyl isocyanide and II as precipitates. The filtrate was concentrated and subjected to column chromatography on silica gel to isolate orange yellow crystals (30 mg, 3.0%) and yellow crystals (8 mg). The orange yellow crystals were recrystallized from hexane–dichloromethane to give purified IV′, mp. 176—177 °C. Found: C, 78.76; H, 6.69; N, 11.28 %. Calcd for $C_{32}H_{30}ON_4$: C, 78.98; H, 6.21; N, 11.52%. IR (KBr): 3365, 3305, 1725, 1655, 1645, 1602 cm^{-1}. NMR ($CDCl_3$): δ 2.03 (s, 6H), 2.61 (s, 6H), 4.7 (broad s, 1H), 6.42 (broad s, 6H), 6.78 (s, 5H), 7.24 (s, 5H). Mass spectrum: $M^+=486$ (486).

Reaction of I with Mercury(II) Chloride in the Presence of Diphenylamine: Diphenylamine (0.85 g, 5 mmol) was added to the mixture of mercury(II) chloride (0.67 g, 2.5 mmol), I (1.31 g, 10 mmol) in dry THF (10 ml). The reaction mixture was heated at reflux for 5 h with stirring under nitrogen. The reaction mixture was concentrated and treated with 20 ml of ether to remove mercury(I) chloride, diphenylamine and II by filtration. The filtrate was concentrated and chromatographed on silica gel. Three compounds were isolated by using hexane–ether as an eluent. Recrystallization from hexane–ether gave the purified 2:1 adduct VII (36 mg, 3.3%), mp 178—180 °C. Found: C, 84.02; H, 6.50; N, 9.57%. Calcd for $C_{30}H_{27}N_3$: C, 83.88; H, 6.34; N, 9.78%. IR (KBr): 1672, 1637, 1589 cm^{-1}. NMR ($CDCl_3$): δ 1.91 (s, 6H), 2.11 (s, 6H), 2.11 (s, 6H), 6.4—6.85 (m, 5H), 6.93 (s, 3H), 7.20 (s, 3H), 7.25—7.60 (s, 4H). UV $\lambda_{max}^{CH_2Cl_2}$: 260 (ε, 4.1×10^4), 245 nm (2.85×10^3). Mass spectrum: $M^+=429$ (429).

Recrystallization of a brown compound from hexane–dichloromethane gave the purified VIII, (142 mg, 21.2%) mp. 295—298 °C. Found: C, 82.13; H, 7.06; N, 10.69%. Calcd for $C_{54}H_{54}N_6$: C, 82.40; H, 6.92; N, 10.68%. IR (KBr): 3380, 1671, 1625, 1507 cm^{-1}. NMR ($CDCl_3$): δ 1.84 (s, 6H), 2.15 (s, 6H), 2.24 (s, 6H), 3.98 (s, 1H), 6.59 (s, 3H), 6.73 (s, 3H), 6.83 (s, 3H). UV $\lambda_{max}^{CH_2Cl_2}$: 279 (ε, 49×10^5), 442 nm (5.8×10^5). Mass spectrum: $M^+=786$ (786).

Recrystallization of an orange compound from hexane–dichloromethane gave the purified IX, (213 mg, 30.7%), mp 211—212°. Found: C, 79.81; H, 6.62; N, 10.27%. Calcd for $C_{36}H_{38}ON_4$: C, 79.97; H, 7.06; N, 10.32%. IR (KBr): 3355, 1734, 1650, 1590 cm^{-1}. NMR ($CDCl_3$): δ 2.12—2.20 (broad m, 24H), 4.51 (s, 2H), 6.5—7.1 (broad m, 12H). UV $\lambda_{max}^{CH_2Cl_2}$: 276 (ε, 3.0×10^4), 487 nm (5.8×10^3). Mass spectrum: $M^+=542$ (542).

Polymerization of Isocyanides in the Presence of Mercury(II) Chloride. Benzyl isocyanide (1.20 g, 10 mmol) and mercury(II) chloride (0.672 g, 2.5 mmol) in 10 ml of dry THF was heated at reflux with stirring for 5 h under nitrogen. The reaction mixture was subjected to GLC analysis, and the formation of benzyl chloride (5% based on $HgCl_2$) was confirmed. White precipitates (Hg_2Cl_2, 280 mg) were removed from the reaction mixture by filtration. The filtrate was concentrated and 20 ml of ether was added to separate light brown powders, which were treated with $LiAlH_4$ in THF solution to remove mercury(II) by reduction. The brown powders were extracted with dichloromethane, dried over magnesium sulfate, concentrated and treated with ether–hexane to spectrate poly(benzyl isocyanide) as brown precipitates.

Poly(cyclohexy isocyanide) was obtained by the same procedure as that of poly(benzyl isocyanide).

The reaction of phenyl isocyanide (2.5 mmol, 20 mmol) with mercury(II) chloride (1.35 g, 5 mmol) was carried out at room temperature for 8 h and poly(phenyl isocyanide) was isolated by the similar manner as described in the reaction of benzyl isocyanide with mercury(II) chloride. Yield data, melting point, elemental analysis, IR data and molecular weight of these polymers are listed in Table 1.

α,β-Unsaturated Carboxylic Acid Derivatives. XI. Convenient Synthesis of *tert*-Butyl 2-Alkoxy- and Hydroxy-2-acetylamino-3-mono- or 3,3-dihaloalkanoates[1]

Chung-gi SHIN, Yoshiaki SATO, and Juji YOSHIMURA*

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

**Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ōkayama, Meguro-ku, Tokyo 152*

(Received December 10, 1975)

It was found that the halogenation of *t*-butyl 2-acetylamino-3-bromo-2-alkenoate (**3**) by NBS or NCS gave *t*-butyl 2-acetylimino-3,3-dihaloalkanoate (**6** and **7**). The addition of water or several saturated, unsaturated and polyhydric alcohols to the carbon–nitrogen double bond of **6** or **7** was accomplished to give *t*-butyl 2-acetylamino-2-alkoxy- and hydroxy-3,3-dihaloalkanoate. Similarly, the treatment of *t*-butyl 2-bromoacetylamino-2-alkenoate in alcohol gave *t*-butyl 2-acetylamino-2-alkoxy-3-bromoalkanoate, *via* the addition of alcohol to the imino intermediate (**2**). The formation mechanism and the structural assignment are discussed.

Because of the possible synthetic utility of α-alkoxy and α-hydroxy-α-acylamino acids as an important skeleton moiety or starting material for the total synthesis of bicyclomycin,[2] 6-methoxypenicillins,[3] 7-methoxycephalosporins,[3] and ergotamine,[4] there have been several reports on the synthetic methods of the above α-acylamino acids,[5–9] but some limitations are present in the above methods.

On the other hand, the present authors have recently reported the facile synthesis of *tert* (*t*)-butyl 2-bromoacetylamino-2-alkenoate (**1**) by the reaction of *t*-butyl 2-acetylamino-2-alkenoate with *N*-bromosuccinimide (NBS),[10] and its bromine migration into *t*-butyl 3-bromo-2-acetylamino-2-alkenoate (**3**).

In this paper, we wish to report that a further reaction of **3** with NBS occurs to give *t*-butyl 2-acetylimino-3,3-dibromoalkanoate (**6**) as a stable intermediate in a quantitative yield, and that the subsequent addition of water or alcohols to the carbon-nitrogen double bond of **6** easily takes place to form *t*-butyl 2-acetylamino-2-alkoxy- or hydroxy-3,3-dibromoalkanoate (**8**). Furthermore, the latter reaction was extended to the direct reaction of **3** with *N*-chlorosuccinimide (NCS) in alcohol and that of **1** with alcohol to give *t*-butyl 2-acetylamino-2-alkoxy-3-bromo-3-chloroalkanoate (**9**) and *t*-butyl 2-acetylamino-2-alkoxy-3-bromoalkanoate (**10**), respectively.

Results and Discussion

Addition of Protic Solvent to the Carbon-nitrogen Double Bond. When the *E*- or *Z*-isomer of **3** separated[10] was treated individually with NBS in chloroform at room temperature for 20 min, an identical yellowish syrup was obtained in a quantitative yield. Since the expected *t*-butyl 2-(*N*-acetyl-*O*-alkylhydroxyamino)-3-bromo-2-alkenoate (**5**) could not be obtained by the reaction of the above syrup with sodium alkoxide in alcohol,[10] and from the following experimental facts, the structure of the syrup isolated was confirmed to be **6**. It was concluded that *t*-butyl 3-bromo-2-bromoacetylamino-2-alkenoate (**4**) formed initially as an unstable intermediate and the subsequent migration of bromine from **4** gave **6**.

It was found that the treatment of **6** (R=CH_3 and C_2H_5) with protic solvent, water or alcohols at temperatures below 60 °C for 2—24 h gave 8 in a *ca.* 60% yield by the addition reaction of water or alcohols to the carbon-nitrogen double bond of **6**. The saturated (methanol, ethanol and benzyl alcohols), unsaturated (allyl and propargyl alcohols) and polyhydric alcohols (ethylene glycol and glycerol) were applied in the above addition. However, it was found that no reaction of **6** with isopropyl alcohol occurred, due to the steric hindrance between the bulkyl bromine in the 3-position and the isopropyl group. Accordingly, the primary hydroxyl group of glycerol should preferentially be added to **6**, in the case of **8h**.

It was found that *t*-butyl 2-acetylamino-3,3-dibromo-2-ethoxybutanoate (**8c**; R=CH_3) was also obtained directly in a 69.3% yield by the reaction of *t*-butyl 2-acetylamino-3-bromo-2-butenoate (**3**; *E*+*Z*) with NBS in ethanol at room temperature for 6 h. To extend this reaction, when compound **3** was treated with NCS in alcohols (methanol and benzyl alcohols), the expected **9** was obtained in a *ca.* 70% yield.

Furthermore, in order to generalize the above reaction, the addition of alcohols (methanol and benzyl alcohols) to the intermediate **2** was attempted, by stirring **1** with alcohol at room temperature for 48 h to give the expected **10** in a *ca.* 30% yield. On the other hand, an independent preparation of **10** by the addition reaction of alcohol to the carbon-carbon double bond of **3** was unsuccessful.

All the new compounds were obtained in high purities as a pale yellow syrup (**6**) or colorless crystals (**8**, **9**, and **10**).

Structure and Formation Mechanism. The structures of all the new products were analyzed spectroscopically and the elemental analysis was satisfactory. From the NMR spectra, the NH proton peak signals of **8**, **9**, and **10** appeared in the δ=6.25—7.02 region as broad singlets, except for **8h** (R=CH_3, δ 8.02). On the other hand, the appearance of secondary amide absorption bands in the regions 3200—3380 (–NH) and 1600—1700 and 1490—1520 cm^{-1} (–NHCO) in the IR spectra of **8**, **9**, and **10**, and the disappearance of the tertiary amide (>NCO) bands in the regions 1720—1725 and

1655—1660 cm^{-1} of **1** and **6** indicate the formation of **8**, **9**, and **10**.

The yields, physical constants, and spectral data of **8**, **9**, and **10** are summarized in Tables 1 and 2.

In recent reports,[8,9] it has been assumed that the formation of methyl 2-acetylamino-2-methoxyalkanoate derived from methyl 2-acetylamino-2-acetylthio- or 2-chloroacetylaminoalkanoate proceeded *via* the addition reaction of methanol to the unstable intermediate, methyl 2-acetyliminoalkanoate. Here, however, the above assumption was proven by isolation of the stable intermediate (**6**) and the subsequent addition of water or alcohols to **6**. Consequently, it was also confirmed that **9** and **10** were derived from the addition reaction of

gel column using benzene–ethyl acetate (30: 1 V/V) as the eluent to give colorless crystals.

Preparation of ***8g.*** After treating **6** (R=CH_3, 0.0036 mol) with ethylene glycol (5 ml) with stirring at room temperature for 5 h, a similar work up gave a pale yellow syrup, which gradually crystallized to give colorless crystals of *t*-butyl 2-acetylamino-3,3-dibromo-2-(2-hydroxyethoxy)butanoate.

In a similar manner, *t*-butyl 2-acetylamino-3,3-dibromo-2-(2-hydroxyethoxy)pentanoate was obtained from the reaction of **6** (R=C_2H_5) with ethylene glycol.

Preparation of ***8h.*** After treating **6** (R=CH_3, 0.0036 mol) with glycerol (5 ml) with stirring at *ca.* 60 °C for 4 h, water (30 ml) was added to the reaction mixture, and then the aqueous mixture was extracted three times with chloroform (60 ml). The chloroform extracts were washed with water twice and then dried over anhydrous sodium sulfate. Concentration of the chloroform solution gave a colorless syrup, which gradually crystallized to give colorless crystals of *t*-butyl 2-acetylamino-3,3-dibromo-2-(2,3-dihydroxypropoxy)-butanoate.

In a similar manner, *t*-butyl 2-acetylamino-3,3-dibromo-2-(2,3-dihydroxypropoxy)pentanoate was obtained from the reaction of **6** (R=C_2H_5) with glycerol. The syrup obtained was purified on a silica gel column using benzene–ethyl acetate (1: 5 V/V) as the eluent to give colorless crystals.

Preparation of ***9b.*** Into a solution of **3** (R=CH_3, 0.0036 mol) in methanol (10 ml) was added NCS (0.004 mol) portion by portion with stirring at room temperature. After stirring for 10 h, the reaction solution was concentrated under reduced pressure to give a colorless syrup containing succinimide. The residue was dissolved in benzene (30 ml) and then the benzene solution was washed three times with water. The benzene layer was dried over anhydrous sodium sulfate and then evaporated under reduced pressure to give colorless crystals, which were identified to be *t*-butyl 2-acetylamino-3-bromo-3-chloro-2-methoxybutanoate.

In a similar manner, *t*-butyl 2-acetylamino-3-bromo-3-chloro-2-methoxypentanoate was obtained from the reaction of **3** (R=C_2H_5) with NCS in the presence of methanol, after stirring for 5 h.

Preparation of ***9d.*** After treating a solution of **3** (R=CH_3, 0.0036 mol) in benzyl alcohol (3 ml) with NCS (0.004 mol), a similar work up gave a colorless syrup, which gradually crystallized. The crystals were identified to be *t*-butyl 2-acetylamino-2-benzyloxy-3-bromo-3-chlorobutanoate.

In a similar manner, *t*-butyl 2-acetylamino-2-benzyloxy-3-bromo-3-chloropentanoate was obtained from the reaction of **3** (R=C_2H_5) with NCS in the presence of benzyl alcohol, after stirring for 20 h.

Preparation of ***10.*** After allowing a solution of **1** (R=CH_3, 0.0036 mol) in methanol (10 ml) to stand at room temperature for 2 days, a similar work up gave colorless crystals of *t*-butyl 2-acetylamino-3-bromo-2-methoxybutanoate.

In a simlar manner, *t*-butyl 2-acetylamino-2-benzyloxy-3-bromobutanoate was obtained from the reaction of **1** (R=CH_3) with benzyl alcohol.

Chemistry of Nitrosoimines. XV.[1] Reactions of 3-Substituted 2-Nitrosoimino-2,3-dihydrobenzothiazoles with Lithium Aluminum Hydride and Diazo Compounds

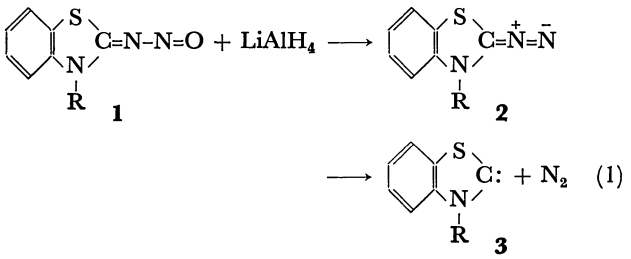
Kin-ya AKIBA, Takayuki KAWAMURA, Masahide OCHIUMI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received December 26, 1975)

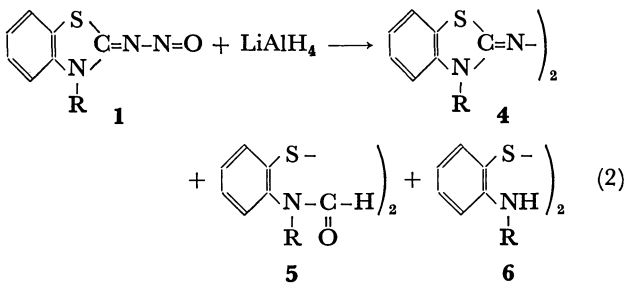
3-Substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) were reduced with lithium aluminum hydride to give the corresponding thiazolone azines and bis[*o*-(*N*-substituted *N*-formylamino)phenyl] disulfides as major products. Reactions of **1** with some substituted diazomethanes gave the corresponding unsymmetrical azine *N*-monoxides (**16**) or azines (**17**) depending on the structure of the diazomethane.

We previously reported on the reactions of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) with Grignard reagents[2] and organolithiums.[3] In this paper, we report on the reactions of **1** with lithium aluminum hydride (LAH).[4] According to the report of Zimmerman and Paskovich on the preparation of the corresponding diazo compound by the reduction of bismesityl-*N*-nitrosoiminomethane with LAH,[5] the formation of the corresponding diazo compounds (**2**) or carbenes (**3**)[6] can be expected in the reaction, together with the products of nucleophilic attack of LAH on *C-2* and the sulfur of the thiazoline ring.



In order to know the reactivity of **1** toward diazo compounds or the corresponding carbenes, the reactions of **1** with some stable diazo compounds were examined under various conditions.

Reaction of 1 with LAH. The main products of reduction of **1** with an excess amount of LAH were 3-substituted 2,3-dihydrobenzothiazol-2-one azine (**4**), bis[*o*-(*N*-substituted *N*-formylamino)phenyl] disulfide (**5**), and bis[*o*-(*N*-substituted amino)phenyl] disulfide (**6**). The yields are given in Table 1.



a) R=Ph, b) R=Me, c) R=Et

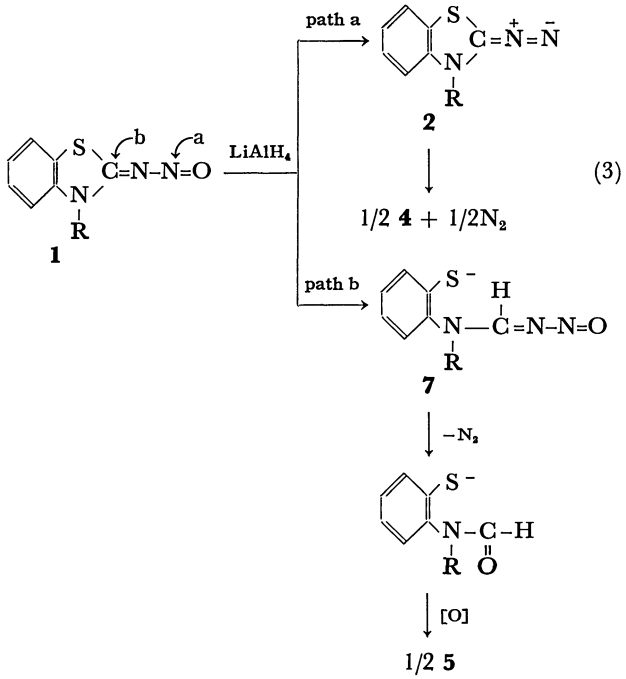
The formation of the azine (**4**) can be ascribed to the intermediacy of the diazo compound (**2**) produced by hydride attack on the nitrogen atom of the nitroso group (*path a*). On the other hand, the formation of the disulfide (**5**) can be explained by invoking the ring opened nitrosoimine (**7**) produced by hydride attack on the *C-2* of the ring (*path b*), **7** thus formed decomposing to the corresponding carbonyl compound and nitrogen gas.[7]

Table 1. Reduction of **1** with excess lithium aluminum hydride

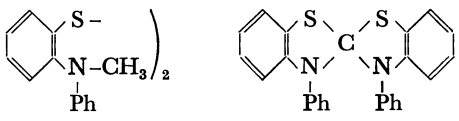
1	4	5	6
a) R=Ph	16	30	20
b) R=Me	27	22	24
c) R=Et	30	28	18

Numerical values show yields (mole %) based on charged **1**.

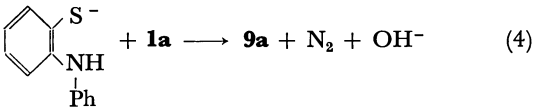
When the reaction was carried out under argon atmosphere in a closed system, the evolved gas was only nitrogen as confirmed by mass spectrometry. This supports the proposed mechanism.



The products were scrutinized by column chromatography for the case of **1a**, two products (**8a** and **9a**)

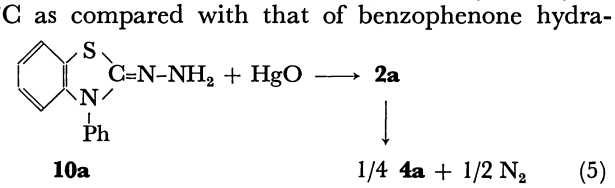


being obtained in very small amounts. The disulfide (**8a**) is a reduction product of **5a** with excess LAH, since **5a** was reduced with LAH in refluxing tetrahydrofuran (THF) to **6a** and **8a**. Formation of **9a** can be explained by means of the reaction of **1a** with *o*-anilinobenzenethiolate anion,[8] a precursor of **6**.

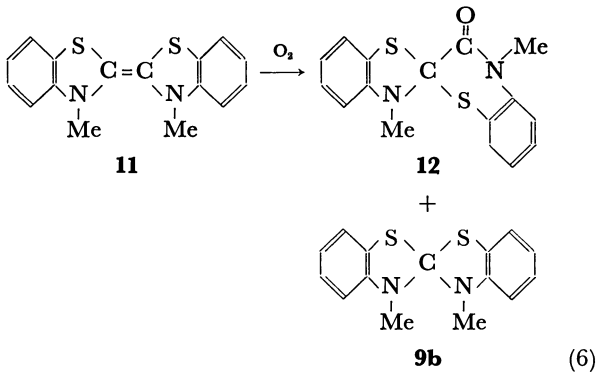


(4)

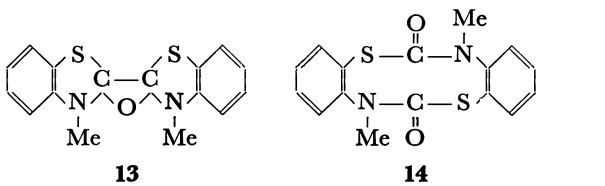
In order to prepare **2**, 2-hydrazono-3-phenyl-2,3-dihydrobenzothiazole (**10a**) was oxidized with mercury (II) oxide. The reaction took place very slowly at 0 °C as compared with that of benzophenone hydrazone, giving **4a** as the major product (*ca.* 70%). This shows that **2a** is too unstable to be isolated and gives **4a** easily. In order to study the nature of the corresponding carbene dimer, 3,3'-dimethylbi(2,3-dihydrobenzothiazolidene) (**11**) was prepared by the deoxygenation of **1** with triethyl phosphite.[9] It was found to be sensitive to air. Thus, air was bubbled into a benzene solution of **11**. Spiro-amide (**12**) was obtained as the major product (71%), which may be decomposition product of epoxide (**13**). Even if carbene dimer (**11**) were formed in the reduction reaction, **11** would be oxidized to **12** by air during the course of isolation. However, **12** could not be isolated from the reaction mixture of **1b** with LAH, indicating the absence of **11**, or fast reaction of **3** with **2**.



10a 1/4 **4a** + 1/2 N_2 (5)



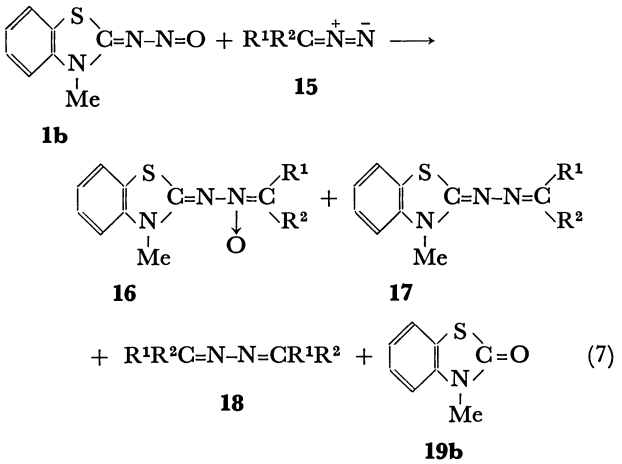
11 **12** **9b** (6)



13 **14**

Wanzlick *et al.* reported that air-oxidation of **11** affords **14** in 75% yield. However, we could not substantiate the result. Our result is similar to that of the air-oxidation of naphthalene analog of **11**.[6c]

Reactions of 1 with Diazo Compounds. A dichloromethane solution of **1b** was refluxed for a week with diphenyldiazomethane (**15a**) and for one day with methylphenyldiazomethane (**15b**), and left to stand at room temperature for five days with phenyldiazomethane (**15c**). In the cases of **15a** and **15c**, the isolated products were unsymmetrical azine *N*-monoxides (**16**), whereas the product was unsymmetrical azine (**17b**) in the case of **15b**. The yields of the products are summarized in Table 2.



1b **15** **16** **17** **18** **19b** (7)

a) $R^1=R^2=Ph$, b) $R^1=Ph$, $R^2=Me$,
c) $R^1=Ph$, $R^2=H$

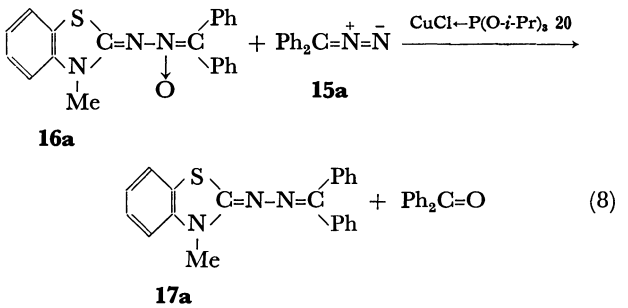
Table 2. Reaction of **1b** with diazo compounds[a]

15	16	17	18	19b	1b recovery
a) $Ph_2C=N_2$	16	—	42	80	—
b) $MePhC=N_2$	—	34	39	—	88
c) $PhHC=N_2$	11	—	46[b]	—	90

a) The yields (mol %) of **16**, **17**, and **19b** were calculated based on the amount of **1b** consumed. The yield of **18** was calculated based on the amount of charged **15**. b) PhCOCHPhN=NCHPhCOPh (11%), probably the by-product in the preparation of **15c**, was obtained.

The reaction of **1b** with **15a** was carried out in *N*,*N*-dimethylformamide (DMF) in the presence of copper-(I) chloride–triisopropyl phosphite complex (**20**) in order to generate carbene at low temperature (30 °C). However, the yields of **16a** and **17a** were low in spite of much effort to improve them and found to be *ca.* 7 and 4%, respectively.

The results indicate that the reactivity of **1** toward diazo compounds and carbenes is very low. This indicates that *path a* [Eq. 3] is the major route for the formation of **4**. Deoxygenation of **16a** with diphenylcarbene, generated from **15a** and **20**, gave **17a** in 75% yield under the same conditions. This shows that the primary product of the reaction of **1** with carbene is



16a **15a** **17a** (8)

azine *N*-monoxide (**16**) which is deoxygenated by incident carbene to give unsymmetrical azine (**17**).

Experimental

Materials. 3-Substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) were prepared by the reported methods; 3-phenyl (**1a**), mp 140 °C (dec.),[10] 3-methyl (**1b**), mp 143 °C (dec.),[11] and 3-ethyl (**1c**), mp 143—144 °C (dec.).[12] Diphenyl-,[13] methylphenyl-,[13] and phenyldiazomethanes[14] were prepared by the reported methods. All the reactions were carried out under nitrogen.

*Reduction of 3-Methyl-2-nitrosoimino-2,3-dihydrobenzothiazole (**1b**) with LAH.* To a stirred solution of **1b** (10.0 g 47.8 mmol) in THF (700 ml) was added LAH (1.68 g, 47.0 mmol) portionwise at −70——40 °C during the period of 1 h. Vigorous gas evolution was observed upon the addition, and stirring was continued for 10 h at room temperature. Methanol (150 ml) was added to the solution and the resulting precipitates were filtered off. The filtrate was concentrated *in vacuo* and the residue was extracted with dichloromethane. The extract was concentrated and chromatographed on silica gel.

Bis(*o*-methylaminophenyl) disulfide (**6b**, 1.36 g, 24%) was eluted with benzene as a yellow oil, which was identified by comparison of IR and NMR spectra with those of an authentic sample.[15a] Bis[*o*-(*N*-formyl-*N*-methylamino)phenyl] disulfide (**5b**, 1.87 g, 22%) was also eluted with benzene, mp 107.0—108.5 °C (from ether) (lit,[8] 108 °C). 3-Methyl-2,3-dihydrobenzothiazolone azine (**4b**, 2.26 g, 27%) was eluted with dichloromethane, mp 259—260.5 °C (from benzene) (lit,[16] mp 260 °C).

*Reduction of 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (**1**) with LAH.* LAH (2.235 g, 59.0 mmol) and **1a** (10.0 g, 39.2 mmol) were used for the reaction, the reaction mixture being treated as described for **1b**. Yellow tar (*A*, 2.16 g), eluted with benzene, was chromatographed on silica gel three times using carbon tetrachloride, carbon tetrachloride–benzene and benzene as eluents. Fractions eluted with carbon tetrachloride–benzene (2: 1) were treated with preparative thin layer chromatography (TLC) to give a small amount of bis[*o*-(*N*-methyl-*N*-phenylamino)phenyl] disulfide (**8**), mp 120—123 °C (from ether); MS: *m/e* 428 (M^+, 1%) and 214 (1/2 M^+, 100). Yellow oil (1.6 g, 4.0 mmol, 20%), eluted with benzene, was identified as bis(*o*-anilinophenyl) disulfide (**6a**) by comparison of its IR spectrum with that of an authentic sample.[15b]

Pale yellow tar (*B*, 2.45 g), eluted also with benzene after elution of tar *A*, was chromatographed again on silica gel to give 3-phenyl-2,3-dihydrobenzothiazolone azine (**4a**, 1.41 g, 16%), mp 274—275 °C (from benzene). IR (KBr): 1610 cm^{-1} (C=N): MS: *m/e* 450 (M^+, 100%).

Found: C, 69.18; H, 3.96; N, 12.61; S, 14.33%. Calcd for $C_{26}H_{18}N_4S_2$: C, 69.32; H, 4.03; N, 12.44; S, 14.21%.

A small amount of spiro compound (**9a**, 60 mg) was also obtained from tar *B*, mp 187—189.5 °C (from ether). MS: *m/e* 410 (M^+, 100%).

Found: C, 72.79; H, 4.12; N, 6.65; S, 15.16%. Calcd for $C_{25}H_{18}N_2S_2$: C, 73.13; H, 4.41; N, 6.82; S, 15.61%.

Bis[*o*-(*N*-formyl-*N*-phenylamino)phenyl] disulfide (**5a**, 2.68 g, 30%) was eluted with chloroform–ether (1: 1), mp 161.5—162.0 °C (from ethyl acetate). IR (KBr): 1670 cm^{-1} (C=O); NMR ($CDCl_3$): δ 6.80—7.65 (m, 18H, Ar–H) and 9.5 (s, 2H, 2CHO); MS: *m/e* 456 (M^+, ≈1%) and 198 ( , 100).

Found: C, 68.52; H, 4.50; N, 5.99; S, 13.96%. Calcd for $C_{26}H_{20}N_2O_2S_2$; C, 68.41; H, 4.42; N, 6.14; S, 14.02%.

Red-brown tar (*ca.* 1 g), eluted finally with ether–chloroform (3: 1), could not be identified.

*Reduction of 3-Ethyl-2-nitrosoimino-2,3-dihydrobenzothiazole (**1c**) with LAH.* Reduction of **1c** (10 g, 44.8 mmol) with LAH (1.94 g, 51.1 mmol) was carried out as described for **1a**, and the corresponding products were obtained as follows: bis(*o*-ethylaminophenyl) disulfide (**6c**,[15a] 1.25 g, 18%), bis[*o*-(*N*-ethyl-*N*-formylamino)phenyl] disulfide (**5c**, 2.43 g, 28%), mp 113—114.5 °C (from ether) (lit,[8] 114—115 °C), and 3-ethyl-2,3-dihydrobenzothiazolone azine (**4c**, 2.59 g, 30%), mp 198.5—199.0 °C (from benzene) (lit,[17] 193—202 °C).

*Reduction of Bis[o-(N-formyl-N-phenylamino)phenyl] Disulfide (**5a**) with LAH.* Disulfide (**5a**, 1.7 g, 3.7 mmol) and LAH (0.442 g, 11.6 mmol) were refluxed in THF (50 ml) for 5 days. The reaction mixture was treated as above. Disulfides **6a** (0.33 g, 48%) and **8a** (0.18 g, 30%), mp 120—122.5 °C (from ether), were eluted with benzene. Unchanged **5a** (1.08 g, 63%) was recovered with chloroform–ether (2: 1). Thus the yields of **6a** and **8a** were calculated on the basis of the consumed **5a**.

*Air-oxidation of 3,3'-Dimethylbi(2,3-dihydrobenzothiazolidene) (**11**).* Air was bubbled for 3 h with stirring into a solution of **11**[9] (5.02 g, 16.2 mmol) in benzene (70 ml). After evaporation of the solvent, the brown residue was chromatographed on silica gel. 3,3'-Dimethylbi(2,3-dihydrobenzothiazolinyl) (0.16 g), which was an impurity contained in **11**, was eluted with benzene, mp 156.2—157.0 °C (from 2-propanol). NMR ($CDCl_3$): δ 3.00 (s, 6H, 2N–CH_3), 5.03 (s, 2H, 2C–H), and 6.4—7.4 (m, 8H, Ar–H); MS: *m/e* 300 (M^+, 20%) and 150 (M^+/2, 100). Spiro-amide (**12**, 20 mg) was eluted with dichloromethane–chloroform (1: 2) and brown tar (4.78 g) was eluted with dichloromethane–chloroform (1: 8). A portion of the brown tar was treated with preparative TLC (silica gel, benzene–dichloromethane (2: 1)). The major fraction was extracted with dichloromethane to give spiro compound (**9b**, 100 mg), mp 200—203 °C (lit,[8] 203.5—204 °C), *m/e* 286 (M^+), and **12** (3.5 g, 71%), mp 132—133.5 °C (from methanol). IR (KBr): 1670 cm^{-1}; δ 3.10 (s, 3H, N–CH_3), 3.55 (s, 3H, CONCH_3), and 6.7—7.4 (m, 8H, Ar–H); MS: *m/e* 298 (M^+−16, 10%), 165 (**19b**$^+$, 72) and 136 (*o*-S=C_6H_4=$\overset{+}{N}$=CH_2, 100).

Found: C, 61.44; H, 4.43; N, 8.96; S, 20.10%. Calcd for $C_{16}H_{14}N_2OF_2$: C, 61.14; H, 4.49; N, 8.91; S, 20.36%.

Essentially the same result was obtained by keeping a chloroform solution of **11** to stand in the air with stirring.

*Reaction of **1b** with Diphenyldiazomethane (**15a**).* Diphenyldiazomethane (5.17 g, 26.4 mmol) and **1b** (2.52 g, 13.1 mmol) in dichloromethane (150 ml) were refluxed for a week. After evaporation of the solvent, the residue was chromatographed on silica gel. Benzophenone azine (**18a**, 1.98 g, 42%) was eluted with benzene–dichloromethane (1: 1), mp 158—161 °C (from ethanol) (lit,[18] 162 °C). The thiazolone (**19b**, 1.73 g, 80%) was eluted with dichloromethane. Unsymmetrical azine *N*-monoxide (**16a**; 0.15 g, 16%) was eluted with dichloromethane–ether (1: 1), mp 188.5—189.5 °C (from ethanol). IR (KBr): 1540, 1435, 1350, and 1225 cm^{-1}; NMR ($CDCl_3$): δ 3.3 (s, 3H, N–CH_3) and 7.1—8.1 (m, 14H, Ar–H); MS: *m/e* 359 (M^+, 10%), 343 (M^+−16, 18), and 149 ( , 100).

Found: C, 70.35; H, 4.43; N, 11.50; S, 9.07%. Calcd for

$C_{21}H_{17}N_3OS$: C, 70.17; H, 4.77; N, 11.69; S, 8.92%.

Reaction of ***1b*** *with Methylphenyldiazomethane (****15b****).* Methylphenyldiazomethane (45 mmol) and **1b** (4.46 g, 23.1 mmol) in dichloromethane (150 ml) were refluxed overnight. After evaporation of the solvent, the residue was chromatographed on silica gel. Acetophenone azine (**18b**, 2.06 g, 39%) was eluted with hexane–benzene (1: 1), mp 118—122 °C (lit,[19] 121 °C). Unsymmetrical azine (**17b**, 0.26 g, 34%) was eluted with hexane–benzene (1: 1) and benzene, mp 115.0—116.0 °C (from ethanol). IR (KBr): 1610, 1575, 1550, and 1475 cm^{-1}; NMR ($CDCl_3$); δ 2.5 (s, 3H, C–CH_3), 3.6 (s, 3H, N–CH_3), and 6.8—8.1 (m, 9H, Ar–H); MS: *m/e* 281 (M^+, 100%).

Found: C, 68.13; H, 5.21; N, 15.17%. Calcd for $C_{16}H_{15}N_3S$: C, 68.30; H, 5.37; N, 14.93%.

Unchanged **1b** (3.92 g, 88% recovery) was eluted with benzene–dichloromethane (1: 1) and dichloromethane.

Reaction of ***1b*** *with Phenyldiazomethane (****15c****).* An ethereal solution (50 ml) of phenyldiazomethane was prepared from azibenzil (11.13 g, 50.1 mmol) by treatment with methanolic sodium hydroxide.[14] To the solution was added **1b** (4.83 g, 25.0 mmol) in dichloromethane (300 ml) and the mixture was stirred for 5 days at room temperature. After evaporation of the solvent, the residue was chromatographed on silica gel. Benzaldazine (**18c**, 2.35 g, 46%) was eluted with hexane–benzene (2: 1), mp 91—93 °C (from ethanol) (lit,[19] 93 °C). *trans*-Stilbene (0.27 g, 6%) was eluted with benzene, mp 122 °C (from ethanol). Azobis(α-benzoyl-α-phenylmethane) (0.90 g, 11%) was eluted with benzene, mp 201—202 °C (from ethanol). IR (KBr): 1680 cm^{-1}.

Found: C, 80.43; H, 5.06; N, 6.78%. Calcd for $C_{28}H_{22}N_2O_2$: C, 80.36; H, 5.30; N, 6.70%. Unsymmetrical azine *N*-monoxide (**16c**, 81 mg, 11%) was eluted with benzene, mp 178—179 °C (from ethanol). IR (KBr): 1550, 1130, and 1120 cm^{-1}; NMR ($CDCl_3$); δ 3.6 (s, 3H, N–CH_3), 7.3 (m, 7H, Ar–H), 7.6 (s, 1H, N–C–H), and 8.2 (m, 2H, Ar–H); MS: *m/e* 283 (M^+, 10%) and 90 ($PhCH^+$, 100).

Found: C, 63.56; H, 4.87; N, 14.54; S, 11.03%. Calcd for $C_{15}H_{13}N_3OS$: C, 63.58; H, 4.62; N, 14.83; S, 11.32%.

Residual **1b** (4.36 g, 90% recovery) was eluted with benzene and dichloromethane.

Unsymmetrical azines (**17**) as authentic samples were prepared by condensation of **10b** with the corresponding carbonyl compounds: **17a**, mp 151—152 °C; **17b**, mp 115—116 °C; **17c**, mp 163—164 °C (lit,[11] mp 163 °C).

Reaction of ***1b*** *with* ***15a*** *in the Presence of* ***20****.* Diphenyldiazomethane (**15a**, 5.17 g, 26.4 mmol) in DMF (50 ml) was added to **1b** (2.51 g, 13.0 mmol) and **20** (1.79 g, 6 mmol) in DMF (40 ml) and the mixture was left to stand overnight at 30 °C. The complex (**20**) was decomposed with a few ml of 30% aqueous hydrogen peroxide under cooling with ice-water. The solution was dried over anhydrous magnesium sulfate and filtered. After evaporation of the solvent under reduced pressure, the residue was chromatographed on silica gel. Benzophenone (3.25 g, 68%) was eluted with benzene and benzophenone azine (**18a**, 0.24 g, 10%) was eluted with benzene–dichloromethane (1: 1). Elution with dichloromethane gave **16a** (mp 186—188 °C, 0.325 g, 7%), **17a** (mp 147—148.5 °C, 0.18 g, 4%) and **19b** (0.24 g, 11%).

The reaction was carried out under various conditions and and **16a** and **17a** were determined by high speed liquid chromatography (HSLC) (Hitachi gel 3010: styrene–divinylbenzene copolymer) using methanol containing concd ammonia (1% v/v) as eluent. Results were essentially the same as described above.

Deoxygenation of Azine N*-Monoxide (****16a****) with Diphenylcarbene.* Diphenyldiazomethane (0.997 g, 5.1 mmol) in DMF (10 ml) was added dropwise to azine *N*-monoxide (**16a**, 0.171 g, 0.48 mmol) and the complex (**20**, 0.280 g, 0.91 mmol) in DMF (10 ml). Almost quantitative formation of azine (**17a**) was shown by HSLC, **17a** (0.21 g, 75%) being isolated by column chromatography.

Syntheses of Polymerizable Acetals. I. Vinylbenzaldehyde Acetals with Perfume Alcohols

Hiroyoshi KAMOGAWA, Shinya OKABE, and Masato NANASAWA

Department of Applied Chemistry, Yamanashi University, Takada, Kofu 400

(Received December 27, 1975)

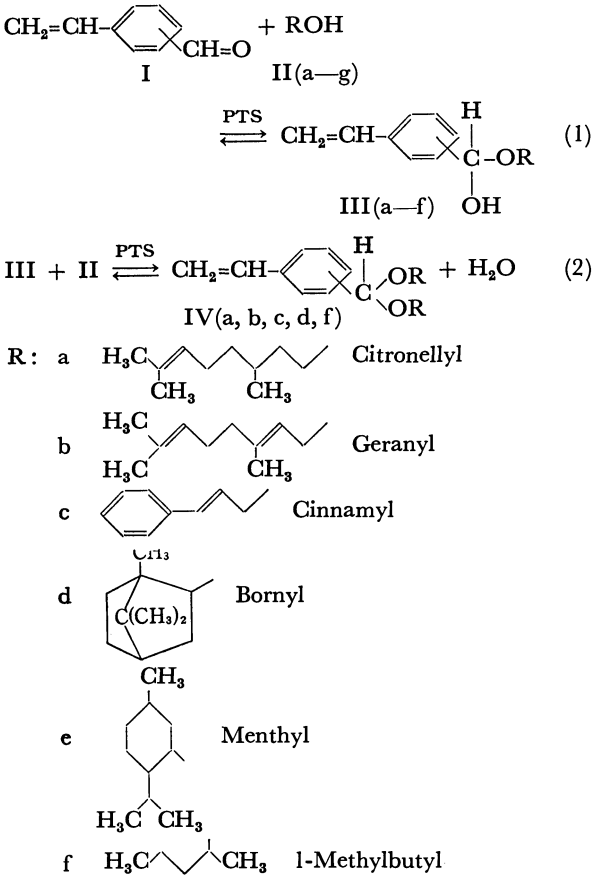
Several acetal monomers and a hemiacetal monomer of vinylbenzaldehydes were synthesized from the reaction with some perfume alcohols in the presence of *p*-toluenesulfonic acid as an acid catalyst. It was found that primary alcohols such as citronellol and geraniol with the exception of cinnamyl alcohol afforded acetal monomers in high yields, secondary alcohols such as borneol and menthol in low yields, with the latter affording only hemiacetal monomer, and linalool, a tertiary alcohol, neither acetal nor hemiacetal monomers. The radical polymerizations of the acetal and hemiacetal monomers synthesized provided soluble polymers which easily release perfume alcohols under mild acidic conditions.

Acetals are well-known for their easily hydrolyzable properties under acidic conditions in spite of their stabilities in neutral or alkaline media. This outstanding characteristic can be utilized for the syntheses of the readily hydrolyzable polymers which might find their use in liberating their functional groups gradually under acidic conditions.

With such intentions, Kamogawa[1] prepared vinyl polymers containing the isoalloxazine functional group in side chains through hemiacetal linkage.

As the first attempt to incorporate functional groups into the side chains of vinyl polymers through pure acetal linkages for the above-mentioned purpose, vinylbenzaldehyde acetals with perfume alcohols were synthesized using *p*-toluenesulfonic acid (PTS) as a catalyst.

Acetal monomers were synthesized as follows:



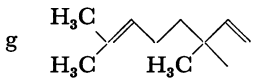


Table 1 shows the analytical results obtained for the acetal monomers synthesized. Since the starting chloromethylstyrene (I) was an unseparable mixture of para- and meta-isomers (40/60), the acetal monomers obtained should also be mixtures of para- and meta-isomers, presumably thereby having an oily appearance in spite of the absence of low-molecular weight impurities, as ascertained by gas chromatograph. The isomers could not be separated; the ratios of the para- to meta-isomers could not be determined.

As is generally recognized in acetal synthesis from aldehydes and alcohols under acidic conditions,[2] primary alcohols such as citronellol and geraniol gave high yields of acetals (IV-a and IV-b); secondary alcohols such as borneol and the reference, 2-pentanol, gave low yields (IV-d and IV-f). 3,7-Dimethyl-1,6-octadien-3-ol (linalool, II-g), a tertiary alcohol, gave neither acetal nor hemiacetal monomers, presumably due to the large steric hindrance exerted against the reaction. Similarly, *l*-menthol, a more sterically hindered secondary alcohol as compared with borneol, only gave a hemiacetal monomer (III-e). The fact that the yield of the monomer IV-c prepared with cinnamyl alcohol, a primary alcohol, was low (26.1%) may denote that steric hindrance is fairly large in this case, owing to the coplanar character of the styryl portion of the alcohol residue due to resonance.

The radical polymerization of acetal monomers appears to be almost unaffected by the kind of alcohol residue of the acetal monomers, as recognized from the results in Table 2. The polymer of III-e (a hemiacetal) is soluble in polar solvents such as alcohol due to the presence of pendant polar hydroxyl groups, but is insoluble in nonpolar petroleum ether, while the other polymers (acetals) are insoluble in alcohol but are soluble in petroleum ether.

The IR spectra of all polymers indicated no absorptions due to the double bond of the vinyl group (disappearance of the 910 cm^{-1} band) but indicated strong $-CH_2-$ absorption characteristic of the back-bone chains of vinyl polymers at 2930 and 2860 cm^{-1}.

The hydrolyses of the acetal polymers with liberation of perfume alcohol and the formyl group in the polymer during storage are dependent upon the extent of contact

TABLE 1. ANALYTICAL RESULTS OF THE SYNTHESIZED ACETAL MONOMERS

Monomer	Yield	Elemental analysis C[a)]%	Elemental analysis H[a)]%	IR (CCl_4) cm^{-1}	Mass peak *m/e*
IV-a	52.3	81.82 (81.69)	10.58 (10.79)	2860—2970(alkyl), 1610 (aryl), 1440 (CH), 1100 and 1060 (ether), 990 and 910 (vinyl)	426 (M^+)
IV-b	61.8	81.44 (82.46)	10.89 (9.95)	2850—2960 (alkyl), 1615 (aryl), 1430 (CH), 1100 and 1060 (ether), 985 and 905 (vinyl)	422 (M^+)
IV-c	26.1	85.51 (84.82)	6.72 (6.80)	3030 and 1610 (aryl), 2850—2950 (alkyl), 1440 (CH), 1120 and 1070 (ether), 980 and 910 (vinyl)	382 (M^+)
IV-d	22.4	81.90 (82.46)	9.98 (9.95)	2870—2980 (alkyl), 1610 (aryl), 1440 (CH), 1060 and 1040 (ether), 990 and 910 (vinyl)	422 (M^+)
IV-f	37.8	78.14 (78.62)	10.20 (10.34)	2870—2960 (alkyl), 1610 (aryl), 1440 (CH), 1080 and 1030 (ether), 990 and 910 (vinyl)	290 (M^+)

a) The figures in the parentheses indicate calcd values.

TABLE 2. POLYMERIZATION BEHAVIOR OF ACETAL MONOMER[b)]

Monomer	Precipitant for polymer	Conversion %	Polymer $[\eta]^{a)}$dl/g	Polymer Appearance	Polymer Solubility
IV-a	Methanol	92	0.32	Glassy	Sol. in pet. ether
IV-b	Methanol	34	0.22	Glassy	Sol. in pet. ether
IV-c	Methanol	84	0.25	White powder	Sol. in pet. ether
IV-d	Methanol	91	0.25	White powder	Sol. in pet. ether
III-e	Pet. ether	58	0.43	White solid	Sol. in ethanol
IV-f	Methanol	78	0.34	Glassy	Sol. in pet. ether

a) Intrinsic viscosity in THF at 30 °C. b) Initiator (AIBN), 0.005 g/l ml THF; monomer, 0.5 g/1ml THF; 70 °C × 48 h.

with moisture, as well as the acidity. Thus, a polymer of IV-a in a carbon tetrachloride solution indicated almost no change in the IR spectrum even after storage of several weeks in air; storage in the solid state, especially in a fluffy powder (*e.g.* the polymer of IV-d), caused considerable change in the IR spectrum even within a week with the appearance of a 1700 cm^{-1} band (formyl groups in polymer), thereby indicating that hydrolysis was in progress.

Experimental

IR, ^{1}H-NMR, and mass spectra were obtained with a Hitachi EPI-G spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively, under standard measurement conditions. Elemental analyses were carried out using a Perkin-Elmer 240 instrument.

Vinylbenzaldehyde (I). The Sommlet reaction[3,4] was applied for the synthesis. Thus, from chloromethylstyrene (Seibi Chem. Co., a 40/60% mixture of para- and meta-isomers) and an equimolar amount of hexamethylenetetramine vinylbenzaldehyde was obtained in 45—50% yields after refluxing in chloroform for 2—4 h and subsequent steam distillation of the resulting hexaminium salt in the presence of a polymerization inhibitor (*e.g.* 4-(*t*-butyl) catechol). Bp, 54—56 °C/0.2—0.3 mmHg. Elemental analysis, IR (CCl_4), and ^{1}H-NMR (CCl_4) demonstrated structure I. Para/meta= 40/60 by NMR.

Vinylbenzaldehyde Dicitronellyl Acetal (IV-a). A solution of 3.0 g (0.023 mol) of vinylbenzaldehyde, 7.2 g (0.046 mol) of citronellol, 0.03 g of 4-(*t*-butyl) catechol, and 0.15 g of *p*-toluenesulfonic acid (PTS) as a catalyst in 30 ml of anhydrous chloroform was refluxed with stirring for 7 h with the addition of a molecular sieve 3A (1/16) as dehydrating agent. Upon cooling the solution was evaporated *in vacuo* at 40 °C leaving an oil, which was extracted with aqueous sodium carbonate and 100 ml of ether. The organic layer was then dried over anhydrous potassium carbonate, filtered, and evaporated *in vacuo* at 40 °C to obtain a crude acetal monomer. The crude product was chromatographed on an alumina column eluted by petroleum ether to afford a colorless oil in a 52.3% yield. The product was soluble in common organic solvents, including petroleum ether, but was insoluble in water.

NMR (CCl_4, Me_4Si): δ 7.26 (d 4H aromatic), 6.77 (q, 1H vinyl), 5.78 (d 1H vinyl), 5.39 (s, 1H acetal), 5.29 (d 1H vinyl), 3.8—0.5 (b 38H dicitronellyl) ppm. [No -CHO peak].

Other acetal monomers, *i.e.*, vinylbenzaldehyde digeranyl acetal (IV-b), dicinnamyl acetal (IV-c), dibornyl acetal (IV-d), and bis(1-methylbutyl) acetal (IV-f), were synthesized in the same manner to provide oily products even after chromatographic purification (Table 1).

Vinylbenzaldehyde Menthyl Hemiacetal (III-e). The same reaction procedure was adopted as that for the synthesis of monomer IV-a, except that methanol was employed as the eluting agent of the alumina column. Thus, from 3.0 g (0.023 mol) of vinylbenzaldehyde and 7.4 g (0.046 mol) of *l*-menthol, a colorless viscous oil was obtained in a 22.4% yield. The product was soluble in common organic solvents and was insoluble in water.

Found: C, 79.31; H, 9.57%. Calcd for $C_{19}H_{28}O_2$ (hemiacetal): C, 79.16; H, 9.72%. IR (CCl_4): 3610 (OH), 2850—2960 (alkyl), 1610 (aryl), 990 and 910 cm^{-1} (vinyl). Mass spectrum *m/e* 288 (M^+). NMR (CCl_4, Me_4Si): δ 7.17 (d, 4H aromatic), 6.62 (q, 1H, vinyl), 5.63 (d, 1H, vinyl), 5.15 (d, 1H, vinyl), 4.53 (s, 1H, OH), 3.0—0.5 (b, 19H, menthyl) ppm. [No -CHO in IR and NMR].

Other acetal monomers synthesized also indicated characteristic peaks in NMR at δ 7.1—7.3 (aryl) and 5—7 (styrenic vinyl) together with peaks of the alcohol residues, the integrator calculations indicating that the monomers were

apparently pure, without any splitting of the singlet peaks due to the presence of isomers.

Polymerization. A conventional procedure for free-radical polymerizations was adopted. In a typical example conforming to the polymerization conditions in Table 2, 0.5 g of monomer IV-d and 0.005 g of α,α′-azobisisobutyronitrile (AIBN) were dissolved in 1 ml of tetrahydrofuran (THF). The solution was put into a glass ampoule, which was evacuated and sealed-off, and left standing for 48 h at 70 °C. Upon cooling, the viscous solution was poured into a large quantity of methanol to afford a white precipitate, which was freeze-dried from dioxane.

A Facile Synthesis of 2,5-Disubstituted Tetrazoles by the Reaction of Phenylsulfonylhydrazones with Arenediazonium Salts[1]

Suketaka Ito, Yumo Tanaka, Akikazu Kakehi, and Ken-ichi Kondo

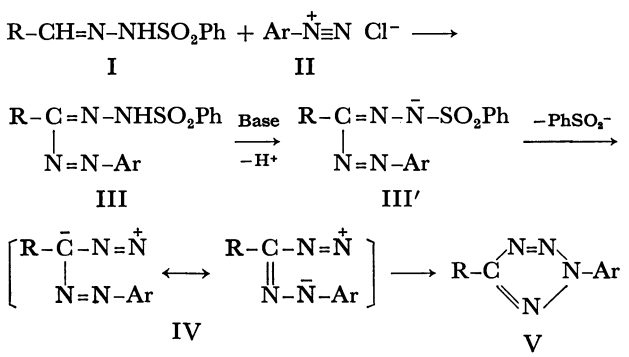
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received January 28, 1976)

2,5-Disubstituted tetrazoles are obtained in good yields by the reaction of phenylsulfonylhydrazones of aromatic aldehydes (and cinnamaldehyde) with arenediazonium salts. From the synthetic viewpoint for tetrazoles, this method may be of high synthetic utility on account of the availability of starting materials, the simplicity of procedure, and higher yields.

The 1,5-dipolar cyclization[2] is a general method for synthesis of five-membered heterocycles; a typical example of this type of reaction is the cyclization of vinyldiazomethane to pyrazole.[3]

Azodiazomethane, an unknown diazalogue of vinyldiazomethane, can be expected to afford tetrazole through the 1,5-dipolar cyclization. As a synthetic route to azodiazomethane, the following scheme may be reasonable:



Scheme 1.

The first step is the well-known formazan formation[4] and the second is the Bamford-Stevens type reaction.[5] Although the Dimroth and Merzbacher method[6] is often employed for preparing 2,5-diaryltetrazoles, this method is troublesome, since it requires aryl azide as a starting material.

The present paper is concerned with an attempt to prepare 2,5-disubstituted tetrazoles[7] according to the above reaction scheme.[8]

Results and Discussion

As shown in Table 1, 2,5-disubstituted tetrazoles could be obtained as was expected, in good yields with a few exceptions. Phenylsulfonylhydrazones[9] were allowed to react with one equivalent of arenediazonium salt(II) in alkaline (NaOH) ethanol at 5—2 °C or in pyridine at −10——15 °C. Extraction of the reaction mixture with chloroform–water gave benzenesulfinic acid and tetrazole(V).[10] When 1.5 equivalents of diazonium salt were used, the yields of tetrazoles increased by a factor of about 1.1.

Attempts to isolate formazan (III) were unsuccessful: the overall reaction generally proceeded fast under these reaction conditions.[11] When the reaction of benzaldehyde phenylsulfonylhydrazone with benzenediazonium salt was carried out in aqueous alkali, there were separated brownish yellow precipitates, which were unstable and changed gradually to a deep red and then to brown mass. This product(mp 40—43 °C) could not be purified by crystallization, but gave 2,5-diphenyltetrazole (5%), 1,3,4,6-tetraphenyl-1,4-dihydro-1,2,4,5-tetrazine[12] (3%), and benzenesulfinic acid (16%) by treatment with hot sodium ethoxide–ethanol solution.

Although formazan(III) could not be isolated and confirmed in this study, the intermediacy of formazan (III) or formazanide anion (III′) should be reasonable from the reaction process.

Thus, the principal process of the reaction is identical with that of the reaction between *N*-phenylsulfonylbenzhydrazonoyl chlorides and arylhydrazines to yield 2,5-diaryltetrazoles.[7]

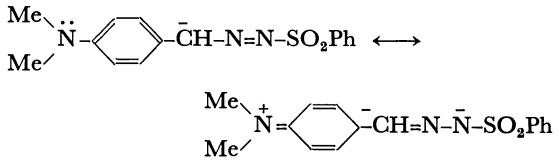
(III')

Scheme 2.

(III), a mechanism which involves the S_N1 type separation of benzenesulfinate ion from formazanide ion (III') and the 1,5-dipolar cyclization of arylazoaryldiazomethane (IV) to tetrazole (V), given in Scheme 1, may be possible. However, the possibility of neighboring-group participation by nitrogen may be conceivable as observed in substitution reactions of δ-haloalkylamines.[13] Thus, the intramolecular displacement may be represented as the most possible mechanism by considering the participation of the lone-pair orbital of arylazo α-nitrogen atom with a planar quasi-aromatic[14] configuration of formazanide anion in the transition state (Scheme 2). Since formazan and formazanide anion are isoelectronic with pentadienide anion, their most favored configuration should be the planar U-shaped form,[15] in which the π-system may gain some quasi-aromatic stabilization. This stabilization would compensate the weak nucleophilicity of azo group.

As shown in Table 1, pyridine resulted in higher yields of tetrazoles than sodium hydroxide–ethanol system. The principal reason for this results should be chiefly attributed to the fact that the hydrazones are not sufficiently soluble in cold alkaline ethanol in contrast in pyridine.

As for the reaction of benzaldehyde hydrazones in pyridine, it may be said that increase in the electrophilicity of diazonium ion generally increases the yields of tetrazoles.[16] The difficulty of obtaining triarylformazans with *p*-dimethylamino or *p*-hydroxyl substituent in the *C*-phenyl group was attributed to the preferential azo-coupling to the activated aromatic ring.[17] This might be questionable[18] and is not adoptable for the present results. The low yields in the case of *p*-(dimethylamino)benzaldehyde hydrazone can be accounted for by the antagonistic resonance effect of *p*-(dimethylamino)phenyl group on the azo-carbanion structure of hydrazonide anion.[19]



That is to say, the electron-donating nature of dimethylamino group should be responsible for the decreased nucleophilicity of α-carbon of aldehyde moiety of hydrazone.

In the present method, the starting materials are readily available, the procedure is simple, and the yield of product is high in general. In conclusion, this method possesses the higher synthetic utility for 2,5-diaryltetrazoles.

Experimental[20]

Preparation of Phenylsulfonylhydrazones (I). General Procedure: Aldehyde (0.1 mol) dissolved in a small amount of hot ethanol (liquid aldehydes were used directly) was mixed with the solution of phenylsulfonylhydrazine (17.2 g, 0.1 mol) in ethanol (100 ml). After being allowed to stand for 30 min, the mixture was cooled and diluted with water. The separated crystalline product was filtered, washed with aqueous ethanol, and air dried. Yield: 79—97%. *p*-Tolualdehyde hydrazone, 92%, mp 124—125 °C. Found: C, 61.32; H, 5.17; N, 10.17%. Calcd for $C_{14}H_{14}N_2O_2S$: C, 61.29; H, 5.14; N, 10.21%. *p*-Cumaldehyde hydrazone, 89%, mp 132—133 °C, Found: C, 63.38; H, 6.05; N, 9.16%. Calcd for $C_{16}H_{18}N_2O_2S$: C, 63.55; H, 6.00; N, 9.27%.

Reaction of Phenylsulfonylhydrazones (I) with Arenediazonium Salts(II). General Procedure: Diazonium salt solutions were prepared as follows: A cooled solution of sodium nitrite (5 mmol) in 2 ml of water was added to a solution of aniline (5 mmol) and 1.3 ml of concentrated hydrochloric acid in 8 ml of 50% ethanol below 5 °C.

(A) Reaction in Pyridine. The solution of arenediazonium chloride(II) was added dropwise over a period of 30 min to a stirred solution of I (5 mmol) in 30 ml of pyridine at −10—−15 °C. The reaction mixture was extracted with chloroform and water. The chloroform layer was washed with dilute hydrochloric acid followed by water and dried. After removal of the solvent from the chloroform extract, the resulting residue was chromatographed on a silica gel (10 g) column using benzene as the eluent to give the corresponding tetrazole, which was purified by recrystallization. The results are summarized in Table 1.

(B) Reaction in Sodium Hydroxide–Ethanol System. The diazonium salt solution was added to a cooled solution of sodium hydroxide (20 mmol) and I (5 mmol) in 40 ml of ethanol at 5—2 °C in a similar manner as above. The successive working-up was the same as that of (A). The results are summarized in Table 1.

The alkaline water layer was neutralized and extracted with chloroform to give unaltered I. The yields of recovered hydrazones (crude) were as follows: hydrazone of benzaldehyde, 38; *p*-tolualdehyde, 44; *p*-cumaldehyde, 35; *p*-anisaldehyde, 39; *p*-dimethylaminobenzaldehyde, 26; *p*-chlorobenzaldehyde, 38; *p*-nitrobenzaldehyde, 71%.

Identification of Benzenesulfinic Acid. The aqueous extract from the reaction mixture, in the reaction between benzaldehyde hydrazone and benzenediazonium chloride in sodium hydroxide–ethanol, was acidified, saturated with sodium chloride, and then extracted with dichloromethane. The dichloromethane extract was dried over sodium sulfate and treated with diphenyldiazomethane to afford phenyl benzhydryl sulfone,[21] mp 188—189 °C (Ref.[22] mp 188 °C), yield: 0.34 g (44% based on the 2,5-diphenyltetrazole obtained). (Found: C, 73.92; H, 5.17%).

8) 2,5-Diaryltetrazoles were obtained by the oxidation of *N*-amidino- or *N*-carbamoylformazan with nitric acid, potassium permanganate, or NBS: E. Wedekind, *Ber.*, **31**, 473 (1898); V. A. Grakauskas, A. J. Tomasewski, and J. P. Horwits, *J. Am. Chem. Soc.*, **80**, 3155 (1958); W. Ried and H. Hillenbrand, *Justus Liebigs Chem. Ann.*, **590**, 128 (1954). These reactions should proceed *via* the formation of tetrazolium salts followed by their hydrolysis.

9) Since aliphatic aldehyde hydrazones could not be obtained in a pure state, none of them were used in the present study: aliphatic aldehydes such as propion- and butyraldehyde reacted with phenylsulfonylhydrazone to yield oily products, which decomposed with an evolution of gas on standing. Bartlett and Stevens also reported that formaldehyde *p*-tolylsulfonylhydrazone decomposed when crystallization was attempted: Ref. 3d.

10) The tetrazoles obtained were identified by their analytical and spectral data and, in the case of known compounds, by comparison with authentic specimens prepared by other synthetic methods. In the IR spectra, all the tetrazoles exhibit four characteristic peaks at 1260—1290 (weak), 1060—1080 (weak), near 1010 (medium to strong), and near 990 cm^{-1} (medium to strong). The absorption at 1260—1290 cm^{-1} can be assigned to the cyclic N–N=N group in analogy with other tetrazoles and triazoles [(a) E. Lieber and T. Enkoji, *J. Org. Chem.*, **26**, 4472 (1961); (b) E. Lieber, C. N. R. Rao, T. S. Chao, and H. Rubinstein, *Can. J. Chem.*, **36**, 1441 (1958)], and those at near 1070, 1010, and 990 cm^{-1} to the tetrazole ring system [(a) E. Lieber, D. R. Leverring, and L. J. Patterson, *Anal. Chem.*, **23**, 1594 (1951); (b) C. W. Roberts, G. F. Fanta, and J. D. Martin, *J. Org. Chem.*, **24**, 654 (1959); (c) C. W. Roberts and M. L. Maskaleris, *ibid.*, **24**, 926 (1959)].

11) The reaction was exothermic. When the diazonium salt solution was added all at once and the reaction mixture was worked up immediately, tetrazoles could be obtained in a decreased yield by a factor of only about 0.2. On the other hand, cinnamaldehyde phenylsulfonylhydrazone remained unchanged when treated with alkali under the same reaction condition as that in the present procedure.

12) The dimerized product of *N*-phenylbenzonitrilimine which might be formed directly from the intermediate precursor of formazan.

13) E. S. Gould, "Mechanism and Structure in Organic Chemistry," Henry Holt and Co., New York (1960), p. 570.

14) Lloyd and Marshall have proposed the definition of the term "quasi-aromatic": D. Lloyd and D. R. Marshall, *Angew. Chem. Int. Ed. Engl.*, **11**, 404 (1972). In the present paper, the term "quasi-aromatic....." is used in the usual sense.

15) R. Hoffmann and R. A. Olofson, *J. Am. Chem. Soc.*, **88**, 943 (1966).

16) This tendency is pronounced in the reaction with *p*-(dimethylamino)benzaldehyde hydrazone.

17) D. D. Libman, A. W. Nineham, and R. Slack, *J. Chem. Soc.*, **1954**, 1565.

18) Experimental data unfit for this explanation were reported: *e.g.* F. R. Fichter and J. Frohlich, *Chem. Zentr.*, **1903**, II. 426; Beilstein's "Handbuch der Organischen Chemie," Hw. Bd. XVI (1933), p. 27.

19) According to the recent study of the mechanism of formazam formation by the action of diazonium salt on arylhydrazone, the reaction intermediate is to be the *gem*-bis(arylazo) compound, ArCH(–N=NAr′)(–N=NAr″), whose rearrangement to formazan is an azo-hydrazone conversion: [A. F. Hegarty and F. L. Scott, *Chem. Commun.*, **1966**, 622].

$$ArCH{=}N{-}NHAr' + Ar''\overset{+}{N}{\equiv}N\ Cl^- \longrightarrow$$

$$ArCH(\underset{\displaystyle N{=}N{-}Ar'}{\underset{|}{}}){-}N{=}N{-}Ar' \longrightarrow ArC(\underset{\displaystyle N{=}N{-}Ar''}{\underset{|}{}}){=}N{-}NHAr'$$

20) Melting points were determined with a Yanagimoto micro-melting point apparatus Model MP-S3 and are corrected. The micro-analysis was performed on a Perkin-Elmer elemental analyzer Model 240. The IR spectra were recorded with a JASCO DS-301 spectrometer.

Reactions of 2,4-Dialkoxy-1,3-diphenyl-1,3,2,4-diazadiphosphetidines with Benzil, Benzalacetophenone, and α-Phenyliminobenzyl Phenyl Ketone

Takayuki KAWASHIMA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

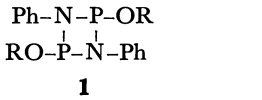
(Received February 3, 1976)

2,4-Diethoxy-1,3-diphenyl-1,3,2,4-diazadiphosphetidine (**1a**) reacted with benzil, benzalacetophenone, and α-phenyliminobenzyl phenyl ketone in refluxing *o*-dichlorobenzene to give 2-ethoxy-3,4,5-triphenyl-Δ^4-1,3,2-oxazaphospholine 2-oxide, 2-ethoxy-1,3,5-triphenyl-Δ^4-1,2-azaphospholine 2-oxide, and 2-anilino-3,4,5-triphenyl-Δ^4-1,3,2-oxazaphospholine 2-oxide, respectively. Under mild conditions, reaction of **1a** with benzil gave a Ramirez type 1 : 2 adduct, which thermally decomposed to give oxazaphospholine derivatives.

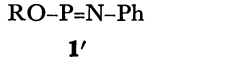
Mitsunobu and Mukaiyama[1] have used "iminophosphite," ArN=POR, in phosphorylation of alcohols to dialkyl phosphites. However, analogous compounds usually exist as cyclic dimers, 1,3,2,4-diazadiphosphetidines.[2] On heating, the dissociation of the dimer to the corresponding monomer may be expected to occur, the monomer being analogous to reactive intermediates such as phosphinylidenes (R–P=O) and phosphinothioylidenes (R–P=S).[3]

In order to get information on these points, we investigated the structure of "alkyl phenyliminophosphites" and the reactions with 1,3-dienes and carbonyl compounds such as benzil, benzalacetophenone, and α-phenyliminobenzyl phenyl ketone.

Structure of "Alkyl Phenyliminophosphites." "Alkyl phenyliminophosphites," prepared by the reported method,[1] were obtained as a viscous liquid, the ethyl derivative solidifying on standing for several weeks. No change of the spectral data was observed before and after solidification.



1



1′

a, R=Et; b, R=Me

The mass spectrum of the ethyl derivative showed parent and base peaks at *m/e* 334 and 167, respectively, supporting the view that the structure is a cyclic dimer, 2,4-diethoxy-1,3-diphenyl-1,3,2,4-diazadiphosphetidine (**1a**). The ^{1}H-NMR spectrum showed two triplets centered at δ 1.22 and 1.25. The ratio of peak area of the triplet of δ 1.25 to that of δ 1.22 was *ca.* 1.4, indicating the existence of two ethoxy group in a different environment.

If we assume a rapid inversion on the nitrogen atoms,[4] the existence of *cis* and *trans* isomers is possible with respect to two ethoxy groups. This was also supported by the ^{31}P-NMR spectrum. Two signals were observed at δ_P −134.9 and −182.0 ppm, the ratio of peak area being *ca.* 1.3. Since two phosphorus atoms are equivalent in this cyclic system, they should be assigned to signals of the phosphorus nuclei of *cis* and *trans* isomers.

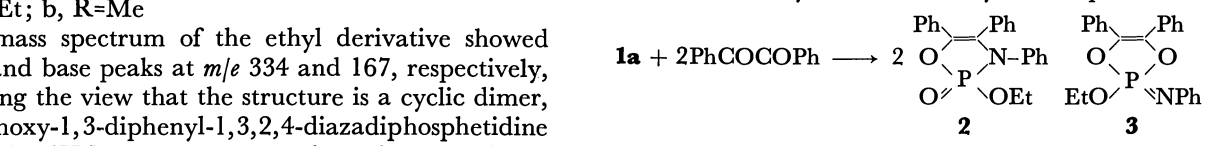
Nielsen and Pustinger[5] observed two signals at δ_P −109.2 and −113.6 ppm in the ^{31}P-NMR spectrum of 2,4-dianilino-1,3-diphenyl-1,3,2,4-diazadiphosphetidine. It is expected in the *cis* isomer of **1a** that steric repulsion between two ethoxy groups causes repulsion of lone pair electrons on two phosphorus atoms and deshields the phosphorus nuclei. Thus, the signal in the *cis* isomer shifts considerably to a low field.

The ^{31}P-NMR spectrum of methyl derivative (**1b**) showed signals due to *trans* and *cis* isomers at δ_P −136.5 and −184.8 ppm, respectively.

Attempts to separate the *cis* and *trans* isomers of **1** were unsuccessful. The mixture was therefore used for reactions described below.

Attempted Reaction with Isoprene. If the dissociation equilibrium between **1** and **1′** was present, the resulting iminophosphite (**1′**) would be expected to undergo Diels-Alder type reaction with dienes analogously to R–P=S.[3a,c] However, the reaction with isoprene in *o*-dichlorobenzene at 190 °C for one day in a sealed tube gave neither Diels-Alder adduct nor Ramirez type adduct, indicating that **1** does not dissociate to **1′** at 190 °C.

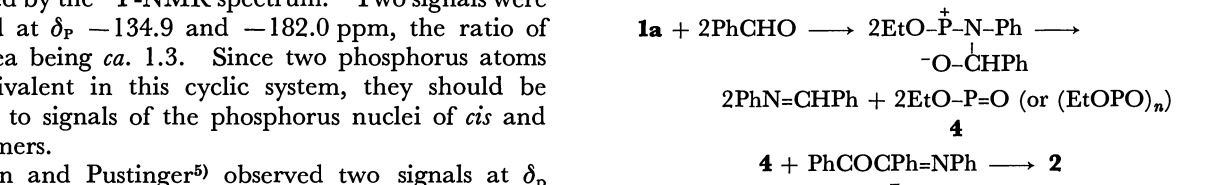
Reaction with Benzil. Under nitrogen atmosphere, benzil reacted with **1a** in refluxing *o*-dichlorobenzene to give 2-ethoxy-3,4,5-triphenyl-Δ^4-1,3,2-oxazaphospholine 2-oxide (**2**) in 17% yield. The structure was determined by elemental analysis and spectral data.



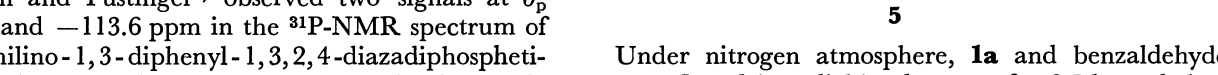
2 **3**

The IR and NMR spectra could not completely rule out another structure (**3**). However, the presence of peaks at *m/e* 268 (2,3-diphenylindole−H) and 180 (PhC≡N$^+$–Ph) in the mass spectrum supports the structure **2**.

Structure **2** was also confirmed by an unequivocal synthesis by another route. The following reaction is expected to take place:[1]



4

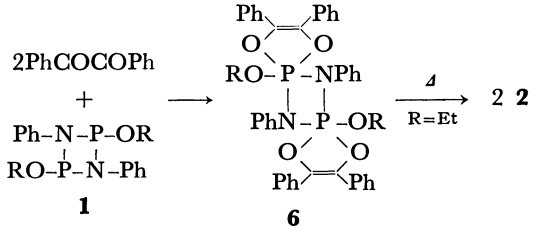


5

Under nitrogen atmosphere, **1a** and benzaldehyde were refluxed in *o*-dichlorobenzene for 3.5 h, and then

α-phenyliminobenzyl phenyl ketone (**5**) was added. After being refluxed for one day, **2** was obtained in 44% yield, the formation of *N*-benzylideneaniline being confirmed by NMR. Reaction of **4** with **5** is analogous to that of phosphinylidenes with benzil.[3b]

Under mild conditions, *viz.*, in boiling benzene or in acetonitrile at room temperature, **1a** reacted with benzil to afford 5,7-diethoxy-2,3,6,9,10,12-hexaphenyl-1,4,8,11-tetroxa-6,12-diaza-5,7-diphosphadispiro[4.1.4.1]-dodeca-2,9-diene (**6a**), a Ramirez type adduct, in 44 or 18% yield, respectively.



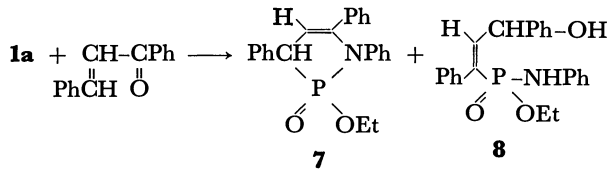
1 **6**

a, R=Et; b, R=Me

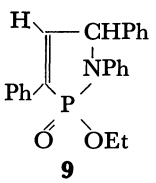
Similarly, **1b** reacted with benzil in acetonitrile at room temperature to give an analogous Ramirez type adduct (**6b**) in 12% yield. The ^{1}H-NMR spectrum showed complicated signals of methyl protons. These complexities can be attributed to virtual couplings observed in the ^{1}H-NMR spectra of some 2,2-diethoxy-1,3,5-triazatriphosphorine derivatives,[6] bis(dimethylamino)- and bis(methylthio)-1,3,2,4-diazadiphosphetidine 2,4-dioxides.[7]

Compound **6a** decomposed in refluxing *o*-dichlorobenzene to give **2** in 21% yield. It seems reasonable that **6** is an intermediate in the formation of **2**.

Reaction with Benzalacetophenone. Benzalacetophenone reacted with **1a** in refluxing *o*-dichlorobenzene to produce 2-ethoxy-1,3,5-triphenyl-Δ^4-1,2-azaphospholine 2-oxide (**7**) and an open-chain product (**8**), *O*-ethyl *N*-phenyl 1,3-diphenyl-3-hydroxy-1-propenylphosphonamidate, in 15 and 7% yields, respectively.



7 **8**

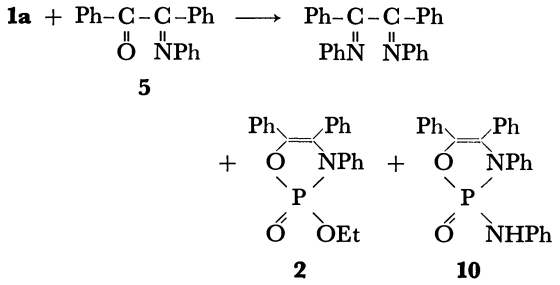


9

Another structure (**9**) is possible for **7**. The MS spectrum of **8** gave no parent peak, but the highest peak was observed at *m/e* 375 (M^+-H_2O), which seems to be due to **9** formed by intramolecular dehydration of **8**. The fragmentation pattern differed from that of **7**, the base peak of **7** being at *m/e* 282 ($M^+-EtOPO-H$), and that of **8** at *m/e* 193 ($Ph_2C_3H_3^+$). NMR signals due to ethoxy protons exhibited doubling. This is explained by the presence of asymmetric carbon at the 2-position of **7**.

From the results, structure **7** is favored over structure **9**.

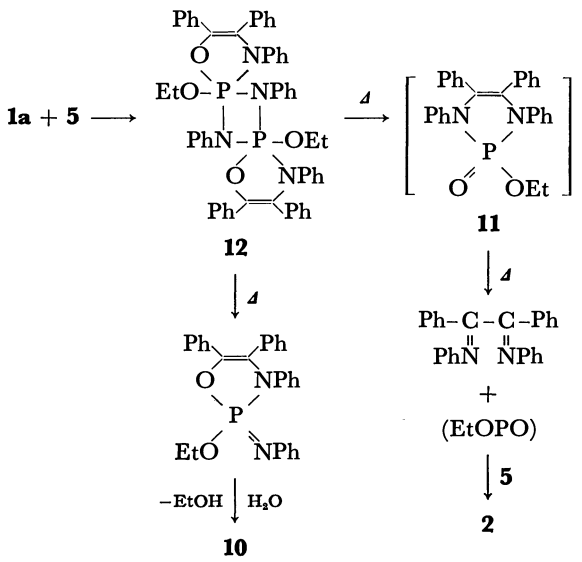
Reaction with α-Phenyliminobenzyl Phenyl Ketone. Under similar conditions, **1a** reacted with α-phenyliminobenzyl phenyl ketone (**5**) to afford α,α′-bis(phenylimino)bibenzyl, **2**, and 2-anilino-3,4,5-triphenyl-Δ^4-1,3,2-oxazaphospholine 2-oxide (**10**) in 20, trace, and 40% yields.



2 **10**

The expected product (**11**) corresponding to **2** and **7** was not obtained.

A possible mechanism is considered as follows, though an attempt to isolate the Ramirez type adduct (**12**) was unsuccessful.



Compound **1a** did not react with α-methoxyiminopropiophenone in a refluxing acetonitrile.

Experimental

All melting and boiling points are uncorrected. IR and mass spectra were recorded on a Hitachi EPI-G2 spectrophotometer and a Hitachi RMU-6L mass spectrometer, respectively. ^{1}H-NMR spectra were measured with Hitachi R-20 B, R-24 (60 MHz) and R-22 (90 MHz) spectrometers using TMS as an internal standard. ^{31}P-NMR spectra were determined with a Hitachi R-20 B-R-204-PB spectrometer using 85% phosphoric acid as an external standard.

All reactions were carried out under nitrogen atmosphere.

Materials. Benzil,[8] α-phenyliminobenzyl phenyl ketone,[9] and benzalacetophenone[10] were prepared by the methods given in the literature.

2,4-Diethoxy-1,3-diphenyl-1,3,2,4-diazadiphosphetidine (1a). Compound (**1a**) was prepared by the reported procedure,[1]

bp 164 °C/0.2 mmHg (lit,[1] 145—147 °C/0.08 mmHg). The viscous liquid solidified on standing for several weeks, mp 45 °C. MS: *m/e* 334 (M^+, 53%) and 167 ($M^+/2$, 100); ^{1}H-NMR (CCl_4): δ 1.22 (t, J=7 Hz), 1.25 (t, J=7 Hz), 4.1 (m, 2H, >P-OC<u>H</u>$_2$Me), and 6.7—7.35 (m, 5H, Ph). The area ratio of the signal at δ 1.25 to that at δ 1.22 was *ca.* 1.4; ^{31}P-NMR (PhH): δ_P −182.0 and −134.9 ppm. The area ratio of the signal at δ_P −134.9 to that at δ_P −182.0 ppm was *ca.* 1.3.

*2,4-Dimethoxy-1,3-diphenyl-1,3,2,4-diazadiphosphetidine (**1b**).* Compound (**1b**) was prepared by a procedure similar to that for **1a**, but could not be distilled under reduced pressure because of thermal decomposition. Thus it was used without further purification. ^{31}P-NMR (PhH): δ_P −184.8 and −136.5 ppm.

*Reaction of **1a** with Benzil.* *a) In o-Dichlorobenzene*: To a solution of benzil (4.20 g, 20.0 mmol) in *o*-dichlorobenzene (30 ml) was added **1a** (3.34 g, 10.0 mmol) in *o*-dichlorobenzene (10 ml) and the mixture was refluxed for 2 h. After removal of the solvent, the residue was chromatographed on a silica gel dry column with dichloromethane to afford 1.32 g (17%) of **2**, mp 146.0—146.5 °C (from ether); IR (KBr): 1650 (C=C), 1240 (P=O), and 1025 cm^{-1} (POC); NMR ($CDCl_3$): δ 1.29 (t, J=7 Hz, 3H, Me), 4.25 (dp, J_{HCCH}=7, J_{POCH}=10 Hz, 2H, OCH_2^-), and 7.14—7.28 (m, 15H, 3Ph); MS: *m/e* 377 (M^+).

Found: C, 70.21; H, 5.11; N, 3.61%. Calcd for $C_{22}H_{20}NO_3P$: C, 70.02; H, 5.34; N, 3.71%.

b) In Benzene: To a solution of benzil (1.06 g, 5.0 mmol) in benzene (35 ml) was added **1a** (0.84 g, 2.5 mmol) in benzene (5 ml) with stirring. The mixture was refluxed for one day and the solvent was removed *in vacuo*. The residue was treated with ether to precipitate 0.835 g (1.1 mmol, 44%) of **6a**, mp 142—143 °C (dec) (from acetone). IR (KBr): 1650 (C=C) and 1020—1050 cm^{-1} (POC); ^{1}H-NMR ($CDCl_3$, 90 MHz): δ 1.11 (t, J=7 Hz, 3H, $POCH_2C\underline{H}_3$), 1.24 (t, J=7 Hz, 3H, $POCH_2C\underline{H}_3$), 3.96 (m, 4H, $POC\underline{H}_2Me$), and 7.1—7.6 (m, 30H, 6Ph); ^{31}P-NMR (PhH): δ_P +62.8 ppm; MS: *m/e* 754 (M^+).

Found: C, 70.27; H, 5.36; N, 3.60%. Calcd for $C_{44}H_{40}N_2O_6P_2$: C, 70.02; H, 5.34; N, 3.71%.

c) In Acetonitrile: A mixture of **1a** (1.69 g, 5.05 mmol) and benzil (2.11 g, 10.0 mmol) in acetonitrile (30 ml) was stirred for one day at room temperature. The resulting precipitates were recrystallized from acetone to give **6a** (0.693 g, 18%).

*Alternative Preparation of **2**.* A mixture of **1a** (1.18 g, 3.5 mmol) and benzaldehyde (0.76 g, 7.2 mmol) in *o*-dichlorobenzene (40 ml) was refluxed for 3.5 h. To the reaction mixture was added a solution of α-phenyliminobenzyl phenyl ketone (2.00 g, 7.0 mmol) in *o*-dichlorobenzene (10 ml). The mixture was then refluxed for one day. After evaporation of the mixture, the NMR spectrum of the residue showed the presence of *N*-benzylideneaniline at δ 8.40 (s, Ph-C<u>H</u>=). The residue was chromatographed on a silica gel dry column with dichloromethane to give crude **2** which was recrystallized from ether to give a pure sample (1.16 g, 3.1 mmol, 44%). Isolation of *N*-benzylideneaniline was unsuccessful because of the easy hydrolysis.

*Thermal Decomposition of **6a**.* A solution of **6a** (0.626 g, 0.83 mmol) in *o*-dichlorobenzene (30 ml) was refluxed for one day. After removal of the solvent under reduced pressure, the residue was chromatographed on a silica gel dry column to afford **2** (0.131 g, 0.35 mmol, 21%).

*Reaction of **1b** with Benzil.* A solution of crude **1b** prepared from aniline (4.185 g, 45 mmol) and methyl phosphorodichloridite (2.00 g, 15 mmol) in acetonitrile (10 ml) was added to a solution of benzil (3.16 g, 15 mmol) in acetonitrile (40 ml) and the mixture was stirred for 2 days at room temperature. The resulting crystals were recrystallized from acetone to give **6b** (0.648 g, 0.89 mmol, 12%), mp 158.0—158.5 °C. IR (KBr): 1640 (C=C) and 1020—1050 cm^{-1} (POC); NMR ($CDCl_3$): δ 3.65 (m, 6H, POMe) and 7.1—7.6 (m, 30H, 6Ph); MS: *m/e* 726 (M^+).

Found: C, 69.18; H, 4.72; N, 3.60%. Calcd for $C_{42}H_{36}N_2O_6P_2$: C, 69.42; H, 4.99; N, 3.85%.

*Reaction of **1a** with Benzalacetophenone.* A solution of **1a** (1.67 g, 5.0 mmol) and benzalacetophenone (2.08 g, 10.0 mmol) in *o*-dichlorobenzene (45 ml) was refluxed for 9 h. After removal of the solvent *in vacuo*, the residue was chromatographed on a silica gel dry column with dichloromethane–carbon tetrachloride (1:1). Elution with ether from the partition of R_f 0.5—0.7 gave **7** (0.555 g, 1.47 mmol, 15%), mp 179—180 °C (from ether). IR (KBr): 1640 (C=C), 1218 (P=O), and 1038 cm^{-1} (POC); NMR ($CDCl_3$): δ 1.08, 1.32 (dt, J=7 Hz, 3H, $POCH_2C\underline{H}_3$), 4.07 (m, 2H, $POC\underline{H}_2CH_3$), 5.72 (d, J_{PH}=20 Hz, 1H, =CH–), 6.70 (m, 1H, >CH–), and 7.0—7.7 (m, 15H, 3Ph); MS: *m/e* 375 (M^+, 75%) and 282 (PhC^+=CHCPh=NPh, 100).

Found: C, 73.84; H, 6.20; N, 3.87%. Calcd for $C_{23}H_{22}NO_2P$: C, 73.59; H, 5.91; N, 3.73%.

Elution with ethanol from the partition of R_f 0.7—0.9 gave 1.23 g of a tarry product. Treatment with a small amount of ethanol gave 0.284 g (7%) of **8**, mp 214 °C (from ethanol). An analytically pure sample could not be obtained. However, its structure was determined by the following spectral data. IR (KBr): 3260 (OH), 3100 (NH), 1630 (C=C), 1213 (P=O), and 1040 cm^{-1} (POC); NMR ($CDCl_3$): δ 1.00 (t, J=7 Hz, 3H, $OCH_2C\underline{H}_3$), 1.95 (s, 1H, OH), 3.64 (d, J=7 Hz, 1H, =CH–C<u>H</u>〈), 3.82 (dq, J_{HH}=7, J_{PH}=10 Hz, 2H, $POCH_3$), 6.10 (s, 1H, NH), 6.29 (t, J_{HH}=J_{PH}=7 Hz, 1H, =C<u>H</u>–CH〈), and 7.0—7.5 (m, 15H, 3Ph); MS: *m/e* 375 (M^+–H_2O, 47%) and 193 (100).

*Reaction of **1a** with α-Phenyliminobenzyl Phenyl Ketone.* A solution of **1a** (1.61 g, 4.8 mmol) and α-phenyliminobenzyl phenyl ketone (2.54 g, 8.9 mmol) in *o*-dichlorobenzene (40 ml) was refluxed for 24 h. After removal of the solvent under reduced pressure, the residue was chromatographed on a silica gel dry column. Elution with dichloromethane from the first partition of R_f 0.7—1.0 gave 0.644 g (1.8 mmol, 20%) of α,α′-bis(phenylimino)bibenzyl, mp 147—148 °C (from ethanol) (lit,[11] 142 °C); MS: *m/e* 360 (M^+). Elution with ether from the second partition of R_f 0.5—0.7 gave a trace of **2**. Elution with ether from the third partition of R_f 0.1—0.5 gave 1.66 g (3.9 mmol, 40%) of **10**, mp 164.5—165 °C (from ethanol). IR (KBr): 3150 (NH), 1640 (C=C), and 1235 cm^{-1} (P=O); NMR ($CDCl_3$): δ 6.7—7.1 (m, 10H, 2Ph), 7.24 (s, 10H, 2Ph), and 7.58 (bs, 1H, NH); MS: *m/e* 424 (M^+).

Found: C, 73.83; H, 4.95; N, 6.45%. Calcd for $C_{26}H_{21}N_2O_2P$: C, 73.58; H, 4.95; N, 6.60%.

Optical Activation of Racemic α-Substituted Carbonyl Compounds Using Optically Active Amines

Hajime MATSUSHITA, Masao NOGUCHI, and Sadao YOSHIKAWA*

Central Research Institute, The Japan Tobacco and Salt Public Corporation, Umegaoka, Midori-ku, Yokohama, Kanagawa 227

**Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received February 19, 1976)

Hydrolysis of immonium salts of enamines consisting of optically active amines and racemic α-substituted carbonyl compounds with hydrochloric acid gave the corresponding optically active carbonyl compounds. The NMR spectra showed that the immonium salt is a mixture of two diastereomeric isomers. The mechanism of the optical activation is discussed on the basis of an isotope labeling experiment and the NMR spectra.

Optically active carbonyl compounds with an asymmetric carbon atom at the α-position of the carbonyl group are widespread in nature as terpenoids, steroids and alkaloids, their synthesis being considered of interest by many workers.[1] The resolution of racemic carbonyl compounds,[2] asymmetric destruction,[3] asymmetric synthesis[4] and asymmetric transformation[5] has been reported. The asymmetric transformation by which racemic compounds are transformed into the corresponding optically active forms has not been much utilized, though nearly 100% yield of one enantiomer has been reported.[6] Compounds with an active proton at the asymmetric carbon are suitable for the asymmetric transformation, but it is difficult to isolate their optically active forms since they undergo racemization easily.[6] On the other hand, the compounds with an inactive proton at the asymmetric carbon are undesirable for their optical activation. The hydrolysis of the immonium salts of enamines of racemic α-substituted carbonyl compounds with optically active acids give the corresponding optically active carbonyl compounds and the original acids.[7] Conversion of the stable α-substituted carbonyl compounds into the labile immonium salts is a key step in the optical activation. This paper deals with another method of optical activation of racemic α-substituted carbonyl compounds. The enamines consisting of racemic α-substituted carbonyl compounds and optically active amines were treated with acid, and hydrolysis of the salts gave the optically active carbonyl compounds. This is a new method to obtain optically active α-substituted carbonyl compounds from their racemic forms.

Experimental

Optical rotations were determined with a JASCO Digital Automatic Polarimeter Model DIP 181. Gas chromatographic analyses were carried out on a 2 m column of 20% Carbowax 20 M on Cromosorb W with a Hitachi Gas Chromatograph, Model K 53. Nuclear magnetic resonance spectra were obtained with a JNM-PS-100 Spectrometer with tetramethylsilane as an internal standard.

S(+)-2-Methylpiperidine. *S*(+)-2-Methylpiperidine was obtained by resolution according to the method of Kostyanovsky *et al.*[8]

R(−)-2-Methylpyrrolidine. *R*(−)-*O*,*N*-Ditosyl-L-prolinol was prepared according to the method described by Kostyanovsky *et al.*[8] Anhydrous benzene (500 ml) and *R*(−)-*O*,*N*-ditosyl-L-prolinol (115 g, 0.28 mol) were placed in a 3 l four-necked round bottom flask equipped with a mechanical stirrer, a reflux condenser and a thermometer. Sodium bis(2-methoxyethoxy)aluminum hydride (700 g in benzene, 3.47 mol) was carefully added with vigorous stirring. The reaction mixture was refluxed and stirred for 5 days. It was then cooled, and ice-cold water was added with vigorous stirring. After separation of the benzene layer, the aqueous layer was made strongly basic with pellets of sodium hydroxide, and extracted with benzene. The separated benzene layer and the extracts were combined and extracted with three 100 ml portions of 6 M hydrochloric acid. The acid solution was made strongly basic with pellets of sodium hydroxide again, and extracted with ether. The ether solution was dried over anhydrous Na_2SO_4, and filtered. The solvent was distilled off and the residue was subjected to fractional distillation. All the fractions boiling up to 100 °C were collected (11.3 g, 47.7% yield based on the ditosylprolinol). This crude amine was subjected to the subsequent procedures without further purification.

Preparation of Enamines. Enamines of α-phenylpropionaldehyde (**1**), 2-methylcyclohexanone (**2**) and 2-ethylhexanal(**3**) were prepared by the usual azeotropic procedure using benzene as the solvent and purified by distillation. *R*(−)-2-methylpyrrolidine and *S*(+)-2-methylpiperidine were used as amine components of the enamines. *S*(+)-2-Methylpiperidine enamine of **1**: bp 129—130 °C (5 mmHg), 81% yield; MS *m/e* 215 (M^+), 200 (base); IR 1638 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers (92: 8 at room temperature), major isomer, 1.03 (N–C–CH_3, d, J=6.7 Hz), 2.09 (C=C–CH_3, s), 6.40 (N–CH=C, s), 7.30 (phenyl, m), minor isomer, 5.81 (N–CH=C, s); $[\alpha]_D^{23}$ −426° (neat). *S*(+)-2-Methylpiperidine enamine of **2**: bp 136 °C (8.5 mmHg), 32% yield; MS *m/e* 193 (M^+), 178 (base); IR 1634 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) 0.83 (N–C–CH_3, d, J=6.0 Hz), 1.70 (CH_3–C=C–N, s); $[\alpha]_D^{23}$ −89° (neat), $[\alpha]_D^{23}$ −71.2° (c=5, benzene). *S*(+)-2-Methylpiperidine enamine of **3**: bp 97—99 °C (6 mmHg), 91.9% yield; MS *m/e* 209 (M^+), 166 (base); IR 1664 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers (60: 40 at room temperature), $[\alpha]_D^{23}$ −11.6° (neat). *R*(−)-2-Methylpyrrolidine enamine of **1**: bp 102—130 °C (5.5 mmHg), 76.1% yield; MS *m/e* 201 (M^+), 186 (base); IR 1631 cm^{-1} ($\nu_{C=C}$); NMR ($CDCl_3$) mixture of two geometrical isomers (89: 11 at room temperature), major isomer, 1.17 (N–C–CH_3, d, J=6.3 Hz), 2.15 (C=C–CH_3, s), 6.40 (N–CH=C, s), 7.3 (phenyl, m), minor isomer, 1.17 (N–C–CH_3, d, J=6.3 Hz), 2.04 (C=C–CH_3, s), 6.11 (N–CH=C, s), 7.17 (phenyl, m); $[\alpha]_D^{23}$ +398° (c=2.90, benzene). *R*(−)-2-Methylpyrrolidine enamine of **2**: bp 93.5 °C (7.5 mmHg), 78.7% yield; MS 179 (M^+), 164 (base); IR 1638 cm^{-1} ($\nu_{C=C}$);

NMR ($CDCl_3$) mixture of two geometrical isomers (85: 15 at room temperature), major isomer, 0.90 (CH_3–CH–C=C, d, J=6.0 Hz), 1.08 (CH_3–C–N, d, J=6.6 Hz), 4.30 (CH_3–CH–C=C, t, J=4.0 Hz), minor isomer, 1.66 (CH_3–C=C, s); $[\alpha]_D^{23}$ +190.5° (c=2.31, benzene).

The Hydrolysis of Enamines. To a solution of enamine (0.02 mol) in benzene (30 ml) was added an equivalent aqueous hydrochloric acid with vigorous stirring in an ice bath. The reaction was continued until the completion of hydrolysis which was confirmed gas chromatographically. The benzene layer was separated, successively washed with water and 5% aqueous sodium carbonate and water, and dried over anhydrous Na_2SO_4, the optical rotation being then measured. The recovery of carbonyl compound was determined with a gas chromatograph. The same results were obtained by another method: Dry HCl gas was bubbled into a benzene solution (50 ml) of enamine (0.02 mol), and the solvent was removed completely under reduced pressure. The residue was dissolved in benzene (30 ml), and to the solution in an ice bath was added water (15 ml) dropwise with vigorous stirring. The subsequent procedure was the same as mentioned above.

Results and Discussion

Hydrolysis of Enamines. The results are summarized in Table 1. The optical rotation of pure **1** is not known. Though the determination of the specific rotation of **1** was attempted by the method of Goering,[9] no pseudocontact-shift differences for enantiomers could be observed in the presence of tris-[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]-europium(III). Cram reported the optical rotation of a mixture of **1** and acetophenone, α_{obs} +75.80°.[10] The optical rotation of the pure **2** was reported to be $[\alpha]_D^{18}$ +14.21° (l=0.5).[11] Calculating from this value, the optical yields are estimated to be 20.2% (in the case of *S*(+)-2-methylpiperidine) and 6.20% (in the case of *R*(−)-2-methylpyrrolidine). The optical activation of **3** was examined only in the case of *S*(+)-2-methylpiperidine. Optical rotations of the recovered **3** were determined at several other wave lengths as well as at 589 nm (D line): $[\alpha]_{577}^{23}$ −0.102°, $[\alpha]_{546}^{23}$ −0.138°, $[\alpha]_{435}^{23}$ −0.255°, $[\alpha]_{365}^{23}$ −0.499°. From the results in Table 1, six membered ring amine seems to contribute to the optical activation more effectively than the five membered amine. The difference in the ability of the optical activation can be attributed to the difference of the *exo* double bond stability. The higher degree overlapping of the lone pair on the nitrogen atom with the π-orbital of *exo* double bond and more favorable conformation of five membered ring with *exo* double bond seem to make the immonium salt with five membered amine more stable and less reactive than that with six membered amine.[12,13] Greater stability and smaller reactivity of the salt with five membered ring amine would be unfavorable for asymmetric transformation by proton exchange.

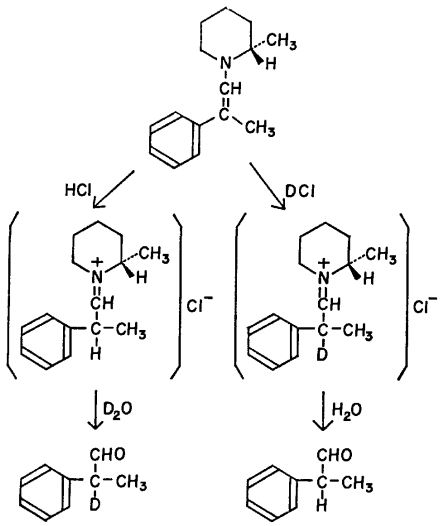

Fig. 1.

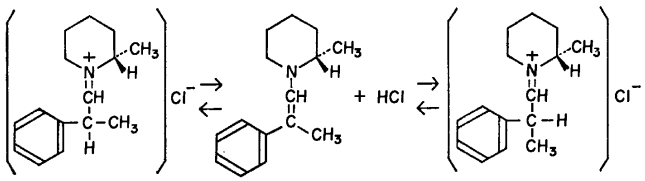
Isotopic Labeling Study. As shown in Fig. 1, hydrolysis of the immonium salt of HCl and 2-methylpiperidine enamine of **1** in D_2O gave deuterated **1**, but not that of the salt of DCl and the enamine in H_2O.

This suggests that the proton exchange at the asymmetric α-carbon of an immonium salt occurs easily. The reversible protonation in favor of one diastereomeric immonium salt results in an optically active **1**. Similar proton exchange reactions *via* enamine were reported by Leonard and Sauers.[14]



Immonium salts of enamines of racemic α-substituted carbonyl compounds with optically active acids gave, on hydrolysis with water, the corresponding optically active carbonyl compounds.[7] The mechanism of this optical activation was considered to be the same as the asymmetric transformation reported by Read and McMath.[15] The result of the isotopic labeling study also supports the mechanism.

NMR Spectra of Enamine and Immonium Salts. Dry HCl or DCl gas was bubbled into a solution of optically

The Reactions of Polychloroethanes with Phenolate and Benzenethiolate Ions in Dipolar Aprotic Solvents

Shigeo TANIMOTO, Ryôzô TANIYASU, Tôru TAKAHASHI, Takatoshi MIYAKE, and Masaya OKANO

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received February 26, 1976)

The reactions of several *gem*- and *vic*-polychloroethanes containing 3—5 Cl atoms with PhONa in dimethyl sulfoxide and with PhSNa in *N*,*N*-dimethylformamide were examined. Either the mono-, di-, or tetra-substituted compounds of polychloroethylenes were obtained as the main products, depending on the kinds of substrates as well as on the amounts of the bases. The reaction products from polychloroethylenes with 2—4 Cl atoms were also examined under similar conditions for the sake of comparison. Reasonable reaction paths leading to these products were given.

Though direct substitution reactions (S_N2) of primary alkyl halides have been widely utilized in the syntheses of various kinds of compounds,[1] the usefulness of alkylidene dihalides in this way is rather limited because of their low reactivities.[2] Thus ,it has been known that the basic substitution of the halogen atom(s) of less-reactive alkylidene dichlorides by nucleophiles other than thiolate ions proceeds only under severe reaction conditions; *e.g.*, the preparation of diphenoxymethane can be accomplished by heating dichloromethane with PhONa in 95% alcohol at 150 °C for 3 h in a sealed tube.[3] We have recently found, however, that this reaction can be conducted even at room temperature by the use of dimethyl sulfoxide (DMSO) as the solvent.[4] Since the basicity of a base is known to be greatly enhanced by the change in solvent from a hydroxylic solvent to DMSO because of the disappearance of a hydrogen-bonding interaction,[5] there is a possibility that, even with a less-basic nucleophile, an olefin-forming elimination might compete considerably with a substitution, at least in basic aprotic solvents. On the other hand, it has been reported that, in the reaction of an alkyl halide with a basic nucleophile, the introduction of an electron-withdrawing group, such as COR, SO_2R, and even Br or Cl, at the β-position results in a large increase in the rate of olefin formation.[6] With these points in mind, we examined the reactions of several *gem*- and *vic*-polychloroethanes containing 3—5 Cl atoms with PhONa in DMSO and with PhSNa in *N*,*N*-dimethylformamide (DMF). The products were mostly the mono- or disubstituted compounds of polychloroethylenes, probably formed by the dehydrochlo-

rination of the original polychlorides and by subsequent vinylic substitution(s) of the resulting olefins. Therefore, the reaction products from various polychloroethylenes with 2—4 Cl atoms were also examined under similar conditions for the sake of comparison.

The direct formation of substituted (chloro)ethylenes from polychloroethanes has never been reported so far as we know. However, there are several reports in the literature regarding vinylic substitution(s) of polychloroethylenes, where the reactions are mostly carried out in protic solvents or neat. Previous preparative data indicate that the substitution by RO^- [7] or ArO^- [8] can be achieved only under severe conditions, whereas the reaction with highly nucleophilic RS^- or ArS^- takes place readily under usual reaction conditions. The only study in a polar aprotic solvent was given by Normant; he found that, in DMF, the reaction of trichloroethylene with equimolar PhONa proceeded smoothly on heating at 65—70 °C.[9]

Results and Discussion

The reaction with PhONa was carried out by adding the chloroethanes to a solution of PhONa in DMSO (prepared by dissolving NaOH and PhOH in the solvent on heating) at an appropriate temperature. The reaction with PhSNa was conducted in a similar way, except for the use of DMF as the solvent under a nitrogen atmosphere, because the reaction in DMSO resulted in the formation of substantial amounts of diphenyl disulfide. The results for the two reactions are summarized in Tables 1 and 2. The reactions of the chloroethylenes with PhONa and PhSNa were similarly carried out in DMSO and DMF respectively. Some results are given in Table 3. The recorded yields in these tables are not always those obtained under optimum conditions. As can be seen from Tables 1 and 2, when more than an equivalent amount of the nucleophile was used, the substituted chloroethylenes and/or substituted ethylenes were isolated as the main products,

depending on the kinds of reactants and their molar ratios. These products are formed by the initial dehydrochlorination, followed by the vinylic substitution(s) of the resulting chloroethylenes once or several times successively. Indeed, a considerable similarity between some data in these tables and those in Table 3 was noted (compare the product for each pair: Runs 2 and 3, 4, and 6 in Table 1 *vs.* Runs 2, 5, and 6 in Table 3 respectively, and also Runs 2 and 3, 5, and 6 in Table 2 *vs.* Runs 7 and 8, 11, and 12 in Table 3 respectively). In only one case, where 1,1,2-trichloroethane (I) was treated with equimolar PhS^-, was the direct substitution product isolated as the main product (Run 1 in Table 2). On the contrary, the reaction with equimolar *n*-BuS^-, which is similarly nucleophilic but more basic than PhS^-,[18] mainly afforded the product with elimination, *i.e.*, *trans*-1-butylthio-2-chloroethylene (Run 7 in Table 2).

In connection with this, the following observation is also of interest. The reaction of 1,2,3-trichloropropane with equimolar PhS^- gave only the substitution product, 2,3-dichloropropyl phenyl sulfide, while the reaction with equimolar PhO^- (more basic than PhS^-[18]) yielded the elimination products, 2-chloroallyl chloride and 2-chloroallyl phenyl ether (Run 9 in Table 2 *vs.* Run 7 in Table 1).

The advantages of the method are the mild reaction conditions and the one-step synthesis of certain substituted (chloro)ethylenes from polychloroethanes. Representative is the synthesis of tetrakis(phenylthio)-ethylene from pentachloroethane (IV) or tetrachloroethylene (VIII). In contrast to our method, the reported one for the preparation of tetrakis(alkyl- or arylthio)ethylenes from VIII was carried out under

quite drastic conditions, even by means of a two-step synthesis.[19] Further, the formation of 1,1-dichloro-2,2-diphenoxyethylene from IV or VIII in DMSO is noteworthy, because the only reported product from VIII and PhO^- in a sealed tube is the monosubstituted chloroethylene.[20] Cope has reported that, when 1,1,1-trichloroethane (II) was treated with two moles of PhONa in water, a mixture of *o*- and *p*-hydroxyacetophenones was formed in a slight yield (by the Reimer-Tiemann reaction).[21] The reaction in DMSO, however, afforded 1-chloro-2-phenoxyethylene and 1,1-diphenoxyethylene as the main products.

Next, we will briefly consider a possible reaction path for each case. The reactions of both I and 1,1-dichloroethylene (V) with PhO^- yielded *cis*-1-chloro-2-phenoxyethylene and 1,1-diphenoxyethylene (Runs 1 and 2 in both Tables 1 and 3), while those with PhS^- (except for the case of Run 1 in Table 2) afforded *trans*-1-chloro-2-phenylthioethylene and *cis*-1,2-bis(phenylthio)ethylene (Runs 2 and 3 in Table 2 and Runs 7 and 8 in Table 3). Truce *et al.*[22] reported the formation of a similar monosubstituted *trans*-olefin and disubstituted *cis*-olefin from V and $p\text{-}CH_3C_6H_4S^-$, and proposed a sequence involving an addition-elimination mechanism and an elimination-addition mechanism for two successive substitutions. When I is used as the starting substrate, however, the first intermediate in this sequence, 1,1-dichloro-2-arylthioethane, is not necessarily formed *via* V, since we have observed the formation of this compound from I, without any accompanying elimination product, as has been described above. On the other hand, in the case of the more basic PhO^-, the formation of the monosubstituted *cis*-olefin from V can be explained by assuming an elimination-addition mechanism. The subsequent vinyl substitution leading to the disubstituted olefin may involve an elimination-addition mechanism, as in the case of PhS^-.

There is an additional remark to make on the dehydrochlorination of I with PhO^-. The generation of V rather than *trans*-1,2-dichloroethylene(VI_t) may be anticipated from electronic considerations; *i.e.*, the α-H of I is more acidic than the β-H because of the effect of the two electron-withdrawing Cl atoms. The reaction products from I were identical with those from II, supporting this expectation (Runs 1, 2, and 3 in Table 1 and Run 2 in Table 3). Further, VI_t did not react with PhO^- to afford any product. Therefore, a route *via* VI_t is unlikely.

$$\text{I or II} \xrightarrow[-HCl]{} \text{V} \xrightarrow[-HCl]{} CH{\equiv}CCl \xrightarrow{PhO^-} \begin{matrix} H & & H \\ & C=C & \\ PhO & & Cl \end{matrix}$$

$$\xrightarrow[-HCl]{} PhOC{\equiv}CH \xrightarrow{PhO^-} (PhO)_2C{=}CH_2 \quad (1)$$

$$\text{I or V} \xrightarrow{PhS^-} PhSCH_2CHCl_2 \xrightarrow[-HCl]{} \begin{matrix} H & & Cl \\ & C=C & \\ PhS & & H \end{matrix}$$

$$\xrightarrow[-HCl]{} PhSC{\equiv}CH \xrightarrow{PhS^-} \begin{matrix} H & & H \\ & C=C & \\ PhS & & SPh \end{matrix} \quad (2)$$

Here, the attack of the second PhS^- occurred exclusively at an electronically unexpected position. Such an unusual orientation may be ascribed to the resonance stabilization of the resulting carbanion with a S atom at the α-position:[23]

$$PhS\text{–}\bar{C}{=}CH\text{–}SPh \longleftrightarrow PhS\bar{}{=}C{=}CH\text{–}SPh$$

cis-1,2-Dichloroethylene (VI_c) has a favorable geometry for *trans* elimination, as has V, and both olefins afforded the identical *cis*-olefin as the monosubstituted product upon treatment with PhO^-, suggesting the involvement of a common intermediate. The reaction of VI_c with PhS^- also afforded *cis*-1-chloro-2-phenylthioethylene, which was isomeric with the product from V. Such a difference may arise from an increased sensitivity toward PhS^- at the β-C of V. The formation of the *cis*-products from VI_c in both reactions may be explained by assuming an elimination-addition mechanism:[24]

$$VI_c \xrightarrow[-HCl]{} CH{\equiv}CCl \xrightarrow{PhX^-} \begin{matrix} H & & H \\ & C=C & \\ PhX & & Cl \end{matrix} \quad (X=O, S) \quad (3)$$

1,1,2,2-Tetrachloroethane (III) reacted with excess PhO^- or PhS^- to give the *trans*-isomer of 1-substituted 1,2-dichloroethylene as the monosubstituted product, implying that both reactions proceed by the same sequence. Trichloroethylene (VII) also afforded the same *trans*-olefin in the reaction with excess PhO^-, but when PhS^- was used as the nucleophile the main product was a disubstituted one. A reaction path involving an elimination-addition sequence is probable. The same mechanism has already been proposed by Truce *et al.* for the reaction of VII with $p\text{-}CH_3C_6H_4SNa$:[25]

$$\text{III} \xrightarrow[-HCl]{} \text{VII} \xrightarrow[-HCl]{} ClC{\equiv}CCl \xrightarrow{PhX^-} \begin{matrix} Cl & & H \\ & C=C & \\ PhX & & Cl \end{matrix} \quad (X=O, S) \quad (4)$$

when X=S

$$\begin{matrix} Cl & & H \\ & C=C & \\ PhS & & Cl \end{matrix} \xrightarrow{PhS^-} PhSCHClCHClSPh$$

$$\xrightarrow{-HCl} \begin{matrix} Cl & & SPh \\ & C=C & \\ PhS & & H \end{matrix} \quad (5)$$

During the experiments of the reactions of III and VII, we occasionally experienced small explosions. This may be an indication of the intermediate formation of dichloroacetylene, since its exploding property has already been reported.[26]

In the reaction of excess PhO^- with IV as well as with VIII, the products were 1,1,2-trichloro-2-phenoxyethylene and 1,1-dichloro-2,2-diphenoxyethylene. Since VIII is incapable of dehydrochlorination, consecutive addition-elimination must take place for the formation of polysubstituted (chloro)ethylenes. Truce *et al.* previously proposed the same sequence for the reaction of VII with $p\text{-}CH_3C_6H_4S^-$:[27]

$$\text{IV} \xrightarrow[-HCl]{} \text{VIII} \xrightarrow{PhX^-} PhXCCl_2CHCl_2$$

$$\xrightarrow[-HCl]{} PhXCCl{=}CCl_2 \quad (X=O, S)$$

tion with CH_3ONa (in CH_3OH, at 50 °C), CH_3X: CH_2X_2= 1.0: *ca.* 10^{-3} and CH_2X_2: CH_2Cl_2=1.0: *ca.* 10^{-1}, where X=I or Br.

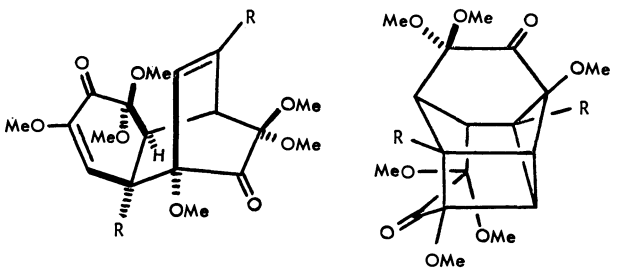
Acid-catalyzed Rearrangements of Tetrahydroasatone and Tetrahydroisoasatone

Shosuke YAMAMURA and Yukimasa TERADA
Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468
(Received March 2, 1976)

Tetrahydroasatone (**3**) and tetrahydroisoasatone (**4**) both are pretty unstable to various kinds of acid. Action of 6M·HCl–AcOH on the former converted it to the naphthalene-type compound (**5**) in high yield, whose structure was determined on the basis of its spectral data. In the case of tetrahydroisoasatone, twofold Wagner-Meerwein rearrangements take place, leading to the formation of the isomer-A (**9**), further rearrangements of which give rise to the bisnordiadamantane-type isomer-B (**10a**).

In the previous paper.[1] We reported the isolation and structures of two novel neolignans, asatone (**1**) and isoasatone (**2**). From a structural point of view, the former has a bicyclo[2.2.2]oct-5-en-2-one system as a part of the structure (**1**). In the case of isoasatone (**2**), it has a highly strained bicyclo[2.2.0]hexane system. Both of them are pretty unstable to various kinds of acid. In this paper, we wish to describe some interesting acid-catalyzed rearrangements of tetrahydroasatone (**3**) and tetrahydroisoasatone (**4**), both of which have been already produced on catalytic hydrogenation from **1** and **2**, respectively. Particularly, the structures of the reaction products are discussed in detail.



1 R=$CH_2CH=CH_2$ **2** R=$CH_2CH=CH_2$
3 R=*n*-Pr **4** R=*n*-Pr

Fig. 1.

As described above, asatone (**1**) and tetrahydroasatone (**3**) both are unstable in acidic solution, and many spots are found on an analytical TLC plate. However, when treated with 6 M·HCl-AcOH under vigorous conditions (100 °C, 1.5 h), tetrahydroasatone was converted in high yield (*ca.* 85%) into the yellow substance with a molecular formula (mp 181—182 °C; $C_{20}H_{22}O_5$), the structure (**5**) of which was elucidated on the basis of its spectral data (see Table 1), as follows.

The IR and UV spectra of this compound (**5**) suggest that it has a highly substituted naphthalene chromophore [ν_{max} 1605, 1570, and 1525 cm^{-1}: λ_{max} 415, 329, 289, and 226 nm]. This is also confirmed by the ^{13}C NMR spectral data of **5** [δ 99.42 (d) and 113.70 (s)—150.71 (s) ppm].[2]

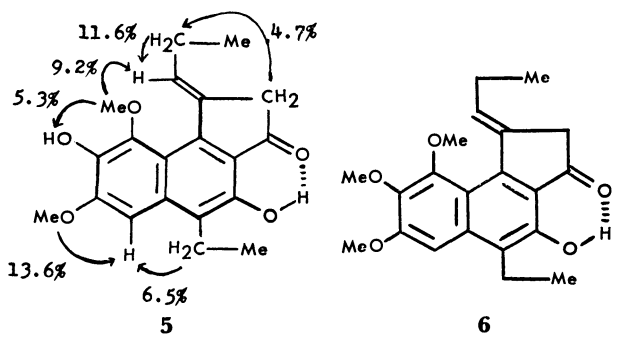
This yellow substance (**5**) has two MeO groups (δ 3.60 and 4.00 ppm) in addition to two OH groups [ν_{max} 3400 br.cm^{-1}: δ 5.93 and 9.53 ppm], one of which has been readily converted into a MeO group on treatment of **5** with diazomethane in ether leading to the formation of the corresponding monomethyl ether (**6**), mp 138—139 °C; $C_{21}H_{24}O_5$; ν_{max} 3200 cm^{-1}; δ 3.72 (3H, s), 4.02 (3H, s) and 4.03 (3H, s) ppm. Of five oxygen atoms in **5**, the remaining one should be included in the CO group [ν_{max} 1640 (s)cm^{-1}; δ 206.55 ppm], the IR absorption band of which is shifted to 1665 cm^{-1} in the case of **6**. Furthermore, it is noted that **5** is proved to have two partial structures [A and B] on the basis of its ^1H and ^{13}C NMR spectral data [A: δ 1.20, 2.96, 13.87, and 24.51 ppm; B: δ 1.09, 2.24, 3.30, 6.76, 13.55, 17.85, 40.17, 134.68, and 113.70—150.71 ppm[2]].

$CH_3CH_2-\dot{C}=$ $CH_3CH_2CH=\dot{C}-CH_2-\dot{C}-$
[A] [B]

Table 1. The spectral data of the yellow substance

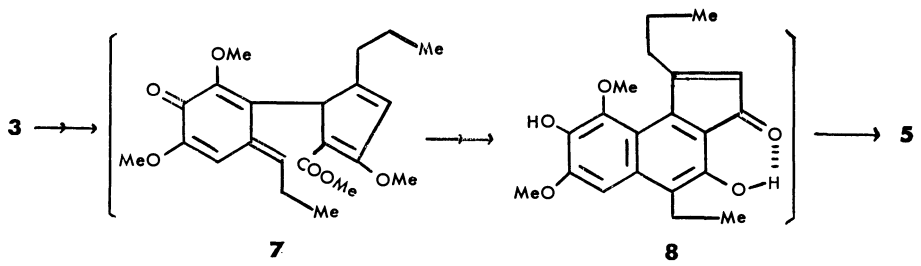
ν_{max}(Nujol)	3400br., 1640, 1605, 1570, and 1525 cm^{-1}
λ_{max}(MeOH)	415, 329, 289, and 226 nm (ε 5000, 11000, 28000, and 20000, respectively)
^{13}C NMR ($CDCl_3$)	13.55(q), 13.87(q), 17.85(t), 24.51(t), 40.17(t), 55.91(q), 61.11(q), 99.42(d), 113.70(s), 122.63(s), 122.88(s), 129.93 (s), 134.16(s), 134.68(d), 137.16(s), 142.19(s), 146.17(s), 148.85(s), 150.71 (s) and 206.55(s) ppm
^1H NMR ($CDCl_3$)	1.09(3H, t, J=7.0 Hz), 1.20(3H, t, J=7.8 Hz), 2.24(2H, quintet, J=7.0 Hz), 2.96 (2H, q, J=7.8 Hz), 3.30 (2H, d, J=1.7 Hz), 3.60(3H, s), 4.00(3H, s), 5.93(1H, s, OH), 6.76(1H, br.t, J=7.0 Hz), 6.95(1H, s) and 9.53(1H, s, OH) ppm

Finally, in the light of the structure of **3** consisting of two C_6-C_3 units, the structure of the yellow substance



5 **6**

Fig. 2.



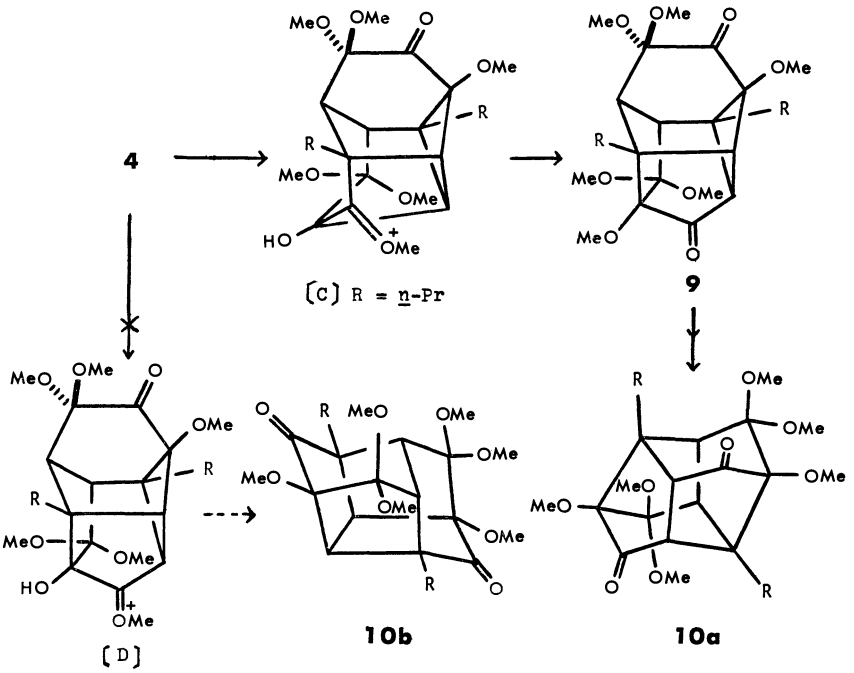
Scheme 1. A plausible reaction path-way from **3** to **5**.

(**5**) was determined by measurements of intramolecular nuclear Overhauser effects, and the final result was shown in Fig. 2.

Probably, the yellow substance (**5**) is produced from a plausible intermediate (**7**) *via* an α,β-unsaturated ketone (**8**) (see Scheme 1), although the formation process of **5** is not clear. In Scheme 1, it is quite reasonable that the conjugated ketone (**8**) is readily converted into the more stable ketone (**5**), for the former has an unstable cyclopentadienone system.

Isoasatone (**2**) and tetrahydroisoasatone (**4**) both are also unstable in acidic solution, and many spots are detected on an analytical TLC plate. However, when treated with dry ether saturated with HCl gas (room temp., 8 h),[3] tetrahydroisoasatone (**4**) with a symmetric structure was readily converted into an isomer-A (**9**) in 87.5% yield (mp 135.5—136.5 °C; $C_{24}H_{36}O_8$; ν_{max} 1755 and 1738 cm^{-1}). The NMR spectrum of **9** indicates that six MeO groups and four methine protons are all in different environment to one another. The IR absorption band at 1755 cm^{-1} indicates the presence of a five-membered ring CO group, which has been newly formed from one of the two six-membered ring CO groups (ν_{max} 1735 cm^{-1}) in **4**. On further treatment with zinc powder in MeOH containing one drop of concd HCl (room temp., 8 h), the isomer-A (**9**) afforded a mixture containing several compounds, from which another symmetrical isomer-B (**10a**) was obtained in *ca.* 10% yield (mp 152—153 °C; $C_{24}H_{36}O_8$; ν_{max} 1760 cm^{-1}). In the NMR spectrum of the isomer-B, only half of the total protons are observed as follows: δ 0.98 (6H, t, J=7.0 Hz), 1.2—2.3 (8H, complex), 2.52 (2H, dd, J=2.1 and 1.4 Hz), 2.89 (2H, dd, J=2.1 and 1.4 Hz), 3.23 (6H, s), 3.38 (6H, s) and 3.46 (6H, s) ppm. From the IR and NMR spectra of the isomer-B, two possible structures (**10a** and **10b**) are considered (see Scheme 2). As suggested by Yonemitsu and Witkop,[4] however, the cationic intermediate [C] at the initial step is unambiguously more favorable than another intermediate [D]. Therefore, the structures of two isomers A and B should be represented by **9** and **10a**, respectively.

In the course of the reaction (**4**—**10a**), twofold Wagner-Meerwein rearrangements take place after protonation of one of the two CO groups in **4**, leading to the formation of the isomer-A (**9**) which is a less strained cage-compound as compared with **4**. Further Wagner-Meerwein rearrangements released the strain energy due to the remaining cyclobutane ring in **9** to give the bisnordiadamantane-type isomer-B (**10a**). In the present study, the cage-compound (**9**) was first isolated as an intermediate between **4** and **10a**.



Scheme 2. Twofold Wagner-Meerwein rearrangements of **4**.

Experimental

All mps were uncorrected. The IR and UV spectra were obtained on a JASCO Model IR-S and on a Perkin-Elmer 202 spectrophotometer, respectively. The NMR spectra were taken on a JEOL JNM-PS 100 (100 MHz) using $CDCl_3$ as solvent. Chemical shifts are given in ppm from TMS as an internal standard. Coupling constants are given in Hz (s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet). The mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating with an ionization energy (70 eV).

*Formation of the Yellow Substance (**5**).* A solution of tetrahydroasatone (200 mg) in 6 M·HCl (8 ml) and AcOH (1.5 ml) was heated at 100 °C for 1.5 h, and then poured into large amounts of water to give yellow crystals which were collected by filtration. Recrystallization from acetone–hexane afforded yellow plates of **5** (128 mg), mp 181—182 °C; *m/e* 342 (M^+) and 327 (Found: C, 70.23; H, 6.51%. Calcd for $C_{20}H_{22}O_5$: C, 70.16; H, 6.48%).

*Formation of the Methyl Ether (**6**).* To a solution of excess diazomethane in ether (50 ml) was added the compound (**5**) (15 mg) with stirring. The resulting solution was stirred at room temp. overnight, and then concentrated under reduced press. to give a crystalline solid (15 mg). Recrystallization from acetone–hexane afforded pale yellow crystals of **6**, mp 138—139 °C; ν_{max} (Nujol) 3200, 1665, 1605, 1565, and 1510 cm^{-1}; λ_{max} (MeOH) 416, 331, 291, and 225 nm (ε, 4600, 9000, 30000, and 19700, respectively); δ 1.15 (3H, t, J=7.5 Hz), 1.26 (3H, t, J=7.5 Hz), 2.31 (2H, quintet, J=7.5 Hz), 3.20 (2H, q, J=7.5 Hz), 3.39 (2H, d, J=2 Hz), 3.72 (3H, s), 4.02 (3H, s), 4.03 (3H, s), 6.92 (1H, br.t, J=7.5 Hz), 7.10 (1H, s), and 9.82 (1H, s, OH) ppm: *m/e* 356 (M^+) and 341 (Found: *m/e* 356.16336. Calcd for $C_{21}H_{24}O_5$: *m/e* 356.16236).

*Conversion of Tetrahydroisoasatone (**4**) to the Isomer-A (**9**).* A solution of **4** (20 mg) in anhydrous ether (5 ml) saturated with HCl gas was allowed to stand at room temp. for 8 h, and then carefully concentrated under reduced press. to give a colorless viscous liquid which was subjected to preparative TLC [Kieselgel PF_{254}; hexane–EtOAc (3: 1)]. From the most nonpolar fraction, a colorless viscous liquid was obtained and dissolved in small amounts of hexane to give white crystals of **9** (17.5 mg), mp 135.5—136.5 °C (from hexane); ν_{max} (Nujol) 1755 and 1738 cm^{-1} (no OH band); δ 0.90 (6H, t, J=6.5 Hz), 1.1—2.0 (8H, complex), 2.56 (1H, dd, J=2.2, and 1.6 Hz), 2.73 (1H, dd, J=6.8, and 1.6 Hz), 2.99 (1H, t, J=2.2 Hz), 3.13 (1H, dd, J=6.8, and 2.2 Hz), 3.24 (3H, s), 3.25 (3H, s), 3.32 (3H, s), 3.33 (3H, s), 3.34 (3H, s), and 3.48 (3H, s) ppm; *m/e* 452 (M^+), 437, 424, 420, 409, 405, and 392 (Found: *m/e* 452.24543. Calcd for $C_{24}H_{36}O_8$: *m/e* 452.24100).

*Further Rearrangement of **9** to the Isomer-B (**10a**).* The isomer-A (50 mg) was dissolved, with stirring, in a solution of MeOH (3 ml) containing one drop of concd HCl at −5 °C. To this solution was added activated zinc powder (500 mg) with vigorous stirring. The reaction mixture was allowed to stand at room temp. for 8 h with continuous stirring, and then poured into large amounts of water and extracted with ether. The ethereal extracts were washed with sat. NaCl aq. solution, and then dried over Na_2SO_4. Removal of the solvent afforded a pale brown oil, which was subjected to preparative TLC [Kieselgel PF_{254}; hexane–EtOAc (5: 1)]. From the most nonpolar fraction, a crystalline solid was obtained by elution with ether. Recrystallization from hexane afforded white crystals of the isomer-B (6 mg), mp 152—153 °C; ν_{max} (Nujol) 1760 cm^{-1} (no OH band); *m/e* 452 (M^+), 421, 406, and 390 (Found: *m/e* 452.24479. Calcd for $C_{24}H_{36}O_8$: *m/e* 452.24100).

The authors wish to thank Drs. M. Kurono and M. Toda (Ono Pharmaceutical Co., Ltd.) for measurements of high resolution mass spectra. They are also indebted to Prof. Y. Okumura and Dr. H. Irikawa (Shizuoka University) for measurements of ^{13}C NMR spectra.

(Received March 2, 1976)

Isolation and structures of two novel neolignans, asatone (**1**) and isoasatone (**2**), are described. The structure of the latter, established by means of an X-ray crystallographic analysis of its dihydroxy derivative, is in full agreement with its chemical and spectral data. From a biogenetic point of view, furthermore, thermal and photochemical reactions of these neolignans and their derivatives were carried out. In particular, asatone was photochemically converted into isoasatone.

The chemical constituents of many species of *Asarum* genus, *Aristolochiaceae*, have been investigated by many authors.[1] Particularly, chemotaxonomic studies on species of *Asarum*, *Asiasarum* and *Heterotropa* have been extensively carried out by Saiki and his co-workers.[2] In most cases, however, chemical constituents have been examined in steam-distillates of the fresh or air-dried whole herb of the plant.

The decoction of the stems and rhizomes of *Asarum taitonense* Hayata (Taiton Kanaoi in Japanese)[3] is used in Taiwan as a remedy for neuralgia by the local people.[4] In the course of our searching for physiologically active substances of this plant, we isolated two neoligans, named "asatone" and "isoasatone". In this paper, we wish to describe the isolation and structures of these neolignans. From a biogenetic point of view, thermal and photochemical reactions of these neolignans are also presented.

Isolation of Asatone (1) and Isoasatone (2). A sample of the dried and pulverized material of the whole herb of *Asarum taitonense* Hayata was directly refluxed with large amounts of hexane for 3 h, and then filtered. The filtrates were concentrated under reduced pressure to give a greenish yellow solid, which was chromatographed on silica gel and eluted with hexane–EtOAc (8: 1) to afford asatone (**1**), mp 101—102 °C, in *ca.* 0.2% yield. On the other hand, the residue was further extracted with $CHCl_3$ (under reflux, 3 h). The extracts were also chromatographed on silica gel, and eluted with hexane–EtOAc (8: 1) to give rise to white crystals of isoasatone (**2**), mp 156.5—158 °C, in *ca.* 0.001% yield. Asatone and isoasatone both have the same molecular formula ($C_{24}H_{32}O_8$). Furthermore, it should be noted that the mass spectra of these two neolignans are quite similar to each other [*m/e* 448 (M^+), 416, 384, 348, and 224]. However, the other spectral data are pretty different, as shown in Table 1.

The Structure of Asatone. As described above, asatone (**1**), a major component of *Asarum taitonense* Hayata, has a molecular formula [$C_{24}H_{32}O_8$ (*m/e* 448 (M^+))]. As cited in Table 1, the NMR methyl singlets at δ 3.0—3.6 ppm and IR absorption bands at 1740 and 1720 cm^{-1} indicate that asatone has six MeO and two CO groups, all of which are in different environment to one another. The presence of two allyl groups in **1** is based on its NMR spectrum [δ4.90—5.28, 5.50—6.20, 2.60—2.95, and 2.15 ppm] coupled with catalytic hydrogenation of **1**, which has been carried out over 10% Pd–C in EtOAc to afford tetrahydroasatone (**3**), mp 128—129 °C: $C_{24}H_{36}O_8$ [*m/e* 452 (M^+)]. The NMR spectrum of **3** has methyl triplet at δ 0.87 (6H, J=6.5 Hz) ppm and multiplets at δ 1.10—1.80 and 1.85—2.15 ppm corresponding to four methylene groups instead of multiplets at δ 4.90—5.28 and 5.50—6.20 ppm in **1**. Furthermore, it should be noted that at least one of the two allyl groups in **1** must be attached to an asymmetric quaternary carbon atom: irradiation at δ 5.85 ppm in **1** caused the quartet at δ 2.15 ppm to collapse to doublet, the large coupling constant (J=14.5 Hz) of which should be regarded as a J-value between geminal protons.

Asatone (**1**) has two CO groups, whose properties can be elucidated by $NaBH_4$ reduction, as follows. When treated with $NaBH_4$ in EtOH (room temp., 1.5 h), **1** afforded a mixture of three reduction products [hydroxyasatone-A (**4**): mp 127—128 °C, $C_{24}H_{34}O_8$,

Table 1. Spectral data of asatone (**1**) and isoasatone (**2**)

	Asatone (**1**)	Isoasatone (**2**)

† To whom inquires should be addressed.

λ_{max} 218 nm (ε, 4500), ν_{max} 3500 cm^{-1} and δ 3.93 (1H, s) ppm; hydroxyasatone-B (**5**): mp 108—109 °C, $C_{24}H_{34}O_8$, λ_{max} 277 nm (ε, 4400), ν_{max} 3510 cm^{-1} and δ 3.92 (1H, s) ppm; dihydroxyasatone (**6**): mp 156—158 °C, $C_{24}H_{36}O_8$, ν_{max} 3550 and 3425 cm^{-1} (no CO band) and δ 3.80 (2H, br. s)]. In particular, each NMR spectrum of **4** and **5** has the sharp singlet corresponding to one proton attached to the carbon atom bearing the resulting OH group, indicating that the α- and α'-positions of each CO group in **1** must be fully substituted. Furthermore, the comparison of the spectral data between **1** and **4** indicates that asatone (**1**) has an α,β-unsaturated carbonyl system [A] in which only one olefinic proton is located at the β-position, since the NMR singlet at δ 5.39 (1H, s) ppm in **1** is shifted to δ 4.60 ppm in **4**. On the other hand, the α,β-unsaturated carbonyl system [A] is present in the isomer (**5**) and the resulting OH group must be derived from the isolated CO group in **1**. In the case of the third compound (**6**), which is further hydrogenated on 10% Pd–C to the corresponding tetrahydro-compound (**7**) (mp 151—152 °C, $C_{24}H_{40}O_8$), two CO groups are completely reduced to OH groups.

The partial structure [A] is further extended to [B], as follows. Catalytic hydrogenation of **1** in MeOH was carried out over 10% Pd–C (room temp., overnight) to afforded a mixture of **3** and hexahydroasatone (**8**) in *ca.* 70 and 10% yields, respectively. The UV and IR spectra of **8** [mp 133—134 °C; $C_{24}H_{38}O_8$: ν_{max} 1750 and 1745 cm^{-1}] indicate that conjugate double bond in [A] has been hydrogenated. Furthermore, the NMR spectrum of **8** has two new signals at δ 2.31 (2H, d, J= 5.5 Hz) and 3.63 (1H, t, J=5.5 Hz) ppm. Irradiation at δ 2.31 ppm caused the triplet at δ 3.63 ppm to collapse to singlet. This finding strongly supports the presence of the partial structure [B] in **1**.

Further information on the structure of asatone (**1**) was obtained by zinc reduction of **1** as well as of **3**.

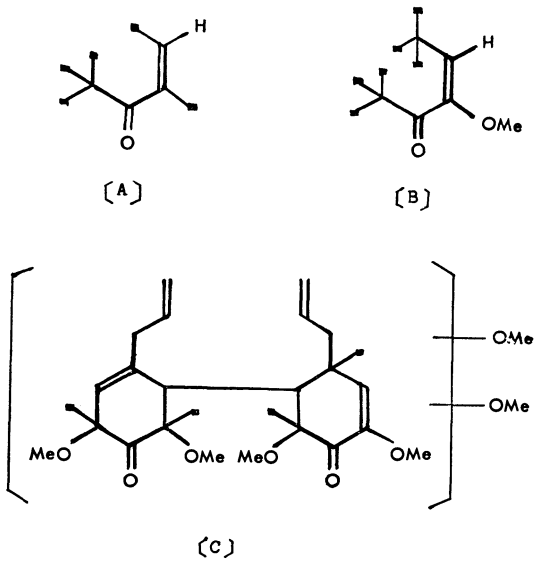

Fig. 1.

When treated with activated zinc powder in AcOH (under reflux, 6 h), tetrahydroasatone (**3**) was readily converted into 2,6-dimethoxy-4-propylphenol (**9**) and a biphenyl-type compound (**10**) in 57 (as 2eq.) and 23% yields, respectively. Further treatment of **9** with Ac_2O–pyridine gave the corresponding acetate (**11**), mp 88—88.5 °C (lit, 87 °C)[5]; $C_{13}H_{18}O_4$ [*m/e* 238 (M^+)]; ν_{max} 1765 cm^{-1}: λ_{max} 275 and 227 nm (ε, 790 and 6140, respectively). In connection with the formation of 9, the symmetric structure (**10**) of the biphenyl-type compound can be deduced on the basis of its spectral and chemical properties: $C_{22}H_{30}O_6$ [*m/e* 390 (M^+)]; ν_{max} 3460, 1610, 1585, and 1495 cm^{-1}; δ 0.81 (6H, t, J=7.0 Hz), 1.15—1.80 (4H, m), 2.22 (4H, td, J=7.0 and 1.5 Hz), 3.60 (6H, s), 3.95 (6H, s) and 6.60 (2H, br. s) ppm. Acetylation of **10** afforded in quantitative yield the corresponding diacetate (**12**), mp 117—118 °C;

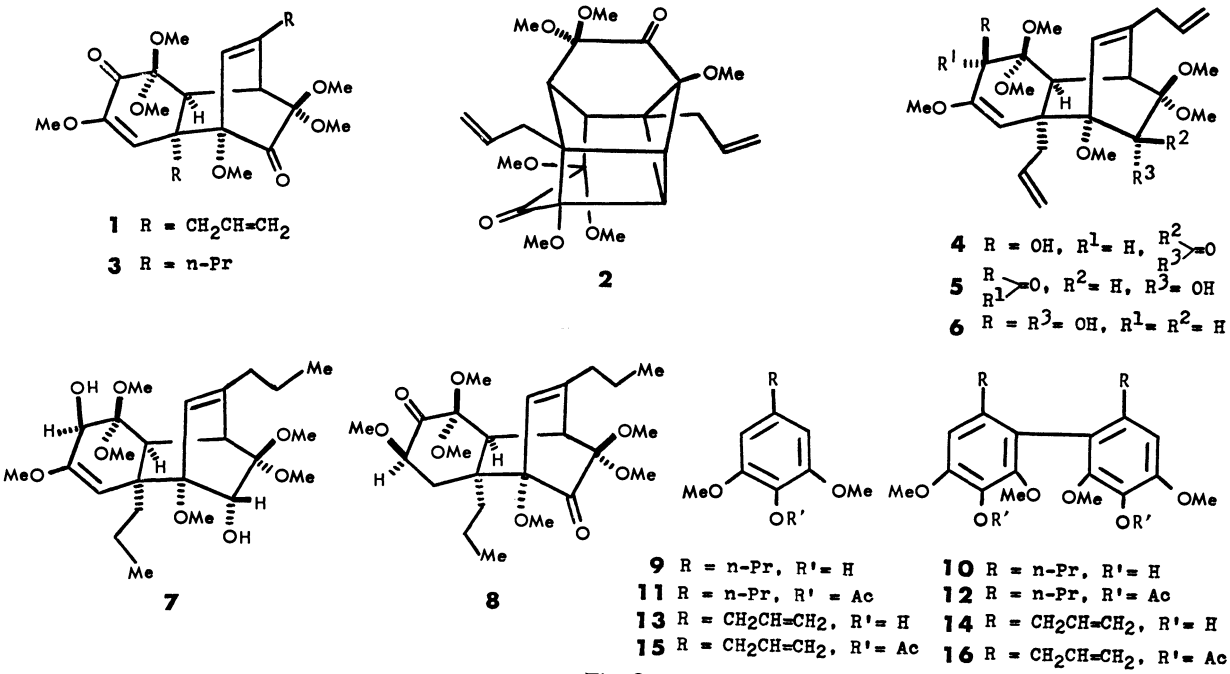

Fig. 2.

$C_{26}H_{34}O_8$: ν_{max} 1770 cm^{-1}; λ_{max} 279 and 232 nm (ε, 2470 and 13750, respectively). These two acetates (**11** and **12**) were also obtained directly from **3** in 51 (as 2 eq.) and 24% yields, respectively, on zinc reduction using Ac_2O (under reflux, 7 h) instead of AcOH. Under essentially the same condition, zinc reduction of asatone (**1**) in AcOH afforded a mixture of 2,6-dimethoxy-4-allylphenol (**13**) and a biphenyl-type compound (**14**) in 37 (as 2 eq.) and 19% yields, respectively. Acetylation of the former followed by catalytic hydrogenation (10% Pd–C in EtOAc) gave rise to **11** *via* 2,6-dimethoxy-4-allylphenyl acetate (**15**). Acetylation of **14** also afforded the corresponding diacetate (**16**), mp 125—125.5 °C; $C_{26}H_{30}O_8$ [*m/e* 470 (M^+)]; ν_{max} 1775 cm^{-1}. Clearly, two allyl groups are present in **16** [δ 3.10 (4H, d, J=6.7 Hz), 4.75—5.10 (4H, m) and 5.45—6.10 (2H, m) ppm]. The formation of these aromatic compounds in high yields strongly suggests that the carbon skeleton of asatone (**1**) consists of two C_6–C_3 units and **1** may have a partial structure [C]. Finally the structure of asatone (**1**) including its stereochemistry was elucidated on the basis of the photochemical reaction of asatone leading to the formation of isoasatone (**2**) in 64% yield,[6] whose structure had been unambiguously established by means of an X-ray crystallographic analysis of dihydroxyisoasatone (**17**),[7] as described later.

On the basis of the structure (**1**) thus obtained, the spectral data of asatone will be discussed below. As seen in Table 1, the UV absorption band [λ_{max} 278 nm (ε, 5100)] of **1** is observed at longer wavelength than calculated one. This is probably due to some effects of α',α'-dimethoxyl groups as well as of the isolated and tri-substituted double bond. Furthermore, the NMR broad singlet at δ 2.88 ppm in **1** (δ 2.84 ppm in **3**) is not due to one methylene group[8], but assignable to two methine protons which have the same chemical shift although these two protons are in different environment to each other. In fact, the ^{13}C NMR spectrum of asatone is in good agreement with the structure (**1**), and a tentative assignment of each signal is as follows: δ ($CDCl_3$) 39.0 (t), 41.3 (t), 116.9 (t), 118.2 (t), 133.4 (d), and 135.2 (d) [2×(CH_2=CH–CH_2)]; 43.9 (d) and 44.5 (d) [2×(>CH–)]; 49.8 (s) (>C<); 50.1—50.2[9], 54.8 (q) and 55.5 (q) (6×OMe); 92.1 (s) [>C(OMe)–]; 93.2 (s) and 98.7 (s) [2×(>C(OMe)$_2$)]; 116.6 (d) and 144.9 (s) (–HC=C<); 121.7 (d) 150.2 (s) and 188.7 (s) [(MeO)C=CH–C=O]; 201.4 (s) ppm (C=O).

The Structure of Isoasatone. Isoasatone (**2**) has been isolated, as a minor component, together with asatone (**1**) and has the same molecular formula ($C_{24}H_{32}O_8$) as that of the latter.

From a structural point of view, asatone and isoasatone both are quite similar to each other, as follows. They have two allyl and two CO groups in addition to six MeO groups. In fact, on catalytic hydrogenation with 10% Pd–C in EtOAc two allyl groups were reduced, giving the corresponding tetrahydro-compound (**18**), mp 161—162 °C; $C_{24}H_{36}O_8$; δ 0.90 (6H, t, J=5.5 Hz) and 1.70—2.30 (8H, complex) ppm. Furthermore, isoasatone was treated with $LiAlH_4$ in THF to give dihydroxyisoasatone (**17**), mp 153—154 °C; $C_{24}H_{36}O_8$; ν_{max} 3500 and 3430 cm^{-1} (no CO band); no UV absorption maximum; δ 3.71 (2H, s) ppm. Finally, this diol as colorless needles was subjected to an X-ray crystallographic analysis,[7] which proved it to have the complex structure (**17**), which is in good agreement with the physical data of dihydroxyisoasatone. Therefore, the

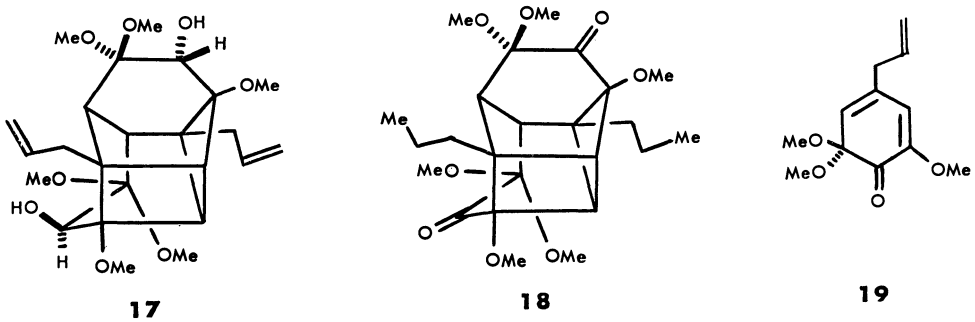

Fig. 3.

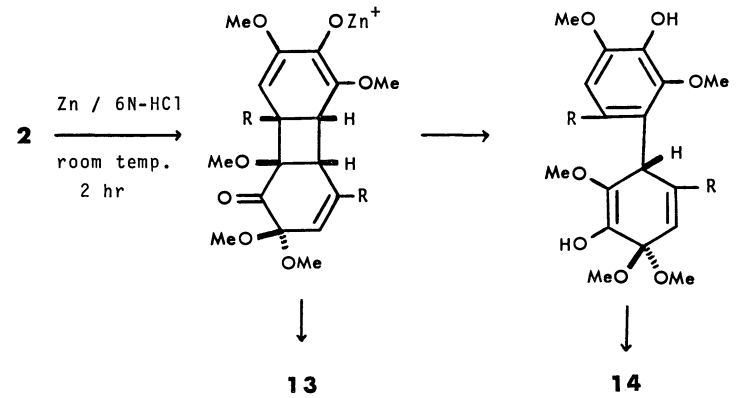


Scheme 1. Zinc reduction of isoasatone (**2**).

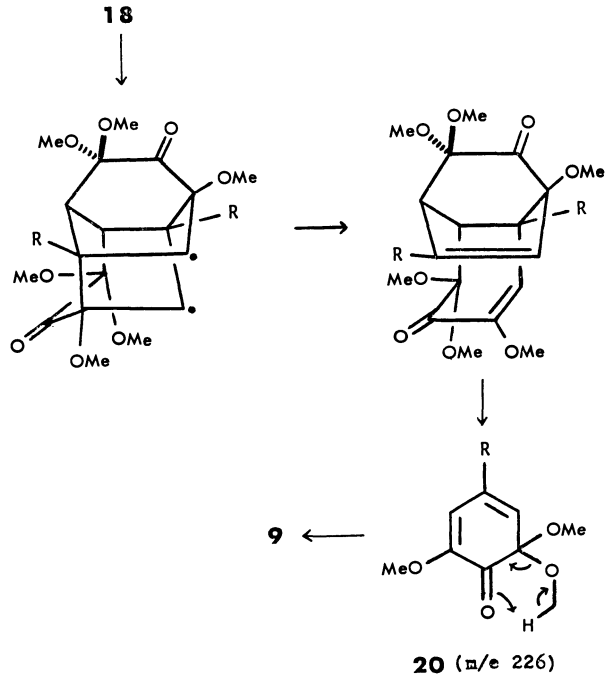
structure of isoasatone should be represented by **2**, in which the UV absorption maximum at 221 nm may be due to the conjugative overlap of the cyclobutane ring with the CO group, the α- and α′-positions of which are fully substituted with MeO groups.

As seen in the case of asatone (**1**), interestingly, zinc reduction of isoasatone (**2**) in 6 M·HCl–MeOH also gave a mixture of two phenolic compounds (**13** and **14**) in 46 (as 2 eq.) and 12% yields, respectively. On the basis of the structure (**2**), the formation process of these compounds is shown in Scheme **1**.

Biogenesis of Asatone and Isoasatone. Asatone (**1**) and isoasatone (**2**) both are optically inactive, and regarded as racemic compounds ($[\alpha]_D^{20}=\pm 0°$). From a biogenetic point of view, the carbon skeleton of these two neolignans consists of two C_6-C_3 units. Probably, 2,6-dimethoxy-4-allylphenol (**13**) is enzymatically oxidized to an optically inactive dienone (**19**), two molecules of which further react to each other to yield asatone (**1**). Further photochemical [π2+π2]cycloaddition of 1 may take place, leading to the formation of isoasatone (**2**) which has a bicyclo[2.2.0]hexane system.

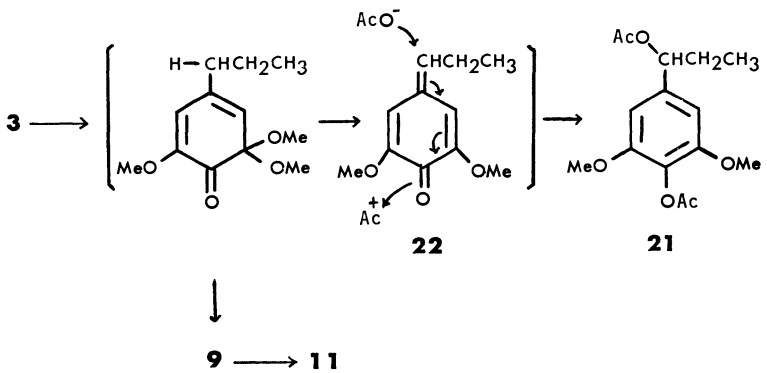
Thermal and Photochemical Reactions of Asatone, Isoasatone and Related Compounds. In connection with the biogenesis of these two neolignans, thermal and photochemical reactions of these compounds were carried out, as follows.

The mass spectra of asatone (**1**) and its derivatives indicate that each base peak is observed at the position corresponding to half of the molecular weight [**1**, 224 ($C_{12}H_{16}O_4$); **3**, 226 ($C_{12}H_{18}O_4$); **4**, 226 ($C_{12}H_{18}O_4$); **5**, 226 ($C_{12}H_{18}O_4$); **6**, 226 ($C_{12}H_{18}O_4$); **7**, 228 ($C_{12}H_{20}O_4$)]. Clearly, the retro-Diels-Alder reaction in each compound must take place regardless of the presence of CO group, giving rise to the corresponding cyclohexadiene or dienone, to which the base peak is assignable. The mass spectra of isoasatone (**2**) and its derivatives are also found to be quite similar to that of asatone (**1**) [2, 224 ($C_{12}H_{16}O_4$); **17**, 226 ($C_{12}H_{18}O_4$); **18**, 226 ($C_{12}H_{18}O_4$)]. In the case of the isoasatone series, a highly strained bicyclo[2.2.0]hexane system of each compound is thermally decomposed in a stepwise manner and then further subjected to the retro-Diels-Alder reaction to give the corresponding cyclohexadiene or dienone, as shown in Scheme 2 (**18**→**20**). When heated in a sealed tube at 290—300 °C for 30 min, tetrahydroisoasatone (**18**) afforded 2,6-dimethoxy-4-propylphenol (**9**) in *ca.* 55% yield. As shown in Scheme 2, the thermal reaction of

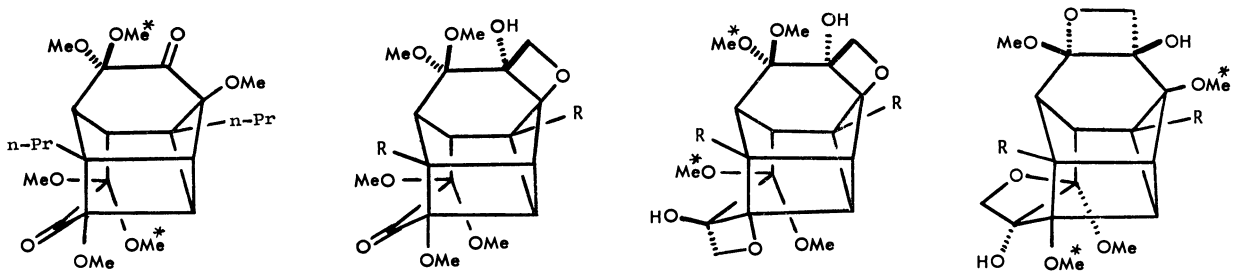


Scheme 2. Thermal reaction of tetrahydroisoasatone (**18**).

18 takes place in the same manner as that of the fragmentation reaction on electron impact, leading to the formation of the corresponding dienone (**20**), which must be further decomposed to **9**. In Scheme 2, it seems to be that the biradical formation process at the initial step requires more vigorous condition as compared with the others. In fact, tetrahydroisoasatone (**18**) is quite stable to acetic anhydride even under reflux conditions. On the other hand, when heated in acetic anhydride under reflux, tetrahydroasatone (**3**) afforded a mixture of 2,6-dimethoxy-4-propylphenyl acetate (**11**) and a diacetate (**21**), 14 and 49 (as 2 eq.) % yields, respectively. The structure of the latter was based on its spectral data: $C_{15}H_{20}O_6$ [m/e 296 (M^+)]; ν_{max} 1770 and 1740 cm^{-1}: λ_{max} 276 and 226 nm (ε, 970 and 9600, respectively); δ 0.90 (3H, t, J=7.5 Hz), 1.87 (2H, quintet, J=7.5 Hz), 2.08 (3H, s), 2.30 (3H, s), 3.78 (6H, s), 5.61 (1H, t, 7.5 Hz) and 6.58 (2H, s) ppm. In particular, the presence of a CH_3CH_2–CH(OAc)–grouping is confirmed by the NMR and IR spectra (δ 0.90, 1.87, 2.08 and 5.61 ppm; ν_{max} 1740 cm^{-1}). The formation process of these two acetates is shown in Scheme 3. It



Scheme 3. The formation process of **11** and **21**.



18a **23** **24a** **24b**

Fig. 4.

is noted that a methylene quinone (**22**) is regared as a plausible intermediate, from which the diacetate (**21**) can be produced.

From the above experiments, it is clear that the dienone (**19**) is the possible precursor for these neolignans.

Asatone (**1**) and isoasatone (**2**) both co-occur in the plant, and the former can be regarded as a plausible precursor of **2**. Thus, chemical correlation between them was successfully carried out by photochemical reaction of asatone, as follows.

When irradiated in hexane using 0.02% aq. K_2CrO_4 solution as a filter at 10 °C, asatone (**1**) was converted into isoasatone (**2**) in 64% yield. In the case of tetrahydroasatone (**3**), the corresponding tetrahydro-compound (**18**) was also obtained in 60% yield. On irradiation of **3** using pyrex filter, two oxetanes (**23** and **24a**) were produced in 47 and 20% yields, respectively, in addition to tetrahydroisoasatone (**18**) (*ca.* 30% yield). Clearly, the dihydroxyoxetane (**24a**) must be produced from **18** *via* the monohydroxyoxetane (**23**). In fact, these two compounds (**18** and **23**) were each subjected to further photochemical reaction to give **24a** in almost quantitative yields. The structures of these oxetanes are discussed below.

The monohydroxyoxetane is a colorless viscous liquid with a molecular formula ($C_{24}H_{36}O_8$), whose IR spectrum indicates the presence of each one OH and CO group (ν_{max} 3550 and 1730 cm^{-1}). This oxetane has five MeO groups (see Table 2) and a methylene group which constitutes a part of the oxetane ring [δ 4.33 (1H, d, J=5.5 Hz) and 4.67 (1H, d, J=5.5 Hz) ppm]. In the case of the dihydroxyoxetane (**24a**, mp 167—168 °C; $C_{24}H_{36}O_8$), which has four MeO groups and no CO group, two oxetane rings must be present [δ 4.11 (2H, d, J=5.0 Hz) and 4.49 (2H, d, J=5.0 Hz) ppm]. Furthermore, it should be noted that only half of the total protons are observed in the NMR spectrum of the dihydroxyoxetane. In connection with tetrahydroisoasatone (**18**), finally, the structure of dihydroxyoxetane (**24a**) was elucidated by measurements of intramolecular nuclear Overhauser effects (NOE), which were focused on the signals corresponding to MeO groups and methine protons (see Table 2).

In the NMR spectrum of **18**, low-intensity irradiation at δ 3.31 ppm caused **12** and 10% enhancements in the integrated intensities of two methine signals at δ 2.82 and 2.90 ppm, respectively. On the other hand, on irradiation at δ 3.22 ppm, any enhancement was not

Table 2. The NMR spectra of **18**, **23**, and **24**

Tetrahydro-isoasatone (**18**)	Monohydroxy-oxetane (**23**)	Dihydroxy-oxetane (**24a**)
2.82 (2H, s)	2.6—2.8 (3H, complex)	2.62(2H, s)
2.90(2H, s)	3.00(4H, s)[a]	2.65(2H, s)
3.22(6H, s)	3.23(3H, s)	2.97(6H, s)
3.31(12H, s)	3.32(3H, s)	3.31(6H, s)
	3.33(3H, s)	
	3.35(3H, s)	

a) One of the four methine protons is included.

detected in the signal intensities of the methine protons (δ 2.82 and 2.90 ppm). From the molecular model of **18**, it is clear that the methyl singlet at δ 3.22 ppm is assigned to one of the two α,α-dimethoxyl groups, that is marked by "asterisk" in **18a**. In the case of the dihydroxyoxetane, only low-intensity irradiation at δ 3.31 ppm caused 12% enhancement in the integrated intensity of the methine singlet at δ 2.62 ppm, and any interaction between the MeO group (δ 2.97 ppm) and two methine protons (δ 2.62 and 2.65 ppm) was not detected. From these data, the structure of the dihydroxyoxetane can be represented by **24a** or **24b**. However, the former is more favorable than **24b**, because the methyl singlet at δ 3.31 ppm is reasonably assigned to the MeO group marked by "asterisk" in **24a**. In the case of **24b**, the signal at δ 3.31 ppm must be assigned to the MeO group marked by "asterisk", although the NMR signal due to the remaining MeO group is expected to be observed in a lower magnetic field that that of the asterisked one, since this MeO group and the newly formed OH group on the oxetane ring both are in a *cis*-configuration to each other. The structure of the monohydroxyoxetane is represented by **23** on the basis of the structure of the dihydroxyoxetane (**24a**), which has been already derived from the former.

Experimental

All mps were uncorrected. The IR and UV spectra were recorded on a JASCO Model IR-S and on a Perkin-Elmer 202 spectrophotometer, respectively. The NMR spectra were (100 MHz) taken on a JEOL JNM-C60H (60 MHz) or JNM-PS 100 using $CDCl_3$ as solvent, unless otherwise stated. Only prominent peaks are cited. Chemical shifts are given in ppm from TMS as an internal standard. Coupling constants are given in Hz (s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet). The mass spectra were obtained on

a Hitachi RMU-6D mass spectrometer operating with an ionization energy (70 eV). Preparative TLC were carried out on Kieselgel PF_{254} (E. Merk A.G., Germany).

Isolation of Asatone and Isoasatone. A sample of the dried and pulverized material of the whole herb (9 kg), which was collected at Chia-I, Taiwan, was extracted with large amounts of hexane (40 l) by refluxing for 3 h. The hot mixtures were filtered from the undissolved residue which was extracted with the same solvent (40 l, each time) for twice. The combined filtrates were concentrated under reduced press. to give a greenish yellow crude crystalline solid (32 g) besides a dark green jelly (140 g) after filtration. The resulting crystalline solid was treated with column chromatography using silica gel (Kieselgel, E. Merk A. G. Germany) (2 kg), and eluted with hexane–EtOAc (8: 1). From the eluates, after recrystallized from hexane, white crystals of asatone (17.6 g) were isolated: mp 101—102 °C; *m/e* 448 (M^+) and 224 (Found: C, 64.01; H, 7.26%. Calcd for $C_{24}H_{32}O_8$: C, 64.27; H, 7.19%).

The undissolved residue from hexane extractions was then extracted with $CHCl_3$ successively by refluxing for three times in the same way as hexane extractions. The combined $CHCl_3$ extracts were concentrated under reduced press. to give a dark green jelly (100 g). The resultant jelly was chromatographed on silica gel (Kieselgel, E. Merk A. G., Germany) (7 kg), and eluted with hexane–EtOAc (8: 1). From the eluates, after recrystallized from hexane, white crystals of isoasatone (120 mg) were isolated; mp 156.5—158 °C; *m/e* 448 (M^+) and 224 (Found: C, 64.55; H, 7.07%. Calcd for $C_{24}H_{32}O_8$: C, 64.27; H, 7.19%).

Catalytic Hydrogenation of Asatone (1). Catalytic hydrogenation of asatone (90 mg) in EtOAc (2.5 ml) was carried out over 10% Pd–C (10 mg) at room temp. overnight. After filtration of the catalyst, the solvent was evaporated under reduced press. to give a white crystalline solid, which was recrystallized from hexane to give white crystals of tetrahydroasatone (**3**) (85 mg), mp 128—129 °C; ν_{max} (Nujol) 1745, 1720, and 1635 cm^{-1}; λ_{max} (MeOH) 278 and 229 nm (ε, 5100 and 3940, respectively); δ 0.87 (6H, t, J=6.5 Hz), 1.10—1.80 and 1.85—2.15 (8H, m), 2.80 (2H, br.s), 3.05 (3H, s), 3.30 (3H, s), 3.37 (3H, s), 3.41 (3H, s), 3.46 (3H, s), 3.60 (3H, s), 5.41 (1H, s), and 5.51 (1H, q, J=1.5 Hz) ppm; *m/e* 452 (M^+), 420, 388, 356, 345, 226, and 211 (Found: *m/e* 452.2425. Calcd for $C_{24}H_{36}O_8$: *m/e* 452.2410. Found: *m/e* 226.1236. Calcd for $C_{12}H_{18}O_4$: *m/e* 226.1205).

$NaBH_4$ Reduction of Asatone (1). To a solution of of asatone (400 mg) in EtOH (3 ml) was carefully added $NaBH_4$ (40 mg), with stirring. The mixture was further stirred at room temp. for 1.5 h, and then decomposed with ice water. After addition of 1M·HCl aq. solution (*ca.* 0.5 ml), the aqueous solution was extracted with ether. The ethereal solution was washed with sat. NaCl aq. solution, and then dried over Na_2SO_4. Removal of the solvent afforded an oily substance, which was purified by preparative TLC using a mixed solvent [hexane–EtOAc (2: 1)] to give three crystalline compounds, namely, hydroxyasatone–A (**4**) (66 mg), hydroxyasatone–B (**5**) (108 mg) and dihydroxyasatone (**6**) (20 mg), respectively, after crystallized from hexane. The physical data of these three reduction products are described below.

Hydroxyasatone-A: Mp 127—128 °C; ν_{max} (Nujol) 3500, 3085, 1745, 1685, 1660, and 1640 cm^{-1}; λ_{max} (MeOH) 235 sh. and 218 nm (ε, 2640 and 4500, respectively); δ 3.93 (1H, s), 4.60 (1H, s), and 5.75 (1H, q, J=1.5 Hz) ppm; *m/e* 450 (M^+), 422, 418, 386, 381, 349, 345, 316, 307, and 226 (Found: *m/e* 450.2232. Calcd for $C_{24}H_{34}O_8$: *m/e* 450.2253. Found: *m/e* 226.1207. Calcd for $C_{12}H_{18}O_4$: *m/e* 226.1205).

Hydroxyasatone-B: Mp 108—109 °C; ν_{max} (Nujol) 3510, 3050, 1715, 1660, and 1635 cm^{-1}; λ_{max} (MeOH) 277 and 213 nm (ε, 4390 and 2510, respectively); δ 3.92 (1H, s), 5.50 (1H, q, J=1.5 Hz), and 5.60 (1H, s) ppm; *m/e* 450 (M^+), 422, 418, 386, 381, and 226 (Found: *m/e* 450.2232. Calcd for $C_{24}H_{34}O_8$: *m/e* 450.2253. Found: *m/e* 226.1197. Calcd for $C_{12}H_{18}O_4$: 226.1205).

Dihydroxyasatone: Mp 156—158 °C; ν_{max} (Nujol) 3550, 3425, 3060, 1685, 1665, and 1635 cm^{-1}; λ_{max} (MeOH) 222 nm (ε, 2590); δ 3.80 (2H, br.s), 4.78 (1H, s) and 5.72 (1H, q, J=1.5 Hz) ppm; *m/e* 452 (M^+ for $C_{24}H_{36}O_8$), 434, 420, 389, 379, and 226. High resolution mass spectrum of this compound has not been measured, but its structure can be supported by its physical data coupled with the next experiment.

Catalytic Hydrogenation of Dihydroxyasatone (6). Catalytic hydrogenation of **6** (15 mg) in EtOAc (3 ml) was carried out over 10% Pd–C (5 mg) at room temp. for 4 h. After filtration of the catalyst, the solvent was removed under reduced press. to give white crystals of dihydroxytetrahydroasatone (**7**) (15 mg), mp 151—152 °C (from hexane); ν_{max} (Nujol) 3500 and 1675 cm^{-1}; λ_{max} (MeOH) 217 nm (ε, 2400); δ 3.77 (2H, br.s), 4.80 (1H, s) and 5.71 (1H, q, J=1.5 Hz) ppm; *m/e* 456 (M^+) and 228 (Found: C, 63.11; H, 8.83%. Calcd for $C_{24}H_{40}O_8$: C, 63.13; H, 8.83%).

Reduction of Tetrahydroasatone (3) with $LiAlH_4$. To a solution of **3** (100 mg) in THF (1.5 ml) was added $LiAlH_4$ (20 mg) with stirring at 0 °C, and then the reaction temperature was elevated to room temp. The reaction mixture was further stirred at room temp. for 6 h, and then poured into ice-water and extracted with EtOAc. The extracts were washed successively with water and with sat. NaCl aq. solution, and then dried over $MgSO_4$. The solvent was removed under reduced press. to give almost colorless crystals of **7** (98 mg) (mp and IR spectrum).

Formation of Hexahydroasatone (8). Catalytic hydrogenation of asatone (200 mg) in MeOH (2 ml) was carried out over 10% Pd–C (40 mg) at room temp. for 12 h. After filtration of the catalyst, the solvent was removed under reduced press. to leave an almost colorless oil, which was separated by preparative TLC using hexane–EtOAc (3: 1) to afford two fractions. The upper fraction afforded white crystals of hexahydroasatone (20 mg), mp 133—134 °C (from hexane); ν_{max} (Nujol) 1750, 1745, and 1635 cm^{-1}; λ_{max} (MeOH) 221 nm (ε, 2812); δ 0.82 (3H, t, J=7.0 Hz), 0.90 (3H, t, J=7.0 Hz), 1.15—1.84 (6H, m), 1.95 (2H, t, J=7.0 Hz), 2.31 (2H, d, J=5.5 Hz)*, 2.78 (2H, s), 3.14 (3H, s), 3.28 (3H, s), 3.35 (6H, s), 3.43 (3H, s), 3.50 (3H, s), 3.63 (1H, t, J=5.5 Hz)*, and 5.85 (1H, q, J=1.9 Hz) ppm; *m/e* 426 (M^+−28), 395, 379, and 363 (Found: C, 63.22; H, 8.65%. Calcd for $C_{24}H_{38}O_8$: C, 63.41; H, 8.43%).

From the lower fraction, tetrahydroasatone (**3**) (144 mg) was isolated (mp and IR spectrum).

Zinc Reduction of Tetrahydroasatone (3) to Hexahydroasatone (8). A mixture of **3** (20 mg) and activated zinc powder (200 mg) in AcOH (2.5 ml) was stirred at room temp. for 14 h, and then poured into a lot of water, and extracted with EtOAc. The extracts were washed with water several times, and then dried over $MgSO_4$. Removal of the solvent under reduced press. afforded a brown oil (15 mg), from which hexahydroasatone (9 mg) was separated by preparative TLC using a mixed solvent [hexane–EtOAc (1: 2)] (mp and IR spectrum).

Formation of Two Phenolic Compounds (9 and 10). A mixture of tetrahydroasatone (100 mg) and zinc powder (450 mg) in AcOH (1.5 ml) was refluxed, with stirring, for

* Irradiation at δ 2.31 ppm caused the triplet at δ3.63 ppm to collapse to singlet. In the case of irradiation at δ 3.63 ppm, the doublet at δ 2.31 ppm was changed to singlet.

4.5 h. The cooled reaction mixture was poured into a lot of water, and then extracted with EtOAc. The extracts were washed with a lot of water several times, and then dried over $MgSO_4$. Removal of the solvent left a brown residue (83.6 mg), the preparative TLC of which was carried out using a mixed solvent [hexane–EtOAc (3: 1)] to afford two fractions. The upper fraction gave a colorless liquid of 2,6-dimethoxy-4-propylphenol (**9**) (49 mg); ν_{max} (Film) 3520, 1610, and 1515 cm^{-1}; δ 0.93 (3H, t, J=6.8 Hz), 1.20—1.85 (2H, m), 2.53 (2H, t, J=7.5 Hz), 3.86 (6H, s), 5.35 (1H, br.s, OH), and 6.37 (2H, s) ppm; *m/e* 196 (M^+ for $C_{11}H_{16}O_3$) and 168. This liquid was characterized as the corresponding acetate.

From the lower fraction, a colorless viscous liquid (**10**) (20 mg) was isolated; ν_{max} (Film) 3460, 1610, 1585, and 1495 cm^{-1}; δ 0.81 (6H, t, J=7.0 Hz), 1.15—1.80 (4H, m), 2.22 (4H, td, J=7.0 and 1.5 Hz), 3.60 (6H, s), 3.95 (6H, s) and 6.60 (2H, br.s) ppm; *m/e* 390 (M^+ for $C_{22}H_{30}O_6$), 329, 315, 301, 297, 287, 167, and 153. This oil was also acetylated with Ac_2O–pyridine.

Acetylation of 2,6-Dimethoxy-4-propylphenol (9). A solution of **9** (15 mg) in Ac_2O–pyridine (1: 1, 1 ml) was stirred at room temp. overnight, and then concentrated under reduced press. on a water-bath (*ca.* 80 °C) to leave white crystals of the acetate (**11**) in quantitative yield, mp 88.0—88.5 °C (from EtOH) (lit, 87 °C)[5]; ν_{max} (Nujol) 1765, 1600, 1510 sh, and 1505 cm^{-1}; λ_{max} (MeOH) 275 and 227 nm (ε, 790 and 6140, respectively); δ 0.95 (3H, t, J=7.5 Hz), 1.57 (2H, sextet, J=7.5 Hz), 2.32 (3H, s), 2.55 (2H, t, J=7.5 Hz), 3.80 (6H, s), and 6.42 (2H, s) ppm; *m/e* 238 (M^+) (Found: C, 65.05; H, 7.62%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%).

Acetylation of the Biphenyl-type Compound (10). A solution of **10** (19 mg) in Ac_2O–pyridine (1: 1, 1.5 ml) was stirred at room temp. overnight, and then worked up as usual to give pale yellow crystals of the diacetate (**12**) (20 mg), mp 117—118 °C (from EtOH); ν_{max} (Nujol) 1770, 1600, and 1585 cm^{-1}; λ_{max} (MeOH) 279 and 232 nm (ε, 2470 and 13750, respectively); δ 0.84 (6H, t, J=7.0 Hz), 1.10—1.80 (4H, m) 2.10—2.45 (4H, m), 2.31 (6H, s), 3.53 (6H, s), 3.87 (6H, s), and 6.67 (2H, s) ppm; *m/e* 474 (M^+) and 431 (Found: C, 65.38; H, 7.18%. Calcd for $C_{26}H_{34}O_8$: C, 65.80; H, 7.22%).

Zinc Reduction of Asatone in AcOH. A mixture of asatone (125 mg) and zinc powder (1 g) in AcOH (2.0 ml) was heated under reflux overnight with stirring, and then worked up as usual to give a brown oil, from which two aromatic compounds were separated by preparative TLC using a mixed solvent [hexane–EtOAc (3: 1)]. The upper fraction gave a colorless liquid of 2,6-dimethoxy-4-allylphenol (**13**) (38 mg); ν_{max} (Film) 3510, 3080, 1635, 1615, and 1513 cm^{-1}; δ 3.30 (2H, d, J=6.0 Hz), 3.82 (6H, s), 4.80—5.25 (2H, m), 5.39 (1H, br.s, OH), 5.55—6.25 (1H, m) and 6.40 (2H, s) ppm; *m/e* 194 (M^+ for $C_{11}H_{14}O_3$) and 166. This liquid was further used for the next experiment.

From the lower fraction, a colorless viscous liquid of the biphenyl-type compound (**14**) (21 mg) was isolated; ν_{max} (Film) 3460, 1640, 1613, 1585, and 1495 cm^{-1}; δ 3.00 (4H, d, J=6.0 Hz), 3.61 (6H, s), 3.90 (6H, s), 4.70—5.15 (4H, m), 5.52 (2H, br., OH), 5.45—6.20 (2H, m), and 6.60 (2H, s) ppm; *m/e* 386 (M^+ for $C_{22}H_{26}O_6$). This viscous liquid was characterized as the corresponding diacetate (**16**).

Conversion of 13 to 2,6-Dimethoxy-4-propylphenyl Acetate (11). A solution of **13** (30 mg) in Ac_2O–pyridine (1: 1, 1.5 ml) was allowed to stand at room temp. overnight, and then concentrated under reduced press. to afford a pale yellow oil of the corresponding acetate (**15**) (31 mg); ν_{max} (Film) 1775, 1640, 1608, and 1510 cm^{-1}; *m/e* 236 (M^+ for $C_{13}H_{16}O_4$), 194, 179, and 167.

Catalytic hydrogenation of the acetate (15 mg) in EtOAc (1.5 ml) was carried out over 10% Pd–C (3 mg) at room temp. overnight. After filtration of the catalyst, the solvent was removed under reduced press. to give white crystals of **11** (14 mg) (mp and IR spectrum).

Acetylation of the Biphenyl-type Compound (14). A solution of **14** (15 mg) in Ac_2O–pyridine (1: 1, 1 ml) was stirred at room temp. overnight, and then worked up as usual to give a crystalline solid (13 mg). Recrystallization from EtOH afforded white crystals of the diacetate (**16**), mp 125—125.5 °C; ν_{max} (Nujol) 1775, 1600, and 1585 cm^{-1}; λ_{max} (MeOH) 277 and 227 nm (ε, 2160 and 17750, respectively); δ 2.36 (6H, s), 3.10 (4H, d, J=6.7 Hz), 3.58 (6H, s), 3.90 (6H, s) 4.75—5.10 (4H, m), 5.45—6.10 (2H, m) and 6.70 (2H, s) ppm; *m/e* 470 (M^+) (Found: C, 66.32; H, 6.44%. Calcd for $C_{26}H_{30}O_8$: C, 66.37; H, 6.43%).

Conversion of 16 to 12. Catalytic hydrogenation of the diacetate (**16**) (10 mg) in EtOAc (1.5 ml) was carried out over 10% Pd–C (2 mg) at room temp. for 5 h, and then worked up as usual to give almost colorless crystals in quantitative yield. Recrystallization from EtOH gave the corresponding tetrahydro-compound (**12**) (mp, TLC and IR spectrum).

Zinc Reduction of Tetrahydroasatone (3) in Acetic Anhydride. A mixture of **3** (100 mg) and activated zinc powder (500 mg) in Ac_2O (2 ml) was heated under reflux for 7 h with stirring. After cooling, the reaction mixture was poured into water, and then extracted with large amounts of EtOAc. The extracts were washed well water and with sat. NaCl aq. solution successively, and then dried over $MgSO_4$. Removal of the solvent gave a brown oil, which was separated by preparative TLC using a mixed solvent [hexane–EtOAc (3: 1)] to give two fractions. The upper fraction afforded a pale yellow liquid, which was crystallized from EtOH to give slightly pale yellow crystals of **11** (54 mg) (mp and IR spectrum).

From the lower part, a pale yellow oil (25 mg) was separated and crystallized from EtOH to give the diacetate of the biphenyl-type compound (**12**) (mp and IR spectrum).

Reduction of Isoasatone (2) with $LiAlH_4$. To a solution of **2** (135 mg) in THF (3 ml) was added excess amounts of $LiAlH_4$ (135 mg) with stirring, and then the reaction mixture was further stirred at room temp. for 3 h. After decomposition of the remaining reagent with EtOH, the reaction mixture was diluted with water, and then extracted with EtOAc. The extract was washed with sat. NaCl aq. solution, and then dried over Na_2SO_4. Removal of the solvent afforded a crystalline solid (140 mg), which was recrystallized from hexane–ether to give white crystals of dihydroxyisoasatone (**17**), mp 153—154 °C; ν_{max} (Nujol) 3500, 3420, 3060, 1635, and 908 cm^{-1}; δ 2.39 (2H, br. dd, J=14.3 and 8.5 Hz), 2.41 (2H, s), 2.49 (2H, s), 2.55 (2H, br. dd, J=14.3 and 7.5 Hz), 3.24 (6H, s), 3.30 (6H, s), 3.35 (6H, s), 3.71 (2H, s), 5.01 (2H, br. d, J=11 Hz), 5.03 (2H, br.d, J=15 Hz), and 5.7—6.2 (2H, m) ppm; *m/e* 452 (M^+), 437, 421, 411, 403, and 226 (Found: C, 63.57; H, 8.20%. Calcd for $C_{24}H_{36}O_8$: C, 63.70; H, 8.02%).

Catalytic Hydrogenation of Isoasatone (2). Catalytic hydrogenation of **2** (15 mg) in EtOAc (2 ml) was carried out over 10% Pd–C (5 mg) at room temp. overnight. After filtration of the catalyst, the solvent was evaporated under reduced press. to give white crystals (15 mg), which were recrystallized from hexane to give white crystals of tetrahydroisoasatone (**18**), mp 161—162 °C; ν_{max} (Nujol) 1735 cm^{-1}; λ_{max} (MeOH) 222 nm (ε, 2070); δ 0.90 (6H, br.t, J=7.0 Hz), 1.7—2.3 (8H, complex), 2.82 (2H, s), 2.90 (2H, s), 3.22 (6H, s), and 3.31 (12H, s) ppm; *m/e* 452 (M^+), 437, 420, 389, and 226 (Found: C, 63.35; H, 8.00%. Calcd for $C_{24}H_{36}O_8$: C, 63.70; H, 8.02%).

Zinc Reduction of Isoasatone (2). Excess amounts of zinc powder (500 mg) were added to a solution of isoasatone (80

mg) in MeOH (5 ml) containing concd HCl (1.5 ml) with stirring. The reaction mixture was stirred vigorously at room temp. for 2 h, and then poured into large amounts of water and extracted with EtOAc. The extract was washed with sat. NaCl aq. solution, and then dried over Na_2SO_4. Removal of the solvent left a brown oil (65 mg), which was subjected to preparative TLC using a mixed solvent [EtOAc–hexane (1:2)]. From the upper fraction, 2,6-dimethoxy-4-allylphenol (**13**) (32 mg) was obtained (TLC and IR spectrum). The biphenyl-type compound (**14**) (8.2 mg) was also obtained from the lower fraction (TLC and IR spectrum).

Thermal Reaction of Tetrahydroisoasatone (18). Tetrahydroisoasatone (38 mg) in a sealed tube was heated at 290—300 °C for 30 min, and then extracted with EtOAc. Removal of the solvent gave a brown viscous liquid, whose analytical TLC showed eight spots. Preparative TLC of this liquid was carried out in hexane–EtOAc (2:1), and a colorless liquid (9 mg) was obtained from the less polar fraction corresponding to that of 2,6-dimethoxy-4-propylphenol (**9**) (TLC and IR spectrum).

Thermal Reaction of Isoasatone (2). Isoasatone (10 mg) in a sealed tube was heated at 280—290 °C for 20 min, and then dissolved in a small amount of $CHCl_3$, and then directly separated by preparative TLC using hexane–EtOAc (2:1) to give a colorless liquid (2 mg), which was isolated from the less polar fraction corresponding to that of 2,6-dimethoxy-4-allylphenol (**14**) (TLC and IR spectrum).

Reaction of Tetrahydroasatone (3) with Acetic Anhydride. A solution of **3** (240 mg) in Ac_2O (2.5 ml) was heated under reflux for 10 h, and then concentrated under reduced press. to give a brown residue, which was purified by preparative TLC using a mixed solvent [hexane–EtOAc (3:1)] to give pale yellow crystals (35 mg) from the upper fraction. Recrystallization from EtOH afforded 2,6-dimethoxy-4-propylphenyl acetate (**11**) in a pure state (mp and IR spectrum).

From the lower part, slightly brown liquid (155 mg)** was isolated. This liquid was further purified by preparative GLC to give a colorless liquid (**21**) [retention time: 2.8 min. (10% OV-17 (ϕ 0.25 inch × 3 m); at 230 °C; Carrier gas: Nitrogen (100 ml/min); Inlet pressure, 25.5 psi)]; ν_{max} (Film) 1770, 1740, 1608, 1510, 1235, and 1200 cm^{-1}; λ_{max} (MeOH) 276 and 226 nm (ε, 970 and 9600, respectively); δ 0.90 (3H, t, J=7.5 Hz), 1.87 (2H, quintet, J=7.5 Hz), 2.08 (3H, s), 2.30 (3H, s), 3.78 (6H, s), 5.61 (1H, t, J=7.5 Hz), and 6.58 (2H, s) ppm; *m/e* 296 (M^+), 254, 183, and 149 (Found: C, 61.10; H, 6.47%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%).

Reaction of Asatone (1) with Acetic Anhydride. A solution of **1** (104 mg) in Ac_2O (1.5 ml) was heated under reflux overnight. Removal of the excess Ac_2O under reduced press. afforded a brown oil, whose analytical TLC showed many spots. Preparative TLC using hexane–EtOAc (3:1) afforded only small amounts of 2,6-dimethoxy-4-allylphenyl acetate (**15**) (5.3 mg) (GLC, TLC, and IR spectrum).

Photochemical Conversion of Asatone (1) to Isoasatone (2). A solution of **1** (70 mg) in hexane (8 ml) was irradiated at 10 °C for 54 h, using 0.02% K_2CrO_4 aq. solution as a filter [Apparatus: Eiko-Sha PIH-100, high pressure Hg lamp (100W)]. The reaction solution was then evaporated under reduced press. to leave an almost colorless oil, which was purified by preparative TLC using hexane–EtOAc (3:1). From the less polar fraction corresponding to that of isoasatone, white crystals (44.8 mg) were isolated after recrystallized from hexane (mp and IR spectrum).

Photochemical Conversion of Tetrahydroasatone (3) to Tetrahydroisoasatone (18). Under essentially the same condition as that of asatone (**1**), a solution of **3** (65 mg) in hexane (8 ml) was irradiated. After removal of the solvent, a colorless oil was purified by preparative TLC using a mixed solvent [hexane–EtOAc (4:1)]. From the less polar fraction corresponding to that of tetrahydroisoasatone, white crystals (39 mg) were obtained after recrystallized from hexane (mp and IR spectrum).

Photochemical Reaction of Tetrahydroasatone (3) Using Pyrex Filter. A solution of **3** (45 mg) in hexane (4 ml) was irradiated at 10 °C for 8 hr, and then the solvent was removed under reduced press. to leave a colorless viscous liquid which was chromatographed on alumina (Nakarai Chem. Co. Ltd., 200 mesh) (1 g) and eluted with hexane–benzene (10:1) to give white crystals of tetrahydroisoasatone (**18**) (13.5 mg) (mp, TLC and IR spectrum). Further elution with hexane–benzene (5:1) afforded a colorless viscous liquid of the monohydroxyoxetane (**23**) (21 mg), ν_{max} ($CHCl_3$) 3550 and 1730 cm^{-1}; δ 0.88 (3H, t, J=6.0 Hz), 0.92 (3H, t, J=6.5 Hz), 1.4—2.1 (8H, complex), 2.6—2.8 (3H, complex), 3.00 (4H, s), 3.23 (3H, s), 3.32 (3H, s), 3.33 (3H, s), 3.35 (3H, s), 3.92 (1H, s, OH), 4.33 (1H, d, J=5.5 Hz), and 4.67 (1H, d, J=5.5 Hz) ppm; *m/e* 452 (M^+), 420, 405, and 226 (Found: *m/e* 452.24050. Calcd for $C_{24}H_{36}O_8$: *m/e* 452.24100). Further elution only with benzene gave white crystals of dihydroxyoxetane (**24a**) (9 mg), mp 167—168 °C (from hexane); ν_{max} (Nujol) 3500 sh. and 3450 cm^{-1}; δ (CCl_4) 0.90 (6H, t, J=6.5 Hz), 1.2—1.9 (8H, complex), 2.62 (2H, s), 2.65 (2H, s), 2.97 (6H, s), 3.31 (6H, s), 4.11 (2H, d, J=5.0 Hz), and 4.49 (2H, d, J=5.0 Hz) ppm; *m/e* 452 (M^+), 420, 404, and 226 (Found: *m/e* 452.24356. Calcd for $C_{24}H_{36}O_8$: *m/e* 452.24100).

The Formation of the Dihydroxyoxetane from Tetrahydroisoasatone (18). Tetrahydroisoasatone (10 mg) in a thin Pyrex NMR tube was dissolved in hexane (*ca.* 2 ml), and then irradiated at room temp. for 8 h [the NMR spectrum of the reaction solution indicated that **18** was completely converted into the oxetane (**24a**)]. Removal of the solvent gave white crystals of the dihydroxyoxetane in quantitative yield (mp and IR spectrum).

Photochemical Conversion of the Monohydroxyoxetane (23) to the Dihydroxyoxetane. Under essentially the same condition as described above, a solution of **23** (10 mg) in hexane (*ca.* 2 ml) was irradiated, and then concentrated under reduced press. to give white crystals of the dihydroxyoxetane in quantitative yield (mp and IR spectrum).

The authors wish to thank Drs. H. Harada and H. Yazawa (Fujisawa Pharmaceutical Co. Ltd.) for measurements of high resolution mass spectra. They are also indebted to Dr. K. Fujita (Nihondenshi Co. Ltd.) for measurements of ^{13}C NMR spectra.

(Received March 5, 1976)

Irradiation of benzophenone *O*-acetyloxime, *O*-phenylacetyloxime, *O*-benzoyloxime, and *O*-(*p*-chlorobenzoyl)-oxime in benzene, toluene, chlorobenzene, or *o*-xylene effected aromatic substitution on the solvent molecules by diphenylmethaniminyl radicals to give *N*-diphenylmethylenearylamines only when benzoxyl or *p*-chlorobenzoxyl radicals were generated concurrently. A mechanism involving a participation of the sufficiently long-lived acyloxyl radicals is proposed for the iminylation reaction on the basis of the reactivity patterns in this substitution reaction. *o*-Phenylbenzophenone *O*-benzoyloxime was also photolyzed in benzene to give 9-phenylphenanthridine, the intramolecular cyclization product of 2-biphenylylphenylmethaniminyl radicals.

Iminyl radicals are generated by various ways, among which thermal decomposition of oxime thionocarbamates[1] and hydrogen abstraction from imines[2] may be the most useful means. However, because of a lack of reactivity of iminyl radicals their chemistry has not received a great deal of attention and thus, recent interest has mainly been focused on their ESR spectra and electronic structure.[1a,b,2,3] Meanwhile, on irradiation of *O*-acyloximes formation of azines was reported and the results were rationalized by the intermediacy of iminyl radicals.[4-7] Recently it was found in our laboratory[5] that photolysis of benzophenone *O*-aroyloximes in benzene affords *N*-diphenylmethyleneaniline, the product formally derived from aromatic substitution of diphenylmethaniminyl radicals on the solvent molecule, together with benzophenone azine. Since there was no precedent for the aromatic substitution by iminyl radicals, we have undertaken to study the mechanism of this substitution reaction, and showed in a previous communication[6] that the above aromatic substitution occurs with an assistance of long-lived acyloxyl radicals. In the present paper we describe the details of our results.

Results

Products from Photolyses of O*-Acyloximes in Benzene.* The photolyses of benzophenone *O*-acetyloxime (Ia), *O*-phenylacetyloxime (Ib), and *O*-(*p*-chlorobenzoyl)-oxime (Ic) were carried out in benzene (0.1 M) so that a comparison could be made between the products from these *O*-acyloximes. The acyloxime Ic was the most feeble to light among them and decomposed completely within 20 h on irradiation with a 400 W high pressure mercury lamp. On the other hand the photolyses of Ia and Ib proceeded rather slowly. The products listed in Table 1 are readily interpretable in terms of the initial N–O bond homolysis followed by free-radical reactions of diphenylmethaniminyl radicals and acyloxyl radicals. Primarily, the results of the photolyses (Table 1) serve to point up the differences between the products resulting from the *O*-acetyloximes (Ia and Ib) and *O*-(*p*-chlorobenzoyl)oxime (Ic). The acetyloximes, Ia and Ib, yielded *N*-diphenylmethylene-methylamine (IIa) and *N*-diphenylmethylenebenzylamine (IIb), respectively, which would result from the coupling of diphenylmethaniminyl radicals (IV) with alkyl radicals derived from decarboxylation of the corresponding acyloxyl radicals, whereas the yield of such a coupling product, *N*-diphenylmethylene-*p*-chloroaniline (IIc), was negligible in the photolysis of Ic. The decomposition of Ib was highly accelerated with benzophenone, the addition of which did not

a) F_o is the reactivity at one *ortho* site in PhX relative to reactivity of one site in benzene; similarly for F_m and F_p. b) BPO stands for dibenzoyl peroxide.

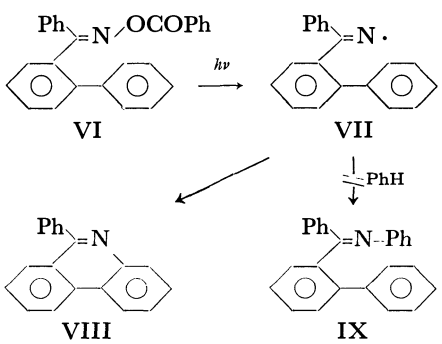
change seriously the product distribution. *N*-Diphenylmethyleneaniline (III), which would be expected to be produced by the homolytic substitution with diphenylmethaniminyl radicals (IV) on the solvent benzene, was found in an appreciable amount only in the photolysis of Ic, but none was obtained in the photolysis of Ia and Ib.

Fluorenone *O*-(*p*-methylbenzoyl)oxime (V) was also irradiated in benzene (0.1 M) to afford *N*-fluorenylidene-*p*-toluidine, the coupling product, in a similar manner to Ic (Table 2).

Reactivity Patterns in Free-Radical Aromatic Substitution by the Iminyl Radicals (IV). Photolyses of benzophenone *O*-benzoyloxime (Id) and *O*-(*p*-chlorobenzoyl)-oxime (Ic) were carried out in toluene and chlorobenzene. The total yields and the isomer proportions of *N*-diphenylmethylenearylamines formed in the iminylation of toluene and chlorobenzene are given in Table 3. In toluene *N*-diphenylmethylenebenzylamine was also obtained, which is supposed to be formed by the coupling of the iminyl radicals with benzyl radicals derived from the solvent. Irradiation of Id in *o*-xylene gave also the substitution products, *N*-diphenylmethylene-2,3-dimethylaniline and -3,4-dimethylaniline, in 4.2 and 0.5% yield, respectively

Conventional competition experiments were carried out in which mixtures of benzene with toluene and with chlorobenzene were allowed to compete for the iminyl radicals (IV), and their relative reactivities were deduced from the composition of *N*-diphenylmethylenearylamines. The relative rates (k_{PhX}/k_{PhH}: the ratio of the total rate of substitution in PhX to that in benzene) and the partial rate factors for iminylation are summarized in Table 4 with similar data for the triphenylmethylation[8] and the benzoxylation.[9]

Photolysis of o-*Phenylbenzophenone* O-*Benzoyloxime (VI).* In addition to the quantitative study of the reactivity patterns of the iminyl radical IV, the reaction was employed to effect intramolecular cyclization onto an aromatic ring. Irradiation of *o*-phenylbenzophenone *O*-benzoyloxime (VI) in benzene in the presence of an equimolar amount of benzophenone resulted in the formation of 9-phenylphenanthridine (VIII, 74% in VPC yield) along with small amounts of *o*-phenylbenzophenone (3%) and 2-biphenylylphenylmethanimine (11%), but afforded none of substitution products, *N*-(2-biphenylylphenylmethylene)aniline (IX), on the solvent benzene by a corresponding iminyl radical (VII)



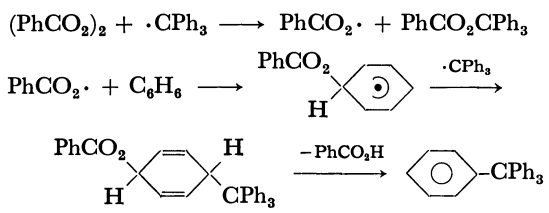
Scheme 1.

(Scheme 1). Isolated yield of the cyclization product (VIII) was 25% after purification.

Discussion

The principal reactions of iminyl radicals are dimerization to azines and β-scission to nitriles and alkyl radicals,[2,10] and only other reactions hitherto known are a hydrogen abstraction[11] and an intramolecular addition to an aromatic nucleus.[12] Thus, *N*-chloroketimines, on thermolysis in the presence of n-Bu_3SnH, gave ketimines, and the reduction was explained by a radical chain sequence involving hydrogen abstraction of iminyl radicals from n-Bu_3SnH.[11] When this reduction was carried out in the presence of 1-octene, no products derived from addition of iminyl radicals to 1-octene were observed.[11] Meanwhile, Forrester *et al.* reported that oxidation of *N*-substituted-methyleneaminooxy-acetic (XIV) or -propionic acids with peroxysulfate gave a phenanthridine (VIII), the product derived from intramolecular cyclization of iminyl radicals (VII) to an adjacent phenyl group[12] (Scheme 5).

In view of such an unreactive nature of iminyl radicals, it is highly notable that *N*-diphenylmethylenearylamines, the products of homolytic substitution by the iminyl radicals on the aromatic solvent, are formed only in the photolyses of benzophenone *O*-benzoyloxime (Id) and *O*-(*p*-chlorobenzoyl)oxime (Ic), whereas none was obtained in the photolyses of benzophenone *O*-acetyloxime (Ia) and *O*-phenylacetyloxime (Ib). These facts suggest that the aromatic substitution by the diphenylmethaniminyl radicals (IV) takes place only when the partner acyloxyl radicals are sufficiently alive like benzoxyl and *p*-chlorobenzoxyl radicals until they decarboxylate; the substitution does not occur when the iminyl radicals IV are generated together with short-lived acyloxyl radicals such as acetoxyl and phenylacetoxyl radicals. It is therefore likely that the aromatic substitution is not effected by IV alone, but is induced with an assistance of aroyloxyl radicals. These observations remind us of the role of benzoxyl radicals in the Wieland triphenylmethylation reaction,[13] in which tetraphenylmethane is a major product of the dibenzoyl peroxide-induced reaction of triphenylmethyl radicals with benzene. This reaction is now elucidated by the following reaction sequence (Scheme 2), in which induced decomposition of the peroxide is followed by attack of benzoxyl radicals on the solvent. The cyclohexadienyl radical formed is scavenged by a triphenylmethyl radical in a coupling reaction. Non-radical elimination of benzoic acid then gives tetraphenylmethane.

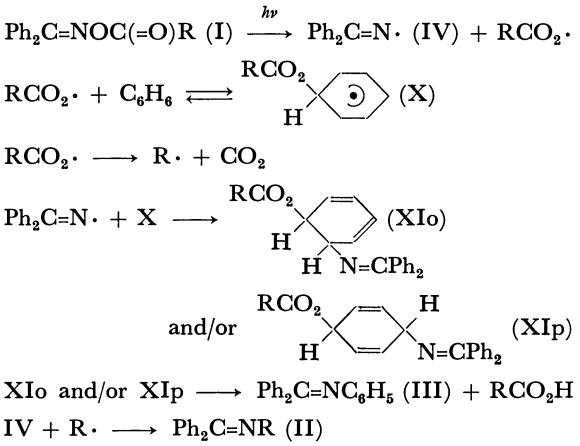


Scheme 2.

When toluene is used as a solvent, a major product is *m*-methyltetraphenylmethane, consistent with preferred *ortho* and *para* attack on toluene by a benzoxyl radical.

Consideration of the figures shown in Table 3 indicates that the proportions of substitutions at the *meta*-positions are unusually high irrespective of the polar character of the substituents. The results differ greatly from those obtained for usual homolytic substitution by free radicals such as alkyl and aryl radicals, which generally attack *ortho*- and *para*-positions of toluene or chlorobenzene in preference to *meta*-positions.[9] The unusual order of apparent reactivity among the nuclear positions ($m > o \gg p$) is again analogous to that of substitution by triphenylmethyl radicals or nitrogen dioxide in the presence of dibenzoyl peroxide. Anomaly in the same sense is also observed in the relative rates and the partial rate factors summarized in Table 4. It is worth noting that the relative rates and the partial rate factors for the iminylation of toluene and chlorobenzene with Id generally parallel those for the triphenylmethylation. With Ic the partial rate factor to toluene is considerably increased, although there is an overall similarity between Ic and Id. It is also observed in Table 4 that the relative rates of toluene and chlorobenzene for the benzoxylation are close to those for the iminylation with Id, but the benzoxylations occur preferentially at the *ortho*- and the *para*-positions. These findings suggest that the attack of the aroyloxyl radicals on the aromatic solvent is a key step in the aromatic substitution.

On the basis of the close correspondence with reactivity patterns in the iminylation and triphenylmethylation reactions as well as the above findings, it is concluded that the aromatic substitution by the iminyl radicals IV takes place through the following sequence of reactions (Scheme 3).



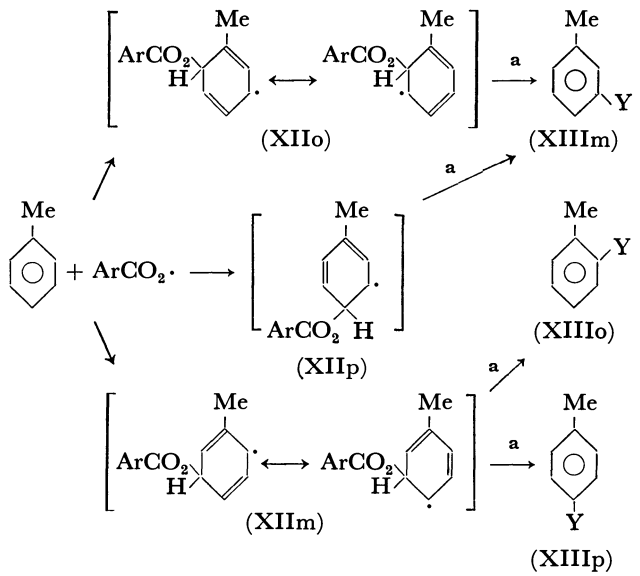
Scheme 3.

The acyloxyl radicals generated by photochemical cleavage of I either add reversibly to benzene to give cyclohexadienyl radicals (X) or decarboxylate. The resulting radicals, X, would combine with IV to give cyclohexadienes, XIo and/or XIp, which would subsequently decompose into III and carboxylic acid. In the irradiation of Ia or Ib, the intermediate acetoxyl or phenylacetoxyl radicals decarboxylate facilely before they add effectively to benzene. The formation of

N-fluorenylideneaniline in the photolysis of fluorenone *O*-(*p*-methylbenzoyl)oxime (V) in benzene is possibly explained in a similar manner.

Benzoxyl radicals are known[9] to add to the *ortho*- and *para*-positions of toluene to give cyclohexadienyl radicals, XIIo and XIIp, in preference to *meta*-positions to give XIIm (Scheme 4). The cyclohexadienyl radicals, XIIo and XIIp, would combine with IV exclusively at the position *meta* to methyl group to give *N*-diphenylmethylene-*m*-toluidine, XIIIm, and the cyclohexadienyl radical, XIIm, on the other hand, would combine necessarily at the positions *ortho* and *para* to methyl group to give *o*- and *p*-toluidine derivatives, XIIIo and XIIIp, respectively, the ratio of which would be regulated mainly by the steric factors of methyl and benzoxy groups on the cyclohexadienyl radical XIIm. This reaction scheme successfully explains the predominant production of XIIIm over XIIIo and XIIIp.

Taking account of the *ortho*- and *para*-orientation of benzoxyl radicals to chlorobenzene,[9] similar considerations can be applied to the preferential formation of *N*-diphenylmethylene-*m*-chloroaniline to *o*- and *p*-chloroaniline derivatives in the photolysis of Id in chlorobenzene.

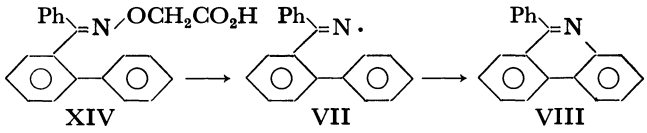


Y: $Ph_2C{=}N$; a: combination with Y· followed by elimination of $ArCO_2H$.

Scheme 4.

Instead of giving *N*-diphenylmethyleneaniline (III) irradiation of Ia and Ib in benzene afforded *N*-diphenylmethylenemethylamine (IIa) and *N*-diphenylmethylenebenzylamine (IIb), respectively, which would result from the combination of IV with the alkyl radicals derived from the decarboxylation of acyloxyl radicals (Scheme 3). We have reported previously[7] that the homolytic cleavage of *O*-acyloximes into iminyl and acyloxyl radicals takes place from the triplet states, in both direct and sensitized irradiation, with excitation energies comparable to those of their parent ketones. In view that the triplet pair of free radicals, in general, does not efficiently lead to a geminate product,[15] the formation of *N*-diphenylmethylenebenzylamine (IIb) from direct irradiation as well as from sensitization is not attributable to the geminate reaction between IV and benzyl radicals in a solvent cage, but to the combination between these radicals diffused out of the initial solvent cage. *A priori* it is reasonable to suppose that the production of *N*-diphenylmethylenemethylamine (IIa) from Ia is attributable to out-of-cage encounter of methyl and iminyl radicals.

Closely related to free-radical aromatic substitutions are intramolecular free-radical aromatic substitutions. The iminyl radicals (VII) produced by the photolysis of *o*-phenylbenzophenone *O*-benzoyloxime (VI) cyclize onto an adjacent phenyl group to give 9-phenylphenanthridine (VIII) (Scheme 1). Forrester *et al.* reported[12] that VII derived from the oxidation of the corresponding aminooxy-acetic acid (XIV) or -propionic acid gives 9-phenylphenanthridine (VIII) and hence the assistance of benzoxyl radicals is not necessarily required in the intramolecular cyclization. These results indicate that the iminyl radicals are sufficiently reactive in the addition to the benzene ring, provided the benzene nucleus is located adjacently to the radical center.



Scheme 5.

Experimental

All melting points are uncorrected. IR and UV spectra were recorded on a Hitachi EPI-G2 grating infrared spectrophotometer and a Hitachi EPS-3 recording spectrophotometer, respectively. NMR spectra were recorded with a Hitachi R-20B NMR spectrometer. Micro-analyses were performed by Organic Analytical Laboratory of our Department under supervision of Mr. S. Masuda. VPC analyses were performed on Hitachi 063 and K53 gas chromatographs equipped with flame ionization detectors. All quantitative results compared to internal standards were based on measured molar response factors determined from known mixtures of authentic materials. Irradiations were conducted with a Riko 400 W and a 1 kW high pressure mercury lamp in a water-cooled immersion well.

Materials. Special grade benzene, toluene, chlorobenzene, and *o*-xylene were distilled prior to use. Benzophenone (reagent grade) was crystallized from ethanol. Benzophenone *O*-acetyloxime,[16] *O*-benzoyloxime,[17] *O*-(*p*-chlorobenzoyl)oxime,[18] were prepared according to the methods described in literatures. Diphenylmethanimine,[19] *N*-diphenylmethylenemethylamine,[20] -benzylamine,[21] -aniline,[22] -*o*-toluidine,[23] -*m*-toluidine,[24] -*p*-toluidine,[22] -*p*-chloroaniline,[25] and -3,4-xylidine,[24] *N*-fluorenylidene-aniline,[22] and -*p*-toluidine,[26] 2-biphenylylphenylmethanimine,[27] and *N*-(2-biphenylylphenylmethylene)aniline[28] were prepared according to the methods described in literatures. Benzophenone azine[29] and fluorenone azine[30] were prepared according to the reported methods.

Benzophenone O-Phenylacetyloxime. Phenylacetic anhydride (14 g) was refluxed for 4 h with benzophenone oxime (6 g) in diethyl ether (100 ml). After cooling, the insoluble product was collected by filtration, and the ethereal filtrate was shaken with 10% sodium carbonate solution and then

water. A white crystalline solid precipitated was collected, combined with the above product, washed with ether, and dissolved in chloroform. To this solution was added hexane and the solution was cooled in an ice bath to afford white crystals (3 g), which were further purified on recrystallization from benzene–hexane; mp 112.5—113 °C (Found: C, 79.92; H, 5.30; N, 4.29%. Calcd for $C_{21}H_{17}NO_2$: C, 79.98; H, 5.43; N, 4.44%); IR (KBr) 1763 cm^{-1}; NMR ($CDCl_3$) δ 3.61 (s, 2H).

Fluorenone O-(p-*Methylbenzoyl*)*oxime.* Fluorenone oxime was acylated with *p*-methylbenzoyl chloride in the presence of pyridine according to the method of Renfrow *et al.*[18]; mp 143.5—144.5 °C (ethanol) (Found: C, 80.37; H, 4.90; N, 4.67%. Calcd for $C_{21}H_{15}NO_2$: C, 80.49; H, 4.83; N, 4.47%); IR (KBr) 1738 cm^{-1}; NMR ($CDCl_3$) δ 2.43 (s, 3H).

o-*Phenylbenzophenone* O-*Benzoyloxime.* *o*-Phenylbenzophenone oxime, prepared from *o*-phenylbenzophenone[31] by the method of Smith,[27] was acylated with benzoyl chloride in a way similar to fluorenone *O*-(*p*-methylbenzoyl)oxime; mp 115.5—116.5 °C (benzene–petroleum ether) (Found: C, 83.04; H, 4.96; N, 3.80%. Calcd for $C_{26}H_{19}NO_2$: C, 82.74; H, 5.07; N, 3.71%); IR (KBr) 1742 cm^{-1}.

N-*Diphenylmethylene*-o-*chloroaniline.* A mixture of 3 g of benzophenone, 3.5 ml of *o*-chloroaniline, and 1 drop of 48% hydrobromic acid was heated for 0.5 h at 250 °C under nitrogen. After cooling, 15 ml of ethanol was added to give light yellow crystals, which were recrystallized three times from ethanol to give pure specimen (1.8 g); mp 101—103 °C (Found: C, 78.04; H, 4.98; N, 4.78; Cl, 12.20%. Calcd for $C_{19}H_{14}ClN$: C, 78.21; H, 4.84; N, 4.80; Cl, 12.15%).

N-*Diphenylmethylene*-m-*chloroaniline.* A mixture of 3 g of benzophenone, 3.5 ml of *m*-chloroaniline, and 2 drops of 48% hydrobromic acid was heated for 1 h at 210 °C under nitrogen. After cooling, 15 ml of ethanol added to give light yellow crystals. Twice recrystallizations from ethanol gave pure specimen (2.4 g); mp 75.5—76.5 °C (Found: C, 77.95; H, 4.74; N, 4.72; Cl, 12.27%. Calcd for $C_{19}H_{14}ClN$: C 78.21; H, 4.84; N, 4.80; Cl, 12.15%).

N-*Diphenylmethylene*-*2,3-xylidine.* A solution of equivalent amounts of benzophenone and 2,3-xylidine in xylene was refluxed for 4 h in the presence of a few drops of 48% hydrobromic acid. The water formed during the reaction was removed as xylene azeotrope. After evaporation of the solvent, the residue was recrystallized from ethanol; mp 60—61 °C (Found: C, 88.50; H, 6.61; N, 4.75%. Calcd for $C_{21}H_{19}N$: C, 88.38; H, 6.71; N, 4.91%).

Photolyses of O-*Acyloximes.* A 0.1 M solution of benzophenone *O*-acyloxime in benzene was irradiated under nitrogen or argon in the absence or in the presence of benzophenone in a Pyrex immersion well with a 400 W mercury lamp. When toluene, chlorobenzene, or xylene was used as a solvent, irradiation was conducted in a Pyrex tube with a 1 kW mercury lamp using a Riko RH400—10 W rotary photochemical reactor.

Benzene solutions (0.1 M) of fluorenone *O*-(*p*-methylbenzoyl)oxime and *o*-phenylbenzophenone *O*-benzoyloxime were irradiated similarly by the 1 kW mercury lamp.

Volatile products other than starting acyloximes and ketazines were analyzed quantitatively by VPC using columns of Apiezon Grease L and Carbowax 20 M. Ketazines were separated by dry column chromatography on silica gel eluting with benzene, and analyzed quantitatively by UV spectrometry. In the photolyses of benzophenone *O*-acetyloxime the unreacted acetyloxime and the products, *N*-diphenylmethylenemethylamine and toluene, were analyzed also by NMR using an internal standard.

A solution of *o*-phenylbenzophenone *O*-benzoyloxime (0.377 g) in benzene (10 ml) in the presence of benzophenone (0.182 g) was irradiated by the 1 kW mercury lamp for 13.5 h. The reaction mixture was analyzed quantitatively by VPC using a column of Apiezon Grease L. 9-Phenylphenanthridine was separated by dry column chromatography on silica gel eluting with benzene as white crystals (0.064 g, 25%); mp 104—105 °C (lit,[32] 106 °C).

Competitive Experiments. A 0.1 M solution of benzophenone *O*-benzoyloxime or *O*-(*p*-chlorobenzoyl)oxime in a mixed solvent, benzene–toluene (22: 8 in a volume ratio) or in benzene–chlorobenzene (8 : 17), was irradiated by the 1 kW mercury lamp. The distributions of substituted products, *N*-diphenylmethylene-aniline, -toluidines, and -chloroanilines, were determined by VPC analysis using a column of Apiezon Grease L.

The authors wish to thank Professor T. Suehiro in Gakushuin University for his helpful discussions. Partial financial assistance through the Ministry of Education for K. T. is gratefully acknowledged.

The Oxidation of 3-(2-Hydroxyphenyl)coumarins with Lead Tetraacetate

Kazu KUROSAWA and Keifumi NOGAMI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received March 10, 1976)

Five 3-(2-hydroxy-4-methoxyphenyl)coumarins (Ia—Ie) were oxidized with lead tetraacetate to the corresponding 6*H*-benzofuro[3,2-*c*][1]benzopyran-6-ones (IIa—IIe) and 3-(1-acetoxy-4-methoxy-2-oxo-3,5-cyclohexadienyl)coumarins (IIIa, IIIb, and IIId). Four 3-(3,4-dimethoxy-2-hydroxy-phenyl)coumarins (If—Ii) gave the corresponding 3-(1-acetoxy-3,4-dimethoxy-2-oxo-3,5-cyclohexadienyl)coumarins (IIIf—IIIi).

In the lead tetraacetate oxidations of phenolic compounds in which a hydroxyl group and a double bond are located in spatially suitable positions, an oxidative cyclization has often been observed.[1-5] A similar reaction of 3-(2-hydroxyphenyl)coumarin with lead tetraacetate is also expected to give 6*H*-benzofuro-[3,2-*c*][1]benzopyran-6-ones.

The 3-(2-hydroxyphenyl)coumarins (Ia—Ii) were prepared by the Perkin reaction of *o*-hydroxybenzaldehydes and *o*-hydroxyphenylacetic acids; the oxidations of Ia—Ii with lead tetraacetate were also carried out. The structures of the products were determined by examining their spectroscopic properties and by elemental analyses.

When the 3-(2-hydroxy-4-methoxyphenyl)coumarins (Ia—Ie) were oxidized, 6*H*-benzofuro[3,2-*c*][1]benzopyran-6-ones—(IIa)(10%), (IIb)(22%), (IIc)(12%), (IId)(14%), and (IIe)(5%)—were obtained, together with 3-(1-acetoxy-4-methoxy-2-oxo-3,5-cyclohexadienyl)coumarins-(IIIa)(32%), (IIIb)(16%), and (IIId)-(26%). IIc was found to be identical with dimethylcoumestrol[6] by a comparison of their melting points and their spectral data.

IIIa,b,d,f~i

When the 3-(3,4-dimethoxy-2-hydroxyphenyl)coumarins (If—Ii) were oxidized, 3-(1-acetoxy-3,4-dimethoxy-2-oxo-3,5-cyclohexadienyl)coumarins—(IIIf)(75%), (IIIg)(82%), (IIIh)(63%), and (IIIi)(84%)—were obtained. In the cases of the oxidation of Ia—Ie, there were considerable amounts of undefined products which could not be purified. It was found that the 6H-benzofuro[3,2-*c*][1]benzopyran-6-ones (IIa—IIe) were best prepared when a 1.5-equivalent of lead tetraacetate was used in boiling benzene.

In contrast to the oxidations of 2'-hydroxychalcones[2,3] and 2-hydroxybenzophenones,[4] which yielded aurones and xanthones respectively in fairly good yields, 3-(2-hydroxyphenyl)coumarins undergo angular acetoxylation in the cyclohexadienone ring rather than ring closure. This could be ascribed to the nature of the phenoxyl radical formed from the 2-hydroxyphenyl group with lead tetraacetate.[7] The phenoxyl radical has an electrophilic character and, therefore, favors an attack on the α-position to one on the carbonyl in the case of 2'-hydroxychalcones, and one on the *p*-position to one on a methoxyl group in the case of 2-hydroxybenzophenones. However, the carbon atom at the 4-position of 3-(2-hydroxyphenyl)coumarin is electron-deficient, as it is an α,β-unsaturated lactone; therefore, the phenoxyl radical is less reactive in this site.

Although several other syntheses of 6*H*-benzofuro-[3,2-*c*][1]benzopyran-6-ones have been reported,[8-10] the oxidative cyclization of 3-(2-hydroxyphenyl)coumarin can be used in the synthesis of 9-oxygenated 6H-benzofuro[3,2-*c*][1]benzopyran-6-ones.

Experimental

All the ^1H NMR spectra were recorded for the deuteriochloroform solution, unless otherwise stated, with a Hitachi R 24 NMR spectrometer, with tetramethylsilane as the internal reference. The IR spectra were recorded either for the chloroform solution or for the KBr disk with a JASCO IRA-1 grating spectrometer, while the UV spectra were measured for the methanol solution with a Hitachi EPS-3T spectrophotometer. The melting points were determined with a Yanagimoto hot-stage apparatus and were uncorrected.

Preparations of 3-(2-Hydroxyphenyl)coumarins (Ia—Ii). The general procedure for the preparation of 3-(2-hydroxyphenyl)coumarin was as follows: a mixture of *o*-hydroxybenzaldehyde (10 mmol), *o*-hydroxyphenylacetic acid (10 mmol), acetic anhydride (24 mmol), sodium acetate (50 mmol), and acetic acid (40 ml) was heated under reflux for 24 h. After the removal of the acetic acid, the resulting mixture was triturated with water, and the precipitates were collected by filtration. The crude product was purified by recrystallization.

3-(2-Hydroxy-4-methoxyphenyl)coumarin (Ia); mp 171—172 °C (EtOH), 62%, ν_{max}^{KBr}: 3180 (OH) and 1700 cm^{-1} (C=O), δ: 3.82 (s, OCH_3), 6.4—6.65 (m, 2H, $H_{(3')}$ and $H_{(5')}$), 7.1—7.7 (m, 5H), 7.82 (s, $H_{(4)}$), and 8.0 (broad s, OH). Found: C, 71.35; H, 4.68%. Calcd for $C_{16}H_{12}O_4$: C, 71.63; H, 4.51%.

3-(2-Hydroxy-4-methoxyphenyl)-6-methoxycoumarin (Ib); mp 179—180 °C (EtOH), 92%, ν_{max}^{KBr}: 3310 (OH) and 1710 cm^{-1} (C=O), δ: 3.80 (s, OCH_3), 3.85 (s, OCH_3), 6.4—6.7 (m, 2H, $H_{(3')}$ and $H_{(5')}$), 6.9—7.4 (m, 4H), 7.78 (s, $H_{(4)}$), and 8.20 (broad s, OH). Found: C, 68.24; H, 4.78%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%. 3-(2-Hydroxy-4-methoxyphenyl)-7-methoxycoumarin (Ic); mp 160—161 °C (EtOH), 79%, ν_{max}^{KBr}: 3330 (OH) and 1715 cm^{-1} (C=O), δ: 3.80 (s, OCH_3), 3.90 (s, OCH_3), 6.5—7.3 (m, 5H), 7.50 (d, $H_{(5)}$), 7.80 (s, $H_{(4)}$), and 8.1 (broad s, OH). Found: C, 68.25; H, 4.78%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

3-(2-Hydroxy-4-methoxyphenyl)-8-methoxycoumarin (Id); mp 182—183 °C ($CHCl_3$–EtOH), 83%, ν_{max}^{KBr}: 3260 (OH) and 1700 cm^{-1} (C=O), δ: 3.80 (s, OCH_3), 3.98 (s, OCH_3), 6.4—7.4 (m, 6H), 7.81 (s, $H_{(4)}$), and 8.1 (s, OH). Found: C, 68.21; H, 4.71%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

6,7-Dimethoxy-3-(2-hydroxy-4-methoxyphenyl) coumarin (Ie); mp 200—201 °C ($CHCl_3$), 84%, $\nu_{max}^{CHCl_3}$: 3240 (OH) and 1700 cm^{-1} (C=O), δ_{CF_3COOH}: 4.00 (s, OCH_3), 4.10 (s, $2\times OCH_3$), 6.7—7.5 (m, 5H), and 8.15 (s, $H_{(4)}$). Found: C, 65.56: H, 4.94%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

3-(3,4-Dimethoxy-2-hydroxyphenyl) coumarin (If); mp 203—204 °C ($CHCl_3$–EtOH), 95%, $\nu_{max}^{CHCl_3}$: 3500 (OH) and 1740 cm^{-1} (C=O), δ: 3.86 (s, OCH_3), 3.90 (s, OCH_3), 6.42 (s, OH), 6.52 (d, J=9 Hz, $H_{(5')}$), 7.0—7.6 (m, 5H), and 7.83 (s, $H_{(4)}$). Found: C, 68.35; H, 4.78%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

3-(3,4-Dimethoxy-2-hydroxyphenyl)-6-methoxycoumarin (Ig); mp 181—182°C (EtOH), 82%, $\nu_{max}^{CHCl_3}$: 3500 (OH) and 1735 cm^{-1} (C=O), δ: 3.82 (s, OCH_3), 3.88 (s, OCH_3), 392 (s, OCH_3), 6.55 (d, J=9 Hz, $H_{(5')}$), 6.55 (s, OH), 6.9—7.5 (m, 4H), and 7.82 (s, $H_{(4)}$). Found: C, 65.69; H, 4.98%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

3-(3,4-Dimethoxy-2-hydroxyphenyl)-7-methoxycoumarin (Ih); mp 136—137 °C (EtOH), 76%, $\nu_{max}^{CHCl_3}$: 3500 (OH) and 1730 cm^{-1} (C=O), δ: 3.88 (s, $2\times OCH_3$), 3.92 (s, OCH_3), 6.52 (d, J=9 Hz, $H_{(5')}$), 6.55 (broad s, OH), 6.8—7.5 (m, 4H), and 7.82 (s, $H_{(4)}$). Found: C, 65.58; H, 4.81%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

3-(3,4-Dimethoxy-2-hydroxyphenyl)-8-methoxycoumarin (Ii); mp 186—188 °C ($CHCl_3$–EtOH), 91%, $\nu_{max}^{CHCl_3}$: 3500 (OH) and 1740 cm^{-1} (C=O), δ: 3.88 (s, OCH_3), 3.92 (s, OCH_3), 3.96 (s, OCH_3), 6.51 (d, J=9 Hz, $H_{(5')}$), 6.50 (s, OH), 6.9—7.4 (m, 4H), and 7.84 (s, $H_{(4)}$). Found: C, 65.79; H, 4.91%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.96%.

Oxidation of 3-(2-Hydroxyphenyl)coumarins with Lead Tetraacetate. The general procedure for the oxidation of 3-(2-hydroxyphenyl)coumarin was as follows: to a solution of 3-(2-hydroxyphenyl)coumarin (1 mmol) in anhydrous benzene (30 ml), lead tetraacetate (1.5 mmol) was added; the mixture was then heated under reflux for 30 min. After the removal of the lead diacetate by filtration, the benzene was evaporated *in vacuo*. The resulting mixture was purified either by TLC or by recrystallization.

Ia yielded 9-methoxy-6*H*-benzofuro[3,2-*c*][1] benzopyran-6-one (IIa); mp 212—213 °C (EtOH), 10%, $\nu_{max}^{CHCl_3}$: 1740 cm^{-1}, λ_{max} (ε): 242 (35000), 334 (31100), and 345 nm (26900), δ: 3.88 (s, OCH_3) and 6.9—7.1 (m, 7H) (Found: C, 71.99; H, 3.74%. Calcd for $C_{16}H_{10}O_4$: C, 72.18; H, 3.79%); and 3-(1-acetoxy-4-methoxy-2-oxo-3,5-cyclohexadienyl) coumarin (IIIa); mp 184—186 °C (EtOH), 32%, $\nu_{max}^{CHCl_3}$: 1680 and 1740 cm^{-1}, λ_{max} (ε): 285 (14000) and 318 nm (10600), δ: 2.15 (s, OAc), 3.76 (s, OCH_3), 5.68 (d, J=2.5 Hz, $H_{(3)}$), 6.25 (dd, J=2.5, 10 Hz, $H_{(5)}$), 6.58 (d, J=10 Hz, $H_{(6)}$), 7.0—7.7 (m, 4H), and 7.84 (s, $H_{(4)}$) (Found: C, 65.95; H, 4.32%. Calcd for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%).

Ib gave 2,9-dimethoxy-6*H*-benzofuro[3,2-*c*][1]benzopyran-6-one (IIb)(mp 191—192 °C (EtOH), 22%, $\nu_{max}^{CHCl_3}$: 1740 cm^{-1}, λ_{max} (ε): 235 (38000), 320 (12300), and 345 nm (20200), δ: 3.90 (s, $2\times OCH_3$), 7.0—7.6 (m, 5H), and 7.90 (d, $H_{(7)}$) (Found: C, 68.81; 4.05%. Calcd for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%)) and 3-(1-acetoxy-4-methoxy-2-oxo-3,5-cyclohexadienyl)-6-methoxycoumarin (IIIb) (mp 176—177 °C (EtOH), 16%, $\nu_{max}^{CHCl_3}$: 1670 and 1740 cm^{-1}, λ_{max} (ε): 284 (20500) and 344 nm (10900), δ: 2.17 (s, OAc), 3.82 (s, $2\times OCH_3$) 5.71 (d, J=2.5 Hz, $H_{(3')}$), 6.26 (dd, J=2.5, 10 Hz, $H_{(5')}$), 6.45 (d, J=10 Hz, $H_{(6')}$), 6.9—7.3 (m, 3H), and 7.8 (s, $H_{(4)}$) (Found: C, 63.75; H, 4.52%. Calcd for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%).

Ic yielded 3,9-dimethoxy-6*H*-benzofuro[3,2-*c*][1]benzopyran-6-one (IIc); mp 198—199 °C (lit,[6] mp 197 °C), 12%.

Id gave 4,9-dimethoxy-6*H*-benzofuro[3,2-*c*][1]benzopyran-6-one (IId) (mp 250—251 °C (EtOH), 14%, $\nu_{max}^{CHCl_3}$: 1740 cm^{-1}, λ_{max} (ε): 242 (28800) and 335 nm (19900), δ: 3.99 (s, OCH_3), 4.05 (s, OCH_3) and 6.9—7.8 (m, 6H) (Found: C, 68.77; H, 4.11%. Calcd for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%) and 3-(1-acetoxy-4-methoxy-2-oxo-3,5-cyclohexadienyl)-8-methoxycoumarin (IIId) (mp 226—228 °C (EtOH), 38%, ν_{max}^{KBr}: 1670, 1740, and 1770 cm^{-1}, λ_{max} (ε): 257 (15400) and 301 nm (13500), δ: 2.15 (s, OAc), 3.77 (s, OCH_3), 3.80 (s, OCH_3), 5.65 (d, J=2.5 Hz, $H_{(3')}$), 6.13 (dd, J=2.5, 10 Hz, $H_{(5')}$), 6.6—6.9 (m, 3H), 7.30 (d, $H_{(5)}$), and 7.71 (s, $H_{(4)}$) (Found: C, 63.74; H, 4.47%. Calcd for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%)).

Ie yielded 2,3,9-trimethoxy-6*H*-benzofuro[3,2-*c*][1]benzopyran-6-one (IIe); mp 253—254 °C (EtOH), 5%, $\nu_{max}^{CHCl_3}$: 1740 cm^{-1}, λ_{max} (ε): 235 (32900) and 353 nm (29800), δ: 3.90 (s, OCH_3), 3.96 (s, OCH_3) 4.00 (s, OCH_3), 6.96 (s, 1H), 7.11 (s, 1H), 6.9—7.3 (m, 2H), and 7.88 (d, J=8.5 Hz, $H_{(7)}$) (Found: C, 66.44; H, 4.39%. Calcd for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%).

If gave 3-(1-acetoxy-3,4-dimethoxy-2-oxo-3,5-cyclohexadienyl)coumarin (IIIf); mp 145—146 °C (EtOH), 75%, $\nu_{max}^{CHCl_3}$: 1660 and 1740 cm^{-1}, λ_{max} (ε): 350 (12600) and 390 nm (inflection) (9720), δ: 2.15 (s, OAc), 3.52 (s, OCH_3), 3.80 (s, OCH_3), 5.53 (d, J=8.5 Hz, $H_{(5')}$), 7.1—7.6 (m, 4H), 7.74 (d, J=8.5 Hz, $H_{(6')}$), and 8.01 (s, $H_{(4)}$) (Found: C, 63.39; H, 4.76%. Calcd for $C_{19}H_{16}O_7\cdot 1/2C_2H_5OH$: C, 63.35; H, 5.02%.)

Ig yielded 2-(1-acetoxy-3,4-dimethoxy-2-oxo-3,5-cyclohexadienyl)-6-methoxycoumarin (IIIg); mp 190—192 °C (benzene), 82%, $\nu_{max}^{CHCl_3}$: 1650 and 1740 cm^{-1}, λ_{max} (ε): 376 nm (12700), δ: 2.18 (s, OAc), 3.49 (s, OCH_3), 3.80 (s, $2\times OCH_3$), 5.45 (d, J=8.5 Hz, $H_{(5')}$), 6.8—7.3 (m, 3H), 7.70 (d, J=8.5 Hz, $H_{(6')}$), and 7.94 (s, $H_{(4)}$) (Found: C, 62.19; H, 4.71%. Calcd for $C_{20}H_{18}O_8$: C, 62.14; H, 4.70%).

Ih yielded 3-(1-acetoxy-3,4-dimethoxy-2-oxo-3,5-cyclohexadienyl)-7-methoxycoumarin (IIIh); mp 178—179 °C (benzene–EtOH), 63%, $\nu_{max}^{CHCl_3}$: 1650 and 1740 cm^{-1}, λ_{max} (ε): 376 nm (12600), δ: 2.16 (s, OAc), 3.54 (s, OCH_3), 3.69 (s, OCH_3), 3.75 (s, OCH_3), 5.50 (d, J=8.5 Hz, $H_{(5')}$), 6.7—7.0 (m, 2H), 7.40 (d, $H_{(5)}$), 7.68 (d, J=8.5 Hz, $H_{(6')}$), and 7.92 (s, $H_{(4)}$) (Found: C, 62.27; H, 4.78%. Calcd for $C_{20}H_{18}O_8$: C, 62.17; H, 4.70%).

Ii gave 3-(1-acetoxy-3,4-dimethoxy-2-oxo-3,5-cyclohexadienyl)-8-methoxycoumarin (IIIi); mp 180—181 °C (benzene), 84%, $\nu_{max}^{CHCl_3}$: 1650 and 1740 cm^{-1}, λ_{max} (ε): 350 (11200) and 390 nm (inflection) (9100), δ: 2.15 (s, OAc), 3.47 (s, OCH_3), 3.75 (s, OCH_3), 3.91 (s, OCH_3), 5.43 (d, J=8.5 Hz, $H_{(5')}$), 6.9—7.3 (m, 3H), 7.80 (d, J=8.5 Hz, $H_{(6')}$), and 7.96 (s, $H_{(4)}$) (Found: 62.26; H, 4.73%. Calcd for $C_{20}H_{18}O_8$: C, 62.17; H, 4.70%).

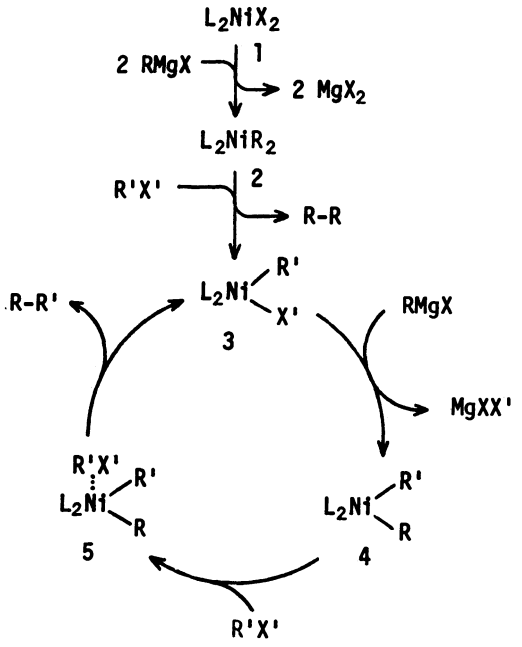

Scheme 1.

Reaction of **3** with the Grignard reagent then forms a new diorgano complex **4** from which the cross-coupling product is released by the attack of the organic halide, possibly *via* the pentacoordinated intermediate **5**, and thereby the original complex **3** is regenerated to complete the catalytic cycle.

The reaction, indeed, could be achieved by the addition of Grignard reagent to a vinylic or an aromatic halide in the presence of a catalytic amount of a dihalodiphosphinenickel and the yields were generally very high. Throughout this paper, the following phosphines and other ligands are described in their abbreviations shown here.

$Ph_2P(CH_2)_nPPh_2$

II. Coupling of Butylmagnesium Bromide with Halobenzenes. To a mixture of chlorobenzene (1 part) and a catalytic amount of [Ni(dppp)Cl_2] (0.01—0.001 part) in anhydrous ether was added the butyl Grignard reagent (1.2 part) at 0 °C under nitrogen to give a tan clear mixture. The mixture was stirred at room temperature and a mildly exothermic reaction set in. After refluxing for 20 h and hydrolysis, GLPC analysis showed that the starting chlorobenzene was no longer present and butylbenzene was formed in quantitative yield. The product was easily isolated pure by simple distillation; there was no contamination with a structural isomer, such as *sec*-butylbenzene.

In the light of the fact that the above reaction readily goes to completion, the coupling of the butyl Grignard reagent with halobenzenes was chosen as a model reaction for the examination of the catalytic ability of various nickel–phosphine complexes and of the reactivity of halobenzenes.

Table 1. Catalytic activity of various [NiL_2Cl_2] for cross-coupling of *n*-C_4H_9MgBr with C_6H_5Cl[a]

L_2	Conversion (%)[b]	Yield (%) of *n*-$C_4H_9C_6H_5$[b]
dppp	100	100
dmpf	100	94
$2Ph_3P$	91	84[c]
$2Ph_3P$[d]	90	50[e]

dppe[f]	78	77
dmpe	53	47
dppc	30	28
dppb	38	28
cis-dpen	19	20
$2Et_3P$	63	6[g]
$2Ph_2MeP$	[h]	4[e]

a) Unless otherwise noted, to a mixture of C_6H_5Cl (~10 mmol), [NiL_2Cl_2] (~0.1 mmol) and anhydrous ether (10 ml) was added *n*-C_4H_9MgBr (~12 mmol), and then the mixture was heated for 20 h under nitrogen. b) Determined by GLPC using mesitylene as an internal standard based on the chlorobenzene used. c) Benzene 10%. d) Used as a mixture of PPh_3 (0.21 mmol) and anhydrous $NiCl_2$ (0.16 mmol). e) Benzene was not determined. f) Petroleum ether was used as additional solvent. g) Benzene 52%. h) GLPC showed the presence of a large amount of unchanged chlorobenzene.

Catalytic Activity of Various Nickel–Phosphine Complexes: Under the similar conditions, catalytic activity of various nickel(II) complexes was examined (Table 1). The catalytic activity of the nickel complexes depends strongly upon the nature of the ligands. This ligand-dependency clearly indicates that a catalytically active species does contain phosphine ligand(s) on nickel. In Table 1, the phosphine ligands are listed in the order of decreasing catalytic activity of their nickel complexes.

Bidentate phosphines as ligands exhibit much higher catalytic activity than unidentate ones; the efficiency of the bidentate phosphine ligands decreases roughly in the sequence: dppp>dmpf>dppe>dmpe>dppb>dppc>*cis*-dpen. It seems of particular interest to note that the catalytic activity depends on the length of the methylene bridge between two diphenylphosphino groups in a homologous series of $Ph_2P(CH_2)_nPPh_2$, *viz.*, $n=3>n=2>n=4$. The prominence of [Ni(dppp)Cl_2] as a catalyst is commonly observed also in different combinations of other Grignard reagents and halides (*vide infra*).

Of the unidentate phosphines as ligands, only triphenylphosphine is practically active for the coupling.

Although with $[Ni(PEt_3)_2Cl_2]$ chlorobenzene is consumed to the same extent as with $[Ni(PPh_3)_2Cl_2]$, benzene is formed as a major product.

The following nickel complexes and salts are practically inactive for the coupling: $[Ni(PPh_2Me)_2Cl_2]$, $[Ni(PPhMe_2)_2Cl_2]$, $[Ni(dppm)_2Cl_2]$, [Ni(bipy)Cl_2], $[Ni(py)_2Cl_2]$, $Ni(acac)_2$, and $NiCl_2$. With [Ni(bipy)Cl_2] as a catalyst the reaction mixture remained a deeply green color characteristic of diorganonickel complexes with the bipy ligand,[33] indicating that the intermediate is too stable to react further with chlorobenzene. It should be noted that an equimolar mixture of [Ni(dppe)Cl_2] and the dppe free ligand exhibited no catalytic activity, apparently owing to the blocking of catalytically active vacant sites on the nickel catalyst by the extra phosphine. Interestingly, $Ni(acac)_2$, which was reported to be efficient for the coupling of aryl Grignard reagents with aryl and alkenyl halides,[20] showed no activity at all for the coupling of simple alkyl Grignard reagents with chlorobenzene.

$[Pd(PPh_3)_2Cl_2]$, $[Pd(PEt_3)_2Cl_2]$, *cis*-$[Pt(PPh_3)_2Cl_2]$, and [Co(dppp)Cl_2] exhibited no catalytic activity, which may be attributable primarily to the fact that chlorobenzene hardly undergoes oxidative addition to the low valent species of these metals.[31d,34] The recently reported palladium(0)catalyzed Grignard coupling may be restricted to more reactive bromides.[22]

TABLE 2. EFFECT OF AGING ON THE CATALYTIC ACTIVITY IN THE COUPLING OF *n*-C_4H_9MgBr WITH C_6H_5Cl[a]

Aging time (h)	Reaction time after addition of C_6H_5Cl (h)	Conversion (%)	Yield (%) C_4H_9–C_6H_5	Yield (%) C_6H_6
		[Ni(dppp)Cl_2]		
1/30	3	>99	99	trace
1	3	>99	97	trace
3.5	3	>99	>99	trace
16	3	>99	98	trace
		[Ni(PPh_3)$_2Cl_2$]		
0[b]	3	63	52	N.d.
0[b]	20	87	72	N.d.
1/20	3	78	58	22
1	3	71	55	20
16	3	53	21	N.d.
16	20	94	69	35

a) To a mixture of the catalyst (0.05 mmol) and ether (5 ml) was added *n*-BuMgBr in ether (6 mmol) at 0 °C. The mixture was stirred at room temperature for a given period of aging time: [Ni(dppp)Cl_2] gave a yellowish clear solution, while [Ni(PPh_3)$_2Cl_2$] gave a dark brown mixture. Chlorobenzene (5 mmol) was then added at room temperature in one portion and the mixture was stirred at room temperature for 30 min and then refluxed for a given period of time. After hydrolysis the mixture was analyzed by GLPC. b) To a mixture of the catalyst, chlorobenzene and ether was added the *n*-C_4H_9MgBr solution.

Aging of Catalysts: Stability of the catalytically active species has been examined for [Ni(dppp)Cl_2] and [Ni(PPh_3)$_2Cl_2$] (Table 2). Thus, a catalytic amount of the nickel complex was firstly added to the butyl Grignard reagent, the resulting mixture was allowed to stand at room temperature under nitrogen for a given period of time, and then chlorobenzene was added. Rather surprisingly, the yellowish clear catalyst solution generated from [Ni(dppp)Cl_2] and the butyl Grignard reagent did not decrease in efficiency even after 16 h at room temperature. Upon addition of chlorobenzene at this point, an exothermic reaction set in and exactly the same results were obtained as the case where the Grignard reagent was finally added to a mixture of chlorobenzene and [Ni(dppp)Cl_2] (without aging).

In contrast with this result, a dark-brown mixture generated from [Ni(PPh_3)$_2Cl_2$] and the butyl Grignard reagent gradually diminished in activity with time. However, the prolonged coupling-reaction time led to essentially the same results as observed in experiments with no aging.

These results demonstrate a great stabilizing effect on the catalytically active species by, notably, the bidentate phosphine ligand.

Reactivity of Halobenzenes: Reactivity of halobenzenes, from fluoro- to iodo-benzene, was examined for the coupling with the butyl Grignard reagent in the presence of [Ni(dppp)Cl_2] or [Ni(dppe)Cl_2] as catalyst.

TABLE 3. REACTIVITY OF HALOBENZENES IN THE COUPLING WITH *n*-C_4H_9MgBr[a]

X in C_6H_5X	Reaction time (h)	Conversion[b] (%)	Yield (%)[b] *n*-$C_4H_9C_6H_5$	Yield (%)[b] C_6H_6
		[Ni(dppp)Cl_2]

a) To a mixture of C_6H_5X (~5 mmol) and [NiL_2Cl_2] (~0.05 mmol) in 15 ml of ether was added a solution of *n*-C_4H_9MgBr (6.3 mmol) in ether at 0 °C and then refluxed for a given period of time, unless otherwise noted. b) Determined by quantitative GLPC based on C_6H_5X. c) Conversion and benzene could not be determined by GLPC, because C_6H_5F and benzene appeared in a single peak. d) Carried out in a 10-mmol scale. e) The reaction occurred vigorously even at 0 °C. Stirred at room temperature for 3 h. f) Biphenyl 2%.

The reactivity of halobenzenes appears to be dependent upon the nature of the catalyst. Thus, while with [Ni(dppp)Cl_2] a rather abnormal reactivity order PhI>PhCl>PhBr>PhF was observed, with [Ni(dppe)Cl_2] the order was normal: PhBr>PhCl>PhF (Table 3). However, from the competitive reactions (Table 4), the normal reactivity order was observed also with [Ni(dppp)Cl_2]. This strange behavior is difficult to

Table 4. Competitive reaction between two kinds of halobenzenes with n-C_4H_9MgBr[a]

Combination of C_6H_5X	Reaction time (h)	run	Conversion (%)[b] 1	2	3

C_6H_5F / C_6H_5Cl	20		19 / 58	20 / 58	— / —
C_6H_5Cl / C_6H_5Br	20		29 / 78	30 / 80	29 / 75[c]

a) For the procedure, see footnote a) of Table 3: C_6H_5X, 5 mmol each; Grignard reagent, 6.4 mmol; catalyst, ~0.05 mmol; ether, 15 ml. b) Determined by GLPC. c) Benzene 22%.

explain, but implies that there are two or more rate-limiting steps in the reaction.

In view of the extremely low reactivity of organofluoro compounds toward metals, it seems of particular interest that even fluorobenzene, if not completely, does undergo the metal-catalyzed coupling reaction. To our knowledge, oxidative addition of a fluorine–carbon bond to a transition metal complex has not yet been reported.[31e] Iodobenzene reacts very vigorously even at 0 °C, with biphenyl being formed only in trace amounts. The formation of benzene also depends on the nature of the halides in the order: PhF<PhCl≪PhBr<PhI.

The foregoing results demonstrate that chlorobenzene exhibits a reasonable reactivity, gives a high yield of the cross-coupling product with no by-product, and hence is the halide that was chosen for the present reaction. The superiority of chlorobenzene as a halide is particularly worthy of note, because bromides or iodides have been used so far in almost all types of coupling reactions of organic halides using metals as coupling agents.

Table 5. Solvent effects on the coupling of C_2H_5MgBr with C_6H_5Cl[a]

Solvent	Reaction time (h)	Conversion[b] (%)	Yield (%)[b] $C_2H_5C_6H_5$	C_6H_6
		[Ni(dppe)Cl_2]		
$(C_2H_5)_2O$	16	99	98	trace
THF	22	78	66	11
		[Ni(PPh_3)$_2Cl_2$]		
$(C_2H_5)_2O$	16	86	59	20
THF	22	51	10	35

a) C_6H_5Cl, 12 mmol; C_2H_5MgBr, 12—14 mmol; catalyst, 0.1 mmol; solvent 20 ml. Refluxed for a given period of time. b) Determined by GLPC.

Solvent Effects: Grignard reagents are usually prepared either in diethyl ether or in THF, and hence these two solvents were examined in regard to solvent effects. The effects on the coupling of the ethyl Grignard reagent with chlorobenzene in the presence of [Ni(dppe)Cl_2] or [Ni(PPh_3)$_2Cl_2$] as catalyst are summarized in Table 5. For both of the catalysts used, the reactions tend to proceed considerably faster in diethyl ether than in THF and the undesired product, benzene, is formed in a larger amount in THF. Therefore, diethyl ether is better than THF as a solvent.

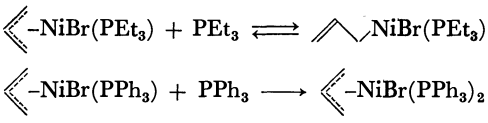
Although reasons for the observed solvent effects are not clear presently, it seems likely that a more basic solvent (THF>Et_2O) interacts more tightly with the nickel center to prevent the approach of the halide and/or the Grignard reagent to it.

III. Coupling of Other Alkyl, Aryl, and Alkenyl Grignard Reagents with Aryl and Alkenyl Halides. The generality of the nickel-phosphine complex-catalyzed Grignard cross-coupling is apparent from the results summarized in Tables 6 and 7.

Catalytic Activity of Nickel–Phosphine Catalysts: Table 6 summarizes a comparison of the catalytic activities of some selected nickel-phosphine complexes for several representative combinations of Grignard reagents and organic halides. The efficiency of the catalysts appears to be dependent mainly on the structur of the organic moieties of Grignard reagents and little on the nature of the organic halides. Several features are worthy of note.

Here again, [Ni(dppp)Cl_2] is the most effective for primary alkyl (regardless of the presence or absence of β-hydrogen(s) (*vide infra*)), secondary alkyl, and aryl Grignard reagents.

Two rather exceptional cases arise. Firstly, [Ni(dmpe)Cl_2], which contains a basic bidentate ligand, is the most suitable catalyst for allylic and vinylic Grignard reagents. Interestingly, both the Grignard reagents contain an unsaturated group potentially capable of coordination with the nickel center of the catalyst. This exceptional behavior may be related to the observations that basic ligands can cause π-σ conversion of an allyl-nickel complex, whereas less basic ligands form a relatively stable five-coordinate π-allyl-nickel complex, as exemplified by the following equations:[35]



It should be noted that the former is coordinatively unsaturated, while the latter saturated.

The other exceptional case is observed in the coupling of the mesityl Grignard reagent for which a unidentate phosphine is better than bidentate phosphine ligands. It has long been recognized that *ortho*-substituted aryl-nickel complexes are of high kinetic stability[36] and hence the enhanced stability of a mesityl-nickel intermediate to be expected with a bidentate phosphine ligand may be responsible for the diminished reaction rates in this case. A reversible ligand dissociation from a dimesitylnickel complex of a unidentate phosphine has been observed.[37]

The pronounced differences in catalytic activity between [Ni(dppp)Cl_2] and [Ni(dppe)Cl_2] were observed for the coupling of the trimethylsilylmethyl Grignard reagent with chlorobenzene; with the former catalyst the coupling product was obtained in quantitative yield.

TABLE 6. CATALYTIC ACTIVITY OF $[NiL_2Cl_2]$ FOR THE COUPLING OF VARIOUS GRIGNARD REAGENTS WITH ORGANIC HALIDES[a]

a) Carried out under nitrogen atmosphere. Unless otherwise mentioned, solvent is diethyl ether. The Grignard reagent was added to a mixture of a halide, a catalyst, and solvent. The reaction conditions are not necessarily optimum. b) Unless otherwise noted, refluxed for the given period of time. c) Isolated yield based on the halide, unless otherwise noted. Yields determined by quantitative GLPC are given in parentheses. d) Conversion 58%. e) Conversion 44%. f) Conversion 59%. g) Np=naphthyl. h) Naphthalene 43%. i) An exothermic reaction occurred. j) In a mixed solvent of benzene, ether, and THF (3:2:1). k) Mes=mesityl. l) Ant=anthryl. m) Room temperature. n) *c*-C_6H_{11}=cyclohexyl. o) Contaminated with a few per cent of dicyclohexyl. p) 1,2-Dicyclohexylbenzene was not formed. q) *c*-C_3H_5=cyclopropyl. r) In tetrahydrofuran. s) 40—50 °C. t) Based on the Grignard reagent. u) About 2 fold excess. v) A complex mixture of products were formed. w) For a detailed stereochemical aspects, see Ref. 26. x) Little $C_6H_5CH_2CH$=$CHCH_2C_6H_5$ was formed. y) Dicyclohexyl 8—9% yield. z) A *m*-xylene solution. z') A vigorous reaction occurred at 0 °C.

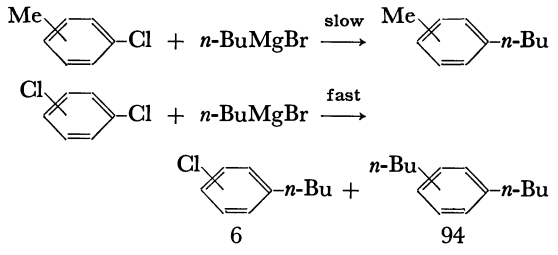
whereas with the latter no reaction occurred at all under similar conditions, the reaction mixture remaining a clear yellow solution. In view of the recently recognized concept that Me_3SiCH_2–transition metal complexes are the best examples of "elimination-stabilized alkyls,"[38] the lack of the catalytic activity of [Ni(dppe)Cl_2] in this case may be attributable primarily to the great stability of the initially formed bis(trimethylsilylmethyl)nickel intermediate. This hypothesis could be partially supported by the isolation of [Ni(dppe)$(CH_2SiMe_3)_2$] as a stable complex in high yield from the reaction of Me_3SiCH_2MgCl with [Ni(dppe)Cl_2] even in chlorobenzene as solvent.[39] However, with the experimental results at hand, it seems hard to find valid reasons for the higher efficiency of dppp as ligand as compared with dppe.[40]

Finally, of particular interest, but rather hard to understand, is that [Ni(dmpe)Cl_2] is among the poor catalysts for reactions with primary alkyl Grignard reagents, but one of the best ones for reactions with secondary alkyl Grignard reagents, although in the latter case extensive isomerization of the alkyl group from secondary to primary takes place during the cross-coupling.[25] This strange trend can not easily be interpreted in terms of the stability order of the organonickel intermediates involved.

Organic Halides and Grignard Reagents: Results summarized in Table 7 contain several features worthy of note.

(1) The present Grignard cross-coupling is equally applicable to substituted halobenzenes, polyhalobenzenes, and condensed aromatic halides. In these cases no positional scrambling is observed. Thus, the organic moiety of the Grignard reagent becomes bonded to the carbon atom which has borne the halogen atom. Therefore, the isomeric purity of the coupling products is very high.

(2) The reactivity order of substituted aryl halides has not yet been studied quantitatively, but judging from the exothermicity of reactions, dichloro- and dibromo-benzene and 1-bromonaphthalene are among the most reactive aryl halides examined, while chlorotoluenes are the least reactive ones. Interestingly, in spite of the low reactivity of monoalkylchlorobenzenes, dichlorobenzenes are smoothly *dialkylated* even in the presence of two-fold excess of dichlorobenzene over the alkyl Grignard reagent to give, for example, a 94: 6 mixture of dibutylbenzene and butylchlorobenzene. The result suggests that the second alkylation step in dichlorobenzene is mechanistically different from the alkylation of chlorotoluenes.



(3) Vinyl chloride is one of the most reactive halides and reacts with aryl and alkyl Grignard reagents with equal efficiency. The reactions using vinyl chloride are usually conducted either in a pressure glass-tube or in an ordinary reaction vessel, as described in Experimental section. These are strongly exothermic reactions and may proceed with violence unless controlled by the dropwise addition of Grignard reagents: care must be taken NOT to add a catalyst to a mixture of the halide and a Grignard reagent, particularly, in a large scale preparation. For example, the addition of a small amount of [Ni(dppp)Cl_2] to a mixture of vinyl chloride and 4-chlorophenylmagnesium bromide in ether at 0 °C led, after a few minutes' induction period, to an uncontrollable violent reaction.

While 1,1- and 1,2-dichloroethylenes react very smoothly with *aryl* Grignard reagents, reactions with *alkyl* Grignard reagents proceed sluggishly to give a mixture of products, usually the homo coupling product of the Grignard reagent predominating. The sluggish and complicated nature of these reactions constitutes, unfortunately, one of the most serious limitations of the present nickel–phosphine catalyzed Grignard coupling.

(4) Vinylic Grignard reagents exhibited relatively low reactivity and vinylmagnesium chloride in THF is one of the least reactive ones. Dihalobenzenes are not completely converted to dialkenylbenzenes even in the presence of [Ni(dmpe)Cl_2]. Therefore, from a synthetic viewpoint, styrene and its derivatives should be prepared from an aryl Grignard reagent and a vinylic halide rather than from an aryl halide and a vinylic Grignard reagent:

Stereochemical aspects of the coupling using vinylic halides or vinylic Grignard reagents have been reported briefly[26] and will be discussed in more detail elsewhere.

(5) The cyclohexyl Grignard reagent couples with almost all of the aryl halides studied, excepting 1,2-dichlorobenzene which gave no dicyclohexylbenzene, but a mixture of cyclohexylbenzene and cyclohexylchlorobenzene. The cyclopropyl Grignard reagent is reluctant to react with halobenzenes; a fair yield of cyclopropylbenzene was obtained with the [Ni(dmpe)-Cl_2] catalyst. It seems of interest to note that the relatively high activity of [Ni(dmpe)Cl_2] in this case is similar to the situation observed for vinylic Grignard reagents, and may be related partially to the special hybridization of cyclopropyl carbon atoms.[43]

(6) Sterically hindered, *ortho*-substituted aryl halides (especially bromides) and Grignard reagents also couple smoothly to afford *ortho*-substituted unsymmetrical biaryls. Chlorobenzene is reluctant to react with the mesityl Grignard reagent. Generally, better yields can be obtained from a combination of a hindered aryl Grignard reagent and a less hindered bromide rather than the reverse combination.

Unfortunately, the action of the *n*-butyl Grignard reagent on mesityl bromide resulted in the formation of mesitylene.

IV. Summary of General Scope and Limitations. The foregoing experimental results reveal that the present nickel–phosphine complex catalyzed Grignard coupling reaction is widely applicable to a variety of

Grignard reagents and various C(sp^2)-halides, with only a few limitations. Generally, for the direct alkylation and arylation of C(sp^2)-halides are required drastic reaction conditions, unless either they are strongly activated by some substituents or certain sophisticated reagents, such as organocuprates, are used.[44] The present reaction requires only a catalytic amount of a nickel–phosphine complex, uses mild reaction conditions, and gives high yields of cross-coupling products of high purity. It seems of interest to compare the present one-step preparation of, for example, the isomeric pure di-*n*-alkylbenzenes with the traditional multistep preparative methods starting with cyclohexenone or phthalic anhydride.[45]

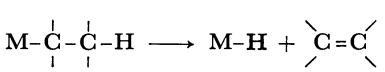
The most serious limitation is that the substituents on the organic halides and on the Grignard reagents are restricted to those which cannot react with Grignard reagents. Reactions of appropriately masked halocarbonyl compounds are now being investigated with a view to overcoming the limitations.

V. A Brief Comment on the Mechanism. Although the mechanism of the present reaction has not yet been fully clarified, almost all of the foregoing results can be rationalized by Scheme 1. The most recent mechanistic studies by Morrell and Kochi[46] also provide results essentially consistent with this Scheme.

On the other hand, Felkin and Corriu and their coworkers have proposed a mechanism involving the oxidative addition of a Grignard reagent to Ni(0) species for a series of nickel-catalyzed Grignard reactions.[19,47]

We recently observed that organolithium reagents cannot be used in place of the corresponding Grignard reagents in the present coupling reaction.[48] Therefore, it seems likely that magnesium moieties of the Grignard reagents may play an important role in the high yield, selective cross-coupling reaction. While much remains to be studied for the elucidation of the mechanism, it seems apparent at least that diorganonickel intermediates are involved in this reaction.

In connection with these mechanistic aspects, it seems of interest to discuss a few special features of this reaction, based on the facts so far recognized concerning organonickel complexes. Firstly, the most remarkable feature of the present reaction is that even alkyl Grignard reagents containing the β-hydrogen(s) give selectively the cross-coupling products in high yields, because a transition metal alkyl containing β-hydrogen(s) is commonly unstable and tends to undergo β-elimination to form a metal hydride and an olefin;[38,49] nickel alkyls being also the case:



For the same reasons, no aging effect on the catalytic activity is also noteworthy. Here again, an important role of magnesium components may be envisaged, as well as the stabilizing effect of the phosphine ligands.

Secondly, the aforementioned reactivity of vinylic halides in striking contrast to vinylic Grignard reagents implies the importance of the interaction between the diorganonickel intermediate and the unsaturated organic component (*cf.* **5** in Scheme 1). Thus, a strong interaction between a vinylic halide and a diorganonickel intermediate favors the catalytic process. On the other hand, the vinylic Grignard reagent as an olefinic component may well compete with the organic halide of comparable or lower coordinating ability for coordination onto the diorganonickel intermediate. This type of interaction may be responsible for the inhibited catalysis encountered with [Ni(dppp)Cl_2] catalyst. The high efficiency of [Ni(dmpe)Cl_2] in this case may be attributable to the expected weak interaction between the electron-rich olefin in the vinylic Grignard reagent and the nickel species bearing the electron-donating phosphine.

Experimental

Materials. Phosphine–nickel(II), –palladium(II), –platinum(II), and –cobalt(II), and amine–nickel(II) complexes were prepared by known methods. In the following list, the references given after the compounds are to the source or method of preparation: [Ni(PPh_3)$_2Cl_2$],[50] [Ni(PPh_2Me)$_2Cl_2$],[51] [Ni($PPhMe_2$)$_2Cl_2$],[52] [Ni{P(*n*-Bu)$_3$}$_2Cl_2$],[53] [Ni(PEt_3)$_2$-Cl_2],[53] [Ni(dppm)$_2Cl_2$],[54] [Ni(dppe)Cl_2],[54] [Ni(dppp)-Cl_2],[54] [Ni(dppb)Cl_2],[55] [Ni(*cis*-dpen)Cl_2],[56] [Ni(dmpe)-Cl_2],[57] [Ni(dmpf)Cl_2],[58] [Ni(dppc)Cl_2],[59] [Ni(bipy)Cl_2],[30b,60] [Ni(py)$_2Cl_2$],[61] [Pd(PPh_3)$_2Cl_2$],[62] [Pd(PEt_3)$_2Cl_2$],[62] [Pt(P-Ph_3)$_2Cl_2$],[62] and [Co(dppp)Cl_2].[63] Cyclopropyl bromide,[64] 1-bromo-[65] and 2-bromo-propene,[65] mesityl bromide,[66] 1-chlorocyclohexene,[67] chloromethyl-trimethylsilane,[68] and -pentamethyldisilane[69] were prepared as reported previously. 9-Bromoanthracene was generously gifted by Dr. T. Kawamura, Department of Hydrocarbon Chemistry, Kyoto University. 4,4′-Dichlorobiphenyl and a solution of chloroprene in *m*-xylene were generously supplied by Kanegafuchi Chemical Industry Co., Ltd. and Toyo Soda Manufacturing Co., Ltd., respectively. Other organic halides were commercially available. Chlorobenzene, bromobenzene, and butyl bromide were purified by distillation before use, but others were used without further purification. Magnesium ribbons were commercially available (Nakarai Chemical). Ether was dried over sodium wire and distilled before use. Tetrahydrofuran (THF) was distilled from $LiAlH_4$ before use.

Grignard Reagents. Grignard reagents were prepared in a standard manner by adding a solution of an organic halide to magnesium ribbons which had been dried under a rapid stream of dry nitrogen by flaming. Magnesium was usually used in 10—20% excess over the halide in order to exhaust the latter. After completion of the addition the mixture was refluxed for about one hour to ensure the reaction. Concentrations of the Grignard reagents were determined by adding one ml of the solution to an excess of standard hydrochloric acid followed by back titration with a standard sodium hydroxide solution.

Coupling Reactions. Detailed procedure for coupling of 1,2-dichlorobenzene with *n*-butylmagnesium bromide will appear in Organic Syntheses,[23] and only several typical procedures are described in detail below. All other reactions were carried out in essentially the same manner. Conversions of reactions and yields of products were determined either by careful distillation or by quantitative GLPC using an appropriate internal standard calibrated against the pure samples. Quantitative GLPC was performed on a Hitachi GC 4B gas-chromatograph using a 3 m × 4 mm column 30% Silicone DC 550 on Celite (60—80). Preparative GLPC was performed on a Varian Aerograph Model 90-P gas-chromatograph, using a 3 or 6 m × 9 mm column packed with 30% Silicone DC 550

on Celite (60—80). Infrared spectra were obtained on a Hitachi EPI G3 Grating spectrophotometer, NMR spectra were obtained with a Varian T-60, EM-360, or HA-100 spectrometer in CCl_4 solutions with TMS, cyclohexane, or benzene as internal standard. Mass spectra were recorded on a Hitachi RMS-4 mass spectrometer.

The following coupling products were identified by spectral (NMR and/or IR) comparison with commercial authentic samples or established spectral data;[70] toluene, ethylbenzene, propylbenzene, cumene, 1,1-diphenylethylene, (*E*)- and (*Z*)-stilbene, styrene, cyclohexylbenzene, 1-phenylnaphthalene, vinylcyclohexane, cyclopropylbenzene, 1-decene, 1-, 2-, and 3-phenylpropene, 1,4-bis(isopropenyl)benzene, 4-isopropenylchlorobenzene and 2,3-dimethyl-1,3-butadiene. Authentic samples of 1-methylcyclohexene,[71] allyltrimethylsilane,[72] benzyltrimethylsilane,[73] and benzylpentamethyldisilane[74] were prepared by reported methods.

Other coupling products are listed below together with some physical constants, spectral and/or analytical data.

A. Procedure for the Examination of Catalytic Activity of Phosphine–Nickel Complexes, Reactivity of Halobenzenes and Solvent Effects. A catalyst was placed in a 50-ml two-necked flask equipped with a stirring bar, a serum cap and a reflux condenser fitted with a three way stopcock. The reaction vessel was then filled with nitrogen after evacuation and charged with an organic halide, anhydrous ether, and an appropriate internal standard (normal alkane) through the serum cap with a syringe. To the mixture was then added a Grignard reagent in a similar way at 0 °C with stirring. The resulting mixture was refluxed for a given period of time and hydrolyzed with a dilute acid. The organic layer was analyzed by GLPC.

B. Procedure for the Examination of Catalytic Activity on Aging. Essentially the same procedure was employed as above, excepting that to the catalyst were added first anhydrous ether and the butyl Grignard reagent at 0 °C, the resulting mixture was allowed to stand at room temperature under nitrogen for a given period of time (aging time), and finally chlorobenzene was added. After refluxing for a given period of time, the mixture was hydrolyzed and an internal standard was added. Data obtained by GLPC analysis are listed in Table 2.

C. Procedures for the Reaction of Aryl Halides. (a) Butylbenzene: In a 300-ml two-necked flask, equipped with a pressure-equalizing dropping funnel, a reflux condenser attached to a nitrogen line and a stirring bar, were placed 430 mg (0.81 mmol) of $[Ni(dppe)Cl_2]$, 10.78 g (95.8 mmol) and 100 ml of anhydrous ether; the nickel complex was insoluble in the mixture. To the mixture was added dropwise butylmagnesium bromide in ether (110 mmol; 40 ml of 2.8 M solution) at room temperature with stirring under nitrogen over 20 min. The mixture changed immediately to an yellow clear and then brown solution. After, 22 h-reflux the mixture was hydrolyzed with diluted hydrochloric acid under cooling with an ice bath. The organic layer and ether extracts from the aqueous layer were combined, washed with water, saturated sodium hydrogencarbonate solution and water, and then dried over calcium chloride. After evaporation of solvent distillation gave 9.80 g (76% yield based on the chlorobenzene) of butylbenzene boiling at 70 °C/19 mmHg;[75] n_D^{15} 1.4928. NMR (CCl_4, TMS): δ 7.11 (s, 5H), 2.59 (t, 7 Hz, 2H), 2.0—0.8 (m, 7H); IR: for monosubstituted benzene; 1945 (w), 1875 (w), 1802 (w), 1750 (w), 746 (s), 702 (s) cm^{-1}. Careful GLPC analysis and mass spectrometry, showing a base peak *m/e* 91 in addition to a parent peak *m/e* 134, but no *m/e* 105, clearly indicated no contamination with *sec*-butylbenzene.[76]

(b) 9-Trimethylsilylmethylanthracene: In a 50-ml two-necked flask equipped as described in A were placed $[Ni(PPh_3)_2Cl_2]$ (32 mg; 0.06 mmol), 9-bromoanthracene (1.017 g; 3.95 mmol) and 5 ml of anhydrous ether. To the stirred mixture was added dropwise an ether solution of trimethylsilylmethylmagnesium chloride (5.14 mmol) through a serum cap with a syringe at room temperature. Immediately an exothermic reaction occurred. The resulting brownish mixture was stirred at room temperature for 18 h. usual work-up and distillation afforded 0.74 g (71% yield based on the halide) of 9-trimethylsilylmethylanthracene as slightly yellow crystals, mp 59—60 °C, NMR (CCl_4) δ: 8.3—7.2 (m, 9H), 3.09 (s, 2H), −0.03 (s, 9H). Found: C, 81.62; H, 7.41. Calcd for $C_{18}H_{20}Si$: C, 81.75; H, 7.62%.

D. Procedures for the Reaction of Vinyl Chloride. (a) In a Pressure Glass Tube; 1-Vinylnaphthalene: Vinyl chloride (6 ml) was dried by passing the gas through a phosphorus pentoxide–calcium chloride column and condensed at −78 °C in a graduated, 100-ml pressure glass tube containing 178 mg (0.34 mmol) of $[Ni(dppe)Cl_2]$. To it were added at the same temperature 10 ml of anhydrous ether and a solution of 1-naphthylmagnesium bromide (55 mmol) in 50 ml of a mixed solvent of benzene, ether, and THF (3: 2: 1). The glass tube was stoppered and allowed to warm up to 0 °C. The resulting homogeneous solution was then kept standing at room temperature for 20 h. Work-up as above and distillation under reduced pressure gave 6.8 g (80% based on the Grignard reagent) of 1-vinylnaphthalene boiling at 89 °C/5 mmHg, n_D^{25} 1.6418 (lit,[78] bp 87 °C/2 mmHg, n_D^{25} 1.6436).

(b) In a Three-necked Flask; 4-Chlorostyrene: A solution of 4-chlorophenylmagnesium bromide was prepared in the usual manner from 4.9 g (0.20 g-atom) of magnesium and 38.3 g (0.20 mol) of 4-chloro-1-bromobenzene in 150 ml of anhydrous ether.

A 500-ml three-necked flask was equipped with a mechanical stirrer, a reflux condenser attached to a drying tube, and a gas inlet tube reaching the bottom. In the flask were placed about 50 mg (≈0.1 mmol) of $[Ni(dppp)Cl_2]$ and 100 ml of dry ether. The flask was cooled in an ice bath. Through the inlet tube was introdued 15 g (0.24 mol) of vinyl chloride which had been dried by passing the gas through a phosphorus pentoxide–calcium chloride column (about 40 cm × 2 cm diameter). The gas inlet tube was replaced by a pressure-equalizing dropping funnel, to which was transferred the Grignard solution prepared above under a nitrogen atmosphere. The Grignard solution was then added dropwise to the mixture containing the nickel catalyst, with stirring and cooling in an ice bath, over 45 min. The reaction mixture changed to yellow-brown with formation of two liquid layers. After completion of the addition the mixture was stirred at 0 °C for 30 min and then at room temperature for 1.5 h. The mixture was then cooled in an ice bath hydrolyzed by slow addition of about 150 ml of about 2 M-hydrochloric acid. After the usual work-up, distillation in the presence of a small amount of hydroquinone through a short Vigreux column under reduced pressure gave 21.5—22.0 g (78—79%) of 4-chlorostyrene, bp 78—80 °C/18 mmHg or 85—85.5 °C/25 mmHg, n_D^{20} 1.5664, (lit,[79] bp 38 °C/2.2 mmHg, n_D^{20} 1.5650), as a colorless to light yellow liquid.

1,2-Dibutylbenzene: bp 76—81 °C/3.5 mmHg, n_D^{20} 1.4920 (lit,[45a,b] n_D^{20} 1.4916). NMR: 7.00 (s, 4H), 2.60 (t, J=8.5 Hz, 4H), 1.7—0.7 (m, 14H). (Found: C, 88.31; H, 11.75%.) *1,3-Dibutylbenzene*: bp 84 °C/5 mmHg, n_D^{20} 1.4873 (lit,[45c] n_D^{25} 1.4860), d_4^{20} 0.8564. NMR: 7.1—6.8 (m, 4H), 2.57 (t, J= 8 Hz, 4H), 1.9—0.7 (m, 14H). (Found: C, 88.19; H, 11.41 %.) *1,4-Dibutylbenzene*: bp 93 °C/6 mmHg, n_D^{20} 1.4905 (lit,[80] n_D^{20} 1.4883). NMR: 6.93 (s, 4H), 2.54 (t, J=8 Hz, 4H), 1.8—0.6 (m, 14H). (Found: C, 88.65; H, 11.84%.) *2-Butyl-1-chlorobenzene*: n_D^{20} 1.5115 (lit,[81] n_D^{25} 1.5087). NMR: 7.4—6.9 (m, 4H), 2.70 (t, J=7.5 Hz, 2H), 1.9—0.7 (m, 7H). *3-Butyl-1-chlorobenzene*: n_D^{20} 1.5093. NMR: 7.3—6.88 (m, 4H), 2.60

(t, J=7.5 Hz, 2H), 1.9—0.7 (m, 7H). Found: C, 71.83; H, 8.15%. Calcd for $C_{10}H_{13}Cl$: C, 71.21; H, 7.77%. *4-Butyl-1-chlorobenzene*: n_D^{20} 1.5091. NMR: 7.11 (cent. of m, 4H), 2.56 (t, J=7.5 Hz, 2H), 1.9—0.7 (m, 7H). Found: C, 71.48; H, 7.86%. Calcd for $C_{10}H_{13}Cl$: C, 71.21; H, 7.77%. *2-Butyltoluene*: bp 85—86.5 °C/20 mmHg, $n_D^{18.5}$ 1.4981 (lit,[82] $n_D^{18.4}$ 1.49662). NMR: 7.03 (s, 4H), 2.58 (t, J=8 Hz, 2H), 2.11 (s, 3H), 1.8—0.8 (m, 7H). *3-Butyltoluene*: bp 90 °C/20 mmHg, $n_D^{18.5}$ 1.4937 (lit,[82] $n_D^{18.4}$ 1.49315). NMR: 7.2—6.8 (m, 4H), 2.55 (t, J=7 Hz, 2H), 2.33 (s, 3H), 1.8—0.7 (m, 7H). *4-Butyltoluene*: bp 81 °C/20 mmHg, n_D^{14} 1.4939 (lit,[82] $n_D^{14.2}$ 1.4912). NMR: 6.95 (s, 4H), 2.54 (t, J=8 Hz, 2H), 2.29 (s, 3H), 1.8—0.8 (m, 7H). (Found: C, 88.90; H, 10.99%.) *4-Butylanisole*: bp 165—170 °C/100 mmHg, n_D^{20} 1.5013 (lit,[83] bp 120 °C/19 mmHg, n_D^{15} 1.5027). NMR: 6.94, 6.66 (q, $A_2'B_2'$, 4H), 3.68 (s, 3H), 2.50 (t, J=7 Hz, 2H), 1.9—0.7 (m, 7H). (Found: C, 80.60; H, 10.06%.) *4-Butyl-1-trifluoromethylbenzene*: n_D^{20} 1.4402. NMR: 7.50, 7.21 (q, $A_2'B_2'$, 4H), 2.68 (t, J=7 Hz, 2H), 1.9—0.7 (m, 7H). Found: C, 65.00; H, 6.69%. Calcd for $C_{11}H_{14}F_3$: C, 65.04; H, 6.95%. *1-Butylnaphthalene*: bp 97.5—100.5 °C/5 mmHg (lit,[84] bp 287—288 °C/745 mmHg). NMR: 8.1—7.2 (m, 7H), 3.03 (t, J=9 Hz, 2H), 2.0—0.7 (m, 7H). *1,2-Bis(trimethylsilylmethyl)benzene*: mp 2—3 °C, n_D^{20} 1.4967 (lit,[85] mp 2—3 °C, n_D^{20} 1.4950). NMR: 6.87 (s, 4H), 1.99 (s, 4H), −0.01 (s, 18H). *1,3-Bis(trimethylsilylmethyl)-benzene*: mp 4—10 °C, n_D^{20} 1.4925 (lit,[86] mp 4 °C, n_D^{20} 1.4919). NMR: 7.17—6.47 (m, 4H), 1.97 (s, 4H), −0.02 (s, 18H). *1,4-Bis(trimethylsilylmethyl)benzene*: mp 64—64.5 °C (lit,[86] mp 61—63 °C). NMR: 6.80 (s, 4H), 1.93 (s, 4H), −0.02 (s, 18 H). *1-Trimethylsilylmethylnaphthalene*: n_D^{20} 1.5751. NMR: 8.04—6.98 (m, 7H), 2.52 (s, 2H), −0.02 (s, 9H). Found: C, 78.18; H, 8.39%. Calcd for $C_{14}H_{18}Si$: C, 78.44; H, 8.46%. *4,4'-Bis(trimethylsilylmethyl)biphenyl*: mp 82—83 °C. NMR: 7.22, 6.84 ($A_2'B_2'$ q, J=8 Hz, 8H), 1.95 (s, 4H), −0.09 (s, 18H). Found: C, 73.65; H, 9.20%. Calcd for $C_{20}H_{22}Si_2$: C, 73.54; H, 9.26%. *2-(o-Anisyl)mesitylene*: mp 55—56 °C. NMR: 7.3—6.8 (m, 4H), 6.76 (s, 2H), 3.67 (s, 3H), 2.24 (s, 3H), 1.89 (s, 6H). Found: C, 84.81; H, 7.76%. Calcd for $C_{16}H_{18}O$: C, 84.91; H, 8.01%. *2-(1-Naphthyl)mesitylene*: mp 70—72 °C. NMR: 7.9—7.05 (m, 7H), 6.88 (s, 2H), 2.33 (s, 3H), 1.85 (s, 6H). Found: C, 92.14; H, 7.71%. Calcd for $C_{19}H_{18}$: C, 92.63; H, 7.36%. *2-Phenylmesitylene*: NMR: 7.5—6.95 (m, 5H), 6.80 (s, 2H), 2.28 (s, 3H), 1.97 (s, 6H). *2-Cyclohexylchlorobenzene*: n_D^{20} 1.5421 (lit,[77] n_D^{20} 1.5436). (Found: C, 73.85; H, 7.64%.) *1,3-Dicyclohexylbenzene*: n_D^{20} 1.5370 (lit,[77] n_D^{20} 1.5356). NMR: 7.27—6.77 (m, 5H), 2.8—2.2 (br, 2H), 2.2—0.6 (m, 20H). *1,4-Dicyclohexylbenzene*: mp 103—103.5 °C (lit,[87] mp 101—102 °C). NMR: 7.05 (s, 4H), 2.8—2.2 (br, 2H), 2.2—0.6 (m, 20H). *1-Cyclohexylnaphthalene*: bp 172—174 °C/8 mmHg, n_D^{20} 1.6044 (lit,[88] bp 178—183 °C/12 mmHg, $n_D^{19.3}$ 1.6040). *4-Isopropenyl-1-bromobenzene*: n_D^{20} 1.5830 (lit,[89] n_D^{20} 1.5834). NMR: 7.57—7.17 (m, 4H), 5.31 (br, 1H), 5.06 (m, 1H), 2.13 (br, 3H). *2-Isopropenyltoluene*: n_D^{20} 1.5152 (lit,[90] n_D^{20} 1.5155). NMR: 7.06 (s, 4H), 5.13 (m, 1H), 4.83 (m, 1H), 2.18 (s, 3H), 2.03 (br, 3H). *3,5-Diisopropenyl-1-chlorobenzene*: n_D^{20} 1.5695. NMR: 7.40—7.23 (m, 3H), 5.37 (m, 2H), 5.11 (m, 2H), 2.13 (m, 6H). Found: C, 74.58; H, 6.89%. Calcd for $C_{12}H_{13}Cl$: C, 74.80; H, 6.80%. *1,4-Dichloro-2,5-diisopropenylbenzene*: n_D^{20} 1.5601. NMR: 7.25 (s, 2H), 5.13 (m, 2H), 5.03 (m, 2H), 2.03 (m, 6H). Found: C, 63.61; H, 5.47%. Calcd for $C_{12}H_{12}Cl_2$: C, 63.45; H, 5.32%. *1-Isopropenylnaphthalene*: n_D^{20} 1.6075 (lit,[91] n_D^{20} 1.6085). NMR: 8.10—7.13 (m, 7H), 5.37 (m, 1H), 5.07 (m, 1H), 2.20 (m, 3H). (Found: C, 92.55; H, 7.37%.) *2-Benzyl-3-phenylpropene*: bp 120—123 °C/5 mmHg, n_D^{20} 1.5652. NMR: 7.10 (br. s, 10H), 4.80 (s, 2H), 3.20 (s, 4H). Found: C, 92.00; H, 7.97%. Calcd for $C_{16}H_{16}$: C, 92.26; H, 7.74%. (E)-*1,2-dicyclohexylethylene*: n_D^{20} 1.4881. NMR: 5.04 (dd, J= 2 and 6 Hz, 2H), 2.5—2.0 (br, 2H), 2.0—0.7 (m, 20H). IR (neat): 965 cm^{-1} (*trans* olefin). Found: C, 87.33; H, 12.61%. Calcd for $C_{14}H_{24}$: C, 87.42; H, 12.58%. *2-Phenyl-1,3-butadiene*: bp 62.5 °C/20 mmHg, n_D^{20} 1.5487 (lit,[92] n_D^{20} 1.5489). NMR: 7.30 (s, 5H), 7.0—6.2 (m, 1H), 5.4—4.9 (m, 4H). *1-Butylcyclohexene*: bp 102 °C/65 mmHg, n_D^{20} 1.4610 (lit,[71] bp 180.8—182.9 °C, n_D^{20} 1.4591). NMR: 5.37 (br, 1H), 2.2—0.6 (m, 17H). IR (neat): 1670 cm^{-1} (trisubstituted olefin).

We thank the Ministry of Education for Grant-in-Aid (No. 911511, 011006, and 985156) and The Asahi Glass Foundation for the Contribution to Industrial Technology for financial support of this work. Our thanks are also due to Toshiba Silicone Co., Ltd. for a gift of chlorosilanes.

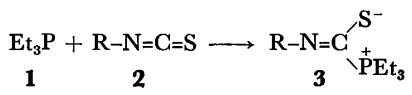
(Received April 13, 1976)

The adducts (**3**) of triethylphosphine (**1**) and several isothiocyanates (**2**) were prepared. Equilibrium constants of the adducts (**5**) from tributylphosphine (**4**) and phenyl (**2b**), benzoyl (**2e**), and *p*-toluenesulfonyl isothiocyanates (**2f**) were determined in some solvents. The ^{31}P chemical shifts of **5** were measured in DMF, and correlated with Hammett σ_p constants. Reactions of **3e** with **1** and **2e** gave phosphonium thiocyanates of **6** and **7**, and of **11**, respectively. Methylation of **3e** gave *S*-methyl *N*-benzoylmonothiocarbamate (**16**).

It has been known for 100 years that triethylphosphine forms the *1*:*1* adducts with carbon disulfide and isothiocyanates,[1] and the presence of *P–C* bond was exemplified by X-ray crystallographic study[2a] after much discussion. However, little is known on the reaction of the adducts and the formation of reactive alkylidenephosphoranes was recently reported by the reaction of tributylphosphine and carbon disulfide adduct with active acetylenes.[3]

This paper describes the general formation of the adducts of trialkylphosphines and several isothiocyanates, the equilibrium of the adducts in solution[4] and ^{31}P chemical shifts of the adducts,[4] and reactions of the adducts of triethylphosphine and benzoyl isothiocyanate.

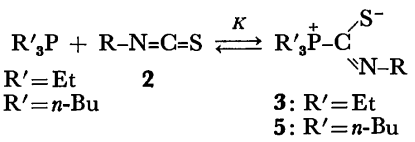
Formation of the Adducts (3). An equimolar mixture of triethylphosphine (**1**) and isothiocyanates (**2**) gave adducts (**3**) in hexane and/or ether. The results are summarized in Table 1.



a, R=Me; **b**, R=Ph; **c**, R=α-$C_{10}H_7$; **d**, R=MeCO; **e**, R=PhCO; **f**, R=*p*-$MeC_6H_4SO_2$; **g**, R=Ph_2P(S)

The yields of **3** were high when the substituent (R) is electron-withdrawing. The adducts (**3b, e,** and **f**) gave correct elemental analyses, but it was not possible to obtain them for other adducts. Especially, **3d** and **3g** decomposed during recrystallization. The adducts of tributylphosphine and methyl and phenyl isothiocyanates could not be precipitated from the reaction mixture under similar conditions. These facts are compatible with observed equilibrium constants (see below).

Equilibrium of the Adducts in Solution. The equilibrium constants (*K*) of the adducts (**3** and **5**) from isothiocyanates (**2**) and tributylphosphine (**4**) or **1** were determined for the first time in some solvents spectrophotometrically, although the presence of the equilibrium was suspected before.[2c]



1: R′=Et **4**: R′=*n*-Bu **2** **3**: R′=Et **5**: R′=*n*-Bu

In the present systems, the extinction coefficients due to starting materials, phosphine and isothiocyanates, were negligible at 340 nm. Therefore, the extinction

TABLE 1. THE ADDUCTS (3) OF TRIETHYLPHOSPHINE AND ISOTHIOCYANATES

3	R	Mp (°C)	Yield (%)	Elemental analyses (%)[a] C	H	N	S

a) The values in the parentheses are the calculated values. b) Mol wt: 329 (VPO method in dioxane) (calcd: 331.9), indicating almost no dissociation in dioxane.

coefficients due to the formation of the adducts at 340 nm were measured at several ratios of phosphine to the corresponding isothiocyanate, and the K value was calculated according to Drago's method.[5] In most cases, isosbestic points were observed, indicating the presence of equilibrium.[4] A typical example is shown in Fig. 1. The results are summarized in Table 2.

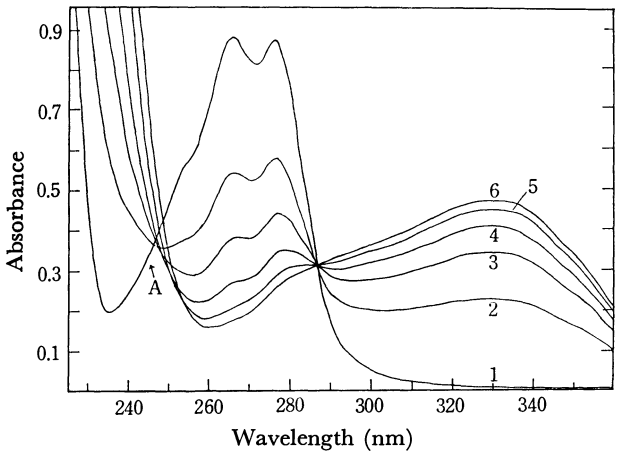

Fig. 1. UV Spectra of triethylphosphine (**1**) and phenyl isothiocyanate (**2b**) system in acetonitrile (24 °C). The ratio of **1** to **2b**: 2=4.22; 3=10.5; 4=21.1; 5=42.1; 6=84.3. 1 is the spectrum of **2b**. Concentration of **2b**, 7.42×10^{-5} M, was maintained constant throughout the measurement (*cf.* Table 4). A: One of isosbestic points should appear here, which is not observed due to absorption of excess **1**.

Table 2. Equilibrium Constants (K) at 24 °C

System	Solv.	K (1/mol)	ε (340 nm)	λ_{max} (nm)	Dielectric constant
4+**2b**	MeCN	840±43	6500	331	37.5
	Me_2CO	323±6	5600	337	20.7
	CH_2Cl_2	277±20	6400	334	8.9
	Et_2O	3.7—6.7		340	4.3
	n-C_6H_{14}	1.5—3.5		340	1.9
1+**2b**	MeCN	2910±120	6100	330	
4+**2e**	MeCN	$(3.4\pm1.0)\times10^4$		315	
4+**2f**	MeCN	$(2.4\pm0.5)\times10^4$		307	

The equilibrium constant becomes larger and hence the stability of the adducts increases according to the increase of polarity of solvents and the introduction of electron-withdrawing substituents. These effects are accompanied by blue shift of λ_{max} of absorption of the adducts. The result is consistent with $n\rightarrow\pi^*$ nature of the absorption but the molar extinction coefficient (*ca.* 6000) is very large for that. In the case of **5f**, the equilibrium lies completely to the adducts when two moles of **4** is added to one mole of **2f** in acetonitrile. The equilibrium constant of **2b** is smaller with **4** than that with **1**, probably because of the bulkiness of **4**, but this does not affect λ_{max} of the absorption. These results are consistent with the easiness of formation of the adducts during their preparation.

Since the attainment of the equilibrium between **4** and methyl isothiocyanate (**2a**) was very slow and isosbestic points could not be observed in the cases of allyl and diphenylphosphinothioyl isothiocyanates (**2g**), equilibrium constants for these systems could not be determined. Similar equilibrium of the betaine with *P–C* bond has been determined in the reaction of tributylphosphine (**4**) with benzylidenemalononitrile.[6a]

^{31}P Chemical Shifts of the Adducts (5). The ^{31}P-NMR chemical shifts (δ_P) of the adducts (**5**) were measured by mixing *N,N*-dimethylformamide (DMF) solutions of **4** and **2** to yield samples of about 0.83 M concentration for each reagent. The results are shown in Table 3.

Table 3. ^{31}P Chemical shifts of the adducts (**5**) in DMF at 34 °C

5	R	δ_P (ppm)	σ_p of R[a]
5a	Me	−18.3	−0.17
	CH_2=$CHCH_2$	−18.1	—
5b	Ph	−20.0	−0.01
5c	α-$C_{10}H_7$	−20.9	—
5g	Ph_2P (S)	−21.9 (J_{PP} 110 Hz)	0.28[8]
	Et_2NCS	−22.2	0.34[b]
5e	PhCO	−23.1	0.43[9]
5d	MeCO	−23.3	0.50
5f	p-$MeC_6H_4SO_2$	−26.8	0.72[c]

a) The σ_p values were taken from Ref. 7, unless otherwise stated. b) For MeNHCS group. c) For $MeSO_2$ group.

The δ_P values of the adducts (**5**) and the adduct of tributylphosphine with carbon disulfide (δ_P=−21.5 ppm in DMF) are similar to those of phosphonium salts (*cf.* $Bu_3\overset{+}{P}Et$ Br^-, δ_P=−35.5 ppm),[6b] supporting the betaine structure of **5** with *P–C* bond in solution.

Plots of the δ_P data against Hammett σ_p values of the R group gave a rather good straight line (ρ=−8.68, r=0.979), where two of σ_p values were quoted from those of the corresponding analogous substituents.

In these measurements, no residual **4** was detected except for **2a**, in which the rate of formation of the adduct should be slow. The equilibrium is shifted almost to the adducts (**5**) in the concentration used, as shown by a simple calculation using the K values shown in Table 2. However, when excess **4** was used for **2b**, two peaks were observed which correspond to **4** and **5b**, respectively, showing that the rate of equilibration is slow for observation by NMR.

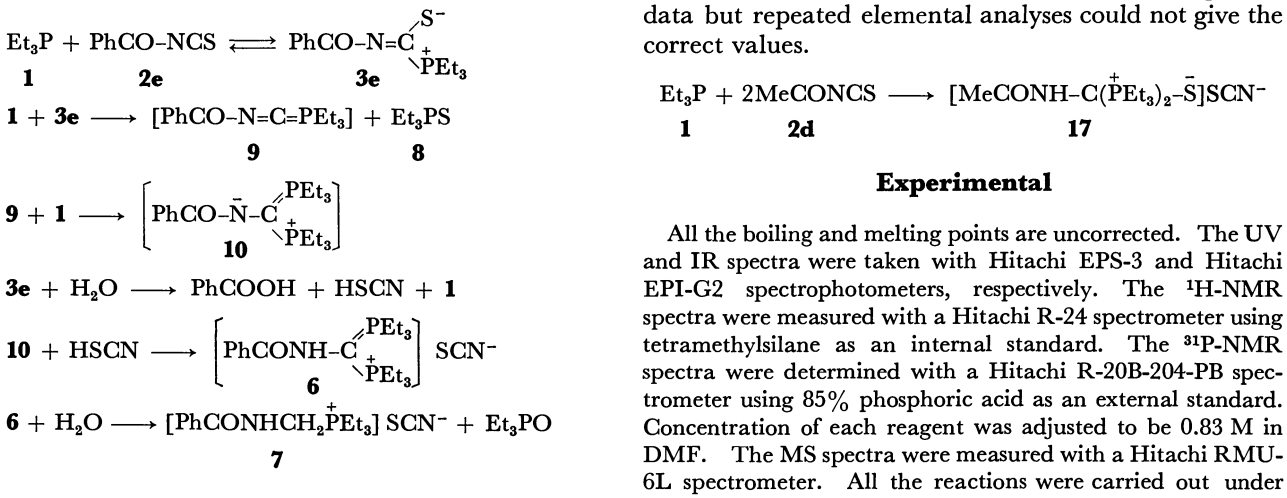
Some Reactions of the Adducts (3). In the measurement of the equilibrium constant of the adduct (**3e**), a deviation from isosbestic points in UV spectra was observed when a large excess of **4** was used.

Therefore, a mixture of benzoyl isothiocyanate (**2e**) and two molar amounts of **1** was refluxed in acetone for 2 h. α-Triethylphosphonio-α-benzoylaminomethylenetriethylphosphorane thiocyanate (**6**), benzoylaminomethyltriethylphosphonium thiocyanate (**7**), triethylphosphine sulfide (**8**), and benzoic acid were obtained in 73, 14, 72, and 53% yields, respectively.

Two phosphorus atoms in **6** were equivalent in ^{31}P-NMR spectrum. Reaction of an equimolar mixture of **1** and **3e** gave a similar result.

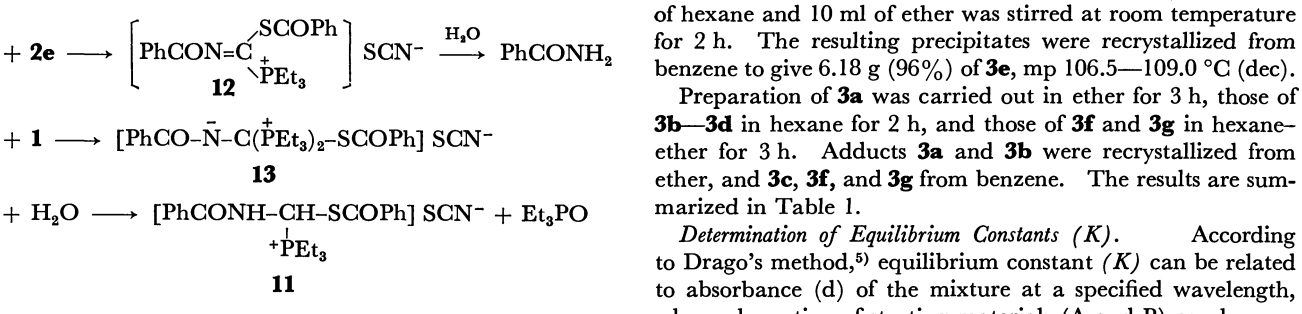
The compound **7** is considered to be a hydrolysis product of **6** by moisture in acetone. In fact, standing of a mixture of **2e** and two molar amounts of **1** in acetone at room temperature for 71 h gave no **6**, but **7**, **8**, and benzoic acid in 61, 65, and 34% yields, respectively.

Their formation can be rationalized by the following scheme.

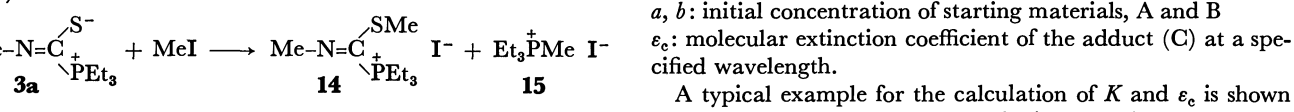


A facile desulfurization of **3e** by **1** to form a new heterocumulene (**9**) is assumed as a preceding step for formation of betaine (**10**), which is stabilized as the phosphonium salt (**6**).

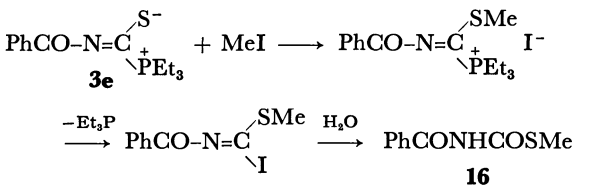
On the other hand, reaction of **1** with two molar amounts of **2e** in refluxing acetone afforded benzamide (23%) and α-benzoylamino-α-benzoylthiomethyltriethylphosphonium thiocyanate (**11**) (27%). This reaction is explained as follows.



Methylation of **3a** with methyl iodide in ether gave triethyl-α-methylimino-α-methylthiomethylphosphonium iodide (**14**, 44%) at room temperature along with a small amount of triethylmethylphosphonium iodide (**15**).



Similar methylation of **3b** gave only **15**. On the other hand, methylation of **3e** in refluxing acetone afforded 31% of *S*-methyl *N*-benzoylmonothiocarbamate (**16**) and 46% of benzamide. The formation mechanism is considered as follows.



The adduct (**3f**) was stable in refluxing acetonitrile against **1** or methyl iodide, but gave 22% of **15** and 64% of *p*-toluenesulfonamide in refluxing methyl iodide.

Reaction of **1** with two molar amount of **2d** afforded a substance considered to be **17** based on the spectral data but repeated elemental analyses could not give the correct values.

Experimental

All the boiling and melting points are uncorrected. The UV and IR spectra were taken with Hitachi EPS-3 and Hitachi EPI-G2 spectrophotometers, respectively. The ^{1}H-NMR spectra were measured with a Hitachi R-24 spectrometer using tetramethylsilane as an internal standard. The ^{31}P-NMR spectra were determined with a Hitachi R-20B-204-PB spectrometer using 85% phosphoric acid as an external standard. Concentration of each reagent was adjusted to be 0.83 M in DMF. The MS spectra were measured with a Hitachi RMU-6L spectrometer. All the reactions were carried out under nitrogen.

Materials. Triethylphosphine,[10] acetyl,[11] benzoyl,[12] *p*-toluenesulfonyl,[13] diphenylphosphinothioyl,[14] and *N,N*-diethylthiocarbamoyl isothiocyanates[15] were prepared by the reported methods. The others were commercially available and used after purification.

Preparation of the Adducts (3). A typical procedure is described for **3e**.

A mixture of 2.72 g (23.0 mmol) of triethylphosphine (**1**) and 3.80 g (23.3 mmol) of benzoyl isothiocyanate (**2e**) in 60 ml of hexane and 10 ml of ether was stirred at room temperature for 2 h. The resulting precipitates were recrystallized from benzene to give 6.18 g (96%) of **3e**, mp 106.5—109.0 °C (dec).

Preparation of **3a** was carried out in ether for 3 h, those of **3b**—**3d** in hexane for 2 h, and those of **3f** and **3g** in hexane–ether for 3 h. Adducts **3a** and **3b** were recrystallized from ether, and **3c**, **3f**, and **3g** from benzene. The results are summarized in Table 1.

Determination of Equilibrium Constants (K). According to Drago's method,[5] equilibrium constant *(K)* can be related to absorbance (d) of the mixture at a specified wavelength, where absorption of starting materials (A and B) can be neglected.

$$A + B \overset{K}{\rightleftharpoons} C$$

$$1/K = d/\varepsilon_c + \varepsilon_c/d \times ab - (a+b)$$

a, b: initial concentration of starting materials, A and B

ε_c: molecular extinction coefficient of the adduct (C) at a specified wavelength.

A typical example for the calculation of K and ε_c is shown in Table 4, and the UV spectra of this system is shown in Fig. 1.

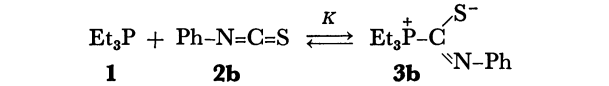


Table 4. Calculation of equilibrium constant of triethylphosphine (**1**) and phenyl isothiocyanate (**2b**) in acetonitrile (24 °C)

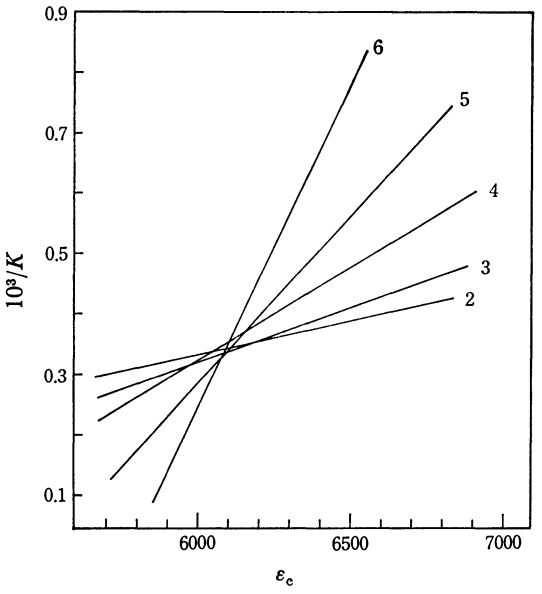

Fig. 2. Plot of ε_c against $10^3/K$ shown in Table 4.

Plot of $1/K$ *vs.* ε_c for each mixture gives a straight line, and $1/K$ and ε_c are determined at the cross point (Fig. 2).

Reactions of Triethylphosphine (1) with Benzoyl Isothiocyanate (2e). a) *2*: *1* reaction: 1) A mixture of 1.76 g (14.7 mmol) of **1** and 1.25 g (7.68 mmol) of **2e** in 30 ml of acetone was refluxed for 2 h. After evaporation of acetone, a small amount of benzene was added to the residue to precipitate 1.20 g (2.80 mmol, 73%) of **6**. Standing of the filtrate afforded 0.163 g (0.52 mmol, 14%) of **7**. The filtrate was chromatographed on silica gel. Elution with benzene–acetone (19: 1) gave 0.25 g (2.05 mmol, 53%) of benzoic acid and 0.415 g (2.76 mmol, 72%) of **8**, the separation of which was carried out using aqueous sodium carbonate. The spectral data of **8** were in agreement with those of an authentic sample.

6: mp 132.5—134.0 °C (from benzene–acetone); IR (KBr): 3240 (NH), 2050 ($^-$SCN), and 1660 cm^{-1} (CO). The ^{1}H-NMR spectrum in $CDCl_3$ showed a broad singlet at δ 8.65 due to NH (1H) proton and the signal disappeared by addition of D_2O; ^{31}P-NMR (DMF): δ_P −35 ppm.

Found: C, 59.13; H, 8.56; N, 6.65; S, 7.60%. Calcd for $C_{21}H_{36}N_2OP_2S$: C, 59.13; H, 8.51; N, 6.57; S. 7.52%.

7: mp 127.5—128.5 °C (from acetone); IR (KBr); 3210 (NH), 2050 ($^-$SCN), and 1650 cm^{-1} (CO). The ^{1}H-NMR spectrum in $CDCl_3$ showed signals at δ 4.51 (dd, J_{NHCH} 6.0, J_{PCH} 5.3 Hz, 2H, CH_2) and 9.35 (bs, 1H, NH). By addition of D_2O, the latter disappeared and the former changed to a doublet (J 5 Hz); ^{31}P-NMR (DMF): δ_P −28 ppm.

Found: C, 57.78; H, 7.75; N, 9.32; S, 10.18%. Calcd for $C_{15}H_{23}N_2OPS$: C, 58.04; H, 7.47; N, 9.02; S, 10.33%.

2) A mixture of 0.573 g (4.85 mmol) of **1** and 1.306 g (4.65 mmol) of **3e** in 50 ml of acetone was refluxed for 3 h. Similar treatment gave 0.543 g (1.27 mmol, 55%) of **6**, 0.133 g (0.43 mmol, 18%) of **7**, 0.283 g (1.9 mmol, 81%) of **8**, and 0.134 g (1.09 mmol, 47%) of benzoic acid.

3) Reaction of 0.959 g (8.11 mmol) of **1** and 0.721 g (4.42 mmol) of **2e** in 20 ml of acetone at room temperature for 71 h afforded 0.42 g (1.35 mmol, 61%) of **7**, 0.216 g (1.44 mmol, 65%) of **8**, and 91 mg (0.75 mmol, 34%) of benzoic acid.

b) *1*: *2* reaction. A mixture of 1.27 g (10.8 mmol) of **1** and 3.55 g (21.7 mmol) of **2e** in 50 ml of acetone was refluxed for 4.5 h. After evaporation, small amounts of benzene and acetone were added to precipitate 1.30 g (2.91 mmol, 54%) of **11**. The filtrate was chromatographed on silica gel. Elution with acetone gave 0.60 g (4.95 mmol, 23%) of benzamide. From other fractions, **8** and benzoic acid were identified by IR.

11: mp 151.0—152.0 °C (from benzene–acetone); IR (KBr): 3150 (NH), 2050 ($^-$SCN), 1652, and 1678 cm^{-1} (CO). The NMR spectrum in $CDCl_3$ showed signals at δ 6.97 (dd, J_{HNCH} 7.8, J_{PCH} 9.6 Hz, 1H, CH) and 10.3 (bd, 1H, NH). By addition of D_2O, the latter disappeared and the former changed to a doublet (J_{PCH} 9.6 Hz). Mol wt (VPO method in pyridine): 451.2 (calcd 477.8).

Found: C, 59.39; H, 6.18; N, 6.27; S, 14.75%. Calcd for $C_{22}H_{27}N_2O_2P_2S_2$: C, 59.17; H, 6.09; N, 6.27; S, 14.36%.

Methylation of 3. a) **3a**: A mixture of 0.761 g (3.98 mmol) of **3a** and 0.652 g of methyl iodide in 10 ml of ether was stirred overnight at room temperature to give 0.58 g (44%) of **14**, mp 101.5—103.0 °C (from 2-propanol).

Found: C, 32.51; H, 6.30; N, 4.06%. Calcd for $C_9H_{21}NPSI$: C, 32.44; H, 6.35; N, 4.20%.

Before the recrystallization of **14**, the presence of **15** was confirmed by NMR.

b) **3b**: A mixture of 1.08 g (4.27 mmol) of **3b** and 0.66 g of methyl iodide in 10 ml of ether was stirred overnight to precipitate **15** (1.01 g, 91%). The spectral data were in agreement with an authentic sample.

c) **3e**: A mixture of 0.622 g (2.21 mmol) of **3e** and 0.5 ml of methyl iodide in 30 ml of acetone was refluxed for 1 h. After evaporation, benzene was added to precipitate 37 mg of benzamide. The filtrate was chromatographed on silica gel. Elution with benzene–acetone (9: 1) gave 0.132 g (0.68 mmol, 31%) of **16**, mp 152 °C (from methanol) (lit,[16] 152—153 °C). IR (KBr): 3250 (NH), 1698 (SCO), and 1630 cm^{-1} (PhCO); MS: *m/e* 195 (M^+, 35%), 147 ($PhCONCO^+$, 95), 105 ($PhCO^+$, *ca.* 100), and 77 (Ph, 100).

Elution with benzene–acetone (3: 1) gave 74 mg of benzamide (46% in total).

d) **3f**: A solution of 0.978 g (2.96 mmol) of **3f** in 30 ml of methyl iodide was refluxed for 20 h. After evaporation, 0.171 g (22%) of **15** was obtained. The filtrate was chromatographed on silica gel. Elution with benzene–acetone (4: 1) gave 0.319 g (64%) of *p*-toluenesulfonamide.

Reaction of 1 and Acetyl Isothiocyanate (2d) in the Ratio of 1: 2.

A mixture of 0.68 g (5.75 mmol) of **1** and 1.15 g (11.4 mmol) of **2d** in 50 ml of acetone was stirred at room temperature for 6 days. The resulting precipitates were collected and recrystallized from methanol to give 0.279 g of **17**. The filtrate was chromatographed on silica gel. Elution with benzene–acetone (3: 1) gave 0.197 g (23%) of **8**. **17**: mp 158–159 °C (from MeOH); IR (KBr): 3150 (NH), 2050 (-SCN), and 1680 cm^{-1} (CO); NMR (D_2O): δ 2.2 (s, 3H, Me) and 0.9—3.0 (m, 30H, 6Et).

Found: C, 47.21—47.48; H, 8.18—8.48; N, 9.93—11.64; S, 14.51—19.09%. Mol wt: 372 (186×2: VPO method in pyridine). Calcd for $C_{16}H_{34}N_2OP_2S_2$: C, 48.46; H, 8.64; N, 7.06; S, 16.17%. Mol. wt.: 396.5.

Synthesis and Biological Activities of 2-Amino-2-deoxy- and 6-Amino-6-deoxy-α-D-glucopyranosyl-2,5-dideoxystreptamines

Seiichiro OGAWA, Yuji FUNAKI, Keiji IWATA, and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received April 17, 1976)

To investigate a relationship between structural features of aminocyclitols and biological activities of aminocyclitol antibiotics, 4-*O*-(2′-amino-2′-deoxy-α-D-glucopyranosyl)- and 4-*O*-(6′-amino-6′-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamines (**8** and **15a**) have been synthesized, and their biological activities against several microorganisms were determined.

Chemical modification of aminocyclitol antibiotics[1] has so far been extensively carried out in order to elucidate a structure-activity relationship and to synthesize new antibiotics that are active against resistant bacteria. Most investigations have however been aimed at modification of aminosugar moieties of antibiotics, but few exploitations of a relationship between structural feature of aminocyclitol and biological activities of the corresponding antibiotics have been attempted.[2]

In continuation of the preceding report,[3] a synthesis of biologically active α-aminoglycosides of 2,5-dideoxystreptamine,[4] *viz.* 4-*O*-(2′-amino-2′-deoxy-α-D-glucopyranosyl)- and 4-*O*-(6′-amino-6′-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamines (**8** and **15a**) is described in the present article.

Condensation of *N*,*N*′-dibenzyloxycarbonyl-2,5-dideoxystreptamine (**1a**)[4] with 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2′,4′-dinitroanilino)-α-D-glucopyranosyl bromide (**2**)[5] was effected in the presence of mercuric cyanide and mercuric bromide in dry dioxane at reflux temperature for three days and afforded, after fractionation by a silica gel column chromatography, 4,6-di-*O*-[3′,4′,6′-tri-*O*-acetyl-2′-deoxy-2′-(2″,4″-dinitroanilino)-D-glucopyranosyl]-*N*,*N*′-dibenzyloxycarbonyl-2,5-dideoxystreptamine (**5**)[6] (5.2%) and a practically homogeneous 4-*O*-[3′,4′,6′-tri-*O*-acetyl-2′-deoxy-2′-(2″,4″-dinitroanilino)-α-D-glucopyranosyl]-*N*,*N*′-dibenzyloxycarbonyl-2,5-dideoxystreptamine (**6**) (13%), together with syrupy 3,4,6-tri-*O*-acetyl-1,2-dideoxy-2-(2′,4′-dinitroanilino)-D-arabino-hex-1-enopyranose (**3**)[7] (33.5% based on **2**) and 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2′,4′-dinitroanilino)-D-glucose (**4**)[5] (6.7% based on **2**). Treatment of **6** with methanolic ammonia at room temperature gave crystalline 4-*O*-[2′-deoxy-2′-(2″,4″-dinitroanilino)-α-D-glucopyranosyl]-*N*,*N*′-dibenzyloxycarbonyl-2,5-dideoxystreptamine (**7**) in 41% yield. Removal of the protecting groups of **7** was then effected by treatment with Dowex 1×2 (OH^-), followed by hydrogenolysis in the presence of palladium black, giving **8** in 63% yield, as a homogeneous glassy product, which was characterized as the tri-*N*-acetyl derivative (**9**).

Biological activity of **8** was determined by a paper disk method comparing with that of antibiotic neamine, and the results were shown in Table 1. No direct proof to establish the absolute configuration of **8** has been done owing to a minute sample. However, on the basis of an empirical results that only 4-*O*-α-D-aminoglycosides of 2-deoxystreptamine have antibacterial activities,[9] **8** was tentatively assigned as 4-*O*-α-D-glucosaminide of

former had a remarkable antibacterial activity almost comparable to that of neamine, but the latter had no activity, confirming the absolute configuration deduced from the PMR data.

According to the present results, it has been presumed that aminocyclitol antibiotics which contain 2,5-dideoxystreptamine possess their antibacterial activities.

Experimental[13]

Modified Kõnigs-Knorr Reaction of N,N′-*Dibenzyloxycarbonyl-2,5-dideoxystreptamine (**1a**) and 3,4,6-Tri-*O-*acetyl-2-deoxy-2-(2′,4′-dinitroanilino)-α-*D*-glucopyranosyl Bromide (**2**).*[5] A mixture of **1a** (2.0 g), Drierite (6.0 g) and dry dioxane (150 ml) was heated at reflux to distil out some of the solvent. Then **2** (7.7 g), mercuric cyanide (7.7 g), and mercuric bromide (6.0 g) were added to this mixture in three portions every 24 h under gentle reflux and stirring. Three days after the last addition of the reagents, TLC (1 : 4 acetone–benzene) showed that all **1a** had been consumed and four main components (R_f 0.73, 0.50, 0.31, and 0.18) formed. An insoluble material was filtered off and the filtrate was evaporated to dryness. The residue was taken up in chloroform (300 ml), washed with a saline water, aqueous sodium hydrogencarbonate, and water, successively, dried over anhydrous sodium sulfate, and evaporated to give a crystalline residue (*ca.* 12 g). TLC indicated the presence of four main components, along with several minor components. The products were chromatographed on a silica gel column (300 g, Wako gel C-200) with 1 : 4 acetone–benzene as an eluant. Fractions were separated according to the results of TLC.

The first fractions (R_f 0.73) were evaporated to give 3,4,6-tri-*O*-acetyl-1,2-dideoxy-2-(2′,4′-dinitroanilino)-D-arabino-hex-1-enopyranose (**3**, 2.2 g, 33.5% yield based on **2** used) as a yellowish glass; $[\alpha]_D^{20}$ −115° (*c* 1, acetone); IR, 3340, 1750, 1670 cm^{-1}; PMR ($CDCl_3$) δ 2.02 (s, 3), 2.17 (s, 3), 2.21 (s, 3) (OAc), 5.44 (t, 1, $J_{3,4}=J_{4,5}=4.5$ Hz, H-4), 5.61 (dd, 1, $J_{1,3}=0.8$ Hz, H-3), 7.01 (d, 1, H-1).

Found: C, 47.57; H, 4.36; N, 8.86%. Calcd for $C_{18}H_{19}N_3O_{11}$: C, 47.69; H, 4.22; N, 9.27%.

The second fractions (R_f 0.50) were evaporated and crystallized from acetone–petroleum ether to give crystalline 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2′,4′-dinitroanilino)-D-glucose (**4**, 0.45 g, 6.7% yield based on **2** used); mp 159—162 °C. This compound was identified with an authentic sample[5] by IR spectra and TLC.

The third fractions (R_f 0.31) were evaporated and crystallized from acetone–petroleum ether to give a crystalline 4,6-di-*O*-[3′,4′,6′-tri-*O*-acetyl-2′-deoxy-2′-(2″,4″-dinitroanilino)-D-glucopyranosyl-*N*,*N*′-dibenzyloxycarbonyl-2,5-dideoxystreptamine (**5**, 330 mg, 5.2% yield based on **1a** used); mp 291—294 °C; $[\alpha]_D^{21}$ +63° (*c* 0.3, pyridine); IR, 3340, 1750, 1520 cm^{-1}; PMR (DMSO-d_6) δ 1.76 (s, 3), 1.78 (s, 3), 1.98 (s, 3), 2.08 (s, 3), 2.10 (s, 3) (OAc), 5.18 (m, 4, C$\underline{H}_2$ of Cbz), 7.52 (s, 10, aromatic protons of Cbz).

Found: C, 52.73; H, 4.83; N, 8.48%. Calcd for $C_{58}H_{64}N_8O_{28}$: C, 52.73; H, 4.97; N, 8.29%.

The third fractions (R_f 0.18) were evaporated and crystal lized from acetone–petroleum ether to give crystalline product (821 mg). Recrystallization from acetone gave 4-*O*-[3′,4′,6′-tri-*O*-acetyl-2′-deoxy-2′-(2″,4″-dinitroanilino)-α-D-glucopyranosyl]-*N*,*N*′-dibenzyloxycarbonyl-2,5-dideoxystreptamine (**6**, 529 mg, 12.5% yield based on **1a** used) as homogeneous crystals; mp 286.5 °C; $[\alpha]_D^{20}$ +61.3° (*c* 0.75, pyridine); IR, 3340, 1740, 1690, 1520 cm^{-1}; PMR (DMSO-d_6), δ 1.77 (s, 3), 1.95 (s, 3), 2.10 (s, 3) (OAc), 5.16 (s, 4, C$\underline{H}_2$ of Cbz), 7.48 (s, 10, aromatic protons of Cbz).

Found: C, 54.98; H, 5.28; N, 7.71%. Calcd for $C_{40}H_{45}N_5O_{17}$: C, 55.36; H, 5.27; N, 8.07%.

*4-O-[2′-deoxy-2′-(2″,4″-dinitroanilino)-α-D-glucopyranosyl]-N,N′-dibenzyloxycarbonyl-2,5-dideoxystreptamine (**7**).* Compound **6** (567 mg) was treated with methanolic ammonia (100 ml) under stirring overnight at room temperature. The reaction mixture was evaporated to give a crystalline residue. Recrystallization from dioxane–methanol gave **7** (198 mg, 41%) as pale yellowish crystals; mp 277—279 °C; $[\alpha]_D^{16}$ +90° (*c* 0.3, *N*,*N*-dimethylformamide); IR, 3300, 1690, 1530 cm^{-1}.

Found: C, 54.51; H, 5.25; N, 9.17%. Calcd for $C_{34}H_{39}N_5O_{14}\cdot 1/2H_2O$: C, 54.39; H, 5.33; N, 9.33%.

*4-O-(2′-Amino-2′-deoxy-α-D-glucopyranosyl-2,5-dideoxystreptamine (**8**).* A solution of **7** (190 mg) in dioxane (30 ml) and water (6 ml) was treated with Dowex 1×2 (OH^-) (8 ml) under stirring overnight at room temperature. The resin was removed by filtration and the filtrate was evaporated to give a powder. The product was directly hydrogenolyzed in the presence of palladium black (30 mg) in a mixture of dioxane (10 ml) and water (10 ml) overnight at room temperature (the initial hydrogen pressure of 3.4 kg/cm^2). The crude product was crystallized from ethanol–ether to give **8** (50 mg, 63%) as a white powder; mp 151—155 °C (bubbling); $[\alpha]_D^{18}$+162° (c 0.8, H_2O); R_f Glucosamine Hydrochloride 0.31, R_f 2,5-Dideoxystreptamine Dihydrochloride 0.37.

Compound **8** (20 mg) was treated with two drops of acetic anhydride in methanol (2 ml) overnight at room temperature. The product was crystallized from ethanol–ether to give the tri-*N*-acetyl derivative (**9**, 20 mg, 71%) as crystals; mp 320—322 °C; $[\alpha]_D^{21}$ +140° (*c* 1.1, H_2O); IR, 1640, 1550 cm^{-1}.

Found: C, 48.58; H, 7.11; N, 9.13%. Calcd for $C_{18}H_{31}N_3O_9\cdot 1/2H_2O$: C, 48.86; H, 7.29; N, 9.49%.

*6-Azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl Chloride (**10**).* This compound was prepared from crystalline methyl 2,3,4-tri-*O*-acetyl-6-azido-6-deoxy-α-D-glucopyranoside[14] by the direction of Umezawa and his coworkers;[9] syrup, $[\alpha]_D^{22}$ +117° (*c* 2.54, chloroform) (lit,[9] $[\alpha]_D^{24}$ +119° (*c* 0.94, chloroform)).

*N,N′-Diethoxycarbonyl-2,5-dideoxystreptamine (**1b**).* To a solution of 2,5-dideoxystreptamine dihydrochloride[4] (303 mg) in water (20 ml) was added sodium carbonate (1.1 g) and ethyl chloroformate (0.50 ml), and the mixture was stirred for 3 h at room temperature. The mixture was evaporated to dryness and the residue was extracted with hot dioxane (4×20 ml). The extracts were evaporated to give a syrup, which was crystallized from 2-propanol to give **1b** (250 mg, 62%) as crystals; mp 200—201 °C; IR, 3300, 1690, 1540 cm^{-1}; PMR (D_2O) δ 1.24 (t, 6, J=7 Hz, 2C$\underline{H}_3$ of Cbe), 4.15 (q, 4, 2C$\underline{H}_2$ of Cbe).

Found: C, 49.88; H, 7.55; N, 9.60%. Calcd for $C_{12}H_{22}N_2O_6$: C, 49.64; H, 7.64; N, 9.65%.

*Modified Kõnigs-Knorr Reaction of **1b** and **10**.* A mixture of syrupy **10** (4.86 g) and Drierite (6 g) in dry benzene (160 ml) and dry dioxane (54 ml) was magnetically stirred at 50—60 °C for 30 min. Then **1b** (1.98 g) and mercuric cyanide (4.92 g) were added to this mixture, and it was gently refluxed under vigorous agitation. After two days, a 5-g portion of mercuric cyanide was added to the mixture, and, after 9 days, **10** (1.32 g) and mercuric cyanide (1.3 g) were added. Twelve days after the last addition of the reagents, TLC (1: 12 acetone–benzene) indicated a disappearance of **1b**. The reaction mixture was cooled to room temperature and an insoluble matter was removed by filtration. The filtrate was evaporated to give a syrup which was taken up in chloroform (180 ml) and washed with aqueous sodium hydrogencarbonate and water, successively. The chloroform solution was dried over

anhydrous sodium sulfate and evaporated to give an amorphous solid (*ca.* 12 g). TLC showed that it contained three main components (R_f 0.31, 0.06, 0.03), together with several minor components. The products were throughly mixed with silica gel (11 g, Wako gel C-300) and the mixture was transfered to a top of a silica gel column (90 g, packed with benzene). The column was eluted with benzene, 10: 1 benzene–ethyl acetate, 5: 1 benzene–ethyl acetate, 1: 5 acetone–benzene, and 1: 3 acetone–benzene, successively. The fractions were separated according to the results of TLC.

The first fractions (R_f 0.31) were evaporated and crystallized from 2-propanol to give crystalline 4,6-di-*O*-(6′-azido-2′,3′,4′-tri-*O*-benzyl-6′-deoxy-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**11**, 2.02 g, 24.6%). Recrystallized sample melted at 150—156 °C; $[\alpha]_D^{32}$ +57.5° (*c* 0.37, chloroform); IR, 3320, 2130, 1630, 1540 cm^{-1}; PMR ($CDCl_3$) δ 1.14 (t, 6, J=7 Hz, 2C$\underline{H}_3$ of Cbe), 4.07 (q, 4, 2C$\underline{H}_2$ of Cbe), 7.30 (s, 30, aromatic protons of Bn).

Found: C, 65.52; H, 6.41; N, 9.18%. Calcd for $C_{66}H_{76}N_8O_{14}$: C, 65.76; H, 6.36; N, 9.30%.

The second fractions (R_f 0.06) were evaporated and crystallized from ethanol to give crystalline 6-*O*-(6′-azido-2′,3′,4′-tri-*O*-benzyl-6′-deoxy-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**12b**, 776 mg, 15%). Recrystallized sample melted at 204—205 °C; $[\alpha]_D^{32}$ +45.9° (*c* 0.47, chloroform); IR, 3320, 2120, 1680, 1540 cm^{-1}; PMR ($CDCl_3$) δ 1.16 (t, 3), 1.23 (t, 3) (J=7 Hz, C$\underline{H}_3$ of Cbe), 4.08 (q, 2), 4.24 (q, 2), (C$\underline{H}_2$ of Cbe), 7.30 (s, 5), 7.32 (s, 5), 7.35 (s, 5) (aromatic protons of Bn).

Found: C, 62.38; H, 6.53; N, 9.11%. Calcd for $C_{39}H_{49}N_5O_{10}$: C, 62.63; H, 6.60; N, 9.37%.

The third fractions (R_f 0.03) were evaporated and crystallized from ethanol to give crystalline 4- or 6-*O*-(6′-azido-2′,3′,4′-tri-*O*-benzyl-6′-deoxy-β-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**13**, 162 mg, 3.2%). Recrystallized sample melted at 221—223 °C; $[\alpha]_D^{20}$ +43.5° (*c* 0.58, chloroform); IR, 3310, 2110, 1680, 1540 cm^{-1}; PMR ($CDCl_3$) δ 1.12 (t, 3), 1.23 (t, 3) (J=7 Hz, C$\underline{H}_3$ of Cbe), 4.13 (q, 4, 2C$\underline{H}_2$ of Cbe), 7.26 (s, 15, aromatic protons of Bn).

Found: C, 61.80; H, 6.52; N, 8.88%. Calcd for $C_{39}H_{49}N_5O_{10}\cdot H_2O$: C, 61.60; H, 6.71; N, 9.14%.

An unresolved mixture (*ca.* 2 g) was rechromatographed on a silica gel column (80 g) and eluted with the same solvents mixture to afford **12b** (86 mg, total yield 16.7%), **13** (67 mg, total yield 4.5%), and a mixture (964 mg) containing the 4-*O*-α-glycoside (**12a**) mainly, along with **12b** and **13**.

*6-O-(2′,3′,4′-Tri-O-benzyl-6′-deoxy-6′-ethoxycarbonylamino-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (**14b**).* A solution of **12b** (258 mg) in a mixture of dioxane (6 ml) and ethanol (6 ml) was hydrogenated in the presence of Raney nickel T-4[11] at room temperature for 24 h (the initial hydrogen pressure of 3.4 kg/cm²). The catalyst was removed by filtration and the filtrate was evaporated to dryness. The residue was dissolved in a mixture of 1: 1: 1 acetone–methanol–water (30 ml) and treated with an excess of ethyl chloroformate in the presence of sodium carbonate overnight at room temperature. An insoluble matter was filtered off and the filtrate was evaporated to dryness. The residue was taken up in chloroform (30 ml), and the solution was washed with aqueous sodium hydrogencarbonate and water, successively, dried over anhydrous sodium sulfate, and evaporated to give a product, which was crystallized from methanol to give crystalline **14b** (166 mg, 60.6%), mp 250—252 °C. Recrystallization from chloroform–ethanol gave an analytical sample, mp 256—258 °C; $[\alpha]_D^{22}$ +13.4° (*c* 0.84, chloroform); IR, no absorption due to an azido group was observed; PMR ($CDCl_3$) δ 1.15 (t, 3), 1.24) (t, 6) (J=7 Hz, C$\underline{H}_3$ of Cbe), 4.06 (q, 2), 4.12 (q, 4) (C$\underline{H}_2$ of Cbe), 5.67 (d, 1, $J_{1',2'}$=3.5 Hz, H-1′), 7.31 (s, 10), 7.34 (s, 5) (aromatic protons of Bn).

Found: C, 63.58; H, 7.01; N, 5.14%. Calcd for $C_{42}H_{55}N_3O_{12}$: C, 63.55; H, 6.98; N, 5.29%.

*4- or 6-O-(2′,3′,4′-Tri-O-benzyl-6′-deoxy-6′-ethoxycarbonylamino-β-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (**17**).* Compound **13** (136 mg) was hydrogenated in a mixture of dioxane (15 ml), ethanol (5 ml), and ethyl acetate (10 ml) similarly as described in the preparation of **14b**. The product was treated with ethyl chloroformate and sodium carbonate in 75% aqueous dioxane to give crude **17**, which was crystallized from ethanol to give crystalline **17** (108 mg, 74%), mp 254—256 °C; $[\alpha]_D^{21}$ +11.1° (*c* 0.39, chloroform); IR, no absorption due to an azido group was observed; PMR (DMSO-d_6) δ 1.00 (t, 3), 1.16 (t, 6) (J=7 Hz, C$\underline{H}_3$ of Cbe), 3.97 (q, 2), 4.01 (q, 4) (C$\underline{H}_2$ of Cbe), 7.26 (s, 5), 7.30 (s, 10) (aromatic protons of Bn).

Found: C, 63.05; H, 6.29; N, 5.11%. Calcd for $C_{42}H_{55}N_3O_{12}$: C, 63.55; H, 6.98; N, 5.29%, and, for hemihydrate: C, 62.83; H, 7.03; N, 5.23%.

*4-O-(2′,3′,4′-Tri-O-benzyl-6′-deoxy-6′-ethoxycarbonylamino-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (**14a**).* A mixture (964 mg) of **12a**, **12b**, and **13** obtained in the condensation reaction of **1b** and **10** was again fractionated by silica gel chromatography to give a fraction (492 mg) containing **12a** mainly. This product was hydrogenated in dioxane similarly as described in the preparation of **17**, and further converted into the tri-*N*-carboethoxy derivative in the usual manner. TLC (30:1 chloroform–ethanol) indicated that it consisted of a main component, along with two minor components identical with **14b** and **17**. The mixture was separated by the silica gel column (40 g) with 40: 1 chloroform–ethanol as an eluent to give a homogeneous syrup, which was crystallized from ethanol–hexane to give **14a** (268 mg, 5.0% yield based on **2b** used) as crystals, mp 189—190 °C; Recrystallized sample melted at 193—196 °C; $[\alpha]_D^{21}$ +31.7° (*c* 0.38, chloroform); PMR ($CDCl_3$) δ 1.14 (t, 3), 1.24 (t, 3), 1.26 (t, 3) (J=7 Hz, C$\underline{H}_3$ of Cbe), 4.07 (q, 2), 4.12 (q, 2), 4.15 (q, 2) (C$\underline{H}_2$ of Cbe), 7.29 (s, 5), 7.31 (s, 5), 7.33 (s, 5) (aromatic protons of Bn); (DMSO-d_6, 100 MHz) δ 0.91 (t, 3), 1.16 (t, 6) (J=7 Hz, C$\underline{H}_3$ of Cbe), 3.18 (q, 2), 4.01 (q, 4) (C$\underline{H}_2$ of Cbe), 5.06 (d, 1, $J_{1',2'}$=4 Hz, H-1′), 7.28 (s, 5), 7.30 (s, 5), 7.33 (s, 5) (aromatic protons of Bn).

Found: C, 63.75; H, 6.98; N, 5.23%. Calcd for $C_{42}H_{55}N_3O_{12}$: C, 63.55; H, 6.98; N, 5.29%.

*4-O-(6′-Amino-6′-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamine (**15a**).* A solution of **14a** (244 mg) in ethanol (25 ml) containing a few drop of acetic acid was hydrogenated in the presence of freshly prepared palladium black at 50—60 °C for 24 h (the initial hydrogen pressure of 3.4 kg/cm²). The catalyst was removed by filtration and the filtrate was evaporated to give a syrup (165 mg), which was taken up in a small amount of methanol. The solution was added dropwise to aqueous barium hydroxide (5 ml, containing 1.3 g of $Ba(OH)_2\cdot 8H_2O$) at 60—70 °C, and the mixture was heated at 120 °C for 6 h. After having been neutralized with cabon dioxide, the reaction mixture was filtered centrifugally to remove barium carbonate and the filtrate was evaporated to give a syrup, which was chromatographed on Amberlite CG-50 (NH_4^+) column (4 ml). After having been washed with water, 0.05 M, and 0.1 M aqueous ammonia, successively, the column was then eluted with 0.2 M aqueous ammonia to give **15a** (69 mg, 74%) as a homogeneous glass; mp 153 °C; $[\alpha]_D^{21}$ +104.6° (*c* 1.39, H_2O); IR, 3350, 1570 cm^{-1}; PMR (D_2O) 5.14 (d, 1, $J_{1',2'}$=3 Hz, H-1′); R_f Glucosamine Hydrochloride 0.19, R_f 2-Deoxystreptamine Dihydrochloride 0.53.

Found: C, 45.15; H, 7.50; N, 12.51%. Calcd for $C_{12}H_{25}N_3$-

$O_6 \cdot 1/3H_2CO_3$: C, 45.16; H, 7.89; N, 12.81%.

Treatment of **15a** (18 mg) with acetic anhydride (1 ml) in methanol (1 ml) at room temperature for 3 h gave the tri-*N*-acetyl derivative (**16a**, 21 mg, 82%) as a glass, mp 235 °C (decomp); $[\alpha]_D^{22}$ +62° (*c* 1.05, H_2O); PMR (D_2O) δ 2.01 (s, 6), 2.05 (s, 3) (NAc), 5.08 (d, 1, $J_{1',2'}$=3 Hz, H-1').

Found: C, 48.56; H, 7.16; N, 9.70%. Calcd for $C_{18}H_{31}N_3O_9 \cdot 1/2H_2O$: C, 48.86; H, 7.29; N, 9.50%.

6-O-(6'-Amino-6'-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamine (***15b***). A solution of **14b** (414 mg) in 90% aqueous 2-methoxyethanol (40 ml) containing a few drop of acetic acid was hydrogenated similarly as described in the preparation of **15a**. The product was digested with ethanol and the precipitates were collected by filtration to give a solid (182 mg). The mother liquor was shown to contain **15b** by TLC, and it was again hydrogenated similarly to give another crop of the solid (86 mg). The product was hydrolyzed with aqueous barium hydroxide as described above and purified by the resin column to give **15b** (106 mg, 67.5%) as a homogeneous glass, mp 140 °C (decomp); $[\alpha]_D^{21}$ +75.1° (*c* 0.9, H_2O); IR, 3350, 1570 cm^{-1}; PMR (D_2O) δ 5.10 (d, 1, $J_{1',2'}$ =3.5 Hz, H-1'); $R_{f\ \text{Glucosamine Hydrochloride}}$ 0.23, $R_{f\ \text{2-Deoxystreptamine Dihydrochloride}}$ 0.56.

Found: C, 41.20; H, 7.16; N, 10.77%. Calcd for $C_{12}H_{25}N_3O_6 \cdot 3/2H_2CO_3$: C, 40.49; H, 7.05; N, 10.50%.

Compound **15b** (16 mg) was converted into the tri-*N*-acetyl derivative (**16b**, 11 mg, 50%) as a white powder, mp 276 °C (decomp); $[\alpha]_D^{22}$ +57.9° (*c* 0.57, H_2O); PMR (D_2O) δ 1.98 (s, 3), 2.01 (s, 3), 2.04 (s, 3) (NAc), 5.03 (d, 1, $J_{1',2'}$=3.5 Hz, H-1').

Found: C, 47.83; H, 6.88; N, 8.68%. Calcd for $C_{18}H_{31}N_3O_9 \cdot H_2O$: C, 47.88; H, 7.37; N, 9.31%.

4- or 6-O-(6'-Amino-6'-deoxy-β-D-glucopyranosyl)-2,5-dideoxystreptamine (***18***). Compound **17** (105 mg) was hydrogenated and hydrolyzed similarly as described in the preparation of **15a**, and the product was purified by the resin column to give **18** (27 mg, 66%) as a glass, mp 144 °C (decomp); $[\alpha]_D^{21}$ +12.8° (*c* 1.33, H_2O); PMR (D_2O) δ 4.59 (d, 1, $J_{1',2'}$=7.5 Hz, H-1'); $R_{f\ \text{Glucosamine Hydrochloride}}$ 0.21, $R_{f\ \text{2-Deoxystreptamine Dihydrochloride}}$ 0.55.

This work has been supported financially in part by a grant of the Asahi Glass Foundation for the contribution to industrial technology.

Studies of Heterocyclic Compounds. VIII.[1] Synthesis and Tautomerism of 2-Hydroxypyrazolo[1,5-*a*]pyridine

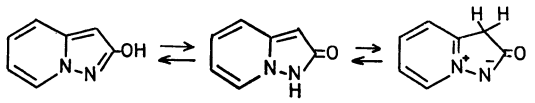
Hisao Ochi, Tadashi Miyasaka, Kiyoshi Kanada,* and Kiichi Arakawa

School of Pharmaceutical Sciences, Showa University, 1-5-8 Hatanodai, Shinagawa-ku, Tokyo 142
**Research and Developing Section, Horiuchi Itaro Co. Ltd., Higashimurayama-shi, Tokyo 189*

(Received March 27, 1976)

2-Hydroxypyrazolo[1,5-*a*]pyridine (I) was synthesized by reaction of ethyl 2-pyridylacetate (IV) with hydroxylamine-*O*-sulfonic acid. I was shown to undergo nitrosation, nitration and bromination at C-3 position. Methylation of I with diazomethane gave 2-methoxypyrazolo[1,5-*a*]pyridine (V), while methylation of I with dimethyl sulfate gave a mixture of V and 1-methyl-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one (VI). The enol form was found to be predominant tautomeric species of I in solution. Treatment of I with acetic anhydride afforded 2-acetoxypyrazolo[1,5-*a*]pyridine (XIII) exclusively. 1-Acetyl-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one (XIV) dose not seem to intervene in the formation of thermally stable *O*-acetylated product (XIII).

In connection with the synthesis and reactivity of pyrazole derivatives[2,3] it seemed to us of interest to examine the chemical properties of 2-hydroxypyrazolo-[1,5-*a*]pyridine (I) as well as possible tautomerization including 1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one (Ib), a pyrazolone form and a ylide form (Ic) (Scheme 1).

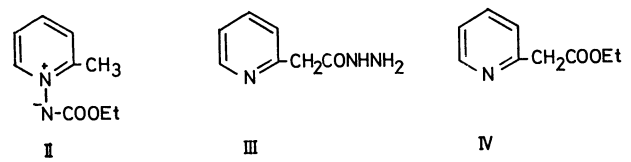


I I-b I-c

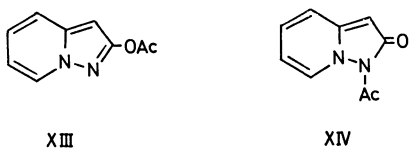
Scheme 1.

Although many papers have appeared on the synthesis of pyrazolo[1,5-*a*]pyridines,[4] only a few deal with the synthesis of condensed pyrazolone system functionalized at 2-position.[5-7]

2-Picoline is considered to be an easily available starting material for the synthesis. Attempts to form I by cyclization of 2-pyridylacetyl azide through the intermediacy of the nitrene (II) or by that of 2-pyridylacetohydrazide (III) with a strong base were unsuccessful. However, *N*-imination of ethyl 2-pyridylacetate (IV) with potassium salt of hydroxylamine-*O*-sulfonic acid (HAS)[8,9] afforded the desired bicyclic system as colorless fluorescent crystals (mp 127—128 °C), whose elemental analysis and mass spectrum agreed with the molecular formula $C_7H_6ON_2$.



II III IV



XIII XIV

The preparation of I was best carried out by adding an aqueous solution of HAS into 3 molar equivalents of 2-pyridylacetate (IV), extraction of the reaction product with a 10% aqueous sodium carbonate solution and recrystallization from benzene–hexane after stirring for 30 h at room temperature. The IR spectrum lacked an ester carbonyl band at around 1700 cm^{-1}, but showed a broad band at 3000 cm^{-1} (associated –O–H) and a strong band at 1635 cm^{-1} (–C=N–), indicating the presence of enol instead of carbonyl grouping. The NMR spectrum displayed a one proton singlet at δ5.83 ppm (C_3–H), a one proton broad doublet at δ 8.29 ppm (C_7–H, $J_{6,7}$=6 Hz) and other signals at δ 6.61 (C_6–H), 7.11 (C_5–H) and 7.34 ppm (C_4–H). Mass spectrum of this compound displayed molecular ion (*m/e* 134) which was the base peak and other ions of *m/e* 105 $[M–CHO]^+$, 91 $[C_6H_5N]^+$ and 79 $[C_5H_5N]^+$ (Fig. 1, Scheme 2).

Treatment of I with an ethereal solution of diazo-

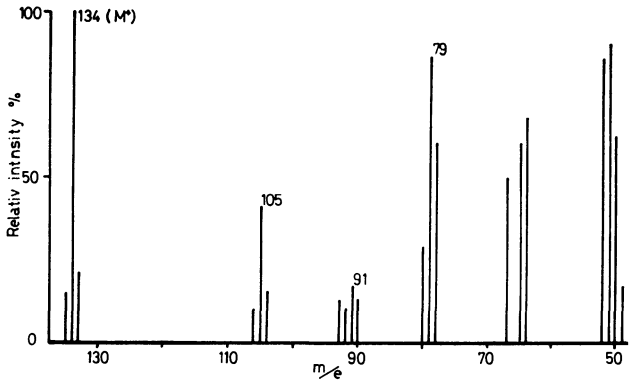


Fig. 1. Mass spectra of 2-hydroxypyrazolo[1,5-*a*]pyridine.

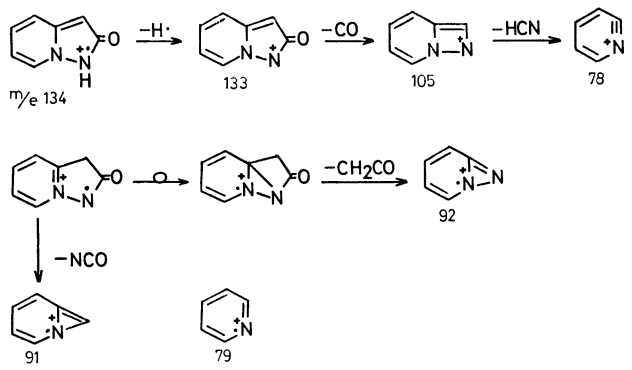

Scheme 2. Mass fragmentation pattern of 2-hydroxypyrazolo[1,5-*a*]pyridine.

methane gave an oily substance $C_8H_8ON_2$ which displayed a single spot on the TLC plate. The IR spectrum lacked a carbonyl band. The NMR spectrum showed an *O*-methyl signal at δ 3.98 ppm, indicating *O*-methylation of I to give 2-methoxypyrazolo[1,5-*a*]-pyridine exclusively. Methylation of I with dimethyl sulfate in aqueous sodium carbonate gave a (3: 1) mixture of two monomethyl derivatives. Separation through a silica gel column afforded the major component which was identical with the *O*-methyl derivative (V) and the minor component which was revealed to be 1-methyl-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one (VI) by the IR (>C=O 1660 cm^{-1}) and by the NMR spectra (δ 3.64 ppm, 3H, s) (Tables 2, 3).

Katritzky and Maine reported the tautomerism of substituted 3-hydroxypyrazoles.[10] The IR and the NMR spectra demonstrate that both keto and enol forms are present in nonprotic solvents such as chloroform in the case of 3-hydroxy-2-methylpyrazoles. However, enol form is present predominantly in the case of 3-hydroxy-1-methylpyrazoles. The UV spectrum of I in methanol as well as in cyclohexane had maxima at 232, 280 and 310 nm (log ε; 4.59, 3.09 and 3.10, respectively) and was very close to the spectrum of 2-methoxypyrazolo[1,5-*a*]pyridine (V). However, the UV spectrum of VI had maxima at the longer wave length: 241.5, 280.5, 288 and 341 nm (log ε: 4.47, 3.89, 3.88 and 3.32, respectively). By addition of a sodium hydroxide solution to the methanolic solution of I, the maxima shifted to the longer wave length of 260, 280 and 335 nm, respectively. This suggests a phenolic character of the hydroxyl group at 2-position. Thus the enol form was a predominant tautomeric species for I in solution.

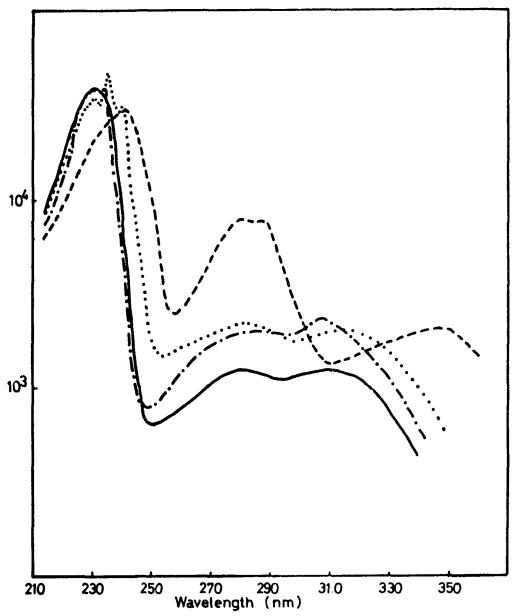

Fig. 2. UV spectra of I (——), V (-·-·-), and VI (------) in methanol and I (·····) in cyclohexane.

The electrophilic substitution of mono-cyclic 3-hydroxypyrazoles usually takes place at 4-position. Nitrosation, nitration and bromination of I afforded exclusively 3-monosubstituted products, 3-nitroso, 3-nitro- and 3-bromo-2-hydroxypyrazolo[1,5-*a*]pyridines (VII), (VIII) and (IX), respectively. The NMR spectra lacked the C_3-proton signals at δ 5—7 ppm (Table 2). Bromination of I with two molar equivalents of bromine gave dibromo compound (X) identical with the further brominated product of monobromide (IX). The IR and the NMR spectra indicated this to be 1,3-dibromo-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one.

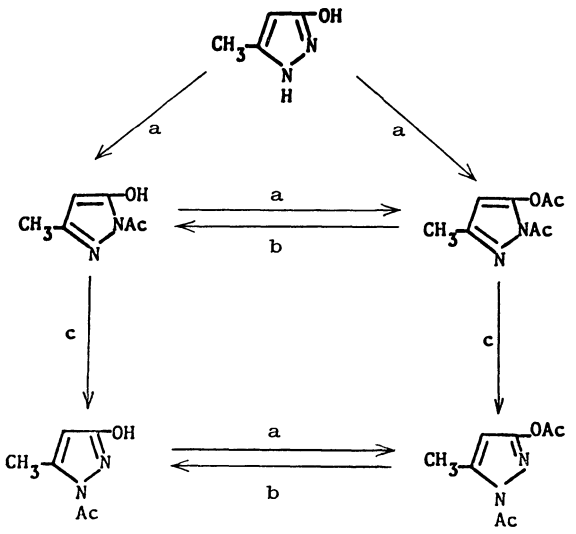
Coupling constants, J, in terms of unit Hz.

Substitution of the hydroxy group of I with chlorine was carried out in the usual way by heating in refluxing phosphoryl chloride only to recover the starting material. By heating in a sealed tube at 145 °C for 6 h I was converted into 2-chloropyrazolo[1,5-*a*]pyridine (XI) in

72% yield.

Catalytic hydrogenation of I with platinum oxide in acetic acid gave colorless crystals (mp 172—174 °C) after sluggish absorption of two molar equivalents of hydrogen. The NMR spectrum (δ 1.90, 2.68, and 3.85 ppm, 8H) indicated that the hydrogenation took place upon the pyridine nucleus to furnish 2-hydroxy-4,5,6,7-tetrahydropyrazolo[1,5-*a*]pyridine (XII). The hydroxypyrazole moiety of I seems to be relatively electron-sufficient and the electron-deficient pyridine moiety seems reactive enough to undergo hydrogenation exclusively.

Arakawa *et al.* reported on the structure of the acetylated products of 3-hydroxy-5-methylpyrazole which had eight potential tautomeric forms[2] and also on the acetyl transfer reaction of 3-acetoxy-1-acetyl-5-methylpyrazole and the related compounds.[3] Among the four mono- and diacetyl derivatives the 2-acetyl-3-hydroxy-5-methylpyrazole formed initially were kinetically controlled products, which gave by thermal treatment 1-acetyl-3-hydroxy-5-methylpyrazole and 3-acetoxy-1-acetyl-5-methylpyrazole as the thermally more stable products (Scheme 3). We have tried acetylation of the bicyclic hydroxypyrazole (I) in order to examine the possible isomeric acetates responsible for the three conceivable tautomers (Scheme 1).



a : Acetylation
b : Basic Hydrolysis
c : Thermolysis

Scheme 3.

Hydroxypyrazole (I) gave an oily acetate (XIII) by heating in refluxing acetic anhydride for 2 h, which displyayed one spot on the TLC plate. The IR spectrum had one peak in the carbonyl region (ν_{max} 1780 cm^{-1}, $-\dot{C}=\dot{C}-O-COCH_3$). Elemental analysis and the NMR spectrum (δ 2.36 ppm, 3H, s) also indicate the compound to be 2-acetoxypyrazolo[1,5-*a*]pyridine. The time-course of acetylation was followed spectrophotometrically in a sample-tube for NMR measurement by observing the singlet signals at δ 5.78 and at δ 6.41 ppm of the C_3-protons of I and XIII, respectively. The signal at δ 5.78 ppm of the spectrum of I in acetic acid started diminishing slowly in its area-intensity as soon as acetic anhydride was added to the mixture. A new peak appearing at δ 6.41 ppm increased greatly in intensity, its spectrum changing completely into that of XIII after being heated 3 h at 35 °C (Fig. 3). Since no signal was observed in the region during the course of reaction, 1-acetyl-1,2-dihydropyrazolo[1,5-*a*]pyridin-2-one (XIV) did not seem to intervene in the formation of the thermally stable *O*-acetylated product (XIII).

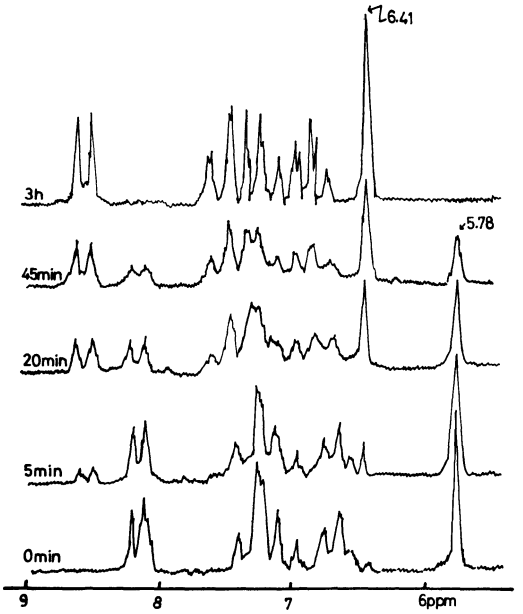


Fig. 3. NMR spectra during the time-course of changing I into XIII in a mixture of acetic acid and acetic anhydride at 35 °C.

Experimental

All the melting points were measured in capillary tubes and were uncorrected. The NMR spectra were measured on Hitachi R-20 60 MHz and Hitachi R-22 90 MHz spectrophotometers, using tetramethylsilane as an internal reference. The IR and the UV spectra were measured on a JASCO IRA-I spectrophotometer and a Hitachi EPS-3 spectrophotometer, respectively.

2-Hydroxypyrazolo[1,5-a]pyridine (I). After a mixture of ethyl 2-pyridylacetate (3.00 g), HAS (0.60 g) and water (3 ml) was stirred at room temperature for 30 h, it was extracted with CH_2Cl_2. The aqueous layer was made alkaline with 10% Na_2CO_3 to pH 9 and was extracted with CH_2Cl_2. The organic extracts were combined, and after drying over $MgSO_4$ the solvent was evaporated. The residual oil was shaken with Et_2O–10% Na_2CO_3. After the ether-layer was dried over $MgSO_4$, the solvent was evaporated to give the starting ethyl 2-pyridylacetate (2.11 g, 70.5% yield). The pH of the basic aqueous layer was adjusted to 5 by adding AcOH to precipitate brown powder (0.36 g, 45.9% yield, based upon the consumed starting material). Recrystallization from benzene–hexane gave 2-hydroxypyrazolo[1,5-*a*]pyridine (0.32 g, 40.7%) mp 127—128 °C, as colorless leaflets. UV λ_{max}^{MeOH} nm (log ε): 232 (4.59), 280.5 (3.09), 310 (3.10). IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 3000, 1635, 1535, 1258. Found: C, 62.53; H, 4.48; N, 20.98%. Calcd for $C_7H_6ON_2$: C, 62.68; H, 4.51; N, 20.89%.

2-Methoxypyrazolo[1,5-a]pyridine (V). To a solution of

I (134 mg) in MeOH (5 ml) was added an excess solution of CH_2N_2 in ether[11] and the mixture was left to stand in an ice-box for a day. Evaporation of the solvent gave colorless oil (135 mg) which exhibited a single spot on a TLC plate (R_f= 0.89, 5% MeOH–$CHCl_3$ silica gel G. F. nach Stahl). Purification by passing a short column of SiO_2 gave colorless oil (118 mg, 80.5% yield). UV λ_{max}^{MeOH} nm (log ε): 234 (4.57), 282 (3.30), 307 (3.31). IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 3000, 1640, 1540, 1360. Found: C, 64.57; H, 5.31; N, 18.71%. Calcd for $C_8H_8ON_2$: C, 64.85; H, 5.44; N, 18.91%.

Treatment of I with Dimethyl Sulfate–Sodium Carbonate, 2-Methoxypyrazolo[1,5-a]pyridine (V) and 1-Methyl-1,2-dihydropyrazolo-[1,5-a]pyridin-2-one (VI). After alternate portionwise addition of dimethyl sulfate (250 mg) and a solution of Na_2CO_3 (2.40 g) in H_2O (6 ml) to a stirred solution of I (268 mg) in EtOH (14 ml), the mixture was stirred at room temperature for 48 h. The precipitate was filtered off and the filtrate was evaporated *in vacuo* to give a brown residue, which was shaken with CH_2Cl_2 and H_2O. Drying and evaporation of the organic layer gave a brown residue, which was fractionated by passing through a SiO_2-column to first give colorless oil (186 mg, 62.8% yield) and next colorless prisms (48 mg, 16.2% yield). The former was found to be identical with V by comparison of TLC, IR and NMR spectra. The latter was recrystallized from benzene to give crystals (VI) melting at 165—167 °C. UV λ_{max}^{MeOH} nm (log ε): 241.5 (4.47), 280.5 (3.89), 288 (3.88), 341 (3.32). IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 2960, 1660, 1630 (br). Found: C, 64.59; H, 5.32; N, 18.68%. Calcd for $C_8H_8ON_2$: C, 64.85; H, 5.44; N, 18.91%.

Nitrosation of I, 2-Hydroxy-3-nitrosopyrazolo[1,5-a]pyridine (VII). To an ice-cold stirred solution of I (100 mg) in a mixture of MeOH (2 ml) and 6M-HCl (2 ml) was added dropwise a solution of $NaNO_2$ (15 mg) in H_2O (0.7 ml). After stirring under ice-cooling for 30 min and at room temperature for 1 h the reaction mixture was cooled in ice-salt mixture to deposit a yellow precipitate, which was collected by filtration and washed with cold water. Recrystallization from MeOH gave golden feather-like crystals (63 mg, 52% yield). Mp>280 °C. UV λ_{max}^{MeOH} nm (log ε): 273 (4.30), 316.5 (3.76). IR ν_{max}^{KBr} cm^{-1}: 3040, 1700, 1680, 1635, 1020. Found: C, 51.53; H, 3.32; N, 27.50%. Calcd for $C_7H_5O_2N_3$: C, 51.54; H, 3.09; N, 27.60%.

Nitration of I, 2-Hydroxy-3-nitropyrazolo[1,5-a]pyridine (VIII). To an ice-cold stirred solution of I (70 mg) in concd HNO_3 (d=1.38) (1 ml) was added dropwise fuming nitric acid (d= 1.50) (0.5 ml). After stirring in an ice-bath for 30 min and at room temperature for 1 h the reaction mixture was poured onto ice–water to give a precipitate, which was collected by filtration. Recrystallization of the powder (61 mg) thus obtained from MeOH gave light brown leaflets (45 mg, 48.2 % yield) mp 243 °C (dec). UV λ_{max}^{MeOH} nm (log ε): 220 (4.30), 276 (3.51), 354 (4.16). IR ν_{max}^{KBr} cm^{-1}: 3440, 1645, 1580, 1360, 1220. Found: C, 46.71; H, 3.07; N, 23.21%. Calcd for $C_7H_5O_3N_3$: C, 46.93; H, 2.81; N, 23.46%.

Bromination of I with Equimolar Amount of Bromine, 3-Bromo-2-hydroxypyrazolo[1,5-a]pyridine (IX). To a stirred mixture of I (134 mg) and $NaOAc \cdot 3H_2O$ (140 mg) in AcOH (4 ml) was added dropwise a solution of Br_2 (160 mg) in AcOH (2 ml). After addition of ice–water the precipitated solid was collected by filtration. The pink-colored powder (146 mg) were recrystallized from MeOH to give prisms (126 mg, 56.3% yield), mp 188.5—190.5 °C. UV λ_{max}^{MeOH} nm (log ε): 235 (4.02). IR ν_{max}^{KBr} cm^{-1}: 1630, 1560 (br), 1520 (br). Found: C, 39.32; H, 2.32; N, 13.34%. Calcd for $C_7H_5ON_2Br$: C, 39.44; H, 2.35; N, 13.15%.

Bromination of I with Excess Brimine, 1,3-Dibromo-1,2-dihydropyrazolo[1,5-a]pyridin-2-one (X). To a stirred solution of I (134 mg) in AcOH (2 ml) was added dropwise at 15 °C a solution of Br_2 (320 mg) in AcOH (2 ml). After stirring for 1 h the reaction mixture was poured onto ice–water. The precipitate was collected by filtration and washed with cold water to give yellow powder (230 mg). Recrystallization from MeOH gave yellow scales (183 mg, 62.7% yield), mp 162 °C (dec). UV λ_{max}^{MeOH} nm (log ε): 249 (4.18), 308.5 (3.62), 350 (3.61). IR ν_{max}^{KBr} cm^{-1}: 1660, 1650, 1640. Found: C, 28.88; H, 1.55; N, 9.76%. Calcd for $C_7H_4ON_2Br_2$: C, 28.76; H, 1.71; N, 9.59%.

Attempted Chlorination of I by Refluxing in Phosphoryl Chloride. After a mixture of I (100 mg) and phosphoryl chloride (5 ml) was heated under reflux for 2 h the reaction mixture was treated in the usual way. The starting material (82 mg) was recovered unchanged.

Reaction of I with Phosphoryl Chloride at 145 °C, 2-Chloropyrazolo-[1,5-a]pyridine (XI). After a mixture of I (100 mg) and phosphoryl chloride (3 ml) was heated in a seald tube at 145 °C for 6 h, the reaction mixture was poured onto ice–water. Extraction with CH_2Cl_2, drying and evaporation of the solvent *in vacuo* afforded red oil (93 mg). Purification of the oil by passing through a column of SiO_2 gave colorless oil (82 mg, 72% yield). IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 1640. Found: C, 54.91; H, 3.52; N, 18.52%. Calcd for $C_7H_5N_2Cl$: C, 55.08; H, 3.28; N, 18.36%.

Catalytic Hydrogenation of I, 2-Hydroxy-4,5,6,7-tetrahydropyrazolo-[1,5-a]pyridine (XII). A solution of I (134 mg) in AcOH (20 ml) was shaken in the presence of Pt which was prereduced from PtO_2 (100 mg) under atmospheric pressure. The absorption of hydrogen ceased after uptake of 2 mmol of hydrogen. After filtration of the solvent the residual colorless crystals (145 mg) were recrystallized from acetone–Et_2O to give colorless scales (89 mg, 69% yield), mp 172—174 °C. UV λ_{max}^{MeOH} nm (log ε): 228.5 (3.72), 260 (3.48). IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 1540, 1035, 955. NMR δ ppm (in $CDCl_3$): 1.90 (4H, m), 2.68 (2H, t, J=5 Hz), 3.85 (2H, t, J=5 Hz), 5.26 (1H, s), 10.20 (1H, br. s, exchangeable with D_2O). Found: C, 60.62; H, 7.42; N, 20.09%. Calcd for $C_7H_{10}ON_2$: C, 60.85; H, 7.30; N, 20.28%.

Acetylation of I, 2-Acetoxypyrazolo[1,5-a]pyridine (XIII). A mixture of I (150 mg) in Ac_2O (10 ml) was heated under reflux for 2 h. After evaporation of solvent *in vacuo*, the residual oil was purified by passing through a column of SiO_2 to give colorless oil (188 mg, 97% yield). UV λ_{max}^{MeOH} nm (log ε): 222.5 (4.60), 286 (3.59). IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 1780, 1645, 1380. Found: C, 61.48; H, 4.43; N, 16.12%. Calcd for $C_9H_8O_2N_2$: C, 61.36; H, 4.58; N, 15.90%.

The authors are grateful to the members of the Central Analysis Division of this school for the elemental analyses and the measurement of NMR spectra.

A Potential Synthetic Intermediate of *dl*-Carnosic Acid

P. Kurian OOMMEN*

Department of Chemistry, McMaster University, Hamilton, Ontario, Canada

(Received January 22, 1975)

The Birch reduction of 2,7-dimethoxy-3-isopropylnaphthalene (IIb), which itself was made from IIa in five steps, followed by acid hydrolysis yielded the tetralone IIIa and the latter was carboxymethylated to IIIb by reaction with dimethyl carbonate and sodium hydride. Michael condensation of IIIb with methyl vinyl ketone yielded the unsaturated ketone IV. The tricyclic ketone IV on methylation followed by thioketalisation gave the thioketal IXa and the latter on Raney nickel desulfurisation yielded Ic.

Ever since Wenkert[1] established the structure of the naturally occuring oxygenated diterpene carnosic acid (Ia) the synthesis of this material with a rare C–20 carboxylic acid function presented great challenge. While the present work[2] was in progress Meyer and Schindler[3] reported the total synthesis of ethyl *dl*-carnosate dimethyl ether (Ib) following an A→B→C sequence. Later Mayer and Shew[4] developed a new method of constructing the 11,12-dihydroxylated C-ring of carnosic acid.

Results and Discussion

The present work[2] is centred around the total synthesis of Ic following a C→B→A sequence. The known 2,7-dimethoxynaphthalene (IIa) was converted to IIb in five steps. This conversion involved (i) lithiation of IIa with butyl lithium and carbonation[5] of the lithiation product using Dry Ice, (ii) esterification of IIc, (iii) reaction of IId with methyl magnesium iodide, (iv) dehydration of the tertiary alcohol IIe and (v) hydrogenation of IIf. The procedure employed in the above reaction sequence was similar to Bergmann's method[6] of converting 2-acetylnaphthalene to 2-isopropylnaphthalene.

The next aim was to selectively reduce the less substituted ring and functionalise C–1 of the resultant tetralone. Thus the Birch reduction[7] of IIb using 2.45 equivalents of sodium in liquid ammonia followed by acid hydrolysis yielded the 2-tetralone IIIa. It is possible that some amount of reduction of the more substituted ring might have taken place at the same time resulting in the tetralone IIIc. Since the carbonyl group of IIIc is sterically hindered it cannot be expected to form a bisulfite adduct and hence this reaction can be used to separate IIIc from IIIa. The tetralone IIIa was carboxymethylated at the 1-position with dimethyl carbonate and sodium hydride in 80% yield by a modification of the procedure of Rhoads.[8,9] It is interesting to note that the reaction of methyl magnesium carbonate with 5-methoxy-2-tetralone has been reported[10] to result in carboxymethylation at the 3-position only. The highly enolic nature of the keto-ester IIIb obtained above implies that the steric interaction between the C–1 ester group and C–8 hydrogen was not sufficient to destabilise its enolic form.

To construct the tricyclic skeleton the Michael addition[11] of the keto-ester IIIb to methyl vinyl ketone was carried out in the presence of triton B methoxide and this resulted in the tricyclic ketone IV in 41.5% yield. The unsaturated ketone IV was methylated with methyl iodide and potassium tertiary butoxide according to the general procedure of Barton.[12] This procedure has been applied to systems similar to the one under study by Meyer[13] and by Stork.[14] The crude methylation product contained in addition to V, minor quantities of poly-methylation products as evidenced by the mass spectrum. Attempts to hydrogenate the crude methylation product at atmospheric pressure in the presence of 5% palladium-on-charcoal in glacial acetic acid resulted in a complex mixture of compounds containing products of reduction of the 5,6-double bond and/or the 3-keto group. Hydrogenation at high pressures yielded the saturated lactone VI. In hydrogenation of similar bicyclic ketone VII Meyer[13] obtained the lactone VIII.

In order to avoid the complicating effects of the 3-keto group during hydrogenation, the methylation product V was converted to the thioketal IXa by treatment with ethane-1,2-dithiol and boron trifluoride etherate in acetic acid. The procedure adopted was that of Stork.[14,15] Thioketalisation was accompanied by partial demethylation of the C–20 ester group. The thioketal acid (IXb)–thioketal ester (IXa) mixture on treatment with diazomethane in ether afforded the thioketal ester (IXa) in a pure form. The reaction proceeded in an overall yield of 80.4% from the unsaturated ketone IV. Desulfurisation of the thioketal IXa was effected by refluxing an alcoholic solution of

* Present address: Department of Chemistry, University of Tabriz, Tabriz, Iran.

IXa with an active variety of Raney nickel prepared by the method of Burgstahler.[16] Desulfurisation was accompanied by partial reduction of the 5,6-double bond. In similar tricyclic compounds with a C–20 methyl group the reduction of the 5,6-double bond has been found[14,15] to occur concomitantly with desulfurisation of the thioketal group. The rationalisation of the resistance of the 5,6-double bond to reduction in compounds with C–20 ester functions is rather difficult. The reduction of the 5,6-double bond was completed by refluxing the mixture obtained from the previous treatment with a large excess of the same active variety of Raney nickel in a current of hydrogen. Methyl *O*-methyl-11-desoxycarnosate (**1c**) was thus obtained in 62.4% yield from the thioketal IXa. An authentic sample of Ic was not available for comparison. But the authenticity of the synthetic sample was proved by the results of microanalysis, NMR and mass spectral data.

Since oxygenation of the C–11 position[3] of 11-desoxycarnosate has been achieved and demethylation of the C–20 ester[3] and the C–12 methyl ether[1] have been carried out, the total synthesis of Ic completes the synthesis of a potential synthetic intermediate of *dl*-carnosic acid.

Experimental

2,7-Dimethoxy-3-naphthoic acid (IIc). The preparation of 2,7-dimethoxynaphthalene (IIa) was effected by the reaction of 2,7-dihydroxynaphthalene with dimethyl sulfate and sodium hydroxide. The naphthoic acid IIc was obtained by carboxylation of IIa by the procedure of Gilman.[5] The reaction proceeded in 64.2% yield. Two crystallisations from 1:1 benzene–ethanol afforded an analytical sample, mp 185—186 °C; reported[5] mp 185.5 °C.

2,7-Dimethoxy-3-carbomethoxynaphthalene (IId). The esterification of the naphthoic acid IIc was carried out by the method of Fisher.[17] Refluxing a solution of the acid IIc in absolute methanol containing catalytic amounts of concentrated sulfuric acid gave the ester IId in 93% yield. Two crystallisations from 1:1 benzene–hexane yielded an analytical sample of IId, m.p. 101—102 °C; IR ($CHCl_3$) 1627, 1722 cm^{-1} (ester carbonyl); PMR δ ($CDCl_3$) 3.83 (s, C–7 methoxyl), 3.87 (s, C–2 methoxyl), 3.92 (s, C–3 ester methyl), 6.94 (q, C–6 H, $J_{5,6}$=9.5 Hz, $J_{6,8}$=2 Hz), 6.95 (d, C–8 H, $J_{5,8}$=2 Hz), 7.03 (s, C–1 H), 7.62 (d, C–5 H, $J_{5,6}$=9.5Hz), 8.19 (s, C–4H); Found: C, 68.32; H, 5.77%. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73%.

2,7-Dimethoxy-3-(2'-hydroxy-2'-propyl) naphthalene (IIe). A solution of 17.5 g of methyl 2,7-dimethoxynaphthalene-3-carboxylate (IId) in about 700 ml of anhydrous ether was added to 100 ml of a stirred solution of methyl magnesium bromide in ether containing 0.43 g of the reagent per ml. As the reaction progressed a white precipitate separated out. When all the ester was added the reaction mixture was refluxed for 1 h. The mixture was allowed to cool to room temperature and decomposed with 10% acetic acid. The reaction product was extracted with ether and the ether solution on evaporation yielded 17.3 g (99%) of naphthalene alcohol IIe, which was sufficiently pure for further reaction. A small portion of IIe was dissolved in hexane and filtered through a small column of alumina. The filtrate on evaporation yielded IIe as colourless crystals and two crystallisations from hexane and one from hexane–ether (3:1) mixture gave an analytical sample, mp 104.5—106 °C; IR ($CHCl_3$) 1630, 3533 (broad, intramolecularly hydrogen bonded OH), 3650 cm^{-1} (sharp, free OH); PMR δ ($CDCl_3$) 1.68 (s, isopropanol methyls), 3.77 (3H, s) and 3.81 (3H, s) (C–2 and C–7 methoxyl groups), 4.1 (1H, s, OH, $W^{h/2}$=7.5 Hz), 6.95 (q, C–6 H, $J_{5,6}$=9.5 Hz, $J_{6,8}$=2.5 Hz), 6.97 (d, C–8 H, $J_{6,8}$=2.5 Hz), 6.99 (s, C–1 H), 7.57 (d, C–5 H, $J_{5,6}$=9.5 Hz), 7.69 (s, C–4 H); Found: C, 73.21; H, 7.45%. Calcd for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%.

2,7-Dimethoxy-3-isopropylnaphthalene (IIb). A solution of the naphthalene alcohol IIe (17 g) in 150 ml of glacial acetic acid was refluxed for 30 min and the volume of the solution was reduced to about 25 ml by evaporation. The isopropenylnaphthalene IIf was not isolated and was hydrogenated in the presence of 1.8 g of 5% palladium on charcoal at 60 psi pressure for 24 h. The catalyst was removed by filtration and the filtrate evaporated to dryness. The residue on work up gave 16.3 g of IIb. A benzene solution of IIb was filtered through a column containing 60—65 g of alumina and this treatment resulted in 15.62 g (98.5%) of pure isopropylnaphthalene. Three crystallizations from hexane–petroleum ether, 30—60°C (3:1) gave an analytical sample, mp 95—96°C; IR ($CHCl_3$) 1602, 1623 cm^{-1}, PMR δ ($CDCl_3$) 1.28 (6H, C–3 isopropyl CH_3, d, J=7 Hz), 3.52 (1H, m, C–3 isopropyl methine H, J=7 Hz), 3.7 (3H) and 3.74 (3H) (s, C–2 and C–7 methoxyl groups), 6.85 (s, C–1 H), 6.88 (d, C–8 H, $J_{6,8}$=2.5 Hz), 6.89 (q, C–6 H, $J_{5,6}$=9.5 Hz, $J_{6,8}$=2.5 Hz), 7.43 (s, C–4 H), 7.51 (d, C–5 H, $J_{5,6}$=9.5 Hz); Found: C, 78.35; H, 7.86%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

1,2,3,4-Tetrahydro-7-methoxy-6-isopropylnaphthalen-2-one (IIIa). The 2-tetralone IIIa was prepared by the reduction of the naphthalene IIb using sodium in liquid ammonia solution. To a solution of the naphthalene IIb (6.4346 g) in a solvent mixture of 25 ml of absolute ethanol, 30 ml of tetrahydrofuran, 150 ml of anhydrous ether and 500 ml of liquid ammonia was added clean metallic sodium (1.572 g) in small pieces at a time. The reaction mixture was left overnight and the residue was acidified to pH 5 and extracted with ether. The

crude dihydronaphthalene (6.5 g) was hydrolysed by boiling with 30 ml of acetone and 6 ml of 3 M hydrochloric acid. The resultant solution was diluted with water, extracted with ether and the ether solution evaporated to dryness to yield 4.336 g of the crude tetralone IIIa. The crude product was purified by conversion to its bisulfite adduct and regeneration of the tetralone with sodium bicarbonate solution. Finally fractional distillation under reduced pressure afforded 4.0961 g (67.1%) of IIIa as a colorless liquid, bp 120—125 °C (0.33 mmHg); IR ($CHCl_3$) 1711 cm^{-1}; PMR δ ($CDCl_3$) 1.16 (6H, d, isopropyl methyls, J=6.5 Hz), 2.4 (t, C-3 H, $J_{3,4}$=6.5 Hz), 2.92 (t, C-4 H, $J_{3,4}$=6.5 Hz), 3.22 (m, isopropyl methine H, J=6.5 Hz), 3.38 (s, C-1 H), 3.75 (s, C-7 methoxyl), 6.46 (s, C-8 H), 6.88 (s, C-5 H); Found: C, 76.87; H, 8.19%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31%.

1,2,3,4-Tetrahydro-7-methoxy-6-isopropyl-1-carbomethoxynaphthalen-2-one (IIIb). To a solution of 5.45 g of the 2-tetralone IIIa in 50 ml of dimethyl carbonate was added sodium hydride derived from 1.32 g of a sample of sodium hydride in mineral oil (51%) made free from mineral oil by washing with anhydrous ether. The reaction mixture was kept at ice-bath temperature for 15 min and at room temperature for 48 h in an atmosphere of nitrogen. It was then refluxed for 30 min, cooled to room temperature and the excess sodium hydride destroyed by pouring the reaction mixture in to ice-cold 10% hydrochloric acid. The organic material was extracted with ether and the solvents evaporated off. The residue on vacuum distillation afforded 5.52 g (80%) of the keto-ester IIIb as a colorless liquid, bp 150—160 °C (0.03 mmHg); IR ($CHCl_3$) 1587, 1629 (hydrogen bonded ester carbonyl), 1700 (weak), 1723 (weak) cm^{-1}; UV (MeOH) max. 212 (ε, 47200), 248 (ε, 15000), 255 (ε, 12400), 292 (ε, 6300), 300 (ε, 6200), 315 nm (ε, 3700); PMR δ ($CDCl_3$) 1.17 (6H, d, isopropyl methyls, J=7 Hz), 2.55 (m, C-3 and C-4 H, A_2B_2 system), 3.31 (m, isopropyl methine H, J=7 Hz), 3.75 (s, C-7 methoxyl), 3.85 (s, ester methyl), 6.81 (s, C-8 H), 7.17 (s, C-5 H), 12.96 (s, C-2 enolic H); Found: C, 69.66; H, 7.20%. Calcd for $C_{17}H_{20}O_4$: C, 69.54; H, 7.20%.

2,3,4,4a,9,10-Hexahydro-4a-methoxycarbonyl-6-methoxy-7-isopropylphenanthren-2-one (IV). To a solution of 5.52 g of the keto-ester IIIb in 200 ml of ice-cold absolute methanol under an atmosphere of nitrogen was added dropwise 1.68 g of methyl vinyl ketone. Triton B methoxide (470 mg) (40% solution of benzyl trimethyl ammonium methoxide in methanol) was then added and the reaction mixture cooled for a further 15 minutes and then left at room temperature for 24 h. The progress of the reaction was followed by periodic testing with ferric chloride. After 20—24 h a negative test was obtained. The reaction was stopped by addition of a few drops of 10% acetic acid until the solution was neutral. The methanol was evaporated under reduced pressure and the residue diluted with water and extracted with ether. The solution was evaporated to dryness and the IR and PMR spectra of the product indicated that it was a hydroxy ester.

It was, without further purification, refluxed with *p*-toluene sulfonic acid (5% by weight) in toluene solution using a Dean-Stark water separator. After 16 h the reaction mixture was evaporated to dryness and the residue chromatographed on alumina. In this way 2.722 g (41.5%) of the unsaturated ketone IV was obtained. Three crystallisations from hexane-ether (8: 1) mixture yielded an analytical sample, mp 94—95 °C: IR ($CHCl_3$) max. 1661, 1722 cm^{-1}; UV (MeOH) max. 230 (ε, 23000), 282 nm (ε, 3000); PMR δ ($CDCl_3$) 1.18 (6H, d, isopropyl CH_3, J=7 Hz), 3.23 (m, isopropyl methine H, J=7 Hz), 3.65 (s, C-6 methoxyl), 3.78 (s, ester methyl), 5.99 (s, C-1 H), 6.87 (s, C-5 H), 6.89 (s, C-8 H); Found: C, 73.17; H, 7.46%. Calcd for $C_{20}H_{24}O_4$: C, 73.14; H, 7.37%.

Methyl O-Methyl-3-keto-11-desoxy-Δ^5-carnosate (V). To a solution of 656 mg of the unsaturated ketone IV in 20 ml of anhydrous *t*-butanol was added a solution of 672 mg of potassium *t*-butoxide with stirring. During the addition of the butoxide the pale yellow solution turned deep orange in coloru. Methyl iodide (0.78 ml, 1.704 g) was then added and after a short interval the solution became turbid due to precipitated potassium iodide. The reaction mixture was left at room temperature under a nitrogen atmosphere for 48 h and the reaction was stopped by addition of 10% hydrochloric acid. The bulk of *t*-butanol was evaporated off under reduced pressure, and the residue extracted with ether after mixing with 50 ml of water. The ether solution on evaporation yielded 680 mg of an unstable dark brown liquid which was used directly to prepare IXa. *Thioketal IXa.* To a well-stirred solution of the methylation product V (680 mg) in 7 ml of glacial acetic acid kept at 5°C in an atmosphere of nitrogen was added 2 ml of ethane-1,2-dithiol and then dropwise 2 ml of boron trifluoride etherate over a 10 min period. The reaction mixture developed deep orange colour and the thioketal derivative separated out. Stirring was continued at 5 °C for 30 min and at room temperature for 1 h. The mixture was again cooled to 5°C and filtered under suction. The product was dissolved in 20 ml of ether and treated with excess of diazomethane solution in ether for 5 min and the ether evaporated off and this resulted in 695 mg (80.4%) of the thioletal IXa as colourless crystals. Three recrystallisations from acetone afforded an analytical sample of IXa, mp 206—207.5 °C; UV (MeOH) max. 238 (ε, 1850), 280 (ε, 1240), 285 nm (ε, 1240); PMR δ ($CDCl_3$) 1.18 (6H, d, C-16 and C-17 methyls, $J_{15,16}$=6.5 Hz), 1.22 (s, C-4 axial CH_3), 1.51 (s, C-4 equatorial CH_3), 3.2 (4H, m, C-3 thioketal $-CH_2-CH_2-$ group), 3.53 (C-20 ester CH_3), 3.77 (s, C-12 $-OCH_3$), 6.12 (m, C-6 H), 6.73 (s, C-11 H), 6.93 (s, C-14 H); Found: C, 66.52; H, 7.34; S, 14.82%. Calcd for $C_{24}H_{32}S_2O_3$: C, 66.65; H, 7.46; S, 14.80%.

Methyl O-Methyl-11-desoxycarnosate (Ic). A solution of 57.6 mg of the thioketal IXa in 20 ml of ethanol (absolute) was heated to reflux in an atmosphere of nitrogen. To the boiling solution was added 5 g of active Raney nickel prepared according to the procedure of Burgstahler.[16] The reaction mixture was refluxed for 30 min, cooled to room temperature and the catalyst filtered off under suction in an atmosphere of carbon dioxide. The filtrate was evaporated to dryness and a PMR spectrum of the product indicated partial reduction of 5,6-double bond. The material was dissolved in 20 ml of ethanol and refluxed with 5 g of active Raney nickel for a further 5 h in an atmosphere of hydrogen. The reaction mixture was cooled to room temperature, the catalyst filtered off and the filtrate evaporated to dryness. The residue on crystallisation from ethanol afforded 28.6 mg (62.4%) of methyl *O*-methyl-11-desoxycarnosate (Ic). Two crystallisations from ethanol yielded an analytical sample of Ic, mp 108—109.5 °C; IR ($CHCl_3$) max. 1605, 1707 cm^{-1}; UV (MeOH) max. 230 (ε, 5730), 280 (ε, 2400), 287 nm (ε, 2350); PMR δ ($CDCl_3$) 0.8 (s, C-4 axial CH_3), 0.98 (s, C-4 equatorial CH_3), 1.18 (6H, d, C-16 and C-17 methyls, J=6.5 Hz), 3.2 (1H, heptet, C-15 H, J=6.5 Hz), 3.55 (s, C-20 ester methyl), 3.75 (s, C-12 methoxyl), 6.72 (s, C-11 H), 6.86 (s, C-14 H); mass spectrum, mol wt calcd for $C_{22}H_{32}O_3$, 344.235; observed, 344.236; mass calcd for $C_{22}H_{31}O_3$, $(M-1)^+$ ion, 343.227; observed, 343.226; mass calcd for $C_{21}H_{29}O_3$, $(M-15)^+$ ion, 329.212; observed, 329.213. Found: C, 76.80; H, 9.43%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

The author wishes to thank Professor R. A. Bell for encouragement and help rendered during the course of this work and the Ontario Government for financial assistance.

Conversion of Alkyl Chlorides to Bromides, Selective Reactions of Mixed Bromochloroalkanes, and Halogen Exchange

W. Edward WILLY, Dennis R. McKEAN, and Barbara A. GARCIA

Chemistry Research Laboratory,[1] *Zoecon Corporation, 975 California Ave., Palo Alto, California 94304, USA*

(Received January 5, 1976)

Primary alkyl chlorides are quantitatively converted to their corresponding bromides in the presence of ethyl bromide, *N*-methyl-2-pyrrolidinone, and a catalytic amount of metal bromide. A variety of chlorides can be converted. Selective functionalization at bromine of several primary bromochloroalkanes was studied in conjunction with the chloride-bromide conversion for multistep syntheses. Methods for halogen exchange between chloride, bromide, and iodide in the octyl halide series are presented.

Alkyl bromides are often synthetically more useful than are their corresponding chlorides, as for example in the preparation of Grignard[2] and lithium reagents[3] and in copper-catalyzed alkylations.[4] Their convenience in these cases is due to their much higher reactivity.[5] For example, alkyl chlorides, other than for small molecules (*e.g.* butyl chloride), are often virtually inert under conditions for conversion to their Grignard reagents.[2] The reactivity difference between chlorides and bromides in copper-catalyzed alkylations is often large enough so that the chlorides are essentially useless.[4] There are other types of reactions in which the reactivity differences between bromides and chlorides are of practical significance.[6]

In view of the practical implications of these Br–Cl reactivity differences and because many alkyl chlorides are commercially available whereas their corresponding and often more reactive bromides are not, we were interested in a method of direct conversion of acyclic alkyl chlorides to their corresponding bromides. Many such attempts at direct conversion have been reported, for example with octyl chloride (**1**),[7] propargyl chloride (**4**),[8] and 4-chloromethyl-1,3-dioxolane (**11**)[9] (*cf.* Table 1), but in all cases[10] yields were low and the crude bromides were always contaminated with chlorides.[11]

We have discovered a simple, cheap, and efficient conversion of primary alkyl chlorides to their corresponding bromides. We wish to report the method (which can be generalized for all Cl, Br, and I interconversions) along with an indication of its synthetic utility.

Results and Discussion

Chloride-Bromide Equilibria. In our early work we sought a method of conversion of chlorides to bromides based upon the solubility difference between NaBr and NaCl. The utilization of the solubility differences (in acetone) between NaI and NaBr or NaCl to effect conversion of chlorides or bromides to iodides has long been known.[12] In all of our attempts, under various conditions, only partial conversion of chlorides to bromides was realized (see Table 3); in the best case (NaBr/*N*-methyl-2-pyrrolidinone)[13] we achieved an 84% conversion to bromide. In several cases the solvents reacted with the chlorides and bromides (Table 3, entries 2,3,11,17,18).

The limiting factor of this unsuccessful approach is that equilibrium is established between RCl and RBr (*cf.* Table 3, entries 27, 28), and a considerable amount of RCl always remains. We realized, then, that the Cl–Br conversion would have to be carried out in the presence of a solvent, or additive, which would react with Cl^- to yield a product which could easily be removed from the reaction mixture.

$$RCl \xrightarrow[\text{Solvent}\ \text{Additive}\ \Delta]{MBr} RBr \qquad (I)$$

M = metal, Li, K, Na, *etc.*
Additive = alkyl bromides

Scheme 1.

Conversion of Chlorides to Bromides. We found that the conversion (Eq. I) of RCl to RBr was quantitative if an alkyl bromide were added to the mixture of alkyl chloride (RCl), inorganic bromide (MBr), and solvent. We found ethyl bromide (bp 38 °C) to be most convenient since it (and ethyl chloride formed from it) is easily removed after the conversion.

We consider that *optimum conditions* on a large scale for the Cl–Br conversion (Eq. I) generally are with 0.2 equivalents of NaBr, 10 equivalents of EtBr, *N*-methyl-2-pyrrolidinone, and usually at 60—70 °C (see Table 1). Under these conditions the conversion is 97—99% complete and occurs within 3—10 days (exception: **11**). The optimum conditions can be varied if complete conversion (≥99.9%) to bromide is desired (*cf.* entry 1, Table 2).

N-Methyl-2-pyrrolidinone was selected as the reaction solvent based upon our preliminary studies (Table 3). *N*,*N*-Dimethylformamide (DMF) was utilized effectively in the Cl–Br conversion in the case of **4**,[8] but not for **7** (chlorohexyl formate forms in that case). The NaBr functions simply as a catalyst in the Cl–Br conversion since octyl chloride is nearly completely converted to octyl bromide with either four equivalents of NaBr or as little as 0.01 equivalents (*cf.* Table 2), although reaction time is considerably longer under catalytic conditions (NaBr is not a unique initiator here, and even if it were omitted, the conversion should eventually proceed if any trace impurities were present which react with ethyl bromide to liberate Br^-). The ethyl bromide additive is convenient, but 2-bromopropane and dibromomethane were found to be useful for the Cl–Br conversion. In principle, many other alkyl bromides could be used.

A general procedure for the conversion is described in the Experimental Section for compound **10**. Some

99.7	30	4	3
99.6	30	2	3
99.3	30	1	3
99.0	30	0.5	3
95.0	30	0.1	3
48.0	30	0.01	3
99.4	30	0.01	10

a) In each case 1 g of octyl chloride was in 18 ml of *N*-methyl-2-pyrrolidinone (exception: 50 ml for the first case). b) Determined by GLPC. c) Solubility in *N*-methyl-2-pyrrolidinone at 70 °C of NaBr=3.52 g/100 ml; of NaCl=0.16 g/100 ml (when EtBr is present the solubility of NaBr drops considerably).

advantages of the process are that it is very simple to carry out even on a large scale, ethyl bromide is inexpensive and easy to remove (and can be recycled), and no solvent is required to extract the product bromide.

The method appears to be general for *primary* alkyl chlorides (or dichlorides)[14] and several functional groups can be present in the chloride. Certain of the functions are mildly unstable to the conversion conditions; for example, the acetal function in **11** and the tetrahydropyranyl (THP) function in **6**. The hydroxyl function in **7** reacts with ethyl bromide so that 2-bromopropane was used to effect the conversion of **7**. Steric hindrance to the conversion was encountered for the acetal **11** and also for 2-chlorooctane (**12**). Note that although 2-bromopropane readily exchanges Cl^-, 2-chlorooctane (**12**) does not.[15] The tertiary ether 6-chloro-3-methoxy-3-methylhexane (prepared by methoxymercuration of **3**)[17] could not be converted to its bromide; under the conversion conditions it was quickly converted to a mixture of isomers of the unsaturated ether corresponding to **3** (Cl replaced by OCH_3) even in the presence of added sodium hydrogen carbonate, pyridine, 3A molecular sieves or the proton-sponge 1,8-bis(dimethylamino)naphthalene.

Selective Reactions with Mixed Halides. In addition to converting many commercially available chlorides to

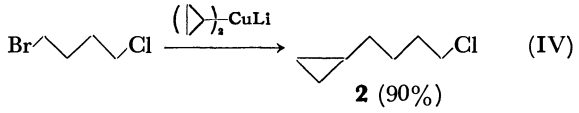
Scheme 2.

their commercially unavailable and more reactive bromides we were interested in utilizing the Cl–Br conversion and the reactivity difference of bromide *vs.* chloride for multistep synthetic schemes (*cf.* Scheme 2).

We have found that certain bromochloroalkanes behave, *towards alkylation and metallation with magnesium*, as if they were simple bromoalkanes; in these cases the chlorine is essentially inert. For example, we found that 1-bromo-4-chlorobutane could be selectively functionalized at the bromine according to the plan of Scheme 2. Thus reaction of 1-bromo-4-chlorobutane with lithium dicyclopropylcuprate (Eq. IV)[18] yields

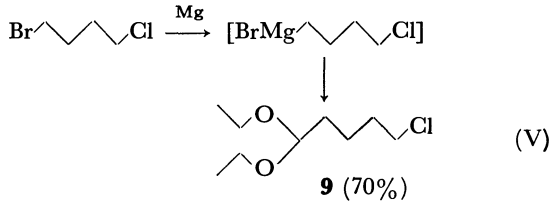
1-chloro-4-cyclopropylbutane exclusively and quantitatively; 1-bromo-3-chloropropane likewise yields 1-chloro-3-cyclopropylpropane.[26] (The corresponding reaction using bromochloromethane yields cyclopropylmethyl chloride but in low yield.) Chloride **3** (Table 1) was also selectively prepared from lithium di-2-butenylcuprate and 1-bromo-3-chloropropane. The



(IV)

2 (90%)

reaction of bromochlorobutane with magnesium yields chlorobutylmagnesium bromide[19] which, when treated with diethyl phenyl orthoformate (Eq. V)[20] yields 5-chloro-1,1-diethoxypentane (**9**); acetal **9** has previously

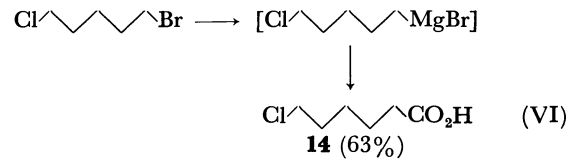


(V)

9 (70%)

been prepared (48% yield) from 5-chlorovaleryl chloride.[21a] The hexyl and heptyl chloroacetals corresponding to **9** were likewise formed from the five and six-carbon bromochloroalkanes, respectively (see Experimental Section). We found that for similar acetal functionalization (*cf.* Eq. V) of the chloro-THP **6** it was first necessary to convert to the bromide. Thus, while **6** (Table 1) was exceedingly unreactive with magnesium in tetrahydrofuran, the bromide of **6** reacted readily to yield $THPO(CH_2)_6MgBr$ which, after treatment with $PhOCH(OCH_2CH_3)_2$, yielded $THPO(CH_2)_6CH(OCH_2CH_3)_2$.

Treatment of 1-bromo-5-chloropentane with magnesium, followed by carbon dioxide, yielded high purity 6-chlorohexanoic acid (Eq. VI).

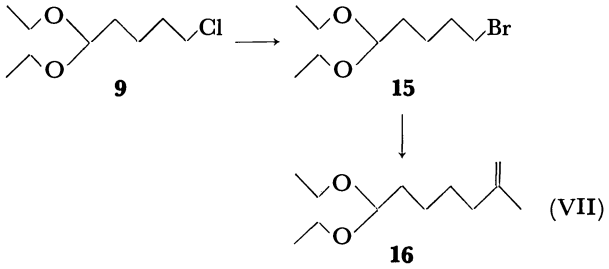


(VI)

14 (63%)

In an effort to find other metals which would selectively attack bromine (*cf.* Scheme 2), we attempted to selectively metallate 1-bromo-6-chlorohexane with lithium in ether; a complex mixture was obtained.

The products of reactions IV and V can be directly utilized for further reactions typical of alkyl chlorides, or can be converted to their corresponding bromides if more reactive molecules are desired for reactions typical of bromides (*cf.* Scheme 2). For example, 5-chloro-1,1-diethoxypentane (**9**, Eq. V) was converted to its bromide which was alkylated with lithium di-2-propenylcuprate to yield 1,1-diethoxy-6-methyl-6-heptene (Eq. VII).



(VII)

Direct reaction of the cuprate with the chloride (**9**) was expected to be poor[18] since the corresponding reaction of lithium di-2-propenylcuprate with 6-chloro-3-methoxy-3-methylhexane (prepared from **3**) was very poor.

Hydrolysis. As part of our study we also found that octyl bromide (**13**) could be directly converted to 1-octanol (*cf.* Table 1). Under the conditions of this hydrolysis, 11-bromoundecanoic acid was completely converted to 11-hydroxyundecanoic acid (see Experimental Section).[29b] However, we were unable to convert ethyl 4-bromobutyrate (from **8**) to ethyl 4-hydroxybutyrate; butyrolactone was apparently formed in that case.

Halogen Exchange. We found that the conversion procedure (Scheme 1) used for the chlorides of Table 1 is also apparently general for all halogen exchanges involving *primary* Cl, Br, and I (see Table 4); similar exchanges to produce fluorides are also known.[22]

a) Except for entry 1 (*cf.* Table 2) all conversions were carried out with 1 ml *N*-methyl-2-pyrrolidinone/mmol R_1X, and % R_1Y was determined by GLPC (response ratios were taken as = 1.0). One gram samples of R_1X were used (except for the 2nd and 4th entries) and yields were not determined. b) Distilled yield of octyl iodide (bp 36.5—38 °C/0.01 mmHg) from 50 g of octyl chloride here was 98%. c) Distilled yield of octyl iodide (bp 80 °C/1.4 mmHg) from 50 g of octyl bromide here was 98%. d) This method in these two cases is more convenient, and of about equal expense (since most of the MeI is recovered and is recyclable: 93% by volume of MeI was recovered from the 4th entry) compared to the original Finkelstein method.[12]

apparatus (40 theoretical plates) from Norell Chemical Co. NMR spectra were recorded on a Varian T-60 instrument and infrared spectra on a Beckman Acculab 4 instrument. All solvents and organic reagents were dried over activated 4A molecular sieves prior to use. The bromochloroalkanes[23] were purchased from Fairfield Chemical Co., Blythewood, S.C. 29016, USA. All compounds not commercially available (described below) were characterized by their IR, NMR, and mass spectra.

Alkyl Bromides, General Procedure. The conversion of chloride **10** to its corresponding bromide is described as a representative example. A mixture of 101.7 g (0.62 mol) of 2-(3-chloropropyl)-2-methyl-1,3-dioxolane (**10**; Aldrich Chem. Co.), 617 ml of *N*-methyl-2-pyrrolidinone, 461 ml (6.2 mol) of ethyl bromide, and 12.7 g (0.124 mol) of sodium bromide (Mallinckrodt) was heated at 65 °C, in a 1-neck flask under a Friedrich condenser, for 3 days. The mixture was then cooled and poured into a mixture prepared from 1 liter each of ice, water, and brine, and contained in a separatory funnel. The lower layer, after shaking, was removed and washed with a mixture of 1 liter of water and 1 liter of brine. The organic phase was again removed and distilled (without drying) through a 45 cm Vigreaux column. Ethyl bromide (containing some ethyl chloride) was collected at 38—40 °C (1 atm). The remaining material was then distilled under vacuum. There was obtained 114.6 g (89%) of 2-(3-bromopropyl)-2-methyl-1,3-dioxolane, of 97% purity, bp 65 °C/3.5 mm Hg (lit,[25] 98—101 °C/13 mm Hg).

Highly volatile halides (*e.g.* **4**) were isolated by spinning-band distillation and thermally unstable ones (*e.g.* **7**) by column chromatography.

In the case of the chlorodioxolane **11** (Table 1) the total conversion time was shortened to 30 days by addition of the EtBr (at 0 °C) after the Cl–Br conversion had proceeded to *ca.* 67% RBr after 2 days at 65 °C in *N*-methyl-2-pyrrolidinone alone.

1-Chloro-4-cyclopropylbutane (2). A solution of 1.1 M cyclopropyllithium in ether (660 ml) was added over 45 min, at −35 °C, to a mixture of 73 g (0.38 mol) of copper (I) iodide and 660 ml of tetrahydrofuran (THF) After a Gilman test was negative, 1-bromo-4-chlorobutane (54 g, 0.32 mol) was rapidly added to the mixture which was held at −35 °C for 1.5 h. Aqueous satd. $(NH_4)_2SO_4$ (NH_4Cl yielded poor quality precipitates) was then added and the mixture was filtered. The product was extracted with 2 liters of 1:1 ether–pentane. The organic layer was washed several times with water, then with brine. After drying ($CaSO_4$) the extract was distilled through a 45 cm Vigreaux column to remove solvents. The pot residue was then short-path distilled to yield 37.4 g (90%) of 1-chloro-4-cyclopropylbutane (**2**):[26] bp 58—59 °C/17 mmHg; IR (neat): 3084 (▷), 3008, 2941, 2864, and 1024 cm^{-1}; NMR (CCl_4): δ 3.48 (t, J=6 Hz, 2H, C$\underline{H}_2$Cl); mass spectrum (70 eV): base peak *m/e* 55 ($\triangle^+$).

1-Chloro-3-cyclopropylpropane[26] was prepared from 1-bromo-3-chloropropane in the same manner as above, but was isolated by spinning-band distillation: bp 73 °C/85 mmHg.

Chloride **2** was converted to 1-bromo-4-cyclopropylbutane (as described above for **10**): bp 71—72 °C/15 mmHg; IR (neat): 3086 (▷), 3010, 2936, 2866, and 1023 cm^{-1}; NMR (CCl_4): δ 3.35 (t, J=6 Hz, 2H, C$\underline{H}_2$Br); mass spectrum (70 eV): base peak *m/e* 55 ($\triangle^+$).

Found: C, 47.39; H, 7.27; Br, 45.03%. Calcd for C_7H_{13}Br: C, 47.48; H, 7.40; Br, 45.12%.

6-Chloro-3-methyl-2-hexene (3). This compound was prepared from lithium di-2-butenylcuprate and 1-bromo-3-chloropropane as described above for **2**. The product (mixture of *cis/trans* isomers) was isolated in 80% yield by spinning band distillation: bp 51—52 °C/15 mmHg; IR (neat): 2874, 1449, 1382, 828, and 727 cm^{-1}; NMR (CCl_4): δ 3.47 (t, J=6 Hz, 2H, C$\underline{H}_2$Cl).

Found: C, 63.16; H, 9.88%. Calcd for $C_7H_{13}Cl$: C, 63.39; H, 9.88%.

Chloride **3** was converted to 6-bromo-3-methyl-2-hexene (as described above for **10**): bp 69—70 °C/17 mmHg; IR (neat): 2867, 1451, 1383, and 824 cm^{-1}; NMR (CCl_4): δ 3.34 (t, J=6 Hz, 2H, C$\underline{H}_2$Br).

Found: C, 47.42; H, 7.48; Br, 45.08%. Calcd for C_7H_{13}Br: C, 47.48; H, 7.40; Br, 45.12%.

5-Chloro-1,1-diethoxypentane (9). 1-Bromo-4-chlorobutane (77.1 g, 0.45 mol) was added to 12.1g (0.496 mol) of magnesium metal (10% excess) in 150 ml of THF as follows: about 2 ml of bromochlorobutane was added at 50 °C and when spontaneous reaction began the mixture was cooled to 0 °C and the rest of the bromochlorobutane was added in five equal portions, followed each time by 150 ml of THF, over a 1 h period. The mixture was stirred 2 h at 0 °C, 2 h at room temperature, then re-cooled to 0 °C. Diethyl phenyl orthoformate (88.4 g, 0.45 mol) was then added to the mixture which was stirred 2 h at 0 °C, overnight at room temperature, then filtered. The filter-cake was washed with 200 ml of ether and the filtrate was evaporated to remove solvents. The residue was diluted with ether (700 ml) and water (300 ml). The ether layer, after shaking, was removed and successively washed three times with aq. 50% sodium hydroxide (50 ml), twice with water (250 ml), once with brine (100 ml), then dried ($CaSO_4$) and evaporated to yield 83.0 g of colorless liquid which was purified by distillation through a 45 cm Vigreaux column. There was obtained from the product fraction 61.0 g (70%) of chloroacetal **9**, of 96% purity: bp 103—105 °C/15 mmHg (lit,[21a] 84—86 °C/5 mmHg); IR (neat): 2992, 2894, 1451, 1381, 1352, 1141, 1082, and 1018 cm^{-1}; NMR (CCl_4): δ 1.16 (t, J=7 Hz, 6H, $OCH_2C\underline{H}_3$) and 4.38 (t, J=5 Hz, 1H, C$\underline{H}$(OCH_2CH_3)$_2$); mass spectrum (70 eV): *m/e* (rel intensity) 151 (17), 149 (44), 121 (26), 103 (100, $CH_3CH_2OCH{=}OCH_2CH_3^+$), 85 (21), 75 (54, $HOCH{=}OCH_2CH_3^+$), and 47 (53).

Found: C, 55.67; H, 9.90; Cl, 18.10%. Calcd for $C_9H_{19}ClO_2$: C, 55.53; H, 9.77; Cl, 18.25%.

The pot residue (18.0 g, 15%) was high purity 1,1,6,6-tetraethoxyhexane: IR (neat): 2990, 2892, 1448, 1381, 1351, 1134, 1074, and 1019 cm^{-1}; NMR (CCl_4): δ 1.15 (t, J=6.5 Hz, 12H, $OCH_2C\underline{H}_3$) and 4.35 (t, J=4.5 Hz, 2H, C$\underline{H}$(OCH_2CH_3)$_2$); mass spectrum (70 eV): *m/e* (rel intensity) 170 (5), 127 (60), 103 (100), 81 (50), 75 (60), 73 (35), 59 (37), 47 (33), and 45 (33).

Found: C, 64.22; H, 11.29%. Calcd for $C_{14}H_{30}O_4$: C, 64.09; H, 11.52%.

The reactions of $Br(CH_2)_nCl$, where n=5 and n=6, with magnesium (10% excess) in THF (0 °C), followed by PhOCH(OCH_2CH_3)$_2$, according to the above conditions for preparation of **9**, similarly led to products in which the ratio of $(CH_3CH_2O)_2CH(CH_2)_nCl$: $(CH_3CH_2O)_2CH(CH_2)_nCH(OCH_2CH_3)_2$ was 89 : 11 for n=5 and 88 : 12 for n=6.

The reaction of 1 mole of $Cl(CH_2)_5Br$ with magnesium in THF (as above), followed by CO_2 gas (24 °C, 3 h),[2] yielded after distillation, 94.9 g (63%) of $Cl(CH_2)_5CO_2H$ (**14**) of 98% purity: mp 27.5—28 °C (lit,[27a] 24—26 °C); IR (neat): 3600—2400 (CO_2H), 1711 (C=O), 1463, 1416, 1283, and 946 cm^{-1}; NMR ($CDCl_3$): δ 2.39 (t, J=6 Hz, 2H, C$\underline{H}_2CO_2H$) and 3.56 (t, J=6.5 Hz, 2H, $ClC\underline{H}_2$).[30]

Chloride **9** was converted to 5-bromo-1,1-diethoxypentane (**15**; as described above for **10**): bp 98 °C/8 mmHg; IR (neat): 2988, 2894, 1448, 1380, 1351, 1138, 1072, and 1015 cm^{-1};

NMR (CCl_4): δ 1.17 (t, J=7 Hz, 6H, $OCH_2C\underline{H}_3$) and 4.39 (t, J=5 Hz, 1H, $C\underline{H}(OCH_2CH_3)_2$); mass spectrum (70 eV): *m/e* (rel intensity) 239 (1, M^+), 194 (41, $Br(CH_2)_4CH{=}OCH_2CH_3^+$), 166 (15, $Br(CH_2)_4CH{=}OH^+$), 148 (6), 103 (100, $CH_3CH_2OCH{=}OCH_2CH_3^+$), 85 (31), 75 (72), and 47 (65).

Found: C, 45.37; H, 8.01; Br, 33.69%. Calcd for $C_9H_{19}BrO_2$: C, 45.21; H, 7.95; Br, 33.44%.

4-Chloromethyl-1,3-dioxolane (11) was prepared, in 70% yield, from chloropropanediol and paraformaldehyde in dichloromethane:[28] bp 150—151 °C (lit,[9a] 144—146 °C; 150 °C[9b]).

1,1-Diethoxy-6-methyl-6-heptene (16) was prepared from the bromoacetal **15** and lithium di-2-propenylcuprate as described above for **2**. The product was isolated in 72% yield (94% purity by GLPC): bp 55 °C/0.3 mmHg; IR (neat): 3091 (>=), 1455, 1382, 1353, 1144, 1074, 1019, and 900 cm^{-1}; NMR (CCl_4): δ 1.17 (t, J=7 Hz, 6H, $OCH_2C\underline{H}_3$), 4.37 (t, J=4.5 Hz, 1H, $C\underline{H}(OCH_2CH_3)_2$) and 4.66 (br s, 2H, $=C\underline{H}_2$).

Found: C, 72.10; H, 12.06%. Calcd for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%.

11-*Hydroxyundecanoic Acid.* A mixture of 5.0 g (0.019 mol) of 11-bromoundecanoic acid, 7 ml (20×0.019 mol) of water, and 50 ml of *N*-methyl-2-pyrrolidinone was heated, at 60 °C, for 24 days. The mixture was then poured into 300 ml of water and extracted three times with 75 ml-portions of ether–pentane (1:1). The combined extracts were washed with water and brine, then dried ($CaSO_4$) and evaporated to yield a solid which was recrystallized from toluene. There was obtained 2.9 g (76%) of white solid, mp 66—67 °C (lit,[29a] 65.5—66 °C); IR (neat): 1708 (C=O) cm^{-1}; NMR ($CDCl_3$): δ 1.30 (br s, 16H, chain $\underline{H}$), 2.33 (t, J=6 Hz, 2H, $C\underline{H}_2CO_2H$) and 3.63 (t, J=6 Hz, 2H, $HOC\underline{H}_2$).

Hydrolysis of bromooctane (**13**) under similar conditions yielded 72% of 1-octanol (*cf.* Table 1).

We wish to thank John H. Jackson and Ralph A. Veit for performing the gas chromatographic analyses.

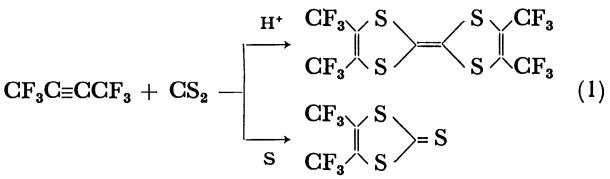
A Novel Synthesis of 2-Trialkylphosphonio-1,3-dithiole-4-carboxylates

Charles U. PITTMAN, Jr. and Mitsuaki NARITA
Department of Chemistry, University of Alabama, University AL 35486 U.S.A.
(Received January 5, 1976)

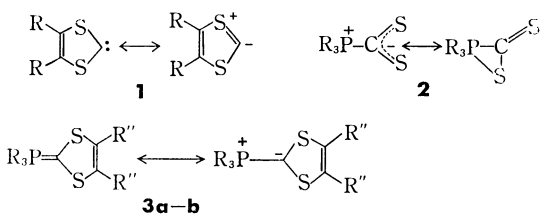
Acetylene carboxylic acids reacted with trialkylphosphine–carbon disulfide ylides to produce fair to good yields of 2-trialkylphosphonio-1,3-dithiole-4-carboxylates (**4**) at temperatures as low as −20 to −30 °C. The formation of these zwitterionic products, by a prototropic shift in the ylide **3**, differs fron the known reaction of acetylenes, such as ethyl propiolate, with carbon disulfide and tributylphosphine to give tetrathiafuvalene derivatives. The structure of these zwitterionic products was confirmed by alkaline hydrolysis, reaction with benzaldehyde, and their IR and NMR spectra. Alkaline hydrolysis of **4** gave the corresponding carboxyl-substituted 1,3-dithioles (**7**). Treatment of 2-tributylphosphonio-1,3-dithiole-4-carboxylate (**4e**) with benzaldehyde in the presence of triethylamine resulted in the formation of 2-benzylidene-1,3-dithiole-4-carboxylic acid (**8**). The methine proton of the 1,3-dithiole ring of **4** in DMSO-d_6, appeared at δ 5.41—6.24 as a singlet peak. These methine protons were readily exchanged by deuterium in the presence of methanol-d_4, and disappeared from NMR spectra.

Electron deficient acetylenes and ring-strained acetylenes are known to react with carbon disulfide to give a variety of complex structures including tetrathiafulvalenes.[2-8] For example, perfluoro-2-butyne and carbon disulfide give perfluorotetramethyltetrathiafulvalene, quantitatively, in the presence of acid.[2] In the presence of sulfur, this reaction gave 4,5-bis(trifluoromethyl)-1,3-dithiole-2-thione.[3] In these reactions (shown in Eq. 1), 1,3-dithiolium carbenes, **1** were postulated as intermediates. The chemical properties of **1** have been discussed in the literatures.[8,9] Trialkylphosphine–



(1)

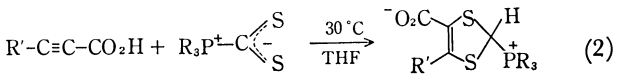
carbon disulfide ylides, **2**, known for 90 years, also react with electron deficient acetylenes to give tetrathiafulvalenes in poor yields.[4] When aromatic aldehydes were



also present, excellent yields of 2-benzylidene-1,3-dithioles were obtained.[5] In these reactions, ylide **3** was presumed to be an intermediate. The unusually high reactivity of ylides, **3**, with aldehydes was attributed to the "antiaromatic" 1,3-dithiol ring. Since the negative charge at the 2-position is not readily accomodated by delocalization over the five-membered ring, the 2-carbon is a relatively strong nucleophile.

Results and Discussion

We now report that propiolic acid and acetylene dicarboxylic acid rapidly reacted with trialkylphosphine–carbon disulfide ylides, **2**, to give the zwitterionic 2-trialkylphosphonio-1,3-dithiole-4-carboxylates, **4** (see Eq. 2). These reactions proceeded at temperatures as low as −20 to −30 °C to give adducts **4a—e** which precipitated from THF. Acetylene dicarboxylic acid reacted more rapidly than propionic acid, as judged by the disappearance of the deep maroon color of the solution, and the former also gave better yields than the latter as shown in Table 1.

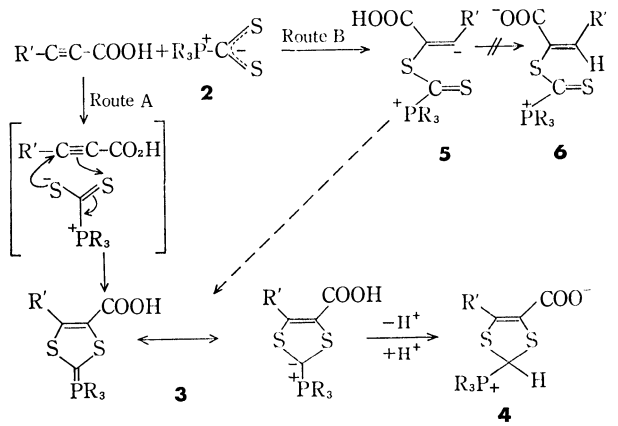


(2)

4a: R′=COOH, R=Me **4b**: R′=COOH, R=Et
4c: R′=COOH, R=*n*-Bu **4d**: R′=H, R=Et
4e: R′=H, R=*n*-Bu

The formation of **4**, instead of the acyclic compound **6** (Scheme 1) is surprising. The absence of **6** suggests the reaction proceeded *via* a concerted one-step addition similar to route A rather than by route B. Stepwise addition of **2** (route B) would initially generate acyclic zwitterion **5** with a vinyl carbanion center. It seems likely that **5** would undergo rapid C-protonation in the acidic media if it had been formed. However, rapid ring closure (**5** to **3**) cannot be definitively ruled out. A route similar to B was previously favored for the reaction of acetylenes with carbon disulfide.[2] In that work,[2] intermediates of the type **3** were implicated.

The formation of 2-trialkylphosphonio-1,3-dithiole-4-carboxylates **4**, contrasts sharply with the analogous reaction of ethyl propiolate with ylides of the type **2**.



Scheme 1.

TABLE 1. RESULTS OF REACTION OF ACETYLENES WITH PHOSPHINE–CARBON DISULFIDE YLIDES AND AQUEOUS NaOH HYDROLYSIS PRODUCTS FROM 2-TRIALKYLPHOSPHONIO-1,3-DITHIOLE-4-CARBOXYLATES, **4**

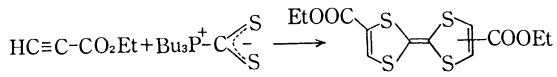
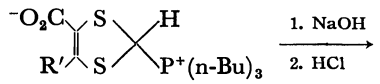
a) Product was purified by washing with acetone.

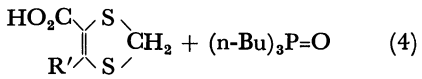
For example where R=*n*-Bu, 2,6(7)-bis(ethoxycarbonyl) tetrathiafulvalene was formed in yields of 14 to 18% (Eq. 3).



The structures of compounds **4a—e** were confirmed by their solubility, analyses, spectra, and hydrolysis reaction products. They were insoluble in benzene, ether, and THF, but soluble in water. Their analyses agreed with the assigned structures (see Table 1). The IR spectra of **4a—e** exhibited ν_{CO} bands at 1600, 1550 and 1350—1340 cm^{-1} ($-COO^-$), (see Table 2). Each compound exhibited a sharp melting (or decomposition) point (Table 1) and an NMR spectra (Table3) in accord with the assigned structure. Finally, the zwitterion structure of **4** was unequivocally confirmed by alkaline (NaOH) hydrolysis of **4e** and **4c**, followed by acidification, to give substituted 1,3-dithioles **7a** and **7b**, respectively (Eq. 4).



4e: R′=H
4c: R′=COOH



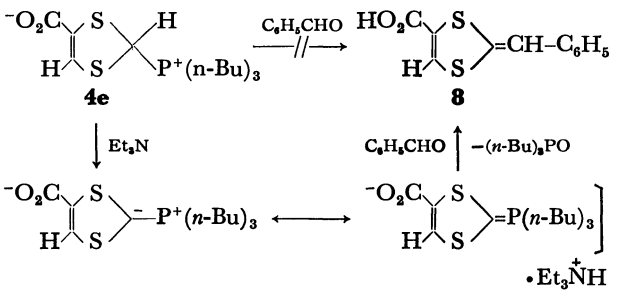
(4)

7a: R′=H
7b: R′=COOH

1,3-Dithiole-4,5-dicarboxylic acid, **7b**, contained a water of crystallization and was obtained as yellow needles which dehydrated at —80 °C to give orange crystals of **7b**. At 160—170 °C, **7b**, smoothly decarboxylated to monoacid **7a** (equation 5). This decarboxylation resembles that of 2-thioxo-1,3-dithiole-4,5-dicarboxylic acid.[11]

(5)

Compounds **4c** and **4e** did not react with benzaldehyde (See Scheme 2). However, when triethylamine



Scheme 2.

was added to **4c** or **4e**, ylides **3c** and **3e**, respectively, were formed. These ylides, as expected, rapidly reacted with benzaldehyde. For example, **4e** gave 2-benzylidene-1,3-dithiole-4-carboxylic acid, **8**, as shown in Scheme 2. This reaction further confirms the zwitterionic structure assigned to **4**.

The NMR spectra of zwitterion structures **4a—e** are summarized in Table 3. In DMSO-d_6, the methine proton of the 1,3-dithiole ring of **4a—e** appeared as a singlet at δ 5.41—6.24. In the case of **4e**, the methine proton

Alkaloids of *Rhazya stricta* Decaisne: Studies on Rhazinaline and Geissoschizine

Asima CHATTERJEE, Avijit BANERJI, Priyalal MAJUMDER, and Rekha MAJUMDER
Chemistry Department, University College of Science, Calcutta-700009, India

(Received January 5, 1976)

Chemical investigation of the basic principles of the leaves of *Rhazya stricta* Decaisne led to the isolation of a number of indolic bases. The studies on two of these, *viz.*, rhazinaline and geissoschizine are described. Rhazinaline, a new alkaloid, has been characterised as 16-formyl-16-epistrictamine. A detailed spectroscopical study of geissoschizine, which had not been previously isolated from a plant source, was carried out confirming the previous structural assignment. The isolation of this alkaloid from a plant source is important from a biogenetic viewpoint, since geissoschizine is one of the key preformed intermediates in the biosynthesis of C_{19}-C_{20} indole alkaloids.

The genus *Rhazya* comprises only two species, *viz.*, *R. stricta* Decaisne and *R. orientalis* A. DC., of which *R. stricta* grows profusely in the northwestern regions of the Indian subcontinent.[1,2] *R. stricta* is reputed in Indian folk medicine as a bitter tonic for sore throat, fever and general debility, and also as a curative for chronic rheumatism.[2] Recent investigations of *Rhazya* species have led to the isolation of a number of indole alkaloids, some of which have novel structural patterns.[3-8] In the present paper our work on the isolation and structure elucidation of two indole alkaloids from this source is described.[9,10]

Results and Discussion

Chemical investigation of the leaves of *R. stricta* Decaisne led to the isolation of five more indole alkaloids, in addition to (−)-quebrachamine,[11] rhazine (akuammidine),[11,12] strictamine[13] and rhazinine (antirhine).[11,20,21] Of these five indolic bases, designated rhazinaline, rhazinilam, R1, R2, and R3, the last two were obtained in very small amounts which precluded a detailed chemical investigation. The structure elucidation of rhazinilam, on which a preliminary report was made,[10] has been recently achieved by Smith *et al.*[14] The present paper reports in detail our studies on rhazinaline and alkaloid R1 (geissoschizine).

The dried powdered leaves of *R. stricta* were extracted successively with petrol (bp 60—80 °C) and chloroform in a Soxhlet apparatus. The marc was then percolated with ethanol. Fractionation of each of these extracts followed by repeated chromatography afforded the different alkaloids (*vide* Experimental).

The petrol extract yielded rhazinaline and an alkaloid R3 in addition to strictamine. Rhazinaline, $C_{21}H_{22}O_3N_2$ (M^+ 350), mp 137 °C, $[\alpha]_D^{25}$ +61° (EtOH) (0.002% yield) exhibited the UV spectrum characteristic of an indolenine chromophore, [λ_{max} (EtOH) 266 nm, log ε 3.78; λ_{min} (EtOH) 243 nm, log ε 3.60]. The presence of a four-proton multiplet in the PMR spectrum in the aromatic region (δ 7.06—7.73) showed the absence of further substitution in the benzenoid moiety. The PMR spectrum also revealed the presence of an ethylidene grouping (3H, double double at δ 1.78, J_1=8.5 Hz, J_2=2.5 Hz, 1H quartet around δ 5.51, J=8.5 Hz). The IR and PMR spectra of rhazinaline showed the absence of -OH or -NH- groups and the presence of a formyl [ν_{max} (Nujol) 1724 cm^{-1}; 1H singlet at δ 9.93] and methoxycarbonyl group [ν_{max} (Nujol) 1751 cm^{-1}; 3H singlet at δ 3.16]. The presence of both the formyl and methoxycarbonyl groups in rhazinaline was also indicated by the appearance of peaks at *m/e* 321 (M–CHO) and *m/e* 291 (M–CO_2Me) in its mass spectrum. Apart from these significant fragments, the mass spectrum of this alkaloid was uncharacteristic. Borohydride reduction of the base under controlled conditions afforded a dihydro compound, rhazinalinol, $C_{21}H_{24}O_3N_2$ (M^+ 352), mp 236 °C, whose IR spectrum lacked the carbonyl absorption at 1724 cm^{-1} but showed an hydroxyl band at 3333 cm^{-1}. The UV spectrum of this compound [λ_{max} (EtOH) 265 nm, log ε 3.78] indicated that the indolenine chromophore was unaffected. Reduction of both the formyl and methoxycarbonyl groups in rhazinaline was effected with lithium aluminium hydride. Rhazinalinediol, $C_{20}H_{24}O_2N_2$ (M^+ 324), mp 242 °C, which was obtained, lacked any carbonyl band in its IR spectrum, but showed an intense hydroxyl band at 3310 cm^{-1}. The presence of an indolenine chromophore in rhazinalinediol was indicated by its UV spectrum [λ_{max} (EtOH) 267 nm, log ε 3.71; λ_{max} (50% $HClO_4$/EtOH) 240, 244, 302 nm; log ε 3.78, 3.80, 3.75]. Attempts to reduce the indolenine double bond in rhazinalinediol by catalytic hydrogenation in ethanol and acetic acid failed. The formation of an acetonide by rhazinalinediol pointed to

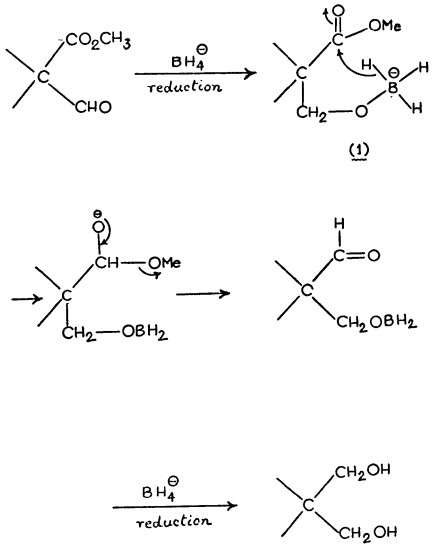

Chart 1.

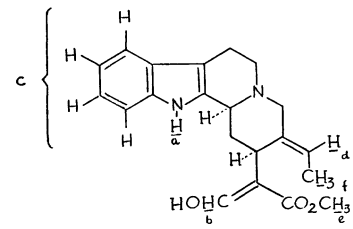
the 1,3-relationship of the two hydroxyls, which in turn showed the presence of a OHC–C(–)–CO_2Me group in rhazinaline itself. Rhazinalinediol was also obtained as the sole product on prolonged action of excess sodium borohydride on rhazinaline. This rather of unexpected reduction of the ester group by borohydride might be explained by the mechanistic scheme shown in Chart 1, which assumes an intramolecular hydride transfer from the intermediate alkoxyborohydride (**1**).

On the basis of the observations outlined above, and from biogenetic considerations rhazinaline could be represented by structure **2**. The absolute configuration at C-15 is fixed from biogenetic considerations. The configuration at this center also determines those at C-3 and C-7, as otherwise the formation of the rigid pentacyclic system in **2** would not be possible. The appearance of the C-16 methoxycarbonyl signal at the high field value of δ 3.16 suggests shielding by a π-electron system and indicates that this group is situated towards the indolenine nucleus as in **2**. The various transformations of rhazinaline should therefore be represented as in Chart 2. The failure of the indolenine double bond in rhazinaline (**2**) and rhazinalinediol (**3**) to undergo reduction under conditions which normally affect reduction of this bond, *e.g.*, in strictamine,[13] was due to the steric hindrance effected by the C-22-methoxycarbonyl and C-22-hydroxymethyl groups respectively, as was apparent in an examination of Dreiding models.

Rhazinaline should therefore be identical with 16-formyl-16-epistrictamine isolated from *R. stricta* by Smith *et al.*[15] However, only the isolation of the substance was reported in their communication, and no account of its chemistry has been subsequently published. Non-availability of a sample of 16-formyl-16-epistrictamine precluded direct comparison with our alkaloid.

An amphoteric alkaloid, designated R1, was isolated from the ethanolic extract of the leaves of *R. stricta*. The properties of this indolic base, $C_{21}H_{24}O_3N_2$ (M^+ 352), mp 187 °C (dec), $[\alpha]_D^{25}$ +72° (chloroform), λ_{max} (EtOH) 221, 267, 280 (sh) (log ε 4.32, 3.88, and 3.57) suggested its identity with the compound geissoschizine (**4**).[16] This was confirmed by direct comparison (mmp, co-TLC, superimposable IR spectra and X-ray powder powder pattern) of our alkaloid with an authentic sample of giessoschizine. The structure of geissoschizine, known as a degradation product of the "dimeric," alkaloid geissospermine, was previously determined mainly on the basis of UV and IR spectral data and chemical correlations.[16] The PMR and mass spectra of geissoschizine are in conformity with structure (**4**). In its mass spectrum the characteristic peaks for tetrahydro-β-carboline alkaloids appeared at *m/e* 168, 169, 170, 171, and 184.[17] In addition significant peaks were observed at *m/e* 323 and *m/e* 251 corresponding to the loss of the formyl group and the C-15 side-chain, respectively, from the molecular ion peak. The 60 MHz PMR spectrum of the alkaloid, recorded in deuteriochloroform, was also consistent with structure (**4**). On borohydride reduction, geissoschizine furnished an amorphous dihydro-derivative, $C_{21}H_{26}O_3N_2$ (M^+ 354), which exhibited a typical tetrahydro-β-carboline UV spectrum [λ_{max} (EtOH) 224, 272, 282, 286 nm; log ε 4.26, 3.77, 3.72, 3.69]. The methoxycarbonyl band in the IR spectrum of this base appeared at the normal position, *viz.*, 1733 cm^{-1}, instead of at 1658 cm^{-1} as in geissoschizine. These observations are compatible with the reduction of the C-17 formyl group to a hydroxymethyl one.



(**4**)
Geissoschizine

a δ 8.20 (1H, s, disappearing on deuteration)
b δ 7.91 (1H, s)
c δ 7.05—7.65 (4H, m)
d δ 5.42 (1H, q, J=7 Hz)
e δ 3.72 (3H, s)
f δ 1.81 (3H, d of d, J_1=7 Hz, J_2=1.5 Hz)

The isolation of geissoschizine, from *R. stricta* is of particular significance from the viewpoint of biogenesis, since it is one of the key preformed intermediates in the biosynthesis of indole alkaloids.[18,19]

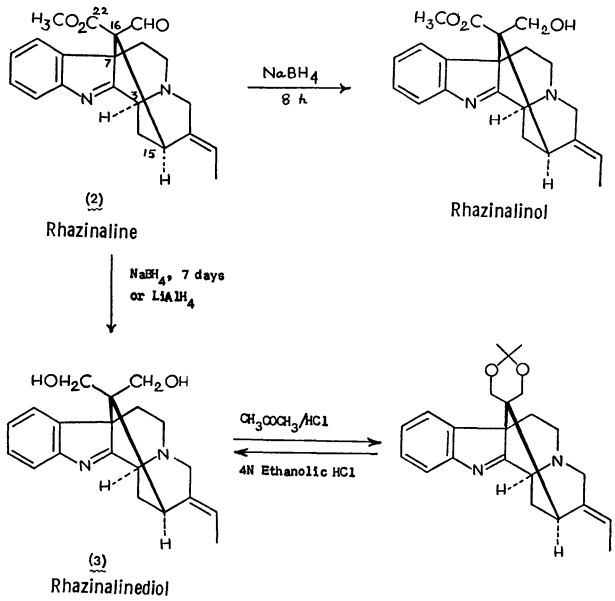


Chart 2. Reaction of rhazinaline.

Experimental

The melting points were determined on the Kofler block and are uncorrected. The analytical samples were routinely dried at 80 °C over P_2O_5 for 24 h *in vacuo*. Anhydrous sodium sulfate was used for drying the organic solutions. Chromatographic resolutions were carried out on Brockmann alumina (activity 1) and silica gel. TLC experiments were performed using silica gel G as adsorbent. Unless otherwise mentioned, the R_f values cited are those obtained using an ethyl acetate–ethanol mixture (3: 1) as the developing solvent.

The colors noted in brackets after the R_f values refer to those developed on spraying the chromatoplate with a 1% solution of ceric ammonium sulfate in 50% phosphoric acid. Those alkaloids which did not give any color with this reagent were visualised by spraying with Dragendorff's reagent.

Isolation and Characterisation of the Alkaloids. In a typical extraction 1 kg of the air-dried powdered leaves of *R. stricta* were defatted with petrol (bp 60—80 °C) (2.5 l) by extraction in a Soxhlet apparatus for 30 h. The defatted plant material was then exhaustively soxhletted with chloroform (2.5 l) for 30 h. The extracted marc was then soaked in ethanol (5 l) for 30 days.

Working-up of the Petrol Extract. The pale green petrol extract was concentrated (200 ml) and then churned for 10 h with 1.5 l of 5% aqueous citric acid solution. The mixture was filtered, and the residue thoroughly washed with 5% aqueous citric acid solution (2×100 ml). The combined aqueous solution was then extracted successively with benzene (4×250 ml) and chloroform (4×250 ml). The chloroform extract was washed with dilute ammonia solution and then with water, dried, concentrated and chromatographed on alumina. Strictamine was obtained from the petrol–benzene (1: 1) eluate and the earlier fractions of the benzene eluate, while the later fractions of the benzene eluate afforded rhazinaline. The combined mother liquor left after the crystallisation of rhazinaline (obtained from 10 kg of plant material) on concentration deposited an amorphous white solid R3, (0.0003% yield) which crystallised as granules, mp 217 °C R_f 0.27, from 30% methanolic chloroform. Alkaloid R3 exhibited a molecular ion peak at *m/e* 350.

Strictamine (0.005% yield), mp 105—106 °C (ether), $[\alpha]_D^{25}$ +60° (chloroform), R_f 0.25, λ_{max} (EtOH) 263 nm (log ε 3.72), was identified by comparison (MS, mmp, and TLC) with an authentic sample.

Rhazinaline (0.002% yield) crystallised from a petrol–benzene mixture (4: 1) as stout needles, mp 137 °C, $[\alpha]_D^{25}$ +61° (ethanol), R_f 0.31, UV: λ_{max} (EtOH) 266 nm (log ε 3.78); λ_{min} (EtOH) 243 nm (log ε 3.60) (λ_{max} and λ_{min} unaffected in 1 M KOH or 2% $HClO_4$/ethanol); IR ν_{max} (Nujol) (cm^{-1}); 1751 (-CO_2Me), 1724 (-CHO), 1621 (>C=C<), 1592 (aromatic), 774, 756, 745 (*o*-disubstituted benzene); PMR (60 MHz, $CDCl_3$) (δ): 9.93 (1H, s; -C<u>H</u>O), 7.06—7.73 (4H, m; aromatic Hs), 5.51 (1H, q; J=8.5 Hz; =C<u>H</u>-CH_3); 4.71 (1H, m; C-3-H), 4.03 (1H, m) and 3.80 (1H, m) ($N_{(b)}$-C<u>H</u>$_2$-C=C), 3.16 (3H, s, -CO_2C<u>H</u>$_3$), 1.78 (3H, d of d, J_1=8.5 Hz and J_2=2.5 Hz; =CH-C<u>H</u>$_3$); MS: *m/e* 350 (M^+), 321 (M—CHO), 291 (M—CO_2Me). Found: C, 71.50; H, 6.00; N, 7.94; -OCH_3, 8.75; -CCH_3, 4.10; active H, 0.00%. Calcd for $C_{21}H_{22}O_3N_2$: C, 72.00; H, 6.29; N, 8.00; -OCH_3 (one), 8.85; -CCH_3 (one), 4.29%.

Working up of the Chloroform Extract. The green chloroform extract was concentrated (100 ml) and the concentrate was churned with 5% aqueous citric acid solution (1 l) for 10 h and then left overnight. The yellow-brown supernatant solution was filtered and the residue thoroughly washed with 5% aqueous citric acid solution (2×200 ml). The combined acidic solution was basified (pH 10) with NH_3 solution and extracted with chloroform (5×200 ml). The combined chloroform extracts were washed with water, dried and then concentrated (50 ml). The concentrate was then chromatographed over alumina. Similar fractions were combined and rechromatographed over alumina and silica gel. In the latter case, mixtures of ethyl acetate–ethanol, in proportions varying from 9: 1 to 1: 1, were used as eluants. Six alkaloids, *viz.*, (−)-quebrachamine, rhazine, rhazinilam, R_2, rhazinine (antirhine) and rhazidine were isolated from this fraction. (−)-Quebrachamine, rhazine, rhazidine and rhazinine (antirhine) were identified by mass spectrometric and TLC comparisons, and mixed mp determinations with authentic samples.

(−)-Quebrachamine (0.002% yield) was crystallised from methanol as needles, mp 140—142 °C, $[\alpha]_D^{25}$ −96° (chloroform), R_f 0.24 (violet rimmed yellow spot), λ_{max} (EtOH) 228, 285, 292 nm (log ε 4.46, 3.78, 3.76). Rhazine (0.05% yield) was obtained by crystallisation from a benzene–chloroform (3: 1) mixture as fine needles, mp 236 °C, $[\alpha]_D^{25}$ +18° (ethanol), R_f 0.54 (pale grey), λ_{max} (EtOH) 227, 281, 288 nm (log ε 4.48, 3.78, 3.68). Rhazidine (0.02% yield) was purified by crystallization from 10% methanolic chloroform as granules, mp 278 °C, $[\alpha]_D^{25}$ −30° (ethanol), R_f 0.025 (red fading to yellow), λ_{max} (EtOH) 236, 292 nm (log ε 3.98, 3.51). Alkaloid R_2 (yield 0.0005%) formed needles, mp 176 °C, R_f 0.40 (red) from a mixture of cyclohexane–benzene (2: 1). It exhibited a molecular ion peak at *m/e* 350.

Rhazinilam (0.003% yield) was purified from ethyl acetate as plates, mp 208—210 °C, $[\alpha]_D^{25}$ −426° (chloroform), R_f 0.68 (orange-yellow), UV in 95% aldehyde free ethanol: End absorption at 213 nm (log ε 4.40); inflection points at 220, 274, 314 nm (log ε 4.31, 3.21, 1.94). Found: Mol wt 294.172705 (from mass spectrometry); C, 77.49; H, 7.41; N, 9.48; -CCH_3, 4.92; active H, 0.28%. Calcd for $C_{19}H_{22}ON_2$ (M^+ 294.1732): C, 77.45; H, 7.48; N, 9.53; -C-CH_3 (one), 5.10; active H (one), 0.34%.

Rhazinine (antirhine) (0.01% yield) crystallised from a benzene–chloroform mixture (1: 1) in fine needles, mp 118°C, $[\alpha]_D^{25}$ +4° (chloroform) and +1.3° (methanol), R_f 0.11. UV λ_{max} (EtOH): 227, 281, 289 nm (log ε 4.54, 3.88, 3.86); λ_{max} (0.1 M HCl/EtOH) 221, 274, 284 nm (log ε 4.62, 3.92, 3.90); IR ν_{max} (KBr) (cm^{-1}); 3630 (-OH), 3265 (-NH-), 1644 (>C=C<), 983 and 926 (-CH=C<u>H</u>$_2$), 1610 (aromatic), 762 and 730 (*o*-disubstituted benzene); PMR (100 MHz, $CDCl_3$) (δ): 8.14 (1H, broad s, disappearing on deuteration, indole -NH-) 6.90—7.54 (4H, m: aromatic Hs), 4.94—5.84 (C<u>H</u>=C<u>H</u>$_2$), 4.09 (1H, ill resolved t; C-3-H); 3.43—3.83 (2H, m; -C<u>H</u>$_2$-, OH). 2.23 (1H, broad s, disappearing on deuteration; -CH_2-O<u>H</u>); MS: M^+ 296.1827 (corresponds to $C_{19}H_{24}ON_2$, calculated 296.1889), 295, 265 (M-CH_2OH), 225, 223, 184, 170, 169, 168, 156.

Working-up of the Ethanolic Extract. The ethanolic extract (5 l) was concentrated to 250 ml under reduced pressure and then churned for 12 h with 5% aqueous citric acid olution (1.5 l). The mixture was filtered, and the filtrate was exhaustively extracted with chloroform (4×250 ml). The solution remaining after this processing was basified with NH_3 solution to pH 8 and extracted successively with ether (4×250 ml) and chloroform (4×250 ml). The ether solution was shaken with 2% aqueous sodium hydroxide solution (3×150 ml) to remove acidic and phenolic components. The ether extract after this treatment was concentrated and mixed with the concentrate obtained from the chloroform extract. The total extract was then chromatographed over alumina to yield rhazine, antirhine and rhazidine.

The alkaline solution containing the acidic and phenolic components was neutralised with dilute acetic acid solution and extracted with ether (3×250 ml). Concentration of this extract afforded crystals of geissoschizine (alkaloid R1).

Geissoschizine was purified by repeated crystallisation from methanol and ethyl acetate, when it was obtained as colourless granules, mp 187 °C, $[\alpha]_D^{25}$ +72° (chloroform). It was soluble in both acidic and alkaline aqueous solutions, UV: λ_{max} (EtOH) 221, 267, 290 (sh) nm (log ε 4.32, 3.88, 3.57); λ_{max} (0.1 M NaOH/EtOH) 280 nm (log ε 4.20); IR ν_{max} (Nujol) (cm^{-1}); 3311 (-OH/-NH), 1658 (>C=C-CO_2Me), 1642 (enolic >C=C<), 1600 (aromatic), 744 (*o*-disubstituted

benzene); PMR (60 MHz, $CDCl_3$) (δ): 8.20 (1H, broad s, disappears on deuteration, indole -NH-), 7.91 (1H, s; MeO_2C-C=CHOH), 7.05—7.65 (4H, m; aromatic Hs), 5.42 (1H, q, J=7 Hz; =CH-CH_3), 3.72 (3H, s, $-CO_2CH_3$), 1.81 (3H, d of d, J_1=7 Hz, J_2=1.5 Hz; =CH-CH_3); MS: *m/e* M^+ 352, 351, 323, 251, 184, 171, 170, 169, 168, 156, 155, 154, 144, 143, 130, 129. Found: C, 71.62; H, 6.70; N, 8.12; $-OCH_3$, 8.58; -C-CH_3, 4.02; active H, 0.52%. Calcd for $C_{21}H_{24}O_3N_2$: C, 71.59; H, 6.82; N, 7.95; $-OCH_3$ (one), 8.81; -C-CH_3 (one), 4.23; active H (two), 0.57%.

Sodium Borohydride Reduction of Geissoschizine. Excess sodium borohydride was added to a solution of geissoschizine (30 mg) in dry methanol (10 ml). The reaction mixture was kept at room temperature for 40 h. It was then evaporated, taken up with water (10 ml), and then extracted with chloroform (3×10 ml). The chloroform extract on evaporation yielded a gummy solid, which on dissolution in methanol followed by evaporation of the methanolic solution gave an amorphous solid (R_f 0.78). This compound exhibited a molecular ion peak at *m/e* 354, corresponding to the formula $C_{21}H_{24}O_3N_2$. UV: λ_{max} (EtOH) 228, 272, 282, 286 nm (log ε 4.26, 3.77, 3.73, 3.69); λ_{max} (0.2M HCl/EtOH) 220, 273 nm (log ε 4.44, 3.81); IR: ν_{max} (Nujol) (cm^{-1}): broad band around 3300 (-OH and -NH-), 1733 ($-CO_2Me$), 1600, 1580, 743 (*o*-disubstituted benzene).

Sodium Borohydride Reduction of Rhazinaline. Rhazialine (50 mg) was dissolved in methanol (10 ml) and treated with sodium borohydride (75 mg). The mixture was kept at room temperature for 8 h. The solution was then evaporated, water (10 ml) was added, and the resulting mixture extracted with chloroform (3×10 ml). The chloroform extract was dried, concentrated and chromatographed over alumina. The benzene–chloroform (3: 1) eluates on concentration yielded rhazinalinol as colorless granules (20 mg), mp 236 °C (R_f 0.22). UV: λ_{max} (EtOH) 265 nm (log ε 3.78); IR: ν_{max} (Nujol) (cm^{-1}); 3333 (-OH), 1750 ($-CO_2Me$); MS: *m/e* M^+ 352, 321 ($M-CH_2OH$), 293 ($M-CO_2Me$). Found: C, 71.20; H, 6.63; N, 7.84%. Calcd for $C_{21}H_{24}O_3N_2$: C, 71.59; H, 6.82; N, 7.95%.

The residue from the benzene–chloroform (1: 1) and the chloroform eluates upon crystallisation from 10% methanolic chloroform gave rhazinalinediol as fine needles (20 mg), mp 242 °C (R_f 0.18). UV: λ_{max} (EtOH) 267 nm (log ε 3.71); λ_{max} (50% $HClO_4$/EtOH) 240, 244, 302 nm (log ε 3.78, 3.80, 3.75); IR ν_{max} (Nujol) (cm^{-1}): 3310 (-OH), 1626, 1595, 745 (*o*-disubstituted benzene): MS: *m/e* M^+ 324, 293 ($M-CH_2OH$). Found: C, 73.96; H, 7.28; N, 8.48; active H, 0.51%. Calcd for $C_{20}H_{24}O_2N_2$: C, 74.07; H, 7.41; N, 8.64; active H (two), 0.62%.

Prolonged Treatment of Rhazinaline with Sodium Borohydride. Sodium borohydride (100 mg) was added to a solution of rhazinaline (25 mg) in methanol (3 ml), and the resulting mixture was allowed to stand at room temperature for 7 days. Working-up of the reaction mixture in the manner described previously gave rhazinalinediol (18 mg), mp 242 °C.

Lithium Aluminium Hydride Reduction of Rhazinaline. A solution of rhazinaline (40 mg) in dry ether (10 ml) was added to a slurry of lithium aluminium hydride (100 mg) in the same solvent (25 ml) at room temperature with stirring. The mixture was then refluxed for 6 h with continued stirring and then cooled. The excess reagent was decomposed by adding ice-cold water (2 ml), and the resulting mixture was refluxed for another 0.5 h. The mixture was filtered, and the residue washed with hot chloroform (5×5 ml). Chromatography of the extracted base over Brockmann alumina gave a solid which crystallised from 10% methanolic chloroform in fine needles (38 mg), mp 242 °C. This compound was found to be identical with rhazinalinediol (mixed mp, co-TLC and superimposable IR spectra).

Preparation of the Acetonide of Rhazinalinediol. To a solution of rhazinalinediol (30 mg) in acetone (25 ml) were added, 2 drops of concentrated hydrochloric acid and the mixture was left at room temperature for 40 h. Acetone was then removed under reduced pressure, and the residue was treated with water (10 ml), basified to pH 10 with dilute ammonia solution and extracted with chloroform (4×10 ml). The chloroform extract was dried and concentrated. The concentrate on TLC analysis showed to spots, one of which was identical with rhazinaline. The other compound (R_f 0.15) was separated by preparative TLC using silica gel G as adsorbent and an ethyl acetate–ethanol mixture (3: 1) as the developing solvent. This compound (12 mg) could not be crystallised. Found: M^+ 364; C, 75.58; H, 7.82; N, 7.61%. Calcd for $C_{23}H_{28}O_2N_2$: C, 75.77; H, 7.74; N, 7.69%.

Hydrolysis of the Acetonide. Rhazinalinediol acetonide (4 mg) was warmed on a water bath with 4M ethanolic hydrochloric acid (10 ml) for 3 h. The solution was then evaporated to a small volume (1—2 ml) under reduced pressure, taken up with water (5 ml), basified to pH 10 with ammonia solution and extracted with chloroform (3×5 ml). The dried and concentrated chloroform extract showed only one spot on TLC analysis, whose R_f value was equal to that of rhazinalinediol.

Catalytic Hydrogenation of Rhazinalinediol. Attempted hydrogenation of rhazinalinediol (20 mg) dissolved in ethanol (10 ml) in the presence of Adams catalyst (20 mg) failed and rhazinalinediol was quantitatively recovered.

Rhazinalinediol (15 mg), dissolved in glacial acetic acid (10 ml), was hydrogenated for 6 h in the presence of Adams catalyst (15 mg). There was no hydrogen uptake in the last two hours. The reaction mixture was filtered. The filtrate was diluted with water (10 ml), basified with ammonia solution and extracted with chloroform (3×10 ml). The chloroform extract on TLC showed the presence of two components (A) (R_f 0.24) and (B) (R_f 0.21) approximately in the same amount, their R_f values differing from that of rhazinalinediol. Separation of (A) and (B) was effected by preparative TLC using silica gel as adsorbent and a 3: 1 mixture of ethyl acetate–ethanol as the developing solvent. The qualitative UV spectra of (A) and (B) taken in ethanol showed maxima at 264 and 266 nm, respectively, indicating that the indolenine chromophore was unaffected. Paucity of material precluded further investigation of these substances.

The authors thank Dr. B. C. Das, Institut de Chimie des Substances Naturelle, France, Dr. G. F. Smith, Manchester University, Dr. S. C. Pakrashi, Institute of Experimental Medicine, Calcutta, and Dr. A. Hofmann, Zürich, for IR, PMR and mass spectra. Thanks are also due to Dr. J. A. Lamberton, CSIRO, Australia and Dr. A. A. Bertho, University of München for gifts of authentic samples of antirhine and geissoschizine, respectively. A Banerji and R. Majumder thank the CSIR (India) for financial assistance.

The Franck-Condon Factor of the $\tilde{A}$-$\tilde{X}$ System of Ammonia

Isao KANESAKA, Mami USUI, and Kiyoyasu KAWAI

Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received December 6, 1975)

Synopsis. The relative intensity of the $\tilde{A}$-$\tilde{X}$ system of ammonia was calculated by using the harmonic and devised harmonic wave functions. The calculated relative intensities do not agree completely with the observed ones. The relative intensity of the vibronic transition was also calculated. However further improvement was not obtained.

We reported an advanced method[1] for the calculation of the Franck-Condon factor of a polyatomic molecule and its application to the A-$\tilde{X}$ system of acetylene and dideuterioacetylene. Since the method might be utilized in other systems, it is desirable to clarify the extent of its potentiality. In the present paper we report on the calculated relative intensities of the A-$\tilde{X}$ system of NH_3 and ND_3.

The molecular structure of ammonia in the first excited state[2] is planar, having D_{3h} symmetry, with an N-H distance of 1.08 Å; that in the ground state[3] is pyramidal, having C_{3v} symmetry, with an N–H distance of 1.012 Å and an H–N–H angle of 106.7°. The long progressions of the A-$\tilde{X}$ system of NH_3[4] and ND_3[2] are represented in cm^{-1} by

$$\nu_{NH_3} = 46136 + 874v_2' + 4v_2'^2$$

$$\nu_{ND_3} = 46714 + 650v_2' + 4v_2'^2.$$

The frequency of 874[4] or 650[2] cm^{-1} has been assigned to the out-of-plane bending vibration ν_2' in the first excited state. The observed intensities relative to the 0 - 0 transition, which are directly estimated from the references,[5,6] are given in Table 1.

Ammonia in the ground state has a double minimum potential. This causes the splitting of vibrational levels. However, the Franck-Condon factor can be calculated with a high approximation without taking the double minimum potential into consideration.[1,7] We thus used the mean value of the two observed frequencies (Table 2).[6,8]

Table 1. Observed and calculated relative intensities of the $\tilde{A}$-$\tilde{X}$ system of ammonia

v'	NH_3				ND_3		
	Obsd[a]	Calcd			Obsd[b]	Calcd	
		[I]	[II]	R_v		[I]	[II]
0	1	1	1	1	1	1	1
1	3.9	6.6	6.5	6.4	4.0	8.3	8.1
2	10	22	21	20	10	34	31
3	17	48	42	41	20	91	75
4	24	77	66	62	35	181	135
5	27	95	83	76	50	277	194
6	30	87	89	80	60	329	240
7	27	81	105	94	80	357	302
8	26	32	85	75	110	227	307
9	21	4.4	62	55	160	83	297
10	16	0.12	41	37	200	8.2	278
11	11	0.65	25	24	160	1.8	258

a) From Ref. 5. b) From Ref. 6.

Table 2. Fundamental frequencies of ammonia in the ground state

Species		NH_3		ND_3	
		Obsd	$\Delta\nu$[a]	Obsd	$\Delta\nu$[a]
A_1	ν_1	3336.7	−3.1	2419.0	−3.4
	ν_2	950.4	0.0	748.8	0.0
E	ν_3	3443.8	3.0	2555.0	3.3
	ν_4	1627.5	0.0	1191.0	0.0

a) $\nu_{obsd} - \nu_{calcd}$. (cm^{-1})

The normal frequencies of NH_3 and ND_3 in the ground state were calculated by the method given by Shimanouchi,[9] by assuming a simplified force field with an interaction force constant between the bending coordinates. The difference between the observed and calculated frequencies can be seem in Table 2. The force constants are given in Table 3. The small difference between the force constants of NH_3 and ND_3 would scarcely affect the Franck-Condon factor.[1] The force constants for the out-of-plane bending modes of NH_3 and ND_3 in the excited state are 0.167 and 0.157 mdyn/Å, respectively.

Table 3. Force constants of ammonia in the ground state

	NH_3	ND_3
K(N-X)	6.424	6.484
H(X-N-X)	0.536	0.558
I(X-N-X, X-N-X)	−0.078	−0.071
(X=H or D)		(mdyn/Å)

Table 4. **L** matrix elements for z axis of nitrogen atom

	NH_3	ND_3
ν_2'	0.113	0.147
ν_1[a]	0.0467	0.0682
ν_2[a]	−0.102	−0.131

a) Designated in Table 2.

The normal coordinate vector of ν_2' is parallel to the C_3 axis. Thus only two normal coordinates of A_1 species in the ground state are taken into consideration. The values of the **L** matrix elements for the nitrogen

atoms are given in Table 4. The values of the overlap integral for the nitrogen atoms of NH_3 and ND_3 are 0.0224 and 0.0123, respectively, at $v'=0$, by considering the double minimum potential in the ground state.[1] Those for the hydrogen atom are the same as those for the nitrogen atom. Actually, the overlap integral for the hydrogen atom is two-dimensional, hence smaller than that for the nitrogen atom, and we therefore do not take it into consideration, since the overlap integral perpendicular to the C_3 axis is omitted in our approximation.[1] This scarcely alters the calculated relative intensities. The value of the oscillator-strength of the $A-\tilde{X}$ system of NH_3 has been reported to be 0.088.[5] This shows that the value of the observed oscillator-strength, f_v, is 4.42×10^{-5} for the 0 - 0 transition.

Calcd [I] and Calcd [II] were obtained by using the harmonic and devised harmonic[1] wave functions, respectively, in the excited state (Table 1). The calculated relative intensities do not agree completely with the observed ones. In higher levels the results of Calcd [II] are much better than those of Calcd [I]. Though the improvements seem to be satisfactory on the basis of our assumptions, the maxima of the observed and calculated relative intensities do not agree. This may be caused by the vibronic transition given by:

$$R_v(v', 0) = \int \Psi'_{v'} Q \Psi''_0 dQ$$

where Q is a normal coordinate, and Ψ' and Ψ'' are vibrational wave functions of the excited and ground states, respectively. We thus calculated $R_v(v', 0)$ by our method (Table 1). The variation in results is similar to that of Calcd [II]; similar results were obtained for ND_3. This shows that further improvement can not be expected from the vibronic transition. Precise wave functions for the excited state should be used.

In the present case the treatment of the overlap integral is essentially the same as that for a diatomic molecule, ammonia being one of the simplest molecules. The results given in Table 1 seem to show the limits of the applicability of our method.

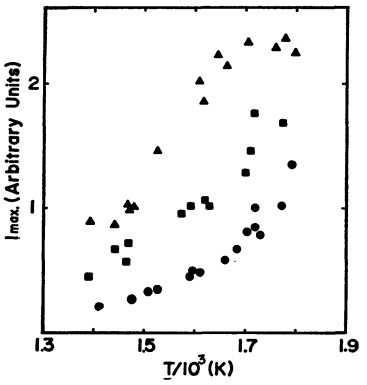

Fig. 2. Comparison of maximum intensity of total ionization at various temperatures.
●: 1.0% O_2+0.5% C_2H_4, ■: 1.5% O_2+0.5% C_2H_4, ▲: 2.0% O_2+0.5% C_2H_4.

and the H_3O^+ ion is not observed in the O_2-lean mixture; on the other hand, in the O_2-rich mixture, the $C_3H_3^+$ ion is rapidly succeeded by the H_3O^+ ion, which becomes the most abundant species.[1)]

From has been mentioned above, it may be considered that the increase in the total ions with the increase in the O_2 concentration is based on the increase in the number of H_3O^+ ions and that the most abundant ion is the H_3O^+ ion. The generally accepted steps for the $C_3H_3^+$ formation are:

$$CH + O \longrightarrow CHO^+ + e^- \qquad \Delta H = +20 \text{ kcal/mol} \qquad (1a)$$

or

$$CH^* + O \longrightarrow CHO^+ + e^- \qquad \Delta H = -46 \text{ kcal/mol} \qquad (1b)$$

$$CHO^+ + H_2O \longrightarrow H_3O^+ + CO \qquad \Delta H = -34 \text{ kcal/mol} \qquad (2)$$

However, there is controversy concerning the electronic state of CH in (1) reactions.[6-10)] Considering that the onset of the ion signal occurs earlier than that of CH* emission, and that the arrival time to the peak of the ion signal was earlier than that of the CH* emission, as has been mentioned above, it may be difficult for the (1b) reaction to be the main route of the CHO^+ formation in a lower-temperature region at comparatively O_2-lean mixtures. The CH* concentration increased with increases in the temperature and the O_2 concentration;[5)] the O concentration may also increase with increases in the temperature and the O_2 concentration. In a higher-temperature region and an O_2-rich mixture, it was found that the onset of the ion signal occurred later than that of the CH*emission, as has been mentioned above. Hence, in a higher-temperature region and an O_2-rich mixture, the (1b) reaction may occur.

The lag time in the total chemi-ionization was defined as the time elapsing between the reflected shock arrival and the time at which the probe current reached a constant value, 2.5×10^{-6} A. The lag time, τ_I increased with decreases in the temperature and O_2/C_2H_4 ratios. The plot of log τ_I *vs.* 1/T of each composition fit a single line, and the log τ_I increased with the decrease in the O_2 concentration. A plot of log $\tau_I[O_2]$ *vs.* 1/T for three compositions fits a single line, as is shown in Fig. 3. The temperature coefficient of the lag time can

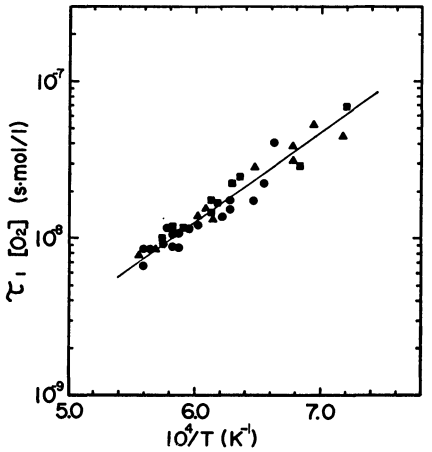

Fig. 3. A plot of log $\tau_I[O_2]$ *vs.* $1/T$ for reaction mixtures.
●: 1.0% O_2+0.5% C_2H_4, ■: 1.5% O_2+0.5% C_2H_4, ▲: 2.0% O_2+0.5% C_2H_4.

be obtained from the slope of the line; the value is 26.4 kcal/mol. Over the experimental temperature and concentration ranges we covered, the lag time can be represented as:

$$\log \tau_I[O_2] = -11.35 + 26.4 \times 10^3/4.58T$$

in units of s mol l^{-1}. This equation agrees with the following equation, which was determined from the measurements of the CH* emission in our previous work:[5)]

$$\log \tau_{CH^*}[O_2] = -11.45 + 27.5 \times 10^3/4.58T$$

Thus, we estimate that the following reaction is the rate-determining step for the ethylene oxidation in a shock tube:

$$C_2H_3 + O_2 \longrightarrow C_2H_3O + O \qquad (3)$$

also, the apparent activation energy obtained from our measurements in the total ionization is 26.4 kcal/mol, and the values, ΔH, of individual ionization reactions would be less than 20 kcal/mol.[6)] Hence, it may be concluded that Reaction 3 is the rate-determining step for chemi-ionization in the ethylene oxidation under the present experimental conditions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (7), 2009—2010 (1976)

Applicability of a Viscosity Formula of Liquid Mixtures to Gaseous Mixtures

Tetsuya ISHIKAWA

Seinan Gakuin University, Nishijin, Nishi-ku, Fukuoka 814

(Received November 22, 1975)

Synopsis. Since 1929, the writer has carried out an elaborate calculation on the viscosity of binary liquid mixtures,[1] using for an ideal mixture the formula

$$\eta = \frac{\eta_1}{1+\frac{k_2a_2}{k_1a_1}\frac{z_m}{1-z_m}} + \frac{\eta_2}{1+\frac{k_1a_1}{k_2a_2}\frac{1-z_m}{z_m}}$$

or that in hyperbolic form

$$\frac{(\eta-\eta_1)(1-z_m)}{(\eta_2-\eta)\cdot z_m} = \frac{k_2a_2}{k_1a_1} = K \text{ (a constant)}$$

where a is the degree of association, k the molecular field constant and z_m the formal mol fraction of component 2. However, if there occurs a maximum in $(\eta-z_m)$ diagram, we can not evaluate K from the formula, since negative values result in the neighborhood of the maximum. In this case the formula $K=\eta_1M_2a_2/\eta_2M_1a_1$ may be preferable provided that the equality $K=k_2/k_1=\eta_1M_2/\eta_2M_1$ holds for gaseous mixtures where $a_1=a_2=1$. The applicability of the formulas is discussed.

The writer tried to compare his formula for the ideal case[2] with that of Thiesen for gaseous mixtures:[3]

$$\eta = \frac{\eta_1}{1+A\frac{z_m}{1-z_m}} + \frac{\eta_2}{1+B\frac{1-z_m}{z_m}}, \quad A=\frac{a_{12}}{a_{11}}, \quad B=\frac{a_{21}}{a_{22}}$$

where a is an empirical constant defined as "Diffusions konstante".

Among the five mixtures, only the one He–H_2 satisfied conditions for the product A×B to be nearly unity: 0.991, 1.021, and 1.022 at 0, 15, and 100 °C, respectively. indicates that the writer's formula is available for gaseous ideal mixtures as well as liquid ideal mixtures.

The writer proposed another form of $K=\eta_1M_2a_2/\eta_2M_1a_1$ deduced from five liquid mixtures having equivalent association degrees or $a_1=a_2$ in his fundamental formula: C_2Cl_3H (0.99—1.02)-C_2Cl_5H (1.02—1.05), CCl_4 (1.09—1.00)-C_2Cl_4 (0.92—1.01), $C_2H_5COOC_2H_5$ (1.13—1.20)-$CH_3COOC_3H_7$ (1.16—1.21), $C_6H_5CH_3$ (1.16—1.14)-C_6H_5Br (1.19—1.05), *m*-$CH_3C_6H_4OH$ (1.81—1.60)-*p*-$CH_3C_6H_4OH$ (1.82—1.62), numbers in parentheses denoting association degrees.[4,5]

Precise measurements were carried out for ideal gaseous mixtures in a few cases: He–H_2 by Gille[6] and Kr–Ar by Kestin *et al.*[7]

			K(II)	1.133	1.125	1.128

Put as follows for the viscosity of an ideal gaseous mixture:

$$\frac{(\eta-\eta_1)(1-z_m)}{(\eta_2-\eta)\cdot z_m} = K \qquad \text{(I)}$$

Applying the relation to the mixtures He–H_2 and Kr–Ar, we obtain the results given in Tables 1 and 2, and Figs. 1 and 2. K(I) denotes the values calculated by means of (I), and K(II) the values obtained from the relation

$$K = \eta_1M_2/\eta_2M_1 \qquad \text{(II)}$$

We see in Tables 1 and 2 that the values of K(I) and K(II) coincide with each other, though all the values of

0.8355	0.5503	0.5609	0.6088	0.6563	0.6592	0.6576	0.6639	0.6322
1.0000	0.5350	0.5553	0.5909	0.6306	0.6347	0.6345	0.6433	0.6299
K(II)	0.5366	0.5459	0.5541	0.5592	0.5637	0.5674	0.5687	0.5678

K(I) are greater than those of K(II) at 380—700 °C, the divergence in $(\eta_{obs}-\eta_0)/\eta_0$ being at most 0.5%. If we take the relation

$$\eta_0 = \frac{\eta_1}{1+K\frac{z_m}{1-z_m}} + \frac{\eta_2}{1+\frac{1}{K}\frac{1-z_m}{z_m}}, \quad K = \frac{\eta_1 M_2}{\eta_2 M_1}$$

as a basic formula, any gaseous mixture can be analyzed as for liquid mixtures.[1]

As an example of non-ideal gaseous mixtures, two mixtures Ar–Ne (100 °C) and Ar–He (99 °C) are quoted from the measurements of Kestin, Wakeham and Watanabe[7] and Kalelkar and Kestin.[8]

The results are summarized in Tables 3 and 4 and Figs. 3 and 4. The curves denoted by η_{calcd} (Wilke) in Figs. 1—4 are plotted by use of Wilke's semi-theoretical formula for gaseous mixtures:[9]

$$\eta = \frac{\eta_1}{1+\phi_{12}\frac{z_m}{1-z_m}} + \frac{\eta_2}{1+\phi_{21}\frac{1-z_m}{z_m}},$$

$$\phi_{12} = \frac{[1+(\eta_1/\eta_2)^{1/2}\cdot(M_2/M_1)^{1/4}]^2}{2\sqrt{2}(1+M_1/M_2)^{1/2}},$$

$$\phi_{21} = \frac{[1+(\eta_2/\eta_1)^{1/2}\cdot(M_1/M_2)^{1/4}]^2}{2\sqrt{2}(1+M_2/M_1)^{1/2}}$$

TABLE 3. Ar–Ne, $\eta(\mu P)$, 100 °C

		K=0.1181		

Coincidence is satisfactory between η_0 and observed η_{obsd}(○) (Figs. 1 and 2), η_0 being less than η_{obsd}(Figs. 3 and 4). We can therefore apply any suitable functional form of z_m, generally $(1-z_m)^{\nu_1} z_m^{\nu_2}$ to the difference $\delta=(\eta_{obsd}-\eta_0)$, where ν_1 and ν_2 are the numbers of both component molecules which take part in a reaction to form a molecular compound or an aggregate or "embryo" as called by Lekenby and co-workers.[10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (7), 2011—2012 (1976)

On the Chemical Structure and Some Labile Hydrogens of 7-Methylguanosine

Mamoru NAKANISHI, Masamichi TSUBOI, and Iwao NAKAGAWA*

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
**Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received April 19, 1976)

Synopsis. Proton magnetic resonance and infrared absorption studies indicate that 7-methylguanosine has 1-NH, 2-NH_2, and 8-CH groups in dimethylsulfoxide solution, while in an aqueous system of pH 6.0 these groups are subjected to rather rapid hydrogen exchange reactions with the solvent molecules, so that their life-times are respectively $\ll 10^{-2}$ s, $=0.025$ s and $=180$ s at 25 °C.

7-Methylguanosine has recently been found as a modified structure of the 5'-end of the messenger RNA in eukaryote system[1-4]. Its chemical structure may be strange and unique among nucleosides, because of the positively charged nitrogen atom at position 7. Thus, the following questions, for example, are to be answered: Is the hydrogen atom located on 1-N or 6-O? and how labile are the protons of the 1-NH, 2-NH_2, and 8-CH groups?

7-Methylguanosine was prepared by a modification of the procedure of Jones and Robins.[5] A solid sample obtained by lyophilization from a pH 4.0 aqueous solution was carefully dried in vacuum and dissolved in dry dimethylsulfoxide-d_6. The proton magnetic resonance spectrum of this solution is shown in the Figure. The 1-NH, 8-CH, and 2-NH_2 signals are observed at 11.9, 9.6, and 7.6 ppm, respectively (from tetramethylsilane). Thus, the structure shown in the Figure is now supported. The 7-NCH_3 signal is found at 4.2 ppm; this is lower than those of other usual N-CH_3, probably because of the positive charge on 7-N.

In aqueous solutions, 7-methylguanosine is found to be stable only in the pH range lower than its pK ($=7.1$[6] at 25 °C). In a H_2O solution of pH 4.0, as well as in that of pH 6.0, the 1-NH signal is not observed. This fact is attributable to a rapid hydrogen exchange reaction of this groups with the solvent molecule. The NH_2 signal (at 6.9 ppm) is broad and from its line width the rate constant of its hydrogen exchange with solvent is estimated to be 40 s^{-1} at 25 °C, pH 6. The hydrogen exchange reaction of 8-CH (at 9.2 ppm) is known to be faster than those of adenosine and guanosine.[7,8] We have followed the reaction not only by means of the proton magnetic resonance measurement but also by means of the infrared absorption measurement of the 8-CH stretching bands (two, at 3100 and 3170 cm^{-1}) in D_2O solutions. The reaction was found to be of the first-order. The rate constant k_e has been determined to be 6.4×10^{-5} s^{-1} at pH 4.0 (25 °C) and 5.5×10^{-3} s^{-1} at pH 6.0 (25 °C). Thus, k_e is proportional to the OH^- concentration. On the basis of the relation,

$$k_e = k_{OH}[OH^-] = \{k_d\, 10^{14-pK}/(10^{14-pK}+1)\}[OH^-],$$

(where k_d is the diffusion constant and was assumed to

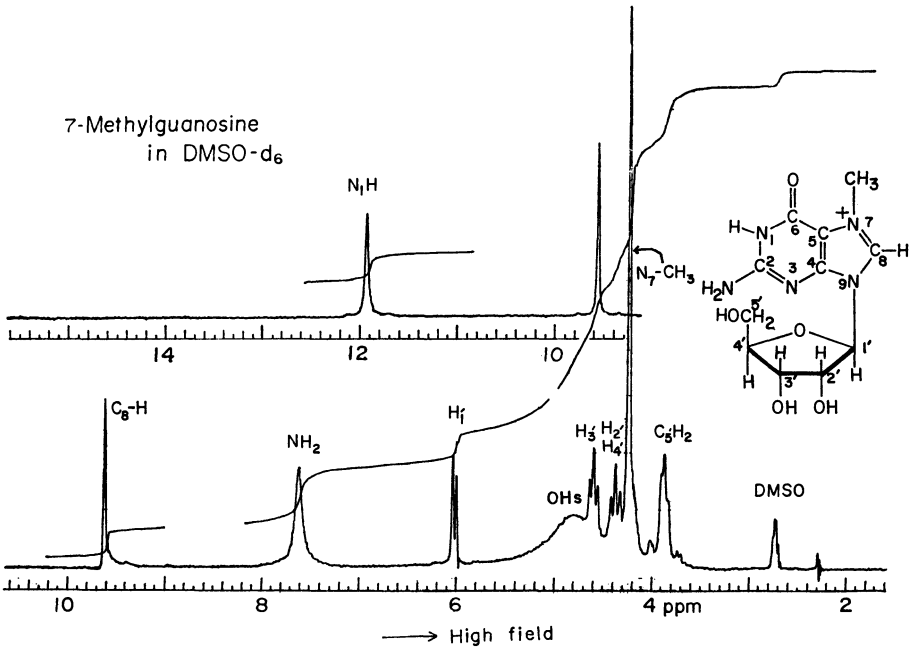

Fig. 100 MHz ^1H NMR spectrum of 7-methylguanosine in dimethylsulfoxide-d_6. The abscissa scale is the chemical shift in ppm from the tetramethylsilane resonance.

be equal to 10^{10} M^{-1} s^{-1}) the pK value of the 8-CH group has been estimated to be $18._3$ at 25 °C. The k_e value just determined would be useful in estimating the "fluctuation amplitude"[9] of the 7-methylguanine residue involved in a secondary structure of a messenger RNA or a transfer RNA.

This work was supported partly by a grant from the Ministry of Education.

Ionization of Hydroxamic Acids in Aqueous Solutions

Shahid Abbas ABBASI* and Jameel AHMED**

Department of Chemistry, Indian Institute of Technology, Bombay-400076, India

(Received October 18, 1975)

Synopsis. Thermodynamic ionization constants of sixteen hydroxamic acids at 25 °C and 35 °C in aqueous solution and the corresponding $\Delta H°$ (standard enthalpy change) are presented.

Hydroxamic acids have extensive application in analytical[1] and medicinal chemistry.[2] The ionization of a hydroxamic acid has been found to have a strong bearing on its effectiveness as an analytical[1] or biological[3] reagent. This led to several studies on the determination of ionization constants of hydroxamic acids.[3-5] Most of these studies, however, were performed in media of high, constant ionic strength and at a single temperature (usually 25 °C) and the results are valid for only these conditions. The determination was carried out without taking necessary precaution to avoid carbon dioxide from the titration-solutions. The presence of dissolved atmospheric gases such as CO_2 in the hydroxamic acid solutions during pH titrations are liable to effect the ionization. In the present communication, thermodynamic ionization constants of a number of hydroxamic acids, determined under rigorously controlled conditions at 25 °C and 35 °C are reported.

Experimental

Hydroxamic Acids. The hydroxamic acids were prepared by following the general method of Blatt.[6] They were recrystallized repeatedly until they showed a sharp melting point. The purity was checked by microanalysis, gas-liquid chromatography and IR spectroscopy. Conductivity water was used throughout. All other reagents were of analytical grade.

Determination of Thermodynamic Ionization Constants. A weighed quantity of hydroxamic acid was placed in a thermostated titration vessel containing 50 ml of aqueous $HClO_4$ solution (1.00×10^{-3} M). Nitrogen, after being passed in succession through a train of guard tubes containing, pyrogallic acid, 3 M KOH solution and distilled water, was bubbled into the titration vessel. The rest of the experimental set-up for pH titration and the method of calculation of ionization constants was essentially the same as that described by Goldberg.[7] The expressions involved are:

$$K_a = \frac{[H^+][A^-]\gamma_{H^+}\cdot\gamma_{A^-}}{[HA]\gamma_{HA}} \quad (1)$$

where HA represents hydroxamic acid. It follows that

$$pK_a = -\log[H^+] + \log\frac{[HA]}{[A^-]} + 2\log\frac{1}{\gamma_\pm} \quad (2)$$

the activity coefficient of uncharged species being taken as unity.

The log $[H^+]$ values are read from the pH meter and $\gamma_\pm$, the mean activity coefficient, is obtained by interpolation of the data from Harned and Owen.[8] The titration was repeated until two sets of values differing within ±0.01 pH units were obtained.

Results and Discussion

The results for one representative titration, namely for salicylohydroxamic acid at 25 °C, are given in Table 1. The thermodynamic ionization constants of fourteen

hydroxamic acids along with those of reference substance benzo- and *N*-phenylbenzohydroxamic acids are given in Table 2, together with the values of standard enthalpy change, $\Delta H°$, obtained by integrating van't Hoff's equation[9] at two temperatures, T_1 (298 K) and T_2 (308 K):

$$\log \frac{K_{a_2}}{K_{a_1}} = \frac{\Delta H°(T_2 - T_1)}{4.567 T_1 T_2}$$

where $\log K_a = -pK_a$.

Since the hydroxamic acids differ widely in structure and basicity (pK_a between 6.89 to 9.45 at 25 °C), it can be assumed that $\Delta H°$ is in general positive for the ionization of hydroxamic acids. There is, however, no definite trend in the magnitudes of change in values of $\Delta H°$ with change in the groups attached to the functional –C=O and –N–OH groups. It can be seen that while increase in the conjugation at the –C=O site (compound XV) increases the basicity of the compound relative to benzohydroxamic acid, introduction of π systems at the –N–OH fragment reduces the basicity (compounds II, XVI). With hydroxamic acids derived from amino acids, the pK_a values are in line with the basicity of the corresponding amino acids.[10]

The author is grateful to Dr. B. G. Bhat and Dr. R. S. Singh of I. I. T. Bombay, and the authorities of Saifia College, Bhopal, for providing necessary facilities, to Chandrashekharan and Unnikrishnan for technical help, and to the C. S. I. R., New Delhi, for a Senior Research Fellowship.

Solvent Effect on the Raman Spectra of Mercury(II) Halides

Kozo Sone, Makiko Aritaki, Keiko Hiraoka, and Yutaka Fukuda

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

(Received April 15, 1976)

Synopsis. Raman spectra show that the Hg-X bond strengths in mercury (II) halides are remarkably weakened by the interaction with certain solvents. Relations between the degree of this weakening and (a) the Lewis basicity (Gutmann's donor number) of the solvent and (b) the ionic character of the Hg–X bond are pointed out, together with a simple explanation.

The Raman spectra of $HgCl_2$ in a number of organic solvents have been studied by Allen and Warhurst[1] and it was found that the frequency of the Cl–Hg–Cl stretching vibration is remarkably influenced by the nature of the solvent. They discussed their results chiefly on the basis of the dielectric constants of the solvents.

We have tried to study this kind of solvent effect further, using a larger variety of solvents, and comparing the obtained results with those of other halides, cyanide and methyl halides of mercury(II).

Experimental

Use was made of a JEOL-Sl Raman Spectrophotometer and an Argon laser (5145 Å). All the reagents (including solvents) used were Extra Pure or Spectro grade chemicals. Since the solubilities of the mercury(II) compounds in many of the solvents are low, the concentrations in many cases were much below 0.1 M.

Results and Discussion

The observed frequencies (ν) of the X–Hg–X symmetrical stretching vibration for the HgX_2 molecules are shown in Table 1,* and those of the Hg–X and Hg–CH_3 stretching frequencies for the CH_3HgX molecules in Table 2. The values of the apparent force constants(k) of the bonds, calculated by means of simple valence force models,[2] are also given. The ν values of $HgCl_2$ reported by Allen and Warhurst[1] were in general confirmed, except that in dioxane for which they reported 302 cm^{-1}.

The data in Table 1 clearly show that the ν and k values of a halide, *i.e.* the strength of the Hg–X bond in it, decrease in the order gas>benzene>acetone>water>methanol>dimethylformamide (DMF)>pyridine or, roughly speaking, with the increase of the coordination ability (Lewis basicity) of the solvent. It is also clear that the rates of this decrease are in the order $HgCl_2$>$HgBr_2$>HgI_2. This is the same as the order of the decrease of the ionic characters of Hg–X bonds which are estimated (from the classical electronegativity scale of Pauling) to be: Hg–Cl 26%, Hg–Br 19%, Hg–I 9%.

If we plot the values of k of the halides against the donor number (DN) of Gutmann,[3] which serves as a simple measure of the Lewis basicity of a solvent, these relations can be very clearly recognized. The results are shown in Fig. 1.

In the case of the methyl halides in Table 2,** there are also similar decreases of ν and k from methanol to pyridine, and the rates of this decrease are again in the order of chloride>bromide>iodide. However, it can

Table 1. Raman frequencies of HgX_2 (cm^{-1}) and apparent force constants of Hg–X bonds ($\times 10^5$ dyn cm^{-1})

$HgBr_2$	208 (2.05)	202 (1.93)	200 (1.89)	196 (1.82)	188 (1.67)	
HgI_2	154 (1.78)	148 (1.64)	145 (1.58)	142 (1.51)	140 (1.42)	

a) J. R. Ferraro, "Low-Frequency Vibrations of Inorganic and Coordination Compounds," Plenum, New York (1971), p. 142.

* In the case of $Hg(CN)_2$, a Raman line due to Hg–C≡N bending was observed at 270—272 cm^{-1} (in acetone, methanol, ethanol, dioxane and water) or at 267 cm^{-1} (in pyridine) and another due to C≡N stretching at 2195—2200 cm^{-1} (in methanol and ethanol) or at 2180 cm^{-1} (in pyridine). Insolubility of this compound in many of the solvents used, and overlapping with the Raman lines of the solvents, hindered closer study of the solvent effect in this case.

** The methyl halides showed two Raman lines, *i. e.* the Hg–X and Hg–CH_3 stretching frequencies; the line corresponding to X–Hg–CH_3 bending could not be located with certainty, probably because of its poor intensity.

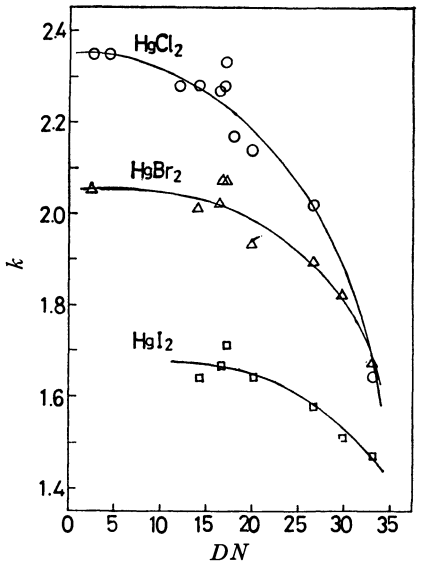

Fig. 1. *k vs. DN.*

Table 2. Raman frequencies of $(CH_3)HgX$ and apparent force constants of Hg–X and Hg–CH_3 bonds

	Methanol	Pyridine	
$(CH_3)HgCl$	328(1.95)	316(1.81)	(Hg–Cl)
	554(2.52)	547(2.46)	(Hg–CH_3)
$(CH_3)HgBr$	225(1.75)	212(1.56)	(Hg–Br)
	546(2.45)	535(2.35)	(Hg–CH_3)
$(CH_3)HgI$	178(1.50)	175(1.57)	(Hg–I)
	535(2.35)	528(2.27)	(Hg–CH_3)

be seen that the effect of solvent change is remarkably smaller than in the case of the simple halides.

All these results can probably be understood if we assume that the molecules of the donor solvents used tend to assemble around the central mercury atom of the linear HgX_2 molecule and to form coordinate bonds with it. If this kind of intetaction is assumed to be chiefly electrostatic in nature, it is easy to see that $HgCl_2$, which contains the most ionic bonds and therefore the most positively charged mercury atom, is the most susceptible to it, and the accumulation of the negative ends of the solvent molecules around the mercury atom will substantially weaken the Hg–Cl bond. This kind of solvent effect will naturally increase with increasing Lewis basicity of the solvent and decrease in the order of $HgCl_2 > HgBr_2 > HgI_2$, and from simple halides to methyl halides which are expected to be more covalent in nature.

It is now of interest to note that decrease of k of HgCl in going from gas to pyridine solution is as large as 30—40%, being comparable with the change of k observed when a double bond is converted into a single bond. This means that strong solvation can weaken a chemical bond to such a great degree. This effect will probably be an important reason for the fact that the Hg–X bond energies in the gas molecules decrease in the order $HgCl_2$ (54 kcal/mol)$\rightarrow HgBr_2$(44)$\rightarrow HgI_2$(35),[4] while the ease of formation of these molecules in aqueous solution increases in the opposite way (heats of formation: $HgCl_2$ (-13 kcal/mol)$\rightarrow HgBr_2(-21)\rightarrow HgI_2(-34)$).

Our thanks are due to Prof. Tsunetake Fujiyama of Tokyo Metropolitan University for his interest in this work and for his helpful discussions.

Rearrangement of 5-Isopropenyl-2-norbornene to 5-Methyl-3a,4,7,7a-tetrahydro-1*H*-indene

Shoji IWASE, Michihiro NAKATA, Sawako HAMANAKA, and Masaya OGAWA*

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received July 21, 1975)

Synopsis. The Diels-Alder reaction between cyclopentadiene and isoprene gave predominantly *endo*- and *exo*-5-isopropenyl-2-norbornenes and also *cis*-5-methyltetrahydro-1*H*-indene produced from the *endo*-product by Cope rearrangement.

In a previous paper,[1] the present have reported the reaction of isoprene (IP) with cyclopentadiene (CP). However, the stereochemical structure has not yet been established because of certain difficulties in the assignments of the ^{1}H-NMR spectra. Here, the authors report the chemical structures of the above reaction products confirmed by means of ^{13}C-NMR spectroscopy.

Experimental

Preparation of the Addition Products.[1,2] The co-dimers obtained in the reaction of IP with CP are both of methylvinylnorbornene (MVN) and methyltetrahydroindene (MTI). After the equi-molar reaction mixture had been stirred for 3 h at 145 or 160 °C in an autoclave and then cooled, the MVN produced was isolated by means of distillation and preparative gas chromatography. Following a similar procedure, MTI was also obtained under the reaction conditions at 145—220 °C for 3 h.

The co-dimer of the reaction of butadiene with CP, employed as a reference was prepared by a previously reported method.[2]

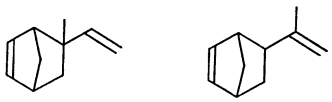
Rearrangement of MVN to MTI. The reaction of 0.1 ml of MVN was carried out in a 1-ml sealed tube in the range of the temperature from 145 to 170 °C. After the reaction had been completed and cooled, the product was analyzed by VPC.

Measurements. The ^{13}C-NMR spectra were recorded with a JNM-EC-100 Fourier transform spectrometer (25.15 MHz) with complete proton decoupling. The chemical shifts were determined in a CCl_4 solution of approximately 50 vol % using TMS as an internal standard. To all samples, the off-resonance proton decoupling technique was applied.

Preparative gas chromatography was carried out on a JEOL GC-750 with a 10 mmϕ × 3 m column packed with 25% silicon H. V. grease at 100 °C. The VPC analysis of the reaction products were made on a HITACHI KGL-2A gas chromatograph using a Golay column Q-90 (0.25 mmϕ × 90 m) at 134 °C.

Results and Discussion

Stereochemical Structure of MVN. The two possible structures for MVN are presented as follows:



1 **2**

The result of the VPC analysis of the fractions of MVN showed the presence of the two components, **A** (R_t=22.4) and **B** (R_t=24.0). The molar ratio of **A** to **B** was found to be 14: 84 and 41: 59 in the fractions reacted at 145 and 160 °C, respectively. These two fractions were also examined by ^{13}C-NMR spectroscopy and the assignments of the signals in each fraction were easily determined. Furthermore, the numbers of protons attached to each carbon atom were obtained by means of the off-resonance proton decoupling technique. This result indicates that each of the components, **A** and **B**, has one nonprotonated sp^2 carbon atom. From this fact, the above structure **2** is in complete agreement with MVN, and thus **A** and **B** appear to be either the *endo*- or the *exo*-isomer of **2**.

Esterification of Alcohols with 1-Acylimidazole Assisted by *N*-Bromosuccinimide

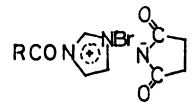
Tsutomu KATSUKI

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

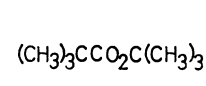
(Received August 13, 1975)

Synopsis. Treatment of 1-acylimidazoles with alcohols in the presence of *N*-bromosuccinimide led to the rapid formation of the corresponding esters. The carboxylic acids with less than two hydrogen atoms at their α-positions generally gave good results. Even such a hindered ester as *t*-butyl pivalate could be prepared by this procedure.

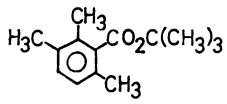
The reaction between alcohols and 1-acylimidazoles[1] is known as one of the elegant esterification methods[2] under mild conditions. Though the above reaction is usually slow at room temperature, the esters of primary and secondary alcohols can be prepared by conducting the reaction at elevated temperatures.[3] For the preparation of hindered esters, however, the method is ineffective and the use of a strong base catalyst, such as sodium alkoxide or sodium amide, is indispensable.[4] *t*-Butyl pivalate, for example, has been prepared by the latter procedure in a 64% yield.[4] The author has found that when 1-acylimidazoles were treated with *N*-bromosuccinimide[5] in the presence of alcohols, rapid esterification took place at room temperature under neutral conditions. In most cases, the reaction terminated within sixty minutes. Hindered esters, such as *t*-butyl pivalate (**2**) and *t*-butyl 2,3,6-trimethylbenzoate (**3**) could be obtained in 48 and 65% yields, respectively, by refluxing the corresponding reactants in methylene chloride for twelve hours.



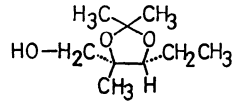
(1)



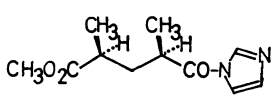
(2)



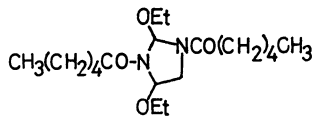
(3)



(4)



(5)



(6)

The esterification is considered to proceed *via* the intermediate represented by **1**. This method could be applied to the acylation of the acid-labile alcohol, 2,3-isopropyridenedioxy-2-methylpentanol (**4**).[6] The imidazolide (**5**) of methyl hydrogen meso-2,4-dimethylglutarate was converted into the corresponding *t*-butyl ester in a 70% yield without any detectable epimerization.

A limitation of the method is that the yield in the esterification of carboxylic acids having two or three hydrogen atoms on the α-carbon atoms, is fairly variable depending on the alcohols used. 1-Hexanoylimidazole was, for example, converted into its ethyl ester in only a 17% yield, and 80% of the product was an unexpected compound for which the tentative formula (**6**) has been given on the basis of spectral data. *s*-Butyl hexanoate was, however, obtained in a 80% yield.

A summary of the yields is given in Table 1 below.

Table 1. Per cent yields of esters

1-Acylimidazole	Alcohol	Solvent	Yield[a]
Pivaloyl	Ethanol	CH_2Cl_2	84
Pivaloyl	2-Methyl-2-propanol	CH_2Cl_2	48[b]
Pivaloyl	Cyclohexanol	THF	95[c]
Pivaloyl	(**4**)	THF	90
2-Methylpentanoyl	Ethanol	CH_2Cl_2	85
2-Methylpentanoyl	Cyclohexanol	CH_2Cl_2	81
2-Methylpentanoyl	2-Methyl-2-propanol	CH_2Cl_2	95
2,3,6-Trimethylbenzoyl	2-Methyl-2-propanol	CH_2Cl_2	65[b]
2,3,6-Trimethylbenzoyl	Benzyl alcohol	CH_2Cl_2	70[d]
Benzoyl	Ethanol	THF	80
Hexanoyl	Ethanol	CH_2Cl_2	17
Hexanoyl	2-Butanol	CH_2Cl_2	80
Hexanoyl	Benzyl alcohol	CH_2Cl_2	80[d]
Hexanoyl	2-Methyl-2-propanol	CH_2Cl_2	57
Acetyl	Cyclohexanol	THF	20

a) All yields are based on 1-acylimidazoles. b) These reactions were run under reflux for 12 h. c) The yield was determined by GLC. d) The yields were calculated from NMR spectra.

The analytical and NMR data of new compounds prepared in this study are given in Table 2.

Experimental

General. All the reactions were carried out in a nitrogen atmosphere. The quality of the reagents employed has a very marked effect upon the yield. Imidazole was purified by sublimation. *N*-Bromosuccinimide was recrystallized from water and dried at 25 °C under reduced pressure (5 mmHg). The alcohols employed were all absolute.

Tetrahydrofuran or dichloromethane was used as the solvent. But dichloromethane was preferable because tetrahydrofuran polymerized slowly under the reaction conditions.

Procedure. All the esters were prepared by almost the same procedure as exemplified by that of *t*-butyl 2-methyl-

Table 2. Analytical and NMR data of new compounds

Compound	Characteristic chemical shifts (δ) and analysis[a)]
1-(2-Methylpentanoyl)imidazole[b)]	0.93(m, 3H), 1.35(d, 3H), 3.13(m, 1H), 7.00(double-d, 1H), 7.12(double-d, 1H), 8.22(broad-s, 1H). Found: C, 64.77; H, 8.40. Calcd: C, 65.03; H, 8.49.

Benzyl 2,3,6-trimethylbenzoate	2.14(s, 3H), 2.20(s, 6H), 4.33(s, 2H), 6.97(qualtet, 2H), 7.30—7.46(m, 5H). Found: C, 79.85; H, 7.04. Calcd: C, 80.28; H, 7.13.
t-Butyl 2,3,6-trimethylbenzoate (**3**)	1.61(s, 9H), 2.23(s, 6H), 2.30(s, 3H), 6.98(qualtet, 2H). Found: C, 76.45; H, 9.28. Calcd: C, 76.32; H, 9.15.
Cyclohexyl 2-methylpentanoate	0.90(m, 3H), 1.11(d, 3H), 2.43(m, 1H), 4.75(m, 1H). Found: C, 72.33; H, 11.22. Calcd: C, 72.68; H, 11.18.
2,3-Isopropyridenedioxy-2-methylpentyl pivalate	1.05(m, 3H), 1.20(s, 9H), 1.30(s, 3H), 1.38(s, 3H), 1.41(s, 3H), 3.70(t, 1H), 3.93(s, 2H). Found: C, 64.01; H, 10.11. Calcd: C, 65.08; H, 10.14.

a) The C and H analyses were carried out on the samples which were obtained by the simple distillation of the reaction products by applying the micro pot-style molecular distillation apparatus at the appropriate bath temperature. b) The 1-acylimidazoles were prepared from the corresponding acyl chlorides and imidazole following the usual procedure.

pentanoate. The esters thus obtained were spectroscopically identified.

t-Butyl 2-Methylpentanoate (**7**): 1-(2-Methylpentanoyl)-imidazole prepared from 2-methylpentanoyl chloride (592 mg) and imidazole (610 mg) was dissolved in dichloromethane (25 ml). To this solution were added 2-methyl-2-propanol (422 mg) and then *N*-bromosuccinimide (814 mg) at one time at room temperature. After 1 h, the mixture was analyzed by GLC. GLC analysis indicated the formation of **7** in a 95% yield. The resulting mixture was distributed between water (20 ml) and pentane (100 ml). The organic layer was separated, washed successively with a saturated aqueous solution of citric acid, water, and a saturated aqueous solution of sodium hydrogencarbonate, dried over anhydrous sodium sulfate, and concentrated to a colorless oil (95%). The ester thus obtained was identified with an authentic sample by NMR spectroscopy.

The author is grateful to Professor Masaru Yamaguchi for his helpful advice and discussions. This work was supported in part by a grant from the Ministry of Education.

The Nucleophilic Substitution of Dicarboxylic Imides on the Chelate Ring of Tris(3-bromo-2,4-pentanedionato)iron(III)

Yasuo YAMAMOTO, Kuninobu KASUGA, and Akira SUMITA

Department of Chemistry, Faculty of Literature and Science, Shimane University, Nishikawatsucho, Matsue 690

(Received September 16, 1975)

Synopsis. Succinimide and phthalimide were found to be capable of acting as a nucleophilic substituent on the chelate ring of tris(3-bromo-2,4-pentanedionato)iron(III) complex. No analogous reaction has been found between this complex and the other dicarboxylic imides, nor between other metal complexes and dicarboxylic imides including these two imides.

The electrophilic substitution on the chelate ring of acetylacetonato complexes is brought about by various reagents such as bromine,[1,2] iodine,[1] *N*-halosuccinimides,[1,5] nitro derivatives,[3,4] acyl derivatives[4] and chloride of iodine[1] or sulfur[6] *etc.*, while only a few reports have appeared on the further conversion of the substituted chelates.[6,7] The nucleophilic substitution reaction reported by Yoshida *et al.*[7] deserves the special attention. They found that the bromine atom on the chelate ring of 3-bromo-2,4-pentanedionato metal complexes is replaced by thiophenol or its para-substituted derivatives. During the course of our investigation on the mechanism of a similar reaction using mercaptanes, alcohols and alkoxides as substituents, we encountered in most cases the decomposition of chelate or the reduction of central metal and occasionally the formation of alkoxy bridged binuclear complexes.[8] In the present studies, we came across an unexpected result in which some dicarboxylic imides were substituted for bromine of tris(3-bromo-2,4-pentanedionato)iron(III).

3-Carbon of tris(2,4-pentanedionato)iron(III) was brominated by means of *N*-bromosuccinimide. Then the brominated compound, after isolation, was to be examined as to the substitution reaction of sodium methoxide. This reagent was accidentally added to the solution of complex without removal of succinimide, which is one of the byproducts of bromination. After being left to stand for three days, deposited white precipitates were separated by filtration, and the filtrate was evaporated in a vaccum. Orange plates thus obtained were recrystallized from dichlormethane–methanol solution. The results of elemental analysis. molecular weight and infrared spectrum indicate that this compound is tris(3-succinimido-2,4-pentanedionato)iron(III), the bromine atom at the 3-position of every chelate being replaced by succinimide, instead of the methoxide group. The departure of bromine was recognized by the fact that the white precipitates were soluble in water and silver bromide was formed by the addition of aqueous solution of silver nitrate. The analytical value and molecular weight were as follows. Found: C, 49.53; H, 4.66; N, 6.38%; mol wt, 631; mp 143—146 °C decomposed. Calcd for $FeC_{27}H_{30}N_3O_{12}$: C, 50.33; H, 4.69; N, 6.52%; mol wt, 644.4.

For the sake of confirmation, the brominated compound was isolated and examined. 1.97 g (0.003 mol) of tris(3-bromo-2,4-pentanedionato)iron(III) and 0.99 g (0.01 mol) of succinimide were dissolved in 180 ml of dichlormethane to which was added 0.54 g (0.01 mol) of sodium methoxide dissolved in 25 ml of methanol. After being left to stand for three days, an orange substance was obtained by the same procedure as above. This was also identified as tris(3-succinimido-2,4-pentanedionato)iron(III), A.

In a similar way, phthalimide reacted with tris(3-bromo-2,4-pentanedionato)iron(III), producing orange red crystals of hexagonal prism, which was confirmed to be tris(3-phthalimido-2,4-pentanedionato)iron(III), B. Found: C, 58.63; H, 3.91; N, 5.15%; mol wt, 750; mp 235—240 °C decomposed. Calcd for $FeC_{39}H_{30}N_3O_{12}$: C, 59.41; H, 3.84; N, 5.33%; mol wt, 788.5.

In the infrared spectra, product A and B show a peak at 1705 and 1725 cm^{-1}, respectively, both of them being attributed to the stretching vibration of carbonyl group vicinal to the imide nitrogen. The stretching vibration of the chelated carbonyl groups appears at 1545 cm^{-1} for the original brominated material. The peak shifts to 1580 cm^{-1} for product A and 1582 cm^{-1} for product B. In the region 1100—710 cm^{-1}, product B has peaks assigned to the benzene ring (Table 1).

$Fe(Br\text{-}acac)_3$	240[sh] (4.15)	292 (4.34)		375 (3.46)	470 (3.57)
Product A	244 (4.43)	268 (4.45)		347 (3.56)	432 (3.67)
Product B	244 (4.65)	270[sh] (4.48)	303[sh] (4.15)	347 (3.59)	433 (3.68)

oxidation bands and the band due to the intraligand transition of each one appear at an adequate position with reasonable extinction for the 1,3-diketone complexes. The shoulder at 303 nm of product B might originate from phthalimide residue, whose intense absorption at around 250 nm seems to hide the π—π^* transition band of product B.

These substitution reactions proceed also with the addition of potassium hydroxide instead of sodium methoxide. No change is observed in the absence of hydroxides or methoxides, in contrast to the substitution of thiophenol which is considerably inhibited by the addition of such a proton acceptor as pyridine or piperidine as well as in the basic solvent such as acetone, methanol, ether or dimethyl sulfoxide.[7] The disparity arises from the fact that the reaction depends on whether intermediate adducts exist in the case of thiophenol substitution or the coulombic attraction is dominant enough to promote the reaction.

The present reaction with succinimide or phthalimide seems to be characteristic of iron(III) complex. Aluminum(III), chromium(III), cobalt(III) and copper(II) complexes of the same ligand show no change with various dicarboxylic imides including these two imides. No other substituent has been found as regards the reaction involving this iron(III) complex.

The reaction seems to be a kind of Gabriel reaction. Bacon and Karim reported on the extension of copper-catalyzed reaction,[10] in which the substitution of phthalimide for halogen of aryl halide is catalyzed by copper(I) iodide. Application of this catalyst to the present reaction resulted in failure, suggesting a different mechanism.

Experimental

The electronic spectra and the infrared spectra were measured on a Hitachi 124 type Spectrophotometer and Hitachi 215 type Spectrophotometer, respectively. The elemental analyses were carried out by means of a Yanagimoto MT 2 CHN corder. A Hitachi 115 Vapour Pressure Osmometer was used for the determination of molecular weights. Reagents of guaranteed grade were used without further purification.

Reaction of Triethylphosphine with Dimethyl Acetylenedicarboxylate in the Presence of *p*-Chlorobenzaldehyde

Kin-ya AKIBA, Toshio YONEYAMA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received April 13, 1976)

Synopsis. Reaction of triethylphosphine (**1**) with dimethyl acetylenedicarboxylate (**2**) in the presence of *p*-chlorobenzaldehyde gave dimethyl α-(*p*-chlorobenzoyl)-fumarate (**5**) and a bicyclic lactone (**6**). In the presence of water, reaction of **1** with **2** afforded dimethyl fumarate and triethylphosphine oxide.

Tertiary phosphines can add to acetylenic bonds.[1] The *1*:*1* adduct is considered to be a 1,3-dipole. Therefore, trapping of the 1,3-dipole with *p*-chlorobenzaldehyde was attempted, in order to check a possibility to prepare phosphorus-containing heterocycles.

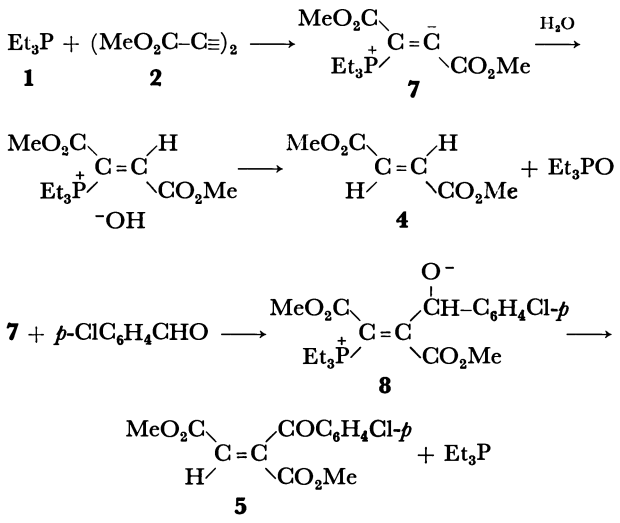
Dimethyl acetylenedicarboxylate (**2**) was added dropwise to a mixture of triethylphosphine (**1**) and *p*-chlorobenzaldehyde (**3**) in ether at room temperature. The reaction products were dimethyl fumarate (**4**) (1.3%), dimethyl α-(*p*-chlorobenzoyl)fumarate (**5**) (13%), a bicyclic lactone (**6**) (1.2%), and triethylphosphine oxide (58%).

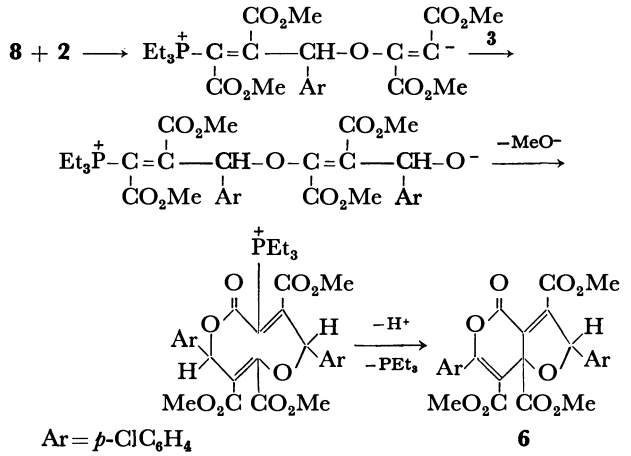
The structure of **5** was determined based on the spectral data, and the NMR data were essentially the same as those of dimethyl α-benzoylfumarate.[2] The structure of **6** was assigned by the spectral data. The carbonyl absorption band at 1760 cm^{-1} is in agreement with those of γ,δ-unsaturated δ-valerolactones.[3]

The methine proton at δ 6.50 is considerably broad, probably due to the presence of syn and anti protons to the bridgehead methoxycarbonyl group.

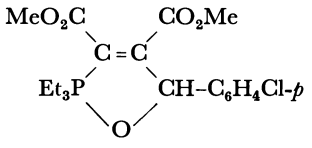
The formation of **4** is attributed to hydrolysis of a 1,3-dipolar intermediate (**7**) by moisture in the solvent, because the reaction of **1** with **2** in the presence of water gave 56% of **4** and 65% of triethylphosphine oxide. The formation of **4** exemplifies *trans* addition of **1** to **2** in accordance with *trans* structure of **5**.

The formation of **4**, **5**, and **6** is explained as follows.





Although the yield of **6** is low, similar result was also obtained when the reaction was carried out at 0 °C. The present result indicates that the 1,3-dipole (**7**) can not afford phosphorus-containing heterocycles such as **9**, probably because of *trans* relation in the cationic and anionic centers of **7**.



Experimental

Reaction of Triethylphosphine (1) with Dimethyl Acetylenedicarboxylate (2). a) In the presence of *p*-chlorobenzaldehyde (**3**): To a mixture of 2.33 g (19.7 mmol) of **1** and 13.3 g (95.1 mmol) of **3** in 20 ml of ether was added 5.23 g (36.8 mmol) of **2** in 40 ml of ether at room temperature over 6 h under nitrogen. Upon the addition of **2**, orange-red color developed in the solution. After evaporation of the solvent, the red tarry residue was chromatographed on silica gel. Elution with benzene recovered 0.372 g (7.1%) of **2** and 11.7 g (87.5%) of **3**. Fractions eluted with benzene–dichloromethane and dichloromethane–chloroform were rechromatographed on a silica gel dry column with dichloromethane to afford 1.35 g (13%) of **5**. Fractions eluted with dichloromethane–chloroform were rechromatographed on a silica gel dry column with dichloromethane to give 68 mg (1.3%) of **4**, mp 101.5—102.5 °C (lit,[4] 102.0 °C). Fractions eluted with chloroform were rechromatographed on a silica gel dry column with ether to give 0.239 g (1.2%) of **6**. Elution with methanol and distillation gave 1.52 g (58%) of triethylphosphine oxide. Red tar is polymerized **2**.

5: mp 79.5—80.5 °C (from ether); IR (KBr): 1730 (MeO-CO) and 1680 cm^{-1} (ArCO); NMR ($CDCl_3$): δ 3.65 (s, 3H, Me), 3.78 (s, 3H, Me), 7.08 (s, 1H, =CH–), 7.45, and 7.83

(A_2B_2, J_{HH}=8.4 Hz, 4H, C_6H_4); MS: *m/e* 282 (M^+, 3.7%) and 139 (ClC_6H_4CO, 100).

Found: C, 55.44; H, 3.73; Cl, 12.68%. Calcd for $C_{13}H_{11}O_5Cl$: C, 55.24; H, 3.92; Cl, 12.54%.

6: mp 203—205 °C (dec) (from acetone); IR (KBr): 1760 (sh) and 1740, 1660, and 1610 cm^{-1}; NMR ($CDCl_3$): δ 3.53 (s, 3H, Me), 3.87 (s, 3H, Me), 3.98 (s, 3H, Me), 6.50 (bs, 1H, CH), and 6.85—7.50 (m, 8H, $2C_6H_4$); MS: *m/e* 532 (M^+, 0.05 %) and 139 (ClC_6H_4CO, 100).

Found: C, 56.52; H, 3.10; Cl, 13.54%. Calcd for $C_{25}H_{18}O_9Cl_2$: C, 56.30; H, 3.40; Cl, 13.30%.

b) In the presence of water: To a mixture of 1.52 g (13.5 mmol) of **1** and 0.5 ml (27.8 mmol) of water in 30 ml of ether was added 2.11 g (27.8 mmol) of **2** in 20 ml of ether over 1.5 h at room temperature under nitrogen. Similar treatment afforded 1.17 g (56%) of **4** and 1.17 g (65%) of triethylphosphine oxide.

This work was supported by a Grant-in-Aid from the Ministry of Education.

Origin of the Oxygen Atom in the Nitrosomesitylene Formed by the Oxidation of Mesidine with Fremy's Salt

Tomoji TAKAHASHI, Hiroshi MINATO, and Michio KOBAYASHI
Department of Chemistry, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received March 6, 1976)

Synopsis. The mechanism of the oxidation of aromatic amines with Fremy's salt was investigated by use of ^{18}O-labelled compounds. It was shown that the nitroso-oxygen atom originates not from water but from the nitroxide oxygen and sulfonate oxygen atoms of Fremy's salt.

Usually it is not possible to isolate nitroso compounds by the oxidation of aromatic amines, but such sterically hindered amines as mesitylenamine give nitroso compounds in good yields by the treatment with Fremy's salt.[1] However, the mechanism of this reaction has not been elucidated yet. We have investigated the mechanism of this reaction by use of ^{18}O-labelled Fremy's salt.

Fremy's salt[nitroxide-^{18}O] was prepared according to the following steps.

$$NaOH + H_2{}^{18}O \text{ (large excess)} \longrightarrow Na^{18}OH$$

$$2Na^{18}OH + NOCl \longrightarrow NaN^{18}OO + H_2{}^{18}O + NaCl$$

$$NaN^{18}OO + 2KHSO_3 \longrightarrow H^{18}O\text{-}N(SO_3K)_2 + NaOH$$

$$6H^{18}O\text{-}N(SO_3K)_2 + 2KMnO_4 \longrightarrow 3[{}^{18}O\text{-}N(SO_3K)_2]_2 + 2MnO_2 + 2KOH + 2H_2O$$

The excess ^{18}O atom% of Fremy's salt[nitroxide-^{18}O] prepared using $H_2{}^{18}O$ (excess ^{18}O, 1.3 atom%) was 0.104 ± 0.009%, and hence the excess ^{18}O atom% in the nitroxide oxygen must be 0.728 ± 0.06%, which roughly corresponds with the value calculated (0.65%) from the excess ^{18}O atom % of the heavy water used (1.3%). This shows that no oxygen exchange with solvents occurred during the above reactions.

The preparation of Fremy's salt[sulfonate-^{18}O] was attempted by the reaction between $NaNO_2$ and $KHS^{18}OO_2$ (obtained from $K^{18}OH$ and SO_2), but the salt prepared contained only 0.004 excess ^{18}O atom %. This suggests that rapid oxygen exchange with water took place. A separate experiment showed that sulfite ions readily exchange oxygen atoms with water under strongly alkaline conditions. Therefore, the above results can be rationalized by assuming that $KHS^{18}OO_2$ reacted with water faster than with $NaNO_2$.

The experimental results of the reaction between mesitylenamine and Fremy's salt may be summarized as follows:

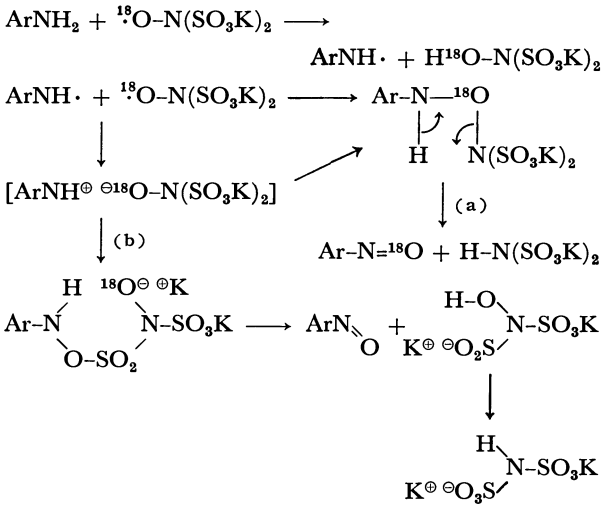
1) When mesitylenamine was oxidized with unlabelled Fremy's salt in acetone–$H_2{}^{18}O$ (1.3 excess atom %), the nitrosomesitylene obtained possessed only 0.002 ± 0.001 excess ^{18}O atom %. Thus no ^{18}O-incorporation from $H_2{}^{18}O$ took place.

2) When mesitylenamine was oxidized with Fremy's salt[nitroxide-^{18}O] in acetone–H_2O, the nitrosomesidine obtained possessed 0.253 ± 0.03 excess ^{18}O atom %.

3) When mesitylenamine was oxidized with Fremy's salt[nitroxide-^{18}O] in dioxane–H_2O, the nitrosomesitylene obtained possessed 0.216 ± 0.005 excess ^{18}O atom %.

The above results clearly show that the oxygen atom of the nitrosomesitylene does not come from water but from Fremy's salt.

If the nitroxide oxygen atom of Fremy's salt directly becomes the nitroso oxygen of the nitrosomesitylene, the excess ^{18}O atom % of the nitrosomesitylene must be the same as that of the nitroxide oxygen of Fremy's salt (0.728 ± 0.06%). However, the value found was only about 1/3 of it. The possibility that the ^{18}O atoms of the nitrosomesitylene formed are lost by subsequent exchange with water can be rejected from our findings[2] that the oxygen atoms of aromatic nitroso compounds virtually do not exchange with water under neutral or strongly acidic conditions. Therefore, the oxygen atom of the nitrosomesitylene comes from both the nitroxide oxygen and the sulfonate oxygen atoms. A plausible mechanism is the following.



In the course (a) the nitroxide oxygen is converted directly into the nitroso group, whereas in the course (b) one of the sulfonate oxygen is converted to the nitroso oxygen. The excess ^{18}O atom % in the nitrosomesitylene found can be explained if course (a) and (b) take place in the ratio of 1 : 2.

Synthesis of 2-Aminonaphthalene-1-thiol and Its Conversion into 8-Nitro-7*H*-benzo[*c*]phenothiazine

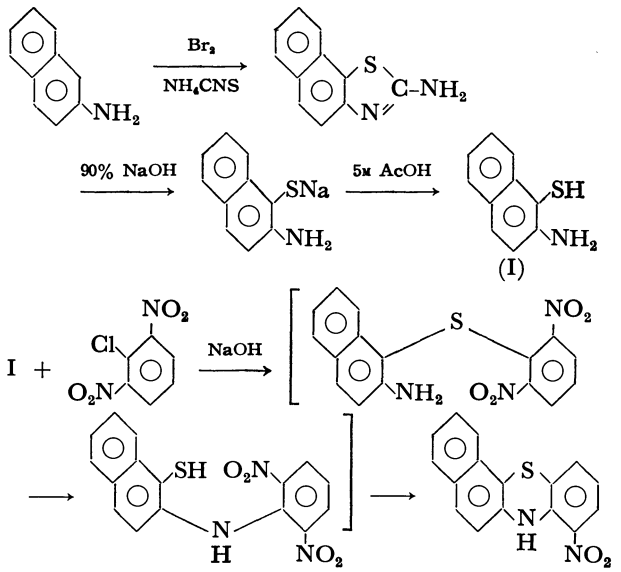
R. R. GUPTA* and S. K. JAIN

Department of Chemistry, University of Rajasthan, Jaipur, India

(Received **January** 5, 1976)

Synopsis. Synthesis of 2-Aminonaphthalene-1-thiol by hydrolytic cleavage of 2-aminonaphtho(2′,1′: 4, 5)thiazole and its conversion into 8-nitro-7*H*-benzo[*c*]phenothiazine *via* Smiles rearrangement *in situ* are reported.

Phenothiazines form an interesting series for Pharmaceutical and industrial uses[1,2] and physical studies.[3] A large number of phenothiazines have been synthesized, but there is no report on the synthesis of 7*H*-benzo-[*c*]phenothiazine and its substituted products. Phenothiazines are generally synthesized by condensation of *o*-aminobenzenethiols with *o*-halonitrobenzenes, but 2-aminonaphthalene-1-thiol has not been prepared so far and consequently 7*H*-benzo[*c*]phenothiazines have not been prepared. In the present investigation preparation of 2-aminonaphthalene-1-thiol and its conversion into 8-nitro-7*H*-benzo[*c*]phenothiazine are reported. The synthetic route is as follows:



Schematic reaction.

Experimental

2-Aminonaphthalene-1-thiol was prepared by reacting *β*-naphthylamine (57.2 g, 0.4 mol) with Br_2 (80 ml) in 200 m of CH_3COOH and NH_4CNS (60.85 g) in 1 l of CH_3COOH and then refluxing 2-aminonaphtho(2′, 1′,: 4, 5)thiazole[4] thus formed with NaOH (550 g in 600 ml of H_2O) for 20 h. The reaction mixture was cooled, diluted with water (750 ml), filtered and neutralized with 5M-acetic acid. It was crystallized from ethanol as yellow crystals, mp 110 °C, yield 10 g (20%). Found: C, 68.50; H, 5.11; N, 7.97%, Calcd for $C_{10}H_9NS$: C, 68.57; H, 5.14; N, 8.00%. IR (KBr) 3330, 3510 (NH_2), and 2600 cm^{-1} (SH). 2-Aminonaphthalene-1-thiol (3.5 g, 0.02 mol) in 40 ml C_2H_5OH was converted into its sodium salt by refluxing with sodium hydroxide (0.8 g, 0.02 mol) in 10 ml H_2O and 20 ml of C_2H_5OH for five minutes. Sodium salt thus obtained was allowed to react with alcoholic solution of 2,6-dinitrochlorobenzene (4.0 g, 0.02 mol). The mixture was refluxed for 4 h and the product was crystallized from benzene–acetone mixture as violet crystals, mp 177 °C, yield 3.2 g (55%). IR (KBr) 3350 (NH), 1350, and 1500 cm^{-1} (NO_2). Found: C, 65.25; H, 3.38; N, 9.51%, Calcd for $C_{16}H_{10}N_2O_2S$: C, 65.30; H, 3.40; N, 9.52%.

The authors express their grateful thanks to Profs. R. C. Mehrotra and K. C. Joshi, for providing facilities in the department.

Synthesis of Succin-as-eins. III.[1] Dyes Derived from β-Benzoylpropionic, β-(3-Acenaphthoyl)propionic and β-(α-Thenoyl)propionic Acids

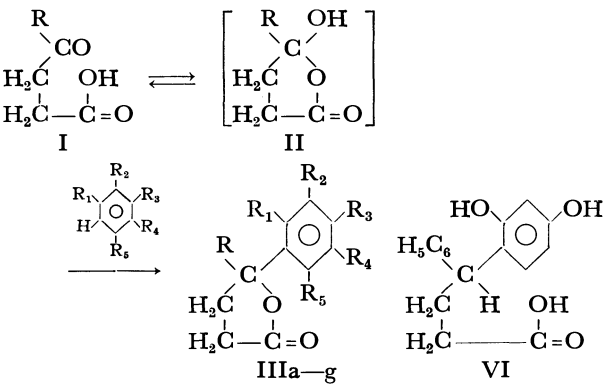
R. GOPAL,* P. C. GUPTA, and S. P. GARG**
Department of Chemistry, University of Allahabad, India

(Received October 14, 1975)

Synopsis. A number of succin-as-eins have been prepared by condensing β-benzoylpropionic, β-(3-acenaphthoyl)propionic and β-(α-thenoyl)propionic acids with phenol, resorcinol, catechol, quinol, phloroglucinol, pyrogallol and orcinol.

The γ-keto acids have been found to cyclize to their γ-hydroxylactones,[2] which yield acetyl derivatives[3-5] retaining their cyclic structures. The β-benzoylpropionic acid[6] (I: R=C_6H_5), β-(3-acenaphthoyl)propionic acid[7] (I: R=$C_{12}H_9$) and β-(α-thenoyl)propionic acid[8] (I: R=C_4H_3S) gave a new series of cyclic compounds succin-as-eins (IIIa—g)[1,9] on condensation with phenols such as phenol, resorcinol, catechol, quinol, phloroglucinol, pyrogallol and orcinol.

The IR (KBr) spectra of IIIa—g, IV and V show strong bands between 1760—1755 cm^{-1} (γ-lactone). The dye (IIIb: R=C_6H_5) (1760 cm^{-1}) on reduction with Zn-dust and acetic acid gave phenyl resorcinol succin-as-in (VI; IR (KBr) bands at 3600—3000 cm^{-1}, -OH in -COOH; 1700 cm^{-1}, >CO in -COOH) (*cf.*, methyl resorcinol succin-as-in[9]). The acid (VI) when left overnight was found changed into IIIb (R=C_6H_5).



IIIa: $R_1=R_2=R_4=R_5=H$; $R_3=OH$
IIIb: $R_2=R_4=R_5=H$; $R_1=R_3=OH$
IIIc: $R_3=R_4=R_5=H$; $R_1=R_2=OH$
IIId: $R_2=R_3=R_5=H$; $R_1=R_4=OH$
IIIe: $R_2=R_4=H$; $R_1=R_3=R_5=OH$

a) The alkaline solution decomposed during the measurement of λ_{max} values.

The absorption maxima (λ_{max}) of acenaphthyl succin-as-eins (IIIa—g, V: R = $C_{12}H_9$) have been found much higher than their analogous succineins and phthaleins but those of phenyl succin-as-eins (IIIa—g, V: R = C_6H_5) and thenyl succin-as-eins (IIIa—g, V: R = C_4H_3S) are comparable with their analogues.

Experimental

All melting points are uncorrected. The λ_{max} (UV and visible) have been recorded on Model DU-2 Beckmann Spectrophotometer and IR determined using a Perkin-Elmer Infracord Spectrometer.

The preparation and purification of the compounds (IIIa—g) taking respective acids (I) and phenols (yield, 40—45%), and diacetyl (IV), and dibromo (V) compounds were done in identical manner as described earlier.[1,9-11]

Zn-dust reduction of IIIb (R=C_6H_5). The dye (IIIb; R = C_6H_5) (1 g) was refluxed in glacial acetic acid (100 ml) with Zn-dust (5 g) for 15 min to yield a light yellow crystalline acid (VI; 0.9 g) mp 180 °C, which does not give fluorescence in alkaline solution. Found: C, 70.42; H, 5.64%. Calcd for $C_{16}H_{16}O_4$: C, 70.58; H, 5.88%.

The acid (VI) when left overnight changed to red compound IIIb (R = C_6H_5), superimposible IR and same λ_{max} values. The acetylation of the mixture of acid (VI) and red compound was carried out as in IV to give diacetyl (IV), mixed mp, identical IR, λ_{max} values and elemental analysis.

One of the authors (R.G.) thanks the C.S.I.R., New Delhi for a grant and fellowship and to Director, Defence Laboratory, Jodhpur for granting permission to publish the work.

The Effect of Metal Oxides on the Transformation of Copper Phthalocyanine Crystals in Organic Solvents

Norimichi KAWASHIMA, Takao SUZUKI, and Kenjiro MEGURO

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 2, 1975)

The dimorphic transformation of copper phthalocyanine crystals was examined by means of X-ray diffraction analysis and electron-micrograph observation, for α-copper phthalocyayine and metal oxides of various mixing ratios with respect to weight were ground using a grinder and suspended in an organic solvent. The α-β transformation of copper phthalocyanine is accelerated by the presence of metal oxides such as alumina, magnesia, and zinc oxide. Particularly, alumina has a remarkable effect on the acceleration of β-copper phthalocyanine formation. The rate of transformation increases with the amount of metal oxide and the grinding time for a mixture of copper phthalocyanine and alumina. The activation energy for the α-β transformation in a (1 : 1) mixture of copper phthalocyanine and alumina ground for 30 min was calculated to be 12.0 kcal/mol.

The phthalocyanine pigments are some of the most important colored pigments owing to their excellent properties. They are remarkably resistant to alkalis and concentrated sulfuric acid and are stable under normal storing conditions. Since their tints have exellent durability in exterior finishes, they are used in paints, lacquers, enamels, and plastics. Their resistance to light, acids, and alkalis also makes them valuable pigments for printing on paper and textile goods.[1]

The polymorphic behavior of copper phthalocyanine was first found by German investigators.[2] Hamm and Norman[3] observed the dimorphic transformation of copper phthalocyanine by means of an electron microscope and electron diffraction. It is well known that the α-form crystal is transformed into the stable β-form either by treatment in various organic suspension media or by thermal treatment. The α-β transformation in organic suspensions is of greatest importance with respect to the decrease of tinting strength and the change of tone in the paint and ink industry. Many investigations have been reported on the transformation of copper phthalocyanine in organic suspensions from the viewpoints of practice and crystallography.[4–11]

Furthermore, in the paint industry, mixtures of several kinds of pigments are used to obtain various colors. Usually, mixtures of organic and inorganic pigments are used. In previous work, the grinding process of mixtures of copper phthalocyanine and inorganic pigments was examined.[12–14] There are no reports concerning the effect of inorganic pigments on the transformation of copper phthalocyanine in organic suspensions. In the work reported here, the effect of metal oxides on the transformation of copper phthalocyanine in organic solvents was investigated by means of X-ray diffraction analysis and electron microscopy.

Experimental

Materials. The α-form copper phthalocyanine (abbreviated α-CuPc) used here was supplied by the Dainippon Ink Chemical, Ltd. Metal oxides used were alumina, magnesia, and zinc oxide of a commercially available high purity (99.9%). The specific surface areas of the alumina, magnesia, and zinc oxide obtained using the BET method are about 170 m^2/g, 30 m^2/g, and 5 m^2/g, respectively. *p*-Xylene of commercial spectrograde quality was used as the organic solvent

Apparatus and Procedure. The mixtures of α-CuPc and metal oxides were ground using an Ishikawa-type grinder with an agate mortar in a closed chamber at room temperature at a (1 : 1) weight mixing ratio. Each mixture containing magnesia and zinc oxide was ground for 30 min after mixing. The mixture of α-CuPc and alumina was ground for 10, 30, and 60 min at weight mixing ratios of (2 : 1), (1 : 1), and (1 : 2). The mixtures were suspended in *p*-xylene to investigate the α-β transformation. The concentration of each suspension was always maintained within the range of 3 to 6 weight percent for *p*-xylene. About 30 cm^3 of the suspension was put in a glass tube with a glass stopper. The suspension was placed in a water bath at constant temperature to within ±0.05 °C. After the required interval of time had elapsed at a definite temperature, the suspension was rapidly cooled with cold water. After being quickly separated from the solvent, the precipitate was washed with a cold inert solvent such as methanol or acetone to remove any trace of the solvent. After being dried, these crystals did not tend to undergo further changes either in external appearance or in crystal structure. The immersion time was in the range of 10 min to 10 h depending on the treating temperature.

To determine the composition of each crystal form, X-ray diffraction analysis was employed using nickel-filtered copper radiation at 35 kV and 10 mA as the X-ray diffraction source, with a scanning speed of 1/2° per min, a time constant of 2 s, a divergence slit of 1° and a receiving slit of 0.2 mm. The X-ray diffraction diagrams were recorded by means of an X-ray diffractometer (Geigerflex). The observation of the powder surface was performed using a Hitachi HSM 2 electron microscope.

Results and Discussion

The X-ray diffraction patterns of original α-CuPc and β-CuPc are presented in Fig. 1. It is worth noting that a common characteristic of the X-ray diffraction patterns for the metastable and stable forms is that a pair of strong reflections appear at smaller angles, as indicated by the letters u and v for the α-form, and by s and t for the β-form crystals. These correspond to lattice spacing of 9 to 13 Å, which are closely related to the size and the stacking of the molecules in approximately 10 Å squares, as well as to the normal crystal arrangements of both forms.

The X-ray diffraction pattern of a (1 : 1) mixture of α-CuPc and β-CuPc is shown in Fig. 2(a). The

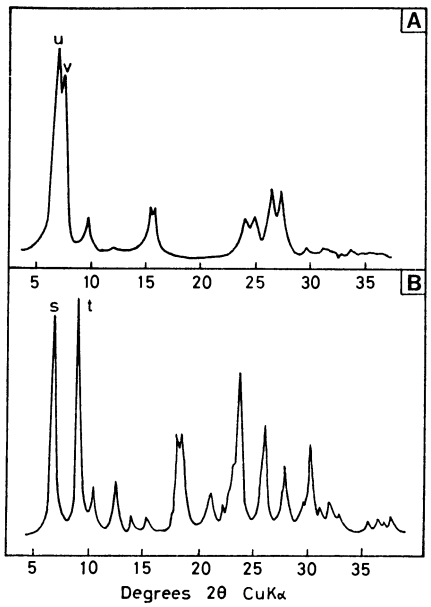

Fig. 1. X-Ray diffraction patterns of dimorphic forms of CuPc. (A): α-CuPc (Metastable form), u: 12.9 Å (200), v: 12.1 Å (002). (B): β-CuPc (Stable form), s: 12.6 Å (001), t: 9.8 Å ($20\bar{1}$).

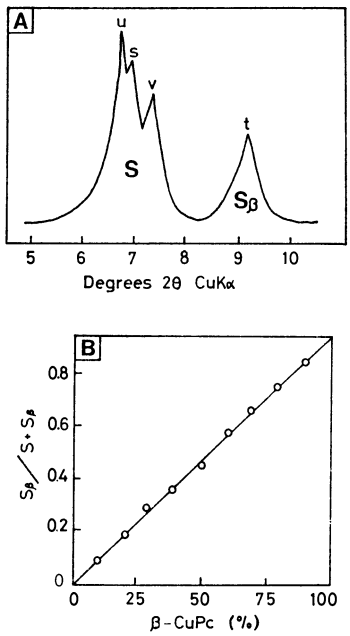

Fig. 2. (a): X-Ray diffraction pattern of a (1 : 1) mixture of α-CuPc and β-CuPc. (b): Calibration curve.

letter Sβ indicates the integral intensities of the reflection of β-CuPc, and S those of α-CuPc overlapping with β-CuPc. Sβ/S+Sβ is plotted against the composition of β-CuPc in mixtures of α-CuPc and β-CuPc of various mixing ratios in Fig. 2(b). The amount of β-CuPc in the samples can be determined from this calibration curve.

The α-β transformation of a mixture of α-CuPc and metal oxides was carried out in *p*-xylene at 50 °C. The reflections characteristic of α-CuPc are gradually

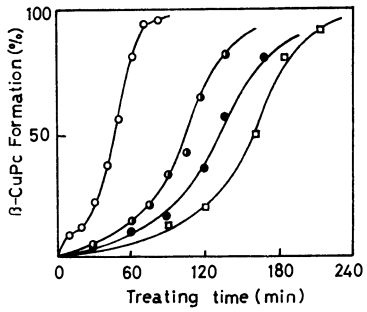

Fig. 3. The amount of β-CuPc formed in mixtures of α-CuPc and metal oxides *versus* the treating time in *p*-xylene at 50 °C.
(□): α-CuPc alone, (●): Mixture of α-CuPc and zinc oxide, (◑): α-CuPc and magnesia, (○): α-CuPc and alumina.

replaced by those of β-CuPc and the two sets of reflections are superimposed at the intermediate stages. By using the calibration curve, the amount of β-CuPc in the mixture of α-CuPc and metal oxide can be calculated. Figure 3 gives the relation between the amount of β-CuPc formed and the treating time. The effect of metal oxides on the transformation of α-CuPc increases in the order: alumina>magnesia>zinc oxide. The addition of alumina produced a remarkable effect on the rate of β-CuPc formation. This order is the same as the increasing order of the surface areas. Consequently, the rate of transformation is considered to depend on the specific surface areas of the oxides.

Our following discussion is mainly devoted to the effect of the addition of alumina on the transformation of α-CuPc.

Scanning electron micrographs of the original specimens and the mixtures of α-CuPc and alumina transformed in *p*-xylene at 40 °C are shown in Photo. 1. The horn-like crystals which formed on the surface of the alumina as shown in Photo. 1(D). It is obvious that almost all the α-CuPc crystals in Photo. 1(E) have transformed into flacky β-CuPc. The nuclei of the β-CuPc crystals formed in the solvent are considered to be adsorbed on the surface of the alumina, and then β-CuPc crystal growth is expected to proceed. The nuclei can be expected to increase with the amount of the addition and the grinding time.

The amount of β-CuPc formed in mixtures of α-CuPc and alumina of various mixing ratios is plotted against the treating time in Fig. 4. The amount of β-CuPc formed in mixtures of α-CuPc and alumina at each treating time increases with the amount of the addition.

This fact is explained by assuming that the adsorption of the nuclei on the surface of the alumina accelerates the β-CuPc crystal growth.

The amount of β-CuPc formed in the mixture ground for various periods is plotted against the treating time in *p*-xylene at 40 °C in Fig. 5. The amount of β-CuPc formed in the mixture increases with the grinding time. This fact indicates that the nuclei of β-CuPc crystals on the surface of the alumina can be formed more easily by mechanical treatment than by

simple mixing. When the organic pigment is admixed with the inorganic one, the surface of inorganic pigment becomes covered with the former and grinding of the inorganic pigment is impeded by the lubricating action of the organic pigment.[12-14] Particularly, in the grinding of mixture of α-CuPc and inorganic powder, the transformation from α-CuPc to β-CuPc is considered to be accelerated by the absorption of the grinding energy.[14]

Figures 6 and 7 show the amounts of β-CuPc formed in α-CuPc alone and in a (1 : 1) mixture of α-CuPc and alumina, respectively, against the treating time

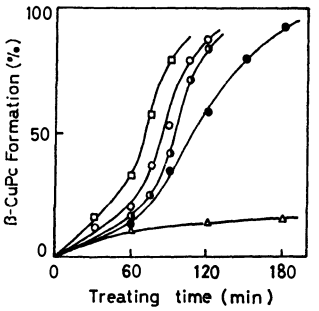

Fig. 5. The amount of β-CuPc formed in a (1 : 1) mixture of α-CuPc and alumina ground for various intervals *versus* the treating time in *p*-xylene at 40 °C.
(△): α-CuPc alone, (◑): Mixture ground for 10 min, (○): Mixture ground for 30 min, (□): Mixture ground for 60 min, (●): Simple mixing.

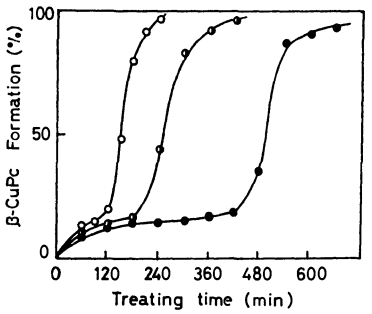

Fig. 6. The amount of β-CuPc formed in α-CuPc alone against the treating time in *p*-xylene at various temperatures.
(●): 30 °C, (◑): 40 °C, (○): 50 °C.

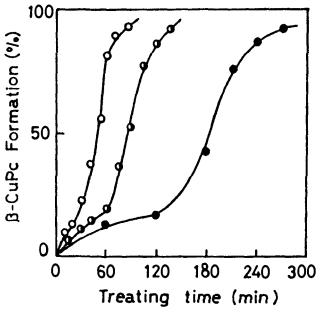

Fig. 7. The amount of β-CuPc formed in a (1 : 1) mixture of α-CuPc and alumina *versus* the treating time in *p*-xylene at various temperatures.
(●): 30 °C, (◑): 40 °C, (○): 50 °C.

in *p*-xylene at various temperatures. It appears difficult to explain the entire curve by a simple mechanism. In the earlier stages of the treatment, it is considered that crystals of meatstable form (α-CuPc) undergo preliminary growth without changing their crystal structure. The latter stages agree with first-order reaction kinetics.

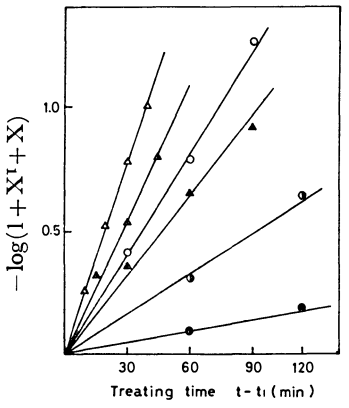

Fig. 8. The logarithm of the amount of β-CuPc formed in α-CuPc alone and the α-CuPc in the mixture *versus* the treating time in *p*-xylene at various temperatures.
(t_1): Induction time, (X_1): The amount of β-CuPc formed for a treating time t_1 in *p*-xylene.
(○): α-CuPc alone, (△): (1 : 1) mixture of α-CuPc and alumina.
(○): 50 °C X_1=0.286, t_1=150 min, (◑): 40 °C X_1=0.770, t_1=300 min, (●): 30 °C X_1=0.897, t_1=540 min, (△): 50 °C X_1=0.204, t_1=40 min, (◭): 40 °C X_1=0.323, t_1=90 min, (▲): 30 °C X_1=0.238, t_1=180 min.

Therefore, the logarithm of the amount of β-CuPc formed was plotted against the treating time, as is shown in Fig. 8. From the result, the activation energy for the transformation of α-CuPc alone and α-CuPc in a (1 : 1) mixture was calculated to be 17.6 kcal/mol and 12.0 kcal/mol, respectively. Other investigators[5,9] have found the activation energy for the transformation of α-CuPc alone in *p*-xylene to be 17.1 kcal/mol. This is in fairly good agreement with our results.

Ion Cyclotron Resonance Study of Ion-molecule Reactions in Benzene: Mechanism of $C_3H_3^+$ Formation

Katsuyuki AOYAGI,[1a] Yoshinori HASUDA,[1b] Masahiro IRIE,[1c] Koichiro HAYASHI,[1c] and Junkichi SOHMA

Faculty of Engineering, Hokkaido University, Sapporo 060

(Received August 5, 1975)

Ion-molecule reactions in gaseous benzene, benzene-d_6, and their mixtures, particularly the formation process of $C_3H_3^+$, have been investigated using ion cyclotron single- and double-resonance techniques. Double-resonance experiments demonstrated that $C_3H_3^+$ is formed by the ion-molecule reaction: $C_6H_7^+ + C_6H_6 \rightarrow C_3H_3^+ +$ neutral product. In C_6H_6–C_6D_6 mixtures, not only $C_3H_3^+$ but also deuterium substituted ions, such as $C_3H_2D^+$ and $C_3HD_2^+$, are formed from $C_6H_7^+$. Quantitative analysis of the double-resonance intensity revealed that $C_3H_3^+$ is formed by the decomposition of the intermediate complex of $[C_6H_7^+–C_6D_6]$, which is a σ-type complex.

Ion-molecule reactions of aromatic hydrocarbons in the gas-phase have been studied using high-pressure mass spectrometry.[2–5] Ions generated from benzene by electron impact are mainly the molecular ion $C_6H_6^+$ and the characteristic fragment ions $C_3H_3^+$, $C_4H_2^+$, $C_4H_3^+$, $C_4H_4^+$, and $C_6H_5^+$.[2–5] It is well known that $C_3H_3^+$ is a stable ion appearing in the mass spectrum of benzene, as well as in a number of hydrocarbon compounds. 2-Propynyl[6] and cyclic[7] structures have previously been proposed as the structure of $C_3H_3^+$, however, at present, $C_3H_3^+$ is considered to be a cyclopropenyl cation.[8] The mechanism of $C_3H_3^+$ formation, however, has not yet been clarified. Ion-molecule reactions in gaseous benzene, especially the mechanism of $C_3H_3^+$ formation, were investigated using ion cyclotron single- and double-resonance (ICSR and ICDR) techniques.[9]

Results and Discussion

Reactions in Benzene. A single-resonance spectrum of benzene obtained at 2×10^{-5} Torr and electron energy of 70 eV is shown in Fig. 1. A number of fragment ions, as well as the molecular ion $C_6H_6^+$, are produced by electron impact on benzene. The spectrum is essentially the same as that obtained by an ordinary mass spectrometer at 1.1×10^{-5} Torr,[2] except for such

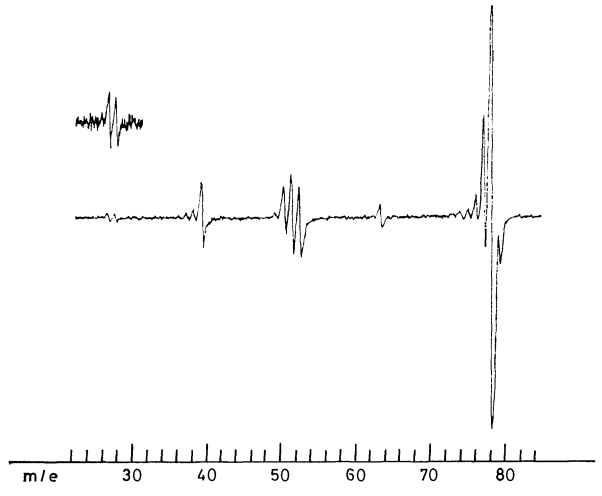

Fig. 1. Single-resonance spectrum of benzene at 2×10^{-5} Torr and 70 eV electron energy. Field modulation yields the derivative presentation.

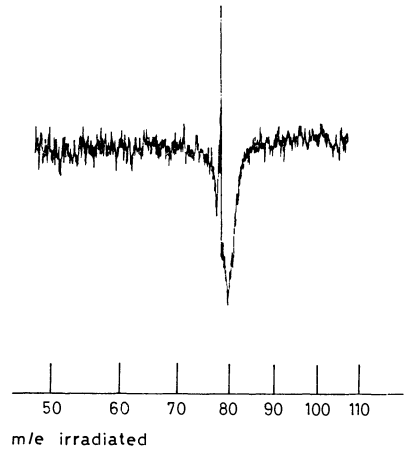

Fig. 2. Double-resonance spectrum of $C_3H_3^+$ in benzene. The sharp spike appearing the frequency (61.4 kHz) corresponding to *m/e* 78 is the first sub-harmonic of the observing frequency. This harmonic peak at double the observed ion mass serves as a convenient check on the mass assignment.

ions as $C_6H_7^+$, $C_7H_7^+$, $C_8H_7^+$, $C_9H_7^+$, $C_{10}H_7^+$, and $C_{11}H_9^+$. From among the many ions, the present double-resonance study concentrated on $C_3H_3^+$ which is one of the major product inos. Irradiation of $C_6H_7^+$ (*m/e* 79) caused on decrease in the intensity of $C_3H_3^+$ (*m/e* 39), as is shown in Fig. 2. This double-resonance indicates that $C_3H_3^+$ is not a primary ion produced by electron impact but is a product ion formed by the ion-molecule reaction:

$$C_6H_7^+ + C_6H_6 \rightarrow C_3H_3^+ + N, \quad (1)$$

where N denotes a neutral product. However, the ICDR peak of the precursor ion ($C_6H_6^+$) producing the reactant ion ($C_6H_7^+$) cannot be distinguished by the broadening of the $C_6H_7^+$ peak due to the strong irradiating field (the irradiating field is 4.8 times as strong as the observing field). The ICDR experiment indicates that if the velocity of the reactant ion R^+ is increased by means of irradiating field of resonance frequency at R^+, then a substantial change will occur in the concentration of product ion P^+, when the two ions are coupled chemically in the absence of irradiation. In reaction (1), a change of the $C_6H_7^+$ velocity reduces the abundance of $C_3H_3^+$, and therefore it is concluded that $C_6H_7^+$ should react with C_6H_6 to produce $C_3H_3^+$.

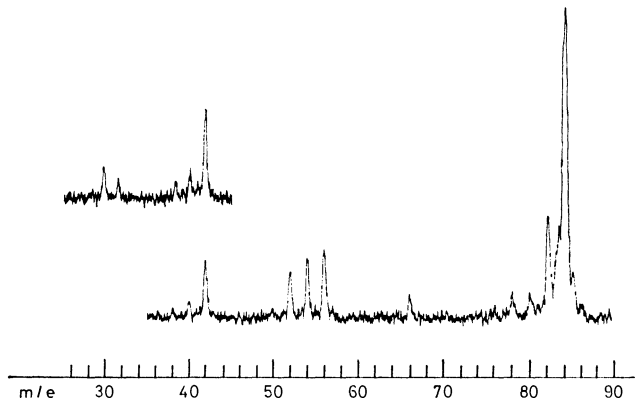

Fig. 3. Single-resonance spectrum of benzene-d_6 at 2×10^{-5} Torr and 70 eV electron energy. Energy modulation yields the absorption presentation.

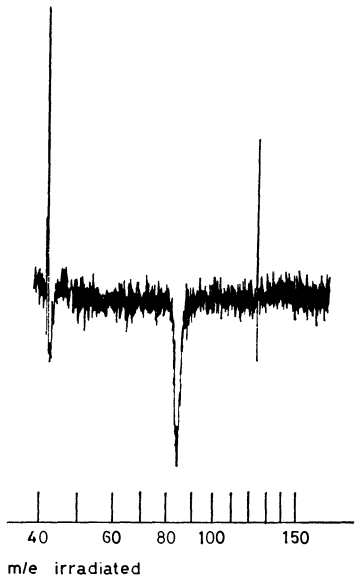

Fig. 4. Double-resonance spectrum of $C_3D_3^+$ in benzene-d_6. The large spike appearing at the frequency (122.8 kHz) corresponding to *m/e* 42 results from the interaction of the irradiating and observing oscillators, and the sharp feature at *m/e* 126 is due to the irradiaitng oscillator exciting the second subharmonic of the observing frequency.

A single-resonance spectrum of benzene-d_6 and a double-resonance spectrum of $C_3D_3^+$ (*m/e* 42) are shown in Figs. 3 and 4, respectively. These spectra are the same as those observed in benzene.

Reactions in Benzene and Benzene-d_6 *Mixtures.* Ionic reactions in a mixture of benzene and benzene-d_6 were investigated to clarify the reaction path for $C_3H_3^+$ formation in detail employing single- and double-resonance experiments. Figure 5 shows the single-resonance spectrum of a mixture of benzene and benzene-d_6 (ratio of 1 : 1). In addition to the spectra observed in benzene or benzene-d_6, the new product ions, $C_6HD_2^+$, $C_6H_5D_2^+$, $C_6H_3D_4^+$, and $C_6HD_6^+$, were observed. The single-resonance spectrum recorded with an increase in sensitivity around *m/e* 41 is shown in Fig. 6, for which the ions are identified as follows:

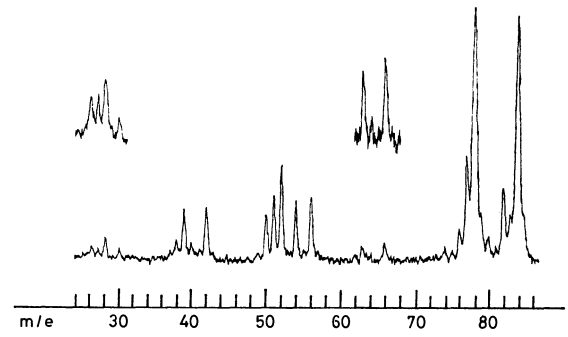

Fig. 5. Single-resonance spectrum of the 1 : 1 mixture of benzene and benzene-d_6 at 2×10^{-5} Torr and 70 eV electron energy.

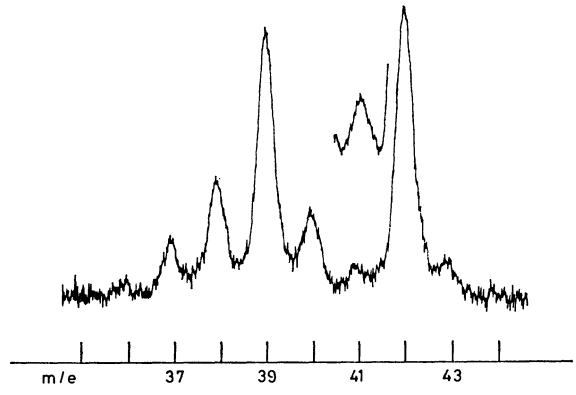

Fig. 6. Single-resonance spectrum recorded with the magnification of the 1 : 1 mixture of benzene and benzene-d_6 at 2×10^{-5} Torr and 70 eV electron energy.

$C_3H_3^+$ and C_3HD^+ at *m/e* 39, $C_3H_2D^+$ and $C_3D_2^+$ at *m/e* 40, $C_3HD_2^+$ at *m/e* 41 and $C_3D_3^+$ at *m/e* 42. The peak at *m/e* 41 is uniquely attributable to the ion which contain both hydrogen and deuterium. The formation of this ion suggests that $C_3H_3^+$ is formed not by the direct decomposition of $C_6H_7^+$ or C_6H_6, but by the decomposition of a mixture ion of the benzene and benzene-d_6 molecules.

Double-resonance experiments on a C_6H_6–C_6D_6 mixture (1 : 1 ratio) are shown in Figs. 7 and 8. The irradiation of $C_6H_7^+$ and $C_6D_7^+$ resulted in a decrease in the intensity of $C_3H_3^+$, as is shown in Fig. 7. This ICDR result predicts that the reactant ions which are coupled chemically with the product ion $C_3H_3^+$ are not only $C_6H_7^+$, but also $C_6D_7^+$. The contributions of $C_6H_6D^+$ and $C_6HD_6^+$ to the formation of $C_3H_3^+$ are scarcely observed. Similarly, the irradiation of $C_6H_7^+$ and $C_6D_7^+$ caused a decrease of the intensity of $C_3D_3^+$, as is shown in Fig. 8. The result indicates that the ions reacting with $C_3D_3^+$ are also $C_6H_7^+$ and $C_6D_7^+$. These ICDR results indicate that $C_3H_3^+$ and $C_3D_3^+$ are formed by the following processes:

$$C_6H_7^+ + \begin{Bmatrix} C_6D_6 \\ C_6H_6 \end{Bmatrix} \xrightarrow[[C_{12}H_{13}^+]]{[C_{12}H_7D_6^+]} C_3H_3^+ + N, \quad (2)$$

$$C_6D_7^+ + C_6H_6 \xrightarrow{[C_{12}H_6D_7^+]} C_3H_3^+ + N, \quad (3)$$

$$C_6D_7^+ + \begin{Bmatrix} C_6H_6 \\ C_6D_6 \end{Bmatrix} \xrightarrow[[C_{12}D_{13}^+]]{[C_{12}H_6D_7^+]} C_3D_3^+ + N, \quad (4)$$

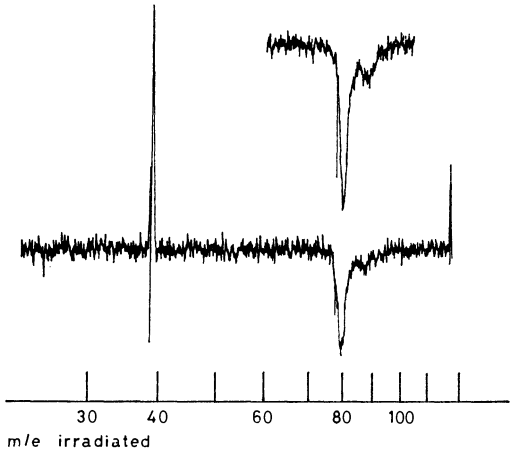

Fig. 7. Double-resonance spectrum of the species at *m/e* 39 in the 1 : 1 mixture of benzene and benzene-d_6. The large spike appearing at the frequency (122.8 kHz) corresponding to *m/e* 39 results from interaction of the irradiating and observing oscillators, and the sharp spikes at the frequencies (61 kHz and 41 kHz) corresponding to *m/e* 78 and *m/e* 117 are due to the irradiating oscillator exciting the first and second sub-harmonics of the observing frequency, respectively.

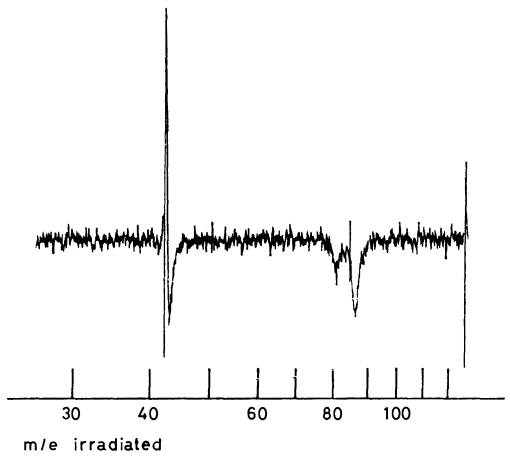

Fig. 8. Double-resonance spectrum of $C_3D_3^+$ in the 1 : 1 mixture of benzene and benzene-d_6. The large spike at *m/e* 42 results from interaction of the irradiating and observing oscillators, and the sharp spikes at *m/e* 84 and *m/e* 126 are due to the irradiating oscillator exciting the first and second overtones of the marginal oscillator, respectively.

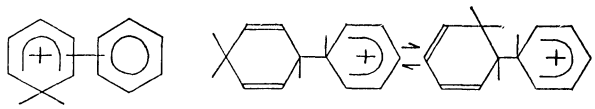
$$C_6H_7^+ + C_6D_6 \xrightarrow{[C_{12}H_7D_6^+]} C_3D_3^+ + N. \quad (5)$$

In order to clarify the structure of the intermediate complex ion $[C_{12}H_{13}^+]$, the intensities of the ICDR peaks were quantitatively examined. The intensity ratio is considered to reflect quantitatively the degree of the contributions of the reactant ions. When the contribution of A ion to the formation of P ion is twice as high as that of B ion, the ICDR spectrum of P should be twice as high at resonance frequency of A than at that of B. Let us assume that the energy dependences of the rate constants for the reactions of $C_3H_3^+$ formation are almost equal, and let us also ignore the isotope effect of hydrogen and deuterium on the $C_3H_3^+$ formation reaction. The ratios of the intensities at the resonant frequencies of $C_6H_7^+$ and $C_6D_7^+$ were found to be $I_{79}/I_{86}=4/1$ and $I_{79}/I_{86}=1/2.7$ for the ICDR spectra of $C_3H_3^+$ and $C_3D_3^+$, respectively. These ratios are not in agreement with the simple ratio of the reactant ion and neutral molecules, which is usually expected for the addition reaction. This means that the ratio directly reflects the decomposition process.

As the intermediate complex for $C_3H_3^+$ formation, it is supposed that there are actually two intermediate complexes, a π-type complex and a σ-type complex:



π-type complex σ-type complex

Here, it is defined that intramolecular exchange exists between H and D in the π-type compex, but does not exist in the σ-type complex. Figure 9 shows the I_{79}/I_{86} ratios of the observed value and the calculated value (see Appendix) in the case of $C_3H_3^+$. Here, I_{79} and I_{86} indicate the ICDR spectral intensities when $C_6H_7^+$ and $C_6D_7^+$ are irradiated, respectively. In the case of the σ-type complex, the I_{79}/I_{86} ratio of the calculated values is in good agreement with that of the observed values. In the case of the π-type complex, however, the calculated ratio does not agree with the observed ratio. This agreement between the observed and calculated ratios is evidence that $C_3H_3^+$ is formed by way of the σ-type complex in the ion-molecule reaction.

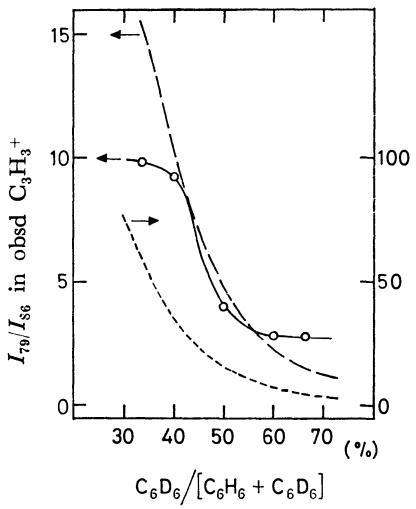


Fig. 9. Dependence of I_{79}/I_{86} on the ratio of the concentration of C_6D_6 to that of $C_6H_6 + C_6D_6$. Calculated (π-type complex), ----; calculated (σ-type complex), ——; observed, —○—.

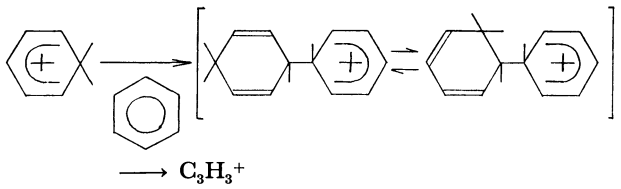
On the other hand, the π-type complex is considered to dissociate into a protonated parent ion and a benzene molecule, and therefore, does not contribute to $C_3H_3^+$ formation.

In conclusion, the mechanism of $C_3H_3^+$ formation in gaseous benzene is explained by the following reaction path:



Experimental

The ICR spectra were obtained with a JEOL JIC-2M spectrometer, and the ICR cell was of a three-section square type similar to conventional ones.[9] Single-resonance spectra were obtained by fixing the frequency of the marginal oscillator and sweeping the magnetic field using field-modulation or energy-modulation phase-sensitive detection modes. Double-resonance experiments were performed by sweeping the frequency of the irradiating oscillator using a pulsed modulation mode for all reaction studies. The experimental conditions were as follows: energy of ionizing electrons 70 eV, trapping voltage 0.25 V, analyzer drift voltages −0.4 and 0.2 V, source drift voltages −2.5 and 0 V, observed of electric field and frequency 0.05 V/cm and 122.837 kHz and modulation frequency 80 Hz.

The analyzer chamber was baked at 150 °C for hours and evacuated below 2×10^{-7} Torr prior to performing the reported studies. Pressure was measured using an ionization vacuum gauge of the Bayard-Alpert type.

Benzene of special reagent grade (Wako Pure Chem. Ind., Ltd.) was purified by trap-to-trap distillation and the purity (>99.99%) was checked by gas-chromatography before use. Hexadeuterobenzene for spectroscopy (E. Merck, >99%D) was used without further purification. The samples were degassed under vacuum utilizing multiple freeze-pump-thaw cycles prior to introduction into the spectrometer.

Appendix

a) Formation of $C_6D_7^+$ in Benzene-d_6. For ICDR studies on benzene-d_6 and benzene, the following results were obtained. The irradiation of $C_6D_6^+$ at *m/e* 84 caused an increase in the intensity of $C_6D_7^+$. This ICDR result indicates that the $C_6D_7^+$ is formed by the ion-molecule reaction:

$$C_6D_6^+ + C_6D_6 \rightarrow C_6D_7^+ + N. \qquad (A1)$$

However, the ICDR peak of $C_6H_6^+$ corresponding to the reaction producing $C_6H_7^+$ was not confirmed due to the proximity of the observing $C_6H_7^+$ frequency to the irradiating $C_6H_6^+$ frequency. The reaction for $C_6H_7^+$ formation, however, could be considered to be the same as reaction (A1).

b) Calculation of the I_{79}/I_{86} Ratio of ICDR Spectral Intensities. $C_3H_3^+$ is formed by reactions (2) and (3). Then, the I_{79}/I_{86} ratio when $C_3H_3^+$ is observed is calculated to be

$$\frac{I_{79}}{I_{86}} = \frac{P(C_6H_7^+)\{C(C_6H_6)\times P[C_{12}H_{13}^+]+C(C_6D_6)\times P[C_{12}H_7D_6^+]\}}{P(C_6D_7^+)\times C(C_6H_6)\times P[C_{12}H_6D_7^+]}, \qquad (A2)$$

where

$$P(C_6H_7^+) = C(C_6H_6^+)\times C(C_6H_6)$$

with $P(C_6H_7^+)$ representing the probability that $C_6H_7^+$ is formed, $C(C_6H_6^+)$ the benzene ion concentration, $C(C_6H_6)$ the benzene concentration, $P[C_{12}H_{13}^+]$ the probability that $C_3H_3^+$ is formed from the complex $[C_{12}H_{13}^+]$ and the other symbols are defined in the same manner.

For example, in the case of a C_6H_6–C_6D_6 mixture in the ratio of 1 : 1, $C_6D_7^+$ is formed by reaction (A1). The concentration of C_6D_6 is 1/2, and that of $C_6D_7^+$ is also 1/2. Therefore, $P(C_6D_7^+)=1/4$. Similarly, $P(C_6H_7^+)=1/4$. Let us assume that $C_3H_3^+$ is formed by the random combination of three carbon and three hydrogen atoms in the π-type complex. The probability that $C_3H_3^+$ is formed from the complex $[C_{12}H_{13}^+]$ is

$$P[C_{12}H_{13}^+] = \frac{{}_{12}C_3\times{}_{13}C_3}{{}_{25}C_6} = \frac{286}{805}.$$

Similarly,

$$P[C_{12}H_7D_6^+] = \frac{{}_{12}C_3\times{}_{7}C_3}{{}_{25}C_6} = \frac{1}{23}$$

and

$$P[C_{12}H_6D_7^+] = \frac{{}_{12}C_3\times{}_{6}C_3}{{}_{25}C_6} = \frac{1}{161}.$$

By substituting the actual values into Eq. A2, we obtain

$$\frac{I_{79}}{I_{86}} = \frac{16.0}{1}.$$

In the case of a σ-type complex, let us assume that $C_3H_3^+$ is formed by a combination of the three adjoining carbon and the three adjoining hydrogen atoms in the σ-type complex. There are 16 combinations of the three adjoining carbon atoms. However, the number of combinations of the three adjoining hydrogen atoms differ for each complex. There are 19 combinations of the three adjoining hydrogen atoms in the complex $[C_{12}H_{13}^+]$, 9 such combinations in the complex $[C_{12}H_7D_6^+]$, and 6 such combinations in the complex $[C_{12}H_6D_7^+]$, respectively. Therefore, the probabilities that $C_3H_3^+$ is formed from each σ-type complex are equal to $P[C_{12}H_{13}^+]=19/16$, $P[C_{12}H_7D_6^+]=9/16$, and $P[C_{12}H_6D_7^+]=6/16$. By substituting the actual values into Eq. A2, we finally obtain $I_{79}/I_{86}=4.7/1$.

Triplet Excitation Energy Transfer in the Vinyl Polymers with Pendant Carbazolyl Groups

Akira ITAYA, Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI
Department of Chemical Engineering, Faculty of Engineering, Yamaguchi Universtity, Ube 755

(Received August 15, 1975)

The triplet energy transfer in poly(*N*-vinylcarbazole)(PVCz) prepared by radical and cationic polymerization (PVCz(r) and PVCz(c) respectively), poly[2-(*N*-carbazolyl)ethyl vinyl ether](PCzEVE), and brominated PVCz (BPVCz) has been investigated by measuring the delayed emission spectra in solid films and rigid solutions at 77 K. The prompt and delayed fluorescence spectra both in the solid film and in the rigid solution at 77 K were different for PVCz(r) and PVCz(c). This seems to be due to the difference in tacticity between them. PCzEVE, in which the Cz groups are connected from afar to the skeletal chains by means of $-O-CH_2-CH_2-$ bonds, showed the delayed fluorescence and the phosphorescence both in the rigid solutions and in the solid films at 77 K. The BPVCz film showed only the excimer phosphorescence. In the solid films of PVCz(r), PVCz(c), and PCzEVE, the Cz chromophore-delayed fluorescence increased with an increase in the concentration of triplet quenchers, such as naphthalene and fluorene. This phenomenon suggests the presence of a heterogeneous triplet-triplet annihilation in these aromatic vinyl polymer films. The quenching of the Cz chromophore phosphorescence both by the doping of the naphthalene in the solid films and by the doping of the 1,3-pentadiene in the rigid solutions obeyed the Stern-Volmer equation, and the migration coefficient, λ, and the mean exciton migration length, L, were obtained. The values of λ and L were in the following order; PVCz(r)>PVCz(c)>PCzEVE (>BPVCz) in the solid film and PVCz(r)>PVCz(c) in the rigid solutions. The order was explained by both the concentration of the intrinsic trap sites for triplet excitons and the distance between neighboring Cz chromophores in one polymer chain.

Recently, the emission spectra of aromatic vinyl polymers have been extensively investigated. The triplet energy transfer in a rigid solution at 77 K has been studied in detail on vinyl polymers with large aromatic rings, such as naphthyl and carbozolyl groups.[1-5] The investigations showed that the triplet excitons can migrate along the polymer chain, and that delayed fluorescence is caused by a homogeneous triplet-triplet (T-T) annihilation between two intramolecular migrating triplet excitons. Concerning the triplet energy transfer in the solid films, David *et al.* reported on vinyl polymers with small aromatic rings which emit only phosphorescence and no delayed fluorescence.[6,7] They showed that the triplet exciton migration frequencies in such polymer films were smaller than in the corresponding crystals. Concerning the vinyl polymer films with large aromatic rings, Fox *et al.* and Klöpffer *et al.* have qualitatively studied poly(1-vinylnaphthalene) and poly(*N*-vinylcarbazole) (PVCz) respectively.[5,8] Klöpffer *et al.* showed that the phosphorescence of PVCz films is governed by two kinds of traps, the concentration of which was estimated to be 5×10^{-3} (mol of trap/mol of basic unit) from the saturated concentration of the sensitized dopant phosphorescence, and that PVCz films emitted no delayed fluorescence. However, the triplet energy transfer in solid films has never hitherto been studied quantitatively on such vinyl polymers, to the knowledge of the authors.

Therefore, it seems that it would be interesting to investigate quantitatively the spectroscopic behavior of the triplet excitons in the vinyl polymers with large aromatic rings and to compare the difference between in rigid solutions and in solid films.

A preliminary short report has been published in *Chem. Lett.*[9] In the present work, the authors have investigated the changes in the delayed emission intensity of the vinyl polymers with pendant carbazolyl groups doped with various concentrations of a triplet quencher, such as naphthalene and 1,3-pentadiene, in rigid solutions as well as in solid films at 77 K.

Experimental

The following four vinyl polymers with pendant carbazole (Cz) chromophores were used.

The PVCz(r) was prepared by the polymerization of a 0.5 M benzene solution of purified *N*-vinylcarbazole (VCz) in the presence of 1 mol% azobisisobutyronitrile in an evacuated sealed tube at 70 °C for 7 h. The molecular weight ($\bar{M}_v$), as measured by the viscosimetrical method,[10] was 2×10^5.

The PVCz(c) was prepared by the polymerization of a 0.5 M toluene solution of purified VCz in the presence of 0.5 mol% BF_3–$(OC_2H_5)_2$ under a nitrogen atmosphere at 20 °C for 18.5 h. $\bar{M}_v=1\times10^5$. Both the PVCz(r) and the PVCz(c) were reprecipitated three times from the benzene solution with a methanol–acetone (1 : 1) mixture.

The poly[2-(*N*-carbazolyl)ethyl vinyl ether] (PCzEVE) has the Cz chromophores connected to the skeletal chain at a distance of about 4 Å by $-O-CH_2-CH_2-$ bonds. This was prepared by a method described previously.[11] $\bar{M}_n=$ 7800.

The brominated poly(*N*-vinylcarbazole)(BPVCz) was obtained by the bromination of PVCz(Luvican M170) with *N*-bromosuccinimide and was reprecipitated three times from the dichloroethane solution with acetone. The fraction of bromination was determined to be 0.9 from the elementary analysis.

Commercial naphthalene (NAPH) and fluorene of a scintillation grade were purified by zone-refining. Commercial 1,3-pentadiene (1,3-PD), a well-known triplet quencher, was used after repeated distillation. All the solvents used were purified by the usual methods. The solutions (donor concentration; 1×10^{-4} Cz unit M, solvent; 2 : 3 mixture of tetrahydrofuran and 2-methyltetrahydrofuran) for the measurements were deairated by means of freeze-pump-thaw cycles. Doped films were prepared by casting a dichloroethane solution of the polymer with a certain amount of the dopant onto quartz plates. The thicknesses of the films were about 7, 5, and 7 μm for PVCz, PCzEVE, and BPVCz respectively. The coated plates were immersed in liquid nitrogen for the measurement of the emission spectra.

The apparatus and techniques for measuring the delayed

emission spectra were described in a previous paper.[9] All the samples were excited by 345 nm light, which was not absorbed by the triplet quenchers. It was confirmed that the application of a phosphoroscope factor[12] was not necessary in the case of solid films. In the case of rigid solutions, the delayed fluorescence spectra were, however, corrected by using a phosphoroscope factor.

Results and Discussion

Delayed Emission Spectra in Rigid Solution and in Solid Film. The delayed emission spectra of PVCz(r), PVCz(c), and PCzEVE in rigid solutions and in solid films at 77 K are in Figs. 1 and 2 respectively. Concerning PVCz (r and c) in rigid solutions, Yokoyama *et al.*[4] and Klöpffer *et al.*[5] have reported as follows:

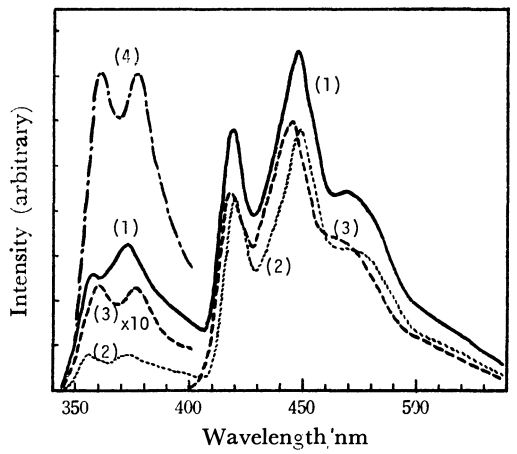

Fig. 1. Delayed emission spectra of (1) PVCz(r), (2) PVCz(c), and (3) PCzEVE in MTHF-THF rigid solutions at 77 K (uncorrected). The prompt fluorescence (4) of PCzEVE in MTHF-THF rigid solution at 77 K was also given for comparison.

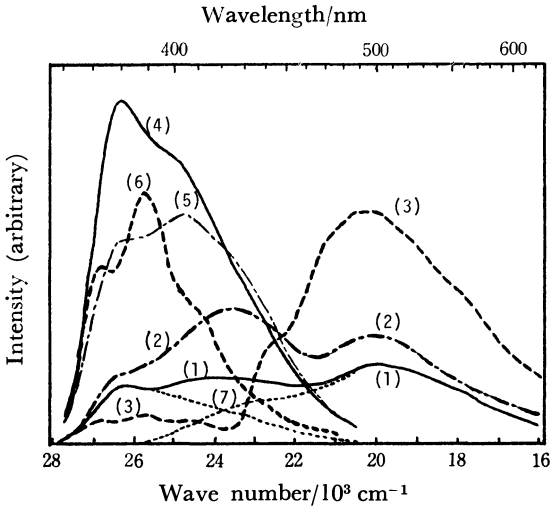

Fig. 2. Delayed emission spectra of (1) PVCz(r), (2) PVCz(c), and (3) PCzEVE films at 77 K. The prompt fluorescence spectra of (4) PVCz(r), (5) PVCz(c), and (6) PCzEVE films at 77 K were also given for comparison. The resolution spectra (7) of delayed emission spectum of PVCz(r) (1) were also given.

(1) The delayed emission spectrum consists of the delayed fluorescence and the phosphorescence; (2) the intensity and the lifetime of the delayed fluorescence are dependent on the molecular weight, and the delayed fluorescence is not observed for PVCz with a low molecular weight ($\overline{DP} \leqq 50$); (3) the phosphorescence is emitted from the trap site in the polymer chain because the phosphorescence (0-0 band; 420 nm) is located at a lower energy than that of the model compound (*N*-isopropylcarbazole) (0-0 band; 412 nm). However, they have not reported on the relationship of the spectra to the chemical preparation of the samples. In our present results, the delayed fluorescence spectra are a little defferent between PVCz(r) and PVCz(c), as is shown in Fig. 1, although the lifetimes (τ_{df}^{0}) are almost the same (11 ms for PVCz(r) and 12 ms for PVCz(c)). The phosphorescence spectra are almost the same between PVCz(r) and PVCz(c). The lifetime (τ_{ph}^{0}) is 1.8±0.2 s for PVCz(r and c).

In the case of solid films, Klöpffer *et al.*[5] showed that PVCz (r and c) films emitted only a phosphorescence governed by two traps (two component decay; 7.9±1 and 1.4 s), and no delayed fluorescence, and that two different types of spectra were observed in the phosphorescence and in the prompt fluorescence at 77 K, independent of the polymerization methods. In our present results, the delayed emission spectra of PVCz (r and c) consist of two emission bands, as is shown in Fig. 2. The prompt fluorescence spectra of the films and the example of the resolution spectrum (PVCz(r)) are also shown in Fig. 2. The further purification of the polymer (for example; reprecipitation up to ten times and/or extraction with hot methanol) gave no change in the spectra. The broad delayed emission in the longer wavelength region is invariably monophotonic in origin, and this lifetime consists of two components (7.9±0.7 and 1.6±0.5 s). Therefore, this emission is considered to be the phosphorescence emitted both from Trap I (excimer-forming site) and from Trap II, as has been described by Klöpffer *et al.*[5] On the other hand, both the position and profile of the delayed emission band in the shorter wavelength region are the same as those observed for the normal fluorescence at 77 K, as is shown in Fig. 2, and the emission intensity depends quadratically on the excitation light intensity. The lifetime of this emission is about 50 ms for PVCz (r and c). These facts indicate that this emission band can be assigned to the delayed fluorescence resulting from a homogeneous T-T annihilation between two migrating triplet exciton in films, as is the case with rigid solutions. The delayed fluorescence spectra also show two different types. One is rich in the excimer component and is observed for PVCz(c). The other is poor in the excimer component and is observed for PVCz(r). This was different from the results reported by Klöpffer *et al.*, but was confirmed using several samples prepared under different polymerization conditions. The difference between PVCz(r) and PVCz(c) is also observed for the prompt fluorescence in films at 77 K.[13] It has previously been reported that the tacticity of vinyl polymers with large aromatic rings was hardly sensitive at all to method of polymerization.[14] However,

recently we have found, by measuring their NMR spectra, that the PVCz, poly(*N*-vinyl-5*H*-benzo[*b*]-carbazole), and poly(*N*-vinyl-7*H*-benzo[*c*]carbazole) prepared by cationic polymerization have a higher isotacticity than those prepared by radical polymerization.[15] Frank *et al.* have found that the concentration of the excimer-forming site depends on the conformation of the polymer chain.[16] Judging from the above-mentioned discussion, the difference in the fluorescence spectra seems to be attributable to the different tacticity between PVCr(z) and PVCz(c).

The delayed emission spectra of PCzEVE in rigid solutions and in solid films at 77 K also consist of two bands, as is shown in Figs. 1 and 2. Both the position ($\bar{\nu}_{max}$; 360 or 376 nm in rigid solutions and 371, 388, or 409 (shoulder) nm in solid films) and the profile of the emission band in the shorter-wavelength region are nearly the same as is observed for the normal fluorescence ($\bar{\nu}_{max}$; 361 or 377 nm in rigid solutions and 370, 388.5, or 410 (shoulder) nm in solid films) at 77 K, and the emission intensity depends quadratically on the exciting-light intensity. Therefore, the emission bands of PCzEVE are identified as delayed fluorescence. It is interesting that PCzEVE in a rigid solution emits the delayed fluorescence, in spite of its short skeletal chain length ($\overline{DP}$=33). The τ_{df}^{0} of PCzEVE in a solid film is 45 ms, while that in a rigid solution could not be determined because of the low intensity. On the other hand, the delayed emission band at a longer wavelength ($\bar{\nu}_{max}$; 418, 446 nm in a rigid solution and about 495 nm in a solid film) is monophotonic in origin. Therefore, this emission band is identified as the phosphorescence emitted from the trap site, by analogy with PVCz(r and c). The τ_{ph}^{0} in a rigid solution is 6.6±0.1 s, while that in a solid film consists of two components (3.5±0.2 and 0.7±0.05 s), which is smaller than that of PVCz(r and c) by a factor of about two.

The BPVCz shows only one broad delayed emission band around 20730 cm^{-1}. This emission is invariably monophotonic in origin, and its position and profile are the same as the normal emission at 77 K. It shows a nonexponential decay with an apparent lifetime of 50 ms. The failure to observe a prompt fluorescence of BPVCz seems to be attributable to the high efficiency of the intersystem crossing from the excited singlet state to the triplet state due to the heavy atom effect of bromine. This delayed emission is considered, by analogy with poly(3,6-dibromo-*N*-vinylcarbazole) in a rigid solution at 77 K, to be the excimer phosphorescence.[18]

Triplet Energy Transfer in Solid Films and Rigid Solutions. The delayed emission spectra of PVCz(r), PCzEVE and BPVCz films doped with NAPH of various concentrations at 77 K are shown in Figs. 3—5. In Figs. 3 and 4, the prompt fluorescence spectra of the polymer films are also shown for the sake of comparison. In every polymer film studied, upon the doping of NAPH, the Cz chromophore-phosphorescence(I_{ph}) decreases significantly and is replaced by a sensitized NAPH phosphorescence(I_{sph}). Although the Cz phosphorescence lifetime(τ_{ph}) in PVCz(r and c) films could not be determined because of the overlapping of I_{ph} and

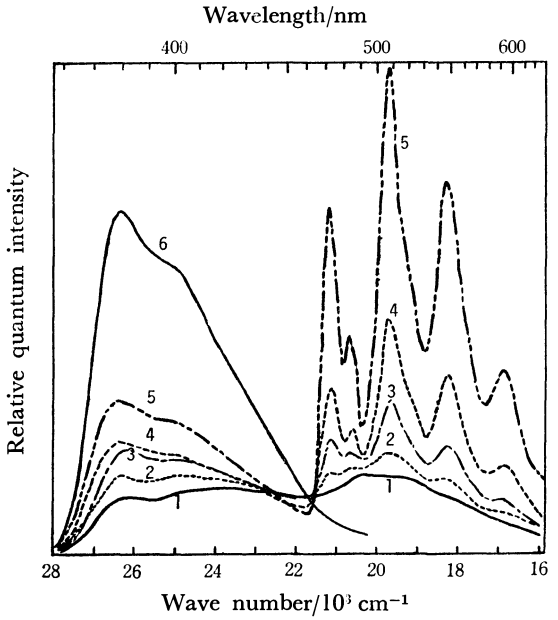

Fig. 3. Delayed emission spectra of PVCz(r) films doped with NAPH at 77 K. NAPH concentration; (1) 0, (2) 1.41×10^{-4}, (3) 7.04×10^{-4}, (4) 1.41×10^{-3}, and (5) 7.04×10^{-3} mol/VCz unit mol. The prompt fluorescence (6) of a PVCz(r) film was also given for comparison.

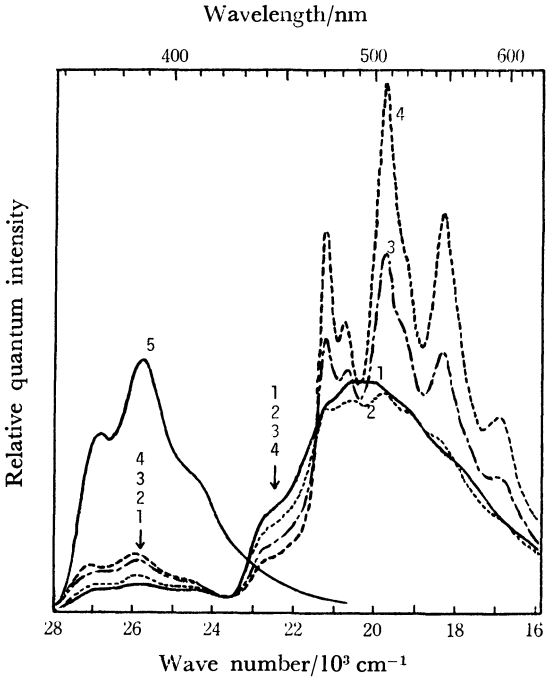

Fig. 4. Delayed emission spectra of PCzEVE films doped with NAPH at 77 K. NAPH concentration; (1) 0, (2) 2.62×10^{-4}, (3) 1.64×10^{-3}, and (4) 8.18×10^{-3} mol/CzEVE unit mol. The prompt fluorescence (5) of a PCzEVE film was also given for comparison.

I_{sph}, τ_{ph} in a PCzEVE film was found, by observing the decay curve at 444 nm, not to decrease upon the doping of NAPH. Therefore, in these films, the triplet energy seems to transfer from the freely migrating triplet exciton to the dopant, and I_{ph} seems to be emitted from the trapped triplet state.

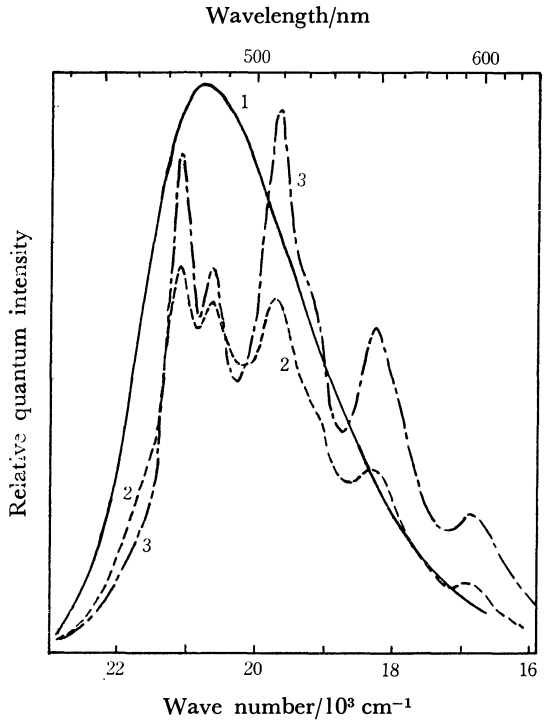

Fig. 5. Delayed emission spectra of BPVCz films doped with NAPH at 77 K. NAPH concentration; (1) 0, (2) 6.16×10^{-3}, and (3) 1.23×10^{-2} mol/BVCz unit mol.

The Cz chromophore-delayed fluorescence(I_{df}) increases with an increase in the concentration of NAPH. The changes in I_{df} and I_{sph} as a function of NAPH mole fraction in solid films are given in Fig. 6. In the case of the highest concentration of NAPH, the I_{ph} is quenched completely and I_{sph} reaches saturation, whereas I_{df} increases steeply and also second-order with respect to the exciting light intensity. The lifetime of the delayed fluorescence(τ_{df}) is gradually lengthened with an increase in the concentration of NAPH, as is shown in Fig. 7. Similar phenomena are observed for PVCz(c and r) and PCzEVE films doped with

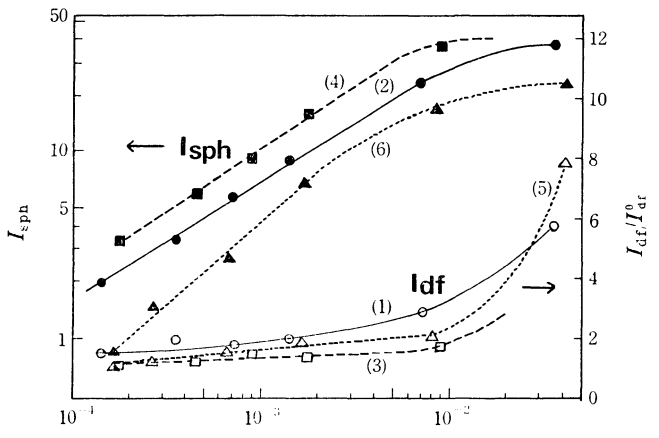

Fig. 6. Dependence of I_{df} and I_{sph} on concentration of NAPH in solid films at 77 K. (1), (2) ——; PVCz(r), (3), (4) ----; PVCz(c), and (5), (6) ……; PCzEVE.

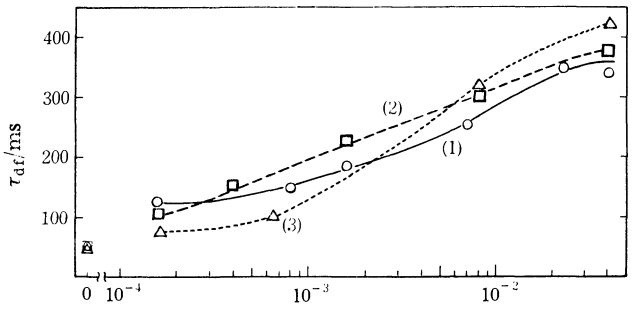

Fig. 7. Dependence of τ_{df} on concentration of NAPH in solid films at 77 K. (1) —○—; PVCz(r), (2) --□—; PVCz(c), and (3) ···△···; PCzEVE.

fluorene.

It is clear from the above-mentioned results that the dopants act as an effective triplet quencher for Cz chromophores in every film. The increase in I_{df} upon the doping of these triplet quenchers, therefore, strongly suggests that a heterogeneous T-T annihilation process occurs with a fairly good efficiency between freely migrating triplet excitons and either the triplet state of the dopant or a shallow trap site introduced by it.

In the case of PVCz(r and c) doped with NAPH in a rigid solution (Fig. 8), I_{ph} decreases and is replaced by I_{sph}, as is the case with solid films. On the other hand, the I_{df} shows an anomalous phenomenon, a little different from that in the solid films; it increases at low NAPH concentrations (up to 5×10^{-3} M) and decreases at higher concentrations. The change in the τ_{df} corresponds approximately to the change in the intensity; for example, the τ_{df} values of PVCz(r) are about 11, 12, 10, and 3 ms for 0, 8.40×10^{-4}, 2.10×10^{-3}, and 1.45×10^{-2} M respectively. In the case of PVCz(r and c) doped with NAPH, the heterogeneous T-T annihilation, therefore, seems to be present even in a rigid solution at 77 K.

In the case of PVCz(r and c) doped with 1,3-PD, a well-known triplet quencher in rigid solutions, both the I_{df} and the I_{ph} decrease significantly with an increase in the concentration of 1,3-PD, as is shown in Fig. 8, where I^0 and I are the Cz chromophore emission intensity in the absence and in the presence of the dopant respectively. The τ_{df} is decreased steeply ($\tau^0_{df}/\tau_{df}=4$—5 for 0.25×10^{-2} M). However, the τ_{ph} is hardly decreased by the doping of 1,3-PD ($\tau^0_{ph}/\tau_{ph}=1.0$—1.1 for 2.0×10^{-2} M). Therefore, it is considered that the triplet energy transfer mainly from freely migrating triplet excitons to the dopant, as is the case with solid films. The degree of quenching is much larger for the I_{df} than for the I_{ph}. This is the behavior usually observed for poly(1-vinylnaphthalene) (PVN) and poly(1-naphtyl methacrylate) (PNMA).[2,3] When 1,3-PD is used as the triplet quencher, the heterogeneous T-T annihilation is not present. No quenching experiment of PCzEVE has been done, because of its short chain length ($\overline{DP}=33$).

The I^0_{ph}/I_{ph} ratios are given in Fig. 9 as a function of the NAPH mole fraction in PVCz(r), PVCz(c), and PCzEVE films. Since the density of the vinyl polymers

(4) —●—; Delayed fluorescence in the PVCz(r)-NAPH system. (5) —□-·-; Phosphoresceence in PVCz(c)-1,3-PD system. The point with arrow was corrected by the phosphoroscope factor which was estimated by assuming the lifetime to be 2 ms.

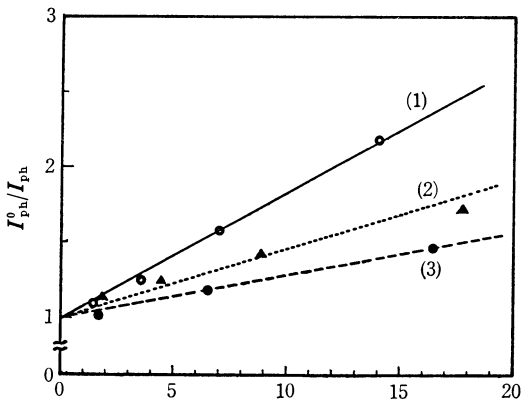

Fig. 9. Stern-Volmer type plots (I^0_{ph}/I_{ph}) for the quenching of the Cz chromophore phosphorescence of (1) PVCz(r), (2) PVCz(c), and (3) PCzEVE films by NAPH at 77 K.

was measured to be 1.19 g/cm^3, a conversion of the unit on the abscissa in Fig. 8 from mole fraction to molarity results in the Stern-Volmer polt;

$$I^0_{ph}/I_{ph} = 1 + k_t\tau[Q]$$

Here, k_t is the bimolecular quenching rate constant, τ is the excited state lifetime in the absence of a quencher, and [Q] is the quencher concentration of the molarity unit. In the case of PVCz(r and c) doped with 1,3-PD in a rigid solution, Stern-Volmer polts are also obtained, as is shown in Fig. 9. In the case of most aromatic vinyl polymers containing the present polymers, the phosphorescence is emitted not from the freely migrating triplet but from the trapped triplet state, so that the lifetime(τ_{ph}) is considered to be that of the trapped triplet state. Two times the τ_{df} value should, therefore, be used as the value of τ. The value of k_t were thus obtained from the slopes of the Stern-Volmer plots. The theory developed by Voltz *et al.*[19] was applied to the present results,

$$k_t = 4\pi N_0 \lambda R_0 \times 10^{-3}\ \mathrm{M^{-1}\,s^{-1}}$$

where N_0 is Avogadro's number, λ is the migration coefficient, and R_0 is the critical transfer distance between donor and acceptor, for which the transfer probability $p=1$ if $R \leq R_0$ and $p=0$ if $R>R_0$. The value of 15 Å is used as R_0.[20] The mean exciton migration length, L, is defined by;[21]

$L = \sqrt{2\lambda\tau}$ (for a one-dimensional random walk)

$L = \sqrt{6\lambda\tau}$ (for a three-dimensional random walk).

These values are listed in Table 1.

The values of λ and L are in the following order: PVCz(r)>PVCz(c)>PCzEVE in solid films and PVCz(r)>PVCz(c) in rigid solutions. If the distance between neighboring Cz rings is estimated to be 3.5 Å, the number of Cz rings which the triplet exciton can cause to migrate during the lifetime is estimated to be in the order of 400 from the values of λ listed in Table 1 both in solid films and in rigid solutions. Therefore, the difference in λ and L seems not to be attributable to the small difference in the degree of polymerization ($\overline{DP}$) between PVCz(r) ($\overline{DP}$=1000) and PVCz(c) ($\overline{DP}$=500).

It is well-known that the singlet exciton migration is limited by the intrinsic trap site (excimer-forming site).[22] Similarly, the triplet exciton migration seems to be limited by the intrinsic trap site, such as excimer-forming site in the polymers, because the observed phosphorescence was emitted only from the trap sites. Therefore, the difference in λ and L between PVCz(r) and PVCz(c) seems to be attributable to the difference in the concentration of the intrinsic trap site for the triplet exciton.

The value of λ in PCzEVE film is expected to be very small as compared with the case of PVCz(r and c), judging from the large distance between neighboring Cz chromophores. However, it is almost the same as the value for PVCz(c). The concentration of trap sites in PCzEVE film as smallest among the polymer films studied.[13] This is also supported by the facts that prompt fluorescence spectrum of PCzEVE film at 77 K (Fig. 2) is mainly monomeric in origin and that the phosphorescence shows a shoulder at about 440 nm. This is the reason for the relatively large λ value in PCzEVE film. This is also supported by the following consideration.

In using the published data on the triplet energy transfer in rigid solution at 77 K which have already been reported, where τ_{ph} was used as τ in the Stern-Volmer equation, we replace τ_{ph} by $2\tau_{df}$ as τ. Then, the migration coefficients λ of PVN[1] and PNMA[3] are estimated to be 3.3×10^{-13} and 4.6×10^{-13} cm^2/s respectively, although the molecular weights of these polymers are unknown. Judging from the structure of their polymer and their fluorescence spectra at room temperature, the concentration of intrinsic trap sites in PVN seems to be larger than that in PNMA. The comparable values in λ between PVN and PNMA seems to be explained by the overlap of two opposite

TABLE 1. SLOPES OF STERN-VOLMER PLOTS ($k_t\tau$), Cz PHOSPHORESCENCE AND DELAYED FLUORESCENCE LIFETIME (τ^0_{ph} and τ^0_{df}), BIMOLECULAR QUENCHING RATE CONSTANT (k_t), EXCITON MIGRATION COEFFICIENT (λ), AND MEAN EXCITON MIGRATION LENGTH (L) IN SOLID FILMS AND RIGID SOLUTIONS AT 77 K

effects—the concentration of the intrinsic trap site and the distance between neighboring naphthalene chromophores.

The $k_t\tau$ in BPVCz film is smallest among the polymers studied. This seems to be caused by the short triplet exciton lifetime resulting from the heavy atom effect of bromine.

In both PVCz(r) and PVCz(c), the lifetime of the triplet exciton in a solid film is larger than that in a rigid solution by a factor of about 5. On the contrary, the diffusion coefficient, λ, in a solid film is smaller than that in a rigid solution by a factor of 10. Although these phenomena are very interesting, a reasonable explanation cannot be offered at the present time. A further investigation of the other vinyl polymers is necessary and is now in progress.

Group Interactions in Polyelectrolytes. XII. Amination Kinetics of Chloromethylated Polystyrene in Binary Solvent Systems Composed of Dioxane and Dipolar Aprotic Solvents

Hiroshi KAWABE

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received August 28, 1975)

The activation parameters ($\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$) in the amination reaction of chloromethylated polystyrene (CMPS) and benzyl chloride with *s*-butylamine in *N,N*-dimethylformamide (DMF)–dioxanes mixtures and with 2-amino-1-butanol in dimethyl sulfoxide (DMSO)–dioxane mixtures were investigated as a function of x_1, the mole fraction of DMF or DMSO in the binary mixed solvents. A similar dependence of the parameters on x_1 was found in both systems, and the observed values of the parameters were in fair agreement with those calculated on the basis of Kondo and Tokura's theory concerning reaction rates in binary mixed solvents, assuming that the activated complex is solvated selectively with DMF or DMSO to form an addition product. The solvation in the DMSO–dioxane system was stronger than that in the DMF–dioxane system. Although $\Delta G^{\ddagger}$ decreases relatively uniformly with the increase in x_1, $\Delta H^{\ddagger}$ decreases sharply and reaches nearly a constant value at $x_1 \approx 0.2$. It was suggested that the increase of $T\Delta S^{\ddagger}$ in the range of $x_1 > 0.2$, which is approximately proportional to that of x_1, may be due to the relative increase in the configurational entropy change of the reaction system on transfer from dioxane to the dipolar aprotic solvents.

It has previously been reported that the amination rates of chloromethylated polystyrene (CMPS) and benzyl chloride with alkylamines and amino alcohols increase markedly on transfer of solvent from dioxane to such dipolar aprotic solvents as *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO).[1-3] This enhanced reactivity was ascribed to the solvation of the activated complex in the dipolar aprotic solvents. The dependence of the amination rate constants of CMPS and benzyl chloride with isobutylamine and *s*-butylamine on the composition of DMF–dioxane system was also investigated at a constant temperature;[4] the relation could be represented by curves calculated on the basis of Kondo and Tokura's theory concerning reaction rates in binary mixed solvents.[5]

In the present study, the amination with *s*-butylamine in the DMF–dioxane system has been surveyed at various temperatures in order to discuss the dependence of the activation parameters on the solvent composition. In the DMSO–dioxane system, since the polymer was precipitated in the initial stage of the amination with *s*-butylamine in pure DMSO, the amination kinetics has been investigated with 2-amino-1-butanol, the alkyl structure of which is the same as that of *s*-butylamine.

Experimental

Materials. The chloromethylated polystyrenes (CMPS-14, chlorine content: 20.30%, degree of chloromethylation: 0.829, mol wt: 1.17×10^5; CMPS-12, chlorine content: 21.83%, degree of chloromethylation: 0.914, mol wt: 1.04×10^5) were prepared and purified by the procedures described in previous papers.[6,7] The (*R*)-2-amino-1-butanol was also prepared as has been reported previously;[7] bp 92—93 °C/30 mmHg, n^{20} 1.457, $[\alpha]_D^{20}$ −9.96. The other chemicals and solvents were of a reagent grade and were distilled before use; they were proved to be pure by their refractive indices.

Kinetic Measurements. The procedures of the kinetic measurements in the amination of CMPS and benzyl chloride were the same as those described in previous papers.[1,6,7] The temperature of the reaction mixture was kept constant within ±0.1°. In the amination with *s*-butylamine in the DMF–dioxane system, the initial concentration of the amine (*a*) was about 0.400 M and that of the chloromethyl group (*b*) was about 0.040 M ($a/b=10$). The polymer used was CMPS-14. In the amination with 2-amino-1-butanol in the DMSO–dioxane system, *a* was about 0.21—0.22 M and *b* was about 0.044 M ($a/b=4.8$—5.0). The polymer used was CMPS-12.

Results and Discussion

Amination with s-Butylamine in DMF–Dioxane Systems. Chloromethylated polystyrene (CMPS) and benzyl chloride were aminated with *s*-butylamine in DMF–dioxane mixtures at 45, 60, and 75 °C. The rate constants in the mixed solvents, k_M, were computed on the basis of the second-order equation, as has been described previously.[4] The values of the activation energy, E_a, and the frequency factor, A, are listed in Table 1.

The plots of log k_M against x_1 are shown in Figs. 1 and 2, where the circles represent the observed values, while the solid and broken lines represent the

0.20	CMPS	12.3±0.3	5.94±0.01
	Benzyl	12.4±0.0$_2$	5.99±0.02
0.35	CMPS	12.2±0.3	6.12±0.18
	Benzyl	12.3±0.3	6.28±0.28
0.50	CMPS	12.2±0.4	6.28±0.24
	Benzyl	12.2±0.4	6.40±0.24
0.60	CMPS	12.2±0.3	6.42±0.18
	Benzyl	12.3±0.2	6.61±0.13
0.80	CMPS	12.1±0.1	6.51±0.09
	Benzyl	12.2±0.4	6.68±0.25

a) A is expressed by l/mol min.

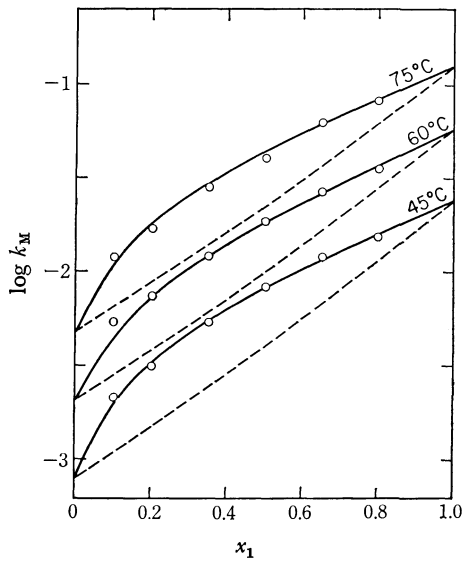

Fig. 1. Plot of log k_M *vs.* mole fraction of DMF, x_1, for the amination of CMPS with *s*-butylamine in DMF-dioxane mixture.
——: Calculated on the basis of Eq. 1.
----: Calculated on the basis of Eq. 2.

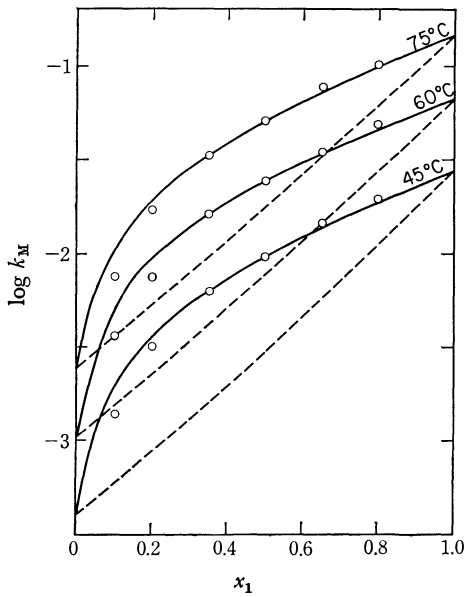

Fig. 2. Plot of log k_M *vs.* mole fraction of DMF, x_1, for the amination of benzyl chloride with *s*-butylamine in DMF-dioxane mixture.
——: Calculated on the basis of Eq. 1.
----: Calculated on the basis of Eq. 2.

values computed on the basis of Eq. 1 and of Eq. 2 respectively:

$$\log k_M = x_1 \log k_1 + x_4 \log k_4 - [x_1 \log (K+1) - \log (x_1K+1) + x_1x_4\,\alpha_{14}/2.303] \quad (1)$$

$$\log k_M = x_1 \log k_1 + x_4 \log k_4 - x_1x_4\,\alpha_{14}/2.303 \quad (2)$$

where x_1 and x_4 ($=1-x_1$) are the mole fractions of DMF and dioxane respectively in a DMF-dioxane system, where k_1 and k_4 are the rate constants in pure DMF and dioxane respectively, where K is the equilibrium constant of the specific interaction between the activated complex and DMF, expressed by the mole fractions of the species, and where α_{14} is an empirical coefficient which is related to the interaction between DMF and dioxane. The α_{14} may be evaluated by means of this relation:[4,8]

$$\Delta G_M^E/RT = x_1x_4\,\alpha_{14} \quad (3)$$

where ΔG_M^E represent the molar excess free energy of mixing in the binary system. The values of α_{14} and K were determined, by the procedures previously described,[4] to be:

α_{14}(at $x_1=0.5$) = 0.408(45 °C), 0.390(60 °C), 0.374(75 °C)

K(for CMPS) = 14.5(45 °C), 11.1(60 °C), 12.4(75 °C)

K(for benzyl chloride) = 37.6(45 °C), 38.1(60 °C), 31.4(75 °C)

The fact that the observed values shown in Figs. 1 and 2 are well expressed by Eq. 1 suggests that the activated complex is solvated selectively with DMF to form an addition product, as has been discussed previously.[4]

By differentiating Eq. 1, Kondo and Tokura gave the following expression for the activation energy in the binary system, ΔE_M^*:[5]

$$\Delta E_M^* = x_1\Delta E_1^* + x_4\Delta E_4^* + \frac{x_1x_4(\Delta E_1^* - \Delta E_4^*)}{x_1 + (1/K)} \quad (4)$$

where ΔE_1^* and ΔE_4^* represent the activation energies in the respective pure solvents.

The ΔE_M^* in the DMF-dioxane reaction system was computed on the basis of Eq. 4; the numerical values of E_a and log A in the pure solvents were given in

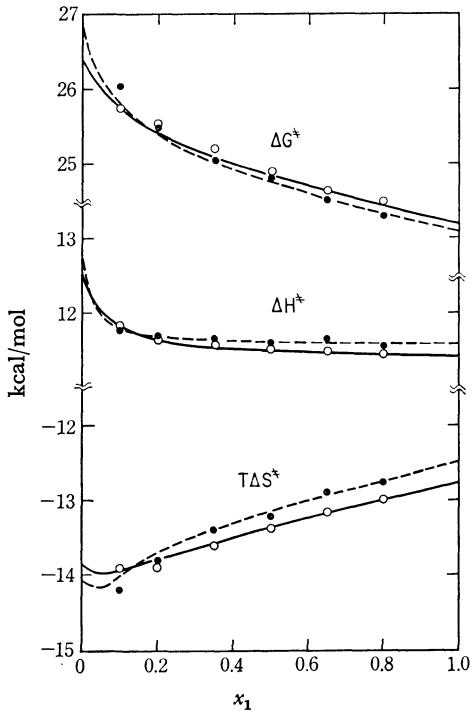

Fig. 3. Plot of the activation parameters *vs.* mole fraction of DMF, x_1, for the amination of CMPS (○) and benzyl chloride (●) with *s*-butylamine in DMF-dioxane mixture at 60 °C.
——: Calculated for CMPS.
----: Calculated for benzyl chloride.

Refs. 2 and 4. The activation parameters ($\Delta G^{\ddagger}_{M}$, $\Delta H^{\ddagger}_{M}$, and $\Delta S^{\ddagger}_{M}$) were calculated for 60 °C from the $\Delta E^{\ddagger}_{M}$ and log k_M values and plotted against x_1 in Fig. 3. The observed values of the activation parameters were obtained from the E_a and log A values listed in Table 1. The observed values expressed by the circles in Fig. 3 fall substantially on the calculated curves.

Amination with 2-Amino-1-butanol in the DMSO–Dioxane System. Although the amination of CMPS with *s*-butylamine in DMSO was heterogeneous because of the deposition of the polymer, the amination with 2-amino-1-butanol was throughly homogeneous in the overall range of the DMSO–dioxane system. Since the activated complex is also considered to be solvated with DMSO, the dependence of log k_M and $\Delta E^{\ddagger}_{M}$ on x_1, the mole fraction of DMSO, is expected to be similar to that in the DMF–dioxane system.

The amination of CMPS with 2-amino-1-butanol in pure dioxane was self-accelerated because of the neighboring group interaction;[7] however, this self-acceleration diminished upon the addition of a small amount of DMSO; the amination of CMPS in the DMSO–dioxane system conformed to the second-order equation in the range of x_1=0.16—1.0. Table 2 shows the values of E_a and log A computed by the least squares method from the observed k_M values at various temperatures.

The plots of log k_M at 60 °C against x_1 are shown in Fig. 4. The α_{14} value used for the calculation was evaluated in accordance with Eq. 3 by using the data on the DMSO–dioxane system given by Quitzsch *et al*:[9]

$$\alpha_{14}(\text{at } x_1=0.5) = 0.626(40\,^{\circ}\text{C})$$

a) A is expressed by l/mol min.

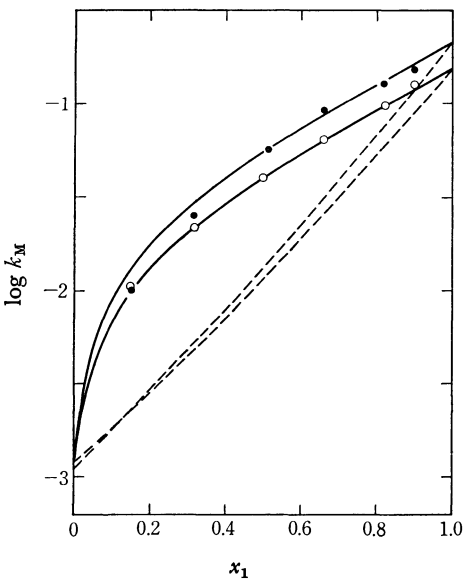

Fig. 4. Plot of log k_M *vs.* mole fraction of DMSO, x_1, for the amination of CMPS (○) and benzyl chloride (●) with 2-amino-1-butanol in DMSO-dioxane mixture at 60 °C.
——: Calculated on the basis of Eq. 1.
----: Calculated on the basis of Eq. 2.

The K values are shown in Table 3. The observed log k_M values fall substantially on the curves calculated on the basis of Eq. 1.

The $\Delta E^{\ddagger}_{M}$ values were calculated on the basis of Eq. 4. The observed values of the activation parameters for 60 °C are compared with the calculated values in Fig. 5. In the calculation of $\Delta E^{\ddagger}_{M}$, we used $\Delta E^{\ddagger}_{1}$= 12.5 ckal/mol for both CMPS and benzyl chloride by considering the E_a values in pure DMSO[1] and those given in Table 2. In the calculation of the solid lines in Fig. 5, we used $\Delta E^{\ddagger}_{1}$=13.5 kcal/mol for both CMPS and benzyl chloride in view of the E_a value in pure dioxane.[7] Recently, however, it has been found that both the k_0 of CMPS, the rate constant independent of the neighboring groups, and the k of benzyl chloride are linear functions of the molar concentration of amine, a, for the amination with 2-amino-1-butanol in dioxane, unlike the amination in DMSO.[10] The Arrhenius plot of the intrinsic rate constants, $k_{int}=\lim_{a\to 0}$ (k_0 and k), gave E_a=16.5 kcal/mol. We used this value for $\Delta E^{\ddagger}_{1}$ in the caluclation of the broken lines in Fig. 5, which indicated that $T\Delta S^{\ddagger}$ decreases in a lower range of x_1; a similar decrease in $T\Delta S^{\ddagger}$ is also shown in Fig. 3 for the DMF–dioxane system.

	Benzyl			−0.8	−3.1	−2.3	1.9

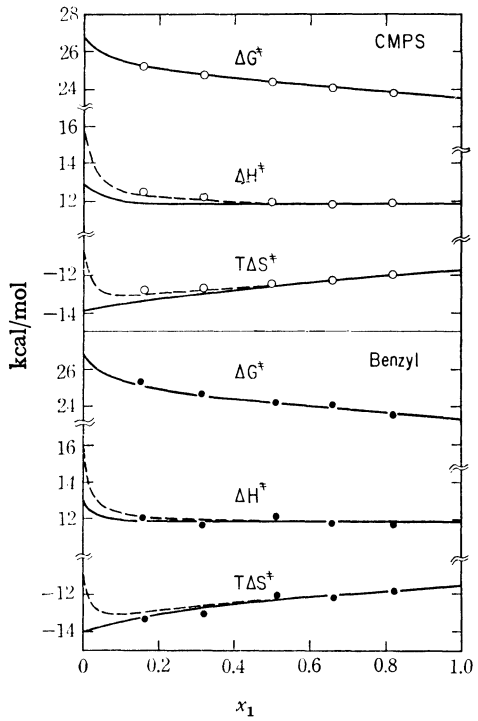

Fig. 5. Plot of the activation parameters *vs.* mole fraction of DMSO, x_1, for the amination of CMPS (○) and benzyl chloride (●) with 2-amino-1-butanol in DMSO-dioxane mixture at 60 °C.
——: Calculated by setting $E_4=13.5$ kcal/mol.
----: Calculated by setting $E_4=16.5$ kcal/mol.

Comparison between DMF–Dioxane System and DMSO–Dioxane System. The activation parameters of the amination change to various extents upon a change in solvent.[1-4] These changes are related to both the specific solvation of the activated complex in the dipolar aprotic solvents and the change in the configurational entropy of the reaction system from the initial state to the transition state, ΔS_1^{*conf}.

On the basis of the present amination data with 2-amino-1-butanol in the DMSO–dioxane system, we calculated the equilibrium constant of the solvation, expressed on the basis of the molar concentration ($K_c=KV_{sol}$), the thermodynamic quantities of the solvation (ΔG^{*solv}, ΔH^{*solv} and $T\Delta S^{*solv}$), and the difference between the configurational entropy change in DMSO and that in dioxane ($\delta\Delta S^{*conf}=\Delta S_1^{*conf}-\Delta S_4^{*conf}$), according to procedures described previously.[4] The value of $\Delta E_4^*=16.5$ kcal/mol was employed for this calculation, because the value of $\Delta E_4^*=13.5$ kcal/mol yielded $T\Delta S^{*solv}\approx 0$. The results listed in Table 3 suggest that the decrease in ΔG^* from dioxane to DMSO is caused not only by the negative ΔG^{*solv}, but also by the positive $T\delta\Delta S^{*conf}$. The $T\delta\Delta S^{*conf}$ value is the same for CMPS and benzyl chloride. Similar findings are obtained for the DMF–dioxane–*s*-butylamine reaction system (or isobutylamine) (*cf.* Table 4 of Ref. 4). Table 3 also shows the parameters of the DMF–dioxane–2-amino-1-butanol reaction system, which were calculated from the previously reported kinetic data in pure DMF[1] on the assumption that the ΔG^{*solv} value of benzyl chloride in this system equals that in the DMF–dioxane–*s*-butylamine (or isobutylamine) system and that the difference in ΔG^* between CMPS and benzyl chloride is based on the difference in ΔG^{*solv}. The $\delta\Delta S^{*conf}$ value in the former system thus obtained is almost the same as that in the latter system.

A comparison between the two systems in Table 3 indicates that the ΔG^{*solv} in the DMSO–dioxane system is lower than that in the DMF–dioxane system. It also indicates that the $T\delta\Delta S^{*conf}$ in the former system is higher than that in the latter system. These results may be ascribed to the fact that DMSO is more polar than DMF.

In view of Figs. 3 and 5, indicating a similar dependence of the activation parameters on x_1 for both DMF–dioxane and DMSO–dioxane systems, it seems that there is the same kind of solvation effect in both systems. Although ΔG^* decreases relatively uniformly with x_1, ΔH^* decreases sharply in the range of $x_1<0.2$ and then reaches an almost constant value. This may be ascribed to the selective solvation of the activated complex with the dipolar aprotic solvents; consequently, $T\Delta S^*$ may be expected to drop in this range. The relatively uniform increase in $T\Delta S^*$ in the range of $x_1>0.2$ may be ascribed to the relative increase in the $T\Delta S^{*conf}$ of the system, which is proportional to x_1.

The author wishes to express his thanks to Dr. Masaya Yanagita for his valuable discussions. He is also grateful to Mr. Yasunori Anami for his helpful assistance in carrying out the measurements.

Infrared Studies of the Isocyanate Species Formed in the Reaction of NO with CO over Pt and Rh

Hiroo NIIYAMA, Motoo TANAKA, Hiroshi IIDA, and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 4, 1975)

The behavior of isocyanates formed on the surface of Rh and Pt in the reaction of nitrogen oxide with carbon monoxide was studied by means of IR spectroscopy using a flow reactor. The isocyanate species readily reacted with N_2O or H_2O, however, it did not decompose when dosed with NO or CO. The catalytic activity of Pt–Al_2O_3 in the reaction of NO+CO declined quickly with an increase in the amount of the surface isocyanate (–NCO). Accordingly, it is concluded that –NCO is not a reaction intermediate but an inhibitor of the reaction.

Recently, Unland[1] has observed the formation of isocyanate (–NCO) on the surface of Pt–Al_2O_3 in the reaction of NO with CO. He has stated that it is a reaction intermediate on the basis of the following findings. Firstly, Pt–NCO is produced when a mixture of NO and CO is dosed over Pt–Al_2O_3 at temperatures higher than 300 °C, where the reaction of NO with CO proceeds at an appreciable rate. Secondly, the amount of Pt–NCO changes with the gas phase composition and it disappears when an NO-rich mixture is dosed.

These findings are, however, not conclusive evidence that the species is a "true" intermediate in the reaction. Bell and London[2] have also observed the formation of –NCO on CuO catalyst, however, they considered that it was not a reaction intermediate but some by-product.

This paper reports the dynamic behavior of –NCO on the surface of Rh and Pt, which was especially studied confirm whether or not it is a reaction intermediate.

Experimental

Catalyst. Pt(1 wt %)–Al_2O_3 and Rh(1 wt %)–Al_2O_3 were prepared by impregnating γ-Al_2O_3 with an aqueous solution of either H_2PtCl_6 or $RhCl_3$. They were then dried at 100 °C for 24 h and calcined at 650 °C for 3 h. Pre-reduction was performed at 500 °C for 1 h in flowing H_2. Disks for IR studies were prepared after the prereduction. They were reduced again in an IR cell (at 300 °C for 1 h at 300 Torr or H_2) or in a flow reactor (at 500 °C for 1 h in flowing H_2) just before use.

The aluminas used as supports were obtained from two sources. Al_2O_3-I was prepared from Alumina Sol 200 (supplied by Nissan Chem. Co.) by drying at 100 °C for 24 h followed by calcination at 650 °C for 3 h. Al_2O_3-II was the commercially available alumina, Alon C.

IR Studies in a Vacuum. A conventional IR cell which was attachable to an appropriate vacuum and gas handling system was employed. The reactant mixture was in contact with the catalyst at 300 °C for 5 min and then was pumped off for 1 min at the same temperature. The isocyanate was produced on the surface of the catalyst by this procedure and was subjected to various treatments as described in the legends of the figures. IR measurements were made after the system had cooled to room temperature. The reactant, NO, CO or a mixture of the two, was introduced through a KOH-packed column into a gas handling system. They were stored in gas containers and were further purified by several freeze-thaw cycles before use.

NO+CO Reaction in a Flow System. Catalytic activity tests were made using a conventional flow system. A flow diagram is shown in Fig. 1. The reaction was occasionally interrupted by replacing the reactants in the system with pure helium (He). The reactor was then immersed in a fluidized thermal bath maintained at 500 °C in order to decompose or desorb surface residues. This procedure is tentatively termed "flash desorption", although not only desorption but also decomposition of the surface residue occurred simultaneously. Several bursts of O_2 were then introduced to establish complete combustion of the surface residues. This procedure is termed "combustion". Liberated gases were analyzed by gas chromatography. An IR cell, similar to that used in the vacuum studies but with slight modification for adaptation to the flow apparatus, was also employed as a reactor in order to observe the development of surface species for changes in catalytic activity.

Results

Rh catalyst. The IR spectra of a mixture of NO and CO (NO=26 Torr, CO=59 Torr) which was dosed over Rh–Al_2O_3-II at 300 °C are given in Fig. 2. The spectra is quite similar, in general, to that reported by Unland,[1,3] as can be seen in Table 1. The small differences in the position of the peak maxima may be explained on the basis of the different histories of the catalysts. As has been pointed out by Primet *et al.*, the peak maximum changes, though slightly, depending

on the particle size of the metals dispersed on the supports. The band at 2250 cm^{-1} is due to -NCO[1,3] as is noted in Table 1. The results stated hereafter are mainly restricted to its behavior.

The band did not change after pumping for 10 min at 300 °C, indicating the high stability of the -NCO, however, it did drastically decrease when a new mixture with a higher NO/CO ratio was dosed. A new equilibrium was established within 5 min. The newly obtained spectrum is quite similar to that obtained when the new mixture was dosed over a fresh catalyst (Fig. 2, sp. 4). Quite interestingly, no such species was found when the same mixture (NO=26 Torr, CO=59 Torr) was introduced into the cell at room temperature and was then heated up to 300 °C. The quantitative reproducibility for bands other than -NCO was poor in this experiment mainly because of the difficulty in controlling the rate of temperature raise. However, in general, large amounts of gaseous N_2O were found. This was confirmed by both the IR spectrum in the gas phase and gas chromatographic analysis. This experiment suggests that N_2O might react with -NCO. More reproducible experiments which show the effect of N_2O on the surface -NCO are given below.

The quick response of the band intensity to changes in the gas-phase composition (Fig. 2) suggested that a reaction of -NCO with some other species readily occurred. The unimolecular decomposition or metathesis of -NCO was negligible because no significant change was observed after the -NCO had been held at the same temperature for 10 min in the absence of any gas.

The behavior of -NCO for the introduction of various gases are shown in Fig. 3. The amount of -NCO drastically decreased when N_2O was admitted, showing that the surface -NCO reacted with N_2O. Contact with CO_2 also resulted in a decrease in the -NCO although to a lesser extent in spite of the fact that larger amounts of CO_2 were admitted for longer times. In the latter case, enhancement of the band intensity at 2020 cm^{-1}, which was assigned to the absorbed CO, was also observed. No significant decrease was found when either NO or CO alone came into contact with the -NCO. The intensity of the -NCO was rather enhanced when NO was admitted.

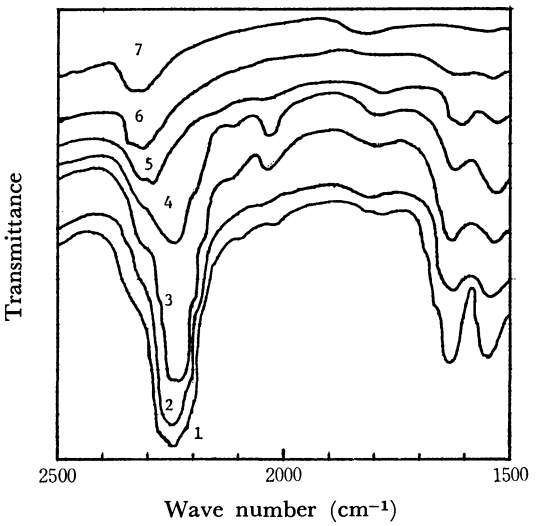

Fig. 3. Behaviors of -NCO and other species on the surface of Rh-Al_2O_3-II when various gases were admitted at 300 °C.

Pt Catalyst. The catalytic activity of Pt-Al_2O_3-I in the reaction of NO with CO declined in a rather curious fashion, as is shown in Fig. 4. The activity declined more rapidly when a reactant of lower NO/CO ratio was introduced as is indicated in Fig. 5. When the reactor containing such a deactivated catalyst in continuously flowing He was immersed in a thermal bath at 500 °C (flash desorption), CO_2 was liberated, as detected by a thermal conductivity cell located

downstream from the reactor. CO_2 was again found in some runs, as is noted later, when the O_2 bursts were subsequently introduced at the same temperature (combustion). The cumulative amount of CO_2 is also plotted in Fig. 4, as a function of the processing time. In the earlier stages of the processing time, all the CO_2 liberated was due to flash desorption. In the later stages, a considerable amount of CO_2 was liberated upon combustion, although, it was still to a smaller extent in comparison with that from flash desorption. It is evident from Fig. 4 that an inverse proportionality exists between the activity decline and the amount of CO_2 liberated. N_2 was also found for both the flash desorption and combustion processes, although with poor quantitative reproducibility.

The adsorption of CO_2 was independently studied by means of the burst technique. It was confirmed that no irreversible adsorption took place at 300 °C either on a fresh or on a deactivated catalyst. This indicates that the CO_2 liberated upon flash desorption was not due to simple "desorption" of adsorbed CO_2 but was due to some reaction (presumably decomposition or metathesis) of the surface complex producing CO_2. The activity was restored when either N_2O or H_2O was introduced over the deactivated catalyst, as is shown in Fig. 4. The formation of NH_3, when H_2O was introduced, was confirmed from the characteristic color change of Nessler's reagent. These findings can

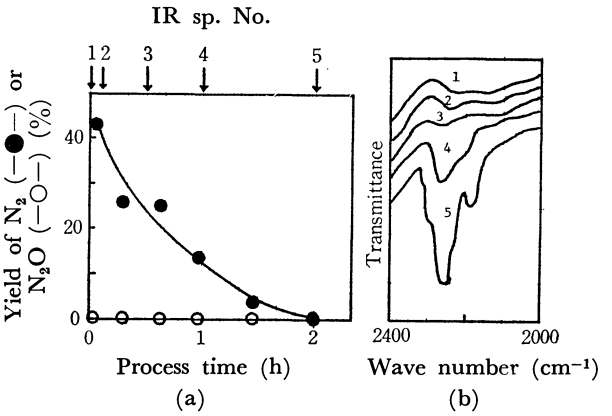

Fig. 6. The changes of catalytic activity (a) and the development of surface -NCO (b) with process time.

be summarized as follows: the species containing carbon, oxygen and nitrogen accumulates on the surface during the reaction of NO with CO and it retards the catalytic activity. If we assume that the retardation is attributed to a unique surface species, we can consider that the formation of –NCO is the primary cause for the deactivation.

In order to confirm the above expectation, the development of the surface species as a function of the processing time was studied. The catalytic activity was also simultaneously measured. This was done by attaching an IR cell to the flow system instead of the reactor. The results are given in Fig. 6. The reaction conditions were not the same as those for the former experiment (Figs. 4 and 5) primarily because of the small weight of catalyst disk. In spite of this, the activity declined with a general tendency similar to that of the former experiments. The IR spectrum above 2000 cm^{-1} was also similar to that obtained for the Rh catalyst in the vacuum experiments. It is apparent that the surface –NCO increases as the activity decreases. The IR spectrum below 2000 cm^{-1} was complex and its reproducibility was poor. As has been pointed out by Unland,[3] hydrogen, which might react with NO to form NH_3 or NH_4^+ in the course of the reaction of NO with CO, is strongly adsorbed on the surface during the pretreatment. Functional groups such as NO_3^-, CO_3^{2-} and C=N, which might be produced under these conditions, also have absorption bands in this region. Since the flow system is not adequate to completely isolate the system from the atmosphere, some effect of impurities, especially of H_2O or O_2, might also be expected. What the authors would like to emphasize here is that no band other than that of –NCO corresponds to the changes of catalytic activity with the processing time.

Discussion

It is well known that Pt and Rh have similar catalytic activities in many reactions. Unland[3] has reported that the adsorbed species in the reaction of NO with CO on several noble metals including Pt and Rh are

similar. The discussion hereafter can be applied, in many aspects, to both the Pt and Rh catalysts. This is an assumption, although it appears probable.

Unland has proposed[1] the following scheme for the formation and decomposition of –NCO.

$$Pt + NO + CO \rightarrow Pt\text{-}NCO + O_{ad} \quad (1)$$

$$CO + O_{ad} \rightarrow CO_2 \quad (2)$$

$$Pt\text{-}NCO + NO \rightarrow Pt + N_2 + CO_2 \quad (3)$$

The scheme explains why –NCO disappears or decreases when an NO-rich mixture is dosed. However, –NCO has been confirmed to be extremely stable when NO alone was introduced at high temperature. Accordingly, scheme of Unland, at least reaction (3), is not appropriate. All the present findings indicate that –NCO is not a typical reaction intermediate but an inhibitor which is produced under the reaction conditions. The quick response of the amount of –NCO to the change of gas-phase composition, which at first glance appears to be the characteristic behavior of a reaction intermediate, can be alternately explained as follows. Isocyanate is produced from NO and CO and reacts with N_2O. Then, the amount of –NCO reaches an equilibrium with the gas-phase components, NO, CO and N_2O. When a new mixture with a different NO–CO ratio is dosed, the gas-phase composition of NO, CO and N_2O also changes, resulting in changes of the amount of –NCO.

The main products in the reaction of NO with CO at lower temperatures were N_2O and CO_2.[5] A large amount of N_2O is expected to be produced upon the heating up of the reactant mixture with the catalyst from room temperature to 300 °C. This is the reason why no –NCO was observed for such a procedure.

It should be noted that –NCO may be a precursor of N_2. This is probable because N_2O is a typical oxygen atom donor. In spite of this, however, the reaction is of secondary importance because the main catalytic reaction is deactivated as the surface –NCO develops (Fig. 6). In addition, it was found in a separate experiment that a large amount of N_2 was produced when the mixture of NO and CO was passed as a burst through the bed of fresh catalyst on which no –NCO had been produced. These results indicate that path other than that through the –NCO intermediate exists for producing N_2.

To the authors' knowledge, no conclusive schemes had been proposed for the formation of –NCO. Arai *et al.* have found nitrosyl-carbonyl mixed adsorption on Rh, $Rh\langle^{NO}_{CO}$, at lower temperatures. They suggested that this is the precursor of –NCO.

The overall process for the deactivation may be written as follows:

$$NO + CO \xrightarrow{M} N_2,\ N_2O,\ CO_2 \cdots\cdots \text{main reaction} \quad (4)$$

$$NO + CO + M \rightarrow M\langle^{NO}_{CO} \rightleftharpoons M\text{-}NCO + O_{ad}$$

$$\xrightarrow{CO} M\text{-}NCO + CO_2 \quad (5)$$

$$M\text{-}NCO + N_2O \longrightarrow M + N_2 + NO + CO \quad (6)$$

$$2CO + M \longrightarrow CO_2 + M\text{-}C \quad (7)$$

$$M\text{-}NCO + H_2O \longrightarrow NH_3,\ CO_2,\ M \quad (8)$$

where M is a noble metal catalyst. The main catalytic reaction route, reaction (4), can be divided into several elementary steps. Since it is not the primary concern of this study to clarify them, the undefined formula (4) is tentatively written here. Reaction (5) appears to be reversible because the band of –NCO decreases upon the introduction of CO_2 (the results for the Rh catalyst, Fig. 3) and O_2 admission promotes the reaction of –NCO (the combustion procedure for the Pt catalyst). Reaction (6) is a tentative formula. What can be said with some certainty is that M–NCO reacts with N_2O to give N_2. Carbon deposition (disproportionation of CO) was also confirmed to take place at 300 °C and is therefore given in reaction (7), however, the rate is slower than that of –NCO formation.

In summary, –NCO is not considered to be an intermediate in the main catalytic reaction of NO with CO. However, the important roles of –NCO in the practical catalytic process of NO with CO, are emphasized here. Isocyanate is readily decomposed by water to form NH_3, which has already been pointed out by Unland[1,3] and also confirmed here. Most research work on the reaction were performed under water-free conditions. The catalytic activity under such conditions declines quickly because of –NCO formation. Under practical conditions, however, it will readily react with water which is always present in any combustion exhaust gases. This results in maintaining a high catalytic activity for a longer time. This is a very important point to be considered in selecting a practical catalyst for the reaction.

The authors are grateful to the Agency of Industrial Science and Technology for the financial support of this work.

The Study of the Raman Band Shape of Sulfuric Acid and Proton Transfer

Shun-ichi IKAWA and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 18, 1975)

The Raman bands of sulfuric acid and ammonium sulfate in aqueous solutions were observed in the S–O stretching region and were resolved into components with a Voigt profile. The concentration dependence of the half band-widths was examined. The 980 cm^{-1} band of SO_4^{2-} in acidic solutions was determined to have a width of 8.0 ± 0.3 cm^{-1} when unbroadened by any chemical process. In the concentration-half-width curve for this band, two conspicuous bends were found, at about 2 M and 8 M stoichiometric concentrations of H_2SO_4. It seems that the former bend is attributable to the disappearance of water clusters, and the latter, to the partial defect of the primary hydration shell of the oxonium ion. The interrelation between the half-widths of the 980 cm^{-1} and 1050 cm^{-1} bands suggests that the formation of the $HSO_4^- \cdot H_3O^+$ ion pair is related to the spectroscopic lifetime of HSO_4^-.

It has been pointed out that the half-width of a Raman line of an anion, A^-, in acidic solutions yields the lifetime of A^-, which is determined by the rate of proton transfer between the A^- and H_3O^+ ions.[1,2] Chen and Irish reported, in their elaborate Raman spectral studies of hydrogensulfate–sulfate systems,[3,4] that the broadening of the 980 cm^{-1} line of SO_4^{2-} in acidic solutions is directly proportional to the oxonium ion concentration, $[H_3O^+]$, in the range lower than 2M, and that the proportionality changes abruptly at about $[H_3O^+]=2$ M. They evaluated the rate constant of proton transfer to be $5.5\times10^{11}M^{-1}s^{-1}$.

The resolution in these spectroscopic measurements was 10—15 cm^{-1}; such a low resolution might considerably affect the estimates of the band widths and the band shapes. The present study has been performed under a higher resolution in order to confirm or improve the previous results, or at least to gain some information.

Experimental

Solutions were prepared from H_2SO_4 (analytical reagent) and $(NH_4)_2SO_4$ (biochemical reagent) purchased from Wako Fine Chemicals. No impurity disturbing band analysis was detected from the observed spectra. The concentrations of sulfuric acid were determined from the specific gravity by referring to the standard table.[5] Raman lines excited by the 6328 Å line of a He–Ne gas laser were recorded on a JASCO R-300S Raman spectrophotometer at room temperature, 22 ± 2 °C. No temperature effect was appreciable on the observed spectra in this temperature range. Spectral slit widths were set at less than 2 cm^{-1} except for the 0.5 and 0.8 M sulfuric acid solutions, for which they were set at about 5 cm^{-1}.

Band Analysis

The observed spectral intensity, $I(\nu)=S(\nu)/(\nu-\nu_e)^4$, ranging from 850 to 1100 cm^{-1}, was resolved into components with the Voigt profile by the least-squares method, where $S(\nu)$ is the observed relative scattering intensity at a Raman shift of ν cm^{-1} and where ν_e is the wave number of the exciting line, 15803 cm^{-1}. The Voigt function is given by a convolution of the Lorentzian and Gaussian functions as follows:

$$V(\nu) = N\int_{-\infty}^{+\infty} \frac{\exp[-(\nu'/\beta_g)^2]}{(\nu-\nu')^2+\beta_l^2}d\nu' . \quad (1)$$

Practically, however, an approximate representation for $V(\nu)$ given by Kielkopf[6] was used to calculate the numerical values of $V(\nu)$. Extraneous scattering light, probably the wing of the Rayleigh scattering, overlaps in this region. It forms a nearly straight background. The $S(\nu)$ was then determined by subtracting the background from the observed total scattering intensity.

The effect of the finite slit width on the band shape cannot necessarily be neglected for the relatively fine band of SO_4^{2-} at 980 cm^{-1}. A spectral slit function is well approximated by a Gaussian function.[7] Therefore, for the 980 cm^{-1} bands of the salt and the 0.5 and 0.8 M sulfuric acid solutions, β_g's were fixed at values given by $\beta_g=S/2\sqrt{\ln 2}$,[8] where S is the spectral slit width. The appropriateness of this processing is shown in Fig. 1 for the salt solution. Twice the best fit values of β_l were then adopted as the true half-widths. They were smaller by about 10% than the apparent half-widths; for example, the apparent half-widths of 13.3 and 15.4 cm^{-1} for 0.5 and 0.8 M sulfuric acid solutions were diminished to 11.4 and 13.8 cm^{-1} respectively. As a band broadens out and as a slit width becomes narrow, the effect of the finite slit width decreases rapidly. Thus, in the analyses of bands other than those mentioned above, the effect of the finite slit width was not taken into account and the half-width of the best-fit Voigt profile was adopted as that of each component band.

Results and Discussion

The spectra of sulfuric acid at all the concentrations studied could be well approximated by a superposition of four Voigt functions with peaks at about 900, 980, 1030, and 1050 cm^{-1}. The observed spectral intensities of sulfuric acid at several concentrations are shown in Fig. 2. Examples of the band resolution are shown in Figs. 3 and 4. Chen and Irish[3,4] reported that each component could be best approximated by a Lorentz-Gaussian product function whose wing falls much faster than that of the Voigt function. The bands observed in those studies might be deformed as a result of the larger slit widths.

The band at about 980 cm^{-1} is assigned to the symmetric stretching vibration of SO_4^{2-}, while the bands at about 1050 cm^{-1} and 900 cm^{-1} are assigned to HSO_4^-.[9-11] The fourth band, at about 1030 cm^{-1}, was first found by Irish and Chen[3,4] and was assigned to the $H_3O^+ \cdot HSO_4^-$ ion pair. They identified an additional weak band near 950 cm^{-1}. However, its counterpart was not recognized in the present analysis.[12]

With an increase in the concentration of sulfuric acid from 0.5 to 10.6 M, the SO_4^{2-} band shifts from 982 to 991 cm^{-1}. On the other hand, the frequency of the HSO_4^- band near 1050 cm^{-1} is lowered from 1052 to 1044 cm^{-1}. These facts suggest that the S–O bond strength in SO_4^{2-} and HSO_4^- is affected by their ionic atmosphere in an opposite manner.

The concentration-half-width curves for the 980 and 1050 cm^{-1} bands are shown in Figs. 5 and 6 respectively. In the simulation of the bands, the uncertainty involved in the background line and the strong correlation between the bands at 1050 and 1030 cm^{-1} more or less obscure the best values of the half-widths. How-

ever, their influences are insignificant on the results obtained for the narrower bands appearing as plain peaks in the observed spectra. As for the 1050 cm^{-1} band, its half-width values in the range beyond 7 M probably have large errors.

The concentration-half-width curve for the 980 cm^{-1} band of H_2SO_4 in solutions has two conspicuous bends, at about 2 M and 8 M, in the stoichiometric concentration. The bend at the lower concentration has already been reported by Chen and Irish,[4] but the bend at 8 M has not been reported previously. The extrapolation of the curve to a zero concentration gives $\omega_0 = 8.0 \pm 0.3$ cm^{-1}. This value is close to that for the aqueous solutions of $(NH_4)_2SO_4$, 6.3 cm^{-1}. As for the 980 cm^{-1} band of the salt solutions, its half-width shows only a slight change, from 6.3 to 7.0 cm^{-1}, as the concentration increases from 0.5 to 3.5 M, and its band center is located almost consistently at 980.5 cm^{-1}. These half-widths are about half for $(NH_4)_2SO_4$ solutions and about 30% smaller for H_2SO_4 solutions as compared with the half-widths reported in the previous papers.[3,4]

Since the symmetry of SO_4^{2-} in aqueous solutions is regular tetrahedral,[13] the width of the totally symmetric stretching band at 980 cm^{-1} must not be affected by the reorientational motion of the ion.[14,15] Therefore, the broadening of the 980 cm^{-1} band is probably caused by the chemical process that extinguishes the SO_4^{2-} ion in the following equilibrium:

$$H_3O^+ + SO_4^{2-} \rightleftharpoons HSO_4^- + H_2O,$$

and by other mechanisms such as the vibrational relaxation.[16] Thus, the ω_0 may be considered to be the linewidth without the broadening due to the chemical process, and the value of $\omega - \omega_0$ for sulfuric acid is related to the mean lifetime, τ, of SO_4^{2-} by the equation:[14]

$$\omega - \omega_0 = 1/\pi c\tau \qquad (2)$$

where c is the velocity of light. The rate constant of proton transfer is given by:[1-4]

$$K_p = \pi c(\omega - \omega_0)/[H_3O^+]. \qquad (3)$$

By making use of values of $[H_3O^+]$ corresponding to the stoichiometric concentration of H_2SO_4, M_s, in the table presented by Chen and Irish[4], the K_p values were calculated; they are plotted against M_s in Fig. 7. The value of $K_p/\pi c$ at M_s values lower than 2 is 5.6 ± 0.2 M^{-1} cm^{-1} ($K_p = 5.3 \times 10^{11}$ M^{-1} s^{-1}), almost independent of the concentration. This value agrees well with that reported by Chen and Irish,[4] 5.8 M^{-1} cm^{-1}, in spite of the large differences in individual ω and ω_0 values between the two studies.[17] The value of K_p begins to decrease abruptly at about $M_s = 2$, corresponding to a bending in the concentration-half-width curve in Fig. 5. According to Eigen and collaborators,[18,19] the rate of proton transfer is much faster in ice than in liquid water because the chains of hydrogen bonds favorable for proton transfer are always arranged in ice. On the other hand, Robertson and Dunford[20] have pointed out, on the basis of their study of the Hammet acidity function of sulfuric acid, that the water clusters disappear rather abruptly at about $M_s = 2$. The results of the present study and the two earlier studies suggest that

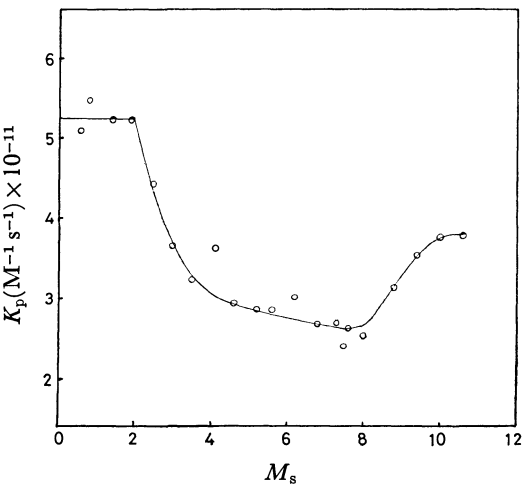

Fig. 7. Concentration dependence of the rate constant $K_p = \pi c(\omega - \omega_0)_{980}/[H_3O^+]$.

the water clusters participate actively in the proton transfer in aqueous solutions of H_2SO_4 because such clusters contain hydrogen-bond networks, even though their sizes are smaller than those in ice. Robertson and Dunford have also found that the average hydration number of the proton in sulfuric acid solutions becomes smaller than four at concentrations beyond $M_s = 8$. This means that a partial defect occurs in the primary hydration shell composed of the four water molecules which stabilize the proton in dilute solutions.[18] Such a defect may activate the proton to react rapidly with SO_4^{2-}. The rise of K_p in concentrated solutions beyond $M_s = 8$ may, then, be attributable to an increase in the defect of the hydration shells about the protons.

If the mean lifetime of HSO_4^- is limited only by the dissociation process,

$$HSO_4^- + H_2O \rightleftharpoons SO_4^{2-} + H_3O^+$$

then the following two relations hold[4]:

$$[1/\tau(HSO_4^-)] \cdot [HSO_4^-] = [1/\tau(SO_4^{2-})] \cdot [SO_4^{2-}] \qquad (4)$$

for the mean lifetime and:

$$(\omega - \omega_0)_{1050} = A(\omega - \omega_0)_{980} \qquad (5)$$

for the half-width, where

$$A = [SO_4^{2-}]/[HSO_4^-] = ([H_3O^+] - [H_2SO_4])/(2[H_2SO_4] - [H_3O^+]),$$

and where ω_0 is the broadening due to certain causes other than the above reaction. The ω_{1050} values in the $M_s < 7$ range, where they are fairly reliable, are plotted against the values of $A \cdot (\omega - \omega_0)_{980}$ in Fig. 8. If the value of $(\omega_0)_{1050}$ is independent of the concentration, the slope of the curve ought to be unity, as is shown by a broken line in Fig. 8. The observed curve has a slope of about 1.6; it can hardly be considered to have a slope of unity. Therefore, we cannot but consider that the value of $(\omega_0)_{1050}$ increases with the concentration. As has been described previously, the broadening of the SO_4^{2-} band due to any causes other than a chemical process does not vary remarkably with the concentration. Therefore, there seems to be another chemical process which serves

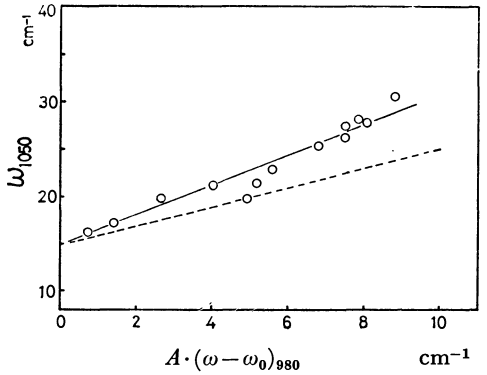

Fig. 8. Interrelation between ω_{1050} and $A\cdot(\omega-\omega_0)_{980}$. The broken line shows a slope of unity.

to shorten the spectroscopic lifetime of HSO_4^-. It seems that the process of forming the $HSO_4^-\cdot H_3O^+$ ion pair is related to the decrease in this spectroscopic lifetime and to the increase in the $(\omega_0)_{1050}$ with concentration.

The authors wish to thank Miss Michiko Kikuchi for her help in spectroscopic measurement. The calculations were performed on a FACOM 230-60 of the Computing Center of Hokkaido University.

12) Since the dissociation process
$$H_3O^+\cdot SO_4^{2-} \rightleftharpoons H_2O + HSO_4^-$$
may proceed much faster than the process
$$H_3O^+\cdot HSO_4^- \rightleftharpoons H_2O + H_2SO_4$$
in aqueous solutions of sulfuric acid below 14 M (see Ref. 11), the $H_3O^+\cdot SO_4^{2-}$ ion pair is considered to be much more unstable than the $H_3O^+\cdot HSO_4^-$ ion pair assigned the 1030 cm^{-1} band at the concentrations employed in the present study. Therefore, a band due to the $H_3O^+\cdot SO_4^{2-}$ ion pair, if it exists, is possibly so weak and broad that it cannot be recognized.

16) The half-width of the 980 cm^{-1} band of the salt solutions should not be broadened by any chemical reaction, but in fact it changes slightly with an increase in the concentration, as was mentioned in the last paragraph. There seem to be several factors influencing the half-width in aqueous solutions in association with the concentration or the structure of aqueous solutions.
17) The observed band is expressed by a convolution of the spectral slit function and the true band-shape function; see Ref. 8. The observed half-width is, in general, smaller than the sum of the half-widths of the two functions. The ω and ω_0, and accordingly $\omega-\omega_0$, are influenced by the finite spectral slit width.

CNDO/2 Calculations of Ionization Potentials of Some Fluorosubstituted Conjugated Hydrocarbons

Toshio HAYASHI and Takeshi NAKAJIMA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received September 23, 1975)

The ionization potentials of the fluorosubstituted derivatives of ethylene, *trans*-1,3-butadiene, and benzene were calculated by using the modified CNDO/2 method. In agreement with the available experimental facts, the ionization potentials due to the π-electron were predicted to change little on fluorination, while those due to the σ-electron were predicted to suffer a more or less large change on fluorination. An explanation for this fact, called the perfluoro effect, can be given by a simple perturbational treatment.

One of the methods which can be of great help in the assignment of the photoelectron spectra of conjugated molecules is the perfluoro effect first studied by Robin *et al.*;[1] the substitution of the hydrogen atoms in a planar conjugated molecule by fluorine atoms will increase the ionization potentials (*IP*'s) of the σ-MO's by 2.5—5 eV, whereas the π-MO's are stabilized by only 0—1 eV.

Most of the molecular orbital calculations thus far made of ionization potentials of fluorosubstituted planar conjugated molecules have been confined to levels due to π-electrons. There have been very few systematic and quantitative studies of ionization potentials due to σ-electrons.

In order to identify the photoelectron spectra of monofluoro- and tetrafluoroethylene, Robin *et al.*[1] and Meza and Wahlgren[2] have performed the GTO calculations of ionization potentials due to π- and σ-electrons and compared the results with those for ethylene in order to examine the effect of fluorination on ionization potentials.

In this paper, we study systematically and quantitatively the fluorosubstituent effects by using a modified CNDO/2 method proposed in a previous paper.[3] In order to examine how the perfluoro effect holds for ethylene in particular, we draw a diagram showing the correlation of ionization potentials at various degrees of fluorination. The calculated ionization potentials are compared with the available experimental values and those obtained by other SCF MO methods. Further, we show that a simple perturbational treatment can give a satisfactory explanation of the perfluoro effect that the ionization potentials due to π-electrons of conjugated hydrocarbons suffer no substitutional change on fluorination.

Method of Calculation

Tajiri *et al.*[4] and Ohmichi *et al.*[5] have calculated the electronic spectra of a number of saturated and unsaturated compounds using a modified CNDO/2 method which is a compromise between the methods of Bene-Jaffé[6] and of Sichel-Whitehead.[7] Our method differs from those above in the following point; the local core matrix element, $U_{\mu\mu}$, of the atomic orbital, μ, is estimated as an additional empirical parameter and adjusted, together with selected values of the bonding parameters, β_A^0, and the separation constant, k, so that a wide range of ionization potentials of a certain molecule may be reproduced. The details of the method were described in a previous paper,[3] in which a good agreement between the calculated ionization potentials and electronic spectra and the experimental ones for several unsaturated hydrocarbons was obtained. The parameter values for the fluorine atom are determined so that they may reproduce a wide range of observed ionization potentials for mono-, 1,1-di-, and tetrafluoroethylene. The new parameter values, together with those of earlier workers, are given in Table 1.

The geometrical structure of tetrafluoroethylene was taken from Sutton's tables.[8] For the other fluoroderivatives, the bond lengths of C–F and C–H are assumed to be 1.33 and 1.08 Å respectively, and all the bond angles are taken to be 120°. The bond lengths of all the formal C=C and C–C bonds are assumed to be 1.34 and 1.47 Å respectively. For the benzene derivatives, the C–C bond lengths of the benzene ring are assumed to be the same as those of benzene.

The calculations were carried out on the NEAC 2200, model 700, computer of Tohoku University.

Results and Discussion

The CNDO/2 Calculations for Fluoroderivatives. The high-resolution photoelectron spectra of ethylene, monofluoroethylene, 1,1-difluoroethylene, and tetrafluoroethylene have been investigated by Robin *et al.*[1] and by Lake and Thompson.[9] From the facts that the vibrational progression of the C=C bond stretching mode appears in the first bands observed at about 10.6 eV in these fluoroderivatives, and that in the

second bands no such progression is observed, it seems that the first *IP*'s are due to a π-electron, and the second *IP*'s, to a σ-electron. It is noted that the first *IP*'s of these fluoroderivatives are almost the same as that of ethylene, while the second *IP*'s suffer a large shift to a higher energy.

Tables 2, 3, and 4 show the calculated and observe ionization potentials of mono-, 1,1-di-, and tetrafluoroethylene respectively. It may be seen that the calculated ionization potentials of monofluoro- and difluoroderivatives and the calculated lower ionization potentials (<18.5 eV) of tetrafluoroethylene are in fairly good agreement with the experimental values. For the first seven levels of tetrafluoroethylene, the order of energy and the atomic populations are in good agreement with those obtained by a GTO calculation.[1]

Figure 1 shows the correlations of the MO's of ethylene with those of various fluoroderivatives of ethylene. The correlation diagram was drawn on the basis of the atomic and overlap population analyses and of the correspondence among the irreducible representations of various point groups. Comparing the atomic and overlap populations of ethylene with those of tetrafluoroethylene, we can correlate the $1b_{1u}$ π orbital and the $1b_{1g}$, $1b_{2u}$, $2b_{3u}$, and $2a_g$ σ orbitals of ethylene with the $2b_{1u}$ π orbital and the $2b_{1g}$, $2b_{2u}$, $3b_{3u}$, and $3a_g$ σ orbitals of tetrafluoroethylene respectively. This is because, in this correlation, the atomic populations on the carbon atoms in these orbitals of ethylene are least affected on fluorination. The $3a_g$ σ orbital of ethylene may be correlated with the $6a_g$ or $4a_g$ orbital of tetrafluoroethylene. The two other symmetrically possible correlations, $3a_g$ (ethylene)-$5a_g$ or $3a_g$ (tetrafluoroethylene), can be rejected, because the atomic population on carbon atoms in the $5a_g$ or $3a_g$ orbital of tetrafluoroethylene are substantially different from those in the $3a_g$ orbital of ethylene.

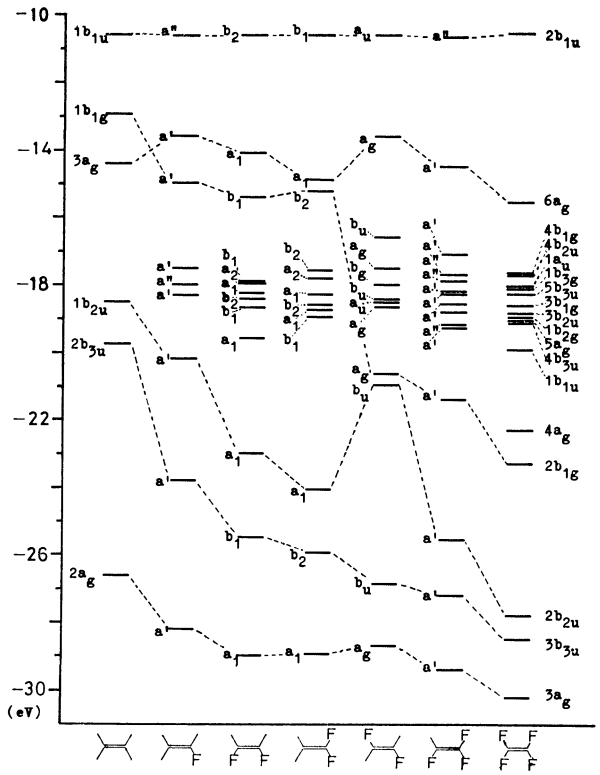

Fig. 1. MO correlation diagram of ethylene and its fluoro-derivatives.

Of the two possible correlations, we prefer the $3a_g$ (ethylene)-$6a_g$(tetrafluoroethylene) correlation. The reason for this preference is as follows; in the mono-, di- and tri-fluoroethylene examined, the orbitals related to the $3a_g$ orbital of ethylene turned out to have negative overlap populations on the C–F bonds, while in tetrafluoroethylene only the $6a_g$ orbitals has the negative overlap populations on the C–F bonds. The correlations of the σ-orbitals of ethylene with those of tetrafluoroethylene proposed by Robin *et al.*[1] are considerably different from the present correlations. For monofluoro- and trifluoroethylene, the correlations are less unambiguous because, for these molecules, the population analyses do not give sufficient information and their molecular symmetries are low.

It may be seen in Fig. 1 that the energy of the MO ($1b_{1u}$) due to π-electrons of carbon atoms of ethylene remains almost constant on fluorination, while the MO's due to σ-electrons are more or less markedly lowered in energy on fluorination, with the exception of the $3a_g$ σ orbital. This orbital is raised in energy in some fluoroderivatives and is lowered in some others, the change in energy being in all cases considerably small compared with those of other σ orbitals. It should be noted that the σ orbitals related to the $3a_g$ orbital of ethylene are characterized by the fact that, in these orbitals, the overlap population between the carbon and fluorine atoms is negative; that is, these orbitals are antibonding between the carbon and fluorine atoms. Furthermore, in these orbitals the atomic population on the fluorine atom is relatively small. On the other hand, all the other σ orbitals of the fluoroderivatives are bonding between the carbon and fluorine atoms, and in these orbitals the atomic populations on the fluorine atoms are relatively large.

The assignment of the ionization potentials of *trans*-1,3-butadiene has not been uniquely determined. There remains the problem of where the two π *IP*'s lie. The earlier study by Robin *et al.*[10] of the photoelectron spectra of the fluorinated derivatives of this molecule indicated that the first three ionization potentials are due to π, σ, and π electrons respectively, but recent investigations[19–20] have suggested that the π, π, and σ sequence is also acceptable.

In order to examine this point, we calculated the ionization potentials of 1,1,4,4-tetrafluorobutadiene (Table 5) and compared them with those of the parent hydrocarbon calculated previously using the same method. In a previous paper[3] the experimental ionization potentials of 9.07, 11.27 and 12.17 eV were assigned to the calculated 9.07 (π), 11.75 (σ), and 12, 39 (π) eV respectively. The ionization potential calculated from the lowest π orbital of 1,3-butadiene (12.39 eV) shifts, though slightly, to a lower energy in its tetrafluoro derivative (12.34 eV). This result suggests that the third band observed at 12.17 eV in 1,3-butadiene corresponds to the second band observed at 12.04 eV in its tetrafluoro derivative, both the bands being due to π-electrons, because, in our calculations, the other two lower ionization potentials of the parent hydrocarbon shift to higher energies on tetrafluorination. Moreover, such an assignment is supported by the results of a simple perturbational treatment (*vide infra*).

Experimentally the intense bands observed at about 16 eV of the tetrafluobutadiene was attributed to the fluorine lone-pair electron. In our calculation this band is assigned to the b_u σ level, and the ionization potentials due to the fluorine lone-pair electrons are predicted to be 17—19 eV.

The photoelectron spectra of fluorobenzene, *p*-difluorobenzene, and 1,2,4-trifluorobenzene have been reported by Turner *et al.*[11] and Clark and Frost.[12] The absorption spectra of the lower energy region (9—14 eV) of fluorobenzene have also been investigated by other authors.[13–15] The calculated ionization potentials of monofluoro-, *p*-difluoro-, and 1,2,4-trifluorobenzene are listed in Tables 6, 7, and 8, together with the experimental values. In these tables the observed third bands are assigned to the calculated fifth ionization potentials (at about 13.8 eV) due to a π-electron. The reason for this assignment will be given below. The first three observed bands in these molecules are predicted to be due to π-electrons, the first two being related to the e_{1g} π levels of benzene observed at 9.3 eV, and the third one, to the a_{2u} π level of benzene observed at 12.1 eV. This assignment is in agreement with those proposed by Turner *et al.*,[11] Clark and Frost,[12] and Gilbert and Sandorfy.[13] On the other hand, Narayan and Murrell[16] have suggested that, in fluoro- and *p*-difluorobenzene, the π level, which is related to the a_{2u} level of benzene, should be preceded by a σ level, as in benzene itself, and that in the higher fluorides the highest σ level would lie below the third π level.

Table 9 lists the calculated energy shifts, measured from the corresponding *IP*'s of benzene, of the first *IP*'s of the fluorobenzenes brought about on fluorination, together with the observed ones. In obtaining the observed shifts we have assumed that the observed third bands are related to the a_{2u} π-orbital of benzene, since the shifts of this band on fluorination are always very small. The energy shifts of the calculated fifth band are also quite small, so that the observed third band should be assigned to the calculated fifth one. The calculated third and fourth levels, predicted to be related to the e_{2g} σ orbitals of benzene, undergo relatively large blue shifts, and the observed fourth and fifth levels should be assigned to these levels.

Thus, the characteristic bands of the photoelectron spectra observed at 13.89 eV in fluorobenzene and at 13.55 eV in *p*-difluorobenzene should be assigned to the bands due to σ electrons. On the other hand, from a nonempirical LCAO MO SCF calculation,

Clark *et al.*[17] have assigned these bands to a fluorine 2p(σ) lone-pair orbital mixed with a benzene σ orbital. In our calculation, the ionization potentials due to fluorine lone-pair electrons are predicted to lie in the 15.5—18.5 eV range in fluorobenzene, the 16.5—19 eV range in *p*-difluorobenzene, and the 17.0—19.5 eV range in 1,2,4-trifluorobenzene.

A Perturbational Treatment of the Perfluoro Effect. In order to understand the origin of the perfluoro effect, we now use a simple perturbation theory in the framework of the Hückel MO approximation in calculating the energy change, due to fluorination, of π molecular orbitals. The energy change, brought about by a fluoro-substituent, of the i-th π molecular orbital of a conjugated molecule can be expressed as;

$$\Delta\varepsilon_i = C_{ir}^2\delta\alpha_C + \frac{C_{ir}^2}{\varepsilon_i-\varepsilon_F}\beta_{CF}^2$$

where C_{ir} is the molecular orbital coefficient of the carbon atom on which the fluoro-substituent is introduced; $\delta\alpha_C$, the change in the Coulomb integral brought about by the inductive effect of a fluorine atom on the attached carbon, and β_{CF}, the resonance integral between the carbon and fluorine 2p π orbitals.

In the Hückel MO approximation, for a fluoro-substituent $\delta\alpha_C$ and β_{CF} are taken usually to be 0.15—0.30 and 0.5—0.7 respectively in β (the standard resonance integral) units. The value of ε_F, the energy of the fluorine 2pπ atomic orbital, is taken to be about 3β (measured from the standard Coulomb integral, α), which corresponds to the ionization potential of the fluorine 2p electron, 17.34 eV. These parameter values indicate that, in case of fluorination, while the inductive effect gives rise to a lowering in the energy of the π molecular orbitals of the parent hydrocarbon, these orbitals are always raised by the conjugative (or mesomeric) effect, and suggest that, for π molecular orbitals which lie within a certain energy range of the parent hydrocarbon, the conjugative and inductive effects may cancel each other, with the result that these orbitals suffer no substantial energy change on fluorination. Actually, if we use $\delta\alpha_C=0.28$, $\beta_{CF}=0.7$, and $\varepsilon_F=2.8$, the sum, $\delta\alpha_C+\beta^2_{CF}/(\varepsilon_i-\varepsilon_F)$, is approximately equal to zero for π molecular orbitals which lie at about $\alpha+\beta$, *i.e.*, about 10 eV. The energies of the b_{1u} π orbital of ethylene and the e_{1g} π orbitals of benzene are equal to $\alpha+\beta$ in the Hückel MO approximation; thus, they can be predicted not to change on fluorination.

TABLE 10. DIFFERENCES OF π-IONIZATION POTENTIALS BETWEEN ETHYLENE AND ITS HALOGENO-DERIVATIVES (eV)[a]

	Mono-			Tetra-		
	F	Cl	Br	F	Cl	Br
Calcd[b]	0.012	−0.269	−0.722	0.049	−1.06	−2.89
Obsd	0.003	−0.34	−0.52	0.02	−1.01	

a) The standard β value is taken to be 3.1 eV.
b) Values for various parameters are taken as follows; $\delta\alpha$(Cl)=0.18, $\delta\alpha$(Br)=0.14, β(C-Cl)=0.6, β(C-Br)=0.5, $\varepsilon_{Cl}=1.8$, $\varepsilon_{Br}=1.4$.

The π molecular orbitals which are higher or lower in energy than $\alpha+\beta$ should, in principle, shift to a lower or a higher energy respectively on fluorination. For example, the b_g π orbital of butadiene, whose energy is $\alpha+0.618\beta$, is predicted to be lowered on fluorination, whereas the a_u π orbital, which lies at $\alpha+1.618\beta$, should be raised. This prediction is in qualitative agreement with the results obtained by the present calculation[3] and the experimental fact.[10]

On the basis of the simple perturbation theory, it is expected that, on halogenations other than fluorination, the π molecular orbitals which lie at about 10 eV of a conjugated hydrocarbon will be raised in energy. In the case, for example, of chlorination, the ionization potential of the chlorine 3p electron (12.95 eV) is considerably smaller than that of the fluorine 2p electron, and the chlorine atom is less electronegative than the fluorine atom, so that the conjugative effect overcomes the inductive effect, with the result that the π MO's of the parent hydrocarbon are raised in energy. In the case of bromination, the π MO's are predicted to be shifted further to a higher energy. Table 10 presents the differences, calculated by using the simple perturbation theory, of the π ionization potential between ethylene and its halogeno-derivatives. The predicted values are in fairly good agreement with the experimental ones[11] listed also in Table 10.

Finally, it may be added that, as for the σ MO's, there seems not to exist any simple way for predicting the amounts of energy change brought about by fluorination.

(Received December 8, 1975)

In order to clarify the accessibility of dextran to both water and dextran the onset of turbidity in dextran solution was studied by means of viscosimetry and near-infrared and PMR measurements. Mole fraction of monomeric and hydrogen-bonded water species in dextran solutions were calculated for various concentrations of dextran solutions from $2\nu_1+\nu_3$ and $\nu_1+\nu_2+\nu_3$ bands where ν_1, ν_2, and ν_3 are the fundamental vibrations of symmetric stretching, bending and asymmetric stretching, respectively. The extent of hydrogen bonds was estimated from PMR chemical shift of water proton. A dextran solution was characterized by a low concentration in monomeric water. An anomalous time dependence of viscosity and PMR chemical shift was observed for concentrated solutions. A mechanism has been proposed for gelation and the onset of turbidity, stress being laid on comparable accessibility of dextran to both water and dextran.

Certain molecular weight fractions of dextran are of significant use as blood plasma substitutes. This brings forward the hydration of dextran as an important physiological subject. However, little attention has been paid to the stability of dextran solutions. A 40% dextran 40 (a fraction of 40000 molecular weight) solution loses transparency with time and turns into a gel.[1] A 10% dextran 40 solution used as blood plasma substitute gives rise to the formation of insoluble substance in an injection vial during the course of sotrage.[2,3] This indicates peculiarity in the stability of a dextran solution. In this paper, the results of studies on the transition from a solution to a sol or a gel are given.

Onset of turbidity and gelation are generally accomapanied by an intermolecular cross-linking of polymer chains.[4] Accessibility of polymer chain to another one and water might play a key role to determine the state of a solution. Accessibility of dextran to water has been characterized by estimating the extent of hydrogen bonds in water by means of near-infrared and proton magnetic resonance (PMR) investigations. Intermolecular interaction of dextran has been evaluated from viscometric data.

Experimental

Dextran 40 from *Leuconostoc* strain cultured in sucrose media was obtained from Fison Ltd., Pharmaceutical Division (London). The average molecular weight was 40000.

Viscosity measurements were carried out with a Tokyo Keiki Type B Viscometer. A Shimadzu Model SV-20 automatic spectrophotometer was used for obtaining near-infrared spectra. A 1 cm-path of cell was jacketed with circulating temperature-controlled water. For PMR a JEOL Model MH-60 was used. Samples were injected in a standard tube and were kept at 25 °C for a fixed time. Measurements were conducted with and without spining a sample tube. Chemical shift was referred to external tetramethylsilane (TMS).

Results

Turbidity and Gelation of Dextran Solutions. Dilute dextran solution remains clear even after storage for a long time. Insoluble substance is formed in a 10% dextran solution during storage. When dextran concentration exceeds 20%, the solution gradually turns turbid. In the concentration range 40—50%, the occurrence of turbidity is followed by gelation. The change is accompanied by an increase in viscosity. The change of viscosity with time for a 48% dextran solution is shown in Fig. 1. Viscosity was determined at 25 °C with a Type B viscometer. Viscosity decreases at first, then increases, attaining more than ten times the initial value in 160 h after preparation.

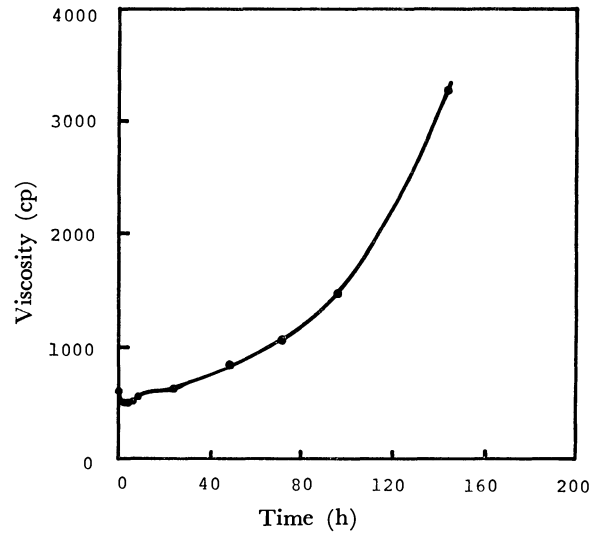

Fig. 1. Time dependence of viscosity of a dextran solution. Viscosity was determined for a 48% of dextran 40 solution at 25 °C.

Increase in viscosity is shown for solutions of various concentrations stored at 25 °C for 7 days. A marked increase is observed for the solution (concn>30%) which exhibited conspicious turbidity.

The results suggest that an increase in viscosity is induced by intermolecular cross-linking of dextran during the course of storage. Dextran might be dissolved in an unstable state, turning gradually to a stable state. Such a transition would be accelerated in a concentrated solution. The following investigation was performed in order to characterize the transition from an unstable solution to a stable solution.

Hydrogen-bonds in a Stable State of Dextran Solutions. In order to estimate the extent of hydrogen-bond formation, near-infrared and PMR investigations were carried out for a dextran solution stored for a long

time. An aqueous dextran solution contains several types of hydrogen-bond: (1) intra-dextran molecule, (2) inter-dextran molecule, (3) dextran–water molecule, and (4) inter-water molecule. Hydrogen-bonds related to water, (3) and (4), were studied with particular attention.

Hydrogen-bond formation of water molecules can be determined by various methods such as vibration spectroscopy and nuclear magnetic resonance (NMR). For an aqueous solution, near-infrared spectroscopy and NMR are effective.

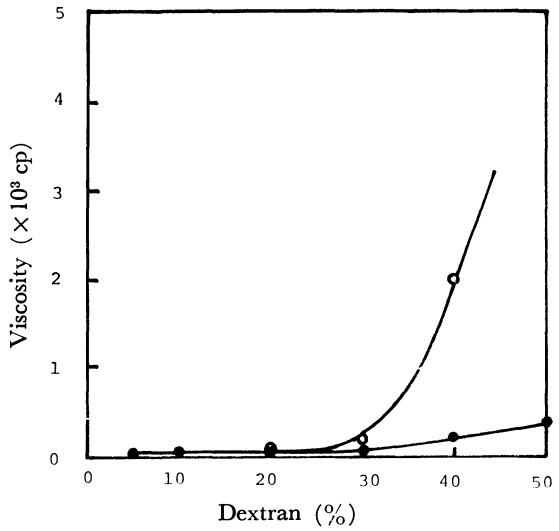

Fig. 2. Viscosity-concentration curves for dextran solutions. Viscosity was determined for a respective concentration of dextran 40 solution at 25 °C, 0 h (—●—) and 7 days (—○—) after preparation.

Water has three fundamental vibrations; ν_1 of symmetric stretching, ν_2 of bending and ν_3 of asymmetric stretching. Combination bands such as $\nu_1+\nu_2+\nu_3$ and $2\nu_1+\nu_3$ appear in near-infrared in the range 900—1300 nm. These two combination bands are sensitive to hydrogen-bond formation.

Water gives absorbance maximum at 977 nm for the $2\nu_1+\nu_3$ combination band at 25 °C. The peak is estimated to shift to 958 nm for monomeric water and 988 nm for entirely hydrogen-bonded water.[5] On the other hand, the $\nu_1+\nu_2+\nu_3$ combination band consists of three peaks, attributed to monomeric water (1160 nm), single hydrogen-bonded water (1200 nm) and double hydrogen-bonded water (1240 nm).[6] Relative intensity of these three peaks depends on the extent of respective hydrogen-bonded water species.

Near-infrared spectra at 25 °C are shown in Fig. 3 for water, 10% and 50% dextran solutions. The $2\nu_1+\nu_3$ peak shifted to a longer wavelength with an increase in the extent of hydrogen-bonded water species. A decrease in intensity for 50% dextran solution might be due to a decrease in the concentration of water.

A complicated change was observed for a $\nu_1+\nu_2+\nu_3$ combination band caused by addition of dextran to water. Absorbance at 1160 nm decreased a great deal for dextran solutions. The effect of dextran on relative intensity at 1160, 1200, and 1240 nm is more

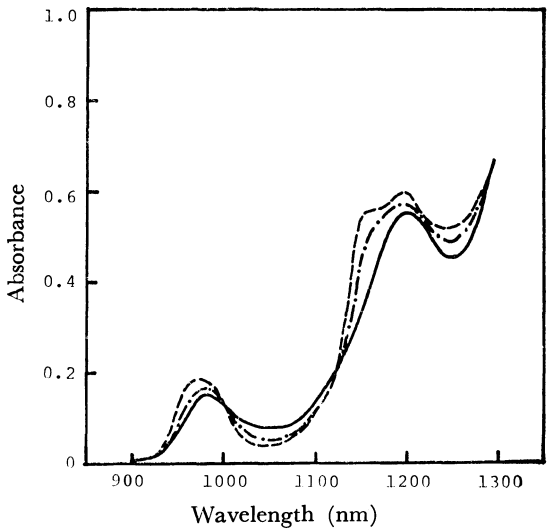

Fig. 3. Near-infrared spectra of water in dextran solutions. Spectra were obtained for a 50% (——), a 10% (—·—) of dextran solutions and water (----) at 25 °C.

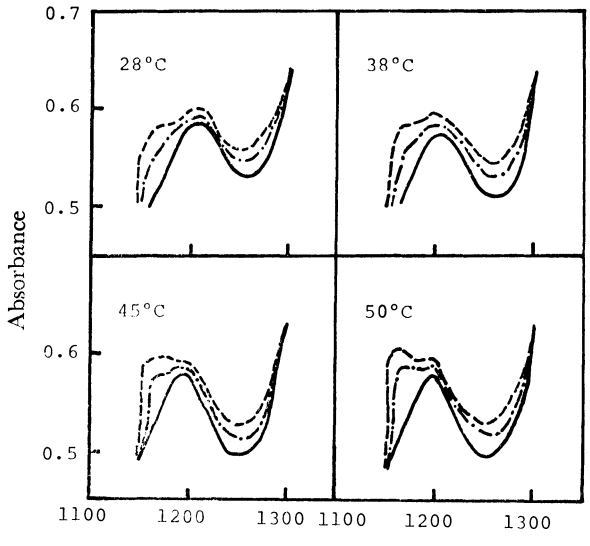

Fig. 4. Temperature dependence of near-infrared spectra of water in dextran solutions.
Spectran were determined for a 50% (——), a 10% (—·—) of dextran solutions and water (----) at respective temperature.

obvious with rise in temperature. Temperature dependence of the $\nu_1+\nu_2+\nu_3$ band is shown in Fig. 4 for water, 10% and 50% dextran solutions. For water, absorbance at 1160 nm increased markedly with an increase in temperature, which was caused by breakingdown of hydrogen-bonds. Formation of monomeric water species might be slightly depressed for the 10% dextran solution with increasing temperature. No obvious decrease in absorbance at 1160 nm was found for the 50% dextran solution even at 50 °C. This suggests that release of monomeric water species is extremely retarded, and that in concentrated solutions hydration becomes very stable against temperature.

The extent of monomeric and hydrogen-bonded

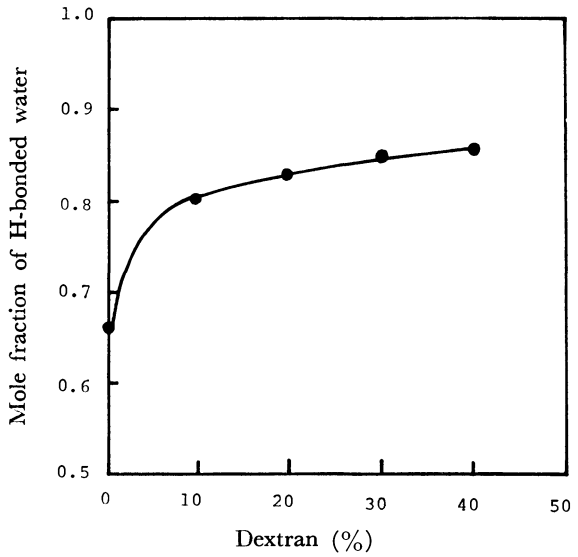

Fig. 5. Molar fraction of hydrogen bonded water species in various concentrations of dextran solutions.
Molar fraction of hydrogen bonded water species was calculated from absorbance at 1160 and 1200 mm at 28 °C.

water species can be estimated from intensity at 1160 and 1200 nm for dextran solutions.[7,8] Hydrogen-bonded water species should be classified into single and double hydrogen-bonded ones. We have calculated both types as hydrogen-bonded water species. Mole fraction of hydrogen-bonded water species is plotted for each concentration of dextran solution at 28 °C in Fig. 5. Hydrogen-bonds might be significantly formed with an increase in concentration of dextran. As an example the extent of monomeric water involved in 40% dextran solution is less than half in pure water at 28 °C.

A similar result was obtained from PMR studies on the state of water in dextran solution. Water proton gives a sharp single peak around 5 ppm *vs.* tetramethylsilane (TMS). Hydrogen-bond formation shifts the peak to lower magnetic field. A 10% dextran solution exhibited a slightly broadened but still sharp single peak at 6 ppm when a sample tube was spinned. Non-spinned sample, however, gave a very broadened signal. At 50% dextran concentration, another broad signal was detected at a higher magnetic field than that of the main signal. The broad signal at higher magnetic field was obtained either with or without spinning of the sample tube (Fig. 6). The signal was attributed to the protons of dextran. Broadening in water proton signal for a 50% dextran solution might be caused by immobilization of water.

The concentration dependence of PMR chemical shift is shown in Fig. 7 for water proton of dextran solutions of various concentrations. Measurements were carried out with a spinned sample tube 24 h after the samples had been prepared. Chemical shift moved sharply to lower magnetic field with an increase in concentration of dextran and reached a constant value at approximately 10%, which indicated a marked increase in the extent of hydrogen-bonds of water.

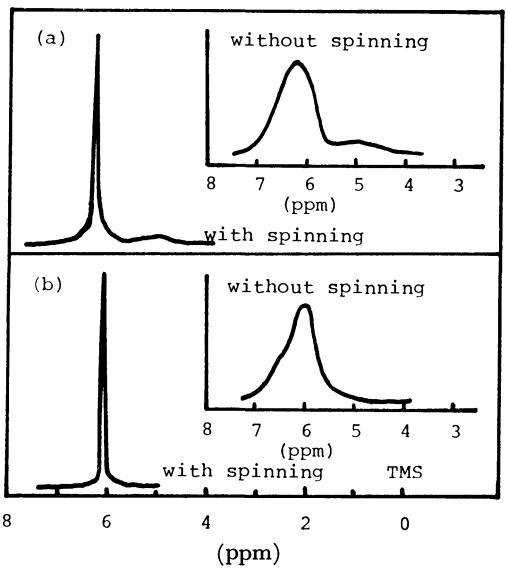

Fig. 6. Proton magnetic resonance spectra of water in dextran solutions.
Measurements were conducted for a 10% (b) and a 40% (a) of dextran solutions with and without spinning a sample tube at 25 °C using tetramethylsilane (TMS) as an external standard.

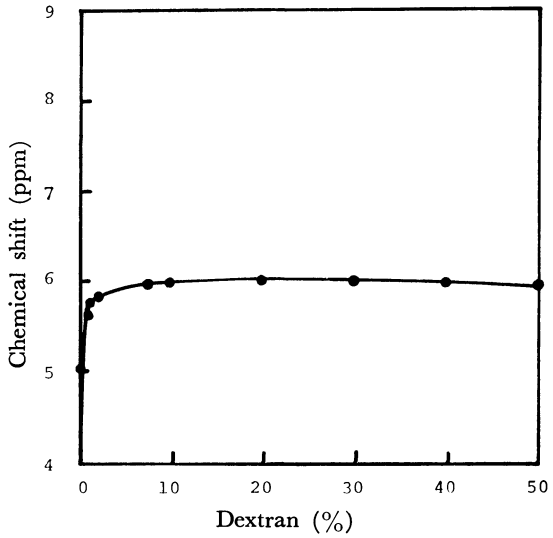

Fig. 7. Concentration dependence of PMR chamical shift for dextran solutions.
Chemical shift was determined from PMR spectrum for respective concentration of dextran solution measured with spinning a sample tube at 25 °C using TMS as an external standard.

Anomalous Time Dependence of Viscosity and PMR Chemical Shift. Investigations on the process of hydration of dextran are necessary to clarify the mechanism of the occurrence of turbidity and gelation. Time dependence of viscosity and PMR chemical shift was examined. An anomalous time dependence was observed in concentrated solutions.

Anomality in viscosity is shown in Fig. 8. Viscosity was measured at 25 °C for a 48% dextran solution. Viscosity was found to decrease sharply in the first few hours, reaching the minimum, and then to in-

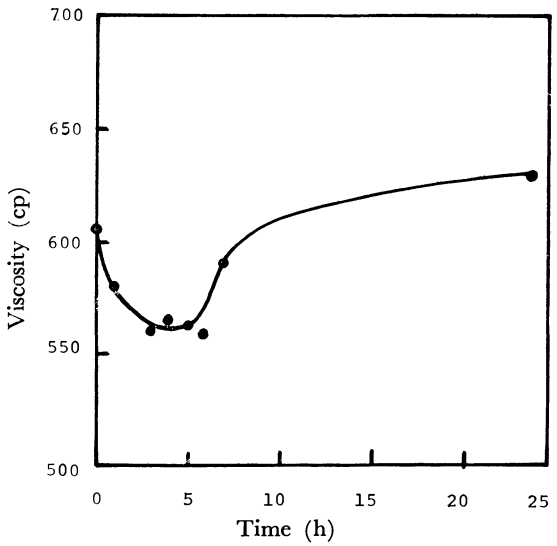

Fig. 8. Viscosity change of a dextran solution.
Measurements were made for a 48% of dextran solution at 25 °C.

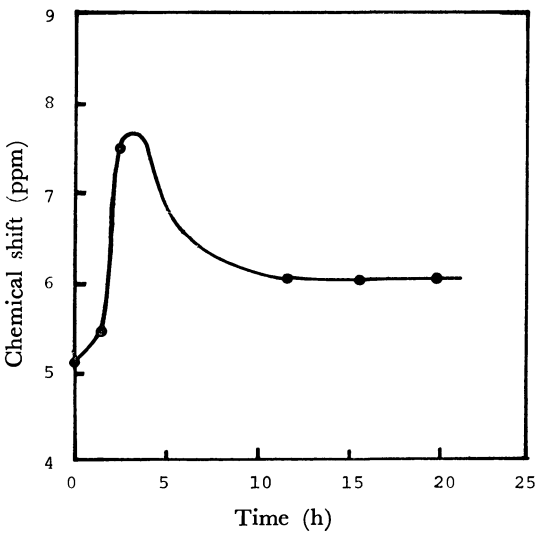

Fig. 9. Time dependence of PMR chemical shift of water in a dextran solution.
A 40% of dextran solution was injected into a standard sample tube with an external reference of TMS. The sample tube was spinned for measurement at 25 °C.

crease over the initial value. No such anomaly was observed for a dilute solution which showed constant viscosity irrespective of time. A 10% dextran solution showed a gradual increase in viscosity with no minimum. A minimum in viscosity–time curve was observed when the dextran concentration exceeds 30%.

Time dependence of PMR chemical shift is shown for a 40% dextran solution in Fig. 9. A marked shift to lower magnetic field in chemical shift took place in a few hours. This was followed by a sharp change to higher magnetic field up to a steady value. The steady value of chemical shift lies at fairly lower magnetic field as compared with that of the initial one. The maximum in a time–chemical shift curve appears in a solution with dextran concentration exceeding 30%. This is in line with viscosity.

Discussion

Maximum viscosity is associated with a PMR chemical shift *vs.* time curve for water proton of a dextran solution. Anomalous time dependences of viscosity and PMR chemical shift suggest that at least two competitive reactions such as hydration and dehydration take place simultaneously.

The viscosity of a dextran solution seems to be closely related to the states of polymer chains. The increase in viscosity might result from the intermolecular cross-linking of dextran, which causes turbidity and gelation. The decrease in viscosity in the first stage might be caused by an opposite reaction such as decoupling of intermolecular interaction followed by intermolecular linking. It seems that several processes such as (1) intermolecular cross-linking, (2) decoupling, (3) hydration, and (4) dehydration of dextran take place simultaneously and competitively. The combined effect of these processes might be determined by competitive accessibility of dextran to water and dextran. Dextran has comparable accessibility to both water and dextran. That is why a dextran solution exhibits a complicated behavior.

Dextrans are highly branched polymers of D-glucose. The linkages between D-glucose units at the branching points are α-1,6, α-1,4, and α-1,3. Taylor *et al.*[9,10] have extensively investigated the effects of variation in branching structure on the water sorption. Dextrans with a high α-1,4 content exhibited the greatest sorption, those with appreciable α-1,3 content exhibited intermediate sorption, while those with predominantly α-1,6 linkages were least hygroscopic. The results of powder X-ray diffraction measurements indicate that the structural correlation is related to the onset of crystalization or crystallinity. Linear polymers are crystallized with the greatest ease, while cross branching tends to prevent the alignment of proximal linear chains.

Dextran 40, in which the α-1,6 linkage predominates, can be characterized by the least hygroscopicity and the greatest ease in crystallization of dextran. Dextran is soluble in water because of an extreme accessibility to water. If dextran has a chance to associate with other polymer chains, intermolecular cross-linking through hydrogen-bonding would be induced due to high accessibility to dextran, giving rise to turbidity and gelation. Although a dextran solution displays turbidity and makes a gel, a neat and clear solution can be obtained by a small driving force to break intermolecular coupling, *e.g.*, heating, since the strength of intermolecular coupling would be no more than that of hydration. A turbid dextran solution can be transformed into a clear one by heating.

The Structure of the Cyclodextrin Complex. III. The Crystal Structure of the α-Cyclodextrin–Sodium Benzenesulfonate Complex

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari-4, Kanagawa-ku, Yokohama 221

(Received December 25, 1975)

The crystal structure of the α-cyclodextrin–sodium benzenesulfonate complex, which has a channel-type structure, was determined by X-ray analysis. The crystals were orthorhombic with the space group of $P2_12_12$, cell dimensions of $a=21.832(3)$, $b=16.529(2)$, and $c=8.356(1)$ Å, and $Z=2$. The structure was determined on the basis of 2894 diffractometer data and refined by the block-diagonal least-squares methods to the final R-value of 0.069. The benzenesulfonate anion is arranged in the channel which is formed by the stack of α-cyclodextrin rings along the c axis. The benzene ring is located in the cavity, while the sulfonato group is hydrogen-bonded to the primary hydroxyl groups of the adjacent α-cyclodextrin molecule. The space outside the channel is filled with water molecules and sodium ions, and the hydrogen-bonding network is formed. The energy of the complex formation was calculated for two possible structures of the 1 : 1 complex in an aqueous solution.

α-Cyclodextrin(α-CDx) forms a number of crystalline adducts with a variety of "guest" molecules.[1] Several types of crystal structures have been investigated by the X-ray method.[2-9] The cage-type structure[2-6] is formed when the "guest" molecule is sufficiently small to be enclosed in the cavity, both sides of which are blocked by adjacent α-CDx molecules. In the case of the *p*-iodoaniline complex,[7] the "guest" molecule is too large to be enclosed in the interior of the cavity; as a result, the amino group protrudes from an open end of the cavity.

In the channel-type structure,[8,9] the α-CDx molecules are stacked along two-fold axes to form endless channels and the "guest" molecules in the channels are hydrogen-bonded to the primary hydroxyl groups of α-CDx. A long molecule as well as a small molecule can be included in the channel. In the potassium acetate complex,[8] the acetate anion is so small that the two water molecules are located in the empty space of the cavity. In the Methyl Orange complex,[9] the "guest" molecule is twice as long as the cavity. Therefore, the "guest" molecule extends through two α-CDx rings. Sodium benzenesulfonate(BS) also forms an α-CDx complex with a channel-type structure. The benzenesulfonate anion is a part of the Methyl Orange anion, and it consists of hydrophobic and hydrophilic groups. It is of interest to know which group is included in the cavity, and whether or not the hydrophilic group forms hydrogen bonds with primary hydroxyl groups. In this paper we will present the crystal and molecular structure of the α-cyclodextrin–sodium benzenesulfonate (1 : 1) complex. The energy of the complex formation in an aqueous solution was also calculated in order to investigate the binding force of the complex.

density was measured by the flotation method in a mixture of chloroform and dioxane. The crystal data are given in Table 1. The intensity data were collected on a Rigaku automated four-circle diffractometer using graphite monochromatized Cu$K\alpha$ radiation and the 2θ-ω scan technique. The crystal was enclosed in a quartz capillary with a small amount of water, since the crystal decomposes in air. 3064 independent reflections were obtained up to 150° in 2θ by using a specimen with dimensions of $0.4\times0.4\times0.4$ mm. 170 reflections with $|F_o|<3\sigma(F)$ were considered to be unobserved; $\sigma(F)$ is the standard deviation estimated according to the counting statistics. No corrections were made for absorption and extinction.

Determination and Refinement of the Structure

The structure was elucidated by assuming the same type of framework as that in the channel-type crystal. The positions and orientations of glucose residues were refined by the rigid-body least-squares method. A Fourier map calculated by using phases based on the glucose residues revealed the locations of BS and water molecules. The occupancy of 0.5 was assigned to the sodium ion, since there are only two BS molecules in the unit cell in spite of there being four equivalent positions. The BS anion was found on the two-fold axis with the statistical disorder of the sulfonato group. A water molecule (O(W5)) was found near the position of the sodium ion. The Na---O(W5) distance, however, is unreasonably short (Fig. 5). Therefore, O(W5) seems to occupy the position when the sodium ion is absent, having the average population of 0.5. O(W6) and O(W6′) are statistically disordered, and the distances of O(W5)---O(W6′) and O(W6)---O(W6′) are also absurdly short. These short distances can reasonably be explained by assigning 0.5 to the respective occupancies of O(W6) and O(W6′). The refinement of atomic parameters was carried out by the block-diagonal least-squares method. The positions of the hydrogen atoms attached to the carbon atoms were calculated and included in the structure factor calculation; the isotropic thermal factors used were equal to those of the carbon atoms to which the hydrogen atoms are bonded. The final R-value was 0.069. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, with $w=1.0$ for all reflections used. The atomic scattering factors were taken from "International Tables for X-ray Crystallography."[10] The atomic parameters are given in Table 2. The observed and calculated structure factors are listed in Table 3*.

* Table 3 is kept as Document at the office of The Chemical Society of Japan. (Document No. 7626).

Description and Discussion of the Structure

The structure and numbering scheme of the complex are shown in Fig. 1. Bond distances, angles, and conformation angles in α-CDx(Table 4) are in good agreement with those of the Methyl Orange complex[9] and the potassium acetate complex.[8] The bond distances and angles of the BS anion are given in Table 5; they are in agreement with those observed in Methyl Orange.[11] The benzene ring has a good planarity (Table 6).

The geometrical data of the complex are shown in Table 7. The macro-cyclic conformation of the α-CDx ring is nearly the same as that in the Methyl Orange complex. The C(6)–O(6) bonds show a *gauche-trans* conformation, as is commonly observed in channel-type crystal. In the α-CDx cavity, the benzene ring is located at the same position as in the *p*-iodoaniline complex. The O(4, G3)---C(3, BS)

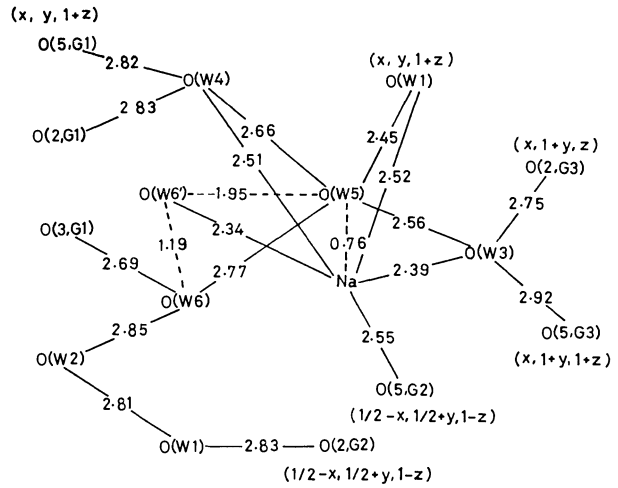

Fig. 5. The hydrogen-bonding scheme in the crystal. Dashed lines indicate the distances between the disordered atoms.

distance is 3.356 Å, while the corresponding distances are 3.25 and 3.35 Å in the *p*-iodoaniline complex.[7] The sulfonato group protrudes from the O(2), O(3) side of the cavity and is hydrogen-bonded to the primary hydroxyl groups of the adjacent α-CDx molecule; the distances of O(6, G1)---O(3, BS), O(6, G3)---O(1, BS), O(6, G1)*---O(2, BS), and O(6, G3)*---O(3, BS) are in the range of 2.708—2.857 Å, while the distances between the sulfonato group and the G2 residue are greater than 3.0 Å. In the water complex[4] and the 1-propanol complex,[6] which have cage-type structures, the hydrogen bonds are observed between the primary hydroxyl groups and the included "guest" molecule, and the hydroxyl groups involved in the hydrogen bonds have a *gauche-trans* conformation.

α-CDx molecules are stacked along the c axis with six O(3)---O(6) hydrogen bonds forming endless channels (Fig. 2). The BS anions are arranged in the channel, while the sodium cations are located outside the channel at nearly the same positions as those found in the other channel-type crystals (Figs. 3 and 4). The sodium ion is surrounded by O(W1), O(W3), O(W4), O(W6′), and O(5, G2), with Na---O distances between 2.34 and 2.55 Å. In the potassium acetate complex, a distorted octahedral coordination has been observed. In the Methyl Orange complex, five oxygen atoms are found around the sodium ion, but four of the Na---O distances are 2.86—2.90 Å, showing weak coordination. The hydrogen-bonding scheme is shown in Fig. 5. Intermolecular distances less than 3.0 Å are given in Table 8. The space outside the channel is filled with water molecules and sodium ions. Water molecules and hydroxyl groups

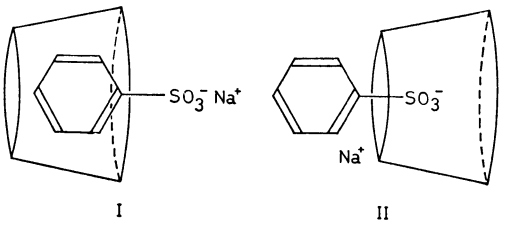

Fig. 6. Two possible structures of the 1 : 1 complex in an aqueous solution.

form the hydrogen-bonding network; O(W4) is hydrogen-bonded to O(2) and O(5) atoms of the Gl residue; O(W3) forms hydrogen bonds with O(2, G3) and O(5, G3); O(W6) and O(Wl) are also hydrogen-bonded to O(3, Gl) and O(2, G2) respectively. These four water molecules are linked to O(W5) by hydrogen bonds.

Formation Energy of the Complex in Aqueous Solution

In the crystalline state, the BS anion extends through two α-CDx rings. In an aqueous solution, the two structures shown in Fig. 6 are possible for the 1 : 1 complex. In the complex I, the hydrophobic benzene ring is located in the α-CDx cavity, while the hydrophilic sulfonato group is hydrogen-bonded to primary hydroxyl groups in the complex II. It has been emphasized[12,13] that the effect of solvation is important as well as the interaction between α-CDx and the "guest" molecule. The formation energy of the complex was calculated for these two complexes by using structural data in order to examine which structure is stable in an aqueous solution. That is, the heat of formation was estimated for the equilibrium in an aqueous solution;

$$\alpha\text{-CDx} + \text{BS} \rightleftharpoons \text{complex}. \tag{1}$$

The complex formation energy is expressed as follows:

$$\Delta E = E(\text{complex}) - E(\alpha\text{-CDx}) - E(\text{BS}) \tag{2}$$

$$E(\alpha\text{-CDx}) = E^{\text{sol}}(\alpha\text{-CDx}) \tag{2a}$$

$$E(\text{BS}) = E^{\text{sol}}(\text{BS}) \tag{2b}$$

$$E(\text{complex}) = E^{\text{sol}}(\text{complex}) + E^{\text{int}}(\text{complex}) \tag{2c}$$

E^{sol} is the solvation energy of the solute, and E^{int} is the interaction energy between α-CDx and the "guest" molecule. The solvation energy was calculated according to Halicioğlu and Sinanoğlu:[14,15]

$$E^{\text{sol}} = E^{\text{sol}}_{\text{cav}} + E^{\text{sol}}_{\text{e.s.}} + E^{\text{sol}}_{\text{vdw}} \tag{3}$$

where $E^{\text{sol}}_{\text{cav}}$, $E^{\text{sol}}_{\text{e.s.}}$, and $E^{\text{sol}}_{\text{vdw}}$ are the cavity term, the electrostatic term, and the van der Waals term respectively. The procedure of evaluating each term will be explained below.

Cavity Term. $E^{\text{sol}}_{\text{cav}}$ is the energy needed to create a cavity which will accomodate a solute molecule, A:

$$E^{\text{sol}}_{\text{cav}} = 4.836\kappa^{\text{e}}(\phi_{1\text{A}})V_{\text{A}}^{2/3}\gamma\left(1-\frac{\partial \ln\gamma}{\partial \ln T}-\frac{2}{3}\frac{1}{v}\frac{\partial v}{\partial T}T\right) \tag{4}$$

$$\kappa^{\text{c}}(\phi_{1\text{A}}) = 1 + \phi_{1\text{A}}^{2/3}(\kappa^{\text{e}}(1)-1) \tag{4a}$$

$$\phi_{1\text{A}} = V_1/V_{\text{A}} \tag{4b}$$

where V_1 and V_{A} are the molecular volumes of water and the solute A respectively, γ and $\kappa^{\text{e}}(1)$ are the surface tension and the cavity factor for water respectively. The values of $\kappa^{\text{e}}(1)$, γ, $\partial\ln\gamma/\partial\ln T$, and $1/v\ \partial v/\partial T$ were taken from Halicioğlu and Sinanoğlu.[14] The V_{A} of α-CDx was estimated from the X-ray data, and the volumes of a water molecule and the BS anion were estimated by means of the van der Waals volumes of atoms and molecules.[16] The parameters used are given in Table 9.

Table 9. Parameters for the calculation of solvation energy

Refractive index	n	1.333
Dielectric constant	ε	77.46
Surface tension	γ	72.00 dyn cm^{-3}
	$\frac{\partial \ln \gamma}{\partial \ln T}$	−0.157

Cavity coefficient	κ^{c} (1)	1.277
Molecular volume		
Water		20.6 Å^3
BS anion		129.7
α-CDx		1330.0
Complex I		1381.0
Complex II		1376.0

Electrostatic Term. The electrostatic interaction energy between solute and solvent molecules was calculated by means of the following equation:

$$E^{\text{sol}}_{\text{e.s.}} = -\frac{D_{\text{d}}}{2}\sum_i \frac{\mu^2_{\text{A}i}}{V_{\text{A}i}(1-\bar{\alpha}_{\text{A}i}/r^3_{\text{A}i})} \tag{5}$$

$$D_{\text{d}} = \frac{2(\varepsilon-1)}{2\varepsilon+1} \tag{5a}$$

$$r^3_{\text{A}i} = \frac{3V_{\text{A}i}}{4\pi} \tag{5b}$$

where $\mu_{\text{A}i}$, $\bar{\alpha}_{\text{A}i}$, and $V_{\text{A}i}$ are the dipole moment, the average polarizability, and the volume of the i-th group in the solute molecule A, respectively, and where ε is the dielectric constant of the solvent. $\bar{\alpha}_{\text{A}i}$ was estimated as a sum of the atomic polarizabilities of the constituent atoms, while $V_{\text{A}i}$ was calculated by means of the van der Waals volumes of atoms and groups. Only the hydroxyl groups of α-CDx and the sulfonato group of BS were included in the calculation because these groups are in contact with solvent molecules. The effect of the sodium cation was neglected. The parameters are given in Table 10.

Table 10. Dipole moments, average polarizabilities, and volumes of C-SO_3^- and C-OH groups

	μ(Debye)	$\bar{\alpha}$	V
C-SO_3^-	5.07[a]	6.23 Å^3	51.3 Å^3
C-OH	1.69[b]	1.94	20.5

a) The value of the BS anion calculated on the basis of atomic charges. b) The value of methanol.

van der Waals Term. The van der Waals energy of solute-solvent interaction was expressed as follows:

$$E_{vdw}^{sol} = B_{1A}U_{1A} \tag{6}$$

$$B_{1A} = 1 - \frac{3}{4}D_r \tag{6a}$$

$$D_r = \frac{n^2-1}{n^2+1} \tag{6b}$$

where n is the refractive index of the solvent and U_{1A} the potential function used to express van der Waals interaction energy. Halicioğlu and Sinanoğlu[14] used the semi-empirical Kihara potential, but we have used the Lennard-Jones potential because it has an analytical form which is convenient for numerical calculation. We assumed that the molecules of the solute or solvent are rigid spheres. The energy of the interaction between a water molecule and the i-th atom in the solute molecule A (Fig. 7) is expressed as follows:

$$U_{1Ai} = \frac{\pi}{V_A}\int_{-l_i^0}^{l_i^0}\left[\frac{a_{1Ai}}{r_{1Ai}^{12}} - \frac{c_{1Ai}}{r_{1Ai}^{6}}\right](l_i^{02}-l^2)dl \tag{6c}$$

$$l_i^0 = R_A - l_{Ai} \tag{6d}$$

$$r_{1Ai} \approx R - l \tag{6e}$$

where a_{1Ai} and c_{1Ai} are coefficients of the potential function. By integrating from R_0 to ∞, the total van der Waals energy is found to be:

$$U_{1A} = \frac{4\pi}{V_1}\int_{R_0}^{\infty}(\sum_i U_{1Ai})R^2dR \tag{6f}$$

where $R_0 = R_A + R_1$. This integral equation was solved numerically.

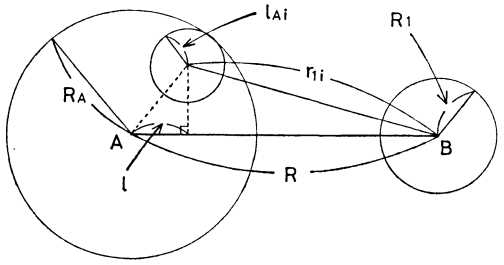

Fig. 7. A schematic drawing of interaction between water(B) and i-th atom in the solute(A).

α-CDx-"Guest" Interaction Term. In the calculation of the α-CDx-"guest" interaction energy, the non-bonded interaction betwwn non-hydrogen atoms was taken into account:

$$E^{int} = E_{e.s.}^{int} + E_{vdw}^{int} \tag{7}$$

$$E_{e.s.}^{int} = \sum_{i,j}\frac{q_iq_j}{\varepsilon r_{ij}} \tag{7a}$$

$$E_{vdw}^{int} = (1-K)\sum_{i,j}\left[\frac{a_{ij}}{r_{ij}^{12}} - \frac{c_{ij}}{r_{ij}^{6}}\right] \tag{7b}$$

$$K = \frac{3}{2}\left(\frac{n^2-1}{n^2+1}\right) \tag{7c}$$

where q_i and q_j are the atomic charges of the i-th and j-th atoms respectively. The atomic charges of the glucose residues and the BS anion were calculated by the CNDO/2 MO method[17] (Table 11). The charges of the C–H and O–H groups were used as those of the carbon and oxygen atoms respectively.

Table 11. Atomic charges

Coefficients of Potential Function. The coefficients of a_{ij} and c_{ij} were calculated by means of the following equation:[18]

$$c_{ii} = \frac{3e\hbar\alpha_i\alpha_j}{2m[(\alpha_i/N_i)^{1/2}+(\alpha_j/N_j)^{1/2}]} \tag{8}$$

$$a_{ij} = c_{ij}(r_{0i}+r_{0j})^6 \tag{8a}$$

where α_i and α_j are the atomic polarizabilities of the i-th and j-th atoms respectively, N_i and N_j are the numbers of electrons in the outer subshell, e and m are the charge and mass of the electron respectively, $\hbar$ is the Plank constant, and r_{0i} and r_{0j} are the van der Waals radii.[16] The values of α, N, and r_0 are given in Table 12, while a_{ij} and c_{ij} are listed in Table 13.

a) Oxygen atom in a hydroxyl group. b) Oxygen atom in ether. c) Oxygen atom in a carboxyl group.

Atomic Polarizability. The atomic polarizabilities of carbon and oxygen atoms were taken from Ketelaar.[19] For the sulfur atom, it was calculated by the following equation:[20]

$$\alpha = \frac{4}{9a_0}\sum_i (\bar{r}^2)^2 \tag{9}$$

$$(\bar{r}^2) = \left[\frac{n_i^*}{2(Z-S_i)}\right]^2 (2n_i^*+1)(2n_i^*+2)a_0^2 \tag{9a}$$

where n_i^* and $Z-S_i$ are the effective quantum number and the effective nuclear charge respectively, and where a_0 is the Bohr radius. In the case of the chlorine atom, the calculated atomic polarizability was twice the observed value; $\alpha_{calcd}=4.57$ and $\alpha_{obsd}=2.28$ Å^3. Therefore, the factor of 0.5 was multiplied to the calculated value for the sulfur atom.

Results and Discussion

The results are given in Table 14. The calculated formation energy of the complex I is larger by 8.74 kcal M^{-1} than that of the complex II, indicating that the inclusion of the hydrophobic group gives a more stable complex. The major part of the energy difference is $\Delta E^{sol}_{e.s.}$ of 7.06 kcal M^{-1}; this may be ascribed to the fact that the $E^{sol}_{e.s.}$ term is greatly reduced when the sulfonato group is included in the α-CDx cavity. The interaction energy between α-CDx and BS is larger in the complex I than in the complex II.

The α-CDx-BS interaction may involve the electrostatic, van der Waals, and hydrogen-bonding contacts. The van der Waals force between α-CDx and BS is an important component of the binding force. However, the contribution of the elcetrostatic interaction to the stability of the complex is small, since the interior of the α-CDx cavity is a relatively non-polar environment compared with the water environment. The effects of hydrogen bonds may also be small. In the complex II, the sulfonato group forms hydrogen bonds with primary hydroxyl groups of α-CDx, but it is also hydrogen-bonded to water molecules in the uncomplexed state.

TABLE 14. CALCULATED ENERGY FOR THE COMPLEX FORMATION (×mol/kcal)

(1) Solvation energy

	E^{sol}_{cav}	$E^{sol}_{e.s.}$	E^{sol}_{vdw}	E^{sol}
BS	22.22	−7.06	−0.65	14.52
α-CDx	98.71	−28.68	−5.36	64.67
Complex I	101.77	−35.63	−5.40	60.03
Complex II	100.93	−28.68	−5.12	67.13

(2) Solvation effects on the complex formation

	ΔE^{sol}_{cav}	$\Delta E^{sol}_{e.v.}$	ΔE^{sol}_{vdw}	ΔE^{sol}
Complex I	−19.76	0.0	0.61	−19.15
Complex II	−20.00	7.06	0.89	−12.05

(3) Interaction energy between α-CDx and BS

	E^{int}_{vdw}	$E^{int}_{e.s.}$	E^{int}
Complex I	−4.59	−0.03	−4.62
Complex II	−2.92	−0.06	−2.98

(4) Total association energy

	E(α-CDx)	E(BS)	E(complex)	ΔE
Complex I	64.67	14.52	55.41	−23.78
Complex II	64.67	14.52	64.15	−15.04

The stability of the complex in solution is determined by the α-CDx-"guest" interaction energy and the solvation energy. It is noteworthy that the effect of solvation on the complex formation is remarkably large; the ΔE^{sol} values are −19.15 kcal M^{-1} in the complex I and −12.05 kcal M^{-1} in the complex II, while the α-CDx-BS interaction energies are −4.62 and −2.98 kcal M^{-1} in the complex I and the complex II respectively. This indicates that the stability of the complex is largely determined by the difference in the solvation energies between the complexed state and the uncomplexed state. The change of the solvation energy is mainly ascribed to the cavity term. The cavity energy is proportional to the surface area of the solute molecule, and the solvation energy decreases when the "guest" molecule is included in the cavity of α-CDx.

The author wishes to thank Dr. Hisashi Uedaira for supporting this study and for his useful discussions. The author also wishes to acknowledge the helpful discussions and critical comments on the manuscript of Professor Jiro Tanaka of Nagoya University. The computation was carried out on a HITAC 8450 computer in our laboratory.

Study of Metal–Polycarboxylate Complexes Employing Ion-Selective Electrodes. Cu(II) and Cd(II) Complexes with Poly(acrylic acid) and Poly(itaconic acid)

Fumitaka YAMASHITA, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 25, 1975)

The complex formation of bivalent metal ions, Cu(II) and Cd(II), with poly(acrylic acid) and poly(itaconic acid) in aqueous solutions was studied by pH titration at 25 °C and at an ionic strength of 0.1, and at the same time the concentration of free metal ions was measured using ion-selective electrodes. In order to calculate the equilibrium constants of metal–polycarboxylate complex formation, a modified Gregor method is proposed and a more reasonable method for the determination of the formation constants of the complexes is also presented. The equilibrium constant of the metal–polycarboxylate complex formation involving two carboxylate groups was calculated from this method. The value for the Cu(II)–poly(itaconic acid) complex formation was $10^{-2.9}$, and was constant in the lower neutralization region. But constant values for the Cd(II) complexes were not obtained over the entire neutralization range.

In order to calculate the stability constants or the equilibrium constants of the complex formation of bivalent metal ions with polyelectrolytes by pH titration, the modified Bjerrum[1] method has been established by Gregor and co-workers,[2] and the reference plot method has been proposed by Mandel and Leyte.[3] In the scheme of Gregor and that of Mandel and Leyte, several hypotheses had to be taken into account, since the concentrations of ionic species for equilibrium in the complex formation cannot be determined at each stage of neutralization using only the equation of stoichiometric material balance.

Recently, ion-selective electrodes which are responsive to specific ions have been available for the investigation of ion activity. Rechnitz[4,5] has shown that the complex formation constants of Cu(II) with low molecular organic acids can be easily and precisely estimated using these electrodes.

In the present study, the equilibrium constants of metal–polycarboxylate complex formations were investigated using the pH titration method using ion-selective electrodes, and the data obtained were analyzed by the newly-proposed method.

Experimental

Material. The poly(itaconic acid)(PIA) sample used was material prepared by Dr. Muto[6] of this laboratory, and its molecular weight was estimated to be about 10^5. The sodium polyacrylate(PAA-Na) obtained commercially was manufactured by the Kishida Chem. Co. The acid form PAA solution was obtained from an aqueous solution of PAA-Na with the addition of hydrochloric acid and was purified by dialysis using cellophane tubing. Its molecular weight was estimated to be 7.6×10^5 by viscometric measurement. These solutions of polyacids were standardized by pH titration and stored in polyethylene containers at 5 °C.

All the chemicals used were of guaranteed reagent grade. The concentrations of the stock solutions of the bivalent metal ion salts, $Cu(NO_3)_2$ and $Cd(NO_3)_2$, were determined by the spectrophotometric chelatometric titration method. A carbonate-free NaOH solution was used as the titrant. The aqueous solutions were prepared using deionized water.

Potentiometric Titration. The pH measurements were carried out using a Yokogawa Model KPH-51A pH meter equipped with Toadenpa Model HG-4005 glass and HC-2005 calomel electrodes, and also with a Denkikagakukeiki Model HG-2 Digital pH meter equipped with Denkikagakukeiki Model MC-511 glass and Horiba Model 2050-05T calomel electrodes connected by a saturated KNO_3-agar salt bridge.

The concentrations of bivalent metal ions were measured with the pH meter equipped either with a Beckman Model 39612 cupric electrode or with a Toadenpa Model CD-125 cadmium electrode.

The titration, namely the measurements of the pH and the concentrations of the bivalent metal ions were carried out in a titration vessel with a water jacket maintained at 25.0 ± 0.05 °C in a nitrogen atmosphere.

Results and Discussion

Potentiometry Using Cu(II) and Cd(II) Ion-Selective Electrodes. The response of the cupric or cadmium electrode, the emf of the cell, was plotted linearly against the logarithm of the concentration for each ion and the corresponding slopes were 30.5 mV and 28.0 mV, respectively, in the concentration range from 10^{-6} to 10^{-2} mol/l at an ionic strength of 0.1 (KNO_3). These values of the slopes are very near to those expected from the Nernstian equation, and, according to their high reproducibility, the measurement of the concentrations of the ions was carried out with calibration at two points. The effect of pH on the response of the metal ions has to be taken into account because metal hydroxides are formed at values of pH more than 6. In the present work, however, the concentrations of the metal ions are much lower than those of the polyacids, therefore, all metal ions exist essentially as chelates in the pH region where the metal hydroxides are formed in the absence of chelating agents. It was shown by Rechnitz[4,5] that the activity measurement of the metal ion by the ion-selective electrode yields a reliable estimation of formation constants for a number of soluble copper complexes. In other words, the value of the electrode response is only due to the free metal ions, and their results suggest that metal ion chelates with polyacids have no effect on the response of the electrodes. Consequently, the activity values obtained for the present measurements were used without any special correction, except that of the activity coefficient of the concentrations.

Theory and Method of Calculation of the Equilibrium Constants of Complexation. Gregor and co-workers[2] have shown that the method of Bjerrum[1] for the evaluation of formation constants of metal complexes

may be adopted to elucidate the specific characteristics of polyelectrolytes.

By defining a reaction which does not cause any change in the charge of the polyacid, an equilibrium constant which can be expected to be independent of the charge on the polyacid was used by Gregor. Thus, the equilibrium exchange reaction between a proton and a metal ion is described as the equilibrium of the complex formation reaction.

A modification by Gregor of the calculation of the average coordination number $\bar{n}$ is as follows. Consider a solution in which the total acid concentration (dissociated, undissociated and chelated) is $[A_t]$ and the metal ion concentration is $[M_t]$. Using HA and A^- to designate a carboxylic group and a nonchelating carboxylate groups, respectively, $\bar{n}$ is given as follows:

$$\bar{n} = \frac{[A_t]-[HA]-[A^-]}{[M_t]}$$

Thus, if a relationship between $\bar{n}$ and $p([H^+]/[HA])$ can be obtained, the values of $\log B_2$ is determined by the following equation:

$$p\left(\frac{[HA]}{[H^+]}\right)_{\bar{n}=1} = \frac{1}{2}\log\left(\frac{[MA_2][H^+]^2[M^{2+}]}{[M^{2+}][HA]^2[MA_2]}\right)_{\bar{n}=1}$$

$$= \frac{1}{2}\log B_2, \quad B_2 = \frac{[MA_2][H^+]^2}{[M^{2+}][HA]^2}$$

where $[M^{2+}]/[MA_2]$ is equal to 1 at $\bar{n}=1$. But for any $\bar{n}$, the values of $[M^{2+}]/[MA_2]$ cannot be estimated, because there is, in general, no direct method for separately determining the values of $[M^{2+}]$ or $[MA_2]$.

Furthermore, in the case of polyacids, there is a difficulty in the determination of $[A^-]$. In order to estimate $[A^-]$, Mandel and Leyte[3] have devised the reference plot method instead of that of Gregor. The essential assumption of Mandel is based on the idea that in the Henderson-Hasselbach equation the α-dependent part of pK is only a function of the charge density on the polyacid. Thus,

$$pK = G + \zeta_\alpha$$

where G is a constant and ζ_α a function depending on α. Further,

$$p\left(\frac{[H^+]}{[HA]}\right) = G - p[A^-] + \zeta_\alpha.$$

On the basis of this equation Mandel and Leyte have suggested the reference plot method. A relationship between $p([H^+]/[HA])$ and $p[A^-]$ without metal ions is first plotted on a graph, and then, assuming that the metal ions added have no influence on this relationship, the values of $[A^-]$ can be obtained on the graph from the values of $p([H^+]/[HA])$ which can always be calculated.

In the present study, on the other hand, in addition to the pH values, the concentrations of free metal ions $[M^{2+}]$ can be determined simultaneously using ion-selective electrodes. Then, considering the relationship between the total metal ion concentration $[M_t]$ and the concentration of free metal ions $[M^{2+}]$, it can be easily seen that the difference between these two values is equal to the concentration of the truly complexed metal ions. Now, it is proposed that a real average coordination number $\bar{n}_r$ is introduced instead of $\bar{n}$ of Gregor (or Bjerrum), from which it can be shown how to calculate the equilibrium constant of the exchange reaction between protons and metal ions. The $\bar{n}_r$ is defined by the following equation:

$$\bar{n}_r = \frac{[A_t]-[HA]-[A^-]}{[M_t]-[M^{2+}]}$$

In contrast to the $\bar{n}$ of Gregor's method, $[M^{2+}]$ appears in the denominator of $\bar{n}_r$, and hence $\bar{n}_r$ is the average coordination number of the metal ions which are complexed with polyacids. Unfortunately, however, even when the value of $[M^{2+}]$ can be determined by the ion-selective electrode, the stoichiometric calculation of $[A^-]$ without any assumptions encounters difficulty. In the present study, the value of $[A^-]$

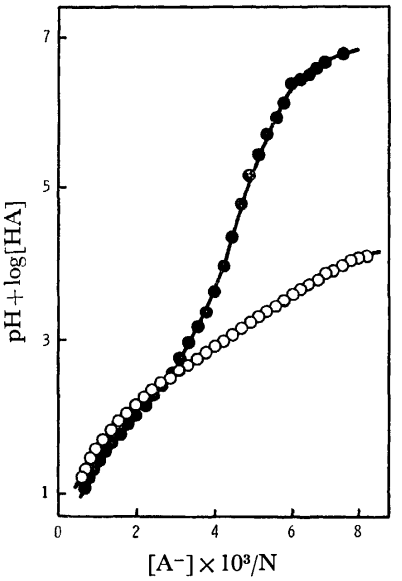

Fig. 1. The reference plots of 9.87×10^{-3} monomol/l PAA (○) and 4.75×10^{-3} monomol/l PIA ($=9.50\times10^{-3}$ N as carboxylic groups)(●) in 0.1 mol/l KNO_3.

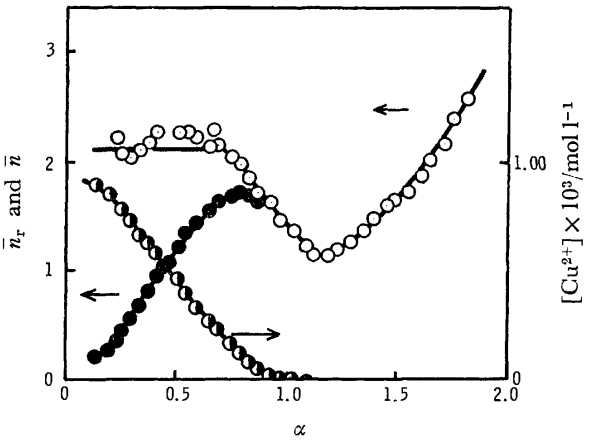

Fig. 2. The formation curves and the concentrations of Cu^{2+} at 4.75×10^{-3} monomol/l PIA and 1.09×10^{-3} mol/l $Cu(NO_3)_2$ in 0.1 mol/l KNO_3. ○: $\bar{n}_r$ by our method, ●: $\bar{n}$ by Gregor's method, and ◑: the concentration of Cu^{2+}.

is estimated by the reference plot method (Fig. 1).

In Fig. 2, not only $\bar{n}_r$ for Cu(II)-PIA, but also $\bar{n}$ and the concentrations of free Cu(II) ions [Cu^{2+}], are plotted against the degree of neutralization α. Comparing the $\bar{n}_r$ with $\bar{n}$, these average coordination numbers agree with each other at the point of zero [M^{2+}]. Consider a system where half of the [M_t] involves two ligands and the other half are free from complexation. Then, $\bar{n}$ is equal to 1, but $\bar{n}_r$ is 2. It is clear that the real coordination number of the metal ion is, in this case, two. This fact shows that $\bar{n}_r$ is more useful than $\bar{n}$. From $\bar{n}$ in Fig. 2, it can only be seen that some complexes whose "true" average coordination numbers are unknown are formed. On the other hand, from $\bar{n}_r$ the "true" average coordination number, and moreover, from the denominator of $\bar{n}_r$, the concentration of the complexes formed can be determined. As is shown in Fig. 2, at the low value of α, $\bar{n}_r$ shows clearly that the complex formed involves two carboxylate groups as ligands. Their equilibrium can be described by the following equation:

$$M^{2+} + 2HA \rightleftharpoons MA_2 + 2H^+;\ B_2 = \frac{[MA_2][H^+]^2}{[M^{2+}][HA]^2}$$

Then, in the region of α where the $\bar{n}_r$ is constant and equal to 2, the equilibrium constant B_2 can be stoichiometrically calculated with the assumption that only complexes involving two carboxylate groups are formed. In such a region of α, all the calculated values of log B_2 are constant, and are equal to -2.9. In comparison with the fact that the apparent acid-dissociation constants for polyacids are not constant, this result is interesting from the view point of chelation in polymeric systems.

Formation Curves and Stability of Complexes. In Figs. 3—5, the formation curves obtained using the present method for the Cd(II)–PIA, Cu(II)–PAA, and Cd(II)–PAA systems are shown. These curves are obtained under approximately the same conditions, and the concentration of polyacids is represented in the following way. Considering that all the carboxylic groups on the PAA and PIA chains are equivalent, concentrations of these groups are expressed in molarity,

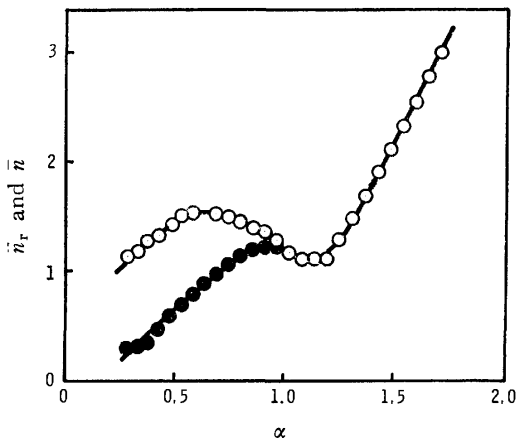

Fig. 3. The formation curves at 4.75×10^{-3} monomol/l PIA and 9.88×10^{-4} mol/l $Cd(NO_3)_2$ in 0.1 mol/l KNO_3. ○: $\bar{n}_r$ and ●: $\bar{n}$.

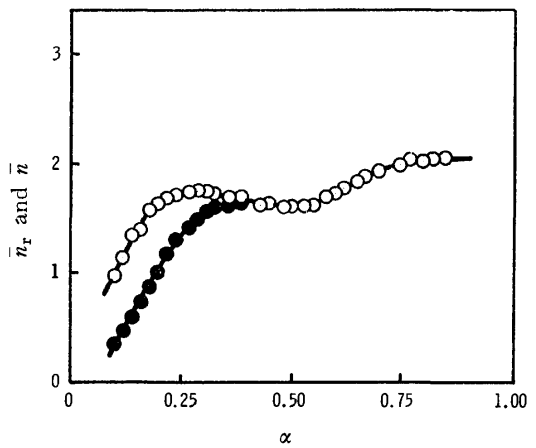

Fig. 4. The formation curves at 9.87×10^{-3} monomol/l PAA and 1.05×10^{-3} mol/l $Cu(NO_3)_2$ in 0.1 mol/l KNO_3. ○: $\bar{n}_r$ and ●: $\bar{n}$.

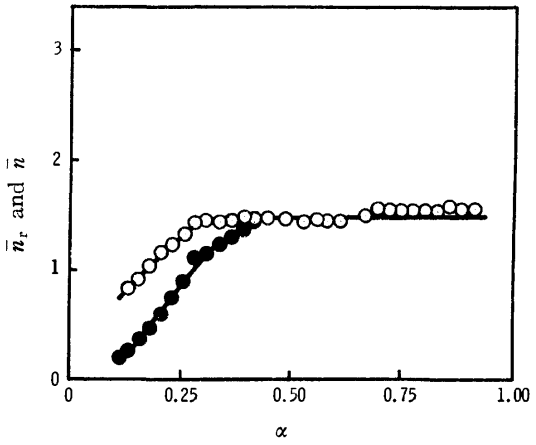

Fig. 5. The formation curves at 9.87×10^{-3} monomol/l PAA and 9.88×10^{-4} mol/l $Cd(NO_3)_2$ in 0.1 mol/l KNO_3. ○: $\bar{n}_r$ and ●: $\bar{n}$.

and hence the concentration of monomer units of PIA is equal to one half of the value of the present concentration of carboxylic groups.

From Fig. 3, it may be seen that no stable Cd(II)–PIA complex involving two carboxylate groups is formed, in contrast to the Cu(II)–PIA complex, and no constant value of log B_2 is obtained. Furthermore, for PIA complexes, Figs. 2 and 3 demonstrate that $\bar{n}_r$ begins to decrease at $\alpha=0.7$ and that for an increase in α, $\bar{n}_r$ increases passing through a minimum.

Figures 4 and 5 show $\bar{n}_r$ plots of PAA complexes of Cu(II) and Cd(II), which are similar in shape to those for $\bar{n}$ found by other workers, except that $\bar{n}_r$ begins from the value of 1. In spite of the existence of a flat region of $\bar{n}_r$ for the Cd(II)–PAA system, no constant value of log B_2 is obtained. For the Cu(II)–PAA system, there is a region $\bar{n}_r$ is equal to 2, but in this region no measurable free Cu(II) ions were present in the system, and therefore, a calculation of the equilibrium constant B_2 is impossible.

It is an interesting result that the stable Cu(II)–PIA complexes involving two carboxylate groups are formed but that no stable Cd(II)–PIA complexes are formed

at low values of α.

This fact can be explained by the fact that PIA is a polymer of dicarboxylic acid. Muto[6] has interpreted the specific counterion binding of alkali metal ions by taking into account the formation of a ring structure involving cooperative hydrogen bonding by two carboxylate groups. Now, we consider that the ring structure reacts with a free bivalent metal ion. If this bivalent ion must break this structure before forming the complex by entering between these two carboxylate groups and replacing a hydrogen ion. The difference in $\bar{n}_r$ between Cu(II)–PIA and Cd(II)–PIA in the region of α below 0.7 may be due to the difference of this ring-breaking ability for the Cu(II) and Cd(II) ions. This concept of hydrogen-bonded ring structure, however, seems not to be necessary, if we attribute the difference in the complexing ability of the Cu(II) and Cd(II) ions, irrespective of the structure of ligand groups.

The curves of $\bar{n}_r$ (and, of course, of $\bar{n}$) of PIA complexes in the region of α above 0.7 show strange behavior that the values of $\bar{n}_r$ increase more and more after a minimum has been reached. This tendency of the curves of the degree of binding for alkali metal ions was also shown by Muto. Therefore, this tendency need not result only from complex formation by bivalent metal ions. In connection with this fact several reasons are presented, for example, conformation change, the formation of metal hydroxides, and/or the formation of more complicated complexes, *etc.* It must be pointed out here that the method of calculation of $\bar{n}_r$ is more important. Thus, in the calculation of $\bar{n}_r$ (or of $\bar{n}$), the primary carboxylic groups are regarded as equivalent to secondary groups in the PIA monomer units and the concentrations of free carboxylate groups are estimated from the reference plot. Therefore, $\bar{n}_r$ shows some deviation due to uncertainty around the first neutralization step.

Calculating the formation constants by the present method, only the result of Cu(II)–PIA was obtained over a wide range of α, but other complexes, for example, Cd(II)–PAA, in spite of the existence of a flat region of $\bar{n}_r$, no constant value of the equilibrium constant is obtained for each value of α. In connection with this fact, in spite of taking into account 1–1 complex formation, the test was not successful. Some reasons may be given, such as unevaluated errors in the potentiometric measurements or the uncertainty in the estimation of the concentration of each ion which participates in the complex formation equilibrium (for example, employing the Mandel reference plot). In some cases, however, a series of values of equilibrium constants which vary monotonously with α has been obtained. This behavior as a function of the difference in the stability of the complexes is as follows. If the complexes formed, whose ligands are two carboxylate groups in a monomer unit, are very stable, the equilibrium of complex formation may not be influenced by, for example, the change of the polymer conformation, and this is the case of the Cu(II)–PIA system. On the other hand, when the complexes are not as stable, the equilibrium constants for complex formation must be influenced, if the conformation of the polymer chain is changed with α. Thus, it can be seen that the Cu(II)–PIA complexes involving two carboxylate groups in the low pH region are more stable than others and that both Cd(II) complexes with PAA and PIA are not so stable. These results are summarized in Table 1.

TABLE 1. $\log B_1$ AND $\log B_2$ VALUES OBTAINED FROM OUR METHOD IN Figs. 3—5

	Cu^{2+}	Cd^{2+}	
PAA complexes			
$\log B_1$	—	—	$(\bar{n}_r=1.5)$
$\log B_2$	-3.4 $(0.55<\alpha)$	—	$(\bar{n}_r=1.5)$
PIA complexes			
$\log B_1$	—	—	
$\log B_2$	-2.9 $(\alpha<0.66)$	—	

The authors wish to thank Dr. Muto for his offer of the PIA samples and for helpful suggestions and discussions.

Temperature Dependence of the Dielectric Constants of Potassium-Chloranil Salt and Würster's Blue Perchlorate

Kikujiro Ishii,* Katsumi Kaneko,** and Haruo Kuroda

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo 113

(Received January 22, 1976)

The dielectric constants of potassium-chloranil salt(K^+CA^-) and Würster's blue perchlorate (WBP) were measured around their phase-transition temperatures in the X-band microwave region. In the case of K^+CA^-, a sudden increase in the dielectric constant was observed accompanying a change to the low-temperature phase. This is interpreted to arise from the change in electronic polarization associated with a marked increase in the intensity of the charge-transfer band in the near-infrared region. An anomalous peak and associated gradual changes were observed in the temperature dependence of the dielectric constant of WBP around the phase transition temperature. The difference in dielectric behavior of these two cases is discussed in relation to the optical absorption spectra and other properties of the crystals.

Although the electronic polarizability of a molecular crystal is affected, more or less, by the electronic interaction between molecules, the effect on the dielectric behavior of molecular crystals has usually been regarded as being of minor importance. However, recent investigations on the dielectric properties of crystals of solid charge-transfer complexes and radical salts have revealed several examples where the charge-transfer interaction between molecules plays an important role in determining their dielectric properties.[1,2]

We previously reported the results of dielectric constant measurement on a series of solid molecular complexes containing tetracyanoquinodimethane (TCNQ) as an electron acceptor, pointing out that, when there is a strong low-energy charge-transfer band in the crystal spectrum of a molecular complex, the dielectric constant of the crystal is larger than the value expected by assuming the additivity of molecular polarizations of the constituent molecules.[1]

In the case of the potassium-chloranil salt (K^+CA^-), the crystal spectrum exhibits a near-infrared absorption band associated with the charge-transfer interaction between chloranil ions, the intensity of this charge-transfer band markedly increasing when the crystal is cooled down below the transition point where the crystal changes from the high-spin state to the low-spin state.[3] A similar temperature dependence of the intensity of low-energy charge-transfer band can be observed in the case of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine(TMPD) perchlorate (Würster's blue perchlorate, WBP).[4] Thus it is of particular interest to examine the dielectric behavior of these solids in the vicinity of transition point to see if their dielectric constants increase with the increase of the intensity of low-energy charge-transfer band.

Experimental

The dielectric constants of K^+CA^- and WBP, in the X-band microwave region, were measured by the cavity perturbation method by using a variable-temperature cylindrical cavity of TM_{012} resonance mode with an operation frequency of 9.4 GHz. The structure of the apparatus is shown in Fig. 1. The sample, in the form of a fine crystalline powder, was packed in a thin fused-quartz tube (A in Fig. 1) which was inserted at the middle of the resonance cavity (H). The cavity was cooled by introducing cold nitrogen gas into the copper tube (B) wound around the copper block (E) installed at the top of the cavity. The temperature of the cavity was controlled by adjusting the flow rate of the cold nitrogen gas and/or by using an electric heater (F). We measured the resonance frequencies of the cavity without and with the sample, f_1 and f_2 respectively, at each temperature, and obtained the value $(f_1^2-f_2^2)/f_2^2$. The latter quantity can be assumed to be proportional to $(\varepsilon-1)$ in the first order approximation, where ε is the dielectric constant of the sample.[5,6] It was difficult to estimate the absolute value of dielectric constant from the above experiment because of the difficulty in avoiding the inhomogeneity as regards the packing of sample powder in the tube. Thus, we separately estimated the actual dielectric constant of the sample at room temperature by the method described previously,[5] using a rectangular cavity of TE_{105} mode.

The crystalline powder of WBP was prepared by the method of Michaelis and Granik.[7] The crystalline powder

of K^+CA^- was obtained by the method reported by Torrey and Hunter.[8] The results of elementary analysis agreed with the calculated values in both cases. Since K^+CA^- is known to form hydrate by absorbing moisture from the atmosphere,[9] the sample was carefully dried in a vacuum so that it was completely converted into anhydrous modification. The X-ray diffraction pattern of the powder sample thus obtained was confirmed to agree with that of the anhydrous state. In order to avoid a change of the sample into hydrous modification, the sample tube of dielectric constant measurement was pumped to the vacuum of 10^{-3} Torr soon after the sample powder had been packed into it.

Differential scanning calorimetry (DSC) was carried out on each sample with a Rigaku low-temperature DSC apparatus.

The polarized absorption spectra of single crystals were measured with a microspectrophotometer with a small cryostat at the specimen stage of the microscope system.

Results and Discussion

Figure 2a shows the plot of the frequency shift, $(f_1^2-f_2^2)/f_2^2$, against temperature in the case of K^+CA^-. An approximate scale of dielectric constant is given[10] on the right-hand side. This was determined by normalizing $(f_1^2-f_2^2)/f_2^2$ to the room temperature value of dielectric constant determined by the separate experiment.

On lowering the temperature, the frequency shift remains almost constant (at the value corresponding to the dielectric constant of about 3.5) from room temperature down to about 220 K, then exhibits a sudden increase in the 220—210 K region, and after showing a maximum at 210 K, it stays constant at lower temperatures.[11] On elevating the temperature, however, the frequency shift stays constant up to 260 K, where it shows a sudden decrease, showing a hysteresis in its temperature dependence.

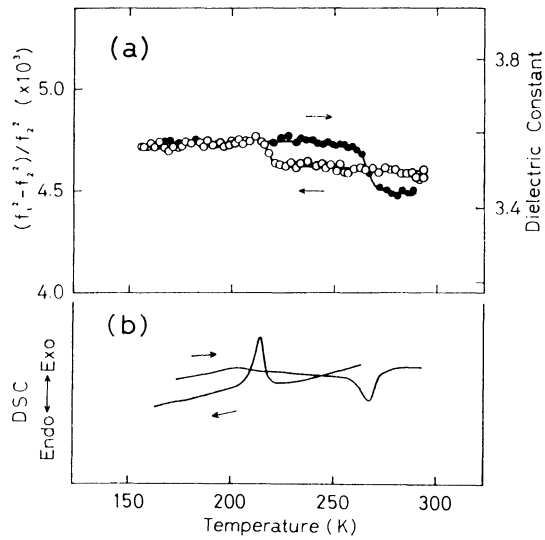

Fig. 2. (a) Temperature dependence of the dielectric constant of potassium-chloranil salt (K^+CA^-). $(f_1^2-f_2^2)/f_2^2$ is plotted as the ordinate, where f_1 and f_2 are the resonance frequencies of the microwave cavity without and with the sample respectively. An approximate scale of the dielectric constant is shown in the right hand side. (b) Differential scanning calorimetry curves of K^+CA^-.

The temperature dependence of the magnetic susceptibility is known to also exhibit an appreciable hysteresis between the heating and cooling processes; the phase transition occurs at 210 K on lowering the temperature, and at 260 K on elevating the temperature.[12,13] This difference of transition temperature is also clearly observable in the DSC curves (Fig. 2b). By comparing Figs. 2a and 2b, we note that the temperature, at which a sudden change of frequency shift occurs, exactly coincides with the transition point, for both the cooling process and heating process.

According to Konno *et al.*,[14] in the high-temperature phase of K^+CA^-, CA^- ions are stacked face-to-face on each other along the c-axis with uniform intermolecular separation, K^+ ions being located at the sites between CA^- columns. Although the details of the crystal structure of the low-temperature phase are not known, it has been inferred that the arrangement of CA^- ions in the CA^- column changes to a dimeric one in the low-temperature phase.[3,9]

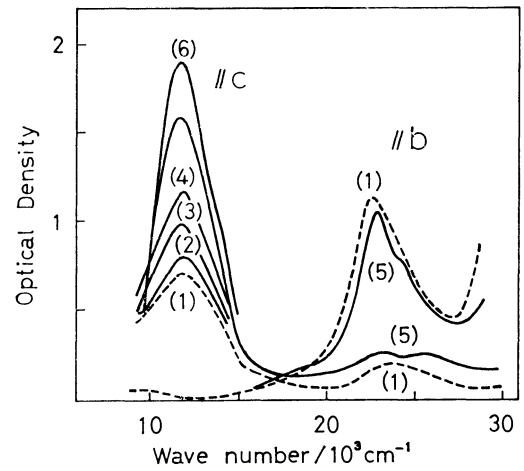

Fig. 3. Temperature dependence of the crystal spectra of the potassium-chloranil salt. (1); 297 K, (2); 280 K, (3); 240 K, (4); 218 K, (5); 209 K, (6); 163 K. (//b and //c denote the b- and c- axis spectrum, respectively).

The crystal spectrum of K^+CA^- is reproduced in Fig. 3.[3] The near-infrared absorption band, at 11.5×10^3 cm^{-1}, is almost completely polarized in the c-axis direction, and has been assigned to the band associated with the charge-transfer interaction between neighboring CA^- ions. As shown in Fig. 3, the intensity of this charge-transfer band markedly increases on lowering the temperature in the vicinity of transition point. Other absorption bands which are associated with the electronic transitions of the CA^- ion are not significantly affected by temperature.

The static electronic polarizability α_e of a semiconductive (or insulating) solid can be related to the electronic transitions of the solid as follows:

$$\alpha_e = \frac{e^2}{4\pi^2 m}\sum_j \frac{f_j}{\nu_j^2}, \qquad (1)$$

where ν_j and f_j are the frequency and oscillator strength, respectively, of the j-th electronic transition of the

solid.[15] We see that if there is any low-frequency electronic transition with a strong oscillator strength, it will make a considerable contribution to the electronic polarizability.

In order to consider the relation between the low-frequency charge-transfer band and the electronic polarizability of K^+CA^-, we rewrite Eq. 1 as follows:

$$\alpha_e = \frac{e^2}{4\pi^2 m}\frac{f_{CT}}{\nu_{CT}^2} + \frac{e^2}{4\pi^2 m}\sum_j \frac{f_j}{\nu_j^2} \qquad (2)$$

where the first term represents the contribution of the charge-transfer transition, and the second term those of other electronic transitions. The crystal spectrum of K^+CA^- exhibits a significant change in the vicinity of transition point only in the region of the charge-transfer band. Thus, one can reasonably assume that the second term of Eq. 2 must be almost the same at temperatures above and below transition point, so that the temperature dependence of the electronic polarizability in the vicinity of transition point will be determined mainly by the change in the first term. In other words, the electronic polarizability is expected to vary parallel to the intensity change of the charge-transfer band. Consequently, we can anticipate that the dielectric constant of K^+CA^- suddenly increases as the crystal changes from the high-temperature phase to the low-temperature phase if its change in the vicinity of transition point is primarily dependent on the variation of the electronic polarizability. This prediction is in agreement with observation. Naturally the dielectric constant of a solid depends not only on electronic polarization but also on atomic and lattice polarizations. At present, we can not exclude the possibility that the observed change of dielectric property of K^+CA^- in the vicinity of transition point is to some extent due to the change in the latter polarizations. But, as we will discuss later in comparison with the dielectric behavior of WBP, the electronic polarization is likely to play a dominant role in determining the observed dielectric behavior of K^+CA^- at transition point.

In the case of WBP, we obtained the results shown in Fig. 4a. The frequency shift, $(f_1^2-f_2^2)/f_2^2$, is almost constant down to 250 K, then gradually increases on lowering the temperature, and reaches a maximum value at 190 K. On undergoing the phase transition, it exhibits a sudden decrease, and thereafter, it gradually decreases on lowering the temperature.[16] In contrast to the corresponding plot of K^+CA^-, there appears no hysteresis in this case between the cooling and heating processes; the plot for both processes exhibits exactly the same temperature dependence. The situation is the same in the DSC experiment as shown in Fig. 4b.

Extensive investigasions have been carried out on the nature of the phase transition of WBP at 190 K, where WBP changes from the high-spin state at higher temperature to the low-spin state at lower temperature.[4,17-21] It was inferred from these studies that in the low-temperature phase the $TMPD^+$ column along the a-axis consists of a dimeric array of $TMPD^+$ ions, while it has a monomeric array of the ions in the high-temperature phase. The structural change was recently confirmed by crystal structure analysis.[22,23]

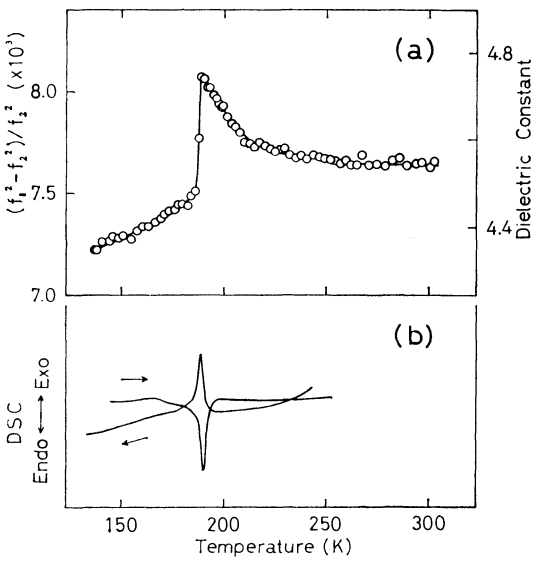

Fig. 4. (a) Temperature dependence of the dielectric constant of Würster's blue perchlorate (WBP). The change in the resonance frequency of the microwave cavity is plotted as the ordinate in the same manner with Fig. 2. An approximate scale of the dielectric constant is also shown in the right hand side. (b) Differential scanning calorimetry curves of WBP.

The polarized absorption spectrum of the WBP crystal is shown in Fig. 5. All the absorption bands in the b- and a-axes spectra at 297 K are attributable to the local-excitations associated with the electronic transitions of $TMPD^+$ ion. No strong absorption band can be found below 15×10^3 cm^{-1} at this temperature. However, as the temperature is lowered below the transition point, a new absorption band grows up at 12.5×10^3 cm^{-1} in the a-axis spectrum. The intensity of this band increases gradually over a wide temperature range on lowering the temperature. The corresponding absorption band has been observed at low temperatures also in the absorption spectrum of a polycrystalline sample of WBP, and attributed to the charge-transfer between $TMPD^+$

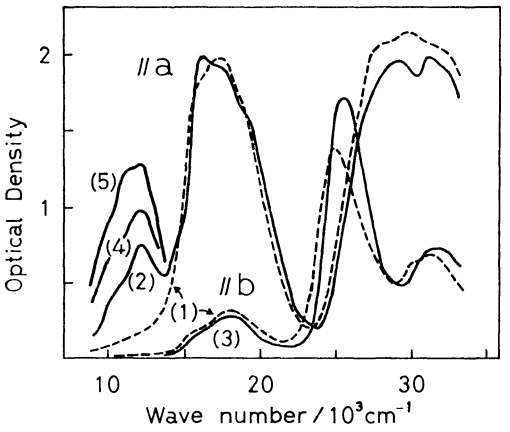

Fig. 5. Temperature dependence of the crystal spectra of Würster's blue perchlorate. (1); 285 K, (2); 138 K, (3); 134 K, (4); 122 K, (5); 83 K. (//a and //b denote the a- and b-axis spectrum, respectively.)

ions.[4] The fact that the above band is completely polarized in the direction of the $TMPD^+$ column, as revealed by the present study, indicates that it is indeed a charge-transfer band associated with the interaction between $TMPD^+$ ions in the $TMPD^+$ column.

Apparently, the change of the absorption spectrum of the WBP crystal accompanying the phase transition is very similar to that of the K^+CA^- crystal. Our discussion on the electronic polarizability of the K^+CA^- crystal should therefore be also applicable to the case of WBP. Since, as in K^+CA^-, the intensity of the low-frequency charge-transfer band of WBP markedly increases below the transition point while those of other absorption bands hardly change at all between above and below the transition point, it should be considered that the electronic polarizability of WBP increases in the low-temperature phase. The dielectric constant should thus be expected to increase as the temperature is lowered below the transition point, if the temperature dependence of dielectric constant is determined by the change in the electronic polarizability. However, the temperature dependence of frequency shift observed for WBP in the vicinity of transition point is just the contrary to that mentioned above (Fig. 4a), and quite different from that observed for K^+CA^-. This seems to indicate that the change of the dielectric constant of WBP is mainly determined by some other factor. The dielectric property of a solid is dependent not only on electronic polarization but also on atomic and lattice polarizations. However, it is very unlikely for atomic polarization to play the determining role for the relatively large change of dielectric constant as observed in the case of WBP at the transition point. In Fig. 4a, we note two features; a sudden decrease at the transition point, and gradual changes above and below this temperature. A similar type of temperature dependence of dielectric constant is known to occur in a crystal containing a component with an electric dipole when the rotational motion of the polar group (or molecule) is allowed above the transition point, but not in the low-temperature phase.[24] However, such a model associated with the orientational polarization can not be applied in the case of WBP.

Generally, in an ionic crystal, the lattice polarization arising from the displacement of ions makes a significant contribution to the static dielectric constant. The magnitude of this contribution is dependent on the frequency of lattice vibration. Recently, Terauchi[25] observed a diffuse X-ray reflection on the WBP crystal at temperatures above the transition point. As the temperature is lowered, the intensity of this reflection increases in proportion to $1/(T-T_c)$, where T_c is a critical temperature close to the transition point. The above reflection is interpreted to arise from the fluctuating dimerization of $TMPD^+$ ions in the $TMPD^+$ column. The fluctuation of β, the angle between the a- and c-axes, is also found to occur in the same temperature range. It is therefore inferred that some optical modes of lattice vibration are softened in the same temperature range. If this is the case, one could expect an anomaly concerning the lattice polarization. Seemingly, the increase of dielectric constant observed in the high-temperature phase of WBP on approaching the transition point is attributable to the above mechanism. On passing through the transition point, the lattice vibrational modes are considered to change suddenly, but the fluctuation of lattice may remain even in the low-temperature phase in the temperature region close to the transition point. The sudden decrease of the dielectric constant at the transition point and the gradual decrease below this point could be understood by this mechanism.

The dielectric behavior in the vicinity of transition point shows a marked difference between K^+CA^- and WBP although the phase transitions of these solids resemble each other in many respects. Two possible causes for the difference might be considered as follows. First, in the case of WBP the charge-transfer band appears at a frequency close to that of a strong local-excition band, while in the case of K^+CA^- it is very much lower than any of the local-excitation bands. The intensity change of the charge-transfer bands of WBP takes place gradually over a relatively wide temperature range, whereas that of K^+CA^- varies steeply on phase transition. Thus, the intensity change of charge-transfer band is expected to give a smaller effect on electronic polarizability in the case of WBP as compared with K^+CA^-. Second, we may consider that the contribution of lattice polarization is considerably larger in WBP than in K^+CA^-. In WBP, the heavy and bulky ClO_4^- ion is loosely bound to the $TMPD^+$ column, so that there can be a low-frequency lattice-vibrational mode giving a significant contribution to the lattice polarization. In K^+CA^-, the K^+ ion is rather tightly bound to the CA^- column through the interaction with the oxygen atoms of the neighboring CA^- ions. In effect, the dielectric constant of WBP, about 4.5 at room temperature, is much larger than that usually obtained for organic crystals composed of neutral molecules, and is comparable to those of inorganic ionic crystals. On the other hand, the dielectric constant of K^+CA^- at room temperature is 3.5, which is comparable to that obtained in the cases of non-ionic charge-transfer complexes involving polycyclic aromatic hydrocarbons as the donor and TCNQ as the acceptor. This indicates that lattice polarization makes a significant contribution to the dielectric constant in the case of WBP, but not in the case of K^+CA^-.

6) The frequency shift $(f_1^2-f_2^2)/f_2^2$ is in reality proportional to (ε_a-1), where ε_a is the apparent dielectric constant of

powder sample. Since (ε_a-1) is proportional to $\delta\cdot(\varepsilon-1)$ when the volume fraction of crystals in the powder sample is expressed by δ, the frequency shift must be proportional to $(\varepsilon-1)/\rho$, where ρ is the crystal density. This means that, if there is an appreciable change in ρ, the observed variation of frequency shift does not directly show the actual change of dielectric constant which must be dependent of the change of crystal density, but shows the variation of polarization after correction has been done as regards the change of crystal density.

Emission Spectra of the Vinyl Polymers with Pendant Carbazolyl Groups

Akira ITAYA, Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube 755

(Received February 9, 1976)

The emission properties of poly(*N*-vinylcarbazole) (PVCz) prepared by radical and cationic polymerization (PVCz(r) and PVCz(c) respectively), the oligomers of *N*-vinylcarbazole, and poly[2-(*N*-carbazolyl)ethyl vinyl ether] (PCzEVE) were investigated in solutions. The fluorescence spectrum of PVCz(r) was different from that of PVCz(c). This seems to be attributable to the difference in the tacticity between them. On the basis of this result, the structure of the second excimer site is discussed. PCzEVE, in which the carbazolyl chromophores are widely spaced on the skeletal chains by $-O-CH_2-CH_2-$ bonds, showed an interesting, new, structureless emission band with a peak at 27000 cm^{-1}. This was different from both the monomeric structured fluorescence and the sandwich-like excimer one which were observed for the model compounds and the polymers. The emission properties of PCzEVE were unique among the vinyl polymers with aromatic chromophores widely spaced on the skeletal chain.

It is known that 1-ethylpyrene and 1-ethylnaphthalene show the excimer fluorescence in concentrated fluid solutions at room temperature. Poly(1-vinylpyrene)[1,2] and poly(1-vinylnaphthalene),[3,4] in which the pyrenyl and naphthyl groups are connected directly to the skeletal chains, show, almost entirely, only the excimer fluorescence in dilute solutions at room temperature. Poly(1-pyrenylmethyl vinyl ether) (PPyMVE),[1,5] poly-(1-naphthylmethyl vinyl ether) (PNMVE),[5] and ploy-(1-naphthyl methacrylate) (PNMA),[6] in which the pyrenyl and naphthyl groups are widely spaced on the skeletal chains by $-O-CH_2-$ and $-CO-O-$ bonds, show both the structured monomeric fluorescence and the excimer one in dilute solutions. On the other hand, *N*-ethylcarbazole(ECz) and 9-ethylacridine show no excimer fluorescence in the concentrated solutions.[1,7] Moreover, ECz shows no excimer fluorescence in either the molten state or the solid state.[7] Poly(9-vinylacridine) shows, almost entirely, only the excimer fluorescence in a dilute solution at room temperature.[1] Poly(*N*-vinylcarbazole) (PVCz), both in solution and in film, shows one broad fluorescence, which is not composed of only one component, but of two components. The broad emission at the longer wavelength(λ_{max}; *ca.* 23900 cm^{-1}) is assigned to the sandwich-like excimer fluorescence, which is the same as was mentioned above. On the other hand, the assignment of the broad emission in the shorter-wavelength region (λ_{max}; *ca.* 27000 cm^{-1}) is controversial because of the absence of the structure and of the large Stokes shift. David *et al.* and Yokoyama *et al.* have assigned it to the monomer fluorescence for PVCz in solution.[7,8] On the other hand, recently Johnson has assigned it to the second excimer fluorescence and reported that the polymer conformation appropriate for the formation of this state exists prior to the initial excitation step.[9] Offen *et al.*,[10] Klöpffer *et al.*,[11] and Powell *et al.*[12] have assigned the shorter-wavelength band to another intrinsic trap site, such as a dimer for PVCz films. However, the structure of the species emitting at *ca.* 27000 cm^{-1} has been amibguous thus far.

Recently, we have revealed, as a result of measuring the NMR spectra,[13] that cationic PVCz(c) have a higher isotacticity than radical PVCz(r). Therefore, it was of interest to investigate how the difference in the tacticity is reflected in the fluorescence spectra. In the present investigations, we have found that the difference influences the intensity of the second excimer fluorescence. On the basis of this result, the structure of the second excimer site, emitting at *ca.* 27000 cm^{-1}, was discussed.

Spectroscopic studies of the vinyl polymers with Cz chromophores widely spaced on the skeletal chains are of interest in connection with those of PVCz. In the present project, we investigated the spectroscopic behavior of poly[2-(*N*-carbazolyl)ethyl vinyl ether] (PCzEVE). It has already been found, from the absorption and NMR spectra,[14] that PCzEVE has no appreciable ground-state interaction among the Cz chromophores of PCzEVE.

Experimental

The vinyl polymers(PVCz(r), PVCz(c), PCzEVE), *N*-vinylcarbazole oligomers(VCz Olig. I and II; degrees of polymerization, 4 and 10 respectively), and the model compounds(*N*-isopropylcarbazole(*i*-PrCz), 1,3-bis(*N*-carbazolyl)-propane(DCzP)) were prepared by the methods described previously.[15,16] The dimethyl terephthalate(DMTP) was recrystallized twice from benzene and subsequently sublimed *in vacuo*. All of the solvents (2-methyltetrahydrofuran(MT-HF), tetrahydrofuran(THF), 1,2-dichloroethane) were purified by the usual methods. The solutions were completely degassed by freeze-pump-thaw cycles if necessary.

The emission spectra were measured with a spectrophotofluorometer constructed using a stabilized 500 W xenon lamp, monochromators, and a PM-55 (S-20) photomultiplier. The spectra were calibrated for the detector response by using a standard tungsten lamp. The fluorescence-decay times were measured with a pulsed N_2 gas laser as the exciting light source. Responses from the photomultiplier were led to a sampling oscilloscope(Tektronix 661) and recorded on a X-Y recorder, or led to a Tektronix 475 oscilloscope and the decay curve was photographed.

For the fluorescence polarization, two polarizers were used, and the data were corrected by the method described by Azumi and McGlynn.[17]

Results and Discussion

*Fluorescence in the Shorter-wavelength Region(*ca. *27000 cm^{-1}) of PVCz (r and c).* The fluorescence spectra of the various PVCz samples in aerated THF solutions at room temperature are shown in Fig. 1. The ratio of the second excimer fluorescence intensity to the

sandwich-like excimer one in PVCz(r) samples is remarkably larger than that in PVCz(c) samples. Figure 2 shows the fluorescence spectra of PVCz(r) and PVCz(c), which have almost the same concentrations in degassed THF–MTHF solutions at room temperature, and their resolution spectra. The resolutions were carried out on the assumption that the location of the sandwich-like excimer fluorescence

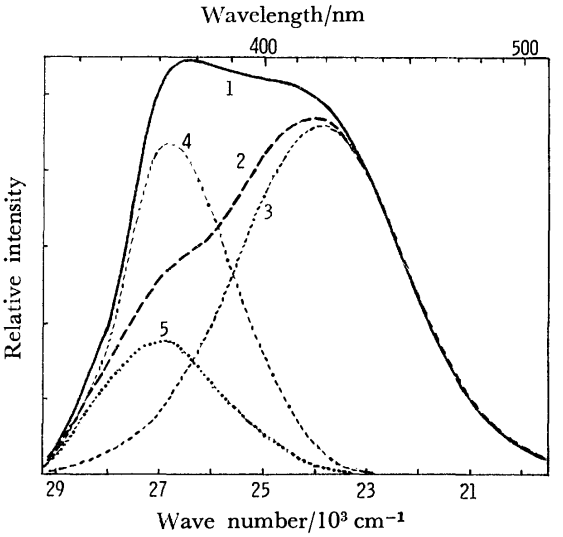

Fig. 2. Fluorescence spectra and the resolution spectra of PVCz(r) and PVCz(c) in MTHF-THF degassed solutions at room temperature. Optical densities at excitation wavelength (310 nm) are 0.132 and 0.131 for PVCz(r) and PVCz(c), respectively.
(1) ——; PVCz(r), (2) — —; PVCz(c), (3) ·····; the component of the sandwich-like excimer fluorescence of PVCz(r) and PVCz(c), (4) ----; the component of the second excimer fluorescence of PVCz(r), (5) ·····; the component of the second excimer fluorescence of PVCz(c).

band in solution was the same as that in film. The efficiency of the singlet-exciton migration along the polymer chain may be different between PVCz(r) and PVCz(c) because of their different tacticities. However, judging from the fact that no monomeric fluorescence is observed, their efficiencies seem to be very high, so that it seems not to be necessary to consider the difference in their efficiencies in the present case. It may safely be considered that the radiative rate constants of each fluorescence (second and sandwich-like excimer bands) of PVCz(r) are equal to those of PVCz(c). Therefore, Fig. 2 shows that the concentration of the sandwich-like excimer site in PVCz(r) is nearly equal to that in PVCz(c), and that the concentration of the second excimer site in PVCz(r) is higher than that in PVCz(c) by a factor of about 2.4. That is, the difference in the fluorescence spectra between PVCz(r) and PVCz(c) seems not to be attributable to any difference in the concentration of the sandwich-like excimer site, but to the difference in the concentration of the second excimer site.

In rigid glass at 77 K, a significant difference in the fluorescence spectra between PVCz(r) and PVCz(c) is found, as is shown in Fig. 3. The intensity of the 370 nm band of PVCz(r) is larger than that of PVCz(c). Johnson has pointed out a molecular-weight dependence of the emission spectrum of PVCz(r) in MTHF at 77 K.[9] The molecular weights of PVCz(r) and PVCz(c) used in this experiment are 1×10^5 and 2×10^5 respectively. Therefore, the difference in the fluorescence spectra between PVCz(r) and PVCz(c) in rigid glasses at 77 K seems not to be attributable to any difference in the molecular weight, but to the

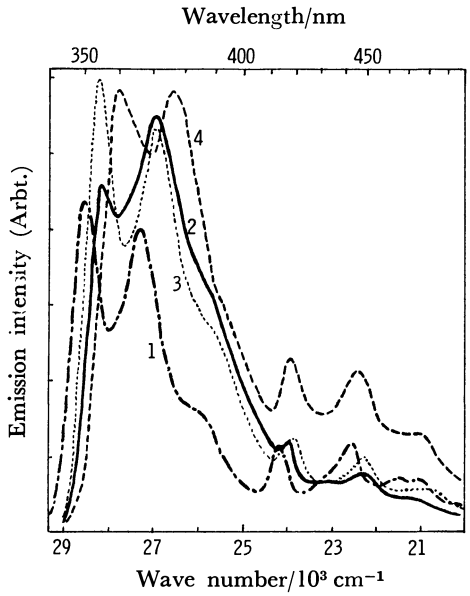

Fig. 3. Emission spectra of (1) ——; VCz Olig, II, (2)——; PVCz(r), (3)----; PVCz(c), and (4)———; PCzEVE in MTHF-THF rigid glasses at 77 K.

difference in their tacticities. The above-described results indicate that the fluorescence spectra both in fluid and in rigid solutions reflect the difference in the tacticity of PVCz and that the concentration of the second excimer site in syndiotactic-rich polymer-(PVCz(r)) is higher than that in isotactic-rich polymer-(PVCz(c)).

In the conformations for a three-skeletal carbon rotational dyad of syndiotactic and isotactic polymer-chain sequences based on a threefold rotational potential,[18] the conformational states with the lowest energy and those corresponding to the sandwich-like excimer site are shown in Fig. 4 (a) and (b). In the syndiotactic case there are a doubly degenerate ground state (g^+g^+,

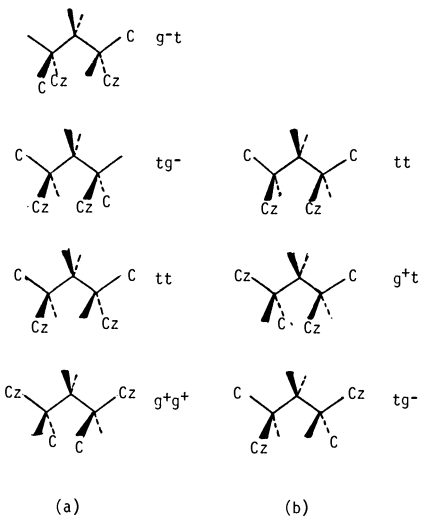

Fig. 4. The lowest energy conformations and excimer forming site ones for a three skeletal carbon rotational dyad of (a) syndiotactic and (b) isotactic polymer chain sequences based on a three fold rotational potential. This figure is quoted from Fig. 10 in Ref. 18.

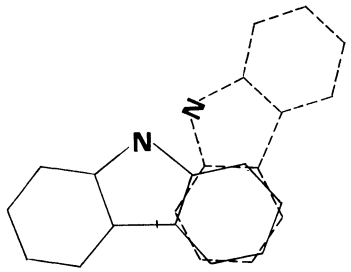

Fig. 5. The model of the second excimer of PVCz.

g^-t, tg^-) and a doubly degenerate excimer state (g^-t, tg^-). On the other hand, in the isotactic case there are a doubly degenarate ground state (g^+t, tg^-) and a singlet excimer state(tt). The formation of the sandwich-like excimer conformation from the ground-state conformation requires rotational motion about the carbon–carbon bond. In the ground-state conformations, we note that the tt conformation of the syndiotactic chain (Fig. 4(a)) has a shortest distance between neighboring Cz chromophores. Since the Cz chromophore is bulky, it seems to be easy to approach and mutually overlap the one benzene ring of the neighboring Cz chromophores in the excited state, as is shown in Fig. 5. The ground-state molecules corresponding to this reduced separation have a repulsive interaction.

It has been reported that 1,2-di(1-anthryl)ethane shows a broad excimer fluorescence in solution at room temperature at wavelengths shorter than the fluorescence of a sandwich-like excimer formed by the decomposition of its photodimer in rigid glass at 77 K, and that the structure of the excimer seems to be the overlap of only one benzene ring in the mutual anthracence chromophores.[19] Therefore, it seems reasonable to consider that the structure of the second excimer state may be the overlap of only one benzene ring in the neighboring chromophores. This structure seems to be supported by the fact that the formation of the sandwich-like excimer from the second excimer requires a rotational motion about the carbon-carbon bond.[9]

Concerning poly(α-methylstyrene) (PαMS)[20] andpolystyrene (PS),[20–22] it has been reported that the ratio of the sandwich-like excimer to the monomer fluorescence intensity, I_E/I_M, for the isotactic polymer is larger than that for the atactic polymer, although an opposite experimental result for PS has also been reported.[3] With regard to the relation between the tacticity of the polymer chain and I_E, Longworth[21] has reported that the I_E for isotactic PS is larger than that for atactic PS. In contrast to these results, in the case of PVCz, the concentration of the sandwich-like excimer site in the isotactic-rich polymer is nearly equal to that in the syndiotactic-rich polymer, as has been metioned above. The difference between the former (PαMS, PS) and the latter (PVCz) may be attributable to the existence of a second excimer resulting from the bulky Cz chromophore. No detailed explanation can, however, be offered at present.

Fluorescence Spectra of PCzEVE. The fluorescence spectra of the compounds with the Cz chromophores in MTHF–THF dilute solutions (2.0×10^{-4} M) at room temperature are shown in Fig. 6. The emission

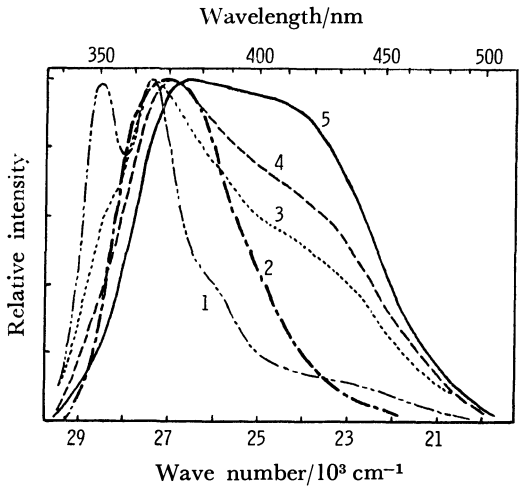

Fig. 6. Normalized fluorescence spectra of the model compound and vinylpolymers in MTHF-THF degassed solution at room temperature. Excitation wavelength; 310 nm.

spectrum of DCzP consists of a monomeric structured fluorescence and a sandwich-like excimer one with a peak at *ca.* 23900 cm^{-1}, as is well-known.[23-25] VCz Olig. I and II show a structureless fluorescence with a peak at 27000—27500 cm^{-1} and a sandwich-like excimer fluorescence, as in the case of PVCz, although VCz Olig. I also shows a monomer fluorescence as a shoulder. On the other hand, PCzEVE shows only a broad, structureless fluorescence with a peak at 27100 cm^{-1}. The Stokes shift (1990 cm^{-1}) is much larger than that of *i*-PrCz and DCzP (380 cm^{-1}). The fluorescence excitation spectra of PCzEVE, obtained by monitoring at several wavelength (350—450 nm) at room temperature, duplicate exactly the absorption spectrum of this solution at room temperature.

The fluorescence decay curve of PCzEVE in the MTHF-THF solution at room temperature is clearly two-component in all wavelength regions (370—430 nm), as is shown in Fig. 7. The decay constant of the long-lived component observed at 370 nm (33±1 ns) is longer than that of *i*-PrCz (17±2 ns) and shorter than that of the sandwich-like excimer fluorescence of PVCz (45±1 ns). The initial fast decay constant is 13±2 ns. This two-component decay of PCzEVE is also observed in rigid glass at 77 K (35±4 and 12±2 ns). The ratio of the short-decay component to the long one in rigid glass at 77 K is larger than that in a fluid solution at room temperature.

Table 1 shows the relative fluorescence quantum yields, taking the value of *i*-PrCz, which forms no excimer, as unity. The fluorescence quantum yield of PCzEVE is higher than that of DCzP, in which the sandwich-like excimer formation is the minimum among the materials used, as is shown in Fig. 6.

The fluorescence spectra of PCzEVE at various temperatures are shown in Fig. 8. At lower temperatures, two peaks appear, and they approach each other with an increase in the temperature. At tem-

PCzEVE	0.79
DCzP	0.57
VCz Olig. I	0.40
VCz Olig. II	0.37
PVCz(r)	0.33
PVCz(c)	0.27

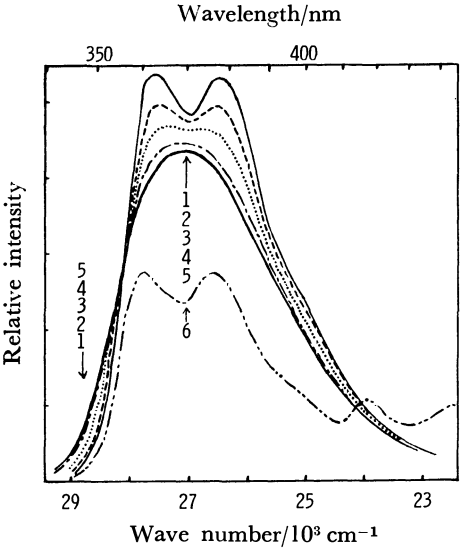

Fig. 8. Temperature dependence of the fluorescence spectra of PCzEVE in MTHF-THF degassed solution. Concentration of PCzEVE; 2.0×10^{-4} M. Excitation wavelength; 310 nm.
(1) 168 K, (2) 208 K, (3) 249 K, (4) 298 K, and (5) 318 K. The fluorescence (6) at 77 K was also given for comparison.

peratures higher than *ca.* 273 K, a structureless fluorescence spectrum with only one peak is observed. The fluorescence intensity decreases with an increase in the temperature. According to the measurement of the temperature dependence of the fluorescence spectra of the such compounds as PVCz(r and c), VCz Olig. I and II, and DCzP, the sandwich-like excimer formation has its maximum at *ca.* 293 K. On the other hand, in the case of PCzEVE, no appreciable change in the fluorescence spectra near 23900 cm^{-1} is observed over a wide temperature range, as is shown in Fig. 8. These facts indicate that PCzEVE does not form the sandwich-like excimer which is formed in PVCz(r and c), VCz Olig. I and II, and DCzP.

The emission spectrum of PCzEVE in rigid glass at 77 K is also shown in Fig. 3. The fluorescence spectrum of VCz Olig. II has, roughly, a so-called "mirror-symmetry" relation between the absorption and the fluorescence spectra (Fig. 3). However, PVCz(r and c) and PCzEVE do not have the mirror-symmetry relation. In particular, the fluorescence spectrum of PCzEVE is at a longer wavelength than that of PVCz(r and c) and has a different shape. The absorption spectra of PVCz(r and c) and PCzEVE in rigid glasses at 77 K are sharper than that in fluid solutions at room temperature, but no appreciable new band is observed. The fluorescence excitation spectra of these polymers in rigid glasses at 77 K are also in agreement with their absorption spectra. The resolution of the phosphorescence spectrum of PCzEVE is lower than those of *i*-PrCz and VCz Olig. I, the spectrum is very similar to that of PVCz(r and c), although its lifetime (6.6±0.1 s) is shorter than that of PVCz(r and c) (8.1±0.2 s).[16] Therefore, the excited-state interactions are present among the Cz chromophores in PCzEVE even at low temperatures, at which the solvent becomes rigid (*ca.* 102 K).

It has been reported that the triplet energy migration in PCzEVE occurs in rigid glass at 77 K.[16] The degrees of polarization of fluorescence for PVCz(r), PCzEVE, DCzP, and *i*-PrCz in rigid glasses at 77 K are shown in Fig. 9. The degrees are almost the same for PCVz(r) and for PCzEVE. This fact indicates that the singlet energy migration in PCzEVE occurs efficiently along the polymer chain, as is the case in PVCz.[7]

The concentrated THF solution of PCzEVE (0.5 M) shows the same spectra as in a dilute solution near 223 K and above.

As has been mentioned above, PPyMVE, PNMVE, and PNMA show both the normal structured monomeric fluorescence and the sandwich-like excimer fluorescence in dilute solutions. On the other hand, poly[2-(9-phenanthryl)ethyl vinyl ether] (PPhEVE), with phenanthryl chromophores widely spaced on the main chain by $-O-CH_2-CH_2-$ bonds, as does PCzEVE, shows, only the monomeric structured fluorescence in a dilute solution at room temperature.[26] The fluorescence structure and lifetime in a dilute solution are almost the same as those of 9-ethylphenanthrene. It is well-known that the excimer fluorescence of phenanthrene is not observed at room temperature.[27] In the case of PCzEVE, in which aromatic chromophores

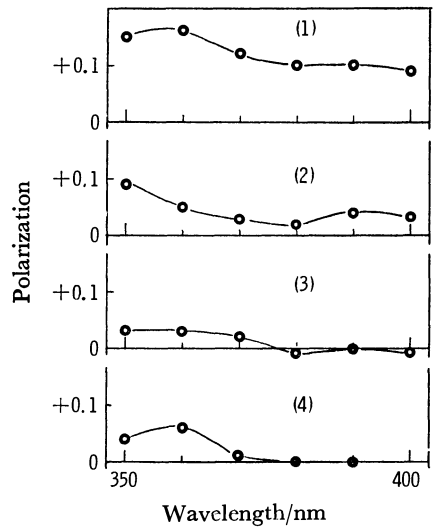

Fig. 9. Fluorescence polarizations of MTHF–THF rigid glasses of (1) *i*-PrCz (6.7×10^{-5} M), (2) DCzP (7.3×10^{-5} M), (3) PCzEVE (9.6×10^{-5} M), and (4) PVC(r) (1.0×10^{-4} M) at 77 K. Excitation wavelength; 334 nm.

are widely spaced on the skeletal chain than in PPyMVE, PNMVE, and PNMA, it is surprising that the normal structured monomeric fluorescence is not observed at all. The fact that the sandwich-like excimer fluorescence of PCzEVE is not observed in either dilute or concentrated solutions at room temperature also supports the idea that the sandwich-like excimer formation in PVCz is possible only between two adjacent chromophores.[7]

The above-described results indicate that the excited-state interaction among the Cz chromophores in PCzEVE is quite different from that is DCzP, VCz Olig. I and II, and PVCz(r and c), and that, in some vinyl polymers with aromatic chromophores widely spaced on the main chain, only PCzEVE is unique. This behavior of PCzEVE may reflect a characteristic of the bulky Cz chromophore.

The position of the PCzEVE fluorescence band in solution at room temperature is almost the same as that of the fluorescence in the shorter wavelength regions of PVCz(r and c) and VCz Olig. I and II, although the appearance of the structure below *ca.* 273 K is different. The initial fast decay constant of the PCzEVE fluorescence (11—14 ns) is nearly equal to the lifetime of the 370 nm fluorescence of PVCz in the polycrystalline THF matrix at 77 K (the order of 15 ns); at 370 nm the emission of PVCz is totally that due to the second excimer.[9] Therefore, one of the emitting species of PCzEVE in solution may be the same as a species emitting in the shorter-wavelength region of PVCz in solution (second excimer), although there remains the problems that the fluorescence lifetime of PCzEVE in solution at room temperature is nearly equal to that in rigid glass at 77 K and that the monomeric fluorescence of PCzEVE is not observed, in spite of the small binding energy of second excimer (*vide infra*).

Formation of an Exciplex. The fluorescence spectra

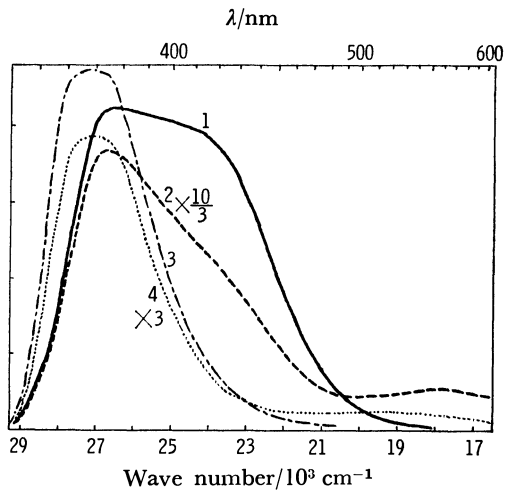

Fig. 10. Fluorescence spectra of PVCz(r) (3.9×10^{-4} M) and PCzEVE (1.9×10^{-4} M) in MTHF-THF degassed solutions in the absence and the presence of DMTP (1.9×10^{-2} M) at room temperature. The intensities of the spectra are not comparative for the different polymers.
(1) ——; PVCz(r) in the absence of DMTP, (2) ----; PVCz(r) in the presence of DMTP, (3) ——; PCzEVE in the absence of DMTP, and (4) ……; PCzEVE in the presence of DMTP.

of PVCz(r) and PCzEVE in degassed THF–MTHF solutions in the absence and in the presence of DMTP (6×10^{-2} M) are shown in Fig. 10. In the cases of PVCz (r and c) and VCz Olig. II, the fluorescence is nonuniformly quenched by DMTP, as in the case of PVCz(r) quenched by acids.[29] That is, the sandwich-like excimer fluorescence is quenched more effectively than the second excimer fluorescence. On the other hand, the fluorescence of PCzEVE is uniformly quenched by DMTP. In all cases, the exciplex fluorescence appears in the longer-wavelength region.

The quenching factor, Q, is defined by $Q=(I_0-I)/I$, where I_0 and I are the fluorescence intensity in the absence and in the presence of DMTP respectively. In determining the quenching factor, Q, of PVCz(r), the following equations have been used to separate the contribution of the second and sandwich-like excimer fluorescences at 370 and 420 nm:

$$I_{370} = I_s + 0.174I_E$$
$$I'_{420} = I_E + 0.064I_s$$
$$I_{420} = I'_{420} + 0.294I_{580}$$

where I_{370}, I_{420}, and I_{580} are the heights of the fluorescence intensity measured at 370, 420, and 580 nm respectively, I_E is the height corresponding to the sandwich-like excimer fluorescence intensity emitted at 420 nm, I_s is the height corresponding to the second excimer fluorescence intensity emitted at 370 nm, and I'_{420} is the height obtained by subtracting the contribution of the exciplex fluorescence intensity emitted at 420 nm from I_{420}. The contribution of the exciplex fluorescence intensity emitted at 420 nm has been estimated from the corrected spectrum of the THF solutions of PVCz(r) (9.2×10^{-5} M) and DMTP (0.155 M). The concentrations of the second excimer fluorescence intensity at 420 nm and the sandwich-like excimer fluorescence at 370 nm have been determined from the resolution spectra of PVCz(r) (Fig. 2). The dependence of the quenching factor, Q, of PVCz(r) on the concentration of DMTP is shown in Fig. 11. The second excimer band is linearly quenched, and the sandwich-like excimer band is superlinearly quenched. The quenching of the second and the sandwich-like excimer fluorescence seems to be described by the same reaction scheme as in the case of acid,[28] assuming that the monomer is replaced by the second excimer. Then,

$$K_s = k_a/(k_f+k_r+k_E) = k_a\tau_s = 57\ \mathrm{M^{-1}}$$
$$K_E = k_a'/(k_f'+k_r') = k_a'\tau_E = 13\ \mathrm{M^{-1}}$$

where k_f, k_r, and k_a are the radiative, nonradiative, and quenching rate constants respectively. The letters with prime and nonprime show the second and sandwich-like excimers respectively. The k_E is the rate constant of the conversion of the second excimer to the sandwich-like one. The τ_s and τ_E are the second and sandwich-like excimer fluorescence lifetimes, both in the presence of k_E and in the absence of DMTP respectively. From the measured fluorescence decay curves of PVCz(r) in an aerated THF solution at room temperature,[29] $\tau_s\sim4\times10^{-9}$ s and $\tau_E\sim17\times10^{-9}$ s. Then, $k_a\sim1\times10^{10}\ \mathrm{M^{-1}\,s^{-1}}$ and $k_a'\sim8\times10^{8}\ \mathrm{M^{-1}\,s^{-1}}$. Therefore, the quenching reaction is much more efficient for the second excimer than for the sandwich-like one.

If the PVCz–DMTP exciplex was formed between the migrating excited singlet state of the Cz chromophores and DMTP, the second excimer fluorescence would be also superlinearly quenched by DMTP, as is the case of the sandwich-like excimer fluorescence

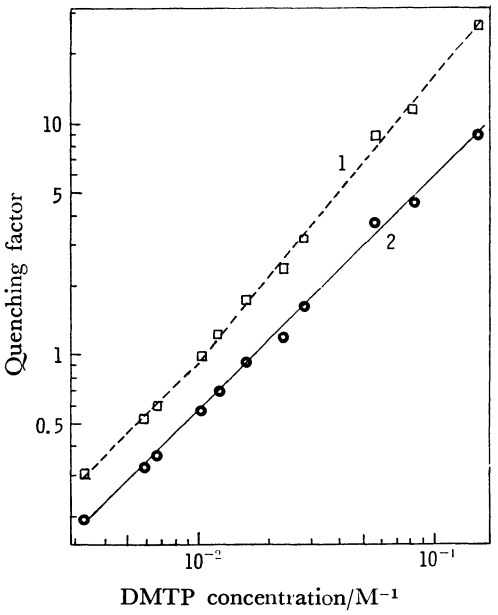

Fig. 11. Quenching of PVCz(r) by DMTP in THF aerated solutions at room temperature. Excitation wavelength; 345 nm.
(1) The sandwich-like excimer band, and (2) the second excimer band.

quenched by DMTP. Therefore, the PVCz–DMTP exciplex seems to be formed between the second excimer site and DMTP. This phenomenon seems to be supported by the fact that the intensity of the PVCz-(r)–DMTP exciplex is larger than that of the PVCz(c)–DMTP exciplex when the concentrations of the same donor and acceptor are the same. Therefore, the second excimer has a very binding energy, so it seems to dissociate to form the exciplex by the diffusive approach of DMTP.

The authors wish to express their thanks to Professor Noboru Mataga, Dr. Tadashi Okada, Dr. Hiroshi Masuhara, and Dr. Nobuaki Nakashima at Osaka University for helping us to measure the decay curve and to construct the N_2 gas laser.

Heat Capacities and Some Vibrational Properties of Rubidium Chloride

Yoshiyuki HIGASHIGAKI and Hideaki CHIHARA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received March 1, 1976)

Molar heat capacities of RbCl were measured between 3 and 300 K with an adiabatic calorimeter and complete thermodynamic properties of the solids have been obtained. The nature of the lattice vibration spectrum of RbCl is examined in terms of the moments of spectrum. Values derived are $\theta_0=184.9\pm1.3$ K, $\theta_\infty=190.0\pm1.0$ K, E_z(zero-point energy)$=3.43\pm0.01$ kJ mol^{-1}. Those properties depend on the kind of cation rather than on the anion in alkali halides. Anharmonicity in the vibration is also discussed.

Because of their simple nature of crystal structure and atomic forces, alkali halides have been investigated by theory and experiment most extensively of all ionic solids. While the nature of lattice vibrations in these solids has been generally understood, the stability of crystal lattices, particularly the relative stability of structures, NaCl type and CsCl type, remains to be explored in relation to the difference in the vibrational properties.

Rubidium chloride occupies a special position among the alkali halide family because it exists in the two modifications, NaCl structure under ordinary conditions and CsCl structure under applied pressure.[1] The reason for the bimorphism lies in the fact that the ratios of radii of the cation and the anion assumes a value close to the critical value of 0.73 which separates the theoretical stability region of the two structures. Decreased stability of NaCl structure in the case of RbCl is expected to be seen in its vibrational properties.

Several papers[2,3,4] have been published to report the heat capacities of rubidium chloride since our measurements were concluded. However, those results are neither mutually consistent where they may be compared nor complete in that only derived quantities are given.

The purpose of the present paper is two fold: One is to provide complete thermodynamic properties of RbCl to help to understand its vibrational properties and the other is to provide heat capacity values of one of the components in the binary system NH_4Cl–RbCl which has been studied in this laboratory.

Experimental

Materials. Reagent grade rubidium chloride (Nakarai Chemicals, Ltd., stated minimum purity 99.5%) was dried *in vacuo* in a temperature-controlled quartz tube at 300 °C for 14 h. The high sensitivity DTA thermogram and the powder X-ray diffraction pattern showed no indications of trace of water or trace of the CsCl-type structure. Sample weight used for calorimetry was 69.0328 g (*in vacuo*) or 0.57980 mol.

Calorimeter and Cryostat. The calorimeter was of adiabatic type, the description of which has been reported elsewhere.[5,6] Helium exchange gas less then 1.6×10^{-6} mol was put into the calorimeter vessel to aid in thermal equilibration within it. No correction was made for the presence of the exchange gas in computing the heat capactiy values.

Temperature Scales. The working thermometer above 15 K is the Leeds & Northrup platinum resistance thermometer (model 8164), the temperature scale of which was fixed in our laboratory by comparison with another thermometer calibrated at the U. S. National Bureau of Standards, based on the IPTS-48 and the provisional NBS-55 scales. Below 15 K the thermometer was the germanium resistance thermometer (CryoCal, Inc., laboratory designation β), which had been calibrated in our laboratory.[7]

Results

Molar heat capacities at constant pressure are given in Table 1 and Fig. 1. The temperature rise in each measurement was small and therefore no curvature correction was necessary. Precision of the measurements was within 7.6% below 11 K, 1.0% from 11 to 20 K, and 0.6% above 20 K. Our results are compared with the results of Paukov and Khriplovich and Kirkham and Yates in Fig. 2, showing that our values lie intermediate between the two previous ones.

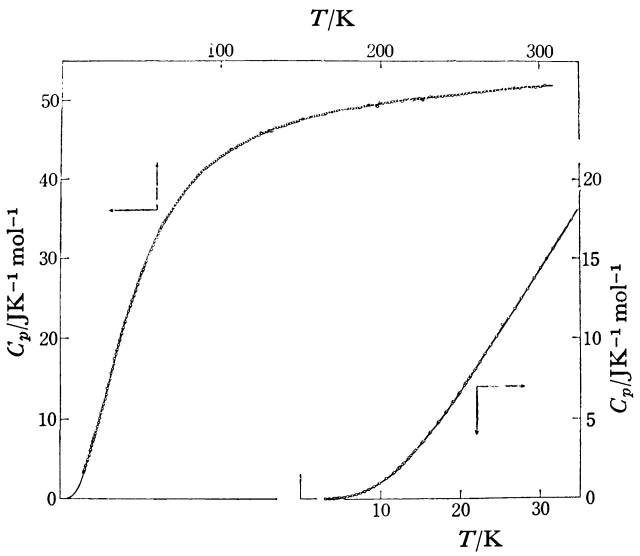

Fig. 1. Molar heat capacity of rubidium chloride.

Thermodynamic functions of rubidium chloride based on the smoothed heat capacity curve are given in Table 2.

Analysis of Experimental Results

Conversion of C_p to C_v and the Debye Temperature. The heat capacity at constant volume C_v was obtained from the heat capacity at constant pressure C_p by help of the standard thermodynamic equation,

$$(C_p-C_v)/C_p = \{1+(\chi_s C_p/\beta^2 VT)\}^{-1}$$

where χ_s is the adiabatic compressibility, β the volume expansion coefficient, V the molar volume, and T the absolute temperature.

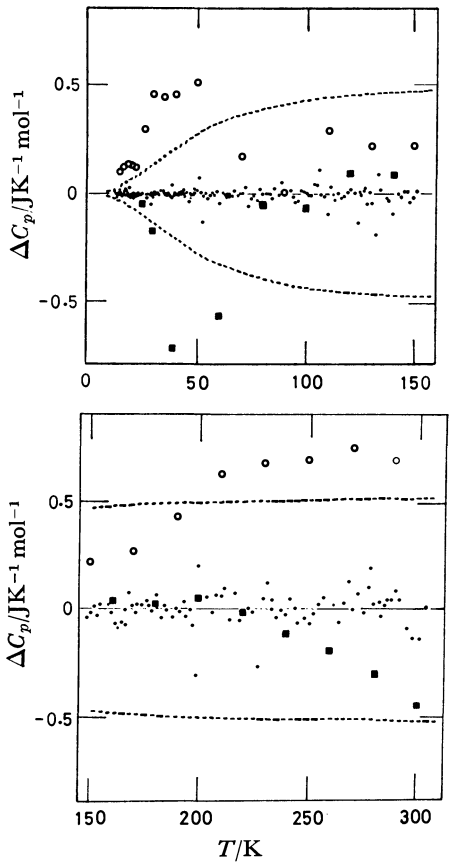

Fig. 2. Deviation plot based on our smoothed values. ----: 1% of C_p, ●: Present results, ■: Kirkham and Yates, ○: Paukov and Khriplovich.

To obtain values of the thermal expansion coefficient, we used Cooper and Yates' results[8] from 30 K to 260 K which were extrapolated to either temperature side in a manner consistent with other alkali halides.[9] Temperature dependence of adiabatic elastic constant of rubidium chloride was taken from the paper by Gluyas *et al.*,[10] because of better accuracy than others.[11,12] The χ_s values below 140 K were obtained by extrapolation. Density below room temperature was also obtained from the published values.[11,12]

The correction $C_p - C_v$ thus evaluated is negligibly small below 50 K, 0.1% of C_p at 100 K, 0.2% at 200 K, and 0.4% at 300 K.

The Debye characteristic temperature $\theta_D(V_T)$ derived from the C_v values depends on the crystal volume at the temperature T. $\theta_D(V_0)$ for the volume at 0 K can be approximated by[13]

$$\theta_D(V_0)/\theta_D(V_T) = (V_T/V_0)^\gamma$$

where γ is the Gruneisen constant. The values of $\theta_D(V_0)$ thus obtained are plotted against T in Fig. 3. The shallow basin at about 90 K is due to the inconsistency inherent in the temperature scale near the normal boiling point of oxygen. The shape of $\theta_D(T)$ curve appears quite normal for an alkali halide crystal with the NaCl-type structure; the rapid decrease at higher temperatures may be attributed to anharmonicity of lattice vibrations. A minimum occurs at about 11 K, showing the deviation of the actual frequency spectrum from the Debye spectrum. Similar minima for sodium chloride and for potassium chloride were explained theoretically by Kellerman[14] and by Jona,[15] respectively, applying the Born-von Karman theory.

The Debye characteristic temperature at 0 K, θ_0, was calculated from the intersection at $T^2=0$ of the C_pT^{-3} *versus* T^2 plot (Fig. 4) to give $\theta_0 = 18.49 \pm 1.3$ K. This value is compared with values determined by other measurements and also with the values for other alkali chlorides and rubidium halides in Table 3.

The θ_0 reported by Rallefson and Perssini is 168.5± 2.5 K, some 16 K lower than ours. However, their θ_D curve shows a peculiar behavior below 2 K which obscures the method by which their value was determined. Within the series of chlorides or the series of rubidium salts, it is seen the θ_0 decreases as the mass of constituent ion increases. This tendency agrees with

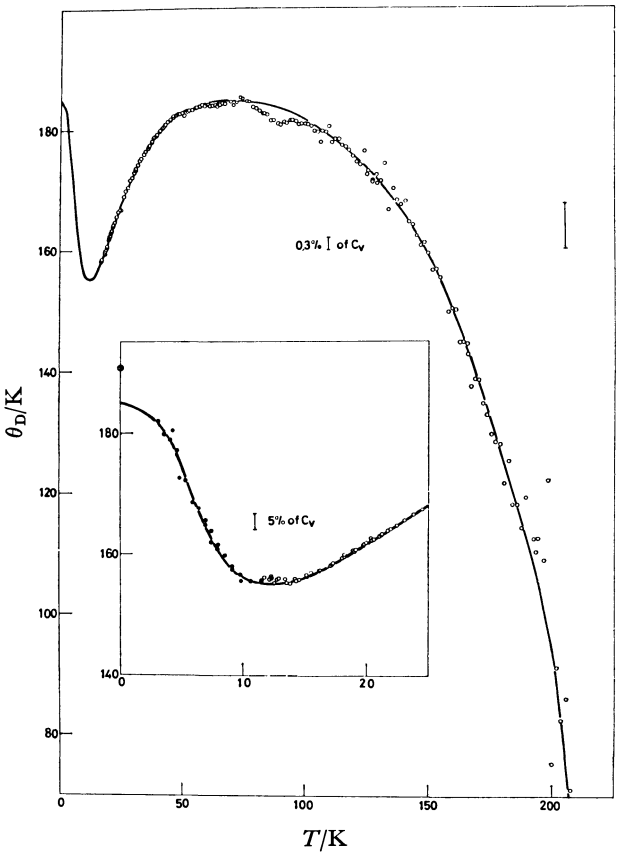

Fig. 3. Temperature dependence of the Debye characteristic temperature, $\theta_D(V_0)$.

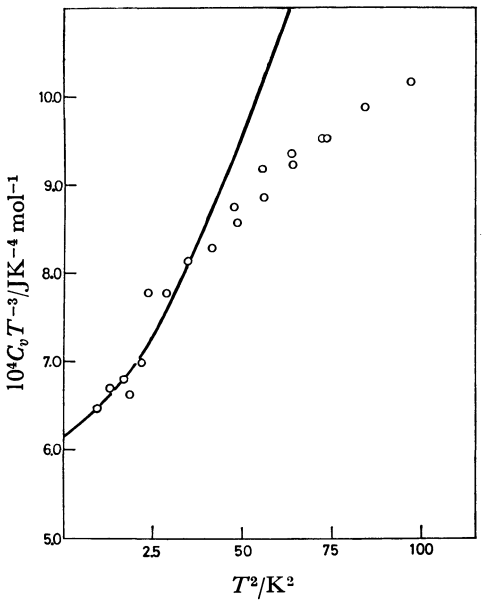

Fig. 4. Determination of θ_0 at 0 K.

the theoretical prediction that the θ_0^2 is inversely proportional to the molecular weight. An interesting feature in this connection is an empirical relation shown in Fig. 5 which is a plot of $\theta_0\sqrt{M}$ *vs.* $\sqrt{r}$ where M is the molecular weight and r the sum of constituent ionic radii.

Moments of Lattice Vibration Spectrum and Related Thermodynamic Properties. The accuracy with which

TABLE 3. COMPARISON OF θ_0 OF ALKALI CHLORIDE AND RUBIDIUM HALIDES

Alkali halide	Calorimetric	Ultrasonic	Inelastic

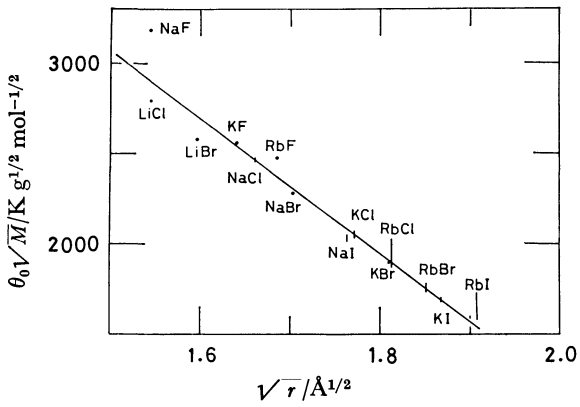

Fig. 5. Plot of $\theta_0\sqrt{M}$ *versus* $\sqrt{r}$.

the heat capacity may be determined for insulators does not permit to deduce the entire lattice vibration spectrum with a reasonable reliability. This was demonstrated by Barron and Morrison in the case of sodium chloride.[20] Instead, it is of more practical significance to derive the moments of vibration spectrum which are readier to compare for different alkali halides and which can be directly related to some thermodynamic properties.

The moment values were thus evaluated by using expansion formulae of the Debye temperature, the harmonic thermal energy, the harmonic entropy, and $C_v^{(h)}/T^n$. The results are summarized in Table 4 in the form of the $\nu_D(n)$ function.[13]

Now we shall attempt to compare the moment values of the thermodynamic properties derived therefrom with the values from other sources.

TABLE 4. VALUES OF $\nu_D(n)$

n	$\nu_D(n)$/10^{12}Hz	n	$\nu_D(n)$/10^{12}Hz
−3	3.85±0.03	1	3.82±0.02
−2	3.48±0.07	2	3.96±0.03
−1	3.41±0.04	4	4.10±0.04
0	3.62±0.02	6	4.17±0.11

The zero-th moment μ_0 is related to the geometric mean frequency $\nu_g=2.59\pm0.02$ THz, which may be compared with values 4.242 ± 0.013 THz for NaCl[13] and 3.412 ± 0.010 THz for KCl.[13] Similarly the zero point energy E_z decreases as the mass of the constituent ion increases; thus E_z of RbCl derived from the first moment in 3434 ± 10 J mol^{-1}, the smallest value for the alkali chloride having the NaCl structure.

The second moment is related to the high-temperature limit of the Debye temperature, $\theta_\infty=190.0\pm1.0$ K. This value agrees with 191 K obtained from inelastic scattering of neutrons[16] and also with 191 ± 1 K obtained from the Blackman's formula.

$$\theta_\chi=\frac{\hbar}{k}\left(\frac{5r_0}{\chi}\right)^{1/2}\left(\frac{1}{m_+}+\frac{1}{m_-}\right)^{1/2}$$

using the compressibility $\chi=5.54\times10^{-12}$ dynes cm^{-2} and the lattice constant $2r_0=6.581$ Å at 300 K.

Negative moments μ_{-1} and μ_{-2} are related to the Debye-Waller factors at $T=0$ and $T=\infty$ respectively, which appear in the diffraction intensity. However, no such information to compare with is available at the present time.

General shape of the $\nu_D(n)$ curve as shown in Fig. 6 is what one would expect for an ionic crystal although there are some differences in absolute values between ours and those by Cooper and Yates.

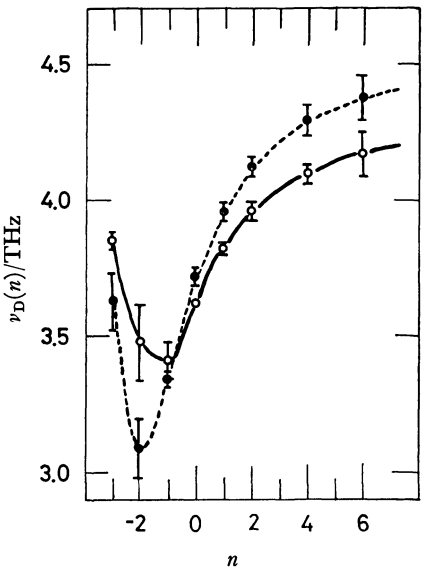

Fig. 6. Comparison of $\nu_D(n)$ function.

The differences come from the fact that Cooper and Yates gave smaller heat capacities than ours in the low temperature region.

Cation Effect and Anharmonicity. Figure 7 compares the reduced characteristic temperature $\theta_D(V_T)/\theta_\infty$ of the alkali chlorides.

It is clearly seen that as the mass of constituent ion increases, the value of θ_D/θ_∞ generally decreases and the temperature at which θ_D/θ_∞ becomes minimum goes lower. Similar tendency is also found in the case of potassium halides[13] although to a much smaller extent: thus this may be called the cation effect.

Blackman[21] showed that the ratio θ_0/θ_∞ should be

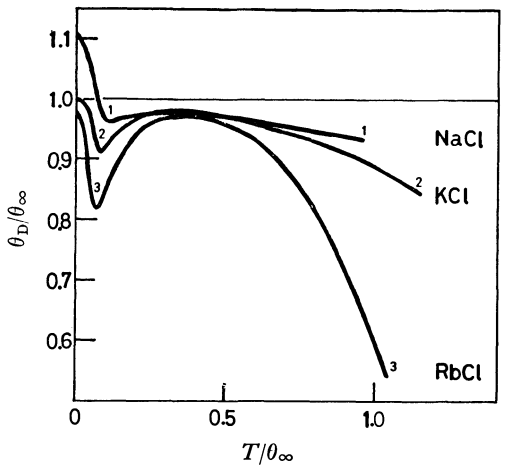

Fig. 7. Comparison of the reduced characteristic temperature.

proportional to $\sqrt{1-\eta^2}$, where $\eta=(m_+-m_-)/(m_++m_-)$. Table 5 suggests that the value of this proportionality constant is not really a constant but depends more critically on the alkali ion than on the halide ion. Barron *et al.*,[13] estimated the constant for RbBr and RbI to be probably within 10% of 0.95, in agreement with the value for RbCl. A simple calculation shows that the magnitude of this constant depends only on the elastic constants. Because the large effect of the alkali metal ion on the magnitude of the elastic anisotropy $c_{44}/(c_{11}-c_{12})$ was shown in Table X of Lewis, Lehoezky, and Briscoe's paper,[19] we may attribute the cation effect that has been demonstrated here also to that appearing in the elastic properties.

Table 5. Dependence of θ_∞/θ_0 upon mass ratio

Salt	θ_∞/θ_0	$\sqrt{(1-\eta^2)}$	$(\theta_\infty/\theta_0)\sqrt{(1-\eta^2)}$
NaCl[a]	0.905	0.977	0.88
NaI[a]	1.188	0.721	0.86
KCl[a]	1.002	0.999	1.00

CsBr[c]	0.8816	0.9685	0.854
CsI[c]	0.8556	0.9997	0.855

a) Barron, *et al.*[13] b) Present work. c) Sorai.[22]

The cation effect also appears in anharmonicity of lattice vibrations. The anharmonic effect comes to be observable in thermodynamic functions such as heat capacity usually at temperatures higher than $(1/2)\theta_\infty$. In the case of RbCl, θ_∞ is 190 K and the maximum of θ_D occurs at 75 K. The magnitude of the anharmonic effect is represented and measured by the anharmonic coefficient A defined by

$$(F-F^h)/6Nk=-\frac{1}{2}AT^2+B+0(T^{-2})$$

or

$$(S-S^h)/6Nk=(C_v-C_v^h)/6Nk=AT$$

for the alkali halides, where $|AT|<1$.

Thus the quantity AT is the leading anharmonic contribution and its coefficient A depends on the volume only. Tosi and Fumi[23] gave more accurate formula for estimating the value of $A(V_0)$;

$$A = \frac{\theta_S - \theta_S^h}{T^2} \frac{d}{d(\theta_S^h/T)} \left(\frac{S^h}{6Nk} \right)$$

where θ_s is the experimental Debye temperature derived from the entropy for the volume at 0 K, θ_S^h the quasiharmonic Debye temperature computed from the ν_g and μ_n, S^h the quasiharmonic entropy, and $T \geqq \theta_\infty$. The coefficient for rubidium chloride was then estimated to be $A = (9.3 \pm 1.7) \times 10^{-5}\,K^{-1}$, using the Tosi-Fumi formula, and this is included in Table 6 for comparison of the anharmonic coefficients of various alkali halides.

Table 6. ANHARMONIC COEFFICIENT $A(V_0)$

Salt	$A(V_0)$ / $10^{-5}\,K^{-1}$	Salt	$A(V_0)$ / $10^{-5}\,K^{-1}$

KBr[c]	3.5 ± 1.0		
KI[b]	0.5 ± 0.5	CsBr[e]	-11.4 ± 0.3
		CsI[e]	-9.0 ± 0.3

a) Vieira and Hortal,[24] using a method different from Tosi-Fumi's method. b) Tosi and Fumi.[23] c) Leadbetter, *et al.*[25] d) Present work. e) Sorai.[22]

The coefficient for rubidium chloride is the largest among the alkali halides having the NaCl-type of structure and the sign and the magnitude of the coefficient is primarily determined by the kind of constituent cation.

The authors wish to express their gratitude to the assistance provided by Dr. T. Atake.

MO-theoretische Untersuchung der Nucleophilen Substitution Einiger Silacycloalkane

Gernot FRENKING, Hiroshi KATO,* und Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

**College of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received March 13, 1976)

CNDO/2 calculations have been carried out for $(CH_2)_{n-1}SiMeH$ and $(CH_2)_{n-1}CMeH$ with $n=3$, 4, 5, and 6. It is found that the electronic structure of the two classes of compounds shows principal differences in the ring-size dependence. It is suggested that this is the reason for the different ring dependence of the reactivity in the nucleophilic substitution reaction.

Die Ringgrößenabhängigkeit der cyclischen Organosilane $(CH_2)_{n-1}SiMeH$ wurde für die Substitutionsreaktion mit wässrigalkoholischem Alkali experimentell mit $n=4 \gg 5>6$ ermittelt.[1,2] Die wesentlich höhere Reaktivität der viergliedrigen Verbindung gegenüber fünfgliedrigen steht im Kontrast zu den Cycloalkanen, bei denen die Ringabhängigkeit von $(CH_2)_{n-1}CMeCl$ in der S_N2 Reaktion mit $n=3<4<5>6$ gefunden wurde.[3] Dabei übernimmt wegen des relativ elektropositiven Charakters des Silizium der damit verbundene Wasserstoff die Rolle des elektronegativen Substituenten im analogen Cycloalkan, im angeführten Beispiel die des Chlor. Zur Erklärung dieses Sachverhaltes wurden sterische Gründe angegeben, wonach für die Silacycloalkane in einem 'flank'-Angriff (Abb. 1a) der CH_2–Si–CH_2 Winkel α im Übergangszustand, 90°, demjenigen der viergliedrigen Ringverbindung im Grundzustand am nächsten kommt. Danach muß für die viergliedrige Ringverbindung zur Bildung des Übergangszustandes die geringste Ringspannung aufgewendet werden.[1] Unsere Berechnungen ergaben jedoch, daß der Wert für α in der fünfgliedrigen Verbindung näher an 90° liegt als der der viergliedrigen. Daher ist die gennante Erklärung fragwürdig.

Einzelheiten der Rechnungen

Die meisten Energieberechnungen wurden mit Hilfe der CNDO/2 Methode von Pople *et al.* durchgeführt.[4] Einige Berechnungen erfolgten im Rahmen von CNDO/2 unter Einschluß der d-Orbitale am Si.[5] Lokalisierte Orbitale wurden mit Hilfe der 'Energieminimisierungsmethode' von Edmiston und Ruedenberg[6] erhalten, basierend auf INDO MOs.[7] Berechnet wurden die Verbindungen $(CH_2)_{n-1}SiMeH$ und $(CH_2)_{n-1}CMeH$ mit $n=3$, 4, 5, und 6, welche von nun an mit Si(3) C(3), Si(4), usw. bezeichnet werden. Si(3) wurde aus Vergleichsgründen miteingeschlossen obwohl es noch nicht synthetisiert werden konnte.[8]

Für die Cycloalkane wurde die Geometrie der unsubstituierten Verbindungen übernommen,[9] und die CH_3-Gruppe wurde mit Tetraederwinkel am Kohlenstoff und einer C–C Bindungslänge von 1.52 Å plaziert.

Für die Geometrie der Silacycloalkane liegen keine experimentellen Daten vor. Für α wählten wir zunächst jene Werte, die entweder in der Literatur vorgeschlagen wurden,[10] oder an Hand von Analogbetrachtungen an Cycloalkanen am wahrscheinlichsten schienen. Fernerhin berechneten wir jedes Molekül mit einem abweichenden Wert. Tabelle 1 zeigt die Werte für α. Jene Geometrien die energetisch günstiger liegen sind mit 'normal', die anderen mit 'deformiert' bezeichnet. Bezüglich der Bindungslängen wurde der Si–C Abstand mit 1.85 Å für Si(6) und Si(5), und mit 1.94 Å für Si(4) als Wert für die Ringbindung eingegeben. Si(3) wurde mit beiden Werten berechnet. Die Bindungsabstände für die Si–CH_3 und Si–H Bindungen sind jeweils 1.85 Å und 1.48 Å. Si(4) wurde mit einer nichtplanaren Geometrie bei einem Biegungswinkel von 36°[11] berechnet; Si(5) wurde mit planarer Ringgeometrie berechnet, Si(6) in der Sesselform und einem Biegungswinkel von 54°45′. Die übrigen Geometriedaten wurden von den analogen Cycloalkanen unter Berücksichtigung der obigen Werte übernommen.

	Si(3)	Si(4)	Si(5)	Si(6)
'Normal'	47°40′	83°	90°	83°
'Deformiert'	50°10′	90°	100°	120°

Ergebnisse und Diskussion

Die CNDO/2-Ergebnisse wurden auf Anhaltspunkte zur Erklärung des experimentellen Sachverhaltes untersucht. Tabelle 2 zeigt für die berechneten Verbindungen die Energielagen und wichtigsten AO-Koeffizienten der LUMOs (lowest unoccupied MO), die gemeinsam mit dem HOMO (highest occupied MO) des OH^- die dominierende Rolle in der Orbitalwechselwirkung spielen. Der antibindende Charakter in der X–H (X=Si, C) Bindung ist in den LUMOs der Si-Verbindungen wesentlich ausgeprägter als in denjenigen der C-Verbindungen. Fernerhin zeigt sich als wichtigster AO-Koeffizient des Si das isotrope s-AO, welches eine bedeutende Rolle in dieser Reaktion spielt, während dies im Falle der C-Verbindungen ein pσ-AO ist. Abgesehen von diesen Unterschieden zeigt sich daß die Energielagen der LUMOs mit der Ausnahme von Si(6) völlig mit der o.g. Reihenfolge der Reaktivität übereinstimmen; außerdem lassen sie für das hypothetische Si(3) eine geringe Reaktivität erwarten. Die Tatsache daß die Energielagen der Si-LUMOs deutlich niedriger als die der C-LUMOs liegen kann als eine Begründung für die höhere Reaktivität der Si-Verbindungen angesehen werden.

In Tabelle 3 ist die Ladungsverteilung an den Angriffszentren (Si bzw. C) und dem damit verbundenen Wasserstoff verzeichnet, sowie die E_{AB}-Werte für die Si–H und C–H Bindungen die während der Reaktion

aufbrechen. Obwohl die CNDO/2 Resultate eine unvernünftige C^+–H^- Polarisation angeben—mit allerdings recht kleinen Absolutwerten—ist der Trend in Abhängigkeit von der Ringgröße deutlich von dem der Si–H Bindung verschieden, und mit der Ausnahme von C(6) stimmt die Größenfolge mit derjenigen der Reaktivität uberein. Die E_{AB}-Werte zeigen mit steigender Ringgröße regelmäßig abnehmende Werte für die C–H Bindung und einen regelmäßigen Anstieg für die Si–H Bindung. Dies deutet einen prinzipiellen Unterschied in der Ringabhängigkeit der elektronischen Struktur für die Silacycloalkane zu den Cycloalkanen an, obwohl die unregelmäßige Ringabhängigkeit nicht reflektiert ist.

Bezüglich der lokalisierten MOs (LMOs) hatten wir in früheren Untersuchungen gefunden, daß in Cycloalkanen der %s Charakter der C–H Bindungen mit steigender Ringgröße abnimmt, während er in der C–C Bindung ansteigt, womit die Ringabhängigkeit der elektronischen Struktur wiedergegeben wird.[12] Obige Resultate lassen typische Unterschiede für silacycloalkane erwarten. In Tabelle 4 ist der %s Charakter am Si für die Si–H und Si–C Ringbindung der Silacycloalkane, sowie des attackierten Kohlenstoffs in der C–H und C–C Ringbindung verzeichnet. Es zeigen sich in der Tat deutliche Unterschiede im Trend zur Ringgröße. Die Reihenfolge für die Si–H Bindung ist $n=3>4<5<6$, und ein umgekehrter Ablauf ergibt sich für die Si–C Bindung, was völlig mit der experimentellen Reihenfolge übereinstimmt. Besonders die extremen Werte des Si(3) sind zu beachten. Der recht geringe %s Wert für die Si–C Bindung deutet eine schwache Ringbindung an und erklärt die Tatsache, daß diese Verbindung bis jetzt nicht synthetisiert werden konnte.

Die Übereinstimmung mit der experimentellen Ringgrößenabhängigkeit ist mit Ausnahme von C(6) auch für die Cycloalkane gegeben. Wie im Falle der Ergebnisse der Ladungsverteilung und der Energielagen der LUMOs ist es die sechsgliedrige Verbindung, bei der die berechneten Daten mit der experimentellen Reihenfolge nicht übereinstimmen und eine zu große Reaktivität angeben. Eine Erklärung liegt darin daß der recht voluminöse sechsgliedrige Ring eine zusätzliche sterische Hinderung der Reaktion bedeutet und die normal erwartete Übereinstimmung mit den theoretischen Daten unterbricht.

Zur Illustrierung der Ringbindungen in den berechneten Verbindungen ist in den Abbildungen 2 und 3 die LMO-Elektronendichteverteilung für die drei- und fünfgliedrigen Moleküle graphisch dargestellt. Es zeigt

sich daß die Ladungsverteilung in den C–C Bindungen durch den Methylsubstituenten bzw. das Siliziumatom kaum beeinflußt ist. Das Si–C LMO zeigt klar die größere Elektronegativität des Kohlenstoffs an. Fernerhin ist in den dreigliedrigen Verbindungen der Charakter der gebogenen Bindung ('bent bond') demonstriert.

Mit Hilfe des CNDO/2 Verfahrens berechneten wir die Energie des kombinierten Systems einer Cyclischen Verbindung und eines angreifenden OH^- Ions, welches einem Übergangszustand entspricht. In der Literatur sind .verschiedene Angriffswege bei der Substitution am

a) A: 'normal flank'; B: 'deformiert flank'; C: 'normal rück'; D: 'deformiert rück'. b) Der Zahlenwert in der Klammer zeigt die Energiedifferenz von Si(n) mit verschiedener Geometrie zum Grundzustand, in eV.

Silizium vorgeschlagen.[1,13] Wir berechneten Übergangszustände für Silacycloalkan+OH^-, die einem 'flank' bzw. 'rück'-Angriff entsprechen; ihre Geometrie ist in Abb. 1 demonstriert. Die Übergangszustände von Cycloalkan+OH^- wurden lediglich mit 'rück'-Konfiguration berechnet, da dies dem normalen S_N2 Mechanismus entspricht. Der C–O Abstand wurde mit 2.00 Å, der Si–O Abstand mit der normalen Si–O Bindungslänge von 1.63 Å eingegeben. Der Grund für die Wahl der normalen Bindungslänge im Falle der Silacycloalkane liegt darin, daß die S_N2 Reaktion am Silizium unter Bildung eines relative stabilen Übergangskomplexes verläuft, dessen Bindungslängen nahe denen von normalen Werten liegen.[14] Die Berechnungen wurden mit linearer Anordnung des OH^- in Richtung auf das Angriffszentrum (Si bzw. C) durchgeführt. Die Energiewerte der Systeme mit dieser Geometrie lagen niedriger als bei einem X–O–H (X=Si, C) Winkel von 105°. Dieses physikalisch unsinnige Ergebnis dürfte auf die CNDO/2 Näherungen zurückzuführen sein.

Die Berechnungen der Si-Übergangszustände wurden mit beiden Werten für α, also 'normaler' und 'deformierter' Ringgeometrie durchgeführt. Die Ergebnisse in Tabelle 5 zeigen zum einen, daß der 'rück'-Angriff in allen Fällen günstiger ist als der 'front'-Angriff.[15] Mit Ausnahme von Si(5) ist auch im Übergangszustand in allen Fällen die 'normale' Ringgeometrie günstiger als die 'deformierte'; im Fall von Si(5) ergibt ein Wechsel zur 'deformierten' Geometrie einen energetisch günstigeren Wert. Berechnungen im Rahmen von CNDO/2 unter Einschluß von d-Orbitalen am Silizium ergaben die gleiche Reihenfolge. Die Werte in Tabelle 5 zeigen jedoch auch daß die Energiedifferenz zwischen der jeweils günstigsten 'rück' und 'flank' Geometrie besonders im Fall von Si(4) und Si(5) nicht sehr groß ist. Dies deutet die Möglichkeit eines 'flank'-Attacks besonders für jene Fälle an, bei denen der 'rück'-Angriff sterisch behindert ist wie etwa bei Brückenkopf-Silacycloalkanen.[3]

Auch die Energiedifferenz der Silacycloalkane in den verschiedenen Übergangsgeometrien zur Grundzustandsgeometrie ist in Tabelle 5 gezeigt. Die Werte ergeben eine geringere Bevorzugung für den 'rück'-Angriff als im Fall der kombinierten System (Tabelle 5); im Fall von Si(3) liegt der Wert für die 'normal flank' Geometrie sogar am günstigsten. Es ist also weniger die geometrische Veränderung des Silacycloalkans die auf Bevorzugung des 'rück'-Angriffs verursacht, als vielmehr die bessere Angriffsmöglichkeit für das OH^- Ion.

In Tabelle 6 sind die Energiedifferenzen der Übergangszustände mit der jeweils günstigstem Geometrie, sowie diejenigen der Cycloalkane zur Summe von (Grundzustand+OH^-) angegeben in Relation zu den Werten für die viergliedrigen Verbindungen. Es zeigt sich daß die Berechnung der Gesamtenergie der kombinierten Systeme die Ringabhängigkeit der Substitutionsreaktion perfekt wiedergibt. Auch von diesen Werten läßt sich auf eine sehr geringe Reaktivität des Si(3) schließen.

Tabelle 7 führt die Ladungsverteilung am zentralen Si—bzw. C—Atom sowie dem damit verbundenen Wasserstoff im Übergangszustand auf. Weiterhin ist die Ladungsdifferenz (Δq(H)) des abgehenden Wasserstoffs verglichen zum Grundzustand sowie der Ladungsübergang (CT) vom OH^- zum attackierten Molekül verzeichnet. Aus den Werten geht hervor daß der Ladungsübergang fast ausschließlich vom OH^- Ion zum abgehenden Wasserstoff stattfindet; im Falle der Cycloalkane sind die Δq(H) Werte in einigen Fällen sogar größer als die CT-Werte, was auf zusätzliche Ladungstrennung im cyclischen Molekül zurückzuführen ist.

Tabelle 6. Energiedifferenz des Übergangszustandes mit der jeweils günstigsten Geometrie zum Grundzustand, relativ zu den Werten für X(4) (X=Si, C), in eV

	$n=3$	$n=4$	$n=5$	$n=6$
Si(n)	+0.68	0	+0.12	+0.17
C(n)	+0.59	0	−0.13	−0.05

Ein +(−) Zeichen kennzeichnet einen größeren (kleineren) Wert relativ zum jeweiligen X(4).

Tabelle 7. Ladung q, Ladungsdifferenz des abgehenden Wasserstoffs, Δq(H), sowie Ladungsaustausch CT vom OH^- zum X(n) (X=Si, C) im Übergangszustand

X	n	q(X)	q(H)	Δq(H)	CT
Si(n)	3	+0.903	−0.466	0.352	0.378
	4	+1.137	−0.531	0.375	0.360
	5	+1.156	−0.507	0.353	0.338
	6	+1.146	−0.512	0.365	0.361
C(n)	3	+0.176	−0.147	0.143	0.092
	4	+0.194	−0.141	0.137	0.089
	5	+0.190	−0.139	0.123	0.086
	6	+0.172	−0.137	0.109	0.128

Tabelle 8. Ladungsbindungsmomente der LMOs für die X-H (X=Si, C) Bindung im Grund (G) und Übergangszustand (T), in D

n	Si(n)		C(n)	
	G	T	G	T
3	1.08	3.56	0.05	0.93
4	1.21	3.84	0.11	0.84
5	1.12	4.05	0.12	0.87
6	1.15	3.98	0.23	0.87

Eine Analyse der LMO-Ergebnisse der Übergangszustände mit linearer X–O–H (X=Si, C) Anordnung zeigt folgende Eigenschaften: Das X–H (X=Si, C) LMO ist im Vergleich zum Grundzustand stärker zum Wasserstoff hin polarisiert, was durch die Werte für die Ladungsbindungsmomente μ_{AB} in Tabelle 8 demonstriert ist. Sie wurden nach folgender Gleichung berechnet:[12]

$$\mu_{AB} = 4.804 R_m (Q_{Ai} - Q_{Bi})$$

$$Q_{Ai} = (2 \sum_{t}^{\text{on A}} C_{it}(A)^2) - 1$$

Dabei ist R_m der halbe AB Bindungsabstand in Einheiten von Å, wobei der Ursprungspunkt der Mittelpunkt der AB Bindung ist. Q_{Ai} ist die atomare Ladung des Atoms A im i-ten LMO, welches in der AB Bindung lokalisiert ist. C_{it} ist der Koeffizient des t-ten AO des Atoms A im i-ten LMO. Die Summierung t läuft über alle Valenz-AOs des Atoms A.

Fernerhin ergaben die LMO Resultate neben einem O–H LMO drei räumlich verschiedene, ansonsten gleichwertige LMOs welche nahezu lone-pair LMOs am Sauerstoff vom sp^3-Typ darstellen, dabei jedoch deutliche Koeffizienten am X-Atom (X=Si, C) aufweisen.

Zusammenfassung

Die Ringgrößenabhängigkeit der elektronischen Struktur der untersuchten Silacycloalkane zeigt deutliche Unterschiede zu derjenigen von analogen Cycloalkanen. Dies wird als Grund für die unterschiedliche Ringgrößenabhängigkeit der Reaktivität dieser beiden Verbindungsklassen in der Substitutionsreaktion vorgeschlagen. Der Trend in den Energielagen der LUMOs, in der Ladungsverteilung am Reaktionszentrum, in den E_{AB}-Werten der sich lösenden Si–H bzw. C–H Bindungen sowie im %s Charakter der Si–H, Si–C bzw. C–H und C–C Bindungen in Relation zur Ringgröße weist einen charakteristisch unterschiedlichen Verauf auf der mit wenigen Ausnahmen mit den experimentellen Ergebnissen übereinstimmt. Lediglich die Werte für die dreigliedrigen Verbindungen weisen ähnlich extreme Daten auf die eine geringe Reaktivität auch für das hypothetische Si(3) andeuten.

Einer der Autoren (G.F.) ist Herrn Tsutomu Minato für die Beschaffung der Computerprogramme und auch Herrn Kazuyoshi Tanaka für die Beihilfe des Maschineschreibens zu Dank verpflichtet. Er bedankt sich ebenfalls beim Japanischen Erziehungsministerium sowie dem Deutschen Akademischen Austauschdienst für die Gewährung eines Stipendiums. Alle drei Autoren möchten ihre Dankbarkeit gegenüber dem Rechenzentrum der Kyoto Universität für die Benutzung des FACOM 230-75 Computers ausdrücken.

Preparation and Stereochemistry of a New Isomer (*Λ-cis-β*) of Cobalt(III) Complexes with (3*S*,8*S*)-3,8-Dimethyl-1,4,7,10-tetraazadecane[1)]

Masahiko SABURI, Teiji SATO, and Sadao YOSHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 17, 1975)

Carbonatocobalt(III) complex of (3*S*,8*S*)-3,8-dimethyl-1,4,7,10-tetraazadecane((3*S*,8*S*)-dimetrien) was prepared from *trans*-[$CoCl_2$((3*S*,8*S*)-dimetrien)]ClO_4 by treating with carbonate or hydrogencarbonate ion. The carbonato complex was assigned to the *Λ-cis-β* configuration, a novel geometry for the (3*S*,8*S*)-dimetrien complexes. The visible absorption, circular dichroism, and proton magnetic resonance data were obtained for the *Λ-β* and other carbonato complexes. Preparation and assignment of dinitrocobalt(III) complex with (3*S*,8*S*)-dimetrien are given. The relative stabilities of the four isomers of (3*S*,8*S*)-dimetrien complexes (*Λ-cis-α*, *Λ-cis-β*, *Δ-cis-β*, and *trans*) are discussed qualitatively.

Five stereoisomers are possible for the dianionocobalt(III) complexes of triethylenetetramine, one *cis-α*, two *cis-β*, and two *trans*. Of these isomers, the central metal ion is a chiral center except for one of the *trans* isomers (*meso-trans*). When a chiral tetramine obtained by introducing methyl group(s) into the carbon chain of trien is employed, the stereoisomers of cobalt(III) complex are sufficiently affected by the steric effects of the methyl substituents and give rise to the isomers of particular geometry and chirality.[2-5)] Three isolated isomers of dichloro- and dinitrocobalt(III) complexes with (3*S*,8*S*)-3,8-dimethyl-1,4,7,10-tetraazadecane (abbreviated as (3*S*,8*S*)-dimetrien), for instance, have the *Λ-cis-α*, *Δ-cis-β* and *trans* geometries, in which the absolute configurations of the two coordinated secondary nitrogen atoms have the combination of (*R*,*R*),[6)] (*R*,*S*), and (*S*,*S*), respectively.[2,3)]

The stereoselectivity found in the formation of the (3*S*,8*S*)-dimetrien complexes has been ascribed to the preferential equatorial orientation of the methyl groups with respect to the five-membered chelate rings.[2,3)] X-Ray diffraction studies demonstrated the preference of equatorial orientation of the methyl groups for the three isomers of dinitrocobalt(III) complexes.[7-9)] So far as the stereoisomers with the equatorial methyl groups are concerned, the possible isomers of (3*S*,8*S*)-dimetriencobalt(III) complex are those mentioned above (*Λ-cis-α*, *Δ-cis-β* and *trans*).

In the course of attempts to convert the *trans*-dichlorocobalt(III) of (3*S*,8*S*)-dimetrien into either of the *cis*-dichloro isomers, we have isolated a carbonato complex, which could be assigned to the *Λ-cis-β* configuration based on the data of circular dichloism (CD) and proton magnetic resonance (PMR). In the present report, the preparation and stereochemistry of the carbonatocobalt(III) complex of (3*S*,8*S*)-dimetrien will be described.

Experimental

Λ-β-Carbonato((3S,8S)-3,8-dimethyl-1,4,7,10-tetraazadecane)-cobalt(III) Perchlorate(Λ-β-[CoCO₃((3S,8S)-dimetrien)]ClO₄). To a solution of *trans*-[$CoCl_2$((3*S*,8*S*)-dimetrien)]ClO_4[2)] (0.50 g) in water (10 ml) was added lithium carbonate (0.20 g) and the mixture was heated for 30 min on a water bath (80 °C). Excess lithium carbonate was filtered off and the filtrate was evaporated to about 5 ml on a water bath. Five ml of methanol was added and the resultant precipitates were immediately removed by filtration. Solid lithium perchlorate (1.5 g) was added and dissolved. The sides of the vessel were scratched with a glass rod until red-violet crystals appeared. After being cooled in a refrigerator overnight, the crystals were collected, washed with methanol and ether, and air-dried. Yield, 0.25—0.30 g. The product was recrystallized from a small volume of water by adding methanol. Found: C, 27.32; H, 5.77; N, 13.75%. Calcd for [$CoCO_3(C_8H_{22}N_4)$]ClO_4: C, 27.57; H, 5.65; N, 14.27%.

This carbonato complex can be obtained in acidic condition as follows:

trans-[$CoCl_2$((3*S*,8*S*)-dimetrien)]ClO_4 (0.40 g) was dissolved in water (10 ml) and aquated for 30 min on a water bath (60 °C). To the resultant orange-red solution was added $NaHCO_3$ (0.20 g), the solution being left to stand at room temperature for 15 min. It was then evaporated to a volume of 5 ml, and methanol (5 ml) and solid lithium perchlorate (1.0 g) were added in succession. After being left to stand in a refrigerator overnight, the crystals which separated were filtered off, washed with methanol and ether, and air-dried. Yield, 0.25 g.

Λ-β-Carbonato((3S,8S)-3,8-dimethyl-1,4,7,10-tetraazadecane)-cobalt(III) Perchlorate (Λ-β-[CoCO₃((3S,8S)-dimetrien)]ClO₄·2H₂O. Crude *Λ-cis-β*-[$CoCl_2$((3*S*,8*S*)-dimetrien)]ClO_4[2)] (1.30 g) was added to 20 ml of 0.01 M $HClO_4$ and dissolved by vigorous shaking. After shaking for 3 min, the undissolved materials (mainly *Λ-cis-α*-[$CoCl_2$((3*S*,8*S*)-dimetrien)]ClO_4) were removed by filtration. The filtrate was heated for 5 min on a water bath (70 °C), and 0.60 g of $NaHCO_3$ was added in small portions. Solid sodium perchlorate (1.0 g) was added and the deep-red solution was kept in a refrigerator overnight. Deep-red crystals were collected, washed with cold water and ethanol, and air-dried. Yield, 0.58 g. More crystals were recovered from the above filtrate by evaporating on a rotary evaporator. (0.20 g). All the products were recrystallized from warm water. Found: C, 25.33; H, 6.08; N, 13.28%. Calcd for [$CoCO_3(C_8H_{22}N_4)$]$ClO_4 \cdot 2H_2O$: C 25.21; H, 6.11; N, 13.07%.

*Λ-β-[CoCO₃((3S,8S)-dimetrien)]ClO₄→*trans*-[CoCl₂((3S,8S)-dimetrien)]ClO₄.* *Λ-β*-[$CoCO_3$((3*S*,8*S*)-dimetrien)]ClO_4 (0.20 g) was dissolved in 5 M HCl (5 ml) and $LiClO_4$ (0.5 g) was added. Green needle-like crystals were obtained on standing at room temperature. The product was identified with *trans*-[$CoCl_2$((3*S*,8*S*)-dimetrien)]ClO_4.

Λ-β-[CoCO₃((3S,8S)-dimetrien)]ClO₄ → trans*-[Co(NO₂)₂((3S,8S)-dimetrien)]ClO₄.* *Λ-β*-[$CoCO_3$((3*S*,8*S*)-dimetrien)]ClO_4 (1.20 g) was added in small portions to 5 ml of 2 M $HClO_4$. The complex dissolved with effervescence to give an orange-red solution. Sodium nitrite (0.50 g) was added in small portions, and the solution was heated for 5 min on

a water bath (70 °C). After being cooled to room temperature, solid lithium perchlorate (1.0 g) was added and dissolved. The resultant solution was allowed to stand in a refrigerator overnight and the crystals separated were filtered off, washed with water, ethanol, and acetone. Yield, 0.50 g. The product recrystallized from warm water was identified with *trans*-$[Co(NO_2)_2((3S,8S)\text{-dimetrien})]ClO_4$.

Trans-$CoCl_2$((3S,8S)-dimetrien)$^+$→Λ-β-$CoCO_3$((3S,8S)-dimetrien)$^+$. A weighed sample (*ca.* 25 mg) of *trans*-$[CoCl_2((3S,8S)\text{-dimetrien})]ClO_4$ was dissolved in 20 ml of 0.01 M $HClO_4$ in a 25 ml volumetric flask. After the solution had been kept at room temperature for 1 h, 0.050 g of $NaHCO_3$ was added and dissolved. After 30 min the final volume was adjusted to 25 ml by adding water, and the visible absorption and CD spectra of the solution were recorded. The spectra agreed with those of the isolated Λ-β-$[CoCO_3((3S,8S)\text{-dimetrien})]ClO_4$ within experimental error.

Δ-cis-β-$CoCl_2$((3S,8S)-dimetrien)$^+$→Δ-β-$CoCO_3$((3S,8S)-dimetrien)$^+$. A weighed sample (*ca.* 17 mg) of Δ-*cis*-β-$[CoCl_2((3S,8S)\text{-dimetrien})]ClO_4$ was dissolved in 20 ml of 0.01 M $HClO_4$ in a 25 ml volumetric flask, and the solution was stood at room temperature for 15 min. 0.050 g of $NaHCO_3$ was added and the volume was adjusted to 25 ml by adding water. After being left to stand for 30 min, the visible absorption and CD spectra of the resultant solution were recorded. The spectral data were almost identical with those for the isolated Δ-β-$[CoCO_3((3S,8S)\text{-dimetrien})]ClO_4\cdot 2H_2O$.

Λ-cis-α-$CoCl_2$((3S,8S)-dimetrien)$^+$ → Λ-α-$CoCO_3$((3S,8S)-dimetrien)$^+$. A weighed sample (*ca.* 17 mg) of Λ-*cis*-α-$[CoCl_2((3S,8S)\text{-dimetrien})]ClO_4$ was dissolved in 20 ml of 0.01 M $HClO_4$ in a 25 ml volumetric flask. The solution was allowed to stand for 16 h at room temperature, followed by the addition of 0.050 g of $NaHCO_3$. The final volume was adjusted to 25 ml by adding water, and the visible absorption and CD spectra of the solution were measured.

Λ-cis-β-Dinitro((3S,8S)-3,8-dimethyl-1,4,7,10-tetraazadecane)-cobalt(III) Chloride (Λ-cis-β-$[Co(NO_2)_2$((3S,8S)-dimetrien)$]Cl\cdot 0.5H_2O\cdot 0.5CH_3OH$). (3*S*,8*S*)-Dimetrien·4HCl (1.60 g), $LiOH\cdot H_2O$ (0.63 g), $CoCl_2\cdot 6H_2O$ (1.09 g) and $NaNO_2$ (0.70 g) were dissolved successively in 50 ml of methanol and the resultant sulution was aerated for 1 h at room temperature. The white precipitates which appeared were filtered off, and the filtrate was transferred into a beaker and heated on a water bath at 80 °C. In a few minutes the solution began to boil and brown crystals began to separate. Boiling was continued for 30 min, with occasional addition of a few mililiters of methanol to maintain the volume at *ca.* 50 ml. The mixture was cooled to room temperature, and then stored in a refrigerator overnight. The crystals separated were collected and washed with methanol. Yield, 1.02 g. The crude product was dissolved in water (15—20 ml) at 70 °C, and the undissolved impurities were removed by filtration. An equal volume of methanol was added to the filtrate, and cooled in a refrigerator overnight. The brown crystals were filtered off, washed with methanol, and air-dried. Yield, 0.70 g. Found: C, 26.87; H, 6.43; N, 21.21%. Calcd for $[Co(NO_2)_2(C_8H_{22}N_4)]Cl\cdot 0.5H_2O\cdot 0.5(CH_4O)$: C, 26.50; H, 6.41; N, 21.82%.

Measurements. The absorption spectra were obtained with a Shimadzu MPS-50 L Spectrophotometer. The circular dichroism spectra were measured with a JASCO J-20 automatic spectropolarimeter. The 60 MHz proton magnetic resonance spectra were obtained with a Hitachi R-20 B spectrometer in D_2O solutions using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an internal standard.

Results and Discussion

It is necessary to adopt basic reaction conditions in order to convert the *trans*(*S*,*S*)-$[CoCl_2((3S,8S)\text{-dimetrien})]^+$ ion into either the Λ-α(*R*,*R*)- or the Δ-β(*R*,*S*)-$[CoCl_2((3S,8S)\text{-dimetrien})]^+$ ion, since the reaction proceeds with the inversion of configuration at the coordinated secondary nitrogen center, which is usually promoted by base. We thus applied the method employed by Sargeson and Searle for the conversion of the *cis*-α-$[CoCl_2(trien)]^+$ into the β-$[CoCO_3(trien)]^+$ ion with carbonate ion.[10]

The carbonato complex, $[CoCO_3((3S,8S)\text{-dimetrien})]ClO_4$, complex (I), was obtained by the reaction of *trans*-$[CoCl_2((3S,8S)\text{-dimetrien})]ClO_4$ with excess Li_2CO_3. Its visible absorption and circular dichroism (CD) spectra are given in Fig. 1. The CD curve exhibits only a large positive band in the first absorption band region, which can be ascribed to the Λ configuration about the central cobalt(III) atom. This leads to the conclusion that complex (I) has the Λ-α configuration, if the possible isomers of *cis* geometry are restricted to Λ-α and Δ-β.

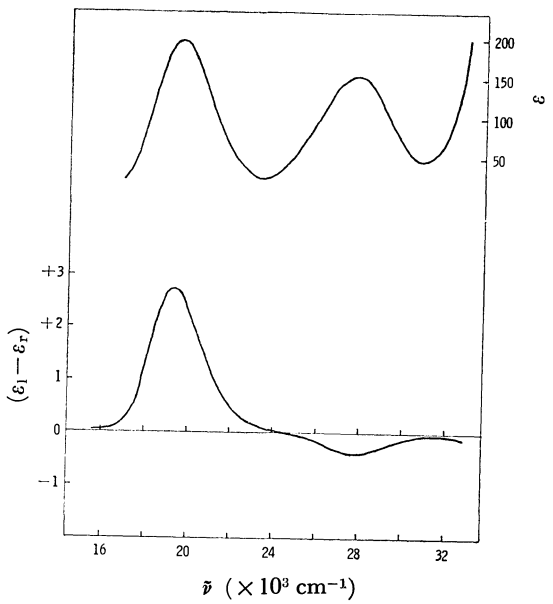

Fig. 1. Visible absorption and CD spectra of complex (I) (Λ-β-$[CoCO_3((3S,8S)\text{-dimetrien})]ClO_4$).

However, attempts to obtain the Λ-*cis*-α isomer of dichloro and dinitro complex, (Eqs. (1) and (2)), were found to give the corresponding *trans* isomer. Under the acidic conditions in (1) and (2), the configuration of the coordinated secondary N centers should be difinitely retained. This indicates that the secondary N atoms of complex (I) take the same configurations as the *trans* isomers, *i.e.* (*S*,*S*).

$$\text{Complex (I)} \xrightarrow{HCl} \xrightarrow{(LiClO_4)} trans\text{-}[CoCl_2((3S,8S)\text{-dimetrien})]ClO_4 \quad (1)$$

$$\text{Complex (I)} \xrightarrow{HClO_4} \xrightarrow{NaNO_2} \xrightarrow{(LiClO_4)} trans\text{-}[Co(NO_2)_2((3S,8S)\text{-dimetrien})]ClO_4 \quad (2)$$

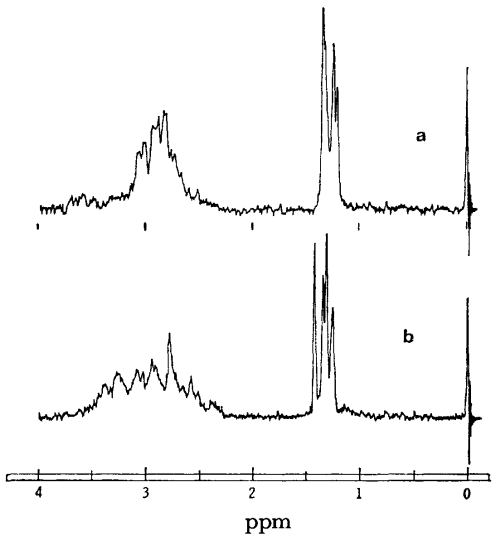

Fig. 2. PMR spectra of $[CoCO_3((3S,8S)\text{-dimetrien})]^+$ ion; (a) Λ-β isomer, and (b) Δ-β isomer.

The proton magnetic resonance (PMR) measurements would be useful for deciding whether (I) has C_2 axis or not. The PMR spectrum of (I) obtained in D_2O is given in Fig. 2(a), which exhibits two overlapped doublet in the 1.2—1.4 ppm region, assignable to the C-methyl groups of the ligand. The PMR spectrum corresponds, therefore, to that for the *cis*-β geometry and not for the *cis*-α form. Consequently, the absolute configuration of (I) can be determined to be the Λ-$\beta(S,S)$, which has been confirmed by X-ray crystallographic study.[11]

Sargeson and Searle provided an alternative method for preparing carbonatocobalt(III) complexes with trien.[10] The *cis*-α and *cis*-β-dichloro complexes were aquated completely and then treated with hydrogencarbonate ion with retention of the configurations. A similar treatment was carried out for the Λ-*cis*-α, Δ-*cis*-β and *trans* isomers of $CoCl_2((3S,8S)\text{-dimetrien})^+$ ion (Eqs. (3)—(5); L indicates the (3*S*,8*S*)dimetrien).

$$\Lambda\text{-}cis\text{-}\alpha\text{-}CoCl_2(L)^+ \xrightarrow{H_3O^+} \Lambda\text{-}cis\text{-}\alpha\text{-}CoCl(H_2O)(L)^{2+} \xrightarrow{HCO_3^-} \Lambda\text{-}\alpha\text{-}CoCO_3(L)^+ \quad (3)$$

$$\Delta\text{-}cis\text{-}\beta\text{-}CoCl_2(L)^+ \xrightarrow{H_3O^+} \Delta\text{-}cis\text{-}\beta\text{-}CoCl(H_2O)(L)^{2+} \xrightarrow{HCO_3^-} \Delta\text{-}\beta\text{-}CoCO_3(L)^+ \quad (4)$$

$$trans\text{-}CoCl_2(L)^+ \xrightarrow{H_3O^+} (\text{red complex}) \xrightarrow{HCO_3^-} \Lambda\text{-}\beta\text{-}CoCO_3(L)^+ \quad (5)$$

The carbonato complexes produced *in situ* according to Eqs. (3) and (4) have a positive and negative CD band, respectively, in the first absorption band region (Fig. 3). If we assume the complete retention of the configurations these CD curves can be ascribed to the Λ-α and Δ-β isomer of $[CoCO_3((3S,8S)\text{-dimetrien})]^+$ ion, respectively. The carbonato complex derived from the *trans* dichloro complex (Eq. (5)) showed the CD curve depicted in Fig. 3, which is identical with that of complex (I) (or Λ-β isomer)

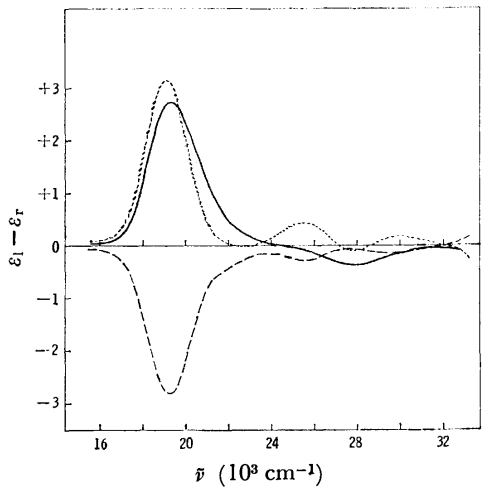

Fig. 3. CD curves for the carbonato complexes formed by the reactions of Eqs. (3) (----), (4) (——·), and (5) (——).

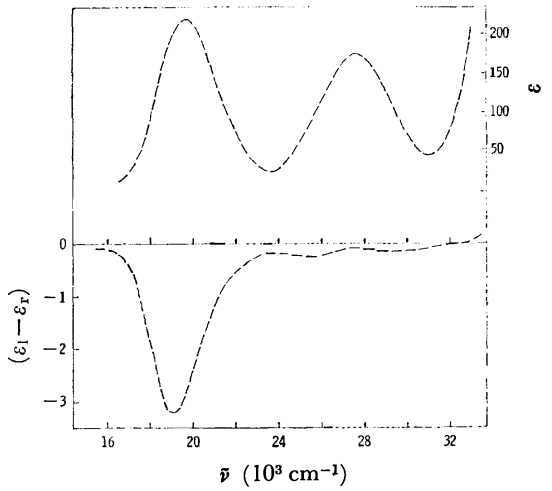

Fig. 4. Visible absorption and CD spectra of Δ-β-$[CoCO_3((3S,8S)\text{-dimetrien})]ClO_4 \cdot 2H_2O$.

shown in Fig. 1. Although both complexes, which result from reactions (3) and (5), have a CD pattern attributable to the Λ configuration, details of the curves apparently differ from each other.

Attempts to isolate the crystalline product of the Λ-α isomer, formed *in situ*, were unsuccessful because of high solubility of the complex. However, the Δ-β and Λ-β isomers could be easily obtained as perchlorate according to reactions (4) and (5). The Δ-β isomer exhibited the PMR spectrum which had two doublets due to the methyl groups in the 1.2—1.4 ppm region (Fig. 2(b)). The visible absorption and CD spectra of this complex are given in Fig. 4. The CD curve of the crystalline product of Δ-β isomer in Fig. 4 is slightly different from that in Fig. 3, probably due to a small contamination of the other complex in the latter case. The Λ-β isomer obtained under acidic condition (Eq. (5)) showed identical CD and PMR spectra for the Λ-$\beta(S,S)$ isomer obtained in the basic medium (complex (I)) (Figs. 1 and 2(a)).

The molecular structure of the Λ-β-$CoCO_3$ $((3S,8S)\text{-dimetrien})^+$ ion determined by the X-ray diffraction

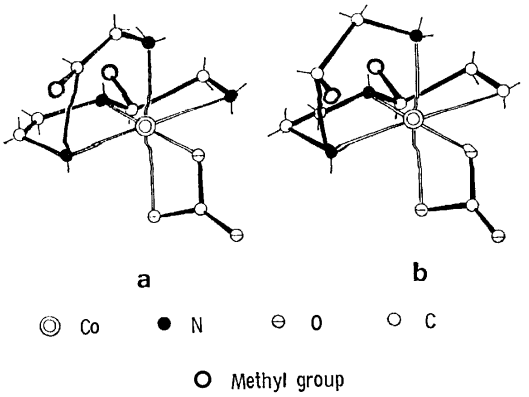

Fig. 5. Possible structures for *Λ*-*β*-[$CoCO_3$((3*S*,8*S*)-dimetrien)]$^+$ ion.

study is illustrated in Fig. 5(a), in which the methyl group on the chelate ring (A) which is not coplanar with the central chelate ring has an unusual axial orientation.[11] An alternative structure of the *Λ*-*β* configuration, both the methyl groups being equatorial, is also shown in Fig. 5(b). Chelate ring (A) in the latter structure takes the *δ* conformation, the methyl group being able to take an equatorial orientation. Chelate ring (A) in the former structure has alternatively the *Λ* conformation. It seems that in solution both conformers (a) and (b) undergo rapid interchange with each other, and are in an equilibrium governed by the free energy difference. The existence of two conformers similar to those in Fig. 5 has been demonstrated in the case of *β*$_2$-[Co(gly)(trien)]$^+$ ion.[12]

The existence of (3*S*,8*S*)-dimetrien complex with the *Λ*-*cis*-*β*(*S*,*S*) configuration was not taken into consideration in previous papers.[2,3] The assumption that the stereoisomers possible for the cobalt(III) complexes with methyl-substituted trien derivatives are restricted to those having the equatorial methyl groups has been found to be incorrect. It is of interest to note that the *Λ*-*β*(*S*,*S*)-[$CoCO_3$((3*S*,8*S*)-dimetrien)]ClO_4 is the sole product which can be isolated under basic preparative conditions. This suggests that the *Λ*-*cis*-*β*(*S*,*S*) geometry is more stable than the other *cis* forms *Λ*-*cis*-*α*(*R*,*R*) and *Λ*-*cis*-*β*(*R*,*S*).

No *Λ*-*cis*-*β*(*S*,*S*) isomer has been obtained for the dichloro and dinitro complexes with (3*S*,8*S*)-dimetrien.[2,5] The reactions carried out following Eqs. (1) and (2) should yield the corresponding dichloro or dinitro complex with *Λ*-*cis*-*β*(*S*,*S*) geometry, at least in the case of ordinary trien complexes.[10] The *trans*-(*S*,*S*) isomer, the actual products of reactions (1) and (2), and the *Λ*-*cis*-*β*(*S*,*S*) isomer are in common as regards the absolute configuration of the secondary N atoms. These isomers can be in an equilibrium in the acidic medium with retention of the secondary N configurations as indicated for the dichloro complexes in Eq. (6). When the perchlorate ion is present in a mixture of these isomers, the precipitation of only the

$$\begin{array}{ccc} \textit{Λ-cis-β}(S,S)\text{-}[CoCl_2(L)]^+ & \rightleftarrows & \textit{trans}(S,S)\text{-}[CoCl_2(L)]^+ \\ & & \downarrow ClO_4^- \\ & & \textit{trans}(S,S)\text{-}[CoCl_2(L)]ClO_4 \end{array} \quad (6)$$

less soluble salt of the *trans* isomer is induced, the *Λ*-*cis*-*β* isomer being highly soluble or hard to crystallize. A similar situation would occur for the *trans* and *Λ*-*cis*-*β* isomers of the dinitro complex.

*The dichlorocobalt(III) complex of (4R,5S)-4,5-*dimethyl-3,6-diazaoctane-1,8-diamine gave rise to the *cis*-*β*(*RS*,*SR*) isomer as the chloride form, while the *trans*(*R*,*S*) isomer was obtained as the perchlorate from a similar reaction mixture.[5] This suggests that either of two equilibrated isomers can be separately crystallized in pure state by use of different counter ions. However, an attempt to get crystalline product of *Λ*-*cis*-*β*-[$CoCl_2$((3*S*,8*S*)-dimetrien)]$^+$ by use of chloride or other anions was not successful and resulted in obtaining the trans isomer.

It was found unexpectedly that the chloride of *Λ*-*cis*-*β*-$Co(NO_2)_2$((3*S*,8*S*)-dimetrien)$^+$ ion crystallizes out in the course of the usual air-oxidation procedure, except that methanol was used as the solvent. The novel dinitro complex contains one half mole of methanol of crystallization per mole of the complex. The PMR and CD spectra of this isomer are shown in Figs. 6(a) and 7, respectively. The PMR spectrum indicates two kinds of doublet assignable to the C-methyl groups of the ligand in the 1.2—1.4 ppm region and can be attributed to the *cis*-*β* topology. The sharp signal at 3.40 ppm is assigned to the methyl group of methanol of crystallization. For the sake of comparison the PMR spectra of the *Λ*-*cis*-*β*, *Λ*-*cis*-*α*, and *trans* isomers are shown in Figs. 6(b), (c), and (d), which are appropriate to the specified geometries of the isomers. The CD curve of the present isomer shows a dominant positive and a minor negative peak in the first absorption band region, which establishes the *Λ* configuration.[3]

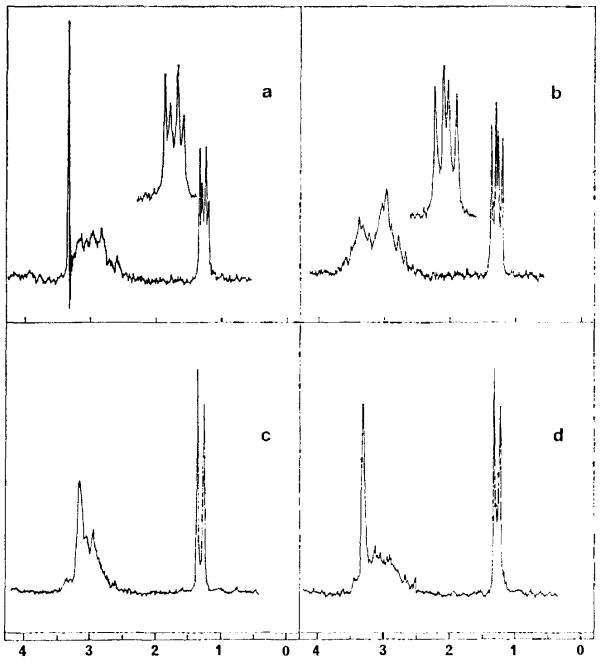

Fig. 6. PMR spectra of [$Co(NO_2)_2$((3*S*,8*S*)-dimetrien)]$^+$ isomers: (a) *Λ*-*cis*-*β*, (b) *Λ*-*cis*-*β*, (c) *Λ*-*cis*-*α*, and (d) *trans* (in D_2O).

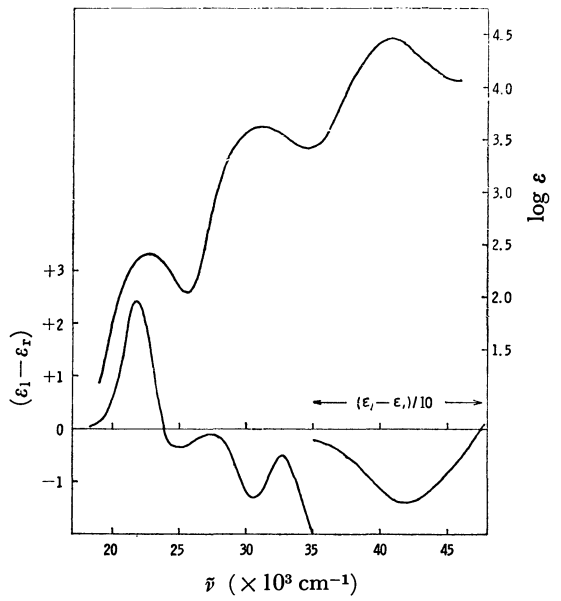

Fig. 7. Absorption and CD spectra of *Λ-cis-β*-[$Co(NO_2)_2$-((3*S*,8*S*)-dimetrien)]Cl·0.5 H_2O·0.5 CH_3OH.

A greyish violet solution was obtained on treating the *Λ-cis-β*-[$Co(NO_2)_2$((3*S*,8*S*)-dimetrien)]Cl with warm concentrated hydrochloric acid, no crystalline material being formed by concentration to near dryness. Addition of perchlorate ion to this solution resulted in the nearly quantitative formation of green crystals of the *trans*-(*S*,*S*)-[$CoCl_2$((3*S*,8*S*)-dimetrien)]ClO_4. The intermediate of the reaction should be highly soluble *Λ-cis-β*(*S*,*S*) dichloro complex which isomerizes into the *trans*(*S*,*S*) isomer in the same manner as in Eq. (6). It is therefore clarified that the *Λ-cis-β* dinitro complex adopts the (*S*,*S*) configuration with respect to the secondary N centers, since there is no possibility of inversion at the secondary N atoms under the conditions mentioned above.

The formation ratio of three isomers of [$CoCl_2$((3*S*,8*S*)-dimetrien)]$^+$ ion is *trans* : *Δ-cis-β* : *Λ-cis-α*= 15 : 5 : 1, when isolated as the perchlorate.[2] No exact estimation of the yields has been made, since it is difficult to isolate completely the materials in solution especially for highly soluble compounds such as the *Δ-cis-β* isomer. Furthermore, isomerization from the *Λ-cis-β* to the *trans* form should take place during the course of isolation, which affect the yield of the *trans* form. Thus, we can estimate the relative stability between the *Δ-cis-β* and *Λ-cis-α*, since these isomers would not undergo conversion or be obtained from the others in the acidic medium.

The strain energy minimization calculations applied to the isomers of [$Co(NO_2)_2$((3*S*,8*S*)-dimetrien)]$^+$ ion indicate that three isomers are in the order *Δ-cis-β*> *trans*>*Λ-cis-α* (according to the calculated enthalpy terms).[9] As far as the order of the *Δ-cis-β* and *Λ-cis-α* is concerned, the result of the calculation is in line with experimental results of the dichloro isomers. On the other hand, there is a distinct discrepancy between the calculated and experimental results with respect to the order of the *trans* isomer. We consider that the *trans* configuration is intrinsically unstable relative to the *Δ-cis-β* configuration due to the unfavorable bond angle distortions involved, as indicated by the strain energy minimization study.[9] Most part of the *trans* dichlorocomplex should be generated by the isomerization of the *Λ-cis-β*.

A preliminary study on the strain energy minimization calculation revealed that the *Λ-cis-β* form has an equivalent or more favorable stability as compared with the *Δ-cis-β* form.[13] It would be certain that higher yield of the *trans* isomer does not reflect its thermodynamic preference. For some metal chelate compounds the stereoisomers with an axially-oriented substituent with appreciable stability might be possible.

Thermal Change of Magnesium Highpolyphosphate Coacervates[1)]

Takao UMEGAKI, Yukihiro NAKAYAMA, and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received December 17, 1975)

The thermal change of magnesium highpolyphosphate coacervates with various sodium contents was studied by means of DTA, TGA and high temperature X-ray diffraction technique. Most of the highpolyphosphates in the coacervates were degraded into hydrated orthophosphates up to about 100 °C, the pyrophosphates and tetrametaphosphates being formed at 200—300 °C and 300—500 °C, respectively. The formation temperature of "X" (a mixture of $Mg_2P_2O_7$ and $MgNa_2P_4O_{12}$) was lowered with an increase of sodium content in the coacervate samples. $Mg(H_2PO_4)_2 \cdot 2H_2O$, $Mg(H_2PO_4)_2$, $MgH_2P_2O_7$, "X" and $Mg_2P_4O_{12}$ were determined in the crystalline substances obtained by the isothermal heat treatment of coacervates at various temperatures.

Kingery[2)] found that various metal oxides react with phosphoric acid to form stable refractory compounds. Some commercial aluminum phosphates are used as binders for castable refractories.[3)] Bonding of basic refractories with sodium polyphosphates was studied by Lyon, Fox and Lyon.[4)] Some phosphate-bonded magnesite refractories of high hot modulus strengths were obtained by Foessel and Treffner.[5)]

In previous works, magnesium highpolyphosphate coacervates (MPC) were examined as potential binders,[6)] and their thermomechanical properties were described at temperatures from −120 to 100 °C.[7,8)] However, there seems to be no detailed report on the thermal change of magnesium highpolyphosphates, although the degradation of some highpolyphosphates in aqueous solutions was studied by Thilo and Wieker[9,10)] and Gill and Riaz.[11)]

This paper deals with the relationship between the sodium content of MPC and its thermal change. MPC always contains sodium, the presence of which in the coacervate is necessary for the formation of "X".[12,13)] We have studied the thermal change of the MPC containing various amounts of sodium by means of DTA, TGA and high temperature X-ray diffraction, in order to clarify the phosphate bonding formation.

Experimental

Preparation of Magnesium Highpolyphosphate Coacervates with Various Sodium Contents. The MPC samples were obtained from mixtures of the aqueous solutions of sodium metaphosphate and magnesium chloride by addition of ethyl alcohol. The sodium contents in the MPC samples are determined by those in sodium metaphosphate solutions. In order to prepare the coacervates of low sodium contents, the sodium metaphosphate solutions were passed through the ion exchange resin (Amberlite IR-120H) twice or more before being mixed with the chloride solutions. The sodium metaphosphate solutions were kept at −5—0 °C during the course of ion exchange to avoid the hydrolytic degradation of the highpolyphosphates. The chemical compositions of the MPC samples are given in Table 1.

Chemical Analysis of the Coacervates. The analytical methods for magnesium, sodium and phosphorus were described previously.[8)] Paper chromatography of the polyphosphate ions in the coacervate solutions was carried out according to the method by Kolloff.[14)]

Determination of the Average Chain Length of Coacervates. The end group titration[15)] was carried out in order to determine the average number of phosphorus atoms per chain in the polyphosphates of the coacervates. Solutions of the coacervate (*ca.* 1%) were titrated with 0.1 M sodium hydroxide with a pH meter (Denki Kagaku Keiki Model HG-2). Small amounts of 0.1 M sodium hydroxide were successively added to the coacervate solutions and the pH values of the solutions were recorded after each addition until the pH became 10.

In ^{31}P NMR spectra of polyphosphate, the chemical shifts of 9.5—12 ppm and of 20—27 ppm show the presence of terminal PO_4 and middle PO_4, respectively. Each integrated intensity represents the quantity of each PO_4 group in the phosphate chain.[16)] The chain length of the polyphosphates was also determined from the ratio of the integrated intensities for the two chemical shifts. All the NMR spectra were recorded on a Nichiden-Varian NMR Spectrometer Model NV-14 operating at 24.3 MHz at room temperature, using a dilute H_3PO_4 solution as an external reference of ^{31}P.

IR Absorption Spectra. The IR absorption spectra of the coacervates were recorded on a Hitachi IR spectrometer Model EPI-G2 in order to examine the presence of the P–O–P bonds.

Thermal Analysis of the Coacervates. DTA curves were recorded on a Shinku Riko AGNE Differential Thermal Analyzer DT-1500 up to 1100 °C at a heating rate of 5 °C/min. The coacervate samples were dried at 100 °C before DTA measurements in order to avoid swelling and foaming of the samples on abrupt dehydration in a platinum cell.

TGA was carried out by measuring the weight decrement of the coacervates with a quartz spring balance, heating rate being 5 °C/min.

X-Ray Analysis. X-Ray powder diffraction patterns were obtained with a Rigaku Denki Diffractometer Model D-3F, to which a device for high temperature measurements of some coacervates was attached.

Results

Average Chain Length of Highpolyphosphates in the Coacervates. The average chain length of highpolyphosphates in the MPC samples was calculated to be 19—23 from the titration curves, assuming that no sample contains cyclic phosphate ions.

The spectra of ^{31}P MNR for the coacervate solutions (Fig. 1) were almost the same as those of polyphosphates reported by Crutchfield *et al.*[16)] The two peaks in these spectra show the presence of the end PO_4 and the middle PO_4. Table 1 shows the average chain length calculated from the ratios of the integrated intensities of the two peaks. The values from the end group measurement coincide with those from the NMR spectra.

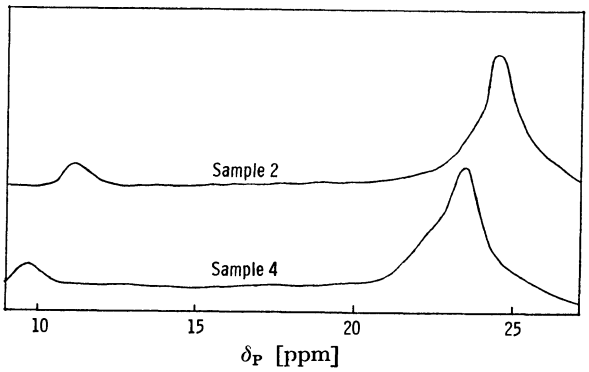

Fig. 1. ^{31}P NMR spectra of coacervates in aqueous solutions.

Table 1. Chemical composition of magnesium highpolyphosphate coacervates

No. of coacervate sample	Contents (%) NaO	MgO	P_2O_5	H_2O	Average chain length
1	1.07	11.8	39.2	53.0	
2	1.50	10.7	38.7	44.5	23
3	2.17	13.0	41.3	53.5	
4	3.46	6.65	34.6	61.1	22
5	7.46	5.60	29.0	58.0	

DTA and TGA of Magnesium Highpolyphosphate Coacervates. From the results of paper chromatography and IR, we see that most of the highpolyphosphates in the coacervates turn to hydrated orthophosphates after being heated at 100 °C. As shown in DTA and TGA curves (Fig. 2), two or more endothermic peaks at 100—200 °C suggest the occurrence of dehydration with various types. The endothermic peaks in the range 800—1000 °C appear due to the melting of some of the dehydrated coacervate samples, these melting temperatures being lowered with an increase in sodium content.

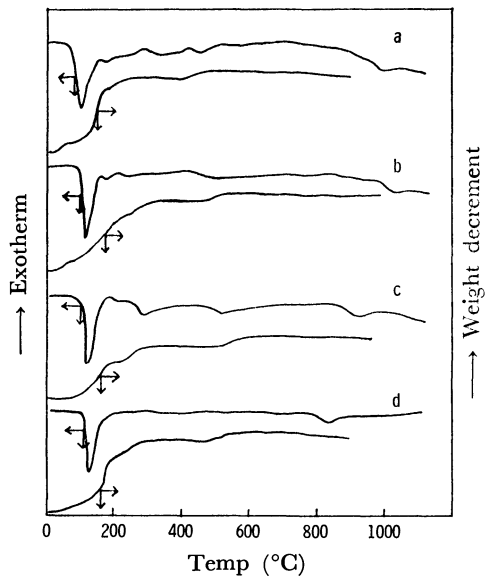

Fig. 2. TGA and DTA curves of coacervates.
a: Sample 1, b: sample 2, c: sample 3, d: sample 4.

Table 2. Products of the isothermal heat treatment of coacervates at various temperatures

No. of coacervate samples	Products[a)]
1	A(~100 °C), $Mg(H_2PO_4)\cdot 2H_2O$(120 °C), $Mg(H_2PO_4)_2$(130 °C), $MgH_2P_2O_7$(300 °C), X(400 °C), MTP(450 °C).
2	A(~100 °C), U(100—400 °C), X(460 °C), MTP(460 °C).
3	A(~100 °C), U(100—300 °C), X(350 °C), MTP(460 °C).
4	A(~100 °C), U(100—300 °C), X(320 °C).
5	A(~120 °C), U(120—300 °C), X(300 °C).

X[18]: a mixture of $Mg_2P_2O_7$ and $MgNa_2P_4O_{12}$, A: amorphous orthophosphates, U: a mixture of unknown crystalline substances, MTP: $Mg_2P_4O_{12}$.
a) Temperatures in parentheses represent those of formation of the products.

X-Ray Analysis of the Products Obtained by the Isothermal Heat Treatment. Taking the above results of DTA and TGA into account, the coacervates were isothermally dehydrated and heated at various temperatures. Table 2 shows the products obtained by the isothermal heat treatment of the coacervates.

After all the coacervates had been heated at 100 °C, orthophosphate ion was detected by paper chromatography and IR spectroscopy. No crystalline phosphate or ortho or pyro form other than $Mg(H_2PO_4)_2\cdot 2H_2O$, $Mg(H_2PO_4)_2$, and $MgH_2P_2O_7$ was found by X-ray diffraction analysis. It seems that the crystallization of magnesium ortho- and pyrophosphates was difficult in the coacervates rich in sodium.

By heat treatment at 300—400 °C most mixtures of the degraded phosphates turned into crystalline $Mg_2P_4O_{12}$ and "X", a new compound,[12,13] only "X" being found in Samples 4 and 5. The temperature for the formation of "X" was lowered with an increase of sodium content in the coacervate samples.

Discussion

The coacervate undergoes degradation, dehydration and condensation on heating as follows:[12,13]

$$\text{Coacervate} \xrightarrow{100°C} \text{Amorphous orthophosphates} \xrightarrow{120°C}$$
$$Mg(H_2PO_4)_2\cdot 2H_2O \xrightarrow{150—190°C} Mg(H_2PO_4)_2 \xrightarrow{210—290°C}$$
$$MgH_2P_2O_7 \xrightarrow{350°C} Mg_2P_4O_{12} \text{ and "X"} \xrightarrow{990°C}$$
Partial melting

The thermal change of the coacervates with various sodium contents seems to be as follows:

$$\text{Sample 1} \xrightarrow{100°C} \text{Amorphous orthophosphates} \xrightarrow{120°C}$$
$$Mg(H_2PO_4)_2\cdot 2H_2O \xrightarrow{130°C} Mg(H_2PO_4)_2 \xrightarrow{300°C}$$
$$MgH_2P_2O_7 \xrightarrow{400°C} MgH_2P_2O_7 \text{ and "X"} \xrightarrow{450°C}$$
$$Mg_2P_4O_{12} \text{ and "X"} \xrightarrow{990°C} \text{Partial melting}$$

Sample 3 $\xrightarrow{100°C}$ Amorphous orthophosphates $\xrightarrow{150—200°C}$
Unknown crystalline substances $\xrightarrow{350°C}$ "X" $\xrightarrow{460°C}$
$Mg_2P_4O_{12}$ and "X" $\xrightarrow{950\,°C}$ Partial melting

Sample 5 $\xrightarrow{120°C}$ Amorphous orthophosphates $\xrightarrow{150°C}$
Unknown crystalline substances $\xrightarrow{300°C}$ "X" $\xrightarrow{910°C}$
Partial melting

The temperature of formation of crystalline "X" is a little lower than that for the appearance of $Mg_2P_4O_{12}$. When the coacervates such as Samples 4 and 5 contain a large amount of sodium, no other crystalline substance than "X" is obtained by isothermal heat treatment. The formation of "X" is closely related to the presence of sodium ion.

The X-ray diffraction patterns of $MagN_2P_4O_{12}$[17] and "X" (Table 3) almost overlap each other. However, some peaks (d=3.0223, 2.9799 and 2.9107 Å), assigned to "X", disappear after the treatment of "X" with aqua regia.[18] Concerning the diffraction pattern of $MgNa_2P_4O_{12}$ there is no peak corresponding to the three peaks of "X". The highest and the next highest peaks of $Mg_2P_2O_7$ (d=3.015 and 2.976 Å) appear in the vicinity of the three peaks of "X" (ASTM X-Ray Powder Data File 8—38). This suggests that "X" is not a single compound but a mixture of $Mg_2P_2O_7$ and $MgNa_2P_4O_{12}$.

$MgNa_2P_4O_{12}$ is insoluble in acidic or alkaline solutions as well as $Mg_2P_4O_{12}$. If magnesium high-polyphosphates are used as binders, the principal bonding phase is expected to consist of chemically inert magnesium tetrametaphosphates.

Table 3. X-Ray powder diffraction data of "X"[12]

d(Å)	I/I_0	d(Å)	I/I_0
13.1	3	2.2553	8

2.4242	2	1.5370	5
2.3131	5	1.4550	6

Conclusion

1) The thermal change is considered to take place in the following order:

a. degradation of polyphosphates into hydrated orthophosphates (≈100 °C).

b. dehydration of the hydrated orthophosphates (100—200 °C).

c. formation of pyrophosphates (200—300 °C).

d. formation of "X" and $Mg_2P_4O_{12}$ (300—500 °C).

e. melting of some phosphates obtained on heat treatment of the coacervate samples (800—950 °C).

2) The crystalline substances obtained by the progress of the thermal change of the coacervates are $Mg(H_2PO_4)_2\cdot 2H_2O$, $Mg(H_2PO_4)_2$, $MgH_2P_2O_7$, "X" and $Mg_2P_4O_{12}$.

3) The formation temperature of "X" is lowered with an increase of sodium content in the coacervate samples.

The authors wish to express their sincere thanks to the staff of Nichiden Varian Co., Ltd. for their co-operation in the NMR measurement.

This work was supported by a grant from Asahi Glass Foundation for Contribution to Industrial Technology.

The Synergistic Extraction of Cobalt Ion Fixed on the Ion Exchange Resin with a Mixture of 2-Thenoyltrifluoroacetone and Pyridine Bases

Tooru TAMURA, Kunio OHZEKI, and Tomihito KAMBARA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 25, 1976)

The extraction of cobalt(II) on the ion exchange resin into a mixture of 2-thenoyltrifluoroacetone(Htta) with pyridine bases in various organic solvents has been studied. In the presence of pyridine bases(B), cobalt ions were extracted from the resin into the organic phase in the form of base adducts, $Co(tta)_2B_n$. The synergistic effect decreased in the order: pyridine>β-picoline>γ-picoline>α-picoline>γ-collidine$\simeq$isoquinoline$\simeq$piperidine>4-benzoylpyridine. This trend was related to its structure, particularly the steric effect of the *ortho*-substituent.

The synergistic effects of neutral ligands have been widely studied in the extraction of a metal ion with β-diketone.[1,2] The effect is well explained by the formation of the base adduct. Akaiwa *et al.* reported that nickel(II) and cobalt(II) ions were extracted synergistically by a mixture of 2-thenoyltrifluoroacetone(Htta) and pyridine base and that the extractability of their metal ions was dependent on the basicity of pyridine bases and the steric effect of their *ortho*-substituent.[3-5]

On the other hand, the conversion of a metal ion fixed on the ion exchange resin to a chelate compound based on the ion exchange reaction in organic medium has been studied.[6] The authors have reported that iron(III),[7] copper(II),[8] and nickel(II)[9] ions on Amberlyst 15 were quantitatively extracted with acetylacetone or Htta into organic medium by the aid of a small amount of pyridine–water mixture. The present paper deals with the synergistic extraction of cobalt ions fixed on Amberlyst 15 with Htta in the presence of pyridine bases.

Experimental

Apparatus and Reagents. A Hitachi 508 atomic absorption spectrophotometer was used for the cobalt absorption measurement at 240.1 nm in air-acetylene flame. Thenoyltrifluoroacetone, β-picoline, and trimetyl phosphate were obtained from Wako Pure Chemical Inc. (Tokyo) and used without further purification. Pyridine, α-picoline, γ-picoline, γ-collidine, isoquinoline, piperidine, 4-benzoylpyridine, tributyl phosphate and all other materials used were of guaranteed grade.

Preparation of Cobalt(II)-form Resin. The resin used was sulfonic acid cation exchanger, Amberlyst 15, with a macroreticular structure. The commercially available Amberlyst 15 was crushed and shieved to a fraction of 60—80 mesh. The resin was converted to Co(II)-form by treatment with a 0.1 M solution of cobalt nitrate and washed with water until the washings showed no color reaction with 1-nitroso-2-naphtol and dried over silica gel. The cobalt ions on the air-dried Co(II)-form resin were eluted by 4 M hydrochloric acid and determined by EDTA titration. It was found that 3.19±0.02 meq of cobalt ions were adsorbed onto 1.00 g of the air-dried Co(II)-form resin. The ratio of exchange capacity of cobalt ion to proton was 0.965 and so the cobalt ions were expected to be adsorbed on the resin in the form of Co^{2+}.

General Procedure. A portion of 5 cm^3 of 0.1 M Htta in organic medium was poured onto the 25 mg of air-dried Co(II)-form resin in a eggplant flask and varying amounts of pyridine were added. The mixture was shaken mechanically for 10 min at room temperature. After filtration, the resin was washed with ethanol and water. The cobalt ions remaining on the resin were eluted by 4 M hydrochloric acid and determined by atomic absorption spectrophotometry in air-acetylene flame.

Results and Discussion

Effect of Pyridine and Solvents. It was found that Htta or pyridine could not remove the cobalt ions fixed on the resin into organic medium, however, the mixture of them was highly effective, as Fig. 1 shows. Upon addition of pyridine, the red color was immediately developed in the organic phase, indicating the formation of a base adduct, $Co(tta)_2py_n$. Cobalt ions were quantitatively extracted into Htta-carbon tetrachloride and Htta–benzene solutions in the presence of pyridine of 4—14% and 4—6% (v/v), respectively. But in the case of Htta–chloroform solution, the extractability was less than 98%. The poor extraction of cobalt ions in ethanol is due to a probable interaction between the solvent and Htta. After all, the effect of the solvent natures on the extraction of cobalt ions from the resin decreased in the order: carbon tetrachloride>benzene>chloroform>ethanol. Except ethanol, this order agreed with that found in the solvent extraction study of cobalt–Htta–pyridine system by Akaiwa *et al.*[5]

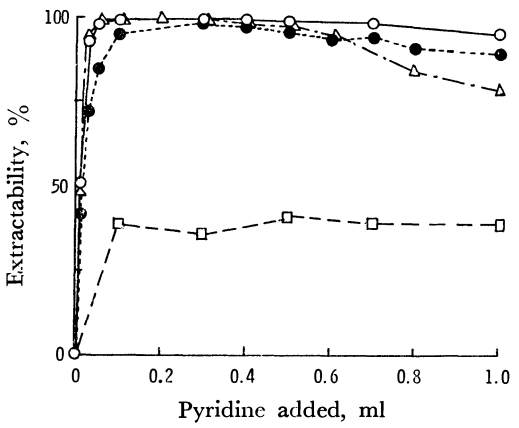

Fig. 1. Extractability of cobalt ions from the resin with 0.1 M Htta solutions in various solvents. Ethanol (□), chloroform (●), benzene (△), and carbon tetrachloride (○).

Composition of the Extracted Species. The composition of the extracted species in benzene was determined by the mole ratio method in the presence of pyridine and found to be Co(II) : Htta=1 : 2. The determination of the composition of a pyridine adduct was unsuccessful, because a considerable amount of pyridine might be adsorbed on the resin matrix.

Effect of Pyridine Bases. In place of pyridine, other neutral ligands were used as synergist. The extractability of cobalt ions from the resin with 0.1 M Htta and 0.245 M neutral ligands in benzene is given in Fig. 2, as a function of the shaking time. Pyridine was most effective and picolines except α-picoline followed it. The effect of α-picoline was inferior to that of other picolines. Pyridine bases such as γ-collidine, isoquinoline, piperidine, and 4-benzoylpyridine were less effective. In the case of trimethyl phosphate and tri-*n*-butyl phosphate, the extractability of cobalt ions was only about 10% after the 60-min shaking. Consequently, it is concluded that 2-substituted pyridine bases such as α-picoline and γ-collidine and those having a bulky structure such as isoquinoline and 4-benzoylpyridine were not effective. The synergistic effect of the neutral ligands on the ion exchange extraction decreased in the order of pyridine > β-picoline > γ-picoline > α-picoline > γ-collidine ≃ isoquinoline ≃ piperidine > 4-benzoylpyridine > trimethyl phosphate ≃ tri-*n*-butyl phosphate. On the other hand, it is reported that the synergistic effect of the pyridine bases on the solvent extraction of Ni(II)–Htta–benzene system decreases in the order of γ-picoline > β-picoline > pyridine > α-picoline, which is accordant with that of the basicity of pyridine bases.[3] The analogous conclusion is reported in the case of the solvent extraction of nickel(II) and cobalt(II) with thiodibenzoylmethane and *N*-phenyl-β-mercaptocinnamamide in the presence of pyridine bases.[10] It is explained that the poor effectiveness of α-picoline may be due to the steric influence by the *ortho*-methyl group. The disagreement of the results between ion exchange extraction and solvent extraction can be explained by the steric influence of the resin matrix with pyridine bases in the case of the ion exchange extraction. Namely, provided that the reaction occurs around cobalt ions on the resin, the pyridine bases must diffuse into the resin hole and so there appears a steric hinderance of the resin matrix with the large size molecule. The stability of adduct is related to the basicity of pyridine bases and has also an influence on the extractability of cobalt ions.

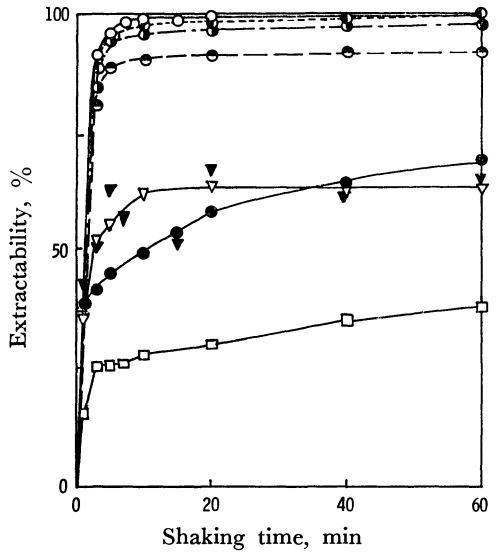

Fig. 2. Effect of shaking time on the synergism of the pyridine bases on the extraction of cobalt ions from the resin with 0.1 M Htta solutions in benzene, containing 0.245 M of pyridine (○), γ-picoline (◑), β-picoline (◐), α-picoline (◓), piperidine (●), isoquinoline (▲), 4-benzoylpyridine (□), and γ-collidine (△).

Effect of the Mesh Size of Co(II)-Form Resin. The Co(II)-form resins of 100—120 and 120—150 mesh ranges were prepared and the extractability of cobalt ions from each of them was compared with that from 60—80 mesh range. The γ-collidine having the *ortho*-substituent to the nitrogen atom of pyridine ring was used as synergist. The result is shown in Fig. 3. Though the extraction rate increased with decreasing mesh size of the resin, the extractability of cobalt ions after 10-min shaking was independent of the mesh size of the resin.

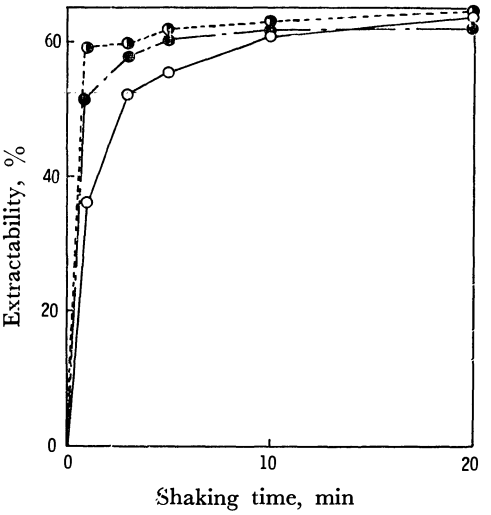

Fig. 3. Effect of the mesh size of Co(II)-form resin on the extraction of cobalt ions with a 0.1 M Htta solution in benzene, containing 0.245 M γ-collidine. The mesh range is 60—80 (○), 100—120 (●), and 120—150 mesh (◑).

Effect of Water Adsorbed to the Co(II)-Form Resin. It has been pointed out that the water played an important role in the reaction of β-diketone with metal ions fixed on the resin.[7-9] In the present case, the difference of the reactivities between the air-dried Co(II)-from resin and the oven-dried one, the latter being prepared by drying the former at 110 °C for 3 h, was investigated. After the 3 h drying at 110 °C. the color of the Co(II)-form resin changed from pink to violet. The water content on the air-dried Co-(II)-form resin was determined by the thermogravimetric analysis. It was found that the air-dried Co(II)-form resin adsorbed eight moles of water to

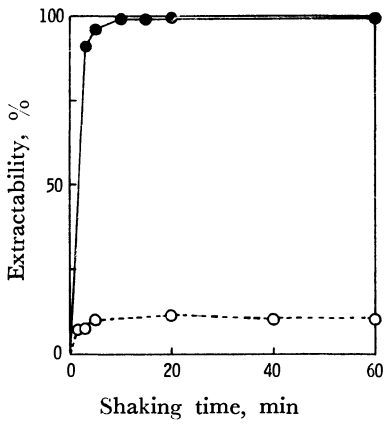

Fig. 4. The difference of the extractabilities between the air-dried Co(II)-form resin (●) and the oven-dried one (○). The extraction of cobalt ions from the resin was carried out with a 0.1 M Htta solution in benzene, containing 0.245 M pyridine.

a mole of cobalt ion on it, and six moles of those were removed by drying at 110 °C. Consequently, the form of the oven-dried Co(II)-form resin is expected to be $(RSO_3)_2Co \cdot 2H_2O$. It is supposed that this color change of the Co(II)-form resin is based on the removal of water molecules from cobalt ions. The use of oven-dried Co(II)-form resin gave a lower extractability in comparison with that of air-dried one, as Fig. 4 shows. Although the role of water remains not clarified, this indicates an importance of trace amounts of water in the extraction of cobalt ion fixed on the ion exchange resin with Htta into the organic medium.

The Coordinative Behavior of the Ethereal Oxygen Atom in Cobalt, Nickel and Copper Complexes with Schiff Bases Obtained from Salicylaldehyde Derivatives and 2-(Aminomethyl)furan

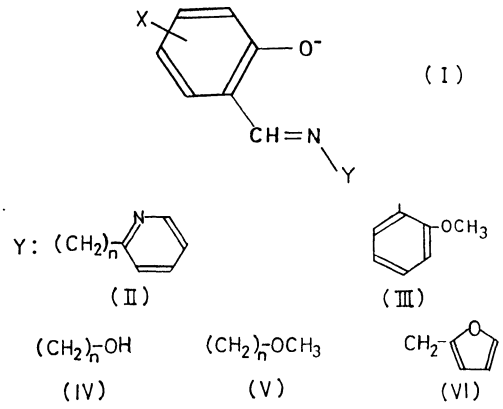
Shoichiro YAMADA, Kuniko YAMANOUCHI, Wasuke MORI, and Michihiko KISHITA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received March 26, 1976)

Cobalt(II), cobalt(III), nickel(II), and copper(II) complexes with *N*-(2-furylmethyl)salicylideneaminates (abbreviated as X-sal-fum) were synthesized. In addition to the M (X-sal-fum)$_2$ type complexes, those of the formula Cu(X-sal-fum)Cl were obtained in crystals. The complexes Co(X-sal-fum)$_3$ are six-coordinate, octahedral. The cobalt(II) complex is four-coordinate, tetrahedral and the nickel(II) complexes are four-coordinate, planar. In these complexes, the ligands X-sal-fum function as bidentates, the furan oxygen atom not being bound to the metal ions. The results are compared with those reported previously for related ligands. It is most likely that the complexes Cu(X-sal-fum)Cl consist of binuclear complexes with spin-spin interaction between copper(II) ions.

Ligands of the type (I), which bear a donor atom in Y, form various complexes with transition metal ions. The structure of these metal compleses is expected to vary in a delicate and complicated way. In previous papers, the present authors studied the synthesis and structure of transition metal complexes with ligands (II),[1] (III), (IV),[2] and (V).[3,4] As extension of these studies, various metal complexes with *N*-(2-furylmethyl)-salicylideneiminates (VI, abbreviated as X-sal-fum) have been synthesized and their structure has been examined in the present work. The results are compared with those of the corresponding complexes with related ligands.



Experimental

Materials. Analytical data of new complexes obtained in the present work are shown in Table 1.

Bis[N-*(2-furylmethyl)salicylideneaminato)copper(II)*, *Cu(X-sal-fum)*$_2$. To a suspension of bis(salicylaldehydato)copper(II) (0.01 mol) in 90% ethanol (50 ml) was added 2-aminomethylfuran (0.02 mol) drop by drop at about 60 °C. The resulting suspension was heated at the same temperature with stirring for about 30 min. An olive green precipitate was recrystallized from acetone to yield olive green (X=H, 5-Cl and 5-Br) or yellow brown (X=3-CH$_3$O) crystals. They are soluble in chloroform, benzene and acetone and moderately soluble in ethanol. The solubility of the complexes with X=5-Br and 3-CH$_3$O is lower than that of the others with X=H and 5-Cl.

Cu(X-sal-fum)Cl (X=H, 5-Cl). A solution of the Schiff base (0.01 mol) in ethanol (50 ml) was added at about 60 °C to a solution of copper(II) chloride dihydrate (0.01 mol) in a small amount of water. The mixture was stirred at

a) μ: BM at room temperature.

this temperature for about 30 min. A brown crystalline precipitate was filtered off and washed with ethyl ether. Any attempt to recrystallize was unsuccessful. The compounds are dark brown (X=H) and yellowish brown (X=5-Cl), respectively. They are insoluble in water, but are soluble in chloroform, benzene, acetone, diethyl ether and ethanol to undergo decomposition.

The corresponding 5-bromo-complex (X=5-Br) was obtained as dark brown microcrystals. Although the elemental analysis for carbon, hydrogen and nitrogen slightly deviates from the formula Cu(5-Br-sal-fum)Cl, its properties agree with those expected for this compound. For example, the electronic spectrum and temperature dependence of magnetic susceptibilities are remarkably similar to those of Cu(H-sal-fum)Cl. The ν(C-O) band appears at about 1558 cm^{-1}, a value which lies in the same region as those of Cu(H-sal-fum)Cl and Cu(5-Cl-sal-fum)Cl.

Bis[N-*(2-furylmethyl)salicylideneaminato]nickel(II), Ni(X-sal-fum)*$_2$. The complexes were prepared by a method similar to that for the corresponding copper(II) complexes. They are olive-green. Their solubility is similar to that of the copper(II) complexes.

Bis[N-*(2-furylmethyl)-5-bromo-salicylideneaminato]cobalt(II), Co-(5-Br-sal-fum)*$_2$. The complex was prepared as red crystals by a method similar to that for the corresponding copper(II) complexes. Its solubility is similar to that of the copper(II) complexes.

Tris[N-*(2-furylmethyl)-salicylideneaminato]cobalt(III), Co(X-sal-fum)*$_3$. The complexes were prepared as dark green crystals by a method similar to that for the copper(II) complexes, except that the ligand to metal ratio was 3 : 1 and that the reaction was conducted for about two to three hours. Addition of such an oxidizing agent as hydrogen peroxide accelerates the oxidation of cobalt(II) to cobalt(III). Their solubility is similar to that of the copper(II) and nickel(II) complexes.

Measurements. Electronic absorption spectra of the complexes were measured on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were obtained from Nujol mulls using a Hitachi EPI-S2 infrared spectrophotometer.

Magnetic measurements at room temperature were carried out by the Gouy method using $CoHg(SCN)_4$ as a calibrant. Magnetic susceptibilities over a temperature range (76—320 K) were measured by the Faraday method. The temperature was controlled with an electric regulating system. For the complexes Cu(X-sal-fum)Cl, the Bleaney-Bowers Eq. 1 was found to hold,

$$\chi_A = g^2N\beta^2/3kT(1+1/3\exp(-2J/kT))^{-1} + N\alpha \quad (1)$$

where the symbols have their usual meanings.

Results and Discussion

Cobalt(II), Cobalt(III), and Nickel(II) Complexes. Both the bis(Schiff base)cobalt(II) and tris(Schiff base)cobalt(III) have been isolated. The cobalt(II) complex Co(5-Br-sal-fum)$_2$ is paramagnetic with a moment of 4.35 BM and shows an electronic absorption spectrum typical of the tetrahedral cobalt(II) complex, as shown in Table 2. The d-d band at about 8.2 kK may be assigned to a transition $^4T_1(F) \leftarrow {}^4A_2$. The cobalt(III) complexes Co(X-sal-fum)$_3$ are diamagnetic, and their electronic spectra are typical of the six-coordinate cobalt(III) complexes. The band at about 16.4—16.6 kK may be assigned to a transition $^1T_{1g} \leftarrow {}^1A_{1g}$, in the scheme of O_h field symmetry. Their d-d band maxima lie at almost the same frequencies as those of the corresponding *N*-alkylsalicylideneaminato-complexes.[5] In any of these complexes, the furan oxygen atom is not bound with the cobalt ion.

As shown in Table 1, complexes of the type Ni(X-sal-fum)$_2$ are diamagnetic in the solid state, indicating that they have a four-coordinate square-planar structure. They show electronic absorption spectra typical of the square-planar nickel(II) complex in non-donor solvents as well as in the solid state. The band at about 16 kK may be assigned to a $d_{x^2-y^2} \leftarrow d_{xy}$ transition. No absorption is observed at about 10—11 kK or lower frequencies, where the octahedral or tetrahedral nickel(II) complex is expected to absorb. Accordingly, it may be concluded that no association of the planar complexes occurs in solution at room temperature. In these nickel(II) complexes, the ligands X-sal-fum are found to function as bidentates, the furan oxygen atom not being bound to the nickel(II) ion.

It may be interesting to compare the results in the present work with those for related ligands as regards the coordination of the oxygen atom in the side chain Y. Of the ligands (III)—(VI), *n* being 2, (IV) has the highest ability to function as a terdentate ligand; the alcoholic oxygen atom is bound to the nickel(II) ion. Previous studies have shown that the nickel(II) complexes Ni(X-sal-Y)$_2$, Y being CH(R)CH(R)OH, have an octahedral configuration, in which the OH-group is bound to the nickel(II) ion.[6]

The oxygen atom in CH_3O has slightly lower capacity

TABLE 2. MAIN ABSORPTION MAXIMA OF M(X-sal-fum)$_2$ AND M(X-sal-fum)$_3$

Compound	Solvent	ν (log ε)
Ni(H-sal-fum)$_2$	$CHCl_3$	16.2(1.84), 23.7(3.66)
Ni(3-CH_3O-sal-fum)$_2$	$CHCl_3$	16.1(1.91), 23.6(3.62)
	Nujol	16.0
Ni(5-Br-sal-fum)$_2$	Nujol	16.0
Co(5-Br-sal-fum)$_2$	$CHCl_3$	8.2(1.67), 11.4(1.49), 26.4(3.93)
Co(H-sal-fum)$_3$	$CHCl_3$	16.6(2.48), 25.7(3.95)
Co(5-Cl-sal-fum)$_3$	$CHCl_3$	16.6(2.58), 25.2(3.95)
Co(5-Br-sal-fum)$_3$	$CHCl_3$	16.6(2.57), 25.2(3.92)
Co(3-CH_3O-sal-fum)$_3$	$CHCl_3$	16.4(2.62), 25.1(3.92)

ν: 10^3 cm^{-1}, sh: shoulder.

to be coordinated with the nickel(II) ion. It was revealed previously that Ni(H-sal-$CH_2CH_2OCH_3)_2$ is square-planar in the solid state, the OCH_3-group not being bound to the nickel(II) ion, although complexes of the type Ni(H-sal-$CH(R)CH_2OCH_3)_2$ have a six-coordinate, octahedral configuration with the CH_3O-group bound to the nickel(II) ion.

The present study shows that of the ligands (III)—(VI), n being 2, the furan oxygen atom in (VI) has the lowest tendency to be bound to the nickel(II) ion. In this respect, the ligand (III) seems to lie between (IV) and (VI). Previous studies have revealed that the CH_3O-group is bound to the metal ion in many of the Ni(X-sal-o-CH_3O-$C_6H_4)_2$ and Co(X-sal-o-CH_3O-$C_6H_4)_2$ type complexes.[3,7]

Summarizing the discussion given above, the following order may be derived as to the donor strength of the oxygen atom in Y of the ligands (I): CH_2CH_2-OH > $C_6H_4OCH_3$(o-) > $CH_2CH_2OCH_3$ > CH_2-furyl.

Copper(II) Complexes. Two types of copper(II) complexes have been isolated. The complexes Cu(X-sal-fum)$_2$ (X=H, 5-Cl, 5-Br, 3-CH_3O) in non-donor solvents show electronic absorption spectra with the first d-d band at about 17 kK, typical spectra being shown in Fig. 1. The absorption curves are similar to those of the complexes Cu(X-sal-n-alkyl)$_2$, the d-d band maxima being at nearly the same frequencies, a fact which implies that the complexes Cu(X-sal-fum)$_2$ may have an essentially planar, four-coordinate configuration.[8-10] Their magnetic moments also lie in the range from 1.83 to 1.95 BM, in agreement with the square-planar configuration. The spectra also show that the complexes in pyridine form pyridine adducts, in which the copper(II) ion assumes a coordination number exceeding four.

The complexes of the formula Cu(X-sal-fum)Cl (X=H, 5-Cl) at room temperature have subnormal magnetic moments of 1.31 and 0.92 BM, respectively,

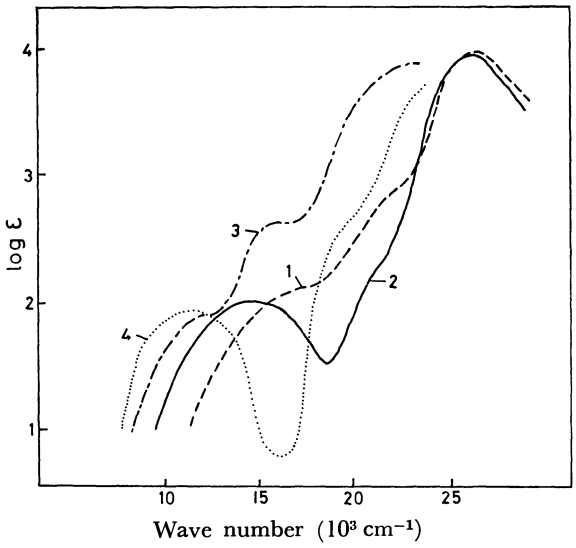

Fig. 1. Electronic absorption spectra of copper(II) complexes: 1, Cu(5-Br-sal-fum)$_2$, in $CHCl_3$; 2, Cu(5-Br-sal-fum)$_2$, in pyridine; 3, Cu(H-sal-fum)-Cl, in Nujol; 4, Cu(5-Cl-sal-fum)Cl, in Nujol.

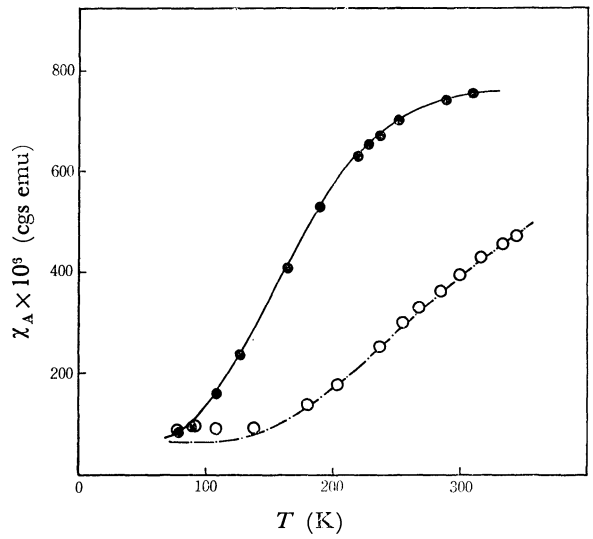

Fig. 2. Variation of magnetic susceptibilities, χ_A, with temperature: ●, Cu(H-sal-fum)Cl ($-2J$=550 cm^{-1}, g=2.26, $N\alpha$=60×10^{-6} emu); ○, Cu(5-Cl-sal-fum)Cl ($-2J$=1000 cm^{-1}, g=2.05, $N\alpha$=60×10^{-6} emu). The curves represent theoretical curves, which are calculated from Eq. 1, using values of J, g and $N\alpha$ given in parentheses.

which are much lower than the normal magnetic moments anticipated for the copper(II) complexes. A sort of interaction, therefore, may be expected to exist between two copper(II) ions. The magnetic susceptibility data over a temperature range 76—300 K, which are shown in Fig. 2, fit the Bleaney-Bowers Eq. 1, probably implying that these copper(II) complexes have a binuclear structure.

Their infrared ν(C-O) bands appear at 1555 (X=H) and 1550 cm^{-1} (X=5-Cl), respectively, which are found to be shifted toward higher frequencies than the typical bis(Schiff base)metal(II) complexes (1520—1530 cm^{-1}). Based on the criteria proposed previously,[11,12] the present finding seems to indicate that these complexes may have a structure with the phenolic oxygen atom bridging two cpoper(II) ions. The J value of Cu(Cl-sal-fum)Cl is significantly larger than that of Cu(H-sal-fum)Cl, a fact which suggests that the spin-spin interaction in the former is stronger than that in the latter.

As may be seen in Fig. 1, the spectrum of Cu(H-sal-fum)Cl widely differs from that of Cu(5-Cl-sal-fum)-Cl. Kato *et al.*[12] reported previously that the spectra of the Cu(X-sal-alkyl)Cl type complexes were classified into two groups, which were designated as B- and Y-type. The present study shows that the spectrum of Cu(H-sal-fum)Cl is similar to that of the B-type and that the spectrum of Cu(5-Cl-sal-fum)Cl is similar to that of the Y-type.

Synthesis and Characterization of Aluminium(III) Complexes with Schiff Bases Obtained from Salicylaldehyde Derivatives and Alkylamines

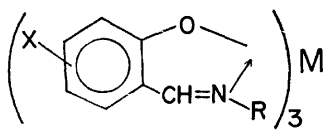
Hiro KUMA and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received April 2, 1976)

Aluminium(III) complexes with Schiff bases (abbreviated as X-sal-R) obtained from salicylaldehyde derivatives and amines (RNH_2) have been synthesized by a method starting from aluminium(III) isopropoxide. Complexes of the type Al(X-sal-*n*-alkyl)$_3$ have been isolated, but any attempt to obtain complexes of the types Al(X-sal-*i*-C_3H_7)$_3$ and Al(X-sal-aryl)$_3$ has not been successful. The tris-complexes obtained show similar electronic absorption spectra, regardless of R. Proton magnetic resonance spectra indicate that the aluminium(III) complexes may have a *fac*-configuration.

Tris(*N*-alkyl- or *N*-aryl-salicylideneaminato)-complexes of tervalent 3d transition elements, such as vanadium(III),[1] chromium(III),[2,3] cobalt(III),[4,5] and iron(III),[6] were studied previously. It seems interesting to study the corresponding complexes (abbreviated as M(X-sal-R)$_3$, I) of other tervalent metal ions having no d-electrons and compare the results with those previously reported for the complexes of the 3d ions. Along that line, yttrium(III) complexes with these ligands were examined in a previous paper.[7]



(I)

As extension of the previous studies, aluminium(III) was taken up as the central metal ion in the present work. No aluminium(III) complexes with these Schiff bases have ever been isolated.

Experimental

Materials. *Tris(N-alkylsalicylideneaminato)aluminium(III)*: To a suspension of aluminium(III) isopropoxide (0.01 mol) in 1-butanol or 2-propanol was added a Schiff base (0.033 mol), and the mixture was heated on an oil-bath at about 90 °C for 5 h. The solution was filtered and allowed to stand in a refrigerator overnight. A yellow, crystalline precipitate was collected by filtration and recrystallized from methanol or ethanol to yield pale-yellow crystals of Al(X-sal-R)$_3$. Difficulty was sometimes encountered in the recrystallization, since the complexes often undergo decomposition in the solution. The compounds are soluble in chloroform, methanol and ethanol, but insoluble in benzene. They undergo decomposition in water very readily.

Analytical data of the complexes are shown in Table 1.

Measurements. Electronic absorption spectra were measured on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were obtained from Nujol mulls using a Hitachi EPI-S2 infrared spectrophotometer.

Proton magnetic resonance spectra were recorded on a JEOL Model C-NMR spectrometer using tetramethylsilane as an internal reference. Measurements at a temperature lower than −4 °C were not possible because of too low solubility.

Since the complexes underwent decomposition in solution, the spectral measurements were carried out as quickly as possible. Moreover, measurements were repeated after the spectra had once been determined, to see if any spectral change due to decomposition during the measurements occurred or not.

Results and Discussion

The reaction in ethylene glycol at a temperature higher than 100 °C was reported to be suitable in synthesizing the chromium(III) tris-complexes.[3,8] This method was employed successfully in the preparation of the tris(*N*-alkylsalicylideneaminato)iron(III) complexes, but did not yield the corresponding aluminium(III) complexes. The reaction of aluminium(III) isopropoxide with a Schiff base in a suitable anhydrous solvent, such as 1-butanol or 2-propanol, proved to be appropriate for synthesizing tris(*N*-alkylsalicylideneaminato)aluminium(III). This method may be considered to be applicable to preparation of the tris-complexes of other metal ions in high oxidation states.

It was not possible to synthesize complexes of the type Al(X-sal-*t*-C_4H_9)$_3$. The complexes of this type have never been reported for 3d elements, owing possibly to steric hindrance arising from the bulky *t*-butyl groups. Any attempt to isolate complexes of the type M(X-sal-*i*-C_3H_7)$_3$ has so far been unsuccessful

Table 1. Analytical data of the Al(X-sal-R)$_3$ type complexes

for M=aluminium(III) and iron(III),[9] whereas the corresponding chromium(III),[3] manganese(III),[9] and cobalt(III)[10] complexes were obtained previously. The failure in isolating the aluminium(III) complexes of this type may be due mainly to the steric factor, since the ionic radius of Al^{3+} (0.57 Å) is much smaller than the other three ions. On the contrary, the radius of Fe^{3+}(0.67 Å) is slightly larger than those of Cr^{3+} (0.65 Å), Mn^{3+}(0.66 Å) and Co^{3+}(0.65 Å). Consequently, the reluctance of iron(III) to form the $Fe(X\text{-}sal\text{-}i\text{-}C_3H_7)_3$ type complexes may be due not to the steric factor alone, but to weaker iron(III)-to-ligand bond, as compared with that for chromium(III), manganese(III), and cobalt(III).

It may also be interesting to note that any aluminium(III) complexes with the neutral *N*-alkyl- or *N*-arylsalicylideneamines have not been isolated in the present work, in contrast to the yttrium(III) complexes.[7]

Main electronic absorption bands of the complexes $Al(X\text{-}sal\text{-}alkyl)_3$ are shown in Table 2. It is found that the electronic absorption bands due to internal transitions within the ligands are shifted very slightly toward higher frequencies on formation of the aluminium(III) complex. This slight band shift seems to show the weak aluminium(III)-to-ligand bond.

TABLE 2. ELECTRONIC ABSORPTION BANDS OF $Al(X\text{-}sal\text{-}R)_3$ IN CHLOROFORM

Compound	ν(log ε)	
$Al(H\text{-}sal\text{-}CH_3)_3$	24.6 (2.74),	31.8 (4.10)
$Al(H\text{-}sal\text{-}C_2H_5)_3$	24.6 (2.71),	31.8 (4.10)
$Al(H\text{-}sal\text{-}n\text{-}C_3H_7)_3$	24.5 (2.74),	31.8 (4.10)
$(H\text{-}sal\text{-}CH_3)H$[a]	24.5 (2.20),	31.6 (3.58)

ν: 10^3 cm^{-1}. a) Free Schiff base.

The complexes show an infrared ν(C=N) band at about 1620 cm^{-1}, indicating that the ligands are coordinated as bidentates in their deprotonated form with the metal ion. Previous studies have shown that the bidentate *N*-substituted salicylideneaminate anion bound with a metal ion exhibits the corresponding band at about 1610—1620 cm^{-1}, whereas the neutral salicylideneamines coordinated to a metal ion show the corresponding band at about 1640 cm^{-1}.[11]

The *fac* and *mer* isomers are possible in tris(chelate)-metal complexes, if the bidentate ligands are not symmetric. Pairs of such isomers have indeed been obtained with ligands, such as amino acids[12] and β-diketonates.[13] For the complexes of the type $M(X\text{-}sal\text{-}R)_3$, however, only the *mer* form has so far been isolated, and the *mer* form was found to be an exclusively predominant species in their solutions as well.[14] This result was ascribed to the steric disposition of the nitrogen substituents on one hand and to the electrostasic repulsion among the three oxygen atoms in the *fac* form on the other.

Main PMR spectral data of the complexes $Al(X\text{-}sal\text{-}CH_3)_3$ in chloroform-*d* are shown in Table 3. The $N\text{-}CH_3$ resonance appears as a sharp singlet at about 6.78 and 6.84 τ for X=H and 5-Br, respectively, at 50, 20, and −4 °C. It should be noted that the $N\text{-}CH_3$ resonance at 50 °C is as sharp as at −4 °C. The *mer* isomer, which has a lower symmetry than the *fac* isomer, would be unambiguously identified by three equally intense signals for the $N\text{-}CH_3$ groups, as was found to be the case with the corresponding cobalt(III) and vanadium(III) complexes.[1,14,15] Hence, the spectra of $Al(H\text{-}sal\text{-}CH_3)_3$ and $Al(5\text{-}Br\text{-}sal\text{-}CH_3)_3$ are found to be consistent with the *fac* form having three-fold symmetry, although their low solubility did not allow PMR spectral measurements at lower temperatures. A recent X-ray structural study[16] has revealed that $Al(H\text{-}sal\text{-}CH_3)_3$ consists of six-coordinate aluminium(III) complexes having a *fac* configuration. These aluminium(III) complexes seem to be the first examples of tris(*N*-substituted salicylideneaminato)metal(III) complexes having a *fac* configuration to be isolated.

TABLE 3. CHEMICAL SHIFTS, $\tau(N\text{-}CH_3)$, OF $Al(X\text{-}sal\text{-}CH_3)_3$ AT DIFFERENT TEMPERATURES

Compound	−4 °C	20 °C	50 °C
$Al(H\text{-}sal\text{-}CH_3)_3$	6.78	6.78	6.78
$Al(5\text{-}Br\text{-}sal\text{-}CH_3)_3$	6.84	6.84	6.84
$(H\text{-}sal\text{-}CH_3)H$[a]	—	6.87	—

a) Free Schiff base.

It is not clarified at the moment why the *fac* form of these aluminium(III) complexes is obtained much more readily than the *mer* form, in contrast to many 3d metal complexes. However, it may be true that the present finding would give rise to renewed controversies over the stability of the *mer* and *fac* isomers of the tris(bidentate)-metal complexes.

Financial support of this work by the Ministry of Education is gratefully acknowledged. Thanks are also due to Dr. Yoshiyuki Namba of Osaka College of Education for informing us of the results of the X-ray study prior to publication.

Studies of the Mixed Amino Acid Complexes of Cobalt(III). IV.[1] Magnetic Circular Dichroism Spectra of the $[Co(ox)_x(gly)_y(en)_z]$ Complexes

Nobuko MATSUOKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 3, 1976)

Magnetic circular dichroism (MCD) spectra of a series of sixteen complexes of the $[Co(ox)_x(gly)_y(en)_z]$ type have been measured. The MCD intensity increases with increasing number of the coordinated carboxylato groups. A negative MCD band whose shape is similar to the corresponding absorption band was observed in the first d-d absorption band region. This negative band is assigned to the "B" term, in which the "A" term is swamped. A positive and a negative MCD band appear in the second d-d absorption band region. The origin of the positive band is discussed.

Only a few papers have reported the magnetic circular dichroism (MCD) spectra of cobalt(III) complexes; these results include $[Co(NH_3)_6]^{3+}$,[2,3] $[Co(CN)_6]^{3-}$,[2] $[CoCl(NH_3)_5]^{2+}$,[2] *trans*- and *cis*-$[CoCl_2(en)_2]^+$,[2] *cis*-$[Co(NH_3)_4(OH_2)_2]^{3+}$,[2] $[Co(en)_3]^{3+}$,[2,3] $[Co(ox)_3]^{3-}$,[2,4] $[Co(rac\text{-}pn)_3]^{3+}$,[3] $[Co(mal)_3]^{3-}$,[4] and $[Co(acac)_3]$.[5]* The purpose of the present work is to take a general view of the MCD spectra of a fundamental series of the sixteen cobalt(III) complexes, whose absorption spectra have been studied already.[6] The sixteen complexes form a complete series of the $[Co(ox)_x(gly)_y(en)_z]$ type,* where x, y, and z are 0, 1, 2, or 3 and $x+y+z$ equals 3. The oxalato, glycinato, and ethylenediamine ligands all produce a five-membered chelate ring; each complex is a tris-(chelate) type and belongs to one of the $[Co^{III}(O)_n(N)_{6-n}]$ types (n=0—6).

Experimental

The complexes were prepared by the methods described in the available literature.[6-13]

Visible and near-ultraviolet absorption spectra were measured by a Shimadzu UV-200 spectrophotometer. MCD spectra were recorded in a magnetic field of 15000 gauss with a Jasco MOE-1 spectropolarimeter. The MCD intensity is expressed in terms of the molar ellipticity per unit magnetic field in the direction of the light beam, $[\theta]_M$, which has the units of degree m^{-1} dm^3 mol^{-1} $gauss^{-1}$.

Measurements were made at room temperature in aqueous solutions, except for *fac*-$[Co(gly)_3]$, which was studied in 3 M H_2SO_4 solution.

Results and Discussion

Band shapes of MCD spectra have been generally interpreted as composed from three terms, A, B, and C, whose shapes are either dispersion type (for A) or absorption type (for B and C). The "A" term arises when at least one of the ground or the excited states is degenerate, while a "B" term is present in principle for every electronic transition. A "C" term exists only when the ground state is degenerate. This term may be disregarded in the present case, since the ground state of an octahedral cobalt(III) complex is nondegenerate, $^1A_{1g}$.

The sixteen complexes of $[Co(ox)_x(gly)_y(en)_z]$ series can be classified into ten types with respect to the coordinated atoms. They are $[Co(N)_6]$, $[Co(N)_5(O)]$, *cis(O)*- and *trans(O)*-$[Co(N)_4(O)_2]$, *mer(N)*- and *fac(N)*-$[Co(N)_3(O)_3]$, *trans(N)*- and *cis(N)*-$[Co(N)_2(O)_4]$, $[Co(N)(O)_5]$ and $[Co(O)_6]$, in which only the *mer(N)*-$[Co(N)_3(O)_3]$ type has no degenerate excited state in any approximation. Thus, the A term may be expected in most of the complexes, except in *mer(N)*-$[Co(gly)_3]$ and *mer(N)*-[Co(ox)(gly)(en)].

The observed MCD spectra of $[Co(ox)_x(gly)_y(en)_z]$ type complexes in the visible and near-ultraviolet region are shown in Figs. 1—6, together with their absorption spectra. The data are summarized in Table 1.

The First d-d Absorption Band Region. A negative band, whose shape resembles greatly the corresponding absorption band, appears in this region for all the present complexes. This result is in accordance with that from the magnetic rotatory dispersion studies of $[Co(en)_3]^{3+}$, $[Co(gly)(en)_2]^{2+}$, *etc.*[14] Thus it seems that only a negative B term is present, while the A

term is not to be seen. This is in agreement with the results of earlier workers, who interpreted the unobservable A term as a quenching of the orbital angular momentum in the excited state.[2]

It should be noted that the extremum of the MCD band has slightly higher energy than the maximum of the corresponding absorption band in most of the complexes (Table 1). This fact can be well explained by considering the presence of a small positive A term which is swamped by the large negative B term, as has been pointed out for $[Co(N)_6]$ type complexes

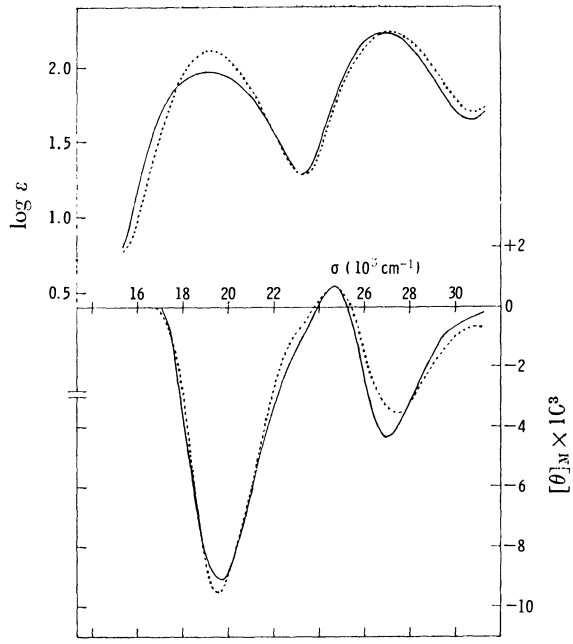

Fig. 4. Absorption and MCD spectra of two geometrical isomers of [Co(ox)(gly)(en)]: *mer*(*N*) (——) and *fac*(*N*) (·····).

by Russell and Douglas.[3]

McCaffery and co-workers mentioned that the d d bands are much more resolved in MCD than in the absorption of *cis*- and *trans*-$[CoCl_2(en)_2]^+$.[2] We cannot detect such an effect, however, for the present complexes in comparing the *cis* and *trans* isomers of $[Co(gly)_2(en)]^+$ or $[Co(ox)(gly)_2]^-$, and the *mer* and *fac* isomers of $[Co(gly)_3]$ or [Co(ox)(gly)(en)] (Figs.

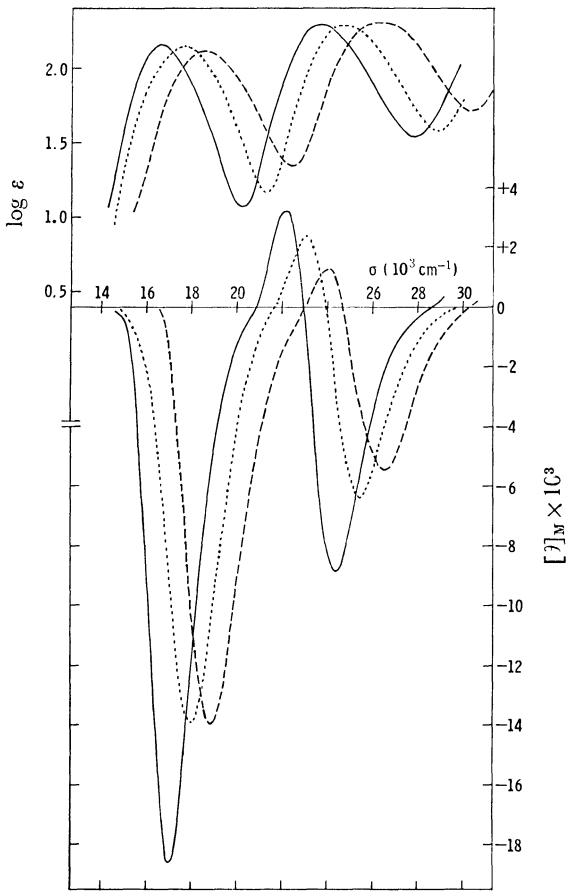

Fig. 6. Absorption and MCD spectra of $[Co(ox)_2(en)]^-$ (----), $[Co(ox)_2(gly)]^{2-}$ (·····), and $[Co(ox)_3]^{3-}$ (——).

a) In the units of 10^{-5}.

complexes, except $[Co(en)_3]^{3+}$, that a positive MCD band is observed on the lower energy side of the main negative MCD band in the second d-d absorption band region (Figs. 1—6). No such positive band was reported for the cobalt(III) complexes studied previously, except for $[Co(ox)_3]^{3-}$.[2,4]

Alternative interpretations may be presented for the origin of the positive MCD band in the second d-d absorption band region. The first would to postulate that this band is a longer wavelength wing of an A term. McCaffery and co-workers interpreted the MCD spectrum of $[Co(ox)_3]^{3-}$ in this region by postulating an A term of trigonal splitting E transition in D_3 symmetry.[2] However, the fact that the *mer(N)*-$[Co(N)_3(O)_3]$ type complexes also have the positive band cannot be so explained, because these complexes do not have a degenerate excited state.

In the second explanation, the positive band is attributed to a positive B term arising from one of the splitting components of the $T_{2g}(O_h)$ transition in the lower symmetry. In this case, it is expected that the energy separation between the two components of the *trans* isomer of $[Co(N)_4(O)_2]$ or $[Co(N)_2(O)_4]$ type is larger than that of the *cis* isomer. This energy separation is $1/2\delta_\sigma - 1/2\delta_\pi$ for the *trans* isomer, and $1/4\delta_\sigma - 1/4\delta_\pi$ for the *cis*, using Yamatera's parameters.[15] Nevertheless, the observed separation between the positive and negative bands is virtually invariant for both isomers (Table 1).

It should be noted that the maximum of the second d-d absorption band is located at slightly higher energy than the negative MCD band for the complexes of $[Co(N)_6]$ and $[Co(N)_5(O)]$ type, while it lies in the intermediate region between the positive and negative MCD bands for the complexes having more carboxylato groups, *e.g.*, for the $[Co(N)_2(O)_4]$, $[Co(N)(O)_5]$, and $[Co(O)_6]$ type complexes. Moreover, the intensity ratio of the positive to the negative band increases in the above order, and in the limiting case the positive MCD band does not appear in the $[Co(en)_3]^{3+}$ complex. These results seem to indicate that the positive MCD band is related to the presence of coordinated carboxylato groups.

In order to confirm the above assumption, MCD spectra of the other complexes were measured. Unexpectedly, no positive band is observed in *mer(N)*- and *fac(N)*-$[Co(\beta\text{-ala})_3]$ (Fig. 7). Also $[Co(mal)_3]^{3-}$ and *cis*-$[Co(NH_3)_4(OH_2)_2]^{3+}$ did not exhibit this band, as was reported in the previous papers.[2,4] From these facts, it is concluded that the positive band is characteristic for the complex having a planar carboxylato chelate ring. It has been well established that the β-ala[16] and mal[17] chelate rings are not planar.

Intensity. It is interesting that the values of $|[\theta]_{Mext}|$ and also $|[\theta]_{Mext}|/\varepsilon_{max}$ increase with increasing number of coordinated carboxylato groups, in both the first and second d-d absorption band regions, as can be seen from Table 1.

The value of $|[\theta]_{Mext}|$ in the first d-d absorption band region is greater than that in the second d-d absorption band region for all the present complexes, although some exceptional complexes, such as $[CoCl(NH_3)_5]^{2+}$ and *cis*-$[CoCl_2(en)_2]^+$, have been reported previously.[2]

(Received December 12, 1975)

Niobium monophosphide single crystals were obtained by chemical vapor deposition from a gas mixture of $NbCl_5$, PCl_3, H_2, and Ar on a quartz substrate using metallic impurity. The existence of Au, Pt, Pd, and Ni resulted in the growth of whiskers or pillar crystals. Maximum whisker length of 5 mm and thickness of 30 μm were obtained at 1150 °C for an hour with the use of Pt impurity. Platelet crystals ($400 \times 1000 \times 20$ μm, max.) were obtained with the use of Pt at 1240 °C. The growth directions of the whiskers and some platelet crystals were assigned to ⟨001⟩ and a direction in (001) plane, respectively. The optimum growth conditions for the pillar crystals in the case of Ni impurity: substrate temperature 1000—1020 °C, gas flow ratio $PCl_3/(NbCl_5+PCl_3)$ of 0.7—0.75. From observation of the tip and base of pillar crystals grown with Ni, the growth mechanism seems to be base VLS followed by VS.

Of the transition metal monophosphides, niobium monophosphide (NbP, niobium phosphide hereafter) is of interest as regards thermal stability. Niobium phosphide is a greyish black material having a metallic luster and good electrical conductor ($\approx 10^{-3}\,\Omega\cdot$cm),[1] and which is moderately hard (microhardness 599 kg/mm^2)[1] and is not attacked by water or dilute acids at room temperature.[2]

The existence of two equiatomic compounds (α- and β-NbP) proposed by Schönberg[3] was disproved by Bollar and Parthe,[4] who showed that there is a single compound with a range of homogeneity 44.7—50 a/o of phosphorus. The structure is body-centered tetragonal, four formulas per unit cell, space group $I4_1md$, the lattice parameter of c slightly varying from 11.40_0 (44.7 a/o P) to 11.37_8 (50 a/o P).[4]

Niobium phosphide has been prepared by heating niobium metal with red phosphorus in sealed tube at 650—1000 °C[1,5] with tricalcium diphosphide,[1] or by electrolyzing phosphate of metals.[6] The single crystal has been prepared by Schaefer and Fuhr[7] by means of chemical vapor transport. However, no work has been reported on whisker or pillar crystal growth from a vapor phase.

We have examined the growth conditions of whisker or pillar crystals with use of metallic impurity from a gas mixture of niobium pentachloride, phosphorus trichloride, hydrogen and argon, and also physical and chemical properties of the crystals. The results are given in this paper.

Experimental

A quartz tube (7 mm I. D. and 65 mm in length) containing a SiC heater was placed as a substrate in the center of a vertical reaction tube (quartz of 35 mm I. D.) heated from outside with a nichrome heater. The quartz substrate was abraded with emery papers, rinsed with deionized water and dried. A stream of niobium pentachloride (bp 240 5.°C) prepared by chlorination of niobium powder (14 mesh) at 500—600 °C and carried by argon, and another stream of hydrogen saturated by phosphorus trichloride at a given temperature were introduced from the upper inlet of the reaction tube. Argon was used for cleaning the reaction system before each experiment. The flow rates of each gas at room temperature were measured with an orifice-type flow meter. Flow rate of niobium pentachloride was calculated from that of chlorine stream to the niobium metal, where this chlorination reaction might be considered to proceed quantitatively in a steady state.

The surface temperature of the substrate was measured with an optical pyrometer through an observation window and was corrected by means of a CA thermocouple. The ambient temperature of the reaction atmosphere was controlled between 300 and 400 °C using the CA thermocouple to keep the niobium pentachloride in gas phase. As the source of impurities to promote the crystal growth, various metals such as Mn, Fe, Co, Ni, Pd, Pt, and Au were painted on the substrate in the form of aqueous solutions of sulphates or chlorides, and were subjected to decomposition or reduction into the corresponding metals inside the reactor at a temperature below that used for the niobium phosphide crystal growth. The surface concentration of the impurity was fixed at *ca.* 0.05 mg/cm^2 of substrate area.

The range of pillar crystal length and thickness in this paper refers to about twenty of the longest samples obtained in each experiment. Crystals were observed with a scanning electron microscope. An X-ray diffractometer, a micro-analyzer and an oscillation camera were used for analysis of the grown crystals, the base of pillar crystals and a well-formed whisker, respectively.

Conductivity of whisker and platelet crystal was measured by conventional two-probe method using a Wheatstone bridge in an argon flow.

Results and Discussion

Growth Conditions of the Pillar Crystals Using Ni Metal.

Effect of Substrate Temperature: Substrate temperature influences pillar crystal growth by a great deal as shown in Fig. 1. An average length of 1.2 mm was attained at 1000—1020 °C, the length decreasing abruptly at a temperature higher or lower than 1000—1020 °C. Above the optimum temperature, pillar crystals grew to a direction perpendicular to the growth axis resulting in considerable rough surface. The lowest temperature for the growth of pillar crystals was approximately 900 °C.

Effect of the Gas Composition: The effect of the gas flow ratio of $PCl_3/(NbCl_5+PCl_3)$ on the length and thickness of pillar crystals is shown in Fig. 2, where the sum of the flow rates of niobium pentachloride and phosphorus trichloride is kept at 0.20 cm^3/s.

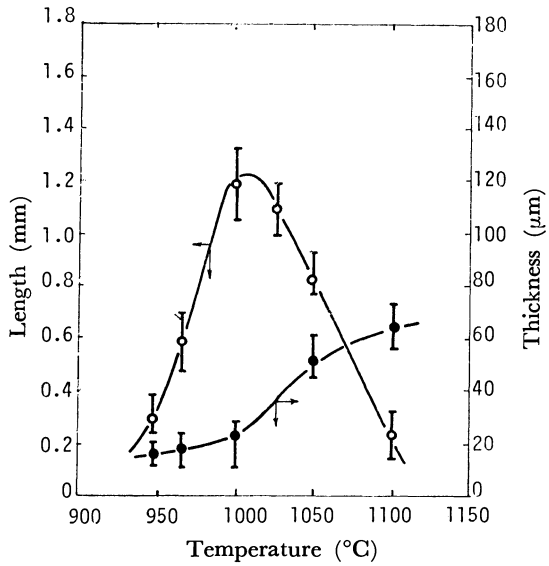

Fig. 1. Effect of substrate temperature on the length and the thickness of pillar crystals.
Impurity: Ni, reaction time: 10 min, $NbCl_5$ flow rate: 0.05 cm^3/s, PCl_3 flow rate: 0.15 cm^3/s, H_2 flow rate: 3.2 cm^3/s, Ar flow rate: 1.0 cm^3/s.

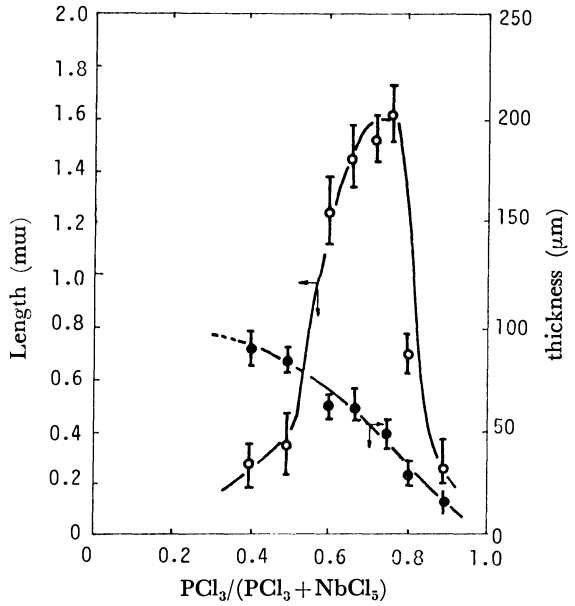

Fig. 2. Effect of gas flow ratio of $PCl_3/(NbCl_5+PCl_3)$ on the length and the thickness of pillar crystals.
Impurity: Ni, substrate temperature: 1050 °C, reaction time: 10 min, $NbCl_5+PCl_3$ flow rates: 0.20 cm^3/s, H_2 flow rate: 3.2 cm^3/s, Ar flow rate: 0.5 cm^3/s.

The length of crystals increased with increase in the ratio, and reached a maximum at a flow ratio of 0.70—0.75, decreasing abruptly above the ratio of 0.75. In contrast, the thickness of the crystals decreased linearly with increase in the ratio, pillar crystals with a well-formed and smooth surface growing preferably at the ratio of above 0.75 (Fig. 3). This optimum flow ratio declined to a PCl_3-rich region as compared with the expected reaction stoichiometry $PCl_3/(NbCl_5+PCl_3)$ of 0.5 and with the optimum flow ratio for the deposition of polycrystalline NbP by use of no impurity

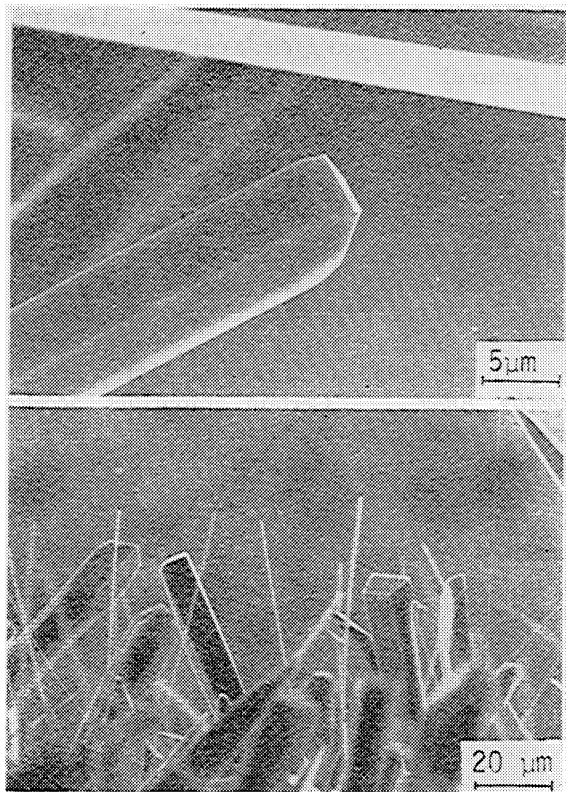

Fig. 3. Well-formed pillar crystals.
Impurity: Ni, substrate temperature: 1020 °C, reaction time: 10 min, $NbCl_5$ flow rate: 0.04 cm^3/s, PCl_3 flow rate: 0.15 cm^3/s, H_2 flow rate: 4.0 cm^3/s, Ar flow rate: 1.0 cm^3/s.

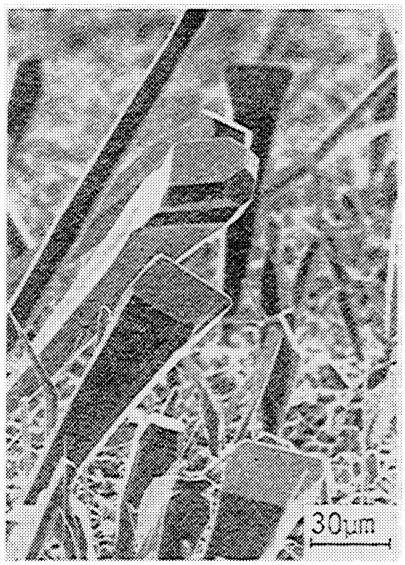

Fig. 4. Pillar crystals having a tapered form.
Impurity: Ni, substrate temperature: 1100 °C, reaction time: 30 min, $NbCl_5$ flow rate: 0.15 cm^3/s, PCl_3 flow rate: 0.15 cm^3/s, H_2 flow rate: 4.0 cm^3/s, Ar flow rate: 1.0 cm^3/s.

of 0.6. On the other hand, at a flow ratio of $PCl_3/(NbCl_5+PCl_3)$, crystals grew to a direction perpendicular to the growth axis; remarkable growth steps or a rough surface being observed. Tapered pillar crystals (Fig. 4) were obtained at 1100 °C and a flow

ratio $PCl_3/(NbCl_5+PCl_3)$ of about 0.8. The tips of the crystals were shaped a clear-cut square or a tetragonal pyramid.

Effect of the Growth Time: The effect of growth time on the crystal length and thickness is shown in Fig. 5. The length of the pillar crystals increased with increase in reaction time up to 15 min after an induction time of about 5 min, and levelled off after the elapse of 15 min. In contrast, the thickness remained constant 10—15 μm until 15 min, beyond which pillar crystals grew in thickness with time. This can be explained by rapid linear growth by VLS, followed by gradual thickening by VS mechanism.

Impurity Effect. Certain impurities accelerate the growth of whiskers or pillar crystals. The growth mechanism can be explained by "VLS mechanism." The impurity effects of various metals on the crystal growth of niobium phosphide at 900—1250 °C are summarized in Table 1. Iron, cobalt, chromium, and manganese give no influence on the whisker growth for all the temperatures examined, the deposition taking place in uniform coatings or polycrystals. Gold and nickel show a conspicuous effect at 1050 °C, giving straight whiskers and pillar crystals, respectively. Platinum gives well-formed straight whiskers and platelet crystals at 1100—1200 °C and 1250 °C, respectively. Palladium gives cubic crystals mixed with thin whiskers above 1100 °C.

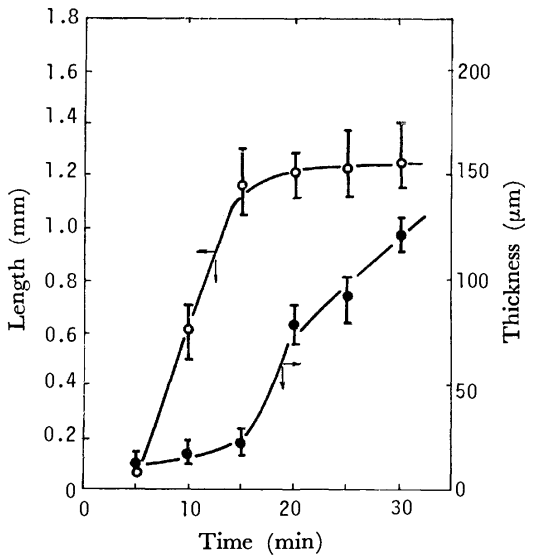

Fig. 5. Effect of reaction time on the length and the thickness of pillar crystals.
Impurity: Ni, substrate temperature: 1020 °C, $NbCl_5$ flow rate: 0.05 cm^3/s, PCl_3 flow rate: 0.15 cm^3/s, H_2 flow rate: 3.2 cm^3/s, Ar flow rate: 1.0 cm^3/s.

Table 1. Impurity effects

Impurity	Effect	Crystal morphology
Fe	−	Polycrystals
Co	−	Polycrystals
Ni	++	Pillars
Cr	−	Polycrystals
Mn	−	Polycrystals
Au	++	Whiskers
Pt	++	Whiskers and pillars (1100—1200 °C), and platelets (>1200 °C)
Pd	+	Cubic crystals (>1100 °C)

Crystal Morphologies. Typical whiskers grown with gold as an impurity are shown in Fig. 6. The whiskers have a square cross section and reach a maximum length of 1 mm and 5 μm in thickness after 2 h. Lateral surfaces are generally smooth, but a square-shaped growth depression appears occasionally (Fig. 6B). The tips of pillars is a clear-cut square (Fig. 6C). Figure 7 shows the appearance of pillar crystals grown on a platinum painted zone at 1150 °C for 15 min, polycrystal coatings depositing in the absence of platinum. Average pillar length reached 3 mm (5 mm max.) and thickness of 30 μm after

Impurity: Pt, reaction time: 15 min.
A) Substrate temperature: 1150 °C, $NbCl_5$ flow rate: 0.03 cm^3/s, PCl_3 flow rate: 0.03 cm^3/s, H_2 flow rate: 4.0 cm^3/s, Ar flow rate: 0.6 cm^3/s.
B) Substrate temperature: 1240 °C, $NbCl_5$ flow rate: 0.03 cm^3/s, PCl_3 flow rate: 0.04 cm^3/s, H_2 flow rate: 3.7 cm^3/s, Ar flow rate: 0.5 cm^3/s.

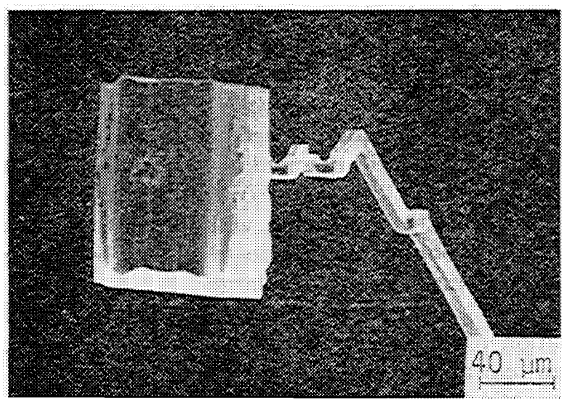

Fig. 8. Peculiar pillar crystals.
Impurity: Pt, substrate temperature: 1070 °C, reaction time: 15 min, $NbCl_5$ flow rate: 0.06 cm^3/s, PCl_3 flow rate: 0.04 cm^3/s, H_2 flow rate: 3.5 cm^3/s, Ar flow rate: 0.5 cm^3/s.

an hour. At a temperature higher than 1200 °C, thin platelet crystals $400 \times 1000 \times 20$ μm with a smooth surface grew on the platinum painted zone (Fig. 7B). Sometimes, peculiar pillar crystals with a deformed 120×100 μm cubic crystal at the middle or the tip of the crystal were observed (Fig. 8). Well-formed $100 \times 100 \times 50$ μm crystals deposited, sometimes mixed

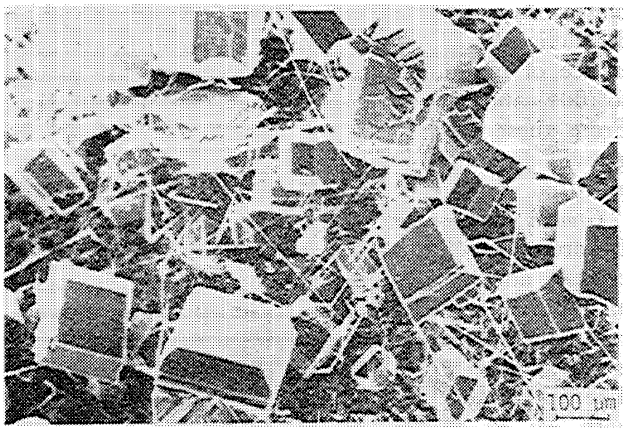

Fig. 9. Well-formed crystals.
Impurity: Pt, substrate temperature: 1145 °C, reaction time: 30 min, $NbCl_5$ flow rate: 0.04 cm^3/s, PCl_3 flow rate: 0.06 cm^3/s, H_2 flow rate: 4.1 cm^3/s, Ar flow rate: 0.6 cm^3/s.

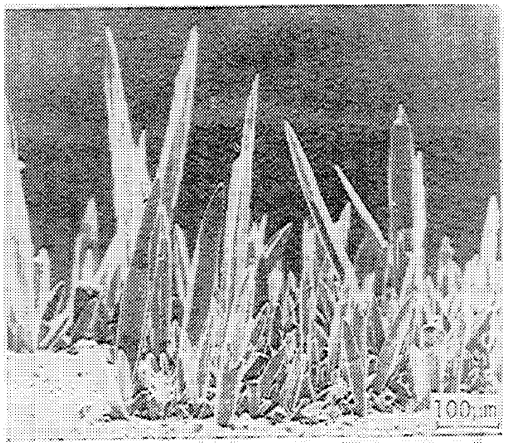

Fig. 10. Phylloid crystals.
Impurisy: Ni, substrate temperature: 1025 °C, reaction time: 15 min, $NbCl_5$ flow rate: 0.05 cm^3/s, PCl_3 flow rate: 0.10 cm^3/s, H_2 flow rate: 4.1 cm^3/s, Ar flow rate: 0.5 cm^3/s.

with thin whiskers on the platinum painted zone at 1145 °C for 30 min (Fig. 9). Similar crystals grew with palladium at 1070 °C.

Nickel impurity considerably accelerated the growth of phylloid crystals with a sharp tip, the maximum length reaching 2 mm and thickness 50 μm. A typical phylloid crystal grown at 1025 °C for 15 min is shown in Fig. 10.

The growth axis of the whisker was confirmed by full-rotation photograph. Indices of an X-ray diffraction photograph are shown in Fig. 11, in which one well-formed whisker (10 μm thick and 3 mm long) is mounted with the whisker axis perpendicular to the incident X-ray beam in an oscillation camera (diameter 57 mm).

X-Ray diffraction diagrams of whiskers (A), platelet crystals (B) and woolly whiskers (C) are shown in Fig. 12 together with that in reference (D),[8] where a collection of whiskers and platelet crystals were dispersed on a holder plate. Thus the axes of the whiskers and faces of platelets are mainly parallel to the holder

plate. A strong single peak is observed on whisker diffraction which corresponds to (200) of the tetragonal lattice of niobium phosphide. Strong peaks assinged to (004) and (008) are observed on platelet diffraction. From these results and the crystal morphologies, the growth direction of whisker is supposed to be ⟨001⟩ and that of platelet in some directions on (001) plane.

Growth Mechanism of Whiskers and Pillar Crystals. In order to clarify the growth mechanism of NbP crystals activated by metallic impurities, the location of impurity on the growing crystal plays an important role, since the evidence for the tip VLS mechanism is the existence of drops of impurity on their tips. The tip part of most whiskers and pillar crystals grown with Au, Pt, or Ni impurity is commonly shaped a clear-cut square or a long square pyramid, a drop like solid being seldom found on the tip, even in the initial stage of growth. The presence of Ni metal could not be confirmed by X-ray microanalysis of the tip of pillar crystals grown with Ni impurity. We might suppose that a tip VLS mechanism does not take part during the course of growth of whisker or pillar. The result of X-ray microanalysis on the cross section of the base of pillar crystals grown with Ni impurity is shown in Fig. 13. The layer is seen to consist of uniform composition of niobium–phosphorus–nickel. The eutectic temperatures[9] of the binary alloy of Nb–Ni and P–Ni are reported to be 1175 °C (40.2 a/o Nb) and 880 °C (19 a/o P), respectively. It seems that niobium atom is dissolved in the Ni–P melt to yield a melt of Nb–Ni–P mixture from which niobium phosphide can be crystallized. Pillar crystal growth was observed 2—5 minutes later after the substrate had been heated at a given temperature in a given reaction atmosphere. The "induction time" can be attributed to a slow diffusion rate of niobium and phosphorus into the nickel metal, or the time necessary for saturation of the drop with niobium and phosphorus. A possible mechanism for the pillar crystal growth of niobium phosphide activated by nickel metal may be base VLS mechanism at least during the course of the initial stage of growth. Appearance of a pillar crystal suggests the growth by VS mechanism. The pillar crystals might grow by base VLS mechanism followed by VS mechanism. However, another mechanism including a center axial screw dislocation mechanism or Chikawa's mechanism[10] cannot be excluded.

B) A collection of platelet crystals dispersed on a holder plate.
C) Woolly whiskers as grown.
D) Data of NbP quoted from the Ref. 8.

Properties of Niobium Phosphide Crystals. Electrical Resistivity: Electrical resistivity of a well-formed whisker (10—20 μm in diameter and 2—3 mm in length) and a platelet crystal (200—300 μm in width and 10—20 μm in thickness) along the crystal axis and some directions in (001) plane was examined in argon atmosphere, respectively. The resistivity increased with a rise in temperature in the range 20—250 °C, characteristic of metallic conduction; 9×10^{-4} for a whisker and 1×10^{-2} Ω·cm for a platelet crystal. The former value is in line with 0.4×10^{-3} Ω·cm of powdered niobium phosphide reported by Ripley,[1] the latter being considerably larger.

Stability of Oxidation in Air: Resistivity against oxidation of niobium phosphide in air was examined at an elevated temperature. Figure 14 shows the change of weight ratio with time at various temperatures between 900 and 1100 °C. The weight ratio increased with a rise in temperature above 970 °C, until the ratio attained a limiting value of *ca.* 1.64. X-Ray diffraction profiles of the products obtained at 1100 °C for an hour exhibited only the peaks of niobium phosphate ($NbPO_5$). Niobium phosphate is a light fluffy white powder and can not form a tight protecting layer on the surface of niobium phosphide crystal. It may be concluded that niobium phosphide is very stable in air up to 950 °C, but oxidizes to the phosphate at above 970 °C. Oxidation products of TiP[11] and ZrP,[12] an analogous phosphide of NbP, are a mixture of titanium pyrophosphate and titanium

oxide, and zirconium oxide, respectively. It is of interest that oxidation products of the transition metal monophosphides differ from metal to metal.

Summary

Single crystals of NbP were obtained by the CVD method on a quartz substrate using metallic impurity.

1) Au, Pt, Pd, and Ni used as an impurity have an essential effect on whisker or pillar crystal growth. In the case of Pt, whisker (5 mm long $\times$ 30 μm thick, max.) and platelet crystals (400 $\times$ 1000 $\times$ 20 μm, max.) were obtained in an hour at 1150 and 1240 °C, respectively.

2) The growth directions of whiskers and platelet crystals were assigned to $\langle 001 \rangle$ and some direction in (001) plane, respectively.

3) In the case of Ni impurity, the longest pillar crystal was obtained at a substrate temperature of 1000—1020 °C, and $PCl_3/(NbCl_5+PCl_3)$ ratio of 0.7—0.75.

4) A drop-like solid was seldom found on the tip of most whiskers and pillar crystals, a layer with uniform Nb–P–Ni compositions being observed in the base of pillar crystals. It is presumed that base site VLS mechanism is responsible for the growth of NbP whiskers or pillar crystals rather than tip VLS mechanism.

The Crystal Structure of $(+)_{350}$-(*R*)-Propylenediamine-*N*,*N*′-dimethylethylenediamineplatinum(II) Di-μ-(+)-tartrato(4−)-bis(antimonate(III)) Dihydrate

Keiji MATSUMOTO, Shun'ichiro OOI, Masao SAKUMA, and Hisao KUROYA

(Received March 11, 1976)

The crystal of the title compound is monoclinic, with $a=9.415(3)$, $b=15.767(7)$, $c=8.786(3)$ Å, $\beta=94.25(4)°$, the space group of $P2_1$, and $Z=2$. The structure was determined from the counter intensity data by heavy-atom techniques and was refined by the block-diagonal least-squares calculations to R 0.050 for 2604 non-zero reflections. The Pt atom has a square-planar coordination by 4N atoms, the secondary N atoms of which are of the *S* absolute configuration.

Few studies have been made of the optical resolution of the platinum(II) complexes as well as of the correlation between the optical activity and structure of the Pt(II) chelates. Ito *et al.*[1] studied the absorption and circular dichroism (CD) spectra of a number of Pt(II) chelates of optically active diamines. The resolution and racemization reaction of some *N*-methylethylenediamineplatinum(II) substances were investigated by Buckingham *et al.*[2] and Goddard *et al.*[3] Recently, Bosnich[4] reported on the conformational and vicinal effects which were observed in the CD spectra of *N*-methyl-substituted ethylenediamine and propylenediamine complexes of Pt(II). As a part of our studies of the CD-structure correlation, we have been attempting for several years to resolve several mixed ligand complexes of Pt(II). This report will describe the absolute configuration of the complex cation of $(+)_{350}$-[Pt(*R*-pn)(Me$_2$en)][Sb$_2$(+)-tart$_2$]·2H$_2$O (*R*-pn: (*R*)-(−)-propylenediamine; Me$_2$en: *N*,*N*′-dimethylethylenediamine; [Sb$_2$(+)-tart$_2$]: di-μ-(+)-tartrato(4−)-bis(antimonate(III))), which was obtained in the course of our studies; we will also show the crystal structure of this compound.

Experimental

Preparation of $(+)_{350}$-[*Pt*(R-*pn*)(*Me*$_2$*en*)][*Sb*$_2$(+)-*tart*$_2$]·2*H*$_2$*O*. [PtCl$_2$(Me$_2$en)] was prepared following a method which is analogous to that used for [PtCl$_2$en].[5] A mixture of [PtCl$_2$(Me$_2$en)] (0.57 g) and an excess of (*R*)-propylenediamine ((*R*)-(−)-pn) in water (15 ml) was heated at 90 ° until the solution became clear. The solution was evaporated to near dryness, whereby the excess of diamine was removed. The resulting [Pt(*R*-pn)(Me$_2$en)]Cl$_2$ is highly hygroscopic and could not be isolated. Ag$_2$[Sb$_2$(+)-tart$_2$] (1.05 g) was added to "[Pt(*R*-pn)(Me$_2$en)]Cl$_2$" in 20 ml of water, and the suspension was warmed for 0.5 h in the dark. The AgCl was then filtered off and washed with hot water (10 ml). The filtrate and washing were combined, and the resultant solution was evaporated to dryness under reduced pressure. The product was dissolved in 14 ml of hot water acidified with a drop of acetic acid. The solution was filtered, and a small amount of unidentified precipitates was removed; then the solution was allowed to stand at room temperature for two days. The colorless crystals thus obtained were recrystallized from hot water involving a drop of acetic acid. They were filtered, and subsequently washed with ethanol and acetone. Yield, 0.51 g (23%).

Found: C, 19.21; H, 3.38; N, 5.68%. Calcd for $(+)_{350}$-[Pt(*R*-H$_2$NCH$_2$CH(CH$_3$)NH$_2$)(H$_3$CNHCH$_2$CH$_2$NHCH$_3$)]-[Sb$_2$(+)-(C$_4$H$_2$O$_6$)$_2$]·2H$_2$O: C, 19.39; H, 3.23; N, 6.03%.

An optical rotation measurement was made on 0.0104 g of the compound in 10 ml of 0.02 M acetic acid at 350 nm, using a JASCO J-20 Automatic Recording Spectropolarimeter; $[\alpha]_{350}$, +510°.

X-Ray Data Collection. The crystals of $(+)_{350}$-[Pt(*R*-pn)(Me$_2$en)][Sb$_2$(+)-tart$_2$]·2H$_2$O are colorless, needle-shaped, and stable in the air. The specimen employed for data collection had dimensions of $0.23\times0.15\times0.13$ mm and was mounted on a glass fibre. Preliminary X-ray photographic studies, using oscillation, Weissenberg, and precession techniques, revealed the approximate unit cell dimensions, the Laue symmetry of 2/m, and the systematic absences of $0k0$ for $k=2n+1$. These extinctions indicate that the space group is $P2_1$, since the compound is optically active. Crystal data: $C_{15}H_{30}O_{14}N_4Sb_2Pt$, monoclinic, $a=9.415(3)$, $b=15.767(7)$, $c=8.786(3)$ Å, $\beta=94.25(4)°$, $U=1300.7$ Å^3, $Z=2$, $D_c=2.40$, $D_m=2.37$ g·cm^{-3}, space group $P2_1$, λ(Mo$K\alpha$)=0.71069 Å, μ(Mo$K\alpha$)=78.0 cm^{-1}.

The cell dimensions were determined by a least-squares fit using 2θ values measured accurately on a Philips PW1100 diffractometer. Intensity data with $6°\leqq2\theta\leqq55°$ were collected at room temperature by the use of graphite-monochromated Mo$K\alpha$ radiation. The ω-2θ scan technique was employed. The scan range was $(0.7+0.2\tan\theta)°$, and the scan speed, 1.0°/min; the background was counted for 20 s at each end of the scan. Three standard reflections, 600, $0\bar{4}0$, 003, measured every 240 min, showed no appreciable decay. A total of 2604 intensities with $I_{top}-2\sqrt{I_{top}}>I_{back}$ were classified as observed; I_{top} is the intensity (counts/s) measured at the top of the peak, and I_{back} is the mean background intensity (counts/s) obtained from the preliminary background measurements for 5 s on each side of the peak. Corrections for Lorentz-polarization and absorption effects were made, and the relative structure factors were derived.[6]

Structure Determination

The structure was solved by heavy-atom techniques. Six cycles of block-diagonal least-squares refinement with the isotropic temperature factor for each atom gave an R of 0.069. Nine cycles of the refinement, based on the anisotropic temperature factors for Pt and Sb atoms, resulted in $R=0.050$. The minimized function was $\Sigma w(F_o-|F_c|)^2$ $(=\Sigma w\Delta F^2)$. The weighting scheme, $w=(39.16/F_o)^2$ for $F_o>39.16$, $w=1$ for $23.30\leqq F_o\leqq39.16$, and $w=0.8$ for $F_o<23.30$, was used to make $w\Delta F_o^2$ approximately constant over the whole range of F_o. The corrections for the anomalous dispersion effect were applied for the Pt and Sb atoms.[7] The

scattering factors for neutral Pt, Sb, O, N, and C atoms were taken from the International Tables for X-Ray Crystallography.[7] The hydrogen atoms could not be located in a difference Fourier synthesis computed at this stage. The maximum shift of parameters in the final cycle was $<0.1\,\sigma$. The absolute configuration of the complex cation was determined on the basis of the known configurations of the (+)-tartrate ion and (*R*)-propylenediamine molecule. The final atomic coordinates, which give the absolute structure of the crystal, are presented in Table 1, together with their temperature factors. The observed and calculated structure factors are preserved at the Chemical Society of Japan (Document Number 7627). All the calculations were performed on a FACOM 270-30 computer at Osaka City University. The programs used included a local version of the UNICS.[8]

Results and Discussion

The absolute configuration of the complex cation is shown in Fig. 1, while the crystal structure viewed along the b axis is presented in Fig. 2. The Pt atom has a square-planar coordination by 4 N atoms. The O(8)($1-x$, $-1/2+y$, $-z$) occupies the apical position of a square pyramid whose basal plane is defined by Pt, N(1), N(2), N(3), and N(4), the Pt···O(8) distance being 3.31 Å. Both of the asymmetric second-

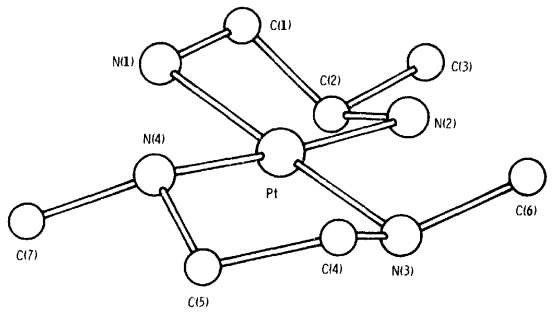

Fig. 1. The absolute configuration of the complex cation in $(+)_{350}$-[Pt(*R*-pn)(Me_2en)][$Sb_2(+)$-tart$_2$]·$2H_2O$.

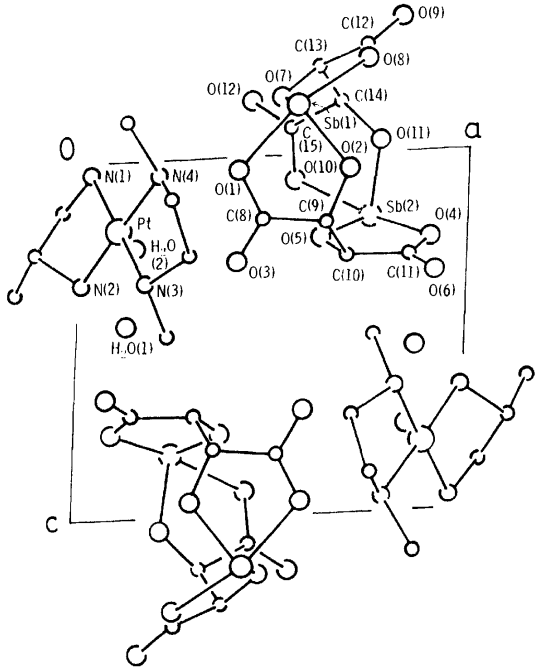

Fig. 2. The crystal structure viewed along the b axis.

ary N atoms of the Me_2en molecule have the *S* absolute configuration, and both the N–CH_3 groups are equatorial with respect to the 5-membered chelate ring (λ conformation) composed of the Me_2en ligand and the Pt atom.

In the solution of [Pt(*R*-pn)(Me_2en)]Cl_2 we prepared, the complex cation can exist in three isomers, (*R,R*), (*S,S*), and (*R,S*), where *R* or *S* denotes the absolute configuration of the asymmetric nitrogen center; the relative amounts of these isomers will be dependent upon the conformational energies of the respective isomers. The [$Sb_2(+)$-tart$_2$]$^{2-}$ anion chooses the (*S,S*) isomer to yield the least soluble diastereoisomer $(+)_{350}$-[Pt(*R*-pn)(Me_2en)][$Sb_2(+)$-tart$_2$]·$2H_2O$. The *S* isomer was also found in the least soluble diastereoisomer, $(+)_{350}$-[$Pt(NH_3)_2(Me_3en)$][$Sb_2(+)$-tart$_2$]·H_2O[9] (Me_3en: *N,N,N'*-trimethylethylenediamine). Thus, the dissymmetric [$Sb_2(+)$-tart$_2$]$^{2-}$ anion is likely to have a preference for the *S* and/or (*S,S*) isomer over the *R* and/or (*R,R*) isomer when the planar Pt(II) chelate of *N*-methyl-substituted ethylenediamine is given.

		N(2)-C(2)-C(1)	106(1)
C(1)-C(2)	1.52(3)	N(2)-C(2)-C(3)	110(2)
C(2)-C(3)	1.53(3)	C(1)-C(2)-C(3)	111(2)
C(4)-C(5)	1.52(3)	N(3)-C(4)-C(5)	106(2)
		N(4)-C(5)-C(4)	109(2)

The bond lengths and angles are given in Table 2. The Pt–N bond lengths are in the range of 2.04—2.07 Å and seem slightly longer than the mean Pt–N bond length of 2.04 Å in [Pt en_2][Mo $O(H_2O)(CN)_4$]·$2H_2O$.[10] The coordination angle in the Pt—Me_2en chelate ring is 84.2°, while that in the Pt—(*R*)-pn chelate ring is 81.9°; the latter is smaller than the values reported in Refs. 9 and 10. The deviations of the atoms from the plane defined by 4 N atoms are as follows: Pt, −0.004; N(1), −0.007; N(2), 0.007; N(3), −0.007; N(4), 0.007; C(1), −0.045; C(2), 0.636; C(3), 0.402; C(4), −0.403; C(5), 0.324; C(6), −0.947; C(7), 0.893 Å. The equation of the plane is $-0.843X+0.512Y-0.168Z=-0.979$, where the coordinates are referred to the orthogonal axes, a, b, and c*. The geometry and dimensions of the [$Sb_2(+)$-tart$_2$]$^{2-}$ anion agree well with those in K_2[$Sb_2(+)$-tart$_2$]·$3H_2O$.[11]

The crystal consists of the [Pt(*R*-pn)(Me_2en)]$^{2+}$ cations, [$Sb_2(+)$-tart$_2$]$^{2-}$ anions, and water molecules. A [Pt(*R*-pn)(Me_2en)]$^{2+}$ cation (*x*, *y*, *z*) is surrounded trigonally by three [$Sb_2(+)$-tart$_2$]$^{2-}$ anions (*x*, *y*, *z*; $1-x$, $-1/2+y$, $-z$; $-1+x$, *y*, *z*). The possible

Table 3. Possible hydrogen bonds

Atoms A — H ··· B			Interatomic distances A···B	Interatomic distances H[b]···B	Positions[a] of A	Positions[a] of B
N(1)	H	O(2)	2.93(2)	1.95	1	2

H_2O(2)		O(1)	2.70(2)		1	1

a) The numerals refer to the following equivalent positions: 1 *x*, *y*, *z*; 2 $1-x$, $-1/2+y$, $-z$; 3 $-x$, $-1/2+y$, $-z$; 4 $-x$, $1/2+y$, $1-z$; 5 $-1+x$, *y*, *z*; 6 *x*, $-1+$y, *z*. b) The coordinates of the H atoms were calculated on the assumption that the N-H distance was 1.03Å.

hydrogen bonds are summarized in Table 3. Both primary amino groups take part in the formation of the N–H···O hydrogen bonds, while, with respect to the secondary amino groups, only one of the two participates in the N–H···O hydrogen bond, which is rather weak in view of the H···O distance (2.07 Å).

This research was supported by a Scientific Research Grant from the Ministry of Education. K. M. also wishes to acknowledge the financial support of the Matsunaga Science Foundation.

Stereoselectivities in Mixed Ligand Complexes of Cobalt(III), with L-Asparagine as a Ligand

Hideto TAKENAKA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 26, 1976)

The [Co(ox)(L-aspNH$_2$)(en)] complex as well as the [Co(L-aspNH$_2$)$_{3-n}$(L-asp)$_n$]$^{n-}$ complexes (n=1,2) have been prepared and separated into their diastereoisomers by means of column chromatography. The structures of the isomers thus isolated have been characterized by their absorption, CD, and PMR spectra. Stereoselectivity in the [Co(ox)(L-aspNH$_2$)(en)] complex has been found for the *fac*-Λ and *mer*-Λ isomers, and those in the [Co(L-aspNH$_2$)$_{3-n}$(L-asp)$_n$]$^{n-}$ complexes, for the *fac*-Λ and *mer*-Λ isomers. These results have provided proof of the stereoselective effect due to the chelated L-asparaginate ion.

Metal complexes containing optically active ligands frequently exhibit stereoselective effects upon the formation of their diastereoisomers. In order to study such stereoselective formation, we previously examined the mixed amino acidato cobalt(III) complexes containing the L- or D-aspartate ion (L- or D-asp) as the primary ligand.[1-3] More recently we examined the complex consisting of the L-aspartate ion, the oxalate ion, and ethylenediamine, [Co(ox)(L-Hasp)(en)], in order to obtain proof of the stereoselective effect due to the chelated optically active aspartate ion.[4]

In the present work L-asparagine (L-HaspNH$_2$) was chosen as the primary ligand; a mixed complex [Co(ox)(L-aspNH$_2$)(en)] has been prepared in order to study the stereoselective influence due to the chelated L-asparaginate ion. Furthermore, a series of complexes, [Co(L-aspNH$_2$)$_{3-n}$(L-Hasp)$_n$] (n=1,2) have been prepared in order to study their stereochemistry and stereoselectivities. Related complexes, [Co(L-aspNH$_2$)$_3$] and [Co(L-aspNH$_2$)$_2$(D-Hasp)] have also been investigated.

Experimental

Preparation. Oxalato(L-asparaginato)ethylenediaminecobalt(III), [Co(ox)(L-aspNH$_2$)(en)]: The diastereoisomers of this complex were obtained much as were those of the corresponding L-aspartato complex.[4] The separation of the diastereoisomers was carried out by the use of a column containing 200—400 mesh Dowex 50WX8 resin in the Na-form (5.0×40.0 cm). During elution with water, six bands of non-charged species descended; the first and fourth bands, formed in very poor yields, were not the desired species. The other four bands corresponded to four isomers of the desired complex and were labeled A-1—A-4 according to the order of elution. These bands were collected in fractions, and each fraction was concentrated to a small volume with a rotary evaporator at *ca.* 35 °C. The concentrated solution was then kept in a refrigerator for a few days in order to crystallize the desired isomers. Recrystallization was performed from warm water (*ca.* 50 °C).

Bis(L-asparaginato)-L-hydrogenaspartato and L-Asparaginatobis(L-hydrogenaspartato)cobalt(III), [Co(L-aspNH$_2$)$_{3-n}$(L-Hasp)$_n$] (n=1, 2): To a green solution of tricarbonatocobaltate(III), (Co(NO$_3$)$_2$·6H$_2$O, 5.82 g, 0.02 mol scale) prepared by the usual method,[5] we added L-asparagine monohydrate (6.0 g, 0.04 mol); the mixture was then stirred at 40 °C for 2 h. To this solution we added L-aspartic acid (3.4 g, 0.025 mol) and activated charcoal (2.0 g), after which the mixture was stirred at *ca.* 50 °C for 1 h. The charcoal and a small amount of precipitates were removed by filtration, and then perchloric acid (60%) was added in order to neutralize the filtrate (pH *ca.* 7.0), whereupon the precipitation of KClO$_4$ and the evolution of CO$_2$ took place. The resulting solution was iced for a while and then filtered two or three times. A quarter of the final filtrate was diluted to *ca.* 1 l with water and then charged on a column of Sephadex QAE-A25 in the Cl-form (3.0×120.0 cm). After washing with water, the gradient elution with aqueous solutions of CaCl$_2$ prepared in 0.01 M and 0.03 M was employed at the rate of *ca.* 0.5 ml/min. The twelve bands completely separated were labeled L-1—L-12 according to the order of elution. The four bands from L-9 to L-12 corresponded to the *mer*-Λ, *mer*-Λ, *fac*-Λ, and *fac*-Λ isomers of the *tris*(L-aspartato)cobaltate(III) complex respectively, which had already been characterized.[6] The L-3 and L-4 bands were very poor in yield and were not the desired ones. The other six bands (L-1, L-2 and L-5—L-8) were collected in fractions, and every fraction was concentrated to a small volume with a rotary evaporator at *ca.* 35 °C. When the L-1 and L-6 concentrates were acidified with aqueous HCl (pH *ca.* 1.0), crude hydrogen compounds were obtained (Compounds L-1 and L-6). After the removal of the L-1 compound, the filtrate, which exhibited a minus CD sign in the first absorption-band region, was passed through a column containing Dowex 50 WX8 resin in the H-form (3.0×20.0 cm). The effluent was evaporated to a small volume, and ethanol was added until silky precipitates appeared. The precipitates (labeled L-1′) were collected by centrifuging. Similarly, after the removal of the L-6 compound the filtrate was also passed through a resin column in the H-form, and the effluent in the earlier stage, which exhibited a minus CD sign, was collected (L-6′). However, we failed to isolate crystals from that fraction because of the extremely poor yield. The L-2, L-5, L-7, and L-8 concentrates were also passed through the resin columns in the H-form. Each effluent was evaporated to a small volume, and a small amount of ethanol was added to precipitate each hydrogen compound. The desired compounds were obtained from the L-2, L-7, and L-8 fractions, but no compound was isolated from the L-5 fraction because of its great solubility and because it was obtained in the poorest yield. Recrystallization of each crude compound was performed by dissolving it in water containing a small amount of NaOH, and by then acidifying it with aqueous perchloric acid, and by finally adding a small amount of ethanol. Of these complexes, the L-6 complex was again recrystallized from a solution of pH *ca.* 4.0 in order to remove another isomer which still contaminated it.

Bis(L-asparaginato)-D-hydrogenaspartatocobalt(III), [Co(L-aspNH$_2$)$_2$(D-Hasp)]: This complex was prepared using D-aspartic acid in place of L-aspartic acid according to the procedure described above. Six bands of univalent anionic species separated on a Sephadex column were collected in

fractions (D-1—D-6). The D-4 and D-6 fractions were very poor in yield and were not the desired complexes. However, from the D-6 fraction a novel complex, *fac*(*N*)-[Co(L-aspNH$_2$)(D-asp)] in which both the ligands act as terdentate, was isolated.[7] The other four fractions (D-1—D-3 and D-5) were concentrated with a rotary evaporator at *ca.* 35 °C. Each of the D-1 and D-5 concentrates was passed through a column of Dowex 50 WX8 resin in the H-form (3.0×20.0 cm). The effluent was evaporated to a small volume. To the D-1 concentrate, methanol was added to give crystals of the desired hydrogen compound (D-1). The filtrate, which exhibited a minus CD sign, was further evaporated almost to dryness to obtain the residue (D-1′). The D-5 concentrate was stored in a refrigerator for a few days to obtain the hydrogen compound (D-5). The concentrated D-2 and D-3 fractions were acidified with aqueous HCl. The D-2 was then stored in a refrigerator for a few days to obtain the hydrogen compound (D-2), while the D-3 fraction, when treated similarly, gave the hydrogen compound (D-3) after the addition of ethanol. The recrystallization of each hydrogen compound was performed by dissolving it in an aqueous NaOH solution, by acidifying it with aqueous perchloric acid, and by then cooling it. As for the D-1′ compound, recrystallization was performed by dissolving it in a warm mixture of methanol and water and by then adding ethanol when cold.

Tris(L-asparaginato)cobalt(III), [*Co*(L-*asp*NH$_2$)$_3$]: The method used for the isolation of the four isomers of the [Co(L-Hasp)$_3$][6] complex was employed; to a green solution of tricarbonatocobaltate(III) (0.02 mol scale) we added L-asparagine monohydrate (9.0 g, 0.06 mol), and the solution was stirred at 60 °C for 2 h. Then the solution was adjusted to pH *ca.* 4.0 with aqueous HCl and stirred for a few min. The solution was again adjusted to pH *ca.* 8.0 with an aqueous solution of NaOH and then stirred at *ca.* 70 °C for 2 h. The resulting solution was kept in a refrigerator for a day in order to precipitate one of the desired isomers (*mer*-*Λ*). After the isomer had been collected by filtration, the filtrate was adsorbed on a column containing Dowex 50 WX8 resin in the Na-form (7.0×15.0 cm); two bands corresponding to non-charged species were collected in one fraction by elution with water. The fraction was concentrated to a small volume, and the concentrate was charged on another column in the Na-form (5.0×30.0 cm); after a while, two separate bands appeared. The fast-descending band was confirmed to be the *mer*-*Λ* isomer, and the slow-descending one, to be the *fac*-*Λ* species. Each band was collected in a fraction and concentrated to crystallize the isomer. Recrystallization was performed from warm water except for the *mer*-*Λ* isomer. The recrystallization of the *mer*-*Λ* isomer was performed by dissolving it in 30% perchloric acid and by then diluting it with water. The last isomer, *fac*-*Λ*, could not be isolated because of its poor yield.

Formation Ratios of the Isomers. Although asparagine is hydrolyzed to aspartic acid under certain conditions,[8] the hydrolysis was negligible in the reactions used in the present work. To every reaction mixture mentioned in *Preparation*, activated charcoal was added in order to favor the formation of an equilibrium mixture of diastereoisomers. From the spectral data on the fractions obtained by chromatographic separation, the formation ratios of the isomers were evaluated. For some isomers not isolated as crystals, the ε and the $|\Delta\varepsilon|$ values were assumed to be the same as those for the corresponding geometrical isomers isolated as crystals.

Measurement. The absorption (AB) spectra were measured with a Hitachi 323 Recording Spectrophotometer. The circular dichroism (CD) spectra were recorded on a JASCO Model ORD/UV-5 spectrophotometer with a CD attachment. The proton magnetic resonance (PMR) spectra were recorded on a JEOL JNM-PS-100 NMR spectrometer at *ca.* 23 °C, using D_2O as the solvent. The values of the chemical shifts were referred to internal sodium d_4-trimethylsilylpropionate (TMSP). The pH values of the solutions were measured with a Hitachi-Horiba M-7E pH meter. Sodium carbonate was used to adjust the pH values.

Results and Discussion

Characterization of Isomers. The [Co(ox)(L-aspNH$_2$)(en)] Complex: No work has been reported on cobalt(III) complexes containing asparagine as ligands except for the *tris*(asparaginato) complex.[9] The results of the elemental analyses for the isolated complexes are summarized in Table 1. The AB and CD spectral data in the d-d transition region are also given in Table 1. The *mer* or *fac* structure of each isomer was determined from the AB spectrum. The *Λ* or *Δ* configuration of the diastereomers was determined from the sign of the main CD peak in the first absorption-band region.

The PMR spectra of the four isomers of the [Co(ox)(L-aspNH$_2$)(en)] complex are shown in Fig. 1. Two protons of the CH$_2$ group and one proton of the CH group of L-aspNH$_2$ correspond to the AB and X portions respectively in an ABX system. The multiplet-like signals at 3.8—4.0 ppm are due to the CH moiety (X proton), and the separation width of the complicated signals is represented by the expression of $(J_{AX}+J_{BX})$.[10] Moreover, since the coupling constant of the vicinal protons, the J_{vic} value, depends on the dihedral angle,[11] the value of $(J_{AX}+J_{BX})/2$ gives information about the orientation of the side-chain of the chelated asparaginate ion, the X proton of the CH moiety being spatially fixed in the chelated state. The $(J_{AX}+J_{BX})/2$ values observed for the four isomers are: *mer*-*Λ*, 4.0 Hz; *mer*-*Δ*, 6.2 Hz; *fac*-*Λ*, 4.0 Hz; *fac*-*Δ*, 6.0 Hz. The corresponding value for the terdentate

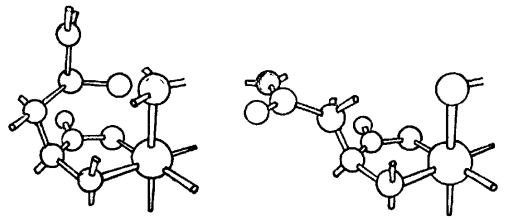

Fig. 2. Orientations of chelated L-aspNH$_2$ side-chain.

L-aspNH$_2$ ion in the [Co(L-aspNH$_2$)(D-asp)] complex is known to be 4.0 Hz.[7] This suggests that, in both the *mer*-*Λ* and *fac*-*Λ* isomers, the side-chain of the chelated L-aspNH$_2$ turns its *β*-acid amide group toward the apical site occupied by an NH$_2$ group of the chelated en, and that, in both the *mer*-*Λ* and *fac*-*Λ* isomers, the side-chain is far from the apical site occupied by an O group in the chelated $C_2O_4^{2-}$ ion (Fig. 2). Thus, these different orientations of the side-chain of chelated L-aspNH$_2$ are caused by the different inter-ligand interactions.

The [Co(L-aspNH$_2$)$_{3-n}$(L-Hasp)$_n$] Complexes: In a mixed tris-type complex with two kinds of amino acidate ion, three *mer* isomers can exist, each of them consisting of a pair of diastereomeric isomers: *cis*(*N*)-*cis*(*O*)-*Δ* and -*Λ*, *cis*(*N*)*trans*(*O*)-*Δ* and -*Λ*, and *trans*(*N*)-*cis*(*O*)-*Δ* and -*Λ*, according to the arrangements of two identical amino acidate ions. Previously, we characterized three isomers of *mer*-*Δ*-[Co(L-pro)(D-Hasp)$_2$] and one isomer of *mer*-*Λ*-[Co(L-pro)(L-Hasp)$_2$] on the basis of the PMR spectral data, the formation ratios, and an examination of the molecular models.[3] Yoneda *et al.*[12] characterized two isomers of *mer*-*Λ*-[Co(gly)$_2$(L-Hglu)][13] on the basis of a semiempirical consideration of the PMR spectrum.

Now, let us attempt to characterize two isomers of *mer*-*Λ*-[Co(L-aspNH$_2$)(L-Hasp)$_2$] on the basis of the PMR spectra. When we pay attention to three methine protons, namely, one proton for the chelated L-aspNH$_2$ ion and two protons for the two chelated L-asp ions, the following four criteria help in the characterization of the *mer*-*Λ* isomers concerned:

1. When an $NH_2CH(R)COO^-$ ion is chelating through a five-membered ring, the methine proton (*α*-hydrogen) shows no chemical shift in the range of pH 6—9.[14]

2. The methine proton adjacent to the coordinated N atom resonates at a higher magnetic field when the O atom occupies the site *trans* to the N atom than when the N atom occupies the same site.[15]

3. When the methine groups of both the chelating L-aspNH$_2$ and L-asp are present in the same types of chemical and magnetical environments, the methine proton of the L-aspNH$_2$ always resonates in a field lower by 0.10—0.12 ppm than that of the L-asp. This was confirmed by comparing the PMR spectra of complexes of the same type (Table 2).

4. The $(J_{AX}+J_{BX})/2$ values of the chelated L-aspNH$_2$ and L-asp give information about the orientations of the side-chains of both ligands.[3,4,16]

We first assign the signals of the methine protons in the spectrum of the *mer*-*Λ*-[Co(L-Hasp)$_3$] complex on the basis of the above criteria; the spectrum and the structure are shown in Figs. 3 and 4 respectively. The signals of the methine protons appear at 3.55, 3.80, and 3.98 ppm. From the second criterion, the two protons at B and C in Fig. 4 are expected to resonate in lower fields than that at A. Thus, the signals at 3.55 ppm are assignable to the methine proton at the A position. From the fourth criterion, the signals centered at 3.80 ppm with the value of $(J_{AX}+J_{BX})/2=$ 3.5 Hz, and those at 3.98 ppm with the value of $(J_{AX}+J_{BX})/2=5.8$ Hz, are assignable to the methine protons situated in the B and C positions respectively. When the L-asp ion chelating at the A position in Fig. 4 is replaced by a L-aspNH$_2$ ion to give *mer*-*Λ*-*trans*(*N*)*cis*(*O*) geometry, the chemical shift of the methine proton of the chelated L-aspNH$_2$ can be expected to be *ca.* 3.65—3.67 ppm from the third criterion, and the

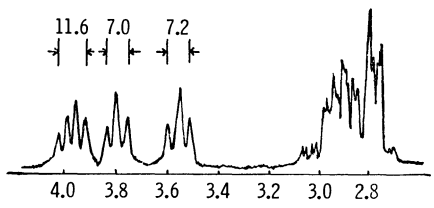

Fig. 3. PMR spectrum of *mer*-*Λ*-[Co(L-Hasp)$_3$] in D_2O (pD 9.1).

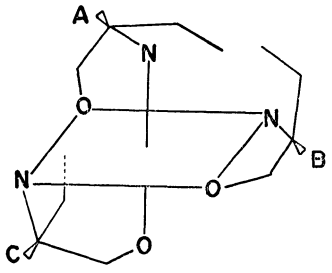

Fig. 4. Structure of *mer*-*Λ*-[Co(L-Hasp)$_3$].

chemical shifts of the two methine protons of the two chelated L-asp ions at the B and C positions can be expected to appear at *ca.* 3.80 ppm and *ca.* 3.98 ppm respectively from a comparison with the known signals for the *mer*-*Λ*-[Co(L-Hasp)$_3$] complex. By analogy, the chemical shifts of the methine protons of the chelating L-aspNH$_2$ and L-asp ions for the *mer*-*Λ*-[Co(L-aspNH$_2$)-(L-Hasp)$_2$] complex are expected to be *ca.* 3.55 ppm (L-asp at A), 3.90—3.92 ppm (L-aspNH$_2$ at B), and 3.80 ppm (L-asp at C) for the isomer of *cis*(*N*)*cis*(*O*) geometry, and *ca.* 3.55 ppm (L-asp at A), 3.80 ppm (L-asp at B), and 4.08—4.10 ppm (L-aspNH$_2$ at C) for the isomer of *cis*(*N*)*trans*(*O*) geometry. The spectra of the L-6 and L-7 isomers are partially shown in Fig. 5, as is that of the crude L-6 complex. From the values predicted above, the L-6 is identified as the *cis*(*N*)*cis*(*O*) isomer and the L-7, as the *trans*(*N*)*cis*(*O*) isomer. The crude L-6 complex shows a more complicated spectrum, indicating an overlapping of the signals arising from the *cis*(*N*)*cis*(*O*) isomer and contaminating *cis*(*N*)*trans*(*O*) isomer. The relative chemical shifts of methine protons for the present *mer*-*Λ* isomers and the *mer*-*Λ*-[Co(L-Hasp)$_3$] complex are illustrated in Fig. 6.

Stereoselectivity. The [Co(ox)(L-aspNH$_2$)(en)] Complex: The percentage distribution of all the isomers for the [Co(ox)(L-aspNH$_2$)(en)] complex are given in Table 3, in which the values for related complexes[4] are also included for comparison. The percentage compositions of the diastereomeric pairs are summarized in Table 4. From Table 3 it is seen that the *mer*-(*Λ*+*Δ*) isomer existing in the present L-asparaginato complex and also those in the other complexes are more abundant than the *fac*(*Λ*+*Δ*) isomer, and that the abundances in the *mer* isomers are roughly 80%. Since the statistical weight of the L-amino acidate (L-am) ion upon chelation in such a reaction system is the same between the formation of the *mer* isomer and that of the *fac* isomer, the above fact suggests that the selective formation of the *mer* isomer in a [Co(ox)(L-am)(en)]-type complex takes place irrespective of the kind of L-am ligand. Table 4 shows that a significant stereoselectivity of over 70% is found in both the *mer*-*Λ* and *fac*-*Λ* isomers for the present L-aspNH$_2$ complex, while the selectivity for the L-asp complex is over 80%. The comparison of the stereoselectivities among the [Co(ox)(L-am)(en)]-type complexes suggests that the stereoselective formation of an isomer relates to the side-chain length and the existence of CO group in the side-chain of the chelated L-am ion. The marked stereoselectivity in the L-asp complex has been explained as a combined result of an interaction of the β-COO^- group in the chelated L-asp ion with an NH_2 group of the chelated en, which is favorable for the stereoselectivity, and an electrostatic repulsion of the β-COO^- with an O atom of the chelated $C_2O_4^{2-}$ ion, which is disadvantageous in the stereo-

a) Ref. 4.

selective formation.[4] For the stereoselectivity in the [Co(ox)(L-aspNH$_2$)(en)] complex, the following explanation can be offered; provided that the stereoselective formation of an isomer depends on the interaction of the CO group rather than on that of the NH_2 group of the free β-$CONH_2$ group with the adjacent group or donor atom in an apical position, for the *mer-Λ* or *fac-Λ* isomer, in which the apical position is occupied by an NH_2 group of the chelated en, the CO group tends to make a hydrogen bond with the NH_2 group to give favorable interaction. On the other hand, for the *mer-Λ* or *fac-Λ* isomer, in which the apical position is occupied by an O atom in the chelated $C_2O_4^{2-}$, the CO group tends to repel the O atom. This explanation is supported by the information about the orientation of the β-acid amide group mentioned before.

The [Co(L-aspNH$_2$)$_{3-n}$(L-asp)$_n$]$^{n-}$ Complexes: The results of the formation ratios through all the isomers of the [Co(L-aspNH$_2$)$_{3-n}$(L-asp)$_n$]$^{n-}$ complexes are given in Table 5. The minor component in each fraction in the chromatographic separations is evaluated as below 10% on the basis of the spectral data. The marked stereoselectivity was found in either the asparaginato complex (n=2) or the *bis*(asparaginato) complex (n=1); in either complex, the selective formation of the *Λ* isomer was found for the *fac* isomer, and that of the *Λ* isomer for the *mer* one. The stereoselectivities found in these complexes can be understood as the combined effects due to the two kinds of ligands. When a chelated L-asp ion is replaced by a D-asp ion to give the [Co(L-aspNH$_2$)$_2$(D-asp)]$^-$ complex, the formation ratio and the degree of the stereoselectivity are expected to vary from those of the [Co(L-aspNH$_2$)$_2$(L-asp)]$^-$ complex. Table 6 shows the results for the [Co(L-aspNH$_2$)$_2$(D-asp)]$^-$ complex. The fact that no appreciable selectivity is found in the [Co(L-aspNH$_2$)$_2$(D-asp)]$^-$ complex can be understood as the net result arising from the opposite stereoselective effects due to the chelated L-aspNH$_2$ and D-asp.

The Extraction Spectrophotometric Determination of Palladium with Monothiodibenzoylmethane

B. N. PRABHU and S. M. KHOPKAR

Department of Chemistry, Indian Institute of Technology, Bombay 400076, India

(Received July 14, 1975)

Monothiodibenzoylmethane (HSDBM) was used for the quantitative extraction of palladium. It was extracted at pH 3.5—6.5, with 0.001 M HSDBM in benzene, as an orange-red colored complex and measured spectrophotometrically at 470 nm. Beer's law was valid in the concentration range of 0.6 to 3.6 μg of palladium per ml. The complex was stable for at least 144 h. Ten milliliters of 0.001 M HSDBM in benzene was adequate for quantitative extraction of palladium. The optimum period of equilibration was 10 min. It was possible to extract palladium in the presence of a large number of elements.

Monothiodibenzoylmethane (3-mercapto-1,3-diphenyl-2-propen-1-one) HSDBM, a monothio-substituted derivative of dibenzoylmethane was used for the extraction and photometric determination of several transition elements.[1] Further studies revealed that it is possible to extract palladium(II) at pH 3.5—6.5 as the orange-red colored complex and determine photometrically at 470 nm.

Amongst β-diketones, acetylacetone[3] was used for the extraction of palladium at pH 8.0. The extractions with benzoylacetone were complete between the pH range of 1.2 to 10.[3] The extractions with dibenzoylmethane were not only incomplete, but also the rate of equilibration was slow. With 2-thenoyltrifluoroacetone (HTTA), palladium was extracted as an orange-yellow complex, in methyl propyl ketone.[4] It was successfully separated from platinum in HTTA-butanol.[5] Monothiothenoyltrifluoroacetone[6,7] was used for the extractive spectrophotometric determination with some advantages. Recent methods for the solvent extraction[8] and photometric determination[9] are summarized in recent monographs.

The method proposed in this paper is simple, rapid and selective and is applicable at tracer concentrations; the special feature being, palladium can be separated from other noble metals by extraction.

Experimental

Apparatus and Reagents. Spektromom-204 spectrophotometer with matched 10 mm quartz cells. Type FEK-57 photoelectric filter photometer with 10 mm corex glass cuvettes. Cambridge pH-meter with glass and calomel electrodes. Wrist action flask shaker. Monothiodibenzoylmethane was prepared from dibenzoylmethane (Koch-light, England), by the procedure of Chaston *et al.*[10] About 0.001 M HSDBM in benzene was used. The reagent may be preferably preserved in the refrigerator.

A stock solution of palladium was prepared by dissolving 1.002 g of palladium chloride (Johnson Matthey and Co., London) in 500 ml distilled water containing 5% concentrated hydrochloric acid. The solution was standardized gravimetrically with dimethylglyoxime.[11] It contained 1.2 mg/ml of palladium. The dilute solution containing 6 μg/ml of palladium was prepared by appropriate dilution.

General Procedure. An aliquot of solution containing palladium (30 μg) was taken. The pH of the solution was adjusted to 5.0 on pH meter with 0.01 M hydrochloric acid or 0.01 M ammonium hydroxide. The total volume of the aqueous phase was made up to 25 ml. The solution was transferred to a separatory funnel. Ten ml of 0.001 M HSDBM in benzene was added to it. Then the solution was shaken on the wrist action flask shaker for about 10 min. The layers were allowed to settle and separate. The aqueous phase was carefully withdrawn. The orange-red colored palladium complex in the organic phase was transferred into a 10 ml volumetric flask. The absorbance of the complex was measured, at 470 nm, against the reagent blank. The amount of the palladium was computed from calibration curve.

Results and Discussion

Absorption Spectra. The absorption spectra of palladium-SDBM complex ($Pd=2.819\times10^{-5}$ M), against the reagent blank (A), is shown in Fig. 1. The spectrum of the reagent blank against benzene (B) is also shown. The complex showed maximum absorbance at 470 nm; with minimum absorbance for the reagent blank. Therefore this wavelength was selected for all measurements. The molar absorptivity at 470 nm was 8.868×10^3. The sensitivity (Sandell's definition) was 0.012 μg/ml/cm^2.

Extraction as the Function of pH. The extraction of palladium was carried out between the pH region of 1.0—10.0, with 10 ml of 0.001 M HSDBM in benzene. The results (Fig. 2) showed that the $pH_{1/2}$ was 3.0. The extraction was quantitative in the pH region of 3.5 to 6.5. The extraction was incomplete below and above this region. Hence pH 5.0 was used for all extractions.

Beer's Law. Different amounts of palladium, from 6 μg to 60 μg, were taken and were extracted with 10 ml of 0.001 M HSDBM in benzene. The absorbance of the complexes was measured at 460, 470, and 480 nm. The system conformed to Beer's law in the concentration range of 0.6 to 3.6 μg of palladium per ml at 470 nm. It is possible to expand this range provided, we use high reagent concentration.

Effect of Reagent Concentration. With all other factors kept constant, palladium was extracted with varying volumes and varying concentration of the reagent (Table 1). The results showed that 10 ml of 0.001 M HSDBM in benzene was adequate for quantitative extraction. The extraction was not quantitative at lower reagent concentration while at higher reagent concentration, there was negligible increase in extraction. The variation in volume of 0.001 M HSDBM showed that 10 ml of the reagent was ade-

1.00	20	0.250
1.00	25	0.250

quate for quantitative extraction of palladium. However, for very high metal ion concentration, it is preferable to use high reagent concentration.

Effect of Salting-out Agents. With all other conditions same, the chlorides of lithium, sodium, potassium, ammonium, magnesium and calcium in the concentration range of 0.5—5 M were used as salting-out agents. The results showed that none of them were effective, possibly on account of high ionic concentration. In few cases, the extraction substantially decreased due to competitive action of chloride ion with reagent anion for central metal atom to form complex. Similar phenomenon was also observed by previous workers.[6]

Stability of the Color of the Complex. The absorbance of the complex was measured at elapsed intervals

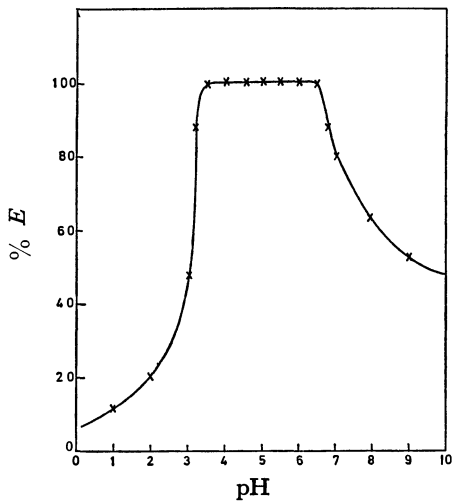

Fig. 2. Extraction as function of pH.

Table 2. Effect of diverse ions
Pd=30 μg; pH=5.0; SDBM=1×10^{-3} M in benzene

Tolerance limit (μg)	Foreign ion present
5.0×10^4	Ca^{2+}, Mg^{2+}, Na^+, K^+, Li^+, NO_3^-, SO_4^{2-}.
2.5×10^4	Sr^{2+}, $tart^{3-}$.
1.0×10^4	Tl^+, UO_2^{2+}, Cs^+, Rb^+, F^-, Cit^{3-}, thiourea, CrO_4^{2-}, $Mo_7O_{24}^{6-}$, ReO_4^-, SeO_3^{2-}, VO_3^-.
0.5×10^4	Ge^{4+}, Ba^{2+}, Be^{2+}, Br^-, AsO_3^-.
0.3×10^4	Sb^{3+}, Os^{8+}, Rh^{3+}, Pt^{4+}, Al^{3+}, Th^{4+}, Zr^{4+}, Y^{3+}, Mn^{2+}, Ga^{3+}, Ce^{4+}, SCN^-, TeO_3^{2-}, WO_4^{2-}.
0.1×10^4	Ti^{4+}, Bi^{3+}.
0.05×10^4	Pb^{2+}, Cd^{2+}, Cr^{3+}, Co^{2+}, Ru^{3+}, Ir^{4+}, Zn^{2+}, In^{3+}.
None	Hg^{2+}, Cu^{2+}, Au^{3+}, Fe^{3+}, Ni^{2+}, CN^-, $EDTA^{4-}$, $S_2O_3^{2-}$, mal^{2-}, $C_2O_4^{2-}$.

of 0, 1, 2, 4, 8, 16, 24, 48, 72, 96, 120, and 144 h. The complex was stable for at least 144 h. In other methods complex was not stable for such long duration.[12]

Period of Equilibration. The period of shaking was varied from 2.5 to 30 min. The extraction was incomplete up to a shaking period of 8 min, but was quantitative in 10 min of equilibration. This is more practicable in contrast to the method proposed by earlier workers.[3]

Composition of the Extractable Species. An attempt was made to ascertain the composition of the extractable species from the $\log C_{HSDBM}$ *vs.* $\log D$ plot.[13] The concentration of the reagent was varied from 1.0×10^{-4} to 5.0×10^{-4} M. The slope was 1.73, indicating that a di-solvated species is present. Therefore the composition of the extractable species is $Pd(SDBM)_2$.

Effect of Diverse Ions. The effect of several ions on the extraction behavior of palladium was studied (Table 2). The tolerance limit was calculated as described earlier.[1] The results showed that the alkali, alkaline earth metals were tolerated in high ratios (>1 : 1000). Thallium(I), uranium(VI) and common oxyanions were tolerated in the ratio of 1 : 300. The noble metals were tolerated in the ratio of 1 : 100. But, mercury, copper, gold, nickel, and iron showed

Table 3. Comparison of methods

Palladium taken (μg)	Palladium found by			
	HSDBM method	HSTTA method[6,7]	2-nitroso-1-naphthol method[14]	2-furildioxime method[15]
6.0	6.05	6.00	6.20	6.10
12.0	12.00	11.95	12.10	12.05
18.0	18.05	18.10	18.20	18.10
24.0	24.10	24.20	23.70	23.90
30.0	29.90	29.95	30.30	30.20

strong interference. The interferences due to some of the ions were eliminated using sequestering agents. Bismuth, chromium, thorium, titanium and gallium were masked with tartaric acid, while zirconium, antimony and aluminium were masked with fluoride. The interference due to osmium(VIII) and cobalt(II) were eliminated by selective extraction with carbon tetrachloride and 1-nitroso-2-naphthol respectively.[8]

Comparison with Other Methods. Four sets of five samples containing various amounts of palladium were taken. Then palladium from each sample was measured with monothiodibenzoylmethane, monothiothenoyltrifluoroacetone (HSTTA),[6,7] 2-furildioxime[14] and 2-nitroso-1-naphthol[15] methods. It was interesting to note (Table 3) that the amount of palladium found by HSDBM method, compares favorably well with other methods of extraction of palladium.

The absorbance of the solutions with 20 determinations was 0.250±0.001. The relative standard deviation was ±0.75%. It was possible to accomplish separation and spectrophotometric determination of palladium in a single operation. The overall process needed 30 min. As little as 0.12 μg of palladium per ml can be determined by this method. The method is selective, as it was possible to separate palladium from many elements including noble metals, with which it is associated.

Thanks are due to the Council of Scientific and Industrial Research (India), for awarding Junior Research Fellowship to one of the authors (B.N.P.).

Ternary Complexs: Equilibrium Studies of Mixed-ligand Complexes of Neodymium Ion with Carboxylic and Phenolic Acids in Aqueous Medium

D. N. SHELKE and D. V. JAHAGIRDAR

Department of Chemistry, Marathwada University, Aurangabad 431002, India

(Received January 12, 1976)

The stability constants of simple and mixed ligand systems of neodymium ion with bidentate ligands such as carboxylic and phenolic acids are studied in an aqueous medium by pH metric titrations at 30±0.1 °C and at an ionic strength of 0.1 M ($NaClO_4$). Neodymium forms 1 : 1 complexes with succinic, adipic, itaconic, malonic, and 3,5-dinitrosalicylic acids and 1 : 1 and 1 : 2 complexes with phthalic, 5-sulfo-, and 4-hydroxysalicylic acids. Ternary complexes of neodymium with these acids when (i) both the ligands are carboxylic acids, (ii) one is carboxylic and the other a phenolic acid, (iii) both ligands are phenolic acids, are studied by potentiometry. The stability constants of these complexes are compared with those of binary complexes. The results have been discussed on the basis of the magnitudes of $\Delta \log K$, K_{DXY}, and $\log \beta_{XY} - 1/2[\log \beta_{XX} + \log \beta_{YY}]$, and also from the comparison of K_{2YX} and K_{MX_1} or K_{2XY} and K_{MY_1}. The values of K_{2YX} are directly related to the acid dissociation constant of the secondary ligand. The overall stability (β_{XY}) is found to be depending on the binary stabilities and the basicities of the ligands.

The simple chelates of lanthanoides with carboxylic and phenolic acids have been studied extensively, though not much work has been reported on the mixed ligand chelates of the lanthanides with these acids. As regards Nd(III), its mixed-ligand chelates with *meso*- and *dl*-tartaric acid have been investigated by Ramamoorthy and Manning.[1] We have reported earlier the formation of mixed-ligand chelates of UO_2^{2+} and Cu^{2+} with bidentate carboxylic and phenolic acids by simultaneous equilibria.[2,3] Nd(III) forms 1 : 1 complexes with carboxylic acids and 1 : 1 and 1 : 2 complexes with phenolic acids. The present work was undertaken to investigate whether the mixed-ligand chelates of Nd(III) with these acids are formed in a stepwise or a simultaneous equilibrium when (i) both the ligands are carboxylic acids, (ii) one is carboxylic and the other is phenolic acid, and (iii) both the ligands are phenolic acids. The calculations of various other factors were done, and the values obtained were utilized to understand some structural aspects of the mixed ligand chelates.

Experimental

Neodymium perchlorate was prepared by the standard procedure. The concentration of Nd(III) in original solution was estimated as Nd_2O_3. Succinic, adipic, itaconic, malonic, phthalic, 5-sulfo-, 3,5-dinitrosalicylic acids, and 4-hydroxysalicylic acids were of B.D.H.(AnalaR) grade. They were recrystallized and their purity was checked by their melting points. All the solutions were prepared in double-distilled water. The details of the measurements of pH are given in earlier paper.[4]

Titrations. The experimental procedure involved, the potentiometric titrations of carbonate-free solutions of (i) free $HClO_4$(4.40×10^{-3} M), (ii) free $HClO_4$(4.40×10^{-3} M)+ligand(X) (2.00×10^{-3} M), (iii) free $HClO_4$(4.40×10^{-3} M)+ligand(X) (2.00×10^{-3} M)+Nd(III) (2.00×10^{-3} M) (M), (iv) free $HClO_4$(4.40×10^{-3} M)+ligand(Y) (2.00×10^{-3} M), (v) free $HClO_4$(4.40×10^{-3} M)+ligand(Y) (2.00×10^{-3} M)+Nd(III) (2.00×10^{-3} M), (vi) free $HClO_4$(4.40×10^{-3} M)+ligand(X) (2.00×10^{-3} M)+ligand(Y) (2.00×10^{-3} M)+Nd-(III) (2.00×10^{-3} M), where the X and Y stands for two respective ligands. The ionic strength of solutions was maintained constant at 0.1 M by the addition of the appropriate amount of 1 M sodium perchlorate solution. The titrations were carried out in an inert atmosphere by bubbling oxygen-free nitrogen gas through an assembly containing the electrodes to keep out CO_2.

Results

Simple Systems. The proton-ligand formation number $\bar{n}_A$ was calculated by the method of Irving and Rossotti.[5] The preliminary values of pK_1 and pK_2 were calculated from the proton-ligand formation curves. The pointwise method was used for the calculations of accurate pK values. These are presented in Table 1. The metal-ligand formation number, $\bar{n}$ were calculated by the Irving and Rossotti's expression.[6] The maximum value of $\bar{n}$ before the pH of precipitation as observed in metal complex titration was 1.9 for phthalic, 5-sulfo-, and 4-hydroxysalicylic acids and 1.0 for succinic, adipic, malonic, and 3,5-dinitrosalicylic acids, showing thereby the ligands belonging to the first set form both 1 : 1 and 1 : 2 complexes and those to the other form only 1 : 1 complex. The pL values were calculated and the formation curves were constructed by plotting pL *vs.* $\bar{n}$. The log-K_1 and log K_2 were calculated initially by half-integral method and finally by the method of pointwise calculations. Since the difference in log K_1 and log K_2 was less than 1.7 in number of cases, their accurate values were calculated by the method of least squares. It is observed that neodymium forms only 1 : 1 complex with succinic, adipic, itaconic, malonic, and 3,5-dinitrosalicylic acids and both 1 : 1 and 1 : 2 complexes with phthalic, 5-sulfo-, and 4-hydroxysalicylic acids. The reported values of log K_1 and log K_2 for phthalic, 5-sulfo-, and 4-hydroxysalicylic acids[7,8] are in good agreement with our values.

In aqueous solution neodymium ion is present as $[Nd(H_2O)_6]^{3+}$, $[Nd(H_2O)_8]^{3+}$ and $[Nd(H_2O)_9]^{3+}$.[9] The metal chelate is formed due to the simultaneous replacement of water molecules from the coordination sphere of neodymium ion with formation of Nd–O bonds. The chelates formed are mainly entropy stabilized as the lanthanide chelates are generally supposed to be ionic in nature.

Mixed-ligand Systems. The formation of a mixed ligand complex was concluded initially from qualitative evidence by noting the pH of precipitation for MX, MY and MYX for the titration curves III, V and VI respectively. It was observed that the pH of precipitation for the mixed ligand system was either the same or higher than that of the simple ligand system. The formation of a mixed ligand chelate was confirmed by comparing the mixed ligand curve with the composite curve. The latter curve was drawn theoretically by the graphical addition of 1 : 1 MX curve to the titration curve of free ligand Y. If there is any interaction between NdX and Y the composite curve should be displaced from the experimental curve. The deviation of the composite curve from the mixed ligand titration one was observed in each case. The nature of the complex equilibrium was investigated according to the method suggested by Carey and Martell.[10]

The pH titration curves for a representative system are shown in Fig. 1. The moles of base added after the neutralization of $HClO_4$ are presented as m.

The procedure adopted to understand the complexation equilibria is discussed for a representative system. For all the remaining systems the conclusions drawn regarding the complexation were on the basis of the considerations given above. The final complexation reactions are given in a consolidated form.

Carboxylic–Carboxylic Acid Systems.

i) Neodymium-succinic (H_2Y)–adipic (H_2X) acid.
ii) Neodymium-succinic (H_2Y)–malonic (H_2X) acid.
iii) Neodymium-succinic (H_2Y)–itaconic (H_2X) acid.
iv) Neodymium-succinic (H_2Y)–phthalic (H_2X) acid.

The pH values of precipitation for four mixed ligand systems i—iv were 7.0, 6.8, 7.0 and 6.6 respectively, while those of Nd(III)–succinic acid, Nd(III)–adipic acid, Nd(III)–malonic acid, Nd(III)–itaconic acid, and Nd(III)–phthalic acid were 7.2, 7.1, 6.9, 7.0, and 6.8 respectively. All the carboxylic acids individually form 1 : 1 complex with neodymium except phthalic acid which forms both 1 : 1 and 1 : 2 complexes in the pH range 3—5. The deviation of the mixed ligand curve from the composite curve was from $m=0$—4 for the systems i, ii, and iii and $m=0$—3 for the system iv. The horizontal difference between the mixed ligand complex curve and the composite one remained nearly constant in all the systems, in the pH range 3—6, except in the case of succinic–phthalic acids, wherein the composite curve was towards right-hand side of the mixed ligand titration curve above pH 5. The formation of a mixed ligand chelate by a simultaneous equilibrium for i—iii can be shown as:

$$Nd^{3+} + H_2X + H_2Y \rightleftharpoons Nd(X)(Y)^- + 4H^+$$

In succinic–phthalic acid the mixed ligand titration curve was towards right hand side of the composite curve between $m=0$—3 and, therefore, the complexa-

a) Y stands for malonic and X stands for adipic.

tion is represented as:

$$Nd^{3+} + H_2Y + H_2Y \rightleftharpoons Nd(X)(HY) + 3H^+$$

In the titrations of the neodymium ion mixed ligand systems against standard sodium hydroxide, the following possible equilibria along with disproportionation reactions are given in Table 2.

In all the cases the equilibria

$$K_{MX_1} = K(M+X \rightleftharpoons MX),$$
$$K_{MX_2} = K(MX+X \rightleftharpoons MX_2),$$
$$K_{MY_1} = K(M+Y \rightleftharpoons MY),$$
$$K_{MY_2} = K(MY+Y \rightleftharpoons MY_2),$$
$$K_{2XY} = K(MX+Y \rightleftharpoons MXY),$$
$$K_{2YX} = K(MY+X \rightleftharpoons MXY), \text{ and}$$
$$\beta_{XY} = K(M+X+Y \rightleftharpoons MXY),$$

must be involved.

The disproportionation constants

$$K_{DXY} = K(MX+MY \rightleftharpoons MXY+M),$$
$$K_{DXY} = K(MX_2+MY \rightleftharpoons MXY+MX),$$
$$K_{DXY} = K(MX+MY_2 \rightleftharpoons MXY+MY), \text{ and}$$
$$K_{DXY} = K(MX_2+MY_2 \rightleftharpoons 2MXY),$$

corresponding to the systems are calculated.

The distinguishable cases depend on the relative value of K_{MX_1}, K_{MX_2}, $\cdots$, β_{XY}. In all the cases $\beta_{XY} = K_{MX_1} \cdot K_{2XY} = K_{MY_1} \cdot K_{2YX}$.

The procedure adopted and the mathematical expressions used for the calculations of the stability constants of mixed-ligand chelates were given earlier.[11] All the mathematical calculations were done on the DCM Moscal 1400 electronic calculator. The β_{XY} values are presented in Table 3.

The stability of ternary complex is conveniently characterized by the following two ways. One is based on the difference of stability constants (logarithmic values), $\Delta\log K$, and the second on the disproportionation constant, $\log K_{DXY}$.

$$\Delta\log K = \log K_{MY_1} - \log K_{2XY}$$

Generally, $K_{MY_1} > K_{MY_2}$ because more coordinating positions are normally available for bonding of the first ligand to a metal ion than for the second ligand. The addition of ligand Y to MX should also show the same trend. Evidently, $K_{MY_1} > K_{2XY}$ or $\Delta\log K$ is positive. $\Delta\log K$ can also be calculated by the expression:

$$\Delta\log K = \log K_{MX_1} + \log K_{MY_1} - \log \beta_{XY}.$$

The positive $\Delta\log K$ value of ternary system indicates that primary ligand anion and secondary ligand anions preferentially form binary complexes to ternary complexes.

From the above expression it follows that the influence of both ligands in a ternary complex is mutual and of the same size. Both ligands are either stabilized or destablished in their coordination to the same metal ion. This is connected with the fact that the difference, $\Delta\log K$, is the result from the subtraction of two constants, and, therefore, also a constant which corresponds to the equation.

$$MX + MY \rightleftharpoons MXY + M$$

Obviously, the observation of positive values for $\Delta\log K$ would indicate that the equation is more on its right side.[12]

Based on the statistical considerations, mixed ligand chelate formation by these disproportionation reactions is favored, if $\log K_{DXY} > 0.6$ log units.[12] The comparison of equilibrium constants $\log K_{2XY}$ and $\log K_{MY_2}$, can be made to find out whether the primary diacid ligand prefers to coordinate to 1 : 1 binary complex of the same ligand. The factors concerning the higher or lower stability of ternary complexes as compared to the binary complexes can also be observed from the $\log \beta_{XY} - 1/2[\log \beta_{XX} + \log \beta_{YY}]$.

In short, the tendency of the formation of a ternary chelate can be examined from the magnitude of a) $\Delta\log K$, b) $\log K_{DXY}$, c) comparison of $\log K_{2XY}$ and $\log K_{MY_2}$ or $\log K_{2YX}$ and $\log K_{MX_2}$ and d) the magnitude of $\log \beta_{XY} - 1/2[\log \beta_{XX} + \log \beta_{YY}]$.

The mixed ligand chelate is formed due to the

TABLE 3. LOGARITHMS OF EQUILIBRIUM CONSTANTS OF TERNARY COMPLEXES OF NEODYMIUM ION

simultaneous or stepwise replacement of four water molecules from the coordination sphere of the Nd^{3+} ion with the formation of four Nd–O bonds. The carboxylate oxygen is not directly bound to the benzene nucleus like the phenolate oxygen. The carboxylate oxygen may, therefore, adjust stereochemically more easily than the phenolate ion which is directly attached to the benzene nucleus. Greater strain in the Nd–O bond is, therefore, expected when the phenolate oxygen is coordinated to the metal ion than when the coordination takes place through the carboxylate oxygen. Further the electronegativity of phenolate oxygen will be higher than that of carboxylate oxygen. The Coulombic repulsion between the end oxygens will, therefore, be stronger when both ligands are phenolic acids than when they are carboxylic acids. Thus, the value of $\Delta\log K$ should be higher when both the ligands are phenolic acids than when both the ligands are carboxylic acids, and the intermediate value is expected when one is a carboxylic acid and the other a phenolic acid. The observed values of $\Delta\log K$ do not strictly fit into this pattern. This behavior can be scrutinized critically, if the values of the factors given in a, b, c and d are examined.

Carboxylic–Carboxylic Acid Systems. a) $\Delta\log K$ is negative for succinic–adipic, succinic–itaconic, malonic–itaconic, and phthalic–itaconic systems. The formation of the mixed-ligand chelates over the binary complexes in these cases is thus favored. On the other hand, systems like succinic–malonic, succinic–phthalic, phthalic–malonic, malonic–adipic, and phthalic–adipic have positive $\Delta\log K$. The value in the case of phthalic–malonic being significantly higher than the other remaining systems.

b) $\log K_{DXY}<0.6$ log units for all the systems except phthalic–itaconic acid system. The ternary complexation in the case of phthalic–itaconic acid system is thus favored by this equilibrium $MX+MY\rightleftarrows MXY+M$.

c) $\log K_{2XY}>\log K_{MY_2}$ for phthalic–malonic and phthalic–adipic acid systems.

d) $\log\beta_{XY}-1/2[\log\beta_{XX}+\log\beta_{YY}]$ is positive for succinic–adipic, succinic–itaconic, malonic–itaconic, and phthalic–itaconic which is complementary to the values of $\Delta\log K$ obtained for these systems and, therefore, confirm the conclusions drawn earlier.

In the series examined, the magnitude of $\Delta\log K$ is maximum for phthalic–malonic system. For this system $\log K_{DXY}$ is not favorable to the mixed ligand

chelate formation, similarly log K_{2XY}<log K_{MY_2}, but log K_{2YX}>log K_{MX_2}. This is the only factor which is favorable for the ternary complex formation. In the case of phthalic–itaconic the factors 'a' and 'b' are favorable to the formation of ternary complexes. For phthalic–adipic 'b' is favorable but 'c' is very much unfavorable giving a positive value of $\Delta\log K$. In the carboxylic–carboxylic acid systems, except phthalic acid, no other carboxylic acid forms 1 : 2 complex independently. The 1 : 1 : 1 mixed-ligand complexation occurs in a pH region where normally 1 : 1 complexes are formed by these acids. This may be probably the reason, for the presence of mixed chelate formation in these cases.

Carboxylic–Phenolic Acid Systems.

a) $\Delta\log K$ are all positive except succinic–3,5-dinitrosalicylic acid system.

b) log K_{DXY} is not favorable for ternary complex formation.

c) log K_{2YX}<log K_{MY_2} for ternary chelates with 5-sulfosalicylic acid is primary ligands. The value of $\Delta\log K$ is positive and higher than any of the systems belonging to group 1. In the case of succinic–3,5-dinitrosalicylic acid log $K_{DXY}=0.43$ which is quite close to 0.6 log units. These two ligands independently do not form 1 : 2 chelates. The value of $\Delta\log K$ and log $\beta_{XY}-1/2[\log\beta_{XX}+\log\beta_{YY}]$ are favorable to the ternary complex formation. In the case of phthalic–3,5-dinitrosalicylic acid system, phthalic acid forms a 1 : 2 complex. The factors a, b, and d are not favorable for malonic–3,5-dinitrosalicylic acid system. Similar is the case for phthalic–3,5-dinitrosalicylic acid system, but because of a positive value of a disproportionation reaction, a slightly higher value of $\Delta\log K$ was obtained for this system than malonic–3,5-dinitrosalicylic acid system.

Phenolic–Phenolic Acid Systems.

a) $\Delta\log K$ is positive for all the three systems. The magnitude of $\Delta\log K$ follows the order Nd^{3+}-3,5-dinitrosalicylic–4-hydroxysalicylic > Nd^{3+}-5-sulfosalicylic–4-hydroxysalicylic > Nd^{3+}-5-sulfosalicylic–3,5-dinitrosalicylic acid systems.

b) log $K_{DXY}>0.6$ for 5-sulfo-3,5-dinitrosalicylic acid and 5-sulfo–4-hydroxysalicylic acid system.

c) log $K_{2YX}>\log K_{MX_2}$ for 5-sulfo–4-hydroxysalicylic acid. log $K_{2YX}<\log K_{MX_2}$ for 3,5-dinitro–4-hydroxysalicylic and log $K_{2XY}>\log K_{MY_2}$ for 5-sulfo-3,5-dinitrosalicylic and 5-sulfo–4-hydroxysalicylic acid.

d) $\log\beta_{XY}-1/2[\log\beta_{XX}+\log\beta_{YY}]$ is positive for 5-sulfo–3,5-dinitrosalicylic and 5-sulfo–4-hydroxysalicylic acid and negative for 3,5-dinitro–4-hydroxysalicylic acid system.

In this series, except Nd^{3+}-3,5-dinitro–4-hydroxysalicylic acid the 'b' factor is much favorable to the remaining two systems, despite of $\Delta\log K$ being positive for them. The mixed-ligand chelation therefore, occurs mainly by the reaction

$$MX_2 + MY_2 \rightleftharpoons 2MXY, \text{ and}$$

$$MX + MY_2 \rightleftharpoons MXY + MY,$$

in the case of 5-sulfo–4-hydroxy- and 5-sulfo–3,5-dinitrosalicylic acid systems respectively. Only 3,5-dinitrosalicylic acid does not form a 1 : 2 complex. In the presence of 4-hydroxysalicylic acid it forms 1 : 1 : 1 chelate in a pH region at which it forms a 1 : 1 complex. In the case of 3,5-dinitrosalicylic acid, the absence of 1 : 2 complex may be due to the steric hindrance of the earlier attached ligand to the incoming ligand anion. The secondary ligand like 4-hydroxysalicylic acid or 5-sulfosalicylic acid which do not afford steric hindrance like 3,5-dinitrosalicylic acid may, therefore, attach to the 1 : 1 complex of Nd^{3+}-3,5-dinitrosalicylic acid to form a 1 : 1 : 1 complex.

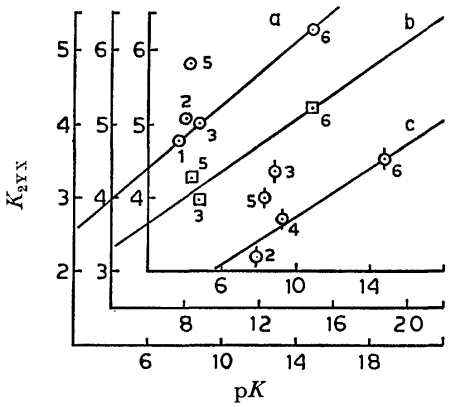

Fig. 2. Relation between log K_{2YX} and the product of the acid dissociation constants of the ligands for neodymium dibasic-dibasic systems.
(a) Neodymium ion-succinic acid(Y)-ligand(X),
(b) neodymium ion-malonic acid(Y)-ligand(X),
(c) neodymium ion-phthalic acid(Y)-ligand(X);
ligand(X): (1) phthalic acid, (2) malonic acid, (3) itaconic acid, (4) adipic acid, (5) 3,5-dinitrosalicylic acid, (6) 5-sulfosalicylic acid. $\mu=0.1$ M ($NaClO_4$), $t=30$ °C.

In the case of 3,5-dinitrosalicylic–4-hydroxysalicylic acid system the factors b, c, and d are not favorable which has resulted in a significantly large value of $\Delta\log K$.

The mixed-ligand chelates are formed in a simultaneous equilibria. The replacement of four water molecules from the hydration sphere of Nd^{3+} ion simultaneously by the two ligands would make the reaction 'entropy stabilized'. An additional factor in favor of the mixed ligand chelates, of some systems are the charge cancellation of the metal ion and the ligand to form a neutral complex.[11–14]

The order of log K_{2YX} is given as:

i) 5-sulfo>3,5-dinitro>itaconic>adipic when the primary ligands are succinic, malonic and phthalic acids.

ii) 4-hydroxy>3,5-dinitrosalicylic acid when 5-sulfosalicylic acid is a primary ligand. This is also the order of the basicities of the ligands. The plots of log K_{2XY} *vs.* ΣpK (Fig. 2) gave a satisfactory direct relationship between these two quantities. However, the points corresponding to adipic acid system deviated from the straight line, which may be due to the ring size effect.[11] We have already established the direct relationship between these two quantities for mixed-ligand chelates of vanadyl ion.[16] In the present investigation, the formation of ternary complexes of

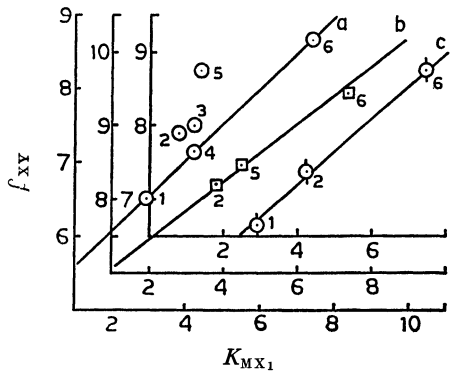

Fig. 3. Relation between β_{XY} and log K_{MX_1} of ternary complexes of neodymium ion. (a) neodymiun ion-succinic acid(Y)-ligand(X), (b) neodymium ion-malonic acid(Y)-ligand(X), (c) neodymium ion-phthalic acid(Y)-ligand(X), ligand(X): (1) adipic acid, (2) itaconic acid-malonic acid (c), (3) malonic acid (4) phthalic acid, (5) 3,5-dinitrosalicylic acid, (6)-5-sulfosalicylic acid. μ=0.1 M ($NaClO_4$), t= 30 °C.

the neodymium ion has been found to be depending on the basicities of the ligand.

The plots of β_{XY} *vs.* K_{MX_2} (Fig. 3) gave straight lines which are parallel. The values of overall stability constants β_{XY} for these systems are as:

5-sulfo > 3,5-dinitro > malonic > phthalic > itaconic > adipic when primary ligands are succinic, malonic and phthalic acids. This is in accordance to the stabilities of 1 : 1 binary complexes. This observation is in good agreement with the earlier work.[14-17].

The authors are grateful to Prof. D. D. Khanolkar, Head, Chemistry Department, Marathwada University, Aurangabad, for his valuable guidance and encouragement in the present work. One of the authors (DNS) thanks to UGC, New Delhi, for the award of a Junior Research Fellowship.

Melting and Solid–Solid Transition Temperatures at High Pressures for NH_4SCN, RbSCN, TlSCN, and CsSCN

William KLEMENT Jr.*

National Physical Research Laboratory, C.S.I.R., P.O. Box 395, Pretoria, South Africa

with an **Appendix—Lattice parameters of NH_4SCN and RbSCN at high temperatures**

by C. W. F. T. PISTORIUS†

(Received March 16, 1976)

Differential thermal analyses at high pressures have yielded the following trajectories for melting and solid-solid transitions in the several thiocyanates: (substance, transition, 1-bar transition temperature in °C, initial slope (dT/dp) in deg kbar^{-1}, initial curvature ($-d^2T/dp^2$) in deg kbar^{-2}, approximate maximum pressure in kbar) NH_4SCN, melting, ≈146, ~20 (tentative), —, ~3.5; NH_4SCN, (upper) solid-solid, 120±4, 12.6±1.5, —, 7.5; RbSCN, melting, 184±2, 15.7±0.3, 0.32±0.05, 36; RbSCN, solid-solid, 166±3, 13.5±1.0, 0.3±0.1, 30; TlSCN, melting, ≥234, ≥10 (tentative) >0, 34; TlSCN, solid-solid, 99±2, 9.6±1.0, ≈0.17, 34; CsSCN, melting, ≥206, ≈14±1.5, ~0.2—0.4, 33; CsSCN, solid-solid, ≥197, ≈11.8 ±1.0, ~0.2, 33. The solid-solid transitions investigated here for NH_4SCN, RbSCN and TlSCN appear to be closely-related, structurally, to the well-investigated transition in KSCN. The thermodynamics of the KSCN transition at 1-bar is discussed anew so as to be consistent with high pressure data. The transitions in these other thiocyanates are probably thermodynamically similar to the KSCN transition but the necessary data to establish the similarities are lacking. Lattice parameters for NH_4SCN and RbSCN show rapid variations with temperature below the solid–solid transition, as for KSCN. DSC and DTA results are presented for the 1-bar transition temperatures and entropy changes for NH_4SCN, RbSCN, TlSCN, CsSCN and also AgSCN. The entropy changes apparently associated with the structurally similar solid–solid transitions decrease with increasing cation polarizability.

Of the univalent thiocyanates, the phase relations[1] in KSCN are, thus far, the most complex, with 5 polymorphs having been postulated up to ~44 kbar, although there is only one rather thoroughly investigated[2,3] solid–solid transition at 1-bar. NaSCN shows[4] only one polymorph to ~40 kbar, which differs in structure from the 1-bar KSCN polymorphs, as do the low temperature phase of NH_4SCN,[5] the only known phase in AgSCN[6] and the CsSCN[7] phases. Besides data on the CsSCN phase relations at high pressures, this paper reports on the phase relations of NH_4SCN, RbSCN and TlSCN—all of which show phase transitions which apparently are similar to the KSCN transition. Also reported, in the Appendices, are a thermodynamic discussion of the KSCN transition more nearly in accord with existing data and lattice parameters for NH_4SCN and RbSCN at high temperatures.

Experimental

General Procedure. Transitions were detected by differential thermal analysis (DTA), using the piston-cylinder apparatus, furnace geometry and experimental procedures described previously.[8] Details of the runs for each substance are given below. After corrections for friction, pressures are believed accurate to ±0.5 kbar. Temperatures, as measured with Chromel-Alumel thermocouples, are believed accurate to ±2 °C.

NH_4SCN. In both runs, Merck reagent grade material was contained in aluminium capsules, which had been treated with HNO_3. The samples were dewatered by holding briefly above ~100 °C before sufficient pressure had been applied to seal the capsules. The lower solid-solid transition, investigated by Bridgman,[9] was not studied. In the first run, the upper solid-solid transition was observed by small but distinct breaks in the DTA signals, the corresponding temperatures agreeing to within ±1 °C on heating and cooling. At least two heating/cooling cycles were run at each pressure to demonstrate reproducibility and, where possible, this is usual in all of these experiments. After increasing pressure ≥8 kbar, signals could not be reproduced satisfactorily and the black contents of the capsule indicated decomposition. No efforts were made to investigate the details of the decomposition. In the second run, the solid-

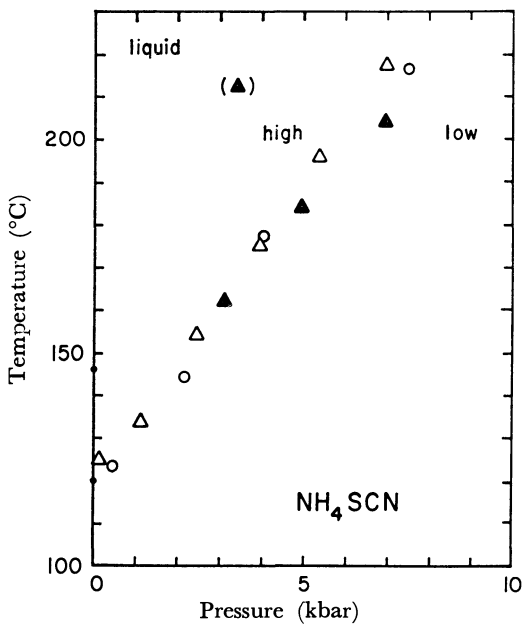

Fig. 1. Solid-solid and melting (point in parentheses and tentative) temperatures for NH_4SCN. Accepted 1-bar transition temperatures are indicated. Open symbols denote upstroke data; filled symbols denote downstroke data. Circles denote data from first run and triangles those from second run, both in aluminium capsules.

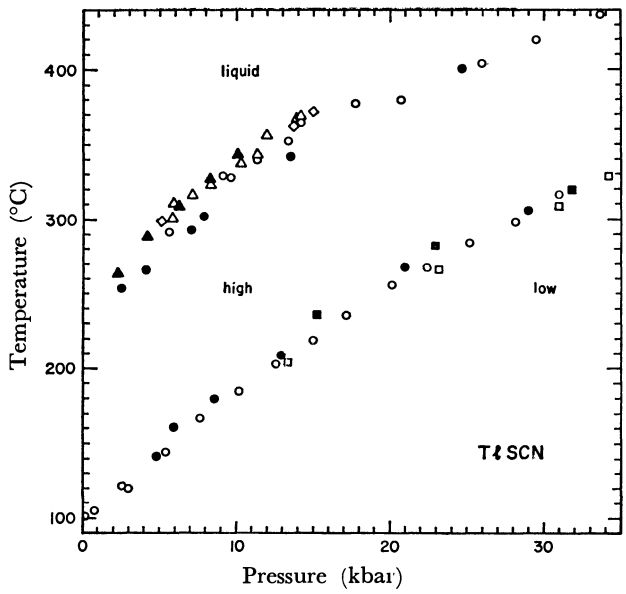

Fig. 4. Solid-solid and melting temperatures for TlSCN. Accepted 1-bar transition temperatures are indicated. Open symbols denote upstroke data; filled symbols denote downstroke data. Symbols for the several runs (capsule materials) are triangles-first (inconel); diamonds-second (copper); circles-third (aluminium); squares-fourth (tantalum). The melting data should be considered tentative.

the transition temperatures, which were the same, within experimental error, on heating and on cooling. The DTA signals for melting again showed only indistinct onsets and undercoolings were obvious from the freezing signals. The data (Fig. 4) for the solid-solid transition can be fitted by a power series with 1-bar intercept 99±2 °C, initial slope 9.6±1.0 deg kbar^{-1} and initial curvature ≈0.17 deg kbar^{-2}. The data (Fig. 4) for melting are disappointing, because of the poorly defined onsets (presumably due to impurities), and should only be considered as tentative. Only a poor fit is obtained with the usual power series but there may be estimated an initial slope≥10 deg kbar^{-1} and an initial curvature>0 for a 1-bar intercept of ~234 °C.

AgSCN. One exploratory run was made with BDH Laboratory Reagent material contained in an aluminium capsule. Large DTA signals were observed ≤2 kbar, with poorly defined onsets near ~180 °C on both heating and cooling. The run was abandoned after these signals disappeared and, subsequently, decomposition was indicated. No further work was attempted because of the lack of agreement with the DSC results (below).

DSC Results

Mr. S.J. Pretorius kindly made DSC runs on several substances. For NH_4SCN, the onset of the lower solid–solid transition was near 364 K, with a transition entropy of ≈2.2 cal mol^{-1} deg^{-1} (in good agreement with Bridgman[9]); the peak of the upper solid–solid transition was near 393 K, with a transition entropy ≥ 0.3_7 cal mol^{-1} deg^{-1}; the onset of melting was near 419 K, with a melting entropy of ≈$5._1$ cal mol^{-1} deg^{-1}; the latter temperatures agree satisfactorily with literature values.[10]

For Rb-SCN, one sample yielded the onset of melting near 455 K, with a melting entropy of ≈$5._9$ cal mol^{-1} deg^{-1}, and the peak of the solid–solid transition near 436 K, with a transition entropy≥0.6_3 cal mol^{-1} deg^{-1}; another sample showed the same transition temperatures but somewhat smaller entropies, which are within the accuracy of the technique—say ±10%; Wrzesnewsky[10] apparently obtained a slightly higher melting temperature. For TlSCN, the material used initially showed the onset of melting near 498 K, with a melting entropy of ≈$7._1$ cal mol^{-1} deg^{-1}, and only a poorly defined signal for the solid–solid transition; for the subsequent sample, the onset of melting was near 507 K, with a melting entropy of ≈$7._7$ cal mol^{-1} deg^{-1}, and the peak of the solid–solid transition was near 372 K, with a transition entropy of ≥0.3 cal mol^{-1} deg^{-1}; although the latter sample appears to be purer than the former, the onset of melting was not so sharp that impurities could be considered negligible. For AgSCN, a single run up from 330 K showed only what appeared to be melting, with onset near 534 K and the entropy ≈7.3 cal mol^{-1} deg^{-1}; decomposition appeared to occur a few degrees higher. Mr. R. A. Pacey kindly made several DTA-DSC runs on the CsSCN used here—which essentially corroborated the previous results[7] for transition temperatures and entropies.

Discussion

For melting, the Clausius-Clapeyron equation may be used to estimate the volume changes on fusion. With the absolute volume change in cm^3 mol^{-1} and the fractional volume change referred to the volume of the melting solid, there are estimated: for NH_4SCN, ~$6._4$ or ~11%; for RbSCN, ~$3._9$ or ≈$6._5$%; for TlSCN, ≥$3._2$ or ≥$6._1$%; for CsSCN, ≈$1._8$ or ≈$2._7$%; also for KSCN, 6.0—7.1[11] or $12._5$±1% and, for NaSCN, 4.3±0.5[4] or ≈9%. There appears to be a roughly linear correlation between the fractional volume change on fusion and the melting entropy for these compounds, the greatest deviations being for the least certain data (*e.g.*, NH_4SCN and TlSCN). The NaSCN datum can be brought into better agreement with this correlation by subtracting an orientational entropy term from the melting entropy since the $(SCN)^-$ ion is not disordered in the melting solid, as it presumably is for the other compounds. Such a correlation has not been discussed extensively for other sequences of chemically and structurally related compounds but then the present sequence offers a wider range of fractional volume changes and fusion entropies than is usually encountered for other sequences.

The solid–solid transition in CsSCN has an entropy change almost twice the melting entropy. The volume change for this transition is ≈1.6 cm^3 mol^{-1} from the X-ray diffraction results of Ref. 7, which leads to a calculated initial slope of ≈6.6 deg kbar^{-1}, in serious disagreement with the present experimental results. It is difficult to imagine how the experimental slope could be too high by some 5 deg kbar^{-1} and, since the entropy change has been corroborated, the data

for the change in volume must be considered further. In particular, the anomalously rapid increase in volume[7] of low-CsSCN with temperature is suspect because the entropy change at the transition is large enough to include all of the orientational entropy due to end-for-end disordering of the $(SCN)^-$ ion. It seems entirely possible that very little of the disordering takes place below the transition temperature and thus an obvious reason for the anomalous volume variation is eliminated. The high-low CsSCN transition is structurally dissimilar to the transitions in the other thiocyanates (which do show variations below the transition temperatures presumably due to progressive disordering) and it also shows hysteresis between transition temperatures on heating and cooling (in Fig. 2 of Ref. 7 and in Pacey's work, if not in the high pressure runs), unlike the other thiocyanate transitions. Correspondence with the senior author of Ref. 7 could not elicit any comment about the suspicions concerning the X-ray diffraction data on low-CsSCN at high temperatures.

Previously, the solid–solid transition in KSCN was discussed[3] entirely as a λ-transition, without any first-order component, *i.e.*, discontinuous volume or entropy change. This model[3], however, is inadequate because it cannot account for the experimental value of dT_λ/dp—which they[3] did not consider at all. Appendix A discusses the thermodynamics of the high-low KSCN transition in a way more nearly in accord with the high pressure data and it is concluded that the transition is mostly λ-like, although with a small first-order component.

Since the structures of the low-KSCN, NH_4SCN, RbSCN and TlSCN phases apparently are isomorphous, it may be assumed that the structures of the high phases are also isomorphous and also that the transitions are similar thermodynamically. Pistorius' data (Appendix B) show that the lattice parameters for low-RbSCN and also low-NH_4SCN vary rapidly with temperature upon approaching the transitions, akin to the analogous data[3] for KSCN; it is not unlikely that TlSCN shows similar behavior. If the estimates for transition entropies and the observed slopes are combined *via* the Clausius-Clapeyron equation to estimate the corresponding volume changes at the transitions in RbSCN and NH_4SCN, it is clear that these volume changes are larger than those which might be deduced by extrapolation of Pistorius' data (Appendix B). Hence, it is suggested that the transition entropies observed by DSC for RbSCN and NH_4SCN include both isothermal and nonisothermal contributions, as for KSCN. More painstaking calorimetric and volumetric determinations will be necessary to establish the variations below and near the high-low transitions for these substances.

Even more careful calorimetry is unlikely, however, to alter the present observation that, despite the uncertainties as to how to subtract the background, the transition entropies vary progressively as 1.30 ± 0.05,[2] $\geq 0.6_3$, $\geq 0.3_7$, and ≥ 0.3 cal mol^{-1} deg^{-1} for KSCN, RbSCN, NH_4SCN, and TlSCN, respectively. On one hand, this progression could be used to argue against the similarity of the transitions whilst, on the other hand, it could be used in an argument against the applicability of the molecular field model.[3] Taking the latter point of view, it is possible that the alternate formulation of Appendix A might be applicable but this is not demonstrable here for lack of necessary data.

It may be observed that the transition entropies decrease in order of increasing cation polarizability and that a similar progression has been recognized[11] for the discontinuous entropy changes attending the isostructural transitions in K_2SO_4, Rb_2SO_4, Cs_2SO_4, and Tl_2SO_4. For these sulfates, it is arguable that much of the disordering takes place gradually below the transition and this is especially well demonstrated by the enthalpy data[12] for Tl_2SO_4 as compared to K_2SO_4. The details of the disordering behavior in a sequence of isostructural compounds could be more conveniently investigated for these thiocyanates than for the sulfates because the temperatures are lower and the disordering more simply envisioned.

In the absence of data for microscopic order parameters, some consideration can be given to possible order parameters using available data and which can be devised from experience on transitions in other sequences of compounds. Thus, for instance, some M_2CO_3 transitions monoclinic→hexagonal with increasing temperature-proved describable[13] with the order parameter [monoclinic angle $-90°$], which became rigorously zero above the transition temperatures; it was also possible[13] to scale the order parameters onto the same curve *vs.* 'reduced temperature' T/T_λ. On heating to the transition temperature, the greatest thermal expansions are in the direction perpendicular to the planar carbonate ion and this also occurs for $NaNO_3$, $AgNO_3$, $CaCO_3$, *etc.* which have planar ions and λ-transitions. Likewise, for KSCN, NH_4SCN, RbSCN, and presumably TlSCN, the thermal expansion upon approaching the transition is greatest in the c-direction, which is perpendicular to the plane in which the $(SCN)^-$ ions are disordering end-for-end.[2,3] Also, it may be verified that the thermal expansions in the a-, b-, and c-directions for the orthorhombic phases are linked to one another by plotting the lattice parameters, at the same temperature, for each pair and observing that straight lines are obtained, within the precision of the data and independent of the uncertainty in temperature. As a possible order parameter for the thiocyanate transitions, one may consider [a−b] since this decreases monotonically with increasing temperature and is rigorously zero above the transition temperature. Comparing the KSCN and RbSCN data which are the most extensive, [a−b] *vs.* T/T_λ show different courses and this can be attributed to the different temperature dependences of the anion disordering, as postulated above.

An important generalization concerning the polymorphism in some structurally similar sequences of substances has emerged from the accumulating data[14] on phase transitions at high pressures. To wit, the larger the ionic radius of the cation the lower the pressure at which structurally identical polymorphs are

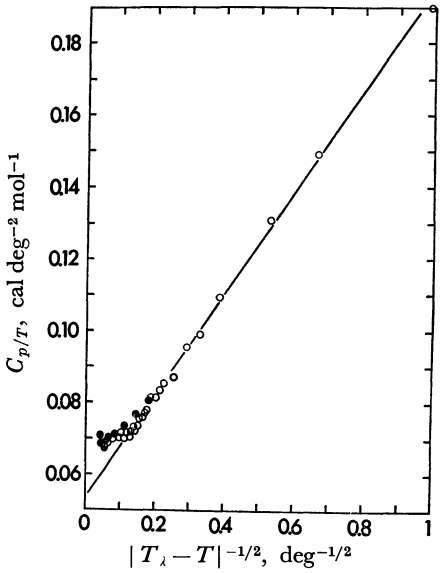

Fig. 5. Plots of $C_{p/T}$ *vs.* $(T_\lambda - T)^{-1/2}$ (open circles, for $T < T_\lambda$) and *vs.* $(1/4)(T - T_\lambda)^{-1/2}$ (filled circles, for $T > T_\lambda$) for KSCN.

encountered—and the validity of this empirical rule is surprisingly extensive.[14] Nevertheless, the lack of any new polymorphs in the present investigation of NH_4SCN, RbSCN, and TlSCN, compared with the several high pressure polymorphs of KSCN,[1] means that this empirical generalization is invalid for these thiocyanates.

Thanks are due to: the late C. W. F. T. Pistorius, P. W. Richter and J. B. Clark for encouragement and assistance; S. J. Pretorius and R. A. Pacey for the DSC and DTA-DSC runs. Much of the thinking about the KSCN transition was done whilst a Guggenheim Fellow at the Australian National University, Canberra, A. C. T.

Appendix A: Thermodynamics of the λ-like transition in KSCN

Yamada and Watanabé[3] have given a description of the KSCN transition in terms of a molecular-field model with a volume-dependent interaction energy. Unfortunately they did not consider that the initial variation of transition temperature with pressure, dT_λ/dp, was an important constraint on their correlations and it does not appear that their model is consistent with the experimental value[1,9] for $dT_\lambda/dp = 18._2 \pm 1._1$ deg kbar^{-1}. Here, the approach is more macroscopic and is along the lines of the discussion[15] of the nematic-isotropic transition in *p*-azoxyanisole, which has a small first-order transition superimposed on a λ-like transition.

The heat capacity data[2] for KSCN are represented (Fig. 5) as

$$C_{p/T} = (C_{p/T})_0 + A|T_\lambda - T|^{-1/2}, \qquad \text{(A-1)}$$

where $(C_{p/T})_0 \approx 0.054$ cal deg^{-2} mol^{-1} and $A \approx 0.14$ cal deg$^{-3/2}$ mol^{-1} for $T < T_\lambda$ and about a quarter of this for $T > T_\lambda$. As shown in Fig. 5, Eq. A-1 is valid down to $(T_\lambda - T)^{-1/2} \approx 0.10$ or $T \approx T_\lambda - 100$ °C and up to $1/4(T - T_\lambda)^{-1/2} \sim 0.1$ or $T \sim T_\lambda + 6$ °C. Within this temperature range and using $T_\lambda = 139.2_0$ °C[2], only the tabulated data[2] for 139.27 °C and 139.52 °C deviate much from Eq. A-1 and the accuracy

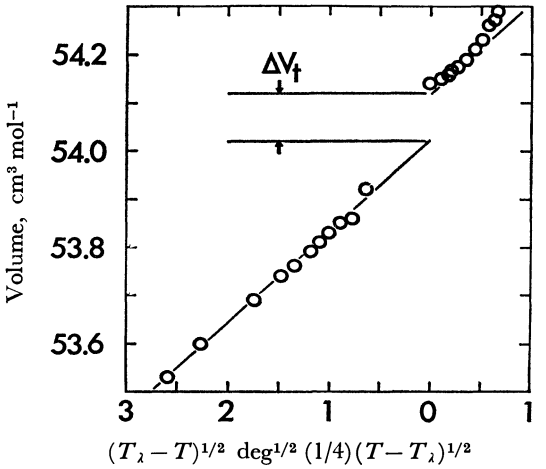

Fig. 6. Plot of molar volumes, for KSCN, *vs.* $(T_\lambda - T)^{1/2}$ for $T < T_\lambda$ and *vs.* $(1/4)(T - T_\lambda)^{1/2}$ for $T > T_\lambda$. The postulated volume discontinuity, ΔV_t, is indicated.

of these data very close to T_λ may be difficult to assess. The variation of thermal expansion with temperature may be anticipated from the Pippard relation[15-17] involving $C_{p/T}$, $(\partial V/\partial T)_p$ and dT_λ/dp. Thus plots of the thermal expansion data[3,18] *vs.* $|T_\lambda - T|^{-1/2}$ yield roughly linear fits over about the same temperature range for which Eq. A-1 is valid. Here, however, it is more accurate to describe the variation with temperature of the volumes—which were actually measured,[3,18] the thermal expansions being derived therefrom—and Fig. 6 shows the molar volumes[18] plotted *vs.* $(T_\lambda - T)^{1/2}$ for $T < T_\lambda$ and *vs.* $1/4(T - T_\lambda)^{1/2}$ for $T > T_\lambda$. For $T_\lambda = 142.7$ °C,[18] the slopes of the drawn lines (Fig. 6) are ≈ 0.19 cm^3 deg$^{-1/2}$ mol^{-1}, both above and below T_λ. It is inferred (Fig. 2) that there is a small, discontinuous volume change of ≈ 0.10 cm^3 mol^{-1} at the transition. Yamada and Watanabé[3] chose not to identify a discontinuous volume change there whereas Plester *et al.*[19] suggested a discontinuity of ~ 0.2 cm^3 mol^{-1}, almost certainly an overestimate due to inadequate data for the rapid variations near T_λ.

The Pippard relation together with the value of *A* (Eq. A-1) and the slope of the plot in Fig. 6 suggest $dT_\lambda/dp \sim 16._3$ deg kbar^{-1}, which compares well with the experimental values.[1,9] For the first-order component of the transition, the Clausius-Clapeyron equation suggests a discontinuous entropy change of ~ 0.14 cal deg^{-1} mol^{-1} and this may be within the uncertainties in the heat capacity data[2] near T_λ.

Appendix B: Lattice parameters of RbSCN and NH_4 SCN at high temperatures

by C. W. F. T. PISTORIUS

Diffractometer scans were made of RbSCN and NH_4SCN from the same stocks as used elsewhere in this paper. High temperature work was done with an MRC X-86-N attachment. For RbSCN at 23 °C, 54 reflections, up to (164), were observed and were consistent with Pbcm—as for KSCN[20] and TlSCN[21] below the solid-solid transition; the lattice parameters thus obtained were $a = 6.842$, $b = 6.895$, and $c = 8.019$ Å. For RbSCN at high temperatures, the following reflections were observed —(020), (200), (112), (022), (202), (122), (212), (130), (310), (224), (412)—and, above the transition, (112), (202), (220), (130), (224), (312). The lattice parameters deduced from these observed reflections are listed in Table B1, perhaps accurate to ±0.1%, at the various temperatures, accurate

Table B1. Lattice parameters of RbSCN and NH_4SCN at high temperatures

T(°C)	a(Å)	b(Å)	c(Å)	β(deg)
RbSCN				
23	6.842	6.896	8.017	
55	6.851	6.903	8.042	
75	6.856	6.909	8.060	
100	6.864	6.915	8.089	
120	6.872	6.922	8.114	
140	6.883	6.929	8.146	
161	6.901	6.938	8.179	
162		6.945	8.245	
180		6.948	8.264

The scavenging of paramagnetic species by nitroalkanes formed during the γ irradiation of aqueous 6.4 molar sulfuric acid glasses has been studied by using ESR. Nitroalkanes give rise to RNO_2H radiclas, the nitrogen hyperfine coupling of which has the values $A_{//}^N=48$ G and $A_{\perp}^N=18$ G with $g_{//}=2.0035$ and $g_{\perp}=2.0075$. The RNO_2H yields for 0.5 molar solutions of nitromethane and 2-nitro-2-methyl-propanol are $G\simeq4$ and $G\simeq3$, respectively. $G(SO_4^- + OH\cdot)$ is roughly idenpendent of the nitroalkane concentration. These results are interpreted as the scavenging of hydrogen atoms due to the energetic recombination of non-hydrated primary species (H_2O^+, $OH\cdot$, e^-) according to an assumption of Hamill.

Since the first report by Livingston[1] of the possibility of trapping hydrogen atoms in glassy acidic matrices below 100 K, several ESR investigations have been made on the mechanism of formation, the spatial distribution and the thermal decay of trapped hydrogen atoms.[2] Only a few studies have been devoted to the radicals formed in the presence of electron and hydrogen atom scavengers. Among these radicals, the nitroalkanes are known to be particularly efficient as shown by ESR[3-6] and optical absorption studies[7,8] on liquid solutions of these compounds in polar solvents or in water.

The present work was carried out to identify the radicals from γ irradiated nitroalkanes at low temperature in glassy sulfuric acid aqueous solutions and to investigate their formation mechanism. The results of this study will be compared to those of a previous one in which nitroalkanes were irradiated in concentrated alkaline aqueous solutions[6] giving rise to unexpectedly high radical yields.

Experimental

Nitromethane (NM) was distilled at 72—74°C at pressure of 400 Torr in an argon atmosphere through a column containing a rotating helicoidal band. 2-Nitro-2-methyl-propanol (NMP) furnished by Aldrich Chemicals was used without further purification. Acidic solutions of nitroalkane were prepared just before degassing under vacuum. They were plunged into liquid nitrogen resulting in clear transparent glasses and stored at 77 K until they were irradiated. The irradiation dose rates were determined by ferrous sulfate dosimetry of the ^{60}Co source taking $G(Fe^{3+})=15.5$. The usual dose rates were 5.8×10^{19} eV mol^{-1} h^{-1} and 1.67×10^{20} eV ml^{-1} h^{-1}.

The ESR spectra were recorded with a Strand Labs 601 BX spectrometer operating at 9250 MHz with a 10 kHz field modulation. The microwave power level was kept below 0.1 mW to prevent saturation of the signals. The absolute yield of radicals trapped in the acidic matrix at 77 K was determined by double integration of the ESR spectra using $G(e_s^- + CH_3CHOH)=8$ for the reference sample of glassy ethanol irradiated under the same conditions and 1.3 for the ratio of the absorbed irradiation doses in 6.4 molar sulfuric acid glass and in ethanol.

The ESR experiments were completed by subsidiary gas chromatographic measurements of the molecular hydrogen yield by the method reported in Ref. 9.

Results and Discussion

Identification of the Free Radicals. Glassy Aqueous Solutions of H_2SO_4 without Additives: The ESR spectrum of γ irradiated H_2SO_4/H_2O glass consists of an asymmetrical singlet centered in the vicinity of $g=2.01$ and two lines separated by 505 G corresponding to trapped hydrogen atoms as shown in Fig. 1a. The singlet is attributed to either SO_4^- or HSO_4 radicals, but are hard to distinguished on account of the absence of hyperfine

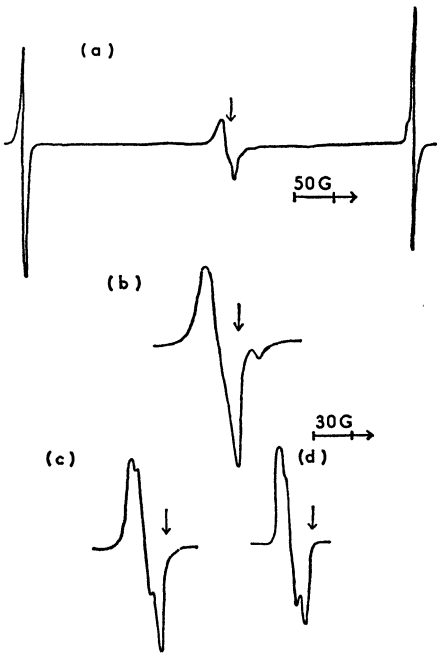

Fig. 1. ESR spectra of the radicals produced by γ irradiation of 6.5 mol dm^{-3} H_2SO_4 glassy solution of 77 K.
(a): Observed spectrum at 77 K immediately after γ irradiation.
(b): Extended spectrum of the central part of the spectrum (a).
(c): Observed spectrum at 77 K after warming above 150 K.
(d): Simulated spectrum corresponding to (c). The used parameters are given in the text. The vertical arrow indicates the position of $g=2.0036$.

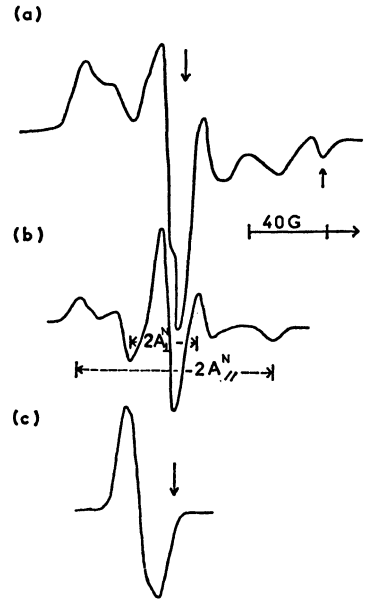

Fig. 2. ESR spectra of γ irradiated 0.5 molar solution of NMP in H_2SO_4/H_2O glasses at 77 K.
(a): Observed at 77 K.
(b) and (c): Simulated spectra of the radicals $(CH_3)_2=\dot{C}(CH_2OH)(NO_2H)$ and $SO_4^{\cdot-}$ (or $HSO_4^{\cdot}$) respectively.
The parameters used for this calculation are given in the text. The arrow shows (↑) a line assigned to $NO_2^{\cdot}$.

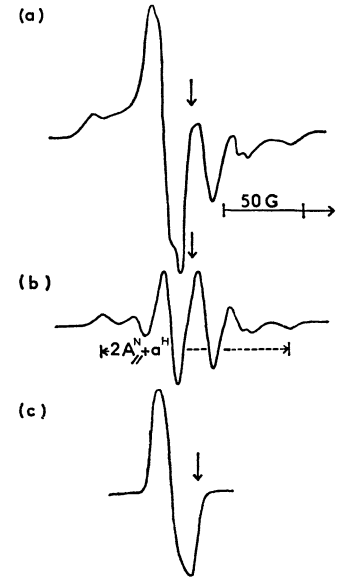

Fig. 3. ESR spectra of the radicals produced by γ irradiation of 0.5 molar solutions of CH_3NO_2 in H_2SO_4/H_2O glasses at 77 K.
(a): Spectrum observed at 77 K.
(b) and (c): Simulated spectra of radicals $CH_3\dot{N}O_2H$ and $SO_4^{\cdot-}$ (or $H\dot{S}O_4$) respectively.

structure (Fig. 1b). Here, it is assumed for the sake of simplicity that we are only dealing with $SO_4^{\cdot-}$. A weak peak is also seen on the high field side of the central asymmetric singlet. This peak belongs most likely to the asymmetrical doublet of the residual $OH^{\cdot}$ radicals (see, for instance, Ref. 2). The signal of $OH^{\cdot}$ is completely removed upon warming of the sample above 150 K, as is shown in Fig. 1c. The spectrum of $SO_4^{\cdot-}$ has been simulated using the program of Lefebvre and Maruani[10] and employing the optimized parameters $g_1=2.0064$, $g_2=2.0134$, $g_3=2.0192$ with a Gaussian line width $\lambda=5$ G (Fig. 1d). These principal values of the $\tilde{g}$ tensor are in good agreement with those given in Ref. 2c and the calculated second moment, $\langle\Delta H^2\rangle_{cal}=289\ G^2$, is fairly close to the experimental value, $\langle\Delta H^2\rangle_{exp}=297\ G^2$.

Radicals Formed in the Presence of Nitroalkanes: Nitromethane and NMP were irradiated in glassy sulfuric acid matrices in a concentration range from 0.01 to 0.5 mol. In both cases the yield of trapped hydrogen atoms is reduced drastically for scavenger concentrations above 0.25 mol dm^{-3}, as shown in Fig. 4d. The ESR spectrum of irradiated NMP in the H_2SO_4/H_2O glassy matrix is interpreted as the superposition of the spectra of $R\dot{N}O_2H$ and $SO_4^{\cdot-}$ radicals, as is shown in Fig. 2. Figure 2b shows that the computer simulation of the spectrum of the $R\dot{N}O_2H$ radical gives the best agreement with the experimental results when using $A_{//}^N=48$ G, $A_{\perp}^N=18$ G ($a_{iso}^N=28$ G) and $g_{//}=2.0035$ and $g_{\perp}=2.0075$ ($g_{iso}=2.0062$) where $A_{//}^N$, $A_{\perp}^N$, $g_{//}$ and $g_{\perp}$ are the principal values of the nitrogen hyperfine coupling tensor $\tilde{A}^N$ and of the $\tilde{g}$ tensor, respectively, the Gaussian line width being $\lambda=5$ G. The relevant second moment is $\langle\Delta H^2\rangle=694\ G^2$ with respect to 2.0036 (DPPH resonance). Exactly the same principal values of the $\tilde{A}_N$ and $\tilde{g}$ tensors as those previously reported for RNO_2H radicals trapped in alcohol matrices[3,4] were obtained, confirming that a species formed by direct hydrogen atom scavenging:

$$RNO_2 + H^{\cdot} \longrightarrow R\dot{N}O_2H \qquad (1)$$

and by electron scavenging followed by protonation of the anion radical:
